(Received May 7, 1977)

The reactivities of hydrogen atoms of aliphatic amino acids toward hydroxyl radicals in the hydrogen atom abstraction reaction have been studied in terms of the energy required for stretching the C–H bond which is attacked. The energy required for stretching the C–H bond by 0.5 Å from the equilibrium bond length has been calculated by the INDO method and compared with the partial rate constants experimentally assigned to the hydrogen atoms of aliphatic amino acids. The energy required has been correlated only with the partial rate constants of the hydrogen atoms on the β-carbon atom. For the hydrogen atoms on the α-carbon atom, although data was insufficient a similar situation has been observed. The reactivities of the hydrogen atoms on the γ and δ-carbon atom failed to correlate with the stretching energy. The reasons are discussed in terms of the effect raised by the configuration of amino acid molecules in solution. The stretching energy has also been found to be consistent with the electrophilicity observed in the hydrogen abstraction reaction by hydroxyl radical.

Reactions of hydroxyl radicals with amino acids have been investigated by a number of researchers with an interest in the radiation-induced damage of proteins. Hydroxyl radicals abstract hydrogen atoms from aliphatic amino acids and the rate constants for the reactions are available.

Recently, it has been reported[1] that the partial rate constants for the hydrogen atom abstraction by hydroxyl radicals may be estimated from the rate constants determined by the *p*-nitroso-*N*,*N*-dimethylaniline method[2,3] for primary, secondary, and tertiary hydrogen atoms bound to the α, β, γ, and δ-carbon atoms of simple aliphatic amino acids. The bimolecular rate constant for the hydrogen atom abstraction by hydroxyl radicals from an aliphatic amino acid has been interpreted by summation of the partial reactivities assigned to hydrogen atoms in the amino acid molecule. However, no theoretical basis of the partial reactivities has been presented.

In the present investigation, the energy required to stretch the C–H bond by 0.5 Å from the equilibrium bond length has been calculated, to ensure a quantum chemical basis to the assigned partial reactivity. This energy is possibly used as a measure of the reactivity of a hydrogen atom toward hydroxyl readicals, since it is approximately the same as the energy required for hydrogen abstraction calculated from a reacting system composed of a hydroxyl radical and an amino acid. The energies calculated for several kinds of aliphatic amino acids have been partly correlated with the assigned parital reactivities. The effect raised by configurational changes in solution has been discussed. The electrophilic behavior of hydroxyl radical observed in the hydrogen abstraction reaction with amino acids has been explained in terms of the stretching energy.

Method

The total energies for the isolated molecules as well as the reacting systems were calculated by the UHF method[4] in the INDO approximation.[5]

Results and Discussion

The total energies and the electron distributions were calculated for glycine, alanine, 2-aminobutyric acid, valine, isoleucine, and leucine. The assumed geometries of the amino acids and hydroxyl radicals are given in Fig. 1 and the total energies in Table 1. For alanine, 2-aminobutyric acid, valine, isoleucine, and leucine, the same bond lengths and bond angles as those of glycine were assumed. In order to find the stable form of valine, the total energies of the other forms were calculated and found to be less stable than that shown in Fig. 1.

Figure 1 shows a model of the hydrogen abstraction by hydroxyl radicals from glycine. It has been assumed that the hydroxyl radical approaches the H^9 atom of glycine along the extension of the C^1–H^9 bond maintaining the angle H^9OH at 104.45° (the bond angle of water) and abstracts the H^9 atom. In a previous paper,[6] the angular dependence of the energy of the CH_4–OH system (θ, the angle of HOH was varied from 90 to 180°) was studied, and it was confirmed that the approach with $\theta=104.45°$ is most favored.

TABLE 1. THE TOTAL ENERGY OF AMINO ACIDS AND HYDROXYL RADICALS CALCULATED BY THE INDO METHOD

Amino acid	Total energy (au)
Glycine	−63.6233
Alanine	−72.0652
2-Aminobutyric acid	−80.5059
Valine	−88.9413
Isoleucine	−97.3754
Leucine	−97.7260
Hydroxyl radical	−18.1505

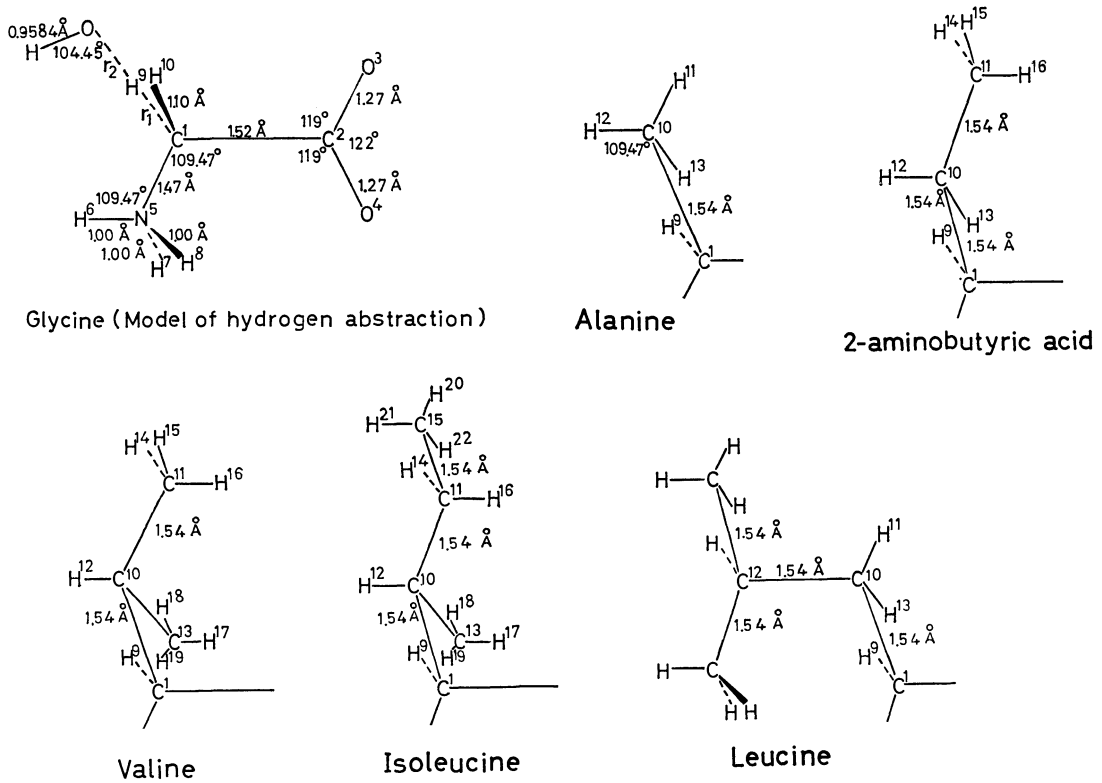

Fig 1. The geometries of amino acids and an assumed model for the abstraction by hydroxyl radical with amino acid.

Consequently, this angle has been adopted for the amino acid–OH system. The hydrogen atom of the hydroxyl radical lies in a anti-direction to the C^1–H^{10} bond with regard to the C^1–O bond. The energy dependence of the reacting system upon the intermolecular H^9–O distance, with the C^1–H^9 distance fixed at 1.10 Å was examined and the results are given in Fig. 2. The minimum quantity of energy was obtained between the intermolecular distances of 1.36 and 1.46 Å. The reacting system is more stable than the isolated state, and this is probably due to the stabilization by hydrogen-bonding between hydroxyl oxygen and the H^9 atom of glycine.

The reaction path is specified with the notation (r_1, r_2), where r_1 represents the distance in Å betweeen carbon C^1 and hydrogen H^9 which is abstracted, and r_2 that between H^9 and hydroxyl oxygen.

Figure 3 illustrates the dependence of the energy of the reacting system upon the C^1–H^9 distance r_1, when the C^1–O distance (r_1+r_2) is varied. It is conceivable that configuration interactions are important in lowering the energy for the transition state of the reacting system. However, calculation of the interactions by the UHF method is very complicated. Thus, it has been tentatively assumed that the effects of the configuration interactions are not so different, molecule to molecule in the series of aliphatic amino acid molecules, and consequently the reactivity may be compared with the energy obtained by the UHF method for the elongated C^1–H^9 bond. The following points A, B, C, and D were taken as possible reaction paths for H^9 abstraction, specified respectively by a set of r_1 and r_2 indicated in parentheses. A(1.10, 1.46), B(1.20, 1.36), C(1.30, 1.26), D(1.40, 1.16).

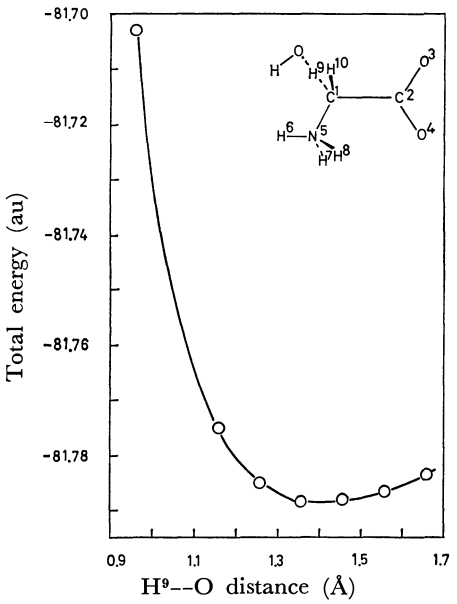

Fig. 2. Potential curve as a function of the distance between hydroxyl radical and H^9 atom in glycine-OH system.

From Fig. 3, it has been inferred that the potential curve appears to approach a maximum near D with the distance C^1–O of 2.56 Å, although the absolute value of the energy is not available. Therefore, it has been assumed that the difference in the total energy between the reacting system at D and the isolated state is an approximate measure of the reactivity of

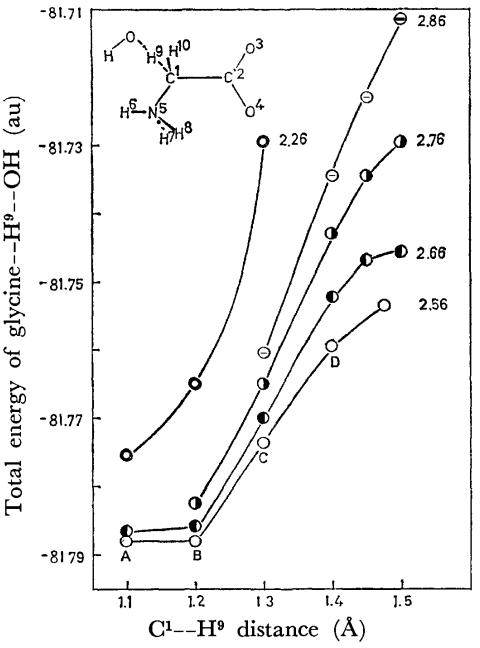

Fig. 3. Potential curves as a function of C^1–H^9 distance at various C^1–O distances in glycine–OH system. The number described near the point is C^1–O distance.

the H^9 atom (α-secondary). In order to examine the suitability of point D for other hydrogen atoms, the interaction energy between the hydroxyl radical and the H^9 atom of alanine has been calculated. As shown in Fig. 4, the favored reaction path has been found to be the same as that observed in the glycine H^9 atom. The results of Figs. 3 and 4 suggest that the path with $r_1+r_2=2.56$ Å is favored for hydrogen atoms of any type. Thus D has been taken as the reference point to compare the reactivities of hydrogen atoms bound to α, β, γ, and δ-carbon atoms.

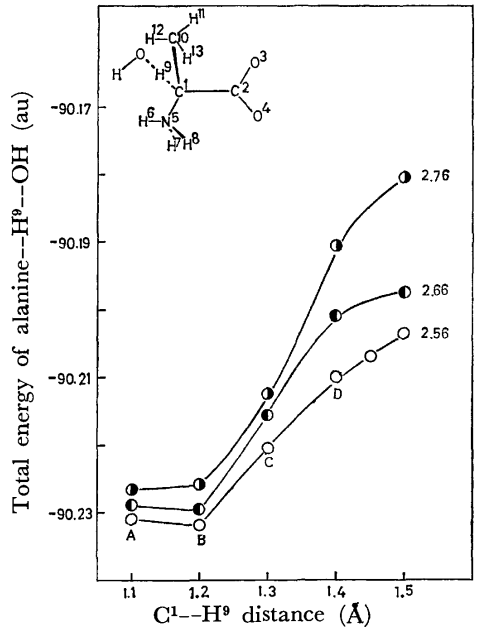

Fig. 4. Potential curves as a function of C^1–H^9 distance at various C^1–O distances in alanine–OH system. The number described near the point is C^1–O distance.

In chemical reactions, it has been recognized that the delocalization of electrons between a reactant and a reagent is a major factor in determining reactivity.[7,8] Although the potential curve should be obtained for the system including both a hydroxyl radical and an amino acid, the interaction energy could not always be obtained, because of divergence in the SCF calculation. This divergence may make the absolute values of the total energy unreliable. However, the relative values of the energy may be useful for a discussion of the relative reactivity. Thus, it has been assumed that the interaction energy could be approximated by the energy change due to the stretching of C–H bond. This model was checked in detail as follows. Several factors contribute to the abstraction reaction, for example, a) the strength of the R–H bond broken, b) the strength of forming the H–X bond, c) the stabilization energy due to delocalization of electrons, d) solvation, and so on. The relative reactivities of hydrogen atoms toward the same attacking reagent have been investigated in the present study and it appears that factors a) and c) dominate. If c) does not vary with types of C–H bonds or if a) and c) correlate linearly with each other, the reactivities of the hydrogen atoms for abstraction may be approximated to the strength of the C–H bond. The interaction energy of the glycine–OH system along the reaction path(A, B, C, D) has been compared with the total energy of glycine obtained by stretching the C^1–H^9 bond from 1.10 to 1.40 Å, in the singlet state. From a linear correlation between the total energy of the composite system and that of glycine at the same bond distance of the C^1–H^9 (Fig. 5), it has been concluded that the reactivity of the H^9 atom may be evaluated in terms of the energy required to stretch the C^1–H^9 bond by a

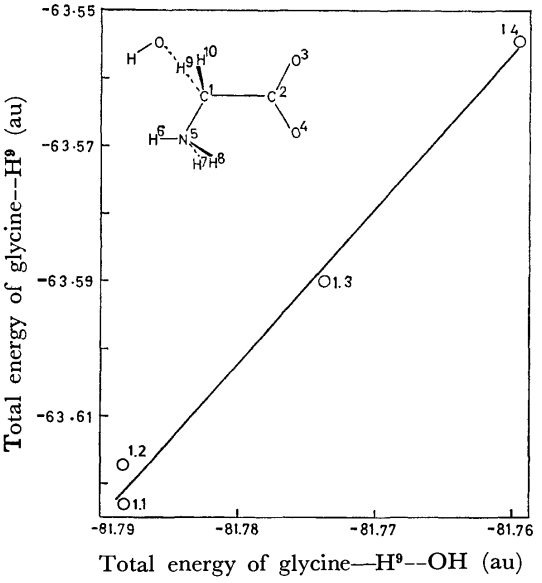

Fig. 5. The linear relationship between the energy changes by elongation of the C–H bond in question in presence and absence of OH group for glycine. The number described near the point is the bond length of the stretching C–H bond.

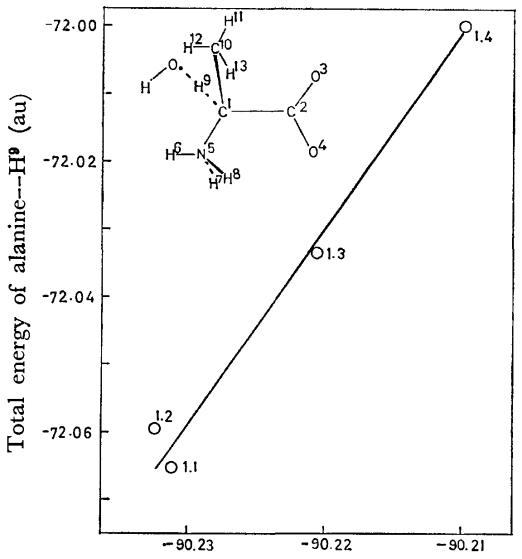

Fig. 6. The linear relationship between the energy changes by elongation of the C-H bond in question in presence and absence of OH group for alanine. The number described near the point is the bond length of the stretching C-H bond.

certain distance from the equilibrium bond length. The same argument is valid for the H^9 (α-tertiary) atom of alanine as shown in Fig. 6.

The conclusion is that the energy change due to stretching of the C-H bond interacting the hydroxyl radical may be approximated by the energy change in the absence of the hydroxyl radical. The validity of this conclusion has been examined for other types of hydrogen-atoms and the results are given in Fig. 7. ΔE_{OH} and ΔE have been difined for the reactivities of the hydrogen atoms in the following equations and have been calculated by two methods.

$$\Delta E_{OH} = E_{\text{amino acid-OH}} \text{ at D(1.40, 1.16)} - E_{\text{amino acid-OH}} \text{ at (1.10, } \infty) \quad (1)$$

$$\Delta E = E_{\text{amino acid}}(\text{C-H } 1.60) - E_{\text{amino acid}}(\text{C-H } 1.10) \quad (2)$$

Where D(1.40, 1.16) and (1.10, ∞) represent the points on the reaction path as previously defined and (C-H 1.60) and (C-H 1.10) indicate the C-H bond length. The point (C-H 1.60) has been tentatively selected in order that ΔE might approximate to ΔE_{OH}, although the absolute value of the energy may be unreliable.

The ΔE for several kinds of hydrogen atoms was found to have a close correlation with ΔE_{OH} with a few exceptions. Consequently, ΔE given by Eq. 2 has been used as an index to represent the reactivity of the hydrogen atoms of amino acids toward hydroxyl radicals in order to avoid the problem of divergency in the SCF calculation of ΔE_{OH}. Here, it should be noticed that the hydrogen atoms bound to the same carbon atom show different reactivities according to the orientation in the amino acid molecule as shown for the H^{11}, H^{12}, and H^{13} atoms of alanine in Fig. 7. This will be discussed in detail below.

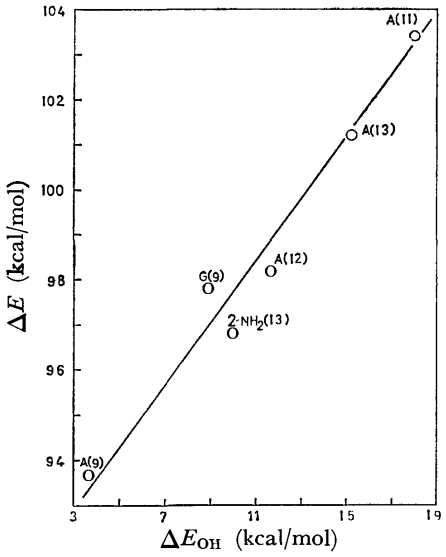

Fig. 7. Comparison of ΔE with ΔE_{OH} for different types of hydrogen atoms. G: glycine, A: alanine, 2-NH_2: 2-aminobutyric acid. The number in parenthesis indicates hydrogen atoms in Fig. 1.

	H^{14}	γ-tert	0.1494

a) α-sec: α-secondary, α-tert: α-tertiary, β-prim: β-primary, β-sec: β-secondary, β-tert: β-tertiary. b) Atomic unit.

To compare ΔE with the experimentally assigned values of the partial reactivities of hydrogen atoms, ΔE's were calculated for various kinds of hydrogen

atoms. The calculated values of ΔE are listed in Table 2. In the case of γ-primary hydrogen atoms (H^{14}, H^{15}, H^{16}) of 2-aminobutyric acid or valine, the prediction is that H^{16} is more reactive than H^{14} or H^{15}.

The differences in the reactivities of hydrogen atoms bound to the same carbon atom have been neglected when the partial reactivities were estimated from the observed rate constants. Therefore, the reactivity of γ-primary hydrogen atoms (also, β-primary, β-secondary, and so on) has been approximated by the average reactivity of H^{14}, H^{15}, and H^{16} atoms assuming Maxwell-Boltzmann distribution among the ΔE's. The results are in Table 3.

Table 3. Comparison of ΔE with the experimentally assigned partial reactivity

Type of C–H bond	Partial reactivity $M^{-1}s^{-1}$	ΔE(kcal/mol)
α-Secondary	8.5×10^{6}	97.835
α-Tertiary	1.7×10^{7}	93.715
β-Primary	2.07×10^{7}	98.188
β-Secondary	1.77×10^{8}	93.540[a]
		96.862[b]
β-Tertiary	3.54×10^{8}	89.575
γ-Primary	4.85×10^{7}	93.465[a]
		93.343[c]
γ-Secondary	5.12×10^{8}	89.701
γ-Tertiary	1.02×10^{9}	93.715
δ-Primary	6.75×10^{7}	100.597

a) Obtained from 2-aminobutyric acid. b) From leucine. c) From valine.

The relationship between the logarithm of the experimental reactivity and ΔE is shown in Fig. 8. If the type of hydrogen atoms is not taken into consideration, no clear correlation can be found. However, when the argument is restricted to only β-hydrogen atoms, a correlation betweeen ΔE and $\ln k$ is observed, though it is not well defined. For α-hydrogen atoms, only two points are available, and consequently no conclusive statement can be inferred. However, the slope is similar to that in the $\ln k \approx \Delta E$ correlation of β-hydrogen atoms. In the case of γ-hydrogen atoms, no correlation was found. To obtain a quantitative relation between the experimentally determined rate constant and the calculated interaction energy, the configurational changes of molecules in solution needs to be taken into consideration. In the present procedure, ΔE has been calculated for the fixed geometry of the amino acid molecule. The effect of the protonated amino group on the reactivity of a given hydrogen atom may vary with the position of the atom in three-dimentional space. For γ-hydrogen atoms, the fluctuation of the reactivity due to the configurational change is probably larger than the α or β-hydrogen atoms.

With regard to the values of ΔE in Table 3, two values of ΔE are given for β-secondary and γ-primary hydrogen atoms. The ΔE of the β-secondary hydrogen atom has been evaluated to be 93.540 kcal/mol as the average for H^{12} and H^{13} atoms of 2-aminobutyric acid, whereas 96.862 kcal/mol has been obtained as the average for H^{11} and H^{13} atoms of leucine. As ΔE for the H^{13} atom of leucine is approximately the same as that for the H^{13} atom of 2-aminobutyric acid, the difference in averaged ΔE's is attributable to the difference in ΔE between the H^{11} atom of leucine and the H^{12} atom of 2-aminobutyric acid. The value for γ-primary hydrogen atoms, 93.465 kcal/mol has been obtained from H^{14}, H^{15}, and H^{16} atoms of 2-aminobutyric acid and it was approximately consistent with 93.343 kcal/mol obtained from the H^{14}, H^{15}, and H^{16} atoms of valine. This suggests that the effect of another CH_3 group (C^{13}, H^{17}, H^{18}, H^{19}) of valine upon the reactivitiy of γ-primary hydrogen atoms is not large and the same value may be used for 2-aminobutyric acid and valine. If the molecular backbone is different, the same value cannot always be applied to represent the reactivity as shown in the cases of 2-aminobutyric acid and leucine, because the reactivity of the hydrogen atom is closely related to the orientation in the molecule. As already described, there is a remarkable difference in ΔE among primary and secondary hydrogen atoms. For γ-primary hydrogen atoms of 2-aminobutyric acid, for example, the large reactivity of the H^{16} atom compared with that of the H^{14} and H^{15} atoms is ascribed to the difference in the two-center interaction energy. The two-center energy in the INDO method[5] is equal to that in the CNDO/2 method by Pople *et al.*[9,10] and consists of the three terms with different characters.

$$E_{A-B} = \sum_{\mu}^{A}\sum_{\nu}^{B} 2P_{\mu\nu}\beta_{\mu\nu} - \frac{1}{2}\sum_{\mu}^{A}\sum_{\nu}^{B} P_{\mu\nu}^{2}\gamma_{AB} + [Z_A Z_B R_{AB}^{-1} - P_{AA}V_{AB} - P_{BB}V_{BA} + P_{AA}P_{BB}\gamma_{AB}] \quad (3)$$

The first term is called the resonance term, the second the exchange term and the third the electrostatic term. The two-center energies calculated for 2-aminobutyric acid are shown in Table 4. ΔE_{C-H}, defined by the following equation, is the local energy required in stretching a C–H bond.

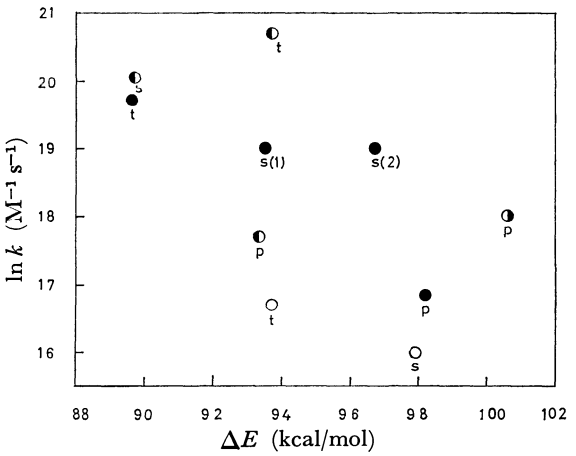

Fig. 8. Comparison of ΔE with the experimentally assigned partial reactivity. ○: α-, ●: β-, ◐: γ-, ◑: δ-, p: primary, s: secondary, t: tertiary. s(1) and s(2) are obtained from 2-aminobutyric acid and leucine respectively, see Table 3.

$$\Delta E_{C-H} = E_{C-H\ 1.60} - E_{C-H\ 1.10}, \quad (4)$$

where $E_{C-H\ 1.10}$ and $E_{C-H\ 1.60}$ are the interatomic interaction energies between carbon and hydrogen atoms at the C–H distance of 1.10 and 1.60 Å, respectively. E_{O-H} (C–H 1.10) and E_{O-H} (C–H 1.60) are the interatomic interaction energies between O^3 oxygen and hydrogen atoms (H^{14}, H^{15}, H^{16} of 2-aminobutyric acid) obtained at the C–H distance of 1.10 and 1.60 Å, respectively. ΔE, defined by Eq. 2, is the total energy required for the stretching and gives an index of the reactivity of hydrogen atoms. From the viewpoint of the energy required to stretch the C–H bond ΔE_{C-H}, the H^{16} atom is expected to the less reactive than the H^{14} and H^{15} atoms. However, ΔE gives the reverse results. For the interatomic interaction energy between O^3 and (H^{14}, H^{15}, H^{16}) atoms (E_{O-H} in Table 4), large stabilization is observed between O^3 and H^{16} atoms when the C^{11}–H^{16} bond is stretched. In the case of H^{14} and H^{15} atoms, destabilization occurred. In order to clarify the effect of the carboxyl group upon the reactivity of the H^{16} atom, a similar calculation was conducted by rotating the carboxyl group around the C^1–C^2 bond by 90°. The stabilization energy due to the interaction between O^3 and H^{16} atoms then reduces to approximately a tenth compared with the case without rotation of the carboxyl group. Accordingly, three hydrogen atoms have approximately equal reactivity as predicted from the magnitude of ΔE_{C-H}.

The interatomic interaction energy between O^3 and H^{16} atoms was further investigated by decomposing it into three components as in Eq. 3. The results given in Table 5 indicate that the resonance term is the most important and the main reason for the negative value of the O^3–H^{16} energy. Consequently it

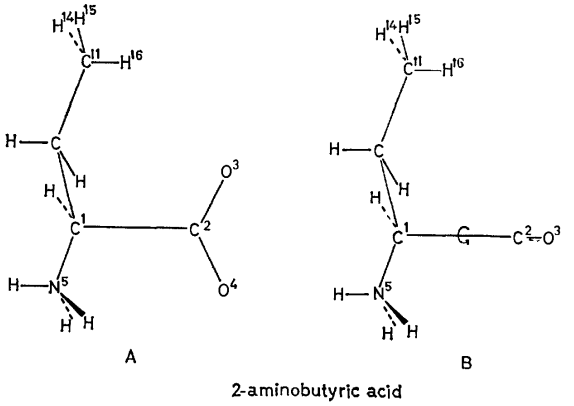

Fig. 9. Carboxyl group lies on the same plane with C^1, C^2, and N^5 atoms in A form, whereas in B form, the carboxyl group is rotated by 90° around C^1–C^2 bond.

may be concluded that the resonance interaction between O^3 and H^{16} atoms leads to an intramolecular hydrogen-bonding and this stabilization results in the large reactivity of the H^{16} atom despite the large value of ΔE_{C-H} of the C^{11}–H^{16} bond.

The reaction mechanism of the hydrogen abstraction by the hydroxyl radical from amino acids will now be discussed in terms of the electronic structure. The bond indices given by Wiberg[11] for the glycine–OH system are listed in Table 6, and the spin density and the charge transferred from glycine to the hydroxyl radical are listed in Table 7. It has been assumed that the hydroxyl readical has four valence electrons of α-spin and three valence electrons of β-spin. As shown in Tables 6 and 7, the approach of the hydroxyl radical decouples the electron pairing in the C^1–H^9 bond. The β-spin electron moves toward the H^9 atom while the α-spin electron in the opposite direction. In accordance with this spin movement, the α-spin

A Computer Program Package for the Analysis, Creation, and Estimation of Generalized Reactions—GRACE. I. Generation of Elementary Reaction Network in Radical Reactions—A/GRACE(I)†

Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 1, 1978)

The system GRACE generates elementary reaction networks for simple reactions including free radicals, ions and even active sites in heterogeneous catalysis, and also predicts the overall reaction rates and the product distributions in radical reactions in the gas phase where the Arrhenius parameters of elementary reactions are available. In this paper, A/GRACE (part A of GRACE) is explained, which prepares elementary reaction networks for radical reactions. The reactant and the product are represented by square symmetric matrices. The off-diagonal elements represent bond multiplicity, or the number of localized electrons, between corresponding atoms, whereas the diagonal elements imply the number of unshared electrons on radical atoms. A reacting system, an ensemble of the participating molecules, is composed of atom groups, each of which consists of a center atom (usually non-hydrogen) and attached hydrogen atom(s), if any. Firstly, all the possible changes in the atom groups are selected, and the permitted combinations are preapred bearing in mind the equivalent groups in the system and the restrictions optioned. The major restriction is the complexity, *i.e.*, the number of ruptured or formed bonds. A direct sum of matrices are prepared from one of the combinations, and the elementary reaction is completed by setting the appropriate numerals, 1 or −1, to the outside elements. Secondly, the procedures are repeated until all the feasible networks are prepared. As an illustration the hydrogenation of ethylene over a heterogeneous catalyst has been cited.

In chemical research and development, both pure and applied, computers can be used for creation and estimation of chemical facts with the aid of chemical logic, as well as mere numerical calculations. Chemical facts may be divided into two groups: the static physical properties of substances and the reaction characteristics among them. The present author has already published[1] the outline of a computer program package, EROICA, for the esitimation and the retrieval of physical properties of organic molecules.

Recently several systems of chemical logic with programs for the creation, or generation, of chemical reactions have been published by Corey,[2] Ugi,[3] Wipke,[4] and Bersohn.[5] Earlier works include DENDRAL by Feigenbaum *et al.*[5a] The features and the aims of these systems are rather different, reflecting the main interests of the authors. The present author has intended to develop a system that is capable of creating all of the possible reaction routes, or an elementary reaction network, in simpler organic reactions, and estimating quantitatively the reaction rates and product distribution. The system, GRACE (*G*eneralized *R*eaction *A*nalysis for *C*reation and *E*stimation) is fundamentally similar to that of Ugi *et al.*,[3] although the systems have been developed independently, and employs square matrices for manipulation of reacting systems. The outline of our system in the earlier stage was first published in 1970 as a part of a review.[6]

This program package has the ability to create radical and ionic reactions and to accurately estimate the quantitative values of overall reaction rates and product distributions of hydrocarbon pyrolyses in gaseous phase. However, the stereochemistry is ignored. This system may be extended to find out parasitic reactions when a target reaction is given, as well as to survey all the possible reaction schemes from given raw materials to valuable products.

† CHEMOGRAM, a Computer Program Package for Chemical Logic, Part 2.

Outline of GRACE

The system of GRACE consists of three sub-systems, A/GRACE, B/GRACE, and C/GRACE, as shown in Fig. 1, and may be operated following the arrows in the flow chart. The functions of the sub-systems are as follows:

(1) A/GRACE: A given overall reaction (radical or ionic reaction) is analyzed into a network of elementary reactions, which generates the product system from the reactant system through various intermediate systems.

(2) B/GRACE: Arrhenius parameters of all the elementary reactions prepared by A/GRACE will be searched by information retrieval from a file of observed data, estimated by searching the data of resembling reactions from the file, or also estimated with the aid of empirical linear free energy relationships. However, processing is at present limited to radical reactions in gaseous phase due to the lack of observed Arrhenius parameters.

(3) C/GRACE: Simultaneous differential equations corresponding to the material balance among

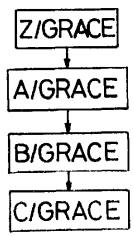

Fig. 1. Flow chart of GRACE.

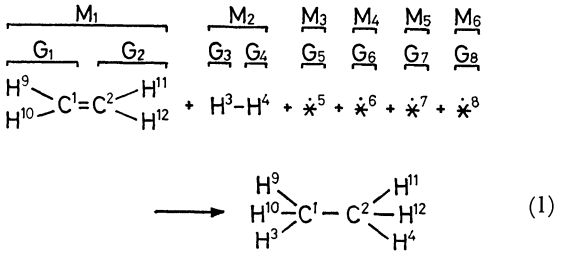
species in the network are prepared automatically. Overall rate and product distribution are calculated with the given initial conditions by direct integration of the equations or assuming the stationary state. Both flow and batch reactions may be dealt with.

In addition to these three sub-systems, a minor sub-system Z/GRACE, the part Zero of GRACE, may be employed to prepare the input data for A/GRACE concerning the reactant and product from a CHEMO input, a linear input of a rational formula also proposed by the present author.[7]

Representation of Reacting System by Matrices

In this paper, a *system* is defined as an *ensemble*[3] of molecules which are employed as components of a given reaction; a *reacting system* implies all of the systems of the reactant, intermediates and the product. The representation method of reacting systems will be explained for heterogeneous hydrogenation of ethylene, as a simple example.



(1)

Equation 1 shows the overall reaction of hydrogenation, where the asterisks, *, represent the active sites over the solid catalyst, *e.g.*, metallic nickel, the dots over the symbols indicate radicals, and the superscripts over atomic symbols give the *atom ordinals* in this system. Symbols G and M given above in the reactant system represent *atom groups* and molecules, respectively. Here, an atom group implies the smallest ensemble of atoms, consisting of a *center atom* (usually non-hydrogen atom) and up to six *attached hydrogen* atoms, if any, although both of the hydrogen atoms in a hydrogen molecule are the center atoms; the reactant in Eq. 1 is thus composed of six molecules and eight atom groups.

Reactant and Product Matrices. A reactant matrix, symmetric and very sparse, may be prepared from Eq. 1 by appropriately assigning a row and a column to each atom. In this way the molecules and atom groups may be arranged to follow faithfully the order of chemical bonds in the system as shown in Fig. 2(a). The matrix elements represent the multiplicity of chemical bonds: 1 for a single bond, 2 for a double bond, and 3 for a triple bond. At the present stage of development, a bond with a bond order of 1.5, that is, a conjugated double bond, may not be entertained. The matrix thus prepared is termed a reactant bonding matrix, $\boldsymbol{X}_b$, where $\boldsymbol{X}$ represents the reactant system and b the bonding matrix. It can be seen that each element of the matrix represents also the number of valence electrons belonging to an

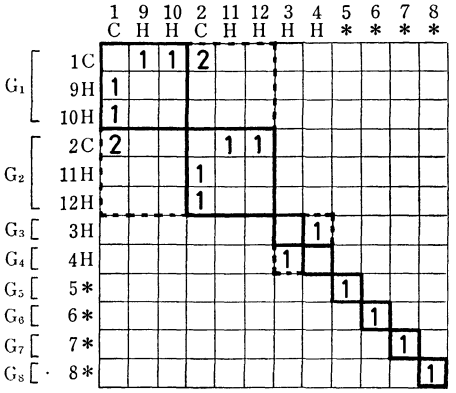


Fig. 2a. Reactant bonding matrix, $\boldsymbol{X}_b$.

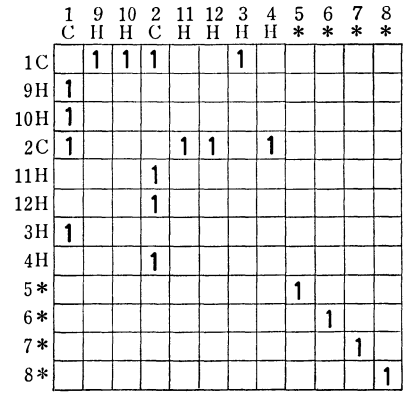

Fig. 2b. Product bonding matrix, $\boldsymbol{Y}(\boldsymbol{X}_b)$.

atom which are localized on a bond designated by the matrix. Hence, a radical atom that has at least one unshared valence electron should have valence electron(s) localized on it; *i.e.*, there is a numeral in the diagonal element.

A *product bonding matrix*, $\boldsymbol{Y}(\boldsymbol{X}_b)$ (Fig. 2(b)), may be prepared from Eq. 1 following the arrangement of the atom ordinals in $\boldsymbol{X}_b$, where $\boldsymbol{Y}$ represents a reactant and $(\boldsymbol{X}_b)$ defines the arrangement of atoms in the matrix as following the matrix $\boldsymbol{X}_b$. In the matrix $\boldsymbol{Y}$, two matrix elements having had a value of 2 in $\boldsymbol{X}_b$ are changed to 1 due to hydrogenation of the double bond.

Reaction Matrix. A reaction matrix, $\boldsymbol{R}_b$, may be defined as the difference between product $\boldsymbol{Y}$ and reactant $\boldsymbol{X}$:

$$\boldsymbol{R}_b = \boldsymbol{Y}(\boldsymbol{X}_b) - \boldsymbol{X}_b. \tag{2}$$

A reaction matrix, Fig. 2(c), is symmetric. The elements in the matrix represent the appearance or the disappearance of the localized valence electrons, and indicate bond formation and rupture, including changes in the bond multiplicity. Usually in elementary reactions, changes in the value of the matrix elements may not exceed two, since the change by two implies, for example, the sudden formation or rupture of a double bond in a single elementary step. The transformation of the double bond in ethylene to a single bond, the rupture of a single bond in a hydrogen molecule and the addition of two hydrogen atoms to ethylene may be found in Fig. 2(c). The active

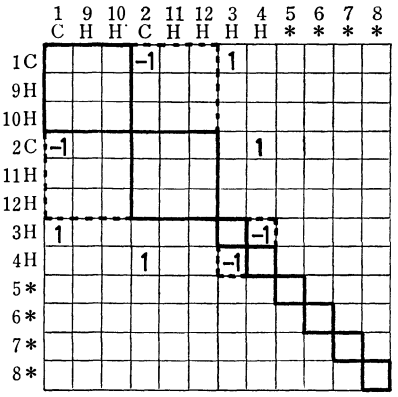

Fig. 2c. Reaction matrix, $\boldsymbol{R}_b = \boldsymbol{Y}(\boldsymbol{X}_b) - \boldsymbol{X}_b$.

sites (*) show no change in overall reaction because they are catalysts.

The sum of the matrix elements in each row as well as in each column of a reaction matrix should be zero, since the number of total valence electrons belonging to each atom does not change during reaction as far as radical reactions are concerned.

Preparation of One Step Reaction in the Elementary Reaction Network

Elementary Reaction Matrix. An elementary reaction may be defined as a simple reaction that cannot be decomposed further into simpler reactions in the sense of the transformation of the bonding. In general, only two-centered and there-centered reactions have been adopted as elementary reactions, although in some cases, such as concerted reactions, four-centered reactions may also be allowable. In a reaction matrix, the number of non-zero off-diagonal elements in the upper-right half implies the number of bonds, formed and ruptured. This number is defined as the *complexity* of a reaction (κ); complexity 1 corresponds to two-centered, complexity 2 to two- and three-centered, complexity 3 to three- and four-centered, and complexity 4 to four-centered reactions, respectively. Hereafter, an elementary reaction will be defined as a reaction with complexity not exceeding the maximum complexity (κ_{max}), for which the value of 3 or 4 is usually chosen.

An overall reaction through the r-th route will be decomposed into elementary reactions $\boldsymbol{R}^{el}{}_{rs}$ as

$$\boldsymbol{R}^{over}(r) = \sum_s \boldsymbol{R}^{el}{}_{rs}, \tag{3}$$

where $\boldsymbol{R}^{over}(r)$ represents the matrix of the above-mentioned overall reaction and s indicates the step number in the network. If the intermediate systems $\boldsymbol{I}_{r,s-1}$ and $\boldsymbol{I}_{r,s}$ are the reactant and the product of step s in route r, respectively, then

$$\boldsymbol{I}_{r,s} = \boldsymbol{R}^{el}{}_{rs} + \boldsymbol{I}_{r,s-1}. \tag{4}$$

By adding Eq. 4 recursively, Eq. 2 will be derived with Eq. 3; $\boldsymbol{R}_b$ in Eq. 2 is exactly the same as $\boldsymbol{R}^{over}(r)$ given in Eq. 3, although the latter clearly indicates the component of the network. The strategy therefore to develop a network that connects the overall reactant and the overall product is to create logically the above mentioned elementary reactions.

Preparation of an Elementary Reaction. During an elementary reaction, a change in valence electrons takes place within atom groups and between them. The change within an atom group may depend on the structure of that group, whereas the change between groups may depend on the change within groups. Thus, the following procedures will be employed as a tactics to create elementary reaction matrices.

(a) Restrictions for an elementary reaction should be given at first. The major restrictions are the maximum complexity of the elementary reaction and the maximum number of radicals involved. There may also be various minor restrictions such as the prohibition of hydrogen radicals in the gaseous phase and the prohibition of homogeneous reactions in which no active sites participate.

(b) Allowable group reaction matrices are selected for each atom group. *A group reaction matrix*, $\boldsymbol{\rho}$, is a small matrix whose order is the same as that of the atom group matrix, and represents the change within the atom group. Each group reaction matrix should satisfy the restrictions mentioned in (a).

(c) Appropriate combinations of $\boldsymbol{\rho}$'s (one $\boldsymbol{\rho}$ for each group) are selected so that these combinations again satisfy the restrictions; for example, odd number of radicals cannot be allowed in Eq. 1. In addition, the systems commonly have equivalent molecules or atom groups; (G_1 and G_2), (G_3 and G_4), and (G_5, G_6, G_7, and G_8) in Eq. 1 are equivalent atom groups, and M_3—M_6 are equivalent molecules. Such redundancy as imposing the same $\boldsymbol{\rho}$ repeatedly on equivalent atom groups should be avoided.

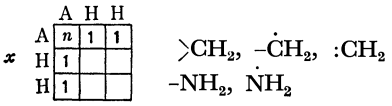
(d) The direct sum of a combination of $\boldsymbol{\rho}$'s are prepared along the diagonal of a blank reaction matrix. The remaining procedure is to supply the appropriate numerals, 1 or -1, in the *intergroup domain*, *i.e.*, the domain outside the atom groups, so that the filled matrix satisfies the requirement of a reaction matrix that the sum of the elements in each row should be zero. When the completed elementary reaction matrix satisfies all the restrictions, it is used to create an intermediate system, otherwise it should be discarded.

(e) Procedure (d) is repeated until all the combinations prepared in procedure (c) are exhausted. Thus all the intermediate systems which are logically allowable are created from the preceding intermediate.

Group Reaction Matrix. In general, there are several group reaction matrices which are applicable for a specified group; an example of a set of the group reaction matrices is shown in Fig. 3. This set is applicable for AH_2 groups where A designates an atomic species that has a valency not less than 2 like carbon and nitrogen; methylene groups in ethylene, dichloroethane or carbene, and an amino group in methyl amine or amino radical is represented by an AH_2 group.

In Fig. 3, $\boldsymbol{x}$ designates a group matrix representing the atom group AH_2, where n (n=0, 1, or 2) implies the number of unshared electrons localized on the

a. Atom group matrix for AH_2.



b. Group reaction matrices for AH_2.

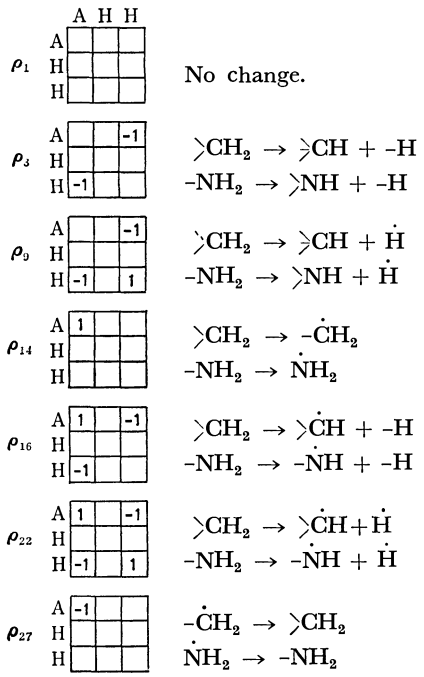


Fig. 3. Group reaction matrices for AH_2 group.

atom A. For example, carbon with $n=2$ represents a carbene molecule, and nitrogen with $n=1$ represents an amino radical.

A blank matrix $\boldsymbol{\rho}_1$ implies that no change takes place within this atom group. Matrices $\boldsymbol{\rho}_3$ to $\boldsymbol{\rho}_{27}$ represent changes illustrated in the right-hand margin, where a short bar indicates one localized electron on a bond connected to other atoms. Thus two bars implies two single bonds or a double bond and a dot indicates an unshared electron. The matrix $\boldsymbol{\rho}_{27}$ represents the disappearance of a radical atom, or an unshared electron, on the atom A, because a diagonal element, -1, on A indicates the decrease of the number of unshared electrons in the reactant. Naturally, this $\boldsymbol{\rho}_{27}$ should be applied only for $\boldsymbol{x}$ with $n \geqq 1$. All the possible changes in the atom group AH_2 are represented with these seven group reaction matrices, as far as it is assumed that only one valence electron on an atom moves from the formerly localized position to the new one.

A practical example using Eq. 1 will now be given. The following processing will be conducted under the restrictions stated in Table 1. Figure 4 shows the allowable $\boldsymbol{\rho}$'s for the methylene group in the overall reactant $\boldsymbol{X}$ under the above restrictions, where $\boldsymbol{\rho}_9$ and $\boldsymbol{\rho}_{22}$ are excluded because the hydrogen radical in the gaseous phase is prohibited, and $\boldsymbol{\rho}_{27}$ is also excluded as the methylene groups in $\boldsymbol{X}$ have no radical atom ($n=0$).

Table 1. Restrictions optioned for generation of elementary reaction network of the reaction in Eq. 1

1. Complexity of elementary reaction should not exceed 3.
2. Number of reaction centers should not exceed 4.
3. Molecularity of reaction including active sites should not exceed 3.
4. Number of radical atoms shold not exceed 4.
5. Number of uupaired electrons on an atom should not exceed 1.
6. No gaseous hydrogen radical is allowed, although hydrocarbon radicals may be allowed even in gaseous phase.
7. Number of valence electrons is 4 for carbon, and 1 for hydrogen and active sites.
8. At least one active site should participate in each elementary reaction.
9. Recombination of active sites is not allowed, as it may be impossible in actual reaction.

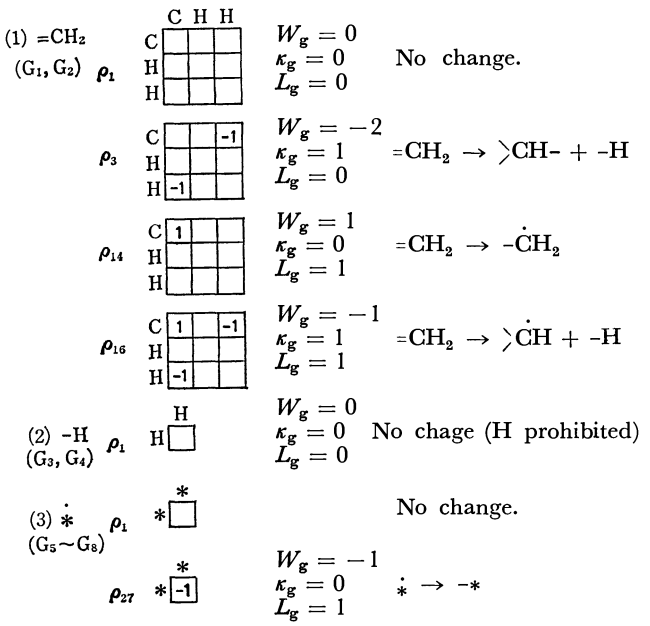

Fig. 4. Allowable group reaction matrices for methylene, hydrogen and active site groups.

For an atom group which consists of only the center atom without any attached atoms, three group reaction matrices of order 1, *i.e.*, $\boldsymbol{\rho}_1$, $\boldsymbol{\rho}_{14}$, and $\boldsymbol{\rho}_{27}$ are allowable. However, only one matrix ($\boldsymbol{\rho}_1$) will be allocated to the hydrogen atom groups in $\boldsymbol{X}$, and two ($\boldsymbol{\rho}_1$ and $\boldsymbol{\rho}_{27}$) to active sites, based on the similar reasoning as in the case of methylene.

Direct Sum of Group Reaction Matrices. The direct sum of group reaction matrices is a succession of an appropriate combination of corresponding group reaction matrices placed along the diagonal of a reaction matrix, which is shown surrounded by bold, solid lines in Fig. 5. The appropriate combination will be selected so that the elementary reaction matrix prepared satisfies both the chemical logic and given restrictions.

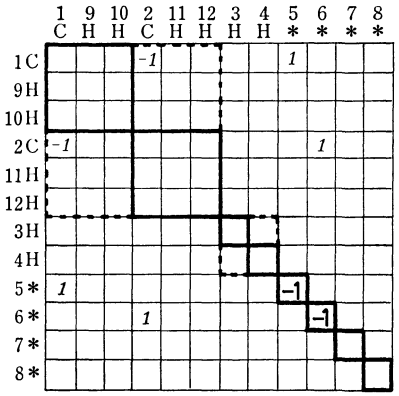

Fig. 5. An example of elementary reaction matrix.

The attributes of a group reaction matrix are defined as follows:

W_g: sum of all the elements.
κ_g: complexity.
L_g: sum of absolute values of diagonal elements.

Figure 4 illustrates the various values.

An elementary reaction matrix $\boldsymbol{R}^{el}$ may be completed by placing the appropriate numerals in the intergroup domain. Since $\boldsymbol{R}^{el}$ is symmetric, the sum of the elements in the intergroup domain is zero or even. Therefore it is a necessary condition that the sum of the elements within the direct sum should be also zero or even, because the sum of the elements of $\boldsymbol{R}^{el}$ is zero by definition. Thus,

$$\sum W_g = \text{zero or even.} \tag{5}$$

A completed direct sum matrix is a direct sum, in which the sum of the elements in every row is zero, satisfying the criteria of a completed reaction matrix. Except for this case, some changes are also necessarily expected in the intergroup domain, and their contribution to κ is not less than unity. Thus, the sum of κ_g's of ρ's should be less than or equal to $\kappa_{max}-1$. Hence,

$$\sum \kappa_g \leqq \kappa_{max} - 1. \tag{6}$$

Finally, since only a pair or pairs of unshared electrons appear or disappear as far as radical reactions are concerned, the grand sum of the absolute values of the diagonal elements should also be zero or even,

$$\sum L_g = \text{zero or even.} \tag{7}$$

The three selection rules mentioned above are still necessary conditions. Table 2 is thus derived, where all the approved combinations of ρ's are shown for each group.

Completion of Elementary Reaction Matrix. The bold lines in Fig. 5 surround the direct sum of combination No. 1 in Table 2. Then, the appropriate numerals, 1 or -1, are given to the intergroup domain so that the resulting matrix satisfies the conditions of a reaction matrix. The datails of the tactics how to allocate them will be published later. It is worthy of mention, however, that more than one set of numerals may exist for one combination of ρ's. The completed matrix should be further checked as to whether it satisfies the given restrictions such as complexity, number of reaction centers, molecularity, and so on. In the GRACE system these critical examinations are made by complex and sophisticated algorithms in the programs.

Since the elementary reaction matrix shown in Fig. 5 satisfies all the restrictions, it will be adopted as a component of the reaction network. By adding this matrix to the overall reactant matrix given in Fig. 2(a), an intermediate matrix $\boldsymbol{I}_1$ will be given as shown in Fig. 6. The change from $\boldsymbol{X}_b$ to $\boldsymbol{I}_1$ represents the reaction in the chemical formula,

$$C_2H_4 + H_2 + 4\dot{*} \rightarrow \underset{\downarrow\ *}{CH_2}\text{-}\underset{\downarrow\ *}{CH_2} + H_2 + 2\dot{*} \tag{8}$$

These procedures will be repeated on all the combinations given in Table 2 under the restriction of $\kappa \leqq 6$, and the resulting intermediates from the overall reactant are tabulated in Table 3, where No. 1a is the intermediate shown in Eq. 6. Four intermediates have

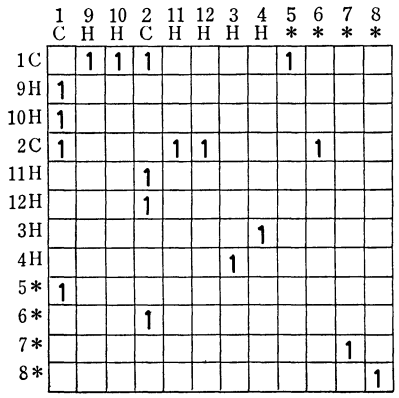

Fig. 6. An example of intermediate matrix, $\boldsymbol{I}_1$, derived from the reaction matrix in Fig. 5.

a) Numerals indicate the combination number in Table 2, and a to c implies that plural intermediates may be created from one combination.

a κ exceeding 3 and must be abandoned at this stage. The remaining five intermediates will thus be employed as the reactants of the second step. These intermediates can be transferred to the memory of the computer in two ways. One is in the form of connectivity tables which can reproduce the matrices, and the other is in the form of canonicalized formulas. The same intermediate may be produced at different steps through varied routes, and, by these algorithms, the same intermediates may be produced even from one and the same direct sum. Therefore, always when intermediates are created, they should be identified by comparing their cannonicalized (unique and unambiguous) chemical formulas. When they are found in the storage and are judged to be the intermediates already created in other step or route, two nodes, or intermediates, must be joined. In the GRACE system, the intermediate of Fig. 6 is stored in the form of Eq. 9, which is prepared with a sub-system CANON, whose details will be reported in a forthcoming paper.

$$1*Sl'\text{-}CH2\text{-}CH2\text{-}Sl'* + 1*Sl'*+1*Sl'* + 1*H\text{-}H** \quad (9)$$

where Sl′ denotes an active site (;*), whereas * implies a delimiter for molecules and an equation.

Completion of Reaction Network

The procedures described above may be repeated step by step until no new intermediate is created from the products of the preceding elementary reactions. The overall product is also found as one of the created intermediate systems.

Figure 7 shows an example of the output format of A/GRACE for the reaction in Eq. 1 under severe restrictions. In this case, no radical has been allowed except for active sites, as usually postulated by catalytic chemists. This output has been interpreted into a more readable form in Fig. 8, where two prevailing reaction schemes can be found. The left-hand route, **1**, (**3** or **4**), **6**, **9**, and **2**, represents the associative adsorption mechanism for the hydrogenation by Horiuti and Polanyi,[8] whereas the right-hand route, **1**, **5**, **8**, and **10**, represents the dissociative adsorption mechanism for isotope exchange between ethylene and hydrogen proposed by Farkas and Farkas.[9]

The computation time to prepare the complete network amounted to 21 s on a HITAC 8800.

[B] Intermediates No. **3** to **10** which appear in the network.

[C] Description of the network. Captions at the right of ROUTE No. imply the sequence of elementaly reactions.

For example,

COMPLETED. Route No. 1 consists of sequence of reactant(**1**)—intermediate **3**—**6**—**9**—product(**2**) and leads the system to the overall product.

JOINED. Route No. 2(**1**—**4**—**6**) is joined to Route No. 1 at the intermediate **6** in th step **2**.

DEAD END. Route No. 4(**1**—**4**—**7**) was terminated at the intermediate **7**, because **7** cannot change further under the given restrictions.

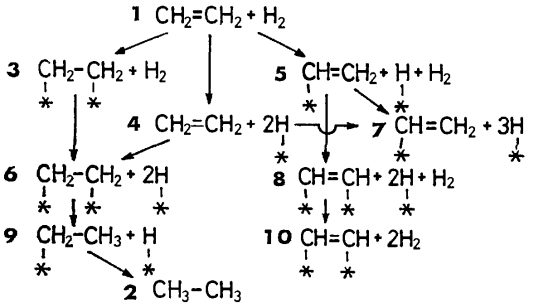

Fig. 8. Reaction routes in catalytic hydrogenation of ethylene.

Option of Restrictions in A/GRACE System. Numerous intermediates were produced even in the simplest system like that mentioned above, and hence the careful selection of restrictions is necessary to avoid the appearance of unrealistic, or thermodynamically unstable, molecules in intermediates. For example, no triple bond may be expected in the hydrogenation of ethylene, and no cyclopropene would be produced during the pyrolysis of propane. Only chemical knowledge and the experience of chemists will create a reasonable reaction network for a given reaction with the aid of the optimum selection of restrictions.

The author is grateful to Dr. Makoto Misono for his valuable discussion and to the Computer Centre of The University of Tokyo for the computation on a HITAC 8800.

Department of Pure and Applied Sciences, College of General Education, the University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received April 1, 1978)

Chemiionization of excited mercury atom with 253.7 nm irradiation was studied. Results on the system Hg–N_2 previously reported were further confirmed. It was found that CH_4 can also induce chemiionization of Hg atoms with 253.7 nm irradiation. The dependence of ionization current on CH_4 pressure and light intensity was investigated, the ionization current being found to be proportional to the square of light intensity and to increase with increase in CH_4 pressure up to 30 Torr, reaching a constant value. N_2 and CH_4 are considered to show a similar behavior in ionization current against pressure and light intensity, and other substances such as H_2, He, CO, NO, Ar, C_2H_4, and 1-butene to give no appreciable ionization current. Thus the mechanism in which chemiionization proceeds through the collision of $Hg(^3P_1)$ with $Hg(^3P_0)$ is further confirmed.

Ionization of mercury atoms excited with 253.7 nm irradiation was first reported by Steubing in 1909,[1] the history of studies in this field being surveyed in detail by Fontijn.[2] An extensive study on this reaction was carried out by Berberet and Clark,[3] the following mechanism being proposed:

$$Hg(^3P_1) + N_2 \longrightarrow Hg(^3P_0) + N_2,$$

$$Hg(^3P_1) + Hg(^3P_0) + N_2 \longrightarrow Hg_2^* + N_2,$$

$$Hg_2^* \longrightarrow Hg_2^+ + e^-.$$

In the present study we attempted to further clarify the mechanism of the chemiionization.

Experimental

Apparatus and Procedure. Vacuum line and gas handling system are conventional ones. For irradiation of 253.7 nm light a commercial germicidal lamp (Toshiba 10 W) was used. The reaction cell and optical arrangement are schematically shown in Fig. 1. A fused quartz reaction cell was furnished with three windows of 20 mmϕ, two Pt plane electrodes (5×10 mm) for ion collection being placed inside parallel to each other 10 mm apart. Exciting light was focussed with a fused quartz condensor lens through a 5 mmϕ hole defined by Al foil in front of the reaction cell to prevent exposure of the electrodes from 253.7 nm radiation. Photoionization in the Hg–N_2 system is due to neither ejection of photoelectrons by direct irradiation nor impact of metastable mercury atoms ($Hg(^3P_0)$) on the electrode surface, provided Pt electrodes are used.[2] We have also confirmed that no appreciable ionization current thought to be caused by direct irradiation of the electrode surface was detected in the absence of N_2.

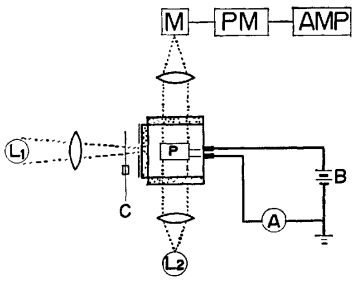

Fig. 1. Schematic view of photoionization cell.
L_1: Lamp for excitation, L_2: lamp for absorption photometry, B: battery, C: chopper, P: platinum electrode, M: monochromator, PM: photomultiplier, A: amplifier for ion current measurement, AMP: lock-in amplifier. For the ion current measurement, chopper is removed.

Ion current was measured either by a vibrating reed electrometer (Yanagimoto GCF 101) or a micro-voltmeter (Okura Denki AM 1001) as a voltage across 4.7 kΩ external resistor, no difference being observed in the values of ionization current measured by the two methods. For determination of concentration of $Hg(^3P_0)$, absorption photometry was carried out at 404.7 nm by modulation technique. The exciting light from a low pressure mercury lamp operated by DC power was chopped with a sector at 8 Hz. The light for absorption photometry was obtained from a lamp of the same type as that used for excitation. Two Vycor lenses, focal length 10 cm, were used, one to make the incident light flux parallel through the reaction cell and the other to focus the light at the position of a slit of monochromator (Fig. 1). The light at 404.7 nm was isolated from the transmitted light by a monochromator (Ritsu MC 10, grating: 600 grooves per mm). Its intensity was determined with a photomultiplier (RCA 1P 21) and a lock-in amplifier (PAR Model 186) using the chopped exciting light as time reference. Since the effective lifetime of $Hg(^3P_0)$ is in the order of ms under the present experimental condition, it can be assumed no phase delay takes place between the exciting light of 8 Hz and the transmitted light at 404.7 nm for photometry. The light for absorption photometry contains 253.7 nm DC component, but we can assume that it does not affect the modulation photometry.

Materials. Two kinds of N_2 (stated purity 99.999% from a glass bottle; stated purity 99.9% from a cylinder) were used. The latter was used after passing through a molecular sieve column cooled at liquid nitrogen temperature. Neither of these N_2 shows appreciable difference in ionization current in the experiments under comparable conditions. Other gasses (CH_4, Ar, H_2, He, CO, NO, C_2H_4, and 1-butene) were used from commercial glass bottles without further purification.

Results and Discussion

1. Collection Efficiency of Ionization Current. The relationship between photoionization current and ion collecting voltage has been studied by many workers, its main feature being summarized by von Engel.[4] At an insufficient voltage the recombination process

of the ion pair formed competes with the ion collecting process at electrodes, resulting in incomplete ion collection. With increase in voltage, the collecting efficiency of ions increases, approaching a saturated plateau value. In the plateau region, all the ions formed in the effective electric field can be collected without appreciable recombination, and the total rate of ion formation under the present experimental setup, R_{exp} (in number of ions per s) is expressed by the simple formula

$$R_{exp} = i/e,$$

where i is the total ion current in A measured at the saturated voltage, and e is elementary charge in C.

We measured the ionization current, DC voltage being varied from 10 to 150 V, keeping the pressure of N_2 constant (3.2 and 23 Torr). Saturation of current is established when 80—120 V is applied, and a higher voltage is required for a higher N_2 pressure. Under the present experimental conditions, the multiplication effect of electrons can be neglected, since the first Townsend coefficient is extremely small (approximately 7×10^{-8} at N_2 pressure of 1 Torr and applied voltage 100 V).[4]

2. Ionization Current and Concentration of Hg($^3P_0$) against N_2 Pressure and Quantum Yield of Ionization. Since it has been pointed out[2,3,5] that the ionization of Hg is closely related with the formation of Hg($^3P_0$), we attempted the determination of ionization current and concentration of Hg($^3P_0$) (denoted as N_0 hereafter) under the same experimental conditions varying the pressure of N_2. As Fig. 2 shows, the variations of ionization current and N_0 *vs.* N_2 pressure behave in a similar way. The N_2 pressure dependence of ionization current would not be expected to be completely the same as that of N_0 (Sec. 6). It was confirmed that the application of DC voltage across electrodes does not affect N_0.

Under the present conditions we can assume that all the input photons of 253.7 nm light are absorbed by mercury atoms in the reaction cell, and determine the quantum yield of ionization by actinometry. Actinometry was carried out in the system Hg–N_2O (100 Torr)–C_2H_6(60—100 Torr), the total number of input photons per s (described as Ia_{exp} hereafter) being found to be 5.0×10^{14} s^{-1}. The quantum yield of ionization ($\phi=R_{exp}/Ia_{exp}$) is thus in the range 10^{-6}—10^{-4}, depending on the pressure of N_2.

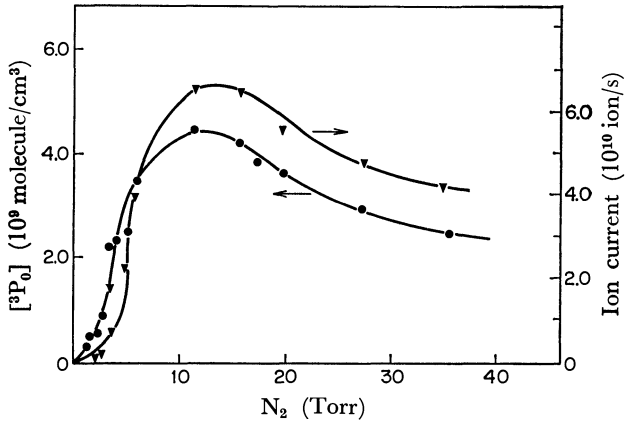

Fig. 2. Simultaneous determination of ion current and concentration of Hg($^3P_0$) *vs.* N_2 pressure in N_2-Hg system.

3. Relationship between Ionization Current and Light Intensity in the N_2–Hg System and the Effect of Hg Pressure. Ionization current was measured varying light intensity with neutral density filters of fused quartz in the range 39—100% at pressures of 1, 5, and 9 Torr of N_2. The ionization current was found to be proportional to the square of light intensity (Fig. 3), in line with the results reported by Houterman,[5] and Berberet and Clark.[3]

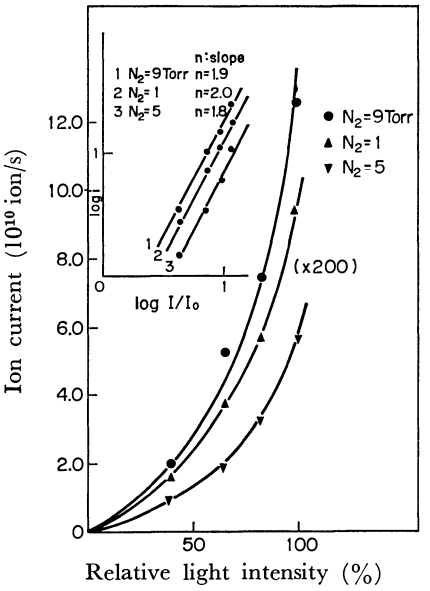

Fig. 3. Plots of ion current *vs.* light intensity in N_2–Hg system. Inserted figure is log-log plot for the same quantities.

Dependence of ionization current on Hg pressure was studied only semiquantitatively, since the actual pressure of Hg in the reaction cell was not measured. We measured the ionization current keeping the mercury reservoir at 0 °C (reported Hg pressure, 1.85×10^{-4} Torr), room temperature 24—25 °C (Hg pressure: 1.7×10^{-3} Torr at 24 °C) and N_2 pressure 10 Torr. The observed ionization current at 0 °C of mercury reservoir is about one third of that at room temperature. We may interpret this decrease of ionization current at 0 °C in terms of the decrease of radiation imprisonment due to the decrease of Hg pressure.

4. Chemiionization of Excited Mercury Atom in the System CH_4–Hg. In the proposed mechanism of chemiionization it has been assumed that the ionization takes place through the collision of Hg($^3P_1$) with Hg($^3P_0$). If this is valid, CH_4 could also induce chemiionization of mercury atom, since CH_4 has a relatively large rate constant to produce Hg($^3P_0$) from Hg($^3P_1$), and a small rate constant to quench Hg($^3P_1$) and Hg($^3P_0$) to ground state (Table 1).[6] Actually we find CH_4 gives an ionization current under 253.7 nm irradiation, the magnitude being 1/50—1/100 as com-

pared with that for N_2. Dependence of ionization current on the pressure of CH_4 has a feature similar to that for N_2(Fig. 4), its dependence on light intensity being of second order. We also investigated H_2, CO, NO, Ar, C_2H_4, and 1-butene–Hg systems. However, none of them gave any appreciable ionization current in the experimentally detectable limit (less than 10^{-11} A) under conditions similar to the cases of N_2 and CH_4.

5. Effect of $NiSO_4$ Solution Filter. The problem is whether radiation other than 253.7 nm light might participate in the chemiionization in view of the finding that the ionization current is proportional to the square of light intensity. An experiment was carried out with irradiation of 253.7 nm isolated from total radiation of the low pressure mercury lamp using a $NiSO_4$ solution filter.[7] Reduction of ionization current to 33% was observed, but it is due to the absorption of light at 253.7 nm by the filter. The pressure dependence of current is similar to that without filter. We may conclude that no direct radiation other than 253.7 nm light contributes to the chemiionization.

6. Reaction Mechanism of Chemiionization. The fact that the ionization current is proportional to the square of light intensity is a strong support for the assumption that two excited mercury atoms($Hg(^3P_0)$ and $Hg(^3P_1)$) are involved. Since only N_2 and CH_4 are known to induce chemiionization, and both have relatively large cross sections to generate $Hg(^3P_0)$ from $Hg(^3P_1)$, it is certain that one atom of $Hg(^3P_0)$ is at least involved in the ionization. The pressure dependence of ionization current is closely related to that of N_0 in the case of N_2. Simultaneous determination of ionization current and N_0 *vs.* CH_4 pressure was not possible for the case of CH_4, since N_0 is too small. However, the general feature of pressure dependence of ionization current is similar to that for Hg–N_2 system (Fig. 4).

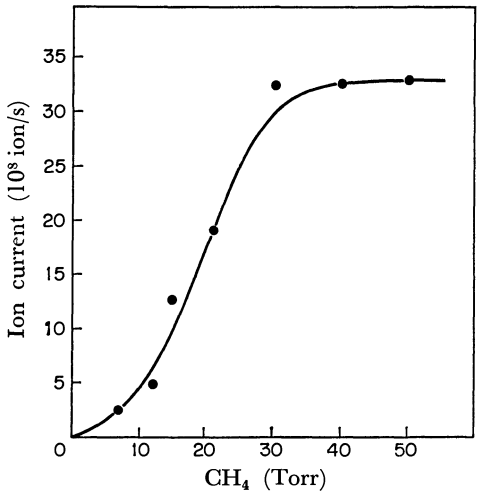

Fig. 4. Plot of ion current *vs.* CH_4 pressure in CH_4–Hg system.

The steady state concentrations of $Hg(^3P_1)$ and $Hg(^3P_0)$ are expressed in respective rate constants according to the following reaction schemes:

$$Hg(^1S_0) + h\nu(253.7\,nm) \xrightarrow{Ia} Hg(^3P_1),$$

$$Hg(^3P_1) \xrightarrow{k_f} Hg(^1S_0) + h\nu_f,$$

$$Hg(^3P_1) + M \xrightarrow{k_1} Hg(^3P_0) + M, \quad (1)$$

$$Hg(^3P_1) + M \xrightarrow{k_2} Hg(^1S_0) + M, \quad (2)$$

$$Hg(^3P_0) + M \xrightarrow{k_3} Hg(^1S_0) + M, \quad (3)$$

$$Hg(^3P_0) \xrightarrow[\text{(at wall)}]{k_4} Hg(^1S_0), \quad (4)$$

$$Hg(^3P_0) \xrightarrow[\text{(very small)}]{k_5} Hg(^1S_0), \quad (5)$$

where Ia is the number of photons absorbed per cm^3 s, k_f is effective radiative decay constant of $Hg(^3P_1)$; k_1, k_2, k_3, are quenching rate constants of excited atoms by M, k_4 is diffusion rate to wall at unit pressure (1 Torr) and k_5 is the disappearing rate of $Hg(^3P_0)$ by quenching by impurity and/or radiative decay. We can express N_1 (steady state concentration of $Hg(^3P_1)$) and N_0 by the steady state treatment as follows, neglecting the disappearance process of the excited mercury atoms by chemiionization, since the quantum yield of chemiionization is very small:

$$N_1 = Ia/(k_f + (k_1+k_2)[M]), \quad (I)$$

and

$$N_0 = N_1k_1[M]/(k_3[M]+k_4/P+k_5), \quad (II)$$

where P is the total pressure in Torr.

