Extraction of Cr(III) with TOPO. Compared with the two simple cases above, the equilibria of the whole extraction process of Cr(III) from trichloroacetate buffer solutions into cyclohexane containing TOPO may be more complicated. The present authors tried first the extraction and the back-extraction of Cr(III). In Fig. 5 the results are shown, together with the extraction conditions. The extraction and the back-extraction curves are symmetrical with each other; therefore, the whole extraction process may be reversible under the given conditions, and the attainment of the equilibria may be as quick as 1 min. In addition, the extraction of Cr(III) in varying amounts was carried out under the same conditions as in the foregoing experiment; the results are shown in Fig.6. When the initial concentration of Cr(III) was less than 2×10^{-3} mol dm^{-3}, the distribution ratio of Cr(III) was constant at a pH value of 3.5. The polymerized or dissociated species of Cr(III) in the organic phase can be left out of consideration. From these results,

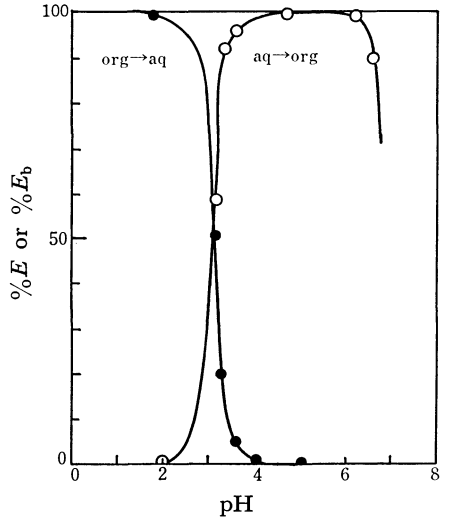

Fig. 5. Extraction and back-extraction of Cr(III) in 0.1 mol dm^{-3} TOPO - cyclohexane - 0.1 mol dm^{-3} TCA$^-$ buffer system. Concentration of Cr(III): 2×10^{-4} mol dm^{-3}, shaking time: 5 min.

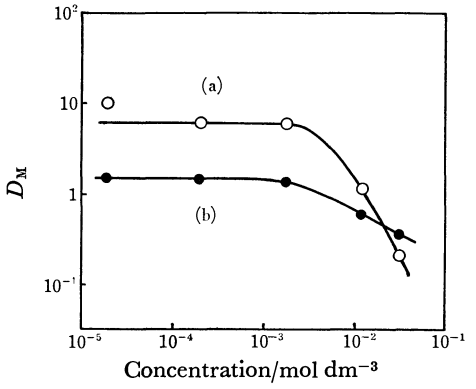

Fig. 6. Effect of the concentration of Cr(III) on the extraction from 0.1 mol dm^{-3} TCA$^-$ buffer solution of pH 3.5. (a): 0.1 mol dm^{-3} TOPO in cyclohexane, (b): 0.2 mol dm^{-3} TOPO in benzene.

the present authors obtain the following equation:

$$Cr(H_2O)_6^{3+} + mTCA^- + nTOPO_{(org)} \rightleftharpoons Cr(H_2O)_p^{3+}(TCA^-)_m\cdot nTOPO_{(org)} + (6-p)H_2O \quad (10)$$

$$K_M = \frac{[Cr(H_2O)_p^{3+}(TCA^-)_m\cdot nTOPO]_{org}}{[Cr(H_2O)_6^{3+}][TCA^-]^m[TOPO]_{org}^n} = \frac{D_M}{[TCA^-]^m[TOPO]_{org}^n}, \quad (11)$$

where K_M is the extraction constant of Cr(III), and D_M, the distribution ratio. Taking logarithms of Eq. 11,

$$\log D_M = m\log[TCA^-] + n\log[TOPO]_{org} + \log K_M. \quad (12)$$

Equation 12 is rewritten by putting Eq. 9 in it:

$$\log D_M = m\log[TCA^-] + n\,pH + \log K_M - n\log K_{HTCA} + n\log D_{HTCA} + n\log K_a. \quad (13)$$

Then the number of trichloroacetate ions participating in the extraction equilibrium of Cr(III) was estimated. The equilibrium concentration of trichloroacetate in the aqueous phase was obtained directly from Fig.2 without any corrections for the trichloroacetate extracted together with Cr(III), since the concentration of Cr(III) was as low as 2×10^{-4} mol dm^{-3}. The plot of log D_M *vs.* log[TCA$^-$] at a constant pH value has a slope of $m=3$, as is shown in Fig. 7. This suggests that the electrically neutral species, $Cr(H_2O)_p^{3+}(TCA^-)_3$, is formed in the aqueous phase and is extracted with TOPO into the organic phase.

The ratio of Cr(III) to TOPO in the extracted species was determined by plotting log D_M against log $[TOPO]_{org}$ at a constant TCA$^-$ concentration. The equilibrium concentration of TOPO was calculated in the same manner as in the acid extraction described above. As is shown in Fig. 8, the log-log plot has a slope of $n=3$, so the chromium(III) ion seemed to be solvated with three TOPO molecules.

The difference in the water concentration, as is shown in Fig. 3(a,b), shows that the additional water is extracted with Cr(III). The relationship between the concentration of Cr(III) extracted in the cyclohexane phase and the increment of water caused by

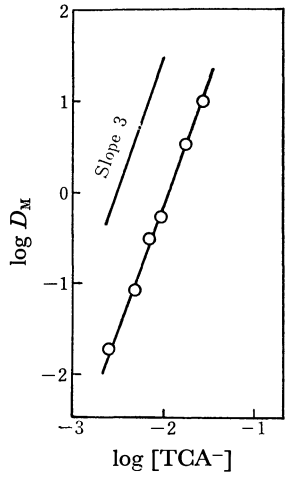

Fig. 7. Dependence of the distribution ratio of Cr(III) on the concentration of trichloroacetate in the aqueous phase at a constant pH value of 3.5.

Table 1. Relationship between the concentration of Cr(III) and the increment of water in cyclohexane after the extraction of Cr(III) with TOPO

Extraction conditions: organic phase: 10 cm^3 of 0.1 mol dm^{-3} TOPO in cyclohexane, aqueous phase: 10 cm^3 of a 0.1 mol dm^{-3} TCA^- buffer solution. a) The initial concentration of Cr(III) in the aqueous phase was 0.19×10^{-2} mol dm^{-3}. b) The initial concentration of Cr(III) in the aqueous phase was 3.1×10^{-2} mol dm^{-3}.

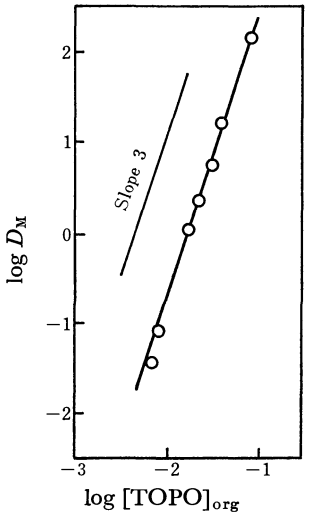

Fig. 8. Dependence of the distribution ratio of Cr(III) on the concentration of free TOPO in the organic phase at pH 4.0.

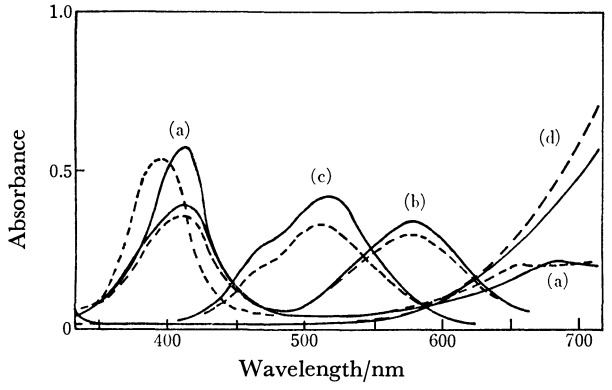

Fig. 9. Absorption spectra of the organic phase(——) after the extraction with 0.1 mol dm^{-3} TOPO and the aqueous phase(----) before the extraction. (a): Ni(II), (b): Cr(III), (c): Co(II), (d): Cu(II). Extraction conditions; organic phase: 0.1 mol dm^{-3} TOPO in cyclohexane, aqueous phase: 0.1—0.5 mol dm^{-3} TCA^- buffer solution of pH 4—5.

the extraction of Cr(III) is summarized in Table 1. The amount of water co-extracted with the Cr(III)–TCA^-–TOPO complex is about 6.2 times that of the Cr(III) extracted. This suggests that a common species of Cr(III) in the aqueous solution, $Cr(H_2O)_6^{3+}$, may be extracted into the organic phase as it is.

This is confirmed by the fact that the absorption spectrum of the extracted Cr(III) species in the organic phase is similar to that of hexaaquachromium(III) in the aqueous solution(Fig. 9(b)). In Fig. 9 the spectra of Co(II), Ni(II), and Cu(II) before and after their extraction in the present system are compared with those of Cr(III). The absorption bands of Co(II), Ni(II), and Cu(II) extracted with TOPO were all shifted to longer wave lengths than those of aqua complexes in the aqueous phase. This suggests that the TOPO molecule acts on the inner solvation sphere of all the metals except Cr(III). On the other hand, a previous report[1] has shown that the inner solvation sphere of any metal does not alter upon its extraction into isopentyl alcohol. These differences may be accounted for by the strong basicity of TOPO and the fast substitution rates of water molecules in the inner coordination sphere of metals other than Cr(III). The absorption bands of Cr(III) were gradually shifted to longer wave lengths when the extract was allowed to stand in the presence of an excess of TOPO. Moreover, the back-extraction curve shown in Fig. 5 was also shifted to a lower pH region; *i.e.*, the shift of $pH_{1/2}$, the pH at the half-extraction, was 0.5 when the extract was allowed to stand for about 48 h at room temperature. These facts suggest that the water molecules in the inner solvation sphere of the Cr(III) extracted are very slowly replaced by TOPO molecules in the organic phase.

On the basis of the above results, it may be stated that the predominant species of Cr(III) extracted from the trichloroacetate buffer solution into cyclohexane containing TOPO is the ion-association complex, $Cr(H_2O)_6^{3+}(TCA^-)_3\cdot3TOPO$, and that the extraction constant of this complex is $10^{7.68}$. In this complex, six molecules of water seem to be present in the inner

solvation sphere of Cr(III), while three molecules of the trichloroacetate ion as well as three molecules of TOPO seem to be present in the outer solvation sphere. The extractability of the Cr(III) ion in the present extraction system depends most on the concentration of TOPO free from trichloroacetic acid in the organic phase and, consequently, on the pH value of the aqueous phase.

Preparation and Solid-phase Thermal *cis-trans* Isomerization of the Mixed Bis(diamine)chromium(III) Complexes of the Type $[CrX_2(aa)(bb)]X \cdot nH_2O$[1)]

Samiran MITRA, Tadatsugu YOSHIKUNI, Akira UEHARA, and Ryokichi TSUCHIYA*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received February 22, 1979)

The mixed bis(diamine)chromium(III) complexes *trans*- and *cis*-$[CrX_2(aa)(bb)]X \cdot nH_2O$ were prepared and characterized where X is chloride or bromide ion; aa and bb are different diamines selected from ethylenediamine (en), propylenediamine (pn) and trimethylenediamine (tn); and *n* is a number of 0 to 2. The *cis-trans* isomerization of the above complexes was investigated non-isothermally (derivatographically) and isothermally in the solid-phase. The isomerization was found to be one-way (*trans*-to-*cis*) and exothermic. The activation energies were estimated for dehydration or dehydration plus dehydrohalogenation (E_d) and isomerization (E_i). The intermediates *mer*-$[CrBr_3(en)(pn)] \cdot 2H_2O$ and *mer*-$[CrBr_3(pn)(tn)] \cdot 2H_2O$ were isolated during the isomerization of *trans*-$[CrBr_2(en)(pn)]Br \cdot 2H_2O$ and *trans*-$[CrBr_2(pn)(tn)](H_5O_2)Br_2$, respectively. Bond rupture was proposed to be operative in the pathway of the isomerization.

We have already studied on the solid-phase *cis-trans* isomerizations of the bis(diamine)dihalogenochromium(III) complexes $[CrX_2(aa)_2]X$,[2-6)] where X is chloride or bromide ion; aa is one of diamines such as ethylenediamine (en), propylenediamine (pn), 2,3-butanediamine (bn) and trimethylenediamine (tn). In the course of our studies, an interesting fact was noticed that the direction of isomerization (whether *trans*-to-*cis* or *cis*-to-*trans*) largely depends upon diamines contained in the complexes. Actually, *trans*-to-*cis* isomerization was recognized in the complexes containing en, pn or bn which is capable of forming five-membered chelate ring with chromium(III) ion, whereas *cis*-to-*trans* isomerization was found in the complexes containing tn which forms six-membered chelate ring. It is, therefore, of much interest to know the details of the isomerization of the complexes having a general formula $[CrX_2(aa)(bb)]X$ where X is the same as described above; aa and bb denote different diamines selected from en, pn, and tn. Among them, the complexes having the combination of five- and six-membered chelate rings are particularly interesting.

As for the chromium(III) complexes containing two different diamines, Pfeiffer *et al.* first reported the mixed tris(diamine) complexes $[Cr(en)_2(pn)]X_3$ (X_3= Cl_3, $(SCN)_3$, I_3, $[Cr(ox)_3]$, or $[Cr(CN)_6]$).[7)] Recently, several mixed bis(diamine) complexes $[CrX_2(aa)(bb)]^+$ (X_2=Cl_2, F_2, $F(H_2O)$, and others) have been characterized and investigated from the viewpoint of hydrolysis kinetics.[8-12)] In general, owing to large solubilities in common solvents, many troublesome steps are required to isolate the mixed bis(diamine) complexes as compared with the simple bis(diamine) complexes $[CrX_2(aa)_2]^+$.[13)] The situation is rather severe for *cis* complexes than for *trans* complexes.

The present study was, therefore, undertaken (1) to prepare *trans*- and *cis*-mixed bis(diamine) complexes $[CrX_2(aa)(bb)]X$, and (2) to investigate the details of thermal *cis-trans* isomerization of the complexes in the solid-phase.

Experimental

Preparation of Complexes. trans-*[CrCl$_2$(en)(pn)]Cl·0.75H$_2$O (I)*, trans-*[CrCl$_2$(pn)(tn)]Cl·H$_2$O (II)*, trans-*[CrCl$_2$(en)(tn)](H$_5$O$_2$)Cl$_2$ (III)*, trans-*[CrBr$_2$(en)(pn)]Br·2H$_2$O (IV)*, trans-*[CrBr$_2$(pn)(tn)](H$_5$O$_2$)Br$_2$ (V)* and trans-*[CrBr$_2$(en)(tn)](H$_5$O$_2$)Br$_2$ (VI)*: For the preparation of these complexes, the starting material *trans*-$[CrF_2(aa)(bb)]Br$ was first prepared by modifying the methods described earlier.[10,11)] One gram of the material was dissolved in 10 ml of concentrated hydrochloric or hydrobromic acid and allowed to stand in a vacuum desiccator containing concentrated sulfuric acid as a desiccant, the desiccator being saturated with hydrogen chloride or hydrogen bromide by placing concentrated hydrochloric or hydrobromic acid in it. After a few days green crystals were separated. They were filtered, washed with ether and dried in a desiccator containing calcium chloride and *in vacuo* over KOH pellets for 2 h. The yields of the chloro complexes and the bromo complexes were about 60% and 65% based on the amounts of the starting materials used, respectively.

cis-*[CrCl$_2$(en)(pn)]Cl (VII)*, cis-*[CrCl$_2$(en)(tn)]Cl (VIII)*, cis-*[CrBr$_2$(en)(pn)]Br·2H$_2$O (IX)* and cis-*[CrBr$_2$(pn)(tn)]Br·H$_2$O (X)*. The *cis* complexes were prepared by using thermal isomerization of the corresponding *trans* complexes in the solid-phase.

First of all, one gram of the corresponding *trans* complexes was triturated thoroughly in a mortar, spread thinly on watch glass and heated in an air-bath at given temperature for a given time. The optimum heating conditions (temperatures and heating times) for obtaining the *cis* complexes were determined non-isothermally (derivatographically) and isothermally. They were 60 min at 140 °C for complex VII, 30 min at 210 °C for complex VIII, 30 min at 125 °C for complex IX, and 70 min at 160 °C for complex X. The products thus obtained were allowed to cool to room temperature, dissolved in *N*,*N*-dimethylformamide (DMF) and filtered (if any insoluble materials remained). To the filtrate appropriate amounts of ether were added drop by drop with stirring, violet crystals being separated. They were filtered, washed with ether and air-dried. The yields of the *cis* complexes were about 40% based on the amounts of the starting *trans* complexes.

As mentioned in the later section, *trans*-$[CrCl_2(pn)(tn)]Cl \cdot H_2O$ (II) decomposed during isomerization at about 220 °C and *trans*-$[CrBr_2(en)(tn)](H_5O_2)Br_2$ (VI) decomposed at 170 °C without isomerization, and so attempts to get the corresponding *cis* complexes failed.

Isolation of Intermediates during Isomerization. *[CrBr$_3$(en)(pn)]·2H$_2$O (XI)* and *[CrBr$_3$(pn)(tn)]·2H$_2$O (XII)*. They were isolated during isomerization of complexes IV and V. Each one gram of these complexes was spread in

thin layer on watch glasses and heated for 25 min at 112 °C and 20 min at 150 °C, respectively. The products thus obtained were repeatedly washed with DMF until the washings became colorless. They were then washed with ether and air-dried. Bluish products were obtained with the yields of about 30%. The lattice waters in the crystals probably came from trace amounts of water present in the solvents employed in the procedures. Table 1 summarizes the results of elemental analyses.

Non-isothermal Measurements. Non-isothermal measurements were carried out with a Derivatograph Typ-OD-102 and the enthalpy changes, ΔH, for dehydration and isomerization were evaluated as previously described.[14]

Isothermal Measurements. The rates of dehydration or dehydration plus dehydrohalogenation of complexes I through VI were determined at different temperatures with a CHYO 1001 thermobalance.

The rates of isomerization were followed by measuring the changes in absorbancies for the samples heated in an Abderhalden apparatus or an Ikemoto Rika Kogyo air-bath at various temperatures. Electronic spectra were monitored on a Hitachi Recording Spectrophotometer. The solvent used is DMF, dimethyl sulfoxide (DMSO), or 0.1 mol dm^{-1} HCl, HBr, or $HClO_4$ solution. The isomerization ratios were calculated by using the following simultaneous equations:

$$\left.\begin{aligned} 34.6x + 76.1y &= D_{400} \\ 10.0x + 74.1y &= D_{530} \end{aligned}\right\} \text{ for complexes I and VII}$$

$$\left.\begin{aligned} 38.2x + 60.3y &= D_{400} \\ 5.8x + 63.4y &= D_{520} \end{aligned}\right\} \text{ for complexes III and VIII}$$

$$\left.\begin{aligned} 53.8x + 12.0y &= D_{540} \\ 39.8x + 29.3y &= D_{390} \end{aligned}\right\} \text{ for complexes IV and IX}$$

$$\left.\begin{aligned} 33.9x + 6.9y &= D_{520} \\ 22.7x + 33.9y &= D_{440} \end{aligned}\right\} \text{ for complexes V and X}$$

where x and y are the molar concentrations of *cis*- and *trans*-isomers, the numerical factors are the molar extinction coefficients of pure *cis*- and *trans*-isomers, and D's represent the observed absorbancies at the wavelengths specified by the subscripts. Figure 1 shows, as an example, the electronic spectra of complexes I and VII.

Thin Layer Chromatography (TLC). TLC was employed to distinguish the mixed bis(diamine) complexes *trans*-$[CrX_2(aa)(bb)]X$ from the simple bis(diamine) complexes *trans*-$[CrX_2(aa)_2]X$ and *trans*-$[CrX_2(bb)_2]X$.[10,15] TLC plates used were those of silica gel 60F-254 made by Merck Ltd. Table 2 lists up the results of complexes I through VI together with those of the simple bis(diamine) complexes.

a) The mixture of acetic acid and methanol (9 : 1) was used as the eluent. For the chloro complexes, single plate is employed in each run (as given in each row), whereas for the bromo complexes two plates are used: one is for the simple bis(diamine) complexes and the other for the mixed bis(diamine) complexes.

Comparison of the R_f values in the table reveals that the values for *trans*-$[CrX_2(aa)(bb)]X$ are just in between those for *trans*-$[CrX_2(aa)_2]X$ and *trans*-$[CrX_2(bb)_2]X$, indicating that all the mixed bis(diamine) complexes are pure.

Results and Discussion

Derivatography. Dehydration or Dehydration plus Dehydrohalogenation: Figure 2 shows the derivatograms of the chloro complexes I, II, and III, and Fig. 3, those of the bromo complexes IV, V, and VI. Complexes I and II are dehydrated at 70—160 °C and 40—120 °C, respectively. Complex IV evolves 2 mol of water at two separate stages (40—103 °C and 125—158 °C). Complexes III, V, and VI lose 2 mol of water and 1 mol of hydrogen halide (dehydration plus dehydrohalogenation) at temperatures below 140 °C. The enthalpy changes, ΔH, for dehydration or dehydration plus dehydrohalogenation for complexes I to VI were determined to be 17, 42, 55, 43, 49, and 57 kJ mol^{-1}, respectively.

Isomerization. Complexes I, II, III, and V give small but clear exothermic DTA peaks at 200, 220, 235, and 195 °C respectively, and they change in color from green to violet. This indicates that the isomerization takes place. Complex II partially decomposed during the isomerization, and therefore isolation of the corresponding *cis* complex was not possible. Prominent peak only due to mere isomerization can not be seen in the DTA curve of complex IV because the isomerization stage (90—130 °C) overlaps with the first dehydration stage (40—103 °C). Complex VI, after dehydration plus dehydrohalogenation (38—135 °C), remained unchanged up to about 170 °C, after that it melted and decomposed rapidly without isomerization.

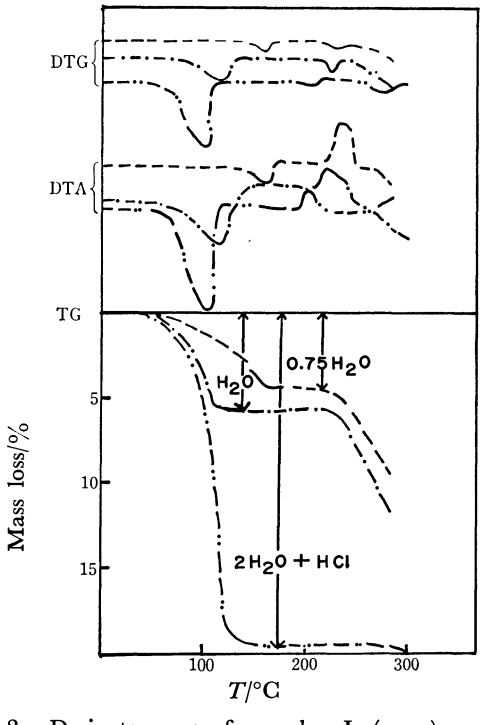

Fig. 2. Derivatograms of complex I (----), complex II (—·—) and complex III (—··—).

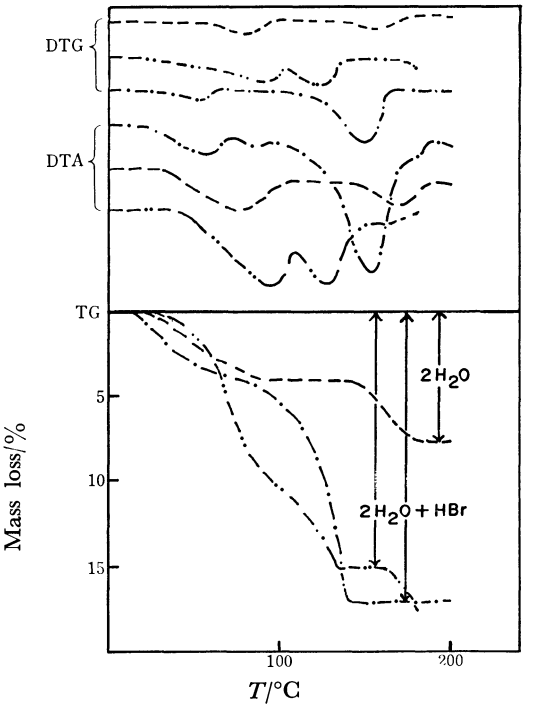

Fig. 3. Derivatograms of complex IV (----), complex V (—·—) and complex VI (—··—).

It must be noted that the *cis* complexes in the present study did not isomerize upon heating. We expected at the beginning of this study that the mixed bis(diamine) complexes having the composition of $[CrX_2(en)(or\ pn)(tn)]X$ might undergo both *trans*-to-*cis* and *cis*-to-*trans* isomerization. The expectation is based on the fact that *trans*-to-*cis* isomerization was recognized in the case of the simple bis(diamine) complexes $[CrX_2en_2(or\ pn_2,\ bn_2)]X$ where en, pn, or bn forms five-membered chelate ring,[2-4] whereas only *cis*-to-*trans* isomerization was detected in the complexes $[CrX_2tn_2]X$ in which tn forms six-membered chelate ring.[5,6] However, as mentioned above, the isomerization in the present case was found to be one-way (*trans*-to-*cis*).

Rate of Dehydration or Dehydration plus Dehydrohalogenation. If the rate of dehydration or dehydration plus dehydrohalogenation at each temperature obeys the first order law, the following equation should hold:

$$2.303 \log a/(a-x) = k_d t$$

where a is the initial amount of the starting complex, x is the amount of dehydrated or dehydrated plus dehydrohalogenated product formed during time t, and k_d is rate constant. Table 3 contains k_d and the rate constants of isomerization (k_1). Linear relationships were obtained when $\log a/(a-x)$ were plotted against time t. From the Arrhenius plots, the activation energies for dehydration of complexes I and II were obtained as 67 and 76 kJ mol^{-1}. For complex IV, the activation energies for the first and second dehydration steps were 46 and 103 kJ mol^{-1} respectively. The dehydration plus dehydrohalogenation stages of complexes III, V, and VI had the activation energies of 55, 112, and 30 kJ mol^{-1} respectively.

Rate of Isomerization. The isomerization of complexes I, III, IV, and V was traced spectrophotom-

IV	83	46103	117	114
V	136	112	163	123
VI	95	30	—	—

a) t_d and t_i stand for dehydration (or dehydration plus dehydrohalogenation) temperatures and isomerization temperatures where k_d and k_i show a constant value (5×10^4 s^{-1}). The constant value was taken for the convenience of comparison. E_d and E_i designate activation energies for dehydration (or dehydration plus dehydrohalogenation) and isomerization.

etrically. In a manner similar to that of dehydration, the value of $\log b/(b-y)$ were plotted against time t, where b is the initial amount of the *trans* complex, and y is the amount of the corresponding *cis* complex formed by isomerization. Linear relationships were obtained, and only in the case of complex IV the value of $\log b/(b-y)$ converged about 0.1, indicating that 20% of isomerization takes place during dehydration plus dehydrobromination and the remaining in the anhydrous state. Rate constants of isomerization (k_i) are given in Table 3. The activation energies of isomerization were estimated to be 155, 181, 114, and 123 kJ mol^{-1} for complexes I, III, IV, and V, respectively. Table 4 summarizes t_d and E_d (temperature and activation energy for dehydration or dehydration plus dehydrohalogenation), and t_i and E_i (temperature and activation energy for isomerization). Comparison of these values between the chloro complexes (I, II, and III) and the bromo complexes (IV, V, and VI) discloses that the bromo complexes are in general more easily dehydrated and dehydrohalogenated than the corresponding chloro complexes; the same tendency may also be true for isomerization.

Mechanism of Isomerization. Several studies have been reported on the mechanism of solid-phase racemization of metal complexes; *e.g.*, twist mechanism was preferably accepted in the solid-phase racemization of tris(oxalato)metallate,[16,17] and LeMay and Bailar reported that the solid-phase racemization of *l-cis*-$[CrCl_2en_2]Cl \cdot H_2O$ proceeds *via* aquation-anation mechanism.[18] The study on the isotopic exchange of anhydrous *cis*- and *trans*-$[CoCl_2en_2]Cl$* showed that the Cl ion in inner-sphere is exchanged by the Cl* ion in outer-sphere in the solid-phase,[19] implying that a bond rupture process may be included in the exchange.

We have noticed that the solid-phase *cis-trans* isomerization of the simple bis(diamine)chromium(III) complexes do not necessarily require the participation of lattice water unlike the corresponding cobalt(III) complexes,[20,21] and the reaction is, in most cases, accompanied by a small but clear exothermic DTA peak.[2-6] We tentatively speculated that a bond rupture may be involved in the isomerization.[3] In this study, we succeeded in isolating the intermediates XI and XII during the isomerizations of complexes

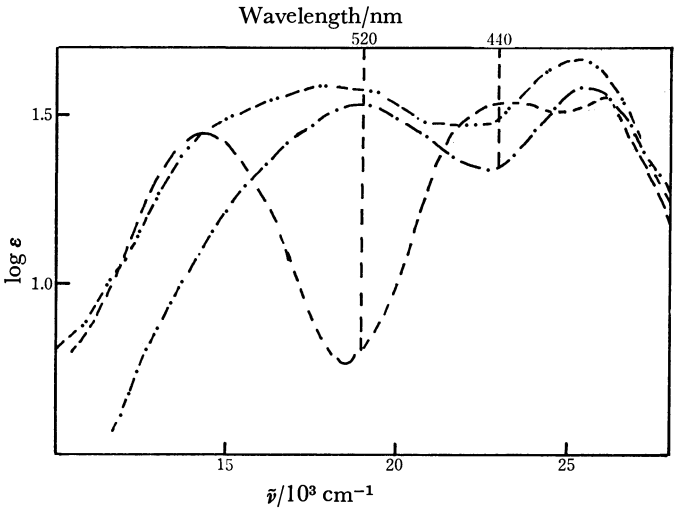

Fig. 4. Electronic spectra of complex V (----), complex X (—·—) and intermediate XII (—··—).

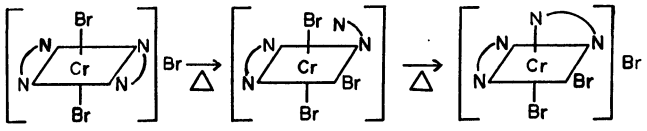

Fig. 5. Possible isomerization pathway.

IV and V as mentioned in the experimental section. Figure 4, as an example, shows the electronic spectra of complex V (*trans*-$[CrBr_2(pn)(tn)](H_5O_2)Br_2$), complex X (*cis*-$[CrBr_2(pn)(tn)]Br \cdot H_2O$) and the intermediate XII ($[CrBr_3(pn)(tn)] \cdot 2H_2O$). As seen from the figure, the *trans* complex V has, as expected, three absorption bands in the range of d-d transition [14.2×10^3 cm^{-1} (log ε=1.44), 23.0×10^3 cm^{-1} (log ε=1.53) and 25.5×10^3 cm^{-1} (log ε=1.51)] and the *cis* complex X has two bands at 19.0×10^3 cm^{-1} (log ε=1.53) and 25.6×10^3 cm^{-1} (log ε=1.58). On the other hand, the intermediate XII has two bands at 18.0×10^3 cm^{-1} (log ε=1.59) and 24.6×10^3 cm^{-1} (log ε=1.66), but the first band is accompanied by two shoulders at $\approx 14.0 \times 10^3$ cm^{-1} (log $\varepsilon \approx 1.42$) and $\approx 21.0 \times 10^3$ cm^{-1} (log $\varepsilon \approx 1.48$). The occurrence of these shoulders in the first band, as has been reported in the studies on [(Cr or Co)Cl_3dien][22] and $[CoCl_3(NH_3)_3]$,[23] supports that three bromide ions in the intermediate XII are arranged in *mer* position. The situation is also true for the intermediate XI (the spectral data were omitted because they were closely similar to those of the intermediate XII). From the above results, it is reasonable to consider that the isomerization of these complexes proceeds through a bond rupture pathway as represented in Fig. 5. It seems that the same mechanism is operative in the simple and mixed bis(diamine)chromium(III) complexes which isomerize with similar exothermic DTA peaks.

The authors wish to express their gratitude to Japan Society for the Promotion of Science for the financial support granted to this research.

(Received February 28, 1979)

The enrichment of a trace amount of manganese(II) from sample water was carried out by the combined use of a mixture of finely divided cation and anion exchangers and 4-(2-pyridylazo)resorcinol (PAR). Manganese–PAR complex was effectively collected onto the mixed resin by batch method in the pH range 9.1—10.2. The manganese on the mixed resin was eluted into hydrochloric acid solution, extracted with 4-benzoyl-3-methyl-1-phenyl-2-pyrazolin-5-one (BMPP) into MIBK and determined by atomic absorption spectrometry. The recovery of 3 μg of manganese from the synthetic sample solution (100—500 ml) was in the range 95—97%.

Recently we reported an analytical utilization of a resin mixture of finely divided anion and cation exchangers, the diameter being smaller than 30 μm.[1] A trace amount of copper(II) in a sample water was concentrated on the mixed resin as the complex with 8-hydroxy-5-quinolinesulfonate and determined by atomic absorption spectrometry. This paper describes some preliminary results with the enrichment of manganese(II) by the combined use of the mixed resins with PAR. The compounds BMPP and 4-cinnamoyl-3-methyl-1-phenyl-2-pyrazolin-5-one (CMPP) were examined as the reagents for the solvent extraction-atomic absorption spectrometric determination of manganese.

Experimental

Reagents. Stock solution of manganese(II) (1.0 g l^{-1}, pH=1) was prepared by dissolving the chloride into hydrochloric acid solution and its factor was determined by titration with EDTA. The Dotite PAR (Dojindo Co.) was used without further purification. Fifty milligrams of the reagent were dissolved into 3 ml of 0.1% sodium hydroxide solution and diluted to 100 ml. The reagents BMPP and CMPP were synthesized from 3-methyl-1-phenyl-5-pyrazolone and benzoyl chloride or cinnamoyl chloride (Wako Chemicals Co.) according to the method of Jensen.[2] The former BMPP was recrystallized twice from methanol. The results of elemental analysis were: Found: C, 73.1; H, 5.0; N, 10.1; O, 11.8%. Calcd for $C_{17}H_{14}N_2O_2$: C, 73.4; H, 5.0; N, 10.1; O, 11.5%. The latter CMPP was recrystallized twice from acetone. The results of elemental analysis were: Found: C, 75.0; H, 5.2; N, 9.1; O, 10.7%. Calcd for $C_{19}H_{16}N_2O_2$: C, 75.0; H, 5.3; N, 9.2; O, 10.5%. Solutions of 5×10^{-2} M (mol dm^{-3}) BMPP and CMPP were prepared by dissolving each acid in alkaline solution, the final solution being neutral.

The resin mixture was prepared by mixing suspension of cation exchanger (CRS) with that of anion exchanger (ARS) in the volume ratio of 1 to 1.6. The exchange capacities were 0.031 meq ml^{-1} for CRS and 0.030 meq ml^{-1} for ARS as reported previously.[1]

Apparatus. A Hitachi 508 atomic absorption spectrometer with a Fe–Co–Ni–Cu–Cr–Mn multielement hollow cathode lamp was used for the determination of manganese in MIBK extract under the following conditions: wavelength 279.5 nm, lamp current 10 mA, slit width 0.18 mm, acetylene flow rate 1.5 l min^{-1} and air flow rate 13 l min^{-1}. A Toyo KG 25 filter holder (Toyo Roshi Co.) was used.

General Procedure. An aliquot of sample solution (40—500 ml) containing 3 μg of manganese(II) is taken into a separatory funnel, 1.0 ml of 0.05% PAR solution being added. The solution pH was adjusted to *ca.* 9.6 with the addition of 2 M ammonia–ammonium chloride buffer solution. A 1.0-ml portion of CRS and 1.6 ml of ARS are then added to the sample solution. After shaking for 10 min the mixture is allowed to stand for several minutes until the coagulated resin settles. The mixed resin is separated by filtration with suction from the solution onto a filter paper (Toyo Roshi No. 1). The manganese species on the resin are then eluted with 20 ml of 0.5 M hydrochloric acid into another separatory funnel. The pH of the solution being adjusted to *ca.* 7.3 with 10 ml of 1 M potassium phosphate, 2.5 ml of 0.05 M BMPP are added. The resulting manganese–BMPP complex is extracted into 5.0 ml of MIBK and the organic extract is then subjected to atomic absorption spectrometry. The absorption is corrected from the blank value observed throughout the whole procedure.

Results and Discussion

Effect of PAR. Manganese(II) reacts with PAR to form a water soluble red complex in alkaline solution.[3] The negative logarithms of acid dissociation constants of the pyridine nitrogen, *p*-hydroxyl, and *o*-hydroxyl groups in the PAR molecule are reported to be 2.3, 12.4, and 6.9, respectively.[4] In the alkaline solution, the manganese complex is expected to be present as mono- or divalent anionic species, which is fixed onto the cationic site in the mixed resin.

The effect of PAR on the recovery of manganese was studied in the presence of varying amounts of calcium and chloride ions which are most commonly present in natural water. The optimal pH range was found to be 9.1—10.2 (Fig. 1), which is comparable to the result observed in the spectrophotometric determination of manganese with PAR.[5]

In the presence of 2.3 μmol of PAR, 3 μg of manganese was effectively collected from 40 ml of a calcium chloride solution containing even 50 mg of calcium ion (Fig. 2). In the absence of PAR, the amount of non-fixed manganese increased when the amount of calcium ion increased beyond the exchange capacity of cation exchanger in the mixed resin.

Manganese on the resin was quantitatively eluted with 20 ml of 0.5 M hydrochloric acid.

Extraction of Manganese with BMPP and CMPP. Determination of manganese in the eluate was carried out by using solvent extraction followed by atomic

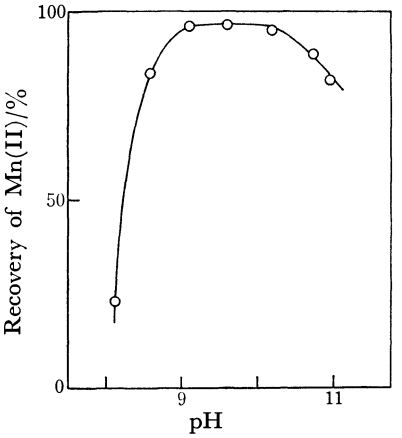

Fig. 1. Effect of pH on the recovery of 3.0 μg of manganese(II) from 40 ml of solutions containing 20 mg of calcium ion and 2.3 μmol of PAR onto the coagulated resin prepared from 1.0 ml of CRS and 1.6 ml of ARS. Buffer solution: NH_3–NH_4Cl, ionic strength: 0.1 (NaCl).

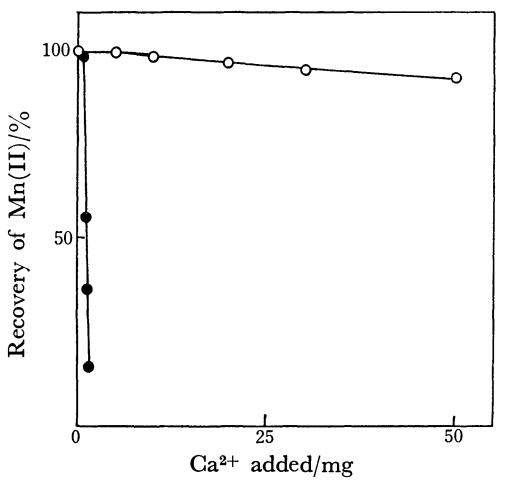

Fig. 2. Recovery of 3.0 μg of manganese(II) from 40 ml of solutions containing varying amounts of calcium chloride in the presence (○) and absence (●) of 2.3 μmol of PAR. ●: Unbuffered, ○: pH 9.6 (ammonia buffer), ionic strength 0.1 (NaCl).

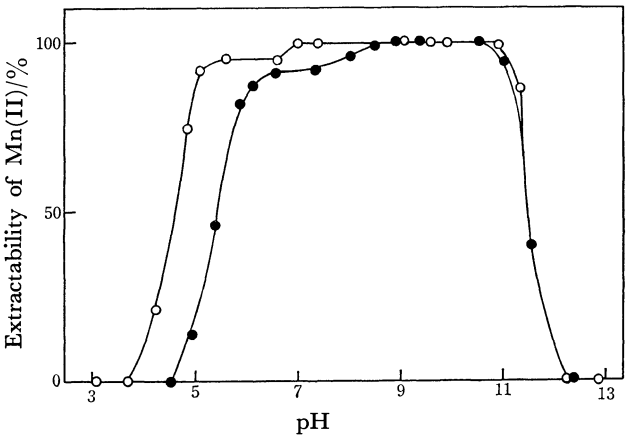

Fig. 3. Effect of pH on the extractability of manganese complex with BMPP (○) and CMPP (●) into MIBK. Solution pH is adjusted with Britton-Robinson buffer solution. Mn 3 μg, ionic strength 0.16 (NaCl), aqueous volume 50 ml, MIBK 5 ml.

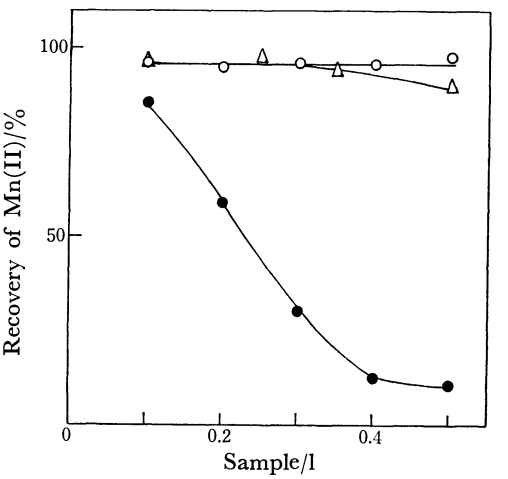

Fig. 4. Recovery of 3 μg of manganese(II) from varying amounts of synthetic sample solution (the composition is found in the text). ●: CRS 1.0 ml, ARS 1.6 ml, PAR 2.3 μmol; △: CRS 2.5 ml, ARS 4.0 ml, PAR 11.5 μmol; ○: CRS 2.5 ml, ARS 4.0 ml, PAR 46 μmol.

absorption spectrometry. The sensitivity of the AAS determination of manganese is enhanced when the organic extract is subjected to analysis.[6,7] In the preliminary tests, the methods employing ammonium 1-pyrrolidinecarbodithioate[8,9] and 8-quinolinolate[7] was examined. In the dithiocarbamate method, the back ground absorption increased with increasing amount of the reagent. On the other hand, the extraction pH higher than 10 was required in the oxinate method.

The use of BMPP and CMPP was studied. In spite of the interest in BMPP,[10] only a little information is available on the extraction of manganese complex into MIBK. The extractability of manganese BMPP complex was constant over the pH range 7.0—11.0 (Fig. 3). Manganese–CMPP complex was quantitatively extracted in the pH range 8.5—10.5. A small step was observed on the extractability-pH curves in both cases. The extraction method with BMPP was tested with the solution containing 20 ml of 0.5 M hydrochloric acid and 2.3 μmol of PAR. The solution composition is almost the same as that of the eluate from the mixed resin. The pH was adjusted by the addition of 1 M potassium phosphate. In the presence of PAR the optimal pH range became narrower in the alkaline region (pH 7.0—8.3), even larger amounts of BMPP up to 125 μmol being added. At the optimum conditions the extraction equilibrium was attained within a few minutes. The organic extract was stable at least within 30 min.

Enrichment of Manganese from Synthetic Sample Solution. The composition of the synthetic sample solution was: Na^+ 32.6, K^+ 7.8, Ca^{2+} 40.0, Mg^{2+} 12.0, Zn^{2+} 0.2, Pb^{2+} 0.005, Fe^{3+} 0.1, Cu^{2+} 0.01, Cl^- 142.22, SO_4^{2-} 58.3, SiO_2 7.5, HCO_3^- 35.4, NO_3^- 0.013, NH_4^+ 0.032 mg l^{-1}. The composition is referred to the ordinary river waters,[11] in which the concentrations of main components are fairly high. With

increasing amounts of PAR and the mixed resin, the recovery of manganese was improved (Fig. 4). By combined use of 2.5 ml of CRS, 4 ml of ARS and 46 μmol of PAR, a 3-μg portion of manganese was effectively recovered from 100—500 ml of the sample solution.

Adsorption Behavior of Phosphate Ion on the Iron(III) Complex of a Chelating Resin

Ryoichi TAKESHITA, Isao YOSHIDA,* and Keihei UENO**

Department of Industrial Chemistry, Kumamoto Institute of Technology, Ikeda 4-22-1, Kumamoto 860

***Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*

(Received March 5, 1979)

Phosphate ion in 0.1 M (1 M=1 mol dm^{-3}) sodium chloride solution was adsorbed selectively on the iron(III) complex of a chelating resin. Coordination unsaturated sites of the resin-bound iron(III) ion were considered to be the adsorption sites for phosphate ion, predominating species being dihydrogenphosphate ion ($H_2PO_4^-$). Adsorption capacity of the resin increased with the increasing amount of iron(III) ion loaded on the chelating resin, while the molar ratio of the adsorbed phosphate ion to the resin-bound iron(III) ion became less than unity, indicating that only a fraction of the resin-bound iron(III) ion acts as the adsorption site at higher iron content. The steric and electrostatic interactions among the phosphate ions in the resin matrix may interfere with the stoichiometric adsorption of phosphate ion on the resin-bound iron at higher iron content.

In a previous paper,[1] a report was given on the selective adsorption of arsenite and arsenate ions on the iron(III) complex of a chelating resin, with possible application to the removal of trace of arsenic from waste water of geothermal power plants.

Since the selective adsorption on such a resin is based on the coordination of anionic ligands to the coordination unsaturated sites of the resin-bound metal ion, adsorption of phosphate ion can also be expected on the iron(III) complex of the chelating resin. Such a process may be useful in the tertiary treatment of urban sewage for the effective removal of phosphate ion. This paper describes the nature of the iron(III) complex of chelating resin (Uniselec UR 10) as an adsorbent for phosphate ion.

Experimental

Materials. Uniselec UR 10 chelating resin (Unitika Ltd. Osaka) of 20—50 mesh size was used. Iron(III) complex of chelating resin was prepared by the following procedure. An iron(III) ion solution prepared by dissolving 0.4—5.4 g of iron(III) chloride hexahydrate in 200 ml of 0.3 M sodium acetate–acetic acid buffer (pH 3.0) was mixed with 10 g of sodium form chelating resin which had been conditioned by successive washings with 2 M hydrochloric acid and sodium hydroxide solutions. The resulting iron(III) complex resin was washed with deionized water until the washings became free from iron(III) ion, sucked off, and stored in a sealed bottle in a refrigerator.

The iron content in the resin was measured on the acid eluate by EDTA titration, and expressed in terms of F (mmol/g of dry iron(III) resin). The iron contents ranged from 0.12 to 1.34. The water content was also determined on each grade of the iron(III) resin by measuring the weight loss after drying to constant weight at 110 °C. A stock solution of phosphate ion was prepared from potassium dihydrogenphosphate. All other reagents were of analytical grade.

Procedure for Adsorption Study. Adsorption equilibria were investigated by batchwise operation. A weighed amount of the iron(III) resin, *ca.* 0.5 g, was shaken with 50 ml of a buffered solution containing phosphate ion at a constant temperature for 24 h, which is sufficient to attain approximate equilibrium. For determination of partition ratio and adsorption isotherms, respectively 1.3×10^{-3} M and (6.4×10^{-4}—3.3×10^{-2}) M of phosphate solution were used. The ionic strength of the solution was adjusted to 0.1—0.2 with sodium chloride.

After equilibration, the phosphate ion concentrations were determined by molybdenum blue photometry on solution and resin phases, the latter being analyzed on the 2 M hydrochloric acid eluate.

The partition ratio, K_{ad}, of phosphate ion between aqueous and resin phases can be expressed by

$$K_{ad} = Q/C$$

where C and Q are the phosphate ion concentration in solution (M) and in iron(III) resin(mmol/g of dry iron(III) resin), respectively. Although wet resin was used throughout the experiment, the corrections were made for dry resin by estimating the water content of the wet resin.

Instruments. A Toa model HM-5A pH meter and Shimadzu MPS-50L spectrophotometer were used.

Results and Discussion

Nature of the Iron(III) Chelating Resin. Uniselec UR 10 chelating resin used in the experiment has a three-dimensional network structure containing an *N*-(*o*-hydroxybenzyl)iminodiacetic acid moiety as a chelating group. Since the chelating site has phenolic oxygen in addition to the iminodiacetic acid group which is often found in the conventional chelating resin such as Dowex A-1, the coordination site of the Uniselec resin behaves as a quadridentate ligand to iron(III) ion, resulting in a more stable chelate than that by the Dowex A-1 type resins. As a result, iron(III) ion is so tightly bound to the resin that it is not easily released from the resin even in the presence of a large excess of alkali and alkaline earth cations above pH 3.

Iron(III) ion which is coordinatively hexavalent is bound to the Uniselec resin under so called "coordination unsaturated" conditions, leaving two coordination sites aquated. The sites are expected to act as adsorption sites for the coordinating anions as suggested by Helfferich.[2] A report appeared on the selective adsorption of arsenite and arsenate ions by the iron(III) chelating resin.[1]

pH *Dependence of the Partition Ratio,* K_{ad}. Figure

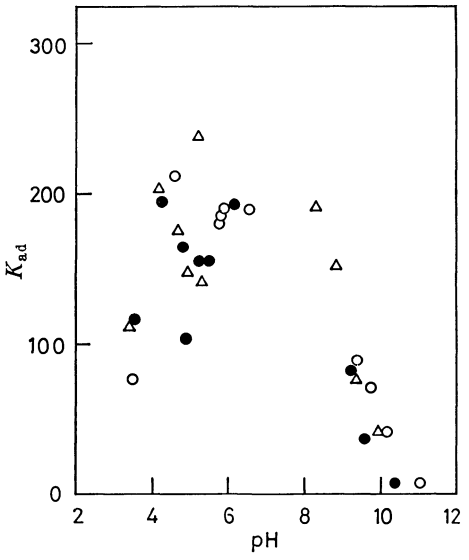

Fig. 1. pH profile of partition ratio, K_{ad}, of the iron(III) resin (F=1.25) at 35 °C. In acidic region, buffered with 0.1 M acetate buffer. In alkaline region, buffered with 0.1 M ammonia–ammonium chloride (○) or with 0.1 M ammonia–ammonium nitrate either in the presence (△) or absence (●) of 0.1 M sodium chloride.

1 shows the pH dependency of the partition ratio, K_{ad}, of phosphate ion at 35 °C. The pH of the aqueous phase was buffered with 0.1 M acetic acid–sodium acetate in the acidic region, and with 0.1 M ammonia–ammonium chloride (○) or 0.1 M ammonia–ammonium nitrate (●, △) in the alkaline region. The symbol (△) shows the partition ratio in the presence of 0.1 M sodium chloride. Though the points are scattered, the adsorption of phosphate seems to be most favorable in the pH region 4—7. The K_{ad} value decreases rapidly with variation in pH on either side of the optimum region. If we consider the acid dissociation constants of phosphoric acid (pK_a; 2.06, 7.03, 12.1), such a pH profile suggests the univalent dihydrogenphosphate ion to be responsible for adsorption. Since the presence of chloride ion gives no adverse effect on K_{ad} value, the adsorption is not due to the ion-exchange reaction.

The nature of the iron(III) resin changes with variation in pH. When pH<1, iron(III) ion may be displaced from the resin with proton, resulting in the loss of adsorption capacity. With increase in pH, the proton dissociation of coordinated water on the resin bound iron(III) ion might occur, forming monohydroxo- and dihydroxo species.

This has been discussed by Harris *et al.*[3] on the iron(III) chelate of monomeric *N*-(*o*-hydroxybenzyl)-iminodiacetic acid in aqueous solution, where the proton dissociation constants of diaquated iron(III) chelate were found to be:

$$FeL(OH_2)_2 \rightleftharpoons FeL(OH_2)(OH)^- + H^+ \qquad \log K = -5.71$$

$$FeL(OH_2)(OH)^- \rightleftharpoons FeL(OH)_2^{2-} + H^+ \qquad \log K = -9.1$$

where H_3L denotes the free ligand. If we assume a similar proton dissociation scheme on the resin bound diaquated iron(III) ion, it may behave as a dibasic

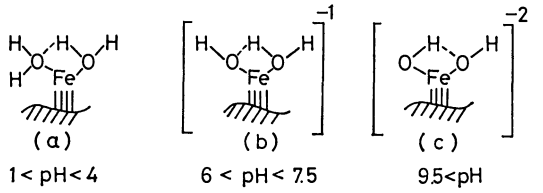

Fig. 2. Possible states of the resin bound iron(III) ion.

acid (Fig. 2). Species (a), (b), and (c) may predominate in the pH regions <4, 6—7.5, and >9.5, respectively. The electrostatic repulsion between the resin bound iron(III) ion and phosphate ion becomes larger in the order (a)<(b)<(c). At the same time, the resistance to the ligand exchange reaction between phosphate ion and the hydrolyzed species would become larger in the order (a)<(b)<(c). Thus, of the three states of the iron(III) resin, the most favorable one for the adsorption of phosphate ion seems to be (a), showing the optimum K_{ad} value in a weakly acidic region.

Adsorption Isotherms with the Iron(III) Resin. The effect of temperature on the adsorption isotherms of phosphate ion with the iron(III) resin is shown in Fig. 3, where the resin of F=1.34 was used at pH 6.0 with ionic strength *ca.* 0.2. The effect of iron(III) ion content on the adsorption isotherms under similar experimental conditions at 35 °C is shown in Fig. 4. The phosphate uptake by the resin, Q, increases with rise in temperature and increase in the iron(III) ion content. It also increases with increase in phosphate ion concentration in the aqueous phase, C, approaching saturation at higher phosphate ion concentration. The results suggest that the adsorption of phosphate is a chemical reaction and that the adsorption sites are the resin bound iron(III) ions.

The adsorption of phosphate ion can be considered to be the ligand exchange reaction between the coordinated water and the phosphate ion. If we assume that the reacting species of the resin bound iron(III) ion is mainly in the state (a), the reaction can be schematically written as follows.

$$RFe(OH_2)_2 + H_2PO_4^- \overset{K_{eq}}{\rightleftharpoons} RFe(H_2PO_4)^- + 2H_2O \qquad (1)$$

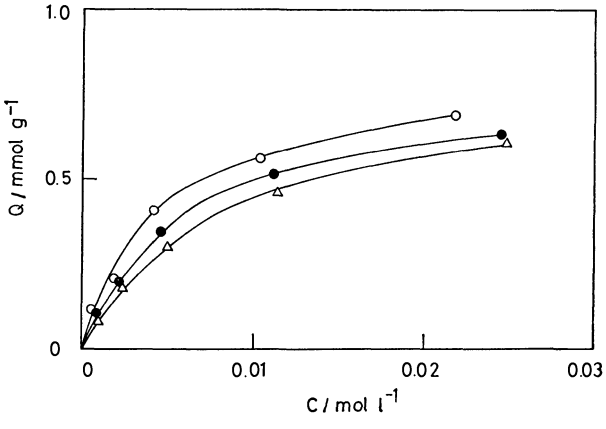

Fig. 3. Adsorption isotherms of the iron(III) resin (F=1.34) at different temperatures (pH=6.0, $\mu \approx 0.2$). —○— 35 °C, —●— 25 °C, —△— 8 °C.

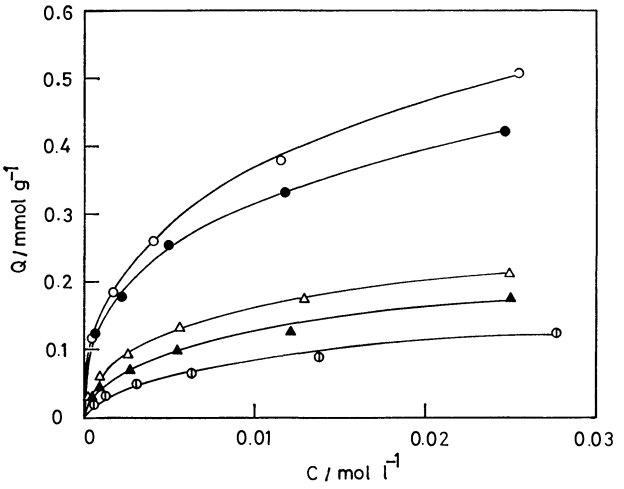

Fig. 4. Adsorption isotherms of the iron(III) resin of various iron contents at 35 °C (pH=6.0, $\mu\approx0.2$). —○— F=0.88, —●— 0.64, —△— 0.31, —▲— 0.23, —⏀— 0.12.

where $RFe(OH_2)_2$ denotes the resin bound iron(III) ion. The equilibrium constant of this reaction can be given by

$$K_{eq} = \frac{X_{RFe(H_2PO_4)^-}}{X_{RFe(OH_2)_2}} \cdot \frac{1}{C} \tag{2}$$

where the mole fractions of unadsorbed and adsorbed sites in the resin, and the molar concentration of phosphate ion in the aqueous phase are expressed as $X_{RFe(OH_2)_2}$, $X_{RFe(H_2PO_4)^-}$, and C, respectively.

The mole fraction of adsorbed site can be written as

$$X_{RFe(H_2PO_4)^-} = \frac{A}{WQ_\infty} = \frac{Q}{Q_\infty} \tag{3}$$

where A is the amount of phosphate adsorbed (mmol) on W g of the iron(III) resin ($Q=A/W$), and Q_∞ is the saturated adsorption capacity of the resin.

By means of the relation

$$X_{RFe(OH_2)_2} + X_{RFe(H_2PO_4)^-} = 1, \tag{4}$$

Eq. 2 can be written as

$$C = -\frac{1}{K_{eq}} + Q_\infty\left(\frac{C}{Q}\right). \tag{5}$$

Thus, the plots of C against C/Q should give a straight line, from which $-1/K_{eq}$ and Q_∞ can be obtained from the intercept and slope, respectively.

The isotherms of the resins of various iron(III) ion contents at various temperatures were treated by means of Eq. 5 where the phosphate ion concentrations of the aqueous phase were in the range (3.2×10^{-4}—2.9×10^{-2}) M after equilibration. The results are shown in Figs. 5 and 6, respectively. The values for K_{eq} and Q_∞, obtained from the intercept and slope of each line drawn by the method of least squares, are summarized in Table 1.

Equilibrium constant, K_{eq}, increased with increase in temperature, indicating that the adsorption is a

Table 1. Parameters for the adsorption on phosphate ion by iron(III) complex of cherating resin (pH=6.0, μ=0.2)

Resin			Parameters for Eq. 5		
Iron content F/mmol g^{-1}	Water content %	Temp °C	Q_∞ mmol g^{-1}	$K_{eq}\times10^{-2}$ l mol^{-1}	Q_∞/F
0.12	110.0	35	0.13±0.02	2.2±1.1	1.08±0.17
0.23	90.1	35	0.19±0.02	2.7±0.9	0.83±0.09
0.31	89.1	35	0.23±0.02	3.0±0.8	0.74±0.06
0.64	84.9	35	0.46±0.05	3.2±1.6	0.72±0.08
0.88	79.9	35	0.54±0.06	3.0±1.6	0.61±0.07
1.34	72.5	35	0.82±0.07	2.7±0.6	0.61±0.05
1.34	72.5	25	0.77±0.02	2.0±0.2	0.57±0.01
1.34	72.5	8	0.82±0.03	1.2±0.1	0.61±0.02

chemical process as shown by Eq. 1. Saturated capacity, Q_∞, does not change with temperature. It increases with increase in iron(III) ion content in the resin, indicating that the resin bound iron(III) ions act as the adsorption sites for phosphate ion.

We could expect a 1:1 binding ratio for phosphate ion: the resin bound iron(III) ion, since we found a 1:1 complex formation in the spectrophotometric study on the interaction of phosphate ion with the iron(III) chelate of *N*-(*o*-hydroxybenzyl)iminodiacetic acid in aqueous solution at pH 6.0.[4] However, as shown in Table 1, the stoichiometric ratio, Q_∞/F, indicates that only one half of the resin bound iron(III) ions act as adsorption sites at higher iron(III) ion content, the value approaching unity with the decreasing iron(III) ion content. This suggests that, at higher iron(III) ion content, the electrostatic and steric repulsions among the phosphate ions in the resin matrix may interfere with the stoichiometric adsorption of phosphate to the resin–bound iron(III) ion, while at lower iron(III) ion content, the adsorption becomes more stoichiometric due to the smaller interaction among adsorbed phosphate ions.

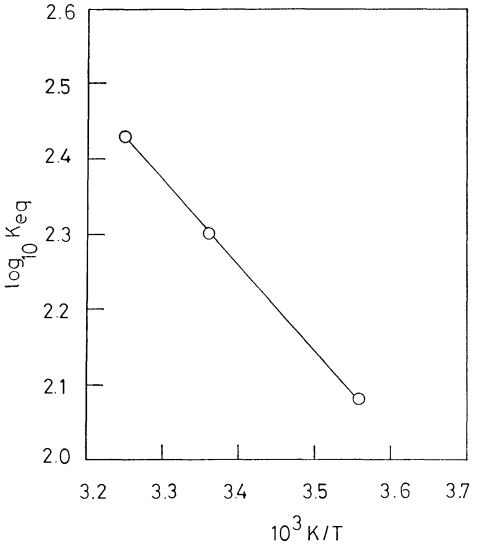

Fig. 7. Arrhenius plots for the standard heat of adsorption. Data from Table 1.

The equilibrium constant, K_{eq}, increases with increase in temperature. Thus we can estimate the apparent standard heat of adsorption from the Arrhenius plots (Fig. 7). The value $\Delta H = 21.8$ kJ mol^{-1} is reasonable for the complex formation.

The authors are grateful to Unitika Ltd. for the supply of Uniselec chelating resin.

The Determination of Berberine by Ion-pair Extraction-Titration, with Tetrabromophenolphthalein Ethyl Ester as the Indicator

Masahiro TSUBOUCHI

Laboratory of Chemistry, Kochi Medical School, Oko, Nankoku, Kochi 781-51

(Received March 8, 1979)

A method has been developed for the determination of berberine as a quinolizinium medicine. The method is based on the solvent extraction-titration of an ion pair. Sodium tetraphenylborate is used as the titrant, with tetrabromophenolphthalein ethyl ester as the indicator in the presence of chloroform. In the two-phase titration, the proposed procedure gives sharp end points as the organic phase changes from blue to yellow. The aqueous phase is colorless throughout the titration. From a p(berberine)-pH diagram, a theoretical titration curve is constructed. The titration curve at pH 6.5 is not too far from the ideal case.

Various reports have appeared regarding the ion-pair extraction-titration (two-phase titration) method. Methylene Blue,[1] Methyl Orange,[2] Azure A,[2] Bromophenol Blue,[3] and Neutral Red[4] have been used as indicators for the determination of anionic surfactants of quaternary ammonium salts. The ion-pair extraction-titration techniques would be convenient for use in the laboratory because, with them, there is no need for sophisticated instrumentation. End-point detection in two-phase titration is based on the movement of a dye as an indicator from one phase to the other. In general, though, it is difficult to detect the end point because a dye color in an aqueous phase or an organic phase will be reflected in the other layer.[1,2]

This paper will deal with the determination of berberine as a quinolizinium medicine. Nonaqueous titrimetric,[5] gravimetric,[6] and spectrophotometric[7–10] methods were investigated for the determination of berberine. In the two-phase titration proposed here, sodium tetraphenylborate is used as the titrant, with tetrabromophenolphthalein ethyl ester (In) as the indicator in the presence of chloroform. This procedure gives sharp end points as the organic layer changes from blue to yellow, and there is less likelihood of error. A singly charged In anion forms a 1:1 ion pair with berberine in the organic solvent.[8] The aqueous layer is colorless throughout the titration. This is because the indicator itself is not soluble in water, but gives a yellow color in chloroform. When the berberine (Bb) is titrated with a sodium tetraphenylborate (TPB) solution, the $[Bb^+ \cdot TPB^-]$ ion pair is formed in the organic phase and the reaction followed at the end point is:

$$\underset{\text{blue}}{[Bb^+ \cdot In^-]_{org}} + H^+ + [TPB^-]_{aq} \longrightarrow [Bb^+ \cdot TPB^-]_{org} + \underset{\text{yellow}}{[In]_{org}}$$

Experimental

Reagents. Tetrabromophenolphthalein ethyl ester potassium salt was dissolved in ethanol to make the solution 0.1%. A proper quantity of berberine chloride was dissolved in the distilled water. Standardization was done spectrophotometrically with a potassium dichromate solution.[7] The phosphate buffer solution (pH 6.5) was prepared from a 0.3 M disodium hydrogenphosphate solution with several drops of dilute sulfuric acid.

Procedure. The berberine solution (1—10 ml of 0.001 M), 5 ml of the phosphate buffer solution, 10 ml of chloroform, and 2—3 drops of a tetrabromophenolphthalein ethyl ester solution were placed in a 200-ml Erlenmeyer flask. The mixture was titrated with a 0.002 M sodium tetraphenylborate solution, with intermittent shaking by hand, to ensure an equilibrium between the organic solvent and the aqueous phase. The organic phase changes from greenish blue to yellow at the end point.

Results and Discussion

When the mixture of the berberine solution, the buffer solution, chloroform, and the indicator solution is shaken as has been described above, the aqueous phase is colorless and the organic phase is greenish blue. Figure 1 shows the visible absorption spectra of the indicator in chloroform. Near the end point of the titration, the organic phase starts to turn green. When one drop excess of the tetraphenylborate solution is added, the organic phase acquires a distinct yellow color, while the aqueous phase is still colorless. This is due to the fact that the indicator forms an organophilic ion pair with berberine. Therefore, some reflection of the color in the aqueous phase does not interfere with the end-point detection.

The effect of the pH on the proposed method was studied by titrating a series of berberine solutions buffered at various pH values. The results are summarized in Fig. 2. When the berberine solution is titrated with sodium dodecylbenzenesulfonate solution, quan-

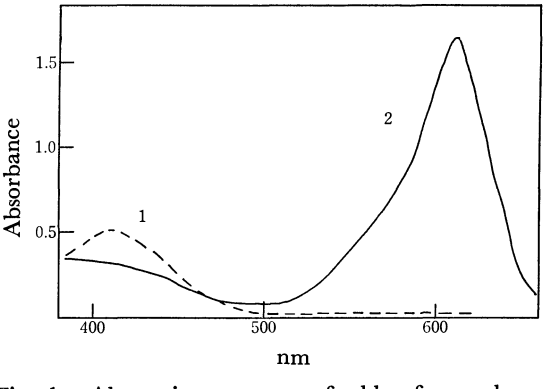

Fig. 1. Absorption spectra of chloroform phase. 1: Extract with 2×10^{-5} M indicator, 2: extract with 2×10^{-5} M indicator and 2×10^{-5} M berberine. Reference: water.

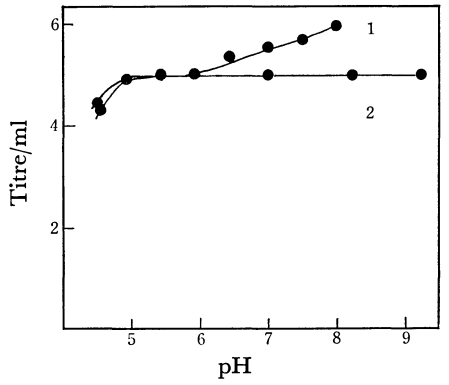

Fig. 2. Effect of pH on titration. 1: Titration with 0.002 M laurylbenzenesulfonate, 2: titration with 0.002 M tetraphenylborate, berberine, 10 ml of 0.001 M.

titative titrations are obtained in the pH range of 5—6. Larger amounts of buffer solution had no influence on the titration, but when less than 1 ml was added, the phase separation was poor.

As in the pH titration of acids and bases or in the pM titration of the metal ion and ethylenediaminetetraacetic acid,[11] berberine titration by the extraction may be generally represented by p(berberine) titration curves. The basic equilibria are given by:

$$(Bb)_w + (TPB)_w \rightleftharpoons (Bb\cdot TPB)_o$$

$$(Bb)_w + (In)_o \rightleftharpoons (Bb\cdot In)_o$$

For simplicity, the charges are omitted. The symbols are: Bb, berberinium ion; TPB, tetraphenylborate ion; In, indicator; o, in the organic phase; w, in the aqueous phase. The corresponding equilibrium constants are:

$$K_{Bb\cdot TPB} = [Bb\cdot TPB]_o/([Bb]_w \times [TPB]_w)$$

$$K_{Bb\cdot In} = [Bb\cdot In]_o/([Bb]_w \times [In]_o)$$

The effective stability constants (12—17 °C) were obtained from absorption measurements with berberine-tetraphenylborate extracts and berberine-indicator extracts at 440 nm[7] and 610 nm[8] respectively. A simple pBb-pH diagram is given in Fig. 3 for the titration. When 50% of TPB is present in free-ion form and 50% in Bb–TPB ion-pair form, the pBb is equal to the logarithm of the effective stability constant (K') of the Bb–TPB ion pair:

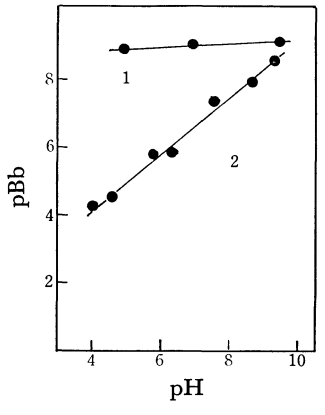

Fig. 3. p(berberine)-pH diagram. 1: $\log K'_{Bb\cdot TPB}$, 2: $\log K'_{Bb\cdot In}$.

$$\log K'_{Bb\cdot TPB} = \log 1/[Bb]_w = pBb$$

Line 2 in Fig. 3 corresponds to the pBb value at which 50% of In is present in free-dye form and 50% in Bb–In ion-pair form:

$$\log K'_{Bb\cdot In} = \log 1/[Bb]_w = pBb$$

From the pBb-pH diagram, a theoretical titration curve is constructed for the 0.002 M TPB titration of 10 ml of 0.001 M Bb at the pH value of 6.5 as is shown in Fig. 4. The pBb at the 50%-color-change point, C, is equal to the logarithm of the effective stability constant of the Bb–In ion pair. A maximum color change is obtained by a minimum increment titrant at this point. The fractional color change from 0.1 to 0.9 covers about 2 pBb units. The shaded areas indicate the region of the color change of the indicator. The titration curve at pH 6.5 is not too far from the ideal one.

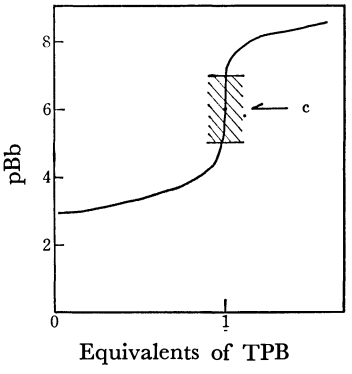

Fig. 4. Titration curve at pH 6.5. 10 ml of 0.001 M berberine is titrated with 0.002 M tetraphenylborate.

Ten identical samples, each with 10 ml of a 0.001 M berberine solution, were titrated with a 0.002 M tetraphenylborate solution according to the procedure. The mean titre was 5.00 ml, with a standard deviation of 0.04 ml.

Various water-immiscible solvents, such as nitrobenzene, isopentyl methyl ketone, butyl acetate, isoamyl alcohol, toluene, 1,2-dichloroethane, chloroform, benzene, carbon tetrachloride, and hexane, were tested. Of these, chloroform was the best solvent for the titration of berberine. The initial volume fluctuations of the aqueous phase (5—20 ml) and the organic phase (7—15 ml) did not have any measurable effect on the determination of the end point.

The effects of other ions on the titration process were studied for 10 ml of the 0.001 M berberine solution. The following ions did not interfere at the 0.01 M level: Na^+, Ca^{2+}, Mg^{2+}, K^+, NH_4^+, NO_3^-, SO_4^{2-}, Br^-, Cl^-, I^-, acetate, carbonate, citrate, and tannate. Amines such as thiamine, papaverine, and diphenhydramine caused positive errors; the maximum permissible amount was the 10^{-4} M level. Dodecyl sulfate, quaternary ammonium, and mercury(II) ions interfered.

Sample of medicine containing berberine chloride (40 mg), tannic acid (40 mg), aluminium 2-hydroxy-3-naphthoate (100 mg), pectin (50 mg), and silicon powder (5 mg) were dissolved in water. The solutions

were filtered and analyzed according to the proposed method and a spectrophotometric method.[7] The mean result of six samples was 39.0 mg of berberine chloride, with a standard deviation of 0.3 mg, while the result was 38.2 mg of berberine chloride by the spectrophotometric method. The proposed indicator has proved applicable to the two-phase titration of anionic surfactants with quaternary ammonium salts.

The author wishes to thank Professor Yuroku Yamamoto of Hiroshima University for his valuable advice.

ESR Study of ^{63}Cu(II) Doped in Single Crystals of Bis(alkyl 3-alkylidenedithiocarbazato)nickel(II) and -zinc(II). II. Proton Hyperfine Structure and Tetrahedral Distortion

Takayuki Oniki

Pre-dental Course, Kyushu Dental College, Manazuru, Kokurakita-ku, Kitakyushu 803

(Received December 11, 1978)

The ESR spectra of ^{63}Cu(II) diluted in several single crystals of the title Ni(II) and Zn(II) complexes are reported. In the substituted benzylidene groups, hyperfine structure(hfs) due to the magnetically equivalent two protons have been observed. The hfs were resolvable only in a limited magnetic direction due to the small anisotropic coupling constants. The coordination around Cu(II) ion has been found to be *cis* in all the Zn(II) complexes and the ESR parameters are more anisotropic than in the Ni(II) complexes. The relationship between the tetrahedral distortion and the ESR parameters has been interpreted using the d-orbital coefficients in the ground state.

There have been a number of theoretical studies on tetrahedral distortion around copper(II) centers and extensive ESR studies on the solid state system.[1—9] The tendency for $g_{\parallel}$ to increase and $|A_{\parallel}|$ to decrease with increasing tetrahedral distortion has been reported for well-characterized complexes of copper(II) with *N*-salicylidenealkylamine,[10,11] bis(pyrazolyl)gallates,[12] and dipyrromethenates.[13] Yokoi and Addision[14] reported the ESR measurements of several bis(*N*-substituted 2-pyrrolylmethyleneaminato)copper(II) complexes in toluene and concluded that the small value of $|A_0|$ is due to the large positive value of $A_{\perp}$ by tetrahedral distortion. Bates explained the small hf coupling constants on the basis of $3d^84p$ mixing in the $3d^9$ configuration.[4]

The ESR parameters of the Cu(II) site which is tetrahedrally distorted from *cis*-CuN_2S_2 planar symmetry has been discussed in a previous report.[15] The Schiff bases derived from alkyl dithiocarbazate were found to form a series of ligands,[16—19] whose properties were greatly modified by the introduction of organic substituents into the ligand thereby inducing different stereochemistry in the resultant metal complexes. The relationship between the ESR parameters and tetrahedral distortion around the Cu(II) ion site have been investigated by measuring the ESR spectra for ^{63}Cu(II) diluted with Zn(II) complexes in place of the Ni(II) complexes which have a *S*-methyl group, and with the Ni(II) complexes which possess a *S*-benzyl group. In either case the tetrahedral distortion is expected to be larger than in Ni(II) complexes with a *S*-methyl group.

In the first report the ESR spectra of Cu(II)/Ni(bdc)$_2$ exhibited additional hfs. The additional hfs are assignable to two azomethine protons or to noncoordinated nitrogen, in order to establish which was the case the ESR spectra of ^{63}Cu(II) diluted in Zn(II) and in Ni(II) complexes with Schiff bases which have azomethine protons were measured. Figure 1 shows the structures of the host complexes used. The alkyl and alkylidene groups denote methyl and 1-phenylethylidene, methyl and 1-(*p*-tolyl)ethylidene, methyl and *o*-tolylidene, methyl and *m*-tolylidene, methyl and *o*-chlorobenzylidene, benzyl and 1-(2-naphthyl)ethylidene, benzyl and 1-(*p*-tolyl)ethylidene, and benzyl and 1-phenylethylidene, and the corresponding ligands have been abbreviated as pedcH, tedcH, omdcH, mmdcH, ocdcH, bndcH, btdcH, and bpdcH respectively.

Fig. 1. The structures of the host complexes used; bis(alkyl 3-alkylidenedithiocarbazato)nickel(II) or -zinc(II), and abbreviations which are classified into *cis* or *trans* form around copper(II) ion site.

Experimental

The complexes were prepared according to the methods of cited in the literature.[16,17] The ESR spectra were recorded every 5° or 10° around three mutually perpendicular rotational axes. The most elongated axis was defined as the 2-axis, and the broadest crystal face was defined as the 12-plane. The room temperature ESR spectra were taken on a JEOL ME 1X spectrometer at the X band. A frequency counter, Mn(II) diluted with MgO, and DPPH were used as the *g* marker. The second order effects of the ESR spectra were calculated by the method of Iwasaki.[20] The forbidden transitions could not be obtained, so that no attempt was made to determine the quadrupole coupling parameters. The calculations were performed on an Olivetti P 652 computer.

Results and Discussion

Proton Hyperfine Structures. The four complexes with the ligands which have azometihne protons were

obtained. Table 1 shows the obtained ESR parameters and direction cosines against 1, 2, and 3 axes. In all the complexes, additional hfs were observed. Figure 2 shows well resolved extra hfs which consist of three lines with an intensity ratio of 1:2:1. It was concluded, that the extra hfs are due to two azomethine protons. The proton hfs were anisotropic and small, and well resolved only in the limited magnetic direction. Table 1 shows, therefore, only the maximum coupling constants(G). The proton hfs were observed in the cases of bis(salicylideneaminato)copper(II),[21] *N,N*-bis(2-pyrrolylmethylene)ethylenediaminatocopper(II),[22] Cu(II) doped in L-alanine,[23] and measured in great

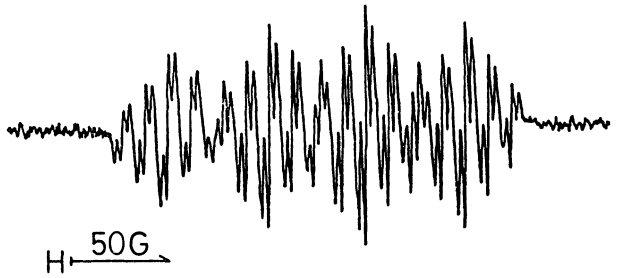

Fig. 2. The well resolved single crystal ESR spectra of ^{63}Cu(II)/Ni(ocdc)$_2$. The proton hfs is well resolved at high field with the intensity ratio of 1:2:1, $(\theta, \varphi)=(15°,0°)$, where θ and φ is the angles in the spherical 123 coordinate.

detail by ENDOR in the case of bis(salicylaldehyde oximato)copper(II).[24] In the present work the proton hfs are observable even if the proton is binded to a carbon atom which is not in the chelate ring.

A methanolic solution of omdcH and copper acetate is deep-green at low temperature, but in a short time, the solution changes in color from deep-green to reddish-brown. Only reddish-brown crystals of Cu(omdc)$_2$ were obtained and readily doped in Ni(omdc)$_2$. Cu(omdc)$_2$, synthesized in the presence of zinc acetate at low temperature, enables the deep-green Cu(omdc)$_2$ to be doped in Zn(omdc)$_2$. In a series of copper(II) complexes, the color is deep-green in the *cis* coordination and reddish-brown in the *trans* coordination. The ESR spectra of deep-green ^{63}Cu(II)/Zn(omdc)$_2$ shows the presence of two magnetically non-equivalent nitrogen hfs in the limited magnetic direction, and small nitrogen hf coupling constants. These results suggest that the coordination around the Cu(II) ion in Zn(omdc)$_2$ is of a *cis* configuration.[15] Cu(bdc)$_2$ and Cu(mmdc)$_2$ are also deep-green in the preparation at low temperature, but the deep-green Cu(II) doped Zn(II) complexes were not obtained due to the inability of achieving single crystals of the Zn(II) complexes at low temperature.

Tetrahedral Distortion. Table 2 shows the ESR parameters of ^{63}Cu(II) in Zn(II) complexes and in the Ni(II) complexes with *S*-benzyl groups. In all the complexes of Table 2, the coordination around the Cu(II) ion was found to be of a *cis* configuration from the same reasoning as described in the case of ^{63}Cu(II)/Zn(omdc)$_2$. The nitrogen hf coupling constants could not be determined accurately for the *cis* coordination since the magnetically non-equivalent nitrogen hfs were well resolved only in the limited magnetic direction along one of the Cu–N axes.

The ESR parameters are more rhombic in the *cis* complexes than in the *S*-methyl containing Ni(II) complexes.[15] The anisotropies of the ESR parameters are probably due to the tetrahedral distortion of the host complexes.

Calculation of d-Orbital Mixing. The electronic spectra of the Cu(II) complexes consist of very strong charge transfer bands, the single d-d transition band being detected in the region 500—650 nm. This band has been tentatively assigned to the $d_{zx}\rightarrow d_{z^2}$ or $d_{zx}\rightarrow d_{x^2-y^2}$ transition for *cis* complexes. The ESR param-

eters could not be completely determined from only this band. The d-orbital coefficients of the ground-state were then determined from the observed ESR parameters.[25] The ground state function for *trans* coordination is given by,[15]

$$\Phi^\alpha = a|x^2-y^2>^\alpha + b|z^2>^\alpha + ic|xy>^\alpha - id|yz>^\beta + e|zx>^\beta, \quad (1)$$

and for *cis* coordination by,

$$\Phi^\alpha = a|zx>^\alpha + ib|yz>^\alpha + c|z^2>^\beta - d|x^2-y^2>^\beta - ie|xy>^\beta. \quad (2)$$

Table 3 shows the coefficients obtained from Eqs. 1 or 2. Changing the x and z directions produces a larger value of d than c. It is uncertain from only the ESR data whether the axis should be assigned as x or z.

The copper hf coupling constants for the *trans* coordination have the same sign which are in reasonable agreement with the ESR spectra of chloroform solutions (83—86 G). The situation around the Cu(II) ion in chloroform solution is not the same as in the Zn(II) complexes. The ESR spectra of chloroform solutions supports the finding that the copper hf coupling constants are the same sign in *cis* Ni(II) complexes (64—72 G). It is reasonable to assume that the copper hf coupling constants are also the same sign in the Zn(II) complexes.

Figure 3 shows the variations of copper hf coupling constants against the values of c/d. The d-orbital coefficients satisfy the observed g values in all regions of c/d values. The acceptable region which satisfies the copper hf coupling constants is in the narrow range of c/d values. McGregor and Hatfield[26] measured the ESR spectra of bis(2,2′-bipyridyl)thioureacopper(II) perchlorate and determined the d-orbital coefficients only from the g values. The copper hf coupling constants could not be obtained from the single crystal. The method of Swalen *et al.*[25] cannot be applied when the copper hf coupling constants are not obtained, if there is no strong evidence for a relationship between the d-orbital coefficients.

In the *cis*-CuN_2S_2 planar symmetry, the d_{zx} orbital is in the ground state, and the coefficient b is a function of the spin orbital coupling and pure $d_{zx}\rightarrow d_{yz}$ energy separation.

In the case of a small tetrahedral distortion, a mixture of the d_{zx} and d_{yz} orbitals become the ground state, and the excited d_{xy}, $d_{x^2-y^2}$, and d_{z^2} orbitals are mixed in the same manner. A spin orbit interaction also occurs between the d_{yz} and other d orbitals, and the ESR parameters cannot be determined solely from one d-d transition. Assuming the $d_{zx}\rightarrow d_{yz}$ energy separation does not vary from complex to complex, the value of $(b/a)^2$ gives a measure of the degree of tetrahedral distortion since the value of $|b|$ increases with increasing tetrahedral distortion. The increase of $|b|$ values is observed in the case of Zn(II) complexes as may be seen from Table 3.

The copper hf coupling constants in Zn(II) complexes are smaller than in other complexes a result in agreement with that found by Yokoi and Addison.[14] The values of A_x and A_z, however, are negative since the distortion is not so large.

The molecular orbital of an unpaired electron in the *cis* coordination is given by,

$$|zx\rangle = N^{1/2}[d_{zx}-(\alpha_1/\sqrt{2})(s^1-s^2)-(\alpha_2/2) \times(-p_x^1-p_x^2-p_z^1+p_z^2)-(\alpha_3/\sqrt{2}) \times(-s^3+s^4)-(\alpha_4/2)(p_x^3+p_x^4-p_z^3+p_z^4)], \quad (3)$$

and in the *trans* coordination by,

$$|A_{1g}\rangle = N^{1/2}[d_{x^2-y^2}+(b/a)d_{z^2}-(\alpha_1/\sqrt{2})(s^1+s^2) -(\alpha_2/\sqrt{2})(-p_x^1+p_x^2)-(\alpha_3/\sqrt{2})(p_y^3-p_y^4)]. \quad (4)$$

The bonding parameters of $N\alpha_1^2$, $N\alpha_2^2$, and $N\alpha_4^2$ in Eq. 3, and of $N\alpha_1^2$, $N\alpha_2^2$, and $N\alpha_3^2$ in Eq. 4 were obtained as in the first report and are shown in Table 4. The normalization constants N have been assumed to be 0.7 in either case. The small A^N values and large $N\alpha_4^2$ values in the *cis* coordination are explainable as follows. In *cis* coordination, the Cu–N bond length is longer than in *trans* coordination because of steric repulsion by the large phenyl group. The Cu–S bond length on the other hand is shorter than in a *trans* coordination since there is no such repulsion. A similar situation occurs in the case of bis(thiosemicarbazide)nickel sulfate.[27]

The author is grateful to Dr. Kazunori Sakata of Kyushu Technical College for kindly allowing him to take ESR measurements.

Circular Dichroism Spectra of Some Transition Metal Complexes with (1*R*,2*R*)-1,2-Cyclopentanediamine

Masafumi GOTO,*Michihiro TAKESHITA, and Tomoya SAKAI

Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467

(Received March 1, 1979)

Bischelates, three isomers of dicyanocobalt(III), *trans*-dichlorocobalt(III), and copper(II), and a monochelate, tetracyanoferrate(II), of the title diamine were prepared, and their CD spectra were reported. Major positive components were found for I_a bands, as was to be expected for the preferred λ conformation, but minor positive components were observed for the I_b band with the *trans*-dianionocobalt(III) complexes. The configurational and the vicinal effects, as calculated from the CD spectra of the *cis*-dicyanocobalt(III) complexes, are shown to be different from those of (1*R*,2*R*)-1,2-cyclohexanediamine. The CD spectra of the Fe(II) and Cu(II) complexes are consistent with the conformational effect of the title diamine.

The optical activity of transition metal complexes has been studied with a variety of ligands. Among them, 1,2-diamines are most widely employed, and the results have been recognized as well established. However, the results have been obtained mostly with en, pn, and chxn as 1,2-diamines.[1,2] The CD spectra of metal chelates with these diamines are almost identical with their corresponding structures, and the proposed empirical rules of the optical activity are based on these results. However, two exceptions are known. Phenyl-substituted diamines, stien[3] and phenen,[4] yield cobalt(III) complexes which have CD spectra different from those of the other diamines mentioned above. Another is the tris cobalt(III) complexes of cptn. An earlier study of the complexes of cptn has been reported by Jaeger and Blumendal.[5] Saito *et al.* have reported that the CD spectrum of Λ-[Co(*S*-cptn)$_3$]Cl$_3$ is anomalous, even though the structure has been confirmed by X-ray crystallography to be similar to that of other corresponding tris(diamine)-cobalt(III) complexes.[6] The CD spectra of Δ- and Λ-[Co(*R*-cptn)$_3$]$^{3+}$ have been reported by Toftlund and Pedersen.[7] The diamine, cptn, may be expected, because of its fused five-membered cyclopentane ring, to form a chelate with a rigid structure on coordination to a metal ion.

Tetragonal complexes, *trans*-dianionobis(diamine)-cobalt(III), exhibit CD spectra which are free from any configurational contribution. The sector rule predicts that the signs of CD components corresponding to the $^1A_{1g}\rightarrow{}^1E_g{}^a$ and $^1A_{1g}{}^a\rightarrow{}^1A_{2g}$ transitions (D_{4h}) are positive and negative respectively with 1,2-diamines which form chelate rings of the λ conformation upon coordination.[2] Anomalous CD spectra can be expected for the tetragonal complexes with resolved cptn if the vicinal effect of this diamine differs from those of other 1,2-diamines.

This paper will deal with the syntheses and CD spectra of *trans*-dichloro and three isomers of dicyanocobalt(III) complexes, the tetracyanoferrate(II) complex, and the biscopper(II) complex with *R*-cptn as the diamine.

Experimental

Materials. The cyclopentanone (Merck, Synthetic Grade) was used without further purification. The pyridine,[8] methanol,[9] and sulfolane[10] were purified according to the known methods. The other chemicals were used as purchased.

*Preparation of (1*R*,2*R*)-1,2-Cyclopentanediamine. 1,2-Cyclopentanedione*: This was prepared by a modification of the method for preparing 1,2-cyclohexanedione.[11] A 3-dm^3 round-bottomed flask containing 1.5 dm^3 of cyclopentanone and fitted with a stirrer and a dropping funnel was placed in a water bath. The contents were warmed to 30 °C, and then a solution containing 361 g (3.25 mol) of selenium dioxide, 420 cm^3 of dioxane, and 155 cm^3 of water was added dropwise into the cyclopentanone over a period of 24 h with stirring. Stirring was continued for further 18 h at 35 °C. The red selenium thus separated was filtered off on a Buchner funnel. The selenium was returned to the reaction flask and extracted with 500 cm^3 of boiling ethanol for 3 h. The solution obtained by filtration was combined with the above filtrate. The combined filtrate was distilled using a 60-cm Vigreau column at 2700 Pa, and the lower-boiling portion (35—90 °C) was removed. The remaining portion was distilled at 1300 Pa until a thick brown residue formed in the distilling flask, thus preventing further distillation. The higher-boiling fraction was redistilled at 2100 Pa, and a fraction which distilled at 86—88 °C was collected. Yield, 74 g (23% based on SeO_2).

The 1,2-cyclopentanedione dioxime and *trans*-1,2-cyclopentanediamine were prepared successively from 1,2-cyclopentanedione according to the method of Jaeger and Blumendal.[5] The optical resolution of the diamine was carried out according to the method of Toftlund and Pedersen[7] to isolate the (1*R*,2*R*)-isomer using (+)-tartaric acid as the resolving agent. The (1*S*,2*S*)-isomer was obtained by employing (−)-tartaric acid as the resolving agent after the recovery of the free base from the remainder of the (1*R*,2*R*)-isomer.

Preparation of Metal Complexes. trans-[*CoCl*$_2$(R-*cptn*)$_2$]-*Cl·0.5H$_2$O*: To 100 cm^3 of an aqueous solution of $CoCl_2\cdot 6H_2O$ (4.76 g, 0.02 mol), *R*-cptn (3.00 g, 0.03 mol) was added, after which, the mixture was aerated for 3 h. To the resultant brown solution, 30 cm^3 of concentrated hydrochloric acid was added. The mixture was then concentrated on a steam bath to near dryness. The separated crystals were collected on a filter and washed thoroughly with acetone until the filtrate showed no blue color. The crystals were then added to 40 cm^3 of methanol. The mixture was refluxed for 2 h and filtered. The filtrate was allowed to stand in a refrigerator overnight; the green crystals thus separated were collected on a filter and washed thoroughly with acetone. Yield, 1.7 g (23%).

Perchlorates: To the filtrate, a large excess of lithium perchlorate was added. The green crystals thus separated were

collected on a filter and washed with ethanol and ether. The analytical data are listed in Table 1, along with those for other complexes.

Preparation and Isolation of the Isomers of Dicyanobis(S-cptn)-cobalt(III) Perchlorates: Potassium cyanide (460 mg) was dissolved in 80 cm³ of dimethyl sulfoxide (DMSO) at 60 °C. Into this solution was added 940 mg of *trans*-$[CoCl_2(S\text{-cptn})_2]Cl\cdot 0.5H_2O$ in portions with stirring. The color of the solution turned from green to orange. The solution was allowed to stand at 60 °C for 30 min, cooled to room temperature, and then poured into a column (10 cm × 3 cm) packed with an SP-Sephadex C-25 ion exchanger. The absorbed resin was washed with water to remove the DMSO and mounted on the top of another SP-Sephadex C-25 exchanger (120 cm × 3 cm). When the absorbed band was eluted with a 0.05 mol dm^{-3} aqueous sodium perchlorate at a rate of 500 cm³ d^{-1}, one orange and then two light yellow bands were separated. The first, orange elute was evaporated to dryness at 40 °C with a rotatory evaporator under reduced pressure. Twenty cm³ of acetone was added to remove the sodium perchlorate, leaving an orange residue, which was subsequently dissolved in a minimum amount of hot water and then filtered. The filtrate was allowed to stand in a refrigerator overnight to obtain orange plates. Yield, 100 mg (9%).

The second and the third, light yellow elutes were evaporated at 40 °C with rotatory evaporators to dryness. Ethanol was added to extract light yellow precipitates, and the ethanol solutions were evaporated again to dryness. The residues were dissolved in minimum amounts of hot water, and the solutions were cooled in refrigerators. Separated crystals were collected on filters. Yields, 23 mg and 57 mg for the second and the third fractions respectively.

$Na_2[Fe(CN)_4$(R-cptn)$]0.5NaClO_4\cdot 0.5H_2O$: In a 200-cm³ three-necked round-bottomed flask equipped with a mechanical stirrer and a dropping funnel, iron(II) perchlorate hexahydrate (6.55 g, 18.2 mmol) was placed under nitrogen, and then a 40-cm³ portion of methanol flushed with nitrogen was added through a serum cap with a syringe. The flask was immersed in an ice–water bath. With stirring, a solution of *R*-cptn (3.63 g, 36 mmol) in 25 cm³ of methanol was then added in small portions. White precipitates were formed. To the mixture, a solution of sodium cyanide (3.56 g, 72 mmol) in 8 cm³ of water was added from the dropping funnel with vigorous stirring. The mixture turned into a dark brown solution and was concentrated with a rotatory evaporator, yielding a viscous liquid. Ethanol (200 cm³) was added, and the mixture was allowed to stand in a refrigerator overnight. The yellow precipitates thus separated were collected on a filter and washed with ethanol and then with ether.

The crude product was dissolved in 12 cm³ of water, while the undissolved materials were removed by centrifugation. A methanol solution of sodium perchlorate (16 g/100 cm³) was added to the supernatant liquid, and then 200 cm³ of ethanol. The mixture was allowed to stand in a refrigerator overnight. Separated yellow crystals were collected on a filter and were washed with ethanol and ether subsequently. Yield, 1.6 g (23%).

$[Cu(S\text{-cptn})_2]SO_4\cdot 0.5H_2O$: To a solution of copper(II) sulfate pentahydrate (500 mg) in 30 cm³ of water, *S*-cptn (0.4 g) was added. The solution turned blue. The solution was warmed, and ethanol (40 cm³) was added. The hot mixture was filtered, and the filtrate was allowed to stand in a refrigerator. Separated blue needles were collected on a filter and washed with ethanol. Yield, 250 mg.

Physical Measurements. The electronic spectra were recorded with a Shimadzu UV-200 spectrophotometer. The CD spectra were measured with a JASCO J-40 recording polarimeter using aqueous solutions, unless otherwise stated. The infrared spectra were measured with a JASCO IRA-2 spectrophotometer using KBr disks. The ^{1}H-NMR spectra were measured with a JEOL JNM-MH-100 spectrometer using D_2O solutions and with sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as the internal standard.

Results and Discussion

The synthesis of *R*-cptn was carried out with cyclopentanone as the starting material. Generally, the yields of 1,2-diketones from ketones with selenium dioxide are affected by the structures of the ketones, and the yield of cyclopentanedione has been reported to be low.[12] The use of cyclopentanone as a solvent improved the yield to 23% based on the SeO_2 but the yield is still low compared to the yield of 60% for 1,2-cyclohexanedione from cyclohexanone. The successive reactions and optical resolution were carried out according to the known methods.[5,7]

The origins of the optical activities of metal chelates have been classified as: (i) configurational, (ii) conformational, and (iii) vicinal effects. The latter two effects correlate with the absolute configuration of a coordinated diamine. The absolute configuration of (−)-cptn was determined by Saito *et al.* as (1*R*,2*R*)-.[6] The absorption and CD spectra of solutions of cobalt(III) complexes of *R*-pn, *R*-bn, and *R*-chxn are similar to each other for the corresponding structures because of their preferred *λ* conformation, in which alkyl group (s) adopt an equatorial position in a five-membered chelate ring.[6] The diamines, *R*-cptn and *R*-chxn, have the same absolute configuration and are expected to coordinate to metal ions exclusively in a *λ* conformation by virtue of their fused ring structures. Therefore,

the electronic and CD spectra of complexes of *R*-cptn are compared with those of *R*-chxn in this report.

trans-*Dichlorocobalt(III) Complex.* Aeration of a mixture of cobalt(II) chloride and *R*-cptn, followed by the addition of concentrated hydrochloric acid, afforded *trans*-dichlorobis((1*R*,2*R*)-1,2-cyclopentanediamine)cobalt(III) chloride. The electronic and CD spectra of this chelate in methanol are shown in Fig. 1, along with the CD spectrum of *trans*-$[CoCl_2(R\text{-chxn})_2]^+$; the latter has been reported by Treptow.[13] The numerical data are listed in Table 2 and compared with those of other complexes. The absorption maximum of the I_a band of the *R*-cptn complex appears at the same energy as the corresponding maximum of the *R*-chxn complex. However, the absorption maximum of the I_b band moved to an energy lower by 1600 cm^{-1} for the *R*-cptn complex. In the CD spectra, the I_a components are almost the same for both complexes. However, the CD spectra for the I_b components are different. A positive component is observed for the *R*-cptn complex. The CD spectra of *trans*-$[CoCl_2(R\text{-cptn})_2]Cl$ were measured in three solvents—pyridine, methanol, and sulfolane. The magnitudes of the major positive CD bands were little affected, but the magnitudes of the minor CD components were changed as follows in $\Delta\varepsilon$:
pyridine, +0.67; methanol, +0.24; sulfolane, +0.19.

*Dicyanobis(*R*-cptn)cobalt(III) Isomers.* Three isomers of $[Co(CN)_2(S\text{-cptn})_2]^+$ were isolated from a reaction mixture of the *trans*-dichloro complex with KCN, followed by column chromatography with SP-Sephadex C-25 resin. The fraction eluted first with a 0.05 mol dm^{-3} $NaClO_4$ was orange in color and exhibited a large splitting in the first absorption band. This was assigned to the *trans*-isomer. The second and third fractions were yellow in color, had similar

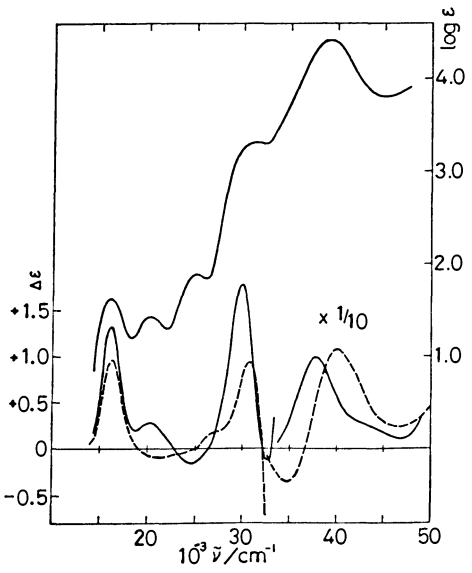

Fig. 1. Electronic and CD spectra of *trans*-$[CoCl_2(diamine)_2]ClO_4$ in methanol. Diamine: *R*-cptn, ——; *R*-chxn, — — —.

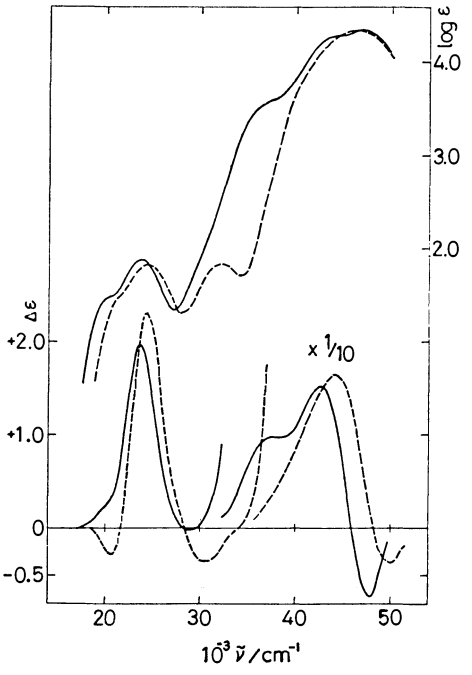

Fig. 2. Electronic and CD spectra of *trans*-$[Co(CN)_2(diamine)_2]^+$ in water. Diamine: *R*-cptn, ——; *R*-chxn, — — —. Data of *R*-chxn are reproduced from Ref. 16.

absorption spectra, and were assigned to *cis*-isomers.

The second fraction was assigned to *cis*-*Λ*-$[Co(CN)_2(S\text{-cptn})_2]^+$, and the third, to *cis*-*Λ*-$[Co(CN)_2(S\text{-cptn})_2]^+$, by comparing the CD spectra in the region between 40000 and 50000 cm^{-1} with those of the corresponding *R*-chxn complexes.[14] The yield of the *cis*-*Δ*-isomer was about one half of that of the *cis*-*Λ*-isomer. The C≡N stretching appeared at 2122 and 2128 for the *trans*-, at 2127 for the *cis*-*Δ*-, and at 2118 cm^{-1} for the *cis*-*Λ*-isomer. The two *cis*-isomers have very similar infrared spectra except for the N–H stretching region. The *cis*-*Δ*-isomer has three absorptions, at 3400, 3200, and 3080 cm^{-1}, while the *cis*-*Λ*-isomer has six absorptions in this region.

The following discussion will be argued, for the sake of brevity, using three complexes, *trans*-$[Co(CN)_2(R\text{-cptn})_2]^+$, *cis*-*Λ*-$[Co(CN)_2(R\text{-cptn})_2]^+$, and *cis*-*Δ*-$[Co(CN)_2(S\text{-cptn})_2]^+$, which should have CD spectra with signs the reverse of those of the enantiomers, *trans*-$[Co(CN)_2(S\text{-cptn})_2]^+$, *cis*-*Δ*-$[Co(CN)_2(S\text{-cptn})_2]^+$, and *cis*-*Λ*-$[Co(CN)_2(S\text{-cptn})_2]^+$ respectively.

The electronic and CD spectra of *trans*-$[Co(CN)_2(R\text{-cptn})_2]^+$ are shown in Fig. 2. The data for the isomers of the *R*-chxn complexes were provided by Kashiwabara.[14] The first absorption band appears at an energy lower by 700 cm^{-1} for the *R*-cptn complex than that for the *R*-chxn complex. The second absorption band of the *R*-chxn complex appears clearly, but that of the *R*-cptn complex is obscured by intense charge-transfer absorptions. In the CD spectra, the first absorption band contains two CD bands of opposite signs for the *R*-chxn complex, while the CD spectrum of the *R*-cptn complex shows two positive components. Another feature of the CD spectrum of the *R*-cptn complex is a positive CD component which appears at 37800 cm^{-1}. The positive CD component, which has a maximum at 42700 cm^{-1} for the *R*-chxn complex, is not symmetric, but has tails on the longer-wavelength side.

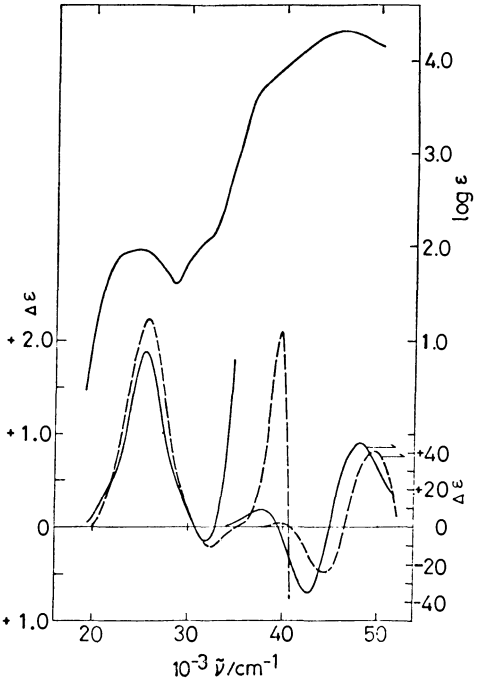

Fig. 3. Electronic and CD spectra of *cis*-*Λ*-$[Co(CN)_2(diamine)_2]^+$ in water. Diamine: *R*-cptn, ——; *R*-chxn, — — —. Data of *R*-chxn are reproduced from Ref. 16.

The electronic and CD spectra of the *cis*-*Λ*- and *cis*-*Δ*-$[Co(CN)_2(R\text{-cptn})_2]^+$ isomers are shown in Figs. 3 and 4 respectively, along with those of the corresponding isomers of the *R*-chxn complexes. For the *R*-cptn complexes, the first absorption bands are not symmetric, and the second absorption bands are obscured

by a partial superposition of intense charge-transfer bands. Their absolute configurations are determined from the CD components between 40000 and 50000 cm^{-1}, which closely resemble those of the *R*-chxn complexes. The absolute configurations of the chxn complexes have been determined[14] from the signs of these components on the basis of the empirical rule presented by Ogino *et al.*[15] In the first absorption bands, both *R*-cptn and *R*-chxn complexes show a positive CD band at 25500 cm^{-1} for *cis*-*Λ*-isomers, but the *R*-chxn complex exhibits a negative CD component at 21600 cm^{-1} in addition to the two components, which are found as a positive component and a negative component in the CD spectra of both complexes for *cis*-*Λ*-isomers.

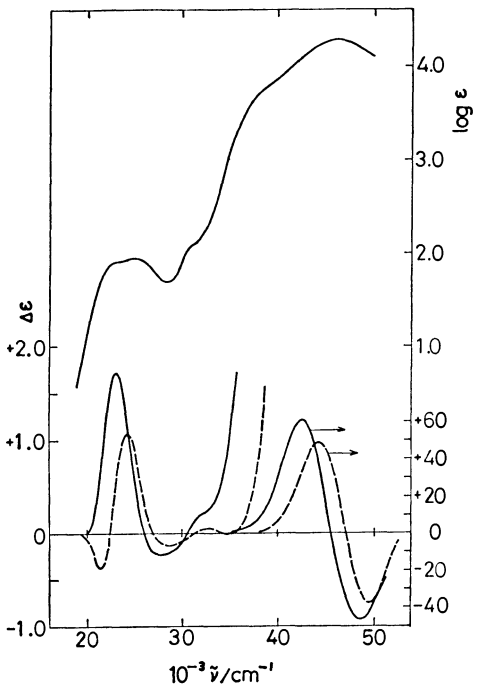

Fig. 4. Electronic and CD spectra of *cis*-*Λ*-$[Co(CN)_2(diamine)_2]^+$ in water. Diamine: *R*-cptn, ——; *R*-chxn, — — —. Data of *R*-chxn are reproduced from Ref. 16.

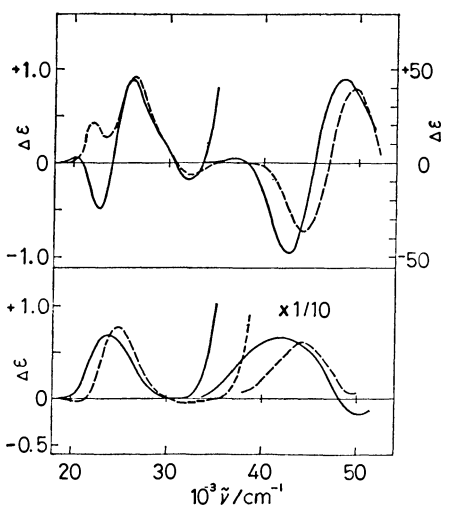

Fig. 5. Calculated configurational (upper, *Λ*) and conformational (bottom, *R*) curves of *cis*-$[Co(CN)_2(diamine)_2]^+$. Diamine: *R*-cptn, ——; *R*-chxn, — — —. Calcd by $\Delta\varepsilon(\Lambda)=1/2[\Delta\varepsilon(\Lambda_{2R})-\Delta\varepsilon(\Delta_{2R})]$ and $\Delta\varepsilon(R)=1/4[\Delta\varepsilon(\Lambda_{2R})+\Delta\varepsilon(\Delta_{2R})]$. Data of *R*-chxn are reproduced from Ref. 16.

The configurational and vicinal curves of *cis*-$[Co(CN)_2(R\text{-cptn})_2]^+$ are shown in Fig. 5, together with those of *cis*-$[Co(CN)_2(R\text{-chxn})_2]^+$.[14] They were derived from the observed curves by the use of the following relations;

$$\Delta\varepsilon(R) = 1/4\{\Delta\varepsilon(\Lambda_{2R}) + \Delta\varepsilon(\Delta_{2R})\}$$
$$\Delta\varepsilon(\Lambda) = 1/2\{\Delta\varepsilon(\Lambda_{2R}) - \Delta\varepsilon(\Delta_{2R})\}$$

where $\Delta\varepsilon(\Lambda_{2R})$ and $\Delta\varepsilon(\Delta_{2R})$ are the observed CD for the *Λ* and *Δ* diastereoisomers of the *cis*-$[Co(CN)_2(diamine)_2]^+$ complexes respectively, and where $\Delta\varepsilon(\Lambda)$ and $\Delta\varepsilon(R)$ are the configurational and the vicinal CD for the complexes.

*Tetracyano(*R*-cptn)ferrate(II) Complex.* Diamagnetic sodium tetracyano(*R*-cptn)ferrate(II) was prepared according to a method similar to that used earlier for preparing this class of compounds.[16] The complex showed absorptions which were almost the same as those of $[Fe(CN)_4(R\text{-chxn})]^{2-}$, as is shown in Table 2. The infrared spectrum showed intense C≡N stretching at 2030 cm^{-1}. The ^{1}H-NMR spectrum showed four types of protons, which resonate at 1.22(2), 1.70(2), 1.86(2), and 2.86(2) ppm, the relative integrated signal areas are indicated in parentheses. The protons corresponding to the signal at 2.86 ppm are the axial protons of methine. The corresponding protons in $[Fe(CN)_4(R\text{-chxn})]^{2-}$ appear at 2.05 ppm.[16] This down-field shift of the axial protons of cyclopentane ring occurs partly because of a decrease in anisotropy from the C–C bond due to the flatness of the cyclopentane ring.

The CD spectra of $[Fe(CN)_4(R\text{-cptn})]^{2-}$ and $[Fe(CN)_4(R\text{-chxn})]^{2-}$ are shown in Fig. 6. The CD spectra differ in the first absorption region. The signs of CD components for the same electronic transitions have been shown not to change in the d^6 diamagnetic isoelectronic and isostructural complexes on the basis of a comparison of the CD spectrum of $[Fe(CN)_4(R\text{-chxn})]^{2-}$ with that of $[Co(CN)_4(R\text{-chxn})]^-$.[16] The CD components of $[Fe(CN)_4(R\text{-pn})]^{2-}$ and $[Fe(CN)_4(R\text{-chxn})]^{2-}$ appear as two components with opposite signs in the first absorption region and are attributed to the conformational effects of *R*-pn and *R*-chxn.[16] The CD spectrum of $[Fe(CN)_4(R\text{-cptn})]^{2-}$ shows a

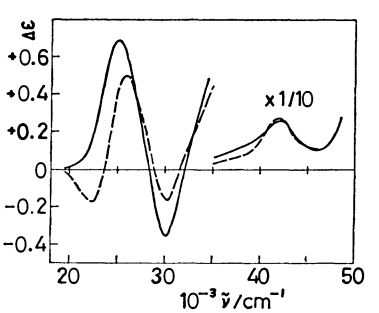

Fig. 6. CD spectra of $[Fe(CN)_4(diamine)]^{2-}$. Diamine: *R*-cptn, ——; *R*-chxn, — — —.

positive component in this region. We attempted to isolate the corresponding tetracyanocobaltate(III) complex, but did not succeed in doing so; however, the difference in the CD spectra between the *R*-cptn and the *R*-chxn complexes is attributable to the difference in the conformational effects of the diamines.

CD Spectra of d^6 Metal Complexes with R-*cptn.* The CD spectra of *trans*-$[CoX_2(R\text{-diamine})_2]^+$ have two components in the region of the first absorption band. The component corresponding to $^1A_{1g}\rightarrow{}^1E_{1g}{}^a$ has a positive sign with a large magnitude and changes in energy depending on the order in the spectrochemical series of the aniono group. The CD components of *trans*-$[CoX_2(R\text{-cptn})_2]^+$ have positive signs as expected for 1,2-diamines of *R*-configurations,[2] and the magnitudes are almost the same as those of the *R*-chxn complexes, as are shown in Figs. 1 and 2. A close relationship holds between the preferred conformation of the coordinated diamines and the sign of this CD component. The other component, corresponding to $^1A_{1g}\rightarrow{}^1A_{2g}$, remains approximately the same in energy as the parent $^1A_{1g}\rightarrow{}^1T_{1g}$ band of $CoN_6{}^{3+}$ ions and has an indefinite sign of a smaller magnitude which depends on the structure of the *R*-diamine and on the solvent. In methanol, the signs of these components of *trans*-dichloro complexes of *R*-pn,[17] *R*-bn,[18] and *R*-chxn[13,18] are negative, while those of phenen[4] and stien[3] are positive, but the signs of these components as well as their magnitudes change as the solvent is varied.[8,18] A good relationship has been found between the donor-power order of the solvent and the change in the CD spectrum for this region.[8] These components of *trans*-$[CoX_2(R\text{-cptn})_2]^+$ were small and positive. The CD component of *trans*-$[CoCl_2(R\text{-cptn})_2]^+$ increased in magnitude in pyridine and decreased in sulfolane, but did not change in sign in the latter solvent. The sign and the magnitude of this CD band suggest that the effect of *R*-cptn on the $^1A_{2g}$ band lies between those of phenyl-substituted diamines and of other alkyl-substituted diamines.

The vicinal curve of the *R*-cptn complexes calculated from *cis*-$[Co(CN)_2(R\text{-cptn})_2]^+$ isomers has positive components and lacks the negative component which appears in the vicinal curve for the *R*-chxn complexes, as is shown in Fig. 5. The vicinal curves of both complexes have features similar to those in the CD spectra of the corresponding *trans*-dicyano complexes in the first absorption region: the *R*-cptn complex exhibits only positive component, while the *R*-chxn complex shows a minor negative and a major positive component.

The CD spectra of $[Fe(CN)_4(R\text{-cptn})]^{2-}$ and $[Fe(CN)_4(R\text{-chxn})]^{2-}$ differ in the first absorption region, as is shown in Fig. 6. The latter CD spectrum shows a minor negative and a major positive component at 22200 and 26000 cm^{-1} respectively, those components are recognized as arising from the $^1A_{2g}$ and $^1E_{1g}{}^a$ transitions of D_{4h} symmetry, *i.e.*, the conformational effect of *R*-chxn.[16] An analogous interpretation is applicable to the positive CD component of $[Fe(CN)_4(R\text{-cptn})]^{2-}$, which lacks a negative component in the first absorption region: the conformational effect intrinsic to the *R*-cptn gives positive CD components in the first absorption band.

The tris complex, Λ-$[Co(S\text{-cptn})_3]Cl_3\cdot 4H_2O$, has shown a significantly different CD spectrum in an aqueous solution from those of Λ-$[Co(en)_3]^{3+}$, Λ-$[Co(S\text{-pn})_3]^{3+}$, and Λ-$[Co(S\text{-chxn})_3]^{3+}$.[6,7] The CD spectrum has a large negative component at 21100 cm^{-1} which is assigned to the $^1A_{1g}\rightarrow{}^1A_{2g}$ component on measurement with a single crystal.[7,19] Therefore, the signs of the D_3 components are the same among these tris complexes. The ratio of the rotatory strength of A_2 to that of the E bands exceeds unity for the cptn complex, but the ratios for the other complexes have values below 0.3.[6]

The calculated configurational curve for the Λ-configuration of *cis*-$[Co(CN)_2(R\text{-cptn})_2]^+$ is composed of two components with opposite signs. The corresponding curve of *cis*-$[Co(CN)_2(R\text{-chxn})_2]^+$ and the CD spectrum of $(+)_D$-$[Co(CN)_2(en)_2]^+$, the absolute configuration of which has been determined to be Λ by Matsumoto *et al.*,[20] are composed of components with the same sign, although the intensity of the component at 26200 cm^{-1} is stronger in the *R*-chxn complex than in the en complex.[14,21] McCaffery *et al.* have assigned the low- and high-energy portions under effective C_2 symmetry to a composite of E_g and A_2 transitions and to a E_g transition under D_3 symmetry respectively, and have stated that two positive CD components appear in this region for $(+)_D$-*cis*-$[Co(CN)_2(en)_2]^+$, since the rotational strength of E_g is greater than that of A_2.[21] The reversal of sign for the CD component at 22600 cm^{-1} for the Λ-configurational curve of the *R*-cptn complexes indicates that the ratio of the rotational strength of A_2 to that of E exceeds unity. This reversed ratio agrees with the ratio for the solution spectrum of Λ-$[Co(S\text{-cptn})_3]^{3+}$. The exceptional CD spectrum of the tris complex arises from the configurational effect intrinsic to cptn as well as from the conformational effect. The solution spectra of Λ- and Δ-$[Co(R\text{-cptn})_3]^{3+}$ also indicate

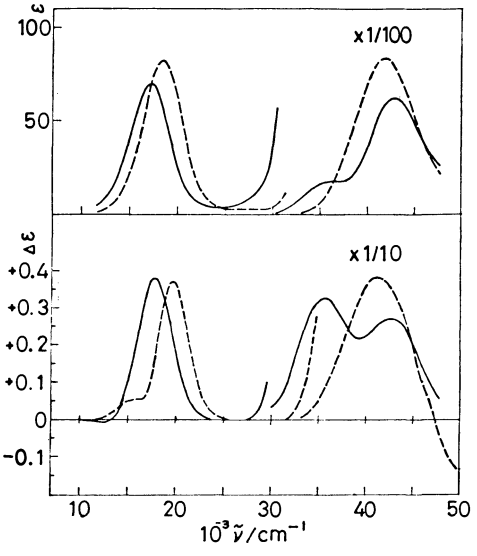

Fig. 7. Electronic and CD spectra of $[Cu(diamine)_2]^{2+}$ in water. Diamine: *R*-cptn, ——; *R*-chxn, — — —.

that the configurational effect for the *Λ*-configuration causes a marked enhancement of the negative CD component[7] and is almost opposite in sign to the configurational effect calculated from the pairs of the tris cobalt(III) complexes of en, *R*-pn, and *R*-chxn.[2]

*Bis(*R*-cptn)copper(II).* The CD and electronic spectra of $[Cu(R\text{-cptn})_2]SO_4\cdot 0.5H_2O$ are shown in Fig. 7, along with those of $[Cu(R\text{-chxn})_2]SO_4\cdot 3.5H_2O$. The d-d transitions of a Cu(II) complex of tetragonal symmetry may be expected to appear as three absorptions in the visible region. These are $^2B_{1g}\rightarrow{}^2A_{1g}$ ($d_{z^2}\rightarrow d_{x^2-y^2}$), $\rightarrow{}^2B_{2g}$ ($d_{xy}\rightarrow d_{x^2-y^2}$), and $\rightarrow{}^2E_g$ ($d_{xz},d_{yz}\rightarrow d_{x^2-y^2}$), where single-electron excitations are shown in parentheses. Hathaway assigned these to: (i) 12200—16800, (ii) 16200—18000, and (iii) 17900—20300 cm^{-1} absorptions respectively.[22] If the sign of the CD component corresponding to each single-electron excitation does not change with an alteration in the electronic configuration from d^6 to d^9, two positive CD components may be expected for $[Cu(R\text{-cptn})_2]^{2+}$, while one negative and one positive components may be expected for $[Cu(R\text{-chxn})_2]^{2+}$ in the region between 16200 and 20300 cm^{-1}. The CD spectrum of $[Cu(R\text{-pn})_2]^{2+}$ has been reported by Gillard and resembles that of $[Cu(R\text{-chxn})_2]^{2+}$.[23] Both have shoulders at 16000 cm^{-1} with intensities of +0.05 in $\Delta\varepsilon$. These CD spectra have been discussed by Kida and Nishida.[24] They resolved the absorption spectra into three absorptions by means of Gaussian curves. Three CD components corresponding to the resolved absorptions are estimated to have a small positive, a small negative, and a large positive signs at 15600, 17500, and 19800 cm^{-1} respectively. The single-electron transfer for these three components are assigned to $d_{z^2}\rightarrow$, $d_{xy}\rightarrow$, and d_{xz}, $d_{yz}\rightarrow d_{x^2-y^2}$ respectively. The sign of each component does not change in Cu(II) complexes from that of the *trans*-dichlorocobalt(III) complexes of these diamines.

The CD spectrum of $[Cu(R\text{-cptn})_2]^{2+}$ in water showed a single positive CD component with a maximum at 17800 cm^{-1}. It shifted to an energy lower by 1800 cm^{-1} from the positive CD component of $[Cu(R\text{-chxn})_2]^{2+}$. In the region between 16000 and 20000 cm^{-1}, two transitions may be expected for $[Cu(R\text{-cptn})_2]^{2+}$, and the observed CD spectrum seems to arise from two positive components spaced with a small energy difference. A very small negative component is found at *ca.* 12500 cm^{-1} and is assigned to the transition of $d_{z^2}\rightarrow d_{x^2-y^2}$.

Circular Dichroism in Charge-transfer Region. The CD components of *cis*-isomers of $[Co(CN)_2(R\text{-cptn})_2]^+$ resembled those of the corresponding isomers of $[Co(CN)_2(R\text{-chxn})_2]^+$ with a decrease in the wave numbers by 1600 cm^{-1} and so were used to identify the absolute configurations. The empirical rule for assigning absolute configurations from these components holds for the cptn complexes. A further characteristic of the *R*-cptn complexes is a moderately strong positive CD component which appears at 37800 and 35600 cm^{-1} for the *trans*-dicyanocobalt(III) and copper(II) complexes respectively. This positive component seems also to be present in the vicinal curve shown in Fig. 5. The origins of this enhancement are, however, ambiguous for the present.

The authors wish to express their thanks to Dr. Kazuo Kashiwabara of Nagoya University for kindly supplying the CD data on the isomers of dicyanobis-(*R*-chxn)cobalt(III) perchlorates.

The Synthesis of 3′-Methoxy-2′,4,4′,6′- and 2′-Methoxy-3′,4,4′,6′-tetrahydroxychalcone and Some Quinochalcones and a Comparison of Them with Carthamin[1)]

Heitaro OBARA,* Jun-ichi ONODERA, and Satoshi ABE

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received November 16, 1978)

3′-Methoxy-2′,4,4′,6′- and 2′-methoxy-3′,4,4′,6′-tetrahydroxychalcone, 2′,4,4′-trihydroxy-, 2′,4-dihydroxy-4′-methoxy-, and 2′-hydroxy-4,4′-dimethoxy-3′,6′-quinochalcone have been synthesized, and their properties have been compared with those of carthamin.

In 1930, Kuroda[2)] proposed Structure **1** for carthamin, the red coloring matter of the flowers of the Safflower (*Carthamus tinctorius* L.); she also reported a yellow unstable tautomeric form, isocarthamin (**2**), which is very liable to be converted into the stable carthamin. On the other hand, Seshadri *et al.*[3)] reported that the yellow hydroxychalcone (**3**), which is the main component of the flowers, should be called carthamin, while they gave the red pigment which was conventionally called "carthamin" by Kuroda, the constitution of the quinochalcone, carthamone (**4**); they also reported that **4** was obtained by the oxidation of **3** in the presence of peroxidase.

In connection with the synthetic studies of carthamin, we have reported the synthesis of 2′,3′,4,4′,6′-pentahydroxychalcone (**14**),[4)] corresponding to the aglycon of **2** or **3**, and its isomerization into 4′,5,6,7- and 4′,5,7,8-tetrahydroxyflavanone (carthamidin and isocarthamidin).[5)] In this paper, the syntheses of some analogs of **2**, **3**, and **4**, *i.e.*, 3′-methoxy-2′,4,4′,6′- and 2′-methoxy-3′,4,4′,6′-tetrahydroxychalcone (**7** and **11**), 2′,4,4′-trihydroxy-, 2′,4-dihydroxy-4′-methoxy-, and 2′-hydroxy-4,4′-dimethoxy-3′,6′-quinochalcone (**17**, **21**, and **23**), and a comparison of their properties with those of carthamin will be described.

The condensation of 3-methoxy-2,4,6-tris(methoxymethoxy)acetophenone (**5**) with *p*-(methoxymethoxy)-benzaldehyde afforded 3′-methoxy-2′,4,4′,6′-tetrakis-(methoxymethoxy)chalcone (**6**), which was then hydrolyzed with dilute hydrochloric acid in methanol to give **7** as yellow crystals. Similarly, 2′-methoxy-3′,4,4′,6′-tetrahydroxychalcone (**11**) was obtained by the hydrolysis of 2′-methoxy-3′,4,4′,6′-tetrakis(methoxymethoxy)chalcone (**10**), prepared by the methylation of the condensation product (**9**) of 2-hydroxy-3,4,6-tris(methoxymethoxy)acetophenone (**8**) with *p*-(methoxymethoxy)benzaldehyde. The structures of these chalcones were identified by elemental analyses and by studies of their UV, IR, and PMR spectra. The structure of **11** was further confirmed by its conversion

into 5-methoxy-4′,6,7-trihydroxyflavanone (**12**) with acid. The trimethyl ether (**13**) of **12** was completely indentical with an authentic sample of 4′,5,6,7-tetramethoxyflavanone.[6]

2′,4,4′-Trihydroxy-3′,6′-quinochalcone (**17**) was obtained by the oxidation of **14**[4] with silver oxide in ether, or by the demethoxymethylation of 2′-hydroxy-4,4′-bis(methoxymethoxy)-3′,6′-quinochalcone (**16**), prepared by the nitric acid oxidation of 2′,3′,4,4′,6′-pentakis(methoxymethoxy)chalcone (**15**)[4] in acetic acid containing 6 M hydrochloric acid. Since this chalcone (**17**) was unstable in solution, and since we failed in our attempt at methylation in a usual way, its mono and dimethyl ethers were prepared by the following method. 2′,4-Dihydroxy-4′-methoxy-3′,6′-quinochalcone (**21**) was obtained by the demethoxymethylation of 2′-hydroxy-4′-methoxy-4-methoxymethoxy-3′,6′-quinochalcone (**20**), prepared by the nitric acid oxidation of 4-methoxymethoxy-2′,3′,4′,6′-tetramethoxychalcone (**18**), which had itself been obtained by the condensation of 2,3,4,6-tetramethoxyacetophenone[4] with *p*-(methoxymethoxy)benzaldehyde. Similarly, 2′-hydroxy-4,4′-dimethoxy-3′,6′-quinochalcone (**23**) was obtained by the oxidation of 2′,3′,4,4′,6′-pentamethoxychalcone (**19**)[4] with nitric acid in acetic acid. On the other hand, the direct nitric acid oxidation of 2′,3′,4′,6′-tetramethoxy-4-hydroxychalcone (**22**), itself prepared by the demethoxymethylation of **18**, gave nitroquinochalcone, 2′,4-dihydroxy-4′-methoxy-3-nitro-3′,6′-quinochalcone (**24**). The structures of these quinochalcones were determined by studies of their UV, IR, and PMR spectra and by elemental analyses.

The electronic spectra of these synthetic analogs (**7**, **11**, and **17**) and carthamin are shown in Fig. 1. Since a tautomerism was expected between carthamin (**1**) and isocarthamin (**2**), as was described at the beginning, the absorption spectrum of **7** was expected to be similar to that of carthamin, in fact, however, these two spectra did not resemble each other at all. Actually, the **7** chalcone is a stable compound and does not show any unstable behavior such as carthamin does. Further, carthamin showed a characteristic absorption band at 520 nm in its electronic spectrum, but the synthetic quinochalcones do not exhibit absorption maxima in such a long-wavelength region. From these results, it is thought that the structures of the red pigment proposed by Kuroda or Seshadri are not reasonable and that carthamin must have a longer conjugated system.

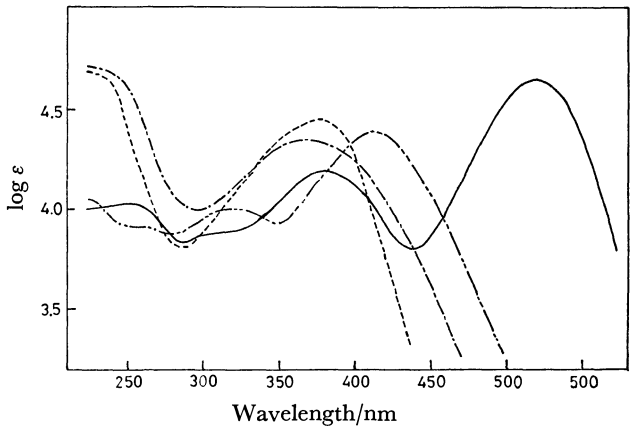

Fig. 1. The electronic spectra of **7** (----), **11** (——–), **17** (————), and carthamin (——) in ethanol.

Experimental

All the melting points are uncorrected. The UV and IR spectra were recorded with a Hitachi 135 spectrophotometer and a Hitachi EPI-S2 spectrophotometer respectively. The PMR spectra were measured with a Hitachi R-22 spectrometer (90 MHz), using tetramethylsilane as the internal standard.

3-Methoxy-2,4,6-tris(methoxymethoxy)acetophenone (**5**). Into a solution of 3-methoxy-2,4,6-trihydroxyacetophenone[7] (2.0 g, mp 169—170 °C, lit,[7] mp 168 °C) in 37 ml of absolute ethanol we vigorously stirred a one-fourth volume of a solution of sodium (3.3 g) in 53 ml of absolute ethanol under a nitrogen atmosphere and under cooling with ice-cold water. After 30 s, a one-fourth volume of chloromethyl methyl ether (11.5 g) was stirred into the above solution over a 5-min interval at 40 °C; this operation was repeated three times under the same conditions. After the addition had been completed, the reaction mixture was evaporated *in vacuo* and the residue was poured into water and extracted with ether. The ether layer was washed with a 5% aqueous $NaHCO_3$ solution and water. The ether was evaporated to give an oily residue, which was then chromatographed over silica gel. Elution with benzene–ethyl acetate (4:1) afforded **5** (1.1 g, 33%) as a light yellow viscous oil, which was used immediately in the subsequent reaction.

3′-Methoxy-2′,4,4′,6′-tetrakis(methoxymethoxy)chalcone (**6**). Into a mixed solution of **5** (0.5 g) and *p*-(methoxymethoxy)-benzaldehyde (0.4 g) in 11 ml of methanol we stirred a 50% aqueous sodium hydroxide solution (5.5 ml) at room temperature. After it had stood overnight, the mixture was poured into cold water and extracted with ether, and then

the ether layer was washed with water. The evaporation of the solvent gave an oily residue, which was then chromatographed over silica gel. Elution with benzene–ethyl acetate (4:1) afforded **6** (0.6 g, 83%). UV (EtOH) λ_{max} 328 nm (log ε=4.38); IR ($CHCl_3$) 1630 cm^{-1} (C=O); PMR ($CDCl_3$) δ 3.41, 3.43, 3.50, and 3.58 (each 2H, s, $-CH_2-\times 4$), 3.89 (3H, s, -OMe), 5.12, 5.17, 5.24, and 5.29 (each 3H, s, $-CH_3\times 4$), 6.87 (1H, s, $C_{5'}$–H), 7.10 (2H, d, J=8.5 Hz, $C_{3,5}$–H), 7.56 (2H, d, J=8.5 Hz, $C_{2,6}$–H), 6.98 (1H, d, J=16.0 Hz, C_α–H), 7.45 (1H, d, J=16.0 Hz, C_β–H), Found: C, 59.87; H, 6.44%. Calcd for $C_{24}H_{30}O_{10}$: C, 60.24; H, 6.32%.

*3'-Methoxy-2',4,4',6'-tetrahydroxychalcone (**7**).* A mixture of **6** (0.4 g), 6 M hydrochloric acid, and methanol (17 ml) was refluxed for 30 s. After cooling, the reaction mixture was poured into 30 ml of cold brine and extracted with ether. The ether layer was dried over anhydrous Na_2SO_4 and concentrated to about 10 ml *in vacuo*. A small quantity of petroleum ether was added to the concentrated solution to give crude **7**, which was then chromatographed over silica gel. Elution with CCl_4–ether–acetic acid (20:10:1) afforded **7** (70 mg, 28%) as yellow crystals; mp 169—171 °C. UV (EtOH) λ_{max} 377 nm (log ε=4.47); IR (KBr) 1620 cm^{-1} (C=O); PMR (acetone-d_6) δ 3.78 (3H, s, -OMe), 6.00 (1H, s, $C_{5'}$–H), 6.92 (2H, d, J=8.5 Hz, $C_{3,5}$–H), 7.57 (2H, d, J=8.5 Hz $C_{2,6}$–H), 7.76 (1H, d, J=16.0 Hz, C_α–H), 8.13 (1H, d, J=16.0 Hz, C_β–H), 8.93, 9.24, 11.10, and 12.18 (each 1H, s, $-OH\times 4$). Found: C, 63.15; H, 4.72%. Calcd for $C_{16}H_{14}O_6$: C, 63.57; H, 4.64%.

*2-Hydroxy-3,4,6-tris(methoxymethoxy)acetophenone (**8**).* To a solution of 2,3,4,6-tetrahydroxyacetophenone[4] (6.0 g) in 150 ml of absolute ethanol, we vigorously stirred a one-fourth volume of a solution of sodium (8.8 g) in 140 ml of absolute ethanol under a nitrogen atmosphere, and under cooling with ice-cold water. After 30 s, a one-fourth volume of chloromethyl methyl ether (31 g) was stirred into the above solution over a 5-min interval at 40 °C; this operation was repeated three times under the same conditions. After the addition had been completed, the reaction mixture was worked up in a manner similar to that used in the preparation of 3-methoxy-2,4,6-tris(methoxymethoxy)acetophenone (**5**) described above. Elution with benzene–ethyl acetate (4:1) afforded **8** (1.34 g, 13%) as a yellow oil. IR ($CHCl_3$) 1620 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.68 (3H, s, -Ac), 3.55 (6H, s, $-CH_3\times 2$), 3.66 (3H, s, $-CH_3$), 5.13 (2H, s, $-CH_2-$), 5.29 (4H, s, $-CH_2-\times 2$), 6.51 (1H, s, C_5–H), 13.80 (1H, s, -OH). Found: C, 53.46; H, 6.44%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.33%.

*2'-Methoxy-3',4,4',6'-tetrahydroxychalcone (**11**).* Into a mixed solution of **8** (1.5 g) and *p*-(methoxymethoxy)benzaldehyde (1.2 g) in methanol (8 ml) we stirred a 50% aqueous sodium hydroxide solution (4 ml) at room temperature. After standing overnight, the reaction mixture was poured into cold 10% acetic acid and extracted with ether. The evaporation of the solvent gave an oily residue, which was then chromatographed over silica gel. Elution with benzene–ethyl acetate (3:1) afforded 2'-hydroxy-3',4,4',6'-tetrakis(methoxymethoxy)chalcone (**9**) (1.66 g, 76%) as yellow crystals; mp 74—76 °C. UV (EtOH) λ_{max} 367 nm (log ε=4.42); IR (KBr) 1622 cm^{-1} (C=O); PMR ($CDCl_3$) δ 3.56 and 3.73 (each 3H, s, $-CH_3\times 2$), 3.60 (6H, s, $-CH_3\times 2$), 5.22 and 5.30 (each 2H, s, $-CH_2-\times 2$), 5.36 (4H, s, $-CH_2-\times 2$), 6.56 (1H, s, $C_{5'}$–H), 7.16 (2H, d, J=8.5 Hz, $C_{3,5}$–H), 7.65 (2H, d, J=8.5 Hz, $C_{2,6}$–H), 7.89 (2H, s, $C_{\alpha,\beta}$–H), 13.80 (1H, s, -OH). This chalcone, **9**, was methylated with dimethyl sulfate–potassium carbonate in acetone, and the resulting oily product was chromatographed over silica gel. Elution with benzene–ethyl acetate (4:1) afforded 2'-methoxy-3',4,4',6'-tetrakis(methoxymethoxy)chalcone (**10**) (74%) as an unstable oil, which was used immediately in the subsequent reaction.

A mixture of the above chalcone, **10** (640 mg), and 6 M hydrochloric acid (4.5 ml) in 11 ml of methanol was refluxed for 1.5 min. After cooling, the reaction mixture was poured into 60 ml of cold brine and extracted with ether. The solvent was evaporated *in vacuo*, and the residue was recrystallized from dilute methanol to give **11** (280 mg, 69%) as bright yellow needles; mp 190—192 °C. UV (EtOH) λ_{max} 368 nm (log ε=4.36); IR (KBr) 1620 cm^{-1} (C=O); PMR (DMSO-d_6) δ 3.76 (3H, s, -OMe), 6.15 (1H, s, $C_{5'}$–H), 6.86 (2H, d, J=8.7 Hz, $C_{3,5}$–H), 7.57 (2H, d, J=8.7 Hz, $C_{2,6}$–H), 7.62 (2H, s, $C_{\alpha,\beta}$–H), 8.23, 10.00, 10.40, and 12.80 (each 1H, s, $-OH\times 4$). Found: C, 63.16; H, 4.65%. Calcd for $C_{16}H_{14}O_6$: C, 63.57; H, 4.64%.

*5-Methoxy-4',6,7-trihydroxyflavanone (**12**).* A mixture of **11** (60 mg) and 6 M hydrochloric acid (1.5 ml) in 8 ml of methanol was refluxed for 8 h. The reaction mixture was then evaporated *in vacuo*, and the residue was extracted with ethyl acetate. The evaporation of the solvent gave a crude product, which was subsequently chromatographed over silica gel. Elution with benzene–ethyl acetate–acetic acid (30:10:1) afforded **12** (26 mg, 43%) as light yellow crystals; mp 232—234 °C. UV (EtOH) λ_{max} 287 nm (log ε=4.16) and 350 nm (log ε=3.67); IR (KBr) 1650 cm^{-1} (C=O); PMR (DMSO-d_6) δ 2.54 (1H, q, J=17.0 and 2.5 Hz, C_3–H), 2.94 (1H, q, J=17.0 and 13.3 Hz, C_3–H), 5.29 (1H, q, J=13.3 and 2.5 Hz, C_2–H), 3.76 (3H, s, -OMe), 6.22 (1H, s, C_8–H), 6.85 (2H, d, J=8.5 Hz, $C_{3',5'}$–H), 7.32 (2H, d, J=8.5 Hz, $C_{2',6'}$–H), 8.25, 9.41, and 10.07 (each 1H, s, $-OH\times 3$). Found: C, 63.46; H, 4.65%. Calcd for $C_{16}H_{14}O_6$: C, 63.57; H, 4.64%. The methylation of this compound with dimethyl sulfate–potassium carbonate in acetone afforded 4',5,6,7-tetramethoxyflavanone (**13**), which was completely identical with an authentic sample.[6]

*2',4,4'-Trihydroxy-3',6'-quinochalcone (**17**).* A mixture of **14**[4] (100 mg), silver oxide (200 mg), and magnesium sulfate (200 mg) in 5 ml of dry ether was stirred for 4 h at room temperature. The reaction mixture was then filtered, and the filtrate was evaporated. The residue was chromatographed over silica gel with toluene–ethyl formate–formic acid (5:2:1) to give crude products. Recrystallization from acetic acid gave **17** (3 mg) as orange needles; mp 234—236 °C. UV (EtOH) λ_{max} 260 nm (log ε=3.90), 310 nm (log ε=3.97), and 412 nm (log ε=4.41); IR (KBr) 1690, 1635, and 1605 cm^{-1} (C=O). Found: C, 62.20; H, 3.80%; M^+, 286. Calcd for $C_{15}H_{10}O_6$: C, 62.94; H, 3.52%; M, 286.

*2'-Hydroxy-4,4'-bis(methoxymethoxy)-3',6'-quinochalcone (**16**).* Into a mixed solution of 2',3',4,4',6'-pentakis(methoxymethoxy)chalcone (**15**)[4] (1.0 g), acetic acid (4 ml), and ether (4 ml) we added 1 ml of nitric acid (d=1.38) under cooling with ice-cold water; the reaction mixture was then kept at 0—5 °C for 10 h. The resulting crystals were filtered and recrystallized from acetic acid–ether to afford **16** (230 mg, 30%); mp 142—143 °C. UV (EtOH) λ_{max} 266, 294, and 406 nm; IR (KBr) 1700, 1630, and 1600 cm^{-1} (C=O); PMR ($CDCl_3$) δ 3.74 (6H, s, $-CH_3\times 2$), 5.23 and 5.26 (each 2H, s, $-CH_2-\times 2$), 6.40 (1H, s, $C_{5'}$–H), 7.08 (2H, d, J=8.5 Hz, $C_{3,5}$–H), 7.66 (2H, d, J=8.5 Hz, $C_{2,6}$–H), 8.05 (1H, d, J=16.0 Hz, C_α–H), 8.28 (1H, d, J=16.0 Hz, C_β–H), 17.76 (1H, s, -OH). Found: C, 60.67; H, 5.02%. Calcd for $C_{19}H_{18}O_8$: C, 60.96; H, 4.85%.

The demethoxymethylation of **16** by warming at 50—60 °C in acetic acid containing 6 M hydrochloric acid af-

forded a small amount of **17**.

*4-Methoxymethoxy-2′,3′,4′,6′-tetramethoxychalcone (**18**).* Into a mixture of 2,3,4,6-tetramethoxyacetophenone[4] (480 mg) and *p*-(methoxymethoxy)benzaldehyde (400 mg) in 5 ml of methanol we added 5 ml of a 50% aqueous sodium hydroxide solution; the reaction mixture was then left to stand over 2 nights at room temperature. The reaction mixture was subsequently worked-up in a manner similar to that of **9**. The resulting products were chromatographed over silica gel with benzene–ethyl acetate (4:1) to give **18** as a light yellow oil (760 mg, 98%). Found: C, 64.36; H, 6.44%; M^+, 388. Calcd for $C_{21}H_{24}O_7$: C, 64.93; H, 6.23%; M, 388.

*2′-Hydroxy-4-methoxymethoxy-4′-methoxy-3′,6′-quinochalcone (**20**).* To a mixture of **18** (200 mg) and acetic acid (1.5 ml) in 1.5 ml of ether we added 0.2 ml of nitric acid (d=1.38), after which the reaction mixture was left to stand overnight in a refrigerator. The resulting product was recrystallized from acetic acid–ether to afford **20** (45 mg, 25%); mp 155—156 °C. IR (KBr) 1702, 1665, and 1620 cm^{-1} (C=O). Found: C, 62.36; H, 4.88%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 6.48%.

*2′,4-Dihydroxy-4′-methoxy-3′,6′-quinochalcone (**21**).* To a solution of **20** (100 mg) in 3 ml of acetic acid we added 0.5 ml of 6 M hydrochloric acid, after which the mixture was warmed at 40—50 °C for 3 min. After cooling, the resulting crude product was recrystallized from acetic acid to afford **21** (55 mg, 63%); mp 252—254 °C. UV (EtOH) λ_{max} 264, 300, and 414 nm; IR (KBr) 1706, 1630, and 1600 cm^{-1} (C=O); PMR (DMSO-d_6) δ 3.82 (3H, s, –OMe), 6.18 (1H, s, $C_{5'}$–H), 6.84 (2H, d, J=8.5 Hz, $C_{3,5}$–H), 7.58 (2H, d, J=8.5 Hz, $C_{2,6}$–H), 7.92 (2H, s, $C_{\alpha,\beta}$–H), 10.30 (bs, –OH). Found: C, 63.60; H, 4.19%. Calcd for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03%.

*2′-Hydroxy-4,4′-dimethoxy-3′,6′-quinochalcone (**23**).* To a solution of 2′,3′,4,4′,6′-pentamethoxychalcone (**19**)[4] (150 mg) in 1.5 ml of acetic acid we added 0.15 ml of nitric acid (d=1.42); the reaction mixture was then left to stand overnight in a refrigerator. The resulting product was filtered and recrystallized from acetic acid to afford **23** (55 mg, 42%); mp 188—189 °C. UV ($CHCl_3$) λ_{max} 261, 297, and 412 nm; IR (KBr) 1714, 1658, and 1630 cm^{-1} (C=O); PMR (DMSO-d_6) δ 3.83 (6H, s, –OMe×2), 6.26 (1H, s, $C_{5'}$–H), 7.08 (2H, d, J=8.5 Hz, $C_{3,5}$–H), 7.71 (2H, d, J=8.5 Hz, $C_{2,6}$–H), 8.00 (2H, s, $C_{\alpha,\beta}$–H). Found: C, 64.96; H, 4.46%. Calcd for $C_{17}H_{14}O_6$: C, 64.82; H, 4.49%.

*2′,4-Dihydroxy-4′-methoxy-3-nitro-3′,6′-quinochalcone (**24**).* This chalcone was obtained by the oxidation of 4-hydroxy-2′,3′,4′,6′-tetramethoxychalcone (**22**) (mp 120—121 °C), which had been prepared by the demethoxymethylation of **18** in a manner similar to that described above. Orange plates from acetic acid; mp 202—204 °C (39%). UV ($CHCl_3$) λ_{max} 277 nm ($\log\varepsilon$=4.32) and 382 nm ($\log\varepsilon$=4.54); PMR (DMSO-d_6) δ 3.84 (3H, s, –OMe), 6.19 (1H, s, $C_{5'}$–H), 7.15 (1H, d, J=8.5 Hz, C_5–H), 7.90 (1H, q, J=8.5 and 2.0 Hz, C_6–H), 7.88 (2H, s, $C_{\alpha,\beta}$–H), 8.20 (1H, d, J=2.0 Hz, C_2–H). Found: C, 55.35; H, 3.26; N, 4.31%. Calcd for $C_{16}H_{11}O_8N$: C, 55.66; H, 3.21; N, 4.06%.

The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Coenzyme Models. 18. Metal Catalysis of NADH Model Reduction in Aqueous Systems

Seiji SHINKAI,* Hisatake HAMADA, Yumiko KUSANO, and OSAMU MANABE

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

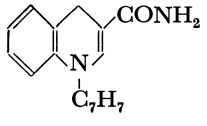
(Received November 17, 1978)

Metal ions (Ni^{2+} and Zn^{2+}) affected the NADH model reduction of 2-pyridinecarbaldehyde and Schiff bases in aqueous systems. In particular, the rate of the dihydroquinoline reduction of *N*-(2-pyridylmethylene)-2-pyridylmethylamine was augmented by more than 200-fold, compared with that in the absence of metal ions. On the other hand, the reduction of benzil, ethyl benzoylformate, and trifluoroacetophenone was not subject to the metal catalysis. The enhanced reactivity is accounted for by the affinity of Schiff bases toward metal ions. The efficiency of the metal catalysis was compared with that of the proton catalysis. This is the first example of the systematic examination of the metal catalysis in aqueous systems.

It is known that some alcohol dehydrogenases contain NAD^+ and Zn^{2+} ion at the active sites and catalyze the interconversion of aldehydes and alcohols coupled to the oxidation-reduction of NAD^+ coenzyme.[1] The role of Zn^{2+} ion, as well as that of NAD^+, has long been a subject of investigation and debate. Recent model studies have established that metal ion not only activates substrates and/or NADH analogues but also helps retaining stereoselective hydrogen transfer from NADH analogues to substrates.[2-6] These successful demonstration in the model system may provide the information relevant to biological NADH dependent oxidation-reduction, but the metal catalysis has been confined strictly to aprotic solvents (*e.g.*, acetonitrile). In fact, it has often been mentioned that metal ion does not act as catalyst in aqueous NADH model reduction.[5,6]

It is proposed that the transition state of NADH reduction is analogous to that pictured for S_N2-type nucleophilic reaction,[7,8] although the detailed mechanism is still a matter of some controversy.[9-12] As for the S_N2-type nucleophilic reaction, Buckingham[13,14] and others[15-17] have reported many examples of metal catalysis in aqueous solutions. For example, metal ions such as Cu^{2+}, Co^{2+}, Ni^{2+}, and Zn^{2+} are good catalysts for the ester hydrolysis of α-amino acids, the rate augmentation amounting to 10^3—10^6 fold. The marked rate acceleration is explained by such that the metal ion can bind to the nitrogen and at the same time remain close to the ester carbonyl group. One would thus anticipate that the metal coordinated substrate may be considerably electrophilic and may serve as a good hydride (or its equivalent) acceptor. The object of the present investigation has been to search for the metal-catalyzed NADH model reduction of the C=O and C=N double bonds by an acid-stable NADH analogue, 1-benzyl-1,4-dihydro-3-quinolinecarboxamide (BzlQH).[18] We thus found that the reduction of Schiff base is remarkably facilitated by added metal ions (Ni^{2+} and Zn^{2+}).

BzlQH;



Experimental

Materials. The preparation of BzlQH has been described elsewhere.[19] 2-Pyridylmethylamine dihydrochloride was prepared by Dr. M. Ohnishi (Nagasaki University). Other reagents (trifluoroacetophenone, ethyl benzoylformate, 2-pyridinecarbaldehyde, and benzil) were purified by distillation or recrystallization before use.

Kinetics. Kinetic measurements were carried out at 50±0.1 °C in a 2.2%(v/v) aqueous acetonitrile solution with an ionic strength of 0.2(KCl). The progress of the reaction was followed spectrophotometrically by monitoring the decrease of BzlQH at λ_{max} (343 nm). The details of the method were described in a previous paper of this series.[19] Since excess substrate was present in all the cases, the pseudo first-order behavior was observed for up to 3-half-lives. In the case where the reaction rate was extremely slow, the rate constans were estimated from the initial slope of the reaction. Here, the overall first-order rate constants (k_{obsd}) is expressed by Eq. 1,

$$k_{obsd} = k_d + k_r \quad (1)$$

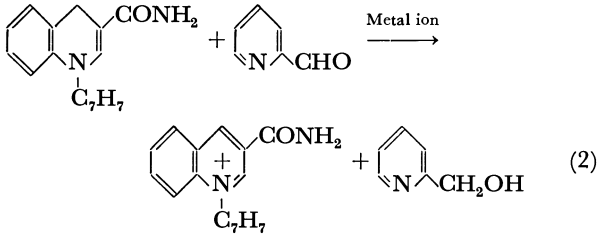
where k_d is the acid-catalyzed (spontaneous) decomposition of BzlQH and k_r is the pseudo first-order rate constants for the reduction reaction. The k_d value was determined separately from the disapperance of the absorption of BzlQH in the absence of substrate, and the k_r value was determined from Eq. 1. Since the k_r value is linearly correlated to substrate concentrations ([substrate]$=(1—5)\times10^{-3}$ M, [Zn^{2+}]$=(0—5)\times10^{-3}$M), the apparent second-order rate constants (k_2') are given by $k_2'=k_r/$[substrate].

Results and Discussion

Suppressed Catalytic Activity of Metal Ions in Aqueous Systems. Dihydronicotinamides in dry acetonitrile interact strongly with Mg^{2+} ion.[20,21] The interaction is substantiated by bathochromic shifts of the absorption maxima. The absorption maximum of BzlQH in acetonitrile (335 nm, $\varepsilon_{max}=11900\ M^{-1}\ cm^{-1}$) also shifted to longer wavelength on the addition of Mg^{2+} ion (346 nm, $\varepsilon_{max}=14700\ M^{-1}\ cm^{-1}$, [$Mg(ClO_4)_2$]$=1.0\times10^{-2}$ M). On the other hand, the spectrum of BzlQH in an aqueous system (λ_{max} 343 nm, $\varepsilon_{max}=13100\ M^{-1}\ cm^{-1}$) was hardly affected by added metal ions ([Ni^{2+}]$=$[Zn^{2+}]$=(2.5—5.0)\times10^{-3}$ M at pH 4—9). The contrasting results indicate that the metal ion in aqueous solutions is deactivated due to strong solvation.

Benzil, ethyl benzylformate, and trifluoroacetophenone are slowly reduced by BzlQH in an acidic aqueous solution (pH 4.0). The dihydronicotinamide reduction of these substrates in aprotic solvents is efficiently catalyzed by Mg^{2+} ion,[2,4,25,26] whereas the aqueous BzlQH reduction was uncatalyzed by added metal ion ([metal ion (Ni^{2+} or Zn^{2+})]=*ca.* 5×10^{-3} M, pH 4—9). It is presumed that neither BzlQH nor substrate interacts with metal ions during the reduction process. Supposedly, one should employ more coordinative substrates to substantiate the metal catalysis in an aqueous solution.

Reduction of 2-Pyridinecarbaldehyde(2-PyCHO). 2-Acylpyridines are frequently employed in the model reduction in aprotic solvents.[4,27] This is probably due to the high coordination ability of 2-acylpyridines. 2-Acylpyridines are presumed to form the relatively stable complexes with metal ions in an aqueous system,[15] so that it would meet the requirement of the present study. Tagaki and coworkers[28] previously reported the reaction of 1,4-dihydronicotinamide with 2-PyCHO. They found, contrary to their expectation, that the isolated is a covalent adduct which is formed by a nucleophilic attack of 5-position of 1,4-dihydronicotinamide on the carbonyl carbon of 2-PyCHO. BzlQH has within the molecule the basic structure of 1,4-dihydronicotinamide, but the adduct-forming 5-position is involved in the fused ring. Thus, the formation of the adduct is almost unconceivable. Spectral examination of the reaction mixture([2-PyCHO]=1.0×10^{-4} M, [BzlQH]=5.0×10^{-5} M, [Zn^{2+}]=(0—1)$\times10^{-2}$ M, pH 4.7) established that the decrease of the absorption band of BzlQH (343 nm) is accompanied by the appearance of products with 215 and 250 nm which may be compared with the spectrum of a mixture of $BzlQ^+$ and 2-(hydroxymethyl)pyridine (209 and 244 nm). In fact, we have found that 2-PyCHO is reduced by BzlQH in 58—65% yield to corresponding alcohol.[29]



(2)

The apparent second-order rate constants (k_2') for BzlQH reduction of 2-PyCHO are plotted against metal concentrations (Fig. 1). In the alkaline pH region (pH 8.7), the rate constants could not be determined due to the ready precipitation of metal ions. The precipitation was not observed in the acidic pH region (pH 4.7), but the reaction was rather retarded by added metal ions. According to Pocker and Meany,[30] divalent metal ions such as Zn^{2+} and Co^{2+} exhibits a dramatic catalytic effect on the hydration of 2-PyCHO. It is expected, therefore, that the rate suppression may be rationalized in terms of the decrease in the fraction of free ketone. Since the hydration causes the diminution of the absorbancy of 2-PyCHO at around 260 nm,[30] the optical density(OD) was

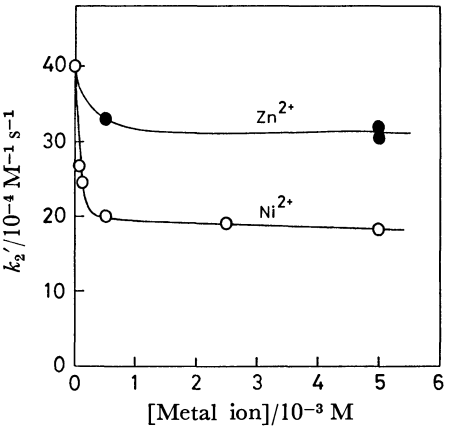


Fig. 1. Metal ion catalysis of the BzlQH reduction of 2-pyridinecarbaldehyde. [2-PyCHO]=5.00×10^{-3} M, [BzlQH]=5.0×10^{-5} M. The pH of the reaction media was maintained with 0.02 M acetate (pH 4.7).

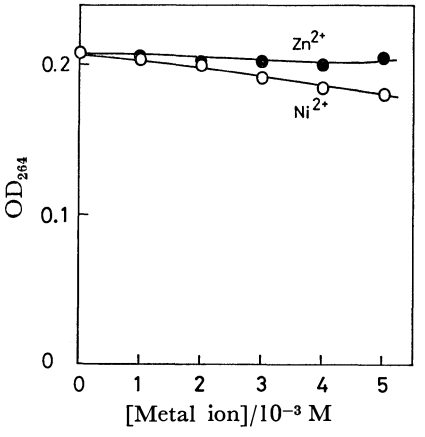

Fig. 2. Hydration equilibrium of 2-pyridinecarbaldehyde: optical density at 264 nm plotted against the concentration of metal ions. pH 4.7 with 0.02 M acetate buffer, [2-PyCHO]=5.0×10^{-5} M.

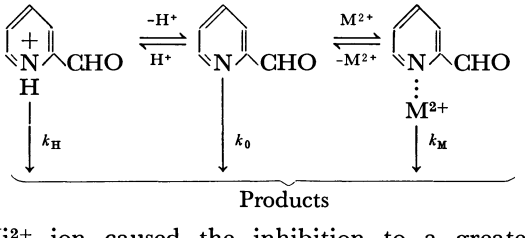
measured as a function of metal ion concentrations. As shown in Fig. 2, however, the absorption band is affected to a small extent (less than 10%) by added metal ions, indicating that the fraction of free ketone is maintained almost constant. Thus, the rate retardation cannot be attributed wholly to the hydration of 2-PyCHO.

As mentioned above, 2-PyCHO(pK_a 3.8)[31] in acetate buffer is reducible by BzlQH in good yields. If *N*-protonated 2-PyCHO which is presumed to be the active species in the acidic pH region exhibits the reactivity greater than metal-coordinated 2-PyCHO (*i.e.*, $k_H>k_M\gg k_0$ in Eq. 3), added metal ions would suppress the observed reduction rates.



(3)

Ni^{2+} ion caused the inhibition to a greater extent

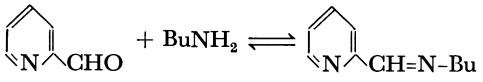
than Zn^{2+} ion. The trend is compatible with the general order of the stability constants.[17,32] Thus, the above explanation seems most likely at present.

Here, one may notice a dilemma occurring in the metal catalysis in aqueous systems. As mentioned above, stability constants of carbonyl substrates such as ethyl benzoylformate and benzil are extremely small.[32] Although 2-PyCHO in which a nitrogen base is closely fixed near the carbonyl group captures the metal ion to a significant extent, *N*-protonation is more effective than metal coordination.

The above summary suggests that the metal ion catalysis would become effective only for the substrate the C=X double bond of which is able to bind metal ions strongly. Schiff base is the case.[32]

Reduction of Schiff Bases of 2-PyCHO. NADH model reduction of Schiff bases in organic solvents was reported earlier by Pandit *et al.*[33] and Shinkai *et al.*,[8] but there is no precedent for the reduction in an aqueous system.

The spectroscopic measurements indicated that the addition of butylamine ($BuNH_2$) to the basic solution of PyCHO (pH 8.9) enhances the absorption band near 350 nm which is characteristic of the Schiff base.[34]



(4)

For example, the OD increase of 0.082 was recorded when butylamine (1.0×10^{-2} M) was added to the solution of 2-PyCHO (5.0×10^{-3} M) at pH 8.9. On the other hand, the formation of the Schiff base was hardly detected in an acetate buffer solution (pH 4.7). In Fig. 3, the OD value at 350 nm was plotted against the concentration of metal ions. The OD value was enhanced gradually with increasing metal ion concentrations and finally reached a plateau. In case 2-pyridylmethylamine ($PyCH_2NH_2$) was employed as an amine counterpart the absorption band was enhanced

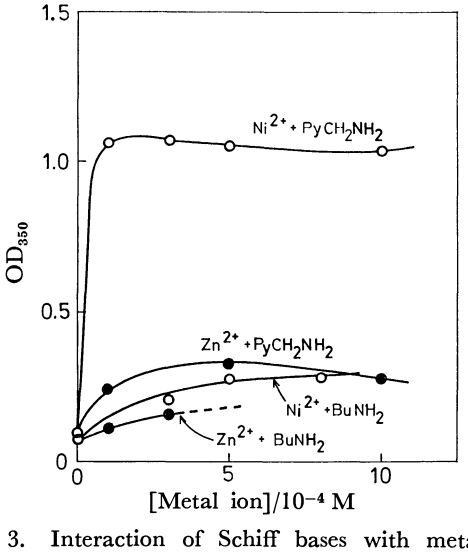


Fig. 3. Interaction of Schiff bases with metal ions: optical density at 350 nm plotted against the concentration of metal ions. pH 8.9 with 0.02 M borate buffer, [2-PyCHO] = 5.00×10^{-3} M, [$BuNH_2$] = [$PyCH_2NH_2$] = 1.00×10^{-2} M. The dotted line indicates the precipitation.

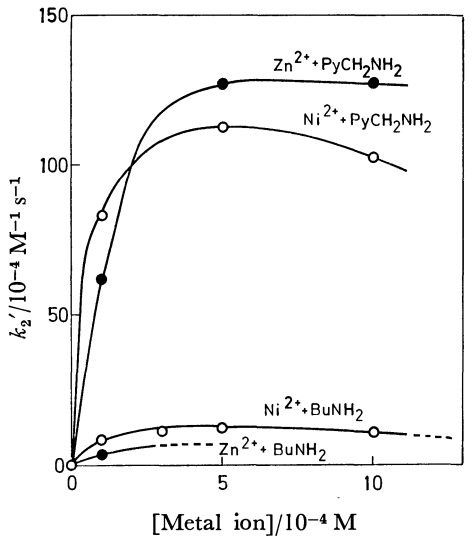

Fig. 4. Metal ion catalysis of the BzlQH reduction of Schiff bases. pH 8.9 with 0.02 M borate buffer, [2-PyCHO] = 5.00×10^{-5} M, [$BuNH_2$] = [$PyCH_2NH_2$] = 1.00×10^{-2} M. The dotted line indicates the precipitation.

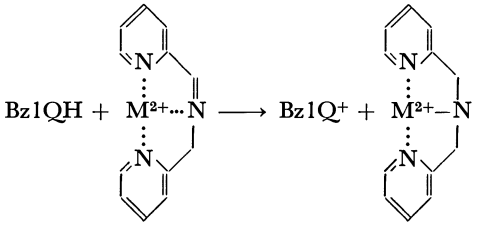
at the very low concentration of metal ions, and the solution containing Ni^{2+} ion became yellow (or orange at the higher concentrations). The result endorses that the Schiff base (particularly, *N*-(2-pyridylmethylene)-2-pyridylmethylamine) efficiently interacts with metal ions in an aqueous solution.

The metal-catalyzed reduction was carried out in basic pH region (pH 8.9). The resultant second-order rate constants (k_2') are plotted as a functions of metal ion concentrations (Fig. 4). The BzlQH reduction was undetectable in the absence of metal ions, indicating that the Schiff base itself is insensitive to the BzlQH reduction. As seen in Fig. 4, metal ions efficiently catalyzed the BzlQH reduction. The plots showed rapid increase at low metal concentrations (1×10^{-4} M) followed by a gradual rate saturation. In particular, the reduction of *N*-(2-pyridylmethylene)-2-pyridylmethylamine, the Schiff base from 2-pyridinecarbaldehyde and 2-pyridylmethylamine, was remarkably accelerated. Since the rate constant in no metal system is estimated to be less than 5×10^{-5} M^{-1} s^{-1}, the rate augmentation of more than 200-fold is achieved. The marked rate acceleration is rationalized in terms of efficient binding of metal ions and efficient metal-induced polarization of the C=N double bond. Probably, the curvature in Fig. 4 reflects the progressive increase in the fraction of metal-bound species of the Schiff base, because the OD_{350} in Fig. 3 shows the dependence similar to that in Fig. 4. Thus, the reaction may be written as Eq. 5.



(5)

Figure 3 shows that Ni^{2+} ion forms the complex more efficiently than Zn^{2+} ion. On the other hand, the catalytic efficiency of Zn^{2+} ion is comparable with that of Ni^{2+} ion (Fig. 4). This endorses that, provided the rate constants are calculated based on the complexed substrate concentration, Zn^{2+} ion would give the greater rate constants than Ni^{2+} ion.

4-Pyridinecarbaldehyde(4-PyCHO) and butylamine also formed the corresponding Schiff base in a borate buffer solution (pH 8.9), the OD_{350} value (0.066) being comparable with that from 2-pyridinecarbaldehyde and butylamine. However, the BzlQH reduction was not catalyzed by added metal ions at all (Table 1). The low reactivity is solely ascribable to the difference in the affinity toward metal ions.

We previously reported the dihydronicotinamide reduction of Schiff bases in refluxing methanol.[8] Although the Schiff bases are totally unreactive toward dihydronicotinamide, the reduction reaction was surprisingly facilitated by the addition of small amounts of acid speices. It is summarized, therefore, that the Schiff base can be reduced with the aid of proton catalysis in the acidic pH region and with the aid of metal catalysis in the basic pH region.

Some Characteristics of NADH Model Reduction in Aqueous Systems. Recently, the mechanistic role of metal ions in non-enzymatic dihydronicotinamide reduction has been dissected in aprotic solvents.[2-6] The catalytic behavior may be roughly summarized as follows: (1) activation of substrate and/or dihydronicotinamide at the initial state and (2) facilitation of hydrogen transfer by "bridge" effect of metal ions at the transition state. In aqueous systems, the interaction of metal ions with dihydronicotinamide itself is hardly expected due to the solvation of metal ions. Although there is an effort to synthesize a NADH model system which has within a molecule both dihydronicotinamide and metal-binding site,[35] the catalytic efficiency seems still equivocal. At present, it seems most expeditious to employ the metal-binding substrates to substantiate the aqueous metal catalysis.

Table 1. Apparent second-order rate constants(k_2') for the BzlQH reduction[a]

Substrate[b]	Metal ion / mM	$k_2' \times 10^4/M^{-1}\,s^{-1}$ at pH 4.7	at pH 8.9
2-PyCHO		40.3	ppt[c]
2-PyCHO	Ni^{2+} (5.0)	19.1	ppt[c]
2-PyCHO	Zn^{2+} (5.0)	32.2	ppt[c]
2-PyCHO+$BuNH_2$		39.3	nd[d]
2-PyCHO+$BuNH_2$	Ni^{2+} (0.5)	20.2	12.2
2-PyCHO+$BuNH_2$	Zn^{2+} (0.1)	28.9	3.7
4-PyCHO+$BuNH_2$			nd[d]
4-PyCHO+$BuNH_2$	Ni^{2+} (0.1)		nd[d]
4-PyCHO+$BuNH_2$	Zn^{2+} (0.1)		nd[d]
2-PyCHO+$PyCH_2NH_2$			nd[d]
2-PyCHO+$PyCH_2NH_2$	Ni^{2+} (0.5)		113
2-PyCHO+$PyCH_2NH_2$	Zn^{2+} (0.5)		126

a) 50 °C, μ=0.2 with KCl, 2.2%(v/v) acetonitrile. b) Abbreviations employed are: 2-PyCHO, 2-pyridinecarbaldehyde; 4-PyCHO, 4-pyridinecarbaldehyde; $BuNH_2$, butylamine; $PyCH_2NH_2$ 2-pyridylmethylamine. c) Precipitation was formed. d) The rate was not detected($k_2' < 5 \times 10^{-5}\,M^{-1}\,s^{-1}$).

The present study established that the reduction of C=O and C=N double bonds with adjacent nitrogen base(s) is subject to the metal-catalysis in aqueous systems. We noticed, however, that the proton catalysis is unexpectedly effective.

Another conclusion obtained in the present study is that the Schiff bases serve as good substrates for the metal-assisted BzlQH reduction in aqueous systems. The rate augmentation of two orders of magnitude is remarkable. It seems, therefore, that the interaction with NADH is not a prerequisite for the facile reduction, as proposed by Dunn and coworkers[36,37] in enzymatic systems. It is conceivable, however, that in the hydrophobic pocket of enzymes metal ions may be relatively desolvated and may act more "acidic" catalysts like metal ions in aprotic solvents. The influence of hydrophobic environments on the metal catalysis is now investigated.

Catalytic Asymmetric Hydroformylation by the Use of Rhodium-complexes of Chiral Bidentate Phosphorus Ligands Bearing Saturated Ring Skeletons

Teruyuki HAYASHI,* Masato TANAKA, Yoshikazu IKEDA, and Ikuei OGATA
National Chemical Laboratory for Industry, Honmachi, Shibuyaku, Tokyo 151

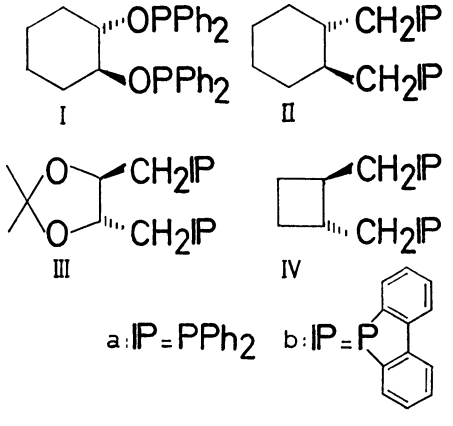
(Received December 27, 1978)

(1*S*,2*S*)-1,2-Bis(diphenylphosphinoxy)cyclohexane, (1*S*,2*S*)-1,2-bis(phosphinomethyl)cyclohexanes, (2*R*,3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(phosphino)butanes, and (1*R*,2*R*)-1,2-bis(phosphinomethyl)cyclobutanes, whose phosphino groups were diphenylphosphino or 5*H*-dibenzophosphol-5-yl groups where the rotation of phenyl–P bonds is impossible, were used as chiral ligands in rhodium-catalyzed asymmetric hydroformylation. The highest stereoselectivity was attained by the use of (1*R*,2*R*)-1,2-bis(5*H*-dibenzophosphol-5-ylmethyl)cyclobutane or (2*R*,3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(5*H*-dibenzophosphol-5-yl)butane.

The asymmetric hydroformylation reaction[1-4] of olefins by the use of chiral rhodium-complex catalysts is a promising method for synthesizing optically active aldehydes which allow numerous transformations to the final products. However, when compared with the hydrogenation of olefinic double bonds or the hydrosilylation of ketones,[5] the optical yields obtained so far in hydroformylation are relatively low and far from having any practical meaning. The difficulty lies in the fact that the reaction is effected at a higher temperature and consists of more steps, such as carbon monoxide insertion, than hydrogenation or hydrosilylation. In addition, a reactant carbon monoxide of a strong coordination power may compete with the chiral ligands in coordinating with rhodium; this complicates the situation as well.

In order to overcome these difficulties, although there is no doubt that the development of more active catalyst systems[6] which would allow the reaction to be carried out at a lower temperature is of primary importance, the breakthrough may come in the use of a chiral bidentate ligand,[3,4,7] which can be expected to chelate the central rhodium atom to make a more rigid and, therefore, more reliable asymmetric catalyst than a monodentate ligand.

In this paper, several kinds of bidentate chiral ligands, (1*S*,2*S*)-1,2-bis(diphenylphosphinoxy)cyclohexane (I),[8] (1*S*,2*S*)-1,2-bis(diphenylphosphinomethyl)-cyclohexane (IIa),[9,10] (1*S*,2*S*)-1,2-bis(5*H*-dibenzophosphol-5-ylmethyl)cyclohexane (IIb),[10] (2*R*,3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane (IIIa),[11] (2*R*,3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(5*H*-dibenzophosphol-5-yl)butane (IIIb),[7] (1*R*,2*R*)-1,2-bis(diphenylphosphinomethyl)-cyclobutane (IVa),[12,13] and (1*R*,2*R*)-1,2-bis(5*H*-dibenzophosphol-5-ylmethyl)cyclobutane (IVb),[13] were prepared and used for the rhodium-catalyzed hydroformylation of four typical kinds of olefins. The results were then compared with those of asymmetric hydrogenation.



Experimental

All the manipulations of organophosphorus compounds were carried out under a pure nitrogen atmosphere. I (85.5% optical purity),[8] (+)-(1*S*,2*S*)-1,2-bis(hydroxymethyl)cyclohexane ditosylate,[14,15] (+)-(1*R*,2*R*)-1,2-bis(hydroxymethyl)cyclobutane ditosylate,[12] (−)-Diop (IIIa),[11] 2-phenyl-1-butene,[16] and α-acetamidocinnamic acid[17] were prepared as has been described in the literature.

Chiral Bisphosphines. Method A (IIa): Eighty mmol of Na and 20 mmol of Ph_2PCl in 20 ml of dioxane were stirred for 6 h at 110 °C. To the cooled solution, THF (15 ml) was added, and then the ditosylate ($[\alpha]_D$+25.5° (benzene, *c* 3.16), lit,[14] +25.0° (benzene, *c* 5)) (6.7 mmol) in THF (12 ml) was added over 10 min at room temperature. Then the solution was refluxed for 2 h and cooled. After filtration, the filtrate was concentrated, water (10 ml) was added, and the product was extracted with benzene. The organic layer was washed and concentrated, and the residue was subjected to molecular distillation.

Method B (IIb, IIIb, IVa, and IVb): Seven mmol of a phenylphosphine (5-phenyl-5*H*-dibenzophosphole or triphenylphosphine) and 16 mmol of Li wire in 16 ml of THF were stirred for 2 h at room temperature and then refluxed for 10 min. After the excess Li wire had been removed, a 7 mmol portion of *t*-butyl chloride was added and the solution was refluxed for 15 min. To the solution, a THF (8 ml) solution of a ditosylate (3.5 mmol) was added over 7 min at room temperature, after which the mixture was stirred for an additional 2 h, refluxed, and worked up as above (liquid) or finally recrystallized (solid).

The properties of the chiral bisphosphines are listed in Table 1.

Catalytic Hydroformylation Procedure. A rhodium complex (1.35×10^{-2} mmol-Rh), a bisphosphine or diphosphinite (2.7×10^{-2} mmol or 5.4×10^{-2} mmol), a solvent (6 ml), and a substrate (3 ml) were placed in a 50-ml Schlenk-type autoclave (SUS 316) under a pure N_2 atmosphere, and 50 kgw/cm² (at 0 °C) of CO and then the same amount of H_2 were pressurized. The sealed reactor was immersed in a temperature-controlled oil bath, and the reaction solution was magnetically stirred.

a) The optical purities were calculated on the following bases: *N*-acetyl-(*R*)-phenylalanine: $[\alpha]_D$ −51.8 (*c* 1, EtOH),[25] (*S*)-2-phenylbutane: $[\alpha]_D$ +27.31° (neat),[26] (*S*)-2-phenylpropanal: $[\alpha]_D$ +160° (neat)[23] (Pino, *et al.* claim +238°,[27] (*S*)-2-methylbutanal: $[\alpha]_D$ +31.2° (neat),[28] (*R*)-3-phenylbutanal: $[\alpha]_D$ −31.3° (neat).[29] b) Rh: $[RhCl(CO)_2]_2$, P/Rh=8 (atom ratio), solvent: benzene for styrene and 2-phenylpropene, or ethylbenzene for butenes. c) Substrate: 0.5 g, solvent: EtOH+benzene (1:1) 3.5 ml. d) Sudstrate: 1 ml, solvent: benzene 3 ml. e) P/Rh=4. f) At 110 °C. g) At 130 °C. h) At 90 °C. i) Rh: $[Rh(CO)_3]_4$.

Catalytic Hydrogenation Procedure. [RhCl(1,5-hexadiene)]$_2$ (1.9×10^{-2} mmol), a bisphosphine or diphosphinite (4.0×10^{-2} mmol), a solvent, and a substrate were placed in a 25-ml Schlenk-type autoclave (SUS 316) under a pure N_2 atmosphere, and then the reactor was immersed in a bath of a designated temperature. H_2 was pressurized up to 50 kgw/cm^2 at that temperature, and the reaction solution was magnetically stirred.

Product Analysis. An aliquot of the reaction solution was analyzed by GLC (DEGS), and the remainder was distilled to afford an optically active product whose $[\alpha]_D$ was measured on a JASCO DIP-180 digital polarimeter. In the case of the hydrogenation of α-acetamidocinnamic acid, the reaction solution was worked up according to the literature.[11]

Results and Discussion

The optical purities were calculated through the optical rotation of isolated products; they are listed in Table 2.

A diphosphinite, I, although it resulted in fairly high optical yields in asymmetric hydrogenation,[8] caused a low asymmetric induction in the hydroformylation of any kind of olefins applied. The methylene-bridged analogue of I, a bisphosphine IIa, whose molecular structure is similar to that of I, brought about a much higher stereoselectivity than I.

On the other hand, IIa, with a saturated six-membered ring, was compared with Diop (IIIa), which has a five-membered dioxolane ring and with the IVa of a cyclobutane ring.[13,18] IIIa showed a certain asymmetric induction ability for each of the four olefins, while those of IIa or IVa depended on the structures of the olefins. That is, the ability decreased in the order of IIIa>IIa>IVa for styrene, in that of IIa>IIIa>IVa for 1-butene, and in that of IIIa>IVa>IIa for *cis*-2-butene. In the reaction of styrene or butenes, IIa of the configuration opposite to that of IIIa or IVa gave the antipode opposite to those given by IIIa and IVa; *i.e.*, the prevailing absolute configurations of the products from styrene or butenes were independent of the skeletal ring sizes of the bisphosphines, IIa—IVa.

The bidentate ligands mentioned above have Ph_2P

Table 3. Relative rates[a] (and product linearities (%)[b]) in catalytic hydroformylation[c]

groups. Upon chelating coordination, the four phenyl groups may protrude toward the coordination sites for a substrate and others, and they are considered to be responsible for the steric regulation. The phenyl group will take various conformations. In contrast to this, in the case of bisphosphines with 5*H*-dibenzophosphol-5-yl (DBP) groups which correspond to the planar Ph_2P groups whose phenyl groups are linked together at the *ortho*-positions, the influence of the rotation of the phenyl group can be excluded.

From this point of view, IIa, IIIa, and IVa, all with Ph_2P groups, were compared with IIb, IIIb, IVb, which have DBP ones. The substitution of DBP groups for Ph_2P ones always brought about a rate enhancement,[19] as is shown in Table 3. Moreover, Table 2 shows that the optical yields in the hydroformylation of styrene and butenes increased in the cases of III and IV upon DBP substitution. The orders of the asymmetric induction abilities among IIb≈IVb were IVb>IIIb>IIb for styrene and IVb—IIIb>IIb for butenes. Thus, IIIb and IVb were the most effective among the bidentate chiral ligands prepared in this study; this is in remarkable contrast to their lower stereoselectivity than IIIa and IVa in asymmetric hydrogenation. On the other hand, the prevailing configuration of the hydrogenation product from α-acetamidocinnamic acid was reversed through the substitution of DBP groups for Ph_2P ones, as is shown in Table 2.[20] In the hydroformylation of styrene and butenes also, IIIb or IVb prefered the opposite antipode to that IIIa or IVa prefered, respectively.

However, by the use of the II of a cyclohexane-ring skeleton, DBP-substitution for Ph_2P groups decreased the optical yields in the hydroformylation of styrene and 1-butene. In addition, the prevailing absolute configuration of the products was not reversed for all the olefins. Thus, the results with II were different from those with III or IV, which has a five- or four-membered ring skeleton, respectively. Furthermore, in the hydroformylation of styrene by the use of IIb, as the reaction temperature rose, the prevailing enantiomer was reversed at around 100 °C, and the optical purity of the product increased with an increase in the temperature up to about 160 °C, as is shown in Fig. 1.[22] This is in contrast with the behavior of IIIb or IVb, which invariably gave prevailing enantiomer

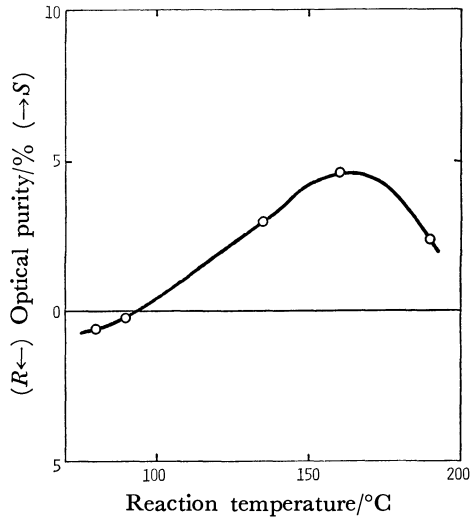

Fig. 1. Effect of reaction temperature on the optical purity of 2-phenylpropanal produced in the hydroformylation of styrene catalyzed by Rh-IIb system. (Other conditions are the same as in Table 2).

with a decrease in the stereoselectivity when the reaction temperature was raised in this range.

The present authors previously reported that the asymmetric induction abilities of IIIb and IVb were fairly high to a vinylidene-type olefin, 2-phenylpropene (V), in hydroesterification.[24] However, it is noteworthy that the abilities of I—IV remained low in the hydroformylation of V (Table 2). This is partly because the low reactivity of V requires a high reaction temperature (150 °C).

Reaction of Diazonium Salts with Transition Metals. II. Palladium-catalyzed Arylation of Ethylene with Arenediazonium Salts

Kiyoshi KIKUKAWA,* Kazuhiko NAGIRA, Nobuyuki TERAO, Fumio WADA, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received January 6, 1979)

Arylation of ethylene (7 atm) was carried out with various arenediazonium tetrafluoroborates (25 mmol) in the presence of bis(dibenzylideneacetone)palladium (0.5 mmol) and sodium acetate (75 mmol). Substituted styrenes were obtained in good yields (61—78%) under mild reaction conditions (1 h, room temperature) in a 1:1 mixture of acetone and dichloromethane, with some exceptions. Phenylbutenes, main by-products in dichloromethane, were presumed to form by the reaction of styrene with ethylene under catalysis of hydridopalladium species.

Previous work[1] has shown that arenediazonium salts are good arylating reagents of olefins in the presence of palladium(0) catalyst. The reaction not only proceeds under much milder conditions than those for the related palladium-catalyzed arylations,[2-4] but also was found to be applicable to unactivated olefins as compared to the copper salt catalyzed arylation (Meerwein arylation[5]). The direct synthesis of 4′-vinylbenzocrown[6] from ethylene and 4′-aminobenzocrown is an example to show synthetic utility of the present arylation, especially to one or more substituted aryl olefins. This paper describes a continuation of our studies on the arylation of ethylene with a variety of monosubstituted benzenediazonium salts to improve yield and to gain a scope of the reaction (reaction 1). A related arylation of ethylene using bromobenzene derivatives has been recently reported.[7]

$$X\text{-}C_6H_4\text{-}N_2^+BF_4^- \xrightarrow[Pd(dba)_2,\ NaOAc]{CH_2=CH_2} X\text{-}C_6H_4\text{-}CH=CH_2 + N_2 \quad (1)$$

X = CH_3, CH_3O, CO_2Et, Cl, Br, and NO_2

Results and Discussion

Reaction of Ethylene with Monosubstituted Benzenediazonium Salts. Although the reaction can be conducted either in aqueous or in non-aqueous media, this study was carried out in the latter system (acetone, dichloromethane or their mixture) by considering increased solubility of ethylene, and tetrafluoroborates (25 mmol) were reacted in the presence of bis(dibenzylideneacetone)palladium(0) [$Pd(dba)_2$] as the catalyst (0.5 mmol). Preliminary experiments with benzenediazonium salt revealed that the formation of stilbene, one of the possible by-products,[7] was very little (below 1%) under the pressure of ethylene of 6—8 atm in both solvents. However, in dichloromethane a considerable amount (30—40% of the product) of higher boiling product was produced (*vide infra*). The by-product did not form in acetone, but the total yield rather decreased (Table 1). Use of a mixture of the solvents(1:1 v/v) was found to give good yield, preventing the formation of the higher boiling product. The amount of the solvent influenced the formation of tarry material which had to be removed from the reaction mixture by chromatography on silica gel, and 150 ml of the solvent to 25 mmol of the diazonium salt was found enough to eliminate the treatment. Thus, the product (styrene and substituted styrenes) could be isolated by simple distillation of the reaction mixture in the presence of a small amount of *t*-butylcatechol. The results were summarized in Table 2. In most cases, substituted styrenes were obtained in good yields in 1 h and at room temperature (20—25 °C). The low yield of vinylmesitylene can be explained by steric effect of the two ortho substituents to suppress the formation of an arenepalladium species, a plausible active intermediate[1], in view of a good result obtained with *o*-methyl counterpart. Nitrobenzenediazonium salts are known to be good substrates in Meerwein arylation, which is generally considered

Table 1. Effects of conditions in the reaction of benzenediazonium salt

to proceed by a radical process, but in the present reaction reduction to nitrobenzene was the principal course, though 11% of substitution product had been obtained in the reaction with cyclopentene.[1] Purity or stability of a diazonium salt seems to be one of the factors influencing the product yield in this procedure. Thus, *m*-methylbenzenediazonium tetrafluoroborate, which is much more sensitive to decomposition than the other isomers, gave a lower yield. Under the similar conditions naphthalene-2-diazonium salt gave 72% yield of 2-vinylnaphthalene, mp 64—66 °C (lit,[8] mp 65—66 °C).

Structure and Its Possible Route of Formation of the Higher-boiling Product. As mentioned above, a considerable amount of higher-boiling product consisted of at least three components was produced in the arylation with benzenediazonium salt in dichloromethane. Hydrogenation of the fraction over Raney nickel gave a mixture containing *s*-butylbenzene and *n*-butylbenzene in a ratio of 11 to 1. The main component of the by-product by preparative GLC was proved to be *trans*-2-phenylbut-2-ene by comparison with an authentic sample (GLC and NMR), but the remainders, probably a combination of 1-phenylbutenes and the other 2-phenylbutenes, could not be isolated in pure form to allow their structural confirmations. In order to obtain some informations suggesting a likely route to the phenylbutene, the reaction of ethylene was carried out in the presence of styrene (30 mmol) under the conditions used in the above reaction except for the use of a reduced amount of benzenediazonium salt (2 mmol). The amount of the salt is only two equivalents of the palladium catalyst (1 mmol), and was selected with the object of generating hydridopalladium species. No phenylbutenes was produced in acetone, while in dichloromethane there was obtained 32% yield of the higher-boiling product and neither stilbene nor any dimers of styrene were detected. The yield was based on styrene added and much over 100% based on the diazonium salt. On hydrogenation the product afforded an 8 : 1 mixture of *s*-butylbenzene and *n*-butylbenzene. The results show that the phenyl butenes produced by the reaction of styrene and ethylene under the catalysis of the hydridopalladium species. The difference between the behavior of the two solvents may be rationalized by the lability of the catalyst to collapse to palladium(0) under the present reaction conditions. In this connection, it is noted that 1-phenylbutenes were the principal products in the related palladium-catalyzed codimerization reported previously.[9,10]

Experimental

Materials. $Pd(dba)_2$ was prepared by the published method.[11] Substituted anilines were commercial origin and used as received. Most of the arylamines were diazotized in aqueous 1:1 mixture of HBF_4 (42%) with aq $NaNO_2$ at 0 °C. White crystals precipitated were washed with cold 5% HBF_4, cold methanol, and cold ether. The tetrafluoroborate was dried under vacuum and stored in a refrigerator until to be used. Diazotization of those with nitro and ethoxycarbonyl groups was performed in aq H_2SO_4, and the precipitates obtained by addition of HBF_4 (42%) to the mixture at 0 °C were treated as above. Authentic 1-phenylbut-1-ene and *trans*-2-phenylbut-2-ene were prepared by dehydration of 1-phenylbutan-1-ol and 2-phenylbutan-2-ol, respectively. The solvents were distilled and used without further purification.

General Procedure for the Arylation of Ethylene. A mixture of $Pd(dba)_2$ (0.29 g, 0.05 mmol), NaOAc(6.15 g, 75 mmol), and 150 ml of a mixed solvent (acetone and dichloromethane, 1:1) in a glass autoclave(300 ml) was cooled in a Dry Ice–acetone bath, and arenediazonium tetrafluoroborare (25 mmol) was added (addition at a higher temperature caused a reaction of the diazonium salt with the catalyst). After the air in the vessel was displaced with ethylene, the mixture was allowed to warm to room temperature. Ethylene was introduced to a pressure of 6—8 atm and the mixture was stirred for 1 h at room temperature. The reaction mixture was neutralized with aq sat $NaHCO_3$ soln and washed with aq sat NaCl soln, and dried ($MgSO_4$). The solution was placed in a distilling flask containing a small amount of *t*-butylcatechol and the solvent was removed. The residue was distilled under vacuum to give the product. After purity of the distillate was checked by GLC, its structure was confirmed by IR and NMR analyses ($\nu_{C=C}$; 1620—1640 cm^{-1}, δ_{C-H}; 900—910 cm^{-1}, and ABX pattern due to $-CH=CH_2$). Formation of stilbene was examined for the distillation residue by recrystallization or column chromatography (silica gel).

Synthesis of Coleon U 12-Methyl Ether

Takashi MATSUMOTO* and Shoji TAKEDA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received January 16, 1979)

Reduction of 11-benzoyloxy-12-methoxyabieta-8,11,13-trien-7-one with sodium borohydride, followed by dehydration of the resulting alcohols with *p*-toluenesulfonic acid, afforded the corresponding 6,8,11,13-tetraene derivative. This was converted into 11-benzoyloxy-12-methoxyabieta-8,11,13-trien-6-one (**8**) *via* an epoxide. The 6-oxo compound (**8**) was reduced with lithium aluminium hydride. Subsequent oxidation of the resulting alcohol with *m*-chloroperbenzoic acid afforded 6*β*-hydroxy-12-methoxyabieta-8,12-diene-11,14-dione. This compound was further transformed into 11,14-diacetoxy-12-methoxyabieta-8,11,13-trien-6-one (**13**) by a series of reactions: Jones oxidation, reduction with a mixture of zinc powder and hydrochloric acid, and acetylation. The diacetate (**13**) was then oxidized with Jones reagent and the 6,7-dioxo product was immediately converted into 11-acetoxy-6,14-dihydroxy-12-methoxyabieta-5,8,11,13-tetraene (**15**) by repeated column chromatography on silica gel. The tetraene (**15**) was finally hydrolyzed with hydrobromic acid to give coleon U 12-methyl ether.

The isolation and structural elucidation have been reported for many naturally-occurring highly-oxygenated tricyclic diterpenes with a fully substituted aromatic C ring. Some of these also possess the oxygen functions at both the C-6 and C-7 positions in ring B, as depicted in coleon U (**1**) and coleon V (**2**), which were isolated as pigments from leaf-glands of *Plectranthus myrianthus* Briq. (*Labiatae*) by Eugster *et al.*[1] As a part of our synthetic studies on the naturally-occurring diterpenes we attempted to devise an efficient synthetic route for these highly-oxygenated tricyclic diterpenes. This paper will describe a successful synthesis of coleon U 12-methyl ether (**3**), starting from the optically active 11-benzoyloxy-12-methoxyabieta-8,11,13-trien-7-one (**4**) which was previously synthesized[2] from (+)-ferruginol (**5**). Since the total synthesis of (+)-**5** has recently been accomplished in our laboratory,[3] the present work can be regarded as a total synthesis of **3**.

2

Reduction of the carbonyl group in **4** with sodium borohydride in methanol afforded a mixture of the corresponding epimeric alcohols (**6**), which was immediately dehydrated with *p*-toluenesulfonic acid in refluxing toluene to give 11-benzoyloxy-12-methoxyabieta-6,8,11,13-tetraene (**7**) in nearly quantitative yield. The tetraene (**7**) was then subjected to epoxidation at 0—5 °C with *m*-chloroperbenzoic acid in dichloromethane. The resulting epoxide, without purification, was refluxed with hydrochloric acid in ethanol to produce 11-benzoyloxy-12-methoxyabieta-8,11,13-trien-6-one (**8**), whose IR spectrum showed an absorption band of a newly formed carbonyl group at 1718 cm^{-1}. Treatment of **8** with lithium aluminium hydride in refluxing ether afforded an alcohol (**9**). The *β*-configuration of the hydroxyl group at the C-6 position was supported by its NMR spectrum, which showed a signal at δ 4.51 ppm with a half-height width of 9 Hz, suggesting the presence of an equatorial α hydrogen. To introduce an oxygen function at the C-14 position, **9** was oxidized at room temperature with *m*-chloroperbenzoic acid in dichloromethane; the desired 6*β*-

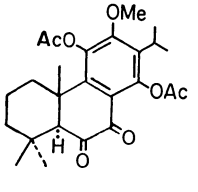
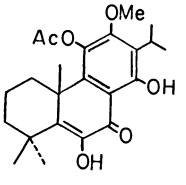
hydroxy-12-methoxyabieta-8,12-diene-11,14-dione (**10**) was obtained in 55% yield. The C-14 aromatic proton singlet (δ 6.32 ppm) in **9** disappeared in the NMR spectrum of **10**, while its IR spectrum showed *p*-quinone bands at 1655, 1640, and 1605 cm^{-1}. Oxidation of **10** with Jones reagent at 0—5 °C gave 12-methoxyabieta-8,12-diene-6,11,14-trione (**11**) which, without purification, was used in the next reaction. For the protection of the unstable C ring, the trione (**11**) was reduced with a mixture of zinc powder and dilute hydrochloric acid in refluxing benzene. The resulting crude phenol (**12**) was further acetylated at 75—80 °C with acetic anhydride in pyridine to give 11,14-diacetoxy-12-methoxyabieta-8,11,13-trien-6-one (**13**: 53% yield from **10**). Subsequently, oxidation of the C-7 position in **13** was carried out with Jones reagent at room temperature. The resulting crude 6,7-dioxo compound (**14**) was immediately subjected to repeated column chromatography on silica gel to afford a diosphenol derivative, 11-acetoxy-6,14-dihydroxy-12-methoxyabieta-5,8,11,13-tetraen-7-one (**15**), whose NMR spectrum showed signals due to an acetoxyl group at δ 2.35 ppm, a C-6 hydroxyl group at δ 6.92 ppm, and a hydrogen-bonded C-14 hydroxyl group at δ 13.00 ppm. The acetate (**15**) was finally hydrolyzed at 95—100 °C with hydrobromic acid in acetic acid under a nitrogen atmosphere to afford a phenol (**3**), mp 174—176 °C, $[\alpha]_D$ −12.4° ($CHCl_3$), which was shown to be identical with the authentic coleon U 12-methyl ether by mixed melting point determination and by IR and NMR spectral comparisons.



14



15

Experimental

All melting points are uncorrected. The IR spectra were taken in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, m, multiplet. The optical rotations were measured in chloroform using a Yanaco OR-50D. Column chromatography was performed using Merck silica gel (0.063 mm).

*11-Benzoyloxy-12-methoxyabieta-6,8,11,13-tetraene (**7**).* Sodium borohydride (650 mg) was added at 15—20 °C to a stirred solution of 11-benzoyloxy-12-methoxyabieta-8,11,13-trien-7-one (**4**)[2] (1.870 g) in methanol (250 ml). The mixture was stirred at this temperature for 4 h, acidified with dilute hydrochloric acid, and concentrated *in vacuo*. The residue was extracted with ether and the ether extract was washed with brine, dried over sodium sulfate, and then evaporated to afford a mixture of the corresponding 7α- and 7β-alcohol (**6**) which, without purification, was used in the next reaction.

The above mixture (**6**) was refluxed for 2 h with *p*-toluenesulfonic acid (250 mg) in dry toluene (12 ml), cooled, and then diluted with ether. The ether solution was washed with aqueous sodium hydrogencarbonate and water, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (100 g) using benzene as the eluent to give a tetraene (**7**) (1.760 g: 97.7%), which was recrystallized from acetone-methanol; mp 151.5—152.5 °C, $[\alpha]_D$ −67.8°; IR: 1734 cm^{-1}; NMR: 0.97 and 1.02 (each 3H and s, $-\underset{|}{C}(CH_3)_2$), 1.14 and 1.20 (each 3H, d, and J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (3H, s, $C_{10}-CH_3$), 3.60 (3H, s, $-OCH_3$), 5.87 (1H, dd, J=3 and 9.5 Hz, C_6–H), 6.43 (1H, dd, J=3 and 9.5 Hz, C_7–H), 6.73 (1H, s, C_{14}–H), 7.3—7.7 (3H, m) and 8.0—8.3 (2H, m) (aromatic protons). Found: C, 80.48; H, 8.16%. Calcd for $C_{28}H_{34}O_3$: C, 80.34; H, 8.19%.

*11-Benzoyloxy-12-methoxyabieta-8,11,13-trien-6-one (**8**).* A solution of **7** (1.760 g) and *m*-chloroperbenzoic acid (70%: 1.14 g) in dichloromethane (20 ml) was allowed to stand at 0—5 °C for 45 min. The solution was diluted with ether and then washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and water. After drying over sodium sulfate, the solution was evaporated *in vacuo* to give a crude epoxide which was immediately subjected to the next reaction.

A solution of the above epoxide and concentrated hydrochloric acid (2.0 ml) in ethanol (40 ml) was refluxed for 1.5 h. After the solution had been concentrated *in vacuo*, the residue was extracted with ether. The ether extract was washed with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and then evaporated *in vacuo*. The crude product was recrystallized from ethanol to give a ketone (**8**) (580 mg: 31.8%); mp 182—184 °C; $[\alpha]_D$ +105°; IR: 1735; 1718 cm^{-1}; NMR: 1.05 and 1.31 (each 3H and s, $-\underset{|}{C}(CH_3)_2$), 1.25 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.31 (3H, bs, $C_{10}-CH_3$), 2.50 and 2.68 (each *ca.* 0.5H and bs, C_5–H),[4] 3.57 and 3.65 (each *ca.* 2.5H and bs, $-COCH_2-$ and $-OCH_3$),[4] 6.79 (1H, s, C_{14}–H), 7.45—7.7 (3H, m) and 8.05—8.35 (2H, m) (aromatic protons). Found: C, 77.29; H, 7.87%. Calcd for $C_{28}H_{34}O_4$: C, 77.39; H, 7.89%.

The mother liquor of the above crystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (80 g) using ether–benzene (1 : 99) as the eluent to give additional **8** (485 mg: 26.6%).

*12-Methoxyabieta-8,11,13,-triene-6β,11-diol (**9**).* A mixture of **8** (1.460 g), lithium aluminium hydride (380 mg), and dry ether (50 ml) was refluxed for 1.5 h. The mixture was poured into a mixture of ice and aqueous ammonium chloride, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (20 g), using ether–benzene (3:97) as the eluent, to give an alcohol (**9**) (908 mg: 80.8%), which was recrystallized from hexane; mp 157.5—158.5 °C; $[\alpha]_D$ +34.8°; IR: 3520, 3410 cm^{-1}; NMR: 1.03 and 1.27 (each 3H and s, $-\underset{|}{C}(CH_3)_2$), 1.19 and 1.21 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.65 (3H, s, $C_{10}-CH_3$), 3.72 (3H, s, $-OCH_3$), 4.51 (1H, m, $W_{1/2}$=9 Hz, C_6–H), 5.92 (1H, s, C_{11}–OH), 6.32 (1H, s, C_{14}–H). Found: C, 75.84; H, 9.73%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%.

*6β-Hydroxy-12-methoxyabieta-8,12-diene-11,14-dione (**10**).* A solution of **9** (386 mg) and *m*-chloroperbenzoic acid (80%: 429 mg) in dichloromethane (10 ml) was allowed to stand at room temperature for 30 h, and then diluted with ether. The solution was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. After drying over

sodium sulfate, the solution was evaporated *in vacuo* and the crude product was purified by column chromatography on silica gel (40 g), using ether–benzene (2:98) as the eluent, to give the recovered **9** (64 mg: 16.6%) and a quinone compound (**10**) (222 mg: 55.2%) which was recrystallized from methanol; mp 212—214 °C; $[\alpha]_D$ −51.9°; IR 3625, 3525, 1655, 1640, 1605 cm^{-1}; NMR ($CDCl_3$): 1.02 and 1.26 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.69 (3H, s, $C_{10}-CH_3$), 3.90 (3H, s, $-OCH_3$), 4.67 (1H, m, $W_{1/2}$=9 Hz, C_6–H). Found: C, 72.81; H, 8.75%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

*11,14-Diacetoxy-12-methoxyabieta-8,11,13-trien-6-one (**13**).* A solution of **10** (495 mg) in acetone (20 ml) was oxidized with Jones reagent (2.67 mol dm^{-3}: 0.75 ml) at 0—5 °C for 5 min and then diluted with ether. The solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude 6-oxo compound (**11**); IR: 1720, 1655, 1640, 1605 cm^{-1}.

The above crude compound (**11**) was dissolved in benzene (12 ml) and the solution was stirred and refluxed for 10 min with a mixture of zinc powder (1.2 g) and dilute hydrochloric acid (10%: 12 ml). After cooling, the mixture was extracted with ether and the extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude phenol (**12**).

The crude phenol (**12**) was immediately acetylated at 75—80 °C for 1.5 h with acetic anhydride (1.0 ml) and pyridine (2.0 ml). After the usual work-up, the product was purified by column chromatography on silica gel (30 g), using ether–benzene (5:95) as the eluent, to give a diacetate (**13**) (327 mg: 53%) which was recrystallized from methanol; mp 183.5—185 °C; $[\alpha]_D$ +130°; IR: 1765, 1720 cm^{-1}; NMR ($CDCl_3$): 1.02 and 1.22 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.29 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.36 (3H, s, $C_{10}-CH_3$), 2.34 (6H, s, 2-$OCOCH_3$), 2.65 (1H, bs, C_5–H), 3.25(2H, bs, $-COCH_2-$), 3.74 (3H, s, $-OCH_3$). Found: C, 69.79; H, 8.06%. Calcd for $C_{25}H_{34}O_6$: C, 69.74; H, 7.96%.

*11-Acetoxy-6,14-dihydroxy-12-methoxyabieta-5,8,11,13-tetraen-7-one (**15**).* A solution of **13** (372 mg) in acetone (6.0 ml) was oxidized with Jones reagent (2.67 mol dm^{-3}: 0.6 ml) at room temperature for 2 h. After the same work-up as described for the preparation of **11**, the crude 6,7-dioxo compound (**14**) was purified by repeated column chromatography (3 times) on silica gel, using hexane–chloroform (3:7) as the eluent, to give a diosphenol derivative (**15**) (129 mg: 37.2%) which was recrystallized from methanol; mp 145—146 °C; $[\alpha]_D$ +17.9°; IR: 3410, 3160, 1765, 1640, 1615, 1595 cm^{-1}; NMR ($CDCl_3$): 1.44 (9H, s, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.38 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.35 (3H, s, $-OCOCH_3$), 3.73 (3H, s, $-OCH_3$), 6.92 (1H, s, C_6–OH), 13.00 (1H, s, C_{14}–OH). Found: C, 68.66; H, 7.61%. Calcd for $C_{23}H_{30}O_6$: C, 68.63; H, 7.51%. Further elution gave the recovered **13** (176 mg: 47.4%).

*Coleon U 12-Methyl Ether (6,11,14-Trihydroxy-12-methoxyabieta-5.8,11,13-tetraen-7-one) (**3**).* A mixture of **15** (157 mg), 47% hydrobromic acid (0.5 ml), and acetic acid (4.0 ml) was heated at 95—100 °C for 1 h in a stream of nitrogen. The reaction mixture was cooled, diluted with ether, and then washed successively with water, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo* and the residue was purified by column chromatography on silica gel (15 g) using hexane–chloroform (1 : 1) to give coleon U 12-methyl ether (**3**) (40 mg: 28.3%), which was recrystallized from hexane; mp 174—176 °C dec; $[\alpha]_D$ −12.4°; IR: 3520, 3410, 1642, 1617, 1598 cm^{-1}; NMR ($CDCl_3$); 1.40 and 1.42 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$) 1.44 (6H, s, $-\dot{C}(CH_3)_2$), 1.65 (3H, s, $C_{10}-CH_3$), 3.79 (3H, s, $-OCH_3$), 5.74 (1H, s, C_{11}–OH), 6.93 (1H, s, C_6–OH), 12.57 (1H, s, C_{14}–OH). Found: C, 70.04; H, 7.94%. Calcd for $C_{21}H_{28}O_5$: C, 69.97; H, 7.83%. The identity of the synthetic sample (**3**) with natural coleon U 12-methyl ether was confirmed by mixed melting point determination and by IR and NMR spectral comparisons.

Further elution gave the recovered **15** (62 mg: 39.4%).

The authors are grateful to Arakawa Chemical Co. Ltd. for a generous gift of rosin. Thanks are also due to Professor C. H. Eugster for kindly supplying the natural sample.

4) These signals arose from rotational isomers due to a methoxyl group, whose free rotation was restricted by two bulky ortho substituents: benzoyloxyl and isopropyl groups.

Asymmetric Cyclization of Propylene Chlorohydrins Catalyzed by an Optically Active Cobalt(salen) Type Complex

Tsutomu TAKEICHI, Michihiro ISHIMORI,* and Teiji TSURUTA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received January 26, 1979)

By using an optically active cobalt complex, *N,N'*-disalicylidene-(1*R*,2*R*)-1,2-cyclohexanediaminatocobalt(II), as a catalyst, optically active methyloxirane was synthesized by the asymmetric elimination of hydrogen chloride with a base from racemic propylene chlorohydrins. The highest optical purity of methyloxirane so far obtained was 35%, observed when 2-chloro-1-propanol and potassium carbonate were used as substrate and base, respectively. The optical rotations of the products and of the unchanged substrates indicate that (*S*)-1-chloro-2-propanol reacted selectively to produce (*S*)-methyloxirane, whereas in the case of 2-chloro-1-propanol, the (*R*)-isomer was preferentially cyclized to give (*S*)-methyloxirane with inversion of the asymmetric carbon. The physicochemical data of the circular dichroism and absorption spectra indicated a complexation of the optically active cobalt(II) species with potassium carbonate, either the (*R*)- or (*S*)-substrate interacting selectively with the Co*/K_2CO_3 complex formed, followed by cyclization of the substrate.

There has been considerable interest in the reactivities of the square-planar, tetradentate Schiff base complexes of cobalt, such as cobaloxime and Co(salen) in connection with coenzyme B_{12}.[1,2] The reactions of low-spin complexes of cobalt(I) and cobalt(II) with organic halides are of some biochemical importance and constitute a versatile preparative method for organocobalt compounds. Schrauzer has presented evidence indicating that the reaction of vitamin B_{12s} with alkyl halide follows an S_N2 mechanism,[3] involving powerfully nucleophilic cobalt(I) species. On the other hand, Halpern *et al.* reported that the cobalt(II) complexes such as pentacyanocobaltate(II) and cobaloxime(II) react with organic halides by a free radical mechanism.[4]

We recently reported the synthesis of an optically active cobalt complex, *N,N'*-disalicylidene-(1*R*,2*R*)-1,2-cyclohexanediaminatocobalt(II), Co(II)(sal)$_2$(*R*-CHXDA), and asymmetric reactions using the Co^I complexes, reduced derivatives of Co(II)(sal)$_2$(*R*-CHXDA).[5] In continuation of our studies,[6–8] we report here the synthesis of optically active methyloxirane by asymmetric cyclization of propylene chlorohydrins in the presence of the Co(II)(sal)$_2$(*R*-CHXDA) complex, a reaction which presumably involves an interaction between the cobalt species and C–Cl bond of the substrate prior to cyclization.

Experimental

Measurements. Absorption spectra were measured with a Shimadzu automatic recording spectrophotometer Model MPS-50L, and CD spectra with a JASCO Model J-20 spectrometer. Optical rotations were observed with a Perkin-Elmer Polarimeter Model 241. GLC analyses were carried out with a Hitachi Model K-53 Gas Chromatograph equipped with a column containing PEG. Thermogravimetry (TG) and differential thermal analyses(DTA) were made using a Rigaku-denki Model TG-DTA instrument.

Preparation of Co(II)(sal)$_2$(R-CHXDA). Reagents were purified by standard methods.[9] The Co(II)(sal)$_2$(*R*-CHXDA) complex was prepared by a method described previously. *N,N'*-Disalicylidene-(1*R*,2*R*)-1,2-cyclohexanediamine, prepared by the reaction of (1*R*,2*R*)-1,2-cyclohexanediamine and two molar equivalents of salicylaldehyde, was allowed to react with anhydrous cobalt acetate in 1-propanol at 60 °C for 1 h with stirring to give Co(II)(sal)$_2$(*R*-CHXDA) as an orange-red powder.[5]

Preparation of Propylene Chlorohydrin. 1-Chloro-2-propanol was prepared by modifying the procedure of Stewart and Vanderwerf.[10] Into a 2-L flask fitted with reflux condenser, stirrer, and dropping funnel was added 1L of dry ether and 50 g(1.28 mol) of $LiAlH_4$. After the mixture was cooled, 330 g(3.6 mol) of chloroacetone was added over a period of 6 h with stirring. The reaction mixture was stirred for 1 h before decomposition of the excess hydride with water. The ether layer was dried over magnesium sulfate, and 1-chloro-2-propanol was obtained by fractional distillation; bp 50.5 °C/30 mmHg, yield 55%. 2-Chloro-1-propanol was prepared by an analogous procedure involving the reduction of α-chloropropionic acid with $LiAlH_4$; bp 53 °C/29 mmHg, yield 35%.

Thermal Analyses of Potassium Carbonate and Co(II)(sal)$_2$(R-CHXDA). The TG and DTA curves of commercial potassium carbonate, Co(II)(sal)$_2$(*R*-CHXDA), and a mixture of the carbonate and Co^{II} complex are shown in Fig. 1. The results indicate that reagent grade potassium carbonate contains a small amount of water and that it can be completely dried by heating at 130—150 °C. The Co(II)(sal)$_2$(*R*-CHXDA) complex does not decompose on heating with carbonate up to 200 °C, as was also confirmed by infrared studies.

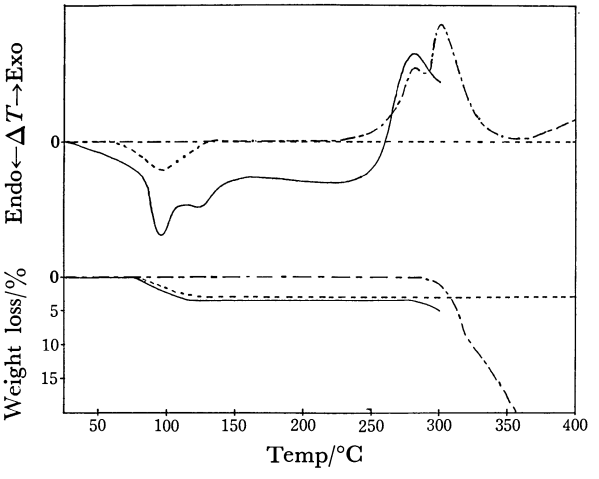

Fig. 1. TG and DTA curves for the systems of Co*(II)/K_2CO_3 (——), K_2CO_3 (----), and Co*(II) (———).

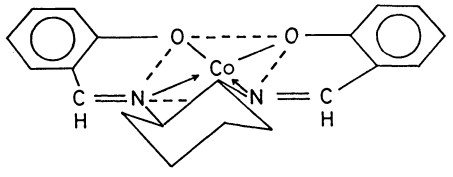
Asymmetric Cyclization of Propylene Chlorohydrins. Into a 50 ml-flask was charged 0.1895 g(0.5 mmol) of Co(II)-(sal)$_2$(*R*-CHXDA) and 8.292 g(60 mmol) of potassium carbonate. The mixture was dried at 130—150 °C for 3 h *in vacuo*. The experiment with hydrous K_2CO_3 did not require this period of heating. After cooling, 40 ml of solvent was added under dry nitrogen. A 120 mmol of 1-chloro-2-propanol or 2-chloro-1-propanol was added to the suspended solution and the reaction mixture was stirred at 25 °C. After an appropriate reaction time, the methyloxirane formed and the unconverted substrate were analyzed by gas chromatography. The optical rotations of the methyloxirane and propylene chlorohydrins recovered by fractional distillation were measured.

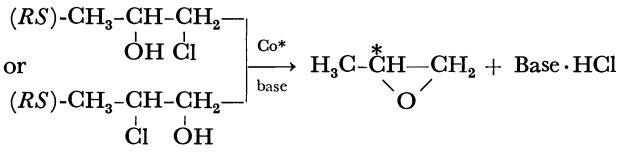
The optical purities (*e.e.*) of methyloxirane were evaluated from the optically pure methyloxirane, $[\alpha_o]_D=+12.53°$ (neat).[11] The expected optical purities ($e.e._{calcd}$) of methyloxirane in Tables 1 and 2 were evaluated from the optical purities of the recovered substrates; $e.e._{calcd}=[\alpha]/[\alpha_o]\{(100-\text{conv.})/\text{conv.}\}\times 100$. $[\alpha_o]_D=-19.19°$ (*c* 5.17 $CHCl_3$)[12] and $[\alpha_o]_D=-6.544°$ (neat) (calculated by, $[\alpha_o](\text{neat})=[\alpha_o](CHCl_3)\cdot[\alpha](\text{neat})/[\alpha](CHCl_3)$) for pure (*R*)-1-chloro-2-propanol. $[\alpha_o]_D=+17.39°$(neat)[13] for pure (*S*)-2-chloro-1-propanol.

Results and Discussion

The complex, *N*,*N*′-disalicylidene-(1*R*,2*R*)-1,2-cyclohexanediaminatocobalt(II), has been established as



low-spin square-planar complex (μ_{eff} 2.41 B.M.) having a λ-conformation of the central chelate ring.[5] By using the Co(II)(sal)$_2$(*R*-CHXDA) complex as a catalyst, asymmetric cyclization of 1-chloro-2-propanol or of 2-chloro-1-propanol was examined, according to the following principle. Namely, optically active methyloxirane may be obtained when either (*R*)- or (*S*)-substrate selectively interacts with the optically



active cobalt species, followed by the elimination of hydrogen chloride from the selected substrate with a base. The results with [Co(III)(sal)$_2$(*R*-CHXDA)]$^+$I$^-$ reported previously,[8] and subsequent experiments using a variety of bases, revealed that the combination of Co(II)(sal)$_2$(*R*-CHXDA) with potassium carbonate was most effective for this asymmetric reaction.

Asymmetric Cyclization. The reactions of 1-chloro-2-propanol and of 2-chloro-1-propanol with potassium carbonate were carried out in the presence of catalytic amounts of Co(II)(sal)$_2$(*R*-CHXDA) in several solvents. To make comparison with these reactions, analogous experiments without the Co^{II} complex were performed under similar conditions. Potassium carbonate is hygroscopic, and thus a small amount of H_2O (or OH^-) contained in it may affect the asymmetric reaction by functioning as a solvating agent for K_2CO_3 and/or axial base for the Co^{II} complex. Thermal analyses (see Experimental) showed that commercial

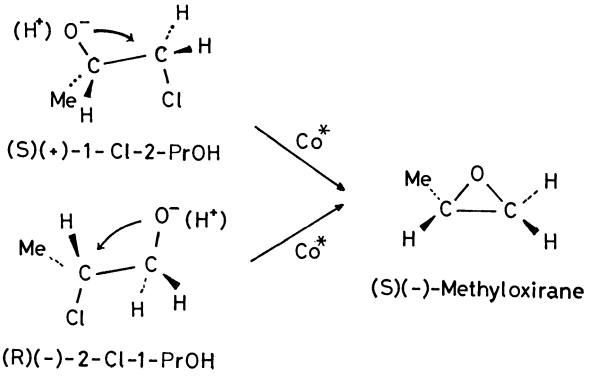
a)—h) As in Table 1. $[\alpha]_D^{25}=17.39°$ (neat) (Ref. 13) for pure (*S*)-2-Cl-1-PrOH. i) Measured in Diox/*m*-xylene soln.

potassium carbonate contained about 2.7% water (*i.e.*, 0.213 mol of H_2O per mol of K_2CO_3) and that the carbonate was completely dried by heating at 130—150 °C *in vacuo*. We used both dry potassium carbonate (dry K_2CO_3) and commercial carbonate (hydrous K_2CO_3) as bases for the cyclization reactions.

The results with 1-chloro-2-propanol and 2-chloro-1-propanol are summarized in Tables 1 and 2, respectively. All the asymmetric reactions gave (*S*)(−)-methyloxirane. The highest optical purity was 35.4% ($[\alpha]_D=-4.44°$), when the cyclization of 2-chloro-1-propanol was carried out in a dioxane solution. The highest *e.e.* value from 1-chloro-2-propanol was 24.3%, which was observed in the reaction with hydrous K_2CO_3 in dioxane as well. The unchanged 1-chloro-2-propanol recovered showed (−) optical rotation, while the unchanged 2-chloro-1-propanol gave (+) rotation. These facts suggest that (*S*)-L-(+)-1-chloro-2-propanol is selectively bound to the optically active cobalt complex and converted to (*S*)-L-(−)-methyloxirane where no reaction is involved at the asymmetric center. They also suggest that the cyclization reaction of (*R*)-D-(−)-2-chloro-1-propanol to (*S*)-L-(−)-methyloxirane involves an inversion of configuration at the asymmetric carbon. The stereochemistry of the oxirane formation from halohydrin can be explained



by assuming a mechanism in which cyclization takes place by a backside attack of the alcoholate anion formed initially by the action of a base, at the carbon atom bearing the leaving halogen atom.[14] This S_N2 ring-formation is considered to hold mainly for the above kinetic resolution reactions.

All the reactions using dry K_2CO_3 resulted in higher conversions of the reacted substrates to methyloxirane, as compared to the corresponding reactions with hydrous K_2CO_3. The ratios of methyloxirane formed to reacted 1-chloro-2-propanol or 2-chloro-1-propanol in Tables 1 and 2 are higher than 80%, implying that side reactions such as polymerization are considerably suppressed. This behavior is also demonstrated by the data in dioxane in Table 1; the ratios are 82, 69, and 47% for dry K_2CO_3 (Diox), hydrous K_2CO_3 (Diox), and hydrous K_2CO_3(Diox–H_2O), respectively. On the other hand, there is a tendency that, in regard to asymmetric selectivity, use of dry K_2CO_3, instead of hydrous K_2CO_3, causes decrease in selectivity in the reactions with 1-chloro-2-propanol, while methyloxirane having higher optical activities is obtained from 2-chloro-1-propanol.

The solvent effects were found to be complicated, as might be expected, since the solvents used have functional groups and heterogeneity of the reaction system is changeable according to the nature of solvent. The reaction in dioxane resulted in the best asymmetric selectivity, although the conversion was poor. In 1-propanol, a satisfactory yield of methyloxirane was obtained but the selectivity was disappointing. The results in 1,2-dichloroethane solvents are of interest; especially in the reaction of 2-chloro-1-propanol with dry K_2CO_3, a fairly high selectivity (*e.e.* 26.7%) was observed in spite of a high conversion (40.3% based on initial substrate and 80.6% on K_2CO_3). A similar result was obtained for the 1-chloro-2-propanol/hydrous K_2CO_3 system.

It is considered that, as for cyclization in the presence of Co(II)(sal)$_2$(*R*-CHXDA), the reaction proceeds by

two parallel pathways, with respective cobalt*-catalyzed and non-Co*-catalyzed mechanisms, as given by Eqs. 1 and 2.

$$\text{substrate} + K_2CO_3 \xrightarrow{Co^*} \text{methyloxirane}^* \quad (1)$$

$$\text{substrate} + K_2CO_3 \longrightarrow \text{methyloxirane} \quad (2)$$

The data with dry K_2CO_3 in Table 2, which were the most reproducible, indicated that the highly asymmetric selectivity was achieved in dioxane because the Co*-catalyzed reaction (Eq. 1) took place almost exclusively. The reaction in 1-propanol, a highly polar solvent, involved to a considerable extent the non-Co*-catalyzed pathway (Eq. 2) in addition to Eq. 1, producing methyloxirane with low optical purity. The *e.e.* values of methyloxirane formed in the three solvents decrease in this order: dioxane>1,2-dichloroethane>1-propanol; this is consistent with the presumed order of the extents of Eq. 1 involved in the asymmetric reactions.

Mechanism of Asymmetric Cyclization. In order to obtain insight into the mechanism of the asymmetric cyclization of propylene chlorohydrins, the reaction systems were investigated by absorption and circular dichroism (CD) spectroscopy. The absorption spectrum of the Co(II)(sal)$_2$(*R*-CHXDA) complex itself and that of a binary system of Co(II)(sal)$_2$(*R*-CHXDA) and dry K_2CO_3 are shown in Fig. 2. The spectrum of the latter is very similar to that of the Co^{II} complex itself and is completely different from those of such Co^{I} complexes as $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$ [5] and $Na^+[Co(I)(salen)]^-$.[15] This indicates that the cobalt species in the Co(II)(sal)$_2$(*R*-CHXDA)/K_2CO_3 system is not reduced to Co^{I}, but remains as the Co^{II} state.

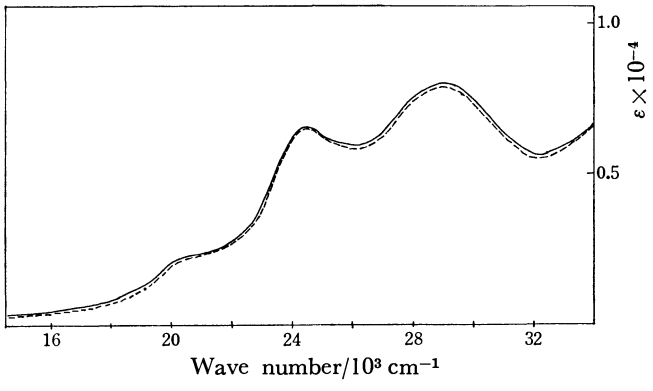


Fig. 2. The absorption spectra of Co*(II) (——) and of Co*(II)/K_2CO_3 (----) in dioxane.

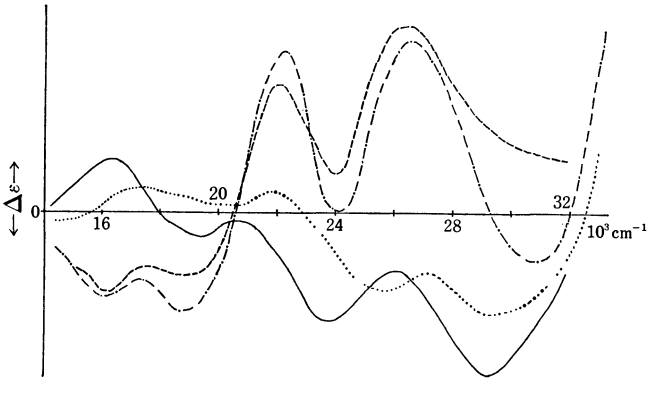

Fig. 3. The CD spectra for the systems of Co*(II)(——), Co*(II)/K_2CO_3 (----), Co*(II)/K_2CO_3/1-Cl-2-PrOH (—·—·), and Co*(II)/K_2CO_3/2-Cl-1-PrOH (·····). Measured as dioxane solutions saturated with the Co* species.

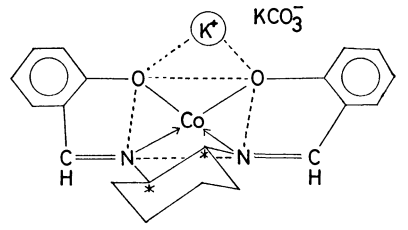

Fig. 4. A possible structure of Co*(II)/K_2CO_3 complex.

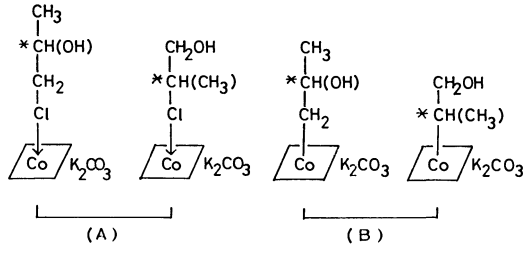
The CD spectra of Co(II)(sal)$_2$(*R*-CHXDA) itself and systems of Co^{II}/K_2CO_3, Co^{II}/K_2CO_3/1-chloro-2-propanol, and Co^{II}/K_2CO_3/2-chloro-1-propanol are depicted in Fig. 3. A marked spectral difference is observed between the Co^{II}/K_2CO_3 system and the Co^{II} complex itself, which indicates the formation of a complex between the Co(II)(sal)$_2$(*R*-CHXDA) and K_2CO_3 by combination of a potassium atom of K_2CO_3 with the two phenolic oxygens (Fig. 4), as suggested by related systems.[16]

Little change occurred in the CD spectrum when 1-chloro-2-propanol was added to the Co^{II}/K_2CO_3 system, whereas a drastic change was observed in the case of 2-chloro-1-propanol, as shown in Fig. 3. The CD spectral data for the Co^{II}/K_2CO_3/propylene chlorohydrin systems suggest the formation of new chiral complexes such as (A) and/or (B).[4]



The large CD spectral change for the system of 2-chloro-1-propanol can be interpreted in terms of large chiral and steric effects of the asymmetric moiety, $ClC^*H(CH_3)CH_2OH$ or $-C^*H(CH_3)CH_2OH$, on the chiral circumstance around the central cobalt atom, compared with the case of 1-chloro-2-propanol system. The complexes of type (B) are considered to be rearranged to ketone or aldehyde under basic conditions; the formation of methyloxirane from the (B)-complexes seems unlikely.[5,17]

On the basis of the results so far obtained, this kinetic resolution type reaction which gives rise to optically active methyloxirane from 1-chloro-2-propanol or 2-chloro-1-propanol is considered to proceed by the mechanism depicted in Scheme 1; the selection of (*R*)- or (*S*)-substrate would take place at the stage of coordination of the substrate onto the chiral cobalt complex.

Further investigations are now in progress.

A New Peptide Synthesis Using 2-Fluoro-1,3,5-trinitrobenzene. Syntheses of Thyrotropin Releasing Hormone and Leucine-Enkephalin

Hideki KINOSHITA,* Katsuhiko INOMATA, Osamu MIYANO, and Hiroshi KOTAKE

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received January 29, 1979)

2-Fluoro-1,3,5-trinitrobenzene has been found to be a useful new condensing reagent for peptide synthesis. A variety of dipeptides have been prepared from the corresponding amino acids with the reagent. The Young test under certain conditions did not cause racemization during the procedures. Subsequent application of this reagent enabled the syntheses of thyrotropin releasing hormone and leucine-enkephalin in good yields.

It has been reported[1,2] that the readily available 2-fluoro-1,3,5-trinitrobenzene(FTNB) is a useful new condensing reagent for the preparation of amides, esters, and thiocarboxylic *S*-esters. In this paper, the syntheses of various dipeptides and biologically active peptides, thyrotropin releasing hormone(TRH) and leucine-enkephalin are described.

As a preliminary, several *N*-benzyloxycarbonyl(Z) dipeptide esters were prepared by the reaction of *N*-benzyloxycarbonyl amino acids with amino acid esters using FTNB as a condensing reagent, as shown in Table 1. To an equimolar solution of *N*-benzyloxycarbonyl amino acid and FTNB in acetonitrile was added an acetonitrile solution of pyridine(one equivalent) at 0 °C under a nitrogen atmosphere. After stirring for 3 h at 0 °C, the amino acid ester(one equivalent) was added to the reaction mixture, followed by the addition of a solution of pyridine(one equivalent) in acetonitrile. The solution was stirred for several hours and then worked up to give the desired dipeptide **1a**—**g** in good yield (Table 1).

In a similar manner, the *N*-*t*-butoxycarbonyl(Boc) dipeptide esters(**2a**—**e**) were obtained in excellent yields, the results of which are given in Table 2.

Compound **1g** was obtained in good yield with no side reactions such as *O*-acyl derivatives[3] without protection of the hydroxyl group of *N*-(benzyloxycarbonyl)serine. The condensation reaction of amino acids containing bulky substituents (**2b**,**c**) also proceeded smoothly giving the desired products in good yields. FTNB is then an excellent condensing reagent for peptide synthesis.

The reaction appears to proceed *via* a mechanism similar to the formation of amides[1] and esters[2] as illustrated in the following scheme: First, the anionic sigma complex **3** is formed by the reaction of the amino acid with FTNB in the presence of pyridine followed by the elimination of the picrate to produce an intermediate acyl fluoride **4**, which then reacts with amino acid esters to give the corresponding dipeptide **5**.

Fragment condensation is frequently used to synthesize the more complex peptides, however, the problem of racemization of the acyl peptide exists. Consequently the Young test[4] was applied to determine the applicability of the FTNB method to fragment condensation. The results of which are given in Table 3. The

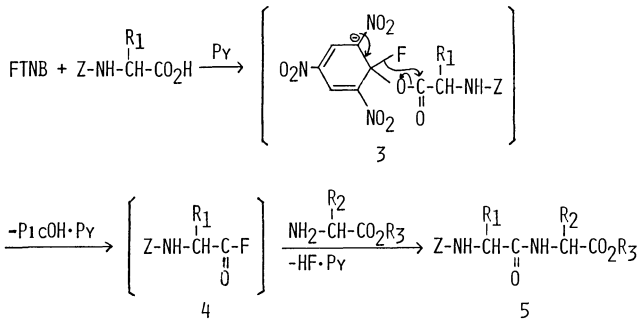
FTNB $\xrightarrow[0\,^\circ C,\ 1.5\,h,\ \text{in } CH_3CN]{\text{Boc-A.A.-OH, Py}}$ $\xrightarrow[0\,^\circ C,\ r.t.,\ 3\,h]{\text{H-A.A.-OMe, Py}}$ Boc-dipeptide-OMe

	Product	Yield/%	Mp/°C (lit)	$[\alpha]_D$/° (lit)	Ref.
2a	Boc-Phe-Val-OMe	85	117—118 (118—119)	−11.0 (1.89, DMF) (−11.6)	17
2b	Boc-Leu-Leu-OMe	81	141—142 (141—142)	−50.0 (0.39, MeOH) (−50.4)	18
2c	Boc-Ile-Ile-OMe	81	157—158 (158—159)	−36.5 (0.51, MeOH) (−33.3)	19
2d	Boc-Ala-Ala-OMe	76	105—106 (105—108)	−63.6 (0.66, MeOH) (−63.8)	17
2e	Boc-Ala-Val-OMe[a]	83	63—64	−49.5 (0.31, MeOH)	

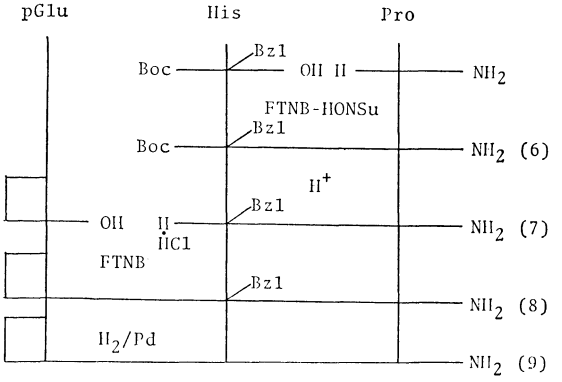
a) **2e** exhibited NMR spectral data and elemental analysis in accordance with assigned structure.



product obtained from the same procedures as described in the preparation of the dipeptides using only FTNB was perfectly optically inactive, regardless of solvent(Entry 1, 2). Accordingly, the reaction conditions which did not induce racemization were investigated; this difficulty was satisfactorily overcome by employing the Eintopf method reported by Wünsch *et al.*[5] As may be seen from the Table, the coexistence of additives such as *N*-hydroxysuccinimide(HONSu) and *N*-hydroxy-5-norbornene-2,3-dicarboximide (HONB) effectively suppressed racemization, twomolar amounts of additive being required. Furthermore, dichloromethane proved to be the best solvent among the solvents investigated. With respect to base, collidine was especially effective. The reaction conditions making use of collidine as a base in the presence of two molar amounts of HONSu in dichloromethane gave optimum results with 98% optical purity(Entry 10).

The results may be explained as follows. In the absence of additive, the intermediary amino acid fluoride is rapidly converted into the oxazolone regarded as an intermediate for racemization.[6,7] In the presence of an additive, the amino acid fluoride reacts more rapidly with HONSu to give the so-called "active ester" of HONSu,[8] which then reacts with the amine component to give the optically pure product.

The optimum conditions for suppression of racemization were utilized to synthesize the biologically active peptides, TRH and leucine-enkephalin uisng the FTNB method.



Scheme 1. Synthesis of thyrotropin releasing hormone.

The synthesis of TRH was conducted as illustrated in Scheme 1. α-*t*-Butoxycarbonyl(Boc)-N^{im}-benzyl (Bzl)histidine was condensed with prolinamide in the presence of two molar amounts of HONSu using the FTNB method to give the dipeptide **6** (81% yield after purification by column chromatography). Cleavage of the *t*-butoxycarbonyl group of the protected dipeptide **6** with 5 M-hydrogen chloride in ethyl acetate gave the deprotected product **7** (nearly quantitative yield), which was condensed with pyroglutamic acid using the FTNB method to give the desired protected tripeptide **8** (56% yield after purification by ion-exchange resin column chromatography followed by preparative TLC). Finally, debenzylation of the protected tripeptide **8** by catalytic hydrogenation over palladium black followed by purification of the reaction mixture by preparative TLC gave the desired product, pyroglutamyl-histidyl-prolinamide (**9**) in 75% yield. The specific rotation was in accordance with the literature.[9]

The synthesis of leucine-enkephalin with opiate-

Table 3. The results of the Young Test

FTNB + Bz-Leu-OH (I) + Additive (II) —Base, Solvent, Time/h→ —H-Gly-OEt→ Bz-Leu-Gly-OEt

Entry	Additive	Molar ratio II/I	Reaction conditions: Base	Reaction conditions: Time/h	Solvent[a]	Yield %	Optical purity/%[b]
1	none		Py	2	CH_3CN	60.0	0
2	none		Py	2	CH_3Cl_2	68.8	0
3	HONSu	1	Py	3	CH_3CN	45.6	39.5
4	HONSu	1	Py	3	THF	61.2	34.1

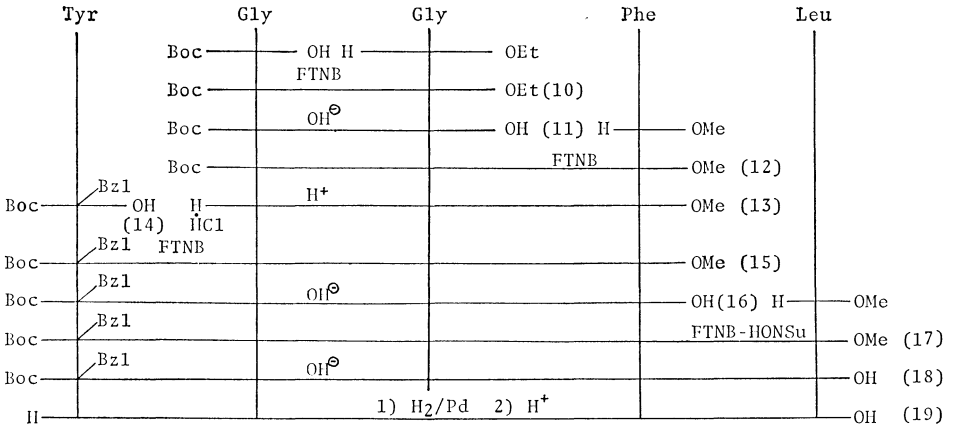
11	HONB	1	Py	2	CH_2Cl_2[c]	50.0	89.0
12	HONB	2	Py	2	CH_2Cl_2[c]	45.0	94.5

a) 5—6 ml of solvent was used. b) Based on $[\alpha]_D^{20}$ −34.0° (3.1, EtOH) reported by M. W. Williams and G. T. Young.[4] c) 1 ml of CH_3CN was added in addition to the solvent to dissolve the additive.