As Berberet and Clark[3] assumed, we may assume the following two step ionization mechanism, if the chemiionization takes place through the collision between $Hg(^3P_1)$, $Hg(^3P_0)$, and M,

$$Hg(^3P_1) + Hg(^3P_0) + M \xrightarrow{k_6} Hg_2^* + M, \quad (6)$$

$$Hg_2^* \xrightarrow{k_7} Hg_2^+ + e^-, \quad (7)$$

and the rate of ion formation, R(in number of ions $cm^{-3}\,s^{-1}$) is given by

$$R = \phi Ia = k_6N_1N_0[M]$$
$$= k_1k_6[M]^2Ia^2/(k_f+(k_1+k_2)[M])^2(k_3[M]+k_4/P+k_5). \quad (III)$$

Berberet and Clark assumed the two step mechanism, considering the fact that the lifetime of Hg_2^* is of the order of ms. The pressure dependence of i is almost similar to that of N_0 in the system N_2–Hg(Fig. 2). However, Eq. III indicates that i is proportional to N_1 and the concentration of third body as well as N_0. In the case $k_f \gg (k_1+k_2)[N_2]$, N_1 would be independent of the concentration of N_2, and the behavior of i may be similar to that of N_0.

Under the high concentration of N_2, $R \approx k_1k_6Ia^2/(k_1+k_2)^2(k_3[M]+k_4/P+k_5)$, and we may expect a linear relationship between $1/R$ and the concentration of M.

In order to evaluate the approximate ratio of the ionization current in the presence of a certain substance M to that for N_2, we derive the following equation from Eq. III, assuming $k_{6,M}$ is equal to k_{6,N_2},

$$i_M/i_{N_2} = \left(\frac{k_{1,M}[M]}{k_{1,N_2}[N_2]}\right)^2\left(\frac{k_f+(k_{1,N_2}+k_{2,N_2})[N_2]}{k_f+(k_{1,M}+k_{2,M})[M]}\right)^2 \times\left(\frac{k_{3,N_2}[N_2]+k_4/P+k_5}{k_{3,M}[M]+k_4/P+k_5}\right). \quad (IV)$$

TABLE 1. RATIOS OF IONIZATION CURRENT CALCULATED BY Eq. IV AND USED QUENCHING RATE CONSTANTS[6] OF $Hg(^3P_1)$ AND $Hg(^3P_0)$ BY SEVERAL GASES

	Ratio of ionization current,[a] i_M/i_{N_2}	Quenching rate constants (cm^3/molecule s)		
		$k_1(^3P_1 \rightarrow {}^3P_0)$	$k_2(^3P_1 \rightarrow {}^1S_0)$	$k_3(^3P_0 \rightarrow {}^1S_0)$
N_2	(1.0)	3.9×10^{-12}	$1.5\times10^{-13}>$	$1.0\times10^{-15}>$
CH_4	0.18>	1.0×10^{-13}	4.6×10^{-13}	2.7×10^{-15}
C_2H_6	0.03>	3.3×10^{-12}	2.0×10^{-12}	2.6×10^{-14}
C_3H_8	$5.0\times10^{-4}>$	1.3×10^{-11}	4.2×10^{-12}	6.3×10^{-13}
NH_3	$4.5\times10^{-4}>$	2.2×10^{-11}	1.7×10^{-11}	2.4×10^{-13}
CO_2	$7.8\times10^{-5}>$	8.0×10^{-13}	1.3×10^{-11}	3.9×10^{-13}
CO	$6.4\times10^{-6}>$	1.1×10^{-10}	1.5×10^{-11}	9.1×10^{-12}
NO	$4.6\times10^{-8}>$	3.4×10^{-11}	1.5×10^{-10}	1.7×10^{-10}
H_2	$1.9\times10^{-8}>$	$5.4\times10^{-12}>$	1.4×10^{-10}	1.1×10^{-10}
C_2H_4	$9.9\times10^{-9}>$	$8.1\times10^{-11}>$	2.4×10^{-10}	6.5×10^{-10}

a) Since k_{2,N_2} and k_{3,N_2} are given as upper limits, all the calculated ratios should be understood as upper limits.

In calculating the ratios, we used the values of the rate constants given in Table 1, 2×10^5 s^{-1} for k_f(calculated according to the Milne-Samson formula[8]), 26 Torr s^{-1} for k_4 and 100 s^{-1} for k_5. The value of k_5 is not definite, but it would not cause serious errors in calculating the ratios since the magnitude of k_5 is small as compared with that of $k_{3,M}[M]$. The calculated upper limit of the ratio, i_{CH_4}/i_{N_2} is 0.18, while the experimental value of i_{CH_4}/i_{N_2} at 10 Torr is 0.005, no measurable ionization current being observed for the other compounds(H_2, He, CO, NO, C_2H_4, Ar, and 1-butene). From Table 1 we may expect C_2H_6 to induce the chemiionization current in a measurable amount.

We observed the decrease of ionization current in the system N_2–Hg at 0 °C as compared with that at room temperature. We have estimated the ratio of ionization current at 0 °C to that at room temperature (24 °C) using Eq. III. We assume that $[N_2]$ and the rate constants defined above except k_f are almost the same at 0 °C and 24 °C, and interpret the decrease of ionization current at 0 °C in terms of the decrease of effective radiative decay lifetime($1/k_f$) of $Hg(^3P_1)$, *viz.*, the decrease of radiation imprisonment. The calculated values of k_f at 0 °C and 24 °C are 2×10^6 and 2×10^5 s^{-1} respectively. We obtain N_1 and N_0 at two temperatures as follows; N_1: 1.5×10^8 at 0 °C and 3.4×10^8 atom cm^{-3} at 24 °C, and N_0: 4.3×10^{11} at 0 °C and 9.5×10^{11} atom cm^{-3} at 24 °C. Using these values of N_1 and N_0 with Eq. III, we obtain the ratio of the ionization current at 0 °C to that at 24 °C to be 0.2, while its experimental value is 0.3. In this calculation, we assumed Ia in Eq. III to be the number of total incident photons at 253.7 nm in the reaction cell, which was determined by actimonetry carried out at room temperature.**

7. Chemiionization of N_2–CH_4–Hg System and Estimation of the Rate Constant of Excimer Formation. Since N_2 and CH_4 are the only substances known to induce chemiionization of Hg, we studied the behavior of ionization current in a mixture of N_2 and CH_4. Since N_2 has a large rate constant to produce $Hg(^3P_0)$ from $Hg(^3P_1)$ and CH_4 has a large rate constant to quench $Hg(^3P_0)$ (more than three times as large as that of N_2), we expect that N_2 mainly produces $Hg(^3P_0)$ and CH_4 quenches $Hg(^3P_0)$ in the mixture (Table 1). For the sake of confirmation we measured the ionization current in the mixture system varying the pressure of CH_4 keeping the N_2 pressure constant. The total pressure (N_2+CH_4+Ar) which may affect the absorption line profile of Hg atoms and the diffusion rate of $Hg(^3P_0)$ to wall was also kept constant. Two series of experiments were carried out, (a) N_2, 3 Torr and total pressure, 10 Torr; (b) N_2, 6 Torr and total pressure, 20 Torr. If we take reciprocals of both sides of Eq. III, we may expect a Stern-Volmer type linear relation between $1/R$ and CH_4 pressure at constant N_2 and total pressures, noting $k_{1,N_2} \gg k_{1,CH_4}$ and k_{2,CH_4}, as follows:

$$1/R = (X/k_6PIa^2)(k_{3,N_2}[N_2]+k_{3,CH_4}[CH_4]+k_4/P+k_5), \quad \text{(V)}$$

where

$$X=(k_f+(k_{1,N_2}+k_{2,N_2})[N_2]+(k_{1,CH_4}+k_{2,CH_4})[CH_4])^2/(k_{1,N_2}[N_2]+k_{1,CH_4}[CH_4])^2 \sim \text{constant}.$$

Figure 5 shows that the linear relation holds. From the empirical values of either slope or intercept, we can calculate k_6 if we substitute the values of other rate constants for N_2 and CH_4 and of Ia into Eq. V. We are aware of the accumulated large errors caused by using many rate constants (k_f, k_{1,N_2}, k_{1,CH_4}, k_{2,N_2}, k_{2,CH_4}, k_{3,N_2}, k_{3,CH_4}) in calculation. Our estimation of k_6 from slope gives the values of 9.6×10^{-29} cm^6 $molecules^{-2}$ s^{-1} (series (a)) and 8.3×10^{-29} (series (b)). The rate constant of the ternary collision (k_6) obtained here may be compared with that of an excimer formation ($Hg_2(1_u) \xleftarrow{k_{1_u}} Hg(^3P_0)+Hg(^1S_0)+N_2$). Phaneuf *et al.*[9] gave the values of the rate constant(k_{1_u}) reported by several workers. They are in the range 10^{-30}—10^{-29} cm^6 $molecule^{-2}$ s^{-1}, differing from that by McAlduff *et al.*[10] which was exceptionally large (1.33×10^{-27} cm^6 $molecule^{-2}$ s^{-1}). The value of k_6 obtained here is several times larger than k_{1_u}, but we consider it reason-

** The authors acknowledge the referee's suggestion on the interpretation of the effect of Hg pressure on the ionization current.

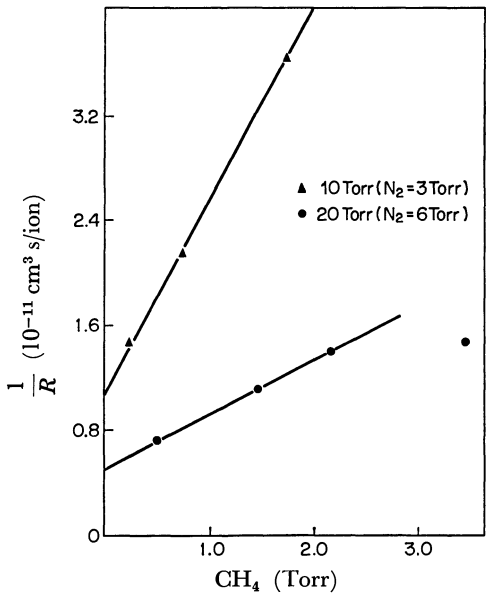

Fig. 5. Plots of reciprocals of rate of ion formation (R) *vs.* CH_4 pressure in the mixture of N_2, CH_4, and Hg for 10 Torr and 20 Torr of total pressure.

Table 2. Rate constants of ternary collision (k_6) in the systems N_2–Hg and CH_4–Hg (cm^6 molecule^{-2} s^{-1})

Pressure (Torr)	3	6	10
N_2	3.4×10^{-29}>	2.8×10^{-28}>	4.9×10^{-28}>
CH_4	1.8×10^{-29}	2.3×10^{-29}	4.0×10^{-29}

able.

The rate constant (k_6) can be also calculated by means of Eq. III instead of Eq. V using the reported rate constants and our experimental results in the system N_2–Hg or CH_4–Hg. The results, given in Table 2, increase with pressure. For the interpretation of this pressure effect and the difference of magnitudes of k_6 among N_2–Hg, CH_4–Hg, and N_2–CH_4–Hg systems we might speculate more complex mechanism in the ionization, but we feel better to refrain from further discussions on this matter, because many pressure terms are included in Eq. III. In the case of N_2, the value of k_3 which is considered to be the most important in the determination of k_6 is known only as an upper limit. Thus the values of k_6 in the system N_2–Hg should be taken as upper limits.

8. Other Possible Mechanisms of Ionization and Energetic Consideration. Since we have found that the ionization current is proportional to the square of light intensity, and that at least one atom of $Hg(^3P_0)$ is involved, the following two mechanisms might also be considered. (1) To assume the participation of one more $Hg(^3P_0)$ atom instead of $Hg(^3P_1)$. If two atoms of $Hg(^3P_0)$ are involved in chemiionization, the reciprocal of ionization current would be proportional to the square of pressure of CH_4 in the mixture experiment of N_2–CH_4. However, this is not compatible with our result (Fig. 5). In addition, the energy requirement for ionization is less favorable with the deficiency

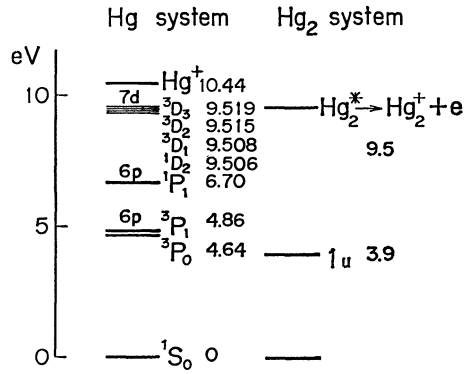

Fig. 6. Energy level diagram for Hg and Hg_2 systems.

of 0.22 eV. (2) Ionization proceeds through the absorption of another 253.7 nm photon by an excimer formed by the collision between $Hg(^3P_0)$ and ground state Hg. The formation of such an excimer (1_u) has been confirmed.[9] However, it is not probable from energetic consideration (Fig. 6) that this excimer can be ionized by absorption of another 253.7 nm photon. Furthermore, the absorption of 253.7 nm photon by the excimer is less likely, since the absorption of 253.7 nm photon by ground Hg would be much stronger.

Since the ionization potential of mercury atom is 10.44 eV, the sum of energy of $Hg(^3P_1)$ and $Hg(^3P_0)$ (4.86+4.64=9.50 eV) is not enough to give Hg atomic ion. It has been assumed[3] that the formation of molecular ion Hg_2^+ is more likely. Arnot and Milligan[11] observed mass-spectrometrically the formation of Hg_2^+ in the electron impact of dense mercury vapor, and determined its appearance potential to be 9.5 eV. They presumed that its formation proceeds through the collision of $Hg(^1D_2)$ generated by electron impact with Hg in ground state, since the energy level of $Hg(^1D_2)$ is 9.506 eV above ground state and is close to the appearance potential of Hg_2^+. In the optical excitation experiments, the formation of $Hg(^1D_2)$ is not possible, and the collision of $Hg(^3P_1)$ with $Hg(^3P_0)$ is an acceptable process for the formation of Hg_2^+ from energetic consideration. Berberet and Clark assumed the formation of an excimer Hg_2^* as a precursor of Hg_2^+, considering the decay of ionization current after switch-off of exciting light to be very slow. They estimated the lifetime of the excimer to be of the order of ms. So far we know nothing about the electronic state of the excimer. However we presume that such an excimer is in a highly excited Rydberg state, since the energy level of the excimer should be very close to its ionization level.

From energetic consideration, we should not discard the possibility of mercury ion pair formation by the collision of $Hg(^3P_1)$ with $Hg(^3P_0)$, if electron affinity of Hg is 1.53 eV exoergic.[12] If this is acceptable, the total energy balance of ion pair formation

$$Hg(^3P_1) + Hg(^3P_0) \longrightarrow Hg^+ + Hg^-$$

would be 0.59 eV exoergic. However, Makita *et al.*[13] pointed out that the value is not based on reliable experimental measurement. They estimated it to be 0.19±0.3 eV endoergic. When we adopt this value,

mercury ion pair formation by the collision of $Hg(^3P_1)$ with $Hg(^3P_0)$ is not possible.

Kinetic Studies of Spin Trapping Reactions. II. Radiolysis of Cyclohexane

Takahisa DOBA, Shoji NODA, and Hiroshi YOSHIDA*
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received May 8, 1978)

In order to extend kinetic utilization of the spin-trapping techniques in radiation chemistry, γ-radiolysis of cyclohexane has been studied at room temperature using pentamethylnitrosobenzene as a spin trap. With increasing radiation dose, the cyclohexyl radical spin adduct has been found by ESR to form and then decay. Consumption of the spin trap has also been monitored by observing the optical absorption. The observed kinetic aspects indicate that the radiation-generated cyclohexyl radicals are completely trapped by 1.3×10^{-4}—6.6×10^{-4} mol dm^{-3} of the spin trap, and their G-value is 3.0. The spin-trapping rate constant has been determined to be 1.6×10^{7} mol^{-1} dm^{3} s^{-1} at 299 K based on the reported rate constant for the reaction between the cyclohexyl radical and tributylstannane. From the optical absorption study, dimeric pentamethylnitrosobenzene has been found to dissociate into the monomer, effective in the spin-trapping, with an equilibrium constant of 8×10^{-4} mol dm^{-3} in cyclohexane at 299 K. The monomer has an absorption coefficient of 48 mol^{-1} dm^{3} cm^{-1} at its absorption peak of 790 nm.

The spin-trapping technique has been developed recently[1,2] and widely used for the identification of free radical intermediates in radiation-chemical,[3-5] photochemical,[6-8] and thermal reactions.[9,10] A recent photochemical study[11] has revealed the problems inherent in this technique: the rate constant of spin-trapping reactions varies widely,[12-17] from 10^{3} to 5×10^{8} mol^{-1} dm^{3} s^{-1}, they generally compete in a complex way with other radical reactions, and spin adduct radicals subsequently react with free radicals to be spin-trapped.[11] Therefore, knowledge of the reactivities of spin traps and spin adduct radicals is needed for the quantitative utilization of the technique.

The radiolysis of cyclohexane is one of the simplest radiation-chemical reaction systems where only atomic hydrogen and cyclohexyl radicals as free radical intermediates are expected. It has been one of the most extensively studied systems.[18-22] This appears as a model reaction system where the validity of the spin-trapping technique can be tested on a quantitative base. Iwahashi *et al.*[23] have applied the technique to this system using *N*-*t*-butyl-α-phenylnitrone (phenyl-*t*-butyl nitrone, PBN) as a spin trap and concluded that "the utilization of the spin trap for the quantitative estimation of products in the radiolysis of hydrocarbons is not a very good technique." In the present study, the spin-trapping technique has been applied to the radiolysis of cyclohexane by using pentamethylnitrosobenzene (PMNB). PMNB reacts with alkyl radicals with a rate constant two orders of magnitude greater than that of PBN so that the kinetic aspects of the spin-trapping are expected to be simpler for PMNB than for PBN.

Experimental

PMNB was synthesized from pentamethylbenzene through $C_6(CH_3)_5Tl(OCOCF_3)_2$,[24,25] and purified by recrystallization from acetone solution. Spectrograde cyclohexane was used without further purification. The monomer-dimer equilibrium and optical absorption of PMNB in cyclohexane solution were studied in the manner as described before.[25] For spin-trapping experiments, solutions of PMNB in cyclohexane were degassed by the freeze-pump-thaw technique at a vacuum of 10^{-5} Torr and sealed in sample cells, which consisted of a quartz ESR tube at one end and quartz optical absorption cell at the other.

Irradiations were conducted with ^{60}Co γ-rays at a dose rate of 2.0—14 krad/min at room temperature, *ca.* 300 K. The concentration of PMNB and that of the spin adduct radicals were simultaneously monitored by a recording spectrophotometer and an X-band ESR spectrometer, respectively.

Results and Discussion

Monomer-Dimer Equilibrium of PMNB in Cyclohexane. PMNB dissolved in cyclohexane is in part present in the dimeric form. Monomeric PMNB has a weak optical absorption with a maximum at 790 nm, while dimeric PMNB has a strong absorption band with a maximum at 327 nm. According to the relationship, $c/A=1/2\varepsilon+A/K\varepsilon^{2}$ where c is the total concentration of PMNB, A is the absorbance at 790 nm, K the equilibrium constant and ε the molar absorption coefficient, K and ε for PMNB are determined to be 8×10^{-4} mol·dm^{-3} and 48 mol^{-1} dm^{3} cm^{-1} at 299 K from the observed linear dependence of c/A on A as shown in Fig. 1. Thus, 45 to 80% of PMNB is in the monomeric form and is effective in spin-trapping free radical intermediates, when dissolved in cyclohexane at the total concentration of 10^{-3} to 10^{-4} mol dm^{-3}. This behavior of PMNB is very similar to that reported previously

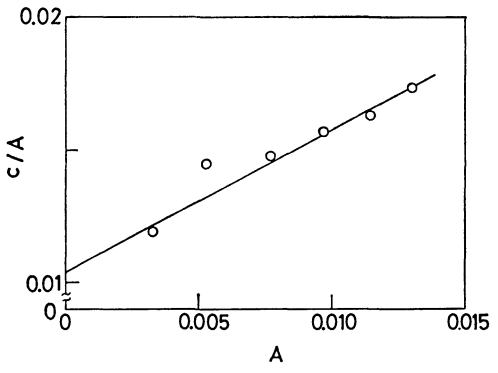

Fig. 1. The relationship between the absorbance, A, at 790 nm and the total concentration of PMNB, c, in cyclohexane at 299 K.

in benzene solution.[25,26]

Radiation-Chemical Reactions of Cyclohexane Solutions of PMNB. ESR spectra observed from the γ-irradiated solutions show a triple-doublet hyperfine structure, as shown in Fig. 2, with coupling constants of 1.40 and 0.76 mT. These have been attributed to the spin adducts of the cyclohexyl radical. Neither the spin adduct of hydrogen nor that of other free radicals could be observed by ESR. The cyclohexyl radical spin adducts decay after γ-irradiation to *ca.* 70% of the initial amount during the first hour, and then remain almost unchanged. The decay cannot be attributed to either the self-decomposition of the spin adducts or their recombination, but is probably due to reactions with some radiolytic products.

The dependence of the yield of spin adducts on the radiation dose is shown, typically in Fig. 3 for a dose rate of 14 krad/min. The yield increases at first with the initial slope independent of the PMNB concentration in the range of 6.6×10^{-4}—1.3×10^{-4} mol dm^{-3},

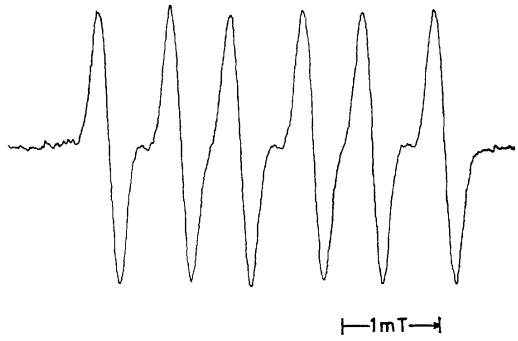

Fig. 2. ESR spectrum of pentamethylphenyl cyclohexyl nitroxide (spin adduct radical) obtained from the γ-radiolysis of cyclohexane in the presence of PMNB at room temperature.

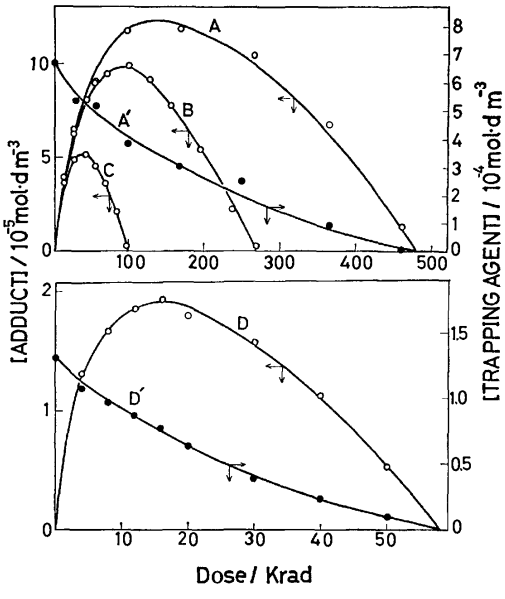

Fig. 3. The dependence of the concentration of the spin adducts (○) and that of the spin trap (●), PMNB, on the radiation dose, at the PMNB concentration (A, A') 6.6×10^{-4}, (B) 4.4×10^{-4}, (C) 2.2×10^{-4}, and (D, D') 1.3×10^{-4} mol dm^{-3}.

reaching a maximum dependent on the PMNB concentration, and then decreases to zero. The *G*-value of the spin adduct formation determined to be 3.0 from the initial slope independent of the PMNB concentration. The decrease of the dose rate to 3.3 krad/min gives no change in the *G*-value. Thus, the cyclohexyl radicals are believed to be effectively spin-trapped by PMNB, and the recombination reactions between themselves is absent at the dose rates examined.

The *G*-value of the cyclohexyl radical spin adducts has been reported to be 3 for the γ-radiolysis of cyclohexane containing PBN as a spin trap.[23] In that case, the *G*-value is slightly dependent on the PBN concentration in the range 0.1—0.01 mol dm^{-3} due to the low reactivity of PBN towards alkyl radicals.[11] It is worth noting that the *G*-values determined by the spin-trapping techniques are generally smaller than the *G*-value of 4.0 determined by using iodine as a radical scavenger.[19]

The change of the PMNB concentration with increasing radiation dose is shown in Fig. 3, representatively for the highest and the lowest initial concentrations of PMNB. The spin traps are completely consumed at the time when the spin adduct concentration reaches zero. Such an exact coincidence indicates that the same entities are responsible for both the formation and the decay of the spin adducts. Therefore, the spin adducts and the spin traps compete with each other in reacting with cyclohexyl radicals. Such a situation is very much like that previously reported for 2-methyl-2-nitrosopropane and *t*-butyl radical in a photochemical reaction system.[11]

Rate Constants and Reaction Kinetics. The change in the spin adduct concentration can essentially be expressed by the following two processes,

$$R\cdot + T \xrightarrow{k_1} A, \tag{1}$$

$$R\cdot + A \xrightarrow{k_2} \text{diamagnetic product(s)}, \tag{2}$$

where R·, T, and A represent the cyclohexyl radical, the spin trap (PMNB), and the spin adduct, respectively. Assuming that PMNB is entirely monomeric, the rate equation

$$\frac{d[A]}{d[T]} = \frac{k_2}{k_1}\cdot\frac{[A]}{[T]} - 1 \tag{3}$$

is readily derived and integrated as

$$\frac{[A]}{[T]_0} = \frac{1}{\alpha-1}\cdot\frac{[T]}{[T]_0}\left\{1-\left(\frac{[T]}{[T]_0}\right)^{\alpha-1}\right\} \tag{4}$$

with the initial condition that $[A]=0$ for $[T]=[T]_0$. α is the ratio of the rate constants, k_2/k_1. According to the above equation, the dependence of [A] on [T] is shown by the plots in Fig. 4 for several values of the variable parameter α. Figure 4 shows some of the aspects of general importance in the spin-trapping technique. As the spin-trapping reaction proceeds (the $[T]/[T]_0$ value decreases from unity to zero), the adduct radical concentration reaches a maximum value which is proportional to the initial spin trap concentration. If α is too large, the adduct radical concentration cannot be enough for the ESR detection of the adduct radical.

The dependence of [A] on [T] has been experimen-

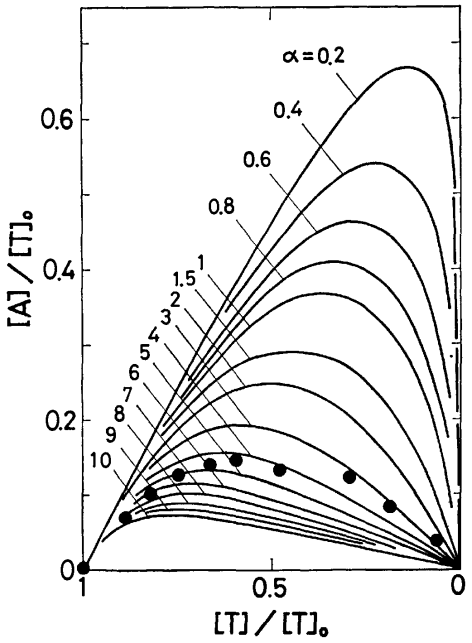

Fig. 4. The relationship between the concentration of the spin adduct and that of the spin trap, PMNB, normarlized by the initial concentration of PMNB. Theoretical curves are derived for several α values based on the Eq. 4, and experimental results (●) are obtained for the initial concentration of PMNB of 1.3×10^{-4} mol dm^{-3} at room temperature.

tally examined for the initial PMNB concentration, $[T]_0$, of 1.3×10^{-4} mol dm^{-3} and the plot is shown in Fig. 4. At this $[T]_0$ value, more than 75% of PMNB is monomeric. The plots fall in the range of $\alpha=3$ to 5. The determined value of α includes errors due to the assumptions of totally monomeric PMNB, and the disregard of the instability of the spin adduct, but it indicates undoubtedly that $k_2>k_1$. The assumed negligibility of the bimolecular recombination of the cyclohexyl radicals (important when the PMNB concentration becomes very low) and the possible effects of hydrogen atoms may also be explain the experimental plot's derivation from the single curve expected from Eq. 4.

The spin-trapping rate constant, k_1, can generally be determined by competition experiments with reactions having known rate constant, *e.g.* the reaction of the cyclohexyl radical with tributylstannane,

$$\dot{C}_6H_{11} + (C_4H_9)_3SnH \xrightarrow{k_5} C_6H_{12} + (C_4H_9)_3Sn\cdot, \qquad (5)$$

was chosen as a reference reaction, for which the rate constant has been reported to be 1.2×10^6 mol^{-1} dm^3 s^{-1} at 298 K in cyclohexane.[27] The ratio of the initial slope of spin adduct concentration *vs.* radiation dose curve in the absence and presence of tributylstannane was found to agree with the expected linear relationship,

$$\frac{d[A]}{d[A]'} = 1 + \frac{k_5[S]}{k_1[T]}, \qquad (6)$$

as shown in Fig. 5, where [A]′ represents the concentrations of the spin adducts generated in the presence

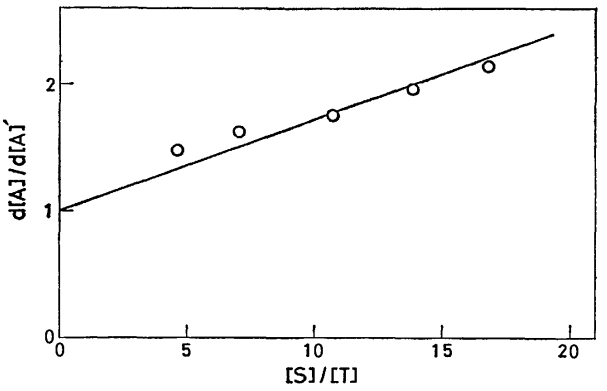

Fig. 5. The dependence of the rate of the spin adduct formation on the concentration of radical scavenger, tributylstannane, in cyclohexane at 299 K.

of tributylstannane, S. The rate constant, k_1, obtained from the slope of the straight line was found to be 1.6×10^7 mol^{-1} dm^3 s^{-1}. This value is smaller than that for the spin-trapping of *t*-butyl radicals by PMNB in benzene solution determined by using the same reference reaction, 9×10^7 mol^{-1} dm^3 s^{-1}.[11,25]

Conclusion

Simultaneous monitoring of both the spin traps and the spin adducts revealed radiation-chemical processes in the γ-radiolysis of cyclohexane solutions of PMNB. The most significant results are: (1) PMNB is an efficient spin trap such that the cyclohexyl radicals generated with *G*-value of 3.0 are thoroughly spin-trapped, (2) the cyclohexyl radical spin adducts readily disappear in the subsequent reaction with the cyclohexyl radicals. The explanation for the *G*-value of the cyclohexyl radical determined by the spin-trapping technique being smaller than the generally accepted value of ≈4 remains unknown.[28] The former results implies however that the spin-trapping technique has a future in the kinetic studies of radiation chemistry with the proper choice of the spin trap based on the rate data of the spin-trapping reactions to be accumulated further. The latter further complicates the kinetic aspects of the spin-trapping. Generally, the data on PMNB, such as the absorptivity, the monomer–dimer equilibrium, and the spin-trapping rate constant, serve as a basis to extend the spin-trapping technique to study the kinetics of free radical intermediates.

This investigation was conducted in part using the experimental facilities at the Research Reactor Institute, Kyoto University.

Proton NMR Spectra of Selectively Deuterated *p,p'*-Azoxyanisoles in the Solid State

Kikuko HAYAMIZU* and Osamu YAMAMOTO

National Chemical Laboratry for Industry, 1 Honmachi, Shibuya-ku, Tokyo 151

(Received May 12, 1978)

Selectively deuterated PAA's, PAA-d_8, and PAA-d_6 have been studied by proton NMR from 77 K to the melting point (390 K). The temperature dependences of T_1, the line width, and the second moment for these compounds are presented. It has been demonstrated that PAA is in the rigid state at 77 K on an NMR time scale, and as the temperature increases the two methyl groups begin to rotate about the C_3 axis, followed by libration about the C–O axis. There is no evidence for motions of the ring protons except self-diffusion and/or slow reorientation of the molecular axis in the higher temperature range from 286 K to the melting point.

p,p'-Azoxyanisole (PAA, 4,4'-dimethoxyazoxybenzene) is one of the most important compounds in nematic liquid crystals and has been widely studied by NMR.[1] In the proton resonance, however, it is difficult to distinguish the two different types of protons, *i.e.*, the ring and the methyl protons, although their spin-lattice relaxation times are expected to show different dependences on temperature. Thus we have synthesized the two selectively deuterated PAA's, *i.e.*, the ring-proton-deuterated PAA (PAA-d_8) and the methyl-proton-deuterated PAA (PAA-d_6), and already reported their proton relaxation times and anisotropic molecular motions in the nematic and isotropic liquid states.[2]

In this paper the spin-lattice relaxation times T_1, the line widths, and the second moments of the two selectively deuterated PAA's are presented from 77 K to the melting point. The internal motions of the methyl protons are distinguishable from the motion of the ring protons, and it is possible to discuss the effects of the internal reorientations of the side chains on T_1 of the benzene protons of the central part of the molecule.

Proton relaxation times T_1 and $T_{1\rho}$ have been studied in the solid state,[3] and the molecular motions depending on temperatures were discussed. It has been suggested that there is a question about the activation of the internal rotation around the C–O axis for PAA in the solid state. It will be shown here that such hindered rotation about this axis does not exist.

Experimental

The method of synthesis and purification of the selectively deuterated PAA's have been described in a previous paper.[2] The compounds were sealed in a 10 mm o.d. glass tube after a number of melt-solidify-pump-thaw cycles.

The proton NMR spectrum was observed by an NMR Specialities PS-60RW spectrometer operating at 55 MHz. The temperature control apparatus has been reported in the previous paper.[2] T_1 measurements were carried out by the usual 180°-τ-90° pulse sequence. The accuracy of the semilogarithmic plot was within ±10%. To obtain the cw spectrum the FID signal was digitized by a Biomation 1010 waveform recorder and then accumulated in a FACOM F-PDT-8 microcomputer. The pulse width for 90° nutation was approximately 4.5 μs. The sampling time was 0.5 to 1 μs, data points were about 200 to 600 and the accumulation was 1 to 16 times depending on the temperature. The accumulated FID signal was punched on to paper tape and Fourier-transformed by a FACOM 270/30 computer. The second moment was also calculated by the computer from the cw spectrum obtained.

Results and Discussion

The Fourier-transformed cw spectra of PAA-d_8 are shown in Fig. 1. At 77 K the methyl protons of PAA-d_8 show a triplet, which is the typical pattern for a three-spin system in the rigid lattice. The spacing between the two outer lines is 14.8 G, which agrees well with the theoretical value of 4α, where $\alpha=(3/2)\mu_H/r^3$ and $r=1.79$ Å. As the temperature increases, each line broadens, the triplet collapeses into a broad single line at about 92 K, and then the line narrows into another triplet with small splitting. The change of the spectral patttern is due to the activation of the reorientation of the methyl group about the C_3 axis and agrees well with the theoretically calculated

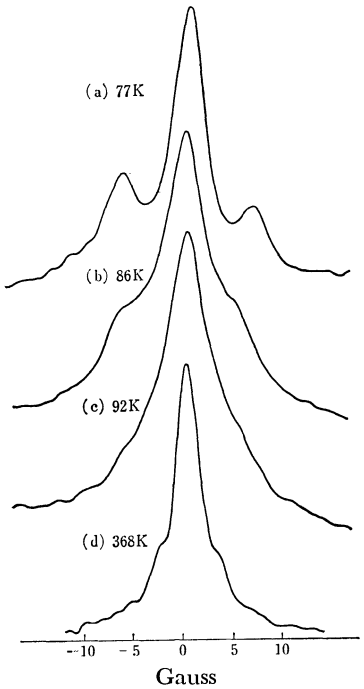

Fig. 1. Fourier transformed cw spectra of PAA-d_8 at (a) 77 K, (b) 86 K, (c) 92 K, and (d) 368 K. Throughout this paper 10^4 G = 1 T.

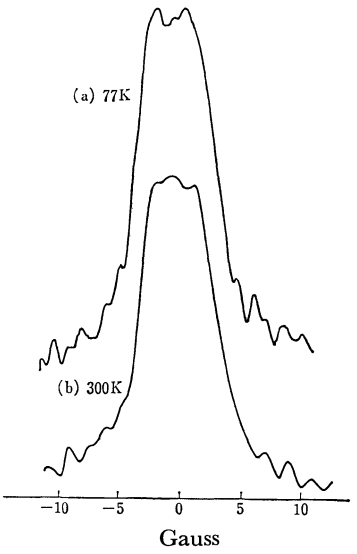

Fig. 2. Fourier transformed cw spectra of PAA-d_6 at (a) 77 K and (b) 300 K.

spectra for an isolated methyl group reported by Cobb and Johnson.[4] The spectral pattern for PAA-d_8 does not change significantly from 103 K to the melting point at 390 K (117.5 °C). The temperature dependences of the outer spacing of the triplet, the half line width of the central line, and the second moment of PAA-d_8 are shown in Fig. 3 (a), (b), and (c) respectively. Since the second moment was calculated from the Fourier-transformed spectrum, where it was difficult to draw a definite base line in the technique employed in this paper, the error was rather large, about 10 to 15% of the obtained value. This error comes directly from the uncertainty of the base line position.

The proton cw spectra of PAA-d_6 are shown in Fig. 2. As may be seen, the spectral pattern is almost unchanged from 77 K to the melting point. The line width is also constant from 77 to 285 K, and a little line narrowing is observed below the melting point, as shown in Fig. 4. The second moment of PAA-d_6 in Fig. 4 also shows a similar behavior to the line width with the change of the temperature.

In discussing the molecular motions of PAA in the solid state, interesting points are the methyl reorientation around the C_3 axis and the C–O axis, the libration of the benzene rings about the C–N axis, the molecular overall reorientation, and the self-diffusion. It has been suggested from the study of proton T_1 and $T_{1\rho}$ of PAA,[3] that the reorientation of the methyl groups about the C_3 axis is the predominant relaxation mechanism between 77 and 167 K, and that the internal rotation about the C–O axis is activated between 167 and 238 K, and in this temperature range there is also proton cross relaxation to the nitrogen. Then as the temperature increases the fast random molecular reorientation and slow self-diffusion take place. In the same paper,[3] however, it was written that as an opinion of other researchers, there is a question on the rotation about the C–O axis in the solid state.

In this study, the second moment of PAA-d_8 decreases from 22.6 to 6.0 G^2 at about 103 K, which corresponds to the change from the methyl group which is isolated in the rigid lattice to the methyl group freely rotating about the C_3 axis. If the rotation of the methyl group around the C–O axis were further activated in higher temperatures, the second moment should become about 0.56 G^2, since the second moment will decrease by a factor of $\left(\frac{3\cos^2\theta-1}{2}\right)^2$ by the additional rotation.[6] The angles COC (θ) have been determined as 118.7 and 118.1° from X-ray analysis.[5] However, at temperatures just below the melting point, the second moment is still 3.8±0.5 G^2. Thus it is concluded that the methyl groups do not rotate around the C–O axis in the solid state.

The second moment of the ring protons of PAA-d_6 is almost constant from 77 K to about 200 K, and a little narrowing is observed near below the melting point, as shown in Fig. 4. The second moment of the

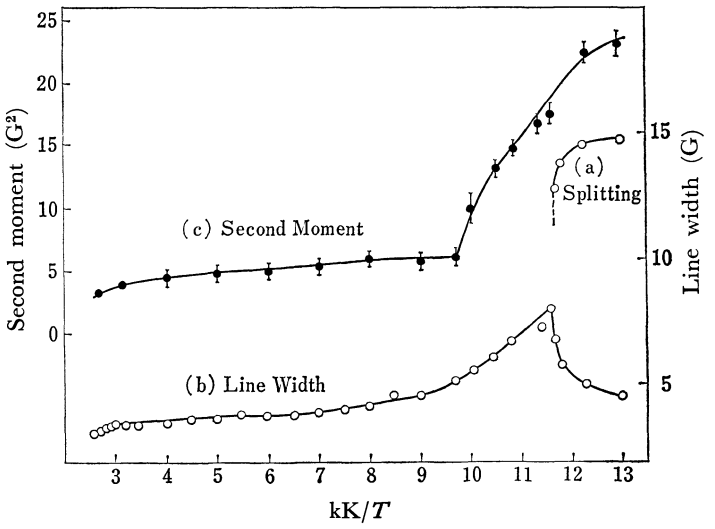

Fig. 3. The temperature dependences of (a) the spacing of the outer lines, (b) the half line width of the central line of the triplet, and (c) the second moment for PAA-d_8.

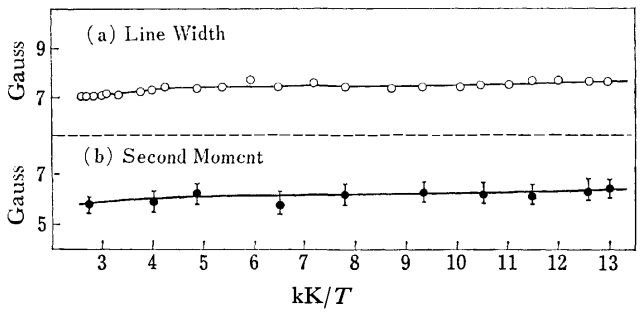

Fig. 4. The temperature dependences of (a) the half line width and (b) the second moment for PAA-d_6.

ring protons calculated for the rigid lattice is 1.67 from the protons on the same benzene ring, 0.07 from the protons of another benzene ring in the same molecule, 1.14 from the intermolecular ring protons, and 0.03 from the inter- and intramolecular CD_3 groups in the G^2 unit. The sum, 2.91 G^2 is expected for the second moment of PAA-d_6 in the rigid lattice with random orientation. However, the observed second moment is 6.2 G^2 at 77 K and 5.8 G^2 just below the melting point, both of which are larger than the calculated value. The sample used in this work was heated to melt in the nematic state for the purpose of degassing. After the rapid or slow cooling from the nematic to the solid states inside or outside the magnetic field, the second moment of PAA-d_6 observed at room temperature was almost the same value within experimental error. One possible interpretation for this disagreement between the observed and calculated second moments is that some orientation in the nematic state may still remain in the solid state. Another interpretation is the polymorphism of PAA in the solid state obtained by cooling from the nematic state as suggested by a recent study.[7] In PAA-d_8 the methyl group may be regarded as an isolated system, so that the effects of the remaining orderness or polymorphism are probably very small on the second moment of PAA-d_8.

In the calculated second moment of PAA-d_6, the intermolecular contribution is about 40%. When the molecular motion, which causes the change of the intermolecular proton-proton distance, were activated, a decreasing of the second moment should occur. Since the second moment of PAA-d_6 does not change significantly, libration about the C–N axis or the fast molecular reorientation suggested before,[3] both of which bring changes in the intermolecular ring proton distances, can not be assumed to take place below 250 K in the solid state.

The above discussion concerning the molecular motion of PAA can be applied to the T_1 behavior of PAA-d_8, PAA-d_6, and PAA. As shown in Fig. 5, the plots of T_1 *vs.* $1/T$ have minimum values at similar temperatures. This fact suggests that the motion, which gives the T_1 minimum, belongs to the same mode of molecular motion for all compounds. Considering the spectral patterns and the second moments, this motion is clearly the reorientation of the methyl groups about the C_3 axis.

T_1 of the reorientating methyl protons may be described by

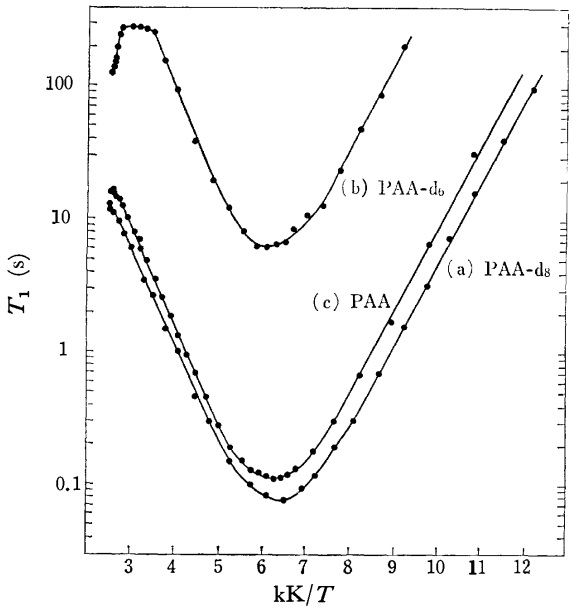

Fig. 5. The temperature dependent spin-lattice relaxations for (a) PAA-d_8, (b) PAA-d_6, and (c) PAA in the solid state observed at 55 MHz.

$$\left(\frac{1}{T_1}\right)_{\text{Methyl}} = \frac{9}{20}\frac{\gamma_H^4\hbar^2}{r^6}\left(\frac{\tau_c}{1+\omega_H^2\tau_c^2}+\frac{4\tau_c}{1+4\omega_H^2\tau_c^2}\right), \quad (1)$$

where r is the distance betweeen the protons within the methyl group, and $\omega_H=2\pi\nu_H$, ν_H being the resonance frequency of the protons (55 MHz). The condition for the T_1 minimum is $\omega_H\tau_c=0.616$. In the case of the ring protons, T_1 is very long and the contribution from the rotating CD_3 becomes important. Assuming that the ^{2}H relaxation of the CD_3 groups takes place mainly by the quadrupolar mechanism and that the correlation time for the reorientation of CD_3 is the same as that for CH_3 of PAA-d_8 at the same temperature, then the magnetic relaxation of the deutrons of the CD_3 is much faster than that of the ring protons by about 10^4 in the vicinity of the T_1 minimum. Theoretically, the non-resonant spins contribute to the relaxation of the resonant spins.[8] In this case, however, the relaxation rate of the non-resonant deuterons of CD_3 is so large that it may be assumed that the effect of the magnetization of CD_3 on the dipolar relaxation time T_1 of the ring protons may be neglected. This dipolar relaxation time T_1 directly arising from the rotating CD_3 in the weak collision limit, may be written as[8,9]

$$\left(\frac{1}{T_1}\right)_{\text{Ring}} = \frac{4}{15}\gamma_H^2\gamma_D^2\hbar^2 I_D(I_D+1)\frac{1}{N_i}\sum_{ij}\frac{1}{r_{ij}^6} \times\left(\frac{1}{2}\frac{\tau_c}{1+(\omega_H-\omega_D)^2\tau_c^2}+\frac{3}{2}\frac{\tau_c}{1+\omega_H^2\tau_c^2} +\frac{3\tau_c}{1+(\omega_H+\omega_D)^2\tau_c^2}\right), \quad (2)$$

where $\omega_D=2\pi\nu_D$ and ν_D is the ^{2}H resonance frequency, γ_D and I_D are the gyromagnetic ratio and the spin quantum number of deuteron, and r_{ij} is the distance between the ring proton i and the deuteron j of the intra- and intermolecular CD_3 groups, and N_i is the number of the ring protons. In Eq. 2, the condition of

the minimum T_1 is $\tau_c=2.7\times10^{-9}$ s ($\nu_H=55.0$ MHz). Using the proton-proton distances for PAA obtained from X-ray analysis, Eq. 2 gives $(T_{1\,min})_{Ring}=3.8$ s, and the observed value is 6.4 s, approximately 60% of the theoretical value. On the other hand, the calculated $(T_{1\,min})_{Methyl}=31$ ms, compared to the observed value of 76 ms, about 40% of the theoretical value. In both cases the observed $T_{1\,min}$ is longer than the calculated one. As described later, the agreement is considered satisfactory, and it can be said that the $T_{1\,min}$ of the ring protons is interpreted by the rotation of the neighboring CD_3 groups.

The discrepancy between the observed and the calculated $T_{1\,min}$ has already been reported for the hindered rotation of the methyl group in an isolated system, and interpreted by Johnson[10] as the following: oscillations of the methyl group, occuring in the reorientation through large angles, partially average the dipolar Hamiltonian and the efficiency of the nuclear relaxation is reduced, leading to a longer T_1 than given by the theory. Furthermore, it has been also shown that if there is cross-correlation, the relaxation is not a simple exponential decay and T_1 obtained by the half-recovery method becomes longer. In our experiments, non-exponential decay for the relaxation of all the compounds studied was not observed, but the discrepancy was a little larger, compared with the simple methyl compounds studied by Johnson. This is attributed to the coupling of the internal rotation of the methyl group about the C_3 axis with another molecular motion. In point of fact, the second moment of PAA-d_8 is smaller than the value of the isolated rotating methyl protons at this temperature.

As given in Table 1, the activation energies obtained from the slopes of log T_1 *vs.* $1/T$ plots are similar for PAA, PAA-d_8, and PAA-d_6 in both the low and high temperature sides. This is another reason why the same mode of the molecular motion affects T_1's of the ring protons as well as the methyl protons. The correlation time τ_0 was obtained from τ according to the equation $\tau=\tau_0\exp(E_a/RT)$. The values of τ_0 for PAA, PAA-d_8, and PAA-d_6 in Table 1 are reasonable for the rotation of the methyl group about the C_3 axis.[11,12] The small deviation of τ_0 for PAA-d_6 is probably due to the assumption contained in Eqs. 1 and 2.

In order to explain the value of $T_{1\,min}$ and the slight narrowing of the second moment of PAA-d_8 from about 100 K to the melting point, some additional process of molecular motion is necessary besides the reorientation of the methyl group about the C_3 axis. From the study of T_1 and $T_{1\rho}$ of PAA, it has been suggested that in the temperature region between 167 and 238 K, the slow rotation of the methyl group about the C–O axis is activated. However, there is not a clear change in the second moment of the methyl protons of PAA-d_8, corresponding to the dual reorientation of the methyl group. The second moment of PAA-d_8 decreases gradually from 6.0 to 3.8 G^2 in the temperature region betweeen 100 K and the melting point. Thus, the slow libration about the C–O axis may be considered, after the reorientation of the methyl group about the C_3 axis is activated. The effect of the libration on the second moment of the ring protons of PAA-d_6 is estimated as being negligible, although the second moment decreases from 6.2 to 5.8 G^2 near the melting point. Thus some other molecular motions are necessary to understand the narrowing.

Above 286 K ($1/T=3.5\times10^{-3}$), a large change appears in the T_1 of PAA-d_6. When the temperature increases, T_1 is nearly constant until 364 K, and then T_1 decreases sharply until the melting point. In this temperature range, however, the second moment and the line width decrease only to a small extent, and the spectral pattern does not change at all. Such change is not apparent in T_1 for the rotating methyl protons of PAA-d_8, but the line width and the second moment of this compound decrease to nearly the same extent as those of PAA-d_6. These facts suggest that motion of the whole molecule takes place at these temperatures. For such motion, the self-diffusion and the reorientation of the molecular axis have been assigned from the study of T_1 and $T_{1\rho}$ of PAA.[3] It should be noted that the motion of the whole molecule begins at temperatures about 105 K below the melting point. This wide temperature region for the self-diffusion and the molecular reorientation, even in the solid state, characterises the nematic liquid crystalline compound PAA.

Assuming that the relaxation mechanism for T_1 of PAA, PAA-d_8, and PAA-d_6 is the dipole-dipole interaction,

$$\left(\frac{1}{T_1}\right)_{PAA}=\frac{8}{14}\left(\frac{1}{T_1}\right)_{PAA\text{-}d_8}+\frac{6}{14}\left(\frac{1}{T_1}\right)_{PAA\text{-}d_8}+\left(\frac{1}{T_1'}\right) \tag{3}$$

then, $1/T_1'$ is the relaxation rate mainly due to interactions between the ring and the methyl protons and a small contribution from the interactions of the protons with deuterons. On the low temperature side of the T_1 minimum, $1/T_1'$ is negeligibly small within experimental error, while on the high temperature side, $1/T_1'$ has a value larger than the relaxation rate of PAA-d_6 at all temperatures. The gradient of the log T_1' *vs.* $1/T$ plot has almost the same as that of log T_1 *vs.* $1/T$ for PAA, PAA-d_6, and PAA-d_8 which are shown in Table 1. Then the molecular motion

TABLE 1.

Compound	$T_{1\,min}$(s)	Temp(K)	$\tau_0(10^{-13}$ s)	Activation energy(kJ/mol)	
				Low temp	High temp
PAA	0.11	159	1.9	12.1(±0.7)	14.3(±0.4)
PAA-d_8	0.076	154	1.7	11.5(±1.5)	15.0(±1.9)
PAA-d_6	6.3	165	6.4	11.8(±0.2)	13.6(±0.6)

which governs the temperature dependence of the interaction between the methyl and the ring protons in PAA is the same as that for the ring protons of PAA-d_6, which is considered to be the reorientation of the methyl groups and the motion of the whole molecule.

In conclusion, at 77 K PAA is in a rigid lattice in an NMR time scale, and as the temperature increases, the methyl groups begins to rotate around the C_3 axis, followed by slow libration about the C–O axis. The other motions which change the relative position of the ring protons do not occur until the molecular overall motions, which may be self-diffusion and slow reorientation of the molecular axis, start to take place at 286 K.

Study of Metal-Polycarboxylate Complexes Employing Ion-selective Electrodes. II.[1] Stability Constants of Copper(II) Complexes with Poly(acrylic acid) and Poly(methacrylic acid)

Fumitaka YAMASHITA,* Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 26, 1978)

The copper(II) complex formation with poly(acrylic acid) and poly(methacrylic acid) in aqueous solution was studied by potentiometric titration employing glass and copper(II) ion-selective electrodes. The values of the equilibrium constants of the complex formation and the stability constants were estimated in various degree of neutralization. Since the concentration of free copper(II) ions could be determined by employing the copper(II) ion-selective electrode, the concentrations of two complex species, involving one and two carboxylato groups, were determined from stoichiometric equations. The equilibrium and stability constants of the complexes obtained were observed to pass through peaks with increase in the degree of neutralization. The order of magnitude of the equilibrium constant of the polyacrylate complex was larger than that of the polymethacrylate complex.

Studies of bivalent metal–polyelectrolyte complex formations by potentiometry have been reported by Gregor and coworkers,[2] as well as by Mandel and Leyte.[3] The formation curves, namely the average coordination numbers, of the bivalent metal–polyelectrolyte systems have a flat region in the range of higher degrees of neutralization and the value of the average coordination number is equal to 2. This result suggests that the predominant complex in the system is the bivalent metal ions chelated by two carboxylato groups.

Marinsky and coworkers[4-6] have investigated the complex formation of bivalent metal ions with polycarboxylic acid. It is concluded, though their systems are composed of gels, that two carboxylato groups of poly(methacrylic acid) coordinate to copper(II) ions in the range of higher degrees of neutralization. The stability constants of some bivalent metal complexes were also calculated.

On the other hand, it seems that the results of spectrophotometric studies have been satisfactorily interpreted. When the degree of neutralization is varied, the absorbance of copper(II) complexes with polycarboxylate passes through a maximum in the course of neutralization. This fact shows that the copper(II) complexes partially change in favor of some other form of binding, and as pointed out by Mandel and Leyte,[7] the spectrophotometric and potentiometric results show a breakdown of the chelate in the higher neutralization region.

In our previous paper,[1] it was shown that the potentiometric titration employing ion-selective electrodes was available for the investigation of complex formation of the bivalent metal ions with polycarboxylic acid, especially with poly(itaconic acid). But poly(acrylic acid) systems were studied for comparison purposes and the discussion was carried out mainly on the basis of the formation curves of complexes. In this study, then, poly(acrylic acid) (PAA) and poly(methacrylic acid) (PMA) were investigated by pH titration and potentiometry employing the ion-selective electrode, and the concentrations of the complexes formed and the formation constants were evaluated from the potentiometric data.

Experimental

Materials. The preparation of all materials used was described previously.[1,8]

Potentiometric Titration. The pH measurements were carried out in nitrogen atmosphere at 25±0.05 °C by use of a Yokogawa Model KPH-51A pH meter equipped with Toadenpa Model HG-4005 glass and HC-2005 calomel electrodes.

The activities of copper(II) ions were measured with an Orion Model 801A digital ion meter equipped with Beckman Model 39612 Cupric and Horiba Model 2010-05T calomel electrodes, and the concentrations of copper(II) ions were estimated with the calibration curve which is obtained by measurements of the systems without only polyligands. The other conditions and techniques of potentiometry were described previously.[1]

Results and Discussion

Potentiometry Employing Copper(II) Ion-Selective Electrode. In our previous paper,[1] the potentiometry employing a copper(II) ion-selective electrode applied to the copper(II) ion-polycarboxylic acid systems was discussed. In this case it was not necessary to consider the effect of pH, because the concentration of the bivalent metal ions compared with that of the polyacid is so low that all the metal ions exist essentially as chelates in the pH region where the metal hydroxides are formed in the absence of polyacid.

In the case of the present study, however, nonchelated copper(II) ions exist in the pH region where the metal hydroxides are to be formed in the absence of polyacid. Thus, all the potentiometric measurements were carried out in the pH region less than 6.00.

Concentrations of Complexes as Functions of Degree of Neutralization. Assuming that both monocarboxylato and dicarboxylato complexes are formed, and that the concentrations of the other complexes are negligible even if they are formed, the following equations hold:

$$[Cu_t] = [Cu^{2+}] + [CuA^+] + [CuA_2],$$

$$[A_t] = [A^-] + [HA] + [CuA^+] + 2[CuA_2],$$

where $[Cu_t]$ is the total concentration of copper(II)

ions and $[A_t]$ is that of carboxylato groups. In these equations, the values of $[CuA^+]$ (designating the concentration of monocarboxylato copper(II) complex), of $[CuA_2]$ (that of dicarboxylato complex), and of $[A^-]$ (that of nonchelating carboxylato groups) are unknown. In the present paper, the concentration of free copper(II) ions, $[Cu^{2+}]$, can be determined by potentiometric measurements employing the copper(II) ion-selective electrode. But these equations cannot be solved stoichiometrically without the estimation of $[A^-]$ based on some assumption.

By use of the reference plot method proposed by Mandel and Leyte,[3] the concentrations of nonchelating carboxylato groups, $[A^-]$, can be estimated. When the concentrations of free copper(II) ions have been determined by employing the copper(II) ion-selective electrode, these two stoichiometric equations make it possible to know the concentrations of the two complex species, $[CuA^+]$ and $[CuA_2]$.

In Figs. 1 and 2, the values of $[CuA^+]$ and $[CuA_2]$ obtained by the above method are plotted against the apparent degree of neutralization α'. In Fig. 1, the results for the copper(II)–PAA system (9.9×10^{-3} monomol/l PAA, 1.0×10^{-3} mol/l $Cu(NO_3)_2$, and 1.0×10^{-1} mol/l KNO_3), and in Fig. 2 those for the copper(II)–PMA system (1.0×10^{-2} monomol/l PMA, 1.0×10^{-3} mol/l $Cu(NO_3)_2$, and 1.0×10^{-1} mol/l KNO_3) are presented. As shown in these figures, the concentrations of the monocarboxylato complex are found to be significantly high, though the values of $[CuA^+]$ are relatively small compared with $[CuA_2]$. As the degree of neutralization increases, the concentrations of the two complex species, $[CuA^+]$ and $[CuA_2]$, increase and reach maxima in both systems, PAA and PMA. The values of the degree of neutralization of PAA at which the complex concentrations reach a maximum are 0.35 for $[CuA_2]$ and 0.45 for $[CuA^+]$. In the case of PMA two maxima are observed; their degree of neutralization values are 0.27 and 0.43 for $[CuA_2]$, and 0.35 and 0.60 for $[CuA^+]$.

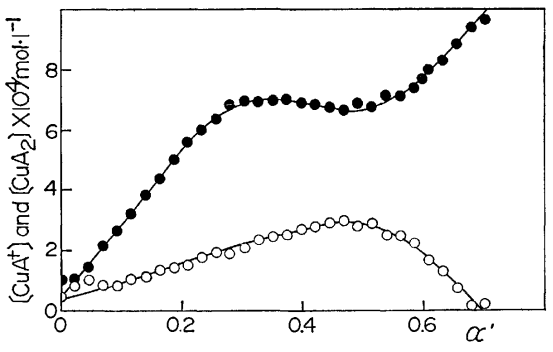

Fig. 1. Dependence of the concentrations of monocarboxylato and dicarboxylato copper(II) complexes, $[CuA^+]$ (○) and $[CuA_2]$ (●), on the apparent degree of neutralization α' for PAA system.

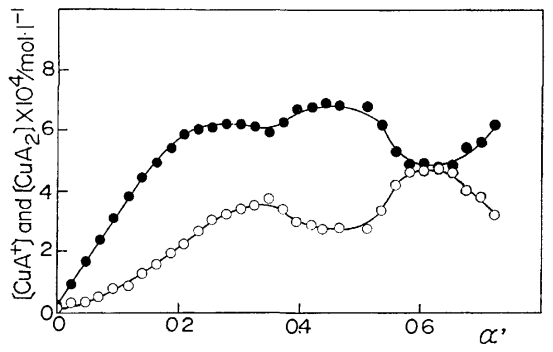

Fig. 2. Dependence of the concentrations of monocarboxylato and dicarboxylato copper(II) complexes, $[CuA^+]$ (○) and $[CuA_2]$ (●), on the apparent degree of neutralization α' for PMA system.

It is very interesting that maxima are obtained in the potentiometric measurements. In most studies[6,7,9,10] of spectrophotometric measurement it has been observed that the absorbance due to the copper(II) complex with carboxylato groups increases and passes through a maximum with increase in the degree of neutralization, and that the value of the degree of neutralization at the maximum of the absorption is about 0.3 to 0.4 for systems composed of similar concentration ratios. In the study of Mandel and Leyte,[7] it is shown that the disagreement between the spectrophotometric and the potentiometric results appears in the region of higher degree of neutralization. In such a neutralization region, the absorbance due to the complex formation begins to decrease, whereas the formation curve by potentiometry shows constant or increasing values. In the present study, however, the variations of $[CuA^+]$ and $[CuA_2]$ against the degree of neutralization show a decreasing tendency; this fact is similar to the spectrophotometric results. Therefore, potentiometric data also show that the monocarboxylato and dicarboxylato copper(II) complexes are partially broken or change in favor of some other form of binding with increase in the degree of neutralization. Since the concentration of hydroxide ions as ligands increases in the high neutralization region, some carboxylato ligands may be released and the concentrations of the complexes may decrease.

In Fig. 2, where the copper(II)–PMA system is treated, two maxima are observed. The maximum in the region of lower neutralization may be due to the conformational transition of PMA which appears in the course of potentiometric titration. Here, it is interesting that the value of the degree of neutralization at the maximum agrees with that found by the spectrophotometric measurement of the similar conditions. But it is not clear whether this maximum came from the reference plot method or the figure actually reflects the fact.

In Figs. 1 and 2, moreover, in the region of higher degree of neutralization the concentrations of dicarboxylato complex show an increasing tendency again. In such a region, the concentrations of nonchelating carboxylato groups are very high, whereas the concentrations of free bivalent metal ions are negligibly low; such an equilibrium is difficult to treat precisely. On the other hand, the estimation of the concentration of nonchelating carboxylato groups by Mandel's reference plot method may become inapplicable because of the higher charge density on the polyions. Thus,

a precise discussion is impossible in the region of such a degree of neutralization.

Stability and Equilibrium Constants of Complexes. The stability and equilibrium constants of the copper(II) complex with PAA calculated from the concentrations of the complexes obtained by the above mentioned method are shown in Table 1.

TABLE 1. STABILITY AND EQUILIBRIUM CONSTANTS OF Cu(II)–PAA COMPLEXES

α'	β_1	β_2	B_2	B_2'

0.50	1.1×10^{4}	8.0×10^{6}	7.2×10^{-4}	7.4×10^{-6}
0.55	1.5×10^{4}	1.2×10^{7}	6.7×10^{-4}	6.7×10^{-6}
0.60	1.7×10^{4}	1.7×10^{7}	6.6×10^{-4}	5.2×10^{-6}
0.65	9.7×10^{3}	2.5×10^{7}	7.0×10^{-4}	4.8×10^{-6}
0.70	3.5×10^{3}	4.0×10^{7}	7.3×10^{-4}	4.3×10^{-6}

The parameters β_1, β_2, B_2, and B_2' in the table will be discussed in some detail. When the concentration of nonchelating carboxylato groups is estimated, the effect of the change in the electrostatic potential on the polyion is considered in the reference plot method. The stability constants of the momocarboxylato and dicarboxylato complexes, β_1 and β_2, apparently vary with increase in the degree of neutralization. In the estimation of such a constant of polymer systems, therefore, it seems that the variation of the charge density on the polyion must be taken into account, as is shown in the series of these constants.

Then, consider the following equilibrium equation and constant:

$$Cu^{2+} + 2HA \rightleftharpoons CuA_2 + 2H^+, \quad B_2 = \frac{[CuA_2][H^+]^2}{[Cu^{2+}][HA]^2}.$$

Since the complex formation on the polyion is described as an exchange of copper(II) ion with two hydrogen ions, the total charge on the polyion remains unchanged by the chelate formation. Then, the B_2 without the effect of the change in the charge density may be constant. As is shown in Table 1, the sufficiently constant values of B_2 were not obtained.

On the other hand, the following equilibrium equation and constant have been proposed by Wall and Gill:[11]

$$Cu^{2+} + H_2A_2 \rightleftharpoons CuA_2 + 2H^+, \quad B_2' = \frac{[CuA_2][H^+]^2}{[Cu^{2+}][H_2A_2]}.$$

The results by this scheme with the relation of $[H_2A_2] = 1/2[HA]$ are shown in Table 1, and the values of B_2' still failed to be constant.

In all ways of evaluating the constants, no constant values independent of the degree of neutralization were obtained, but orders of magnitude of the constants may be estimated as 10^6 for β_2 and 10^{-3} for B_2 in the copper(II)–PAA system.

In Table 2, the results with the copper(II)–PMA system obtained by the same scheme of estimation are shown. Since the values of the stability and equilibrium constants of the copper(II) complex with PMA vary over a wider range, it is rather difficult to determine the order of magnitude of these constants, and the values are roughly 10^{-5} for B_2.

Comparing the values of these constants and their dependence on the degree of neutralization, it is seen that the PAA complex is relatively more stable than the PMA complex. But it is also suggested that the effect of the charge density on the polyion is not the only predominant factor in such a complicated complex formation as polyelectrolytes, and the conformational transition must be considered not only by acid dis-

TABLE 3. COMPARISON OF STABILITY AND EQUILIBRIUM CONSTANTS WITH VALUES OBTAINED BY SOME AUTHORS

	$[A_t]$	$[Cu_t]$	μ	Constant	Ref.
Cu(II)–PAA	1×10^{-2}	1×10^{-3}	0.1(KNO_3)	$B_2=7\times10^{-4}$	by present analysis
	1×10^{-2}	1×10^{-3}	0.2($NaNO_3$)	$B_2=4.6\times10^{-3}$	2
	2.5×10^{-3}	2×10^{-4}	0.25($NaNO_3$)	$B_2=1.5\times10^{-4}$	12
	2×10^{-3}	2×10^{-4}	0.1($NaNO_3$)	$B_2=4\times10^{-2}$	13
Cu(II)–PMA	1×10^{-2}	1×10^{-3}	0.1(KNO_3)	$B_2\simeq10^{-4}$	by present analysis
	2×10^{-2}	2×10^{-3}	0.1($NaNO_3$)	$B_2=2.5\times10^{-4}$	3
	5.5×10^{-3}	4.4×10^{-4}	0.1($NaNO_3$)	$B_2=2.5\times10^{-4}$	14

sociation but also by chelation and the other steric factors.

In Table 3, the stability and equilibrium constants reported previously and estimated by the present analysis are summarized. Although it is meaningless to compare the absolute values of these constants, as was stated above, the agreement of the order of magnitude of these constants is apparent.

Thus, the conclusion is as follows. The stability and equilibrium constants of the copper(II) complexes with PAA and PMA (apparently) change with increase in the degree of neutralization; the order of magnitude of these constants can be estimated; and the B_2 values of the dicarboxylato copper(II) complex are of the order 10^{-3} for PAA and 10^{-4} for PMA, respectively.

Monolayer Studies of Chiral and Racemic 12-Hydroxyoctadecanoic Acids

Taro TACHIBANA,* Tokiko YOSHIZUMI, and Kayako HORI
Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received June 12, 1978)

The monolayer properties of chiral and racemic 12-hydroxyoctadecanoic acids (12HOA) have been studied. Both acids showed, in each pressure-area isotherm, a pressure plateau. This was interpreted as a two-dimensional phase transition region: from the expanded monolayer composed of bent chain molecules with both the hydroxyl and carboxyl groups attached to the water surface, to the condensed monolayer composed of straight chain molecules oriented steeply to the water surface. It was suggested by measuring infrared spectra of the collapsed films and the built-up films that the condensed monolayer involves intermolecular hydrogen bonds. Differences between (*R*)- and *dl*-12HOA were found in the plateau pressure and its temperature dependence leading to the transition energy. These results were attributed to the formation of a recemic molecular compound during condensation of monolayers of *dl*-12HOA, prior to collapse, followed by a different manner of hydrogen bonding. Electron microscope observation gave strong evidence for the two-dimensional racemic compound formation. On the basis of these results and the X-ray diffraction data, molecular packing models in the condensed monolayers were proposed.

A racemic modification forms a racemic molecular compound, a solid solution, or a mixture in the crystalline solid state, while it behaves as a mixture in the liquid state and in solution. Since monolayers at the air–water interface show some different phases during compression, it is interesting to examine the formation of a racemic compound in the monolayer state. Lundquist[1] found, for 2-alkanols and certain derivatives, a monolayer behavior which was interpreted as the formation of a racemic molecular compound between enantiomer molecules. For study of this problem, 12-hydroxyoctadecanoic acid (12HOA) is especially well suited, since both enantiomers and the racemic form of this acid are readily prepared and they form stable monolayers at the air–water interface. Electron microscopic evidence was given in a recent communication from our laboratory that the racemic compound formation occurs in a monolayer state of this acid prior to collapse.[2]

The present paper has two main objects. First, monolayer studies of (*R*)-12HOA[3] are described in detail, since such studies have hitherto not been published. Next, the monolayer data for the chiral form and the racemic form are compared.

Experimental

Materials. (*R*)-12HOA was purified from commercial products as previously described.[4] The *S*-enantiomer (the *S*-acid) and the racemic acid (the *dl*-acid) were prepared by the methods described previously from the methyl ester of the *R*-enantiomer (the *R*-acid).[4] The purity estimated from gas chromatography and melting points of these samples were as follows: *R*-acid, 99.9%, 353.1 K (lit,[4] 353.6 K); *S*-acid, 99.0%, 352.7 K; *dl*-acid, 99.1%, 349.8 K (lit,[4] 352.3 K).

Methods. All films were spread from solutions in doubley-distilled benzene on a substrate of 0.01 M hydrochloric acid. The water for the substrate was twice distilled. Surface pressure was measured on a Wilhelmy-plate balance with an accuracy of ± 0.2 mN m^{-1}. Compression was done manually and, in certain cases, by a motor-driven device. The temperature of the substrate was controlled within ± 0.1 K of the desired value. The surface potential was measured by an ionization method.

Infrared spectra were recorded with a JASCO IR-A3 spectrophotometer. Powder X-ray diffraction patterns were obtained by a Rigaku Geiger-Flex 2001 diffractometer. Samples of collapsed films were transferred from the film balance to collodion-covered supports, shadow-cast with Pd-Pt alloy at an angle of 20° to the surface, and examined in a JEM-T6 electron microscope.

Results and Discussion

Monolayer Isotherms of (R)-12HOA. Molecular Conformations in Monolayers: The isotherms are shown in Fig. 1. The pressure-area curve (π-A curve) is composed of three parts: (i) a compressible region above about 95 Å^2 molecule^{-1}, a—b, (ii) a plateau, b—c, characterized by a nearly constant pressure in a range of 25 to 95 Å^2 molecule^{-1} and (iii) a highly incompressible region, c—d, with the extrapolated area at zero pressure of 24 Å^2 molecule^{-1} and a collapse at a pressure of about 35 mN m^{-1}. The a—b region appears to be a part of an expanded film, as has been seen with long chain fatty acids having *cis*-double

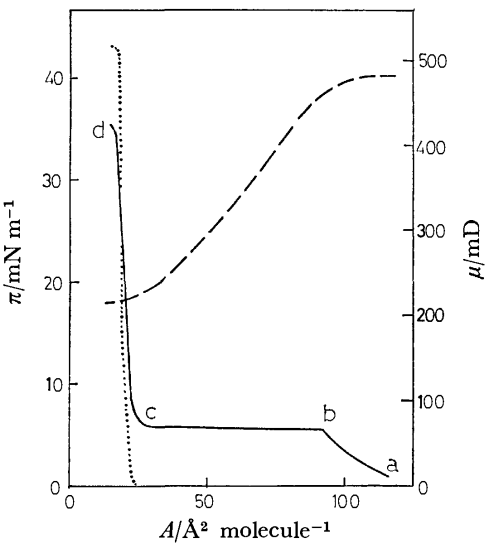

Fig. 1. Monolayer isotherms of (*R*)-12HOA and octadecanoic acid (OA). ——, π-A of (*R*)-12HOA (20 °C); ----, μ-A of (*R*)-12HOA (27 °C); ·····, π-A of OA (20 °C).

bonds or side chains. The c—d region is part of a condensed film; it is close to the isotherm of a condensed film of octadecanoic acid, represented by a dotted line in Fig. 1. Thus the isotherm shape indicates that the plateau represents not the collapse of the film, but a sharp phase transition between the expanded film and the condensed film.

The π-A curve in Fig. 1. could be interpreted in terms of an orientation and a conformation of the long chain molecule with a hydroxyl group at the 12 position, as made for isotherms of 2-(10-carboxydecyl)-2-hexyl-4,4-dimethyl-3-oxazolidinyloxyl (12-nitroxide stearic acid),[5] 9-hydroxyhexadecanoic acid,[6] and 4-hydroxyoctadecanoic acid,[7] which resemble the isotherm of 12HOA in shape. Although the 12HOA molecule can assume various conformations, it seems to be reasonable to take the following two conformations into consideration: (a) a straight chain molecule, in which the long chain is steeply oriented to the water surface with only the carboxyl group in the surface and the hydroxyl group out of the surface, and (b) a bent chain molecule, in which the long chain is bent with both the carboxyl group and the hydroxyl group attached to the surface. These forms are illustrated in Fig. 2. The packing mode of these molecules in monolayers was considered using molecular models, for which one should refer to the Appendix. The closest packing area for the straight chain molecule was 24.1 Å^2 molecule^{-1}, assuming that the straight chain molecules are steeply oriented to the interface and that intermolecular hydrogen bonds are formed between the hydroxyl groups of the adjacent molecules. This value agrees well with the limiting area, extrapolated to zero pressure, of 24.0±1.0 Å^2 molecule^{-1}. When the bent chain molecules are most closely packed with the $CH_3(CH_2)_5$— chain oriented steeply to the water surface, the minimum area calculated from the molecular model was 91 Å^2 molecule^{-1}, as

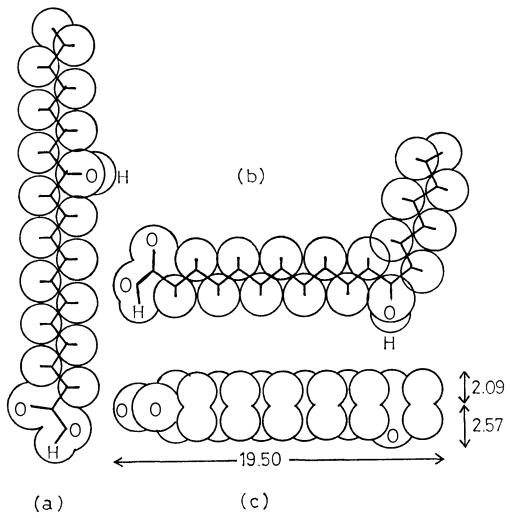

Fig. 2. Conformations of (*R*)-12HOA at the air-water interface. a) Straight chain molecule; b) bent chain molecule; c) occupation of a bent chain molecule at the water surface. The close-packed area per molecule is approximated to that of a rectangle, 19.5×4.66=91 (Å^2 molecule^{-1}).

shown in Fig. 2(c). This value is close to the observed value of the area at an inflection point, b in Fig. 1, 92—104 Å^2 molecule^{-1} (dependent on temperature), at which further compression gives the plateau. It can therefore be presumed that the a—b region in Fig. 1 exhibits an isotherm of the expanded film composed of the bent chain molecules, and that the sharp break at the point b indicates the expulsion of the hydroxyl groups from the interface. Adopting such a picture, the plateau region, b—c in Fig. 1, could be regarded as a transition state between film phases composed of the straight chain molecules and of the bent chain molecules. Thus, in this region, coexistence of the two phases under a constant pressure and temperature can be postulated from the two-dimensional phase rule.

The above-mentioned explanation was also supported by the data of surface dipole moments, μ, calculated from the surface potential. The μ-A curve is given by a broken line in Fig. 1. Here it is seen that the values of μ are little changed by compression in the same areas as the a—b region of the π-A curve, and that they decreased sharply from 490 to 220 mD in the plateau of the π-A curve. The final value, 220 mD, is comparable with the value reported for octadecanoic acid monolayer, 210 mD.[8] This result presents evidence that the molecule in the a—b region lies with a certain orientation of the polar groups on the surface and that the orientation or/and the change of conformation of the molecule occurred during compression in the pressure plateau region. Thus, the μ-A isotherm confirms the above-mentioned explanation for the π-A curve; the plateau is a transition region between a film phase composed of close-packing of the bent chain molecules and that composed of close-packing of the straight chain molecules. A gaseous film would presumably exist at pressures lower than those in the a—b region.

Recentl , Kellner and Cadenhead[6] obtained the π-A and μ-A isotherms for *dl*-9-hydroxyhexadecanoic acid. These are very similar to those for (*R*)-12HOA, and show the presence of a plateau in the π-A curve and the sharp change of μ in that region. This indicates that these two substances behave in a similar manner. They also interpreted the point of inflection corresponding to the point b in Fig. 1 as the area at which there occurs the expulsion of the hydroxyl groups from the interface. The value of the area at the point estimated from their curve is 68—74 Å^2 molecule^{-1} (28.0—8.4 °C); this is close to the value of the most closely packed area calculated from our molecular model of the bent chain molecules, 69 Å^2 molecule^{-1}.

Temperature Dependence: The temperature dependence of the π-A curves, as shown in Fig. 3, was normal; the plateau pressure rose with increasing temperature. As mentioned already, the plateau is the result of a phase transition connected with a change in the molecular conformation. On the basis of this consideration, the heat of transition, ΔH, from a film of bent chain molecules to that of straight chain molecules can be calculated from the two-dimensional Clausius-Clapeyron equation, $d\pi_t/dT=\Delta H/T\Delta A$, where π_t is

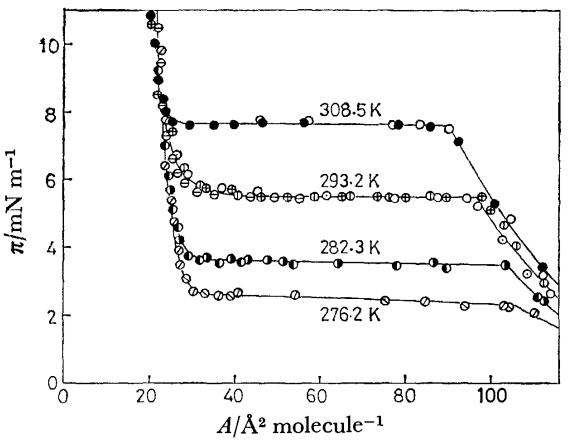

Fig. 3. Temperature dependence of π-A curves of (R)-12HOA.

the plateau pressure, ΔA is net change in molar area, and ΔH is the molar enthalpy change accompanying the transition at this temperature. The calculation was made by the same procedure as that of Glazer and Alexander,[9] who estimated the energy change involved in the phase transition of long chain urea monolayers. From the thermodynamical equation, $\Delta H=\Delta E+\pi\Delta A$, the net change in molar internal energy accompanying the transition, $\Delta E=-17.1\pm 0.3$ kJ mol^{-1} was obtained. The value is negative, indicating an energy generation during the transition from the expanded film to the condensed film. The observed value of ΔE is the sum of the energy for breaking hydrogen bonds between the hydroxyl groups on the bent chains and the water molecules, and the cohesional energy between close-packed steeply-oriented straight chains. It is interesting to investigate whether or not the cohesional energy includes hydrogen bond formation energy between the hydroxyl groups on the straight chains, in addition to van der Waals energy between the methylene groups. This will be described in the following section.

Hydrogen Bonding in Monolayers: As shown in Fig. 1, the π-A curve in the condensed film of (R)-12HOA resembles closely that of octadecanoic acid. However, differences were seen for the apparent viscosity and the collapse pressure. The condensed film of (R)-12HOA was very viscous, as compared with that of octadecanoic acid. This fact was found by blowing talc powder sprinkled on the film surface. The collapse pressure (the maximum pressure attainable) was 35 mN m^{-1} for (R)-12HOA and 42 mN m^{-1} for octadecanoic acid. These differences should be undoubtedly attributed to some effect of the hydroxyl groups on the formation of the condensed films. In bulk also, the effect of the hydroxyl groups is clearly observed; the melting point is 10 K higher for (R)-12HOA (353.6 K) than for octadecanoic acid (343.6 K).

The role of the hydroxyl groups in the molecular cohesion was investigated by measuring infrared spectra for (R)-12HOA in various states. Figure 4 shows the hydroxyl bands due to the stretching vibrations accompanied by bands due to the vibrations of the methylene and methyl groups. Two sharp bands at 3190 and 3290 cm^{-1} due to the hydrogen bonded hydroxyl

groups[10] are found for the crystalline powder. The spectral appearance is very similar to that of crystalline methanol,[11] in which infinite zigzag chains of hydrogen bonds are formed.[12]

On the other hand, it is particularly noteworthy that solutions of (R)-12HOA in carbon tetrachloride or aromatic solvents form jellies above a certain concentration, while octadecanoic acid separates out as crystals from the saturated solutions in the same solvents. An isotropic solution of (R)-12HOA in carbon tetrachloride exhibited the absorption bands at 3640 and 3550 cm^{-1} due to the free hydroxyl groups and the free carboxyl groups, respectively, in addition to the absorption bands at 3190 and 3290 cm^{-1} due to the hydrogen bonded hydroxyl groups. When concentration was above 0.4 percent (w/v) at 25 °C, the solutions became jellies which gave only the hydroxyl bands at 3190 and 3290 cm^{-1}. This result indicates that the jelly is held by molecular association due to intermolecular hydrogen bonding in which almost all the hydroxyl groups are taking part. Evidently, hydrogen bonding plays a prominent role in determining the intermolecular properties of (R)-12HOA in bulk.

Infrared spectra were measured also for the collapsed films obtained out of the interface, and for the built-up films transferred to a calcium fluoride plate from the condensed film at a pressure of 16 mN m^{-1} on a 0.01 M hydrochloric acid substrate by using the Blodgett technique.[13] Both the collapsed films and the built-up films gave almost the same hydroxyl absorption characteristics as did the crystals. The spectral results suggest that molecular association in the condensed monolayers at the water surface also involves intermolecular hydrogen bonding in a similar manner to that in the condensed states in bulk.

Comparison between the Chiral and Racemic Forms.

The Bulk States: Before the monolayer behavior of the chiral form is compared with that of the racemic

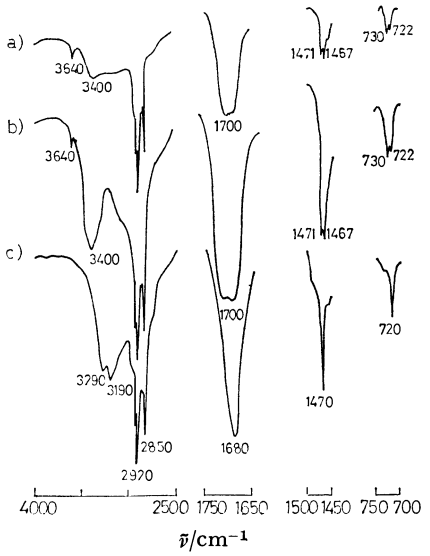

Fig. 5. IR spectra of (a) collapsed film of *dl*-12HOA, (b) crystalline powder of *dl*-12HOA, and (c) that of (*R*)-12HOA in hexachlorobutadiene mull. KBr disk method sometimes gave the spectra without 3640 cm^{-1} band of *dl*-12HOA.

form, it is necessary to elucidate differences between the two forms in the bulk behavior. The phase diagram of the *R*–*S* system for 12HOA was reported by Uzu and Sugiura,[14] who provided evidence that the *R*- and *S*-acids form a racemic compound in the crystalline state. The infrared spectra of the chiral and racemic forms in the crystalline state in Fig. 5 exhibited a difference in the absorption due to the hydroxyl groups; the *dl*-acid exhibited an absorption band at 3640 cm^{-1} due to the free hydroxyl groups in addition to that at 3400 cm^{-1} due to the hydrogen bonded hydroxyl groups, whereas the *R*-acid had no absorption band due to the free hydroxyl groups. This result revealed that appreciable numbers of free hydroxyl groups exist in the crystalline state of the racemic form, in contrast with that of the chiral form.

Furthermore, a difference was found for the location of the hydrogen-bonded hydroxyl bands; they shifted to lower frequencies for the *R*-acid than for the *dl*-acid. As is well known, the hydrogen-bonded hydroxyl band shifts to lower frequency when the hydroxyl groups form multiple hydrogen bonding. For exapmle, such a result was presented for methanol by Thiel *et al.*[15] Therefore, the present spectral results led to the following interpretations as to the arrangement of 12HOA molecules in the crystalline state.

(i) The *R*-acid molecules are favorably located in such a way that their hydroxyl groups link them by multiple hydrogen bonding, forming long sequences of hydrogen bonds.

(ii) The *dl*-acid forms a racemic compound, and the resulting steric hindrance prevents participation of all the hydroxyl groups in the formation of hydrogen bonds, leaving free a part of the hydroxyl groups and making impossible the development of the hydrogen bond sequences.

The *R*-acid sets, as described already, to a jelly in carbon tetrachloride solution above a certain concentration, whereas the *dl*-acid separates out as crystals of a racemic compound from carbon tetrachloride solution. This fact also would be explained by a difference in the mode of the hydrogen bonding between the *R*-acid and the *dl*-acid, since it is well known that a gel is composed of a network structure of polymer chains in which the solvent is trapped. The *dl*-acid behaves like octadecanoic acid in carbon tetrachloride solution in the point that both acids separate out as crystals and do not form jellies.

The miscibility of the chiral form and the racemic form with octadecanoic acid also shows a difference of the *R*-acid from the *dl*-acid in cohesional property. This was found by examining X-ray diffraction patterns for powder specimens which were prepared by fusing the *R*-acid or the *dl*-acid with octadecanoic acid. Figure 6 illustrates the typical patterns for the binary systems. It is seen from the results that the *dl*-acid forms a series of solid solutions with octadecanoic acid in a range of up to 25 mole percent of the latter, while the *R*-acid forms no solid solution with octadecanoic acid. Here again one finds a similarity of the *dl*-acid to octadecanoic acid in cohesional property. Probably, in the *R*-acid–octadecanoic acid system, formation of the solid solution is prevented by strong cohesion between the *R*-acid molecules due to the formation of the hydrogen bond sequences.

The Monolayer States: The isotherms for the *S*-acid, as one expects, agreed quite well with those of the *R*-acid. The π-*A* and μ-A isotherms for the *dl*-acid were essentially similar to those for the enantiomers, except that the *dl*-acid exhibited higher plateau pressures than did the enantiomers at the same temper-

○, (*R*)-12HOA; ●, (*S*)-12HOA; ◫, *dl*-12HOA.

atures. The temperature dependence of the plateau pressure revealed the difference more clearly, as seen in Fig. 7. The value of ΔE was -14.0 ± 0.3 kJ mol^{-1} for the *dl*-acid, compared with -17.1 ± 0.3 kJ mol^{-1} for the *R*-acid. Since there is no reason to believe that the chiral and racemic forms exhibit a difference in the energy which is involved when the film molecules change their conformations from the bent chain to the straight chain, detaching the hydroxyl groups from the interface, the difference of ΔE observed may be taken as that of the cohesional energy for formation of the condensed film from the expanded film. Thus, it can be seen that the condensed film of the *R*-acid is thermodynamically more stable than that of the *dl*-acid. This is consistent with the observation that the plateau pressure (*i.e.* the phase transition pressure) at the same temperature is lower for the *R*-acid than for the *dl*-acid. On the other hand, the chiral form (mp 353.6 K) has a higher melting point than the racemic form (mp 352.3 K), *i.e.*, in the crystalline state, the former has stronger cohesion than the latter. The similarity of the *dl*-acid to octadecanoic acid observed in bulk was found also for their monolayer behavior; addition of 10 mole percent of octadecanoic acid led to a pressure rise of 0.7 mN m^{-1} for the plateau pressure of the *R*-acid, while little rise was found for that of the *dl*-acid. On the basis of these facts, it is supposed that the condensed films of the *R*-acid and the *dl*-acid respectively have structures corresponding to those in bulk. Thus there is a possibility that a racemic compound of the *dl*-acid is formed in the condensed monolayer state as well as in the crystalline state. In order to investigate this problem, infrared spectral observations were made on collapsed films removed from the compressed monolayer of the *dl*-acid. The same spectra as those for the crystalline powder were obtained, as shown in Fig. 5.[16] This is taken as evidence that a racemic compound is formed in the condensed monolayers at the air–water interface. At the same time, presumably free hydroxyl groups are present in the monolayer as well as in the crystals. This explains the weaker cohesion in the monolayer of the *dl*-acid than in that of the *R*-acid.

The condensed monolayer states of the *R*-acid and the *dl*-acid respectively were examined by using two-dimensional packing models of molecules. The models demonstrate that: (i), the *R*-acid molecules are capable of forming multiple hydrogen bonds which leads to long sequences of hydrogen bonds, and (ii), when the *dl*-acid forms a racemic compound with simultaneous formation of intermolecular hydrogen bonds between *R*- and *S*-acid molecules, steric hindrance imposes restraint on the formation of multiple hydrogen bonds through the *dl*-acid molecular compounds and leaves some of the hydroxyl groups free. The details will be described in the Appendix. These models explain satisfactorily the differences between the *R*-acid and the *dl*-acid not only in the monolayer state, but also in the crystalline state, because X-ray diffraction studies showed that the crystals of both the *R*-acid and the *dl*-acid are composed of layer structures.

Electron Microscope Observation. It has been found by electron microscope observation that, when 12HOA is crystallized out from solution, the enantiomer produces helically twisted fibers, the helical sense of which is left-handed for the *R*-acid and right-handed for the *S*-acid, and that the racemic *dl*-acid separates as crystals in the form of flat platelets.[4] To study whether or not similar structures are also found for collapsed fragments of the monolayer, the monolayers were compressed continuously to a certain area at a rate of 18 Å^2 molecule^{-1} h^{-1} and immediately thereafter they were transferred to collodion supports by using the horizontal lifting method.[17] Prior to the transfer, the surface of the support had been treated with a dilute aqueous solution of Aerosol OT. This treatment made the surface hydrophilic and facilitated adhesion of the film samples to the support. Collapse structures were found to appear when the films were compressed below 21 Å^2 molecule^{-1}. Figure 8 shows electron micrographs at an apparent area of 16 Å^2 moleucle^{-1}. The micrographs for the enantiomers show twisted fibers around 800 Å in width, in addition to flat planer structures, which have been observed in the monolayer collapse of long chain fatty acids.[18] Twisting seems to occur when collapse structures are very thin ribbon-like fibers. Special attention was paid to the twisted fibers, which are characteristic of the hydroxy acid. The sense of twist is left-handed for the *R*-acid and right-handed for the *S*-acid. This chiral relationship is quite the same as that observed for the twisted fibers separated from solution. Rapid compression to areas smaller than the collapse point yielded no twisted fibers but flat structures and amorphous molecular aggregates. The twisted fibers observed here seem to result from a slow collapse process, as described by Neuman.[19]

The *dl*-acid produced not fibers but platelets, as shown in Fig. 8(c), from the monolayer as well as from solution. By comparing this result with the phase diagram of the *R*–*S* system,[14] it is reasonable to consider that the platelets are composed of a racemic molecular compound which appears in the bulk crystalline solid. Presumably the two enantiomers exist in a merely stoichiometric mixture in the monolayer at large areas

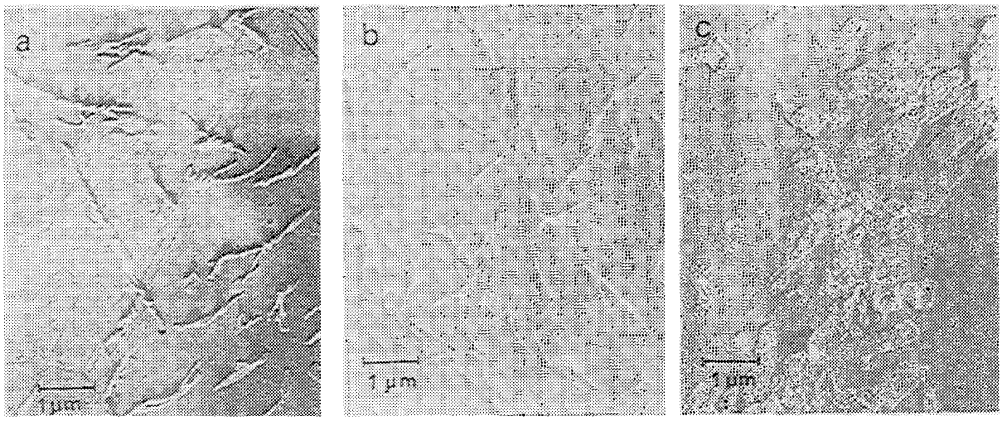

Fig. 8. Electron micrographs of collasped films of 12HOA.

These photographs were made to show the same sense as that of the twist in the specimen.

as in the bulk liquid phase,[14] but form a racemic molecular compound during compression of the plateau region in the isotherm.

Summarizing these results, the present studies lead us to conclude that the enantiomeric mixture forms a racemic compound in the condensed monolayer state, as realized in the crystalline solid.

Appendix

Molecular Packing in Condensed Monolayers of 12HOA.
In considering the molecular packing in the condensed monolayers, the arrangement of both the carboxyl groups and the hydrogen-bonded hydroxyl groups should be taken into account at the same time. It seems reasonable to consider the packing models with reference to the bulk crystalline data, since a relationship between molecular packing in monolayer states and bulk phase structures has been recently found for long chain fatty acids[20] and phospholipids.[21] It was also found for cholesterol that the polymorphic crystalline transition was reflected in the temperature dependence of the equilibrium spreading pressure.[22] For 12HOA, the present studies revealed that various properties in the bulk crystalline phases are retained in the monolayer states. This fact implies that the monolayer structure is closely related to the crystal structure.

X-Ray analyses for single crystals of 12HOA have not been carried out on account of the difficulty of obtaining appropriate single crystals. However, the powder X-ray diffraction patterns and the infrared spectral results give considerable information about the crystal lattice, particularly for the subcell introduced by Vand[23] for packing of long hydrocarbon chains in unit cells. Powder X-ray diffraction patterns showed that side spacings of the *R*-acid and the *dl*-acid were quite different and that, therefore, the two acids belonged to different packing modes. Infrared absorption spectra for the CH_2 vibration of hydrocarbon chains showed that the splittings for CH_2 scissoring (at about 1470 cm^{-1}) and CH_2 rocking (at about 720 cm^{-1}) vibrations were found for the *dl*-acid crystals, but not for the *R*-acid (Fig. 5). If this result leads to the same relationship as that between the type of subcell and the CH_2 vibration spectra established for normal paraffins[24] and for octadecanoic acid,[25] it seems reasonable to assume that: the *R*-acid belongs to triclinic subcell, as does the A-form of octadecanoic acid; the *dl*-acid belongs to the orthorhombic subcell, as do the B- and C-forms of octadecanoic acid; and the hydrocarbon chains are, in respective cases, packed in each subcell. The main difference between the two packing modes is that every second chain plane is almost perpendicular to its neighbors in the orthorhombic subcell, while all chain planes are parallel to one another in the triclinic subcell.

The long spacing was obtained to be 46.7 Å for the *R*-acid and 43.8 Å (lit,[26] 44.3 Å) for the *dl*-acid. The latter value is close to that for the B-form of octadecanoic acid (lit,[27] 43.85 Å). Furthermore, it may be mentioned that the acute angle between the edges in rhombic plate-shaped crystallites of the *dl*-acid in Fig. 7(c) is about 70°. The B- and C-forms of octadecanoic acid are known to give rhombic plate-shaped crystals with acute angles of 74°[27] and of 56°,[28] respectively. These facts imply that the crystal structure of the *dl*-acid could be associated with that of the B-form of octadecanoic acid.

In the condensed monolayers at the water surface, molecules are two-dimensionally close-packed with the straight chain oriented steeply to the water surface. In this case, the molecular packing will be discussed with reference to that in the crystalline states described above; the concept of 'subcell' is utilized in order to predict the arrangement of hydrocarbon chains close-packed in the condensed monolayers.

Thus, packing models were constructed as follows.
(i) A projection of a straight chain molecule of the *R*-acid is illustrated in Fig. 9(a), as suggested by Vold.[29] The *S*-acid is a mirror image of it.
(ii) The extent of a carboxyl group attached to an end of the chain is neglected, when hydrocarbon chains are packed in subcells. The assumption that the lateral packing in monolayers is similar to that in the crystals leads to tilting of the chains, which facilitates packing of carboxyl groups.[30]
(iii) A hydrogen atom of a free OH group occupies the range enclosed by a dotted line in Fig. 9(a), because of free rotation of the OH bond around the C–O bond axis. On the other hand, when the chains are linked by hydrogen bonds, two oxygen atoms on the adjacent chains are brought almost into contact and the extent of a hydrogen atom, which is located between the oxygen atoms, can be neglected.
(iv) Units of CH_2CHO (represented by a thick line in Fig. 9(a)) are packed in the above-designated subcells: a triclinic subcell for the *R*-acid and an orthorhombic subcell for the *dl*-acid.

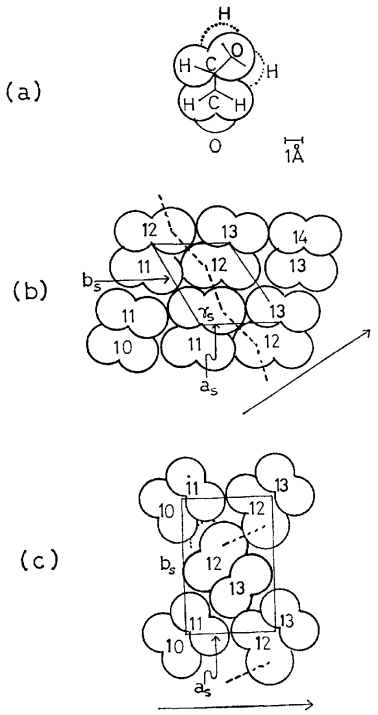

Fig. 9. Molecular models viewed from above.
a) A projection of a straight chain molecule of (*R*)-12HOA on a plane perpendicular to the chain axis; b) proposed packing model for (*R*)-12HOA in the condensed monolayer state; c) proposed packing model for the *dl*-12HOA in the condensed monolayer state. The a_sb_s planes are in the sheet of the paper, to which the molecular axis is perpendicular for *dl*-12HOA, but not for (*R*)-12HOA. The direction of a slope of the water surface is denoted by an arrow for each model.

(v) The OH direction is determined by hydrogen bond formation between adjacent molecules.
The proposed packing models for the *R*-acid and the *dl*-acid in each subcell are shown in Figs. 9(b) and (c), respectively, where the integers mean the carbon numbers on a hydrocarbon chain, and broken lines denote hydrogen bonds.

For the *R*-acid, molecules can be closely packed, with simultaneous formation of hydrogen bond sequences, in the triclinic subcell, whose dimensions (a_s, b_s, and γ_s) are 4.5 Å, 5.4 Å, and 120°. Hydrogen bond formation between adjacent chains in the triclinic subcell makes the adjacent chains shift by one CH_2 unit, as shown by the integers in Fig. 9(b). This avoids the overlapping of OH groups and leads to the tilting of the molecules to the water surface. The tilt angle of the molecules with the normal to the surface, θ, and the close-packing area per molecule in the surface, A_c, are calculated geometrically, assuming the remaining subcell dimensions, c_s, α_s, and β_s, to be 2.6 Å, 70°, and 108°, respectively, which are typical values reported for triclinic subcells.[31] The values of θ and A_c are obtained to be 21° and 24.1 Å^2 molecule^{-1},[32] respectively. The former is in good agreement with that estimated from the long spacing in the crystals, assuming that the bimolecular length is 50 Å.

For the *dl*-acid, molecules are packed in a similar manner to that in the B-form of octadecanoic acid, the structure of which was determined by von Sydow.[27] In this case, the chains in the condensed monolayer are packed in a slightly larger subcell (a_s=5.2 Å, b_s=8.0 Å) than that of octadecanoic acid, avoiding any overlapping of oxygen atoms of the OH groups. The *R*-enantiomer chain and the *S*-enantiomer chain occupy alternate positions in the subcell, forming a racemic compound with an intermolecular hydrogen bond. Steric hindrance leaves another hydrogen atom free; this is represented by a dotted line in Fig. 9(c). This model gives a packing area of 23.3 Å^2 molecule^{-1}, with a tilt angle of 27° with the normal to the surface.

The authors wish to express their thanks to Professor Makoto Hayashi of Chiba University for surface potential measurements. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Effects of Pressure on the Cloud Point of Nonionic Surfactant Solutions and on the Solubilization of Hydrocarbons

Shoji KANESHINA,* Osamu SHIBATA, and Makoto NAKAMURA

College of General Education, Kyushu University-01, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received June 26, 1978)

Cloud points in 1.0 wt % aqueous solutions of penta- and hexa(oxyethylene) dodecyl ether increase monotonously with an increase of pressure up to 150 MPa. The elevation of the cloud-point temperature with pressure was 1.05×10^{-7} and 1.09×10^{-7} K Pa^{-1} for respective surfactant. Both volume and enthalpy changes on the separation of the surfactant-rich phase had the positive values. The rise of cloud points on compression is attributable to the enhancement of the hydrogen bonds formation between water and ether oxygens of the poly(oxyethylene) group and partly to the disruption of the "hydrophobic bonding." The cloud-point temperature at constant pressure and the cloud-point pressure at constant temperature were also examined as a function of the amount of solubilizate such as hexane and octane. There was an optimum pressure at a given temperature, as well as an optimum temperature at a given pressure, at which the solubilizing power of surfactant is maximum.

So far a few studies have been made about the effect of pressure on the properties of surfactant solutions, especially on the critical micelle concentration of ionic surfactants.[1] With respect to the nonionic surfactant, however, the effect of pressure on the cloud point has only been reported by Suzuki and Tsuchiya.[2] They found that the cloud point of aqueous solution of poly(oxyethylene) *p*-nonylphenyl ether had its maximum at about 100—200 MPa.

In this paper some results of the effect of pressure on the cloud point of aqueous poly(oxyethylene) dodecyl ether solutions are presented, and then the pressure dependence of the solubilization will be elucidated from the cloud points in the presence of hydrocarbons. No information on the pressure dependences of the solubilization is available in the literature.

Experimental

Penta(oxyethylene) dodecyl ether and hexa(oxyethylene) dodecyl ether (Tokyo Kasei Kogyo Co., Ltd.,) were used without further purification. The cloud points in 1.0 wt % aqueous solution of respective surfactant were 23.5 and 48.1 °C. Hexane and octane used as solubilizate were extra-pure grade.

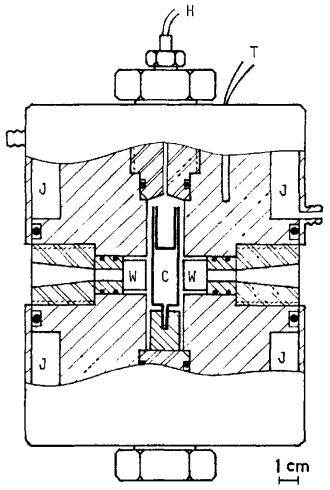

Fig. 1. Schematic diagram of the high pressure vessel equipped with optical windows. C: Syringe cell with Teflon cap in which the solution is filled, H: pressure tubing with which the pressure pump and gauge are connected, J: water jacket, T: thermocouple, W: quartz window. The pressure was sealed by means of an O-ring with a back-up ring of Teflon.

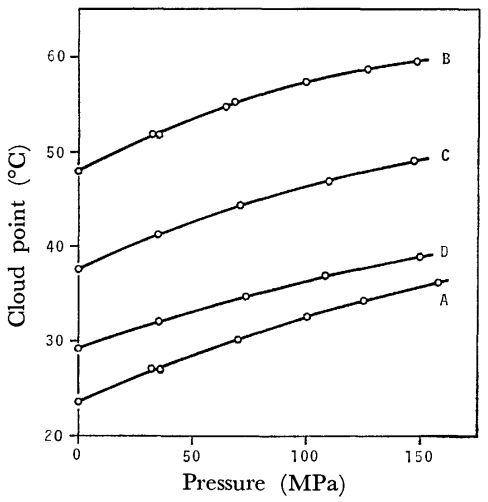
The cloud points under high pressure were determined by using the high pressure vessel with optical windows, which is shown schematically in Fig. 1. The high pressure vessel was made of stainless steel with 140 mm o.d., 20 mm i.d., and 180 mm hight. The solutions were heated or cooled slowly (0.1 °C per minute) by circulation of temperature-controlled water to the jacket. The temperature of the system was determined by the thermocouple attached to the pressure vessel. Pressures were generated by means of a screw- and hand-pump (Hikari Kikai Co.,) and measured within an accuracy of ±0.2 MPa by means of a Heise pressure gauge. Ligroin was used as pressure transmitting medium. The cloud points were decided by observing the appearence and disappearence of turbidity during the cource of heating and cooling at a given pressure. Measurements of the transmittance at 540 nm were performed with a Hitachi 139 spectrophotometer. The difference between the cloud points determined on heating and on cooling were within 1 °C.

Results and Discussion

Effect of Pressure on the Cloud Point. The cloud points in 1.0 wt % aqueous solution of nonionic surfactants are shown in Fig. 2 as a function of pressure. The cloud points for all the surfactant solutions increase monotonously with an increase of pressure up to 150 MPa. This elevation of cloud points on compression is within that caused by an increase of one oxyethylene unit in the poly(oxyethylene) chain. In other words, the alteration in the hydrophilic-lipophilic balance (HLB) of the surfactant by the compression up to 150 MPa seems to be less than that by the addition of one oxyethylene group in the poly(oxyethylene) chain. It is clear from Fig. 2 that the pressure up to 150 MPa is favorable for the dissolution of surfactant molecules in water although most of dissolved-surfactant molecules are in the micellar state. The cloud point for aqueous solutions of surfactants is generally taken to be the point where separation of the surfactant-rich phase is casued by the dehydration of ether oxygens of the poly(oxyethylene) group. Le Chatelier's principle brings about the positive volume change on separation of the sur-



Eig. 2. Effect of pressure on the cloud point of nonionic surfactant solutions. Curve A: 1.00 wt % penta(oxyethylene) dodecyl ether solution, B: 1.00 wt % hexa(oxyethylene) dodecyl ether solution, C: 1.02 wt % hexa(oxyethylene) dodecyl ether solution containing hexane of 2.42 g/kg H_2O, D: 1.02 wt % hexa(oxyethylene) dodecyl ether containing hexane of 4.26 g/kg H_2O.

factant-rich phase. From data of apparent molal volumes of nonionic surfactants and polyethylene glycol(PEG) oligomers with various lengths of poly(oxyethylene) chain the apparent molal volume assigned for one oxyethylene group can be calculated. The values assigned for the group are 37.1 cm^3/mol for surfactant in micellar state[3] and 36.9 cm^3/mol for PEG,[4] which are found to be apparently smaller than the molal volume assigned for an oxyethylene unit in the state of pure liquids, 38.9—39.1 cm^3/mol.[4,5] That is, the volume change on formation of hydrogen-bonds between water and ether oxygens of the poly(oxyethylene) group is negative, and the increase of pressure enhances the formation of hydrogen bonds.

In the two-component, two-phase system, the Clausius-Clapeyron type equation is written as follows:[6]

$$\left(\frac{\partial T}{\partial P}\right)_{x_2} = \frac{T(y_1\Delta\bar{v}_1+y_2\Delta\bar{v}_2)}{y_1\Delta\bar{h}_1+y_2\Delta\bar{h}_2}, \quad (1)$$

where subscripts 1 and 2 refer to components 1 and 2, x and y the mole fraction in the phase α and β, respectively. $\Delta\bar{h}$ and $\Delta\bar{v}$ are the change of partial molal enthalpy and volume, respectively, on the transfer from phase α to β. In the present system, we choose surfactant as component 2 and the micellar solution as the phase α. Assuming $y_1 \ll y_2$,

$$\left(\frac{\partial T}{\partial P}\right)_{x_2} = \frac{T\Delta\bar{v}_2}{\Delta\bar{h}_2}. \quad (2)$$

As is seen from Fig. 2, $(\partial T/\partial P)_{x_2}$ is positive. That is, $\Delta\bar{h}_2$ and $\Delta\bar{v}_2$ have the same sign. The dehydration of the poly(oxyethylene) chain, *i.e.*, the hydrogen bond breaking contributes to the positive change in both $\Delta\bar{h}_2$ and $\Delta\bar{v}_2$. Further, the positive volume change is also caused by the elimination of hydrocarbon–water contact. This "hydrophobic bonding" also brings about the positive contribution to $\Delta\bar{h}_2$ because of the breakdown of ice-like structure around the hydrocarbon chain. Therefore, the rise of cloud points on compression is attributable to the enhancement of the hydrogen bonds formation and partly to the disruption of the hydrophobic bonding.

The values of $(\partial T/\partial P)_{x_2}$ are $1.05(\pm0.05)\times10^{-7}$ K Pa^{-1} for penta(oxyethylene) dodecyl ether and $1.09(\pm0.03)\times10^{-7}$ K Pa^{-1} for hexa(oxyethylene)dodecyl ether. The value for poly(oxyethylene) *p*-nonylphenyl ether is found to be $(0.8—1.3)\times10^{-7}$ K Pa^{-1} for the various compositions.[2] Assuming that the hydrophillic-lipophilic property of surfactant balances at the cloud point, the pressure of about 10 MPa is required for the temperature rise of 1 °C to keep the original HLB.

Effect of Solubilizate on the Cloud Point. The cloud points in the presence of solubilizate as hexane and octane increase monotonously with an increase of pressure. Some results are included in Fig. 2.

In Fig. 3, the cloud-point temperatures of the solutions containing 1.0 wt % hexa(oxyethylene) dodecyl ether at constant pressure are shown as a function of the amount of solubilized hexane. The solubilization end points, below which the excess hydrocarbon separates from micellar solution, are also shown only at an atmospheric pressure. As is seen from Fig. 3, the region between the cloud-point temperature isobar and solubilization curve is a homogeneous transparent phase. According to Shinoda,[7] in the region (denoted by II_{W-D}) above the cloud-point temeperature isobar the nonionic surfactant phase containing oil separates. On the other hand, the excess oil separates in the II_{W-O} region below the solubilization curve. In Fig. 4, the cloud-point temperatures of the system with solubilized octane are shown as a function of the amount of octane. The pattern of isobars is analogous in both the systems; namely, the isobars are shifted to higher

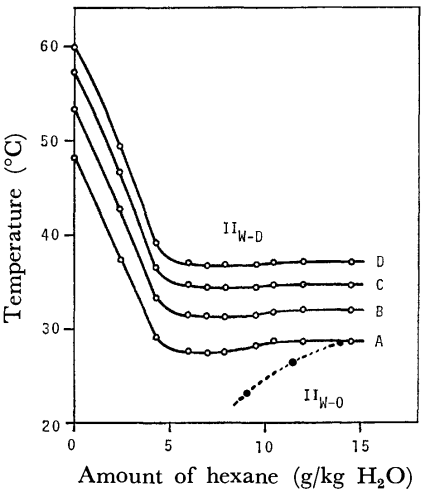


Fig. 3. The cloud-point temperature as a function of the amount of hexane solubilized at 0.1 MPa (curve A), 50 MPa (B), 100 MPa (C), and 150 MPa (D). The solubilization end points (●) are also shown only at an atmospheric pressure.

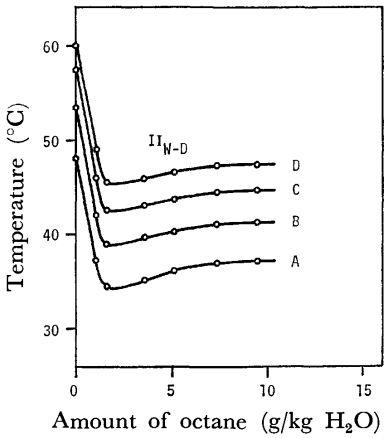

Fig. 4. The cloud-point temperature as a function of the amount of octane solubilized at 0.1 MPa (curve A), 50 MPa (B), 100 MPa (C), and 150 MPa (D).

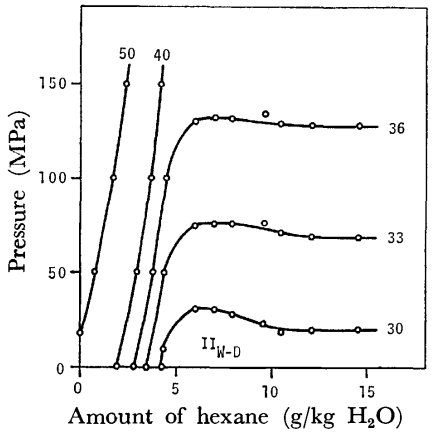

Fig. 5. The could-point pressure as a function of the amount of hexane solubilized. Numerical values refer to the temperature in °C.

temperature as the pressure increases. The cloud-point temperature is initially depressed by the addition of solubilizate and then approaches a definite temperature *via* a minimum. At the definite temperature the solubilizing power of surfactant becomes maximum. The compression up to 100 MPa elevates the optimum temperature by 6.0 and 7.6 °C for the systems with solubilized hexane and octane, respectively.

The cloud-point pressure of the solutions containing 1.0 wt % hexa(oxyethylene) dodecyl ether at constant temperature are shown in Figs. 5 and 6 as a function of the amount of solubilized hexane and octane, respectively. The cloud-point pressure isotherms for all the systems with solubilized hexane and octane are similar; the higher the pressure, the larger the area of homogeneous phase. The cloud-point pressure of the solution containing solubilized hexane more than 6 g/kg H_2O is little affected by the additional

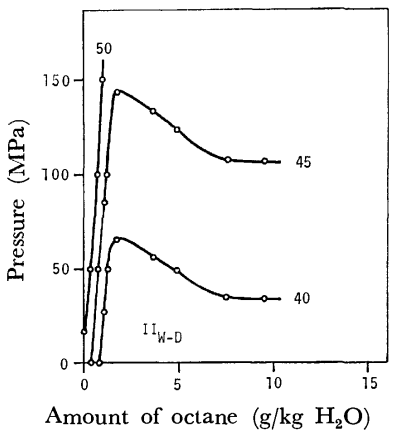

Fig. 6. The cloud-point pressure as a function of the amount of octane solubilized. Numerical values refer to the temperature in °C.

solubilization of hexane. That is, there is the optimum pressure for the maximum solubilization at a given temperature. The solubilizing power of surfactant becomes maximum at a slightly higher pressure than the pressure in the plateau region of isotherms. Also in the system with solubilized octane, there is an optimum pressure for the solubilization. The higher the temperature, the higher the optimum pressure in both systems.

The authors wish to thank Professor R. Matuura of the Department of Chemistry, Kyushu University, for useful discussion in the preparation of the manuscript.

Dimer and Excimer Fluorescence Spectra of Highly Polar Molecules, 3,5-Dialkyl-4-methoxybenzylidenemalononitrile

Kenji INOUE and Michiya ITOH*

Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920

(Received June 30, 1978)

Dual fluorescence of the ground state dimer of highly polar molecules of 3,5-dialkyl-4-methoxybenzylidenemalononitrile in 3-methylpentane solution at low temperature was investigated by steady-state and nonsecond fluorescence spectroscopies. The dimerization of these compounds was confirmed by concentration dependence of absorption and fluorescence spectra at 77 K. The dimer exhibits dual fluorescence consisting of a short-lived dimer fluorescence and a long-lived excimer fluorescence, while the monomer is almost non-fluorescent at room temperature to 77 K. The excimer formation by an orientational relaxation from the excited state of the dimer was discussed in terms of determination of the activation barrier and the fluorescence polarization.

Dual fluorescence of a highly polar molecule, *p*-dimethylaminobenzonitrile (MABN), was identified by Lippert[1] as arising from two different excited states in polar solvent. However, Rotkiewicz *et al.*[2] suggested that the dual fluorescence arose from states with the same fluorescence polarization, and that the two emitting states differed in the orientation of the dimethyl amino group with respect to the benzene ring. On the other hand, McGlynn and coworkers[3] reported that the dual fluorescence of this compound was identified as arising from a ground state dimer in a number of different solvents and suggested that the dual fluorescence consisted of the dimer and an excimer. However, Nakashima and Mataga[4] claimed that the dimer and the excimer assignment could not be correct by their concentration dependence of fluorescence spectra.

Very recently, Itoh *et al.*[5] reported dual fluorescence of a ground state dimer of a highly polar molecule, 3,5-dialkyl-4-hydroxybenzylidenemalononitrile (dialkyl-HO-BMN), in 3-methylpentane (MP) solution at low temperature. The dual fluorescence was ascribed to the short-lived dimer and to the long-lived excited species generated by the duoble proton transfer reaction in the excited state of the dimer. The excited-state proton transfer of 3,5-di-*t*-butyl-4-hydroxybenzylidenemalononitrile (*t*-Bu_2-HO-BMN) in the solid state was also reported.[6]

This paper describes the dimer formation of several dialkyl-4-methoxybenzylidenemalononitrile (dialkyl-MO-BMN) in the ground state in MP solution at low temperature, and dual fluorescence consisting a short-lived dimer fluorescence and a long-lived excimer one by the steady-state and nanosecond (ns) fluorescence spectroscopies. The structure of the dimer is proposed to be a sandwich type dimer with a center of symmetry by taking account of a crystal structure of *t*-Bu_2-HO-BMN.[6] The excimer seems to be generated by an orientational relaxation in the excited state of the dimer. The dimer and excimer fluorescence spectra are discussed in terms of an activation barrier and fluorescence polarization at low temperature.

Experimental

Materials. The preparation of the model compounds are as follows. The products were purified by colum chromatography and recrystallizations, and chracterized by IR and NMR.

4-Methoxybenzylidenemalononitrile (MO-BMN) was prepared from 4-methoxybenzaldehyde with malonitrile in benzene solution containing small amount of acetic acid and piperidine.[7] The product was recrystallized from benzene-hexane: Mp 113—116 °C.

Found: C, 71.90; H, 4.20; N, 15.09%. Calcd for $C_{11}H_8N_2O$: C, 71.74; H, 4.35; N, 15.21%.

3,5-Dimethyl-4-methoxybenzylidenemalononitrile (Me_2-MO-BMN) was prepared from 3,5-dimethyl-4-methoxybenzaldehyde by the same manner as described above. The product was recrystallized from benzene-hexane: Mp 120—122 °C.

Found: C, 73.78; H, 5.66; N, 13.01%. Calcd for $C_{13}H_{12}N_2O$: C, 73.58: H, 5.66: N, 13.20%.

3,5-Di-isopropyl-4-methoxybenzylidenemalononitrie (*i*-Pr_2-MO-BMN) was prepared by the same manner as described above. Though the product is noncrystalline syrup, the compound was identified by NMR and IR.

Measurements. Determination of the fluorescence and absorption spectra, and fluorescence polarization were described previously.[8,9] Fluorescence lifetimes and time-resolved fluorescence were determined by analysing exponential decay curves measured by an oscilloscope and by a coaxial N_2 gas-laser excitation. The decay curve was analyzed by a deconvolution method using a computer.[10]

Results and Discussion

Dimer Formation in the Ground State. The MP solution of 4-methoxybenzylidenemalononitrile (MO-BMN) shows an absorption band in the 330—360 nm region at room temperature, which shows considerable red-shift (*ca.* 10—20 nm) at low temperature (<150 K), as shown in Fig. 1. Figure 2 shows concentration dependence of absorption spectra of MP solutions of MO-BMN at 77 K. Here, a monomer dimer equilibrium of this compound in MP solution is assumed, and an association constant (K) can be written as follows:[2]

$$K = [D]/([C]-2[D]),$$

where [C] and [D] are concentrations of MO-BMN and dimer. If an absorption band at 390 nm is due almost exclusively to the dimer, an absorbance [A] at 390 nm is expressed as $A=\varepsilon[D]l$, where ε is a molar extinction coefficient of the dimer at this wavelength. The following equation is obtained:[11]

$$[C]/A = 2/\varepsilon + (1/\varepsilon K)^{1/2}(1/A)^{1/2}.$$

Fig. 1. An MP solution of MO-BMN exhibits a strong green fluorescence at 77 K as shown in Fig. 1, while the solution is almost non-fluorescent at room temperature. MP solutions of 3,5-dimethyl- and 3,5-di-isopropyl-4-methoxybenzylidenemalononitrile (Me_2-MO-BMN and *i*-Pr_2-MO-BMN) also show strong fluorescence at 77 K as shown in Fig. 1. However, an MTHF solution of dialkyl-MO-BMN exhibits no significant temperature dependence of fluorescence and absorption spectra. The green fluorescence in the MP solution markedly increases in intensity with increasing concentration of MO-BMN, but the fluorescence due to the monomer does not seem to exhibit even in the dilute solution, as shown in Fig. 3. Since intensity (I) of the green fluorescence may be proportional to the concentration of the dimer [D], the following equation is obtained for the monomer dimer equilibrium;

$$[C]/I = 2/q + (1/qK)^{1/2}(1/I)^{1/2},$$

where q is a constant including several experimental factors. Plots of $[C]/A$ and $[C]/I$ exhibit linear relationship *vs.* $(1/A)^{1/2}$ and $(1/I)^{1/2}$, respectively, as shown in Figs. 2 and 3. Two straight lines confirm an assumption of the monomer dimer equilibrium, and

Table 1. Equilibrium constants (K) for the dimerization of dialkyl-MO-BMN in MP at 77 K, and fluorescence properties of the dimer (D*) and the excimer (E*), and their activation energy (E_a)

	K (M^{-1})	λ_{max} (nm) and lifetimes (ns) in bracket		E_a (kcal M^{-1})

afford equilibrium constants; $K=1.6\times10^5\ M^{-1}$ from absorption spectra and $1.5\times10^5\ M^{-1}$ from fluorescence spectra. Concentration dependence of the absorption spectra of the other alkyl-MO-BMN in MP solution also shows the dimer formation at 77 K, whose K are summarized in Table 1.

Excimer Fluorescence. Nanosecond time-resolved fluorescence spectra of an MP solution of MO-BMN at 77 K shown in Fig. 4 demonstrate that the fluorescence consists of two fluorescence spectra; a short-lived fluorescence (λ_{max} 480—490 nm, $\tau=4$ ns) and a long-lived one (λ_{max} 500 nm, $\tau=21$ ns). The dual fluorescence of the dimer was also observed in the other dialkyl-MO-BMN. Figure 4 shows a fluorescence decay curve of an MP solution of MO-BMN at 77 K in comparison with a computer simulated one. Table 1 summarizes the fluorescence maxima and lifetimes in the dimers of these compounds at 77 K. The excitation spectra of the short-lived fluorescence and the long-lived one are identical each other, and are

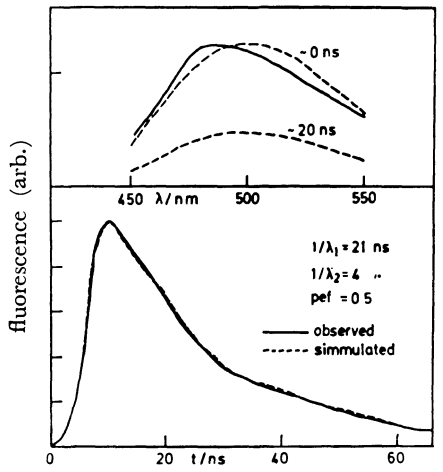

Fig. 4. Time-resolved fluorescence spectra of the MP solution of MO-BMN (3.9×10^{-5} M) at 77 K. A fluorescence decay curve monitored at 490 mn, and a simulated one; (——) and (----) are time-resolved spectra of a short-lived and a long-lived components depicted on the obtained time constants and pre-exponential factor (pef). Time indicated in the time-resolved spectra is virtually after a signal maximum of the fluorescence.

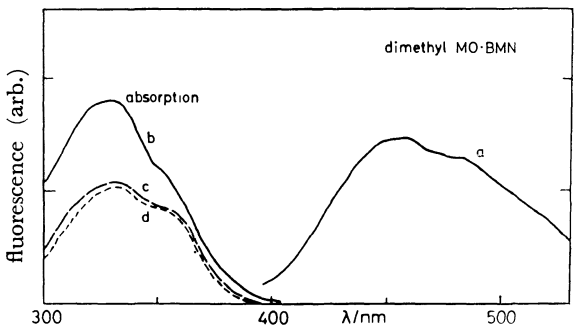

Fig. 5. Fluorescence (a) and absorption (b) spectra of an MP solution of Me_2-MO-BMN (5.1×10^{-5} M) at 77 K; fluorescence excitation spectra (c) monitored at 420 nm and (d) at 520 nm.

corresponding to the dimer absorption spectra (Fig. 5). Taking account of a large Stokes shift of the long-lived fluorescence, the fluorescence may be ascribed to the excited species (E*) generated from the excited state of the MO-BMN dimer (D*), while the short-lived one to the dimer (D*).

The photochemical reaction scheme is as follows:

$$\begin{array}{ccccc} & & h\nu & & k_3 \\ & & & & \\ D & \longrightarrow & D^* & \rightleftharpoons & E^* \\ & & & & k_4 \\ & & \swarrow^{k_1} \quad \downarrow^{k_2} & & \swarrow^{k_5} \quad \searrow^{k_6} \\ & & D+h\nu' \quad D & & D+h\nu'' \quad D \end{array}$$

Time dependent concentrations of D* and E* are expressed by the following well known equations:[12,13]

$$[D^*] = C_1 \exp(-\lambda_1 t) + C_2 \exp(-\lambda_2 t), \quad (1)$$

$$[E^*] = C_3 \exp(-\lambda_1 t) - C_3 \exp(-\lambda_2 t), \quad (2)$$

$$\lambda_1, \lambda_2 = 1/2[k_1+k_2+k_3+k_4+k_5+k_6 \mp (\{k_1+k_2+k_3 - (k_4+k_5+k_6)\}^2+4k_3k_4)^{1/2}].$$

Here, if $k_3 \gg k_4 \approx 0$, [D*] may be approximately represented by the second term of Eq. 1. The fluorescence lifetimes of D* and E* are expressed as follows:

$$\tau_D = \lambda_2^{-1} = (k_1+k_2+k_3)^{-1},$$

$$\tau_E = \lambda_1^{-1} = (k_5+k_6)^{-1}.$$

Since two fluorescence decay curves of D* and E* at a certain wavelength overlap each other, actual decay curves at several wavelengths were analyzed by the following equation:

$$[D^*] + [E^*] \propto \exp(-\lambda_1 t) + \frac{C_2-C_3}{C_3} \exp(-\lambda_2 t).$$

Fluorescence lifetimes of D* and E* of an MP solution of MO-BMN at 77 K were determined to be 4 ns and 21 ns, respectively, by computer simmulation mentioned above. Unfortunately, the fluorescence rise of E* was not detectable, because the D* fluorescence overlaps on the decay curve of E*.

Fluorescence spectra of an MP solution of *i*-Pr_2-MO-BMN at several temperatures shown in Fig. 6 reveal remarkable decrease of the short-lived fluorescence with increasing temperature (77 to 130 K). Since no significant shift of the monomer dimer equilib-

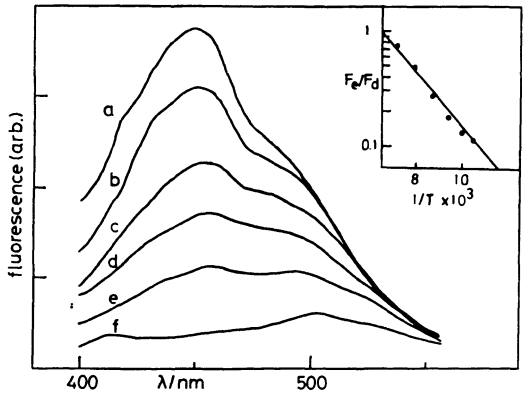

Fig. 6. Temperature dependence of fluorescence spectra of an MP solution of *i*-Pr_2-MO-BMN (3×10^{-5} M); a) 100 K; b) 108 K; c) 115 K; d) 120 K; e) 125 K; f) 132 K.

rium was detected in this temperature region, and since no monomer fluorescence was detected, the remarkable temperature dependence may be attributable to a dynamic process between D* and E* requiring a small amount of activation energy. From the fluorescence spectra shown in Fig. 6, the activation energy can be obtained to be 1.1 kcal/mol by the aid of the conventional method and assumption reported previously.[8] The activation energy in the dimer of Me_2-MO-BMN was also obtained to be 0.9 kcal/mol. However, an MP solution of MO-BMN shows no significant temperature dependence of fluorescence spectra which seems to imply a very small amount of activation energy in this photochemical process.

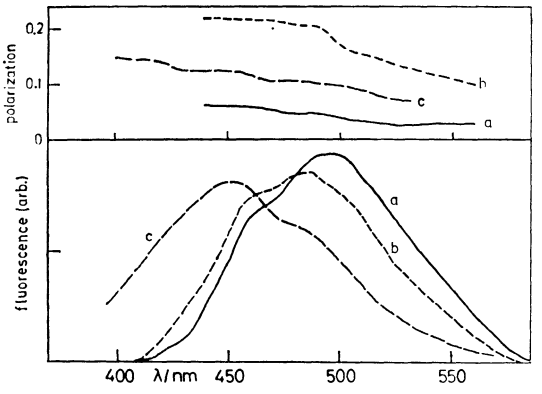

Fig. 7. Fluorescence spectra and their polarizations of MP solutions at 77 K; a) MO-BMN (4.6×10^{-5} M); b) Me_2-MO-BMN (5.9×10^{-5} M); c) i-Pr_2-MO-BMN (6.8×10^{-5} M).

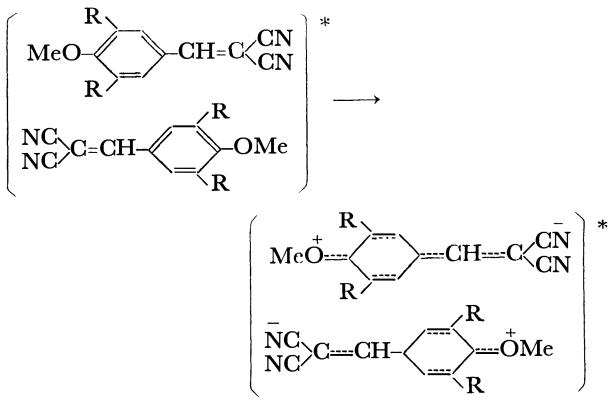
Figure 7 shows the fluorescence polarizations of MP solutions of MO-BMN and dialkyl-MO-BMN at 77 K.[14] The fluorescence polarization were observed to decrease from 0.22 to 0.1 with increasing wavelength in Me_2-MO-BMN. Further, a similar behavior of the polarization was observed in i-Pr_2-MO-BMN, though no significant change of the polarization was detected in MO-BMN. The shorter wavelength (also lifetime) fluorescence and the longer wavelength (also lifetime) one were ascribed to the dimer and the excimer, respectively, as mentioned above. Therefore, the larger and the smaller polarizations may be attributable to the dimer and the excimer. The results indicate that the dimer and excimer fluorescence spectra have considerably different character of electronic transition each other. Since these compounds are highly polar molecules with strong electron donor and acceptor groups, the dimer formation may be attributable to the exciton and the charge transfer interactions between two component molecules in the sandwich dimer with a center of symmetry.[6] It seems that the photoexcitation of the dimer leads to an access of the electronic polarization of the component molecules including an orientational relaxation in the excited state, as follows:



R=H, CH_3, and i-$CH(CH_3)_2$

Here, a small amount of activation energy may be required in the orientational relaxation in the excited state of the dimer. The relaxation process leading to the formation of the excimer (E*) seems to include a rotation of 4-CH_3O- group with respect to the benzene ring. The rotation of this group may be hindered by a steric effect of 3,5-dialkyl groups.[15] The argument is consistent with the activation barriers (MO-BMN<Me_2-MO-BMN<i-Pr_2-MO-BMN) as summarized in Table 1. However, it is difficult to depict the concrete structure of the dimer as well as the excimer at this stage.

Crystal Structure of 5-Bromocytosine

Masuhiro KATO, Akio TAKENAKA,* and Yoshio SASADA*

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received July 14, 1978)

The crystal structure of 5-bromocytosine has been determined by X-ray analysis to investigate the bromination effect on the cytosine moiety. The space group is $P2_1/a$, with dimensions $a=16.943(2)$, $b=9.155(1)$, $c=3.846(1)$ Å, $\beta=99.89(1)°$, and $Z=4$, The structure was solved by the heavy-atom method and refined by the full-matrix least-squares method. A comparison with the cytosine structure indicates some large deviations in bond lengths and angles, which are attributed to the steric and electronic effects caused by bromination. After the VSEPR theory, the slight increase of C(2)-N(3)-C(4) angle (0.8°) is interpreted as the decrease of the effective charge of the lone pair on N(3), and this is related to the difference of pK_a values between 5-bromocytosine and cytosine.

In the course of the studies on the elementary pattern of interactions between purine-pyrimidine base and amino acid, Ohki, Takenaka, Shimanouchi, and Sasada have found that the hydrogen bond scheme between 5-bromocytosine and *N*-acylglutamic acids is quite different from that found in the complexes between cytosine and some amino acids.[1-6] To explain this in terms of molecular structure, the crystal structure of 5-bromocytosine has been determined by X-ray diffraction method.

Experimental and Structure Determination

Colourless, needle-like crystals were obtained from an aqueous solution. The crystal density was measured by flotation in a mixture of bromoform and carbon tetrachloride. Weissenberg photopraphs showed systematic absences, $h0l$ $h=2n+1$ and $0k0$ $k=2n+1$, indicating the space group $P2_1/a$. Accurate unit cell dimensions and diffraction intensities were measured on a Rigaku four-circle automated diffractometer using graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Five reference reflexions monitored periodically showed no significant intensity fluctuations during the course of data collection. The intensities collected with an $\omega/2\theta$ scanning technique were corrected for Lorentz and polarization factors. Of the 1337 independent reflexions ($2\theta\leqq55°$), 1121 had intensities greater than $3\sigma(I)$. Crystallographic data are summarized in Table 1.

The structure was solved by the heavy-atom method and refined by the full-matrix least-squares method, the minimized function being $\sum w\{|F_o|-|F_c|\}^2$. All the hydrogen atoms, found on a difference map, were included in the subsequent refinement. In the refinement, the zero-reflexions for which $|F_c|$ values were smaller than $|F_o|_{lim}$ (3.748) were omitted

in each cycle of refinement. The weight functions used were: $w=1/(\sigma_p^2+q|F_o|^2)$ for $|F_o|\geqq|F_o|_{lim}$, where σ_p is the standard deviations based on counting statistics; $w=w(|F_o|_{lim})$ for $|F_o|<|F_o|_{lim}$. The coefficient q was 0.883×10^{-3}, derived from the intensity variance of the monitored reflexions.[7] The refinement was terminated when the maximum shifts of positional and thermal parameters were less than 0.16σ and 0.22σ, respectively, for non-hydrogen atoms. The final value of R is 0.069 ($R=0.056$ for the non-zero reflexions). Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[8] Atomic parameters are given in Table 2, and observed and calculated structure factors in Table 3.[9]

Results and Discussion

Bond lengths and angles are shown in Fig. 1, and a comparison with the cytosine values[10] is given in Fig. 2. Rather large deviations from cytosine bond lengths and angles may be attributed to the steric and electronic effects caused by bromination. The lengthening of C(4)–C(5) and C(5)–C(6) bonds accompanied by the decrease of C(5)–C(4)–N(3) and C(5)–C(6)–N(1) angles are due to repulsions from Br to C(4) and C(6) atoms. The marked deviation at C(5)–C(4)–N(4) angle is obviously ascribed to the repulsion between Br and N(4). After an interpretation for benzene ring deformation[11] on the basis of the valence shell electron pair repulsion theory, the bromination at C(5) makes the C(4)–C(5)–C(6) angle enlarge, but these repulsions cause the opposite effect, so that this angle is not so large. Such steric effect of bromination may spread to the C(2)–N(3)–C(4) and C(2)–N(1)–C(6) angles, and further the N(1)–C(2)–N(3) angle, so that they slightly expand. It is plausible that the shrinkage of lone-pair lobe on N(3), which is caused by electron-withdrawing property of bromine, facilitates the release of constrain by opening of the C(2)–N(3)–C(4) angle. Therefore, the slight increase of the angle (0.8°) supports the decrease of the effective charge of lone pair on N(3), and this is related to the difference of pK_a values between 5-bromocytosine and cytosine [4.58 and 3.04, respectively[12-13]].

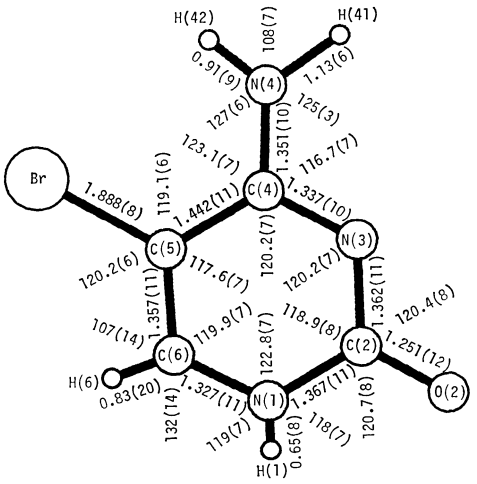

Fig. 1. Bond lengths (l/Å), angles (ϕ/°), and their standard deviations.

On the other hand, the C(4)–N(4) length is considerably short, while the C(2)–O(2) length is rather long, as compared with the average distances.[14] Such a trend which is also found in cytosine[10] indicates the contribution from the canonical formulae 2, 3, and 4 in Fig. 3, in which the amino nitrogen and carbonyl oxygen carry positive and negative charges, respectively. The shortening of C(6)–N(1) bond is due to the electronic effect of bromine as described by canonical formulae 4 and 5 in Fig. 3. This suggests the ability of proton donation of N(1)–H to be rather strong.

The least-squares plane of 5-bromocytosine together with the deviations from the plane is listed in Table 4. Although the pyrimidine ring with carbonyl oxygen O(2) and amino nitrogen N(4) is planar within 0.04 Å, the bromine atom shifts by 0.18 Å from the mean plane to relieve its steric hindrance.

As shown in Fig. 4, two hydrogen bonds between molecules related by the 2_1 axis, N(4)–H···O(2) and N(1)–H···N(3), constitute a ribbon along [010] direction. Hydrogen bond distances and angles are

		N(4)-H(41)···O(2)[b]	162(5)

listed in Table 5. The N···O and N···N distances are short as compared with the related compounds,[15] though the hydrogen bonds show poor linearity. Similar hydrogen bonding scheme is observed in the crystal structures of cytosine,[10] cytosine monohydrate,[10] and 5-bromocytosine: dioxan (2: 1) crystal.[16] Such a common feature can be interpreted by the preference of N–H···O hydrogen bond between positively charged amino group and negatively charged carbonyl group. The hydrogen donating property of the remaining N(4)–H becomes weak, so that N(1)–H is a hydrogen-donor to N(3).

The pyrimidine rings are stacked with the spacing of 3.368 Å along the c axis. There are no abnormal contacts between atoms.

Figures 1, 2, and 4 were drawn by TSD:XTAL which is a graphic display programme system for NOVA 3 mini-computer to produce crystal and molecular structures.[17] The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Hydrates of Organic Compounds. IV. Clathrate Hydrates of Various Bolaform Salts

Haruo NAKAYAMA

Department of Chemistry, Faculty of Engineering, Yokohama National University, Ooka-machi, Minami-ku, Yokohama 232

(Received August 1, 1978)

The solid-liquid phase diagrams are presented for binary mixtures of water with various polymethylenebis(tributylammonium) difluorides, $[(n\text{-}C_4H_9)_3N(CH_2)_nN(n\text{-}C_4H_9)_3]F_2$ (n=4, 5, 6, 8, and 10); and with hexamethylenebis(tributylammonium) dihydroxide and its salts, $[(n\text{-}C_4H_9)_3N(CH_2)_6N(n\text{-}C_4H_9)_3](X_2$ or Y) (X=OH, Cl, and Br; Y=OOC-COO and OOC-$(CH_2)_3$-COO). It has been found that all the compounds form congruently melting hydrates which have large hydration numbers. The hydrates appear to be clathrate-like hydrates essentially similar to those formed by many tetrabutyl(or isopentyl)ammonium salts. The most stable hydrate found in this study is $[(n\text{-}C_4H_9)_3N(CH_2)_6N(n\text{-}C_4H_9)_3]F_2$ hydrate (mp 20.4 °C). The melting points of hexamethylenebis(tributylammonium) hydrates have been compared with those of the corresponding tetrabutylammonium hydrates.

Bisquaternary ammonium salts (bolaform salts) having various hydrophobic groups have been studied from several points of view; the thermodynamic and transport properties *e.g.* molal volumes,[1-3] molal heat contents and solvation enthalpies,[4,5] heat capacities,[3,6] and conductances,[7,8] colloidal properties *e.g.* micelle formation,[9] flocculating action,[10] and emulsion polymerization,[11] pharmacological properties[12] *e.g.* protein binding,[13] resistance to metabolic degradation and accumulation in the kidneys,[14] affinity to choline and its related compounds,[15] and curarelike agent action.[16]

The thermodynamic and transport properties for aqueous solutions of bolaform salts as well as numerous symmetrical tetraalkylammonium salts[17] have extensively been studied in order to examine the structural changes in the solvent in the neighborhood of the solute particles. Broadwater and Evans[1] studied the apparent (ϕ_2) and partial molal volumes of a bolaform electrolyte $[(n\text{-}C_4H_9)_3N(CH_2)_8N(n\text{-}C_4H_9)_3]Br_2$ (C_8Br_2) and found the change of ϕ_2 with concentration for C_8Br_2 was very similar to that observed for $(n\text{-}C_4H_9)_4NBr$,[18] with ϕ_2 decreasing to a minimum and increasing with concentration. The minima in the ϕ_2 *vs.* concentration curves for $(n\text{-}C_4H_9)_4NBr$ have been correlated with the formation of a stable clathrate-like hydrate.[19-21]

In the same context it is of interest to examine the ability of bolaform salts to form clathrate-like hydrates. Although only a brief note has been given concerning the formation of C_8F_2 hydrate (which melts at 5 °C and has approximately 40 water molecules),[1] no other study has been reported about the formation of clathrate hydrates of bolaform salts. It is the purpose of this paper, through the examination of the solid-liquid phase diagrams, to find the conditions for the formation of clathrate-like hydrates of bolaform salts: (1) the length of methylene chain (n) between the two nitrogen atoms in the salt having the general formula $[(C_4H_9)_3N(CH_2)_nN(C_4H_9)_3]F_2$; and (2) the kind of anions in the salt $[(C_4H_9)_3N(CH_2)_6N(C_4H_9)_3]$ (X_2 or Y) (X=OH, F, Cl, and Br; Y=OOC-COO and OOC-$(CH_2)_3$-COO). The six alkyl chains attached to the two terminal nitrogen atoms have been restricted to butyl groups since it was concluded in a previous paper[22] that either the butyl or isopentyl chain was the most suitable size for the formation of stable clathrate hydrates of tetraalkylammonium fluorides.

The clathrate-like hydrates of bolaform salts may be regarded as extended hydrates which have large guest molecules rather than tetraalkylammonium salts, although tetraalkylammonium hydrates, in a sense, may be thought of as extended hydrates compared with ordinary gas hydrates.

Experimental

Polymethylenebis(tributylammonium) dibromides $[(C_4H_9)_3N(CH_2)_nN(C_4H_9)_3]Br_2$ (n=4, 5, 6, 8, and 10; which have been denoted as C_4Br_2, C_5Br_2, C_6Br_2, C_8Br_2, and $C_{10}Br_2$ hereafter) have been prepared by refluxing an excess of tributylamine with the corresponding α,ω-dibromoalkane in ethanol.[1] The excess amine was removed by extraction with diethyl ether and recrystallizations were carried out either in an acetone/ethyl acetate mixture or an diethyl ether/methanol mixture. Since it was fairly difficult to obtain pure $C_{10}Br_2$ by recrystallization, the C_{10}-compound was obtained as the iodide, $C_{10}I_2$, by the following procedure: $C_{10}I_2$ was precipitated by adding KI solution to aqueous $C_{10}Br_2$ solution which was then extract from the reaction mixture and recrystallized from ethyl acetate.

All the salts were confirmed by IR, NMR, and elemental analysis.