Scheme 2. Synthesis of leucine-enkephalin.

agonist activity was conducted according to Scheme 2. Saponification of the dipeptide **10**, derived from the coupling of *N*-(*t*-butoxycarbonyl)glycine with ethyl glycinate using the FTNB method, gave the dipeptide **11** which was condensed with methyl phenylalaninate using the FTNB method to give the protected ester **12** in 76% yield. Treatment of **12** with 5 M-hydrogen chloride in ethyl acetate gave the desired deprotected tripeptide ester hydrochloride **13** in 81% yield. The melting point and specific rotation were however in disagreement with the values reported by Voelter *et al.*[10] In order to clarify the discrepancy, **12** was prepared by two other methods, the azide and DCC-HONSu methods, and subsequent deprotection of the *t*-butoxycarbonyl group of compound **12** was conducted under the same conditions as described for the FTNB method. It was found that the physical constants of the products obtained from the two methods were consistent with the values obtained from the FTNB method. α-*t*-Butoxycarbonyl-*O*-benzyltyrosine (**14**) was condensed with the tripeptide **13** to give the tetrapeptide ester **15** in 81% yield, which was saponified to give the deprotected tetrapeptide **16** in 86% yield. The desired pentapeptide ester **17** was obtained from the coupling of **16** with methyl leucinate in the presence of two molar amounts of HONSu thereby avoiding racemization (71% yield). Saponification of **17** gave the pentapeptide **18** in 81% yield, which was hydrogenated over 10%-palladium on charcoal followed by cleavage of the *t*-butoxycarbonyl group to give the desired product, leucine-enkephalin (**19**) in 44% yield after treatment with ion-exchange resin column chromatography. The melting point and specific rotation of the product were in accordance with the reported values.[11]

Experimental

All melting points are uncorrected. The NMR spectra were recorded on a JEOL/MH-60. The chemical shifts are reported on the δ scale relative to TMS as an internal standard. The IR spectra were measured with a JASCO IRA-1 diffraction grating infrared spectrometer. The optical rotation values were measured with a JASCO DIP-SL polarimeter.

Materials. All solvents were distilled according to the usual methods and stored over a drying agent. Thin-layer chromatography (TLC) and column chromatography were performed on Merck's Silica gel 60 PF_{254} (Type 7749), on Alumina Woelm (Act. 1), and on Merck's Aluminium oxide 90 (Type 1077).

*Z-Ile-Gly-OEt (**1a**).* To a solution of FTNB (116 mg, 0.5 mmol) and Z-Ile-OH (113 mg, 0.5 mmol) in CH_3CN (5 ml) was added a solution of pyridine(Py) (40 mg, 0.5 mmol) in CH_3CN (1 ml) dropwise at 0 °C under a nitrogen atmosphere. After stirring for 3 h at 0 °C, H-Gly-OEt·HCl (70 mg, 0.5 mmol) was added to the reaction mixture, followed by the addition of a solution of Py (79 mg, 1 mmol) in CH_3CN (1 ml). The solution was stirred at 0 °C for 1.5 h and for additional hours at room temperature. The reaction mixture was evaporated to dryness under reduced pressure and the residue partitioned between AcOEt and water. The AcOEt layer was washed successively with 1M-HCl, 10%-$NaHCO_3$, and a saturated solution of NaCl, dried over Na_2SO_4 and evaporated to dryness *in vacuo*. The residue was subjected to neutral alumina column chromatography using benzene–AcOEt (1:1 v/v) as solvent to give a crystalline product. Recrystallization from benzene–hexane gave the desired product **1a** in 85% yield (149 mg).

In a similar manner, the dipeptides **1b—g** were obtained as shown in Table 1.

*Boc-Phe-Val-OMe (**2a**).* To a solution of FTNB (116 mg, 0.5 mmol) in CH_3CN (5 ml) was added slowly a mixed solution of Boc-Phe-OH (113 mg, 0.5 mmol) and Py (40 mg, 0.5 mmol) in CH_3CN (5 ml) at 0 °C. After stirring for 1.5 h at 0 °C, H-Val-OMe·HCl (84 mg, 0.5 mmol) was added to the solution followed by the addition of a solution of Py (79 mg, 1 mmol) in CH_3CN (0.5 ml). The reaction mixture was stirred for 3 h at room temperature and worked up as described for **1a**. The residue was subjected to neutral alumina column chromatography using benzene–AcOEt (1:1 v/v) as solvent, followed by preparative TLC using benzene–AcOEt (3:2 v/v) as solvent to afford the desired product. Recrystallization from benzene–hexane gave pure **2a** in 85% yield.

By a similar procedure, the dipeptides **2b—e** were obtained as shown in Table 2. The physical constants of **2e** were in disagreement with the reported values,[17] but the structure was confirmed by elemental analysis and NMR data as shown below: NMR ($CDCl_3$) δ 0.93 (d, 6H, J=7 Hz), 1.35 (d, 3H, J=6 Hz), 1.44 (s, 9H), 1.80—2.40 (m, 1H), 3.70 (s, 3H), 4.00—4.67 (m, 2H), 4.95—5.30 (bd, 1H, J=8 Hz), 6.45—6.90 (bd, 1H, J=8 Hz). Found: C, 55.59; H, 8.70; N, 9.27%. Calcd for $C_{14}H_{26}N_2O_5$: C, 55.61; H, 8.67; N, 9.27%.

Young Test (Bz-Leu-Gly-OEt). *Entry 1*: To a solu-

tion of FTNB (116 mg, 0.5 mmol) and Bz–Leu–OH (118 mg, 0.5 mmol) in CH_3CN (5 ml) was added dropwise a solution of Py (40 mg, 0.5 mmol) in CH_3CN (1 ml) at 0 °C under a nitrogen atmosphere. After stirring for 3 h at 0 °C, a solution of H–Gly–OEt (52 mg, 0.5 mmol) in CH_3CN (2 ml) was added to the solution at 0 °C, followed by the addition of a solution of Py (40 mg, 0.5 mmol) in CH_3CN (1 ml). The reaction mixture was allowed to stand overnight at room temperature and evaporated to dryness. The residue was dissolved in AcOEt and the solution washed successively with 10%-$NaHCO_3$, 1M-HCl, and a saturated solution of NaCl and dried over Na_2SO_4. After evaporation of the solvent, the residue was subjected to neutral alumina column chromatography using benzene–AcOEt (1:1 v/v) as solvent followed by preparative TLC using benzene–AcOEt (3:2 v/v) as solvent to afford the product in 60% yield (96 mg): mp 146—147 °C; $[\alpha]_D^{20}$ 0° (2.98, EtOH). *Entry 10*: To a solution of Bz–Leu–OH (118 mg, 0.5 mmol), FTNB (116 mg, 0.5 mmol), and HONSu (115 mg, 1 mmol) in CH_3CN (1 ml) was added CH_2Cl_2 (5 ml) at 0 °C, followed by the addition of a solution of collidine (112 mg, 1 mmol) in CH_2Cl_2 (1 ml). After stirring for 3 h at 0 °C, a solution of H–Gly–OEt (52 mg, 0.5 mmol) in CH_2Cl_2 (2 ml) was added at 0 °C to the solution. The reaction mixture was allowed to stand overnight and worked up as described for Entry 1. Yield, 108 mg (64%): mp 153—154 °C; $[\alpha]_D^{29}$ −33.4° (2.15, EtOH).

*Boc–His(Bzl)–Pro–NH_2 (**6**).* To a solution of FTNB (116 mg, 0.5 mmol) and HONSu (115 mg, 1 mmol) in CH_3CN (1 ml) was added CH_2Cl_2 (5 ml). To the resulting clear solution was added dropwise a solution of Boc–His(Bzl)–OH (173 mg, 0.5 mmol) and triethylamine(TEA) (101 mg, 1 mmol) in CH_2Cl_2 (2 ml) at 0 °C. After stirring for 3 h at 0 °C, H–Pro–NH_2·HCl (76 mg, 0.5 mmol) was added to the solution followed by the addition of a solution of TEA (51 mg, 0.5 mmol) in CH_2Cl_2 (1 ml). The reaction mixture was allowed to stand overnight at room temperature. After evaporation of the solvent, the residue was subjected to ion-exchange resin chromatography (Amberlite IRA-410) using MeOH as solvent and basic alumina column chromatography using benzene–EtOH (8:1 v/v) as solvent to give a solid material. This was separated by preparative TLC using chloroform–MeOH (10:1 v/v) as solvent to give the desired product in 81% yield (179 mg); $[\alpha]_D^{28.5}$ −23.4° (0.64, MeOH); NMR (CD_3OD) δ 1.37 (s, 9H), 1.70—2.20 (m, 4H), 2.70—3.00 (m, 2H), 3.10—3.50 (m, 2H), 4.20—4.60 (m, 1H), 5.06 (s, 2H), 6.90 (s, 1H), 7.20 (s, 5H), 7.53 (s, 1H).

*H–His(Bzl)–Pro–NH_2·2HCl (**7**).* A solution of **6** in AcOEt (2 ml) was treated with 6M-HCl (6 ml) in AcOEt, and the solution allowed to stand at room temperature for 30 min. To the reaction mixture was added dry ether (30 ml). The supernatant liquid was decanted, and the residue washed with dry ether (4×30 ml) to give the salt **7** which was dried *in vacuo* in the presence of solid potassium hydroxide and phosphorous pentoxide, yield, 164 mg. The product was used without further purification in the subsequent reaction.

*pGlu–His(Bzl)–Pro–NH_2 (**8**).* A solution of FTNB (70 mg, 0.3 mmol) in CH_2Cl_2 (1 ml) was cooled at 0 °C and to the solution was added dropwise a mixed solution of pGlu–OH (39 mg, 0.3 mmol) and TEA (31 mg, 0.3 mmol) in CH_2Cl_2 (2 ml). After stirring for 2 h at 0 °C, **7** (120 mg, 0.3 mmol) was added to the reaction mixture followed by the addition of a solution of TEA (91 mg, 0.9 mmol) in CH_2Cl_2 (1 ml). The reaction mixture was allowed to stand overnight at room temperature. The solvent was evaporated *in vacuo*, and the residual oil purified by ion-exchange resin chromatography using MeOH as solvent followed by preparative TLC using chloroform–MeOH (3:1 v/v) as solvent to afford the product in 56% yield (59 mg).

*pGlu–His–Pro–NH_2 (**9**).* The protected tripeptide **8** (57 mg, 0.13 mmol) was dissolved in EtOH (25 ml) and hydrogenated for 12 h over palladium black (20 mg) at room temperature under atmospheric pressure. The catalyst was filtered off followed by evaporation of the filtrate. The crude product was subjected to preparative TLC using chloroform–MeOH (3:1 v/v) to afford the desired TRH (**9**) in 75% yield (35 mg): $[\alpha]_D^{28.5}$ −40.7° (1.00, MeOH) [lit,[8] −42.4° (1.00, MeOH)]. The product gave a positive Paulitest and showed a single spot on TLC in several solvent systems.

*Boc–Gly–Gly–OEt (**10**).* To an CH_3CN solution (6 ml) of FTNB (232 mg, 1 mmol) cooled at −30 °C, was added a solution of Boc–Gly–OH (175 mg, 1 mmol) and TEA (101 mg, 1 mmol) in CH_3CN (5 ml). After stirring for 2 h at 0 °C, H–Gly–OEt·HCl (140 mg, 1 mmol) and then a solution of TEA (202 mg, 2 mmol) in CH_3CN (1 ml) were added to the reaction mixture. The solution was allowed to stand overnight at room temperature and worked up as described for **1a**. After evaporation of the solvent, the residue was subjected to basic alumina column chromatography using benzene–EtOH (1:2 v/v) as solvent and to preparative TLC using benzene–EtOH (8:1 v/v) as solvent to give the desired product as an oil in 82% yield (212 mg).

*Boc–Gly–Gly–OH (**11**).* To a solution of **10** (1.30 g, 5 mmol) in MeOH–H_2O (5 ml) (4:1 v/v), was added 1M-NaOH (5 ml) at 0 °C and the reaction mixture maintained at 0 °C for 2 h and then allowed to stand overnight. The MeOH was removed *in vacuo* and water (5 ml) added to the solution. The resulting aqueous solution was washed with AcOEt and neutralized with 1M-HCl (5 ml). The separated oil was extracted with AcOEt after salting-out, and the organic layer dried over Na_2SO_4 and evaporated to dryness *in vacuo* to give a crystalline product. Recrystallization from AcOEt gave an 87% yield (1.01 g): mp 133—134 °C; Found: C, 46.70; H, 7.02; N, 12.18%. Calcd for $C_9H_{16}N_2O_5$: C, 46.54; H, 6.94; N, 12.06%.

*Boc–Gly–Gly–Phe–OMe (**12**).* To a solution of FTNB (232 mg, 1 mmol) in CH_3CN (2 ml) was added slowly a solution of **11** (232 mg, 1 mmol) and TEA (101 mg, 1 mmol) in CH_3CN (3 ml) at 0 °C. After stirring for 2 h at 0 °C, H–Phe–OMe·HCl (215 mg, 1 mmol) was added to the solution followed by the addition of a solution of TEA (202 mg, 2 mmol) in CH_3CN (1 ml). The reaction mixture was allowed to stand overnight and worked up as described in the preparation of **1a**. The desired product was separated from the residue by basic alumina column chromatography using benzene–EtOH (1:1 v/v) as solvent followed by preparative TLC using benzene–EtOH (8:1 v/v) as solvent; 76% yield as an oil (297 mg): NMR ($CDCl_3$) δ 1.43 (s, 9H), 3.05 (d, 2H, J=6.0 Hz), 3.65 (s, 3H), 3.75 (d, 2H, J=6.3 Hz), 3.87 (d, 2H, J=6.3 Hz), 4.84 (t, 1H, J=6.0 Hz), 5.38—5.65 (m, 1H), 6.85—7.16 (bs, 2H), 7.00—7.43 (m, 5H).

*H–Gly–Gly–Phe–OMe·HCl (**13**).* *Method A*: The product **12** obtained from the FTNB method was dissolved in AcOEt, and 5M-HCl (5 ml) in AcOEt added to the solution at room temperature. After 3 h, the solvent was evaporated to dryness *in vacuo* to give a crude product which was recrystallized from 1-propanol in 81% yield (202 mg): mp 179—180 °C; $[\alpha]_D^{21.5}$ +31.4° (1.05, AcOH). Found: C, 50.81; H, 6.15; N, 12.96%. Calcd for $C_{14}H_{20}N_3O_4Cl$: C, 50.98; H, 6.06; N, 12.74%.

Method B: Boc–Gly–Gly–NH–NH_2 derived from the reac-

tion of **10** with hydrazine was condensed with H–Phe–OMe using the azide method to give the desired tripeptide **12** in 66% yield. **12** was deprotected with hydrogen chloride according to method A. Recrystallization from 1-propanol gave the product **13** in 81% yield: mp 178—179 °C; $[\alpha]_D^{21.5}$ +31.4° (1.05, AcOH).

Method C: **12** was obtained from the reaction of **11** with H–Phe–OMe using the DCC–HONSu method in 89% yield, which was treated according to Method A. Recrystallization from 1-propanol gave the product **13** in 76% yield; mp 178—179 °C; $[\alpha]_D^{22}$ +30.4° (0.99, AcOH).

*Boc–Tyr(Bzl)–Gly–Gly–Phe–OMe (**15**).* To a solution of FTNB (232 mg, 1 mmol) in CH_3CN (4 ml) was added slowly a mixed solution of Boc–Tyr(Bzl)–OH (**14**) (371 mg, 1 mmol) and TEA (101 mg, 1 mmol) in CH_3CN (2 ml) at 0 °C. After stirring at 0 °C for 2 h, **13** (330 mg, 1 mmol) was added to the solution followed by the addition of a solution of TEA (202 mg, 2 mmol) in CH_3CN (2 ml). The reaction mixture was allowed to stand at room temperature, and worked up as described for **1a**. After evaporation of the solvent, the crude product was purified by gradient elution on basic alumina using benzene–EtOH (8:1 v/v to 1:1 v/v). Recrystallization from AcOEt–hexane gave the pure product in 81% yield: mp 112—113 °C; $[\alpha]_D^{32.5}$ +13.8° (1.23, MeOH). Found: C, 64.69; H, 6.64; N, 8.70%. Calcd for $C_{19}H_{27}N_3O_6$: C, 65.00; H, 6.55; N, 8.70%.

*Boc–Tyr(Bzl)–Gly–Gly–Phe–OH (**16**).* To a solution of **15** (406 mg, 0.63 mmol) in MeOH–H_2O (5 ml) (4:1 v/v) was added with stirring 1M-NaOH (0.8 ml) at 0 °C and worked up as described in the preparation of **11**. Recrystallization from chloroform–hexane gave the desired product in 84% yield (341 mg): mp 83—84 °C; $[\alpha]_D^{21}$ +17.3° (1.38, MeOH). Found: C, 63.56; H, 6.59; N, 8.89%. Calcd for $C_{34}H_{40}N_4O_8 \cdot 1/2H_2O$: C, 63.65; H, 6.39; N, 8.74%.

*Boc–Tyr(Bzl)–Gly–Gly–Phe–Leu–OMe (**17**).* To a mixed solution of **16** (327 mg, 0.51 mmol), FTNB (120 mg, 0.52 mmol), and HONSu (120 mg, 1.04 mmol) in CH_3CN (1 ml) was added CH_2Cl_2 (5 ml) at 0 °C followed by the addition of a solution of collidine (126 mg, 1.04 mmol) in CH_2Cl_2 (2 ml). After stirring at 0 °C for 3 h, H–Leu–OMe·HCl (95 mg, 0.52 mmol) was added followed by the addition of a solution of TEA (53 mg, 0.52 mmol) in CH_2Cl_2 (1 ml). The reaction mixture was allowed to stand overnight at room temperature, and then worked up as described for **12**. Recrystallization from chloroform–hexane gave the pure product in 72% yield (280 mg): mp 153—154 °C; $[\alpha]_D^{22}$ −11.4° (1.74, MeOH). Found: C, 64.55; H, 7.08; N, 9.26%. Calcd for $C_{41}H_{53}N_5O_9$: C, 64.80; H, 7.03; N, 9.22%.

*Boc–Tyr(Bzl)-Gly–Gly–Phe–Leu–OH (**18**).* To a solution of **17** (400 mg, 0.53 mmol) in MeOH–H_2O (5 ml) (4:1 v/v) was added with stirring 1M-NaOH (0.6 ml) at 0 °C and worked up as described in the preparation of **11**. Recrystallization from AcOEt gave the desired product in 81% yield (321 mg): mp 149—150 °C; $[\alpha]_D^{28}$ +1.6° (1.26, MeOH). Found: C, 64.53; H, 6.95; N, 9.43%. Calcd for $C_{40}H_{51}N_5O_9$: C, 64.51; H, 6.89; N, 9.39%.

*H–Tyr–Gly–Gly–Phe–Leu–OH (**19**).* The protected pentapeptide **18** (90 mg, 0.12 mmol) was dissolved in MeOH (15 ml), and hydrogenated over 10% palladium on charcoal (250 mg) for 2 h at room temperature under atmospheric pressure. The catalyst was filtered off and the filtrate evaporated to dryness *in vacuo* to give the debenzylated product which was dissolved in 5M-HCl (1 ml) in dioxane. The reaction mixture was allowed to stand for 6 h at room temperature. Evaporation of the solvent gave a residue which was washed with dry ether. The residual product was dissolved in a small amount of water and the aqueous solution passed through an ion-exchange resin column (Amberlite IR-120B) using 5%-NH_4OH as solvent. The eluate was evaporated to dryness *in vacuo* to give the desired leucine-enkephalin (**19**) in 44% yield (30 mg): mp 208—210 °C (dec); $[\alpha]_D^{25}$ −24.0° (1.0, DMF) [lit,[11] mp 206 (dec), $[\alpha]_D^{23}$ −23.4° (1.0, DMF)]. Amino acid analysis (after acidic hydrolysis) showed the presence of tyrosine, glycine, phenylalanine, and leucine in the ratio 1.00:2.15:1.26:0.98.

Nucleophilic Ion Pairs. 8. Facile Nucleophilic Cleavage of Dinitrophenyl Sulfate in the Presence of Micellar Zwitterionic Hydroxamates†

Toyoki KUNITAKE* and Tetsuo SAKAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received January 29, 1979)

The sulfate transfer reaction from dinitrophenyl sulfate to hydroxamate nucleophiles was studied in the presence of several types of aqueous micelles at 30 °C, pH 8—9. The zwitterionic hydroxamate was a nucleophile much better than the anionic hydroxamate in the CTAB micelle. The kinetic behavior of the zwitterionic hydroxamate nucleophile was not straightforward and the reactivity of the nucleophile increased with the increase in the relative concentration of the nucleophile and surfactant. These results in the CTAB micelle was analyzed in terms of the two phase model and the rate enhancement relative to the nonmicellar reaction was attributed to substrate binding in the micellar phase and the micellar activation of the hydroxamate nucleophile. The cleavage of dinitrophenyl sulfate by the micellar zwitterionic nucleophile was faster than that by the nonmicellar hydroxamate and the water cleavage by factors of *ca.* 10^4 and more than 10^7, respectively: the fastest cleavage ever observed at the ambient condition.

The hydrolysis of sulfate monoesters has been studied increasingly well in recent years, due to realization of the importance of sulfate group transfer *in vivo*.[1] In general, sulfate monoesters are difficult to be cleaved in the neutral pH region and detailed mechanistic studies have been rarely made, apart from acid and alkali hydrolyses.[2]

In relation to the enzymatic catalysis, the sulfate transfer reaction has been investigated in the presence of cyclodextrins,[3] macrocyclic compounds[4] and micelles.[5,6] The rate accelerations in these systems, however, are not large. In the hydrolysis of phenyl esters, the micellar hydroxamate and imidazole anions show extremely high nucleophilicities.[7] These reagents, however, are not effective for negatively-charged sulfate esters.

In order to circumvent this disadvantage, a zwitterionic nucleophile, *N*-benzyl-α-(1-dodecyl-3-imidazolio)acetohydroxamate (C_{12}-Im$^+$-HA, **1**), was used in the present study for the sulfate transfer reaction (Eq. 1) in the presence of aqueous micelles of representative surfactants.

The reaction with simpler nucleophiles, *N*-dodecylbenzohydroxamate(LBHA, **2**) and *N*-benzylbenzohydroxamate(BBHA, **3**) was also performed for the comparison purpose.

Experimental

Materials. The zwitterionic nucleophile, C_{12}-Im$^+$-HA, was prepared by the reaction of *N*-dodecylimidazole with benzyl *N*-benzylchloroacetohydroxamate accompanied by hydrogenolysis over Pd/$SrCO_3$,[8] mp 157—158 °C. It was identified by elemental analysis and by NMR and IR spectroscopies. Potassium 2,4-dinitrophenyl sulfate (DNPS) was prepared according to the procedure of Sunamoto *et al.*[4] Its purity was 95% as determined by UV spectroscopy: the impurity was 2,4-dinitrophenol. Hexadecyltrimethylammonium bromide (CTAB) was recrystallized two times from ethanol. Poly(oxyethylene)oleyl alcohol (n=10)(α-(9-octadecenyl)-ω-hydroxydeca(oxyethylene)), POOA was used without further purification. (Carboxymethyl)dodecyldimethylammonium chloride, $C_{12}N^+2C_1CO_2$ was obtained by reaction of *N,N*-dimethyldodecylamine and chloroacetic acid and recrystallized from ethyl acetate:[8] mp 158—160 °C. (2-Hydroxyethyl)dimethyloctadecylammonium bromide, $C_{18}N^+2C_1C_2OH$, was prepared by refluxing an ethanol solution of 10.0 g (0.03 mol) of octadecyl bromide and 3.5 g (0.04 mol) of 2-(dimethylamino)ethanol for 10 h. After solvent removal, the solid residue was recrystallized two times from acetone; colorless needles, mp 209—211 °C (dec), yield 9.3 g (73%). Found: C, 62.43; H, 11.42; N, 3.31%. Calcd for $C_{22}H_{48}NOBr$: C, 62.54; H, 11.45; N, 3.32%.

Rate Measurement. The hydroxamates and surfactants were dissolved in ethanol and water, respectively. DNPS was dissolved in a 3:7 mixture of water and acetonitrile and kept with ice cooling. These solutions were added to

† Contribution No. 537 from Department of Organic Synthesis.

buffer solutions in a UV cell which had been maintained at 30 °C. Water was added so that the fraction of organic solvents (acetonitrile and ethanol) became 3 v/v %. The reaction rate was determined by following the absorbance increase of 2,4-dinitrophenolate anion at 360 nm (ε_{360}= 12800 M^{-1} cm^{-1}), using a Hitachi UV-visible spectrophotometer (type 124 and 200).

Results

Sulfate Transfer to Anionic Hydroxamates. The time course of DNPS hydrolysis in the LBHA–CTAB system obeyed pseudo first-order kinetics: [DNPS]= 1.9×10^{-5} M, [CTAB]=4.50×10^{-3} M. However, the pseudo first-order rate constant $k_{1,obsd}$ did not vary with the concentration change ($(2—6)\times10^{-4}$ M) of LBHA. Furthermore, the logarithm of the apparent second-order rate constant, log $k_{2,obsd}$, increased linearly with pH at pH 8—10. This pH-rate profile is not consistent with the pK_a value(8.41) of LBHA in the CTAB micelle. Because of the complex kinetic behavior and a relatively small reactivity (*ca.* 10% of C_{12}-Im^+-HA under comparable conditions), LBHA was not used in the subsequent experiment.

The sulfate transfer reaction with a non-micellar hydroxamate, *N*-benzylbenzohydroxamic acid(BBHA), [9] was also studied under the following conditions: pH 9.23, 0.01 M borate buffer, μ=0.01(KCl), 30 v/v %EtOH–H_2O, [BBHA]=2.5×10^{-2} M and [DNPS] =2.0×10^{-5} M. $k_{1,obsd}$ obtained from the Guggenheim plot was only slightly larger than that obtained without the hydroxamate under otherwise the same conditions: 9.8×10^{-5} s^{-1} *vs.* 7.3×10^{-5} s^{-1}. Therefore, $k_{2,obsd}$ is estimated to be smaller than 1×10^{-3} M^{-1} s^{-1}.

Sulfate Transfer to Micellar Zwitterionic Hydroxamates. In the presence of excess DNPS, the nucleophilic attack of C_{12}-Im^+-HA obeyed the pseudo first-order kinetics for more than 80% consumption of the nucleophile: [DNPS]=$(0.52—4.6)\times10^{-4}$ M, [C_{12}-Im^+-HA]=0.13×10^{-4} M, [CTAB]=1.0×10^{-3} M, pH 9.2, 30 °C. The spontaneous hydrolysis was similarly carried out in the absence of the nucleophile and its rate constant, k_{spont}, was subtracted from the overall first-order rate constant, $k_{1,obsd}$. In reality, k_{spont} was approximately 1.0×10^{-4} s^{-1} without regard to the pH change, and much smaller than $k_{1,obsd}$ which was $(2—4)\times10^{-3}$ s^{-1}. Therefore, the correction was not necessary at pH 9.

The pseudo first-order rate constant was proportional to the substrate concentration: correlation coefficient= 0.993. Therefore, the reaction was first order with respect to nucleophile and substrate, and the second-order rate constant ($k_{2,obsd}$) was calculated to be 20.8 M^{-1} s^{-1}. Precipitates were formed when the substrate concentration was increased beyond 5×10^{-4} M.

The pseudo first-order kinetics were similarly observed when excess nucleophile was employed: [DNPS]= 1.7×10^{-5} M, [C_{12}-Im^+-HA]=$(0.51—2.6)\times10^{-4}$ M, [CTAB]=4.0×10^{-3} M, pH 9.0, 30 °C. However, the pseudo first-order rate constant was not a linear function of the nucleophile concentration beyond 1.5×10^{-4} M, as shown in Fig. 1. $k_{2,obsd}$ estimated from the linear portion of Fig. 1 is 2.45 M^{-1} s^{-1}.

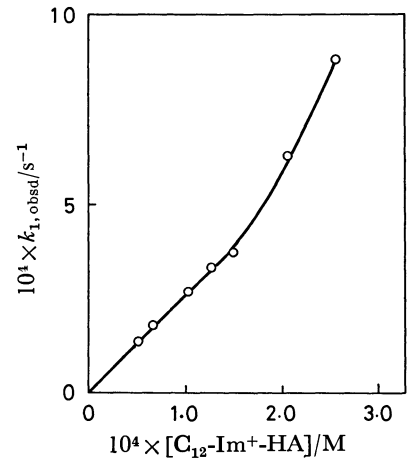

Fig. 1. Rate dependence on nucleophile concentration. pH 9.00±0.1, 30 °C, 3 v/v % EtOH–H_2O, 0.02 M borate buffer, μ=0.01(KCl), [DNPS]=1.72×10^{-5} M, [CTAB]=4.00×10^{-3} M.

This value is only 12% of the rate constant obtained by varying substrate concentrations. Since the pseudo first-order kinetics were always observed for a given run, the discrepancy must arise from the change in the relative concentration of nucleophile, substrate and/or surfactant.

Rate Dependence on Surfactant Concentration. The zwitterionic nucleophile C_{12}-Im^+-HA may form micelles by itself. The property of the mixed micelle of C_{12}-Im^+-HA and CTAB will be affected by their relative concentration, hence the reactivity change of C_{12}-Im^+-HA. Figure 2 shows the variation of the apparent second-order rate constant $k_{2,obsd}$ (pseudo first-order rate constant divided by the nucleophile concentration) with the surfactant concentration at fixed concentrations of DNPS and C_{12}-Im^+-HA. After abrupt increases $k_{2,obsd}$ decreases with increasing surfactant concentrations, irrespective of the type of the surfactant used. The same trend was observed for the hydrolysis of an anionic phenyl ester, 4-acetoxy-3-nitrobenzoic acid (NABA) catalyzed by C_{12}-Im^+-HA in the nonionic micelle.

On the other hand, $k_{1,obsd}$ exhibits a saturation tendency with the simultaneous increase in the concentrations of C_{12}-Im^+-HA and CTAB(the relative concentration of C_{12}-Im^+-HA and CTAB is fixed at 0.26): see Fig. 3. Therefore $k_{2,obsd}$ ($k_{1,obsd}$ divided by the hydroxamate concentration) decreases with the CTAB concentration as also shown in Fig. 3. This tendency corresponds to those in Fig. 2.

pH-*Rate Profile.* The pH-rate profile of the nucleophilic and spontaneous cleavages was studied in the presence of the CTAB and POOA micelles (Fig. 4). log $k_{2,obsd}$ in the presence of the CTAB micelle increases initially with pH but levels off at *ca.* pH 8. This profile appears to reflect the dissociation of the hydroxamic acid. In fact, a linear relation(r=0.997) was obtained when $k_{2,obsd}$ was plotted against α_{HA} (degree of dissociation) which was calculated from Eq. 2 assuming pK_{app}=7.70.

$$\alpha_{HA}=\frac{1}{1+10^{(pK_{app}-pH)}} \quad (2)$$

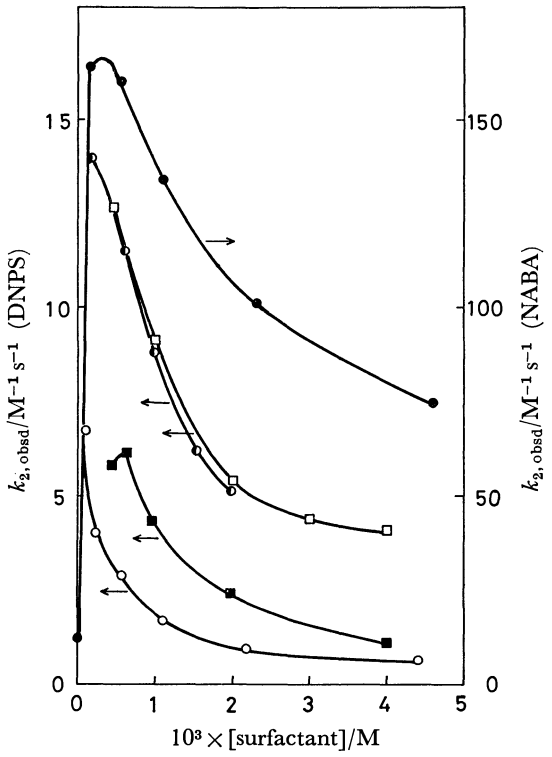

Fig. 2. Rate dependence on surfactant concentration. pH 8.5±0.1, 30 °C, 3 v/v % EtOH-H_2O, 0.02 M borate buffer, μ=0.01(KCl). a) [DNPS]=2.98×10^{-5} M, [C_{12}-Im^+-HA]=3.91×10^{-4} M. b) [NABA]=4.26×10^{-5} M, [C_{12}-Im^+-HA]=3.43×10^{-4} M. —●—, POOA(NABA); —□—, CTAB; —◐—, C_{18}-N^+-$2C_1C_2OH$; —■—, $C_{12}N^+2C_1CO_2^-$; —○—, POOA.

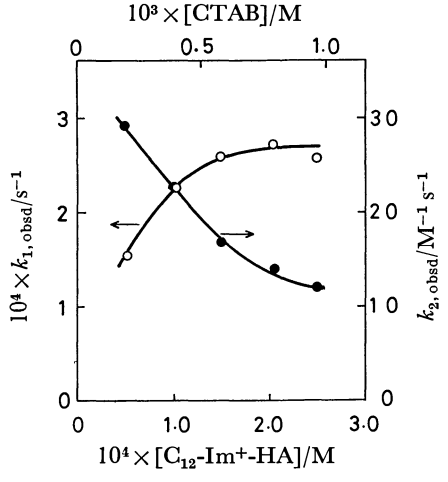

Fig. 3. Rate dependence on concentrations of nucleophile and surfactant at a fixed relative concentration. pH 9.0±0.1, 30 °C, 3 v/v % EtOH-H_2O, 0.02 M borate buffer, μ=0.01(KCl), [DNPS]=1.72×10^{-5} M, [C_{12}-Im^+-HA]/[CTAB]=0.26.

This pK_{app} value agrees with pK_{app} (7.78) obtained in the hydrolysis of *p*-nitrophenyl acetate in the CTAB micelle.[8]

In the POOA system, the pH-rate profile is bell-shaped with the maximum at pH 8.4. This behavior is quite different from what is observed with *p*-nitrophenyl acetate as substrate. In the latter case, a typical saturation profile was found with pK_{app}=8.18. The

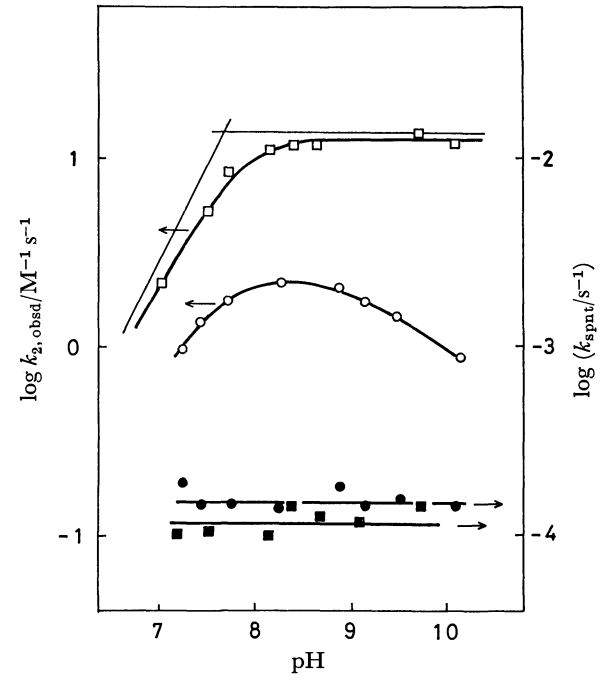

Fig. 4. pH-rate profile. 30 °C, 3 v/v % EtOH-H_2O, 0.01 or 0.02 M borate buffer, μ=0.01(KCl), [DNPS]=(3.2—3.5)$\times10^{-5}$ M, [C_{12}-Im^+-HA]=(2.7—3.0)$\times10^{-4}$ M, [CTAB]=5.13×10^{-4} M, [POOA]=1.00×10^{-3} M. —□—, —■—; CTAB. —○—, —●—; POOA.

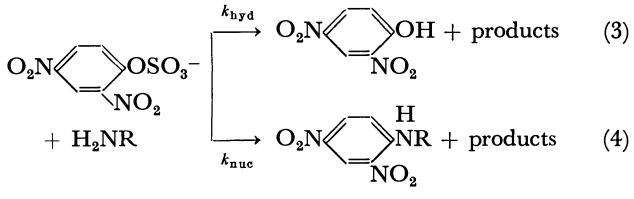
interaction of anionic DNPS substrate with C_{12}-Im^+-HA in the nonionic micelle is not so straightforward as that in the cationic micelle.

Figure 4 also contains pH-rate profiles of the spontaneous hydrolysis in the presence of POOA and CTAB. The rate of the spontaneous hydrolysis($\approx10^{-4}$ s^{-1}) does not depend on pH, in consistence with the result of Fendler's.[2]

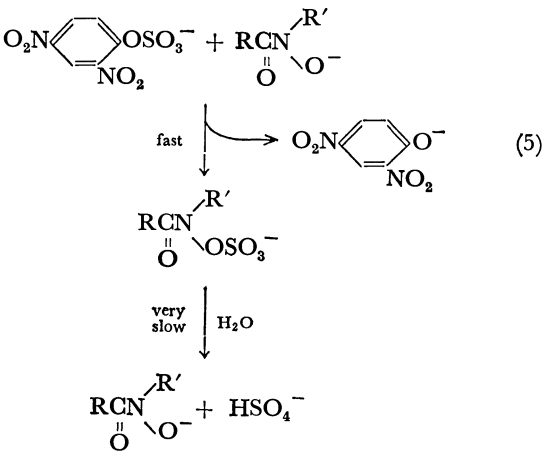
Discussion

Reaction Scheme. The nucleophilic reaction toward dinitrophenyl sulfate has been studied by several groups of the investigator. For instance, Fendler *et al.* noted that hydrolysis and aminolysis competed in the reaction with a variety of amines.[6]



Definite results on the reaction of DNPS with anionic nucleophiles have not been published, probably with the exception of the paper by Sunamoto *et al.*[4] They concluded that the reaction of DNPS with a paracyclophanone oxime involved sulfate transfer to the oximate anion. We do not have direct evidence for the formation of the sulfohydroxamate intermediate; however, the hydroxamate anion would be expected to behave in the same way as the oximate. In our system, the substrate, if decomposed, was completely

converted to dinitrophenol as confirmed spectrally. Therefore, the reaction would proceed by the following equation.



(5)

The stoichiometric reaction of DNPS and C_{12}-Im$^+$-HA was observed in the presence of excess DNPS; thus turnover of the hydroxamate nucleophile was excluded.

The undissociated hydroxamic acid is not involved in the reaction, because the sulfate transfer is observed only in the alkaline region.

Catalytic Efficiency. Some of the rate constants of the DNPS cleavage are collected in Table 1. The uncatalyzed hydrolysis of DNPS in the neutral to alkaline aqueous media is quite slow and barely detectable: $k_{1,obsd}=2.7\times10^{-5}$ s^{-1} at 25 °C, pH 8.0(or 4.9×10^{-7} M^{-1} s^{-1} when divided by 55.5 M). Some rate enhancements are observed in the presence of β-cyclodextrin and a paracyclophanone oxime; however these enhancements are mostly attributed to substrate binding and, in fact, the rate constant of the intracavity sulfate transfer is not necessarily large relative to that of simple alkaline hydrolysis under similar reaction conditions.[4] Micellar CTAB also shows rate acceleration of at most several fold. Larger rate enhancements are found for functional micelles such as CTAB–piperidine[6] and for a reversed micelle (dodecylammonium propionate in benzene).[10] The micellar hydroxamates possess much greater nucleophilicity. However, the coulombic repulsion of the nucleopile and the substrate renders the kinetic behavior rather complex, as observed for the LBHA–CTAB system. The use of the zwitterionic hydroxamate is advantageous in this respect and produces larger reaction rates. $k_{2,obsd}$ for C_{12}-Im$^+$-HA in the CTAB micelle is larger than that for CTAB–piperidine by at least 100 fold and is *ca.* 2×10^7 times larger than that of the water hydrolysis. The different behavior of the anionic and zwitterionic nucleophiles (LBHA and C_{12}-Im$^+$-HA) is observed only in the sulfate cleavage. They possessed similar reactivities in the cleavage of phenyl esters in the CTAB micelle.[8] The enhanced reactivity of a nucleophilic group bound to an ammonium group was also detected in the sulfate cleavage by a partly quaternized poly(ethylenimine).[11]

Kinetic Analysis of Micellar Catalysis. The kinetic behavior of the DNPS cleavage by the micellar hydroxamate is quite complex.

Several cases related to this behavior have been observed in the micellar catalysis. Gitler *et al.*[12] and Tonellato[13] proposed in the hydrolysis of hydrophobic phenyl esters that the saturation kinetics are explicable by assuming active and inactive binding sites in the micelle. However, this interpretation is difficult to accept, since the conventional micellar phase is quite mobile. In fact, the two phase model in which the micellar phase is assumed to be homogeneous has been successfully applied to micellar reactions by Berezin *et al.*[14] and more recently by other workers.[15,16]

This model may be applied to the present system. The kinetic derivation is given in the Appendix. Figure 5 gives plots of $1/k_{2,obsd}$ against the surfactant concentration for the data of Fig. 2. Linear relations are obtained for all cases. According to Eq. 17, the

TABLE 2. KINETIC CONSTANTS IN VARIOUS MICELLES[a]

Micelle	$10^3 \times \bar{k}_M$/s^{-1}	K_b/M^{-1}
CTAB	14.6	1600
$C_{18}N^+2C_1C_2OH$	13.6	1600
POOA	2.38	1400
$C_{12}N^+2C_1CO_2^-$	7.06	3300

a) See Fig. 2 for the reaction condition.

reciprocal of the slope corresponds to the first-order rate constant in the micellar phase ($\bar{k}_M$): see Table 2. The "micellar" rate constant increases in the order: CTAB $\simeq$ $C_{18}N^+2C_1C_2OH$ > $C_{12}N^+2C_1CO_2^-$ > POOA. The same order of the micellar effectiveness was observed in the hydrolysis of *p*-nitrophenyl acetate by several zwitterionic hydroxamates.[8]

The K_b value can be calculated from the intercept of Fig. 5 and is in the range of 1400—3300 M^{-1} as given in Table 2. These values are in reasonable agreement with those of Fendler *et al.*(1300—3100 M^{-1}) which were given as K/N in the hydrolysis of DNPS in the presence of the CTAB micelle.[2]

These results suggest that the kinetic analysis based on the two phase model is essentially valid if the micellar phase is not greatly perturbed. Since dependencies of $k_{2,obsd}$ on the surfactant concentration are alike for an anionic phenyl ester(NABA) and for a sulfate ester(DNPS), the above-mentioned kinetic behavior is never specific to the sulfate ester. A very similar rate dependence was reported for the electron transfer between negatively-charged metal chelates in the presence of the CTAB micelle.[16]

On the other hand, the simple two phase model fails when the micellar microenvironment is significantly altered by the varying nucleophile concentration. $k_{1,obsd}$ shows upward curvature in Fig. 1 beyond the nucleophile concentration of 1.5×10^{-4} M. $k_{2,obsd}$ obtained from the data of Fig. 2 does not agree with that estimated in Fig. 3. These anomalies appear to arise mainly from the change in the microenvironment of micelles which contain different amounts of the nucleophile molecule. The presence of a maximum in the pH-rate profile of the POOA system in Fig. 4 may be explained in the same context.

Appendix

The two phase model is used in the following kinetic analysis. Assuming that catalyst C forms comicelles with surfactants and that substrate S is distributed in the micellar and bulk phases,

$$[C]_{total} = [C]_M DV, \tag{6}$$

$$[S]_{total} = [S]_M DV + [S]_W(1-DV), \tag{7}$$

where D is the surfactant concentration and V is the molar volume of the surfactant. Suffix M and W indicate micellar and bulk (water) phases, respectively.

If the reaction proceeds only in the micellar phase, the overall reaction rate is given by

$$v = v_M DV = k_{2,obsd}[C]_{total}[S]_{total} \tag{8}$$

and

$$v_M = k_M[C]_M[S]_M, \tag{9}$$

where k_M is the second-order rate constant in the micellar phase. The partition coefficient of the substrate is given by

$$P_S = \frac{[S]_M}{[S]_W}. \tag{10}$$

The binding constant of the substrate K_b is expressed in terms of P_S as follows.

$$K_b = \frac{[S]_{total}-[S]_W}{[S]_W \cdot D} = \frac{1}{D} \cdot \frac{[S]_M DV - [S]_W DV}{[S]_W} = (P_S - 1)V. \tag{11}$$

When the substrate stays predominantly in the micellar phase ($P_S \gg 1$)

$$K_b = P_S V. \tag{12}$$

From Eqs. 6, 7, and 8,

$$k_M[C]_M \cdot [S]_M DV = k_{2,obsd}[C]_{total} \cdot [S]_{total}. \tag{13}$$

Therefore,

$$k_M P_S = k_{2,obsd}\{1+(P_S+1)DV\} \tag{14}$$

$$k_{2,obsd} = \frac{\bar{k}_M \cdot K_b}{1+K_b D}, \tag{15}$$

$$\text{where } \bar{k}_M = k_M/V. \tag{16}$$

The reciprocal relation of Eq. 15 is

$$\frac{1}{k_{2,obsd}} = \frac{1}{\bar{k}_M \cdot K_b} + \frac{D}{\bar{k}_M}. \tag{17}$$

$\bar{k}_M$ and K_b are determined from the slope and intercept, respectively, of the relation of Eq. 17.

(Received January 31, 1979)

Stereoselectivity in the peroxy acid oxidation of methyl 4,6-*O*-benzylidene-3-*O*-methyl-2-*C*-methylene-α-D-*ribo*-hexopyranoside (**1b**), its 3-epimer (**2b**), β-anomer of **1b** and **2b**, methyl 4,6-*O*-benzylidene-2-*O*-methyl-3-*C*-methylene-α-D-*arabino*-hexopyranoside and its 2-epimer was examined. The results were compared with those of rigid methylenecyclohexane systems.

In previous papers reports were given on the stereoselectivity examined in the reaction of methyl 4,6-*O*-benzylidene-α- and -β-D-hexopyranosid-2-uloses and -3-uloses with nucleophiles.[2–5] It was found that in the reaction of diazomethane stereoselectivity is mainly controlled by the electrostatic attractive interaction between neighboring axial oxygens and diazomethyl cation in the zwitterionic intermediates.[4,5] The interaction sometimes resulted in a complemental stereoselectivity of diazomethane reaction to that of usual nucleophiles such as hydride anions and carbanions, valuable for a stereospecific synthesis of a proper branched-chain sugar.[6] However, the diazomethane reaction of uloses is sometimes accompanied by ring-expansion reaction, even when the stereoselectivity is the desired one.[7–9] For such cases, it was found that the peroxy acid oxidation of the corresponding methylene derivative provides a reliable pathway to obtain the spiro epoxide which is also afforded by the diazomethane reaction of the ulose.[10,11]

We have examined the stereoselectivity in the peroxy acid oxidation of several 2- or 3-methylen-α- and β-D-hexopyranosides in comparison with that of the diazomethane reaction of the corresponding uloses.

Results and Discussion

As the substrates, methyl 4,6-*O*-benzylidene-3-*O*-methyl-2-*C*-methylene-α-D-*ribo*-hexopyranoside (**1b**), its 3-epimer (**2b**), β-anomer of **1b**(**3b**) and **2b**(**4b**), methyl 4,6-*O*-benzylidene-2-*O*-methyl-3-*C*-methylene-α-D-*arabino*- (**5b**) -β-D-*ribo*-hexopyranosides (**6b**) were synthesized from the corresponding uloses[12] and methyltriphenylphosphonium bromide by the usual method. In the case of **3b**, the corresponding ulose (**3a**)[13] was synthesized by the dimethyl sulfoxide–trifluoroacetic anhydride oxidation[12] of methyl 4,6-*O*-benzylidene-3-*O*-methyl-β-D-altropyranoside (**7**) obtained by the preferential ring-opening of the corresponding 2,3-epoxide of D-*manno* configuration with methanol. The 2,3-epoxide was synthesized by an improved method.[14]

b: X=CH_2

m-Chloroperbenzoic acid oxidation of methylene derivatives was carried out in dry 1,2-dichloroethane at 60 °C, until the starting material disappeared on TLC.

Oxidation of **1b** exclusively gave methyl 2,2′-anhydro-4,6-*O*-benzylidene-2-*C*-hydroxymethyl-3-*O*-methyl-α-D-altropyranoside (**8**) in 82% yield, the product being identical with that obtained by the diazomethane reaction of the corresponding ulose (**1a**).[5] Similarly, oxidation of **2b** exclusively gave the corresponding spiro epoxide (**9**) of D-*manno* configuration in 86% yield, the main product in the reaction of diazomethane with **2a**.[5] Oxidation of **3b** gave an epimeric mixture of the corresponding spiro epoxides (**10**) and (**11**) in 79% yield. Separation of the mixture on preparative TLC gave pure **10** and **11** in the ratio 2:1. In order to determine the configuration of these epimers, they were reduced with lithium aluminum hydride to give the corresponding 2-*C*-methyl derivatives (**12** and **13**), subsequent acetolysis afforded the corresponding tetra-*O*-acetates (**14** and **15**), respectively. By comparison of these α,β-acetates with those obtained from methyl 4,6-*O*-benzylidene-2-*C*-methyl-3-*O*-methyl-α-D-altro- and -allopyranoside,[5] the configuration of the main products (**10**, **12**, and **14**) was determined to be D-*altro* (H_1 protons of **14** appeared at δ 6.41 and 6.22), and that of the minor product D-*allo* (**15**; δ 6.37 and 5.86).

Oxidation of **4b** also gave an epimeric mixture of the corresponding spiro epoxides (**16** and **17**) in 84% yield in the ratio 1.2:1. The configuration of the main product was determined to be D-*gluco* by comparison with that obtained by the diazomethane reaction of **4a**.[5] Similarly the oxidation of **5b** and **6b** gave an epimeric mixture of the corresponding spiro epoxides (**18** and **19**, and **20** and **21**), respectively. The configurations of these compounds were also determined by comparison with those obtained by the diazomethane reaction of **5a** and **6a**.[4] The results are summarized

Table 1. Comparison of stereoselectivity in the peroxy acid oxidation of methyl 4,6-*O*-benzylidene-2- or -3-methylene-α- and -β-D-hexopyranosides and in the diazomethane reaction of the corresponding uloses

Substrates		Yields (%) of spiro epoxides in the reaction of uloses with diazomethane[a] (a series) and that of methylene derivatives with *m*-chloroperbenzoic acid (b series)	
		Axial attack product	Equatorial attack product
1	a		83.5 (**8**)
	b	82.0 (**8**)	
2	a	31.1	63.7 (**9**)
	b	86.0 (**9**)	
3	a	21.8 (**11**)	65.3 (**10**)
	b	52.7 (**10**)	26.3 (**11**)
4	a	92.5 (**16**)	
	b	38.2 (**17**)	45.2 (**16**)
5	a		41.0 (**19**)[b]
	b	39.5 (**19**)	47.5 (**18**)
6	a	17.6 (**20**)	76.5 (**21**)
	b	42.0 (**21**)	30.0 (**20**)

a) The results are cited from Refs. 4 and 5, except those of **3a**. b) The ring-expansion product of **19** was obtained in 36.9% yield.

in Table 1.

The reaction of **3a** and diazomethane in ethanol was carried out in order to confirm our hypothesis on stereoselectivity. Separation of the products (87% yield) on preparative TLC gave **10** and **11** in the ratio 3:1. Since **4a** exclusively gave an axial attack product in the diazomethane reaction,[4] the predominant equatorial attack also supports our hypothesis, in which the electrostatic attractive force of axial oxygen at C-3 position is stronger than that of lone pair electron of ring oxygen at β-position of the carbonyl group.

By considering both steric (non-bonded interactions) and electrostatic (attractive or repulsive) factors (Table 1), the stereoselectivity in the diazomethane reaction of uloses could be explained by the electrostatic attractive interaction between neighboring axial oxygen atom and diazomethyl cation in the transition state.

Peroxy acid oxidation is known to involve an electrophilic attack of the reagent from the less hindered side of the alkene to give the less hindered epoxide, through a highly ordered transition state.[15,16]

In the *m*-chloroperbenzoic acid oxidation of rigid methylenecyclohexane systems, Carlson and Behn showed that the axial attack percentage[17] is 59—69% due to stronger steric hindrance of axial hydrogen on α-carbon than that of β-carbon in the transition state.[18] From the results obtained here, the axial attack percentage in the case of **4b** (46%) and **6b** (58%) can be considerd as standards for 2-methylene and 3-methylene pyranosides, respectively, since they have no axial substiuents. The lower percentage of axial attack in the case of **4b** than that of cyclohexane systems suggests "the product development control"[18] of C_2–O dipole bisecting C_1–O_1 and C_1–O_5 torsional angle in axial attack epoxide formation of β-anomers. The higher percentage in the case of **3b** (68%) than that of **4b** is estimated as the steric factor of the axial 3-methoxyl group. The predominant axial attack in the case of α-anomer of 2-methylene derivatives (**1b** and **2b**) is attributed to the strong steric factor of the axial methoxyl group at C-1 position, as is known in the reduction of 2-uloses with hydride anions.[5,19]

The lower percentage in the case of **5b** (45%) than that of **6b** should be attributed to the balance of steric factors between axial 1- and 2-methoxyl groups. However, the hindrance of the former seems to be larger than the latter, since the percentage of methyl 4,6-*O*-benzylidene-2-deoxy-3-methylene-α-D-*erythro*-hexopyranoside having no 2-methoxyl group is 25%.[11]

Experimental

General Methods. All melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. Solvents were evaporated under reduced pressure at a bath temperature not exceeding 50 °C. Optical rotations were measured in a 0.2 dm tube with a Carl Zeiss LEP-Al polarimeter in chloroform unless otherwise stated. IR spectra were recorded with a Hitachi Model EPI-G2 spectrometer, and NMR spectra with a JNM-PS-100 spectrometer in deuteriochloroform containing tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

*Methyl-4,6-O-benzylidene-3-O-methyl-β-D-ribo-hexopyranosid-2-ulose (**3a**).* Mesylation of methyl 4,6-*O*-benzylidene-3-*O*-benzoyl-β-D-glucopyranoside in pyridine with methanesulfonyl chloride gave the conceponding 2-*O*-mesylate in 82% yield, which was recrystallized from ethanol–hexane. Mp 194—197 °C; $[\alpha]_D^{22}$ −81.5° (*c* 1.1). IR: 1735 (ester); NMR: 8.20—8.00 and 7.60—7.20 (Ph: m), 5.65 (H_3: t, $J_{2,3}=J_{3,4}=9.0$), 4.80—4.50 (H_2 and H_1: m), 4.38 (H_6: q, $J_{5,6}=4.4$, $J_{6,6'}=10.2$), 3.93—3.44 (H_4, H_5, and $H_{6'}$: m), 3.57 (OMe), 2.99 (OMs).

Found: C, 56.75; H, 5.19; S, 6.26%. Calcd for $C_{22}H_{24}O_9S$: C, 56.89; H, 5.21; S, 6.90%.

A solution of the above mesylate (1 g, 2.2 mmol) and sodium (60.7 mg, 2.6 mmol) in absolute methanol (50 ml) was refluxed for 1 h until the starting material and its de-*O*-benzoylated product disappeared on TLC. The reaction mixture was poured into water, and then extracted with chloroform. The usual work-up of the extract gave methyl 4,6-*O*-benzylidene-2,3-anhydro-β-D-mannopyranoside, which was recrystallized from ethanol–hexane in 83% yield. Mp 181—183 °C; $[\alpha]_D^{22}$ −30.2° (*c* 0.7), [lit,[13] mp 182 °C; $[\alpha]_D^{22}$ −30.4° (*c* 0.82)].

Found: C, 63.91; H, 6.22%. Calcd for $C_{14}H_{16}O_5$: C, 63.62; H, 6.10%.

A solution of the above 2,3-anhydro-mannopyranoside (500 mg) and sodium methoxide (700 mg sodium) in methanol (20 ml) was refluxed for 24 h, poured into water, and then extracted with chloroform. The chloroform layer was evaporated to give a mixture of crystals which were separated on preparative TLC (ether–hexane=1:1, Merck type 60 Kieselgel). Lower R_f product was methyl 4,6-*O*-benzylidene-2-*O*-methyl-β-D-glucopyranoside. Yield, 38%; mp 172—175 °C (ethanol–hexane); $[\alpha]_D^{22}$ −69.6° (*c* 1.5), [lit,[20] mp 175—176 °C; $[\alpha]_D^{14}$ −67.3° (*c* 1.6)].

Found: C, 60.86; H, 7.02%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%.

Higher R_f product was methyl 4,6-*O*-benzylidene-3-*O*-methyl-β-D-altropyranoside (**7**). Yield, 41%, mp 94—96 °C (ethanol–hexane); $[\alpha]_D^{22}$ −63.0° (*c* 1.2). IR: 3536 (OH); NMR: 7.60—7.30 (Ph: m), 5.57 (PhCH: s), 4.77 (H_1: d, $J_{1,2}=1.2$), 4.38 (H_6: q, $J_{5,6}=4.0$, $J_{6,6'}=7.0$), 4.15—3.67 (H_2, H_3, H_4, H_5, and $H_{6'}$: m), 3.60 (2×OMe), 2.66 (OH: d, $J_{2,OH}=2.0$).

Found: C, 61.10; H, 6.85%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%. Coupling constants ($J_{1,2}=1.6$, $J_{2,3}=3.6$) in the NMR spectrum of the corresponding 2-acetate support the structure.

Oxidation of the above β-D-altropyranoside with dimethyl sulfoxide–trifluoroacetic anhydride, under similar conditions to those reported,[12] afforded **3a** in 87% yield, which was recrystallized from ethanol–water. Hydrate of **3a**: Mp 85—90 °C; $[\alpha]_D^{22}$ −56.8° (*c* 0.8). IR: 3500 and 3380 (OH); NMR 7.60—7.25 (Ph: m), 5.50 (PhCH: s), 4.52 (H_1: s), 4.37 (H_6: q, $J_{5,6}=3.0$, $J_{5,6'}=7.8$), 4.15—3.50 (H_4, H_5, and OH: m), 3.86 ($H_{6'}$: t, $J_{6,6'}=7.8$), 3.70 (H_3: d, $J_{3,4}=2.0$), 3.67 and 3.63 (2×OMe).

Found: C, 57.76; H, 6.60%. Calcd for $C_{15}H_{18}O_6\cdot H_2O$: C, 57.68; H, 6.46%.

*Wittig Reaction of Uloses (**1a**—**6a**).* A solution of butyllithium (10%; 2.9 ml, 4.5 mmol) in hexane was added dropwise with stirring to a suspension of methyltriphenylphosphonium bromide (2.9 g, 5.6 mmol) in dry tetrahydrofuran (7 ml) cooled in an ice–water bath. A solution of methyl 4,6-*O*-benzylidene-3-*O*-methyl-α-D-*ribo*-hexopyranosid-2-ulose (**1a**)[5] (1 g, 3.4 mmol) in tetrahydrofuran (30 ml) was then rapidly added with vigorous stirring to the resulting yellowish orange suspension. The reaction mixture was kept at room temperature for 30 min until **1a** disappeared on TLC. After addition of ether (70 ml) to the mixture, the precipitate was collected by filtration. The filtrate was evaporated, and the residue was placed on a silica-gel column (Wako-gel C-200: 30 g) followed by elution with benzene to give white crystals (437 mg, 44%), methyl 4,6-*O*-benzylidene-3-*O*-methyl-2-*C*-methylene-α-D-*ribo*-hexopyranoside (**1b**) which were recrystallized from ether–hexane. Mp 82—84 °C; $[\alpha]_D^{22}$ +40.3° (*c* 0.6). NMR: 7.64—7.20 (Ph: m), 5.51 (PhCH: s), 5.30 and 5.25 (exo-CH_2: each s), 4.38 (H_5: m), 4.34 (H_6: q, $J_{5,6}=4.8$), 4.07 (H_3: d, $J_{3,4}=3.2$), 3.66 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}=11.0$), 3.65 (H_4: q, $J_{4,5}=8.0$), 3.40 and 3.35 (2×OMe).

Found: C, 65.82; H, 6.83%. Calcd for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90%.

A similar reaction of methyl 4,6-*O*-benzylidene-3-*O*-methyl-α-D-*arabino*-hexopyranosid-2-ulose (**2a**) gave the corresponding 2-*C*-methylene derivative (**2b**) in 52% yield, which was recrystallized from ether–hexane. Mp 149—151 °C; $[\alpha]_D^{22}$ +55.4° (*c* 0.9). NMR: 7.60—7.20 (Ph:m), 5.54 (H_1: s), 5.35 and 5.17 (exo-CH_2: each q, $J_{4,CH_2}=1.0$, $J_{gem}=2.0$), 4.23 (H_5: sex), 4.26 (H_4: t, $J_{3,4}=J_{4,5}=9.2$), 3.97 (H_6: q, $J_{5,6}=4.0$), 3.73 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}=9.4$), 3.58 (H_3: dd), 3.58 and 3.38 (2×OMe).

Found: C, 65.77; H, 6.90%. Calcd for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90%.

A similar reaction of **3a** gave methyl 4,6-*O*-benzylidene-3-*O*-methyl-2-*C*-methylene-β-D-*ribo*-hexopyranoside (**3b**) in 57% yield, which was recrystallized from ethanol. Mp 95—97 °C; $[\alpha]_D^{22}$ −95.5° (*c* 2.8). NMR: 7.60—7.20 (Ph: m), 5.52 (PhCH and H_1: superimposed s), 5.18 and 5.01 (exo-CH_2: each broad s), 4.37 (H_6: q, $J_{5,6}=5.0$, $J_{6,6'}=9.8$), 4.13 (H_5: m), 4.12 (H_3: d, $J_{3,4}=3.0$), 3.73 ($H_{6'}$: t, $J_{5,6'}=9.8$), 3.67 (H_4:q, $J_{4,5}=9.0$), 3.60 and 3.36 (2×OMe).

Found: C, 65.66; H, 7.03%. Cacld for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90%.

A similar reaction of methyl 4,6-*O*-benzylidene-3-*O*-methyl-β-D-*arabino*-hexopyranosid-2-ulose (**4a**)[5] gave the corresponding 2-*C*-methylene derivative (**4b**) in 67% yield, which was recrystallized from ethanol. Mp 156—157 °C; $[\alpha]_D^{22}$ −71.2° (*c* 1.2). NMR: 7.60—7.25 (Ph: m), 5.56 (PhCH: s), 5.50 and 5.42 (exo-CH_2: each broad s), 4.80 (H_1: s), 4.35 (H_6: q, $J_{5,6}=4.0$, $J_{6,6'}=10.0$), 4.00—3.45 (H_3, H_4, and H_5: m), 3.80 ($H_{6'}$:t, $J_{6,6'}=J_{5,6'}=10.0$), 3.62 and 3.60 (2×OMe).

Found: C, 65.49; H, 6.99%. Calcd for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90%.

A similar reaction of methyl 4,6-*O*-benzylidene-2-*O*-methyl-α-D-*arabino*-hexopyranosid-3-ulose (**5a**)[4] gave the corresponding 3-*C*-methylene derivative (**5b**) in 72% yield, which was recrystallized from ethanol. Mp 88—90 °C; $[\alpha]_D^{22}$ +108.7° (*c* 1.1). NMR: 7.70—7.20 (Ph: m), 5.60 (PhCH: s), 5.38 and 5.14 (exo-CH_2: each t, $J_{gem}=J_{4,CH_2}=1.6$), 4.73 (H_1: d, $J_{1,2}=1.2$), 4.40—4.05 (H_5 and H_6: m), 4.00—3.70 (H_4 and $H_{6'}$:m), 3.75 (H_2: d), 3.40 and 3.32 (2×OMe).

Oxidation of exo-*Methylene Compounds* (***1b*—*6b***) *with* m-*Chloroperbenzoic Acid.* A solution of **1b** (300 mg, 1.0 mmol) and *m*-chloroperoxybenzoic acid (85% purity, 406 mg, 2.0 mmol) dissolved in 1,2-dichloroethane (15 ml) was heated at 60 °C overnight. The mixture was washed with 0.1 M sodium hydroxide and water, and dried with magnesium sulfate. The organic layer was evaporated to give crystalline methyl 2,2′-anhydro-4,6-*O*-benzylidene-2-*C*-hydroxymethyl-3-*O*-methyl-α-D-altropyranoside (**8**) in 82% yield which was recrystallized from ethanol–hexane. Mp 108—109 °C; $[\alpha]_D^{22}$ +85.0° (*c* 0.7). NMR spectrum was identical with that of the authentic sample.[5]

A similar reaction of **2b** gave methyl 2,2′-anhydro-4,6-*O*-benzylidene-2-*C*-hydroxymethyl-3-*O*-methyl-α-D-mannopyranoside (**9**) in 86% yield which was recrystallized from ethanol–hexane. All the physical constants were identical with those of the authentic sample derived from the reaction of **2a** and diazomethane. Mp 140—141 °C; $[\alpha]_D^{22}$ +76.5° (*c* 0.8).

A similar reaction of **3b** and separation of two products on preparative TLC (ether–hexane 1:1) gave the epimeric pair of spiro epoxides, methyl 2,2′-anhydro-4,6-*O*-benzylidene-2-*C*-hydroxymethyl-3-*O*-methyl-β-D-altropyranoside (**10**) and the corresponding β-D-allopyranoside (**11**), in 52.7 and 26.3% yields, respectively, which were recrystallized from ethanol–hexane.

10: Mp 114—115 °C; $[\alpha]_D^{22}$ −81.6° (*c* 0.8). NMR: 7.60—7.25 (Ph: m), 5.54 (PhCH: s), 5.00 (H_1: s), 4.40 (H_6: q, $J_{5,6}$=4.0), 4.10 (H_5: m), 3.95 (H_4: q, $J_{4,5}$=8.6), 3.83 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}$=9.0), 3.30 (H_3: d, $J_{3,4}$=2.4), 3.56 and 3.52 (2×OMe), 3.11 and 2.78 (epoxy CH_2: ABq, J=5.3).

Found: C, 61.89; H, 6.65%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%.

11: Mp 150—151 °C; $[\alpha]_D^{22}$ −61.2° (*c* 0.7). NMR: 7.60—7.25 (Ph: m), 5.50 (PhCH: s), 5.30 (H_1: s), 4.37 (H_6: q, $J_{5,6}$=5.0), 4.16 (H_5: sex), 3.76 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}$=10.0), 3.76 (H_4: q, $J_{3,4}$=2.2, $J_{4,5}$=9.0), 3.45 (H_3: d), 3.62 and 3.53 (2×OMe), 3.23 and 2.57 (epoxy CH_2: ABq, J=5.4).

Found: C, 62.21; H, 6.57%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%. Configutations of **10** and **11** were determined by conversions into **14** and **15**, respectively.

A similar reaction of **4b** gave the epimeric pair of spiro epoxide, methyl 2,2′-anhydro-4,6-*O*-benzylidene-2-*C*-hydroxymethyl-3-*O*-methyl-β-D-glucopyranoside (**16**) and the corresponding β-D-mannopyranoside (**17**). Separation of the mixture on preparative TLC (ether–hexane 1:1) gave pure **16** in 45.2% yield, which is identical with the authentic sample obtained by the diazomethane reaction of **4a**.[5] However, pure **17** could not be obtained in a pure state due to its instability on TLC plate. The yield and structure of **17** were estimated form the NMR spectrum of the mixture.

17: NMR 7.60—7.25 (Ph: m), 5.63 (PhCH: s), 4.75 (H_1: s), 4.40 (H_6: q), 3.60 and 3.52 (2×OMe), 3.06 and 2.99 (epoxy CH_2: ABq, J=5.8), H_3, H_4, H_5, and $H_{6'}$, could not be analyzed.

A similar reaction of **5b** and separation of two products on preparative TLC (ether–hexane 1:1) gave the epimeric pair of spiro epoxides, methyl 3,3′-anhydro-4,6-*O*-benzylidene-3-*C*-hydroxymethyl-2-*O*-methyl-α-D-mannopyranoside (**18**) and the corresponding α-D-altropyranoside (**19**) in 47.5 and 39.5% yields, respectively.

18: Sirup; $[\alpha]_D^{22}$ +62.0° (*c* 1.9). NMR: 7.55—7.20 (Ph: m) 5.56 (PhCH: s), 4.76 (H_1: d, $J_{1,2}$=1.8), 4.47—3.75 (H_4, H_5, H_6, and $H_{6'}$: m), 3.11 (H_2: d), 3.54 and 3.37 (2×OMe), 3.17 and 2.70 (epoxy CH_2: ABq, J=6.0).

Found: C, 62.21; H, 6.50%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H. 6.54%.

19: Mp 141—143 °C (from ether–hexane); $[\alpha]_D^{22}$ +75.3° (*c* 1.3). NMR and IR spectra were identical with those of the authentic sample[4] obtained by the diazomethane reaction of **5a**.

Oxidation of **6b** and separation of two products on preparative TLC (ether–hexane 1:1) gave the epimeric pair of methyl-**3,3′-a**nhydro-4,6-*O*-benzylidene-3-*C*-hydroxymethyl-2-*O*-me**thyl-β**-D-glucopyranoside (**20**) and the corresponding β-D-allopyranoside (**21**) in 30.0% and 42.0% yields, respectively, which were recrystallized from ethanol–hexane.

20: Mp 150—151 °C; $[\alpha]_D^{22}$ −74.2° (*c* 0.8).

21: Mp 156—157 °C; $[\alpha]_D^{22}$ −62.9° (*c* 0.9).

NMR and IR spectra of both **20** and **21** were identical with those of the authentic samples[4] obtained by the diazomethane reaction of **6a**.

Reduction of ***10*** *and* ***11*** *with Lithium Aluminium Hydride.* Lithium aluminium hydride (50 mg) was added to a solution of **10** (150 mg, 0.52 mmol) in tetrahydrofurane (5 ml) and the mixture was then stirred at room temperature for 1 h. The excess hydride was carefully decomposed with water and then filtered. The filtrate was extracted with chloroform. The extract was washed with water, dried with anhydrous magnesium sulfate, and evaporated to give crystalline methyl 4,6-*O*-benzylidene-2-*C*-methyl-3-*O*-methyl-β-D-altropyranoside (**12**) in 91% yield which was recrystallized from ethanol–hexane. Mp 113—114 °C; $[\alpha]_D^{22}$ −64.4° (*c* 1.0). IR: 3520 (OH); NMR: 7.60—7.20 (Ph: m), 5.47 (PhCH: s), 4.44 (H_1: s), 4.34 (H_6: q, $J_{5,6}$=4.0, $J_{6,6'}$=9.0), 4.14 (H_4: q, $J_{3,4}$=2.0, $J_{4,5}$=10.0), 3.94 (H_5: sex), 3.77 ($H_{6'}$: t, $J_{5,6'}$=9.0), 3.47 (H_3: d), 3.56 and 3.47 (2×OMe), 2.70 (OH: broad s), 1.27 (CMe).

Found: C, 61.90; H, 7.30%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

A similar reduction of **11** (150 mg) in THF (5 ml) afforded methyl 4,6-*O*-benzylidene-2-*C*-methyl-3-*O*-methyl-β-D-allopyranoside (**13**) in 89% yield wihch was recrystallized from ethanol–hexane. Mp 118—119 °C; $[\alpha]_D^{22}$ −68.0° (*c* 1.1). NMR: 7.60—7.20 (Ph: m), 5.44 (PhCH: s), 4.43 (H_1: s), 4.35 (H_6: q, $J_{5,6}$=4.0, $J_{6,6'}$=10.4), 4.00—3.48 (H_3, H_4, H_5, and $H_{6'}$: m) 3.60 and 3.48 (2×OMe), 3.30 (OH: broad s), 1.27 (CMe).

Found: C, 61.82; H, 7.41%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

Determination of the Configuration of ***12*** *and* ***13***. A solution of **12** (100 mg) in acetic anhydride (3 ml) containing a drop of 60% perchloric acid was heated at 60 °C for 6 h. Since acetolysis was incomplete, the reaction was repeated at room temperature for 18 h, using *p*-toluenesulfonic acid as a catalyst. The reaction mixture was then poured into cold sodium hydrogencarbonate solution and the resulting solution was extracted with chloroform.

The extracts were washed with water, dried, and evaporated to give a mixture of sirupy 1,2,4,6-tetra-*O*-acetyl-2-*C*,3-*O*-dimethyl-α- and -β-D-altropyranoses (**14**). The configutation was determined without isolation of anomers by direct comparison of the R_f value and NMR spectrum with those of the authentic sample prepared by acetolysis of methyl 4,6-*O*-benzylidene-2-*C*,3-*O*-dimethyl-α-D-altropyranoside.[5]

Compound **13** was also converted into a mixture of sirupy 1,2,4,6-tetra-*O*-acetyl-2-*C*,3-*O*-dimethyl-α- and -β-D-*allo*-pyranoses (**15**), which was identical with that obtained by the acetolysis of methyl 4,6-*O*-benzylidene-2-*C*,3-*O*-dimethyl-α-D-allopyranoside.[5]

14: R_f values, 0.41 and 0.36 (on DC Fertigplatten Kieselgel 60, Merck AG; benzene–acetone 8:1). NMR: 6.37 and 5.86 (H_1:each s), 3.57 (2×OMe), 2.15—2.05 (8×OAc), 1.60 and 1.54 (CMe).

15: R_f values, 0.36 and 0.31 (under the same conditions as above). NMR: 6.41 and 6.22 (H_1: each s), 3.50 and 3.40 (OMe), 2.15—2.05 (8×OAc), 1.68 and 1.56 (CMe).

*Reaction of **3a** with Diazomethane.* To a solution of **3a** (294 mg, 1.0 mmol) in ethanol (30 ml) was added dropwise a solution of diazomethane (2.0 mmol) in ether (10 ml) at 0 °C. After the mixture had been left at room temperature for 12 h, the solution was evaporated to give a sirup. Separation of two products on preparative TLC (ether: hexane= 1:1) gave **10** and **11** in 65.3% and 21.8% yields, respectively. Both were respectively identical with authentic samples obtained *via* the peroxy acid oxidation of (**3b**).

The present work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Diazotization of Aromatic Primary Amines of Weak Basicity. II.[1] Reduction of Arenediazonium Salts with Alkylbenzene Derivatives

Ikuo TAKAGISHI, Yoji HASHIDA, and Kohji MATSUI*

Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received February 3, 1979)

The diazonio group of arenediazonium salts derived from weakly basic amines were efficiently substituted by hydrogen with alkylbenzenes in sulfuric acid. Several types of evidence, including kinetic results and experiments to trap an intermediate, indicated that the reduction occurs *via* an aryl radical intermediate. In the reduction with toluene, analyses of by-products suggested a radical chain mechanism, which would involve a propagation cycle caused by electron transfer from the benzyl radical to the diazonio group.

The diazonio group of arenediazonium salts is known to be replaced by hydrogen with various reducing agents. These include alcohols,[2] alcohols in combination with metals or metal oxides,[3] ethers,[4] formaldehyde,[5] formic acid and its esters and amides:[6] the ordinary reducing agents of the organic type. However, there has been no report on the reduction of arenediazonium salts by aromatic hydrocarbons.

During the course of our studies on the reaction of arenediazonium salts derived from weakly basic amines, we found that the diazonio group was effectively replaced by hydrogen with alkylbenzene derivatives in sulfuric acid. This paper reports this novel reduction of arenediazonium salts with alkylbenzenes.

Results and Discussion

Reaction of 2-Bromo-4,6-dinitrobenzenediazonium Salt with Alkylbenzenes and Their Derivarives. In this paper, 2-bromo-4,6-dinitrobenzenediazonium salt was chosen as typical of those derived from weakly basic amines. The diazotization was carried out in nitrosylsulfuric acid, which was prepared by adding an 20% excess of sodium nitrite into sulfuric acid. When benzene, halobenzene, or phenol was added to the diazonium solution, the corresponding 2-bromo-4,6-dinitrobiphenyl derivatives resulting from an arylation (acidic Gomberg reaction)[7] of the aromatic substrates with the diazonium compound were obtained, along with a tarry substance.

On the contrary, in the presence of toluene, 1-bromo-3,5-dinitrobenzene was obtained as the main product, showing that the diazonio group was replaced by hydrogen. Similarly, other alkylbenzenes such as ethylbenzene, cumene, and *p*-xylene reduced the diazonium salt effectively. Derivatives of toluene are also able to reduce the diazonium salt very quickly. The results are summarized in Table 1.

As can be seen, there is no observable correlation between *m*- and *p*-substituents and product yields. But the introduction of *o*-substituents into toluene decreases their reducing ability; *e.g.* the reaction with 2,4-dinitrotoluene gave only a tarry substance and unchanged 2,4-dinitrotoluene was recovered quantitatively. In the reaction with *p*-nitrotoluene, *p*-nitrobenzaldehyde was obtained in 51% yield along with 1-bromo-3,5-dinitrobenzene (80%). This observation and the fact that no reduction took place in the presence of benzene indicate that alkyl groups are responsible for the reduction.

TABLE 1. REDUCTION OF 2-BROMO-4,6-DINITROBENZENEDIAZONIUM SALT WITH ALKYLBENZENES

Alkylbenzene[a]				Yield (%) of 1-bromo-3,5-dinitrobenzene
R_1	R_2	R_3	R_4

CH_3	OCH_3	H	NO_2	60
CH_3	Cl	H	NO_2	27
CH_3	NO_2	H	NO_2	0

a) Alkylbenzene: 
TABLE 2. REDUCTION OF 2-BROMO-4,6-DINITROBENZENEDIAZONIUM SALT WITH BENZENE DERIVATIVES

Reducing agent	Yield (%) of 1-bromo-3,5-dinitrobenzene
Tetralin	44
$C_6H_5CH_2OH$	16
C_6H_5CHO	18
$C_6H_5OCH_3$	11
$C_6H_5C(CH_3)_3$	37

Therefore, to answer the question whether the reducing ability is really limited to alkyl groups, several benzene derivatives containing side chains other than an alkyl group were examined (Table 2).

Table 2 shows that, even though the reducing ability is not high, side chains such as hydroxymethyl-, formyl-, and methoxyl groups are also able to reduce the diazonium compound, as was expected. Since aldehyde[5] and ethers[4] have been known to reduce diazonium compounds, a hydroxymethyl compound would be an intermediate on the course of reduction from methyl compound to aldehyde.

Reactions of 2-Bromo-4,6-dinitrobenzenediazonium Salt with Aliphatic Compounds. From the results described above, it has become apparent that an alkyl group attached to an aromatic nucleus is effective for the reduction. However, it is questionable whether the

Table 3. Reduction of 2-bromo-4,6-dinitrobenzenediazonium salt with alcohols and nitro compound

Reducing agent	Yield (%) of 1-bromo-3,5-dinitrobenzene
CH_3OH	77
CH_3CH_2OH	66
$(CH_3)_2CHOH$	52
$(CH_3)_3COH$	trace
$(CH_3)_2CHNO_2$	62

presence of the aromatic nucleus is really necessary for the reducing ability. To answer this question and to get an insight into the reduction mechanism, the reducing ability of some aliphatic compounds was examined (Table 3).

In accord with our expectation, aliphatic alcohols reduced the diazonium salt. It is noteworthy that the reactions with alcohols gave only the 1-bromo-3,5-dinitrobenzene, suggesting that the reaction proceeded by a radical mechanism, *via* an aryl radical intermediate.[8] Furthermore, diazonium salt could be reduced with an aliphatic nitro compound, resulting in the formation of 1-bromo-3,5-dinitrobenzene. This observation also suggests a radical process for the reaction, because arenediazonium salts are known to decompose in nitroalkanes to give phenols by a heterolytic process.[9]

Reactions of Some Arenediazonium Salts with p-*Toluenesulfonic Acid.* No detailed study has been reported on the reduction of an diazonio group with alkylbenzene.[10] Therefore, to make clear the relation between the chemical constitution of a diazonium salt and its susceptibility to reduction by alkylbenzene, reactions of several arenediazonium salts derived from weakly basic amines with *p*-toluenesulfonic acid were investigated (Table 4).

From Table 4 it is evident that for the effective reduction by *p*-toluenesulfonic acid, a diazonium salt should fulfil the following conditions: 1) The presence of at least two strong electron-withdrawing groups.

Table 4. Reduction of arenediazonium salt with *p*-toluenesulfonic acid

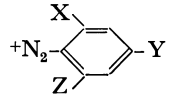
H	NO_2	H	0

a) Diazonium salt:



2) The presence of a bulky group at the 2 and 6 positions to the diazonio group; 2,6-dinitrobenzenediazonium salt yielded the reduced product in 45% yield, while in the case of 2,4-dinitrobenzenediazonium salt no reduced product was obtained.[11]

Effects of Sodium Nitrite. In the previous paper[1] we reported that 2-bromo-4,6-dinitrobenzenediazonium salt reacted with sodium nitrite to effect a replacement of the diazonio group by the nitro group. However, in the presence of alkylbenzenes, sodium nitrite was found to act in a different manner. When 2-bromo-4,6-dinitrobenzenediazonium salt was allowed to react with *p*-toluenesulfonic acid in nitrosylsulfuric acid containing an equivalent amount of sodium nitrite, the yield of the reduced product was very poor (≈2%). But when nitrosylsulfuric acid containing 20% excess of sodium nitrite was used, the reduced product was obtained in 81% yield. Figure 1 shows the effect of the amount of sodium nitrite on the decomposition rate of 2-bromo-4,6-dinitrobenzenediazonium salt in sulfuric acid; in the absence of an excess of sodium nitrite, most of the diazonium salt remained unchanged even after 200 min.

These results suggest that an excess of sodium nitrite plays an important role in the decomposition of the diazonium salt to yield the reduced product. It is known that the nitrite ion promotes the homolytic decomposition of a diazonium ion in water[12] and in DMSO;[13] the function of a nitrite ion for the decomposition of a diazonium ion has been explained by suggesting that it combines with the diazonium ion to form a covalent azo compound which decomposes homolytically.[12-15] A similar radical process may be expected in our system. This assumption may be supported by the fact that, when 2,2-diphenyl-1-picrylhydrazyl radical was employed instead of an excess of sodium nitrite, the diazonium salt easily decomposed to give the reduced product in 60% yield. Furthermore, when *p*-iodobenzenesulfonic acid was added to the reaction mixture as a scavenger for the aryl radical[16] in place of *p*-toluenesulfonic acid, 1-

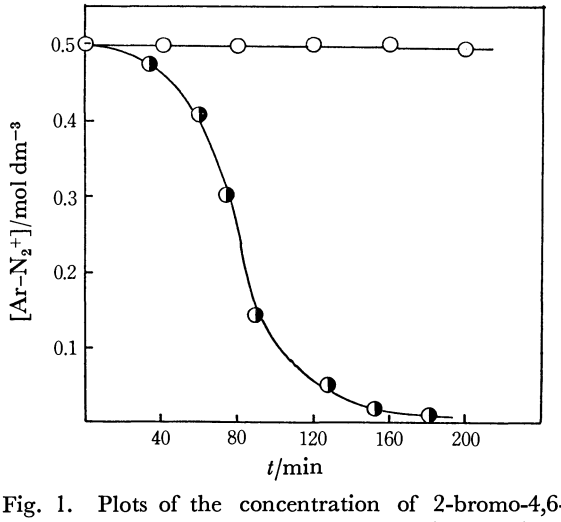


Fig. 1. Plots of the concentration of 2-bromo-4,6-dinitrobenzenediazonium ion as a function of time in sulfuric acid at 52 °C. ○: $NaNO_2/ArNH_2$ (molar ratio) = 1.00, ◑: $NaNO_2/ArNH_2$ (molar ratio) = 1.24.

bromo-2-iodo-3,5-dinitrobenzene was obtained. This result supports the assumption that an intermediary aryl radical abstracts an iodo atom from *p*-iodobenzenesulfonic acid.

By-products of the Reaction of 2-Bromo-4,6-dinitrobenzenediazonium Salt with Toluene. It seemed worthwhile to check the by-products in this reduction from a mechanical point of view.

When toluene was employed as the reducing reagent, phenyltolylmethane was obtained in 10% yield together with the reduced product. Phenyltolylmethane was a mixture of two isomers: one of the isomers was found to be phenyl-*p*-tolylmethane by a comparison with an authentic sample, while the other isomer is still unidentified because of the difficulty in purification.

On the other hand, when a mixture of toluene and chlorobenzene was added to the diazonium solution, a mixture of chlorodiphenylmethanes was obtained, together with phenyltolylmethanes (Table 5).

Chlorodiphenylmethanes were found to consist of a mixture of 60% *o*- and 40% *p*-chlorodiphenylmethane; no *m*-derivative could be detected, suggesting that an electrophilic attack by the benzyl cation upon chlorobenzene took place.[17] In addition, competitive benzylations of mixtures of benzene and chlorobenzene with diazonium salt gave a ratio of chlorodiphenylmethanes (*o*- and *p*-isomer)/diphenylmethane of 0.29, which is close to that of the Friedel-Crafts benzylation in

Table 5. Minor products in the decomposition of 2-bromo-4,6-dinitrobenzenediazonium ion in the presence of an aromatic substrate

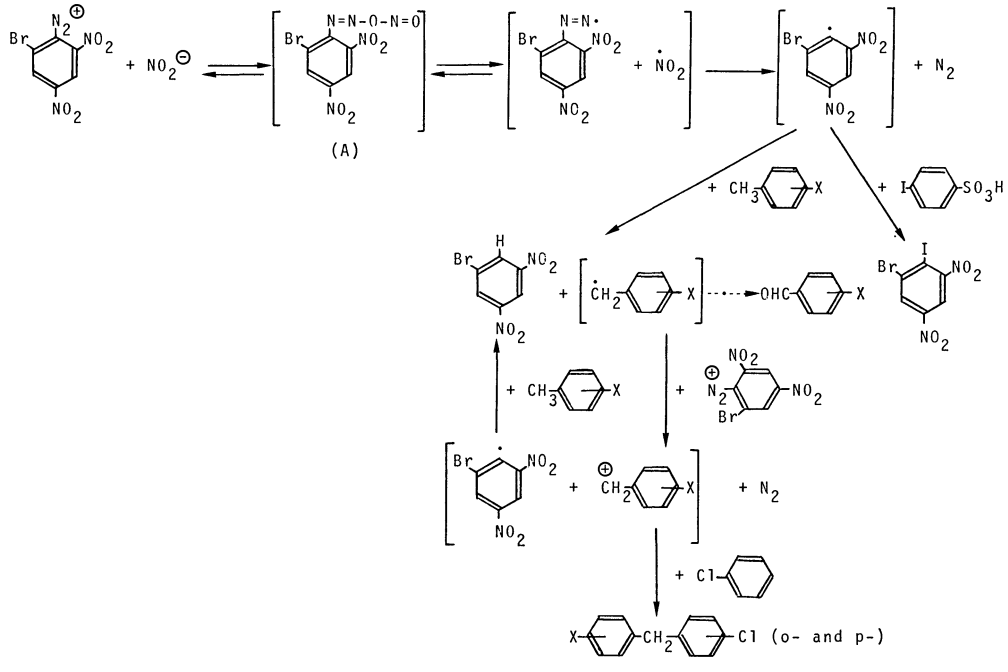

Scheme 1.

nitromethane (0.24).[17] Moreover, when oxygen was bubbled into the reaction mixture as a radical scavenger, the yield of diphenylmethane derivatives decreased to a great extent.[18] These results clearly suggest that the reduction process involves a radical intermediate, but the benzylation of aromatic substrate was performed by the benzyl cation, not by the benzyl radical.

Reduction Process of Arenediazonium Salts with Alkylbenzenes. From the results and considerations described above, the process of reduction of arenediazonium ions may be reasonably explained by Scheme 1.

In a benzenediazonium salt containing several strong electron-withdrawing groups, the electrophilicity of the diazonio group is undoubtedly large. Thus, it can combine with a nitrite ion even in sulfuric acid to give an intermediate (**A**), which easily decomposes, resulting in the formation of an aryl radical. The bulky groups at 2- and 6-positions would accelerate the decomposition of the intermediate (**A**), because the resulting aryl radical is more free from steric strain than the intermediate (**A**). The resulting aryl radical abstracts a hydrogen from toluene to give benzyl radical and reduced product. A subsequent electron transfer from benzyl radical to diazonium ion results in the formation of benzyl cation and aryl radical, which enters the propagation cycle as indicated in Scheme 1. This interpretation is consistent with the observation that slight excess of sodium nitrite is enough to decompose the diazonium ion in our system.

Experimental

Materials. 2,6-Dinitroaniline,[20] 2,6-dibromo-4-nitroaniline,[21] 4-bromo-2,6-dinitroaniline,[22] 2,4-dibromo-6-nitroaniline,[23] and *p*-iodobenzenesulfonic acid[24] were prepared according to the procedures described in the literature. Other reagents, solvents, and starting materials were purchased from standard sources and purified according to literature procedures.

General Procedure for Reduction: Summarized in Tables 1 and 4. Let us take as an example the reaction of 2-bromo-4,6-dinitrobenzenediazonium salt with *p*-nitrotoluene. To nitrosylsulfuric acid, which was prepared from sulfuric acid (20 ml) and sodium nitrite (1.65 g, 0.024 mol), was added in portions 2-bromo-4,6-dinitroaniline (5.20 g, 0.020 mol) at room temperature. The mixture was warmed up to 50 °C and stirred for 3 h to complete the diazotization. Then, with mechanical stirring, *p*-nitrotoluene (2.74 g, 0.02 mol) was added into the diazonium solution and stirring was continued for 3 h at 50 °C. The mixture was then poured into a mixture of ice and water and was extracted with chloroform. The extract was dried with sodium sulfate and concentrated by distillation. The residue was subjected to column chromatography on silica gel eluting with benzene–petroleum ether (1:1 v/v) to yield 1-bromo-3,5-dinitrobenzene (3.87 g, 78%) and *p*-nitrobenzaldehyde (1.38 g, 51%). The products obtained were identified by their NMR, IR, and MS spectra and by a mixed-melting point test with an authentic sample.

The reactions of diazonium salt with substituted benzenes (Table 2) and alcohols (Table 3) were carried out in the same way.

Thermolysis of 2-bromo-4,6-dinitrobenzenediazonium salt (0.02 mol) in the presence of *p*-iodobenzenesulfonic acid (0.06 mol) was carried out in the same way to yield 1-bromo-2-iodo-3,5-dinitrobenzene (1.34 g, 18%), which was identified by a mixed-melting point test with an authentic sample.[1]

Kinetic Measurements. In a volumetric flask, a solution of *ca.* 0.5 mol/dm^3 of diazonium salt containing *p*-toluenesulfonic acid (0.5 mol/dm^3) was prepared at thermostat temperature as described previously. An aliquot of this diazonium solution was taken at a recorded time and was added to an alkaline R-salt (2-naphthol-3,6-disulfonic acid) solution to quench the remaining diazonium salt. After the diazo-coupling, the solution was diluted to a fixed volume and its optical density was measured at the maximum wavelength of absorbance of the dye formed (497 nm).

Analyses of By-products from 2-Bromo-4,6-dinitrobenzenediazonium Salt: Summarized in Table 5. 2-Bromo-4,6-dinitrobenzenediazonium salt (5.20 g, 0.02 mol) was allowed to decompose completely in the presence of toluene (1.84 g, 0.02 mol) and worked up as previously described. Chromatography on silica gel with petroleum ether as the eluent yielded the reduced product (3.52 g, 71.1%) and crude phenyltolylmethane (0.36 g, 10%). The phenyltolylmethane was further fractionated by preparative GLC, and one of the components was identified as phenyl-*p*-tolylmethane by comparison of its NMR spectrum and retention time of GLC to those of an authentic sample.[25] The benzylation in the presence of a mixture of toluene (0.04 mol), benzene (0.04 mol), and chlorobenzene (0.04 mol) was performed as previously described. The isomer ratio and the relative reactivity for the benzylation of chlorobenzene were determined by GLC (10% Carbowax 20M–Diasolide, He; 20 ml/min, 170 °C, 4 mm×4 m) using biphenyl as the internal standard. 2-Chloro- and 4-chlorodiphenylmethane employed as reference compounds for GLC were prepared as described in the literature.[26]

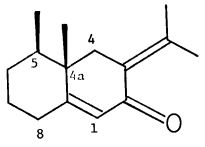
(Received February 10, 1979)

A procedure for the preparation of *dl*-dehydrofukinone (**1**), an eremophilane type sesquiterpene, from the diene adducts (**3**), prepared from the reaction of 4-methyl-3-methoxycarbonyl-2-cyclohexen-1-one with butadiene, is described. Acetalization-reduction ($LiAlH_4$) of **3** followed by treatment of the corresponding mesylate with base provided 5,6-*cis*-5-methyltricyclo[4.4.1.$0^{1,6}$]undec-8-en-2-one (**7**) in 69% overall yields. Reductive cleavage of **7** with lithium metal afforded *trans*-4β,4aβ-dimethyl-$\Delta^{6,7}$-octalin-1-one (**8**), bearing a set of vicinal *cis* two methyl groups on the C-4 and C-4a carbons in an 83% yield. Functionalization of the double bond of **8** involves (1) reduction of carbonyl group and following tetrahydropyranylation, (2) epoxidation followed by regiospecific reduction of the oxirane ring at the C-6 position, and (3) subsequent oxidation of the hydroxyl group, giving *trans*-4aβ,5β-dimethyl-8β-tetrahydropyranyloxydecalin-2-one (**14b**) in good yields. The conversion of **14b** into the desired **1** was achieved smoothly by (1) hydrolysis of tetrahydropyranyl ether, (2) pyrolysis of its mesylate, and (3) subsequent aldol reaction with acetone followed with dehydration and isomerization of the double bond.

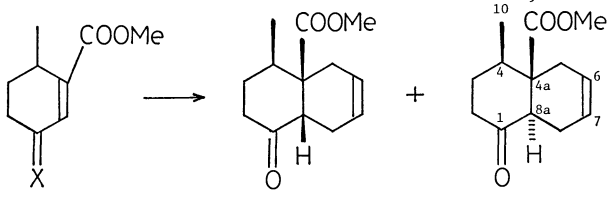
As a part of our studies aimed to develop the stereocontrolled construction of a set of vicinal *cis* two methyl groups at the C-4a and C-5 carbons on eremophilane skeleton,[1] we investigated a different approach for the preparation of *dl*-dehydrofukinone (**1**), isolated from the leaves of Gobō (*Arctium lappa* L.).[2] Reported



1

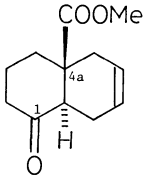
synthetic procedures to eremophilanes involve Robinson annelation reaction,[3] being associated with the inevitable epimerization at the C-4a carbon. With respect to stereochemical control of A, B ring junction, the *endo* rule of Diels-Alder reaction[4] is considered to be promising for the present requirement. In this paper, we record Diels-Alder reaction of 4-methyl-3-methoxycarbonyl-2-cyclohexen-1-one (**2b**) with butadiene as well as the transformation of the adducts (**3**) into *dl*-dehydrofukinone (**1**).

The diene addition of **2b**, prepared from methyl 6-methyl-1-cyclohexene-1-carboxylate (**2a**), with butadiene did take place at 150—160 °C in a sealed tube to give the adducts **3a** (11%) and **3b** (45%). Treatment of **3a** with base led to **3b** in a quantitative yield. The cis configuration of the C-4 methyl and C-4a ester groups of the adduct **3b** can be assigned based on their NMR data. The tentative assignment of



2a: X = H_2
2b: X = O

3a **3b**



4

the C-4 methyl group of **3b** was carried out by comparison of ^{13}C NMR results of **3b** with methyl *trans*-1-oxo-$\Delta^{6,7}$-octalin-4a-carboxylate (**4**),[5] which lacks the C-4 methyl group. The chemical shift values of the C-2 (δ 40.0) and C-8a (δ 50.5) carbons (Table 1) of **3b** are close to the C-2 (δ 40.0) and C-8a (δ 50.9) of **4**, suggesting absence of the γ-effect[6] between the C-4 methyl and the C-2 and C-8a carbons of **3b**, due to the equatorial conformation of the C-4 methyl group. On the other hand, the steric compression shift of the C-9 carbon (δ 173.1) of **3b** appears at 2.0 ppm higher field than the value (δ 175.1) of **4**.

The conversion of the ester group of **3b** into the corresponding methyl group was explored. By the reported procedure for the preparation of methyl group from ester function by (1) reduction of COOR with $LiAlH_4$, (2) following oxidation of CH_2OH to CHO, and (3) subsequent Wolf-Kishner reduction,[7] we have examined the conversion of **3b** into **8**. But, difficulties were encountered in the attempted reduction of the hindered formyl group of **5d**. Instead, in the preceding paper[1] we described a preparative procedure of the vicinal *cis* two methyl groups *via* methylation of the enolate anion generated by the reduction of cyclopropyl ketone. The promising procedure prompted us to examine reduction of the cyclopropane ring fused on the C-1, C-6 carbon of **7**, prepared by treatment of the mesylate **6** with base[1,8] (Scheme 1). Thus, reduction of **5a**, after acetalization of **3b**,[9] with $LiAlH_4$ provided **5b** in 86% yield (from **3b**). Mesylation of **5b**, giving the corresponding mesylate **5c**, followed with hydrolysis with $HClO_4$ afforded the mesylated ketone **6** in 95% yield (from **5b**). Cyclization of **6** with sodium methoxide in methanol resulted in the

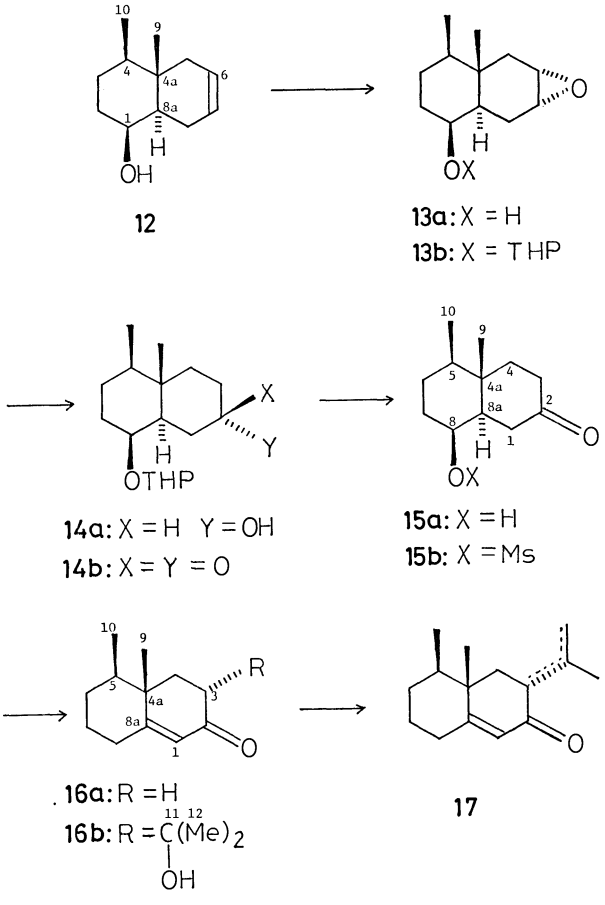
Scheme 2.

desired **7** in 84% yield.

Reductive cleavage of the cyclopropane ring of **7** with lithium metal in liquid ammonia gave a mixture of **8**[10] (83%) and **9** (10%). The product distribution of the reduction would depend on preferential conformations of the transition states **7a** and **7b** (Scheme 2). Either bond **a** or **b** of the cyclopropane ring of **7** being close to the carbonyl π-electron would be opened by electron transfer from metal lithium.[11] As the result, it appears that the present reduction does preferentially take place through the conformation **7a**. The marked upfield shift in ^{13}C NMR spectra of the C-9 methyl signal of **10** at δ 11.9, contrasting to that of **11**[12] at δ 18.2, can rationally interpret the assigned stereochemistry of **10**, compatible with the calculated values of Crews's substituents increment parameter.[13]

In pursuing the approach from **8** to the important intermediate **14b**, we examined the functionalization of the double bond of **8** by epoxidation followed with regiospecific reduction at the C-6 position and subsequent oxidation of hydroxyl group. Reduction of **8** with $LiAlH_4$ afforded the 1β-alcohol **12** in 90% yield. The structure of **12** can be interpreted on the basis of 1,3-diaxial downfield shift of ^1H NMR signal due to the C-4a methyl group of **12** (δ 0.88), comparing to the value of δ 0.63 of **8**. Epoxidation of **12** with *m*-chloroperbenzoic acid (*m*-CPBA) at 0—10 °C gave the 6α,7α-epoxide **13a** preferentially by attack of the bulky reagent from the less hindered α-face.[14] Assignment of the epoxy ring of **13a** can be made by analysis of the ^{13}C NMR spectra of the C-4a and C-8a carbons, appearing at 1.0 and 5.0 ppm higher fields than those of **12** (Table 1), due to the presence of the γ-effect[6] between either the C-4a or C-8a carbon and the ring of the 6α,7α-epoxide. After protection of the hydroxyl group of **13a** as a tetrahydropyranyl ether, **13b** was treated with lithium metal in liquid ammonia to give the alcohol **14a** (65% yield based on **12**). The reductive cleavage of the carbon–oxygen bond of **13b** can be expected to occur at the C-6 position based on the axial ring opening rule,[15] giving **14a** as a sole product. The structure of **14a** can be confirmed by further elaboration into the enone **16a**. Oxidation of **14a** with pyridinium chlorochromate[16] gave the desired ketone **14b** in 95% yield. The conversion of **14b** into **16a**[17] *via* **15a** and **15b** was carried out in 54% overall yields by hydrolysis of **14b** with pyridinium *p*-toluenesulfonate[18] at 60—63 °C in ethanol and subsequent pyrolysis of the mesylate **15b** at



Scheme 3.

130—140 °C in DMSO.

Kinetically controlled aldol reaction[1] of **16a** with acetone in the presence of zinc chloride was allowed to lead to **16b** in 79% yield. The compound **16b** was dehydrated by warming the mesylate of **16b** at 40—50 °C in pyridine and the resulting *exo* and *endo* double bond isomers **17** were converted into the desired *dl*-dehydrofukinone (**1**) either by passing an activated alumina column or by treatment with $RhCl_3 \cdot 2H_2O$ (72% yield). The desired product **1** was shown to be identical by IR and ^1H NMR spectral comparison with those of authentic specimen.[19]

Experimental

The melting points and boiling points are uncorrected. IR spectra were determined with a JASCO IRA-1 grating spectrometer. ^1H NMR spectra were determined at 60 MHz with a Hitachi R-24 instrument and at 100 MHz with a JEOL MH-100 spectrometer. ^{13}C NMR spectra were determined at 25.05 MHz with a JEOL pulsed Fourier transform spectrometer, Model FX-100. Samples were dissolved in $CDCl_3$ and the chemical shift values were expressed in δ values (ppm) relative to Me_4Si as an internal standard Elemental analyses were performed in our laboratory.

*Methyl 6-Methyl-1-cyclohexene-1-carboxylate (**2a**).* A solution of 6-methyl-1-cyclohexene-1-carboxylic acid[20] (18.1 g, 129 mmol) in MeOH (40 ml, 989 mmol) and 1,2-dichloroethane (300 ml) containing concd H_2SO_4 (10 ml) was refluxed for 24 h and worked up in the usual manner to give 18.5 g (93%) of **2a**: bp 85.0—90.0 °C/25 Torr; IR (neat) 1712 (ester C=O), 1641 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 1.05 (d, 3, J=6.5 Hz, CH_3), 1.44—2.73 (m, 4, CH_2), 1.98—2.32 (m, 2, CH_2), 2.42—2.91 (m, 1, CH), 3.66 (s, 3, OCH_3), 6.83 (t, 1, J=4 Hz, HC=C). Found: C, 70.22; H, 9.31%. Calcd for $C_9H_{14}O_2$: C, 70.10; H, 9.15%.

*4-Methyl-3-methoxycarbonyl-2-cyclohexen-1-one (**2b**).* A mixture of **2a** (1.79 g, 12 mmol) and SeO_2 (1.92 g, 17 mmol) in dioxane (10 ml) was heated at 85 °C for 20 h and at reflux for 3 h. The precipitate was filtered and washed with benzene. The combined filtrates were concentrated and the residue was dissolved in CH_2Cl_2 (20 ml). To this solution was added dropwise a chromium trioxide solution[21] with vigorous stirring for 30 min under N_2 at 0 °C. The mixture was worked up in the usual manner and the crude product was chromatographed (SiO_2, hexane–ether 2:1) to give 928 mg (46%) of **2b** as an oil: bp 132.0—133.0 °C/9 Torr; IR (neat) 1722 (ester C=O), 1683 (C=O), 1620 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 1.23 (d, 3, J=7 Hz, CH_3), 1.63—2.27 (m, 2, CH_2), 2.35 (t, 2, J=2 Hz, $COCH_2$), 2.65—3.20 (m, 1, CH), 3.76 (s, 3, OCH_3), 6.42 (s, 1, HC=C); ^{13}C NMR δ 18.0 (q, C_4–Me), 28.8 (d, C-4), 29.1 (t, C-5), 33.4 (t, C-6), 52.4 (q, OMe), 131.8 (d, C-2), 153.2 (s, C-3), 166.7 (s, ester C=O), 199.6 (s, C-1). Found: C, 64.13; H, 7.35%. Calcd for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

*Methyl cis-4β-Methyl-1-oxo-Δ^{6,7}-octalin-4a-carboxylate (**3a**) and Methyl trans-4β-Methyl-1-oxo-Δ^{6,7}-octalin-4a-carboxylate (**3b**).* A mixture of **2b** (2.95 g, 17.5 mmol), 1,3-butadiene (2.3 g, 41.0 mmol) and 2,5-di-*t*-butylhydroquinone (50 mg) in benzene (10 ml) was heated at 150—160 °C for 3 days in a sealed tube and extracted with hot MeOH. The extract was filtered and the filtrate was concentrated. Distillation at 80—90 °C/3 Torr afforded an unchanged **2b** (1.14 g) and the residue in the flask was chromatographed (SiO_2, hexane–AcOEt 2:1) to give 263 mg (11% based on recovered **2b**, R_f 0.75, hexane–AcOEt 2:1) of **3a** and 1.08 g (45%, R_f 0.68) of **3b**. The physical constants together with elemental analyses of **3a** and **3b** are as follows: **3a**, mp 84.0—85.0 °C (hexane); IR (Nujol) 3027, 1720 (ester C=O), 1714 (C=O), 1653 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 1.12 (d, 3, J=7 Hz, CH_3), 1.70—2.60 (m, 9, CH_2, CH), 3.00—3.40 (m, 1, COCH), 3.69 (s, 3, OCH_3), 5.55 (m, 2, HC=C). Found: C, 70.38; H, 8.32%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%. **3b**: mp 88.0—89.0 °C (hexane); IR (Nujol) 3018, 1721 (ester C=O), 1698 (C=O), 1655 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 0.94 (d, 3, J=6.5 Hz, CH_3), 1.68—2.50 (m, 9, CH_2, CH), 2.69—3.10 (m, 1, COCH), 3.59 (s, 3, OCH_3), 5.60 (m, 2, HC=C). Found: C, 70.36; H, 8.32%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

*Conversion of **3a** into **3b**.* A mixture of **3a** (32 mg, 0.14 mmol) and MeONa (10 mg, 0.19 mmol) in MeOH (0.5 ml) was stirred for 24 h at room temperature and worked up in the usual manner to give 32 mg (100%) of **3b** as a solid.

*Methyl 1,1-Ethylenedioxy-4β-methyl-Δ^{6,7}-octalin-4a-carboxylate (**5a**).* A mixture of **3b** (420 mg, 1.89), ethylene glycol (2.3 g, 37.0 mmol), and *p*-toluenesulfonic acid (50 mg) in benzene (40 ml) was refluxed for 24 h in a Dean-Stark apparatus and worked up in the usual manner to give 466 mg (92%) of **5a** as an oil: bp 61.0—63.0 °C/0.01 Torr (Kugelrohr); IR (neat) 3022, 1727 (ester C=O), 1664 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 0.92—1.05 (m, 3, CH_3), 1.35—2.85 (m, 10, CH_2, CH), 3.62—3.80 (m, 3, OCH_3), 3.95 (br s, 4, CH_2O), 5.49—5.88 (m, 2, HC=C). Found: C, 67.57; H, 8.49%. Calcd for $C_{15}H_{22}O_4$: C, 67.65; H, 8.33%.

*4aβ-Hydroxymethyl-4β-methyl-Δ^{6,7}-octalin-1-one Ethylene Acetal (**5b**).* To a suspension of $LiAlH_4$ (50 mg, 1.32 mmol)

in THF (2 ml) was added a solution of **5a** (115 mg, 0.43 mmol) in THF (2 ml) at 0 °C. The mixture was stirred for 10 h at room temperature, quenched with AcOEt (1 ml) and 5% aqueous $NaHCO_3$, and worked up in the usual manner to give 95 mg (93%) of **5b** as an oil: bp 57.0—59.5 °C/0.005 Torr (Kugelrohr); IR (neat) 3450 (OH), 3021, 1660 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 0.79—1.09 (m, 3, CH_3), 1.18—2.64 (m, 10, CH_2, CH), 3.59 (br s, 1, OH), 3.00—3.70 (m, 2, CH_2O), 3.78—4.10 (m, 4, CH_2O), 5.60 (br s, 2, HC=C). Found: C, 70.68; H, 9.41%. Calcd for $C_{14}H_{22}O_3$: C, 70.56; H, 9.30%.

*4β-Methyl-4aβ-methylsulfonyloxymethyl-Δ^{6,7}-octalin-1-one Ethylene Acetal (**5c**).* A mixture of **5b** (386 mg, 1.62 mmol), $MeSO_2Cl$ (592 mg, 5.2 mmol), and pyridine (2.5 ml) was stirred for 2 h at 0 °C and for 3 h at room temperature, quenched with cold aqueous 5% $NaHCO_3$, and worked up in the usual manner to give 500 mg (97%) of **5c** as an oil: IR (neat) 3028, 1671 (C=C), 1175 cm^{-1} (SO_2); ^1H NMR (60 MHz) δ 0.92 (d, 3, J=7 Hz, CH_3), 1.40—2.59 (m, 10, CH_2, CH), 3.01 (s, 3, SO_2CH_3), 3.93 (s, 4, CH_2O), 4.29 (AB_q, 2, J=8 Hz, CH_2O), 5.63 (br s, 2, HC=C). Found: C, 57.11; H, 7.79%. Calcd for $C_{15}H_{24}O_5S$: C, 56.95; H, 7.65%.

*1,1-Ethylenedioxy-4β-methyl-Δ^{6,7}-octalin-4aβ-carbaldehyde (**5d**).* To a suspension of pyridinium chlorochromate (117 mg, 0.44 mmol) and AcONa (42 mg, 0.51 mmol) in CH_2Cl_2 (3 ml) was added a solution of **5b** (35 mg, 0.15 mmol) in CH_2Cl_2 (1 ml) at 0 °C. The mixture was stirred for 30 min at 0—5 °C and for 3 h at room temperature, diluted with ether, and passed through short silica gel column eluting with ether. The elute was concentrated and the residue was chromatographed (SiO_2, hexane–AcOEt 3:1) to give 29 mg (84%) of **5d** as an oil: bp 88.5—90.0 °C/0.015 Torr (Kugelrohr); IR (neat) 3015, 2750, 2680, 1712 (C=O), 1662 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 0.83—1.08 (m, 3, CH_3), 1.27—2.81 (m, 10, CH_2, CH), 3.85—4.01 (m, 4, CH_2O), 9.50, 10.02 (s, 1, CHO). Found: C, 71.31; H, 8.76%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

*4β-Methyl-4aβ-methylsulfonyloxymethyl-Δ^{6,7}-octalin-1-one (**6**).* A solution of **5c** (90 mg, 0.28 mmol) and 70% $HClO_4$ (90 mg) in THF (3 ml) and water (1.5 ml) was stirred for 1 h at 0 °C and for 10 h at room temperature and worked up in the usual manner to give 76 mg (98%) of **6**: IR (neat) 3033, 1710 (C=O), 1656 (C=C), 1177 cm^{-1} (SO_2); ^1H NMR (60 MHz) δ 0.92—1.34 (m, 3, CH_3), 1.57—2.78 (m, 10, CH_2, CH), 2.93, 3.02 (s, 3, SO_2CH_3), 4.18 (s, 2, CH_2O), 5.64 (m, 2, HC=C). Found: C, 57.30; H, 7.66%. Calcd for $C_{13}H_{20}O_4S$: C, 57.34; H, 7.40%.

*5,6-cis-5-Methyltricyclo[4.4.1.0^{1,6}]undec-8-en-2-one (**7**).* To a solution of **6** (257 mg, 0.95 mmol) in MeOH (2 ml) was added a solution of MeONa (254 mg, 4.7 mmol) in MeOH (2.5 ml). The mixture was stirred for 24 h at room temperature and worked up in the usual manner to give 139 mg (84%) of **7** as an oil: bp 40.5—42.0 °C/0.02 Torr (Kugelrohr); IR (neat) 3079, 3030, 1680 cm^{-1} (C=O); ^1H NMR (60 MHz) δ 0.76—2.83 (m, 11, CH_2, CH), 1.05 (d, 3, J=6 Hz, CH_3), 5.49—5.33 (m, 2, HC=C); ^{13}C NMR δ 14.4 (t, C-11), 18.4 (q, C-12), 25.1 (t, C-10), 26.7 (t, C-4), 29.4 (t, C-7), 31.6 (s, C-6), 32.9 (d, C-5), 34.2 (s, C-1), 36.4 (t, C-3), 122.2, 123.6 (d, C-9, C-8), 210.1 (s, C-2). Found: C, 81.84; H, 9.03%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

trans-*4β,4aβ-Dimethyl-Δ^{6,7}-octalin-1-one (**8**) and 5,6-cis-5-Methylbicyclo[4.4.1]undec-8-en-2-one (**9**).* To a blue solution of lithium (84 mg, 12.1 mmol) in liquid NH_3 (*ca.* 30 ml) was added a solution of **7** (245 mg, 1.39 mmol) and *t*-BuOH (104 mg, 1.39 mmol) in DME (4 ml). After being stirred for 1.5 h at −78 °C, the blue solution was quenched with NH_4Cl (500 mg), allowed to stand at room temperature until liquid NH_3 had evaporated, and worked up in the usual manner. The crude product was chromatographed (SiO_2, hexane–AcOEt 4:1) to give 202 mg (83%) of **8** (R_f 0.8, hexane–AcOEt 2:1) and 24 mg (10%) of **9** (R_f 0.5). Physical constants together with elemental analyses of **8** and **9** are as follows: **8**, bp 38.0—39.5 °C/0.02 Torr (Kugelrohr); IR (neat) 3025, 1711 (C=O), 1658 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 0.63 (s, 3, CH_3), 0.91 (d, 3, J=6 Hz, CH_3), 1.53—2.56 (m, 10, CH_2, CH), 5.63 (m, 2, HC=C). Found: C, 80.94; H, 10.27%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%. **9**: mp 91.0—95.0 °C; IR (Nujol) 3019, 1698 (C=O), 1656 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 0.93 (m, 3, CH_3), 1.05—2.56 (m, 13, CH_2, CH), 5.65 (m, 2, HC=C). Found: C, 80.94; H, 9.94%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

trans-*4β,4aβ-Dimethyl-Δ^{6,7}-octalin-1-one Ethylene Acetal (**10**).* A mixture of **8** (131 mg, 0.73 mmol), ethylene glycol (700 mg, 11.3 mmol), and *p*-toluenesulfonic acid (40 mg) in benzene (30 ml) was refluxed for 24 h in a Dean-Stark apparatus and worked up in the usual manner to give 158 mg (97%) of **10** as an oil: bp 73.0—75.0 °C/0.03 Torr (Kugelrohr); IR (neat) 3020, 1559 (C=C), 1159, 1092, 1040, 985, 897 cm^{-1}; ^1H NMR (100 MHz) δ 0.81 (s, 3, CH_3), 0.84 (d, 3, J=6 Hz, CH_3), 1.10—2.44 (m, 10, CH_2, CH), 3.72—4.04 (m, 4, CH_2O), 5.61 (br s, 2, HC=C). Found: C, 75.64; H, 10.03%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

trans-*4β,4aβ-Dimethyl-Δ^{6,7}-octalin-1β-ol (**12**).* To a suspension of $LiAlH_4$ (64 mg, 1.69 mmol) in THF (2 ml) was added a solution of **8** (100 mg, 0.56 mmol) in THF (2 ml) at 0 °C. The mixture was stirred for 1 h at 0—5 °C and for 9 h at room temperature, and worked up in the usual manner to give 91 mg (90%) of **12** as white crystals: mp 52.5—53.5 °C; IR (Nujol) 3330 (OH), 3012, 1658 cm^{-1} (C=C); ^1H NMR (60 MHz) δ 0.86 (complex d, 3, J=5 Hz, CH_3), 0.88 (s, 3, CH_3), 1.07—2.65 (m, 10, CH_2, CH), 1.64 (s, 1, OH), 3.76 (m, 1, CHO), 5.55 (m, 2, HC=C). Found: C, 79.68; H, 10.99%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

trans-*6α,7α-Epoxy-4β,4aβ-dimethyldecalin-1β-ol (**13a**).* To a solution of *m*-CPBA (208 mg, 1.21 mmol) in CH_2Cl_2 (3 ml) was added a solution of **12** (128 mg, 0.71 mmol) in CH_2Cl_2 (1 ml) at 0 °C. The mixture was stirred for 1 h at 0 °C and for 20 h at 5 °C, washed with aqueous 10% $Na_2S_2O_3$ (3 ml), aqueous 5% NaOH, and brine, dried (Na_2SO_4), and concentrated. The crude product was chromatographed (SiO_2, hexane–AcOEt 2:1) to give 127 mg (91%) of **13a** as an oil: bp 37.0—38.0 °C/0.0075 Torr (Kugelrohr); IR (neat) 3444 (OH), 3020, 1258, 1227, 1150, 1043, 1013 cm^{-1}; ^1H NMR (60 MHz) δ 0.82 (unresolved m, 3, CH_3), 0.88 (s, 3, CH_3), 1.07—2.26 (m, 11, CH_2, CH, OH), 2.98—3.36 (m, 2, CHO), 3.70 (br s, 1, CHO). Found: C, 73.59; H, 10.45%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%.

trans-*6α,7α-Epoxy-4β,4aβ-dimethyldecalin-1β-ol Tetrahydropyranyl Ether (**13b**).* A mixture of **13a** (123 mg, 0.63 mmol), 2,3-dihydropyran (1.01 g, 11.9 mmol), and pyridinium *p*-toluenesulfonate[18] (79 mg, 0.31 mmol) in CH_2Cl_2 was stirred for 20 h at room temperature, diluted with ether (5 ml), and worked up in the usual manner. The crude product was chromatographed (SiO_2, hexane–AcOEt 4:1) to give 136 mg (77%) of **13b** as an oil: bp 63.0—66.0 °C/0.004 Torr (Kugelrohr); IR (neat) 1439, 1352, 1202, 1129, 1072, 1031, 1022 cm^{-1}; ^1H NMR (60 MHz) δ 0.70—0.99 (m, 3, CH_3), 0.88 (s, 3, CH_3), 1.06—2.41 (m, 16, CH_2, CH), 2.97—3.33 (m, 2, CHO), 3.33—4.18 (m, 3, CH_2O, CHO),

4.43—5.54 (m, 1, CHO). Found: C, 72.59; H, 10.09%. Calcd for $C_{17}H_{28}O_3$: C, 72.82; H, 10.06%.

trans-*7α-Hydroxy-4β,4aβ-dimethyldecalin-1β-ol Tetrahydropyranyl Ether (**14a**).* To a blue solution of lithium (84 mg, 12.1 mmol) in liquid NH_3 (*ca.* 25 ml) was added a solution of **13b** (136 mg, 0.48 mmol) in DME (4 ml). The mixture was stirred for 1 h at −78 °C and for 1.5 h at −33 °C, quenched with NH_4Cl (500 mg), and worked up in the usual manner. The crude product was chromatographed (SiO_2, hexane–AcOEt 2:1) to give 116 mg (85%) of **14a** as an oil: bp 123.0—126.0 °C/0.005 Torr (Kugelrohr); IR (neat) 3370 (OH), 1255, 1200, 1132, 1110, 1077, 1056, 1022, 1000 cm^{-1}; ^1H NMR (60 MHz) δ 0.80 (unresolved d, 3, J=6 Hz, CH_3), 0.87 (s, 3, CH_3), 1.08—2.17 (m, 19, CH_2, CH, OH), 3.26—4.00 (m, 3, CH_2O, CHO), 4.12 (m, 1, CHO), 4.45—4.73 (m, 1, CHO). Found: C, 72.16; H, 10.78%. Calcd for $C_{17}H_{30}O_3$: C, 72.30; H, 10.71%.

trans-*8β-Tetrahydropyranyloxy-4aβ,5β-dimethyldecalin-2-one (**14b**).* To a suspension of pyridinium chlorochromate (299 mg, 1.12 mmol) and AcONa (183 mg, 2.23 mmol) in CH_2Cl_2 (3 ml) was added a solution of **14a** (105 mg, 0.37 mmol) in CH_2Cl_2 (2 ml) at 0 °C. After being stirred for 0.5 h at 0—5 °C and for 3 h at room temperature, the mixture was diluted with ether (3 ml) and passed through a short silica gel column eluting with ether. The elute was concentrated and the residue was chromatographed (SiO_2, hexane–AcOEt 2:1) to give 97 mg (93%) of **14b** as an oil: bp 96.0—99.0 °C/0.01 Torr (Kugelrohr); IR (neat) 1710 cm^{-1} (C=O); ^1H NMR (60 MHz) δ 0.91 (d, 3, J=5 Hz, CH_3), 1.09 (s, 3, CH_3), 1.28—2.99 (m, 18, CH_2, CH), 3.27 (m, 3, CH_2O, CHO), 4.41—4.74 (m, 1, CHO). Found: C, 72.91; H, 10.15%. Calcd for $C_{17}H_{28}O_3$: C, 72.82; H, 10.06%.

trans-*8β-Hydroxy-4aβ,5β-dimethyldecalin-2-one (**15a**).* A solution of **14b** (96 mg, 0.34 mmol) and pyridinium *p*-toluenesulfonate (20 mg, 0.08 mmol) in EtOH (3 ml) was stirred for 20 h at 60—63 °C. The mixture was concentrated and the residue was chromatographed (SiO_2, hexane–AcOEt 2:1) to give 64 mg (95%) of **15a** as a white solid: mp 87.0—88.5 °C; IR (Nujol) 3405 (OH), 1695 cm^{-1} (C=O); ^1H NMR (100 MHz) δ 0.91 (d, 3, J=6 Hz, CH_3), 1.13 (s, 3, CH_3), 1.25—2.09 (m, 8, CH_2, CH), 2.00 (s, 1, OH), 2.13—2.99 (m, 4, CH_2CO), 3.76 (br s, 1, CHO); ^{13}C NMR δ 13.2 (q, C-9), 15.6 (q, C-10), 25.3 (t, C-6), 34.2 (t, C-7), 35.9 (s, C-4a), 38.2 (t, C-3), 39.6 (t, C-4), 42.1 (d, C-8a), 42.1 (t, C-1), 42.7 (d, C-5), 70.7 (d, C-8), 213.3 (s, C-2). Found: C, 73.26; H, 9.99%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%.

trans-*4aβ,5β-Dimethyl-8β-methylsulfonyloxydecalin-2-one (**15b**).* A mixture of **15a** (60 mg, 0.31 mmol), $MeSO_2Cl$ (178 mg, 1.55 mmol), and pyridine (1.5 ml) was stirred for 1 h at 0 °C and for 2 h at room temperature, quenched with cold water and worked up in the usual manner to give 73 mg (88%) of **15b**; IR (neat) 1710 (C=O), 1378, 1178 cm^{-1} (SO_2); ^1H NMR (100 MHz) δ 0.94 (d, 3, J=6 Hz, CH_3), 1.08 (s, 3, CH_3), 1.17—2.87 (m, 12, CH_2, CH), 3.00 (s, 3, SO_2CH_3), 4.72 (m, 1, CHO). Found: C, 57.06; H, 8.28%. Calcd for $C_{13}H_{22}O_4S$: C, 56.92; H, 8.08%.

*4aβ,5β-Dimethyl-$\Delta^{1,8a}$-octalin-2-one (**16a**).* A mixture of **15b** (73 mg, 0.266 mmol) and DMSO (2 ml) was heated at 130—140 °C for 2 h, and worked up in the usual manner. The crude product was chromatographed (SiO_2, hexane–AcOEt 3 : 1) to give 33 mg (64%) of **16a** as an oil: bp 72.5—75.0 °C/0.02 Torr (Kugelrohr) (lit,[17] 96.0—99.0 °C/0.2 Torr); IR (neat) 1675 (C=O), 1615 (C=C), 1235, 1188, 1030, 955, 877 cm^{-1}; ^1H NMR (60 MHz) δ 0.93 (unresolved d, 3, J=6 Hz, CH_3), 1.10 (s, 3, CH_3), 1.10—2.53 (m, 11, CH_2, CH), 5.69 (br s, 1, HC=C); ^{13}C NMR δ 15.3 (q, C-10), 16.0 (q, C-9), 26.5 (t, C-7), 30.5 (t, C-8), 33.3 (t, C-6), 34.0 (t, C-3), 35.5 (t, C-4), 39.0 (s, C-4a), 43.2 (d, C-5), 124.0 (d, C-1), 171.4 (s, C-8a), 199.7 (s, C-2).

*3α-(1-Hydroxy-1-methylethyl)-4aβ,5β-dimethyl-$\Delta^{1,8a}$-octalin-2-one (**16b**).* To a stirred solution of *i*-Pr_2NLi (103 mg, 0.96 mmol) in THF (1.5 ml) was added a solution of **16a** (19 mg, 0.11 mmol) in THF (0.5 ml). After being stirred for 40 min at −78 °C, a solution of $ZnCl_2$ (14 mg, 0.11 mmol) in ether (0.5 ml) was added and to this mixture acetone (62 mg, 1.1 mmol) was added. The mixture was stirred for 10 min, quenched with cold aqueous 5% tartaric acid, and extracted with ether–benzene. The extract was washed with brine, dried (Na_2SO_4), and concentrated. The residue was chromatographed (SiO_2, hexane–AcOEt 4:1) to give 20 mg (79%) of **16b**; IR (neat) 3440 (OH), 3027, 1650 (C=O), 1626 cm^{-1} (C=C); ^1H NMR (100 MHz) δ 0.93 (unresolved d, 3, J=6 Hz, CH_3), 1.14 (s, 3, CH_3), 1.23 (s, 6, CH_3), 1.29—2.62 (m, 10, CH_2, CH), 4.72 (br s, 1, OH), 5.70 (s, 1, HC=C); ^{13}C NMR δ 15.1 (q, C-10), 15.9 (q, C-9), 24.6 (q, C-12), 26.2 (t, C-7), 28.3 (q, C-13), 30.4 (t, C-8), 32.9 (t, C-6), 38.6 (t, C-4), 39.6 (s, C-4a), 43.6 (d, C-5), 51.2 (d, C-3), 72.4(s, C-11), 124.6 (d, C-1), 172.0 (s, C-8a), 203.3 (s, C-2), Found: C, 76.33; H. 10.37%. Calcd for $C_{15}H_{24}O_2$: C, 76.32; H, 10.24%.

dl-*Dehydrofukinone (**1**).* To a solution of **16b** (18 mg, 0.076 mmol) in pyridine (0.5 ml) was added $MeSO_2Cl$ (74 mg, 0.65 mmol) at 0 °C. The mixture was stirred for 2 h at room temperature and for 2 h at 40—45 °C, quenched with cold water, and worked up in the usual manner. The crude product was chromatographed (SiO_2, hexane–AcOEt 4:1) to give 12 mg (72%) of a mixture of double bond isomers **17** (3-isopropenyl:3-isopropylidene *ca.* 5:1 based on ^1H NMR): bp 47.0—52.0 °C/0.01 Torr (Kugelrohr); IR (neat) 1674 (C=O), 1624 (C=C), 883 cm^{-1}; ^1H NMR (60 MHz) δ 4.83, 4.98 (br s, HC=C). Without further separation of the double bond isomers, **17** was passed through an activated alumina 300 (Nakarai Chemicals) column (10 g) with hexane–AcOEt (10:1) to give **1** in a quantitative yield: bp 48.0—53.0 °C/0.01 Torr (Kugelrohr); IR (neat) 1663 (C=O), 1629 (C=C), 1459, 1439, 1373, 1294, 1221, 1196, 1101, 1035, 884, 846 cm^{-1}; ^1H NMR (100 MHz) δ 0.92 (unresolved m, 3, CH_3), 0.97 (s, 3, CH_3), 1.16—1.66 (m, 5, CH_2, CH), 1.85, 2.09 (s, 3, $C=C(CH_3)_2$), 2.16—2.40 (m, 5, CH_2), 2.88 (d, 1, J= 14 Hz, COCH), 5.76 (s, 1, HC=C); ^{13}C NMR δ 15.4 (q, C-10), 16.0 (q, C-9), 22.0 (q, C-12), 22.5 (q, C-13), 26.5 (t, C-7), 30.5 (t, C-8), 32.5 (t, C-6), 41.0 (t, C-4), 41.9 (s, C-4a), 42.5 (d, C-5), 126.1 (d, C-1), 128.1 (s, C-3), 142.1(s, C-11), 168.6 (s, C-8a), 192.2 (s, C-2).

*Conversion of **17** into **1** with $RhCl_3 \cdot 2H_2O$.* A solution of **17** (26 mg, 0.12 mmol) and $RhCl_3 \cdot 2H_2O$ (2 mg, 0.008 mmol) in EtOH (2.5 ml) was heated at 95—100 °C for 6 h in a sealed tube. The mixture was concentrated and the residue was chromatographed (SiO_2, hexane–AcOEt 4:1) to give 18 mg (86%) of **1**.

Synthesis of α-Trialkylsilyl Ketones[1,2]

Michio OBAYASHI, Kiitiro UTIMOTO,* and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received February 19, 1979)

The isomerization of 2-trimethylsilyl-2,3-dialkyloxiranes occurs in the presence of MgI_2 to give α-trimethylsilyl ketones only, if one starts from (2*S**,3*S**)-isomers. In contrast, however, the reaction of (2*S**,3*R**)-oxiranes produces enol silyl ethers in addition to α-trimethylsilyl ketones. The reaction proceeds *via* the Mg salts of regio- and stereoselectively produced β-iodo-β-trimethylsilyl alcohols, each diastereomer of which behaves differently. Remarkably, Li salts of both iodohydrins [(2*S**,3*S**)- and (2*S**,3*R**)-isomers] give α-trimethylsilyl ketones exclusively. This provides efficient procedures for preparing α-trimethylsilyl ketones from a mixture of diastereomeric silyloxiranes.

Organosilicon chemistry has contributed much to the development of modern methodology of organic synthesis.[3] Particularly, α-trialkylsilyl ketones (IV) have attracted considerable attention as precursors for olefins with predictable geometry.[4,5] The preparation of IV usually involves acylation of α-trimethylsilyl Grignard compounds[6] or oxidation of the β-trimethylsilyl alcohols,[4] as direct silylation of the corresponding ketones gives none of the expected products.[7] This article describes a synthetic route to IV including the rearrangement of silyloxiranes (II and VI) as a key step.

The rearrangement of II and VI proceeds in the presence of MgI_2.[1a,8] The required oxiranes are readily accessible from internal olefins silylated on sp^2 carbon (I and V).[9]

For example, oxidation of (*E*)-5-trimethylsilyl-4-decene (Ic)[9g] with *m*-chloroperbenzoic acid gave IIc in 86% yield. Treatment of IIc with MgI_2 (10 equiv.) in ether at reflux afforded 5-trimethylsilyl-4-decenone (IVc) in 72% yield (Scheme 1 and Table 1).

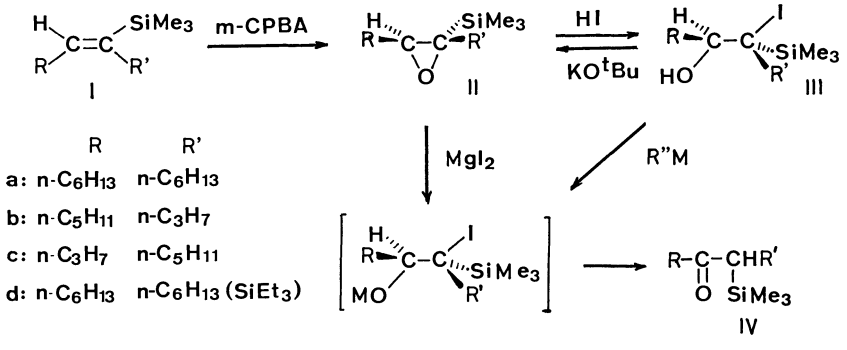
Table 1. Reaction of silyloxiranes with MgI_2

Oxirane	Isomeric purity %	Products	
		IV (%)	VIII (%)
IIa	>99	93 (quant.)[a]	0
VIa	91	48	9
IIb	>99	74	0
VIb	96	40	18
IIc	>99	72	0

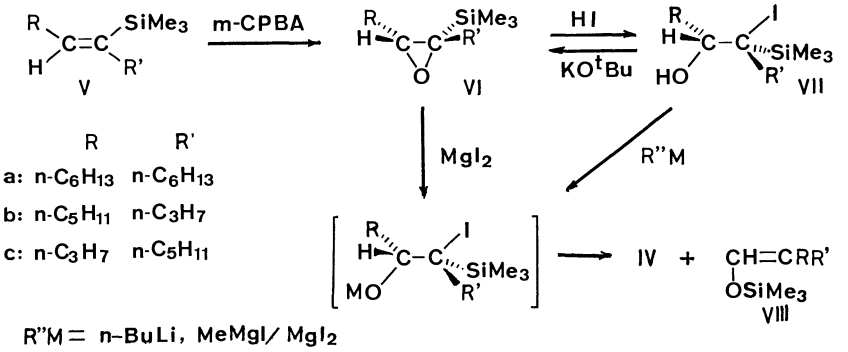
a) The yield in parentheses is that before purification.

In contrast with II the corresponding diastereomer VI gave a mixture of IV and trimethylsilyl enolate VIII (Scheme 2).

Regioselective formation of IV should be ascribed to the oxirane cleavage at the silylated carbon to oxygen bond followed by the hydride shift to that carbon. Furthermore, oxirane cleavage accompanied by R migration and the 1,3 shift of Me_3Si group from carbon to oxygen should explain the formation



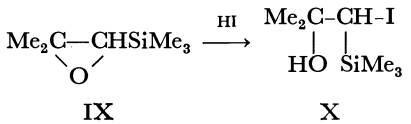
Scheme 1.



Scheme 2.

of VIII. Reasonable accounts for the observed reactivity difference between II and IV have stemmed from the following investigations.

As known already, the reaction of trimethylsilyloxiranes with $MgBr_2$ or HBr gives β-bromo-β-trimethylsilylalkanols, regio- and stereoselectively.[8,10e-g] We have found that treatment of IIa with aq HI gives iodohydrin IIIa in a quantitative yield.[13] Silyloxiranes VIa and VIc were transformed analogously into iodohydrins VIIa and VIIc, respectively. Furthermore, Scheme 3 shows that IX gives X, with the preferential cleavage of O–$CHSiMe_3$ bond.[14]



Scheme 3.

This is in contrast to the general belief that silicon stabilizes β-carbocation instead of the plus charge on the carbon directly attached to silicon.[3] The stereochemistry of the iodohydrins was established by regeneration of the starting silyloxiranes by the action of KO^tBu. All observations indicate that iodide ion is attached regio- and stereoselectively to the silylated carbon upon iodohydrin formation.

The iodohydrins III and VII thus obtained were treated with an organometallic reagent R″M. For example, reaction of IIIa with *n*-BuLi (1 equiv.) in ether gave IVa in a quantitative yield (Table 2).[15] Unexpectedly analogous treatment of the diastereomer VIIa afforded the same product IVa in 90% yield. It is remarkable that both diastereomeric iodohydrins give the same α-trimethylsilyl ketone in excellent yields.[16] α-Triethylsilyl ketone (IVd) could also be obtained from IIId. These and other results are listed in Table 2.

The silylated olefins (I and V) are prepared by the alkylation of C≡CSi moiety.[9a-d,9g] Furthermore, the silylated ketones (IV) are transformed into trisubstituted ethylenes by the published procedure stereoselectively.[5] The present study, therefore, links two synthetic sequences to afford a means of preparing trisubstituted ethylenes of any desired stereochemistry starting from silylacetylenes.

Remarkably, treatment of IIIa with MeLi in THF gave predominantly the starting silyloxirane (IIa) instead of α-silyl ketone (IVa) obtained above. Solvent effect must play an important role in the reaction of Li salt of iodohydrin. The O–Li should have become more nucleophilic in THF than in ether.

Furthermore, Mg salts of diastereomeric iodohydrins behaved differently from Li salts. Treatment of IIIa with MeMgI (1 equiv.) and MgI_2 (10 equiv.) at reflux gave IVa[17] in 92% yield. The diastereomeric iodohydrin (VIIa), however, was transformed into a mixture of IVa (29%) and trimethylsilyl enolate VIIIa (43%).

The rearrangement of silyloxiranes in the presence of MgI_2 showed similar product distributions depending on the sorts of the starting diastereomers. Furthermore, treatment of IIa with MgI_2 at room temperature provided IIIa (28%) along with IVa (30%). These observations indicate that the Mg salt of iodohydrin should be an intermediate[18,19] in the MgI_2 reaction giving IV or VIII in the subsequent step.

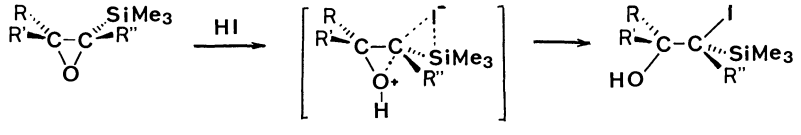
The relative orientations of the C–Si and the C–O bonds deviate markedly from the coplanar alignment which favors the β-carbocation stabilized by the C–Si bond.[3] The preference for oxirane cleavage at the silylated carbon with inversion in the iodohydrin formation suggests that the silyl group actually facilitates bimolecular nucleophilic displacements at the carbon attached to silicon.[20,21] Penta-coordinated silicon intermediate explains the observations,[22] as shown in Scheme 4.

Rearrangement of iodohydrin to α-trialkylsilyl ketone is ascribed to MI-elimination under 1,2-hydrogen

Table 2. Conversion of silyloxiranes to IV and VIII *via* iodohydrins III and VII

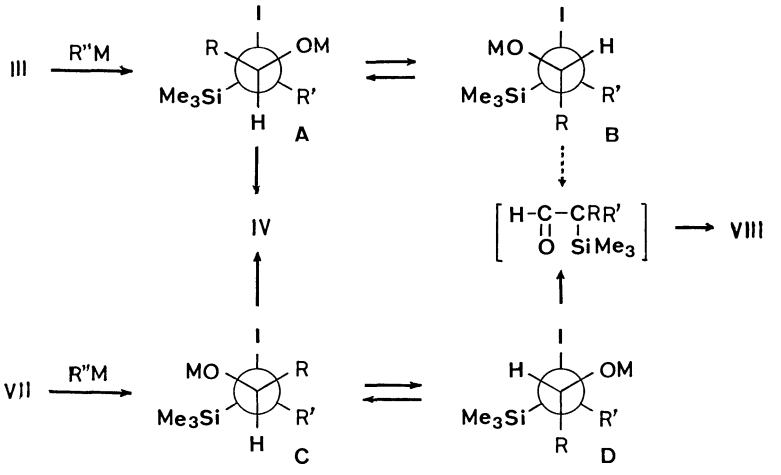
Oxirane	Isomeric purity %	Iodohydrin %	Reagent (R″M)	Products	
				IV (%)	VIII (%)
IIa	>99	IIIa, quant.	*n*-BuLi	(quant.)[a]	0
VIa	91	VIIa, 94	*n*-BuLi	90 (99)[a]	0
IIb	>99	IIIb, (92)[a]	*n*-BuLi	(quant.)[a]	0
IId	>99	IIId, (quant.)[a]	*n*-BuLi	87	0
VIc	97	VIIc, (92)[a]	*n*-BuLi	(quant.)[a]	0
IIa	>99	IIIa, quant.	$MeMgI/MgI_2$	92	0
VIa	91	VIIa, 94	$MeMgI/MgI_2$	29	43

a) Yields in parentheses are those before purification. The crude products were almost pure on GLPC, TLC, and NMR analysis.



(One of R, R', and R" is H)

Scheme 4.

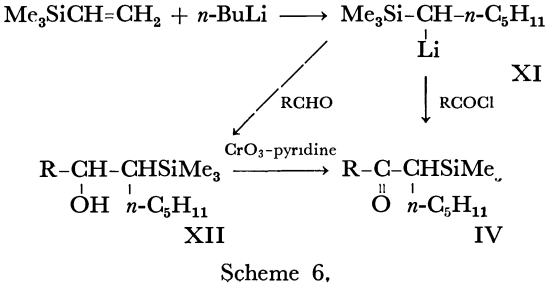


Scheme 5.

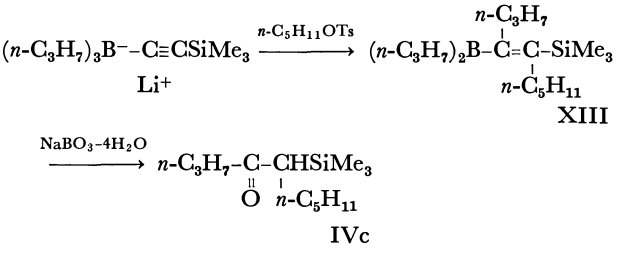
migration, while the one affording IV is accounted for by assuming MI elimination under 1,2-migration of R and the subsequent 1,3-migration of Me_3Si group (Scheme 5). The observed selectivity is explained on the following assumption: (i) migratory aptitude H> R; (ii) anti conformation of the migrating group and iodine;[23] (iii) Me_3Si>R, I in effective size; (iv) if M=Li, **A** (→IV)>**B** (→VIII) and **C** (→IV)>**D** (→VIII) in populations as R>OLi>H in effective size; (v) if M=MgI, **A**>**B** but **C**<**D** as OMgI and Me_3Si should be in anti positions each other because of the larger effective size of OMgI group. Possibly $\Delta F^{\ddagger}$ (**D**→VIII) is comparable with $\Delta F^{\ddagger}$ (**D**→**C**→IV).

Finally, other methods for obtaining α-trialkylsilyl ketones have been studied.

The procedure *via* β-trimethylsilyl alcohols XII (Scheme 6) reported by Hudrlik[4] was reinvestigated and applied to the synthesis of α-triethylsilyl ketones. Furthermore, T. H. Chan and his coworkers have reported that the reaction of α-silylalkyllithium with acid chlorides afforded, after hydrolysis with dilute hydrochloric acid, the desilylated ketones in moderate yield.[24] This reaction must proceed *via* α-silyl ketone, which is easily desilylated in acidic conditions. It was expected that careful work-up should afford α-silyl ketones. Indeed, 1-trimethylsilylhexyllithium (XI) was prepared by the addition of *n*-BuLi to $Me_3SiCH{=}CH_2$ and treated with butyryl chloride to give IVc in 45% yield (Scheme 6). Analogously 1-trimethylsilylhexylcopper obtained from XI and one equivalent of CuI afforded IVc in 71% yield. Reaction of XI with acetyl chloride gave 3-trimethylsilyl-2-octanone in 17% yield. On the other hand reaction of 1-triethylsilylhexyllithium prepared from *n*-BuLi and



Scheme 6.



Scheme 7.

$Et_3SiCH{=}CH_2$ with butyryl chloride gave no desired product.

α-Trimethylsilyl ketone (IVc) has alternatively been obtained by the mild oxidation of 4-dipropylboryl-5-trimethylsilyl-4-decene (XIII)[25] with $NaBO_3$–$4H_2O$ in 57% overall yield (Scheme 7).

Experimental

Gas chromatography was performed on Shimadzu GC-4BPT with 3 m×3 mm glass column packed with 20% polyethylene glycol and 20% HVSG on Chromosorb W-AW (80—100 mesh). Mass spectra were obtained on Hitachi RMU-6L with 70V chamber voltage, NMR were measured on Varian EM-360, JEOL JNM-PMX 60, and Varian EM-390 with Me_4Si as internal standard and CCl_4 as solvent. ^{13}C-NMR on Varian CFT-20 with Me_4Si as internal standard and $CDCl_3$ as solvent. IR on Shimadzu IR-27G spectrometer. Elemental microanalyses were performed by Elemental Analyses Center of Kyoto University. All the reactions were carried out under an atmosphere of dry argon. All mass spectra were those of the samples after gas chromatographic separation.

Silylated Olefins I and V. (E)-7-Trimethylsilyl-7-tetradecene (Ia, R=R'=n-C_6H_{13}): The chloroplatinic acid-catalyzed reaction of trichlorosilane and 7-tetradecyne and the following treatment with MeMgI gave Ia in 70% yield (E>99%).[26,27] Bp 120 °C/0.07 mmHg; IR (neat) 1611, 1200, 830, 747, 685 cm^{-1}; MS *m/e* (rel. %), 268 (M^+, 0.4), 253 (8), 194 (13), 96 (13), 73 (100), 59 (21); NMR (CCl_4) δ=0.00 (9H, s), 0.67—1.07 (6H, m), 1.07—1.70 (16H, m), 1.70—2.30 (4H, m), 5.58 (1H, br-t, J=7 Hz).

Found: C, 76.20; H, 13.46%. Calcd for $C_{17}H_{36}Si$: C, 76.03; H, 13.51%.

(E)-7-Triethylsilyl-7-tetradecene (Id, $R=R'=$n-C_6H_{13}): Yield, 77%; $E>99\%$; IR (neat) 1610, 1232, 1010, 722 cm^{-1}; NMR (CCl_4) δ=0.30—1.70 (37H, m), 1.70—2.35 (4H, m), 5.62 (1H, t, J=6 Hz).

Found: C, 77.39; H, 13.39%. Calcd for $C_{20}H_{42}Si$: C, 77.33; H, 13.63%.

Silylated Olefins I ($R\neq R'$). These materials were prepared by the double alkylation of $HC\equiv CSiMe_3$.[9g]

Silylated Olefins V ($R=R'$ and $R\neq R'$). These compounds were prepared by the reductive alkylation of the corresponding $RC\equiv CSiMe_3$ according to the reported procedure.[9c,d]

(Z)-7-Trimethylsilyl-7-tetradecene (Va, $R=R'=$n-C_6H_{13}):[9d] Yield, 95%; E/Z=9/91; bp 120 °C/0.07 mmHg.

(Z)-4-Trimethylsilyl-4-decene (Vb, R=n-C_5H_{11}, R'=n-C_3H_7): Yield, 79%; E/Z=4/96; bp 100 °C/10 mmHg; IR (neat) 1611, 1240, 830, 750, 682 cm^{-1}; MS *m/e* (rel. %), 212 (M^+, 2), 197 (24), 169 (3), 156 (4), 155 (4), 138 (20), 127 (8), 113 (8), 99 (10), 73 (100), 59 (30); NMR (CCl_4) δ=0.08 (9H, s), 0.67—1.05 (6H, m), 1.05—1.67 (8H, m), 1.70—2.30 (4H, m), 5.85 (1H, br-t, J=7 Hz).

Found: C, 73.68; H, 13.54%. Calcd for $C_{13}H_{28}Si$: C, 73.50; H, 13.28%.

(Z)-5-Trimethylsilyl-4-decene (Vc, R=n-C_3H_7, R'=n-C_5H_{11}): Yield, 72%; E/Z=3/97; bp 118—122 °C/20 mmHg; IR (neat) 1610, 1240, 837, 758, 690 cm^{-1}; MS *m/e* (rel. %), 212 (M^+, 0.2), 197 (11), 169 (3), 155 (2), 138 (14), 127 (7), 113 (6), 101 (3), 99 (8), 95 (7), 82 (9), 74 (10), 73 (100), 59 (28), 45 (12), 43 (7), 41 (5); NMR (CCl_4) δ=0.10 (9H, s), 0.90 (6H, t, J=6 Hz), 1.10—1.60 (8H, m), 1.80—2.25 (4H, m), 5.85 (1H, br-t, J=7 Hz).

Found: C, 73.45; H, 13.00%. Calcd for $C_{13}H_{28}Si$: C, 73.50; H, 13.28%.

1-Trimethylsilyl-1-alkynes. These precursors of silylated olefins V[9c,d] were obtained by the usual trimethylsilylation of the corresponding alkynyl Grignard compounds. 1-Trimethylsilyl-1-pentyne was, however, prepared by the following procedure. To a solution of $Me_3SiC\equiv CSiMe_3$ (3.3 g, 19 mmol) in 15 ml of THF and 13 ml of HMPA was added MeLi (21 mmol, 14 ml of 1.48 M ethereal solution) at −78 °C. The mixture was warmed up to 0 °C and stirred for 1 h at 0 °C. The resulting mixture was treated with *n*-PrBr (2.0 ml, 22 mmol), stirred for 3 h at a room-temperature, and poured into aq NH_4Cl overlaid with hexane. The hexane layer was washed (aq NH_4Cl, sat. NaCl), dried ($MgSO_4$), and concentrated, affording 1.5 g (56%) of *n*-$C_3H_7C\equiv CSiMe_3$.

2-Trialkylsilyl-2,3-dialkyloxiranes II and VI. These oxiranes were prepared by *m*-CPBA oxidation of the corresponding silylated olefins.

(2S,3S*)-2-Trimethylsilyl-2-pentyl-3-propyloxirane (IIc, R=n-C_3H_7, R'=C_5H_{11})*: To a solution of *m*-chloroperbenzoic acid (85% purity, 1.2 g, 6.0 mmol) in CH_2Cl_2 was added (*E*)-5-trimethylsilyl-4-decene (Ic, 1.0 g, 4.9 mmol) at 0 °C. The mixture was poured into aq K_2CO_3 overlaid with ether. The ether layer was washed (aq K_2CO_3, sat. NaCl) and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (benzene) afforded IIc (0.96 g). Yield, 86%; >99% purity; bp 72—77 °C/3 mmHg; IR (neat) 1243, 839, 752, 693 cm^{-1}; MS *m/e* (rel. %), 228 (M^+, 0.5), 213 (2), 199 (13), 185 (3), 171 (5), 143 (4), 130 (11), 113 (4), 75 (29), 73 (100), 59 (15), 43 (9); NMR (CCl_4) δ=0.00 (9H, s), 0.67—1.10 (6H, m), 1.10—1.70 (12H, m), 2.45—2.70 (1H, m).

Found: C, 68.60; H, 12.62%. Calcd for $C_{13}H_{28}OSi$: C, 68.35; H, 12.35%.

(2S,3S*)-2-Trimethylsilyl-2,3-dihexyloxirane (IIa, R=R'=n-C_6H_{13})*: Yield, 68%; >99% purity; oil; IR (neat) 1241, 834, 747 cm^{-1}; MS *m/e* (rel. %), 284 (M^+, 1), 269 (2), 227 (6), 213 (23), 199 (4), 185 (4), 155 (7), 143 (17), 130 (14), 129 (9), 113 (5), 95 (5), 75 (28), 73 (100), 59 (13), 43 (14); NMR (CCl_4) δ=0.00 (9H, s), 0.67—1.05 (6H, m), 1.05—1.65 (20H, m), 2.40—2.70 (1H, m); ^{13}C-NMR ($CDCl_3$) δ=−2.94, 14.06, 22.64, 26.34, 27.03, 28.20, 29.37, 30.08, 30.87, 31.77, 31.89, 57.16, 60.59.

Found: C, 71.91; H, 12.93%. Calcd for $C_{17}H_{36}OSi$: C, 71.76; H, 12.75%.

(2S,3S*)-2-Trimethylsilyl-2-propyl-3-pentyloxirane (IIb, R=n-C_5H_{11}, R'=n-C_3H_7)*: Yield, 86%; >99% purity; bp 70—75 °C/3 mmHg; IR (neat) 1239, 830, 746 cm^{-1}; MS *m/e* (rel. %), 228 (M^+, 0.4), 213 (2), 199 (1), 185 (1), 171 (29), 143 (8), 130 (7), 113 (15), 75 (28), 73 (100), 59 (13), 43 (9); NMR (CCl_4) δ=0.00 (9H, s), 0.65—1.13 (6H, m), 1.13—1.65 (12H, m), 2.45—2.73 (1H, m).

(2S,3R*)-2-Trimethylsilyl-2-propyl-3-pentyloxirane (VIb, R=n-C_5H_{11}, R'=n-C_3H_7)*: Yield, 93%; 96% purity; oil; IR (neat) 1243, 840, 756, 693 cm^{-1}; MS *m/e* (rel. %), 228 (M^+, 1), 213 (2), 199 (2), 185 (2), 171 (27), 157 (3), 143 (10), 130 (7), 113 (20), 75 (32), 73 (100), 59 (15), 43 (10); NMR (CCl_4) δ=0.08 (9H, s), 0.70—1.10 (6H, m), 1.10—1.80 (12H, m), 2.40—2.67 (1H, m).

Found: C, 68.23; H, 12.47%. Calcd for $C_{13}H_{28}OSi$: C, 68.35; H, 12.35%.

(2S,3R*)-2-Trimethylsilyl-2-pentyl-3-propyloxirane (VIc, R=n-C_3H_7, R'=n-C_5H_{11})*: Yield, 68%; 97% purity; oil; IR (neat) 1240, 840, 755, 690 cm^{-1}; MS *m/e* (rel. %), 228 (M^+, 0.3), 213 (1), 199 (12), 185 (3), 171 (7), 157 (2), 143 (4), 141 (11), 130 (10), 129 (7), 115 (5), 113 (5), 99 (7), 85 (5), 81 (5), 75 (31), 74 (10), 73 (100), 59 (18), 45 (12); NMR (CCl_4) δ=0.10 (9H, s), 0.90 (3H, t, J=6 Hz), 0.98 (3H, t, J=6 Hz), 1.13—1.70 (12H, m), 2.46—2.62 (1H, m).

Found: C, 68.64; H, 12.55%. Calcd for $C_{13}H_{28}OSi$: C, 68.35; H, 12.35%.

Isomerization of 2-Trimethylsilyl-2,3-dialkyloxiranes II and VI in the Presence of MgI_2. *5-Trimethylsilyl-4-decanone (IVc, R=n-C_3H_7, R'=n-C_5H_{11})*: To a solution of MgI_2 (10 mmol) in 10 ml of ether was added trimethylsilyloxirane IIc (R=C_3H_7, R'=C_5H_{11}, 0.23 g, 1 mmol dissolved in 5 ml of ether). The resulting mixture was stirred at reflux for 2 h and then treated with 6 ml of 1,4-dioxane at 0 °C overnight. The solution was freed from solids by filtration. The solids were washed with hexane several times and the combined organic layer was washed (sat. $NaHCO_3$, sat. NaCl) and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (benzene) afforded 0.16 g (72%) of IVc. Bp 110—

120 °C/23 mmHg; IR (neat) 1686, 1249, 837, 750, 690 cm^{-1}; NMR (CCl_4) δ=0.00 (9H, s), 0.87 (6H, t, J=6 Hz), 1.00—1.90 (10H, m), 1.90—2.33 (3H, m).

Found: C, 68.85; H, 12.11%. Calcd for $C_{13}H_{28}OSi$: C, 68.35; H, 12.35%.

Attempted purification of IVc by GLPC resulted in 1,3-migration of Me_3Si group affording the respective silyl enol ether; IR (neat), 1671, 1243, 838, 749 cm^{-1}; MS *m/e* (rel. %), 228 (M^+, 5), 213 (8), 185 (7), 171 (59), 158 (10), 143 (12), 130 (35), 75 (31), 73 (100), 43 (10).

*8-Trimethylsilyl-7-tetradecanone (IVa, R=R'=*n*-C_6H_{13})*: Yield, 93% based on IIa; oil; IR (neat) 1686, 1240, 833, 747 cm^{-1}; NMR (CCl_4) δ=0.00 (9H, s), 0.60—1.03 (6H, m), 1.03—1.80 (18H, m), 1.80—2.45 (3H, m).

Found: C, 69.37; H, 12.97%.[28] Calcd for $C_{17}H_{36}OSi$: C, 71.76; H, 12.75%.

Purification of IVa by GLPC afforded the silyl enol ether; IR (neat) 1670, 1242, 836, 747 cm^{-1}; MS *m/e* (rel. %), 284 (M^+, 10), 269 (13), 255 (2), 241 (4), 227 (83), 213 (100), 200 (20), 185 (14), 157 (13), 143 (53), 140 (70), 75 (23), 73 (81); NMR (CCl_4) δ=0.13 (9H, s), 0.67—1.05 (6H, m), 1.05—1.67 (16H, m), 1.67—2.30 (4H, m), 4.15—4.65 (1H, m).

*4-Trimethylsilyl-5-decanone (IVb, R=*n*-C_5H_{11}, R'=*n*-C_3H_7)*: Yield, 74% based on IIb; bp 120—130 °C/16 mmHg; IR (neat) 1686, 1245, 840, 754, 694 cm^{-1}; NMR (CCl_4) δ=0.00 (9H, s), 0.65—1.03 (6H, m), 1.03—1.80 (10H, m), 2.00—2.45 (3H, m).

Found: C, 68.30; H, 12.65%. Calcd for $C_{13}H_{28}OSi$: C, 68.35; H, 12.35%.

Purification of IVb by GLPC gave the enol silyl ether; MS *m/e* (rel. %), 228 (M^+, 13), 213 (8), 199 (47), 185 (48), 171 (8), 157 (5), 143 (16), 130 (72), 75 (28), 73 (100), 45 (10), 43 (4).

*Isomerization of Trimethylsilyloxirane Va to α-Trimethylsilyl Ketone IVa and 1-Trimethylsilyloxy-2-hexyl-1-octene (VIIIa, R=R'=*n*-C_6H_{13})*: The mixture containing 48% of IVa and 9% of VIIIa was separated by chromatography on silica-gel column (hexane and benzene). VIIIa: Oil; IR (neat) 1661, 1251, 1190, 1156, 1100, 881, 845, 757 cm^{-1}; MS *m/e* (rel. %), 284 (M^+, 10), 269 (3), 255 (1), 227 (1), 213 (38), 199 (5), 157 (9), 143 (79), 81 (16), 75 (20), 73 (100), 67 (15), 55 (16), 43 (20); NMR (CCl_4) δ=0.13 (9H, s), 0.60—1.05 (6H, m), 1.05—1.65 (16H, m), 1.65—2.30 (4H, m), 5.90 (1H, br-s).

Found: C, 72.06; H, 13.04%. Calcd for $C_{17}H_{36}OSi$: C, 71.76; H, 12.75%.

*Isomerization of Trimethylsilyloxirane Vb to α-Trimethylsilyl Ketone IVb and 1-Trimethylsiloxy-2-propyl-1-heptene (VIIIb, R=*n*-C_5H_{11} R'=*n*-C_3H_7)*: The products contained 40% of IVb and 18% of VIIIb. VIIIb: Oil; IR (neat) 1664, 1245, 1154, 1092, 874, 838, 748 cm^{-1}; MS *m/e* (rel. %), 228 (M^+, 10), 213 (4), 171 (50), 157 (8), 143 (35), 129 (5), 75 (20), 73 (100), 45 (13), 43 (7); NMR (CCl_4) δ=0.13 (9H, s), 0.65—1.07 (6H, m), 1.07—1.63 (8H, m), 1.63—2.30 (4H, m), 5.93 (1H, br-s).

Found: C, 68.49; H, 12.48%. Calcd for $C_{13}H_{28}OSi$: C, 68.35; H, 12.35%.

β-Iodo-β-trialkylsilyl Alcohols III and VII. (7S,8S*)-8-Iodo-8-trimethylsilyl-7-tetradecanol (IIIa, R=R'=*n*-C_6H_{13})*: To a solution of trimethylsilyloxirane IIa (0.28 g, 1 mmol) in 5 ml of ether was added 1 ml of 57% HI at 0 °C. After stirring for 1 h, the mixture was poured into sat. $NaHCO_3$ overlaid with ether. The ether layer was washed (10% $Na_2S_2O_3$, sat. $NaHCO_3$, sat. NaCl) and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (benzene) gave 0.41 g (quantitative yield) of IIIa. Oil; IR (neat) 3475, 1240, 840, 756, 690 cm^{-1}; NMR (CCl_4) δ=0.23 (9H, s), 0.90 (6H, t, J=6 Hz), 1.07—1.80 (20H, m), 1.50 (1H, d, J=6.6 Hz, CH-OH), 3.44 (1H, m, CH-OH). Hydroxyl proton was checked by D_2O-added NMR as well as double resonance irradiated at 3.44 which induced singlet at 1.50.

Found: C, 49.40; H, 9.23%. Calcd for $C_{17}H_{37}OSiI$: C, 49.50; H, 9.04%.

(7S,8S*)-8-Iodo-8-triethylsilyl-7-tetradecanol (IIId, R=R'=*n*-C_6H_{13})*: Quant. yield based on IId; oil; IR (neat) 3475, 1230, 1003, 725 cm^{-1}; NMR (CCl_4) δ=0.40—1.15 (21H, m), 1.15—2.15 (20H, m), 1.52 (1H, d, J=6.8 Hz), 3.45 (1H, m). IIId was used for the successive reaction without purification.

(7R,8S*)-8-Iodo-8-trimethylsilyl-7-tetradecanol (VIIa, R=R'=*n*-C_6H_{13})*: Yield, 94% based on VIa; oil; IR (neat) 3500, 1367, 1240, 840, 758, 690 cm^{-1}; NMR (CCl_4) δ=0.23 (9H, s), 0.90 (6H, t, J=6 Hz), 1.10—1.87 (18H, m), 1.37 (1H, d, J=8.3 Hz), 1.87—2.20 (2H, m), 3.00 (1H, m).

Found: C, 49.27; H, 8.83%. Calcd for $C_{17}H_{37}OSiI$: C, 49.50; H, 9.04%.

(4R,5S*)-5-Iodo-5-trimethylsilyl-4-decanol (VIIc, R=*n*-C_3H_7, R'=*n*-C_5H_{11})*: Crude yield, 92% based on VIc; oil; IR (neat) 3500, 1369, 1240, 840, 755, 690 cm^{-1}; NMR (CCl_4) δ=0.23 (9H, s), 0.76—1.13 (6H, m), 1.13—1.87 (10H, m), 1.38 (1H, d, J=9 Hz), 1.87—2.30 (2H, m), 3.05 (1H, m). VIIc was used for the successive reaction without purification.

Reaction of (4R,5S*)-5-Iodo-5-trimethylsilyl-4-decanol (VIIc) with KO^{t}Bu.* To a solution of KO^{t}Bu (1.0 g, 9 mmol) in 5 ml of THF was added VIIc (0.16 g, 0.92 mmol) in 5 ml of THF at 0 °C. The resulting mixture was warmed up to a room-temperature, stirred for 1 h, and poured into aq NH_4Cl overlaid with ether. The ether layer was washed (aq NH_4Cl, sat. NaCl) and dried ($MgSO_4$), affording 97 mg (92%) of (2*S**,3*R**)-2-trimethylsilyl-2-pentyl-3-propyloxirane (VIc, 96% purity) after chromatography of the concentrate on silica-gel column (benzene).

Reaction of β-Iodo-β-trialkylsilyl Alcohols III and VII with n*-BuLi. 8-Trimethylsilyl-7-tetradecanone (IVa)*: To a solution of (7*S**,8*S**)-8-iodo-8-trimethylsilyl-7-tetradecanol (IIIa, 0.35 g, 0.85 mmol) in 5 ml of ether was added *n*-BuLi (0.85 mmol, 1.12 ml of 0.76 M hexane solution) at −20 °C. The reaction mixture was warmed up to a room-temperature, stirred for 1.5 h, and poured into aq NH_4Cl overlaid with ether. The ether layer was washed (aq NH_4Cl, sat. NaCl) and dried ($MgSO_4$), yielding 0.24 g (quantitative) of IVa.

*8-Triethylsilyl-7-tetradecanone (IVd, R=R'=*n*-C_6H_{13})*: Yield, 87% based on IIId; oil; IR (neat) 1687, 1230, 1130, 1002, 725 cm^{-1}; NMR (CCl_4) δ=0.40—1.10 (21H, m), 1.10—1.90 (18H, m), 2.00—2.45 (3H, m).

Found: C, 73.77; H, 12.77%. Calcd for $C_{20}H_{42}OSi$: C, 73.54; H, 12.96%.

Purification of IVd by GLPC gave the enol silyl ether; MS *m/e* (rel. %), 326 (M^+, 10), 297 (16), 269 (44), 255 (48), 241 (10), 227 (11), 213 (18), 185 (33), 157 (42), 143 (25), 116 (15), 115 (90), 104 (12), 103 (100), 87 (75), 75 (40), 59 (42), 43 (17), 41 (17), 29 (29).

Reaction of 8-Iodo-8-trimethylsilyl-7-tetradecanol (IIIa and VIIa) with MeMgI/MgI_2. To a solution of (7*S**,8*S**)-8-iodo-8-trimethylsilyl-7-tetradecanol (IIIa, 0.40 g, 0.96 mmol) in 4 ml of ether was added MeMgI (1 mmol, 0.79 ml of 1.27 M ethereal solution) at −20 °C. The reaction mixture was warmed to a room-temperature and treated with MgI_2 (10 mmol) in 10 ml of ether. The resulting mixture was stirred at reflux for 2 h and then treated with 6 ml of 1,4-dioxane at 0 °C followed by stirring at a room-temperature

overnight. The solution was freed from solids by filtration. The solids were washed with hexane several times and the combined organic layer was washed (sat. $NaHCO_3$, sat. NaCl) and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (benzene) gave 0.25 g (92%) of 8-trimethylsilyl-7-tetradecanone (IVa). The same treatment of (7*R**,8*S**)-isomer (VIIa) afforded 1-trimethylsilyloxy-2-hexyl-1-octene (VIIIa, 43%) along with IVa (29%) after chromatography on silica-gel column (hexane and benzene).

Further Methods for Obtaining α-Trialkylsilyl Ketones.

Preparation of 5-Trimethylsilyl-4-decanone (IVc) via *5-Trimethylsilyl-4-decanol (XIIc)*: To a solution of $Me_3SiCH{=}CH_2$ (2.0 g, 2.9 ml, 20 mmol) in 60 ml of THF was added *n*-BuLi (26 mmol, 20 ml of 1.28 M hexane solution) at −78 °C and the reaction mixture was stirred for 1 h at a room-temperature.[29] The resulting mixture was treated with butyraldehyde (1.6 g, 1.8 ml, 22 mmol) at −78 °C and overnight at a room-temperature. The whole mixture was worked up with aq NH_4Cl, washed (aq NH_4Cl, sat. NaCl), and dried (Na_2SO_4). Chromatography of the concentrate on silica-gel column (hexane/THF=10/1) gave 4.0 g of 5-trimethylsilyl-4-decanol (yield, 87%; bp 89—91 °C/1 mmHg). To a mixture of CrO_3 (15 g, 150 mmol) and pyridine (24 ml, 300 mmol) in 300 ml of CH_2Cl_2 was added the above alcohol (4.0 g) in 16 ml of CH_2Cl_2 and the resulting mixture was stirred at a room-temperature for 15 min. After filtration, the filtrate was washed (aq NH_4Cl, 1M-HCl, sat. $NaHCO_3$, sat. NaCl) and dried (Na_2SO_4). Chromatography of the concentrate on silica-gel column (benzene) gave 3.1 g (77%) of IVc.

Preparation of 3-Trimethylsilyl-2-octanone via *3-Trimethylsilyl-2-octanol*: Yield, 36% based on $Me_3SiCH{=}CH_2$; bp 102 °C/20 mmHg; NMR (CCl_4) δ=0.06 (9H, s), 0.70—1.80 (11H, m), 1.80—2.45 (1H, m), 1.99 (3H, s).

Found: C, 65.87; H, 12.07%. Calcd for $C_{11}H_{24}OSi$: C, 65.93; H, 12.07%.

Purification by GLPC gave the enol silyl ether; MS *m/e* (rel. %), 200 (M^+, 8), 185 (6), 171 (11), 157 (5), 144 (12), 143 (75), 130 (7), 115 (8), 75 (30), 73 (100), 45 (14).

Preparation of 5-Triethylsilyl-4-decanone via *5-Triethylsilyl-4-decanol*: A solution of 1-triethylsilylhexyllithium prepared from $Et_3SiCH{=}CH_2$ (2.8 g, 20 mmol) and *n*-BuLi (26 mmol) in 30 ml of THF, was treated with butyraldehyde (1.8 ml, 22 mmol) at −78 °C and then at a room-temperature for 3 days. The same treatment as described above gave 4.2 g (77%) of 5-triethylsilyl-4-decanol.[30] The oxidation of this alcohol (3.5 g, 13 mmol) with CrO_3–pyridine afforded 3.0 g (86%) of 5-triethylsilyl-4-decanone. Oil; IR (neat) 1687, 1235, 1137, 1004, 723 cm^{-1}; NMR (CCl_4) δ=0.25—2.00 (31H, m), 2.00—2.57 (3H, m).

Found: C, 71.29; H, 12.59%. Calcd for $C_{16}H_{34}OSi$: C, 71.04; H, 12.67%.

Purification by GLPC gave the enol silyl ether; IR (neat) 1670, 1230, 1170, 998, 730 cm^{-1}; MS *m/e* (rel. %), 270 (M^+, 3), 255 (2), 241 (5), 227 (5), 213 (30), 185 (10), 171 (9), 157 (19), 115 (35), 103 (37), 87 (30), 75 (27), 59 (25), 55 (14), 40 (100).

Preparation of 5-Trimethylsilyl-4-decanone (IVc) by the Acylation of 1-Trimethylsilylhexyllithium (XI): To a solution of butyryl chloride (0.55 ml, 5.0 mmol) in 5 ml of THF was added XI, prepared from $Me_3SiCH{=}CH_2$ (5.0 mmol) and *n*-BuLi (6.5 mmol) in 30 ml of THF, at −78 °C. The reaction mixture was stirred at a room-temperature overnight, washed (aq NH_4Cl, sat. $NaHCO_3$, sat. NaCl), and dried over Na_2SO_4. Chromatography of the concentrate on silica-gel column (benzene) gave 0.51 g (45%) of IVc.

Preparation of 5-Trimethylsilyl-4-decanone (IVc) by the Acylation of 1-Trimethylsilylhexylcopper: To a suspension of CuI (2.1 g, 11 mmol) in 10 ml of THF was added XI prepared from $Me_3SiCH{=}CH_2$ (10 mmol) and *n*-BuLi (13 mmol), at −30—−40 °C. The mixture was gradually warmed up to −20 °C and stirred for 0.5 h at −20 °C. The resulting mixture was treated with butyryl chloride (10 mmol, 1.1 ml) at −78 °C and overnight at a room-temperature. The whole was poured into aq NH_4Cl overlaid with ether. The ether layer was washed (aq NH_4Cl, sat. $NaHCO_3$, sat. NaCl) and dried ($MgSO_4$). Chromatography of the concentrate on silica-gel column (benzene) gave 1.6 g (71%) of IVc.

Preparation of 5-Trimethylsilyl-4-decanone (IVc) by the Oxidation of 4-Dipropylboryl-5-trimethylsilyl-4-decene (XIII): To a solution of $LiC{\equiv}CSiMe_3$, prepared from $HC{\equiv}CSiMe_3$ (0.54 ml) and *n*-BuLi (3.3 mmol, 4.2 ml of 0.78 M hexane solution) in 10 ml of THF, was added n-Pr_3B (0.66 ml, 3.3 mmol) at 0 °C. The mixture was stirred at a room-temperature for 1 h and at reflux for 16 h. The resulting mixture was treated with $NaBO_3$–$4H_2O$ (2.0 g, 13 mmol) at a room-temperature for 5 h and poured into aq NH_4Cl overlaid with ether. The ether layer was washed (aq NH_4Cl, sat. NaCl) and dried ($MgSO_4$). Distillation of the concentrate afforded 0.30 g (57%) of IVc.

The authors wish to thank the Ministry of Education, Science and Culture, Japan, for the Grant-in-Aid (911506, 011010, 110309, 203014, 303023).

Soc.*, **99**, 1993 (1977). For an application see P. Magnus and G. Roy, *J. Chem. Soc., Chem. Commun.*, **1978**, 297.

11) Silyloxiranes as carbonyl precursors: (a) G. Stork and E. Colvin, *J. Am. Chem. Soc.*, **93**, 2080 (1971); (b) G. Stork and M, E. Jung, *ibid.*, **96**, 3682 (1974).

12) Products resulting from both cleavage at silylated carbon and cleavage at β carbon were formed in the reactions of triphenylsilylethylene oxide with HCl, with $MgBr_2$, and with amines.[10d]

13) The structure of iodohydrins was determined by NMR.

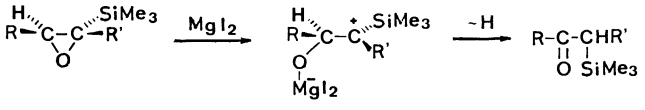
14) Yield of X, 61% based on 2-trimethylsilyl-3,3-dimethyloxirane (IX); NMR (CCl_4) δ=0.23 (9H, s), 1.39 (3H, s), 1.41 (3H, s), 1.60—1.80 (1H, m), 3.42 (1H, s). The structure of X was determined by selective formation of 1-iodo-2-methylpropene (yield 77%) by the action of BF_3–etherate.[10g] NMR (CCl_4) δ=1.83 (3H, s), 1.92 (3H, s), 5.83 (1H, br-s).

15) Direct treatment of VIa with LiI in ether gave no rearranged product. This fact excludes another path through the starting silyloxirane VIa.

16) No product resulting from the reaction of IVa with *n*-BuLi[5] was observed. This fact means the rearrangement of iodohydrin is sufficiently slower than the addition of *n*-BuLi to α-silyl ketones.

17) Reaction of IVa with *i*-Bu_2AlH in hexane,[4] after acidic work-up, gave 7-tetradecene in 70% yield based on IIa.

18) The following scheme seems unprobable.



According to this scheme, 1-trimethylsilylcyclohexene oxide would afford 2-trimethylsilylcyclohexanone. Such a product, however, was not formed but trimethylsiloxymethylenecyclopentane was obtained in 12% yield. NMR (CCl_4) δ= 6.06 (1H, br-s).[8]

19) I. Kuwajima and his coworkers published another type of α-trimethylsilyl ketone synthesis by the rearrangement of silyl-substituted chlorohydrin; T. Sato, T. Abe, and I. Kuwajima, *Tetrahedron Lett.*, **1978**, 259.

20) C. Eaborn and J. E. Jeffrey, *J. Chem. Soc.*, **1954**, 4266.

21) ^{13}C NMR data of oxiranes shown below gave no correlation between the chemical shift (δ ppm, $CDCl_3$) in the ground state and the oxirane cleavage at the silylated carbon.

Syntheses of Steroidal π-Allyl Palladium Chloride Complexes†

J. Yasuo SATOH and C. Akira HORIUCHI*

Department of Chemistry, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received February 24, 1979)

The reaction of the following steroidal olefins with palladium(II) chloride in the presence of potassium acetate in acetic acid afforded the corresponding steroidal π-allyl palladium chloride complexes: 5α-cholest-1-, -2-, and -3-ene; cholest-4- and -5-ene; 3-methyl- and 3-phenyl-5α-cholest-2-ene; 3β-chloro- and 3β-acetoxycholest-5-ene; and 5β-cholest-1-, -2-, and -3-ene.

There has been a considerable amount of work done on the syntheses of π-allyl palladium complexes in the area of the chain compound.[1] Also, in the case of monocyclic π-allyl palladium complexes, their syntheses have been reported for 1-*p*-menthen-3-ol,[2] 3-halocycloalkene,[3] β-pinene,[4] cycloalkene,[5] and alkylidenecycloalkanes.[5] On the other hand, with respect to steroids there have been no reports of syntheses except for the case of π-allyl palladium complexes of Δ^4-3-oxo steroids,[6] and of 5α-cholest-3-ene,[7] cholest-4-ene,[7] cholest-5-ene,[7] 5α-cholest-6-ene,[7] ergosterol,[8] and 3-methoxy-*cis*-19-norpregna-1,3,5(10),17(20)-tetraene.[10] These syntheses have mainly depended on methods using sodium tetrachloropalladate(II) or bis(benzonitrile)dichloropalladium(II). In addition, the preparations of π-allyl palladium complexes of chain compounds[11] using palladium(II) chloride and sodium acetate have also been described.

There is one report which does make some reference to a π-allyl palladium complex: F. J. McQuillin and D. G. Parker[12] reported that the reaction of (+)-3,7-dimethyl-1,6-octadiene with palladium(II) chloride and potassium acetate in acetic acid gave α-terpinyl acetate as the main product and π-allyl palladium complex as a minor product. However, there has been no report concerning the synthesis of cycloalkenyl π-allyl palladium complexes using palladium(II) chloride and potassium acetate. Hence, we attempted the syntheses of some steroidal π-allyl palladium complexes according to the procedures described by McQuillin and Parker. Not only did we want to demonstrate such syntheses, but we are planning a research project to investigate the stereospecificity of nucleophilic substitutions for the steroidal π-allyl palladium complexes.

In the present paper, we would like to report that the reaction of the following steroidal olefins readily yielded the corresponding steroidal π-allyl palladium chloride complexes: 5α-cholest-1- (**1**), -2- (**2**), and -3-ene (**3**); cholest-4- (**4**) and -5-ene (**5**); 3-methyl- (**6**) and 3-phenyl-5α-cholest-2-ene (**7**); 3β-chloro- (**8**) and 3β-acetoxycholest-5-ene (**9**), with a functional group at the C_3-position; and 5β-cholest-1- (**10**), -2- (**11**), and -3-ene (**12**).

Results and Discussion

The reactions of 5α-cholest-1- (**1**) and -2-ene (**2**) with palladium(II) chloride both yielded yellowish crystals (**19**); mp 154—159 °C. When **1** was used as the starting material, **2** was given in a 25% yield. It is considered that **1** was isomerized to the more stable 2-ene compound (**2**) by a 1:3 shift of a hydrogen from the allylic position to a double-bond carbon in the presence of palladium(II) chloride in acetic acid.[13] The NMR spectrum of **19** showed a multiplet at δ 4.9—5.6 ppm due to three protons. From this spectrum, however, it could not be determined whether the structure of **19** was of the 1-3η- or 2-4η-type; and so the following procedure was carried out: the 2α-bromo-5α-cholestan-3-one (**13**) was reduced with sodium borodeuteride to give the 3-deuteriobromohydrin (**14**). This bromohydrin was then converted to 3-deuterio-5α-cholest-2-ene (**15**). By treating **15** with palladium(II) chloride according to the method mentioned above, yellowish crystals (**19'**) were obtained. The NMR spectrum of **19'** showed AB-type signals, doublets (J=6.8 Hz) at δ 5.45 and 5.05 ppm. From this fact, complex **19** was confirmed to be a 1-3η-type complex, namely, di-μ-chloro-bis[(1-3η-5α-cholesten-2α-yl)palladium(II)], in which the palladium is coordinated at the α-face of the steroid, not showing the C-19 methyl signal in the low field.[7-9]

Similarly, 5α-cholest-3-ene (**3**) gave the α-3-5η-complex (**20**).[7] In the case of cholest-4-ene (**4**), a yellowish crystalline material was also obtained, and on chromatography two π-allyl complexes were yielded, which were confirmed to be α-3-5η- (**20**)[7] and β-3-5η-type complexes (**21**);[7] on the other hand, with cholest-5-ene (**5**) the two complexes which were obtained were crystals (**22**, mp 105—109 °C and **23**, mp 151—155 °C) which had α-5-7η- (**22**)[7] and α-4-6η-type (**23**)[7] structures.

The reaction of 3-methyl-5α-cholest-2-ene (**6**) gave complex (**24**); mp 161—165 °C. This product was presumed to be an α-1-3η-type complex from the AB-type signals due to the C_1–H and the C_2–H in its NMR spectrum. In the case of 3-phenyl-5α-cholest-2-ene (**7**), two compounds, **25** and **26**, were given. Compound **25** showed doublets due to the C_1- and C_2-protons at δ 4.80 and 5.30 ppm respectively in the NMR spectrum, while compound **26** showed two multiplets due to the C_2- and C_4-protons at δ 4.6—5.2 and 5.5—5.8 ppm respectively in the NMR spectrum. From these data, the two complexes were confirmed to be α-1-3η- (**25**) and α-2-4η-type complexes (**26**). These results suggest that the reaction of a 2-ene derivative possessing a methyl group at the C_3 position gives a product which has a greater regioselectivity than in the case of the phenyl group.

Similarly, the reaction of 3β-chloro- (**8**) and of 3β-acetoxycholest-5-ene (**9**) with palladium(II) chlo-

† A preliminary report on this work was presented at the 34 th National Meeting of the Chemical Society of Japan, Hiratsuka, April 1976.

Table 1. Yields and physical data of steroidal π-allyl palladium chloride complexes (**19**—**29′**)

Materials	Products	Isolated yield/%	Mp(dec) °C	NMR ($CDCl_3$, δ/ppm)	Elemental analysis(%)
1	**19**	51	154—159	0.92 (s, 3H) 4.9—5.6 (m, 3H)	Found (Calcd for $C_{54}H_{90}Pd_2Cl_2$) C H 64.61 8.77 (63.40) (8.86)

ride yielded 3β-chloro-α-5-7η- (**27**) and 3β-acetoxy-α-5-7η-type complexes (**28**) respectively. These structures were determined from the NMR spectra, which showed the doublets due to the C_6- and C_7-positions.

5β-Cholest-1- (**10**) and -2-ene (**11**) gave the same product (**29**). The NMR spectrum showed two multiplets at δ 5.18—5.55 ppm (1H) and at δ 4.70—5.18 ppm (2H). From the NMR spectrum, however, it could not be determined whether the structure of **29** was of the 1-3η- or 2-4η-type; therefore, the following procedure was carried out: the deuteride derivative, namely, 3-deuterio-5β-cholest-2-ene (**18**), was prepared from 2β-bromo-5β-cholestan-2-one (**16**) according to the procedure described for **15**. This structure was determined from the fact that no signal due to the C_3–H appeared in the NMR spectrum. The reaction of **18** with palladium(II) chloride gave a yellowish compound (**29'**). The NMR spectrum of **29'** showed doublets at δ 4.96 and 5.40 ppm and showed the C-19 methyl signal at δ 1.27 ppm.[7-9] From these data, compound **29'** was determined to be di-μ-chloro-bis[(1-3η-5β-cholesten-2β-yl)palladium(II)]. The reaction of 5β-cholest-3-ene (**12**) with palladium(II) chloride yielded a compound which was identical with the compound, **21**, obtained in the case of cholest-4-ene.

Thus, on the basis of all of the foregoing results, it can be concluded that the reagent used in this work [palladium(II) chloride containing potassium acetate in acetic acid] is applicable to the steroidal olefins. In the reaction of 5α- and 5β-steroidal olefins with this reagent, the former products were α-π-allyl palladium complexes, in which palladium coordinated at the α-face, while the latter products were β-π-allyl palladium complexes in which palladium coordinated at the β-face. These results are also in agreement with the facts that the α-face of 5α-steroidal olefins is less hindered than the β-face, and that the β-face of 5β-steroidal olefins is less hindered than the α-face.[14] This method showed more regioselectivity than the method using bis(benzonitrile)palladium chloride reported by Knox *et al.*[7]

Experimental

All the melting points are uncorrected. The IR and NMR spectra were measured using a Hitachi model 215 grating infrared spectrometer and a nuclear magnetic resonance spectrometer, Hitachi-Perkin Elmer R-20A, in carbon tetrachloride and deuteriochloroform, with TMS as the internal standard.

General Procedure. A mixture of steroidal olefin (1.30×10^{-3} mol), palladium(II) chloride (2.60×10^{-3} mol), potassium acetate (2.60×10^{-3} mol), and acetic acid (15 ml) was stirred at 55—60 °C. After 20—25 h, the reaction mixture turned to brownish yellow; and then it was filtered to remove the unchanged palladium(II) chloride. The filtrate was taken up in ether, and the ether extracts were washed with a sodium hydrogen carbonate solution and with water, and then dried and evaporated. The resultant oil was chromatographed on neutral aluminum oxide. Elution with benzene gave yellowish or greenish crystals from acetone.

Materials. The following compounds were synthesized by the methods described in literature: 5α-cholest-1-[15] (**1**), -2-[15] (**2**), and -3-ene[16] (**3**); cholest-4-[17] (**4**) and -5-ene[18] (**5**); 3-methyl-[19] (**6**) and 3-phenyl-5α-cholest-2-ene[20] (**7**); 3β-chloro-[18] (**8**) and 3β-acetoxycholest-5-ene[21] (**9**); and 5β-cholest-1-[22] (**10**), -2-[22] (**11**), and -3-ene[23] (**12**).

*Synthesis of 3-Deuterio-5α- (**15**) and 3-Deuterio-5β-cholest-2-ene (**18**).* A mixture of 2α-bromo-5α-cholestan-3-one (**13**) (100 mg) and methanol-d_1 was treated with sodium borodeuteride (80 mg) with at room temperature. After 1 h, water was added and the mixture was extracted with ether. The ethereal solution was washed with water, dried, and evaporated under reduced pressure. The resultant oil, on crystallization from methanol, gave needles of 3-deuteriobromohydrin (**14**) (53 mg); mp 103—105 °C, IR (KBr): 3400 cm^{-1}, NMR (CCl_4): δ=4.05 (1H, q, J=12 and 4.5 Hz). A mixture of **14** (50 mg) and zinc powder in acetic acid was stirred under refluxing conditions. After the usual work-up, the resultant oil, on crystallization from acetone, gave needles of **15** (33 mg); mp 73—74 °C, IR (KBr): 1640 cm^{-1}; NMR (CCl_4): δ=5.50 (1H, m, $W/2$= 7.5 Hz). The reduction of 2β-bromo-5β-cholestan-3-one (**16**) (233 mg) was done in accordance with the procedure described for **14**. Attempts to crystallize the resultant oil (**17**) were unsuccessful, and so the products were used in the next step without purification [IR (NaCl): 3384 cm^{-1}]. A mixture of the 3-deuteriobromohydrin (**17**) (200 mg), zinc powder, and acetic acid was stirred under refluxing conditions. After the usual work-up, the resultant oil, on crystallization from acetone, gave needles of **18** (108 mg); mp 46.5—47.5 °C, IR (KBr): 3025, 2250, and 1647 cm^{-1}; NMR (CCl_4): δ=5.45 (1H, m, $W/2$=10.5 Hz).

The authors are indebted to Professor Masayoshi Nakahara and Associate Professor Eiichi Miki for their valuable suggestions and to Messrs. Kohei Nakamichi, Ryusuke Misago, and Masami Sawayama for their collaboration in the experimental work. This research was supported in part by a Matsunaga Research Grant from the Matsunaga Science Foundation.

ortho-Disubstituted *F*-Benzenes. II.[1] One-pot Syntheses of (*F*-Benzo)heterocyclic Compounds

Yoshinari INUKAI,† Takaaki SONODA, and Hiroshi KOBAYASHI*

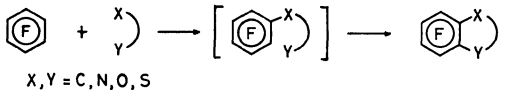
Research Institute of Industrial Science, Kyushu University 86, Hakozaki, Fukuoka 812

† *Department of Organic Synthesis, Faculty of Engineering, Kyushu University 36, Hakozaki, Fukuoka 812*

(Received February 26, 1979)

Convenient one-pot methods of converting *F*-benzene into substituted (*F*-benzo)furans, (*F*-benz)oxazole, -imidazolines, and -thiazoline are described. Ambident nucleophiles are generated *in situ* from ketone, amide, urea, thiourea, and their derivatives in the presence of sodium hydride. Enolate-anion nucleophiles are also generated *in situ* from silyl enol ethers in the presence of potassium fluoride in anhydrous DMF.

Research in our laboratories has been directed at the *ortho*-difunctionalization of simple, commercially available *F*-benzene.[2] This has led to the preparation of related (*F*-benzo)heterocyclic compounds, which were in most cases synthesized through laborious reaction sequences.[3] In a previous paper[1] we described the intramolecular cyclization of *ω*-functionalized *F*-anilide into some (*F*-benz)azacyclic compounds. Here we wish to report a convenient one-pot method for converting *F*-benzene into substituted (*F*-benzo)-furans, (*F*-benz)oxazole, -imidazolines, and -thiazoline by the use of such ambident nucleophiles as ketone, amide, urea, and their derivatives. Several preceding works with similar schemes have appeared in the literature.[4]

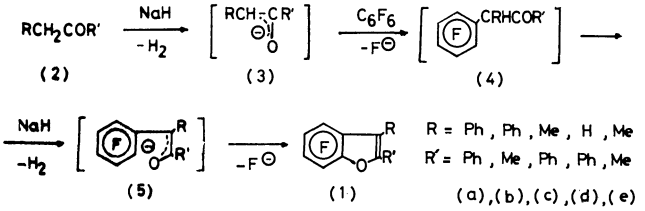


Scheme 1.

Results and Discussion

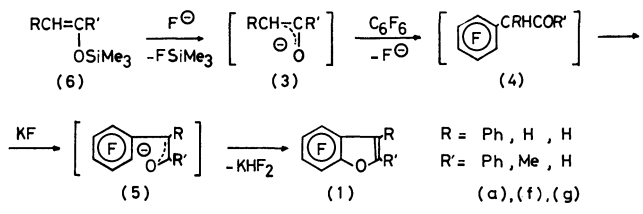
A range of (*F*-benzo)furans (**1**) were obtained by the reaction of *F*-benzene with the corresponding ketones (**2**). The reactions were carried out by adding the ketone to a mixture of *F*-benzene and two equivalents of sodium hydride in DMF.

The presence of four unequivalent fluorines in (**1a**) and (**1e**), based upon their ^{19}F-NMR spectra, and the regio-isomerism between (**1b**) and (**1c**) indicate the compounds (**1**) to have a benzofuran skeleton, which is compatible with their characteristic UV bands.



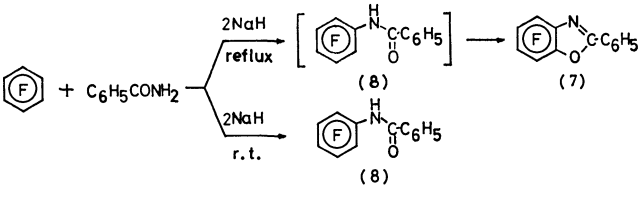
Scheme 2.

The reaction presumably proceeds in two steps *via* an intermediary (*F*-phenyl) ketone (**4**), as shown in Scheme 2. The presence of a phenyl group seems to give a higher yield than does a methyl group. One reason for this might be the resonance stabilization of the enolate anion forms, (**3**) and (**5**), resulting from the *α*- and *β*-phenyl groups, promoting the nucleophilic substitution of fluorine on the aromatic nucleus. Also, the steric bulkiness of a phenyl group, especially that adjacent to the ketone carbonyl, favors the intramolecular cyclization by hindering intermolecular aromatic substitution or aldol condensation. This presumption is compatible with the observation that the inverse addition of *F*-benzene to a mixture of ketone and sodium hydride afforded yields of less than 5% of the expected products (**1**) except for the 49% yield from phenyl benzyl ketone (**2a**). Sterically less hindered ketones would promote the aldol condensation or intermolecular aromatic substitution in basic media, thus consuming the starting ketones or intermediary (*F*-phenyl) ketones (**4**) prior to the intramolecular cyclization.



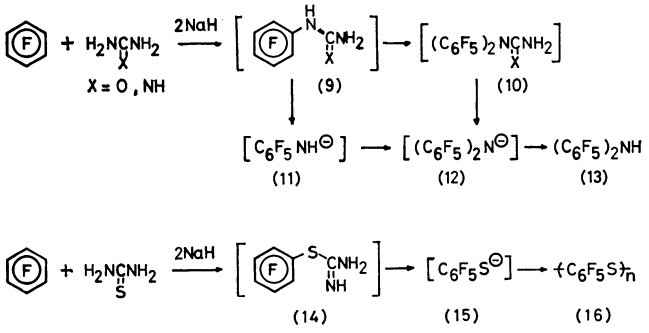
Scheme 3.

The generation of an enolate anion in neutral media can be achieved by the Si–O bond cleavage of silyl enol ethers in the presence of fluoride ions.[5] Also, one may expect that the protection of a ketone in the form of silyl enol ether suppresses the condensation reactions with the enolate. However, no satisfactory results have far been obtained except in the case of trimethylsilyl 1,2-diphenylvinyl ether (**6a**). The reactions using the trimethylsilyl enol ethers, (**6f**)[6] and (**6g**),[7] which were derived from acetone and tetrahydrofuran respectively, afforded none of the expected products (**1**), in which the intermolecular condensation or aromatic substitution of intermediary (*F*-phenyl) ketones (**4**) seemed to be preferred.



Scheme 4.

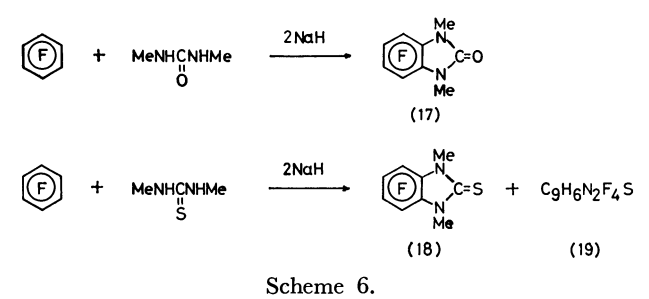
2-Phenyl-*F*-benzoxazole (**7**) was previously synthesized from *F*-aniline by way of benz-*F*-anilide (**8**).[1] The preparation of this compound was much simplified by the present one-pot reaction of *F*-benzene and benzamide under reflux. The reaction proceeds step-by-step *via* benz-*F*-anilide (**8**), and the intramolecular cyclization of the intermediary anilide required a higher temperature,[1] since the anilide (**8**) was isolated in an 80% yield when the reaction was carried out at room temperature.



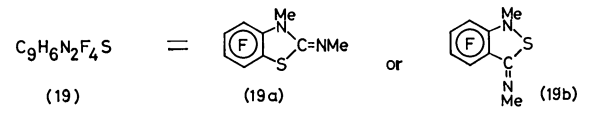
Scheme 5.

Urea, guanidine, and thiourea were also regarded as possible polyfunctional nucleophiles. The reactions with these nucleophiles, however, afforded no heterocyclic products; instead, di(*F*-phenyl)amine (**13**) was obtained from the former two and poly(thio-*F*-*p*-phenylene) (**16**) from the last one. The occurence of the above products indicates that the intermediary *F*-phenyl derivatives (**9**) and (**14**) cleave at the α–β bond prior to the intramolecular cyclization, thus liberating *F*-anilide anion (**11**) and *F*-benzothiolate anion (**15**) respectively, in the presence of an excess of hydride ions. The anions (**11**) and (**15**) afford the amine (**13**) and sulfide (**16**) respectively upon subsequent aromatic substitution. The intermediary *N*-carbamoyl-*F*-aniline (**9**), though not isolated, would be deprotonated at the α-amide in preference to the γ-amide. Such an α-amide anion favors the intermolecular nucleophilic aromatic substitution rather than the intramolecular cyclization, and in the presence of *F*-benzene it forms *N*,*N*-di(*F*-phenyl)urea (**10**), which then liberates the di(*F*-phenyl)amide anion (**12**) in the presence of an excess of sodium hydride. This may provide another possible route to di(*F*-phenyl)-amine.

The reaction with *N*,*N*′-dimethylurea gave 1,3-dimethyl(*F*-benz)imidazolin-2-one (**17**), where the active α-amide hydrogen of the intermediary *N*-carbamoyl-*F*-aniline is replaced with a methyl group; the only dissociable hydrogen of the intermediate is that of the γ-amide, and the α,β-bond cleavage seems to be suppressed. Increased steric hindrance by the methyl group would also favor the intramolecular cyclization.

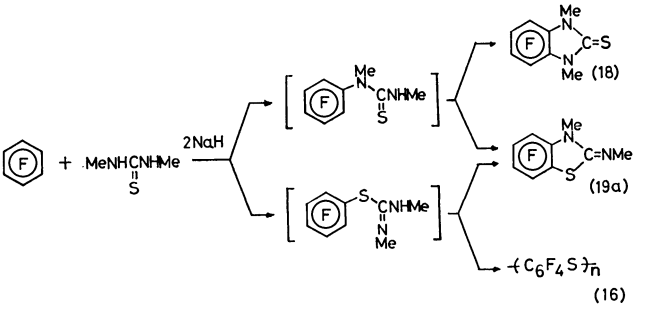


Scheme 6.



Scheme 7.

The reaction with the *N*,*N*′-dimethylthiourea similarly afforded 1,3-dimethyl(*F*-benz)imidazoline-2-thione (**18**) and a comparable amount of poly(thio-*F*-*p*-phenylene) in addition to an isomeric product, $C_9H_6N_2F_4S$ (**19**). The ^{19}F-NMR and ^{1}H-NMR of the last product indicate the presence of four unequivalent aromatic fluorines and two unequivalent methyl groups on hetero atoms respectively, suggesting that the heterocyclic moiety has either thiazoline (**19a**) or isothiazoline (**19b**) structure. The rearrangement into the isothiazolidine structure seems less probable under the present reaction conditions. The results indicate that, in the reaction with *N*,*N*′-dimethylthiourea, the nucleophilic attacks by the amide and thiolate anions proceed competitively at the stage of the first aromatic substitution and/or the subsequent intramolecular cyclization.



Scheme 8.

Experimental

The melting points are uncorrected. The IR and UV spectra were obtained with JASCO IR A-1 and Hitachi 220 spectrophotometers respectively. The ^{1}H-NMR and ^{13}C-NMR chemical shifts were recorded on Hitachi R-24 and JEOL JNM FX 100 instruments respectively, against the internal TMS reference. The ^{19}F-NMR chemical shifts were recorded on Varian EM 390 and JEOL PS-100 instruments as positive values downfield from the internal *F*-benzene reference. The mass spectra were obtained with JEOL JMS-07 and Hitachi RMS-4 spectrometers.

*Preparation of (F-Benzo)furan Derivatives (**1a**—**e**).* *General Procedure Using Sodium Hydride*: A solution of a ketone (**2**) (10 mmol) in anhydrous DMF (5 ml) was added dropwise into a stirred mixture of *F*-benzene (10 mmol), sodium hydride (20 mmol), and anhydrous DMF (10 ml) over a 30-min period at room temperature and under a dry nitrogen atmosphere. The mixture was stirred at 80 °C for an additional 5 h and then poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated. The residue was fractionated by chromatography on a neutral

alumina column. The fraction eluted with hexane gave a (*F*-benzo)furan derivative (**1**), which was further purified by sublimation.

2,3-Diphenyl-F-*benzofuran* (***1a***); Yield: 50%. White needles, mp 163.5—164.5 °C. ^{1}H-NMR ($CDCl_3$): 7.2—7.6 ppm (m, arom.). ^{19}F-NMR ($CHCl_3$): −1.8 (1F), 0.0 (1F), 1.2 (1F), 14.2 ppm (1F).[8] UV: λ_{max} (cyclohexane); 232 (log ε 4.34), 297 nm (4.40).[9] Found: C, 70.12; H, 2.83%; M$^+$, 342. Calcd for $C_{12}H_{10}F_4O$: C, 70.18; H, 2.95%, M, 342.

2-Methyl-3-phenyl-F-*benzofuran* (***1b***); Yield: 29%. White needles, mp 86—87 °C. ^{1}H-NMR ($CDCl_3$): 2.45 (s, 3H, CH_3), 7.4—7.9 ppm (m, 5H, arom.). ^{19}F-NMR ($CHCl_3$): −2.1 (1F), −0.5 (2F), 15.2 ppm (1F).[8] UV: λ_{max} (cyclohexane); 246 nm (log ε 4.19).[9] Found: C, 64.47; H, 3.03%; M$^+$, 280. Calcd for $C_{15}H_8F_4O$: C, 64.29; H, 2.88%; M, 280.

2-Phenyl-3-methyl-F-*benzofuran* (***1c***); Yield: 27%. White needles, mp 109.5—110.5 °C. ^{1}H-NMR ($CDCl_3$): 1.6 (s, 3H, CH_3), 7.3—7.5 ppm (m, 5H, arom.). ^{19}F-NMR ($CHCl_3$): −2.6 (1F), 0.5 (2F), 9.5 ppm (1F).[8] UV: λ_{max} (cyclohexane); 285 nm (log ε 4.40).[9] Found: C, 64.06; H, 3.10%; M$^+$, 280. Calcd for $C_{15}H_8F_4O$: C, 64.29; H, 2.88%; M, 280.

*2-Phenyl-(*F-*benzo)furan* (***1d***); Yield: 49%. White needles, mp 112—114 °C (lit,[10] 114.5—115.5 °C). Found: C, 62.93; H, 2.23%; M$^+$, 266.

2,3-Dimethyl-F-*benzofuran* (***1e***); Yield: 2.3%. White needles, mp 37.5—38.5 °C. ^{1}H-NMR ($CDCl_3$): 2.25 (s, 3H, CH_3), 2.35 ppm (s, 3H, CH_3). ^{19}F-NMR ($CHCl_3$): −3.5 (1F), −1.3 (1F), −0.5 (1F), 8.7 ppm (1F).[8] UV: λ_{max} (cyclohexane); 247 nm (log ε 4.11).[9] Found: C, 54.89; H, 2.76%; M$^+$, 218. Calcd for $C_{10}H_6F_4O$: C, 54.89; H, 2.77%; M, 218.

General Procedure Using Trimethylsilyl Enol Ethers (***6***).[6,7] A solution of a trimethylsilyl enol ether (**6**) (2.5 mmol) in anhydrous DMF (10 ml) was added, dropwise into a stirred mixture of *F*-benzene (2.5 mmol), anhydrous potassium fluoride (5 mmol), and anhydrous DMF (10 ml) over a 30-min period at room temperature and under a dry nitrogen atmosphere. The mixture was stirred at 80 °C for an additional 8 h and subsequently worked-up in a manner similar to that described above. **1a**; Yield: 49%. The reactions using trimethylsilyl isopropenyl ether (**6f**) and trimethylsilyl vinyl ether (**6g**), which had been prepared according to the literature,[6,7] afforded neither the expected (*F*-benzo)-furan (**1g**) nor 2-methyl derivative (**1f**).

Reactions of F-*Benzene with Benzamide. 2-Phenyl*-F-*benzoxazole* (***7***): A solution of benzamide (1.21 g, 10 mmol) in anhydrous DMF (20 ml) was added dropwise into a stirred mixture of *F*-benzene (1.86 g, 10 mmol), sodium hydride (20 mmol) and anhydrous DMF (2.5 ml) over a 15-min period at room temperature and under a dry nitrogen atmosphere. The mixture was stirred at 80 °C for an additional 2 h, subsequently refluxed for an additional 3 h, and then poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated off. The residue was chromatographed on a silica gel column. The fraction eluted with hexane gave 2-phenyl-*F*-benzoxazole (**7**) (0.85 g, 32%). The product was indentified by comparison with an authentic specimen.[1]

Benz-F-*anilide* (***8***): A solution of benzamide (2.42 g, 20 mmol) in anhydrous DMF (10 ml) was added dropwise into a stirred mixture of *F*-benzene (3.72 g, 20 mmol), sodium hydride (40 mmol), and anhydrous DMF (10 ml) over a 30-min period at room temperature and under a dry nitrogen atmosphere. The mixture was then stirred at room temperature for an additional 24 h and subsequently worked-up in a manner similar to that described above. The residue obtained after evaporation was recrystallized from benzene to give benz-*F*-anilide (**8**) (4.59 g, 80%). The product was identified by comparison with an authentic specimen.[1]

Reactions of F-*Benzene with Urea and Its Derivatives.*

Reaction with Urea: A solution of urea (0.50 g, 7.5 mmol) in anhydrous DMF (15 ml) was added dropwise into a stirred mixture of *F*-benzene (1.40 g, 7.5 mmol), sodium hydride (15 mmol), and anhydrous DMF (15 ml) over a 30-min period at room temperature and under a dry nitrogen atmosphere. The mixture was stirred at 80 °C for an additional 3 h and poured into ether. The ethereal solution was washed with water, dried over sodium surfate, and evaporated off. The residue was chromatographed on a silica gel column. The fraction eluted with hexane gave di(*F*-phenyl)amine (**13**) (0.73 g, 56%). The product was identified by comparison with an authentic specimen.[11]

Reaction with Guanidine: Di(*F*-phenyl)amine (**13**) was obtained in an 8% yield according to the above procedure by using guanidine in place of urea.

Reaction with Thiourea: A solution of thiourea (0.57 g, 7.5 mmol) in anhydrous DMF (15 ml) was added dropwise into a stirred mixture of *F*-benzene (1.40 g, 7.5 mmol), sodium hydride (15 mmol), and anhydrous DMF (15 ml) over a 30-min period at room temperature and under a dry nitrogen atmosphere. The mixture was stirred at 80 °C for an additional 3 h and then poured into a mixture of ether and water. The resulting precipitates were filtered off and washed with water and ether successively. Drying in a desiccator resulted in poly(thio-*F*-*p*-phenylene) (**16**) (1.21 g) as a pale yellow powder; mp>290 °C. The sulfur test using sodium tetracyanonitrosylferrate(III) was positive. The product was assigned by means of IR spectral comparison.[12]

Reaction with N,N′-*Dimethylurea.* A solution of *N,N′*-dimethylurea (1.93 g, 23 mmol) in anhydrous DMF (20 ml) was added dropwise into a stirred mixture of *F*-benzene (3.72 g, 20 mmol), sodium hydride (46 mmol), and anhydrous DMF (40 ml) over a 30-min period at room temperature and under a dry nitrogen atmosphere. The mixture was stirred at 80 °C for an additional 2 h and then poured into ether. The ethereal solution was washed with water, dried over sodium sulfate, and evaporated off. The residue was chromatographed on a neutral alumina column. The fraction eluted with hexane gave 1,3-dimethyl(*F*-benz)imidazolin-2-one (**17**) (0.86 g, 19%). Recrystallization from aqueous methanol afforded white needles; mp 104.5—105.5 °C. IR(KBr): 1710 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$): 3.55 ppm (s). ^{19}F-NMR ($CHCl_3$): −6.6 (2F), −5.1 ppm(2F). ^{13}C-NMR ($CDCl_3$): 29.60 (CH_3), 154.23 ppm (C=O). UV: λ_{max} (EtOH); 209.5 (log ε 4.23), 224 (3.94), 277 nm (3.49). Found: C, 46.25; H, 2.59; N, 12.00; F, 29.7%; M$^+$, 234. Calcd for $C_9H_6N_2F_4O$: C, 46.17; H, 2.58; N, 11.96; F, 32.5%; M, 234.

Reaction with N,N′-*Dimethylthiourea.* A solution of *N,N′*-dimethylthiourea (1.04 g, 10 mmol) in anhydrous DMF (15 ml) was added dropwise into a stirred mixture of *F*-benzene (1.86 g, 10 mmol), sodium hydride (20 mmol), and anhydrous DMF (40 ml) over a 25-min period at room temperature and under a dry nitrogen atmosphere. The mixture was stirred at 80 °C for an additional 2 h, subsequently refluxed for an additional 3 h, and then poured into a mixture of ether and water. The resulting precipitates, poly(thio-*F*-*p*-phenylene) (**16**) (1.71 g), were filtered out, and the filtrate was extracted with ether. The ethereal extract was washed with water, dried over sodium sulfate, and evaporated off. The residue was separated into two components by elution chromatography using hexane on a

silica-gel column.

An earlier fraction gave 1,3-dimethyl(*F*-benz)imidazoline-2-thione (**18**) (19%).[13] Recrystallization from ethanol afforded white needles; mp 123.5—124.5 °C. IR(KBr): 1160 cm^{-1} (C=S). ^{1}H-NMR ($CDCl_3$) 3.90 ppm (s). ^{19}F-NMR ($CDCl_3$): −2.2 (2F), −0.1 ppm (2F). ^{13}C-NMR ($CDCl_3$): 33.86 (CH_3), 172.90 ppm (C=S). UV: λ_{max} (EtOH); 218 (log ε 4.08), 248 (4.24), 302 nm (4.35). Found: C, 43.53; H, 2.53; N, 11.22; F, 30.7%; M^+, 250. Calcd for $C_9H_6N_2F_4S$: C, 43.20; H, 2.42; N, 11.20; F, 30.4%; M, 250. The sulfur test using sodium tetracyanonitrosylferrate(III) was positive.

A later fraction gave the isomeric product (**19**) (7%).[13] Sublimation afforded white needles; mp 80—81 °C. IR (KBr): 1670 cm^{-1} (C=N). ^{1}H-NMR ($CDCl_3$): 3.10 (s, 3H, CH_3), 3.60 ppm (d, J=3Hz, 3H, CH_3). ^{19}F-NMR ($CHCl_3$): −5.8 (1F), 0.3 (1F), 2.7 (1F), 20.5 ppm (1F). ^{13}C-NMR ($CDCl_3$): 32.53 (d, J=0.34 Hz, CH_3), 40.93 (CH_3), 154.91 ppm (C=N). UV: λ_{max} (EtOH); 220 (log ε 4.41), 263 (3.80), 290 nm (3.44). Found: C, 42.94; H, 2.48; N, 11.12; F, 30.1%; M^+, 250. Calcd for $C_9H_6N_2F_4S$: C, 43.20; H, 2.42; N, 11.20; F, 30.4%; M, 250. The sulfur test using sodium tetracyanonitrosylferrate(III) was positive. The combined fractions eluted with hexane amounted to a total of 0.64 g.

We wish to thank Professor Nobuo Ishikawa and Mr. Kiyoshi Tanaka of the Tokyo Institute of Technology and Messrs. Akira Kito and Atsushi Iyoda of the Government Industrial Research Institute at Osaka for their measurements of the ^{19}F-NMR spectra. Financial support from the Ministry of Education under a Grant-in-Aid for Co-operative (A) Research (Project No. 335041) is also gratefully acknowledged.

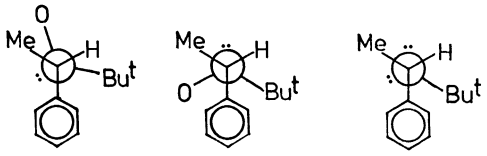
††*Research Centre for Spectrochemistry, Faculty of Science, The University of Tokyo, Tokyo 113*

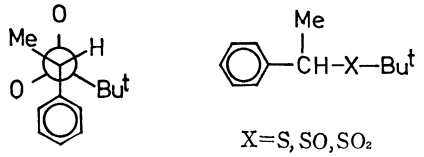
(Received March 7, 1979)

The conformations of a diastereoisomeric pair of 2,2-dimethyl-4-phenyl-3-pentanols were studied by means of ^{1}H-NMR, ^{13}C-NMR, IR, GC, and MS analyses. All of the results point to an unambiguous conclusion that these molecules are present dominantly in conformers where the *t*-butyl and the phenyl group lie close to each other. The generality of the phenomenon (favored *gauche* interaction) as well as the nature of the interactions involved were discussed in light of the conformational problems of the structurally related molecules. The presence of an attractive interaction (CH/π interaction) is suggested between an alkyl and a phenyl group, the possible importance of which in some dynamic phenomena (*e.g.*, selectivities in certain reactions) has then been discussed on this basis.

Evidence has been accumulated that an alkyl group orients itself close to a phenyl group in some molecular environments. The *t*-butyl group in (*SR*/*RS*)[4)] (**1**) and (*SS*/*RR*)-1-phenylethyl *t*-butyl sulfoxides (**2**) as well as in the corresponding sulfide (**3**) and sulfone (**4**), for example, has been shown to be oriented *gauche* with respect to the phenyl group (Fig. 1). Thus,



1 X=SO **2** X=SO **3** X=S



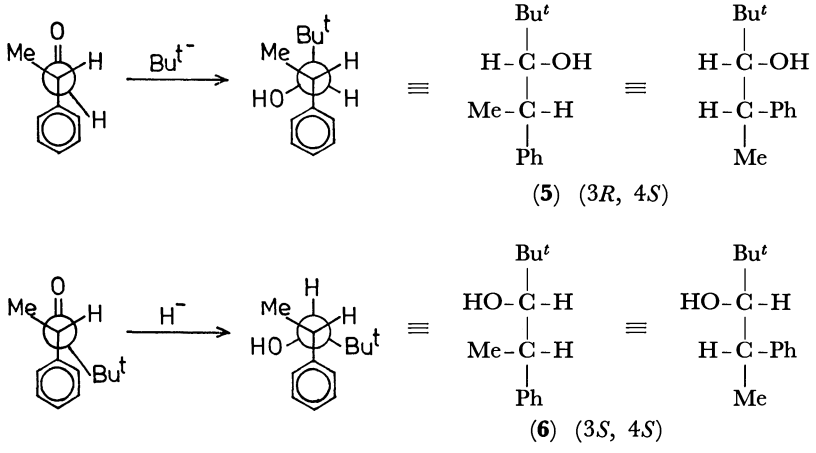
4 X=SO_2 X=S, SO, SO_2

Fig. 1.

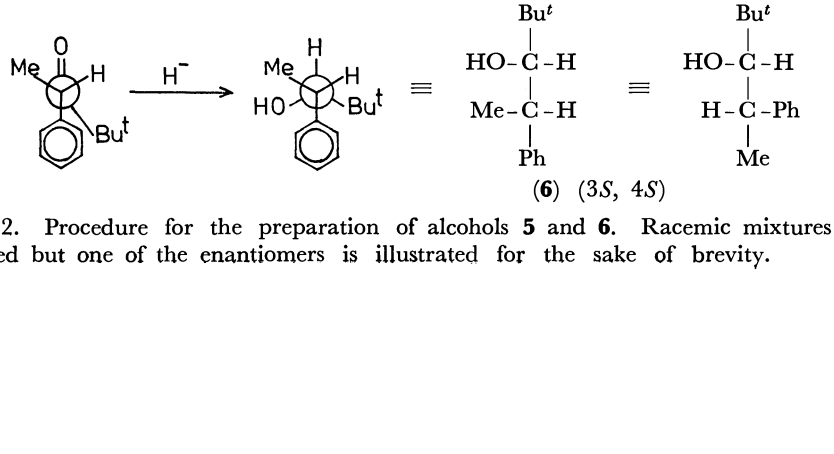
X-ray crystallographic works on these sulfoxides (*p*-Br derivatives) have demonstrated that the dihedral angle defined by C(Bu^t)–S–C–C(Ph) is *ca.* 84° and 65° in **1** and **2**[5)] respectively. Conclusions regarding the conformations of **3** and **4** have been drawn from indirect evidence (for **3**)[6)] and an unpublished X-ray work (for **4**).[7)] The above findings led us to NMR,[5,8)] ORD/CD[5)] and dipole-moment studies[9)] of the diastereoisomeric sulfoxides; the conformations adopted by **1** and **2** in the crystal fields have been shown to be maintained in solutions. In an attempt to explore the generality of the phenomenon, we also extended this work to a conformational study of some structurally related alcohols, (*RS*/*SR*)- and (*SS*/*RR*)-2,2-dimethyl-4-phenyl-3-pentanols.

Experimental

Preparation of Alcohols. The treatment of 2-phenylpropionaldehyde with *t*-butylmagnesium chloride gave 2,2-dimethyl-4-phenyl-3-pentanol, with an (*RS*/*SR*) configuration (**5**, Fig. 2).[4,10)] The reaction mixture was shown to be almost diastereoisomerically pure.[11)] The oxidation of **5** to a ketone, followed by $LiAlH_4$ reduction, gave (*SS*/*RR*)-alcohol (**6**).



(**5**) (3*R*, 4*S*)



(**6**) (3*S*, 4*S*)

Fig. 2. Procedure for the preparation of alcohols **5** and **6**. Racemic mixtures were used but one of the enantiomers is illustrated for the sake of brevity.

This was again shown to be produced with an almost total exclusion of the other isomer.[10,11] The samples prepared as above and purified chromatographically gave correct analytical data (see Tables 1, 2, and 4 for the spectral data). The configuration assignment of the alcohols has been made by Felkin and his group;[10-12] it is consistent with our own conclusion.

NMR Measurements. The NMR spectra were determined for 0.2 mol/l solutions on a JEOL MH-100 spectrometer (for ^1H) and a JEOL FX-100 spectrometer (for ^{13}C). The chemical shifts are given relative to tetramethylsilane as the internal reference and are accurate to ± 0.01 ppm for the ^1H data and ± 0.04 ppm for the ^{13}C data. The coupling constants are accurate to ± 0.02 Hz. The assignments of the ^{13}C resonances were made by the use of the gated decoupling technique.

IR Measurements. The infrared spectra were obtained at 20 °C for dilute solutions (5.6—8.0 mmol/l) in carbon tetrachloride with a Perkin-Elmer model 112G or a JASCO DS-402G spectrometer. The error in the measurements is estimated to be less than 2.5 cm^{-1}.

GC. A Hewlett-Packard 5830A gas chromatograph equipped with a 6-foot column was packed with Diasolid ZS. The temperature was maintained at 150 °C. The flow rate of the He carrier gas was 35 ml/min. The retention times were 1.61 and 1.46 min respectively for **5** and **6**.

MS. A Hitachi RMU-6MG mass spectrometer was used. The samples were introduced gas-chromatographically. The temperature at the ion source, the ionizing potential, and the accelerating voltage were 230 °C, 20 eV, and 3.2 kV respectively.

Results

NMR Results. Tables 1 and 2 list the proton and carbon magnetic resonance parameters respectively for **5** and **6**.

Vicinal H/H Coupling: An inspection of the Newman projections in which the "bulkiest" groups (Bu^t and Ph) are arranged *anti* (Fig. 3) would lead us to a prediction that the vicinal coupling constant, $^3J_{HH}$, is larger in the (*SS*/*RR*) isomer (**6**) than in the (*RS*/*SR*) alcohol (**5**). This stems from a simple consideration of the Karplus relationship,[13] in which $^3J_{HH}$ is largest (*ca.* 10—12 Hz) when the relevant protons are oriented *anti* or eclipsed. The experimental values, however, were found to be smaller than 4 Hz for both compounds. This promptly rules out the conformation depicted in Fig. 3 for **6**; a much larger $^3J_{HH}$ value is expected for this conformation (H/H *anti*). Possible valence angle deformations involving the respective atoms could render the vicinal coupling constant a poor guide with regard to the conformational problem. In this

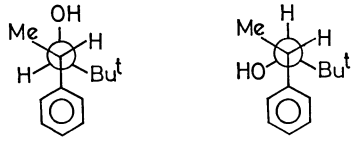
(**5**) (**6**)

Fig. 3.

regard, it should be noted that the one-bond coupling constants, $^1J_{CH}$, are quite normal for relevant sp^3-hybridized linkages[14] (for C^7–H and C^8–H, see Table 2). It follows, therefore, that there are no appreciable distortions about the bond angles and bond lengths involving these nuclei. It was also noted that there was little effect in $^3J_{HH}$ with the change in the solvent or the addition of a lanthanoide-shift reagent (LSR). This demonstrates that the conformational equilibria of these alcohols are not much perturbed by the change in the solvent polarity or by complexation.

Lanthanoide Shift Reagent-induced Shift (LIS): One of the most remarkable features to be seen in Table 1 is that the LIS for H_a is appreciably larger in **5** than in **6**, whereas the reverse is true for the *ortho* and *meta*-protons on the phenyl ring. To explain this, we must consider that the hydroxyl oxygen (the substrate-LSR complexation site) is closer to H_a and remoter from the phenyl group in **5** than in **6**. This, along with the coupling data, rules out the possibility that the conformations of these alcohols are like those shown in Fig. 3 (Bu^t/Ph *anti*). To be consistent with the LIS data, we must presume that such conformations as illustrated in Fig. 4 are predominant in these solutions. Note that in both conformations the *t*-butyl group orients itself *gauche* to the phenyl group. For the (*RS*/*SR*)-isomer (**5**), however, a completely staggered conformation is incompatible with the coupling data.

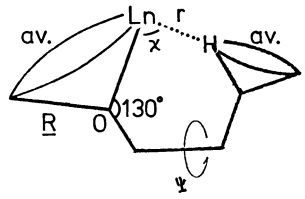


(**5**) (**6**)

Fig. 4.

We, therefore, carried out computer simulations of the LIS for these compounds. Thus, a program was written in which the LIS for each proton could be calculated[8] according to the McConnell and Robertson equation.[15] The necessary parameters were assumed as usual, and the LIS data listed in Table 1 were used. For the protons of Me, Bu^t, H_o, and H_m, the contributions of various rotational forms were averaged. The lanthanoide(Ln)–O–C angle was taken to be 130°. The procedure is illustrated in Fig. 5. A Gaussian weight factor (w) for the rotamer population was defined as in Eq. 1,[16] where A is the distribution coefficient and θ is a torsional angle for the rotation of Ln around the C–O bond. For steric reasons,

$$w(\theta) = \frac{A}{\sqrt{\pi}} \exp\left[-A^2(\theta-\theta_0)^2\right] \quad (1)$$



$$\Delta\nu_i = K(3\cos^2\chi_i - 1)/r_i^3$$

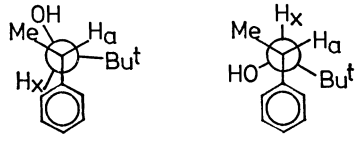
Fig. 5. Procedure for calculating the pseudocontact shifts.

θ_0 was taken so that the position of LSR was farthest from the center of the phenyl ring. The agreement factor (AF) was defined as in Eq. 2:

$$AF(\%) = 100(\sum_i |\mathrm{LIS}_{\mathrm{obsd},i} - \mathrm{LIS}_{\mathrm{calcd},i}|)/\sum_i \mathrm{LIS}_{\mathrm{obsd},i} \quad (2)$$

while the Ln–O distance (R) and the O–C–C–C(Ph) dihedral angle (ψ) were allowed to vary in order to enable us to obtain the best fit with the experimental values.

The AF values of 5 and 6% were the best fits where R=0.30 nm, ψ=210°, and A=0.2 for **5** and R=0.30 nm, ψ=285°, and A=0.6 for **6**. From these data, the H_a–C–C–H_x dihedral angles were estimated to be around 150° and 45° for **5** and **6** respectively.



(**5**) (**6**)

Fig. 6. Computer-simulated conformations for **5** and **6**.

This is illustrated in Fig. 6. On the basis of the Karplus relationship (Eq. 3):

$$^3J_{HH} = 8.5\cos^2\theta - 0.28 \quad (0°—90°)$$
$$= 9.5\cos^2\theta - 0.28 \quad (90°—180°) \quad (3)$$

the H_a/H_x dihedral angles, 45°, 50°, 150°, and 135°, give $^3J_{HH}$ values of *ca.* 4.0, 3.2, 6.8, and 4.5 Hz respectively. The computational results are, therefore, not so incompatible with the coupling data in view of the fact that they merely reflect the weighted mean of the possible rotamers. This conclusion is consistent with the solvent effect induced by benzene (ASIS) as well; a larger ASIS was observed for H_a in **6** than in **5** (Table 1). This is expected since H_a in **6** is oriented more apart from the hydroxyl oxygen than in **5**. The trend observed for the LSR distribution index (A) is also reasonable in view of steric considerations. On the basis of the simulated conformations (Fig. 6), the phenyl group in **6** can be said to hinder more effectively the approach of LSR and, hence, give rise to a larger A (0.6 *vs.* 0.2). Also noteworthy are the differences observed in the shielding constants for the *t*-butyl and hydroxyl protons of the isomers. The signals appropriate to the *t*-butyl and OH protons in **6** are appreciably shifted toward the high-field region compared to those in **5** (0.79 *vs.* 0.90 ppm and

1.3 *vs.* 1.48 ppm in CCl_4 respectively). This can be ascribed to the anisotropic shielding effect of the phenyl group. According to the suggested conformations, the *t*-butyl and the hydroxyl group in **6** lie closer to the phenyl ring than do those in **5**; therefore, they suffer from a more profound ring-current effect.

^{13}C-Chemical Shift: In Table 2 are included the differences $[\Delta=\delta(RS/SR)-\delta(SS/RR)]$ in the carbon resonances between these isomers. Table 3 lists the corresponding data for some structurally related sulfoxide diastereoisomers, **1** and **2**. The most remarkable differences are those (Δ) observed for the quaternary ring carbon (C^1) and for the methyl carbon (C^{11}) shifts. The peak assignable to C^1 appears at a magnetic field lower by 3.9 ppm for **5** than for **6**. The methyl carbon of **5**, in contrast, gives rise to a signal which is 5.9 ppm higher than that of **6**. Similar trends are also noted for the sulfoxide pairs.

The above results can be explained in terms of the γ-effect or the so-called steric compression shift.[17] On the basis of the suggested conformations (Fig. 6), the hydroxyl group in **5** lies closer to the methyl group than in **6**. It is, therefore, reasonable to expect a more pronounced γ-effect for the methyl carbon in **5**. For the quaternary ring carbon C^1, on the other hand, it is anticipated that such an effect is more profound in the (*SS/RR*) alcohol (**6**) than in the (*RS/SR*) one (**5**). Thus, both OH and Bu^t lie closer to the aromatic carbon in **6** than in **5**. The same trend observed for the sulfoxide pairs (Δ=2.7 and −1.8 ppm respectively for C^1 and C^{11}, where R=H; see Table 3) can be understood on a similar basis. The S–O oxygen atom has been established to be closer to the methyl group in **1** than in **2**.[5] The reverse is true for the spatial relationships of O and Bu^t with respect to the phenyl group. The chemical-shift differences between isomers (Δ) are somewhat smaller for sulfoxides than for the case of alcohol. This is also reasonable in view of the longer bond lengths (S–C *vs.* C–C and S–O *vs.* C–O) for sulfoxides relative to alcohols. The interatomic distances of the respective nuclei are longer for the sulfur compounds; hence, the γ-effects are smaller.

Intramolecular OH/π Interaction. IR Spectra: The above findings led us to an expectation that, whereas an intramolecular OH/π bonding can be operative in the (*SS/RR*)-isomer (OH/Ph *gauche*), this interaction will be absent for the (*RS/SR*)-isomer (**5**), which has a hydroxyl group apart from the phenyl ring. In order to clarify this point, we have examined the IR spectra of these compounds, together with the lower homologues in which the *t*-butyl group is replaced by the methyl, ethyl, and isopropyl groups.[10] Table 4 summarizes the results.

As is shown by a typical example of the IR traces of **5** and **6** in Fig. 7, these alcohols possess characteristic doublet O–H stretching bands, one at 3630—3645 cm^{-1} and the other at 3600—3610 cm^{-1}. It goes without saying that the former is to be assigned to the free OH group.[18] The trend for the position of the high-frequency band to move still to the higher-frequency side as the substituents go from the methyl through ethyl to isopropyl and *t*-butyl seems to demonstrate the effect of steric congestion by the alkyl groups.[18,19] Thus, the conformation in which the torsion angle between the OH and alkyl groups is small ($\leq 60°$) is suggested for the free OH species.

In the *threo* (see footnote a in Table 4 for these

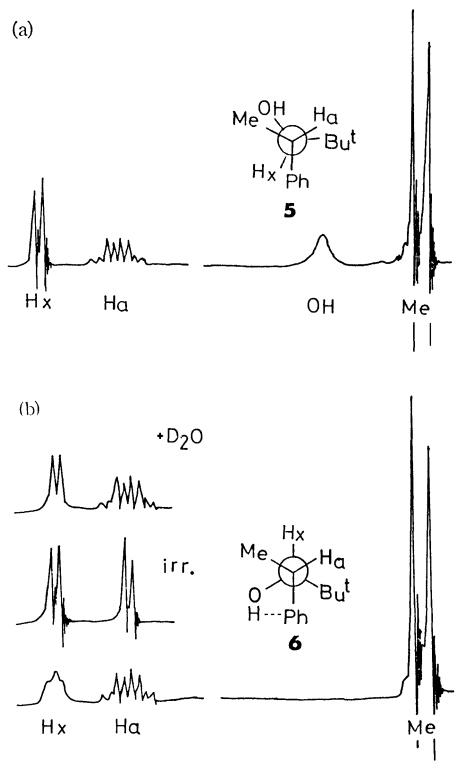

Fig. 8. Proton NMR spectra of **5** and **6** obtained for CCl_4 solutions. See text for inserts.

notations) series, the lower-frequency band is always stronger than the higher-frequency band.[11] It is also suggested by the wave number, as well as by the intensity of the lower-wave-number bands, that the OH/π bonding is strongest in the methyl and gets weaker as the substituent goes to the ethyl and isopropyl.[20] In other words, the OH and the phenyl groups come closer as Group R becomes smaller.

In the *erythro* series, the low-frequency bands are at *ca.* 3610 cm^{-1}. There are two possibilities for the origin of these bands: a weak OH/π bonding, or just a second free OH due to the presence of a OH rotamer in which the hydrogen atom bisects the hydrogen and carbon atoms. If the former is the case, we have to assume the contribution of a conformer with Bu^t/Ph *trans* (see Fig. 3) for **5**. We must reserve our conclusion on this matter until the effects of ring substituents on these low-frequency bands have been studied by performing a standard operational test for the OH/π interaction.[21] (The ν_{O-H} absorptions of these alcohols has already been reported by Sicher *et al.*[11] The present work conforms mostly to their method, but differs in some details because of differences in the resolution of the spectra and the method of the dissection of the doublet bands.)

NMR, GC, and MS Analyses: It has been shown by the above results that a major portion of the hydroxyl group in **6** interacts with the phenyl group, whereas in **5** it is almost free from intramolecular OH/π interaction. This conclusion is supported by an inspection of the NMR spectra. Parts of the proton NMR spectra are given in Fig. 8. The signal appropriate to H_x in **6** appears as a broad peak in both the solvents examined. In contrast, H_x in **5** gives rise to a sharp doublet (spin-coupled only with H_a). This is ascribed to the presence of a further coupling with the hydroxyl proton by H_x in **6**. The broad H_x signal collapsed to a doublet on decoupling (irradiation at *ca.* 130 Hz from TMS, where the broad signal of OH proton was assumed to be present under these conditions) or when the solution was treated with deuterium oxide. Also, the alcoholic hydrogen of **6** could hardly be observed because of the line broadening, while OH in **5** gives rise to a singlet. In the (*RS*/*SR*) isomer the non-bonded alcoholic hydrogen rapidly (at the NMR time scale) exchanges with that in the other molecules, thus giving rise to an observable peak. In the (*SS*/*RR*)-alcohol, on the other hand, the exchange rate is slowed down by the complexation of the hydroxyl group with the π-system, thus resulting in the disappearance of the OH signal.

Further support for the contribution of the intramolecular OH/π interaction in **6** (and its absence in the case of **5**) comes from comparisons of the chromatographic behavior[11] and the mass-fragmentation patterns.[12] Thus, the gas-chromatographic retention time is appreciably shorter for **6** than for **5**.[11] The relative intensity of the molecular ion peak *vs.* the dehydrated ion peak (M^+/M^+-H_2O) is larger for **6** (2.0) than for **5** (0.6). These results can be explained[12] in terms of the presence of OH/π bonding for **6**.

In summary, all of the results point to an unequivocal conclusion that, in the molecules presently studied,

the *t*-butyl group lies *gauche* to the phenyl group.

Discussion

Generality of the gauche *Conformation.* The conformations of **5** and **6** are indeed the consequences of the balance of a number of effects. The interactions involving the hydroxyl group, among others, should be taken into consideration. This seems to be of relatively minor importance in this particular case, however, since, in the (*RS*/*SR*) isomer (**5**), the conformer which lacks the OH/π interaction is found to be preferred. We wish here to emphasize that, in the cases studied thus far (**1**—**6**), the *t*-butyl group is always found to be close to the phenyl group, irrespective of the nature of the X group in the following general structure (Fig. 9) and irrespective of the conditions studied. Moreover, our preliminary data suggest that the above situation (alkyl/Ph *gauche*) holds also in the lower alkyl homologues.[6,22] It, therefore, follows that, in these compounds, an alkyl group has a general tendency to be closer to the phenyl group (or apart from Me) if these groups are present in the molecule.

	1	2	3	4	5	6
X =	SO	SO	S	SO_2	CHOH	CHOH

Fig. 9.

The conformations of molecules have frequently been interpreted in terms of the repulsive forces arising from interaction between nonbonded groups.[23] Such approaches assume that bringing "bulky" groups into proximity leads to unfavorable interactions; the nature of which is generally ascribed to the van der Waals repulsion. However, evidence has been accumulated that this approach does not apply in a number of cases. Thus, the two large groups in a rotamer are very often found to be *gauche* or to eclipse one another, not only in sp^3-sp^3 single-bond systems, but also in most sp^2-sp^3 as well as in certain double-bond systems. To cite only a few cases, it is established that 1,2-difluoroethane and propyl halides prefer a *gauche* rather than an *anti* conformation. Propionaldehyde is known to exist dominantly in the conformation where the methyl group is eclipsed with the C=O double bond. Enthalpy differences in favor of a *cis* over a *trans* isomer are well documented for 1-halopropenes, 1,2-difluoroethylenes, *etc.*[24]

The most impressive of all, however, are probably the cases where such groups as *t*-butyl or trimethylsilyl groups are involved. The examples include *meso*-3,4-dichloro-2,2,5,5-tetramethylhexane (**7**),[25] tetra-*t*-butyldiphosphine (**8**),[26] 1,1,2,2-tetra-*t*-butylethane (**9**),[27] 1,1,2,2-tetrakis(trimethylsilyl)ethane (**10**),[27] and 1,3,5-trineopentylbenzene (**11**)[28] systems (Fig. 10). In all these cases, the bulkiest groups are found to be close to each other in the preferred conformations. It seems, therefore, that this situation (favored *gauche* interaction) is a rule rather than an exception.

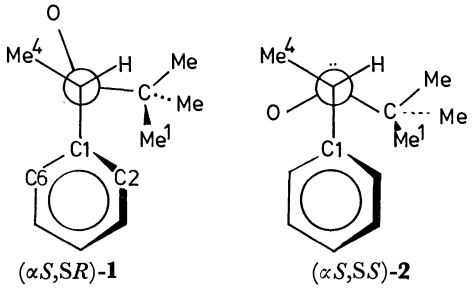
Fig. 10.

A number of approaches have been made to account for these "anomalies." The importance of attractive forces between nonbonded groups or atoms was suggested recently, while other workers favor interpretations in terms of repulsive steric effects or a conjugative stabilization (or destabilization) transmitted through bonds.[29] In particular, Carter and his group[28] advanced a concept of attractive steric effects on the basis of their findings regarding the conformational preference of the neopentyl groups in symmetrically substituted trineopentylbenzene systems (**11**). Their suggestion finds support in molecular mechanics calculations,[30] where the origin of the attractive forces is ascribed to London dispersion forces.

In the present case, where the interactions of an alkyl group with a phenyl group are concerned, the same approach will probably not apply, however. In the framework of the traditional approach, *i.e.*, the bulk-repulsive concept, the present result might be explained by regarding the "size" of a phenyl group as effectively smaller than that of a methyl group. A phenyl group is, of course, nonspherical and is capable of relieving the "steric constraint" which might occur in the interaction with the *t*-butyl group by a rotation about the C–C(Ph) bond. This possibility was argued in our earlier papers.[5,6] However, we found recently[31] that benzyl *t*-butyl sulfoxide (**12**) also adopts a conformation (in solution) similar to those established for **1**—**6**. This conclusion is based on NMR (LIS-simulation) evidence. Moreover, the stereospecificity and the stereoselectivities in the diastereotopos-differentiating reactions of **12** can be understood only on the basis of the *gauche* conformation.[32] In short, the preferred rotamer of **12** in solution again suggests that the *t*-butyl group is *gauche* with respect to the phenyl group. Note that in **12** the methyl group is absent. It follows that an interaction other than repulsive Me/Bu^t interaction should also be taken

into consideration.