Fluoride solutions (C_nF_2) have been prepared by the triple decomposition of a mixture of BaF_2, Ag_2SO_4, and the corresponding bromide (or iodide) by using stoichiomet-

ric amounts of the latter two components and excess of the former.[20,22] When a small amount of bromide (or iodide) ion was found in the filtrate, an aqueous AgF solution, obtained by the neutralization of AgOH with an aqueous HF solution, was added, and the precipitated silver bromide (or iodide) was removed by either filtration (pore size 1.0 μm) or centrifuge (2000G, 30 min). Solutions of $[(C_4H_9)_3N(CH_2)_6N(C_4H_9)_3]Cl_2$ and $[(C_4H_9)_3N(CH_2)_6N(C_4H_9)_3]Y$ (Y=OOC-COO and OOC-$(CH_2)_3$-COO) (which we denote by C_6Cl_2, C_6Oxa, and C_6Glu hereafter) were prepared by neutralizing $[(C_4H_9)_3N(CH_2)_6N(C_4H_9)_3](OH)_2$ ($C_6(OH)_2$) solutions with the corresponding acids. The hydroxide $C_6(OH)_2$ was obtained by treating a solution of C_6Br_2 with freshly prepared silver hydroxide, and purified by recrystallization from water[19,20,23] in the form of a clathrate hydrate crystal (see below). Both oxalic and glutaric acids were reagent grade commercial materials and recrystallized from water. The two fluoride solutions prepared by different methods (neutralization of $C_6(OH)_2$ with HF and triple decomposition of C_6Br_2 with BaF_2 and Ag_2SO_4) showed exactly the same behavior.

The experimental procedures for determing the solid-liquid phase diagrams for the binary mixtures of these salts with water were almost the same as in previous papers.[22,23] A sample solution (about 1.0—1.5 g) was prepared by weighing out water and a concentrated sample solution obtained by dehydrating a dilute solution using a rotary evaporator and whose water content was determined by the Karl Fischer titration method. No attempt was made to remove the air dissolved in the solution.

Results

The solid-liquid phase diagrams for the binary mixtures of water with C_4F_2, C_5F_2, C_6F_2, C_8F_2, and $C_{10}F_2$ are shown in Fig. 1, indicating that all the salts form hydrates which melt congruently and have large hydration numbers. The formation of these hydrates except for C_8F_2,[1] is confirmed for the first time. Judging from the large hydration numbers, the hydrates appear to be clathrate-like hydrates. The melting points and hydration numbers of these hydrates which have been read off each phase diagram are summarized in Table 1.

Table 1. The melting points and the hydration numbers of $[(C_4H_9)_3N(CH_2)_n(C_4H_9)_3]F_2$ hydrates

n	Melting point (°C)	Hydration number
4 (stable)	2.8	39±3
4 (metastable)	−3.1	45±2
5	12.4	42±2
6	20.4	46±2
8	6.8	48±2
10	−2.2	50±2

The most appropriate methylene chain connecting the two terminal $(C_4H_9)_3N$ groups for the formation of a stable hydrate is a hexamethylene chain. The stability of the C_6F_2 hydrate (mp 20.4 °C) is comparable to that of several tetrabutyl (or isopentyl)ammonium salt hydrates.[20,22-24] The melting point and hydration number for the C_8F_2 hydrate are fairly different from those reported by Broadwater and Evans (5 °C and about 40).[1] A detailed comparison of the data is impossible because of the lack of experimental information. It has often been noticed that, for many tetraalkylammonium salt hydrates, the composition and the melting point of a hydrate which is separated from its solution phase and exposed to the atmosphere vary considerably with time.[22] Two types of hydrates (stable and metastable phases) have been found for the C_4F_2 salt. The stable phase has less water molecules (39±3) than the metastable one (45±2).

The effect of anions on the formation of clathrate-like hydrates has been examined for a series of C_6-compounds, whose cation is most suitable in size for the formation of stable hydrate as mentioned above. In Fig. 2 the solid-liquid phase diagrams for a series of C_6-compounds ($C_6(OH)_2$, C_6F_2, C_6Cl_2, C_6Br_2,

C_6Oxa, and C_6Glu) are shown and indicates that all C_6-compounds examined form hydrates similar to those found in Fig. 1: characterized by their high water contents and congruent melting points. The melting points and hydration numbers obtained are summarized in Table 2, together with those of the corresponding tetrabutylammonium salts.

Discussion

The Effect of n *on the Formation of* C_nF_2 *Hydrates.* As can be seen from Fig. 1 and Table 1, C_6F_2 forms the most stable hydrate (mp 20.4 °C). From the fact that, in the clathrate hydrates of tetrabutyl(or isopentyl) ammonium salts, 7—8 water molecules are required in order to surround one butyl (or isopentyl) group, and that the C_6F_2 molecule has seven hydrophobic groups (six butyl groups and one hexamethylene chain), the hydration number of 46±2 observed for the C_6F_2 hydrate is a little bit smaller than expected. This indicates that the hydrogen-bonded water framework around the C_6F_2 molecule becomes efficient by the sharing of the common faces of adjacent polyhedra. Although the solution properties caused by the promotion of additional hydrogen bonding of the water molecules in the vicinity of the hydrocarbon groups have been studied exclusively in aqueous solutions of C_8Br_2,[1,3-5,7] the results here suggest that the structural effect in C_6-salt (and also C_5-salt) solution will be greater than that in C_8-salt solutions. The enthalpy of the $H_2O \rightarrow D_2O$ (and also $H_2O \rightarrow$propylene carbonate) transfer for C_8-cation clearly indicates that the structural effect for this ion in water is considerably smaller than that for two tetrabutylammonium ions.[5]

In Fig. 3, the melting points and hydration numbers of C_nF_2 hydrates have been plotted against n. It may be seen from the figure that both the melting points and hydration numbers vary differently with n depending upon whether n is smaller or larger than 6. When n is smaller than 6, both the melting points and the hydration numbers increase with increasing n, whereas when n is larger than 6, the melting points drastically decrease with increasing n while the hydration numbers increase in a similar manner as before but less sharply.

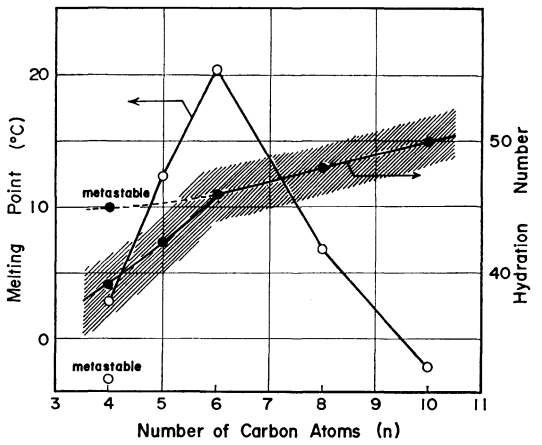

Fig. 3. The melting points and the hydration numbers of the $[(C_4H_9)_3N(CH_2)_nN(C_4H_9)_3]F_2$ hydrates as a function of n.

The hydration number of the metastable C_4F_2 hydrate lies approximately on the extention of the line for $n \geq 6$.

Although there is no evidence concerning the crystal structure of these hydrates, the following structure is consistent with the behavior shown in Fig. 3: the principal constituent of the hydrates may be considered as a clump consisting of three hydrogen-bonded water frameworks (presumably distorted tetrakaidecahedra or pentakaidecahedra) each of which surrounds one of the butyl radicals in the terminal $(C_4H_9)_3N$ group. This unit is schematically depicted in Fig. 4, with the assumption that each polyhedron is 14-hedron. The $(C_4H_9)_3N$-group sheath is denoted hereafter by 3P (P stands for polyhedron). The C_nF_2 hydrate crystal is then made up of two 3P's arranged face to face, in the interstitial space of which is accommodated a polymethylene chain, $-(CH_2)_n-$, which connects the two $(C_4H_9)_3N$-groups.

In the C_4F_2 hydrate (stable phase), the two 3P's are drawn together since they are covalently combined by a short polymethylene chain (the maximum distance between the two nitrogen atoms is 6.2—6.3 Å). The most probable configuration for this would be the

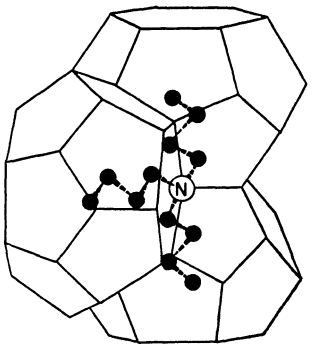

Fig. 4. The schematic representation of the water frameworks which enclathrate a $(C_4H_9)_3N$-group (3P).

twisted combination — a rotating 60° about the N–N axis as in the staggered ethane molecule conformation. The water framework within which the $-(CH_2)_4-$ chain is accommodated is automatically formed when the two 3P's approach, in agreement with the observation that the hydration number of the C_4F_2 hydrate is considerably small (39±3). The low melting point of this hydrate is presumably due to the strong distortion of the framework. The increase of both hydration number and melting point with increasing n from 4 to 6 is due to the formation of a larger and less distorted cage to accommodate a longer polymethylene chain ($-(CH_2)_5-$ and $-(CH_2)_6-$). In the compound C_6F_2, which gives the most stable hydrate, the stretched chain-length between the two nitrogen atoms, 8.8 Å, is very close to the average cage diameter of a typical polyhedron (8.7 Å for a 14-hedron and 9.4 Å for a 16-hedron[25]).

The slight increase in the hydration numbers and the drastic decrease in the melting points with increasing n from 6 to 10 reflects the situation that a few more water molecules are necessary to form a larger cage than in the case of C_6F_2 hydrate in order to accommodate the longer chain. Chain flexibility cancels this out to some extent, and furthermore the cage thus constructed is inevitably distorted compared with the most stable polyhedra such as the 14-hedron and 16-hedron. As to the structure of the metastable C_4F_2 hydrate, from the experimental results, *i.e.* a considerably low melting point and a hydration number (45±2) much larger than that in the stable phase (39±3) and position nearly on the extention of the line for $n\geq6$ as previously pointed, it appears essentially similar to the structure for $n\geq6$, but much more strained because of the short methylene chain. Presumably the two 3P's would take an eclipsed conformation in contrast to the staggered conformation which was assumed to be the stable phase as discussed earlier. Further detailed crystallographic studies of these hydrates are needed.

The Effect of Anion on the Formation of the C_6-Hydrates. The correlation between the melting points of the hydrates of C_6-compounds with various anions and those of the corresponding tetrabutylammonium compounds is shown in Fig. 5. This figure indicates two interesting facts: (1) the melting points of the C_6-compound hydrates are about 10 °C lower than those

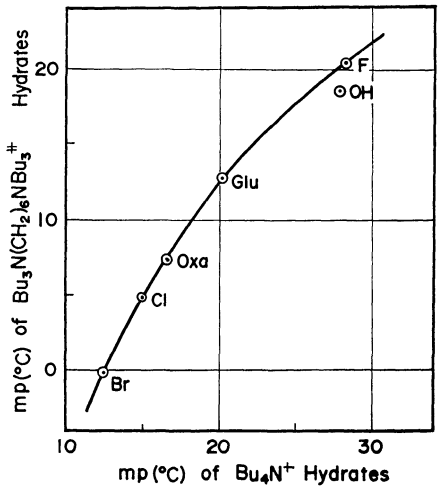

Fig. 5. The correlation between the melting points of the $[(C_4H_9)_3N(CH_2)_6N(C_4H_9)_3]^{2+}$ hydrates and those of the $(C_4H_9)_4N^+$ hydrates.

of the tetrabutylammonium compound hydrates irrespective of the type of anion; (2) there exists approximately linear relationship between the two sets of melting points. The former point emerges since the formation of the hydrogen-bonded water framework around the C_6-cation is considerably more difficult compared with the case of the tetrabutylammonium cation. The latter point indicates that the lattice distortion caused by the presence of the anion affects the stabilities of the hydrates in a similar manner in both series of salts. As may be seen from Table 2, all the C_6-compounds, except C_6Glu and $C_6(OH)_2$, have the same hydration numbers — around 47. This, suggests that they are isostructural, having a strong resemblance to the finding that the corresponding tetrabutylammonium salt hydrates are isomorphous (tetragonal).[20] The relatively large hydration number found for glutarate hydrate may be a consequence of the additional water molecules needed in order to surround the large $OOC-(CH_2)_3-COO$ anion, a striking contrast to the $[(C_4H_9)_4N]_2OOC-(CH_2)_3-COO$ hydrate which has a cosiderably small hydration number.[23] Hydroxide hydrate has also a large hydration number. A similar but less sharp trend is seen for tetrabutylammonium hydroxide hydrate and this may be due in part to the strong hydration of the hydroxide ion.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Studies of the Metal Complexes of Cyclohexane Derivatives. V.[1] Copper(II) and Nickel(II) Complexes of *cis*-1,3-Cyclohexanediamine

Reiko SAITO* and Yoshinori KIDANI†

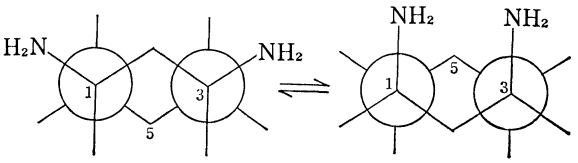
Aichi Junior College of Nursing, Kamishidanmi, Moriyama-ku, Nagoya 463

† *Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467*

(Received May 12, 1978)

A series of 1,3-chxn(*cis*-1,3-cyclohexanediamine) copper(II) and nickel(II) complexes have been prepared and studied using spectroscopic and magnetic techniques. The violet and red copper(II) complexes of 1,3-chxn were found to consist of monomeric distorted octahedra and slightly distorted square planers, respectively. The nickel(II) complexes have a square planar structure. The conformational change of the ligand from diequatorial to diaxial on coordination has been confirmed by infrared analysis.

cis-1,3-Cyclohexanediamine(abbreviated as 1,3-chxn[2]) is



(a) diequatorial conformation (b) diaxial conformation

known to take exclusively the diequatorial conformation(a). Assuming that the transformation to the less stable diaxial form(b) occurs, this diamine is able to form metal complexes containing six membered rings as bidentate ligands. The Pd(II) and Pt(II) complexes of 1,3-chxn have been prepared and there is some evidence for the square planar structure in which the ligand exists as the diaxial conformer(b).[3] Kamisawa *et al.*[4] recently determined the molecular structure of $[Pd(1,3\text{-chxn})_2]Cl_2$ by X-ray diffraction. A similar structure for the mixed Pt(II) complex with 1,3-chxn and 2,2′-bipyridyl has been reported by Sarneski *et al.*[5]

The copper(II) and nickel(II) complexes with *cis*- and *trans*-1,2-cyclohexanediamine(abbreviated to *c*- and *t*-chxn) have been studied and it has been found that the structures of the bis complexes of nickel(II) were greatly affected by the steric configuration of these ligands.[1] In a series of studies examing the influence of the stereochemistry of the cyclohexane derivatives upon complex formation, the copper(II) and nickel(II) complexes of 1,3-chxn were prepared and studied.

Experimental

Materials. 1,3-chxn was prepared from *cis*-1,3-cyclohexanedicarboxylic acid according to the procedure in the literature.[6] *cis*-1,3-Cyclohexanedicarboxylic acid used was isolated by the method of Skita[7] from the mixed *cis*- and *trans*-diacid resulting from hydrogeneration of isophthalic acid.

Measurements. The magnetic moments were measured with a Shimadzu MB-2 magnetic balance at room temperature. Measurements of the absorption spectra were carried out using a Hitachi 124-spectrophotometer. The reflectance spectra were measured with a Shimadzu MPS-5000 spectrophotometer. The infrared spectra were recorded with a JASCO IR-2A spectrophotometer using a KBr disc.

Preparation of the Complexes. *Cu(1,3-chxn)$_2$Cl$_2$*: Copper(II) chloride dihydrate (2 mmol in 2 ml of MeOH) and 1,3-chxn (4 mmol in 2 ml of MeOH) were mixed together. The resulting violet product was recrystallized from methanol–ethanol.

Cu(1,3-chxn)$_2$ClClO$_4$: Dihydrochloride of 1,3-chxn (6 mmol) and $CuCl_2 \cdot 2H_2O$ (1.2 mmol) were dissolved in H_2O (7.5 ml) and the pH was adjusted to approximately 10 by 1 mol l^{-1} NaOH solution. To this solution $NaClO_4$ (6 mmol) was added. On warming the solution, a blue violet complex began to precipitate, and this was recrystallized from methanol.

Cu(1,3-chxn)$_2$Br$_2$ (A) and Cu(1,3-chxn)$_2$Br$_2$ (B): Copper(II) bromide (2 mmol in 15 ml of EtOH) and 1,3-chxn (4 mmol in 2 ml of EtOH) were mixed together. This method predominantly produced the violet complex, Recrystallization from ethanol gave violet crystalline powder of (A), while, recrystallization from methanol afforded the wine red needles of (B).

Cu(1,3-chxn)$_2$(NO$_3$)$_2$: Copper(II) nitrate trihydrate (1 mmol in 5 ml of H_2O) and 1,3-chxn (2 mmol in 10 ml of MeOH) were mixed and the resulting violet solution was warmed. The wine red crystals were recrystallized from methanol.

[Ni(1,3-chxn)$_2$]X$_2$ (X=Cl$^-$, Br$^-$, NO$_3^-$, and ClO$_4^-$): All the nickel(II) complexes were prepared in a similar manner as described here. To an ethanoic solution of the ligand (4—5 mmol), an ethanoic solution of the Ni(II) salt (2 mmol) was added. The yellow crystals obtained were recrystallized from methanol.

Results and Discussion

Properties of the Complexes. The results of the elemental analyses, the magnetic moments, and the colors of the complexes prepared are listed in Table 1. The copper(II) complexes are magnetically normal and are assumed to consist of monomeric species. The 1,3-chxn ligand was found to produce two forms of copper(II) complexes, a violet and a red, depending on the anion. The copper(II) complexes coordinating Br^- exist in two forms, however, the violet complex was recrystallized with some difficulty. On the other hand, this ligand afforded only diamagnetic nickel(II) complexes. The tris and bis nickel(II) complexes having octahedral or tetragonally distorted octahedral structures were not obtained.

Electronic Spectra. Some typical electronic spectra of the complexes obtained are shown in Fig. 1 and the numerical data, in Table 2. The band maxima of the red copper(II) complexes in the solid state were observed at 20400—20600 cm^{-1}, higher in energy than

c) In MeOH solution. b) In DMF solution. c) The absorption spectrum could not be measured because of the low solubility of the complex.

occurs in the z-axis. Consequently, only the anionic X group which has strong bond strength would be expected to occupy tetragonal positions. As the axial field strength weakens, the in-plane field strength increases. That the structure of the red form complexes is very close to being square planar is supported and this is unusual for $Cu(diamine)_2X_2$.[9,10] In methanol solution, the copper(II) complexes of both forms, except the nitrate, have essentially the same ν_{max} and ε_{max}. It can be said that the equilibrium in the methanol solution shifts greatly towards the formation of $Cu(1,3\text{-chxn})_2(MeOH)_2^{2+}$ (Scheme 1). With the violet complexes having a distorted octahedral structure ligand-substitution reactions between the coordinated anions and solvent molecules appears to hold, while, in the case of the red complexes, the square planar structure appears to transform to the distorted octahedral structure by bonding solvent molecules.

$$\begin{array}{ccc} & & Cu(1,3\text{-chxn})_2Cl_2(\text{violet}) + 2MeOH \\ & & \uparrow\downarrow \\ Cu(1,3\text{-chxn})_2Br_2(\text{red}) + 2MeOH & \rightleftharpoons & Cu(1,3\text{-chxn})_2(MeOH)_2^{2+} + 2X^- \\ & & \uparrow\downarrow \\ & & Cu(1,3\text{-chxn})_2Br_2(\text{violet}) + 2MeOH \end{array}$$

Scheme 1.

As Table 2 shows, the visible spectrum of $[Ni(1,3\text{-chxn})_2]Cl_2$ in methanol is similar to the reflectance spectra of all the nickel(II) complexes prepared. The spectral properties of the nickel(II) complexes with 1,3-chxn suggested that only reasonable structure for these complexes is square planar. This trend has been known for the nickel(II) complexes of the bulky diamine involved.[11]

Infrared Spectra. The representative infrared spectra of the complexes in the δ_{NH_2}, ρ_{rCH_2}, ρ_{rNH_2} region are shown in Fig. 2, and the main bands are listed in Table 3. The three copper(II) complexes of the violet form exhibit a very similar infrared spectra. The characteristic bands assignable to the rocking vibration of NH_2 are observed at 600—750 cm^{-1}. For the analogue of the violet complexes, the ρ_{rNH_2} values appear due to the anionic groups bonded in the tetragonal positions. Therefore, more than four peaks corresponding to ρ_{rNH_2} appear in the spectra of $Cu(1,3\text{-chxn})_2ClClO_4$. No relationship between the frequencies of ρ_{rNH_2} and structures of the red copper(II) and nickel(II) complexes have been found.

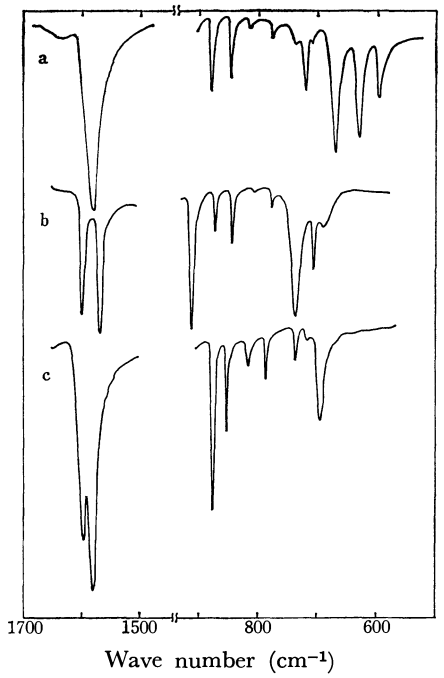

Fig. 2. Infrared spectra of (a) $Cl(1,3\text{-chxn})_2Br_2$ (A), (b) $Cu(1,3\text{-chxn})_2Br_2$ (B), and (c) $[Ni(1,3\text{-chxn})_2]Br_2$ in the δ_{NH_2}, ρ_{rCH_2}, and ρ_{rNH_2} region.

The δ_{NH_2} of the nickel(II) complexes described here show two peaks. The similar frequency separation for the red copper(II) complexes is significantly larger than that for the violet copper(II) complexes. The splitting of this band may be due to the distortion of the chelate ring or the degree of hydrogen bonding between the NH_2 groups and the anion. In the spectra of a similar type of complexes having stronger metal–N bonds, such as $[Pt(1,3\text{-chxn})_2]Cl_2$ and $[Pd(1,3\text{-chxn})_2]Cl_2$, the corresponding band shows no splitting.[3] From the δ_{NH_2} data, the structure of the red copper(II) complexes is thought very similar to the square planar complexes of nickel(II).

It is generally recognized that the degenerated stretching mode of the perchlorate ion splits into two bands on coordination.[12] As shown in Fig. 3, the infrared spectrum of $Cu(1,3\text{-chxn})_2ClClO_4$ gives evidence of the covalently bonded perchlorate group. The same band of $[Ni(1,3\text{-chxn})_2](ClO_4)_2$ appears to be single and broad, reflecting the existence of free ions. The infrared spectra of $Cu(1,3\text{-chxn})_2(NO_3)_2$ shows a broad profile of ν_{N-O} ascribable to the free ion[13] at 1300—1400 cm^{-1}, which is very similar to that of $[Ni(1,3\text{-chxn})_2](NO_3)_2$. This suggests that in the former complex the copper(II) ion is present in a planar rather than a distorted octahedral configuration.

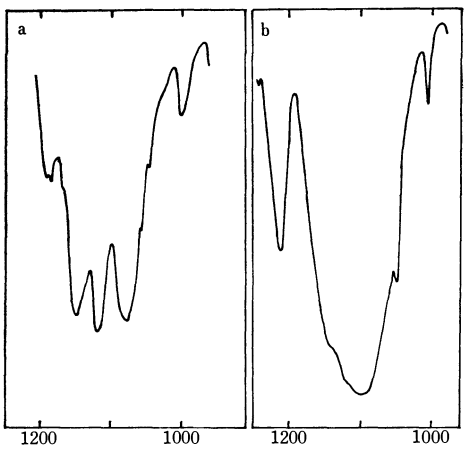

Fig. 3. Infrared spectra of (a) $Cu(1,3\text{-chxn})_2ClClO_4$ and (b) $[Ni(1,3\text{-chxn})_2](ClO_4)_2$ in the ν_{Cl-O} region.

$[Ni(1,3\text{-chxn})_2](ClO_4)_2$	3300, 3260, 3200[a]	1601, 1580	778	742, 710

a) A shoulder was observed besides these bands. sh=shoulder.

As previously discussed, for coordination of the 1,3-chxn ligand to the metal ion the interconversion from the diequatorial(a) to the diaxial(b) conformer is necessary. In the infrared spectra of the cyclohexane derivatives involving axially bonded substituents, the weak rocking vibration of CH_2 appears around 800 cm^{-1}.[14] It has been found that the *c*-chxn complexes show these characteristic bands which are absent in the *t*-chxn complexes.[15] Dihydrochloride of 1,3-chxn have no bands in the region of 560—840 cm^{-1}. However, in the spectra of the complexes one or two bands were observed around 770—810 cm^{-1} as shown in Table 3 and Fig. 2. These results support the complexes involve ligands with diaxial conformation(b). Similar complex formation of 1,3,5-triaminocyclohexane taking conformational inversion have been revealed in several investigations.[16–18]

The authors would like to thank Dr. Noboru Nakayama and Dr. Haruo Matsui of the Goverment Industrial Institute, Nagoya, for the use of a Shimadzu MB-2 magnetic balance and a Shimadzu MPS-5000 spectrophotometer, respectively. Thanks are also due to Miss Masae Ishiguro and Miss Shizuko Iwauchi of the Analytical Center of Nagoya City University for the elemental analyses.

Preparation and Isomerization of Isomers of the L- or D-Aspartato(L-histidinato)cobalt(III) Complex

Masatoshi WATABE,* Hisao YANO, and Sadao YOSHIKAWA†

General Education Department, Kogakuin University, Hachioji, Tokyo 193

† *Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received May 16, 1978)

The six isomers of the [Co(L- or D-asp)(L-his)] complex (asp=aspartate ion and his=histidinate ion) have been prepared and the isomerization studied in the absence of any catalyst. The equilibrium mole fractions of these isomers in water has been found for L-*trans*O_5*cis*N_5, L-*cis*O_5*trans*N_5, L-*fac*, to be 0.53, 0.06, and 0.41, respectively, those for D-*cis*O_5*cis*N_5, D-*trans*O_5*trans*N_5, and D-*fac* to be 0.48, 0.01, and 0.51 respectively. The indication is that the relative positions of the six coordinated atoms around a cobalt atom cause these unequal isomer concentration ratios. The isomerisms are dealt with by means of a network of first order reversible reactions and the absolute values of the rate constants at 80 °C have been determined.

In a previous work,[1] the isomerzation of D-aspartato(L-2,4-diaminobutyrato)cobalt(III), [Co(D-asp)(L-2,4-dba)] was studied in the presence of active carbon. The relative rate constants of the isomerization and the mole fractions of the isomers at equilibrium were determined. However, those of the [Co(L-asp)(L-2,4-dba)] complex could not be determined on account of their low solubilities. In this paper, the preparation and the isomerization of the isomers of the D- or L-aspartato(L-histidinato)cobalt(III) complex are presented. All isomers are soluble in water.

Experimental

Preparation of [*Co*(L- *or* D-*asp*)(L-*his*)]. To a solution of $CoCl_2 \cdot 6H_2O$ (2.4 g) in water (20 cm^3) containing 10% H_2O_2 (5 cm^3) was added an aqueous solution containing L-aspartic acid (1.33 g), L-histidine (1.55 g), and NaOH (0.95 g). The pH of this mixed solution became *ca.* 7. The solution was stirred for 24 h at 30 °C, concentrated to about 20 cm^3 and passed through a column (30 mmϕ × 700 mm) containing a strong acid cation exchange resin (Dowex 50WX8, Na^+ form). By slowly washing the column with water, five bands were distinguished, the last three bands corresponding to the isomers of the [Co(L-asp)(L-his)] complex. The three fractions were violet (H1), brick red (H2), and red violet (H3) in that order of elution. In order to separate the bands of H1 and H2 precisely, the fractions were circulated several times in the column using a quantitative micropump. The three fractions were evaporated to dryness below 30 °C by a rotatory evaporator. The isomers of the [Co(D-asp)(L-his)] complex were similarly prepared using D-asp insted of L-asp. The three fractions were violet (I1), brick red (I2), and red violet (I3) in that order of elution. Found: (H1) C, 30.66; H, 4.95; N, 13.80%. Calcd for $CoC_{10}H_{13}O_6N_4 \cdot 3H_2O$: C, 30.21; H, 4.81; N, 14.01%. Found: (I2) C, 35.08; H, 3.87; N, 16.63%. Calcd for $CoC_{10}H_{13}O_6N_4 \cdot 0.5H_2O$: C, 34.95; H, 3.81; N, 16.31%. Found: (H2) C, 33.01; H, 3.81; N, 14.81%. (H3) C, 32.65; H, 4.15; N, 15.00%. (I1) C, 32.81; H, 4.18; N, 15.40%. (I3) C, 32.35; H, 4.25; N, 14.89%. Calcd for $CoC_{10}H_{13}O_6N_4 \cdot 1.5H_2O$: C, 32.41; H, 4.35; N, 14.89%.

The method of isomerization for the [Co(L- or D-asp)(L-his)] complex was similar to that described in a previous paper.[1] Since the H1(I1), H2(I2), and H3(I3) isomers could be easily separated by means of high speed liquid chromatography (column contained a strong cation exchange resin, TSK LS-212 Toyo Soda Ind., Na^+ form), the concentrations of these isomers were determined with a UV spectrophotometer (at 254 nm) by comparison with the peak height of a known concentration of isomer.

Results and Discussion

Characterrization. Figure 1 shows the possible isomers of the [Co(L- or D-asp)(L-his)] complex. They are denoted by L- or D-series with respect to the asp used. Both series of mixed complexes are composed of two meridional and one facial about the chromophore $[Co(N)_3(O)_3]$. The isomers are denoted by considering the 5-membered glycinato N and O atoms. The two mer isomers for the L-series are denoted by L-*trans*O_5 *cis*N_5 and L-*cis*O_5 *trans*N_5. Similarly the three isomers of [Co(D-asp)(L-his)] are designated

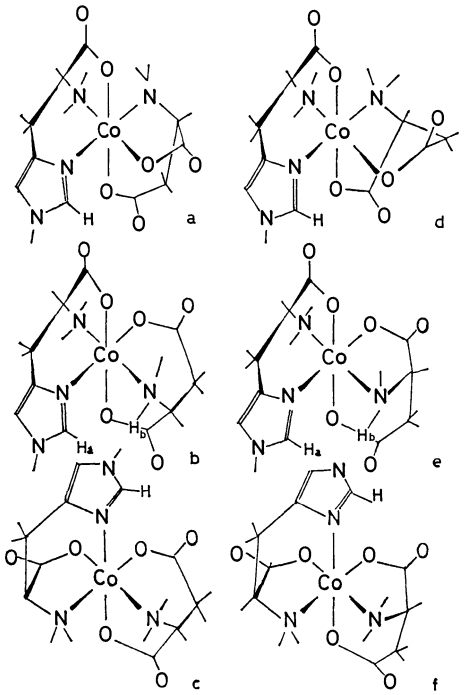

Fig. 1. The six possible geometrical isomers of the [Co(L- or D-asp)(L-his)] complex, a; *cis*O_5*cis*N_5, b; *trans*O_5*trans*N_5, c; D-*fac*, d; *trans*O_5*cis*N_5, e; *cis*O_5-*trans*N_5, and f; L-*fac*.

by D-*cisO*$_5$*cis*N_5, D-*transO*$_5$*trans*N_5, and D-*fac*. Figures 2a and 3a show the electronic absorption spectra.

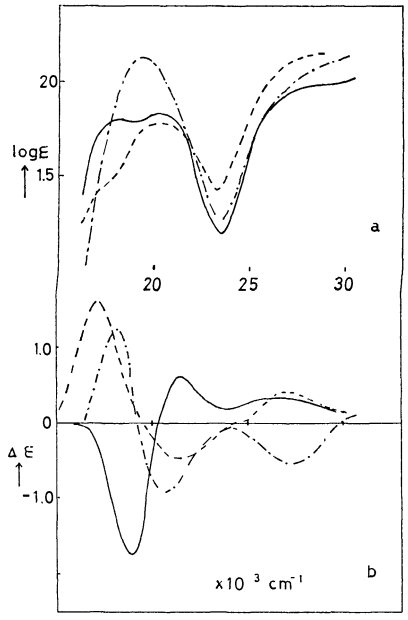

Fig. 2. Absorption (upper) and CD (lower) spectra of [Co(L-asp)(L-his)]. H1 (——), H2 (----), and H3 (— — —).

Table 1 shows the numerical data for the electronic absorption spectra of [Co(L- or D-asp)(L-his)], together with those for the isomers of [Co(L- or D-asp)(L-2,4-dba)].[1] The absorption spectra of the [Co(L- or D-asp)(L-his)] complexes were similar to those for [Co(L- or D-asp)(L-2,4-dba)]. The ligand L-2,4-dba differs from the histidine only in that it contains the NH_2–CH_2-group in the position occupied by the imidazole group in histidine. The charge transfer bands which tail into the visible region in the spectra of the [Co(L- or D-asp)(L-his)] complexes are absent in the [Co(L- or D-asp)(L-2,4-dba)] complexes. When the elution order and the similarity of the visible absorption spectra between [Co(L- or D-asp)(L-his)] and [Co(L- or D-asp)(L-2,4-dba)] are taken into account, the isomers H1, H2, and H3 are tentatively assigned as L-*transO*$_5$*cis*N_5, L-*cisO*$_5$*trans*N_5, and L-*fac*. The isomers I1, I2, and I3 are also assigned as *D*-*cisO*$_5$*cis*N_5, D-*transO*$_5$*trans*N_5, and D-*fac* in the same manner. Figures 2b and 3b show the CD spectra of the six isomers of [Co(asp)(his)]. The CD spectrum for a specific isomer *e.g.* the first eluate of the [Co(L- or D-asp)-(L-his)] complex is quite similar to that for the isomer being eluted in the same order *e.g.* the first eluate of the [Co(L- or D-asp)(L-2,4-dba)] complex. Both isomers may have the same configuration as shown in Fig. 1. However, the coordination of the L-his in place of L-2,4-dba for the [Co(L- or D-asp)(L-2,4-

a) Wave numbers are given in 10^3 cm^{-1}.
b) The figures in the parentheses denote the data for [Co(L- or D-asp)(L-2,4-dba)].

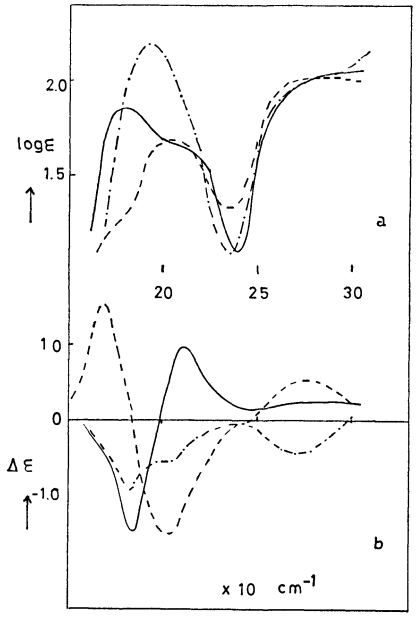

Fig. 3. Absorption (upper) and CD (lower) spectra of [Co(D-asp)(L-his)]. I1 (——), I2 (----), and I3 (———).

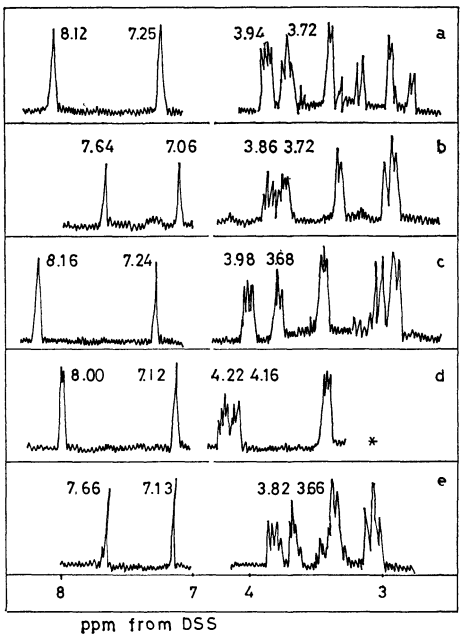

Fig. 4. PMR spectra of a; H1, b; H3, c; I1, d; I2, and e; I3.

dba)] complex decreases the magnitude of the CD peaks of the four mer isomers in the first absorption band region. It is interesting that the CD spectrum for the H1 isomer resembles that for the I1 isomer in spite of the coordination of the enantiomeric ligand.

PMR Spectra. Figure 4 shows the PMR spectra of the five isomers. The spectrum of I2 could not be obtained because of its low solubility. The L-his has the patterns of ABX and AX and the L- or D-asp that of AX only. The peaks near δ 8.0 ppm for the five PMR spectra are ascribed to the 2-protons of imidazole and the peaks near δ 7 ppm to the 5-protons of imidazole having a higher electronegativity than that for the 2-proton. The peaks at *ca.* 3.4 ppm are due to the methylene protons of asp and the peaks higher than those to the methylene protons of L-his. The peaks at *ca.* δ 4.2—3.6 ppm are assigned to those of the methine protons for L-his and L- or D-asp. The distribution of all the peaks for the five isomers agree with the prediction based on the empirical rule as developed by the authors.[2] Consequently H1, H2, and H3 were assigned as *trans*O_5*cis*N_5, *cis*O_5*trans*N_5, and L-*fac*, and I1, I2, and I3 as *cis*O_5*cis*N_5, *trans*O_5*trans*N_5, and *D-fac*, respectively.

Isomerization of the Isomers of [*Co*(L- *or* D-*asp*)(L-*his*)]. All the isomers of [Co(L- or D-asp)(L-his)] isomerized in water without any catalyst. Figure 5 shows a series of chromatograms corresponding to the change in concentration of each isomer due to the isomerization of H3. Each isomer can be separated from the mixture by high speed liquid chromatography. The TSK-212 resin is eminently suitable for the separation of the isomers of a complex with no charge. Since no concentration loss of the complex due to other reactions was found within experimental error, it was possible to treat the concentration of the complex as constant throughout the experiment and so network analysis[3] is available for this reaction. The system of differrential equations representing the behavior of the system is shown as follows:

$$da_1/dt = -(k_{12}+k_{13})a_1 + k_{21}a_2 + k_{31}a_3,$$
$$da_2/dt = k_{12}a_1 - (k_{23}+k_{21})a_2 + k_{32}a_3,$$
$$da_3/dt = k_{13}a_1 + k_{23}a_2 - (k_{31}+k_{32})a_3,$$

where a_1, a_2, and a_3 are the molar fractions of H1(I1), H2(I2), and H3(I3), respectively. The rate constant of the reaction, for which the notation of the Hi(Ii)-(i=1,2,3) isomer is transformed into Hj(Ij), is represented by k_{ij}. This analysis was applicable for obtaining the relative value of the rate constant (k_{ij}'). In order to obtain absolute values (k_{ij}), the relative rate constans are substituted in a certain differential equation, for example,

$$da_2/dt = k[k_{12}'a_1-(k_{23}'+k_{21}')a_2+k_{32}'a_3],$$

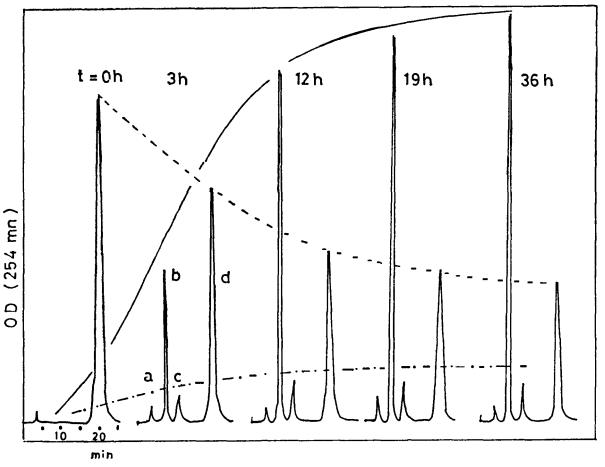

Fig. 5. High speed liquid chromatograms indicating the isomerization of the H2 isomer. a: Marker, b: H1(I1), c: H2(I1), and d: H3(I3).

where k is the ratio (k_{12}/k_{12}'). All the k_{ij} of Hi and Ii systems are shown in Fig. 6. In the case of the Hi system, the values of the rate constants decrease in the order $k_{23}>k_{31},k_{13},k_{21}>k_{12},k_{32}$. Figure 7 shows the experimentally observed compositions for isomerization. The molar fractions at equilibrium are as follows; H1(0.53), H2(0.06), and H3(0.41). The free energy differences at 25 °C are as follows: $\Delta G_{12}=G(\mathrm{H1})-G(\mathrm{H2})=-RT\ln(53/6)=-5.40$ kJ/mol and $\Delta G_{23}=RT\ln(41/6)=4.76$ kJ/mol. In case of the Ii system, the values of the rate constants decrease in the order $k_{23}\gg k_{13},k_{31}>k_{21},k_{32}>k_{12}$. This order closely resembles

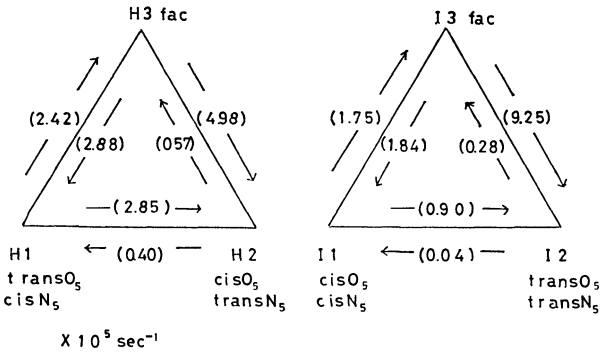

Fig. 6. Rate constants of the isomerization at 80 °C.

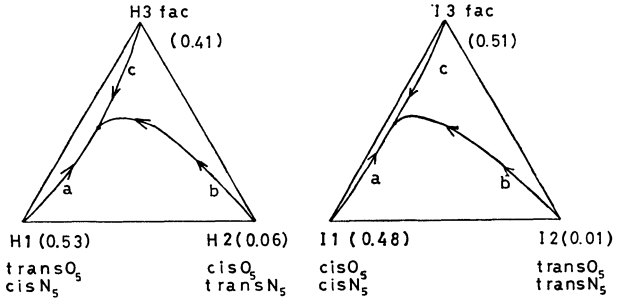

Fig. 7. Experimentally observed compositions for the isomerization at 80 °C. a: From H1(I1), b: from H2(I2), and c: from H3(I3).

the Hi system. The molar fractions at equilibrium are as follows: I1(0.48), I2(0.01), and I3(0.51). The free energy differences at 25 °C are as follows: $\Delta G_{12}'=G'(\mathrm{I1})-G'(\mathrm{I2})=-RT\ln(0.48/0.01)=-9.74$ kJ/mol and $\Delta G_{23}'=RT\ln(0.51/0.01)=9.74$ kJ/mol. In both systems each isomer may have only a little steric hindrance and hydrogen bonding between the coordinated his and asp. The fact that the molar fractions are in the order *trans*O_5*cis*N_5>L-*fac*≫*cis*O_5*trans*N_5 for [Co(L-asp)(L-his)], and D-*fac*≈*cis*O_5*cis*N_5≫*trans*O_5-*trans*N_5 for [Co(D-asp)(L-his)] suggests the existance of a common effect determing the molar fractions. Firstly the *trans*N_5 isomers must be less stable than the *cis*N_5 isomers in both systems and secondly the *trans*O_5 isomers are a little less stable than the *cis*O_5 isomers between mer isomers. In the case of the iosmerization of [Co(D-asp)(L-2,4-dba)], the molar fraction of the *trans*O_5*trans*N_5 isomer at equilibrium was the smallest of the three, although the molar distribution for the fac isomer was smaller than that for *cis*O_5*cis*N_5 (*cis*O_5*cis*N_5, *trans*O_5*trans*N_5, *fac*=0.68, 0.11, 0.21).[1] Recently, investigations of the *trans* effect for the cobalt(III) complex containing S-bonded sulfite ligands have been reported.[4] In cobalt(III) chemistry, S-bonded sulfite produces a specific and dramatic labilization of the ligands situated in the *trans* position. This electronic effect which is transmitted through the bonds may apply in this our study, *i.e.* it is suggested that the two α-nitrogen atoms avoid the *trans* position around a Co(III).

Chemical Ionization Mass Spectrometry of Alkyl Nitrates and Nitrites†

Rebati C. Das,†† Osamu Koga, and Shin Suzuki*

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260

(Received May 23, 1978)

The mass spectrometry of alkyl nitrites and alkyl nitrates with chemical ionization using methane and isobutane as reagent gases produces quasi-molecular ions, $(M+1)^+$ and/or $(M-1)^+$. These ions have maximum abundance for lower nitrates and nitrites. The chemical ionization mass spectrometry, in conjunction with gas chromatography, can be used for quantitative estimation of alkyl nitrates and nitrites in very low amounts.

The behaviors of nitrogeneous compounds formed in the photochemical reactions of NO_x–hydrocarbon–O_2 system in the atmospheric smog as well as in the chamber model have recently gained much interest.[1-3] Unfortunately, all compounds have not been completely and unequivocally identified.[1-3] Alkyl nitrates and nitrites, present in the above system, have been analyzed in low quantities by GC method using ECD detector,[4] but many other compounds *e.g.* chloride interfere in the method. Independent confirmation is, therefore, necessary. Mass spectrometry is a very convenient method of analysis but conventional electron impact ionization (EI)method is not always suitable due to easy fragmentation of unstable compounds by electron beams producing structurally insignificant low mass fragments. Chemical ionization (CI) mass spectrometry, recently developed,[5] has been used to obtain quasi-molecular peaks [$m/e=(M+1)$ or $(M-1)$] of many organic compounds of high abundance, thus making their identification more confirmatory.

This paper reports our results on the CI mass spectrometry of alkyl nitrates and nitrites as a part of our overall program of complete identification and analysis of all the products formed in the NO_x–hydrocarbon–O_2 system.

Experimental

A Shimadzu GC-MS apparatus was used. Mostly commercially available alkyl nitrates and nitrites were used. Ethyl nitrate, pentyl and isopentyl nitrate (Tokyo Kasei Kogyo) were directly used after having checked their purity chromatographically. All other compounds were separated from the constituents present with them in the GC column consisting of PEG 400 at room temperature using helium as carrier gas (flow rate 8—11 ml/min) before introduction to the ionization chamber. Ethanolic solutions of ethyl nitrite (Wako), pentyl and isopentyl nitrite (Tokyo Kasei Kogyo) were used. Ethyl nitrite being a gas at room temperature is market as solution in ethanol. Pentyl and isopentyl nitrite are market in the mixed form. Methyl nitrate is not commercially available. It was prepared by gas phase photolysis of ethyl nitrite-O_2 system[6] and separated from other products in the above manner.

Results and Discussion

Figures 1 to 8 give the EI and CI mass spectral patterns of some common alkyl nitrates and nitrites.

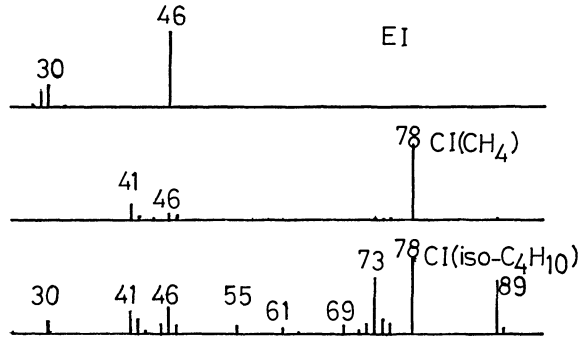

Fig. 1. Mass spectra of methyl nitrate (MW 77).

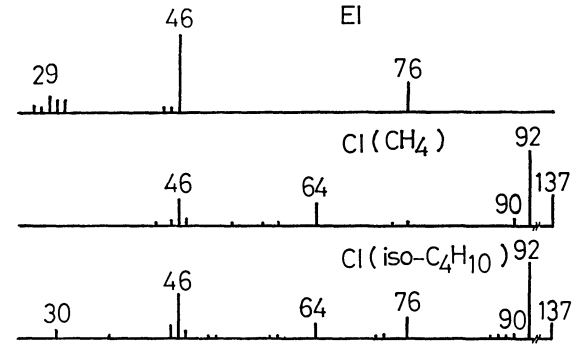

Fig. 2. Mass spectra of ethyl nitrate (MW 91).

The CI patterns are for CH_4 and i-C_4H_{10} as reagent gases. The conditions of the mass spectra presented in Figs. 1 to 8 are as follows. EI spectrum: Ion-source temperature 170 °C, Electron energy 70 eV, Pressure††† 7×10^{-7} Torr. CI(CH_4) spectrum: Ion-source temperature 170 °C, Electron energy 500 eV, Pressure††† 3×10^{-5} Torr. CI(i-C_4H_{10}) spectrum: Ion-source temperature 170 °C, Electron energy 500 eV, Pressure††† 0.75×10^{-5} Torr.

The main reactant ions are known to be CH_5^+ and $C_2H_5^+$ when methane is used as the reagent gas.[5] Similarly with i-C_4H_{10} as the reagent gas, t-$C_4H_9^+$ is the main reactant ion.[5,7] The proton and hydride transfer reactions of these ions are important for analytical purpose, because they generate the quasi-molecular $(M+1)^+$ and $(M-1)^+$ ions respectively.

† Presented at the 37th National Meeting of the Chemical Society of Japan, Yokohama, April 1978.

†† Present address: Department of Chemistry, University College of Engineering, Burla, Orissa, India.

††† Pressure is monitored between the ionization chamber and the vacuum pump in the apparatus. This pressure relates only to the reagent gas pressure.

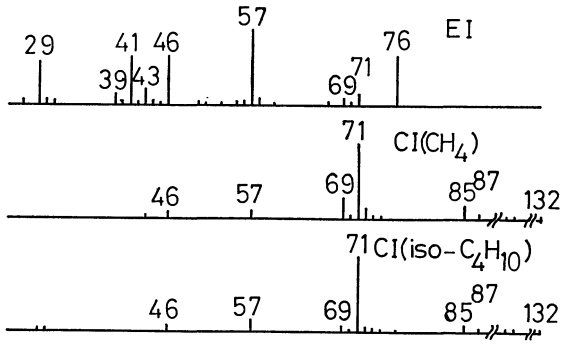

Fig. 3. Mass spectra of pentyl nitrate (MW 133).

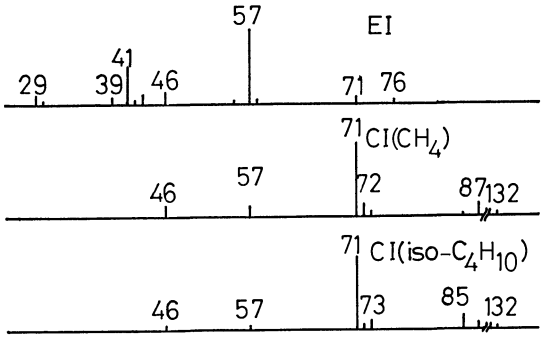

Fig. 4. Mass spectra of isopentyl nitrate (MW 133).

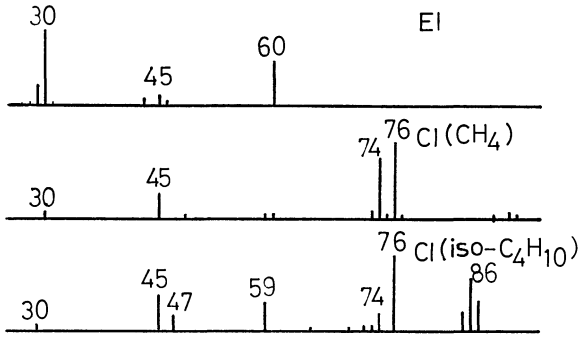

Fig. 5. Mass spectra of ethyl nitrite (MW 75).

$$RH + CH_5^+/C_2H_5^+/t\text{-}C_4H_9^+ \longrightarrow RH_2^+ + CH_4/C_2H_4/C_4H_8 \quad (1)$$

$$RH + C_2H_5^+/t\text{-}C_4H_9^+ \longrightarrow R^+ + C_2H_6/C_4H_{10} \quad (2)$$

A perusal of the figures shows that the mass spectral patterns obtained with CH_4 as the reagent gas are generally simpler (less fragments) and therefore, CH_4 is more suitable for the identification and analysis of alkyl nitrates and nitrites by CI mass spectrometry.

Almost all the compounds produce $(M+1)^+$ ion, but only in the lower homologues of nitrates and nitrites(with 1 and 2 C-atoms), it is the most abundant one. There may be two reasons for this *viz.*(i) with the increase of chain length of the molecule, the bond energy decreases causing easy fragmentation of the quasi-molecular ion and (ii) Reaction 1 producing $(M+1)^+$ ion may be sufficiently exothermic in higher homologues to exceed the bond dissociation energies. The latter explanation is more reasonable, because the decrease of bond dissociation energy from 1-C to 5-C compounds is not likely to be high.[8] Thus, the proton

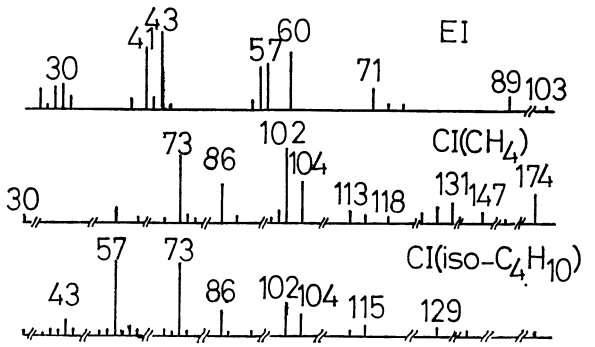

Fig. 6. Mass spectra of butyl nitrite (MW 103).

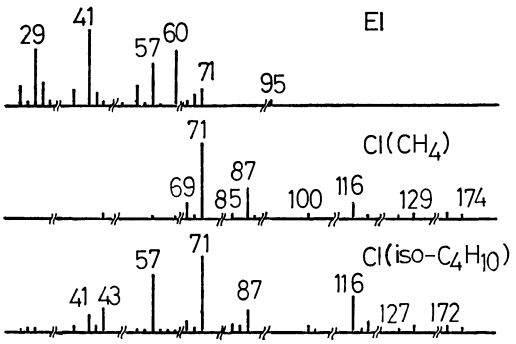

Fig. 7. Mass spectra of pentyl nitrite (MW 117).

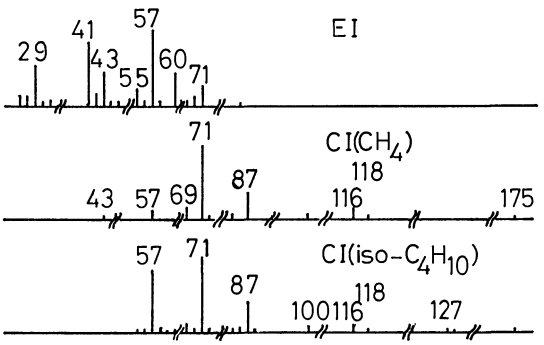

Fig. 8. Mass spectra of isopenthyl nitrite (MW 117).

affinity of ethyl nitrates and nitrites may be higher for higher homologues, because heat of Reaction 1 is given by the following equation.[7]

$$\Delta H_1 = PA(CH_4/C_2H_4/C_4H_8) - PA(RH) \quad (3)$$

(PA stands for proton affinity)

The $(M-1)^+$ ions generally do not have high abundance. It is also observed with our limited data that these ions are present in relatively greater abundance in the nitrite spectra than in the corresponding nitrate spectra with any particular reagent gas.

The EI spectra of the compounds reported in this paper are consistent with those documented in the literature.[9,10] Two characteristic ions present in the EI spectra of the nitrates are, NO_2^+ (m/e=46) and $CH_2ONO_2^+$ (m/e=76).‡[,10] The corresponding ions,

‡ Present in normal-type alkyl nitrates and nitrites except in CH_3ONO_2 and CH_3ONO.

NO^+(m/e=30) and CH_2ONO^+ (m/e=60)‡ are also present in the EI spectra of the nitrite esters. In addition to the above characteristic ions, many fragments from the alkyl carbon chain are also present. In higher homologues of the nitrate and nitrite compounds, these mass fragments from the carbon chain have relatively high abundance. Details of the EI spectra are not intended to be discussed in this paper.

Influence of Temperature and Pressure. The influence of temperature and pressure on the CI mass spectral pattern was studied in detail with ethyl nitrate as the substrate. Figure 9 shows the fraction of the relative abundance of the main ion (m/e=92) *vs.* temperature of the ionization chamber and pressure. It can be seen that the quasi-molecular ion has got maximum abundance at low temperature (170 °C) and pressure of $\approx 3\times10^{-5}$ Torr and $\approx 0.8\times10^{-5}$ Torr respectively for CH_4 and i-C_4H_{10} as reagent gases. The CI mass spectral patterns presented in this paper have, therefore, been taken at 170 °C and the above mentioned pressures.

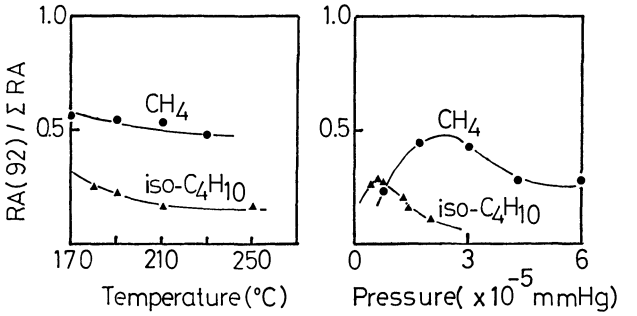

Fig. 9. Pressure and temperature dependence of mass fragments of ethyl nitrate.

Identification of Major Fragmentation Products. Complete identification of all fragments could not be made and is difficult. However, some speculations may be useful.

Methyl Nitrate (MW 77)(Fig. 1). $(M+1)^+$ is the ion with maximum abundance. Other major ions present are m/e=41, 46 (NO_2^+), and 47(NO_2H^+) for CH_4 as reagent gas and m/e=30 (NO^+), 41, 42, 45 (CH_3ON^+), 46 (NO_2^+), 47 (NO_2H^+), 55, 61 (CH_3ONO^+), 69, 72, 73 ($C_4H_9O^+$), 74, 75, and 89($C_4H_9O_2^+$) for i-C_4H_{10} as reagent gas. m/e=73 and 89 ions may be formed by the separation of CH_3ONO (m=61) and CH_3ON (m=45) groups from the cluster ion, $(RH+C_4H_9)^+$. Such cluster ions are very common in CI mass spectra with i-C_4H_{10}.[11] Unfortunately there are many unassigned ions, but only m/e=41 ion has relatively high abundance.

Ethyl Nitrate (MW 91)(Fig. 2). As in the case of methyl nitrate, the $(M+1)^+$ ion has maximum abundance. Other ions present are m/e=30 (NO^+), 45 ($C_2H_5O^+$), 46 (NO_2^+), 47 (NO_2H^+), 64 ($H_2NO_3^+$), 76 ($CH_2ONO_2^+$), and 137. The m/e=64 ion may be formed by the reaction between the reactant ions and RH or RH_2^+ by intramolecular rearrangement and fragmentation. The m/e=137 ion may also be speculated as $[(2M+1)-NO_2]^+$ ion, derived from $(2M+1)^+$ ion very often seen in the CI spectra.

Pentyl and Isopentyl Nitrate (MW 133)(Figs. 3 and 4). Quasi-molecular $(M-1)^+$ ion is present in very low abundance. $(M+1)^+$ ion has still less abundance. The base peak is due to $C_5H_{11}^+$ (m/e=71). Other ions produced in significant amounts are m/e=46 (NO_2^+), 57 ($C_4H_9^+$), 69 ($C_5H_9^+$), 72 ($C_5H_{12}^+$/$C_4H_8O^+$), 73 ($C_4H_9O^+$), 85 ($C_5H_9O^+$), and 87 ($C_5H_{11}O^+$).

Ethyl Nitrite (MW 75)(Fig. 5). As in the case of ethyl nitrate, $(M+1)^+$ ion has got maximum abundance. The $(M+1)^+$ peak is more prominent in this compound than in ethyl nitrate. The other major ions are m/e=30 (NO^+), 45 ($C_2H_5O^+$), 47 (NO_2H^+), 59 ($C_2H_5ON^+$), 85 ($C_6H_{13}^+$), 86 ($C_6H_{14}^+$), and 87 ($C_4H_9ON^+$). The last three ions are seen mainly in the i-C_4H_{10} spectrum. They may be formed by the separation of NO_2H (m=47), NO_2(m=46), and C_2H_5O (m=45) groups respectively from the cluster ion $(RH+C_4H_9)^+$.

Butyl Nitrite (MW 103)(Fig. 6). Quasi-molecular $(M-1)^+$ and $(M+1)^+$ ions are present in fairly good abundance. In the CH_4-spectrum, the former is the base peak. Other major ions present are m/e=30 (NO^+), 43 ($C_3H_7^+$), 57 ($C_4H_9^+$), 73 ($C_4H_9O^+$), 86 ($C_4H_8ON^+$), 88 ($C_3H_6ONO^+$), 113, 115, 118, 129, 131, 147, and 174. The last seven ions are obviously cluster ions whose origins are difficult to speculate. However, except m/e=131 and 174 ions, all of them are present in relatively low abundance.

Pentyl and Isopentyl Nitrite (MW 117)(Figs. 7 and 8). Both $(M+1)^+$ and $(M-1)^+$ ions are present in low abundance, but the latter ion has comparatively greater abundance. Other major ions present are, m/e=41 ($C_3H_5^+$), 43 ($C_3H_7^+$), 57 ($C_4H_9^+$), 69 ($C_5H_9^+$), 71 ($C_5H_{11}^+$), 85 ($C_5H_9O^+$), 86 ($C_4H_8ON^+$), 87 ($C_5H_{11}O^+$), and 100 ($C_5H_{10}ON^+$). Many cluster ions are also formed in very low abundance.

Quantitative Analysis by Mass Fragmentography. To study the possibility of quantitative analysis of alkyl nitrates and nitrites in trace amounts by CI mass spectrometry, mass fragmentography was attempted. This was measured at m/e=76 and 92 respectively for ethyl nitrite and ethyl nitrate using CH_4 as the reagent gas. PEG 400 at room temperature was used as the column material. It has earlier been successfully used for the separation of many organic materials, including PAN, in the atmospheric smog.[12] This

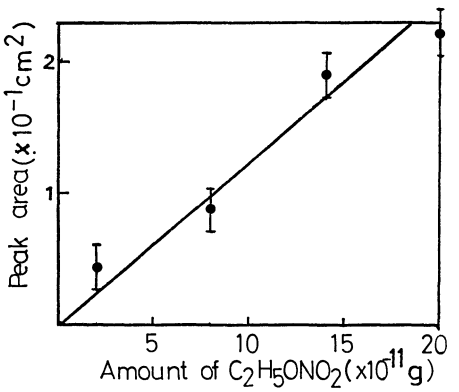

Fig. 10. Calibration curve for the analysis of ethyl nitrate by GC-CI-MF.

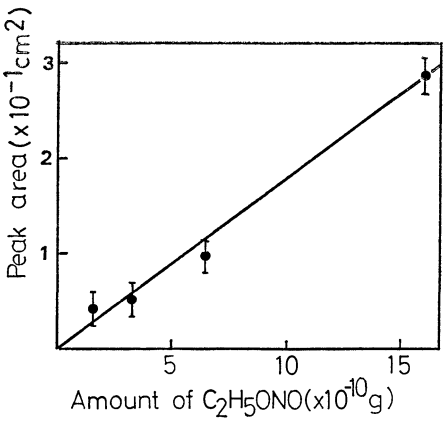

Fig. 11. Calibration curve for the analysis of ethyl nitrite by GC-CI-MF.

also has been used to separate different alkyl nitrates of low molecular weights from one another.[12] Helium was used as the carrier gas (flow rate 8—11ml/min). Standard solutions of the compounds in ethanol, in which they are stable, were injected into the column of the GC-MS apparatus and mass fragmentograms taken at appropriate GC peaks and mass numbers. The above column material could adequately separate the compounds from ethanol.

Figures 10 and 11 show the calibration curves (peak area of mass fragmentogram *vs.* amount of the compound injected into the column) at the lowest possible limits for both ethyl nitrate and ethyl nitrite respectively to give an idea about the sensitivity of the method. Qualitative detection is possible at still lower amounts of the samples (picogramme level). Quantitative analysis at picogramme level was not successful presumably due to adsorption of the samples on the glass surface of the syringe. A better sampling technique may improve the sensitivity limit.

The authors are grateful to the Japan Society for the Promotion of Science (JSPS) for award of a Senior Co-operative Fellowship to one of them (RCD). Also they wish to thank the Ministry of Education of the Government of Japan for supporting this research from the Fund for Environmental studies.

The Rates of the Hydrogenation of the Coordinated Styrene and Acrylonitrile in a Rhodium-Olefin Complex [$RhClH_2(ol)(PPh_3)_2$]

Yoshimi OHTANI, Akihiko YAMAGISHI, and Masatoshi FUJIMOTO*

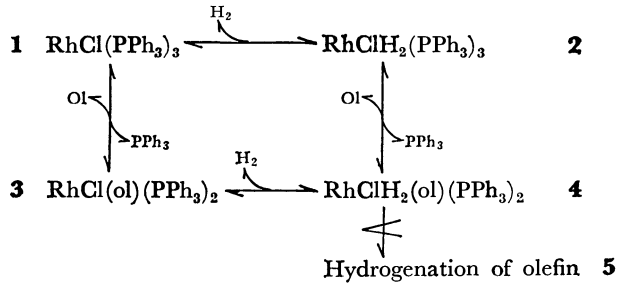
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 21, 1978)

Kinetics of the hydrogenation of coordinated styrene and acrylonitrile in a rhodium-olefin complex $RhClH_2(ol)(PPh_3)_2$ (ol=styrene or acrylonitrile) was studied by stopped-flow method and by the direct measurements of hydrogen-gas uptake. The equilibrium constant of the reaction $RhCl(ol)(PPh_3)_2+H_2 \rightleftharpoons RhClH_2(ol)(PPh_3)_2$, K_{34}, and the rate of the hydrogenation of the olefin in the complex $RhClH_2(ol)(PPh_3)_2$, k_{45}, were determined to be 3.2×10^3 mol^{-1} dm^3 and 2.7 s^{-1} for styrene, and 3.5×10^2 mol^{-1} dm^3 and 0.50 s^{-1} for acrylonitrile, respectively. The differences in the values for these two olefins were discussed. The data for cyclohexene were also briefly mentioned.

The catalysis of the homogeneous hydrogenation of olefins by Wilkinson's complex $RhCl(PPh_3)_3$ has been the main subject of many investigations on the homogeneous catalyses by transition metals.[1] In recent years the detailed reaction mechanism of this system has been revealed by studying independently the individual step of the complex formation processes.[2–5] However, in most investigations concerning hydrogenation of olefins, only the overall rate of the catalytic reaction has been reported.[6–8] Since the discussions based only on the observed rate constants of the overall reaction sometimes leave significant ambiguities, we need to elucidate the detailed mechanism involving the behavior of the catalytically active intermediate species by distinguishing the information on the intermediate species from those on the overall reaction.

Though no direct evidence was reported so far, the catalytic hydrogenation of olefins is believed to proceed in the molecule of an intermediate dihydrido-olefin complex, $RhClH_2(ol)(PPh_3)_2$ (ol=olefin), the rate-determining step being suggested to be the insertion of the coordinated olefin into an Rh–H bond to yield an alkyl complex (Scheme 1).[5,9] Thus the direct measurements of the step of production of an alkane from the intermediate dihydrido-olefin complex $RhClH_2(ol)(PPh_3)_2$ would be desired.



Scheme 1.

Recently Halpern *et al.* reported the value of k_{45} for cyclohexene as an olefin measured in the presence of a large excess of the free ligand PPh_3.[9,10] Since the predominant species involved under this condition are **1** and **2**, they did not observe directly the process **4**→**5**. The value estimated by them from the small intercept, however, can include a serious error. The value obtained by them ($k_{45}=0.20\pm0.04$ s^{-1}, at 25 °C) seems to be too small (*vide infra*).

In the previous paper on the catalytic hydrogenation of acrylonitrile, we confirmed the formation of $RhClH_2(ac)(PPh_3)_2$ (ac=acrylonitrile) in the absence of free PPh_3 added, and evaluated the value of k_{45}.[11,12] However, for the value of K_{34} only the lower limit could be determined by the stopped-flow measurements, giving consequently only an upper limit for the value of k_{45}.

In the present study, we adopted styrene as an olefin having a much lower coordinating ability than acrylonitrile. The values of K_{34} and k_{45} were determined by the stopped-flow method and the direct measurements of the hydrogen-gas uptake. The corresponding values for acrylonitrile, which had been estimated only from the stopped-flow method,[11] were also re-examined by the direct measurements of the uptake of hydrogen gas.

Experimental

Chlorotris(triphenylphosphine)rhodium(I) and chloro(ethylene)bis(triphenylphosphine)rhodium(I) were prepared according to Osborn *et al.*[6] Triphenylphosphine was recrystallized from ethanol. Benzene was distilled. Acrylonitrile and styrene were distilled under reduced pressure and used within a day. Commercial hydrogen and nitrogen were used without further purification. The concentration and the purity of hydrogen were determined by gas chromatography through Molecular sieve 5A.

All measurements were carried out at 20±1 °C in oxygen-free benzene. A solution of $RhCl(ol)(PPh_3)_2$ was prepared by dissolving $RhCl(C_2H_4)(PPh_3)_2$ in benzene containing styrene or acrylonitrile, and by removing the dissociated ethylene. The coordinated ethylene was easily replaced by the olefin, leaving a pure $RhCl(ol)(PPh_3)_2$ in benzene. The resultant solution was confirmed to contain no free PPh_3.[11]

The equilibria of the reaction were measured at 450 nm under an anaerobic condition with a Hitachi EPS-3T spectrophotometer or a Union Giken RA-1300 stopped-flow apparatus. The rates of the hydrogenation of olefins were measured by the uptake of hydrogen-gas as described previously.[11]

Results and Discussion

Styrene. Equilibria: The mechanism shown in Scheme 1 is proposed for the hydrogenation of olefins.[11] The steps of the complex formations are assumed to be in pre-equilibria. The hydrogenation of the

coordinated olefin is the rate-determining.[5,9] The equilibrium constant for each step of the complex formations was obtained separately from the equilibrium measurements.

The value of K_{13} was obtained from the measurements carried out by the addition of the solution of PPh_3 little by little to the solution of $RhCl(st)L_2$ (st=styrene and L=PPh_3) containing no free ligand PPh_3. Figure 1 shows the dependence of the absorbance of the solution on the concentration of added PPh_3. The solid curve reproduced with the value $K_{13}=2.4\times10^{-4}$ agrees well with the experimental values.

When a benzene solution containing hydrogen was rapidly mixed with the solution of $RhCl(st)L_2$ by stopped-flow technique under the condition of $[Rh]<[H_2]_0\ll[St]$, the stepwise changes in the absorbance at 450 nm were observed. First, a rapid exponential decrease in absorbance owing to the formation of $RhClH_2(st)L_2$ was observed. The signal terminated within 0.1 s. Then the absorbance slowly increased as the hydrogen in the solution was consumed for the hydrogenation of the styrene.[11] After 20 s the absorbance was again increased to the initial value, showing the consumption of all hydrogen molecule and the reproduction of $RhCl(st)L_2$. Figure 2 shows the dependence on the concentration of hydrogen of the decrease in absorbance in the first step. The value of K_{34} was calculated from the change in absorbance. In order to ascertain the validity of the values obtained above, we compared these values with those obtained from the direct measurements of the hydrogen-gas uptake. The curve in Fig. 2 is reproduced using the value of $K_{34}=3.2\times10^3$ mol^{-1} dm^3 evaluated from the measurements of the hydrogen-gas uptake, showing a good agreement with the results of the stopped-flow measurements.

The value of K_{12} was estimated to be 2.1×10^4 mol^{-1} dm^3.[13] Thus, from the relationship $K_{24}=K_{13}K_{34}/K_{12}$ the value of K_{24} was calculated to be 3.7×10^{-5}.

Hydrogen-gas Uptake:[11] The rate of the hydrogenation of styrene was directly measured by the hydrogen-gas uptake at 1 atm hydrogen. Figure 3 shows the rate constants observed at various concentrations of added PPh_3. From the results, the values of K_{34} and k_{45} can be estimated by the curve-fitting method.

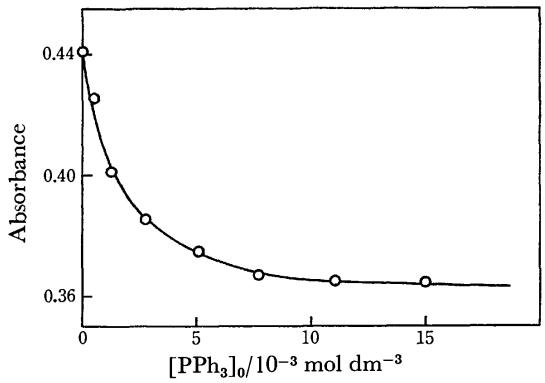


Fig. 1. The dependence of the absorbance of the $RhCl(st)(PPh_3)_2$ solution on the concentration of PPh_3 added. $[RhCl(st)(PPh_3)_2]_0=2.6\times10^{-4}$ mol dm^{-3}, at 450 nm, and 20 °C. The solid curve in the figure is reproduced with the value $K_{13}=2.4\times10^{-4}$.

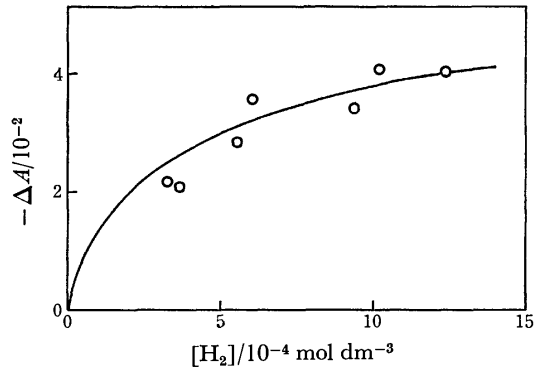

Fig. 2. The dependence of the absorbance decrease on the concentration of hydrogen in the reaction of $RhCl(st)(PPh_3)_2$ with hydrogen. The solid line in the figure is reproduced using the value $K_{34}=3.2\times10^3$ mol^{-1} dm^3, which is obtained from the measurements of hydrogen-gas uptake.

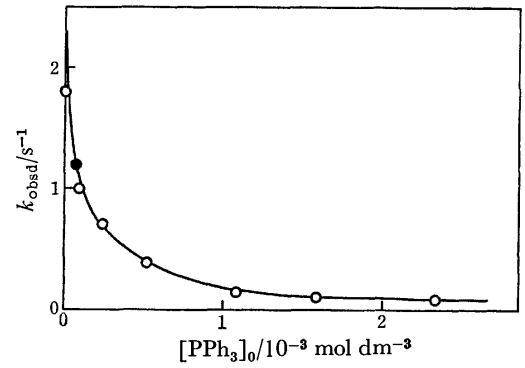

Fig. 3. The plot of the observed rate constant k_{obsd} for the hydrogenation of styrene *vs.* the concentration of PPh_3 added. The initial rates of the hydrogen-gas uptake were measured. $[Rh]_0=6.4\times10^{-5}$ (1.3×10^{-6} mol), [St]=2.6, and $[H_2]=2.8\times10^{-3}$ mol dm^{-3}. ●; $RhCl(PPh_3)_3$ without adding PPh_3. The solid line in the figure is reproduced using $K_{34}=3.2\times10^3$ mol^{-1} dm^3 and $k_{45}=2.7$ s^{-1}.

According to Scheme 1, the observed overall rate constant is expressed by

$$k_{obsd}=k_{45}\frac{[RhClH_2(st)L_2]}{[Rh]_t}, \quad (1)$$

where $[Rh]_t$ denotes the total concentration of rhodium species. Since the value of $[RhClL_3]$ is about 1/60 of $[RhClH_2L_3]$ at 1 atm hydrogen, as calculated from the value $K_{12}=[RhClH_2L_3]/[RhClL_3][H_2]=2.1\times10^4$ mol^{-1} dm^3, the contribution of $RhClL_3$ can be neglected. Therefore, $[Rh]_t$ and the total concentration of added PPh_3, $[L]_0$, are approximated as follows:

$$[Rh]_t \simeq [RhClH_2L_3]+[RhCl(st)L_2]+[RhClH_2(st)L_2] \quad (2)$$

$$[L] \simeq [L]_0-[RhClH_2L_3] \quad (3)$$

The value of equilibrium constant K_{23} is calculated by

$$K_{23} = K_{13}/K_{12} = \frac{[RhCl(st)L_2][H_2][L]}{[RhClH_2L_3][St]}$$
$$= \frac{[RhCl(st)L_2][H_2]\{[L]_0 - [RhClH_2L_3]\}}{[RhClH_2L_3][St]} \quad (4)$$
$$= 1.2 \times 10^{-8} \text{ mol dm}^{-3}.$$

The concentrations of $RhClH_2(st)L_2$ are calculated from Eqs. 2 and 4 by estimating an adequate value for $K_{34}=[RhClH_2(st)L_2]/[RhCl(st)L_2][H_2]$. The value of k_{45} can be determined by introducing the calculated value of $[RhClH_2(st)L_2]$ into Eq. 1. A set of K_{34} and k_{45} used for the calculations, which fit well with the experimental values, is evaluated to be $K_{34}=3.2\times10^3$ mol^{-1} dm^3 and $k_{45}=2.7$ s^{-1}, giving the solid line depicted in Fig. 3. Disagreement of the values obtained under the condition without PPh_3 added may be caused by the partial decomposition of the bis(triphenylphosphine) complex.

The experiments at varying concentrations of styrene were not possible, since at lower concentrations the formation of the dimeric species could not be neglected, and at higher concentrations other unidentified species were formed.

The equilibrium constant K_6 in Eq. 6 was determined to be 5.5×10^{-4} mol^{-1} dm^3 from the measurements of the reaction varying amounts of styrene with the dimer.

$$(RhClL_2)_2 + 2St \overset{K_6}{\rightleftharpoons} 2RhCl(st)L_2 \quad (6)$$

$$2RhClL_3 \overset{K_7}{\rightleftharpoons} (RhClL_2)_2 + 2L \quad (7)$$

The value of K_{13} was determined also from K_6 and K_7[14] to be 2.2×10^{-4} based on the relationship $K_{13}=K_6^{1/2}K_7^{1/2}$. The value agrees well with that obtained above.

Acrylonitrile. *Hydrogen-gas Uptake*:[8] In the previous paper we reported the values, $K_{34}\geq150$ mol^{-1} dm^3 and $k_{45}\leq0.74$ s^{-1}. In the present study, the rate of the hydrogen-gas uptake was directly measured at various concentrations of acrylonitrile and added PPh_3 (Fig. 4). The values of K_{34} and k_{45} were calculated in a similar manner to the case of styrene, to be 350 mol^{-1} dm^3 and 0.50 s^{-1}, respectively, the value $K_{23}=K_{13}/K_{12}=0.22/(2.1\times10^4)=1.0\times10^{-5}$ being used. The solid line in Fig. 4 are reproduced using these values of K_{34} and k_{45}.

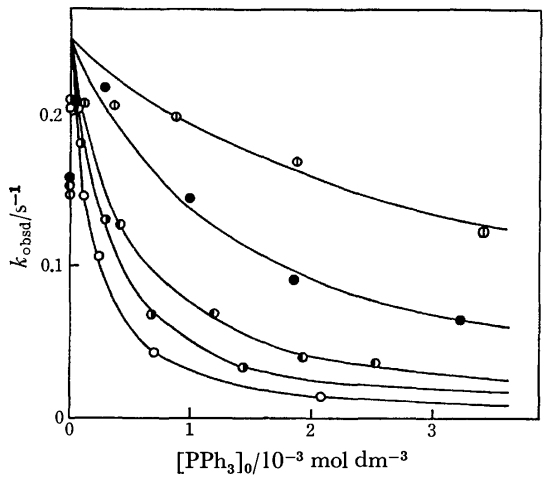

Fig. 4. The plot of the observed rate constant for the hydrogenation of acrylonitrile *vs.* the concentration of PPh_3 added. The initial rates of the hydrogen-gas uptake were measured. $[Rh]_0=1.5\times10^{-4}$ (2.9×10^{-6} mol), $[H_2]=2.8\times10^{-3}$, and [Ac]=○; 0.015, ◑; 0.031, ◐; 0.046, ●; 0.15, ⓘ; 0.46 mol dm^{-3}. The solid curves in the figure are reproduced using the values of $K_{34}=3.5\times10^2$ mol^{-1} dm^3 and $k_{45}=0.50$ s^{-1}.

Discrepancies in the data observed without PPh_3 added may be due to the dissociation of the coordinated ligand PPh_3, which causes the formation of some catalytically inactive species.

The distinct differences observed in the behavior of acrylonitrile and styrene are summarized as follows: Whereas the value of K_{13} for acrylonitrile is about 10^3 times as large as that for styrene, the values of K_{34} and k_{45} for styrene are by several times larger than those for acrylonitrile. These differences may be attributed to the difference in the coordinating properties of the two olefins having a cyano and a phenyl group as substituents. Acrylonitrile having a strong electron-withdrawal cyano group shows a large K_{13} because of the strong back-donation from the central rhodium atom. Therefore, the addition of hydrogen molecule to $RhCl(ac)L_2$ would become difficult, since the electron density on the central rhodium atom is decreased owing to the strong back-donation. The electron-releasing phenyl group in styrene would act oppositely.

Recently Halpern *et al.* reported the value of k_{45} for cyclohexene 0.20 ± 0.04 s^{-1} at 25 °C in the presence of a large excess of PPh_3. Although we intended also to obtain the value of k_{45} for cyclohexene without PPh_3 added, the measurements were not possible owing to the unfavorable precipitation of the dimeric species under the given conditions. The value of K_{13} for cyclohexene may be much smaller than that for styrene, suggesting a much lower concentration of the resultant intermediate dihydrido-olefin complex, $RhClH_2(ol)L_2$, than that for styrene. When tris(triphenylphosphine) complex, $RhClL_3$, is used as the catalyst, the observed overall rate constant for the catalytic hydrogenation of cyclohexene is about 1/3 as small as that of styrene.[7] Thus, the value of k_{45} for cyclohexene is expected not to be much smaller than that for styrene. It may be estimated to be at least larger than 0.20 s^{-1}.

The Mechanism of the Spin-Spin Coupling of Dimethyllead(IV) Complexes with ONNO Quadridentate Schiff Base Ligands and the Magnetically Non-equivalent Methyl Protons of a Dimethyllead(IV) Complex

Tetsuro MAJIMA and Yoshikane KAWASAKI*

Department of Petroleum Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 31, 1978)

Several dimethyllead(IV) complexes with ONNO quadridentate Schiff base ligands have been prepared. The spin-spin couplings between the lead nucleus and the azomethine proton of the ligands, $^3J(^{207}Pb\text{–}N{=}CH)$, as well as the lead-methyl proton couplings, $^2J(^{207}Pb\text{–}CH_3)$, have been observed in various solvents. Both J values inclease with an increase in donor strength of the solvents. The mean excitation energy, the ΔE term in the Fermi contact term plays a dominating role for the lead-proton spin-spin coupling constants. Two methyl proton signals were, for the first time, found to be magnetically non-equivalent in the dimethyllead(IV) complex of sapr.

The metal-proton spin-spin coupling constants, J(M, H), in methyl compounds of Sn, Hg, Tl, and Pb have been known to sensitively reflect changes in the configuration and electronic state around the central metal.[1] The various studies on the coupling mechanism of J(M,H), have been considered to be mainly governed by the Fermi contact interaction as approximately expressed by[2]

$$J(\mathrm{M,H}) = \mathrm{const}\cdot\alpha_M{}^2\cdot a_M(ns)\cdot a_H(1s)/\Delta E, \quad (1)$$

where $\alpha_M{}^2$ is the s character of the metal orbitals in the metal–carbon bonds, $a_M(ns)$ and $a_H(1s)$ are the hyperfine coupling constants of the ns electron in a metal atom and the 1s electron of a proton respectively. ΔE is the mean singlet-triplet excitation energy.

It has been reported that in methyltin compounds the $^2J(^{119}Sn\text{–}CH_3)$ values depend almost entirely on the s character of the tin orbitals used in the tin–carbon bonds,[1b,3] and in the methyl compounds of Hg and Tl, the effective nuclear charge is the dominating factor in addition to the s character.[4] In dimethyllead(IV) compounds changes of the $^2J(^{207}Pb\text{–}CH_3)$ values with the solvent depends largely on the ΔE term.[5]

In dimethyllead(IV) complexes, the spin-spin coupling constants between the lead nucleus and the ligand protons have, in most cases, not been observed, for example in $(CH_3)_2Pb(acac)_2$ (acac=acetylacetonato).[5a] The $^2J(^{207}Pb\text{–}CH_3)$ values have however been observed. One of the possible explanations is ligand dissociation; Eq. 2 and/or intermolecular exchange of the acac; Eq. 3 on the ^1H NMR time scale.[6]

$$(CH_3)_2Pb(acac)_2 \rightleftharpoons (CH_3)_2Pb(acac)^+ + acac^- \quad (2)$$

$$(CH_3)_2Pb(acac)_2 + (CH_3)_2Pb(acac^*)_2 \rightleftharpoons 2(CH_3)_2Pb(acac)(acac^*) \quad (3)$$

Therefore, the mechanism of the lead-proton spin-spin coupling of dimethyllead(IV) complexes has been discussed mainly on the basis of changes in the $^2J(^{207}Pb\text{–}CH_3)$ values.[1e,5a–f,7] However, observation of the lead-ligand protons spin-spin coupling constants are of importance to verify our previous assumptions that changes of the spin-spin coupling constants of dimethyllead(IV) complexes depend on changes in the ΔE term.[5]

In this work, ONNO quadridentate Schiff base ligands, shown below, were selected, since these ligands have been known to coordinate storongly to the central metal atom[8] and a spin-spin coupling constant between the lead nucleus and the azomethine proton of the ligands, $^3J(^{207}Pb\text{–}N{=}CH)$, may be predicted.

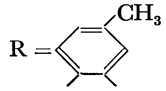
; *N,N'*-*o*-phenylenebis(salicylideneaminato): saph



; *N,N'*-(4-methyl-1,2-phenylene)-bis(salicylideneaminato): sato

Experimental

Materials. Dimethyllead dichloride was prepared by the chlorination of tetramethyllead in ethyl acetate at −10 °C.[9] Schiff bases, *N,N'*-alkyl- or -aryl-substituted-bis(salicylideneamine)s (H_2**L**) were prepared from dehydration reactions between salicylaldehyde and the corresponding diamines by refluxing in ethanolic solution.[10] The solvents used were reagent grade and purified according to the standard method except for $CDCl_3$ which was used as supplied.

*Preparation of $(CH_3)_2Pb$**L**$\cdot S$ (**L**=saln, sapr, saph, and sato; $S=CH_3OH$ or H_2O).* Dry methanol solution (20 dm^3) of the sodium salts of an appropriate Schiff base (Na_2**L**), prepared from sodium methoxide in methanol (Na; 0.5 g, 20 mmol) and H_2**L** (10 mmol), was added dropwise under stirring to dimethyllead dichloride (2.5 g, 10 mmol) in dry methanol (30 dm^3) and the mixture was stirred for a few hours. The precipitates were filtered, washed with benzene and methanol, and recrystallized from hot methanol. The crystalline complexes obtained in this manner contained one molecule of methanol or water.[11]

Molecular Weight and Conductivity Measurements. The molecular weight of $(CH_3)_2Pb(saln)\cdot CH_3OH$ in $CHCl_3$

(0.5 wt %) was established using a Mechrolab vapor-pressure osmometer at 25 °C and was found to be 562 (504 calcd for $(CH_3)_2Pb(saln)$). This suggests that the methanol in the complex is free in solvents.[12] Molar conductances in DMSO were measured by a Yokogawa F-225A Universal bridge and a cell with a cell constant of 0.377 cm^{-1} at 25±0.1 °C. The specific conductance of DMSO used was $\kappa=4.2\times10^{-7}\,\Omega^{-1}\,cm^{-1}$. Molar conductances ($\Lambda_m$) of $(CH_3)_2PbL\cdot S$ in DMSO (10^{-3} mol dm^{-3}) were $<0.8\,\Omega^{-1}\,cm^2\,mol^{-1}$ (Table 1). All complexes were found to be non-electrolytes.

The IR, ^1H NMR, and UV Spectra. The IR spectra were recorded on a Hitachi 225 spectrophotometer. The ^1H NMR studies were conducted on a JEOL-PS-100 spectrometer operating at 100 MHz. All data were obtained in *ca.* 4 wt %. Chemical shifts were measured wih TMS as internal standard at ambient temperature. The UV spectra were recorded on a Hitachi model 356 spectrophotometer with 0.1 cm quartz cells.

Analytical data, physical properties, and IR, ^1H NMR, and UV spectral data for the dimethyllead(IV) complexes prepared in this study are summarized in Tables 1—6.

Results and Discussion

As expected, the spin-spin coupling constants between the azomethine proton and the lead nucleus, $^3J(^{207}Pb–N=CH)$, were observed for all complexes; $(CH_3)_2PbL\cdot S$ (**L**=saln, sapr, saph, and sato; S=CH_3OH or H_2O) (Tables 2—5).[13] The chemical shifts of the ligand protons, in all cases, moved to a higher magnetic field upon complex formation. In the case of the sapr complex two azomethine proton signals with different $^3J(^{207}Pb–N=CH)$ values were observed, thought due to the effect of the methyl group in the propylene unit in sapr and the difference in the strength of coordination of the two azomethine nitrogen atoms to the lead atom. One azomethine proton being closer to the methyl group (H_a) is more shielded (up-field shifts of *ca.* 0.05 ppm) and has a larger spin-spin coupling to the lead nucleus than the other (H_b). Similarly, in the sato complex two azomethine proton signals were observed, the difference in chemical shift being smaller than in the sapr complex, and the two $^3J(^{207}Pb–N=CH)$ values were equal within experimental error. Assignment of two signals is difficult to make from this result only. In IR spectra (Table 1), the stretching frequencies of the C–N double bond in CH_2Cl_2 (1608—1620 cm^{-1}) and in hexamethylphosphoric triamide (HMPA) (1608—1625 cm^{-1}) are almost the same but move to lower frequencies from those of the free Schiff bases (1618, 1620, 1628, and 1635 cm^{-1} for H_2saln, H_2sapr, H_2saph, and H_2sato in CH_2Cl_2 respectively). None of these complexes exhibited electric conductivity in DMSO (Table 1). Consequently, the ligand in these complexes may be assumed to coordinate to the lead atom as ONNO quadridentate ligands in all the solvents, according to a similar discussion in the dimethyllead complexes series.[5] In the UV spectra of $(CH_3)_2Pb(saln)\cdot CH_3OH$ (Table 6), a blue shift for the longest wavelength band was observed in the change from

non-coordinating solvent to donor solvent. Other bands exhibited small changes. This, however, is quite different for $(CH_3)_2Pb(ox)_2$ (ox=8-quinolinolato) in which the red shift was obtained at the longest wavelength[5c] and this may arise from a difference in coordination to the lead atom.

The $^2J(^{207}Pb-CH_3)$ values of these complexes in $CDCl_3$ (154—158 Hz) are comparable to those of many dimethyllead(IV) complexes having a six-coordinate configuration with a linear C–Pb–C skeleton (for

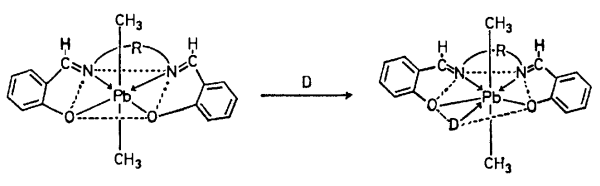
example, 154.7 and 152.5 Hz in $(CH_3)_2Pb(acac)_2$[5a] and $(CH_3)_2Pb(ox)_2$[5c] respectively in $CDCl_3$). It is, therefore, reasonable to assume that these complexes have a six-coordinate configuration (**A**) in such non-coordinating solvents as $CDCl_3$ and CH_2Cl_2.

The proton resonances of the methyl groups attached to the lead atom, δ(Pb–CH_3), shift to a higher magnetic field and the $^2J(^{207}Pb–CH_3)$ values increase with an increase in donor strength of the solvents,[14] as in the case of other dimethyllead(IV) complexes; $(CH_3)_2PbL_2$ (L=ox, acac, $OCOC_6H_5$).[5] Therefore, the present complexes, $(CH_3)_2Pb$**L**·S, with ONNO quadridentate Schiff base ligands take a seven-coordinate configuration (**B**) in such donor solvents as DMSO and HMPA and this is supported by the $^2J(^{207}Pb–CH_3)$ values (175—190 Hz) which are comparable to or larger than those of an isolated seven-coordinated complex, $(CH_3)_2Pb(gbha)(H_2O)$ (gbha= 2,2′-(ethanediylidenediimino) diphenolato) (178—181 Hz).[15]



(**A**) (**B**)

D=HMPA, DMSO, pyridine, $(CH_3O)_3PO$, CH_3OH.

One of remarkable features in ^{1}H NMR spectral data shown in Tables 2—5 is that the $^3J(^{207}Pb–N=CH)$ values increase with the $^2J(^{207}Pb–CH_3)$ values. The $^3J(^{119}Sn–N=CH)$ values of $(CH_3)_2Sn(saln)$ have been reported to decrease with an increase in donor strength of the solvents, although the $^2J(^{119}Sn–CH_3)$ values increase.[16] Figures 1 and 2 show the linear relationships between the δ(Pb–CH_3) values and the $^2J(^{207}Pb–CH_3)$ and $^3J(^{207}Pb–N=CH)$ values for the dimethyllead complexes of saln and sapr respectively in various solvents. (The linear relationship was also obtained for saph and sato complexes.) In Figs. 3 and 4, the higher magnetic field shifts of the phenol ring proton resonances in these complexes with the methyl protons attached to the lead atom are shown. Interestingly, the amount of up-field shifts for 3-H and 5-H (*o*- and *p*-position to the oxygen atom respectively) are significantly larger than those for 4-H and 6-H (*m*-positions). This indicates that coordination of the solvent molecule brings about some electron donation to the lead atom and ligand, resulting in a decrease of the positive charge on the lead atom and an increase of electron density on the oxygen atom.

These results support a previous suggestion that a change of the mean excitation energy, ΔE, in the Fermi contact term plays a dominant role on the solvent dependence of the $^2J(^{207}Pb–CH_3)$ values.[5] Namely,

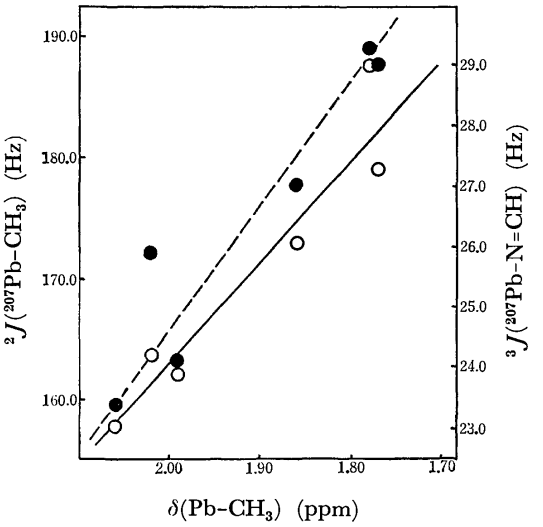


Fig. 1. Plots of the $^2J(^{207}Pb\text{-}CH_3)$ (—○—) and $^3J(^{207}Pb\text{-}N{=}CH)$ (--●--) *vs.* $\delta(Pb\text{-}CH_3)$ values for $(CH_3)_2Pb(saln)\cdot CH_3OH$ in several solvents.

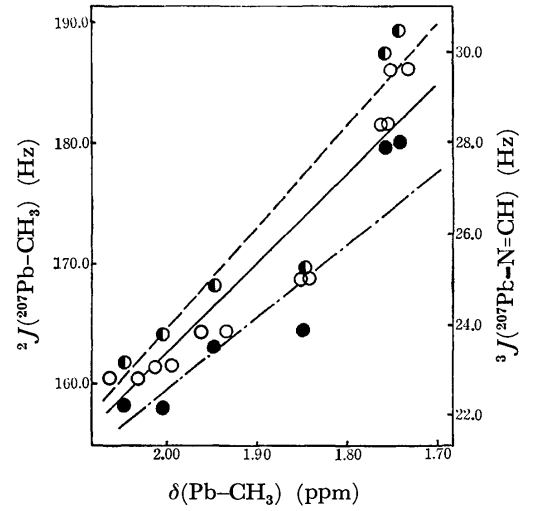

Fig. 2. Plots of the $^2J(^{207}Pb\text{-}CH_3)$ (—○—) *vs.* two $\delta(Pb\text{-}CH_3)$ values and of the $^3J(^{207}Pb\text{-}N{=}CH_a)$ --◐--) and $^3J(^{207}Pb\text{-}N{=}CH_b)$ (-·—●—·-) *vs.* the average of two $\delta(Pb\text{-}CH_3)$ values for $(CH_3)_2Pb(sapr)\cdot CH_3OH$ in several solvents. See Table 3, regarding sings of azomethine protons.

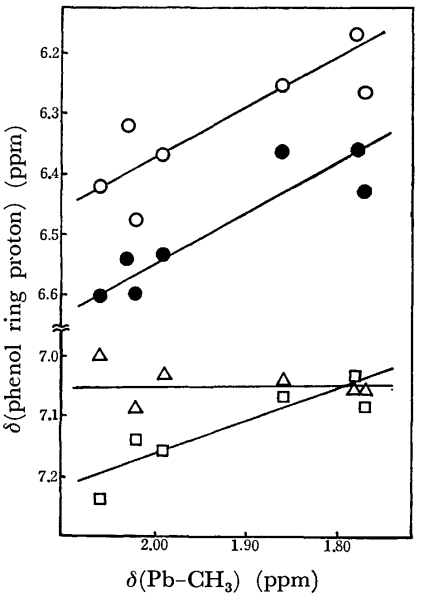

Fig. 3. Plots of the δ(phenol ring proton) *vs.* $\delta(Pb\text{-}CH_3)$ values for $(CH_3)_2Pb(saln)\cdot CH_3OH$ in several solvents; 5-H (—○—), 3-H (—●—), 6-H (—△—), and 4-H (—□—). Signs of these protons are written in Table 2.

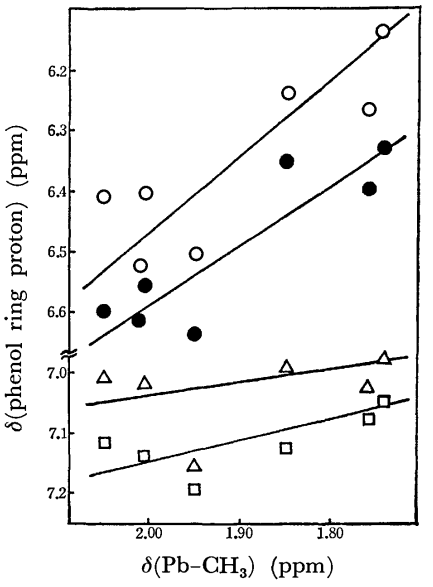

Fig. 4. Plots of the δ(phenol ring proton) *vs.* $\delta(Pb\text{-}CH_3)$ values for $(CH_3)_2Pb(sapr)\cdot CH_3OH$ in several solvents; 5-H (—○—), 3-H (—●—), 6-H (—△—), and 4-H (—□—). Signs of these protons are written in Table 3.

the increase of the $^2J(^{207}Pb\text{-}CH_3)$ values together with the $^3J(^{207}Pb\text{-}N{=}CH)$ values depend on a decrease of ΔE, which results from a decrease in the positive charge on the lead atom as a result of electron donation from the solvent molecules. It is difficult to interpret the results by the d-s mixing scheme,[1e] which has been proposed to account for the increase in the $^2J(^{205}Tl\text{-}CH_3)$ values of some dimethylthallium compounds in donor solvents. If the d-s mixing scheme were dominating, the s electron of the lead atom in the coordination plane of the ligands would transfer to the C–Pb–C bond, resulting in an increase of the s character of the lead atom for Pb–C bonds and a decrease in the coordination plane of ligands. Therefore, decrease in the $^3J(^{207}Pb\text{-}N{=}CH)$ values was expected when the $^2J(^{207}Pb\text{-}CH_3)$ values increased, and *vice versa*. This is not consistent with the results reported here. Similarly, the results can not be explained in terms of the change of $a_{Pb}(6s)$ term in Eq. 1 which decreases with decreasing positive charge on the lead atom.

From Tables 2—5, it may be seen that the δ(N=CH) values shift to a lower magnetic field with an increase in donor strength of the solvents. This change may be accounted for by two compensating factors; 1) the down-field shift due to hydrogen bonding with oxygen atom of the solvents, which grows stronger with an increase of donor strength of the solvents, (the down-

field shift of the azomethine proton for free H_2saln is as follows: 8.32, 8.53, 8.60, 8.73, 8.73, and 9.04 in $CDCl_3$, CH_2Cl_2, CH_3OH, $(CH_3O)_3PO$, DMSO, and HMPA respectively.) and 2) the up-field shift caused by the coordination of the solvent molecules to the lead atom. Indeed, the down-field shift of the N=CH proton in the saln complex from in $CDCl_3$ to in HMPA; 0.30 ppm was observed and is much smaller than that in H_2saln; 0.72 ppm. (These behaviors were observed also in sapr, saph, and sato complexes.)

It shoud be noted that the two methyl groups attached to the lead atom show different chemical shifts in the case of $(CH_3)_2$Pb(sapr)·CH_3OH, although the $^2J(^{207}Pb-CH_3)$ values were the same within experimental error. In the other three complexes only one methyl signal was observed. The magnetic non-equivalence of the methyl protons is attributed to the rigidity of the N–C–C–N skeleton of the sapr ligand and to no dissociation of the ligand attached to the lead atom. The location of the methyl group of the propylene unit outside the coordination plane, induces magnetic non-equivalence above and below the coordination plane. The sapr complex is the first example of a dimethyllead(IV) complex that has magnetically non-equivalent methyl protons, a similar observation found in the case of [$(CH_3)_2$Tl(*cis-syn-cis*-6,7,9,10,17,18,20,21-octahydrodibenzo[*b.k*][1,4,7,10,13,16]-hexaoxacyclooctadecin)]$^+$[picrato]$^-$.[17]

In conclusion, from the present work on dimethyllead(IV) complexes with ONNO quadridentate Schiff base ligands, together with a series of spectroscopic studies for several other dimethyllead(IV) complexes previously reported,[5] the ΔE term in the Fermi contact term plays a dominant role in the solvent dependence of the indirect spin-spin coupling between the lead nucleus and proton, J(M,H).

Metal Complexes of Amino Acids. XI.[1] Preparation and ^{13}C NMR Spectra of the Cobalt(III) Complexes Containing β-Alanine and Glycine

Tomoharu AMA* and Takaji YASUI

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

(Received June 17, 1978)

A series of complexes or geometrical isomers, $[Co(\beta\text{-ala or gly})(en)_2]^{2+}$, $[Co(\beta\text{-ala or gly})_2(en)]^{+}$, $[Co(\beta\text{-ala or gly})(ox)_2]^{2-}$, and $[Co(\beta\text{-ala or gly})_2(ox)]^{-}$, were prepared and their ^{13}C NMR spectra were measured. Assignments of their structures and ^{13}C NMR signals were made. The β-alaninate carbons in the complexes resonate at 33.6±0.5, 38.3±0.6, and 183.0±1.5 ppm and the glycinate carbons at 46.3±1.3 and 187.4±1.4 ppm. The ^{13}C chemical shifts of the mixed (β-alaninato)(glycinato) complexes consist of those of the corresponding isomers of bis(β-alaninato) and bis(glycinato) complexes.

^1H NMR has been widely used to study the structures and reactions of the cobalt(III) complexes containing amino carboxylate as the chelate ligands. Recently, ^{13}C NMR has been applied to the study of cobalt(III) complexes, and it has been found that the ^{13}C NMR is useful to determine the geometrical structures of the cobalt(III) complexes with organic ligands.[2-15] Determination of the geometrical structure of the complex by ^1H NMR is sometimes difficult because of the complicated signals caused by spin-spin couplings. In most case, since carbon atoms are closer to cobalt(III) atom than hydrogen atoms in the complexes, ^{13}C NMR makes it possible to obtain more useful information than ^1H NMR concerning the structures of the cobalt(III) complexes. However, ^{13}C NMR data of the cobalt(III) complexes are few for satisfactory discussion of the relation between the chemical shifts and the stereochemical structure of the complex.

In the present study, we attempted the preparation of the complexes, $[Co(\beta\text{-ala or gly})(en)_2]^{2+}$, $[Co(\beta\text{-ala or gly})_2(en)]^{+}$, $[Co(\beta\text{-ala or gly})(ox)_2]^{2-}$, and $[Co(\beta\text{-ala or gly})_2(ox)]^{-}$ (C_2- and C_1-*cis*(*O*)-$[Co(\beta\text{-ala})_2(en)]^{+}$ and *trans*(*O*)-, *cis*(*O*)*trans*(N_g,*O*)-, *cis*(*O*)*trans*(*N*)-, and *cis*(*O*)*trans*(N_β,*O*)-$[Co(\beta\text{-ala})(gly)(en)]^{+}$ are new complexes), and measured their ^{13}C NMR spectra. In this paper we report on their preparation, absorption and ^{13}C NMR spectral data, and assignments of the structures.

Experimental

Preparation of the Complexes. Isomers of Bis(β-alaninato)(ethylenediamine)cobalt(III) Chloride: An aqueous solution containing 19 g of β-alanine, 6 g of ethylenediamine, and 4 g of sodium hydroxide in 100 cm³ of water was added to an aqueous solution containing 24 g of cobalt(II) chloride hexahydrate in 80 cm³ of water. The mixed solution was oxidized with 20 g of lead dioxide at 75 °C for about 30 min with stirring, and cooled to room temperature. After removal of insoluble matter by filtration, the filtrate was poured into a column (30 mm×800 mm) containing a cation exchange resin (Dowex 50WX8, 200—400 mesh, K^+ form). After the column had been swept with 3 dm³ of water, the adsorbed band was eluted with 0.05 M aqueous solution of potassium chloride. The band separated into three bands, another violet-red band remaining at the top of the column. The eluted solution from each band was concentrated to a few milliliters in a vaccum evaporator at 30—35 °C. To the concentrated solution was added a large amount of methanol, potassium chloride deposited being filtered off. Acetone was added to the filtrate in order to deposit crude complex. Each crude complex obtained was recrystallized from aqueous solution by addition of methanol and acetone. The first eluted band was confirmed to be *trans*(O)-$[Co(\beta\text{-ala})_2(en)]Cl$ from its absorption spectrum.[16] Isomer from the second eluted band: Found: C, 27.12; H, 6.44; N, 15.89%. Calcd for $[Co(\beta\text{-ala})_2(en)]Cl\cdot 1.5H_2O$: C, 26.86; H, 6.48; N, 15.66%. Isomer from the third eluted band: Found: C, 26.22; H, 6.64; N, 15.33%. Calcd for $[Co(\beta\text{-ala})_2(en)]Cl\cdot 2H_2O$: C, 26.20; H, 6.60; N, 15.28%.

Isomer of (β-Alaninato)(glycinato)(ethylenediamine)cobalt(III) Chloride: 10 cm³ of 60% perchloric acid was gradually added to a suspension of 5.0 g of *mer*(*N*)-(carbonato)(glycinato)-(ethylenediamine)cobalt(III) monohydrate in 50 cm³ of water. After vigorous evolution of gas had subsided, the solution was adjusted to pH 9 by addition of 2 M NaOH, and then 5 g of β-alanine was added to the alkaline solution. The solution was kept at 65 °C for 3 h and then cooled to room temperature. The resulting solution was poured into a column (30 mm×800 mm) containing a cation-exchange resin (Dowex 50WX8, 200—400 mesh, K^+ form). After the column had been swept with 3 dm³ of water, the adsorbed band was eluted with 0.05 M KCl. The band separated gradually into four violet-red ones, a red-violet band remaining at the top of the column. Each eluted solution was concentrated to a few milliliters in a vacuum evaporator at 35—40 °C. A large amount of methanol was added to the concentrated solution, potassium chloride deposited being filtered off. Acetone was added to the filtrate and then crude complex deposited was collected. Each crude complex was recrystallized from aqueous solution by addition of methanol and acetone. Isomer from the first eluted band: Found: C, 24.97; H, 5.98; N, 16.56%. Calcd for $[Co(\beta\text{-ala})(gly)(en)]Cl\cdot H_2O$: C, 25.12; H, 6.02; N, 16.74%. Isomer from the second eluted band: Found: C, 25.11; H, 6.00; N, 16.61%. Calcd for $[Co(\beta\text{-ala})(gly)(en)]Cl\cdot H_2O$: C, 25.12; H, 6.02; N, 16.74%. Isomer from the third eluted band: Found: C, 27.07; H, 6.07; N, 16.87%. Calcd for $[Co(\beta\text{-ala})(gly)(en)]Cl\cdot 0.5MeOH$: C, 27.08; H, 6.06; N, 16.84% (methanol containing in this ratio was checked by ^1H NMR). Isomer from the fourth eluted band: Found: C, 26.22; H, 5.55; N, 17.67%. Calcd for $[Co(\beta\text{-ala})(gly)(en)]Cl$: C, 26.55; H, 5.73; N, 17.70%.

C_1-cis(O)-(Glycinato-2,2-d_2)(glycinato)(ethylenediamine)cobalt(III) Chloride: C_1-*cis*(*O*)-bis(glycinato)(ethylenediamine)-cobalt(III) chloride (150 mg) was dissolved in 9 cm³ of deuterium oxide, and then deuterium oxide solution of sodium carbonate (1 M, 1 cm³) was added to the solution. The solution was allowed to stand at 40 °C until the ^1H

NMR signal at 3.44 ppm, assigned to the methylene proton of I-position glycine (see Results and Discussion), disappeared (about 3 h).[17] To the solution was added 0.5 cm³ of 2 M deuteriochloric acid, and a large amount of acetone. The red crystals deposited were collected and recrystallized from deuterium oxide solution by addition of acetone.

C_1-cis(O)-, C_2-cis(O)-, and trans(O)-Bis(glycinato-2,2-d_2)-(ethylenediaamine)cobalt(III) Chloride and (Glycinato-2,2-d_2)-bis(ethylenediamine)cobalt(III) Dichloride: The complexes were prepared in a similar way to that described above. Chloride of each complex (150 mg) was dissolved in 10 cm³ of 0.1 M sodium cabonate-deuterium oxide solution. The solution was allowed to stand at 50 °C for *ca.* 3 h. To this was added 0.5 cm³ of 2 M deuteriochloric acid, followed by a large amount of acetone, and the deuterated complex deposited was collected. ^{1}H NMR spectra of the deuterated glycinato complexes are shown in Fig. 1 with those of the non-deuterated complexes.

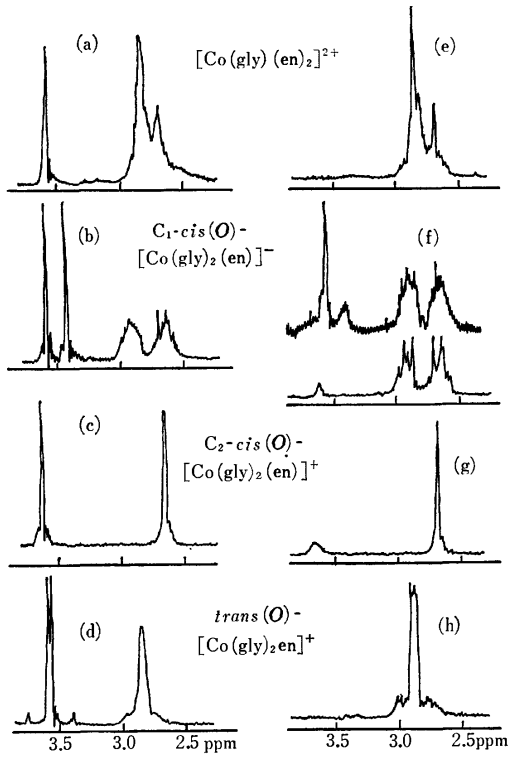

Fig. 1. ^{1}H NMR spectra of the glycinato complexes. (a), (b), (c), and (d): Non-deuterated complexes, (e), (f), (g), and (h): deuterated complexes.

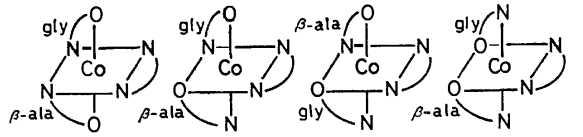
The other complexes examined were prepared by the methods reported.[1,18-20]

Measurements. The electronic absorption spectra of the complexes were measured with a Hitachi EPS-3T spectrophotometer in aqueous solution. The ^{13}C NMR spectra were measured on a JEOL Model MFT-100 spectrometer in pulse Fourier transform/proton noise decoupled mode at 25.15 MHz in deuterium oxide solution. The ^{13}C chemical shifts were measured relative to benzene (in capillary) and converted into chemical shifts from TMS by means of the relation $\delta_{TMS}=\delta_{benzene}-128.5$ ppm. The errors were about $\pm$0.15 ppm. The ^{1}H NMR spectra were recorded on a JEOL Model MH-100 spectrometer with DSS as an internal standard.

Results and Discussion

Both $[Co(gly)_2(en)]^+$ and $[Co(\beta\text{-ala})_2(en)]^+$ ions provide three geometrical isomers, *trans(O)*, C_1-*cis(O)*, and C_2-*cis(O)*. On the other hand, the mixed complex ion, $[Co(\beta\text{-ala})(gly)(en)]^+$, exists in four geometrical isomers of *trans(O)*, *cis(O)trans(N_β,O)*, (N_β represents the coordinated nitrogen atom in β-alanine), *cis(O)-trans(N_g,O)* (N_g represents the coordinated nitrogen atom in glycine), and *cis(O)trans(N_β,N_g)* (Fig. 2). Absorption spectral data are given in Table 1.



trans(O) *cis(O)trans(N$_\beta$O)* *cis(O)trans(N_gO)* *cis(O)trans(N)*

Fig. 2. The geometerical structures of possible four isomers in the $[Co(\beta\text{-ala})(gly)en)]^+$ complex ion.

Absorption Spectra. The visible absorption band at lower energy side (so-called first absorption band) of *trans(O)* isomers of $[Co(O)_2(N)_4]$ type complexes shows a marked split as compared with that of the corresponding *cis(O)* isomers. The marked split of the first absorption band was observed for the complex obtained from the first eluted band in chromatographical separation of the $[Co(\beta\text{-ala})_2(en)]^+$, the absorption spectrum of the complex quite agreeing with that of the *trans(O)*-$[Co(\beta\text{-ala})_2(en)]^+$ in the Ref. 16. Thus, we concluded that the isomer from the first eluted band takes the *trans(O)* configuration. On the other hand, the second and third eluted isomers are expected to take the *cis(O)* configuration since no marked split in the first absorption band was observed.

Matsuoka *et al.*[21] found that D_I/D_{II} value in C_2-*cis(O)* isomer of bis(amino acidato)(ethylenediamine)-cobalt(III) is smaller than that in C_1-*cis(O)* one, where D_I and D_{II} are the optical densities at the absorption maxima of the first and second absorption bands, respectively. As shown in Table 1, D_I/D_{II} value of the second eluted isomer of bis(β-alaninato)(ethylenediamine) complex is smaller than that of the third eluted isomer. Thus, we assigned the geometrical structures of the second and third eluted isomers to C_2-*cis(O)* and C_1-*cis(O)*, respectively. These assignments are in line with those from the ^{13}C NMR data.

The structure of the first eluted isomer in chromatographical separation of $[Co(\beta\text{-ala})(gly)(en)]^+$ can be assigned to *trans(O)*, since a marked split was observed in the first absorption band, which is characteristic of the complex of *trans(O)*-$[Co(O)_2(N)_4]$ type. The structure of the third eluted isomer of $[Co(\beta\text{-ala})(gly)-(en)]^+$ might be assigned to *cis(O)trans(N)* (C_2 symmetry if the chelate rings of β-ala and gly are neglected), since the D_I/D_{II} value of the third eluted isomer is smaller than that of the second and fourth eluted isomers (Table 1).

^{13}C NMR Spectra. The ^{13}C chemical shifts of carboxy carbons (C_o), α-carbons (C_α), and β-carbons (C_β) of the glycinato and β-alaninato complexes are

a) Weakened in the [Co(ND_2CD_2COO)(en)$_2$]$^{2+}$ complex ion. b) Weakened in the [Co(ND_2CD_2COO)$_2$(en)]$^+$ complex ion. c) Weakened in the C_1-*cis*(*O*)-[Co(ND_2CD_2COO)(ND_2CH_2COO)(en)]$^+$ complex ion.

summarized in Table 2. The chemical shifts of C_o, C_α, and C_β in the complexes (in which the glycinate and β-alaninate coordinate to cobalt(III) in the chelated form) are represented by $\delta_{ch}(C_o)$, $\delta_{ch}(C_\alpha)$, and $\delta_{ch}(C_\beta)$, respectively. Symbols $\delta(C_o)$, $\delta(C_\alpha)$, and $\delta(C_\beta)$ represent the chemical shifts of C_o, C_α, and C_β, respectively, of free glycine and β-alanine in acidic solutions.

The carboxy carbon resonances of the chelated glycines ($\delta_{ch}(C_o)$) were observed in the range 186.0—

188.7 ppm. On the other hand, the $\delta(C_o)$ of free glycine was 171.1 ppm. Thus, the $\Delta_{ch}(C_o)$ values ($\delta_{ch}(C_o)$ minus $\delta(C_o)$) of these glycinato complexes are found in the range 14.9—17.6 ppm. The $\delta(C_\alpha)$ of free glycine was 40.4 ppm and the $\delta_{ch}(C_\alpha)$ of glycinato complexes were observed in the range 45.0—47.6 ppm. Consequently, the $\Delta_{ch}(C_\alpha)$ values of the glycinato complexes are found in the range 4.6—7.2 ppm. The $\Delta_{ch}(C_o)$ and $\Delta_{ch}(C_\alpha)$ values of glycinato complexes are comparable to those of the other α-amino acids.[2]

The $\delta(C_o)$, $\delta(C_\alpha)$, and $\delta(C_\beta)$ values of free β-alanine are 175.9, 31.2, and 35.6 ppm, respectively. The $\delta_{ch}(C_o)$, $\delta_{ch}(C_\alpha)$, and $\delta_{ch}(C_\beta)$ values of the chelated β-alanine were observed in the ranges 181.5—184.4 ppm, 33.1—33.9 ppm, and 37.7—38.8 ppm, respectively. The $\Delta_{ch}(C_o)$ values of β-alaninato complexes are *ca.* 7 ppm, smaller than those of α-amino acidato complexes. Similarly, the $\Delta_{ch}(C_\alpha)$ values (1.9—2.7 ppm) of β-alaninato complexes are smaller than those of the α-amino acidato complexes. In this manner, the chemical shift changes caused by chelation can be used to differentiate β- and α-amino acids.[2]

In $[Co(\beta\text{-ala})_2(ox)]^-$ complex ion, one and two resonance lines of the carboxy carbons were observed for the isomers **21** and **19** (Table 2), respectively, since the chemical environments of the carboxy carbons of the two β-alaninate are equivalent in the former isomer but not in the latter one.[1] A similar relationship can be applied to the structural assignments of the two isomers of **5** and **9** in the $[Co(\beta\text{-ala})_2(en)]^+$ complex ion. The second and third eluted isomers in chromatographical separation of $[Co(\beta\text{-ala})_2(en)]^+$ show respectively one and two resonance lines arising from the carboxy carbons of β-alaninates. Thus, the structures can be assigned to C_2-*cis*(*O*) for the former (**5**) and C_1-*cis*(*O*) for the latter (**9**), respectively.

Yoneda *et al.*[22] pointed out the importance of the effect of magnetic anisotropy induced on the central cobalt(III) chromophore. Application of this magnetic anisotropy to the **6** and **3** complexes leads to the following prediction. Two chelated glycinates in the **6** complex do not occupy equivalent positions; one is present in the plane formed by the coordinated oxygen atoms of glycinates and cobalt(III) (I-position), and the other is out of plane (O-position). On the other hand, the chelated glycinates in **3** at the O-position and their steric relation to the cobalt(III) chromophore ($[Co(O)_2(N)_4]$) are identical with the O-position glycinate of **6**. The O-position glycinate in **6** is expected to show nearly equal chemical shifts of the carboxy carbon to those in **3**. A similar relation is expected between **9** and **5**. In **16**, one glycinate is in the plane formed by the nitrogen atoms of the glycinates and cobalt(III) (I*-position), and another glycinate out of the N–Co(III)–N plane (O*-position). Two glycinates in **20** present at the O*-positions and their relation to the cobalt(III) chromophore (*cis*(*N*)-$[Co(O)_4(N)_2]$) are identical with the O*-position glycinate of **16**. In this manner, the following assignments are possible. In **6**, the carbon resonances at 46.0 and 187.2 ppm are for the O-position glycinate, at 46.0 and 186.0 ppm for the I-position glycinate. In **9**, those at 33.5, 37.7, and 181.8 ppm are for the I-position β-alaninate. In **16**, those at 46.1 and 182.2 ppm are for the O*-position glycinate, at 47.8 and 186.8 ppm for the I*-position glycinate. In **19**, those at 33.7, 38.0, and 183.1 are for the O*-position β-alaninate, at 33.7, 38.6, and 184.2 ppm for the I*-position β-alaninate.

The chemical shifts of the glycinate carbons in **11** are in fair agreement with those of the glycinate carbons in **10**. The chemical shifts of the β-alaninate carbons in **11** agree with those of the β-alaninate carbons in **12**. Similar agreements in chemical shifts were observed among the same geometrical isomers of bis(β-alaninato), bis(glycinato), and (β-alaninato)(glycinato) complexes. In the case of the **17** or **18** complex ion, the following consideration, in line with the above observations, is possible. When the I*-position (O*-position) glycinate of **16** is exchanged by β-alaninate, forming **17** (**18**), the carbon resonances of the I*-position (O*-position) glycinate will disappear and those of the I*-position (O*-position) β-alaninate will appear. As we expected, the glycinate carbons in **17** resonates at 187.2 and 46.1 ppm and these chemical shifts consist of those of the O*-position glycinate in **16** (187.2 and 46.1 ppm). The chemical shifts of β-alaninate carbons in **17** are nearly equal to those of the I*-position β-alaninate in **19**. A similar relation can be expected for the *cis*(*O*) of the second eluted isomer (**8**) in chromatographical separation of $[Co(\beta\text{-ala})(gly)(en)]^+$; the resonance peaks at 186.0 and 45.9 ppm for glycinate carbons and at 33.6, 38.4, and 183.7 ppm for the β-alaninate carbons consist of those of the O-position β-alaninate in **9** and I-position glycinate in **6**, respectively. The structure of the second eluted isomer can be assigned to *cis*(*O*)*trans*(N_g,*O*). As the chemical shifts of the fourth eluted isomer (**7**), resonating at 46.5 and 187.2 ppm (glycinate), and at 33.3, 37.8, and 182.0 ppm (β-alaninate), consist of those of O-position glycinate and I-position β-alaninate. The structure of this isomer can be assigned to *cis*(*O*)-*trans*(N_β,*O*).

In the present work, the ^{13}C chemical shifts were measured in ^1H noise decoupled mode. Since the signal of the carbon bonding to hydrogen is enhanced due to the nuclear Overhauser effect from ^1H atom and no splitting resonance is observed in noise decoupled mode, the resonance peak of the methylene carbon (α-carbon) of the glycinate is expected to be fairly intense. On the other hand, the resonance of the deuterated methylene carbon of the glycine will be very weak, since the signal of the carbon bonding to deuterium is split due to the carbon-deuterium coupling, no enhancement due to the NOE from ^1H atom being expected.[8] In the chelated glycine, the resonance of the carboxy carbon (which neighbors methylene carbon) is enhanced by the NOE from the methylene protons, but the deuteration of the methylene group results in weakening of the carboxy carbon resonance. Consequently, it is possible to confirm which glycinate possesses the deuterated methylene group by comparing the ^{13}C NMR spectra of the deuterated complex with that of the non-deuterated complex.

The methylene protons in the chelated glycine are easily deuterated in basic deuterium oxide solution.[23] We succeeded in preparing five glycinato-2,2-d_2 complexes, $([Co(ND_2CD_2COO)(en)_2]^{2+}$, C_1-*cis*(*O*)-$[Co(ND_2CD_2COO)(ND_2CH_2COO)(en)]^+$, and C_1-*cis*(*O*)-, C_2-*cis*(*O*)-, and *trans*(*O*)-$[Co(ND_2CD_2COO)_2(en)]^+$, by leaving each corresponding glycinato complex in basic deuterium oxide solution to stand for an appropriate time.

It is difficult to distinguish the methylene carbon of glycinate from that of the ethylenediamine, since the chemical shifts of the methylene carbons in chelated ethylenediamine are close to those of the methylene carbon of the chelated glycinate. The ^{13}C NMR measurements of these deuterated glycinato complexes make it possible to distinguish the signals of the carbons in the deuterated glycinate ring from those of the carbons in chelated ethylenediamine.

Yoneda *et al.*[22] showed for the **6** complex that the ^{1}H NMR signal resonating at 3.44 ppm arises from the methylene protons of the I-position glycinate. It was found that the I-position methylene protons are deuterated more rapidly than the O-position methylene protons (Fig. 1 (b)).[17] Since the methylene carbon resonance at 46.0 ppm and the carboxy carbon resonance at 186.0 ppm in **6** are weakened in the C_1-*cis*(*O*)-$[Co(ND_2CD_2COO)(ND_2CH_2COO)(en)]^+$, it is concluded that these methylene and carboxy carbons belong to the I-position glycinate, and methylene carbon at 46.0 ppm and carboxy carbon at 187.2 ppm in **6** to the O-position glycinate. The assignments of the ^{13}C NMR spectra based on the deuteration method are consistent with the assignments concluded from the comparison of the bis(glycinato) complexes with (β-alaninato)(glycinato) complexes.

The ^{13}C chemical shifts of the coordinated glycinate in bis(glycinato) complexes remained unchanged by the replacement of one of the two glycinates with β-alaninate. The ^{13}C chemical shifts of the β-alaninate in bis(β-alaninato) complexes also remained unchanged by the replacement of one of the β-alaninates with glycinate. These observations suggest that the main factor which determines the chemical shifts of the coordinated glycinate or β-alaninate is the steric position of the ligands to the central cobalt(III) chromophore. This recalls the theory of the magnetic anisotropy arising from the cobalt(III) chromophore.[22] However, the Co(III) magnetic anisotropy does not account for all the behavior of the chemical shifts of the ligands. It is expected from the Co(III) magnetic anisotropy in complex **6** that the ^{13}C chemical shift of the O-position methylene carbon of glycinate is located at lower magnetic field than that of the I-position methylene carbon, but really both carbon resonances were observed at 46.0 ppm as an overlapping signal. The carboxy carbon resonances of **10** should be located at much higher magnetic field than the observed ones, according to the cobalt(III) magnetic anisotropy.

Luminescence Spectra of Cobalt(III) Cyano Complexes

Yusuke YAMAMOTO

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received July 7, 1978)

Luminescence spectra of $M_3[Co(CN)_6]$ (M=K, Rb, Cs), *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$, and *trans*-$Na_5[Co(CN)_4(SO_3)_2]$ were measured at 20 K. Single crystal luminescence spectra of the hexacyanocobaltates(III), centered at 14100—14200 cm^{-1}, exhibited vibrational structure associated with three components, and the separation between the members of the progression was about 400 cm^{-1}. Luminescence spectra of powdered *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$ and *trans*-$Na_5[Co(CN)_4(SO_3)_2]$ were structureless and broad centered at 13200 and 14400 cm^{-1}, respectively. Comparison of these luminescence spectra with the corresponding spin-forbidden bands indicated that the 0-0 transition lies at 18300—18600 cm^{-1} for hexacyanocobaltates(III), at 16500—17000 cm^{-1} for *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$, and at 17700—18200 cm^{-1} for *trans*-$Na_5[Co(CN)_4(SO_3)_2]$. The vibrational structure in luminescence spectra of hexacyanocobaltates(III) can be interpreted in terms of the ν_8, ν_9, ν_{12}, and ν_{13} ungerade skeletal modes, a lattice mode, and the totally symmetric ν_2 vibrational mode. Analysis of the relative intensity of the vibrational structure in the luminescence spectra gave information about the change in the Co–C internuclear equilibrium distance from the ground state to the excited luminescent state. The relationship between luminescence and photochemical behavior of cobalt(III) complexes was also considered.

In recent years, there has been a rapidly expanding interest in the luminescence of transition-metal coordination compounds.[1] A luminescence spectrum provides a great deal of useful information not only about an excited state but also about a ground state. There have been many studies on luminescence spectra of chromium(III) complexes from the viewpoints of both their spectroscopic and photochemical aspects.[1,2] On the other hand, although there have also been extensive spectroscopic and photochemical studies of cobalt(III) complexes, there has been few papers on their luminescence.

Luminescence of cobalt(III) complex was first reported on $K_3[Co(CN)_6]$ by Porter and Mingardi[3] in 1966. They observed a broad and structureless band centered at 14400 cm^{-1}, and assigned it as $^3T_{1g}\rightarrow{}^1A_{1g}$ phosphorescence on the basis of the band position and the lifetime. Later, the luminescence spectrum of $[Co(CN)_6]^{3-}$ was studied by some workers,[4-9] but most of them have also only reported it to be structureless and broad. The author has reported vibrational structure of the luminescence spectrum of powdered $K_3[Co(CN)_6]$ at 20 K, which exhibited a progression with about 400 cm^{-1} spacing interpreted in terms of the Co–C stretching frequency for the first time.[7] Recently, Hipps and Crosby[9] have also reported vibrational structure whose spacing between the members of the progression was 420 cm^{-1} in the luminescence spectrum of $K_3[Co(CN)_6]$ at 4.2 K.

Another example of luminescence of cobalt(III) complex was *trans*-$Na_5[Co(CN)_4(SO_3)_2]$ reported by Zuloaga and Kasha.[10] They reported a broad and structureless spectrum centered at 14300 cm^{-1} at 77 K and assigned it as the $^3T_{1g}\rightarrow{}^1A_{1g}(O_h)$ phosphorescence. As mentioned above, investigations of luminescence of cobalt(III) complexes have been very limited.

This paper deals with the luminescence of cobalt(III) complexes, the luminescence of one among them, *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$, having been observed for the first time. For single crystals of $K_3[Co(CN)_6]$, $Rb_3[Co(CN)_6]$, and $Cs_3[Co(CN)_6]$, the luminescence spectra were measured with particular care for the fine structure to make clear what kind of vibration was responsible for the intensity. Also, the position of the 0-0 transition of the $^3T_{1g}\leftrightarrow{}^1A_{1g}(O_h)$ of hexacyanocobaltates(III) and of *cis*- and *trans*-tetracyanodisulfitocobaltates(III) are presented.

Finally, the possible relationship between photochemical behavior and luminescence is discussed.

Experimental

Preparation of Materials. $K_3[Co(CN)_6]$,[11] $Rb_3[Co(CN)_6]$,[12] $Cs_3[Co(CN)_6]$,[12] *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$,[13] *trans*-$Na_5[Co(CN)_4(SO_3)_2]$,[14] *fac*-$[Co(CN)_3(NH_3)_3]$,[15] *cis*-$[Co(CN)_2(en)_2]ClO_4$,[16] $[Co(CN)(NH_3)_5]Cl_2$,[17] and $[Co(NH_3)_6]Cl_3$[18] were prepared according to the published methods. These compounds, except for *fac*-$[Co(CN)_3(NH_3)_3]$, were recrystallized several times. Single crystals of $K_3[Co(CN)_6]$, $Rb_3[Co(CN)_6]$, and $Cs_3[Co(CN)_6]$ were obtained by slow evaporation of aqueous solutions.

Measurement of Luminescence Spectra. Excitation light from a Ushio UM-102 mercury lamp (120 W) was isolated by a Spex Micromate grating monochromator (10 cm, f 2.5, blazed at 300 nm, 1200 l/mm), then passed through a Toshiba UV-D25 filter, and projected on the sample at an incident angle of 45°. Luminescent light at right angles to the excitation light was passed through a yellow cut-off filter to reduce scattered excitation light, and was dispersed by a JASCO CT-100 grating monochromator (100 cm, f 8.6, blazed at 750 nm, 1200 l/mm). The light from the monochromator was detected by a cooled Hamamatsu R-649S (S-20) photomultiplier, a Hamamatsu C-716 preamplifier, and a Hamamatsu C-767 photon counter, and recorded by a Yokogawa 3051 recorder equipped with a Yokogawa 3053-12 DC unit. Sometimes a set of a Hamamatsu R-666 photomultiplier, with GaAs photocathode, and a JASCO L-125 lock-in amplifier was used for the detection system. The sample was cooled with an Air Products and Chemicals Cryo-Tip AC-2 for measurements at liquid hydrogen temperature and with the optical cryostat designed in our laboratory for those at liquid nitrogen temperature. The sample temperature was measured using a chromel/constantan and a chromel/Au-0.07%Fe

thermocouple.

Spectral slit width was about 8 cm^{-1} for hexacyanocobaltates(III) and *trans*-$Na_5[Co(CN)_4(SO_3)_2]$, and about 16 cm^{-1} for other compounds.

The luminescence spectra thus obtained were corrected by the standard lamp method.

Measurements of Visible and Ultraviolet Absorption, Diffuse Reflectance, Infrared, and Raman Spectra. The absorption spectra of aqueous solutions were measured with a Hitachi EPS-3T spectrophotometer. The spin-forbidden band of a single crystal of $K_3[Co(CN)_6]$ was measured with a JASCO CT-50 grating monochromator (50 cm, f 5.6, blazed at 300 nm, 1200 l/mm) equipped with a Hamamatsu R-649S photomultiplier connected with the photon counting system at liquid helium temperature. The sample was cooled with the optical cryostat.

The diffese reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer, using a diffuse reflectance accessory, at room temperature.

The infrared spectra in the 200—700 cm^{-1} region were obtained with a JASCO IR-F far-infrared spectrophotometer using the Nujol mull method.

Raman spectra were measured on powdered samples with a He-Ne laser Raman spectrophotometer.[19]

Results and Discussion

Luminescence Spectra of $K_3[Co(CN)_6]$. The 20 and 77 K, 313 nm excited luminescence spectra measured on a single crystal are shown in Fig. 1. The peak position of 14200 cm^{-1} was almost the same as that of other authors,[4-9] and the half band width of the total band was about 2600 cm^{-1}. The luminescence band increased gradually in intensity with a lowering in the temperature from room temperature to about 30 K, and decreased slightly with lowering in the temperature from about 30 to 20 K. This can be explained as having been caused by the competition between non-radiative relaxation and sharpening of the each component bands; that is, from room temperature to about 30 K, the dominant effect is depression of the non-radiative process, which increases luminescence intensity, and from about 30 to 20 K, sharpening of each component band is dominant, which decreases luminescence intensity. Even at room temperature,

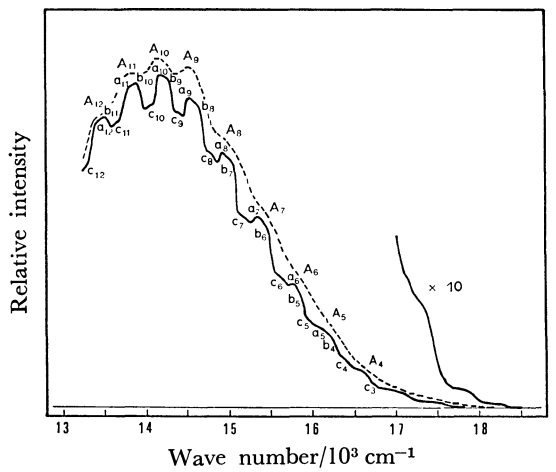

Fig. 1. Luminescence spectra of $K_3[Co(CN)_6]$.
——, 20 K; ——, 77 K.

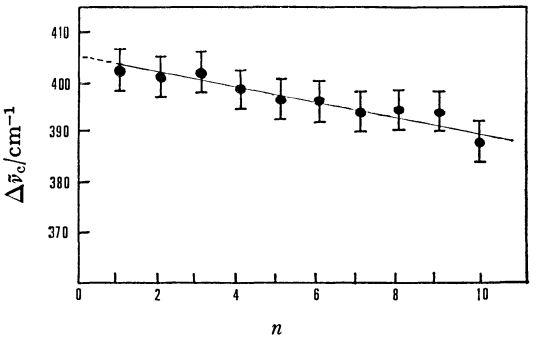

Fig. 2. Energy differences between c_n peaks, $\Delta\tilde{\nu}_c = \tilde{\nu}_{c_{n+1}} - \tilde{\nu}_{c_n}$, in $K_3[Co(CN)_6]$ at 20 K.

a structureless and very weak spectrum was observed. At 77 K, the spectrum exhibited vibrational structure with about 400 cm^{-1} spacing between the members of the progression. When the temperature was lowered from 77 to 20 K, the A_n progression at 77 K was resolved into two components, a_n and b_n progressions; moreover, a weak c_n progression appeared between the A_n progression. The average spacing of 394 cm^{-1} between the members of each progression was slightly decreased with increase in n, and the fundamental vibrational frequency was extrapolated to about 405 cm^{-1} as shown in Fig. 2.

Luminescence Spectra of $Rb_3[Co(CN)_6]$ and $Cs_3[Co(CN)_6]$. The 313 nm excited luminescence spectra of the rubidium and caesium salts were measured on single crystals at 20, 77 K, and room temperature. The spectral pattern was practically the same as that of the potassium salt. At 20 K, the maximum positions of the total bands were at 14100 and 14200 cm^{-1} for the rubidium and caesium salts, respectively. The vibrational structure, consisting of three components, was observed, but it was not so clear as in the potassium salt. The energy separation between the members of the progression was about 400 cm^{-1} as in the potassium salt. Even at 77 K, the spectra showed vibrational structure.

Position of the 0-0 Transition. Since the three salts of hexacyanocobaltates(III) showed the same vibrational pattern, the potassium salt, whose spectrum was the best resolved of the three, will be discussed.

The $^3T_{1g} \leftarrow {}^1A_{1g}$ spin-forbidden band of $K_3[Co(CN)_6]$ has been reported at different peak energy by some authors. Kida *et al.*[20] found a shoulder at 24000 cm^{-1}, while Porter and Mingardi,[3] and Jain *et al.*[21] observed weak bands at 18500 and 20833 cm^{-1}, respectively; and these three bands have been assigned as the $^3T_{1g} \rightarrow {}^1A_{1g}$ spin-forbidden transition. Recently, this spin-forbidden band was carefully reexamined by Kataoka[8] by microspectrophotometry at 77 K. A small shoulder, which was not observed at room temperature, appeared clearly at 26000 cm^{-1} when the temperature lowered to 77 K, and was assigned as the $^3T_{1g} \leftarrow {}^1A_{1g}$ spin-forbidden band.

The first component of the luminescence band, which lies at highest energy, was observed at *ca.* 18200 cm^{-1} in the 20 K sepctrum obtained. This indicates that the 0-0 transition lies at some 100 cm^{-1} higher than 18200 cm^{-1}. Comparison of the absorption peak

values with a position of the 0-0 transition obtained from the luminescence spectrum clearly shows that the positions of 18500 and 20833 cm^{-1} in absorption are too low in energy; while the peak positions observed at 24000 and 26000 cm^{-1} are consistent with the 0-0 transition obtained from this luminescence measurement. On the other hand, the calculated value for $^3T_{1g} \leftarrow {}^1A_{1g}$ spin-forbidden band is *ca.* 27000 cm^{-1}.[22] Consequently, it is more probable to assign the 26000 and/or 24000 cm^{-1} band than the 18500 and 20833 cm^{-1} bands as the $^3T_{1g} \leftarrow {}^1A_{1g}$ spin-forbidden band.

It is expected that the 0-0 transition would not obtain any appreciable intensity either in luminescence or in absorption. Thus, in order to obtain a more exact position of the 0-0 transition, vibrational structure measurement in the spin-forbidden absorption band is required. That is, comparison of the vibrational structures in both the luminescence and absorption spectra can be expected to give the 0-0 band position between their first components.

To determine the position of the 0-0 transition, the 4.2 K single crystal absorption was measured, but no vibrational structure was observed in the 17000—23000 cm^{-1} region. Consequently, the position of the 0-0 transition was not exactly determined, but would lie between 18300 and 18600 cm^{-1}.

Assignment of Vibrational Structure. To assign the vibrational structure associated with the luminescence spectrum, the normal modes of vibration of $[Co(CN)_6]^{3-}$ must be considered. Raman and infrared spectra of this complex have been studied by many workers,[23-29] but there has been some uncertainty in position and assignment, especially for low energy region skeletal vibration. The assignments of some workers are listed in Table 1.

There are five vibronic active skeletal modes, $\nu_7(t_{1u})$, $\nu_8(t_{1u})$, $\nu_9(t_{1u})$, $\nu_{12}(t_{2u})$, and $\nu_{13}(t_{2u})$; thus the fine structure of the spectrum would consist of $(\nu_7, \nu_8, \nu_9, \nu_{12}, \nu_{13})+n\nu_2(a_{1g})$ $(n=0, 1, 2, \ldots)$ peaks.[30] In these vibrational modes, it can be considered that the contribution of the deformation modes, ν_8, ν_9, ν_{12}, and ν_{13}, to the intensity would be large.[31-33] It is possible that the lattice motion would couple with the electronic level; but its contribution to the intensity, which is proportional to the degree of destruction of the center of symmetry, would be much weaker than that of the ungerade skeletal vibration.

The luminescence spectra seem to consist of three kinds of progressions, and members of each progression have about 400 cm^{-1} spacing. These progressions may be vibronic bands originated from one or more electronic levels. The ground state, $^1A_{1g}$, is not split by any perturbation, but the excited luminescent state, $^3T_{1g}$, splits into E, T_2, T_1, and A_1 by spin-orbit interaction. For $K_3[Co(CN)_6]$, the separation between the E and other upper levels, T_2, T_1, and A_1, have been reported as 30, 318, and about 500 cm^{-1}, and the lifetimes of the E, T_2, and T_1 as 463, 2615, and 28.3 μs, respectively, determined from the temperature dependence analysis of the lifetime.[9] On the basis of these separations and lifetimes, the contribution to the luminescence intensity of each level, I_l, is given by[34]

$$I_l \propto k_l \cdot g_l \cdot \exp(-\Delta E/kT) = 1/\tau_l \cdot g_l \cdot \exp(-\Delta E/kT), \quad (1)$$

where k_l is the rate constant of the luminescence process, τ_l is the lifetime, and g_l is the multiplicity. Thus the calculated intensity ratios of I_{T_2}/I_E and I_{T_1}/I_E are 2.1×10^{-2} and 2.9×10^{-9} at 20 K and 1.5×10^{-1} and 6.6×10^{-2} at 77 K. This indicates that, at 20 K, the luminescence from the T_2 and other upper levels would contribute less to the spectrum. Thus it is possible to neglect the T_2, T_1, and A_1 levels as luminescent ones.

Comparison of the energy separations betweeen adjacent components of the luminescence spectrum with those of the ungerade skeletal vibrations indicates that the most reasonable assignments are as follows. The most intense component, a_n progression, can be assigned as the transition to $(\nu_9+n\nu_2)$ or $(\nu_{13}+n\nu_2)$ level, or it may consist of two peaks corresponding to those, since the ν_9 and ν_{13} modes have nearly the same energy. Similarly, b_n progression is assigned as the transition to $(\nu_8+n\nu_2)$ or $(\nu_{12}+n\nu_2)$ level, or again it may consist of two peaks corresponding to those; while the weak component, c_n progression, cannot be assigned as any of the skeletal vibrational modes. The energy difference between the a_n and c_n progression is about 175 cm^{-1}; and the lattice modes appeared strongly at 172 and 189 cm^{-1},[26] hence the c_n progression can be assigned as the transition to the (a_n+lattice mode) level.

Calculation of the Relative Intensity of the Luminescence Band. The intensity ratio of the individual component bands from the 0-th vibrational state in the electronic state A to the n-th vibrational state in the electronic state B is given by[35]

Table 1. Raman and infrared spectra of $[Co(CN)_6]^{3-}$ ($\bar{\nu}$/cm^{-1})

	$\nu_2(a_{1g})$ νCo-C	$\nu_3(e_g)$ νCo-C	$\nu_7(t_{1u})$ νCo-C	$\nu_8(t_{1u})$ δCo-C-N	$\nu_9(t_{1u})$ δC-Co-C	$\nu_{12}(t_{2u})$ δCo-C-N	$\nu_{13}(t_{2u})$ δC-Co-C	Ref.

a) Calculated value.

$$\frac{I(B_n \leftarrow A_0)}{I(B_0 \leftarrow A_0)} = \frac{I_n}{I_0} = \left[\frac{1}{2}\alpha(\Delta r)^2\right]^n \frac{1}{n!}, \quad (2)$$

where $\alpha = 4\pi^2 m\bar{\nu}c/h$ and Δr is the difference in the equilibrium nuclear distance between the A and B states.