Possibility of Attractive Alkyl···π-System Interaction; CH/π Interaction Hypothesis. A reexamination of the X-ray data on (*SR*/*RS*) (**1**) and (*SS*/*RR*)-1-(*p*-bromophenyl)ethyl *t*-butyl sulfoxide (**2**) (Fig. 1, X=SO) has revealed that a methyl group on Bu^t is oriented so as to be in close proximity to the phenyl ring, the C(Me^1)–C^1 distance being *ca.* 0.33 nm in both compounds (Fig. 11).[33] This is much shorter than the sum of the so-called van der Waals radii of the relevant groups (0.37 nm: 0.20 for a methyl and 0.17 nm for the half-thickness of a benzene molecule). To account for these findings, we recently suggested the importance of an attractive force involving an alkyl and an unsaturated group, namely, CH/π interaction.[31,32] A complexation of the benzene π-system has been known to occur with the acidic hydrogen atom of chloroform[35] or phenylacetylene.[36] For the non-acidic hydrogens of simple alkyl moieties in aliphatic molecules, however, the importance of such an interaction has not yet been suggested.[37]



(α*S*,S*R*)-**1** (α*S*,S*S*)-**2**

Fig. 11. Newman projections for the X-ray crystallographic structures of **1** and **2** (*p*-Br derivatives).

The presence of such a weak interaction has been supported by a semi-empirical MO calculation of a methane/benzene model system.[31] Thus, attractive potential curves were obtained by the CNDO/2 method, where the stabilization energy was estimated to be *ca.* 3.5 kJ/mol at the maximum,[38] the approximate distance between a methane hydrogen (carbon) at this position and the benzene plane being 0.20 nm (0.31 nm: 0.20+0.11). This compares well with the X-ray data cited above.

The magnitude of the interaction energy is very small for a single CH/π bonding. However, a CH group does not generally exist in an isolated state. They are present, more frequently, as parts of an atomic cluster, such as a methyl, ethyl or isopropyl group. It seems, therefore, to be reasonable, in some molecular environments, to expect a simultaneous action of multiple interactions. It might well be that the total interaction energy becomes significant.[39]

The recognition of the above fact would be of help in explaining certain well-known but poorly understood phenomena, especially in the dynamic interaction of reacting molecules. To mention briefly a few examples, it has long been recognized that the extent of asymmetric synthesis is uniformly higher for the phenyl keto esters (R=Ph) than for the methyl keto esters (R=Me) in the Prelog reaction system (Fig. 12).[40a] We suggest that the free-energy level at the competing diastereomeric transition states can be

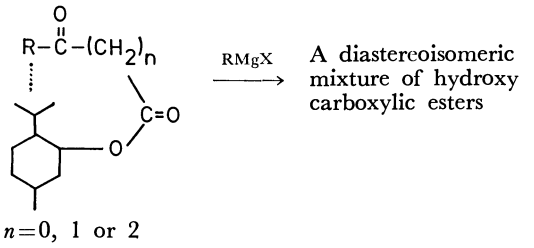


Fig. 12.

affected by an intervention of CH/π complexation. In the case of benzoylformate (R=Ph, n=0), the difference in the activation free energy, $\Delta\Delta G^{\ddagger}$, can be amplified by the interaction of Ph with the chiral aliphatic alcohol moiety (menthol group). Such an effect is absent in the case of pyruvate (R=Me, n=0), where we have a non-π system as R. Similar relationships hold also for the β-keto (n=1) and γ-keto ester (n=2) series.

A similar argument likely applies to the asymmetric reduction of ketones with optically active Grignard reagents (Fig. 13). The data listed in Table 5 are extracted from the works of Mosher and his group.[40b] A significant increase in the optical yield (%e.e.) has been reported when a phenyl group is incorporated in both the substrate and the chiral-reagent part (compare Tables 5a and 5b). In terms of the traditional

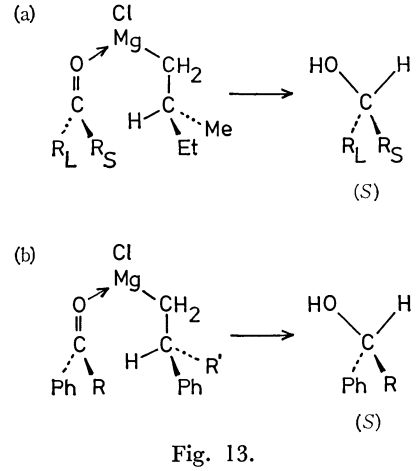

Fig. 13.

bulk-repulsive concept, the optical yield would be anticipated to decrease as the "bulk" of the substituent increases. Quite an inverse trend is observed for all cases, however, where we have a phenyl group in either side of the reacting species (Table 5b and column 3 in Table 5a). The results are comprehensible if one assumes the intervention of an attractive alkyl/phenyl interaction.[32,41] An interaction of this type could well be expected to increase with the number of CH groups in the aliphatic moieties, R and/or R′.

In this respect, the most interesting is probably the recent finding of Endo and his group.[42] In the course of an effort to find the factors controlling chemical reactions, they arrived at a model reaction system. This is composed of the oxidative coupling of a pair of thiols (D-SH and A-SH, Fig. 14) to disulfides. The ratio of the unsymmetrical disulfide over a symmetrical one (r=DSSA/DSSD) reflects the probability of the

a) (*S*)-alcohols obtained in excess. *Cf.* Tables 5.6 and 5.7 in Ref. 40. b) See also G. P. Giacomelli, R. Menicagli, and L. Lardicci, *Tetrahedron Lett.*, **1971**, 4135; R. Kretchmer, *J. Org. Chem.*, **37**, 801 (1972).

molecular recognition between the interacting species. The recognition has been found to be most selective when an isopentyl group is introduced as the alkyl substituent (R) in the A-SH molecule (r=21.2, but it gradually decreases on going from $i\text{-}C_5H_{11}$ to $i\text{-}C_6H_{13}$ and then to $i\text{-}C_7H_{15}$ group). Such a remarkable dependence of the selectivity on the structure was not observed for A-SH where a series of straight-chain alkyl groups were used as R. An inspection of the CPK molecular models suggests that the complexes of the reacting species may well be stabilized by the CH/π type interaction; with the aromatic part of the D-SH molecule (dimethylaminophenyl group), the interaction is possible if we have an alkyl group as R in A-SH. This might be expected to be most selective when the R is a branched one and has an appropriate length (Fig. 14b).

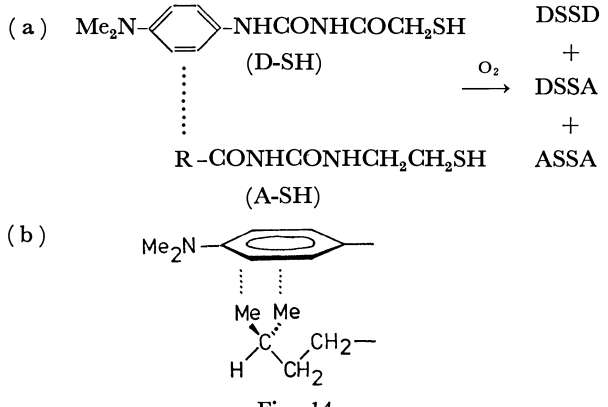

Fig. 14.

We wish to take this opportunity to point out the possibility that a weak interaction of such a kind plays an important role in determining the 3-D structure and the specificity of some globular proteins. These include enzymes, hemoglobins, or immunoglobulins.[43)] As has been emphasized by Watson,[46)] the secondary forces involved in the specific biopolymer interactions should never be too strong. Instead, they should be moderately weak, thus making it possible to assume a rapid recombination of biochemically important molecules (and therefore to be compatible with the cellular existence). Our knowledge about the weak chemical interactions is, however, still very incomplete.[46)] To be a candidate for these forces an interaction must be weak and also have the proper steric requirements. In addition to this, the groups involved in a weak secondary force used in biological devices must be widely distributed in nature. All of the prerequisites are fulfilled by the CH/π interaction—it is weak enough and orientation-dependent. Simple aliphatic groups are so abundant that we can find these moieties in virtually all components of natural sources. As to the abundancy of the groups, we will cite here the case of amino acid: both the aliphatic residues (Ala, Val, Leu, Ile, Met) and the aromatic ones (Phe, Tyr, Trp, His) are commonly found in proteins.

We wish to thank Drs. Tadashi Endo (Aoyama Gakuin Univ.), Naoya Nakagawa (Univ, of Electro-Communications), and Minoru Hirota (Yokohama National Univ.) for their valuable discussions and comments.

36) N. Nakagawa and S. Fujiwara, *Bull. Chem. Soc. Jpn.*, **33**, 1534 (1961).
37) See, however, N. Nakagawa, *Nippon Kagaku Zasshi*, **82**, 141 (1961). See also D. J. Sutor, *J. Chem. Soc.*, **1963**, 1105 for the case of CH_3/O.
38) The datum was erroneously reported to be 4.8 kJ in Ref. 31. For a CH_4/C_2H_2 system, the stabilization energy has been estimated to be *ca.* 4.8 kJ/mol (N. Nakagawa, personal communication). These data probably represent the maximum values, since the energies are frequently overestimated by this approximation.
39) It might be that this type of interaction (CH_3/π and CH_3/X, X=O or N) is entropically advantageous in that the chance for the interaction increases upon a clustering of CH groups into certain arrangements. We wish to refer this concept (a multiple as well as a chance effect) to the "isopropyl effect," the implications of which will be discussed elsewhere (M. Nishio and T. Endo, to be published; *cf.* Ref. 34).

Enantioface-differentiating (Asymmetric) Hydrogenation of Keto Ester with Modified Nickel Catalyst. XXXII. Structural Requirements of Modifying Reagent and Substrate

Shinji Okamoto, Tadao Harada, and Akira Tai*

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received March 29, 1979)

The enantioface-differentiating hydrogenation of α-, β-, γ-, and δ-keto esters over α-, β-, and γ-amino acid-MRNi has been conducted. The optimum enantio-differentiating power of α-amino acid-MRNi has been found in the hydrogenation of the β-keto ester and that of β-amino acid-MRNi found in the hydrogenation of the γ-keto ester. The results have been explained in terms of the intermolecular recognition between substrate and modifying reagent through the functional groups.

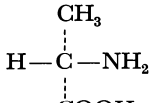
Asymmetrically modified nickel catalysts (MNi) provide attractive catalysts for the enantioface-differentiating hydrogenation of prochiral unsaturated compounds because of their simplicity and wide applicability.

The modifying reagents which have high enantio-differentiating power with one type of substrate do not necessarily do so with another substrates.[1] Therefore, the choice of modifying reagent suited to each type of substrate is the most important criteria for preparing an effective catalyst. In general, α-amino acid- or α-hydroxy acid-MRNi show good enantio-differentiating power with β-keto esters but not with α- and γ-keto esters. In a preceding paper which dealt with the hydrogenation of β-keto esters with tartaric acid-MNi, it was shown that the intermolecular hydrogen bond between substrate and the modifying reagent were one of the most important factors governing the optical yield of the reaction.[2] On this basis, the effect of the structural relation between the modifying reagent and the substrate on the enantio-differentiating power of the modified catalyst has been investigated by monitoring the optical yields of the hydrogenations of α-, β-, γ-, and δ-keto esters over α-, β-, and γ-amino acid-MRNi.

Results and Discussion

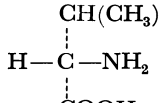
The substrates and the modifying reagents used in this study are as follows;

Modifying reagents



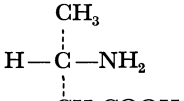
(*S*)-alanine

(I)



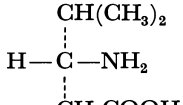
(*S*)-valine

(II)



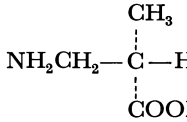
(*S*)-3-aminobutyric acid

(III)



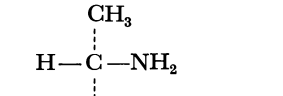
(*S*)-3-amino-4-methylpentanoic acid

(IV)



(*S*)-3-amino-2-methylpropionic acid

(V)



(*S*)-4-aminopentanoic acid

(VI)

Substrates

$CH_3CO(CH_2)_nCOOCH_3$

- $n=0$ methyl pyruvate (**1**)
- $n=1$ methyl acetoacetate (**2**)
- $n=2$ methyl 4-oxopentanoate (**3**)
- $n=3$ methyl 5-oxohexanoate (**4**)

The modification of Raney nickel was conducted as previously reported.[3]

The hydrogenation of each substrate was performed in an autoclave at 100 kg/cm² of initial hydrogen pressure at 60 °C. The optical yields of the reactions are summarized in Table 1.

In the hydrogenation of various keto esters over α-amino acid-MRNi the maximum optical yield was obtained with methyl acetoacetate as shown in Fig. 1. Methyl 4-oxopentanoate gave the optimum optical yield on hydrogenation with a β-amino acid-MRNi (Fig 2). In the β-amino acid-MRNi, III and IV, in which the chiral center is at the β-position of the carboxyl group and V in which the chiral center is at the α-position of the carboxyl group, the same trend in enantio-differentiating power with change in substrate was observed.

From a geometrical point of view, it is thought that the positions of the $-NH_2$ and $-COOH$ groups in the modifying reagent and those of the $-CO-$ and $-COOCH_3$ groups in the substrate are the most important factors in the optical yield of hydrogenation, *i.e.*, a reasonable optical yield is only attained when the substrate can make a stabilized complex with the modifying reagent involving more than two pairs of interaction through functional groups as indicated above.

As shown in Fig. 2, with a structural fit between the substrate and the modifying reagent, the optical yield is not influenced by the position of the chiral center.

In the case of the γ-amino acid-MRNi, no significant enantio-differentiating power was observed in all substrates examined ($n=0$ to 3). The low optical

yields in the reactions with the γ-amino acid–MRNi, even in the case of the δ-keto ester, may be ascribed to the lack of rigid intermolecular interaction due to the flexible nature of the molecules. Thus, the formation of rigid interaction between the substrate and the modifying reagent is the most important factor in obtaining a reasonable optical yield in this reaction system.

No special models demonstrating the mode of differentiation between the direction of enantioface-differentiation and absolute configuration of the modifying reagent, were derive from the present data. The structural requirement between the substrate and the modifying reagent provides, however, useful information as to the design of effective catalysts for enantio-differentiating reactions.

Experimental

Gas chromatographic analysis was conducted with a Shimadzu GC-4APF apparatus using a 300×0.5 cm glass column packed with neopentyl glycol succinate (5%) on Chromosorb W. Optical rotation was measured with a Perkin Elmer 241 polarimeter at 589 nm. NMR and IR spectra were measured on Hitachi R-24 and Shimadzu IR-27G spectrometers respectively.

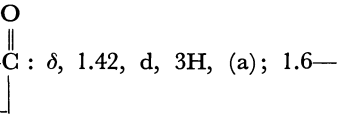
Modified Raney Nickel Catalyst. The Raney nickel

catalyst was prepared as reported before.[3] A portion of the Raney nickel (0.1 g) was added to a 1% aqueous solution of the modifying reagent (20 ml). The mixture was allowed to stand with occasional shaking at 0 °C for 15 min. After decantation, the catalyst was washed with a portion of water (1 ml) and three portions of methanol (3×10 ml).

Hydrogenation and Optical Yield. Into a 10 ml flask equiped with a small gas inlet tube, was introduced the modified catalyst (0.1 g) suspended in the substrate (0.028 mol). The flask was placed in an autoclave and the hydrogenation conducted under hydrogen (90 kg/cm²) at 60 °C until no more consumption of hydrogen was observed. After filtration of the catalyst, the filtrate was distilled under reduced pressure. GLC analysis of each distillate indicated that the hydrogenation was complete.

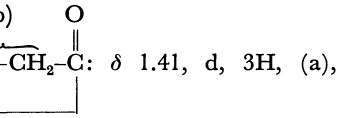
Methyl lactate, bp 60—61 °C/35 mmHg† and methyl 3-hydroxybutyrate bp 61—62 °C/12 mmHg were obtained almost quantitatively from methyl pyruvate and methyl acetoacetate respectively.

A mixture of methyl 4-hydroxypentanoate and 4-pentanolide, and a mixture of methyl 5-hydroxyhexanoate and 5-hexanolide were obtained from methyl 5-oxopentanoate and methyl 5-oxohexanoate respectively. The optical yields of the hydrogenations of methyl pyruvate and methyl acetoacetate were calculated from the optical rotation of the products based on the values of $[\alpha]_D^{20}$ −8.25° (neat) for methyl (*S*)-lactate[4] and $[\alpha]_D^{20}$ −22.95° (neat) for methyl (*R*)-3-hydroxybutyrate.[5] The hydrogenation product of methyl 5-oxopentanoate was refluxed with Amberlyst 15 in benzene for 3 h to give 4-pentanolide bp 88—84 °C/13 mmHg.



NMR for $CH_3C(a)-CH_2(b)-CH_2(b)-C(=O)O(a)$: δ, 1.42, d, 3H, (a); 1.6—2.6, m, 4H, (b); 4.68, m, 1H, (c). The optical yield of the hydrogenation was indirectly evaluated from the optical rotation of 4-pentanolide derived from the hydrogenation product based on the value of $[\alpha]_D^{22}$ −35.1±1° (*c* 4.018, dioxane) for (*S*)-5-pentanolide.[6]

The hydrogenation product of methyl 5-oxohexanoate was also converted to 5-hexanolide (bp 97—99 °C/12 mmHg)



NMR for $CH_3C(a)-CH_2(c)-CH_2(b)-CH_2(b)-C(=O)O(a)$: δ 1.41, d, 3H, (a), 1.6—2.8, m, 4H, (b), 2.5, m, 2H, (c), 4.5, m, 1H, (d), by the same method as above. The optical yield of the hydrogenation was indirectly determined from the optical rotation of 5-hexanolide thus obtained based on $[\alpha]_D^{20}$ −51.4° (*c*=4, ethanol) for (*S*)-5-hexanolide.[7]

Modifying Reagents. *(S)-3-Aminobutyric Acid (III)*: This compound was obtained by the optical resolution of ethyl (*RS*)-3-aminobutyrate with (*R,R*)-tartaric acid in methanol and saponification of the resolved ester. From ethyl (*RS*)-3-aminobutyrate (131 g), optically pure (+)-(*S*)-III (7.5 g) was obtained. $[\alpha]_D^{25}$ +37.0° (*c* 0.5, H_2O) (lit, $[\alpha]_D^{19}$ 38.8° (*c* 0.8, H_2O)).[8] Mp 221 °C. Found: C, 46.69; H, 8.99; N, 13.60%. Calcd for $C_4H_9O_2N$: C, 46.59; H, 8.80; N, 13.58%.

(S)-3-Amino-4-methylpentanoic Acid (IV): (*S*)-Valine was converted to (+)-methyl (*S*)-3-phthalimido-4-methylpentanoate (VII) by the reported method.[9] To a solution of hydrazine hydrate (90%, 13 g) in a mixture of water (100 ml) and methanol (200 ml), VII (32 g) was added and the mixture maintained at room temperature for one week. After removal of the methanol from the reaction mixture and acidification of the residue with hydrochloric acid to pH 4, the precipitate was removed. Condensation of the filtrate to dryness gave crude 3-amino-4-methylpentanoic acid hydrazide as an oil. The oil was refluxed with 2M†† hydrochloric acid (300 ml) for 4 h and the resulting solution concentrated to dryness to give 3-amino-4-methylpentanoic acid hydrochloride. The crude amino acid hydrochloride was charged on to a column of IR 120B (H^+ type) and eluted with 0.2 M aqueous ammonia. Evaporation of water from the eluate gave crude crystals of IV. Recrystallization from a mixture of methanol and ether yielded (*S*)-(+)-IV (6 g). Mp 212 °C, $[\alpha]_D^{23}$ +52.3° (*c* 0.6, H_2O), (lit, $[\alpha]_D^{24}$ −39.2° (*c* 0.51, H_2O) for (*R*)-(−)-IV.[11]) Found: C, 54.66; H, 10.09; N, 10.49%. Calcd for $C_6H_{13}O_2N$: C, 54.94; H, 9.99; N, 10.68%.

(S)-3-Amino-2-methylpropionic Acid (V): This compound was obtained by the Hoffman degradation of (*S*)-3-carbamoyl-2-methylpropionic acid (VIII) ($[\alpha]_D^{23}$ −22° (*c* 2, ethanol)) which was prepared from (*E*)-3-carbamoylmethacrylic acid.[10] To a solution of KOBr prepared from bromine (12 g) and 10% aqueous potassium hydroxide (400 ml), VIII was added (9.8 g). The mixture was maintained at 55 °C for 1 h and then cooled to 0 °C. The solution was acidified to pH 2 with hydrochloric acid and concentrated to dryness. The residue was extracted with three portions of ethanol (3× 30 ml) and the combined extracts condensed to dryness to give crude crystals of 3-amino-2-methylpropionic acid hydrochloride. The hydrochloride was dissolved in water (200 ml) and passed through a column of Dowex-50. The amino acid loaded on the resin was eluted with 0.2 M aqueous ammonia. Evaporation of water from the eluate gave crystals of V. Recrystallization from a mixture of methanol and ethanol gave (*S*)-(+)-V (5.3 g), mp 194—5 °C, $[\alpha]_D^{21}$ +15.4° (*c* 5, H_2O), (lit, (*R*)-(−)-V, $[\alpha]_D^{26}$ −15.4° (*c* 1, H_2O).[11]) Found: C, 46.06; H, 9.10; N, 13.31%. Calcd for $C_4H_9NO_2$: C, 46.59; H, 8.80; N, 13.58%.

(S)-(+)-4-Aminopentanoic Acid (VI): This compound was obtained by the optical resolution of 4-(benzoylamino)-pentanoic acid with quinine and saponification of the resolved acylamino acid.[12] 4-(Benzoylamino)pentanoic acid (65 g) gave (*S*)-(+)-VI (2.7 g) as crystals, mp 205 °C, $[\alpha]_D^{23}$ +12.1° (*c* 10, H_2O) (lit, $[\alpha]_D^{20}$ +12.0° (*c* 10, H_2O)).[8] Found: C, 50.88; H, 9.69; N, 11.57%. Calcd for $C_5H_{11}NO_2$: C, 51.26; H, 9.46; N, 11.96%.

*Substrate. Methyl Pyruvate (**1**)*: This was obtained from silver pyruvate (190 g) and methyl iodide (164 g) by a conventional procedure (yield 70%), bp 61—63 °C/13 mmHg. GLC (80 °C) showed a single peak. The IR spectrum (neat) was identical with that from an authentic sample.

*Methyl Acetoacetate (**2**)*: The commercial product (Nihongosei Co.) was used without further purification.

*Methyl 4-Oxopentanoate (**3**)*: This compound was obtained by the esterification of 4-oxopentanoic acid with methanol in the presence of Amberlyst 15 (yield 90%). GLC (130 °C) showed 98% purity. H^1 NMR (CCl_4) and IR spectra were consistent with the structure of **3**. Elementary analysis was conducted as the 2,4-dinitrophenylhydrazone of **3**. Found: C, 48.19; H, 4.97; N, 17.30%. Calcd for $C_{13}H_{16}O_6N_4$; C, 48.15; H, 4.97; N, 17.28%.

*Methyl 5-Oxohexanoate (**4**)*: 5-Oxohexanoic acid was obtained from methyl acetoacetate and methyl acrylate (yield 68%).[13] The esterification of the acid with methanol

† 1 mmHg=133.3 Pa.

†† 1 M=1 mol dm^{-3}.

in the presence of Amberlyst 15 gave **4** (yield 90%). Bp 96 °C/15 mmHg. GLC analysis (130 °C) showed a single peak. Elemental analysis was conducted as the 2,4-dinitrophenylhydrazone of **4**. Found: C, 48.19; H, 4.97; N, 17.30%. Calcd for $C_{13}H_{16}O_6N_4$: C, 48.15; H, 4.97; N, 17.28%.

The authors would like to thank Professor Yoshiharu Izumi for his helpful suggestions and discussions. Thanks are also due to Mrs A. Kobatake for the elemental analyses. The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

One-electron Reduction of 1-Benzyl-3-carbamoylpyridinium as a NAD$^+$ Model

Yutaka OHNISHI* and Miyoko KITAMI

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received April 2, 1979)

The pyridyl radical generated chemically or electrochemically by the 1e-reduction of 1-benzyl-3-carbamoylpyridinium undergoes dimerization to give mainly four dimers, diastereomers of 4,4′- and 4,6′-linked dimers. Isomerization between the dimers proceeds readily.

A pyridyl redical NAD· is recognized as a significant intermediate[1] in biological interconversion between NAD$^+$ and NADH, this being supported by results from oxidation and transhydrogenation in model systems.[2] Pyridyl radicals having carbamoyl group on C_3 can be readily generated by chemical,[3] photochemical,[4] electrochemical,[5–7] or radiochemical[8,9] one-electron reduction of the corresponding cations. The transient radicals react with each other to give dimerized products. However, there seems to be confusion concerning the products, particularly in the structures of the dimers.[3–7,10] Recently, Moracci *et al.* reported that 1e-reduction of 1-benzyl-3-carbamoylpyridinium (BzNA$^+$) gives a diastereomeric pair of 4,4′-linked dimer.[7] Formation of 4,6′- and 6,6′-dimers has also been postulated by other investigaters. Furthermore, Kosower *et al.* predicted the formation of a dihydronicotinamide by the dispropotionation of the 3-substituted pyridyl radical.[11] The formation of a dihydronicotinamide was also demonstrated in the electrolysis of the corresponding 1-alkyl-3-carbamoylpyridinium at a potential on the polarographic first wave.[12]

We have studied biomimetic conversion from a pyridinium into the corresponding dihydropyridine and found that a pyridyl radical, BzNA·, arising in the 1e-reduction of BzNA$^+$, gives none of 1-benzyldihydronicotinamides (BzNAH); it mainly gives two pairs of 4,4′- and 4,6′-linked dimers in analogy with the dimerization of 1-methyl-3-cyanopyridyl radical.[13] Isomerization between the dimers of BzNA· was also observed. In this article we wish to describe the details.

Results and Disscusion

Chemical 1e-reduction of the chloride of BzNA$^+$ was carried out using zinc powder–copper sulfate in methanol–aqueous ammonia.[3,4] Electrochemical 1e-reduction was performed with an Hg-pool electrode at

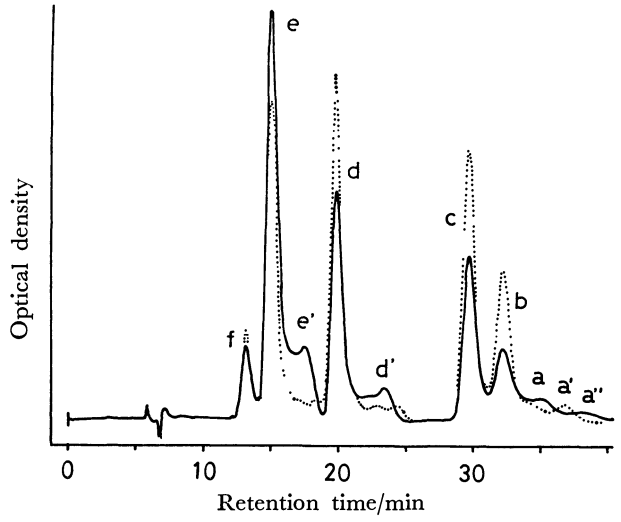

Fig. 1. HPLC trace of the reaction mixtures of one-electron reduction of BzNA$^+$ chemically (——) and electrochemically (·····).

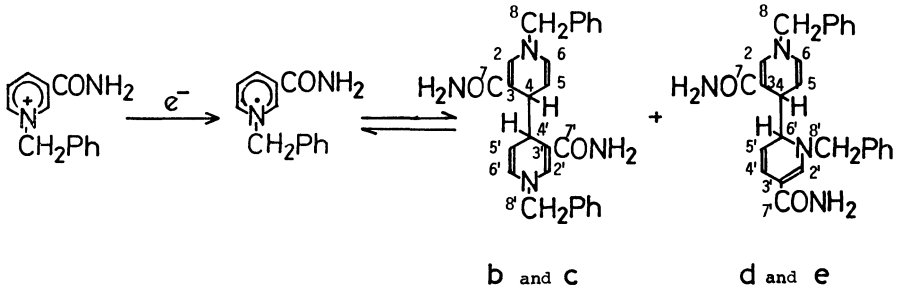
−1.30 V, where the reversible 1e-reduction occurs[14] at pH 7.4 with McIlvaine's buffer. As shown in Fig. 1, many products were found in both chemical and electrochemical reaction mixtures by means of high pressure liquid chromatography (HPLC). We have confirmed the formation of 1,2-, 1,4-, or 1,6-BzNAH with HPLC. However, none of the products was found in the reaction mixtures. This result shows that disproportionation of BzNA·'s did not take place.[11,12] We have attempted the isolation and identification of four major products, **b**, **c**, **d**, and **e**. They could be isolated and purified by careful fractional recrystallization and column chromatography. In order to obtain unequivocal information on coupling positions of the dimers, the reduction of BzNA$^+$ deuterated on the C_4 of the nicotinamide ring was also carried out chemically.



Scheme.

Table 1. ^{1}H NMR data for dimers[a)]

	b	c	d	e

$C_{8'}$	58.3	56.1 or 55.9		
$C_{4'}$	122.7	123.3		

a) The numbers present chemical shifts, δ with ppm, from TMS in $(CD_3)_2SO$. b) Moracci's data.[7)]

^{1}H and ^{13}C NMR data of these compounds are summarized in Tables 1 and 2. Spectra of both **b** and **c** provide reasonable evidence for a symmetric structure. The tracer experiment established the coupling positions in the dimers. ^{1}H NMR spectra of **b** and **c** derived from BzNA$^+$-4d_1 showed no methine signal at δ 3.34 and 3.22, respectively, indicating that they have only 4-substituted 1,4-dihydronicotinamide structure; namely **b** and **c** can be identified as 4,4'-dimers of BzNA· and are a diastereomeric pair with respect to the C_4–$C_{4'}$ stereochemistry.[15)]

The complexity of ^{1}H and ^{13}C NMR spectra of **d** where two types of amide-signals are present suggest unsymmetric structure. The ^{1}H NMR signals at δ 3.20 and 6.37, not present in the spectrum of **d** obtained in the tracer experiment, should be due to the methine proton on C_4 of the 4-substituted 1,4-dihydropyridine structure and the vinyl proton of the 1,2- or 1,6-dihydro structure, respectively. However, the signal at δ 4.80, which is assigned to the proton on C_5, has a large coupling constant, J=5.2 Hz. This excludes the 1,2-dihydropyridine structure for the dimer **d**.[17)] The ^{13}C NMR spectrum of **d** is composed of that of 1,4- and 1,6-BzNAH expect that signals for methylene carbons appear as signals for methine carbons. Since a similar agreement between ^{13}C NMR spectra of 1,4-BzNAH and **b** or **c** is recognized, this observation and ^{13}C NMR spectrum with the off-resonance proton decoupling technique in the dimer **d** strongly indicate the presence of 4-substituted 1,4-dihydro and 6-substituted 1,6-dihydronicotinamide structures. The ^{1}H and ^{13}C NMR spectral data are in line with the structure of 4,6'-linked dimer.[18)] The complex signals could be assigned as shown in Tables 1 and 2. By similar analyses of ^{1}H and ^{13}C NMR spectra of **e** and the corresponding deuterated one, it can be concluded that **e** is the other diastereomer of 4,6'-dimer **d**.

Thus, the structures of four products isolated in the 1e-reduction of BzNA$^+$ can be established as two pairs of diastereomeric isomers of 4,4'- and 4,6'-linked dimers. The ratios of the yields of compounds **b**, **c**, **d**, and **e** from the chemical reduction are 1.0 : 1.4 : 3.0 : 4.5 at 4 °C and 1.0 : 2.6 : 2.3 : 3.3 at 60 °C, respectively. The ratio in the electrolysis at ambient temperature is 1.0 : 1.8 : 1.7 : 1.4. Although the ratios are labile, the total yield of four major products is larger than 95% in all cases. We assume that the residue should contain 2,2'-, 2,4'-, 2,6'- and 6,6'-dimers.

Statistically dimerization of BzNA· may give 12 dimers; six pairs of diastereomeric isomers. However, taking into account the far larger spin densities on

C_4 and C_6 of pyridyl radicals than C_2,[19] three pairs, 4,4′-, 4,6′- and 6,6′-dimers, may predominate. Actually, it was proved that the dimers obtained mainly have 4,4′- or 4,6′-bonding, the formation of other dimers not being appreciable. A small or negligible amount, if any, of 6,6′-dimers results from steric hindrance for dimerization. Furthermore, it should be taken into account that pyridyl radical in our reaction systems was generated on and participated by a metal surface, Zn or Hg. The difference of the metal might contribute to the dissimilarity between chemical and electrochemical reductions with respect to the ratios of the yields of four major dimers.

We have found isomerization between dimerization products. Even upon being left to stand overnight at room temperature in the dark with exclusion of air, a solution of 4,6′-dimer **d** gave 4,4′-dimer **c** mainly together with minor amounts of **a**, **b**, **d**, **d′**, **e**, and **e′**. **e** in methanol kept at 82 °C for 2 h also isomerized into a mixture of **a**, **a′**, **b**, **c**, **d**, **d′**, **e**, and **e′**; **c** was predominant. A solution of the most stable dimer **c** gave a mixture of **a**, **a′**, **b**, and **c** by heating at 82 °C for 15 h. In this mixture, small amounts of **a″**, **e**, and **d** were also detected. It was observed that the rate of the isomerization of **d** is accelerated by exposing the solution to scattered light. The isomerization indicates that the 4,4′-dimers are thermally more stable than the 4,6′-dimers and that the C–C bond coupling two pyridyl moieties is so weak that the dimer dissociates reversibly into two BzNA·'s.[20] The latter seems reasonable because of steric crowd of the dimers and of the resonance-stabilized structure of the radical.

Experimental

^1H and ^{13}C NMR spectra were taken on a Varian XL-100-15A. HPLC was effected with a Toyo Soda HLC-803 instrument and 30 cm LS-410K column under the following conditions. For BzNAHs, mobile phase, methanol–water (5:4 v/v); flow rate, 0.30 ml/min; detecter, UV-photometer at 350 nm; for the dimers, methanol–water (2:1 v/v); 0.54 ml/min, UV-photometer at 360 nm, respectively. Polarogram was recorded with a Yanaco Type P8-D Polarograph, macro scale electrolysis being performed with a potentiostat (Hokuto Denko Ltd.).

Reduction in Zinc Powder/Copper Sulfate System. To zinc powder (1.4 g) in 10 ml of water was added 0.5 g of copper sulfate pentahydrate in 20 ml of water under vigorous magnetic stirring, a mixture of 28% aqueous ammonia (10 ml) and methanol (50 ml) then being added. A solution of 0.1 g of $BzNA^+Cl^-$ in 20 ml of water was added to the above mixture at a definite temperature. After 20 min, the mixture was analyzed by HPLC (Fig. 1).

In preparative experiments, zinc powder (0.6 g)/H_2O (10 ml), $CuSO_4 \cdot 6H_2O$ (2.5 g)/H_2O (20 ml), 28% aqueous ammonia (10 ml)/methanol (50 ml) and 5.0 g of $BzNA^+Cl^-$/H_2O (20 ml) or 6.0 g of $BzNA^+$-$4d_1$ ClO_4^- in a mixture of H_2O (15 ml) and methanol (15 ml) were used, the reaction being carried out precipitate and inorganic materials were collected by filtration and were washed with 70 ml of hot methanol. Crystals of **c** obtained by cooling the methanol solution were separated by filtration. The filtrate was concentrated partially and cooled to give crystals of **d**. Further concentration and filtration gave crude crystals of **e** and the filtrate containing **b** predominantly. The filtrate was concentrated and chromatographed on a basic alumina eluting with a mixture of methanol and hexane (3:7 v/v). Several fractions containing only **b** were collected. Elimination of the solvents gave crystals of **b**. On the other hand, when the first aqueous filtrate was left to stand at room temperature for some time, yellow solids of **d** and **e** and orange viscous oil containing **b**, **d**, **e**, and **f** separated. After removal of the yellow solids and the oil by filtration and decantation, the solution was cooled in an ice bath to give crystals of **e** which were recrystallized from an aqueous methanol: mp (dec) 155 °C. Found: C, 72.99; H, 6.13; N, 13.19%. Calcd for $C_{26}H_{26}N_4O_2$: C, 73.22; H, 6.14; N, 13.14%. The yellow solids and the oil were treated similarly by fractional recrystallization to give pure dimers.

Absorption maxima of **b**, **c**, **d**, and **e** were observed at 355, 355, 359, and 359 nm, respectively, with a spectrometer (Shimadzu SPD-1) equipped with the HPCL instrument. In the treatments described above, HPLC was used effectively to estimate the composition of mixture and purity of isolated product.

Electrochemical Reduction. Electrolysis was carried out in a three-compartment cell, the cathode being a mercury pool (area, 12.6 cm^2), the anode a coil of Pt wire, and the reference electrode a saturated calomel electrode. The cathode was isolated from the anolyte with a glass filter and agar gel. Argon was blown continuously through the catholite before and during electrolysis. After preelectrolyzing the McIlvaine's buffer (pH 7.4, 30 ml), 102.5 mg of $BzNA^+Cl^-$ was added. Electrolysis was carried out at −1.30 V and stopped coulometrically at 25% conversion because of coating on the mercury surface with solid products. Dimethyl sulfoxide was then poured into the cathodic cell. After the mixture had been stirred until the mercury became clear, the solution was analyzed by HPLC.

We thank Dr. Y. Kikuchi for his help in the electrochemistry and Mr. K. Sato for measuring NMR spectra.

Induced Circular Dichroism of β-Cyclodextrin Complexes with Substituted Benzenes

Hiroshi SHIMIZU, Akira KAITO, and Masahiro HATANO*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received November 7, 1978)

The induced circular dichroism (ICD) of β-Cyclodextrin(β-CDx)-substituted benzene complexes was investigated. We observed the ICD on the absorption bands of achiral substituted benzene molecules, which is considered to be induced by the dissymmetric field of the chiral β-CDx host molecule. The electronic transitions which are polarized along the long axis of the substituted benzenes showed positive ICD, while the sings of the ICD of short-axis polarized transitions are negative. The rotational strengths of these inclusion complexes were calculated by the Kirkwood-Tinoco expression. From the comparison between the experimental and calculated results, it is concluded that these β-CDx complexes favor the axial inclusion in which the long axis of the substituted benzenes is parallel to the axis of the β-CDx cavity.

The cyclodextrins (CDxs) are a series of oligosaccharides produced by the action of *Bacillus macerans* amylase on starch.[1] CDxs are cyclic oligosaccharides composed of D(+)-glucopyranose units which are connected with each other by the α-(1,4)-glucoside bond. The number of glucose units of CDx is designated by a Greek letter: α- for 6, β- for 7, γ- for 8, and so on.

CDx has a hydrophobic cavity in the center of a CDx molecule. And it is known that CDx includes aromatic compounds, alkyl halides, gases, *etc.* as guest molecules in the CDx cavity, resulting in the formation of inclusion complexes.[2] These inclusion phenomena of CDx have been employed as one approach to the enzyme model, since CDx exhibited the steric specificity in a way similar to the formation of enzyme–substrate complexes.[3]

Inclusion complex formation is associated with a favorable enthalpy change and an unfavorable or slightly favorable entropy change. Several proposals[4] for the driving force of the complex formation have been made to interpret this favorable enthalpy change:

a) van der Waals interactions between the guest and host molecules

b) hydrogen bonding between the guest molecule and the hydroxyl groups of CDx

c) release of high energy water molecules in complex formation

d) decrease in strain energy in the ring frame of CDx.

From the results of the X-ray crystallography of the α-cyclodextrin–potassium acetate complex, Hybl *et al.*[5] revealed that α-CDx has a doughnut-shape with all the glucose units in substantially undistorted chair conformations. In addition, many investigations on the structure of inclusion complexes have been made by means of various physicochemical methods, *e.g.*, X-ray analysis,[6] NMR,[7] ESR,[8] UV,[9] CD,[10–12] *etc.*

Since CDxs are composed of chiral glucose units, the circular dichroism (CD) is expected to be induced on the absorption bands of the achiral guest molecules which are included in the cavity of chiral β-CDx. We thus investigated ICD spectra of β-CDx inclusion complexes with substituted benzenes in aqueous solution, and calculated the rotational strength on the basis of the Kirkwood-Tinoco equation,[13] with the goal of predicting the orientation of the guest molecules in these inclusion complexes.

Experimental

β-CDx and substituted benzenes were commercial products. β-CDx, benzoic acid, and *p*-nitrophenol were recrystallized from aqueous solutions. Aniline, phenol, and nitrobenzene were distilled under reduced pressure. *p*-Nitroaniline and *p*-hydroxybenzoic acid were recrystallized from methanol and ether, respectively. An inclusion complex was prepared by mixing β-CDx and the corresponding substituted benzene in an aqueous solution or in 0.1 M aqueous HCl.

The circular dichroism and absorption spectra were measured at room temperature using a JASCO J-20A spectropolarimeter and a Hitachi EPS-3T spectrophotometer, respectively.

Formation constants, K, and the difference in the molar extinction coefficients for right and left circularly polarized light in liter mol^{-1} cm^{-1}, $\Delta\varepsilon$, of inclusion complexes were determined by means of Benesi-Hildebrand method.[14]

On the other hand, the composition ratio of inclusion complexes was defined by Job's continuous variation method.[15]

The dipole strengths, D, of substituted benzenes were estimated from the absorption spectra as accurately as possible by use of the following approximate expression:

$$D = 0.92 \times 10^{-38}\sqrt{\pi}\cdot\varepsilon_{max}\cdot\frac{\Delta}{\lambda_{max}} \quad (1)$$

where ε_{max} is the maximum value for the molar extinction coefficient, λ_{max} is the wavelength at absorption maximum, and Δ is the half-band width at 1/e of maximum absorption. Similarly, the experimental rotational strengths, R, were obtained by the expression of Moscowitz:[16]

$$R = 0.696 \times 10^{-42}\sqrt{\pi}\cdot[\theta]_{max}\cdot\frac{\Delta}{\lambda_{max}} \quad (2)$$

where $[\theta]_{max}$ is the maximum value for the molar ellipticity and Δ is the half-band width at 1/e of maximum ellipticity.

Theoretical

The theoretical rotational strength of the transition from the ground state, 0, to the excited state, a, in benzene derivative, R_{i0a}, was calculated by the following expression developed by Kirkwood and Tinoco:

$$R_{i0a} = \pi\tilde{\nu}_{ai}\mu_{i0a}^2\sum_j\frac{\tilde{\nu}_{bj}^2(\alpha_{33}-\alpha_{11})_j(GF)_{ij}}{\tilde{\nu}_{bj}^2-\tilde{\nu}_{ai}^2} \quad (3)$$

$$(GF)_{ij} = \frac{1}{r_{ij}^3}\left[\hat{e}_i\cdot\hat{e}_j-\frac{3(\hat{e}_i\cdot\vec{r}_{ij})(\hat{e}_j\cdot\vec{r}_{ij})}{r_{ij}^2}\right]\hat{e}_i\times\hat{e}_j\cdot\vec{r}_{ij} \quad (4)$$

Table 1. The averaged wave number of the electronic transitions ($\tilde{\nu}_{bj}$) and polarizability (α) of the bonds in a glucose residue

Bond	$(\alpha_{33}-\alpha_{11})\times10^{24}$ / cm^3	$\tilde{\nu}_{bj}\times10^{-3}$ a) / cm^{-1}

number of the electronic transitions of the bond in β-CDx.

In this paper, $\tilde{\nu}_{bj}$ is approximated by a wavenumber midway between the first absorption band in the bond of β-CDx and its ionization potential. The values of $(\alpha_{33}-\alpha_{11})$ and $\tilde{\nu}_{bj}$ for each bond are listed in Table 1.

Table 2 shows the observed and calculated wave number, $\tilde{\nu}$, and dipole strength, D, of the electronic transitions of benzene derivatives, along with the assignment of each electronic transition.[17] The calculated values in this table were obtained by the Pariser-Parr-Pople (PPP) method. The experimental values in Table 2 were used for the calculation except in the case of nitrobenzene. The experimental value of nitrobenzene could not be estimated because of its insolubility in water.

As shown in Fig. 1, the origin of the coordinates was chosen in the center of a ring of β-CDx which was assumed to have a seven-fold symmetry axis, The

coordinates of a glucose residue were determined so as to fit the distance of O(4)–O(4′) with X-ray data (4.23 Å).[18] In the determination of the coordinates of β-CDx, hydroxyl groups of O(2)–H and O(3)–H were assumed to form hydrogen bonding with the hydroxyl group of the neighboring glucose unit. The effect of all the C–H bonds was neglected, since these bonds may have isotropic polarizability.

In the present calculation, we considered two models for the inclusion complexes, as shown in Fig. 2: *i.e.*, the axial inclusion (I) in which the long axis of benzene derivatives is parallel to the axis of β-CDx cavity (z-axis) and the equatorial inclusion (II) in which the short axis is parallel to the z-axis.

Finally, the calculation of the rotational strengths of these complexes were carried out by putting the electric dipole moment at the origin.

Results and Discussion

Figures 3—10 show the CD (upper) and UV (lower) spectra of β-CDx complexes with various substituted benzenes. The β-CDx complex with phenol (in Fig. 3) showed positive and negative ICD bands at 224 and at 275 nm, respectively. These ICD bands were assigned to the $^1A_1 \leftarrow {}^1A_1$ and $^1B_2 \leftarrow {}^1A_1$ transitions, respectively, from the results calculated by use of the PPP method in Table 2. The β-CDx–aniline complex (Fig. 4) and the β-CDx–benzoic acid complex (Fig. 5) exhibited ICD bands similar to the bands of the β-CDx–phenol complex.

On the other hand, as shown in Fig. 6, the β-CDx complex with *p*-nitrophenol showed negative and positive ICD bands at 227 and at 329 nm. These bands were attributed to the $^1B_2 \leftarrow {}^1A_1$ and $^1A_1 \leftarrow {}^1A_1$ transitions, respectively. Each sign of the ICD spectra of β-CDx with nitrobenzene (Fig. 7) and *p*-hydroxybenzoic acid (Fig. 8) is the same as that of the β-CDx–*p*-nitrophenol complex.

Two negative ICD bands of β-CDx–*p*-nitroaniline complex observed at 230 and 296 nm were assigned to the $^1B_2 \leftarrow {}^1A_1$ transitions, and the lowest positive ICD band was attributed to the $^1A_1 \leftarrow {}^1A_1$ transition (Fig. 9).

As seen from each figure, the ICD bands of these inclusion complexes were observed at the absorption of benzene derivatives. In addition, from the assignment based on the SCF-MO calculation by the PPP method, it was found that the electronic transitions which are polarized along the long axis of substituted benzenes showed positive ICD, while the sign of the ICD of short-axis polarized transitions are negative.

In Table 3, formation constants, *K*, and UV and CD spectral data of β-CDx inclusion complexes are summarized.

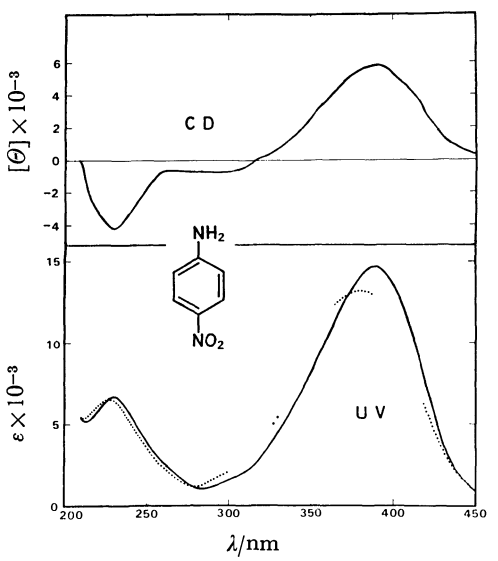

Fig. 9. CD (upper) and UV absorption (lower) spectra of β-CDx complex with *p*-nitroaniline in aqueous solution at room temperature. Dotted line; in the absence of β-CDx, solid line; β-CDx (1.47×10^{-2} M) + *p*-nitroaniline (8.41×10^{-5} M).

Figure 10 illustrates Job's continuous variation plots for β-CDx and benzoic acid systems. From this figure, it can be seen that the composition ratio of β-CDx to benzoic acid is 1:1.

The observed and calculated rotational strengths of β-CDx complexes with benzene derivatives are compared in Table 4. It is seen from Table 4 that the values calculated by assuming the axial inclusion (I) are in fairly good agreement with the experimental values. On the contrary, the signs of the calculated rotational strengths for equatorial inclusion (II) disagree with the experimental results. Therefore, the orientation of the guest molecule which is included in the β-CDx cavity can be regarded as the axial inclusion (I).

Finally, the effects of the translation and rotation of the guest molecules in the β-CDx cavity on the signs and magnitudes of the calculated rotational

	A′	216	−3.08	−9.16	18.85

strengths were investigated. The sign of the calculated rotational strength was unchanged by the translations of the guest molecules along the x-, y-, and z-axes, while their magnitudes were affected by the translation and became maxima when the center of the guest molecule was placed on the point about 2 Å away from the origin along the z-axis. The rotation of the guest molecule in the x-y plane had no influence on the calculated rotational strengths. On the other hand, the calculated rotational strengths were very sensitive to the rotation of the guest molecules in the x-z plane, as demonstrated in Fig. 11.

In conclusion, when the direction of the electric dipole moment is known, we can estimate the orientation of the chromophore which is included in the cavity of β-CDx.

Finally, it is stated that the measurements of ICD spectra in combination with the theoretical calculation

of rotational strengths are quite useful for the investigations of the structure of these inclusion complexes.

Zeeman Absorption Spectra of 2,3-Dichloro-9,10-anthraquinone Crystals

Mizuka SANO,* Takatoshi NARISAWA, Kohji IZAWA, and Yasumasa J. I'HAYA

Department of Materials Science, The University of Electro-Communications, Chofu 182

(Received March 26, 1979)

Polarized $T \leftarrow S_0$ absorption spectra were measured for 2,3-dichloro-9,10-anthraquinone melt-grown single crystals in a magnetic field of 50 kOe. From the analysis of the Zeeman absorption patterns, the lowest triplet state of 2,3-dichloro-9,10-anthraquinone in the crystalline state has been assigned to $^3A_1(\pi\pi^*)$. The c-polarized first absorption peak at 21734.7 cm^{-1} has been interpreted as gaining intensity mainly from an x-polarized transition from the ground state to a $B_1(n\pi^*)$ perturbing singlet state, which is directly spin-orbit-coupled with the y spin-sublevel of the $^3A_1$ state. The a- and b-polarized first peaks, at 21733.9 and 21733.6 cm^{-1}, respectively, have been interpreted as gaining intensity through the configurational mixing of the $^3A_1(\pi\pi^*)$ state with a nearby $^3B_1(n\pi^*)$ state.

Recently, we have studied the triplet states of 9,10-anthraquinone (abbreviated to AQ) crystals by Zeeman absorption spectroscopy,[1] and assigned the origin peak of the lowest triplet state at 22154.0 cm^{-1} to $^3B_{1g}$ ($n\pi^*$). The phosphorescence spectrum of an AQ crystal was also indicative of an $n\pi^*$ emitting state, the strongest peak being located 1680 cm^{-1} from the origin peak of the phosphorescence. We have extended our study to 2,3-dichloro-9,10-anthraquinone (abbreviated to 2,3-DCAQ) in order to determine whether the compound, a substituted AQ, also possesses the lowest triplet state of $n\pi^*$ character.

We chose 2,3-DCAQ because it crystallizes in such a manner that its molecular x, y, and z axes are nearly parallel to the crystallographic c, b, and a axes, respectively.[2] This kind of molecular alignment in a crystal is favorable for determining the direction of the electronic transition moment. We will present an assignment of the triplet-state electronic configuration of 2,3-DCAQ crystals, based on experimental proof obtained by means of Zeeman spectroscopy.

Experimental

2,3-DCAQ was prepared by cyclocondensation of *o*-(3,4-dichlorobenzoyl)benzoic acid obtained by the Friedel-Crafts reaction between *o*-dichlorobenzene and phthalic anhydride.[3] Crude 2,3-DCAQ was purified by recrystallization twice from benzene, sublimation *in vacuo*, and then by zone-refining carried out for 150 passes, three successive refinings of 50 passes each. A single crystal was melt-grown in a Bridgman furnace. Crystal samples of suitable size, *ca.* 5×5 mm^2 in area and 2—5 mm in thickness, were cut from the crystal, and their faces identified by the X-ray diffraction method.

Absorption spectra were analyzed with an NLM-E2M spectrometer equipped with an Echelles grating in a Czerny-Turner mount. The reciprocal dispersion of the spectrometer was 0.055 nm mm^{-1} at 460 nm in the 12 th order of the grating. The incident light from an Osram 450 W regulated xenon-arc-lamp was chopped at 720 Hz, the light passing through the sample being detected by a combination of an HTV R376 photomultiplier tube and an NF LI-572 lock-in amplifier.

Two types of optical cryostats including superconducting magnets, an Oxford 55 and a Sinkukiko 60, were used for Zeeman spectroscopy. The incident light propagates along the magnetic field in the former and passes through the sample perpendicular to the magnetic field in the latter. The magnetic field could be controlled to any required value up to *ca.* 55 kOe†. Phosphoresence of a crystal immersed in pumped liquid helium was excited by 365 nm radiation filtered from an ORC 1 kW superhigh-pressure mercury arc through Toshiba UV-D1C and IRQ-80 filters.

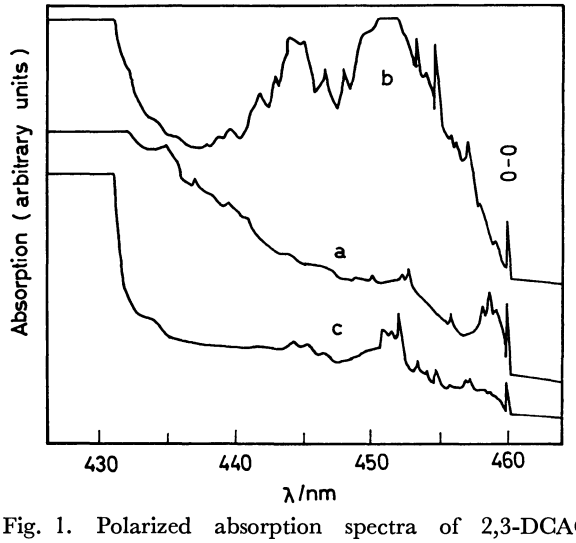

Fig. 1. Polarized absorption spectra of 2,3-DCAQ crystals at 1.7 K. (a) E//a, (b) E//b, (c) E//c.

Results and Discussion

Figure 1 shows the polarized absorption spectra of 2,3-DCAQ crystals at 1.7 K. The recordings of spectra (a) and (b) refer to a 3.8 mm thick crystal with light incident on the ab plane; the recording of (c) refers to a 2.3 mm crystal with light incident on the ac plane. The first peak, moderately intense and sharp (*ca.* 1.5 cm^{-1} in width) was observed at approximately 460 nm. Several successive intense peaks were observed in the spectral region 460—440 nm. All the peaks were found to split into sublines upon the application of a magnetic field, which indicates that they could be ascribed to the $T \leftarrow S_0$ transitions.

The high-resolution spectrometer revealed that the a- and the b-polarized first peaks were located at 21733.9 and 21733.6 cm^{-1} (A=0.87 for a 3.8 mm thick crystal), respectively, and the c-polarized first peak at 21734.7 cm^{-1}. The wave-number difference of *ca.* 1 cm^{-1} observed between the c-polarized peak and the a- or b-polarized peak is understood as an indication of the triplet factor group splitting.

† $Oe = 1000/4\pi$ A m^{-1}.

The phosphorescence spectrum observed for a 2,3-DCAQ crystal at 1.7 K shows sharp and intense peaks at 460.4 nm (21712 cm^{-1}) and 499.0 nm (20033 cm^{-1}) (Fig. 2), the former located *ca.* 22 cm^{-1} below the first peak in the absorption spectrum, and the latter 1679 cm^{-1} from the former peak. The wave-number difference corresponds to the C=O stretching mode frequency of 1676 cm^{-1} observed for AQ in the IR spectrum.[4] A moderately intense peak was observed at 543.5 nm (18393 cm^{-1}), which could be assigned to the overtone frequency of the C=O stretching mode.

The phosphorescence spectrum of 2,3-DCAQ in heptane (Shpol'skii matrix) at 1.7 K, on the other hand, shows a weak peak at 457.6 nm (21844 cm^{-1}) and a sharp, strongest peak at 495.9 nm (20157 cm^{-1}), located 1687 cm^{-1} from the weak peak (Fig. 3). Each peak is accompanied by two other peaks at intervals of 66 and 29 cm^{-1}. The peaks seem to arise from molecules in different sites in the matrix. A similar multiple structure has been reported for AQ in heptane.[5]

From the results, the first peaks in the absorption spectra are considered to arise from the origin for the lowest $T_1 \leftarrow S_0$ transition of 2,3-DCAQ.

The crystal structure of 2,3-DCAQ corresponds to a space group symmetry of D_2 with four molecules per unit cell. The molecules can be regarded as planar in the crystal, belonging to the C_{2v} point group.[2] The z axis is taken along the molecular twofold axis, and the z,y-plane as the plane of the molecule. Table 1 gives the squared direction cosines of the molecular axes with respect to the crystallographic axes. The x, y, and z molecular axes are nearly parallel to the c, b, and a crystallographic axes, respectively.

Figure 4 shows the Zeeman patterns for the first absorption peaks observed with polarized light, E, in the presence of a magnetic field, *H*, of 50 kOe, directed along the a, b, and c crystallographic axes of the 2,3-DCAQ single crystal. A single peak was found to split into sublines in the magnetic field. The transition to a triplet state from the ground state acquires the polarization of the transition to a perturbing singlet state, and assumes a spin-orbit interaction between the perturbing singlet state and the triplet state in the first-order approximation. The intensities of the individual Zeeman sublines depend on the polarization of the transition to the perturbing singlet state, p, and the route effective in the spin-orbit interaction, u.

The relative intensities of the Zeeman sublines for

Table 3. Intensity ratios, $I_0/I_{\pm1}$, calculated for x-, y-, and z-routes in the spin-orbit interaction for 2,3-DCAO

H	u		
	x	y	z
a	0.18	0.00	22.2
b	0.16	23.9	0.01
c	10.8	0.17	0.17

a triplet factor group of D_2 symmetry, obtained on the assumption that only one of the spin-orbit-coupling routes is effective,[6] are summarized in Table 2, where l_p, m_p, and n_p (also l_u, m_u, and n_u) represent the direction cosines of the axes a, b, and c with respect to the molecular axis p (also u), respectively, and I_0 and $I_{\pm1}$ represent the relative intensity of the central Zeeman line and that of the wing lines, respectively.

In the absence of a magnetic field, the absorption intensities observed with the a-, b-, and c-polarized lights, I_a, I_b, and I_c, are given as $2l_p^2$, $2m_p^2$, and $2n_p^2$, respectively, which are seen to be independent of the effective route in the spin-orbit interaction. The intensity ratios, $I_a : I_b : I_c$, are calculated to be 0.1 : 0.09 : 1 for an x-polarized transition in the molecular framework, showing that such a transition provides its intensity predominantly to the c-polarized absorption. The ratios are similarly calculated to be 0 : 1 : 0.08 for a y-polarized transition, and 1 : 0 : 0.09 for a z-polarized transition. However, the absorptions for the 2,3-DCAQ crystal were observed along all three crystallographic axes, and the ratios, $I_0 : I_b : I_c$, were found to be 1 : 0.6 : 0.4. This indicates that not only a z-polarized transition but also y- and x-polarized transitions are included in the absorption.

Table 2 gives the intensity ratio, $I_0/I_{\pm1}$, for each direction of a magnetic field. The ratios are equal to $2l_u^2/(1-l_u^2)$, $2m_u^2/(1-m_u^2)$, and $2n_u^2/(1-n_u^2)$ for a magnetic field directed along the a-, b-, and c-axes, respectively, which are seen to be independent of the polarization of the transition in the molecule. Ratios calculated for x-, y-, and z-routes in the spin-orbit interaction are given in Table 3.

As shown in Fig. 4, the Zeeman pattern such that the central line is stronger than the wing lines is observed only in a b-directed magnetic field for the c-polarized peak, in an a-directed field for the b-polarized peak, and in a b-directed field for the a-polarized peak. This indicates that each peak gains intensity through only one route in the spin-orbit interaction. The Zeeman pattern with a strong central line appears in a b-directed magnetic field for the y route, and in an a-directed field for the z route (Table 3).

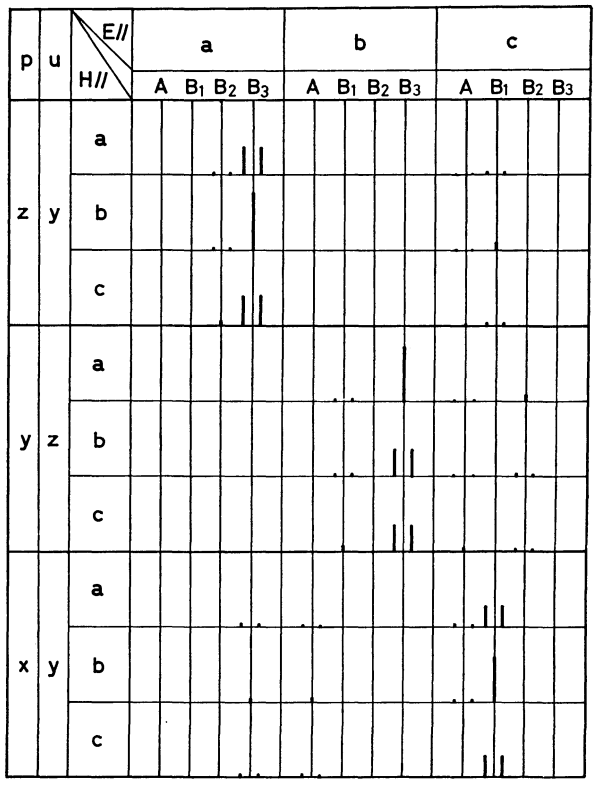

Fig. 5. Calculated relative intensities of the Zeeman sublines for a 2,3-DCAQ crystal.

The c-polarized peak, which arises mainly from an x-polarized transition in the molecular framework, shows the Zeeman pattern with a strong central line in a b-directed magnetic field. Thus an x-polarized transition to a perturbing singlet state is considered to provide intensity through the y route to the transition to the triplet state of A_1 species. Similarly, the Zeeman patterns for the b- and a-polarized peaks show that y- and z-polarized transitions also provide intensity to the absorption to the lowest triplet state through

the z and y routes, respectively.

The intensities of the Zeeman sublines, I_0 and $I_{\pm 1}$, for each triplet factor group state of a 2,3-DCAQ crystal are calculated from Tables 1 and 2 for these three combinations of polarization, p, and spin-orbit-coupling route, u. Figure 5 shows the relative values of the intensities in thick bars. It is seen that the a- and b-polarized absorptions arise mainly from the transition to the B_3 factor group state, and the c-polarized absorption mainly from the transition to the B_1 state. This seems to explain the wave-number difference of *ca.* 1 cm^{-1} observed between the c- and the a- or b-polarized first absorption peaks, *i.e.*, the triplet factor group splitting.

A simple molecular-orbital description of 2,3-DCAQ leads to the prediction that the low-energy $\pi\pi^*$ state is of species A_1 or B_2, and the $n\pi^*$ state is of species A_2 or B_1. In general, the transition to an $n\pi^*$ triplet state is much stronger, 10^2—10^3 times, than that to a $\pi\pi^*$ triplet state. Thus if the $\pi\pi^*$ triplet state is mixed more than 10% with the triplet state of $n\pi^*$ character, the general appearance of the spectrum and the polarization characteristics are expected to resemble those of pure $^3n\pi^*$ state.[7]

The absorption to the lowest triplet state of the 2,3-DCAQ crystal was found to have a mixed character of the $^3\pi\pi^*$ and $^3n\pi^*$ states, as shown by the direction of its polarization. It is therefore concluded that the lowest triplet state belongs to $^3A_1(\pi\pi^*)$, gaining $n\pi^*$ character from a nearby-located $n\pi^*$ triplet state. The location of the $n\pi^*$ state could not be determined precisely, but a broad and intense b-polarized absorption arising mainly from the y-polarized transition in the molecular framework was observed at approximately 452 nm, though the maximum absorption was off-scale. The lowest $n\pi^*$ triplet state may be located in this spectral region, *ca.* 400 cm^{-1} above the lowest $\pi\pi^*$ triplet state.

For the 0—0 transition to the $^3A_1(\pi\pi^*)$ state, the possible mechanisms[8] for gaining the major part of the intensity are (i) direct spin-orbit coupling between the $^3A_1$ state and an $n\pi^*$ perturbing singlet state, (ii) configurational mixing between the $^3A_1$ state and a nearby $n\pi^*$ triplet state,[7] and (iii) mixing of the $^3A_1$ state with a nearby $n\pi^*$ triplet state through spin-orbit interaction.[9] The observed c-polarized $T_1 \leftarrow S_0$ absorption can be explained in terms of mechanism (i): The transition to the $^3A_1(\pi\pi^*)$ state gains its intensity from an x-polarized transition to a $B_1(n\pi^*)$ perturbing singlet state through the y route in the spin orbit interaction.

We must further explain the contribution of the y route associated with the z polarization and that of the z route associated with the y polarization to the $T_1 \leftarrow S_0$ absorption. Mechanism (ii) can explain these contributions: The y and z spin-sublevels of the $^3A_1(\pi\pi^*)$ state are mixed electrostatically with the y and z spin-sublevels of a nearby $^3B_1(n\pi^*)$ state, respectively, which are in turn spin-orbit-coupled to $A_1(\pi\pi^*)$ and $B_2(\pi\pi^*)$ perturbing singlet states, respectively. The transitions from the ground state to these singlet states are expected to be z- and y-polarized, respectively. This is what we have observed for the 2,3-DCAQ crystal. Mechanism (iii) can not explain the observed z-polarized absorption from a group-theoretical point of view.

The $^3A_1(\pi\pi^*)$ state can be mixed with the other $n\pi^*$ triplet state, *i.e.*, $^3A_2(n\pi^*)$ by mechanisms (ii) and (iii). However, this scheme can not explain the observed polarization characteristics.

For a 2,3-DCAQ crystal, the absorption to the lowest triplet state of $A_1(\pi\pi^*)$ species can be explained by a mechanism in which direct spin-orbit coupling with a perturbing $^1B_1(n\pi^*)$ state and electrostatic mixing with a nearby $^3B_1(n\pi^*)$ state operate for the $^3A_1(\pi\pi^*)$ state simultaneously.

The phosphorescence spectrum of 2,3-DCAQ in heptane showed a weak origin peak and a strongest peak corresponding to the C=O stretching mode. The same features were observed in the phosphorescence spectra of 1-chloro-AQ and 2-chloro-AQ in heptane at 1.7 K. The spectra are indicative of an $n\pi^*$ emitting state. If the emitting state is regarded as the T_1 state for 2,3-DCAQ in heptane, a comparison between the heptane-solution spectrum and the crystal spectrum shows that a low-lying $^3\pi\pi^*$ state is lowered in energy below the $^3n\pi^*$ state by changing the environment from heptane to 2,3-DCAQ. The phosphorescence spectra of aromatic carbonyl compounds, where the $n\pi^*$ and $\pi\pi^*$ triplet states are very close to each other, have been reported to be strikingly dependent on the nature of the environment.[10–13]

The Liquid-phase Oxidation of Hydrocarbons with Molecular Oxygen. II.[1] A Highly Selective Formation of α-Tetralone by the Metal-catalyzed Oxidation of Tetralin in the Presence of *N,N*-Dialkylamides

Fujio MIZUKAMI, Yutaka HORIGUCHI, Masaki TAJIMA, and Juichi IMAMURA*

(Received February 20, 1979)

The metal-ion catalyzed oxidation of tetralin was carried out in different solvents in which metal salts tend to be soluble. It was found that, for the production of α-tetralone, a chromium salt is the best catalyst among the first-transition-metal salts employed, while *N,N*-dialkylamides are the best solvents or the best additives. For example, in the tris(acetylacetonato)chromium(III)-catalyzed oxidation of tetralin in the presence of *N,N*-dimethylacetamide, α-tetralone was obtained in a 93.0% yield at a 27.2% tetralin conversion. The decomposition of α-tetralyl hydroperoxide (THP) with different first-transition-metal catalysts was also carried out in *N,N*-dimethylformamide in order to elucidate the formation mechanism for α-tetralone in the oxidation of tetralin in the presence of *N,N*-dialkylamides. It was concluded that the product distribution in the oxidation mainly depends on the decomposition mechanism of THP, and that *N,N*-dialkylamides seem to promote the reaction of the α-tetralylperoxyl radical with low valent metal ions, $ROO\cdot + M^{n+} \longrightarrow \alpha\text{-tetralone} + OH^- + M^{(n+1)+}$.

The dehydrogenation of α-tetralone is a commercial process for the production of α-naphthol.[2–4] α-Tetralone can be easily obtained by the liquid-phase autoxidation of tetralin, but in this oxidation α-tetralol is also produced in a large amount. α-Tetralol tends to undergo dehydration rather than dehydrogenation[5–7] and is unsuitable as a raw material for the production of α-naphthol. What is worse, the boiling point of α-tetralol is very close to that of α-tetralone. For these reasons, many investigations[6–12] have been undertaken in search of a method for the highly selective formation of α-tetralone in the autoxidation of tetralin. However, no satisfactory process for the production of α-tetralone has so far been found. In order to seek a better method of producing α-tetralone, we first studied the oxidation of tetralin in both the presence and absence of additives in acetic acid, using first-transition-metal salts as a catalyst. Chromium salts showed the highest ratio of α-tetralone/α-tetralol (ON/OL), while cobalt salts showed the highest activity in this tetralin oxidation. On the basis of this result, we further studied the effects of solvents and additives on the oxidation of tetralin; we thus found a satisfactory process for the production of α-tetralone by the liquid-phase oxidation of tetralin with molecular oxygen. This new process will now be reported in the present paper.

Experimental

Materials. The tetralin, metal salts, additives, and solvents employed were all of a reagent grade and were used without further purification. The α-tetralyl hydroperoxide (THP) was synthesized according to the procedure of Knight and Swern.[13] This peroxide was 97% pure, as confirmed by iodometric titration.

Oxidation of Tetralin. The oxidation of tetralin was performed in closed systems at higher pressures (a SUS-316 autoclave equipped with a magnetic stirrer, a thermocouple, and a pressure controller) and at atmospheric pressures (a 200 cm³ three-necked flask equipped with a thermometer, a reflux condenser, an oxygen inlet, and a Teflon stirring bar).

A mixture of tetralin and a solvent or an additive containing a catalyst was placed in a reaction vessel and warmed to the desired temperature. Oxygen was then introduced into the vessel. However, in the oxidation under atmospheric pressure, the air in the vessel was quickly expelled by 600 cm³ of oxgen in order to increase oxygen content in the reaction mixture when the temperature of the mixture had reached the desired temperature.

The oxidation was terminated by stopping the oxygen feed and by quickly cooling the vessel in an ice-cold bath.

Decomposition of THP. A four-necked flask (200 cm³, round-bottomed) equipped with a thermometer, a reflux condenser, a dropping funnel, and a nitrogen inlet was filled with nitrogen gas. Into the flask, were placed a Teflon stirring bar and a 50 cm³ solution of *N,N*-dimethylformamide (DMF) containing a catalyst. A stream of nitrogen was gently bubbled through the solution. The solution was then stirred and warmed to the desired temperature. To the vigorously stirred solution, was added a 25 cm³ solution of DMF containing 2.5 g of THP.

Analysis. The peroxide concentration was determined by the usual method.[14] The α-tetralone, α-tetralol, and tetralin in the reaction mixture were identified and their amounts were determined using gas chromatography with a Shimadzu GC-4CPT chromatograph (2 m × 3 mm column packed with 10% Carbowax 4000 on Chromosorb AW; programming, 5 °C/min from 120 to 173 °C, He 40 cm³/min). *o*-Bromoanisole was used as the internal standard. Before GLC analysis, the remaining peroxide was reduced with an excess of triphenylphosphine.[15] The "net α-tetralol" is the difference between the total amount of α-tetralol after reduction and the amount of peroxide before reduction.

Results

The best conditions for producing α-tetralone in the liquid-phase oxidation of tetralin were examined using cobalt and chromium salts as catalysts.

The Selection of Solvents. The $Co(C_6H_5COO)_2$-catalyzed oxidation of tetralin under an atmospheric pressure at 51 °C was carried out in different solvents in which metal salts tend to be soluble. The results are shown in Table 1. Tetralin was almost not oxidized at all in either dimethyl sulfoxide or tetrahydrothiophene 1,1-dioxide for 3 h. Although DMF brought a very high yield of peroxide, DMF gave by far the highest ON/OL ratio and the lowest α-tetralol yield among the solvents listed in Table 1.

Reaction conditions: the O_2 pressure was 20 kg/cm² G. a) Based on the amount of tetralin consumed. b) The O_2 absorption rate fell suddenly about 20 min after the introduction of oxygen.

tion Temperature. Table 2 shows the effects of the catalyst concentration and the reaction temperature on the product distribution in the $Cr(acac)_3$-catalyzed oxidation of tetralin in DMF. The α-tetralone yield decreased with an increase in the reaction temperature (Runs 11—13). At reaction temperatures above 120 °C, it was also difficult to carry out the oxidation of tetralin at an approximately constant temperature. Accordingly, the optimum reaction temperatures for producing α-tetralone in the $Cr(acac)_3$-catalyzed oxidation of tetralin in the presence of DMF seem to be below 120 °C.

It was seen from Runs 18—20 that, at catalyst concentrations above 5×10^{-3} M**, the product distribution in the oxidation of tetralin is almost not at all dependent on the catalyst concentration, and all the α-tetralone yields obtained in these three runs are above 83%. A high α-tetralone yield was also obtained in the oxidation at the 3×10^{-3} M $Cr(acac)_3$ concentration, although the oxidation rate was very slow (Run 17). However, in the oxidation at the 1×10^{-3} M $Cr(acac)_3$ concentration, the peroxide yield was relatively high and the α-tetralone yield was relatively low (compare Run 15 with Run 16). Therefore, the best region of catalyst concentrations for the selective formation of α-tetralone appears to be 10^{-3} M$<$[Cr]$\leqq10^{-2}$ M in the $Cr(acac)_3$-catalyzed oxidation of tetralin in the presence of DMF.

The Effects of Ligands and Additives. Table 3 shows the oxidation of tetralin with nine kinds of chromium catalysts in DMF. Chromium(III) oxide, which is insoluble in a mixed solution of DMF and tetralin, showed a low α-tetralone yield and a very high peroxide yield in comparison with the other Cr catalysts. However, all the other Cr catalysts which are more or less soluble in the reaction mixture gave high α-tetralone yields (above 74%) and showed similar product distributions, although their oxidation activities were considerably different from each other. Such a phenomenon was also observed for the $Co(acac)_2$-catalyzed oxidation of tetralin in DMF in both the presence and absence of an additive, as is shown in Table 4. The four product distributions were very similar to each other (Runs 30—33). It was thus found that, for the tetralin oxidation in the presence of the appropriate amount of DMF, the counter anions and additives employed have much influence on the oxidation rate, but almost none on the product distribution. This fact seems to indicate that the counter anions and additives do not alter the oxidation mech-

anism of tetralin, but the solubilities of metal (Co or Cr) catalysts and the ligand-replacement rates of active metal complexes in the reaction solution.

The Effects of Metal Ions. The effects of different first-transition-metal ions on the oxidation of tetralin in DMF are shown in Table 5. Chromium catalysts showed the highest α-tetralone yields among the catalysts employed and showed relatively high ON/OL ratios. Iron and Ni catalysts also showed high ON/OL ratios, but they also gave quite high peroxide yields. On the other hand, Mn, Co, and Cu catalysts were more favorable for producing α-tetralol than Cr, Ni, and Fe. Therefore, chromium salts are the best catalysts for producing α-tetralone in the oxidation of tetralin.

As can be seen from Runs 39—41 in Table 5, Co showed the highest activity, and Ni and Cu showed quite high activities, but these activities fell suddenly twenty minutes after the introduction of oxygen. This phenomenon was examined in detail for the oxidation of tetralin with Co catalysts, and it was observed that the tetralin conversion decreases with an increase in the Co concentration or the reaction temperature (Fig. 1 or Runs 39 and 44 in Table 5). This is thought to be due to the action of autoxidation inhibitors generated in consecutive oxidations, because the primary oxidation products of tetralin are easily oxidized with an increase in the Co concentration and in the reaction temperature. Actually, Martan *et al.*[16] have isolated α-naphthol and 1,4-dihydroxynaphthalene, both inhibitors, as higher products in the oxidation of tetralin

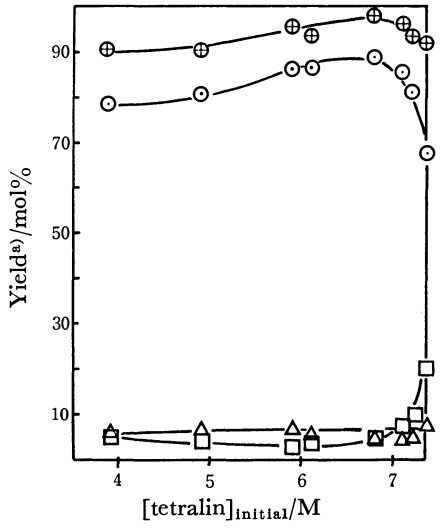

Fig. 2. The $Cr(acac)_3$-catalyzed oxidation of tetralin in DMF at 90±2 °C. Reaction conditions: $[Cr(acac)_3]=6.0\times10^{-3}$ M, the O_2 pressure was 20 kg/cm²G, the tetralin conversion was 26.0±2.5%. ⊙: Tetralone, △: α-tetralol, □: peroxide, ⊕: total. a) Based on the amount of tetralin consumed.

catalyzed by $Co(OAc)_2$.

The Effects of the Initial Tetralin Concentration. Figure 2 shows the dependence of the product distributions on the initial substrate concentration in the oxidation of tetralin catalyzed by $Cr(acac)_3$ in the presence of DMF at 90 °C. The right end of the abscissa in Fig. 2 indicates a neat tetralin solution without DMF. At initial tetralin concentrations above 7 M, the α-tetralone yield decreased suddenly and the peroxide yield increased rapidly with an increase in the tetralin concentration, although the α-tetralol yield was almost independent of the initial substrate concentration. At initial tetralin concentrations below 6.8 M, the α-tetralone yield decreased slowly upon a decrease in the tetralin concentration. From these facts and the solubility of $Cr(acac)_3$, the optimum region of initial tetralin concentration for producing α-tetralone seems to be 5.5—6.5 M in the oxidation of tetralin catalyzed by $Cr(acac)_3$ in the presence of DMF.

The Oxidation of Tetralin in the Presence of Different Amides and Oxygen Pressure. Table 6 shows the oxidation of tetralin catalyzed by $Cr(acac)_3$ in the presence of five kinds of *N,N*-dialkylamides at 80 °C,

All these amides brought about high α-tetralone yields and product distributions very similar to one another; that is, we could observe almost no substituent effect of these amides on the product distribution, although these amides had much influence on the oxidation rate of tetralin. Table 7 shows the effect of the oxygen pressure on the oxidation of tetralin in the presence of *N,N*-dimethylacetamide (DMA), which gave the highest oxidation rate among the amides employed. The oxidation rate of tetralin fell with a decrease in the oxygen pressure. This indicates that, at oxygen pressures below 20 kg/cm² G, the oxidation rate depends on the concentration of molecular oxygen in a mixed solution of DMA and tetralin. Accordingly, the differences between the oxygen absorption rates listed on Table 6 appear to be attributable mainly to the differences between the solubilities of oxygen in mixed solutions of different amides and tetralin. For the tetralin oxidation in the presence of *N,N*-dialkylamides (Runs 47—56), the recoveries of these amides ranged from 93 to 98%. Tetralin was also oxidized with molecular oxygen in the presence of acetamide at 95 °C under atmospheric pressure ($[\text{tetralin}]_{\text{initial}}=$ 6.12 M). This oxidation stopped at about a 10% tetralin conversion (the α-tetralone, α-tetralol, and peroxide yields are 47.3, 2.0 and 7.0% respectively), and the recovery of acetamide in this run was very low. This acetamide reactivity seems to come from the property[17–19] that primary and secondary amides can easily liberate their amino protons.

The Time-course of the Product Distributions. The product formation for different tetralin conversions was examined in the oxidation of tetralin catalyzed by $Co(OAc)_2 \cdot 4H_2O$ in DMF at 65 °C (Fig. 3). The yields of both α-tetralone and α-tetralol increased with an increase in the tetralin conversion; on the contrary, the peroxide yield decreased as the tetralin conversion increased. The total amount of the increment in the α-tetralone yield and that in the α-tetralol yield was nearly equal to the decrement in the peroxide yield. The increment in the α-tetralone yield was appreciably more than that in the α-tetralol yield. Accordingly, THP seems to be preferentially converted into α-tetralone, although THP decomposes to both α-tetralone and α-tetralol.

The product formation for various tetralin conversions was also examined in the $Cr(acac)_3$-catalyzed oxidation of tetralin in the presence of DMA at 80 °C

Table 8. Product distribution for the metal-catalyzed decomposition of THP in DMF in a nitrogen atomosphere

Run No.	Metal salt	THP conversion %	Yield[a]/mol% α-Tetralone	Yield[a]/mol% α-Tetralol	ON/OL	Reaction time min
57	$Cr(OAc)_3$	87.9	85.3	6.2	14	210
58	$Mn(OAc)_2 \cdot 4H_2O$	97.6	54.7	27.0	2.0	50

Reaction conditions: [metal salt] $=6.0\times10^{-3}$ M; $[THP]_{initial}=0.20$ M; the reaction temperature was 71—75 °C.
a) Based on the amount of THP converted.

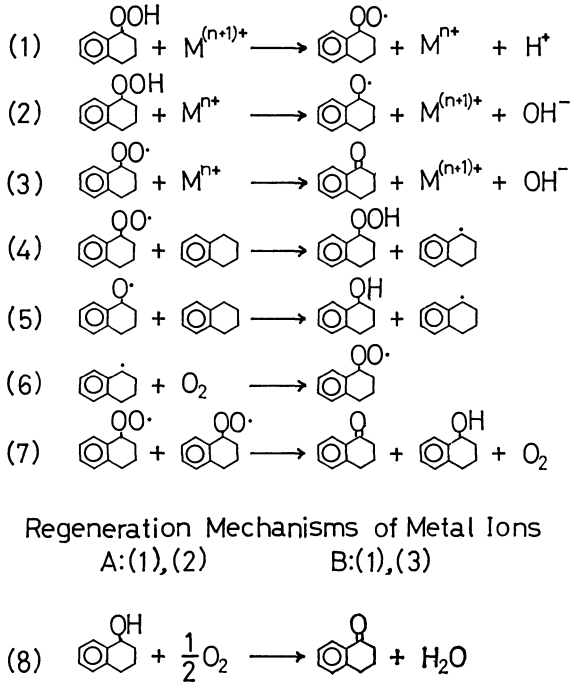
(Fig. 4). For tetralin conversions below 25%, the percentage of the decrease in the peroxide yield was nearly equal to that of the increase in the α-tetralone yield, and α-tetralol was only produced in a very low yield below 2%. This seems to show that the THP generated by the tetralin oxidation is converted almost exclusively into α-tetralone. On the other hand, for tetralin conversions above 25%, the α-tetralone yield decreased and the peroxide yield increased as the tetralin conversion was increased. The α-tetralol yield also had a minus sign for tetralin conversions above 50%. These facts suggest that the α-tetralone produced in the oxidation is further oxidized into a peroxide different from THP during the prolonged reaction time. Accordingly, in order to obtain α-tetralone in a high purity and a high yield, the $Cr(acac)_3$-catalyzed oxidation of tetralin in the presence of DMA should be stopped at 20—30% tetralin conversions.

The Decomposition of THP. The decomposition of THP with six kinds of first-transition-metal catalysts was carried out in DMF 71—75 °C in a nitrogen atmosphere. The ON/OL ratios decreased in this order: Ni>Cr>Cu>Fe>Co>Mn, as is shown in Table 8. This order is fully consistent with that of the decreasing reduction potentials[20-22] for these low-valent metal ions. In the oxidation of tetralin shown in Table 5, the ON/OL ratios decreased in this order: Ni>Cr>Fe>Co$\simeq$Cu>Mn. This order is inconsistent with that in the THP decomposition. However, except for the Cu catalyst, which gave too low a tetralin conversion in the oxidation (Run 41 in Table 5), the decreasing order of ON/OL ratios in the oxidation is in fair agreement with that in the THP decomposition. In addition, the product distributions in the decomposition of THP with six kinds of transition-metal catalysts are similar to those in the corresponding oxidation of tetralin. Accordingly, the product distribution in the tetralin oxidation is thought to depend mainly on the decomposition mechanism of the THP produced in the oxidation.

Discussion

The liquid-phase oxidation of tetralin has been widely studied, and the following elementary reactions (Eqs. 1—7) have been proposed in previous reports.[1,16,23-30] Equations 1—3 are elementary reactions involving metal ions. From Eqs. 1—3, two kinds of regeneration mechanisms of metal ions can be derived; one (the A-mechanism) is composed of Reactions 1 and 2, and the other (the B-mechanism), of Reactions 1 and 3.[31] The A-mechanism is the so-called Haber-Weiss mechanism[32-35] and is much more common as a regeneration mechanism of metal ions than the B-mechanism.

If metal ions catalyze both the tetralin oxidation and the THP decomposition by only the A-mechanism, α-tetralol will be produced in a higher yield than α-tetralone, as can be seen from Reactions 4—7, which follow Reactions 1 and 2. For most runs in the present work, however, the α-tetralol yields were lower than the α-tetralone yields. Although α-tetralol resulting from the tetralin oxidation can be converted into α-tetralone according to Reaction 8, Reaction 8 con-



tributes almost nothing to the formation of α-tetralone in the oxidation of tetralin in the presence of *N,N*-dialkylamides, as can be seen from Figs. 3 and 4. Also, α-tetralone was always the main product in the decomposition of THP with six kinds of first-transition-metal catalysts in DMF under a nitrogen atmosphere. This fact cannot be explained by only the A-mechanism. On the other hand, if the B-mechanism contributes

only to the regeneration of metal ions, the main products in both the tetralin oxidation and the THP decomposition will be α-tetralone. However, for the oxidation of tetralin in aliphatic acids, the α-tetralol yields were higher than the α-tetralone yields, as is shown in Table 1. Accordingly, it seems reasonable to assume that the regeneration of metal ions actually proceeds by both mechanisms, A and B, with A or B predominating according to the reaction conditions.

As is shown in Tables 1 and 6, DMF brought about relatively a very high ON/OL ratio and in the presence of *N,N*-dialkylamides α-tetralone was produced in a very high yield. These facts suggest that, in the presence of *N,N*-dialkylamides, the B-mechanism rather than the A-mechanism performs the regeneration of metal ions. The predominance of the B-mechanism is further strengthened by the simultaneous use of highly reductive metal catalysts and *N,N*-dialkylamides, as can be seen from Tables 5 and 8. However, the actions of *N,N*-dialkylamides for the selective formation of α-tetralone cannot be interpreted explicitly at present. If *N,N*-dialkylamides promote Reaction 1 and suppress Reaction 2, Reaction 3 will be remarkably accelerated by highly reductive metal ions such as Cr^{2+}, and such metal catalysts will give high ON/OL ratios and high α-tetralone yields. It has been reported that *N,N*-dialkylamides have high hydrogen-bonding abilities[36] and DMF forms electron-donor-acceptor complexes[37] with halo hydrocarbons with acceptor properties. It was also observed in the present work that, when THP is dissolved in a solution of *N,N*-dialkylamides, the solution turns pale pink. Accordingly, the association between THP and *N,N*-dialkylamides may promote Reaction 1 and may inhibit Reaction 2. Furthermore, the absorption spectra of the DMF complexes of Cr(III)[38] show that DMF has a ligand-field strength comparable to that of the SCN^- ligand, which occupies a higher position in the spectrochemical series[39,40] than the H_2O, RCO_2^-, ROOH ligands. Compared with ligands such as aliphatic acids, anhydrides, ethers and water, therefore, *N,N*-dialkylamides stabilize t_{2g} orbitals and unstabilize e_g orbitals in octahedral transition-metal complexes. This suggests that Cr^{2+} ($(t_{2g})^3(e_g)^1$ electron configuration) and Co^{2+} ($(t_{2g})^5(e_g)^2$) ions are labilized by *N,N*-dialkylamides ligands, while on the contrary, Cr^{3+} ($(t_{2g})^3(e_g)^0$) and Co^{3+} ($(t_{2g})^6(e_g)^0$) are stabilized by them; *i.e.*, the reducing power of both Cr^{2+} and Co^{2+} ions is increased by the coordination of *N,N*-dialkylamides. Accordingly, it may be concluded that, in the presence of *N,N*-dialkylamides, Reaction 3 proceeds relatively smoothly and that α-tetralone is produced in a very high yield.

(Received August 19, 1978)

Electrical potentials arising across barium(II) phosphate, mercury(II) iodide and cobalt(II) chromate membranes using various 1:1 electrolytes are reported. Thermodynamically effective fixed charge density, which is an important parameter governing the membrane phenomena, has been evaluated by the theory of Toyoshima and Nozaki. Using the values of effective fixed charge density determined, the theory of bi-ionic potentials developed by Toyoshima and Nozaki based on the principles of the irreversible thermodynamics has been examined. Theoretical predictions were borne out quite satisfactorily by our experimental results.

In recent years we have studied a large number of parchment supported inorganic precipitate and polymeric composite membranes.[1-6] Various transport parameters such as ion migration, self diffusion coefficient, hydrodynamic permeability *etc.* occuring across the membranes have been evaluated in the light of the theory described by Speigler[7] and by the use of the generalized Stefan-Maxwell equations. The theory of absolute reaction rates,[8] Eisenman-Sherry theory of membrane selectivity[9] and the theory of irreversible thermodynamics developed by Kedem and Katchalsky,[10] Smit and Staverman,[11] Bearman and Krikwood,[12] and Kobatake and coworkers[13-16] have been applied to evaluate apparent fixed charge density as well as to examine the various aspects of membranes.

In this communication a series of membrane potentials and bi-ionic potentials observed across parchment supported barium(II) phosphate, mercury(II) iodide and cobalt(II) chromate membranes using various 1:1 electrolytes are presented. Thermodynamically effective fixed charge density, which is an important parameter governing the membrane phenomena has been evaluated by the recently developed theory of Toyoshima and Nozaki based on the principles of irreversible thermodynamics.[17] An effort has been made to examine the validity of the theory of Toyoshima and Nozaki[17] for bi-ionic potential.

Experimental

Preparation of Membranes. Parchment supported barium(II) phosphate, mercury(II) iodide and cobalt(II) chromate membranes were prepared by the method of interaction suggested by Siddiqi, Beg, and coworkers.[1-6] To precipitate barium(II) phosphate in the interstices of parchment paper, a 0.2 M solution of barium(II) chloride was placed inside a glass tube, to one end of which was tied the parchment paper (supplied by M/s- Baired and Tatlock London Ltd.). The tube was suspended for 72 h in a 0.2 M solution of potassium dihydrogenphosphate. The two solutions were interchanged later and kept for another 72 h. The membrane was taken out and washed with deionized water to remove free electrolyte. Similar procedure was adopted for the preparation of mercury(II) iodide and cobalt(II) chromate membranes by taking 0.2 M solutions of mercury(II) chloride and potassium iodide, cobalt(II) chloride and potassium chromate, respectively.

Measurements of Membrane Potential and Bi-ionic Potential. Membrane potential E_m were obtained by constructing a cell of the following type taking different concentrations C'_N and C''_N of an electrolyte such that $C''_N/C'_N=10$

SCE	Solution C'_N	Membrane	Solution C''_N	SCE

and the bi-ionic potentials (BIP) were determined by setting up another cell of the type

SCE	Solution AP	Membrane	Solution BP	SCE

and keeping the same concentration of both the electrolytes AP and BP. The various salt solution (chlorides of Li^+, Na^+, K^+) were prepared from analytical grade reagents and deionized water. All measurements were carried out using a water thermostate maintained at 25±0.1 °C. The solutions on either sides of the membrane were vigorously stirred by a pair of magnetic stirrer.

Results and Discussion

When two electrolyte solutions of different concentrations are separated by a membrane, the mobile species penetrate the membrane and various transport phenomena are induced in the system. The fixed charge theory of Teorell-Meyer-Seivers (TMS) for charged membranes is a pertinent starting point for the investigation of the actual mechanisms of the ionic or molecular processes which occur in the membrane phase. Based on the fixed charge concept various mathematically rigorous equations for membrane potential and bi-ionic potential have in recent years been derived.[17-22] Most recently Toyoshima and Nozaki[17] have derived equations for membrane potential and bi-ionic potential using the principles of non-equilibrium thermodynamics and by utilizing appropriate assumptions for the mobilities and activity coefficients of small ions in the membrane phase.[17] The effect of ionic interaction, mass flow and osmotic effect were neglected. For a negatively charged membrane separating two 1:1 electrolytes (common co-ions) of the same concentration, these authors derived following expression for bi-ionic potential, E_{BIP},

$$E_{BIP} = (F/RT)[2\ln K_A/K_B + \ln(JV_A + 1/JV_B + 1)]. \quad (1)$$

Knowing the values of parameters K_A, K_B, V_A, V_B, and the flux J, the values of theoretical E_{BIP} can be

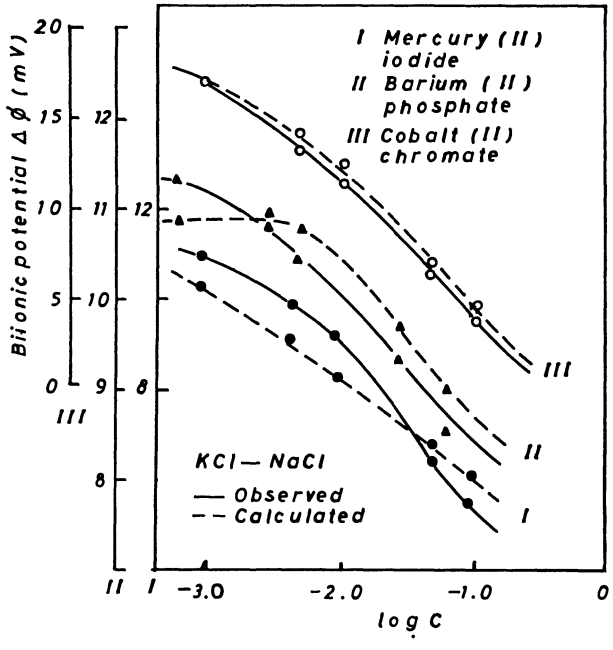

Fig. 2. Plots of bi-ionic potentials against log C for KCl–NaCl pair of electrolytes across (i) mercury(II) iodide, (ii) barium(II) phosphate and (iii) cobalt(II) chromate membranes.

calculated using Eq. 1. For the evaluation of these parameters, following equations have been forwarded[17]

$$(2J+1)\ln(g_A+2J/g_B+2J) - \ln(JV_A+1/JV_B+1) - \ln(g_A/g_B) = 0 \quad (2)$$

where

$$V_N = 1 + V_N^\circ/V_P^\circ \quad (N=A, B) \quad (3a)$$

and

$$g_N = 1 + [1+(2K_NC/\overline{X})^2]^{1/2} \quad (N=A, B) \quad (3b)$$

In Eq. 3a, V_N° and V_P° are the mobilities of cation N and anion P, respectively in bulk solution. In Eq. 3b, $\overline{X}$ is the effective charge density of the membrane and K_N is defined by

$$1/K_N = \exp[(\mu_N^{\circ m} - \mu_N^{\circ b} + \mu_P^{\circ m} - \mu_P^{\circ b})/2RT] \quad (3c)$$

where $\mu_N^{\circ m}$ is the standard chemical potential of cation N ion in the membrane phase and $\mu_N^{\circ b}$ is that in bulk solution and $\mu_P^{\circ m}$ and $\mu_P^{\circ b}$ are the corresponding values of anion P. In order to derive the values of the parameters V_N and $\overline{X}$ occuring in Eq. 3a and 3b Toyoshima and Nozaki[17] derived another equation for membrane potential E_m arising across a membrane when it is used to separate two solutions of an electrolyte at

different concentrations C'_N and C''_N

$$(F/RT)E_m = -\ln\gamma - (1-2/V_N)X \ln\frac{\sqrt{1+(2C''_N K_N/\overline{X})^2}+(1-2/V_N)}{\sqrt{1+(2C'_N K_N/\overline{X})^2}+(1-2/V_N)} + \ln\frac{\sqrt{1+(2C''_N K_N/\overline{X})^2}+1}{\sqrt{1+(2C'_N K_N/\overline{X})^2}+1} \quad (4)$$

where $\gamma = C''_N/C'_N$.

Equation 4 on expansion in powers of concentration ratio=10 being kept constant yield

$$(F/RT)E_m = -(1-2/V_N)\ln\gamma - 2(1-1/V_N)X (1/V_N)(1-1/\gamma)(\overline{X}/K_N)(1/C''_N) + \cdots \quad (5)$$

The apparent transference number t_- for co-ion was defined by the Nernst equation

$$-(F/RT)E_m = (1-2t_-)\ln\gamma. \quad (6)$$

Combining Eqs. 5 and 6 and expanding $1/t_-$ as a power of series of $1/C''_N$, following expression was obtained

$$1/t_- = V_N + (V_N-1)\left[\frac{\gamma-1}{\gamma\ln\gamma}\right]\left(\frac{\overline{X}}{K_N}\right)\left(\frac{1}{C''_N}\right) + \cdots \quad (7)$$

Equation 7 predicts a linear relationship between $1/t_-$ and $1/C''_N$. The values of V_N and $(\overline{X}/K_N)$ can be determined from the ordinate intercept and initial slope of a plot for $1/t_-$ against $1/C''_N$. The apparent transference number t_- was calculated from membrane potential data (Table 1) using Eq. 6. The values of V_N and $\overline{X}/K_N$ thus derived for the membrane and various 1:1 electrolyte systems using Fig. 1 are given in Table 2. The values of V_N and $(\overline{X}/K_N)$ were then used to calculate J and g_N using Eqs. 2 and 3. Once the membrane parameters V_N, g_N, J and $(\overline{X}/K_N)$ are known for the membrane electrolyte systems, one can calculate theoretical bi-ionic potential using Eq. 1. The bi-ionic potential thus obtained were plotted as a function of log C in Fig. 2 (shown by dotted lines). In order to compare theoretical bi-ionic potential values, the observed bi-ionic potentials were also plotted in the same graph (shown by solid lines). Figure 2 demonstrates that the theoretical predictions are borne out quite satisfactorily by our experimental results on parchment supported membranes. However, a slight deviation in the values may be accounted due to various reasons, most notably due to the various degree of interaction of ions with the membranes of low fixed charge site.

The authors are grateful to Professor Wasiur Rahman, Head, Department of Chemistry for providing research facilities and to C.S.I.R. (India) for the award of fellowship to SPS, VG, and PP.

Vibrational Spectra and Assignments for the Fundamental Vibrations of Imidazolidine-2-thione and -2-selenone

K. DWARAKANATH and D. N. SATHYANARAYANA*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

(Received November 18, 1978)

Infrared spectra of imidazolidine-2-thione (*N,N'*-ethylenethiourea, ETU) and its *N,N'*-deuterated (ETU-d_2) and *S*-methylthiouronium iodides have been recorded from 4000 to 30 cm^{-1}. Normal coordinate analyses of ETU and ETU-d_2 have been made for all the fundamental frequencies, employing a Urey-Bradley potential function supplemented with valence type constants for the out of plane modes of the planar skeleton. Raman frequencies of ETU from literature have been utilised. The results of the vibrational analyses are discussed in relation to the group frequencies in structurally related molecules and frequency shifts on deuteration and *S*-methylation. The normal coordinate treatment is also performed for the planar vibrations of imidazolidine-2-selenone (*N,N'*-ethyleneselenourea, ESU) to propose assignments for ESU and so also to support the assignments of ETU.

Imidazolidine-2-thione, commonly referred to as *N,N'*-ethylenethiourea (ETU), is of considerable importance as a ligand in transition metal chemistry. ETU is an interesting molecule as a simple symmetrically disubstituted cyclic thiourea, NH–CH_2–CH_2–NH–C=S, which has a –NHCSNH– group constrained in a *cis-cis* position. It may be expected to exhibit vibrations characteristic of this grouping and a comparison of the vibrations of ETU with those of sym. *N,N'*-dimethylthiourea[1] may be of interest. Very recently, the normal coordinate calculations on *N,N'*-ethyleneurea (imidazolidin-2-one) have been published[2] and its extension to the analogous sulfur and selenium compounds is desirable. On these accounts, a knowledge of the normal coordinates of ETU and its seleno analo ue would be valuable.

Previous assignments of the principal bands of ETU were based upon empirical criteria.[3–5] An approximate normal coordinate analysis of only the in-plane vibrations of ETU treating methylene groups as point masses has also been reported.[6] However, the vibrational assignments are not complete and many of the fundamentals are uncertain or unassigned. In order to obtain as complete a vibrational assignment of the fundamentals as possible, the infrared spectra of ETU as well as its *N,N'*-deuterated (ETU-d_2) and the *S*-methyl derivatives are studied. The Raman data from literature[4,7] are also made use of. The assignments are supported by accomplishing normal coordinate analyses of ETU and ETU-d_2 for all the fundamental vibrations. The coordinate treatment is also extended to the in-plane vibrations of imidazolidine-2-selenone (*N,N'*-ethyleneselenourea, ESU) with which it can profitably be compared since only the sulfur-involving frequencies of ETU are expected to vary principally in ESU.

Experimental

ETU was prepared and purified according to Allen *et al.*[8] mp 197—198 °C. The *N,N'*-deuterated compound (ETU-d_2) was obtained by repeated exchange reaction with heavy water. The *S*-methyl derivative of ETU was prepared by a standard procedure.[9]

Spectra. Infrared spectra of the solid samples were measured on a Carl-Zeiss UR10 spectrophotometer from 4000 to 400 cm^{-1} in Nujol mull and KBr pellet. The observed frequencies were calibrated with standard frequencies of polystyrene. Infrared spectra between 400 to 30 cm^{-1} were recorded on a Polytec FIR 30 Fourier transform spectrometer. The instrument was calibrated by means of water vapor frequencies. The Raman frequencies[7] of ETU and the infrared bands[5] of ESU are quoted from published spectra. The infrared spectra of ETU-d_0 and ETU-d_2 between 300 to 50 cm^{-1} are given in Fig. 1.

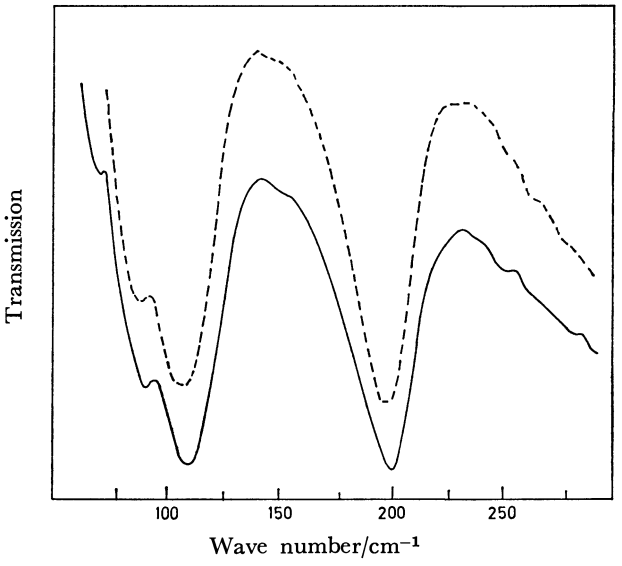

Fig. 1. Infrared spectra of ETU-d_0 (—) and ETU-d_2 (----).

Normal Coordinate Analysis

It is known by the X-ray crystal structure determination[10] that ETU has a C_{2v} symmetry. The 30 normal vibrations of ETU and ESU in the C_{2v} symmetry are classified into 19 in-plane ($10A_1$ and $9B_2$) and 11 out-of-plane ($5A_2$ and $6B_1$) modes of which the vibrations belonging to A_1, B_1, and B_2 species are infrared active and all are Raman active. The internal coordinates are depicted in Fig. 2. The out of plane vibrations of the planar ring are described in terms of the out of plane bending of the C–S and N–H groups and the torsional coordinates of the CN and C'N bonds.

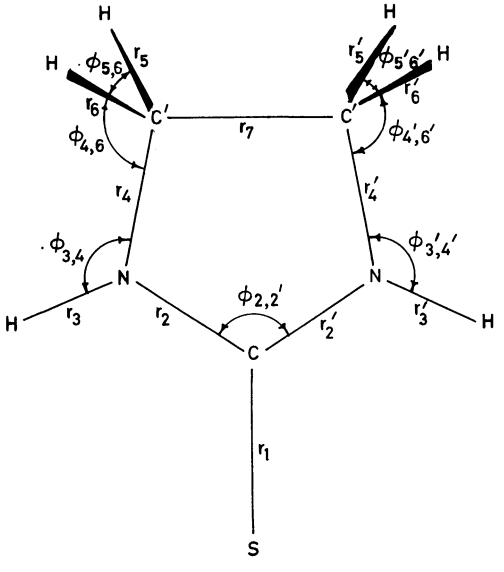

Fig. 2. Structure and internal coordinates of *N,N′*-ethylenethiourea.
Torsional coordinates are formed from the bond numbers.

The molecular parameters were taken from the X-ray structure data[10]—r(N–H) 0.99, r(C–H) 0.90, r(C–C) 1.536, r(C–N) 1.322, r(C′–N) 1.471 and r(C–S) 1.708 Å; ∠SCN 125.0°, ∠CNC 112.6°, ∠NCC 102.4°, ∠CNH 123.7°, ∠NC′H 104.07°, ∠CCH 109.6°, and ∠HCH 126.5°. For ESU, C=Se distance was assumed to be 1.86 Å and the rest of the structural parameters were the same as those of ETU. The symmetry coordinates used were constructed by standard procedures[11,12] and are not reported here for the sake of briefness.

The Wilson's GF matrix method[13] was employed. The numerical computations were performed with an IBM 360/44 Computer using programs similar to those of Shimanouchi.[14] Infrared frequencies were used for the calculations. Since the Urey-Bradley force (UBF) function has been successful in satisfactorily explaining the vibrational spectra of thioamides[15–18] and thioureas,[19,20] it was employed presently. For the out of plane A_2 and B_1 fundamentals, the Urey-Bradley force constants for the CH_2 groups, and the valence force constants for the out of plane deformations and torsional modes were used. The initial UBF constants were taken from succinonitrile[21] for the $-CH_2-CH_2-$ part and from *N*-methyl thioacetamide[15,16] (NMTA) for the –NHCSNH– part. The zeroth order calculated frequencies were close to the observed ones lending confidence to the assignments obtained. For the out-of-plane vibrations of the molecular skeleton, valence force constants were used and the initial values were taken from *N*-methylthiourea.[22] The force constants were refined by an iterative procedure and the final values of the force constants of ETU are presented in Table 1. The force constants of ETU were then transferred to ESU. In accord with the concept of selenation,[23] minimum modifications were effected in the force constants of ETU, particularly for those connected with the thioureide group to obtain a desired agreement between the calculated and observed frequencies for the in-plane fundamentals of ESU. The final values of the force constants of ESU are also given in Table 1.

Results and Discussion

Force Field. The agreement between the observed and calculated frequencies for both ETU and ETU-d_2 is good. The final values of the force constants of ETU seem appropriate and they are comparable with the corresponding ones in NMTA[15,16] and thioacetamide[15,17] (TAM) for the –NHCSNH– part and those from succinonitrile[21] for the $-CH_2-CH_2-$ part. These demonstrate the transferability of the UBF constants. For example, the C=S stretching constant of ETU (3.40 mdyn/Å) is similar to that of TAM[17] and NMTA[16] (3.40 and 3.45 mdyn/Å, respectively). Similarly, the C–N stretching constant of ETU (5.90

mdyn/Å) is also comparable with that of TAM and NMTA (5.70 mdyn/Å).

The agreement between the calculated and observed frequencies of ESU is good and the final values of the force constants of ESU differ very little from the transferred force constants of ETU. The C=Se stretching constant (2.80 mdyn/Å) is lower than the C=S stretching force constant of ETU (3.40 mdyn/Å), and the C–N constant of ESU (6.05 mdyn/Å) is slightly higher than that of ETU (5.90 mdyn/Å). A similar trend is noticed in the C–S and C–N force constants for thiourea and selenourea.[19] This indicates the increased contribution of the cannonical form $S^{-}-\overset{|}{C}=N^{+}<$ over the other structure, $S=\overset{|}{C}-N<$ in the selenium compound compared to the analogous sulfur compound.

Vibrational Assignments. Imidazolidine-2-thione: The observed and calculated fundamentals of ETU and ETU-d_2 are presented in Table 2 along with the assignments as derived from the potential energy distributions among the symmetry coordinates.

In-plane Vibrations: *Vibrations of the Methylene Groups*: *CH_2 Stretching and Bending.* There are two CH_2 stretching vibrations of ETU one each belonging to A_1 and B_2 species. A medium broad band at 2900 cm^{-1} has been attributed to both these modes. The CH_2 bending modes (ν_4 and ν_{14}) are assigned to the bands at 1470 and 1480 cm^{-1} (respectively). These are compatible with those of *N,N'*-ethyleneurea.[2]

CH_2 Wagging. The symmetric CH_2 wagging (A_1) is found as a mixed vibration contributing almost equally to the bands at 1286 and 1212 cm^{-1} whereas the asymmetric CH_2 wagging (B_2) may be assigned at 1312 cm^{-1}. The assignment of CH_2 wagging vibrations is similar to the corresponding modes in *N,N'*-ethyleneurea[2] at 1274 and 1207 cm^{-1}, in ethylene trithiocarbonate[24] at 1279 and 1248 cm^{-1}, and in thiazolidine[25] around 1320 and 1260 cm^{-1}.

Vibrations of the Thioureide Group: *NH Group Vibrations.* The symmetric and antisymmetric NH stretching modes (ν_1 and ν_{11}) are easily assigned to the broad bands centered at 3275 and 3250 cm^{-1}, which on deuteration are replaced by new bands at 2435 and 2400 cm^{-1}, respectively. In *N,N'*-ethyleneurea[2] both NH stretching vibrations are observed as a single strong band at 3285 cm^{-1}.

The symmetric NH bending (A_1) is found to be a mixed vibration contributing equally to the bands at 1528 and 1212 cm^{-1}. This assignment qualitatively agrees with the earlier ones of Klaboe,[4] and Mecke *et al.*[3] However, in *N,N'*-ethyleneurea, the corresponding mode is observed as a pure vibration at 1385 cm^{-1}. The asymmetric NH bending (B_2) is however found as a pure vibration at 1376 cm^{-1} and this assignment is similar to that of *N,N'*-ethyleneurea for a medium band at 1423 cm^{-1}. In ETU-d_2, the ND bending contributes to the bands at 860 and 892 cm^{-1} in the A_1 symmetry species whereas in the B_1 type the 927 cm^{-1} band originates from ND bending.

C–N and C=S Group Vibrations. The symmetric C–N stretching (A_1) coupled with NH bending is associated with the 1528 cm^{-1} band, whereas the asymmetric C–N stretching (B_2) is pure and is assigned at 1508 cm^{-1}. The CN stretching frequency (B_2) of ETU is about 50 cm^{-1} higher than the corresponding mode in *N,N'*-ethyleneurea as expected due to the increased C–N bond order. The infrared bands at 1508 and 1528 cm^{-1} show a pronounced shift towards higher frequencies and are observed at 1557 and 1570 cm^{-1} in the *S*-methylated ETU, the shift being explained by the increased double bond character of the CN bond following the methylation of the sulfur atom.

The nature of the C=S stretching mode of ETU is interesting. The C=S stretching coordinate is distributed principally among two vibrations giving rise to the strong bands in the infrared at 516 and 925 cm^{-1}, a major proportion of 42% for the 516 cm^{-1} and a lesser proportion of 26% for the 925 cm^{-1} band. In support of this assignment, very strong bands are observed in the Raman[4,7] at 927 and 513 cm^{-1}. The assignment of the 516 cm^{-1} band qualitatively agrees with the recent one of Verani[5] but differs from that of Klaboe,[4] and Mecke *et al.*,[7] who have assigned the C=S stretching frequency around 1200 cm^{-1}.

The attribution of the 516 cm^{-1} band to the C=S stretching mode is further supported from the infrared spectra of ESU and the *S*-methyl derivative of ETU. On *S*-methylation, which diminishes the double bond character of the C=S bond, the 516 cm^{-1} band of ETU shows a pronounced red shift and is found in the spectrum of the *S*-methyl derivative at 477 cm^{-1}. The 516 cm^{-1} band of ETU is replaced in the spectrum of ESU by a band at a much lower wave number, 357 cm^{-1}, thus confirming its assignment. In the metal complexes of ETU, increase in the C–N stretching band and decrease in the C–S stretching band (at 516 cm^{-1}), similar to that on *S*-methylation but of smaller magnitude, are observed.[25,26]

The C=S bending may be assigned at 343 cm^{-1}. This frequency is in between the corresponding frequency in NMTA[15,16] at 370 cm^{-1} and in thiazolidine-2-thione[28] at 292 cm^{-1}. In support of this assignment, the 345 cm^{-1} band of ETU is replaced in ESU by a new band at a lower frequency, 280 cm^{-1}.

Ring Vibrations. There are two ring deformation vibrations. The ring deformation belonging to the A_1 species is coupled and contributes chiefly to the bands at 925 and 516 cm^{-1}. The ring deformation belonging to the B_2 representation, on the other hand, is associated with the 678 cm^{-1} band. The latter assignment differs from that of Klaboe,[4] and Devillanova and Verani[5] who have assigned it to an NH out-of-plane bending. The assignment of the 678 cm^{-1} band to a ring deformation mode is comparable with the 703 cm^{-1} band of *N,N'*-ethyleneurea[2] and with similar assignments made for other five membered heterocyclic compounds. For instance, a ring deformation mode has been assigned in 2,5-pyrrolidinedithione[29] at 649 cm^{-1} and in thiazolidines[25,28] near 675 cm^{-1}. It is interesting to note that the 678 cm^{-1} band of ETU almost completely vanishes on *N*-deuteration. However, there is a new weak band at 645 cm^{-1} in the infrared spectrum of ETU-d_2 corresponding to the 678 cm^{-1} absorption of ETU as expected from the computed frequencies of ETU-d_2 and confirming its assignment to a ring deformation mode.

a) The frequencies of ETU-d_2 are so arranged as to approximately correspond to the assignments and the PEDs given for ETU-d_0; ν=stretching, δ=bending, r=rocking, w=wagging, t=twisting, π=out-of-plane bending and τ=torsion. b) PED=Potential energy distributions ($100 L_{ik}^2 F_{ii}/\lambda_k$); those less than 15% are omitted.

Out-of-plane Vibrations: B_1 *Vibrations.* The out-of-plane CH_2 stretching is assigned to a weak band at 2967 cm^{-1} comparable with the very weak Raman band of *N,N'*-ethyleneurea[2] at 2980 cm^{-1}. The CH_2 twisting of ETU at 1312 cm^{-1} is slightly higher than that in thiazolidines[25,28] and succinimides[30] assigned around 1230 to 1270 cm^{-1}. According to the normal coordinate treatment, the band at 925 cm^{-1} could also be assigned to CH_2 rocking and this is compatible with CH_2 rocking in ethylene trithiocarbonate[24] and thiazolidines[25,28] assigned between 935 to 950 cm^{-1}.

There are three skeletal modes belonging to B_1 species. The NH out-of-plane bending is assigned at 598 cm^{-1} and its origin from an NH group is confirmed by deuteration studies. On deuteration a new strong broad band at 450 cm^{-1} is observed in agreement with the calculated frequency at 465 cm^{-1}. If, on the other hand, the 678 cm^{-1} band is assigned to NH out-of-plane bending and the 598 cm^{-1} band to ring deformation, then the calculated frequencies for ETU-d_2 are not consistent with observed ones. The strong 598 cm^{-1} absorption of ETU is rather broad and typical of NH bands due to out-of-plane bending. The 678 cm^{-1} band may however be assigned to an NH bending of A_2 symmetry overlapping with the B_2 fundamental due to ring deformation.

The infrared and Raman spectra of ETU exhibit a strong band near 110 cm^{-1} (which is rather broad

n. a.=not available. a), b): as in Table 2.

in the infrared with a shoulder band at 90 cm^{-1}). This band has been assigned to ring torsion of species B_1. Such features have been observed in related five-membered ring systems,[24,31-34] such as ethylene trithio-[24] and -triselenocarbonate[34] (at ≈90 and 70 cm^{-1}, respectively) and other cyclic carbonates[33] (≈95 cm^{-1}), *etc.* Lattice modes are assigned at still lower frequencies. The calculations for ETU indicate that the other ring puckering mode (of A_2 species) could be assigned in the same region. Since it was not possible to record the far infrared spectra of ETU in solution a doubt can arise that the band around 110 cm^{-1} could be due to lattice modes. An alternate choice for ring torsions may then be the strong band at 200 cm^{-1}, compatible with the assignment in ethylene carbonate[35] (at 215, 230 cm^{-1}) and *N,N'*-ethyleneurea[2] (near 250 cm^{-1}). In such a case, the assignment of C=S out of plane bending presents a difficulty. The former assignment is therefore preferred. Since the out of plane vibrations are fairly independent of each other, even if the latter assignment is preferred, it does not affect the overall results.

A_2 Vibrations. The vibrations belonging to A_2 species, according to the selection rules, are infrared inactive but Raman active for the molecular symmetry C_{2v}. These modes may be observed in the infrared if the molecule is not exactly of C_{2v} symmetry or if the site symmetry is lower. The X-ray structure data[10] of ETU indicate some deviations from C_{2v} symmetry.

The infrared and Raman bands observed corresponding to the calculated vibrations of the A_2 species of ETU and ETU-d_2 are also shown in Table 2. This seems to indicate the overlapping of the fundamentals. No new Raman band without a corresponding infrared band was observed. This shows that the effective molecular symmetry of ETU in the solid state may be slightly lower than C_{2v}.

Imidazolidine-2-selenone: The normal coordinate calculations for ETU is extended to the in-plane vibrations of ESU in an attempt to assign the planar frequencies of ESU and also to confirm some of the assignments made for ETU themselves. The frequency data together with their potential energy distributions derived from the calculations are shown in Table 3. The experimental frequencies are quoted from a published spectrum.[5]

As observed from Tables 2 and 3, the nature of the bands of ESU are very similar to the corresponding ones of ETU and only the bands at 925 and 516 cm^{-1} in the A_1 symmetry species and 343 cm^{-1} in the B_2 species of ETU are significantly shifted to lower frequencies suggesting the higher contribution from the C–S group vibrations to these bands. The assignments of ESU are thus straightforward.

Of particular interest in the spectrum of ESU are the C=Se stretching and bending vibrations. Notably, the potential energy distributions indicate that the observed band at 357 cm^{-1} may be assigned to C=Se stretching and it has considerable contribution from ring deformations. The C=Se stretching also contributes significantly (27%) to the (calculated) higher frequency band at 828 cm^{-1}. The present assignment of the 357 cm^{-1} band qualitatively agrees with Devillanova and Verani[5] who have attributed it to a coupled mode consisting of C=Se stretching, NCSe and NCN bending. The 357 and 828 cm^{-1} bands of ESU correspond approximately to the 516 and 925 cm^{-1} bands of ETU and thus represent a large decrease of over 100 to 140 cm^{-1} from sulfur to the corresponding selenium-involving vibration. The C=Se bending mode is found at 280 cm^{-1} thus producing a decrease of over 60 cm^{-1} from the C=S bending of ETU at 343 cm^{-1}.

An ESR Study of the Photolysis of *N*-Nitrosodialkylamines

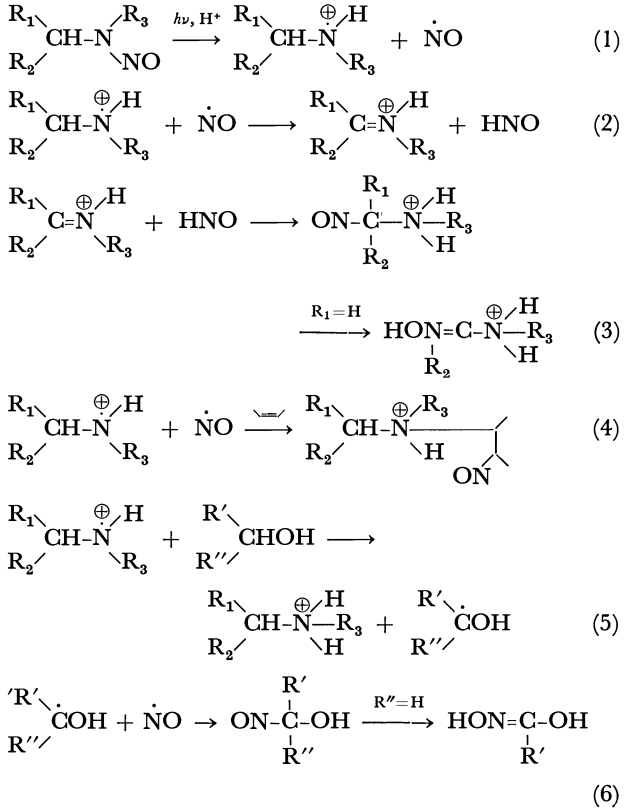
A. John ELLIOT† and Jeffrey K. S. WAN*

Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6

(Received November 20, 1978)

The nitroxide radicals which are formed when acidic, neutral, and alkaline solutions containing *N*-nitrosodialkylamines are photolysed, have been characterized by electron spin resonance spectroscopy. Nitrosamines are found to be photolytically active only in acidic solutions. In neutral and alkaline solutions nitrosamines only participate in secondary reactions involving the alcohol derived radicals. Some possible reaction pathways have been postulated.

As a class of compounds, *N*-nitrosodialkylamines when photolysed in neutral solutions, are effectively stable towards UV irradiation.[1-3] However in dilute acid solutions, nitrosamines undergo a large variety of photoinitiated free radical reactions, many of which are of interest in synthetic organic chemistry.[1-4] The primary photochemical event have been established to be an acid catalysed breaking of the nitrogen-nitrogen bond to produce an aminium radical and nitrogen monoxide. A generalized reaction scheme is given below: (for more detailed information the reader is directed to the review article by Chow[3] and references therin).



To the best of our knowledge, the only photochemical ESR investigations of the photolysis of nitrosamines are two communications from this laboratory[5,6] which supported the N–N cleavage as the primary chemical event. As can be seen from the above scheme, any ESR study to characterize the free radical intermediates will be bedevilled by a host of nitroxide radicals formed from the various *C*-nitroso compounds by spin trapping,[7]

or by secondary photolysis.[3,7]

Many of these problems can be minimized by photolysing flowing solutions and in this report we will describe the radicals obtained when solutions containing either *N*-nitrosodimethylamine, *N*-nitrosodicyclohexylamine or 1-nitrosopyrollidine were photolysed.

Experimental

The chemicals were purchased from Aldrich (*N*-nitrosodicyclohexylamine, 1-nitrosopyrollidine, acetone oxime, cyclopentanone oxime, maleic acid), K and K (*N*-nitrosodimethylamine), Baker (triethylamine), BDH (propionic acid), McArthur Chemicals (acetic acid). The solvents were obtained from a number of commercial sources. All chemicals were used as supplied except triethylamine which was distilled before use.

The concentrations of the nitrosamines in the solutions were 0.03—0.1 mol dm^{-3} and when di-*t*-butyl peroxide was added, its concentration was 1—2 vol %. All solutions were deoxygenated by purging with gaseous nitrogen. The flowing solutions were photolysed directly in the cavity of a Varian E-3 spectrometer with light from a 1000 W high pressure mercury lamp. The flow rate was varied (0—4 ml min^{-1}) to optimize the spectrum under study. For most samples this flow was 0.5 to $\approx$1.0 ml/min. The sample temperature in the cavity was regulated by flowing thermostated nitrogen gas by the spectrosil flow tube. The ESR simulations were performed on a Nicolet 1180 computer.

Results

Photolysis of Acidic Solutions. *(a)*N-*Nitrosodimethylamine (NDMA)*: No radicals were detected on photolysis of flowing solutions of NDMA in acetic acid, or 10 vol % acetic acid : benzene, however, if an alcohol was added to this solution an ESR spectrum was observed. In general the spectrum arose from two radicals, one of which, a nitroxide with $a^N \approx$ 1.45 mT, was formed through secondary processes as its intensity increased markedly relative to the second radical on decreasing the flow rate. This secondary radical was not studied in detail. With the other radical (I), the number of interacting nuclei varied depending on the alcohol added. With 2-propanol and 2-butanol, splittings from two nitrogens and two protons were observed from I (see Fig. 1 and Table 1)

† Present address: Department of Chemistry, University of Calgary, Calgary, Canada T2N 1N4.

Table 1. The hyperfine coupling constants (mT) for radical I

Solvent	a^H	a^H	a^H	a^N	a^N
10 vol% acetic acid : 2-propanol	0.87	0.83	—	0.29	1.40
8 vol% acetic acid : 30 vol% water : 2-propanol	0.94	0.94	—	0.29	1.39
10 vol% acetic acid : 10 vol% 2-propanol : benzene	0.78	0.78	—	0.38	1.34
4 vol% 2-propanol : acetic acid	0.86	0.86	—	0.34	1.38
10 vol% acetic acid : 2-butanol	0.94	0.77	—	0.31	1.38
10 vol% acetic acid : 1-propanol	0.98	0.66	0.62	0.34	1.34
10 vol% acetic : ethanol	0.91	0.76	0.71	0.31	1.35

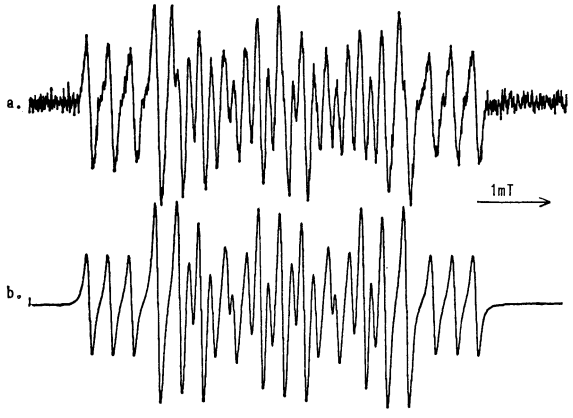


Fig. 1. (a) The ESR spectrum recorded when a NDMA: 8 vol % acetic acid: 30 vol % H_2O: 1% di-*t*-butyl peroxide: 2-propanol solution was photolysed at 22 °C. (b) The simulated ESR spectrum of radical I.

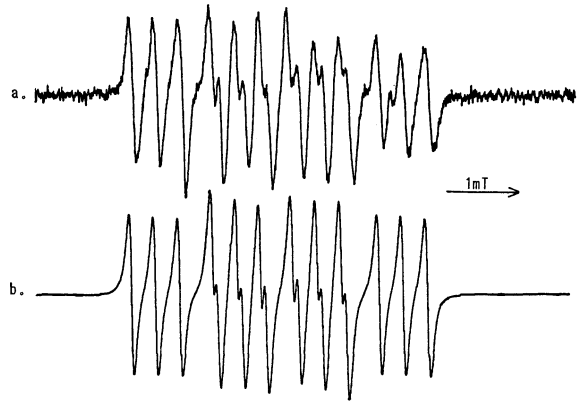

Fig. 2. (a) The ESR spectrum recorded when a NDCHA: 10 vol% acetic acid: ethanol solution was photolysed at 8 °C. (b) The simulated ESR spectrum of radical II.

but when the alcohol was ethanol or 1-propanol, an additional proton splitting was found (Table 1). When di-*t*-butyl peroxide was added to the solution, the spectral intensity of I increased about five fold. Although the hyperfine coupling constants showed little variation with temperature (−30 °C to +35 °C), they did vary slightly with solvent (Table 1). Linewidth effects associated with the coupling of the ***g***- and ***A***-tensors as the radical tumbled slowly could be observed as temperature was lowered in the alcoholic solvents.

For a DMNA:2-propanol solution (with and without di-*t*-butyl peroxide), the same spectrum was observed

Table 2. The coupling constants (mT) for radical II

Solvent	a^H	a^N	a^N
10 vol% acetic acid : 2-propanol	1.20	0.33	1.11
10 vol% HCl (concd) : 2-propanol	1.21	0.40	1.13
10 vol% acetic acid : ethanol	1.20	0.33	1.10
10 vol% acetic acid : 20 vol% H_2O : 2-propanol	1.25	0.36	1.15
acetic acid	1.22	0.39	1.16

regardless of whether the acid was acetic or propionic but if maleic acid (0.2 mol dm^{-3}) or concentrated hydrochloric acid (2—10 vol %) was added, no spectrum was observed. Addition of 10 vol % cyclohexene to a DMNA : 10 vol % acetic acid : 2-propanol solution (8 °C) only slightly reduced the yield of I. However, if the flow was stopped, the solution photolysed for a few minutes, and then the spectrum recorded with the light blocked, the spectrum of a persistent nitroxide radical (a^N=1.55 mT, a^H=0.18 mT, linewidth≈0.2 mT) was recorded. In the absence of cyclohexene, no spectrum was observed after this sequence as both I and the other nitroxide decay within seconds.

(b) N-*Nitrosodicyclohexylamine (NDCHA)*: In contrast to DMNA, when DCHNA was photolysed in acetic acid, 2-propanol containing 10 vol % acetic acid or 10 vol % hydrochloric acid, ethanol containing 10 vol % acetic acid or 0.2 mol dm^{-3} maleic acid, the same radical (II) was always observed. A representative spectrum is shown in Fig. 2 and the coupling constants (for two nitrogens and a proton) are given in Table 2. As with NDMA solutions, a second nitroxide radical spectrum was also observed but its intensity relative to II decreased on increasing the flow rate and it is considered to arise from secondary processes. When di-*t*-butyl peroxide was added to any of the NDCHA solutions studied the intensity of II remained unaltered. Addition of cyclohexene to the solutions did not affect the intensity either.

(c) 1-Nitrosopyrollidine (NP): A limited number of experiments were undertaken with NP. On photolysing a NP:10 vol % acetic acid : 2-propanol solution, radicall III was observed (in addition, a secondary nitroxide was also observed). The coupling constants for III in the solution were a^N=1.36 mT and a^N=a^H= 0.28 mT. The intensity of III increased on the addition of di-*t*-butyl peroxide to the solution. When the 2-propanol was replaced by either ethanol or 1-propanol, the spectrum of radical III (which was weak) appeared to have an extra proton coupling(a^H ≈0.58 mT) in

Table 3. Coupling constants (mT) of radicals formed in neutral solutions from NDCHA

Alcohol	a^N	a^N a)	a^H a)	Assignment
Ethanol	1.44	0.07 (2)	0.03 (6)	$\left(\mathrm{HO-\overset{CH_3}{\overset{\vert}{C}}-\overset{H}{\overset{\vert}{}}}\right)_2\mathrm{NO}$
	1.41	0.51 (2)	0.03 (2)	?
2-Propanol	1.54	—	—	$\left(\mathrm{HO-\overset{CH_3}{\overset{\vert}{C}}-\overset{CH_3}{\overset{\vert}{}}}\right)_2\mathrm{NO}$
	1.32	1.23	—	$\mathrm{HO-\overset{CH_3}{\overset{\vert}{C}}-\overset{CH_3}{\overset{\vert}{}}-HNO}$
1-Propanol b)	1.40	0.49 (2)	—	$\left(\mathrm{HO-\overset{CH_2CH_3}{\overset{\vert}{C}}-\overset{H}{\overset{\vert}{}}}\right)_2\mathrm{NO}$
2-Butanol	1.51	0.27	—	?

a) The number of equivalent nuclei are given in parentheses if different from one. b) Other radicals also present but spectrum too complicated to analysed (see Fig. 4).

addition to the above.

It should be noted that while radicals I, II, and III had half lives of about a second at 10—20 °C, their spectral intensities were not excessively large. When a 10 vol % acetic acid : 2-propanol solution containing either NDMA or NDCHA was photolysed, the respective radicals, I or II, were still observed (although at reduced intensity) when a filter (which blocked light $\lambda<320$ nm) was inserted in the light beam.

Photolysis of Neutral and Basic Solutions. Photolysis of DCHNA in static alcohol solutions will, after a few minutes, produce strong spectra of nitroxide radicals but if the solutions were flowed no radicals could be detected. However, if di-*t*-butyl peroxide was added to the flowing solutions nitroxide radicals were observed. The effect of adding di-*t*-butyl peroxide was to generate alcohol-derived radicals.

$$t\text{-BuOOtBu} \xrightarrow{h\nu} 2t\text{-BuO}\cdot \quad (8)$$

$$t\text{-BuO}\cdot + \mathrm{R'R''CHOH} \longrightarrow t\text{-BuOH} + \mathrm{R'R''\dot{C}OH} \quad (9)$$

The results are summarized for NDCHA in Table 3. The spectra obtained for the alcohols, ethanol and 1-propanol, with NDCHA are shown in Figs. 3 and 4. Only ethanol and 2-propanol were studied for DMNA and, although the spectral intensity was greatly reduced in ethanol, the radicals were the same as in DCHNA.

When a NDCHA : ethanol solution (with or without di-*t*-butyl peroxide) has 10 vol % triethylamine added, only the diethyl nitroxide radical was observed ($a^N=$ 1.58 mT, $a^H=1.08$ mT (4 protons)). Photolysis of a blank solution containing no NDCHA produced no detectable radicals. If the base pyridine was added to a NDCHA : ethanol solution, no radicals were detected on photolysis, whereas on addition of di-*t*-butyl peroxide, the spectrum was the same as when the pyridine was absent.

Fig. 3. (a) The ESR spectrum recorded when a NDCHA: ethanol solution containing di-*t*-butyl peroxide was photolysed at −10 °C. (b) The centre portion of the spectrum expanded. (c) The simulated ESR spectrum of (b) using the coupling constants in Table 3.

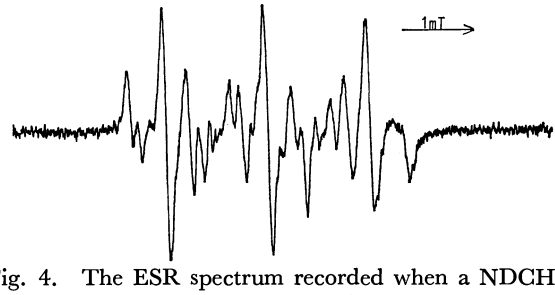

Fig. 4. The ESR spectrum recorded when a NDCHA: 1-propanol solution containing di-*t*-butyl peroxide was photolysed at 10 °C.

Photolysis of Acetone Oxime (AO) and Cyclopentanone Oxime (CPO). As oximes are generated in the photolysis of nitrosamines (Reaction 3), alcohol (2-propanol or ethanol) solutions containing di-*t*-butyl peroxide and AO or CPO were photolysed to see if the oximes would act as spin traps for the alcohol derived radicals (Reaction 9). Only the alcohol radical was observed on photolysis.

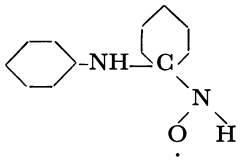
If AO or CPO were photolysed in a 25 vol % 2-propanol (or ethanol): acetic acid solution, a nitroxide radical $a^N=a^H=1.40$ mT was observed. When di-*t*-butyl peroxide was added to the solution, the alcohol derived radical was also observed. Obviously the oximes do not act as efficient spin trapping agents for those alcohol derived radicals.

Discussion

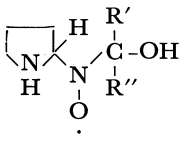
Identification of the Radicals. The likely structures for radicals I, II and III, are given below:

$$\mathrm{CH_3-NH-CH_2-\underset{\underset{O}{\vert}}{N}-\overset{\overset{R'}{\vert}}{\underset{\underset{R''}{\vert}}{C}}-OH}$$

I

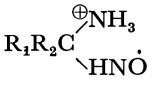


II



III

R′ and R″ are the substituents on the alcohol (see Reaction 9). The secondary amine nitrogen may also be protonated in these acidic solutions. The large nitrogen coupling constants (1.1—1.4 mT) observed for all radicals are consistent with nitroxide radicals.[7–14] For radicals I and III, the observation of an extra proton splitting (≈0.6 mT) when ethanol or 1-propanol was present is indicative of spin trapping of the alcohol radical[7,8] whereas for II, the a^{H}—a^{N}_{NO} is characteristic of a –NHO fragment.[12] From the magnitude of the smaller nitrogen coupling constant (≈0.3 mT) in all three radicals, it is possible to assign this nitrogen as being directly bonded to the nitroxide nitrogen[9–11] or to a carbon adjacent to this nitrogen.[11,12] However since proton splittings consistent with a CH_2 fragment (a^{H}≈0.8 mT) in I and CH (a^{H}≈0.3 mT) in III were always present and, together with the close similarity between the coupling constants for I, II, and III and those observed for radicals of the form[12]



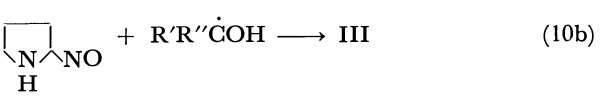
all suggest our assignment for I, II, and III are correct.

All the nitroxide radicals observed when neutral solutions containing di-*t*-butyl peroxide and NDCHA (or NDMA) were photolysed had a^{N}_{NO}≈1.3 to 1.6 mT. This indicates that the radicals are not alkoxy-substituted nitroxides (a ≈2.8 mT)[7,8] formed from *t*-BuO. Some tentative assignments are given in Table 3. In ethanol solutions, where the linewidths were small enough to resolve splittings of about 0.03 mT (Fig. 3), only one of the two radicals could be assigned. The small splittings in both radicals are consistent with protons bound to a β-carbon.[13–14]

Possible Reaction Pathways. As I, II, and III were relatively long lived ($t_{1/2}$≈second) and their steady state concentrations were relatively low, this implies that these radicals are formed by minor pathways. Although I, II, and III are structurally similar it is obvious that II is formed from a mechanism different to I and III as alcohol derived radicals (Reaction 9 and/or 5) are involved in the generation of I and III but not II.

Since the alcohol-derived radicals appear not to be trapped by oximes, it is likely that they are trapped by the *C*-nitroso intermediate[7,8] formed in Reaction 3 to generate I and III

(10a)

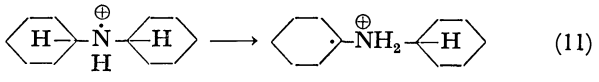


(10b)

The lifetime of the *C*-nitroso compound before it isomerizes to the oxime should be sufficiently long for Eq. 10 to occur as *C*-nitrosomethane and -ethane *etc.* can be isolated and characterized.[15] The increase in yield of I and III on addition of di-*t*-butyl peroxide reflects the additional formation of alcohol radicals through Eq. 9 over the original reaction (Eq. 5).

While II is formed through an alternative mechanism to I and III, the photoproducts from NDCHA are also different from *N*-nitrosodi-*n*-alkylamines and *N*-nitrosocyclicamines (*e.g.* 1-nitrosopiperidine) in that no oxime can be formed (although the *C*-nitroso intermediate might be). The principal product for NDCHA is the imine

formed *via* Reaction 2, whereas oximes are principal products for the other two classes of nitrosamines.[1,2] The isotopic labelling experiments of Axenrod and Milne[16] have demonstrated that the reactants in Eq. 2 are not necessarily those formed in the original photochemical cage in Eq. 1. Hence the aminyl radical and NO must have a reasonable lifetime in solution (although they were not detected). It is not unreasonable to suggest that some of the dicyclohexylaminyl radicals might rearrange to a carbon centre radical



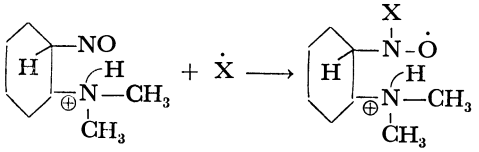
(11)

which then could react with HNO formed in Reaction 2.

(12)

Circumstantial evidence supporting this mechanism is the observation of II but not I when hydrochloric acid was used instead of acetic acid in the photolyses. In NDMA solution, the presence of the stronger acid may increase the rate of nitroso-oxime isomerization and hence minimize the spin trapping reaction (Eq. 10). In the mechanism proposed above for II, there is no equivalent step to be interfered with by the hydrochloric acid.

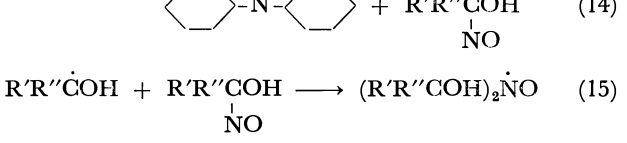
The absence of I when maleic acid was present is evidence for the facile photoaddition of NDMA to double bonds[17] Eq. 4 whereas with NDCHA, which does not undergo photoaddition[18], radical II was still observed. Apparently photoaddition of NDMA to cyclohexene is not as efficient as to maleic acid since I was still observed with 10 vol % cyclohexene present. However some photoaddition did occur as evidenced by the persistent nitroxide radical (a^{N}_{NO}=1.55 mT, a^{H}=0.18 mT) observed after a static solution was photolysed. This radical is consistent with what would be expected from spin trapping by the photoaddition product in an acetic acid: 2-propanol solution.



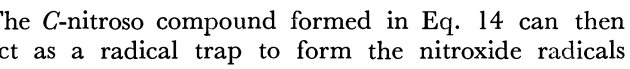
(13)

Although positive identification was not possible of all the nitroxide radicals generated when neutral alcohol and alkaline solutions of DCHNA containing

di-*t*-butyl peroxide were photolysed, these experiments do indicate that nitrosamines are susceptible to reaction with alcohol radicals. The absence of a nitrogen splitting extra to that of the nitroxide nitrogen suggests the pathway, in part, might be Reactions 8 and 9 followed by

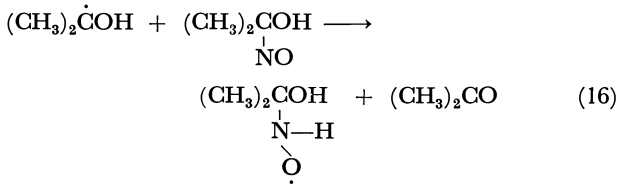


(14)



(15)

The *C*-nitroso compound formed in Eq. 14 can then act as a radical trap to form the nitroxide radicals observed in Eq. 15. When the alcohol is 2-propanol apparently a minor reaction is



(16)

Reaction 14 may not occur in acid solutions due to protonation of NDCHA.[3] Furthermore, we have no explanation for the results observed when triethylamine was present. However, these results in neutral and alkaline solution support the product analyses[1–4] which conclude that nitrosamines are photolytically active only in acid solutions. In neutral solutions they are only involved in secondary reactions initiated photochemically.

Kinetics and Mechanism of Formation of Pentaammine(glycine)rhodium(III) Ion from Pentaammineaquarhodium(III) Ion and Glycine in Weakly Acidic Media

C. CHATTERJEE* and A. K. BASAK†

(Received July 25, 1978)

The rates of formation of pentaammine(glycine)rhodium(III) ion from pentaammineaquarhodium(III) ion and glycine in weakly acidic media have been studied spectrophotometrically at different glycine and acid concentrations in the temperature range of 60—80 °C. The rate has been found to be insensitive towards the change in ionic strength from μ=0.5 to 2.0 M of the medium. The activation parameters, ΔH^* and ΔS^* values are 22.2±1.0 kcal mol^{-1} and −9.2 e.u. respectively. The results are in accord with a mechanism involving a fast 1:1 outer-sphere association between the pentaammineaquarhodium(III) ion and glycine in zwitter ionic form followed by its transformation into the product by a process where the incoming ligand is appreciably bonded to the metal ion in the transition state.

Kinetics and mechanism of the substitution reactions involving replacement of coordinated water in pentaammineaquacobalt(III), ($3d^6$) ion by various nucleophiles including neutral and anionic in nature have been the subject of several investigations. However, there has been increasing interest in recent years on rhodium(III), ($4d^6$) complexes, which furnish further data for a comparative analysis of the reactivity of related octahedral structures. Though the rates of reactions have been generally found dependent upon the entering ligand concentration, they actually proceed by different mechanisms due to bond formation by the incoming nucleophile which is more significant in the transition state in the case of rhodium(III) than in cobalt(III) as is evident from the water exchange and anation reactions of the complexes of the type $M(NH_3)_5OH_2^{3+}$, where M=Co(III)[1,3a-c] and Rh(III).[2,4,5] In order to test further the generality of nucleophilic attack of the entering group on the substrate Rh(III) complex, it appeared worthwhile to extent the work to uncharged ligands, and with this end in view the kinetics of reactions of pentaammineaquarhodium(III) ion with glycine in weakly acidic media (pH=*ca.* 2—4) forming pentaammine(glycine)rhodium(III) ion $[Rh(NH_3)_5glyH]^{3+}$ has been studied in detail. In order to study the kinetics of such reaction the hitherto unknown $Rh(NH_3)_5glyH^{3+}$ in the form of perchlorate salt has been isolated. The results presented here show indeed a difference in mechanistic behaviour between cobalt(III) and rhodium(III) ions in conformity with the investigations reported earlier.

Experimental

Materials. The pentaammineaquarhodium(III) perchlorate was prepared from pentaamminechlororhodium(III) complex as described in the literature.[6] The purity of the complex was checked by elemental and spectral analyses.[7]

The pentaammine(glycine)rhodium(III) perchlorate was prepared for the first time by refluxing an aqueous solution (50 ml) of pentaammineaquarhodium(III) perchlorate (0.0005 mol) and an excess of glycine(0.005 mol) for few hours at 90 °C. The solution was then concentrated to one third of its original volume and kept in a refrigerator. The resulting crystals were filtered and washed with a water–ethanol(1:1) mixture. The complex was recrystallized from a cold aqueous solution by the addition of 30% perchloric acid. The recrystallized product was washed first with a water–ethanol mixture and finally with absolute ethanol. The purity of the complex was ascertained by the elemental analysis: Calcd for $[Rh(NH_3)_5glyH](ClO_4)_3$: C, 4.28; N, 14.96; H, 3.56%. Found: C, 4.45; N, 14.85; H, 3.58%.

Glycine used were of reagent grade (G. R., E. Merck). All other chemicals used were either of reagent grade purity or prepared in the pure state by suitable methods.

Besides elemental analysis, spectral measurements of glycine complex of rhodium(III) furnish further evidence regarding the mode of bonding of amino acid in the complex. It is well known that an amino acid usually coordinates to a metal ion with its amino and carboxyl groups. In some complexes of cobalt(III),[8,9] however, glycine has been observed to act as an unidentate ligand although no such complexes of rhodium(III) have been isolated before. The analytical results of pentaammine complex clearly indicate the unidentate nature of coordinated glycine molecule. Since the complex was obtained from an acidic solution, the amino acid retains an acidic proton and is coordinated as a neutral ligand in agreement with the elemental analysis. Glycine may be bound with the rhodium(III) ion as an unidentate ligand either with an oxygen atom of the carboxyl group or with the nitrogen atom of the amino group. The results of the absorption measurements for the present complex, however, suggest that the coordination of glycine correspond to the former. The position and intensities of the first and second bands of the glycine complex (λ_{max}; 322 nm, ε_M=144.0, λ_{max}; 266 nm, ε_M=111.0) corresponding to $^1A_{1g}\rightarrow{}^1T_{1g}$ and $^1A_{1g}\rightarrow{}^1T_{2g}$ transitions, match very well with those of the pentaammine carboxylatorhodium(III) ion[7] in which the ligand undoubtedly coordinates to rhodium(III) ion with its carboxyl group. In accord with the postulate of the oxygen-bonded amino acid, IR spectrum of the complex shows a close similarity to that of the corresponding Co(III) complex, with a strong band at about 1630 cm^{-1} assignable to C–O stretching band of the coordinated carboxyl group and the deformation band of $-NH_3^+$ group at about 1490 cm^{-1}.

Apparatus and Procedure. The kinetic measurements were performed employing a Carl-Zeiss(VSU-2P) spectrophotometer with a quartz cell of suitable light path. The pH measurements were made using a radiometer pH meter with a glass electrode and a reference calomel electrode connected to the experimental solution through 1 M NaCl–1 M $NaClO_4$ salt bridges connected in series. The course

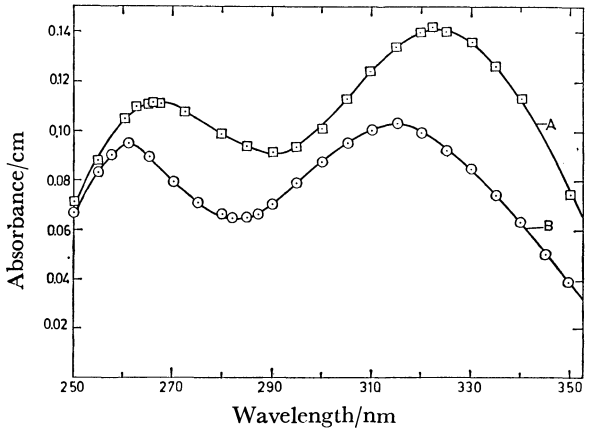

Fig. 1. Absorption spectra.
A: $[Rh(NH_3)_5glyH](ClO_4)_3$, 0.001 M; B: $[Rh(NH_3)_5OH_2](ClO_4)_3$, 0.001 M.

of the anation reactions of pentaammineaquarhodium(III) ion with glycine in weakly acidic media was followed by observing the increase in absorbance at 322 nm where the molar extinction coefficients of the reacting complex and the product differ appreciably (Fig. 1). A sample quenching technique was used. Ionic strength of the solutions was kept constant with sodium perchlorate. The absorbances of the solutions at the end of the reactions were found to be in close agreement with those of the solution containing isolated complex, indicating that under the experimental conditions there was no interference due to reverse aquation of the glycine complex. The concentrations of the reactants were such that the pseudo first order rate law was applicable and the pseudo first order anation rate, k_{obsd}, was evaluated graphically for each experiment by plotting $\log (A_\infty - A_0)/(A_\infty - A_t)$ *versus* time (t), where A denotes measured absorbance and subscripts denote time as usual. A_∞ is the calculated value for complete transformation of the aqua complex to the pentaammine(glycine)rhodium(III) complex.

Results and Discussion

The pseudo first order rate constant, k_{obsd}, was evaluated under different sets of experimental conditions (*viz.* glycine concentration, acid concentration, temperature and ionic strength). It has been observed that at constant pH, (*i.e.*, keeping T_G/T_A constant, where T_G and T_A are the concentrations of total glycine and perchloric acid respectively in the experimental solution) the rate shows first order dependence on total glycine concentration (Fig. 2), and at a fixed glycine concentration the rate decreases with increase in acid concentration (Fig. 3). The experimental conditions were so chosen that the reacting complex present in the aqua form and the results are consistent with the sequence of changes as delineated below:

$$GH + H^+ \rightleftharpoons GH_2^+ \quad (1)$$

$$R^{3+}\text{-}OH_2 + GH \rightleftharpoons R^{3+}\text{-}OH_2\cdots GH \quad \text{(outer sphere association)} \quad (2)$$

$$\downarrow k' \text{ slow}$$

$$R^{3+}\text{-}GH + H_2O \quad (3)$$

where $R^{3+}=Rh(NH_3)_5^{3+}$.
According to the above scheme,

$$k_{obsd} = K_{o.s.} \cdot k'[GH] \quad (4)$$

where $K_{o.s.}$ is the outer sphere association constant.

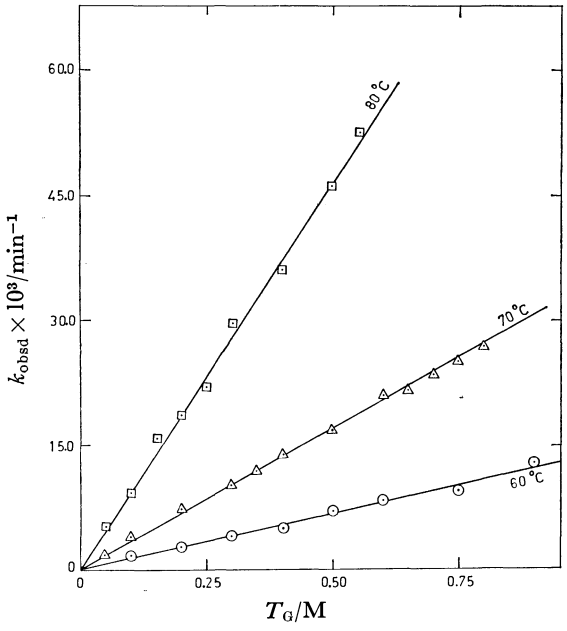

Fig. 2. Dependence of k_{obsd} on total glycine concentration (T_G). $[Rh(NH_3)_5OH_2^{3+}]$, 0.001 M; $T_G/T_A=20.0$; $T_A=[HClO_4]$; $\mu(HClO_4+NaClO_4)$, 1.0.

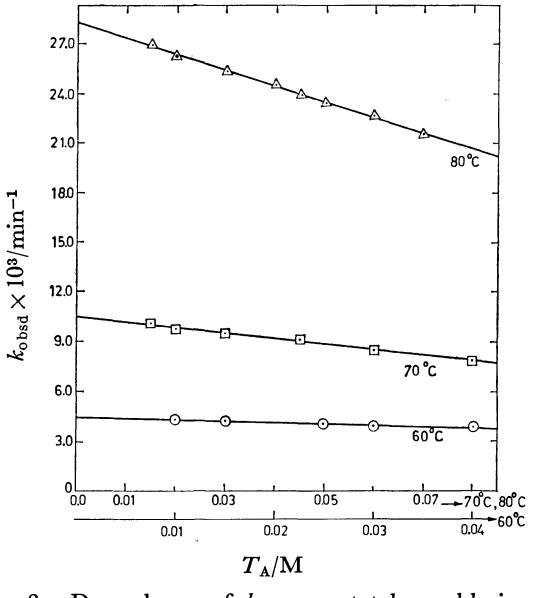

Fig. 3. Dependence of k_{obsd} on total perchloric acid concentration (T_A) at constant glycine concentration. $[Rh(NH_3)_5OH_2^{3+}]$, 0.001 M; $T_G=0.3$ M; $\mu(HClO_4+NaClO_4)$, 1.0.

From the protonation equilibrium of glycine (Eq. 1), the value of GH in terms of T_G and T_A can be expressed in the following manner:

$$T_G = [GH] + [GH_2^+],$$

$$T_A = [GH_2^+] + [H^+],$$

$$K_H = T_A - [H^+]/(T_G - T_A + [H^+])[H^+]. \quad (5)$$

On simplifying Eq. 5 and neglecting insignificant $[H^+]^2$ term we have $[H^+]=T_A/K_H T_G - K_H T_A + 1$.
Substituting the value of $[H^+]$

$$[GH] = T_G(1 + T_G K_H - T_A K_H)/(1 + T_G K_H). \quad (6)$$

Hence Eq. 4 can be written as

TABLE 1. VALUES OF THE RATE CONSTANTS AND ACTIVATION PARAMETERS ($\mu=1.0$)

Temp °C	$k/10^2$ M^{-1} min^{-1} I[a]	II[b]	III[c]	Average
60	1.35	1.47	1.38	1.40
70	3.42	3.50	3.38	3.43
80	9.36	9.40	9.45	9.40

ΔH^*, 22.2±1.0 kcal mol^{-1}. ΔS^*, −9.2 e.u.
a) From k_{obsd} *vs.* T_G plot at fixed value of T_G/T_A. b) From intercept of k_{obsd} *vs.* T_A plot at fixed value of T_G. c) From slope of k_{obsd} *vs.* T_A plot at fixed value of T_G.

TABLE 2. ACTIVATION PARAMETERS FOR THE REACTIONS OF $M(NH_3)_5OH_2^{3+}$ IONS (M=Co or Rh)

System	ΔH^* kcal mol^{-1}	ΔS^* e.u.	Ref.
$Co(NH_3)_5OH_2^{3+}/O^{18}H_2$	26.6±0.3	6.7	1
$Co(NH_3)_5OH_2^{3+}$/glyH	27.6	5.2	11
	29.0	—	12
$Rh(NH_3)_5OH_2^{3+}/O^{18}H_2$	23.9±0.3	−3.0	2
$Rh(NH_3)_5OH_2^{3+}$/glyH	22.2±1.0	−9.2	Present work

$$k_{obsd} = kT_G - kT_AT_GK_H/(1+T_GK_H) \quad (7)$$

where $k=k'\cdot K_{o.s.}$ and K_H=equilibrium constant for the protonation of glycine (Eq. 1). Under the experimental conditions the value[10] of K_H is *ca.* 200 and hence $T_GK_H \gg 1$. Consequently Eq. 7 may be written as

$$k_{obsd} \approx k(T_G - T_A) \quad (8)$$

$$\approx k(1-T_A/T_G)T_G. \quad (9)$$

The observed dependence of rate on T_A and T_G mentioned above are in conformity with the Eqs. 8 and 9 respectively. The value of k for any particular temperature could be evaluated independently from (i) the slope of k_{obsd} *vs.* T_G plot (Fig. 2) and also from (ii) the slope and intersept of k_{obsd} *vs.* T_A plot (Fig. 3). The values thus obtained are in good agreement with each other and are listed in Table 1. In case of anation of amino acid complex, $K_{o.s.}$ represents the outer sphere complex formation constant between $[Rh(NH_3)_5OH_2]^{3+}$ and the amino acid zwitter ion. Although the net charge of amino acid is zero, the zwitter ion has a separated negative charge on the carboxylate part and can undergo ion pair formation with multivalent cation. Since the net charge of glycine zwitter ion is zero, the $K_{o.s.}$ value should be smaller than those for anionic ligands. The influence of ionic strength on the anation reaction has been studied and the value of rate constant at fixed T_G/T_A has been found to be almost independent of the variation of ionic strength from μ=0.5 to 2.0 M of the medium. This lack of dependence of rate on ionic strength clearly excludes the participation of either G^- or GH_2^+ ion as a reactive species in the anation process. Hence, the overall reaction is best accounted for as an ion pair equilibrium followed by the slow interchange of the bound water and the entering ligand in the ion pair. The ΔH^* and ΔS^* values for the reactions were evaluated in the usual way by making use of Eyring equation from the k values at different temperatures (Table 1). The activation parameters for the water exchange and formation of glycine complex of similar octahedral cobalt(III) and rhodium(III) complexes are collected in Table 2 for the sake of comparison. A perusal of the results reveals that ΔH^* values for the water exchange[2] and for the present system of rhodium(III) complex are fairly close and much smaller than those of the corresponding cobalt(III) systems.[1,11,12] On the basis of the values of the activation parameters, the water exchange of $[Co(NH_3)_5OH_2]^{3+}$ and replacement of aqua ligand by glycine have been proposed to take place by dissociative mechanism. However, if the same type of mechanism is operative for the present system, owing to the greater loss of crystal field energy one would expect a higher enthalpy of activation for the rhodium(III) complex compared to analogous and isoelectronic (d^6) cobalt(III) substrates. Thus the experimental results cannot be explained by above mechanism, but suggest significant bond formation by the reagent in the transition state in the transformation of the outer sphere associated species. Moreover, a decrease of ΔS^* towards a negative value, going from cobalt(III) to rhodium(III) system is also in keeping with a mechanism involving a more pronounced participation of the incoming ligand in the transition state for the latter. Hence, on the basis of ΔH^* and ΔS^* values it may be concluded that the transformation of outer sphere complex into the product occurs by a sort of associative process in which the bond making and bond breaking in the transition state proceed synchronously.

The authors thank Professor K. Saito of Tohoku University, Japan, for the sample of $RhCl_3\cdot 3H_2O$ used in the preparation of the title compounds. Helpful discussions with Professor D. Banerjea are gratefully acknowledged.

†*Department of Chemical Engineering, A.C. College of Technology, Madras 600025, India*

(Received September 7, 1978)

Polarographic investigation of uranyl complexes with potentially bidentate α-, β-, and γ-amino acids have been carried out. The polarographic behaviour of these complexes as a function of pH and ligand concentration has revealed the nature of binding to be unidentate carboxylate coordination in the complexes. The amino group is not involved in coordination. The relative stabilities of α-, β-, and γ-amino acid complexes are discussed.

While the chelates formed by amino acids with 3d metal ions have been fairly well characterized, the amino acid complexes of *f* block metal ions have received relatively much less attention. Even among the few investigations carried out on uranyl–amino acid complexes reports are conflicting regarding the chelating ability of the amino acids towards this ion, and the effect of ring size and substituents of the complexes. Cefola *et al.*,[1] Farooq *et al.*,[2] and Tewari *et al.*[3] have postulated chelation involving the carboxyl oxygen and the amino nitrogen in uranyl complexes with glycine, α-alanine, asparagine and glutamine, while Li *et al.*[4] and Feldman *et al.*[5] have suggested that the amino nitrogen is not involved in coordination in uranyl complexes of glycine, serine, aspartic acid and glutamic acid.

The present investigation is oriented primarily towards establishing the nature of binding in uranyl complexes with simple amino acids, *i.e.* to find whether complexation occurs through the amino nitrogen and carboxyl oxygen leading to chelation or whether the ligand is bound only through the carboxyl oxygen. When a complex is reduced under polarographic conditions, the magnitude of the shift in $E_{1/2}$ relative to the simple aqua ion is a measure of the stability of the complex. A chelate complex shows, because of its higher stability, a much larger shift in $E_{1/2}$ than a non-chelate one. Further the amino acid ligand (anion) on liberation from the complex undergoing polarographic reduction gets protonated depending on pH conditions. A study of the polarographic behaviour under varying pH conditions yields useful information on the way in which the ligand is bound as an anion or as a zwitter ion and so on, from which the nature of binding can be inferred.[6,7] Stability constants obtained from polarographic measurements of the complexes are reported.

Experimental

The effect of varying pH on the $E_{1/2}$ of uranyl complexes at constant concentration of ligand and the effect of varying ligand concentration on $E_{1/2}$ at constant pH were investigated by measuring the $E_{1/2}$ values for solutions containing 8×10^{-4} M (M=mol dm^{-3}) $UO_2(ClO_4)_2$ maintained at a constant ionic strength of 0.1 M with respect to $NaClO_4$ and at a temperature of 30.0±0.1 °C. The polarograms were recorded with an automatic Metrimpex type OH 105 Universal Polarograph with a three-electrode set up. Some of the complexes were studied with a manual set up consisting of the polarographic bridge of Physics Instruments Co., in conjunction with a Multiflex galvanometer for measuring diffusion currents and a Leeds Northrup K 3 Universal Potentiometer for measuring the applied potentials. The electrode characteristics were: $h=40.0\pm0.5$ cm, $t=3.85$ s, and $m^{2/3}t^{1/6}=4.25$ mg$^{2/3}$ s$^{-1/2}$. The $E_{1/2}$ values were measured to an accuracy of ±0.5 mV and were reproducible to ±2 mV. The reversibility of each system studied was checked by logarithmic analysis or by measuring the difference in $E_{1/4}-E_{3/4}$ values. The reduction of UO_2^{2+} ion was found to be a reversible one electron process with an $E_{1/2}$ of −0.175 V (*vs.* SCE).

Conductometric titrations of the sodium salts of the ligands against uranyl perchlorate were performed for determining the maximum number of ligand molecules coordinated to the uranyl ion. A direct-reading conductance meter (Toshniwal Conductivity Analyser type L 01.06) provided with a cell of cell constant 0.738 was used. All pH measurements were made with an Elico pH meter (Model L I.10T). The dissociation constants of the amino acids were determined potentiometrically. All the chemicals used were of BDH or Fluka puriss grade.

Results and Discussion

The ligands chosen were glycine, DL-α-alanine, DL-2-aminobutyric acid, β-alanine, 4-aminobutyric acid and isobutyric acid, all except the last one potentially bidentate ligands capable of forming five-, six-, or seven- membered rings. Isobutyric acid was chosen as a reference ligand having only unidentate function through its carboxyl group. A comparison of the shift in $E_{1/2}$ for polarographic reduction of the amino acid complexes with that for the isobutyrate complex would show whether chelation occurs or not, and if it occured, yield information correlating ring size and stability of the complex.

Effect of pH *on the* $E_{1/2}$ *of the Complexes.* The manner in which $E_{1/2}$ depends on pH often provides useful information regarding the electrode reactions and the different species existing under different pH conditions and thus the mode of binding in the complex.

The coordinating(donor) atom exists in the protonat-

Table 1. Stability constants of uranyl complexes of α-, β- and γ-amino acids

Complex	Dissociation constants of ligands		pH range	$\log \beta UO_2(HL)_2^{2+}$
	pK_{COOH}	$pK_{NH_3^+}$		
Glycinate	2.45	9.69	2.5—4.0	2.14
α-Alaninate	2.48	9.67	2.7—4.0	2.15
2-Aminobutyrate	2.36	9.60	2.7—4.0	2.12
β-Alaninate	3.60	10.07	3.5—4.3	3.49
4-Aminobutyrate	4.04	10.26	3.00—4.10 and 4.1—5.4	4.44
Isobutyrate	4.76	—	3.00—4.8	5.66[a]

a) $\log \beta_{ML_2}$

ed form over a range of pH, and complexation takes place with deprotonation. On polarographic reduction of the complex, the liberated ligand will recombine with protons if pH conditions suit such protonation. In solutions of pH greater than the pK of the coordinating group, protonation would not occur. If, however, the solution pH is below the pK of the coordinating group, the released ligand will get protonated. A plot of the variation of the measured $E_{1/2}$ with pH would show breaks corresponding to the pK values of the coordinating groups present in the ligand.

For the potentially bidentate amino acid with amino and carboxyl groups as possible coordinating groups the following relationships between $E_{1/2}$ and pH are valid.

1. At $pH<pK_{COOH}<pK_{NH_3^+}$:

$$E_{1/2} = E^\circ_s - \frac{0.0591}{n}\log \beta_{ML_p} - p\frac{0.0591}{n}\log K_1K_2[L^-] - 2Z\frac{0.0591}{n}pH.$$

2. At $pH=pK_{COOH}<pH<pK_{NH_3^+}$:

$$E_{1/2} = E^\circ_s - \frac{0.0591}{n}\log \beta_{ML_p} - p\frac{0.0591}{n}\log K_2[L^-] - Z\frac{0.0591}{n}pH.$$

3. At $pH>pK_{NH_3^+}>pK_{COOH}$:

$$E_{1/2} = E^\circ_s - \frac{0.0591}{n}\log \beta_{ML_p} - p\frac{0.0591}{n}\log [L^-].$$

Here K_1 and K_2 correspond to pK_{COOH} and $pK_{NH_3^+}$ respectively. $E_{1/2}$ is the half-wave potential of the complex and E°_s is the standard reduction potential of the cation $\simeq E_{1/2}$ of the uncomplexed aqua ion; β_{ML_p} is the overal stability constant of the complex ML_p, and Z is the number of protons involved in the electrode reaction.

The slope $d(E_{1/2})/d(pH)$ of each region of the $E_{1/2}$ *vs.* pH diagram is equal to $0.0591/n$ Z, where Z is the number of protons involved in the electrode reactions which will be 2, 1, and 0 at $pH<pK_{COOH}$, $pK_{COOH}<pH<pK_{NH_3^+}$, and $pH>pK_{NH_3^+}>pK_{COOH}$, respectively.

Uranyl-α-Amino Acid Complexes. The variation of $E_{1/2}$ as a function of pH was investigated between pH 1.80 and 4.0 with all the three α-amino acid complexes. The $E_{1/2}$ *vs.* pH diagrams (Fig. 1) show breaks at pH values 2.35 for glycinate, 2.70 for α-alaninate, and 2-aminobutyrate complexes. The pK_{COOH} values of these acids are presented in Table 1. Below pH 1.80 the $E_{1/2}$ values were found to be independent of pH with a constant value of −0.175 V (*vs.* SCE). Since this is the $E_{1/2}$ of the uncomplexed aqua uranyl cation, the inference is that no complexation occurs. Beyond pH 4.0 the polarograms were distorted possibly due to hydrolysis. In the region of $pH>pK_{COOH}$, the $E_{1/2}$ values were very nearly independent of pH upto about pH 4 in all the cases. With the experimental pH below the $pK_{NH_3^+}$ of the acids concerned, the amino group, if involved in coordination, would get protonated at the electrode surface on liberation when the complex undergoes polarographic reduction. No such protonation was indicated from the experimental studies. The inference is that the amino group is not involved in coordination. In other words, no chelate ring is formed.

The effect of the ligand concentration was investigated at pH 3.15±0.1 for glycinate, 3.25±0.1 for α-alaninate, and at pH 3.5±0.1 for 2-aminobutyrate complex. The plots of $E_{1/2}$ *vs.* $\log HL$[10] for all the three complexes gave a $(p\text{-}q)$ (where p and q are the number of ligands attached to the metal in the oxidised and reduced forms respectively) value of two in the ligand concentration range of 0.17—0.6 M. Since polarographic reduction of the complexed $(UO)_2^{2+}$ ion occurs only to the lower oxidation state (UO_2^+) and not to the metallic state, the variation of $E_{1/2}$ with ligand concentration will indicate only the difference in the number of ligands coordinated to the higher and lower oxidation states and thus only the ratio of stability constants of the complex between the oxidized and reduced forms can be determined.[8] However, if the absolute value of 'p' or 'q' is known, it is possible to calculate the individual stability constants.[9] The value of 'p' was found to be two from conductometric titrations. Figure 3 gives the conductemetric titration of the sodium salt of α-alaninate against uranyl perchlorate. The break at 5 ml of uranyl perchlorate corresponds to the formation of the complex species with the metal: ligand ratio of

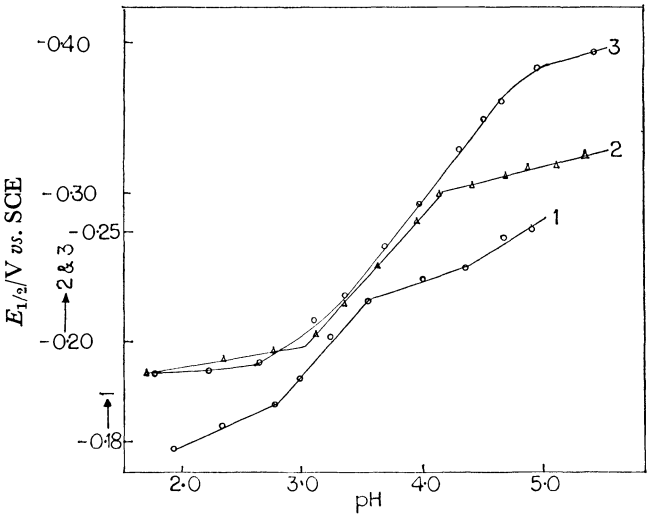

Fig. 2. Variation of $E_{1/2}$ with pH for uranyl complexes. 1: β-Alaninate, 2: 4-aminobutyrate and 3: isobutyrate. Concentrations: $[UO_2^{2+}]=0.0008$ M, [β-alanine]= 0.1007 M, [4-aminobutyric acid]=0.1008 M, [isobutyric acid]=0.100 M.

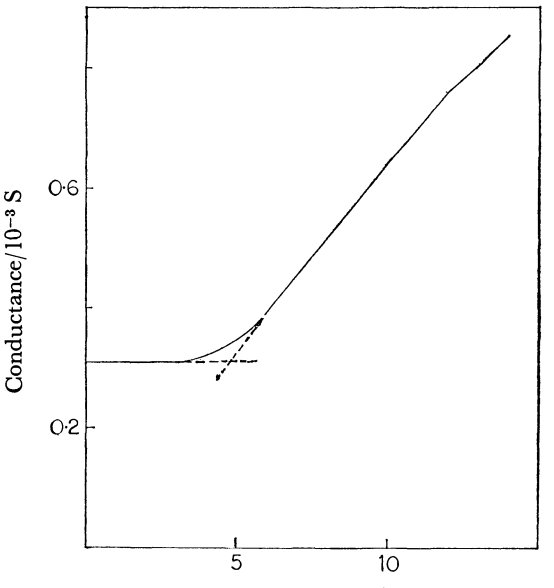

Fig. 3. Concudctometric Titration of sodium salt of α-alanine *vs.* uranyl perchlorate. 10 ml of ligand (0.08072 M)+100 ml water titrated against uranyl perchlorate (0.0801 M).

1:2. The value of '*p*', the maximum number of ligands coordinated to the metal is thus 2. Since (*p-q*) values determined polarographically are also found to be equal to two, it is evident that '*q*' is zero and that UO_2^+ ion does not form a complex. The stability constants of the complexes calculated using Lingane equation[10] give the $\log \beta_{M(HL)_2^{2+}}$ values presented in Table 1.

The similarity in the nature of binding in these complexes is evident from (a) the identical nature of the $E_{1/2}$ *vs.* pH curves, (b) the similar $\Delta E_{1/2}$ values for similar concentrations of the ligands under similar conditions of pH and (c) the close similarity in the $\log \beta_{M(HL)_2^{2+}}$ values. The low $\log \beta_{M(HL)_2^{2+}}$ values are indicative of the absence of chelation. The electrode reaction for all the three complexes may be expressed in the general form (at $pH > pK_{COOH}$)

$$UO_2(HL)_2^{2+} + e^- \rightleftharpoons UO_2^+ + 2HL,$$

HL being the zwitter ion of the type $H_3N^+-CH_2-COO^-$.

Uranyl–β-Alaninate Complex. The variation of $E_{1/2}$ with pH investigated in the pH region of 1.90—4.90 indicated that below pH 1.90 complexation did not occur and beyond pH 4.90 the polarograms were distorted. The $E_{1/2}$ *vs.* pH diagram (Fig. 2) showed a break at pH 3.5 corresponding to pK_{COOH} of β-alanine (*cf.* Table 1). In the pH region between 2.75 and 3.5 the $d(E_{1/2})/d(pH)$ slope has a value of 0.055 corresponding to the involvement one proton per metal atom in the reduction process. The variation of $E_{1/2}$ with ligand concentration indicated the (*p-q*) value to be one. However, conductometric titrations of the sodium salt of β-alanine with uranyl perchlorate indicated the value of '*p*' to be two. It is evident that one ligand molecule is coordinated to the UO_2^+ ion. The electrode process may be formulated as (at $pH < pK_{COOH}$)

$$UO_2(HL)_2^{2+} + H^+ + e^- \rightleftharpoons UO_2(HL)^+ + H_2L^+$$

H_2L^+ being the species $H_3N^+-(CH_2)-COOH$.

In the pH region beyond pK_{COOH}, the $E_{1/2}$ values were very nearly independent of pH upto about pH 4.30, beyond which once again the $E_{1/2}$ values became pH dependent possibly due to hydrolytic reactions and formation of hydroxo species. The fact that protons are not involved in the reduction process in the pH region between 3.5 and 4.3 leads to the inference that the amino nitrogen is not coordinated to the metal atom. The plot of $E_{1/2}$ *vs.* log HL indicated the value of (*p-q*) to be two in the ligand concentration range of 0.1 to 0.7 M. Since the value of '*p*' determined conductometrically was also equal to two, '*q*' was taken to be zero meaning that UO_2^+ ion was not complexed. The electrode reaction in this region is expressed by the following equation at $pK_{COOH} < pH < pK_{NH_3^+}$,

$$UO_2(HL)_2^{2+} + e^- \rightleftharpoons UO_2^+ + 2HL.$$

The stability constant was calculated using Lingane equation, and the $\log \beta_{M(HL)_2^{2+}}$ value was found to be 3.49 ± 0.05.

Uranyl–4-Aminobutyrate Complex. The variation of $E_{1/2}$ with pH (Fig. 2) indicated that below pH 1.70, UO_2^{2+} ion was not complexed and beyond pH 5.4, precipitation occurred for a metal concentration of 8×10^{-4} M and ligand concentration of 0.1 M. The break corresponding to pK_{COOH} (4.04) was observed at pH 4.10. In the pH region 3—4.1 the number of protons involved in the reduction was found to be two. The $E_{1/2}$ values were independent of pH at $pH > pK_{COOH}$, clearly indicating the absence of coordination by the amino nitrogen. The variation of $E_{1/2}$ with ligand concentration investigated at pH 4.9 indicated the value of (*p-q*) to be two, and the value of '*p*' was found to be two from conductometric titrations. The electrode processes between pH 3.00 and

4.10 ($pH < pK_{COOH}$)

$$UO_2(HL)_2^{2+} + 2H^+ + e^- \rightleftharpoons UO_2^+ + 2H_2L^+,$$

and at pH 4.9 ($pH > pK_{COOH}$)

$$UO_2(HL)_2^{2+} + e^- \rightleftharpoons UO_2^+ + 2HL.$$

The $\log \beta_{M(HL)_2^{2+}}$ calculated using the Lingane equation was found to be 4.44±0.05.

Uranyl–Isobutyrate Complex. Below pH 2.0 complexation of uranyl was not observed and above pH 5.7 the metal precipitated. The break in the $E_{1/2}$ *vs.* pH relationship (Fig. 2), was observed at 4.8, the pK_{COOH} of the ligand being 4.76. In the pH region below pK_{COOH} the $d(E_{1/2})/d(pH)$ has a value of 0.11 corresponding to the involvement of two protons in the reduction process. The effect of ligand concentration on $E_{1/2}$ was investigated at pH 3.05. The plot of $E_{1/2}$ *vs.* $\log L^-$ gave a value of two for $(p\text{-}q)$ and the value of 'p' was found to be two from conductometric titrations. The stability constant ($\log \beta_{ML_2}$) was found to be 5.66±0.10. The electrode process may be formulated as ($pH < pK_{COOH}$)

$$UO_2L_2 + 2H^+ + e^- \rightleftharpoons UO_2^+ + 2HL.$$

Conclusions. The $\Delta E_{1/2}$ values for the typical amino acid complexes of uranyl reported here are lower than that for the unidentate complex formed by isobutyric acid. So are the $\log \beta_{M(HL)_2^{2+}}$ values. The results clearly indicate that the amino acids do not form chelate complexes with uranyl ion. Furthermore, the carboxyl group itself is rendered a poorer complexing site because its basicity is lowered by the proximity of the more basic amino group in the same molecule. It may be seen from the figures that $\Delta E_1/_2$ for uranyl ion in the presence of α-, β-, and γ-amino acids are all lower than the value in the presence of isobutyric acid for similar conditions of pH and ligand concentration. If chelate rings had been formed, the $\Delta E_{1/2}$ values would have been larger.

The range of pH in which the complexes undergo reduction reversibly before hydrolysis sets in is also indicative of the relative stabilities of the complexes. For α-amino acid systems the maximum pH upto which hydrolysis can be neglected is 4.0, 4.9 for β-alaninate, 5.4 for 4-aminobutyrate, and 5.7 for isobutyrate complexes.

The order of stability of uranyl complexes in the present investigation turns out to be isobutyrate>4-aminobutyrate>β-alaninate>glycinate = α-alaninate = 2-aminobutyrate. This order clearly points to the absence of chelation in uranyl amino acid complexes.

Flat-band Potential of p-Type GaP in Acetonitrile Solutions

Kiyoshi SATOH, Hiroshi YONEYAMA,* and Hideo TAMURA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received February 20, 1979)

Synopsis. An interaction of quinone compounds such as tetrachloro-*p*-benzoquinone and *p*-benzoquinone with surface hydroxyl groups of a p-type GaP electrode seems to play an important role in determining the magnitude of photovoltage in acetonitrile solutions. The same holds for p-type InP and Si.

The maximum photovoltage at an illuminated semiconductor electrode in a redox electrolyte is equal to the potential difference between the flat-band potential of the electrode E_{fb} and the redox potential of the electrolyte.[1] In aqueous solutions, E_{fb} is in many cases a function of the solution pH, not being influenced by the redox species. Thus, a theoretical maximum photovoltage can be estimated easily by using E_{fb} measured in a base electrolyte into which a redox species is added. However, this may not be true in nonaqueous electrolytes,[2] although the invariance of E_{fb} has sometimes been assumed.[3-5] This note reports on the finding that the interaction of an organic redox species with hydroxyl groups of the electrode surface changes E_{fb} to a large extent.

Experimental

p-Type GaP, InP, and Si were used. Etching of GaP and InP was carried out with HCl, and that of Si with CP-4A.[6] Immediately after chemical etching, the electrodes were washed with de-ionized water for 15 min, followed by rinsing with acetonitrile (AN), and finally dried under evacuated conditions. An Ag wire immersed in AN containing 0.01 mol dm^{-3} $AgNO_3$ was used as a reference electrode. The potential given in this paper refers to this electrode.

Acetonitrile was purified according to the procedure reported.[7] Tetraethylammonium perchlorate (TEAP) as a supporting electrolyte was prepared in this laboratory. Its concentration was usually 0.1 mol dm^{-3}. Tetrachloro-*p*-benzoquinone (Chloranil CA) and *p*-benzoquinone (BQ) used as redox species were of reagent grade. The redox electrolytes of CA/CA$^{\cdot-}$ and BQ/BQ$^{\cdot-}$ were prepared by electrolyzing CA and BQ in TEAP/AN at -0.45 and -0.95 V, respectively, where CA$^{\cdot-}$ and BQ$^{\cdot-}$ denote the anion radicals of CA and BQ. A 500 W xenon lamp was used as a light source.

Results and Discussion

BQ and CA were found to be reduced almost reversibly to give BQ$^{\cdot-}$ and CA$^{\cdot-}$, respectively, making it possible to estimate the formal potential E^0 of BQ/BQ$^{\cdot-}$ and CA/CA$^{\cdot-}$ from the halfwave potentials of the reduction reaction,[8,9] the estimated E^0 being -0.81 and -0.31 V, respectively. The value of E_{fb} of p-type Si reported[4] is *ca.* -0.4 V; that of p-type GaP would be *ca.* 0.8 V, as judged from the reported value for n-type GaP.[2] The value of E_{fb} of p-type InP determined in TEAP/AN is *ca.* 1.2 V. Although the reproducibility is poor, it is not a serious problem. If the redox species has no significant influence on E_{fb}, the maximum photovoltage values given in Table 1 would be expected. In the case of InP the potential difference between E_{fb} and the redox potential exceeds the bandgap of InP, so that no electrochemical equilibrium can be established.

The open circuit potentials of the semiconductor electrodes in the dark were almost equal to the redox potentials of the electrolytes. When illumination of 1.8 W/cm^2 was made, the electrode potential shifted anodically by the amount of the photovoltage (Table 1). The photovoltage increased by 60—80 mV with increasing illumination intensity from 0.18 to 1.8 W/cm^2, gradually tending to saturation. This suggests that the maximum photovoltage cannot be achieved even under imaginary intense illumination conditions. In addition it should be noted that (1) the photovoltage appeared in the system where it was not expected (Si–CA/CA$^{\cdot-}$), and (2) almost the same photovoltage was obtained at the same electrode independent of the kind of the redox electrolyte. These results suggest that E_{fb} is variable in such a manner that the more negative the redox potential of a chemical species added to TEAP/AN, the larger the negative shift of E_{fb}. This was investigated in detail for p-type GaP.

Values of E_{fb} of a p-type GaP electrode in a variety of electrolytes, obtained by Schottky-Mott plots of the electrode capacitance, are given in Table 2. The capacitance was measured at 0.5, 1.0, and 5 kHz, the same E_{fb} being obtained. However, E_{fb} was scattered to about ± 0.2 V when pretreatment of the electrode was repeated in each run. The scatter was large enough to shadow a small change in E_{fb} which

TABLE 1. THE MAXIMUM PHOTOVOLTAGE PREDICTED AND VALUES EXPERIMENTALLY OBTAINED WITH ILLUMINATION OF 1.8 W/cm^2

Electrode	Redox species[a)]	ΔE_{max}/V	ΔE_{expt}/V
p-Si	BQ/BQ$^{\cdot-}$	0.4	0.23
p-Si	CA/CA$^{\cdot-}$	0	0.21
p-GaP	BQ/BQ$^{\cdot-}$	1.6	0.40
p-GaP	CA/CA$^{\cdot-}$	1.1	0.42
p-InP	BQ/BQ$^{\cdot-}$	—	0.41
p-InP	CA/CA$^{\cdot-}$	—	0.42

a) The concentration was 9.1×10^{-3} mol dm^{-3} CA/7.1×10^{-4} mol dm^{-3} CA$^{\cdot-}$, and 8.5×10^{-3} mol dm^{-3} BQ/6.6×10^{-4} mol dm^{-3} BQ$^{\cdot-}$.

Table 2. Flat-band potential of a p-type GaP in a variety of acetonitrile solutions

	Solution[a)]	E_{fb}/V
1	0.1 M TEAP/AN	0.75
2	0.01 M CA	0.3
3	0.01 M BQ	−0.3
4	1.0×10^{-4} M CA	0.6
	1.0×10^{-3} M CA	0.5
	1.0×10^{-2} M CA	0.4
5	4.6×10^{-3} M HCl	0.72
	4.6×10^{-2} M HCl	0.78
	4.1×10^{-1} M HCl	0.84
6	5.6×10^{-2} M HCl+1.0×10^{-4} M CA	0.80
	5.6×10^{-2} M HCl+1.0×10^{-3} M CA	0.80
	5.6×10^{-2} M HCl+1.0×10^{-2} M CA	0.80

a) M = mol dm^{-3}.

should have been brought about by changing the electrolyte from one kind to another. Thus, the pretreatment of the electrode was made only at the beginning of a series of runs. In this way, a small change was noticeable.

The following results were obtained. (1) Addition of CA and BQ to the base electrolyte of TEAP/AN greatly shifts E_{fb} towards negative potentials. The shifts is higher for BQ than for CA. (2) E_{fb} shifts cathodically with an increase in the concentration of CA, but a reverse tendency was obtained in the case of HCl. (3) When HCl and CA coexist, E_{fb} is primarily determined by HCl. The results were obtained in the electrolytes containing 150—500 ppm water. The water content increased steadily during the course of measurements, and it was not possible to clarify the effect of water on E_{fb}. A trial was made to decrease the water content to 34 ppm in the initial stage of the measurments, but no appreciable difference was observed.

The results (1)—(3) show that a dissociative equilibrium of surface hydroxyl groups of the electrode with the electrolyte should be a principal factor in determining E_{fb}. The positive shift of E_{fb} by addition of HCl should be related to

$$-GaOH + H^+ \rightleftharpoons Ga^+ + H_2O \quad (1)$$

as in the cases of aqueous solutions.[10] On the other hand, the negative shift by addition of the quinone compounds indicates that negatively charged sites become abundant at the electrode surface by the addition. A tentative model for explanation is

$$-GaOH + Q \rightleftharpoons GaO^- + QH^+ \quad (2)$$

where Q denotes the quinone molecule. The magnitude of the change in E_{fb} caused by the addition of a quinone compound to the base solution of TEAP/AN would be high for a molecule having a large effective electron density of the quinone ring, which is in agreement with the results. BQ/BQ^- has a more negative E^0 value than CA/CA^-. A large photovoltage is expected for the former redox electrolyte than the latter if E_{fb} does not differ a great deal. However, the larger negative shift of E_{fb} in the former cancels the advantage of E^0, so that almost the same photovoltage is obtained.

Equation 2 gives a tentative explanation of the observed phenomena. Any model is applicable if the formation of negative sites by addition of quinone compounds is reasonably explained. The interaction of organic species with the electrode surface was postulated in the case of GaAs in AN solutions,[11] but its mechanism has not been clarified.

According to the present results, the invariance of E_{fb} may be expected when complete elimination of hydroxyl groups on the electrode surface is achieved. In order to prepare such an electrode, anodic polarization of the electrode in an electrolyte free of water may be useful. However, the preparation of such an electrolyte is practically difficult at least for AN,[12] so that E_{fb} will be varied more or less by adding an organic redox species to AN solutions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (9), 2719—2720 (1979)

Infrared Emission Spectra of CO_2 in the Explosion Reaction of CO and O_2 Using a Rapid-Scan Spectrometer

Masako TANAKA,* Shigeo NAGASAKA, Sadao SAWAMURA, and Meiseki KATAYAMA

Department of Atomic Science and Nuclear Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received October 9, 1978)

Synopsis. The infrared emission spectra of CO_2 were observed by means of a rapid-scan infrared spectrometer during the explosion of CO–O_2 in a cylindrical vessel. The R-branch band heads of 001-000 and 011-010 were detected. The time dependences of the emission intensities of these band heads, $\nu_1+\nu_3$, and $2\nu_2+\nu_3$, were studied.

It is well known that infrared emissions due to CO_2 are observed in a CO–air flame; past studies have been reviewed by Gaydon.[1] However, there have been very few studies of the CO_2 emission spectra in the explosion of a CO–O_2 mixture by means of a rapid-scan spectrometer other than those by Bullock *et al.*[2,3] As previously reported,[4] we constructed a new rapid-scan spectrometer which had a better resolving power than that of Bullock. This paper will be concerned with the detailed spectra and the time dependence of each band after the explosion.

The rapid-scan infrared spectrometer was constructed by modifying a Shimadzu IRG-27 apparatus which is equipped with an oscillating mirror and a PbSe detector. The details of the optics and electronic circuits for synchronization have been described elsewhere.[4] The scan time was 10 ms. The scan rate was 125 cm^{-1}/ms at 3000 cm^{-1} and 12 cm^{-1}/ms at 500 cm^{-1}. The time interval of the repetition was 20 ms. The observed resolving power was 15 cm^{-1} at 3000 cm^{-1}, with the slit width of 700 μm.

The explosion was provoked by a spark discharge. A pyrex cylindrical vessel of 70 mmϕ and 40 cm long was used for the reaction. The vessel had electrodes at one end and an optical window 12 cm away from the electrodes. The CO and O_2 were passed through a liquid nitrogen trap before they were used. The total pressure was 225—350 mmHg. All the spectra were recorded at the slit width of 500 μm.

Some typical emission spectra after the explosion are shown in Figs. 1(a) and (b). In Fig. 1(a), well-resolved R-branch band heads due to the 001-000 and 011-010 transitions are observed at 2401 and 2389 cm^{-1} respectively. The bands in the band-head region are very similar to those in the spectrum obtained in the stationary flames of CO and O_2 by Benedict.[5] Two absorption bands are observed. One is the self absorption of CO_2 at around 2350 cm^{-1}, while the other is the absorption due to unreacted CO at around 2150 cm^{-1}. The band shape of CO seems very broad because the linearity of the sweeping time with the wave number is not established beyond 7.5 ms, as has been described in a previous report.[4] The emission band maximum of the CO_2 fundamental seems to be at around 2280 cm^{-1} immediately after the explosion. The rise and decay of this band maximum was more rapid compared with the other bands.

As is shown in Fig. 1(b), broad emission bands at 3480 cm^{-1} and a shoulder at 3700 cm^{-1} are observed. The weak, fine structures observed of these bands are considered to be due to the absorption of the H_2O in the optical path. The 3480 cm^{-1} and 3700 cm^{-1} bands were assigned to the 021-000 and 101-000 transitions respectively. When 5 mmHg of H_2O are added, the explosion proceeds vigorously, as is well known. The emission spectra are shown in Figs. 2(a) and (b). Again, bands similar to those seen in Fig. 1 appeared, but the emission intensity of each band, especially that at 2280 cm^{-1}, were very much higher than in a dry mixture at the initial stage.

The time dependences of the combination bands and the fundamental band heads are plotted in Figs. 3 and 4. In the explosion shown in Fig. 3, the time for the flame fromt to run across the optical window was estimated to be less than 10 ms. The rise time of the emission to the peak intensity in Fig. 3 is 70—80 ms, which is much longer than the value given above, and CO was found to decrease during the emission rise. These facts suggest that the emission-rising process is caused by the combustion occurring after the flame front has passed and that the emission-decay

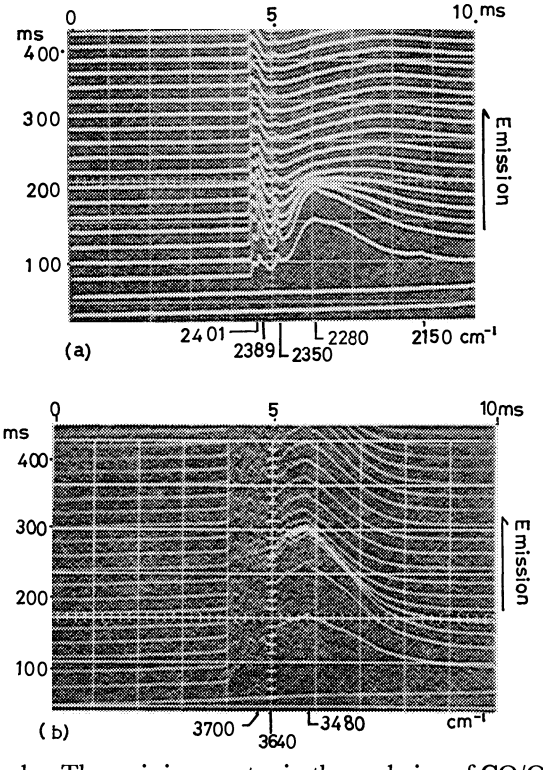

Fig. 1. The emission spectra in the explosion of CO/O_2. CO 150 and O_2 75 mmHg. 5 mV/div and 1 ms/div. Center wave number is 2350 cm^{-1} in (a) and 3640 cm^{-1} in (b). The spectra were recorded with the slit width of 300 μm in (a).

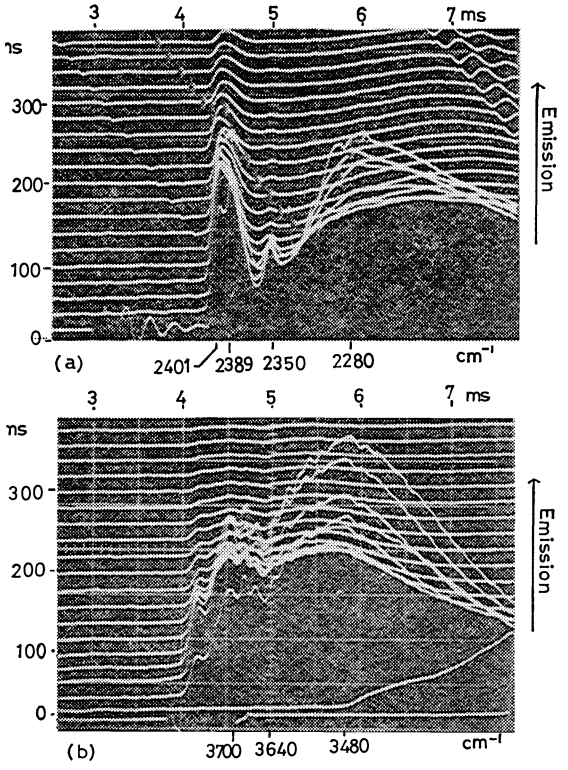

Fig. 2. The emission spectra in the explosion of $CO/O_2/H_2O$. CO 150, O_2 75 and H_2O 5 mmHg. 5 mV/div and 0.5 ms/div. The center wave number are the same as in Fig. 1.

process is the cooling process. It may be seen in Fig. 3(a) that the rises and decays of the two combination bands are similar. On the other hand, in the band-head region, as is shown in Fig. 3(b), the rise times of the 001 band and the 011 band are about the same, but the decay of the 011 band is faster than that of the 001 band. Then the intensities of the two bands are reversed after 300 ms. In H_2O-added mixtures, the rise and the decay of the emission bands are considerably increased. In this case, the reversing of the intensities in the band-head region occurred early, at 60 ms, as is shown in Fig. 2(a). "Afterglows" appeared during the emission-decay process, as is shown in Fig. 3. Bullock had already observed the "afterglows," but only in the self-absorption region. However, in this experiment they were observed in the combination bands and band heads, and not in the region of the absorption or on the low-frequency side of the emission. Figure 4 indicates that the combination band decayed faster than the fundamental band head. Such differences in the decay rate were observed also when excess O_2 or N_2 was added to CO–O_2 stoichiometric mixtures. In the O_2-rich mixtures, the decay rates of the combination bands and the two band heads increased to about an equal extent, but when 20 mmHg of N_2 was added, only those of the band heads increased. It should be pointed out that different time dependences were observed between the two band heads and between the band heads and the combination bands in the cooling process, although

the reason for this is not clear.

We are greatly indebted to Mr. Yuji Matsui of Shimadzu Seisakusho, Ltd., for the design and construction of the optics of the intrument. We also wish to thank Messers Ikuo Murai and Masatoshi Kitaichi for their help in making the spark-discharge circuits.

Dissociation Constants of Several Protonated Amines in Propylene Carbonate

Kosuke IZUTSU,* Toshio NAKAMURA, and Izumi IIJIMA

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received November 6, 1978)

Synopsis. The dissociation constants pK(BH$^+$) of five protonated monoamines in propylene carbonate have been determined potentiometrically using a glass electrode which was calibrated in a picric acid-picrate buffer solution. The pK(BH$^+$) values found at 25 °C were 10.1 for aniline, 11.9 for pyridine, 15.9 for ammonia, 17.0 for 1,3-diphenylguanidine, and 17.9 for triethylamine.

The dissociation and homoconjugation constants of several acids (HA) have been determined in propylene carbonate,[1] the results of which showed that propylene carbonate is a somewhat stronger base than acetonitrile, being of the same order of strength as acetone. In the present paper, the dissociation constants, pK(BH$^+$), of five protonated monoamines (BH$^+$) in propylene carbonate are presented. The pK(BH$^+$) values were obtained potentiometrically using a glass electrode which had been shown to respond with a Nernstian slope to paH in propylene carbonate. In each measurement, the electrode was calibrated in a picric acid–tetraethylammonium picrate buffer solution, the paH of which was calculated from the pK(HA) of picric acid of 9.30.[1]

Experimental

Materials. Propylene carbonate was a synthetic grade Merck product and purified as described in a previous report.[1] The water content of the purified solvent was less than 0.005%. Aniline, pyridine, 1,3-diphenylguanidine, and triethylamine were analytical reagent grade products (Wako Chemicals Co.), and purified by the method of Coetzee and Padmanabhan.[2] Pyridine was distilled from potassium hydroxide and then from barium oxide.[3] Ammonia was drawn into the propylene carbonate and the concentration of the resulting solution was determined by titration with perchloric acid.

The perchlorates of aniline, pyridine, 1,3-diphenylguanidine, triethylamine, and ammonia were prepared by neutralizing the bases with 70% perchloric acid, followed by recrystallization and careful drying *in vacuo*.[2] In the neutralization of triethylamine and the recrystallizations of the perchlorates of pyridine, 1,3-diphenylguanidine, and triethylamine, ethanol was used as the solvent.

Potentiometric Measurements. Potentiometric measurements were conducted at 25.0±0.5 °C as previously reported.[1] In the paH measurement of mixtures of a base and its perchlorate, 50 ml of the perchlorate solution was placed in the cell and appropriate volumes of the stock solution of the base were titrated to change the value of $\log(C_{BH^+}/C_B)$ from +1.0 to −1.0. Before and after each titration, the glass electrode was checked in the standard buffer solution (4×10^{-3} mol dm^{-3} picric acid and 4×10^{-3} mol dm^{-3} tetraethylammonium picrate) of paH 9.3_3. The potentials obtained in the standard buffer solution before and after each titration agreed within ±1 mV.

Results and Discussion

Typical results of the potentiometric measurements are shown in Table 1. In this case, 50 ml of 3.0×10^{-3} mol dm^{-3} pyridinium perchlorate in propylene carbonate was titrated with 3.0 mol dm^{-3} pyridine in the same solvent. The pK(BH$^+$) value was calculated according to Eq. 1,

$$pK(BH^+) = paH + \log\frac{C_{BH^+}f_{BH^+}}{C_B} \quad (1)$$

where $\log f_{BH^+} = -0.69C_{BH^+}^{1/2}$.[1] In Table 1, the p$K$(BH$^+$) values for $\log(C_{BH^+}/C_B)$ between +1.0 and −1.0 are constant within ±0.02. The titrations were conducted three or four times for each of the five protonated monoamines. In all cases, the values of pK(BH$^+$) in each titration were nearly constant (the largest standard deviation, 0.06). This indicates that under the experimental conditions the reaction BH$^+$= B+H$^+$ predominates in solution.

In Table 2, the pK(BH$^+$) values obtained are summarized. The standard deviations of the pK(BH$^+$) values in Table 2 are equal to or less than 0.1. But since the Nernstian response of the glass electrode was verified only at the paH range between 5 and 10,[1] it seems better to consider that the uncertainties of the pK(BH$^+$) values are about ±0.15 pK units.[4]

The values of pK(BH$^+$) in propylene carbonate are smaller than those in acetonitrile by approximately 0.5 pK units (except in the case of 1,3-diphenylguanidine where the difference is 0.9 pK units). As reported,[1] propylene carbonate is a 10 to 40 times stronger

b) Values from Ref. 2.

base towards protons than acetonitrile. The solvation of protonated amines would also be stronger in propylene carbonate than in acetonitrile, though the difference between the two solvents appears to be smaller than in the case of the proton. On the basis of these considerations, the above differences in $pK(BH^+)$ values between the two solvents are reasonable.[5)]

Thermochromism of Metal Chelates with Triphenylmethane Complexons in Aqueous Solutions. II. Inhibitive Effects of the Protolysis of Aqua Cu^{2+} Ion on the Thermochromism of Cu(II)–Xylenol Orange Chelate

Shoji NAKADA, Mutsuo YAMADA, Tasuku ITO,† and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 18, 1979)

Synopsis. Temperature-dependent protolytic equilibrium, $Cu(OH_2)_n^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cu(OH)(OH_2)_{n-1}^{+}+H^+$, was found to inhibit thermochromic changes of Cu(II)–Xylenol Orange (XO) chelate in unbuffered weakly acid aqueous solutions. The rate constants, k_1 and k_{-1}, at 25 °C and I=0.1 mol dm^{-3} were evaluated to be 10^3—10^4 s^{-1} and *ca.* 2×10^9 mol^{-1} dm^3 s^{-1}, respectively.

In previous papers we reported the thermochromism of the metal chelates of triphenylmethane complexons in aqueous solutions.[1] For the Cu(II)–XO complex the observed thermochromism was primarily ascribed to the temperature-dependent acid-dissociation equilibria between two 2 : 1 Cu(II)–XO chelates, AH and A: AH⇌A+H, where AH denotes a complex species having an uncoordinated free phenolic hydroxyl group and A a complex species having a coordinated phenolate group,[1] the charges being omitted. In unbuffered weakly acid aqueous solutions containing a large excess of Cu(II) ion the thermochromic change was not observed. In the present communication we aim to solve the problems on this phenomenon based on the spectrophotometric and the temperature-jump measurements.

Figure 1 shows the absorption spectra at various temperatures of an unbuffered aqueous solution containing 500-fold excess of Cu(II) ion over XO (2×10^{-5} mol dm^{-3}). With the rise of temperature from 15 to 60 °C the absorbance at 574 nm increases only by 7% and the thermochromic change was not observed.** The pH of the solution varies from 4.86 at 15 °C to 4.46 at 60 °C. On the basis of the values of ΔH and ΔS determined for the equilibrium AH⇌A+H,[1] only a negligibly small change in pH should be expected. The large decrease in pH observed above strongly suggests the possibility of a contribution of the temperature-dependent protolysis of a large excess of Cu^{2+} ion. This possibility was proved based on the temperature-jump data for aqueous solutions of Cu(II) ion containing uncomplexing acid-base indicators, Bromocresol Green (BCG), Bromocresol Purple (BCP), and Bromophenol Blue (BPB).

The pH of unbuffered solution containing 2×10^{-5} mol dm^{-3} BCG and 1×10^{-2} mol dm^{-3} $Cu(ClO_4)_2$ varied from 5.40 at 14 °C to 5.10 at 60 °C, and the absorbance at 628 nm, the λ_{max} of BCG, markedly decreased with the rise of temperature.

Figures 2(a) and 2(b) show the typical relaxation signals observed for the unbuffered systems, Cu(II)–XO and Cu(II)–BCG, respectively. In the Cu(II)–XO system, a fast relaxation signal of an increasing absorbance at 574 nm was observed in 5 μs region,

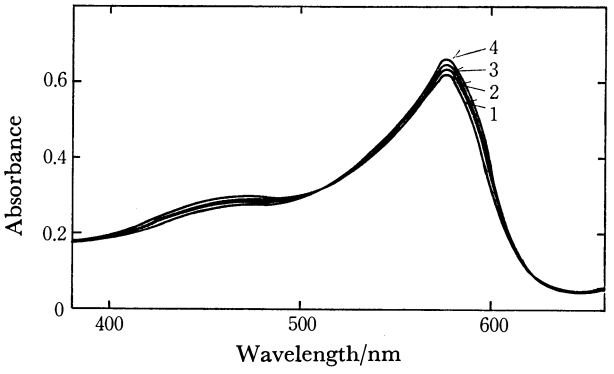

Fig. 1. Absorption spectra of an aqueous solution of Cu(II)–XO. At 15 (1), 25 (2), 44 (3), and 60 °C (4). $[Cu]_0=1.0\times10^{-2}$ and $[XO]_0=2\times10^{-5}$ mol dm^{-3} ($[\ ]_0$ denotes the total concentration). I= 0.1 mol dm^{-3} ($NaClO_4$). The pH of the solution varied from 4.86 (15 °C) to 4.46 (60 °C).

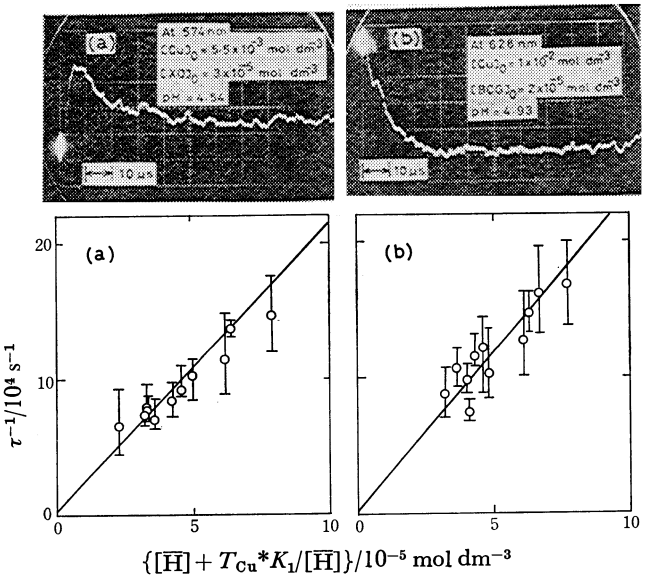

Fig. 2. Temperature-jump signals and the plots of τ^{-1} *vs.* $([\overline{H}]+T_{Cu}{}^*K_1/[\overline{H}])$ at 25 °C and I=0.1 mol dm^{-3} ($NaClO_4$) for Cu(II)-XO (a) and Cu(II)-BCG (b).

† Present address: Institute for Molecular Science, Okazaki 444.

** In the case of a solution of the same pH containing only a small excess of Cu(II) ion over XO the absorbance at 574 nm increased so markedly as *ca.* 30% even in unbuffered systems.[1]

Table 1. The rate constants, k_1 and k_{-1}, for the protolytic reaction, $Cu(OH_2)_n^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cu(OH)(OH_2)_{n-1}^{+} + H^+$ (I=0.1 mol dm^{-3} ($NaClO_4$))

X	$k_1/10^4$ s^{-1}	$k_{-1}/10^9$ mol^{-1} dm^3 s^{-1}	T/K
XO	1.4±1.0	1.8±0.3	298

	2.4±2.0	2.0±0.4	298

prior to a slower signal in 10 μs region indicating a decrease in the absorbance (Fig. 2(a)). The signal in the 5 μs region corresponds to the fast protonation-deprotonation AH⇌A+H.[1] The slower relaxation signal is ascribed to the protolysis of Cu^{2+} ion coupled with the fast thermochromic change of the Cu(II)–XO system. In the Cu(II)–GCB system, however, the fast relaxation signal in the region of 5 μs was not observed, only the slower signal was invariably observed in the 10 μs region (Fig. 2(b)). The slower signals observed in both systems are interpreted as a process involving the protolysis of the excess of Cu^{2+} ion.[2]

Assuming pre-equilibria for the thermochromic changes of the Cu(II)–XO system and also for the protonation-deprotonation process of the indicator, and regarding the protolysis of the Cu^{2+} ion in the unbuffered aqueous solution as a rate-determining step, we describe the given coupled reactions by the following two-step mechanism:

$$HX \underset{}{\overset{K_x}{\rightleftharpoons}} H + X \qquad (1)$$

and

$$Cu(OH_2)_n^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cu(OH)(OH_2)_{n-1}^{+} + H^+, \qquad (2)$$

where X denotes the base form of the chelate, A, or that of the acid-base indicator, In, and $K_x=K_a$ or K_{In}. In Eq. 1 the charges are omitted. With appropriate assumptions on the experimental conditions the relaxation time τ observed in the 10 μs region can be expressed as Eq. 4:

$$\tau^{-1} = k_1 + k_{-1}\left\{[\overline{H}] + [\overline{CuOH}]\cdot\frac{[\overline{H}]+K_x}{[\overline{X}]+[\overline{H}]+K_x}\right\} \qquad (3)$$

$$\simeq k_1 + k_{-1}\left\{[\overline{H}] + \frac{T_{Cu}{}^*K_1}{[\overline{H}]}\right\}, \qquad (4)$$

where T_{Cu} denotes the total concentration of Cu(II), and $^*K_1=[\overline{CuOH}][\overline{H}]/[\overline{Cu}]=10^{-7.34}$.[3] [¯] denotes the equilibrium concentration. CuOH indicates the deprotonated species, $Cu(OH)(OH_2)_{n-1}^{+}$.

The plots of τ^{-1} against $[\overline{H}]+T_{Cu}{}^*K_1/[\overline{H}]$ give fairly good straight lines for both systems, Cu(II)–XO and Cu(II)–BCG (Figs. 2(a) snd 2(b)). Table 1 shows the values of the rate constants, k_1 and k_{-1}, for the protolytic reaction (2) estimated from the intercepts and the slopes of the straight lines. The estimated value of k_{-1} ($\simeq 2\times10^9$ mol^{-1} dm^3 s^{-1}) lies nearly in the order of magnitude of the rate constant for the recombination of $CuOH^+$ and H^+ reported by Eigen *et al.* based on the sound absorption measurements ($k_{-1}\simeq 1\times10^{10}$ mol^{-1} dm^3 s^{-1}).[4] The value of $^*K_1$ derived from the ratio k_1/k_{-1}, however, varies in the range 10^{-5} —10^{-7} mol dm^{-3} owing to the large errors inherent in the estimation of the intercepts.

The system Cu(II)–BCP gave a slower relaxation signal in the 10 μs region only in the pH-region 5.2—5.9. In this system no linear relationship was obtained, presumably due to the contribution of the dimer formation in the Cu(II) species above pH 5.5.

As regards the Cu(II)–BCG system we estimated the activation enthalpies for k_1 and k_{-1} to be $\Delta H^{\ddagger}=19$ kcal mol^{-1} and $\Delta H^{\ddagger}=9$ kcal mol^{-1}, respectively. The difference in the values, 10 kcal mol^{-1}, agrees well with the value of ΔH for the protolytic equilibrium (2), 10—12 kcal mol^{-1}.[3]

On the basis of the results mentioned above we ascribe the observed inhibition of the thermochromism of Cu(II)–XO chelate in the presence of a large excess of Cu(II) ion in unbuffered aqueous solutions to the protolysis of the excess of aqua Cu^{2+} ion.

Experimental

A highly purified specimen of 3,3′-bis[*N*,*N*-bis(carboxymethyl) aminomethyl]-*o*-cresolsulfonaphthalein (Xylenol Orange) was used throughout the present work.[5] Reagent grade acid-base indicators, BCG, BCP, and BPB (Wako), were used. The pH values of the unbuffered solutions were adjusted with $HClO_4$ and NaOH (0.1 mol dm^{-3}) in the ranges 4.0—5.2, 4.4—5.2, and 4.3—5.9 for Cu(II)–BCG, –BPB, and –BCP systems, respectively. In the case of buffered systems, acetate, citrate, and phthalate buffers were used. The details on the measurements using a co-axialcable temperature-jump apparatus were described in a previous paper.[6]

Isomerism of the Metal Complexes Containing Multidentate Ligands. VIII. Chromatographic Behavior of $[CoN_6]^{3+}$-type Complexes on an SP-Sephadex Column[1)]

Katsumi SAKAKIBARA, Yuzo YOSHIKAWA,* and Hideo YAMATERA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 26, 1979)

Synopsis. An empirical rule is presented for the elution order of $[CoN_6]^{3+}$-type complexes in chromatography on SP-Sephadex columns. The relative elution rates have been correlated with the number and the kind of the octahedral faces of the complex on which ion association with a phosphate ion occurs.

The application of ion-exchange Sephadex to the column-chromatographic separation of isomers of a metal complex was first described by Yoshikawa and Yamasaki, who successfully resolved the optical isomers[2)] of $[Co(en)_3]^{3+}$ and separated the three geometrical isomers[3)] of $[Co(dien)_2]^{3+}$. Subsequently the technique has been widely used to separate and resolve the isomers of many complexes. It is still difficult, however, to predict the elution order for a given mixture of isomers.

This note is concerned with a working hypothesis, which correlates the elution order with the structure of geometrical isomers of the $[CoN_6]^{3+}$-type complexes. The predictions from the hypothesis have been compared with the experimental results of isomer separation on several complexes with five-membered chelate rings.

Experimental

Materials. All Complexes,** $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_4(en)]^{3+}$, $[Co(NH_3)_2(en)_2]^{3+}$, $[Co(en)_3]^{3+}$, $[Co(dien)_2]^{3+}$,[3)] $[Co(en)(trien)]^{3+}$,[4,5)] $[Co(linpen)]^{3+}$,[6)] $[Co(hexaen)]^{3+}$,[7)] and $[Co(pn)_3]^{3+}$,[8)] were prepared according to the literature. For each complex in which geometrical isomerism occurs, an equimolar mixture of the geometrical isomers was prepared with the isomers isolated in advance.

Chromatography. The mixture of $[Co(dien)_2]^{3+}$ isomers was adsorbed at the top of an SP-Sephadex C-25 column (ϕ 1.4×*ca.* 130 cm) and eluted with 0.1 M Na_3PO_4. The elution curve was drawn by measuring the absorbance of each fraction of the eluate. Similar experiments were also made on the same column with 0.15 M Na_2SO_4, 0.15 M $Na_2\{(+)\text{-}C_4H_4O_6\}$(sodium tartrate), 0.3 M NaCl, and 0.3 M $NaClO_4$ as eluents. The isomer contained in each band was identified by the IR spectra, the results of which are shown in Fig. 1, where the vertical lines indicate the peak positions (in elution volume) in each curve.

The mixtures of the isomers of $[Co(NH_3)_2(en)_2]^{3+}$, $[Co(dien)_2]^{3+}$, $[Co(en)(trien)]^{3+}$, $[Co(linpen)]^{3+}$, $[Co(hexaen)]^{3+}$, and $[Co(NH_3)_4(en)]^{3+}$ were examined for elution order on another column (ϕ 2.7×127 cm) with 0.1 M Na_3PO_4 as the eluent. In each experiment either $[Co(en)_3]^{3+}$ or $[Co(NH_3)_6]^{3+}$ was added as a reference, of which the peak position in each elution curve is shown by a dashed vertical line (Fig. 2). The separation of $[Co(pn)_3]^{3+}$ isomers was also made in a similar manner.

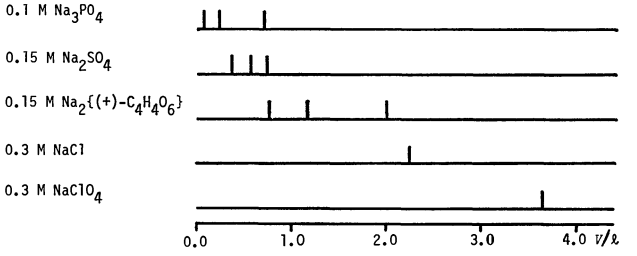

Fig. 1. Separation of the isomers of $[Co(dien)_2]^{3+}$ with different eluents. Column size: ϕ1.4×*ca.* 130 cm (SP-Sephadex C-25).

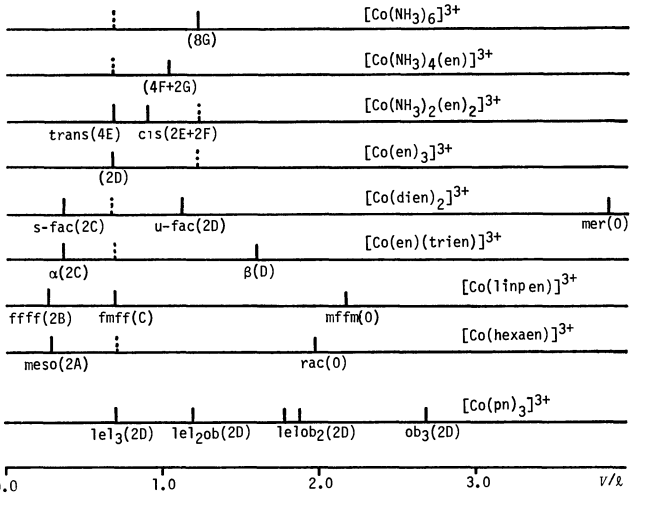

Fig. 2. The elution order of $[CoN_6]^{3+}$-type complexes. Column size: ϕ2.7×127 cm (SP-Sephadex C-25). Eluent: 0.1 M Na_3PO_4.

Results and Discussion

The factors influencing the relative rates of elution of geometrical isomers of cationic Co(III) complexes on an SP-Sephadex column are probably two: the interaction between SP-Sephadex and the complex cation, and the interaction between the complex cation and the eluent anion. Different eluents were used to separate the isomers of $[Co(dien)_2]^{3+}$ (Fig. 1). The same elution order (*s-fac*, *u-fac*, and *mer*) was shown by 0.1 M Na_3PO_4, 0.15 M Na_2SO_4, and 0.15 M $Na_2\{(+)\text{-}C_4H_4O_6\}$ eluents, whereas 0.3 M NaCl and 0.3 M $NaClO_4$ resulted in no clear separation. These results indicate that the interaction of the complex cation with the eluent anion, not with SP-Sephadex, is the dominant factor in the separation of geometrical

** The following abbreviations are used in this note: en, ethylenediamine; dien, diethylenetriamine; trien, triethylenetetramine; linpen, linear pentaethylenehexamine; hexaen, hexaethylenehexamine; pn, propylenediamine.

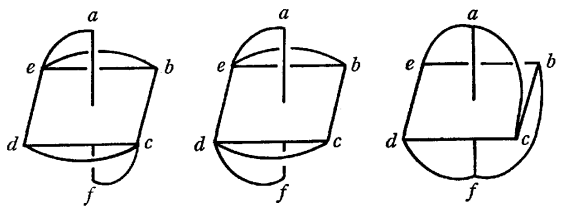

Fig. 3. Three geometrical isomers of $[Co(dien)_2]^{3+}$.

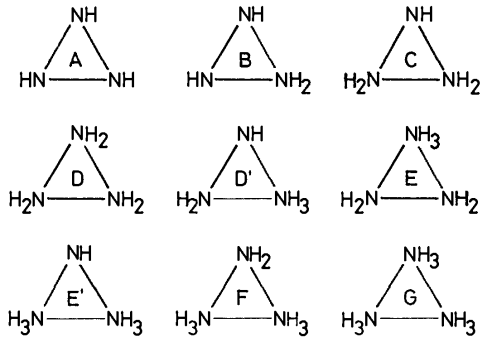

Fig. 4. Classification of the octahedral faces available for ion-pairing.

isomers.[9]

The structure of each geometrical isomer may or may not favor ion association. Experimental results so far reported on $[Co(en)_3]^{3+}$–oxo anion systems have indicated that three hydrogen bonds can be formed between a trigonal-pyramidal or tetrahedral oxo anion and a set of three N–H bonds extending along a direction perpendicular to an octahedral face of the complex. Two faces of the $[Co(en)_3]^{3+}$ octahedron are suitable for such ion association, whereas chelate rings will sterically interfere with ion association on the six other faces of the octahedron.[10]

In the three geometrical isomers of $[Co(dien)_2]^{3+}$ (Fig. 3), ion association will occur on the two faces, *abc* and *def*, in the *s-fac* isomer and on the two faces, *abc* and *bcf*, in the *u-fac* isomer. Each octahedral face of the *mer* isomer, however, is hindered from ion association by the chelate ring, which is consistent with the experimental results that the *mer* isomer was the final one to be eluted.

The elution behavior of the *s-fac* and *u-fac* isomers will be discussed in connection with the tendency for hydrogen bonding of the N–H protons with an oxo anion. That tendency will be in the order: secondary amine>primary amine>ammonia.[9] Consequently the octahedral faces may be classified according to the types of amine groups on the faces, in effect, according to the number of hydrogen atoms attached to the nitrogen atoms; the face containing three secondary amine groups is designated A, the face containing two secondary and one primary amine groups is designated B, *etc.* (Fig. 4). In this way a letter of the alphabet is affixed to each face in the order of increasing number of total hydrogen atoms attached to the nitrogen atoms on the face. This serves as an index. In the situation that two types of faces exist with an equal number of attached hydrogen atoms, the designation is D and D′ for example. A face carrying a prior alphabetical name will have a greater tendency to ion-pair formation. The *s-fac* isomer of $[Co(dien)_2]^{3+}$ has two C faces, and the *u-fac* isomer has two D faces. Consequently the tendency to associate with eluent anions will be in the order: *s-fac*>*u-fac*>*mer*. This order agrees with the order found experimentally.

Based on the preceding discussion, the elution order for $[CoN_6]^{3+}$-type complexes can be predicted and explained. Figure 2 gives the experimental results, where the position of the peak is shown for each isomer together with the number and type of octahedral face on which ion association with a phosphate ion occurs. The experimental elution results agreed completely with the prediction for the isomers of each complex investigated. There are however some cases where comparison is not straight-forward, *e.g.*, *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (4E), $[Co(en)_3]^{3+}$(2D), and *fmff*-$[Co(linpen)]^{3+}$ (C) were eluted at similar positions, a fact attributed to the counterbalance of the effect of decreasing number of faces available for ion-pairing and that of the increasing tendency of the faces to ion-pairing. Elution was slower for *u-fac*-$[Co(dien)_2]^{3+}$(2D) than for $[Co(en)_3]^{3+}$(2D), which has been attributed to the fact that the two D faces of the former complex cannot simultaneously have suitable N–H orientations for hydrogen bonding with the eluent anion.

$[Co(pn)_3]^{3+}$(2D) represents an example of a special case where the conformational effect is important; in this complex, the conformation of the chelate rings are not as flexible as in other complexes. Combination of the asymmetries at the ligands and the central cobalt gives rise to four enantiomeric pairs of isomers, in which the flexibility of the chelate rings is restricted by steric interaction of the bulky methyl group of pn. The N–H bonds at the both ends of a *lel* chelate ring are suitably oriented for hydrogen bonding, while those of the *ob* chelate ring are not.[8] The experimental result for $[Co(pn)_3]^{3+}$ indicates that the N–H orientation greatly affects the rate of elution.

(Received September 13, 1978)

Synopsis. Benzyl alcoholysis and hydrolysis of tetrakis-*N*-(benzyloxycarbonyl)fortimicin B and further transformation of the solvolysis products are described. Several derivatives of 6-*epi*-purpurosamine B and fortamine potentially useful for the synthesis of fortimicin analogs are presented.

Fortimicins A and B were found by Nara and his coworkers in the culture broth of *micromonospora* sp. MK-70.[1] It was also found that fortimicin B is obtained by hydrolysis of fortimicin A.[2] Both antibiotics belong to a class of pseudodisaccharide composed of 6-*epi*-purpurosamine B and fortamine which is a novel diaminocyclitol. In the course of the synthetic studies of fortimicins and their analogs through coupling reaction of these two components, it will be useful to obtain them from the natural products as their suitable protected derivatives. The present paper reports the preparation of fortamine and 6-*epi*-purpurosamine B by solvolysis of protected fortimicin B and their derivatives.

Fortimicin B was benzyloxycarbonylated to 1,4,2′,6′-tetrakis-*N*-(benzyloxycarbonyl)fortimicin B (**1**). Upon benzyl alcoholysis, **1** afforded α- and β-benzyl glycosides of 2,6-bis-*N*-(benzyloxycarbonyl)-6-*epi*-purpurosamine B (**2** and **3**) and 1,4-bis-*N*-(benzyloxycarbonyl)fortamine (**4**) after separation by silica gel chromatography. Each structure was confirmed by the PMR spectra.

When **2** was hydrogenolyzed with a palladium catalyst α-benzyl glycoside (**5**) was obtained. It should be noted that the 1-*O*-benzyl group resisted even to prolonged hydrogenolysis.

Upon hydrolysis of **1** with 2 M hydrochloric acid, 2,6-bis-*N*-(benzyloxycarbonyl)-6-*epi*-purpurosamine B (**6**) and **4** were obtained. Hydrogenolysis of **6** and hydrolysis of **4** afforded 6-*epi*-purpurosamine B (**7**) and fortamine (**8**) respectively as their hydrochloride.

Acetylation of **6** gave crystalline product of acetate (**9**) and when it was hydrogenolyzed 1-*O*-acetyl-6-*epi*-α-purpurosamine B (**10**) was obtained. **4** and **10** are important intermediates for fortimicin analog syntheses.

Experimental

TLC was carried out on 7.5×2.5 cm slides coated with silica gel (Wakogel B-5, Wako Pure Chemicals Co., Ltd., Osaka) for protected compounds and 20×5 cm plates of cellulose (Avicel SF, Funakoshi Pharmaceutical Co., Ltd., Tokyo) for free compounds. Silica-gel column chromatography was performed with Kiesel gel 60 (E. Merck, Darmstadt, Germany). Melting point was not corrected.

*1,4,2′,6′-Tetrakis-*N*-(benzyloxycarbonyl)fortimicin B (**1**).* To an ice-cooled suspension of fortimicin B (10.0 g) and anhydrous sodium carbonate (8.79 g) in aqueous acetone (1:1, 250 ml), benzyloxycarbonyl chloride (25.1 ml) was added and the mixture was stirred for 1 h in the ice bath and then for 2 h at room temperature. The reaction mixture was evaporated to remove acetone and extracted with chloroform. The chloroform solution was dried over anhydrous magnesium sulfate and evaporated to give a pale yellow sirup, which was washed with hexane to give a colorless powder, 24.8 g (96.6%); $[\alpha]_D^{26}$ +42°(*c* 1, MeOH); R_f 0.41 (benzene:ethanol=9:1); PMR (in CD_3OD): δ 2.96 (3H, s, NCH_3), 3.31 (3H, s, OCH_3).

Found: C, 63.68; H, 6.38; N, 6.06%. Calcd for $C_{47}H_{56}N_4O_{13}$: C, 63.78; H, 6.38; N, 6.33%.

*Benzyl Alcoholysis of **1**.* A solution of **1** (1.20 g) in 1 M hydrogen chloride–benzyl alcohol (60 ml) was heated at 50 °C for 4 h. Basic lead carbonate (7.45 g) was added and the mixture was stirred for several hours to render pH about 5. The mixture was centrifuged and the clear supernatant was evaporated under reduced pressure to give a yellow sirup, which was washed with hexane and chromatographed on a silica-gel column with benzene:ethyl methyl ketone (EMK)(25 : 1—4 : 1, gradually changed). Evaporation of the fractions in turn gave benzyl 2,6-bis-*N*-(benzyloxycarbonyl)-α-6-*epi*-purpurosaminide B (**2**), benzyl 2,6-bis-*N*-(benzyloxycarbonyl)-β-6-*epi*-purpurosaminide B (**3**) and 1,4-bis-*N*-(benzyloxycarbonyl)fortamine (**4**), respectively (cited in the order of elution).

*Benzyl 2,6-Bis-*N*-(benzyloxycarbonyl)-α-6-*epi*-purpurosaminide B (**2**).* Crystals (from ethanol), 397 mg (56%); mp 131.5—134.5 °C; $[\alpha]_D^{26}$ +78° (*c* 1, MeOH); R_f 0.49 (benzene:EMK=15:1); PMR (in $CDCl_3$): δ 1.16 (3H, d, *J*=6 Hz, 6-CH_3), 4.55 (2H, ABq, *J*=12 Hz, 1-O-$C\underline{H}_2Ph$), 4.83 (1H, d, *J*=3 Hz, H-1), 5.07, 5.10 (each 2H, s, CO·O$C\underline{H}_2Ph$).

Found: C, 69.48; H, 6.61; N, 5.40%. Calcd for $C_{30}H_{34}N_2O_6$: C, 69.41; H, 6.74; N, 5.30%.

*Benzyl 2,6-Bis-*N*-(benzyloxycarbonyl)-β-6-*epi*-purpurosaminide B (**3**).* Crystals (from ethanol), 61 mg (9%); mp 180.5—183.5 °C; $[\alpha]_D^{27}$ −77° (*c* 0.6, $CHCl_3$); R_f 0.29 (benzene : EMK=15:1); PMR (in $CDCl_3$): δ 1.21 (3H, d, *J*=6 Hz, 6-CH_3), 4.27 (1H, d, *J*=8 Hz, H-1), 4.70 (2H, ABq, *J*=12 Hz, 1-O-$C\underline{H}_2Ph$), 5.11 (4H s, CO·O$C\underline{H}_2Ph$).

Found: C, 69.28; H, 6.86; N, 5.28%.

*1,4-Bis-*N*-(benzyloxycarbonyl)fortamine (**4**).* Crystals (from ether), 340 mg (53%); mp 161—166 °C; $[\alpha]_D^{27}$ +47° (*c* 1, MeOH); R_f 0.41 (chloroform:methanol=24:1); PMR (in $CDCl_3$): δ 3.05 (3H, s, NCH_3), 3.29 (3H, s, OCH_3), 5.10, 5.16 (each 2H, s, CO·O$C\underline{H}_2Ph$).

Found: C, 60.75; H, 6.37; N, 5.90%. Calcd for $C_{24}H_{30}$-

N_2O_8: C, 60.43; H, 6.17; N, 5.89%.

Benzyl α-6-epi-Purpurosaminide B Dihydrochloride (5). A solution of **2** (871 mg) in dioxane (23 ml) was hydrogenolyzed in the presence of 10% palladium on carbon for 24 h under 50 psi hydrogen atmosphere. After filtration the filtrate was neutralized with 2 M hydrochloric acid, and then evaporated under reduced pressure to give a solid, 351 mg (90%), $[\alpha]_D^{26}$ +78°→+80° (*c* 1, H_2O); R_f 0.23 (1-butanol : pyridine : water : acetic acid=6 : 4 : 3 : 1); PMR (in D_2O): δ 1.16 (3H, d, *J*=7 Hz, 6-CH_3), 4.62 (2H, s, 1-O-C<u>H</u>$_2$Ph), 5.10 (1H, d, *J*=4 Hz, H-1), 7.37 (5H, s, C_6H_5).

Hydrolysis of 1. To a solution of **1** (1.00 g) in dioxane (30 ml), 4 M hydrochloric acid (30 ml) was added and the mixture was heated at 90 °C for 2 h. The solution was evaporated to 20 ml. Water (200 ml) was added and precipitates were filtered to give a solid, which was chromatographed on a silica-gel column with toluene: EMK(6 : 1—4 : 1, gradually changed). Evaporation of the fractions in turn gave, 2,6-bis-*N*-(benzyloxycarbonyl)-6-*epi*-purpurosamine B (**6**) (70 mg, 15%) and 1,4-bis-*N*-(benzyloxycarbonyl)-fortamine (**4**) (140 mg, 27%) in the order of elution.

2,6-Bis-N-(benzyloxycarbonyl)-6-epi-purpurosamine B (6). A solid; $[\alpha]_D^{26}$ +11° (*c* 1, MeOH); R_f 0.60 (toluene: EMK=3:2); PMR (in $CDCl_3$): δ 1.13 (d, *J*=6 Hz), 1.22 (d, *J*=6 Hz) (3H in total, 6-CH_3), 5.11 (4H, s, C<u>H</u>$_2$Ph), 7.37 (10H, s, C_6H_5).

Found: C, 64.40; H, 6.60; N, 6.34%. Calcd for $C_{23}H_{28}N_2O_6$: C, 64.47; H, 6.59; N, 6.54%.

Fortamine Dihydrochloride (8). A suspension of **4** (100 mg) in 6 M hydrochloric acid (25 ml) was heated to reflux for 2 h. The resulting clear solution was evaporated to give a solid, which was dissolved in water and washed with ether. The aqueous layer separated was evaporated to give a residue, which was crystallized from ethanol to give needles, 54 mg (91%); mp 230—240 °C (dec); $[\alpha]_D^{25}$+4° (*c* 0.8, H_2O); R_f 0.27 (1-butanol : pyridine : water : acetic acid=6 : 4 : 3 : 1); PMR (in D_2O): δ 2.87 (3H, s, NCH_3), 3.53 (3H, s, OCH_3), 3.54 (1H, H-1), 3.77 (1H, q, H-4), 3.91 (1H, t, H-6), 4.03 (1H, q, H-3), 4.25 (1H, q, H-5), 4.26 (1H, q, H-2). $J_{1,2}$=8 Hz, $J_{2,3}$=3 Hz, $J_{3,4}$=6 Hz, $J_{5,6}$=8 Hz, $J_{1,6}$=8 Hz. Free base (in D_2O): δ 2.38 (3H, s, NCH_3), 2.83 (1H, t, H-1), 3.13 (1H, q, H-4), 3.37 (1H, t, H-6), 3.45 (3H, s, OCH_3), 3.64 (1H, q, H-2), 3.81 (1H, q, H-5). $J_{1,2}$=10 Hz, $J_{2,3}$=3 Hz, $J_{3,4}$=3 Hz, $J_{4,5}$=5 Hz, $J_{5,6}$=10 Hz, $J_{1,6}$=10 Hz.

Found: C, 34.42; H, 7.22; N, 10.04%. Calcd for $C_8H_{18}N_2O_4 \cdot 2HCl$: C, 34.53; H, 7.39; N, 9.72%.

6-epi-Purpurosamine B Dihydrochloride (7). To a solution of **6** (5.10 g) in dioxane (250 ml), 2 M hydrochloric acid (11.7 ml) was added and hydrogen was bubbled through the solution in the presence of palladium–carbon. After 2 h water (100 ml) was added and the reaction was continued for further 1 h. The solution was filtered and evaporated to give a solid, 2.60 g (93%), which was crystallized from ethanol–ether to give colorless crystals, mp 186—191 °C (dec), $[\alpha]_D^{24}$ +6°→+23° (*c* 0.6, water), R_f 0.26 (1-butanol: pyridine : water : acetic acid=6 : 4 : 3 : 1), PMR (in D_2O): δ 1.29 (d, *J*=7 Hz), 1.30 (d, *J*=7Hz) (total 3H, 6-CH_3), 4.80 (more intense, d, *J*=8.5 Hz), 5.38 (d, 3Hz) (total 3H, H-1).

Found: C, 36.43; H, 7.29; N, 11.65%. Calcd for $C_7H_{16}N_2O_2 \cdot 2HCl$: C, 35.72; H, 6.85; N, 11.42%.

1-O-Acetyl-2,6-bis-N-(benzyloxycarbonyl)-α-6-epi-purpurosamine B (9). To a solution of **6** (2.0 g) in pyridine (55 ml), acetic anhydride (1.5 ml) was added and the solution was allowed to stand at room temperature overnight. After a drop of water was added, the solution was evaporated and the residue was dissolved in chloroform. The solution was washed with water and evaporated to give a solid, which was crystallized from toluene to give needles of **9**, 1.81 g (79%), mp 153.5—156.5 °C, $[\alpha]_D^{26}$ +41° (*c* 1, MeOH), R_f 0.52 (toluene : EMK=3 : 1), PMR (in $CDCl_3$): δ 1.12 (3H, d, *J*=7Hz, 6-CH_3), 2.10 (3H, s, Ac), 5.09 (4H, s, C<u>H</u>$_2$Ph), 6.08 (1H, d, *J*=3Hz, H-1), 7.33 (10H, s, C_6H_5).

Found: C, 63.95; H, 6.45; N, 5.85%. Calcd for $C_{25}H_{30}N_2O_7$: C, 63.82; H, 6.43; N, 5.95%.

1-O-Acetyl-α-6-epi-purpurosamine B Dihydrochloride (10). Hydrogen was bubbled through a solution of **9** (600 mg) in dioxane (26 ml) in the presence of palladium–carbon. During the course of the reaction pH was maintained at 3—4 with 2 M hydrochloric acid, and water (0.2 ml×3) was added at 30 min intervals. The solution was filtered and evaporated to give a solid, 357 mg (99%), $[\alpha]_D^{24}$ +40° (*c* 1, MeOH), R_f 0.25 (1-butanol : pyridine : water : acetic acid=6 : 4 : 3 : 1), IR: 1730 (ester) cm^{-1}, PMR (in CD_3OD): δ 1.32 (3H, d, *J*=6Hz, 6-CH_3), 2.25 (3H, s, Ac), 6.30 (1H, bs, H-1).

Found: C, 32.87; H, 7.78; N, 8.22%. Calcd for $C_9H_{18}N_2O_3 \cdot 2HCl \cdot 3H_2O$: C, 32.83; H, 7.96; N, 8.50%.

A Synthetic Route to 5-Aryl-2-oxazolidinone Derivatives

Yuji TSUJIMOTO,* Atsushi KOSAKA, Mitsunori HAYASHI,
Takuji MIYAMOTO, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received September 20, 1978)

Synopsis. 5-Aryl-2-oxazolidinones have been synthesized readily by the elimination of dimethylamine from the corresponding (2-hydroxyethyl)ureas. The ureas are obtainable by the photoreaction of tetramethylurea with *para*-substituted benzaldehydes (Method A) or with *para*-substituted methyl benzoates (Method B). The electronic character of the substituent on the benzene ring determines which method is suitable for the preparation of (2-hydroxyethyl)ureas.

2-Oxazolidinones (*e.g.*, Furazolidone[1a] and Methoxadone[1b]) are of pharmaceutical importance,[2] and research has been devoted to establishing convenient synthetic routes for 2-oxazolidinones.[3-5] Most of the reported methods, however, consist of tedious multiple steps.[6]

As part of the studies on the application of *N,N*-dimethylcarbamoyl compounds to synthetic chemistry,[5,7-10] a convenient synthetic route to 5-aryl-2-oxazolidinones (**7**) by the photoreaction of tetramethylurea with aromatic compounds such as benzaldehyde and methyl benzoate, followed by the thermal cyclization has been found.

It may be reasonable to consider that the exploitation of convenient synthetic route to **3** is essential, because the desired ones (**7**) are accessible from a series of (2-hydroxyethyl)ureas (**3**) in satisfactory yields as described later. Consequently one-step preparation for **3**, through photochemical hydrogen abstraction of the *para*-substituted benzaldehydes (**1**) from tetramethylurea (**2**) was designed.

Irradiation of an acetonitrile solution of **1** and **2** gives the desired ureas (**3**) in one-step, although the yields are low as shown in Table 1, together with pinacols derived from the photoreduction of the corresponding **1** (20—40%) and dimeric urea (**4**). In some cases, **7** was also found, for example, **1c** gave **7c** (11% yield).

The ureidomethylation (Method A) is apparently induced by hydrogen abstraction by the excited n-π^* triplet state of **1** from **2**. The formation of **3** was heavily suppressed in the case of **1d** and **1e** which has an electron withdrawing group substituent in the benzene ring because of the low efficiency for hydrogen abstraction.[11]

To overcome this defect in Method A, the photoreaction of *para*-substituted methyl benzoates (**5**) with **2** (Method B) was designed, based on the result that the photoreaction of aromatic esters such as **5d** or **5e** in an appropriate hydrogen donating solvent readily affords some alcohol derivatives derived from reduction

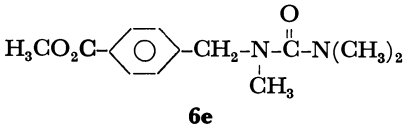
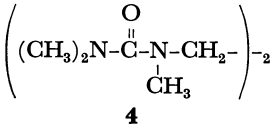
of the ester group and subsequent coupling of the resulting radicals.[12] Irradiation of **5d** with **2** in acetonitrile through a quartz filter led to the formation of **3d** in 53% yield. In the case of **5e**, photoureidomethylation of the aromatic ring described previously in aromatic nitriles[8] proceeded to give benzylurea (**6e**) (15% yield), and **3e** (11% yield).



6e



4

(2-Hydroxyethyl)ureas (**3**), prepared by Method A or B, were subsequently subjected to thermal reaction. A solution of **3** (0.05 M) in xylene was refluxed for 10 h, enabling the cyclization to proceed smoothly to give the 5-aryl-2-oxazolidinone derivatives (**7**) in good yields (Table 2).

Experimental

Materials. Methyl terephthalaldehydate (**1d**) was obtained by the Sommelet reaction.[12] *p*-Cyanobenzaldehyde (**1e**) was prepared according to the procedure of Lieberman *et al.*[13] Methyl *p*-cyanobenzoate (**5e**) was prepared by the esterification of the corresponding acid. All other aldehydes, dimethyl terephthalate (**5d**) and tetramethylurea (**2**) were commercially available.

General Procedure for Preparation of (2-Hydroxyethyl)ureas (3). *Method A*: The aldehydes (**1**) and a three molar excess of tetramethylurea (**2**) were dissolved in acetonitrile. After nitrogen was bubbled through the solution for 15 min, the solution was irradiated with a 500 W high pressure mercury arc through a Pyrex filter for 10 h at room temperature. After evaporation of the solvent, the unreacted **2** was recovered *in vacuo* and the residue chromatographed on silica gel. The products (**3**) were eluted with a mixture of benzene–ether.

Method B: A solution of **5d** or **5e** and a ten molar excess of **2** in the same solvent was similarly irradiated through a quartz filter for 20 h. After irradiation, a similar procedure was conducted. From the volatile components, methanol was detected by GLC (20% PEG, 20 M on Celite 545). Benzylurea (**6e**) was confirmed by a comparison with an authentic sample alternatively prepared.

Alternate Synthesis of 1-(p-Methoxycarbonylbenzyl)-1,3,3-trimethylurea (6e). **6e** was prepared from *p*-methoxycarbonylbenzyl bromide and an excess of trimethylurea in the presence of potassium amide in liquid ammonia according to the method by Bryant *et al.*[14] Bp 120 °C (0.6 Torr); IR (neat) 1700, 1600 cm^{-1}; NMR ($CDCl_3$) δ 2.5 (s, 3H), 2.6 (s, 6H), 3.8 (s, 3H), 4.4 (s, 2H), 7.2—8.0 (A_2B_2, 4H). Found: C, 62.22; H, 7.39; N, 10.90%. Calcd for $C_{13}H_{18}N_2O_3$: C, 62.38; H, 7.25; N, 11.19%.

General Procedure for Synthesis of 5-Aryl-2-oxazolidinones (7). A solution of **3** (0.35—0.45 mmol) in xylene (8 ml) was heated under reflux for 10 h. After removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene–ether gave **7**.

A Stereoselective Total Synthesis of Methyl α-DL-Daunosaminide

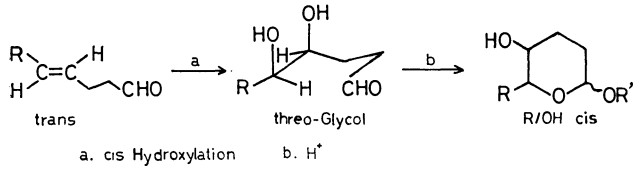
Isao IWATAKI, Yasuo NAKAMURA, Koji TAKAHASHI, and Takeshi MATSUMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

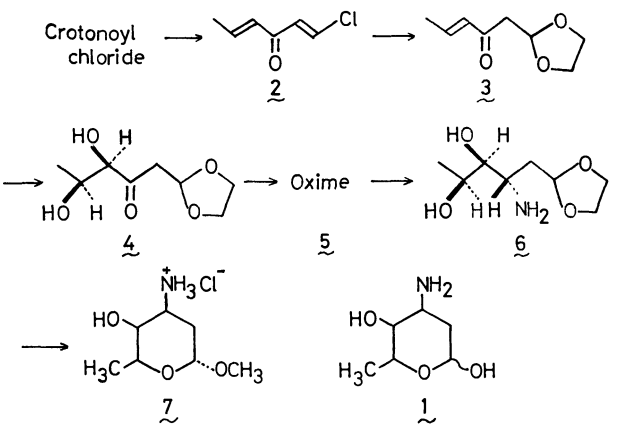
(Received December 4, 1978)

Synopsis. Starting from crotonoyl chloride, methyl α-DL-daunosaminide was synthesized through the *cis* hydroxylation of a key intermediate, 1,1-ethylenedioxy-4-hexen-3-one, followed by oxymation, catalytic hydrogenation (Pt, AcOH), and treatment with MeOH/HCl.

Daunosamine (**1**) is the amino sugar moiety of the two antibiotics daunomycin[1] and adriamycin.[2] Both of these antibiotics, but adriamycin in particular, have attracted attention as promising anticancer agents. A number of syntheses of daunosamine have previously been described.[3–7] However, all these syntheses were carried out, starting from naturally occurring hexoses, through rather lengthy routes. In previous papers[8] we reported the synthesis of some deoxyhexoses from unnatural compounds through 2-ethoxy-6-methyl-3,4-2*H*-dihydropyran as a key intermediate. We wish to report here a new route to daunosamine as racemic methyl glycoside hydrochloride, starting from crotonoyl chloride and vinyl chloride.[9] The success of the present synthesis suggests the possibility of extending the new route as a general synthetic method for 2,6-dideoxyhexoses.



First, crotonoyl chloride was converted, by means of the Friedel-Crafts reaction with vinyl chloride, to 1-chloro-1,4-hexadien-3-one (**2**). α-Keto acetal, **3**, was obtained by the reaction of **2** with 1,2-ethanediol in the presence of potassium carbonate at −10 °C. The *cis* hydroxylation ($KMnO_4$, acetone, −40 °C) of **3** afforded dihydroxy derivative, **4**, which was transformed to the oxime, **5**, and was then hydrogenated over a Pt catalyst under acidic conditions (AcOH), according to the Roth method.[10] The amino diol, **6**, thus obtained was treated with methanolic hydrogen chloride to give methyl pyranoside, **7**. The 3-epimer of **7** was not isolated. The following NMR data (pyridine-d_5) indicate the **7** stereostructure. The signals around δ 2.45 ppm (q, 2H, J=9 and 3 Hz) are attributable to the C_2 protons. They are practically magnetically equivalent (the AA′ part of the AA′XY system) and couple to the anomeric proton H_1 (δ 4.78, t) with J=3 Hz. This establishes the equatorial configuration of H_1, therefore, **7** is the α-anomer. The coupling constant $(J_{2a,3a}+J_{2e,3a})/2$=9 Hz[11] was confirmed by the double-resonance technique, showing the presence of the axial proton at C_3. The broad triplet (1H, J=3 Hz) at δ 4.43 indicates the equatorial configuration of H_4, and $J_{4,5}$=3 Hz was acertained by the spin decoupling. Since the C_4–C_5 moiety has the *threo* configuration, the methyl group at C_5 is equatorial.



Experimental

All the melting points and boiling points are uncorrected. The IR spectra were recorded on a JASCO IR-S spectrophotometer. The NMR spectra were measured on a Varian A-60 instrument. For column chromatography, Merck silica gel (0.08 mm) was used, while for TLC, Wakogel B-5 was utilized. The starting material, 1-chloro-1,4-hexadien-3-one (**2**), was prepared by a modification of the Kochetkov method,[12] using vinyl chloride instead of acetylene, in a yield of 53%.

*1,1-Ethylenedioxy-4-hexen-3-one (**3**).* Into a suspension of potassium carbonate (65 g, 0.47 mol) in a mixture of water (20 cm³) and 1,2-ethanediol (100 cm³, 1.8 mol), a solution of **2** (50 g, 0.38 mol) in tetrahydrofuran (50 cm³) was stirred at −10 °C. The mixture was stirred for a further 3 h at this temperature and then for 24 h at room temperature. The reaction mixture was poured into water and extracted with petroleum ether, and the extract was dried (Na_2SO_4). The subsequent evaporation of the solvent and distillation (78—82 °C/2 mmHg**) of the residue gave **3** as a colorless liquid (8.5 g, 14%); 2,4-dinitrophenylhydrazone mp 121 °C. Found: C, 61.42; H, 7.71%. Calcd for $C_8H_{12}O_3$: C, 61.53; H, 7.69%.

*1,1-Ethylenedioxy-4,5-dihydroxyhexan-3-one (**4**).* The acetal **3** (10 g, 0.064 mol) in acetone (100 cm³) was cooled to −40 °C, and then, to the solution a cold solution of potassium permanganate (12 g, 0.075 mol) in water (400 cm³) and acetone (200 cm³) was added. After the manganese dioxide formed had been filtered off, the solvent was distilled off, the residue was poured into water and extracted with ethyl acetate, and the organic phase was dried. The removal of the solvent *in vacuo* gave a colorless oil, which was subsequently purified by column chromatography on silica gel (150 g), with ethyl acetate–benzene (1 : 1) as an eluent, to give **4** (4.3 g, 35%). Found: C, 50.52; H, 7.38%. Calcd for $C_8H_{14}O_5$: C, 50.50; H, 7.73%. NMR ($CDCl_3$) δ=1.2 (3H, d, J=7 Hz), 3.2 (2H, d, J=5 Hz), 3.6 (4H, m), 4.2—4.44 (2H, m),

** 1 mmHg≈133.322 Pa.

5.4 (1H, t, J=5 Hz) and 5.9 ppm (2H, s); IR (neat) 3440 (OH) and 1718 cm^{-1} (C=O).

*1,1-Ethylenedioxy-3-hydroxyimino-4,5-hexanediol (**5**).* To a mixture of sodium ethoxide (0.5 g, 0.0073 mol) and hydroxylamine hydrochloride (0.7 g, 0.01 mol) in 50 cm^3 of ethanol, **4** (2.3 g, 0.012 mol) was added at room temperature, after which the soln was stirred for 24 h. After the solvent had been removed *in vacuo*, the oxime, **5**, was extracted with ether and the solvent was evaporated to give a colorless oil (1.4 g, 56%). This was used in the subsequent reaction without purification. IR (neat) 3120 and 1030 cm^{-1} (N–OH).

*1,1-Erhylenedioxy-3-amino-4,5-hexanediol (**6**).* The oxime, **5** (2 g, 0.0098 mol), was hydrogenated over the Adams catalyst (0.2 g of PtO_2) in 30 cm^3 of acetic acid at atmospheric pressure for 12 h at room temperature.[9] Then the catalyst was filtered off, and the solvent was removed *in vacuo*. The residue was dissolved in a mixed solvent of water (1.2 dm^3) and methanol (400 cm^3), and the solution was passed through Amberlite IR-400 to remove the residual acetic acid. The subsequent evaporation of the solvent under reduced pressure left 1.5 g (81%) of crystalline **6**, which was recrystallized from 1-propanol–ether as colorless crystals. Mp 111—112 °C. Found: C, 50.06; H, 8.75; N, 7.63%. Calcd for $C_8H_{17}NO_4$: C, 50.25; H, 8.96; N, 7.35%. IR (Nujol) 1705 (NH) and 1135 cm^{-1} (acetal).

*Methyl α-DL-Daunosaminide Hydrochloride (**7**).* The amine, **6** (0.3 g, 0.016 mol), was dissolved in 2%-methanolic hydrogen chloride (9 cm^3), after which the soln was stirred for 24 h at 40 °C under a N_2 stream. The reaction mixture was then cooled, and the excess hydrochloric acid was neutralized with sodium hydrogen carbonate. After the evaporation of the filtered solution *in vacuo*, the residue was extracted with ethanol. The solvent was distilled off, and the residual solid was recrystallized from 1-propanol to afford 0.28 g (84%) of colorless crystals. Mp 161—163 °C. Found: C, 42.80; N, 7.84; N, 7.14%. Calcd for $C_7H_{16}NO_3Cl$: C, 42.53; H, 8.10; N, 7.09%. NMR (pyridine-d_5) δ=4.78 (1H, t, J=3 Hz), 4.43 (1H, br s), 4.32 (1H, m), 3.87 (1H, dq, J=1.5 and 6 Hz), 3.20 (3H, s), 2.45 (2H, q, J=9 and 3 Hz) and 1.39 (3H, d, J=6 Hz); IR (Nujol) 3300 (OH), 1620, 1580, 1510 (NH_3^+), 1200, 1130, 1080, 1060, and 980 cm^{-1}.

Preparation of Anhydrous *N,N'*-Dicyclohexylalloxan and Its Use in Dehydration

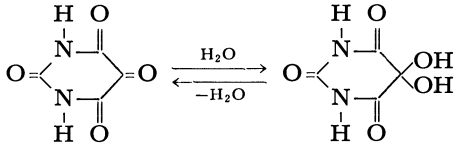
Takeshi ENDO and Makoto OKAWARA*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received December 15, 1978)

Synopsis. Anhydrous *N,N'*-dicyclohexylalloxan has been prepared and used as a dehydrating agent for carboxylic acids in the esterification of carboxylic acids with alcohols.

Alloxan(A), a vicinal carbonyl compound (reducton), is known to play an important role in biological oxidation-reduction systems in the same way as ascorbic acid. The central carbonyl, activated by the two adjacent carbonyl groups, is reactive such that it readily combines with one mole of water to form the hydrate (A-hydrate).[1] The photochemical reactions of the A-hydrate have been reported.[2,3]

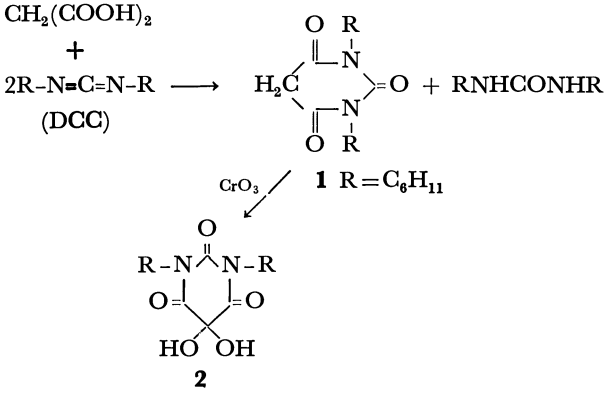


(A) (A-hydrate)

The study of alloxan has been extended especially in the redox system mediated by the alloxan radical produced photochemically or chemically from the A-hydrate.[4,5]

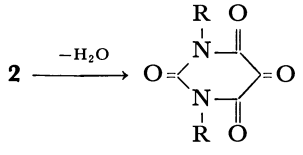
This paper describes the synthesis of anhydrous *N,N'*-dicyclohexylalloxan and the use of the hydrate in the esterification of carboxylic acids with alcohols.

A and A-hydrate are soluble in water and alcohols, but insoluble in common organic solvents. The preparation of *N,N'*-dialkylalloxan was directed to achieving soluble alloxan in general organic solvents. Alloxans may be prepared by oxidation of the corresponding barbituric acids, which are obtained from diethyl malonate and ureas, using chromium trioxide.[6] *N,N'*-Dicyclohexyl barbituric acid(**1**) was prepared by the reaction of malonic acid and dicyclohexylcarbodiimide (DCC).[7] *N,N'*-Dicyclohexylalloxan (**2**) as the hydrate was obtained by the oxidation of **1** with chromium trioxide at room temperature in a mixture of acetic acid and water, and identified by IR and elemental analyses.



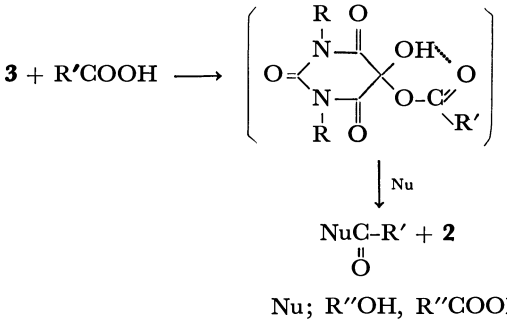
2

Anhydrous alloxan was prepared by heating alloxan hydrate *in vacuo* (4 mmHg†) at 150 °C.[8] Anhydrous *N,N'*-dicyclohexylalloxan was prepared by 1) heating the hydrate at reduced pressure (170—180 °C/1 mmHg), 2) treatment with acetic anhydride at 80 °C or 3) treatment with DCC at room temperature. Synthetically method 1 is the most convenient, since for methods 2 and 3 a process is needed to separate **3** from the reaction mixture. In the IR spectrum of **3** the OH group absorption (3450 cm^{-1}) disappeared completely and was accompanied by the appearance of a new absorption band of the C–O group at 1760 cm^{-1}.



3

Compound **3** thus obtained was examined in terms of its suitability as a dehydrating agent. Anhydrous alloxan (A) is not suitable as a dehydrating agent because of possible side reactions. Acetic acid was treated with equimolar quantities of **3** in tetrahydrofuran (THF) at room temperature to give quantitatively acetic anhydride together with **2**. The esterification of carboxylic acids with alcohols using **3** was conducted in THF at room temperature. The corresponding esters were obtained in reasonable yields as shown in Table 1. In the condensation of carboxylic acids and amines the same method is impossible to use since **3** reacts preferentially with amines.[9] The reaction may proceed *via* an activated intermediate of the carboxylic acid as shown below:



Nu; R″OH, R″COOH

Several anhydrous inorganic salts (*e.g.* Na_2SO_4, $MgSO_4$) have been used as dehydrants. **3** is novel example of a dehydrating agent for ester formation which can be reproduced by heating **2** and can be used repeatedly.

† 1 mmHg=133.322 Pa.

Table 1. Esterification of carboxylic acids with alcohols by anhydrous *N,N*-dicyclohexylloxan (**3**)

Carboxylic acid (R′)	Alcohol (R″)	Yield of isolated ester (%)
CH_3	CH_3CH_2	55
CH_3	$CH_2C_6H_5$	60
CH_3	$C_{12}H_{25}$	53
C_6H_5	CH_3CH_2	40

Experimental

The synthesis of *N,N′*-dicyclohexylbarbituric acid(**1**) (mp 207—208 °C) was prepared from DCC and malonic acid.[7]

Preparation of N,N′-*Dicyclohexylalloxan (**2**).* To a solution of chromium trioxide (15 mmol) in a mixture of water–acetic acid (15 ml) (1/4, v/v) was added a solution of **1** (10 mmol) at 30 °C. After stirring for 2 h at 25—30 °C, the reaction mixture was poured into water and then the precipitate filtered and dried under vacuum. The alloxan was recrystallized from carbon tetrachloride. Yield; 90%, mp 212—214 °C. IR (KBr, cm^{-1}): 3370 (ν_{OH}); 1690 (ν_{CO}). Found: C, 59.20; H, 7.47; N, 8.62%. Calcd for $C_{16}H_{24}O_5N_2$: C, 59.24; H, 7.46; N, 8.64%.

Preparation of Anhydrous N,N′-*Dicyclohexylalloxan (**3**).* **3** was synthesized by three methods: 1) **3** was sublimated by heating **2** at 170—180 °C/1 mmHg for 15 h (97% yield). 2) A solution of **2** (10 mmol) in acetic anhydride (30 ml) was heated at 80 °C for 5 h. After the excess acetic anhydride was removed under vacuum, the residue was recrystallized from carbon tetrachloride to give **3** (90% yield). 3) To a solution of **2** (10 mmol) in THF (30 ml), DCC (10 mmol) was added at room temperature and the reaction mixture stirred at 40 °C for 7 h. The *N,N′*-dicyclohexylurea was filtered and the THF evaporated under vacuum. The residue was recrystallized from carbon tetrachloride to give **3′** (85 yield). Mp 229—231 °C. IR (KBr, cm^{-1}): 1760, 1710, 1690 (ν_{CO}). UV (THF, nm): 420, 257 (λ_{max}). Found: C, 62.70; H, 7.59; N, 9.45%. Calcd for $C_{16}H_{22}O_4N_2$: C, 62.75; H, 7.52; N, 9.48%.

*Reaction of **3** with Acetic Acid.* To a solution of **3** (30 mmol) in THF (30 ml) was added acetic acid (33 mmol) at room temperature and the reaction mixture was stirred at room temperature for 7 h. The THF was removed and the residue was distilled to give acetic anhydride quantitatively and **2** was recovered from the residue.

*Esterification of Carboxylic Acids with Alcohols by the Use of **3**.* To a solution of **3** (10 mmol) in THF (30 ml) was added the carboxylic acid at room temperature; alcohol (11 mmol) was then added to the reaction mixture. After the mixture was stirred at room temperature for 10 h, the THF was evaporated. The obtained residue was distilled to give the corresponding ester as shown in Table 1, and **2** was obtained quantitatively from the residue after distillation.

Synopsis. Vinyl acetate gives selectively (*S*)-2-acetoxypropanal in 10—24% optical yields by the asymmetric hydroformylation with μ,μ'-dichlorotetracarbonyldirhodium-(—)-DIOP. (*R*)-Benzylmethylphenylphosphine and neomenthyldiphenylphosphine give low optical yields. The reaction depends essentially on the DIOP/rhodium ratio. Just 2 mol or more of (—)-DIOP per g-atm of rhodium is required for the asymmetric reaction. Other reaction variables (temperatures and pressures of hydrogen and carbon monoxide) have minor effects.

More recently, a chiral phosphine–rhodium complex system has been shown to be effective for the asymmetric hydroformylation of olefins.[1] These studies have been mainly concentrated on styrene and butenes. Styrene gives 2-phenylpropanal as the major product in moderately high optical yields up to 44%[1b] but such 1-alkenes as 1-butene and 1-octene give branched chain-aldehydes with optically active carbons as minor products in only low optical yields. Little attention, however, has been paid to the asymmetric hydroformylation of *O*- and *N*-vinyl compounds, which are selectively formylated on the inner carbon adjacent to the oxygen and nitrogen to produce aldehydes with an optically active carbon.[2] Thus, vinyl acetate gives 2-acetoxypropanal in an excellent yield. Compared with simple olefins, *O*- and *N*-vinyl compounds appear to be more suitable for the asymmetric hydroformylation.

The present study will deal with the asymmetric hydroformylation of vinyl acetate using a chiral phosphine–rhodium complex, and the effects of several reaction variables (ligands, temperatures, and pressures of hydrogen and carbon monoxide) will be described in some detail.

Experimental

All the ^{1}H NMR spectra were recorded on a JEOL JNM-PM-60 spectrometer, using Me_4Si as the internal standard. The optical rotations were measured on a JASCO model DIP-180 automatic polarimeter using samples as a neat liquid. The GPC analysis was carried out on a Shimadzu model GC-3B apparatus equipped with a column (3 mmϕ, 3 m) packed with diethylene glycol adipate polyester on Chromosorb.

Materials. The vinyl acetate was refluxed over active calcium sulfate for one or two days, distilled, and stored in a refrigerator. Neomenthyldiphenylphosphine(abbreviated as nmdpp),[3] (*R*)-benzylmethylphenylphosphine(bmpp),[4] 2,2-dimethyl-4,5-bis(diphenylphosphino)-1,3-dioxolane ((—)-DIOP),[5] and μ,μ'-dichlorotetracarbonyldirhodium[6] were prepared according to the methods in the literature.

Reaction Procedure. The reaction was carried out in a manner similar to that described in a previous paper.[1a] The 2-acetoxypropanal was separated by vacuum distillation (bp, 65—68 °C/30 Torr), and then the optical rotation was measured. The 2- and 3-acetoxypropanal were identified by GPC and ^{1}H NMR analysis. 2-Acetoxypropanal, ^{1}H NMR ($CDCl_3$): δ (ppm) 1.35 (d, 3H, J=7.5 Hz, CH_3), 2.15 (s, 3H, CH_3), 4.95 (q, 1H, J=7.5 Hz, CH), 9.94 (s, 1H, CHO). 3-Acetoxypropanal, ^{1}H NMR ($CDCl_3$): δ (ppm) 2.03 (s, 3H, CH_3), 2.83 (t, d, 2H, J_t=6, J_d=1 Hz, CH_2), 9.98 (t, 1H, J=1 Hz, CHO).

Reduction of 2-Acetoxypropanal. Optically active 2-acetoxypropanal, whose configuration and maximum rotation are unknown, was reduced to a known compound, (*S*)-1,2-propanediol ($[\alpha]_{D\ max}$=+16.28°[7]): To a suspension of lithium aluminum hydride (3 g) in tetrahydrofuran (20 ml) was added, drop by drop, a 2-acetoxypropanal (5 ml, $[\alpha]_D$=—11.26°) solution in tetrahydrofuran (20 ml), and then the mixture was refluxed for 4 h. The resultant solution was hydrolyzed with 1M HCl (30 ml), and the precipitates thus formed were filtered off. The filtrate was dried with disodium sulfate, concentrated, and analyzed by GPC. $[\alpha]_D$=+2.35°; optical yield, 14.4%.

Results and Discussion

Under the typical oxo reaction conditions (120 °C and CO/H_2=50/50 atm) using a rhodium catalyst such as $[RhCl(CO)_2]_2$, vinyl acetate is readily hydroformylated to give 2-acetoxypropanal selectively. The reaction is completed in less than 1 h. A chiral phosphine–$[RhCl(CO)_2]_2$ system is effective for the asymmetric hydroformylation. The reaction was examined in some detail by changing several reaction variables, using (—)-DIOP, (*R*)-bmpp, and nmdpp as chiral phosphines. Some typical results are summarized in Table 1.

$$AcOCH{=}CH_2 \xrightarrow[[RhL^*]]{CO,\ H_2} AcOC^*(CHO)-CH_3 + AcOCH_2CH_2CHO$$

A tertiary phosphine–rhodium catalyst requires a much longer reaction time for completion than does $[RhCl(CO)_2]_2$; even at the DIOP/Rh ratio of 1.0, the product yields amounted to only 25% even after 18 h (Run 1). Such a retardation effect appears to come from the coordination of the phosphine to the rhodium, showing that the active catalyst species are $HRh(CO)_{3-n}L_n$ (n=1, 2, L=ligand) in place of $HRh(CO)_3$. The retardation effect appears to be largest with bmpp, followed by (—)-DIOP and nmdpp. The stereochemical control, however, is largest with (—)-DIOP. (*R*)-Bmpp and nmdpp are much less effective (Runs 13 and 14).

With (—)-DIOP, the (—)-DIOP/Rh ratio has a great effect on the stereoselectivity (see Runs 1—3), while the other reaction conditions are fixed. At the ratios of 1.0 and 1.5, the stereochemical control was not effective, giving only low optical yields, 0.8 and

1.7% respectively. A small increase in the ratio to 2.0, however, resulted in a larger stereoselectivity, an optical yield of up to 15%. Additional increases in the ratio, to 3.0, 4.0, and 8.0, however, showed no additional increase in the stereoselectivity. Thus, the (−)-DIOP/Rh ratio clearly has a critical point at 2.0 in the reaction. The efficiency of the DIOP ligand in some asymmetric reactions has been considered to come from its chelating ability as a bidentate,[8] and some metal complexes chelated by DIOP are known.[9] The results obtained here, however, appear to throw doubt on the idea that (−)-DIOP acts as a bidentate ligand in this reaction.

The active catalyst species for the asymmetric hydroformylation has normally been considered to be $HRh(CO)L_2$* rather than $HRh(CO)_2L$*, where L* is a chiral ligand.[1] Even at the (−)-DIOP/Rh ratio of 1.0, a retardation in the reaction rate was observed, showing that the rhodium catalyst is changed into the $HRh(CO)_2P\frown P$ species (DIOP is presented as P⌒P), still with no effect on the stereochemical control. Just one additional mole of (−)-DIOP per g-atm of rhodium seems to change the rhodium catalyst into another species, $HRh(CO)(P\frown P)_2$, with a conformational rigidity; this species is really active in the asymmetric reaction. Thus, the fact described above could be explained by considering that the DIOP acts as a monodentate ligand. A similar doubt has been suggested in the asymmetric hydrocarboxylation catalyzed by (−)-DIOP–palladium chloride.[10]

Among other reaction variables, such as the reaction temperatures and partial pressures of carbon monoxide and hydrogen, the reaction temperature has the largest effect on the stereoselectivity (see Runs 3, 5—8). Under fixed conditions, a (−)-DIOP/Rh ratio of 2.0 and an initial partial pressure of 50 atm of either carbon monoxide or hydrogen, a lower reaction temperature (70—140 °C) gave a higher stereoselectivity. At 70 °C the highest optical yield of 23% was achieved, but the reaction rate became remarkably slow. At lower temperatures (70—100 °C), 3-acetoxypropanal was produced as a by-product. Lowering the reaction temperature exhibits the same tendency as with styrene.[1]

The stereoselectivity of this reaction, however, was not significantly affected by changing the initial pressures of carbon monoxide and hydrogen. Under the fixed conditions, a (−)-DIOP/Rh ratio of 2.0 and at 120 °C, the effects of the pressures on the stereoselectivity were examined. When the pressure of hydrogen was fixed at 50 atm, the stereoselectivity was almost unchanged, giving 15% optical yields at 20—50 atm of carbon monoxide, but it decreased to 12% at 65 atm (Runs 3, 9, and 10). When the pressure of carbon monoxide was fixed at 50 atm, the stereoselectivity was the largest (15% optical yield) at 50 atm of hydrogen, but decreased to 13 and 11% at higher (70 atm) and lower (20 atm) pressures of hydrogen respectively (Runs 3, 11, and 12). Accordingly, the pressures have a minor effect on the reaction of vinyl acetate.

In the present study, vinyl acetate shows a larger stereoselectivity than any other olefins except styrene. The largest stereoselectivity with styrene has been considered to arise from the conformational rigidity concerned with the phenyl group,[1a] though the mechanism of the asymmetric induction is not clear. With vinyl acetate, the acetoxyl group seems to play some role in the asymmetric induction.

The present work was partially supported by a grant-in-Aid for Development Scientific Research and for Scientific Research from the Ministry of Education.

Studies on the Syntheses of Sesquiterpene Lactones. III. Improved Synthesis of Vulgarin

Masayoshi ANDO,* Kiyoshi TAJIMA, and Kahei TAKASE

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received January 18, 1979)

Synopsis. An improved synthesis of vulgarin is described. Epoxidation of 1-oxo-5α*H*,6β,11β*H*-eudesm-3-en-6,13-olide and successive treatment of the resulting epoxide with silica gel gave vulgarin. Oxidation of 1-oxo-5α*H*,6β,11β*H*-eudesm-3-en-6,13-olide with air or oxygen gas gave 4α-hydroperoxy-1-oxo-5α*H*,6β,11β*H*-eudesm-2-en-6,13-olide and 4β-hydroperoxy-1-oxo-5α*H*,6β,11β*H*-eudesm-2-en-6,13-olide, which were transformed into vulgarin and C_4-epivulgarin, respectively.

Many compounds with a γ-hydroxy α,β-unsaturated carbonyl moiety fused on various skeletons have been found in natural products. Since some of them have considerable biological activities as shown in abscisic acid and ecdysone, the synthesis of γ-hydroxy α,β-unsaturated carbonyl moiety has drawn much attention, several efficient methods for preparing this functional group being reported.[1] Vulgarin (**5**) is a typical example of the sesquiterpenes possessing a γ-hydroxy α,β-unsaturated carbonyl group.[2] Reports have been given on the synthesis of vulgarin[3,5] and its α-methylene γ-lactone derivative, arglanine.[4,5] In connection with the general synthesis of γ-hydroxy α,β-unsaturated carbonyl moiety we have examined a more efficient synthesis of vulgarin.

The starting material is a β,γ-unsaturated acetal (**1**) prepared from the corresponding α,β-unsaturated ketone.[5] Treatment of **1** with boiling 50% aqueous acetic acid gave the desired β,γ-unsaturated ketone (**2**)[2,4] in a quantitative yield. Methods for the preparation of γ-hydroxy α,β-unsaturated ketones *via* the corresponding β,γ-unsaturated ketones are limited[1] probably because of difficulty in the preparation of the intermediates.[6] Since the β,γ-unsaturated ketone (**2**) was obtained in an excellent yield, the synthesis of vulgarin *via* intermediate (**2**) was examined in two procedures.

Epoxidation of **2** with *m*-chloroperbenzoic acid gave an epoxy ketone (**4**) in a quantitative yield. The stereochemical assignment of the epoxide ring of **4** is based on the consideration that the epoxidation proceeds from the less hindered α-side. **4** was transformed into vulgarin in 90% yield by treatment with silica gel TLC for 1 h.

During the course of attempted purification of **2** by TLC of silica gel we observed that this compound gradually turned into two kinds of more polar substances at the surface of silica gel. In order to examine the transformation, **2** was allowed to stand on the surface of silica gel in TLC on exposure to air for 12 days to give 4α-hydroperoxide (**7**) in a 46% yield and 4β-hydroperoxide (**8**) in a 13% yield accompanied by vulgarin in a 9% yield. The structure of **7** and **8** were deduced from the analyses of their NMR spectra. The assigned stereochemistry at C_4 in **7** and **8** was unambiguously demonstrated by their conversion into vulgarin and C_4-epivulgarin (**6**) in quantitative yields by treatment with KI in aqueous acetic acid.

The oxidation reaction of **2** by molecular oxygen in solution was also investigated. Since the γ-lactone moiety was considered to be sensitive in autoxidation in strong basic conditions, we chose neutral or slightly acidic[7] conditions. The β,γ-unsaturated ketone (**2**) gave vulgarin by bubbling oxygen gas into 50% aqueous acetic acid solution at refluxing temperature. This reaction was very slow at room temperature but proceeded in a moderate rate by addition of active charcoal[8] into the reaction mixture. In this case the major product was not vulgarin but the corresponding hydroperoxide (**7**). In MeOH and DMF solutions, the oxidation reaction of **2** by molecular oxygen in the presence of active charcoal proceeded in the same manner as in 50% aqueous acetic acid solution. The results are summarized in Table 1. The resulting hydroperoxides (**7**) and (**8**) were transformed into vulgarin and C_4-epivulgarin, respectively, in quantitative yields.

The acetal (**1**) also gave vulgarin (**5**) in a 50% yield by bubbling oxygen gas in boiling 50% aqueous acetic acid solution. Yamakawa *et al.* reported a similar reaction in an acetal (**3**), but did not mention the reaction path.[4] These reactions probably proceeded through autoxidation of the corresponding β,γ-unsaturated ketones formed under the reaction conditions and successive decomposition of the resulting hydroperoxides to the corresponding alcohols.

Experimental

All the melting points were uncorrected. IR spectra were determined on Shimadzu IRG-1 and Nihonbunko IRA-2 spectrometers. NMR spectra were recorded on a Hitachi R-24 spectrometer in $CDCl_3$ containing TMS as an internal standard.

1-Oxo-5αH,6β,11βH-eudesm-3-en-6,13-olide (2) from 1,1-Ethylenedioxy-5αH,6β,11βH-eudesm-3-en-6,13-olide (1). A solution of **1** (800 mg, 2.74 mmol) in 50% AcOH aq (76 ml) was refluxed for 1 h and 15 min under N_2, cooled and poured into satd. NaCl aq soln. The mixture was worked up as usual to give 677 mg (100%) of **2**, (mp 139 °C).

a) The reactions were stopped at the time when **2** disappeared in the reaction mixture by TLC analysis except in the case of run i. b) Active charcoal (powder).

*3α,4α-Epoxy-1-oxo-5αH,6β,11βH-eudesman-6,13-olide (**4**).* A mixture of **2** (47 mg, 0.19 mmol) and *m*-chloroperbenzoic acid (33 mg, 0.19 mmol) in CH_2Cl_2 (3 ml) was allowed to stand at room temperature for 75 h. The mixture was worked up as usual to give 50 mg (100%) of spectroscopically pure **4** as a crystalline material, which was recrystallized from ether to give prisms, mp 151 °C. IR (KBr): 1770 and 1712 cm^{-1}. NMR: δ 1.24 (3H, d, J=6.4 Hz, C_{11}–Me), 1.27 (3H, s, C_{10}–Me), 1.59 (3H, s, C_4–Me), 2.05 (1H, d, J=11.5 Hz, C_5–H), 2.79 (1H, d, J=1.6 Hz, C_2–H), 2.83 (1H, d, J=4.0 Hz, C_2–H), 3.25 (1H, dd, J=1.6 and 4.0 Hz, C_3–H), 4.06 (1H, broad t, J=11.5 Hz, C_6–H). Found: C, 67.82; H, 7.71%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

*Vulgarin from **4**.* The $CHCl_3$ solution of **4** (50 mg, 0.19 mmol) was impregnated into TLC of silica gel (Merck GF_{254}, thickness 0.25 mm, 20 cm×20 cm sheet), which was developed by dipping in AcOEt–$CHCl_3$ (1:1) for 1 h. The most polar band was collected and extracted with acetone to give 45 mg (90%) of vulgarin.

*Air Oxidation of **2** at the Surfaces of Silica Gel TLC.* The $CHCl_3$ solution of **2** (21 mg, 0.08 mmol) was impregnated into TLC of silica gel (Merck GF_{254}, thickness 0.25 mm, 20 cm×10 cm sheet), which was developed by dipping in AcOEt–$CHCl_3$ (1:1). The TLC plate was dried and allowed to stand at room temperature exposed to air for 12 days. The black band monitored by an UV lamp was collected from TLC and extracted with acetone to give 22 mg of oil, which was shown to be a 10:3 mixture of **7** and **8** from the analysis of the NMR spectrum. This was purified by preparative TLC [Merck silica gel GF_{254}, thickness 0.25 mm, EtOAc:$CHCl_3$ (1:1)]. The first band (R_f 0.50) gave 3 mg (13%) of **8**, which was recrystallized from ether to give colorless prisms; mp 178 °C. IR (KBr): 3360, 3300, 1765, 1745, and 1682 cm^{-1}. NMR: δ 1.21 (3H, d, J=6.8 Hz, C_{11}–Me), 1.32 (3H, s, C_{10}–Me), 1.67 (3H, s, C_4–Me), 2.14 (1H, d, J=11.6 Hz, C_5–H), 4.24 (1H, m, C_6–H), 5.98 (1H, d, J=10.2 Hz, C_2–H), and 6.76 (1H, d, J=10.2 Hz, C_3–H). The second band (R_f 0.40) gave 11 mg (46%) of **7**, which was recrystallized from ether to give colorless prisms; mp 175 °C. IR (KBr): 3320, 1770, 1748, 1677, and 1660 cm^{-1}. NMR: δ 1.22 (3H, d, J=6.4 Hz, C_{11}–Me), 1.25 (3H, s, C_{10}–Me), 1.48 (3H, s, C_4–Me) 2.85 (1H, d, J=11.6 Hz, C_5–H), 4.13 (1H, dd, J=8.0 and 11.6 Hz, C_6–H), 6.02 (1H, d, J=10.6 Hz, C_2–H), 6.72 (1H, d, J=10.6 Hz, C_3–H). Found: C, 63.86; H, 7.41%. Calcd for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19%.

*Oxidation of **2** by Molecular Oxygen in MeOH in the Presence of Active Charcoal.* Oxygen gas was bubbled into a solution of **2** (20 mg, 0.08 mmol) in MeOH (3 ml) in the presence of active charcoal (20 mg) at room temperature for 87 h. The mixture was worked up as usual to give 22 mg of oil, which was separated by TLC (Merck silica gel GF_{254}, thickness 0.25 mm, EtOAc:$CHCl_3$=1:1) to give 16 mg (71%) of **7**, 3.5 mg (16%) of **8**, and 2.5 mg (12%) of vulgarin.

*Vulgarin from **7**.* A mixture of **7** (9 mg, 0.032 mmol), KI aq soln (KI 30 mg, H_2O 1.5 ml), AcOH (0.1 ml), and $CHCl_3$ (0.5 ml) was stirred for 2 h at room temperature. The mixture was worked up as usual to give 8.5 mg (100%) of vulgarin.

*C_4-Epivulgarin from **8**.* **8** (9 mg, 0.032 mmol) was treated as mentioned above to give 8.5 mg (100%) of C_4-epivulgarin.

*Oxidation of **1** by Molecular Oxygen in Boiling 50% AcOH Aq Soln.* Oxygen gas was bubbled into a solution of **1** (30 mg, 0.10 mmol) in 50% AcOH aq soln (3 ml) under refluxing for 3 h, cooled and poured into satd. NaCl aq soln. The mixture was worked up as usual to give an oily crude product, which was chromatographed over silica gel (Merck, <230 mesh, 1.5 g) and eluted with $CHCl_3$ to give 13.5 mg (50%) of vulgarin.

Phase Transfer Catalyzed Reaction of Organic Thiocyanates with Hydroxide Ion

Yumihiko YANO, Akira KURASHIMA, and Waichiro TAGAKI*

Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received February 26, 1979)

Synopsis. The reactions of 9-fluorenyl, phenacyl, benzhydryl, and benzyl thiocyanates (or the corresponding bromides with sodium thiocyanate) with hydroxide ion under phase transfer conditions afforded 9,9′-bifluorenylidene, 2,3-dibenzoylthiirane, thiobenzophenone and dibenzyl disulfide, respectively.

It is well known that carbanion-forming reactions are accelerated by cationic micelles.[1] Favored formation of carbanion is also known for phase transfer catalyzed reactions,[2] including our own works.[3–5] Recently, we have demonstrated that the mechanism of hydrolysis for esters bearing α-hydrogen changes from addition-elimination to elimination-addition mechanism under micellar conditions.[6] This finding has led us to check the reaction in the title.

In this paper, we describe the reactions of organic thiocyanates with hydroxide ion in the two-phase system, together with the reactions of the corresponding organic bromides with hydroxide ion in the presence of sodium thiocyanate, in the hope of finding a convenient method for the preparation of thiocarbonyl compounds.

Results and Discussion

Thiocarbonyl compounds are usually prepared by the reaction of the corresponding carbonyl compounds or acetals with hydrogen sulfide in the presence of H^+ or by HCN elimination from organic thiocyanates with base.[7] In these reactions anhydrous conditions are usually required. The present reaction was carried out by stirring two phases of organic thiocyanates dissolved in CH_2Cl_2 or benzene and aqueous sodium hydroxide in the presence of hexadecyltrimethylammonium bromide (CTABr) as the phase transfer catalyst. Other catalysts, such as methyltrioctylammonium chloride and benzyltriethylammonium bromide, did not make much difference in the yields of products. The reactions could also be performed by using organic bromides and sodium thiocyanate to give the corresponding organic thiocyanates *in situ* during the reaction. The results are summarized in the Table.

The run 1 indicates the formation of 9,9′-bifluorenylidene in more than 90% yield. The same result was obtained by using 9-bromofluorene and sodium thiocyanate. Although 9-bromofluorene is known to give 9,9′-bifluorenylidene with base,[8] the present reaction was found to be much slower in the absence of sodium thiocyanate than in its presence. Thus, the reaction of 9-bromofluorene is considered to proceed through the formation of 9-thiocyanofluorene.

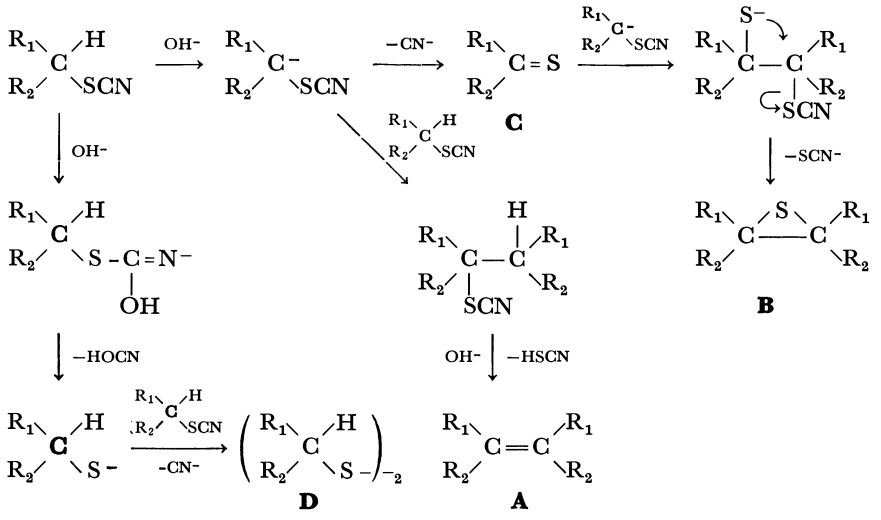
The episulfide obtained in the reaction of benzoylmethyl thiocyanate (run 2) is presumably the *trans*-isomer since *trans*-1,2-dibenzoylethylene was obtained on treatment of the episulfide with triphenylphosphine. In the case of benzhydryl thiocyanate (run 3) thiobenzophenone was obtained in a quantitative yield. Finally, dibenzyl thiocyanate gave disulfide (run 4).

These results may be tentatively accounted for by the following reaction scheme where **A**, **B**, **C**, and **D** stand for the products of runs 1—4, respectively.

TABLE 1. $R_1R_2CHSCN \xrightarrow[\text{CTABr, under } N_2]{\text{aq NaOH/}CH_2Cl_2 \text{ or benzene}}$ Products

Run	R_1	R_2	Conditions [NaOH]	Conditions Temp	Conditions Time	Products (yield)	
1			5 M[a]	r.t	2—3 h		(90—96%)
2	C_6H_5CO	H	5 M[a]	r.t	18 h	$C_6H_5COCH(S)CHCOC_6H_5$	(37—45%)
						Unidentified[c]	
3	C_6H_5	C_6H_5	15 M[b]	60—70 °C	2—3 days	$(C_6H_5)_2C{=}S$ [d]	(90%)
4	C_6H_5	H	15 M[a]	60—70 °C	24 h	$(C_6H_5CH_2S)_2$ [e]	(30%)

a) With CH_2Cl_2. b) With benzene. c) This was found in the aqueous layer and precipitated by acidifying the solution. d) The absorption spectrum (λ_{max} 595 nm, ε=167 in *i*-PrOH)[10] indicated a quantitative yield. e) Starting material was recovered (65%).



Scheme 1.

Carbene coupling can be conceivable for the formation of **A**.[9] However, no carbene adduct was obtained in the presence of cyclohexene or styrene. Episulfide (**B**) might be formed by the addition-elimination of SCN^- to **A**. However, 1,2-dibenzoylethylene (**A**) did not give the episulfide of run 2 in the presence of NaSCN under the present reaction conditions. In the case of run 4 to form **D**, the benzyl methylene may not be active enough to form carbanion under the present phase transfer conditions.

The above reaction is highly dependent on the structure of substrate and does not appear to be generally useful for synthetic purposes except for the run 3. In the run 3, benzhydryl bromide or thiocyanate can be readily converted to the thioketone in a quantitative yield, and this method may be generally applicable to the synthesis of diaryl thioketone.

Experimental

All melting points are uncorrected. The thiocyanates were prepared from the corresponding bromides and sodium thiocyanate in dry acetone.[10]

Phenacyl thiocyanate, mp 75 °C (from ether) (lit,[11] mp 75—76 °C), 70%.

9-Fluorenyl thiocyanate, mp 118—119 °C (from benzene), 78%.

Benzhydryl thiocyanate, mp 35 °C (from ether) (lit,[12] mp 35—36 °C), 93%. The other reagents were purchased from Tokyo Kasei Co.

Reaction of Thiocyanates with Hydroxide Ion under Phase Transfer Conditions. A mixture of the organic thiocyanate (10 mmol), CTABr (0.1 mmol) in CH_2Cl_2 (6 ml) and aqueous sodium hydroxide (2 ml) was stirred under N_2 atmosphere. The CH_2Cl_2 layer was separated and dried over Na_2SO_4. After CH_2Cl_2 was evaporated, the products were isolated by column chromatography (silica gel; benzene) for phenacyl and benzyl thiocyanates. 9,9′-Bifluorenylidene and 2,3-dibenzoylthiirane were isolated by recrystallization.

9,9′-Bifluorenylidene, mp 189—190 °C ($CHCl_3$–EtOH) (lit,[13] mp 188 °C).

2,3-Dibenzoylthiirane, mp 77—77.5 °C (CH_2Cl_2–EtOH); NMR ($CDCl_3$) δ 4.00 (2H, s), 7.3—8.1 (10H). Found: C, 71.30; H, 5.00; S, 11.80%. Calcd for $C_{16}H_{12}O_2S$: C, 71.64; H, 4.47; S, 11.95%.

Reaction of the Bromides with a Mixture of Sodium Thiocyanate and Sodium Hydroxide under Phase Transfer Conditions. A mixture of the bromides (5 mmol), CTABr (0.1 mmol) in benzene (5 ml) and an aqueous solution containing equal amount of sodium thiocyanate and sodium hydroxide was stirred at a given temperature. The product isolation was performed with the same procedure as in the above reaction of thiocyanates.

Desulfurization of 2,3-Dibenzoylthiirane by Triphenylphosphine. A mixture of 2,3-dibenzoylthiirane 0.32 g (1.2 mmol) and triphenylphosphine 0.5 g (1.9 mmol) in 10 ml of xylene was refluxed overnight. Xylene was evaporated and the residue was subjected to column chromatography (silica gel; benzene). *trans*-1,2-Dibenzoylethylene was obtained (0.24 g, 85%), mp 109 °C (lit,[14] mp 109—110 °C).

Kinetics of Reaction of 4-Substituted ω-Bromo-1-acetonaphthones with Aniline in Methanol

P. ANANTHAKRISHNA NADAR* and C. GNANASEKARAN
Postgraduate Department of Chemistry, V.H.N.S.N. College, Virudhunagar 626002, India

(Received September 25, 1978)

Synopsis. Rate constants have been measured for the reactions of 4-substituted ω-bromo-1-acetonaphthones with aniline in methanol at three temperatures. Arrhenius parameters, the enthalpies and the entropies of activation have been evaluated. The Hammett ρ value of 0.90 obtained at 40 °C indicates that a triangular transition state is more likely in this reaction.

In a previous paper[1] we reported a study of the reaction of 4-substituted ω-bromo-1-acetonaphthones with benzoate ion. The reaction between 4-substituted ω-bromo-1-acetonaphthones and aniline is now investigated with a view to examine the applicability of the Hammett equation.

Experimental

Materials. All the 4-substituted ω-bromo-1-acetonaphthones were prepared from the corresponding acetonaphthones by treatment with bromine. Their purities were ascertained by microanalysis and TLC.[2]

Methanol was dried and purified by the method of Lund and Bjerrum.[3]

Rate Measurement. The kinetic procedure was similar to that employed previously[4] and the rate constants were calculated using the suitable second-order rate equation when two moles of aniline are consumed per mole of the ω-bromoacetonaphthones.

Products. Standard solutions of the appropriate ω-bromo-1-acetonaphthone and aniline in methanol were mixed in the molar ratio 1:4 and maintained at the kinetic temperature until completion. After concentration of the solution to small volume under reduced pressure, the products precipitated were collected, and recrystallized. In all cases only the ω-anilinoacetonaphthone was formed. No other product was detected. Table 1 lists the compounds isolated, their mp and elemental analyses.

Results and Discussion

The reaction is found to be first order in each of the reactants. This was established by usual procedure with ω-bromo-1-acetonaphthone. Hence we assume that the reaction follows a two-stage mechanism, with the bimolecular rate-determining first stage.

$$RCOCH_2Br + PhNH_2 = RCOCH_2NHPh + HBr \quad (1)$$

$$HBr + PhNH_2 = PhNH_3^+Br^- \quad (2)$$

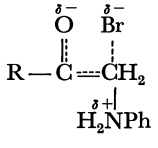
where R is 4-substituted 1-naphthyl group.

The kinetic data are presented in Table 2. The entropies of activation are found to be negative as expected for bimolecular reactions.[5] But they are more negative than those observed in reactions with benzoate ion.[4] This may be due to the fact that charge is dispersed in the transition state in the case of reactions with benzoate ion, while in the present case the charge is newly produced in the transition state.

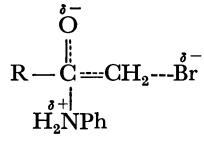
A linear relationship between the enthalpies and the entropies of activation has been realised. As explained by Exner,[6,7] the isokinetic relationship has also been examined through a plot of $\log k_1$ *versus* $\log k_2$ where k_1 and k_2 refer to the rate constants at temperatures T_1 and T_2 respectively with $T_1 > T_2$. From the slope (b=0.854) of the linear plot, the isokinetic temperature (β) is calculated to be 508 K, when T_1=323 and T_2=303 K.

The plot of $\log k/k_0$ at 40 °C against σ constants[8] of the 4-substituents in 1-naphthyl system is linear. The ρ value is 0.90 at 40 °C (excluding the result for 4-OCH_3). The correlation coefficient is 0.998 showing excellent Hammett fit.

Depending upon the mode of attack of aniline, one may consider transition states I and II in this reaction.

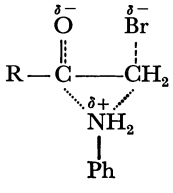


I



II

The formation of II may require very high ρ value in view of the ρ values of 3.2 and 2.76(2.24) found for the addition reactions of methoxide, and hydroxide ion, respectively, to substituted benzaldehydes.[9,10] The low ρ value observed in the reaction of 6-substituted ω-bromo-2-acetonaphthones[4] with aniline was ascribed to S_N2 attack of aniline at the methylene carbon. The ρ value of 0.90 calculated in the present case is significantly higher than the ρ values obtained in S_N2 displacement of substituted ω-bromoacetonaphtones at methylene carbon by different nucleophiles.[11] This may, therefore, point out that a triangular transition state III which is a hybrid between I and II is more likely in the present case.



III

The cause for the difference in the nature of the transition state in the present case compared to that in the case of 6-substituted ω-bromo-2-acetonaphthones may possibly be due to the partial inhibition of resonance between >C=O group and the ring as a result of the

ω-bromoacetyl group going out of coplanar configuration in the presence of *peri*-H interaction.[12)] Such inhibition of resonance is absent in the 2-series. The inhibition of resonance helps the carbonyl carbon to acquire more positive charge in 1-series than 2-series. Presumably this may be responsible for the operation of the transition state III in 1-series as compared to its counterpart in 2-series, thereby making the ρ value larger in the former case than in the latter case.[4)]

The authors dedicate this paper to Professor V. Baliah, Vice-Chancellor, Nagarjuna University, India on the occasion of his 60 th birthday and thank the managing board of V.H.N.S.N. College, Virudhunagar for the research facilities.

Configuration et Conformation en Solution de Quelques α-Hydroxyiminocetones Cycliques

Jean BERNADOU* et Monique BONNAFOUS

Laboratoire de Pharmacie Chimique, Université Paul Sabatier, 31077 Toulouse Cedex, France

(Manuscrit reçu le 9 Novembre, 1978)

Synopsis. Les dérivés α-hydroxyiminés des cyclanones en C_6 (un isomère), C_8 (deux isomères) et C_{12} (un isomère) ont tous la configuration *anti* ; la conformation est variable selon la taille du cycle: *s-cis* pour le terme en C_6, *s-cis* ou *s-trans* pour les termes en C_8, *s-trans* pour le terme en C_{12}.

Les configurations et les conformations en solution de certaines α-hydroxyiminocétones RC(NOH)COR′ sont encore discutées: ainsi pour la benzile-monoxime Z(R=R′=C_6H_5) Sadler[1] et Armand[2] proposent une conformation *s-cis*, Cherry[3] et Pigenet[4] une conformation *s-trans*; Kataoka[5] attribue à l'hydroxyimino-2 cyclohexanone (R–R′=–$(CH_2)_4$–) la configuration Z et Ferris[6] la configuration E.

Dans le cas des benzile-monoximes Z et E et de leurs dérivés dichlorés en para, nous avons déja démontré une conformation de type *s-trans*.[7]

En série cyclique nous reprenons ici les travaux de Kataoka sur les dérivés α-hydroxyiminés de la cyclohexanone (un seul isomère: **1**), la cyclooctanone (deux isomères: **2** et **3**) et la cyclododécanone (un seul isomère **4**); grâce à une analyse en spectroscopie infra-rouge complétée par l'étude de la complexation avec le Cu^{2+} et des réactions de réarrangement de Beckmann, nous confirmons pour **2** et **4** la configuration E annoncée en précisant leur conformation (*s-trans*) et nous proposons pour **1** et **3** une configuration E et une conformation *s-cis* (Tableau 1).

Spectroscopie Infrarouge. Des solutions de concentrations variées sont analysées (Tableau 2) : l'intensite relative des bandes O–H libre et O–H lié, les premieres augmentant au dépens des secondes par dilution, traduit pour les quatre dérivés étudiés l'existence de liaisons hydrogènes intermoléculaires; celles-ci n'intéressent pas le groupe carbonyle (une seule bande C=O libre) ; elles sont difficilement rompues par dilution pour **1** et **3** et beaucoup plus facilement pour **2** et **4**. Ceci correspond (Tableau 2):

— dans le premier cas à des constantes d'association élevées (K_2=750 pour **1** et 110 pour **3**) que l'on peut rapprocher de celle de l'isonitrosocamphre E (K_2=150) de structure bien définie (*s-cis* E)[8,9] et qui se présente en solution suffisamment concentrée sous forme de dimères fermés A (Tableau 3); ces résultats

a) Intensité relative des bandes: F (fort), m (moyen), f (faible). b) Cuve de 0.5 mm. c) Cuve de 50 mm. d) En solution diluée dans CCl_4, l'autoassociation des molécules étudiées peut être décrite par les équilibres (13): $D_1+D_1 \rightleftarrows D_2$, $D_2+D_1 \rightleftarrows D_3$ et $D_{n-1}+D_1 \rightleftarrows D_n$ avec les constantes d'équilibre: $K_2=x_2/x_1^2$, $K_3=x_3/x_1x_2$ et $K_n=x_n/x_1x_{n-1}$ (dans ces expressions, x_1, x_2,⋯, x_n désignent les fractions molaires des monomolécules D_1, des dimères D_2 et des différents polymères). Pour **1** et **3** no us avons vérifié expérimentalement que $K_n=K_3=0$.

Tableau 4. Réarrangement de Beckmann

Produit	Réactif	Produit final	Référence
1	$C_6H_5SO_2Cl$ + alcali dil.	$NC(CH_2)_4COOH$	6
	PO_4H_3 97%/H_2O	—	5
2	PO_4H_3 97%/H_2O	$NC(CH_2)_6COOH$	5
3	PO_4H_3 97%/H_2O	$NC(CH_2)_6COOH$	5
4	PO_4H_3 97%/H_2O	$NC(CH_2)_{10}COOH$	5

nous permettent de proposer pour **1** et **3** une structure *s-cis E*.

— dans le deuxième cas les constantes d'association sont beaucoup plus faibles (K_2=10 pour **2** et 9 pour **4**), voisines de celle mesurée pour la diacétylmonoxime (K_2=5) qui se présente en solution suffisamment concentrée sous forme de polymères ouverts de type B ou C (Tableau 3) et de structure *s-trans E* bien définie.[9] Ces résultats nous permettent de proposer pour **2** et **4** une structure *s-trans E*.

Complexation avec le Cuivre. Seules les α-hydroxyiminocétones cycliques *s-cis E* peuvent donner avec l'ion cuivrique Cu^{2+} un complexe vert (Tableau 3)[10]; c'est ce que l'on observe pour **1** et **3**; pour **2** et **4**, il n'y a pas de complexation, on observe seulement la coloration bleu pale du réactif et on doit rejeter la structure *s-cis E*.

Réarrangement de Beckmann.[5,6,11] L'obtention d'un nitrile R–CN est caractéristique d'une configuration *E*, celle d'un isonitrile R–NC d'une configuration *Z*. Pour les quatre dérivés étudiés, la réaction de réarrangement de Beckmann (Tableau 4) conduit aux acides nitriles correspondants $HOCO(CH_2)_nCN$, ce qui est en faveur de la configuration *E*.

Ainsi nous confirmons pour **1** la structure *s-cis E* proposée par Ferris. Nous pensons que **2** et **3** sont deux isomères de configuration identique mais de conformation différente (**2**: *s-trans E*; **3**: *s-cis E*); le caractère partiel de double liaison de la liaison centrale du motif α-hydroxyiminocétone confère au cycle une certaine analogie avec celui du cyclooctène pour lequel on connait effectivement les deux isomères *s-cis* et *s-trans*.[12] Enfin pour **4** nous confirmons la configuration *E* attribuée par Kataoka et proposons la conformation *s-trans*.

Partie Experimentale

*Synthese. L'hydroxyimino-2 Cyclohexanone **1** a été Obtenue selon la Technique de Geissman*:[14] Saponification de l'éthoxycarbonyle-2 cyclohexanone (0.05 mol) par de la potasse diluée (0.06 mol) puis traitement par le nitrite de sodium (0.06 mol) en milieu sulfurique ; en même temps que la nitrosation se produit une décarboxylation qui libère **1** avec un bon rendement (90%). Le produit après extraction éthérée peut être purifié par chromatographie sur colonne (silice G, solvant d'élution: butanone–ether de pétrole 6-14). $C_6H_9NO_2$ calculé % C 56,69; H 7,09; N 11,02; O 25,20; trouvé % C 56,47; H 6,99; N 11,07; O 25,40; RMN δ_{TMS}: 1,83 (4H; m), 2,55 ($C\underline{H}_2$-C(NOH); t), 2,75 ($C\underline{H}_2$-CO; t), 12,17 (NO$\underline{H}$; s).

La Nitrosation de la Cyclooctanone a été Conduite selon des Conditions Voisines de celle de Kataoka: La cyclooctanone (0.2 mol) en milieu éthéré chlorhydrique (0.02 mol de HCl) est traitée à 0 °C par du nitrite d'isopropyle (0.24 mol); les produits de la réaction, après neutralisation, sont extraits à l'éther puis sépares par chromatographie sur colonne de gel de silice (solvant cyclohexane–acétate d'éthyle 1–1); en tête sort l'*hydroxyimino-2 cyclooctanone **2*** sous forme d'une huile légèrement jaune; $C_8H_{13}NO_2$ calculé % C 61,93; H 8,39; N 9,03; O 20,65; trouvé % C 61,86; H 8,46; N 8,86; O 20,72; RMN δ_{TMS}: 1,55 (8H; m), 2,40 ($C\underline{H}_2$-C(NOH) et $C\underline{H}_2$-CO; 2t), 10,83 (NO$\underline{H}$; s). *L'hydroxyimino-2 cyclooctanone **3*** qui sort ensuite de la colonne est un produit bien cristallise: F 99 °C; $C_8H_{13}NO_2$ calculé % C 61,93; H 8,39; N 9,03; O 20,65; trouvé % C 61,85; H 8,50; N 9,02; O 20,46. RMN δ_{TMS}: 1,53 (8H; m), 2,57 ($C\underline{H}_2$-C(NOH); t), 2,67 ($C\underline{H}_2$-CO; t), 11,77 (NO$\underline{H}$; s).

La nitrosation de la cyclododécanone, conduite comme pour la cyclooctanone, mène avec un bon rendement (80%) à un seul dérivé bien cristallisé, l'*hydroxyimino-2 cyclododécanone **4***: F 70 °C ; $C_{12}H_{21}NO_2$ calculé % C 68,25; H 9,95; N 6,63; O 15,17; trouvé % C 68,16; H 9,84; N 6,49; O 15,40; RMN δ_{TMS}: 1,22 (16H; m), 2,58 ($C\underline{H}_2$-C(NOH); t), 2,77 ($C\underline{H}_2$-CO; t), 12,48 (NO$\underline{H}$; s).

Spectroscopie Infrarouge. Spectrophotomètre Perkin Elmer 337; cuves de 0,5 et 50 mm avec fenêtres en NaCl; solvant CCl_4. La détermination graphique des constantes d'association a été faite selon la methode de Ossart.[13]

Spectrométrie de Résonnance Magnétique Nucléaire. Spectromètre Varian T 60; Solvant DMSO-d_6; concentration 5%.

Complexes avec Cu^{2+}. Une pincée de produit est mise en solution dans de l'alcool à 95 °C; on rajoute quelques gouttes d'une solution aqueuse saturée d'acétate de cuivre et on note la coloration verte (formation d'un complexe) ou bleu (pas de formation de complexe).

The Relationship of π-Binding Energy with Molecular Connectivity in Hydrocarbons

Satya P. GUPTA* and Prithvi SINGH

Department of Chemistry, Birla Institute of Technology and Science, Pilani-333031, India

(Received September 11, 1978)

Synopsis. Hückel's π-binding energy, E_π, in hydrocarbons is found to be parallel to Kier's molecular connectivity index, χ. In either class of hydrocarbons, alternant or non-alternant, the regression analysis reveals a highly significant linear correlation between E_π and ${}^1\chi^v$ (the first order valence connectivity index).

The molecular connectivity index, χ, signifies the degree of branching or connectivity in a molecule and is derived from the numerical extent of branching or connectivity in the molecular skeleton.[1-3] Kier *et al.* have shown that this index can be correlated with several physicochemical and biological properties of the molecules.[3] The χ has several versions. The simplest as well as extended versions in it (${}^m\chi$) all are calculated from a hydrogen suppressed graph of the molecule. The simplest version designated as ${}^1\chi$ and known as first-order term in χ is computed by[1-3]

$$ {}^1\chi = \sum (\delta_i \delta_j)^{-1/2} \qquad (1) $$

where the sum is over all connections or edges in the hydrogen suppressed graphs, and δ_i and δ_j are numbers assigned to each atom reflecting the number of atoms adjacent or connected to atoms i and j, which are formally bonded. The nature of the atoms is not considered in the calculation.

To account for the nature and unsaturation of the bonds in χ, Kier and Hall[3,4] proposed the valence molecular connectivity (χ^v) where the atom connectivity term, δ^v, is defined as:

$$ \delta_i^v = Z_i^v - h_i \qquad (2) $$

in which Z_i^v represents the number of valence electrons of atom i, and h_i the number of hydrogen atoms attached to it. Thus the use of δ^v permits the calculation of valence χ term of first-order, ${}^1\chi^v$, by the expres sion:

$$ {}^1\chi^v = \sum (\delta_i^v \delta_j^v)^{-1/2}. \qquad (3) $$

The details of calculation of this term and other higher terms in χ can be seen in Ref. 3.

The electronic interaction depends upon the specific orientation of atoms in a molecule, hence it becomes obvious that the binding energy of electrons must be in some way related with χ.

Using Eqs. 2 and 3, the ${}^1\chi^v$ values are calculated for some alternant and non-alternant hydrocarbons and listed in Tables 1 and 2 respectively. Hückel's π-binding energy values, E_π, are taken from the literature.[5] A plot of E_π *versus* ${}^1\chi^v$ is shown, for alternant hydrocarbons, in Fig 1, and for non-alternant hydrocarbons, in Fig 2. A straight line is obtained in both the cases. The level of significance of this linear correlation between E_π and ${}^1\chi^v$ in two cases is shown by Eqs. 4 and 5 respectively.

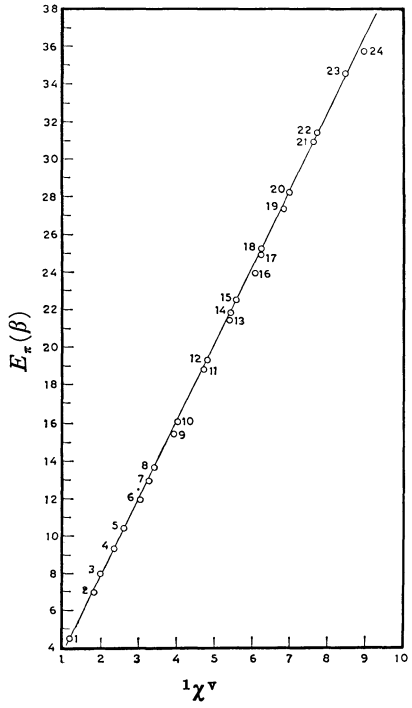

Fig. 1. A plot of E *versus* χ in alternant hydrocarbons. Numbers refer to compounds in Table 1.

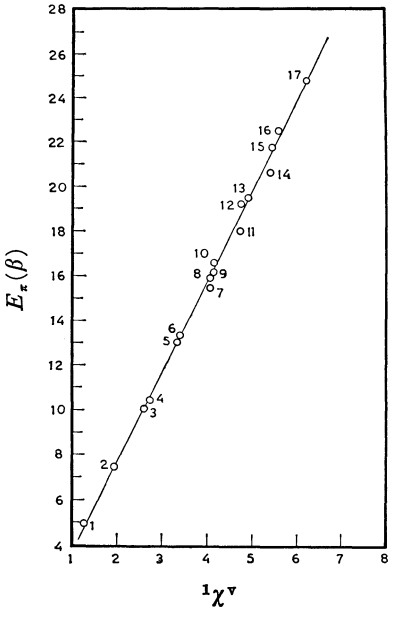

Fig. 2. A plot of E *versus* χ in non-alternant hydrocarbons. Numbers refer to compounds in Table 2. To save space compounds 18 and 19 were not shown.

Table 1. E_π and $^1\chi^v$ values for alternant hydrocarbons

Compd No.	Compound	$^1\chi^v$	E_π (β) Hückel	E_π (β) Calcd from Eq. 4
1	1,3-Butadiene	1.150	4.472	4.378
2	1,3,5-Hexatriene	1.817	6.988	7.093
3	Benzene	2.000	8.000	7.837
4	3,4-Dimethylene-1,5-hexadiene	2.351	9.332	9.266
5	Styrene	2.608	10.422	10.312
6	3,4-Divinyl-1,3,5-hexatriene	3.038	11.925	12.062
7	1-Phenyl-1,3-butadiene	3.274	12.932	13.023
8	Naphthalene	3.405	13.683	13.556
9	1-Phenyl-1,3,5-hexatriene	3.941	15.459	15.737
10	1-Vinylnaphthalene	4.019	16.129	16.055
11	Stilbene	4.732	18.878	18.957
12	Anthracene	4.810	19.314	19.274
13	1,4-Diphenyl-1,3-butadiene	5.399	21.401	21.671
14	9-Vinylanthracene	5.429	21.790	21.793
15	Pyrene	5.560	22.505	22.326
16	1,6-Diphenyl-1,3,5-hexatriene	6.065	23.934	24.382
17	Naphthacene	6.215	24.931	24.992
18	Triphenylene	6.232	25.274	25.061
19	Triphenylethylene	6.810	27.270	27.414
20	Perylene	6.976	28.245	28.089
21	Picene	7.637	30.943	30.780
22	Benzo[*ghi*]perylene	7.720	31.425	31.118
23	Coronene	8.464	34.572	34.146
24	Tetraphenylethylene	8.974	35.719	36.221

$$E_\pi = 4.070\,^1\chi^v - 0.302$$
$$n=24,\ r>0.999,\ s=0.229,\ F_{1,22}>20000 \quad (4)$$
$$E_\pi = 4.068\,^1\chi^v - 0.551$$
$$n=19,\ r=0.999,\ s=0.358,\ F_{1,17}=8483. \quad (5)$$

In these two equations, as obtained by regression analysis, the statistical parameters: n (the number of data points), r (the correlation coefficient), s (the standard deviation), and F (the F ratio between the variances of calculated and observed data) exhibit very high level of significance of the correlations. The E_π values reproduced from Eqs. 4 and 5 are found to be in very good agreement with the Hückel ones (Tables 1 and 2).

Now these correlations can be used to predict the binding energy of any conjugated system. The calculation of χ is utterly simple. These correlations suggest that in biochemical studies χ would be very well able to account for the activity that would depend upon the binding energy of the compounds.

Molecular Structure of Bromoform as Determined by a Joint Analysis of Electron Diffraction and Microwave Data†

Koichi TAMAGAWA and Masao KIMURA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 2, 1978)

The gas phase molecular structure of bromoform has been studied by electron diffraction. By a joint analysis of the diffraction results and the moments of inertia for $CH^{79}Br_3$, $CD^{79}Br_3$, $CH^{81}Br_3$, and $CD^{81}Br_3$ obtained by Williams *et al.*, the bond distances in r_g and the bond angles in φ_{av} have been determined as follows: r_g(C–Br) = 1.924±0.005 Å, r_g(Br···Br) = 3.175±0.003 Å, r_g(C–H) = 1.11_1±0.04_6 Å, φ_{av}(BrCBr) = 111.7±0.4°, and φ_{av}(HCBr) = 107.2±0.5°. The uncertainties represent the estimated limits of error. The anharmonicity parameter of the Morse-type potential, a_3, for the nonbonded Br···Br atom pair has been estimated as -1.3 ± 0.9 Å^{-1}.

In a series of fluoromethanes, $CH_{4-n}F_n$ (n=1—4), the systematic decrease in the C–F distances and the F–C–F bond angles with an increase in the number of F atoms has been observed.[1-4] The results of population analysis for these compounds have supported these trends.[6] According to our recent studies on a series of chloromethanes,[7-9] the C–Cl distances have shown a similar shortening with increasing number of Cl atoms, while the Cl–C–Cl bond angles increase in contrast with the trend observed in fluoromethanes.

In the molecular structures of the bromomethanes, $CH_{4-n}Br_n$ (n=1—4), only the r_e structure of CH_3Br investigated by Duncan[1] and the r_a structure of CH_2Br_2 determined by Beagley *et al.*[5] have been reported. The molecular structure of $CHBr_3$ was studied by Morino *et al.* by means of the visual method of electron diffraction[10] and by Williams *et al.* by means of microwave spectroscopy.[11] The results of structural analysis for $CHBr_3$ are however not precise and accurate enough to be compared critically with those of related molecules. There is no reliable structural data for CBr_4. Thus, in order to investigate the variations in structure with the number of bromine atoms, it is necessary to determine the structures of $CHBr_3$ and CBr_4 and moreover, it is desirable to reinvestigate the structures of CH_2Br_2 and CH_3Br in a series of studies. In the present study the structure of $CHBr_3$ was determined by a joint analysis of the diffraction data newly obtained and the rotational constants determined by Williams *et al.*[11] The structures of carbon tetrabromide,[12] methylene dibromide,[12] and methyl bromide[13] will be reported later.

Experimental

A guaranteed reagent purchased from Nakarai Chemical Co., Ltd. was used after distillation. Diffraction photographs were taken at 19 °C with a diffraction unit equipped with an r^3-sector.[14] The experimental conditions were as follows: camera length: 244.3 and 109.3 mm; sample pressure: about 3 Torr; exposure times: about 120 and 240 s for the long and

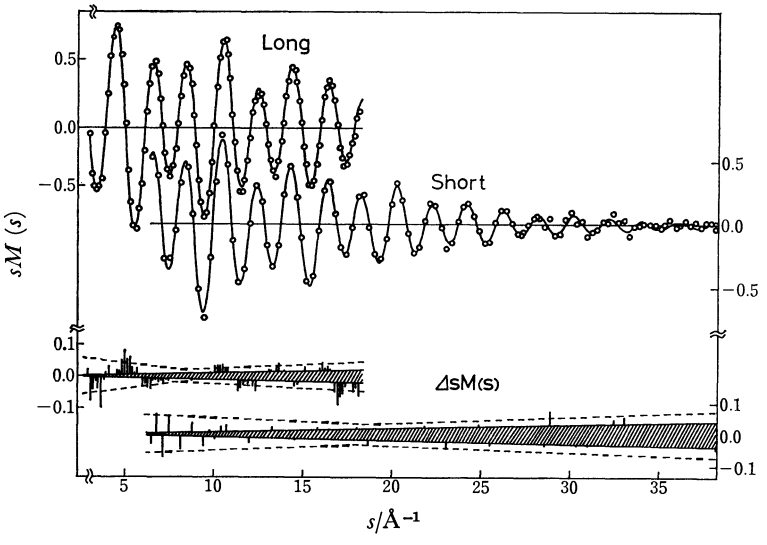

Fig. 1. Experimental (open circles) and theoretical (smooth curve) molecular intensities for $CHBr_3$; $\Delta sM(s) = sM(s)^{obsd} - sM(s)^{calod}$. The indices of resolution are 0.918—0.967 and 0.869—0.928 for the long and short camera lengths, respectively.

† Throughout this paper 1 Å = 100 pm and 1 Torr = 133.322 Pa are used. For the definitions of various distances, see, *e.g.*, K. Kuchitsu and S. J. Cyvin, "Molecular Structures and Vibrations," ed by S. J. Cyvin, Elsevier, Amsterdam (1972) Chap. 12; see also L. S. Bartell, K. Kuchitsu, and H. M. Seip, *Acta Crystallogr., Sect. A*, **32**, 1013 (1976). Notations r_{av} and φ_{av} are used for the values determined by joint analysis.

short camera lengths respectively; accelerating voltage: about 42 kV; beam current: 0.20 μA. The scale factor for the diffraction patterns was determined with reference to the diffraction patterns of carbon disulfide taken under the same experimental conditions.[15]

The data were reduced to the molecular intensities by our usual procedures.[16] Three and four plates from the long and short camera lengths, respectively, were used for analysis. The observed molecular intensities covered the ranges of $3.0 \leqq s \leqq 18.0$ Å^{-1} and $6.5 \leqq s \leqq 38.2$ Å^{-1} for the long and short camera lengths, respectively.

The observed molecular intensities and the theoretical curves calculated using the best-fit parameters are shown in Fig. 1 together with the differences (experimental minus theoretical).[17] The narrow shaded area corresponds to ±2 in the last digit of the digital voltmeter reading, *i.e.*, the limits of detection in photometry. The outer boundaries drawn by the broken lines show the estimated limits of error in the intensity measurements. They indicate the normally expected range of random scattering of differences between experimental and theoretical intensities. Some points exceed the boundaries for accidental reasons. The least-squares refinement with zero-weights for these points showed that the irregularities did not affect the derived parameter values. Figure 2 shows the radial distribution curve corresponding to the molecular intensities from the short camera length shown in Fig. 1.

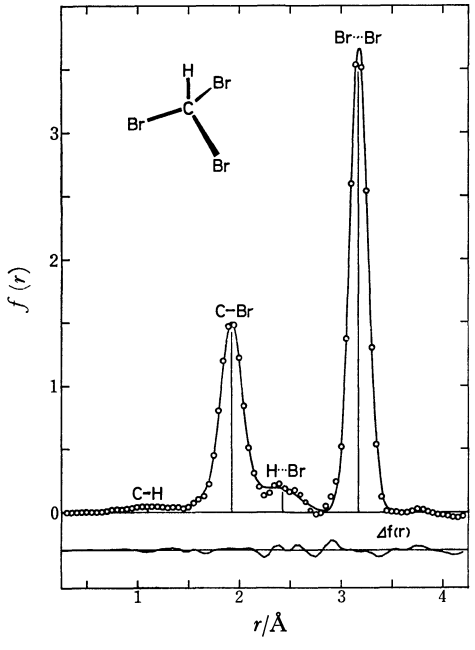

Fig. 2. Experimental (open circles) and theoretical (smooth curve) radial distribution curve for $CHBr_3$: $\Delta f(r) = f(r)^{obsd} - f(r)^{calcd}$. Damping factor, exp[−0.00153 s^2].

Analysis of Electron Diffraction Intensities

The structural parameters were determined by applying the least-squares method to the reduced molecular intensities with a conventional diagonal-weight matrix.[16] The elastic and inelastic scattering factors and the phase shifts between C, H, and Br atoms were taken from the Tables of Schäfer *et al.*[18] C_{3v} symmetry was assumed for the geometry in equilibrium. Five independent parameters were chosen for refinement: the C–Br and Br···Br distances, the mean amplitudes, and the index of resolution. The r_g(C–H) distance was fixed at 1.107 Å, a value determined from methane,[19] and also at values shifted by ±0.050 Å. The mean amplitudes of the C–H and H···Br pairs were fixed at 0.078 and 0.113 Å, which were calculated using the force constants given by Galasso *et al.*[20] The asymmetry constants, $\kappa (= (1/6)a_3(1+8\chi/(1+\chi)^2)l^4)$, for the C–H and C–Br bonds were estimated to be 1.2×10^{-5} and 3.5×10^{-6} Å^3, assuming the anharmonicity parameters, a_3,[21] to be 1.98 and 2.0 Å^{-1}, respectively. The a_3 values for the nonbonded H···Br and Br···Br pairs were assumed to be zero. The results of the least-squares analysis thus obtained are summarized in Table 1. The errors in the scale factor were estimated to be 0.06% and 0.10% for the long and short camera lengths, respectively. The shifts of ±0.050 Å in an assumed r_g(C–H) value brought about changes of ±0.0012 Å in the resulting r_g(C–Br), but caused no significant changes in the other structural parameters as compared with the random errors. The limits of error for the parameter values, except for r_g(C–Br), were estimated from 2.6 times the random standard deviations and the error in the scale factor. For r_g(C–Br), the error due to the uncertainty of the r_g(C–H) distance was further added. Variations in the plausible ranges of mean amplitudes for the nonbonded pairs and κ values for the C–Br, C–H, and H···Br pairs caused no significant changes in the resulting parameter values. Variation in the κ_{BrBr} value associated with variation in a_3(Br···Br) was found to cause only a little change in the r_g(Br···Br) distance, while the a_3(Br···Br) value itself took a significant role in the determination of the r_{av} structure by the joint analysis. The details of this however will be deferred

Table 1. Results of the least-squares analysis of diffraction intensities for bromoform[a] (in Å units)

Parameter	Long	Short	Weighted average	$r_g - r_\alpha^0$[b]	r_α^0
r_g(C–Br)	$1.922_3(5_9)$	$1.925_3(5_8)$	$1.923_8(4_2)$	0.002_8	1.921_0
r_g(Br···Br)	$3.176_7(2_6)$	$3.174_2(3_9)$	$3.175_9(2_2)$	0.001_6	3.174_3
r_g(C–H)	[1.107±0.050]	[1.107±0.050]		[0.014$_4$]	[1.093]
l(C–Br)	$0.062_0(9_1)$	$0.051_0(8_5)$	$0.056_1(6_3)$		
l(Br···Br)	$0.074_6(5_8)$	$0.071_1(2_5)$	$0.071_7(2_4)$		
R[c]	$0.094_3(8_1)$	$0.125_9(13_8)$			

a) Parenthesized values represent the limits of error. The values in brackets were those assumed. b) Vibrational corrections were calculated from the force constants cited in Ref. 20. a_3 for the nonbonded Br···Br pair was assumed to be 0 Å^{-1}. c) $R = \{\sum_i w_i(\Delta sM(s)_i)^2 / \sum_i w_i(sM(s)_i^{obsd})^2\}^{1/2}$ where $\Delta sM(s)_i = sM(s)_i^{obsd} - sM(s)_i^{calcd}$.

until the next section. The structural parameters determined from the data for the long and short camera lengths agree with each other within the limits of error. The most probable parameter values from the diffraction data were determined by taking the weighted average of both results. The observed mean amplitudes for the C–Br and Br···Br pairs agree with the calculated values, 0.0533 and 0.0740 Å, respectively, within the limits of error.

Joint Analysis of Diffraction and Microwave Data

The r_g distances determined by electron diffraction were converted to r_α^0 distances using the equation:[22]

$$r_g - r_\alpha^0 \cong \left(\frac{3}{2}\right) a_3(\langle\Delta z^2\rangle_T - \langle\Delta z^2\rangle_0) + \frac{\langle\Delta x^2\rangle_0 + \langle\Delta y^2\rangle_0}{2r_g} + \delta r_{\text{cent}}$$

The corrections were calculated using the force constants determined by Galasso *et al.*,[20] and the $r_g - r_\alpha^0$ values thus obtained are listed, together with the r_α^0 values in Table 1.

The ground state rotational constants, B_0, for $CH^{79}Br_3$, $CD^{79}Br_3$, $CH^{81}Br_3$, and $CD^{81}Br_3$ have been determined by Williams *et al.* using microwave spectroscopy.[11] The B_0 values were converted to the effective moments of inertia, $I_b^{(\text{eff})}$. The $I_b^{(\text{eff})}$ values thus obtained were reduced to the zero-point average moments of inertia, $I_b^{(z)}$, by correcting for harmonic vibrations by the standard method.[23]

In calculating the corrections, ΔI_b, the contribution from the centrifugal distortion was neglected[24] and the electronic contribution[24] was assumed to be zero because the g tensors were not available for $CHBr_3$. This assumption would not introduce significant errors, since the electronic contribution estimated from the results for formaldehyde[25] and ethylene[26] appears to be less than a few percent of the corrections themselves. A significant part of the corrections derives from terms of the $1/\omega$ type, where ω is the vibrational frequency.[27] The experimental frequencies and the frequencies calculated using the force constants agree within a few percent. Thus in the present study the overall uncertainties included in $\Delta I_b^{(z)}$ were tentatively assumed to be 10% of the correction values themselves. The uncertainties in the moments of inertia, $I_b^{(z)}$, were then estimated from the errors included in the experimental moments of inertia, $I_b^{(\text{eff})}$, and the errors included in the corrections, $\Delta I_b^{(z)}$. Table 2 lists the results.

The isotope effects for the bond distances were estimated using the equation:[28]

$$\delta r_z \cong \left(\frac{3}{2}\right) a_3 \delta\langle\Delta z^2\rangle_0 - \delta(\langle\Delta x^2\rangle_0 + \langle\Delta y^2\rangle_0)/2r_z$$

Assuming the anharmonicity parameters, a_3, to be 2.0 ± 0.5 and 1.98 ± 0.5 Å^{-1} for C–Br and C–H, respectively, the isotopic differences were estimated to be -0.0009 ± 0.0015 Å for δr_z(C–D) (r_z(C–D) minus r_z(C–H)). The secondary isotope effect for r_z(C–H) and the primary and secondary isotope effects for r_z(C–Br) were estimated to be of the order of 1×10^{-6} Å, and consequently were neglected in the analysis. The isotope effect for the Br–C–Br bond angle, $\delta\varphi_z$(BrCBr) (φ_z of the isotopic species minus φ_z of the parent species $CH^{79}Br_3$), was tentatively assumed for all isotopic species to be $0.00\pm0.01°$ because of a lack of an established method of estimation.

Table 3. r_{av} and the final r_g structure for $CHBr_3$[a] (in Å and degree units)

	r_{av} and φ_{av}[b]	r_g[c]
C–Br	$1.921_0(4_2)$	1.924(5)
Br···Br	$3.179_1(1_5)$	3.175(3)
C–H	$1.09_7(4_6)$	$1.11_1(4_6)$
BrCBr	$111.6_3(3_8)$	
HCBr	$107.1_6(4_2)$	

a) Parenthesized values represent the limits of error referred to the last digits. b) Calculated from the r_{av} distances. c) Estimated from the r_{av} distances using a_3(Br···Br) $=-1.3\pm0.9$ Å^{-1}.

Four moments of inertia, $I_b^{(z)}$, are available. Unfortunately however the Br isotopic species provide no independent information, as we have usually experienced for molecules containing heavier atoms. The observed $I_b^{(z)}$ give relations among three parameters (r_z(C–Br), r_z(Br···Br), and r_z(C–H)). The relations from $CH^{79}Br_3$ and $CD^{79}Br_3$ practically coincide however with those from $CH^{81}Br_3$ and $CD^{81}Br_3$, respectively. Therefore, a complete r_z structure cannot be determined by the microwave data alone. The process of joint analysis to determine the complete r_{av} structure is illustrated in Fig. 3, where the r_z(C–Br) $-$ r_z(Br···Br) space is spread out. Assigning r_z(C–H) at a certain value, an approximately linear relation between r_z(C–Br) and r_z(Br···Br) is defined by a given $I_b^{(z)}$

Parenthesized values are estimated errors. b) Taken from Ref. 11. c) The errors of $I_b^{(\text{eff})}$ were taken to be 3 times the errors of B_0. d) Average moments of inertia ($I_b^{(z)} = I_b^{(\text{eff})} + \Delta I_b$). e) Calculated from the final average structures.

for each of the H- and D-species. The observed $I_b^{(z)}$ for both species and the isotope species, δr_z(C–D) and δr_z(Br···Br) for the D-species possess uncertainties however and the relationships between r_z(C–Br) and r_z(Br···Br) for both species are manifested by two approximately straight belts on the r_z(C–Br)-r_z(Br···Br) space. Thus, a parallelogram, formed by the crossing of the two belts is the range allowed by $I_b^{(z)}$ for the r_z(C–H) value. Two parallelograms, a and b, are depicted in Fig. 3 by broken lines as examples, indicating the allowed ranges for r_z(C–H) values of 1.060 and 1.140 Å, respectively. Setting different values of r_z(C–H) shifts the parallelogram along the two parallel lines M_1 and M_2. The point ED in Fig. 3 represents the r_α^0 structure determined by electron diffraction with a_3(Br···Br) equal to zero, and the elliptical curve indicates the limits of error. The ranges satisfying the electron diffraction data and the moments of inertia from microwave spectroscopy do not overlap. Among the parameter values assumed in the present analysis the most ambiguous and influential one is a_3(Br···Br). The inconsistency between the electron diffraction data and the microwave data is in all probability due to the assumption that a_3(Br···Br) is zero. Variation in the value of a_3(Br···Br) affects the isotopic differences, δr_z(Br···Br), and consequently the range between M_1 and M_2 shifts. This shifts however is small and cannot be depicted in Fig. 3 discriminately. Variation in the value of a_3(Br···Br) causes a small change in the r_g(Br···Br) distance and a relatively large change in the correction value, r_g(Br···Br)$-$ r_α^0(Br···Br). As a result, the point ED and consequentry the elliptical curve (error limits) in Fig. 3 shifts along the Br···Br axis without influencing the other parameter values. As an example, a change in the a_3(Br···Br) value of -1.0 Å^{-1} brings about changes of -0.0011, -0.0047, and 0.0036 Å in r_g(Br···Br), the correction, r_g(Br···Br)$-r_\alpha^0$(Br···Br), and r_α^0(Br···Br) respectively. The two ellipses, ED_1 and ED_2, depicted by the dotted lines are the extreme cases where the results from both electron diffraction and microwave data overlap, corresponding to the a_3(Br···Br) values of -0.4 and -2.2 Å^{-1}, respectively. The shaded area is the range allowed by both the diffraction and the microwave data, assuming the a_3(Br···Br) value takes the range discussed above. On the basis of this, the most probable average distances, r_{av}(Br···Br) and r_{av}(C–Br), and the limits of error were determined from the center, O, and the boundary of the shaded area in Fig. 3. The most probable value for r_{av}(C–H) was taken as the value that brings the center of the parallelogram to the point O, and the limit of error was taken as the range where the parallelogram overlaps with the shaded area. The r_{av} values thus determined are listed in Table 3. The most probable value of a_3 and error limit are -1.3 ± 0.9 Å^{-1} from values corresponding to the extreme cases, ED_1 and ED_2. As may be seen in Table 3 and also in Fig. 3, r_{av}(C–H) cannot be determined precisely. Most of the r_g(C–H) distances reported so far for several molecules are in the range 1.100—1.110 Å, which corresponds to 1.085—1.095 Å in r_{av}(C–H). Even though the range of r_{av}(C–H) in the present molecule is limited to the range mentioned above, the limit of error for the r_{av}(Br···Br) becomes smaller by only 0.0003 Å. The calculated moments of inertia corresponding to the r_{av} structure are compared with the observed moments of inertia in the bottom row of Table 2. The r_g(Br···Br) distance converged

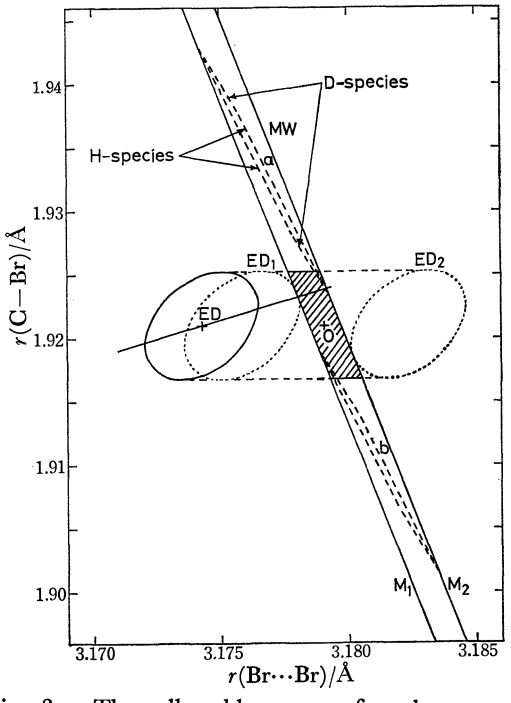

Fig. 3. The allowable range for the parameters, r(C–Br) and r(Br···Br). The values allowed by the four moments of inertia (MW) are shown by the range between the two parallel solid lines, M_1 and M_2. Two parallerograms drawn by the broken lines show the ranges allowed at r_z(C–H) = 1.06 Å (a) and 1.14 Å (b), respectively. The point ED represents the r_α^0 distances determined by electron diffraction with a_3-(Br···Br) equal to 0 Å^{-1}, and the ellipse indicates the limits of error. The ellipses, ED_1 and ED_2, correspond to the a_3(Br···Br) values of -0.4 and -2.2 Å^{-1} respectively (see text). The shaded area shows the probable range of the average structure. The point O is the center of this range. The solid line passing through the point ED shows the direction of change in r(C–Br) and r(Br···Br) when the scale factor used in the electron diffraction analysis is allowed to change.

TABLE 4. C–H DISTANCES AND BOND ANGLES OF BROMOFORM AND RELATED MOLECULES[a] (in Å and degree units)

at 3.175 Å with analysis of the diffraction data assuming a_3(Br···Br) to be -1.3 Å^{-1}.

Discussion

The Br–C–Br bond angle shown in Table 3 is larger than the tetrahedral angle by about 2°. The XCX bond angles and the C–H distances of related molecules are listed in Table 4. The XCX bond angles for molecules with larger substituents are larger than the tetrahedral angle in all probability due to repulsion. A general trend for the C–H bond lengths cannot be found from the data in Table 4.

In the present study, it has been found that the anharmonicity parameter, a_3, for the nonbonded Br···Br pair must be negative in order that the electron diffraction results and the moments of inertia may be consistent. A recent study on $CHCl_3$[8] has shown that a negative a_3 values is preferable for the nonbonded Cl···Cl pair. No theoretical method for estimating these values is available at the present.

The authors wish to thank Professor Takao Iijima of Gakushuin University and Professor Shigehiro Konaka for their helpful advice and discussion. The computations were performed on an electronic computer FACOM 230-75 of the Computing Center, Hokkaido University.

Nitrogen 14 Nuclear Quadrupole Resonance Study of Several Condensed Ring Compounds

Yukio HIYAMA, Takuya MARUIZUMI, and Eiji NIKI*

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received October 3, 1978)

The ^{14}N nuclear quadrupole resonance spectra of 2-mercaptobenzothiazole, isatin(1*H*-indole-2,3-dione), and isatoic anhydride(2*H*-3,1-benzoxazine-2,4(1*H*)-dione) have been observed at room temperature by the nuclear double resonance method. The quadrupole coupling constants and the asymmetry parameters thus obtained were interpreted by the Townes and Dailey theory.

In this paper, we wish to report the first observation of the nuclear quadrupole resonance (NQR) of the ^{14}N in several condensed ring heterocyclic compounds. The parameters thus obtained, *i.e.*, the quadrupole coupling constant (e^2Qq/h) and the asymmetry parameter (η) correspond to the electronic environment around each nitrogen atom. In the case of nitrogen, these parameters are usually dominated almost entirely by the distribution of the valence electrons in each nitrogen atom. The three frequencies[1] of ^{14}N NQR are given by:

$$\nu_{\pm} = 3/4e^2Qq/h(1\pm\eta/3) \quad (1), (2)$$

$$\nu_0 = \nu_+ - \nu_- = 1/2\eta e^2Qq/h \quad (3)$$

where e^2Qq/h and η are the quadrupole coupling constant and the asymmetry parameter respectively.

The frequency, ν_0, is relatively low, almost always below 1000 kHz. In this case, such conventional NQR techniques as using a regenerative spectrometer may not be accessible because of their low sensitivity. Therefore the nuclear double resonance technique[2] in the laboratory frame (^1H–^{14}N cross relaxation) was employed.

Experimental

The double resonance technique will be briefly described. A single cycle in an experiment consists of three stages. In the first, the major nuclei which give strong NMR signals, such as ^1H, are polarized in a high magnetic field ($\simeq$1T) for two or three high-field spin-lattice relaxation times, T_1. Next, the sample demagnetization is performed adiabatically. The minor nuclei (searched for NQR signals) are irradiated with a certain RF field; intensity, H_{1B}, and frequency, ν_B, after the sample has been removed from the magnet to the region of a zero external field for a cerain time period, τ s. In the third stage, the sample is returned to the magnet. A 90° pulse is immediately applied to monitor the remaining magnetization of the major nuclei. The amplitude of the free induction decay (FID) or echo is recorded. If H_{1B} is applied at the frequency of the quadrupole resonance of the minor nuclei, the monitored magnetization, $M(\tau)$, can be expected to vary as;

$$M(\tau) = M(0)\exp[-(1/T_{1d}+1/\tau_{AB})]. \quad (4)$$

Here, T_{1d} is the spin-lattice relaxation time in a zero magnetic field for the major nuclei and τ_{AB} is the cross relaxation time between the major spin and the minor spin, which has a finite value if ν_B is equal to the resonance frequency. The NQR absorption line is recorded as a dip of the magnetization of the major nuclei. If T_1 is 100 s, one scanning of ν_B from 2 MHz to 3 MHz by 10 kHz steps takes 6 h.

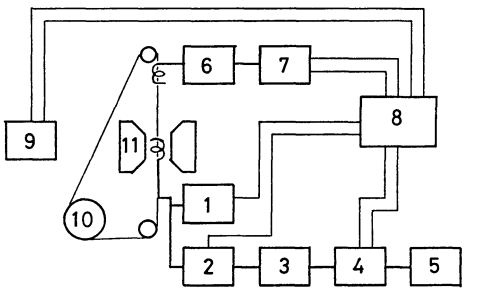

Fig. 1. Nuclear double resonance apparatus.
1) Transmitter, 2) preamplifier, 3) receiver amplifier, 4) gated integrator, 5) chart recorder, 6) wideband power amplifier, 7) PLL synthesizer, 8) pulse generator, 9) motor driver, 10) stepping motor, 11) magnet pole piece.

The double resonance apparatus was built in this laboratory[3] (Fig. 1).

Pulsed NMR. We used a conventional, single-coil, pulsed, proton magnetic resonance spectrometer operating at 26.7 MHz (6.28×10^{-1} T). The transmitter was a modified YAESU FL-101 apparatus operating as a C-class amplifier. The pre-amplifier and receiver amplifier were hand-made. The spectrometer was constructed with care taken to insure stability of sensitivity and a short recovery time.

Gated Integrator. The monitored FID was stored by means of a gated integrator. We used a box-car detector as the gated integrator by inserting a reset circuit. The integrated signal was recorded on a chart recorder as one bar, whose height was proportional to the remaining magnetization $M(\tau)$.

Sample Elevator Mechanism. The sample is moved by a small elevator mechanism driven by a stepping (pulse) motor. The advantage of the stepping motor is that the velocity and the distance can be controlled electronically by means of the pulse frequency and the total number of pulses respectively. The stepping motor is ASTROSYN 34 PM-C004.

Frequency Synthesizer and Wide-band Power Amplifier. The frequency, ν_B, must be fixed during each experimental cycle. The stability required in this experiment is higher than that of a standard signal generator. Also, it is necessary to set the irradiation frequency programmably. Therefore, we employed a PLL (phase-locked loop) frequency synthesizer, whose frequency program can be set automatically. The output of the synthesizer, which is sometimes phase- or pulse- modulated, is fed to an ENI 240L wide-band power amplifier. H_{1B} is applied to the sample within a soleniod coil.

Helmholtz Coil. A small Helmholtz coil is used to cancel any remaining fields to within$\pm10^{-4}$ T over the volume of the sample in the zero-field region. Sometimes, a pure iron magnetic shield is used in order to cancel the fairly high

remaining field ($\simeq 10^{-2}$ T).

Coherent Pulse Generator. The timing of the entire experimental cycle is automatically and programmably controlled by a coherent pulse generator, which was designed and built up in our laboratory. This generator, whose components are almost all TTLs(7400 series), is composed of a quartz time base and programmable dividers.

All experiments were done at room temperature. The sweeping of the minor spin irradiation (H_{1B}) was performed in 10 kHz steps from 400 kHz to 3800 kHz; therefore the total experimental error may amount to about 10 kHz.

Sample. All the samples were polycrystalline guaranteed-grade chemicals obtained from the Tokyo Kasei Kogyo Co., Ltd. Each sample volume was approximately 1 cm^3, packed in a test tube 10 mm in diameter. We tried to detect the ^{14}N NQR spectra of some other condensed ring compounds, but failed. The compounds which did not give resonances were indigo, thionine, luminol, uric acid, *N,N'*-dithiobismorpholine, and thiooxy purine. In these six compounds, the proton spin-lattice relaxation time, T_1, was too short to satisfy the adiabatic condition for the double resonance experiment.

Results

T_1, the Spin-lattice Relaxation Time in a High Magnetic Field. The T_1 of each compound was determined by the 90° pulse-t-90° pulse method. The obtained time constant of each compound is listed in the 2nd column in Table 1. For a compound with the time constant of 50 s, the experimental cycle was set at 120 s.

Table 1. Observed parameters

Compound	Resonance freq./kHz					
	T_1/s	ν_+	ν_-	ν_0	e^2Qq/h	η
2-Mercapto-benzothiazole 	50	2140	1520	620	2440	0.51
Isatin 	20	2540	2050	490	3060	0.32
Isatoic anhydride 	60	2790	—	750	3220	0.47

NQR. The observed frequencies, coupling constants, and asymmetry parameters are given also in Table 1, together with the formula of each molecule.

2-Mercaptobenzothiazole gave two strong signals, which correspond to ν_+ and ν_0 lines, and also a weak signal at 1520 kHz. This corresponds to ν_- line. The crystal and molecular structure[4] shows that there are four molecules per unit cell. However only one set of signals was obtained.

Proton relaxation time of isatin is 20 s at room temperature. For the double resonance experiment, a relaxation time constant of the major spin of about 20 or 30 s may be most favorable because of the stability of the apparatus and the lesser demands on the experimenter's patience. This chemical also gave all three lines, ν_+, ν_-, and ν_0, as is illustrated in Fig. 2. The crystal and molecular structure of isatin was elucidated by Goldschmidt and Llewellyn.[5]

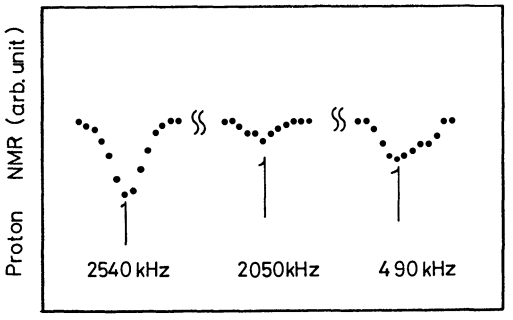

Fig. 2. Chart recorder outputs which show ^{14}N nuclear quadrupole resonance of isatin by proton-nitrogen double resonance method. B spin irradiation (searching irradiation) was performed in 10 kHz steps.

Isatoic Anhydride gave only two resonance lines, which correspond to the ν_+ line and the ν_0 line respectively. No structural data by X-ray diffraction has been reported for this compound.

Discussion

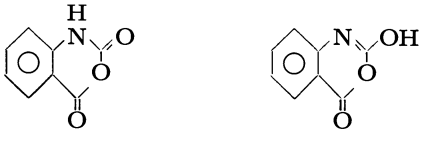
In 2-mercaptobenzothiazole(I), thione-thiol tautomerism is possible, as is illustrated below:

(Ia) (Ib) (I)

The X-ray structural study[4] supports the thione(Ia) form, while it gives no evidence for the thiol(Ib) form.

In isatin(II) and isotoic anhydride(III), lactam-lactim tautomerism can exist, as is shown below:

(IIa) (IIb) (II)



(IIIa) (IIId) (III)

The infrared results[6,7] support the lactam form(a) for both compounds.

In order to interpret the observed NQR results, the Townes and Dailey theory[1] was employed. For all three compounds, the electronic environment around each nitrogen atom may be assumed to be pyrrole-like, considering the other spectroscopic results.[4-7] The pyrrole-type formula[1] is as follows;

$$(e^2Qq/e^2Qq_0)(1+\eta/3) = L-B \quad (5)$$

$$(e^2Qq/e^2Qq_0)\eta = 3/2(A-B)(1-\cot^2\gamma). \quad (6)$$

Here, L is the pi population, A is the the N–H sigma population, B is the averaged N–C sigma population, 2γ is the CNC angle, and q_0 is the electric-field gradient caused by a 2p electron of the nitrogen atom.

For the two compounds whose molecular structures have been determined by the X-ray studies,[4,5] each bond angle, 2γ, was replaced by the corresponding value obtained from the studies. On the other hand, for isatoic anhydride, 2γ was assumed to 120°. In order to calculate the population numbers, L and A, the N–C population, B, and the atomic coupling constant, e^2Qq/h, were assumed to 1.15 and 9.1 MHz[8] respectively. Using the coupling constants and asymmetry parameters obtained at this time, the population numbers, L and A, were calculated by the above formulas [(5), (6)]; they are shown in Table 2. One may easily note that, for all the compounds, the L values are much less than 2.0, around 1.5; this fact may be explained by considering that the pi electrons take part in the conjugation of the heterocyclic ring.

Table 2. The Townes and Dailey analysis by means of a pyrrole-type formula

Compound	A(N–H)	L(pi)	NET $(2.3+A+L)$
2-Mercapto-benzothiazole	1.30	1.46	5.06
Isatin	1.28	1.52	5.10
Isatoic anhydride	1.32	1.56	5.18

e^2Qq_0/h=9.1 MHz. B=1.15.

Neutron Diffraction Study of Aqueous Ionic Solutions. I. Aqueous Solutions of Lithium Chloride and Caesium Chloride

Norio OHTOMO† and Kiyoshi ARAKAWA*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

†*Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received November 10, 1978)

The structure factors $S_m(Q)$ for aqueous solutions of LiCl and CsCl at room temperature, including those for heavy water, have been determined by means of the time-of-flight (TOF) neutron diffraction method using an electron linear accelerator (LINAC). Analysis of the diffraction data has been carried out for the aqueous ionic solutions as well as for pure heavy water. The following results were obtained with respect to the structure of the nearest hydration shell: (a) the coordination numbers are 4 for Li^+ and 6 for Cl^- in the LiCl solution, and 8 for Cs^+ and 6 for Cl^- in the CsCl solution, (b) the average ion-oxygen distances are 1.90 ± 0.05 Å for Li^+, 2.95 ± 0.10 Å for Cs^+ and 3.10 ± 0.05 Å for Cl^-, and (c) around cations water molecules take the configuration to orient the axis of one of two lone-pair hybrids on a straight line joining an oxygen atom and a cation.

Since the work of Bernal and Fowler in 1933,[1] many X-ray diffraction studies have been carried out for clarification of the liquid structure of ionic solutions. Lawrence and Kruh made a comprehensive X-ray diffraction study on ionic solutions.[2] In the last decade neutron diffraction studies have appeared as a new means for giving basic data such as the number of hydrated water molecules in the first shell (coordination number), the ion-oxygen distances, and the orientational arrangements within the shell. The results obtained so far, such as on the coordination number, were found to be greatly diverse, as pointed out by Hinton and Amis.[3] A more precise determination of these quantities is desirable.

The first application of the neutron diffraction method to aqueous electrolyte (LiCl) solutions was attempted by Narten *et al.*,[4] who analyzed their data of aqueous LiCl solutions on the basis of their "near-neighbor model" for water. Licheri *et al.* carried out studies on aqueous solutions of electrolytes along the same line.[5–11] However, the present authors have shown that the structure model of water of Narten *et al.* used as a basis for their analysis is physically unacceptable.[12] Soper *et al.* in another approach by means of the neutron diffraction method have given an ion-water configuration using their "first-order difference spectroscopy".[13]

Many problems remain unsolved with respect to the hydrated structure within ionic solutions, but the neutron diffraction method is becoming one of the most powerful means for its elucidation. We have carried out studies on aqueous ionic solutions by means of the method for which neutron diffraction data of heavy water are required. Since there are small discrepancies in the structure factor curves for heavy water given by us,[12] by Page and Powles[14] and by Narten,[15] measurement on heavy water (D_2O) was carried out again.

Measurements were carried out for aqueous solutions of LiCl and CsCl, the former for observing the pronounced effects of Li^+ on the configuration of water molecules in the first hydration sphere due to the small size of the ion, and the latter in view of the different behavior of Cs^+ expected in water as compared with Li^+. The results obtained by means of TOF neutron diffraction are reported, together with the new results for heavy water.

Apparatus and Procedures

Details of the apparatus and procedure have been reported.[12,16] The neutron diffraction experiment was performed by means of the TOF diffraction method using pulsed neutrons produced by LINAC. Thin-walled cylindrical vanadium and quartz were used as container of samples. Measurements were made at room temperature and at the scattering angle $2\theta = 45°$.

All the data were smoothed out according to the usual least-square fitting procedure and corrections (multiple scattering, absorption, background counting and Placzek corrections) were made for the smoothed spectrum. Absolute calibration was then performed by comparison of the count rate time-spectrum from the sample with that from a polycrystalline vanadium rod of the same shape and dimension as the sample.[12]

Results and Analysis of Heavy Water

Neutron diffraction data for heavy water are required for analysis of the data of aqueous ionic solutions.

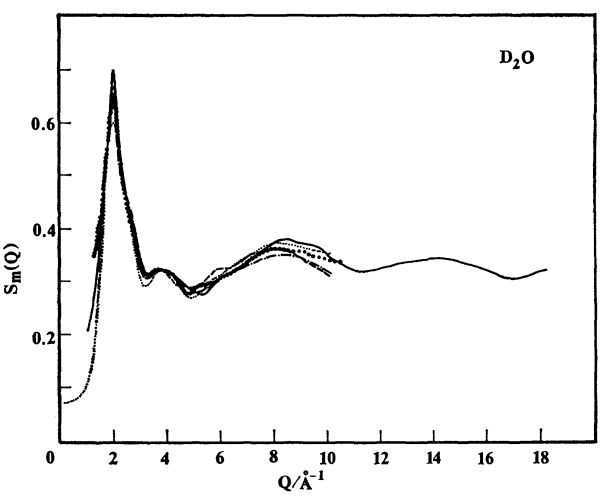

Fig. 1. Observed structure factors for D_2O.
• : $S_m(Q)$ by the authors (14 °C), ——: $S_m(Q)$ by the authors (17 °C),[12] – – –: $S_m(Q)$ by the authors (25 °C), —·—: $S_m(Q)$ by Page and Powles (22 °C), ·····: $S_m(Q)$ by Narten (25 °C).

Measurements for D_2O (99.75% D) were carried out at room temperature (14, 18, and 25 °C).

The absolute structure factors $S_m(Q)$ obtained for liquid heavy water are shown in Fig. 1, together with reported factors for the sake of comparison.[12,14,15] All five curves agree as a whole. The two curves except for the authors' were obtained by the conventional steady-state experiment using reactors as neutron sources. The accuracy of the present TOF experiment using LINAC ($2\theta=45°$) as a neutron source is as follows: the statistical errors are 0.5—0.6% in the Q range 2—5 Å^{-1} and 0.9% at about 8 Å^{-1}.

We proposed the "revised watery model" as a structure model for liquid water and made an analysis by means of the formula[12]

$$S_m(Q) = f_1(Q) + f_{2C}(Q)[(S_C(Q)-1]. \quad (1)$$

A further slight refinement of the model was performed as follows. (a) The rotational angle ξ[17] is taken to be 60°. (b) Concerning the factor $[S_c(Q)-1]$, we used the values obtained according to the procedure of Page and Powles[14] starting from the X-ray data of Narten instead of the direct use of Narten's value of $[S_c(Q)-1]$.[18] (c) The intramolecular contribution $f_1(Q)$ has been taken to be the weighted average value of three varieties of the intramolecular factors, which correspond to the three groups of water molecules in the tetrahedral pentamer according to the manner of hydrogen-bonding (Fig. 5, Ref. 12).[19] This improves the agreement between the calculated and observed curves in the high Q region ($Q \gtrsim 8$ Å^{-1}). The $S_m(Q)$ for the present "revised watery model" is given in Fig. 2 and is compared with the calculated factors for other models, the "uncorrelated orientation model"[14] and the "revised watery model" (free rotation) by the authors.[12] The main features of the three curves are in good agreement with each other except for the bump at about 4 Å^{-1}.

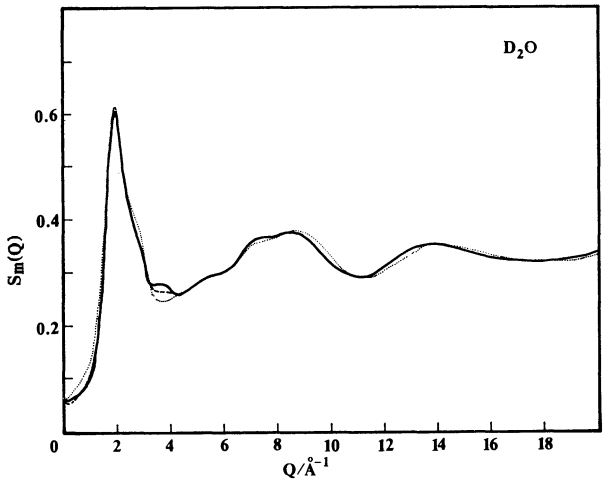

Fig. 2. Comparison between the calculated curves of $S_m(Q)$ for various structure models of liquid water.
——: $S_m(Q)$ for the "revised watery model" ($\xi=60°$),
– – – –: $S_m(Q)$ for the "revised watery model" (free rotation),
……: $S_m(Q)$ for the "uncorrelated orientation model".

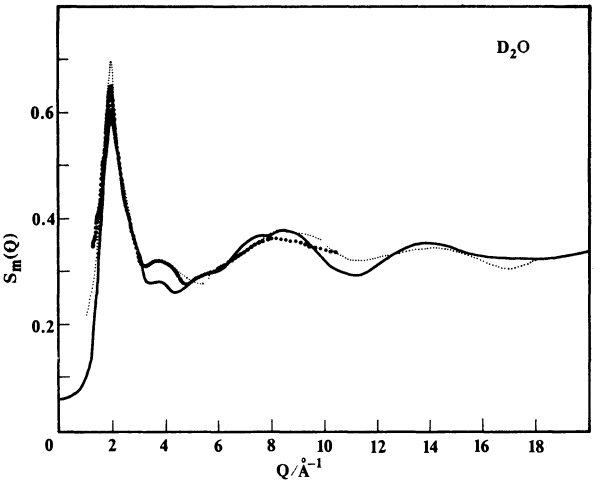

Fig. 3. Comparison between the calculated $S_m(Q)$ values for the present "revised watery model" and the observed ones by the authors.
——: Calculated $S_m(Q)$ for the "revised watery model",
• : observed $S_m(Q)$ in the present study (14 °C),
……: observed $S_m(Q)$ previously.[12]

In Fig. 3, the calculated curve of $S_m(Q)$ for the present "revised watery model" is compared with the observed $S_m(Q)$ curve. From Figs. 2 and 3, we see that the behavior of the curves near 4 Å^{-1} is essential for judging the adequacy of the model proposed.[14] The curves (Fig. 2) show a gradual approach to the observed curve, indicating that the "revised watery model" is the best of all the models for liquid water presented so far in neutron diffraction studies.

Results and Analysis of Aqueous Solutions of LiCl and CsCl

Diffraction Data. Two 1.0 M alkali halide solutions (M: mol dm^{-3}) were prepared by the addition

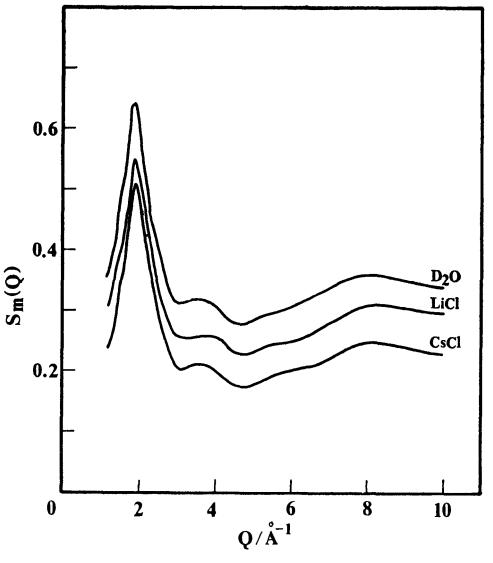

Fig. 4. Observed structure factors for LiCl and CsCl solutions at 1 M, compared with the factor for D_2O (14 °C).

of extra pure anhydrous lithium chloride and caesium chloride to heavy water.[20]

The structure factors are shown in Fig. 4 for LiCl and CsCl solutions including those for pure heavy water.[21] The change of the bump at *ca.* 4 $Å^{-1}$ as well as that of the main peak with a shoulder at 2.8 $Å^{-1}$ indicates the effects of ions on the structure of the first hydration sphere.

Method for Analysis. All the neutron diffraction studies for aqueous ionic solutions have been made so far for concentrated solutions (>1 M).[4,13] We give here the diffraction data for more dilute solutions (1 M). In order to analyze the data of dilute solutions, we have subtracted the structure factor $S_m(Q)_{D_2O}$ of D_2O multiplied by an appropriate fraction from the total structure factor $S_m(Q)_{total}$ of solutions. The remaining factor, $\Delta S_m(Q)$, becomes

$$\Delta S_m(Q) = S_m(Q)_{total} - (1-x)S_m(Q)_{D_2O}, \quad (2)$$

$$x = \frac{c(n_+ + n_-)}{55.3}, \quad (3)$$

where x is the mole fraction of D_2O coordinated in the nearest hydration shell around ions, n_+ and n_- are the coordination number about the cation and the anion, respectively, and c is concentration.

In order to determine the structure of the nearest hydration shell we compare the observed values of $\Delta S_m(Q)$ with those calculated for various structure models assumed.

Procedure for Analysis of LiCl and CsCl Solutions. The structure of the hydration shell is characterized by parameters, coordination number n, ion-oxygen distances, and orientational arrangements of water molecules around ions (Fig. 5).

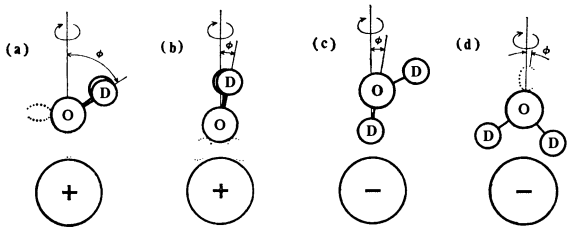

Fig. 5. Orientational arrangements of water molecules around ions.
(a) Linear form for cation, (b) bifurcated form for cation, (c) linear form for anion, (d) bifurcated form for anion.

The coordination number and ion-oxygen distances, so far obtained experimentally, are given in Tables 1 and 2. They are very diversified. As regards configuration of water molecules around ions, two forms, "linear" and "bifurcated," are expected for cations where lone-pair electrons are in the vicinity of the ions (Figs. 5(a) and (b)) and also for anions, where deuterium atoms are located in the vicinity of the ions (Figs. 5(c) and (d)). Very few experimental results have been reported so far concerning the orientation of water molecules around ions.

We have calculated $\Delta S_m(Q)$ for a number of structure models in which the magnitudes of parameters have been varied (Table 3). For each of the LiCl and CsCl solutions, the 24 different structures with respect to the coordination number and the type of orientational configurations are assumed, ion-oxygen distances and the angle ϕ being varied successively at intervals of 0.05 Å and 10°, respectively, for each of the 24 structure models. As a whole, we calculated the $\Delta S_m(Q)$ curves for 264 different models of the structure of the

first hydration shell in the LiCl solution, comparing the calculated curves with those observed, and those for 744 different models in the CsCl solution.

Results of Analysis. We determined the best structure model of the first hydration shell for both solutions. However, it is not possible to show all the curves calculated for the assumed models for comparison (264 and 744 models for LiCl and CsCl solutions, respectively); only typical features of the curves are given.

The calculated $\Delta S_m(Q)$ curves for different sets of coordination numbers are shown for both solutions in Fig. 6; for the LiCl solution, those with various magnitudes of parameter ($r_{Li^+\text{-}O}$, $r_{Cl^-\text{-}O}$, and orientational configurations *etc.*) are shown in Figs. 7(a)—(d) in the case of $n_{Li^+}=4$ and $n_{Cl^-}=6$.

The calculated $\Delta S_m(Q)$ curves of the best mode's thus determined for both solutions are given in Fig. 8 (each curve in Figs. 6(a) and (c') is identical with the best fit curve, respectively). The magnitudes of parameter and orientational configurations for the best structure model of the first hydration shell are given in Table 4.

Concerning the configuration of water molecules within the first hydration shell around cations, the results agree with the conclusion obtained by the

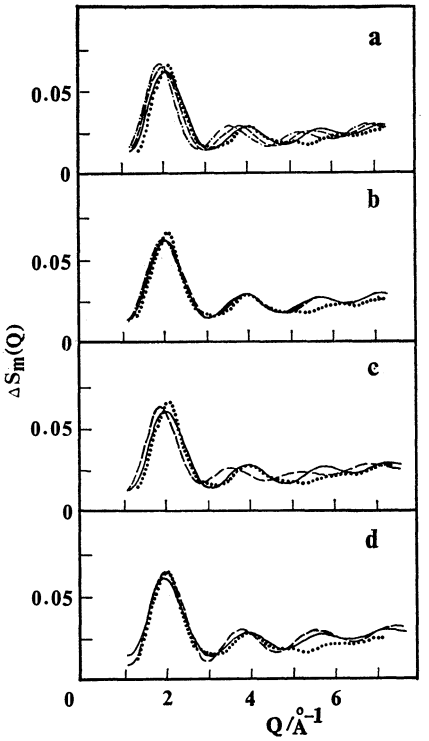

Fig. 7. Changes in the calculated $\Delta S_m(Q)$ with variation of physical parameters for the LiCl solution.
• : Observed $\Delta S_m(Q)$ (14 °C), (a) r_{Li^+-O} (all other parameters are identical with those given in Table 4), ——: 1.90 Å, – – –: 2.00 Å, —•—: 2.10 Å,
(b) r_{Cl^--O} (all other parameters are identical with those given in Table 4), ——: 3.10 Å, – – –: 3.05 Å, —•—: 3.15 Å,
(c) configurations around Li^+ (all other parameters are identical with those given in Table 4), ——: linear, – – –: bifurcated,
(d) configurations around Cl^- (all other parameters are identical with those given in Table 4), ——: linear, – – –: bifurcated.

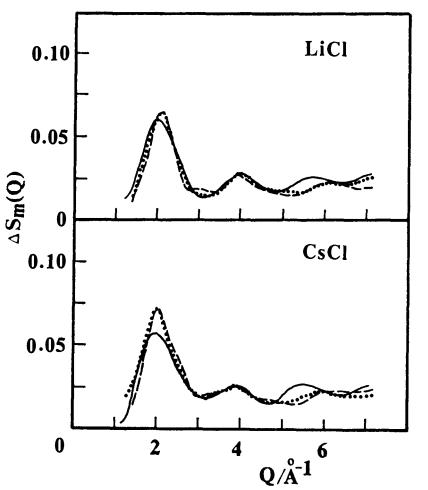

Fig. 8. The best fit curves with the observed $\Delta S_m(Q)$.
• : Observed $\Delta S_m(Q)$ (14 °C), ——: observed $\Delta S_m(Q)$ (18 °C),[21] – – –: calculated $\Delta S_m(Q)$.

molecular dynamics study of Briant and Burton.[22] However, with respect to the configuration around Cl^-, we can not determine which type of configuration, linear or bifurcated, is predominant (Fig. 7(d)).

From the structure analysis where the parameters have been varied systematically (Table 3), we conclude that the structure models shown in Table 4 give the best fit curves with those observed for the LiCl and CsCl solutions at 1 M.

Oxidation of 3,5-Di-*t*-butylcatechol Catalyzed by Metal Acetylacetonates in Organic Solvents

Hiroyuki SAKAMOTO, Takuzo FUNABIKI,* Satohiro YOSHIDA, and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received November 21, 1978)

The oxidation of 3,5-di-*t*-butylcatechol (3,5-DTBC) has been studied in organic solvents in the presence of metal acetylacetonates ($M(acac)_2$). The catalytic activity of $M(acac)_2$ decreased in the order M=Mn>Co> Ni≫Fe, and the product was 3,5-di-*t*-butyl-*o*-benzoquinone (3,5-DTBQ). The kinetic analysis has suggested a mechanism in which the radical chain reactions involving 3,5-di-*t*-butyl-*o*-benzosemiquinone (3,5-DTBSQ·) and hydroperoxyl radical (·OOH) are initiated by the reaction of 3,5-DTBC with the initially formed dioxygen metal complexes. Kinetic parameters for the complexation of molecular oxygen by $Mn(acac)_2$ and $Co(acac)_2$ were estimated: $\Delta H^{\neq}$(kJ mol^{-1})=4.6±0.8 for Mn, 29.7±0.8 for Co; $\Delta S^{\neq}$(J mol^{-1} K^{-1})=−200±2 for Mn, −135±2 for Co.

There has been much interest recently in the study of the oxidation of catechol and the reversible absorption of oxygen by transition metal complexes, because both are related to biological phenomena which involve enzymes and hemoglobin. The oxidation of catechols is accompanied by the aromatic ring cleavage[1–4] or by the dehydrogenation to form *o*-benzoquinones.[3–9] The latter reaction has been catalyzed by enzymes,[5] aqueous bases,[4,6] metal ions in basic media,[4,7] metal oxides such as PbO_2 and Ag_2O,[8] and metal salts such as Ag_2CO_3,[9] but transition metal complexes have rarely been used as catalysts.[10] Recently, the formation of the dioxygen complex of cobalt(II) acetylacetonate, in which the metal-oxygen bond is very weak, has been proposed in the oxidation of cumene,[11] α-methylstyrene,[11] and 1-phenylethanol.[12] Thus, the dioxygen complex is expected to be an active species in the oxidation of catechol. We have studied the oxidation of 3,5-di-*t*-butylcatechol (3,5-DTBC) by metal acetylacetonates ($M(acac)_2$: M=Mn, Fe, Co, Ni, Cu) in order to determine the catalytic activity of these readily available complexes for the oxidation of catechol and to obtain information about the activation of oxygen by coordinating to metal complexes. 3,5-DTBC was used as reactant to avoid the solvolytic attack on the quinonoid nucleus,[4,6,13] and the reactions were performed in the organic solvents without base to avoid the complexity caused by the dissociation of the catechol to catechol anion. The coordination of catechol to the metal complex as mono- or dianion, which was proposed by Grinstead[4] or Martell,[7] will be neglected in the present conditions.

Experimental

Materials. Metal acetylacetonates and 3,5-DTBC were recrystallized from chlorobenzene and heptane, respectively. 3,5-Di-*t*-butyl-*o*-benzoquinone (3,5-DTBQ) was prepared by the method of Grinstead[4] and recrystallized from 2,2,4-trimethylpentane. All the solvents were distilled before use.

Manometric Study. All the reactions were performed at 25 °C in a 50 cm^3 two-necked flask which was attached to an ordinary vacuum line system. The reaction was started by the addition of the 3,5-DTBC solution with an injection syringe through a serum cap to the catalyst solution, which was stirred magnetically in an oxygen atmosphere. The reaction was followed by measuring the oxygen absorption with a gas burette under a constant pressure. The yield of 3,5-DTBQ was determined spectrophotometrically.

Spectroscopic Study. The rate of the reaction (rate of the formation of 3,5-DTBQ) in acetone was measured spectrophotometrically on a JASCO UVIDEC-1 spectrophotometer with a 1 cm quartz cell in air. λ_{max} and ε of 3,5-DTBQ in acetone were 399 nm and 1.85×10^3 mol^{-1} dm^3 cm^{-1}, respectively. The initial concentration of the dissolved oxygen was estimated by the use of the tabulated data.[15] ESR spectra were taken on a JEOL PE-2X spectrometer modified with a JEOL ES-SCXA gunn diode microwave unit.

Results and Discussion

Catalytic Activity. Figure 1 shows the oxygen absorption curves in the oxidation of 3,5-DTBC by $M(acac)_2$ in acetonitrile. Oxygen was absorbed without an induction period by the manganese, cobalt, and nickel complexes, but $Cu(acac)_2$ exhibited a different mode of the oxygen absorption. This suggests that the mechanism for the former three complexes is

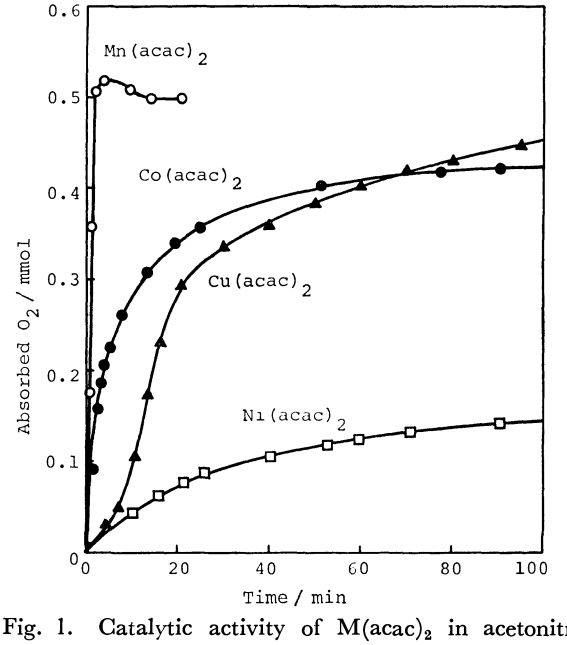

Fig. 1. Catalytic activity of $M(acac)_2$ in acetonitrile solvent at 25 °C under oxygen atmosphere.
$[M(acac)_2]_0$=0.1 mmol; $[3,5\text{-DTBC}]_0$=1.0 mmol; total volume=10 cm^3.

different from that for $Cu(acac)_2$. The catalytic activity evaluated from the maximal rate of the oxygen absorption decreased in the order M=Mn>Co>Cu>Ni≫Fe(no reaction). This order is different from that reported for the oxidation of cumene and α-methylstyrene (Co>Mn>Ni).[11] The inactivity of $Fe(acac)_2$ is due to its ready conversion to an inactive Fe(III) species in the presence of oxygen.[16]

Table 1. Catalytic activity and solvent effect[a]

Catalyst	Solvent	Reaction time (min)	Moles O_2 absorbed per mole 3,5-DTBC	Yield of 3,5-DTBQ (%)
non	Acetonitrile	120	0	0
$Mn(acac)_2$	Acetonitrile	5	0.50	95—100
$Fe(acac)_2$	Acetonitrile	120	0	0
$Co(acac)_2$	Acetonitrile	120	0.42	75—80
$Ni(acac)_2$	Acetonitrile	180	0.23	40—45
$Cu(acac)_2$	Acetonitrile	120	0.48	45—50
$MnCl_2 \cdot 4H_2O$[b]	Acetonitrile	120	0	0
$FeCl_2 \cdot 4H_2O$	Acetonitrile	120	0.07	0
$CoCl_2 \cdot 6H_2O$	Acetonitrile	120	0	0
$NiCl_2 \cdot 6H_2O$	Acetonitrile	120	0	0
$CuCl_2 \cdot 2H_2O$	Acetonitrile	120	0	0
$Mn(OAc)_2 \cdot 4H_2O$	Acetonitrile	20	0.48	75—80
$Co(OAc)_2 \cdot 4H_2O$	Acetonitrile	120	0.45	75—80
$Ni(OAc)_2 \cdot 4H_2O$	Acetonitrile	180	0.24	40—45
$Cu(OAc)_2 \cdot H_2O$	Acetonitrile	70	0.70	95—100
$Mn(acac)_2$	Acetone	5	0.51	95—100
$Mn(acac)_2$	Benzene	7	0.49	95—100
$Mn(acac)_2$	Methanol	10	0.51	95—100

a) $[Catalyst]_0=0.1$ mmol; $[3,5\text{-DTBC}]_0=1.0$ mmol; total volume=10 cm^3 at 25 °C under oxygen atmosphere. b) The solution was somewhat heterogeneous.

The solvent effect was studied with $Mn(acac)_2$. As shown in Table 1, the rate decreased in the order: acetone≳acetonitrile>benzene>methanol, but the solvent effect was not so remarkable. Catalytic activity in organic solvent was also studied with some metal salts. As shown in Table 1, metal halides, which are active in $KHCO_3$ buffered aqueous methanol,[4] were not active. Metal carboxylates were active as metal acetylacetonates, but induction periods were clearly observed in the oxygen absorption curves, as in the case of $Cu(acac)_2$.

The oxidation product, which was isolated by ether extraction, was 3,5-DTBQ, and its yield was >95% in the case of $Mn(acac)_2$. The result that the maximal amount of the absorbed oxygen with $Mn(acac)_2$ was slightly greater than one-half of 3,5-DTBC (see Fig. 1) suggests a two-step reaction (Reactions 1 and 2) rather than the single step 3.

$$3,5\text{-DTBC} + O_2 \longrightarrow 3,5\text{-DTBQ} + H_2O_2 \quad (1)$$

$$H_2O_2 \longrightarrow H_2O + 0.5O_2 \quad (2)$$

$$3,5\text{-DTBC} + 0.5O_2 \longrightarrow 3,5\text{-DTBQ} + H_2O \quad (3)$$

The formation of hydrogen peroxide was confirmed by iodometry and the blue color of potassium ferricyanide.[17] It was also observed that the complex catalyzed the rapid decomposition of hydrogen peroxide (Reaction 2).

Kinetic and Spectroscopic Studies. Kinetic studies were performed with $Mn(acac)_2$ and $Co(acac)_2$ in acetone, which was the most effective solvent for the oxidation. The reaction catalyzed by $Ni(acac)_2$ was too slow to be followed spectrophotometrically. Acetone was stable under the oxidation conditions, for no

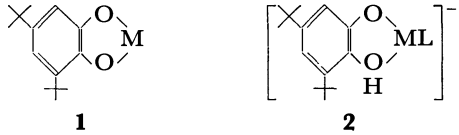
oxidation product of acetone was detected by GLC in gaseous or liquid phase. A typical example of the oxidation of 3,5-DTBC is shown in Fig. 2. Figures 3 and 4 show the clear linear relations between the initial rate and catalyst concentration and between the reciprocals of the initial rate and of 3,5-DTBC concentration. As shown in Fig. 2, the addition of 3,5-DTBQ decreased the initial rate (r_0). Since Mn(III) and Co(III) species ($\lambda_{max} = 590$ nm (Mn), 595 nm (Co)) were formed by the addition of 3,5-DTBQ, the retardation may be attributed to the formation of these inactive species. Although Vásvari and Gál reported that Co(III) was formed in the initial stage of the oxidation of 1-phenylethanol catalyzed by $Co(acac)_2$,[13] the oxidation of the metal complexes was rather slow in the present condition and was affected by 3,5-DTBQ. Retardation by the addition of water, which was observed in the oxidation of acrylaldehyde[18] and tributylphosphine[19] by $Co(acac)_2 \cdot 2H_2O$, was not observed even in the presence of 5.0×10^{-4} mol dm^{-3} of water. The effect of the oxygen concentration (oxygen pressure) on the initial rate was studied manometrically in the presence of high concentrations of 3,5-DTBC and catalysts; a first order dependence was observed, as shown in Fig. 5. We have tried to detect radical intermediates by the spin trapping method, as previously reported.[20] Double triplets were observed with 5,5-dimethyl-1-pyrroline 1-oxide in the reaction solution catalyzed by $Mn(acac)_2$: $a_N = 14.6$ G (in acetone), 14.2 G (in benzene), $a_{\beta H} = 16.6$ G, $g = 2.0060$. The radical has not been assigned yet, but it may be a radical such as 3,5-di-*t*-butyl-*o*-benzosemiquinone (3,5-DTBSQ·) rather than the hydroxyl radical ($a_N = 14.3$ G, $a_{\beta H} = 11.7$ G, $g = 2.0061$ in H_2O) or the hydroxyl radical ($a_N = 15.3$ G, $a_{\beta H} = 15.3$ G, $g = 2.0060$ in H_2O).[21]

Reaction Mechanism. In the studies of oxidation of catechol catalyzed by metal ions[4] or metal chelates,[7] aqueous methanol was used as a solvent, and the reaction was promoted in the basic media. The proposed mechanisms in these conditions involved the initial coordination of catechol dianion to metal ion (**1**) or of monoanion to metal chelate (***2***, L: 4-nitrocatechol or tetrabromocatechol),[7] followed by the reaction with oxygen. A ternary complex coordinated by oxygen and catechol anion has been proposed as an active complex.[4,7] In our present con-



1 **2**

ditions, in organic solvents without base, the coordination of catechol to metal complexes as a mono- or dianion is improbable. This is reflected by the small solvent effect. We can expect that catechol itself coordinates to the metal complexes, but the coordination must be much weaker than that of anions in the basic aqueous media. In addition, the acac ligand initially occupies four coordination sites; this is less desirable for the coordination of catechol than the system by Martell,[7] in which a 1: 1 ratio of metal ion and ligand was used to leave a maximum number of coordination sites open.

On the other hand, Kamiya has studied the oxidation

of hydrocarbons (cumene, α-methylstyrene) by metal acetylacetonates, and proposed that the reaction was initiated by the activated oxygen molecule coordinated to metal acetylacetonates (M=Co(II), Mn(II)).[11]

$$M(acac)_2 + O_2 \rightleftharpoons M(acac)_2^{\delta+}O_2^{\delta-}$$

$$M(acac)_2^{\delta+}O_2^{\delta-} + \diagdown C{=}C \diagup \longrightarrow$$

$$M(acac)_2{-}O_2{-}\overset{|}{C}{-}\overset{|}{C}\cdot \longrightarrow$$

Since the present reaction condition is similar to that suggested by Kamiya rather than those of Grinstead or Martell, it seems likely that the oxidation of 3,5-DTBC is initiated by a process similar to the oxidation of hydrocarbon rather than the processes proposed in the basic aqueous media. We propose here the following reaction sequences as a very probable mechanism; it well explains the kinetic results and the formation of hydrogen peroxide and a radical intermediate.

$$M(acac)_2 + O_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} M(acac)_2 \cdots O_2 \quad (4)$$

$$M(acac)_2 \cdots O_2 + 3,5\text{-DTBC} \xrightarrow{k_2} M(acac)_2 + 3,5\text{-DTBSQ}\cdot + \cdot OOH \quad (5)$$

$$3,5\text{-DTBC} + \cdot OOH \xrightarrow{k_3} 3,5\text{-DTBSQ}\cdot + HOOH \quad (6)$$

$$3,5\text{-DTBSQ}\cdot + 3,5\text{-DTBSQ}\cdot \xrightarrow{k_4} 3,5\text{-DTBQ} + 3,5\text{-DTBC} \quad (7)$$

$$3,5\text{-DTBSQ}\cdot + \cdot OOH \xrightarrow{k_5} 3,5\text{-DTBQ} + HOOH \quad (8)$$

$$M(acac)_2 + 3,5\text{-DTBQ} \xrightarrow{k_6} \text{Inactive species} \quad (9)$$

$$M(acac)_2 + HOOH \xrightarrow{k_7} M(acac)_2 + H_2O + 0.5O_2 \quad (10)$$

The high initial rate of oxidation without the induction period can be explained by the activation of oxygen by the formation of a weak metal-oxygen bond, followed by the abstraction of hydrogen from 3,5-DTBC to form 3,5-DTBSQ· and ·OOH. The Reactions 6 and 7 were assumed by reference to the autoxidation of hydrocarbon[22] and the dismutation of 3,5-DTBSQ· anion.[6] The possible termination reactions other than 7 are 8 and 11, but the latter may be neglected for a low concentration of

$$\cdot OOH + \cdot OOH \longrightarrow HOOH + O_2 \quad (11)$$

the ·OOH radical compared with that of 3,5-DTBSQ·. Reactions 9 and 10 explain the retardation effect of 3,5-DTBQ and the decomposition of hydrogen peroxide, respectively.

In the initial period of the reaction, we can neglect Reactions 9 and 10. By applying the steady-state treatment for $M(acac)_2\cdots O_2$, 3,5-DTBSQ·, and ·OOH (Eqs. 12—14), we obtain the rate equation 15 for the formation of 3,5-DTBQ:

$$\frac{d[M(acac)_2\cdots O_2]}{dt} \equiv 0 = k_1[M(acac)_2][O_2] - k_{-1}[M(acac)_2\cdots O_2] - k_2[M(acac)_2\cdots O_2][3,5\text{-DTBC}] \quad (12)$$

$$\frac{d[3,5\text{-DTBSQ}\cdot]}{dt} \equiv 0 = k_2[M(acac)_2\cdots O_2][3,5\text{-DTBC}] + k_3[3,5\text{-DTBC}][\cdot OOH] - 2k_4[3,5\text{-DTBSQ}\cdot]^2 - k_5[3,5\text{-DTBSQ}\cdot][\cdot OOH] \quad (13)$$

$$\frac{d[\cdot OOH]}{dt} \equiv 0 = k_2[M(acac)_2\cdots O_2][3,5\text{-DTBC}] - k_3[3,5\text{-DTBC}][\cdot OOH] - k_5[3,5\text{-DTBSQ}\cdot][\cdot OOH] \quad (14)$$

$$\frac{d[3,5\text{-DTBQ}]}{dt} = k_4[3,5\text{-DTBSQ}\cdot]^2 + k_5[3,5\text{-DTBSQ}\cdot][\cdot OOH] = k_2[M(acac)_2\cdots O_2][3,5\text{-DTBC}] \quad (15)$$

Using the stoichiometric equation 16, we obtain Eq. 17:

$$[M(acac)_2] = [M(acac)_2]_0 - [M(acac)_2\cdots O_2] \quad (16)$$

$$[M(acac)_2\cdots O_2] = \frac{k_1[M(acac)_2]_0[O_2]}{k_1[O_2]+k_{-1}+k_2[3,5\text{-DTBC}]} \quad (17)$$

Assuming $[3,5\text{-DTBC}] \simeq [3,5\text{-DTBC}]_0$ and $[O_2] \simeq [O_2]_0$, we obtain the equation for the initial rate of the formation of 3,5-DTBQ and its linearized form:

$$\left(\frac{d[3,5\text{-DTBQ}]}{dt}\right)_0 = r_0 = \frac{k_1k_2[3,5\text{-DTBC}]_0[O_2]_0[M(acac)_2]_0}{k_1[O_2]_0+k_{-1}+k_2[3,5\text{-DTBC}]_0} \quad (18)$$

$$1/r_0 = \frac{k_1[O_2]_0+k_{-1}}{k_1k_2[M(acac)_2]_0[O_2]_0}\left(\frac{1}{[3,5\text{-DTBC}]_0}\right) + \frac{1}{k_1[M(acac)_2]_0[O_2]_0} \quad (19)$$

Eqs. 18 and 19 are consistent with the results shown in Figs. 3 and 4, respectively. If we ignore the pre-equilibrium (Eq. 4), the reactions of Eqs. 4 and 5 are described by Eq. 20.

$$M(acac)_2 + O_2 + 3,5\text{-DTBC} \xrightarrow{k} M(acac)_2 + 3,5\text{-DTBSQ}\cdot + \cdot OOH \quad (20)$$

In this case, the initial rate equation 21 is obtained by a similar steady-state treatment.

$$r_0 = k[M(acac)_2]_0[O_2]_0[3,5\text{-DTBC}]_0 \quad (21)$$

Eq. 21 is not consistent with the results in Fig. 4, indicating that we can not neglect the pre-equilibrium.

The first order dependence of the rate on the oxygen concentration, as shown in Fig. 5, is consistent with the rate equation 18, because the rate equation 22 is derived by assuming $k_1[O_2]_0+k_{-1} \ll k_2[3,5\text{-DTBC}]_0$. This assumption

$$r_0 = k_1[M(acac)_2]_0[O_2]_0 \quad (22)$$

is not unreasonable in the presence of a high concentration of 3,5-DTBC (about 10^3 greater than the concentrations in the spectroscopic studies). We observed that the rate was independent of the concentration of 3,5-DTBC in the region of 0.1—0.3 mol dm^{-3}; this result supports our assumption.

Reaction 5 is the step of the abstraction of the hydrogen of catechol by the activated oxygen, and may proceed stepwise *via* a ternary complex, but the kinetic results are not enough to discriminate

$$M(acac)_2\cdots O_2 + 3,5\text{-DTBC} \rightleftharpoons M(acac)_2\cdots O_2(3,5\text{-DTBC})$$

$$M(acac)_2\cdots O_2(3,5\text{-DTBC}) \longrightarrow M(acac)_2 + 3,5\text{-DTBSQ}\cdot + \cdot OOH$$

between a one-step and a two-step process. The coordination of 3,5-DTBC to the oxygen complex is not impossible, because acac can coordinate as a monodentate ligand, but the complex seems far less stable than the ternary complexes proposed by Grinstead[4] or Martell.[7] Vásvari and Gál has proposed the splitting of the O–O bond by the following reactions in the oxidation of 1-phenylethanol (ROH) with $Co(acac)_2$,[12] but the process

$$ROH\cdot Co(acac)_2\cdots O_2 + Co(acac)_2 \longrightarrow Co(acac)_2O\cdot + ROH\cdot Co(acac)_2\cdot O$$

$$ROH\cdot Co(acac)_2O\cdot \longrightarrow Co(acac)_2OH(RO\cdot)$$

$$Co(acac)_2O\cdot + ROH \longrightarrow Co(acac)_2OH(RO\cdot)$$

is not consistent with the formation of hydrogen peroxide in the present system.

The reversible formation of a 1:1 dioxygen-transition metal complex and the reaction of the activated oxygen are of current interest. Many examples of a dioxygen cobalt complex have been found,[23] and recently the formation of dioxygen complexes of manganese tetraphenylporphyrin[24] and phthalocyanin[25] have been reported. Thus, the formations of the dioxygen complexes of metal acetylacetonates are probable. The values of k_1 (Reaction 4) were estimated from the intercepts Fig. 4 (Table 2), or from the slopes in Fig. 5 (27.5 and 0.2 $dm^3\ mol^{-1}\ s^{-1}$ for Mn and Co, respectively). The agreement of the values estimated in the different conditions was fairly good for $Mn(acac)_2$, but rather poor for $Co(acac)_2$. The smaller values obtained from Fig. 5 may be ascribed to the fact that the reaction was retarded by 3,5-DTBQ even in the initial stage, especially in the case of $Co(acac)_2$. The activation parameters (ΔH^* and ΔS^*) for this step are given in Table 2, and the values for the cobalt complex are comparable to those of $[Co(Ph_2PCH{=}CHPPh_2)(O_2)]^+$ ($\Delta H^*=14.2$ kJ mol^{-1}, $\Delta S^*=-117$ J $mol^{-1}\ K^{-1}$).[26] The proposed mechanism is consistent with the order of the catalytic activity (Mn>Co>Ni), because it is expected that the low redox potential facilitates the electron transfer from metal to oxygen. The inactivity of $Fe(acac)_2$ may be ascribed to the stabilization of a Fe(III) species rather than $Fe(acac)_2\cdots O_2$ by the extreme electron transfer. We could not find any product formed by the aromatic ring cleavage, and this indicates that the activation of oxygen by coordination to $M(acac)_2$ is not enough, compared with that of superoxide[3] or singlet oxygen.[27]

Table 2. Kinetic parameters of k_1

Catalyst[a]	Temp (°C)	$1/(k_1\times[M(acac)_2]\times[O_2])$[b]	k_1 ($dm^3\ mol^{-1}\ s^{-1}$)	ΔH^* (kJ mol^{-1})	ΔS^* (J $mol^{-1}\ K^{-1}$)
$Mn(acac)_2$	20	3.96×10^5	29.9	4.6 ± 0.8	-200 ± 2
	25	4.09×10^5	31.5		
	30	4.33×10^5	33.0		
	35	4.79×10^5	34.0		
$Co(acac)_2$	20	1.55×10^6	3.17	29.7 ± 0.8	-135 ± 2
	25	1.35×10^6	3.96		
	30	1.20×10^6	4.95		
	35	1.15×10^6	5.98		

a) The concentrations of catalysts were same as those of Fig. 4. b) The concentrations of oxygen at 20, 25, 30, and 35 °C were estimated to be 2.63, 2.42, 2.18, and 1.88 mmol dm^{-3}, respectively.[15]

From the viewpoint of the potential use of the dioxygen metal complex as catalysts for the oxidation of organic substrates, this work has shown that metal acetylacetonates function as an efficient catalyst for the oxidation 3,5-DTBC. Mckillop and Ray[10] have recently shown that $Co(acacene)(O_2)\cdot H_2O$ catalyzes the oxidation of hydroquinones; $Co(acacene)(O_2)\cdot H_2O$ was presumed to be an active species, but no mechanism has been proposed. The mechanism proposed here is a new radical mechanism for the oxidation of 3,5-DTBC which does not involve the redox of metal ion[4] and is different from the ionic mechanism.[7] We have not studied in detail the oxidation catalyzed by $Cu(acac)_2$ and metal carboxylates, which may be explained by the most common pathway for catalysis by transition metal complexes involving the decomposition of peroxides.

The Oxidation Activity and Acid-Base Properties of Co_3O_4-V_2O_5 and Co_3O_4-MoO_3 Systems

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received November 27, 1978)

The acidity and basicity of Co_3O_4–V_2O_5 and Co_3O_4–MoO_3 systems, with different compositions, were measured by means of the adsorption of NH_3, pyridine, and CO_2. The values of acidity were also confirmed by studying the catalytic activity for acid-catalyzed reactions, such as the dehydration of isopropyl alcohol and the isomerization of 1-butene. With the addition of V_2O_5 or MoO_3, the basicity rapidly decreases and the acidity gradually increases. The catalytic activity for the oxidation of hexane is well correlated with the basicity of the catalysts. With the Co_3O_4-rich catalysts, $V/(Co+V)$ or $Mo/(Co+Mo)<0.4$, butadiene is mainly oxidized to CO_2; the rate is also correlated to the basicity. However, the Co_3O_4-poor catalysts, $V/(Co+V)$ and $Mo/(Co+Mo)>0.6$, show a good selectivity for the maleic anhydride formation. The Co_3O_4-containing catalysts, regardless of the composition, are not effective for the selective oxidation of butene to butadiene. In the oxidation of methanol, the Co_3O_4-rich catalysts give only CO_2. However, with the Co_3O_4-poor catalysts, formaldehyde is almost the sole product. It is concluded that the catalytic behavior is to be interpreted, to a considerable extent, in terms of the acid-base properties of the metal oxides.

Co_3O_4 is a typical metal oxide with an eminent oxidizing power; it is, therefore, employed as a main component of catalysts suitable for the complete combustion of organic compounds. In the preceding paper,[1] we reported on the Co_3O_4-based catalysts modified by controlling the amount of P_2O_5 and K_2O added. It was found that the catalytic activity for the complete oxidation of various types of reactants, such as hexane, butene, phenol, and methanol, was correlated with the basicity of the catalysts.

It is interesting to note that, as a component of mixed-oxide catalysts suitable for certain selective oxidations, Co_3O_4 is also employed.[2] What is the role of Co_3O_4 in the multi-component catalysts?

In this work, Co_3O_4 was combined with an acidic oxide, such as V_2O_5 and MoO_3, which are widely used as the main components of various catalysts suitable for selective oxidation. We attempted to find how the addition of V_2O_5 or MoO_3 to Co_3O_4 modifies the catalytic behavior and to see whether or not the oxidation activity and selectivity for different types of oxidations can be interpreted in terms of the acid-base properties of the composite oxides.

Experimental

The catalysts used in this study were two series of binary oxides, Co_3O_4–V_2O_5 and Co_3O_4–MoO_3, with different compositions. As the starting materials, $Co(NO_3)_2 \cdot 6H_2O$, NH_4VO_3, and $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ were used. They were prepared by the procedures described in the preceding paper.[1]

The acidity and the basicity of the catalysts were determined by studying the adsorption of basic and acidic molecules, such as NH_3, pyridine, and CO_2, from the gas phase using either the static or pulse method. The technique of the measurements has also been described previously.[1,3-6]

The vapor-phase oxidation of 1-butene, butadiene, hexane, and methanol, the isomerization of 1-butene, and the dehydration of isopropyl alcohol (IPA) were carried out in an ordinary continuous-flow reaction system. The reactor and the experimental procedures were the same as those employed in earlier works.[1,3-7]

Results

Surface Areas. The effect of the V_2O_5 and MoO_3 content on the specific surface area was first checked by the BET method using nitrogen at −196 °C. The results are shown in Table 1. The surface area increases gradually with the addition of V_2O_5 or MoO_3 and reaches a broad maximum when the amount of the second components is about 10 at %.

Table 1. Surface areas of the Co_3O_4–V_2O_5 and Co_3O_4–MoO_3 catalysts used

Acidity. Since pure Co_3O_4 has a fair amount of acidic sites, probably of a weak acid strength compared with those of V_2O_5 and MoO_3, NH_3 was adsorbed on the Co_3O_4-rich catalysts to the same extent as on the V_2O_5- and MoO_3-rich catalysts, even at 175 °C. At higher temperatures, the decomposition of NH_3 was enhanced because of the eminent oxidizing power of Co_3O_4. Therefore, it seems difficult to measure the acidity by means of the NH_3 adsorption.

Therefore, another attempt was made to determine the acidity; that is, the amount of pyridine required to poison the isomerization activity for 1-butene was measured by the pulse method in the same way as in earlier studies.[3–5,7] A difficulty arose in this method, too, especially in the case of the Co_3O_4-rich catalysts, because they exhibit a very low isomerization activity; moreover, they oxidize the adsorbed pyridine at high temperatures. The results are shown in Figs. 1 and 2.

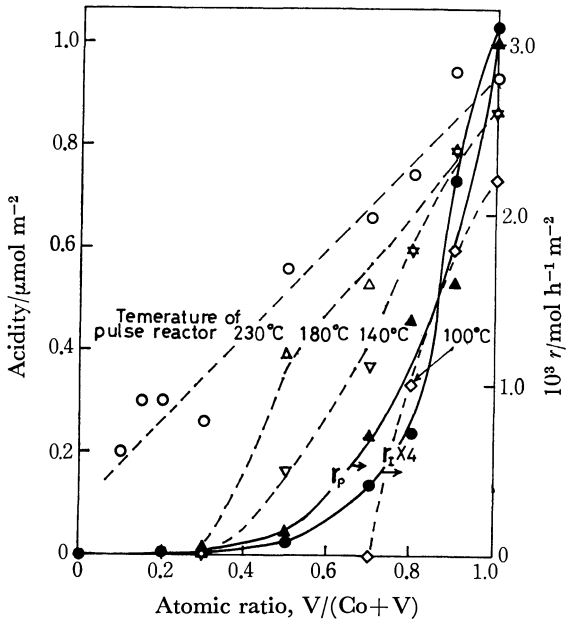

Fig. 1. Acidity of Co_3O_4–V_2O_5 as a function of the V_2O_5 content. Amount of pyridine required to poison the isomerization of 1-butene (pulse method): broken line, dehydration activity for IPA at 187 °C (r_p): ▲, isomerization activity for 1-butene at 260 °C (r_I): ●.

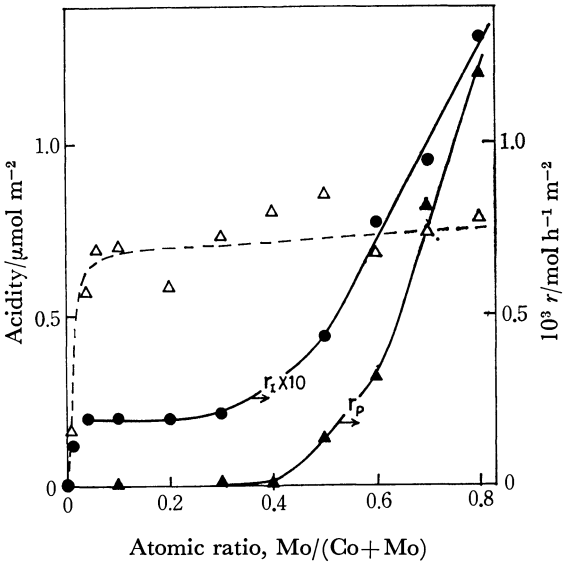

Fig. 2. Acidity of Co_3O_4–MoO_3 as a function of the MoO_3 content. Amount of pyridine required to poison the isomerization of 1-butene at 175 °C (pulse method): △, broken line, dehydration activity for IPA at 187 °C (r_p): ▲, isomerization activity for 1-butene at 272 °C (r_I): ●.

In order to confirm the values of the acidity, the catalytic activity for certain acid-catalyzed reactions was investigated. The dehydration of IPA to propylene and the isomerization of 1-butene to 2-butenes, in the presence of an excess of air, were chosen as the model reactions.[3–5,7] The reactions were carried out at the IPA and butene concentrations of 1.33 and 1.0 mol % in air, and at the total flow rate of 1.0 l/min, by changing the amount of catalyst in the range from 1 to 20 g. The initial rate of IPA dehydration at 187 °C, r_p, and that of butene isomerization at 260 or 272 °C, r_I (mol h^{-1} m^{-2} of catalyst), are plotted together with the values of acidity, in Figs. 1 and 2.

Basicity. The basicity of the Co_3O_4-containing catalysts, as determined by the amounts of CO_2 irreversibly adsorbed at 20 °C, is plotted in Fig. 3.

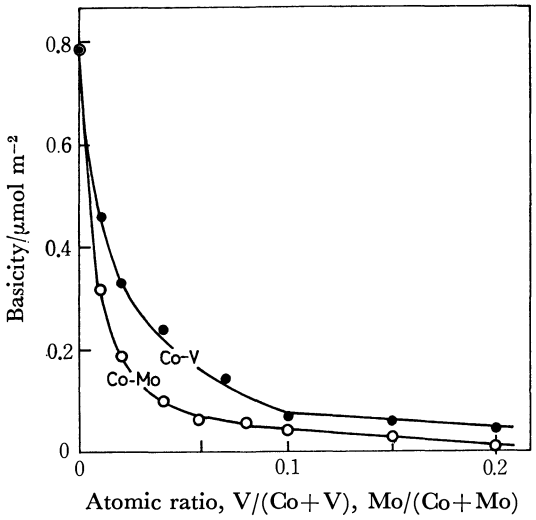

Fig. 3. Basicity of Co_3O_4–V_2O_5 and Co_3O_4–MoO_3 as a function of the V_2O_5 or MoO_3 content. Irreversible adsorption of CO_2 at 20 °C (static method).

Oxidation of Hexane. Alkanes and hydrogen act upon metal-oxide catalysts more or less as electron-donating reagents. However, this tendency might be so weak that the activity for the combustion of these compounds is really governed by the intrinsic oxidation activity rather than by the activation of the reactant molecules.[1,3,8] For convenience in the experimental procedures, combustion of hexane was chosen as a model reaction which reflects the intrinsic oxidation activity of the catalysts.

The reaction was carried out keeping the following conditions constant at T=262 °C; hexane=0.6 mol % in air, and total flow rate=1.0 l/min, while the amounts of the catalysts were varied in the range from 1 to 20 g to achieve a proper conversion. The main product was CO_2. The initial rate of CO_2 formation, r_{CO_2}(mol h^{-1} m^{-2} of catalyst), was measured with each catalyst as an index of the activity. The results are plotted as a function of the basicity of the catalysts in Fig. 4. A fairly good correlation is obtained between the activity and the basicity.

Oxidation of Butadiene. As a model reaction of "acid-formation" reactions, the oxidation of butadiene

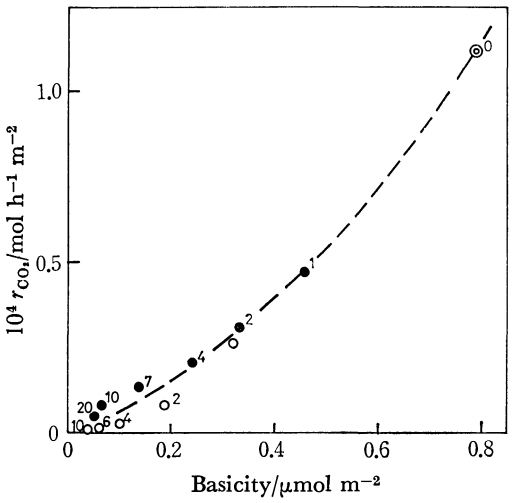

Fig. 4. Relation between the basicity and the oxidation activity for hexane. Co_3O_4–V_2O_5: ●, Co_3O_4–MoO_3: ○. r_{CO_2}: rate of CO_2 formation at T=262 °C and hexane=0.6 mol % in air. Numbers correspond to the content (atomic percent) of V_2O_5 or MoO_3 in the binary oxides.

to maleic anhydride was chosen in the same way as in the previous studies.[3-5,7] The reaction was carried out in the temperature range from 250 to 480 °C, at the butadiene concentration of 1.0 mol % in air, and with a total flow rate of 1.0 l/min, by changing the amounts of the catalysts from 1 to 20 g. The Co_3O_4-rich catalysts, V/(Co+V) and Mo/(Co+Mo)<0.4, were very active. However, the main product was CO_2, and the amount of CO were far lower than those of CO_2. The maleic anhydride, acetic acid, and the other compounds were formed in negligibly small amounts. The initial rates of CO_2 formation at 255 °C for the Co_3O_4–V_2O_5 and at 275 °C for the Co_3O_4–MoO_3, r_{CO_2}(mol/h·m^2 of catalyst), are plotted as a function of the basicity of the catalysts in Fig. 5.

On the other hand, the Co_3O_4-poor catalysts, V(Co+V) and Mo/(Co+Mo)>0.6, were fairly inactive compared with the Co_3O_4-rich catalysts. However, they were selective in forming acidic products. The selectivity to maleic anhydride at a fixed conversion, 50 to 60%, is shown in Fig. 6.

Oxidation of 1-Butene. As a model of the "base-formation" reactions, the oxidation of butene to

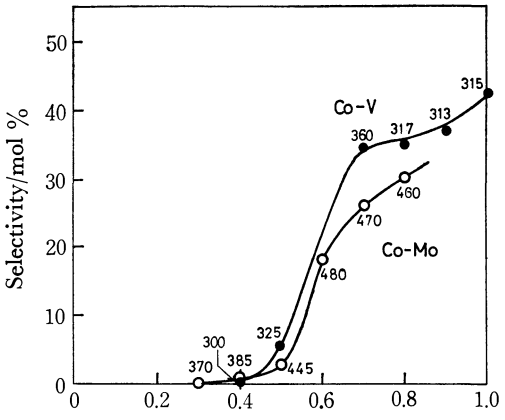

Fig. 6. Selectivity of butadiene to maleic anhydride as a function of the catalyst composition. Co_3O_4–V_2O_5: ●, Co_3O_4–MoO_3: ○. Conversion=50—60%, butadiene=1.0 mol % in air. Numbers correspond to the reaction temperatures (°C).

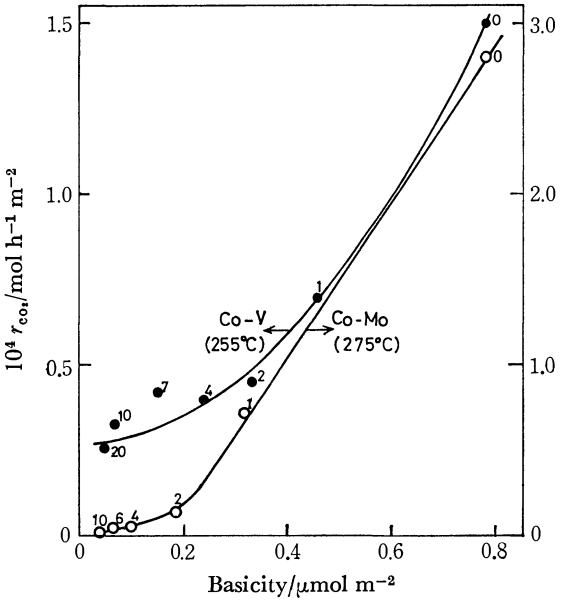

Fig. 5. Relation between the basicity and the activity for the oxidation of butadiene to CO_2. Co_3O_4–V_2O_5 (255 °C): ●, Co_3O_4–MoO_3 (275 °C): ○. Butadiene =1.0 mol% in air. Numbers correspond to the content (atomic percent) of V_2O_5 or MoO_3.

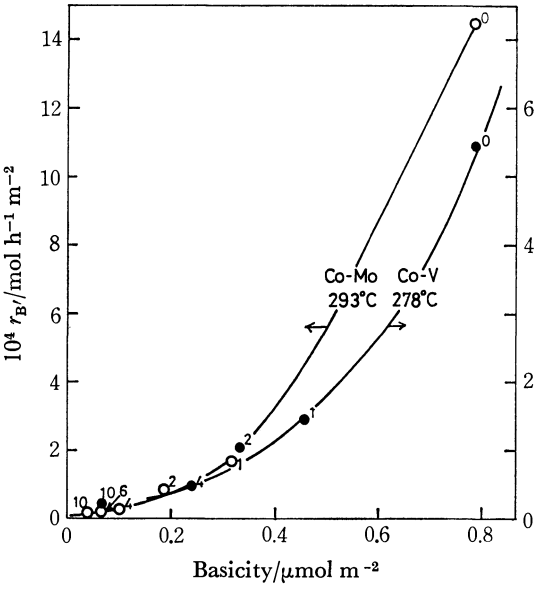

Fig. 7. Relation between the basicity and the activity for the oxidation of 1-butene to butadiene. Co_3O_4–V_2O_5 (278 °C): ●, Co_3O_4–MoO_3 (298 °C): ○. Concentration: 1-butene–oxygen–nitrogen=1.0–1.0–98.0 mol %. Numbers correspond to the content (atomic percent) of V_2O_5 or MoO_3.

butadiene was investigated.[3-5,7] The reaction was carried out in the temperature range from 270 to 420 °C, keeping the conditions constant at the concentrations of 1-butene, oxygen, and nitrogen of 1.0, 1.0, and 98.0 mol % respectively, and at the total flow rate of 1.0 l/min, while the amounts of the catalysts were varied in the range from 1 to 20 g. The main products were butadiene, CO_2, and CO; the amounts of the other products were very small.

The initial rates of butadiene formation at 278 °C for the Co_3O_4–V_2O_5 and at 293 °C for the Co_3O_4–MoO_3, r_β' (mol h^{-1} m^{-2} of catalyst) are plotted as a function of the basicity of the catalysts in Fig. 7. The selectivity to butadiene is shown in Fig. 8.

Oxidation of Methanol. Since it has been found that the catalytic activity and selectivity in the oxidation of methanol can be interpreted in terms of the acid-base properties of the catalysts,[9] the catalytic behavior of the Co_3O_4-containing catalysts for methanol oxidation was investigated.

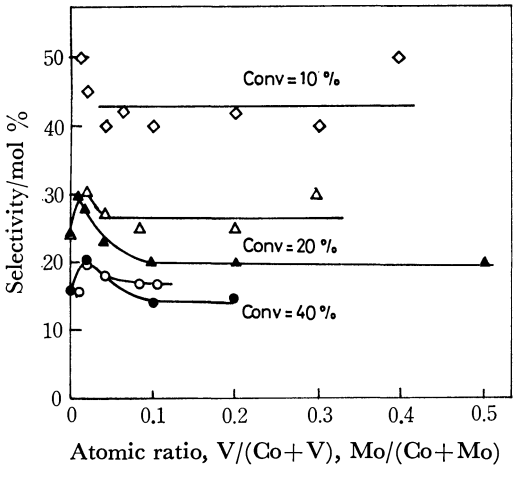

Fig. 8. Selectivity of 1-butene to butadiene as a function of the catalyst composition. Co_3O_4–V_2O_5: ▲ ●, Co_3O_4–MoO_3: ◇ △ ○. T=270—420 °C.

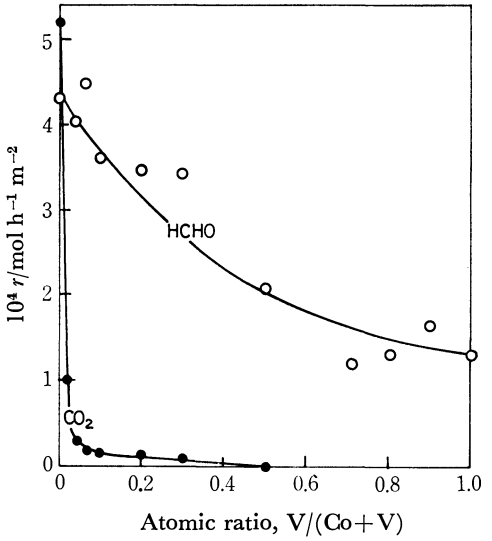

Fig. 9. Activity of Co_3O_4–V_2O_5 for the oxidation of methanol. Formaldehyde: ○, CO_2: ●. T=193 °C, methanol=2.6 mol % in air.

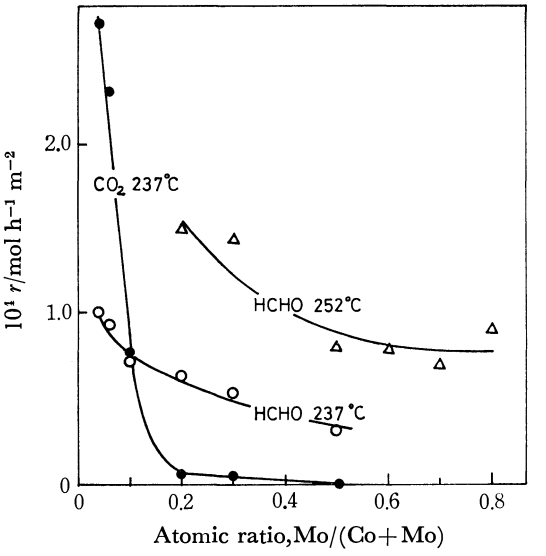

Fig. 10. Activity of Co_3O_4–MoO_3 for the oxidation of methanol. Formaldehyde: ○ △, CO_2: ●. Methanol =2.6 mol % in air.

The reaction was carried out at 193 °C for the Co_3O_4–V_2O_5 and at 237 and 252 °C for the Co_3O_4–MoO_3. The methanol concentration was 2.6 mol % in air, the total flow rate was 1.0 l/min, and the amounts of the catalysts used were from 1 to 20 g. The main products were formaldehyde and CO_2, and the amounts of the other products were very small. The initial rates of formaldehyde and CO_2 formation, r_F and r_{CO_2} (mol h^{-1} m^{-2} of catalyst), were measured following the principle of the differential reactor. The results are shown in Figs. 9 and 10.

Discussion

In the case of the Co_3O_4–V_2O_5 catalysts, the catalytic activities for the two acid-catalyzed reactions varied in the same direction as do the values of acidity (Fig. 1). We would like here to advance the theory that the amounts of pyridine required to poison the isomerization at different temperatures reflect the numbers of acidic sites with different acid-strengths; that is, the activity at a low temperature corresponds to the number of acidic sites of a strong acid-strength. According to the theory, it may be supposed from Fig. 1 that the V_2O_5 or V_2O_5-rich catalysts have stronger acidic sites than do the Co_3O_4-rich catalysts.

In the case of the Co_3O_4–MoO_3 system, however, a large discrepancy in the shape of curves is observed between the acidity and the activities for the acid-catalyzed reactions. Taking into consideration the fact that, because of the low isomerization activity, reliable data cannot be obtained even by the pulse method, especially in the Co_3O_4-rich catalysts, it is believed that the catalytic activities reflect the true acidity better than the amounts of pyridine. That is, the acidity of the Co_3O_4–MoO_3 increases steadily with an increase in the MoO_3, as in the case of the Co_3O_4–V_2O_5 system.

From the results shown in Figs. 1—3 and the above consideration, the following arguments may be put forward. The generation of marked acidic or basic properties is not observed upon the combination of Co_3O_4 with V_2O_5 or MoO_3. As can easily be expected from the acidic nature of V_2O_5 and MoO_3, the basicity of Co_3O_4 is extinguished rapidly with a small amount of these additives. In contrast, the acidity increases steadily with the content of the acidic oxides; in other words, the acidity of the acidic oxides is rapidly extinguished by combination with a basic oxide such as Co_3O_4.

The results shown in Fig. 4 indicate that the activity for hexane oxidation is independent of the acidity of the catalyst and is dependent on the basicity. This finding is in line with the results obtained from the Co_3O_4–P_2O_5 and Co_3O_4–K_2O systems.[1]

The results shown in Figs. 5 and 7 indicate that, even for the oxidation of olefins, the activity of the Co_3O_4-rich catalysts is correlated with the basicity rather than with the acidity of the catalysts. With regard to this finding, we would make the following proposal.

As has been proposed in the previous studies,[1,5,7] the oxidation activity is governed generally by three functions; (i) the activation of olefin by acidic sites; (ii) the activation of gaseous oxygen, which is connected with the basic character, and (iii) the oxidizing power of the surface oxygen species. The Co_3O_4-rich catalysts are poor in the acidic property; consequently, their ability to activate olefin is low, and, moreover, they have an extremely high oxidizing power. Possibly, a sufficient activation of the olefin by acidic sites is not a necessary condition for the oxidation and the reaction is mainly decided by the (ii) function and the (iii) function. This is the reason why the oxidation activity for olefin is correlated with the basicity.

On the other hand, the results in Fig. 6 indicate that the Co_3O_4-poor catalysts are effective for the "acid-formation-type" oxidation. This finding is also in line with the results obtained with other V_2O_5- and MoO_3-based catalysts and supports the proposal that a requirement for an effective catalyst for "acid-formation" reaction is the possession of a sufficient acidic property.[1,3–5,7]

With regard to the oxidation of butene to butadiene, both the Co_3O_4–V_2O_5 and Co_3O_4–MoO_3 are not effective over a full range of compositions. To explain the results, the following consideration is envisaged as a possibility. When the contents of V_2O_5 or MoO_3 are low, the oxidizing power is so strong that the reaction without the activation of butene on acidic sites takes place non-selectively. On the other hand, when the content of V_2O_5 or MoO_3 are high, the oxidizing power is highly suppressed; this is surely one of the necessary conditions for any type of selective-oxidation catalyst. However, another condition is also required for an effective catalyst for the "base-formation-type" oxidation; that is, the possession of a moderate character both in the acid and the base is required for the butadiene formation.[1,3–5] The V_2O_5- and MoO_3-rich catalysts are too acidic to be satisfactory for this type of oxidation.

Actually, the Co_3O_4-containing catalysts are proposed as catalysts suited only for "acid-formation" reactions such as the synthesis of acrylic acid[2,10] and of methacrylic acid.[2]

As for the oxidation of methanol, the activity to form CO_2 (Figs. 9 and 10) varies in the same fashion as does the basicity (Fig. 3). This finding supports the view that the CO_2 formation is catalyzed by the basic sites.[9] However, it seems difficult to explain the activity for formaldehyde formation merely by the acidity, as in the previous study.[9] At any event, it is also true in the case of the Co_3O_4-containing catalysts that formaldehyde is the sole product as long as the catalysts are acidic enough and that the selectivity to formaldehyde decreases, and that of of CO_2 increases, with an increase in the basic properties.[9]

It can be concluded that the acidic and basic properties of the Co_3O_4-containing mixed oxides are modified, as can be expected from the acidic nature of the additives, and that the catalytic behavior in oxidation is to be interpreted, to a considerable extent, in terms of the acid-base properties.

(Received November 28, 1978)

The photooxygenation of dibenzo[*a,j*]perylene by visible light irradiation was studied spectroscopically. The structure of unstable photooxygenation product was deduced from spectroscopic data and results of MO calculations to be as 8,12b-endoperoxide of dibenzo[*a,j*]perylene. This endoperoxide released oxygen gradually at room temperature, recovering the original hydrocarbon. The activation energy for this dark reaction was determined to be 21.4±0.5 kcal/mol in benzene and 22.6±0.5 kcal/mol in ethanol.

Reactions of excited aromatic hydrocarbons with molecular oxygen have been extensively studied in relation to the properties of singlet oxygen and quenching of excited singlet or triplet states.[1] However, the mode of reaction is by no means simple and investigations have been concentrated on rather small molecules as anthracene and 9,10-diphenylanthracene. Rubrene may be the only medium size aromatic hydrocarbon which received detailed and sufficiently unambiguous investigations.[2] Helianthrene (dibenzo[*a,o*]perylene) and its derivatives have also attracted the interest of several authors but the structures of their photooxygenation products have yet to be determined by further investigations.[2]

In the course of the syntheses and the study of photoconductive properties of aromatic hydrocarbons,[3] we observed that dibenzo[*a,j*]perylene, a structural isomer of helianthrene, underwent a typical photochemical reaction in organic solvents like benzene and ethanol. This phenomenon had already been reported by Clar[4] and could be interpreted as photooxygenation reaction like those of helianthrene and its derivatives. We have further investigated this reaction and the properties of the rather unstable oxygenation product because Clar's report was not much more than mere observation and also because photooxygenation process might possibly be related to the photoconductive properties of evaporated thin films or crystals of similar aromatic hydrocarbons.

Experimental

Synthesis of Dibenzo[a, j]*perylene.* Dibenzo[*a,j*]perylene was synthesized by almost the same method as Clar's.[4] 1-Chloroanthrone (mp 138 °C) was boiled and stirred with zinc chloride in pyridine at 200 °C for 20 h. Then it was treated with sodium dithionite to give dibenzo[*a, j*]perylene-3,9-dione. The dibenzoperylenequinone was boiled with zinc dust in pyridine, and glacial acetic acid was gradually added to the solution, which was then boiled and stirred for 5 h. From the reaction product, dibenzo[*a, j*]perylene was extracted with benzene and was purified by column chromatography with activated alumina. Further purification was carried out by high vacuum sublimation.

Photooxygenation and Related Measurements. Benzene or ethanol solution of dibenzo[*a, j*]perylene in 1 cm rectangular silica cell was irradiated by a 30 W tungsten lamp through a sharp cut off filter, Toshiba VY-50, transparent only for wavelength longer than 500 nm. The spectral change induced by the irradiation was observed with a Shimadzu UV-210 spectrophotometer.

The rate of thermal detachment of oxygen from the photooxygenation product was also observed by the same spectrophotometer, while the temperature of the sample solution was controlled to within ±0.5 °C by a specially designed bronze cell holder and a thermister temperature controller. Benzene and ethanol were used as solvents and temperature was controlled at several points between 40 °C and 75 °C.

The ESR spectrum of *ca.* 10^{-5} mol/l benzene solution of dibenzoperylene[5] was measured with ESR spectrometer NIHON DENSHI JES-PE-3X, before and after visible light irradiation under air pressure of about 0.1 Pa and 100 kPa.

A preliminary measurement of the overall efficiency of the photooxygenation reaction was also performed as follows. Benzene solution of dibenzo[*a,j*]perylene in a 1 cm rectangular silica cell was irradiated with the 556 nm monochromatic light, and the decrease of the hydrocarbon was monitored by the optical density change at 556 nm. The photon flux of the impinging light was measured making use of potassium tris-(oxalato)ferrate(III) actinometer.

It has also been ascertained that singlet molecular oxygen reacts with dibenzo[*a, j*]perylene in its ground state to give the same oxygenation product as that obtained by photooxygenation. The singlet molecular oxygen was produced by adding NaOCl (*ca.* 5% commercial antiseptic solution PURELOX) onto H_2O_2 (35%, Koso Chemical Ltd.), and was immediately introduced, bubbling, into benzene solution of the hydrocarbon, which had previously been placed upon 30% H_2O_2.[6] The concentration of the benzene solution was about 10^{-5} mol/l and its spectra were measured before and after reaction and compared to each other.

Benzene and ethanol were reagent grade and were used without further purification.

Results and Discussion

Benzene or ethanol solution of dibenzo[*a,j*]perylene had been pink color but it changed to brownish color upon irradiation by room light. When the brownish solution was left in the dark at room temperature for a few days, the original color recovered. This phenomenon, which might be said a kind of photo- and thermo-chromism, could be repeated several times, although some percentage of dibenzo[*a,j*]perylene suffered permanent destruction due to some unknown side-reaction.

The absorption spectra of dibenzo[*a,j*]perylene in benzene are shown in Fig. 1. A strong absorption band with a typical vibrational structure is observed in the region between 450 and 600 nm. The region around 330—430 nm (especially 340—390 nm) seemed to be overlapped by some impurity absorption and

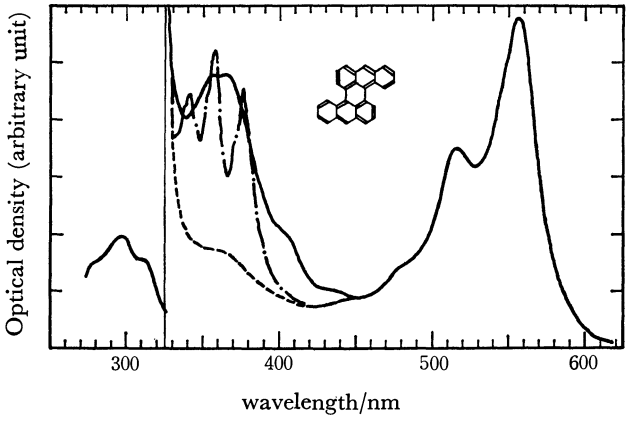

Fig. 1. Absorption spectra of dibenzo[*a*,*j*]perylene in benzene.
—— and -·-·-: Uncorrected spectra of two samples obtained by different purification procedures, ——: corrected spectra.

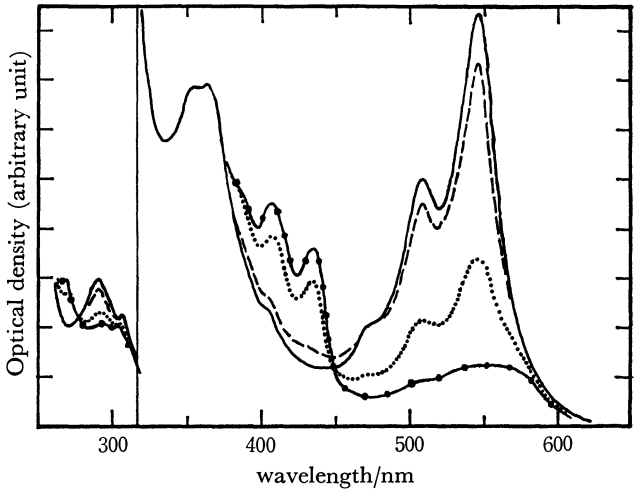

Fig. 2. Change of absorption spectra by visible light irradiation in ethanol.
——: Before irradiation, ·····: after 12 minutes irradiation, ——: after 50 minutes irradiation, -·-·-: left in the dark at room temperature for a day after 50 minutes irradiation.

was different from sample to sample. Repeated purification procedures by column chromatography and high vacuum sublimation could not eliminate completely the impurities responsible to those absorption. The fluorescence excitation spectra of very dilute benzene solution (*ca.* 10^{-7} mol/l) monitored by the fluorescence band shown in Fig. 4 under unaerobic conditions showed a broad and rather weak absorption band around 370 nm. This excitation spectra should resemble to the true absorption spectra. Taking also account of the spectral change during photochemical reaction, which will be described later, we deduced the true spectral shape in this region and showed it in Fig. 1.† Fortunately, there was only little change in this region of spectra during the photooxygenation and thermal deoxygenations. Therefore, we are free from complications due to these impurities in the present study.

When irradiated by a tungsten lamp through a sharp cut off filter, Toshiba VY-50, the spectra of ethanol solution changed as shown in Fig. 2. We could observe an isosbestic point near 455 nm. It is also illustrated in this figure that the solution regained about 85% intensity of original spectra after keeping it about a day in the dark at room temperature. We could observe the same spectral change also for benzene solution. A small deviation of the recovered spectra from the isosbestic point indicates that a small fraction of dibenzo[*a*,*j*]perylene was permanently destroyed. By a careful treatment up to 95% intensity could be recovered both in benzene and ethanol. The spectral change above mentioned did not occur when the solution was evacuated to about 0.1 Pa as was expected.

The following two types of reaction paths can be proposed for this type of photooxygenation reaction.

(1) $A(Ground) + h\nu \longrightarrow A^*(Singlet)$
$A^*(S) \longrightarrow A^*(Triplet)$
$A^*(T) + O_2(G, {}^3\Sigma_g^-) \longrightarrow AO_2$

(2) $A(G) + h\nu \longrightarrow A^*(S)$
$A^*(S) \longrightarrow A^*(T)$
$A^*(T) + O_2(G, {}^3\Sigma_g^-) \longrightarrow A(G) + O_2(S, {}^1\Delta_g)$
$A(G) + O_2(S, {}^1\Delta_g) \xrightarrow{k} AO_2$

We could observe that the rate of photobleaching of dibenzo[*a*,*j*]perylene was much faster in CCl_4 than in benzene. Because it has been reported that the lifetime of $^1\Delta_g O_2$ in CCl_4 is 700 μs, and is much longer than in benzene (lifetime 24 μs),[9] this observation suggests the participation of singlet oxygen. Furthermore, a similar spectral change was observed, when the benzene solution of dibenzo[*a*,*j*]perylene was treated under dark with singlet molecular oxygen as has been described in the experimental section. It should be also mentioned that A (Ground)$+O_2(^1\Delta_g)$ correlates with the ground state of the product AO_2 exothermically and $A^*(T)+O_2$ (G, $^3\Sigma_g$) can only correlate with the excited state of AO_2 endothermically[10] (see Fig. 6). These observations and consideration lead to the conclusion that the type (2) is the appropriate reaction. Also it is reasonable to assign the new band between 370 and 450 nm to some sort of endoperoxide as is usually obtained or assumed in cases of similar reactions of other aromatic hydrocarbons.[2,4] We can assume several possible structures for the endoperoxide as shown in Fig. 3.

† The spectrum of helianthrene reported by Clar (p. 49, Ref. 5) was quite similar to that of our dibenzo[*a*, *j*]perylene, which implied that we synthesized helianthrene instead of dibenzo[*a*, *j*]perylene through some error. Brockmann and Mühlmann have reported different absorption maxima of helianthrene,[7] but they didn't give the whole spectra. We ascertained that our hydrocarbon could not be helianthrene because the intermediate quinone, which we used for dibenzo-[*a*, *j*]perylene synthesis, did not give bisanthene-3,10-dione by photochemical reaction in pyridine under unaerobic condition. Helianthrene quinone, which is an inevitable intermediate for helianthrene synthesis, should give bisanthene-3,10-dione by such a reaction.[8]

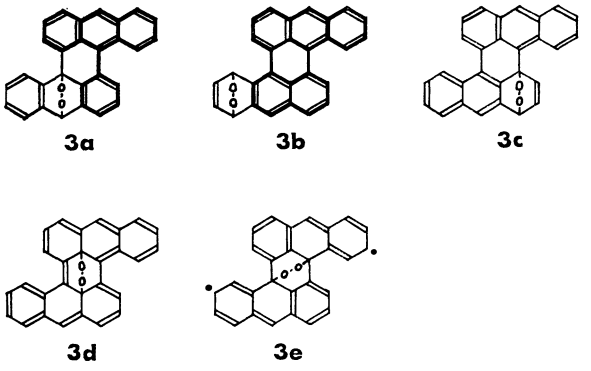

Fig. 3. Possible structures of photooxygenation products of dibenzo[a,j]perylene.
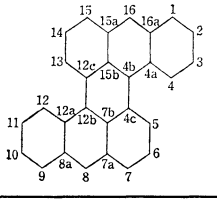
a: 9-Phenylanthracene type structure (8,12b-endoperoxide), **b**: benzo[a]perylene type structure (9,12-endoperoxide).

A biradical form similar to the structure **3e** in Fig. 3 was proposed for the thermochromic form of $\Delta^{10,10'}$-bianthrone by Woodward and Wasserman.[11] We performed ESR measurement as described before but it didn't show any increase of ESR signal that could be attributed to the formation of any kind of biradical endoperoxide. Thus we can disregard the structure **3e**.

In order to select the most probable structure out of **3a**—**3d**, we carried out MO calculations. Table 1 shows the calculated self-polarizabilities for all carbon sites of dibenzo[a,j]perylene.

In view of the structures of similar hydrocarbons, tetrabenzo[*a,cd,j,lm*]perylene[12] and dibenzo[*jk,uv*]-dinaphtho[2,1,8,7-*defg*: 2′,1′,8′,7′-*opqr*]pentacene,[13] dibenzo[a,j]perylene must have a non-planar structure due to the steric hindrances of two pairs of hydrogen atoms, the mean angle between two anthracene skeleton planes being about 30° (see Fig. 6a). However, we assumed a planar structure for the present MO calculations to avoid less important but cumbersome problems. Since the qualitative or semiquantitative features of π-electron systems are not very sensitive to these moderate deviations from planarity. The present calculation based on the planarity approximation seems to be sufficient for our purpose to select the appropriate structure of photooxygenation product. The calculated results indicate that the structure **3a** is the most probable one because the sum of two self-polarizabilities corresponding to this structure is larger than the pair self-polarizabilities corresponding to the other structures. Thus we may be able to disregard **3c**, **3d**, and **3e** from the possible structures of the endoperoxide.

Table 1. Self-polarizabilities (πrr) of dibenzo[a,j]perylene

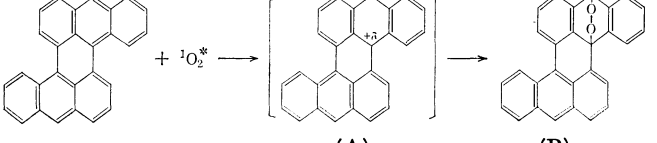


Position	πrr	Fr	Position	πrr	Fr
1, 9	0.461	0.462	4c, 12c	0.355	0.140
2, 10	0.406	0.405	5, 13	0.491	0.473
3, 11	0.421	0.415	6, 14	0.400	0.397
4, 12	0.438	0.446	7, 15	0.509	0.484
4a, 12a	0.355	0.143	7a, 15a	0.330	0.102
4b, 12b	0.395	0.188	8, 16	0.604	0.544
7b, 15b	0.354	0.152	8a, 16a	0.329	0.102

Pair positions	Sum of πrr's	Corresponding endoperoxide in Fig. 3
8+12b(16+4b)	0.999	**3a**
1+4(9+12)	0.899	**3b**
7+4c(15+12c)	0.864	**3c**
7b+15b	0.708	**3d**

It may be of some interest to note that although the sums of self-polarizabilities of para-positions corresponding to the structures **3a**, **3b**, and **3c** (0.999, 0.899, and 0.864, respectively) are similar to the corresponding values of anthracene (1.052 for 9,10-positions and 0.908 for 1,4-positions), the value of the self-polarizability of the 8-(and 16-) position of dibenzo[a,j]perylene, 0.604, is much larger than that for the 9-position of anthracene (0.526) and even larger than the value, 0.601, of the very reactive 6-(and 13-) position of pentacene. This may be the reason why dibenzo[a,j]-perylene is so liable to react with singlet oxygen. The calculated values of free valence, which are given in Table 3, also suggest that 8-(and 16-) position is very reactive.

Thus we presume that the course of the reaction is as follows.



The second step from (A) to (B) should be very fast because of the enhanced density of reacting electron as a result of the first step reaction.

Further, we tried to see if the observed spectra of the photooxygenation product is compatible with this structure. Because of the high sensitivity of dibenzo-[a,j]perylene to light and the instability of its photo-oxygenation product, it was difficult to obtain its correct spectra by a single run of the experiment. Figure 4 shows the spectrum composed of several experimental data.

The spectrum has some ambiguity in two regions. First, we could not completely bleach the region longer than 450 nm because the thermal decomposition of the oxygenation product brought about the reverse reaction and furthermore because the oxygenation product was also gradually decomposed, probably by further photochemical reaction,[7] to give some unknown final product which had a long absorption tail in this region. But it is certain that there is at most only

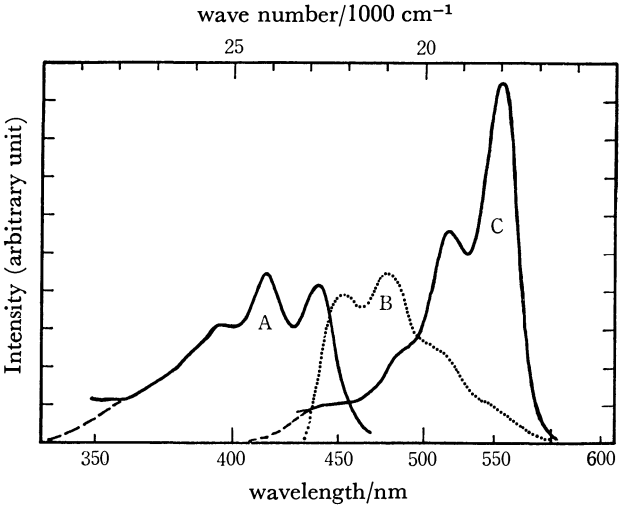


Fig. 4. Absorption and fluorescence spectra of photooxygenation product.
A: Corrected absorption spectra, benzene solution, B: fluorescence spectra, benzene solution, C: absorption spectra of dibenzo[*a*,*j*]perylene, the concentration of which is the same as A.

very weak absorption in this region, which can not be assigned to any allowed transitions. Another evidence to assure that the endoperoxide has no allowed absorption band in the region longer than 450 nm is that a fluorescence spectrum, which shows a good mirror image relation with the new absorption band between 380 and 450 nm, was observed for the partly photobleached benzene solution of dibenzo[*a*,*j*]perylene (Fig. 4).

Since the absorption bands in the long wavelength region of the spectra of such endoperoxides are considered to be due to π-π^* transitions, we calculated the transition energies for the conjugated π-electron systems as dwawn with thick lines in Fig. 3 on the basis of the P-P-P method. From the consideration of self-polarizabilities and free valences, it is sufficient to consider only the two structures, 8,12b-endoperoxide (**3a**) and 1,4-endoperoxide (**3b**).

The results of the calculation are shown in Table 2. The observed transition energies of benzo[*a*]perylene and 9-phenylanthracene, which have similar π-conjugation systems as those of **3a** and **3b**, respectively, are also shown in Table 2 together with the transition energies of related compounds, dibenzo[*a*,*j*]perylene and perylene. It is well-known that there are many factors that prevent a precise comparison between the observed and calculated results. But the overall correspondence is fairly good as is shown in Table 2.

Firstly, we assume that the structure of the photooxygenation product corresponds to **3b**. Both the calculated results and observed spectra of benzo[*a*]perylene predict that 1,4-endoperoxide (**3b**) should show the longest wavelength absorption band (so-called p-band) near 500 nm (20000 cm^{-1}). This value is rather larger than the observed one for the photooxygenation product, 435 nm. Furthermore, the observed oscillator strength for p-band of the photooxygenation product (about 80% of the p-band of

a) The approximations used for calculations are the same as in Table 2a. b) R. S. Becker, *J. Chem. Phys.*, **38**, 2144 (1963). c) This work and E. Clar, "Aromatic hydrocarbons, Academic Press, New York (1964), Vol. 2, p. 43.

dibenzo[a,j]perylene†† is considerably smaller than the calculated value for the p-band of benzo[a]perylene (about 90% of the p-band of dibenzo[a,j]perylene).

On the other hand, as we can see in Table 2, the calculated transition energy and oscillator strength of the 9-phenylanthracene type structure (corresponding to 8,12b-endoperoxide, **3a**), agree fairly well with the observed ones, if its phenyl plane has a proper angle (about 60°) with the plane of anthracene skeleton.

Of course, these agreements should not be taken too seriously since the adopted model of the molecular structure holds only the minimum characteristics of the endoperoxide and neglects all the finer details belonging to the real endoperoxide molecule and also because of the well-known limitations of MO calculations. Nevertheless all the observed data and calculated results seem to lead to the conclusion that the photooxygenation product of dibenzo[a,j]perylene is 8,12b-endoperoxide.†††

As has been already mentioned, the molecular structure of dibenzo[a,j]perylene should be such as depicted in Fig. 5a.

O_2 may attach this hydrocarbon as illustrated in Fig. 5b; the angle between phenyl (A) plane and the anthracene plane should increase owing to the increased

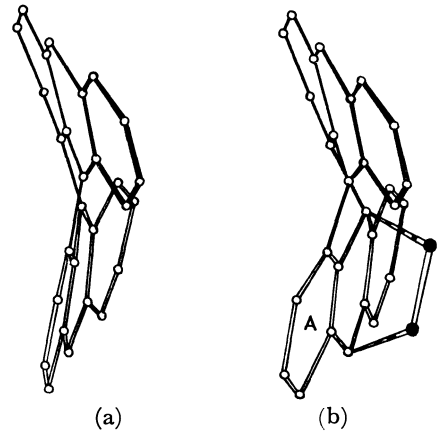

Fig. 5. Possible three dimentional structures of dibenzo-[a,j]perylene and its photooxygenation product (8,12b-endoperoxide). a: Dibenzo[a,j]perylene, b: 8,12b-endoperoxide. ○: Carbon, ●: oxygen.

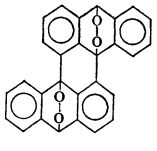
sp³ nature of the bonds extending from the 8- and 12b-carbon atoms and also owing to the steric hindrance of the H-atoms bonded to the 12- and 13-carbon atoms. Thus we can explain the rather high value of the angle, 60°, that has been predicted from the calculation. This structure also answers the question why a doubly photooxygenated product such as



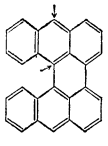
was not obtained, which seems to be quite probable considering the well-known reactivity of 9-phenylanthracene to singlet molecular oxygen. The second molecular oxygen, if attached to the 8,12b-endoperoxide, will introduce intolerable steric hindrance,

†† This value was estimated from the ratio of area under each absorption band shown in Fig. 4, using the following formula

$$f = 4.02 \times 10^{-9} \int \varepsilon d\bar{\nu}$$

where f is the oscillator strength, ε the decadic molar extinction coefficient (l/mol cm), and $\bar{\nu}$ the wave number in cm^{-1}.

††† It is reported that helianthrene is most probably attacked by the singlet oxygen at similar positions.[2]



TABLF 3. RATES OF THE OXYGEN DETACHMENT FROM 8,12b-ENDOPEROXIDE OF DIBENZO[*a*,*j*]PERYLENE

T/K	Rate/s^{-1}	
	in benzene	in ethanol
318	3.4×10^{-4}	
323	5.2×10^{-4}	
328	9.0×10^{-4}	
333	1.7×10^{-3}	7.2×10^{-4}
338	2.6×10^{-3}	1.2×10^{-3}
343	4.0×10^{-3}	1.9×10^{-3}
348		3.1×10^{-3}

and the double-photooxygenation product may be unstable and may decompose rapidly.††††

The rate of O_2 detachment from the endoperoxide are shown in Table 3.

The detachment was monitored with the increasing band at 556 nm in benzene (and 546.5 nm in ethanol) of the recovered hydrocarbon and obeyed the first-order reaction scheme fairly well. The rate depends strongly on temperature and its temperature dependence seems to be explained by the existence of an activated transient state. The activation energy was calculated from the data in Table 3 to be 21.4 ± 0.5 kcal/mol in benzene and 22.5 ± 0.5 kcal/mol in ethanol. The frequency factor was also calculated to be 1.9×10^{11} s^{-1} in benzene and 4.9×10^{11} s^{-1} in ethanol, and these values suggest that the O_2-detachment reaction is spin allowed. The activation energy can be explained by the fact that the endoperoxide ground state necessarily correlates endothermically with an excited state of composite system A (Ground State)$+O_2$ ($^1\Delta_g$) owing to spin conservation as is illustrated in Fig. 6. It is interesting that the observed activation energy is almost the same as the energy of the singlet O_2 $^1\Delta_g$ state (22.5 kcal/mol), even if it might be only an accidental coincidence. Thus it may be possible that O_2 is released from the oxygenated hydrocarbon in its $^1\Delta_g$ singlet state,[14] but this must be clarified by further investigation.

Finally, we report a preliminary measurement of the overall efficiency of the present photooxygenation reaction. Though unfortunately, we could not afford to perform detailed measurements of lifetimes of A*(S), A*(T), and $O_2(^1\Delta_g)$ that are necessary to analyse each step of complicated photooxygenation reactions, we measured only the overall quantum efficiency of the photooxygenation upon irradiation of benzene solution by 556 nm under atmospheric pressure. The apparent overall quantum efficiency depended moderately on the concentration of dibenzo[*a*,*j*]perylene. They were *ca.* 1/30 for 7.2×10^{-6} mol/dm^3 and *ca.* 1/45 for 5.6×10^{-6} mol/dm^3. These values were about fifteen times larger than those for rubrene photooxygenation

†††† It has been reported that, similar hydrocarbons, dimethoxyhelianthrene and dibenzoyloxyhelianthrene uptake equimolar molecular oxygen rapidly, but further photooxygenation takes place only very slowly leading to final decomposition products.[7]

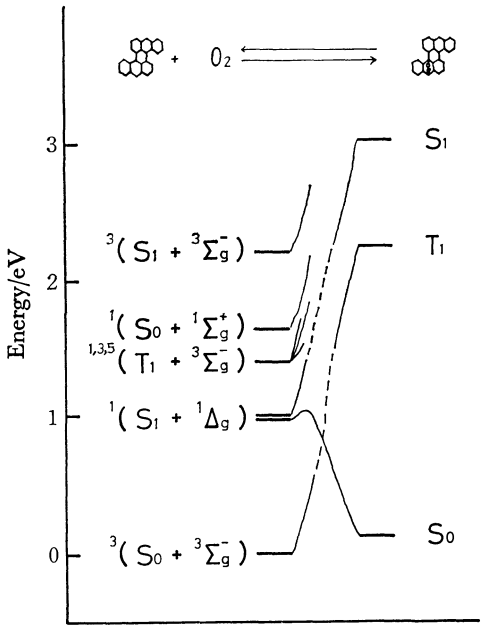


Fig. 6. State correlation diagram depicting the photooxygenation of dibenzo[*a*,*j*]perylene and thermal deoxygenation of the photooxygenation product, 8,12b-endoperoxide. The relative energies of the states were estimated from spectroscopic data and the activation energy for the reaction as is given in the text.

measured under similar conditions, and indicates that sensitized $^1\Delta_gO_2$ production may be quite efficient in this system. Assuming that the efficiency of $^1\Delta_gO_2$ producton by the energy transfer from triplet dibenzo[*a*,*j*]perylene is nearly 100%,[1,2] and using the reported lifetime, 24 μs, of the O_2 $^1\Delta_g$ state in benzene, we obtained 2×10^8 dm^3/mol s^{-1} as a lower limit of k, the rate of the reaction $A(G)+O_2(S, ^1\Delta_g)\longrightarrow AO_2$.

Finally, it might be better to mention that the application of NMR, IR, and X-ray crystallography, which are very powerful methods for structural analysis in many fields of organic chemistry, is presently very difficult for unstable derivatives of large condensed aromatic hydrocarbons.

The authors are grateful to Prof. Ryo Hirasawa of the University of Tokyo for his assistance in ESR measurements and helpful discussion.

The Base-catalyzed Tautomerization of Acetylacetone in Organic Solvents. The Correlation of the Catalytic Coefficient with the Partition Coefficient

Hitoshi WATARAI and Nobuo SUZUKI*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received January 5, 1979)

The keto-enol tautomerization rate of acetylacetone catalyzed by triethylamine or tributylamine was observed in eight organic solvents, and the catalytic coefficient for each process of the ketonization and enolization was obtained. A remarkable solvent effect on the catalysis was discussed following the linear free-energy relationship between the catalytic coefficient and the liquid-liquid partition coefficients of the keto and enol forms. It was concluded that, in the homogeneous base-catalysis, the solvent affects the free-energy change of the transition state more greatly than those of the keto and enol forms. On the contrary, in the heterogeneous catalysis by the silica surface, the free-energy change of the keto and enol forms was suggested to be the main factor governing the kinetic solvent effect.

In the course of our study of the kinetic behavior of acetylacetone, a well-known extractant,[1] in a liquid-liquid partition system, we found that the keto-enol tautomerization rate in an organic phase is very slow and that the addition of a base, such as amine, trialkyl phosphate and trialkylphosphine oxide, which are often used in synergic extractions,[1] remarkably enhances the tautomerization rate in an organic phase. Those catalytic effects strongly depend on the nature of the solvent.

From the standpoint of the transition-state theory,[2] a kinetic solvent effect is thought to be due to the difference in solvent effects on the reactant and on the transition state. Many kinetic studies of the solvent effect, however, have dealt with the solvent effect only on a rate constant, which reflects the free-energy difference between the reactant and the transition state. We think that the experimental resolution of an activation free energy into two parts is more worthwhile than a qualitative and conventional discussion of the relationship between an activation energy and the solvent property. Previously, we reported the utility of a liquid-liquid partition coefficient in evaluating the contribution of the free-energy change of the reactant to the activation free energy.[3,4] In the present study, we will show a further application of the rate-partition approach to the solvent effect on the base-catalyzed tautomerization rate of acetylacetone in organic solvents.

Experimental

Materials. The acetylacetone was used after the distillation of a commercially purchased reagent (Nakarai,G. R.). The triethylamine (TEA) and tributylamine (TBA) used as catalysts were purified by double distillation over sodium and kept in a darkened desiccator. The organic solvents were distilled after drying over sodium or phosphorus pentaoxide. The purity of the amines and the solvents were checked by GLC. Redistilled water was used throughout. The preparation of a nonaqueous solution was carried out in a gloved box desiccated by silica gel.

Kinetic Measurements. Although the keto-enol equilibrium of acetylacetone in an inert solvent is not attained even after one week, the addition of an amine at a concentration of 10^{-3} M (1 M=1 mol dm^{-3}) remarkably accelerates the tautomerization rate. The measurement of the rate of the catalysis has been carried out by means of a Hitachi 356 spectrophotometer at 290 nm for aromatic–solvent systems and at 271 nm, the absorption maximum of acetylacetone, for the other systems. The catalysis was initiated by one of the following two methods, depending on the solvent used: when the enol fraction at equilibrium in a given solvent was below 0.8, the vapor injection method[5] was employed, while in a solvent in which the enol fraction was over 0.8, an alternative method was employed since the vapor injection method does not produce a sufficient absorbance difference between that at the initial time and at equilibrium; *ca.* 1 ml of the pure liquid of acetylacetone was heated for one hour at 100 °C, cooled to room temperature rapidly, and diluted with an organic solvent in a Teflon flask, and then a 50-μl portion of this solution was spiked into 4 ml of the solution of a catalyst in an optical cell which was thermostated with circulating water at 25±0.1 °C. By the heating procedure, the enol fraction of 0.82 at room temperature decreases to 0.66. From the absorbance change, as recorded on a Hitachi 056 recorder, an observed rate constant $k_{obsd}(s^{-1})$ was obtained within an error of ±3%. The rate constants obtained by the two different initiation methods were confirmed to coincide in the benzene system.

It was noted in a preliminary experiment that the surface of the quartz cell acts as an effective catalyst on the tautomerization. The catalytic activity of the surface depends on the solvent and increases in an inert solvent such as hexane. Hence, it was necessary to make the surface inert by treating the cell and all of the volumetric glassware with a 1% benzene solution of dichlorodimethylsilane.[6]

An increase in the TEA concentration up to 0.2 M shows no influence on either the apparent absorption coefficient or on the shape of the spectrum of acetylacetone, so that the amine is confirmed to participate only in a kinetic process as a catalyst in the tautomerization process. The catalytic experiment was carried out in $8—10\times10^{-5}$ M for acetylacetone, in $10^{-5}—10^{-1}$ M for TEA, and in 10^{-5}—0.15 M for TBA.

Equilibrium Measurements. The apparent partition coefficient of acetylacetone (P) between water (10^{-3} M perchloric acid) and heptane, chlorobenzene, or 1,2-dichloroethane was determined spectrophotometrically within a precision of ±3% by the batch method. Similarly, P in the nonaqueous two-phase system of heptane/acetonitrile was determined. Each solvent of heptane and acetonitrile was mutually saturated before the partition experiment, since the mutual solubility is not negligible, it is determined by GLC to be 2.8 wt % acetonitrile in heptane and 10.1 wt % heptane in acetonitrile at 25 °C. The enol fractions of acetylacetone in the organic

solvents were determined within a precision of ±0.01 by the NMR method[7] using a Varian A-60 NMR apparatus at 25 ±1.5 °C.

Results

The Catalytic Coefficients of TEA and TBA. The observed tautomerization rate constant was proportional to the concentration of amine, [B], in all the systems investigated;

$$k_{obsd} = k_B[B] \quad (1)$$

where $k_B(M^{-1}\,s^{-1})$ refers to a catalytic coefficient. Some typical examples of the plot of k_{obsd} *vs.* [B] in heptane and benzene systems are shown in Fig. 1. The slopes of Fig. 1 give the catalytic coefficients. The catalytic coefficients for the eight solvent systems

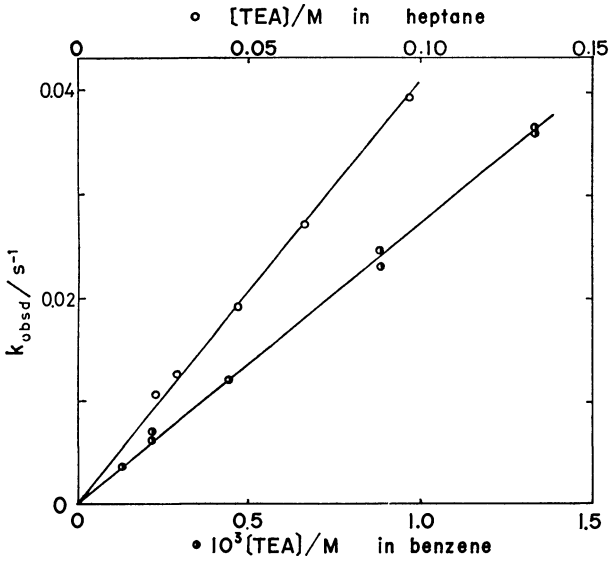

Fig. 1. The effect of TEA on the keto-enol tautomerization rate of acetylacetone in heptane and in benzene.

Table 1. The catalytic coefficients of the amines in relation to the tautomerization rate, the apparent partition coefficients (P) between water and organic solvent, and the enol fraction (f_0) in organic solvents of acetylacetone

No. Solvent	$k_B/M^{-1}\,s^{-1}$ TEA	$k_B/M^{-1}\,s^{-1}$ TBA	P	f_0
1. Heptane	4.17×10^{-1}	2.00×10^{-1}	0.887	0.97
2. Cyclohexane	5.25×10^{-1}	2.37×10^{-1}	1.03[a]	0.95[b]
3. Toluene	2.10×10	3.27	4.57[a]	0.91
4. Benzene	2.73×10	4.22	5.93[a]	0.88

7. Dichloromethane	4.42×10^2	1.97×10^2	22.5[a]	0.78
8. Acetonitrile	5.88×10^2	2.02×10^2	7.85[c]	0.60

a) Quoted value; H. Johansson and J. Rydberg, *Acta Chem. Scand.*, **23**, 2797 (1969). b) Quoted value; R. A. Dwek and G. Allen, *J. Chem. Soc., B*, **1966**, 161. c) Estimated value; see text.

are tabulated in Table 1. It appeares that the catalytic coefficient increases with the increase in the dielectric constant of the solvent. TEA is more effective than TBA in every solvent. A linear correlation between the logarithmic values of the catalytic coefficients of TEA and TBA appeared.

The Partition Coefficients and the Enol Fractions. The apparent partition coefficients (P) and the enol fraction (f_0) are listed in Table 1. The partition coefficient in the system of acetonitrile-water was estimated from the results in the systems of heptane/water and heptane/acetonitrile. It appears that the organic solvent with a smaller f_0 shows a larger value of P.

Discussion

Correlation between the Catalytic Coefficient and the Partition Coefficient. The catalytic coefficients for the ketonization ($k_{B,k}$) and the enolization ($k_{B,e}$) were estimated by the following equations, neglecting any spontaneous process:

$$k_{B,k} = (1-f_0)k_B$$
$$k_{B,e} = f_0 k_B \quad (2)$$

The calculated results are listed in Table 2, together with the partition coefficients of the keto (P_K) and enol (P_E) forms of acetylacetone calculated using the values of P, f_0, and the enol fraction in the aqueous phase, f=0.15.[5]

In order to examine the free-energy relationship between the two processes, *i.e.*, the base catalysis in an organic solvent and the transfer of acetylacetone from water to the solvent, log $k_{B,k}$ and log $k_{B,e}$ were plotted against log P_E and log P_K respectively. The results are shown in Figs. 2 and 3. In the catalyses by both TEA and TBA, satisfactory linear correlations are obtained.

A free-energy consideration of the base catalysis leads to the following equation;

$$\Delta G^{*} - \Delta G^{*\circ} = \delta\Delta G_X - \sum_i \delta\Delta G_i \qquad (3)$$

where ΔG^{*} and $\Delta G^{*\circ}$ are, respectively, the activation free energies in a given solvent and in the hypothetical standard solvent and where $\delta\Delta G_X$ and $\delta\Delta G_i$ are the respective transfer free energies of the transition state and the reactant, i, from the standard solvent to the other solvent. For the ketonization and the enolization reactions, Eq. 3 leads to;

$$\begin{aligned} \Delta G_k^{*} - \Delta G_k^{*\circ} &= \delta\Delta G_X - \delta\Delta G_E - \delta\Delta G_B, \\ \Delta G_e^{*} - \Delta G_e^{*\circ} &= \delta\Delta G_X - \delta\Delta G_K - \delta\Delta G_B, \end{aligned} \qquad (4)$$

where the subscripts X, E, K, and B correspond to the transition state, the enol form, the keto form, and the base catalyst respectively. Equation 4 can be rewritten by introducing the catalytic coefficient and the partition coefficient;

$$\begin{aligned} RT\ln(k_{B,k}/k^{\circ}_{B,k}) &= \delta\Delta G_B - \delta\Delta G_X - RT\ln(P_E/P_E^{\circ}), \\ RT\ln(k_{B,e}/k^{\circ}_{B,e}) &= \delta\Delta G_B - \delta\Delta G_X - RT\ln(P_K/P_K^{\circ}), \end{aligned} \qquad (5)$$

where the superscript ○ denotes the standard solvent. The linear relationships obtained in Figs. 2 and 3 for the seven inert solvents prove that the term of $\delta\Delta G_B - \delta\Delta G_X$ is proportional to both $RT\ln(P_E/P_E^{\circ})$ and $RT\ln(P_K/P_K^{\circ})$.

Now, we may assume the following proportionality:

$$\begin{aligned} \delta\Delta G_B &= a\delta\Delta G_K = a'\delta\Delta G_E, \\ \delta\Delta G_X &= b\delta\Delta G_K = b'\delta\Delta G_E, \end{aligned} \qquad (6)$$

where a, b, a', and b' are proportional constants following the relation of $a'/a = b'/b = c$ (constant). Equation 6 is based on the assumption that the solute-solvent interaction which occurs during the base catalyzed tautomerization process does not include specific interactions, *e.g.*, a strong dipole-dipole interaction and a hydrogen-bonding interaction. The correlation between $\delta\Delta G_K$ and $\delta\Delta G_E$ is shown in Fig. 4, in which the linear correlation between the logarithmic values of the partition coefficients of the keto and enol forms of acetylacetone

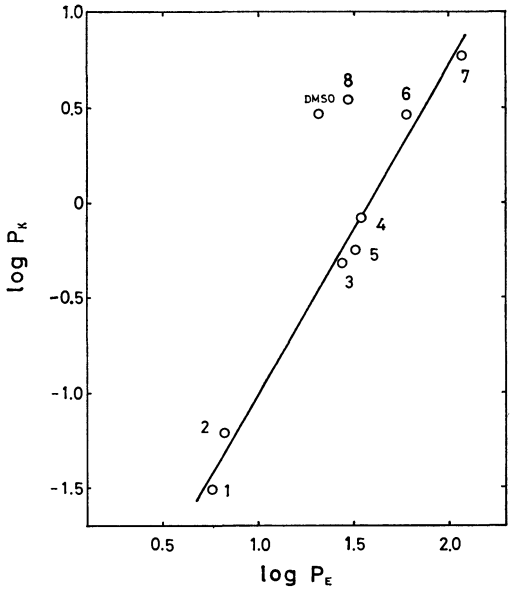

Fig. 4. The correlation between the partition coefficient of the keto (P_K) and the enol (P_E) forms of acetylacetone. The numbers in this figure correspond to those in Table 1.
log P_K=1.71 log P_E+2.73, r=0.993 except for acetonitrole and DMSO[3]

is shown for the seven inert solvents, allowing the estimation of the "c" constant from the slope as 1.71. A linear relationship was observed among the gas solubilities[8] and between the solubilities of bis(acetylacetonato)copper(II) and bis(dipropionylmethanato)-copper(II),[9] also. By the introduction of Eq. 6 into Eq. 5, we obtain the following equations;

$$\begin{aligned} \log k_{B,e} &= (b-a-1)\log P_K \\ &\quad + \{\log k^{\circ}_{B,e} - (b-a-1)\log P_K^{\circ}\}, \\ \log k_{B,k} &= (b'-a'-1)\log P_E \\ &\quad + \{\log k^{\circ}_{B,k} - (b'-a'-1)\log P_E^{\circ}\}. \end{aligned} \tag{7}$$

Consequently, the slopes of Figs. 2 and 3 give the set of the proportional constants of $(b-a)$ and $(b'-a')$ —2.32 and 4.16 for TEA-catalysis and 2.37 and 4.01 for TBA-catalysis. The deviation observed for the acetonitrile system in Figs. 2 and 3 may be attributed to the destabilization in a polar solvent such as acetonitrile of the enol form, which is less polar than the keto form; this is also suggested by the deviation in Fig. 4.

Relationship among $\delta\Delta G_X$, $\delta\Delta G_K$, and $\delta\Delta G_E$. In the above section, the relationship between the catalytic coefficient and the partition coefficient has been proved in terms of the free energy. The result shows that the lowering of the standard free energy of the tautomers causes a descrease in the activation free energy because of the further lowering of the standard free energy of the transition state compared to those of the tautomers. The values of $\delta\Delta G_X$ are more sensitive to the solvent than those of $\delta\Delta G_K$ and $\delta\Delta G_E$. The transition state is expected to be a complex of an ion-pair or charge-transfer type between the amine and acetylacetone. Then, $\delta\Delta G_X$ can be separated into $\delta\Delta G_B$ and $\delta\Delta G_{X,r}$,

$$\delta\Delta G_X = \delta\Delta G_B + \delta\Delta G_{X,r}, \tag{8}$$

where $\delta\Delta G_{X,r}$ is the residual part which is obtained by substracting $\delta\Delta G_B$ from $\delta\Delta G_X$. $\delta\Delta G_{X,r}$ can be expected to be the transfer free energy of a state like an ion-pair of the proton and the enolate anion of acetylacetone. Equations 6 and 8 lead to this relation,

$$\delta\Delta G_{X,r} = (b-a)\delta\Delta G_K = (b'-a')\delta\Delta G_E, \tag{9}$$

or

$$\begin{aligned} \delta\Delta G_{X,r} &= 2.43\delta\Delta G_K = 4.16\delta\Delta G_E \\ &\qquad \text{for TEA-catalysis,} \\ \delta\Delta G_{X,r} &= 2.37\delta\Delta G_K = 4.01\delta\Delta G_E \\ &\qquad \text{for TBA-catalysis.} \end{aligned} \tag{10}$$

Equation 10 shows that $\delta\Delta G_{X,r}$ is most affected by the solvent in the transfer free energies of the three states and that the change in $\delta\Delta G_{X,r}$ is the main factor governing the solvent effect on the rate of the catalysis. The difference in the solvent effect on the three states is probably due to the difference in the electric property; *e.g.*, the expected order of the delocalization of the electron density is the transition state> the keto form> the enol form.

Although the details of the reaction mechanism of the base-catalyzed tautomerization are still obscure, it can reasonably be expected that the proton transfer will occur *via* an intramolecular process assisted by the amine, rather than by an intermolecular process, as proposed by Baba and Takemura[10] for the base-catalysis of anthrone–anthranol interconversion in nonpolar solvents. This interpretation is supported by the fact that, even in inert solvents, TEA and TBA effectively catalyze the tautomerization of acetylacetone.

Free-energy Consideration of the Effect of the Silica Surface. As was mentioned in the Experimental section, the tautomerization rate is extremely enhanced by the contact with the wall of the quartz cell, depending on the solvent used. In considering the solvent effect in this heterogeneous catalysis, we applied the free-energy treatment developed in this study. It was assumed that the transition state is the adsorbed acetylacetone on the silica surface and that the solvation effects on the transition state and on the silica surface are negligible or compensate each other, *i.e.*, $\delta\Delta G_B - \delta\Delta G_X = \text{const}$ in Eq. 5. Then, Eq. 5 degenerates to;

$$\log k_{obsd} = -\log f_0(1-f_0)P + \text{const.} \tag{11}$$

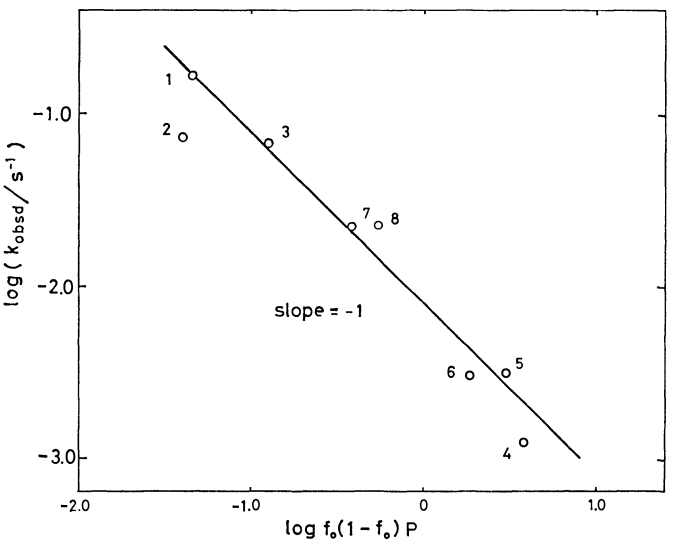

Fig. 5. The solvent effect on the silica surface catalysis. Solvent; 1: hexane, 2: cyclohexane, 3: carbon tetrachloride, 4: dichloromethane, 5: chloroform, 6: 1,2-dichloroethane, 7: benzene, 8: toluene.

According to the above equation, the experimental results are plotted in Fig. 5. A satisfactory linear relationship, with the slope of minus one, was obtained, in agreement with the prediction from Eq. 11. If the assumption of $\delta\Delta G_B - \delta\Delta G_X = \text{const}$ does not hold, the slope will differ from a minus one. Consequently, in this case the states most affected by the solvent are suggested to be the keto and enol forms, contrary to the results of the homogeneous amine catalysis. It is of interest that the solvent effect is in reverse directions in the two systems, *i.e.*, the heterogeneous and homogeneous catalyses. Further investigation employing a variety of solvents will enable us to assess the generality of this conclusion.

The Kinetics of Oxygen Exchange between Arsenate Ions and Water. III. Catalysis by Periodate Ions

Akiko OKUMURA,* Seiko WATANABE, Miyoko SAKAUE, and Nobukazu OKAZAKI

Department of Chemistry, Nara Women's University, Nara 630

(Received January 9, 1979)

Oxygen exchange between arsenate ions and water is remarkably catalyzed by the addition of a small amount of periodate ions.† The reaction has been studied at 30.0 °C over the pH range of 6.7—11.4. The rate law of the catalytic reaction has been found to be $R_C=k\cdot[H^+][As(V)][I(VII)]$, where R_C is defined as the increase in the rate of oxygen exchange of arsenate ions by the addition of periodate ions. The catalytic process has been interpreted in terms of the reversible condensation of arsenate ions with periodate ions to form the arsenatoperiodate ions, and the rate constant of the condensation reaction between $H_2AsO_4^-$ and $H_4IO_6^-$ has been estimated to be 340 $M^{-1}\,s^{-1}$ at 30.0 °C.

In a previous paper,[1] it has been shown that the oxygen exchange reaction of arsenate ions with water is strongly accelerated by the addition of a small amount of arsenious acid. The catalytic process has been identified with the reversible condensation of arsenate ions with arsenite species to form the arsenatoarsenite ions, and the rate constants of this condensation reaction have been estimated.

The study of an oxygen exchange reaction of an oxoanion in the presence of a catalytic amount of another oxoanion may provide a means of studying the kinetics and equilibriums of the condensation reactions involving the two oxoanions. In this paper a study of the interaction of arsenate ions with periodate ions in solution by means of the oxygen exchange reaction will be reported.

Experimental

Materials. Water enriched in oxygen-18 (2 atom %) was obtained from a fractionating column in this laboratory. It was refluxed with alkaline permanganate, and distilled twice. Normal water was treated in the same way. Disodium hydrogenarsenate heptahydrate(Guaranteed reagent, Merck), sodium periodate (Guaranteed reagent, Merck), and all the other chemicals (Guaranteed reagent, JIS) were used without further purification.

The concentration of the stock solution of sodium periodate (1.63×10^{-2} M) was checked spectrophotometrically each time before use with iron(II)-2,4,6-tri-2-pyridyl-1,3,5-triazine.[2]

Procedure. The procedures were almost the same as those used earlier.[1,3] The exchange reaction was started by mixing an isotopically equilibrated solution of disodium hydrogenarsenate in $H_2{}^{18}O$ with water of normal isotopic composition. A small amount of the stock solution of periodate was added, and the pH of the solution was fixed by the addition of a measured quantity of either a solution of sodium hydroxide or hydrochloric acid. The pH of the solution was measured with a Radiometer PHM type-26 pH meter. All experiments were performed at 30.0 °C. At intervals aliquots of the reacting solution were drawn, and the reaction was quenched by precipitating the arsenate ions as $BaHAsO_4\cdot H_2O$ with barium chloride solution. The precipitate, after being washed three times with absolute ethanol and dried, was converted into carbon dioxide by the guanidinium chloride method.[4] The isotopic analysis of the carbon dioxide was made on a Hitachi RMS-I type mass-spectrometer.

The rate of the oxygen exchange of arsenate ions was calculated by means of the formula:

$$R=-\frac{1}{t}\cdot\frac{[As(V)][H_2O]}{4[As(V)]+[H_2O]}\cdot\ln\left(1-\frac{O_0-O_t}{O_0-O_\infty}\right)$$

where O_0, O_t, and O_∞ are the ^{18}O-contents of the carbon dioxide at times 0, t, and infinity, respectively, and where [As(V)] and $[H_2O]$ are the molar concentrations of the arsenate and water, respectively.

Results and Discussion

pH *Dependence.* In Fig. 1, log R_0 and log R are plotted against pH, where R_0 and R designate the rates of the oxygen exchange reaction between arsenate ions and solvent water without and with the addition of periodate ions, respectively. The concentration of arsenate was 0.07 M, and no inert salt was added. The concentrations of the periodate were 10^{-5} M for series

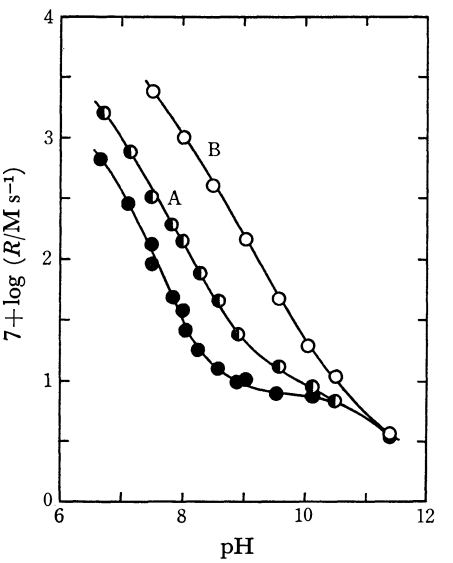

Fig. 1. The rate of oxygen exchange reaction of arsenate ions with water *versus* pH.
([As(V)]=0.07 M, I=0.2 M, 30.0 °C)
●: In the absense of periodate ions.
◐ (A): in the presence of periodate ions, [I(VII)]=8.4×10^{-6} M.
○ (B): in the presence of periodate ions, [I(VII)]=8.2×10^{-5} M.

† In this paper the word "periodate" is used to signify both periodate and orthoperiodate.

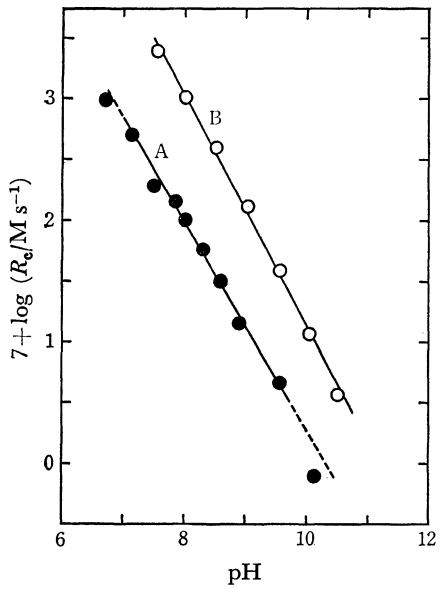

Fig. 2. pH dependence of the catalyzed portion of the exchange rate R_c.
● (A): [I(VII)]=8.4×10^{-6} M.
○ (B): [I(VII)]=8.2×10^{-5} M.

A and 10^{-4} M for series B. The catalytic effect decreases with the increasing pH value and disappears at pH 10.5 for series A and at 11.4 for series B. Even in the low concentration ratio: [I(VII)]/[As(V)]=10^{-4}, the catalytic action of periodate ions is so large as to increase the oxygen exchange rate 3.5 fold at pH 8.5.

Figure 2 shows the dependence of R_c on pH. R_c is defined as $R-R_0$ and corresponds to the catalyzed portion of the exchange reaction. The slopes of the lines passing through the plots are -0.86 ± 0.02 for series A and -0.95 ± 0.03 for series B within the pH regions 7.17—9.57 and 7.52—10.51, respectively. R_c depends upon the first power of the hydrogen ion concentration in both series. It may be inferred from these results that the acidic species of arsenate and periodate ions are more reactive. The role of hydrogen ion in the rate equation is to shift the acid dissociation equilibrium of the oxoanions in favor of the more reactive ionic species.

Dependence of the Catalytic Rate R_c on [I(VII)]. This has been studied at two pH's, 8.0 and 9.2. The concentration of periodate was varied between 3.0×10^{-5} M and 11.6×10^{-5} M (pH 8.0) and between 8.9×10^{-5} M and 44.0×10^{-5} M (pH 9.2). The plots of log R_c against log [I(VII)] are shown in Fig. 3. The slopes of the straight lines obtained by least square fits of the data are 1.03 ± 0.01 and 0.93 ± 0.07 for the pH values of 8.0 and 9.2, respectively. The log R_c: log [I(VII)] plot deviates downwards from the straight line at [I(VII)] $<3.0\times10^{-6}$ M (pH 8.0) (not shown in the figure). This is probably due to the decomposition of the periodate by a trace amount of reducing impurities which are present in the solution.

Dependence of the Catalytic Rate R_c on [As(V)]. This has been studied under the following conditions. A: pH=8.00, [I(VII)]=8.10×10^{-5} M, I(NaCl)=0.55 M, [As(V)]=0.034—0.138 M; B: pH=9.08, [I(VII)]=8.84×10^{-5} M, I(NaCl)=1.00 M, [As(V)]=0.035—0.275 M. The plots of log R_c against log [As(V)] are shown in Fig. 4. The slopes of the straight lines obtained are 0.97 ± 0.07 for A and 1.04 ± 0.11 for B.