Setting $\frac{1}{2}\alpha(\Delta r)^2 = K$,

$$\frac{I_n}{I_0} = K^n \frac{1}{n!}. \quad (3)$$

The relative intensity of individual members of the a_n progression in the luminescence band, calculated from Eq. 3, is shown in Fig. 3 together with the observed spectrum of $K_3[Co(CN)_6]$ at 20 K. The calculated relative intensities shown by the heights of vertical lines in Fig. 3 are the one when $K=10.7$, and those of the other marks are the ones when $K=11.7$ and 12.7. When the maximum of the band occures at the n-th component, it can be seen that $n=K$ in Eq. 3, so that $K=10.7$ means that the first component of 18200 cm^{-1} in the luminescence spectrum should involve no ν_2 vibration. It is clear from Fig. 3 that the intensity ratio when $K=10.7$ is the best fit; thus it is highly probable that the 0-0 transition lies at 18300—18600 cm^{-1}.

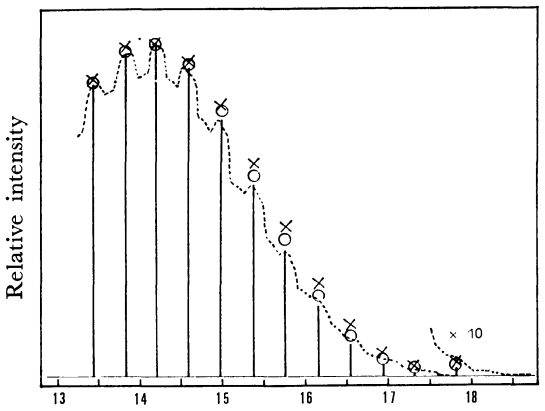

Fig. 3. Calculated relative intensity of $K_3[Co(CN)_6]$. Broken line indicates the observed spectrum. Vertical line, $K=10.7$; O, $K=11.7$; ×, $K=12.7$.

By fitting the relative intensities of the individual components in the observed luminescence band to the calculated ones, the change in the Co–C equilibrium nuclear distance, Δr, between the luminescent excited state and the ground state can be computed. The calculated change in the distance is 0.3 Å, when $K=10.7$. This value can be compared to 0.20—0.23 Å in Pt–F distance in $[PtF_6]^{2-}$.[36]

Luminescence Spectrum of cis-$K_3Na_2[Co(CN)_4(SO_3)_2]$. The 20 K, 365 nm excited luminescence spectrum is shown in Fig. 4. A broad and structureless band was observed at 13200 cm^{-1}, and its half band width was about 2000 cm^{-1}. The higher energy threshold value of the luminescence band was observed at 16500 cm^{-1}. The intensity of the luminescence was somewhat weaker than that of the hexacyanocobaltates(III).

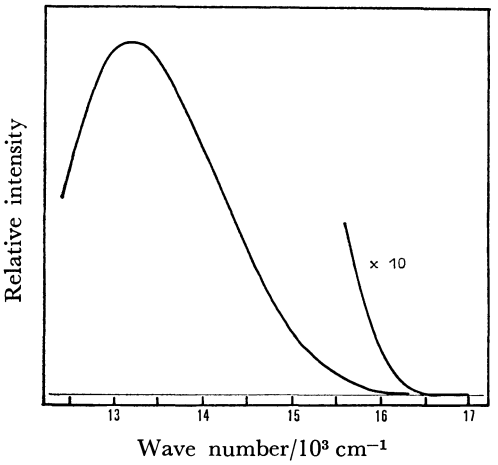

Fig. 4. Luminescence spectrum of *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$ at 20 K.

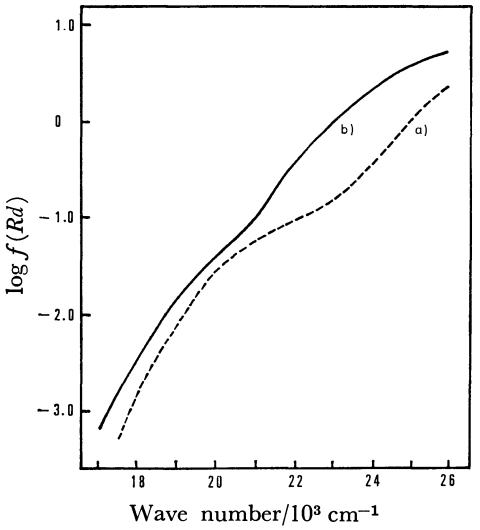

Fig. 5. Spin-forbidden bands of a) *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$ and b) *trans*-$Na_5[Co(CN)_4(SO_3)_2]$ measured by diffuse reflectance method.

On the other hand, in the absorption spectrum obtained by the diffuse reflectance method, a weak shoulder was observed at *ca.* 20000 cm^{-1}, as shown in Fig. 5. In the figure the reflectance spectrum of *trans*-$Na_5[Co(CN)_4(SO_3)_2]$ is also shown.

The luminescence can be assigned as the transition from the lowest triplet state, $^3T_{1g}(O_h)$, to the $^1A_{1g}(O_h)$ ground state, on the basis of its position and intensity. It is consistent with the position of the luminescence band that the weak shoulder at *ca.* 20000 cm^{-1} in absorption was regarded to be the spin-forbidden band, hence it can be assigned as the $^3T_{1g} \leftarrow {}^1A_{1g}(O_h)$ spin-forbidden transition, which is the reverse process of luminescence. The 0-0 transition would lie at 16500—17000 cm^{-1} on the basis of the threshold value of the luminescence band and the maximum position of both luminescence and absorption.

Luminescence Spectrum of trans-$Na_5[Co(CN)_4(SO_3)_2]$. The 20 K, 365 nm excited luminescence spectrum is shown in Fig. 6. A broad and structureless band as in the cis salt was observed at 14400 cm^{-1}, and its

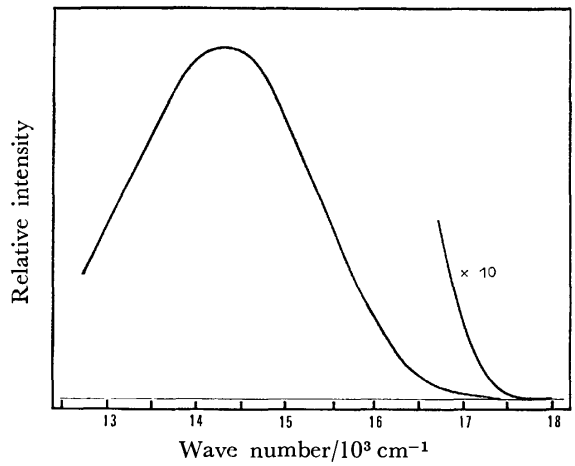

Fig. 6. Luminescence spectrum of *trans*-$Na_5[Co(CN)_4(SO_3)_2]$ at 20 K.

half band width was about 2300 cm^{-1}. The threshold value was observed at *ca.* 17700 cm^{-1}. Intensity of the luminescence was comparable to that of the hexacyanocobaltates(III). The diffuse reflectance spectrum showed a weak shoulder at *ca.* 20000 cm^{-1}, as shown in Fig. 5.

The luminescence spectrum of this complex salt has already been measured at 77 K by Zuloaga and Kasha,[10] and the spectrum obtained in the present work was essentially the same as that in this previous investigation. The luminescence can be assigned as $^3T_{1g} \rightarrow {}^1A_{1g}(O_h)$ phosphorescence and the weak shoulder observed in the absortpion spectrum can be assigned as the reverse process of the luminescence, that is the $^3T_{1g} \leftarrow {}^1A_{1g}(O_h)$ transition. The 0-0 transition would lie at 17700–18200 cm^{-1} on the basis of the threshold value of the luminescence band and the maximum position of both luminescence and absorption bands. Finally, it is interesting to note that there is some difference in ligand field strength between this complex and hexacyanocobaltates(III), but the luminescence of both appeared at almost the same position in spite of their defference in energy of the $^3T_{1g} \leftarrow {}^1A_{1g}(O_h)$ spin-forbidden band.

Luminescence of Other Cobalt(III) Complexes. Luminescence spectra of *fac*-$[Co(CN)_3(NH_3)_3]$, *cis*-$[Co(CN)_2(en)_2]ClO_4$, $[Co(CN)(NH_3)_5]Cl_2$, and $[Co(NH_3)_6]Cl_3$, excited by 365 and 313 nm light were measured in the 12000—20000 cm^{-1} region, but no luminescence was observed even at 20 K. Thus the luminescent complexes are probably restricted to those having four or more cyano ligands.

Relationship between Luminescence and Photochemical Behavior. Photochemical reaction of cobalt(III) complexes in aqueous solution have been extensively studied by many authors.[1b,1c,37] Generally, they can be classified into the following two types:

(A) Redox reaction from Co(III) to Co(II) with release of ligands,

(B) Ligand substitution reaction without reduction of central cobalt atom.

Cobalt(III) complexes almost all belong to type (A), for example, $[Co(NH_3)_6]^{3+}$,[38] $[Co(en)_3]^{3+}$,[38] $[CoCl(NH_3)_5]^{2+}$,[39,40] $[CoBr(NH_3)_5]^{2+}$,[40,41] $[CoI(NH_3)_5]^{2+}$,[42,43] $[Co(ox)_3]^{3-}$,[44] *etc.* But to date there have been reported a few that belong to type (B), for example, $[Co(CN)_6]^{3-}$,[45] $[CoCl(CN)_5]^{3-}$,[40,46] $[CoBr(CN)_5]^{3-}$,[40,46] and $[Co(CN)_5I]^{3-}$,[46] as listed in Table 2. It is interesting to note that all of them that belong to type (B) contain five or more cyano ligands.

In the photochemical reaction of type (A), the oxidation state of the cobalt atom changes from +3 to +2, hence it is considered that the reaction occurs from a ligand-to-metal charge transfer(LMCT) state. This means that the LMCT level mainly is the most populated state after irradiation of ultraviolet light and that the potential minimum of the LMCT level is lower than that of the ligand field leves, as shown in Fig. 7a). In the complexes of type (A), ligand

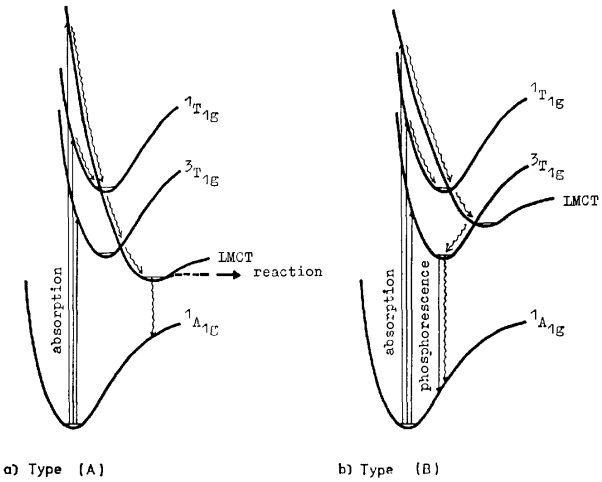

Fig. 7. Schematic diagram of potential curves of type (A) and type (B) cobalt(III) complexes.

substitution reaction also may occur, the cobalt atom maintaining its oxidation state of +3 when the complex is irradiated with a ligand field absorption band; but even in those cases when this reaction has occured, the quantum yield is lower than in the redox reaction by from 10 to 100 times. In the solid state, although there are only a few cobalt(III) complexes that undergo photochemical reaction,[47,48] the situation of electronic level of these complexes does not differ as much as in an aqueous solution. Thus in the solid state, the irradiated energy may be finally populated also to the LMCT level and would deactivate non-radiatively. Therefore, it may be concluded that the complexes of type (A) do not luminesce the $^3T_{1g} \rightarrow {}^1A_{1g}$ phosphorescence.

On the other hand, in complexes that belong to type (B), the cobalt(III) atom is not reduced, but the ligand substitution reaction does occur; hence it is considered that the energy irradiated is not populated to the LMCT level, but to the ligand field level, and a photochemical reaction occurs from this level in aqueous solution. This indicates that the lowest ligand field triplet level, $^3T_{1g}(O_h)$, would be the main populated state and lower than the LMCT level, as shown in Fig. 7b). Hence, in the solid state, the $^3T_{1g} \rightarrow {}^1A_{1g}(O_h)$ luminescence would be observed. Actually, the luminescent complexes belong to type (B), as shown in Table 2.

The author wishes to express his sincere thanks to Professors Yukio Kondo and Masayoshi Nakahara for their helpful suggestions and discussions throughout this work. He is also indebted to Mr. Hiroshi Saito of the laboratory of Physical Chemistry of Rikkyo University for making available a Raman spectrophotometer and for his help with measurements, and to Dr. Akio Urushiyama for his help with single crystal absorption measurements at liquid helium temperature.

Solubility Isotherms of Reciprocal Salt-Pairs of Optically Active Cobalt(III) Complexes

Akira FUYUHIRO,* Kazuaki YAMANARI, and Yoichi SHIMURA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received June 13, 1978)

Two kinds of four-component solubility isotherms consisting of (Λ-$[Co(ox)(en)_2]^+$, Δ-$[Co(ox)(en)_2]^+$)–(Cl^-, X^-)–H_2O, where X^- stands for Δ-$[Co(edta)]^-$ or (R,R)-$C_4H_5O_6^-$, have been determined experimentally at 25 °C. It has been found that neither double salt nor solid solution exists and no configurational activity is observed in these systems. The applications of these phase diagrams to the practical optical resolutions are discussed.

Several solubility isotherms of reciprocal salt-pairs which have two cations and two anions such as (Na^+, NH_4^+)–(Cl^-, HCO_3^-)–H_2O and (K^+, Mg^{2+})–(Cl^-, SO_4^{2-})–H_2O have been reported[1–3] and applied to the alkali industry. However no such isotherm has been reported for the system of metal complexes. The four-component solubility isotherms of reciprocal salt-pairs containing a pair of diastereomers are especially interesting in a viewpoint of optical resolution.

In this connection, some of the three-component solubility isotherms of chiral cobalt(III) complexes have already been reported from our laboratory.[4]

The present paper deals with the solubility isotherms (at 25 °C) of two kinds of reciprocal salt-pairs, (Λ-$[Co(ox)(en)_2]^+$, Δ-$[Co(ox)(en)_2]^+$)–(Cl^-, X^-)–H_2O, where X^- stands for Δ-$[Co(edta)]^-$ or $(+)_{589}$-(R,R)-$C_4H_5O_6^-$ (abbreviated to d-H_3tart^-). These four-component systems provide the model cases of the optical resolutions of *rac*-$[Co(ox)(en)_2]Cl$ with resolving agents containing the chiral anion X^-.

Experimental

Materials. *$[Co(ox)(en)_2]X$, $X=Cl\cdot H_2O$ and d-$H_3tart\cdot nH_2O$*: Racemic chloride monohydrate and racemic acetate were prepared and optically resolved by the methods of Dwyer *et al.*[5] and Jordan *et al.*,[6] and that improved by Koine.[7] The Δ-$[Co(ox)(en)_2]Cl\cdot H_2O$ complex was obtained from the filtrate from the less soluble diastereomer Λ-$[Co(ox)(en)_2](d\text{-}H_3tart)\cdot H_2O$ in these procedures by adding 12 M HCl, and was optically purified by repeated crystallizations from warm water. The more soluble diastereomer Δ-$[Co(ox)(en)_2](d\text{-}H_3tart)\cdot 2H_2O$ was prepared from Δ-$[Co(ox)(en)_2]Cl\cdot H_2O$, d-H_4tart, and $Ag_2(d\text{-}H_2tart)$ in the mole ratio of 2 : 1 : 1, and recrystallized from warm water. Found: C, 26.42; H, 5.56; N, 12.40%. Calcd for Δ-$[Co(ox)(en)_2](d\text{-}H_3tart)\cdot 2H_2O$: C, 26.56; H, 5.57; N, 12.39%. The Λ-$[Co(ox)(en)_2]Cl\cdot H_2O$ complex was obtained by adding 12 M HCl to a warm solution of the less soluble diastereomer.

Δ-K[Co(edta)]$\cdot 2H_2O$: This complex was resolved by the method of Jordan *et al.*[6] and optically purified by fractional crystallization after treating with a cation exchange resin K^+ form.

$[Co(ox)(en)_2]\Delta$-$[Co(edta)]\cdot nH_2O$: The less soluble diastereomer Δ-$[Co(ox)(en)_2]\Delta$-$[Co(edta)]\cdot H_2O$ was obtained by the method of Dwyer *et al.*[5] The more soluble diastereomer was prepared from Λ-$[Co(ox)(en)_2](CH_3COO)$ and Δ-$K[Co(edta)]\cdot 2H_2O$ and recrystallized from warm water. Found: C, 28.97; H, 5.11; N, 12.70%. Calcd for Λ-$[Co(ox)(en)_2]\Delta$-$[Co(edta)]\cdot 3H_2O$: C, 28.75; H, 5.13; N, 12.57%.

Measurements. Solubility was measured at 25 °C as follows: a mixed aqueous solution containing an excess of one, two, or three solid complex salt(s) in a conical flask was stirred mechanically for *ca.* 1.5 h at 25 °C in a thermostat regulated within ±0.1 °C. After the resulting saturated solution had been left to stand for a while, a portion of the supernatant solution was sucked into a weighing bottle through a cotton plug and then weighed. The amount of each ion in the saturated solution was determined as follows. The sample was diluted with water to a known volume, and its optical density and CD were measured. In the cases of containing Δ-$[Co(edta)]^-$ ion, optical densities were measured at 470.0 and 580.0 nm, and CD at 540.5 and 590.0 nm. The concentrations of {Λ-$[Co(ox)(en)_2]^+$+Δ-$[Co(ox)(en)_2]^+$} and Δ-$[Co(edta)]^-$ were derived from the observed optical densities, referring to the established values for the molar absorption coefficients of the component ions: ε(470.0 nm)=89.1 and ε(580.0 nm)=11.7 for Λ- and Δ-$[Co(ox)(en)_2]^+$, and ε(470.0 nm)=93.2 and ε(580.0 nm)=199 for Δ-$[Co(edta)]^-$. The concentrations of {Λ-$[Co(ox)(en)_2]^+$−Δ-$[Co(ox)(en)_2]^+$} and Δ-$[Co(edta)]^-$ were also derived from the observed CD values, referring to the data: $\Delta\varepsilon$(540.5 nm)=±2.31 and $\Delta\varepsilon$(590.0 nm)=±0.255 for Λ- and Δ-$[Co(ox)(en)_2]^+$ (+ and − for Λ and Δ, respectively), and $\Delta\varepsilon$(540.5 nm)=0 and $\Delta\varepsilon$(590.0 nm)=−1.66 for Δ-$[Co(edta)]^-$. The concentrations of Λ- and Δ-$[Co(ox)(en)_2]^+$ were separately calculated from those of {Λ-$[Co(ox)(en)_2]^+$+Δ-$[Co(ox)(en)_2]^+$} and {Λ-$[Co(ox)(en)_2]^+$−Δ-$[Co(ox)(en)_2]^+$}. The concentration of Δ-$[Co(edta)]^-$ was obtained from the mean values through the absorption and CD measurements. In the cases of not containing Δ-$[Co(edta)]^-$, optical densities and CD of the diluted sample solutions were measured at 497.0 and 523.0 nm, respectively, and the concentrations of Λ- and Δ-$[Co(ox)(en)_2]^+$ were separately derived, referring to the data: ε(497.0 nm)=119 and $\Delta\varepsilon$(523.0 nm)=±27.5 for Λ- and Δ-$[Co(ox)(en)_2]^+$ (+ and − for Λ and Δ, respectively). In the cases of containing d-H_3tart^- and Cl^- ions, a titration method was combined with the spectral one in order to determine the amount of d-H_3tart^-: the sample solution, which was sucked up and then weighed, was diluted to an appropriate volume and titrated with a 0.01 mol dm^{-3} NaOH solution to the end point of pH jump of the second step dissociation of the dicarboxylic acid.

In these ways, the amounts of all the cations and anions and then the amount of water in the saturated solution were obtained. Thus the concentrations of all the complex salts were calculated in molality. From a few reference experiments, it was confirmed that the optical densities and CD of the present cobalt(III) complex ions were not influenced by the coexistence of the counter ions, and that the absorption or CD value obtained for a mixed solution of several complex ions at a given wavelength was equal

to the sum of those measured for the individual complex ions.

The solid phases were identified from the elemental analyses, the absorption and CD spectra, and so on. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

Definition of Solubility Diagrams of Reciprocal Salt-Pairs. Solubility isotherms of reciprocal salt-pairs, (A^+, B^+)–(X^-, Y^-)–solvent, can be drawn in space as shown in Fig. 1.[1] Four vectors along four axes starting from an origin O show the solubilities of AX, AY, BX, and BY in a solvent. In this definition, the mutual nearest neighbor axes are situated at an angle of 60° and have a common-ion. The angle between an axis and the opposite one becomes 90°. Any saturated solution can be expressed as a point defined by summing up the position vectors of the solubilities of the salts contained. So the points of the solubilities of the binary and ternary systems are situated on the axes and the side faces of the tetragonal pyramid, respectively, except for the two ternary systems such as AX–BY–solvent and AY–BX–solvent which have only the solid phases of $A_pB_{1-p}X_pY_{1-p}\cdot n$(solvent) and $A_qB_{1-q}X_{1-q}Y_q\cdot n'$(solvent), respectively ($0\leqq p\leqq 1$ and $0\leqq q\leqq 1$). In the four-component system, there are two ways to attribute a solution to three salts and the solvent, assuming the concentrations of all the salts to be positive; for example, the choice is possible between the sets AX+BX+AY+solvent and AX+BX+BY+solvent. However, the points of these two systems are the same in space, when each axis is graduated in molality.

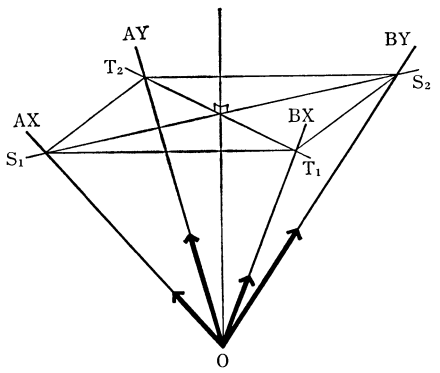

Fig. 1. Solubility diagram of reciprocal salt-pairs (A^+, B^+)-(X^-, Y^-)–solvent.

In this way, the phase diagram of reciprocal salt-pairs is strictly determined,[8] and the isotherms can be drawn by three kinds of plane figures: they are the plane projection on the horizontal base, the side elevation projected by parallel light along S_1S_2 or T_1T_2, and the clinographic projection with a light source at the origin O in Fig. 1. The clinographic projection has the property that the abscissa and ordinate indicate the mole fractions of B^+ and Y^-, respectively, to all the cations or anions (see Figs. 3 and 5).

Solubility Isotherms of (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$–(Cl^-, X^-)–H_2O; X^-=Δ-[Co(edta)]$^-$ and d-H_3tart^-. The solubility data obtained are given in Tables 1 and 2, and in Figs. 2—5. Neither double salt including racemic compound nor solid solution

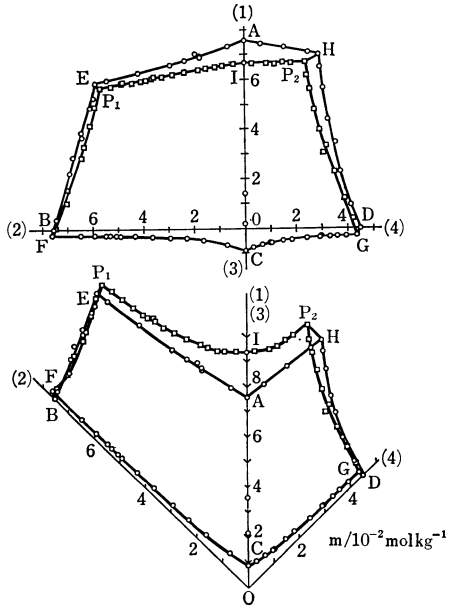

Fig. 2. The plane projection (upper) and the side elevation of the solubility isotherm of the reciprocal salt-pairs (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl^-, Δ-[Co(edta)]$^-$)-H_2O at 25 °C: solubility is presented in molality m of anhydrous salt; (1) Λ-[Co(ox)(en)$_2$]Cl, (2) Δ-[Co(ox)(en)$_2$]Cl, (3) Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)], (4) Λ-[Co(ox)(en)$_2$]Δ-[Co(edta)]; □, solubility of four-components; ○, solubility of two- or three-components.

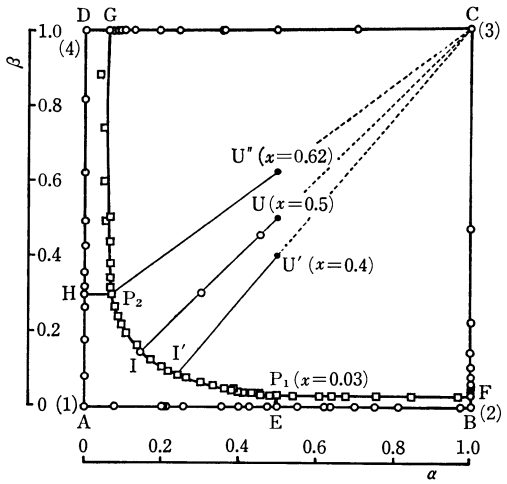

Fig. 3. The clinographic projection of the solubility isotherm of the reciprocal salt-pairs (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl^-, Δ-[Co(edta)]$^-$)-H_2O at 25 °C: α, mole fraction of Δ-[Co(ox)(en)$_2$]$^+$ to all the cations; β, mole fraction of Δ-[Co(edta)]$^-$ to all the anions; (1) Λ-[Co(ox)(en)$_2$]Cl, (2) Δ-[Co(ox)(en)$_2$]Cl, (3) Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)], (4) Λ-[Co(ox)-(en)$_2$]Δ-[Co(edta)]; □, solubility of four-components; ○, solubility of two- or three-components.

Table 1. Equilibrium of (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl$^-$, Δ-[Co(edta)]$^-$)-H_2O system at 25 °C
In liquid phases, solubility is presented in molality m of anhydrous salt. Abbreviations are as follows: Λ-[Co(ox)(en)$_2$]Cl·H_2O=ΛCl, Δ-[Co(ox)(en)$_2$]Cl·H_2O=ΔCl, Λ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·$3H_2O$=ΛR_1, Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·H_2O=ΔR_1.

a) Positions of the points in Figs. 2 and 3. In these expressions A↔E, for example, does not contain the points A and E. b) Number of components. c) The values in parentheses are estimated errors and were calculated from twice the standard deviations of the experimental measurements, which were repeated 3—25 times.

TABLE 2. EQUILIBRIUM OF (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl$^-$, d-H$_3$tart$^-$)-H$_2$O SYSTEM at 25 °C
In liquid phases, solubility is presented in molality m of anhydrous salt. Abbreviations are as follows: Λ-[Co(ox)(en)$_2$]Cl·H$_2$O=ΛCl, Δ-[Co(ox)(en)$_2$]Cl·H$_2$O=ΔCl, Λ-[Co(ox)(en)$_2$](d-H$_3$tart)·H$_2$O=ΛR$_2$, Δ-[Co(ox)(en)$_2$](d-H$_3$tart)·2H$_2$O=ΔR$_2$. The data for A, B, E, A↔E, and B↔E are listed in Table 1.

a) Positions of the points in Figs. 4 and 5. A↔E, for example, does not contain the points A and E. b) Number of components. c) The values in parentheses mean the same in Table 1. d) The point I, where P$_1$↔P$_2$ intersects the OBD plane, has exceptionally number of components 3.

exists in these systems. In the areas of AEP$_1$P$_2$H, BFP$_1$E, CGP$_2$P$_1$F, and DHP$_2$G in Figs. 2 and 3, the saturated solutions are in equilibrium with the solids, Λ-[Co(ox)(en)$_2$]Cl·H$_2$O, Δ-[Co(ox)(en)$_2$]Cl·H$_2$O, Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·H$_2$O, and Λ-[Co(ox)(en)$_2$]-Δ-[Co(edta)]·3H$_2$O, respectively. In the areas of AEP$_1$H, BFP$_2$P$_1$E, CGP$_2$F, and DHP$_1$P$_2$G in Figs. 4 and 5, the saturated solutions are in equilibrium with the solids, Λ-[Co(ox)(en)$_2$]Cl·H$_2$O, Δ-[Co(ox)(en)$_2$]-Cl·H$_2$O, Δ-[Co(ox)(en)$_2$](d-H$_3$tart)·2H$_2$O, and Λ-[Co-(ox)(en)$_2$](d-H$_3$tart)·H$_2$O, respectively.

In the region along the G↔P$_2$ line (Figs. 3 and 5) which has four-components containing ΛX and ΔX as solid phases (X=R$_1$ or R$_2$, and the abbreviations are the same as those in Tables 1 and 2), it was observed experimentally that the mole ratio of Λ^+ to Δ^+ in

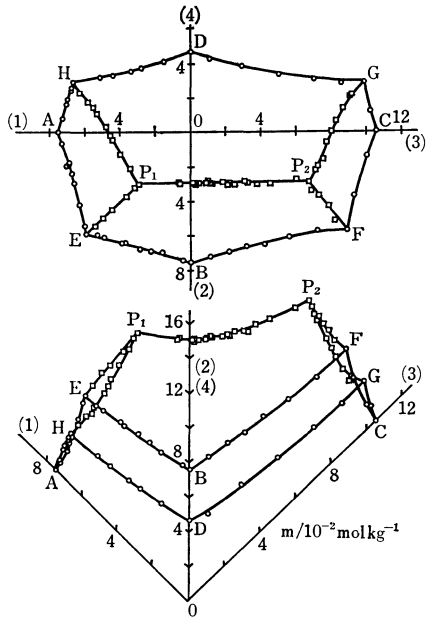

Fig. 4. The plane projection (upper) and the side elevation of the solubility isotherm of the reciprocal salt-pairs (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl$^-$, d-H$_3$tart$^-$)-H$_2$O at 25 °C: solubility is presented in molality m of anhydrous salt; (1) Λ-[Co(ox)(en)$_2$]Cl, (2) Δ-[Co(ox)(en)$_2$]Cl, (3) Δ-[Co(ox)(en)$_2$](d-H$_3$tart), (4) Λ-[Co(ox)(en)$_2$](d-H$_3$tart); □, solubility of four-components; ○, solubility of two- or three-components.

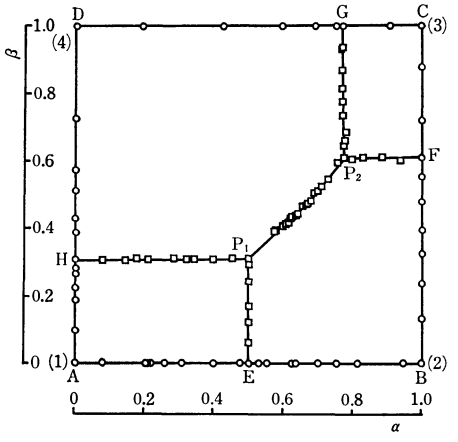

Fig. 5. The clinographic projection of the solubility isotherm of the reciprocal salt-pairs (Λ-[Co(ox)-(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl$^-$, d-H$_3$tart$^-$)-H$_2$O at 25 °C: α, mole fraction of Δ-[Co(ox)(en)$_2$]$^+$ to all the cations; β, mole fraction of d-H$_3$tart$^-$ to all the anions; (1) Λ-[Co(ox)(en)$_2$]Cl, (2) Δ-[Co(ox)(en)$_2$]Cl, (3) Δ-[Co(ox)(en)$_2$](d-H$_3$tart), (4) Λ-[Co(ox)(en)$_2$](d-H$_3$tart); □, solubility of four-components; ○, solubility of two- or three-components.

the liquid phase was almost constant. The analogous situations exist in the regions of E↔P$_1$, F↔P$_1$ and H↔P$_2$ (X=R$_1$), and E↔P$_1$, H↔P$_1$ and F↔P$_2$ (X =R$_2$). In other words, when two solids having a common-ion are in equilibrium with a solution, the mole ratio between the counter ions in its solution does not change by adding the fourth ion; thus no configurational activity[9-11] was observed in the present systems.

Applications to Optical Resolution. (1) (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl$^-$, Δ-[Co(edta)]$^-$)-H$_2$O System: The Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·H$_2$O diastereomer is predominant in the solid phases (Figs. 2 and 3), and this system can be applied successfully to the practical optical resolution. One mole of *rac*-[Co(ox)(en)$_2$]Cl·H$_2$O is dissolved in an excess of water and x mol of Δ-Ag[Co(edta)] is added to it ($0 \leqq x \leqq 1$). After the resulting precipitate AgCl has been filtered off, the filtrate is concentrated at 25 °C. Ignoring the dissolved AgCl, this operation produces just the same condition as that of the above solubility isotherm (Figs. 2 and 3).

There are several cases about the values of x: in the case of $0 \leqq x < 0.03$, the situation corresponds to the region of E↔P$_1$ in Figs. 2 and 3, giving no success in the optical resolution because of the precipitation of the racemic mixture [Co(ox)(en)$_2$]Cl·H$_2$O. The value, $x=0.03$, corresponds to the point P$_1$; the optical resolution is also unsuccessful because of the simultaneous precipitations of the $\Delta+\Lambda$ mixture of [Co(ox)(en)$_2$]Cl·H$_2$O and the diastereomer Δ-[Co(ox)-(en)$_2$]Δ-Co[(edta)]·H$_2$O. In the case of $0.03 < x < 0.62$, which relates to the region of P$_1$↔P$_2$, the optical resolution is possible since the precipitation of the diastereomer Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·H$_2$O occurs firstly and that of Λ-[Co(ox)(en)$_2$]Cl·H$_2$O later, but the yield of the pure less soluble diastereomer is not maximum. If an unsaturated solution having the composition U′ ($x=0.4$) in Fig. 3 is concentrated at the constant temperature 25 °C, the composition of the solution will remain at the point U′ so long as the solution is unsaturated. When the solution becomes saturated, the precipitation of the less soluble diastereomer will appear in this system and the point will move along the line U′→I′. At the point I′ the second precipitation Λ-[Co(ox)(en)$_2$]Cl·H$_2$O will begin to appear, and the trace of the point will proceed along I′→P$_1$. Finally at the invariant point P$_1$ the third solid Δ-[Co(ox)(en)$_2$]Cl·H$_2$O will appear. If we start from the point U ($x=0.5$), the solution composition will finally reach the point I (the invariant point in the ternary system, Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)]-Λ-[Co(ox)(en)$_2$]Cl–H$_2$O), and then the composition of the liquid phase will never change. And if we start from U″ ($x=0.62$), the solution composition will finally reach the invariant point P$_2$, where the solids, Δ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·H$_2$O, Λ-[Co(ox)(en)$_2$]Cl·H$_2$O, and Λ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·3H$_2$O, coexist. The yield of the pure less soluble diastereomer will become maximum in the range $0.62 \leqq x \leqq 1$. From the viewpoint of saving the resolving agent, the condition, $x=0.62$, which relates to the point P$_2$ is the most desirable. The calculated yield of the pure diastereomer is 93% of Δ-[Co(ox)(en)$_2$]$^+$ (47% of the racemic one).

It has been reported that the solubility ratio of Λ-[Co(ox)(en)$_2$]Δ-[Co(edta)]·3H$_2$O to Δ-[Co(ox)-(en)$_2$]Δ-[Co(edta)]·H$_2$O in the ternary system be-

comes larger with increasing temperature.[4] Therefore, more desirable conditions of the optical resolution may be found at higher temperatures.

(2) (Λ-[Co(ox)(en)$_2$]$^+$, Δ-[Co(ox)(en)$_2$]$^+$)-(Cl$^-$, d-H$_3$tart$^-$)-H$_2$O System: In this system (Figs. 4 and 5), all the complex salts have comparable solubilities in contrast to the case (1) containing Δ-[Co(edta)]$^-$ ion. This system can be also applied in the same manner as mentioned above; the resolving agents practically used are $x/2$ mol of *d*-H$_4$tart and $x/2$ mol of Ag$_2$(*d*-H$_2$tart). The optical resolution will be successful in the range $0.31<x\leqq 1$ which correlates to the regions of $P_1 \leftrightarrow P_2$ and $P_2 \leftrightarrow G$ in Figs. 4 and 5. The yield of the pure less soluble diastereomer becomes maximum in the range $0.75\leqq x\leqq 1$ and reaches 71% of Λ-[Co(ox)(en)$_2$]$^+$ (35% of the racemic one).

The Formation of the Oxidized Fe_3O_4-Fe_2TiO_4 Solid Solution by the Air Oxidation of the Aqueous Suspension

Takashi KATSURA,* Yutaka TAMAURA, and Gyong Sun CHYO

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 14, 1978)

The oxidized Fe_3O_4-Fe_2TiO_4 solid solution with the spinel type structure was synthesized by means of ferrite methods at pH 9.0 and 65 °C. When the solid solution thus obtained was heated at 200 or 300 °C in air for 20 h, it was completely oxidized to form a ferromagnetic product, which retained the spinel type structure for Ti/Fe_{total} ratios from 0 to 0.5.

Akashi *et al.*[1] proposed a "Ferrite Method" to eliminate many kinds of heavy metal ions in waste waters with concentrations as high as 1000 ppm. It should be emphasized that the ferromagnetic sludges thus formed are completely separated from solutions by a magnet. Katsura *et al.*[2] have examined this method for treating concentrated laboratory waste waters, and have succeeded in establishing a station for eliminating the harmful heavy metal ions. Of course, the background of the ferrite method is greatly indebted to many previous fundamental studies of the formation of Fe_3O_4 by the air oxidation of a ferrous hydroxide suspension in slightly alkaline solution. During these investigations, Kiyama[3] established the stability field for the formation of Fe_3O_4 with respect to the temperature and alkalinity of the aqueous suspensions. Yasuoka *et al.*,[4] Hamamura *et al.*,[5] and Kiyama[6,7] have synthesized $MnFe_2O_4$, $ZnFe_2O_4$, $BaFe_2O_4$, and Mn- and Co-ferrites, respectively. Katsura *et al.*[2] and Kaneko and Katsura[8] have also studied the formation of a solid solution of $FeCr_2O_4$-Fe_3O_4 and the $MgFe_2O_4$-Fe_3O_4 solid solution by the ferrite method, respectively. Tamaura *et al.*[9] have studied the formation of Fe_3O_4 in the presence of a dispersing reagent. The formations of solid solutions between Fe_3O_4 and the double oxides are of much interest not only for the ferrite method, but also for the fundamental studies.

The presnet objectives are to: (1) ascertain whether or not a Fe_3O_4-Fe_2TiO_4 solid solution having the spinel type structure could be formed in its complete composition range by the ferrite method, and to (2) obtain a strongly oxidized Fe_2O_3-Fe_2TiO_5 solid solution having the ferromagnetic spinel type structure by heating the samples synthesized by the ferrite method at some higher temperatures. The latter objective is especially valuable for studying the magnetic or geomagnetic properties of highly oxidized titanomagneite found in igneous rocks.

Experimental

Reagents. The guaranteed reagent grade of $FeSO_4 \cdot 7H_2O$ and the reagent grade of $Ti(SO_4)_2 \cdot nH_2O$ were employed for preparing solutions with various Ti/Fe_{total} ratios ranging from 0 to 0.5.

Chemical Analysis. To determine Ti content in the reagent $Ti(SO_4)_2 \cdot nH_2O$ and the Ti^{4+}, Fe^{2+}, and Fe^{3+} contents in the ferrites obtained, the improved method of Iwasaki *et al.*[10] was used. But the ferrites containing various amounts of Ti^{4+} were easily dissolved by the 4 mol dm^{-3} sulfuric acid solution. Thus, there was no need to use the mixed acid solution of sulfuric acid and hydrofluoric acid.

Apparatus. The reaction vessel was a beaker with a capacity of 1 dm^3, as shown in Fig. 1. The temperature of the vessel was kept constant to 65±0.5 °C by a mantle heater controlled by an electric temperature controller. A glass tube (8) with a flat end having eight holes (0.1 cm in diameter) at equal intervals is kept in contact with the bottom of the beaker. A platinum electrode, and a calomel elctrode with a double junction are 1, 5, and 6 in Fig. 1. A thermister to control the temperature is 3 in Fig. 1, and 4 is a condenser.

Procedures. Re-distilled water (800 cm^3) was added to a separable beaker, and was flushed, using nitrogen gas free from carbon dioxide and oxygen for about 1 h. After the separable beaker was sealed, the solution was heated at 65±0.5 °C while the nitrogen gas bubbling was continued. $FeSO_4 \cdot 7H_2O$ (14.4 g) and a desired amount of the titanium(IV) sulfate solution were then added still continuing the flow of the nitrogen gas. Then, a 2 mol dm^{-3} sodium hydroxide solution free from carbon dioxide was added; the pH-stat controller was used to adjust the pH value at 9.0 or any desired value. After the solution stood for about 1 h, the pH value and the oxidation potential (ORP) became constant without further addition of the

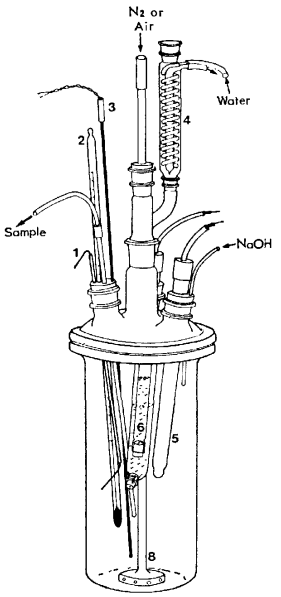

Fig. 1. The reaction vessel used in this study. The reaction vessel is separable. 1: Platinum electrode, 2: thermometer, 3: thermister, 4: condenser, 5: glass electrode, 6: calomel electrode with double junction 7, 8: glass tube with a flat end having eight holes (0.1 cm in diameter).

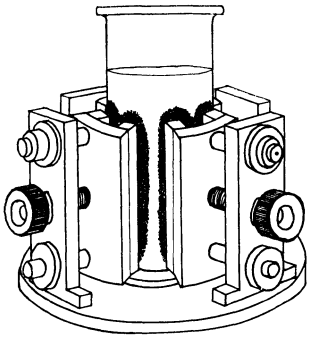

Fig. 2. Magnetic separator used in this experiment. The product is attracted by the four magnets with 1600 Oe and separated from the solution within 2—5 min.

2 mol dm^{-3} sodium hydroxide solution. Then, pre-purified air free from carbon dioxide was passed at a rate of 3 dm^3 min^{-1} through the solution in place of the nitrogen gas for a desired period of time. The temperature and the pH were kept constant during the course of the air oxidation. The end of the oxidation which completed the formation of the ferromagnetic spinel type product was easily recognized by mean of an oxidation potential measurement, as pointed out in previous studies.[8] The relationship between the ORP value and the Fe^{2+}/Fe_{total} ratio will be seen later. The oxidation product was separated from the solution in the nitrogen atmosphere by a magnetic separator devised specially for the present experiment. The magnetic separator used is illustrated in Fig. 2. The product attracted by the magnet was then washed with redistilled water several times, then with acetone to remove the water in the precipitate as completely as possible. The precipitate thus obtained was dried by the freeze-dry technique. The product was analyzed chemically to determine the contents of Fe^{2+}, Fe^{3+}, and Ti^{4+}. The dried product was examined by the powder X-ray diffraction method, infrared spectroscopy, and electron microscopy to identify the phases present in the product. The 2θ angles of the diffraction peaks were calibrated against the standard Si powder by using the Mn-filtered Fe $K\alpha$ radiation. The magnetic susceptibility and the Mössbauer spectra were also obtained for extremely oxidized Fe_2O_3-Fe_2TiO_5 solid solution having the spinel type structure. The results obtained from these magnetic and Mössbauer studies will be publised in the near future.

In order to determine the oxidation rate in the aqueous suspension, an aliquot portion of the suspended solution containing oxide and/or hydroxide was taken out by a syringe in the course of the air oxidation, as seen in Fig. 1, without any air contamination.

Results and Discussion

(1) *The Hydrolysis of Titanium in the Presence of the Fe^{2+} Ion in Aqueous Suspension.* Kaneko and Katsura[8] pointed out that the process of hydrolysis is important for producing the ferrite solid solution. In this paper, the acidic solution containing titanium(IV) and iron(II) ions (Ti/Fe ratio of 0.304) was titrated with a 2 mol dm^{-3} sodium hydroxide solution. The result is shown in Fig. 3. As seen here, the titanium(IV) ions were almost completely hydrolyzed at about pH 9. So, at pH 9.0, all ions of titanium(IV) and

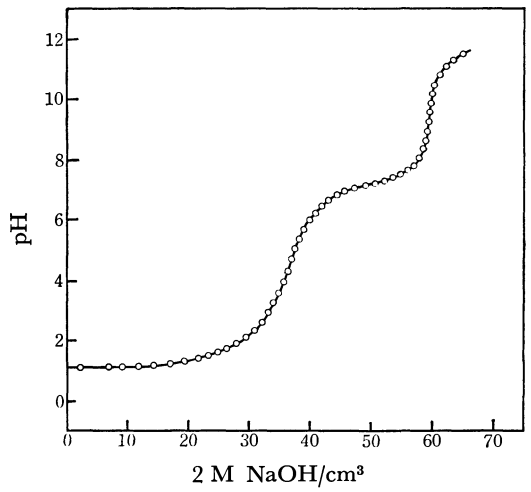

Fig. 3. The titration curve for Ti^{4+} and Fe^{2+}. The Ti/Fe_{total} ratio is 0.304, and the concentration of the NaOH solution is 2 M.

iron(II) were in the hydrous state. This suggests that the complete solid solution of Fe_2TiO_4–Fe_3O_4 could be produced by the ferrite method at a pH of 9.0 and at 65 °C, provided that the hydrolysis is one of the definite steps needed to form the ferrite, as pointed out in the previous paper.[8]

(2) *The Oxidation Rate to Form the Fe_3O_4–Fe_2TiO_4 Solid Solution.* Figure 4 shows the relationship between the Fe^{2+}/Fe_{total} ratio in the suspended solution and the reaction time(min) in the case of the ferrous hydroxide alone($Ti/Fe_{total}=0$). The measurements were performed at pH 9.0 and 11.0 at 65 °C. The ORP dependence of the Fe^{2+}/Fe_{total} ratio is also plotted in Fig. 4. As seen here, the ORP values changed abruptly from about −800 to −50 mV at pH values 9.0 and 11.0, as pointed by the letters a and b. In the early stage of the oxidation, which ranged from

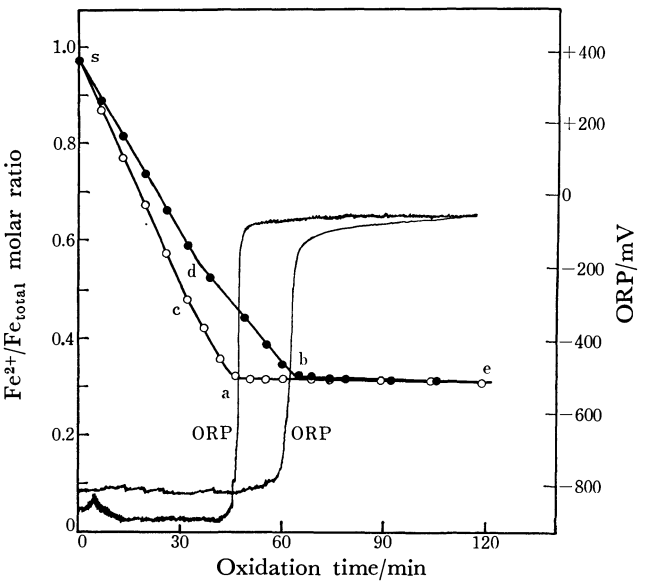

Fig. 4. The oxidation rate of the $Fe(OH)_2$ suspension by the air and the change of the oxidation potential (Pt-Calomel couple). The Ti/Fe_{total} molar ratio is 0.

point s to a or b, as is clear in Fig. 4, the oxidation rate was high, and the rate seems to be a zero order reaction. However, considering the present accuracy of chemical analysis, we may say that the oxidation rate in the early stage is constructed by two somewhat different straight lines; one is from s to d the other is from d to b at pH 9.0, and from s to c and c to a at pH 11.0. According to the results of the X-ray diffraction method and the electron microscopy, there was a large amount of ferrous hydroxide in the suspensions produced during the course from s to c or d, then gradually the amount of ferrous hydroxdie was decreased to form a large amount of ferrite in the course from d or c to b or a. At point a or b, no ferrous hydroxide crystals were found in the suspension. The oxidation rate changed greatly at just the same point as where the ORP value changed abruptly by a or b in Fig. 4. The electrochemical discussion on this phenomenon will be presented in the near future.

Figures 5 and 6 show the same relationship between the Fe^{2+}/Fe_{total} ratio in the suspended solution and the reaction time in cases of the Ti/Fe_{total} ratios of 0.071 and 0.304, respectively. As seen in Figs. 5 and 6, the great changes in the ORP values correspond to the end points of the oxidation reaction for producing the ferrite containing titanium. Because of these results, the oxidation by the air was stopped just 10 min after the abrupt change of the ORP value, and the ferromagnetic suspension was separated and dried as described before. We call the dried product thus obtained series A.

(3) *The Non-stoichiometry in Composition.* As seen in Figs. 4, 5, and 6, the compositions of the series A are not stoichiometric and the deviation from the stoichiometric composition increases with increasing the Ti/Fe_{total} ratio. For example, in the case of the Ti/Fe_{total} ratio of 0.304, the Fe^{2+}/Fe_{total} ratio should be 0.739 if the composition is stoichiometric, but as

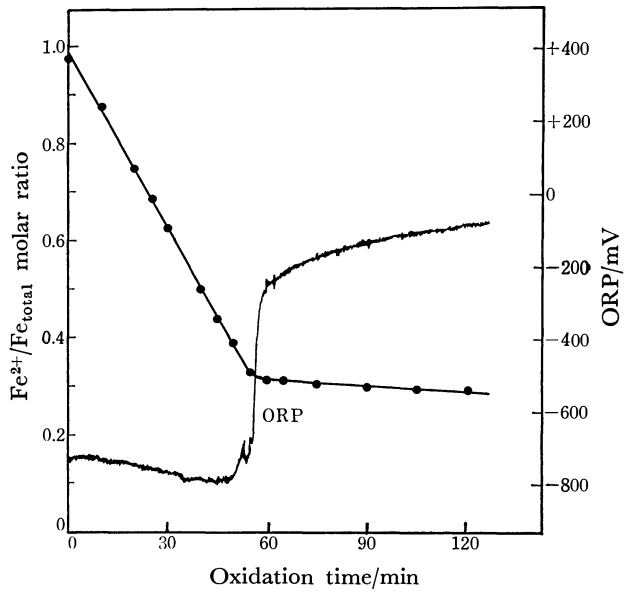

Fig. 5. The oxidation rate of the suspension by the air (Pt-Calomel couple). The Ti/Fe_{total} molar ratio is 0.071.

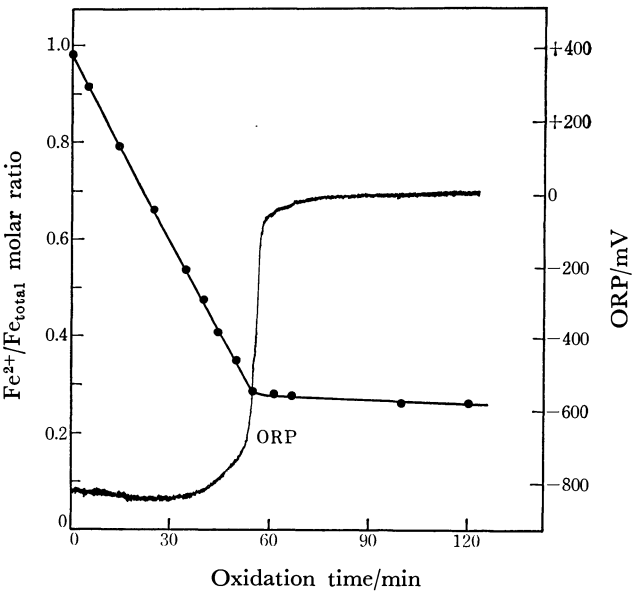

Fig. 6. The oxidation rate of the suspension by the air (Pt-Calomel couple). The Ti/Fe_{total} molar ratio is 0.304.

seen in Fig. 6, the real ratio was only 0.290. This means that the series A is oxidized. The X-ray diffraction pattern of each product showd only a typical spinel type structure.

(4) *Synthesis of the Extremely Oxidized Fe_2TiO_4–Fe_3O_4 Solid Solution.* The series A was subsequently heated at a temperature range from 80 to 400 °C in air by an electrical furnace for desired periods of time. The product thus obtained is called the series B. The series B was examined by the X-ray diffraction method, infrared spectroscopy, electron microscopy, and the Mössbauer method. Chemical analysis was also performed to determine the contents of FeO, Fe_2O_3, and TiO_2. Here we will discuss the results obtained from the chemical analysis and the X-ray diffraction method. The other results will be discussed in the near future.

It is convenient to show the chemical composition of the series B together with the series A as a ternary system: FeO, Fe_2O_3, and TiO_2. Figure 7 shows the chemical composition of the series A and B. It is well known that there exist three solid solution series in the FeO–Fe_2O_3–TiO_2 system at high temperatures: Fe_3O_4–Fe_2TiO_4(titanomagnetite with spinel type), Fe_2O_3–$FeTiO_3$(rhombohedral), and Fe_2TiO_5–$FeTi_2O_5$(orthorhombic). These are shown in Fig. 7 as straight lines. The oxygen reaction lines are also drawn by straight lines. For example, if the stoichiometric composition M in Fig. 7 is oxidized, then the composition moves along the oxygen reaction line to a point N. Some chemical compositions deviate from these oxygen reaction lines. These are due to errors in the chemical analysis. The points on the curved dotted line give the chemical compositions of the series A. The letter x means the mole fraction of Fe_2TiO_4 in the Fe_3O_4–Fe_2TiO_4 solid solution. The values of the Ti/Fe_{total} ratio of 0.071 and 0.304 which were seen in this paper

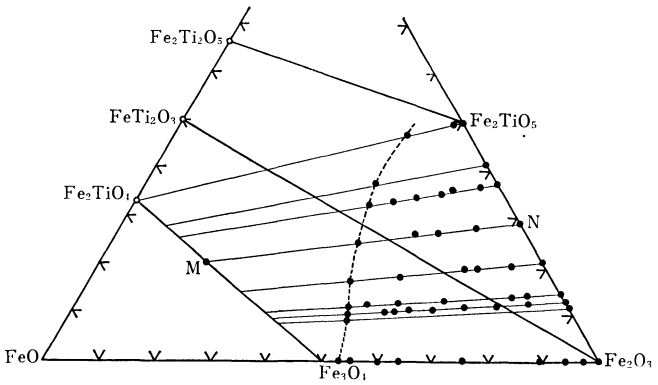

Fig. 7. The chemical composition of the series A and B expressed as FeO, Fe_2O_3, and TiO_2. Three solid solutions of Fe_3O_4-Fe_2TiO_4, Fe_2O_3-$FeTiO_3$ and Fe_2TiO_5-$FeTi_2O_5$ are given by three straight lines. The *oxygen reaction lines* are also shown by the straight lines.

correspond to the mole fractions of 0.2 and 0.7, respectively. As seen in Fig. 7, it is clear that the series A is oxidized, and the chemical composition of the series B is strongly oxidized, depending on the heating temperature and time. When we heated the series A at 200 or 300 °C for 15—20 h, then the products were completely oxidized. At high temperatures, the phase obtained by the complete oxidation of $x=1$ should be pseudobrookite (Fe_2TiO_5), and the compositions in between Fe_2TiO_5 and Fe_2O_3 should be composed of both hematite(Fe_2O_3) and pseudobrookite, if the system is in an equilibrium state.

(5) *The Identification of Phases in the Series A and B.* The X-ray powder diffraction method was adopted to identify the phases present. Infrared spectroscopy was also used to identify the presence of the α-FeOOH phase. Some examples of the diffraction patterns are shown in Fig. 8. Sample series A and B have a spinel type structure irrespective of the oxidation degree and of the Ti/Fe_{total} ratio.

Recently, Readman and O'Reilly[11] and Nishikawa *et al.*[12] have studied the magnetic properties of oxidized (cation-deficient) titanomagnetite (the Fe_3O_4-Fe_2TiO_4 solid solution which naturally occurs). They have synthesized the oxidized titanomagnetite by grinding the stoichiometric solid solution prepared at high temperatures, and have determined the relationships among the chemical composition, the magnetic susceptibility, and lattice constant of the oxidized titanomagnetite. However, it was very hard to obtain any extremely oxidized titanomagnetite with relatively large particles. Thus, the peak intensity of the powder X-ray pattern was very weak, and some people[13] do not believe in the existence of the extremely oxidized titanomagnetite. The particle size of the series A and B ranges from 1000 to 2000 Å,** and the peak intensity is strong enough to determine the precise lattice constant.

(6) *The Relationship between the Lattice Constant and the Oxidation Degree of the Spinel Type Solid Solution.* In this paper, we define the oxidation degree(OD) of each oxidized spinel type solid solution as follows:

OD=number of vacant sites/maximum number of vacant sites when completely oxidized.

Table 1 shows the relationship between the mole fraction of Fe_2TiO_4 in the solid solution and the maximum number of the vacant sites when the stoichiometric solid solution was completely oxidized. The lattice constants of completely oxidized samples are also given in Table 1. As seen here, the lattice constant is almost identical in spite of the different mole fractions of Fe_2TiO_4. This fact was suggested qualita-

** Å=0.1 nm.

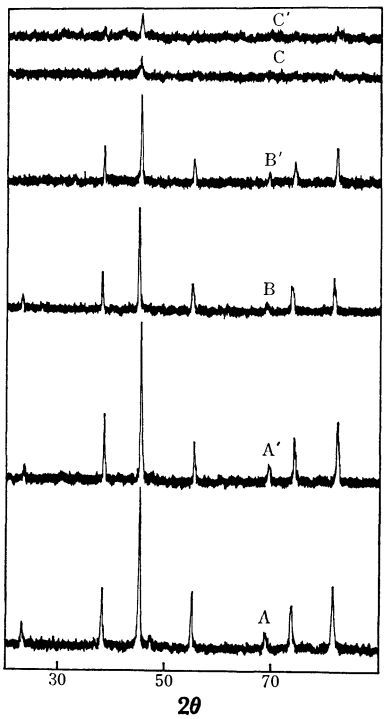

Fig. 8. The X-ray diffraction of the series A and B with radiation of Fe $K\alpha$ (Mn filtration). A: series A with $x=0$. A': Heated the sample A at 200 °C for 15 h in air, B: series A with $x=0.5$, B': Heated the sample B at 200 °C for 15 h, C: Series A with $x=1$, C': Heated the sample C at 300 °C for 15 h.

Table 1. The maximum number of the vacant sites, in the spinel type structure of the completely oxidized Fe_2TiO_4-Fe_3O_4 solid solution (based on 4 oxygen) and the lattice constants measured in this study (Å=0.1 nm)

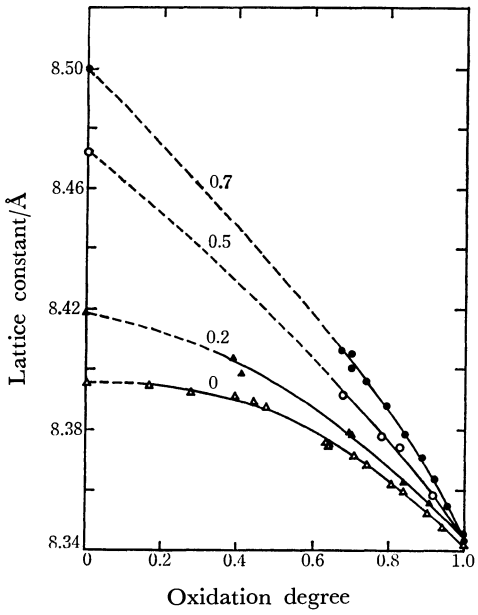

Fig. 9. The relationship between the lattice constant of the series A and B and the oxidation degree. Numbers mean the value x.

tively by Readman and O'Reilly.[10] Figure 9 shows the relationship between the oxidation degree of the series B and the lattice constant. As seen here, the lattice constant decreases gradually with increasing the oxidation degree in each sample with the same mole fraction of Fe_2TiO_4. The precise lattice constants of the stoichiometric Fe_2TiO_4–Fe_3O_4 solid solution have been determined by Katsura *et al.*[14] When we extrapolate the present results to the stoichiometric composition (OD=0), all curves fit the points for the stoichiometric solid solution.

The authers are greatly indebted to Drs. T. Nishikawa of the University of Tokyo and T. Sugihara of the Tokyo Institute of Technology for the cooperation in completing this study.

Bridges in Polynuclear Complexes. I. The Reaction and Reaction Products of $\mu(NH_2,O_2)$ Dicobalt Complexes with Nitrites†

Shigekazu KUBO,* Takashi SHIBAHARA,†† and Masayasu MORI

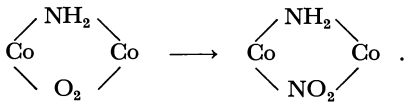
Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received August 17, 1978)

The IR spectroscopy of the μ-amido-μ-nitro complex, $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4\cdot 2H_2O$ obtained from normal and ^{18}O-labeled $[(NH_2,O_2)\{Co(NH_3)_4\}_2](NO_3)_4$ has revealed that the O atom in the Co-N-O-Co chain comes from the O_2 bridge of the starting complex, whereas the O atom attached to the N atom from outside the chain comes from the nitrite used in the bridge conversion, $\mu O_2 \rightarrow \mu NO_2$. A reaction mechanism involving N_2O_3 as the reacting species is proposed. The reaction of $[(NH_2,O_2)\{Co(NH_3)_4\}_2]X_3$ with the nitrite in neutral solution gave a non-electrolytic μ-hyperoxo dicobalt complex, $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$ (I). Treatment of I with perchloric acid gave a triple-bridged complex, $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]^+$, which reproduces I when treated with sodium nitrite.

Dioxygen-bridged dicobalt complexes may be classified into two series, one of which includes brown μ-peroxo complexes, and the other green μ-hyperoxo complexes. Both react with nitrite ion but the reaction features are quite diverse depending on the nature of the starting complex and the condition of the reaction. In the case of $[O_2\{Co(NH_3)_5\}_2]^{n+}$, in an acidic solution there occurs reduction of the μ-hyperoxo complex ($n=5$) to the μ-peroxo complex ($n=4$) followed by cleavage of the O_2 bridge and formation of the mononuclear complex.[1] In the case of the ethylenediamine analog $[O_2\{Co(en)_2NH_3\}_2]^{n+}$, oxidation of the μ-peroxo complex ($n=4$) to the μ-hyperoxo complex ($n=5$) occurs in an acidic solution, whereas in a neutral solution substitution of the ammine ligands by nitro groups takes place.[2]

The double-bridged complex also reacts with the nitrite ion, and in an acidic solution, conversion of the O_2 bridge into the NO_2 bridge occurs without any change on the NH_2 bridge:[3]



The kinetic study of the reaction of the μ-amido-μ-hyperoxo complex, $[(NH_2,O_2)\{Co(en)_2\}_2]^{4+}$, by Edwards *et al.* suggested that reduction ($\mu O_2^- \rightarrow \mu O_2^{2-}$) and bridge conversion ($\mu O_2 \rightarrow \mu NO_2$) should occur successively.[4] The first part of the present paper is concerned with the investigation into the reaction mechanism of such bridge conversion ($\mu O_2 \rightarrow \mu NO_2$) by the combined use of ^{18}O-labeling and the IR study of the reaction product.

The work on the reaction of the μ-NH_2-μ-O_2 complex with the nitrite ion in a neutral or a basic solution still seems to be meager[2] especially with the ammine complex. The remaining part of the present paper describes the study of such a reaction and some new dicobalt complexes obtained as the reaction product, one of which is a non-electrolytic μ-amido-μ-hyperoxo complex.

Experimental

Materials. $^{18}O_2$ (^{18}O atom % = 92) gas was obtained commercialy from International Chemistry and Nuclear Corp.

Analyses. Ammoniacal N was determined by titration of ammonia after distillation from aqueous sodium hydroxide with arsenic(III) oxide;[5] total N was determined similarly except for use of Devarda's alloy in place of arsenic(III) oxide; Cl in perchlorate was determined as silver chloride after decomposition of the sample with melted sodium nitrite in a nickel crucible.[6] Other elements were analysed by the standard methods.

Reaction and Preparation. 1. Preparation of ^{18}O-Substituted $[(NH_2,O_2)\{Co(NH_3)_4\}_2](NO_3)_4$: This ^{18}O-labeled dicobalt complex was prepared by the adaption of the usual method[7] by using a closed system: A 100-ml flask containing 2.5 g of cobalt(II) nitrate hexahydrate, 15 ml of water previously boiled and cooled under nitrogen, and a magnetic bar coated with Teflon was connected to a vacuum line. The flask was degassed by three freeze-pump cycles, then filled with *ca.* 1 atm ammonia gas from cylinder connected to the line. The content was stirred with a magnetic stirrer until the blue precipitate which had once appeared redissolved and the solution turned red. Although some temperature rise was observed during the absorption of ammonia, it was allowed to be, because absorption of too large excess of ammonia by cooling is unfavorable for the succeeding dioxygen-bridging reaction. After the supply of ammonia gas was stopped the reaction flask was cooled in an ice bath, and 100 ml (N. T. P.) of $^{18}O_2$ gas was introduced into it *via* a Toeplar pump, and was allowed to be absorbed by the solution for 3 h. The mercury of the pump was previously covered with liquid paraffine because it is easily oxidised in the presence of ammonia. At this stage, black crystals of $[O_2\{Co(NH_3)_5\}_2](NO_3)_4$ were precipitated. The reaction mixture was exposed again to 1 atm ammonia gas, and kept at 35 °C for 2 h to introduce the NH_2 bridge; addition of potassium hydroxide was omitted in this experiment to minimize the contamination by normal oxygen. After the reaction mixture was freezed, the flask was removed from the vacuum line, and succeeding procedures were carried out under air. Upon the freezed mixture, 3.5 g of ammonium cerium(IV) nitrate, 30 ml of nitric acid, and 50 g of ice was placed. The whole mixture was melted and stirred. The precipitate was separated from the solution,

† Presented at the 29th Annual Meeting of the Chemical Society of Japan, Hiroshima, Oct. 1973, and the 25th Symposium on Coordination Chemistry, Tokyo, Oct. 1975.

†† Present address: Department of Chemistry, Okayama University of Science, 1-1 Ridaicho, Okayama 700.

and purification *via* practically insoluble sulfate gave 380 mg of ^{18}O-substituted $[(NH_2,O_2)\{Co(NH_3)_4\}_2](NO_3)_4$; in addition, 160 mg of ^{18}O-labeled $[O_2\{Co(NH_3)_5\}_2](NO_3)_5$ was obtained as a co-product in the course of the purification of the former. The complexes were examined by the IR spectroscopy.

2. Reaction of $[(NH_2, {}^{18}O_2)\{Co(NH_3)_4\}_2](NO_3)_4$ with NO_2^- in an Acidic Solution and Isolation of Product: The procedure was modified from the method of Werner[3] owing to the scantiness of the reactant complex available for the experiment.

To a solution of 500 mg of sodium nitrite in 10 ml of water, 100 mg of the complex was added, and then 1.5 ml of 14 M nitric acid was added dropwise with stirring. The mixture was cooled in an ice bath, and the precipitated orange μ-amido-μ-nitro dicobalt complex nitrate was filtered with suction, washed with methanol, and dissolved in 1.5 ml of 12 M hydrochloric acid. After filtration, 3 ml of ethanol was added to it, and the mixture was cooled in an ice bath. The precipitate (complex chloride) was filtered, and recrystallized in the same manner. The product was washed with ethanol, and dried by aeration; yield 70 mg.

The product with normal oxygen prepared by the same procedure was submitted to chemical analysis; each product obtained in the experiments with $^{18}O_2$ and with normal oxygen respectively gave the identical X-ray diffraction pattern and IR spectrum except for the isotopic shift. Found: Co, 23.81; N(total), 28.08; N(ammoniacal), 25.23; Cl, 28.54; H, 6.02%. Calcd for $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4\cdot 2H_2O$: Co, 23.86; N(total), 28.35; N(ammoniacal), 25.52; Cl, 28.71; H, 6.21%.

3. Reaction of $\mu(NH_2,O_2)$ Complex with NH_4NO_2 in a Neutral Solution (Preparation of $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$): To 750 ml of 10% ammonium nitrite, 20 g of $[(NH_2,O_2)\{Co(NH_3)_4\}_2]Na(ClO_4)_4$ (prepared by the method in Ref. 7) was added with stirring, and the mixture was allowed to stand at *ca.* 5 °C in a refrigerator. From the next day, 1 g of ammonium persulfate was added every day until the solution assumed a reddish orange color and no more precipitate increased (It took *ca.* 20 days). The green precipitate was filtered, washed with water and then with acetone, and dried by aeration; yield 8 g.

The product obtained was insoluble in any solvents so far examined, and could not be recrystallized by the usual method. For the purification, the crude product was once changed to $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]ClO_4\cdot 0.5H_2O$ by the process described in the next section, and brought back to the original compound by the following procedure: To a solution of 1 g of the perchlorate dissolved in 130 ml of water was added 10 ml of 10% aqueous sodium nitrite. The mixture was allowed to stand in a refrigerator overnight. The precipitate was filtered, washed with water and then with acetone, dried by aeration, and kept over calcium chloride. Green powder; yield 0.6 g. Found: Co, 27.92; N(total), 29.66; N(ammoniacal), 16.31%. Calcd for $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$: Co, 28.20; N(total), 30.16; N(ammoniacal), 16.75%.

4. Preparation of $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]ClO_4\cdot 0.5H_2O$: Six grams of the crude $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$ (described above) were added to 150 ml of ice-cold perchloric acid (60%) and the mixture was stirred under reduced pressure of aspirator for 2 h for dissolution. (Without reduced pressure it took longer time for dissolution and decomposition to form by-products was more pronounced.) The cold green solution was filtered with a sintered-glass filter and added in small portions to 900 ml of ether wihch had been cooled in an ice bath, care being taken to minimize the temperature rise. The flocky precipitate was filtered and washed with ether. After the ether was eliminated with aeration, the product was washed with two small portions of cold water and air dried. The green material was dissolved in 150 ml of acetone and an equal volume of ether was added to it. The mixture was allowed to stand in an ice bath for *ca.* 1 h and the precipitate was filtered, washed with ether, and air-dried. Green thin plates; yield 1.9 g. Found: Co, 24.85; N(total), 23.16; N(ammoniacal), 14.60; Cl, 7.45; H, 3.16%. Calcd for $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]ClO_4\cdot 0.5H_2O$: Co, 24.53; N(total), 23.32; N(ammoniacal), 14.58; Cl, 7.38; H, 3.14%.

5. Preparation of $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]Cl$: To a solution of 3 g of the perchlorate (described above) dissolved in 400 ml of water, 80 ml of 6 M hydrochloric acid was added, and the mixture was cooled in an ice bath. The precipitate was filtered, and washed with cold 2 M hydrochloric acid and then with acetone. The product was dissolved in 700 ml of cold water, and 70 ml of 6 M hydrochloric acid was added. The precipitate was filtered, washed with 0.5 M hydrochloric acid and then with acetone, and dried by aeration. Green thin prisms; yield 1.6 g. Found: Co, 29.02; N(total), 26.96; N(ammoniacal), 17.02; Cl, 8.81%. Calcd for $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]Cl$: Co, 28.93, N(total), 27.50; N(ammoniacal), 17.19; Cl, 8.70%.

6. Preparation of $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]Br$: To a solution of 2 g of the perchlorate (described above) dissolved in 400 ml of water, 50 ml of 24% hydrobromic acid was added, and the mixture was allowed to stand in an ice bath. The precipitate was filtered, and washed with cold water and then with acetone. The product was recrystallized from the aqueous solution by addition of hydrobromic acid and dried by aeration after filtration and washing. Green needles; yield 1.7 g. Found: Co, 26.20; N(total), 24.30; N(ammoniacal), 15.37; Br, 17.69%. Calcd for $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]Br$: Co, 26.08; N(total), 24.79; N(ammoniacal), 15.50; Br, 17.68%.

Apparatus. IR spectra were recorded with samples in Nujol on a JASCO IR-E or IR-G spectrometer. Recording of absorption spectra was carried out with a Hitachi 124 spectrometer, and that of reflectance spectra with the same apparatus by use of an integration sphere attachment. ESR spectra were recorded on a JEOL JES-3B spectrometer at room temperature. Magnetic susceptibilities were determined by the Faraday technique with a Shimadzu MB-2 balance. Powder X-ray diffraction patterns were recorded on a Rigaku 2171 diffractometer with the Ni $K\alpha$ radiation.