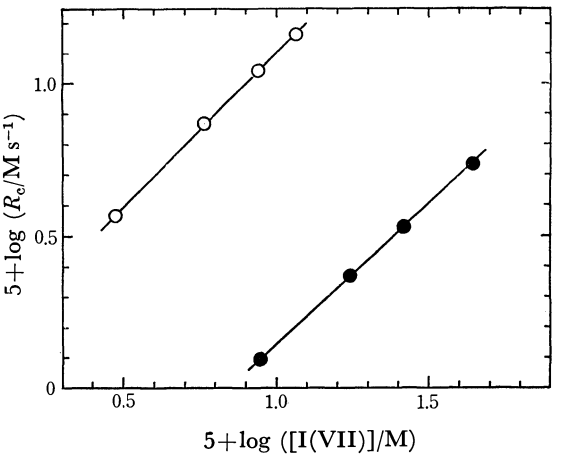

Fig. 3. Dependence of the catalytic rate R_c on [I(VII)] ([As(V)]=0.07 M, I=0.2 M)
○: pH=8.0, [I(VII)]=$(3.0-11.6)\times10^{-5}$ M.

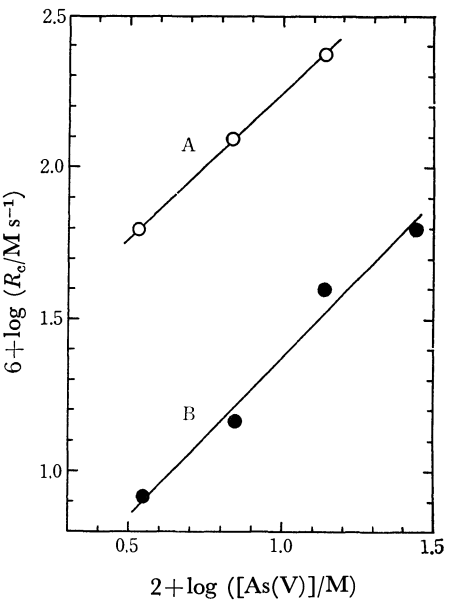

Fig. 4. Dependence of the catalytic rate R_c on [As(V)].
○ (A): pH=8.0, [I(VII)]=8.10×10^{-5} M, I(NaCl) =0.55 M, [As(V)]=0.034—0.138 M.
● (B): pH=9.08, [I(VII)]=8.84×10^{-5} M, I(NaCl) =1.0 M, [As(V)]=0.035—0.275 M

Evaluation of the Rate Constants. The catalytic reaction rate R_c may be expressed generally as the sum of the kinetic terms as follows:

$$R_c = \sum k_{ij}[\mathrm{As(V)}]_i[\mathrm{I(VII)}]_j$$

where $[As(V)]_i$ denotes the various ionic species of the arsenate ions, and $[I(VII)]_j$ those of the periodate ions, and k_{ij} is the rate constant of the reaction between $[As(V)]_i$ and $[I(VII)]_j$. In the pH range 6—11, the dominating ionic species of the arsenate are $H_2AsO_4^-$, $HAsO_4^{2-}$, and AsO_4^{3-}, and those of the periodate are $H_4IO_6^-$, IO_4^-, and $H_3IO_6^{2-}$. The concentrations of

$H_4IO_6^-$ and IO_4^- are mutually related by the relation $K_d = a_{IO_4^-} \cdot a_{H_2O}^2 / a_{H_4IO_6^-} = 40$ [5] and are kinetically equivalent.

The rate law of the catalytic process may now be given as

$$R_c = k_1[H_4IO_6^-][H_2AsO_4^-] + k_2[H_3IO_6^{2-}][H_2AsO_4^-] + k_3[H_4IO_6^-][HAsO_4^{2-}] + k_4[H_3IO_6^{2-}][HAsO_4^{2-}] + k_5[H_4IO_6^-][AsO_4^{3-}] + k_6[H_3IO_6^{2-}][AsO_4^{3-}],$$

where $[H_4IO_6^-]$ is the concentration of the periodate monoanions inclusive of IO_4^-. The value of R_c becomes negligible at the pH values greater than 10.5, where the dominating ionic species are $H_3IO_6^{2-}$, $HAsO_4^{2-}$, and AsO_4^{3-}, the concentration of AsO_4^{3-} increasing with the increase in pH. If the rate constants k_4, k_5, and k_6 had significant values, the k_4-, k_5-, and k_6-terms should contribute appreciably to the catalytic rate R_c. The contributions of the k_4-, k_5-, and k_6-terms may be ignored.

The rate law can be rewritten as:

$$\frac{R_c}{[H_2AsO_4^-][H_4IO_6^-]} = k_1 + \left(k_3 + \frac{K_2'(I)}{K_2(As)} \cdot k_2\right) \frac{K_2(As)}{[H^+]} \quad (1)$$

where $K_2(As)$ and $K_2'(I)$ are the second ionization constant of arsenic acid and the apparent second ionization constant of periodic acid, respectively, under the conditions of the kinetic runs. The concentrations of the ionic species of the periodate were evaluated by means of the apparent ionization constants written in the forms:

$$a_{H^+}(a_{IO_4^-} + a_{H_4IO_6^-})/a_{H_4IO_6^-} = K_1'(I)$$
$$a_{H^+} \cdot a_{H_4IO_6^-}/(a_{H_4IO_6^-} + a_{IO_4^-}) = K_2'(I)$$

The values of the ionization constants necessary to calculate the concentrations of the ionic species of the arsenate and the periodate are indicated in Table 1.

Table 1. Acid dissociation constants of arsenic acid and periodic acid under the condition of the kinetic runs: I=0.2 M, 30 °C.

As(V)	pK_2 [3]	6.56	I(VII)	pK_1'	1.34
	pK_3 [3]	11.33		pK_2'	7.87
				pK_3	11.35

$K_1'(I)$(I=0) at 30.0 °C was obtained by interpolation of the data determined by Crouthamel *et al.*[5] to 30.0 °C, and this value was converted to $K_1'(I)$(I=0.2 M) using Guntelberg's equation. $K_2'(I)$ and $K_3(I)$ were evaluated similarly by using $K_2'(I)$(I=0) and $K_3(I)$(I=0.1 M) determined by Buist and coworkers[6] at various temperatures.

In Fig. 5, the data corresponding to pH 6.7—9.8 in Fig. 1 are replotted according to equation 1. From the intercept of the straight line through the plots, the value of k_1 is determined to be 338±27 M^{-1} s^{-1}. From the slope of the line, the value of $[k_3 + k_2 \cdot K_2'(I)/K_2(As)]$, is obtained as 35.9±0.1 M^{-1} s^{-1}. It is impossible to evaluate the values of k_2 and k_3 separately. Taking 4.8×10^{-2} as the value of $K_2'(I)/K_2(As)$, k_3= 36 M^{-1} s^{-1} and k_2=750 M^{-1} s^{-1} may be obtained as the upper limits of these constants.

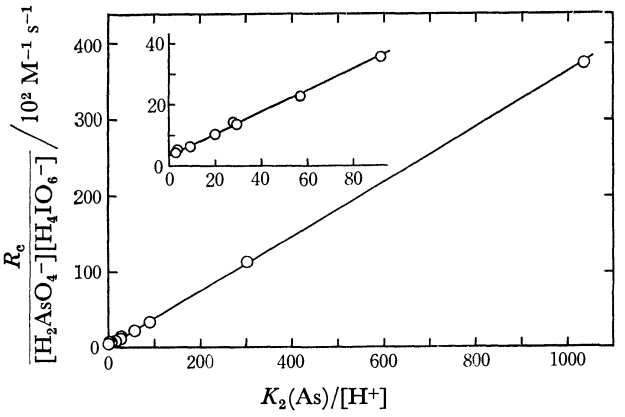

Fig. 5. $R_c/[H_2AsO_4^-][H_4IO_6^-]$ as a function of $K_2(As)/[H^+]$.

By analogy with the case of arsenious acid catalysis of the arsenate oxygen exchange,[1] it is natural to interpret the rate term $k_{ij}[As(V)]_i[I(VII)]_j$ in terms of the reversible condensation of arsenate ions with periodate ions. The possibility of general acid catalysis of the arsenate oxygen exchange by oxoanions has been ruled out in the previous paper.[1] In the present case, general acid catalysis by periodate ions is also ruled out by the fact that the value of k_1 in the rate term $k_1[H_2AsO_4^-][H_4IO_6^-]$ is larger than that of k in the rate term $k[H_2AsO_4^-][H_2AsO_4^-]$, since $H_4IO_6^-$ is weaker acid than $H_2AsO_4^-$. The hydrogen-bond association of arsenate ions with periodate ions would not affect the rate of the oxygen exchange of arsenate ions significantly.

The rate constants of the condensation reactions between anions obtained in this work are listed in Table 2, along with those obtained before.[1,3]

Table 2. The rate constants of the condensation reactions between anions

Reactions	Rate const/M^{-1} s^{-1}	Ref.
$H_2AsO_4^- + H_2AsO_4^-$	0.074	3
$H_2AsO_4^- + HAsO_4^{2-}$	0.0064	3
$H_2AsO_4^- + H_3AsO_3$	6.8	1
$H_2AsO_4^- + H_2AsO_3^-$	<7	1
$HAsO_4^{2-} + H_3AsO_3$	<0.02	1
$H_2AsO_4^- + H_4IO_6^-$	338	This work
$H_2AsO_4^- + H_3IO_6^{2-}$	<750	This work
$HAsO_4^{2-} + H_4IO_6^-$	<36	This work

For the reversible condensation process, two paths are possible. Path a): Periodate acts as the nucleophile, and arsenate as the substrate (an oxygen atom of periodate ion attacking the arsenic atom of the arsenate). Path b): Arsenate acts as the nucleophile, and periodate as the substrate (an oxygen atom of the arsenate ion attacking the iodine atom of the periodate). In both cases an identical dianion, arsenatoperiodate, is formed.

In the periodate oxidation of the organic substances, the periodate ion acts as an electrophile or a nucleophile depending on the nature of the substrate.[7,8]

By the principle of microscopic reversibility, the bond

fission in the reverse reaction must occur at the same position as in the forward reaction. The result that the oxygen exchange reaction of arsenate is catalyzed by periodate ions requires the reaction to proceed *via* Path a). Path b) does not lead to the oxygen exchange of arsenate with water.

If it is assumed that Path a) and Path b) occur simultaneously in a solution containing arsenate and periodate ions, a path in which the condensation proceeds through Path b) and the hydrolysis through Path a) would be an alternative mechanism for the periodate catalysis.

Another possibility is a mechanism which involves the rapid exchange of periodate ions with solvent water[9] and subsequent condensation through Path a) and hydrolysis through Path b).

In order to see whether or not the catalytic action of the periodate ion is observed in the oxygen exchange of other oxoanions, we have studied the oxygen exchange reactions of selenic acid, phosphate ions, and chromate ions with water in the presence of periodate ions. It was found that the periodate ion has a remarkable effect on the oxygen exchange between chromate and water, the effect being greater than that on the arsenate exchange. From the results obtained so far, the rate constant for the reaction: $HCrO_4^- + H_4IO_6^- \rightleftharpoons H_3CrIO_9^{2-} + H_2O$, may be estimated to be $10^4\ M^{-1}\ s^{-1}$ at 0 °C. The effect could not be found with selenic acid and phosphate ions. It is known that the reversible condensation process: $2HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O$, plays a dominant role in the oxygen exchange of chromate ion with water,[10] while the oxygen exchange of selenic acid[11] and phosphate ions[12] does not involve the condensation mechanism. It is probable that the condensation process is responsible for the periodate catalysis.

The catalysis of the hydration of carbon dioxide by various anions has been studied by Dennard and Williams.[13] They have found that $H_4IO_6^-$ is a weak catalyst, and $H_2AsO_3^-$ is a far better catalyst than H_3AsO_3, the catalytic constant of $H_2AsO_3^-$ being $1.9 \times 10^3\ M^{-1}\ s^{-1}$ at 0 °C. These results are in contrast with those obtained for the arsenate exchange, for which H_3AsO_3 and $H_4IO_6^-$ are excellent catalysts and H_3AsO_3 is a better catalyst than $H_2AsO_3^-$. The mechanism of the oxoanion catalysis of the hydration of carbon dioxide would be different from that of the oxygen exchange of arsenate ions.

Ultrasonic Velocity and Compressibility in Aqueous Solutions of Alkali Metal Chlorides

Hisashi UEDAIRA* and Yasuko SUZUKI

Research Institute for Polymers and Textiles, 1-1-4 Yatabe-Higashi, Tsukuba, Ibaraki 300-21

(Received February 8, 1979)

The ultrasonic velocity of aqueous solutions of alkali metal chlorides was measured by the use of the sing-around technique at 0.5 and 1 mol kg^{-1} over the temperature range from 30 to 85 °C; compressibilities of the solutions were also determined. It was found that the ultrasound velocity *versus* temperature curves show a maximum, while the compressibility *versus* temperature ones show a minimum. Both maxima and minima appear at lower temperatures than that observed for pure water. The maximum shifted values were found for Na^+ ion. The results were explained by the dynamic structure of the water around the ions.

One of the abnormal properties of water is the variation of ultrasound velocity with temperature in water. That is, the propagation velocity of ultrasound in normal liquids falls off with increasing temperature; however, for water the ultrasonic velocity attains a maximum value of 1557 m s^{-1} at a temperature of 74 °C, and only above this temperature does the ultrasound velocity diminish. The adiabatic compressibility of water shows a minimum at 64 °C. These phenomenon are due to the peculiar liquid structure of water.

The temperature of maximum sound velocity in water is changed by the presence of ions,[1-3] since the water structure is affected by the ions. Thus, from the effects upon the ultrasound velocity and the compressibility of water by the ions it is possible to obtain some information with regard to the ion–water interactions.

There have been several studies of the ultrasound velocity in aqueous electrolyte solutions. However, only a few systematic investigations[1-3] have been reported so far over a sufficiently wide range of concentration and temperature.

We have, therefore, attempted to measure the ultrasound velocity of aqueous solutions of alkali metal chlorides over a wide range of temperature; the adiabatic compressiblities of these solutions were also determined. The results are discussed on the basis of the dynamic structure of water around cations.

Experimental

Alkali metal chlorides (G. R., E. Merck Co.) were used without further purification.

Sound velocity was measured by the "sing-around" technique, using an apparatus (Choonpa Kogyo Co.) at 5 MHz. Procedures of the measurement of the sound velocity are described elesewhere.[4] Ultrasound velocity in the solutions was determined at 5 °C intervals over a temperature range from 30 to 85 °C and at 1 °C intervals in case of need. The constancy of temperature was ± 0.01 °C.

Adiabatic compressibility κ was calculated by the following relation:

$$\kappa = 1/u^2 d, \tag{1}$$

where u is the velocity of ultrasound and d the density of the solution. Values of the densities at the experimental temperature and concentration were calculated from the following polynomials of the concentration or temperature:

$$d = d_0 + \sum_{i=1}^{5} a_i m^i \tag{2}$$

and

$$d = d_0 + \sum_{i=1}^{5} b_i t^i, \tag{3}$$

where d_0 is the density of pure water, m the molality, and t the temperature (°C). Values of the coefficients a_i and b_i in the polynomials were determined from the densities of solution of alkali metal chlorides,[5] using a HITAC 8400.

Results and Discussion

The temperature dependence of ultrasonic velocities in aqueous solutions of alkali metal chlorides are shown in Figs. 1 and 2 at salt concentrations 0.5 and 1 mol kg^{-1}. Only the ultrasound velocity in CsCl solution is lower than that in water over all the range of temperature at both concentrations. The difference of the sound velocities in the salt solutions and water increases with increasing concentration. The temperature of maximum sound velocity, T_{vm}, varies according to the kinds of salts and their concentrations, and shifts to lower temperatures than 74 °C.

At any temperature the sound velocity in the salt

solutions decreases in the order:

$$\text{NaCl} > \text{LiCl} > \text{KCl} > \text{RbCl} > \text{CsCl}$$

but above 70 °C the velocity in the 1 mol kg^{-1} solution of LiCl becomes larger than that in NaCl solution.

The temperature dependence of the compressibilities are shown in Figs. 3 and 4. The compressibilities of RbCl solution at temperature higher than 50 °C could not be calculated, since the values of densities in the temperature range were not found in the literature.

All the values of compressibilities for the salt solutions are smaller than that of water and the order of magnitude differes in different concentrations. Below 70 °C the compressibility of NaCl solution is the lowest at each concentration. Judging from the fact that the values of compressibilities for LiCl, RbCl, and CsCl solutions do not differ markedly from one another, the large density of CsCl solution is thought to account for the fact that the sound velocity in CsCl solution is smaller than that in water. From the above-mentioned results, it seems difficult to connect directly the sound velocity and compressibility with the structure of solutions.

According to Hirata and Arakawa,[6] the compressibility of water is equal to $\kappa_\infty + \kappa_{\text{relax}}$ under our experimental conditions, where κ_∞ and κ_{relax} are the instantaneous and the relaxational parts of the compressibility, respectively.[7] As the temperature rises, κ_∞ increases due to thermal motion but κ_{relax} decreases due to thermal rupture of water structure. The competition between these two opposing tendencies leads to the compressibility minimum at 64 °C and the sound velocity maximum at 74 °C.

An ion affects the thermal motion of the water molecules around it. Thus the temperature of the

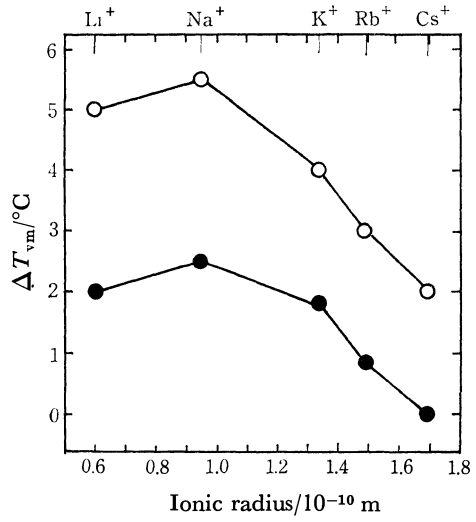

Fig. 5. Relation between ΔT_{vm} and ionic radius.
-●- 0.5 mol kg^{-1}; -○- 1 mol kg^{-1}.

compressibility minimum(T_{cm}) and the sound velocity maximum(T_{vm}) must reflect the change of water structure due to the presence of the ions. Because the chlorine ion is common to all the salts treated in the present study, the relative effects of the cations can be compared.

Figure 5 shows the relation between the ionic radius and $\Delta T_v = T^\circ_{vm} - T_{vm}$, where T°_{vm} is 74 °C. Figure 6 shows the relation between the ionic radius and $\Delta T_{cm} = T^\circ_{cm} - T_{cm}$, where T°_{cm} is 64 °C. These results show a maximum at the Na^+ ion. The curves shift to nearly parallel accordingly to the concentration or the kind of anion.

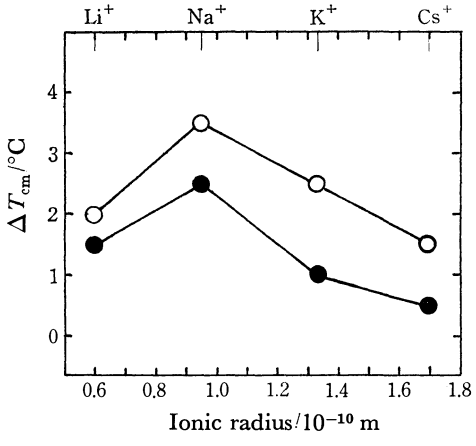

Fig. 6. Relation between ΔT_{cm} and ionic radius.
-●- 0.5 mol kg^{-1}; -○- 1 mol kg^{-1}.

Eigen and Mass[8] measured "the absorption-volume of particle" $Q\cdot\lambda$ in the reaction of alkali metal nitrilotriacetate and alkali metal acetylenediaminetetraacetate complex in aqueous solutions. $Q\cdot\lambda$ is a parameter which characterizes the chemical equilibrium. $Q\cdot\lambda$ *versus* the frequency of the ultrasound curve shows a maximum. The values of $(Q\cdot\lambda)_{max}$ were greatest at Na^+ ion. Hindeman[9] measured the chemical shifts of protons in aqueous solutions of alkali metal halides. The absolute value of the chemical shift for the cations shows a maximum at Na^+ ion.

There are many thermodynamic properties which do exhibit a maximum at Na^+ ion. Desnoyers and Jolicoeur[10] proposed a possible explanation; these maxima may appear because "the strength of ion–solvent interactions decreases with increasing size of the ions, but the coordination number of the ion increases with increasing size." According to X-ray analysis and neutron scattering, the coordination numbers of alkali metal ions are 4 for Li^+, Na^+, and K^+ ions,[11] and 8 for Cs^+ ion.[12] The above suggestion leaves something to be desired. In order to explain the above results, it is necessary to consider the state of the water molecules around the ion more deeply.

The compressibility of the solution will be discussed, since it is a fundamental thermodynamic quantity. Attention will be directed to the concentration range, at which the cospheres of the cation and the anion do not overlap.

The compressibility of an aqueous electrolyte solution is smaller than that of pure water. This is ascribed to two effects:[6] (1) the decrease of compressibility caused by the introduction of incompressible ions, and (2) the change of water structure around the ion. Among the effects, the contribution of effect (1) is larger, and depends more on the concentration rather than on the kind of ions (see Figs. 3 and 4). Recently, Subrahmanyan and Moorthy[13] showed that if these are no interactions between water and solutes, T_{cm} is always lower than T°_{cm}. What they called the dilution effect corresponds to effect (1). Thus, we have the following relation, taking account of effects (1) and (2):

$$T_{cm} = T^{id}_{cm} + T^{ion}_{cm} \quad (4)$$

$$\Delta T_{cm} = T^\circ_{cm} - (T^{id}_{cm} + T^{ion}_{cm}) \quad (5)$$

where T^{id}_{cm} and T^{ion}_{cm} are the contribution by the dilution effect and the ion–water interaction, respectively, and $T^{id}_{cm} > T^{ion}_{cm}$. The value of T^{id}_{cm} is about constant in the case of the alkali metal ions if the concentration is constant, and so ΔT_{cm} depends mainly on T^{ion}_{cm}.

The Na^+ ion is a weak structure-making ion. According to Samoilov,[14] τ_i/τ_o for Na^+ ion is 1.3 at 25 °C, where τ_i and τ_o are the mean residence times of a water molecule in the immediate neighborhood of the ion in the aqueous solution and in the immediate vicinity of a water molecule in pure water, respectively. Since the coordination number of the water molecule around Na^+ ion is 4, the water structure around Na^+ ion is like that of pure water. No disordered water molecules exist outside the reoriented water molecules around an Na^+ ion. Therefore, T^{ion}_{cm} for Na^+ ion is very small and the decrease of the compressibility of the NaCl solution is mainly caused by the dilution effect.

The alkali metal ions do not change the water structure so much. The structure-breaking ion make the thermal motion of water molecules more intense, but the structure-making ions show a contrary effect. Samoilov[14] proved that the surface density of the distribution of water molecule around the ion decreases with increasing the ionic radius. The surface densities

of K^+, Rb^+, and Cs^+ ions are smaller than that of pure water. Therefore, the structure-breaking ion causes the compressibility of the solution to increase in comparison with that of NaCl solution, as seen in Figs. 3 and 4. The value of T_{cm}^{ion} increases and so ΔT_{cm} decreases with increasing size of the ions in the case of K^+, Rb^+, and Cs^+ ions. Nomoto and Endo[3] found that ΔT_{vm} of NH_4I solution is zero up to the concentration of 25 wt%. Both NH_4^+ and I^- ions are the structure-breaking ions. They mentioned that neither ion destroys the water structure markedly and both expand the water lattice.

Water molecules adjacent to Li^+ ion strongly reorient around it; according to Passynski,[15] they should be regarded as incompressible. The disordered water molecules exist outside these reoriented water molecules.[16] The Li^+ ion with immobile water molecules, therefore, behaves like a structure-breaking ion in the case of the acoustic and some thermodynamic phenomena. This model is supported by the fact that the compressibilities of the LiCl, RbCl, and CsCl solutions have values close to each other.

Now we shall call attention to fact that the compressibilities of the solutions are divided into two groups. In the first group, as mentioned above, are the compressibilities of the solutions of LiCl, RbCl, and CsCl. These cations interact strongly with water molecules, though there is a difference in that Li^+ ion is a structure maker but Rb^+ and Cs^+ ions are structure breakers. The second group includes the compressibilities of the solutions of NaCl and KCl. Na^+ and K^+ ions interact weakly with water molecules, and their effects are directly opposite to each other. In the case of the alkali metal–chelate complex, the reactions are divided into two groups in the same way (Ref. 7, Fig. 3).

Charge-transfer Absorption Intensity and Magnetic Property of Solid Ion Radical Salts

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 9, 1979)

The electronic spectrum of solid ion radical salt is known to be different from the monomer spectrum of the radical ion and to show an intermolecular charge-transfer transition between ion radicals in the low-energy region. The intensity of the charge-transfer absorption was theoretically obtained by applying one-dimensional half-occupied Hubbard model to the segregated stack of ion radicals of solid ion radical salts. The intensity of the charge-transfer absorption was then correlated to the magnetic properties of those solid ion radical salts.

The prominent magnetic, electrical and optical properties of a number of solid ion radical salts have been the subject of many theoretical and experimental investigations over the past fifteen years.[1–15] In such solid ion radical salts, the planar ion radical molecules are known to form, in themselves, a plane-to-plane stacking into infinite one-dimensional columns so as to make a large overlap between their half-occupied molecular orbitals.[5–8] In this case, since any individual radical molecule interacts through charge-transfer most strongly with two other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution but shows a charge-transfer transition between ion radicals in the low-energy region. So far, many investigators have observed such charge-transfer absorptions of solid ion radical salts and attempted to explain the electronic state of segregated stack of ion radicals in terms of an isolated cluster model such as a dimer of ion radicals.[3–5] Rigorously speaking, however, the cluster model approximation is not applicable to one-dimensional column composed of infinite stack of ion radical molecules.

In a previous paper,[9] we applied infinite one-dimensional Hubbard model to the columns of ion radical molecules, and investigated the transition energy and the line shape of such charge-transfer absorptions on the basis of Green's function method. In the present paper, we further attempted to explain the intensity of the charge-transfer absorption of solid ion radical salts in terms of the same model. So far, it has been suggested that ion radical salts with strong intensity of the charge-transfer absorption show almost diamagnetic susceptibility and possess strong antiferromagnetic spin exchange interaction between nearest neighbor ion radical molecules, while ion radical salts with weak charge-transfer absorption show almost free paramagnetism obeying Curie law.[2–5,13–15] By using our theoretical approach, we shall give strong theoretical basis to such a close correlation between the intensity of the charge-transfer absorption and the magnetic properties of solid ion radical salts.

Theoretical

For the sake of simplicity, we consider one-dimensional segregated stacks of ion radical molecules in simple solid ion radical salts where each ion radical has one unpaired electron. Hereafter, we take only the half-occupied molecular orbital of the unpaired electron for one site of the ion radical molecule, and assume a model of non-alternant one-dimensional column composed of infinite number of such sites. In this model, each ion radical site has one identical molecular orbital with equal energy level, and there is one electron per each site. Along such one-dimensional column, an unpaired electron transfers from one site to another site, but a strong repulsive force will take place when an electron happens to come onto a site which is already occupied by another electron with opposite spin. Let us denote the intra-site Coulomb repulsive energy as I, and consider a system of electrons described by the following Hamiltonian, which is often called the Hubbard Hamiltonian,[10]

$$\mathcal{H} = \sum_{i,j,\sigma} t_{ij} C_{i\sigma}^{+} C_{j\sigma} + I \sum_{i} n_{i\downarrow} n_{i\uparrow}, \tag{1}$$

where $n_{i\sigma}=C_{i\sigma}^{+}C_{i\sigma}$, and $C_{i\sigma}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where t_{ij} is the transfer matrix element between the i-th and j-th sites, and the repulsive potential, I, appears only when two electrons with up and down spins are at the same site. Since each ion radical site has identical molecular orbital with equal energy level, we put $t_{ii}=0$ without loss of generality. The unperturbed band energy, ε_k, of the system is related to t_{ij} by

$$\varepsilon_k = \sum_{j} t_{ij} e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_i-\boldsymbol{R}_j)}. \tag{2}$$

In the case of non-alternant one-dimensional model, we assume that the transfer matrix elements exist only between nearest neighbor sites. Then, the unperturbed band energy is simply given by

$$\varepsilon_k = 2T\cos ka, \quad \left(-\frac{\pi}{a}\leq k\leq\frac{\pi}{a}\right), \tag{3}$$

where $T(<0)$ is the transfer matrix element between nearest neighbors and a is the lattice separation.

Hereafter, we confine our system within the framework of the one-particle Green's function given by Hubbard in his first paper (it is often referred to as Hubbard I).[10] The Green's function is given by

$$G_{k\sigma}(E) = \frac{1}{2\pi}\left\{\frac{E_{k\sigma}^{U}-I(1-n_{-\sigma})}{E_{k\sigma}^{U}-E_{k\sigma}^{L}}\,\frac{1}{E-E_{k\sigma}^{U}} + \frac{I(1-n_{-\sigma})-E_{k\sigma}^{L}}{E_{k\sigma}^{U}-E_{k\sigma}^{L}}\,\frac{1}{E-E_{k\sigma}^{L}}\right\}, \tag{4}$$

where

$$n_\sigma = \langle n_{i\sigma} \rangle,$$

$$E^U_{k\sigma} = \frac{1}{2}(\varepsilon_k + I + \sqrt{\varepsilon_k^2 + 2(2n_{-\sigma}-1)\varepsilon_k I + I^2}),$$

$$E^L_{k\sigma} = \frac{1}{2}(\varepsilon_k + I - \sqrt{\varepsilon_k^2 + 2(2n_{-\sigma}-1)\varepsilon_k I + I^2}).$$

Here $E^L_{k\sigma}$ is the energy of an electron with σ-spin which moves about avoiding other electrons with $-\sigma$-spin, while $E^U_{k\sigma}$ is the energy of an electron which propagates mainly among sites already occupied with electrons with $-\sigma$-spin. The optical transition from $E^L_{k\sigma}$ to $E^U_{k\sigma}$ corresponds to the intermolecular charge-transfer absorption of the one-dimensional system of solid ion radical salt. The charge-transfer absorption spectrum corresponds to the real part of frequency-dependent conductivity tensor, $\sigma_{\mu\nu}(\omega)$, which is given by[11]

$$\sigma_{\mu\nu}(\omega) \sim \frac{ie^2}{V} \lim_{\delta \to 0_+} \sum_{k,\sigma} \frac{1}{\omega - E^U_{k\sigma} + E^L_{k\sigma} - i\delta} \frac{1}{E^L_{k\sigma} - E^U_{k\sigma}} \times \frac{\partial E^U_{k\sigma}}{\partial k_\mu} \frac{\partial E^L_{k\sigma}}{\partial k_\nu} (f(E^L_{k\sigma}) - f(E^U_{k\sigma})), \quad (5)$$

where ω is the frequency of electromagnetic wave, V is the volume of the system, and $f(E)$ is the Fermi distribution function. If the direction of the one-dimensional column is chosen as x axis, the total intensity of the charge-transfer absorption per unit volume, A, is given by

$$A = \int_0^\infty \mathrm{Re}\, \sigma_{xx}(\omega) \mathrm{d}\omega = -\frac{\pi e^2}{V} \sum_{k,\sigma} \frac{1}{E^L_{k\sigma} - E^U_{k\sigma}} \times \frac{\partial E^U_{k\sigma}}{\partial k_x} \frac{\partial E^L_{k\sigma}}{\partial k_x} (f(E^L_{k\sigma}) - f(E^U_{k\sigma})). \quad (6)$$

We assume a paramagnetic state for simple ion radical salt where each ion radical carries one unpaired electron. This leads to half-occupied Hubbard model with $n_\downarrow = n_\uparrow = 1/2$. In the case when the intra-site Coulomb repulsion energy, I, is much larger than the energy due to the observed temperature, we can well put $f(E^L_{k\sigma}) - f(E^U_{k\sigma}) = 1$. If our system has N one-dimensional chains per unit area perpendicular to the chain axis, we have

$$A = \frac{2\pi N e^2}{L} \sum_{k_x} \frac{1}{(\sqrt{\varepsilon_k^2 + I^2})^3} \frac{1}{4}(\varepsilon_k + \sqrt{\varepsilon_k^2 + I^2}) \times (\sqrt{\varepsilon_k^2 + I^2} - \varepsilon_k) \left(\frac{\partial \varepsilon_k}{\partial k_x}\right)^2, \quad (7)$$

where L is the length of the chain. The summation with k_x in Eq. 7 was carried out by integrating with $(L/2\pi)\int \mathrm{d}k_x$ in the first Brillouin zone. By the use of Eq. 3, we have

$$A = Ne^2 \int_{-\pi/a}^{\pi/a} \frac{1}{4} I^2 \frac{(2Ta)^2 \sin^2 k_x a}{(\sqrt{I^2 + 4T^2 \cos^2 k_x a})^3} \mathrm{d}k_x. \quad (8)$$

By replacing the parameters of $k_x a$ and $2T/I$ into x and t, respectively, we have

$$A = \frac{Ne^2}{4a} I(at)^2 \int_{-\pi}^{\pi} \frac{\sin^2 x}{(\sqrt{1 + t^2 \cos^2 x})^3} \mathrm{d}x. \quad (9)$$

This function can be evaluated only in terms of elliptic integral. However, in the limit of small transfer matrix element region of $|t| = |2T/I| \ll 1$, we have an approximation by expanding

$$1/(\sqrt{1 + t^2 \cos^2 x})^3 = 1 - \frac{3}{2} t^2 \cos^2 x + \frac{3 \cdot 5}{2 \cdot 4} t^4 \cos^4 x + \cdots \quad (10)$$

Therefore, we can obtain

$$A = \frac{Ne^2}{4a} I(at)^2 \int_{-\pi}^{\pi} (\sin^2 x - \frac{3}{2} t^2 \sin^2 x \cos^2 x + \cdots) \mathrm{d}x = \frac{N\pi e^2}{4a} I(at)^2 \left(1 - \frac{3}{8} t^2 + \cdots\right). \quad (11)$$

This is the final expression for the absorption intensity of the charge-transfer transition between ion radicals in non-alternant one-dimensional column of simple solid ion radical salt.

Discussion

In the preceding section, the charge-transfer absorption intensity, A, was expressed as a function of intra-site Coulomb repulsion energy, I, and the nearest neighbor transfer matrix element, T. Obviously, if $T=0$, that is, if no transfer of unpaired electron between ion radical molecules takes place in solid ion radical salt, we have $A=0$ in Eq. 11 and no charge-transfer absorption appears in the solid-state spectrum. On the other hand, for non-zero T value, as long as $2|T| \ll I$, the intensity, A, will be non-zero and will increase progressively with the increase of the $|t| = 2|T|/I$ value, as is given by Eq. 11. In most solid ion radical salts, the I values are known to be of the order of 1 eV, while the magnitudes of $|T|$, to be of the order of 0.1 eV or more.[9,13-15] Therefore, in these solid salts, the magnitude of A is not zero, and this is the reason why a number of solid ion radical salts, such as 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical salts, show marked charge-transfer absorptions in their solid-state spectra.[3-5] According to our previous paper,[9] we obtained theoretically the transition energy and the line shape of the charge-transfer absorption of the same system as the present model. The peak energy of the charge-transfer absorption corresponds to $\omega = I$. Thus, from the peak position of the observed charge-transfer absorption, we can estimate the I value experimentally. Therefore, by the use of Eq. 11 together with the estimated I value, we can estimate the T value if the absolute intensity measurements are made with the charge-transfer absorption of solid ion radical salt. This procedure will be the most direct way to estimate the I and T values of our Hubbard model.

Next, we examine how the intensity of the charge-transfer absorption is related to the magnetic properties of solid ion radical salt. In a region of small $|T|$ limit, the system of the present Hubbard model leads to a stabilization of antiferromagnetic state between ion radical molecules.[12] For a pair of nearest neighbor ion radicals, if the direct small exchange interaction is neglected, the energy gap between the parallel and antiparallel spin state is given by $2J = 4T^2/I$. The stabilization of the antiparallel spin state is caused by the intermolecular charge-transfer effect of the unpaired electrons. Therefore, we can well consider our system

of simple solid ion radical salt as one-dimensional Heisenberg antiferromagnetic system with an exchange interaction, J. On the other hand, the charge-transfer absorption intensity, A, in Eq. 11 can be approximated as $A \approx N\pi e^2 I(at)^2/4a = N\pi e^2 a\, T^2/I$ in a region of small $|T|$ limit, where we neglected the terms higher than t^4. In this case, we obtain the relation of $A \approx N\pi e^2 aJ/2$, so that A is nearly proportional to the magnitude of J. The physical meaning of this situation is as follows. Those solid ion radical salts which have very weak charge-transfer absorption intensity will possess very small J values, and thus, show the magnetic properties of almost free paramagnetism obeying Curie law.[14-16] On the other hand, those ion radical salts which have very strong charge-transfer absorptions will possess large J values, and thus, show almost diamagnetic susceptibilities.[2-5,13] So far, these theoretical correlations between the optical and magnetic properties have agreed qualitatively with the experimental observations in a number of solid ion radical salts.[2-5,13-16] Here, we note that, in such ion radical salts, as the I values are of the order of 1 eV and the $|T|$ values are of the order of 0.1 eV, the condition of the small $|T|$ limit approximation is fulfilled. More quantitative measurements of the charge-transfer absorption intensity together with the J values are required to confirm our theoretical relationship $A \propto J$ as well as to determine the magnitudes of the I and $|T|$ values of those solid ion radical salts in more detail.

16) The theoretical approach in the present paper is applicable not only to solid ion radical salts but also to crystals of neutral free radicals such as 2,2-diphenyl-1-picrylhydrazyl (DPPH). DPPH crystals show antiferromagnetic spin exchange interaction between unpaired electrons of nearest neighbor DPPH molecules but have the exchange interaction parameter as small as $J = 1.55 \times 10^{-5}$ eV. In accordance with this small exchange interaction, the electronic spectrum of solid DPPH is very similar to the spectrum of free DPPH in solution and shows no intermolecular charge-transfer absorption (*i.e.*, $A \approx 0$). (Received February 14, 1979)

The geometry of the radical ions of tetraphenylethylene was studied by means of electronic absorption spectroscopy. The spectrum of the anion radical produced by γ-ray irradiation in frozen 2-methyltetrahydrofuran changes markedly on controlled warming. The resultant spectrum resembles the spectra of the anion radical in fluid solutions produced by potassium reduction and by pulse radiolysis. These spectra are distinctly different from the spectra of diphenylmethanide ion and of diphenylmethyl radical. From these facts it is inferred that the relaxed anion radical has a geometry in which the central ethylenic bond is twisted by an angle considerably smaller than 90°, in contrast with the near 90° twist in the dianion, and in which each bond connecting a phenyl group with an ethylenic carbon atom is twisted by a smaller angle than in the molecule. The spectrum of the cation radical produced by γ-ray irradiation in frozen matrices is similar to that of the cation radical produced by pulse radiolysis in fluid solutions and changes only slightly on controlled warming. The geometry of the relaxed cation radical is suggested to be similar to that of the molecule, in contrast with that of the anion radical.

The geometries of the tetraphenylethylene molecule (TPE), anion radical ($TPE^{-\cdot}$), and dianion (TPE^{2-}) are an interesting subject of study because of the possibility of twisting of the central ethylenic bond ("α-α' bond") as well as the bonds connecting a phenyl group with an ethylenic carbon atom ("α-1 bonds").

TPE is considered to have a propeller-like geometry, in which each phenyl group is twisted around an α-1 bond by about 35—42° out of the plane of the α-α' bond.[1]

In order to explain the strong tendency of alkali salts of $TPE^{-\cdot}$ in ethereal solvents to disproportionate to TPE and alkali salts of TPE^{2-},[2-16] Garst *et al.*[6-9,17,18] and Szwarc *et al.*[10-16,19-21] suggested the hypothesis that $TPE^{-\cdot}$ and TPE^{2-} had markedly different geometries. According to their hypothesis, $TPE^{-\cdot}$ has a geometry similar to that of TPE, while TPE^{2-} has a geometry in which two $-CPh_2^-$ groups are perpendicularly twisted around the α-α' bond; owing to the difference in the geometry, $TPE^{-\cdot}$ forms a loose solvent-separated ion pair with an alkali metal ion, while TPE^{2-} forms a tight contact ion aggregate with two metal ions.[10-14,22] This hypothesis also accounts for the relative slowness of the disproportionation.[15,16,23]

The suggested geometry of TPE^{2-} seems to be supported by the similarity of the electronic absorption spectrum of the dianion[24] to those of carbanions of $R-CPh_2^-$ type (*i.e.*, 1,1-diphenyl-1-alkanides), such as 1,1-diphenyl-1-hexanide $[CH_3(CH_2)_4CPh_2^-]$[26] and 1,1,4,4-tetraphenyl-1,4-butanediide $[Ph_2C(CH_2)_2CPh_2^{2-}]$,[31] since this similarity would indicate that the the π-π interaction across the α-α' bond is almost completely absent in TPE^{2-}.

As to the geometry of $TPE^{-\cdot}$, however, no reliable evidence has been presented. In the present work the geometry of this anion radical as well as that of the corresponding cation radical ($TPE^{+\cdot}$) is studied by means of electronic absorption spectroscopy mainly using radiation-chemical techniques, which enable us to study counterion free systems.

Experimental

Spectra of the Radical Ions in Fluid Solutions. The electronic absorption spectrum of $TPE^{-\cdot}$ produced by alkali metal reduction is contaminated to some extent by the concomitantly produced TPE^{2-}. Therefore, the spectrum of $TPE^{-\cdot}$ has been revised several times in the literature.[2-4,6,7,10,15,23,25] In the present work TPE was reduced by potassium in 1,2-dimethoxyethane (DME). Since the disproportionation of alkali salts of $TPE^{-\cdot}$ is endothermic,[2-4,7,10-15] the spectrum ascribable mainly to $TPE^{-\cdot}$ was obtained by measurement at low temperature (about −50 °C) in the presence of a large excessof TPE.

Attempts to produce $TPE^{+\cdot}$ in fluid solution by oxidation with antimony(V) chloride and to measure its spectrum were unsuccessful.

Spectra of the Radical Ions Produced by Pulse Radiolysis of Fluid Solutions at Room Temperature. In order to obtain the spectra of the counterion free radical ions in fluid solutions at room temperature, pulse radiolysis measurements were made. Solutions of TPE were irradiated with 1—2-μs pulses of a 2.5-MeV electron beam with a peak current of 80 mA. Spectra immediately after pulses are assignable to the solute anion if degassed 2-methyltetrahydrofuran (MTHF) or ethanol is used as solvent, and to the solute cation if aerated acetone is used as solvent.[32]

Spectra of the Radical Ions Produced by γ-Ray Irradiation of Frozen Solutions at 77 K. It is known that unambiguous spectra of radical ions can be obtained by γ-ray irradiation of rigid solutions at low temperature.[33-35] The details of experimental procedure have been described in previous papers,[35-38] so only minimum essential information on the experimental conditions will be given here.

TPE was dissolved in MTHF, *s*-butyl chloride (BuCl), or a Freon mixture (FM: an equivolume mixture of trichlorofluoromethane and 1,2-dibromo-1,1,2,2-tetrafluoroethane), to a concentration of 15—60 mol m^{-3}, unless otherwise indicated. The solution was degassed, frozen to a glassy solid at 77 K in liquid nitrogen, and irradiated with γ-rays from ^{60}Co to the dose of $(1—3)\times10^{19}$ eV g^{-1}. The measurement of the spectra was carried out by the use of a Cary 14RI spectrophotometer. The spectrum obtained with the MTHF solution can be

assigned to $TPE^{-\cdot}$ and the spectrum obtained with the BuCl solution, as well as that obtained with the FM solution, to $TPE^{+\cdot}$.[34,35]

The spectra after "illumination (photobleaching)" or after "controlled warming" of γ-irradiated solutions were also measured. Illumination was made by using a tungsten lamp and glass filters. Controlled warming was carried out by taking the γ-irradiated solution out of the liquid nitrogen for a limited time (a few seconds) and then refreezing it at 77 K.

Molecular Orbital Calculation

A semiempirical SCF-MO-CI calculation of π electronic states of the radical ions was made for various geometries by the use of a method developed by Longuet-Higgins and Pople.[39] The details of the calculation procedure are substantially the same as those described in a previous paper.[38]

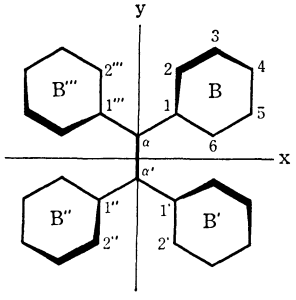

Fig. 1. The carbon skeleton of TPE.

The carbon skeleton of TPE and the numbering of the carbon atoms are illustrated in Fig. 1. All the carbon atoms were assumed to be trigonal. The dihedral angle between the σ-bond planes centered on atoms α and α', for example, is denoted by $\theta_{\alpha\alpha'}$. The calculation was made only for geometries belonging to symmetry group D_2 or D_{2h} with the relation $\theta_{\alpha 1}=\theta_{\alpha' 1'}=\theta_{\alpha' 1''}=\theta_{\alpha 1'''}$. Such a geometry in which $\theta_{\alpha 1}=A°$ and $\theta_{\alpha\alpha'}=B°$ is represented as (A, B).

As a matter of course, the MO calculation based on the π electron approximation becomes less valid as the planarity of the system is lost. However, the calculation is useful as a limited guide for rough characterization of the absorption bands and for qualitative prediction of the relation between the bands and the geometry of the system.

Results and Discussion

Designation of Spectra and of Geometries. For the sake of convenience, the electronic absorption spectra of a radical ion measured under different conditions are designated as follows: The spectrum of a radical ion immediately after its production by γ-ray irradiation in a frozen matrix is designated as F (*frozen*), that after illumination as P (*photobleached*), that after controlled warming as W (*warmed*), and that in a fluid solution as R (*relaxed*). The same designations also apply to the geometries of the radical ion under the respective conditions. In addition, the geometry of the parent neutral molecule is designated as N (*neutral*).

Curve 13: spectrum at 6 μs after the pulse.

The Anion Radical. Assignment of Absorption Bands: Representative spectra of $TPE^{-\cdot}$ measured under various conditions are shown in Fig. 2, and relevant data are shown in Table 1. The values of molar absorption coefficient (ε) for spectra F were determined on the basis of the fact that the yield of the electron from the solvent per unit energy absorbed, $G(e^-)$, is 2.55 for MTHF,[35,37,38] and those for spectra P and W were determined on the assumption that the concentration of the anion radical did not vary on illumination

a) Taken from Ref. 15.

or on controlled warming.

Most of the spectra shown in Fig. 2 cover only the visible region, because the intense absorption by TPE in the near-ultraviolet region obscures the absorption by $TPE^{-\cdot}$ in the same region. By reducing the concentration of TPE in the MTHF solution, part of the electrons produced upon γ-ray irradiation survived scavenging by TPE and became trapped electrons, which exhibited an absorption in the near-infrared region.[37] The absorption, however, could be eliminated by illuminating the γ-irradiated sample with red light. The spectrum of $TPE^{-\cdot}$ which appeared after the illumination extends to the near-ultraviolet region (Curve 1 in Fig. 2). The main bands are designated as A, B, and C, as shown in Fig. 2.

According to the results of the MO calculation, the π bond order of each α-1 bond increases in going from TPE to $TPE^{-\cdot}$. Therefore, the resistance to torsion of the bond will be stronger in $TPE^{-\cdot}$ than in TPE. This, in turn, suggests that the torsion angle of the bond, $\theta_{\alpha 1}$, is possibly smaller in $TPE^{-\cdot}$ than in TPE. Thus, as a tentative model for geometry F of $TPE^{-\cdot}$, geometry (30, 0) was adopted, instead of geometry (35—42, 0) assumed for TPE.[1] The result of the MO calculation for geometry (30, 0) is shown in Table 2, which includes all the transitions having oscillator strength (f) larger than 0.01 and having transition energy (ΔE) smaller than 4.5 eV. By comparison between Fig. 2 and Table 2, bands A, B, and C are ascribed to transitions 2, 7, and 8, respectively.

As is seen in Table 2, transitions 2, 7, and 8 can be well approximated as one-electron excitations. The orbitals involved can be approximately expressed as follows:

$$(b_1)\quad \psi_{13} \approx a\phi_{+1}(E) - b[\phi_{+1}(B) + \phi_{+1}(B') + \phi_{+1}(B'') + \phi_{+1}(B''')]$$

$$(b_3)\quad \psi_{14} \approx a\phi_{-1}(E) + b[\phi_{-1}(B) - \phi_{-1}(B') - \phi_{-1}(B'') + \phi_{-1}(B''')]$$

$$(a)\quad \psi_{15} \approx a[\phi_{-1}(B) - \phi_{-1}(B') + \phi_{-1}(B'') - \phi_{-1}(B''')]$$

$$(b_1)\quad \psi_{21} \approx b\phi_{+1}(E) - a[\phi_{-1}(B) + \phi_{-1}(B') + \phi_{-1}(B'') + \phi_{-1}(B''')]$$

In these expressions, a and b represent coefficients bearing the relation $a>b>0$; $\phi_{+1}(E)$ and $\phi_{-1}(E)$ represent the bonding and the antibonding π orbital of the central ethylenic bond (the $\alpha-\alpha'$ bond), respectively; $\phi_{+1}(B)$ and $\phi_{-1}(B)$, for example, represent the following π orbitals of benzene ring B (see Fig. 1):

$$\phi_{+1}(B) = 12^{-1/2}(2\chi_1+\chi_2-\chi_3-2\chi_4-\chi_5+\chi_6)$$

$$\phi_{-1}(B) = 12^{-1/2}(2\chi_1-\chi_2-\chi_3+2\chi_4-\chi_5-\chi_6)$$

Comparison of Spectra and Inference of Geometries: The spectrum of a DME solution of the potassium salt of $TPE^{-\cdot}$ at -50 °C (Curve 11 in Fig. 2) is very similar to the spectra of tetrahydrofuran (THF) solutions of the lithium and the sodium salt of $TPE^{-\cdot}$ reported by Lundgren *et al.*[15] The latter two spectra are virtually identical, and do not vary with temperature. Furthermore, the enthalpy changes on the dissociation of the ion pairs of $TPE^{-\cdot}$ with the alkali metal cations have small negative values.[15] From these facts the following inferences are drawn: The alkali salts of $TPE^{-\cdot}$ form loose solvent-separated ion pairs in THF and probably in DME also; the spectra of the ion pairs and the spectrum of $TPE^{-\cdot}$ free from the counterion are almost identical, suggesting that the effect of the counterion in the ion pairs on the spectrum of $TPE^{-\cdot}$ is very small and that the geometry of $TPE^{-\cdot}$ in the ion pairs is similar to the geometry of $TPE^{-\cdot}$ free from the counterion in the fluid solutions. Thus, the spectra of ethereal solutions of alkali salts of $TPE^{-\cdot}$ can be considered to directly reflect geometry R of $TPE^{-\cdot}$.

Table 2. Results of the MO calculation for $TPE^{-\cdot}$ of geometry (30, 0)

a) Transitions are numbered in the order of increasing transition energy. b) The polarization of the transition. For the coordinate axes, see Fig. 1. c) The wave function of the excited state of the transition. Only the electron configuration whose coefficient in the wave function is the largest is shown, together with the coefficient. Symbol (i—j) denotes the electron configuration arising from the ground configuration by promotion of an electron from the ith π SCF-MO (ϕ_i) to the jth one (ϕ_j). The orbital index i runs from 1 for the lowest orbital to 26 for the highest one in the order of increasing energy. The coefficient of the ground configuration in the wave function of the ground state is 0.993. d) The change in the π bond order of the α-1 bond ($P_{\alpha 1}$) on the transition. The value of $P_{\alpha 1}$ in the ground state is 0.331. e) The change in the π bond order of the α-α' bond ($P_{\alpha\alpha'}$) on the transition. The value of $P_{\alpha\alpha'}$ in the ground state is 0.659.

Transient spectra of $TPE^{-\cdot}$ produced by pulse radiolysis of a degassed ethanol solution of TPE at room temperature (Curves 12 and 13 in Fig. 2) resemble the spectra of alkali salts of $TPE^{-\cdot}$ in ethereal solutions. Therefore, the geometry of $TPE^{-\cdot}$ produced by pulse radiolysis is probably similar to that of $TPE^{-\cdot}$ produced by alkali metal reduction. It is inferred that $TPE^{-\cdot}$ produced by pulse radiolysis in fluid solution takes the relaxed geometry within the time interval of a pulse width.

The end-of-pulse spectrum of a degassed MTHF solution of TPE closely resembles that of the ethanol solution, except for the appearance of an absorption band at about 500 nm in the former, a band which is ascribed to a relatively long-lived chemical species other than $TPE^{-\cdot}$.

The spectra of γ-irradiated MTHF frozen solutions of TPE (spectra F of $TPE^{-\cdot}$; Curve 4 in Fig. 2) are markedly different from spectra R of $TPE^{-\cdot}$. Controlled warming of the frozen solutions distinctly changed the color of the solutions from purple to dark blue. The spectra after the warming, *i.e.*, spectra W (Curves 3 and 7 in Fig. 2), resemble spectra R. These facts indicate that $TPE^{-\cdot}$ produced in frozen solutions nearly retains the geometry of the neutral TPE (geometry N) owing to the rigidness of the environment, and that during the process of controlled warming the geometry of $TPE^{-\cdot}$ is relaxed to a geometry (geometry W) which is almost identical with geometry R. This means that geometry R of $TPE^{-\cdot}$ is distinctly different from geometry N, in opposition to the aforementioned hypothesis proposed by Garst *et al.* and by Szwarc *et al.* Since the same spectral change from F to W was observed both for solutions of concentration of about 50 mol m^{-3} and for much more dilute solutions, and since spectra W closely resemble spectra R, the spectral change cannot be due to formation of chemical species other than $TPE^{-\cdot}$, such as dimer anions.

Thus, geometry F is inferred to be nearly similar to geometry N, although it may have been partially relaxed towards geometry R, and the spectral change from F to W is interpreted as a result of the geometrical change from F to W. In the spectral change, band A shifts to shorter wavelengths and increases in intensity, band B shifts to shorter wavelengths and decreases in intensity, and band C shifts to longer wavelengths and increases in intensity. This spectral change is in qualitative agreement with what is expected from the result of the MO calculation shown in Tables 3 and 4 if the geometrical change occurs in such a way that $\theta_{\alpha 1}$ becomes smaller and/or $\theta_{\alpha\alpha'}$ becomes larger. Such a geometrical change is conceivable, in view of the result

Table 3. Dependence of transitions in $TPE^{-\cdot}$ on torsion angle $\theta_{\alpha 1}$

of the MO calculation that on the change from TPE to $TPE^{-\cdot}$ the π bond orders of the α-1 bond and of the α-α' bond increases and decreases, respectively.[40]

Even in geometry W, $\theta_{\alpha\alpha'}$ cannot be too large. If $\theta_{\alpha\alpha'}$ were so large that the π-π interaction across the α-α' bond were negligibly small, the spectrum of $TPE^{-\cdot}$ would be the superposition of the spectra of a 1,1-diphenyl-1-alkanide ion and of a 1,1-diphenylalkyl radical. Solvent-separated ion aggregates formed of 1,1-diphenyl-1-alkanides and alkali metal cations exhibit an intense absorption band which has its maximum at about 495—501 nm;[26,31] diphenylmethyl radical exhibits a weak band with its maximum at 460 nm and an intense band with its maximum at 335 nm.[41] The observed spectra of $TPE^{-\cdot}$ are definitely different from the superposition of such absorptions.

Angles $\theta_{\alpha 1}$ and $\theta_{\alpha 1'''}$, for example, cannot be simultaneously 0° because of the steric interference of the geminal phenyl groups. Therefore, it is considered that, in going from TPE to the relaxed $TPE^{-\cdot}$, $\theta_{\alpha 1}$'s (*i.e.*, $\theta_{\alpha 1}$, $\theta_{\alpha' 1'}$, $\theta_{\alpha' 1''}$, and $\theta_{\alpha 1'''}$) decrease from about 35—42° not to 0° but to an angle appreciably larger than 0°, while $\theta_{\alpha\alpha'}$ increases from 0° not to 90° as in TPE^{2-} but to an angle considerably smaller than 90°. By consulting the result of the MO calculation (*cf.* Tables 3 and 4), a geometry in which $\theta_{\alpha 1}$'s are about 15—30° and $\theta_{\alpha\alpha'}$ is about 0—30° is proposed as a plausible geometry of the relaxed $TPE^{-\cdot}$. Thus, it is concluded that the geometry of the relaxed $TPE^{-\cdot}$ is different from the geometries of both TPE and TPE^{2-}.

Extensive warming until the rigid MTHF matrix became a viscous fluid brought about a change of the color of the solution to greenish blue and a homogeneous diminution of the absorption by $TPE^{-\cdot}$ with a concomitant appearance of new peaks at 445 and 413 nm (see Curves 9 and 10 in Fig. 2). The new absorption is attributable to 1,1,2,2-tetraphenylethyl radical formed by neutralization of $TPE^{-\cdot}$ with a proton produced upon γ-ray irradiation.[35] Part of the absorption at about 450 nm in the spectrum at 6 μs after the pulse obtained by pulse radiolysis of an ethanol solution of TPE (Curve 13 in Fig. 2) may be attributed to the tetraphenylethyl radical.

Illumination of the γ-irradiated MTHF frozen solution with light of $\lambda > 630$ nm and with light of $\lambda > 420$ nm only slightly changed the spectrum. Thus, the change from spectrum F to spectrum P (Curves 5 and 6 in Fig. 2) is much smaller than the change from F to W. However, the tendencies induced by illumination and by warming are similar. This suggests that illumination may cause a local heating of the matrix to allow the limited relaxation of the radical ions.

Controlled warming of samples exhibiting spectrum P changed the spectrum to spectrum W (Curve 7 in Fig. 2), which was almost identical with that obtained by direct controlled warming of γ-irradiated samples.

The Cation Radical. Assignment of Absorption Bands: Spectra of $TPE^{+\cdot}$, so far unknown in the literature, were measured under various conditions, and representative ones are shown in Fig. 3. Relevant data are given in Table 5. The molar absorption coefficient cannot be precisely evaluated for spectra F of cation radicals.[35] The values of the molar absorption coefficients shown in Fig. 3 and Table 5 were tentatively determined on the assumption that all the positive charges produced in the matrix by γ-ray irradiation were transferred to TPE molecules to produce $TPE^{+\cdot}$. The main bands are designated as A and B, as shown in Fig. 3.

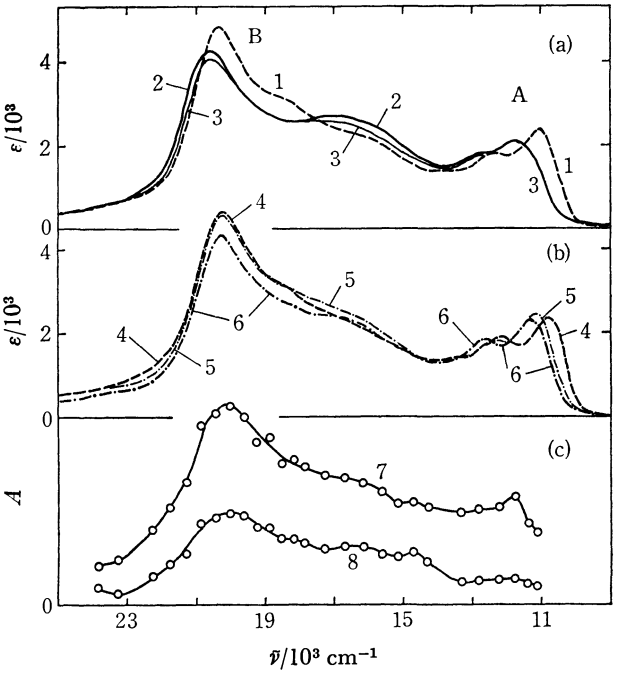

Fig. 3. Electronic absorption spectra of $TPE^{+\cdot}$.
(a) Curve 1: spectrum of a sample obtained by γ-ray irradiation of a solution of TPE in FM at 77 K. Curve 2: spectrum obtained after controlled warming of the sample for curve 1. Curve 3: spectrum obtained after repeated controlled warming of the same sample. (b) Curve 4: spectrum of a sample obtained by γ-ray irradiation of a solution of TPE in BuCl at 77 K. Curve 5: spectrum obtained after illumination of the sample for curve 4 with light of $\lambda>660$ nm. Curve 6: spectrum obtained after illumination of the sample for curve 5 with light of $\lambda>370$ nm. (c) Spectra obtained by pulse radiolysis of a solution of TPE in aerated acetone at room temperature. Curve 7: spectrum at the end of the pulse. Curve 8: spectrum at 5 μs after the pulse.

Table 5. Data on electronic absorption spectra of $TPE^{+\cdot}$

Class	Spectrum No. in Fig. 3	Solvent	Band B λ_{max}/nm	Band B $\varepsilon/10^3$	Band A λ_{max}/nm	Band A $\varepsilon/10^3$
F	4	BuCl	494	4.85	929	2.33
F	1	FM	492	4.85	907	2.41
P	6	BuCl	493	4.28	887	2.26
W	2	FM	484	4.23	853	2.08
R(Pulse)	7,8	Acetone	*ca.* 500		*ca.* 850	

Prolonged γ-ray irradiation for 20—30 min of dilute (2—4 mol m^{-3}) frozen solutions of TPE in FM and in a 5: 1 mixture of 3-methylpentane and BuCl gave spectra of $TPE^{+\cdot}$ which exhibited a band having its maximum at 358 nm (band C). The intensity of band C is comparable to that of band B.

The result of the MO calculation for $TPE^{+\cdot}$ is quite similar to that for $TPE^{-\cdot}$, as should be the case because of the pairing properties of π orbitals of the alternant hydrocarbon. Similarly to the case of $TPE^{-\cdot}$, bands A, B, and C are ascribed to transitions 2, 7, and 8, respectively. As is seen in Table 6, these transitions can be well approximated as one-electron transitions. Of the orbitals involved, ϕ_{13} and ϕ_{14} are similar to the corresponding orbitals of $TPE^{-\cdot}$, and ϕ_6 and ϕ_{12} can be approximately expressed as follows:

$$(b_3)\quad \phi_6 \approx b\phi_{-1}(E) + a[\phi_{+1}(B)-\phi_{+1}(B')-\phi_{+1}(B'')+\phi_{+1}(B''')]$$

$$(b_2)\quad \phi_{12} \approx a[\phi_{+1}(B)+\phi_{+1}(B')-\phi_{+1}(B'')-\phi_{+1}(B''')]$$

The behavior of transitions 2, 7, and 8 with the change in geometry is expected to be quite similar to that of the corresponding transitions in $TPE^{-\cdot}$.

Comparison of Spectra and Inference of Geometries: Spectrum F of $TPE^{+\cdot}$ (Curves 1 and 4 in Fig. 3) is similar as a whole to spectrum F of $TPE^{-\cdot}$ (Curve 4 in Fig. 2). Thus, geometries F of $TPE^{+\cdot}$ and of $TPE^{-\cdot}$ seem to be similar.

In contrast with the case of $TPE^{-\cdot}$, spectrum F of $TPE^{+\cdot}$ changes only slightly both on controlled warming and on illumination [*cf.* Fig. 3, (a) and (b)]. The spectra of $TPE^{+\cdot}$ produced by pulse radiolysis of solutions of TPE in aerated acetone at room temperature (spectrum R; Curves 7 and 8 in Fig. 3) are similar to the spectra of $TPE^{+\cdot}$ in rigid matrices, especially to spectra W (Curves 2 and 3 in Fig. 3). This indicates that geometry R of $TPE^{+\cdot}$ is only slightly different

Table 6. Results of the MO calculation for $TPE^{+\cdot}$ of geometry (30, 0)[a]

Transition	ΔE/eV	$\bar{\nu}/10^3$ cm^{-1}	λ/nm	f	P	Character	ΔP_{a1}	$\Delta P_{aa'}$
2	1.576	12.70	787	0.297	x	0.968(12—13)	−0.061	+0.148
7	2.063	16.63	601	0.141	y	0.959(6—13)	−0.096	+0.167
8	3.015	24.30	412	0.381	y	0.942(13—14)	+0.098	−0.312

a) See footnotes of Table 2. The coefficient of the ground configuration in the wave function of the ground state is 0.993. The values of P_{a1} and $P_{aa'}$ in the ground state are 0.331 and 0.660, respectively.

from geometry F and probably from geometry N.

A detailed comparison of the spectra, however, reveals that there are small, but significant, differences among the spectra of $TPE^{+\cdot}$ measured under different conditions. Especially, in going from spectrum F to spectrum W, both bands A and B shift to shorter wavelengths (*cf.* Table 5), probably indicating that, in going from geometry F to geometry W, $\theta_{\alpha 1}$'s become slightly smaller and/or $\theta_{\alpha\alpha'}$ becomes slightly larger. Both bands A and B are located at slightly shorter wavelengths in spectrum F of the FM solution (Curve 1 in Fig. 3) than in spectrum F of the BuCl solution (Curve 4 in Fig. 3). This fact suggests that the FM glass at 77 K is softer than the BuCl glass at 77 K[35] and that $TPE^{+\cdot}$ in the former is relaxed to some extent immediately after its production, while $TPE^{+\cdot}$ in the latter is almost unrelaxed.

In conclusion, the geometries of relaxed $TPE^{-\cdot}$ and $TPE^{+\cdot}$ are considerably different. This is a rather unexpected finding, because the π bond orders of each bond in the anion and the cation of an alternant hydrocarbon should be equal and hence one would not expect a significant difference for the geometries of the two ions within the framework of π electron approximation. However, a few similar examples are found in the literature: While the geometry of the anion radical of cyclooctatetraene is inferred to be planar,[42,43] the geometry of the corresponding cation radical is suggested to be similar to that of the neutral cyclooctatetraene, a tub form;[35] according to Ishizu *et al.*,[44] the torsion angle of the coannular bond (the 1-1′ bond) of the cation radical of 2,2′,4,4′,6,6′-hexamethylbiphenyl is close to that of the parent neutral molecule (about 70°), while that of the anion radical of 2,2′,6,6′-tetramethylbiphenyl is much smaller (45—50°) (although Sullivan and Fong[45] have cast some doubt on this conclusion). It is of interest that in all these examples, including the present case, the geometry of the cation radical is inferred to be similar to that of the parent neutral molecule while that of the anion radical is considered to be different from that of the molecule.

(Received February 14, 1979)

The polarities (nucleophilicity and electrophilicity) of free radicals in abstraction reactions were studied by the comparison of the stabilization energies due to delocalization of electrons (SEDE) between a radical and a substrate. The stabilization energies were calculated by the CNDO/2 method for several substrate–radical systems. For the reactions of the methyl radical with chlorinated methanes, the nucleophilicity of the radical was well interpreted by the SEDE from the radical to the substrate. Similarly, the nucleophilicity of the hydrogen atom in chlorine abstraction from chlorinated methanes was indicated by the SEDE from the hydrogen atom to the substrate. In an electrophilic reaction such as hydrogen abstraction by the methyl radical from aliphatic hydrocarbons, the activation energy was found to decrease linearly with an increase in the SEDE from the substrate to the radical. This result is consistent with the electrophilic tendency of the reaction. The SEDE calculated for the reactions of a radical with a series of substrate thus indicates the polarity of the free radical in the abstraction reactions.

The polarity of a free radical has been an interesting subject in organic chemistry ever since a number of observations were published on the polar effect in radical reactions.[1] The Hammett and the Taft equations allow the quantitative study of polar effects in radical reactions as well as ionic reactions. On the basis of ρ values, various kinds of radicals have been found to react as electrophiles in abstraction reactions,[1-8] while a few radicals undergo the nucleophilic reactions.[9-16] The argument about the polarity of the radical, however, was generally empirical and no successful theoretical elucidation of the factors determining the polarity has been given.

The theory of chemical reactivity has succeeded in explaining the relative reactivity of the substrate toward a given radical. The Evans-Polanyi relationship[17] and the delocalizability[18] in the frontier electron theory developed by Fukui and his coworkers are typical theories. In the Evans-Polanyi relationship, the resonance stabilization energy of the formed radical is an important factor in determining the reactivity. On the other hand, the delocalizability is a measure of the stabilization energy due to delocalization of electrons (SEDE) between a substrate and a radical, and is recognized as an excellent reactivity index. Imamura has recently developed a molecular orbital (MO) method which evaluates semiempirically the SEDE from a substrate to a radical or *vice versa*.[19]

In the present work, an attempt was made to explain the polarity of free radicals in terms of the SEDE, which was calculated by the CNDO/2 method for the substrate–radical system. In the nucleophilic reactions, such as hydrogen abstraction by the methyl radical from chlorinated methanes[20] and chlorine abstraction by the hydrogen atom from chlorinated methanes,[21] the SEDE from the radical to the substrate was found to correlate linearly with the activation energy. The SEDE from the substrate to the radical also correlates with the activation energy in electrophilic reactions such as the hydrogen abstraction by the methyl radical from aliphatic hydrocarbons.[21] For several kinds of radicals, the polarity in abstraction reactions is discussed on the basis of both the SEDE and their physical properties.

Method of Calculation

The total energies for the isolated molecule as well as the reacting system were calculated by the UHF method[22] in the CNDO/2 approximation.[23,24] The values of the parameters included in the method are the same as those used in the original papers.[23,24]

Geometries. Geometries used for the calculation are as follows: for CH_4,[25] r(C–H) = 1.09 Å; for CH_3Cl,[26] r(C–H) = 1.103 Å and r(C–Cl) = 1.782 Å; for CH_2Cl_2,[27] r(C–H) = 1.082 Å and r(C–Cl) = 1.772 Å; for $CHCl_3$,[27] r(C–H) = 1.10 Å and r(C–Cl) = 1.758 Å; for CCl_4,[27] r(C–Cl) = 1.755 Å; for aliphatic hydrocarbons, r(C–H) = 1.09 Å and r(C–C) = 1.54 Å. The bond angles for chlorinated methanes and aliphatic hydrocarbons are assumed to be the same as that of methane (109.47°).

Stabilization Energy Analysis. To calculate the SEDE, it was assumed that in a hydrogen abstraction by a radical from a substrate the reaction proceeds through the following steps:

$$RH + X \longrightarrow [R\cdots H\cdots X] \longrightarrow R + HX$$

where RH and X denote a substrate (hydrogen donor) and a radical, respectively. The SEDE (ΔE) is defined by Eq. 1

$$\Delta E = E(R\cdots H \quad X) - E(R\cdots H\cdots X) \qquad (1)$$

where the first term on the right hand side in Eq. 1 denotes the energy of the reacting system in which the delocalization of electrons between RH and X is forbidden. The second term includes the delocalization of electrons. The SEDE is calculated as follows. (i) The total energy of the reacting system [R···H···X] without delocalization of electrons is calculated with the UHF method in the CNDO/2 approximation after dropping all the resonance integrals (I_{rs}) between atomic orbitals (AO's) on the fragment RH and those on the fragment X. Thus we obtain the MO's localized on the fragments RH and X. (ii) By using the MO's obtained in step (i), the modified resonance integrals between AO's (I'_{rs}) are calculated according to Eq. 2

in order to take the delocalization of electrons between particular MO's into account:

$$I'_{rs} = \sum_{(i_1-j_1)} C_{RHi_1,r} C_{Xj_1,s} I_{i_1 j_1}, \quad (2)$$

where $C_{RHi_1,r}$ is the coefficient of AO in the i_1-th MO of substrate RH and $C_{Xj_1,r}$ is for radical X. $\sum_{(i_1-j_1)}$ denotes the summation over a particular orbital set (i_1-j_1). (iii) I'_{rs} is employed to calculate the total energy of the reacting system with the delocalization of electrons, which corresponds to the nucleophilic or the electrophilic nature of the radical in question. (iv) When the vacant MO's of the substrate and the occupied MO's of the radical are chosen for i_1 and j_1, respectively, in Eq. 2, the difference between the two energies obtained in steps (i) and (iii) corresponds to the SEDE from radical to substrate. This energy should be the nucleophilic stabilization energy; it is represented by the symbol N. When the occupied MO's of the substrate and the vacant MO's of the radical are chosen for i_1 and j_1, respectively, the electrophilic stabilization energy E is obtained. Table 1 shows the schematic representation of intermolecular interaction between the MO's of RH and X obtained by dropping the I_{rs} (they interact electrostatically with each other, but the delocalization of electrons is prohibited).

TABLE 1. THE SCHEMATIC REPRESENTATION OF THE ORBITAL INTERACTIONS BETWEEN SUBSTRATE RH AND RADICAL X[a)]

Interaction	α-Spin			β-Spin		
Electrostatic (Zero)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac
Nucleophilic-1 (1N)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac
Electrophilic-1 (1E)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac
Nucleophilic-2 (2N)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac
Electrophilic-2 (2E)	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac
All	RH	Occ	Vac	RH	Occ	Vac
	X	Occ	Vac	X	Occ	Vac

a) The symbols for the orbital interactions used in the text are given in the parentheses. An interaction including the $I_{i_1 j_1}$ is represented by a solid line.

Results

A. Hydrogen Abstraction Reaction by the Methyl Radical. A-1: The Nucleophilicity of the Methyl Radical in Hydrogen Abstractions with Chlorinated Methanes:[20] The coordinate system assumed for the reaction of the methyl radical with methyl chloride is shown in Fig. 1 as an example. Without loss of generality, it is assumed that the methyl radical has four valence electrons with α-spin and three valence electrons with β-spin. The electron distribution shown in Fig. 2 indicates that the delocalization of electrons occurs from the methyl radical to methyl chloride by the interaction $1N$, and from methyl chloride to the methyl radical by $1E$. Thus the stabilization energy represented by N or E corresponds to the

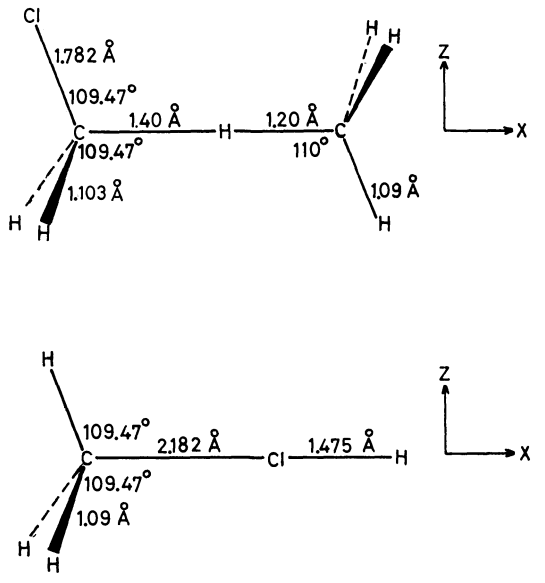

Fig. 1. Interaction models for hydrogen and chlorine abstraction reactions by radicals.

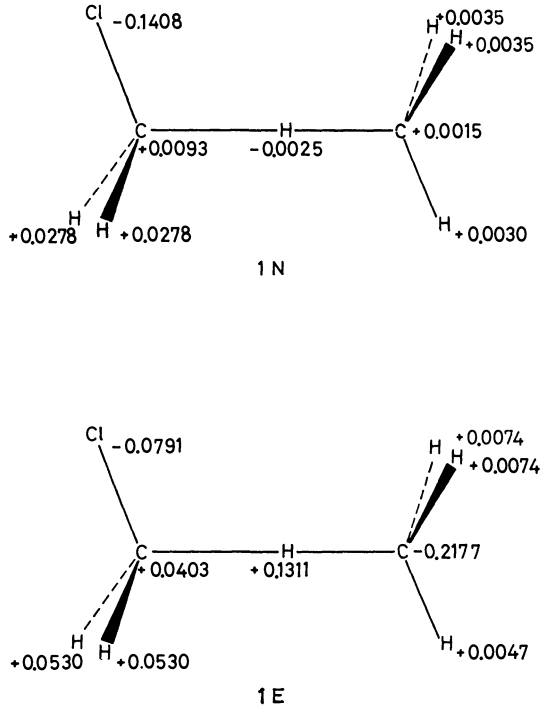

Fig. 2. The electron distribution of CH_3Cl–CH_3 system by the nucleophilic and the electrophilic interactions.

direction of the delocalization of electrons occurring between a substrate and a radical. Figure 3a shows the correlation between the activation energy[20] and the electron density on the hydrogen atom to be abstracted. The activation energy decreases with a decrease in the electron density, and thus the methyl radical reacts as a nucleophile. The nucleophilicity of the methyl radical is explained essentially by the SEDE, as summarized in Table 2. In the reactions with chlorinated methanes the electrophilic stabilization energy $2E$ decreases with the increasing number of chlorine atoms, while the nucleophilic stabilization energy $2N$ increases. As is shown

in Fig. 3b, the reactivities of chlorinated methanes are correlated with the sum of $2N$ and $2E$ calculated by the present procedure. It should be noted that the change of $2N$ from molecule to molecule is much larger than that of $2E$, although $2E$ is larger than $2N$. This suggests that the nucleophilic stabilization energy governs the relative reactivities (Fig. 3c). The conclusion is consistent with the linear relation between the electron density and $2N$, as is shown in Fig. 3d.

The electrophilic stabilization energy depends mainly on the delocalization of electrons with β-spin from the occupied MO's of the substrate to the vacant MO's of the methyl radical, because the stabilization energy for the $2E$ interaction is almost the same as that for the $1E$ interaction, as indicated in Table 2. On the other hand, the nucleophilic stabilization energy depends not only on the delocalization of electrons with α-spin from the occupied MO's of the methyl radical to the vacant MO's of the substrate, but also on the delocalization of

electrons with β-spin, although the former contribution is larger than the latter. The total stabilization energy including the interaction between the occupied MO's of the substrate and the methyl radical ("All" in Table 2) is larger than that due to the delocalization of electrons, as is shown in Table 2. This energy can be considered to include the redistribution energy in addition to the delocalization energy, which is much larger than the redistribution energy and comes to about 70% of "All". As the ratio of $(2N+2E)$ to "All" is nearly constant for every substrate, a good correlation between the activation energy and "All" is also observed in Table 2.

A-2: The Electrophilicity of the Methyl Radical in Hydrogen Abstraction Reactions with Aliphatic Hydrocarbons:[21] The coordinate system assumed for the reaction is the same as that used in Fig. 1. Figure 4a shows the correlation between the activation energy and the electron density on the hydrogen atom. Contrary to the methyl chloride–methyl radical system, the activation energy decreases with an increase in the electron density and, in this case, the methyl radical reacts as an electrophile. The electrophilic stabilization energy $2E$ was found to correlate linearly with the activation energy, as is shown in Fig. 4a. The results suggest that the electrophilic stabilization energy gives a theoretical basis for the electrophilicity of the methyl radical. A linear relation between the electron density and $2E$ is also shown in Fig. 4b.

On the basis of the results obtained above, the polarity of a free radical can be defined as follows: If the reactivity of the radical toward a series of substrates

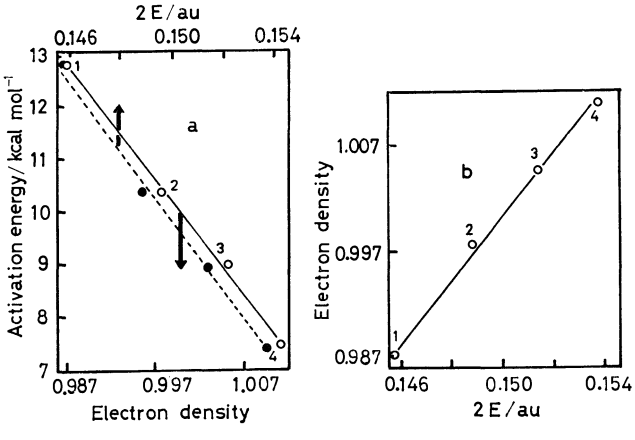

Fig. 4a. The correlation of the activation energy[21] with the electron density and $2E$ for hydrogen abstraction by the methyl radical from aliphatic hydrocarbons. 1: CH_3–H, 2: CH_3CH_2–H, 3: $(CH_3)_2CH$–H, 4: $(CH_3)_3C$–H. For the reaction of the methyl radical with CH_4, 12.8 kcal/mol of the activation energy was used in the present work as the average value in Ref. 12 and 42.

increases with an increase in the nucleophilic stabilization energy, the radical is a nucleophile. Similarly, the radical is an electrophile when the reactivity increases with the increase in the electrophilic stabilization energy.

B: Chlorine Abstraction Reactions by the Hydrogen Atom. Nagai *et al.*[11] reported the nucleophilicity of the triethylsilyl and phenyldimethylsilyl radicals in chlorine abstractions with polychloroalkanes. If the present analysis is applied to the reactions, the information on the theoretical basis of the Taft equation will be obtained from the reactivities of polychloroalkanes toward these radicals. Unfortunately, the molecules and the radicals are too large for the calculation to be carried out. Thus the chlorinated methane–hydrogen atom system[20] was taken as a model case. As will be discussed below, the nucleophilic nature of a radical in hydrogen abstraction depends on the ionization potential of the radical. When the ionization potential is rather low, the nucleophilicity is observed. If the hydrogen atom, which is known to have a high ionization potential (13.6 eV),[28] reacts as a nucleophile in chlorine abstractions with chlorinated methanes, the silyl radical would be expected to react as a nucleophile, because its ionization potential is lower than that of the hydrogen atom. The coordinate system assumed for the reaction is given in Fig. 1. As shown in Fig. 5, the nucleophilic stabilization energy $1N$ correlates with the relative reactivity, so that the hydrogen atom reacts as a nucleophile. The result suggests that the nucleophilicity of the silyl radicals in chlorine abstractions from polychloroalkanes will be interpreted by the SEDE, if the energy is calculated for the reacting system.

C: Hydrogen Abstraction Reactions by Various Kinds of Radicals.[29] For the hydrogen abstractions involving several radicals with hydrocarbons, the activation energy

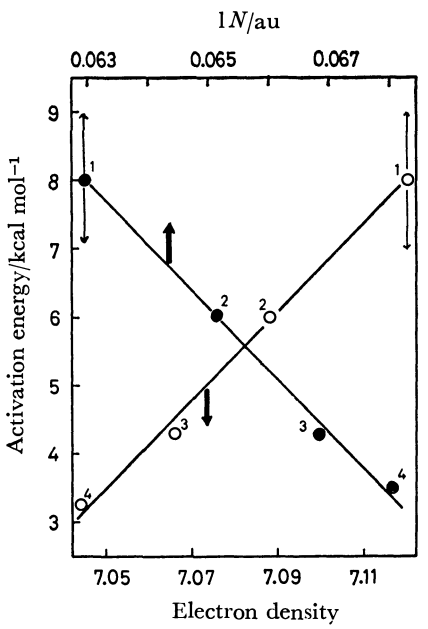

Fig. 5. The correlation of the activation energy[20] with the electron density and $1N$ for chlorine abstraction by the hydrogen atom from chloromethanes. 1: CH_3Cl, 2: CH_2Cl_2, 3: $CHCl_3$, 4: CCl_4.

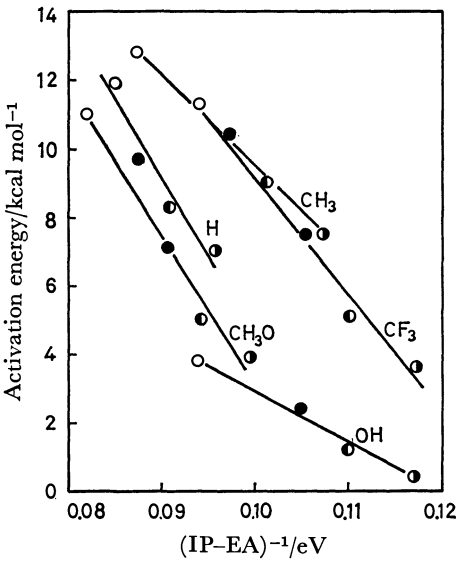

Fig. 6. The correlation between the activation energy[28] and 1/(IP–EA) for hydrogen abstractions by various kinds of radicals from aliphatic hydrocarbons. EA: electron affinity of the radical, IP: ionization potential of the aliphatic hydrocarbon. ○: CH_4, ●: CH_3CH_3, ◐: $CH_3CH_2CH_3$, ◑: $(CH_3)_3CH$.

is plotted against the reciprocal of the difference between the ionization potentials of the hydrocarbons and the electron affinities of the radicals in Fig. 6. The reciprocal of the difference between the ionization potential of hydrocarbon and the electron affinity of the radical is not directly related to the electrophilic stabilization energy, but is qualitatively associated with it. From the linear correlation shown in Fig. 6, it may be inferred that the electrophilic stabilization energy is an important factor in determining the reaction rates for the radicals with low electron affinity (H: 0.80 eV, CH_3O: 0.38 eV)[28] and with high electron affinity (CF_3: 1.85 eV, OH: 1.83 eV).[28] The correlation in Fig. 6 is also consistent with the order of reactivity of the C–H bonds (primary<secondary<tertiary). The result supports the significance of the electrophilic stabilization energy in hydrogen abstractions from aliphatic hydrocarbons, although the important role of the dissociation energy of the C–H bond should also be taken into consideration.[30]

Figure 7 shows the difference in the polarity between the phenyl[31] and the hydroxyl[32] radicals in the reactions with chlorinated methanes. In spite of its high electron affinity (2.20 eV),[28] the phenyl radical reacts as a nucleophile, while the hydroxyl radical and the chlorine atom (3.61 eV)[33] react as electrophiles in the reactions. The difference in behavior is interpreted by the ionization potentials of the radicals (C_6H_5: 9.90 eV,[28] OH: 13.18 eV,[28] Cl: 13.01 eV[34]). The low ionization potential of the phenyl radical is a cause of the nucleophilicity. A radical with a high ionization potential, such as the hydroxyl radical, on the other hand, reacts as an electrophile. Although the stabilization energy analysis was not carried out for these radicals, the correlation between the electron density and the SEDE in Figs. 3d, 4, and 5 indirectly interprets the nucleo-

philicity of the phenyl radical[35] and the electrophilicity of the hydroxyl radical or the chlorine atom.

Discussion

The polar effect may explain the substituent effect in hydrogen abstraction reactions[1,2,5-7] where an empirical linear energy relation such as the Hammett or the Taft equation holds. In the present work, the electron density on the hydrogen atom was found to correlate with the activation energy. However, for a more fundamental understanding, the polarity of a radical in hydrogen abstraction should be explained by a quantity derived from the reaction system, not one taken from an individual reactant. The stabilization energy due to delocalization of electrons (SEDE), calculated by the CNDO/2 method for the reaction system which consists of a substrate and a radical, is a more essential quantity. As described above, the change of the electrophilic stabilization energy indicates the electrophilic tendency of the radical, and the nucleophilic stabilization energy corresponds to the nucleophilicity.

Since the electron affinity or the ionization potential of a radical can be related with the electrophilic or the nucleophilic stabilization energy,[36] respectively, the Hammett ρ values are expected to correlate with the physicochemical properties of the radical. In fact, Sakurai *et al.*[37] reported a linear relation between the negative ρ values and the electron affinity of the radical for hydrogen abstraction from substituted toluenes. Pryor *et al.*[38] revealed that the isopropyl and the *t*-butyl radicals react as nucleophiles. The positive ρ values increase with the decreasing ionization potentials (IP) of the radicals (CH_3: $\rho=-0.10$,[39] IP=9.86 eV,[28] *i*-C_3H_7: $\rho=0.8$, IP=7.90 eV,[28] *t*-C_4H_9: $\rho=1.0$, IP=7.07 eV[28]). The quantitative correlation may be given by the SEDE, because it is calculated for the reacting system and includes both reactants.

The present analysis is based on the zero differential overlap approximation,[23,24] and thus the quantitative treatment is not sufficient. Furthermore, the SEDE were not calculated for the transition state in the reacting system. The geometries shown in Fig. 1 were tentatively chosen as interaction models, because the reaction path could not be obtained by the CNDO/2 method. However, the essential features of the radical reagent obtained in the present work will probably be valid, because for an argument on the polarity[40] the absolute value of the stabilization energy is not necessarily required but a relative one is sufficient. For a more elaborate approach, the *ab initio* MO method might be adapted to the present analysis. The method of Kitaura and Morokuma,[41] which divides the intermolecular interaction energy into the electrostatic, the polarization, the exchange, and the delocalization energies, will make it possible to apply the *ab initio* method to the present analysis.

We would like to express our gratitude to the Computer Center of Tokyo University for the generous permission to use the HITAC 8700/8800 computer.

Binding Forces Contributing to the Association of Cyclodextrin with Alcohol in an Aqueous Solution

Yoshihisa MATSUI* and Kazuo MOCHIDA

Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue 690

(Received February 16, 1979)

The association constants and thermodynamic parameters were determined for complexes of α- and β-cyclodextrins (CD) with a variety of alcohols (ROH) by the spectrophotometric examination of the inhibitory effect of ROH on the association of CD with azo dyes, and they were analyzed in connection with the partition coefficients of ROH in a diethyl ether–water solvent system in order to elucidate the binding forces contributing to the association of CD with an organic substrate. Hydrophobic and van der Waals interactions were of primary importance in the complexation. Among them, the latter was preferential in α-CD–1-alkanol adducts, while the former, in β-CD–1-alkanol adducts. As the bulkiness of ROH increased, the stability of the α-CD adduct was lowered owing to van der Waals repulsion between ROH and the relatively small α-CD cavity, whereas that of the β-CD adduct was enhanced by the attainment of the close van der Waals contact of ROH with the relatively large β-CD cavity.

Cyclodextrin (CD) is a doughnut-shaped molecule and includes a variety of substrates within the hole of the doughnut.[1–4] The stability of the CD adducts varies markedly either with the size of the CD cavity or with the structure of a substrate. In order to understand the mechanism from which the substrate specificity arises, it is necessary to clarify binding forces contributing to the inclusion process. Hydrogen bonding,[5–8] van der Waals interactions,[8–13] and/or hydrophobic interactions[2,12–17] have been proposed to explain the inclusion phenomena. Among them, hydrophobic interactions have been regarded as especially significant on the basis of the fact that the inclusion phenomena of CD exclusively occur in an aqueous solution.[2] However, a number of thermodynamic parameters determined for the inclusion equilibria indicated that the process is governed by a negative enthalpy change. The entropy term was always negative and contributed unfavorably to the complexation, despite hydrophobic interactions being normally caused by a favorable positive entropy change.[18–19]

Bender *et al.*[2,10] and Bergeron *et al.*[11,20] explained the thermodynamic parameters in terms of the relief of high energy water from the CD cavity. According to them, the water molecules associated with the cavity are enthalpy rich, because they can not have a full complement of hydrogen bonds owing to interference from the glucopyranose rings of CD. The inclusion of a substrate results in the expulsion of these high energy water molecules into bulk water. Another binding force was proposed by Saenger *et al.*,[21–24] who systematically examined the molecular structures of α-CD adducts by means of X-ray crystallography. They found that the macrocycle of α-CD bears an unstrained hexagonal geometry in most of α-CD adducts except for a α-CD–water adduct, in which the macrocyclic conformation of α-CD is unsymmetrically distorted and energetically unstable. The relief of conformational strain energy in the α-CD–water adduct upon substrate inclusion was regarded as the main binding force of complexation. However, Tabushi *et al.*[13] recently showed that the strain relief as well as the relief of high energy water molecules is not major driving force of inclusion, but van der Waals interactions and the breaking of water clusters around an apolar guest molecule are of primary importance in the stabilization of an inclusion complex.

The present study was undertaken to estimate the extent of the contribution of these binding forces to the inclusion process on the basis of the association constants (K_a) and the thermodynamic parameters for the complexation of α- and β-CD with a variety of alcohols (ROH). The observed K_a values were analyzed in connection with the partition coefficients (P_e) of ROH's which are a reasonable measure of hydrophobicity and is often successfully applied to biological structure-activity relationship studies.[25–31] ROH's are well suited for substrates, since they are the simplest organic analogs of water which plays an important role in the inclusion process.

Experimental

Materials. The α- and β-CD were prepared by the method of Lane and Pirt.[32] These substances were separated and purified according to the directions of Cramer and Henglein.[33] Unless otherwise noted, ROH's of reagent grade were used after distillation. 3-Methyl-2-butanol and 3,3-dimethyl-2-butanol were prepared by the reduction of the corresponding 2-butanones with $LiAlH_4$: bp 112.8—113.2 °C (lit,[34] bp 113—114 °C) for the former and bp 120.5—122.2 °C (lit,[34] bp 120—121 °C) for the latter. 2-Methyl-2-pentanol and 2-methyl-2-hexanol were prepared by the reaction of acetone with propyl- and butylmagnesium bromides respectively: bp 52—56 °C/45 mmHg (1 mmHg=133.322 Pa) (lit,[34] bp 122.5—123.5 °C/762 mmHg) for the former and bp 64—67 °C/30 mmHg (lit,[34] bp 141—142 °C/755 mmHg) for the latter. 3-Methyl-3-pentanol and 3-ethyl-3-pentanol were prepared by the reaction of ethylmagnesium bromide with 2-butanone and 3-pentanone respectively: bp 121—123 °C (lit,[34] bp 122.5 °C/758 mmHg) for the former and bp 56—58 °C/33 mmHg (lit,[34] bp 142 °C/764 mmHg) for the latter. 2-Methyl-1-butanol, 2-pentanol, 2-hexanol, 4-methyl-2-pentanol, cyclobutanol, cyclopentanol, cycloheptanol, and cyclooctanol of reagent grade were used without further purification. An azo dye, sodium 4-(4-hydroxy-1-naphthylazo)-1-naphthalenesulfonate (**1**), was prepared and purified as has been described previously.[35] Methyl Orange (**2**) of reagent grade was used without further purification.

Apparatus. Absorption spectra were recorded using a Hitachi Model 124 spectrophotometer. The cells (1.0 cm) were maintained at a constant temperature by means of a

jacket through which water was circulated from a constant-temperature bath. The pH of an aqueous solution was measured by means of an Orion Model 801A digital pH/mV meter. A Hitachi Model 063 gas chromatograph with a FID detector and 2% DEGS columns was used for the quantitative determination of ROH in diethyl ether and in water.

Spectrophotometric Determination of Equilibrium Constants for the Association of α- and β-CD with ROH. The association constant (K_a) for a CD–ROH system was determined by the spectrophotometric examination of the inhibitory effect of the ROH on the association of the CD with a dye. In order to obtain the K_a values in a satisfactory accuracy by this method, it is necessary to choose such a dye as to exhibit a large absorbance change upon the addition of a small amount of CD. If the concentration of CD is high, a large amount of ROH must be added to a CD–dye solution for the sufficient observation of the inhibitory effect of ROH on the association of CD with the dye. However, the addition of a large amount of ROH is undesirable owing either to low solubility in some ROH's or to alteration in solvent composition. In the present study, azo dyes, **2** and **1**, were used for α- and β-CD systems respectively. In 0.10 mol/dm^3 H_2SO_4 containing Na_2SO_4 for the adjustment of the ionic strength (I_c) to be 0.50 mol/dm^3, **2** gave an absorption maximum at 507 nm, the absorbance of which was markedly lowered by the addition of a small amount of α-CD (Fig. 1). Similarly, the addition of β-CD to a solution of **1** in a citrate–phosphate buffer (pH 6.4, I_c=0.05 mol/dm^3, and 25 °C) markedly lowered the absorbance at λ_{max} of 485 nm.[35] Each azo dye forms a 1:1 complex with CD at a CD concentration below 2 mmol/dm^3.[35] Although such experimental conditions as pH and I_c were different between α- and β-CD systems, these may little affect the K_a values since both of CD and ROH are neutral molecules.

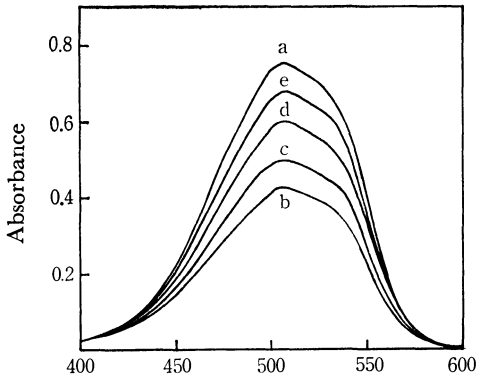

Fig. 1. Effect of α-CD and 1-butanol on the spectrum of **2** in 0.10 mol/dm^3 H_2SO_4 (I_c=0.50 mol/dm^3) at 25 °C.
a) 1.86×10^{-5} mol/dm^3 **2**; b) a+1.01 mmol/dm^3 α-CD; c) b+6.07 mmol/dm^3 1-butanol; d) b+24.3 mmol/dm^3 1-butanol; e) b+70.7 mmol/dm^3 1-butanol.

The addition of ROH to each CD–azo dye system resulted in an increase in absorbance (Fig. 1), indicating that a part of the added ROH is included by CD to expel the complexed azo dye to a bulk solution. Upon an assumption that each ROH also forms a 1:1 inclusion complex with CD, a relation between the absorbance and the concentration of the added ROH was analyzed by the application of the law of mass action and Lambert-Beer's law to the following two chemical equilibria:

$$\mathrm{CD} + \mathrm{AZO} \rightleftharpoons \mathrm{CDAZO} \quad (1)$$

$$\mathrm{CD} + \mathrm{ROH} \rightleftharpoons \mathrm{CDROH} \quad (2)$$

where AZO represents an azo dye, and CDAZO and CDROH, corresponding CD complexes. The initial and equilibrium concentrations were designated by a_0 and a for AZO, b_0 and b for ROH, and c_0 and c for CD respectively. Since CD, ROH, and CDROH are spectrophotometrically transparent in a visible region, the change (ΔA) in absorbance of an azo dye with the addition of CD and ROH is related to the equilibrium concentration (a_0—a) of CDAZO by Eq. 3:

$$a_0 - a = \frac{\Delta A}{\Delta\varepsilon}, \quad (3)$$

where $\Delta\varepsilon$ is the difference in molar absorbance between AZO and CDAZO. Similarly, a is given by

$$a = \frac{(\Delta A_\infty - \Delta A)}{\Delta\varepsilon}, \quad (4)$$

where ΔA_∞ is the difference in absorbance between AZO and CDAZO ($\Delta A_\infty = \Delta\varepsilon \cdot a_0$). The dissociation constant (K_d) for CDAZO is represented by $K_d = c\cdot a/(a_0-a)$, so that the equilibrium concentration of CD is given by

$$c = \frac{K_d(a_0-a)}{a}. \quad (5)$$

On the other hand, the association constant (K_a) for CDROH is represented by

$$K_a = \frac{c_0-c-(a_0-a)}{c[b_0-c_0+c+(a_0-a)]}. \quad (6)$$

Since the value of a_0-a is very small compared with either c_0-c or b_0-c_0+c under the experimental condition of $a_0 \ll b_0$, c_0, Eq. 6 is simplified as Eq. 7:

$$K_a = \frac{c_0-c}{c(b_0-c_0+c)}. \quad (7)$$

The values of K_d and $\Delta\varepsilon$ are easily determined by the Hildebrand-Benesi plot[36] (Table 1). By indroducing these values and the observed ΔA value into Eqs. 3, 4, and 5, we obtain the value of c, which is in turn introduced into Eq. 7 to give the K_a value. Actually, absorption spectra were measured at five or more different concentrations of ROH for each CD–ROH system. The calculated values of log K_a were in good agreement with one another wihin the standard error of ±0.04.

Table 1. The K_d and $\Delta\varepsilon$ values for CD–azo dye inclusion complexes at various temperatures

T/K	K_d/mmol/dm^3	$\Delta\varepsilon\times10^{-4}$/(mmol/dm^3)$^{-1}$ cm^{-1}

b) pH 6.4, I_c=0.05 mol/dm^3, and λ=485 nm.

Determination of Thermodynamic Parameters for the Association of CD with ROH. The K_a values were determined at 10, 15, 20, and 25 °C for α-CD–ROH systems and at 15, 20, 25, 30, and 35 °C for β-CD–ROH systems. The method of least squares was applied to the relationship between log K_a and $1/T$. The values of ΔH and ΔS were calculated from the slope and the intercept respectively of the straight line obtained. The values of K_d and $\Delta\varepsilon$ at temperatures used for the determination of K_a are shown in Table 1.

Determination of Partition Coefficient of ROH in a Diethyl Ether–Water System. A proper amount of ROH was added to a mixture of diethyl ether (5 cm³) and water (5 cm³). The resulting mixture was vigorously shaken in a constant-temperature bath at 25 °C for *ca.* 1—2 min and was then allowed to stand in the bath. The aliquots of diethyl ether and aqueous solutions were analyzed by gas chromatography to determine the concentrations of ROH in diethyl ether (c_e) and in water (c_w). The partition coefficient (P_e) of ROH was evaluated as the mean of the values of c_e/c_w determined at five or more different amounts of the added ROH. The standard errors of log P_e were less than 0.04 except for the case of methanol, where it was 0.08.

Results

Table 2 shows the values of log K_a for each CD–ROH system, log P_e for ROH in a diethyl ether–water system, and a few related parameters for each ROH. The number of ROH examined is thirty-four, involving twenty-seven saturated aliphatic ROH's, five alicyclic ROH's, and two aromatic ROH's. Among the saturated aliphatic ROH's, twelve are primary, nine, secondary, and six, tertiary. All the structural isomers are involved among them with regard to saturated aliphatic monofunctional ROH's containing less than five carbon atoms in a molecule. Table 3 shows the thermodynamic parameters determined for the association of several ROH's with CD.

Discussion

Three characteristic relationships were recognized between the structure and log K_a for the examined

Table 2. The values of log K_a, log P_e, log P_o, E_s, and ν (25 °C)

No.	ROH	log K_a		log P_e	log P_o[a]	E_s[b]	ν[c]

ROH's by a direct comparison of the data in Table 2 with one another.

1) The values of K_a for CD–ROH adducts change with a change in the structure of ROH to a great extent (from −0.03 to 3.80 and from −0.49 to 3.30 for α- and β-CD systems respectively). This fact suggests that neither hydrogen bonding nor the relief of conformational strain energy of CD is of primary importance in stabilizing an inclusion complex between CD and ROH, since these binding forces have been regarded as either weak[2] or virtually constant,[21–24] independent of the structure of a guest molecule, in an aqueous solution.

2) A considerably high positive correlation exists between the observed log K_a and log P_e values. Thus, for α-CD systems;

$$\log K_a = 0.83 \log P_e + 1.00, \quad (8)$$
$$n=29,\ r=0.895,\ \text{and}\ s=0.381,$$

and for β-CD systems;

$$\log K_a = 0.90 \log P_e + 0.98, \quad (9)$$
$$n=34,\ r=0.871,\ \text{and}\ s=0.441,$$

where n, r, and s are the number of data, a correlation coefficient, and the standard deviation of residuals respectively. These observations indicate that hydrophobic interactions play a significantly important role in the complexation.

3) Virtually half of the examined ROH's associate with α-CD more strongly than with β-CD, while the others are reverse. The log K_a values for α-CD complexes with the following ROH's are larger, by 0.5 or more, than those for the corresponding β-CD complexes: Ethanol, 1-propanol, 1-butanol, 1-, 2-, and 3-pentanols, 1- and 2-hexanols, 1-heptanol, and 1-octanol. All of these ROH's contain a straight-chain alkyl group. On the other hand, the following ROH's associate with β-CD more strongly than with α-CD by 0.5 or more in log K_a: 2-Methyl-2-propanol, 2,2-dimethyl-1-propanol, 3-methyl-2-butanol, 3,3-dimethyl-2-butanol, cyclohexanol, cycloheptanol, and cyclooctanol. All of these ROH's contain a bulky alkyl group. It is interesting to compare data for the structural isomers of 1-pentanol and 2,2-dimethyl-1-propanol with each other. The log P_e values for the isomers are 1.20 and 1.21, being virtually equal to each other. Nevertheless, the log K_a value for a α-CD–1-pentanol adduct (2.51) is larger than that for a α-CD–2,2-dimethyl-1-propanol adduct (1.47) by more than unity, whereas the log K_a value for a β-CD–1-pentanol adduct (1.80) is smaller than that for a β-CD–2,2-dimethyl-1-propanol adduct (2.76) by nearly unity. These observations indicate that not only hydrophobic interactions but also the bulkiness of a guest molecule relative to the size of the CD cavity affects on the stability of a CD–ROH adduct. It seems that straight-chain alkanols with rod-like structure are closely fitted to the relatively small α-CD cavity, whereas they are too small in size to be in close contact with the relatively large cavity of β-CD. On the other hand, bulky or globular molecules, such as multi-branched alkanols and cycloalkanols, may be too large in size to be included deeply within the α-CD cavity, while they may be closely fitted to the β-CD cavity. In this connection, it is interesting that the log K_a value for a β-CD–3-ethyl-3-pentanol adduct (2.28) is significantly smaller than that for the corresponding straight-chain isomer (1-heptanol) system (2.85). In this case, the guest molecule is so large in size that it may be difficult even for β-CD to include deeply the guest within the cavity. The above presumptions were substantiated by an examination with the Corey-Pauling-Koltum molecular models, too. Thus, ROH's in α-CD–1-pentanol and β-CD–2,2-dimethyl-1-propanol adducts are readily inserted into the bottom of the corresponding CD cavity to come into close contact with the C-5 hydrogens which locate at the bottom-half of the CD cavity. On the other hand, ROH's in α-CD–2,2-dimethyl-1-propanol and β-CD–3-ethyl-3-pentanol adducts are only able to be inserted into the top-half of the corresponding CD cavity not or hardly to come into contact with the C-5 hydrogens. Taking into account the fact that the CPK models are constructed on the basis of van der Waals radii of atoms, we may say that van der Waals interactions also significantly contribute to the complexation of CD with ROH.

Correlation between log K_a and log P_e. In order to learn the implication of the results in Table 2 more closely, the correlation between log K_a and log P_e was examined either graphically or by regression analysis. The partition coefficient of an organic compound in an apolar solvent–water system is a practical and reasonable index of the hydrophobicity of the compound.[25–31] Although 1-octanol is ordinarily used as an apolar solvent,[27,30] diethyl ether was used in the present study, since a number of ethereal oxygens are aligned within the CD cavity to give an ether-like atmospher.[10] However, it was found that a good linear correlationship exists between the observed P_e and the partition coefficient (P_0) in a 1-octanol–water system for twenty ROH's thus far reported.

$$\log P_e = (1.03\pm0.03)\log P_0 - (0.26\pm0.04), \quad (10)$$
$$n=20,\ r=0.993,\ \text{and}\ s=0.115.$$

A similar equation has been reported by Leo *et al.*[27] for a variety of organic compounds including ROH's:

$$\log P_e = (1.13\pm0.04)\log P_0 - (0.17\pm0.05), \quad (11)$$
$$n=71,\ r=0.988,\ \text{and}\ s=0.186.$$

Accordingly, no difference may arise in conclusion whether $\log P_e$ or $\log P_0$ is used as an index of the hydrophobicity of ROH.

Regression analysis of $\log P_e$ for twenty-seven acyclic alkanols examined showed that the following equation holds for with a very high multiple correlation coefficient:

$$\log P_e = -1.72 + 0.58N - 0.22S - 0.61T, \quad (12)$$
$$n=27,\ r=0.998,\ \text{and}\ s=0.061,$$

where N is the number of carbon atoms contained in ROH, S and T, indicator variables which are equal to zero or unity. If the ROH is primary, $S=T=0$; if secondary, $S=1$ and $T=0$; if tertiary, $S=0$ and $T=1$. Equation 12 indicates that $\log P_e$ of ROH is virtually defined only by the number of carbon atoms in ROH and the class of the ROH.

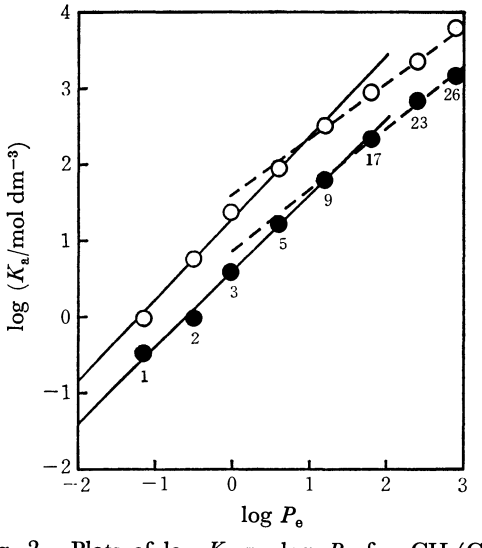

Fig. 2. Plots of $\log K_a$ *vs.* $\log P_e$ for $CH_3(CH_2)_nOH$ (n=0—7).
○: α-CD system; ●: β-CD system.
The solid and dashed lines were obtained by the application of the least squares method to the set of data for n=0—4 and n=4—7 respectively. Numbers shown refer to the numbers in the first column of Table 2.

Figure 2 shows the plot of $\log K_a$ *vs.* $\log P_e$ for CD–1-alkanol systems. Both the plots for α- and β-CD systems gave approximately straight lines with a slope of *ca.* unity. For the α-CD system,

$$\log K_a = 0.92\log P_e + 1.25, \quad (13)$$
$$n=8,\ r=0.994,\ \text{and}\ s=0.153,$$

and for the β-CD system,

$$\log K_a = 0.94\log P_e + 0.58, \quad (14)$$
$$n=8,\ r=0.998,\ \text{and}\ s=0.099.$$

However, it was recognized in each system that a refractive point does exist around the point corresponding to 1-pentanol and the plots for the higher alkanols tend to locate below a straight line drawn through the plots for the lower alkanols. The solid and dashed lines in Fig. 2 were obtained by the application of the least squares method to the sets of data from methanol to 1-pentanol and from 1-pentanol to 1-octanol respectively. Taking into account the depth of the CD cavity (*ca.* 7 Å[2]) together with the mean length of an aliphatic C–C bond (1.537 Å[37]), we can presume that the whole molecule of 1-butanol or even 1-pentanol is completely included within the CD cavity, while a part of the molecule of 1-hexanol or higher alkanols is protruded from the CD cavity to a bulk solution. In the case of the latter, interactions between CD and ROH may be lowered either by the incomplete liberation of iceberg water[18] or water cluster[19] around the apolar alkyl chain of ROH upon inclusion or by the incomplete van der Waals contact of the alkyl group with the CD cavity.

It is also evident from Fig. 2 that each 1-alkanol associates with α-CD more strongly by a factor of 6—7 than with β-CD. Although pH and I_c of solutions used are different between α- and β-CD systems for the sake of experimental convenience (*cf.* Experimental), such difference may have no or little effect on the value of $\log K_a$, since both of CD and ROH are neutral molecules. The difference in $\log K_a$ between α- and β-CD systems might be attributed to the difference either in size or, if any, in hydrophobicity between the α- and β-CD cavities. However, no evidence has ever been offered for a postulate that the hydrophobicity of the α-CD cavity is greater than that of the β-CD cavity. The solubility of α-CD in water is rather 8 times that of β-CD.[1] Thus, it is unlikely that the α-CD cavity is more hydrophobic than the β-CD cavity to cause the difference in $\log K_a$ between α- and β-CD systems. It is much reasonable to consider that α-CD includes 1-alkanol in closer contact with each other than β-CD does. According to Bergeron and Meely,[20] the relief of high-energy water molecules in the inclusion process of CD is substantiated by the fact that a number of organic molecules associate with β-CD more strongly than with α-CD. However, the reverse is true for the present CD–1-alkanol systems, indicating that the basis given by them is not always general.

Figures 3 and 4 show the plots of $\log K_a$ *vs.* $\log P_e$ for branched or cyclic ROH–CD systems. Both of the plots for the α- and β-CD systems showed considerable scatter in contrast to the plots for 1-alkanol systems. However, a remarkable trend was found by comparing both plots with each other. Most of the plots for a α-CD system (Fig. 3) locate below the straight line obtained by the regression analysis of the data for a α-CD–1-alkanol system (Eq. 13), while those for a β-CD system (Fig. 4) locate above the straight line given by Eq. 14. This observation shows that it is general for a bulky ROH to associate with α-CD less strongly and with β-CD more strongly than a rod-like 1-alkanol if the $\log P_e$ values are the same.

An interesting indication is afforded by the plots of $\log K_e$ *vs.* $\log P_e$ for cycloalkanols shown by solid circles

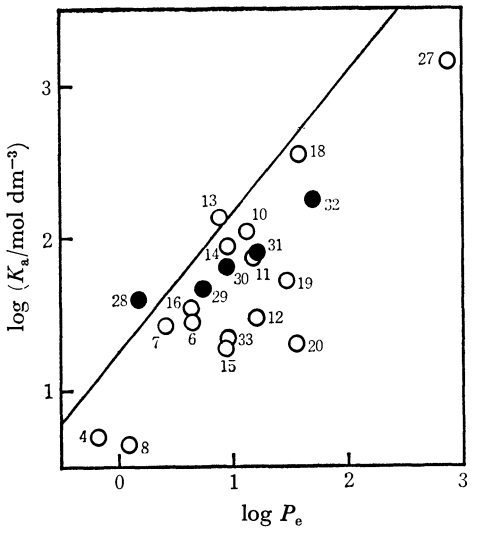

Fig. 3. Plots of log K_a *vs.* log P_e for complexes of α-CD with branched ROH's (○) and cycloalkanols (●). The solid line was given by the plots for a α-CD–1-alkanol system. Numbers shown refer to the numbers in the first column of Table 2.

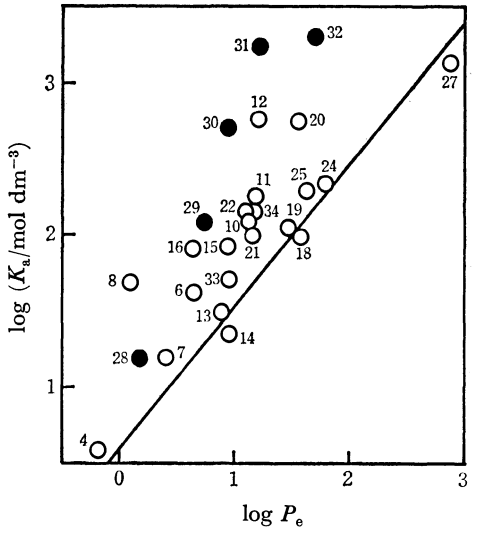

Fig. 4. Plots of log K_a *vs.* log P_e for complexes of β-CD with branched ROH's (○) and cycloalkanols (●). The solid line was given by the plots for a β-CD–1-alkanol system. Numbers shown refer to the numbers in the first column of Table 2.

in Figs. 3 and 4. In the case of a α-CD system, a plot for cyclobutanol locates slightly above the straight line for a 1-alkanol system. As the size of the cycloalkanol ring increases, the plot comes to locate below the line and the difference between them increases. On the other hand, each plot for a β-CD–cycloalkanol system locate above the straight line for 1-alkanols. The difference between them increases with increasing size of the cycloalkanol ring. The maximum difference is attained at the plot for cycloheptanol and the difference for cyclooctanol is significantly smaller than that for cycloheptanol. These results suggest that the α- and β-CD cavities are large in size enough to come into the closest contact with cyclobutanol and cycloheptanol respectively.

Polarizability, molar refraction (MR), Taft's steric substituent constant (E_s),[38] and the ν parameter given by Charton[39] are frequently used for a comparative index of molecular bulkiness in the quantitative study of structure-activity relationship. Among them, the first two were not suitable for the present study, since they vary markedly with a change in the number of carbon atoms in molecule but slightly with a change in structure among isomers. In contrast, the values of E_s and ν for structural isomers are significantly different from one another, so that the possibility is present that either E_s or ν is accessible for the index of molecular bulkiness in the present case. A correlation analysis for ROH's with the known values of E_s and ν (Table 2) gave Eqs. 15—18. For a α-CD system,

$$\log K_a = 0.92 \log P_e + 0.42E_s + 1.24, \quad (15)$$
$$n=17,\ r=0.953,\ \text{and}\ s=0.271,$$
$$\log K_a = 0.95 \log P_e - 0.88\nu + 1.67, \quad (16)$$
$$n=17,\ r=0.968,\ \text{and}\ s=0.269,$$

and for a β-CD system,

$$\log K_a = 0.97 \log P_e - 0.65E_s + 0.60, \quad (17)$$
$$n=18,\ r=0.938,\ \text{and}\ s=0.383,$$
$$\log K_a = 0.91 \log P_e + 1.36\nu - 0.17, \quad (18)$$
$$n=18,\ r=0.962,\ \text{and}\ s=0.296.$$

The results of the F- and t-tests showed that all of Eqs. 15—18 are reliable with a 95% level of confidence, although the values for r and s indicate that ν is somewhat preferred to E_s as an index of molecular bulkiness. In each equation, the dependence of log K_a on log P_e was virtually constant (0.91—0.97) and equal to those for 1-alkanol systems (0.92—0.94, *cf.*, Eqs. 13 and 14). On the other hand, the dependence of log K_a on either E_s or ν was remarkably different between α- and β-CD systems: The coefficient of E_s was positive in sign for a α-CD system and negative for a β-CD system, while the reverse is true for the coefficients of ν. These clear-cut differences in sign between α- and β-CD systems reflect the fact that a bulky ROH is subject to van der Waals repulsion by the α-CD cavity and to van der Waals attraction by the β-CD cavity.

Thermodynamic Parameters for CD–ROH Systems. The above presumptions on the driving forces of inclusion were substantiated by the determination of thermodynamic parameters, ΔH and ΔS, for the association of CD with ROH (Table 3). It is very interesting that both of ΔH and ΔS for β-CD–1-alkanol systems are positive. This fact indicates that the complexation is not governed by enthalpy but by entropy. It has rarely been reported that the inclusion process of CD is accompanied by a positive entropy change. Only a α-CD–1-adamantanecarboxylate system, reported by Komiyama and Bender,[17] falls under this category. Among the binding forces proposed for the inclusion phenomena of CD, only hydrophobic interactions are governed by entropy. Thus, it is obvious that hydrophobic interactions play a primary role in the complexation of β-CD with 1-alkanols.

As the bulkiness of ROH increases, the ΔH term becomes negative and the contribution of ΔS to the binding becomes low even in the case of a β-CD system. Such a change may be attributed to an increase in contribution of van der Waals interactions ($\Delta H<0$, $\Delta S<0$) to the complexation.

On the other hand, both of ΔH and ΔS are negative in the case of α-CD–1-alkanol systems, where it was suggested that the contribution of van der Waals interactions is very large. A decrease in the stability of α-CD–ROH adducts with an increase in bulkiness of ROH is mainly caused by a marked decrease in contribution of the ΔH term to the complexation. Komiyama and Bender[17] have also suggested that the contribution of the ΔH term to complexation is very little compared with that of the ΔS term in the complexation of bulky 1-adamantanecarboxylate with α-CD.

In conclusion, it was shown that hydrophobic and van der Waals interactions are of primary importance in the inclusion process of CD–ROH systems. Among them, the latter is preferential for α-CD–1-alkanol adducts and the former for β-CD–1-alkanol adducts. As the bulkiness of ROH increases, the stability of α-CD adducts decreases owing to van der Waals repulsion, while that of β-CD adducts increases owing to the attainment of the close van der Waals contact of ROH with the β-CD cavity. The present conclusion is very similar to that given by Tabushi *et al.*[13] by means of theoretical calculation.

The authors are indebted to Miss Mutsuko Kanzaki for her help in making some of the measurements.

NMR Studies on Zerovalent Metal π-Complexes of Dibenzylideneacetone. II. Structure and Pt-H Coupling in the Binuclear Platinum Complex

Hisao TANAKA and Hiroshi KAWAZURA*

Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02

(Received March 1, 1979)

The NMR analysis on the olefinic protons of the binuclear complex $Pt_2[(C_6H_5CH{=}CH)_2CO]_3$ was conducted on the deuteriated compounds $Pt_2[(C_6D_5CH{=}CH)_2CO]_3$, $Pt_2[(C_6D_5CD{=}CH)_2CO]_3$, and $Pt_2[(C_6D_5CH{=}CD)_2CO]_3$. Examination of the various ^1H NMR parameters revealed the individual characteristics of the six coordinated olefins of three dibenzylideneacetone ligands with respect to the metal-olefin bonding and coordination geometry. The three ligands which triply bridge the two Pt atoms are composed of one *s-cis,cis* ligand which is distant from the Pt atoms and of two *s-cis,trans* ligands which are close to the Pt atoms. Asymmetry in the coordination, which is caused by the gliding of the olefinic double bond to the metal atom, becomes greater as the olefinic moiety approaches the metal atom more closely. The major transmission route of the Pt–olefinic proton coupling is attributable to metal to olefin π-back bonding.

The first introduction of the zerovalent Pd complex of dibenzylideneacetone(dba), $Pd_2(dba)_3$(solvent) (solvent: dba, $CHCl_3$, CH_2Cl_2, and so on) was made by Ishii's group.[1] Maitlis' group[2] prepared its Pt analog $Pt_2(dba)_3$(dba). A novel type of these Pd and Pt complexes, which contains a ligand where only the olefinic portions are involved in the bonding to the metals, has attracted much interest and has been extensively investigated, especially in connection with the reactivity with various compounds.[3–6] For the Pd complex, the X-ray analyses on $Pd_2(dba)_3(CHCl_3)$[6] and $Pd_2(dba)_3(CH_2Cl_2)$[7,8] have been also performed. However, the bonding and structural studies on $Pt_2(dba)_3$ have not been done until now.

In the preceding paper,[9] the ligand conformations of $Pd_2(dba)_3$ in solution have been clarified by the ^1H NMR method and have been compared with those in crystalline state.[6,8] In this study, the treatment established with $Pd_2(dba)_3$ is applied to evaluate the structure of $Pt_2(dba)_3$. Our continuing interest in the relation between NMR parameters and metal-olefin bonding is intensified by a new insight into the coordination geometry of the olefins in the present complex; we now have a suitable model for olefin coordination.

Results and Discussion

The ^1H NMR spectra of the olefinic protons in the deuteriated $Pt_2(dba)_3$ compounds, $Pt_2[(C_6D_5CH{=}CH)_2CO]_3$, $Pt_2[(C_6D_5CD{=}CH)_2CO]_3$, and $Pt_2[(C_6D_5CH{=}CD)_2CO]_3$, are shown in Figs. 1-A, B, and C, respectively. These spectra exhibit some additional absorptions due to the couplings of the olefinic protons with the ^{195}Pt isotope (natural abundance 34%). The chemical shift δ_A of the olefinic proton on the carbonyl side (H_A) and the chemical shift δ_B of the olefinic proton on the phenyl side (H_B) were exactly determined from each main peak in the spectra of Figs. 1-B and C, respectively. Further analysis was conducted by spin decoupling in the spectrum of Fig. 1-A, to find the pairs of H_A and H_B in *trans* position of the olefinic moieties and hence to determine the olefinic coupling constant J_{AB}. Thus the spectrum was found to consist of six AB quartet patterns with attendant ^{195}Pt satellites. The J_{AB}, δ_A, and δ_B values together with the internal shift $\delta_{AB}(=\delta_B-\delta_A)$ and the mean shift $\delta_H[=(\delta_A+\delta_B)/2]$ are summarized in Table 1, where the six olefins **a** to **f** are arranged in the decreased order of $\bar{\delta}_H$ (in the

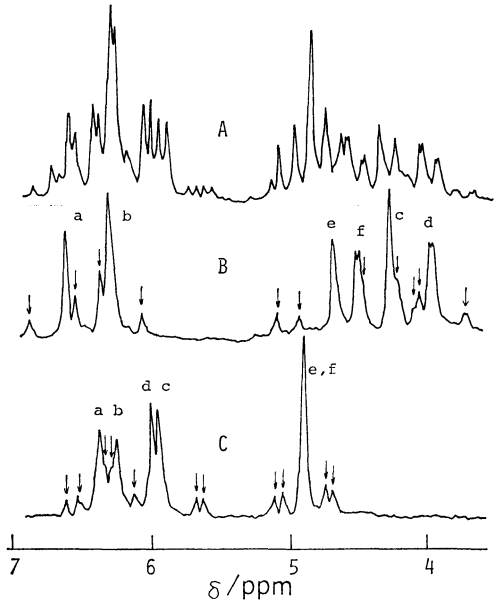

Fig. 1. ^1H NMR spectra of $Pt_2[(C_6D_5CH{=}CH)_2CO]_3$ (A), $Pt_2[(C_6D_5CD{=}CH)_2CO]_3$ (B), and $Pt_2[(C_6D_5CH{=}CD)_2CO]_3$ (C) recorded in $CDCl_3$ at 25 °C. In B and C, **a**—**f** denote the proton signals of the respective olefins and the arrows indicate the satellites due to the ^{195}Pt couplings of the olefinic protons.

TABLE 1. ^1H NMR PARAMETERS OF THE OLEFINIC PROTONS OF dba IN $Pt_2(dba)_3$ IN $CDCl_3$ AT 25 °C

Olefins	J_{AB}/Hz	δ_A/ppm	δ_B/ppm	δ_{AB}/ppm	$\bar{\delta}_H$/ppm
a	12.7	6.666	6.396	−0.270	6.531
b	12.7	6.357	6.278	−0.079	6.318
c	10.9	4.301	5.969	1.668	5.135
d	11.2	4.000	6.023	2.023	5.012
e	10.9	4.704	4.905	0.201	4.805
f	11.1	4.537	4.905	0.368	4.721

δ_A and δ_B: in ppm with tetramethylsilane. $\delta_{AB}=\delta_B-\delta_A$ and $\bar{\delta}_H=(\delta_A+\delta_B)/2$. For free dba (in $CDCl_3$ at 25 °C): J_{AB}, 16.0 Hz; δ_A 7.090; δ_B 7.750; δ_{AB}, 0.660; and $\bar{\delta}_H$, 7.420 ppm.

increased order of the chemical screening).

The ^{195}Pt coupling with H_A (J_{Pt-A}) and that with H_B (J_{Pt-B}) were definitely determined[10] from the separation of the two satellites which are symmetrically disposed on either side of each main signal in the spectra of Figs. 1-B and C, respectively. But for the couplings with H_B's of olefins **e** and **f** a definitive assignment was difficult, because of an identity of the chemical shifts of the respective protons. Table 2 lists the coupling constants J_{Pt-A} and J_{Pt-B}, together with their average $\bar{J}_{Pt-H}[=(J_{Pt-A}+J_{Pt-B})/2]$ and difference $J_{Pt-A,B}(=J_{Pt-A}-J_{Pt-B})$.

TABLE 2. 195 Pt–OLEFINIC PROTON COUPLINGS IN $Pt_2(dba)_3$ IN $CDCl_3$ AT 25 °C

Olefins	J_{Pt-A}/Hz	J_{Pt-B}/Hz	$\bar{J}_{Pt-H}$/Hz	$J_{Pt-A,B}$/Hz
a	53.7	49.3	51.5	4.4
b	48.3	56.6	52.5	−8.3
c	43.9	65.4	54.7	−21.5
d	50.8	63.8	57.3	−13.0
e	84.0	43.0 a) (32.2)	63.5 (58.1)	41.0 (51.8)
f	87.9	32.2 a) (43.0)	60.1 (65.5)	55.7 (44.9)

a) The coupling of H_B's of olefins **e** and **f** were not determined (see text).

Bonding Nature. The chemical shifts $\bar{\delta}_H$'s for all the olefinic portions move to the high field side and the coupling constants J_{AB}'s are reduced as a consequence of direct coordination of the olefinic double bond to the Pt atom. However, the degrees of the up field shift ($\Delta\bar{\delta}_H$) and of the reduction of the coupling (ΔJ_{AB}) from $\bar{\delta}_H$ and J_{AB} of free dba allow us to divide the six olefinic moieties into two groups: the two olefins **a** and **b** have ΔJ_{AB} of 3.3 Hz and $\Delta\bar{\delta}_H$ of about 1.0 ppm, and for the remaining four, **c**—**f**, ΔJ_{AB} and $\Delta\bar{\delta}_H$ lie in the narrow range of 4.8—5.1 Hz and 2.3—2.7 ppm. When we recall[9] that both the parameters directly reflect the strength of metal-olefin π-bonding which is controlled mainly by the distance from each olefin to the metal atom, the above fact leads us to state that olefins **a** and **b** with the smaller ΔJ_{AB} and $\Delta\bar{\delta}_H$, are weaker in the π-bonding and are more distant from the Pt atom than the other four.

The average values of ΔJ_{AB} and $\Delta\bar{\delta}_H$ in the six olefins are 4.4 Hz and 2.00 ppm, respectively. These are small compared with the corresponding values 6.1 Hz and 3.3 ppm in the zerovalent dba complex $Pt(PPh_3)_2(dba)$.[11] This can be understood in terms of the stabilization effect of the electron donative ligand PPh_3, whose the ionization potential is lower than that of olefin.[12,13] The average values of ΔJ_{AB} and $\Delta\bar{\delta}_H$ in $Pt_2(dba)_3$ are larger than those[9] of 2.7 Hz and 1.51 ppm in $Pd_2(dba)_3$. The larger values in $Pt_2(dba)_3$ can be explained from the view of $nd^{10}-nd^9(n+1)s^1$ promotion energies[14,15] of these d^{10} metals. The above facts indicate that in so far as judging from the average bonding strength in all the coordinated olefins, the binuclear complex is ordinary and to be expected. The characteristics of the binuclear complex appear in the remarkably unbalanced distribution of the bonding strength to the chemically equivalent olefins, as appreciated from the $\Delta\delta_H$ spreading from 0.89 ppm, a popular value of the divalent Pt–olefin complexes, to 2.70 ppm, a typical value of the zerovalent Pt–olefin complexes.[16]

Ligand Conformation. The six olefinic moieties of the three dba ligands can also be classified into two distinct groups with respect to the internal shift δ_{AB}: the two olefins **c** and **d** with δ_{AB} larger than 1.6 ppm and the remaining four with δ_{AB} smaller than 0.4 ppm. Referring to the definitive relation[9,17] between the magnitude of δ_{AB} and the conformation of olefinic moiety ($\delta_{AB}\gtrsim 1.0$ ppm for *s-trans* form and $\delta_{AB}\lesssim 0.4$ ppm for *s-cis* form), we can assign the olefins **c** and **d** with the larger δ_{AB} values to be in the *s-trans* form and the olefins **a**, **b**, **e**, and **f** with the smaller δ_{AB} values to be in the *s-cis* form. Another support for the above assignment was obtained from the temperature dependence of δ_{AB} (Fig. 2). Raising the temperature from −60 to 25 °C the δ_{AB} values of olefins **a** and **b** increased by *ca.* 0.1 ppm, while those of olefins **c** and **d** decreased by *ca.* 0.03 ppm and those of olefins **e** and **f** were unchanged. The temperature change of δ_{AB} implies a conformational distortion of the ligand in which the *s-cis* and *s-trans* olefins acquire some *s-trans* and *s-cis* characters, respectively. Then, since the δ_{AB} is a minimum in the *s-cis* form and a maximum in the *s-trans* form,[17] the δ_{AB} values of *s-cis* and *s-trans* olefins should increase and decrease, respectively, with a rise of temperature. Thus, the preceding assignment for olefins **a**—**d** can be established. The constancy[18] of the δ_{AB} in the *s-cis* olefins **e** and **f** may be due to their diminished thermal flexibilities, which are suggested by their stronger π-bonding with the Pt atom than that of the other *s-cis* olefins.

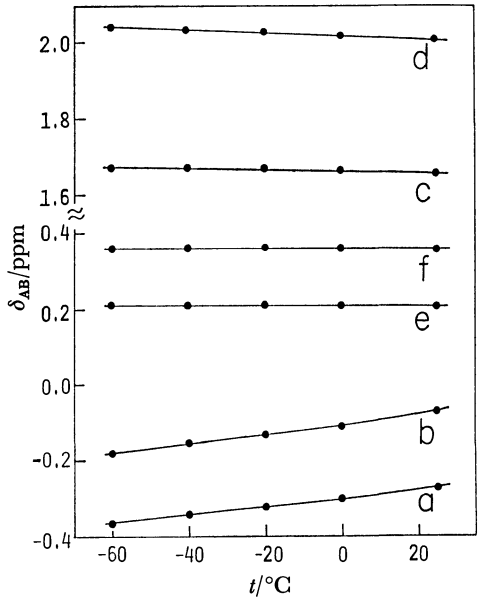

Fig. 2. Temperature dependence of the internal shift δ_{AB} for each olefinic moiety **a** to **f** in $Pt_2(dba)_3$, measured in $CDCl_3$.

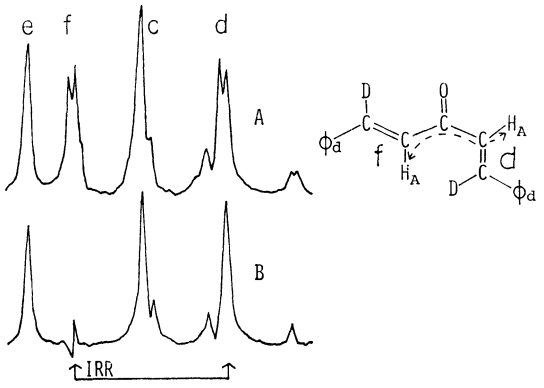

Fig. 3. The high field spectrum of $Pt_2[(C_6D_5CD{=}CH)_2\text{-}CO]_3$ showing the splitting of 1.5 Hz of H_A's in olefins **d** and **f** (A) and the spectrum decoupled by the irradiation of H_A of olefin **f** (B).

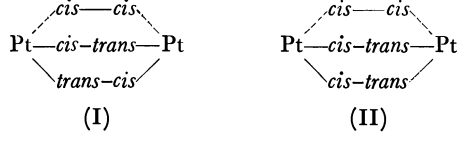
A clue to find the pair of the olefinic moieties which constitute one dba ligand was provided by the observation of the fine splitting (1.5 Hz) of the H_A signals in olefins **d** and **f** (Fig. 3-A); decoupling of the H_A signal showed that these splittings came from the long range coupling between the H_A's (Fig. 3-B). This indicates that *s-cis* olefin **f** and *s-trans* olefin **d** are linked to constitute the *s-cis,trans* dba ligand. The remaining three *s-cis* and one *s-trans* olefins inevitably give one *s-cis,trans* and one *s-cis,cis* dba. The most probable pair yielding another *s-cis,trans* conformation would be olefins **c** and **e**, because not only *s-trans* olefins **c** and **d** but also *s-cis* olefins **e** and **f** are closely similar to each other in all the NMR data gathered in Tables 1, 2, and Fig. 2. Thus, third dba ligand with *s-cis,cis* conformation should be composed[19] of olefins **a** and **b**, which also have analogous NMR parameters to justify the combination. This is the first finding of the *s-cis,cis* form fixed as a ligand, though it is a prevailing conformation[17] in the free dba.

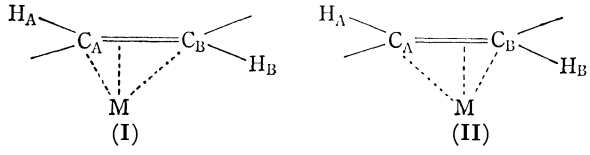
Two types of the bonding scheme will be considered from the manner where the two *s-cis,trans* ligands, together with the symmetric *s-cis,cis* ligand, are bridged to the two Pt atoms:



The solid and broken lines denote the strong and weak bonds, respectively in the π-bonding strength as already determined. Scheme I is reasonable if we consider the fact that in a crystal[8] of $Pd_2(dba)_3(CH_2Cl_2)$ the two *s-cis,trans* ligands together with the symmetric *s-trans,trans* ligand are allocated in such a manner as in I. Scheme I with *the same* conformational combination (*cis-cis-trans*) around each metal atom is also rationalized by the fact that *the same* bonding strength is given for each metal atom; it binds the two of the three olefins strongly and the one weakly: this situation is completely complementary with the situation[9] in $Pd_2(dba)_3$, which is obtained by substituting the word *different* instead of *the same* in the above description. It may be reasonable to say that the olefin conformations around the metal can control the geometry about the metal-olefin bonds and hence the bonding strength to the metal. Scheme II is in conflict with the above consideration.

Pt–H Coupling. As shown in Table 2, the Pt couplings with the individual protons ($J_{Pt\text{-}A}$ and $J_{Pt\text{-}B}$) distribute in so much large a range, from 32 to 88 Hz, as to cover the values[16] for various Pt–olefin complexes, but the average value of the twelve couplings falls in 56.6 Hz, a popular value of the Pt–olefinic proton coupling. Interestingly, the mean coupling $\bar{J}_{Pt\text{-}H}$ keeps an approximate correlation with the mean shift $\bar{\delta}_H$; as $\bar{\delta}_H$ decreases with going from olefin **a** to **f**, $\bar{J}_{Pt\text{-}H}$ tends to increase. This means that the Pt–olefinic proton coupling is influenced mainly by the same origin as that in the up field shift, *i.e.* metal to olefin π-back donation. This deduction is easily accepted if one considers[20] that in zerovalent Pt–olefin complexes the π-back bonding plays a major role[25] in the total Pt–olefin bonding. The coupling may be transmitted by a Fermi contact mechanism *via* the σ-π mixing[26] on the olefinic carbon with the strong π-back bonding. Thus, the Pt–H coupling increases with an increase of the π-back donation, closely related to an approach of the olefin to the metal atom.

Another interesting feature appears in the coupling difference $J_{Pt\text{-}A,B}$. The absolute value of $J_{Pt\text{-}A,B}$ also correlates roughly with $J_{Pt\text{-}H}$ and with $\bar{\delta}_H$. The origin of the appearance of $J_{Pt\text{-}A,B}$ must be ascribed to an asymmetric coordination owing to the gliding[27] of the olefinic double bond to the metal atom:



Through the gliding, one of the carbons C_A and C_B approaches the metal while the other departs from the metal. In the first approximation, it could be said that the carbon close to the metal takes the larger π-back donation and so the proton attached to this carbon spin-couples with the metal atom more strongly. Thus, the positive sign of $J_{Pt\text{-}A,B}$ in olefins **a**, **e**, and **f** can be interpreted on the basis of gliding model I, where the metal atom glides toward C_A, whereas the negative sign in olefins **b**, **c**, and **d** can be interpreted on the basis of gliding model II where the metal atom glides toward C_B. The magnitude of $J_{Pt\text{-}A,B}$ can be explained in terms of the extent of coordination asymmetry coming from the gliding such as exemplified by the ratio of the C_A–M and C_B–M distances. The X-ray analysis[8] on the analogous compound $Pd_2(dba)_3$ has clarified the existence of the glidings shown in I and II. Eventually, the correlation between $\bar{J}_{Pt\text{-}H}$ and $J_{Pt\text{-}A,B}$ in $Pt_2(dba)_3$ indicates that the closer the olefinic moiety approaches the metal, the greater becomes the asymmetry in coordination, as expected from the structure where the two olefinic moieties of dba ligand bridge the two metal atoms.

Experimental

Materials. The binuclear Pt complex $Pt_2(dba)_3(dba)$ was synthesized according to the literature.[4] Recrystallization of the complex in $CHCl_3$ gave deep purple solids with the formula $Pt_2(dba)_3(CHCl_3)$, where an involvement of the solvent molecule was found by mass and elemental analyses. $Pt_2[(C_6D_5CH{=}CH)_2CO]_3(CHCl_3)$, $Pt_2[(C_6D_5CD{=}CH)_2CO]_3(CHCl_3)$, and $Pt_2[(C_6D_5CH{=}CD)_2CO]_3(CHCl_3)$ were prepared by the above procedure using the respective deuteriated dba.[17]

^1H NMR Measurements. The ^1H NMR spectra of the deuteriated complexes in $CDCl_3$ were recorded through a number of pattern accumulations by a JEOL PS-PFT/EC 100 pulsed Fourier transform system. This system overcame the low solubility of the binuclear complex. The measuring conditions were the same as those stated in the preceding paper.[9]

17) H. Tanaka, K. Yamada, and H. Kawazura, *J. Chem. Soc., Perkin Trans. 2*, **1978**, 231.

18) This constancy is to be expected if one considers that the δ_{AB} in the *s-trans* olefins **c** and **d**, with the bonding strength similar to that of the *s-cis* olefins **e** and **f**, changes only slightly. The δ_{AB} does not increase so remarkably with a distortion around the *s-cis* form, while it decreases rapidly around the *s-trans* form.[17]

19) Thus, the *s-cis,cis* ligand (olefins **a** and **b**) with the larger separation between the two olefinic double bonds, together with the two *s-cis,trans* ligands with the smaller separation, bridges the two Pt atoms. Then, the *s-cis,cis* ligand should be distorted so as to reduce the C–C(O)–C angle, in contrast to an increase[8] of the angle of the *s-trans, trans* ligand in a crystal of $Pd_2(dba)_3(CH_2Cl_2)$. This seems to be the reason for the abnormal negative sign of δ_{AB} in the *s-cis* olefins **a** and **b**.

20) In divalent Pt–olefin complexes where the σ and π-bonds contribute nearly equally to the total Pt–olefin bond, the σ-bond as well as the π-bond should be important for the coupling transmission. For example, the up field shift ($\Delta\delta_H$) for ethylene in zerovalent $Pt(PPh_3)_2(C_2H_4)$[21] is 3.26 ppm much larger than the value of 1.11 ppm in divalent $[PtCl_3(C_2H_4)]^-$,[22] in contrast to the similar J_{Pt-H} values of 62 and 66.8 Hz in the respective complex. The distance[23] between Pt and C in the zerovalent complex (2.11 Å) is similar to that[24] in the divalent complex (2.14 Å), indicating a similar total bonding (σ and π) strength in both the complexes. These facts lead us to consider that the Pt-H coupling is generally affected both by σ and π-bondings, while the up field shift is only affected by π-bonding.

Magnetic Study of *N,N,N′,N′*-Tetramethyl-*p*-phenylenediamine (Wurster's Blue) Tetrafluoroborate Cation Radical

Jun YAMAUCHI,* Hideo FUJITA, and Yasuo DEGUCHI
College of Liberal Arts and Sciences, Kyoto University, Kyoto 606

(Received March 15, 1979)

Wurster's Blue cation radical, which is composed of TMPD cation and BF_4 anion moieties, was prepared and its magnetic properties were examined. The cation radical shows similar magnetic behavior to that of the TMPD–ClO_4 cation radical, but there is a slight perturbation when changing the counteranions from perchlorate to tetrafluoroborate. A phase transition takes place at 190.5 K, which is attributable to a dimerization involving a small molecular displacement in the crystal lattice. These phenomena are discussed using the magnetic susceptibility data, thermal study, and ESR observations due to triplet exciton. The magnetic data are described by comparison with Wurster's Blue perchlorate cation radical.

The phase transition of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) perchlorate has been studied extensively. The cation radical called Wurster's Blue perchlorate experiences the first-order phase transition at about 190 K, as was ascertained from magnetic susceptibilities,[1–2] heat capacity,[3] electron spin resonance,[4] nuclear magnetic resonance,[5] and crystal structure determinations.[6] The nature of the phase transition was discussed previously.[7] Some of the anion radicals composed of tetracyanoquinodimethane (TCNQ)[8] and several kinds of neutral radicals[9] also exhibit magnetic phase transition; the former undergo first-order transitions and the latter second-order. On the other hand, Wurster's Blue iodide (TMPD-I) is paramagnetic from room temperature till liquid nitrogen temperature and no phase transition has been observed in this temperature range.[10] In the case of donor and acceptor complexes of TMPD, there exist both diamagnetic and paramagnetic species. For instance, the complex compounds of TMPD with chloranil and bromanil are almost diamagnetic, while TMPD–iodanil compound is weakly paramagnetic.[11] TCNQ salt with TMPD, which is also one of the donor and acceptor complexes, shows a weak paramagnetism; there is a thermally accessible triplet state lying above a singlet ground state with an energy separation $\Delta E=0.075$ eV.[12] Thus, the magnetic properties of the cation radical of TMPD vary with counteranions.

Hunig has pointed out a two-step redox system for the stable radical ions of nitrogen-containing aromatic molecules.[13] According to the fundamental work of Michaelis, the three oxidation levels are called "reduced form," "semiquinone," and "oxidized form."[14] Among these oxidation levels "semiquinone" has one unpaired electron in each molecule. Hunig isolated the above-mentioned three types of compounds with a careful choice of counteranions (perchlorate or tetrafluoroborate).[15] Thus, it might be an interesting problem to see the influence of tetrafluoroborate anion moiety upon magnetic interactions between unpaired electrons of TMPD cation moiety. After a successful attempt to prepare Wurster's Blue tetrafluoroborate, its magnetic properties were made clear and discussions on the magnetic phase transition were made in comparison with Wurster's Blue perchlorate.

Experimental

A detailed description of the apparatus and experimental techniques used in this experiment was published previously.[16] Only a brief comment will be given here. The diamagnetic contribution was calculated from Pascal's constants to be -153×10^{-6} emu/mol, on the assumption that diamagnetism of BF_4^- is -32×10^{-6} emu/mol. This contribution is a little larger than that of TMPD–ClO_4 obtained by Michaelis *et al.*,[17] -138×10^{-6} emu/mol, in spite of the minor difference between the presumed diamagnetic susceptibilities of BF_4^- and ClO_4^- anion moieties. As a paramagnetic susceptibility standard, we used the 4-methyl derivative of 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl (TANOL), which conforms to the Curie law from room temperature down to 1.8 K.[18] The differential scanning calorimeter was a conventional one, Perkin-Elmer DSC-1. We made a temperature calibration using hexane and chloroform.

Samples were prepared following the procedure of Michaelis and Granick,[17] with a slight modification as required. One gram of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine, prepared by the method of Cox *et al.*,[19] was dissolved in a mixed solution of 18 ml water and 24 ml methanol containing 9 g of sodium tetrafluoroborate. It was cooled to -10 °C, then 32 ml of 0.252 mol kg^{-1} aqueous bromine solution was added dropwise. The crystals were filtered, washed several times with small portions of ice-cold methanol, then abundantly with dry ether. The yield of TMPD–BF_4 melting at 126—127 °C (dec) after recrystallization from methanol was 0.8 g (52%). The crystals have a brownish purple metallic luster. Chemical analysis gave 6.64% (H), 47.85% (C), and 11.12% (N), which is to be compared with calculated values of $C_{10}H_{16}N_2BF_4$: 6.42 % (H), 47.82% (C), and 11.16% (N).

Results

Figure 1 shows the magnetic susceptibility versus temperature curve, in which one can recognize a sharp peak around 190 K. Upon lowering the temperature, the susceptibility drops steeply and then decreases gradually. This behavior is quite similar to that of TMPD–ClO_4 salt. In order to compare the magnetic behavior between Wurster's Blue tetrafluoroborate and perchlorate salts we also carried out a susceptibility measurement on the perchlorate salt as shown in Fig. 2, although many investigations have already been published.[1–2] It should be noted here that some of the differences are found in the maximum value of magnetic

TABLE 1. MAGNETIC SUSCEPTIBILITY RESULTS AND TRANSITION TEMPERATURE

	χ_{max} [a]	T_{max}/K	$\Delta\chi_{tr}$ [a]	χ_{77} [a]	T_{tr}/K	
TMPD–BF_4	16.0	191	3.1	0.82	190.5 [b]	Present work
TMPD–ClO_4	16.8	190	2.8	2.00	190	Present work
	15.8	186	0.8		186	Duffy[1]
	14.5	189	1.4		189	Okumura[2]

a) $\times 10^{-4}$ emu/mol. b) The transition temperature was determined from thermal studies.

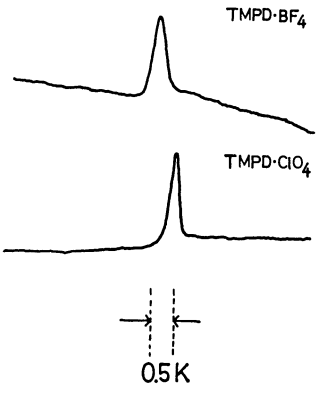

Fig. 3. Differential scanning calorimetry. The temperature was gradually elevated from right to left. The temperature difference was calibrated by the melting points of hexane and chloroform.

susceptibility (χ_{max}), in the temperature where the susceptibility takes its maximum value (T_{max}), and in the temperature dependence of the susceptibility below T_{max}. The former two characteristics are summarized in Table 1 and the latter is depicted in Fig. 2.

According to the thermal study using the differential scanning calorimeter (DSC), endothermic or exthothermic behavior was observed with TMPD–BF_4 at a slightly higher temperature than with TMPD–ClO_4. The temperature difference was found to be 0.5 K, as

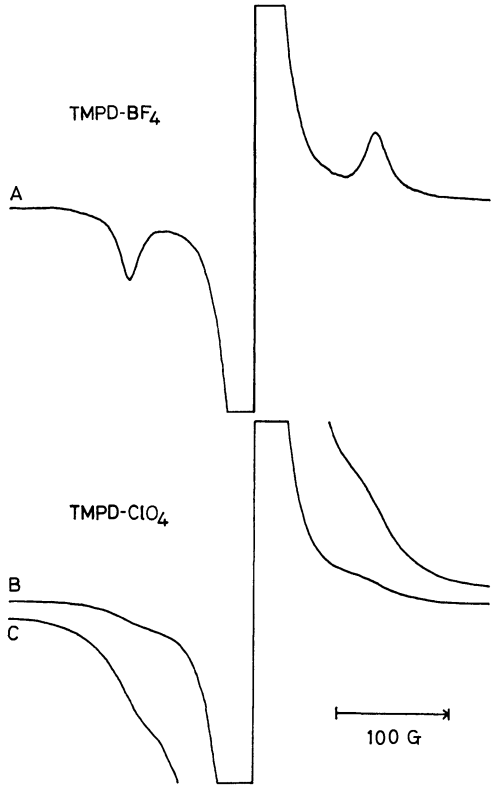

Fig. 4. Polycrystalline ESR spectra at 77 K. The triplet excitons can be clearly observed in TMPD–BF_4 (A), while the fine structure in TMPD–ClO_4 is exchange-narrowed because of the fast motion of triplet excitons (B and C). The field modulation was 1 G in A and B and 10 G in C.

shown in Fig. 3. The abscissa is a temperature scale, but only the difference between the peaks was calibrated using the standard materials described in the experimental section.

Electron spin resonance was observed at room temperature and at liquid nitrogen temperature in order to obtain information on the phase transition. The polycrystalline spectrum at 77 K is given in Fig. 4. This is characteristic of triplet exciton spectrum of polycrystalline samples.[20] A single crystal study of this exciton in TMPD-ClO_4 has been reported elsewhere.[4] The powder pattern of TMPD-ClO_4 at 77 K is also drawn in Fig. 4 for comparison. The ESR data are tabulated in Table 2.

Table 2. ESR results and zero field splitting parameters

	g-value[a]	Linewidth/G[a]	E/G	D/G

Discussion

The magnetic behavior of Wurster's Blue tetrafluoroborate and that of perchlorate salts above the transition temperature are identical, as seen from Tables 1 and 2. The ESR g-values and linewidths at room temperature show the same experimental values. The magnetic susceptibility also shows the same temperature variation, as far as we could determine, although Duffy[1] and Okumura[2] have published smaller values in TMPD-ClO_4. These facts indicate that the crystal structure of TMPD-BF_4 may have the same molecular packing of TMPD cations as that of TMPD-ClO_4 salt along the a-axis.[6]

The magnetic susceptibilities of TMPD-BF_4 and -ClO_4 salts start to deviate from each other in the vicinity of the transition temperature and then exhibit sharp decreases at 191 and 190 K, respectively. The decreases ($\Delta\chi_{tr}$) at these temperatures are steeper than those published previously for TMPD-ClO_4 salt (see Table 1). The discontinuity comes from cooperative phenomena of a first-order nature, as suggested in TMPD-ClO_4, so that the above fact may be concerned with the degree of purification of the crystals. In fact, Okumura reported 81% radical contribution due to a deterioration of the crystal. On the other hand, Duffy observed 94% radical concentration calculated from the Curie constant. However, both their room temperature susceptibilities show nearly the same value, 10.5×10^{-4} emu/mol.

TMPD-BF_4 salt also experiences a magnetic phase transition accompanied by a crystal distortion. The proposed model in TMPD-ClO_4 salt is that there is a strongly alternating antiferromagnet and a regular antiferromagnet in the low and high temperature phases, respectively.[21] This is caused by a dimerization of TMPD cation molecules in the crystal. This may be also true in TMPD-BF_4 and can be ascertained partly from the low temperature ESR study which indicates the presence of triplet excitons.

The transition temperature of TMPD-ClO_4 salt has been reported by many investigators: 186 K (Duffy),[1] 189 K (Okumura),[2] and 189.9 K (Chihara *et al.*).[3] In our study a good agreement with a precise heat capacity measurement by Chihara *et al.* was obtained in TMPD-ClO_4. However, the DSC study gave 0.5 K difference between the transition temperatures of BF_4 and ClO_4 salts, so that we concluded that the transition temperature of TMPD-BF_4 is 190.5 K in spite of the susceptibility maximum at 191 K. This is partly because we believe the experimental errors in the heat capacity and DSC measurements are smaller than those in the susceptibility measurement. The error found in the susceptibility is at most 0.5 K.

The magnetic susceptibilities below the transition temperature are different, as is shown in Fig. 2. This means that, although both of the cation radicals have dimerized structures which form a strongly alternating antiferromagnet, the triplet exciton density in TMPD-BF_4 is much smaller at a given temperature than that of TMPD-ClO_4. This fact suggests that the observation of triplet exciton spectra of TMPD-BF_4 may be possible at a higher temperature region, because one can observe fine-structure due to triplet entities in ESR measurements at a relatively low triplet density.[22] In fact, we were able to observe clearly the fine-structure of triplet excitons in TMPD-BF_4 at 77 K, while in the case of TMPD-ClO_4 the spectrum at 77 K shown in Fig. 4 was an exchange-narrowed one with a feeble indication of triplet excitons around the strong absorption. At 77 K the exchange interactions between triplet excitons are not small enough to be neglected in the case of TMPD-ClO_4 salt. McConnell *et al.*[4] noted that they have seen clear exciton paramagnetic resonance spectra in polycrystalline samples of TMPD-ClO_4 at 50 K. The spectra in Fig. 4 can be accounted for by the spin Hamiltonian:

$$\mathcal{H} = DS_z^2 + E(S_x^2 - S_y^2),$$

where S_x, S_y, and S_z are the components of spins in the direction of the principal fine structure axes, and D and E are zero-field splitting parameters. The spectral analysis implies the vanishing of D as in the case of TMPD-ClO_4 salt.[4] The spectral separation between the two side-absorptions was 219.1 G, leading to $|E|=73.0$ G for TMPD-BF_4, while $|E|=75.7$ G for TMPD-ClO_4. These facts give microscopic evidence for a dimerization of TMPD cations below the transition temperature. In order to obtain the principal coordinates of dipolar interactions, however, more detailed experiments using single crystals must be performed.

A comparison of the ionic radii of BF_4^- and ClO_4^- suggests that tetrafluoroborate anions have a smaller ionic radius. However, the conjecture that both of the crystals have the same structure in the high temperature region is reasonable if we take into account that there are no significant differences in the magnetic properties. On the contrary, in the low temperature phase, the smaller anion moiety makes it easier for the TMPD cations to get nearer. Therefore, the presumption that the molecular displacement of TMPD cations

of BF_4 salt at the transition temperature may be larger explains the larger $\Delta\chi_{tr}$ and smaller susceptibility values, that is, the larger antiferromagnetic interactions at or below T_{tr}. In this context, the triplet interaction parameters, D and E, are also dependent on the distance between the dimerized molecules. Since D and E are inversely proportional to the third power of distance, the shorter the distance between TMPD cations, the larger the D and E values. However, BF_4 salt has a smaller E value, 73.0 G, than that of 75.7 G for ClO_4 salt. This is because the D and E values also depend on the molecular symmetry around the pairing axis. The most perfect vanishing of the D value is also explainable by the molecular conformation.[4)]

In conclusion, the cation radical TMPD–BF_4 experiences a phase transition of the first-order at 190.5 K. This transition may be accompanied by a dimerization of TMPD cation molecules, as proposed in the case of TMPD–ClO_4 salt. The magnetic susceptibility measurements, thermal calorimetry, and ESR observations support these conclusions. Observation of the triplet excitons at the low temperature phase supports the strongly alternating antiferromagnetic interaction. The magnetic properties of the two cation radicals, TMPD–BF_4 and –ClO_4, are almost identical. The few discrepancies might be due to the ionic radii of the anions, BF_4^- and ClO_4^- and this influence should be clarified by X-ray crystal analysis.

An Analysis of the UV, ORD, and CD Bandshapes of the DNA–Acridine Orange Complex by the Linear Response Polarizability Theory

Hirotoshi Ito and Yasumasa J. I'Haya*

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182

(Received March 12, 1979)

The linear response polarizability theory of the spectral bandshapes is applied to the numerical analysis of the UV, ORD, and CD spectra of the DNA–Acridine Orange complex by using various models of conformation. In all calculations, we make use of an infinite orders approximation for the intermonomer electronic interaction, since convergence of the Dyson-type series for the polymer polarizability tensor sometimes becomes seriously slow, in particular in such case that the transition moments of a constituent monomer such as Acridine Orange are quite large. It is found that among the various outside-stacking models, a dimer-pairs repeating sequence model newly proposed leads to reasonable results for the UV, ORD, and CD spectral bandshapes.

The binding of dye molecules to some species of macro-biomolecules exhibits metachromasy, *i.e.*, appreciable change in the UV absorption spectra of the dye molecules. Such formation of molecular complexes often accompanies the extrinsically induced Cotton effect which usually appears in the corresponding UV absorption region of the dye. For instance, the interaction of nucleic acids with acridine dyes is the case for this phenomena. The spectral profiles for the UV, ORD, and CD bands of the DNA–dye and/or RNA–dye complexes remarkably change depending upon the several binding modes of the dyes to the polymers, which have specifically been discussed in terms of the phosphate/dye ($=P/D$) ratio in the literature. It is a hard task to analyze these profiles in detail, since there is a difficulty in properly assuming the definite models of conformation for such complicated molecular complexes. Nevertheless, there have been published several investigations on the bandshapes of biopolymer–dye complexes.[1–7]

In order to elucidate the spectral profiles, there have been mainly two models proposed; one is the outside-stacking model of dyes bound weakly to the phosphate groups corresponding to the case $P/D \approx 1$, and the other is the intercalation model in which monomeric dyes are strongly penetrated between the base-pairs corresponding to the case $P/D \gg 1$. In opposition to this, there is a finding that the latter model is good enough even for the low P/D ratio, for example $P/D=4$.[8] If we can clarify further detail of the bandshapes for these models in terms of Green's function method, some useful information which we might have discarded up to now will be expected to become available for the determination of unknown structures of biopolymer–dye complexes, including the mutual geometries among dyes and the binding sites of dyes. This paper is a mere trial but the first attempt to attain this aim. In our method, dye molecules play a roll as kinds of probes to see the structures of macromolecules in the bandshape analysis. In order to provide a theoretical foundation for analyzing these bandshapes of molecular complexes, we firstly need to prepare such a theoretical tool that is capable of being satisfactorily checked with a model polymer of known structure.

Recently, we have presented the linear response theory of the UV, ORD, and CD bandshapes for homopolymer systems[9–12] which has satisfactorily, to some extent, been applied to polyadenylic acid to which an X-ray analysis datum is available. By applying this theory to various models of the DNA–Acridine Orange (AO) complex, we compute the UV, ORD, and CD bandshapes in order for seeking possibilities of a further detailed analysis for such a complicated system.

Basic Formulas for Computing the UV, ORD, and CD Curves

The basic formulas necessary for the calculations of the UV, ORD, and CD bandshapes are collected below:

$$\boldsymbol{\alpha}_m^{\mathrm{M}}(\bar{\nu}) = \underset{(+)}{-}(hc)^{-1}\sum_{\lambda}\boldsymbol{\mu}_{0\lambda}^{(m)}\boldsymbol{\mu}_{\lambda 0}^{(m)}[(\bar{\nu}-\bar{\nu}_{\lambda 0}^{(m)}+i\eta_{\lambda}^{(m)})^{-1} - (\bar{\nu}+\bar{\nu}_{\lambda 0}^{(m)}-i\eta_{\lambda}^{(m)})^{-1}], \quad (1)$$

$$\boldsymbol{\alpha}_{mn}^{\mathrm{P}}(\bar{\nu}) = \boldsymbol{\alpha}_m^{\mathrm{M}}(\bar{\nu})\delta_{mn} \underset{(+)}{-} \boldsymbol{\alpha}_m^{\mathrm{M}}(\nu)\cdot\mathbf{U}_{mn}\cdot\boldsymbol{\alpha}_n^{\mathrm{M}}(\nu) + \sum_{l}^{\mathrm{N}}\boldsymbol{\alpha}_m^{\mathrm{M}}(\bar{\nu})\cdot\mathbf{U}_{ml}\cdot\boldsymbol{\alpha}_l^{\mathrm{M}}(\bar{\nu})\cdot\mathbf{U}_{ln}\cdot\boldsymbol{\alpha}_n^{\mathrm{M}}(\bar{\nu}) \underset{(+)}{-} \cdots, \quad (2)$$

$$\mathbf{U}_{mn} = \mathbf{I}_{mn}/r_{mn}^3 - 3\mathbf{r}_{mn}\mathbf{r}_{mn}/r_{mn}^5, \quad (3)$$

$$\mathbf{r}_{mn} = \mathbf{r}_n - \mathbf{r}_m = x_{mn}\mathbf{i} + y_{mn}\mathbf{j} + z_{mn}\mathbf{k}, \quad (4)$$

$$\beta(\bar{\nu}) = (1/12)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\mathbf{r}_{mn}\cdot(\boldsymbol{\alpha}_{mn}^{\mathrm{P}}(\bar{\nu}):\boldsymbol{\varepsilon}), \quad (5)$$

$$\varepsilon_{xyz} = -\varepsilon_{xzy} = \varepsilon_{zxy} = -\varepsilon_{zyx} = \varepsilon_{yzx} = -\varepsilon_{yxz} = 1, \quad (6)$$

$$\varepsilon(\nu) = \underset{(-)}{+}(8\pi^2 N_{\mathrm{A}}/2302.6)\bar{\nu}[N^{-1}\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}(1/3)\mathrm{Tr}\,\boldsymbol{\alpha}_{mn}^{\mathrm{P}}(\bar{\nu}), \quad (l\ \mathrm{mol}^{-1}\ \mathrm{cm}^{-1}), \quad (7)$$

$$[\Phi(\nu)] = \underset{(-)}{+}288\pi^2 N_{\mathrm{A}}\bar{\nu}^2[N^{-1}\mathrm{Re}\,\beta(\bar{\nu})], \quad (\mathrm{deg\ cm^2/dmol^{-1}}), \quad (8)$$

$$[\Theta(\nu)] = \underset{(-)}{+}288\pi^2 N_{\mathrm{A}}\bar{\nu}^2[N^{-1}\mathrm{Im}\,\beta(\bar{\nu})], \quad (\mathrm{deg\ cm^2/dmol^{-1}}). \quad (9)$$

The notations and units used above are just the same as those of our previous paper.[12] $\boldsymbol{\mu}_{0\lambda}^{(m)}\boldsymbol{\mu}_{\lambda 0}^{(m)}$ is a dyadic product of the transition moment between the λth excited state and the ground state of the mth monomer. To avoid confusion in the formulations which have appeared in the literature on this subject, it seems well to comment upon the sign convention. Depending upon the definition for the monomer polarizability tensor α_m^{M}, that is, either the minus or the plus signs before Eq. 1, the upper or the lower (parenthesized) signs in Eqs. 2, 7, 8, and 9 appear respectively. Although we have chosen the plus sign before Eq. 1 in our previous papers, the

minus sign in Eq. 1 is rather recommended because it is the customarily used definition. Another reason is that if we choose the minus sign in Eq. 1 the plus and the minus signs appear alternately in the expansion formula (Eq. 2) derived perturbatively from the classical electromagnetic theory,[13,14] Note that in the literature we sometimes find the opposite sign convention for $\mathbf{U}_{mn}$[15] which leads to Eq. 2 with all the plus signs even by using the conventional definition (minus) for Eq. 1.

Let us consider a biopolymer–dye complex in which the dyes are regularly arrayed and bound to the biopolymer one way or another. It is now assumed that experimentally and/or theoretically we will be able to know the monomer polarizability tensor $\boldsymbol{\alpha}^{p}_{mn}(\bar{\nu})$ for the mth constituent dye chromophore bound to the biopolymer. Then, we can derive the matrix element of the polarizability tensor $\boldsymbol{\alpha}^{p}_{mn}(\bar{\nu})$ for the biopolymer–dye complex, by using hypothetically a Dyson-type equation (Eq. 2). In Eq. 2, the interactions among the dyes and the macromolecular skeleton are neglected for simplicity. Actually, this means that the macromolecule–dye complex could be approximated as a polymer (N-mer) of aggregated dyes, in so far as we are concerned with the specific wavelength region of our interest.

From Eq. 2, we can calculate the UV absorbance $\varepsilon(\bar{\nu})$ and the optical rotatory parameter $\beta(\bar{\nu})$.[14] Different from our previous paper,[12] let us relate $\beta(\bar{\nu})$ of Eq. 5 with the familiar scalar triple product $\mathbf{r}_{mn}\cdot\boldsymbol{\mu}^{(m)}_{\lambda 0}\times\boldsymbol{\mu}^{(n)}_{\lambda 0}$:

$$\begin{aligned}\beta(\bar{\nu}) &= (1/12)\sum_{m}^{N}\sum_{n}^{N}\sum_{k}(\mathbf{r}_{mn})_k\sum_{t}\sum_{j}\alpha^{\mathrm{P}ij}(\bar{\nu})\varepsilon_{jik}\\ &= -(1/12)\sum_{m}^{N}\sum_{n}^{N}\sum_{i}\sum_{j\neq k}\sum_{k}(\mathbf{r}_{mn})_k(\alpha^{\mathrm{P}ij}_{mn}(\bar{\nu})-\alpha^{\mathrm{P}ji}_{mn}(\bar{\nu}))_k\\ &= -(1/12)\sum_{m}^{N}\sum_{n}^{N}[x_{mn}\vdots y_{mn}\vdots z_{mn}]\begin{bmatrix}\alpha^{\mathrm{P}yz}_{mn}(\bar{\nu})-\alpha^{\mathrm{P}zy}_{mn}(\bar{\nu})\\ \cdots\cdots\cdots\\ \alpha^{\mathrm{P}xz}_{mn}(\bar{\nu})-\alpha^{\mathrm{P}zx}_{mn}(\bar{\nu})\\ \cdots\cdots\cdots\\ \alpha^{\mathrm{P}xy}_{mn}(\bar{\nu})-\alpha^{\mathrm{P}yx}_{mn}(\bar{\nu})\end{bmatrix},\end{aligned}\tag{10}$$

where the symbol $(\ )_k$ denotes the kth component of the vector and $i,j,k=x,y,z$. Equation 10 is a working formula for the evaluation of $\beta(\bar{\nu})$, with simultaneous use of Eq. 2.

On the other hand, if we formally assume the polymer polarizability tensor as

$$\begin{aligned}\alpha^{\mathrm{P}}_{mn}(\bar{\nu}) = \underset{(+)}{-}(hc)^{-1}\sum_{\lambda}\boldsymbol{\mu}^{\mathrm{P}(m)}_{0\lambda}\times\boldsymbol{\mu}^{\mathrm{P}(n)}_{\lambda 0}[(\bar{\nu}-\bar{\nu}^{\mathrm{P}}_{\lambda 0}+i\eta^{\mathrm{P}})^{-1}\\ -(\bar{\nu}+\bar{\nu}^{\mathrm{P}}_{\lambda 0}-i\eta^{\mathrm{P}}_{\lambda})^{-1}],\end{aligned}\tag{11}$$

Eq. 10 leads to the familiar formula for describing optical rotation:

$$\begin{aligned}\beta(\bar{\nu}) = \underset{(+)}{-}(-12hc)^{-1}\sum_{m}^{N}\sum_{n}^{N}\sum_{\lambda}\mathbf{r}_{mn}\cdot\boldsymbol{\mu}^{\mathrm{P}(m)}_{0\lambda}\times\boldsymbol{\mu}^{\mathrm{P}(n)}_{\lambda 0}[(\bar{\nu}-\bar{\nu}^{\mathrm{P}}_{\lambda 0}+i\eta^{\mathrm{P}}_{\lambda})]^{-1}\\ -(\bar{\nu}+\bar{\nu}^{\mathrm{P}}_{\lambda 0}-i\eta^{\mathrm{P}}_{\lambda})^{-1}],\end{aligned}\tag{12}$$

which indicates the conformationally induced exciton-type optical rotation. However, Eq. 12 contains unknown quantities relating to the polymer and can not be practically used for the evaluation of $\beta(\bar{\nu})$. Instead, going back to Eq. 5, we can derive the following equation to a first order approximation with respect to $\mathbf{U}_{mn}$ in Eq. 2:

$$\begin{aligned}\beta(\bar{\nu}) &= (1/12)\sum_{m}^{N}\sum_{n}^{N}\mathbf{r}_{mn}\cdot[\boldsymbol{\alpha}^{\mathrm{M}}_{m}(\bar{\nu})\vdots\boldsymbol{\varepsilon}-(\boldsymbol{\alpha}^{\mathrm{M}}_{m}(\bar{\nu})\cdot\mathbf{U}_{mn}\cdot\boldsymbol{\alpha}^{\mathrm{M}}_{n}(\bar{\nu}))\vdots\boldsymbol{\varepsilon}]\\ &= 0\underset{(+)}{-}(12)^{-1}\sum_{m}^{N}\sum_{n}^{N}\sum_{k}(\mathbf{r}_{mn})_k\sum_{i}\sum_{j}(\alpha^{\mathrm{M}}_{m}(\nu)\cdot\mathbf{U}_{mn}\cdot\alpha^{\mathrm{M}}_{n}(\nu))_{ij}\varepsilon_{jik}\\ &= \underset{(+)}{-(-12)^{-1}}(hc)^{-2}\sum_{m}^{N}\sum_{n}^{N}\sum_{\lambda}\sum_{\lambda'}(\boldsymbol{\mu}^{(m)}_{0\lambda}\cdot\mathbf{U}_{mn}\cdot\boldsymbol{\mu}^{(n)}_{\lambda' 0})\\ &\quad\times(\mathbf{r}_{mn}\cdot\boldsymbol{\mu}^{(m)}_{0\lambda}\times\boldsymbol{\mu}^{(n)}_{\lambda' 0})[(\bar{\nu}-\bar{\nu}^{(m)}_{\lambda 0}+i\eta^{(m)}_{\lambda})^{-1}\\ &\quad-(\bar{\nu}+\bar{\nu}^{(m)}_{\lambda 0}-i\eta^{(m)}_{\lambda})^{-1}][(\bar{\nu}-\bar{\nu}^{(n)}_{\lambda' 0}+i\eta^{(n)}_{\lambda'})^{-1}\\ &\quad-(\bar{\nu}+\bar{\nu}^{(n)}_{\lambda' 0}-i\eta^{(n)}_{\lambda'})^{-1}].\end{aligned}\tag{13}$$

Equation 13 does not contain any unknown polymer parameter and is found to be quite similar to the equations derived by Applequist[14] and Kirkwood *et al.*[16,17] Equations 12 and 13 are exactly the same formulas from a viewpoint of a first order approximation. However, we can preferentially make use of Eq. 13 when we wish to take higher order terms into account. For example, replacing $\mathbf{U}_{mn}$ in Eq. 13 with

$$\begin{aligned}\mathbf{U}_{mn} = \mathbf{U}_{mn} + \sum_{l}\mathbf{U}_{ml}\cdot\boldsymbol{\alpha}^{\mathrm{M}}_{l}\cdot\mathbf{U}_{ln}\\ + \sum_{l}\sum_{s}\mathbf{U}_{ml}\cdot\boldsymbol{\alpha}^{\mathrm{M}}_{l}\cdot\mathbf{U}_{ls}\cdot\boldsymbol{\alpha}^{\mathrm{M}}_{s}\cdot\mathbf{U}_{sn}+\cdots,\end{aligned}\tag{14}$$

we can to infinite order approximation describe $\beta(\bar{\nu})$ in terms of a sum of the product of the scalar triplet product $\mathbf{r}_{mn}\cdot\mu^{(m)}_{0\lambda}\times\mu^{(n)}_{\lambda' 0}$ and the intermonomer interaction $\boldsymbol{\mu}^{(m)}_{0\lambda}\cdot\mathbf{U}_{mn}\cdot\boldsymbol{\mu}^{(n)}_{\lambda' 0}$.

Infinite Orders Approximation for the Polymer Polarizability Tensor

In a previous calculation of the bandshapes of polyadenylic acid,[12] we took into account Eq. 2 up to the second order terms with respect to $\mathbf{U}_{mn}$. However, the expansion series of Eq. 2 very slowly converge in the case that chromophores have large transition moments, so that we must include higher order terms in Eq. 2 for the present calculation of the DNA–AO complex. It may rather be clever to choose the following computational scheme which involves the intermonomer interactions $\mathbf{U}_{mn}$ to infinite orders, since such a calculation in the expanded form of power series becomes time-consuming due to the increase in the number of overlappings of the *DO* loops in a computer program.

If we follow the upper sign convention in Eqs. 1, 2, 7, 8, and 9, Eq. 2 reduces to

$$\begin{aligned}\alpha^{\mathrm{P}} &= (1+\boldsymbol{\alpha}^{\mathrm{M}}\cdot\mathbf{U})^{-1}\boldsymbol{\alpha}^{\mathrm{M}}\\ &= \begin{bmatrix}\mathbf{1} & \boldsymbol{\alpha}^{\mathrm{M}}_{1}\cdot\mathbf{U}_{12}\cdots\boldsymbol{\alpha}^{\mathrm{M}}_{1}\cdot\mathbf{U}_{1\mathrm{N}}\\ \boldsymbol{\alpha}^{\mathrm{M}}_{2}\cdot\mathbf{U}_{21} & \mathbf{1}\quad\cdots\boldsymbol{\alpha}^{\mathrm{M}}_{2}\cdot\mathbf{U}_{2\mathrm{N}}\\ \cdots\cdots & \cdots\cdots\\ \boldsymbol{\alpha}^{\mathrm{M}}_{\mathrm{N}}\cdot\mathbf{U}_{\mathrm{N}1} & \boldsymbol{\alpha}^{\mathrm{M}}_{\mathrm{N}}\cdot\mathbf{U}_{\mathrm{N}2}\cdots\quad\mathbf{1}\end{bmatrix}^{-1}\begin{bmatrix}\boldsymbol{\alpha}^{\mathrm{M}}_{1} & \mathbf{0}\cdots\mathbf{0}\\ \mathbf{0} & \boldsymbol{\alpha}^{\mathrm{M}}_{2}\cdots\mathbf{0}\\ & \cdots\cdots\\ \mathbf{0} & \mathbf{0}\cdots\boldsymbol{\alpha}^{\mathrm{M}}_{\mathrm{N}}\end{bmatrix},\end{aligned}\tag{15}$$

where

$$\mathbf{1}=\begin{bmatrix}1&0&0\\0&1&0\\0&0&1\end{bmatrix},\qquad \mathbf{0}=\begin{bmatrix}0&0&0\\0&0&0\\0&0&0\end{bmatrix}.\tag{16}$$

The tensor components of the 3×3 matrix for $\boldsymbol{\alpha}^{\mathrm{M}}_{m}(\bar{\nu})$ are given as

$$\alpha^{\mathrm{M}ij}_{m}(\bar{\nu}) = \mathrm{Re}\,\alpha^{\mathrm{M}ij}_{m}(\bar{\nu}) + i\mathrm{Im}\,\alpha^{\mathrm{M}ij}_{m}(\bar{\nu}),\quad (i,j=x,y,z),\tag{17}$$

and we finally obtain

$$\mathrm{Re}\,\alpha_m^{Mij}(\bar{\nu}) = -\sum_{\lambda}(hc)^{-1}[\mu_{0\lambda}^{(m)}]_i[\mu_{\lambda 0}^{(m)}]_j\{(\bar{\nu}-\bar{\nu}_{\cdot 0}^{(m)})[(\bar{\nu}-\bar{\nu}_{\lambda 0}^{(m)})^2 + \eta_\lambda^{(m)2}]^{-1} - (\bar{\nu}+\bar{\nu}_{\lambda 0}^{(m)})[(\bar{\nu}+\bar{\nu}_{\lambda 0}^{(m)})^2+\eta_\lambda^{(m)2}]^{-1}\}, \quad (18)$$

$$\mathrm{Im}\,\alpha_m^{Mij}(\nu) = +\sum_{\lambda}(hc)^{-1}[\mu_{0\lambda}^{(m)}]_i[\mu_{\lambda 0}^{(m)}]_j\{\eta_\lambda[(\bar{\nu}-\bar{\nu}_{\lambda 0}^{(m)})^2 + \eta_\lambda^{(m)2}]^{-1} + \eta_\lambda[(\bar{\nu}+\bar{\nu}_{\lambda 0}^{(m)})^2+\eta_\lambda^{(m)2}]^{-1}\}. \quad (19)$$

Being utilized the subroutine to compute the inverse of the $3N\times 3N$ complex matrix, the matrix elements $\alpha_{mn}^{p}(\bar{\nu})$ can easily be obtained, and then the three bandshape functions for the molar absorptivity (Eq. 7), molar rotation (Eq. 8), and molar ellipticity (Eq. 9) are computed by making use of Eqs. 10 and 15.

Specification of Models and Computational Procedures

As shown in Fig. 1, we assume such a regular model that the dyes are helically aggregated on the sites of the polymer skeleton. Here, the Cartesian coordinate is taken along the radial (r), tangential (t), and vertical (z) directions of the first dye monomer site considered. By doing so, we can relate the non-interacting monomer polarizability tensor of the mth site, $\boldsymbol{\alpha}_m^{M}(\bar{\nu})$, with that of the first site, $\boldsymbol{\alpha}_1^{M}(\bar{\nu})$:

$$\boldsymbol{\alpha}_m^{M}(\bar{\nu}) = \mathbf{R}[+(m-1)\phi]\cdot\boldsymbol{\alpha}_1^{M}(\bar{\nu})\cdot\mathbf{R}[-(m-1)\phi] = \mathbf{R}_z[-(m-1)\phi]\cdot\boldsymbol{\alpha}_1^{M}(\bar{\nu})\cdot\mathbf{R}_z[+(m-1)\phi], \quad (20)$$

where

$$\mathbf{R}(\phi) = \mathbf{R}_z(-\phi) = \begin{pmatrix} \cos\phi & -\sin\phi & 0 \\ \sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (21)$$

For instance, if we put the first dye on the r',t'-plane determined by the parameters of angles such as $\theta°$, *tilt*°, and *twist*° as depicted in Fig. 1, the components of the transition moment $\boldsymbol{\mu}_{0\lambda}^{(1)}$ in the Cartesian coordinate are given by

$$\begin{bmatrix} [\mu_{0\lambda}^{(1)}]_r \\ [\mu_{0\lambda}^{(1)}]_t \\ [\mu_{0\lambda}^{(1)}]_z \end{bmatrix} = \mathbf{R}_t(+|twist|)\cdot\mathbf{R}_{r'}(-|titl|)\begin{bmatrix} [\mu_{0\lambda}^{(1)}]_{r'} \\ [\mu_{0\lambda}^{(1)}]_{t'} \\ [\mu_{0\lambda}^{(1)}]_{z'} \end{bmatrix}$$

$$= \begin{bmatrix} \cos(+|twist|) & 0 & -\sin(+|twist|) \\ 0 & 1 & 0 \\ \sin(+|twist|) & 0 & \cos(+|twist|) \end{bmatrix} \times \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(-|tilt|) & \sin(-|tilt|) \\ 0 & -\sin(-|tilt|) & \cos(-|tilt|) \end{bmatrix}\begin{bmatrix} [\mu_{0\lambda}^{(1)}]_{r'} \\ [\mu_{0\lambda}^{(1)}]_{t'} \\ [\mu_{0\lambda}^{(1)}]_{z'} \end{bmatrix}. \quad (22)$$

By defining the plus sign of the angles counter-clockwise, we can write more generally

$$\begin{bmatrix} [\mu_{0\lambda}^{(1)}]_r \\ [\mu_{0\lambda}^{(1)}]_t \\ [\mu_{0\lambda}^{(1)}]_z \end{bmatrix} = \mathbf{R}_t[-|twist|\cdot\mathrm{sgn}(twist)]\cdot \mathbf{R}_{r'}[-|tilt|\cdot\mathrm{sgn}(tilt)]\begin{bmatrix} [\mu_{0\lambda}^{(1)}]_{r'} \\ [\mu_{0\lambda}^{(1)}]_{t'} \\ [\mu_{0\lambda}^{(1)}]_{z'} \end{bmatrix}. \quad (23)$$

Thus, we can compute the bandshapes by making use of Eqs. 7, 8, and 9 for either the outside-stacking or the intercalation model by changing the parameters (a, ϕ, *pitch*, θ, *tilt*, *twist*) as illustrated in Fig. 1.

With the scope of outside-binding models, we newly propose a dimerpairs repeating sequence model illustrated in Fig. 2. Looking at this model, every dye is

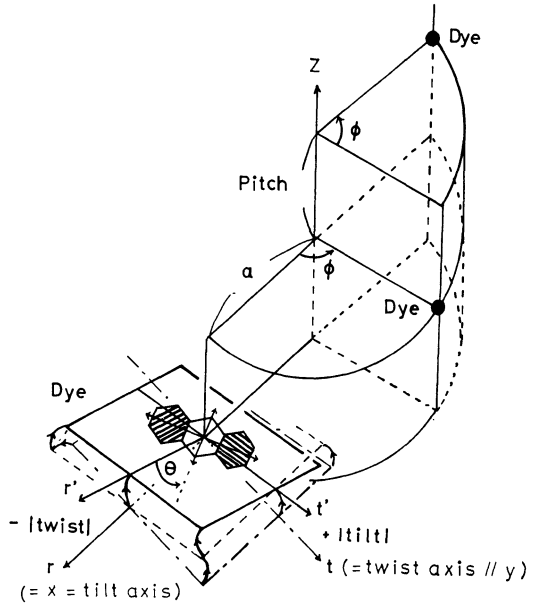

Fig. 1. A model of the Acridine Orange polymer helically stacked on the one-strand of DNA–AO complex and its geometrical parameters.

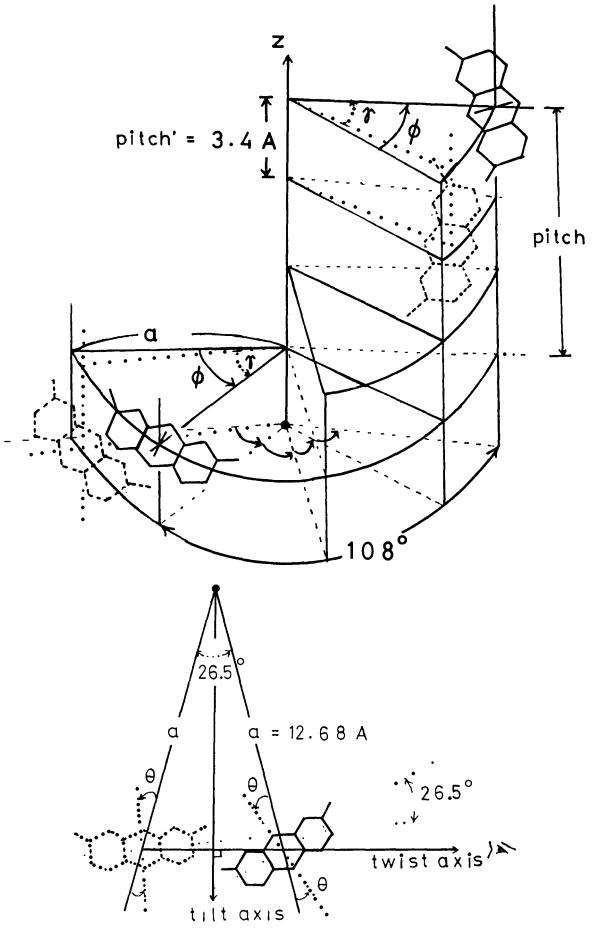

Fig. 2. A dimer-pairs repeating sequence model $[(\mathrm{dye})_2]_N$ for DNA–AO complex and its geometrical parameters.

found to be arrayed on the site of the same strand. However, if we change our views just for the computational convenience, we can readily regard this single-stranded polymer of the dyes as the double-stranded one, *i.e.*, one strand consisting of the dyes shown with the dotted line and another strand building from the dyes drawn with the solid line. This may be the special case of the double-stranded model shown in Fig. 1 of our previous paper.[12] In Table 1, the double-stranded DNA–AO polymer model presented by Tinoco *et al.*[1] is described by the parameters assigned in Fig. 2. Corresponding to Eq. 20 which defines the polarizability tensor of the mth monomer, the polarizability tensor of the m'th monomer can be obtained by a simple rotation from the position m, being assumed the geometry of the double-stranded DNA–AO complex, so as to satisfy

$$\boldsymbol{\alpha}^{M}_{m'}(\bar{\nu}) = \mathbf{R}(\gamma)\cdot\boldsymbol{\alpha}^{M}_{m}(\bar{\nu})\cdot\mathbf{R}(-\gamma), \quad (m' = \text{opposite site of } m), \tag{24}$$

and the position vectors are given by

$$\mathbf{r}_m = a\cos(m\phi)\hat{\mathbf{i}} + a\sin(m\phi)\hat{\mathbf{j}} + n\,\text{pitch}\,\hat{\mathbf{k}}, \tag{25}$$

$$\mathbf{r}_{m'} = a\cos(m\phi+\gamma)\hat{\mathbf{i}} + a\sin(m\phi+\gamma)\hat{\mathbf{j}} + (n\,\text{pitch}+\text{pitch}')\hat{\mathbf{k}}. \tag{26}$$

Results and Discussion

The spectroscopic parameters of the monomer dye, Acridine Orange, necessary for the calculations of the UV, ORD, and CD bandshapes of the polymer complex are experimentally determined as given in Table 1. In Table 2 are listed the various models assumed for the DNA–AO complex and the parameters describing the corresponding models. The results of model calculations are given through Fig. 3 to Fig. 10. In what follows, we are concerned specifically with the visible region of the whole bandshapes obtained. Tentatively, we assume that the dyes helically aggregate as if they were tilted and twisted in their molecular planes (see Fig. 1), with the parameters which are quite similar to the base parameters of the B-DNA geometry; *i.e.* *tilt*=2.1°, *twist*=−4.9°, a (variable in Å). Incidentally, the model presented by Tinoco *et al.*[1] corresponds to *tilt*=0.0°, *twist*=0.0°, a=12.68 Å. The assumption above implies that the molecular planes of the bound dyes are almost vertical to the helical axis of DNA, and in fact this nearly vertical orientation has experimentally been suggested.[19] It was shown in the study of polyadenylic acid[12] that the tilt and twist of the chromophores in the polymer system give rise to a large effect in the spectral bandshapes. We do not enter into the effect of tilting and twisting of the dyes beyond that, since there are some other unknown factors with regard to the parameters describing the DNA–AO complex.

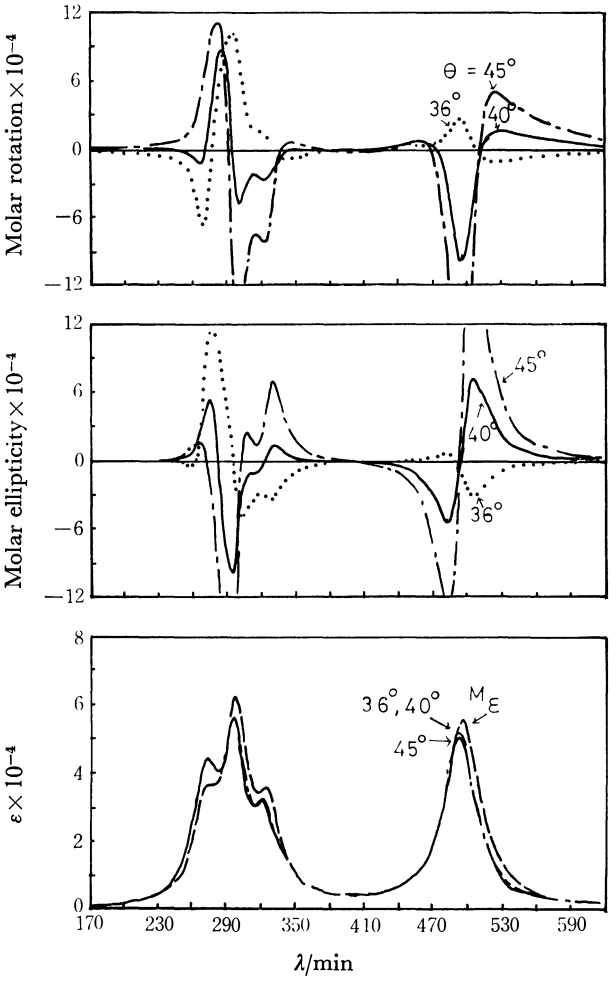

Fig. 3. The ORD (top), CD (middle), and UV (bottom) bandshapes for the intercalation model (see Table 2). $^{M}\varepsilon$ in the bottom shows the UV absorption spectrum of the AO monomer through Fig. 3 to Fig. 10.

Intercalation Model. Let us assume a simple model that the dyes are penetrated between every two base-pairs and constitute the single-stranded pentamer (5-mer) of the dyes as given in Table 2. This corresponds to the intercalation model for $P/D=4$—5. The spectral profiles computed with this model are shown in Fig. 3. In the visible region of the ORD and CD curves computed for the $\theta=40°$ model (see Fig. 1), we obtain the bandshapes having reasonable peaks and troughs in their spectral intensities in comparison with the curves of $P/D=5$ observed by Yamaoka and Resnik.[18] The first (longest wavelength) UV band computed shows only a minor blue shift and a slight decrease of intensity, even if whatever values are given for θ. Since the chain-length effect in the bandshapes is small even if we take N to be larger than 5 for the outside-stacking model (see below), qualitative feature to be obtained for the $N>5$ cases of the intercalation model might not be much different from Fig. 3. In short, in so far as the ORD and CD curves for low P/D ratios are concerned, the adequacy of this model is numerically proved. It seems that the feature of the first UV band observed for $P/D=5$ can qualitatively be reproduced for the specific θ-value ($\theta=40°$), though there still remains dissatisfaction about the intensity of the first UV band.

*Outside-stacking Models. Chain-length (*N*) Effect and Radius (*a*)-Dependence of the ORD, CD, and UV Bandshapes*: In Fig. 4, we investigated the chain-length effect of the bandshapes for the parameter $N=2$, 3, 5, 11 in the single-stranded models, fixing $\theta=52°$, which reproduces appropriately the ORD and CD curves. We found a tendency such that the computed curves for the $N=8$—11 models converge to certain shapes (approximately to that of the $N=5$ model). Therefore, for saving computational time, we carried out the model calculations of the DNA–AO complex only with the $N=2$ and $N=5$ species.

With a fixed θ-value $\theta=90°$, the dependence of the bandshapes for the single-stranded models upon the value of the radius, $a=12.68$, 13.5, and 14.5 Å, was examined as shown in Fig. 5. When we fix the parameters except the position of the binding site ($\vec{a}$), and make the value of $|\vec{a}|$ larger by degrees, the intermonomer interaction $\mathbf{U}_{mn}$ between the dyes becomes small, so that the ORD and CD curves decrease their

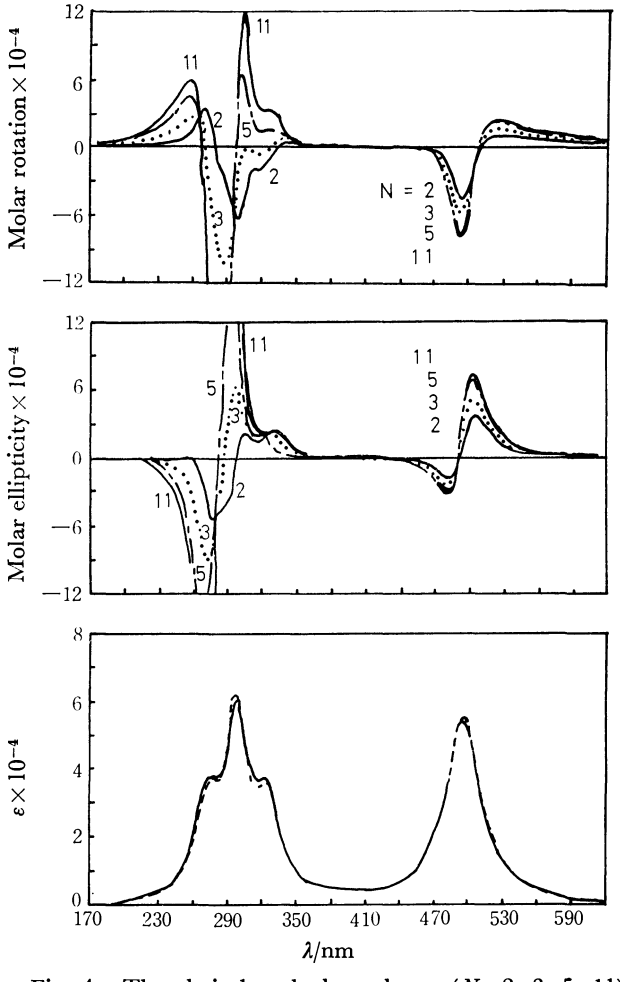

Fig. 4. The chain-length dependence ($N=2$, 3, 5, 11) of the ORD (top), CD (middle), and UV (bottom) bandshapes of the single-stranded outside-stacking N-mer model (see Table 2).

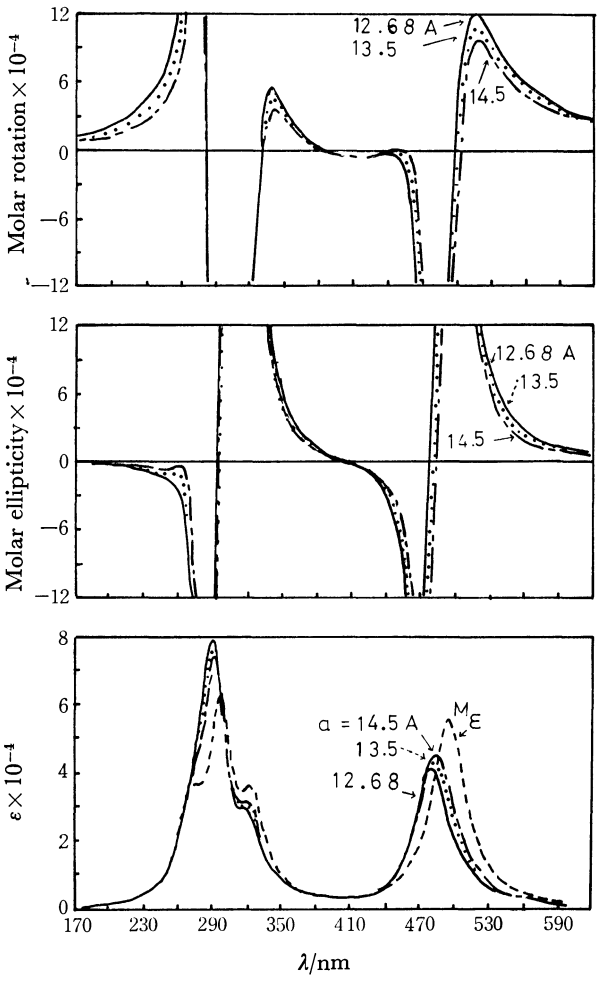

Fig. 5. Dependence of the ORD (top), CD (middle), and UV (bottom) bandshapes of the single-stranded outside-stacking 5-mer model (see Table 2) on the radius (a) of the helix.

intensities with the increase of $|\vec{a}|$ while the first UV band hardly change its peak and intensity. It is thus difficult to consider the possibility that the dyes will bind to the sites inside beyong the limit of 12.68 Å. For instance, in the stacking model presented by Obendorf *et al.*,[21] the binding site was set to be $|\vec{a}|=$ 6 Å and other parameters adopted were quite similar to our values. From Fig. 5, it is predicted that their model is indisputably denied.

Single-Stranded Dimer Model: From comparison of Figs. 4, 6, 7, and 8 it can be concluded that the qualitative feature of the UV, ORD, and CD bandshapes computed for the dimer does not very much change even for the $N>3$ polymers. In other words, the qualitative feature of these bandshapes in the visible region is mainly determined by the nearest neighbor interactions of the dyes with the intermonomer distance nearly equal to 3.4 Å. This suggestion also coincides with the experimental conclusion for the complexes of the low P/D ratios that the main binding species are dimeric molecules bound to the outside sites, while for those of $P/D\gg1$, it is usually accepted that the main binding species are monomeric. From our calculation, we have confidence in suggesting a model such that not the monomeric but the dimeric dyes are sparsely dispersed on the binding sites. If this assumption is correct, such a dimer model flexibly applies to the cases for $P/D\approx1$ as well as $P/D\gg1$. However, if this dimeric model is denied for $P/D\gg1$, we must consider that the optical activity may be induced not only by the local steric interaction between the monomeric dye and the base-pair (*i.e.*, conformationally induced optical activity), but also by the interaction between the dye and the sugar phosphate groups (*i.e.*, the intrinsic optical activity induced by the assymmetric environments). This monomeric binding is certainly the consensus ascertained experimentally for $P/D\gg1$. We do not carry out possible model calculations taking account of such effects, since there is no definite experimental datum in the shorter wavelength region available.

In Fig. 6, the model calculation for $\theta=90°$ gives the reasonable blue shift and intensity descent in the first UV band which are comparable to the bandshapes experimentally observed for $P/D=2$—5.[18] On the other hand, the calculation for $\theta=50°$ gives the reasonable ORD and CD curves for the corresponding experimental curves.[18] We could not find out a proper θ-value so as

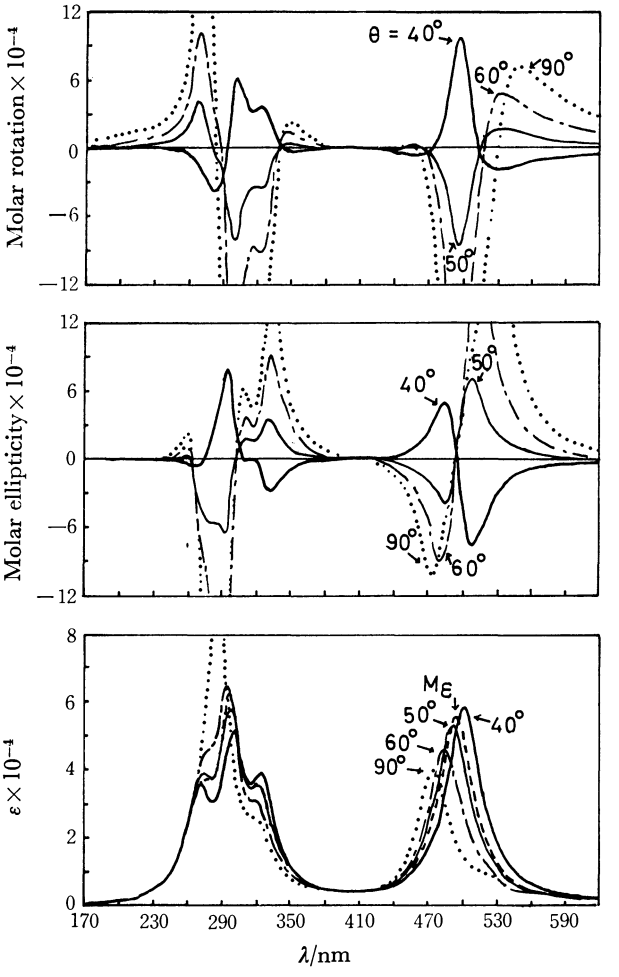

Fig. 6. The ORD (top), CD (middle), and UV (bottom) bandshapes for the outside-stacking dimer model (see Table 2).

to obtain the agreement of the computed UV, ORD, and CD bandshapes with experiments at the same time. It should be noticed that for $0°\leq\theta\leq40°$ the red shift and the intensity ascent are observed in the first UV band and that the reversed Cotton effect and the red shift in the ORD and CD bands come to be large. Such bandshapes computed happen to correspond to the experimental ones for $P/D\gg1$ and may be true if the species of the dimeric dyes are dispersedly bound to DNA. However, we must not forget that depending upon the experimental condition the reversed Cotton effect can be seen even for $P/D\approx1$.[6,22]

Single- and Double-Stranded 5-mer Models: As will be expected from the discussion of the chain-length effect, we obtain almost the same results in Fig. 7 as those in Fig. 6. The model calculation for $\theta=90°$ (the radial orientation of the long axis of the dye molecule) gives the reasonable blue shift and intensity descent which are comparable with the first UV band observed for the low P/D ratios, but the ORD and CD curves computed are too intense in comparison with the experimental ones. Our previous study[20] on the shift of the UV band suggested the radial orientation, but found that although the qualitative feature of the bandshapes is satisfied,[5] the ORD curves computed are extraordinarily strong in their intensites which may be brought about just due to the assumption of a smaller value of $|\vec{a}|=9.1$ Å compared with $|\vec{a}|=12.68$ Å, as is readily understood from the present results. On the other hand, the model calculation for $\theta=0°$ (tangential orientation of the long axis) gives a large red shift and a large reversed Cotton effect.

In Fig. 7, it should be noticed that the single-stranded models for $\theta=50°$—$55°$ give the ORD and CD curves comparable for the experimental ones of the low P/D ratios, while we have only the imperceptible UV intensity descent. When we compute the bandshapes in more detail, particularly for $\theta=49°$—$55°$ using the same model, we obtain the results as shown in Fig. 8. It is interesting to note that drastic changes of the ORD and CD curves occur for small changes in the vicinity of a specific value $\theta=55°$, and that the UV bandshape computed changes a little comparing with the experimental UV band.

By using the model presented by Tinoco *et al.*,[1] we computed the bandshapes for the single- and double-stranded DNA–AO complexes fixing $\theta=90°$, which are shown in Fig. 9. In this calculation, we used the spectral

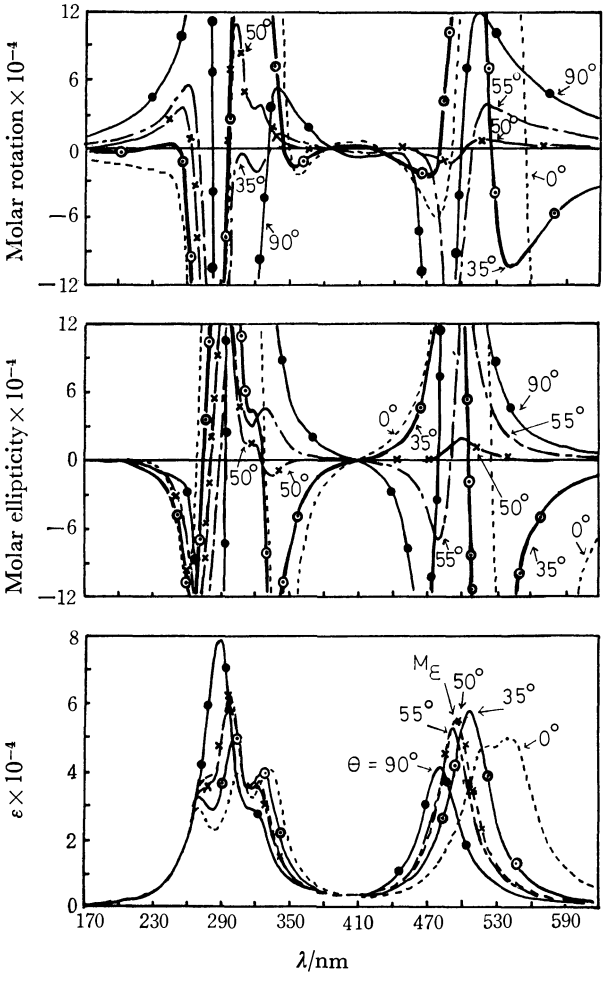

Fig. 7. Dependence of the ORD (top), CD (middle), and UV bottom) bandshapes for the outside-stacking 5-mer model (see Table 2) on the twisting angle (θ) of the short axis of the AO dye from the radial direction of the helix.

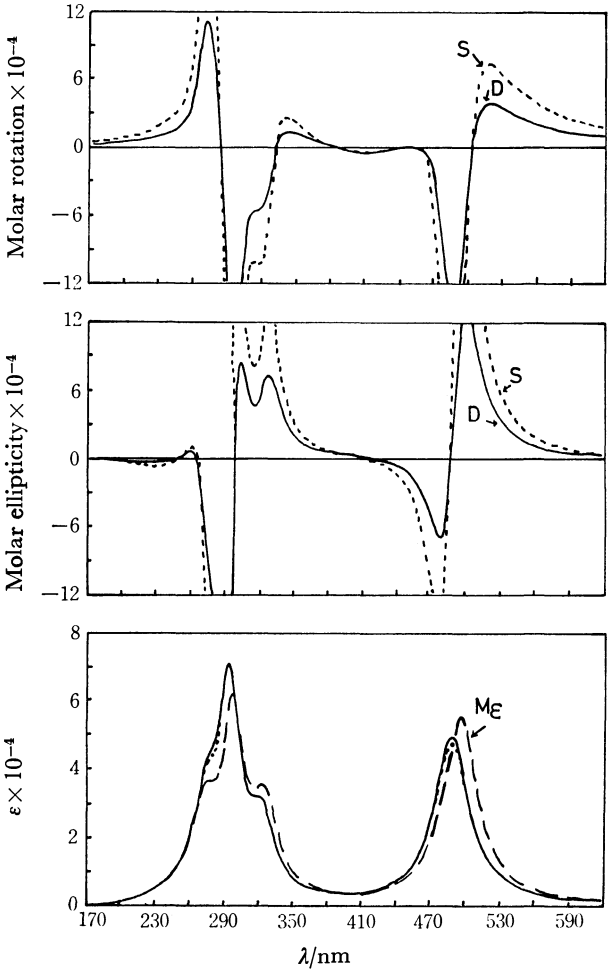

Fig. 9. The ORD top), CD (middle), and UV (bottom) bandshapes for the single-stranded 5-mer model (see Table 2) similar to the Tinoco-Woody-Bradley model. The S and D denote the single- and double-strands, respectively.

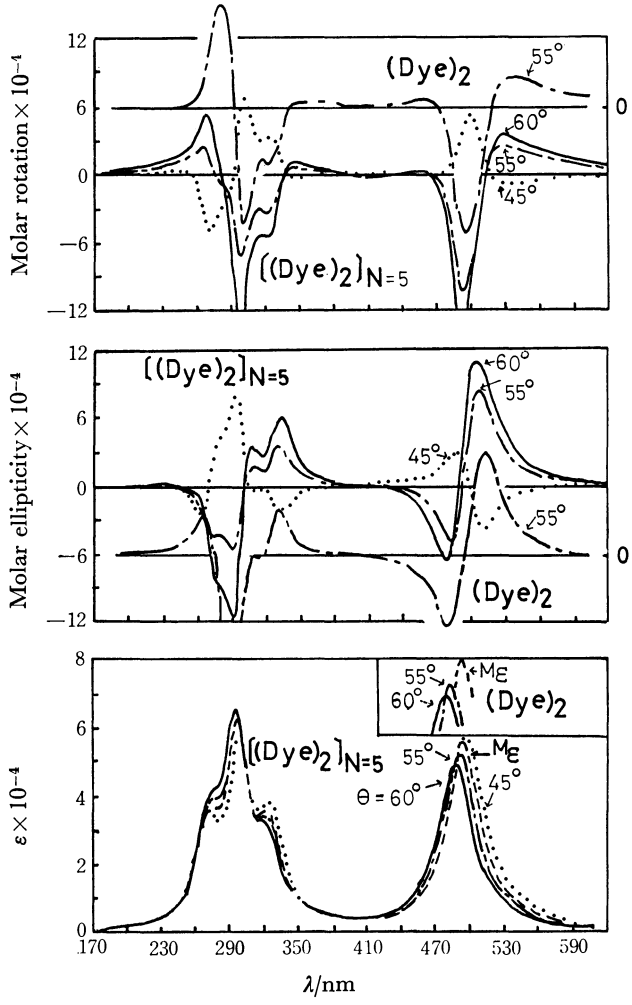

Fig. 10. The ORD (top), CD (middle), and UV (bottm) bandshapes for the one dimer-pair $(Dye)_2$ and/or the five dimer-pairs repeating sequence models $[(Dye)_2]_5$ (see Table 2).

parameters given in Table 1 and the screened potential $\mathbf{U}^{\text{screen}}_{mn}=(1/\varepsilon)\mathbf{U}^{\text{bare}}_{mn}$ with the dielectric constant $\varepsilon=2.0$, instead of the bare interaction $\mathbf{U}_{mn}=\mathbf{U}^{\text{bare}}_{mn}$. If we assume that the radial orientation ($\theta=90°$) of the dyes is experimentally correct, the discrepancy mentioned about Figs. 7 and 8 is found to be overcome in Fig. 9 by the inclusion of the dielectric screening effect and the dye-dye interaction between the double strands. However, ε is simply the parameter assumed tentatively and it may be difficult to choose the value which has a real physical meaning. We notice in Fig. 9 that the qualitative feature of the bandshapes for the single-stranded polymer is not definitely changed by allowing for the dye-dye interaction between the double strands. Concerning this model, there also remains dissatisfaction with regard to the fact that the extent of the blue shift and the intensity descent in the first UV band is small compared with the experimental bandshapes for the low P/D ratios.

Dimer-Pairs Repeating Sequence Model: For the dimer model mentioned in the previous paragraphs, we assume a rather different model as shown in Fig. 2 and in the bottom line of Table 2, which we call a dimer-pairs repeating sequence model. It is necessary to note that the model drawn in Fig. 2 is a kind of visualization of an external association model of dimer dyes, *i.e.*, the polymer of the dimer units which was used by Imae and Ikeda[6] for the calculations of CD curves. As shown in Fig. 10, the $(Dye)_2$- and $[(Dye)_2]_5$-models for $\theta=55°$ and 66° give the similar bandshapes, which are approximately comparable with the UV, ORD, and CD bandshapes observed for the low P/D ratios. For the models within the range $0°\leq\theta\leq45°$, the reversed Cotton effect can be seen in the visible region, and only small intensity increase and red shift in the first UV band are observed.

From the discussions mentioned above, it is found that the outside-stacked *one* dimer-pair model and/or the outside-stacked *five* dimer-pairs repeating sequence model is a good example to be able to well predict the experimental UV, ORD, and CD bandshapes for the low P/D ratios, as far as the models assumed in Table 2 are concerned. We obtain the reasonable bandshapes for the intercalation models of the low P/D ratio ($P/D=5$), but in the present paper we do not consider the possible intercalation models for $P/D\gg1$.

There still remain a lot of problems such as the correct assignment of the transition energies and the polarization directions of the transitions for the monomer dye, the introduction of the bandshape functions involving the vibrational levels, and the suitable determination of the damping factors ($=\Gamma/2$) of the monomer band governing the bandshapes of the polymer. The study on this line is now in progress.

The Mass-transfer Rate through the Liquid-Liquid Interface. VII. Diffusion through a Spherical Interface Involving the Adsorption-Desorption Process

Teruya SHIMBASHI

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received March 14, 1979)

A theoretical formula for the transfer rate of a solute through a spherical interface has been proposed, considering the adsorption-desorption process and the variation in the amount of adsorption. Computational results indicate that, in the usual particle-diameter (radius <1 mm), the diffusion coefficient has practically no relation to the transfer rate in the case of a significant interfacial resistance, such as is observed in the transfer of fatty acids. The concentrations of butylamine in the aqueous, continuous phase in a stirred extraction vessel have been predicted.

In the treatment of mass transfer through oil–water interfaces, the adsorption-desorption process on the interface has usually been disregarded in chemical engineering practice; that is, the two concentrations in both phases next to the interface have been assumed to be in equilibrium. The ground of this disregard of the process is supposedly that the transfer rate has not physically, but rather formally been treated in terms of the "mass-transfer coefficient;" also, that the resistance encountered when a solute molecule transfers through an oil–water interface has been generally considered to be negligible.

Some authors have studied and investigated, however, about the magnitudes of the interfacial resistances; their results[1-7] indicate that usually the resistance is fairly significant. A theoretical formula[8] of mass-transfer rates was derived in the case of linear diffusion through the plane interface in a finite composite medium, considering the adsorption-desorption process on the interface and also the variation in the amount of adsorption; the analytical results[7] from the observed transfer rates of propylamine and butylamine through the water–benzene interface using the derived formula showed that the activation free energies of desorption of the solutes from the interface were about 18 kcal†/mol at 50 °C, which agreed with the results[4-6] obtained by other procedures from the transfer rates of fatty acids through oil–water interfaces.

In an actual and effective operation of the technical extraction of substances, the oil–water system is composed of a dispersed phase and a continuous phase in a stirred vessel or in a dropping tower; the role of the interfacial process of transfer may become important as the liquid-drop goes to smaller sizes.

Below we shall treat theoretically, from the above point of view, the mass-transfer rates through a spherical interface involving the adsorption-desorption process and the variation in the amount of adsorption.[9]

Theory

Modified Fick's diffusion equations for a composite spherical system[10] are defined by

$$\partial u_1/\partial t = D_1(\partial^2 u_1/\partial r^2), \quad 0 \leq r < R_1, \quad t > 0; \tag{1}$$

$$\partial u_2/\partial t = D_2(\partial^2 u_2/\partial r^2), \quad R_1 < r < R_2, \quad t > 0, \tag{2}$$

where u_1 and u_2 are related to c_i, $i=1$ or 2, as $u_i \equiv rc_i$; here, c_i is the local concentration of the solute in Phase i; D_1 and D_2 are the diffusion coefficients; r is the distance from the center of the composite (concentric) sphere; t is the time, and R_1 and R_2 are constants.

The boundary conditions are represented by

$$-D_1\{(\partial u_1/\partial r)/r-(u_1/r^2)\} + D_2\{(\partial u_2/\partial r)/r-(u_2/r^2)\} = \Gamma_\infty(\mathrm{d}\theta/\mathrm{d}t), \quad r = R_1, \quad t > 0; \tag{3}$$

$$-D_1\{(\partial u_1/\partial r)/r-(u_1/r^2)\} = k_{a1}(1-\theta)u_1/r - k_{d1}\theta, \quad r = R_1, \quad t > 0; \tag{4}$$

$$D_2\{(\partial u_2/\partial r)/r-(u_2/r^2)\} = k_{a2}(1-\theta)u_2/r - k_{d2}\theta, \quad r = R_1, \quad t > 0; \tag{5}$$

$$u_1 = 0, \quad r = 0, \quad t > 0; \tag{6}$$

$$u_2 = R_2 c_{2\omega}, \quad r = R_2, \quad t > 0, \tag{7}$$

where Γ_∞ is the saturated value of the amount of adsorption per unit of area of the interface; θ is the fraction of the total interface occupied by adsorbed molecules; k_{a1} and k_{a2} are the rate constants of adsorption to the interface from Phase 1 and Phase 2 respectively; k_{d1} and k_{d2} are the rate constants of desorption from the interface to Phase 1 and Phase 2 respectively, and $c_{2\omega}$ is a constant. Equation 3 relates the variation in the amount of adsorption to the fluxes, while Eqs. 4 and 5 give the relation between the adsorption-desorption mechanism and the fluxes.

The initial conditions are assumed to be

$$u_1 = rc_{10}, \quad 0 \leq r < R_1, \quad t = 0; \tag{8}$$

$$u_2 = rc_{2\omega}, \quad R_1 < r \leq R_2, \quad t = 0; \tag{9}$$

$$\theta = \theta_0, \quad t = 0, \tag{10}$$

where c_{10} and θ_0 are constants as well as $c_{2\omega}$.

Equations 1—10 are to be solved by means of the Laplace transformation; in an extreme case, $(R_2-R_1)\to 0$ (then $R_1=R_2=R$), considering a dynamic system such as in a stirred vessel, the solution may be expressed as

$$c_{1,t} = (k_{a1}k_{d2})^{-1}k_{a2}k_{d1}c_{2\omega} + (2/r)\sum_{n=1}^{\infty}\boldsymbol{D}^{-1}\xi_t \sin(r\alpha_n) \times \exp(-D_1\alpha_n^2 t); \tag{11}$$

$$\theta_{,t} = (k_{a2}/k_{d2})c_{2\omega} + 2(\Gamma_\infty R)^{-1}\sum_{n=1}^{\infty}\boldsymbol{D}^{-1}\{\zeta_{1,t}\sin(R\alpha_n) + \zeta_{2,t}\cos(R\alpha_n)\}\exp(-D_1\alpha_n^2 t); \tag{12}$$

$$\boldsymbol{D} \equiv \phi_1 \sin(R\alpha_n) + \phi_2 \cos(R\alpha_n);$$

† 1 kcal=4184 J.

$$\phi_1 \equiv \{D_1R^{-1}(k_{d1}+k_{d2})-k_{a1}k_{d2}\}(\Gamma_\infty D_1 R\alpha_n)^{-1} + \{R^{-1}(D_1R^{-1}-k_{a1}) - \Gamma_\infty^{-1}(k_{d1}+k_{d2})\}\alpha_n + D_1\alpha_n^3;$$

$$\phi_2 \equiv \{k_{a1}k_{d2}-D_1R^{-1}(k_{d1}+k_{d2})\}(\Gamma_\infty D_1)^{-1} - (D_1R^{-1}+k_{a1})\alpha_n^2;$$

$$\xi_i \equiv \{k_{a1}(c_{10}+D_1\alpha_n^2 I_{1,i})-k_{d1}\theta_0\}\alpha_n - \{k_{a1}k_{d2}(c_{10} + D_1\alpha_n^2 I_{1,i})-k_{a2}k_{d1}(c_{2\omega}+D_1\alpha_n^2 I_{2,i})\}(\Gamma_\infty D_1\alpha_n)^{-1};$$

$$\zeta_{1,i} \equiv -(D_1\alpha_n)^{-1}\{D_1R^{-1}[k_{a1}(c_{10}+D_1\alpha_n^2 I_{1,i})-k_{d1}\theta_0] - (k_{a1}-D_1R^{-1})[k_{a2}(c_{2\omega}+D_1\alpha_n^2 I_{2,i})-k_{d2}\theta_0]\};$$

$$i_{2,i} \equiv k_{a1}(c_{10}+D_1\alpha_n^2 I_{1,i}) - k_{d1}\theta_0 + k_{a2}(c_{2\omega}+D_1\alpha_n^2 I_{2,i}) - k_{d2}\theta_0;$$

$$I_{1,i+1} \equiv \frac{1}{2\pi i}\int_{\sigma_1-i\infty}^{\sigma_1+i\infty}\{\bar{c}_{1,i}(\sigma)\}_{r=R}\bar{\theta}_{,i}(-D_1\alpha_n^2-\sigma)d\sigma;$$

$$I_{2,i+1} \equiv \frac{1}{2\pi i}c_{2\omega}\int_{\sigma_1-i\infty}^{\sigma_1+i\infty}\sigma^{-1}\bar{\theta}_{,i}(-D_1\alpha_n^2-\sigma)d\sigma,$$

where the subscript i designates including perturbation[11] to the ith term, provided $I_{1,0}=I_{2,0}=0$; $\bar{c}_1(p)$ and $\bar{\theta}(p)$ are the image functions corresponding to $c_1(t)$ and $\theta(t)$ respectively; here, p is the conversion parameter of the Laplace transformation; $\pm\alpha_n$ are the roots (generally complex) of α in the next equation:

$$a_1\sin(R\alpha) + a_2\cos(R\alpha) = 0; \quad (13)$$

$$a_1 \equiv \{D_1R^{-1}(k_{d1}+k_{d2})-k_{a1}k_{d2}\} \times(\Gamma_\infty\alpha)^{-1}-(D_1R^{-1}-k_{a1})D_1\alpha;$$

$$a_2 \equiv D_1^2\alpha^2 - \Gamma_\infty^{-1}D_1(k_{d1}+k_{d2}).$$

The amount of solute in the sphere of Phase 1 on the condition that $(R_2-R_1)\to 0$ is represented by

$$q = 4\pi\int_0^R c_1^* r^2 dr = (4/3)\pi R^3(k_{a1}k_{d2})^{-1}k_{a2}k_{d1}c_{2\omega} + 8\pi\sum_{n=1}^{\infty}(\alpha_n\boldsymbol{D})^{-1}\xi^* \times\{\alpha_n^{-1}\sin(R\alpha_n)-R\cos(R\alpha_n)\}\exp(-D_1\alpha_n^2 t), \quad (14)$$

where the superscript* indicates the convergence in the progress of the perturbation.

Let us consider a stirred vessel with a certain volume, V, which is filled with Phase 1 (dispersed) and Phase 2 (continuous), with liquids of Phase 1 and Phase 2 constantly flowing in and out at the volumetrical rates of F_1 and F_2 respectively; these liquids (solvents) are immiscible and dissolved a solute in the initial concentrations of c_{10} and c_{20} respectively.

We calculate the concentration, $c_{2\omega}$, of the solute in Phase 2 (continuous) in the steady state; the dispersed particles are taken to be spheres of complete mixing,[12] and the distribution of the particle-diameters as well as the coalescence and fission of particles are disregarded for the sake of simplification.

The transfer rate of the solute from a sphere of Phase 1 to Phase 2 that is continuous (we use Eq. 14) is approximately given as

$$v = -dq/dt = 8\pi D_1\sum_{n=1}^{\infty}\boldsymbol{D}^{-1}\xi^*\{\sin(R\alpha_n)-R\alpha_n\cos(R\alpha_n)\} \times\exp(-D_1\alpha_n^2 t).$$

The probability of the residence of a particle in the vessel (for complete mixing) may be represented as $Z=\exp(-Ft/V)$, where $F=F_1+F_2$; the probability density of the residence time is given by

$$f(t)=d(1-Z)/dt=(F/V)\exp(-Ft/V);$$

so the average rate of transfer may be expressed as

$$\bar{v} = \int_0^\infty vf(t)dt = 8\pi D_1(F/V)\sum_{n=1}^{\infty}\boldsymbol{D}^{-1}\xi^*\{D_1\alpha_n^2+(F/V)\}^{-1} \times\{\sin(R\alpha_n)-R\alpha_n\cos(R\alpha_n)\}.$$

Considering the mass-balance, we obtain this relation: $\bar{v}nV=(c_{2\omega}-c_{20})F_2$, where n is the number of particles per unit volume in the vessel, and after rearranging the relation, we may obtain a representation (for $\theta_0=0$) of the concentration sought as

$$c_{2\omega} = \{c_{20}+6D_1(R^3\gamma)^{-1}\sum_{n=1}^{\infty}[\psi_1(\alpha_n)+D_1\alpha_n^2 I_2^*\psi_2(\alpha_n)]\} \times\{1-6D_1(R^3\gamma)^{-1}\sum_{n=1}^{\infty}\psi_2(\alpha_n)\}^{-1}; \quad (15)$$

$$\psi_1(\alpha_n) \equiv k_{a1}(c_{10}+D_1\alpha_n^2 I_1^*)(\Gamma_\infty D_1\alpha_n^2-k_{d2})\Delta;$$

$$\psi_2(\alpha_n) \equiv k_{a2}k_{d1}\Delta; \quad \gamma \equiv F_2/F_1;$$

$$\Delta \equiv \{\alpha_n^{-1}\sin(R\alpha_n)-R\cos(R\alpha_n)\}\{\boldsymbol{D}[D_1\alpha_n^2+(F/V)]\}^{-1}.$$

Some Computational Results

Figure 1 shows the time-dependences of the amount of solute in a sphere (where q_∞ is the value in a transfer-equilibrium), with hypothetical values given to the parameters in Eq. 14; Curve a, in the case of an insignificant interfacial resistance ($\Delta F^*_{di}\approx 4$ kcal/mol), and Curve b (where $k_1=(5/6)\times10^{-5}$ cm/s; see Appendix), in the case of a significant interfacial resistance ($\Delta F^*_{di}\approx$

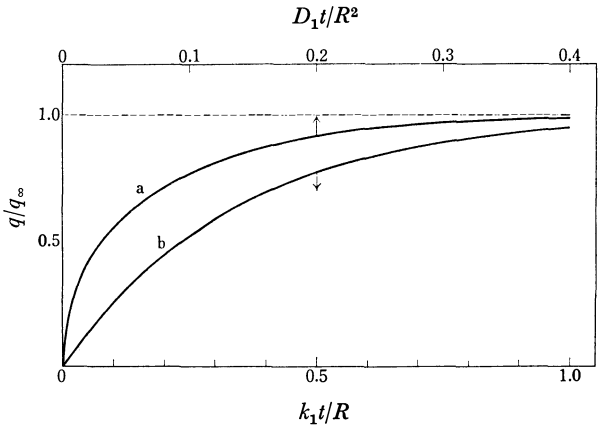

Fig. 1. Change in the amount of solute in a sphere. $D_1=10^{-5}$—10^{-3} cm²/s; $R=1$—0.01 mm.

Curve	a	b[a]
Γ_∞/mol m^{-2}	7×10^{-6}	7×10^{-6}
k_{d1}/mol cm^{-2} s^{-1}	1	1 (5)$\times10^{-9}$
k_{d2}/mol cm^{-2} s^{-1}	1	5 (1)$\times10^{-9}$
k_{a1}/cm s^{-1}	10^1	1 (5)$\times10^{-5}$
k_{a2}/cm s^{-1}	10^1	5 (1)$\times10^{-5}$
$c_{2\omega}$/mol m^{-3}	1	1
c_{10}/mol m^{-3}	0	0
θ_0	0	0

a) The values of k_{d1}, k_{d2}, k_{a1}, and k_{a2} substituted all the figures in the parentheses for ones on the left of the parentheses were also examined.

16 kcal/mol);[5,7] here, $\Delta F^{\ddagger}_{di}$ is the activation free energy of desorption from the interface to the ith phase; the diffusion coefficient, D_1, was changed at intervals from 10^{-5} to 10^{-3} cm^2/s, and the radius of the sphere, R, from 1 to 0.01 mm, in both cases.

The values of the rate constants of adsorption and desorption were given by the following formulas:[1]

$$k_{ai} = \lambda_i(kT/h) \exp(-\Delta F^{\ddagger}_{ai}/RT);$$
$$k_{di} = \Gamma_\infty(kT/h) \exp(-\Delta F^{\ddagger}_{di}/RT);$$

i=1 and 2, where λ_i($\approx$10 Å††) is the length of the adsorption path from the boundary site of Phase i to the interface; $\Delta F^{\ddagger}_{ai}$ is the activation free energy of adsorption from Phase i to the interface; k is the Boltzmann constant; h is the Planck constant; R is the gas constant, and T (=300 K) is the absolute temperature.

The procedure of calculation was as follows. Definite values were assigned to D_1, Γ_∞, R, k_{a1}, k_{d1}, and k_{d2} in Eq. 13, and the roots were found; although the roots, α_m (m=1, 2, ···), were generally complex, they were real[13] in those cases.

The values were assigned to D_1, Γ_∞, R, k_{a1}, k_{a2}, k_{d1}, k_{d2}, c_{10}, $c_{2\omega}$, θ_0, and α_n's ($n \leq 20$ usually suffices for convergence) in Eq. 14, and the amount of solute in the sphere, q, was computed as a function of the time, t. In those cases, $\theta \approx 0.005 \ll 1$, and the q value was computed approximately by the zero perturbation (substitute $c_{1,0}$ and ξ_0 for c_1* and ξ* in Eq. 14 respectively; see also Eqs. 4 and 5).

The computational results fell closely near the curves, a and b, in Fig. 1, in agreement with the values on the curves to the third decimal-digit. This means that, in the above ranges of conditions, the q value may be expressed approximately by the following sublimate relations in the cases of "an insignificant interfacial resistance" and of "a significant interfacial resistance" respectively:

$$q/q_\infty = f_1(D_1t/R^2), \text{ and } q/q_\infty = f_2(t/R),$$

where f_1 and f_2 designate functional relations.

The a curve well fits the next equation[14] of no interfacial resistance:

$$q/q_\infty = 6\pi^{-1/2}(D_1t)^{1/2}/R - 3D_1t/R^2 + \{12(D_1t)^{1/2}/R\} \times \sum_{n=1}^{\infty} \text{ierfc}\{nR/(D_1t)^{1/2}\}. \quad (16)$$

This may be an expression of the functional relation, f_1.

The b curve indicates that the q value in the case of "a significant interfacial resistance" ($\Delta F^{\ddagger}_{di} \approx 16$ kcal/mol) has practically no relation to the diffusion coefficient, D_1. This means that the diffusion process in bulk phases cannot be the rate-determining step under these conditions (see Appendix).

The a, b, and c curves in Fig. 2 predict the changes in the concentration of solute ($c_{2\omega}$) in the continuous phase (aqueous) as functions of F/V, as calculated by means of Eq. 15 (of I_1*=I_2*=0) when a 1 mol/m^3 (c_{20}) aqueous solution of butylamine and a solvent, benzene, was allowed to flow into a stirred vessel in the flow ratio γ=5 (water/benzene) at 50 °C, and the spherical particles of the dispersed phase had radii (R) of exactly 1, 0.1, and 0.01 mm respectively; the other parameters were set as follows: $D_1=3.206\times10^{-5}$ cm^2/s;[15] $\Gamma_\infty=6.83\times10^{-6}$ mol/m^2;[18] $k_{a1}=7.85\times10^3$ cm/s;[7] $k_{a2}=1.089\times10^{-4}$ cm/s;[7] k_{d1}=1 mol/cm^2 s;[7] $k_{d2}=5\times10^{-9}$ mol/cm^2 s;[7] $c_{10}=\theta_0=0$.

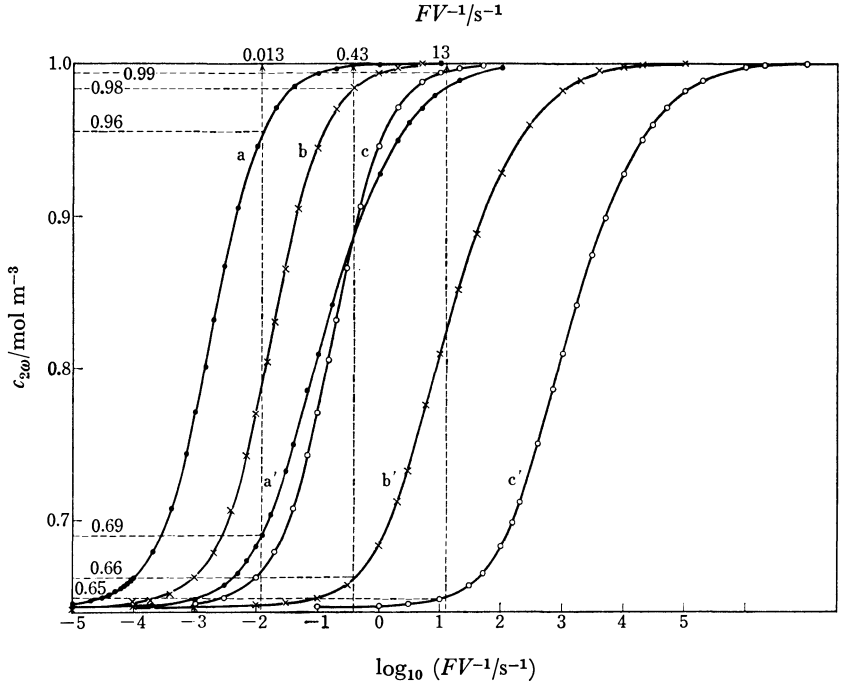

Fig. 2. F/V Dependence of $c_{2\omega}$. Sample: 1 mol/m^3 aqueous solution of butylamine and benzene; γ (water/benzene)=5; temperature=50 °C. a, a′: R=1 mm; b, b′: R=0.1 mm; c, c′: R=0.01 mm.

†† 1 Å=10^{-10} m.

The a′, b′, and c′ curves in Fig. 2 indicate the relation supposing the interfacial resistance was negligible; the two parameters were reset as follows: $k_{a2}=2.178\times10^4$ cm/s and $k_{d2}=1$ mol/cm² s.

An examination of the magnitude of the interfacial resistance may be effectively made under the given conditions provided the F/V ratios are set as 0.013, 0.43, and 13 s^{-1} in experiments with $R=1$, 0.1, and 0.01 mm respectively: If the resistance is significant ($\Delta F^{\neq}_{d2}=18$ kcal/mol), the $c_{2\omega}$ values are determined to be 0.96, 0.98, and 0.99 mol/m³ respectively, while if the resistance be negligible, the $c_{2\omega}$ values are determined to be lower[19] than 0.69, 0.66, and 0.65 mol/m³ respectively.

The author is indebted to Professors Hikoji Inazumi and Tadao Shiba of this Institute for their helpful discussions concerning this subject.

Appendix

When the transfer resistance in the bulk phases is negligible as compared with the interfacial resistance, the next equation may be derived as a specific case of Eq. 14, neglecting also the variation in the amount of adsorption on the interface:[1,3]

$$q = q_\infty - (q_\infty - q_0)\exp(-3k_1 t/R); \quad (17)$$
$$k_1 \equiv k_{a1}\{1+(k_{d1}/k_{d2})\}^{-1},$$

where q_0 is the initial amount of solute in a sphere and k_1 is the effective rate constant for transferring through the interface from Phase 1 to Phase 2. Equation 15 may then be simplified as follows:

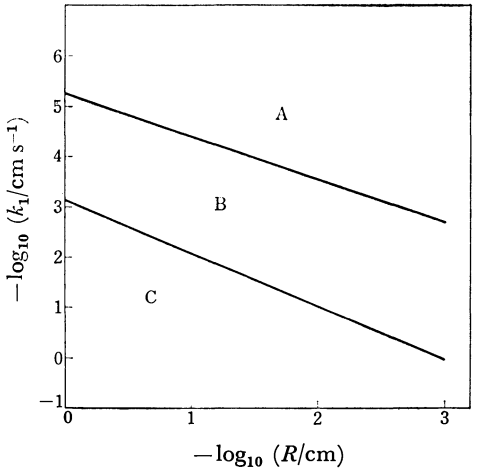

Fig. 3. Limits of application of the specific equations. $D_1=10^{-5}$ cm²/s; $q/q_\infty=0.5$. A: Bulk-diffusional resistance is negligible (Eq. 17 is applicable). B: Neither bulk-diffusional nor interfacial resistance is negligible. C: Interfacial resistance is negligible (Eq. 16 is applicable).

$$c_{2\omega} = (c_{10}+c_{20}H)(K+H)^{-1}; \quad (18)$$
$$H \equiv \gamma\{1+(R/3k_1)(F/V)\};\ K \equiv (k_{a1}k_{d2})^{-1}k_{a2}k_{d1}.$$

The computational values using these formulas also fit well the b curve in Fig. 1 and the a, b, and c curves in Fig. 2.

Figure 3 shows the limits of the application of Eqs. 16 and 17 to pairs of values of k_1 and R at $D_1=10^{-5}$ cm²/s. The lines indicating the limits were drawn on the assumption that every pair of k_1 and R on the lines made the q value computed by means of the specific equations (Eq. 16 or 17) deviate from that computed by means of Eq. 14 exactly 5% at the time of q/q_∞(Eq. 14)$=0.5$;[20] these lines should be considered to give a sort of standard, and the change in the time, t, as well as in the diffusion coefficient, D_1, transfers the position of the 5% lines.

18) This is equivalent to the value of $B=24.3\times10^{-16}$ cm²/molecule cited in the literature of Ref. 7.
19) It is considered that the apparent diffusion coefficient is greater than the value estimated because of agitations.
20) Change in the values of the rate constants of adsorption and desorption on condition that $k_1=$const, $k_{a1}/k_{d1}=$const, and $k_{a2}/k_{d2}=$const gives practically constant q's computed by Eq. 14, agreeing to the third decimal-digit.

The Electronic Spectra of Anthraquinone in Shpol'skii Matrices and in Crystals at 4.2 K

Eiji KANEZAKI,† Nobuyuki NISHI, and Minoru KINOSHITA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received March 28, 1979)

The lower excited singlet and triplet states of 9,10-anthraquinone-d_0 and -d_8 are examined in normal alkanes and in crystals at 4.2 K with the phosphorescence excitation method. The $S\leftarrow S_0$ and $T\leftarrow S_0$ excitation spectra are analyzed by considering environmental effects on and isotopic changes in the vibrational structure. The low energy region of the spectra can be explained without taking the A_u origin in close proximity of the B_{1g} origin into account. The latter origin band in the singlet and triplet spectra in hexane and in crystals, respectively, is weaker by a factor of 10^{-3}—10^{-2} than the strongest vibronic band in the respective regions. No clear evidence has been found about the location of the singlet and triplet A_u states in the excitation spectra.