Results and Discussion

IR Spectroscopy of ^{18}O-Labeled Complexes. 1. $\mu(NH_2,O_2)$ Complex: The IR spectra of normal and isotopically labeled $[(NH_2,O_2)\{Co(NH_3)_4\}_2](NO_3)_4$ in the region of *ca.* 700—1200 cm^{-1} are shown in Fig. 1. The fact that the labeled complex shows no peak corresponding to $^{16}O_2$ stretching vibration proves that there has been no shuffling of oxygen between O_2 and H_2O or NO_3^- in the formation process of the single-bridged complex $[O_2\{Co(NH_3)_5\}_2]^{4+}$, as well as in the transformation process to the double-bridged complex. The possibility of scrambling of oxygen atoms among the oxygen molecules and the O_2-moieties of complex ions also was excluded because a sample prepared by using a mixture of $^{18}O_2$ and $^{16}O_2$ showed no peak of ^{18}O-^{16}O stretching vibration.

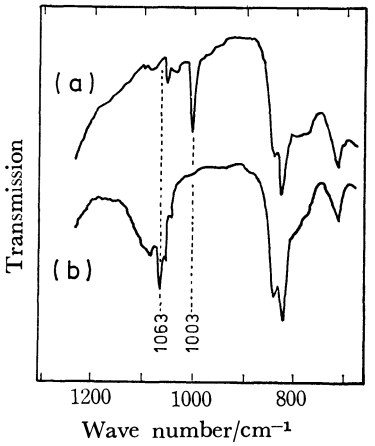


Fig. 1. IR spectra of $[(NH_2,O_2)\{Co(NH_3)_4\}_2](NO_3)_4$ (a) with ^{18}O-labeled O_2-bridge and (b) with normal O_2-bridge.

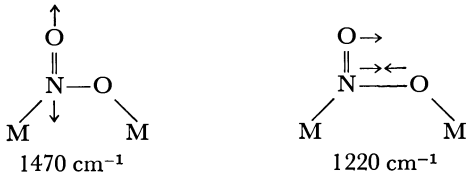
2. $\mu(NH_2,NO_2)$ Complexes: Werner[3] reported two hydrates of $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4$, one of which was monohydrate crystallized from dilute hydrochloric acid and the other tetrahydrate crystallized from aqueous solution containing some pyridine. The IR spectrum and the X-ray powder pattern of the ^{18}O-labeled complex chloride prepared as described showed that it was a third form; the chemical analysis of the corresponding normal complex conformed to the formula of dihydrate. The authors later knew that this dihydrate was reported in 1975 by Huang *et al.*[8] who crystallized it from 6 M hydrochloric acid. Not only the IR peaks due to water of crystallization the content of which is different in these three forms, but also the IR peaks due to nitro bridge and ammonia ligand showed slight differences in their frequency and intensity, such differences in some cases being of comparable magnitude to those due to isotopic effect. The variation in the IR spectrum owing to the difference in the crystal form was noticed in this laboratory, with $[(NH_2,O_2)\{Co(NH_3)_4\}_2](NO_3)_4$.[9] Thus in the detailed examination of IR spectra and especially in the discussion of their isotopic shifts, one must make sure of the identity of the number of crystal water or the crystal form of the complexes compared.

The IR spectrum of $[(NH_2, NO_2)\{Co(NH_3)_4\}_2]Cl_4$ was reported by Gatehouse[10] although it is not clear which type of the above three hydrates was examined. He assumed an asymmetric structure of the nitro bridge and assigned two strong IR peaks as shown below:



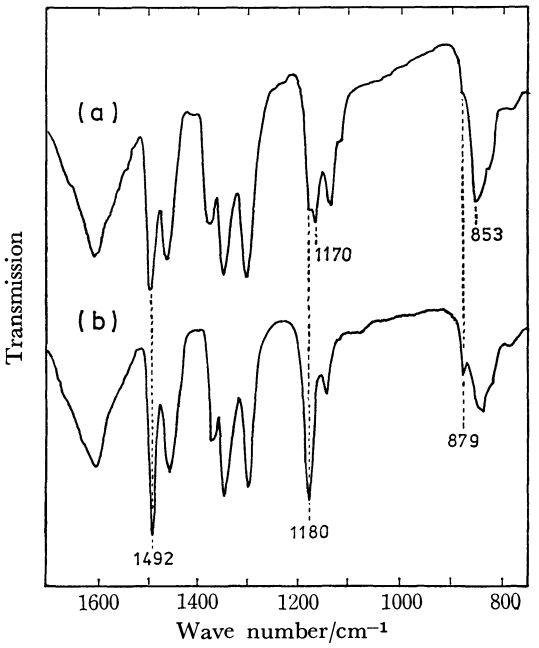


Fig. 2. IR spectra of $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4 \cdot 2H_2O$ prepared (a) from ^{18}O-labeled $\mu(NH_2,O_2)$ complex and (b) from normal complex.

Nakamoto *et al.*[11] examined a similar nitro-bridged compound $[(NO_2,OH,OH)\{Co(NH_3)_3\}_2]Cl_3$ and made the same sort of assignment.

The X-ray structural study of $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4 \cdot 4H_2O$ by Thewalt and Marsh[12] and that of $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4 \cdot 2H_2O$ by Huang *et al.*[8] both proved the correctness of the formula postulated by Gatehouse, and his assignment of the two IR bands also seems to be a sound one.

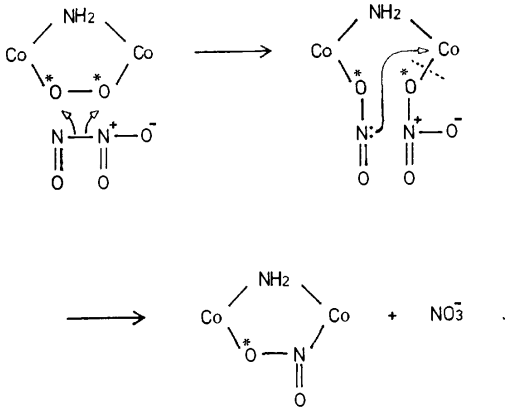
The IR spectra of two samples of $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4 \cdot 2H_2O$, one derived from ^{18}O-substituted $[(NH_2,O_2)\{Co(NH_3)_4\}_2](NO_3)_4$ and the other from the same complex with natural isotopic abundunce are shown in Fig. 2, and relevant frequencies are listed in Table 1. As the band in the normal $\mu(NH_2, NO_2)$ complex at 1180 cm^{-1} which is assigned to the vibration mainly consisting of the stretching of NO bond in the Co–N–O–Co chain shifts to 1170 cm^{-1} in the ^{18}O-labeled complex, the O atom in the Co–N–O–Co chain is concluded to have come from the O_2 bridge of the starting complex. On the other hand, the O atom attached to the N atom from outside the chain must have come from the nitrite ion since the band at 1492 cm^{-1} mainly attributable to the stretching of NO bond that makes the branch does not show appreciable shift.

The above results bear some resemblance to the case of nitrosation of aquapentaammine complex, and seems to be equally explained by assuming N_2O_3 as the

Table 1. IR frequencies of $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4 \cdot 2H_2O$ in cm^{-1}

	$\nu_{as}(NO_2)$	$\delta_s(NH_3)$		$\nu_s(NO_2)$		$\delta(NO_2)$	$\rho_r(NH_3)$
^{18}O-enriched	1493 s	1350 m	1304 m	1170 s	1138 w	853 m	843 sh
				1180 sh		879 sh	
Normal oxygen	1492 s	1351 m	1305 m	1180 s	1146 w	879 w	843 m

reacting species as[13]



The new situation here is that the reaction seems to occur more homolytically, and that the remaining nitrite group is oxidized to a nitrate ion.

Although the $\mu(NH_2,OH)$ complex which is formed by reduction of $\mu(NH_2,O_2)$ complex is also known to react with the nitrite to form the $\mu(NH_2,NO_2)$ complex, such a reaction is reported to be very slow[14] and bridge conversion $\mu O_2 \rightarrow \mu NO_2$ through this path may be excluded.

The IR spectra of the $[(NH_2,NO_2)\{Co(en)_2\}_2]Br_4 \cdot 5H_2O$ is somewhat more complicated, but the positions and intensities of peaks assignable to NO_2 stretching vibration (1492 and 1151 cm^{-1}) are very similar to those of the corresponding ammine complex and this IR feature again is explicable only on the assumption of a nitro bridge as shown by Gatehouse and by Nakamoto *et al.* for ammine complexes. One of the reasons which led Garbett and Gillard[15] to assume a *nitrito* bridge instead of a *nitro* bridge was the high resistivity to acids, but our ^{18}O-labeled μ-amido-μ-nitro-octaammine complex also showed high stability, retaining ^{18}O in the Co-N-O-Co chain even after two cycles of recrystallization from hydrochloric acid. The other reason on which they based their conclusion was the formation of hydroxo complex ions on base hydrolysis, but nitro complexes also are known to form hydroxo complexes on base hydrolysis.

Thus the general similarity of the behavior of the ammine and the corresponding ethylenediamine complex seems to be present also in the present case of the reaction of the $\mu(NH_2,O_2)$ complex to form the $\mu(NH_2, NO_2)$ complex.

The IR absorption band due to the bending mode of the coordinated nitro group and that due to the rocking mode of ammonia ligand appears in the region of 900—750 cm^{-1}, and when both are present it is difficult to discriminate them. On the basis of ^{18}O isotope shift, the absorption at 879 cm^{-1} could be assigned to $\delta(NO_2)$ for $[(NH_2,NO_2)\{Co(NH_3)_4\}_2]Cl_4 \cdot 2H_2O$.

Reaction in Neutral or Basic Solutions. Treatment of $[(NH_2,O_2)\{Co(NH_3)_4\}_2]X_3$ with an aqueous solution of ammonium nitrite followed by oxidation with ammonium persulfate gave green powder of composition, $Co_2O_2NH_2(NH_3)_4(NO_2)_4$ (I). The ammonium nitrite was replaceable by an equimolar mixture of sodium nitrite and ammonium salt, but not by sodium nitrite alone, in which case the mixture turned red showing decomposition.

The IR spectrum of the green product (Table 2) indicated the existence of nitro ligands as well as ammine ligands and a peroxo bridge,[9] but no peaks corresponding to a nitro bridge nor those corresponding to a free nitrite ion were observable (*cf.* the preceding section). The compound is thus considered to be $[(NH_2,O_2)\{Co(NH_3)_2(NO_2)_2\}_2]$ or $[(NH_2,O_2)\{CoNH_3(NO_2)_3\}\{Co(NH_3)_3NO_2\}]$, and is the first example of non-electrolytic μ-hyperoxo dicobalt complex.

Table 2. IR absorption frequencies of $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$ (I) and $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]X$ (II-X) in cm^{-1}

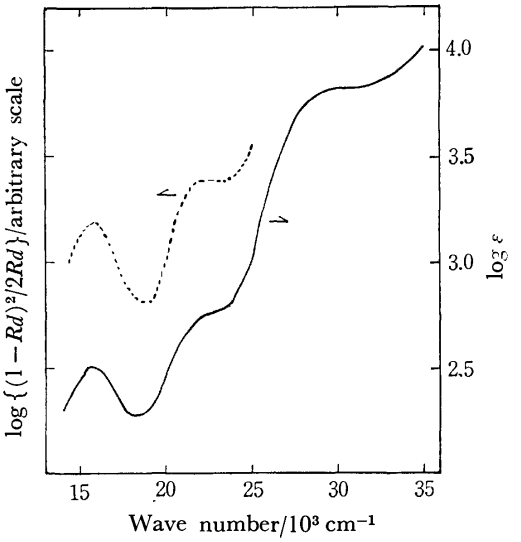

Fig. 3. Absorption spectrum of $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]ClO_4$ (in 0.5 M acetic acid, ——) and diffuse reflectance spectrum of $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$ (in K_2SO_4, ----).

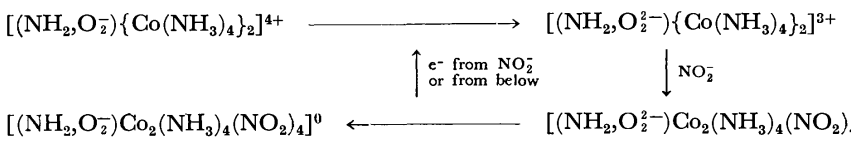
The presence of the amido bridge was inferred from the consideration of the composition, balance of charge, and the high stability of $\mu(NH_2,O_2)$ dicobalt moiety usually observed. The possibility of the formula $[(NH_2,O_2)\{Co(NO_2)_4\}\{Co(NH_3)_4\}]$ seems to be excluded from the consideration of the reaction with perchloric acid (*cf.* next section).

The electronic spectrum obtained from diffuse reflectance measurement (Fig. 3) showed peaks of comparable intensities at $15.8\times10^3\,cm^{-1}$ ($d\pi Co^{3+}$-$\pi^*(\mu O_2^-)$) and at $22.3\times10^3\,cm^{-1}$ ("$^1A_{1g}$-$^1T_{2g}$").[16] Such intensity relation is usually encountered when the ammine complex has a second bridge such as NH_2 in addition to the hyperoxo bridge; in single-bridged μ-hyperoxo dicobalt ammine complexes the band at *ca.* $15\times10^3\,cm^{-1}$ is distinctly more intense than that at *ca.* $20\times10^3\,cm^{-1}$.

Compound I can also be obtained in a somewhat lower yield by the treatment of μ-hyperoxo complexes such as $[(NH_2,O_2)\{Co(NH_3)_4\}_2]X_4$ or $[(NH_2,OH,O_2)\{Co(NH_3)_3\}_2]X_3$ with ammonium nitrite solution. In this case oxidizing agent is unnecessary: Probably the starting μ-hyperoxo complex itself acts as an oxidizing agent as represented by the following scheme;



That only the terminal ammine ligands are replaced by nitro ligand and the O_2 bridge remains unattacked in the reaction of $[(NH_2,O_2)\{Co(NH_3)_4\}_2]X_3$ with the nitrite in neutral solution is in the same line as the similar reaction of $[O_2\{CoNH_3(en)_2\}_2]X_4$ which gave $[O_2\{CoNO_2(en)_2\}_2]X_2$.[2] It indicates that the bridge conversion, $\mu O_2\rightarrow\mu NO_2$ does not proceed through the reaction of the peroxo bridge with the nitrite ion but with some other chemical species present only in acidic solutions of nitrites, such as N_2O_3 as suggested in the preceding section.

Reaction of $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$ with Perchloric Acid. It has not been successful to find a proper solvent of I which dissolves it without decomposition. Sixty-percent perchloric acid dissolves it with a loss of one nitrite group, the species in solution being $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]^+$ (II), which can be isolated as the perchlorate by treatment with ether.

The aqueous solution of II reacts with sodium nitrite to reproduce I with a capture of one nitrite group. These reactions are very peculiar and seem to deserve closer studies. The structure of II was inferred from the chemical analysis and IR spectra (Table 2) which showed peaks assignable to a hyperoxo bridge, a nitro bridge, terminal nitro ligands, and ammine ligands. The amido bridge is considered to be present because it is usually very resistant to acids, and also because II reproduces I on treatment with sodium nitrite. The formation of nitro bridge in 60% perchloric acid in the reaction I→II again proves the stability of the nitro bridge in acids.

The absorption spectrum of II-ClO_4 solution (Fig. 3) showed peaks at $15.8\times10^3\,cm^{-1}$ ($\varepsilon=320$) ($d\pi Co^{3+}$-$\pi^*(\mu O_2^-)$), $22.8\times10^3\,cm^{-1}$ ("$^1A_{1g}$-$^1T_{2g}$"), and $29.8\times10^3\,cm^{-1}$ (specific band of nitro ligand).

Magnetic Properties. The magnetic susceptibility measurements of I, II-$ClO_4\cdot0.5H_2O$, II-Cl, and II-Br proved the existence of one unpaired electron in each complex (Table 3).

The ESR spectrum of I in powder gave $g=2.035$, and that of II-ClO_4 in solution exhibited a symmetrical pattern at $g=2.027$ with well-resolved fifteen hyperfine lines ($A_{Co}=11.8$) such as is observed with many μ-amido-μ-hyperoxo dicobalt ammine complexes.[17]

Table 3. Magnetic susceptibilities of $[(NH_2,O_2)Co_2(NH_3)_4(NO_2)_4]$ (I) and $[(NH_2,NO_2,O_2)Co_2(NH_3)_4(NO_2)_2]X$ (II-X)

Complex	μ_{eff}[a]/B. M.
I	1.60 (24.5 °C)
II-Cl	1.88 (22.6 °C)
II-Br	1.83 (24.9 °C)
II-$ClO_4\cdot0.5H_2O$	1.91 (24.5 °C)

a) Corrected for diamagnetic susceptibilities of terminal ligand, anion, and crystal water.

The authors thank Mr. Kazuyoshi Kawashima for his able assistance with some of the experimental work. They are grateful also to Dr. Hanako Kobayashi (Univ. of Kyoto) for her kind guidance on the measurements of magnetic susceptibility, to Dr. Yôzô Miura for the ESR measurements, and to Mr. Junichi Gôda for the elemental analyses.

Structure of 5-Hydroxy-2-hydroxymethyl-4-pyridones

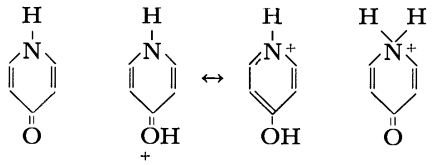
Kimiaki IMAFUKU,* Makoto ISHIZAKA,† and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received September 8, 1977)

5-Hydroxy-2-hydroxymethyl-4-pyridone and its *N*-methyl, *N*-ethyl, and *N*-phenyl derivatives were prepared from kojic acid. The UV spectra in neutral, acid, and alkaline solutions showed that the neutral species and the conjugate acids existed in the pyridone and the pyridine form, respectively. The conjugate bases may exist in both forms. The acid dissociation constants and the halochromism have been measured and discussed.

In the protonation of the 4-pyridone (A), structure (B) represents the *O*-protonated form and (C) the *N*-protonated form.



(A) (B) (B′) (C)

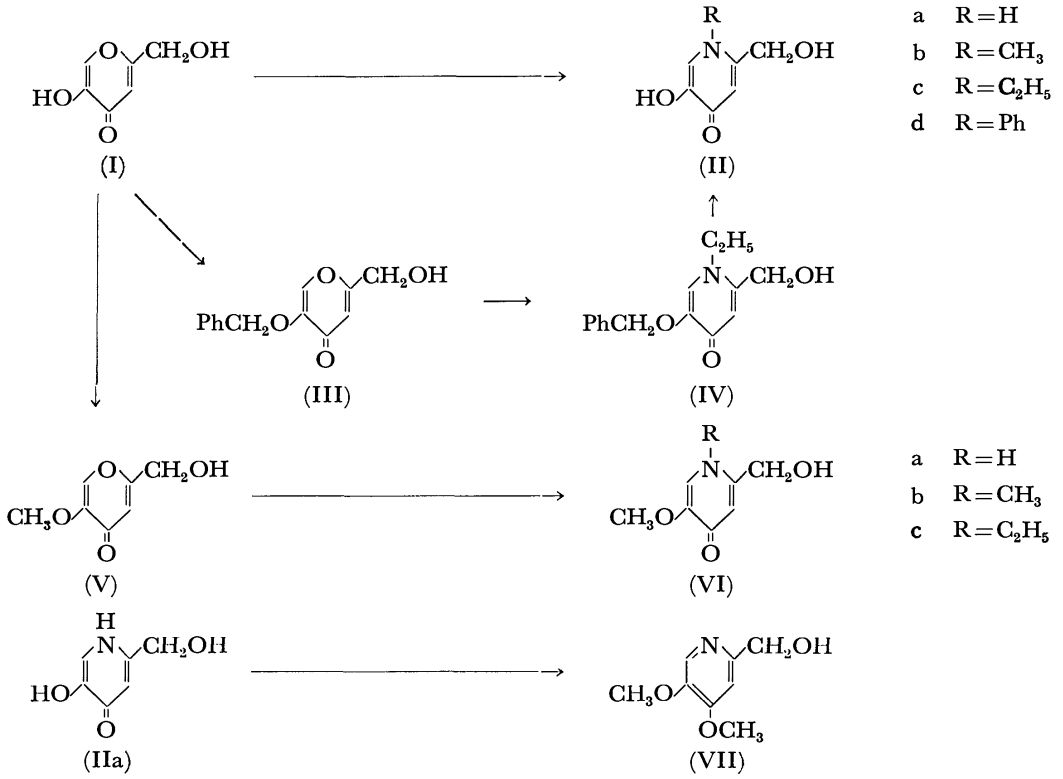
The theory of mesomerism predicts that the two cationic forms of B, B↔B′ should be greatly stabilized relative to type C, and their predominance has been assumed. The similarity among the ultraviolet spectra of the conjugate acids of 4-methoxypyridine, 1-methyl-4-pyridone, and 4-pyridone was taken to support such an assumption.[1] The NMR spectra also support the structure of type B↔B′.[2,3] However, the infrared and Raman spectra of these cations have been interpreted in favor of the structure of type C.[4,5]

The structure of 5-hydroxy-2-hydroxymethyl-4-pyridone in the acidic and alkaline solutions and the halochromism of its *N*-substituted derivatives are reported together with the acid dissociation constants.

Results and Discussion

Synthesis. 5-Hydroxy-2-hydroxymethyl-4-pyridone (IIa)[6] and its *N*-substituted derivatives (IIb[7] and IId) were obtained by the reaction of kojic acid (I) with the corresponding amines, while the *N*-ethyl-substituted compound (IIc) was prepared from I *via* 5-benzyloxy-2-hydroxymethyl-4-pyrone (III)[8] and 5-benzyloxy-1-ethyl-2-hydroxymethyl-4-pyridone (IV). 2-Hydroxymethyl-5-methoxy-4-pyridone (VIa)[9] and its *N*-substituted derivatives (VIb[9] and VIc) were obtained from kojic acid methyl ether (V)[9] by the reaction with the corresponding amines. The reaction of IIa with diazomethane gave 3,4-dimethoxy-6-hydroxymethylpyridine (VII) in 33% yield.

Acid Dissociation Constants. The acid dissociation constants of 5-hydroxy-2-hydroxymethyl-4-



(I) (II) (III) (IV) (V) (VI) (IIa) (VII)

Scheme 1.

† Present address: Fundodai Shoyu Co., Ltd., Hokubu-machi, Houtaku-gun, Kumamoto 861-55.

pyridones IIa—d were determined spectrophotometrically in water at 25 °C. The results are summarized in Table 1, where the pK_2 and pK_1 values represent the acid dissociation exponent (pK_a) of a neutral compound and that of its conjugate acid, respectively. The pK_1 values are comparable to the pK_a values for the conjugate acids of some 4-pyridones,[10,11] and the pK_2 values to the pK_a values for some 3-hydroxy-4-pyrones.[12] These values are increased by introduction of an electron donative substitutent on the nitrogen atom, but do not give a good Hammett relationship.

UV Spectra. The UV spectral data of the conjugate acids, neutral species, conjugate bases of 5-hydroxy-2-hydroxymethyl-4-pyridone (IIa) and its *N*-substituted derivatives (IIb—d) and 2-hydroxymethyl-5-methoxy-4-pyridone (VIa) and its *N*-substituted derivatives (VIb and VIc) are summarized in Tables 2 and 3, respectively. The spectra of 5-hydroxy-2-hydroxymethyl-4-pyridone (IIa), the *N*-methyl derivative (IIb) and 3,4-dimethoxy-6-hydroxymethyl-pyridone (VII) in water and M/10 hydrochloric acid are presented in Figs. 1 and 2 as examples. The spectra of 5-methoxy derivatives VIa and VIb are also presented together with the spectra of VII in Figs. 3 and 4.

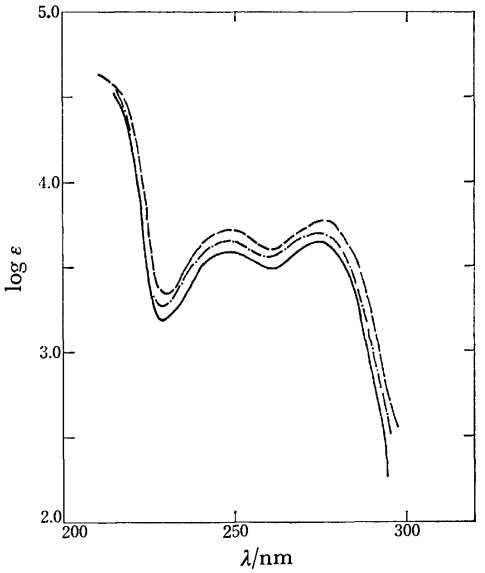

Fig. 4. The UV spectra of the cationic species.
——: VIa, —·—: VIb, ----: VII.

It may be seen from Figs. 1 and 3 that the spectra of the neutral species of IIa and VIa are similar to those of IIb and VIb, but are different from the spectrum of VII, indicating that the 4-pyridones exist predominantly in the NH-form.

As Figs. 2 and 4 illustrate, the spectra of the conjugate acids of 5-hydroxy-4-pyridones IIa and IIb and 5-methoxy-4-pyridones VIa and VIb are very similar to the spectrum of the conjugate acid of VII. This shows that the protonation of the 4-pyridones occurs at the oxygen atom at the 4-position in agreement with Katritzky and Lagowski's results.[1]

The NMR spectral data were also examined. In deuterium oxide, the positions of the peaks of the α- and β-protons of VIa (7.61 and 6.52 ppm) are considerably different from those of VII (7.93 and 7.00 ppm), while in 20% sulfuric acid those of VIa (8.72 and 7.30 ppm) are close to those of VII (8.31 and 7.57 ppm). This indicates the *O*-protonation to be in agreement with the results of Katritzky *et al.*[2,3]

The UV spectra of the conjugate bases of the 4-pyridones IIa and IIb are shown in Fig. 5 together with that of the neutral species of VII. As shown in Fig. 5 and Table 2, the maximum absorption band of IIa is shifted to a shorter wavelength from those of the *N*-substituted 4-pyridones. The spectral pattern is also different from those of the *N*-substituted derivatives, in that a broad shoulder exists at 270—280 nm.

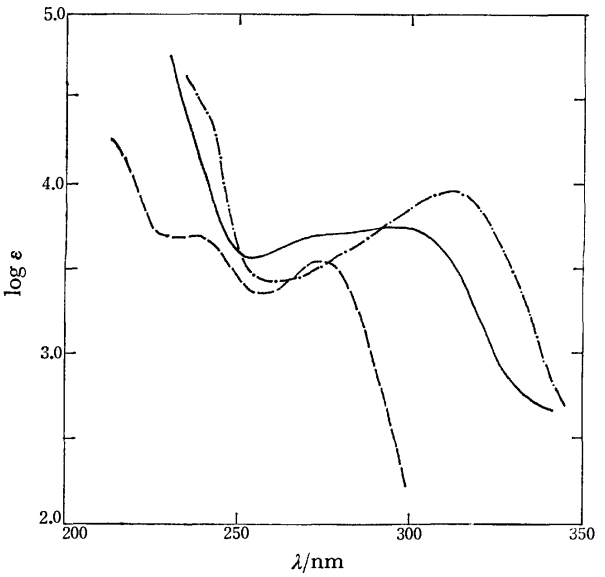

Fig. 5. The UV spectra of the anionic species.
——: IIa, —·—: IIb, ----: VII (neutral).

This shoulder closely corresponds to the maximum absorption band of the pyridine derivative VII. Thus, IIa might exist not only in the pyridone form but also in the pyridine form.

Halochromism. Rapoport *et al.*[13] measured the absorption spectra of 4-substituted 2-nitrophenols in neutral and alkaline solutions, and showed that the difference in wave number between the maxima of the longest-wavelength absorption bands in the two solutions is quantitatively related to the dissociation constant. The wave number shift is also proportional to the Hammett substituent constant. This phenomenon of halochromism is well documented and the degree of halochromism of a compound may be defined as the wave number difference ($\Delta\bar{\nu}$) between the longest-wavelength band of the neutral species and that of its conjugate acid or base.

The $\Delta\bar{\nu}$ values (Table 2) of the 4-pyridones plotted against the pK_a ($\equiv$pK_2) values, produces a straight line as shown in Fig. 6, giving the following equation by the least-square method.

$$\Delta\bar{\nu} = -583\mathrm{p}K_a - 2311 \quad (r=1.000,\ s=1)$$

The slope was comparable to that reported for the phenols.[13]

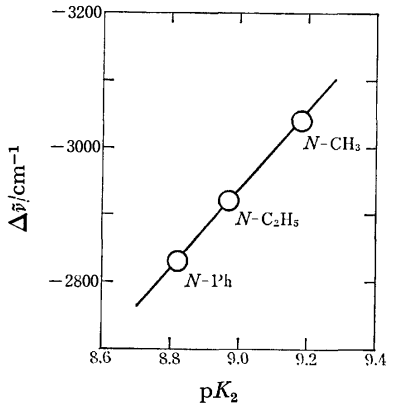

Fig. 6. The relationship between $\Delta\bar{\nu}$ and pK_2.

Experimental

All the melting points were measured on a Yanagimoto micro-melting point apparatus and are uncorrected. The IR and NMR spectra were taken on JASCO IRA-1 spectrophotometer and a Hitachi-Perkin-Elmer R-24 (60 MHz) spectrometer, respectively. The UV spectra were recorded on a Hitachi EPS-2U and EPS-3T spectrophotometer. The pH values were measured by a Hitachi-Horiba F-5 pH meter. The pK_a determination was conducted according to Albert-Serjeant's method.[14]

Materials. All the known compounds were prepared according to the methods described in the references: IIa, mp 232—234 °C (lit,[6] 237—238 °C); IIb, mp 220 °C (lit,[7] 225—227 °C); III, mp 132 °C (lit,[8] 133 °C); V, mp 165—166 °C (lit,[9] 165 °C); VIa, mp 170 °C (lit,[9] 173—175 °C); VIb, mp 203—205 °C (lit,[9] 203—204 °C).

5-Benzyloxy-1-ethyl-2-hydroxymethyl-4-pyridone (IV). A mixture of 5-benzyloxy-2-hydroxymethyl-4-pyrone (III)[8] (2 g) and 70% ethylamine solution (4 ml) was heated in a sealed tube at 130 °C for 5 h. The excess amine was evaporated off and the residue recrystallized from methanol to afford IV (1.8 g, 80.6%) as colorless needles, mp 183 °C. Found: C, 69.25; H, 6.87; N, 5.32%. Calcd for $C_{15}H_{11}NO_3$: C, 69.48; H, 6.61; N, 5.40%. IR (KBr): 1620 cm^{-1}. UV (MeOH) λ_{max}/nm (log ε): 225 (4.35), 286 (4.16).

1-Ethyl-5-hydroxy-2-hydroxymethyl-4-pyridone (IIc). A mixture of 5-benzyloxy-1-ethyl-2-hydroxymethyl-4-pyridone (IV) (2 g) and 5% palladium carbon (0.8 g) in methanol (20 ml) was stirred for 2 h at room temperature under a hydrogen atmosphere. After removal of the catalyst the solvent was evaporated off and the residue recrystallized from ethanol to afford IIc (0.9 g, 69.0%) as colorless needles, mp 187 °C. Found: C, 56.68; H, 6.67; N, 8.18%. Calcd for $C_8H_{11}NO_3$: C, 56.79; H, 6.55; N, 8.28%. IR (KBr): 1640 cm^{-1}. UV (MeOH) λ_{max}/nm (log ε): 226 (4.22), 290 (4.10).

5-Hydroxy-2-hydroxymethyl-1-phenyl-4-pyridone (IId). A mixture of kojic acid (I) (1.5 g) and aniline (2 ml) in water (5 ml) was heated on a water-bath in the presence of 12 M hydrochloric acid (0.7 ml) in a sealed tube for 3 h. Water was added to the reaction mixture, which gave a red-brown precipitate. This precipitate was recrystallized from methanol to afford IId (0.85 g, 37.1%) as colorless needles, mp 238 °C. Found: C, 66.00; H, 5.33; N, 6.44%. Calcd for $C_{12}H_{11}NO_3$: C, 66.35; H, 5.10; N, 6.45%. IR (KBr): 1645 cm^{-1}. UV (MeOH) λ_{max}/nm (log ε): 292 (4.24).

1-Ethyl-2-hydroxymethyl-5-methoxy-4-pyridone (VIc). 2-Hydroxymethyl-5-methoxy-4-pyrone (V)[9] (1.5 g) was heated with 70% ethylamine solution (3 ml) in a sealed tube at 140 °C for 4 h. After evaporation of the excess amine and water, the residue was recrystallized from methanol to give VIc (1.6 g, 90.9%) as colorless needles, mp 177 °C. Found: C, 58.93; H, 7.22; N, 7.81%. Calcd for $C_9H_{13}NO_3$: C, 59.00; H, 7.15; N, 7.65%. IR (KBr): 1635 cm^{-1}. UV (MeOH) λ_{max}/nm (log ε): 224 (4.21), 287 (4.13).

3,4-Dimethoxy-6-hydroxymethylpyridine (VII). An excess of diazomethane in ether was added to a solution of 5-hydroxy-2-hydroxymethyl-4-pyridone (IIa) (1 g) in methanol (600 ml), and the mixture allowed to stand in a refrigerator until the purple color with iron(III) chloride disappeared. After evaporation of the solvents, the residue was recrystallized from ethanol and sublimed to afford VII (0.4 g, 33%) as colorless needles, mp 121—122 °C. Found: C, 56.61; H, 6.55; N, 8.20%. Calcd for $C_8H_{11}NO_3$: C, 56.79; H, 6.55; N, 8.28%. IR (KBr): 1595 cm^{-1}. UV (MeOH) λ_{max}/nm (log ε): 234 (3.77), 274 (3.44). NMR ($CDCl_3$): 3.90 (s, 6H), 4.66 (s, 2H), 6.91 (1H), 7.97 (s, 1H).

We wish to thank Professor Satoru Yokota of Kumamoto Institute of Technology for the supply of kojic acid.

Substituent Effects on 6-Substituted 3-Hydroxy-1-methyl-4-pyridones

Kimiaki IMAFUKU,* Kumio TAKAHASHI,† and Hisashi MATSUMURA

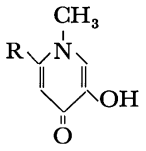
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received September 10, 1977)

Acid dissociation constants and UV and NMR spectra of a series of 6-substituted 3-hydroxy-1-methyl-4-pyridones have been measured. The acid dissociation constants have been analyzed in terms of the Hammett equation to give linear relationships, with $\rho=1.16$ for the conjugate acids and $\rho=1.06$ for the neutral compounds. Halochromism in the UV spectra gave the equation: $\Delta\bar{\nu}=689\,pK_a-9399$, and the Hammett plots of the chemical shifts of the 2-H, 5-H, and CH_3 protons gave linear relationships, with $\rho=1.78$, 2.56, and 1.39, respectively.

In 1967 Choux and Benoit[1] reported the substituent effects on the physical properties such as the acid dissociation constants and UV and NMR spectra of 4-pyrone derivatives. However, little is known about the 4-pyridone derivatives. The substituent effect on tautomerism of 6-substituted 3-methoxy-4-pyridones has been examined and it has been reported that the tautomeric ratios are affected by the substituents.[2]

In this paper the substituent effects on the acid dissociation constants and UV and NMR spectra of 6-substituted 3-hydroxyl-1-methyl-4-pyridones will be reported in which tautomerism does not exist.



Results and Discussion

Acid Dissociation Constants. The acid dissociation constants of five 6-substituted 3-hydroxy-1-methyl-4-pyridones have been determined spectrophotometrically in water at 25 °C. The results are summarized in Table 1, where the pK_2 and pK_1 values represent the acid dissociation exponent (pK_a) of a neutral compound and that of its conjugate acid, respectively. The pK_1 values are comparable to the pK_1 values for 4-pyridone (3.37)[3] and *N*-methyl-4-pyridone (3.33).[4] The pK_2 values are slightly larger than the pK_2 values for the 3-hydroxy-4-pyrones,[1] *i.e.* the 3-hydroxy-1-methyl-4-pyridones are less acidic than the 3-hydroxy-4-pyrones.

A correlarion between pK_2 and the Hammett σ_p constants[5] has been established for the 6-substituted 3-hydroxyl-1-methyl-4-pyridones, as shown in Fig. 1,

Table 1. pK_a values

No.[a]	R	σ	pK_1	pK_2
1	CH_3	−0.170	3.43	9.29
2	H	0	3.07	9.15
3	CH_2OH	0.08[b]	3.07	9.07
4	COO^-	0.132		9.03
5	CH_2Cl	0.184	3.02	8·88

a) Numbers correspond to those in Fig. 1. b) Ref. 1.

† Present address: Prefectural Office of Hiroshima, Hiroshima 730.

and gives the following equation by the least-squares method:

$$pK_2 = 9.13 - 1.06\sigma \qquad (r=0.969,\ s=0.03)$$

The reaction constant ($\rho=1.06$) is apparently smaller than that for the proton loss of 6-substituted 3-methoxy-4-pyridones ($\rho=4.94$).[2] In the latter case tautomerism produces the 4-pyridinols but since tautomerism does not exist in the former, transmission of the substituent effect is decreased.

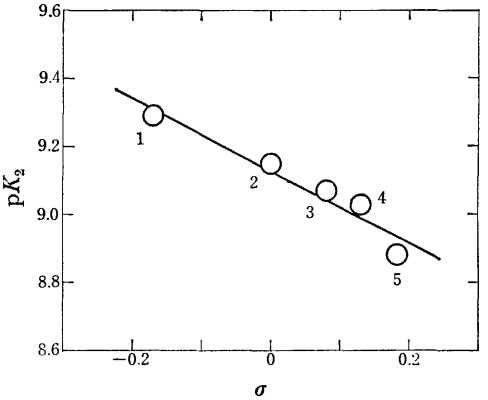


Fig. 1. The Hammett plot of pK_2 values.

The Hammett plots of the pK_1 values gave the equation:

$$pK_1 = 3.17 - 1.16\sigma \qquad (r=0.860,\ s=0.06)$$

Although the correlation is not good, the transmission of the substituent effect is enhanced by the existence of a conjugated double bond, but is considerably smaller than that in the 3-methoxy-4-pyridones ($\rho=3.01$).[2]

Halochromism in UV Spectra. The UV spectra of the 6-substituted 3-hydroxy-1-methyl-4-pyridones have been measured in neutral and alkaline solutions. The wavelengths and wave numbers are listed in Table 2 as λ_{HA} and $\bar{\nu}_{HA}$ for the neutral species and λ_{A^-} and $\bar{\nu}_{A^-}$ for the conjugate bases, respectively. The $\Delta\bar{\nu}$ values are the differences between the $\bar{\nu}_{A^-}$ and $\bar{\nu}_{HA}$ values.

A general relationship between the electronic spectra and dissociation constants has been established for 4-substituted 2-nitrophenols.[6] Plots of the $\Delta\bar{\nu}$ values against pK_a ($\equiv pK_2$) values give a linear relationship as shown in Fig. 2, which is represented by the following equation.

$$\Delta\bar{\nu} = 689\,pK_a - 9399 \qquad (r=0.959,\ s=31)$$

TABLE 2. UV SPECTRAL DATA

No.[a]	R	Neutral species			Conjugate base			$\Delta\bar{\nu}$
		λ_{HA} nm	$\bar{\nu}_{HA}$ cm^{-1}	$\log \varepsilon_{HA}$	λ_{A^-} nm	$\bar{\nu}_{A^-}$ cm^{-1}	$\log \varepsilon_{A^-}$	cm^{-1}
1	CH_3	278	35970	4.08	304	32890	3.96	−3080

4	COO^-	284	35210	4.04	312	32050	3.90	−3160
5	CH_2Cl	283	35340	4.00	312	32050	3.89	−3290

a) Numbers correspond to those in Fig. 2.

TABLE 3. NMR SPECTRAL DATA

No.[a]	R	δ			
		2-H	5-H	1-CH_3	Others
1	CH_3	7.43 (s)	6.40 (s)	3.61 (s)	2.30 (s) for 6-CH_3
2	H	7.59 (d)[b]	6.58 (d)[c]	3.82 (s)	7.58 (dd)[d] for 6-H
3	CH_2OH	7.71 (s)	6.80 (s)	3.89 (s)	e)
4	COOH	7.88 (s)	7.13 (s)	3.98 (s)	
5	CH_2Cl	8.11 (s)	7.31 (s)	4.14 (s)	e)

a) Numbers correspond to those in Fig. 3. b) $J_{2,6}=3$ Hz. c) $J_{5,6}=7$ Hz. d) $J_{6,2}=3$ Hz and $J_{6,5}=7$ Hz. e) The δ values for 6-C**H**$_2$OH and 6-C**H**$_2$Cl could not be measured accurately because of overlapping with the signal of HOD.

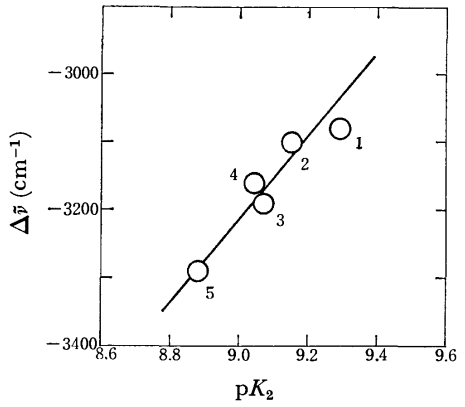

Fig. 2. The relationship between $\Delta\bar{\nu}$ and pK_2.

NMR Spectra. The ^{1}H-NMR spectral data in deuterium oxide are listed in Table 3. The chemical shifts of 3-OH could not be determined becasue of hydrogen exchange with deuterium in the solvent. The chemical shifts of 2-H, 5-H, and 1-CH_3 have been plotted against the respective σ_p constants (Fig. 3). The plots have yielded the following equations.

$$\delta_{2\text{-H}} = 1.78\sigma + 7.66 \quad (r=0.937,\ s=0.05)$$
$$\delta_{5\text{-H}} = 2.56\sigma + 6.73 \quad (r=0.939,\ s=0.11)$$
$$\delta_{CH_3} = 1.39\sigma + 3.83 \quad (r=0.977,\ s=0.03)$$

From this data the substituents have a stronger effect on the chemical shifts of the 5-H proton than on that of the 2-H proton. The chemical shifts of the 1-CH_3 are less sensitive to the substituent effects than those of the 2-H and 5-H protons. Transmission of the substituent effects was apparently larger than for the 4-pyrones.[1]

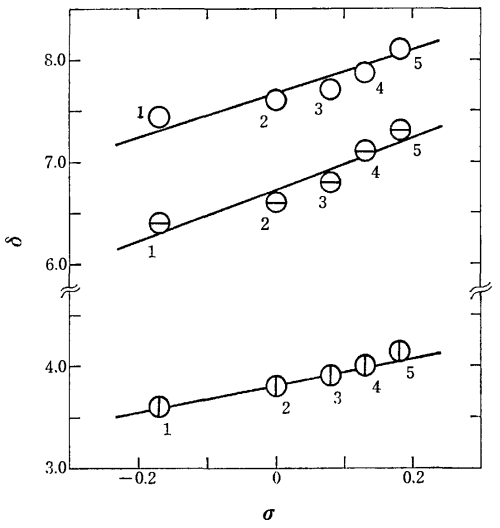

Fig. 3. The relationships of the chemical shifts with σ constants. ○: $\delta_{2\text{-H}}$, ⊖: $\delta_{5\text{-H}}$, ⏀: δ_{CH_3}.

Experimental

All the melting points were measured on a Yanagimoto micro-melting point apparatus and are uncorrected. The IR, UV, and NMR spectra were taken on JASCO IRA-1, Hitachi EPS-3T, and Hitachi-Perkin-Elmer R-24 (60 MHz) spectrometers, respectively. The pH values were measured by a Hitachi-Horiba F-5 pH meter. The pK_a values were obtained by the method of Albert and Serjeant.[7]

Materials. All the known compounds were prepared from kojic acid according to the methods in the literature: 3-hydroxy-1-methyl-4-pyridone, mp 215—217 °C (lit,[8] 212—216 °C); 1,2-dimethyl-5-hydroxy-4-pyridone, mp 270—274 °C (lit,[9] 273—274 °C); 5-hydroxy-2-hydroxymethyl-1-methyl-4-

pyridone, mp 220 °C (lit,[8] 225—227 °C).

2-Chloromethyl-5-hydroxy-1-methyl-4-pyridone was obtained by the treatment of 5-hydroxy-2-hydroxymethxl-1-methyl-4-pyridone[8] (1.0 g) with thionyl chloride (4.0 ml) at 60—70 °C for 30 min. Yield, 0.38 g (34.0%); mp 220—230 °C (from methanol-ethyl acetate); IR (KBr): 1628 cm^{-1}. Found: C, 48.36; H, 4.87; N, 8.06%. Calcd for $C_7H_8ClNO_2$: C, 48.43; H, 4.64; N, 8.07%.

2-Carboxy-5-hydroxy-1-methyl-4-pyridone was obtained by reaction of comenic acid (1.1 g) with 48% methylamine solution (2.5 g) at 60—80 °C for 4 h. Yield, 0.28 g (23.5%); mp 224—230 °C (dec) (from water); IR (KBr): 1630, 1607 cm^{-1}. Found: C, 49.68; H, 4.37; N, 8.27%. Calcd for $C_7H_7NO_4$: C, 49.71; H, 4.17; N, 8.28%.

The authors are grateful to Professor Satoru Yokota of Kumamoto Institute of Technology for the supply of kojic acid.

(Received April 7, 1978)

Volatile and odorous components were isolated from anaerobically or aerobically digested liquid swine manure by direct solvent-extraction and flash-distillation under reduced pressure. The concentrations of indole, oxindole, dimethylsulfoxide, phenol, and a few carboxylic acids increased, and *o*-aminoacetophenone decreased during digestion. Alkaline components were not so important for the odor. Offensive odor was formed by mixing phenols and carboxylic acids. Complete aeration resulted in a remarkable decrease of lower carboxylic acids.

Research on malodor has attracted only few researchers in contrast to studies concerned with flavor and perfume, and therefore, it is retarded. In Japan a piggery is one of the most malodor-evolving sources. Measurements have been carried out for ammonia, trimethylamine, hydrogen sulfide, methyl mercaptan, dimethyl sulfide, *etc.* which are controlled by the Japanese law on malodor, but there are only a few studies that have investigated other compounds or have considered the nature of the malodor. In research on malodor, it is very important and difficult to isolate odorous substances from samples effectively. Broadly speaking, there are three malodor-evolving sources in a piggery, that is, pig itself, solid manure, and liquid manure. A series of past studies have been concerned with liquid manure which had accumulated, rotted, and evolved a strong malodor.[1,2]

Carboxylic acids and many other compounds have already been detected in liquid swine manure by steam distillation.[1,2] It may be true that some substances decompose thermally during steam distillation, although it is a very useful method to separate volatile compounds from nonvolatiles. In this study direct solvent-extraction and flash-distillation under reduced pressure were used for isolation of odorous compounds in order to avoid thermal decomposition.

This paper deals with the isolation and the identification of odorous compounds having a medium or high boiling point in liquid swine manure and with the change of these odorous compounds under anaerobic or aerobic digestion.

Experimental

Material and Procedure. Liquid swine manure was collcted from a drain under pigsties near Takezono, Tsukuba New Town, Ibaraki Prefecture, at an inlet of a pit.

Two experiments were carried out. In the first experiment the air-flow rate was adjusted so that liquid manure was not digested completely in order that information on intermediate changes of some components due to chemical or microbial action was obtained. An aim of the second experiment was to obtain information on the relative ratio of typical odorous components between anaerobic digestion and completely aerobic digestion. The latter experimental conditions were similar to situation of odor control for liquid manure in pigsty.

In the first experiment the liquid swine manure was divided into three parts. One part (2.5 l) was shaken with dichloromethane (400 ml) for 15 min and the lower slurry containing the organic layer was separated. The other two parts (each 2.5 l) were digested at 35 °C for a week under bubbling of nitrogen (100 ml/min) or air (100 ml/min) respectively. Then the respective digested liquid manure was shaken with dichloromethane (400 ml) for 15 min, and the lower slurry was separated. Each slurry was centrifuged at 10000 rpm for 10 min and the organic layer was separated. The extract was fractionated into three fractions as described in Fig. 1.

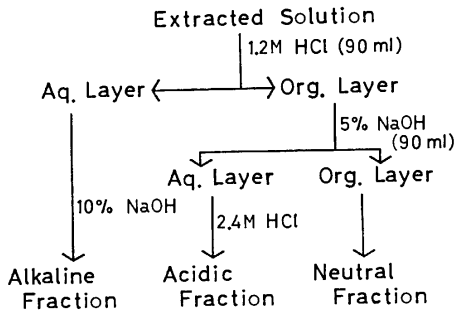

Fig. 1. Fractionation of liquid swine manure extract.

In the second experiment the liquid swine manure was divided into two parts. One part (50 l) was kept in glass bottles and digested at 20—25 °C for a week. The liquid manure became dark green and the surface was covered with a black formy film after a day, so the manure corresponded to anaerobic digestion. In the case of anaerobic digestion an inert gas such as nitrogen was not passed, when the experimental conditions approached the same situation where piggery liquid manure was stored in an anaerobic situation. The other part (each time 2 l, total 18 l) was aerobically digested by bubbling air at a rate of 2 l/min in a glass vesel at 20—25 °C for a week and then, malodor became very weak. Both parts of the rotten swine manure were flash-distilled under reduced pressure by means of the apparatus shown in Fig. 2. The receiver was chilled with ice, the two traps were cooled with Dry Ice and methanol to condense water vapor and volatiles completely, and the third trap chilled with liquid nitrogen was used

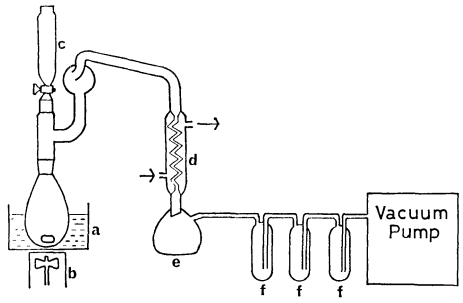

Fig. 2. Apparatus for flash-distillation under reduced prssure.

to prevent contamination from oil of the vacuum pump. The distillate was extracted continuously for 24 h with ethyl ether after saturation with sodium chloride. The extract was fractionated into three fractions as shown in Fig. 1.

Each fraction in both experiments was evaporated, after drying with anhydrous sodium sulfate, by means of a Kvrderna-Danish concentrator under atmospheric pressure.

Gas Chromatography. A Shimadzu Model GC-5A gas chromatograph was used. The flame detectors were operated using a hydrogen-flow rate of 50 ml/min and an air-flow rate of 0.5 l/min. Thermoconductivity detectors were used for the organoleptic tests. For the acidic fraction the gas-chromatographic conditions were as follows: injector and detector temperatures, 250 °C; column, 3 m×3 mm i.d. glass column packed with 2% DEGS+0.5% H_3PO_4 on 60- to 80-mesh, acid-washed, DMCS-treated Chromosorb W; column temperatures, 50 to 190 °C by an increase at a rate of 8 °C/min; carrier-gas (nitrogen) flow rate, 30 ml/min at 5 kg/cm^2. For alkaline and neutral fractions the gas-chromatographic conditions were as follows: injector and detector temperatures, 300 °C; column, 3 m×3 mm i.d. glass column packed with 2% OV-17 on 60- to 80-mesh, acid-washed, DMCS-treated Chromosorb W; column temperatures, 100 to 250 °C with temperature increase of 10 °C/min; carrier-gas (nitrogen) flow rate, 30 ml/min at 5 kg/cm^2.

Organoleptic Test for Odor. This test was carried out by means of smelling the odor of compounds progressively eluted from the outlet of the gas chromatograph.

Mass Spectrometry. A JEOL Model JMS-D 100 mass spectrometer was connected with a JEOL JGC-20 K gas chromatograph and a JEOL JMA-2000 mass data analysis system. The gas-chromatographic conditions were the same as above except for the size of the column. The size of the column was 3 m×2 mm i.d. The mass-spectrometric conditions were as follows: ion-source temperature, 140 °C; ion-source pressure, 1.2×10^{-6} Torr; ionizing corrent, 3×10^{-4} A; ionizing energy, 75 eV; accelerating voltage, 3 kV; mass range, *m/e* 10 to 450; scan time, 2.7 s; scan interval, 5 s. The mass data analysis procedures were subtraction of the background mass spectra, normalization by the most intense peak, and a search of mass spectra catalogue.

Results and Discussion

Digested liquid swine manure gave a pH of 8—9 regardless of anaerobic or aerobic digestion. The odors from digested liquid manure under anaerobic and aerobic conditions were very different each other. Though sulfur-containing compounds would be assumed to contribute to the difference of odor, studies on sulfur-containing components are in progress and the results will be reported at a later date. Many odorous compounds were isolated and identified from anaerobically stored piggery liquid manure by steam distillation,[1,2] but the odor of the steam-distillate has been different from the original odor. The reason for this is that some compounds are thought to decompose during steam distillation. A direct extraction has the benefit of minimizing those losses and decomposition and to keep the content ratio of many components identical to the original manure. Centrifuging above 5000 rpm was very effective for separating the organic layer of the slurry formed by shaking liquid manure with dichloromethane. The odor of the organic layer resembled that of the original manure. Typical gas chromatograms of fractions in the first experiment are shown in Fig. 3 to Fig. 5. The identification of each peak in the gas chromatogram was carried out by gas chromatography-mass spectrometry and the quantification was done by gas chromatography. The results of identification and quantification of the components related to the odor are shown in Table 1. In performing fractionation, removal of the alkaline fraction did not change the odor of the extracted solution, but removal of the neutral or acidic fraction, particularly the latter fraction, greatly altered the odor. The organoleptic test showed that the alkaline fraction did not contribute so much to the odor of swine liquid manure. Of course, ammonia and trimethylamine play an important role on the malodor,[3] but they cannot be detected by the method used in this study.

Indole and di-2-ethylhexyl phthalate decomposed easily, and skatole decomposed slowly under aerobic conditions. Indole concentration increased but for skatole the concentration hardly changed under anaerobic conditions. The results show that indole was formed from protein or its decomposed products under

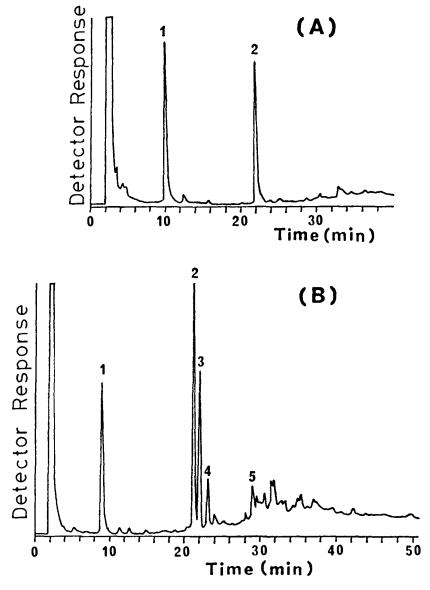

Fig. 3. Gas chromatograms of alkaline fractions.

anaerobic conditions and agreed with the results reported by Spoelstra.[4] Oxindole may be supposed to be formed from indole by microbial action. Dimethylsulfide may also be supposed to change to dimethylsulfoxide. Indole, skatole, and dimethylsulfoxide were malodorous among neutral components.

In alkaline fraction, aniline, methylquinazoline, dimethyl- or ethylquinazoline, isatin, and *o*-aminoacetophenone were detected. Quinazoline derivatives and isatin were assumed to be formed during aerobic digestion. *o*-Aminoacetophenone which existed in relatively large quantities at first decreased in the same way for both digestion conditions. The odor qualities of aniline, quinazoline derivatives, and *o*-aminoacetophenone were significantly less than the odor qualities of other components.

It has been reported that concentrations of phenol, *p*-cresol, and *p*-ethylphenol have increased in anaerobically stored piggery wastes.[4] The change of phenol in this study was identical with the above result. Acetic acid, isobutyric acid, and butyric acid were not detected in raw manure, but they were found at almost the same concentrations in both anaerobically and aerobically digested manure. In this experiment there was little difference in contents of carboxylic acids among raw, anaerobically digested, and aerobically digested

Table 1. Identification and quantification of volatile and odorous components[a]

Peak No.	Compound	Raw wt/l	Anaerobic wt/l	Aerobic wt/l
1	Aniline	8.2 μg	16 μg	15 μg
2	*o*-Aminoacetophenone	294 μg	20 μg	30 μg

21	Indole	0.87 mg	1.63 mg	trace
22	Skatole	2.05 mg	1.89 mg	1.46 mg
23	Di-2-ethylhexyl phthalate	0.24 mg	0.14 mg	0.06 mg

a) These values are not corrected with extraction coefficients.

manures. McGill and Jackson[5] reported the content ratio of carboxylic acids in pig slurry filtrates that showed acetic acid as a major component (65.5%). This experiment gave different results, but an exact comparison was not possible since the above study[5] did not report quantitative values, but relative values. In this experiment the acidic fraction did not have an irritating odor such as acetic acid and propionic acid, but had a sweaty and putrid odor. This odor was a little different from the odor of each carboxylic acid such as butyric or isovaleric acid and phenol. The organoleptic test showed that C_4—C_6 carboxylic acids and phenylacetic acid were malodorous and that phenols had a characteristic odor. However, an offensive odor was strengthened by mixing carboxylic acids and phenols and phenols added an adhensive nature to the total odor.

Strong aeration used in the second experiment is one of the most useful methods for deodorization. Strong malodor from liquid manure almost disappeared and the odor attributed to skatole remained when air was passed at a rate of 2 l/min for a week. A complete digestion under anaerobic conditions needs more than two months.[4] Gas-chromatographic analysis is facilitated by removing nonvolatile substances from sample. Therefore, a distillation method is very convenient, but steam distillation is not so good for this purpose. Distillation under reduced pressure, although it would be expected to be a useful method, was unsuccessful because of the violent frothing of the sample. In such a case flash-distillation under reduced pressure is very valuable and it was used successfully in this experiment. This method is suitable for isolating relatively volatile compounds, although it is time consuming. Continuous extraction with ethyl ether was used in order to avoid an accumulation of impurities from the large volume of solvent.

The gas chromatograms of each fraction were essentially identical. Each peak in the gas chromatograms was assigned by gas chromatography-mass spectrometry. The quantifications of fractions were carried out by gas chromatography and their results are shown in Table 2. The quantities of alkaline components did not change so much. The odor of anaerobically stored manure was attributed to the acidic components. The odor of indole and skatole from the anaerobically stored manure was felt a little, but it was fairly strong from aerobically digested manure. The aerobically digested manure did not exhibit the odor of phenols and carboxylic acids. This fact is compatible with the result of quantification. In particular, the concentrations of lower carboxylic acids decreased or were not detected after aeration. As the concentration of the valeric acid did not decrease significantly by bubbling nitrogen gas into the aqueous solution of the acid, its disappearance during aeration would be presumed to be caused by microbial action. The function of phenols with regard to odor diminished with decreasing carboxylic acids. As indole and skatole did not decrease so much and their threshold values for odor were very low, the odor of aerobically digested manure was dominated by them.

Table 2. Quantification of odorous components in anaerobically and aerobically digested liquid swine manure[a]

Compound	Anaerobic wt/l	Aerobic wt/l
Aniline	76 μg	41 μg
o-Aminoacetophenone	248 μg	129 μg
Methylquinazoline	46 μg	29 μg
Dimethyl- or ethylquinazoline	44 μg	18 μg
Phenol	3.6 mg	0.79 mg
p-Cresol	29.2 mg	0.85 mg
p-Ethylphenol	3.8 mg	0.55 mg
Isovaleric acid	60 μg	—
Valeric acid	44 μg	—
2-Methylbutyric acid	12 μg	4 μg
4-Methylpentanoic acid	54 μg	—
Hexanoic acid	166 μg	6 μg
2-Methylpentanoic acid	18 μg	3 μg
4-Methylhexanoic acid	92 μg	9 μg
Heptanoic acid	166 μg	18 μg
Octanoic acid	166 μg	37 μg

a) These values are not corrected with recovery coefficients.

The authors wish to thank Mr. Minoru Kuriyama, a hog raiser near Tsukuba New Town, Ibaraki Prefecture, for his offer of liquid swine manure.

(Received May 8, 1978)

DL-Validamine and its amino deoxy and deoxy analogs were synthesized as the acetyl derivatives from *endo*-7-oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid, the Diels-Alder adduct of acrylic acid and furan.

In a previous paper[2] a report was given on the first synthesis of penta-*N,O*-acetyl-DL-validamine starting from the Diels-Alder adduct of furan with acrylic acid, *endo*-7-oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid (**1**).[3] Acetolysis of tri-*O*-acetyl-2,3-dihydroxy-6-hydroxymethyl-7-oxabicyclo[2.2.1]heptane gave a poor yield of the desired intermediate, penta-*O*-acetyl-(1,3,5/2,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (pseudo-β-D-glucopyranose),[4] since anhydro ring formation occurs simultaneously to give a dioxatricyclo compound.[5] Thus, bromination of the substituted 2-hydroxymethyl-7-oxabicyclo[2.2.1]heptane with hydrogen bromide in acetic acid has been studied in order not only to open the 1,4-anhydro ring, but also to introduce a bromine substituent into the cyclohexane ring, which can be replaced by an amino function. In the present paper, we report on the alternative synthesis of acetyl derivatives of DL-validamine and its several analogs starting from the substituted bromohydroxymethylcyclohexanes derived from **1**.

Hydrogenation of **1** with palladium black gave *endo*-7-oxabicyclo[2.2.1]heptane-2-carboxylic acid (**2**)[3] in high yield. This was reduced by lithium aluminum hydride (LAH) in tetrahydrofuran (THF) followed by acetylation with acetic anhydride in pyridine to give *endo*-2-acetoxymethyl-7-oxabicyclo[2.2.1]heptane (**3**) as a syrup in 80% yield.

Reaction of **2** with 15% hydrogen bromide in acetic acid in a sealed tube overnight at 85—90 °C resulted in cleavage of the 1,4-anhydro ring to give rise to a mixture of acetoxybromocyclohexanecarboxylic acids, from which crystalline (1,5/2)-2-acetoxy-5-bromocyclohexanecarboxylic acid (**4**) was isolated in 59% yield. In its ^{1}H NMR spectrum, a triplet of doublets at δ 5.00 having 4.5, 10, and 10 Hz-splittings could be ascribed to H-2, in line with the 1,2-trans configuration between the acetoxyl and carboxyl groups. Under similar reaction conditions, **3** afforded crystalline dibromo compound (**5**) in an isolated yield of 35%. In this case, the primary acetoxyl group was replaced by a bromide ion in addition to opening the anhydro ring. The ^{1}H NMR spectrum of **5** contained a pattern of the signals due to methine protons very similar to that of **4**. The structure of **5** was tentatively assigned to (1/2,4)-4-bromo-2-(bromomethyl)cyclohexyl acetate.

Scheme 1.

On the other hand, bromolactonization of **1** proceeded smoothly to give the bromolactone (**6**) in 91% yield. Reduction of **6** with LAH in THF followed by acetylation gave *endo*-2-acetoxy-*endo*-6-acetoxymethyl-*exo*-3-bromo-7-oxabicyclo[2.2.1]heptane (**8**) in 84% yield. Hydrogenolysis of **8** with Raney nickel in the presence of Amberlite IRA-45 (OH^-) gave the corresponding debromo compound (**9**) in 94% yield, which was also obtained analogously from the lactone (**7**) derived by hydrogenolysis of **6**.

The same treatment of **8** with hydrogen bromide in acetic acid gave selectively a single crystalline tribromide (**10**) almost quantitatively. Similarly, dibromide (**11**) was obtained from **9** in 75% yield. The structures of **10** and **11** were deduced on the basis of analytical data and ^{1}H NMR spectroscopy. Thus, the ^{1}H NMR spectrum of **10** revealed two one-proton relatively wide triplets coupled with each other at δ 4.92 and 5.22, respectively, indicating the presence of two acetoxyl groups in vicinal trans positions. These were accounted for by opening of the anhydro ring at C-4 by a bromide ion, the structure being tentatively assigned to di-*O*-acetyl-(1,3/2,4,6)-3,4-dibromo-6-bromomethyl-1,2-cyclohexanediol. In the ^{1}H NMR spectrum, **11** showed a triplet of doublets at δ 4.76 having 3.5, 8.5, and 8.5 Hz-splittings and a doublet of doublets at δ 4.96 having 8.5 and 10 Hz-splittings attributed to H-1 and H-2, respectively. Thus, **11** was assigned to di-*O*-acetyl-(1,3,5/2)-5-bromo-3-bromomethyl-1,2-cyclohexanediol.

Accordingly, the 1,4-anhydro ring was cleaved by a bromide ion regioselectively in **8** or **9** at the carbon atom adjacent to the methylene group, while, in the case of **2** and **3**, the selectivity appears to decrease, somewhat presumably, owing to the stereoelectric effects.

Dideoxyvalidamine and Its Analog. Reduction of **4** with LAH in THF followed by acetylation gave the corresponding di-*O*-acetyl-bromohydroxymethylcyclohexanol (**12**) as a syrup in 46% yield, which,

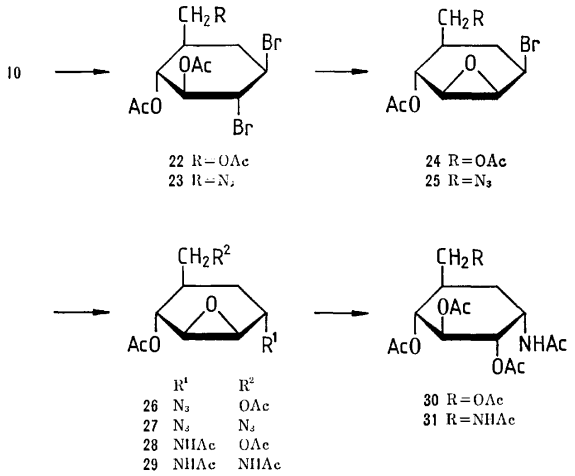

Scheme 3.

without purification, was treated with sodium azide in boiling 90% aqueous 2-methoxyethanol for 2 days to give the crude azido compound (**13**). Its ^{1}H NMR spectrum showed a relatively narrow multiplet due to the proton attached to the carbon atom bearing the azido group, suggesting that the bromine group was replaced by an azide ion with inversion of the configuration. Compound **13** was hydrogenated with Raney nickel followed by acetylation to give crystalline tri-*N,O*-acetyl-(1,4/2)-4-amino-2-hydroxymethyl-1-cyclohexanol (dideoxyvalidamine) (**14**) in 25% yield.

The similar treatment of **5** with sodium azide gave a syrupy diazido compound (**15**), which was hydrogenated and successively acetylated to give tri-*N,O*-acetyl-(1,4/2)-4-amino-2-aminomethyl-1-cyclohexanol (**16**) in 30% overall yield.

Deoxyvalidamine and Its Analog. Compound **11** was treated with 2 molar equiv. of sodium acetate in 90% aqueous 2-methoxyethanol at 90 °C overnight and then the product was acetylated to give tri-*O*-acetyl-(1,3,5/2)-5-bromo-3-hydroxymethyl-1,2-cyclohexanediol (**17**) in 78% yield. The ^{1}H NMR spectrum was compatible with the proposed structure, in which only C-7 bromine atom of **11** was replaced by an acetoxyl group. Thus, in **17**, C-7 methylene signal shifted downfield as compared with that of **11**. Reaction of **17** with an azide ion gave a syrupy azido compound (**18**) with inversion of the configuration at C-5, which was directly hydrogenated followed by acetylation to give a crystalline tetra-*N,O*-acetyl-(1,3/2,5)-5-amino-3-hydroxymethyl-1,2-cyclohexanediol (deoxyvalidamine) (**19**) in 40% yield. The structure was fully supported by the ^{1}H NMR spectrum (see Experimental).

Analogously, **11** was converted to the diazido compound (**20**) which was hydrogenated and then acetylated to give tetra-*N,O*-acetyl-(1,3/2,5)-5-amino-3-aminomethyl-1,2-cyclohexanediol (**21**) in 58% overall yield. Its ^{1}H NMR spectrum showed a pattern of ring proton signals very similar to that of **19**.

Validamine and Its Analog. Treatment of **10** with sodium acetate (2 molar equiv.) in 90% aqueous 2-methoxyethanol at 90 °C for 2 days led to the selective displacement at C-7 with an acetate ion affording tri-*O*-acetyl-(1,3/2,4,6)-3,4-dibromo-6-hydroxymethyl-1,2-cyclohexanediol (**22**) as the major product in 50% yield.[6] Similarly, on treatment with sodium azide (2 molar equiv.), **10** gave the corresponding 7-azido compound (**23**) in 91% yield. Reaction of **22** with excess methanolic sodium methoxide in chloroform followed by acetylation gave di-*O*-acetyl-1,2-anhydro-(1,2,4,6/3)-6-bromo-4-hydroxymethyl-1,2,3-cyclohexanetriol (**24**) in a quantitative yield. The ^{1}H NMR spectrum revealed a doublet due to H-3 having 9 Hz-splitting at δ 4.88, which confirmed the assigned structure of **24**, excluding the 2,3-anhydro structure resulting from an oxirane ring migration under basic conditions. Under the same conditions, **23** gave the corresponding epoxide (**25**) in 78% yield.

The reaction of **24** with 1.5 molar equiv. sodium azide in *N,N*-dimethylformamide at 90 °C was monitored by TLC.[7] After **24** had been consumed in 2.5 h, one major component was formed together with four minor components. Separation of the mixture by column chromatography gave the epoxy azide (**26**) in 30% yield as a homogeneous syrup. In its ^{1}H NMR spectrum, the signal due to proton on a carbon atom attached to the azido group appeared as a doublet of doublets having 3 and 9.5 Hz-splittings at δ 4.19. Lack of a coupling between H-1 and H-6 suggests that the azido group is located in the trans position to the adjacent anhydro ring. Hydrogenation of **26** with Raney nickel in methanol containing acetic anhydride gave the epoxy amide (**28**) which, without purification, was successively treated with boiling 80% aqueous acetic acid followed by acetylation to give a crystalline penta-*N,O*-acetyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (validamine) (**30**) in 30% yield. The compound was identical with an authentic sample[8] except for an optical activity. The anhydro ring in **28** seems to be cleaved at C-1 preferentially by an anchimeric assistance of the neighboring acetamido group, giving rise to the triol with the desired configuration.

By an analogous sequence of reactions (**27**→**29**→**31**), the 7-amino-7-deoxy analog (**31**) of validamine was prepared in an overall yield of 21%. The structure was supported by comparison of its ^{1}H NMR spectrum with that of **30**.

Experimental

Unless otherwise noted, melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. Solutions were evaporated under reduced pressure at 40—50 °C. ^{1}H NMR spectra were measured at 60 MHz on a Varian A-60D spectrometer in deuteriochloroform ($CDCl_3$) or dimethyl-d_6 sulfoxide (DMSO-d_6) with reference to tetramethylsilane as an internal standard, the peak positions being given in δ-values. Values given for chemical shifts and coupling constants are of first-order. TLC was performed on silica gel (Wakogel B-10, Wako Pure Chemical Industries, Ltd.) using a mixture of butanone and toluene as an eluent. Column chromatography was carried out on Wakogel C-200.

endo-2-Acetoxymethyl-7-oxabicyclo[2.2.1]heptane (3). To a solution of the acid (**2**)[3] (6.0 g) prepared by catalytic reduction of *endo*-7-oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid (**1**)[2b] in tetrahydrofuran (THF) (100 ml) was added a slurry of lithium aluminum hydride (LAH) (2.1 g) in THF (20 ml), and the mixture was stirred at an ambient temperature for 4 h. A mixture of THF (4.2 ml) and water (4.2 ml) was added to the reaction mixture and it was left to stand overnight. A white solid was removed by filtration and washed with hot THF (20 ml). The filtrate and washings were combined and evaporated to give a colorless syrup (5.4 g), whose TLC showed a single spot in butanone–toluene (1 : 1, v/v). A 2.3 g-portion of this syrup was treated with acetic anhydride (10 ml) in pyridine (20 ml) overnight at an ambient temperature. The reaction mixture was evaporated to dryness and the residue was dissolved in ethyl acetate and washed with 0.5 M hydrochloric acid, aqueous saturated sodium hydrogencarbonate solution, and water, successively. The solution was dried over anhydrous sodium sulfate and then evaporated to give **3** (2.7 g, 89%) as a homogeneous syrup.