The investigation of the energy separation between the two low lying n,π^* states of quinones has attracted much interest,[1–8] because its determination measures the magnitude of the electronic interaction of the nonbonding orbitals. In a *p*-quinone molecule, only the through bond interaction is dominant, as in the cases of pyrazine and quinoxaline,[9] in which the two interacting nonbonding orbitals are concluded to have an energy separation of the order of 1 eV ($\simeq$8067 cm^{-1}), in good agreement with the theoretical calculation.[9,10]

Although there is a discrepancy in the assignment of the He-I photoelectron spectrum of *p*-benzoquinone between the two groups,[2,10,11] the energy levels of the two nonbonding orbitals are separated by 0.9[10] or 0.3 eV.[2,11] The Coulomb integrals for the n_+,π^* and n_-,π^* states, J_{n_+,π^*} and J_{n_-,π^*}, may differ from each other and modify the energy separation between the two zero-order n,π^* states. From the absorption experiments on *p*-benzoquinone crystals, the separation has been reported to be about 225 cm^{-1} in the singlet state[3] and 320 cm^{-1} in the triplet state.[6] Recently Goodman and Brus[12] have examined excitation spectra of *p*-benzoquinone in a neon host. They could not observe the broad band, which had been assigned to a different electronic origin, but observed very strong origin bands which they assigned to the ^1A_u and ^3A_u states. Their conclusion is that the two n,π^* states are nearly degenerate in *p*-benzoquinone. Although we do not agree with their conclusion, because they did not consider the possibility of a structural change induced by the host, their results give us very important information about the assignment of the two origins.

The assignment of the lowest triplet state of anthraquinone (AQ) has also attracted much attention from many workers.[13–17] The polarization measurement indicates that the phosphorescence of AQ has the transition dipole moment along the oxygen-oxygen direction(z).[13] Thus, it is concluded that the radiative transition from the lowest triplet state of AQ borrows its activity from the z axis polarized $^1B_{1u}(\pi,\pi^*)\rightarrow{}^1A_g$ transition.

The phosphorescence spectrum of AQ in hexane is known to arise from the $^3B_{1g}(n,\pi^*)\rightarrow{}^1A_g$ transition. The AQ molecules in this matrix seem to retain the inversion symmetry, because the 0,0 band is missing.[17] On the other hand, the spectrum in pentane was analyzed to be a two-site emission. One of the sites produces a strong origin band induced by breakdown of the inversion symmetry.[17]

The $T\leftarrow S_0$ absorption spectrum of crystalline AQ has been obtained and the Zeeman experiment has been performed on the individual bands in the spectrum. From the very weak intensity and the Zeeman patterns of the 0,0 band, the lowest triplet state of AQ is assigned to $^3B_{1g}(n,\pi^*)$, which is located at 22154 cm^{-1} [14] or at 22150 cm^{-1}. [15] The vibronic bands appearing in the spectrum are ascribed to the ungerade-type vibrations, since the inversion symmetry of the molecule is conserved even in the crystal.[18]

The purpose of this work is to analyze the excitation spectra of AQ-d_0 and AQ-d_8 in the above two Shpol'skii matrices and to find evidence for the location of the A_u state. We will also discuss the structure of the $T\leftarrow S_0$ excitation spectra of both isotope crystals.

Experimental

9,10-Anthraquinone (AQ-d_0) and spectrograde hexane were purchased from Tokyo Kasei Co., Ltd. Merck Uvasol pentane was used without further purification. 2,3-Dichloroquinoxaline (DCQ) and 9,10-anthraquinone-d_8 (AQ-d_8) were from Eastman Kodak and Merck Sharp and Dohme Ltd., respectively.

An Ushio UXL-1000DO 1 kW xenon lamp was used as a light source for excitation and absorption experiments. A Molectron DL-200 tunable dye laser equipped with a Molectron UV-1000 1 MW N_2 laser was used to detect the origin bands in the $T\leftarrow S_0$ excitation spectra. Most of the high resolution spectra were observed through a Jobin Yvon HR 1000 monochromator fitted with a 1800 grooves/mm, 120 $\times$ 140 mm^2 grating, and a Spex 1700-III 3/4 m or a Bausch & Lomb 1/2 m monochromator was used to isolate a specific band of emission for excitation studies or microwave experiments.

Results and Discussion

Phosphorescence. The spectra of AQ-d_0 in hexane and pentane showed sharp bands. These spectra were essentially the same as those reported by Khalil and Goodman.[17] The high resolution spectra of AQ-d_8 in these matrices are shown in Fig. 1. We could detect

† Present address: Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770.

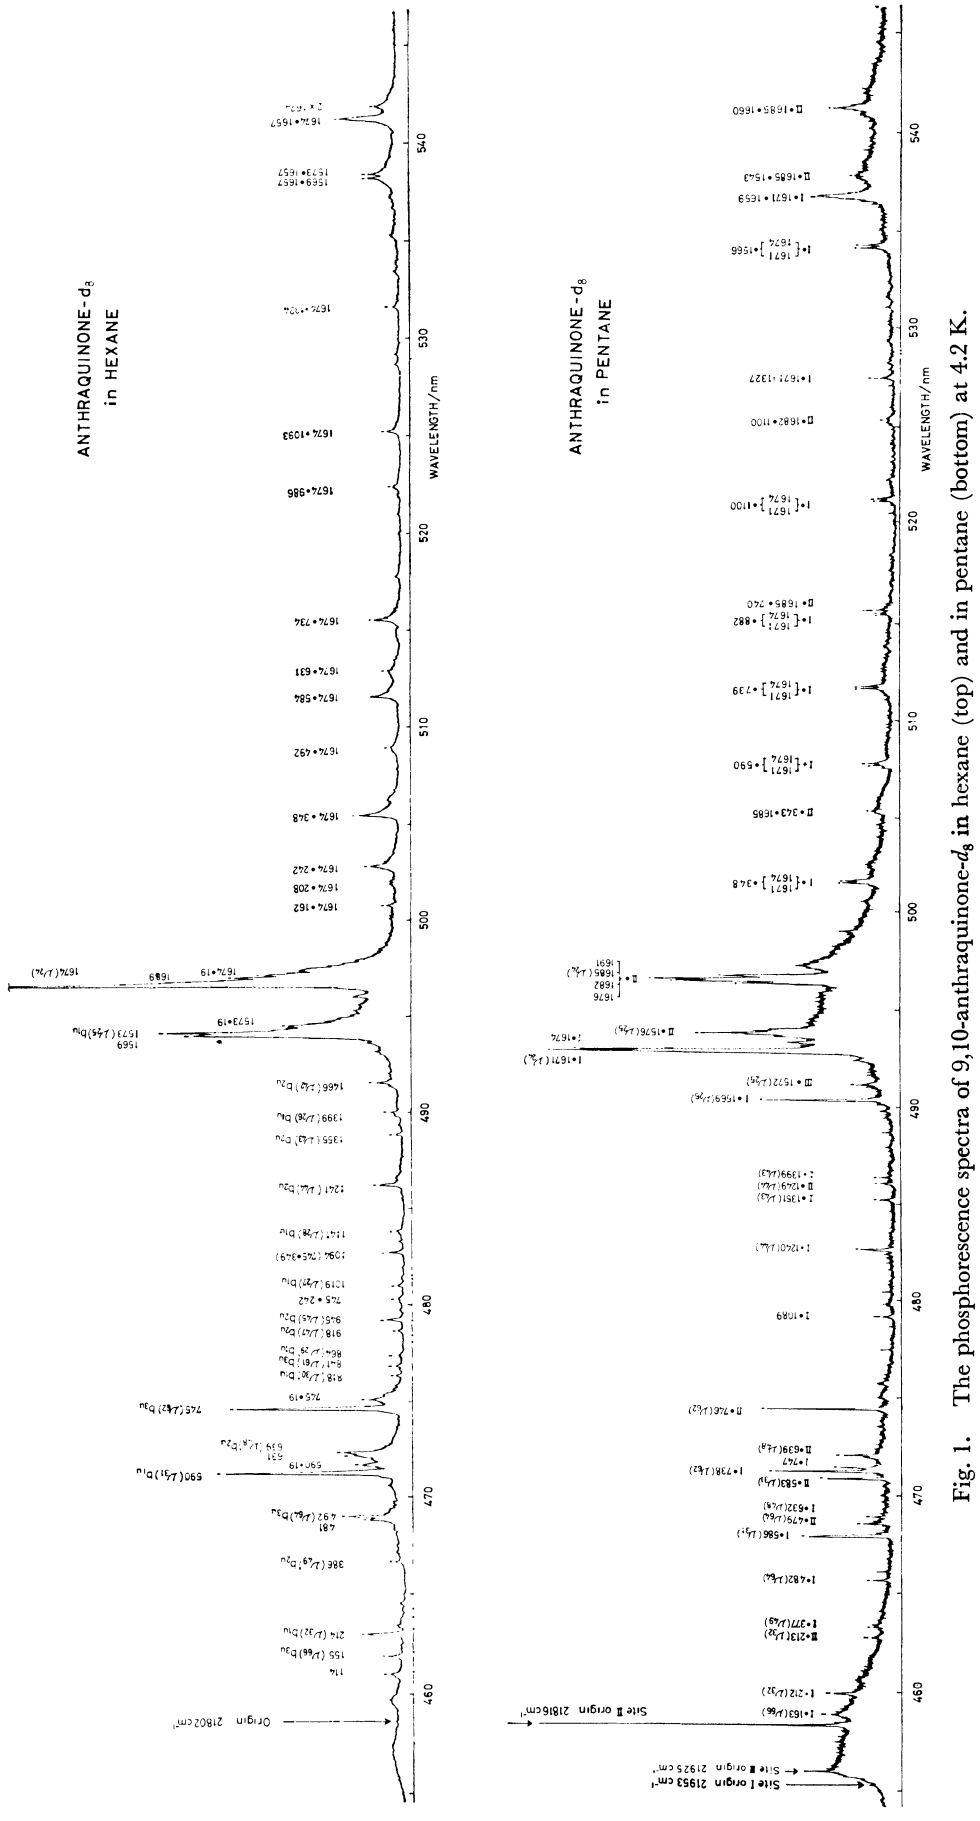

Fig. 1. The phosphorescence spectra of 9,10-anthraquinone-d_8 in hexane (top) and in pentane (bottom) at 4.2 K.

the origin band at 21802 cm^{-1} in hexane, the intensity of which was about 10^{-3} of that of the strongest band assigned as being due to the b_{1u} C=O stretching vibration(ν_{24}). This vibronic band has a single peak and is accompanied with a broad tail towards the low energy side. This feature is also seen in its combination bands with totally symmetric vibrations. The shape of this tail is apparently different from that seen in the band at 0—745 cm^{-1}. The band assigned to ν_{25} shows a doublet structure at 0—1569 and 0—1573 cm^{-1}. Most of the b_{1u} and b_{2u} vibrations, except for the two C–D stretching modes, are found in the spectrum.

Three-site emission is observed in pentane at 4.2 K. Most of the active bands were analyzed to be bands originating from two sites. The emission from site I has a very, very weak origin at 21953 cm^{-1}. The vibrational structure is almost the same as that in hexane. The origin band of the emission from site II reveals the strongest intensity in the spectrum. The energy of this origin band is close to that in hexane. The most intense vibronic band due to ν_{24} splits into two lines for site I and into four or more for site II. The combination bands with a_g vibrations show a similar band shape, which is very helpful for the analysis.

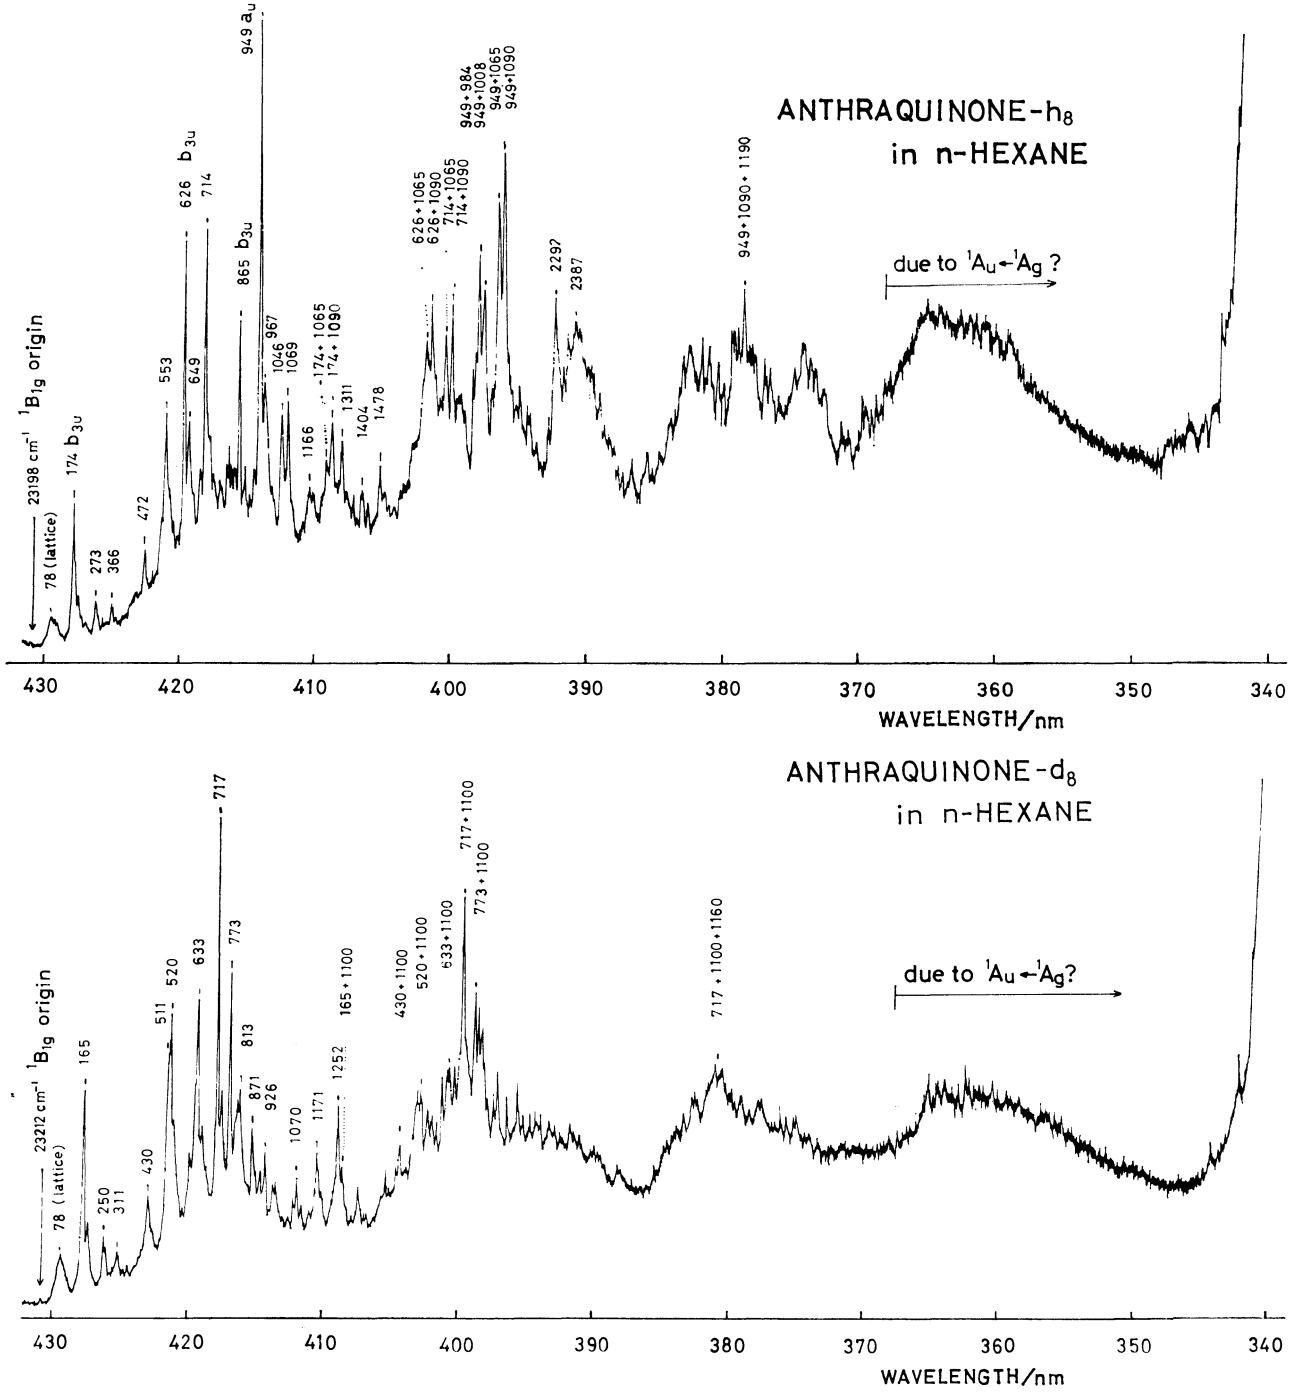

Fig. 2. The S←S_0 excitation spectra of 9,10-anthraquinone-d_0 and -d_8 in hexane at 4.2 K. Detection bandwidth is 4 nm centered at 497 nm.

The band width of the site II origin is about 2 cm^{-1} and those of other bands are generally much narrower in pentane than those in hexane. In spite of the very strong intensity of the origin band of site II, no other a_g fundamental band shows distinguishable activity in the spectrum. This indicates that any distortion of the site II molecules is not very large.

$S(n,\pi^*)\leftarrow S_0$ Excitation. The two n,π^* states in question are $^1B_{1g}$ and ^1A_u in the low energy region of AQ. The transitions from the ground state to both of these n,π^* states are symmetry forbidden processes, and would become allowed by borrowing intensities mainly from $^1B_{1u}(\pi,\pi^*)\leftarrow{}^1A_g$ and $^1B_{2u}(\pi,\pi^*)\leftarrow{}^1A_g$ transitions through u-type out-of-plane vibrations for the transition to the $^1B_{1g}$ state and g-type vibrations for that to the ^1A_u state, or by molecular distortion to a lower symmetry.

Spectra in Hexane: The excitation spectra of AQ-d_0 and -d_8 in hexane are shown in Fig. 2. A very, very weak but distinct band at 23198 cm^{-1} in the spectrum of AQ-d_0 and at 23212 cm^{-1} in that of AQ-d_8 was observed in the hexane matrix. The vibrational structures were analyzed by taking these bands as an electronic origin and the results are given in the figure.

The spectrum of AQ-d_0 has a structure quite similar to that of crystalline *p*-benzoquinone observed by Trommsdorff.[3] The bands in the spectra of AQ-d_0 and *p*-benzoquinone exhibit a good correspondence with each other, except for the strong bands, which have been assigned to the $^1B_{1g}$ and ^1A_u origins of *p*-benzoquinone. The strongest band in the *p*-benzoquinone spectrum is the one at 0+946 cm^{-1}. The corresponding band also appears as the strongest band in the AQ-d_0 spectrum in hexane at 0+949 cm^{-1}. Other bands seen in the *p*-benzoquinone spectrum at 0+141, 0+597, 0+679, 0+836, 0+1044, 0+1069, and 0+1161 cm^{-1} correspond well to the bands at 0+174, 0+553, 0+626, 0+865, 0+1046, 0+1066, and 0+1166 cm^{-1}, respectively, in the spectrum of AQ-d_0. These frequencies are surprisingly closely related to each other. In the case of AQ-d_0, however, there is no strong band in the lower energy region which corresponds to the strong broad band assigned as the ^1A_u origin of *p*-benzoquinone.

The broad band at 0+78 cm^{-1} and the sharp band at 0+174 cm^{-1} of AQ-d_0 correspond well with the first two vibrational bands of AQ-d_8 at 0+78 and 0+165 cm^{-1} in their intensity and frequency. The corresponding bands are also observed in the phosphorescence spectra of AQ-d_0 and -d_8 in hexane (at 0*−76 and 0*−167 cm^{-1} for AQ-d_0, where 0*=21783 cm^{-1}) and assigned to a lattice mode and a b_{3u} out-of-plane vibration, respectively.[17] The vibration of 141 cm^{-1} found in the spectrum of a *p*-benzoquinone crystal was also assigned to a b_{3u} skeletal mode by Trommsdorff.[3] The appearance of the b_{3u} vibration clearly indicates that these bands are associated with the $^1B_{1g}\leftarrow{}^1A_g$ transition.

The spectra of the two isotopes show different structures in the region from 0+500 to 0+1200 cm^{-1} mainly in their intensity relation. The strongest band of AQ-d_0 at 0+949 cm^{-1} shifts to 0+717 cm^{-1} for AQ-d_8. This frequency lowering by about 230 cm^{-1} excludes an assignment of these bands to vibrations belonging to another electronic state. The isotopic ratio of 1.32 (=949/717) indicates that these vibrations are to be assigned to a C–H(D) bending mode. Considering the assignment of the 946 cm^{-1} vibration of *p*-benzoquinone,[3] we also assign the 949 cm^{-1} vibration tentatively to an a_u out-of-plane C–H bending vibration. However, we could not eliminate the possibility of a b_{3u} vibration, because the band observed at 970 cm^{-1}

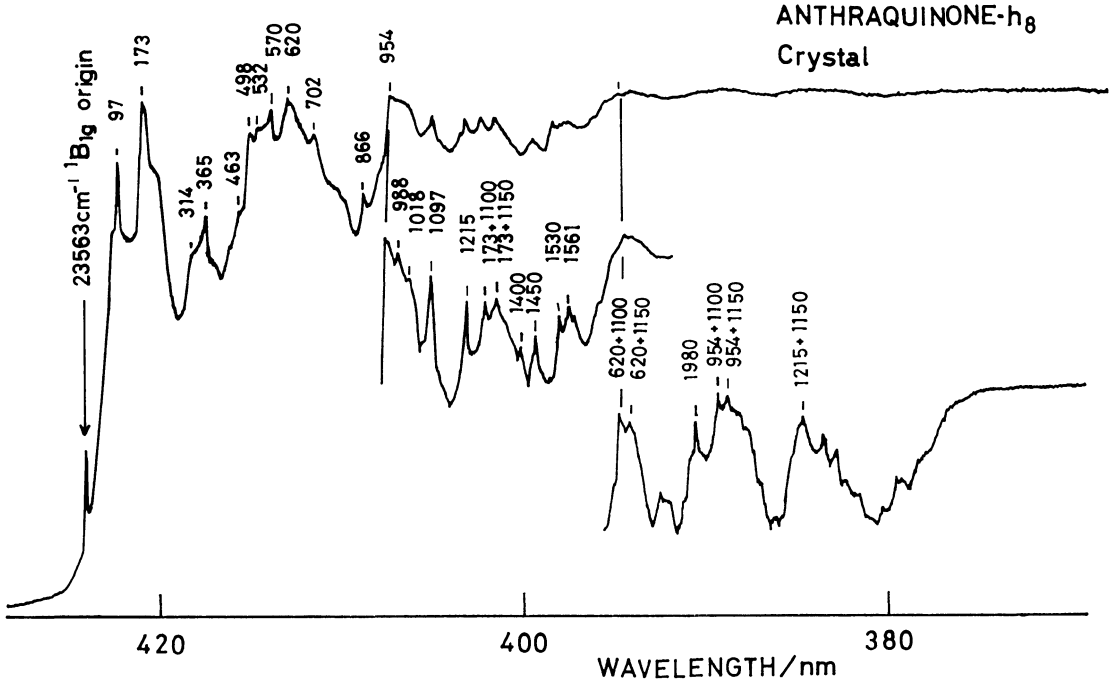

Fig. 3. The $S\leftarrow S_0$ absorption spectrum of crystalline 9,10-anthraquinone-d_0 at 4.2 K.

in the infrared spectrum was assigned to ν_{61}, a b_{3u} C–H bending mode.[18]

Other strong bands of AQ-d_0 at 0+553, 0+626, 0+714, and 0+865 cm^{-1} correspond with those of AQ-d_8 at 0+511, 0+520, 0+633, and 0+813 cm^{-1}, respectively. The combination bands of these strong lines with the 1065 and 1090 cm^{-1} vibrations of AQ-d_0 and the 1100 cm^{-1} vibration of AQ-d_8 are found strongly and this proves that these bands do not belong to a different electronic transition. Such combination bands were also observed in the spectrum of a *p*-benzoquinone crystal by Trommsdorff,[3] who assigned the 1100 cm^{-1} vibration as being due to the totally symmetric C=O stretching vibration.

Spectrum of Neat Crystal: The absorption spectrum of the AQ-d_0 crystal is shown in Fig. 3. The origin band was observed at 23563 cm^{-1}, which is about 360 cm^{-1} higher in energy than the $^1B_{1g}$ origin in hexane. The

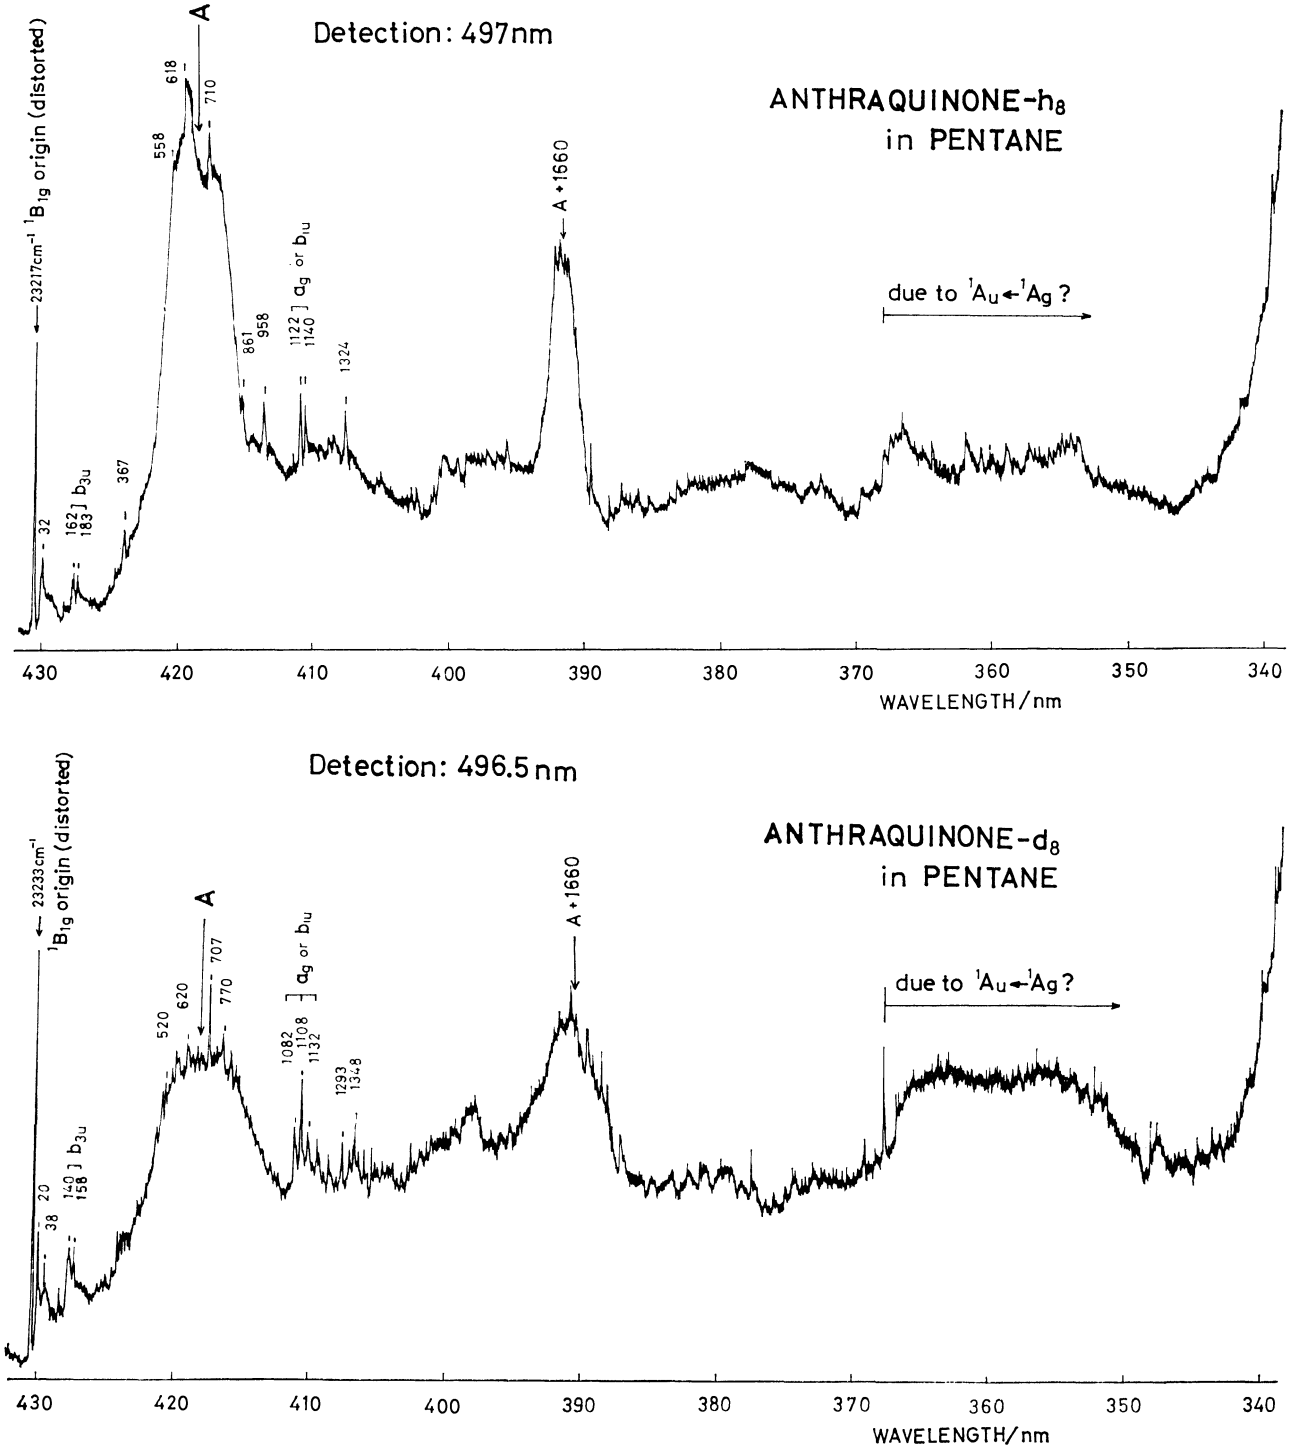

Fig. 4. The S←S_0 excitation spectra of 9,10-anthraquinone-d_0 and -d_8 in pentane at 4.2 K. Detection bandwidth is 5 nm centered at 497 nm.

band at 0+97 cm^{-1} corresponds with a lattice mode. and the band at 0+173 cm^{-1} to the b_{3u} mode found in the hexane system. The vibrational structure of the strong bands in this spectrum coincides quite well with that in hexane. Combination bands with a_g vibrations of 1100 and 1150 cm^{-1} are also active in the crystal.

Spectra in Pentane: The excitation spectra of AQ-d_0 and -d_8 in pentane were observed by monitoring the strong bands around 497 nm of the phosphorescence from site II with a detection bandwidth of 4—5 nm The observed spectra in Fig. 4 show a strong origin band to the higher energy side by about 20 cm^{-1} with respect to the origin band in hexane. The appearance of the strong origin band is consistent with that observed at 21790 cm^{-1} for AQ-d_0 and at 21816 cm^{-1} for AQ-d_8 in the phosphorescence in pentane. Therefore, we are really observing the same species with a distorted structure.

Apart from the intense broad bands around 420 and 390 nm, which will be shown to be due to molecular aggregates, the spectra consist of a number of sharp bands and a hump around 365 nm. The sharp bands in the lower energy region may be classified into two groups. One of the groups consists of the bands which correspond to those found in the hexane system; these bands can be assigned to b_{3u} and a_u vibrations. Since the fundamental frequencies measured from the origin band fit quite well to those observed in hexane, there is no possibility that these bands belong to the $^1A_u \leftarrow {}^1A_g$ transition which could be observed for the distorted species. If the bands belonging to the $^1A_u \leftarrow {}^1A_g$ transition appeared in the same region, the vibrations should be assigned to b_{1g} or b_{2g} symmetry.

The bands in the other group are characteristic of a distorted species, for which a_g and b_{1u} in-plane vibrations may show some activity. The bands appearing around 0+1100 cm^{-1} do not have a corresponding band in the spectrum in hexane. The vibration of about 1100 cm^{-1} is known to form combination bands with b_{3u} and a_u vibrations in hexane and is assigned to the a_g C=O stretching vibration. The b_{1u} C=O stretching vibration is also expected to acquire activity, if the molecular symmetry is reduced by the environment to C_{2v} with the C_2 axis along the C=O bonds.

In pentane, the phosphorescence emission shows strong sharp bands overlapping a very broad background. The broad background was assigned to molecular aggregates.[17] As a matter of fact, the strong broad bands also appear at 420 and 390 nm in the excitation spectra monitored at 497 nm. The position and relative intensity of the broad band around 420 nm were found to change markedly when the wavelength setting of the detecting monochromator was changed; some examples are shown in Fig. 5. The energy shift of the band center seems to be just equivalent to the difference in the wavelength of the monitored light. Furthermore, the intensity of the broad band relative to that of the origin band at 23217 cm^{-1} also changes with cooling condition of the sample and initial guest concentration. The spectra of the two isotopes in Fig. 4 were taken at the concentrations differing by a factor

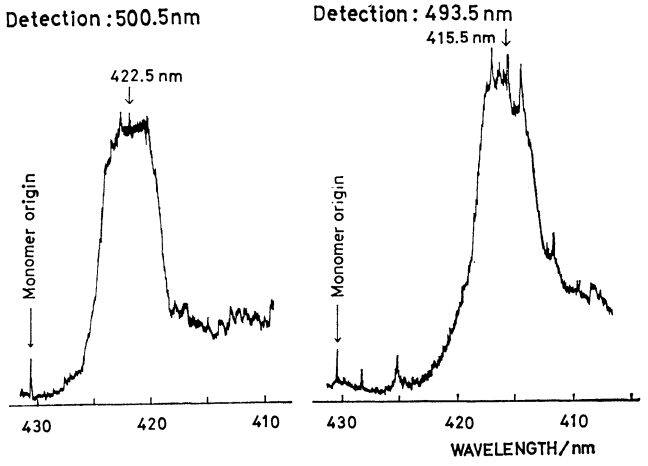

Fig. 5. Variation of the broad band position in the excitation spectrum with detection wavelength of the emission from anthraquinone-d_0 in pentane at 4.2 K.

of three. These results suggest that the broad band around 420 nm arises from molecular aggregates. The broad band around 390 nm (about 1660 cm^{-1} higher in energy) seems to be its combination band, although the bandwidth is about half.

The $^1A_u \leftarrow {}^1A_g$ Transition: It was expected that the forbidden $^1A_u \leftarrow {}^1A_g$ transition would appear in the excitation spectrum in pentane, when the phosphorescence from the distorted species was monitored. For this purpose, we have carefully adjusted the detecting monochromator to a desired wavelength. In this respect, it is of great interest to pay attention to the sharp band appearing at 367.65 nm in the excitation spectrum of AQ-d_8 in pentane. The band lies at 4033 cm^{-1} from the strong origin and could not be assigned to a combination band or an overtone band. Furthermore, the hump with weak but sharp bands is commonly found around 365 nm in all the four spectra in Figs. 2 and 4. As the $^1B_{1g}$ origin lies within 35 cm^{-1} in the four systems, the origin of the $^1A_u \leftarrow {}^1A_g$ transition in these systems is also expected to appear at nearly the same position. The region where the hump is observed clearly satisfies this condition. The sharp band at 367.65 nm in the spectrum of AQ-d_8 is quite within the reasonable bounds of possibility of the ^1A_u origin. A weak similar band is also seen at 367.7 nm in the spectrum of AQ-d_0 in pentane.

$T(n,\pi^*) \leftarrow S_0$ Excitation. A mixed crystal of AQ with 0.1% of 2,3-dichloroquinoxaline (DCQ) emits a strong phosphorescence from the lowest triplet state of DCQ. The vibrational structure of the phosphorescence spectrum is in good agreement with the result reported by Tinti and El-Sayed.[19] The excitation spectrum of crystalline AQ was observed by monitoring this emission. The spectra for the AQ-d_0 and -d_8 crystals are shown in Fig. 6. The excitation spectrum of AQ-d_0 is essentially the same as the absorption spectrum reported by Drabe *et al.*[14] and Narisawa *et al.*,[15] except for minor details. Carefully comparing the spectra of the two isotopes, we could notice a structural difference around 443 nm. AQ-d_8 shows an intensity increment of the broad band around 0+327 cm^{-1}. Another obvious

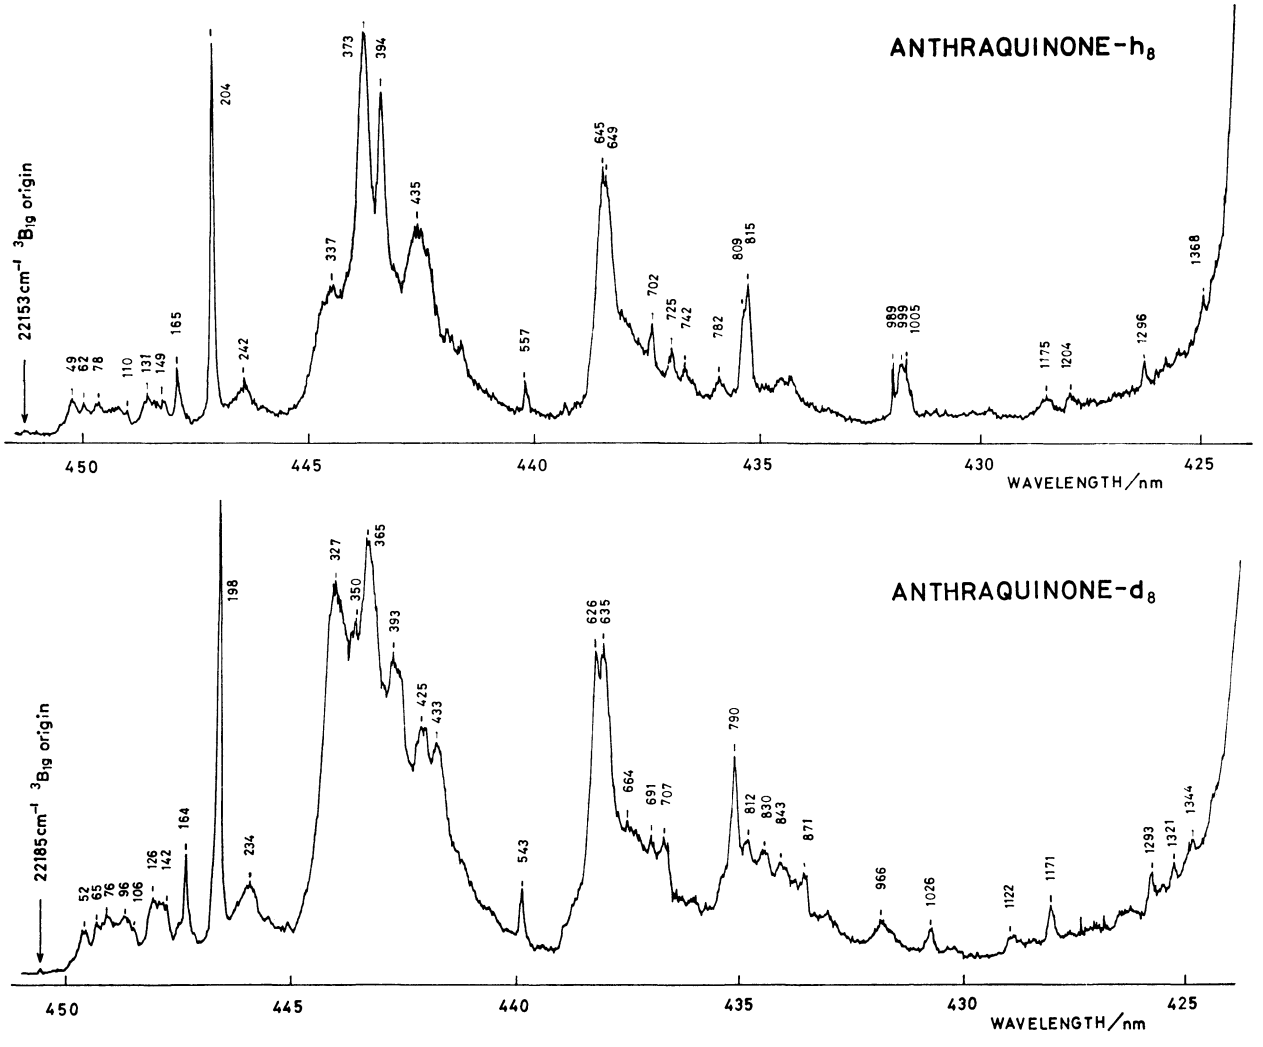

Fig. 6. The T←S_0 excitation spectra of crystalline 9,10-anthraquinone-d_0 (top) and -d_8 (bottom) at 4.2 K. The whole phosphorescence from the doped 2,3-dichloroquinoxaline was monitored.

difference can be found around 0+830 and 0+1000 cm^{-1}. This difference can be attributed to an isotopic frequency shift of vibrations, thereby suggesting some participation of hydrogen bending vibrations in the transition mechanism.

MIDP Excitation Spectra: Since each of the transitions from the ground state to the three spin states in a single vibronic level of an excited triplet state has a different selection rule, depending on the spin-orbit coupling processes involved, microwave induced delayed phosphorescence (MIDP)[20] signals in an isolated molecule reflect the transition probability characteristic of each sublevel excitation. In a mixed crystal, however, the selective populations of the spin states are sometimes not maintained during energy transfer processes, and MIDP signals show a modified spin population depending on the relative orientations of the molecular spin axes between the guest and host and between the host molecules.[20,21]

The short axes(z) of the AQ molecules in a crystal are nearly parallel to each other, but the long axis(y) of an AQ molecule is approximately parallel to the normal axis(x) of the translationally inequivalent molecules.[22] In the mixed crystal of AQ with DCQ, it is reasonably assumed that the guest molecules replace the host molecules substitutionally. Therefore, it is expected that the population of T_z produced in DCQ by direct T←S_0 excitation of the mixed crystal may not be affected very much by energy transfer and trapping processes, whereas the populations of T_y and T_x may or may not mix with each other depending on whether the main energy transfer mechanism is one-dimensional or not. A single band excitation of the AQ-d_0 crystal yielded the steady state population ratios of $N_z: N_y: N_x$ to be approximately 1.9: 2.1: 1 for the 0+165 cm^{-1} band and 5.5: 0.55: 1 for the 0+204 cm^{-1} band. From these results, it was concluded that the mechanism is mainly one-dimensional and that the mixing of the populations of T_y and T_x during the energy transfer has a minor effect on the relative populations in our systems.

The excitation spectrum shown in the upper part of Fig. 7 was taken by sampling the DCQ phosphorescence in the AQ-d_8 crystal for a period of 110 ms just after excitation lasting 30 ms. The repetition rate was 2 Hz. Since the decay times of T_z, T_y, and T_x were observed

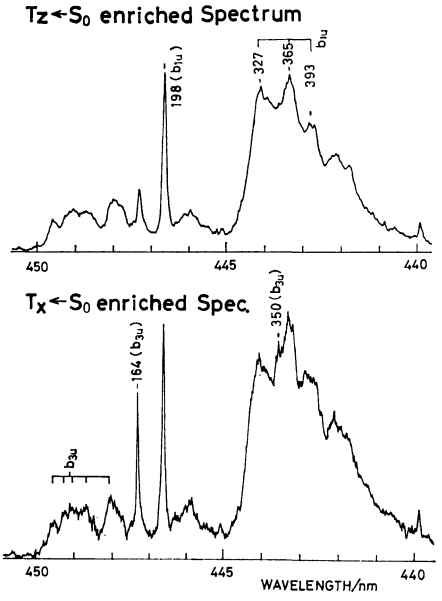

Fig. 7. The $T\leftarrow S_0$ excitation spectra of crystalline 9,10-anthraquinone-d_8 at 1.4 K. The absorption to T_z is enhanced in the upper spectrum by choosing the sampling time, while that to T_x is enhaced in the lower spectrum by using microwave modulation.

to be 150, 260, and 2700 ms, respectively, this spectrum contains an enhanced contribution from the $T_z\leftarrow S_0$ transition of AQ-d_8, by comparison with an excitation spectrum taken under steady state condition.

The lower spectrum of Fig. 7 is an MIDP excitation spectrum taken by sampling only the portion of the MIDP signal on sweeping the microwave frequency through the $T_y\leftrightarrow T_x$ transition of DCQ 950 ms after excitation. The microwave sweep increases the T_y emission in proportion to the population of T_x produced mostly by the $T_x\leftarrow S_0$ transition of the host molecules The assignments of the vibronic bands were performed according to the selection rule that a b_{1u} vibration is actively involved in the excitation to the T_z sublevel in the $^1B_{1g}$ state and a b_{3u} vibration is involved in the excitation to the T_x sublevel. Some of the results are shown in Fig. 7.

The sharp band at $0+164\ cm^{-1}$ is notably enhanced by the $T_y\leftrightarrow T_x$ pumping and assigned to a b_{3u} vibration. The vibration of $165\ cm^{-1}$ has also appeared in the $S\leftarrow S_0$ excitation spectrum of AQ-d_8 in hexane. This was assigned to the $\nu_{66}(b_{3u})$ mode. The intensity of the band at $0+350\ cm^{-1}$ is markedly increased by the $T_y\leftrightarrow T_x$ pumping, and this band can be assigned to a b_{3u} vibration. At first sight, the broad bands at $0+365$ and $0+393\ cm^{-1}$ also seem to be intensified by the microwave transition, but this could be due to their overlapping with the band at $0+350\ cm^{-1}$. The broad low frequency bands which should be considered as being due to lattice modes behave like b_{3u} vibrations. Murao and Azumi[23] also found that the fundamental lattice band is exceedingly active in the emission spectrum from the T_x sublevel of AQ-d_0 in octane.

Except for several broad bands around $0+400\ cm^{-1}$, most of the strong bands in Fig. 6 were assigned on the basis of the relation of the isotopic ratio of the vibrational frequency and the relative intensity found in the phosphorescence spectra of both isotopes in hexane and in octane.[23] The fundamental frequencies obtained are summarized in Table 1, together with those found in the emission[17] and in the infrared absorption spectra.[18] The frequency changes of these vibrations in the $^3B_{1g}$ state are not very large, except for the C–H(D) bending mode(ν_{45}), which shows a frequency reduction of 16—17 per cent.

The antisymmetric C=O stretching mode(ν_{24}) and the out-of-plane C–H bending mode(ν_{63}) are found to be active in the phosphorescence spectrum.[17] However, we are not certain whether these vibrations appear in the $T\leftarrow S_0$ excitation spectrum. If the frequency of ν_{24} is increased for any reason in the $^3B_{1g}$ state or is decreased by less than 16 per cent, then the vibronic band due to ν_{24} would be hidden in the region of $S\leftarrow S_0$ absorption. The symmetric C=O stretching mode(ν_3) of about 1100 cm^{-1} is known to form several combination bands in the $S\leftarrow S_0$ excitation in hexane, as discussed above. Therefore, we may also expect the appearance of its combination bands in the $T\leftarrow S_0$ excitation spectrum. The band appearing at $0+1295\ cm^{-1}$ might be attributed to a combination band with the ν_{32} mode. However, this band seems to be too weak to be assigned to the combination band of ν_3.

Any strong vibronic interaction between the $^3B_{1g}$

Table 1. The vibrational frequencies observed in the $^3B_{1g}\leftarrow{}^1A_g$ excitation spectra of the anthraquinone crystals with the corresponding frequencies found in the phosphorescence spectra in hexane and in the infrared absorption spectra of crystals

and ^3A_u states through the ν_{24} mode would have a possibility of causing a frequency shift of this vibration. The strong band at $0+373\ cm^{-1}$ for AQ-d_0 and at $0+365\ cm^{-1}$ for AQ-d_8 might be considered to be due to ν_{24} of reduced frequency, as a result of the pseudo-Jahn-Teller effect. However, the PMDR studies of *p*-benzoquinone[24] and AQ-d_0[23] did not demonstrate any detectable molecular distortion along the b_{1u} coordinate. These results are therefore consistent with the fact that the origin band is vanishingly weak in the excitation spectra of the AQ crystals and in the emission spectra of AQ-d_0 and -d_8 in hexane. The frequency reduction from $1676\ cm^{-1}$ in the ground state to 373 (or 365) cm^{-1} in the $^3B_{1g}$ state would be too large to explain the absence of molecular distortion along the b_{1u} direction. The above discussion suggests that the frequency of the ν_3 vibration and possibly that of the ν_{24} vibration are higher than $1100\ cm^{-1}$ in the $^3B_{1g}$ state.

The Broad Band Cluster: Drabe *et al.* assigned the center of the broad band cluster from 445 to 441 nm (*i.e.*, $22560\pm10\ cm^{-1}$) as the origin of the ^3A_u state.[14] Instead of taking the origin at the center of the cluster, the strongest band position may be a more adequate choice for the origin, that is, $22526\ cm^{-1}$ ($0+373\ cm^{-1}$) for AQ-d_0 and $22550\ cm^{-1}$ ($0+365\ cm^{-1}$) for AQ-d_8. This assignment was proposed mainly from analogy with the absorption spectrum of a *p*-benzoquinone crystal, which exhibited a strong broad absorption at $320\ cm^{-1}$ to the higher energy side from the $^3B_{1g}$ origin. However, this broad band assigned as the ^3A_u origin was not found in the excitation spectrum of the isolated *p*-benzoquinone molecule in a neon matrix.[12] Goodman and Brus concluded that this broad band might be vibronic absorption induced by the environment.[12] Therefore, it seems that the assignment of the cluster is still inconclusive. The cluster may be interpreted in several ways.

In the first place, we examine the possibility that the ^3A_u origin may be in the cluster and the vibronic bands thereafter would belong to the $^3A_u \leftarrow {}^1A_g$ transition. In this case, a vibronic band is expected to have a band shape similar to that of the origin, because the ^3A_u origin band has an allowed character and coupling with a non-totally symmetric phonon is not expected in this transition. The shapes of the clusters are different in the spectra of the two isotopes, although the spectral positions of the clusters are coincident. Therefore, the vibrational bands coupled with the origin band would give rise to a more complex spectrum for AQ-d_8 than for AQ-d_0. The observed spectrum of AQ-d_8, however, does not include such a complicated structure and the difference between the two spectra is thus attributed to the involvement of C–H(D) bending vibrations. This cluster does not seem to behave as an origin in the spectrum.

The second case is that the strongest band in the cluster would be assigned to the ^3A_u origin as before, but the vibronic bands in the cluster are built on the $^3B_{1g} \leftarrow {}^1A_g$ transition and are induced by a strong interaction between the vibronic levels in $^3B_{1g}$ and the ^3A_u origin. In this case, the fact that the intensity of the band at $0+327\ cm^{-1}$ is comparable with that at $0+365\ cm^{-1}$ in the spectrum of AQ-d_8 indicates that the coupling should be very strong in AQ-d_8. However, the intensity of the corresponding band at $0+337\ cm^{-1}$ in the spectrum of AQ-d_0 is less than half of that of the strongest band at $0+373\ cm^{-1}$ and the energy gap between the two bands is nearly the same as that for AQ-d_8. This fact probably eliminates the possibility that the strong interactions exist between the vibrational levels in $^3B_{1g}$ and the ^3A_u origin.

Thirdly, the coupling of a vibronic band with phonon modes may be considered. Vibrational frequencies of 350—450 cm^{-1} correspond to those of in-plane C=O bending vibrations in the ground state. A b_{2u} mode is found at $387\ cm^{-1}$ in the infrared absorption spectrum and assigned to ν_{49}.[18] A Raman band at $485\ cm^{-1}$ was attributed to the b_{3g} C=O bending mode.[25] The former b_{2u} vibration was also found in the phosphorescence spectrum of AQ-d_8 in hexane (Fig. 1) and in that of an isotopically mixed crystal.[14] Since the triplet state is n,π^* in character, frequency reduction of C=O bending vibrations can be expected, although delocalization of the nonbonding orbitals over the whole σ framework probably decreases this effect to some extent. Such a change in the force field around the C=O groups is considered to induce an interaction with local lattice modes. Here, we have to attach importance to the fact that the lattice modes coupled with the very weak $^3B_{1g}$ origin band appear with different relative intensities among the bands in the spectra of the two isotopic crystals. It would then be possible that these b_{2u} and b_{3g} vibrations couple with some lattice modes of b_g and b_u symmetries, respectively, resulting in the same behavior as b_{1u} vibrations. This explains the similarity in frequency and the difference in relative intensity of the peaks in the broad band clusters in the two excitation spectra. This idea is consistent with the interpretation suggested by Goodman and Brus[12] that the broad absorption band of *p*-benzoquinone may be vibronically induced by the environment.

Finally, it is also possible to consider that the Duschinsky effect[26,27] is prominent in the triplet manifold and that the transition intensity shared by ν_{24} is distributed over several bands with b_{1u} symmetry, including the bands coupled with lattice modes. This allows some strong bands to appear in the low frequency region, where the fundamental band of the ν_{24} mode in the ground state coordinate cannot be expected to appear.[28]

As discussed above, the assignment of the ^3A_u origin to the broad band around 443 nm does not explain satisfactorily the intensity relation among the near lying bands. We conclude that no tangible evidence for that assignment has been found in the excitation spectra of the AQ crystals. From analogy with the singlet system, we presently lean towards the possibility that the ^3A_u state in the AQ crystal lies outside the region accessible by the $T \leftarrow S_0$ excitation technique. Further studies are indispensable to draw a final conclusion.

The technical assistance of Noriko Iwasaki in the experiments is gratefully acknowledged. The present

work was partially supported by a Grant-in-Aid for Special Project Research from the Ministry of Education, Science, and Culture (No. 310901).

Enthalpies of Dilution of Aqueous Sodium Chondroitin 4-Sulfate and 6-Sulfate

Hideya Tsuge,* Masakatsu Yonese, and Hiroshi Kishimoto

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received March 29, 1979)

Enthalpies of dilution of aqueous sodium chondroitin 4- and 6-sulfate were measured by a microcalorimeter from the various initial concentrations $m=0.16$—0.07 monomole kg^{-1} to the final concentration $m'=3.85\times10^{-3}$ monomole kg^{-1} at various temperatures. The concentration and temperature dependencies of measured enthalpies well agreed quantitatively with the theoretical ones calculated by Manning's limiting law, when the distance between the neighboring charges of polyion, b, was assumed to be 4.8 Å, which was obtained from X-ray diffraction measurement.

Chondroitin 4- and 6-sulfate, whose repeating units are composed of *N*-acetyl-D-galactosamine 4- and 6-sulfate together with D-glucuronic acid, respectively, are known to be the important components of mammalian connective tissues and have been investigated from various points of view. In our laboratory, the counter ion binding of chondroitin sulfates was confirmed to exist at low concentrations from the measurements of two thermodynamic properties, molal osmotic coefficients[1] and partial molar volumes.[2] Also, the electrolyte permeability of the gelatin–chondroitin sulfate mixed membrane as a model of connective tissue has been investigated.[3] In this work, the enthalpies of dilution ($\Delta_{dil}H$) of aqueous chondroitin 4- and 6-sulfate were measured by a twin-type microcalorimeter, and the behaviors of chondroitin sulfate at moderate concentrations were discussed by applying Manning's limiting law[4,5] to our results.

Experimental

Materials. Chondroitin 4-sulfate (ChS-A), extracted from whale cartilage as sodium salt, was obtained from Seikagaku Kogyo Co., Ltd. (Tokyo, Japan). It has an average molecular weight of 2.0×10^4 as determined by viscosity measurement.[6,7]

Two kinds of chondroitin 6-sulfate (ChS-C), extracted from shark cartilage as sodium salts, were offered from Kaken Yakukako Co., Ltd. (Tokyo, Japan). Their molecular weights were determined to be 5.7×10^4 and 1.1×10^4, respectively. Distilled and deionized water was used for the preparation of aqueous ChS salt solutions.

Method.[8] The calorimeter used was a twin-type conduction microcalorimeter (CM 204 D1 of Rhesca. Co., Ltd.). A micro volt meter AM-1001 B of Ohkura Electric Co. was used as an output amplifier. Each solution cell (sample side or reference side) of the calorimeter consists of a reaction-vessel and an ampoule. The content of the ampoule can be mixed with that of the reaction-vessel by destroying the ampoule.

Sample Side: Aqueous solution of ChS salt (1—2 ml) in the ampoule. Water (30—50 ml) in the reaction-vessel.

Reference Side: The same amounts of water as the sample side in the ampoule and the reaction-vessel, respectively.

After a steady state had been reached (after about 20 h), ampoules of both sides were destroyed at the same time and the heats arised from mixing were measured. The heats correspond to the dilution enthalpies of ChS salts from the various initial concentrations $m=0.16$—0.07 monomole kg^{-1} to the final concentration $m'=3.85\times10^{-3}$ monomole kg^{-1}, where monomole means the molar amount of the repeating disaccharide unit of ChS. The heats divided by the amount of ChS in monomole give the dilution enthalpies per ChS monomole, $\Delta_{dil}H$.

Results

The exothermic quantities, *i.e.* $-\Delta_{dil}H$, of NaChS-A and NaChS-C at several temperatures were plotted against the initial concentrations m in Figs. 1 and 2, respectively. The value of $-\Delta_{dil}H$ increased monotonously with m.

Of NaChS-C samples having different molecular weights, the higher molecular weight sample showed the greater $-\Delta_{dil}H$ by about 400 J monomole^{-1} at different m and temperatures than the lower one.

Since the plots in Figs. 1 and 2 showed qualitatively the greater $-\Delta_{dil}H$ at the higher temperature, we plotted $-\Delta_{dil}H$ against temperature in Figs. 3 and 4 for the NaChS-A and NaChS-C, which were diluted from 0.1 monomole kg^{-1} to $m'=3.85\times10^{-3}$ monomole kg^{-1}, showing fairly linear relations.

Discussion

To examine to what extent the enthalpies of dilution of aqueous NaChS solutions may be explained by the electrostatic interaction of polyion with counterions, $\Delta_{dil}H$ was divided as follows.[9,10]

$$\Delta_{dil}H = \Delta_{dil}H^\circ + \Delta_{dil}H^{el}, \quad (1)$$

where $\Delta_{dil}H^\circ$ is the enthalpy of dilution of polyelectrolyte solution into a hypothetical reference state, in which all the ions are discharged and $\Delta_{dil}H^{el}$ is the contribution from the electrostatic interaction of polyion with counterion and can be evaluated by various electrostatic theories, *e.g.* Manning's limiting law.[4] Manning's theory replaces a polymer chain with infinitely long line charges and considers the two modes of interaction: Debye-Hückel "ion atmosphere" and condensation of counterions on the line charge. There, polyions are assumed to interact only negligibly with each other. Recently, this theory was applied to the thermodynamic properties of polyelectrolyte solutions, showing that this model is a good representation of the polyelectrolyte solution at low concentration.[11] T. Okubo *et al.* used successfully Manning's theory for the enthalpies of dilution of polyacrylate, carboxymethylcellulose, *etc.*

According to Manning, the electrostatic Helmholtz free energy F^{el} for this model[4] may be shown to be

$$F^{el}/VkT = -\xi n_e \ln \kappa, \quad (2)$$

where V is total volume, k is Boltzmann constant, T is absolute temperature, ξ is charge density parameter, n_e is equivalent polyion concentration (charge/ml), and κ is Debye screening parameter. The value of κ is given by Eq. 3 at a salt-free solution.

$$\kappa^2 = \frac{4\pi e^2}{\varepsilon kT} n_g z_g, \quad (3)$$

where e is a protonic charge, ε is the dielectric constant of solvent and n_g and z_g are the concentration (ion/ml) and valence, respectively, of counterion. The value of ξ is given by

$$\xi = e^2/\varepsilon kTb, \quad (4)$$

where b is the distance between the neighboring charges of a polyion. Different theoretical treatments are given for the case of $\xi\geq1$ and $\xi\leq1$. For the critical value of $\xi=1$, b is equal to 7.1 Å in water at 298.15 K. The ξ value of ChS salt equals to the case of $\xi\geq1$ as can be presumed by its structure. Starting from Eq. 2, $\Delta_{dil}H^{el}$ could be finally expressed as follows.[12]

$$\Delta_{dil}H^{el} = RT/\xi\left(1+\frac{T\mathrm{d}\varepsilon}{\varepsilon \mathrm{d}T}\right)\ln(m/m'), \quad \xi\geq1 \quad (5)$$

There, the choice of ξ value, which is the only adjustable parameter in Manning's theory, of ChS salts is a subject of discussion.

Two theoretical values of b were discussed with experimental $\Delta_{dil}H$ as follows. One was a structural value which obtained from X-ray diffraction measurement.[13,14] It was reported that ChS salts have eight-fold, three-fold and two-fold single stranded helical conformations. Their disaccharide lengths are 9.3—9.8 Å. The value of $b=4.8$ Å, which is a half of 9.6 Å for

disaccharide lengths of three-fold helical molecule of ChS-A and ChS-C salts, gives the structural value. Another was the value of $b=6.3$ Å. We previously measured the molal osmotic coefficients of ChS-A and ChS-C salts by vapor pressure osmometry. If the ξ value was considered as an adjustable parameter, experimental coefficients at infinite dilution ϕ_0 well agreed with the theoretical coefficients calculated from $\phi=(2z_g\xi)^{-1}$ using $b=6.3$ Å.[1)]

Theoretical $-\Delta_{dil}H^{el}$, calculated from Eqs. 4 and 5, are shown by solid lines with $b=4.8$ Å in Figs. 1, 2, 3, and 4 and by broken line with $b=6.3$ Å, for the case of NaChS-A only, in Figs. 1 and 3, respectively. It was confirmed that the theoretical enthalpic values for $b=4.8$ Å well agreed quantitatively with experimental values. In the above-mentioned treatment, the non-electrostatic enthalpies of dilution had been implicitly assumed to be negligible. However, it can be safely stated that the assumption is at least relatively a self-consistent one over the experimental range of temperature and concentration.

As the conclusion, at least tentative, ChS salt in aqueous solution may behave in such a way that the polyion of ChS has a stretched conformation with disaccharide lengths of *ca.* 12.6 Å at infinite dilution and a conformation nearly like solid state at moderate concentration.

Direct Measurement of Interaction Energy between Solids and Gases. IV. Acidic and Catalytic Properties of Amorphous and Crystalline Alumino-silicates

Tatsuo MASUDA,*,† Hitofumi TANIGUCHI, Kazuo TSUTSUMI, and Hiroshi TAKAHASHI
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received April 3, 1979)

Surface acidities and acid strength distributions of amorphous silica–alumina, Y-type faujasite and mordenite have been examined by measuring the differential heats of adsorption of ammonia. The number of acid sites with adsorption heats higher than 70 kJ/mol increased in the order: $NH_4Y > NH_4M > RENH_4Y >$ silica–alumina. On the other hand, the order of the acid strength was: $NH_4M > RENH_4Y >$ silica–alumina $> NH_4Y$. The high catalytic activities of zeolites for cumene cracking and toluene disproportionation were correlated with acid strength, Brönsted acidity, and electrostatic effect.

Zeolite have been shown to be more active than amorphous silica–alumina catalysts for many reactions. Miale *et al.*[1] compared the relative rates of hexane cracking reaction by a wide variety of zeolite catalysts with those by amorphous silica–alumina catalysts. They showed the superior activity of zeolite catalysts, that is, the relative rate, compared with silica–alumina taken as 1, was more than 10000. Plank *et al.*[2] showed the high activity of zeolite catalysts for gas oil cracking. Venuto and co-workers have shown that zeolites can catalyze a wide range of organic reactions.[3] In a previous paper,[4] the cumene cracking activities were measured for several FCC catalysts and the present authors concluded that the higher activity of zeolite-cracking catalysts could not be explained only by an acidity increase. Tung[5] proposed the time variant Brönsted acidity of zeolite catalysts to explain their high activity compared with that of amorphous silica–alumina. The nature of active centers of zeolite catalysts has been reviewed recently.[6]

In this work, cumene cracking and toluene disproportionation reaction were measured over amorphous silica–alumina, Y-faujasite and mordenite. The results of activity were correlated with acid strength distribution, IR spectra of adsorbed pyridine and electrostatic effects evaluated from nitrogen adsorption.

Experimental

Materials. The solid acids used in this study were shown in Table 1. Silica–alumina (Al_2O_3 contents, 28 wt %), Na-type mordenite and rare-earth(RE)exchanged Y-faujasite supplied by Catalysts and Chemicals Ind. Co. Ltd. NH_4M and $RENH_4Y$ were prepared by a conventional cation exchange procedure with NH_4NO_3 solution and then calcined in air at 600 °C and 400 °C for 3 h, respectively. NH_4Y, prepared by an ion exchange with NH_4Cl solution of NaY-faujasite supplied by Linde Co. was calcined in air at 400 °C for 3 h. The degree of ion-exchange was determined by flame photometry. All the catalysts were used as granule of 28—60 mesh.

Apparatus and Procedure. Experimental procedures and analysis of differential heats of adsorption of ammonia to estimate the acidity and acid strength distribution were carried out as described in a previous paper.[7] The same apparatus was used to measure the heat of adsorption of nitrogen and argon on solid acid catalysts. Each catalysts received a heat treatment at 400 °C under a pressure of 1.3×10^{-3} Pa for 5 h before calorimetric measurements.

The infrared absorption spectra of the adsorbed pyridine on solid acid catalysts were recorded on Hitachi infrared spectrometer model EPI-G3 by use of a conventional *in situ* cell connected to a vacuum line. The catalysts were pressed into a wafer with a thickness of about 10 mg/cm² and heat-treated at 400 °C under a pressure of 1.3×10^{-3} Pa for 4 h. The infrared spectra were measured at 25 °C.

The catalytic reactions were carried out in a pulse reactor system. The apparatus and experimental procedure were described in detail in a previous paper.[4] The catalysts were pretreated at 400 °C for 4 h in a stream of helium gas as a carrier. The helium flow rate during the pretreatment was 30 cm³/min. The catalyst bed used in a cumene cracking reaction consisted of 20 mg catalysts diluted with 130 mg of catalytically inert quartz beads and the reaction was carried out at 300 °C and at a helium flow rate of 60 cm³/min. Toluene disproportionation reaction was carried out at 400 °C and at a helium flow rate of 30 cm³/min over 150 mg of catalysts. The catalytic activity was estimated by means of a conversion rate of cumene and toluene.

Results

Catalytic Activity. The cumene cracking and toluene disproportionation activities over mordenite, Y-faujasite and silica–alumina are shown in Table 2. $RENH_4Y$ had higher initial activity for cumene cracking than NH_4Y and NH_4M. A large drop in conversion with an increase in the pulse number was observed over NH_4M, indicating the formation of non-volatile residure which left portions of the active site inaccessible to the reactants. NH_4M showed higher activity for toluene disproportionation and the order of activity was: $NH_4M > RENH_4Y > NH_4Y >$ silica–alumina in agree-

ment with the results of Nakano *et al.*[8] Conversions of cumene or toluene over amorphous silica–alumina were slight or none under these reaction conditions.

Differential Heats of Adsorption of Ammonia. In Fig. 1, the differential heats of adsorption of ammonia on silica–alumina, NH_4Y, $RENH_4Y$, and NH_4M are shown. The nature of differential heat curves of silica–alumina and NH_4Y has been discussed previously.[7] The differential heat curve of $RENH_4Y$ showed the existence of strong acid sites of heats of adsorption higher than 105 kJ/mol compared with that of NH_4Y, but the number of acid sites between adsorption heats of 80—100 kJ/mol decreased markedly. Initial heat of NH_4M was higher than 150 kJ/mol and the differential heat curve was very similar to that of $RENH_4Y$.

The acid strength distributions of these solid acid catalysts are shown in Fig. 2. The maximum distributions were observed at *ca.* 98 kJ/mol for mordenite and Y-faujasites and the other maximum distributions were also observed at 110 kJ/mol and 77, 120 kJ/mol for $RENH_4Y$ and NH_4M, respectively. Silica–alumina possessed a maximum distribution at 105 kJ/mol.

Infrared Spectra of Adsorbed Pyridine. Infrared spectra of pyridine on silica–alumina and zeolites are shown in Fig. 3. The adsorbed pyridine has strong and

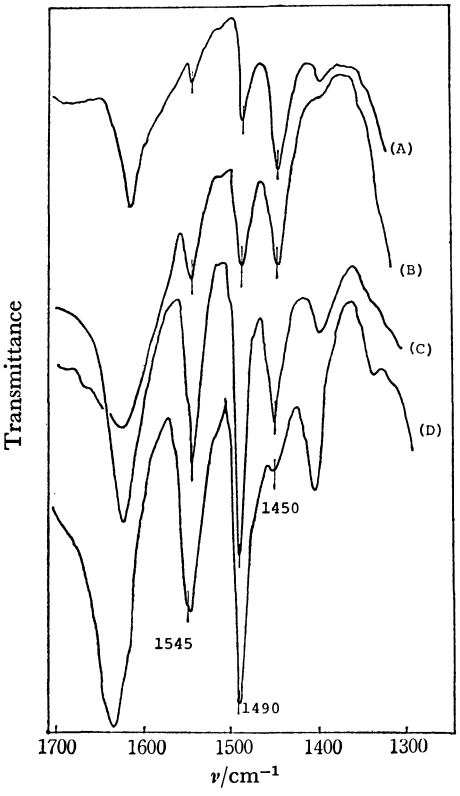

Fig. 3. Spectra of adsorbed pyridine on solid acids after pyridine dosing at 25 °C and evacuating at 150 °C for 1 h, (A) SA; (B) NH_4M; (C) $RENH_4Y$; (D) NH_4Y.

sharp bands characteristic of pyridinum ions (B-Py) at 1545 cm^{-1} and coordinately-bonded pyridine (L-Py) at 1450 cm^{-1}. In these spectra, the hydrogen-bonded species were removed by evacuation at 150 °C for 1 h, which was confirmed by the disappearences of their characteristic absorption bands at 1593 and 1438 cm^{-1}. It is apparent that the fraction of L-Py was higher in silica–alumina than in zeolites. The exchange with rare-earth cations in $RENH_4Y$ results in a formation of Lewis acid sites and enhances the acid strength as shown in Fig. 2. The band near 1443 cm^{-1} due to pyridine interacted with the rare-earth cations could not be observed after the evacuation at 150 °C. Strong adsorption band of L-Py was observed on NH_4M in contrast with the results of Yashima *et al.*[9]

Heats of Adsorption of Nitrogen and Argon. The integrated heats of adsorption of nitrogen and argon on silica–alumina, NH_4Y, $RENH_4Y$, and NH_4M are collected in Table 3. They were taken up to 20—35 μmol/g of the amount adsorbed for zeolites and about 10 μmol/g for silica–alumina. The order of integral heats was: $NH_4M > RENH_4Y > NH_4Y >$ silica–alumina. For zeolites, this order coincides with that of acid strength in Fig. 2. A large difference in adsorption heats between argon and nitrogen was observed over NH_4M.

Discussion

A high activity of zeolites has led to suggestions that the active sites such as Brönsted acid sites, Lewis acid sites and electrostatic fields on crystalline alumino-silicates are considerably different from those on amorphous alumino-silicates. Oblad[10] has compared the acidic nature of zeolite cracking catalysts with that of silica–alumina and concluded that the activity of zeolites was related to the intrinsic "protonic acidity" of the alumino-silicate lattice.

The present authors have previously shown that the cumene cracking activity over amorphous silica–alumina had a linear correlation with the number of acid sites higher than 70 kJ/mol of adsorption heats of ammonia.[4] The surface acidities obtained from Fig. 1 are 0.65, 1.32, 1.56, and 3.95 mmol/g for silica–alumina, $RENH_4Y$, NH_4M, and NH_4Y, respectively. An increase in acid strength in $RENH_4Y$ can be explained by inductive effects of rare-earth cation on the acidic hydroxyl groups. These values suggest that the excellent activity of zeolite catalysts for cumene cracking can not be explained only in terms of acidity increase. However, the existence of strong acid sites in NH_4M and $RENH_4Y$ leads to a large aging of cumene cracking activity, *i.e.*, the formation of non-volatile residue.

It is evident that the catalysts such as NH_4M and $RENH_4Y$ which possessed stronger acid sites showed higher conversion for toluene disproportionation, indicating that the reaction was effectively promoted by strong acid sites, *i.e.*, the sites having the heat of adsorption of ammonia higher than *ca.* 100 kJ/mol. However, it is difficult to explain the difference in activities for toluene disproportionation between silica–alumina and NH_4Y in terms of acid strength.

Differential heats in Fig. 1 contain both the interaction of ammonia with Brönsted and with Lewis acid sites, and it is difficult to differentiate these two sites from heat curves. The relatively homogeneous acid sites at 98 kJ/mol in adsorption heats of NH_4Y in Fig. 2, combined with the results of infrared spectra, can probably attributed to protonic acid sites because of the existence of weak band of L-Py in Fig. 3. The apparent ratios of the peak height of L-Py to B-Py, compared with that of silica–alumina taken as 1, were 0.57, 0.19, 0.03 for NH_4M, $RENH_4Y$, and NH_4Y, respectively. If we assume that the number of Brönsted acid sites is equal to that of Lewis acid sites in silica–alumina, the Brönsted acidities of silica–alumina, NH_4M, $RENH_4Y$, and NH_4Y should be 0.32, 0.99, 1.11, and 3.82 mmol/g, respectively. Brönsted and Lewis acid sites concentration of the solid acids were summarized in Table 4. If Brönsted rather than Lewis acid sites are the seats of activity for toluene disproportionation as mentioned by Benesi,[11] the absence of activity over silica–alumina must somewhat be due to its small Brönsted acidity and this is also true for cracking activity. The higher initial activity over $RENH_4Y$ for cumene cracking can be related to its relatively strong acid sites and larger number of Brönsted acid sites.

It has long been believed that the zeolite surfaces were heteropolar. Therefore, molecules occuluded within the zeolite framework are subject to its electrostatic field. Huang *et al.*[12] obtained the isosteric heat of adsorption of krypton from adsorption isotherms and discussed the surface electrostatic effects associated with lattice cations of Y-faujasites. They concluded that the existence of bivalent cations on zeolite surface had no influence on the adsorption of krypton because of its smaller contribution to polarization energy. Meanwhile the use of nitrogen molecules should be suitable for studies of electrostatic effects of solid surfaces because of its large quadrupole moment and relatively large polarizability.

If we can assume that the polarizability of nitrogen is almost the same as that of argon, the difference of

L-sites[b]/mmol g^{-1}	0.33	0.57	0.21	0.13

a) The number of Brönsted acid sites. b) The number of Lewis acid sites.

adsorption heats between them is probably due to the quadrupole-electrostatic field gradient interaction. Therefore, the higher adsorption heats of nitrogen on $RENH_4Y$ compared with that on NH_4Y can be ascribed to the contribution of quadrupole interaction of nitrogen with rare-earth cations. It is noteworthy that the order of integral heats of nitrogen coincides with that of activity for toluene disproportionation. These facts indicate that the cages and channels of zeolitic crystalline structure are characterized by the existences of high electrostatic field and its gradient, and therefore they act as strong polarizing agents for hydrocarbon transformation reactions.

It may be concluded from the present work that the acidity of zeolite catalysts appears to be the same kind as silica–alumina but differs in both quantity and quality of acid sites. Acid strength distributions of each solid acids obtained from differential heats of adsorption of ammonia are extensively different depending upon their crystalline structure and the existence of cations. The acid sites having the adsorption heats of ammonia higher than *ca.* 100 kJ/mol are effective for toluene disproportionation at 400 °C and these values are considerably high compared with the effective acid strength for cumene craking. Heats of adsorption of nitrogen indicate the high electrostatic field over zeolite surfaces. The low Brönsted acidity as well as the low electrostatic effects probably correlate with the low activity of amorphous silica–alumina.

This work was partly supported by a Grant-in-Aid for Science Research from the Ministry of Education.

An Analysis of Impedance in the Kolbe Reaction on Platinum and Gold Anodes in Aqueous Acetate Solutions

Isao SEKINE* and Hideki OHKAWA

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received July 31, 1978)

The Kolbe reaction occurring on platinum or gold anodes in aqueous acetate was studied by analyzing the equivalent circuit of the impedance obtained with a phase-sensitive detector. In the case of platinum, the equivalent circuit at the potential for the Kolbe reaction is represented by a parallel combination of the double-layer capacity, C_{dl}, and the charge-transfer resistance, θ, in series with the solution resistance, R_{sol}. The C_{dl} value of 2.00 V obtained by a complex impedance plane plot is nearly identical to that calculated by assuming that the Helmholtz layer is occupied by CH_3COO^-. In the potential range more negative than 2.00 V, the Kolbe reaction occurs. The steep decrease in the differential capacity is considered to be a result of the decrease in the adsorption pseudo-capacity. The θ value of the oxygen evolution increases with an increase in the acetate concentrations. It is shown that the surface coverage of CH_3COO^- may be obtained by "Frumkin's treatment" in conjunction with the high-frequency capacitance, C_{HF}, and the low-frequency capacitance, C_{LF}, from the complex capacitance plane plot (Y/ω plane plot). The Kolbe reaction does not occur at all with gold anodes, and the specific circular arc was not seen in the Y/ω plane plot. Impedance measurements, therefore, confirm that an adsorption pseudo-capacity of CH_3COO^- is not present with gold anodes.

Electrochemical studies of the Kolbe reaction using various techniques have been reported by many investigators.[1-3] The Kolbe reaction was, for example, examined with platinum or gold anodes in acetate or propionate solutions.[4-7] In aqueous acetate solutions the Kolbe reaction proceeds efficiently on platinum at anodic potentials greater than *ca.* 2.00 V, with the release of ethane and carbon dioxide, whereas the reaction does not occur at any potentials on gold anodes.[1] These phenomena result from the difference in anode surface states; ellipsometry[8] shows that the adsorption of a layer of CH_3COO^- or $CH_3COO\cdot$ about 10 Å thick on the platinum at anodic potentials greater than 2.00 V is favorable to the Kolbe reaction, while the oxide (Au_2O_3) more than 30 Å thick formed on gold anodes inhibits the reaction.

According to an analysis of the impedance of the Kolbe reaction by Kunugi *et al.*,[9] the double-layer capacity decreases from 30 to 10 $\mu F/cm^2$ when the anodic reaction changes from the oxygen evolution to the Kolbe reaction. Such behavior can be explained by attributing it to the change from the acetate ion to the methyl radical. However, only this explanation for these phenomena seems not to be sufficient. Furthermore, the equivalent circuit has not appeared in the literature.

In the present study, impedance measurements were made on platinum and gold anodes in aqueous acetate solutions using a phase-sensitive detector (PSD). The equivalent circuits corresponding to the adsorbed layer on the platinum anode or the oxide layer on the gold anode are derived from the impedance analysis. The possibility of the occurrence of the Kolbe reaction is discussed.

Experimental

Apparatus. The impedance was measured with a PSD (Fuso Seisakusho, model 332). The reference signal of the sinusoidal wave in PSD was within 3.5 mV (RMS) over the frequency range of 9 kHz—10 Hz.

Electrodes. A section (0.10 cm in diameter) of platinum or gold wire served as the working electrode. The pretreatment of these anodes was carried out as has been described previously.[4] The counter electrode was a spiral platinum wire. The potential was measured with reference to a saturated calomel electrode (SCE), and the electrode was gradually polarized to the positive potential with 10 mV/s. The parallel capacity and resistance were simultaneously plotted with a two-pen recorder. All the circuits were shielded and grounded.

Solutions. Test solutions were prepared from the reagent-grade chemicals and triply distilled water. Acetic acid was refluxed in the presence of potassium permanganate to oxidize the contaminating aldehydes, and was then redistilled in the presence of fresh diphosphorus pentaoxide to remove the water. Potassium acetate was used without further purification. The aqueous acetate solutions used were 1: 1 mixtures of equimolar solutions of potassium acetate and acetic acid at 0.5, 1, 2, and 5 M respectively. All the experiments were carried out at 25 °C.

Results and Discussion

Platinum Electrode. It has previously been reported that the remarkable decrease at 2.00 V in the differential capacity obtained by an impedance bridge is a necessary condition to promote the Kolbe reaction on a platinum anode in an aqueous acetate solution.[4]

Figure 1 shows the relationship between the parallel capacitance and the potential (C_p—E), as measured by a PSD. Two peaks were observed at around 0.80 and 1.35 V. The capacity at potentials greater than 1.35 V markedly decreases and levels off to a constant value at 2.25 V. It has already been reported that an oxygen evolution reaction and adsorption of CH_3COO^- compete in the potential range where the Kolbe reaction does not occur. Such a competition can be analyzed with the aid of the complex impedance plane plot[10] (Z plane plot) obtained at various acetate concentrations.

Figure 2 shows the results of the Z plane plot observed on a platinum anode at various acetate concentrations.

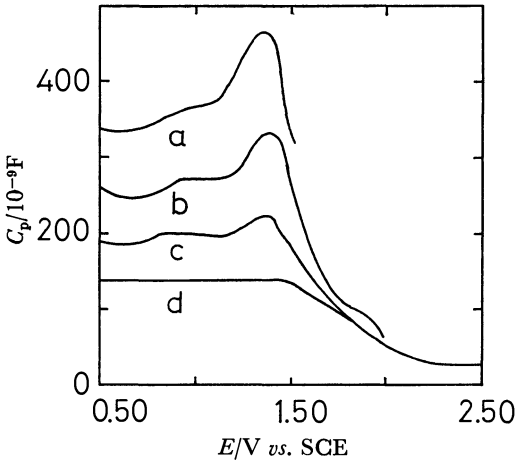

Fig. 1. Parallel capacitance *vs.* potential curves on Pt in 2 M acetate with various frequencies.
sweep rate: 10 mV/s,
a: 15 Hz, b: 60 Hz, c: 3 kHz, d: 8 kHz.

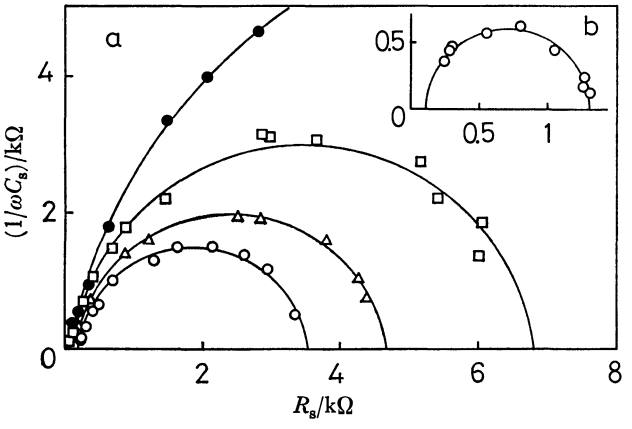

Fig. 2. Complex impedance plane plot of Pt in various acetate concentrations.
a: 1.50 V, -○-: 0.5 M, -△-: 1 M, -□-: 2 M, -●-: 5 M, b: 2.00 V, -○-: 0.5 M.

The diameter of the semicircle in the Z plane shows the charge-transfer resistance, θ. If the value of θ at 1.50 V is determined only by oxygen evolution, it will not be affected by the acetate concentrations. Since θ increases with an increase in the acetate concentration, it may be concluded that an oxygen-evolution reaction is inhibited by the adsorption of CH_3COO^-. Since the loci of the Z plane plot are given only by the semicircle, the rate-determining step of the Kolbe reaction or the oxygen evolution on the platinum is regarded as a charge-transfer process, representing an activation polarization.

The C_{dl} values at each concentration, as calculated from, $\omega_{max}(=1/\theta C_{dl})$, corresponding to the top of the semicircle, are shown in Fig. 3. At more negative potentials than 2.00 V, where the oxygen evolution proceeds, the C_{dl} value of platinum depends on the bulk concentration of the acetate ion and decreases with an increase in the concentration. By contrast, C_{dl} at 2.10 V, where the Kolbe reaction proceeds, is almost independent of the bulk concentration. From the above results, it can be said that, when the electrode

reaction changes from the oxygen evolution to the Kolbe reaction, C_{dl} decreases and then remains approximately constant (5—8 μF/cm²). Such behavior in C_{dl} was found to be similar to that observed for C_p in the C_p—E curve described above.

To elucidate further the decrease and then the constancy in C_{dl} at the potential where the Kolbe reaction proceeds, the above results were analyzed on the basis of the complex capacitance-plane plot[11,12] (Y/ω plane plot) (Fig. 4). At the more negative potentials than 2.00 V, the quarter circle was found in the high-frequency region, while the straight line was found in the lower-frequency region.

If the high-frequency capacitance, C_{HF}, is determined by extrapolation to an infinite frequency ($\omega=\infty$) in a

quarter circle, and the low-frequency capacitance, C_{LF}, by linear extrapolation to the C_p axis, the definitions of C_{HF}, C_{LF} and the adsorption pseudo-capacity, ΔC, are as follows:[13]

$$C_{HF} = (\partial q/\partial E)_{\mu,\Gamma} \quad (1)$$

$$C_{LF} = (\partial q/\partial E)_{\mu} = (\partial q/\partial E)_{\mu,\Gamma} + (\partial q/\partial \Gamma)_{\mu,E}(\partial \Gamma/\partial E)_{\mu} \quad (2)$$

$$\Delta C = C_{LF} - C_{HF} = (\partial q/\partial \Gamma)_{\mu,E}(\partial \Gamma/\partial E)_{\mu} \quad (3)$$

where Γ, q, and μ represent surface excess, the surface charge density, and the chemical potential respectively.

The quarter circle was obtained at 0.75 and 1.35 V, where the first and second capacity peaks were obtained respectively in the C_p—E curves. It is known that the first capacity peak is due to an adsorption of oxygen-containing species (OH^-, H_2O, O^{2-}, *etc.*)[4] and that the rate-determining step of adsorption is a diffusion process when the Y/ω plane plot gives a quarter circle.[11,12] As has been described above, the adsorption of oxygen-containing species is diffusion-controlled and the adsorption pseudo-capacity gives a value of 10—20 $\mu F/cm^2$. The second peak is regarded as the adsorption of CH_3COO^- in the potential range of oxygen evolution.[4] In this case, the CH_3COO^- is specifically adsorbed by forming a partly covalent bond with platinum and is perhaps responsible for the pseudo-capacity.[14]

Since the Y/ω plane plot gives a quarter circle at 1.37_5 V, the rate-determining step in the adsorption of CH_3COO^- is a diffusion-controlled process and produces an adsorption pseudo-capacity, ΔC. A ΔC value of 20 $\mu F/cm^2$ is observed at 1.37_5 V. In the C_p—E curve noted above, the C_p value decreased markedly with an increase in the positive potentials to more than 1.30—1.40 V indicated a second capacity peak, and C_{dl} decreased similarly (Figs. 1 and 3). These results can be explained by a diminution of the quarter circle, representing the magnitude of the adsorption pseudo-capacity, ΔC; *i.e.*, if $(\partial \Gamma/\partial E)_{\mu}=0$ in Eq. 3, the ΔC due to the adsorption of CH_3COO^- will vanish. The above conditions are satisfied by the fact that Γ for the adsorption of CH_3COO^- is constant against the potentials. The limiting case in the Y/ω plane plot is at 2.00 V, where the quarter circle almost disappears and a straight line is obtained.

In order to determine the surface coverage of CH_3COO^- from the C_{HF} values, "Frumkin's treatment" was performed. If the electric double layer is constructed by two parallel condensers, one is covered by the adsorbate, while the other is not; the charge on the electrodes is then given as follows:[15]

$$q = q_0(1-\theta_s) + q^*\theta_s$$

where q_0 and q^* correspond to the electrode charges when $\theta_s=0$ and $\theta_s=1$ respectively; and where θ_s is the fractional coverage of the surface $(=\Gamma/\Gamma_{max})$. The C_{LF} value given in Eq. 2 is converted to Eq. 4:

$$C_{LF} = dq/dE = (\partial q/\partial E)_{\theta_s} + (\partial q/\partial \theta_s)(d\theta_s/dE) = \{C_0(1-\theta_s)+C^*\theta_s\} + (q^*-q_0)(d\theta_s/dE) \quad (4)$$

where $C_0=dq_0/dE$ and $C^*=dq^*/dE$. The first two terms of Eq. 4 are replaced by Eq. 1 and:

$$C_{HF} = (\partial q/\partial E)_{\theta_s} = C_0(1-\theta_s) + C^*\theta_s \quad (5)$$

As an example, θ_s of CH_3COO^- was obtained from the platinum anode in a 2 M acetate solution; the values of C_{HF} for C^* and C_0 were 6 and 24 $\mu F/cm^2$, obtained at 2.00 and 0.90 V, respectively. Because the adsorption of CH_3COO^- is negligible at potentials less than 1.30 V, as shown by a previous study,[9] the condition of $\Delta C \fallingdotseq 0$ is satisfied at 2.00 V in Fig. 4. The values of θ_s were calculated from Eq. 5; *e.g.*, when $C_{HF}=20$ $\mu F/cm^2$ at 1.50 V, then $\theta_s=0.2$, and when $C_{HF}=12$ $\mu F/cm^2$ at 1.75 V, $\theta_s=0.7$. The θ_s values obtained by the above method agreed approximately with the surface coverage obtained from the difference between the currents observed in the presence and in the absence of acetate ions in a phosphate solution using the linear-potential-sweep method.

The admittance for a first-order electrode reaction proceeding on the Y/ω plane is characterized by Eq.6.[16] Since only the perpendicular line against the C_p axis is observed, the straight lines obtained at 1.50 and 1.75 V indicate that the oxygen evolution follows a first-order electrode reaction:

$$Y/\omega = jC_{dl} + 1/\omega\theta \quad (6)$$

The intercept at the C_p axis gives both C_{dl} and C_{LF}, according to Eq. 6. Therefore, it may be concluded that the C_{dl} value on the Z plane at the potentials of oxygen evolution contains the adsorption pseudo-capacity, ΔC, of CH_3COO^-. For example, at 1.50 V in a 2 M acetate solution, the C_{dl} obtained on the Z plane corresponding to C_{LF} on the Y/ω plane is 33 $\mu F/cm^2$. Consequently, $\Delta C(=C_{LF}-C_{HF})$ is 13 $\mu F/cm^2$, since C_{HF} is equal to 20 $\mu F/cm^2$. For the above derivation, the adsorption of CH_3COO^- was taken to proceed simultaneously with the oxygen evolution on the Y/ω plane.

As ΔC approximates zero at 2.00 V, where the Kolbe reaction proceeds, the C_{dl} value extrapolated to the C_p axis almost represents that of C_{HF}. Thus, a C_{HF} value of 5—6 $\mu F/cm^2$ was found at 2.00 V in 0.5—2 M acetate solutions. Accordingly, the equivalent circuit of platinum at potentials less than 2.00 V is shown in Fig. 5(a). That the adsorption of CH_3COO^- is the diffusion-controlled process and gives the pseudo-capacity, ΔC, is shown by the elements of C_{HF}, ΔC, and Z_w. This impedance, Z_w, is considered to be equivalent to the Warburg impedance in a diffusion process:

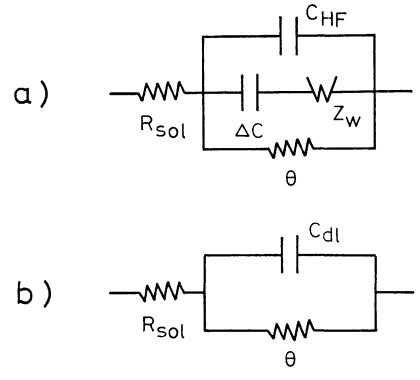

Fig. 5. Electrical equivalent circuit.

$$Z_w = (1-j)(\tau_D/2\omega)^{1/2}\cdot\Delta C^{-1} \quad (7)$$
$$\tau_D = (\partial\Gamma/\partial C_A)_E^2/D$$

τ_D: mean diffusion-controlled relaxation time;
C_A: concn of adsorbate; D: diffusion coefficient.

The coefficient, $(\tau_D/2)^{1/2}\cdot\Delta C^{-1}$, was about 200—400 $\Omega\cdot cm^2\cdot s^{-1/2}$ in the potential range from 0.90 to 1.50 V in the 0.5 M acetate solution. The τ_D was calculated from ω_{max} $(=1/\tau_D)$, corresponding to the top of the quarter circle. The θ, combined with other parallel elements, shows the charge-transfer resistance for the oxygen-evolution reaction. Since ΔC is almost equal to zero at potentials greater than 2.00 V, the equivalent circuit for the Kolbe reaction is simply shown by Fig. 5(b).

The facts that C_p is constant at potentials greater than 2.00 V and that C_{dl} decreases to an almost constant value of 5—8 $\mu F/cm^2$ result from the fact that: the constancy in C_{dl} is explained on the basis of the concept of electric double layer, and the results of ellipsometry.[8] The total capacitance, C_{dl}, is generally considered to be the serial combination of a Helmholtz capacity, C_H; a diffuse double-layer capacity, C_D, and a film capacity, C_{film}, due to the formation of a film on a solid electrode interface:

$$1/C_{dl} = 1/C_{film} + 1/C_H + 1/C_D \quad (8)$$

Since a sufficiently high concentration is employed in this study $1/C_D$ becomes small and:

$$1/C_{dl} = 1/C_{film} + 1/C_H \quad (9)$$

According to Hoare,[17] oxygen evolves from the platinum surface covered by an electronically conducting monolayer of adsorbed oxygen (Pt–O). In addition, ellipsometry confirmed that the thickness of an adsorption layer does not exceed 10 Å, even in the Kolbe reaction region.[8] Therefore, the incorporation of CH_3COO^- into the Pt–O layer seems more reasonably to be expected than that of the adsorption layer of CH_3COO^- onto the oxide film (PtO). Hence, C_{dl}, represented by C_H, is due to the specific adsorption of CH_3COO^- into the Helmholtz layer. This C_H can be explained on the basis of a Helmholtz parallel-plate condenser model:

$$C_{dl} \fallingdotseq C_H = \varepsilon/4\pi d \quad (10)$$

where d is the distance between the condenser plates and ε is the dielectric constant. Using a dielectric constant of acetic acid of 6.2 and a thickness of C_H of the order of 10 Å, C_H can be estimated to be about 6 $\mu F/cm^2$. This C_H value is almost equal to those of C_{dl} and C_{HF} obtained from the Z plane plot and the Y/ω plane plot respectively at 2.00 V.

The Kolbe reaction at the surface covered by CH_3COO^- or $CH_3COO\cdot$ at potentials above 2.00 V is due to:

$$CH_3COO\cdot_{(ad)} + CH_3COO^- \longrightarrow C_2H_6 + 2CO_2 + e$$ [18]

Gold Electrode. The differential capacity on a gold anode in an aqueous acetate solution, as measured with an a.c. bridge in series with a capacitor and a resistor, increased markedly at potentials above 1.50 V.[19]

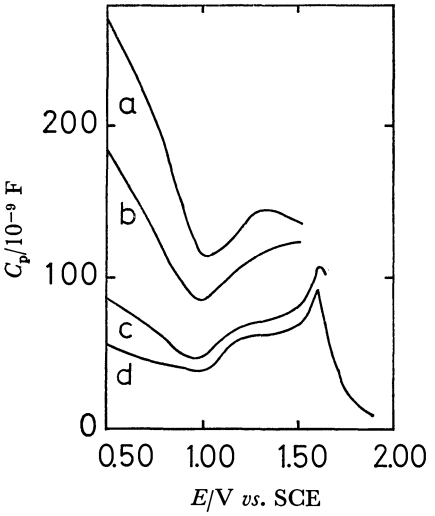

Fig. 6. Parallel capacitance *vs.* potential curves on Au in 2 M acetate with various frequencies.

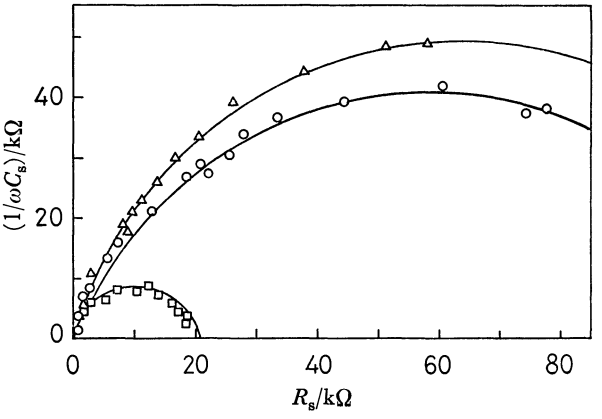

Fig. 7. Complex impedance plane plot of Au in 5 M acetate.
-○-: 1.00 V, -△-: 1.30 V, -□-: 1.50 V.

Figure 6 shows the C_p—E curves of gold anodes measured with the PSD in parallel with a capacitor and resistors. A constant value was reached at potentials above 1.60 V, in contrast to the results of a previous paper.[19] In order to determine the rate-determining step of the oxygen evolution reaction in the presence of CH_3COO^- with gold anodes, the Z plane plot was worked out; the results are shown in Fig. 7. The rate-determining step that occurs at potentials above 1.36 V[20] was found to be a charge-transfer process according to Eq. A, because the only semicircle was observed in the Z plane at 1.50 V.

$$H_2O_{(ad)} \longrightarrow OH_{(ad)} + H^+ + e \quad (A)$$
$$OH_{(ad)} + OH_{(ad)} \rightleftarrows O_{(ad)} + H_2O \quad (B)$$
$$O_{(ad)} + O_{(ad)} \rightleftarrows O_{2(ad)} \rightleftarrows O_2 \quad (C)$$

The C_{dl} value on gold in a 5 M acetate solution is shown in Fig. 3.

The Y/ω plane plot (Fig. 8) was worked out with a gold anode in an acetate solution in order to examine the behavior of CH_3COO^-, since the adsorption of CH_3COO^- on platinum occurs at around 1.30 V, with

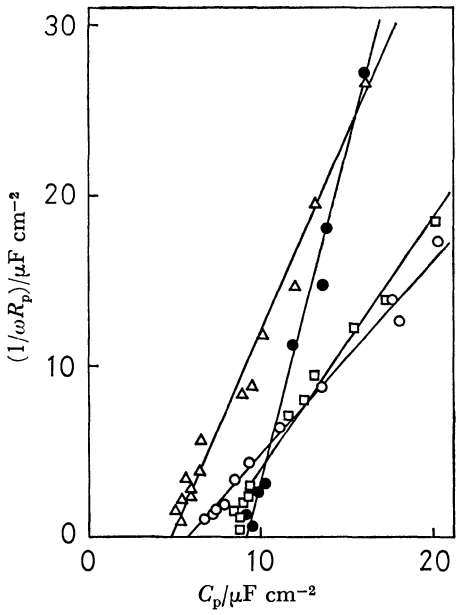

Fig. 8. Complex capacitance plane plot of Au in 2 M acetate.
-○-: 0.75 V, -△-: 1.00 V, -□-: 1.30 V, -●-: 1.50 V.

the evolution of oxygen. The loci of the plot in the potential range of 0.75 to 1.50 V differ from those on platinum anodes; they represent an approximately straight line without a specific circular arc. The C_{dl} value obtained at the intercept of the C_p axis (Eq. 6) is of the order of 6—10 $\mu F/cm^2$ in the potential range from 0.75 to 1.50 V. These potentials are on the Y/ω plane. Since the presence of the semicircle or the quarter circle is quite doubtful, the adsorption of CH_3COO^- on a gold anode is unlikely. In addition, the surface coverage of CH_3COO^- on a gold anode is negligible at concentrations higher than 0.5 M, as has previously been reported.[6]

Since the characteristics of the C_p—E curve at potentials less than 1.50 V shown in Fig. 6 are similar to those of the capacity-potential curve of gold anodes in perchloric acid reported by Schmid and Hackerman,[21] it may be concluded that the present C_p—E curves are not affected by the adsorption of CH_3COO^-. According to Schmid and Hackerman,[21] the capacity hump in the potential range from 0.9 to 1.3 V is due to the adsorption of oxygen-containing species, *i.e.*, OH^-, O^{2-}, *etc.*

Thermodynamically, the formation of oxide on gold anodes at potentials above 0.93 V (*vs.* SCE) in acetate solutions (pH=4.80) is possible *via* Eq. D;

$$2Au + 3H_2O = Au_2O_3 + 6H^+ + 6e^{22)} \qquad (D)$$

$$E^\circ = 1.457 - 0.591pH\ (vs.\ NHE)$$

E°: equilibrium potential

Therefore, the adsorption of oxygen-containing species, *e.g.*, water, on gold seems reasonable.

The specific circular arc with gold anodes, however, was not observed on the Y/ω plane at the potentials where the oxygen-containing species adsorbs. The quarter circle on platinum anodes was obtained on the Y/ω plane in the potential range from 0.75 to 0.90 V, where the first peak of the capacity was observed with the C_p—E curves. In this potential range, the adsorption of oxygen-containing species on platinum anodes is possible.

The difference between the adsorption of oxygen-containing species on platinum and gold anodes is considered to be as follows. Since the adsorption of reacting species can be detected by the specific arc on the Y/ω plane, the adsorption of oxygen-containing species on platinum is verified by the quarter circle. Water adsorbed on a gold anode is immediately changed to the oxide, Au_2O_3, according to Eq. D, and the surface is completely covered with the oxide.

Since the time constant of the adsorption layer differs from that of oxide, the Y/ω plane plot with gold anodes will not show a circular arc indicating the adsorption.

The results presented above support the notion that the Kolbe reaction occurs on surfaces covered with CH_3COO^- or $CH_3COO\cdot$.[3] The equivalent circuit of the oxygen evolution on a gold anode, which does not contain the adsorption pseudo-capacity of CH_3COO^-, is shown in Fig. 5b.

The Mechanism of Catalyzed Hydrogen-Deuterium Exchange on Gold Deposited over Poly(tetrafluoroethylene)

Itsuo IIDA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received September 13, 1978)

The H_2–D_2 exchange reaction over Au(0.3%)/PTFE(poly(tetrafluoroethylene)) was studied. The apparent activation energy was found to be 29 kJ mol^{-1}. The dependence of the reaction rate on the total pressure was measured at 518, 432, and 393 K. It was found that the pressure exponent of the exchange reaction decreases with the increase in the total pressure and that in the lower pressure range, the reaction order is as high as 2. The rate equation obtained from the pressure dependence was $R=k\{KP/(1+KP)\}^2$. Accordingly, it was concluded that the H_2–D_2 exchange reaction over gold takes place between molecularly adsorbed hydrogen and deuterium through a dimeric intermediate. The heat of adsorption on the active sites in the gold surface was 5.9 kJ mol^{-1}.

The H_2–D_2 exchange reaction on metal catalysts has been extensively studied as a measure of hydrogen activation.[1,2] Transition metals are known to be effective catalysts for this exchange. By contrast, non-transition metals are notably less efficient than transition metals, due to their smaller ability to interact with hydrogen.

The earliest views on the mechanisms of this exchange were those of Bonhoeffer and Farkas,[3] who suggested the following steps:

$$\left.\begin{aligned} H_2 + 2* &\rightleftarrows 2H* \\ D_2 + 2* &\rightleftarrows 2D* \\ HD + 2* &\rightleftarrows H* + D* \end{aligned}\right\} \quad (1)$$

This mechanism should operate when the adsorption-desorption process is rapid. Certain drawbacks to this mechanism soon, however, became evident. For example, Benton and White[4] showed that the desorption of adsorbed hydrogen from the surface of nickel powder only occurred above 173 K, although the H_2–D_2 exchange reaction proceeded measurably on nickel at about 83 K.

An alternative mechanism was therefore proposed as follows:[5,6]

$$\left.\begin{aligned} H_2 + D* &\rightleftarrows H* + HD \\ D_2 + H* &\rightleftarrows D* + HD \end{aligned}\right\} \quad (2)$$

This is called the Rideal-Eley mechanism.

It has been accepted that the Bonhoeffer-Farkas mechanism operates with transition metals above room temperature, where the adsorption-desorption process is fast. The Rideal-Eley mechanism is likely to apply to low-temperature reactions, where dissociated atoms are irreversibly adsorbed.

There have been many studies on the H_2–D_2 exchange reaction which attempted to distinguish between the Bonhoeffer-Farkas mechanism and the Rideal-Eley mechanism.[1,2]

On the other hand, Schwab and Killman suggested the following reaction mechanism for the exchange reaction over nickel foil, on the basis of the isotope effect of the reaction rate:[7,8]

$$\left.\begin{aligned} H_2 + * &\rightleftarrows H_2* \\ D_2 + * &\rightleftarrows D_2* \\ H_2* + D_2* &\rightleftarrows 2HD* \\ HD + * &\rightleftarrows HD* \end{aligned}\right\} \quad (3)$$

In this case, the isotope exchange takes place between molecularly adsorbed hydrogen and deuterium. However, A. Farkas made the criticism that their treatment on the basis of the isotope effect cannot provide proof for or against any mechanism.[8]

In this paper, we examine the H_2–D_2 exchange reaction on gold supported over poly(tetrafluoroethylene) (PTFE), which has already been proved to be a good support for platinum.[9] Although there are a few works on the H_2–D_2 exchange reaction over gold catalyst,[10,11] the kinetic behaviour of this exchange reaction has not yet been fully studied. In our study, the diagnostic test of a mechanism is based on the pressure dependence of the reaction rate.

Experimental

The rate of the H_2–D_2 exchange reaction was measured in a closed circulation system with a volume of 330 cm^3. Auxiliary equipment consisted of a mercury diffusion pump backed by a mechanical pump and isolated from the reaction apparatus by a liquid nitrogen trap. The pressure of the reaction system was measured with a mercury manometer which was covered with a small amount of silicone oil (Dow Corning 705 Fluid Lot. No. 33) at the top.

The isotope distribution in the gas phase was determined by gas chromatography at 77 K, using a column filled with alumina/5% manganese chloride. Prior to each measurement, the catalyst was subjected to heat-treatment *in vacuo* at 518 K.

Hydrogen of seven nine purity (Nippon Sanso Co., Ltd.,) and deuterium of 99.5% purity (Showa Denko Co., Ltd.,) were passed through a liquid nitrogen trap before use.

Gold (0.3%) supported on PTFE catalyst was prepared as follows: PTFE (914J. Mitsui Fluoro Chemicals Co., Ltd.,) was soaked in an acetone solution of chloroauric acid and the solvent was evaporated; after evacuation at room temperature, the sample was heated to 463 K and evacuation was continued for 30 min at the same temperature, after which hydrogen gas (40 kPa) was circulated over the catalyst at 463 K for 3 h, followed by evacuation overnight at the same temperature. The amount of the catalyst used was 5.06 g.

For the blank test, an equimolar mixture of H_2 and D_2 at the pressure of 46.3 kPa was circulated over 5.26 g of PTFE at 503 K; it was found that no appreciable amount of HD was formed even after 140 min.

Results

The time course of the H_2–D_2 exchange reaction is

described by the first order equation:

$$\ln \frac{\chi_e - \chi_t}{\chi_e - \chi_0} = -k_e t, \quad (4)$$

where χ_0, χ_t, and χ_e are the fractions of hydrogen deuteride present at times zero and t and at equilibrium. The total rate of exchange, R (cm³/min), is given by

$$R = k_e N \quad (5)$$

where N is the total amount of hydrogen gas (H_2, D_2) introduced. We could not calculate the absolute rate (the exchange rate per unit metal surface area) since the surface area of gold was not determined.

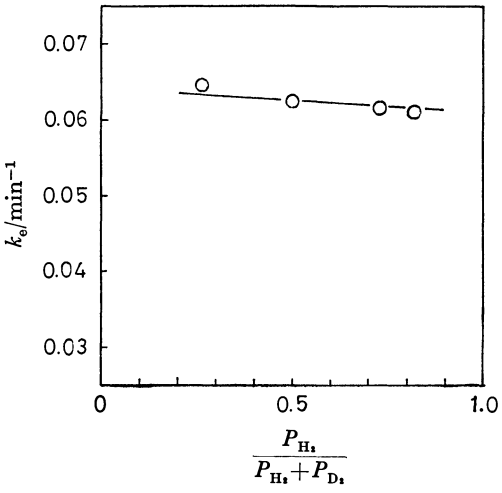

Fig. 1. First order rate constant (k_e) at 518 K against the fraction of hydrogen. Total pressure was kept constant at 24.9 kPa.

The dependence of the first order rate constant, k_e, on the composition of the mixture of H_2 and D_2 under the total pressure of 24.9 kPa was studied. The results (Fig. 1) show that there exists little isotope effect in the H_2–D_2 exchange reaction on Au/PTEE. Therefore, an equimolar mixture of H_2 and D_2 was employed in contact with the catalyst in all later experiments.

The temperature dependence of the first order rate constant, k_e, plotted in Arrhenius form is shown in

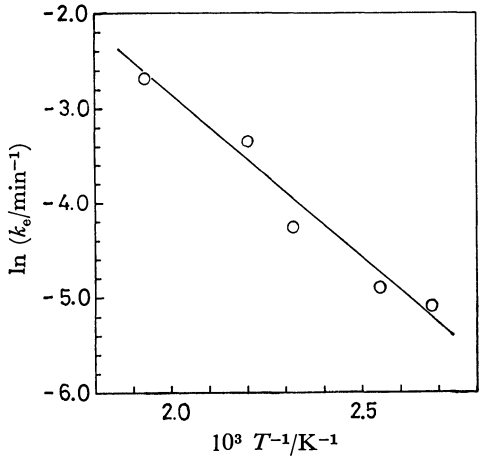

Fig. 2. Arrhenius plots for the H_2–D_2 exchange reaction on Au(0.3%)/PTFE. P=34.7 kPa.

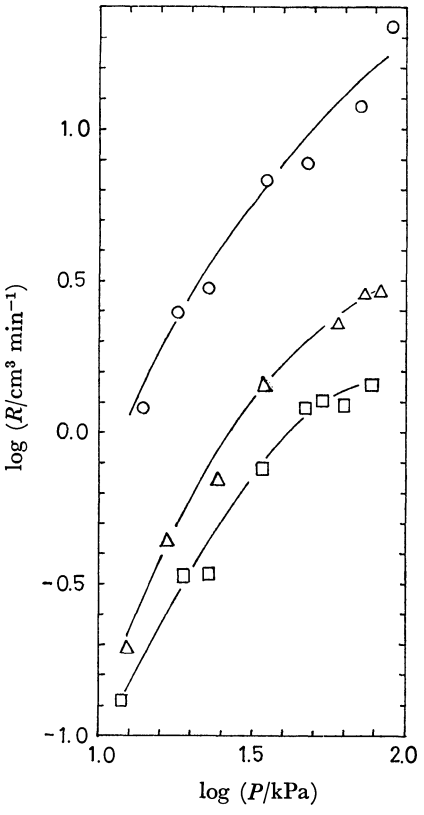

Fig. 3. Dependencies of the H_2–D_2 exchange reaction on the total pressure at 518, 432, and 393 K. -○-; 518 K, -△-; 432 K, -□-; 393 K.

Fig. 2. The apparent activation energy calculated from the slope of the line is 29 kJ mol^{-1}, which is the same as that over gold wire obtained by Avdeenko *et al.*[12]

The logarithms of the total rates of the exchange at 518, 432, and 393 K are plotted against those of the total pressure P of hydrogen in Fig. 3. It is shown in Fig. 3 that the pressure exponent of this exchange reaction decreases with the increase in the total pressure. For example, at 518 K, the pressure exponent decreased from 2 at pressures between 13 and 20 kPa to 1.0 at pressures between 50 and 70 kPa; at 393 K, it decreased from 2 at pressures between 13 and 20 kPa to 0.5 at pressures between 50 and 70 kPa.

It is surprising that the reaction order was found to be 2 in the lower pressure range, because neither the Bonhoeffer-Farkas mechanism nor the Rideal-Eley mechanism can explain such a high reaction order. For the Bonhoeffer-Farkas mechanism, where the exchange reaction proceeds by way of dissociative adsorption and desorption, the reaction order should vary from first at low coverages to zero at high coverages. For the Rideal-Eley mechanism, the order should be first, providing the atomic layer is complete and the molecular species only weakly adsorbed or not at all.

Consequently, we must consider the Schwab mechanism, in which the H_2—D_2 exchange reaction goes through an associative intermediate, as expressed by

$$H_2(a) + D_2(a) \rightleftarrows \begin{matrix} H\cdots H \\ \vdots \quad \vdots \\ D\cdots D \end{matrix} \rightleftarrows 2HD(a). \quad (6)$$

In this case, the reaction velocity is proportional to the square of the coverage of the molecularly adsorbed hydrogen. Using the Langmuir equation, total rate of exchange is given by

$$R = k\left(\frac{KP}{1+KP}\right)^2, \tag{7}$$

where K denotes the adsorption constant.

By rearranging Eq. 7, we get the following equation:

$$\frac{P}{\sqrt{R}} = \frac{1}{\sqrt{k}K} + \frac{P}{\sqrt{k}}. \tag{8}$$

Therefore, it can be expected that when $P/\sqrt{R}$'s are plotted against total pressure, P, a straight line will be obtained.

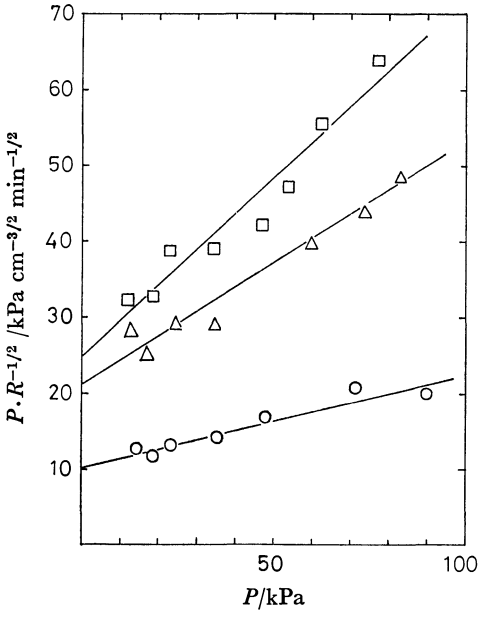

Fig. 4. Relation between the total pressure (P) and $P/\sqrt{R}$. -○-; 518 K, -△-; 432 K, -□-; 393 K.

The graphs of $P/\sqrt{R}$ against P at 518, 432, and 393 K are shown in Fig. 4; they give reasonably good straight lines. Accordingly, we get Eq. 7 as the rate equation for the H_2–D_2 exchange reaction on Au/PTFE.

From the slopes and intercepts of the graphs in Fig. 4, we can calculate the rate constant, k, for the surface exchange and the adsorption constant, K, at 518, 432, and 393 K; these are summarized in Table 1.

TABLE 1. RATE CONSTANT OF THE H_2–D_2 EXCHANGE REACTION AND ADSORPTION CONSTANT OF HYDROGEN MOLECULE ON Au/PTFE

T/K	k/cm^3 min^{-1}	K/kPa^{-1}
518	65.6	0.0122
432	9.66	0.0152
393	4.49	0.0190

In Fig. 5, ln k and ln K are plotted against $1/T$. The heat of hydrogen adsorption on the surface of gold and the activation energy of the surface reaction, given by the slopes of the lines in Fig. 5, are 5.9 kJ mol^{-1} and 37

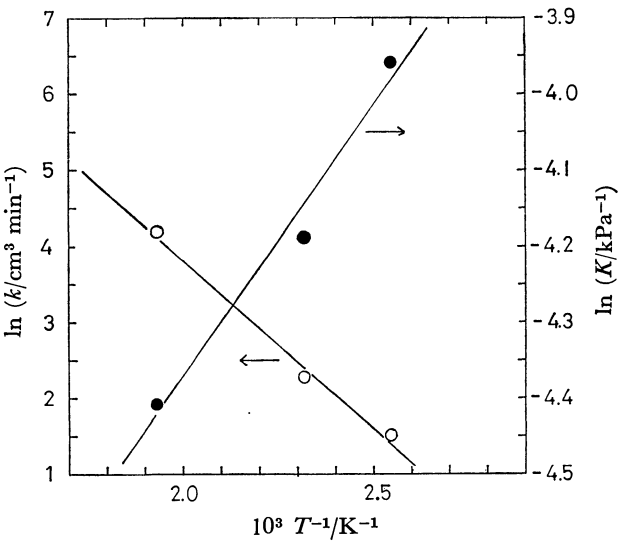

Fig. 5. Temperature dependencies of logarithm of rate constant (k) and that of adsorption constant (K).

kJ mol^{-1}, respectively. Although in the case of the H_2–D_2 exchange reaction on copper catalyst Kiyomiya *et al.* found a marked isotope effect,[13] we found little isotope effect for the reaction on gold. Therefore, the heat of adsorption obtained is not the average of that for hydrogen and deuterium. The heat of adsorption for hydrogen and that for deuterium are the same and are both 5.9 kJ mol^{-1}.

Discussion

Although Trapnell did not find chemisorption of hydrogen on the evaporated film of gold in the temperature range 293 K to 93 K,[14] there are a few reports on the H_2–D_2 exchange reaction on gold which indicate that the adsorption of hydrogen on gold does occur.[10,11] For example, Taylor and his coworkers[11] found the H_2–D_2 exchange reaction to take place on gold foil. They speculated that the hydrogen atoms were chemisorbed on the vacant d-orbital created by a promotion of a d-electron to the top of the s-band, since no d-orbitals are normally available in gold for surface bond formation.

On the other hand, Wise and Sancier found that after treatment of gold foil with hydrogen plasma, the rate of the H_2–D_2 exchange reaction on it became greater and that the activation energy was reduced from 90.0 kJ mol^{-1} over the untreated catalyst to 46 kJ mol^{-1}. Since the high activity of treated gold was reduced by evacuation at 615 K, chemisorbed hydrogen seems to have been formed, giving rise to the enhanced activity and presumably reacting with gaseous hydrogen (Rideal-Eley mechanism). However, they also paid attention to the fact that over gold foil treated with hydrogen plasma, another heterogeneous reaction of higher activation energy takes place which predominates at temperatures in excess of 450 K. They suggested that the reaction may proceed by the Bonhoeffer-Farkas mechanism in the higher temperature range.

In both of the works mentioned above, the pressure dependence of the exchange reaction was not studied

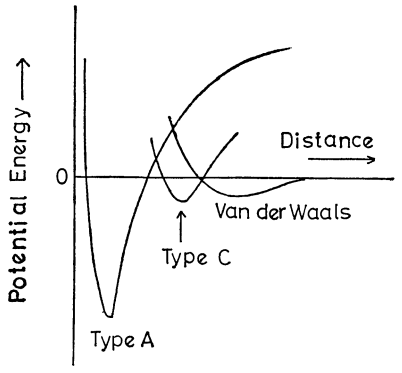

Fig. 6. Potential energy curves for Type A (M–H) and Type C (M···H_2) chemisorbed hydrogen.

and the interpretations are not more than conjectures. It could be said that the results in these works do not exclude the possibility that the reaction goes through an associative intermediate.

As far as we know, we were the first to study the pressure dependencies of the H_2–D_2 exchange reaction on gold catalyst. We found that the pressure exponent of the H_2–D_2 exchange reaction was as high as 2 at the lower pressure range. Usually one cannot decide the mechanism of the H_2–D_2 exchange reaction only by measuring the pressure dependencies. In our case, however, the pressure exponent we obtained precludes mechanisms other than that proposed by Schwab and Killman. Moreover, the rate equation (Eq. 7) which we confirmed at 518, 432, and 393 K strongly supports the mechanism; the exchange reaction takes place between molecularly adsorbed hydrogen and deuterium.

At this stage, we consider the nature of the hydrogen adsorbed. Dowden[15] has pointed out that there is probably an initial state of chemisorption in many cases, named Type C chemisorption (molecular), on the empty atomic d-orbitals; this type is intermediate between physical adsorption and strong chemisorption, as shown in Fig. 6. Concerning this suggestion, Clark[16] commented that the potential energy curves of chemisorption of hydrogen on sp and d metals may be quite similar and that, for transition metals, the Type C potential curve may intersect the curve for strong atomic adsorption in such a way that very little activation energy is required for the hydrogen to transfer to the final atom curve, Type A, whereas in a nontransition metal, the crossing point may be located in a postition that requires a large activation energy for the transfer. Actually, preformed hydrogen atoms can be chemisorbed on Group IB metals,[17] which may indicate that chemisorption of hydrogen atom is limited by a large activation energy and not by the inability of gold to chemisorb.

Our results showed that hydrogen is adsorbed on a gold surface molecularly and that the heat of adsorption is as low as 5.9 kJ mol^{-1}, which seems correspond to Type C chemisorption.

On the other hand, it was shown by Hoffmann,[18] using arguments based on the conservation of orbital symmetry,[19] that in the gas phase reaction, the coplanar path proceeding through a square transition state is thermally forbidden. An approximate energy barrier for the process is that amount of energy necessary to raise two electrons from the bonding σ_g orbital in H_2 up to the non-bonding hydrogen 1s level, or 498 kJ mol^{-1}. In the study of the H_2–D_2 exchange reaction in the gas phase, Bauer and Ossa found that the activation energy was 177 kJ mol^{-1} and the possibility of an atomic exchange mechanism, *i.e.* $H_2 \rightarrow 2H$ followed by $H+D_2 \rightarrow HD+D$ was considered to be ruled out.[20] Various theoretical studies searching for a low-lying four-centre transition state have been, done but none of them has succeeded in explaining the low activation energy observed.[21]

On the other hand, in our study the activation energy for the surface exchange was found to be 37 kJ mol^{-1}. Therefore, a large amount of stabilization of H_4 intermediate does occur on the surface of gold. Although Mango and Schachtschneider pointed out that the reactions which are symmetry forbidden can become allowed by interaction with the d-orbital of a transition metal,[22] the argument cannot proceed in a similar fashion in the case of the reaction on gold for the lack of the vacant d-orbital. Nevertheless, there are various kinds of approaches for two hydrogen molecules to form a H_4 intermediate: *e.g.* an orthogonal approach passing through a tetrahedron, rectangle, and rhombus, and an allowed path suggested by Gimarc[23] passing through Y- and T-shaped transition states. Moreover, various kinds of sites differing in electronic or in geometric structure exist in the metal surface. Therefore, it seems that further theoretical studies will be necessary to understand the transition state of the surface exchange on gold completely.

The author is grateful to Professor Kenzi Tamaru of the University of Tokyo and Professor Atsumu Ozaki of Tokyo Institute of Technology for helpful comments. Acknowledgement is made to Dr. Toshihiko Kondo for helpful discussions.

Reversible Binding of NO to Fe(II)edta

Yukio HISHINUMA,* Ryuichi KAJI,* Hidetoshi AKIMOTO, Fumito NAKAJIMA, Toshikatsu MORI, Tomoichi KAMO, Yoshijiro ARIKAWA,** and Shigeru NOZAWA**

Hitachi Research Laboratory, Hitachi Ltd., Hitachi, Ibaraki 317

***Babcock-Hitachi Ltd., Kure, Hiroshima 737*

(Received September 27, 1978)

The equilibrium constants, enthalpy, and entropy of the reversible binding of nitrogen oxide to Fe(II)edta in an aqueous solution have been measured in the temperature range 38.5 to 70 °C. Experiments were carried out by absorbing NO under O_2 free conditions. The results show that, in the absorption of NO with Fe(II)edta solution, the value of $\Delta H°$ is -15.8 kcal/mol and $\Delta S°$ is -20.7 e.u.

A number of nitrogen monoxide complexes have been known for many years and have attracted the attention of many chemists because the way that NO interacts with transition metal complexes is similar to the way that CO and O_2 interact with those complexes. And recently, the structure of these complexes, the coordination geometry of the NO ligand,[1-4] ways of synthesizing nitrosyl complexes, and the coordinated NO reaction[5] have been under investigation.

In the course of our attempts to develop a method of removing nitrogen monoxide from a flue gas, we found that many of the peptide and amino acid complexes of iron(II) and cobalt(II) bind NO reversibly in aqueous solutions and, therefore, it became necessary to make a detailed investigation of the conditions under which this binding occurs. But only a few data are available with respect to the thermodynamics of this reaction. The experiments reported in this paper were carried out to determine the thermodynamics of the reversible binding of molecular NO to Fe(II)edta.

Although it has been known that the aqueous solution of Fe(II)edta absorbs NO, it has not been known whether Fe(II)edta binds NO reversibly, and the data have not been reported in its thermodynamics in detail. We found that, under O_2 free conditions, a light yellow aqueous solution of Fe(II)edta turns dark green as it absorbs NO, and it turns light yellow again upon heating, in a vacuum or when purged with nitrogen. We have been able to show that these color changes are caused by the following reversible reaction.

$$Fe^{II}edta + NO(g) \rightleftharpoons Fe^{II}(NO)edta. \quad (1)$$

In this paper, we discuss the thermodynamics of the coordination of molecular NO to Fe(II)edta in an aqueous solution in the temperature range 38.5 to 70 °C.

Experimental

Materials. Reagent grade iron(II) sulfate and EDTA were used without further purification. The nitrogen monoxide gas that was used was an extra pure mixture of NO and N_2 (NIHON SANSO).

Preparation of Fe(II)edta. The aqueous solution of Fe(II)edta was prepared according to the following method. EDTA was first dissolved in distilled water under O_2 free conditions and the pH of the solution was adjusted to *ca.* 9 by adding a dilute NaOH solution. An equivalent amount of $FeSO_4$ was added to the solution and the pH of the solution was adjusted to the desired values by adding a dilute HCl or NaOH solution.

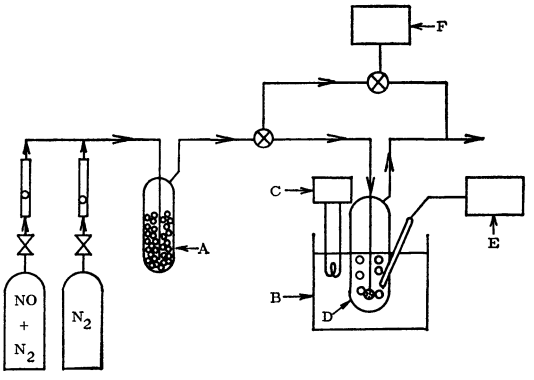

Fig. 1. Schematic diagram of apparatus.
A: gas mixer, B: water bath, C: thermostat
D: absorber, E: pH meter, F: NO_x meter.

The concentration of iron(II) was measured with the usual 1,10-phenanthroline method.[6]

Equilibrium Measurements. Equilibrium constants were determined at 38.5, 55, and 70 °C. A schematic diagram of the apparatus is shown in Fig. 1. The temperature was controlled to within ±1 °C by a thermostat. All experiments were carried out under O_2 free conditions to avoid irreversible oxidation of the Fe(II)edta. A 100 ml quantity of the Fe(II)-edta solution (0.008—0.036 M) was introduced to an absorber. A mixture of NO and N_2 of known NO concentration was bubbled through the solution and the NO concentration in the outlet gas was measured with Beckman Model 951 NO_x meter. The gas flow rate was 0.73 N.T.P. l/min. NO absorption was carried out until equilibrium was reached, *i.e.* until the NO concentration in the outlet gas became equal to that n the inlet gas.

The amount of NO absorbed was determined by graphical integration of the NO concentration in the outlet gas.

Results and Discussion

To confirm the stoichiometry of NO uptake by Fe(II)edta, we first measured the quantitative NO uptake of an aqueous Fe(II)edta solution. The experiments were performed by absorbing pure NO gas obtained from Matheson Co. with a 0.1 M Fe(II)edta solution at pH 6 at room temperature. It was found from these experiments that 1.0 mol of NO was taken up by each mole of Fe(II)edta initially present, and hence that Fe(II)edta binds NO in a molar ratio of unity. The NO uptake by Fe(II)edta was also found by visible spectroscopy measurements to be reversible.

Figure 2 shows the visible absorption spectrum of the

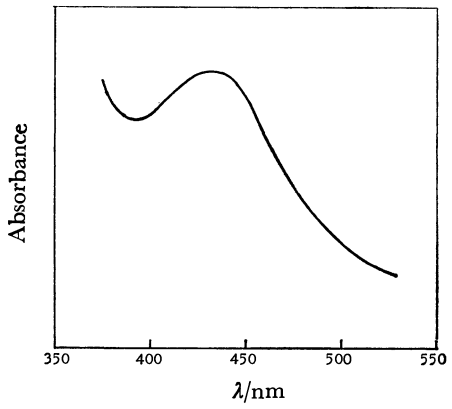

Fig. 2. Spectrum of $Fe^{II}(NO)$ edta at 15 °C.

aqueous Fe(II) (NO)edta solution. The initial light yellow color of the Fe(II)edta solution changes to dark green upon NO absorption and an absorption peak appears at λ=434 nm. When the solution is heated or purged with N_2, it regains its original light yellow color, with the desorption of NO. This indicates that Reaction 1 is completely reversible. Furthermore, the pH of the solution increased from 6.0 to 7.2 after absorbing NO. This increase is probably caused by the displaced carboxylic group since it binds the H^+ in the solution. The expression of the equilibrium constant for Eq. 1 can be written as

$$K_c = \frac{[Fe^{II}(NO)edta]}{[Fe^{II}edta]\cdot[NO]_{aq}} \quad (2)$$

Equation 2 can also be written as

$$K_c = \frac{[Fe^{II}(NO)edta]\cdot H}{\{[Fe^{II}edta]_0 - [Fe^{II}(NO)edta]\}\cdot[NO]_g} \quad (3)$$

where $[Fe^{II}edta]_0$ is the initial molar concentration of Fe(II)edta, $[Fe^{II}(NO)edta]$ is the equilibrium molar concentration of the NO adduct, $[NO]_g$ is the partial pressure of the NO in the gas, and H is the Henry's constant for the solubility of NO in water.

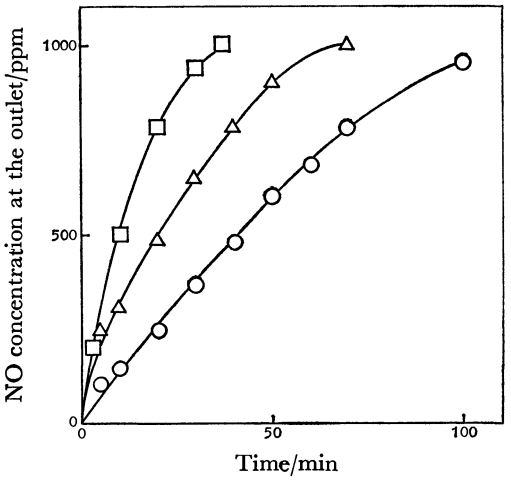

Fig. 3. Graphical illustration of the canges in NO concentration at the absorber outlet.
Inlet gas contents: NO 1000 ppm, N_2 balance, gas flow rate: 730 Nml/min, temperature: 55 °C, pH: 3.0, Fe(II)edta concentration: -□- 0.008 M, -△- 0.016 M, -○- 0.036 M.

Figure 3 shows changes in NO concentration at the absorber outlet for various concentrations of the Fe(II)-edta solution. By graphically integrating the outlet NO concentration curves, the amount of absorbed NO in each solution can be obtained.

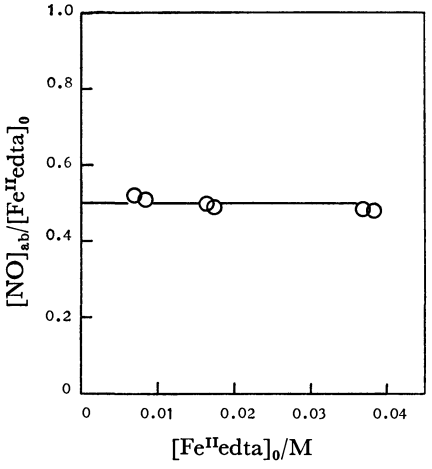

Fig. 4. Effect of $Fe^{II}edta$ concentration on NO absorption.

Figure 4 shows the effect of $[Fe^{II}edta]_0$ on the molar ratio of the absorbed NO to $[Fe^{II}edta]_0$ obtained from Fig. 3. It was found that the ratio was not affected by $[Fe^{II}edta]_0$ of 0.008—0.036 M at pH 3.

The effect of pH on the molar ratio of absorbed NO to total iron(II) ($[Fe^{II}]_0+[Fe^{II}edta]_0$) is shown in Fig. 5. The ratio was not affected by the pH value of the solution in the pH range of 3—6, but this ratio decreased drastically below a pH of 3.

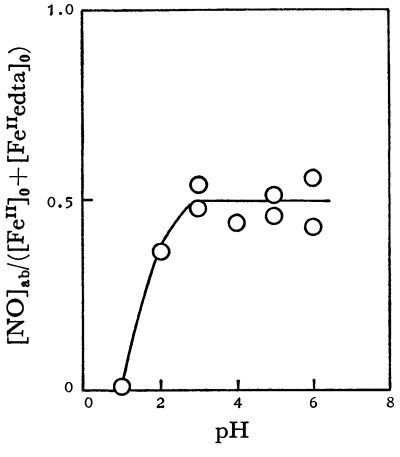

Fig. 5. Effect of pH on NO absorption.
Inlet gas content: NO 1000 ppm, N_2 balance, gas flow rate: 730 Nml/min, temperature: 55 °C, Fe(II): 0.02 M, edta: 0.02 M.

Because Fe(II)edta is very stable and almost 100% of the Fe(II) in the solution exists as Fe(II)edta,[7] in the pH-range 3—6, Eq. 3 can be rewritten as

$$\frac{[Fe^{II}edta]_0}{[NO]_{ab}} = 1 + \frac{H}{[NO]_g\cdot K_c} \quad (4)$$

In this experiment, the NO concentration and tempera-

Table 1. Thermodynamic data for reversible NO coordination to iron complexes

Complex	State	Temperature °C	H/K_c atm	K_c M^{-1}	$\Delta H°$ kcal/mol	$\Delta S°$ e.u.
Fe(II)edta	aqueous solution	38.5	0.18×10^{-3}	3.48×10^{6}		
		55.0	0.850×10^{-3}	0.859×10^{6}	−15.8	−20.7
		70.0	2.38×10^{-3}	0.339×10^{6}		
Fe(II)edta[9]	aqueous solution	60—70	—	—	−14.1	—
Fe(III)Cl(TPP)[10]	solid	25.0	—	$3.45\ atm^{-1}$	−5.26	−15

ture were kept constant and, therefore, $H/[NO]_g$ was constant. This indicates that the equilibrium constant K_c which is defined by Eqs. 2 and 3, is not affected by pH in the range 3—6. But below a pH of 3 the dissociation of Fe(II)edta takes place, which gives rise to a decrease in the NO absorption.

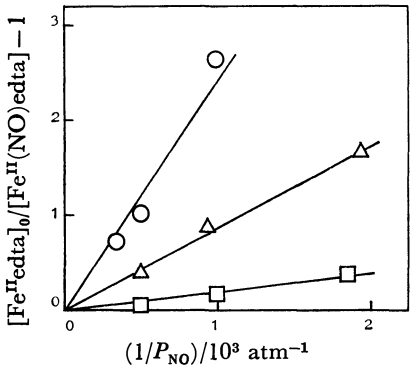

Fig. 6. Plot of $[Fe^{II}\ edta]_0/[Fe^{II}(NO)edta]-1$ *vs.* $1/P_{NO}$
pH: 3.0, temperature: -○- 70 °C, -△- 55 °C, -□- 38.5 °C.

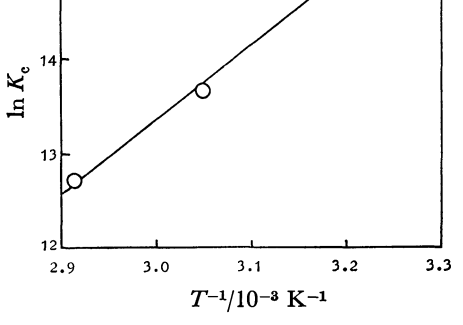

Fig. 7. van't Hoff plot of equilibrium constants for Eq. 1.

Figure 6 shows the relation between $[Fe^{II}edta]_0/[Fe^{II}(NO)edta]-1$ and $1/P_{NO}$ at temperatures of 38.5, 55, and 70 °C. H/K_c can be obtained from the slope of each line for each of these temperatures. Using Henry's constants,[8] the equilibrium constant at each temperature was obtained. These values are summarized in Table 1. Figure 7 shows the van't Hoff plot of these equilibrium constants. The values of thermodynamic quantities obtained from the van't Hoff plot are also given in Table 1. Enthalpy and entropy for Reaction 1 are $\Delta H°=-15.8$ kcal/mol and $\Delta S°=-20.7$ e.u., respectively. Recently Hasui studied the binding of NO to Fe(II)edta in an aqueous solution and measured its equilibrium constants in the temperature range 60—70 °C in the pH range 2.4—8.5.[9] They reported that the enthalpy change for the coordination of NO to Fe(II)edta was $\Delta H°=-14.1$ kcal/mol. This value is approximately same as our data.

The binding of gases with metal complexes is characterized by a small negative change in enthalpy and a relatively large change in entropy to compensate for the enthalpy change. This occurs because a gas loses its translational and rotational degree of freedom by coordination. The stability of such reversible complexes is examined by comparing their $\Delta H°$ values. But to the authors' knowledge, the only available thermodynamic data to date for the reversible binding of NO with iron complexes other than Fe(II)edta are those obtained by Vasca.[10] Their data are shown in Table 1 together with our data. But their data are for NO absorption by Fe(III)Cl (TPP) (TPP=tetraphenyl porphinate)in the solid state. Further extensions of the present work to different solvent systems and ligands will enable us to establish more fully the factors contributing to the stability of reversible NO complexes.

Decay of Naphthalene Phosphorescence in the Presence of Some Chlorinated Compounds. An External Heavy Atom Effect

Nozomu EBARA,* Yusuke YAJIMA, and Hiroshi WATANABE

Department of Chemistry, College of General Education, The University of Tokyo, Meguro-ku, Tokyo 153

(Received January 12, 1979)

The decay of the phosphorescence of naphthalene in the mixed solutions of methylcyclohexane and several chlorinated compounds has been analyzed. In many cases the decay was almost exponential and the decay constant was a function of the concentration of chlorinated compounds. In the case of carbon tetrachloride, the decay was distinctly non-exponential. The decay was analyzed by a Laplace transformation method. In this case a complex was formed, in equilibrium with the free naphthalene molecule, and the decay constant of the former increased when the concentration of CCl_4 increased. The external heavy atom effect takes place in two ways: one by complex formation with the molecule containing heavy atoms and another by a long range interaction through a statistical distribution of the latter molecules around the phosphorescing molecule.

The interaction of a molecule with molecules containing heavy atoms may frequently result in an apparent decrease in the triplet lifetime of the former. This external heavy atom effect has been the subject of a number of experimental and theoretical investigations. Quantitative treatment of the effect has led to an elucidation of the mechanism in terms of enhanced spin-orbit interaction through formation of CT complexes in which emitting triplet species may be either a locally excited state of one of the component molecules[1-9] or a CT state.[10-13] Previous investigators have laid stress on a particular route of enhancement, for example,

a) mixing of the triplet state with the locally excited singlet state,[1-3]

or

b) mixing of the triplet state with the CT singlet state.[4,5,13]

The heavy atom effect on the phosphorescence of stable CT complexes has been investigated.[7-12] It has been shown that the rate constants of both $S_1 \rightsquigarrow T_1$ and $T_1 \rightarrow S_0$ transitions are increased. Furthermore, it has also been demonstrated that the $T_1 \rightsquigarrow S_0$ radiationless transition is not much enhanced and the observed reduction in the triplet lifetimes is mainly due to a change in the radiative lifetime.[7]

The decay of benzene phosphoresence in rare gas hosts has been reported.[14-20] It has been found that heavy atoms such as Kr or Xe have a drastic effect on the decay rate. Moreover, the geometrical arrangement of the heavy atoms around the molecule has been found to affect its lifetime. The mechanism has been elucidated by K. C. Lin and S. H. Lin[3] in terms of enhanced spin-orbit coupling in the benzene ring in the presence of a heavy atom perturber. Najbar[17-20] has discussed their experimental results in terms of a mean lifetime averaged over different sites, each occupied by a benzene molecule and a variable number of heavy atoms.

The dependence of the heavy atom effect on the distance between the emitting molecule and the heavy atom has also been investigated. Kavarnos *et al.*[21] have synthesized several bromine-substituted naphthonorbornanes and have measured their radiative as well as non-radiative lifetimes. Giaccino and Kearns[22] have doped naphthalene molecules into crystals of various halogen-containing molecules and have measured the phosphorescence lifetimes. None of them, however, could find any distinct relationship between the lifetime and the halogen–naphthalene distance.

Eisenthal[8] has found that in the presence of tetrachloro- or tetrabromophthalic anhydride or in the presence of propyl iodide the phosphorescence of 2-chloronaphthalene becomes very similar to that of naphthalene. He claimed that the CT singlet state playes an important role in the donor phosphorescence. Similar observations were also reported by other authors.[23]

It has been shown that the lifetime is dependent on the concentration of concomitant heavy atom compounds. If the heavy atom effect manifests itself through formation of a CT complex, the decay of phosphorescence would consist of two exponential components, one for the complex and another for naphthalene itself, and the ratio of their coefficients would be a function of the concentration. In a separate experiment on the phosphorescence of haloalkylnaphthalenes, we have found some evidence for a non-complexed external heavy atom effect. If such is the case, the concentration dependence is a function of the distribution of heavy atom molecules around the phosphorescing molecule.

In the following, we have employed chlorinated compounds because they seemed least liable to form complexes with naphthalene. The decay curve of naphthalene molecule in the presence of chlorinated moleculas was analyzed as a function of the concentration of the latter.

Experimental

Naphthalene-d_0 and naphthalene-d_8 were zone-refined several times. Methylcyclohexane (MCH) and the following liquid samples were purified by column chromatogram or distilled: carbon tetrachloride, dichloromethane, propyl chloride, butyl chloride, cyclohexyl chloride, benzyl chloride, chlorobenzene, *o*-dichlorobenzene, and *m*-dichlorobenzene. Naphthalene was dissolved in a chlorinated compound–MCH mixture in various mole fractions from 0: 1 to 1: 0. The concentration of naphthalene molecule was kept at 5×10^{-3} mol dm^{-3} in every case. Samples were excited at 315 nm at 77 K and the decay of phosphorescence was displayed on a recorder. In the photoselection experiment, the exciting light was passed through a Gran-Thomson prism and the emission was observed through a plastic polarizer.

Results and Discussion

The decay of naphthalene phosphorescence in the presence of the above chlorinated compounds was almost exponential, except for the case of carbon tetrachloride (Figs. 1—3). The decay constants were sometimes very sensitive to the presence of chlorinated molecules and sometimes quite insensitive. There seemed no distinct relation to the extent of CT interaction. Generally, compounds with one chlorine atom were insensitive and compounds with more than one chlorine atom were sensitive. In the latter case, the concentration dependence was remarkable, although the exponential behavior seemed to appear quite clearly. There were two characteristic observations to be noted.

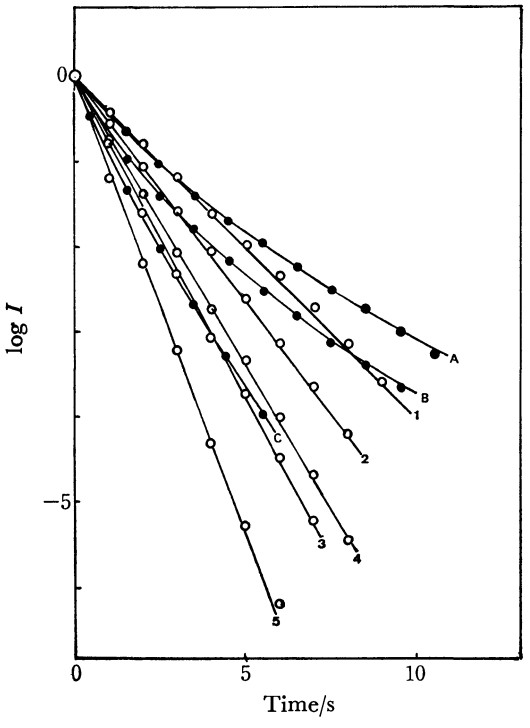

Fig. 1. Phosphorescence decay of naphthalene in MCH in the presence of CH_2Cl_2 or CCl_4 of various mole fractions: CH_2Cl_2, 1) 0.0, 2) 0.02, 3) 0.14, 4) 0.87, 5) 1.00; CCl_4, A) 0.25, B) 0.35, C) 0.60.

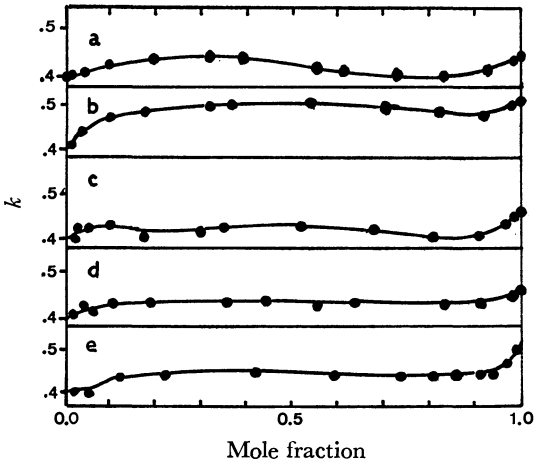

Fig. 2. Phosphorescence decay constant of naphthalene in the mixed solution of MCH and monochloro compounds: a) C_6H_5Cl, b) $C_6H_5CH_2Cl$, c) $C_6H_{11}Cl$, d) C_4H_9Cl, e) C_3H_7Cl.

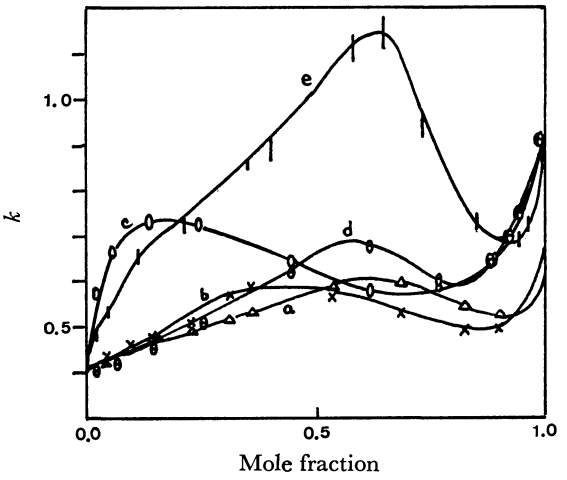

Fig. 3. Phosphorescence decay constant of naphthalene in the mixed solution of MCH and di- or tetrachloro compounds: a) o-$C_6H_4Cl_2$, b) m-$C_6H_4Cl_2$, c) CH_2Cl_2, d) CH_2Cl_2 in EtOH, e) CCl_4.

(1) The decay constant increased when the mole fraction of chlorinated compound increased, until it reached a maximum. After this concentration, the solid solution lost its transparency, indicating that two solid phases separated out.

(2) The decay constant increased again when the mole fraction of chlorinated compound approached 1.0. However, the rate constant in this region was less than the maximal value. As this region was very near to the pure phase of chlorinated compound, it may be reasonable to assume that the sample was again single phase.

Hence, the regions of monotonic increase (from the mole fraction of 0.0 to the maximum of k and from the minimum of k to mole fraction 1.0) seem to be important.

If the concentration dependence is the result of complex formation, the decay should be non-exponential. One may well think that the experimental accuracy had failed to detect its bicomponent character, but then the observed large change in the rate constant should be within this inaccuracy, which is unrealistic. Moreover, the molecule employed seemed quite unsusceptible to complex formation. It can be shown by a model calculation that a decay of a statistical body, of which the distribution of the decay constant has a fairly sharp peak, seems like a true exponential decay. Hence, it may be concluded that the decay is not bicomponent, but is multicomponent and that the decay component distribution has a sharp peak around a point which moves toward larger values with increasing concentration of the chlorinated compound.

We assume that the distribution of chlorinated compound around naphthalene molecules is random but statistically uniform, and that the decay constant of each naphthalene molecule is determined by its environment. As the heavy atom effect is short-range, the decay constant of each naphthalene molecule is mainly determined by the distance to its nearest chlorinanated

molecule. The distribution of the nearest distance is expressed[24] by

$$\rho dr = 4\pi r^2 C \exp(-4\pi r^3 C/3) dr$$

with a peak at

$$r_{max} = (2\pi C)^{-1/3}$$

where C is the concentration of the chlorinated molecule in $Å^{-3}$ and r in Å (Fig. 4). The distribution of k itself can not be estimated, but it is a sharp function of r and would have a sharp peak at the respective value of $k(r_{max})$, which would shift monotonically toward larger values according to the concentration.

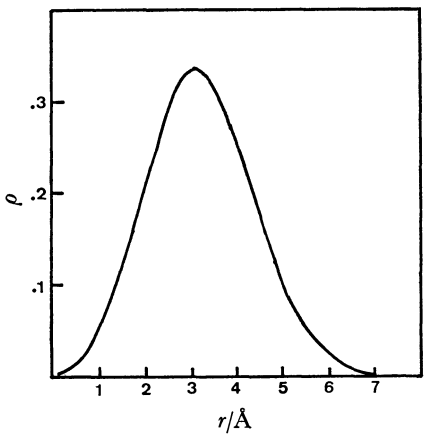

Fig. 4. Distribution of nearest distance $\rho(r)$ at $C=5.3 \times 10^{-3}$ $Å^{-3}$.

It may be asked that the observed effect may be ascribed to a medium-range CT interaction, rather than a heavy atom effect. It can be discarded because the observed effect seemed irrelevant to the extent of the donor character of the chlorinated compounds. It is often suggested that the overlap integrals between orbitals of the heavy atom and those of atoms participating in the triplet state serve as a measure of the heavy atom effect. In our experiment, however, they are somewhat smaller to account for the observed concentration dependence of the heavy atom effect. We assume that the effect is mainly carried by the framework of the surrounding solvent molecules, as can be shown by a CNDO calculation. In addition, the heavy molecule would exert an out-of-plane interaction. In this respect, we have carried out a photoselection measurement of the phosphorescence of naphthalene in the mixture solution of CCl_4 and EPA (Fig. 5). The phosphorescence tended to depolarize when CCl_4 was added, indicating that the phosphorescence has some in-plane character. It follows that the triplet state mixed with π-π^* singlet states by the presence of a perturber. If the interaction of the perturber destroys the planar symmetry of the molecule, one center spin-orbit integral on the heavy atom suffices to effectively mix the π-π^* triplet state with the π-π^* singlet states, thereby remarkably decreasing the radiative lifetime.

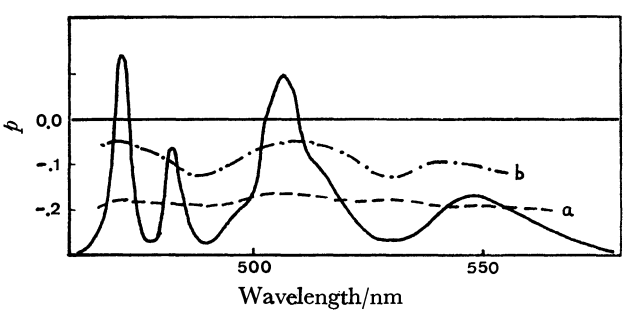

Fig. 5. Polarization of the phosphorescence of naphthalene in a) EPA and b) CH_2Cl_2–EPA (mole fraction 0.23).

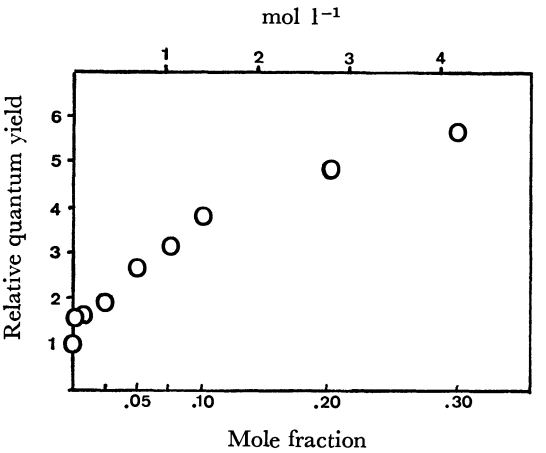

Fig. 6. Apparent quantum yield of $C_{10}D_8$ in EPA in the presence of CCl_4.

We have measured a relative quantum yield of the phosphorescence as a function of the concentration of CCl_4 in the EPA–CCl_4 mixture solution (Fig. 6). If we assume that the radiationless lifetime is not affected and that the lifetime of $C_{10}D_8$ (22 s) is equal to the radiative lifetime of $C_{10}H_8$, then a six time increase of the radiative decay constant leads to a mean total decay constant of 0.59—0.64 s^{-1} at 0.3 mole fraction, according to the extent to which the fluorescence ($q=0.18$) is quenched by an enhanced intersystem crossing. This value of the decay constant can be compared with the observed mean value of 0.78 s^{-1}. Thus the experiment of Eisenthal, in which the phosphorescence spectrum of chloronaphthalene becomes very similar to that of naphthalene in the presence of alkyl bromide or iodide, may also be interpreted by assuming that the totally-symmetric bands acquire large oscillator strengths from π-π^* singlet states.

If the solvent molecules participate in the heavy atom effect, the latter may be sensitive to the kind of solvent. In Fig. 3 the same chlorinated compound CH_2Cl_2 was examined with two different solvents, methylcyclohexane and ethanol. They had quite different profiles, although the decay constant of naphthalene was the same in either solvent when the perturber was absent.

In the case of monochloro compounds (Fig. 2), the heavy atom effect manifested itself only slightly. The decay constant in the presence of the perturber is always very near to that in the absence of the perturber. In contrast, the change was remarkable in the case of

dichloro compounds (Fig. 3). There seemed to be no parallelism between the heavy atom effect and the ability of forming a CT complex. Only a tentative explanation can be given at present. The contraction of MCH when chilled from room temperature to 77 K was measured to be 75%, so that the mean distance between two solvent molecules is 5.4 Å, which we assume to be the same as the mean distance between a naphthalene molecule and a nearest solvent molecule. In a solution of 0.6 mole fraction of chlorobenzene the mean distance from a naphthalene molecule to the nearest chlorobenzene molecule is 6.4 Å, and the mean distance from a naphthalene molecule to the nearest chlorine atom is also 6.4 Å, assuming a free rotation for the chlorobenzene molecule. But in the case of *p*-dichlorobenzene, the mean distance to the nearest chlorine atom is reduced by 1.6 Å, a half of the center-of-molecule chlorine distance. The difference may give rise to a drastic change, as the distance dependence of the heavy atom effect is large.

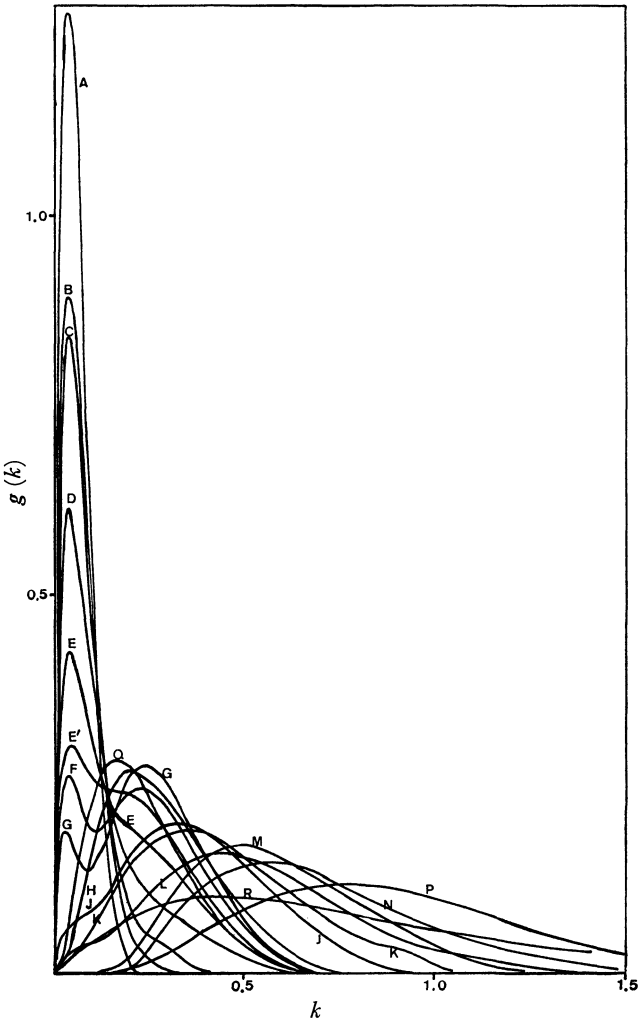

Fig. 7. Distribution function of the decay constant of $C_{10}D_8$ in the mixed solution of CCl_4 and MCH in varying mole fraction of CCl_4: A) 0.00, B) 0.005, C) 0.01, D) 0.025, E) 0.05, F) 0.07, G) 0.10, H) 0.15, J) 0.20, K) 0.25, L) 0.30, M) 0.41, N) 0.51, P) 0.60, Q) 0.99, R) 1.00.

The decay of naphthalene in CCl_4 was non-exponential (Fig. 1). As CCl_4 can form a CT complex with naphthalene, we expected that the decay had two components and the peak of the complex would move in accordance with the advent of statistical heavy atom effect. Very rough estimates of the mean rate constants are illustrated in Fig. 3; these show a similar inflecting profile. The decay curves were analyzed by a method of Laplace transformation developed by one of the authors.[25] The decay function can be expressed as

$$f(t) = \int_{s_0}^{\infty} g(s) \exp(-st) \mathrm{d}s$$

where $g(s)$ is a normalized distribution function of the decay constant. $g(s)$ is approximated by a power series with an exponential function which guarantees the convergence:

$$g(s) = \sum_{i}^{N} A_i (s - s_0)^i \exp(-Bs)$$

where A_i's are the coefficients to be determined and N and B are ajustable parameters. A method of least squares was applied for A_i's to obtain the best fit to the observed decay curve. The results are shown in Fig. 7. The peak of the complex is gradually formed at the expense of that of free naphthalene molecule, and the former moves according to the concentration. Thus the external heavy atom effect takes place in two ways: one by forming a CT complex with a molecule containing heavy atoms, and the other by a statistical approach of heavy molecules to the phosphorescing molecule.

When the mole fraction of the halogenated compound was large, the rate constant became small again, contrary to expectation. It might be supposed that in an incommodious crystal lattice of the halogenated compound the naphthalene molecule is deprived of the solvent molecules which bring the heavy atom effect in a favorable position or that the disposition of the naphthalene molecule itself is unfavorable. The singular nature at high concentration limit is open to future investigation.

This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Raman Spectra of a Compound under Inversion Motions: *N,N'*-Dimethylpiperazine

Kunio FUKUSHIMA

Department of Chemistry, Faculty of Science, Shizuoka University, 836, Oya, Shizuoka 422

(Received February 16, 1979)

Raman spectra of methanol and aqueous solutions of *N,N'*-dimethylpiperazine were measured. Forms of stable conformers in various states were studied by comparison of the spectra obtained under various conditions. It was found that hydrogen bonding to nitrogen atoms of *N,N'*-dimethylpiperazine causes a conformational change.

Many proofs of the inversion motion of the molecule have been given by NMR studies.[1-6] In order to study the conformation of molecules subjected to inversion motions, ring inversion and inversion at nitrogen, *N,N'*-dimethylpiperazine was studied by Raman spectroscopy because of its high molecular symmetry. Since suppression of inversion motion at nitrogen by hydrogen bonding was expected, effect of the suppression on molecular conformation was studied by measuring Raman spectra of solutions of the substance.

Experimental

Commercial *N,N'*-dimethylpiperazine (grade GR, Tokyo Kasei Chemical Co., Ltd.) was used without further purification. Raman spectra were measured with a Model R-800T Raman spectrophotometer (Japan Spectroscopic Co., Ltd.) under excitation with a Spectra Physics argon ion laser (model 165) using 514.5 nm line (300 mW). 0.1 ml or 0.3 ml Raman cells were used. Infrared spectra of the liquid were recorded on a Hitachi EPI-G3 spectrophotometer and a Hitachi FIS-3 far infrared spectrometer. The results of the measurements are shown in Table 1 and Fig. 1.

Results and Discussion

Comparison of Raman Spectra of N,N'-*Dimethylpiperazine in Liquid State with Infrared Spectra.* Coincidence of Raman shift frequency with infrared absorption maximum frequency is observed only for 1420 cm^{-1} and 630 cm^{-1} (Table 1). The couples, 1450 cm^{-1} (Raman) and 1455 cm^{-1} (IR), 1020 cm^{-1} (Raman) and 1018 cm^{-1} (IR), are close, both being in the higher frequency region (>1000 cm^{-1}), and the difference in Raman shift frequency and infrared absorption maximum frequency is expected to be intrinsically small. For all the other couples, frequencies of Raman shift and infrared absorption maximum differ a great deal. This suggests that the mutual exclusion rule holds for the Raman spectra and infrared spectra. Thus, conformers in the liquid take molecular forms each having a center of symmetry, diaxial conformer (AA), diequatorial conformer (EE) or some other form. A Raman line and the corresponding infrared band are observed at *ca.* 630 cm^{-1}, their intensity or absorbance being very small. This can be interpreted as due to cis form (AE conformer), as confirmed by dipole moment measurement to exist in mole fraction of 0.103 for a benzene solution.[7]

Raman Spectrum Change Associated with the Change of State, Pure Liquid to Solutions. The Raman lines having shift frequencies (1313 cm^{-1}, 1173 cm^{-1}, 457 cm^{-1}, 277 cm^{-1}) higher than those of the pure liquid (1306 cm^{-1}, 1160 cm^{-1}, 440 cm^{-1}, 251 cm^{-1}) appear in the spectrum of aqueous solution A (Table 1 and Fig. 1), the weaker Raman lines corresponding to the latter coexisting with the former. In the case of aqueous solution B, where the fraction of water is smaller than that of aqueous solution A, shift frequency values of the

Figures in parentheses represent relative intensities, the maximum value being 100. a) Frequency in cm^{-1}. b) Degree of depolarization. c) Raman lines, the frequency, the intensity and ρ of which could not be determined because of overlapping with the Raman lines of methanol. d) Intensity and ρ could not be determined precisely.

four Raman lines have intermediate values between those for the pure liquid and those for aqueous solution A. For aqueous solution C (mole ratio, solute 1 : water 9.015) the four Raman lines corresponding to those of the pure liquid disappear. For a methanol solution, almost the same spectrum as that of aqueous solutions is observed.

Interpretation of Results. The spectrum change associated with the change of state, pure liquid to solution, is considered to be due to the conformational

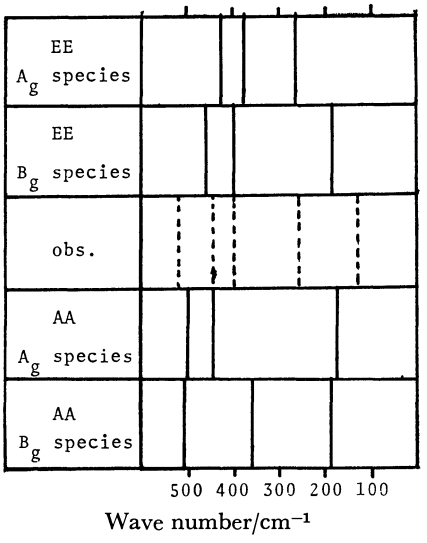

Fig. 2. Calculated frequencies of A_g and B_g species of *N,N'*-dimethylpiperazine compared with observed Raman shift frequencies.

change caused by hydrogen bonding or the change of nature of bonding in *N,N'*-dimethylpiperazine molecule. As the number of Raman lines arising from hydrogen bonded species is the same as that of the liquid, the species is also considered to have a center of symmetry. The molecular shape of species can be deduced as follows.

Normal vibration calculation of conformers (AA conformer and EE conformer belonging to C_{2h} point group) was carried out using force constants of related molecules.[8,9] The calculated frequencies of Raman active skeletal deformation vibrations (Table 2 and Fig. 2) are sensitive to conformational change. They are compared with the observed frequencies of the liquid in the table and the figure. Assigning polarized Raman lines ($0<\rho<0.75$) to calculated frequencies of A_g species and depolarized Raman lines ($\rho=0.75$) to those of B_g species, the calculated frequencies of EE conformer almost fit the observed Raman lines. However, those of AA conformer do not correspond exactly to the observed frequencies. The Raman lines of the pure liquid (440 cm^{-1}, 251 cm^{-1}), whose shift frequencies change with change of state, pure liquid to solution, are assigned to C–N(–CH_3)–C skeletal deformation vibrations.

The change can be interpreted as due to the conformational change arising from the change of valence state of nitrogen atoms. It can not be explained in terms of the conformational change of EE conformer to AA conformer for the following reason. Of the calculated frequencies of A_g species of EE conformer, both 422 cm^{-1} and 369 cm^{-1} increase and 254 cm^{-1} decreases by the conformational change. Thus, the observed frequency of polarized Raman line (251 cm^{-1}) of the pure liquid is expected to decrease if the change is caused by the conformational change. However, the frequency increases to 277 cm^{-1}. Of the calculated frequencies of B_g species of EE conformer, 457 cm^{-1} increases and 186 cm^{-1} does not change its frequency considerably, while 395 cm^{-1} decreases its frequency by the conformational change of EE conformer to AA conformer. Therefore, if the change is due to the conformational change, a depolarized Raman line is expected to appear in the region 300 cm^{-1}—400 cm^{-1}. However, this is not the case. It can thus be concluded that the conformer having a center of symmetry and a molecular shape similar to that of EE conformer exists in pure liquid in abundance and that another conformer, also having a center of symmetry and differing from the above conformer in the molecular conformation around nitrogen atoms, appears in aqueous solutions and in a methanol solution as a results of hydrogen bonding to nitrogen atoms.

Probable Conformers in Solutions and in Pure Liquid. Hydrogen-bonded species. By the formation of hydrogen bonding to nitrogen atoms of *N,N'*-dimethylpiperazine, valence orbitals of the nitrogen atoms may become similar to sp^3 hybrid orbitals, and the molecular conformation having bond angles close to tetrahedral angles would become abundant. Conformers in pure liquid. For trimethylamine, C–N–C angles have been found to be $108.7°\pm1°$, which is almost a tetrahedral angle corresponding to sp^3 hybrid orbitals.[10] Considering resemblace of the skeleton of C–N(–CH_3)–C of *N,N'*-dimethylpiperazine with trimethylamine, the valence orbitals of nitrogen atoms in *N,N'*-dimethylpiperazine are expected to be almost sp^3 orbitals, which do not seem to be affected much by hydrogen bonding to the

nitrogen atoms. However, a remarkable frequency change in the deformation vibrations of C–N(–CH_3)–C skeleton by hydrogen bonding is observed, suggesting the change in the valence state of nitrogen atoms. In pure liquid, therefore, time-averaged orbitals of the nitrogen atoms during inversion motions might be in sp^2 state. In accordance with the assumption, a simple calculation revealed that planar conformation around the nitrogen atoms can be realized by changing the azimuthal angle of N–CH_2–CH_2–N internal rotation axis from 60° to 46°34′ and all the C–N–C angles from at tetrahedral angle to 120° with no changes in all the bond lengths and other bond angles (tetrahedral angles), which require large energy. In the model, CH_2–CH_2 bond length is assumed to be the same as that of CH_2–N bond length on the basis of Rerat's work.[11]

Vibrational Spectra and Normal Coordinate Calculations for Methyl-1-propynylmercury(II) and Its Deuterated Analogues†

Yoshika IMAI* and Koyo AIDA

Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai 980

(Received March 31, 1979)

Infrared spectra (4000—80 cm^{-1}) of $CH_3HgC{\equiv}CCH_3$, $CD_3HgC{\equiv}CCH_3$, $CH_3HgC{\equiv}CCD_3$, and $CD_3HgC{\equiv}CCD_3$ have been obtained in carbon tetrachloride, carbon disulfide and benzene solutions, as well as in the solid state at liquid nitrogen temperature. Raman spectra (4000—0 cm^{-1}) have also been recorded on benzene solutions and on solids at room temperature. Assignments for all the fundamentals have been made assuming C_{3v} molecular symmetry. Normal coordinate calculations have been carried out in order to confirm the proposed assignments.

In a previous paper[1] a report was given on the vibrational spectra and normal coordinate calculations for methylethynylmercury(II). The study has now been extended to methyl-1-propynylmercury(II). Although many acetylides of the type $RHgC{\equiv}CR'$ have been prepared,[2] no vibrational study on these compounds except methylethynylmercury(II) seems to have been reported. In the present study, infrared and Raman spectra have been obtained for methyl-1-propynylmercury(II) and its deuterated analogues. Assignments for all the fundamentals are made assuming C_{3v} symmetry. Normal coordinate calculations have been carried out in order to confirm the proposed assignments.

Experimental

Methyl-1-propynylmercury(II) was prepared in the following way.

Methylmercury(II) iodide was dissolved in an aqueous solution of potassium hydroxide. Methylacetylene, generated by the action of 1,2-dibromopropane with potassium hydroxide in ethanol,[3] was passed through the solution. White precipitates were filtered and washed with water and then dried in a desiccator over potassium hydroxide pellets. The crude product was purified by sublimation in a vacuum.

Deuterated compounds were prepared in a similar way using methyl-d_3-mercury(II) bromide and/or methylacetylene-d_4, prepared from methyl-d_3-magnesium bromide and mercury(II) bromide, and by the action of D_2O with magnesium carbide,[4] respectively.

Methyl-1-propynylmercury(II) melts at 80—81 °C (no value was found in literature). The mercury content was determined for the undeuterated compound by the method of Spahr *et al.*[5] Found, 78.0%. Calcd for C_4H_6Hg, 78.8%. The molecular weight was also cryoscopically determined in benzene. Calcd for C_4H_6Hg, 255. Measured, 260.

The infrared spectra in the range 4000—400 cm^{-1} were recorded on a Perkin-Elmer 337 spectrophotometer in annealed solid films at liquid nitrogen temperature. Cooling was necessary to prevent sublimation during the course of the measurements. The spectra were also obtained in carbon tetrachloride and carbon disulfide solutions. The instrument was calibrated in the usual way.[6]

Far-infrared spectra in the range 400—80 cm^{-1} were recorded on a Hitachi FIS-III Far-infrared spectrophotometer which had been evacuated in order to remove atmospheric water vapor. The spectra were measured in annealed solid films at liquid nitrogen temperature in order to prevent sublimation. The spectra in benzene solutions were also obtained using polyethylene bags. The instrument was calibrated with water vapor frequencies.

Raman spectra were recorded in the solid state in capillary tubes on a JEOL JRS-S1 Raman spectrophotometer equipped with a 50 mW NEC GLG 108 He-Ne laser. The instrument was calibrated with the emission lines of Ne. The spectra were also measured in benzene solutions in order to obtain qualitative polarizations.

Results and Vibrational Assignments

The infrared and Raman spectra of the four isotopic methyl-1-propynylmercury(II) are shown in Figs. 1 and 2. The symmetry coordinates are summarized in Table 1 and observed frequencies are given in Tables 2—4.

The CHgC skeleton is linear in many organomercurials.[7] It is thus reasonable to assume the same skeleton for the present compounds. Since the two methyl groups in each compound are separated from each other to a greater extent than those in dimethylmercury(II),[8] where the free rotation of methyl groups is believed to be present, it is likely that the free rotation

takes place also in methyl-1-propynylmercury(II). However, the observed spectra can satisfactorily be explained on the assumption of C_{3v} symmetry (a staggered form) for these molecules. With this symmetry, the molecule is expected to have $8A_1$, A_2, and 9E vibrational modes, in which the A_2 mode is inactive in both the infrared and Raman spectra, while the A_1 and the E modes are active in both.

Since the vibrational coupling of the two methyl groups in a molecule is expected to be very small, vibrations of one methyl group are hardly influenced by deuteration of the other. Taking their isotopic shifts and polarizations of Raman bands into consideration, together with the data for related compounds,[9,10] assignments for the methyl groups are easily made.

A strong infrared absorption at *ca.* 2150 cm^{-1} in each isotopic species is hardly affected by deuteration and the corresponding Raman band in solution is polarized. This is undoubtedly assigned to the C≡C stretching.

C–C stretching vibrations for $CH_3C{\equiv}N$ and $CH_3C{\equiv}CH$[10] have been observed at *ca.* 900 cm^{-1}. We have assigned the strong infrared bands at *ca.* 990 cm^{-1} for $CH_3HgC{\equiv}CCH_3$ and $CD_3HgC{\equiv}CCH_3$ to this mode. Upon deuteration of the 1-propynyl group, these bands shift to *ca.* 900 cm^{-1} for $CH_3HgC{\equiv}CCD_3$ and $CD_3HgC{\equiv}CCD_3$, suggesting a vibrational coupling between the C–C stretching and the vibrations of the neighbouring methyl group.

The remaining skeletal vibrations are expected to appear below 600 cm^{-1}. In the solution Raman spectrum for $CH_3HgC{\equiv}CCH_3$, the four bands appear at 556, 363, 340, and 205 cm^{-1}, the bands at 556 and 340 cm^{-1} being polarized. Upon deuteration of the methyl group ($CD_3HgC{\equiv}CCH_3$), the 556 cm^{-1} band shifts to 508 cm^{-1}, while the 340 cm^{-1} band remains at the same position. In contrast, the 340 cm^{-1} band shifts to 325 cm^{-1} upon deuteration of the 1-propynyl group ($CH_3HgC{\equiv}CCD_3$). Thus, the 556 cm^{-1} band can be assigned to the CH_3–Hg stretching and the 340 cm^{-1} to the Hg–CC stretching vibrations. The remaining two bands at 363 and 205 cm^{-1} seem to be due to the skeletal deformations. The former band slightly shifts to lower frequency upon deuteration of the 1-propynyl group, while the latter band exhibits a very small isotopic shift upon deuteration of either methyl or 1-propynyl group. The HgCC deformation in $CH_3HgC{\equiv}CH$[1] has been assigned at 272 cm^{-1}, lower than the CCC deformation in $CH_3C{\equiv}CH$[10] at 336 cm^{-1}. From

the results, the 205 cm^{-1} band is assigned to HgCC deformation and the 306 cm^{-1} to CCC deformation.

The assignment of CHgC deformation is fairly difficult, since the mode is expected to appear below 150 cm^{-1} in weak intensity. In this study, the Raman bands at *ca.* 70 cm^{-1} in the solid state were tentatively assigned to this mode. No solution Raman spectra in this range could be observed owing to obscurity in the background.

Normal Coordinate Calculations and Discussion

Normal coordinate calculations were carried out by Wilson's GF-matrix method on an ACOS 77/700 computer at the Computer Center, Tohoku University, using the iterative least-squares procedure in the usual way. For lack of structural data, the molecular parameters were transferred from those of CH_3HgCl,[11] $CH_3HgC{\equiv}N$[12] and $CH_3C{\equiv}CH$;[13] r(C–H) of CH_3CC, 1.11 Å; r(C–H) of CH_3, 1.10 Å; r(C–C), 1.46 Å; r(C≡C), 1.21 Å; r(CH_3–Hg), 2.08 Å; r(Hg–CC), 2.05 Å; ∠HCH of CH_3CC, 108.5°; ∠HCH of CH_3, 110.7°. The least-squares refinement was carried out in terms of the symmetry force constants, which were fitted to the infrared frequencies in solutions, except for the HgCC and CHgC deformations which were taken from the Raman spectra for solutions and solids, respectively, for the four isotopic species simultaneously.

The symmetry force constants, together with uncertainties from the last cycle of the least-squares refinements, are given in Table 6. The average errors are 0.35% and 0.97% for the A_1 and E vibrations, respectively, the sum of the weighted squares of errors $\sum(\lambda_{obsd}-\lambda_{calcd})^2/\lambda_{obsd}$ being 2.39×10^{-3} and 2.54×10^{-3} for the A_1 and E vibrations, respectively. The agreements between the calculated and the observed frequencies are satisfactory for the four isotopic species (Tables 2—5). The potential energy distributions are also given in these tables. A strong vibrational coupling exists between the C–C stretching and the CD_3 symmetric deformations (Tables 4 and 5, mode Nos. 4 and 6).

a) This work.

In these calculations, the symmetry force constants F_7 and F_8 turn out the CH_3–Hg and Hg–CC valence stretching force constants. A comparison of force constants is given in Table 7. We see that the force constants for the M–CC bond are always larger than those for the M–CH_3 bond. This is in line with the expectation on the basis of the hybridization of the carbon atom adjacent to the metal atom; the sp hybrid in M–CC and the sp^3 hybrid in M–CH_3, make the former bond stronger than the latter.

One of authors (Y.I.) wishes to express his thanks to Assist. Prof. Fumio Watari for helpful suggestions throughout this work and for the computer programs used in calculations.

(Received May 4, 1979)

The volume changes on mixing aqueous solutions of guanidinium bromide with those of tetrabutyl- and tetramethylammonium bromide were measured with a vibration densimeter at 25 °C. The excess volume change of mixing was positive and large for the system of tetrabutylammonium bromide–guanidinium bromide–water. On the basis of the interaction parameters of Friedman's formalism, this result was interpreted in terms of an interaction between guanidinium cation and tetrabutylammonium cation through the change of water structure.

In a previous paper,[1] we reported that the free energy of mixing for the ternary system, guanidinium bromide (GuBr)–tetrabutylammonium bromide (Bu_4NBr)–water was negative and large in magnitude. This result was interpreted in terms of either direct (complex formation) or indirect (through the change of water structure) interaction between the guanidinium cation (Gu^+) and the tetrabutylammonium cation (Bu_4N^+). In other words, $g_{B^+C^+}$, the interaction parameter of the mixed cation pair in Friedman's formalism,[2] was the predominant factor for the mutual salting-in of this system.

In contrast to this result, in the ternary system containing Bu_4NBr and alkali halides, such as KBr or CsBr,[3] the mutual salting-out was observed, in spite of the facts that both K^+ and Cs^+ were structure breaker ions similar to the guanidinium ion.

The volume changes of mixing for the ternary systems KBr–Bu_4NBr–H_2O[4] and NaBr–tetrapropylammonium bromide–H_2O[5] were also determined and large excess volume changes of mixing with positive signs were obtained. The increase of the solution volume by mixing was attributed mainly to the interaction of hydrophobic cations through the change of water structure.

Previously,[6] the authors reported that in organic solutes including ions, the size, shape, and functional groups were the important factors which determine the nature of the solute-water interaction. The structure breaking action of guanidinium ion would thus be different from K^+ and Cs^+, and similar to that of urea with regard to the hydrogen bonding with water molecules.

From these standpoints, it is interesting to investigate the volume change on mixing aqueous solutions of GuBr and Bu_4NBr. In this paper, we reported the volume changes of mixing of the ternary system GuBr–Bu_4NBr–H_2O and GuBr–tetramethylammonium bromide (Me_4NBr)–H_2O up to 2 molalities of total concentration. The data obtained were analyzed by Friedman's formalism and the results are discussed in terms of the interionic interactions and concomitant structural change of water.

Experimental

Materials. GuBr was prepared and purified by the method described elsewhere.[1] Bu_4NBr and Me_4NBr were purchased from Wako Junyaku Co., Ltd. and recrystallized two or more times from the appropriate solvents, as described elsewhere.[7] These compounds were dried *in vacuo* over phosphorous pentoxide before use. The salts were dissolved in redistilled and deionized water.

Method. Stock solutions of total molalities of 2 mol·kg^{-1} with different ionic mole fractions were prepared by weighing and mixing each salt solution. Each stock solution was diluted by weight to the desired molalities before use. About fifteen kinds of sample solutions with different molalities and the same ionic mole fraction were used for the measurement. Solution densities were determined by Seiko SDM 421 and 422 vibration densimeters, which were linked with a quartz oscillator and a digital counter. Pure water and aqueous sodium chloride solution were used as the standards for the calibration of the apparatus. Measurements were done at least twice for every solution and were accurate to $\pm 1 \times 10^{-5}$ g/cm^3. The temperature of the cell chamber was maintained at 25±0.01 °C.

Results and Discussion

Apparent Molal Volumes. The apparent molal volume ϕ_v of the 1 : 1 electrolyte in the solution volume V has been defined in the molality scale:

$$\phi_v = \frac{V - 55.51\bar{V}_A^0}{m} \quad (1)$$

where $\bar{V}_A^0$ is the molal volume of pure water, and m is the solute molality. If we consider a solution in which two electrolytes, B and C having a common ion are dissolved, Eq. 1 can be modified into the following form by using the density and molality and rewriting ϕ_v as $\phi_v(x,m)$,

$$\phi_v(x, m) = \frac{1}{m}\left\{\frac{1000 + m_B M_B + m_C M_C}{d} - \frac{1000}{d_A}\right\}, \quad (2)$$

where d and d_A are the densities of the solution and pure water, respectively, and $m_B(m_C)$ and $M_B(M_C)$ are the molalities and molecular weight of B(C), respectively. In this paper, B denotes GuBr and C denotes tetraalkylammonium bromide. $\phi_v(x,m)$ is the mean apparent molal volume of the mixed electrolyte or the pseudo binary salt at total molality m and ionic mole fraction x, given as

$$m = m_B + m_C, \text{ and } x = m_C/m. \quad (3)$$

For the various x's, the relation between $\phi_v(x,m)$ and m is obtained from the density data, and is shown in Fig. 1 for the GuBr–Bu_4NBr–H_2O system and in Fig. 2

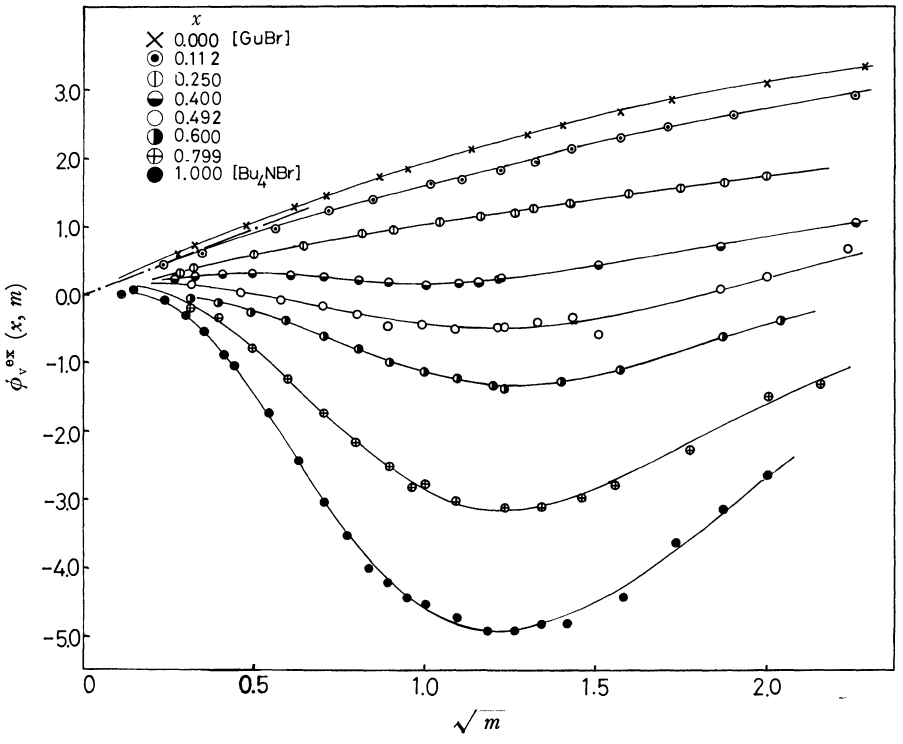

Fig. 1. The concentration dependence of the excess apparent molal volume of H_2O–GuBr–Bu_4NBr system at 25 °C. —— Debye-Hückel line.

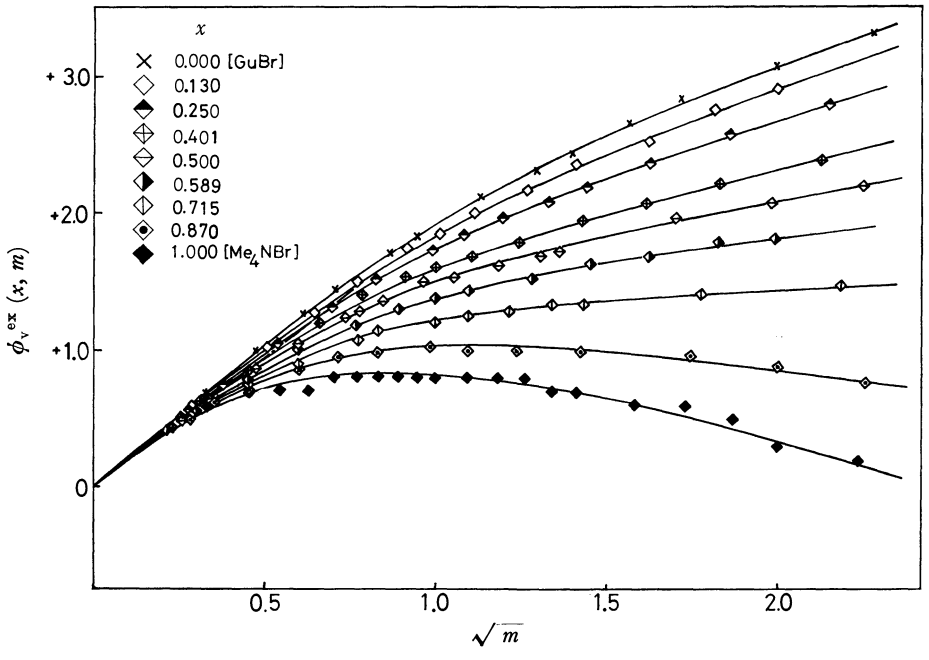

Fig. 2. The concentration dependence of the excess apparent molal volume of H_2O–GuBr–Me_4NBr system at 25 °C. —— Debye-Hückel line.

for the GuBr–Me_4NBr–H_2O system. In both figures the ordinate represents the excess apparent molal volume $\phi_v^{ex}(x,m)$, defined as the deviation from $\phi_v(x,0)$, the mean apparent molal volume at infinite dilution.

$$\phi_v^{ex}(x, m) = \phi_v(x, m) - \phi_v(x, 0). \quad (4)$$

The additivity rule has to hold for $\phi_v(x,0)$ as

$$\phi_v(x, 0) = x\phi_v(1, 0) + (1-x)\phi_v(0, 0), \quad (5)$$

where $\phi_v(0,0)$ and $\phi_v(1,0)$ are the apparent molal volume at infinite dilution for the electrolyte B and C, respectively. As seen in Figs. 1 and 2, the concentration dependence curves of $\phi_v^{ex}(x,m)$ are located between those of binary solutions in both the systems. These curves are expressed in the form of Eq. 6:

$$\phi_v^{ex}(x, m) = \sum_i q_i m^{i/2}, \quad (q_1 = 1.865) \quad (6)$$

and each q_i coefficient is obtained by a least squares

fit with a computer program. These coefficients represent the various intetractions contributing to the solution volumes; they are not useful, however, for interpreting the volume change in terms of ionic interactions, except for calculating ϕ_v at the desired molality.

In the mixing of inorganic electrolytes, the Young's mixture rule[8] is an adequate description of the volume properties of a mixture:

$$\phi_v(x, m) = x\phi_v(1, m) + (1-x)\phi_v(0, m). \quad (7)$$

Equation 7 means that the mixing of two binary solutions at constant total molality produces a ternary solution whose volume is exactly the sum of the volumes of the binary solutions. Combining Eqs. 4, 5, and 7, we have

$$\phi_v^{ex}(x, m) = x\phi_v^{ex}(1, m) + (1-x)\phi_v^{ex}(0, m). \quad (8)$$

This equation may express that the volume changes resulting from the new ionic interaction in the ternary solution are equal to the arithmetic means of the volume changes resulting from the ionic interaction in each binary solution. Most inorganic electrolyte mixtures obey this rule, although slight deviations are obtained.[9] The x-dependence of $\phi_v^{ex}(x,m)$ is shown in Fig. 3 at

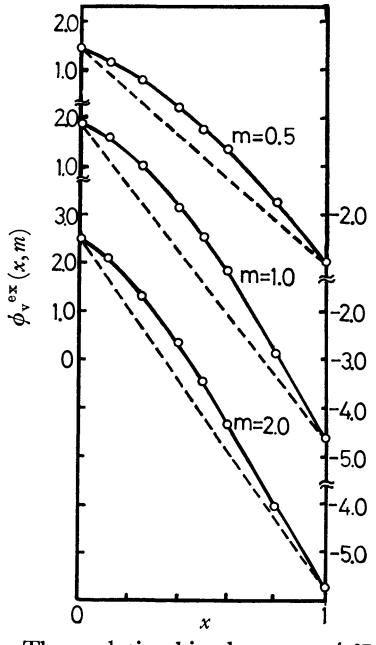

Fig. 3. The relationship between ϕ_v^{ex} and x for H_2O–GuBr–Bu_4NBr system at various m. Dotted line is obtained from Young's rule. Solid line is obtained from experiment.

m=0.5, 1.0, and 2.0 for the GuBr–Bu_4NBr–H_2O system, for which the mixture rule does not hold, and a positive deviation from Eq. 8 is observed. In this case, the addition of term Δ to Eq. 8 is required:

$$\phi_v^{ex}(x, m) = x\phi_v^{ex}(1, m) + (1-x)\phi_v^{ex}(0, m) + \Delta. \quad (9)$$

In the case of the common anion mixing, this deviation may be attributed to the difference in the cation-cation interactions; these are discussed in next section.

Excess Volume Change of Mixing. The excess volumes of the pseudo-binary salt solution may be defined as the product of the total molality and the excess apparent molal volume:

$$V^{ex}(x, m) = m\phi_v^{ex}(x, m). \quad (10)$$

The excess volume change of mixing $\Delta_m V^{ex}$ has been given as the deviation from the linear relationship between V^{ex} and x at constant molality.[4]

$$\Delta_m V^{ex}(x, m) = V^{ex}(x, m) - xV^{ex}(1, m) - (1-x)\phi_v^{ex}(0, m). \quad (11)$$

On substituting Eq. 10 to Eq. 11, we obtain

$$\Delta_m V^{ex}(x, m) = m\{\phi_v^{ex}(x, m) - x\phi_v^{ex}(1, m) - (1-x)\phi_v^{ex}(0, m)\} = m\cdot\Delta. \quad (12)$$

Therefore the Δ in Eq. 9 correspond to $\Delta_m V^{ex}/m$. As shown in Figs. 4 and 5, $\Delta_m V^{ex}$ plotted against x are

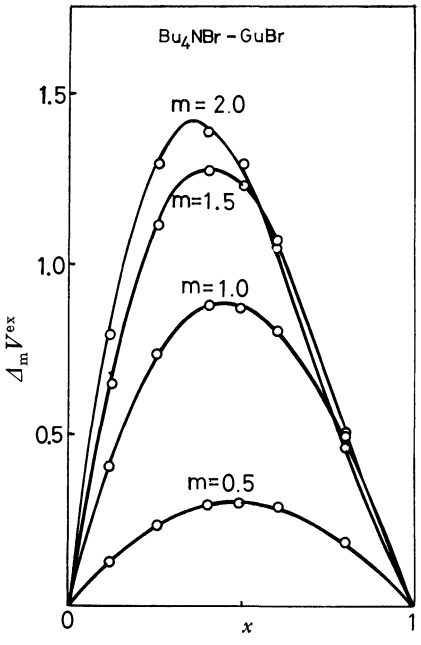

Fig. 4. The relationship between $\Delta_m V^{ex}$ and x at various m of the H_2O–GuBr–Bu_4NBr system.

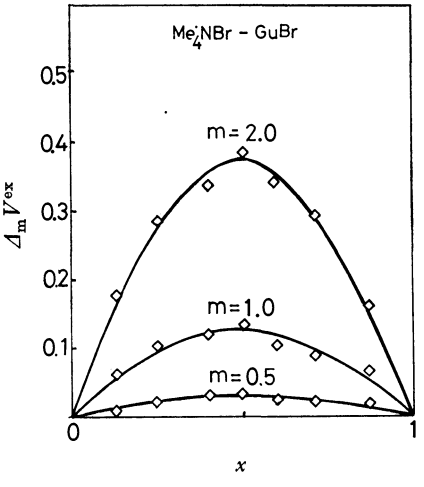

Fig. 5. The relationship between $\Delta_m V^{ex}$ and x at various m of the H_2O–GuBr–Me_4NBr system.

both positive and nearly parabolic. The maximum points for the system GuBr–Bu_4NBr–H_2O are left from the vertical line of $x=0.5$. The $\Delta_m V^{ex}$ values and the degree of the skewness increased with increasing the total molality. The magnitude of $\Delta_m V^{ex}$ for the system containing Bu_4NBr is six or seven times larger than that for the system containing Me_4NBr. From this experimental result, the observed large values of $\Delta_m V^{ex}$ are considered to be due to the change of the hydration of tetraalkylammonium salts as shown in next section, because the mixing of inorganic salts solution is not accompanied by such a large volume change and the hydration cosphere of the Bu_4N^+ is more extensive than that of the Me_4N^+. In the binary tetraalkylammonium salt solutions in the relatively low concentration range, the decrease of the apparent or partial molal volume was considered to take place because of the formation of cage-like structure around the tetraalkylammonium ion[10] and the overlap of the cage by cation-cation interactions.[11] To interpret the $\Delta_m V^{ex}$ dependences on the ionic strength and/or ionic mole fraction in Figs. 4 and 5, one may introduce the following Friedman's treatment:[2,4]

$$\Delta_m V^{ex}(x, m) = x(1-x)\{v_0+v_1(1-2x)+\cdots\} \qquad (13)$$

where v_0 and v_1 are volumetric interaction parameters. To evaluate v_0 and v_1, the quantities $\Delta_m V^{ex}(x,m)/x(1-x)$ are plotted against x. This relation would be linear if the higher terms are negligibly small. As seen in the upper corner of Fig. 6, v_0 and v_1 has been obtained from the intercept and slopes.

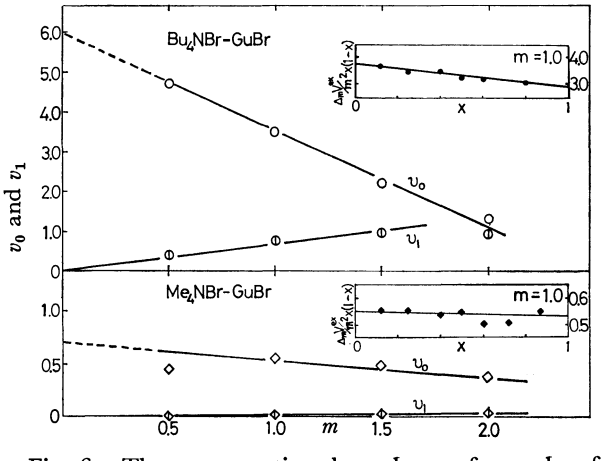

Fig. 6. The concentration dependence of v_0 and v_1 for the ternary systems.

In the common ion mixing, one can easily consider the pairwise and triplet interactions between like-charged ions, which mainly influence the excess function of mixing at relative low concentrations. Applying a treatment similar to the excess free energy of mixing,[1,2] v_0 and v_1 can be described as

$$v_0 = (2v_{B^+C^+}-v_{C^+C^+}-v_{B^+B^+}) + v_0(\text{trip})\cdot m, \qquad (14\text{-a})$$

and

$$v_1 = v_1(\text{trip})\cdot m, \qquad (14\text{-b})$$

where v_{ij} is the concrete interaction parameter of cation i and j, and v_0(trip) and v_1(trip) are the triplet interaction parameters.[1] As predicted from Figs. 4 and 5, the signs and magnitude of $\Delta_m V^{ex}$ are determined mainly by the v_0 values, while the skewness of the curve depends on the v_1 values.

The large excess volume change does not always arise from the volume difference of two kinds of solutes. In the volume changes of mixing of the ternary system KBr–tetrapropylammonium bromide–H_2O and KBr tetrakis(2-hydroxyethyl)ammonium bromide–H_2O, the former system showed large $\Delta_m V^{ex}$, while the latter underwent almost no volume change, although the ion sizes of the two kinds of cations are nearly the same.[4] Based on the above result and the similar properties of Bu_4N^+ and tetrapropylammonium ion($Pr_4(N^+)$), we will discuss the large $\Delta_m V^{ex}$ for the system GuBr–Bu_4NBr–H_2O by focusing on the change of water structure and the structuredness of a hydration cosphere by the interionic interactions.

The curves in Fig. 6 can be expressed by Eq. 13 within experimental error. According to Eq. 13, the contribution of the triplet interaction term(v_0(trip)) become large with increase of total molality, but the pairwise interaction term $(2v_{B^+C^+}-v_{C^+C^+}-v_{B^+B^+})$ contributes more significantly to v_0 in the concentration range studied. Since v_0 decreases almost linearly with m, as seen in Fig. 6, the value of $(2v_{B^+C^+}-v_{C^+C^+}-v_{B^+B^+})$ was obtained by extrapolating Eq. 13 to infinite dilution. Although it is quite difficult to evaluate the v_{ij} from the present approach, the free energy of mixing for the same system will help us in estinating the signs and magnitude of the v_{ij}. Among the three parameters of the pairwise term, $v_{B^+B^+}$ the interaction parameter between Gu^+'s, must be small, because of the weak hydration of the guanidinium cation.[12] Therefore, it is reasonable to neglect the contribution of $v_{B^+B^+}$ to the pairwise term. The $v_{C^+C^+}$ between Bu_4N^+'s has a negative sign, because two cations approach each other at a suitable distance and tend to link up to release water molecules of the cosphere to bulk solution,[11] leading to a small volume. On the other hand, the $v_{B^+C^+}$ between Gu^+ and Bu_4N^+ must be positive, since the hydrophobic hydration originally makes a negative contribution to the solution volume.[10] Indeed the hydration cosphere itself around a hydrophobic ion is more bulky than pure water, but the tight packing based on the formation of cage decreases the void space of liquid water. The latter effect dominate over the former. The guanidinium ion reduces and breaks the cage-like structure around a hydrophobic ion, leading to a large volume. From the consideration above, both parameters, $v_{B^+C^+}$ and $-v_{C^+C^+}$ make positive contributions to the solution volume.

In the free energy of mixing of the system KBr–Pr_4NBr–H_2O,[3] where the mutual salting-out was observed, the formation of like-cation pairs were more favoured than that of mixed cation pairs. On the other hand, the positive value of $\Delta_m V^{ex}$ was obtained from the volume of mixing of the same system and attributed also to the interaction of a like cation pair.

In contrast to the above results, a large mutual salting-in was observed in the free energy of mixing of the system GuBr–Bu_4NBr–H_2O,[1] where the forma-

tion of mixed cation pair was preferred to that of the like cation pairs.

These facts strongly suggest that $v_{B^+C^+}$ parameter should contribute more significantly than $v_{C^+C^+}$ parameter to the large $\Delta_m V^{ex}$ of the system GuBr–Bu_4NBr–H_2O. Consequently, the increase of solution volume observed in the above two systems would depend on the different cation-cation interaction, that is, C^+–C^+ interaction for the system KBr–Pr_4NBr–H_2O and B^+–C^+ interaction for the system GuBr–Bu_4NBr–H_2O. This concept is consistent with the general aspects of dissolution of hydrophobic solute in aqueous guanidinium solution, that is, the guanidinium ion breaks the water structure and weakens the water-structure-enforced association of hydrophobic solute. Since the interaction of hydrophobic solute with K^+ and guanidinium ion take place through the structure of water, the difference in the interaction indicates that the guanidinium ion breaks water structure in a different way from K^+.

Partial Molal Volumes, $\bar{V}_i$. Since $\phi_v(x,m)$ are regarded as the apparent molal volumes of the pseudo-binary salt, the partial moal volume of this salt $\xi(x,m)$ may be defined as[13]

$$\xi(x, m) = \left(\frac{\partial V}{\partial m}\right)_x = \phi_v(x, 0) + \frac{\sqrt{m}}{2}\left(\frac{\partial \phi_v(x, m)}{\partial \sqrt{m}}\right), \quad (15)$$

Using Eq. 6, we obtain

$$\xi(x, m) = \phi_v(x, 0) + \sum q_i\left(1+\frac{i}{2}\right)m^{i/2}. \quad (16)$$

$\xi(x,m)$ are computable. As the solution volume is the sum of the partial molal volumes of the individual components,

$$V(x, m) = 55.51\bar{V}_A + (1-x)m\bar{V}_B + xm\bar{V}_C. \quad (17)$$

Differentiating Eq. 17 with m or x, and applying the Gibbs-Duhem relation to the differentiated equation, we have the partial molal volume of solute B and C,

$$\bar{V}_B = \xi(x, m) - x\left(\frac{\partial \phi_v(x, m)}{\partial x}\right)_m \quad (18\text{-a})$$

$$\bar{V}_C = \xi(x, m) - (1-x)\left(\frac{\partial \phi_v(x, m)}{\partial (1-x)}\right)_m \quad (18\text{-b})$$

$\bar{V}_A$ values did not change appreciably with m and were nearly the same as $\bar{V}_A^0$ in this experimental method. The partial molal volumes of tetrabutylammonium bromide $\bar{V}_C$ are calculated from Eq. 18-b and are shown in Fig. 7 at various x values. With decreasing x, the curves of $\bar{V}_C$ *vs.* $\sqrt{m}$ become flat, accompanying the shift of the minimum values. However, this figure is not suitable for the comparison of the m_C dependence of $\bar{V}_C$ in water and with that in aqueous GuBr solution. To elucidate the volume change of Bu_4NBr in the GuBr solution, $\bar{V}_C$ at constant rational mole fraction, N_C were calculated and replotted against m_C'. N_C and m_C' are defined as[1]

$$N_C = \frac{2m_C}{55.51+2m_C} = \frac{2m_C'}{55.51+2m_C'+2m_B} \quad (19)$$

where m_C' is the molality of Bu_4NBr in ternary solution

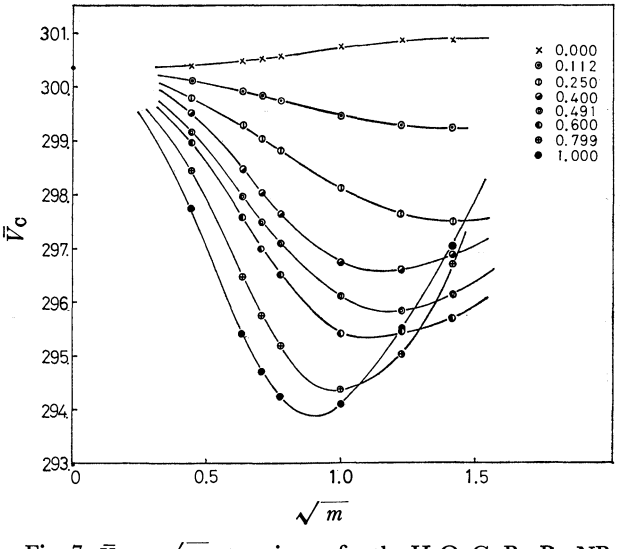

Fig. 7. $\bar{V}_C$ *vs.* $\sqrt{m}$ at various x for the H_2O–GuBr–Bu_4NBr system.

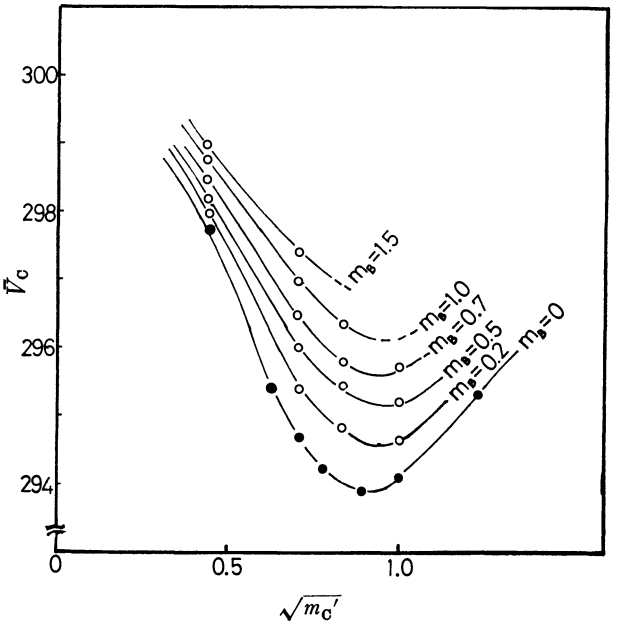

Fig. 8. $\bar{V}_C$ *vs.* $\sqrt{m_C'}$ at various m_B for the H_2O–GuBr–Bu_4NBr system.

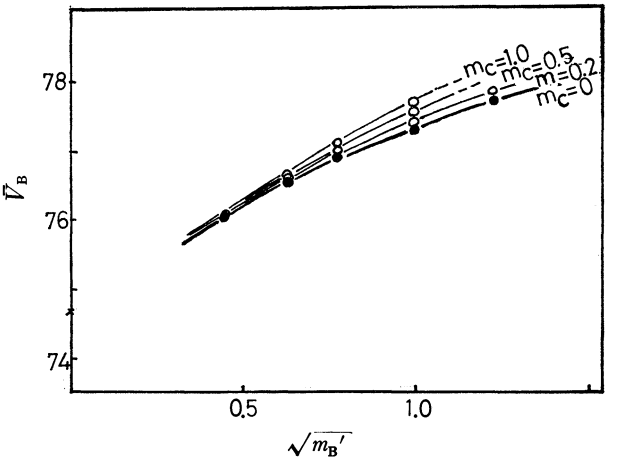

Fig. 9. $\bar{V}_B$ *vs.* $\sqrt{m_B'}$ at various m_C for the H_2O–GuBr–Bu_4NBr system.

having the same N_C in the binary solution. This treatment means that the guanidinium bromide solution is regarded as a solvent. As seen in Fig. 8, the $\bar{V}_C$ *vs.* m_C' curves clearly shift upward with increase of m_B, but the concentrations of Bu_4NBr having the minimum $\bar{V}_C$ value are independent of m_B. $\bar{V}_B$ *vs.* $\sqrt{m_B'}$ curves are shown in Fig. 9. The V_B values change only slightly with increase of m_C. These facts indicate that the large volume change of mixing for this system is due to the change of the hydration of Bu_4N^+ caused by the change of solvent structure.

(Received May 14, 1979)

Vapor-pressure depressions and electric conductivities have been measured for bis(tetraalkylammonium) electrolytes in methanol, ethanol, and 2-propanol. The analysis of the data of vapor pressure osmometry (VPO) of these bolaform salts was carried out taking into account the two-step dissociation equilibrium as follows.

$$M^{2+} + 2X^- \underset{K_d^I}{\rightleftharpoons} MX^+ + X^- \underset{K_d^{II}}{\rightleftharpoons} MX_2$$

In each solvent, the ionic association constants, K_a^I and K_a^{II} ($K_a = 1/K_b$), tend to decrease with increasing ionic size. This tendency is greater in K_a^I than in K_a^{II}. The K_a^I values of bis(tetraalkylammonium) electrolytes show virtually no dependence on the dielectric constant of solvent. On the contrary, the values of K_a^{II} strongly depend on the dielectric constant of solvent. Using the values of K_a^I and K_a^{II} in 2-propanol, the ultrasonic relaxation data were analyzed.

In a recent series of papers,[1-5] vapor pressure lowering data obtained by means of vapor pressure osmometer (VPO) measurements have been reported for a variety of electrolytes in nonaqueous solvents. The concentration dependence of the activities of the salts has been analyzed assuming the existence of a dissociation and/or association equilibrium. Vapor pressure osmometry is particularly useful in studying cases of neutral species where the use of conductance techniques is precluded.[5] As well, in the case where ionic equlibria are being studied, it provides a method of estimating equilibrium constants complementary to conductance studies.

There have been numerous investigations of solution properties of 1:1 electrolytes in nonaqueous solutions. However, because of the low solubility of 2:1 electrolytes in nonaqueous solvents,[6-8] only a few results have been reported for these systems. A series of electrolytes that circumvent this solubility problem in nonaqueous solvents is the bis(tetraalkylammonium) or bolaform type of electrolyte. Their moderately high solubility is due to the rather large portion of hydrocarbon moieties in their elemental composition. These salts had been considered as model systems to examine the contribution of cation-cation ion pairing to the non-ideal behavior of R_4N^+ ions in aqueous solutions. Conductance studies of several of these systems have been reported by Evans *et al.*[9]

In the present paper we report vapor pressure lowering and conductance measurements of some bis(tetraalkylammonium) salts in methanol, ethanol and 2-propanol in order to estimate the degree of ionic dissociation in these solvents. Also, the present results are compared with those previously obtained[10] by means of ultrasonic relaxation studies of these electrolytes in 2-propanol.

Theoretical

A salt, MX_2, dissolved in non-aqueous solvent can exhibit a two-step dissociation equilibrium, as follows:

$$\begin{aligned} M^{2+} + 2X^- &\underset{K_d^I}{\rightleftharpoons} MX^+ + X^- \quad \text{step I} \\ MX^+ + X^- &\underset{K_d^{II}}{\rightleftharpoons} MX_2 \quad \text{step II} \end{aligned} \tag{1}$$

The activity of the solvent is related to the activity coefficients of the undissociated salt and ions by an integrated form of the Gibbs-Duhem equation. For the reactions represented by equation 1 this expression is given as

$$\ln a_1 = -\frac{1}{N_1}\left(m_2 + m_3 + m_4 + m_5 + \int_0^{m_3} m_3 \, d\ln \gamma_3 + \int_0^{m_4} m_4 \, d\ln \gamma_4 + \int_0^{m_5} m_5 \, d\ln \gamma_5\right) \tag{2}$$

where a_1 is the activity of the solvent,
N_1 is the mole number of the solvent ($=1000/M_1$; M_1 is the molecular weight of the solvent),
m is the molal concentration of the added solute,
m_2 is the molality of undissociated salt MX_2,
m_3 is the molality of cation M^{2+},
m_4 is the molality of anion X^-,
m_5 is the molality of cation MX^+,
α is defined as $\alpha = m_5/m$ ($0 < \alpha < 1$),
β is defined as $\beta = m_3/m_5$ ($\beta > 0$),
γ_i is the mean activity coefficients of the ions, suffixes 3, 4, and 5 referring to M^{2+}, X^-, and MX^+, respectively, and γ_2, the activity coefficient of the undissociated salt, is assumed to be unity.

From these definitions it follows that in Eq. 2

$$\begin{aligned} m_2 &= m[1-\alpha(1+\beta)] \\ m_3 &= m\alpha\beta \\ m_4 &= m\alpha(1+2\beta) \\ \text{and } m_5 &= m\alpha \end{aligned} \tag{3}$$

The dissociation equilibrium constants are obtained by curve fitting procedures using Eq. 2. In order to do this, values of the activity coefficients in terms on the

right-hand side of Eq. 2 must be evaluated. We have assumed that the activity coefficients of the ions are represented by the Güntenberg-type equation:[11]

$$\ln \gamma_{\pm} = -\frac{A|z_1 z_2|\sqrt{I}}{1+\sqrt{I}}, \quad A = \frac{1.825\times 10^6}{(\varepsilon T)^{3/2}} \tag{4}$$

Numerical values of the density d_0 and the dielectric constant ε of the solvent used in calculations were obtained from Ref. 12.

As in previous work,[4] a function, h, defined as

$$h = \frac{N_1 \ln a_1}{m} + 1 \tag{5}$$

was used for the analysis of the experimental results.

Experimental

Materials. The bis(tetraalkylammonium) salts, 1,4-bis-(triethylammonio) butane dibromide, 1,5-bis(triethylammonio) pentane dibromide, and 1,10-bis(triethylammonio) decane dibromide, abbreviated hereafter J4, J5, and J10, respectively, were prepared and purified as described eleswhere.[13] Before use, the salts were dried for a period of five days in a vacuum oven at 50 °C over molecular sieves 3A (1/8 in. pellet). Fresh molecular sieves were used each day.

Reagent grade methanol and 2-propanol (Kishida Chemical Co. Ltd.) were further purified by drying with anhydrous calcium sulfate and finally distilled in the presence of molecular sieves in a nitrogen atmosphere. Reagent grade ethanol (Nakarai Chemical Co., Ltd.) was refluxed with magnesium metal and magnesium ethoxide in a dry nitrogen atmosphere for a period of 12 h and then distilled over molecular sieves in a dry nitrogen atmosphere. The water content of the purified solvents was checked by Karl-Fisher analysis and found to be less than 0.0018, 0.028, and 0.009 wt % for methanol, ethanol, and 2-propanol, respectively.

The preparation and handling of the salts and their solutions was carried out in a dry box under a nitrogen atmosphere in order to avoid contact with the moist air.

Vapor Pressure Osmometry and Conductance. The experimental method and equipment have been reported in a previous paper.[4]

Results

Vapor Pressure Osmometry. The proportionality constants K_s of the apparatus were determined using standard substances: benzil for methanol and ethanol and 1-octadecanol for 2-propanol. The values of the constants K_s and K_e ($=BrR/\Delta H$, see Ref. 3 for definition of terms), and their ratios are summarized in Table 1. Vapor pressure depression measurements were carried out at 45.0, 55.1, and 60.0 °C for methanol, ethanol, and 2-propanol, respectively.

Table 1. Proportionality constants of VPO in various solvents

T/°C	K_s/Ω	$K_e(=BrR/\Delta H)/\Omega$	K_s/K_e
	MeOH–Benzil		
45	−42100	−43200	0.974
50	−38000	−37200	1.022
	EtOH–Benzil		
55.1	−27600	−28300	0.973
	i-PrOH–1-Octadecanol		
60	−21800	−23900	0.911
70	−17300	−18200	0.951

Values of h, calculated by introducing the experimental values of activity coefficients a_1 in Eq. 5, are given in Table 2. Plots of h *vs.* the concentration in molality units are shown in Figs. 1—3. The behavior of the values of h ($h \leqq 0$) clearly shows the existence of a dissociation equilibrium.[3]

Attempts to fit the profiles of h *vs.* concentration using the procedures of one-step dissociation equation such as R_4NX in acetone did not give good fitting in this case. In order to estimate the two-step dissociation constants K_d^{I} and K_d^{II} in Eq. 1, the following procedures

were carried out; From Eq. 1, one can write the following equations:

$$K_d^{I} = m\alpha\beta(1+2\beta)\frac{\gamma_{M^{2+}}\gamma_{X^-}}{\gamma_{MX^+}}$$
$$K_d^{II} = \frac{m\alpha^2(1+2\beta)}{1-\alpha(1+\beta)}\frac{\gamma_{MX^+}\gamma_{X^-}}{\gamma_{MX_2}} \quad (6)$$

In the first approximation, to simplify the calculations, assume the values of $(\gamma_{M^{2+}}\gamma_{X^-}/\gamma_{MX^+})$ and $(\gamma_{MX^+}\gamma_{X^-}/\gamma_{MX_2})$ to be unity. The function h can be expressed as

$$h = -\alpha(1+2\beta) \quad (7)$$

By means of the complete grid search techniques, the dissociation constants, K_d^{I} and K_d^{II}, were estimated so that the standard deviation

$$\sigma^2 = \sum\left(\frac{h_{exp}-h_{cal}}{h_{exp}}\right)^2 \quad (8)$$

is minimized.

In the second step, using the values of K_d^{I} and K_d^{II} obtained and Eq. 4 for $\gamma_{\pm}$, the values of α and β in Eq. 6 are corrected, then the computer method used in the first step was repeated, still assuming the γ_{MX^+} and γ_{MX_2} to be unity, because of their very low concentration.

The values of K_d^{I} and K_d^{II} obtained using this method are summarized in Table 3. The solid lines in Figs. 1—3 are the results obtained using these "best fit" values. It can be seen that there is good agreement between experimental and calculated values.

Conductometry.[14] The concentration dependence of the equivalent conductivities of J5 and J10 in 2-

The values in the brackets show the corrected values at 25 °C.

propanol obtained at 25 °C is shown in Fig. 4. Conductance data have been analyzed by the treatment proposed by Davis[6] and Monk,[7] in which deviations from the limiting Onsager equation are interpreted in terms of ion-association. At concentrations where the extent of association is small, the second step of Eq. 1 can be disregarded and the solution contains three species: M^{2+}, MX^-, and X^-. If α is the fraction of intermediate product, MX^-, defined in Eq. 2 (neglecting the difference between m (mol/kg) and c (mol/l), this α is consistent with that defined in Eq. 2. This assumption can be acceptable in these experimental conditions.), the equivalent conductivity will be given by:

$$\Lambda = (1-\alpha)\Lambda_{M^{2+}} + \frac{1}{2}\Lambda_{MX^-} + \left(1-\frac{\alpha}{2}\right)\Lambda_{X^-}$$
$$\Lambda = (1-\alpha)(\Lambda_{M^{2+}}+\Lambda_{X^-}) + \frac{\alpha}{2}(\Lambda_{MX^-}+\Lambda_{X^-}) \quad (9)$$

In this equation, the solution is regarded as a mixture

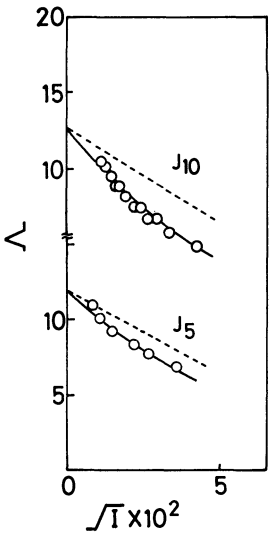

Fig. 4. Relationships between Λ and concentration for J5, and J10 in 2-propanol at 25 °C.

of a completely dissociated uni-bivalent salt of concentration c, where c refers to the molar concentration of the solution (mol/l).

In solving the equation for α, the equivalent conductivity at infinite dilution of the intermediate ion is indespensable. The equivalent conductivity of intermediate product, Λ_{MX^+}, is assumed to be 0.6 times of $\Lambda_{M^{2+}}$, similarly to that of Monk *et al.* Using the values of λ_{Br^-} in the literature,[15] the values of $\lambda^\circ_{M^{2+}}$ were determined by the extrapolating procedure in the plots of Λ *vs.* $I^{1/2}$. Using the limiting Onsager equation, the empirical equations were obtained:

$$\Lambda = 12.0-111.13I^{1/2}-\alpha(6.11-74.07I^{1/2}) \text{ for J5,}$$
$$\Lambda = 15.6-125.23I^{1/2}-\alpha(8.61-86.18I^{1/2}) \text{ for J10} \quad (10)$$

The dissociation constant K_d^I can be obtained *i.e.*

$$K_d^I = \frac{c(2-\alpha)(1-\alpha)}{\alpha}\frac{\gamma_{M^{2+}}\gamma_{X^-}}{\gamma_{MX^+}} \quad (11)$$

By means of the usual computer method, using Eqs. 10 and 11, the dissociation constant K_d^I was determined so that the standard deviation

$$\sigma^2 = \Sigma\left(\frac{\Lambda_{exp}-\Lambda_{cal}}{\Lambda_{exp}}\right)^2 \quad (12)$$

is minimized.

The values obtained for J5 and J10 are summarized in the 5 th column of Table 3; In Fig. 4, solid lines show the best fitting ones. In Fig. 4, the dashed lines show the limiting Onsager's law.

Discussion

The VPO measurements were carried out at different temperatures because of the different optimum experimental conditions for the three solvents. In order to compare the K_d values obtained from the two techniques it was necessary to estimate the K_d^I and K_d^{II} values from VPO measurements for 25 °C. In a previous paper,[10] the apparent activation energy ΔH of ionic association was estimated to be 3.3 and 3.9 kcal/mol for J5 and J10,

respectively, in 2-propanol. As well, the ionic association constants in nonaqueous solvent depend mainly on the dielectric constant and its temperature dependence. Assuming the temperature dependence of K_d^I and K_d^{II} to be equivalent, the activation energies in methanol and ethanol were estimated from the values in 2-propanol, taking into consideration the difference in dielectric constants of the solvents. The estimated values for the VPO method at 25 °C are shown in brackets, in Table 3. It is seen that the agreement between K_d^I values at 25 °C derived from VPO and conductance data is within an order of magnitude. Figures 1—4 also show that there is no apparent evidence of micell formation in these systems.

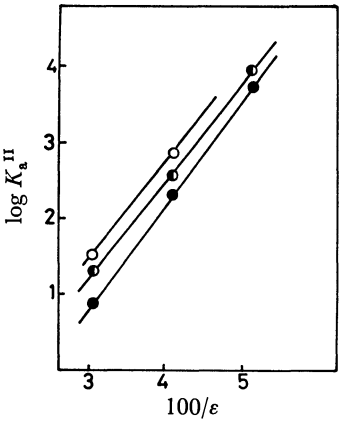

Fig. 5. Relationships between log K_a^{II} and $100/\varepsilon$
○; J4, ◐; J5, ●; J10.

Solvent and Ionic Dependence of Ionic Accosiation Constants. In each solvent, the ionic association constant, K_a^I and K_a^{II}, defined as $K_a=1/K_d$, tends to decrease with increasing ionic size. (As usual, the equilibrium properties of electrolytes in nonaqueous solvents are discussed using the ionic association constant, K_a, rather than K_d. We will talk about K_a instead of K_d.) This tendency is greater in K_a^{II} than in K_a^I. The K_a^I values of bis-(tetraalkylammonium) electrolyte show virtually no dependence on the dielectric constant of solvent. On the contrary, the values of K_a^{II} strongly depend on the dielectric constant of the solvent. The relationship between log K_a^{II} and $100/\varepsilon$, where ε refers to the dielectric constant of solvent, is shown in Fig. 5. As is seen in Fig. 5, log K_a^{II} increases linearly with increasing values of $100/\varepsilon$. This behavior is in good agreement with that of tetraalkylammonium ions in nonaqueous solvents.[15] This result indicates that the ionic association in step II (in Eq. 1) is a solvent-separated type. It looks strange that in 2-propanol, the values of K_a^{II} are greater than that of K_a^I for both J5 and J10. However, as pointed by Evans *et al.*[15] and discussed in our previous paper,[10] the Et_4N^+, Br^- ions and Et_4NBr in 2-propanol are strongly solvated with 2-propanol. It may be considered that J5 and J10 are also strongly solvated with 2-propanol as solvent. At this stage, the solvent effects on the dissociation equilibria of J5 and J10 in 2-propanol can not be explained completely, but it may be roughly considered as follows: The value of K_a^I and K_a^{II} for J10 in 2-propanol are comparable and also of the same order of magnitude as K_a for Et_4NBr in 2-propanol, 8.45×10^{-4} by conductometry[15] and 5.05×10^{-4} by VPO. This fact clearly indicates that in a solvent of low dielectric constant, the ionic sites of $J10^{2+}$ ion act independently because of the long distances between them.

Interpretations for Dynamic Data by Means of Ultrasonic Method: In a previous paper,[10] ultrasonic absorption data obtained over the frequency range 5—95 MHz by the pulse method were reported for tetraethylammonium bromide, J5, and J10 in 2-propanol in the temperature range 0—25 °C. A single relaxation curve was observed under all experimental conditions. However, because of the lack of thermodynamic and conductance data for J5 and J10, a complete kinetic analysis could not be carried out.

The equilibria, Eq. 1, can be symbolized as

$$\mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{C} \qquad \begin{matrix} & \mathrm{D} & & \mathrm{D} \end{matrix} \tag{13}$$

where A, B, C, and D refer to MX_2, MX^+, M^{2+}, and X^- in Eq. 1 respectively, and the equilibrium concentration of them is shown as $\bar{A}$, $\bar{B}$, $\bar{C}$, and $\bar{D}$, respectively. As shown by the VPO data, this two-step reaction should be closely coupled. Under such conditions, the reciprocal relaxation terms can be expressed as[16,17]

$$\left.\begin{aligned} 2\pi f_{r1} &= \frac{1}{\tau_1} = \frac{a_{11}+a_{22}}{2}[1+(1-b)]^{1/2} \\ 2\pi f_{r2} &= \frac{1}{\tau_2} = \frac{a_{11}+a_{22}}{2}[1-(1-b)]^{1/2} \end{aligned}\right\} \tag{14}$$

and

$$b = \frac{4(a_{11}a_{22}-a_{12}a_{21})}{(a_{11}+a_{22})^2}$$

where

$$\begin{aligned} a_{11} &= k_1 + k_{-1}(\bar{B}+\bar{C}) \\ a_{12} &= -k_1(\bar{B}-\bar{C}) \\ a_{21} &= -(k_2+k_{-2}\bar{C}) \\ a_{22} &= -k_2 + k_{-2}(\bar{C}+\bar{D}) \end{aligned}$$

and the maximum excess absorption per wavelength is in this case represented by

$$\left.\begin{aligned} \mu_{max\,1} &= \frac{\pi(\Delta V_1+X\Delta V_2)^2}{2\beta_0 RT}\left\{\left(\frac{1}{\bar{A}}+\frac{1}{\bar{B}}+\frac{1}{\bar{C}}\right)\right. \\ &\quad \left. + 2X\left(\frac{1}{\bar{D}}-\frac{1}{\bar{B}}\right) + X^2\left(\frac{1}{\bar{B}}+\frac{1}{\bar{C}}+\frac{1}{\bar{D}}\right)\right\}^{-1} \\ \mu_{max\,2} &= \frac{\pi(Y\Delta V_1+\Delta V_2)^2}{2\beta_0 RT}\left\{\left(\frac{1}{\bar{A}}+\frac{1}{\bar{B}}+\frac{1}{\bar{C}}\right)Y^2\right. \\ &\quad \left. + 2Y\left(\frac{1}{\bar{D}}-\frac{1}{\bar{B}}\right) + \left(\frac{1}{\bar{B}}+\frac{1}{\bar{C}}+\frac{1}{\bar{D}}\right)\right\}^{-1} \end{aligned}\right\} \tag{15}$$

where

$$X = \frac{-k_2-k_{-2}\bar{C}}{a_{11}+1/\tau_2}$$

$$Y = \frac{k_{-1}(\bar{D}-\bar{B})}{a_{22}+1/\tau_1}$$

Using the ionic association constants for J5 and J10

reported here, we can estimate the experimental relaxation frequencies. Since the kinetic constants, k_{-1} and k_{-2}, can be considered to represent diffusion control processes, their values are of the order of 10^{-10} $M^{-1}\,s^{-1}$. Assuming the values of k_{-1} and k_{-2} to be 2.35×10^{-10}, which is obtained for Et_4NBr in 2-propanol, the values of k_1 and k_2 can be estimated from the values of K_a^{I} and K_a^{II}.

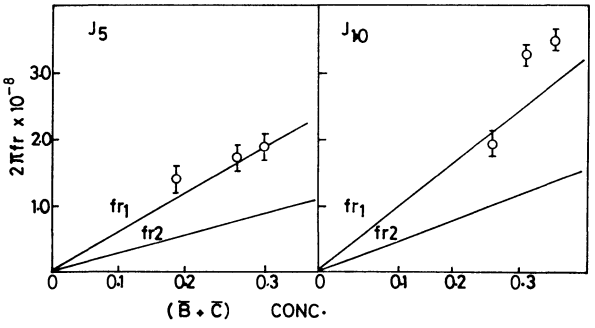

Fig. 6. Relationships between $2f_r$ and $(\bar{B}+\bar{C})$ in Eq. 14 (solid lines show the estimated one) for J5 and J10 in 2-propanol.

Figure 6 shows the relaxation frequencies estimated by the above method for J5 and J10 in 2-propanol at 25 °C. For J5 in 2-propanol, the agreement between the estimated and experimental values of higher relaxation frequencies is good. However, for J10 the agreement is not so good, but still within an order of magnitude. Considering the assumptions used for VPO data analysis and the method of obtaining these estimates, this difference is acceptable.

For the case of J5 in 2-propanol, the maximum excess absorption per wavelength should be expressed by Eq. 15. In Eq. 15, the value of Y is almost zero and from a plot of $\mu_{max\,2}$ against $(1/\bar{B}+1/\bar{C}+1/\bar{D})$. One can estimate the value of ΔV_2 to be 52.9 ml/mol. This value is of a reasonable magnitude and compares with that for malonic acid in aqueous solution, 50.3 ml/mol.[17]

Unfortunately, at this stage, we have no experimental values of ionic radii of bis(tetraalkylammonium) electrolytes in nonaqueous solvents, and so we have used Eq. 4 to calculate values of $\gamma_\pm$. However, as seen in Ref. 12, in the very low concentrations, as in this work, the difference between observed and calculated ones from Eq. 4 can be negligible small.

(Received January 24, 1979)

The natural abundance of the principal inorganic elements in five human tissues (brain, kidney, lung, liver, and heart) have been determined by neutron activation analysis. Cl, K, and Mn are equally distributed in all tissues. The highest concentration of Sc(0.22 ± 0.044 ppm) is found in the liver. V(0.64 ± 0.51 ppm) and Cr (0.19 ± 0.11 ppm) concentrations in the lung are significantly higher than in other tissues at a 95% confidence level. The lowest concentration of Br(2.7 ± 1.8 ppm) is found in the brain. The highest concentration of Cd (74 ± 11 ppm) appears in the kidney and differs significantly from that in other tissues. Significant correlations appear to exist between many pairs of elements in the kidney and the lung, whereas there are relatively few in the liver. The normal significant correlations between Na, Cl, K, Sc, Zn, Se, Cd, and other elements are given.

There are increasing reports concerning the physiological activity of small or micro amounts of metals contained in the cells or tissues of several organs. For example, micro amounts of Cu in the human body play an important role in hematopoitic activity.[1] Wilson's disease (hepato-lenticular degeneration) is at times characterized by an accumulation of Cu in the liver and brain tissues.[2] Schroeder[3] reported that Cd is related to the hypertension found in man. Hadjimarkos[4,5] suggested that trace amounts of Se appear capable of increasing the susceptibility to dental caries. Se is also reported to offer protection against human cancer.[6,7] Dick[8] has reported the physiological interactions between Cu, Mn, Mo, and sulfate. And Gather *et al.*[9] reported the role of Se in preventing the hazardous action of organic mercury. Sufficient information, however, concerning the effect of trace amounts of heavy metals in human tissues on physiological activities remains scant. Physiological functions in the human body are influenced by the heavy metals and chemical compounds are required further investigation. In this study, an attempt has been made to determine simultaneously the concentration of 15 elements in specified pathological conditions. The organs studied have been the brain, kidneys, lung, liver, and heart. The abundances and interactions of the elements in these tissues have been determined by neutron activation analysis.

Experimental

Collection and Preparation of the Samples. The human tissues analyzed were obtained from 9 autopsy cases examined in the Pathological Institute, Juntendo University, School of Medicine, Tokyo. Tissue samples were taken from minimally affected areas in the above mentioned organs, taking special care to avoid local neoplastic invention. All samples were dried in the desiccator (P_2O_5) for 7 days. The dried tissues (50 mg) were weighed and heat-sealed in clean polyethylene bags. The distribution of age, sex, and the causes of death are shown in Table 1.

Preparation of the Reference Samples. High purity metals, Mg, Cr, Mn, Fe, Co, Cu, Zn, and Cd, and special grade NaCl, KBr, Sc_2O_3, SeO_2, and V_2O_5 were used as standard material. A definite amount of each metal or compound was dissolved in nitric acid or pure water. A reference standard was prepared by pipetting an appropriate volume of the stock solution, impregnating it in a small sheet of filter paper and drying at room temperature. The amounts of Na, Mg, K, Cr, Mn, Fe, Cu, Zn, Se, and Cd in the reference standard were 1 μg, those of Co, Sc, and V were 0.1 μg and those of Cl and Br were 1.54 and 2.04 μg. The sheets of filter paper

TABLE 1. DISTRIBUTION OF AGE, SEX AND THE CAUSES OF DEATH FOR THE SUBJECTS

Age (years)	Sex	The causes of death
7	f	Pyothorax

were then heat-sealed in clean polyethylene bags.

Neutron Activation and Determination of γ-Ray Spectra. Samples and reference standards were irradiated in a rotary specimen rack in a TRIGA MARK II reactor (Rikkyo University) with a thermal neutron flux of 5×10^{11} n·cm^{-2}·s^{-1}. The irradiation period was 3 min for short-lived nuclides, and 24 h(intermittent irradiation of 6 h a day for 4 days) for long-lived nuclides. Irradiated samples and reference sample were removed from the polyethylene bag and transferred to new one before measuring the γ-ray spectra.

The γ-ray spectra were determined on a Ge(Li) γ-ray detector and 4096 channel pulse height analyzer (Type 8100: Camberra Inductries Inc. USA).

The nuclear data of the nuclides used in this study, are shown in Table 2.

Results and Discussion

The data have been analyzed by evaluating the mean values and the standard deviations for 15 elements in each tissue, after rejection of the widely different values according to the method of Smirnoff, the results of which are shown in Table 3. The results of the t-test for the elemnts for every two tissues are shown in Tables 4(1)—(8). In the Tables, the symbol "*" illustrates the significant difference in mean values between two tissues at a 95% confidence level. The coefficient of correlation for every two elements in each tissue are shown in Tables 5(1)—(3). In Table 5, the symbols

Bn: Brain, Ky: Kidney, Lg: Lung, Lr: Liver, Ht: Heart.

"**" and "*" show the significant correlation at 95% and 99% confidence levels respectively. The symbols "−**" and "−*" show the reverse correlations at the same levels. The symbols "+" and "−" show the tendency of normal and reverse interactions.

The Abundances of the Elements in Human Tissue (Table 3). *Sodium*: The highest concentration of Na is found in the lung, but no significant difference exists in the average value of Na for any pair of tissues. Na and Cl are the main electrolytes in blood serum and therefore, it appears that the high content of Na and Cl in the lung are influenced by the blood volume existing at the time of death. The standard deviation of Na level is small in the brain and the mean value differs significantly from those in the kidney and liver at a 95% confidence level (Table 4 (1)).

Magnesium: The concentration of Mg in the brain is relatively higher than that in other tissues and is significantly different from the smallest level found in the heart at a 95% confidence level. The mean values of Mg were found to be small for all tissues except the brain (Table 4 (1)).

Chlorine: The highest concentration of Cl as well as Na is in the lung. No significant differences were found

between the pairs of tissues analyzed (Table 4 (2)).

Potassium: The distribution of K is similar to that for Na and Cl (Table 4 (2)).

Scandium: Little data on the physiological activities and/or toxicities of Sc in human body exists.[10] Sc is widely distributed in all the organs but the highest concentration of Sc is observed in the liver. The concentrations of Sc decrease in the following order: lung, heart, brain and kidney (Table 4 (3)).

Vanadium: The highest mean value of V is found in the lung, corroborating the data of Tipton and Cook.[11] The average value of V in the lung significantly differs from that found in the other organs at a 95% confidence level, but in the other organs there are no significant differences in the V contents. Schroeder[12] found trace amounts of V in the lungs of sucklings and higher V levels in the adult lungs. In the lung of a 7 year old girl the V concentration was found to be 0.0083 ppm, although the average level in adult lungs is 0.72 ± 0.49 ppm. This suggests that the large amounts of V in the adult lung results from an accumulation of inhaled fly ash (Table 4 (3)).

Chromium: The abundances of Cr are similar to V. As Cr is one of the essential elements in living cells, it is widely distributed in all organs. The higher abundance in the lung may be attributed to the accumulation of fly ash deposition in the pulmonary tissues through inhalation. The Cr concentration gradually enriches in the lung due to ageing[13] (Table 4 (4)).

Manganese: Manganese is widely distributed in all the tissues. No significant differences however were found in any two tissues and the results are slightly higher than that reported by Sumino *et al.*[14] and Tipton *et al.*[11] The weight loss of the tissues after drying for 7 days is *ca.* 80% for the wet weight, and consequently the figures cannot be compared without a calibration (Table 4 (4)).

Iron: The mean value of Fe is slightly lower in the brain and the heart than in other tissues (Table 4 (5)).

Cobalt: The highest value of Co is found in the kidney and the lowest in the brain. The average content of Co is widely distributed in each tissue (Table 4 (5)).

Copper: The highest content of Cu is present in the brain and significant differences exist between some pairs of tissues such as the brain and the kidney, the lung and the heart, the lung and the liver at 95% confidence level. The value of 22 ppm in the liver is lower than the value of 35 ppm reported by Bruckmann and Zondek[15] (Table 4 (6)).

Zinc: Similar abundances of Zn were detected in the kidney and the liver and these results agree with the values of Tipton and Cook.[11] The Zn content in the kidney is significantly higher than in the brain (Table 4 (6)).

Selenium: There are few reports on the Se contents in human tissue.[6,16] The Se concentration in the kidney is significantly higher than in the other tissues. Allaway *et al.*[6] have reported that the Se contents in blood serum inversely correlate with the cancer death rate. Such a trend was not found in the present work (Table 4 (7)).

Bromine: The highest content of Br is found in the lung and the lowest in the brain which amounts to only 6.1% of the lung. One of the authors has reported that the abundance of Br in the optic nerve is smaller than in the other eye organs. Suggesting that Br interferes with the actions of the nervous organs (Table 4 (7)).

Cadmium: An extremely high value of Cd was found in the kidney (74 ± 11 ppm). Several reports[17,18] have suggested that Cd accumulates in the kidney and is not excreted. The Cd content of the standard American has been found to be 30—40 ppm in the kidney and 2—3 ppm in the liver,[19] Whereas in the Japanese it is twice this value.[17] These results therefore are in good agreement[19] (Table 4 (8)).

Interaction of the Elements in Human Tissue. Several interesting facts have emerged from the present study and are shown in the Tables 5 (1)—(3). The principal points are:

Characteristics in the Brain: Several elements have been correlated with other elements, for example, Na normally correlates with Cl, Sc, V, Co, Se, Cd, and inversely with Mg, Cr. Significant inverse correlations were found between (Mg and Na, Cl, K, Cd), (Cr and Na, Cl, Sc, V, Cd) and (Mn and Sc, V, Fe, Cd), and a significantly normal correlation between (Na and Cl, Sc, V, Co, Se, Cd), (Sc and Na, Cl, K, V, Se Cd), (Co and Na, V, Fe, Zn, Se, Br), and (Se and Na, Cl, Sc, Fe, Co, Br). Cu in the brain normally correlates with only Cr and other pairs of elements including Cu have inverse interactions.

Characteristics in the Kidney and the Lung: Similar tendencies of correlation of the elements are found in the kidney and the lung. Normal significant correlations exist for each of the pairs of elements in both tissues, and significant inverse correlations in four pairs in the kidney and one pair in the lung. Inverse interactions between V and other elements except Mg, Cr, Co, and Br at the kidney exist.

Sc significantly correlates with Na, Mg, Cl, K, V, Cr, Cu, Zn, Se, Br, and Cd in the lung. A more characteristic factor is that there is a significant inverse correlation between Cr and Se, and there appears inverse interactions in the lung.

Characteristic in the Liver: Inverse interactions exist although no significant correlations are present in the liver.

Characteristics in the Heart: Significant inverse correlations are found between (Cr and Na, Cl, K, Mn, Cu, Se) and (Sc and Na, Zn, Cd). Normal significant correlations are also found between (Cl and Na, K, Mn, Zn) and (K and Na, V, Mn, Se). Such tendencies as reported above are almost uniformly distributed in the elements in the heart.

Trimethylenediamine Complexes. VII.[1] Optically Active Mixed-Ligand Cobalt(III) and Chromium(III) Complexes Containing Trimethylenediamine and the Acetylacetonate Anion

Mamoru NAKANO, Shinichi KAWAGUCHI,* and Hiroshi KAWAGUCHI[2]

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received February 16, 1979)

The $[M(acac)(tn)_2]^{2+}$ and $[M(acac)_2(tn)]^+$ complexes (M=Co and Cr) have been prepared and resolved by (*R,R*)-tartratoarsenate(III) and hydrogen-(*R,R*)-di-*O*-benzoyltartrate, respectively. On the basis of the CD-spectral studies in comparison with the corresponding ethylenediamine complexes, the absolute configurations of $(+)_{589}$-$[Co(acac)(tn)_2]^{2+}$, $(-)_{589}$-$[Co(acac)_2(tn)]^+$, $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$, and $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ were all assigned to *Λ*. Electronic spectra of these complexes and proton NMR spectra of the cobalt(III) complexes are also reported.

There have been published many papers dealing with the interrelation between the Cotton effect and the absolute configuration of dissymmetric metal complexes.[3] The absolute configurations of $(+)_{589}$-$Co(en)_3^{3+}$ [4] and $(-)_{589}$-$Co(tn)_3^{3+}$ [5] were determined by X-ray analysis both to be *Λ*. By comparison of the CD spectrum with that of *Λ*-$Co(en)_3^{3+}$, absolute configurations of a number of dissymmetric D_3 and D_2 complexes have been assigned. Although the CD-spectral feature in the first d-d band region of *Λ*-$Co(tn)_3^{3+}$ [6] is remarkably different from that of *Λ*-$Co(en)_3^{3+}$,[7] the empirical criterion of McCaffery *et al.*[8] seems to be applicable also to the six-membered chelate compounds.[9] However, the assignment of the E and A_2 components of the CD band in the first absorption region is not unambiguous for $Co(tn)_3^{3+}$,[10] whereas *Δ*-$[Co(R,R\text{-ptn})_3]Cl_3 \cdot 2H_2O$ (ptn=2,4-pentanediamine) was confirmed to have negative E and positive A_2 components in the solid-state CD spectrum[11] in accordance with the informations from the solution spectra.[12]

Thus synthesis and examination of the absolute configuration of still more dissymmetric trimethylenediamine complexes especially of metal ions other than cobalt(III) are desired. The present paper is concerned with the optically active $Cr(acac)_x(tn)_{3-x}$ complexes (x=1 or 2), which are compared with the $Cr(acac)_x(en)_{3-x}$ complexes and also with the corresponding cobalt(III) complexes.

Experimental

Preparation and Resolution of Complexes. The starting compounds, *trans*-$[CoCl_2(tn)_2]Cl$,[13] $Na[Co(NO_2)_2(acac)_2]$,[14] *trans*-$[CrCl_2(tn)_2]Cl$,[15] and *cis*-$[CrCl_2(tn)_2]Cl \cdot H_2O$[15] were prepared according to the literatures. The resolving agents, sodium (*R,R*)-tartratoarsenate(III) and (*R,R*)-di-*O*-benzoyltartaric acid were prepared by the reaction of sodium hydrogen-(*R,R*)-tartrate with arsenic(III) oxide[16] and that of (*R,R*)-tartaric acid with benzoyl chloride,[17] respectively.

$(-)_{589}$-Acetylacetonatobis(trimethylenediamine)cobalt(III) Iodide, $(-)_{589}$-[Co(acac)(tn)$_2$]I_2: Preparation and optical resolution of this compound were performed in a similar way as that for the corresponding ethylenediamine complex.[18] To a 1 M sodium hydroxide solution (60 ml) containing acetylacetone (8 g) was added *trans*-$[CoCl_2(tn)_2]Cl$ (12.5 g), and the solution was heated at about 70 °C until it turned red. The solution was then cooled to room temperature and an excess amount (37.5 g) of potassium iodide was added to the solution kept in ice to deposit a red precipitate, which was filtered, washed with cold water followed by cold methanol, and air-dried. The yield was 20.0 g (89.6%) and recrystallization from hot water gave red prisms. Found: C, 23.54; H, 4.94; N, 9.90%. Calcd for $C_{11}H_{27}O_2N_4I_2Co$: C, 23.59; H, 4.86; N, 10.00%.

A mixture of the racemic complex (8 g) and silver acetate (5 g) was stirred in water (25 ml) for 30 min. Silver iodide and unreacted silver acetate were filtered and washed with water (10 ml). To the filtrate was added slowly a solution (8 ml) of sodium (*R,R*)-tartratoarsenate(III) hydrate (3.75 g) and the mixture was kept in a desiccator to precipitate red orange crystals. The yield was 1.5 g (13.4%). Found: C, 29.10; H, 4.50; N, 7.14%. Calcd for $C_{19}H_{35}O_{16}N_4As_2Co$: C, 29.75; H, 4.39; N, 6.98%.

A mixture of the diastereomer (1.5 g) and potassium iodide (1.0 g) was stirred in an 0.1 M sodium hydroxide solution (10 ml) for 10 min to separate out white and red precipitates. When washed with methanol, the red precipitate was dissolved to leave the white one. A red precipitate was recovered on addition of diethyl ether to the washings. The yield was 0.6 g (56.0%). Found: C, 23.49; H, 4.92; N, 9.60%. In order to assure the optical purity, the resolution process was repeated and the final product showed the following molar rotation in aqueous solution at room temperature: $[M]_{589}=-430°$, $[M]_{546}=-1180°$, $[M]_{436}=+6970°$.

$(-)_{589}$-Bis(acetylacetonato)(trimethylenediamine)cobalt(III) Iodide Hydrate, $(-)_{589}$-[Co(acac)$_2$(tn)]$I \cdot H_2O$: A method of preparation analogous to that for $[Co(acac)_2(en)]ClO_4$[19] was employed. Trimethylenediamine (1.2 g) and active charcoal (1.0 g) were added to a solution (100 ml) of $Na[Co(NO_2)_2(acac)_2]$ (6.2 g). After stirring for 15 min at room temperature, the charcoal was filtered and washed with water (30 ml). The filtrate and washings were combined and concentrated to *ca.* 50 ml by evaporation at 50 °C. The concentrate was then filtered and potassium iodide (30 g) was added to the filtrate to precipitate deep red needles on cooling. The yield was 6.5 g (81.9%), and recrystallization from hot water gave deep red needles. Found: C, 32.99; H, 5.52; N, 5.88%. Calcd for $C_{13}H_{26}O_5N_2ICo$: C, 32.79; H, 5.50; N, 5.88%.

After a mixture of the racemic complex (4.5 g) and silver acetate (4.0 g) was stirred in water (20 ml) for 10 min, silver iodide and remaining silver acetate were separated by filtration and washed with water (10 ml). A solution (50 ml) of sodium hydrogen-(*R,R*)-di-*O*-benzoyltartrate (3.6 g) was added slowly to the filtrate and the solution was kept in a desiccator to deposit a deep violet precipitate. The yield was 1.5 g (23.1%). Found: C, 54.13; H, 5.44; N, 3.95%. Calcd for $C_{31}H_{37}O_{12}N_2Co$: C, 54.07; H, 5.42; N, 4.07%.

A mixture of the diastereomer (1.0 g) and silver acetate (1.0 g) was stirred in methanol (20 ml). A precipitate was

filtered and washed with methanol (20 ml). The washings was combined with the filtrate and the solvent was evaporated to dryness. The residue was dissolved in water (5 ml) and the solution was filtered. Solid potassium iodide was added to the filtrate to separate out a deep red precipitate. The yield was 0.3 g (43.4%). Found: C, 32.80; H, 5.50; N, 5.85 %. The specimen was dissolved in a minimum amount of water and the solution was cooled to deposit a precipitate. After filtration, potassium iodide was added to the filtrate to obtain a precipitate which showed an improved optical activity. This procedure was repeated to attain the following constant molar rotation in aqueous solution at room temperature: $[M]_{589}=-1810°$, $[M]_{546}=+9140°$, $[M]_{436}=-15610°$.

$(+)_{589}$-Acetylacetonatobis(trimethylenediamine)chromium(III) Iodide Hemihydrate, $(+)_{589}$-[Cr(acac)(tn)$_2$]I$_2\cdot 0.5H_2O$: To an aqueous solution (25 ml) of acetylacetone (1.0 g) and sodium hydroxide (0.4 g) was added *cis*-[$CrCl_2(tn)_2$]Cl·H_2O (3.3 g), and the mixture was stirred at 70 °C to become a clear orange solution. After cooling to room temperature, solid potassium iodide (10 g) was dissolved in the solution, which was then kept in an ice bath to separate out an orange precipitate. The crude product was filtered, washed with small portions of water and acetone successively and air-dried. The yield was 2.0 g (35.0%) and recrystallization from hot water gave orange plates. Found: C, 23.61; H, 5.01; N, 9.94; I, 45.09 %. Calcd for $C_{11}H_{28}O_{2.5}N_4I_2Cr$: C, 23.50; H, 5.02; N, 9.96; I, 45.14%.

In a similar manner to the corresponding cobalt(III) complex, the racemic compound (2.0 g) was converted to the acetate and resolved by the (*R,R*)-tartratoarsenate(III). The diastereomer (0.9 g) was then treated with potassium iodide to give $(+)_{589}$-[Cr(acac)(tn)$_2$]I$_2\cdot 0.5H_2O$ (0.3 g). Found: C, 23.58; H, 4.98; N, 9.73%. After repeated resolution the final specimen showed the following molar rotation in aqueous solution at room temperature: $[M]_{589}=+310°$, $[M]_{546}=+630°$, $[M]_{436}=-5020°$.

$(-)_{589}$-Bis(acetylacetonato)(trimethylenediamine)chromium(III) Iodide Hydrate, $(-)_{589}$-[Cr(acac)$_2$(tn)]I·H_2O: To an aqueous solution (50 ml) of acetylacetone (2.0 g) and sodium hydroxide (0.8 g) was added *trans*-[$CrCl_2(tn)_2$]Cl (3.1 g), and the mixture was heated at 70 °C to result in a red solution. After cooling solid potassium iodide (10 g) was added and the solution was kept in ice to form a red precipitate, which was filtered and extracted with acetone. The solvent was evaporated and the residue was recrystallized from hot water to obtain red needles. The yield was 1.5 g (32.2%). Found: C, 33.67; H, 5.59; N, 6.09; I, 27.45%. Calcd for $C_{13}H_{26}O_5N_2ICr$: C, 33.27; H, 5.58; N, 5.97; I, 27.04%.

The racemic iodide (1.5 g) was converted to the acetate and resolved by the (*R,R*)-di-*O*-benzoyltartrate. The diastereomer (2.7 g) was treated in a similar manner as the case of $[Co(acac)_2(tn)]^+$ to obtain $(-)_{589}$-[Cr(acac)$_2$(tn)]I·H_2O (1.4 g). Found: C, 34.18; H, 5.40; N, 5.98%. The resolution procedure was repeated until the following constant molar rotation was observed in aqueous solution at room temperature: $[M]_{589}=-420°$, $[M]_{546}=+5000°$, $[M]_{436}=-5750°$.

Measurements. The electronic absorption spectra were measured by a Hitachi EPS-3T spectrophotometer. The optical rotations were determined with a Yanagimoto OR-50 polarimeter, and the CD spectra with JASCO J-20 recording spectrometer. The proton NMR spectra were recorded on a JEOL-C 60HL spectrometer with TMS as an external reference.

Results and Discussion

The mixed ligand complexes [Co(acac)(en)$_2$]I$_2$·H_2O,[18] [Co(acac)$_2$(en)]I,[20] [Cr(acac)(en)$_2$]Cl$_2$·H_2O,[21] and [Cr(acac)$_2$(en)]Cl·$1.5H_2O$[21] were prepared and resolved by $Na_2[(R,R)As_2(C_4H_2O_6)_2]\cdot 2H_2O$ according to previously reported procedures. The same resolving agent was successfully applied to the acetylacetonatobis(trimethylenediamine) complexes. The enantiomer of $[Co(acac)(tn)_2]^{2+}$ forming a less-soluble diastereomer with the resolving agent shows an opposite CD pattern as compared with that of the corresponding diastereomer of $[Co(acac)(en)_2]^{2+}$ as is seen in Fig. 1. It is worth noting that the solubility criterion for relative configuration does not hold even in this couple of quite similar complexes. In the case of bis(acetylacetonato)(trimethylenediamine) complexes, on the other hand, the tartratoarsenate was not suitable and the di-*O*-benzoyltartrate was used as a resolving agent. Brennan, Igi, and Douglas resolved $[Co(acac)_2(tn)]^+$ as the (*R,R*)-tartrate.[22]

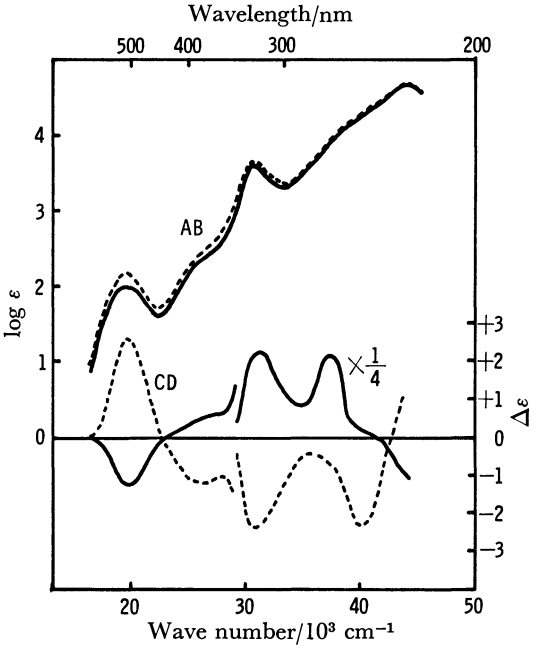

Fig. 1. Absorption (AB) and circular dichroism (CD) spectra of $(-)_{589}$-[Co(acac)(tn)$_2$]I$_2$ (——) and $(+)_{589}$-[Co(acac)(en)$_2$]I$_2$·H_2O (----) in water.

The cobalt(III) complexes $(-)_{589}$-$[Co(acac)(tn)_2]^{2+}$ and $(-)_{589}$-$[Co(acac)_2(tn)]^+$ are quite stable and the aqueous solutions showed no change in the optical rotation at room temperature over one month. On the contrary, the corresponding chromium(III) complexes are not so stable. The optical rotations of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ and $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ in aqueous solutions diminished gradually on standing at room temperature to one-half after six days. The absorption spectra also changed, indicating that reactions other than racemization proceeded.

Electronic Spectra. The electronic absorption spectra of the complexes obtained are displayed in

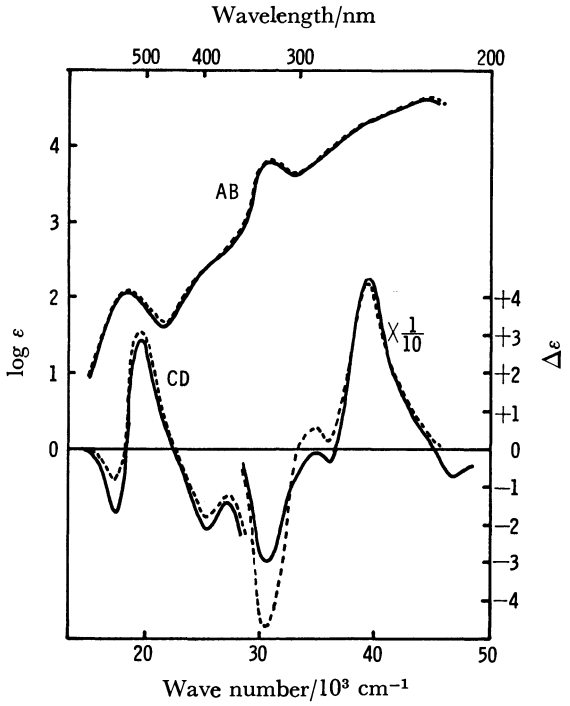

Fig. 2. Absorption (AB) and circular dichroism (CD) spectra of $(-)_{589}$-$[Co(acac)_2(tn)]I \cdot H_2O$ (——) and $(-)_{589}$-$[Co(acac)_2(en)]I$ (– – –) in water.

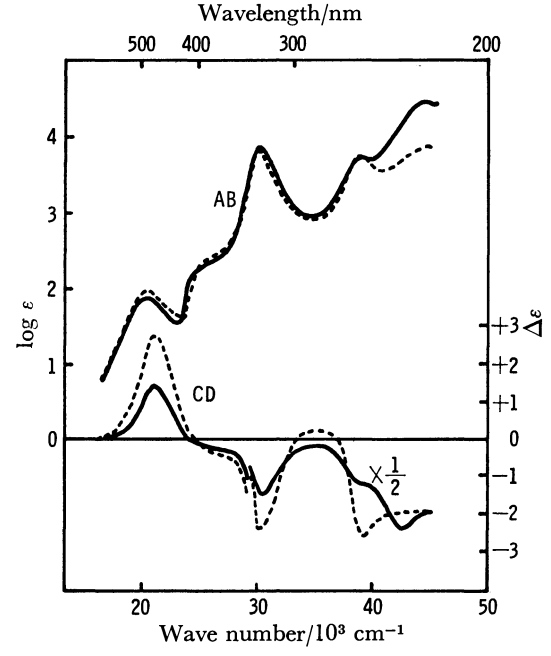

Fig. 3. Absorption (AB) and circular dichroism (CD) spectra of $(+)_{589}$-$[Cr(acac)(tn)_2]I_2 \cdot 0.5H_2O$ (——) and $(+)_{546}$-$[Cr(acac)(en)_2]Cl_2 \cdot H_2O$ (– – –) in water.

Figs. 1—4 together with those of the corresponding ethylenediamine complexes for the sake of comparison. In the earlier papers of this series,[23–25] several dianionobis(trimethylenediamine)cobalt(III) complexes have been reported, of which the first absorption maxima all located in the lower energy region than those of the corresponding ethylenediamine complexes, indicating that the ligand field of trimethylenediamine

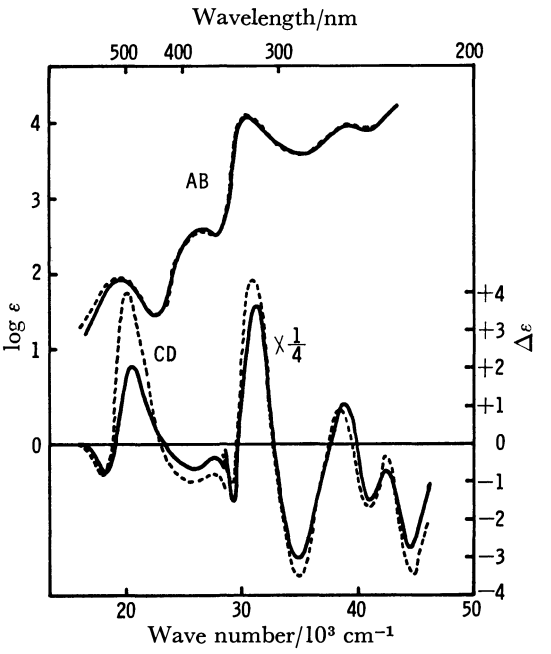

Fig. 4. Absorption (AB) and circular dichroism (CD) spectra of $(-)_{589}$-$[Cr(acac)_2(tn)]I \cdot H_2O$ (——) and $(+)_{546}$-$[Cr(acac)_2(en)]Cl \cdot 1.5H_2O$ (– – –) in water.

is a little weaker than that of ethylenediamine. In the present case, however, the first bands of $[Co(acac)(tn)_2]^{2+}$ (19800 cm^{-1}) and $[Co(acac)_2(tn)]^+$ (18500 cm^{-1}) nearly coincide with the data for $[Co(acac)(en)_2]^{2+}$ (19800 cm^{-1})[26] and $[Co(acac)_2(en)]^+$ (18600 cm^{-1}),[20] respectively, and those of $[Cr(acac)(tn)_2]^{2+}$ (20300 cm^{-1}) and $[Cr(acac)_2(tn)]^+$ (19200 cm^{-1}) are even higher in frequency than $[Cr(acac)(en)_2]^{2+}$ (20200 cm^{-1}) and $[Cr(acac)_2(en)]^+$ (19000 cm^{-1}).[21] In either of cobalt(III) and chromium(III) complexes, participation of acetylacetone as ligand diminishes the frequency of the absorption maximum due to its lower field as compared with ethylenediamine and trimethylenediamine. As to the assignment of the UV absorption bands, Boucher[20] discussed on $[Co(acac)_2(en)]^+$ and Kaizaki *et al.*[21] on $[Cr(acac)_2(en)]^+$.

CD Spectra and Absolute Configuration. Figures 1—4 show the CD spectra of the $[Co(acac)_x(tn)_{3-x}]$ and $[Cr(acac)_x(tn)_{3-x}]$ complexes ($x=1$ or 2) together with those of the corresponding ethylenediamine complexes. The CD pattern of $(-)_{589}$-$[Co(acac)(tn)_2]^{2+}$ in aqueous solution is just opposite in sign as compared with that of $(+)_{589}$-$[Co(acac)(en)_2]^{2+}$ which was reported to have the *Λ* configuration.[26] Thus a *Λ* configuration is assigned to $(-)_{589}$-$[Co(acac)(tn)_2]^{2+}$ and has in fact been confirmed by X-ray analysis.[27] The CD spectra of $(-)_{589}$-$[Co(acac)_2(en)]^+$ and $(-)_{589}$-$[Co(acac)_2(tn)]^+$ show a striking resemblance to each other (Fig. 2). Boucher assigned the *Λ* configuration to the ethylenediamine complex on the basis of the positive sign of the dominant CD band (A_2+B_2) in the first absorption region.[20] Then the *Λ* configuration of $(-)_{589}$-$[Co(acac)_2(tn)]^+$ is quite obvious and the same conclusion was drawn already by Brennan *et al.*[22]

Kaizaki *et al.* prepared and characterized $(+)_{546}$-$[Cr(acac)(en)_2]Cl_2$ and $(+)_{546}$-$[Cr(acac)_2(en)]Cl$ by the

absorption and CD spectra in both the visible and ultraviolet region, assigning the *Λ* configuration to both of the mixed-ligand complexes.[21] As is seen in Figs. 3 and 4, the CD spectra of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ and $(-)_{589}$-$[Cr(acac)_2(tn)]^{+}$ are quite similar to those of $(+)_{546}$-$[Cr(acac)(en)_2]^{2+}$ and $(+)_{546}$-$[Cr(acac)_2(en)]^{+}$, respectively, except that the rotational strength of each CD band is smaller for the tn complex than for the corresponding en complex. Thus the two (acetylacetonato)(trimethylenediamine)chromium(III) complexes may be concluded to have the *Λ* configuration. The X-ray analysis of a red prism of $(-)_{589}$-$[Cr(acac)_2(tn)]I \cdot H_2O$ now in progress confirms the *Λ* configuration with a tn chelate ring of chair form.[28]

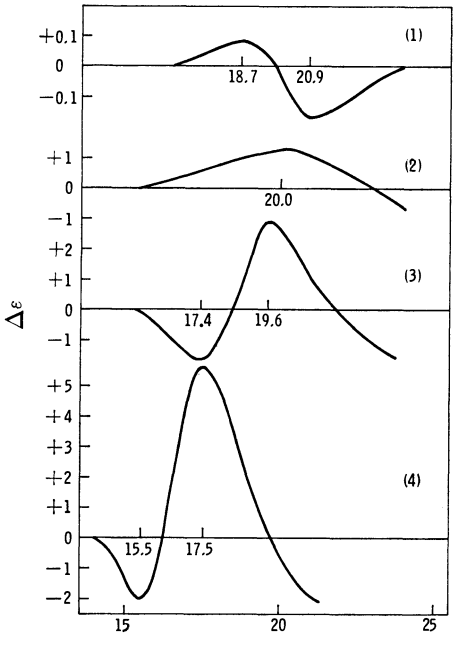

Fig. 5. Circular dichroism spectra in the first d-d absorption region of *Λ*-$[Co(tn)_3]^{3+}$ (1),[6] *Λ*-$[Co(acac)(tn)_2]^{2+}$ (2), and *Λ*-$[Co(acac)_2(tn)]^{+}$ (3) in water and of *Λ*-$[Co(acac)_3]$ (4)[29] in ethanol.

Figure 5 compares the CD patterns of the $[Co(acac)_x(tn)_{3-x}]$ complexes (x=0—3) in the first absorption region. The absolute configuration of $(-)_{546}$-$[Co(acac)_3]$ was determined as *Λ* by X-ray analysis.[29] The predominant positive CD band at 17500 cm^{-1} was assigned to the E component on the basis of the polarized crystal spectrum[30] in accordance with the empirical spectroscopic rule that for the *Λ* isomer the CD component with E symmetry has positive rotational strength.[8] The CD spectral pattern of *Λ*-$[Co(acac)_2(tn)]^{+}$ is quite similar to that of $[Co(acac)_3]$ except that the peak positions are shifted to the higher energy region due to the higher ligand field of tn than that of acac. Thus the positive CD band at 19600 cm^{-1} of *Λ*-$[Co(acac)_2(tn)]^{+}$ may be assigned to the E component.

The positive CD band of $[Co(tn)_3]^{3+}$ was attributed to the E component based on the ion-pairing effect.[31,9] It should be noted that the E component lies at lower energy side of the A_2 component for $[Co(tn)_3]^{3+}$ on the contrary to the $[Co(acac)_3]$ case where the E component lies at higher energy side of the A_2 component. *Λ*-$[Co(acac)(tn)_2]^{2+}$ exhibits a single positive CD band which is drawn as a reverse of the band observed for *Δ*-$[Co(acac)(tn)_2]^{2+}$ (Fig. 1). The E-A_2 split seems small and cancellation of the two components with each other is extensive, leaving residue of the predominant E component.

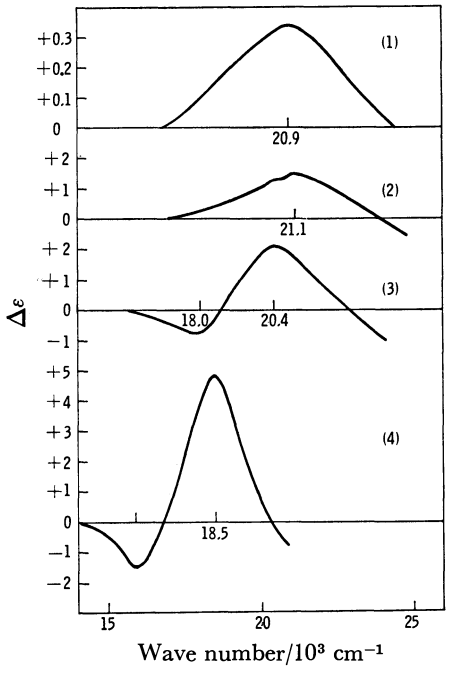

Fig. 6. Circular dichroism spectra in the first d-d absorption region of *Λ*-$[Cr(tn)_3]^{3+}$ (1),[35] *Λ*-$[Cr(acac)(tn)_2]^{2+}$ (2), and *Λ*-$[Cr(acac)_2(tn)]^{+}$ (3) in water and of *Λ*-$[Cr(acac)_3]$ (4)[32] in ethanol.

In a similar fashion Fig. 6 shows the CD spectra of the $[Cr(acac)_x(tn)_{3-x}]$ complexes in the first d-d absorption region. Mason *et al.*[32] prepared optically pure $(-)_{589}$-$[Cr(acac)_3]$ and assigned the absolute configuration to *Δ* based on comparison of the CD spectrum with those of four isomers of tris((+)-3-acetylcamphorato)chromium(III)[33] of which *Λ*(+)-*trans*-$[Cr((+)\text{-atc})_3]$ had been confirmed to be *Λ* by X-ray analysis.[34] The curve (4) in Fig. 6 is drawn as a reverse of the CD spectrum reported by Mason *et al.* for *Δ*-$[Cr(acac)_3]$,[32] showing the CD spectrum of *Λ*-$[Cr(acac)_3]$. Thus the positive major band at 18500 cm^{-1} can be assigned to the E component. The CD spectrum of *Λ*$(-)_{589}$-$[Cr(acac)_2(tn)]^{+}$ is also similar in the pattern to that of *Λ*-$[Cr(acac)_3]$ and the positive major band is assigned to the E component.

The CD spectrum of $(+)_{546}$-$[Cr(tn)_3]^{3+}$ reproduced in Fig. 6 was reported by Kaizaki *et al.*[35] On addition of sodium selenite to the solution, intensity of the positive CD band at 477 nm was diminished and a new negative CD band appeared at 435 nm. Thus the positive band was assigned to the ^4E component and the absolute configuration of $(+)_{546}$-$[Cr(tn)_3]^{3+}$ was concluded to be *Λ*.[35] The CD pattern of $(+)_{589}$-$[Cr(acac)(tn)_2]^{2+}$ (curve 2 in Fig. 6) is similar to that of $(+)_{546}$-$[Cr(tn)_3]^{3+}$

and the positive CD band is considered to be a residue of the predominant ^4E component after cancellation with a negative ^4A component.

The ligand-metal-ligand bond angle θ exceeds 90° in the six-membered chelate ring formed by trimethylenediamine with cobalt(III), whereas θ is generally less than 90° in the five-membered ethylenediamine cobalt(III) chelates. The empirical criterion relating the positive E component of the lowest-energy d-d absorption band to the Λ isomer of the cobalt(III) ethylenediamine chelate[8] has been shown to apply to the cobalt(III) trimethylenediamine complexes in spite of the larger angle θ.[31] In contrast with the N–Co–N angle of 96(1)° in $(-)_{589}$-$[Co(acac)(tn)_2]^{2+}$,[27] the N–Cr–N angle in $(-)_{589}$-$[Cr(acac)_2(tn)]^+$ was found to be 88.8(4)°.[28] The striking resemblance of the CD patterns depicted in Fig. 6 to those in Fig. 5 indicates that the same generalization as established for the cobalt(III) complexes applies to the chromium(III) complexes, too.

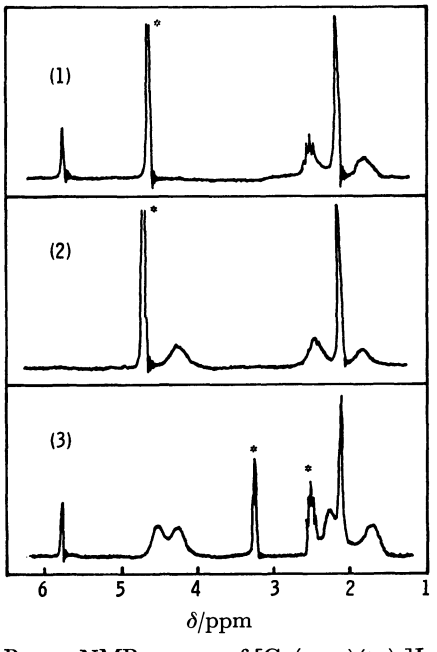

Fig. 7. Proton NMR spectra of $[Co(acac)(tn)_2]I_2$ in D_2O (1), *ca.* 0.1 M DCl–D_2O (2), and dimethylsulfoxide-d_6 (3). The asterisks denote the peaks due to solvent impurities.

Proton NMR Spectra. Figure 7 shows the proton NMR spectra of $[Co(acac)(tn)_2]I_2$ in D_2O, DCl–D_2O and DMSO-d_6. Two sharp signals observed at 5.75 and 2.16 ppm in D_2O with the area ratio of *ca.* 1:6 are assigned to the methine and methyl protons of the acetylacetonate ligand. The methine signal is lost in acidic solution due to the exchange reaction. Three broad signals observed at 4.24, 2.51, and 1.84 ppm in 0.1 M DCl–D_2O solution with the relative intensity of 2:2:1 are assigned to the NH_2, α-CH_2 and β-CH_2 protons of trimethylenediamine, NH_2–$CH_2(\alpha)$–$CH_2(\beta)$–$CH_2(\alpha)$–NH_2. In neutral D_2O the amine protons are deuterated and the methylene signals become sharper.

In DMSO-d_6 solution the methylene protons resonate at a little higher field (2.28 and 1.70 ppm) and the amine protons exhibit two signals at 4.55 and 4.27 ppm with equal intensities. Clifton and Pratt found that the chemical shifts of ammine or amine protons trans to halide or oxygen-donor ligand in $[CoX(NH_3)_5]^{(3-n)+}$ and *cis*-$[CoCl_2(en)_2]^+$ are appreciably smaller than those of the cis amine protons.[36] The same situation is realized in $[Co(acac)(tn)_2]^{2+}$ and the 4.27 ppm signal is assigned to the amine groups trans to the acetylacetonate oxygen and the 4.55 ppm signal to the mutually trans amine groups.

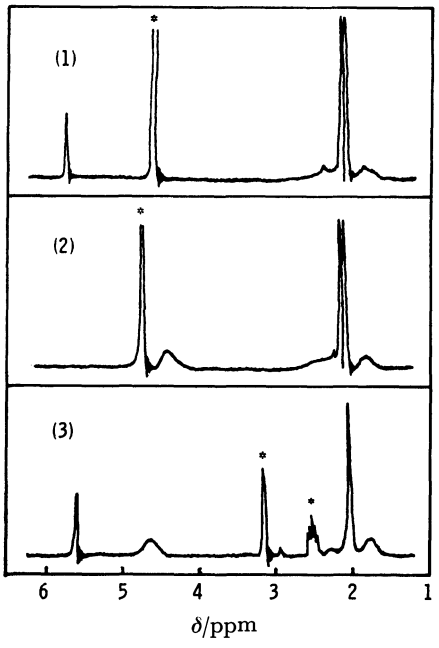

Fig. 8. Proton NMR spectra of $[Co(acac)_2(tn)]I \cdot H_2O$ in D_2O (1), *ca.* 0.1 M DCl–D_2O (2), and dimethylsulfoxide-d_6 (3). The asterisks denote the peaks due to solvent impurities.

As is seen in Fig. 8 the spectrum of $[Co(acac)_2(tn)]^+$ in D_2O shows two methyl signals at 2.11 and 2.15 ppm together with a methine signal at 4.28 ppm in accord with expectations. In DCl–D_2O solution three signals due to trimethylenediamine are observed at 4.47, 2.43, and 1.88 ppm with the relative intensity of 2:2:1 and assigned to the NH_2, α-CH_2 and β-CH_2, respectively. In DMSO-d_6, however, the relative intensities of the two methylene signals are reversed, the higher-field signal at 1.80 ppm being twice as large in area as the lower-field one at 2.27 ppm. It is not conceivable that the α-CH_2 protons resonate at a higher field than the β-CH_2 in this case, but nonequivalence of the geminal α-CH_2 protons may be responsible for this phenomenon. The complex *cis*-$[Co(CN)_2(tn)_2]^+$ shows three methylene signals of equal intensity in D_2O.[25] The two protons in each methylene group of $NH_2CH_2CHXCH_2NH_2$ (X=OH or Cl) coordinated to platinum(II) are not equivalent, the axial proton resonating at higher field than the equatorial one.[37] In the spectrum of $[Co(acac)_2(tn)]^+$, the signal at 2.27 ppm may be attributed to the equatorial protons of the two α-CH_2 groups and the chemical shift of the axial α-CH_2 protons may be

assumed to coincide with that of β-CH_2 by chance. The trimethylenediamine molecule coordinated to cobalt(III) has the chair conformation in crystals of $(-)_{589}$-$[Co(tn)_3]Br \cdot H_2O$,[5] $(+)_{589}$-$[Co(en)_2(tn)]Br_3$,[38] $(-)_{589}$-$[Co(acac)(tn)_2][As\text{-}(+)\text{-}tart]_2 \cdot H_2O$,[27] $(-)_{589}$-*cis*-$[Co(NCS)_2(tn)_2][Sb\text{-}(+)\text{-}tart] \cdot 2H_2O$,[39] *trans*-$[Co(NO_3)_2(tn)_2]NO_3$,[40] and $[Co(CO_3)(tn)_2]ClO_4$.[41] However, the chair conformation of the six-membered chelate ring seems only slightly more stable than the skew-boat conformation,[42] and the CD spectra of $[Co(tn)_3]^{3+}$ ions in solutions were interpreted to indicate the equilibrium between these two conformers.[43] The remarkable difference now observed in the NMR spectra in D_2O and DMSO-d_6 may reflect the change of the equilibrium among conformers with solvent.

The authors wish to thank Mr. J. Gohda for the elemental analyses and Dr. T. Kinoshita for the PMR measurements. This work was supported in part by the Grant-in-Aid administered by the Ministry of Education.

Potentialities of Field Desorption Mass Spectrometry Using Emitter Current Programmer for Direct Analysis of Multicomponents

Hiroaki SHIRAISHI,* Akira OTSUKI, and Keiichiro FUWA

Department of Chemistry and Physics, National Institute for Environmental Studies, Yatabe, Ibaraki 300-21

(Received February 26, 1979)

The influence of emitter current on field desorption (FD) mass spectra was examined with use of an emitter current programmer (ECP). Reproducibility of FD mass spectra measured by electronic detection is improved with ECP and the integration of stored spectra on the computer. The FD mass spectra of some surfactants are shown as an example of complex mixture. The FD mass spectra of poly(oxyethylene) alkylphenyl ethers show that the distribution pattern of molecular ion peaks depends upon emitter current. The fractional desorption also occurs in the FD mass spectra of α-hydro-ω-(octadecylamino)poly(oxyethylene) measured with a constant emitter current. The emitter current required for desorption of hexadecyltrimethylammonium chloride is greatly affected by coexisting with another ammonium salt. Use of ECP supplies information on the analysis of multicomponents.

Field desorption mass spectrometry (FDMS) has been found to be useful for analysis of thermally labile and non-volatile compounds. However, the formation of ions in FD-MS is affected by various parameters such as electric field strength, emitter temperature, morphology and surface properties of the emitter needles and kind of sample loading.[1,2] Maine *et al.*[3] found that automatic control of the emitter temperature is essential for obtaining reproducible results from successive analysis of the same sample. They suggested that the most important factors are the emitter temperature and the use of an emitter current programmer, which provides precise control of the magnitude and rate of change of current in the emitter wire, for obtaining reproducible FD mass spectra.

Several emitter current control devices[3–5] were reported; they are not yet available commercially. In an attempt to develop a method for identification and analysis of several types of surfactants, an emitter current programmer was constructed with a slight modification of that by Maine *et al.* The possibility for separation and analysis of multicomponents using the ECP has been examined.

Experimental

Apparatus. Mass spectrometry was performed on a JEOL JMS-OlSG double focusing mass spectrometer with a combined field desorption/field ionization/electron impact ion source, connected to JMS-2000 mass data analysis system (Japan Electronic and Optics laboratory). FD-emitter used was 10 μm tungsten wire with carbon needles grown at high temperature.[6] An anode potential of 10 kV and cathode potential of −3 kV were applied. Emitter curent was increased linearly by use of a modified emitter current programmer during the course of repetitive magnet scanning. The emitter was loaded with 0.2—1 μg samples from stock solutions (*ca.* 1 μg/μl) using microsyringe technique.[7]

Figure 1 shows a block diagram of the modified ECP. Operation modes are the same as those described by Maine *et al.* The current programming rate can be set at a desired value in the range 1–100 mA/min. The emitter current is regulated within 0.05 mA at any level between 0 and 60 mA. Initial and final current values can be controlled within this range.

Initial focussing was done on acetone introduced *via* the batch inlet. After measurements of each sample the emitter current was increased to 60 mA in order to clean the emitter.

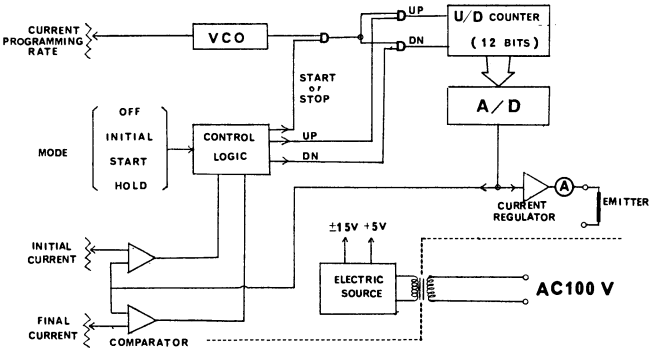

Fig. 1. The block diagram of ECP.

Materials. Poly(oxyethylene) octylphenyl and dodecylphenyl ethers supplied by Gasukuro Kogyo Co., Ltd. and Daiichi Seiyaku Co., Ltd., respectively, and other surfactants from Wako Pure Chemical Industries, Ltd. were used.

Results and Discussion

The FD mass spectrum of sodium dodecylbenzenesulfonate (DBS), a typical anionic surfactant, was measured by repetitive magnet scanning at 11 s intervals, the emitter current increasing linearly at a rate of 3 mA/min. Integration of all the spectra collected on the computer showed *m/e* 719 $(2M+Na)^+$, 371 $(M+Na)^+$, and 348 $(M)^+$ ion peaks (Fig. 2). Each coefficient of variation calculated from seven measurements of the same sample was ±4% for the intensity of the base peak $(M+Na)^+$ to the total intensity of all peaks, ±30% and ±20% for those of M^+ and $(2M+Na)^+$ peaks, respectively. FD mass spectra obtained with a single magnet scan and electric detection gave less reproducible spectra due to the fluctuation of ion current. FD mass spectrum of DBS was considerably affected by emitter current (Fig. 2(b)). In general, $(2M+Na)^+$ ion has a relatively high intensity at lower emitter current, but at higher emitter current the intensity of this cluster ion rapidly decreased whereas $(M)^+$ and $(M+Na)^+$ peaks increased. Emission controlled FD mass spectra of some sulfonates were studied by Schulten and Kummler.[8] They used a vacuum evaporated AgBr plate for photographic detection and found that $(nM+Na)^+$ cluster ion with $n=1$ is mostly prominant, molecular ion having

relatively smaller intensity. The integration of spectra, obtained by electric detection and linear current program, gives reproducible spectra consisting of the spectrum obtained by Schulten and Kummler by potographic detection and emission controlled time/current program.

Figure 3 shows the integrated FD mass spectrum (a) of hexadecyltrimethylammonium chloride (CA), a typical cationic surfactant, and the reconstructed mass chromatogram (b) obtained under the same conditions as those of DBS except for the initial current value. The ion peaks at *m/e* 284, 603, and 269 were assigned to salt cation (molecular ion minus chloride ion), cluster ion of the type, molecular ion plus cation portion, and fragment ion peak $(M-Me)^+$, respectively. The intensities of these ion peaks were also dependent upon emitter current. Reconstructed mass chromatogram (Fig. 3(b)) indicates that the intensity of cluster ion $(M+C)^+$ decreases at higher emitter current, while the intensities of salt cation and fragment ions increase. Disappearance of the cluster ion at the higher emitter current can be attributed to weak binding of the cluster ion that thermally decomposes. Figures 4(a) and (b) show the FD mass spectra of equimolar mixture of hexadecyltrimethylammonium chloride(CA)and benzylhexadecyldimethylammonium chloride (BA). Lower emitter current gave ion peaks of two salt cations (*m/e* 284, 360) and relatively high intensities of three cluster ions (*m/e* 603, 679, 755) of the type $(M+C)^+$. The ion peak at *m/e* 679 demonstrates the production of a mixed cluster ion consisting of both cation portions and chloride ion. A similar phenomenon has been observed by Veith,[9] who used simple ammonium salts. On the

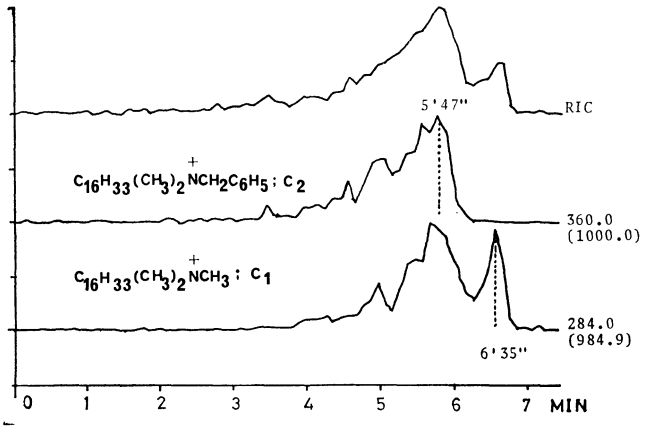

Fig. 5. Reconstructed mass chromatogram of equimolar mixture of CA and BA.
Current programming rate 3 mA/min.

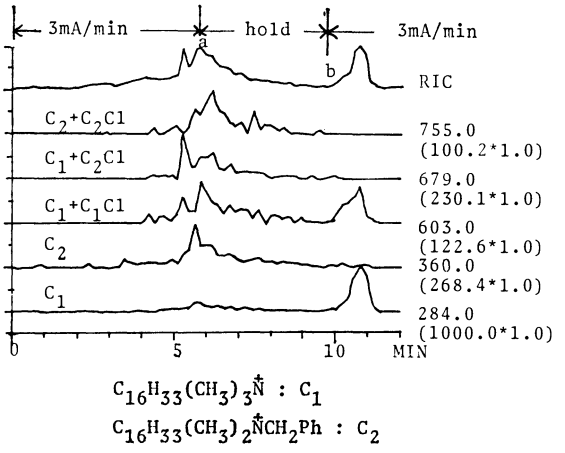

Fig. 6. Reconstructed mass chromatogram of equimolar mixture of CA and BA.

other hand, higher emitter current gave only the spectrum of CA due to the disapperance of BA at lower emitter current. Figure 5 shows the reconstructed mass chromatogram of two salt cations during the course of a linear emitter current programming, suggesting that the part of CA on the emitter wire can be desorped at lower emitter current when BA coexist, compared with that in Fig. 3(b), but further increase in emitter current is required for the desorption of the remaining part of CA after all BA was desorped. The results indicate that emitter current required for desorption of CA is greatly affected by the presence of BA, *viz.*, emitter current required for field desorption changes with not only the properties of individual compounds but also the interaction of each component loaded on emitter wire. When emitter current was increased to 17 mA at a rate of 3 mA/min and kept constant for 4 min, a mixture of CA and BA was found to be separated by fractional desorption (Fig. 6). This suggests that the use of ECP producing programmed thermal gradients makes the separation and analysis of multicomponents in complex mixtures by mass chromatograpy or selected ion monitoring techniques possible.

The FD mass spectra of poly(oxyethylene) alkylphenyl ethers, nonionic surfactants, were measured. The results indicate only molecular ions with different polymerization degree of ethylene oxide unit.[10] Single scan FD mass spectra of poly(oxyethylene) octhylphenyl ethers (PO) obtained during the course of a linear emitter current programming are shown in Fig. 7. The distribution pattern of molecular ion peaks is also dependent upon emitter current, *viz.*, at lower emitter current the distribution pattern of ions is weighted for low mass region, whereas at higher emitter current it is weighted for high mass region, suggesting that fractional desorption occurs. The integrated FD mass spectrum of PO and the reconstructed mass chromatogram of selected ions are shown in Figs. 8(a) and (b). Figure 8(b) shows that the fractional desorption of mixtures occurs by thermal gradient. A similar fractional desorption was observed in the FD mass spectra

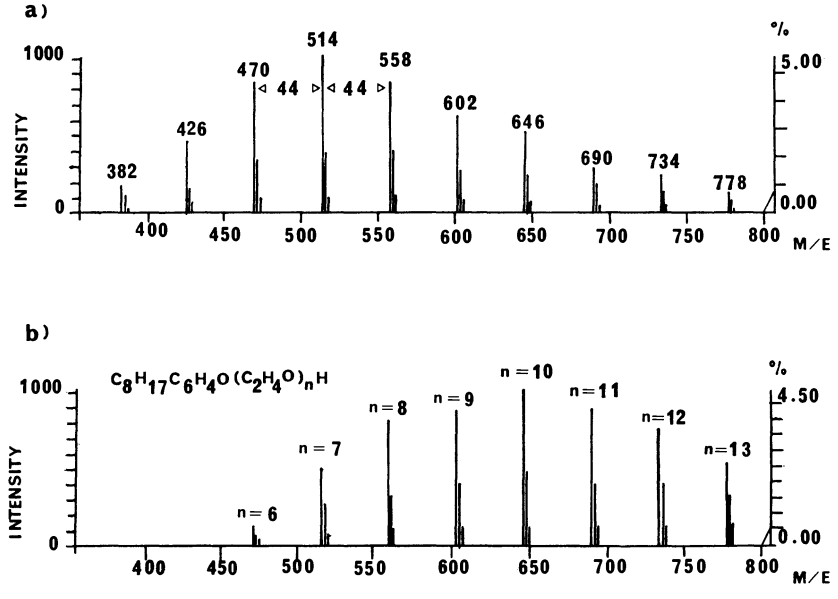

Fig. 7. The FD mass spectra of PO; emitter current (a) 14 mA (b) 16 mA.

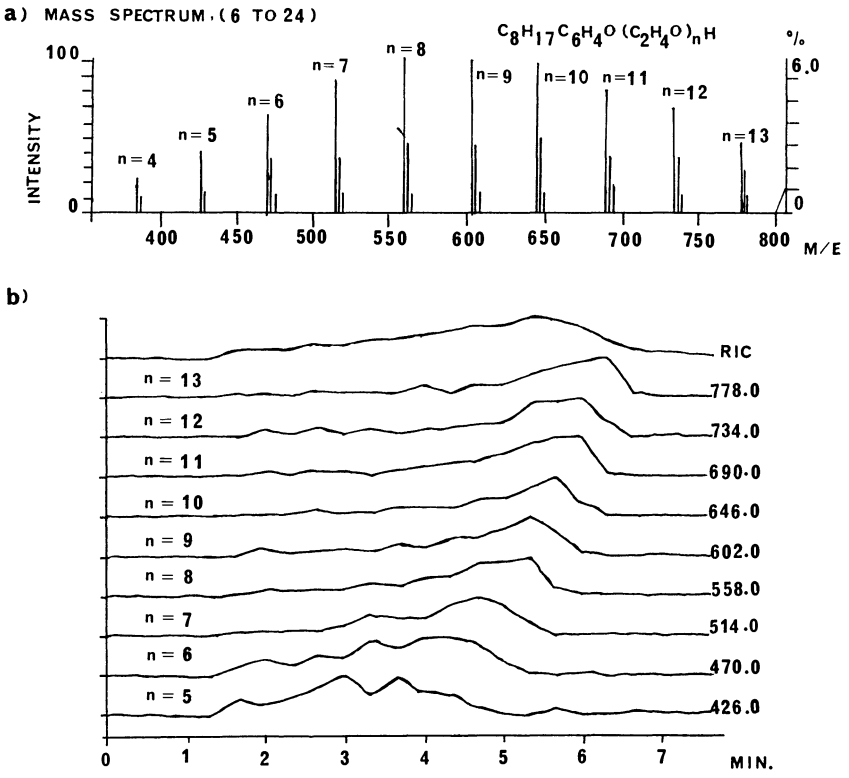

Fig. 8. (a) The FD mass spectrum of PO; sum of the stored spectra, small peaks are neglected. (b) Reconstructed mass chromatogram; current programming rate 3 mA/min.

of poly(oxyethylene) nonylphenyl and dodecylphenyl ethers. The result suggests that the true distribution of multicomponents in the original sample can be estimated at least from an integration of stored spectra during the course of slow increase in emitter current or photographic detection. The series of weak peaks found at *m/e* 14 lower and higher than the major ion peaks exhibit the existence of impurities having different alkyl side chains. The impurities correspond to poly(oxyethylene)nonylphenyl and hexylphenyl ethers. The FD mass spectra of α-hydro-ω-(octadecylamino)poly(oxyethylene) obtained under the following conditions are shown in Figs. 9(a) and (b): initial emitter current was set at 14 mA and kept constant during repetitive magnet scanning at 18 s intervals. Integration of the spectra of first 20 scans (a) and next 30 scans (b) indicates different distribution pattern of protonated molecular ions, suggesting that a similar fractional

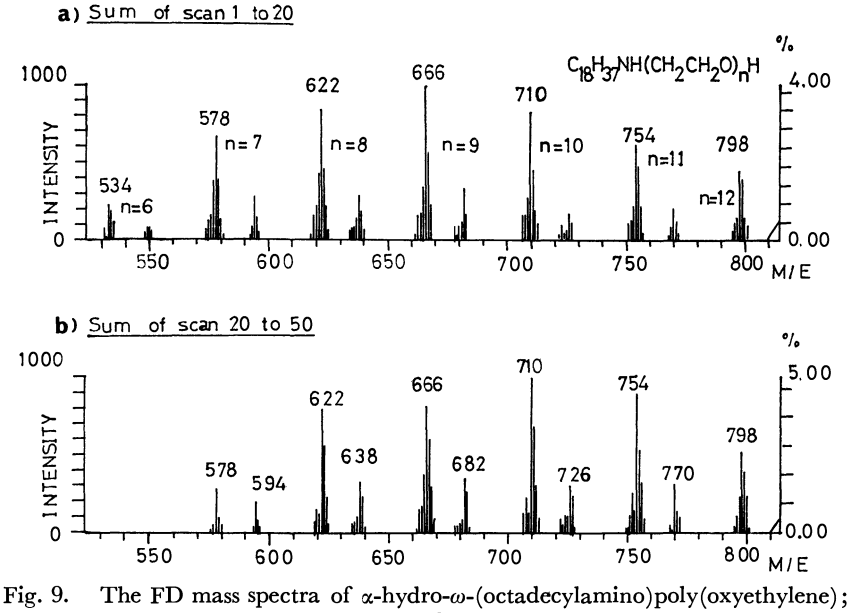

Fig. 9. The FD mass spectra of α-hydro-ω-(octadecylamino)poly(oxyethylene); emitter current 17 mA, (a) sum of the first 20 scans and (b) next 30 scans.

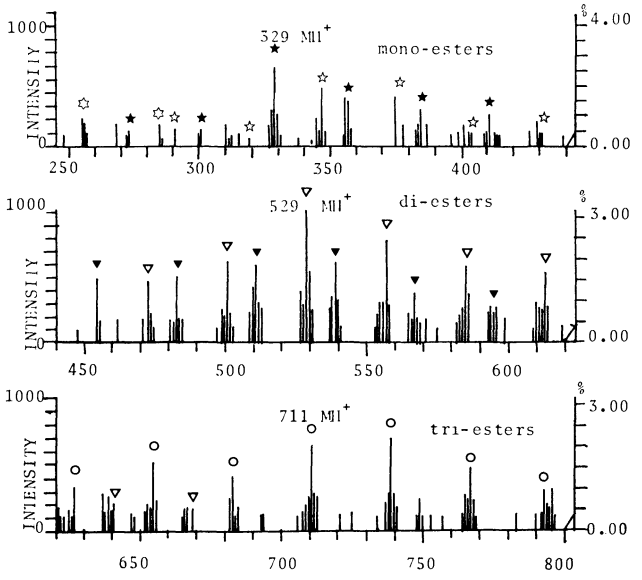

Fig. 10. The FD mass spectrum of "Span 20", Current programming rate 3 mA/min, sum of 20 scans, ☆, ▽ and ○ indicate mono-, di- and tri-esters of sorbitans respectively. ★ and ▲ indicate mono- and di-esters of sorbid respectively, ☆ indicates unreacted fatty acids.

desorption was taking place. The series of minor ion peaks found at 28 mass lower than the protonated molecular ion peaks correspond to the protonated molecular ions of α-hydro-ω-(hexadecylamino)poly-(oxyethylene) contained in the commercial samples as impurities.

The FD mass spectra of a group of nonionic surfactant, called "Span" known as a complex mixture of mono-, di-, tri-, and tetra-esters of 1,5- and 1,4-sorbitans and mono- and di-esters of 1,4: 3,6-sorbid were measured. Figure 9 shows the integrated FD mass spectra of "Span 20" as an example of complex mixtures, showing many protonated molecular ion peaks of the esters and molecular ion peaks of unreacted fatty acids and fragment ions at m/e 183, 211, 239, and 269 $(RCO)^+$ in low mass region. The protonated molecular ions of esters of sorbitan and sorbid observed in the FD mass spectra of various "Span"s are given in Table 1. Since these ions might consist of some isomers, the total carbon number of acyl groups ($l+n$, $l+n+m$) can be calculated. The composition of acyl groups in the samples can be estimated from the distribution of protonated molecular ion peaks of mono-esters. With linear increase in emitter current, desorption of di-esters occurs before that of tri-esters, the esters of sorbid being generally desorped prior to the esters of sorbitans. Because of fractional desorption, an integration of single scan spectra was needed to identify all the components in the mixtures.

The present study and others[11] indicate that there are two types of FD mass spectrum, one obtained from single scanning at near the best anode temperature and the other an integrated FD mass spectrum obtained from repetitive magnet scanning or photoplate detection, the latter being much more reproducible than the former when the cluster and fragment ions are produced.

Table 1. Protonated molecular ions of esters observed in the FD mass spectra of "Span"s

Mono-esters			Di-esters			Tri-esters	
n	A	B	$n+m$	A	B	$l+m+n$	A
8	291	273	20	473	455	28	599
10	319	301	22	501	483	30	627
12	347	329	24	529	511	32	655

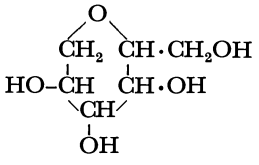
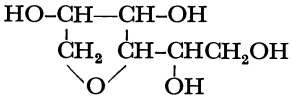
18	431	413	30	613	595	38	739
$18F_1$	429	411	32	641	623	40	767
			34	669	651	42	795
			36	697	679		

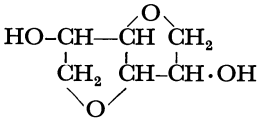
A and B indicate esters of sorbitans and sorbid, respectively. l, m, and n indicate carbon numbers of each fatty acid.



1,5-Sorbitan



1,4-Sorbitan



1,4:3,6-Sorbid

The present study also suggests that the compounds, from which cluster and fragment ions will be produced, and a complex mixture sample in which fractional desorption occurs, should be measured with ECP as an integrated FD mass spectrum. It seems that when the integrated FD mass spectrum is taken, the effect of the difference in morphology of emitter needles on the reproducibility of FD mass spectrum can be reduced. In FD-MS, the thermal gradient produced by ECP has become a powerful means for analysis of complex mixtures.

An X-Ray Photoelectron Spectroscopic Study of 2-Mercaptobenzothiazole Metal Complexes

Tooru YOSHIDA,* Kiyoshi YAMASAKI, and Shigemasa SAWADA
Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received March 1, 1979)

The X-ray photoelectronic spectra of 2-mercaptobenzothiazole (LH) and its metal complexes have been measured. On the basis of the chemical shifts of the N(1s), S(2p), and Cu($2p_{3/2}$) electron binding energies, the coordination mode of the ligand and the oxidation state of the copper atom have been examined. It is suggested that, in HgL_2, PbL_2, AgL, and CuL_3H_2Cl complexes, the ligand is solely coordinated through the exocyclic sulfur atom, and that, in CuL, CuL_2, PtL_2, PdL_2, NiL_2, and CdL_2 complexes, the ligand is coordinated through both the exocyclic sulfur and nitrogen atoms. In CuL_2 and CuL_3H_2Cl, it was found that the copper was present in a (+1) oxidation state, and that part of the ligand molecules, bis(benzothiazol-2-yl) disulfide, resulted from oxidation of LH by the Cu^{2+} ion on complex formation.

The use of 2-mercaptobenzothiazole as an analytical reagent has been known for a long time,[1-3] and the structures of its complexes with several metal ions have been investigated using a variety of physical techniques.[4-9]

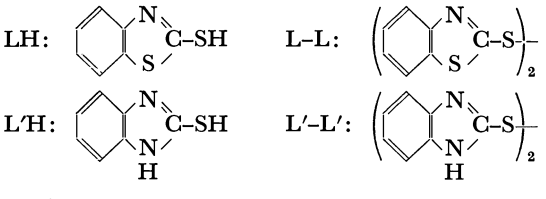
In the copper complex prepared from the reaction of 2-mercaptobenzothiazole with copper(II) chloride, the copper has been reported to be in a (+2) oxidation state, in spite of its diamagnetism.[7,9] Clear evidence for this assignment has however not been given. Furthermore, it is well known that sulfur-containing ligands often reduce the Cu(II) ion to Cu(I) on complex formation.[10]

X-Ray photoelectron spectroscopy (XPS) is sensitive to charge distribution and is suitable for the detection of protonated atoms and the oxidation state.[11]

The purpose of the present study is to confirm the oxidation state of copper in complexes with 2-mercaptobenzothiazole, and to examine the mode of coordination of the ligand in several metal complexes.

Experimental

Chemicals. 2-Mercaptobenzothiazole, the sodium salt, and 2-mercaptobenzimidazole (abbreviated as LH, LNa, and L'H, respectively) were obtained commercially and were of analytical grade. They were used after recrystallization from ethanol. Bis(benzothiazol-2-yl) and bis(benzimidazol-2-yl) disulfides (abbreviated as L–L and L'–L') were obtained by standard methods: the oxidation of LH and L'H in ethanol by H_2O_2 and I_2, respectively. L'H and L'–L' were used as reference compounds. All the copper salts used were analytical reagents. All ligands and metal complexes were analysed elementally.



Preparation of the Metal Complexes. *CuL*: Method (a) (according to the literature). An ethanol solution of LH was added to an aqueous solution of copper(I) chloride saturated with KCl[3] which gave an orange yellow precipitate. Found: C, 36.86; H, 1.71; N, 6.09; S, 27.47; Cu, 27.50%. Calcd for CuL: C, 36.60; H, 1.74; N, 6.10; S, 27.89; Cu, 27.67%. Method (b). A solution of LH (4—6 mmol) in ethanol (100 ml) was added to a solution of CuX_2 ($X=CH_3COO$ or NO_3) (2 mmol) in ethanol (50 ml). The orange-yellow and pale yellow compounds precipitated were digested on a water bath for approximately 1 h. The suspension was cooled and filtered on a suction pump through a qualitative filter paper to give a pale yellow crystalline precipitate (L–L). The filtrate, containing a fine orange-yellow precipitate was filtered through a quantitative filter paper and the resulting amorphous precipitate (CuL) washed with hot ethanol. The yields were approximately 90% for CuL and L–L. Found: C, 37.00; H, 1.67; N, 6.11; S, 27.57; Cu, 27.90%.

CuL_2: Method (a). A solution of CuX_2 ($X=Cl$, CH_3COO, NO_3, $1/2(SO_4)$) (2 mmol) in water (50 ml) was substituted for the solution of CuX_2 in ethanol in the above preparation procedure for CuL by method (b). The orange-yellow precipitate was washed with water and ethanol (yield>95%). Found: C, 42.34; H, 2.03; N, 7.08; S, 32.12; Cu, 16.20%. Calcd for CuL_2: C, 42.48; H, 2.02; N, 7.08; S, 32.36; Cu, 16.06%. Method (b). A solution cotaining LH and L–L (2 mmol and 1 mmol, respectively) in a mixture of ethanol (100 ml) and *N,N*-dimethylformamide (DMF) (50 ml) was added to a solution of CuCl (2 mmol) in an aqueous solution saturated with KCl (30 ml). The pale orange-yellow precipitated was digested with stirring on a water bath for approximately 1 h. The suspension was cooled and filtered and the collected precipitate washed with water, an ethanol–DMF mixture (30 ml, 2: 1), and ethanol (yield 80%). Found: C, 42.26; H, 1.99; N, 7.00; S, 32.02; Cu, 16.11%.

CuL_3H_2Cl: A solution of $CuCl_2$ (2 mmol) in ethanol (50 ml), in a procedure similar to method (b) above for CuL, gave a pale yellow complex (yield>95%). Found: C, 42.43; H, 2.17; N, 7.04; S, 31.23; Cl, 5.80; Cu, 10.63%. Calcd for CuL_3H_2Cl: C, 42.07; H, 2.34; N, 7.01; S, 32.05; Cl, 5.93; Cu, 10.60%. In the preparation of CuL_3H_2Cl, more than 5% water produced a mixture of CuL_2 and CuL_3H_2Cl, and greater than 20% gave CuL_2 quantitatively.

Other Metal Complexes: PtL_2, PdL_2, NiL_2, CdL_2, HgL_2, PbL_2, and AgL were prepared according to the literatures.[7,8]

All compounds used were dried in an air oven at 105 °C for a minimum of 2 h.

The structures of the two complexes prepared by methods (a) and (b) in the cases of CuL and CuL_2 were analysed by powder X-ray diffraction analysis.

Physical Measurements. The X-ray photoelectron spectra were measured on an AEI-ES200 spectrometer. Al $K\alpha$ (1486.6 eV) X-ray radiation was used as the excitation source. Samples were ground and dusted onto a double-backed adhesive tape. The measurements taken at room temperature

under vacuum (about 10^{-7} Torr). The binding energy of the C(1 s) peak assigned to the carbon of benzene was used as the energy standard throughout the experiments and taken to be 285.0 eV. The reproducibility was ± 0.1 eV.

The IR spectra of LH and the copper complexes were recorded on an IR spectrometer, model IR-G (Japan Spectroscopic Co., Ltd.). The spectrum of CuL_3H_2Cl was the only one which exhibited a similar N–H band to that of LH in the region 2800—3150 cm^{-1}. Magnetic measurements were conducted at room temperature using the Faraday method on a magnetic balance, model MB-2 (Shimadzu Co., Ltd.). The diamagnetic corrections were estimated by the use of Pascal's Constants[12] and all copper complexes were found to be diamagnetic.

Results

The measured binding energies are given in Table 1.

Free Ligands. The N(1s) electron spectra of L'H and L'–L', and the S(2p) electron spectrum of L'H are shown in Fig. 1. The N(1s) spectrum of L'H showed a single peak with the full-width at a half-maximum height (FWHM) of 1.7 eV. L'–L' showed two peaks with almost equal intensities. The S(2p) spectrum of L'H as well as that of L'–L' showed an unsymmetrical peak with a FWHM of 2.3 eV. Two peaks, p_1 and p_2, indicated by broken lines in the figure, have been attributed to $S(2p_{1/2})$ and $S(2p_{3/2})$ electrons, respectively. The S(2p) spectra of LH, LNa, and the metal complexes were resolved graphically on the basis of the shape L'H containing one type of sulfur atom.

Table 1. Binding energies

Compound	Binding energy/eV		
	N(1s)	$S(2p_{3/2})$	$Cu(2p_{3/2})$
LH	400.6	164.5; 162.3	
LNa	398.9	164.2; 162.2	
L–L	399.0	164.5	
L'H	400.6	162.4	
L'–L'	400.5; 399.1	164.5	
CuL	399.4	164.4; 162.8	933.5
CuL_2	399.4	164.4; 162.8	933.5
CuL_3H_2Cl	400.6; 398.9	164.5; 162.7	933.5
PtL_2	399.8	164.5; 162.9	
PdL_2	399.7	164.5; 162.9	
NiL_2	399.6	164.4; 162.6	
CdL_2	399.4	164.4; 162.6	
HgL_2	399.0	164.2; 163.1	
PbL_2	399.0	164.3; 162.4	
AgL	399.1	164.4; 162.7	
$CuCl_2$			935.8
$Cu(CH_3COO)_2$			935.2

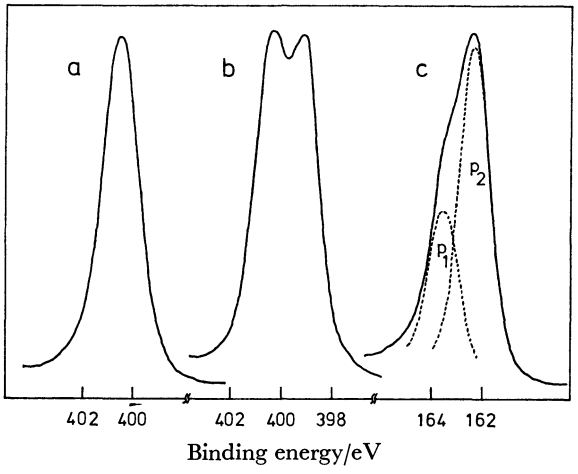


Fig. 1. Electron spectra of the reference compounds.
a: N(1 s) of L'H, b: N(1 s) of L'–L', c: S(2 p) of L'H.

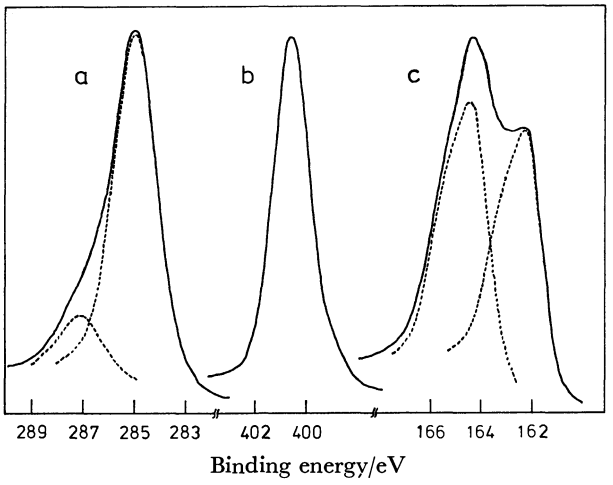

Fig. 2. Electron spectra of LH.
a: C(1 s), b: N(1 s), c: S(2 p).

The C(1s), N(1s), and S(2p) electron spectra of LH are shown in Fig. 2. The C(1s) spectrum showed a main peak and a weak peak on the higher energy side. The former has been assigned to the carbon in the benzene ring and the latter to the thioamide group. The N(1s) spectrum together with the L'H showed a single peak, but the S(2p) spectrum showed a broad peak with a shoulder suggesting two types of sufur atoms. The two peaks indicated by the broken lines which were obtained by a graphical resolving, were almost equal in intensity. The peak with the lower binding energy of the two appeared to weaken with X-ray radiation time. Such X-ray damage in the S(2p)

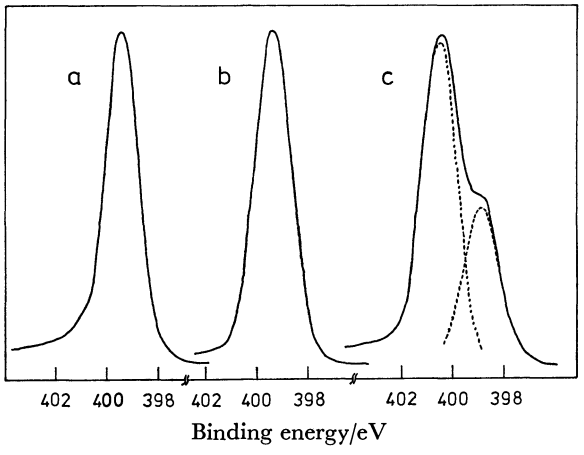

Fig. 3. N(1 s) electron spectra of the copper complexes.
a: CuL, b: CuL_2, c: CuL_3H_2Cl.

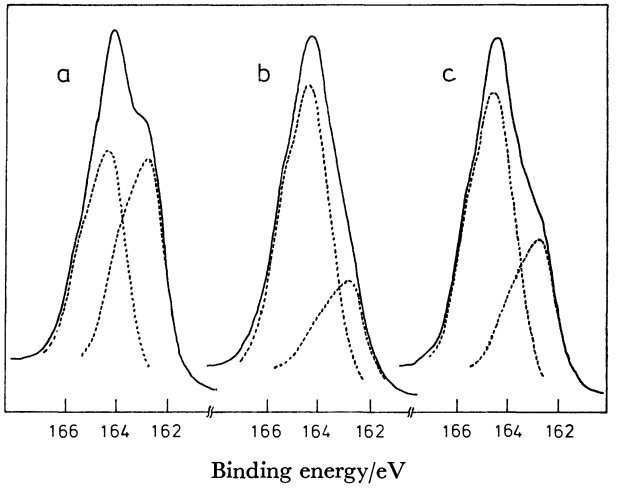

Fig. 4. S(2 p) electron spectra of the copper complexes.
a: CuL, b: CuL_2, c: CuL_3H_2Cl.

spectra was not observed in the other samples. The N(1s) and S(2p) spectra of LNa were similar to those of LH in shape. The S(2p) spectrum of L–L, which contains two types of sulfur atoms, was almost the same as those of L'–L' and L'H in shape.

Complexes. The N(1s) and S(2p) spectra of CuL CuL_2, and CuL_3H_2Cl are shown in Figs. 3 and 4. The N(1s) spectra of CuL and CuL_2 as well as those of the other metal complexes showed a single peak with a FWHM of 1.5—1.7 eV. The N(1s) spectrum of CuL_3H_2Cl showed two peaks with an intensity ratio of approximately 2: 1. The S(2p) spectra of the three copper complexes as well as those of the other metal complexes showed the presence of two types of sulfur atoms. The two peaks, indicated by broken lines in the figures were obtained by graphical resolving. The approximate intensity ratio of the two peaks of CuL as well as the other complexes was 1: 1, however, that of CuL_2 was 3: 1, and that of CuL_3H_2Cl 2: 1.

The $Cu(2p_{3/2})$ electron region spectra of CuL_2, $CuCl_2$, and $Cu(CH_3COO)_2$ are shown in Fig. 5. In the case of CuL_2 as well as CuL_3H_2Cl the broad satellite was not observed in the higher energy region than a main peak as was seen for $CuCl_2$ and $Cu(CH_3COO)_2$.

Discussion

Free Ligands. The peak with the higher binding energy of the two in the N(1s) spectrum of L'–L' may be assigned to the protonated nitrogen atom and the other to the deprotonated atom, considering that the N(1s) binding energy of a protonated nitrogen atom is approximately 1.5 eV higher than that of a deprotonated one.[13]

LH and L'H are able to exist in two tautomeric conformations, the thiol form and the thioketo form. IR, NMR, and X-ray analysis studies[6,8,14] have indicated that the thioketo form dominates in LH and L'H in the solid state. The results in this study indicate that both LH and L'H exist entirely in the thioketo form, since the N(1s) spectra showed a single peak with a binding energy corresponding to the –NH type.

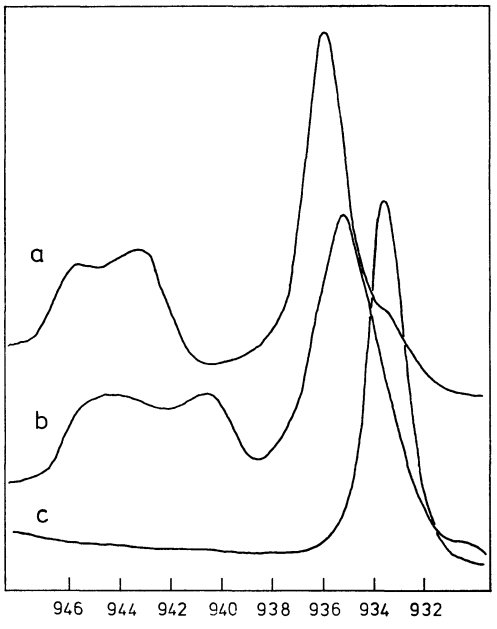

Fig. 5. $Cu(2\ p_{3/2})$ electron region spectra.
a: $CuCl_2$, b: $Cu(CH_3COO)_2$, c: CuL_2.

The peak with the higher binding energy of the two in the S(2p) spectrum of LH can be readily assigned to the endocyclic sulfur atom and the other to the exocyclic, by comparing the binding energies (164.5 and 162.3 eV) with that of L'H, which has only the exocyclic atom. The binding energies of two types of sulfur atoms of LNa, when compared with those of the corresponding sulfur atoms of LH, give a difference of 0.3 eV for the endocyclic sulfur atom and 0.1 eV for the exocyclic atom. Furthermore, the N(1s) binding energy of LNa was only 0.2 eV lower than that of the deprotonated nitrogen of L'–L'. From these results, it is suggested that in LNa, the contribution of $-\overset{-}{N}-\underset{|}{C}=S$ dominates that of $-N=\underset{|}{C}-S^-$, and that an apparent unit negative charge on the nitrogen atom is delocalized by conjugation within the hetero five-membered ring.

Complexes. It has been reported that CuL_2 may be prepared by the reaction of $CuCl_2$ with LH in ethanol.[7,9] Repeated attempts to prepare CuL_2 in this way however failed and a complex with an elemental analysis of CuL_3H_2Cl was obtained. CuL_2 was obtained only in the presence of some amount of water as described above.

CuL_2 involves only one type nitrogen atom, a deprotonated type, whereas CuL_3H_2Cl involves both protonated and deprotonated nitrogen atoms, with a ratio of 2: 1. This result supports the experimental evidence that CuL_2 does not show the N–H band in the IR spectrum, whereas CuL_3H_2Cl does.

The diamagnetism of Cu(II) complexes has been explained by two theories. One is that the paramagnetism is quenched by a strong spin-spin interaction between the two copper(II) ions,[15] and the other is a reduction of the Cu(II) ion to Cu(I) by a ligand on complex formation.[10] The diamagnetism of the complex of the copper(II) salt with LH has been explained by

the former theory.[7,9] This explanation was however found to be completely excluded on the basis of the following evidence obtained.

A Cu(II) complex typically exhibits a satellite on the higher-energy side of the primary peak in the $Cu(2p_{3/2})$ electron region spectrum, as seen for $CuCl_2$ and $Cu(CH_3COO)_2$ in Fig. 5. A Cu(I) complex does not exhibit this.[16] On the basis of the absence of the satellite in the spectra of CuL_2 and CuL_3H_2Cl, it is suggested that CuL_2 and CuL_3H_2Cl are Cu(I) complexes. This agrees with their magnetic moments, *i.e.* both complexes are diamagnetic. Furthermore, the $Cu(2p_{3/2})$ binding energies of CuL_2 and CuL_3H_2Cl, as well as CuL, are about 2 eV lower than those of $CuCl_2$ and $Cu(CH_3COO)_2$. This difference in binding energy is comparable to the difference between CuCl and $CuCl_2$ (1.8 eV).[16]

The inequality of intensities of the two types of peaks in the S(2p) spectra of CuL_2 and CuL_3H_2Cl is thought due to the change in the state of a part of the exocyclic sulfur atoms, *i.e.* the change of a thiocarbonyl group to a disulfide group. This is supported by the following facts; the S(2p) binding energy of the sulfur atom of a disulfide group is close to that of an endocyclic one and L–L was obtained from the reaction of LH with copper(II) salts instead of H_2O_2. CuL_2 could be prepared from the reaction of CuCl with LH and L–L.

It is thought that the Cu(II) ion is reduced to the Cu(I) ion by LH on complexing giving CuL_2 and CuL_3H_2Cl, and that the resulting L–L is coordinated to the Cu(I) ion. Therefore, it is thought that, in the stoichiometric forms of CuL_2 and CuL_3H_2Cl, the half and the one-third of the ligands, respectively, should be replaced by 1/2(L–L).

In general, coordination of a ligand to a metal ion causes a decrease in the electron density on the coordinating atom, giving rise to an increase in the core-electron binding energy of the atom. The N(1s) chemical shifts, which are the differences between the N(1s) binding energies of the complexes and LNa, were 0.5—0.9 eV in CuL, CuL_2, PtL_2, PdL_2, NiL_2, and CdL_2, and very small in HgL_2, PbL_2, and AgL. The N(1s) chemical shift of the deprotonated nitrogen atom of CuL_3H_2Cl was not appreciable, and the N(1s) binding energy of the protonated nitrogen of the complex was the same as that of LH.

From these results, it may be concluded that, in CuL, CuL_2, PtL_2, PdL_2, NiL_2, and CdL_2 an M–N bond is present, and in HgL_2, PbL_2, AgL, and CuL_3HCl_2 it is absent.

The S(2p) binding energies of the two types of sulfur atoms of all the present complexes, when compared with the corresponding ones of LNa, were equal to or larger than those of the latter; the differences were 0—0.3 eV for an endocyclic sulfur atom and 0.2—0.9 eV for an exocyclic one. The S(2p) chemical shfts for an exocyclic sulfur were comparable with the values (0.3—0.9 eV)[17] due to the coordination of thiourea or thiazole through the sulfur atom. Therefore, it may be concluded that the exocyclic sulfur atom-metal ion bond is present in all the complexes.

The small positive chemical shifts of an endocyclic sulfur atom appears to suggest the absence of the sulfur-metal ion bond based on the following. The binding energies of the endocyclic sulfur atoms of all the complexes were equal to or smaller than that of the corresponding sulfur atom of LH. The sulfur atom present in the skeleton of the five-membered ring has very weak coordinating ability, since the lone pairs on the sulfur atom are involved in the resonance structures of the molecule.[18]

These results concerning the mode of coordination of LH largely supports the IR results[6–8] in all the complexes. The IR data however suggested that bonding occurred only through the sulfur atom in CuL,[3] and through both the sulfur and the nitrogen in PbL_2 and AgL.[7] This difference of assignments by XPS and IR can not be explained, but may be due to large uncertainties encountered in assigning C=S, M–N, and M–S vibrations in the ligands containing H–N–C=S and their metal complexes.[19]

The authors wish to thank Mr. Yukihiro Sato for his aid in performing these experiments, and Mr. Taichiro Hirohara for the elemental analysis.

(Received March 15, 1979)

A multielement detection system which uses a programmable monochromator and a SIT image detector has been constructed, and evaluated by measuring the flame emission of 22 elements in the nitrous oxide–acetylene flame. The detection limits for the elements under optimized experimental conditions are reported, and are compared with those obtained by a standard photomultiplier tube.

The silicon intensified target tube (SIT) coupled with an optical multichannel analyser (OMA) has been utilized as a detector system in emission,[1–6] absorption[7–9] and fluorescence[10] spectroscopic studies. Attractive analytical features of the SIT detection system, which have been well-documented in the reports from Morrison and his coworkers,[1,4–6] include the simultaneous multielement analysis capability, the facility to correct for spectral and background interference and detection power equivalent to the photomultiplier tube (PMT) in the visible region, although detection performance is relatively poorer in the ultraviolet. As is well known,[11] the standard SIT image detector consists of about 500 light sensitive elements (channels) within an area of approximately 62.5 mm^2 (length 12.5 mm, height 5 mm) so that, when situated in a dispersing instrument, simultaneous detection of atomic lines is possible. The range of wavelengths which are detected simultaneously is determined primarily by the reciprocal linear dispersion (RLD) of the monochromator. In order to take advantage of the SIT–OMA system for simultaneous multielement analysis, relatively low-dispersion monochromators which provide a spectral window generally greater than 20 nm have been preferred. The use of the low-dispersion monochromator, however, may result in severe spectral interference in atomic emission spectroscopy in high temperature media, particularly in inductively coupled plasma (ICP) emission spectroscopy.

In the present study, the SIT–OMA system has been combined with a medium resolution monochromator (focal length, 1 m; RLD, 0.4 nm/mm) to evaluate detectability performance. The use of the medium resolution monochromator reduces the spectral region spatially detected by the SIT–OMA system (5 nm for present instrumentation) and sacrifices to some extent the capability for simultaneous multielement analysis.

Recently, the present authors have developed a programmable monochromator controlled by a minicomputer, where a slew-scan technique was employed as has been reported by other workers.[12–16] The programmable monochromator of the slew scan type is convenient for rapid sequential multielement analysis and has more inherent flexibility for multielement detection than the well-established direct reading system where only fixed wavelengths of the desired elements are available.[17] However, the slew scan technique suffers from the problem of irreproducibility in wavelength setting, precision being limited to $\pm$0.1 nm, as has already been pointed out.[13,16] To avoid the error caused by irreproducible wavelength setting in the slit-based spectrometer, it was decided to adopt the SIT as the spatial detector in the slew scan system. The important capability of simultaneous multielement analysis is still retained provided element lines are within a 5 nm range for the present instrumentation ($\pm$2.5 nm from the central OMA channel).

In this study, the analytical performance of the SIT–OMA-detector is considered when combined with the programmable monochromator system. The nitrous oxide–acetylene flame was selected as the excitation source for initial studies.

Experimental

Instrumentation. The experimental system is shown in Fig. 1. A nitrous oxide†† –acetylene flame was supported on a burner assembly (5 cm slot burner) of a commercially available spectrophotometer (Shimadzu AA 650). The monochromator (Jobin Yvon HR 1000; focal length, 1 m) had dual entrance and exit ports and was equipped with a holographic grating (2400 grooves/mm); the desired optical path

† Present address: Department of Chemistry, The University of Alberta, Edmonton, Alberta, Canada T6G 2G2.

†† N_2O, dinitrogen oxide in IUPAC nomenclature.

was selected by mirrors positioned beside the entrance and exit slits. The entrance slits were used to receive radiation from the flame and a mercury penray lamp, respectively, the latter being used for wavelength calibration of the monochromator scanning system. The flame focused on the entrance slit was imaged down a factor of 2 using a single spherical silica lens (diameter, 60 mm; focal length, 219 mm). The SIT detector tube (Princeton Applied Research Co., SIT 1205D/01) and a standard photomultiplier (Hamamatsu TV Co., R919) sensitive to ultraviolet and visible light were positioned at the exit ports. The slit unit was removed in the former case, and a plate was equipped on the SIT adaptor to obstruct 50% of the incident light to enable dark current correction. The lateral length of the SIT detector was 12.5 mm and for the monochromator RLD of 0.4 nm/mm, a 5 nm spectral window was obtained. The resolution power for the SIT, 0.032 nm, was about 7 times poorer than that by PMT (slit width, 10 μm). The SIT signal after processing in the OMA (Princeton Applied Research Co., OMA 1205A) was displayed on the oscilloscope and/or could be recorded by an external X-Y recorder (Yokogawa Electric Works, Ltd., 3078).

For PMT detection, a pre-amplifier (laboratory constructed), a light chopper and a lock-in-amplifier (Princeton Applied Research Co., 125A and 5203, respectively) were used.

A minicomputer (Hewlett Packard 2108) was employed to control the monochromator wavelength by the slew scanning technique. A mercury penray lamp (Ultra-Violet Co., 11SC-I) was used for initial wavelength calibration.

Procedure. For wavelength calibration, the scanning system was referenced to the mercury lines at 253.65 and 507.30 nm using the Hg lamp. This procedure determined the number of steps/wavelength (nm) to be employed in wavelength selection by the stepping motor, when controlling the grating angle. After calibration, the wavelengths of the desired atomic lines could be set arbitrarily by command from the computer. The details of the slew scanning system will be described elsewhere.[18]

The experimental conditions for the measurement of atomic emission using the nitrous oxide–acetylene flame were optimized in terms of the flame and slit conditions. Once the conditions had been optimized, a standard solution was aspirated and the accumulated spectrum was stored in OMA memory [A]. The procedure was repeated for the blank solution using memory [B]. The subtracted spectrum [A-B] provided the emission line(s) of the element(s). The emission intensity was obtained by noting the peak height (generally for channel 250±2) and subtracting the average reading of the side background for 10 channels around the peak channel. The background noise level ([A-B] spectrum for the channel range 240—260) was obtained when distilled water was aspirated and subtraction of the [A] and [B] memories was performed. The PMT detection system was used for comparison studies. The signal and background noise were measured from the pen deflection on the chart recorder paper.

The detection limits in Tables 1 and 2 are defined as the concentrations which represent a signal equivalent to twice the standard deviation of the background noise level. The values were obtained from the standard calibration curve for each element prepared by the least squares method. The optimized conditions determined are also summarized in Table 1 with the wavelengths of analytical lines. The chemicals used were of analytical reagent grade and deionized and distilled water was used as the blank solution.

Results and Discussion

Flame Background Correction. The atomic emission

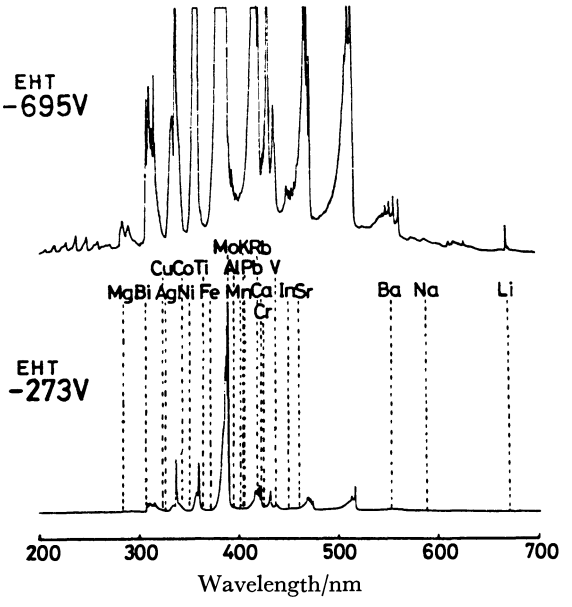

Fig. 2. Emission spectra of nitrous oxide–acetylene flame observed by photomultiplier tube.

of 22 elements in the nitrous oxide–acetylene flame was measured by the SIT–OMA system coupled to the programmable monochromator. Figure 2 shows the N_2O–C_2H_2 flame emission spectra recorded by the PMT when only distilled water was aspirated. The upper curve was recorded at a high EHT (—695 V) to indicate the prominent background constituents of the flame. Background species at approximate wavelengths are NO (200—280 nm), OH (280—330 nm), NH (336 nm), CN (350—442 nm), CH (387—431 nm), and C_2 (437—600 nm). The analytical lines of the elements used in the study are indicated by the dotted lines on the lower spectrum.

Flame emission spectra observed by the SIT–OMA system for a 5 nm spectral window are shown in Figs. 3

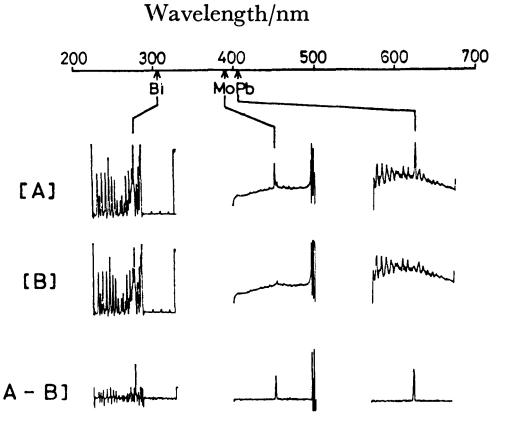

Fig. 3. Emission spectra observed by SIT–OMA system near Bi(306.8 nm), Mo(390.3 nm), and Pb(405.8 nm) lines in nitrous oxide–acetylene flame (Bi 100 μg/ml, Mo 10 μg/ml, Pb 50 μg/ml).

and 4 for Bi, Mo, Pb, and Cr, Sr, and Li, respectively. Since the SIT–OMS system has 2 memories, each memory was used for the emission measurements of the sample solution and the blank solution, respectively. Spectra [A-B] in Figs. 3 and 4 are the corrected spectra calculated from the [A] and [B] memories, and subtraction is automatically performed in the OMA. The background at the Bi wavelength is particularly severe and corresponds to the OH vibrational fine structure. The predominant background species at the Mo wavelength is CH, while at the Pb wavelength CN is predominant. For Sr and Li, the predominant species is C_2, while at the Cr wavelength flame background is negligible.

Detection Limits and Precision. The analytical performance data summarized in Table 1 were obtained by accumulating the signals for 4.1 s. In the SIT–OMA system, the scanning rate of the electron beam over 500 channels was 32.8 ms, and the 4.1 s accumulation time corresponded to 125 times accumulation of the signals at each channel in the SIT detector. The dynamic range of the SIT–OMA system is 10^5 counts and the real-time dynamic range (real-time is a single scan) is about 750 counts for each channel. Therefore, the entrance slit width and slit height were required to be adjusted to obtain the appropriate signal intensities which were within the dynamic range of the SIT–OMA system. Before adjustment of the slit conditions mentioned above, the flame conditions and height above the burner head were optimized for each element using a constant nitrous oxide flow rate of 7.5 l/min. The experimental results obtained through the above procedures are summarized in Table 1, along with the analytical lines and other experimental conditions. The detection limit data are similar to those obtained by Howell and Morrison[6] who used a 0.5 m monochromator–SIT combination. The relative standard deviation (RSD) values for the concentration indicated in parenthesis were generally in the 3% range, although for some elements of low sensitivity, *e.g.* Bi, Pb where concentrations were relatively closer to the respective detection limits, higher RSD values were obtained.

Regarding the flame operating conditions, it can be seen from Table 1 that the elements such as Ti, V, Al, and Mo were atomized effectively in the reducing atmosphere of the C_2H_2-rich flame and in the high temperature region corresponding to a high position above the burner head. These conditions are required to prevent formation of the refractory oxide species. In contrast, optimum sensitivity for Co, Pb, Fe was obtained in the oxygenated atmosphere of the C_2H_2-lean flame and at a low position above the burner. In this way, the optimum conditions in the N_2O–C_2H_2 flame are very different for the elements. This spread in the optimum values constitutes a major problem in utilizing the N_2O–C_2H_2 source for multielement analysis, since fixed flame conditions and flame height would be desirable for rapid analysis. The other major drawback in the N_2O–C_2H_2 excitation source is that elements whose resonance lines are in the UV region are not sufficiently excited to observe atomic emission.[19]

Comparison of SIT and PMT Detection. So far, to evaluate SIT detector performance, the detection limits obtained by the SIT image detector have been compared with those obtained in separate studies by the PMT.[1–10] In the present study, the detection limits of 8 elements were also obtained by a PMT (R919). The experimental conditions for the SIT detector were the same as those shown in Table 1, and the conditions for the PMT were independently determined by optimization procedures for each element.

As is well known,[6] the photon quantum yield of the SIT in the ultraviolet region is worse by 1—2 orders of magnitude when compared to that of the PMT, while it is almost comparable with or better than that of the PMT in the visible region. Although a rigorous comparison of data is ruled out due to fundamental design differences between the SIT and the PMT, for standard measurement conditions, *i.e.* SIT accumulation time of 4.1 s and a PMT time constant of 2 s, a general trend in the results can be pointed out. Poor SIT detector performance is evident in the UV, *e.g.* for Mg and Ag where detection limits are about 20 times poorer than the PMT data. The excellent detection power in the visible region is, however, clearly seen from Table 2.

Conclusions

Use of the SIT detector for slew scan multielement analysis is advantageous in that it allows for a less accurate wavelength setting of the monochromator than otherwise would be required for PMT detection. Rapid analysis may be performed with the present system (*e.g.*, less than 5 min required for 10 elements). The results shown in Tables 1 and 2 and Figs. 3 and 4 demonstrate the following important capabilities of the SIT–OMA system: 1) high detection limits for many elements, 2) multielement detection over a small wavelength range (5 nm), 3) the facility to correct for background interference. However, the relatively poor sensitivity of the SIT in the ultraviolet region and the insufficient excitation efficiency of the N_2O–C_2H_2 flame detract from the

use of the present instrumental system for analytical flame emission spectrometry. Particularly, the flame requires tedious optimization procedures to achieve sufficient sensitivity for each element. The ICP excitation system would overcome to some extent the poor SIT sensitivity in the UV. A further advantage of the ICP source relative to the N_2O–C_2H_2 flame is that near-optimum sensitivity for all elements is provided by one set of ICP operating conditions.[20] The application of the present instrumental system to ICP emission spectrometry is in progress, and will be reported in the near future[21].

The authors express their thanks to Dr. A. Otsuki, National Institute for Environmental Studies, for his helpful discussion and encouragement. C.W.M. is grateful to the Inner London Education Authority (U.K.) for the award of The Robert Blair Fellowship and receipt of a travel grant.

Phase Transformation of Iron Vanadium Sulfides at High Temperatures

Hiroaki WADA

National Institute for Researches in Inorganic Materials, Namiki 1-1, Sakura-Mura, Niihari-Gun, Ibaraki 300-31

(Received March 27, 1979)

The phase relations of iron vanadium sulfides with the atomic Fe: V ratios 3: 2 and 71: 29 were examined by the high-temperature DTA and X-ray measurements. It was found that the structure of iron vanadium sulfide changes gradually from a less symmetric form to a highly symmetric form with the increase in temperature. Two types of phase transformations by vacancy order-disorder were observed at temperatures above 800 °C. One was due to the intralayer disordering of metal vacancies: V_3S_4-type⟶$Cd(OH)_2$-type (type Ia) or V_3S_4-type+NiAs-type⟶$Cd(OH)_2$-type (type Ib) at T_1. The other was due to the entirely interlayer disordering of metal vacancies: $Cd(OH)_2$-type⟶NiAs-type (type II) at T_2 ($T_2 > T_1$). The tentative phase diagram of iron vanadium sulfides with the atomic Fe: V ratio 3: 2 was constructed on the basis of the DTA results.

The phase equilibrium study of a part of the Fe–V–S system has been made recently by means of thermogravimetry.[1] The phase relations of the Fe–V–S system at high temperatures (500—800 °C) were presented in an earlier publication.[2] From the powder X-ray diffraction patterns of the quenched specimens and the behavior of the composition-equilibrium sulfur pressure relations, it has been shown that the Fe–V–S system has extensive solid solution phases, *i.e*, $(Fe,V)_{1-x}S$, $(Fe,V)_{3\pm x}S_4$, and $(Fe,V)_{5\pm x}S_8$, which have a lattice intermediate between the NiAs-type and the $Cd(OH)_2$-type lattice. These phases exhibited the ordered structures of the metal vacancies due to the removal of metal atoms from every second metal layer in the fundamental NiAs-type structure, in spite of the quenching of specimens from high temperature to room temperature. This fact appears to indicate the non-quenchability of the high-temperature state, because the energy of thermal agitation promotes a state of disorder of metal vacancies with increasing temperature and the disordered phases become stable at high temperatures. Hence, it is desirable to observe the crystal structure of sulfide specimens *in situ* in order to know its real phase relations at high temperatures. However, comparatively few data have been collected on this subject with respect to iron vanadium sulfides.

The vacancy order-disorder transformation of compounds in the V–S system has been reported recently by several investigators. Nakazawa *et al.* studied a V_5S_8 single crystal by means of high-temperature X-ray measurements and found that the V_5S_8 phase has the intralayer order-disorder transformation at about 800 °C.[3] Oka *et al.* called attention to the order-disorder transformation of the metal vacancies and determined the phase diagram of the V–S system in the compositional range from $VS_{1.30}$ to $VS_{1.70}$ by means of high-temperature DTA and X-ray measurements.[4] Also, they explained the order-disorder transformation on the basis of statistical thermodynamic theory.[5] From these reports, it is expected that compounds in the ternary system Fe–V–S have similar phase transformations at high temperatures owing to the disordering of metal vacancies.

The primary aim of this investigation was to observe the structural change of iron vanadium sulfides with temperature and to elucidate the process of its structural phase transformations. The high-temperature DTA and X-ray measurements were employed in this study to obtain direct information on the thermal behavior and structural property of compounds. The author reports in this paper the results of high-temperature experiments of iron vanadium sulfides with the atomic Fe: V ratios 3: 2 and 71: 29.

Experimental

Materials and General Procedure. The sulfide samples were synthesized by heating the mechanical mixtures of reagent grade $VOSO_4 \cdot 3H_2O$ and $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ in an H_2S atmosphere at 1050 °C for 4 h, and were used as starting materials. The sulfur composition of the sample was adjusted to the desired one by holding it for 5 h at the pre-determined sulfur pressure and temperature and quenching it to room temperature. The general experimental procedures, the apparatus, and the chemical analyses are the same as those described in the previous paper.[1] $Fe_{0.60}V_{0.40}S_x$ and $Fe_{0.71}V_{0.29}S_x$, in the compositional range of $x = 1.20$—1.35, were used chiefly in the high-temperature experiments.

X-Ray Study and DTA Method. The high-temperature X-ray measurements were carried out by the film method. The X-ray powder diffraction patterns of samples were recorded at various temperatures with a precession camera ($R = 100$ mm, Mo $K\alpha$ radiation with Zr filter). A high-power X-ray generator (Rigaku RU-200: 60 kV-200 mA) was employed for rapid measurements at high temperatures. The sulfide sample was sealed in vacuum in a silica-glass capillary (diameter 0.2 mm and thickness 0.01 mm). The capillary was mounted on a usual type of goniometer head and covered by a minifurnace with two small windows along the path of the X-ray beams. Temperature regulation was carried out up to 950 °C within the accuracy of ±5 °C with the P.I.D control system by using a Pt–13%Rh thermocouple. The temperature of the sample was raised and kept at the desired one. The sample was exposed to X-rays for 3 h and powder photographs were taken under the conditions of 50 kV-180 mA.

The DTA measurements were carried out at the heating rate of 20 °C/min up to 1100 °C by using a Rigaku Thermoflex DTA. About 130 mg of the sulfide powder was sealed in vacuum in a micro silica capsule specially designed for the DTA method; pure α-Al_2O_3 was used as the reference substance.

Results and Discussion

The High-temperature X-Ray Study. The high-temperature X-ray studies were carried out in orde-

to clarify the real phase relations and the phase transformation of iron vanadium sulfide which could not be determined directly only from the thermochemical data on its composition-equilibrium sulfur pressure relations.[2] Representative compounds of $Fe_{0.60}V_{0.40}S_{1.31}$, $Fe_{0.60}V_{0.40}S_{1.28}$, and $Fe_{0.71}V_{0.29}S_{1.20}$, were selected for this study. Photographs were taken first at room temperature, and then at various temperatures up to 950 °C during both the heating and cooling processes.

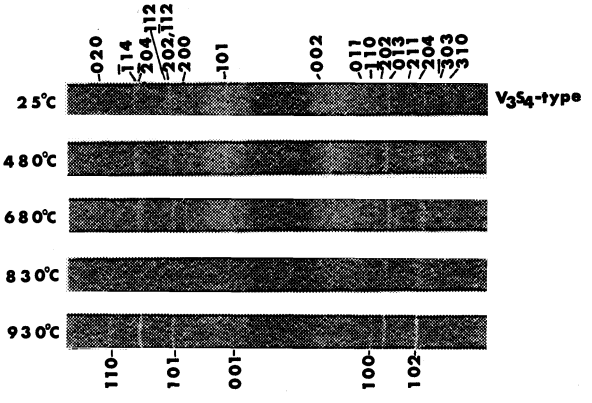

Fig. 1. The X-ray powder photographs of $Fe_{0.60}V_{0.40}S_{1.31}$.

Figure 1 shows a series of diffraction patterns for $Fe_{0.60}V_{0.40}S_{1.31}$, which has the monoclinic V_3S_4-type structure (nonreduced space group I2/m referred to the fundamental NiAs-type cell) at room temperature; its composition corresponds to that of the metal-rich phase boundary of $(Fe,V)_3S_4$ solid solution at 727 °C.[2]

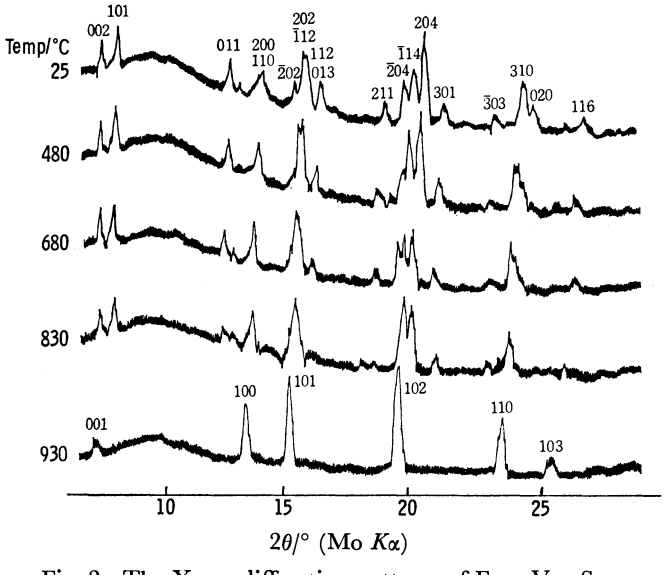

Fig. 2. The X-ray diffraction patterns of $Fe_{0.60}V_{0.40}S_{1.31}$.

Figure 2 gives the X-ray diffraction profiles which were reproduced from Fig. 1 by means of the micro photo-densitometer in order to represent the 2θ-intensity relations of reflections. It can be seen from these figures that the splitting of reflections which would be characteristic of the V_3S_4-type cell decreases gradually with increasing temperature and its peak positions are shifted slightly to the lower side of 2θ values at high temperatures. This result suggests a gradual structural transformation of the monoclinic V_3S_4-type phase from a less symmetric low temperature form to a highly symmetric high temperature form. It should be emphasized that a new phase with the trigonal $Cd(OH)_2$-type structure appears at about 930 °C. However, the high-temperature phase was not quenchable at all. On cooling the sample to room temperature, only the original patterns of V_3S_4-type was observed. This suggests that the phase transformation process of $(Fe,V)_3S_4$ solid solution is reversible.

Table 1. The relation of the unit cell dimensions of $Fe_{0.60}V_{0.40}S_{1.31}$ with temperature

Temp °C	a Å[b]	b Å	c Å	β °	Volume Å^3
25	5.90±1	3.33±1	11.19±2	92.1±1	219±1
480	5.96±2	3.39±1	11.30±2	91.9±1	228±1
680	5.99±2	3.42±1	11.33±4	91.7±1	232±1
830	6.01±2	3.44±1	11.40±4	91.2±2	236±1
930	3.477±6[a]		5.738±9[a]		60.1±2[a]

a) Trigonal phase. The unit cell dimensions are calculated on the basis of a $Cd(OH)_2$-type hexagonal lattice.
b) Å$=10^{-1}$ nm.

Lattice parameters of $Fe_{0.60}V_{0.40}S_{1.31}$ were calculated by the least-squares method[6] from the data which were obtained by the film method. Temperature dependence of the unit cell dimensions is given in Table 1. It is noted that the a-, b-, and c-dimensions and the unit cell volume, V, expand linearly with the increase in temperature. On the contrary, the β-angle decreases gradually from 92.1 to 91.2 at temperatures between 25 and 830 °C. Also, the value of the $c\cdot\sin\beta/2b$ ratio, which corresponds to the c/a ratio in the NiAs-type structure, decreases from 1.68 to 1.65 in the temperature range from 25 to 930 °C. This indicates that the interlayer spacing is reduced relative to the intralayer spacing with increasing temperature, due to the difference of the directional character of the structure in the thermal expansion. In this connection, the relative expansion coefficients ($\alpha_a=1/a_{25°C}\cdot da/dT$ and analogously for α_b and α_c) were calculated from the linear relations of the unit cell dimensions with temperature. It was found that α_a, α_b, and α_c, and the volume expansion coefficient, β, are 24×10^{-6} K^{-1}, 41×10^{-6} K^{-1}, 22×10^{-6} K^{-1}, and 95×10^{-6} K^{-1}, respectively.

A few remarks should be made here regarding the process of the phase transformation of a V_3S_4-type cell. A possible model of the structural transformation process is shown schematically in Fig. 3. The crystal structure of the monoclinic V_3S_4-type is characterized by the ordered arrangement of metal vacancies which are confined to the alternate metal layers in the fundamental NiAs-type structure.[7] This vacancy-ordered phase is stable at lower temperatures. As the temperature is raised, the energy of thermal agitation gradually increases the degree of disorder. The ordered arrangement of vacancies within the metal-deficient layer

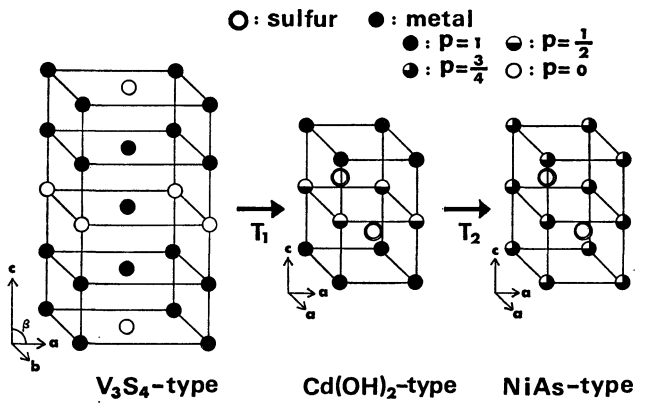

Fig. 3. A schematic model of the structural transformation of the V_3S_4-type phase with $a \approx \sqrt{3} \cdot a_{NiAs}$; $b \approx a_{NiAs}$; $c \approx 2c_{NiAs}$; $\beta \approx 92°$. Hexagonal array of sulfur is omitted in a picture of the V_3S_4-type structure for convenience. Symbol p denotes the occupation probability of a metal atom for each site.

changes to the entirely disordered one of the solid solution at high temperatures. A trigonal $Cd(OH)_2$-type phase with the complete intralayer disordering becomes stable at temperatures above T_1. Further temperature elevation promotes the successive phase transformation from a trigonal $Cd(OH)_2$-type to a hexagonal NiAs-type, based on the complete intra- and inter-layers disordering. A nonstoichiometric NiAs-type phase appears at temperatures above T_2. The schematic model of a disordering process of metal vacancies, however, may need some modifications because both the intra- and inter-layers disordering take place concomitantly with increasing temperature.[3] As shown in Fig. 2, the intensity of the (001) reflection of a trigonal

a) (100) and (110) reflections are referred to the hexagonal NiAs-type structure.

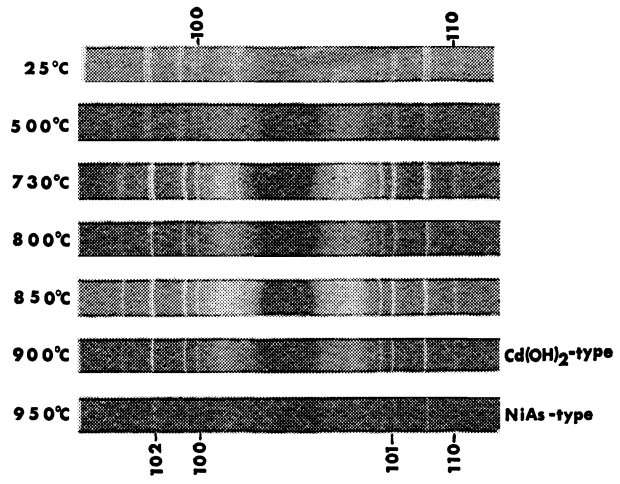

Fig. 4. The X-ray powder photographs of $Fe_{0.60}V_{0.40}S_{1.28}$.

phase is very weak compared with that of the corresponding (002) reflection of the ordered V_3S_4-type phase. This may be indicative of some degree of the interlayer disordering in the process of the phase transformation.

Figure 4 shows a series of the high-temperature X-ray diffraction patterns of $Fe_{0.60}V_{0.40}S_{1.28}$. The temperature dependence of *d*-spacings is listed in Table 2. The X-ray powder photograph taken at room temperature indicates clearly the presence of two phases, which are composed of $(Fe,V)_{1-x}S$ with hexagonal NiAs-type structure and $(Fe,V)_3S_4$ with the monoclinic V_3S_4-type structure. However, both phases show very similar X-ray diffraction patterns, so that some reflections overlap each other. The former could be distinguished from the latter only by the presence of (100) and (110) reflections, referred to the hexagonal structure.

On heating the sample up to 850 °C, the splitting of reflections which are attributed to the V_3S_4-type structure gradually decreases, but the two phases still coexist. However, mutual solubility of both phases increases with increasing temperature. A new solid solution phase is formed due to the reaction of two phases at temperatures above 850 °C. The phase described above has a trigonal $Cd(OH)_2$-type structure with intralayer disordering. Again, on heating the sample up to 950 °C, the trigonal phase transforms perfectly to the high-temperature phase with the hexagonal NiAs-type structure. This phase transformation was reversible. The trigonal phase decomposed to the original two different phases on quenching below 850 °C, owing to the phase separation.

Figure 5 shows the results of the high-temperature X-ray study of $Fe_{0.71}V_{0.29}S_{1.20}$, which is composed of a two-phase mixture of $(Fe,V)_{1-x}S$ and $(Fe,V)_3S_4$ at room

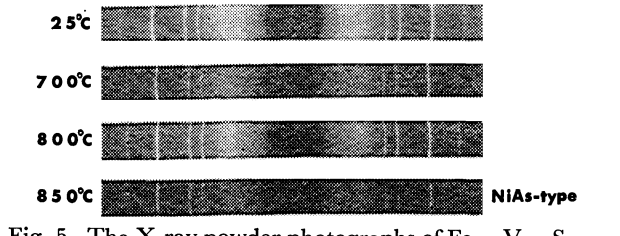

Fig. 5. The X-ray powder photographs of $Fe_{0.71}V_{0.29}S_{1.20}$.

temperature. The intensity of the super-structure reflections derived from the $(Fe,V)_3S_4$ phase decreases gradually with increasing temperature. Finally, a high-temperature phase with the hexagonal NiAs-type structure appears at about 850 °C. However, the trigonal phase with the complete intralayer disordering could not be observed in the process of this phase transformation. This may suggest that the occurrence of the trigonal phase at high temperatures is affected by the bulk concentration of metal vacancies in the original low-temperature phases.

The High-temperature DTA Measurement. In order to determine the temperature of the phase transformation accurately, the DTA measurements were carried out in the temperature range from 25 to 1100 °C. Iron vanadium sulfides with the atomic Fe: V ratios 3: 2 and 71: 29 were used chiefly for the comparison with the results of the high-temperature X-ray experiments.

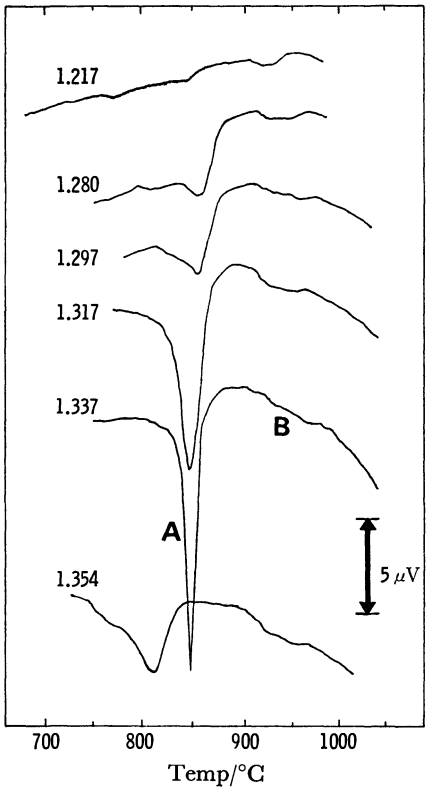

Fig. 6. DTA curves for $Fe_{0.60}V_{0.40}S_x$.

Figure 6 shows representative differential heating curves obtained with the composition $Fe_{0.60}V_{0.40}S_x$, where x lies in the range from 1.217 to 1.354. It is evident that each heating curve has two endothermic peaks in the temperature range from 700 to 1000 °C. As shown in Fig. 6, the lower one, A, is large and rather sharp in shape. On the other hand, the higher one, B, is small and broad. Note that the profile of the endothermic peaks varies clearly with the composition of sulfides. The sharpest and largest peak is observed at 842 °C in the heating curve of the composition $x=1.337$, which is close to the stoichiometric composition, $(Fe_{0.60}V_{0.40})_3S_4$. The A peak for the compositions on the sides more rich in metal than $x=1.333$ becomes broader and smaller with decreasing sulfur content. Also, the heating curve of the composition $x=1.354$ shows the tendency for the A peak to grow broader and to be shifted significantly to the low temperature side with increasing sulfur content that characterizes the thermal behavior of the composition on the side more rich in sulfur than $x=1.333$. On the other hand, the B peaks exhibit essentially similar profiles for all of the composition studied and observed at temperatures above 900 °C.

By the direct comparison with the results of the high-temperature X-ray experiments, it is concluded that: (1) the A peak is related to the phase transformations, such as V_3S_4-type→$Cd(OH)_2$-type (type Ia) and V_3S_4-type+NiAs-type→$Cd(OH)_2$-type (type Ib), at the temperature T_1, and (2) the B peak is related to the phase transformation from $Cd(OH)_2$-type to NiAs-type (type II) at the temperature T_2. The tentative phase diagram of iron vanadium sulfides with the atomic Fe: V ratio 3: 2 is shown in Fig. 7, where the temperatures (T_1 and T_2) at which maxima were observed on the heating curves are plotted against composition. The transformation temperature, T_1, of type Ia is connected smoothly to that of type Ib. The phase boundary curve which was determined by the T_1 values has the maximum temperature of 854 °C at the composition near $x=1.27$. A rapid decrease of the temperature T_1 is observed at the compositions on the sulfur-richer side of $x=1.333$. For example, T_1 is about 813 °C at $x=1.354$. Such a compositional

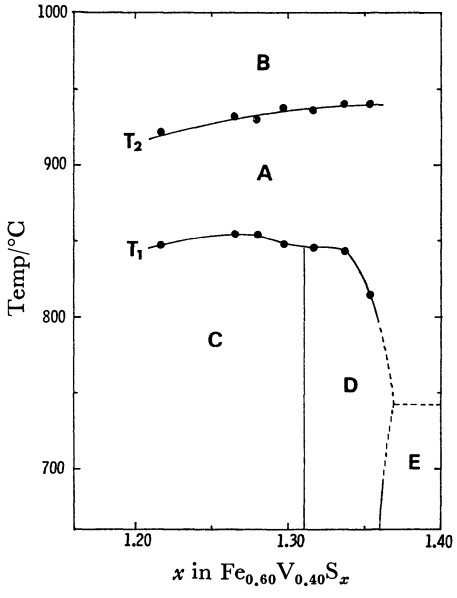

Fig. 7. Tentative phase diagram of a part of the Fe–V–S system at section with atomic Fe: V ratio 3: 2. Phase relations are represented as follows.
A: $(Fe_{0.60}V_{0.40})_{1-x}S$ ($Cd(OH)_2$-type),
B: $(Fe_{0.60}V_{0.40})_{1-x}S$ (NiAs-type),
C: $(Fe,V)_{1-x}S$ (NiAs-type)+$(Fe,V)_{3\pm x}S_4$ (V_3S_4-type),
D: $(Fe_{0.60}V_{0.40})_{3\pm x}S_4$ (V_3S_4-type),
E: $(Fe,V)_{3\pm x}S_4$ (V_3S_4-type)+FeS_2 (pyrite).
The phase boundary between A and E is determined on the basis of the stability limit of pyrite.[8]

dependence of T_1, as mentioned above, is similar to that of the V–S system which has been reported by Oka *et al.*[4] As shown in Fig. 7, the transformation temperature T_2 of the type II increases slightly with increasing sulfur content. The T_2 changes from 920 to 940 °C in the compositional range of x=1.217—1.354. However, the T_2 value is quite ambiguous because of the broadness of the B peak, as shown in Fig. 6.

The profiles on the differential heating curves of $Fe_{0.71}V_{0.29}S_x$ was essentially the same as those of $Fe_{0.60}V_{0.40}S_x$, except that the phase transformation took place at lower temperatures. The T_1 and T_2 of $Fe_{0.71}V_{0.29}S_{1.30}$ are 820 °C and 910 °C, respectively. The T_1 of $Fe_{0.71}V_{0.29}S_{1.20}$ is about 770 °C. These temperatures are relatively lower than those of the corresponding composition of $Fe_{0.60}V_{0.40}S_x$. According to Oka *et al.*, the T_1 of $VS_{1.33}$ is about 1200 °C.[4] This temperature is much higher than that of $Fe_{0.60}V_{0.40}S_{1.337}$ (about 840 °C). From these facts, it can be concluded that the temperature of the phase transformation of iron vanadium sulfides decreases with increasing Fe content, when the S/(Fe+V) ratio is held constant.

The author wishes to express his thanks to Professor Mitsuoki Nakahira of Okayama College of Science for his encouragement and helpful discussion throughout this study. Thanks are also due to Dr. Hiromoto Nakazawa for his invaluable discussion, and to Drs. Akihiko Nukui and Mamoru Watanabe for their technical assistance with the high-temperature X-ray measurements during this work.

Sodium Ion Exchange on Crystalline Zirconium Titanium Phosphate

Yutaka YAZAWA, Toru EGUCHI, Kazunori TAKAGUCHI, and Isao TOMITA*,†

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received March 28, 1979)

A new ion exchanger, crystalline zirconium titanium phosphate with variable zirconium to titanium mole ratios has been prepared and the sodium ion exchange behavior studied. In the zirconium-rich exchanger a half-exchanged monosodium phase was produced. This differs from the titanium-rich exchanger where a disodium phase was formed without formation of the intermediate monosodium phase. The pH titration curves were complicated but a trend emerged with variation in the Zr/Ti ratio. On the basis of the X-ray evidence and the shapes of the titration curves it is thought that the synthesized phosphates are solid solutions rather than a mechanical mixture of the two metal phosphates.

Considerable work have been reported on the ion exchange behavior of alkali metal ions on inorganic ion exchangers of the α-zirconium phosphate type.[1] Among the exchangers, α-titanium phosphate, $Ti(HPO_4)_2 \cdot H_2O$ (designated as α-TP) has the same layer structure as α-zirconium phosphate (α-ZP) with approximately the same interlayer distance of 7.56 Å. The ion exchange properties however differ in some respects from that of α-ZP. For example, in H^+–Na^+ ion exchange, both a monosodium phase and a disodium phase exist for α-ZP, which are immiscible with each other when they coexist. In X-ray powder diffractometry of α-TP, the monosodium phase[2] was not observed as was the case of H^+–Li^+ exchange.[3] The ion sieve effect exhibited by exchangers of this type also differs in that in acid media α-ZP can absorb K^+ ions but α-TP cannot.

Synthesis of the crystalline mixed phosphate of zirconium and titanium having variable zirconium to titanium mole ratios has been attempted and the sodium ion-exchange behavior studied.

Experimental

Synthesis of the Exchangers. Hydrochloric acid solutions (2 mol dm^{-3}) of zirconium dichloride oxide and titanium tetrachloride were prepared. The zirconium to titanium mole ratio in the mixed solutions was varied between experiments. The solution was added dropwise, with stirring to H_3PO_4 (2 mol dm^{-3}) kept at 60—70 °C. The resultant colorless gel was allowed to stand overnight, filtered and washed with 2% H_3PO_4 solution until free from chloride ion. The obtained amorphous salt was refluxed at the boiling point in concentrated H_3PO_4 for 48 to 200 h. The product was centrifuged and washed with deionized water until the pH of the supernatant solution exceeded 3. The microcrystalline product was stored over silica gel. The exchanger will be designated as ZTP hereafter.

Analysis of the Exchangers. The zirconium to titanium mole ratio in the exchangers was determined as follows. A weighed amount (100 mg) of the exchanger was dissolved in hot concd H_2SO_4 (20 cm^3). After cooling, the solution was diluted to 200 cm^3, and the ice-cooled 5% cupferron aqueous solution (10 cm^3) added. The precipitate was filtered and washed with 1.2 mol dm^{-3} HCl, ignited and weighed as the sum of ZrO_2 and TiO_2.

In a separate experiment, the exchanger (120 mg) was dissolved in hot concd H_2SO_4 (20 cm^3). After cooling, the solution was added to 1.5% H_2O_2 (200 cm^3). To this was added $NH_4H_2PO_4$ (1.5 g) and the resulting gelatinous precipitate aged on a steam bath at 50—60 °C for 2 h. The precipitate was filtered and washed with 1% NH_4NO_3, ignited and weighed as ZrP_2O_7. The zirconium to titanium mole ratio was estimated from the results of both experiments.**

Ion Exchange. The experiment was conducted by the batch method. Mixed solutions of 0.1 mol dm^{-3} NaCl and 0.1 mol dm^{-3} NaOH at variable mixing ratios were prepared to give solutions of differing values of pH keeping the sodium concentration constant. ZTP (250 mg) was placed in contact with each of the above mentioned solutions (25 cm^3), and shaken for 4 days at 25 °C. The solution was centrifuged, and the supernatant liquid subjected to pH measurement. Analysis for sodium was by flame photometry, and for phosphorus colorimetrically by the phosphomolybdic acid method. X-ray powder diffractometry was conducted on the exchangers obtained at various stages of ion exchange. Thermal analysis (TG and DSC) was performed to determine the number of waters of crystallization per formula weight of the exchanged phase.

Results and Discussion

Synthesized Exchangers. In Table 1, the zirconium to titanium mole ratios in the starting mixture and in the product together with the theoretical exchange capacity of the exchangers are shown. In each exchanger, the Zr/Ti ratio in the product was less than that in the starting mixture.

The X-ray powder patterns of the exchangers resembled that of α-ZP and α-TP, but the interlayer distance (d_{002}) estimated from the first reflection peak

Table 1. Composition of synthesized ion exchanger, $Zr_xTi_{1-x}(HPO_4)_2 \cdot H_2O$

Notation	Mixing mole ratio (Zr/Ti) of starting materials	Mole ratio (Zr/Ti) of products	x	Estimated exchange capacity (meq/g)
ZTP(3.25)	3.38	3.25	0.77	6.87
ZTP(0.93)	1.13	0.93	0.48	7.17
ZTP(0.25)	0.37	0.25	0.20	7.50

† Present address: Tokyo University of Fisheries, Kōnan, Minato-ku, Tokyo 108.

** There is the possibility that a small amount of titanium coprecipitates with the zirconium phosphate. Volumetric determination of titanium after reduction to the +3 state by liquid zinc amalgam gave a somewhat lower Zr/Ti ratio.[4]

at the lowest angle was 7.63 Å in each case. This figure is slightly larger than that for α-ZP and α-TP. Furthermore, a mechanical mixture of α-ZP and α-TP gave a more complicated powder pattern in which a single reflection from the (002) plane existed but several reflections at higher angles appeared separately as shown in Fig. 1.

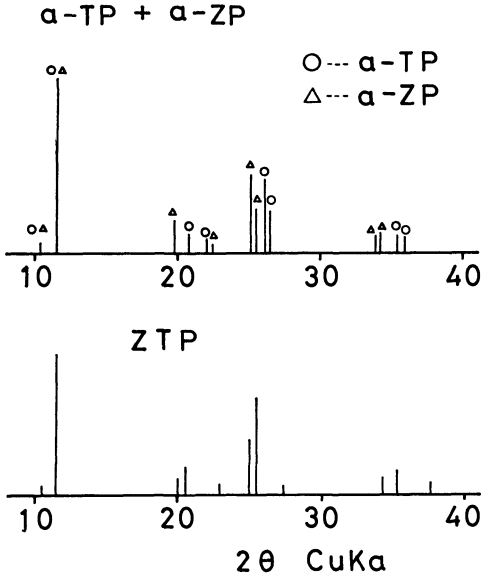

Fig. 1. Comparison of X-ray powder diffraction patterns between α-TP, α-ZP, and ZTP.

The results of thermogravimetric analysis are given in Table 2. The weight loss at 100—250 °C is ascribed to the water of crystallization, and the loss at 400—550 °C to condensation of the phosphate group. These data indicate that ZTP with all Zr/Ti mole ratios is monohydrate. Thus, ZTP is assumed to be isomorphous with α-ZP and α-TP. Analogously with α-ZP, the three oxygen atoms of the phosphate group are bonded to the three metal atoms in a layer. In ZTP, the three metal atoms consist of Zr and/or Ti. Since the crystal ionic radius of Zr^{4+} and Ti^{4+} differs considerably (0.79 and 0.68 Å respectively), the structure of the lattice is assumed to be less ordered than that of α-ZP or α-TP, and the remaining P–O bond of each phosphate group, to which an exchangeable H atom is bonded, may tilt from the perpendicular. This may result in a slight expansion of the interlayer distance and lead to the phosphate groups in ZTP having different values of acidity. The synthesized exchangers will be designated as ZTP(3.25), ZTP(0.93), and ZTP(0.25), depending upon the Zr/Ti ratios. The refluxing time was 200 h for ZTP(0.93) and 48 h for the others but the degree of crystallization did not greatly differ.

TABLE 2. RESULTS OF THERMOGRAVIMETRY

Exchanger	Water of crystallization (mol/mol ZTP)	Dehydration due to condensation of phosphate (mol/mol ZTP)
ZTP(3.25)	1.09	1.05
ZTP(0.93)	1.05	1.00
ZTP(0.25)	1.03	1.04

Ion Exchange. Figure 2 illustrates the pH-titration curves for sodium ion exchange and the phosphate release curves indicate the extent of hydrolysis of the exchanger. The titration curve for ZTP(3.25) has a point of inflection at approximately 3.5 meq Na^+ absorbed/g ZTP corresponding to approximately one half of the calculated exchange capacity of 6.87 meq/g.

In the titration curve for ZTP(0.93), the inflection is observed at approximately 3 meq/g, which is less than one half of the theoretical capacity of 7.2 meq/g. In the

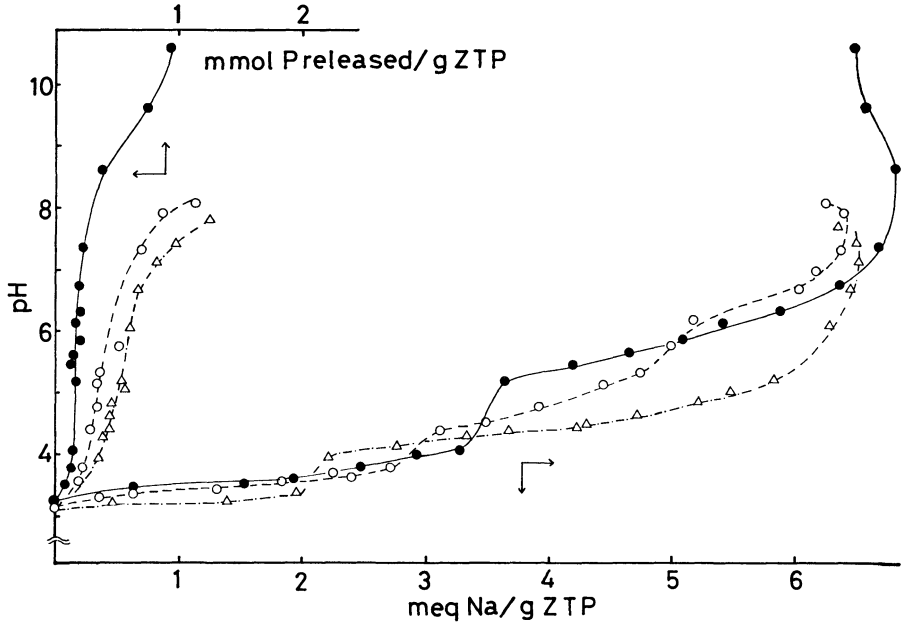

Fig. 2. The pH-titration curves for sodium ion exchange and the phosphate release curves.
-●-: ZTP (3.25), --○--: ZTP (0.93), and -·-△-·-: ZTP (0.25).

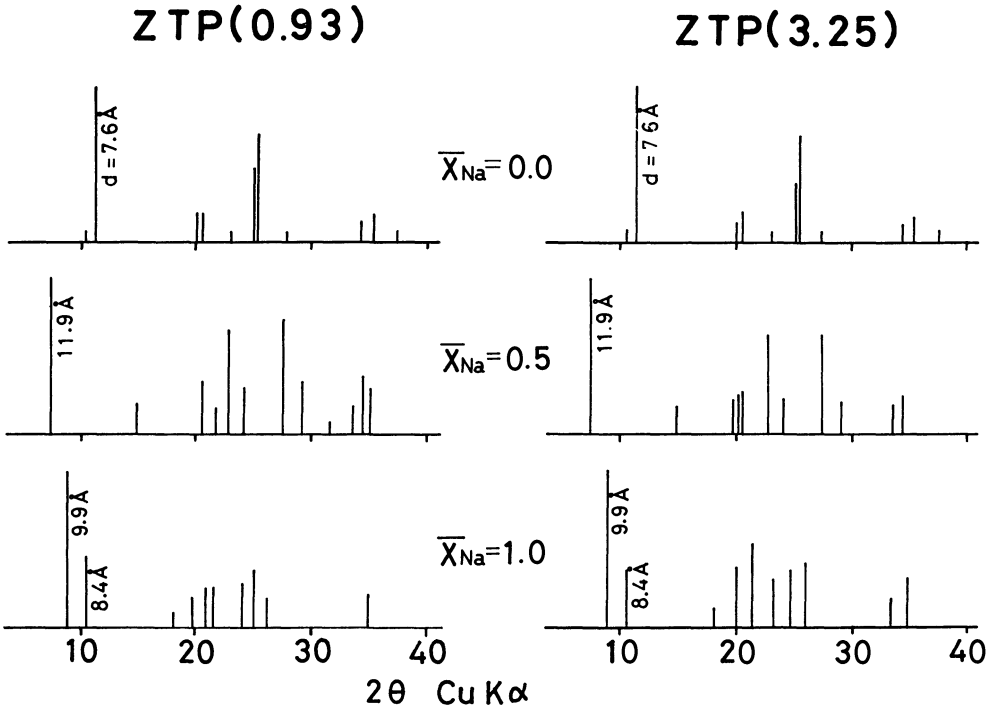

Fig. 3. The X-ray powder diffraction patterns of ZTP (3.25) and ZTP (0.93) at various stages of exchange. $\bar{X}_{Na}$ denotes the ionic fraction of sodium ion in the exchanger.

titration curve for ZTP(0.25), the inflection point is at approximately 2.2 meq/g, a value far less than half of the exchange capacity of 7.50 meq/g. This shift of the inflection has neither been observed in α-ZP nor in α-TP. Furthermore, the rise in pH at the inflection was very small compared to the clear and large pH change in the case of α-ZP. The cause for the "inflection shift" is not clear, but if the exchanger was a mechanical mixture of α-ZP and α-TP, the pH titration curve should be the composite curve for both exchangers. This however was not the case in the present study, and the curves indicate the solid-solution character of ZTP, in which the acidity of the phosphate protons varies depending upon the Zr/Ti mole ratio.

The ease of hydrolysis increased as the titanium mole fraction of the exchanger increased. As a result, the observed exchange capacity did not increase as suggested from the theoretical value.

Figure 3 illustrates the X-ray powder patterns for the exchangers (ZPT(3.25) and ZTP(0.93)) at several stages of exchange. The ionic fraction of sodium in the exchanger phase is denoted by $\bar{X}_{Na}$. In ZTP(3.25) and ZTP(0.93), the trend was very similar, namely, as the exchange of sodium ion proceeded, a new phase having an interlayer distance of 11.9 Å appeared. The diffraction peak intensity increased until, at the mid point of exchange, only this phase was observed.*** Up to $\bar{X}_{Na}$=0.61 for ZTP(3.25) and $\bar{X}_{Na}$=0.54 for ZTP(0.93), two peaks appeared at 9.9 and 8.4 Å. Finally at $\bar{X}_{Na}$=0.95 for ZTP(3.25) and $\bar{X}_{Na}$=0.90 for ZTP(0.93), the peak at 11.9 Å completely disappeared leaving the peaks at 9.9 and 8.4 Å.

For the sodium ion exchange on α-ZP, the point of inflection is found at the point of half exchange. Clearfield *et al.*[5] reported that the monosodium salt having an interlayer distance of 11.8 Å and the disodium salt having an interlayer distance of 9.9 Å exist, where the monosodium salt is a pentahydrate when stored at a relative humidity of 100%. Dried overnight at 35 °C or over diphosphorus pentaoxide this salt is converted to a monohydrate with an interlayer distance of 7.9 Å.

Similar phenomena were observed for ZTP(3.25) and ZTP(0.93). The monosodium form of ZTP(3.25) when stored at a relative humidity of 75%, it contained 4.7 mol of water of crystallization per formula weight. Dehydration of this monosodium form took place in two steps. Dried at 50 °C for 1 h it converted to the monohydrate having an interlayer distance of 7.9 Å (Fig. 4). The disodium salt when dried at 50 °C overnight, lead to the disappearance of the peak at 9.9 Å, the peak at 8.4 Å remained. The results for ZTP(0.93) were essentially the same. The indication is that the two peaks correspond to two types of disodium forms having different waters of crystallization, although the accurate number of the hydration could not be estimated. The monohydrate of the disodium form of α-ZP has an interlayer distance of 8.42 Å and thus the disodium form of ZTP with a spacing of 8.4 Å is most probably a monohydrate. The monohydrates of the monosodium and disodium forms did not regain the interlayer spacings when stored over saturated aqueous sodium chloride solution (relative humidity ≈75%).

In Fig. 5, the X-ray powder patterns for ZTP(0.25) at several stages of exchange together with those of the

*** Under some conditions of drying, the reflection peak appeared at 7.9 Å instead of 11.9 Å. The interlayer distance is relatively sensitive to the water content of the exchanger, and consequently to the drying conditions.[4]

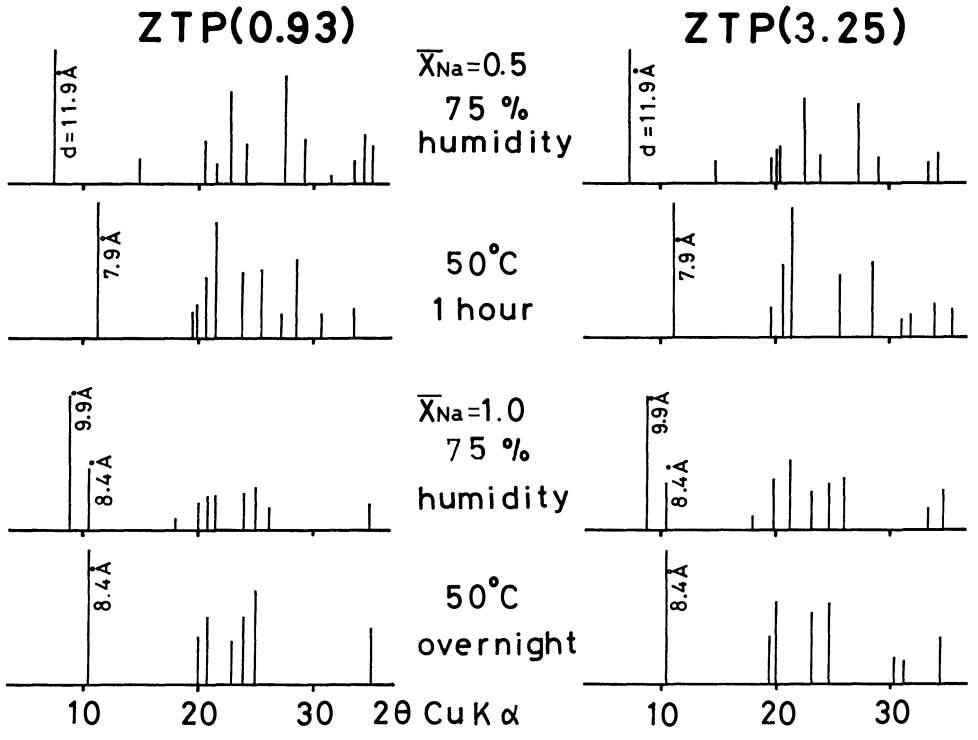

Fig. 4. Change in X-ray powder diffraction patterns of ZTP (3.25) and ZTP (0.93) depending on storage conditions.

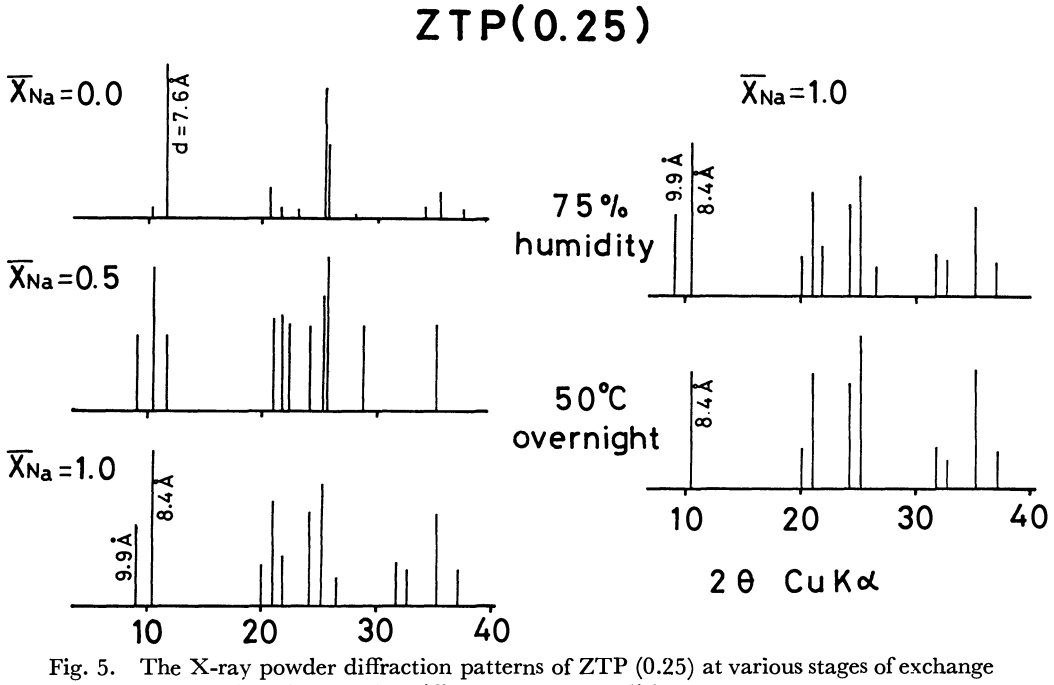

Fig. 5. The X-ray powder diffraction patterns of ZTP (0.25) at various stages of exchange and those of sodium form under different storage conditions.

disodium form under different storage conditions are shown. The X-ray pattern at $\bar{X}_{Na}=1.0$ was the same as for the foregoing two exchangers. The monosodium form however was not observed in this case, *i.e.*, as exchange proceeded, the disodium form phases were formed without the formation of the intermediate. In fact, at $\bar{X}_{Na}=0.5$, two peaks of the disodium form, 9.9 Å and 8.4 Å coexisted with the peak at 7.6 Å, which belongs to the unexchanged hydrogen form. Nevertheless, a small pH jump existed in the titration curve. In this case, the absence of a monosodium form does not correspond to a smooth titration curve without structure.

Further experimentation is continuing on the ion exchange behavior of other alkali metal ions such as lithium and potassium, and will be reported in due course.

Conclusions

A crystalline phosphate ion exchanger containing both zirconium and titanium has been synthesized. The sodium ion exchange behavior on the exchanger is interesting in that the presence or absence of the monosodium phase is dependent upon the Zr/Ti mole ratio in the exchanger. As an ion exchanger, ZTP is preferred to α-TP since it has higher resistance to hydrolysis.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

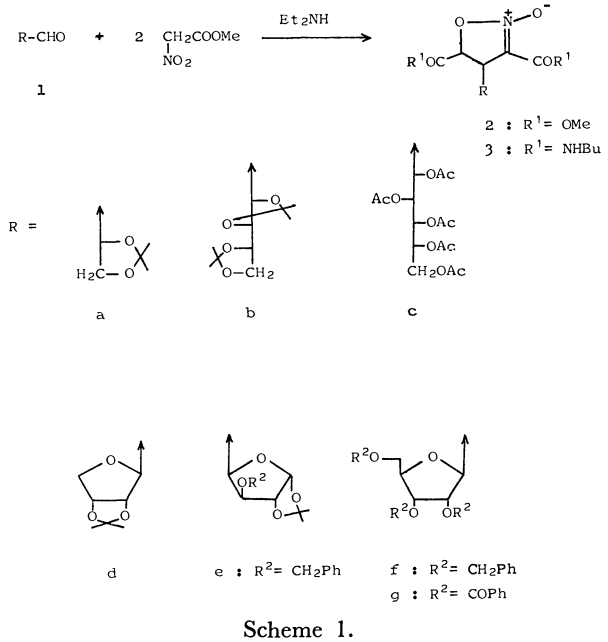
Synthesis of 4-(Glycosyl)isoxazoline *N*-Oxides and Related Substances[1)]

Eisuke KAJI,* Hiromi ICHIKAWA, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received February 13, 1979)

4-(Glycosyl)isoxazoline *N*-oxides were synthesized directly from *aldehydo* sugars by one-step cyclization with double mole of methyl nitroacetate in a satisfactory yield. 2,3-*O*-Isopropylidene-D-glyceraldehyde reacted with methyl nitroacetate to give 4-(1,2-*O*-isopropylidene-D-*glycero*-dihydroxyethyl)-3,5-bis(methoxycarbonyl)isoxazoline *N*-oxide. The same treatment of 2,3: 4,5-di-*O*-isopropylidene-*aldehydo*-L-arabinose and penta-*O*-acetyl-*aldehydo*-D-glucose also gave the corresponding homologs. From the corresponding cyclic *aldehydo* sugars, 4-aldofuranosyl-3,5-bis(methoxycarbonyl)isoxazoline *N*-oxides, *e.g.* 4-(2,3-*O*-isopropylidene-β-D-erythrofuranosyl)-, 4-[(4*R*)-3-*O*-benzyl-1,2-*O*-isopropylidene-β-L-threofuranos-4-yl]-, 4-(2,3,5-tri-*O*-benzyl-β-D-ribofuranosyl)-, and 4-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-derivatives were synthesized. The latter was converted into 3,5-dicarbamoyl-4-(β-D-ribofuranosyl)isoxazoline by deoxygenation followed by carbamoylation and deprotection.

Recently numerous reports have appeared on the synthesis of *C*-glycosyl heterocycles related to *C*-nucleoside antibiotics and their analogs in the quest of potential chemotherapeutic compounds,[2)] such as polyhydroxyalkyl-[3)] or *C*-glycosyl[4)] isoxazolines and isoxazoles, and their carbocyclic analogs.[5)] The heterocyclic moiety was obtained mostly by 1,3-dipolar cycloaddition of olefinic or acetylenic dipolarophiles to sugar nitrile oxides, or by that of olefinic sugars to some nitrile oxides, affording 3- or 5-(glycosyl)isoxazolines or isoxazoles. However, no 4-(glycosyl)isoxazoline or isoxazole appears to have been prepared. A previous work[6)] on the synthesis of 4-substituted isoxazoline *N*-oxide led us to develop a new route to the above-mentioned *C*-nucleoside. In the present paper we give syntheses of some 4-(polyhydroxyalkyl)- and 4-(glycosyl)isoxazoline *N*-oxides by means of one-step cyclization of *aldehydo* sugars with double mole of methyl nitroacetate.

First we examined the condensation of 2,3-*O*-isopropylidene-D-glyceraldehyde (**1a**) with methyl nitroacetate in order to confirm the reaction conditions. It was found that **1a** reacts with two equivalents of methyl nitroacetate in the presence of one equivalent of diethylamine in *N*,*N*-dimethylacetamide (DMA) to afford 4-(1,2-*O*-isopropylidene-D-*glycero*-dihydroxyethyl)-3,5-bis(methoxycarbonyl)isoxazoline *N*-oxide (**2a**) in 74% yield. The structure of **2a** was confirmed by its IR, UV, and ^{1}H-NMR spectra and elemental analysis. Fractional recrystallization of **2a** from hexane resulted in the isolation of two diastereomers (**2a**$_1$: mp 121.5—124 °C and **2a**$_2$: mp 86.5—87.5 °C) in a *ca.* 3: 2 ratio. The relatively small $J_{4,5}$ value (3.5—4.0 Hz) shows the 4,5-*trans* configuration of **2a**$_1$ and **2a**$_2$.[6,7)] The opposite sign of CD spectra centered at 270 nm might be attributed to a symmetric relationship on the configuration of the isoxazoline ring as shown is Scheme 3. Accordingly (4*R*,5*S*) and (4*S*,5*R*) configuration could fit both isomers. However, we can offer no convincing argument as to the assignment of each isomer.



Scheme 1.

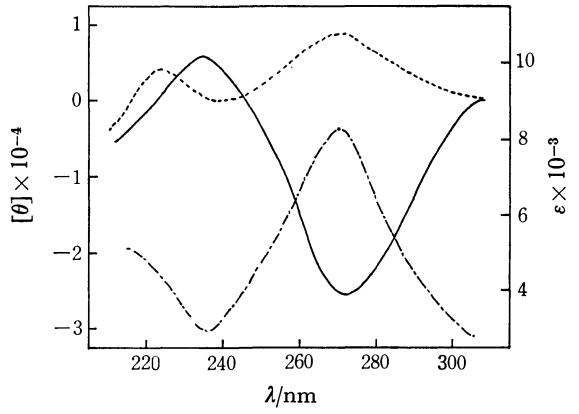


Fig. 1. CD and UV spectra of **2a**$_1$ and **2a**$_2$ in MeOH
——: CD (**2a**$_1$), – – –: CD (**2a**$_2$), —·—: UV (**2a**$_1$ and **2a**$_2$).

The same treatment of 2,3,: 4,5-di-*O*-isopropylidene-*aldehydo*-L-arabinose (**1b**) and penta-*O*-acetyl-*aldehydo*-D-glucose (**1c**) also gave the corresponding homologs (**2b** and **2c**) in 48 and 64% yields, respectively, their diastereomers not being detected. 3,5-Bis(butylcarbamoyl) derivatives (**3a**$_1$ and **3b**) were prepared by treatment of **2a**$_1$ and **2b** with butylamine in methanol. Deisopropylidenation of **2a**$_1$ and **2b** by Dowex 50 W in methanol gave **5a**$_1$ and **5b**, respectively. The latter

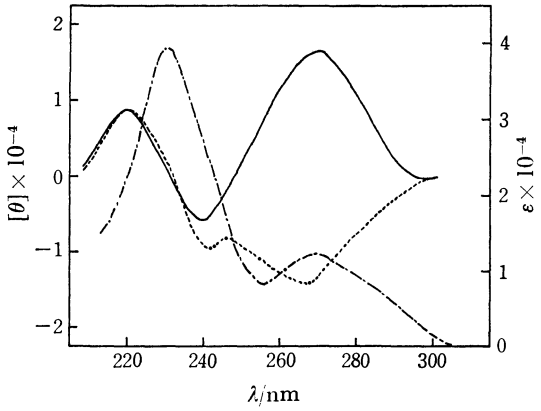

Fig. 2. CD and UV spectra of $\mathbf{2g_1}$ and $\mathbf{2g_2}$ in MeOH. ——: CD ($\mathbf{2g_1}$), ----: CD ($\mathbf{2g_2}$), —·—: UV ($\mathbf{2g_1}$ and $\mathbf{2g_2}$).

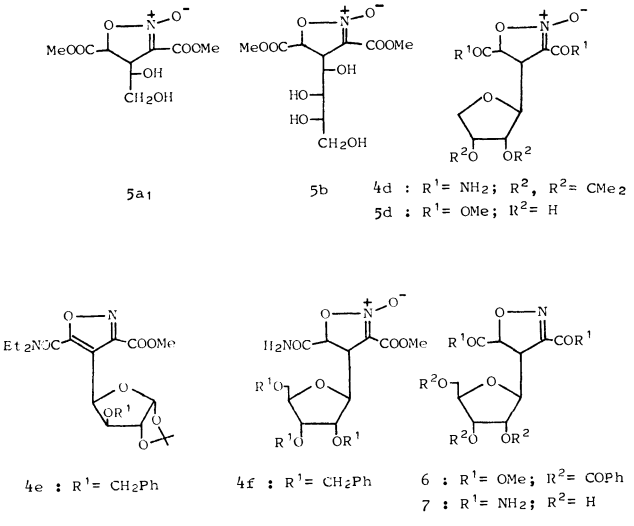
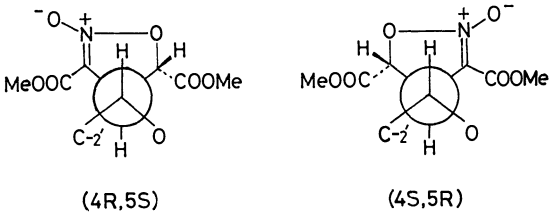
seems to have been formed through the 3,4-deprotected intermediate which was isolated. Deacetylation and carbamoylation of **2c** led to a mixture of products which could not be characterized.

It is of interest to explore a route to 4-aldofuranosylisoxazolines, since naturally occurring *C*-nucleosides contain a D-ribofuranosyl moiety. For synthesis of 4-aldofuranosylisoxazolines, 2,5-anhydro-aldoses and 1,4-pentodialdofuranose were employed. 2,5-Anhydro-3,4-*O*-isopropylidene-D-ribose (**1d**), 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-*xylo*-pentodialdo-1,4-furanose (**1e**), 2,5-anhydro-3,4,6-tri-*O*-benzyl-D-allose (**1f**) and its 3,4,6-tri-*O*-benzoyl analog (**1g**) were condensed with methyl nitroacetate by the above-mentioned procedure, affording the corresponding 4-aldofuranosylisoxazoline *N*-oxides (**2d**—**2g**) in a satisfactory yield except **2e** (6%). *C*-Glycoside **2f** was obtained as a mixture of two diastereomers indicated by two sets of singlet for the methyl of the methoxycarbonyl groups of **2f** in its ^{1}H-NMR spectrum. With regard to compound **2g**, two diastereomers ($\mathbf{2g_1}$: mp 97.5—99 °C and $\mathbf{2g_2}$: mp 68—71 °C) were isolated through column chromatography on silica gel in a *ca.* 1 : 3 ratio. The ^{1}H-NMR



Scheme 2.



Scheme 3.

and CD spectra (Fig. 2) of $\mathbf{2g_1}$ and $\mathbf{2g_2}$ also indicate that the isomers have either (4*R*,5*S*)- or (4*S*,5*R*)-isoxazoline moiety as described for compound **2a**.

In view of biological activities of several nucleosides possesing carbamoyl groups in the heterocyclic portion, carbamoylation of **2d**—**2f** with methanolic ammonia or butylamine in methanol was carried out, affording mono- or dicarbamoyl derivatives (**3d**, **4d**, and **4f**). On the other hand carbamoylation of **2e** with diethylamine in methanol gave 5-diethylcarbamoyl-3-methoxycarbonylisoxazole (**4e**), the structure of which was confirmed by its spectral and elemental analysis. The formation of **4e** would have resulted from a base catalyzed transformation of isoxazoline *N*-oxide into isoxazole.[6,8] In other cases, however, no isoxazole derivative was observed.

Deisopropylidenation of **2d** was achieved using Dowex 50 W resin in aqueous methanol, giving **5d**. Since direct debenzoylation of $\mathbf{2g_2}$ (major isomer) with saturated methanolic ammonia was unsuccessful because of the lability of $\mathbf{2g_2}$ in such a medium, it was subsequently deoxygenated with triethyl phosphite, leading to an isoxazoline (**6**) in 49% yield. Debenzoylation and carbamoylation of **6** was accomplished with saturated methanolic ammonia, giving **7** in 55% yield, biological assay of which is now in progress.

Experimental

Melting points are uncorrected. ^{1}H-NMR spectra were recorded with a 60 MHz Varian T-60 and a 100 MHz JEOL PS-100 spectrometer with a spin decoupler using tetramethylsilane as an internal standard in chloroform-*d*, acetone-d_6 and methanol-d_4 solution, and sodium 2,2-dimethyl-2-silapentane-5-sulfonate in deuterium oxide. IR, UV, CD, and MS were measured with JASCO IRA-1, Hitachi 340, JASCO J-20, and JMS D-100 spectrometers, respectively. TLC was carried out on Kiesel gel G (Merck), spots being detected with iodine vapor or 10% sulfuric acid on a hot plate. Silica gel (Kanto Kagaku, up to 100 mesh) was used for column chromatography. For preparation of *aldehydo* sugars, reported procedures were applied to 2,3-*O*-isopropylidene-D-glyceraldehyde (**1a**),[9] 2,3:4,5-di-*O*-isopropylidene-*aldehydo*-L-arabinose (**1b**),[10] penta-*O*-acetyl-*aldehydo*-D-glucose (**1c**),[11] 2,5-anhydro-3,4-*O*-isopropylidene-D-ribose (**1d**),[12] 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-*xylo*-pentodialdo-1,4-furanose (**1e**),[13] 2,5-anhydro-3,4,6-tri-*O*-benzyl-D-allose (**1f**),[14] and 2,5-anhydro-3,4,6-tri-*O*-benzoyl-D-allose (**1g**).[14]

*4-(1,2-O-Isopropylidene-*D-glycero-*dihydroxyethyl)-3,5-bis(methoxycarbonyl)isoxazoline* N-*Oxide (2a) (A Typical Procedure for Condensation).* To a solution of **1a** (0.69 g, 5.3 mmol) in 30 ml of anhydrous DMA were added methyl nitroacetate (1.2 g, 10.6 mmol) and an equivalent of diethylamine (0.52

ml, 5.3 mmol). The mixture was stirred at room temperature for 16 h. After the starting materials had been almost consumed by TLC (silica gel, ethyl acetate–hexane (1:1)) analysis, the mixture was poured into a mixture of benzene (40 ml) and ice–water (80 ml), and the aqueous phase was extracted with benzene (3×40 ml). The combined extract was washed with water (3×80 ml) and dried over anhydrous sodium sulfate. Evaporation gave a yellowish syrup, which was purified by column chromatography on silica gel eluted with ethyl acetate–hexane (1:1), giving 1.2 g (74%) of **2a**. Fractional recrystallization of **2a** from ethyl acetate–hexane resulted in isolation of two diastereomers (**2a**$_1$ and **2a**$_2$) in a ratio of *ca.* 3:2. **2a**$_1$: mp 122.5—123.5 °C; $[\alpha]_D^{20}$ −117° (*c* 2.5, $CHCl_3$); UV_{max} (MeOH) 270 nm (ε 8400); IR (KBr) 1760—1740 (ester C=O), 1630—1620 (C=N), 1380 and 1150 cm^{-1} (CMe_2); ^{1}H-NMR ($CDCl_3$) δ=1.37 and 1.50 (each 3 H, s, CMe_2), 3.87 and 3.90 (each 3 H, s, ester Me), 3.97—4.07 (3H, m, H-1′,2′), 4.57 (1H, dd, $J_{4,1'}$=6 Hz, H-4), 5.08 (1H, d, $J_{4,5}$=3.5 Hz, H-5); CD (MeOH) $[\theta]_{273}$ −26000 (negative maximum).

Found: C, 47.52; H, 5.58; N, 4.59%; M$^+$, 303. Calcd for $C_{12}H_{17}NO_8$: C, 47.52; H, 5.65; N, 4.62%; M, 303.

2a$_2$: mp 86.5—87.5 °C; $[\alpha]_D^{20}$ −23° (*c* 2.5, $CHCl_3$); UV_{max} (MeOH) 270 nm (ε 8300); IR (KBr) 1760—1740 (ester C=O), 1630—1620 (C=N), 1380 and 1150 cm^{-1} (CMe_2); ^{1}H-NMR ($CDCl_3$) δ=1.37 and 1.50 (each 3H, s, CMe_2), 3.90 and 4.07 (each 3H, s, ester Me), 4.65 (1H, m, H-4), 5.21 (1H, d, $J_{4,5}$=4 Hz, H-5); CD (MeOH) $[\theta]_{268}$+8140 (positive maximum).

Found: C, 47.28; H, 5.60; N, 4.48%; M$^+$, 303.

*4-(1,2: 3,4-Di-*O*-isopropylidene-*L*-arabino-tetrahydroxybutyl)-3,5-bis(methoxycarbonyl)isoxazoline* N-*Oxide* (**2b**) *from* **1b**. Reaction time 2.5 h; Yield 48%; mp 86—87 °C (hexane); $[\alpha]_D^{20}$ −36° (*c* 2.6, $CHCl_3$); IR (KBr) 1755 and 1710 (ester C=O), 1635 (C=N), 1380 and 1150 cm^{-1} (CMe_2); ^{1}H-NMR ($CDCl_3$) δ=1.40 (12H, m, CMe_2), 3.87 (6H, s, ester Me), 3.5—4.2 (5H, m, H-4,2′,3′,4′), 4.52 (1H, m, H-1′), 5.05 (1H, d, $J_{4,5}$=2 Hz, H-5).

*4-[(4R)-3-O-Benzyl-1,2-O-isopropylidene-β-*L*-threofuranos-4-yl]-5-diethylcarbamoyl-3-methoxycarbonylisoxazole (**4e**).* A solution of **2e** (74 mg, 0.16 mmol) in methanol (5 ml) was kept with diethylamine (0.17 ml, 1.6 mmol) at room temperature for 5 h. After evaporation the residue was crystallized from methanol–diethyl ether to give 26 mg (35%) of **4e**: mp 174—179.5 °C; $[\alpha]_D^{20}$ −189° (*c* 0.32, $CHCl_3$); IR (KBr) 1760 (ester C=O), 1710 cm^{-1} (amide); ^{1}H-NMR ($CDCl_3$) δ=1.19 (6H, t, $CH_2C\underline{H}_3$), 1.32 and 1.50 (each 3H, s, CMe_2), 2.96 (4H, q, $C\underline{H}_2CH_3$), 3.82 (3H, s, ester Me), 4.35 (1H, d, H-3′), 4.46 (2H, d, $C\underline{H}_2Ph$), 4.58 (1H, d, $J_{1',2'}$=4 Hz, $J_{2',3'}$=0 Hz, H-2′), 5.42 (1H, d, $J_{3',4'}$=4 Hz, H-4′), 5.82 (1H, d, $J_{1',2'}$=4 Hz, H-1′), 7.16 (5H, s, Ph).

Found: C, 60.35; H, 6.50; N, 5.69%; M^+, 475. Calcd for $C_{24}H_{30}N_2O_8$: C, 60.75; H, 6.37; N, 5.90%; M, 475.

*4-(2,3,5-Tri-O-benzyl-β-*D*-ribofuranosyl)-5-carbamoyl-3-methoxycarbonylisoxazoline* N-*Oxide (**4f**).* A solution of **2f** (208 mg, 0.34 mmol) in saturated methanolic ammonia (1 ml) was stored at room temperature for 1 h and then evaporated to dryness. The residue was chromatographed on silica gel eluted with ethyl acetate–hexane (3: 2). A fraction of R_f 0.3 was collected and crystallized from ethyl acetate–hexane, giving 44 mg (22%) of **4f**: mp 128.5—129.5 °C; $[\alpha]_D^{20}$ +1.4° (*c* 0.3, $CHCl_3$); IR (KBr) 3415 (NH), 1730 (ester C=O), 1680 (amide), 1615 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$) δ=3.3—3.65 (3H, m, H-1′,5′), 3.79 (3H, s, ester Me), 3.85—4.18 (3H, m, H-2′,3′,4′), 4.11 (1H, dd, H-4), 4.4—4.62 (6H, m, $C\underline{H}_2Ph$), 5.14 (1H, d, $J_{4,5}$=3.3 Hz, H-5), 5.60 and 6.45 (each 1H, broad, $CONH_2$), 7.2—7.3 (15H, m, Ph).

Found: C, 65.10; H, 5.79; N, 4.73%; M^+, 590. Calcd for $C_{32}H_{34}N_2O_9$: C, 65.07; H, 5.80; N, 4.74%; M, 590.

*4-(*D*-glycero-Dihydroxyethyl)-3,5-bis(methoxycarbonyl) isoxazoline* N-*Oxide (**5a**$_1$) (A Typical Procedure for Deisopropylidenation)*: A solution of **2a**$_1$ (major isomer, 726 mg, 2.4 mmol) in aqueous methanol (50 ml) was treated with acidic resin (Dowex 50 W-X8, 4 g) under stirring at room temperature for 4 h. After evaporation the residue was crystallized from ethyl acetate–hexane, giving 630 mg (quantitative) of **5a**$_1$: mp 145.5—147 °C; $[\alpha]_D^{20}$ −124° (*c* 0.2, MeOH); IR (KBr) 3430 and 3320 (OH), 1730 (ester C=O), 1615 cm^{-1} (C=N); ^{1}H-NMR (acetone-d_6) δ=3.6—3.7 (3H, m, H-1′,2′), 3.80 (6H, s, ester Me), 4.06 (1H, m, H-4), 5.28 (1H, d, $J_{4,5}$=2 Hz, H-5).

Found: C, 40.91; H, 4.97; N, 5.16%. Calcd for $C_9H_{13}NO_8$: C, 41.07; H, 4.98; N, 5.32%.

*4-(*L*-arabino-Tetrahydroxybutyl)-3,5-bis(methoxycarbonyl)isoxazoline* N-*Oxide (**5b**) from **2b**.* The reaction mixture obtained after stirring for 0.5 h was chromatographed on silica gel eluted with ethyl acetate–chloroform (3: 1), giving 3,4-diol (colorless syrup, R_f 0.4); yield 36%; $[\alpha]_D^{20}$ −93.7° (*c* 2.7, MeOH); IR (liq. film) 3460 (OH), 1760—1735 (ester C=O), 1630 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$) δ=1.42 and 1.45 (each 3H, s, CMe_2), 2.4—3.2 (2H, broad, OH), 3.87 and 3.90 (each 3H, s, ester Me), 3.75 (4H, m, H-2′,3′,4′), 4.18 (1H, dd, H-4), 4.58 (1H, dd, H-1′), 5.12 (1H, d, $J_{4,5}$=2.5 Hz, H-5) and 1,2,3,4-tetrol (**5b**, R_f 0.1); yield 17%; mp 66 °C (dec); $[\alpha]_D^{20}$ +39.7° (*c* 3.0, MeOH); IR (KBr) 3360 (OH), 1735 and 1700 (ester C=O), 1630 cm^{-1} (C=N); ^{1}H-NMR (methanol-d_4) δ=3.83 and 3.87 (each 3H, s, ester Me), 3.70—4.03 (5H, m, H-4,2′,3′,4′), 4.37 (1H, m, H-1′), 5.68 (1H, d, $J_{4,5}$=3 Hz, H-5).

Found: C, 40.46; H, 5.08; N, 3.98%. Calcd for $C_{11}H_{17}NO_{10}$: C, 40.87; H, 5.30; N, 4.33%.

*4-(β-*D*-Erythrofuranosyl)-3,5-bis(methoxycarbonyl)isoxazoline* N-*Oxide (**5d**) from **2d**.* Reaction time 10 h. Solvent system for chromatography, ethyl acetate–acetone–benzene (4: 5: 3); yield 29%; mp 167—169.5 °C (ethyl acetate–hexane); $[\alpha]_D^{20}$ +14.7° (*c* 0.2, MeOH); IR (KBr) 3480 (OH), 1765 and 1730 (ester C=O), 1620 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$) δ=2.9—3.3 (2H, broad, OH), 3.71 and 3.84 (each 3H, s, ester Me), 5.02 (1H, d, $J_{4,5}$=2 Hz, H-5), 3.8—4.35 (6H, m, other protons).

Found: C, 42.89; H, 4.91; N, 4.33%; M^+ 306. Calcd for $C_{11}H_{15}NO_9$: C, 43.28; H, 4.95; N, 4.59%; M 306.

*4-(2,3,5-Tri-O-benzoyl-β-*D*-ribofuranosyl)-3,5-bis(methoxycarbonyl)isoxazoline (**6**).* A mixture of **2g**$_2$ (major isomer, 970 mg, 1.5 mmol) and triethyl phosphite (300 mg, 1.8 mmol) in anhydrous toluene (4 ml) was refluxed for 5 h under nitrogen atmosphere. The solvent was evaporated and the residue was chromatographed on silica gel eluted with ethyl acetate–hexane (1: 1), giving 632 mg of amorphous solid. Recrystallization from benzene–hexane gave 461 mg (49%) of **6** as colorless prisms: mp 92.5—93.5 °C; $[\alpha]_D^{20}$ −134° (*c* 0.25, $CHCl_3$); UV_{max} (MeOH) 230 nm (ε 42000), 272^{sh} nm (ε 4600); IR (KBr) 1720 (ester C=O), 1630 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$) δ=3.60 and 3.68 (each 3H, s, ester Me), 4.36 (1H, dd, $J_{4,5}$=5.0 Hz, $J_{4,1'}$=5.0 Hz, H-4), 4.48—4.66 (3H, m, H-4′,5′), 4.77 (1H, dd, $J_{4,1'}$=5.0 Hz, $J_{1',2'}$=7.8 Hz, H-1′), 5.23 (1H, d, $J_{4,5}$=5.0 Hz, H-5), 5.43 (1H, dd, $J_{1',2'}$=7.8 Hz, $J_{2',3'}$=5.8 Hz, H-2′), 5.65 (1H, dd, $J_{2',3'}$=5.8 Hz, $J_{3',4'}$=3.5 Hz, H-3′).

Found: C, 62.48; H, 4.54; N, 2.15%. Calcd for $C_{33}H_{29}NO_{12}$: C, 62.76; H, 4.63; N, 2.22%.

*3,5-Dicarbamoyl-4-(β-*D*-ribofuranosyl)isoxazoline (**7**).* A solution of **6** (200 mg, 0.32 mmol) in saturated methanolic ammonia (15 ml) was stored at room temperature for 7 h, when TLC (silica gel, ethyl acetate–hexane (1: 1)) showed complete consumption of **6**. The syrupy residue on evaporation was dissolved in methanol and chromatographed on silica gel eluted with methanol–ethyl acetate (1: 3), giving 51 mg (55%) of **7** as colorless prisms: mp 198—198.5 °C; $[\alpha]_D^{20}$ −173° (*c* 0.14, MeOH); UV_{max} (MeOH) 225 nm (ε 5400); IR (KBr) 3400—3280 (NH, OH), 1655 (amide), 1605 cm^{-1} (C=N); ^{1}H-NMR (D_2O) δ=3.5—3.8 (2H, m, H-5′), 3.9—4.1 (3H, m, H-1′,2′,4′), 4.16 (2H, m, H-4,3′), 5.25 (1H, d, $J_{4,5}$=3.7 Hz, H-5).

Found: C, 41.58; H, 5.23; N, 14.32%. Calcd for $C_{10}H_{15}N_3O_7$: C, 41.52; H, 5.23; N, 14.53%.

The authors are indebted to Mr. Chiharu Ichikawa and Miss Yohko Tabuchi for their technical assistance. The present work was supported in part by a Grant-in-Aid for Scientific Research No. 255337 from the Ministry of Education, Science and Culture.

(Received February 13, 1979)

Synthesis of some pyrimidines and pteridines with an amino acid residue at the 2-position was investigated. 4-Amino-6-hydroxy-2-methylthio-5-nitrosopyrimidine, on heating with amino acids in water, underwent aminolysis at the 2-position to give the corresponding *N*-(4-amino-6-hydroxy-5-nitroso-2-pyrimidinyl)amino acids. These (5-nitroso-2-pyrimidinyl)amino acids, after reduction of the nitroso group to an amino group, condensed with biacetyl or a pentose phenylhydrazone to give *N*-(4-hydroxy-6,7-dimethyl-2-pteridinyl)amino acids and *N*-(4-hydroxy-6-polyhydroxypropyl-2-pteridinyl)amino acids, respectively.

Various 2-amino-4-hydroxypteridines and their 5,6,7,8-tetrahydro derivatives having an alkyl or polyhydroxyalkyl substituent at the 6-position possess distinctive biological activities. For example, biopterin [2-amino-4-hydroxy-6-(L-*erythro*-1,2-dihydroxypropyl)-pteridine] is a growth factor for *Crithidia fasciculate*[2,3] and the 5,6,7,8-tetrahydro derivative is a potent coenzyme for phenylalanine,[4] tyrosine,[5,6] and tryptophan hydroxylases.[7]

The relation between the structure of 6-substituted 5,6,7,8-tetrahydro-2-amino-4-hydroxypteridines and the coenzyme activities for tyrosine hydroxylase has been studied extensively by Nagatsu and his coworkers.[6,8,9] However, the pteridines used in their study vary only in the substituents attached to the pyrazine ring of the compounds except a few cases.[8] It is of interest to investigate how the biological activities of such pteridines will be changed by modification in the pyrimidine rather than the pyrazine moiety. This paper describes the synthesis of 6- or 6,7-disubstituted 2-amino-4-hydroxypteridines possessing a carboxyalkyl group attached to the 2-amino group. The choice to introduce a carboxyalkyl group rather than a simple alkyl group stemmed from an anticipation that such polar group would cause a stronger interaction of the pteridine with the biological systems. In addition, it is expected that further modification of the compounds at the carboxyl group, for example the formation of an amido linkage to polyamines or proteins, would widen the utility of these compounds.

The amino acid residue of the pteridines (**3**, **4**, and **5**) was introduced prior to the formation of the pteridine ring by nucleophilic displacement of the methylthio group of 4-amino-6-hydroxy-2-methylthio-5-nitrosopyrimidine (**1**) by an appropriate amino acid in analogy to the aminolysis of **1** by simple aliphatic amines.[10] When the methylthiopyrimidine was heated with an excess amount of 6-aminohexanoic acid in an aqueous solution, the solution changed the color from blue to dark red and evolved methanethiol. The displacement became complete after refluxing for 1 h and the yield of 6-[(4-amino-6-hydroxy-5-nitroso-2-pyrimidinyl)amino]hexanoic acid (**2a**) was about 70%. The reaction of **1** with 4-aminobutanoic acid and β-alanine took place in a similar manner to give the 4-(2-pyrimidinylamino)butanoic and 3-(2-pyrimidinylamino)propanoic acids (**2b** and **2c**), respectively. However, the displacement reaction of **1** with several α-amino acids proceeded much easier when the sodium salts of the acids in place of the free acids were employed. Thus, heating of **1** with L-alanine in the presence of an equivalent amount of sodium hydroxide yielded *N*-(4-amino-6-hydroxy-5-nitroso-2-pyrimidinyl)-L-alanine (**2d**) in 53% yield; in the absence of sodium hydroxide, the yield was 22%. Under similar conditions, **1** reacted with D-alanine and glycine to give the *N*-(2-pyrimidinyl)-D-alanine (**2e**) and the *N*-(2-pyrimidinyl)glycine (**2f**), respectively.

These *N*-(2-pyrimidinyl)amino acids showed two pK_a values at about 2.4 and 7.9, which were attributed to the ionization of the pyrimidine ring to form a cation (pK_a 2.4) and to form an anion (pK_a 7.9); pK_a values due to the ionization of the carboxyl group could not be determined on a spectroscopic measurement. Thus, all the *N*-(2-pyrimidinyl)amino acids, despite of the different carbon chain between the carboxyl and amino groups, exhibited UV spectra (Table 1) very similar to those of known 4-amino-6-hydroxy-2-methylamino-5-nitrosopyrimidine.[11] These physical data, together with elemental analyses, confirmed the structure of the aminolysis products.

The nitrosopyrimidines (**2a**—**f**) were converted to the corresponding 2-amino-4-hydroxy-6,7-dimethylpteridines (**3a**—**f**) having a carboxyalkyl group attached to the 2-amino group in a conventional way: by reduction of the 5-nitroso group to an amino group by catalytic hydrogenation, followed by condensation with biacetyl. By using glyoxal instead of biacetyl in the above course, **2f** gave *N*-(4-hydroxy-2-pteridinyl)glycine (**4**).

Several pteridines analogous to biopterin or neopterin having a di- or trihydroxypropyl substituent at the 6-position were also synthesized starting from the 5-nitrosopyrimidines (**2a** and **2f**). Condensation of the 5-amino analogue of **2a** or **2f** with L-arabinose phenylhydrazone at pH 2—3, followed by air oxidation at pH 7—8 gave 6-[[4-hydroxy-6-(L-*erythro*-1,2,3-trihydroxypropyl)-2-pteridinyl]amino]hexanoic acid (**5a**) and the lower homologue (**5b**), respectively. Condensation of the 5-amino analogue of **2a** with 5-deoxy-L-arabinose phenylhydrazone in a way similar to that for biopterin[1] afforded 6-[[4-hydroxy-6-(L-*erythro*-1,2-dihydroxypropyl)-2-pteridinyl]amino]hexanoic acid (**5c**).

Table 1. The pK_a values and UV spectra of *N*-(2-pyrimidinyl)amino acids and *N*-(2-pteridinyl)amino acids

a) Negative figures are H_0 values. b) Wavelength in nm measured in aqueous buffer of given pH; shoulders or inflexions in italics. c) Ionic species shown by 2+ (dication), + (monocation), ○ (neutral molecule), and − (monoanion) are regarded only to the pyrimidine or pteridine chromophore unless otherwise indicated. d) Zwitter ions.

The structures of these *N*-(2-pteridinyl)amino acids (**3**, **4**, and **5**) were confirmed by the elemental analyses and the close similarity of their UV spectra (Table 1) to those of 4-hydroxy-6,7-dimethyl-2-methylaminopteridine[12] or biopterin.[13] The pteridines (**3d—f**, **4**, and **5b**) derived from α-amino acids exhibited four pK_a values at about 8.8, 3.3, 1.0, and −3.0 which were measured by a spectroscopic method.[14] The values at 8.8, 3.3, and −3.0 are attributed to the ionization of the pteridine ring to form anionic species by losing a proton from the ring (pK_a 8.8) and to form cationic species by single or double protonation (pK_a 3.3 and −3.0, respectively). The pK_a value at 1.0 could be attributed to the ionization of the carboxyl group, since no pK_a was detected by a spectroscopic measurement at this range with **3a—c** where the carboxyl group was separated far from the pteridine chromophore by a long carbon chain of two or more carbon atoms. The acidity of the monocations (protonated at the pteridine ring) of **3d—f**, **4**, and **5b** (pK_a about 1.0) was fairly strengthened compared to those of glycine (pK_a 2.22[15]) and alanine (pK_a 2.22[15]) owing to the electron withdrawing pteridinyl group attached to the nitrogen atom.

As a model for making a peptide linkage between the present synthesized *N*-(2-pteridinyl)amino acids and a protein, conversion of the carboxyl group of **3a** into a carbamoyl group was examined. First, the carboxylic acid (**3a**) was treated with hydrogen chloride in methanol to give the methyl ester which on subsequent treatment with ammonia gave 6-[(4-hydroxy-6,7-dimethyl-2-pteridinyl)amino]hexanamide (**6a**). The conversion, however, was found to undergo much easier by employing a mixed anhydride[16] as an intermediate: **3a** was treated with ethyl chloroformate in *N*,*N*-dimethylformamide in the presence of triethylamine to form an anhydride. Without isolation, the anhydride was treated with butylamine to give the *N*-butyl-6-(2-pteridinylamino)hexanamide (**6b**) in a good yield. The latter method involving an anhydride would be applicable for making a peptide linkage between the present synthesized pteridines and a protein.

Experimental

The elemental analyses were conducted at the Analytical Section, Meijo University, Nagoya. The pK_a values were determined spectroscopically,[14] and the UV spectra in an appropriate buffer solution on a Shimadzu UV-300 spectrophotometer.

Synthesis of N-*(4-Amino-6-hydroxy-5-nitroso-2-pyrimidinyl)amino Acids(2a—f).* *Method A*: A mixture of 4-amino-6-hydroxy-2-methylthio-5-nitrosopyrimidine (**1**)[17] (10 g) and 6-aminohexanoic acid (20 g) in water (400 ml) was heated under reflux for 1 h. The resulting solution was adjusted to pH 2—3 with formic acid and chilled. Filtration and washing with water gave an orange powder (8.5 g) of 6-[(4-amino-6-hydroxy-5-nitroso-2-pyrimidinyl)amino]hexanoic acid (**2a**), which was pure enough for further reactions. The analytical sample (orange needles) was prepared by dissolving in hot dilute ammonia then acidifing with formic acid, mp 232.5—233.5 °C, dec (Found: C, 44.53; H, 5.65; N, 25.69%. Calcd for $C_{10}H_{15}N_5O_4$: C, 44.60; H, 5.62; N, 26.01%). A similar treatment of **1** with 4-aminobutanoic acid or β-alanine gave the 4-(2-pyrimidinylamino)butanoic acid(**2b**)[77% yield, mp 240—241 °C, dec (from water)(Found: C, 39.33; H, 4.92;

N, 29.32%. Calcd for $C_8H_{11}N_5O_4$: C, 39.83; H, 4.60; N, 29.04%)] and the 3-(2-pyrimidinylamino)propanoic acid(**2c**) [68% yield, mp >300 °C (Found: C, 37.58; H, 4.11; N, 30.65%. Calcd for $C_7H_9N_5O_4$: C, 37.01; H, 3.99; N, 30.83 %)], respectively.

Method B: A solution of **1** (9.0 g) and L-alanine (8.9 g) in 0.25 M sodium hydroxide (400 ml) was heated under reflux for 2 h. After concentration *in vacuo* to about 200 ml, the solution was adjusted to pH 2—3 with formic acid and chilled. The orange flakes (5.8 g, 53%) of the *N*-(2-pyrimidinyl)-L-alanine (**2d**), purified in the same way as above, darkened without melting above 245 °C (Found: C, 34.42; H, 4.50; N, 28.46%. Calcd for $C_7H_9N_5O_4 \cdot H_2O$: C, 34.29; H, 4.52; N, 28.56%). Similarly, **1** reacted with D-alanine and glycine to give the *N*-(2-pyrimidinyl)-D-alanine(**2e**)[18% yield; darkened above 245 °C without melting (Found: C, 34.38; H, 4.52; N, 28.28%. Calcd for $C_7H_9N_5O_4 \cdot H_2O$: C, 34.29; H, 4.52; N, 28.56%)] and the *N*-(2-pyrimidinyl)-glycine(**2f**)[63% yield; darkened above 280 °C without melting (Found: C, 31.42; H, 3.71; N, 30.33%. Calcd for $C_6H_7N_5O_4 \cdot H_2O$: C, 31.17; H, 3.92; N, 30.30%)], respectively.

Synthesis of N-*(4-Hydroxy-6,7-dimethyl-2-pteridinyl)amino Acids (3a—f)*. A solution of **2a** (4.3 g) in 2 M sodium hydroxide (60 ml) was hydrogenated over palladium on carbon (5%, 2 g) at room temperature and atmospheric pressure till the calculated amount of hydrogen was absorbed. After acidifing with concd hydrochloric acid (20 ml), the catalyst was removed by filtration. The filtrate, after being adjusted to pH 2—3 with ammonia, was heated with biacetyl (3.0 g) under reflux for 1 h. Refrigeration gave a yellow solid, which was crystallized from 50% aqueous methanol to give yellow needles (70 % yield) of 6-[(4-hydroxy-6,7-dimethyl-2-pteridinyl)amino]-hexanoic acid (**3a**), mp 215—219 °C, dec (Found: C, 51.94; H, 6.61; N, 21.30%. Calcd for $C_{14}H_{19}N_5O_3 \cdot H_2O$: C, 52.00; H, 6.55; N, 21.66%).

In an analogous way, its lower homologues (**3b—f**) were synthesized from the corresponding pyrimidines (**2b—f**): the 4-(2-pteridinylamino)butanoic acid (**3b**) [80% yield, mp 238—240 °C, dec (from water) (Found: C, 48.72; H, 5.82; N, 23.40%. Calcd for $C_{12}H_{15}N_5O_3 \cdot H_2O$: C, 48.80; H, 5.80; N, 23.72%)], 3-(2-pteridinylamino)propanoic acid (**3c**) [70% yield, darkened above 275 °C without melting (Found: C, 49.73; H, 4.98; N, 26.44%. Calcd for $C_{11}H_{13}N_5O_3$: C, 50.18; H, 4.98; N, 26.61%)], *N*-(2-pteridinyl)-L-alanine (**3d**) [50% yield, darkened above 180 °C and did not show sharp mp (from water) (Found: C, 46.95; H, 5.40; N, 24.63%. Calcd for $C_{11}H_{13}N_5O_3 \cdot H_2O$: C, 46.97; H, 5.38; N, 24.90%)], *N*-(2-pteridinyl)-D-alanine (**3e**) [45% yield, darkened above 180 °C without showing sharp mp (from water) (Found: C, 46.84; H, 5.14; N, 24.59%. Calcd for $C_{11}H_{13}N_5O_3 \cdot H_2O$: C, 46.97; H, 5.38; N, 24.90%)], *N*-(2-pteridinyl)glycine (**3f**) [87 % yield, mp 206—210 °C, dec (from water) (Found: C, 45.13; H, 4.87; N, 25.95%. Calcd for $C_{10}H_{11}N_5O_4 \cdot H_2O$: C, 44.94; H, 4.90; N, 26.21%)].

N-*(4-Hydroxy-2-pteridinyl)glycine (4)*. A solution of the 5-amino analogue of **2f** (2.0 g) in water (pH 6—7, 80 ml), prepared in the same way as above, was heated with glyoxal sodium hydrogensulfite (3.5 g) under reflux for 1 h. The solution was adjusted to pH 2—3 with hydrochloric acid and chilled to give a solid. Crystallization of the solid from water gave colorless prisms (1.1 g) of **4** which darkened above 250 °C without melting (Found: C, 40.28; H, 3.77; N, 28.94%. Calcd for $C_8H_7N_5O_3 \cdot H_2O$: C, 40.17; H, 3.79; N, 29.28%).

*6-[[4-Hydroxy-6-(*L-erythro-*1,2,3-trihydroxypropyl)-2-pteridinyl]amino]hexanoic Acid (5a) and the Homologue (5b)*. A solution of **2a** (4.0 g) in 2 M sodium hydroxide (100 ml) was hydrogenated and separated from the catalyst as above. The filtrate was adjusted to pH 3—4, diluted with methanol (100 ml), and then heated with L-arabinose phenylhydrazone (3.8 g) under nitrogen and reflux for 2 h. After cooling, the solution was adjusted to pH 8—9 with ammonia and stirred under bubbling air at room temperature for 20 h. The orange solution was evaporated to dryness *in vacuo* and the residue was extracted with 1 M ammonia (200 ml). The extract was adjusted to pH 2—3 with formic acid and chromatographed on a Florisil column[1] (4.5×40 cm) using water as the elution solvent. The eluate was evaporated to dryness and the residue was extracted with hot water (100 ml). The extract, on concentration to about 50 ml and chilling, gave pale yellow prisms (2.0 g) of **5a**, mp 186—190 °C, dec (from water) (Found: C, 46.55; H, 5.84; N, 17.95%. Calcd for $C_{15}H_{21}N_5O_6 \cdot H_2O$: C, 46.75; H, 6.02; N, 18.17%).

By using **2f** in place of **2a** in the foregoing condensation, *N*-[4-hydroxy-6-(L-*erythro*-1,2,3-trihydroxypropyl)-2-pteridinyl]glycine (**5b**) was obtained in 53% yield as colorless needles, mp 177—180 °C, dec (from water) (Found: C, 40.15; H, 4.49; N, 20.98%. Calcd for $C_{11}H_{13}N_5O_6 \cdot H_2O$: C, 40.12; H, 4.59; N, 21.27%).

*6-[[4-Hydroxy-6-(*L-erythro-*1,2-dihydroxypropyl)-2-pteridinyl]-amino]hexanoic Acid (5c)*. The 5-nitrosopyrimidine (**2a**) (4.0 g) was hydrogenated in the same way as above to the 5-amino analogue, which was heated under reflux with 5-deoxy-L-arabinose phenylhydrazone (4.5 g) in 50% aqueous methanol (200 ml) at pH 3—4 and under nitrogen for 20 min. The solution, after cooling in an ice bath, was added to an ice chilled solution of potassium hexacyanoferrate (III) (30 g), potassium iodide (5 g), 35% hydrogen peroxide (10 ml), and formic acid (10 ml) in water (200 ml). The mixture was stirred under bubbling oxygen at 0—5 °C for 2 h and then at 20—25 °C for 10 h. The resulting solution was concentrated *in vacuo* to about 100 ml and chromatographed on a Florisil column as above. The eluate was evaporated to dryness and the residue was extracted with methanol (200 ml). Evaporation of the extract and subsequent crystallization from 90% ethanol gave pale yellow needles (0.47 g) of **5c**, mp 216—218 °C, dec (from 90% ethanol) (Found: C, 48.55; H, 6.25; N, 18.55%. Calcd for $C_{15}H_{21}N_5O_5 \cdot H_2O$: C, 48.77; H, 6.28; N, 18.96%).

Conversion of 3a into the Carboxamides (6a and 6b).

Method A: To a solution of **3a** (300 mg) in anhydrous methanol (30 ml), dry hydrogen chloride was passed till saturation. The solution, after being allowed to stand at 25 °C for 10 h, was evaporated to dryness *in vacuo*. The residue was dissolved in 20% aqueous ammonia (100 ml) and kept at 25 °C for 10 h. Evaporation of the solution gave a solid which was chromatographed on a Florisil column (2× 20 cm), eluted by 0—2% ammonia (500 ml) gradiently. The eluate, on evaporation to dryness and subsequent crystallization from dil formic acid, gave colorless needles (200 mg) of the 6-(2-pteridinylamino)hexanamide (**6a**), mp 212—215 °C dec (from water) (Found: C, 52.07; H, 6.88; N, 26.01%. Calcd for $C_{14}H_{20}N_6O_2 \cdot H_2O$: C, 52.16; H, 6.88; N, 26.07%).

Method B: Ethyl chloroformate (50 mg) was added to a solution of **3a** (125 mg) and triethylamine (100 mg) in *N,N*-dimethylformamide (1 ml) at −5 °C. After stirring for 15 min, butylamine (75 mg) was added to the solution. The mixture was stirred at −5 °C for 30 min and then at 25 °C for 1 h. Evaporation of the solution *in vacuo* gave an oily residue, which was chromatographed on a Florisil column (1×20 cm) eluted by 20% aqueous acetone containing 2% ammonia. The eluate was evaporated to dryness and the residue was extracted with ethanol (50 ml). Concentration of the extract to about 5 ml and chilling gave pale yellow

needles (47 mg) of the *N*-butyl-6-(2-pteridinylamino)hexanamide (**6b**), which decomposed above 150 °C (from 90% ethanol) (Found: C, 57.21; H, 7.53; N, 22.04%. Calcd for $C_{18}H_{28}N_6O_2 \cdot H_2O$: C, 57.11; H, 7.99; N, 22.21%).

The authors would like to thank Mrs. Noriko Nishioka for the measurement of pK_a values and UV spectra.

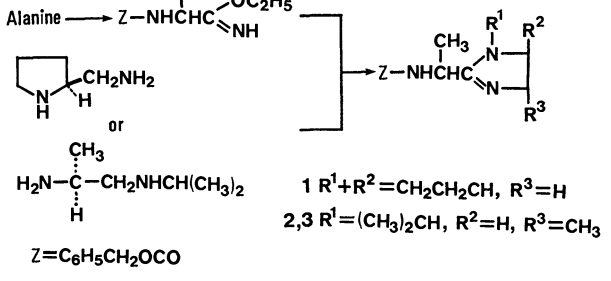
(Received February 14, 1979)

Hydrolysis of an imidazoline derived from (*S*)-alanine and (*S*)-2-(aminomethyl)pyrrolidine afforded (*R*)-alanine in the optical yield of 93.8% (e.e.). The asymmetric transformation was explained on the basis of preferential crystallization of one epimer followed by epimerization of the other epimer in a solution. It was found that the epimerization was catalyzed by amines. (2*S*)-*N*-isopropyl-2-aminopropylamine was also examined as a diamine component of imidazolines.

In an ideal and complete optical resolution, a racemic compound would be separated into 50% of each enantiomer. On the other hand, an asymmetric transformation is a unique method to obtain optically active compounds because it is possible to convert a racemic compound into one of the isomerides in 100% yield. Optically labile compounds are suitable for the asymmetric transformation and it has been reported by many workers.[1] On the other hand, optically stable compounds are not suitable for the transformation, and conversion of the compounds into the optically labile intermediates is indispensable. From this point of view, amino acids, aldehydes, and ketones have been studied in our laboratories.[2]

We also studied on the asymmetric transformation of carboxylic acids. It was reported by Yonetani *et al.* that imidazoline derivatives of amino acids are racemized easily.[3] The asymmetric transformation of α-substituted carboxylic acids might be possible using the optical lability of the derivatives in an asymmetrical circumstance. The *N*-protected alanine was used as a model of the carboxylic acid. (*S*)-2-(Aminomethyl)-pyrrolidine and (2*S*)-*N*-isopropyl-2-aminopropylamine were used as chiral diamine components to prepare the imidazoline derivatives.



Experimental

Optical activities were determined with a JASCO Digital Automatic Polarimeter Model DIP 4. Nuclear magnetic resonance spectra were obtained with a JNM-PS-100 Spectrometer with tetramethylsilane as an internal standard. Accurate mass determinations were carried out on a Hitachi RMU-7 instrument operated at 70 eV.

(S)-(+)-2-(Aminomethyl)pyrrolidine. This compound was prepared as reported previously:[4] bp 72.5—74 °C/2933 Pa; (lit, bp 65 °C/1466 Pa).

(2S)-(+)-N-Isopropyl-2-aminopropylamine. (*S*)-Alanine (60 g, 0.67 mol) was converted to (*S*)-*N*-phthaloylalanyl chloride by the method described by Job and Bruice:[5] bp 149—154 °C/400 Pa; yield 125.7 g (79%). Isopropylamine (34.3 g, 0.58 mol) and sodium hydrogencarbonate (53.6 g, 0.64 mol) were dissolved in 426 ml of water and the solution was cooled in an ice bath to 10 °C. To this solution, a solution of (*S*)-*N*-phthaloylalanyl chloride (125.7 g, 0.53 mol) in dioxane (193 ml) was added dropwise with vigorous stirring. After the addition had been completed, the white precipitates thus formed were collected by filtration and washed with water. Recrystallization of the crude product from methanol gave *N*-isopropylamide of (*S*)-*N*-phthaloylalanine (55.1 g, 0.21 mol). Removal of the phthaloyl group from *N*-isopropylamine of (*S*)-*N*-phthaloylalanine (55.1 g, 0.21 mol) by equimolar hydrazine hydrate gave (*S*)-*N*-isopropylalaninamide (*ca.* 0.2 mol). (*S*)-*N*-Isopropylalaninamide (*ca.* 0.2 mol) was reduced by lithium aluminium hydride in tetrahydrofuran (reflux 15 h). After the usual treatment, (2*S*)-*N*-isopropyl-2-aminopropylamine was obtained by fractional distillation: bp 144—146 °C (13.5 g, 0.116 mol, 17.3% yield based on (*S*)-alanine); $[\alpha]_D^{20}$ +22.2° (neat); MS *m/e* 116.1296 (M^+, $C_6H_{16}N_2$; calcd 116.1313); IR (Nujol) 1370 and 1380 cm^{-1}($CH(CH_3)_2$);NMR ($CDCl_3$) δ=1.07 (N–C–CH_3, *d*) and 1.07 ppm (N–C–$(CH_3)_2$, *d*).

(−)-Ethyl (S)-2-(Benzyloxycarbonylamino)propioimidate. Preparation of this compound was previously reported:[6] mp 72.5—74 °C; $[\alpha]_D^{25}$ −1.3° (*c* 12.65, 99.5% ethanol); (lit, mp 71.5—73.0 °C; $[\alpha]_D^{24}$ −1.4° (*c* 12.65, anhydrous ethanol)).

(+)-Ethyl (R)-2-(Benzyloxycarbonylamino)propioimidate. This compound was prepared from (*R*)-alanine by the same method described for the preparation of (−)-ethyl (*S*)-2-(benzyloxycarbonylamino)propioimidate:[6] mp 72.5—74 °C; $[\alpha]_D^{23}$ +1.3° (*c* 12.65, 99.5% ethanol); MS *m/e* 250.1306 (M^+, $C_{13}H_{18}N_2O_3$; calcd 250.1316); IR (Nujol) 1645 (C=N) and 1710 cm^{-1} (C=O); NMR ($CDCl_3$) δ=7.27 (phenyl, s), 5.08 (phenyl–CH_2–O, s), 1.35 (N–C–CH_3, d) and 1.29 ppm (O–C–CH_3, t).

Preparation of Imidazolines. Imidazoline derivatives of alanines were prepared by the coupling method described by Hirotsu *et al.*[6]

Imidazoline Derivative (1): The reaction of (*S*)-2-(aminomethyl)pyrrolidine and the (*S*)- or the (*R*)-imidate mentioned above gave the imidazoline derivative (**1**). Preparation from the (*S*)-imidate: Yield 86%; mp 86—87.5 °C; $[\alpha]_D^{23}$ −94.1° (*c* 1.0, methanol); MS *m/e* 287.1634 (M^+, $C_{16}H_{21}N_3O_2$, calcd 287.1633); IR (Nujol) 1620 (C=N) and 1710 cm^{-1} (C=O);

Table 1. Configuration and optical purity of alanine residues of imidazoline derivatives

Diamine component	Config. of starting alanine	Imidazoline	Alanine obtained after hydrolysis[a]		
			Config.	e.e. (%)	Yield (%)

NMR ($CDCl_3$) $\delta=1.40$ (N=C–C–CH_3, d) and 5.05 ppm (phenyl-CH_2–O, s). Preparation from the (*R*)-imidate: Yield 75%; mp 86—87.5 °C; $[\alpha]_D^{23}$ −94.9° (*c* 1.0, methanol); MS *m/e* 287.1643 (M^+, $C_{16}H_{21}N_3O_2$, calcd 287.1633); IR (Nujol) 1620 (C=N) and 1710 cm^{-1} (C=O); NMR ($CDCl_3$) $\delta=1.40$ (N=C–C–CH_3, d) and 5.05 ppm (phenyl–CH_2–O, s).

Imidazoline Derivative (2): This compound was prepared from (2*S*)-*N*-isopropyl-2-aminopropylamine and the (*S*)-imidate: Yield 57%; mp 71.5—73 °C; $[\alpha]_D^{23}$ −57.9° (*c* 1.0 methanol); MS *m/e* 303.1930 (M^+, $C_{17}H_{25}N_3O_2$, calcd 303.1945); IR (Nujol) 1610 (C=N) and 1710 cm^{-1} (C=O); NMR ($CDCl_3$) $\delta=1.38$ (N=C–C–CH_3, d) and 5.03 ppm (phenyl–CH_2–O, s).

Imidazoline Derivative (3): This compound was prepared from (2*S*)-*N*-isopropyl-2-aminopropylamine and the (*R*)-imidate: Yield 64%; mp 120—122.5 °C; $[\alpha]_D^{23}$ −36.2° (*c* 1.0, methanol); MS *m/e* 303.1955 (M^+, $C_{17}H_{25}N_3O_2$, calcd 303.1945); IR (Nujol) 1600 (C=N) and 1695 cm^{-1} (C=O); NMR ($CDCl_3$) $\delta=1.37$ (N=C–C–CH_3, d) and 5.08 ppm (phenyl–CH_2–O, s).

Determination of the Optical Purity and the Configuration of the Alanine after the Asymmetric Transformation. The configuration and the optical purity of the alanine residues of the imidazoline derivatives were determined as DNP-alanine (DNP; 2,4-dinitrophenyl) prepared after hydrolysis of the derivatives according to the method described by Yonetani *et al.*[3] (hydrolysis conditions: 6 M HCl, 110 °C, 20 h). The specific optical rotation of the prepared DNP-alanine was observed at 546 nm and the concentration of the solution was calculated from the extinction coefficient at 360 nm; authentic DNP-(*S*)-alanine: $[\alpha]_{546}^{32}$ +221° (*c* 0.22, 1% $NaHCO_3$); $\lambda_{max}^{1\%\ NaHCO_3}$ 360 nm ($\varepsilon=1.72\times10^4$).

Results and Discussion

Imidazoline derivatives prepared from (*S*)-2-(aminomethyl)pyrrolidine and the imidates derived from (*S*)-alanine and (*R*)-alanine have the same crystal habit (platelets) and melting point, and showed identical spectral data. The hydrolysis of these imidazoline derivatives gave (*R*)-alanine (Table 1). These facts indicate that the bond between α-carbon and hydrogen is labile enough to epimerize in the course of the preparation. (Hereafter the imidazoline was called **1**).

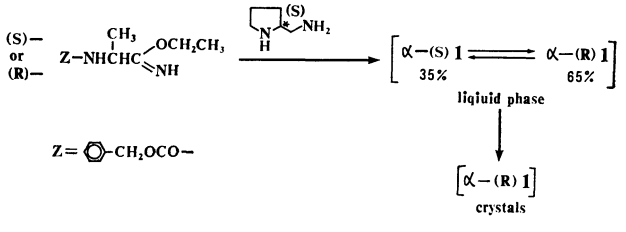
High optical yield (93.8 or 93.2%) of alanine obtained in the case of **1** was considered to be due to a combination of epimerization and resolution by preferential crystallization of one diastereomer. In order to clarify the resolution process, optical purity of alanine residue of **1** in the reaction mixture was examined. Two batches of a reaction mixture of **1** were examined. After removal of the solvent from the reaction mixture under reduced pressure, the oily residue was directly hydrolyzed in one

Table 2. Configuration and optical purity of alanine obtained by the hydrolysis of the reaction mixture of **1** before and after crystallization

	Alanine obtained after hydrolysis[a]		
	Config.	e.e. (%)	Yield (%)
Oily mixture	*R*	35.1	84.1[b]
Crystallized crude mixture	*R*	63.5	87.0

a) Configuration, optical purity, and yield were determined according to the DNP-method after hydrolysis of imidazoline.[3] b) Based on imidate

experiment. In another experiment, the oily residue was allowed to stand at room temperature for 12 h. The crystallized crude mixture was then subjected to hydrolysis without any purification, and the configuration and the optical yields of the resultant alanine were determined. The results are shown in Table 2. The optical yield (35.1%) of the alanine obtained from the oily mixture was the same as that obtained from the hydrolyzate of the imidazoline derivatives after the mutarotation in methanol (*vide infra*). Since no purification was performed in both cases, the difference between the oily mixture and the crystallized mixture is attributable to the epimerization promoted by the preferential crystallization of one diastereomer out of the liquid phase in which a rapid equilibration is maintained.



It is required for this mechanism that the rate of epimerization is fast enough. The rates of epimerization of **1** in several solvents (methanol, ethanol, benzene, and dichloromethane) were observed (Fig. 1). It was fast in methanol or ethanol but the epimerization was not detected in the aprotic solvents. A mixture of dichloromethane and ethanol (equimolar quantities with **1**) was examined as a solvent because, in the course of coupling reaction of ethyl (*S*)- or (*R*)-2-(benzyloxycarbonylamino)propioimidate with (*S*)-2-(aminomethyl)pyrrolidine in dichloromethane, ethanol in amounts equimolar to **1** is to be produced. No epimerization

could be observed under such circumstance. An increase in the content of ethanol and an addition of some triethylamine in dichloromethane was also examined. As shown in the figure, no epimerization was observed. On the other hand, when the crystalline imidazoline **1** was dissolved in the crude reaction mixture of imidazoline, which contains an excess amount of (*S*)-2-(aminomethyl)pyrrolidine, an appreciable epimerization was observed. The rate was as fast as that in methanol. This suggested that (*S*)-2-(aminomethyl)pyrrolidine catalyzes this epimerization. Accordingly, the rate of epimerization in a dichloromethane solution containing (*S*)-2-(aminomethyl)pyrrolidine was studied, and it is observed that the rate was fairly fast. There are a pyrrolidine ring moiety and a primary amine group in (*S*)-2-(aminomethyl)-pyrrolidine. In order to reveal the effect of the nature of amines on the ability of acceleration of the rate, the rates in dichloromethane solutions each containing propylamine, pyrrolidine, *N*-methylpyrrolidine and quinuclidine are examined. The acceleration of the rate of epimerization was found to be in the order of pyrrolidine (cyclic secondary amine)>propylamine (acyclic primary amine)>*N*-methylpyrrolidine and quinuclidine (tertiary amine). The small effect of tertiary amine on the acceleration of the rate suggests that this catalytic action of amines does not depend only on the basicity of amines.

Imidazoline derivatives **2** and **3** were prepared from (2*S*)-*N*-isopropyl-2-aminopropylamine and the imidates derived from (*S*)-alanine and (*R*)-alanine respectively. The imidazoline derivative **2** was isolated as longitudinal crystals by recrystallization from petroleum ether and **3** was isolated as fine needles by recrystallization from acetone–petroleum ether. The physical data of these imidazoline derivatives were apparently different. Hydrolysis of **2** and **3** gave the starting alanines, (*S*) and (*R*) respectively, both with high optical purity (Table 1). It is considered that the epimerizations of both diastereomers **2** and **3** are rather slow. Epimerization of **2** was examined and the results are shown in Fig. 2. The results indicate that the rate of epimerization promoted by primary or acyclic secondary amine was far slower than pyrrolidine. Since the rate of crystallization of **2** or **3** seemed to be similar to that of **1**, the failure of asymmetric transformation in the case of **2** or **3** may be attributed to the slow epimerization. This fact suggests that the efficient catalytic action of (*S*)-2-(aminomethyl)pyrrolidine was attributed to the pyrrolidine moiety and does not due to the chelate effect of the diamine.

It is explicable that the alanine was obtained in low yield by the hydrolysis of **2** and **3**. The existence of an isopropyl group on nitrogen atom in diamine moiety is common to these imidazolines. The difficulty of the hydrolysis is explained on the basis of the steric hindrance of this isopropyl group. Similar description was given in the case of hydrolysis of proteins containing valine or isoleucine residue.[7]

It was revealed that the epimerization of the imidazoline derivatives were efficiently catalyzed by pyrrolidine. The asymmetric transformation of **2** was attempted using pyrrolidine. The imidazoline **2** (53 mg) was dissolved in the dichloromethane solution containing pyrrolidine (5.7 molar equivalent). After 24 h the solvent was removed under reduced pressure. Because the excess pyrrolidine prevented the crystallization, the residue was dissolved in dichloromethane and washed with water to remove the pyrrolidine. The dichloro-

methane layer was dried and evaporated under reduced pressure, and the residue was recrystallized from acetone–petroleum ether to give 23 mg of crystals in the form of fine needles. The melting point (111—115°) and IR spectrum of the crystals were almost identical with those of **3**. It showed that the asymmetric transformation from **2** to **3** occured by the catalytic action of pyrrolidine. The low yield of **3** based on **2** was considered the removal of the pyrrolidine interrupted the epimerization during crystallization.

An Examination of the Displacement Reactions in Alkyldicyclohexylborane and Alkyldi-exo-norbornylborane

Hiroaki TANIGUCHI*

Richard B. Wetherill Laboratory, Purdue University West Lafayette, Indiana 47907, USA

(Received February 20, 1979)

Displacements involving the reaction of olefins with alkyldicyclohexylborane and alkyldi-*exo*-norbornylborane were studied. In the case of alkyldicyclohexylborane, the 1-ethylbutyl group could be displaced selectively by 1-decene to produce hexenes. However, the hexyl group could not be displaced selectively, the reaction proceeding to produce both 1-hexene and cyclohexene. In contrast, in the case of alkyldi-*exo*-norbornylborane, the norbornyl group bonded so tightly to the boron atom that it was possible to displace both the 1-ethylbutyl and the hexyl groups selectively and completely by 1-decene with no loss of 2-norbornyl–boron bonds. The results suggest the possibility of contrathermodynamic isomerization of olefins by the combination of "isomerization-displacement" with di-*exo*-norbornylborane.

Organoboranes undergo displacement of contained olefins when they are heated in the presence of another olefin.[1-4]

$$(RCH_2CH_2)_3B + 3R'CH{=}CH_2 \rightleftharpoons 3RCH{=}CH_2\uparrow + (R'CH_2CH_2)_3B$$

Detailed studies of this reaction have been published by Brown and his coworkers using homogeneous trialkyl- or dialkylboranes (R_3B or R_2BH).[5,6]

The displacement reaction is a reversible reaction and can be brought to completion by using an excess of olefin or by removing the displaced olefin from the reaction media by distillation.

The rate of the displacement reaction is essentially independent of the concentration of the displacing olefin.

The rate of displacement varies with the type and structure of the olefin bonded to boron atom.

Results and Discussion

In this study, the displacement reaction involving the organoboranes derived from the hydroboration of several types of olefins with dicyclohexylborane and di-*exo*-norbornylborane has been examined. It was thought to be interest to clarify the displacement reaction with organoboranes which have more than one alkyl group in a molecule in order to confirm which alkyl group is more easily displaced. Such a study would establish the conditions under which only one attached alkyl group could be selectively displaced, making it possible to use repeatedly a particular dialkylboryl unit, such as dicyclohexylboryl- or di-*exo*-norbornyl-boryl-group.

In studying the displacement reaction, it was very difficult to follow on a small scale the reaction process quantitatively by determining the amounts of olefin displaced.

An alternative procedure was adopted. Aliquots of the reaction mixture were removed and oxidized and the decreasing or increasing amounts of alcohols determined by glpc analysis were taken as a measure of the displacement reaction. The following standard procedure was utilized.

A three-necked flask fitted with a thermometer and a side arm closed by rubber septum was attached to a microdistillation system. The olefins were hydroborated using dicyclohexylborane or di-*exo*-norbornylborane, which had been prepared from cyclohexene or norbornene in THF solvent and used *in situ*. Hydroboration was carried out in diglyme or triglyme solution. After the completion of the hydroboration, all THF was removed by vacuum evaporation. Then a 100% excess of 1-decene and calculated amount of the internal standard were added to the reaction mixture. The mixture was rapidly heated to the desired temperature. At appropriate intervals of time, aliquots were withdrawn from the reaction flask and oxidized with alkaline hydrogen peroxide. Alcohols thus produced were taken up in ether and the dried ether extract was analyzed by NMR. The ratio of the original alkyl groups displaced from the organoborane was calculated from the decreasing amount of alcohols found in each aliquot.

During the course of reaction, the displaced olefins were removed from the distillation system into a cooled receiver and the distillate was analyzed by GLPC. A static nitrogen atmosphere was maintained throughout the reaction.

Displacements Involving Hexyldicyclohexylboranes. The displacement reaction with hexyldicyclohexylborane was carried out at different temperatures in the hope that only the hexyl group would be displaced by 1-decene so that the dicyclohexylborane moiety could be used repeatedly. However, it was found that the cyclohexyl group was readily eliminated to generate cyclohexene so that it was not practical to remove the hexyl group selectively. The results are given in Table 1. We see that the hexyl moiety of hexyldicyclohexylborane is displaced a little more easily than cyclohexyl moiety. However, the difference in the rate of displacement is too small to displace only the hexyl group. Both the hexyl and the cyclohexyl groups are displaced almost completely under these conditions and analysis of the decanols by GLPC established that there is no significant loss of boron–hydrogen bond in the process.

The purity of displaced hexene is much more selective at higher temperature than at lower temperature. This indicates that at lower temperature the displacement rate of the hexyl group is low. Consequently, some of

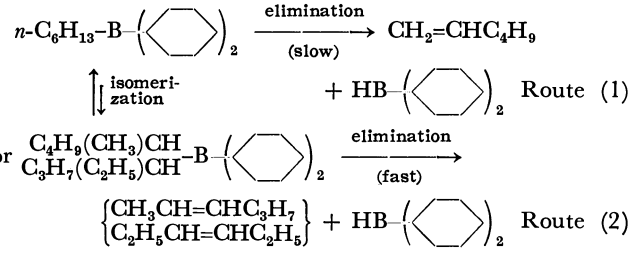
the hexyldicyclohexylborane is isomerized to the isomeric *sec*-hexyldicyclohexylborane and the *sec*-hexyl groups thus formed are much more easily eliminated from the boron atom than the hexyl group. The relationship is illustrated as follows:



At lower temperature, Route 1 is so slow that Route 2 would play an important role.

$C_3H_7(C_2H_5)CH$–B–(cyclo-$C_6H_{11})_2$: It has been established that the secondary alkyl group is displaced much more easily than the normal alkyl group.[6] The displacement reaction with 1-ethylbutyldicyclohexylborane was undertaken in order to compare the displacement rate of the secondary alkyl group with that of the cyclohexyl group. The results are given in Table 2. We see that it is possible to displace the 1-ethylbutyl group selectively. The best results were obtained under the conditions 130 °C for 1—1.5 h in triglyme solvent, more than 94% of the 1-ethylbutyl group being displaced by 1-decene with negligible loss of the cyclohexyl group.

The concentration of 1-hexene in the displaced olefins was very low although under these conditions some isomerization of 1-ethylbutyldicyclohexylborane to hexyldicyclohexylborane would have been expected. The reason must be that the elimination of 1-ethylbutyl group is relatively fast and the dissociated internal hexenes fail to associate again with the dicyclohexylborane because of the faster reason with 1-decene. This behavior is different from that observed in the case of hexyldicyclohexylborane in which only a little of 2- and 3-hexenes were present in the distilled hexenes.

There is a considerable difference in the distribution of the displaced hexenes at different temperatures.

n-*C_6H_{13}–B–(cyclo-$C_6H_{11})_2$*. *Under Neat Conditions*: The displacement reaction with hexyldicyclohexylborane under neat conditions was carried out in the hope that the rate of elimination of the cyclohexyl group would be much smaller in the absence of etheric solvent so that the selective displacement of the hexyl group would be possible. The results are summarized in Table 3 and compared with those of the displacement reaction in diglyme.

It was unexpected that the absence of the etheric solvent failed to decelerate the rate of the displacement reaction (Table 3). It was impossible to displace only the hexyl group under the conditions of a neat reaction.

Cyclopentyldicyclohexylborane. In order to examine which group, cyclopentyl- or cyclohexyl-, is more easily eliminated from the mixed organoborane, the displacement reaction with cyclopentyldicyclohexylborane was

undertaken. The cyclopentyl group is displaced at approximately twice the rate of the cyclohexyl group (Table 4).

Displacement Reaction with Alkyldi-exo-*norbornylborane.* The norbornyl group is so tightly bound to a boron atom that is not displaced by 1-decene under the same conditions as at which displacement of other olefins could proceed.[6] Thus, it was anticipated that treatment of hexyldi-*exo*-norbornylborane with 1-decene might result in selective elimination of the hexyl group. Difficulty in testing this procedure is caused by the relative unavailability of pure dinorbornylborane which cannot be synthesized directly from norbornene and BH_3.[7] Thus crude (71%) di-*exo*-norbornylborane, which can be prepared directly from BH_3 and norbornene, was used.

The best conditions for preparing di-*exo*-norbornylborane directly are as follows. A norbornene solution in THF is added to a BH_3–THF solution in the ratio (norbornene/BH_3)=2.0 at 0 °C and the mixture is stirred at 0 °C for 1 h. On completion of the process, the mixture contained 71% di-*exo*-norbornylborane, 13% tri-*exo*-norbornylborane, 16% BH_3, but no mono-*exo*-norbornylborane.

It might be possible to determine the relative elimination rate of the norbornyl group and other alkyl groups from the data obtained by using the crude di-*exo*-norbornylborane.

			trans-2-Hexene, 3-Hexene	58.6	

a) Initial charge: raw material 10 mmol, 1-decene 60 mmol, solvent (triglyme) 10 ml, internal standard (tridecane) 5.1 mmol.

Hexyldi-exo-*norbornylborane and 1-Ethylbutyldi*-exo-*norbornylborane.* Displacement reaction with hexyldi-*exo*-norbornylborane and 1-ethylbutyldi-*exo*-norbornylborane were carried out to see whether selective displacement of hexyl group is possible in these derivatives (Table 5). It was confirmed that selective displacement of the hexyl group is possible. For example, 90% of the hexyl group was removed with only 2% loss of the norbornyl group by the displacement reaction with hexyldi-*exo*-norbornylborane at 160 °C for 8 h. Even more favorable conditions would be found for complete selective displacement in hexyldi-*exo*-norbornylborane by working at lower temperatures. The results indicate

Table 6. Displacement reaction with cyclohexyldi-*exo*-norbornylborane[a] at 160 °C

Reaction time/h	Displaced ratio of original alkyl group	
	Cyclohexyl %	Norbornyl %
0	0	0
0.5	28	0
1	47	0
2	63	0
4	85	1.7
6	94	14
8	97	11.5

a) Initial charge: cyclohexyldi-*exo*-norbornylborane 10 mmol, 1-decene 60 mmol, solvent (triglyme) 10 ml, internal standard (tridecane) 5.29 mmol.

that the norbornyl group can be eliminated by 1-decene under severe conditions. It was found by means of GLPC analysis of the distilled olefins after 24 h reaction that norbornene is present in a large amount.

Cyclohexyldi-exo-*norbornylborane*. The displacement reaction with cyclohexyldi-*exo*-norbornylborane was carried out to make clear the relative rate of displacement by 1-decene of the cyclohexyl group and the norbornyl group (Table 6). It is evident that the cyclohexyl group can be displaced selectively by 1-decene from cyclohexyldi-*exo*-norbornylborane.

Di-*exo*-norbornylborane is an excellent agent for the contrathermodynamic isomerization of olefin.[8] The isomerization rate was almost the same as that of dicyclohexylborane, the selectivity of the primary position being a little better. It was found that di-*exo*-norbornylborane is an excellent agent for a selective displacement reaction, much better results being expected by using pure di-*exo*-norbornylborane which could be synthesized by indirect methods.

Di-*exo*-norbornylborane is an excellent agent for achieving the movement of a double bond from the interior of a carbon chain to the terminal position of olefins *via* hydroboration-isomerization displacement.

Experimental

Materials. The solvents, olefins and preparation of the BH_3–THF solution have been described.[6] Norbornene (reagent grade, Aldrich Chemical Co.) was used without further purification and stored under nitrogen as a THF solution in a volumetric flask. 1-Decene (Chem Samples Co.) was distilled from lithium aluminum hydride and stored under nitrogen.

Hydroboration-Displacement Experiments. Alkyldicyclohexylborane: After all systems were dried and flushed with nitrogen, 4 ml (10.8 mmol) of BH_3–THF solution (2.70 M) and 10 ml of solvent (diglyme or triglyme) were placed in a 50 ml three-necked flask fitted with a thermometer, a side arm containing a rubber septum and a distillation system, consisting of a Vigreaux column ($2\phi \times 13$ 1 cm), a distillation head, a Liebig condenser, and a receiver which can be cooled in an ice bath, the top of which is connected to a Hg bubbler to maintain a static pressure of nitrogen gas. 2.10 ml (21 mmol) of cyclohexane was added slowly at 0 °C by means of a hypodermic syringe. After addition, the ice bath was removed and the mixture was stirred at room temperature for 2 h. The dicyclohexylborane thus prepared was used *in situ* in subsequent processes.

The reaction mixture, containing precipitated dicyclohexylborane dimer was cooled in an ice bath and 10 mmol of each olefin (directly or as a THF solution) was added dropwise at 0 °C. Stirring was continued at 0 °C for 3 h. The ice bath was then removed and the reaction mixture was stirred overnight (13—15 h) at room temperature in order to complete the reaction.

The flask was connected to a vacuum system at the top of the receiver and almost all of the THF and unreacted olefins were removed from the mixture by vacuum evaporation (35 °C, 10—13 mmHg, 20 min). 11.4 ml (60 mmol) of 1-decene and a measured amount of internal standard (*n*-dodecane or *n*-tridecane) were then added by means of a hypodermic syringe. The flask was dipped into an oil bath, the temperature of which was controlled with an electric temperature controller. At certain time intervals, 1 ml aliquots were withdrawn with a hypodermic syringe, the samples being oxidized by alkaline hydrogen peroxide in the usual manner. The alcohols formed were extracted with 10 ml of ether and dried on K_2CO_3.

The samples were analyzed by gas chromatography (Carbowax 20 M, 10% on Varaport 100/120, 1/8″ × 12 ft, FID). During the course of displacement reaction, the displaced olefin was collected into an ice-cooled receiver, and the distribution of isomers of displaced olefins was analyzed by gas chromatography. During the entire operation, the system was maintained under a static pressure of nitrogen gas.

Alkyldi-exo-*norbornylborane*: A 4 ml sample of BH_3–THF solution (10.7 mmol) was placed in a 50 ml three-necked flask and cooled in an ice bath. A 6.69 ml (21.4 mmol) of norbornene–THF solution (3.20 M) was added slowly at 0 °C by means of a hypodermic syringe and the mixture was maintained at 0 °C for 1 h. Crude di-*exo*-norbornylborane solution was used *in situ* in subsequent processes. 10 ml of each of the olefins and 10 ml of solvent (diglyme or triglyme) were added slowly at 0 °C to the mixture. The same procedure as that for monoalkyldicyclohexylborane then followed.

The author wishes to express his gratitude to Professor Herbert C. Brown for his guidance and encouragement.

Distribution of Alkylboranes in the Reaction of Norbornene and Cyclopentene with Borane-THF

Hiroaki TANIGUCHI*

Richard B. Wetherill Laboratory, Purdue University, West Lafayette, Indiana 47902, USA

(Received February 28, 1979)

Systematic studies of the partial alkylation of diborane with norbornene and cyclopentene were carried out in THF and the equilibrium distribution of the borane derivatives was determined. Di-*exo*-norbornylborane was obtained in 71% yield with no mono-*exo*-norbornylborane as a by-product, under the conditions: initial ratio of norbornene to borane 2: 1, temperature 0 °C and reaction time 1 h. Mono-*exo*-norbornylborane was obtained in 72—75% yield under the conditions: initial ratio of norbornene to borane 1: 1, temperature 25 °C, and reaction time 48 h. In the dialkylborane $[R_2BH]_2$, norbornene and cyclopentene exhibit very different behavior during the course of equilibration reaction.

Di-*exo*-norbornylborane is promising as a new agent for the contrathermodynamic isomerization of olefins.[1] It is desirable to find a simple synthetic route for this dialkylborane.

The easiest route to obtain the disubstituted boranes would be the partial alkylation of BH_3, but direct partial alkylation of BH_3 by norbornene does not seem to have been studied. It is possible to obtain a mixture of BH_3, RBH_2, R_2BH, and R_3B from the direct reaction of 2 mol olefin and 1 mol BH_3, but not pure dialkylboranes.[2] However, pure dialkylboranes such as bis(1,2-dimethylpropyl)borane and dicyclohexylborane can be obtained from some special types of hindered olefins.[3] A complete study of the composition or the equilibrium distribution realized in the partial alkylation of diborane with different types of olefins does not seem to have been carried out. I herewith report a systematic study on the partial alkylation of diborane with norbornene, cyclopentene being considered as a comparable raw material.

Results and Discussion

Kinetic Study of Partial Alkylation. (1) Partial Alkylation of Diborane with Norbornene and Cyclopentene in THF at 0 °C: Partial alkylation of BH_3 with norbornene in the ratios 1: 1, 1: 2, and 1: 3 was carried out at 0 °C.

A solution of norbornene in THF was slowly added to a solution of diborane in THF at 0 °C. After 1 h, excess methanol was added and the amounts of methyl borate $[B(OCH_3)_3]$, dimethoxy-*exo*-norbornylborane methoxy-di-*exo*-norbornylborane obtained were determined by titration and NMR analysis. The amounts of tri-*exo*-norbornylborane were calculated from the difference between the theoretical amounts of the borane compounds found and the sum of the amounts of the rest three boron derivatives found. Partial alkylation of BH_3 with cyclopentene under the same conditions was also undertaken to clearify the influence of the particular olefin and to compare results with the data obtained by Brown *et al.*[2] The results are summarized in Table 1.

We see that the derivative of the alkylboranes formed is dialkylborane $[R_2BH]$. Under mild conditions it is possible to obtain R_2BH as the main product of both the 1: 1 and 1: 2 ratio reaction mixtures. This could be accounted for as follows: RBH_2 exists neither as a complex with other alkylboranes nor THF, but exists either free or as a very weak complex reacting much faster than BH_3 which undergoes fairly strong complexation with THF. On the other hand, R_2BH sould form a relatively stable dimer  . The rate of reaction of this dimer with olefin should be smaller than that of the corresponding dimer of monoalkylborane.

The difference between norbornene and cyclopentene is not remarkable but appreciable. In the case of norbornene, it is possible to obtain alkylborane products containing no RBH_2. If the reaction is to be used for synthesis, this undesirable by-product should be avoided.

The data differ considerably from those obtained in the earlier study.[2] Cause of this difference might be due to the difference in analytical procedure. The amounts of the alkylborane derivatives were determined by distillation of the methoxyalkylboranes formed after methanolysis of reaction products. It was found that methoxyalkylboranes can easily undergo redistribution at higher temperature.[4] In the present procedure, NMR analysis was carried out for the methanolyzed product, no high temperature treatment being involved.

The conditions for these experiments were too mild to complete the hydroboration of norbornene. Thus in Expt. H-60 (Table 1) large amounts of R_2BH and unreacted norbornene remained in the reaction mixture.

(2) Partial Alkylation of Diborane with Norbornene and Cyclopentene in THF at Room Temperature: Interesting results were obtained in the kinetic study of partial alkylation. Partial alkylation reactions were carried out at 25—28 °C for 24 h. Olefins were added to the BH_3–THF solution at 0 °C, and the reaction mixture was left to stand at room temperature for 24 h with stirring. Excess methanol was added, the same analytical procedure as that given in (1) being applied. The results are summarized in Table 2.

RBH_2 is obtained as the main product in the reaction at the ratio 1: 1, indicating the complex $[(R_2BH)_2]$, which is evidently formed initially, undergoes rearrangement during the course of longer reaction time at higher temperature to produce RBH_2.

$$R_2BH + BH_3 \rightleftharpoons 2RBH_2$$

The most evident difference between norbornene and cyclopentene is the disparity in the (RBH_2/R_2BH) ratio in the 1:1 reaction. The (RBH_2/R_2BH) ratio in norbornene is 3:4 (Expt. H-65). In contrast, the (RBH_2/R_2BH) ratio in cyclopentene is only 1:4—1:5 (Expt. H-58, H-70). This indicates that the stability of the (dicyclopentylborane)$_2$ complex is much higher than that of (di-*exo*-norbornylborane)$_2$ complex. A possible reason could be the difference in the steric hindrance of the two alkyl groups with large steric requirement of norbornyl group in the dimer decreasing the stability of $(R_2BH)_2$. In the 1:3 mixture of BH_3 and norbornene, the reaction proceeds almost completely to form the trialkylborane.

Thermodynamic Study of Partial Alkylation. Equilibration of BH_3–Norbornene and BH_3–Cyclopentene System in THF at Room Temperature: The reaction of BH_3 and norbornene or cyclopentene in THF was studied at room temperature in order to estimate the approximate rate of equilibration and the composition at equilibrium. The equilibration reaction was carried out using two kinds of starting materials in order to confirm that the attained composition was that of true equilibrium mixture: distribution of the kinetic mixture from BH_3 and olefin, redistribution of trialkylborane with borane. It was confirmed that the same equilibrium distribution is attained from both combinations of starting materials.

In the experiments using (BH_3+olefin) as the starting materials, the addition of olefin to BH_3–THF solution was carried out at 0 °C by the usual method, the reaction mixtures being stirred at room temperature. 1/10 aliquots were taken out at appropriate intervals and analyzed.

In the experiments using (R_3B+BH_3) as the starting material, R_3B was synthesized first by the reaction of BH_3 with olefin in 1:3 ratio at room temperature for 1 h and BH_3 was added to the solution of R_3B in THF at 0 °C. The reaction mixtures were allowed to stand at room temperature and the same sampling procedure was carried out. Representative results are shown graphically in Figs. 1—5. Data of the equilibrium

Table 3. Equilibrium distribution of the partial alkylation of diborane with cyclopentene and norbornene at room temperature in THF

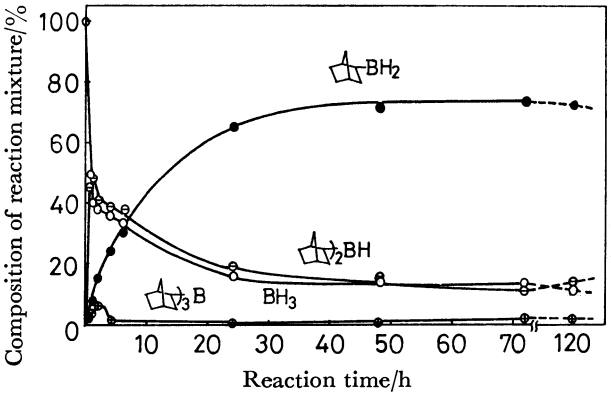

Fig. 1. The equilibration of BH_3+norbornene (1: 1)⟶ in THF solution at R.T.

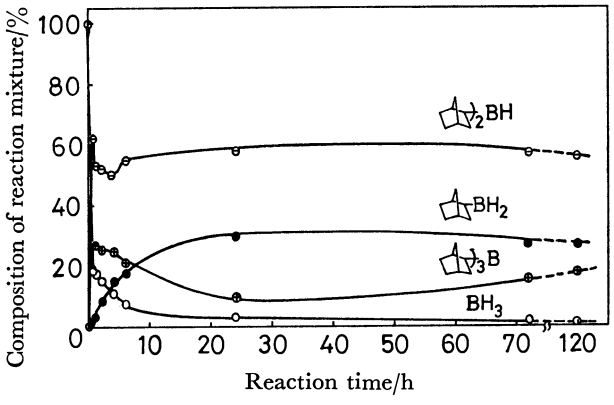

Fig. 2. The equilibration of BH_3+norbornene (1: 2)⟶ in THF solution at R.T.

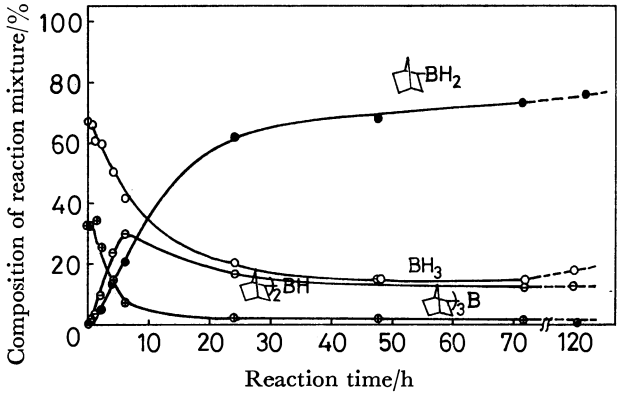

Fig. 3. The equilibration of tri-*exo*-norbornylborane +BH_3 (1: 2)⟶ in THF solution at R. T.

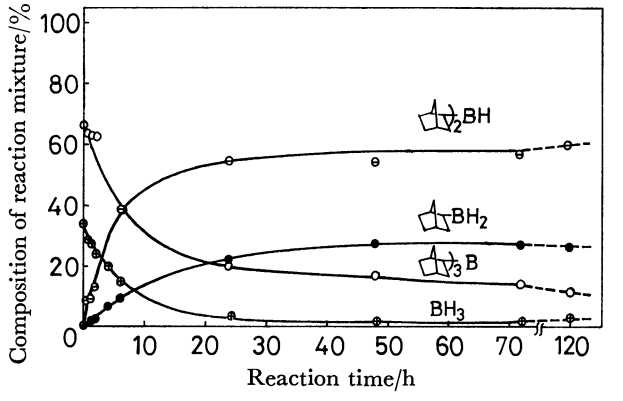

Fig. 4. The equilibration of tri-*exo*-norbornylborane +BH_3 (2: 1)⟶ in THF solution at R. T.

distributions are summerized in Table 3.

We see that the distribution of the borane products from borane and olefin and that from borane and trialkylborane of the same (olefin: BH_3) ratio are almost the same, indicating they are true equilibrium distributions. In the (olefin: BH_3) ratio=2, the composition of the equilibrium is almost the same in both norbornene and cyclopentene. On the other hand, in the (olefin: BH_3) ratio=1, it is quite different, indicating that the stabilities of the $(R_2BH)_2$ complexes of these two olefins differ considerably. The main route to give RBH_2 is postulated to be as follows.

(i) Starting material: Olefin+BH_3

$$BH_3 + 2\text{Olefin} \xrightarrow{\text{fast}} R_2BH$$

$$R_2BH + BH_3 \xrightarrow{\text{slow}} 2RBH_2$$

(ii) Starting material: R_3B+BH_3

(ii-a) $R_3B + BH_3 \rightleftharpoons$ 
$\longrightarrow R_2BH + RBH_2$

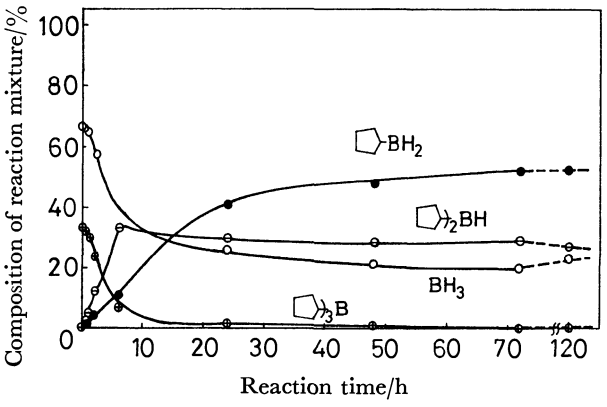

Fig. 5. The equilibration of tricyclopentylborane+BH_3 (1:2)→ in THF solution at R. T.

(ii-b) $R_2BH + BH_3 \rightleftharpoons$  $\rightleftharpoons$  $\longrightarrow 2RBH_2$

In the case of norbornene (Fig. 3), the rate of (ii-b) reaction should be much smaller than that of cyclopentene (Fig. 5).

Mono-*exo*-norbornylborane can be synthesized in 72—75% yield by the reaction of norbornene and BH_3 in 1:1 ratio at room temperature for 40 h.

Experimental

Materials. Norbornene (reagent grade, Aldrich Chemical Co.), mesitylene (Coleman and Bell Co.) for the internal standard of NMR analysis and methanol (Mallinckrodt Chemical Works) for the methanolysis of products were used without further purification. Cyclopentene (Phillips Petroleum Co.) was distilled from lithium aluminum hydride and stored under nitrogen. The other reagents were the same as those used by Brown *et al.*[2]

Partial Alkylation of BH_3 with Olefin at 0 °C. Experiments were carried out with use of a 100-ml 2-necked round-bottom flask fitted with a reflux condenser which was connected with glass stopcock and a bubbling gas outlet at the top and a side arm fitted with a rubber cap to permit the flushing of all systems with nitrogen before the reaction.

A solution of 10 mmol, 20 mmol, or 30 mmol norbornene in THF (2.20 M) was added to a solution of 10 mmol of BH_3 in THF (2.69 M) at 0 °C over a period of 13 min.

The reaction was carried out at 0 °C for 1 h. The ice bath was then removed and methanol (50—100% excess) was added dropwise at room temperature. Stirring was continued for 10 min, and all the hydrogen gas generated during the course of methanolysis was collected into the gas burrette and measured. The solvent (THF), excess MeOH, and methylborate [$B(OCH_3)_3$] were removed by vacuum distillation (30—35 °C, 15—13 mmHg, 20 min) and trapped with a Dry Ice bath. The trapped mixture was analyzed for boric acid by titration with standard sodium hydroxide in the presence of 10 mmol of mannitol.

The residue containing dimethoxy-*exo*-norbornylborane, methoxy-di-*exo*-norbornylborane, and tri-*exo*-norbornylborane was analyzed by NMR. The amounts of mono- and di-*exo*-norbornylborane could be estimated. The amount of tri-*exo*-norbornylborane was calculated as the difference of the sum of the initial borane and the amounts of $B(OCH_3)_3$, $RB(OCH_3)_2$, $R_2B(OCH_3)$ found.

Equilibration of BH_3 and Olefin (1: 1 or 1: 2). 80 mmol of norbornene in 26 ml of THF was added slowly to a stirred solution of 80 mmol (2.69 M) BH_3–THF solution at 0 °C over a period of 13 min. The ice bath was then removed and the reaction mixture was stirred at room temperature.

At certain intervals, 1/10 aliquots were withdrawn with a hypodermic syringe, weighed and put into a 50-ml two-necked flask fitted with a reflux condenser and a side arm for a rubber cap purged with nitrogen, subsequent treatment being the same as described above.

Equilibration of BH_3 and R_3B. 90 mmol of norbornene in 20 ml of THF was added slowly to a stirred solution of 30 mmol BH_3–THF at 0 °C over a period of 13 min. The reaction mixture was kept at room temperature for 1 h to complete the formation of tri-*exo*-norbornylborane. The mixture was then cooled in an ice bath to 0 °C and 15 mmol of BH_3–THF solution was added dropwise to the mixture. The ice bath was removed and the reaction mixture was stirred at room temperature. At certain time intervals, 1/10 aliquots were withdrawn with a syringe, subsequent treatment being the same as described above.

NMR Analysis. The methoxyl protons of $RB(OCH_3)_2$ and $R_2B(OCH_3)$ have a sharp singlet peak. The contents of these compounds in the residue were measured by use of mesitylene as an internal standard. It has a sharp singlet peak of benzene proton at $\delta=6.67$, no absorption at $\delta=3$—4. The experiments were carried out in nitrogen. NMR spectral data are given in Table 4.

Table 4. NMR spectral data

Methoxy borane	δ/ppm
Methoxydi-*exo*-norbornylborane	3.61
Dimethoxy-*exo*-norbornylborane	3.50
Methoxydicyclopentylborane	3.65
Dimethoxycyclopentylborane	3.52

The author wishes to express his sincere thanks to Prof. Herbert C. Brown for his guidance throughout the course of this study.

The Synthesis of 5,2′-Dihydroxy-6,8-dimethoxyflavone and Its Isomers: A Revised Structure of Skullcapflavone I

Tokunaru HORIE,* Masao TSUKAYAMA,** Mitsuo MASUMURA,**
Mitsuru NAKAYAMA,*** and Shûichi HAYASHI***

Technical College, Tokushima University, Minamijosanjima-cho, Tokushima 770

(Received February 20, 1979)

5,2′-Dihydroxy-6,8-dimethoxyflavone, which had been proposed as the structure of skullcapflavone I isolated from *Scutellaria baicalensis* Georgi, was synthesized from 2-hydroxy-3,5,6-trimethoxyacetophenone. However, the synthetic flavone was not identical with the natural flavone. Thus, two isomeric flavones, 5,2′-dihydroxy-7,8-dimethoxyflavone and 5,2′-dihydroxy-6,7-dimethoxyflavone, were prepared from the corresponding acetophenones; the structure of skullcapflavone I was confirmed to be 5,2′-dihydroxy-7,8-dimethoxyflavone.

Skullcapflavone I has recently been isolated from roots of *Scutellaria baicalensis* Georgi, along with skullcapflavone II; its structure has been proposed as 5,2′-dihydroxy-6,8-dimethoxyflavone (**1**) on the basis of the spectroscopic data and degradative studies.[1] The properties of skullcapflavone I are not, however, consistent with those of 5,2′-dihydroxy-6,8-dimethoxyflavone (**1**) synthesized from 2-hydroxy-3,5,6-trimethoxyacetophenone (**7**). Therefore, two isomers of **1**, 5,2′-dihydroxy-7,8-dimethoxyflavone (**2**) and 5,2′-dihydroxy-6,7-dimethoxyflavone (**3**), were prepared in order to confirm the structure of skullcapflavone I; consequently, the properties of the former were thus found to be identical with those of skullcapflavone I. We wish now to report that the structure of natural skullcapflavone I is 5,2′-dihydroxy-7,8-dimethoxyflavone (**2**).

1,3-Diacetyl-2,5,6-trimethoxybenzene (**4**)[2] was oxidized with 30% hydrogen peroxide in a mixture of acetic acid and concentrated sulfuric acid; the hydrolysis of the resultant compound gave 3-hydroxy-2,5,6-trimethoxyacetophenone (**5**). The acetophenone **5** was converted into the methyl ether (**6**) and was then demethylated with anhydrous aluminum chloride in ether to give 2-hydroxy-3,5,6-trimethoxyacetophenone (**7**). After the condensation of **7** with 2-benzyloxybenzoyl chloride, the debenzylated diketone (**8**) was obtained by the Baker-Venkataraman rearrangement. The compound **8** was cyclized with anhydrous sodium acetate in acetic acid to yield a 2′-hydroxyflavone derivative (**9**), which was then converted with anhydrous aluminum chloride in acetonitrile into 5,2′-dihydroxy-6,8-dimethoxyflavone (**1**) (mp 246.5—248 °C). The flavone **1** afforded the corresponding diacetate (**10**). The flavone **1** and the diacetate **10** should be consistent with skullcapflavone I and its diacetate respectively, but they were not identical with each other, as is shown in Tables 1 and 2. That is, in the NMR spectra of the acetate of skullcapflavone I and the diacetate **10**, it appears that there is a remarkable difference between the chemical shifts of protons on the A ring of the flavone nucleus, but that other proton signals show very similar chemical shifts. Therefore, it may be assumed that the structure of skullcapflavone I is the isomer of **1**, that is, **2** or **3**.

2′-Hydroxy-5,7,8-trimethoxyflavone (**13**) could not be prepared from the acetophenone (**11**)[3] *via* the corresponding diketone by the method described above. The condensation of the acetophenone **11** with 2-benzyloxybenzaldehyde in the presence of piperidine gave an oily chalcone derivative, which was then converted into a benzyloxyflavone derivative (**12**) by oxidative cyclization with selenium dioxide. The flavone **12** was debenzylated with palladium charcoal to give a hydroxyflavone derivative (**13**) and was then demethylated with anhydrous aluminum chloride in acetonitrile to afford the desired flavone **2** (mp 253—254 °C), which was subsequently converted into the diacetate (**14**). 5,2′-Dihydroxy-6,7-dimethoxyflavone **3** was also synthesized from the acetophenone (**15**)[4] *via* the corresponding chalcone by using the same method as was used in the case of the flavone **2**. The flavone **3** led to the diacetate (**17**).

The physical and spectral data of synthetic flavones and these acetates are listed in Tables 1 and 2. In Tables 1 and 2, the NMR and UV spectral data of skullcapflavone I and its diacetate are shown to be identical with those of the synthetic flavone **2** and the

a) The NMR spectra of 2 and 14 could be superimposed on those of the literature.[1)]

diacetate **14** respectively. The melting point of the flavone **2** was not depressed by admixture with the natural flavone, and the UV spectrum of the flavone **2** was also superimposable on that of the natural flavone. On the basis of these results, the structure of skullcapflavone I was confirmed to be 5,2′-dihydroxy-7,8-dimethoxyflavone **2**, which had previously been proposed as the structure of andrographin isolated from *Andrographis paniculata*.[5)] The flavone **2** has also been produced in differentiating tissue cultures of *Andrographis paniculata*.[6)]

Experimental

All the melting points were determined in glass capillaries and are uncorrected. The NMR spectra were measured with a JEOL PS-100 spectrometer (100 MHz), using tetramethylsilane as the internal standard (δ, ppm). The UV spectra were taken on a Hitachi 124 spectrophotometer.

*2,3,5,6-Tetramethoxyacetophenone (**6**).* 1,3-Diacetyl-2,5,6-trimethoxybenzene (**4**)[2)] (10 g) and concd sulfuric acid (5 ml) were dissolved in acetic acid (5 ml) below 10 °C, and to the solution with stirring was then added dropwise a mixture of 30% hydrogen peroxide (7 g) and acetic acid (10 ml) below 10 °C. The resulting mixture was subsequently stirred for 5 h at room temperature. After the addition of water to the reaction mixture, the mixture was extracted with ether, and the ethereal solution was washed with aqueous sodium carbonate and water. The solvent was evaporated from the ethereal solution to give crude 3-acetoxy-2,5,6-trimethoxyacetophenone.[7)] The acetophenone was hydrolyzed with 10% sodium hydroxide in methanol (50 ml) for 10 min; then, a crude phenol derivative (**5**) (6 g) was obtained by a usual treatment. A mixture of **5** (16 g) and dimethyl sulfate (20 g) was refluxed with anhydrous potassium carbonate (40 g) in anhydrous acetone (65 ml) for 5 h. After water had been added to the mixture, the solvent was removed, and then the residue was extracted with ether. The ethereal solution was washed with 10% aqueous sodium hydroxide and water, and dried. The solvent was removed, and the residue was distilled under reduced pressure to give an acetophenon (**6**) (15.5 g); it solidified at room temperature: bp 108 °C/0.25 mmHg; NMR ($CDCl_3$) δ 2.47 (3H, s, CH_3CO), 3.73 and 3.83 (each 6H, s, OCH_3), 6.51 (1H, s, Arom H). Found: C, 60.02; H, 6.78%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%.

2-Hydroxy-3,5,6-trimethoxyacetophenone (7). A mixture of **6** (5 g) and anhydrous aluminum chloride (5.2 g) in anhydrous ether (40 ml) was stirred for 5 h in an ice bath and then allowed to stand overnight in a refrigerator. The reaction mixture was poured into diluted hydrochloric acid, and the solvent was evaporated to afford a precipitate (**7**), which was subsequently recrystallized from methanol as yellow needles (2.6 g): mp 62—63.5 °C; NMR (DMSO) δ 2.41 (3H, s, CH_3CO), 3.63 (3H, s, OCH_3), 3.76 (6H, s, $OCH_3\times2$), 6.80 (1H, s, Arom H), 9.43 (1H, s, OH). Found: C, 58.48; H, 6.24%. Calcd for $C_{11}H_{14}O_5$: C, 58.40; H, 6.24%.

2-Hydroxy-3,5,6-trimethoxy-ω-(2-hydroxybenzoyl)acetophenone(8). A mixture of **7** (2 g) and 2-benzyloxybenzoyl chloride (3.5 g) was heated in the presence of pyridine (3.5 g) at 100 °C for 5 h, and then the reaction mixture was poured into a mixture of ice and hydrochloric acid. The mixture was extracted with ethyl acetate and treated by a usual method. The solvent was then evaporated, and the residue was dried sufficiently to give a crude ester (3.2 g). The ester was stirred in the presence of freshly powdered potassium hydroxide (3.5 g) in pyridine (10 ml) at 60 °C for 4 h, and then a mixture of ice and hydrochloric acid was added to the mixture. After the mixture had been extracted with ether and treated by a usual method, the ether was evaporated to yield a precipitate (**8**), which was subsequently recrystallized from ethyl acetate as yellow plates (300 mg): mp 140—140.5 °C. Found: C, 62.56; H, 5.35%. Calcd for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24%.

2'-Hydroxy-5,6,8-trimethoxyflavone (9). A mixture of **8** (150 mg) and anhydrous sodium acetate (1 g) in acetic acid (6 ml) was heated for 4 h, and then water was added to the reaction mixture to give a precipitate (**9**), which was subsequently recrystallized from methanol as pale yellow needles (100 mg): mp 231—232 °C; NMR (DMSO) δ 3.66, 3.87, and 3.96 (each 3H, s, OCH_3), 6.9—7.9 (6H, m, Arom H). Found: C, 65.66; H, 4.94%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

5,2'-Dihydroxy-6,8-dimethoxyflavone (1). A mixture of **9** (240 mg) and anhydrous aluminum chloride (0.5 g) in acetonitrile (3 ml) was heated at 80 °C for 4 h, and then 2% aqueous hydrochloric acid was added to the reaction mixture. The mixture was heated on a water bath for 30 min and then allowed to stand at room temperature to give a precipitate (**1**), which was subsequently recrystallized from methanol as yellow needles (200 mg); mp 246.5—248 °C. Found: C, 65.02; H, 4.66%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

The Diacetate (10) of 1. The flavone **1** was converted into a diacetate (**10**) by an acetic anhydride-pyridine method; it was subsequently recrystallized from methanol as colorless prisms; mp 195—196.5 °C. Found: C, 63.41; H, 4.67%. Calcd for $C_{21}H_{18}O_8$: C, 63.31; H, 4.55%.

2'-Benzyloxy-5,7,8-trimethoxyflavone (12). A mixture of 2-hydroxy-3,4,6-trimethoxyacetophenone (**11**)[3] (3.5 g) and 2-benzyloxybenzaldehyde (bp 153—155 °C/1 mmHg) (3.5 g) was refluxed in the presence of piperidine (4.5 g) in ethanol (20 ml) for 7 h; the solvent was then removed under reduced pressure, and the residue was extracted with ethyl acetate. The solution of ethyl acetate was washed with diluted hydrochloric acid and water, and dried. The solvent was evaporated to give a crude chalcone, which was subsequently refluxed in the presence of selenium dioxide (4 g) in 1-pentanol for 22 h. The reaction mixture was filtered out, and the filtrate was condensed sufficiently under reduced pressure. The residue was extracted with ethyl acetate, and the extract was washed with aqueous sodium carbonate solution and diluted hydrochloric acid, and dried. After the removal of the solvent, the residue was solidified in a small amount of ether and the solid was recrystallized from ethyl acetate as yellow prisms of **12** (2.6 g): mp 145.5—146.5 °C. Found: C, 71.52; H, 5.23%. Calcd for $C_{23}H_{22}O_6$: C, 71.76; H, 5.30%.

2'-Hydroxy-5,7,8-trimethoxyflavone (13). The flavone **12** (1.01 g) was hydrogenated over palladium on charcoal (10%; 190 mg) in methanol until the uptake of hydrogen ceased. The solvent was then removed under reduced pressure, and the residue was recrystallized from methanol to give yellow needles (**13**) (744 mg): mp >270 °C. Found: C, 65.82; H, 4.91%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

5,2'-Dihydroxy-7,8-dimethoxyflavone (2). The flavone **13** (147 mg) was heated with anhydrous aluminum chloride (0.4 g) in acetonitrile (1 ml) at 80 °C for 2.5 h. The mixture was then heated with diluted hydrochloric acid (15 ml) for 3 min on a water bath to give a precipitate (**2**), which was subsequently recrystallized from methanol to give yellow needles (118 mg): mp 253—254 °C. Found: C, 64.69; H, 4.43%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

The Diacetate (14) of 2. The flavone **2** was converted into a diacetate (**14**) as colorless needles: mp 135—136 °C. Found: C, 63.08; H, 4.51%. Calcd for $C_{21}H_{18}O_8$: C, 63.31; H, 4.55%.

2'-Hydroxy-5,6,7-trimethoxyflavone (16). A mixture of 2-hydroxy-4,5,6-trimethoxyacetophenone (**15**)[4] (1.1 g) and 2-benzyloxybenzaldehyde (1.15 g) was refluxed in the presence of piperidine (1.2 ml) in ethanol (8 ml) for 7 h, and then the reaction mixture was worked-up in the same manner as in the case of **12** to give an oily chalcone. After the chalcone had been treated with selenium dioxide (1.5 g) in 1-pentanol for 20 h to afford an oily flavone, the oily compound was chromatographed over a polyamide column with methanol. The eluate containing the major product was again chromatographed over a silica-gel column with chloroform to give a yellow oily compound (1 g). This oily compound was treated with palladium on charcoal to give a precipitate (**16**), which was subsequently recrystallized from methanol as colorless prisms (550 mg): mp 241—242 °C. Found: C, 65.69; H, 4.85%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

5,2'-Dihydroxy-6,7-dimethoxyflavone (3). A mixture of **16** (100 mg) and anhydrous aluminum chloride (0.3 g) in acetonitrile (1 ml) was heated at 70 °C for 2 h, and then the reaction mixture was worked-up in the same manner as in the case of **1** to give a precipitate, which was subsequently recrystallized from methanol as pale yellow needles (**3**) (52 mg): mp 254—255 °C. Found: C, 64.99; H, 4.40%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

The Diacetate (17) of 3. The flavone **3** was converted into a diacetate (**17**), which was then recrystallized from aqueous methanol as colorless plates: mp 145—146 °C. Found: C, 63.25; H, 4.46%. Calcd for $C_{21}H_{18}O_8$: C, 63.31; H, 4.55%.

The authors are grateful to professor Michio Takido, Department of Pharmacy, College of Science and Technology, Nihon University, for the sample of natural skullcapflavone I.

(Received February 28, 1979)

The crystal structure of tryptamine: adenin-9-ylacetic acid (1 : 1) hemihydrate complex has been determined by the X-ray method. The crystal is monoclinic, space group $P2_1/c$ with unit-cell dimensions: $a=9.164(2)$, $b=6.908(1)$, $c=29.524(4)$ Å and $\beta=110.98(2)°$. The structure was solved by application of MULTAN and refined by the block-diagonal least-squares method to give a final R-value of 0.064. No specific interaction between indole and adenine rings is observed. Both component molecules are held together by three-dimensional frameworks of hydrogen bonds around a twofold screw axis to form an infinite helical array along the b-direction. Two kinds of dimer formation around a center of symmetry are observed between adenin-9-ylacetic acid molecules.

In previous communications, reports were given on the crystal structures of 1-methyl-3-carbamoylpyridinium: indole-3-acetic acid (1 : 1) complex[1] and 7,8-dimethyl-isoalloxazine-10-acetic acid: tryptamine (1 : 1) complex[2] selected as suitable models for indole–NAD^+ and indole–FAD interaction, respectively.

Prominent stacking of indole–pyridinium or indole–isoalloxazine rings by charge-transfer interactions was observed. However, when we compare the spectroscopic data of these model complexes with those of indole–NAD^+ and the indole–FAD complexes, we see that there is a slight difference in the association constant and λ_{max} of charge-transfer band.

We thus synthesized the title complex. The present paper deals with crystal structure analysis of the complex which may provide further insight into intermolecular stacking interaction of indole–adenine rings suggested from spectroscopic studies.[3–12]

Experimental

Potassium adenin-9-ylacetate was synthesized according to the reported procedure.[13] Its aqueous solution was absorbed to the Amberlite-IRA-401 anion-exchange resin (OH-type) column, and eluted with an equimolar aqueous solution of tryptamine hydrochloride. Transparent platelet crystals were obtained by slow evaporation of the elute at room temperature.

The UV spectra and thermal analysis of the crystals indicated a one-to-one stoichiometry of adenin-9-ylacetic acid (AAA) and tryptamine (TPA) with a halfmolar water molecule.

Oscillation and Weissenberg photographs showed the space group to be $P2_1/c$. The density was measured by the floatation method in a benzene–carbon tetrachloride mixture. The cell dimensions were refined by the least-squares method, using 30 reflections measured on a Rigaku-Denki automatic four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The crystal data are given in Table 1.

Intensity data were collected on a diffractometer with the same radiation using $\omega/2\theta$ scanning technique within $\sin\theta/\lambda$ less than 0.55 Å^{-1} with scan speed 4°/min, and background being measured for 5s. A total of 2431 independent reflections were corrected for Lorentz and polarization factors, but not for absorption because of the smallness of the crystal (dimension: 0.3×0.3×0.4 mm). The intensities of three standard reflections, measured every 50 reflections, showed no deterioration during the course of data collection.

TABLE 1. CRYSTAL DATA OF TPA: AAA(1 : 1) COMPLEX

All the numerical calculations were carried out on an NEAC-2200-700 computer of the Computation Center of Osaka University using "UNICS" program (1973).[14] Atomic scattering factors cited in "International Tables for X-Ray Crystallography"[15] were used.

Determination and Refinement of the Structure

The structure was solved by the direct method with the program MULTAN[16] using 493 reflections with $|E|\geqq 1.20$. An E-map computed with the phase set of the highest figure of merit (1.249) revealed the positions of all non-hydrogen atoms except a water molecule. At the stage $R=0.143$, a difference Fourier synthesis gave two peaks related by a center of symmetry at (0,1/2,0) which could be assigned to the disordered oxygen atoms of the water molecules (occupancy: 1/2 per one peak), and nineteen hydrogen atoms other than those of the water molecule. The final block-diagonal least-squares refinement was computed with the following weighting scheme: $w=0.30$ for $F_o=0.0$, $w=1.0$ for $0<F_o\leqq 21.0$ and $w=1.0/[1.0+0.263(F_o-21.0)]$ for $F_o>21.0$. In the last cycle of refinement, none of the positional parameters shifted more than one-fourth of

the planes. The torsion angles are given in Table 7. The bond lengths and angles of the adenine ring agree with those found in related compounds within their standard deviations.[18] The purine base is planar with a maximum deviation of 0.024 Å for AN3. The bond parameters for the carboxyl group are also within their expected ranges as having no hydrogen atom, the group being almost planar and at approximately right angles to the purine base (dihedral angle=78.0°). The molecular conformation of AAA with the torsion angle, τ and ω, is very similar to one of the same molecule determined by Voet[19] (τ=84.3°, ω=7.7°), both molecules lying in (+)clinal and synperiplanar for τ and ω, respectively.

The bond lengths and angles of the TPA molecule agree with the values found in the crystal structures of the other TPA molecules: TPA,[20] TPA picrate,[21] TPA hydrochloride,[22] TPA phenylacetate,[23] TPA thymine-1-ylacetate,[24] and TPA 7,8-dimethylisoalloxazine-10-acetate.[2] The indole ring is also planar with a maximum shift of 0.025 Å for TC8, the dihedral angle between the indole ring and the aminoethyl group being 74.6°. Three hydrogen atoms (TH12A—TH12C) found in the difference map are tetrahedrally bound to TN12, indicating the amino group to be in a cationic $-NH_3^+$ form. The conformation of the TPA molecule in this crystal is similar to the hitherto analysed TPA molecules except thymine-1-ylacetate. The conformation having the torsion angles, χ and ϕ, in (+)anticlinal and in (−)synclinal regions, respectively, is thought to be the most stable one.[20]

Crystal Structure. The crystal structure projected along the b-axis is shown in Fig. 2. The intermolecular distances and angles for the hydrogen bonds and the

short contacts less than 3.5 Å are given in Table 8.

In the crystal, the complex formation is mainly due to the salt bridge between the amino and carboxyl groups. Both the molecules are linked by the hydrogen bonds of the amino nitrogen atom(TN12) to the carboxyl oxygen atom(AO12 and AO13), which are formed around a twofold screw axis, AO13 participating further

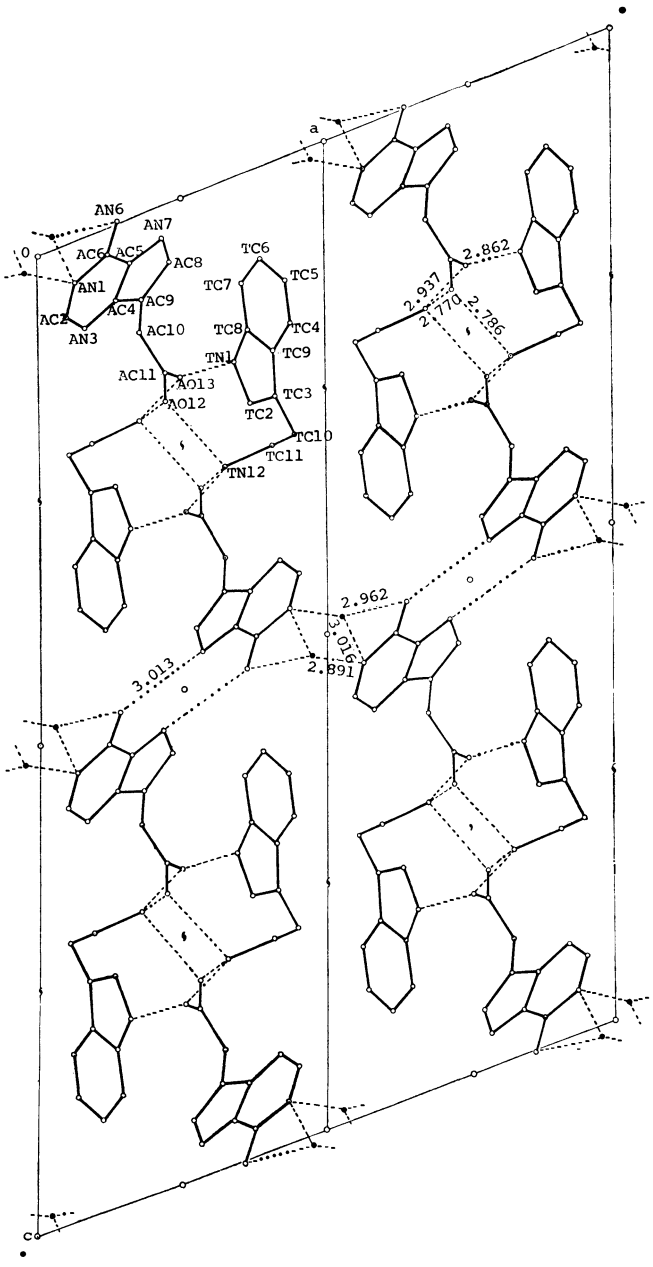

Fig. 2. The crystal structure viewed along the b-axis.

in a hydrogen bond with TN1 of the indole ring, which may strengthen the salt bridge formation. The complex molecules form an infinite helical array with two complex pairs per turn (Fig. 3). The packing mode is found frequently in the crystal structures of the complex formed by a salt bridge between the acid and amine components, such as the 5-methoxytryptamine: 5-methoxyindole-3-acetic acid (1 : 1) complex,[25] 5-methoxytryptamine: indole-3-acetic acid (1 : 1) complex,[25] TPA: phenylacetic acid (1 : 1) complex[23] and TPA: thymine-1-ylacetic acid (1 : 1) complex.[24]

On the other hand, AAA molecule is further linked by two kinds of hydrogen-bonding schemes with the neighboring AAA molecules related by a center of symmetry. One is a linkage by two identical hydrogen bonds of AN6 to AN7. This kind of dimer formation is frequently observed in adenine derivatives.[19,26–29] The

other is the bond to the disordered crystal water (AN1··· O(H_2O)). The water molecule is not located on a center of symmetry, but found at two equally disordered positions separated from a center of symmetry by 0.715 Å. The water molecule is further hydrogen bonded to AN6.

The dihedral angle between the indole and adenine rings is at approximately right angles (72.7°). Neither hydrogen bond nor short contacts less than 3.5 Å exist between both rings. Contrary to our expectation, there is no specific interaction between the indole and adenine rings in this complex, whereas the interaction through the hydrogen bond is observed in the related crystal structures.[30,31] The hydrogen bonds between the carboxyl and amino groups might be preferable to any specific interaction of indole–adenine rings.

New Applications of Crown Ethers. I. Primary Alkylamine-Water-Crown Ether System as a Hydroxide Ion Source in the Reduction with Carbonylhydridoferrate Anion

Fumio WADA,* Ryoji ISHIHARA, Yasufumi KAMOHARA, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 1, 1979)

Utility of the primary alkylamine–water–crown ether system as an effective source of hydroxide ion was studied by the reduction of benzylideneacetone with carbonylhydridoferrate anion. Excellent conversion and selectivity for the reduction were attained in a two-phase system (benzene–water) in the presence of dicyclohexano-18-crown-6, comparable to those obtained with use of potassium hydroxide in place of the amine. Effects of several alkylamines and crown ethers were presented. IR examination of pentacarbonyliron–butylamine–water in benzene with or without the crown ether showed that the presence of the crown ether markedly alters the route of formation of the reducing agent(s).

The macrocyclic polyethers (crown ethers) form stable complexes with alkali and alkaline earth metal cations as well as primary alkylammonium ions. The chemistry of the ammonium salt complexes was investigated in detail by Cram and his collaborators.[1] They utilized the nature of the complexes as a novel method for optical resolution of amino acids.[2]

Primary alkylamine in water is in equilibrium as shown by Eq. 1. When an alkylammonium hydroxide is brought into formation of a complex (**1**) with a crown ether, the equilibrium would shift to the right, and in a two phase, *e.g.* benzene and water, the resulting complex could be transferred to the organic phase to greater extent. The phenomenon can be considered to be production of an increased concentration of hydroxide ion from an alkylamine and water, especially in the organic phase.

$$RNH_2 + H_2O \rightleftharpoons \overset{+}{R}NH_3\,OH^- \quad (1)$$

$$\overset{+}{R}NH_3\,OH^- + \text{crown ether} \rightleftharpoons [\overset{+}{R}NH_3 \cdot \text{crown ether}]\,OH^- \quad (2)$$

1

The postulate led us to study the use of primary alkylamine–water–crown ether system as a source of hydroxide ion in organic reactions.

Pentacarbonyliron and its polynuclear homologs can be converted into carbonylhydridoferrate anions ($HFe(CO)_4^-$ from $Fe(CO)_5$) by the action of a strong base. The hydrido anions have been used in the selective reduction of activated double bonds.[3] This paper reports on the use of primary alkylamine–water–crown ether combination as an effective alkali in the hydrido anion reduction. Unsaturated esters (acrylates or cinnamates) could be reduced by the reduction system, but side reactions such as transamination and Michael addition as well as hydrolysis are involved, thus affording unreproducible results. Benzylideneacetone was selected as an adequate substrate, although its reduction was also accompanied by Michael addition. The present study was undertaken in order to confirm the possibility of suppression of the side reaction by a technique consisting of phase-transfer effect and enhancement of hydroxide ion activity.

Results and Discussion

Effect of Dicyclohexano-18-crown-6 (DC18C6). Benzylideneacetone (1 mmol) was allowed to react with a reduction system, butylamine(2 mmol)–water(0.5 ml)–$Fe(CO)_5$(4 mmol)–benzene(2 ml), at 25 °C under vigorous stirring for 24 h. GLC analysis of the product in the benzene layer showed a 77% consumption(conversion) of the substrate and 22% formation of 4-phenyl-2-butanone (based on benzylideneacetone reacted; selectivity). The balance represents the extent of side reaction. Two of the by-product A and B were observed in the ratio 9: 1. Treatment of benzylideneacetone with 2 molar excess of butylamine in benzene gave the main by-product which coincided with peak A and was considered to be the Michael adduct. Attempt to isolate the two peaks from the reduction mixture for structural identification by preparative GLC was unsuccessful because of decomposition of the components during the course of separation. The results of the reduction under various conditions are summarized in

a) Reaction conditions: benzalacetone, 1 mmol; crown ether (CE), 1 mmol; base, 2 mmol, at 25 °C. b) Determined by GLC.

Table 1. When an equimolar amount of DC18C6 was added, the reduction of benzylideneacetone proceeded to give 100% conversion and 88% selectivity. The result is nearly comparable to that obtained with $Fe(CO)_5$–KOH–DC18C6 combination (Run 5, Table 1), and evidences pronounced effect of the crown ether addition. The expected phase-transfer effect in the present system is also observed in the $Fe(CO)_5$–KOH combination. Other weak bases, K_2CO_3 and CH_3CO_2K, can also act as a hydroxide ion source in the presence of DC18C6, though less effectively in the latter. Fedoryński *et al.*[4] recently reported that a combination of K_2CO_3 and a crown ether in non-polar solvents can be used effectively for generating carbanions from active methylene compounds in a solid-liquid system.

Effect of Structures of Primary Alkylamines and Crown Ethers. The stability of primary alkylammonium ion–crown ether complexes depends on the structure of the amines, and steric bulk of the alkyl groups is an important factor.[5] The steric effect was examined with the use of *t*-butylamine in the reduction. Its use in place of butylamine gave a low conversion as expected, but selectivity for reduction was considerably high even in the absence of DC18C6. The low conversion could be much improved by the addition of the crown ether, accompanied by increase in selectivity. The high selectivity obtained with the tertiary-amine under both conditions can be interpreted by the decrease in nucleophilic function of the amine due to the bulky *t*-butyl group. Octylamine was more efficient than butylamine for the reduction probably because of an increase of its solubility and the resulting increase of hydroxide ion concentration in the benzene layer even in the absence of the crown ether. However, the increase of solubility of the amine seems to cause an increase of Michael adduct leading to a lower selectivity.

18-Crown-6(18C6) is a more favorable complexing agent to alkylammonium salts than DC18C6. However, it gave no improvement in both conversion and selectivity as compared to the latter. This might be attributed to a larger solubility of 18C6 and its ammonium ion complex in water. Benzocrown ethers, benzo-18-crown-6 and dibenzo-18-crown-6, were less efficient than 18C6. This indicates that conversion and selectivity in the present reduction depend not only on the stability of **1** but also on solubilities of **1** and free amines in the benzene layer.

Routes of the Formation of Reducing Agent. In the present reduction, reducing agents are considered to be $HFe(CO)_4^-$ and $HFe_2(CO)_8^-$ which might be formed from the mononuclear anion under the reaction conditions. Collman *et al.*[3d] reported that $Na^+HFe_2(CO)_8^-$ is more reactive (>26 times) than $Na^+HFe(CO)_4^-$ in the reduction of activated double bonds in THF. A qualitative examination for the presence of the reagents and also for the effect of DC18C6 on their formation was made by IR measurement.[6] When $Fe(CO)_5$ (1 mmol) was allowed to react with a mixture of butylamine (2 mmol) and water (0.5 ml) in benzene (4 ml) at 25 °C under vigorous stirring in the presence of the crown ether, the color of the mixture turned rapidly from yellow to deep-red. A spectrum of the benzene layer taken 2 h after mixing showed the formation of $HFe(CO)_4^-$ (ν_{CO} 1915 cm^{-1} sh), 1880 cm^{-1} (s)) and $HFe(CO)_{11}^-$ (ν_{CO} 2070 cm^{-1} (vw), 1995 cm^{-1}(s), 1978 cm^{-1} (m), 1950 cm^{-1} (sh)), and the presence of a small quantity of unreacted $Fe(CO)_5$ (ν_{CO} 2020 cm^{-1} (s), 1995 cm^{-1} (s)). On the other hand, in the absence of the crown ether the color change to deep-red proceeded slowly, the IR spectrum of the benzene layer indicating a large quantity of $Fe(CO)_5$ remaining unreacted. Hydrido anions observed in the spectrum were small amounts of $HFe_2(CO)_8^-$ (ν_{CO} 1913 cm^{-1}) and $HFe_3(CO)_{11}^-$, the absorption of $HFe(CO)_4^-$ being very weak.

The marked effect of DC18C6 in the formation of $HFe(CO)_4^-$ strongly suggests that there are two major routes for the formation of the anion, the reaction of $Fe(CO)_5$ with free amine and that with hydroxide ion in **1** derived according to Eq. 2. The reaction of $Fe(CO)_5$ with alkylamines, especially with secondary amines, was studed in detail by Edgell *et al.*[7] Application of their results to the present primary amine system gave the following results. A reaction of a primary amine with $Fe(CO)_5$ gives an equilibrium mixture of $R\overset{+}{N}H_2COFe(CO)_4^-$ (**3**) and $[R\overset{+}{N}H_3][RNHCOFe(CO)_4^-]$ (**4**); in the presence of water and excess amine they are hydrolyzed to an equimolar mixture of $[R\overset{+}{N}H_3][HFe(CO)_4^-]$ (**2**) and $[R\overset{+}{N}H_3][RNHCO_2^-]$ (**5**) (Scheme 1). Under the present conditions containing only a small quantity of water (especially in the benzene layer) hydrolysis would be sluggish and far from complete. The lower selectivity for benzylideneacetone in the absence of DC18C6 (Table 1) can be accommodated with the slow formation of the hydrido anions (HFe-

Scheme 2.

Scheme 2 is a modification of the pathway commonly accepted for the formation of carbonylhydridoferrate anions by causic alkalis (so-called base reaction), and could be realized by complexization of the alkylammonium hydroxide with crown ether. Hydroxide ion of **1** would effectively react with $Fe(CO)_5$ to give **6** and **7** (and/or **8**). The rapid formation of $HFe(CO)_4^-$ in a large quantity and the enhanced conversion in the reduction, as high as that observed when KOH was used, could be interpreted by this route, though the extent of the participation of $HFe_2(CO)_8^-$ in the reduction is not clear. IR inspection of the reduction mixture obtained in the presence of DC18C6 indicated the presence of hydrogencarbonate and/or carbonate ions (*ca.* 1620 cm^{-1}) and a marked decrease of the butylcarbamate ion (Fig. 1). It is obvious that the increased formation of **6** (and its polynuclear homologs) as well as **7** and **8** cause a decrease of free alkylamine, especially in the benzene layer, by its conversion into the onium ion complexes. An interpretation for the increase in selectivity in the reduction effected by the addition of DC18C6 is given by Scheme 2.

It is concluded that the primary alkylamine–water–crown ether system can be used as effective hydroxide ion source especially in a two phase system.

Eoperimental

Materials. Benzylideneacetone, DC18C6,[8] and benzocrown ethers[8] were prepared by conventional methods. Commercial 18C6 (Bokusuy Brown Co.) was used. Pentacarbonyliron (Alfa Products), primary amines, water, and benzene were distilled and stored under nitrogen.

General Procedure. All reactions were carried out under nitrogen with a vessel (*ca.* 10 ml) equipped with an outer jacked for circulation of water (thermostated at 25±0.5 °C) and a serum cap for introduction of pentacarbonyliron by means of a syringe. Water (0.5 ml), alkylamine (2 mmol), benzene (2 ml) containing heptadecane as an internal standard, benzylideneacetone (1 mmol) and a crown ether (1 mmol) were placed in the vessel, and then pentacarbonyliron (4 mmol) was added. The mixture was vigorously stirred at 25 °C. After a certain time (24 h or 8 h), the reaction mixture was neutralized by addition of aq HCl, and the aqueous layer was extracted by ether twice. The products in the combined organic layer were analyzed by GLC (PEG 20M 10%-Celite 545, 3 mm×2 m, FID).

Sodium Methoxide Catalyzed Isomerization of Dimethyl 1-Oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates to Dimethyl 3-Oxo-1,7-indandicarboxylates

Tadao UYEHARA,* Shoichi MIYAKOSHI, and Yoshio KITAHARA†

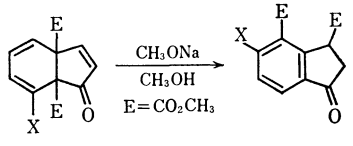
(Received March 6, 1979)

Treatment of dimethyl 1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates (**A**) with sodium methoxide in methanol gave particular dimethyl 3-oxo-1,7-indandicarboxylates (**F**). A multistep mechanism for the isomerization was proposed on the basis of the positional correlations between the dihydroindenones **A** and the corresponding isomers **F**. The isomerization seems to be initiated by the addition of a methoxide to the 1 position of the dihydroindenones **A** affording the cyclohexadienide anions (**B**), which cyclize to give dimethyl 1-oxo-*cis*-3a,7a-dihydroindene-3a,4-dicarboxylates (**C**). The dihydroindenones **C** become enolates (**D**), whose methoxycarbonyl group at the 3a position (E_9) shifts to the 1 position of the enolates of **F**, (**E**), with the aid of aromatization. The same treatment of methyl 3-oxo-*cis*-3a,7a-dihydroindene-3a-carboxylates gave key information on the process for the isomerization of **A**.

Dimethyl 1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylate (**1**) is a product of a thermal rearrangement of dimethyl 2-oxobicyclo[3.2.2]nona-3,6,8-triene-6,7-dicarboxylate (dimethyl homobarrelenone-6,7-dicarboxylate).[1] During the course of investigation on the structure of **1**, it was found that the dihydroindenone is sensitive to sodium methoxide in methanol.[2] When a solution of **1** in methanol was added to a solution of sodium methoxide at 0 °C or at room temperature, the mixture immediately turned violet and then rapidly became pale yellow. The product, obtained in 95% yield, was dimethyl 3-oxo-1,7-indandicarboxylate (**2**). Under the same conditions the 7-methoxy derivative of **1**, (**3**), was isomerized to dimethyl 6-methoxy-3-oxo-1,7-indandicarboxylate (**4**).[2] This paper deals with an attempt to clarify the mechanism of isomerization.

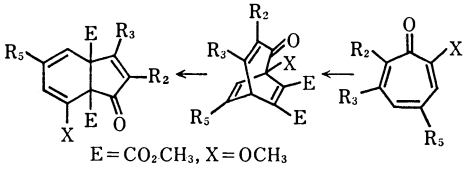


1 X=H **2** X=H
3 X=OCH_3 **4** X=OCH_3

Results and Discussion

Several alkyl derivatives of **3** were prepared and treated with sodium methoxide in methanol to examine the generality and limit of isomerization and the positional correlations between the *cis*-3a,7a-dihydroindenones and the products.

Dimethyl 2-isopropyl-7-methoxy-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylate (**5**) is the product of a thermal rearrangement of dimethyl 3-isopropyl-1-methoxyhomobarrelenone-6,7-dicarboxylate (**5a**) derived by the regioselective Diels-Alder reaction of 7-isopropyl-2-methoxy-2,4,6-cycloheptatrien-1-one (7-isopropyl-2-methoxytropone, **5b**) with dimethyl acetylenedicarboxylate.[3] Similarly, dimethyl esters of 3-isopropyl- and 5-isopropyl-7-methoxy-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylic acids (**6** and **7**) were prepared from 6- and 4-isopropyl-2-methoxytropones (**6b** and **7b**) *via* the homobarrelenones (**6a** and **7a**), respectively.[3]



5 R_2=*i*-Pr, R_3=R_5=H **5a** **5b**
6 R_2=R_5=H, R_3=*i*-Pr **6a** **6b**
7 R_2=R_3=H, R_5=*i*-Pr **7a** **7b**

The conditions and results of the reactions of the *cis*-3a,7a-dihydroinden-1-ones with sodium methoxide in methanol are given in Table 1. A solution of **5** was added to a solution of sodium methoxide in methanol at room temperature (Run 5). The mixture soon turned reddish violet and then slowly became pale yellow. After being left to stand for 4 h, the solution was acidified and extracted promptly with three portions of dichloromethane. The product (**8**) is an isomer of **5** whose infrared spectrum shows a typical absorption due to the carbonyl of a 1-indanone, at 1691 cm^{-1}. The ultraviolet spectrum of **8** exhibits an absorption maximum of the electron transfer band at 270 nm, which is 25 nm longer than that of **2**. The difference suggests that **8** is one of the 5-methoxy-1-indanones.[4] The NMR spectrum of **8** indicates that the compound is dimethyl 2-isopropyl-6-methoxy-3-oxo-1,7-indandicarboxylate, showing an AB pattern at δ=7.10 and 7.88 (J=8.6 Hz) for H_5 (R_6) and H_4 (R_5), respectively, a doublet at δ=4.25 (J=3.4 Hz) for H_1 (R_3) and a doublet of doublets at δ=2.81 (J=4.1 and 3.4 Hz) for H_2.

Under the same conditions, **7** was isomerized to dimethyl 4-isopropyl-6-methoxy-3-oxo-1,7-indandicarboxylate (**9**) (Run 6), whose structure was deduced on the basis of its spectra.

3-Isopropyldihydroindenone **6** was inactive to sodium methoxide in methanol at room temperature (Run 7), whereas the isomer (**10**) was obtained when **6** and the base were heated under reflux in methanol (Run 8).

† Deceased February 4, 1976.

Product **10** has a characteristioc absorption maximum at 271 nm, its NMR spectrum showing an AB pattern at δ=7.05 and 7.93 (J=8.7 Hz) for H_5 (R_6) and H_4 (R_5), respectively, and AB pattern at δ=2.67 and 3.08 (J=19.2 Hz) for the *geminal* protons at the 2 position. Thus compound **10** should be dimethyl 1-isopropyl-6-methoxy-3-oxo-1,7-indandicarboxylate. The fact that **6** was isomerized to **10** seems to supply valuable information on the mechanism of the isomerization, but the reaction conditions were different from those for other dihydroindenones.

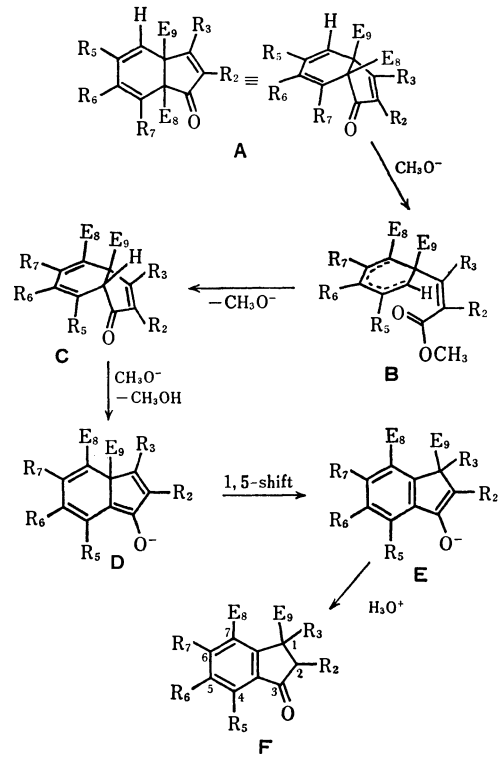
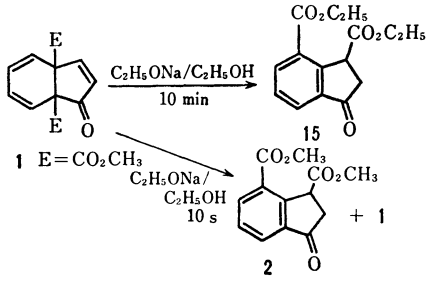
In order to know the generality of formation of dimethyl 1-alkyl-3-oxo-1,7-indandicarboxylates from the corresponding dimethyl 3-alkyl-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylate, we developed a general synthetic method for 3-methyl-2-cyclopenten-1-ones from 2-cyclopenten-1-ones, prepared dimethyl 3-methyl-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates (**11** and **12**)[5] and treated them with sodium methoxide.

Isomerization of **11** proceeded at room temperature to give dimethyl 1-methyl-3-oxo-1,7-indandicarboxylate (**13**) (Run 9). The other 3-methyldihydroindenone **12** was not isomerized at room temperature, giving the somer (**14**) in boiling methanol (Runs 10 and 11, respectively). Thus dimethyl 3-alkyl-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates in general are isomerized with sodium methoxide to the corresponding dimethyl 1-alkyl-3-oxo-1,7-indandicarboxylates.



Scheme 1.

From the results we are able to estimate positional correlations between the dihydroindenones and the isomeric indanones. A mechanism for the isomerization is proposed as a working hypothesis which satisfies the positional correlations (Scheme 1). The mechanism shows that sodium methoxide acts as a catalyst in the first and second steps (**A** to **C**). To know the role of sodium methoxide in the reactions, **1** was teated with sodium ethoxide in ethanol. The reaction of **1** at room temperature for 10 min gave diethyl 3-oxo-1,7-indandicarboxylate (**15**) in 64.2% yield. The same reaction for 10 s afforded a mixture of **1** (recovered) and *dimethyl* 3-oxo-1,7-indandicarboxylate **2** in a 81 : 19 ratio. Thus, the alkoxides are shown to be the catalysts for the isomerization.



The tentative mechanism shows that E_9 of the dihydroindenones shifts to the 1 position of the indan-3-ones and E_8 of the former corresponds to the methoxycarbonyl group at the 7 position of the latter. For confirmation of the working hypothesis, either methyl ester of 1-oxo-*cis*-3a,7a-dihydroindene-3a- or 7a-carboxylic acid is necessary. We were able to prepare methyl 4-methoxy-3-oxo-*cis*-3a,7a-dihydroindene-3a-carboxylate

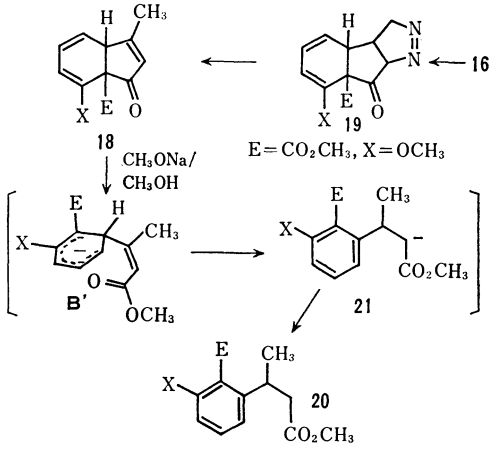
(**16**).[3]

When **16** was treated with sodium methoxide in methanol (Run 12), methyl 5-methoxy-1-oxo-4-indancarboxylate (**17**) was obtained in 70% yield. Thus, the methoxycarbonyl group at the 7a position of the dihydroindenones should correspond to that at the 7 position of the products, indan-3-ones.

Formation of the intermediate **B** is supported by the following results. When methyl 4-methoxy-1-methyl-3-oxo-*cis*-3a,7a-dihydroindene-3a-carboxylate (**18**), derived from **16** *via* the pyrazoline (**19**), was treated with sodium methoxide in methanol, 1,2,3-trisubstituted benzene (**20**) was formed selectively. Its absorption spectra show that the compound is not methyl 5-methoxy-3-methyl-1-oxo-4-indancarboxylate. The ultraviolet spectrum does not exhibit the typical absorption maximum of 1-indanones, at *ca.* 300 nm. The infrared spectrum shows no absorption at *ca.* 1700 cm^{-1} due to the carbonyl of 1-indanones. The NMR spectrum of **20** indicates that the compound is methyl 3-(3-methoxy-2-methoxycarbonylphenyl)butanoate: the spectrum exhibits a doublet at δ=1.24 (3H, J=6.8 Hz) for CH_3–(CH), an ABC pattern at δ=6.68 (dd, J=8.0 and 0.9 Hz), 6.78 (dd, J=8.0 and 0.9 Hz) and 7.20 (t, J=8.0 Hz) for the three adjacent protons on the benzene ring, an ABC pattern at δ=2.34 (dd, J=15.0 and 9.0 Hz), 2.59 (dd, J=15.0 and 5.6 Hz) and 3.14 (ddq, J=9.0, 5.6, and 6.8 Hz) for the $-CH_2-CH(CH_3)$ system, and three singlets at δ=3.54 (3H), 3.73 (3H), and 3.81 (3H) for the methyl protons of the ether and the esters.

The process for formation of **20** should be addition of a methoxide to the 3 position of **18** giving the anion (**B'**), which corresponds to the intermediate **B** in Scheme 1, followed by aromatization to the intermediate (**21**).[6]

The reaction of dimethyl 4,7-dimethoxy-1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylate (**22**)[3] and sodium methoxide gave a mixture of several products which could not be separated.



The infrared spectrum of the mixture shows no typical absorption for the carbonyl of 1-indanones. If the working hypothesis is correct, **22**, would not give 1-indanones.

The fourth step of the mechanism (**D** to **E**) is the 1,5-shift of the methoxycarbonyl group and the aromatization. This type of migration of an alkoxycarbonyl group was observed on a cyclopentadiene skeleton.[7]

So far, the mechanism (Scheme 1) seems to be adequate for the isomerization of dimethyl 1-oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates to dimethyl 3-oxo-1,7-indandicarboxylates.

Experimental

General. Melting point were determined on a Thomas Hoover MP apparatus, and are uncorrected. Infrared spectra were recorded on Hitachi EPI-3 and Model 215 Spectrophotometers. Ultraviolet spectra were recorded on a Hitachi EPS-2T spectrometer. NMR spectra were obtained on Varian A-60 and HA-100 spectrometers equipped with spin decouplars, using tetramethylsilane as an internal standard. Mass spectral studies were conducted using a Hitachi RMU-6D spectrometer.

*Reaction of Dimethyl 1-Oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates with Sodium Methoxide in Methanol at Room Temperature. General Procedure*: To a freshly prepared solution of sodium methoxide in methanol (100 mg of sodium and 10 ml of absolute methanol) was added rapidly a solution of the dihydroindenones (*ca.* 100 mg) in methanol (10 ml) at room temperature (on a water bath), and the mixture was allowed to stand for 5 min to 12 h. The reaction was quenched by 2 M-hydrochloric acid, diluted with water and extracted rapidly with three portions of dichloromethane (20 ml each). The extracts were combined, washed with two portions of water (20 ml each), dried over Na_2SO_4, and concentrated *in vacuo*. Isolation and purification of each product were performed with chromatography on silica gel and/or recrystallization.

*Reaction of Dimethyl 1-Oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylates with Sodium Methoxide in Boiling Methanol. General Procedure*: A solution of sodium methoxide in methanol, prepared from 100 mg of sodium and 10 ml of methanol, was heated under reflux. To the solution was added a solution of the dihydroindenones (*ca.* 100 mg) in methanol (10 ml). After 10 min or 12 h reflux, the mixture was poured on a mixture of 2 M-hydrochloric acid and ice, and extracted with three portions of dichloromethane (20 ml each). The usual work-up followed by recrystallization or molecular distillation gave the 1-indanones.

Physical Properties of the New Dimethyl 3-Oxo-1,7-indandicarboxylates. Dimethyl trans*-2-Isopropyl-6-methoxy-3-oxo-1,7-indandicarboxylate (**8**)*: Colorless needles (from CH_3OH), mp 105—106 °C; UV_{max} (CH_3OH) 233 (log ε 4.28), 270 (4.16), and 296 nm (3.88); IR (KBr) 1725, 1691, 1581, and 814 cm^{-1}; NMR ($CDCl_3$) δ=0.85 (3H, d, J=7.0 Hz, CH_3), 1.05 (3H, d, J=7.0 Hz, CH_3), 2.37 (1H, doublet of sept, J=4.1 and 7.0 Hz, $CH(CH_3)_2$), 2.81 (1H, dd, J=4.1 and 3.4 Hz), 3.68 (3H, s), 3.90 (3H, s), 3.97 (3H, s), 4.25 (1H, d, J=3.4 Hz, H_1), 7.10 (1H, d, J=8.6 Hz, H_5), and 7.88 (1H, d, J=8.6 Hz, H_4). Found: C, 63.68; H, 6.30%. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%.

*Dimethyl 4-Isopropyl-6-methoxy-3-oxo-1,7-indandicarboxylate (**9**)*: Colorless needles (from ether–CH_3OH), mp 177–178 °C; UV_{max} (CH_3OH) 236 (log ε 4.41), 275 (4.17), and 300 nm (3.69)^{sh}; IR (KBr) 1728, 1698, 1597, and 1461 cm^{-1}; NMR ($CDCl_3$) δ=1.25 (3H, d, J=6.9 Hz, CH_3), 1.27 (3H, d, J=6.9 Hz, CH_3), 2.84 (1H, dd, J=18.2 and 4.2 Hz, H_2-*cis* to C_1-ester), 2.92 (1H, dd, J=18.2 and 7.8 Hz, H_2-*trans* to C_1-ester), 3.67 (3H, s), 3.86 (3H, s), 3.95 (3H, s), 4.24 (1H, sept, J=6.9 Hz, $CH(CH_3)_2$), 4.47 (1H, dd, J=7.8 and 4.2 Hz, H_1), and 6.97 (1H, bs, $W_{1/2}$=1.6 Hz, H_5). Found: C,

63.51; H, 6.41%; M+, 320. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%; M, 320.

*Dimethyl 1-Isopropyl-6-methoxy-3-oxo-1,7-indandicarboxylate (**10**)*: Colorless prisms (molecular distillation, bp 160 °C (bath)/0.2 Torr), mp 150—151 °C; UV_{max} (CH_3OH) 228 (log ε 4.31), 271 (4.20), 285 (4.10)^{sh}, and 294 nm (3.95)^{sh}; IR (KBr) 1735, 1709, 1581, 1470, and 828 cm^{-1}; NMR ($CDCl_3$) δ=0.51 (3H, d, J=6.8 Hz, CH_3), 1.03 (3H, d, J=6.8 Hz, CH_3), 2.67 (1H, d, J=19.2 Hz, H_2), 2.89 (1H, sept, J=6.8 Hz, $CH(CH_3)_2$), 3.08 (1H, d, J=19.2 Hz, H_2), 3.65 (3H, s), 3.93 (6H, s), 7.05 (1H, d, J=6 8 Hz, H_5), and 7.93 (1H, d, J=8.7 Hz, H_4). Found: C, 63.59; H, 6.29%; M+, 320. Calcd for $C_{17}H_{20}O_6$: C, 63.74; H, 6.29%; M, 320.

*Dimethyl 1-Methyl-3-oxo-1,7-indandicarboxylate (**13**)*: Colorless oil; UV_{max} (CH_3OH) 219 (log ε 4.51), 241 (4.01)$^{++}$, 292 (3.39), and 301 nm (3.39); IR (film) 1740, 1722, 1600, 1588, 1479, and 773 cm^{-1}; NMR ($CDCl_3$) δ=1.68 (3H, s, CH_3), 2.72 (1H, d, J=18.8 Hz, H_2), 2.98 (1H, d, J=18.8 Hz, H_2), 3.68 (3H, s), 3.91 (3H, s), 7.57 (1H, t, J=7.4 Hz, H_5), 7.99 (1H, dd, J=7.4 and 1.5 Hz, H_6 or H_4), and 8.35 (1H, dd, J=7.4 and 1.5 Hz, H_4 or H_6). Found: M+, 262 Calcd for $C_{14}H_{14}O_5$: M, 262.

*Dimethyl 6-Methoxy-1-methyl-3-oxo-1,7-indandicarboxylate (**14**)*: Colorless needles (from CH_3OH), mp 118—119 °C; UV_{max} (CH_3OH) 228 (log ε 4.43), 271 (4.33), and 295 nm (4.13); IR (KBr) 1740^{sh}, 1732, 1713, 1706, 1581, and 824 cm^{-1}; NMR ($CDCl_3$) δ=1.60 (3H, s, CH_3), 2.60 (1H, d, J=18.5 Hz, H_2), 3.06 (1H, d, J=18.5 Hz, H_2), 3.67 (3H, s), 3.89 (3H, s), 3.97 (3H, s), 7.07 (1H, d, J=8.5 Hz, H_5), and 7.90 (1H, d, J=8.5 Hz, H_4). Found: C, 61.34; H, 5.49%; M+, 292. Calcd for $C_{15}H_{16}O_6$: C, 61.64; H, 5.52%; M, 292.

*Reactions of Dimethyl 1-Oxo-*cis*-3a,7a-dihydroindene-3a,7a-dicarboxylate (**1**) with Sodium Ethoxide in Ethanol. A)*: To a solution of sodium ethoxide in ethanol, prepared from 100 mg of sodium and 10 ml of absolute ethanol, was added rapidly a solution of 98.8 mg (0.40 mmol) of **1** in 10 ml of ethanol, and the mixture was allowed to stand at room temperature for 10 min. The solution was poured on 2 M-hydrochloric acid (20 ml), diluted with water and extracted with three portions of dichloromethane (20 ml each). The usual work-up afforded 101 mg of red oil, which was chromatographed on silica gel. The product (71 mg, 64.2%) was identical with diethyl 3-oxo-1,7-indandicarboxylate (**15**) which was derived from **2** with sodium ethoxide in ethanol. **15**: Colorless needles (from ethanol), mp 78—80 °C; UV_{max} (CH_3OH) 218 (log ε 4.70), 240 (4.06)^{sh}, 265 (3.28)^{sh}, 290 (3.53), and 299 nm (3.55); IR (KBr) 1729, 1715, 1703, 1588, and 763 cm^{-1}; NMR ($CDCl_3$) δ=1.23 (3H, t, J=7.1 Hz), 1.39 (3H, t, J=7.1 Hz), 2.72 (1H, dd, J=19.2 and 4.4 Hz, H_2-*cis* to C_1-ester), 3.07 (1H, J=19.2 and 8.2 Hz, H_2-*trans* to C_1-ester), 4.19 (2H, q, J=7.1 Hz), 4.38 (2H, q, J=7.1 Hz), 4.71 (1H, dd, J=8.2 and 4.4 Hz, H_1), 7.55 (1H, t, J=7.4 Hz, H_5), 7.95 (1H, dd, J=7.4 and 1.5 Hz, H_6 or H_4), and 8.30 (1H, dd, J=7.4 and 1.5 Hz, H_4 or H_6). Found: C, 64.87; H, 5.74%; M+, 276. Calcd for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84%; M, 276.

B): To a solution of sodium ethoxide in ethanol, prepared from 150 mg of sodium and 10 ml of absolute ethanol, was added a solution of 104 mg of **1** in 10 ml of ethanol in one portion. After 10 s, 10 ml of 2 M-hydrochloric acid was added to the solution which was still violet. The mixture was extracted rapidly with three portions of dichloromethane (20 ml each). The usual work-up gave 108.1 mg of pale red oil, whose chromatography on silica gel gave 81 mg (77.9%) of **1** and 19 mg (18.3%) of dimethyl 3-oxo-1,7-indandicarboxylate **2**.

*Reaction of Methyl 4-Methoxy-3-oxo-*cis*-3a,7a-dihydroindene-3a-carboxylate (**16**) with Sodium Methoxide in Methanol.* To a solution of sodium methoxide in methanol, freshly prepared from 150 mg of sodium and 15 ml of absolute methanol, was added a solution of 101.2 mg of **16** in 10 ml of methanol, and the mixture was allowed to stand at room temperature for 4 h. The usual work-up afforded pale red oil (81.3 mg), which was chromatographed on silica gel giving 71 mg (70 %) of methyl 5-methoxy-1-oxo-4-indancarboxylate (**17**), as colorless oil. **17**: UV_{max} (CH_3OH) 224 (log ε 4.48), 253 (3.92)^{sh}, and 303 nm (3.30); IR (film) 1723, 1692, and 1598 cm^{-1}; NMR ($CDCl_3$) δ=2.72 (2H, m, H_2), 3.12 (2H, m, H_3), 3.90 (3H, s), 4.02 (3H, s), 7.19 (1H, dt, J=8.0 and 0.5 Hz, H_6), and 7.95 (1H, d, J=8.0 Hz, H_7). 2,4-DNP of **17**: mp 221 °C (dec). Found: C, 53.75; H, 4.27; N, 13.90%. Calcd for $C_{18}H_{16}N_4O_7$: C, 54.00; H, 4.03; N, 14.00%.

*Preparation of Methyl 7-Methoxy-3-methyl-1-oxo-*cis*-3a,7a-dihydroindene-3a-carboxylate (**18**).* To a solution of 473 mg (2.15 mmol) of **16** in 10 ml of ether was added an excess of an ethereal solution of diazomethane, and the mixture was allowed to stand overnight at room temperature. After removal of the excess of diazomethane and the solvent, crystallization of the residue gave 379 mg (67.3%) of the pyrazoline (**17**). A solution of 186.4 mg (0.71 mmol) of **17** in 5 ml of xylene was heated under reflux for 1 h. Removal of the solvent *in vacuo* followed by recrystallization from methanol gave 136 mg (0.52 mmol, 73%) of **18**. **17**: Colorless prisms (from CH_3OH), mp 150—151 °C (dec); IR (KBr) 1758, 1742, and 1653 cm^{-1}; Found: C, 59.51; H, 5.31; N, 10.71%. Calcd for $C_{13}H_{14}N_2O_4$: C, 59.54; H, 5.38; N, 10.68%. **18**: Colorless prisms (frm CH_3OH), mp 143—144 °C; IR (KBr) 1723, 1708, 1655, 1638, and 1599 cm^{-1}; NMR ($CDCl_3$) δ= 2.18 (3H, t, J=1.4 Hz, CH_3), 3.64 (3H, s), 3.73 (3H, s), 3.88 (1H, dddd, J=5.2, 2.2, 1.8, and 1.4 Hz, H_{7a}), 5.14 (1H, d, J=6.5 Hz, H_6), 5.51 (1H, dd, J=9.5 and 6.5 Hz, H_5), 5.99 (1H, ddd, J=9.5, 6.5, and 1.8 Hz, H_4), and 6.03 (1H, dq, J=2.2 and 1.4 Hz, H_2). Found: C, 66.51; H, 6.03%. Calcd for $C_{13}H_{14}O_4$: C, 66.66; H, 6.02%.

*Reaction of Methyl 7-Methoxy-3-methyl-1-oxo-*cis*-3a,7a-dihydroindene-3a-carboxylate (**18**) with Sodium Methoxide in Methanol.* To a solution of sodium methoxide in methanol, freshly prepared from 100 mg of sodium and 10 ml of absolute methanol, was added a solution of 135 mg (0.576 mmol) of **18** in 10 ml of methanol at room temperature, and the mixture was allowed to stand for 1 h. The usual work-up gave 149.7 mg (0.562 mmol, 97%) of methyl 3-(3-methoxy-2-methoxycarbonylphenyl)butanoate (**20**), as colorless oil which was purified by molecular distillation: 90—95 °C (bath)/0.06 Torr. **20**: UV_{max} 280 nm (log ε 3.43); IR (film) 1733, 1588, and 802 cm^{-1}. Found: C, 63.24; H, 6.94%; M+, 266. Calcd for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81%; M, 266.

Acyl Cyanide. V. The Synthesis of 1-Cyano-1-alkenyl Esters by the Reaction of Acyl Cyanides with Acid Anhydrides and Isocyanates

Akira Oku,* Shigeru Nakaoji, Toshio Kadono, and Hideki Imai

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received March 9, 1979)

The reactions of enolizable acyl cyanides (acetyl, propionyl, and isobutyryl cyanide) with acid anhydrides (acetic, propionic, butyric, isobutyric, and benzoic anhydride) in the presence of a catalytic amount of tertiary amines (pyridine, lutidines, 4-(dimethylamino)pyridine) produced the corresponding 1-cyano-1-alkenyl carboxylates. In the reactions of propionyl cyanide, (*Z*)-1-cyano-1-propenyl carboxylates were formed predominantly over the (*E*)-isomers (isomer ratios *Z*/*E* were *ca.* 80/20). The reactions of the cyanides with isocyanates also gave the corresponding 1-cyano-1-alkenyl carbamates in moderate yields, and the acid-treatments of 1-cyano-2-methyl-1-propenyl phenylcarbamate induced its annelation into 3-phenyl-1,3-oxazolidine-2,4-dione derivatives.

Only a limited number of methods have been known for the synthesis of 1-cyano-1-alkenyl esters, known as versatile reagents for ring formations[1] and polymerizations,[2] and they are classified into two groups: dehydrohalogenation of 1-cyano-2-haloethyl acetate by tertiary amines,[3] and base-catalyzed addition of hydrogen cyanide to ketene.[4] However, these methods are limited to the preparation of 1-cyanovinyl esters. We therefore have tried to find a more general and convenient method for the synthesis of a variety of unsubstituted and substituted 1-cyano-1-alkenyl esters.

Related to the synthetic method of the cyanoalkenyl esters, it has been reported[5] that when the reaction of aliphatic acyl chloride with metal cyanide (Eq. 1) known as an authodox preparative method[6] of acyl cyanides was carried out in the presence of crown ether, acyl cyanide was not isolated. In addition, our analogous examination in the reaction of acetic anhydride with potassium cyanide in the presence of crown ether proved it unsuccessful in the synthesis of acetyl cyanide. However, 1-cyanovinyl acetate was obtained instead. The formation of the ester seems to be accountable by the base-catalyzed dimerization of acetyl cyanide followed by dehydrocyanation as was proposed by Tate[7] (Eq. 2). If this mechanism is correct, then the maximum yield of the ester, calculated upon the basis of inorganic cyanide consumed, should not exceed 50%. However, the ester was isolated in 52% from the reaction of isobutyric anhydride (two parts) and potassium cyanide (one part) in the presence of 18-crown-6 in 1,2-dimethoxyethane. Evidently, this fact implies that an alternative reaction path must (co)exist to produce the ester. We clarified this is the acylation of acyl cyanide intermediate by acetic anhydride (Eq. 3). We have extended this reaction to a variety of acyl cyanide–acid anhydride combinations and established its versatile characters. Also the carbamoylation of acyl cyanides with isocyanates was investigated to prepare 1-cyano-1-alkenyl carbamates (Eq. 4).

$$R^1R^2CHCOCl + Metal\text{–}CN \longrightarrow R^1R^2CHCOCN \quad (1)$$

$$R^1R^2CHCOCN + CN^- \longrightarrow R^1R^2CH\text{–}C(CN)_2O^-$$

$$\xrightarrow{base} R^1R^2C{=}C(CN)OCOCHR^1R^2 \quad (2)$$

$$R^1R^2CHCOCN + (R^3CO)_2O \longrightarrow R^1R^2C{=}C(CN)OCOR^3 \quad (3)$$

$$R^1R^2CHCOCN + R^4\text{–}NCO \longrightarrow R^1R^2C{=}C(CN)OCONHR^4 \quad (4)$$

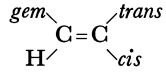
Results and Discussion

Both acyl cyanides and acid anhydrides are known as acylating reagents and they stay unchanged when mixed. However, a catalytic amount of tertiary amines, usually pyridine derivatives, induced a condensation reaction between these two reagents affording the corresponding 1-cyano-1-alkenyl esters in good yields.

Reaction of Acetyl Cyanide with Acid Anhydrides. When a mixture of acetyl cyanide and an acid anhydride was treated with a catalytic amount of pyridine in tetrahydrofuran at ambient temperature, the corresponding 1-cyanovinyl carboxylate (**1**—**3**) was obtained. The results are tabulated in Table 1. All the product esters showed $\nu(C{\equiv}N)$ at 2210 cm^{-1} about 50 cm^{-1} lower than that of saturated nitriles, and the terminal methylene protons in NMR around δ 5.7 (J=3 Hz), thus demonstrating the product structures to be the expected ones.

Reaction of Propionyl Cyanide with Acid Anhydrides. As shown in Table 1, the product esters 1-cyano-1-propenyl carboxylates (**5**—**8**) consisted of two geometrical isomers (*Z*- and *E*-isomer). Their NMR assignment was carried out as follows.

First, we noticed that the major isomer shows higher chemical shifts of the terminal methylene protons than the minor one in any isomeric couple. If the Pascual's equation[8] which was proposed for the substituent effects in determining the chemical shifts of olefinic protons is applicable in our cases (Eq. 6), then the calculated chemical



$$\delta(H) = 5.28 + \sigma(gem) + \sigma(cis) + \sigma(trans) \quad (6)$$

shifts δ(H) are 5.90 for *E*-isomer and 5.83 for *Z*-isomer, thus indicating the major isomer should have a *Z*-configuration. Second, the greater deshielding effect of an acetoxyl group than a cyano group on a vicinal *cis* proton in β-substituted styrenes[9] also suggests that

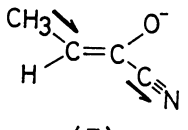
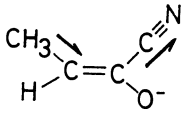
a) Temperature 25 °C. Reactant ratios were 1:1:0.03 (cyanide/anhydride/pyridine). b) Isolated yields. c) 1.0 mol equiv of pyridine was added. d) 1,1-Dicyanoethyl acetate (**4**) was formed (76%). e) Determined by VPC, **6** was also formed (9%). f) Determined by VPC, 1-cyano-2-methyl-1-propenyl isobutyrate (**13**) was also formed (19%).

the olefinic proton of the *Z*-isomer should appear at higher field than the *E*-isomer. Third, on geometrical analysis of the shielding effect of the cyano group on the chemical shifts of allylic methyl group, it became evident that the methyl protons of the *E*-isomer should appear at a higher field than the *Z*-isomer, and this agreed with the observed results (see Table 1). Therefore, we concluded that the major isomers are (*Z*)-1-cyano-1-propenyl carboxylates. The demonstrated *Z*-configuration of the major product suggested us that this configuration is stabilized by a dipolar interaction rather than by steric factors in the structure determining step.



(Z)



(E)

Reaction of Isobutyryl Cyanide with Acid Anhydrides. In the NMR spectra of the products, the differences in chemical shifts between the two allylic methyl groups ($\Delta\delta$) are analogous to those between *E* and *Z* isomers in the case of 1-cyano-1-propenyl esters (Table 1). The reaction with benzoic anhydride produced 1-cyano-2-methyl-1-propenyl isobutyrate (**13**) as a by-product. (Analogous side reaction was also observed in the reaction of propionyl cyanide with the same anhydride). Despite of the fact that isobutyryl cyanide undergoes dimer formation followed by the elimination of hydrogen cyanide to afford this ester, another reaction channel *via* acyl exchange between cyanide and benzoic anhydride seems also plausible (Eq. 7).

$$(CH_3)_2CHCOCN + (PhCO)_2O \rightleftharpoons (CH_3)_2CHCOOCOPh + PhCOCN \quad (7)$$

Tertiary Amine Catalysts. The presence of tertiary amine catalysts is essential in the present synthesis of cyanoalkenyl esters. Among several tertiary amines examined, pyridine derivatives with moderate basicity were found to be suitable for this purpose, *e.g.*, 4-(dimethylamino)pyridine, pyridine, lutidines, and picolines. Such strong bases as triethylamine and 1,7-diazabicyclo[4.3.0]non-6-ene were inadequate because they induced considerable degradation of the product esters. Solid-phase catalysts such as basic alumina and Amberlite IRA-400 were inactive in this reaction. Calcined anhydrous Hydrotalcite,[10] however,catalyzed the reaction to give the expected ester **5** (17%) in the reaction of propionyl cyanide with acetic anhydride besides 1,1-dicyanopropyl acetate **15** (22%) and 1,1-dicyanopropyl propionate **16** (13%) as by-products.

Reaction of Acyl Cyanides with Isocyanates. The above-mentioned reactions of acyl cyanides seemed to signify that acyl cyanide reacted in its enol (or enolate) form with acid anhydride. This prompted us to examine the reaction of acyl cyanides with isocyanates where the latter reacted as carbamoylating reagents to the former

Table 2. Reaction of acyl cyanides with isocyanates[a]

giving rise to the formation of 1-cyano-1-alkenyl carbamates. Results are shown in Table 2. None of *C*-acylated products anticipated from the result of the reaction of carbamoyl cyanides with isocyanates[11] was detected in the reaction mixture. The rate of carbamate formation was relatively slow in this reaction that the formation of the acyl cyanide dimer became unnegligible, especially in the reactions with aliphatic isocyanate.

As part of structure-determining experiments of the carbamates, the hydrogenation of 1-cyano-2-methyl-1-propenyl phenylcarbamate (**17**) over Pd/carbon catalyst was carried out in acetic acid. The carbamate slowly absorbed one mole of hydrogen to give not the expected acyclic carbamate but a cyclic iminourethane, *i.e.*, 3-phenyl-4-imino-5-isopropyl-1,3-oxazolidin-2-one (**21**). Analogous five-membered heterocyclic compound was obtained when carbamate **17** was hydrolyzed in aqueous sulfuric acid and its structure was attributed to 3-phenyl-5-isopropylidene-1,3-oxazolidine-2,4-dione (**20**).

Experimental

General. The NMR spectra were measured by Varian T-60A spectrometer in CCl_4 solutions unless otherwise stated and the chemical shifts are given in δ-units. The IR and MS spectra were taken on JASCO IRA-1 and Hitachi RMU-6L spectrometer respectively. Acyl cyanides were prepared from the corresponding carboxylic acids *via* the reaction of acyl bromides with copper(I) cyanide.[6a]

Reaction of Acyl Cyanides with Acid Anhydrides. A General Procedure: The mixture of an acyl cyanide (0.02 mol) and an acid anhydride (0.02 mol) dissolved in 10 ml of solvent (1,2-dimethoxyethane or tetrahydrofuran) was cooled at 0 °C, to which a solution of pyridine (0.001 mol) which was dissolved in 10 ml of the same solvent was added. The reaction mixture then was stirred at 25 °C for a certain period. After removing solvents, the residue was distilled in vacuum to give the corresponding 1-cyano-1-alkenyl carboxylate. For the product yields and reaction conditions, see Table 1. The spectroscopic data are as follows.

*1-Cyanovinyl Acetate (**1**)*: Bp 48—52 °C/9 Torr. IR (liquid) 2220 and 1765 cm^{-1}. NMR 5.74 (2H, a pair of d, J=2.8 Hz), 2.27 (3H, s).

*1-Cyanovinyl Propionate (**2**)*: Bp 34—38 °C/0.5 Torr. IR (liquid) 2240 and 1770 cm^{-1}. NMR 5.77 (2H, a pair of d, J=3 Hz), 2.54 (2H, q, J=7.3), 1.24 (3H, t, J=7.3).

*1-Cyanovinyl Butyrate (**3**)*: Bp 55—58 °C/3 Torr. NMR 5.64 (2H, d, J=2.8 Hz), 2.40 (2H, t, J=6.8), 1.70 (2H, sext, J=7.2 and 6.8), 0.99 (3H, t, J=7.2).

*1-Cyano-1-propenyl Acetate (**5**)*: Bp 95—98 °C/37 Torr. IR (liquid) 2220 and 1765 cm^{-1}. NMR: (*Z*)-isomer 6.15 (1H, q, J=7.3 Hz), 2.20 (3H, s), 1.75 (3H, d, J=7.3); (*E*)-isomer 6.18 (1H, q, J=7.3), 2.15 (3H, s), 1.98 (3H, d, J=7.3). *Z*/*E*=77/23.

*1-Cyano-1-propenyl Propionate (**6**)*: Bp 108—110 °C/29 Torr. IR (liquid) 2220 and 1765 cm^{-1}. NMR: (*Z*)-isomer 6.25 (1H, q, J=7.2), 2.54 (2H, q, J=7.6), 1.75 (3H, d, J=7.2), 1.18 (3H, t, J=7.6); (*E*)-isomer 6.28 (1H, q, J=7.4), 2.55 (2H, q, J=7.6), 1.93 (3H, d, J=7.4), 1.15 (3H, t, J=7.6). *Z*/*E*=8/2.

*1-Cyano-1-propenyl Isobutyrate (**7**)*: Bp 115 °C/26 Torr. IR (liquid) 2220 and 1760 cm^{-1}. NMR: (*Z*)-isomer 6.23 (1H, q, J=7.2), 2.75 (1H, hept. J=7.2), 1.73 (3H, d, J=7.2), 1.24 (6H, d, J=7.2); (*E*)-isomer 6.26 (1H, q, J=7.5), 2.78 (1H, hept. J=7.2), 1.93 (3H, d, J=7.5), 1.20 (6H, d, J=7.2). *Z*/*E*=76/24.

*1-Cyano-1-propenyl Benzoate (**8**)*: Separated by VPC. IR (liquid) 2220 and 1730 cm^{-1}. NMR: (*Z*)-isomer 8.2—7.95 (3H, m), 7.7—7.3 (2H, m), 6.22 (1H, q, J=7.2), 1.80 (3H, d, J=7.2); (*E*)-isomer 6.28 (1H, q, J=7.4), 2.03 (3H, d, J=7.4). *Z*/*E*=69/31.

*1-Cyano-2-methyl-1-propenyl Acetate (**9**)*: Bp 90 °C/25 Torr. IR (liquid) 2210 and 1760 cm^{-1}. NMR 2.17 (3H, s), 2.02 (3H, s), 1.77 (3H, s).

*1-Cyano-2-methyl-1-propenyl Propionate (**10**)*: Bp 125 °C/60 Torr. IR (liquid) 2220 and 1765 cm^{-1}. NMR 2.47 (2H, q, J=7.5), 2.04 (3H, s), 1.77 (3H, s), 1.20 (3H, t, J=7.5).

*1-Cyano-2-methyl-1-propenyl Butyrate (**11**)*: Bp 125—130 °C/45 Torr. IR (liquid) 2200 and 1760 cm^{-1}. NMR 2.43 (2H, t, J=6.5), 1.70 (2H, sext. J=6.5 and 7.0), 1.00 (3H, t, J=7.0), 2.06 (3H, s), 1.77 (3H, s).

*1-Cyano-2-methyl-1-propenyl Benzoate (**12**)*: Separated by VPC. IR (liquid) 2230 and 1750 cm^{-1}. 8.07 (2H, m), 7.6 (3H, m), 2.09 (3H, s), 1.83 (3H, s).

Reaction of Isobutyric Anhydride with KCN in the Presence of 18-Crown-6. A mixture of isobutyric anhydride (7.1 g, 0.04 mol), KCN (1.5 g, 0.02 mol), and 18-crown-6 (0.5 g, 2 mmol) in 30 ml of dimethoxyethane was stirred at 25 °C for 7 h. The mixture was poured into 60 ml of petroleum ether, filtered, and the filtrate was evaporated followed by fractional distillation to give 1-cyano-2-methyl-1-propenyl isobutyrate (**13**) 2.35 g (52%), bp 110—115 °C/20 Torr. IR (liquid) 2210 and 1760 cm^{-1}. NMR 2.60 (1H, hept, J=7.2), 2.01 (3H, bs), 1.75 (3H, bs), 1.25 (6H, d, J=7.2).

Reaction of Propionyl Cyanide with Acetic Anhydride in the Presence of Calcined Hydrotalcite. Propionyl cyanide (2.49 g, 0.03 mol) and acetic anhydride (3.09 g, 0.03 mol) were mixed in 20 ml of THF, to which was added 3.0 g of Hydrotalcite (calcined at 470 °C for 2 h under vacuum) under N_2-atmosphere. The reaction mixture was stirred at ambient temperature for 23 h, filtered, and the solvent was removed. The residue contained three products which were separated preparatively by VPC; 1-cyano-1-propenyl acetate (**5**) 17%, *Z*/*E*=7/3; 1,1-dicyanopropyl acetate (**15**) 22%, NMR 1.32 (3H, t, J=7.2), 2.25 (3H, s), 2.35 (2H, q, J=7.2), IR (nujol) 2260 and 1770 cm^{-1}; 1,1-dicyanopropyl propionate (**16**) 13%, NMR 1.27 (3H, t, J=7), 1.33 (3H, t, J=7), 2.17—2.77 (4H, a mixture of two q).

Reaction of Acyl Cyanide with Isocyanate. A mixture of phenyl isocyanate (6.1 g, 0.05 mol), isobutyryl cyanide (5.0 g, 0.05 mol) and pyridine (1.0 g) in 50 ml of dry benzene was warmed at 33 °C for 20 h. After removing solvent, the residue was washed with petroleum ether and the obtained solid (7.6 g) was then chromatographed (silica gel, chloroform) to give 1-cyano-2-methyl-1-propenyl phenylcarbamate (**17**) 6.9 g (62 %), mp 129 °C (benzene). NMR ($CDCl_3$) 1.83 (3H, s), 2.06 (3H, s), 6.95 (1H, bs), 7.1—7.4 (5H, m). IR (Nujol) 3300, 2240, 1740, and 1550 cm^{-1}. MS (*m*/*e*) 216 (M^+). Found: C, 66.90; H, 5.79; N, 12.70%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%.

*1-Cyano-2-methyl-1-propenyl ethylcarbamate (**18**)*: Yield 25%, mp 53.5—54 °C, recrystallized from cyclohexane/benzene=10/2. NMR ($CDCl_3$) 1.20 (3H, t, J=7.5), 1.81 (3H, s), 2.05

(3H, s), 3.23 (2H, quintet, J=7.5 and 6), 5.97 (1H, bt, J=6). MS (*m/e*) 168 (M^+). Found: C, 57.53; H, 7.29; N, 16.43%. Calcd for $C_8H_{12}N_2O_2$: C, 57.23; H, 7.19; N, 16.66%.

*1-Cyano-1-propenyl phenylcarbamate (**19**)*: Yield 53% (by NMR), not isolated. NMR (*Z*)-isomer 7.30 (5H, m), 5.76 (1H, q, J=7.5), 1.78 (3H, d, J=7.5). (*E*)-isomer 7.30 (5H, m), 6.15 (1H, q, J=7.2), 1.72 (3H, d, J=7.2). *Z*/*E*=7/3.

*Hydrolysis of **17** in 25% Sulfuric Acid*: The mixture of **17** (0.945 g, 4.4 mmol, in 5 ml of dioxane) and 5 ml of 50% H_2SO_4 was heated at 100 °C for 17 h. After cooling the solution, water (50 ml) was added to separate colorless solids, which was filtered, dried, and chromatographed (silica gel, chloroform). The fraction eluting faster than the unreacted **17** was collected and recrystallized from cyclohexane to give 3-phenyl-5-isopropylidene-1,3-oxazolidine-2,4-dione **20**, 95 mg (10%), mp 93—94 °C. NMR ($CDCl_3$) 2.03 (3H, s), 2.27 (3H, s), 7.43 (5H, m). IR (Nujol) 1800, 1720, and 1185 cm^{-1}. MS (*m/e*) 217 (M^+). Found: C, 66.51; H, 5.14; N, 6.42%. Calcd for $C_{12}H_{11}O_3N$: C, 66.36; H, 5.07; N, 6.45%.

*Hydrogenation of **17***: A solution of **17** (1 mmol) dissolved in a mixture of acetic acid and methanol (5 ml+30 ml) absorbed *ca.* 25 ml of H_2 (1 mmol) over 5% Pd–carbon (100 mg) during 10 days. Evaporation of solvents separated a half-solidified material, which was then washed with CCl_4 and the residue was chromatographed (silica gel, chloroform) to give colorless solids of 3-phenyl-4-imino-5-isopropyl-1,3-oxazolidin-2-one (**21**), 175 mg (80%), mp 219—220 °C. MS (*m/e*) 218 (M^+). NMR (acetone-d_6) 0.80 (3H, d, J=7 Hz), 1.15 (3H, d, J=7), 2.48 (1H, m, probably a pair of splitted heptets, J=2.2 and 7), 5.02 (1H, d, J=2.2), 7.2—7.55 (3H, m), 7.7—7.9 (2H, m). IR (Nujol) 3250, 3070, 1740, 1625, and 1560 cm^{-1}. Found: C, 65.80; H, 6.41; N, 12.68%. Calcd for $C_{12}H_{14}N_2O_2$: C, 66.04; H, 6.47; N, 12.83%.

The authors wish to express their thanks to Mr. Hiroyuki Ueda for his assistance in this study.

Reduction of Methylene Blue with L-Ascorbic Acid or L-Cysteine in Micellar Systems

Manabu Senō,* Kouichi Kousaka, and Hideo Kise

Institute of Industrial Science, The University of Tokyo, Roppongi 7-22, Minato-ku, Tokyo 106

(Received April 27, 1979)

The reduction of Methylene Blue (MB) with L-ascorbic acid to the corresponding leuco compound has been studied in aqueous surfactant solutions. The reduction was accelerated in the presence of cationic surfactant hexadecyltrimethylammonium bromide, but tetrabutylammonium bromide, which has no ability of micelle formation, does not show any effects on the reaction rate. The micellar effects are largely affected by pH of the medium, and the rate enhancing effects of the micelles are retarded by KCl. These results could be interpreted by the change in dissociation state of the substrate on the micelle surface and by the binding of the reaction product, leuco MB, to the micelles. The binding site of leuco MB was found to be outer core of the HTAB micelle by NMR. Similar results were obtained in the reduction of MB with L-cysteine, although the reduction did not proceed without the addition of cationic surfactant. The interaction between dissolved oxygen and the substrate in HTAB micellar solutions was also investigated.

Oxidation and reduction are fundamentally important reactions of metabolism in living systems catalyzed by oxidase and reductase. These enzymes are usually composed of two parts, coenzyme and apo-enzyme. Coenzymes are compounds which transfer electrons to substrates, whereas apo-enzymes are spherical proteins which provide the reaction sites. Associates of surfactant molecules are similar to spherical proteins in several respects.[1] (1) The micellar structure has many similar features to spherical proteins; (2) denaturants of proteins also destroy micellar structure; (3) the binding constants of substrates with micelles are in the same order as those with enzymes; (4) kinetics of micellar catalysis obeys the Michaelis-Menten equation which is applied extensively to the enzyme catalysis.

This report describes the results of micellar effects on the reduction of Methylene Blue (MB) with L-ascorbic acid or L-cysteine, and the oxidation of leuco MB with oxygen in the presence of surfactants.

Experimental

Materials. Methylene Blue was recrystallized three times from ethanol. L-Ascorbic acid and L-cysteine of reagent grade were used without further purification. Hexadecyltrimethylammonium bromide (HTAB) and sodium dodecyl sulfate (SDS) were recrystallized three times from ethanol–ether. Poly(oxyethylene) oleyl ether (POOE) was obtained commercially and used without further purification.

Reduction Rate Measurement of Methylene Blue. After mixing an aqueous solution of L-ascorbic acid (1.29×10^{-3} M) with an aqueous solution of MB (1.23×10^{-5} M) containing a certain amount of a surfactant, the decrease in the intensity of absorption peak of MB at 660 nm was followed. The pH of the solution was adjusted with a phosphate buffer, but sometimes sodium hydroxide or hydrochloric acid were used in order to avoid complexity caused by the buffer solution. The pH of reaction mixtures was measured with a Toa HM-5A pH meter. The reactions were carried out in UV cells of 10 or 2 mm path length and the decrease in absorption intensity of MB was recorded with a Union stopped-flow spectrophotometer model RA-1100 with a RA-1085 digital memory unit. For tracing slower reactions, a Union SM-401 spectrophotometer was employed. The reactions of MB with L-cysteine were examined by similar procedures.

Oxidation of Leuco Methylene Blue with Oxygen. Leuco MB was prepared by the electrolytic reduction of MB in 0.01 M hydrochloric acid solution. The solution was diluted with air-saturated water containing a given amount of surfactant. The oxidation rate was determined by measuring the increase in absorbance of MB at 660 nm in a UV cell of 10 mm path length at 25 °C.

Determination of Dynamic Solubilization Site of Leuco Methylene Blue. The ^{1}H NMR spectra were recorded on a Hitachi 60 MHz spectrometer and used for the determination of solubilization site of leuco MB. All spectra were measured on freshly prepared solutions at 35 °C. A 30% solution of tetramethylsilane in deuteriochloroform was used as an external standard.

Results and Discussion

Reduction of Methylene Blue with L-Ascorbic Acid. Under neutral conditions the reduction of MB with L-ascorbic acid is a reversible reaction as shown below and the position of equilibrium lies far to the left.

$$\mathrm{MB} + \mathrm{AsH} \rightleftarrows \mathrm{MBH} + \mathrm{As}$$

In the present investigation an excess amounts of L-ascorbic acid over those of MB were used, and the pseudo first order rate constants k_1 were determined from the relation shown below.

$$-\mathrm{d[MB]}/\mathrm{d}t = k_1[\mathrm{MB}]$$

The effects of the addition of various surfactants on the rate constant k_1 and the apparent equilibrium constant $K=[\mathrm{MBH}]/[\mathrm{MB}]$ were examined.

Figure 1 shows the effects of the addition of surfactants on k_1. The reduction of MB is accelerated by the addition of a cationic surfactant HTAB. The addition of a nonionic surfactant POOE also accelerates the reduction, but the effect is not so large as that of HTAB. On the other hand, an anionic surfactant SDS inhibits the reduction due to the formation of complex salt with MB. Tetrabutylammonium bromide, which is the compound of the same type as HTAB but has no ability of micelle formation, does not show any acceleration effect on the reaction. This indicates that micelle formation is essential for catalytic activity.

The dependence of k_1 on the HTAB concentration near critical micelle concentration (CMC) is shown in Fig. 2. Unlike the ordinary behavior of micellar

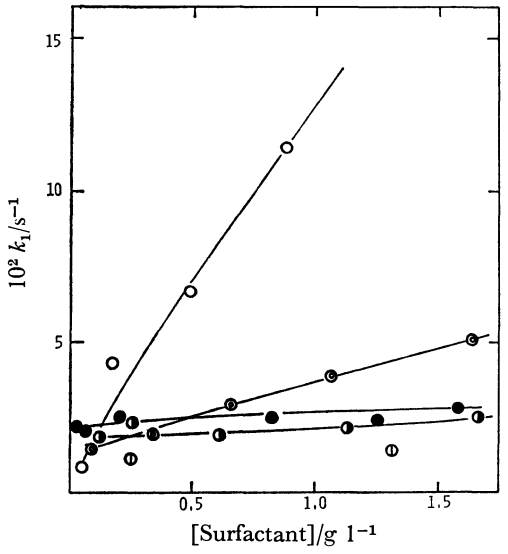

Fig. 1. Rate constant for the reaction of Methylene Blue with L-ascorbic acid as a function of surfactant concentration. Methylene Blue 1.23×10^{-5} M, ascorbic acid 1.29×10^{-3} M, 25 °C, pH 6.80.

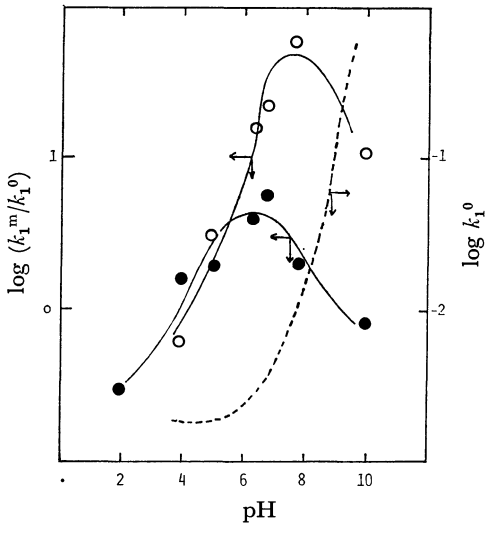

Fig. 4. Relationship between relative rate and pH. k_1^m and k_1^0 are rate constants with and without surfactant, respectively. Methylene Blue 1.23×10^{-5} M, ascorbic acid 1.29×10^{-3} M, 25 °C. ○, HTAB 1.37×10^{-3} M; ●, POOE ($n=10$) 1.97×10^{-3} M.

catalyses,[2] a linear relationship between k_1 and HTAB concentration is observed far above the CMC where the micelle concentration is much higher than those of the substrates. This lack of saturation in the rate profile suggests that the interaction between the cationic micelle and MB is weak, *i.e.* the binding constant is small. This seems reasonable because MB has the same positive charge as HTAB. The association between them is considered to be originated from hydrophobic interaction which competes with electrostatic repulsion between MB and the cationic head groups of the micelle.

Figure 3 shows the effect of surfactants on the apparent equilibrium constant K. HTAB has a large effect on K as well as on k_1, while POOE shows a medium effect on K. As will be discussed later, reduced MB (leuco MB) is most likely solubilized in the HTAB micelle core, and this would reduce the direct contact with oxidizing species leading to the increase in the apparent equilibrium constant.

The dependence of k_1 on pH is shown in Fig. 4. In these experiments, pH of the solutions was adjusted by using dilute aqueous solutions of hydrochloric acid or sodium hydroxide in order to exclude the possible effect of buffer solution.[3] The reduction rate in HTAB or POOE micellar solutions increases with increasing pH as well as in the absence of surfactants over most of the range of pH investigated. This implies that ascorbic acid reacts with MB faster in anionic form than in neutral form. The above observation suggests that the rate acceleration by HTAB is likely to be attributed to the concentration of MB and anionic ascorbic acid on the surface of the micelle where the pH is higher than

bulk water phase.

It should be noted that, as shown in Fig. 4, both HTAB and POOE have inhibitory effects on the reaction below pH 4. Under these acidic conditions ascorbic acid is considered to be neutral and binds easier with the micelles. The separate solubilization of MB and ascorbic acid into the micelles may be the reason for the rate retardation, although it is difficult to draw any definite conclusion from these pH studies.

It was reasonably expected that competitive binding of counter ions on the micellar surface occurs by the addition of inorganic salts, so that the local concentration of anionic substrates on HTAB micelle surface was expected to be reduced. Figure 5 shows the effect of potassium chloride on k_1 in HTAB solutions. The acceleration effect of HTAB is markedly reduced which may be due to the reduction of the binding of the substrate on the micelle surface.

To clarify the origin of nonionic micellar effects on the reduction rate shown above, the effect of solvent polarity was examined. The reactions were carried out in methanol–water mixed solvents. The reaction rate increases with increasing content of methanol (Fig. 6). This implies that less polar media favor the reaction and that the micellar effects of nonionic surfactants arise at least partly from the change of local polarity of the micellar systems.

The Dynamic Solubilization Site of Leuco Methylene Blue. Leuco MB is expected to be solubilized in surfactant micelles for its low solubility in water. NMR studies of surfactant solutions have been carried out in order to determine the dynamic solubilization site of organic compounds.[4] We studied the ^1H NMR of aqueous HTAB solutions in the presence of leuco MB in order to determine the solubilization site of leuco MB. Table 1 summarizes the observed chemical shifts and the results on pyrene reported by Grätzel *et al.*[5] Pyrene has been considered to be solubilized in HTAB micelle core causing higher shifts of resonance band of HTAB

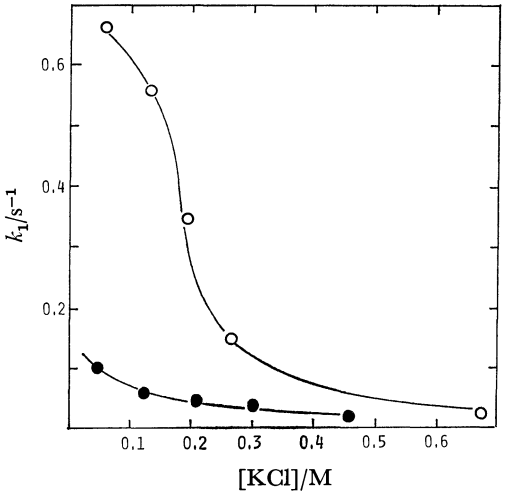

Fig. 5. Effect of KCl on the reduction rate of Methylene Blue with ascorbic acid in surfactant solutions. Methylene Blue 1.23×10^{-5} M, ascorbic acid 1.29×10^{-3} M, 25 °C, pH 6.80. ○, HTAB 8.05×10^{-3} M; ●, POOE ($n=10$) 5.00×10^{-3} M.

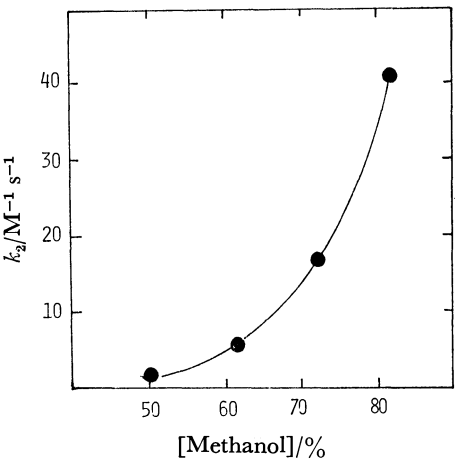

Fig. 6. Effect of methanol content on the reduction rate of Methylene Blue with ascorbic acid at 25 °C. Methylene Blue 8.05×10^{-5} M, ascorbic acid (Na salt) 5.82×10^{-3} M, without buffer.

Table 1. Change in chemical shift of HTAB protons by the addition of solubilizates[a)]

Proton	Δδ			
	MB 5.0×10^{-3} M	Leuco MB 1.3×10^{-4} M	Leuco MB 8.2×10^{-4} M	Pyrene[b)] 1.0×10^{-2} M
$N(CH_3)_3$	0.00	0.027	0.039	0.033
$(CH_2)_n$	0.00	0.005	0.008	0.016

a) Ppm relative to an external TMS standard. [HTAB]= 0.1 M. Δδ=Difference in chemical shifts of HTAB protons with and without solubilizates. MB=Methylene Blue. b) Ref. 5.

protons. As seen in Table 1, the protons of methyl groups attached to nitrogen exhibit upfield shifts by the addition of leuco MB which are comparable to that of pyrene of higher concentration. This seems to suggest that leuco MB is located in the outer core and near surface of the micelle.

Reduction of Methylene Blue with L-*Cysteine.* Similar to the reduction with ascorbic acid, both acceleration by HTAB and inhibition by KCl were observed in the reduction of MB with L-cysteine as shown in Figs. 7

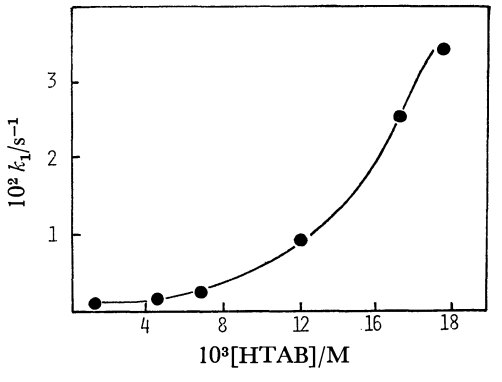

Fig. 7. Effect of HTAB on the reduction rate of Methylene Blue with L-cysteine. Methylene Blue 1.27×10^{-5} M, cysteine 3.12×10^{-3} M, 25 °C, pH 6.80.

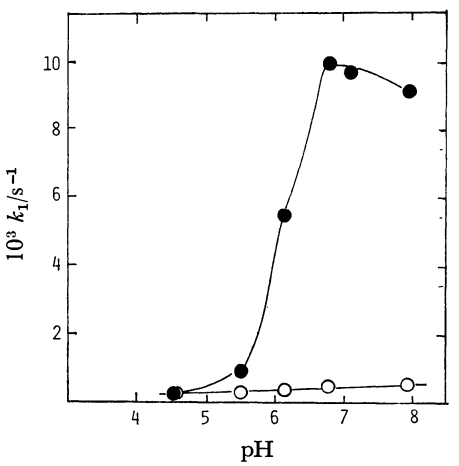

Fig. 9. Effect of pH on the reduction rate of Methylene Blue with L-cysteine at 25 °C. Methylene Blue 1.27×10^{-5} M, cysteine 8.25×10^{-3} M.
○, Without surfactant; ●, HTAB 1.13×10^{-2} M.

and 8. However, quite different results were obtained for the dependence of k_1 on pH as shown in Fig. 9. In HTAB micellar systems k_1 increases with the increase of pH followed by rate saturation above pH 7, whereas k_1 is almost independent of pH in the reaction without surfactants.

In general, there are two distinguished factors govering the micellar effects on organic reactions. One is the local concentration effect of substrates or catalysts at the reaction site, which is caused by electrostatic or hydrophobic interactions between micelles and the substrates. Another is the medium effect on the stability of transition states.[6] Many studies have revealed that the surface of cationic micelles is more basic than bulk water phase. Heitmann[7] suggested that the pK_a value of the SH group of *N*-dodecanoyl-DL-cysteine incorporated in cationic micelles is larger by unity than the value in micelle free solutions.

It is obvious that the results shown in Fig. 9 cannot be explained by pH effect of the cationic micelle surface and other factors must be effective in this case. It should be noted that, contrary to L-cysteine, the solubility of L-cystine in water is very low and in the presence of HTAB micelles it is likely to be solubilized in the micelles. In the present system, a large excess of HTAB micelles would solubilize the reaction products separately for each other, which would suppress the reverse reaction of leuco MB with L-cystine and increase the apparent k_1.

Another factor which should be taken into consideration is the effect of dissolved oxygen. It has been reported that the reduction of MB is inhibited by dissolved oxygen in aqueous solutions.[8] There is a possibility that oxygen participates in the reduction with L-cysteine through the following two processes. One is the inhibition of reduction by L-cysteine, and another is the rapid oxidation of leuco MB. Although we found it difficult to examine the effect of the former process, the latter was examined by the following method. Leuco MB was prepared electrolytically and the effect of HTAB micelle on its oxidation by dissolved oxygen was examined. Since the dissociation state and the micro environment of leuco MB would change by the addition of HTAB as describe above, the oxidation rate by dissolved oxygen was expected to be affected by HTAB. Actually however, the oxidation rate was found to be almost independent of HTAB concentration as seen in Fig. 10. It is interesting to note that different trends for the effect of added KCl on the oxidation rate

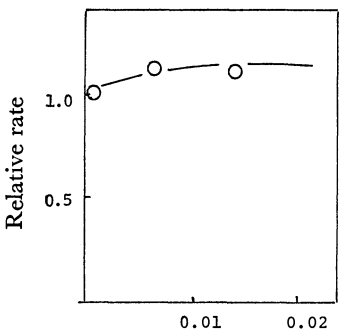

Fig. 10. Effect of HTAB on the relative oxidation rate of leuco Methylene Blue with dissolved oxygen in aqueous solutions.

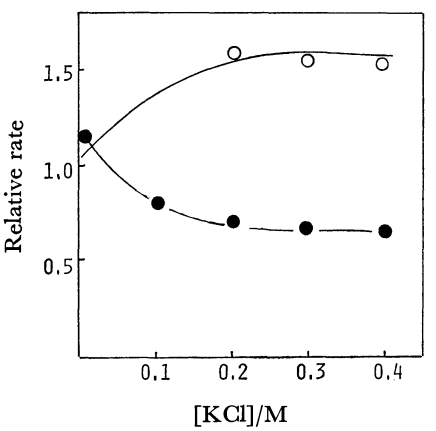

Fig. 11. Effect of KCl on the relative oxidation rate of leuco Methylene Blue with dissolved oxygen in aqueous HTAB solutions.
Leuco Methylene Blue 1.33×10^{-5} M, at 25 °C, pH 6.80. HTAB ○, 5.49×10^{-4} M; ●, 1.42×10^{-2} M.

were observed below and above cmc of HTAB (Fig. 11). The rate is lowered by the addition of KCl above cmc of HTAB, and this implies that cancelling the electric charge on the micelle surface would lead to the inhibition of the oxidation. The above observations tentatively lead to the conclusion that dissolved oxygen has, if any, small effect on the reduction system of MB by L-cysteine.

Electronic State of Ethoxycarbonylnitrene Generated by α-Elimination under Two-phase Conditions

Manabu SENŌ,* Tomiyuki NAMBA, and Hideo KISE

Institute of Industrial Science, The University of Tokyo, 7-22 Roppongi, Minato-ku, Tokyo 106

(Received November, 1, 1978)

The base decomposition of ethyl *p*-nitrophenylsulfonyloxycarbamate in organic-aqueous two-phase systems in the presence of *cis*- or *trans*-4-methyl-2-pentene and quaternary ammonium or phosphonium halides afforded both stereospecific and nonstereospecific addition products of ethoxycarbonylnitrene. The electronic state of the nitrene was analyzed on the basis of Skell's hypothesis.

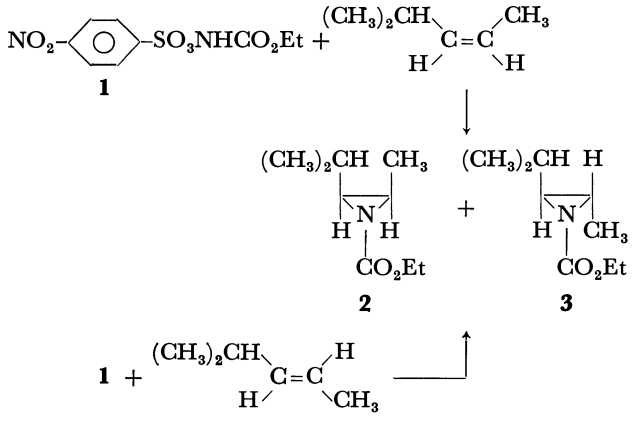
In the previous paper,[1] we reported that ethoxycarbonylnitrene was generated by α-elimination reaction of ethyl *p*-nitrophenylsulfonyloxycarbamate (**1**) and reacted with cyclohexene in organic-aqueous two-phase systems in the presence of phase transfer catalysts. In these reactions the variation of reaction path through singlet or triplet nitrene was shown as the dependence of addition/insertion product ratio on the concentration of cyclohexene.

In the present study the electronic state of ethoxycarbonylnitrene generated under two-phase conditions is examined by analyzing the composition of the reaction products with *cis*- or *trans*-4-methyl-2-pentene on the basis of Skell's hypothesis.[2]

Results and Discussion

Table 1 shows the yield of aziridines and the fraction of nonstereospecific addition (inversion) products in the reaction with *cis*- and *trans*-4-methyl-2-pentene under two-phase conditions (Scheme 1). No significant differences were observed in the catalysis of ammonium chlorides and bromides, but ammonium iodides gave unusual results; that is, the yields of addition product are low and the fractions of nonstereospecific addition product are decreased.

The ethoxycarbonylnitrene generated by α-elimination is supposed to be a singlet nitrene, which adds stereospecifically to olefins with complete retention of configuration.



Scheme 1.

Since the ground state of the nitrene is triplet, a part of the singlet nitrene decays to the triplet nitrene, which adds nonstereospecifically to olefins. As a side reaction, ethyl carbamate is formed by hydrogen abstraction reaction from the triplet nitrene. The reaction scheme is summarized in Fig. 1.

When triethylbenzylammonium chloride (TEBACl) was used as a phase transfer catalyst, the relationship between the concentration of *cis*- or *trans*-4-methyl-2-

●; *cis*-4-Methyl-2-pentene under two-phase conditions, ▲; *trans*-4-methyl-2-pentene under two-phase conditions, ○; *cis*-4-methyl-2-pentene in the homogeneous system,[3] △; *trans*-4-methyl-2-pentene in the homogeneous system.[3]

pentene in dichloromethane and the fraction of inversion product is shown in Fig. 2. In comparison with the results for the homogeneous system investigated by Lwowski *et al.*,[3] which are also shown in Fig. 2, the portion of the inversion product of the reaction with *cis*-4-methyl-2-pentene under two-phase conditions is a little low, while that of the reaction with *trans*-4-methyl-2-pentene is a little high, but concerning the dependence on the olefin concentration, the same trend is found for both the homogeneous and the two-phase systems. Thus, the increase in the concentration of olefin leads to a descrease in the inversion product. This can be explained as a consequence of an increasing frequency of the singlet nitrene reaction at higher concentrations of the olefins.

Now we consider the electronic state of the ethoxycarbonylnitrene generated in the present system according to the method proposed by Lwowski *et al.*[3,4] The fraction of the aziridine produced from the triplet nitrene in the total aziridine obtained is designated $[T]$, and the fraction of the "*trans*-aziridine" **3** in the aziridine produced from the triplet nitrene is designated α. If one assumes that the composition of the aziridine mixture produced from the triplet nitrene depends on the position of the equilibrium of the two conformers of open-chain biradical intermediate and not on the nature of the starting olefin, the fraction A of **3** in the aziridine mixture obtained from the *cis*-olefin and the fraction B of the "*cis*-aziridine" **2** in the aziridine mixture obtained from the *trans*-olefin are expressed respectively as;

$$A = [T]\alpha, \quad B = [T](1-\alpha) \tag{1}$$

The following relation is derived from Eq. 1.

$$\alpha = A/(A+B) \tag{2}$$

In order to know the value of A/B from the experimental data, the difference in the reactivity of *cis*- and *trans*-olefins toward the nitrene should be taken into consideration. From the measurements on the homogeneous system by Lwowski *et al.*,[3] the ratio of the reactivity $k_{4,trans}$: $k_{4,cis}$ is determined to be 0.7. This value is affected by the nature of olefin, but not affected by the nature of nitrene. Then, we can adopt this value for the present systems and then we can obtain the value of A/B from the experimental data shown in Fig. 2, by comparing the value of A at a given concentration with the value of B at 1/0.7 of that concentration. The values of A/B thus obtained vary from 1.5 to 2.1 in the concentration range from 33 to 1.5 mol %. The average value of A/B is 1.8, and the value of α is determined to be 0.64 from Eq. 2.

When the fraction of the aziridine produced from the singlet nitrene in the total aziridine is denoted as $[S]$, we get from Eq. 1

$$[T] = 1.56A, \quad [S] = 1 - [T] \tag{3}$$

From the reaction scheme shown in Fig. 1, the following relation is obtained by assuming the stationary state with respect to the triplet nitrene,

$$\frac{[T]}{[S]} = \frac{k_2}{k_3\{[\text{olefin}] + (k_5/k_4)\}} \tag{4}$$

Then, a plot of $[T]/[S]$ *vs.* $1/\{[\text{olefin}]+(k_5/k_4)\}$ should give a strainght line having the slope of k_2/k_3. Various plots were drawn by assuming various values of k_5/k_4 and the value of k_5/k_4 which gives the best straight line was determined. The selected value of k_5/k_4 for the two-phase reaction with TEBACl is 0.005, and then

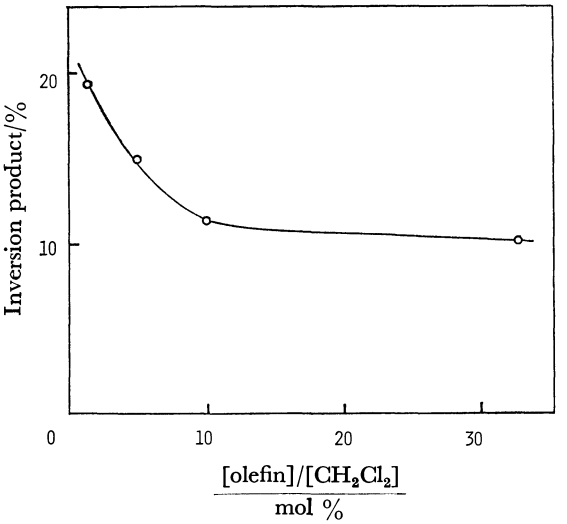

Fig. 3. Addition of ethoxycarbonylnitrene to *cis*-4-methyl-2-pentene under two-phase conditions in the presence of TEBAI.

the value of k_2/k_3 is determined to be 0.033 from the slope of the line.

When triethylbenzylammonium iodide (TEBAI) is used as a phase transfer catalyst, the relationship between the concentration of *cis*-4-methyl-2-pentene in dichloromethane and the inversion product is shown in Fig. 3. According to the same procedure as the case of TEBACl, the values of k_5/k_4 and k_2/k_3 were determined to be 0.07 and 0.033, respectively.

Table 2. Rate constant ratios k_2/k_3 and k_5/k_4 of the reactions of ethoxycarbonylnitrene under various conditions

	Two-phase system		Homogeneous system	
	TEBACl	TEBAI	α-Elimination with triethylamine[a]	Thermolysis of ethyl azidoformate[b]
k_2/k_3	0.033	0.033	0.036	0.10
k_5/k_4	0.005	0.07	0.015	0.03

a) From Ref. 4. b) From Ref. 3.

Table 2 summarizes the values of k_2/k_3 and k_5/k_4. The results of the two-phase reactions using TEBACl or TEBAI as phase transfer catalysts are compared with those of α-elimination reaction by triethylamine in a homogeneous system[3] and the thermolysis of ethyl azidoformate.[4] It is revealed from these results that the singlet nitrenes generated in the two-phase system and in the homogeneous system have the similar reactivity and the addition reaction of the singlet nitrene is about 30 times faster than the decay to the triplet state. However, there is a difference in the reactivity of the triplet nitrene. In the case of TEBACl, the ratio of side reactions such as hydrogen abstraction to form ethyl carbamate is low compared with the case of homogeneous system, while the ratio of side reactions (k_5/k_4) is very high in the case of TEBAI. Iodide ions from the catalyst is considered to enter into the organic phase easier than chloride or bromide ions, and the results imply that triplet nitrene is consumed by iodide ions in some unknown processes.

Experimental

The materials used and the authentic samples of the aziridines are described in the previous paper.[1] The reactions of ethyl *p*-nitrophenylsulfonyloxycarbamate (**1**) with *cis*- or *trans*-4-methyl-2-pentene were carried out in dichloromethane solutions and aqueous sodium hydrogencarbonate solutions in the presence of phase transfer catalysts. The details of the reactions and the analyses of the products are also described in the previous paper.[1]

Modifizierte Wichterle-Reaktion. Ein Weg zur Darstellung von 2-Cyclohexenonen und 1,4-Diketonen. Synthese von 4-Estren-3,17-dion und Dihydrojasmon

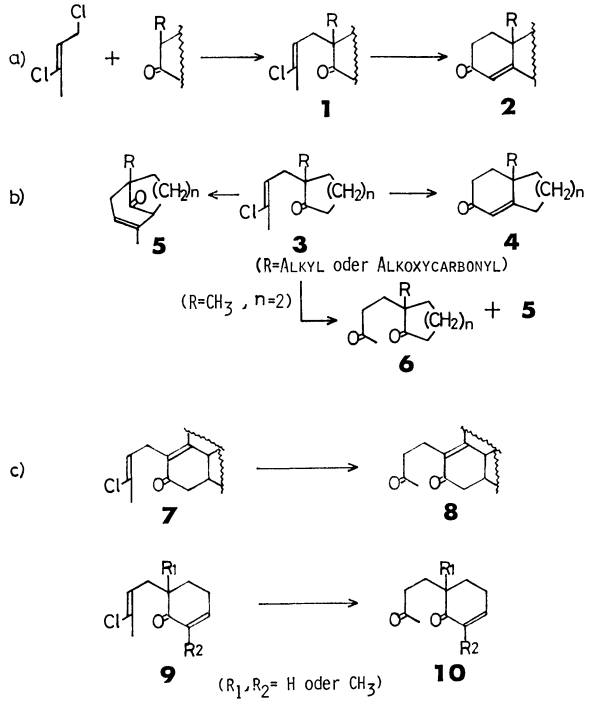
Makoto KOBAYASHI und Takeshi MATSUMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Eingegangen November 20, 1978)

Während die Behandlung von 2-(3-Chlor-2-butenyl)-2-methylcyclohexanon mit konz. H_2SO_4 2,5-Dimethylbicyclo[3.3.1]non-2-en-9-on als Hauptprodukt ergab, wurde beim Erhitzen in HCO_2H in Anwesenheit von $HClO_4$ 4a-Methyl-$\Delta^{1(8a)}$-2-octalon in 70 bis 98%-iger Ausbeute erhalten. Unter diesen Bedingungen reagierten andere α-(Chlorbutenyl)ketone analog und lieferten die entsprechende Annelierungsprodukte in hohen bis mässigen Ausbeuten. Aus α-(2-Haloallyl)ketonen wurden 1,4-Diketone gewonnen. Als Anwendungsbeispiele wurden 4-Estren-3,17-dion und Dihydrojasmon synthetisiert.

Bei Synthesen von Naturstoffen spielen Cyclisierungsreaktionen eine wichtige Rolle. Die Robinson-Annelierung ist eine der wirksamsten Cyclisierungsreaktionen, die bis jetzt entwickelt worden ist.[1] 1947 berichteten Wichterle *et al.* über eine Modifizierung der Robinson-Annelierung,[2] in der 1,3-Dichlor-2-buten (DCB) anstatt Methylvinylketons verwendet wurde: d.h., das durch Alkylierung von Carbonylverbindung mit DCB dargestellte α-(3-Chlor-2-butenyl)keton **1** wurde mit konz. H_2SO_4 behandelt, wobei das entsprechende 2-Cyclohexenon-Derivat **2** entstand (Schema-1a). Wie bereits Prelog sowie andere Autoren gezeigt haben, führt aber die Einwirkung von konz. H_2SO_4 auf α-(Chlorbutenyl)ketone **3** in den meisten Fällen nicht zu bicyclischen Produkten **4**, die für den Aufbau von gewissen Naturstoffen wertvoll sind, sondern zu verbrückten Olefinen von Typ **5**.[3] Marshall *et al.* untersuchten daher die Cyclisierungsbedingungen von **3** näher und es gelang, unter relativ milden Bedingungen das



Schema 1. Wichterle-Reaktion unter konventionellen Bedingungen.

1,5-Diketon **6** in mässiger Ausbeute zu isolieren (Schema-1b).[4] Anderseits liefern unter den oben erwähnten konventionellen Bedingungen chlorbutenylierte α,β-Enone **7** sowie **9** die entsprechenden 1,5-Diketone **8** und **10** in guten Ausbeuten, was zur Konstruktion des Steroid-A-Rings angewandt wurde (Schema-1c).[5] Wegen des oben beschriebenen Nachteils, dass oft verbrückte Bicyclene als Hauptprodukt entstehen, wurde die Wichterle-Reaktion zur Synthese von Naturstoff bisher selten verwendet.[6]

Es ist wohlbekannt, dass ein Vinylhalogenid wegen des Doppelbindungscharakters zwischen Halogen- und Kohlenstoffatom im allgemeinen eine geringe Reaktionsfähigkeit besitzt. Ausser der gewöhnlicher Hydrolyse unter stark saueren Bedingungen wurden vor kurzem einige milde Umwandlungen von Vinylhalogeniden zu den entsprechenden Ketonen berichtet, bei welchen Übergangsmetalle verwendet wurden.[7]

Im Zusammenhang mit dem Versuch zur Darstellung eines Zwischenproduktes bei der Totalsynthese eines Diterpens war es erforderlich, die Cyclisierungsbedingungen der Wichterle-Reaktion zu untersuchen. Dabei stellte sich heraus, dass sich α-(Chlorbutenyl)keton beim Erhitzen mit Mineralsäure in saueren Lösungsmitteln wie HCO_2H leicht ins entsprechende 2-Cyclohexenon-Derivat umwandeln lässt. Darüber möchten wir hier zusammen mit den einfachen Anwendungen zur Darstellung von Steroid-Skeletten und Dihydrojasmon berichten.[8]

A. Lösungsmitteleffekt und Reaktionsweg

Unter Verwendung von 2-(3-Chlor-2-butenyl)-2-methylcyclohexanon (**11**) als Modellverbindung wurde der Optimierungsversuch durchgeführt. Der Lösungsmitteleffekt ist in Tabelle-1 zusammengestellt. Daraus ergab sich, dass dieser Ringschluss von **11** zu 4a-Methyl-$\Delta^{1(8a)}$-2-octalon (**12**) in Lösungsmittel wie HCO_2H sowie CH_3NO_2 in Anwesenheit von starker Säure (Nr. 4, 8) und H_2O (Nr. 3) unter Kochen leicht stattfindet. Bei Verwendung von HCO_2H als Lösungsmittel und $HClO_4$ als Säure-Katalysator erhielt man die beste Ausbeute an **12** (Nr. 1).[9] Weder 1,5-Diketon **13** noch verbrücktes Bicyclen **14** wurden isoliert (Schema-2).[4] Besonders bemerkenswert ist

Tabelle 1. Lösungsmitteleffekt in cyclisierung von **11** zu **12**[a]

Nr.	Lösungsmittel	pK_b[b]	Säure	Rückflussdauer	Ausb. an **12**[c]

*) als Methylester isoliert.

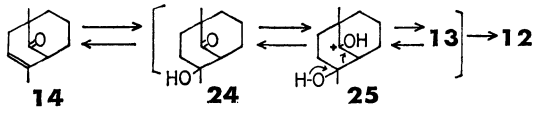
Schema 3.

die Tatsache, dass diese Cyclisierung sehr stark vom Lösungsmittel abhängig ist. Es scheint, dass eine enge Beziehung zum pK_b-Wert des Lösungsmittels besteht. In den Lösungsmitteln wie HCO_2H (pK_b≈20.2) sowie CH_3NO_2 (pK_b≈25), die schwächer basisch als Olefin (pK_b≈18) sind, sollte die Protonierung an die C=C-Doppelbindung des Chlorbutenyl-Restes viel günstiger sein als in den stärker basischen alkoholischen (pK_b≈16) bzw. ätherischen (pK_b≈17.5) Lösungsmitteln. Das durch Addition des Protons an den Chlorbutenyl-Rest gebildete intermediäre Ion **15** würde über das 1,5-Diketon **13** ins Endeprodukt **12** umgewandelt werden. Dass die Reaktion die Anwesenheit von H_2O erfordert (Nr. 7), ist verständlich, wenn man die intermediäre Bildung des 1,5-Diketons **13** annimmt. Obwohl die Möglichkeit der Carbonylgruppenbeteiligung (**15**→**16**→**13**, Schema-2) nicht ausgeschlossen werden kann, erscheint dieser Verlauf auf Grund der unten beschriebenen Befunde weniger wahrscheinlich.

Um den Reaktionsweg von **11** zu **12** genauer zu untersuchen, wurden Dichlordiolefine **17** und **19** dargestellt und den neuen Cyclisierungsbedingungen der Wichterle-Reaktion unterworfen. Da diese beiden Verbindungen keine Carbonylgruppe enthalten, ist eine Carbonylgruppenbeteiligung beim Hydrolysierungsschritt zum Diketon nicht möglich. Obwohl die Reaktionszeit im Vergleich mit **11** etwas länger dauerte, ergaben diese Dichlordiolefine in mässigen Ausbeuten Octalon-Derivate **18** bzw. **12** (Schema-3).[3a] Dies weist darauf hin, dass die Nachbargruppenbeteiligung (**15**→**16**→**13**→**12**) beim Ringschluss unter diesen neuen Bedingungen nicht so wichtig sein sollte. Um diesen Punkt weiter aufzulkären, wurde die Umwandlung von 2-(3-Chlorallyl)cyclohexanon (**20**) in den entsprechenden Ketoaldehyd **21** versucht. Nicht nur unter den neuen, sondern auch unter den konventionellen (konz· H_2SO_4) Bedingungen wurde **21** nicht erhalten. Des weitern verlief die Hydrolyse von 5-Chlor-2,2-dimethyl-4-hexensäure (**22**) zur Ketocarbonsäure **23** nicht so glatt. Dies deutet darauf hin, dass eine Beschleunigung der Hydrolyse durch einen Nachbargruppeneffekt der Carboxylgruppe nicht stattfindet. Diese Ergebnisse

könnten zeigen, dass bei der Cyclisierung von α-(Chlorbutenyl)ketonen ein intermediäres Carboniumion wie **15** zuerst entsteht und dessen Stabilität sehr wichtig ist, und dass die Methylgruppe des Chlorbutenyl-Restes für die Stabilisierung von **15** eine grosse Rolle spielt. Alle bisher erwähnten Befunde zusammengenommen, könnte der Reaktionsweg der neuen Ringschlussreaktion von **11** über **15** und **13** zu **12** führen (Schema-2).

Sehr interessant ist, dass das verbrückte Bicyclen **14** unter den oben beschriebenen Bedingungen in guter Ausbeute ins Octalon **12** überführt wurde, während in EtOH keine Reaktion eintrat und das Ausgangsmaterial **14** fast quantitativ zurückgewonnen wurde. Die basekatalysierte Retro-Aldolkondensation von **24** zu **12** ist schon bekannt.[10] In diesem Fall würde **14** zuerst zum Ketol **24** hydratisiert, das weiter ins 1,5-Diketon **13** über **25** säurekatalysiert überführt und zum **12** recyclisiert würde (Schema-4).



$HClO_4$-HCO_2H, 1 h RÜCKFLUSS, 82%
$HClO_4$-EtOH , 3 h RÜCKFLUSS, 0%

Schema 4.

B. Reaktionsbeispiele[11]

Um den Anwendungsbereich und die Grenze dieser Annelierung zu untersuchen, liessen sich viele α-(Chlorbutenyl)ketone HCO_2H mit $HClO_4$ bzw. HBr umsetzen. Die Resultate sind in Tabelle-2 zusammengefasst. In allen Fällen wurden weder das entsprechende 1,5-Diketon noch verbrückte Bicyclen wie Typ **5** isoliert. Aus 6-Chlor-3,3-dimethyl-5-hepten-2-on (**28**) wurden Trimethylcyclohexenone **29** und **30** im Verhältnis von *ca.* 1 : 2 erhalten.[13] Die Konstitutionen von **29** und **30** folgten aus den charakteristischen NMR-Signalen (2 breite Tripletts bei 2.43 ppm für die Methylenprotonen an C-6 von **29** und bei 2.30 ppm für die Methylprotonen an C-4 von **30**) sowie MS-Fragmentierungen (*m/e* 112 ($M^+-C_2H_2$) von **29** und *m/e* 82 ($M^+-C_4H_8$) von **30**). Ausserdem unterstützt die mechanistische Überlegung auch, dass **30** das Hauptprodukt wird, weil der Weg zu **30** im Übergangszustand die kleinere sterische Hinderung erfährt als derjenige zu **29**.[13] Bei der Umsetzung von **26** und **33a** war im Vergleich mit **11** eine längere Reaktionszeit erforderlich. Es scheint, dass die Reaktionszeit auch von der Menge der zugesetzten Säure abhängt. In den in der Tabelle-1 gezeigten Beispielen wurde 1 ml 60% $HClO_4$ zugegeben, die im Fall des Substrates **11** (100 mg) 18 Äq. entspricht. Setzt man beim grossen Ansatz der Reaktion von **11** zu **12** eine kleinere Menge $HClO_4$ (≈2 Äq.) zu, so wurde eine Abnahme der Reaktionsgeschwindigkeit (≈8 h) und der Ausbeute (≈70%) beobachtet.

2-(3-Chlor-2-butenyl)-3-methyl-2-cyclohexenon (**35**) und 4-(3-Chlor-2-butenyl)-7a-methyl-5,6,7,7a-tetrahydroindan-1,5-dion (**40**) wurden jeweils direkt bis zum α,β: γ,δ-Dienon **36** und -Diendion **41** cyclisiert.[3a,15] Im Genensatz dazu fand im Fall des 6-(3-Chlor-2-butenyl)-6-methyl-2-cyclohexenons (**37**) eine intramolekulare Michael-Reaktion statt und 5-Acetyl-1-methylbicyclo-

TABELLE 2.

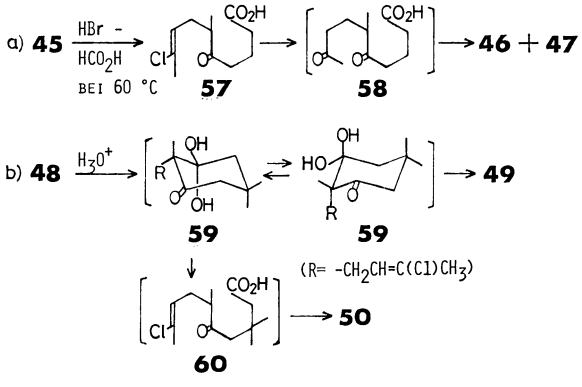
a) $HClO_4$–HCO_2H. b) HBr–HCO_2H. c) als Methylester isoliert.

[2.2.2]octan-2-on (**39**) entstand als Hauptprodukt.[4] Das erwartete Annelierungsprodukt **38** wurde als Nebenprodukt nur in 22%-iger Ausbeute erhalten.[4] Ein 1,5-Diketon wie Typ **8** oder **10**, das bei der Behandlung mit konz·H_2SO_4 hauptsächlich entsteht, wurde in keinen Fall isoliert.

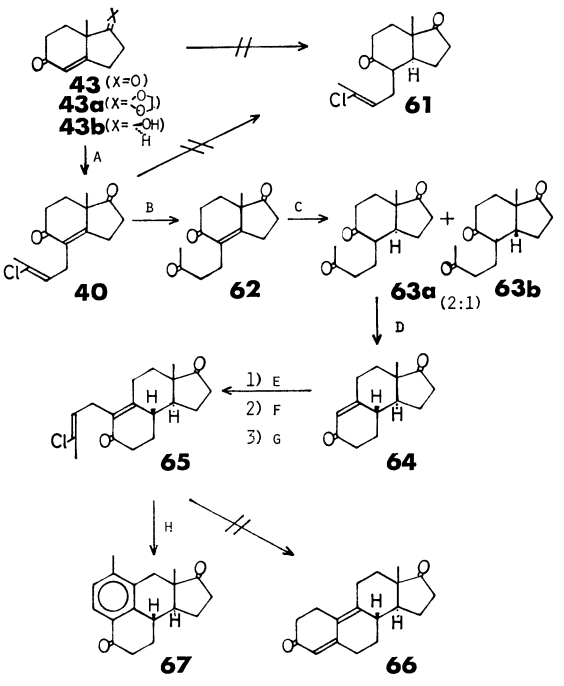
Bei Ringschlüssen von 2-(3-Chlor-2-butenyl)-2-methylcycloalkan-1,3-dion konnte man im allgemeinen mit HBr eine bessere Ausbeute erziehen als mit $HClO_4$. Beim Erhitzen in HCO_2H mit HBr wurde aus 2-(3-Chlor-2-butenyl)-2-methylcyclopentan-1,3-dion (**42**)das Annelierungsprodukt **43** in mässiger Ausbeute erhalten,[16] wobei ein Nebenprodukt **44** mit der gleichen Formel ($C_{10}H_{12}O_2$) wie **43** in einer Ausbeute von 10% kristallin isoliert wurde.[17] Bei 2-(3-Chlor-2-butenyl)-2-methylcyclohexan-1,3-dion (**45**) verlief anderseits bei 60 °C eine Ringöffnung zur Chlorketocarbonsäure **57** glatt,[18] die über **58** zu den 2-Cyclohexenon-Derivaten **46** und **47** weiter cyclisiert wurde.[19,20] Das erwünschte Wieland-Miescher-Keton, 8a-Methyl-1,6-dioxo-1,2,3,4,-6,7,8,8a-octahydronaphthalin wurde nicht erhalten. Im Gegensatz dazu wurde aus dem Trimethylkörper **48** das Dioxohydronaphthalin-Derivat **49** neben **50** im Verhältnis von *ca.* 1:1 isoliert. Wegen der sterischen Hinderung zwischen Hydroxygruppe und *gem*-Dimethylgruppe (**59a** und **59b**) sollte sich die Ringspaltung von **48** zu **60** im Vergleich mit **45** ziemlich unterdrücken lassen (Schema-5). Analog wurden aus Chlorketocarbonsäuren **51** und **54** die entsprechenden 2-Cyclohexenon-Derivate **52**[21] und **53** bzw. **55** und **56** dargestellt. Die oben beschriebenen Ketocarbonsäuren wurden alle nach Behandlung mit ether. CH_2N_2 als Methylester isoliert und die Ausbeuten bestimmt.



Schema 5.

C. Synthese von 4-Estren-3,17-dion

Als ein weiteres Anwendungsbeispiel wurde die Synthese von 19-Nor-steroid versucht. Es wurde zuerst versucht, ausgehend von **43**[22] und dessen Derivaten **43a**, **b**[2,23] durch die Stork'sche reduktive Alkylierung[6d] oder aus dem von **43** leicht abgeleiteten **40** durch selektive Hydrierung 4-(3-Chlor-2-butenyl)-7a-methylhexahydroindan-1,5-dion (**61**) darzustellen, das in ein wichtiges Zwischenprodukt **64** überführt werden könnte. Alle Versuche waren aber erfolglos. Dan wurde **40** mit konz. H_2SO_4 zum ungsättigten Triketon **62** hydrolysiert, das in AcOH mit 10% Pd–C unter Normaldruck



A) DCB-^{t}AmOK. B) H_2SO_4. C) H_2/Pd-C. D) p-TsOH. E) PYRROLIDIN. F) DCB. G) H_2O. H) $HClO_4$-HCO_2H.

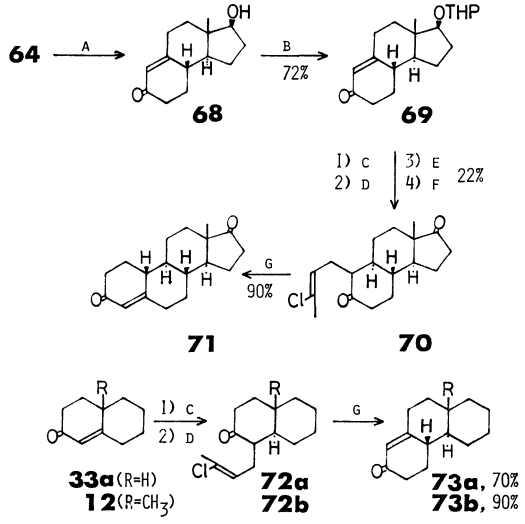
Schema 6.

hydriert wurde, wobei man ein Gemisch von **63a** und **63b** im Verhältnis von 2:1 erhielt. Ohne Trennung und Reinigung wurde das rohe Hydriergemisch in AcOH mit *p*-TsOH under Rückfluss weiter zum bekannten tricyclischen Diketon **64** cyclisiert, das nach der Säulenchromatographie an SiO_2 in 40%-iger Ausbeute aus **62** isoliert wurde.[15] **64** wurde dann über Dienamin mit DCB weiter zu **65** alkyliert. Die Cyclisierung von **65** in HCO_2H mit $HClO_4$ ergab aber kein 4,9-Estradien-3,17-dion, sondern ein bekanntes tetracyclisches Diketon **67** (Schema-6).[15] Als nächstes wurde die reduktive Alkylierung von **68** versucht, das aus **64** mit $NaBH_4$ leicht zugänglich ist.[15] Die reduktive Chlorbutenylierung von **68** in flüss·NH_3 mit Li-DCB und die anschliessende Oxydation mit CrO_3 lieferten die gewünschte Verbindung **70** in geringer Ausbeute. Bei der Alkylierung von **69** liess sich die Ausbeute ebenfalls nicht verbessern (≈17%). Deshalb wurden die Bedingungen der Stork'schen reduktiven Alkylierung von **12** sowie **33a** als Testverbindungen untersucht (Tabelle-3). Wenn man 0.8 Äq. ^{t}BuOH zusetzte und

TABELLE 3. TESTEXPERIMENT DER REDUKTIVEN ALKYLIERUNG

Substrat	Medium	Alkylierungsreagenz	Ausb.
33a	NH_3	DCB	20%
33a	NH_3–THF	DCB	15
33a	NH_3–^{t}BuOH–THF	$H_3CC(Cl)=CH-CH_2I$	30
12	NH_3–^{t}BuOH–THF	$H_3CC(Cl)=CH-CH_2I$	23

anstatt DCB 1-Jod-3-chlor-2-buten als Alkylierungsreagenz verwendete,[25] konnte die Ausbeute wenig erhöht werden. Die hier erhaltenen Verbindungen, 1-(3-Chlor-2-butenyl)-2-decalon (**72a**) und 1-(3-Chlor-



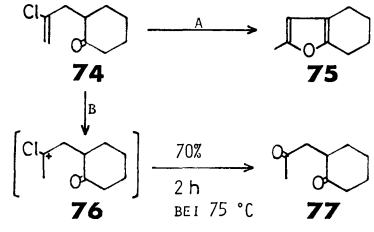
Schema 7.

2-butenyl)-4a-methyl-2-decalon (**72b**) wurden durch Behandlung in HCO_2H mit $HClO_4$ in die entsprechenden Hydrophenanthren-Derivate **73a** bzw. **73b** in guten Ausbeuten überführt.[6d] Analog zum oben erwähnten Testexperiment wurde **69** in flüss·NH_3–THF mit Li und ^{t}BuOH versetzt und dann mit 1-Jod-3-chlor-2-buten reduktiv alkyliert. Das nach üblicher Aufarbeitung erhaltene Rohprodukt wurde zur Abspaltung der Schutzgruppe in MeOH mit H_2SO_4 versetzt und anschliessend mit CrO_3 oxydiert, so dass man nach der chromatographischen Reinigung 10-(3-Chlor-2-butenyl)-des-A-estran-5,17-dion (**70**) in 22%-iger Ausbeute erhielt. Ausserdem wurde Des-A-estran-5,17-dion als Hauptkomponente isoliert und dessen Ausbeute betrug *ca.* 40%. **70** wurde in HCO_2H in Gegenwart von $HClO_4$ erhitzt, wobei das Zielprodukt **71** in einer Ausbeute von 90% entstand (Schema-7). Die IR-, NMR-, und MS-Spektren vom hier synthetisierten **71** sind in Übereinstimmung mit denjenigen in der Literatur und die Konstitution von **71** wurde dadurch ermittelt.[26]

D. Darstellung von 1,4-Diketonen und Synthese von Dihydrojasmon

Wie in Abschnitten A, B, und C beschrieben, wurde festgestellt, dass die modifizierte Wichterle-Reaktion zur Darstellung von 2-Cyclohexenonen geeignet ist. Es wurde dann versucht, sie auf die Umwandlung von α-(2-Haloallyl)keton wie **74** ins 1,4-Diketon wie **77** zu übertragen.[27]

Nienhaus *et al.* haben bereits darüber berichtet, dass die Behandlung von 2-(2-Chlorallyl)cyclohexanon (**74**)



Schema 8.

Tabelle 4.

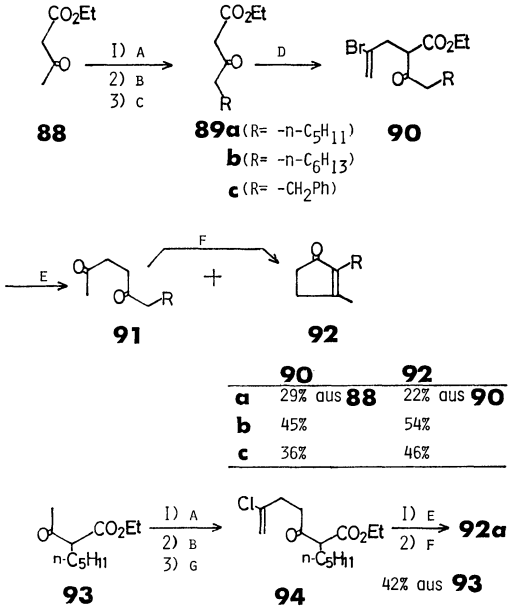
Nr.	Substrat	Produkt	Reaktionszeit (h)	Ausb. (%)
1	 **78**	 **79**	1.5 bei 70 °C	75
2	 **80**	 **81**	5 bei 75—80 °C	(Kompliziertes Gemisch)
3	 **82**	 **83**	3.5 Rückfluss	30[b]
4	 **84**	 **85**	2.5 bei 80 °C	55[c]
5	 **86**	 **87**	1 Rückfluss	80

a) In HCO_2H mit $HClO_4$. b) Als Methylester isoliert. c) Die Ausbeute ist auf die reagierte Ausgangsverbindung **84** benzogen. Eine kleine Menge **84** wurde zurückgewonnen.

mit konz·H_2SO_4 2-Methyl-4,5,6,7-tetrahydrobenzofuran (**75**) in guter Ausbeute liefert.[28] Dagegen entstand beim Erhitzen von **74** in HCO_2H in Gegenwart von $HClO_4$ 1,4-Diketon **77** in 70%-iger Ausbeute,[29] vermutlich über das Carboniumion **76**. Im NMR-Spektrum des Rohproduktes war das Furan-Derivat **75** nicht zu erkennen. Die Optimierungesversuche zeigten, dass die Umwandlung von **74** in **77** im Vergleich mit α-Chlorbutenylketon wie Typ **1** bei relativ tieferer Temperatur verläuft und dass beim Kochen weniger 1,4-Diketon **77** entsteht. Es zeigte sich auch, dass durch den Zusatz von fast äquimolarer Menge $HClO_4$ eine bessere Ausbeute resultiert (Schema-8).

In Tabelle-4 sind andere Beispiele zusammengefasst. Während 2-(2-Bromallyl)-6-methylcyclohexanon (**78**) das entsprechende 1,4-Diketon **79**[27c] in 75%-iger Ausbeute ergab, wurde aus 2-(2-Chlorallyl)-2-methylcyclohexanon (**80**) kein erwünschtes Produkt **81**,[29,30] sondern nur ein kompliziertes Gemisch erhalten. Sogar durch die Behandlung mit konz·H_2SO_4 konnte **80** nicht in **81** überführt werden. Wie das Molekülmodell zeigt, könnte der Angriff eines Nucleophils auf das zwischenstufige Carboniumion wegen der sterischen Hinderung in der Umgebung des in α-Stellung zur Carbonylgruppe liegenden quartären Kohlenstoffatoms gestört werden. 2-(2-Chlorallyl)-2-methylcyclohexan-1,3-dion (**82**) ergab analog zu **45** beim Kochen über Ringöffnung und anschliessende Cyclisierung 2-(2-Carboxyethyl)-3,6-dimethyl-2-cyclopentenon (**83**), das nach Veresterung mit CH_2N_2 isoliert und dessen Konstitution spektroskopisch bestätigt wurde. Anderseits wurden aus den leicht enolisierbaren α-(2-Haloallyl)ketonen **84** bzw. **86** die Furan-Derivate **85** bzw. **87** erhalten.[31]

Aufgrund der oben beschriebenen Ergebnisse wurde die Synthese von Dihydrojasmon versucht.[32] Ausgehend von Acetessigsäureethylester wurde **89a** durch γ-Alkylierung mit NaH/*n*-BuLi/*n*-$C_5H_{11}Br$ in THF



88 **89a** (R= -n-C_5H_{11}) **b** (R= -n-C_6H_{13}) **c** (R= -CH_2Ph) **90** **91** **92**

	90	92
a	29% aus **88**	22% aus **90**
b	45%	54%
c	36%	46%

93 **94** 42% aus **93**

A) NaH. B) n-BuLi. C) R-Br. D) NaH/CH_2=C(Br)CH_2Br. E) $HClO_4$-HCO_2H. F) 0.5n-NaOH. G) CH_2=C(Cl)CH_2Cl.

Schema 9.

dargestellt.[33] Ohne Reinigung wurde **89a** mit NaH/2,3-Dibrompropen zu **90a** alkyliert. Beim Erhitzen von **90a** in HCO_2H mit $HClO_4$ entstand ein Gemisch von Undecan-2,5-dion (**91a**) und Dihydrojasmon **92a** im Verhältnis von 8:3 (NMR), das ohne Trennung anschliessend mit 0.5 M-NaOH umgesetzt wurde.[34] Nach chromatographischer Reinigung wurde Dihydrojasmon **92a** in 22%-iger Ausbeute aus **90a** isoliert. Auf die gleiche Weise wurde aus Acetessigsäureethylester 2-Hexyl-3-methyl-2-cyclopentenon (**92b**) und 2-Benzyl-3-methyl-2-cyclopentenon (**92c**) in 24%-iger bzw. 16.5%-iger Gesamtausbeute synthetisiert (Schema-9a).

Die Totalausbeute an Dihydrojasmon durch den oben erwähnten Syntheseweg ist gering. Ein Grund dazu scheint in der γ-Alkylierungsstufe zu liegen, weil die α-Alkylierung von **89a** mit 2,3-Dibrompropen gut verläuft. Folgenderweise wurde die verbesserte Ausbeute verwirklicht. Der α-pentylierte Ketoester **93**, der nach einer Vorschrift in guter Ausbeute zugänglich ist,[35] wurde in THF mit NaH 1 h bei Raumtemperatur gerührt und nach Abkühlen auf 0 °C mit *n*-BuLi und anschliessend mit 2,3-Dichlorpropen versetzt. Das NMR-Spektrum des Rohproduktes zeigte, dass das γ-Alkylierungsprodukt **94** in 80%-iger Ausbeute entsteht (isolierte Ausb. 60%). Ohne Reinigung wurde das Rohprodukt in HCO_2H mit $HClO_4$ 4 h bei 90 °C erhitzt, wobei Decarboxylierung, Hydrolyse des Vinylchlorides und teilweise Ringschluss stattfanden und eine Mischung von **91a** und **92a** (*ca.* 1:2) erhalten wurde. Die anschliessende Behandlung dieser Mishung mit 0.5 M-NaOH lieferte Dihydrojasmon in 42%-iger Ausbeute aus **93**. Das hier dargestellte Dihydrojasmon wurde durch den Vergleich der spektroskopischen Daten mit denjenigen in der Literatur identifiziert.[32] Die modifizierte Wichterle-Reaktion erwies sich somit als eine Methode zur Darstellung von 2,3-disubstituierten 2-Cyclopentenonen.

Experimenteller Teil

Allgemeine Bemerkungen. Die IR-Spektren wurden mit einem Gerät JASCO.IR-S gemessen und die Lage der Banden in cm^{-1} angegeben. Die MS-Spektren wurden mit einem Gerät Hitachi RMU-6E erhalten. Die NMR-Spektren wurden mit den Geräten Hitachi R-20B bei 60MHz und JEOL.PS-100 bei 100 MHz aufgenommen. Die chemische Verschiebungen sind in ppm (interner Standard; TMS=0 ppm) angegeben. Die Signale wurden durch folgende Abkürzungen charakterisiert; s=Singulett, d=Dublett, t=Triplett, q=Quartett, m=Multiplett und b=breites Band. Die Schmelzpunkte wurden in einer Kapillare bestimmt und sind nicht korrigiert. Es wurden 99—100% HCO_2H und 60% oder 70% $HClO_4$ sowie 47% HBr verwendet. Die Abkürzung RT. bedeutet Raumtemperatur.

Abschnitte A und B.

Darstellung von Ausgangsmaterien.

2-bzw. 6-(3-Chlor-2-butenyl)-1-chlor-cyclohexen (17). Zu einer Lösung von 1 g **33a** in 20 ml CCl_4 fügte man 5 g PCl_5 und erhitzte 4 h unter Rückfluss. Nach Abkühlen auf RT. wurde das Reaktionsgemisch auf 50 ml H_2O gegossen und mit $CHCl_3$ extrahiert. Die $CHCl_3$-Auszüge wurden mit gesätt. $NaHCO_3$-Lösung neutralgewaschen, getrocknet und

eingedampft. Der Rückstand wurde an der 100-fachen Menge SiO_2 mit Hexan chromatographiert. Man erhielt 830 mg (75%) **17** als ein Gemisch von 2- und 6-Alkylisomeren; IR (Film): 1667, 1653 cm^{-1}; NMR (CCl_4): 2.09 (3H, d, J=1.5 Hz), 5.35 (1H, qt, J=1.5, 7 Hz), 5.75 (0.7 H, t, J=3 Hz); MS: 204, 206, 208 (M^+), 169, 171 (M^+-Cl), 115, 117 ($M^+-C_4H_6Cl$).

*1-Chlor-6-(3-chlor-2-butenyl)-6-methylcyclohexen (**19**).* Gleicherweise wurden 125 mg **19** (57%) aus 200 mg **11** und 1 g PCl_5 erhalten; IR (Film): 1668, 1644 cm^{-1}; NMR (CCl_4): 1.14 (3H, s), 2.10 (3H, d, J=1.5 Hz), 5.32 (1H, qt, J=1.5, 7 Hz), 5.74 (1H, t, J=3.5 Hz); MS: 218, 220, 222 (M^+), 183, 185 (M^+-Cl), 129, 131 ($M^+-C_4H_6Cl$).

*2-(3-Chlorallyl) cyclohexanon (**20**).* Eine Lösung von 5 g Pyrrolidinenamin des Cyclohexanons[36] und 5 ml 1,3-Dichlorpropen in 20 ml Dioxan wurde 18 h unter Ar gekocht. Nach Abkühlen auf RT. wurde die Lösung mit 1 ml konz.HCl und 10 ml H_2O versetzt und 4 h weiter unter Rückfluss erhitzt. Nach Entfernung von Dioxan extrahierte man die wässrige Phase mit AcOEt. Die AcOEt-Auszüge wurden mit gesätt. $NaHCO_3$-Lösung neutralgewaschen, getrocknet und eingedampft. Man erhielt 4.5 g (80%) **20**; Kp. 93 °C/3 Torr; IR (Film): 1710, 1630 cm^{-1}; NMR ($CDCl_3$): 5.3—6.2 (2H, m); MS: 172, 174 (M^+), 137 (M^+-Cl); Gef: C, 62.45; H, 7.38; Cl, 20.45%. Ber. für $C_9H_{13}ClO$: C, 62.61; H, 7.54; Cl, 20.58%.

*5-Chlor-2,2-dimethyl-4-hexensäure(**22**).* Das zur Darstellung von **28** verwendete rohe Chloraldehyd (2 g) in 10 ml Aceton wurde bei RT. mit CrO_3 (Jones-Reagenz) versetzt und 48 h bei RT. gerührt. Nach Zugabe von *i*-PrOH wurde die Reaktionsmischung mit H_2O verdünnt und mit AcOH extrahiert. Die AcOEt-Extrakte wurden dann mit 5% NaOH-Lösung ausgeschüttelt. Die alkalische Phase wurde mit 3 M-HCl schwach angesäuert und wieder mit $CHCl_3$ extrahiert. Nach Abdampfen des Lösungsmittels wurde der Rückstand bei 135—140 °C (Öl-Bad)/12 Torr destilliert. Ausb. 1.1 g (50%); IR (Film): 1705, 1670, 1640 cm^{-1}; NMR (CCl_4): 1.24 (6H, s), 2.10 (3H, d, J=1.5 Hz), 5.42 (1H, qt, J=1.5, 7 Hz); Gef: C, 54.48; H, 7.38; Cl, 20.12%. Ber. für $C_8H_{13}ClO_2$: C, 54.39; H, 7.36; Cl, 20.11%.

*6-Chlor-5-hepten-2-on (**26**).* Zu einer Lösung von 13.6 g EtONa in 100 ml EtOH fügte man 25 g Acetessigsäureäthylester und 25 g 1,3-Dichlor-2-buten (DCB) bei 0 °C unter Rühren und N_2. Die Lösung wurde 24 h bei RT. stehengelassen und dann 1 h gekocht. Das ausgefallene NaCl wurde abgesaugt, und das Filtrat zur Trockene eingeengt. Zur Suspension des oben erhaltenen Rückstandes in 320 ml H_2O wurde eine Lösung von 25 g NaOH in 180 ml H_2O unter Rückfluss innerhalb von 2 h tropfenweise gegeben und weiter 4 h gekocht. Nach Abkühlen auf RT. wurde die wässrige Phase mit NaCl gesättigt und mit Ether mehrmals extrahiert. Die organische Phase wurde mit 3 M-HCl, mit gesätt. $NaHCO_3$-Lösung gewaschen, getrocknet und eingedampft. Der Rückstand wurde dann bei 78—80 °C/20 Torr destilliert. Ausb. 15 g (53%); IR (Film): 1720, 1663 cm^{-1}; NMR (CCl_4): 2.06 (6H, bs), 5.42 (1H, qt, J=1.5 Hz); MS: 146, 148 (M^+), 111 (M^+-Cl).

*6-Chlor-3,3-dimethyl-5-hepten-2-on (**28**).* Zur Suspension von 12.4 g NaOH, 1.13 g *n*-Bu_4NBr, 12.4 g H_2O und 17.4 ml Benzol wurde eine Mischung von 25 g Isobutyraldehyd und 32.5 g DCB bei 70 °C unter Rühren langsam zugetropft und weiter 2 h bei der gleichen Temp. gerührt.[37] Nach Abkühlen wurde das Reaktionsgemisch auf H_2O gegossen und mit AcOEt ausgezogen. Nach üblicher Aufarbeitung destillierte man das Rohprodukt bei 75 °C/12 Torr. Zu einer Lösung von 64 mmol CH_3MgI in 30 ml Ether wurde eine Lösung von 8 g (53 mmol) des oben erhaltenen alkylierten Aldehydes in 10 ml Ether bei 0 °C zugegeben und 18 h bei RT. gerührt. Nach Zugabe der gesätt. NH_4Cl-Lösung extrahierte man mit Ether und erhielt 7 g Alkohol, der anschliessend ohne Reinigung oxydiert wurde. Eine Lösung vom rohen Chloralkohol (7 g) in 200 ml Aceton wurde mit CrO_3 (Jones-Reagenz) bei 0 °C versetzt und bei RT. über Nacht gerührt. Nach Entfernung von Aceton wurde der Rückstand in Ether aufgenommen. Die etherische Phase wurde mit 5% NaOH-Lösung, mit H_2O gewaschen, getrocknet und eingedampft. Man erhielt nach Destillation bei 89—90 °C/12 Torr 3 g **28** (14% aus Isobutyraldehyd); IR (Film): 1708, 1663 cm^{-1}; NMR ($CDCl_3$): 1.17 (6H, s), 2.07 (3H, d, J=1.5 Hz), 2.12 (3H, s), 5.33 (1H, qt, J=1.5, 7 Hz); MS: 174, 176 (M^+), 139 (M^+-Cl); Gef: C, 61,91; H, 8.68; Cl, 20.04%. Ber. für $C_9H_{15}ClO$: C, 61, 89; H, 8.68; Cl, 20.34%.

*2-(3-Chlor-2-butenyl)-2-methylcyclopentanon (**31**).* Ein Gemisch von 2-Methylcyclopentanon (5 g) und $NaNH_2$ (2 g) in 30 ml Benzol wurde 5 h unter Rühren und N_2 gekocht. Nach Abkühlen auf RT. wurde die Lösung mit 6 ml DCB in 6 ml Benzol tropfenweise versetzt und 3 h unter Rückfluss erhitzt. Nach üblicher Aufarbeitung wurde das Rohprodukt an der 10-fachen SiO_2 mit Benzol–Hexan (1: 1) chromatographiert und man erhielt 3.2 g (34%) **31**; IR (Film): 1740, 1665 cm^{-1}; NMR (CCl_4): 0.99 (3H, s), 2.05 (3H, d, J=1.5 Hz), 5.35 (1H, qt, J=1.5, 7 Hz); Gef: C, 64.33; H, 8.18; Cl, 18.62%. Ber. für $C_{10}H_{15}ClO$: C, 64.34; H, 8.10; Cl, 18.99%.

*2-(3-Chlor-2-butenyl)cyclohexanon (**33a**).*[38a] Analog zur Darstellung von **20** wurde eine Lösung von Pyrrolidinenamin von Cyclohexanon (16 g) in 55 ml Dioxan mit 16 ml DCB 18 h unter Ar gekocht. Nach der schon beschriebenen Aufarbeitung erhielt man 11 g (58%) **33a** nach Destillation bei 85—100 °C/3 Torr; IR (Film): 1715, 1675 cm^{-1}; NMR (CCl_4): 2.07 (3H, d, J=1.5 Hz), 5.49 (1H, qt, J=1.5, 7 Hz).

*2-(3-Chlor-2-butenyl)-2-methylcyclopentan-1,3-dion (**42**).* 2-Methylcyclopentan-1,3-dion[38] (2.2 g) wurde in 5.6 ml 20% KOH-Lösung gelöst und mit 0.5 g KI und 2.2 ml DCB versetzt. Die Reaktionsmischung wurde *ca.* 1.5 h bei 90 °C gerührt, bis diese gegen Lackmus neutral reagierte. Nach Abkühlen auf RT. und Zugabe von H_2O wurde die Mischung mit Ether extrahiert. Die Ether phase wurde mit gesätt. $NaHCO_3$-Lösung neutralgewaschen, über Na_2SO_4 getrocknet und eingedampft. Das Rohprodukt (3.9 g) wurde an der 15-fachen Menge SiO_2 mit Benzol–AcOEt (9: 1) chromatographiert. Man erhielt 2.7 g (67%) **42**; IR (Film): 1765, 1725, 1660 cm^{-1}; NMR (CCl_4): 1.15 (3H, s), 2.10 (3H, d, J=1.5 Hz), 2.36 (2H, d, J=7 Hz), 2.70 (4H, s), 5.34 (1H, qt, J=1.5, 7 Hz); Gef: C, 59.95; H, 6.45; Cl, 17.43%. Ber. für $C_{10}H_{13}ClO_2$: C, 59.85; H, 6.53; Cl, 17.67%.

Analog wurden **45** als Öl aus 2-Methylcyclohexan-1,3-dion[38] (76%) und **48** als farblose Kristalle aus 2-Methyldimedon[38] (80%) dargestellt.

*2-(3-Chlor-2-butenyl)-2-methylcyclohexan-1,3-dion (**45**):* IR (Film): 1730, 1690, 1665 cm^{-1}; NMR ($CDCl_3$): 1.25 (3H, s), 2.09 (3H, d, J=1.5 Hz), 5.30 (1H, qt, J=1.5, 7 Hz).

*2,5,5-Trimethyl-2-(3-chlor-2-butenyl)cyclohexan-1,3-dion (**48**):* Schmp. 69—70 °C (Hexan); IR (Nujol): 1725, 1690, 1665 cm^{-1}; NMR ($CDCl_3$): 0.90 (3H, s), 1.10 (3H, s), 1.23 (3H, s), 2.09 (3H, d, J=1.5 Hz), 5.32 (1H, qt, J=1.5, 7 Hz); Gef: C, 64.50; H, 7.90; Cl, 14.41%. Ber. für $C_{13}H_{19}ClO_2$: C, 64.33; H, 7.86; Cl, 14.64%.

*8-Chlor-5-methyl-4-oxo-7-nonensäure (**51**).* 1 g **42** in 18 ml H_2O wurde mit 6.3 g $Ba(OH)_2 \cdot 8H_2O$ versetzt und 4 h unter Rückfluss erhitzt.[39] Nach Abkühlen wurde das überschüssige $Ba(OH)_2$ durch Einleitung von CO_2 in die Reaktionsmischung ausgefällt, bis diese gegen Lackmus neutral reagierte. Das ausgefallene $BaCO_3$ wurde abgesaugt, die

Carbonsäure durch Zugabe von 2 M-HCl in Freiheit gesetzt und mit $CHCl_3$ extrahiert. Die $CHCl_3$-Auszüge wurden über Na_2SO_4 getrocknet und eingedampft. Man erhielt 880 mg (81%) **51**, die ohne weitere Reinigung in HCO_2H mit HBr umgesetzt wurde. Zur Analyse wurde **51** mit CH_2N_2 in den Methylester umgewandelt; IR(Film): 1740, 1715 cm^{-1}; NMR ($CDCl_3$): 1.14 (3H, d, J=7 Hz), 2.06 (3H, d, J=1.5 Hz), 3.65 (3H, s), 5.37 (1H, qt, J=1.5, 7 Hz); MS: 232, 234 (M^+); Gef: C, 57.93; H, 7.48; Cl, 13.60%. Ber. für $C_{11}H_{17}ClO_3$: C, 56.77; H, 7.36; Cl, 15.24%.

*9-Chlor-5-oxo-8-decensäure (**54**).* Zu einer Lösung von 1.5 g Cyclohexan-1,3-dion in 3.5 g 20% KOH-Lösung fügte man 1.4 ml DCB und 0.5 g KI und erhitzte 1.5 h bei 85 °C unter Rühren. Nach Abkühlen auf RT. wurde die Reaktionsmischung auf 15 ml 3% NaOH-Lösung gegossen und dreimal mit Ether ausgeschüttelt, um das dialkylierte Produkt zu entfernen. Unter Eiskühlung und Rühren wurde die wässrige Phase mit 6 M-HCl auf pH 4 eingestellt, wobei 2-(3-Chlor-2-butenyl)cyclohexan-1,3-dion (1.2 g, 44%) ausfiel. Dieses monoalkylierte Dion wurde ohne weitere Reinigung mit $Ba(OH)_2$ umgesetzt.

0.5 g vom oben erhaltenen monoalkylierten Dion wurden in 7 ml H_2O mit 1.7 g $Ba(OH)_2 \cdot 8H_2O$ 4 h unter Rückfluss gekocht.[39] Analog zu **51** erhielt man 520 mg (95%) **54**, die auch ohne Reinigung in HCO_2H mit $HClO_4$ umgezetzt wurde. Zur Analyse wurde die Säure mit CH_2N_2 in den Methylester überführt; IR(Film): 1740, 1715, 1670 cm^{-1}; NMR ($CDCl_3$): 2.05 (3H, d, J=1.5 Hz), 3.65 (3H, s), 5.43 (1H, qt, J=1.5, 7 Hz); Gef: C, 56.95; H, 7.44; Cl, 14.90%. Ber. für $C_{11}H_{17}ClO_3$: C, 56.75; H, 7.36; Cl, 15.24%.

Allgemeine Vorschrift der Cyclisierung.

Eine Lösung von α-chlorbutenyliertem Keton in HCO_2H wurde mit einer kleinen Menge $HClO_4$ (60% od. 70% wässrig) oder HBr (47% wässrig) versetzt und unter Rückfluss erhitzt, bis das Ausgangsmaterial dünnschichtchromatographisch nicht nachgewiesen wurde. Danach wurde die Reaktionsmischung i. Vak. eingeengt und in einem organischen Lösungsmittel wie AcOEt, $CHCl_3$ usw. aufgenommen. Die organische Phase wurde dann vorsichtig mit gesätt. $NaHCO_3$-Lösung neutralgewaschen, getrocknet und eingedampft. Der Rückstand wurde danach chromatographisch oder durch Destillation gereinigt. Das Verhältnis von Mineralsäure und HCO_2H zu Substrat kann man gegebenfalls vielfach ändern.

*4a-Methyl-$\Delta^{1(8a)}$-2-octalon (**12**).* a) 100 mg **11** in 9 ml HCO_2H wurden mit 1 ml $HClO_4$(60%) versetzt und 1.5 h gekocht. Nach der oben erwähnten Aufarbeitung wurde das Rohprodukt an der 50-fachen Menge SiO_2 mit AcOEt–Benzol (1: 19) chromatographiert. Ausb. 80 mg (98%).

b) 14 g **11** in 200 ml HCO_2H wurden mit 15 ml $HClO_4$ (60%) 8 h gekocht. Nach Abdampfen von HCO_2H und Aufarbeitung wurde der Rückstand bei 94—96 °C/3 Torr destilliert. Ausb. 8 g (70%); NMR ($CDCl_3$): 1.26 (3H, s), 5.75 (1H, bs); MS: 164 (M^+).

*Behandlung von **17** und **19**.* *a) **18** aus **17**:* 245 mg **17** wurden in 10 ml HCO_2H suspendiert und mit 1 ml $HClO_4$ (70%) 5 h rückfliessend erhitzt. Ausb. 90 mg (50%).

*b) **12** aus **19**:* Analog wurde eine Lösung von 110 mg **19** in 10 ml HCO_2H mit 1 ml $HClO_4$(60%) 4.5 h gekocht. Ausb. 30 mg (35%).

*2,2-Dimethyl-5-oxohexansäure (**23**).* a) mit $HClO_4$. Zu einer Lösung von 465 mg **22** in 10 ml HCO_2H fügte man 1.5 ml $HClO_4$ (70%) und kochte 40 Min. unter Rückfluss. Nach Abkühlen auf RT. wurde das Reaktionsgemisch auf 100 ml H_2O gegossen und mit $CHCl_3$ extrahiert. Die $CHCl_3$-Auszüge wurden mit H_2O gewaschen, getrocknet und eingedampft. Der Rückstand wurde in AcOEt gelöst und mit ether. CH_2N_2 verestert. Man erhielt 225 mg (50%) **23** als Methylester; Kp. 95 °C/12 Torr; IR (Film): 1730, 1725 cm^{-1}; NMR ($CDCl_3$): 1.20 (6H, s), 2.12 (3H, s), 3.65 (3H, s); MS: 172 (M^+), 141 ($M^+ - OCH_3$), 129 ($M^+ - COCH_3$); Gef: C, 62.17; H, 9.45%. Ber. für $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

b) mit HBr. 522 mg **22** in 20 ml HCO_2H wurden mit 3 ml HBr versetzt und 1.5 h gekocht. Nach Veresterung mit CH_2N_2 wurden 336 mg (66%) **23** erhalten.

*Umwandlung von **14** in **12**.* Eine Lösung von 255 mg **13** in 20 ml HCO_2H wurde mit 1 ml $HClO_4$ (70%) versetzt und 1 h unter Rückfluss erhitzt. Nach üblicher Aufarbeitung erhielt man 210 mg (82%) **12**.

*3-Methyl-2-cyclohexenon (**27**).* 19 g **26** wurden in 300 ml HCO_2H mit 30 ml $HClO_4$ (60%) 3 h unter Rückfluss gekocht. Nach Aufarbeitung ergab Destillation bei 79—80 °C/15 Torr 11 g (77%) **27**; IR (Film): 1673, 1635 cm^{-1}; NMR (CCl_4): 1.93 (3H, s), 5.20 (1H, q, J=1 Hz); MS: 110 (M^+), 82 ($M^+ - C_2H_4$).

*3,4,4-Trimethyl-2-cyclohexenon (**29**) und 3,6,6-Trimethyl-2-cyclohexenon (**30**).* Eine Lösung von 500 mg **28** in 25 ml HCO_2H wurde mit 2.5 ml $HClO_4$ (70%) 45 Min. unter Rückfluss erhitzt. Nach Abdampfen von HCO_2H wurde der Rückstand in Ether gelöst und mit gesätt. $NaHCO_3$-Lösung neutralgewaschen, getrocknet und eingedampft. Das Rohprodukt wurde dann dünnschichtchromatographisch(Laufmittel: Hexan–AcOEt 1: 1) abgetrennt. Man erhielt 100 mg (25%) **29** und 193 mg (48%) **30**. **29**; Kp. 106—110 °C (Öl-Bad)/12 Torr; IR (Film): 1666, 1615 cm^{-1}; NMR ($CDCl_3$): 1.20 (6H, s), 1.90 (3H, d, J=1 Hz), 2.43 (2H, bt, J=6 Hz), 5.75 (1H, bs); MS: 138 (M^+), 110 ($M^+ - C_2H_4$ bzw. CO), 96 ($M^+ - C_3H_6$). **30**; Kp. 87—90 °C (Öl-Bad)/12 Torr; IR (Film): 1668, 1640 cm^{-1}; NMR ($CDCl_3$): 1.10(6H, s), 1.80 (2H, bt, J=6 Hz), 1.92 (3H, d, J=1 Hz), 2.30 (2H, bt J=6 Hz), 5.71 (1H, q, J=1 Hz); MS: 138 (M^+), 110 ($M^+ - CO$), 82 ($M^+ - C_4H_8$).

*7a-Methyl-5,6,7,7a-tetrahydro-5-indanon (**32**).* Eine Lösung von 250 mg **31** in 9 ml HCO_2H wurde mit 1 ml $HClO_4$ (60%) versetzt und 1 h rückfliessend gekocht. Nach Aufarbeitung wurde das Rohprodukt säulenchromatographisch gereinigt, wobei 100 mg (50%) **32** mit Benzol–AcOEt (19: 1) eluiert wurden; IR (Film): 1665 cm^{-1}; NMR (CCl_4): 1.17 (3H, s), 5.60 (1H, d, J=1 Hz); MS: 150 (M^+), 112 ($M^+ - C_2H_4$).

*$\Delta^{1(8a)}$-2-Octalon (**18**).* 19 g **33a** wurden in 300 ml HCO_2H mit 30 ml $HClO_4$ (60%) 3 h gekocht. Nach üblicher Aufarbeitung ergab Destillation bei 90—106 °C/3 Torr 11.5 g (75%) **18**; IR (Film): 1670, 1620 cm^{-1}; NMR (CCl_4): 5.79 (1H, s).

*8-Methyl-$\Delta^{1(8a)}$-2-octalon (**34**).* Eine Lösung von 600 mg **33b** in 30 ml HCO_2H wurde mit 3 ml $HClO_4$ (60%) versetzt und 1 h gekocht. 345 mg (70%) **34** wurden säulenchromatographisch abgetrennt; IR (Film): 1670, 1615 cm^{-1}; NMR (CCl_4): 1.10 (3H, d, J=6 Hz), 5.80 (1H, d, J=1 Hz).

*5-Methyl-2-oxo-2,3,4,6,7,8-hexahydronaphthalin (**36**).* 150 mg **35**[38a] wurden in 10 ml HCO_2H mit 1 ml $HClO_4$ (60%) 1 h rückfliessend umgesetzt. Nach chromatographischer Reinigung erhielt man 86 mg (70%) **36**; IR (Film): 1660, 1632, 1585 cm^{-1}; NMR (CCl_4): 1.35 (3H, s), 5.54 (1H, bs).

*4a-Methyl-2-oxo-2,3,4,4a,5,6-hexahydronaphthalin (**38**) und 5-Acetyl-1-methylbicyclo[2.2.2]octan-2-on (**39**).* Eine Lösung von 510 mg **37**[4] in 30 ml HCO_2H wurde mit 3 ml $HClO_4$ (60%) versetzt und 3 h unter Rückfluss umgesetzt. Nach Aufarbeitung wurde der Rückstand an der 50-fachen Menge SiO_2 chromatographiert, wobei 90 mg (22%) **38** und 320 mg (71%) **39** mit Benzol–AcOEt (19: 1) abgetrennt wurden. Die Konstitution von **38** wurde durch den Vergleich der spektroskopischen Daten mit denjenigen in der Literatur[4] ermittelt. **39**; Schmp. 76—77 °C (Isopropylether); IR (Nujol): 1715

cm^{-1}; NMR ($CDCl_3$): 0.92 (3H, s), 2.15 (3H, s); MS: 180 (M^+); Gef: C, 73.33; H, 9.02%. Ber. für $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

*Des-A-estra-$\Delta^{9(10),8(14)}$-dien-5,17-dion (**41**).* 370 mg **40**[15] wurden in 15 ml HCO_2H gelöst und mit 1 ml $HClO_4$ (60%) 1 h gekocht. Das Rohprodukt wurde an der 50-fachen Menge SiO_2 mit Benzol–AcOEt (4: 1) chromatographiert. Man erhielt 205 mg (65%) **41**. Die spektroskopischen Daten von **41** sind in Übereinstimmung mit denjenigen in der Literatur[15]; IR (Film): 1745, 1663, 1635, 1585 cm^{-1}; NMR (CCl_4): 1.14 (3H, s), 5.68 (1H, bs).

*7a-Methyl-5,6,7,7a-tetrahydroindan-1,5-dion (**43**) und 1-Methyl-brexan-4,9-dion (**44**).* Eine Lösung von 1.89 g **42** in 100 ml HCO_2H wurde mit 10 ml HBr 1.5 h unter Rückfluss gekocht. Nach Abdampfen von HCO_2H wurde der Rückstand in AcOEt aufgenommen. Die organische Phase wurde mit gesätt. $NaHCO_3$-Lösung neutralgewaschen, getrocknet und eingedampft. Das Rohprodukt wurde dann an der 100-fachen Menge SiO_2 chromatographiert, wobei 150 mg (10%) **44**[17] mit Benzol–AcOEt (4: 1) eluiert wurden, dann folgten 620 mg (40%) **43**. **43**; Schmp. 70—71 °C (Ether); IR (Nujol): 1745, 1675 cm^{-1}; NMR ($CDCl_3$): 1.32 (3H, s), 5.94 (1H, d, J=1.5 Hz); Gef: C, 73.32; H, 7.12%. Ber. für $C_{10}H_{12}O_2$: C, 73.14; H, 7.37%.

*2-(2-Carboxyethyl)-3,6-dimethyl-2-cyclohexenon (**46**) und 3-(3-Carboxypropyl)-4-methyl-2-cyclohexenon (**47**).* Eine Lösung von 240 mg **45**[18] in 18 ml HCO_2H wurde mit 2 ml HBr versetzt und 1 h bei 60 °C erhitzt. HCO_2H wurde abgezogen und der Rückstand in $CHCl_3$ gelöst. Die organische Phase wurde mit H_2O gewaschen, getrocknet und eingedampft. Man erhielt 207 mg (77%) **57**. Zur Analyse wurde **57** mit CH_2N_2 in den Methylester umgewandelt; IR (Film): 1740, 1710, 1675 cm^{-1}; NMR ($CDCl_3$): 1.12 (3H, d, J=6 Hz), 2.09 (3H, d, J=1.5 Hz), 3.65 (3H, s), 5.49 (1H, qt, J=1.5, 7 Hz); Gef: C, 58.66; H, 7.98; Cl, 13.73%. Ber. für $C_{12}H_{19}ClO_3$: C, 58.41; H, 7.76; Cl, 14.37%. 1.38 g von der oben erhaltenen rohen Carbonsäure **57** wurden in 60 ml HCO_2H mit 6.5 ml HBr 1.5 h rückfliessend erhitzt. Nach üblicher Aufarbeitung erhielt man ein Gemisch **46** und **47**, das mit CH_2N_2 verestert und chromatographisch mit Benzol–AcOEt (4: 1) auseinander abgetrennt wurde. Methylester von **46** (940 mg, 58.5% aus **45**); IR (Film): 1740, 1660, 1630 cm^{-1}; NMR ($CDCl_3$): 1.12 (3H, d, J=6 Hz), 1.96 (3H, s), 3.62 (3H, s); Gef: C, 68.56; H, 8.58%. Ber. für $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%. Methylester von **47** (155 mg, 9.7% aus **45**); IR (Film): 1744, 1670, 1625 cm^{-1}; NMR ($CDCl_3$): 1.21 (3H, d, J=6 Hz), 3.65 (3H, s), 5.76 (1H, bs); MS: 210 (M^+); Gef: C, 68.56; H, 8.59%. Ber. für $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

*3,3,8a-Trimethyl-1,6-dioxo-1,2,3,4,6,7,8,8a-octahydronaphthalin (**49**) und 4-Methyl-3-(2,2,-dimethyl-3-carboxypropyl)-2-cyclohexenon (**50**).* Eine Lösung von 800 mg **48** in 40 ml HCO_2H wurde mit 4 ml HBr 1.5 h gekocht. Nach Entfernung von HCO_2H wurde der Rückstand auf H_2O gegossen und mit AcOEt extrahiert. Die AcOEt-Auszüge wurden mit 10% NaOH-Lösung geschüttelt, getrocknet und eingedampft. Der erhaltene neutrale Teil wurde dünnschichtchromatographisch gereinigt. Man erhielt 220 mg (32%) **49**; Schmp. 93—94 °C (Ether); IR (Nujol): 1705, 1660, 1615 cm^{-1}; NMR ($CDCl_3$): 0.80 (3H, s), 1.15 (3H, s), 1.42 (3H, s), 5.82 (1H, d, J=2 Hz); MS: 206 (M^+); Gef: C, 75.59; H, 8.74%. Ber. für $C_{13}H_{18}O_2$: C, 75.69; H, 80.8%. Die alkalische Phase wurde unter Eiskühlung mit 6 M-HCl angesäuert und mit $CHCl_3$ extrahiert. Der sauere Teil wurde dann in AcOEt mit CH_2N_2 verestert. Der Methylester wurde dann durch Dünnschichtchromatographie an SiO_2 (Laufmittel: AcOEt–Hexan 1: 1) gereinigt. Man erhielt 240 mg (30%) **50** als Methylester; IR (Film): 1730, 1660, 1615 cm^{-1}; NMR (CCl_4): 1.07 (6H, s), 1.22 (3H, d, J=6 Hz), 3.60 (3H, s), 5.64 (1H, bs); MS: 238 (M^+); Gef: C, 70.01; H, 9.46%. Ber. für $C_{14}H_{22}O_3$: C, 70.55; H, 9.31%.

*2-Carboxymethyl-3,6-dimethyl-2-cyclohexenon (**52**) und 3-(2-Carboxyethyl)-4-methyl-2-cyclohexenon (**53**).* Eine Lösung von 510 mg **51** in 20 ml HCO_2H wurde mit 2.7 ml HBr 1.5 h rückfliessend erhitzt. Nach üblicher Aufarbeitung und Versterung mit CH_2N_2 wurde die Reaktionsmischung dünnschichtchromatographisch an SiO_2(Laufmittel: Benzol–AcOEt 4: 1) gereinigt. Als Methylester erhielt man 230 mg (50%) **52** und 20 mg (4%) **53**. Methylester von **52**; IR (Film): 1740, 1662, 1640 cm^{-1}; NMR (CCl_4): 1.09 (3H, d, J=6 Hz), 1.88 (3H, s), 3.21 (2H, s), 3.57 (3H, s); Gef: C, 67.10; H, 8.16%. Ber. für $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%. Methylester von **53**; IR (Film): 1730, 1665, 1630 cm^{-1}; NMR ($CDCl_3$): 1.24 (3H, d, J=7 Hz), 2.54 (4H, s), 3.68 (3H, s), 5.74 (1H, bs); MS: 196 (M^+); Gef: C, 66.94; H, 8.13%. Ber. für $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

*2-(2-Carboxyäthyl)-3-methyl-2-cyclohexenon (**55**) und 3-(3-carboxypropyl)-2-cyclohexenon (**56**).* Eine Lösung von 260 mg **54** in 13 ml HCO_2H wurde mit 2 ml $HClO_4$ (60%) versetzt und 2 h gekocht. Analog wurden die beiden Carbonsäuren **55** (136 mg, 63%) und **56** (40 mg, 18.5%) als Methylester abgetrennt (Laufmittel: AcOEt–Hexan 1: 1). Methylester von **55**; IR (Film): 1745, 1665, 1630 cm^{-1}; NMR ($CDCl_3$): 1.99 (3H, s), 3.65 (3H, s); Gef: C, 67.33; H, 8.14%. Ber. für $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%. Methylester von **56**: IR (Film): 1745, 1670, 1630 cm^{-1}; NMR ($CDCl_3$): 3.65 (3H, s), 5.81 (1H, t, J=1 Hz); MS: 196 (M^+); Gef: C, 66.34; H, 8.38%. Ber. für $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

Abschnitt C.

*1-(3-Chlor-2-butenyl)-2-decalon (**72a**).* *a*) Zu einer Lösung von 210 mg (0.03 g-Atom) Li in *ca.* 50 ml NH_3 wurden 1.5 g (0.01 mol) **33a** bei −33 °C hinzugefügt und 1 h bei der gleichen Temp. gerührt. Dazu wurden 4.5 ml DCB bei −33 °C tropfenweise gegeben und die Reaktionslösung weiter 1 h gerührt. Nach Entfernung von NH_3 wurde die Reaktionsmischung mit H_2O verdünnt, mit 6 M-HCl schwach angesäuert und mit AcOEt extrahiert. Die AcOEt-Auszüge wurden mit H_2O gewaschen, getrocknet und eingedampft. Der Rückstand wurde an der 30-fachen Menge SiO_2 chromatographiert, wobei 430 mg (20%) **72a** mit Benzol eluiert wurden; IR (Film): 1710, 1670 cm^{-1}; NMR ($CDCl_3$): 2.05 (3H, bs), 5.51 (1H, bt, J=7 Hz); MS: 240, 242 (M^+), 205 (M^+—Cl); Gef: C, 69.41; H, 8.81; Cl, 14.61%. Ber. für $C_{14}H_{21}ClO$: C, 69.84; H, 8.79; Cl, 14.73%.

b) Zu einer Lösung von 105 mg (15 mg-Atom) Li in 30 ml NH_3 wurde eine Lösung von 750 mg (5 mmol) **33a** und 0.38 ml (4 mmol) *t*BuOH in 20 ml THF bei −33 °C gegeben und 1 h bei der gleichen Temp. gerührt. Dann wurde eine Lösung von 1.6 ml (15 mmol) 1-Jod-3-chlor-2-buten in 3.5 ml THF bei −33 °C zugetropft und die Reaktionslösung 1 h gerührt. Nach der oben erwähnten Aufarbeitung erhielt man 350 mg (30%) **72a**.

*2-Oxo-2,3,4,4a,4b,5,6,7,8,8a,9,10-dodecahydrophenanthren (**73a**).* Eine Lösung von 138 mg **72a** in 6 ml HCO_2H wurde mit 0.5 ml $HClO_4$ (70%) versetzt und 1 h unter Rückfluss gekocht. Nach üblicher Aufarbeitung wurde das Rohprodukt durch präparative Dünnschichtchromatographie an SiO_2 (Laufmittel: Benzol–AcOEt 9: 1) gereinigt. Man erhielt 83 mg (70%) **73a** als farbloses Öl; IR (Film): 1670, 1623 cm^{-1}; NMR ($CDCl_3$): 5.77 (1H, bs); MS: 204 (M^+), 176 (M^+—C_2H_2); Gef: C, 81.00; H, 9.90%. Ber. für $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

*1-(3-Chlor-2-butenyl)-4a-methyl-2-decalon (**72b**).*[6d] Analog

zur Darstellung von **72a** (Vorschrift b) wurden 820 mg **12** reduktiv alkyliert. Man erhielt 300 mg (23%) **72b**; IR (Film): 1708, 1663 cm^{-1}; NMR ($CDCl_3$): 1.11 (3H, s), 2.05 (3H, d, J=1.5 Hz), 5.49 (1H, qt, J=1.5, Hz).

*8a-Methyl-2-oxo-2,3,4,4a,4b,5,6,7,8,8a,9,10-dodecahydrophenanthren (**73b**).* Analog **73a** wurde eine Lösung von 256 mg **72b** in 8 ml HCO_2H mit 0.5 ml $HClO_4$ (70%) versetzt und 0.5 h bei 95 °C erhitzt. 197 mg (90%) **73b** wurden erhalten; Schmp. 125—127 °C (Ether); IR (Nujol): 1660, 1615 cm^{-1}; NMR ($CDCl_3$): 1.00 (3H, s), 5.80 (1H, bs).

*17-Tetrahydropyranyloxy-des-A-estr-9-en-5-on (**69**).* Eine Lösung von 1 g **68**[15] in 20 ml abs. THF wurde bei RT. in Gegenwart von einer katalytischen Menge $POCl_3$ mit 4 ml Dihydropyran versetzt und 1 h stehengelassen. Die Reaktionslösung wurde dann mit H_2O, mit gesätt. $NaHCO_3$-Lösung gewaschen, getrocknet und eingedampft. Der Rückstand wurde dünnschichtchromatographisch an SiO_2 (Laufmittel: AcOEt–Hexan 1:1) gereinigt. Man erhielt 1 g (72%) 69 als farbloses Öl; IR (Film): 1670, 1620 cm^{-1}; NMR ($CDCl_3$): 0.95 (3H, s), 5.85 (1H, bs); MS: 304 (M^+).

*10-(3-Chlor-2-butenyl)-des-A-estran-5,17-dion (**70**).* *a*) Zu einer Lösung von 70 mg Li in 50 ml NH_3 wurde eine Lösung von 1 g **69** und 0.25 ml *t*BuOH in 25 ml THF gegeben. Die blaue Lösung wurde 0.5 h bei −33 °C gerührt, mit 1.3 ml DCB in 5 ml THF tropfenweise versetzt und 1 h bei der gleichen Temp. gerührt. Nach Abdampfen von NH_3 wurde das Reaktionsgemisch auf H_2O gegossen, mit 6 M-HCl schwach angesäuert und mit AcOEt extrahiert. Nach Eindampfen von AcOEt wurde der Rückstand in 15 ml MeOH gelöst, mit einer katalytischen Menge H_2SO_4 versetzt und 24 h bei RT. stehengelassen. Nach Entfernung von MeOH wurde der Rückstand in 50 ml Aceton aufgenommen, mit CrO_3(Jones-Reagenz) versetzt und bei RT. über Nacht gerührt. Nach Abdampfen von Aceton wurde der Rückstand in $CHCl_3$ gelöst. Die organische Phase wurde mit H_2O gewaschen, getrocknet und eingedampft. Das Rohprodukt wurde dann an der 50-fachen Menge SiO_2 mit Benzol–AcOEt (7:3) chromatographiert, wobei 170 mg (17%) **70** eluiert wurden, dann folgten 310 mg (42%) Des-A-estran-5,17-dion.

b) Auf die gleiche Weise wurden 300 mg **69** mit 1-Jod-3-chlor-2-buten reduktiv alkyliert. Die anschliessenden Abspaltung der Schutzgruppe und Oxydation ergaben 65 mg (22%) **70**; IR (Film): 1740, 1710, 1660 cm^{-1}; NMR ($CDCl_3$): 0.98 (3H, s), 2.07 (3H, bs), 5.50 (1H, bt, J=7 Hz); MS: 308, 310 (M^+), 273 (M^+−Cl); Gef: C, 70.18; H, 7.95; Cl, 11.72%. Ber. für $C_{18}H_{25}ClO_2$: C, 70.00; H, 8.16; Cl, 11.48%.

*4-Estren-3,17-dion (**71**).* Eine Lösung von 95 mg **70** in 5 ml HCO_2H wurde mit 0.5 ml $HClO_4$ (70%) versetzt und 0.5 h bei 95 °C erhitzt. Nach üblicher Aufarbeitung wurde das Rohprodukt dünnschichtchromatographisch gereinigt. Man erhielt 75 mg (90%) **71**; Schmp. 152—154 °C (CH_2Cl_2–Isopropyl ether); IR (Nujol): 1738, 1668, 1620 cm^{-1}; NMR ($CDCl_3$): 0.95 (3H, s), 5.82 (1H, bs); MS: 272 (M^+), 244.

Abschnitt D.

Darstellung von α-(2-Haloallyl)ketonen.

*2-(2-Bromallyl)-6-methylcyclohexanon (**78**).* Eine Lösung von 4 g Pyrrolidinenamin des 2-Methylcyclohexanons[36] in 15 ml Dioxan wurde mit 2.6 ml 2,3-Dibrompropen versetzt und 18 h unter Ar rückfliessend gekocht. Danach wurden 1 ml 6 M-HCl und 5 ml H_2O zugegeben und die Reaktionslösung 3 h gekocht. Nach Abkühlen auf RT. wurde das Reaktionsgemisch auf Eis gegossen und mit AcOEt extrahiert. Die organische Phase wurde mit gesätt. $NaHCO_3$-Lösung neutralgewaschen, getrocknet und eingedampft. Der Rückstand wurde an der 20-fachen Menge SiO_2 mit Benzol chromatographiert. Man erhielt 3.5 g (62%) **78** als Öl; IR (Film): 1720, 1630 cm^{-1}; NMR (CCl_4): 0.99 (3H, d, J=6 Hz), 5.40 (1H, t, J=1 Hz), 5.60 (1H, t, J=1 Hz); MS: 230, 232 (M^+): Gef: C, 51.83; H, 6.57; Br, 34.80%. Ber. für $C_{10}H_{15}BrO$: C, 51.96; H, 6.54; Br, 34.57%.

*2-(2-Chlorallyl)-2-methylcyclohexanon (**80**).* Ein Gemisch von 3 g 2-Methylcyclohexanon und 1.3 g $NaNH_2$ in 20 ml Benzol wurde 5 h unter Rückfluss und Ar gerührt. Nach Abkühlen anf RT. wurde eine Lösung von 3.6 ml 2,3-Dichlorpropen in 7 ml Benzol unter Rühren tropfenweise hinzugefügt und die Reaktionslösung 2 h rückfliessend erhitzt. Nach üblicher Aufarbeitung wurde das Rohprodukt an der 20-fachen Menge SiO_2 chromatographiert, wobei 1 g (20%) 6-Methyl-2-(2-chlorallyl)cyclohexanon mit Benzol–Hexan (3:1) eluiert wurde, dann folgten 2.1 g (42%) **80**; IR (Film): 1715, 1635 cm^{-1}; NMR (CCl_4): 1.26 (3H, s), 2.62 (2H, s), 5.09 (1H, t, J=1 Hz), 5.21 (1H, d, J=1.5 Hz); MS: 186, 188 (M^+), 151 (M^+–Cl); Gef: C, 64.46; H, 8.13; Cl, 19.10%. Ber. für $C_{10}H_{15}ClO$: C, 64.34; H, 8.04; Cl, 19.03%.

*2-(2-Chlorallyl)-2-methylcyclohexan-1,3-dion (**82**).* Zu einer Lösung von 1.1 g 2-Methylcyclohexan-1,3-dion und 0.56 g KOH in 2.24 ml H_2O fügte man 1 ml 2,3-Dichlorpropen und 0.3 g KI und rührte 1.5 h bei 90 °C. Nach Abkühlen auf RT. wurde die Reaktionsmischung auf Ether gegossen. Die etherische Phase wurde mit H_2O gewaschen, getrocknet und eingedampft. Der Rückstand wurde an der 30-fachen Menge SiO_2 mit Benzol–AcOEt (4:1) chromatographiert. Man erhielt 1 g (50%) **82** als farbloses Öl; IR (Film): 1730, 1700, 1630 cm^{-1}; NMR ($CDCl_3$): 1.32 (3H, s), 2.90 (2H, s), 5.09 (1H, t, J=1 Hz), 5.12 (1H, d, J=1.5 Hz); MS: 200, 202 (M^+); Gef: C, 59.78; H, 6.61; Cl, 17.74%. Ber. für $C_{10}H_{13}ClO_2$: C, 59.85; H, 6.53; Cl, 17.67%.

*2-(2-Bromallyl)cyclohexan-1,3-dion (**84**).* Zu einer Lösung von MeOK aus 1.6 g K in 14 ml abs. MeOH wurden 4.4 g Cyclohexan-1,3-dion hinzugefügt. Diese Lösung wurde bei 50 °C mit einer Lösung von 4.6 ml 2,3-Dibrompropen versetzt und 10 Min. unter Rückfluss erhitzt. Nach Entfernung von MeOH wurde der Rückstand in 40 ml 3% NaOH-Lösung aufgenommen und mit Ether geschüttelt. Die wässrige Phase wurde unter Eiskühlung mit 6 M-HCl auf pH 4 eingestellt, wobei 3.1 g (33%) **84** ausfielen; Schmp. 119—120 °C (MeOH–Isopropylether–AcOEt); IR (Nujol): 1635, 1565 cm^{-1}; MS: 151 (M^+−Br); Gef: C, 46.82; H, 4.84; Br, 34.58%. Ber. für $C_9H_{11}BrO_2$: C, 46.77; H, 4.80; Br. 34.59%.

*α-(2-Chlorallyl)-4-methoxydeoxybenzoin (**86**).* Ein Gemisch von 1 g 4-Methoxydeoxybenzoin[40] und 276 mg NaH (50% Ölsuspension) in 10 ml Benzol wurde 1 h unter Rühren und Ar gekocht. Nach Abkühlen wurde 0.55 ml 2,3-Dichlorpropen in 10 ml Benzol zugetropft und die Reaktionslösung 1.5 h unter Rückfluss erhitzt. Nach üblicher Aufarbeitung wurde das Rohprodukt an der 30-fachen Menge SiO_2 mit Benzol chromatographiert. Man erhielt 930 mg (70%) **86**; Schmp. 114—115 °C (CH_2Cl_2–Isopropyläther); IR (Nujol): 1665, 1635 1605, 1575 cm^{-1}; NMR ($CDCl_3$): 2.74 (1H, dd, J=7, 14.5 Hz), 3.24 (1H, dd, J=7, 14.5 Hz), 3.75 (3H, s), 4.93 (1H, t, J=7 Hz), 4.98 (1H, d, J=1 Hz), 5.04 (1H, d, J=1 Hz), 7.24 (5H, s), 6.80 (2H, d, J=9 Hz), 7.95 (2H, d, J=9 Hz); MS: 265 (M^+−Cl); Gef: C, 71.76; H, 5.69; Cl, 11.97%. Ber. für $C_{18}H_{17}ClO_2$: C, 71.88; H, 5.66; Cl, 11.81%.

*2-(2-Bromallyl)-3-oxononansäureethylester (**90a**).* γ-Alkylierung von 2.6 g Acetessigsäureethylester mit n-$C_5H_{11}Br$ wurde nach der Vorschrift von Huckin *et al.*[33] durchgeführt. Zu 365 mg NaH (50% Ölsuspension) in 5 ml THF wurden 1.5 g **89a** in 10 ml THF tropfenweise gegeben, 0.5 h bei RT. und dann 10 Min. bei 50 °C unter Ar gerührt. Die so erhaltene Enolatlösung von **89a** wurde mit 0.84 ml 2,3-Dibrompropen in 5 ml THF versetzt und 18 h bei RT. gerührt. Die

Reaktionsmischung wurde auf H_2O gegossen, mit 6 M-HCl schwach angesäuert und mit Benzol extrahiert. Die Benzolauszüge wurden mit gesätt. NaCl-Lösung gewaschen, getrocknet und eingedampft. Der Rückstand wurde an der 10-fachen Menge SiO_2 mit Benzol chromatographiert. Man erhielt 1.7 g (29% aus **88**) **90a**; IR (Film): 1745, 1720, 1630 cm^{-1}; NMR ($CDCl_3$): 0.89 (3H, bt, J=5 Hz), 1.27 (3H, t, J=7 Hz), 2.93 (2H, bd, J=7 Hz), 3.90 (1H, t, J=7 Hz), 4.17 (2H, q, J=7 Hz), 5.39 (1H, d, J=2 Hz), 5.62 (1H, m); MS: 239 (M^+−Br); Gef: C, 52.81; H, 7.41; Br, 25.03%. Ber. für $C_{14}H_{23}BrO_3$: C, 52.67; H, 7.26; Br, 25.03%. Analog wurden **90b** und **c** dargestellt.

2-(2-Bromally)-3-oxodecansäureethylester (90b): IR (Film): 1750, 1725, 1633 cm^{-1}; NMR ($CDCl_3$): 0.88 (3H, bt, J=7 Hz), 1.25 (3H, t, J=7 Hz), 2.95 (2H, bd, J=7 Hz), 3.91 (1H, t, J=7 Hz), 4.18 (2H, q, J=7 Hz), 5.42 (1H, d, J=2 Hz), 5.62 (1H, m); MS: 253 (M^+−Br); Gef: C, 54.19; H, 7.63; Br, 24.52%. Ber. für $C_{15}H_{25}BrO_3$: C, 54.05; H, 7.56; Br, 23.97%.

2-(2-Bromallyl)-3-oxo-5-phenylpentansäureethylester (90c); IR (Film): 1750, 1725, 1633 cm^{-1}; NMR (CCl_4): 1.19 (3H, t, J=7 Hz), 2.82 (4H, s), 2.86 (2H, bd, J=7 Hz), 3.78 (1H, t, J=7 Hz), 4.05 (2H, q, J=7 Hz), 5.31 (1H, d, J=2 Hz), 5.53 (1H, m), 7.08 (5H, s); MS: 259 (M^+−Br); Gef: C, 56.78; H, 5.73; Br, 23.98%. Ber. für $C_{16}H_{19}BrO_3$: C, 56.64; H, 5.64; Br, 23.56%.

6-Chlor-3-oxo-2-pentyl-6-heptensäureethylester (94). **93** wurde nach der Vorschrift von Marvel *et al.*[35] dargestellt (Kp. 120 °C/12 Torr). Zu einer Suspension von 500 mg NaH (55% Ölsuspension) in 25 ml THF wurden 2 g **93** bei 0 °C unter Ar hinzugefügt und 1 h bei RT. gerührt. Dann wurde die Lösung bei 0 °C mit 6.8 ml 15% *n*-BuLi in Hexan versetzt und weiter 10 Min. gerührt. Dazu wurde 1 ml 2,3-Dichlorpropen in 2 ml THF bei 0 °C tropfenweise gegeben und die Reaktionsmischung 0.5 h bei RT. gerührt. Nach Zugabe von 7 ml 3.5 M-HCl und 15 ml Ether unter Eiskühlung wurde die Reaktionsmischung mit Ether ausgezogen. Die Ether auszüge wurden mit H_2O neutralgewaschen, getrocknet und eingedampft. Man erhielt 3 g (80%) vom Rohprodukt **94**, das ohne weitere Reinigung in **92a** umgewandelt wurde. Zur Analyse wurde eine Probe an SiO_2 chromatographiert (isolierte Ausb. 60%); IR (Film): 1745, 1718, 1635 cm^{-1}; NMR ($CDCl_3$): 0.89 (3H, bt, J=6 Hz), 1.28 (3H, t, J=7 Hz), 3.44 (1H, t, J=7 Hz), 4.17 (2H, q, J=7 Hz), 5.12 (2H, bs); Gef: C, 61.49; H, 8.44; Cl, 12.60%. Ber. für $C_{14}H_{23}ClO_3$: C, 61.72; H, 8.44; Cl, 12.90%.

Allgemeine Vorschrift der Hydrolyse.

Eine Lösung von α-(2-Haloallyl)keton in HCO_2H wurde mit einer kleinen Menge $HClO_4$ (60 od. 70% wässrig) versetzt und bei 70—75 °C erhitzt. Nach der in Abschnitten A und B beschriebenen Aufarbeitung wurde das Rohprodukt säulen- oder dünnschichtchromatographisch gereinigt.

2-(2-Oxopropyl)cyclohexanon (77). Eine Lösung von 500 mg **74**[28] in 20 ml HCO_2H wurde mit 0.3 ml $HClO_4$ (70%) versetzt und 2 h bei 75 °C erhitzt. Man erhielt 320 mg (70%) **77**; IR (Film): 1710 cm^{-1}; NMR (CCl_4): 2.10 (3H, s).

6-Methyl-2-(2-oxopropyl)cyclohexanon (79). 410 mg **78** wurden in 10 ml HCO_2H mit 0.2 ml $HClO_4$ (70%) 1.5 h bei 70 °C erhitzt. 224 mg (75%) **79** wurden erhalten; Kp. 77—80 °C (Öl-Bad)/1 Torr; IR (Film): 1710 cm^{-1}; NMR CCl_4): 0.95 (3H, d, J=6 Hz), 2.12 (3H, s); MS: 168(M^+); Gef: C, 70.41; H, 9.34%. Ber. für $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

2-(2-Carboxyethyl)-3,5-dimethyl-2-cyclopentenon (83). Zu einer Lösung von 500 mg **82** in 20 ml HCO_2H fügte man 1.5 ml $HClO_4$ (70%) und kochte 3 h unter Rückfluss. Nach Abdampfen von HCO_2H wurde der Rückstand in AcOEt aufgenommen. Die organische Phase wurde mit H_2O gewaschen, eingeengt und mit CH_2N_2 versetzt. Der Methylester wurde dünnschichtchromatographisch an SiO_2 (Laufmittel: Benzol–AcOEt 4: 1) gereinigt. Ausb. 146 mg (30%); IR (Film): 1740, 1695, 1643 cm^{-1}; NMR ($CDCl_3$): 1.14 (3H, d, J=7 Hz), 2.07 (3H, s), 2.47 (4H, s), 3.65 (3H, s); MS: 196 (M^+); Gef: C, 67.47; H, 8.25%. Ber. für $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

2-Methyl-4-oxo-4,5,6,7-tetrahydrobenzofuran (85). 1 g **84** wurde in 30 ml HCO_2H mit 3 ml $HClO_4$ (60%) 2.5 h bei 80 °C erhitzt. Nach Aufarbeitung wurde der Rückstand dünnschichtchromatographisch an SiO_2 (Laufmittel: AcOEt–Hexan 1: 1) abgetrennt. Neben dem nicht umgesetzten Ausgangsmaterial **84** (195 mg) erhielt man 290 mg (55%) **85** als Öl; IR (Film): 1675, 1582, 1240 cm^{-1}; NMR ($CDCl_3$): 2.30 (3H, s), 2.88 (2H, t, J=6 Hz), 6.22 (1H, q, J=1 Hz); MS: 150 (M^+); Gef: C, 71.59; H, 6.78%. Ber. für $C_9H_{10}O_2$: C, 71.98; H, 6.71%.

5-Methyl-2-(p-methoxyphenyl)-3-phenylfuran (87). 160 mg **86** wurden in 10 ml HCO_2H mit 1.5 ml $HClO_4$ (60%) 1 h rückfliessend erhitzt. Man erhielt 112 mg (80%) **87** als Öl; IR (Film): 1610, 1580, 1564, 1250 cm^{-1}; NMR (CCl_4): 2.31 (3H, s), 3.67 (3H, s), 5.98 (1H, bs), 6.63 (2H, d, J=8.5 Hz), 7.28 (2H, d, J=8.5 Hz), 7.20 (5H, s); MS: 264 (M^+); Gef: C, 81.61; H, 6.04%. Ber. für $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

Dihydrojasmon (92a). *a*) aus **90a**. Eine Lösung von 950 mg **90a** in 33 ml HCO_2H wurde mit 4.5 ml $HClO_4$ (60 %) versetzt, langsam bis auf 80 °C erwärmt und 2 h bei 80—90 °C erhitzt. Nach Abdampfen von HCO_2H wurde der Rückstand auf gesätt. $NaHCO_3$-Lösung gegossen und mit AcOEt extrahiert. Die AcOEt-Auszüge wurden mit gesätt. NaCl-Lösung gewaschen, getrocknet und eingedampft. Der Rückstand wurde 1 ml EtOH gelöst und mit 3 ml 0.5 M-NaOH 2.5 h gekocht. Nach üblicher Aufarbeitung wurde das Rohprodukt chromatographisch an SiO_2 (Laufmittel: AcOEt–Hexan 1: 1) gereinigt. Man erhielt 110 mg (22% aus **90a**) **92a**; IR (Film): 1706, 1648 cm^{-1}; NMR (CCl_4): 0.89 (3H, bt, J=6 Hz), 2.01 (3H, s); MS: 166 (M^+), 151, 110.

b) aus **94**. Eine Lösung von 1 g **94** in 25 ml HCO_2H wurde mit 3 ml $HClO_4$ (70%) und 2 ml H_2O 4 h bei 90 °C erhitzt. Das erhaltene Gemisch (*ca.* 600 mg) von **91** und **92a** wurde in 2 ml EtOH gelöst und mit 6 ml 0.5 M-NaOH 4 h bei 90 °C erhitzt. 233 mg (42% aus **93**) **92a** wurden erhalten.

Analog wurden **92b** und **92c** dargestellt.

2-Hexyl-3-methyl-2-cyclopentenon (**92b**);[41] IR (Film): 1700, 1644 cm^{-1}; NMR (CCl_4): 0.85 (3H, bt, J=6 Hz), 1.97 (3H, s); Gef: C, 79.35; H, 11.33%. Ber. für $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

2-Benzyl-3-methyl-2-cyclopentenon (92c); IR (Film): 1700, 1645, 1605, 1586 cm^{-1}; NMR (CCl_4): 2.02 (3H, s), 3.44 (2H, s), 7.08 (5H, s); MS: 186 (M^+); Gef: C, 83.73; H, 7.67%. Ber. für $C_{13}H_{14}O$: C, 83.83; H, 7.58%.

Herrn Dipl.-Chem. G. Stoll und Herrn G. Burger danken wir für die Korrektur des Deutschen. Herren Y. Shoji und K. Okada danken wir für die experimentelle Mitarbeit.

Conformational Equilibria of 8-Alkyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes

Toshihiro KAMADA* and Osamu YAMAMOTO

National Chemical Laboratory for Industry, Honmachi 1-1-5, Shibuya-ku, Tokyo 151

(Received November 30, 1978)

The conformations of 8-methyl (**4**) and 8-ethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (**5**) have been studied on the basis of the NMR spectra. It was found that both compounds exist as an equilibrium mixture of the axial-boat (**ab**) and the equatorial-boat (**eb**) conformers in solution. The ^{1}H spectra revealed that the boat conformations of all these isomers are somewhat in the distorted form due to the steric repulsion between the interior benzyl protons. The free-energy differences ($-\Delta G°$) between the two isomers (**ab**$\rightleftarrows$**eb**) in **4** and **5** were calculated from the ^{13}C spectra and found to be 0.09 and -0.07 kcal/mol, respectively. These results are discussed in terms of the structural and conformational features of the 8-membered pericyclized naphthalene ring and compared with the cyclohexane ring.

Recently, as a part of our studies on the chemistry of the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene system (**1**),[1-4] the conformations of 8-alkyl-9-oxo derivatives, **2** and **3**, were reported.[5] In the present paper, we have extended our study to the deoxo compounds **4** and **5** in order to examine in detail the effect of the alkyl substituent on the stability of the peri ring in these pericyclized naphthalene system. Here, we will report the conformational equilibria in these 8-alkylated compounds by a study of the ^{1}H- and ^{13}C-NMR spectra and make some discussion about the conformational and spectral features of the 8-membered pericyclized naphthalene system in comparison with the cyclohexane ring.

Results and Discussion

The room-temperature ^{1}H-NMR spectrum of 8-methyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10,10-d_3 (**4**-d_3) in a *ca.* 10% solution in deuteriochloroform shows broad signals for both the methyl and the benzyl protons. As the temperature of the sample is progressively lowered, the methyl signal broadens and then splits into two different lines with a chemical-shift difference of 0.36 ppm, while the benzyl proton signal changes into four sets of AB quartets of different intensities, centered at δ 3.29, 3.38, 3.44, and 3.46 ppm, respectively. The proton-decoupled ^{13}C-NMR spectrum of **4** at 30 °C gives a broad line for each of the peri ring carbons and the methyl group, all of which split into a doublet of different peak heights on lowering the temperature. Similar spectral changes were observed for the ethyl compound **5**.

From these spectra it is apparent that both **4** and **5** assume two different forms interchanging to each other by the inversion of the peri ring. Analysis of the low-temperature spectra of **4** and **5** as well as their 8,10,10-trideuterated derivatives (**4**-d_3, **5**-d_3) affords the ^{1}H- and ^{13}C-data for each conformational isomer of these compounds which are summarized in Tables 1 and 2.

It has previously been shown[1-6] that the interior benzyl protons (H_{in}) in the 8-membered pericyclized naphthalene ring suffer a severe steric interaction and resonate at much lower field than the corresponding exterior protons (H_{ex}). Thus the strong vicinal couplings (J=13 Hz) observed in the lower-field signals of the C-11 methylene groups in all the conformations (Table 1) clearly suggest that only boat conformations are significantly populated in these 8-alkylated compounds, since, as can be seen in Fig. 1, the H_{in} proton of the boat conformation (**B**) is situated in a position trans to an adjacent equatorial proton (H_{eq}), and thus a strong coupling is expected between these two protons.

Table 1. ^{1}H-NMR data of conformational isomers of **4** and **5**[a,b]

Conformer	7-CH_2	11-CH_2	CH_3
4-eb	4.25 (J=−14.4, 6.1 Hz)	3.99 (J=−14.3, 13.0, 7.0 Hz)	0.84 *d* (J=6.8 Hz)
	2.64 (J=−14.4, 1.0 Hz)	2.92 (J=−14.3, 6.0 Hz)[d]	
4-ab	3.67 (J=−14.1, 12.7 Hz)	3.87 (J=−14.3, 13.0, 7.0 Hz)	1.20 *d* (J=7.0 Hz)
	2.90 (J=−14.1, 6.0 Hz)	2.90 (J=−14.3, 6.0 Hz)[d]	
5-eb	4.20 (J=−14.6, 6.1 Hz)	3.98 (J=−14.5, 13.0, 7.0 Hz)	*ca.* 1.0[c]
	2.75 (J=−14.6, 1.0 Hz)	2.93 (J=−14.5, 6.0 Hz)[d]	
5-ab	3.57 (J=−14.4, 11.5 Hz)	3.83 (J=−14.3, 13.0, 6.0 Hz)	*ca.* 1.0[c]
	2.89 (J=−14.4, 6.0 Hz)	2.96 (J=−14.3, 6.0 Hz)[d]	

a) At −45.1 °C in $CDCl_3$, δ in ppm from internal TMS. b) Signals due to the C-9 protons are buried under those of the methyl group. c) Because of overlapping of signals splitting of this signal was not observed. d) The coupling ($J_{ex,ax}$) is small enoguh not to be observed.

TABLE 2. CARBON-13 CHEMICAL SHIFTS OF CONFORMATIONAL ISOMERS OF **4** AND **5**[a]

Conformer	C-7	C-8	C-9	C-10	C-11	$\underline{C}H_3$[b]	$\underline{C}H_2$[b]
4-eb	42.6	33.2	29.6	29.4	35.9	22.0	
4-ab	44.6	34.1	26.9	24.4	36.3	20.0	
5-eb	39.5	40.7	26.6	29.2	36.5	12.4	27.7
5-ab	43.2	40.7	23.8	24.6	36.5	12.4	27.7

a) At −56.1 °C in $CDCl_3$, δ in ppm from internal TMS. b) Carbons due to the alkyl group.

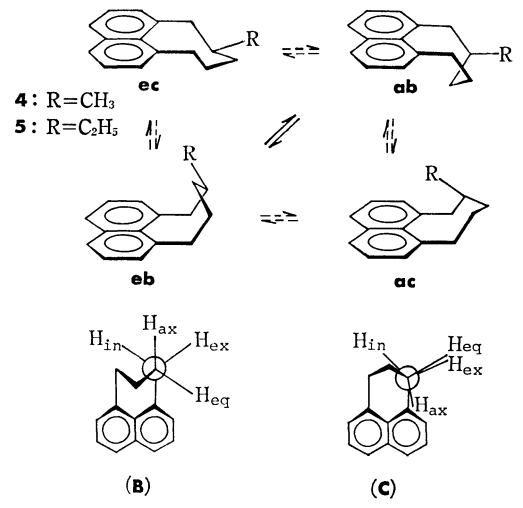

Fig. 1. The boat (**B**) (**eb**, **ab**) and the chair (**C**) (**ec**, **ac**) conformations for **4** and **5**, and their Newman projections about the C_{10}–C_{11} bond.

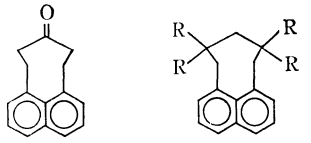
On the contrary, if the chair (**C**) would be the predominant conformation for **4** and **5**, then the strong vicinal coupling could be observed for the H_{ex} protons (see Newman projections in Fig. 1). The splitting pattern of the C-11 interior proton signal (J=14.3, 13.0, 7.0 Hz) in each conformer of **4** and **5** is analogous to that of the parent compound **1** (J=14.2, 12.9, 6.5 Hz),[4] which exists in the boat conformation alone.

Then the positions of the alkyl group in each conformation can be obtained from the magnitude of the vicinal couplings of the C-7 interior protons. Thus the isomers which have larger values (12.7 Hz in **4** and 11.5 Hz in **5**) have the alkyl groups at axial (**4-ab** and **5-ab**), while the others with smaller values (6.1 Hz in both **4** and **5**) have the equatorial alkyl groups (**4-eb** and **5-eb**).

This result is consistent with the ^{13}C chemical shifts in Table 2. Thus, high-field shifts of the C-7 carbons in the equatorial isomers (**eb**) relative to those in the axials (**ab**) ($\Delta\delta$=2.0—3.7 ppm) are caused by a gauche interaction between the alkyl substituent and the peri bond in the **eb** isomer (see Fig. 1), whereas marked shieldings of the C-9 ($\Delta\delta$=2.7—2.8 ppm) and C-10 carbons ($\Delta\delta$=4.6—5.0 ppm) in the **ab** conformations as compared to those in the **eb** result from the so-called γ-effect.[7] By these effects the chemical-shift differences in the C-8 ($\Delta\delta$=0.0—0.9 ppm) and in the alkyl carbons ($\Delta\delta$=0.0—2.0 ppm) between the axial (**ab**) and the equatorial (**eb**) isomers in these peri-8-membered ring system are rather small as compared to those observed in the cyclohexane system ($\Delta\delta$=4.5 and 6.0 ppm for the α and the methyl carbons, respectively).[7]



6 **7**

Consequently, compounds **4** and **5** exist as an equilibrium mixture of the axial-boat (**ab**) and the equatorial-boat (**eb**) conformers in solution. The unusually overwhelming preference of the boat conformations (**ab**, **eb**) over the chair (**ac**, **ec**) observed in these compounds results chiefly from much lower torsional energy about the C_7–C_8 and C_{10}–C_{11} bonds of the boat conformation (staggered) than the chair (eclipsed), which is one of the unique features in the peri-8-membered ring system of naphthalene (Fig. 1). All the other compounds of this ring system studied so far, including the substituted (**2**, **3**,[5] and **7**[1]) and unsubstituted (**1**[4] and **6**[2]) compounds exist solely in the boat conformation, too. The interconversion between **ab**⇄**eb** in **4** and **5** is likely to proceed by pseudorotations of the peri bonds *via* the twist-boat as in the parent compound **1**.[4,6]

TABLE 3. CONFORMATIONAL EQUILIBRIA BETWEEN **ab** ⇌ **eb** IN **4** AND **5**[a]

	R=CH_3		R=C_2H_5	
	4	**2**	**5**	**3**
K(**eb**/**ab**)	1.27		0.89	
$-\Delta G°$/(kcal/mol)	0.09	0.10[b]	−0.07	−0.59[b]
	1.70[c]	1.6—1.8[d]	1.75[c]	1.1—1.2[d]

a) Obtained from the intensity ratio of the C-7 carbon signal at −56.1 °C. b) Data taken from Ref. 5. c) For the alkylcyclohexane (Ref. 8). d) For the 2-alkylcyclohexanone (Ref. 10).

In order to determine the effect of the naphthalene moiety on the stabilities of isomers in **4** and **5** (the C-8–C-9–C-10 moiety of the boat has a geometry very similar to that of the cyclohexane ring;[1] Fig. 1), the isomer ratios (**eb**/**ab**) in these compounds were then calculated from the C-7 carbon signal intensities of each conformational isomer in the low-temperature ^{13}C spectra. The results are shown in Table 3 together with the corresponding free energy differences ($-\Delta G°$). In **4**, the equatorial methyl group at C-8 is slightly favored *vis-à-vis* the corresponding axial group, by *ca.* 0.09 kcal/mol, while the C-8 ethyl group in **5**, on the contrary, prefers the axial conformation by *ca.* 0.07 kcal/mol at −56.1 °C. This result is in striking contrast with the situation of the cyclohexane system, in which both the methyl and the ethyl substituting groups have a strong preference for the equatorial conformation ($-\Delta G°$=1.7 and 1.75 kcal/mol, respectively).[8]

The unusual high stability of the axial isomers (**ab**) observed in these 8-membered pericyclized naphthalenic compounds **4** and **5** as compared to those in the cyclohexane ring may be explained on the basis of molecular models as follows:[5] The axial alkyl group

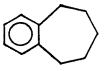
in the **ab** conformation involves one gauche arrangement around the C_9–C_{10} bond and one *syn*-axial hydrogen at C-10 position. This corresponds to only one half of the steric interaction present in the axial isomer of the alkylcyclohexanes.[9] In the case of the equatorial isomer, however, the cyclohexane ring has no significant steric interaction within molecules,[9] while the equatorial alkyl group in the peri-8-ring (**eb**) involves one gauche arrangement with the C-7 peri bond.

Here, it is of interest to note that the bulkiness of the substituting group in the peri-8-ring system can play a more significant role in determining the conformational equilibria than in the cyclohexane ring, since, with increasing the steric bulkiness of the alkyl group, the conformation **eb** additionally suffers a non-bonded interaction between the alkyl group and the naphthalene nucleus, which is absent in the cyclohexane system. Thus, the $\Delta G°$ difference ($\Delta\Delta G° = -0.16$ kcal/mol) on going from the methyl (**4**) to the ethyl (**5**) derivative may be attributed chiefly to the alkyl-naphthalene interaction mentioned above, by which the stability of the **5-eb** conformation is further decreased as compared to that of the equatorial isomer of the alkylcyclohexane ($\Delta\Delta G° = 0.05$ kcal/mol).[8]

We have already studied[5] the NMR spectra of the 8-alkyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-ones (**2** and **3**) and shown that these compounds exist also as an equilibrium mixture of the **ab** and the **eb** conformers in solution. Comparison of the $\Delta G°$ values between the hydrocarbons (**4**, **5**) and the ketones (**2**, **3**) reveals that $-\Delta G°$ value of the methyl compound **4** (0.09 kcal/mol) is almost equal to that of the corresponding ketone **2** (0.10 kcal/mol), whereas in the case of the ethyl derivatives the $-\Delta G°$ value of the ketone **3** is considerably decreased (−0.59 kcal/mol) relative to the value of the deoxo compound **5** (−0.07 kcal/mol) (Table 3). This can be reasonably explained in terms of the so-called "2-alkylketone effect," since the geometry around the C-8–C-9–C-10 moiety of the peri-8-membered ring system is very similar to that of the cyclohexane ring.[1] That is, because of the eclipsed interaction between the equatorial ethyl group and the carbonyl function, the **3-eb** isomer is more destabilized than the **5-eb** isomer by the energy of *ca.* 0.5 kcal/mol, which is almost comparable to the value (0.55—0.65 kcal/mol)[10] found in the cyclohexane system.

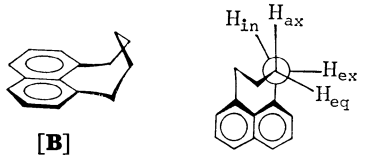
The ^{1}H- and ^{13}C-data in the tables show other spectral and conformational features inherent in the 8-membered pericyclized naphthalene ring. The chemical-shift difference between the axial and the equatorial methyl protons in **4** ($\Delta\delta = 0.36$ ppm) is greatly increased relative to the value (0.07 ppm)[11] found in the cyclohexane system. This may be caused chiefly by the ring-current effect of the naphthalene nucleus, since, in the boat conformation of the peri-8-membered ring, the equatorial methyl group on C-8 has a position closer to the naphthalene ring than the corresponding axial methyl group (see Fig. 1). Actually, the magnitude of the shift difference of the two methyl protons observed in the spectrum (0.36 ppm) well agrees with the result of the calculation that the equatorial methyl protons resonate at *ca.* 0.46 ppm higher field than the axial methyl protons by the effect of the ring current of naphthalene.[1]

In all the isomers of **4** and **5**, the chemical shifts of the exterior benzyl protons ($\delta = 2.64$—2.96 ppm) are approximately equal to the values reported for the benzyl protons of 6,7,8,9-tetrahydro-5*H*-benzocycloheptene **8** ($\delta = 2.721$—2.827 ppm),[12] whereas the interior protons of **4** and **5** are deshielded markedly ($\delta = 3.57$—4.25 ppm) as a result of the steric compression effect. The calculation[4] revealed that the interatomic distance between the two interior protons of the boat conformation is 0.652 Å, much smaller than the sum of the van der Waals radii of the two hydrogens (2.4 Å). This suggests that although the boat (**ab**, **eb**) is the most favored conformation for **4** and **5**, it still involves severe steric repulsion between the two interior protons.



8

Thus it is expected that as in the case of the parent compound **1**,[4] the boat conformations of **4** and **5** are also in the distorted form [**B**], in which the two interior benzyl protons are pushed apart to relieve the steric repulsion between them. In this case, in view of the fact that the splitting patterns observed in the C-11 protons of **4** and **5** are very similar to those of **1** and **6**, it is reasonable to consider that the peri bonds of **4** and **5** undergo in-plane deformation as in the compounds **1**[4] and **6**[2,4] to result in the symmetric (C_s) conformation [**B**] as is shown in Fig. 2 (in studies on the peri-



[**B**]

Fig. 2. The distorted boat conformation [**B**] for the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring and its Newman projection about the C_7–C_8 (C_{10}–C_{11}) bond (see text).

substituted naphthalenes, it was revealed that the peri bonds of 1,8-dimethylnaphthalene undergo in-plane deformation,[13,14] while, in 1,8-di-*t*-butylnaphthalene,[15,16] the peri bonds undergo out-of-plane deformation). Table 1 shows that in all the isomers the vicinal spin couplings between the C-11 exterior and the C-10 axial protons are very small (splitting is not observed) as compared to the values observed between the C-11 interior and the C-10 axial protons ($J = 6.0$ and 7.0 Hz). Similar trend is observed in the vicinal couplings about the C_7–C_8 bond of the **eb** isomer, where the axial protons are coupled more strongly with the interior benzyl protons ($J = 6.1$ Hz) than with the exterior protons ($J = 1$ Hz). These facts strongly support that all the isomers of **4** and **5** exist in the distorted boat [**B**] rather than in the normal boat (**B**), since as is seen in Fig. 2, the observed couplings are explained much

better by the space arrangement in the distorted molecule [**B**] (H_{ex}/H_{ax}; $\theta>60°$, H_{in}/H_{ax}; $\theta<60°$) than by the space arrangement in the normal boat conformation (**B**) ($\theta\approx60°$).

In our previous paper,[5] we have reported the NMR spectra of **2** and **3**. The interior benzyl protons in these compounds suffer also marked deshieldings (δ=4.22—4.89 ppm) and show splitting patterns (**2**; J=14.8, 13.4, 7.3 Hz, **3**; J=14.7, 13.5, 5.6 Hz) similar to those of the distorted conformations (**6**; J=14.8, 13.0, 5.9 Hz).[2,4] Thus, taking account of this fact, it is most probable that **2** and **3** also experience the ring distortions as in the deoxo compounds **4** and **5**, though the magnitude of the vicinal splitting ($J_{ex,ax}$) is not known in **2** and **3**. It should be noted here that the interior benzyl protons in the ketones (**2**, **3**) are *ca.* 0.5—0.7 ppm more deshielded than those of **4** and **5**, which makes the chemical-shift differences of the benzyl methylene protons in the former molecule much larger ($\Delta\delta$=1.21—2.11 ppm) than those in the latter molecules ($\Delta\delta$=0.68—1.61 ppm). Similar trend is observed between the unsubstituted compounds **1** and **6** ($\Delta\delta$= 1.03 and 1.55 ppm for **1** and **6**, respectively). This results probably from the differences in the steric interaction of the interior benzyl protons. A calculation reveals that the distance between the interior benzyl protons of the peri-8-ring system is somewhat shortened when the bond of the C-9 carbon changes from the sp^3 (0.652 Å)[4] into the sp^2 hybrid (0.632 Å). Thus it can be expected that the interior benzyl protons of the ketones (**2**, **3**, and **6**) suffer the steric repulsion larger than that of the hydrocarbons (**4**, **5**, and **1**) and are deshielded more largely than in the case of the latter compounds.

Comparison of the ^{13}C chemical shifts of **4** and **5** with those of the ketones (**2**, **3**) reveals that the axial methyl group in the ketone **2-ab** is only slightly shielded (0.9 ppm) relative to that of the hydrocarbon **4-ab**, whereas the methyl group in the equatorial isomer suffers a marked shielding (7.4 ppm) by introduction of the carbonyl group. Similar trend is observed in the ethyl derivative, where the methylene carbon of the equatorial ethyl group (**eb**) is greatly shielded (6.0 ppm) relative to that of the axial isomer (**ab**) by the effect of the carbonyl group. This chiefly arises from the eclipsed interaction of the carbonyl function and the alkyl group in the equatorial isomer as is noted in the cyclohexane system.[17] This interaction is also reflected in the chemical shifts of the peri ring carbons of both alkyl compounds, in which the C-8 and the carbonyl carbons of the equatorial isomers are shielded by 5.8—7.1 ppm relative to those of the axial isomers (for the other peri ring carbons, which are remote from the interacting groups, the effects are rather small (0.0—1.0 ppm)). This result is interesting in comparison with the result of the norbornane system previously reported.[18] In 3-methyl-2-norbornanones, in which the carbonyl group is nearly in the same orientation with respect to the exo- and the endo-methyl groups, the carbonyl substituent effects differ only by 0.9—2.3 ppm between the two isomers.

Table 5 shows the effect of the 8-alkyl group on the chemical shifts of the C-7 benzyl protons. In both hydrocarbon (**4**) and ketone (**2**), the exterior protons are shielded markedly (0.30—0.31 ppm) by the effect of the equatorial methyl group, whereas the interior protons, on the contrary, are markedly deshielded (0.25—0.28 ppm) by the same substituting group. On the other hand, the introduction of an axial methyl group shields both the interior and the exterior protons on C-7, but the effects for the former protons are much larger (0.30 and 0.33 ppm) than those for the latter protons (0.03 and 0.04 ppm). Similar effect was

observed in the cyclohexane ring[11,19] and some theories to explain this were reported.[20,21] In the present case, although details are not known at present, the above results may be interpreted qualitatively in terms of carbon–carbon single-bond anisotropies.[19] Since the peri rings of **4** and **5** have a geometry analogous to that of the parent compound **1**, the torsional angle about the C_7–C_8 bond of **4** and **5** can be estimated from the data of **1** as follows; $H_{7in}/CH_3(ax)=H_{7ex}/CH_3(eq)=46°$, $H_{7ex}/CH_3(ax)=74°$ and $H_{7in}/CH_3(eq)=166°$ (the peri-eight-membered ring of 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene system is more greatly distorted (internal dihedral angle $\Psi=46°$)[4] than the cyclohexane ring ($\Psi=58°$),[22] see Fig. 2). These angles could adequately explain the trend of the shift values of the C_7-benzyl protons of **4** described above. For the ethyl compounds (**3**, **5**), almost the same trend is observed except for the H_{7in} proton of the **eb** isomer (see Table 5). The small shift value (0.07 ppm) observed in the ketone **3-eb**, in contrast to the case of the hydrocarbon **5-eb** (0.23 ppm), might be related chiefly to the 2-alkylketone effect described above.

Experimental

The synthesis of 8-methyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**4**) was reported previously.[3] 8-Ethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**5**) was synthesized from diethyl 9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta-[*de*]naphthalene-8,10-dicarboxylate (**9**)[3] as follows.

To a stirred solution of sodium ethoxide in ethanol (obtained by dissolving 1.7 g of sodium into 150 ml of absolute ethanol) was added a solution of 5 g of keto ester **9** in 50 ml of absolute ethanol and 30 ml of dry dimethyl sulfoxide. After 1 h heating, excess ethyl bromide was added and the mixture was refluxed overnight. The mixture was poured into ice–water and the resulting cloudy solution was extracted with ethyl acetate. The organic solution was worked up as usual to leave a brown oil, which then treated with alkaline solution. The solid precipitated was crystallized from ethanol to give 1.2 g of 8-ethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one (**3**) as white needles; mp 97—98 °C; Found: C, 85.87; H, 7.83%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%. Clemmensen reduction of the ketone **3** gave the hydrocarbon **5**. The product was obtained as white needles after recrystallization from aqueous ethanol; mp 38—39 °C; Found: C, 90.95; H, 8.70%. Calcd for $C_{17}H_{20}$: C, 91.01; H, 8.99%.

8-Methyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10,10-d_3 (**4**-d_3) and 8-ethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10,10-d_3 (**5**-d_3) were synthesized by Clemmensen reduction of the corresponding 8,10,10-trideuterated derivatives[5] of **2** and **3**, which had been obtained by the deuterium exchange reactions described previously.[4] The structures of the deuterated compounds were confirmed based on TLC, mp (**4**-d_3; 39—40 °C, **4**; 40—41 °C,[3] **5**-d_3; 38—39.5 °C) and their spectra (IR and NMR).

^{1}H NMR spectra were determined on a Varian HA-100D spectrometer operating at 100 MHz. ^{13}C NMR spectra were determined on a Varian NV-14 spectrometer operating at 15.087 MHz with a Varian 620/L computer (16K) in the pulsed FT mode (pulse flipping angle, 48°; pulse repetition time, 1.3 s). The samples were dissolved in chloroform-*d* (*ca.* 10% (w/v) solution), and tetramethylsilane was used as an internal standard. The temperature was controlled by using cooled nitrogen and measured by calibrated copper–constantan thermocouple.

Catalytic Efficiency of Synthetic Micellar Catalysts Bearing a Mercapto Group as the Reaction Center†

Yukito MURAKAMI,* Akio NAKANO, and Kiyoshi MATSUMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received December 25, 1978)

In order to obtain a clue to understanding the micro-environmental effect on the reactivity of a mercapto group placed in a reaction center of enzymes, micellar surfactants bearing a mercapto group were synthesized and their catalytic activity in the degradation of *p*-nitrophenyl carboxylates was studied. *N*-Hexadecyl-N^{α}-glutaryl-L-cysteinamide (AM·Cys-1) has an ability to form anionic micelles in aqueous media. The catalytic activity of AM·Cys-1 was compared with that of another synthetic surfactant, *N*-hexadecanoyl-L-cysteine (AM·Cys-2). These surfactants below their critical micelle concentrations markedly accelerated the degradation of several *p*-nitrophenyl carboxylates. On the contrary, the concentration-rate profiles for the degradation of *p*-nitrophenyl dodecanoate (PNPL) as catalyzed by the surfactants indicate that the reactivity of the mercapto group is reduced upon formation of the anionic micelles. The large rate retardation is primarily due to the decrease in concentration of the active thiolate anion. This was supported by the fact that the pK_a values for mercapto groups of the anionic micelles, for which the carboxyl group acts as an anionic head, were increased by 0.8—1.6 pK_a unit over those of the corresponding monomeric surfactants in the bulk phase. These surfactants showed profound reactivity even in a neutral pH region when mixed with cationic CTAB micelle. The electrostatic field effect provided by the cationic head of CTAB micelle seems to enhance the nucleophilicity of the mercapto group in the mixed micelles.

The mercapto group is located at the active site of thiol proteases such as papain, ficin, and bromelain and playes an important role in enzymatic reactions.[1] The reactivity of the mercapto groups of these enzymes, however, drastically changes from one to another depending on the nature of micro-environment where they are located. Because of the complexity of protein molecules, the difference in reactivity among various types of mercapto groups has not yet been satisfactorily clarified. Only a few studies on the reactivity of mercapto groups of non-enzymatic systems in the degradation of *p*-nitrophenyl acetate have been reported so far.[2] Some studies were carried out in cationic micelles such as hexadecyl- and octadecyltrimethylammonium bromide as enzyme model systems.[3] Shinkai and Kunitake introduced the concept of hydrophobic ion pair for the reaction of coenzyme A (CoASH) and glutathione (GSH) with *p*-nitrophenyl acetate in a cationic micelle in which the hydrophobic environment has an important role for the development of catalysis.[4] Recently, Moss and his coworkers synthesized self-contained thiol-functionalized surfactants and investigated their catalytic activity in the degradation of *p*-nitrophenyl acetate.[5] In their system, the mercapto group seems to be placed in the cationic Stern layer judging from the molecular structure of surfactants.

In order to clarify the various features of reactivity of the mercapto group in enzymatic reactions and to create more elaborated models of thiol proteases, we prepared in this work a novel type of surfactants, *N*-hexadecyl-N^{α}-glutaryl-L-cysteinamide (AM·Cys-1). The mercapto group is expected to be placed in a hydrophobic core of the micellar phase. The catalytic activity of AM·Cys-1 was compared with that of another synthetic surfactant, *N*-hexadecanoyl-L-cysteine (AM·Cys-2). The structural and micellar effects provided by the present cysteine-containing surfactants have been clarified in the deacylation of *p*-nitrophenyl carboxylates. The effective catalysis by mixed micelles composed of hexadecyltrimethylammonium bromide (CTAB) and either AM·Cys-1 or -2 in the deacylation has also been investigated here.

† Contribution No. 509 from this Department.

Experimental

Spectroscopic data were taken on a JASCO DS-403G grating IR spectrophotometer, a Varian A60 NMR spectrometer, and a Hitachi 124 spectrophotometer. pH-Measurements were carried out with a TOA HM-9A pH meter equipped with a TOA GC-125 combined electrode after calibration with a combination of appropriate aqueous standard buffers.

Materials. Hexadecyltrimethylammonium bromide (CTAB) of Nakarai Chemicals was recrystallized from ethanol, mp 237—239 °C (dec). Sodium dodecyl sulfate (SDS) and α-hydro-ω-dodecyloxytricosa(oxyethylene) (Brij 35) were purchased from Nakarai Chemicals as extra pure grade and used without further purification. 1-Dodecanethiol (C_{12}-SH) was obtained from Ishizu Pharmaceutical Co. and distilled under nitrogen, bp 145—147 °C/16 mmHg. 2-Mercaptoethanol was purchased from Nakarai Chemicals and distilled under nitrogen, bp 54.5 °C/13 mmHg. Glutathione (GSH, Wako Pure Chemical Industries), L-cysteine hydrochloride (Cys·HCl, Ishizu Pharmaceutical Co.), and 2,2′-dinitro-5,5′-dithiodibenzoic acid (DTNB, Nakarai Chemicals) of bio-analytical grade were used without further purification. Rhodamine 6G was purchased from Daiwa Chemicals as extra pure grade. *p*-Nitrophenyl carboxylates were prepared by the reaction of the corresponding carbonyl chlorides with *p*-nitrophenol. The esters were identified by elemental analyses and spectroscopic measurements.[6]

N-Hexadecanoyl-L-cysteine (AM·Cys-2). This was prepared by the condensation of hexadecanoic acid with *S*-benzyl-L-cysteine in the presence of ethyl chloroformate followed by elimination of the benzyl group in a manner reported by Heitmann.[7]

N-Hexadecanoyl-*S*-benzyl-L-cysteine: mp 79—81 °C. IR (KBr disc): 3320 (NH str.); 2920 and 2860 (CH str.); 1750 and 1650 (C=O str.); 825, 770, and 700 cm^{-1} (CH bend. of benzene). NMR ($CDCl_3$, TMS): δ 0.87 (3H, t, $C\underline{H}_3(CH_2)_{13}$-$CH_2$–), 1.24 (26H, broad, $CH_3(C\underline{H}_2)_{13}CH_2$–), 2.20 (2H, t,

$CH_3(CH_2)_{13}C\underline{H}_2CO$–), 2.91 (2H, d, –NHCH($C\underline{H}_2SCH_2Ph$)-$CO_2H$), 3.68 (2H, s, $-SC\underline{H}_2Ph$), 4.80 (1H, t, –NHC$\underline{H}$-(CO_2H)–), 6.37 (1H, d, –N$\underline{H}$–), and 7.51 (5H, s, phenyl H's).