Found: C, 63.60; H, 8.20% Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

Treatment of the alcohol with *p*-nitrobenzoyl chloride in pyridine at 70 °C for 30 min gave a crystalline *p*-nitrobenzoate. An analytical sample was obtained by recrystallization of the crude product from ethanol, mp 104—105 °C.

Found: C, 60.79; H, 5.61; N, 5.12%. Calcd for $C_{14}H_{15}NO_5$: C, 60.65; H, 5.45; N, 5.05%.

(1,5/2)-2-Acetoxy-5-bromocyclohexanecarboxylic Acid (4). A mixture of **2**[3] (0.2 g) and 15% hydrogen bromide in acetic acid (2 ml) was heated at 80—85 °C in a sealed tube for 17 h, the reaction mixture being then poured into ice-water (40 ml). The resulting gum was collected by decantation and dissolved in chloroform. The solution was washed with water, dried, and evaporated to give a partially crystalline product. Recrystallization from ethanol–hexane gave **4** (0.23 g, 59%): mp 156—158 °C; ^{1}H NMR ($CDCl_3$) δ 1.23—2.90 (7H, m, H-1 and the six methylene protons), 2.02 (3H, s, OAc), 3.97 (1H, tt, $J_{4ax,5}=J_{5,6eq}=11$ Hz, $J_{4eq,5}=J_{5,6eq}=4.5$ Hz, H-5), 5.00 (1H, td, $J_{1,2}=J_{2,3ax}=10$ Hz, $J_{2,3eq}=4.5$ Hz, H-2), 9.35 (1H, s, COOH).

Found: C, 40.51; H, 4.77; Br, 30.45%. Calcd for $C_9H_{13}O_4Br$: C, 40.78; H, 4.94; Br, 30.14%.

(1/2,4)-4-Bromo-2-(bromomethyl)cyclohexyl Acetate (5). Compound **3** (1.6 g) was treated with hydrogen bromide in acetic acid in the same way as for **4**. The reaction mixture was poured into ice-water and extracted with chloroform, and the extracts were processed in the usual manner. The crude product was crystallized from ethanol to give **5** (1.03 g, 35%): mp 110.5—112 °C; ^{1}H NMR ($CDCl_3$) δ 1.23—2.90 (7H, m, H-2 and the six ring methylene protons), 2.05 (3H, s, OAc), 3.32—3.45 (2H, m, CH$_2$Br), 3.99 (1H, tt, $J_{3ax,4}=J_{4,5ax}=11$ Hz, $J_{3eq,4}=J_{4,5eq}=4.5$ Hz, H-4), 4.77 (1H, td, $J_{1,2}=J_{1,6ax}=10$ Hz, $J_{1,6eq}=4.5$ Hz, H-1).

Found: C, 34.37; H, 4.48; Br, 51.11%. Calcd for $C_9H_{14}O_2Br_2$: C, 34.42; H, 4.49; Br, 50.89%.

exo-*9-Bromo-2,7-dioxabicyclo[4.2.1.0^{4,8}]nonan-3-one (6).* Compound **1**[3] (10 g) was dissolved in water (300 ml) containing sodium hydrogencarbonate (7.2 g). Bromine (4 ml) was added dropwise to this solution under vigorous agitation. After completion of the addition, the mixture was stirred for 1 h, and precipitates were collected by filtration and washed with water thoroughly. Recrystallization of the crude product from ethyl acetate gave **6** (14.2 g, 91%) as prisms: mp 155—156 °C; ^{1}H NMR (DMSO-d_6) δ 2.00—2.29 (2H, m, C-5 methylene), 2.69 (1H, m, H-4), 4.37 (1H, s, H-9), 4.75 (1H, m, H-6), 4.95 (1H, d, $J_{1,8}=5$ Hz, H-1), 5.53 (1H, t, $J_{4,8}=5$ Hz, H-8).

Found: C, 38.11; H, 3.26; Br, 36.34%. Calcd for $C_7H_7O_2Br$: C, 38.39; H, 3.22; Br, 36.48%.

2,7-Dioxabicyclo[4.2.1.0^{4,8}]nonan-3-one (7). A solution of **6** (1.1 g) in ethyl acetate (20 ml) was hydrogenated in the presence of Raney nickel T-4[9] and Amberlite IR-45 (OH^-) (7.5 ml) in the initial hydrogen pressure of 3.4 kg·cm^{-2} at an ambient temperature overnight. The catalyst and resin were removed by filtration and the filtrate was evaporated. The residue was crystallized from ethyl acetate–hexane to give **7** (0.46 g, 65%) as needles: mp 85.5—87 °C; ^{1}H NMR ($CDCl_3$) δ 1.42—2.46 (4H, m, C-5 and C-9 methylene), 2.71 (1H, broad five-line peak, $J_{4,5endo}=4.5$ Hz, $J_{4,5exo}=8.5$ Hz, H-4), 4.65—4.92 (2H, m, H-1 and H-6), 5.31 (1H, t, $J_{1,8}=J_{4,8}=5$ Hz, H-8).

Found: C, 60.20; H, 5.82%. Calcd for $C_7H_8O_3$: C, 60.00; H, 5.75%.

endo-*2-Acetoxy*-endo-*6-acetoxymethyl*-exo-*3-bromo-7-oxabicyclo-[2.2.1]heptane (8).* To an ice-cooled solution of **6** (10 g) in THF (250 ml) was added dropwise a slurry of LAH (2 g) in THF (30 ml) with vigorous agitation. The reaction mixture was stirred at an ambient temperature for 3 h and worked up in the usual manner to give a syrup, which was directly acetylated by the conventional method. The product was crystallized from ethyl acetate–hexane to give **8** (11.7 g, 83.5%) as colorless needles: mp 61—62 °C; ^{1}H NMR ($CDCl_3$) δ 1.35 (1H, dd, $J_{5gem}=12.5$ Hz, $J_{5endo,6}=5.5$ Hz, H-5*endo*), 1.63—2.79 (2H, m, H-5*exo* and H-6), 2.02 (3H, s) and 2.06 (3H, s) (OAc), 3.85 (1H, d, $J_{2,3}=3$ Hz, H-3), 4.19 (1H, dd) and 4.32 (1H, dd) ($J_{6,7}=J_{6,7'}=3$ Hz, $J_{7gem}=7$ Hz, CH$_2$OAc), 4.61 (1H, d, $J_{4,5exo}=6$ Hz, H-4), 4.65 (1H, t, $J_{1,2}=5$ Hz, H-1), 5.36 (1H, broad dd, H-2).

Found: C, 42.88; H, 4.82; Br, 26.14%. Calcd for $C_{11}H_{15}O_5Br$: C, 43.12; H, 4.92; Br, 26.02%.

endo-*2-Acetoxy*-endo-*6-acetoxymethyl-7-oxabicyclo[2.2.1]heptane (9).* a) A solution of **8** (10 g) in ethyl acetate (20 ml) was hydrogenated with Raney nickel and Amberlite IR-45 (OH^-) in the same way as for **7**. The product was crystallized from ethyl acetate–hexane to give **9** (7 g, 94%) as needles: mp 48—49 °C; ^{1}H NMR ($CDCl_3$) δ 1.12—1.51 (2H, m, H-3*endo* and H-5*endo*), 2.02 (6H, s, two OAc), 1.67—2.66 (3H, m, H-3*exo*, H-5*exo*, and H-6), 4.21—4.67 (4H, m, H-1, H-4, and CH$_2$OAc), 5.04 (1H, m, H-2).

Found: C, 57.67; H, 6.91%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.06%.

b) Compound **9** was also prepared, in 52% yield, by reduction of **7** with LAH in THF as in the preparation

of **8**.

The di-*p*-nitrobenzoate was prepared by the usual method. An analytical sample crystallized from ethanol melted at 206 °C.

Found: C, 57.11; H, 4.27; N, 6.19%. Calcd for $C_{21}H_{18}N_2O_9$: C, 57.02; H, 4.10; N, 6.33%.

*Di-O-acetyl-(1,3/2,4,6)-3,4-dibromo-6-bromomethyl-1,2-cyclohexanediol (**10**).* Compound **8** (1.6 g) was treated with hydrogen bromide in acetic acid in the same way as for **4**. Recrystallization of a crude crystalline product (2.2 g) gave **10** (1.75 g, 74%) as prisms: mp 153—154 °C; ^{1}H NMR ($CDCl_3$) δ 1.79—2.85 (3H, m, C-5 methylene and H-6), 2.04 (3H, s) and 2.08 (3H, s) (OAc), 3.22 (1H, dd, $J_{6,7}$= 3.5 Hz, J_{7gem}=10 Hz, H-7), 3.45 (1H, dd, $J_{6,7'}$=1.5 Hz, H-7'), 4.02 (1H, m, H-4), 4.10 (1H, t, $J_{2,3}=J_{3,4}$=9 Hz, H-3), 4.92 (1H, t, $J_{1,2}=J_{1,6}$=9 Hz, H-1), 5.22 (1H, t, H-2).

Found: C, 29.22; H, 3.33; Br, 52.96%. Calcd for $C_{11}H_{15}O_4Br_3$: C, 29.30; H, 3.35; Br, 53.16%.

*Di-O-acetyl-(1,3,5/2)-5-bromo-3-bromomethyl-1,2-cyclohexanediol (**11**).* Compound **9** (1 g) was treated with hydrogen bromide in acetic acid in the same way as for **4**. The crude product was recrystallized from ethanol to give **11** (1.2 g, 75%): mp 136—137 °C; ^{1}H NMR ($CDCl_3$) δ 1.63—2.86 (5H, m, H-3, and C-4 and C-6 methylene), 2.01 (3H, s) and 2.05 (3H, s) (OAc), 3.26—3.40 (2H, m, CH_2Br), 4.00 (1H, nine-line peak, H-5), 4.76 (1H, td, $J_{1,2}=J_{1,6ax}$=8.5 Hz, $J_{1,6eq}$=3.5 Hz, H-1), 4.96 (1H, dd, $J_{2,3}$=10 Hz, H-2).

Found: C, 35.50; H, 4.27; Br, 43.07%. Calcd for $C_{11}H_{16}O_4Br_2$: C, 35.51; H, 4.33; Br, 42.95%.

*Tri-N,O-acetyl-(1,4/2)-4-amino-2-hydroxymethyl-1-cyclohexanol (**14**).* To a solution of **4** (0.53 g) in THF (10 ml) was added a suspension of LAH (0.09 g) in THF (6 ml) at 0 °C, and the reaction mixture was stirred at an ambient temperature for 1.5 h, and then worked up in the usual manner. The syrupy product was acetylated and purified by chromatography on silica gel with chloroform to give di-*O*-acetyl-(1/2,4)-4-bromo-2-hydroxymethyl-1-cyclohexanol (**12**) (0.27 g, 46%) as a homogeneous syrup; ^{1}H NMR ($CDCl_3$) δ 1.19—2.57 (7H, m, H-2, and C-3, C-4, and C-5 methylene), 2.03 (3H, s) and 2.06 (3H, s) (OAc), 4.00 (1H, tt, $J_{3ax,4}=J_{4,5ax}$=13 Hz, $J_{3eq,4}=J_{4,5eq}$=4.5 Hz, H-4), 4.01 (2H, d, CH_2OAc), 4.65 (1H, td, $J_{1,2}=J_{1,6eq}$= 4 Hz, H-1).

A mixture of crude **12** (0.21 g), sodium azide (0.2 g), and 90% aqueous 2-methoxyethanol (10 ml) was heated at reflux for 45 h, and then evaporated to dryness. The residue was directly acetylated in the usual manner and the product was purified by chromatography on alumina with chloroform to give di-*O*-acetyl-(1,4/2)-4-azido-2-hydroxymethyl-1-cyclohexanol (**13**) as a homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ 1.45—2.41 (7H, m, H-2, and C-3, C-5, and C-6 methylene), 2.04 (6H, s, two OAc), 3.76—3.99 (1H, m, H-4), 3.96—4.11 (2H, m, CH_2OAc), 4.65 (1H, td, $J_{1,2}=J_{1,6ax}$=10 Hz, $J_{1,6eq}$=4.5 Hz, H-1).

A solution of crude **13** (0.16 g) in ethanol (6 ml) was hydrogenated with Raney nickel at an ambient temperature overnight. The product was acetylated in the usual manner. Recrystallization of the crude product from ethanol–ether gave **14** (0.043 g, 25%) as needles: mp 111—112.5 °C; ^{1}H NMR ($CDCl_3$) δ 1.19—2.21 (7H, m, H-2, and C-3, C-5, and C-6 methylene), 1.99 (3H, s, NAc), 2.05 (6H, s, two OAc), 3.88—4.26 (3H, m, H-4 and CH_2NHAc), 4.73 (1H, td, $J_{1,2}=J_{1,6ax}$=8.5 Hz, $J_{1,6eq}$=4.5 Hz, H-1), 5.73 (1H, d, J=6 Hz, NH).

Found: C, 57.23; H, 7.58; N, 5.29%. Calcd for $C_{13}H_{21}NO_5$: C, 57.55; H, 7.80; N, 5.16%.

*Tri-N,O-acetyl-(1,4/2)-4-amino-2-aminomethyl-1-cyclohexanol (**16**).* A mixture of **5** (0.47 g), sodium azide (0.59 g), and 90% aqueous 2-methoxyethanol (15 ml) was heated at 110 °C for 17 h, and then evaporated to dryness. The residue was acetylated in the usual manner and the product was purified by chromatography on alumina to give (1,4/2)-4-azido-2-(azidomethyl)cyclohexyl acetate (**15**) as a homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ 1.21—2.41 (7H, m, H-2, and C-3, C-5, and C-6 methylene), 2.06 (3H, s, OAc), 3.32 (2H, d, J=4.5 Hz, CH_2N_3), 3.78—3.96 (1H, m, H-4), 4.95 (1H, td, $J_{1,2}=J_{1,6ax}$=9.5 Hz, $J_{1,6eq}$=5 Hz, H-1).

Crude **15** was hydrogenated in ethanol with Raney nickel as in the case of crude **13**. The product was acetylated in the usual manner. Recrystallization of the crude product from ethanol gave **16** (0.12 g, 30% based on **5** used) as needles: mp 189—190 °C; ^{1}H NMR ($CDCl_3$) δ 1.10—2.38 (7H, m, H-1, and C-3, C-5, and C-6 methylene), 1.97 (6H, s, two NAc), 2.06 (3H, s, OAc), 2.83—3.72 (2H, m, CH_2-NHAc).

Found: C, 57.53; H, 8.12; N, 10.12%. Calcd for $C_{13}H_{22}N_2O_4$: C, 57.76; H, 8.20; N, 10.36%.

*Tetra-N,O-acetyl-(1,3/2,5)-5-amino-3-hydroxymethyl-1,2-cyclohexanediol (**19**).* A mixture of **11** (1.86 g), anhydrous sodium acetate (1.23 g), and 90% aqueous 2-methoxyethanol (35 ml) was heated at 90 °C with stirring overnight. The reaction mixture was evaporated and the residue was extracted with hot chloroform (50 ml). The extracts were passed through a short alumina column and then evaporated to give tri-*O*-acetyl-(1,3,5/2)-5-bromo-3-hydroxymethyl-1,2-cyclohexanediol (**17**) (1.37 g, 78%) as a homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ 1.62—2.87 (5H, m, H-3, and C-6 methylene), 2.01 (3H, s), 2.03 (3H, s), and 2.06 (3H, s) (OAc), 3.75—4.27 (3H, m, H-5 and CH_2OAc), 4.76 (1H, td, $J_{1,2}=J_{1,6ax}$=9.5 Hz, $J_{1,6eq}$=5 Hz, H-1), 4.96 (1H, t, $J_{2,3}$=9.5 Hz, H-2).

A mixture of crude **17** (1.05 g), sodium azide (0.6 g), and 90% aqueous 2-methoxyethanol (30 ml) was refluxed for 20 h. The reaction mixture was evaporated and acetylated in the usual manner. The product was purified by chromatography on alumina to give tri-*O*-acetyl-(1,3/2,5)-5-azido-3-hydroxymethyl-1,2-cyclohexanediol (**18**) (1.05 g) as a homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ 1.52—2.57 (5H, m, H-3, and C-4 and C-6 methylene), 1.99 (3H, s) and 2.03 (6H, s) (OAc), 3.72—4.28 (3H, m, H-5 and CH_2OAc), 4.72—5.25 (2H, m, H-1 and H-2).

Compound **18** (1.0 g) was hydrogenated in ethanol (20 ml) containing acetic anhydride (0.5 ml) with Raney nickel in the same way as for **7**. The product was crystallized from ether to give **19** (0.37 g, 40% based on **17** used) as needles: mp 193—194 °C; ^{1}H NMR ($CDCl_3$) δ 1.49—2.48 (5H, m, H-3, and C-4 and C-6 methylene), 1.99 (6H, s), 2.02 (3H, s), and 2.03 (3H, s) (OAc), 3.88 (1H, dd, J_{7gem}=11.5 Hz, $J_{3,7}$=4.5 Hz, H-7), 4.15 (1H, dd, $J_{3,7'}$=4 Hz, H-7'), 4.28 (1H, m, H-5), 4.88 (1H, t, $J_{1,2}=J_{2,3}$=9 Hz, H-2), 4.97 (1H, td, $J_{1,6ax}$=9 Hz, $J_{1,6eq}$=3 Hz, H-1), 6.38 (1H, d, $J_{5,NH}$=7 Hz, NH).

Found: C, 55.00; H, 7.01; N, 4.27%. Calcd for $C_{15}H_{23}NO_7$: C, 54.70; H, 7.04; N, 4.25%.

*Tetra-N,O-acetyl-(1,3/2,5)-5-amino-3-aminomethyl-1,2-cyclohexanediol (**21**).* A mixture of **11** (0.74 g), sodium azide (0.78 g), and 90% aqueous *N,N*-dimethylformamide (20 ml) was heated at 125 °C for 20 h. The reaction mixture was processed by the usual method and the syrupy product was purified by alumina column to give di-*O*-acetyl-(1,3/2,5)-5-azido-3-azidomethyl-1,2-cyclohexanediol (**20**) (0.61 g, 97%) as a homogeneous syrup. The compound was di-

rectly hydrogenated as in the case of **18** and the product was crystallized from ethanol to give **21** (0.39 g, 59%) as needles: mp 236—237 °C (capil); ^{1}H NMR (DMSO-d_6) δ 1.36—2.46 (5H, m, H-3, and C-4 and C-6 methylene), 1.88 (3H, s) and 1.92 (3H, s) (NAc), 2.02 (3H, s) and 2.08 (3H, s) (OAc), 3.2—3.56 (2H, m, CH_2NHAc), 4.08—4.39 (1H, m, H-5), 4.85 (1H, t, $J_{1,2}=J_{2,3}=9.5$ Hz, H-2), 5.22 (1H, td, $J_{1,6ax}=9.5$ Hz, $J_{1,6eq}=5$ Hz, H-1), 7.93 (1H, t, $J_{7,NH}=J_{7',NH}=5.5$ Hz, CH_2NHAc), 8.27 (1H, d, $J_{5,NH}=6.5$ Hz, CHNHAc).

Found: C, 54.63; H, 7.28; N, 8.54%. Calcd for $C_{15}H_{24}N_2O_6$: C, 54.87; H, 7.37; N, 8.53%.

Tri-O-*acetyl-(1,3/2,4,6)-3,4-dibromo-6-hydroxymethyl-1,2-cyclohexanediol* (**22**). A mixture of **10** (9.0 g), anhydrous sodium acetate (4.9 g), and 90% aqueous 2-methoxyethanol (100 ml) was heated at 90 °C for two days. The reaction mixture was worked up by the usual method and the product was directly acetylated. TLC indicated the formation of one major and three minor components. Crystallization of the mixture from ethanol gave the main product, **22** (4.3 g, 50%) as prisms: mp 128—129 °C; ^{1}H NMR ($CDCl_3$) δ 1.77—2.71 (3H, m, H-6 and C-5 methylene), 2.01 (3H, s) and 2.06 (6H, s) (OAc), 3.74—4.26 (4H, m, H-3, H-4, and CH_2OAc), 4.91 (1H, dd, $J_{1,2}=9$ Hz, $J_{1,6}=10$ Hz, H-1), 5.20 (1H, t, $J_{2,3}=10$ Hz, H-2).

Found: C, 36.42; H, 4.17; Br, 37.65%. Calcd far $C_{13}H_{18}O_6Br_2$: C, 36.30; H, 4.22; Br, 37.16%.

Di-O-*acetyl-(1,3/2,4,6)-6-azidomethyl-3,4-dibromo-1,2-cyclohexanediol* (**23**). A mixture of **10** (4.5 g), sodium azide (1.95 g), and 90% aqueous 2-methoxyethanol (60 ml) was heated at 95 °C for 90 min. The reaction mixture was worked up by the usual method. The product was recrystallized from ethanol to give **23** (3.8 g, 91%) as needles: mp 114—115 °C; ^{1}H NMR ($CDCl_3$) δ 1.71—2.73 (3H, m, H-6 and C-5 methylene), 2.04 (3H, s) and 2.07 (3H, s) (OAc), 3.18 (1H, dd, $J_{7gem}=11$ Hz, $J_{6,7}=3.5$ Hz, H-7), 3.44 (1H, dd, $J_{6,7'}=2$ Hz, H-7'), 3.94—4.18 (2H, m, H-3 and H-4), 4.86 (1H, t, $J_{1,2}=J_{1,6}=10$ Hz, H-1), 5.19 (1H, t, $J_{2,3}=10$ Hz, H-2).

Found: C, 32.08; H, 3.68; N, 10.26; Br, 38.78%. Calcd for $C_{11}H_{15}N_3O_4Br_2$: C, 31.99; H, 3.66; N, 10.17; Br, 38.69%.

Di-O-*acetyl-1,2-anhydro-(1,2,4,6/3)-6-bromo-4-hydroxymethyl-1,2,3-cyclohexanetriol* (**24**). To a solution of **22** (2.15 g) in methanol (20 ml) was added 1 M-methanolic sodium methoxide (10 ml, 2 molar equiv.) and the mixture was stirred at an ambient temperature for 3 h. The solution was neutralized with 1 M-hydrochloric acid and then evaporated to dryness. The residue was treated with acetic anhydride (5 ml) and pyridine (10 ml) overnight. The product was purified by alumina column to give a syrup which crystallized spontaneously to give **24** (1.5 g, 98%) as prisms: mp 58—59.5 °C; ^{1}H NMR ($CDCl_3$) δ 1.54—2.19 (3H, m, H-4 and C-5 methylene), 2.05 (3H, s) and 2.11 (3H, s) (OAc), 3.26 (1H, d, $J_{1,2}=3.5$ Hz, H-2), 3.52 (1H, broad d, $J_{1,6}=2$ Hz, H-1), 3.90—4.02 (2H, m, CH_2OAc), 4.37 (1H, eight-line peak, $J_{5ax,6}=J_{5eq,6}=6$ Hz, H-6), 4.88 (1H, d, $J_{3,4}=9$ Hz, H-3).

Found: C, 42.92; H, 4.90; Br, 26.12%. Calcd for $C_{11}H_{15}O_5Br$: C, 43.02; H, 4.92; Br, 26.02%.

O-*Acetyl-1,2-anhydro-(1,2,4,6/3)-4-azidomethyl-6-bromo-1,2,3-cyclohexanetriol* (**25**). To a solution of **23** (3.3 g) in methanol (30 ml) was added 1 M-methanolic sodium methoxide (16 ml, 2 molar equiv.) and the mixture was left to stand at an ambient temperature for 5 h. The reaction mixture was processed as in the preparation of **24**. The product was chromatographed on silica gel (85 g) with butanone-toluene (1 : 12, v/v) as an eluent to give **25** (1.82 g, 78%) as a homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ 1.56—2.19 (3H, m, H-4 and C-5 methylene), 2.13 (3H, s, OAc), 3.20—3.35 (3H, m, H-2 and CH_2N_3), 3.51 (1H, broad q, $J_{1,2}=4$ Hz, $J_{1,6}=2$ Hz, H-1), 4.36 (1H, eight-line peak, $J_{5ax,6}=11$ Hz, $J_{5eq,6}=6$ Hz, H-6), 4.84 (1H, broad d, $J_{3,4}=9$ Hz, H-3).

Found: C, 37.19; H, 4.14; N, 14.41; Br, 27.27%. Calcd for $C_9H_{12}N_3O_3Br$: C, 37.26; H, 4.17; N, 14.48; Br, 27.54%.

Di-O-*acetyl-1,2-anhydro-(1,2,4/3,6)-6-azido-4-hydroxymethyl-1,2,3-cyclohexanetriol* (**26**). A mixture of **24** (0.92 g), sodium azide (0.59 g), and *N,N*-dimethylformamide (15 ml) was heated at 90 °C for 2.5 h. TLC indicated the formation of one major component, together with **24** and three minor components. The reaction mixture was processed by the usual method and the product was purified in the same way as for **25** to give the main product, **26** (0.25 g, 31%) as a homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ 1.51—2.55 (3H, m, H-4 and C-5 methylene), 2.05 (3H, s) and 2.12 (3H, s) (OAc), 3.10 (1H, d, $J_{1,2}=3$ Hz, H-2), 3.23 (1H, t, $J_{1,6}=3$ Hz, H-1), 3.94—4.01 (2H, m, CH_2OAc), 4.19 (1H, broad q, $J_{5ax,6}=J_{5eq,6}=3$ Hz, H-6), 4.87 (1H, d, $J_{3,4}=9.5$ Hz, H-3).

Found: C, 48.83; H, 5.56; N, 15.37%. Calcd for $C_{11}H_{15}N_3O_5$: C, 49.07; H, 5.62; N, 15.61%.

Penta-N,O-*acetyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (validamine)* (**30**). A solution of **26** (0.47 g) in methanol (14 ml) containing acetic anhydride (0.5 ml) was hydrogenated in the presence of Raney nickel as in the preparation of **7** to give a crude syrup of tri-*N,O*-acetyl-1,2-anhydro-(1,2,4/3,6)-6-amino-4-hydroxymethyl-1,2,3-cyclohexanetriol (**28**). The compound was treated with refluxing 80% aqueous acetic acid (10 ml) for 13 h and the reaction mixture was evaporated to dryness. The residue was acetylated in the usual manner and the product was crystallized from ethanol to give **30** (0.2 g, 30%) as prisms: mp 197—198 °C. The compound was identified with an authentic active sample[8] by comparison of ^{1}H NMR ($CDCl_3$) and IR spectra.

Penta-N,O-*acetyl-(1,3,4/2,6)-4-amino-6-aminomethyl-1,2,3-cyclohexanetriol* (**31**). A mixture of (0.87 g), sodium azide (0.59 g), and *N,N*-dimethylformamide (15 ml) was heated at 90 °C for 2 h. TLC indicated the formation of one major and five minor components. The products were fractionated by silica gel column (50 g) with butanone-toluene (1 : 12, v/v) as an eluent. The major fraction gave *O*-acetyl-1,2-anhydro-(1,2,4/3,6)-6-azido-4-azidomethyl-1,2,3-cyclohexanetriol (**27**) (0.37 g, 50%) as a homogeneous syrup: ^{1}H NMR ($CDCl_3$) δ 1.48—2.30 (3H, m, H-6 and C-5 methylene), 2.14 (3H, s, OAc), 3.09 (1H, d, $J_{1,2}=3.5$ Hz, H-2), 3.17—3.55 (3H, m, H-1 and CH_2N_3), 4.19 (1H, q, $J_{1,6}=J_{5ax,6}=J_{5eq,6}=2.5$ Hz, H-6), 4.83 (1H, d, $J_{3,4}=9.5$ Hz, H-3). Compound **27** decomposed on being left to stand at an ambient temperature, no satisfactory analytical data being obtained. Thus, crude **27** was directly used in the next step.

A solution of **27** (0.34 g) in methanol containing acetic anhydride (0.5 ml) was hydrogenated with Raney nickel in the same way as for **7**, and the reduction product was treated with aqueous acetic acid as in the preparation of **30**. The acetylated product was crystallized from ethanol-ether to give **31** (0.11 g, 21%) as needles: mp 246—248 °C; ^{1}H NMR ($CDCl_3$) δ 1.41—2.38 (3H, m, H-6 and C-5 methylene), 2.01 (6H, s, two NAc), 2.03 (3H, s) 2.17 (3H, s), and 2.19 (3H, s) (OAc), 2.66—3.11 (1H, m) and 3.41—3.88 (1H, m) (CH_2NHAc), 4.35—4.76 (1H, m, H-4), 4.78 (1H, t, $J_{1,2}=J_{1,6}=9.5$ Hz, H-1), 4.91 (1H, dd, $J_{2,3}=$

9.5 Hz, $J_{3,4}=4$ Hz, H-3), 5.30 (1H, t, H-2), 6.00—6.28 (2H, broad d, two NH).

Found: C, 52.52; H, 6.65; N, 7.18%. Calcd for $C_{17}H_{28}N_2O_8$: C, 52.84; H, 6.78; N, 7.25%.

The authors express their sincere thanks to Mr. Saburo Nakada for his elementary analyses.

High Performance Liquid Chromatographic Analysis of Individual Bile Acids: Free, Glycine- and Taurine-conjugated Bile Acids

Sumihiko OKUYAMA,* Daisuke UEMURA,† and Yoshimasa HIRATA†

Nagoya University College of Medical Technology, Daiko-cho, Higashi-ku, Nagoya 461

(Received May 8, 1978)

High performance liquid chromatographic analyses of individual bile acids (cholic, chenodeoxycholic, deoxycholic, and lithocholic acids), free and conjugated with glycine and taurine, are described. The analyses of the free and glycine-conjugated bile acids are based on the esterification of the carboxyl group of bile acids with *O*-(*p*-nitrobenzyl)-*N,N'*-diisopropylisourea (PNBDI). The bile acids in the biological samples were extracted by an Amberlite XAD-2 column, and separated by DEAE-Sepharose CL-6B into free, glycine- and taurine-conjugated bile acids. After separation, the free and glycine-conjugated bile acids were directly esterified with PNBDI. Taurine-conjugated bile acids are unable to be esterified with PNBDI, the bile acids were hydrolyzed with NaOH to produce the free bile acids, and then esterified. The *p*-nitrobenzyl ester of bile acids has a characteristic ultraviolet absorption. Consequently the compounds were separated into the individual bile acids by high performance liquid chromatography, and detected by an UV-detector. An analysis of the individual bile acids in human bile is given for an example.

Despite the progress in gas-chromatographic analysis for the estimation of free bile acids,[1,2] individual conjugated bile acids can not be separated by this method. Moreover, the preparation of samples for gas-chromatography is complicated, incurring difficulties both in precision and accuracy. A method has been developed using high performance liquid chromatography[3] to give data on conjugated as well as free bile acids in clinical medicine.

The *p*-nitrobenzyl esters of glycine-conjugated and free bile acids possess characteristic ultraviolet absorption spectra, and based on this an attempt to apply this special quality for the analysis of these bile acids has been conducted. Taurine-conjugated bile acids have been separated from free and glycine-conjugated bile acids by anion exchange column-chromatography with DEAE-Sepharose CL-6B. After collection of the taurine-conjugated bile acids, hydrolysis with NaOH at 120 °C, esterification was conducted with PNBDI as well as the free and glycine-conjugated bile acids.

Experimental

Apparatus. A Varian LC 8500 liquid chromatograph was used throughout this work and fitted with an UV detector (JASCO UVIDEC 100), and a gradient elution accessory. A μBondapak C_{18} column, commercially available from Waters Associates, was used for the analysis of the *p*-nitrobenzyl esters of bile acids.

Materials. The bile acids were obtained from Sigma, Calbiochem, and Katayama Kagaku Kogyo. PNBDI was obtained from Regis Chem. Amberlite XAD-2 and Amberlyst A-15 from Rohm and Haas. Amberlite XAD-2 was washed with methanol, acetone, and water. Amberlyst A-15 was thoroughly washed with 2 M NaOH in 70% aqueous ethanol and followed by 70% ethanol until the elutant was neutral. It was subsequently washed with 2 M HCl in 70% ethanol and followed by 70% ethanol until the elutant was again neutral. DEAE-Sepharose CL-6B was made into the acetic form with acetic acid in 70% ethanol.

Procedure. Figure 1 outlines the analytical procedure. The mixture of 12 each individual bile acids (1 mg), free, glycine and taurine-conjugated, was dissolved in 0.1 M NaOH (10 ml) in saline and the solution agitated ultrasonically for 15 min. The solution was then applied to the column of Amberlite XAD-2[4] in water (1.0 g). The sample was allowed to flow through the column (100 mm/5 mm i.d.) at a rate of about 0.2 ml/min. The column was then washed with water until neutal and the bile acids eluted with methanol (30 ml). The elutant was then evaporated to dryness *in vacuo* at 50 °C, and the residue dissolved in 72% ethanol (30 ml). This was filtered through a column of Amberlyst A-15 in the H^+ form which removed interfering cations. The effluent from the column was passed through a column of DEAE-Sepharose CL-6B in the acetate form. Free bile acids passed directly through this column and were recovered in the first fraction (A). Glycine-conjugated and a small amount of the free bile acids were eluted with 0.1 M acetic acid in 72% ethanol (B). The taurine-conjugated bile acids were eluted with 0.15 M ammonium acetate (pH 6.6) in 72% ethanol (C). The separation was quantitative with minimal overlap between groups. The fractions were taken to near dryness on a rotary evaporator.

Fractions A and B were dissolved in 0.1 M NaOH (10 ml) in saline. The mixture of fraction A and B was allowed to flow through the column XAD-2 and after elution with methanol (30 ml), the elutant was evaporated to dryness. The residue was dissolved in water (10 ml), and the solution passed over a column of CM-Cellulose (1.0 g) in order to obtain the free acid from sodium salt. The flask used in the evaporation was washed subsequently with water (10 ml), ethanol (2 ml) and water (10 ml), and then each fraction passed through the column. The final volume of collected elutant was 30 ml. The solution was evaporated to dryness *in vacuo*.

Fraction C was dissolved in 7.5% NaOH (15 ml), and then hydrolyzed in a sealed tube at 120 °C for 4 h, since taurine-conjugated bile acids are unable to be esterified with PNBDI. After the hydrolysis, the hydrolysate was directly applied to the column of XAD-2, and the bile acids extracted with methanol (30 ml). After evaporation of the extract, the residue was dissolved in water (10 ml), and passed through a column of CM-Cellulose. The elutant was collected and evaporated to dryness. The bile acids in the mixture of fraction A and B, and the bile acids in fraction C were esterified with PNBDI in *t*-butyl alcohol (1 ml) for 24 h at room-temperature, as shown in Fig. 2.

The bile acid derivatives were treated with 0.1 M HCl

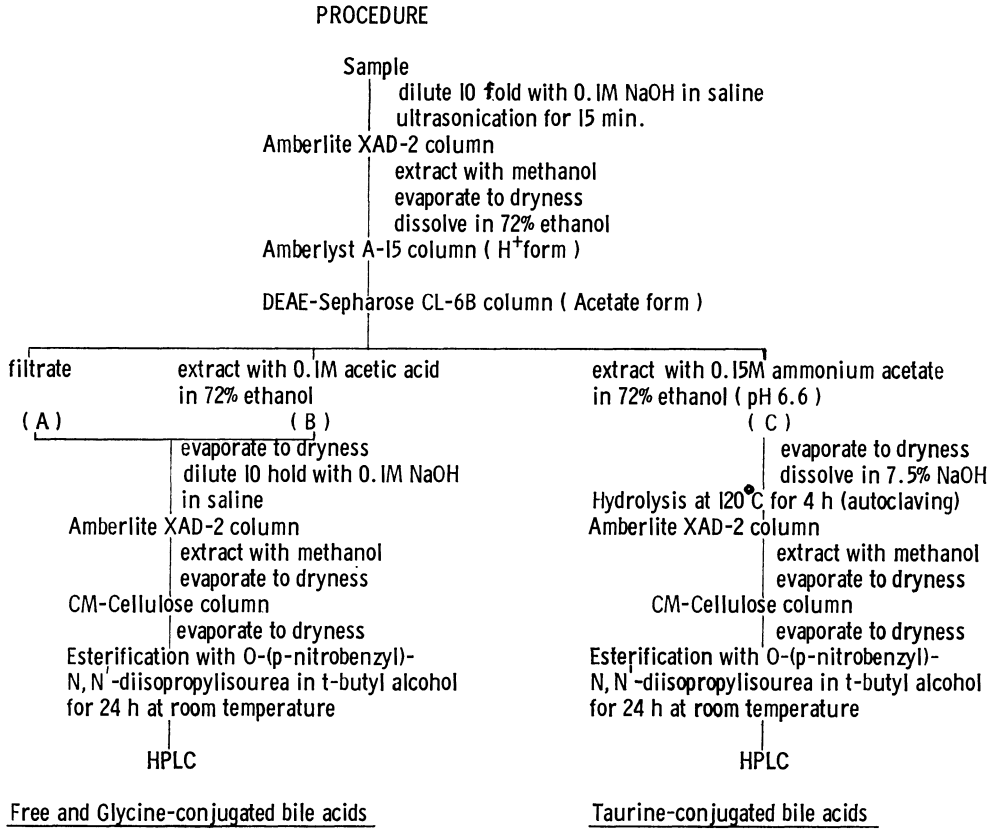

Fig. 1. The outline of analytical procedure of bile acids.

and water, and then analyzed by high performance liquid chromatography.

Operating Conditions. The conditions are shown in Table 1. The sample was injected with a microsyringe.

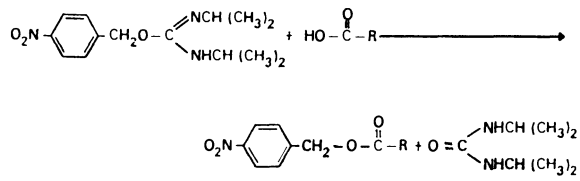

Fig. 2. The esterification reaction of bile acids with PNBDI.

Results and Discussion

High Performance Liquid Chromatographic Analysis of Bile Acids. The high performance liquid chromatographic separation of the *p*-nitrobenzyl esters of the individual free and glycine-conjugated bile acids is shown in Fig. 3. The quantity of each bile acid was

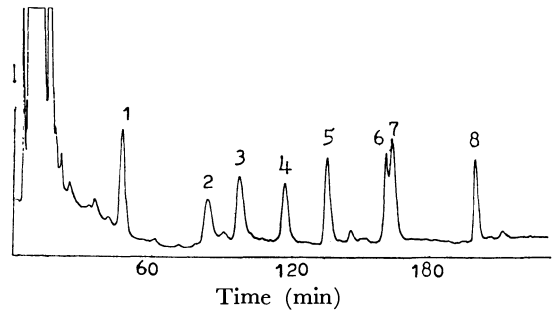

Fig. 3. High performance liquid-chromatographic separation of individual free and glycine-conjugated bile acids.

Bile acids

1.	glycocholic acid	GC
2.	glycochenodeoxycholic acid	GCDC
3.	glycodeoxycholic acid	GDC
4.	cholic acid	C
5.	glycolithocholic acid	GLC
6.	chenodeoxycholic acid	CDC
7.	deoxycholic acid	DC
8.	lithocholic acid	LC

6 μg. Each peak was identified by the addition of the *p*-nitrobenzyl ester of each authentic bile acid respectively. The separation between deoxycholic acid and chenodeoxycholic acid however was not sufficient.

High Performance Liquid Chromatographic Analysis of Bile Acids in Human Bile. Bile (1 ml), obtained by autopsy from a patient with obstructive jaundice due to cancer of pancreas head, was used in this experiment. Figure 4 shows the chromatogram of the free and glycine-conjugated bile acids in bile. The peaks were identified by the retention times. Figure 5 shows the chromatogram of taurine-conjugated bile acids in human bile. Since taurine-conjugated bile acids were hydrolyzed, each peak of the taurine-conjugated bile acid appears as the peak of the corresponding free bile acid. The concentration of individual bile acids in human bile is shown in Table 2. The total bile acid concentration in bile was 14.64 μM/ml, free 3.74 μM/ml, glycine-conjugated 8.08 μM/ml, taurine-conjugated 2.82 μM/ml. Accordingly glycine- and taurine-conjugated bile acids occupied 74% of the total bile acid in this human bile. The ratio of glycine-conjugated bile acid to taurine-conjugated bile acid (G/T) was 2.78.

The abbreviations of individual taurine-conjugated bile acids are expressed as follows:

taurcholic acid (TC)
taurochenodeoxycholic acid (TCDC)
taurodeoxycholic acid (TDC)
taurolithocholic acid (TLC)

$$\frac{C+GC+TC}{CDC+GCDC+TCDC} = 1.46$$

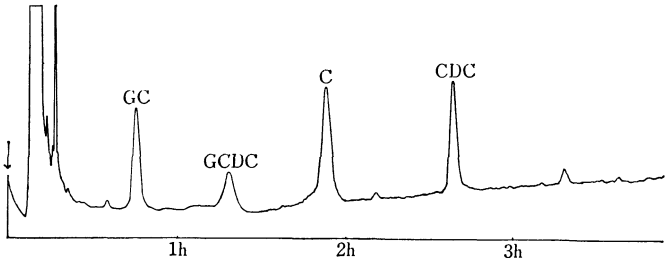

Fig. 4. High performance liquid-chromatographic analysis of free and glycine-conjugated bile acids in human bile.

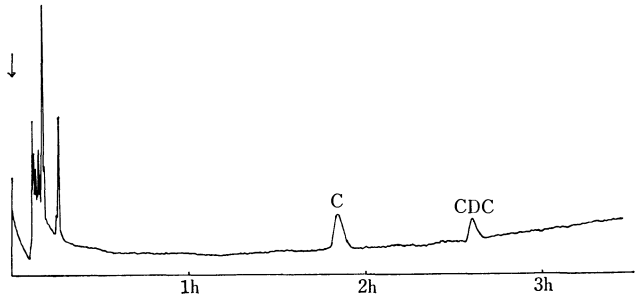

Fig. 5. High performance liquid-chromatographic analysis of taurine-conjugated bile acid in human bile.

Table 2. Bile acid in bile of a patient with obstructive jaundice due to pancreas head cancer

	Concentration in bile μM/ml
GC	4.93
GCDC	3.15
	8.08
TC	1.89
TCDC	0.93
	2.82
C	1.86
CDC	1.88
	3.74
Total	14.64

$\frac{C}{CDC}$	0.99	$\frac{GC}{GCDC}$	1.57	$\frac{TC}{TCDC}$	2.03
$\frac{GC+TC}{GCDC+TCDC}$	1.67	$\frac{C+GC+TC}{CDC+GCDC+TCDC}$			1.46
$\frac{\text{Conjugated}}{\text{Total}}$	0.74	$\frac{G}{T}$	2.78		

Significantly it means in obstructive jaundice that

$$\frac{C+GC+TC}{CDC+GCDC+TCDC}$$

is greater than 1.0.

Conclusion

The procedures described here make possible the individual separation of the conjugated and free bile acids. However, in order to complete the separation between DC and CDC in free bile acids, it is necessary to examine the conditions of the mobile phase and column. The investigation for the micro-determination of individual bile acids is in progress.

The development of the quantitative analysis of individual conjugated and free bile acids by high performance liquid chromatography may extend the value of bile acid studies in the clinical investigation of hepatobiliary disease.

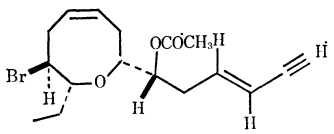
Synthetic Studies of Laurencin and Related Compounds. IV.[1] Synthesis of *cis*-2-Ethyl-8-formyl-3,4,7,8-dihydro-2*H*-oxocin-3-one 3-Ethylene Acetal and Related Compounds

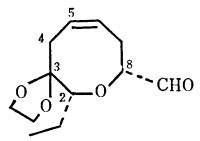
Tadashi MASAMUNE,* Hajime MATSUE, and Hisashi MURASE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 11, 1978)

The synthesis of *cis*-2-ethyl-8-formyl-3, 4, 7, 8-dihydro-2*H*-oxocin-3-one and its derivatives, key intermediates for synthesis of laurencin, from methyl 2-ethyl-2,5-dihydro-2-furoates is described. The structure and configuration of these compounds and the synthetic intermediates are defined clearly on the basis of the chemical and spectral evidence.

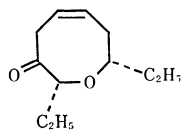
Laurencin[2] (**1**) and related compounds are a group of naturally occurring halogeno compounds with (a) medium-sized ether ring(s) as well as an enyne moiety, and the structure and configuration have been established well.[3] In recent communications[1,4] we reported the synthesis of the title compound (**2**) and its transformation into (±)-laurencin. The present paper describes details of the synthesis of the key intermediate (**2**) and related compounds.



1



2



3a *cis*
3b *trans*

The synthesis of *cis*-2-ethyl-8-formylhydrooxocinone ethylene acetal (**2**) and related compounds was carried out in an analogous manner to that of the corresponding *cis*- and *trans*-2,8-diethylhydrooxocinones[5] (**3a** and **3b**), and hence required preparation of 4-ethyl-2-formyl-9-methyl-3-oxa-9-azabiocyclo[3.3.1]nonan-7-ones or their synthetic equivalents, *e.g.*, 2-acetoxymethyl-4-ethyloxaazabicyclononanones (**4**). These relevant intermediates were finally prepared by the Robinson-Schöpf condensation as described below.

The Birch reduction of 5-ethyl-2-furoic acid followed by esterification produced a 1:1 mixture of methyl *cis*- and *trans*-5-ethyl-2,5-dihydro-2-furoates[6] (**5**), which were reduced with lithium aluminium hydride to give the corresponding alcohols (**6**) in good yield. The alcohols (**6**) were submitted to ozonolysis at −70 °C in methanol, and the resulting dialdehyde mixture was immediately treated with methylamine and acetonedicarboxylic acid under the Robinson-Schöpf conditions (room temp, pH 5, 2 d). Total basic products were treated with acetic anhydride in pyridine and then purified by chromatography, giving a 3:2:1 mixture of the relevant oxaazabicyclononanones (**4a**, **4b**, and **4c**) in 7.8% yield from **6**. Further purification by column chromatography and subsequent preparative TLC effected isolation of each stereoisomer (**4a**), mp 76—78 °C, (**4b**), oil, and (**4c**), oil, in 2.2, 0.4, and 0.2% yields, respectively. In accordance with the assigned (planar) structure, each compound had the same molecular formula $C_{13}H_{21}O_4N$, and displayed ester and ketone carbonyl bands near 1730 and 1710 cm^{-1} and the same fragmentation peaks at *m/e* 225 (M^+), 196, 138, 111, and 110 in the IR and mass spectra. The configuration in question of these bicyclononanones was elucidated on the basis of the NMR spectra, which are summarized in Table 1 with those of the related compounds, 2-(acetoxymethyl)-oxaazabicyclononanones (**7a** and **7b**) (*cf.*, Experimental).

5 R=$COOCH_3$ (*cis* and *trans*)
6 R=CH_2OH (*cis* and *trans*)

As shown in Table 1, all compounds (**4a**—**4c**, **7a** and **7b**) revealed the following coupling constants; $J_{1,8a}=J_{5,6a}=6$ Hz and $J_{1,8e}=J_{5,6e}\fallingdotseq 0$ Hz. These constants indicated that the dihedral angles between the proton at C_1 (C_5) and the equatorial and axial protons at C_8 (C_6) would be about 90 and 30°, respectively. Judging from these values as well as the previous result,[5,7] the piperidone ring would exist as a slightly deformed chair form. On the other hand, the coupling constants $J_{1,2e}$, $J_{1,2a}$, $J_{5,4e}$, and $J_{5,4a}$ were small for these compounds. Such constants were also observed in the NMR spectra of several 3-oxabi-

cyclo[3.3.1]nonane derivatives,[8] which also adopt a double-chair conformation. The spectral similarity between these compounds, coupled with our previous result on the conformation of 9-methyl-9-aza-3-oxabicyclo[3.3.1]nonan-7-one (**8**) and its 2,5-diethyl derivatives[5] (**9a** and **9b**), indicated that all the compounds would probably take a double-chair conformation. This assignment was confirmed by the X-ray crystallographic analysis of 2-acetoxymethyl-4-ethyloxaazabicyclononanone (**4a**),[9] one of the most important key compound; namely, in spite of the presence of 2,4-diaxial substitutents, the compound (**4a**) exists in the double-chair conformation, as illustrated in Fig. 1.

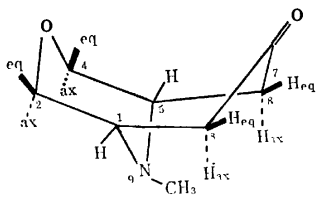

Fig. 1.

Stereochemistry of the substituent(s) at C_2 and/or C_4 in compounds **4b**, **4c**, **7a**, and **7b** was deduced from the chemical shift and signal pattern of the ethyl methylene and acetoxymethyl methylene protons. Signals due to the acetoxymethyl methylene protons of **4a**, **4b**, and **7a** were very similar each other; two double doublets (one with J=11 and 5—6 Hz and another with J=11 and 7.5—8 Hz, *cf*, Table 1) appeared at δ 4.38 and 4.18, at δ 4.69 and 4.22, and at δ 4.68 and 4.23, respectively. To the contrary, the corresponding protons of **4c** and **7b** were observed as broad singlets at higher field, δ 4.00 and 3.98, respectively. The striking difference in chemical shift and splitting pattern indicates that the acetoxymethyl methylene protons of the former three oxaazabicyclononanones (**4a**, **4b**, and **7a**) are disposed 1,3-diaxially with the nitrogen lone pair electrons[10] and free rotation of the acetoxymethyl group would be hindered. The same discussion holds for the ethyl groups of compounds **4a**—**4c**, **9a**, and **9b**; absorption peaks due to the ethyl methylene protons of **4a**, **4c**, and **9a** were observed at lower field than δ 1.58, while those of **4b** and **9b** at higher field than δ 1.40. In summary, all the compounds in Table 1 are represented by the respective assigned configurations and conformations, which would be interpreted well as the result of interaction between the ether oxygen and carbonyl carbon atoms.[11]

Treatment of *cis*-2-acetoxymethyl-4-ethyloxaazabicyclononanone (**4a**) with tosylhydrazine in acidic tetrahydrofuran under reflux and then with methyllithium in benzene and ether[12] produced olefinic alcohols (**10**), which were converted into a crystalline mixture of methiodides (**11a** and **11b**) in good yield. The methiodides, when eluted through Amberlite IRA-400 and then heated at 60—80 °C, underwent the Hofmann elimination with concurrent facile 1,5-sigmatropic hydrogen transfer to give a mixture of dienamines (**12a** and **12b**). The dienamine mixture, without isolation, was hydrolyzed in 7% fluoroboric acid under reflux to yield a mixture of keto alcohols (**13a** and **13b**), which were purified by column chromatography to give **13a** and **13b** in pure state in 32

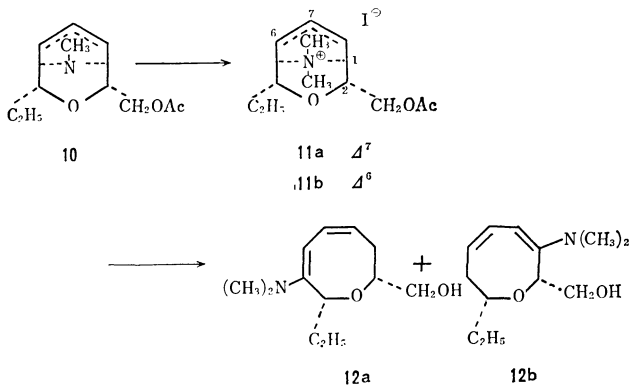
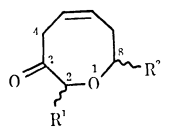
a) The spectra were measured in $CDCl_3$ at 100 MHz, and the abbreviations "H_{2e} and $J_{1,2e}$" refer to "equatorial proton at C_2 and coupling constant between H_1 and H_{2e}," respectively. b) The chemical shifts of N-CH_3 (s), acetoxyl methyl (s) and ethyl methyl protons (t, J=6.5—7.0 Hz) fell within δ 2.49—2.61, 2.02—2.05, and 0.85—0.93, respectively. c) The coupling constans were estimated by first-order approximations. d) The geminal couplings followed as: $J_{6a,6b}$ and $J_{8a,8e}$ were 15—16 Hz for all compounds, $J_{4a,4e}$ 11—11.5 Hz for **7a** and **7b**, and J_{AB} (CH_AH_BOAc) 11 Hz for **4a**, **4b**, and **7a**, respectively.

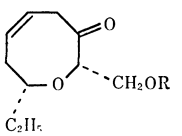
and 13% yields (from the total methiodides), respectively. The structure of these ketones was assigned on the basis of the spectral data.



10 11a Δ^7 11b Δ^6 12a 12b

Compound **13a**, $C_{10}H_{16}O_3$ [MS, *m/e* 184 (M^+)], exhibited absorption maxima at 294 nm (ε 147, sh), 303 (173), 312 (161), and 323 (84, sh) with enhanced intensity due to the n-π^* transition, characteristic for β,γ-unsaturated carbonyl chromophores, and those at 3480 (OH), 1720 (C=O), and 1645 (C=C) cm^{-1} in the UV and IR spectra, respectively. Compound **13b** also displayed essentially the same mass, UV, and IR spectra as **13a**, indicating both the compounds to be isomers. The NMR spectra, coupled with the spin decoupling studies, provided definite evidence for disposition of the carbonyl groups in both the compounds (**13a** and **13b**). In the spectrum of **13a**, a double doublet (J=5 and 7 Hz) at δ 3.82 [C_2H_5-C<u>H</u>(O)–] was simplified to a singlet on irradiation at δ 1.70 ($CH_3C\underline{H}_2$–), but remained unchanged on that near δ 2.3 (–$C\underline{H}_2CH$=CH–). On the other hand, a double double doublet (J=2, 6, and 12 Hz) at δ 3.40 [$C_2H_5C\underline{H}$(O)–] in the spectrum of **13b** was collapsed to a broad doublet (J=6 Hz) and to a double doublet (J=6 and 12 Hz) on irradiation at δ 1.62 ($CH_3C\underline{H}_2$–) and near δ 2.3 (–$C\underline{H}_2CH$=CH–), respectively. The result reveals the presence of partial formulas $C_2H_5\underline{C}H(-O-)C(=O)-$ and $C_2H_5\underline{C}H-O-CH_2CH=CH-$ in **13a** and **13b**, respectively, confirming the assigned structures.



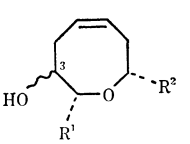


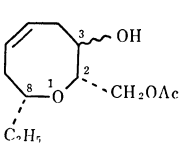
13a R^1=···C_2H_5, R^2=—CH_2OH
15a R^1=···C_2H_5, R^2=—CH_2OAc
13c R^1=—C_2H_5, R^2=···CH_2OH
14a R^1=R^2=···C_2H_5
14b R^1=···C_2H_5, R^2=—C_2H_5

13b R=H
15b R=Ac

Repetition of the aforementioned sequence on a 2:2:1 mixture of the oxaazabicyclononanones (**4a**, **4b**, and **4c**), free from pure **4a**, led to formation of a mixture of β,γ-unsaturated ketones, from which compounds **13a** and **13b** and a new compound (**13c**) were isolated in 6, 3, and 2% yields, respectively. The compound (**13c**) revealed essentially the same mass, UV, and IR spectra as **13a**, and also exhibited two characteristic double doublets (one with J=14 and 4 Hz and another with J=14 and 2 Hz) at δ 3.08 and 3.44 in the NMR spectrum. These signals are corresponding to the following peaks due to the C_4-protons of **13a**, *cis*- and *trans*-2,8-diethyltetrahydrooxocins[5] **14a** and **14b**: **13a**, δ 2.82 and 3.86 (each J=12 and 6 Hz); **14a**, δ 2.77 and 3.82 (each J=13 and 6 Hz); **14b**, δ 2.93 and 3.52 (J=16, 3 and 16, 2 Hz).[5] The spectral similarity indicated that the new compound (**13c**) would be a stereoisomer of **13a**. Indeed, compound **13c** was converted by treatment with base under mild conditions into **13a** quantitatively. The low yields of these unsaturated ketones would result from difficult separation of the products and also incomplete 1,5-hydrogen transfer in aminodienes (to dienamines corresponding to **12** derived from the *trans*-oxaazabicyclononanones (**4b** and **4c**).

Before proceeding with the synthesis, we examined the stereochemistry of reduction of the carbonyl group of the tetrahydrooxocinones. Compound **13a** was converted into the acetate (**15a**), which on treatment with sodium borohydride gave hydroxy acetate (**16**) in 60% yield as an isolable main product. The compound (**16**) showed a double doublet (J=12 and 8 Hz) at δ 2.62 in the NMR spectrum, which was attributed to one of the C_4-protons. In view of the different signal pattern due to the corresponding proton of laurencin (**1**) (δ 3.2, do do d, J=3, 7, and 13 Hz),[2] the alcohol (**16**) was suggested to possess all *cis*-configuration concerning the substituents at C_2, C_3, and C_8. In order to ascertain this assignment, the isomeric *cis*-2-hydroxymethyl-8-ethyltetrahydrooxocinone (**13b**) was likewise converted into the acetate (**15b**) and then reduced with the hydride reagent to give a 1:1 mixture of new hydroxy acetates (**17a** and **17b**), which could be isolated by column chromatography. The NMR spectrum of more polar alcohol (**17b**) revealed two characteristic peaks at δ 2.81 (do do d, J=3, 7, and 13 Hz) and 3.80 (do t, J=9, 3, and 3 Hz), which were ascribed to one of the C_4-protons and a proton on the carbon (C_3) bearing the hydroxyl group, respectively. These absorption patterns were practically the same as those of the corresponding protons (do do d, J=3, 7, and 13 Hz, and do t, J=9, 3, and 3 Hz)[2] of laurencin (**1**). On the other hand, the relevant proton at C_4 of less polar alcohol (**17a**) appeared at δ 2.64 as a double doublet (J=12 and 8 Hz) in the spectrum. All these splitting patterns, combined with the previous result [the C_4-proton in question of two reduction products, major (**18a**) and minor (**18b**), from *cis*-diethyltetrahydrooxocinone (**14a**) [δ 2.63 (do d, J=8 and 12 Hz) for **18a**, and δ 2.82 (do do d, J=3, 7, and 13 Hz) for **18b**][5] indicate that all-cis assignment to the three substituents at



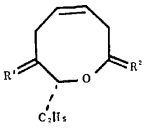


16 R^1=C_2H_5, R^2=CH_2OAc, 3α-OH
18a R^1=R^2=C_2H_5, 3α-OH
18b R^1=R^2=C_2H_5, 3β-OH

17a 3α-OH
17b 3β-OH

C_2, C_3, and C_8 of alcohol **16** is correct. The predominant formation of all-*cis*-substituted alcohol (**16**) would be convenient for substitution of the hydroxyl group to a bromine atom with the desired configuration by triphenylphosphine and carbon tetrabromide, because the bromination usually proceeds in S_N2 manner.[13]

Compound **13a** was transformed into several derivatives including the title compound (**2**). Acetalization of **13a** under usual conditions gave the ethylene acetal (**19**) in quantitative yield. The NMR spectrum revealed two double doublets (each $J=13$ and 8 Hz) due to the C_4-protons at δ 2.89, indicating that the double bond at C_5 and C_6 did not migrate during the reaction. Oxidation of **19** with chromium(VI) oxide and pyridine in dichloromethane[14] afforded crystalline aldehyde, the title compound (**2**), mp 73—74 °C, in quantitative yield, whose spectra were completely consistent with the assigned structure. On the other hand, treatment of **2** with 1 equiv of 1,2-ethanedithiol in the presence of boron trifluoride in dichloromethane resulted in thioacetalization with concomitant hydrolysis of the acetal group at C_3 to give monothioacetal (**20**), showing a β,γ-unsaturated carbonyl band at 1720 cm^{-1} in the IR spectrum. The compound (**20**) also exhibited two double doublets (each $J=13$ and 6 Hz) due to the relevant C_4-protons at δ 2.86 and 3.82, indicative of retention of the relative configuration of the substituents at C_2 and C_8.[5] The same treatment of **2** with 2 equiv of ethanedithiol led to formation of bis(dithioacetal) (**21**), while the mono(dithioacetal) (**20**) was converted into acetal dithioacetal (**22**), showing two double doublets (each, $J=13$ and 9 Hz) at δ 2.15 and 2.89 in the NMR spectrum. All these compounds (**2**, **20**—**22**) possess all functional groups convertible into those of laurencin (**1**), and hence the present result implies the synthesis of most appropriate intermediates leading to the natural product (**1**) as described in the following paper.



2 $R^1=OCH_2CH_2O$, $R^2=$—H, ···CHO
19 $R^1=OCH_2CH_2O$, $R^2=$—H, ···CH_2OH

22 $R^1=OCH_2CH_2O$, $R^2=$—H, ···CH(S—)(S—)

Experimental

All the mps and bps were uncorrected. The homogeneity of each compound was always checked by TLC over silica gel (Wakogel B-5) and/or GLC (Hitachi K-53) over 10% SE-30. Column chromatography was carried out over silicic acid (Merck, Kieselgel 60, 70—230 mesh) and/or alumina (Merck, standard, Active I and II—III). The UV, IR, and NMR (100 MHz) spectra were measured in 2,2,4-trimethylpentane, in liquid state, and in chloroform-*d*, respectively, unless otherwise stated. The abbreviations "s, d, t, q, qui, m, br, do, and sh," in the NMR and IR spectra denote "singlet, doublet, triplet, quartet, quintet, multiplet, broad, double, and shoulder," respectively.

*5-Ethyl-2,5-dihydrofurfuryl Alcohols (**6**).* To a stirred slurry of lithium aluminum hydride (LAH, 6 g) in anhydrous ether (1.2 l) at 0 °C was added dropwise a solution of methyl 5-ethyl-2,5-dihydro-2-furoates[6] (**5**, 28 g) in ether (200 ml). The mixture was stirred at room temperature for 20 h, cooled, mixed with water (7.5 ml), 30% aq sodium hydroxide (7.5 ml) and then water (7.5 ml). The resulting inorganic salts were removed by filtration, and the filtrate was dried over anhydrous sodium sulfate and evaporated to leave oil, which was distilled to give **6** (11.3 g), bp 72—73 °C/15 Torr; MS, *m/e* 128 (M^+) and 99: IR (CCl_4), ν_{max} 3410, 1075, and 1030 cm^{-1}; NMR, δ 0.90 and 0.91 (total 3H, each t, $J=7$ Hz, $C\underline{H}_3CH_2$), 1.57 (2H, qui, $J=7$ Hz, $CH_3C\underline{H}_2$), 3.45 (1H, br, O$\underline{H}$), 3.57 (2H, br s, $C\underline{H}_2OH$), 4.85 (2H, m, 2$\underline{H}$ at C_2 and C_5), 5.78 and 5.91 (2H, ABq, $J=6$ Hz, 2$\underline{H}$ at C_3 and C_4). Found: C, 65.59; H, 9.47%. Calcd for $C_7H_{12}O_2$: C, 65.59; H, 9.44%.

*(2R,4R)-, (2S,4R)-, and (2R,4S)-2-Acetoxymethyl-4-ethyl-9-methyl-3-oxa-9-azabicyclo[3.3.1]nonan-7-ones (**4a**, **4b**, and **4c**).* Into a solution of **6** (29 g) in methanol (300 ml) or dichloromethane (300 ml) containing three drops of pyridine, cooled at −70 °C in a Dry Ice-ethanol bath, was passed ozonized oxygen gas, until the reaction mixture became blue. The mixture, while still at −70—−60 °C, was flushed with nitrogen for 10 min, when the blue color disappeared. After addition of dimethyl sulfide (20 ml) at the temperature, the mixture was stirred at −70—−30 °C for 30 min, then at ice-bath temperature for 2 h, and finally at room temperature for 1 h, and evaporated below 45 °C to leave oily residue containing dimethyl sulfoxide, which was treated with 25% aq acetic acid (40 ml) under reflux for 45 min and cooled to room temperature. To the solution was immediately added an aqueous solution (300 ml) containing sodium monohydrogenphosphate (4.25 g) and potassium dihydrogenphosphate (2.43 g), acetonedicarboxylic acid (36 g) and methylamine hydrochloride (16 g). The whole solution was adjusted to pH 5 with 6 M aq sodium hydroxide and stirred at room temperature for 2 d, the pH being maintained at 5.0 by occasional addition of citric acid. The solution was concentrated under reduced pressure to one-half of the volume, made acidic strongly by addition of concd hydrochloric acid and washed with ether (2×200 ml). The acidic aqueous solution was then made strongly basic with concd aq potassium hydroxide and extracted with chloroform (4×300 ml). The chloroform solutions were combined, dried and evaporated to leave oil (17.3 g). The oil was passed through a short alumina column (Merck, Active II—III, 60 g, benzene) to give oil (11.8 g), which was treated with acetic anhydride (48 g) and pyridine (120 ml). The resulting acetate mixture (14 g) was again passed through a short alumina column (45 g) to give oily basic material (12.3 g), which was purified by chromatography over silica gel (Merck, 250 g, benzene : acetone = 10 : 1) to yield a 3 : 2 : 1 mixture (3.55 g) of **4a**, **4b**, and **4c** (estimated by measurement of the NMR signals due to the C_2-protons). The mixture was further chromatographed over silica gel to give crystalline base, which was recrystallized from ether to yield **4a** (1.0 g), mp 76—78 °C. This was recrystallized from ether for analysis, mp 77—78.5 °C; mass (the text); IR (Nujol), ν_{max} 1730, 1710, 1240, 1160, and 1038 cm^{-1}; NMR (Table 1). Found: C, 60.98; H,

8.36; N, 5.51%. Calcd for $C_{13}H_{21}O_4N$: C, 61.15; H, 8.29; N, 5.49%.

A part (700 mg) of the residual oil (a 2 : 2 : 1 mixture of **4a**, **4b**, and **4c**), free from pure **4a**, was separated into two fractions by repeated preparative TLC over silica gel (benzene : acetone=9 : 1). Fractions (100 mg) with higher R_f value gave **4b** (95 mg), oil, showing a single spot; MS (the text), IR, ν_{max} 1730, 1710, 1240, 1160, and 1038 cm^{-1}; NMR (Table 1). Found: C, 61.28; H, 8.10; N, 5.31%. Calcd for $C_{13}H_{21}O_4N$: C, 61.15; H, 8.29; N, 5.49%. Fractions (520 mg) with lower R_f value were again purified by repeated preparative TLC (benzene : acetone= 9 : 1) to give **4c** (40 mg), oil, showing a single spot; MS (the text); IR, ν_{max} 1743, 1712, 1240, 1160, and 1038 cm^{-1}; NMR (Table 1). Found: C, 60.99; H, 8.32; N, 5.61%. Calcd for $C_{13}H_{21}O_4N_4$: C, 61.15; H, 8.29; N, 5.49%.

2,5-Dihydrofurfuryl Alcohol. To suspension of ether (1 l) and LAH (4.7 g) was added dropwise methyl 2,5-dihydro-2-furoate (20 g) in ether (100 ml). The mixture was allowed to stir overnight and then refluxed for 2 h. To the mixture were added water (5 ml), 30% aq sodium hydroxide (5 ml) solwly. After removal of the resulting inorganic salts by filtration, the filtrate was evaporated to leave oil, which was distilled to give the alcohol (11.3 g), bp 51—52 °C/15 Torr; MS, *m/e* 83 (M^+-CH_2OH); IR (CCl_4), ν_{max} 3400, 1090, and 1040 cm^{-1}; NMR, δ 3.12 (1H, br s, OH), 3.45 (2H, m, CH_2OH), 4.56 (2H, m, H at C_5), 4.70 (1H, m, H at C_2), 5.74 and 5.90 (2H, ABq, J=6.5 Hz, 2H at C_3 and C_4). Found: C, 59.87; H, 8.00%. Calcd for $C_5H_8O_2$: C, 59.98; H, 8.05%.

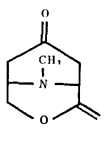
2-Acetoxymethyl-9-methyl-3-oxa-9-azabicyclo[3.3.1]nonan-7-ones (7a and 7b). Into a solution of 2,5-dihydrofurfuryl alcohol (11.3 g) and two drops of pyridine in dichloromethane (400 ml), cooled at −60—−70 °C, was passed ozonized oxygen, and the resulting blue reaction mixture was flushed with nitrogen at the temperature for 15 min. After addition of dimethyl sulfide (10 ml) at −60 °C, the mixture was stirred at −10 °C for 1 h, then at ice-bath temperature for 1 h and, finally, at room temperature for 1 h, washed with water (2×50 ml) and dried over sodium sulfate. No reaction product was obtained after removal of the dichloromethane. The aqueous washings were mixed with an aqueous solution (1.8 l) containing sodium monohydrogenphosphate (25.6 g), potassium dihydrogenphosphate (15 g), methylamine hydrochloride (26.4 g) and acetonedicarboxylic acid (53.2 g). The whole solution was adjusted to pH 5 by addition of 40% aq sodium hydroxide, and then stirred at room temperature for 2 d, the pH being maintained at 5.0 by occasional addition of citric acid. After being concentrated to one-half of the volume, the solution was made strongly acidic by addition of concd hydrochloric acid and washed with ether 2×200 ml). The aqueous solution was then made basic strongly with concd aq potassium hydroxide and extracted continuously with chloroform (1.6 l) for 48 h. The chloroform solution was washed with water, dried and evaporated to give oily residue (34.1 g), showing several spots on TLC (benzene : acetone= 3 : 1). The residue was separated into two fractions by column chromatography over alumina (500 g, benzene : methanol=60 : 5). Early fractions, eluted with benzene, gave 2-methylene-9-methyl-3-oxa-9-azabicyclo[3.3.1]nonan-7-one (**23**, 9.3 g), oil, showing a single spot on TLC; MS, *m/e* 167 (M^+), 124, and 110; IR, ν_{max} 1710, 1660, 1130, 1070, 1020, and 915 cm^{-1}; NMR, δ 2.34 and 2.40 (each 1H, br d, J=16 Hz, H_{8e} and H_{6e}), 2.60 (3H, s, NCH_3), 2.78 and 2.82 (each 1H, do d, J=16 and 6 Hz, H_{6a} and H_{8a}), 3.12 and 3.48 (each 1H, br d, J=6 Hz, H_5 and H_1), 3.80 and 4.19 (each 1H, br d, J=11 Hz, 2H at C_4), 4.25 and 4.50 (each 1H, ABq, J=9 Hz, CH_2=C_2). Rechromatography of the oil under the same conditions afforded an analytical sample of **23**. Found: C, 64.65; H, 7.84; N, 7.83%. Calcd for $C_9H_{13}O_2N$: C, 64.85; H, 8.07; N, 7.03%.

Later fractions, showing two major spots on TLC (benzene : acetone=3 : 1), gave oily substance (7.3 g), which was treated with acetic anhydride (30 ml) and pyridine (50 ml) at room temperature for 24 h. The acetates (7.8 g) were separated by chromatography over silica gel with benzene and acetone (9 : 1) to yield crystalline acetate (**7a**, 1.12 g), mp 105.5—108 °C, as an initial eluate. Recrystallization from hexane and ethanol gave an analytical sample of **7a**, mp 108—109 °C; MS, *m/e* 227 (M^+), 168, 124, and 110; IR ($CHCl_3$), ν_{max} 1730, 1710, and 1230 cm^{-1}; NMR (Table 1). Found: C, 57.83; H, 7.50; N, 6.14%. Calcd for $C_{11}H_{17}O_4N$: C, 58.13; H, 7.54; N, 6.16%. Oily acetate (**7b**), showing a single spot on TLC, was then eluted and purified by rechromatography to give an analytical sample of **7b**; MS, *m/e* 227 (M^+), 168, 124, and 110; IR ($CHCl_3$), ν_{max} 1730, 1710, and 1220 cm^{-1}; NMR (Table 1). Found: C, 57.83; H, 7.50; N, 6.14%. Calcd for $C_{11}H_{17}O_4$: C, 58.13; H, 7.54; N, 6.16%.

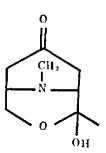
Acetates **7a** and **7b** were converted into the corresponding alcohols (**7a′** and **7b′**) by the method described below. To an ice-cooled solution of **7a** (280 mg) in ethanol (25 ml) was added sodium borohydride (NBH, 50 mg), and the mixture was stirred for 4 h at 0 °C. After addition of acetic acid (100 mg) and one drop of concd hydrochloric acid to decompose excess of NBH, the mixture was concentrated, made basic with aq sodium hydroxide and extracted with chloroform (2×40 ml). The chloroform solution was worked up as usual to give **7a′** (168 mg), which crystallized on trituration with ether and then recrystallized from ether to yield an analytical sample of **7a′**, mp 100—102 °C; MS, *m/e* 185 (M^+), 154, 128, and 110; IR ($CHCl_3$), ν_{max} 3330, 1710, 1100, and 1060 cm^{-1}; NMR, δ 2.26 (2H, d, J=15 Hz, H_{8e} and H_{6e}), 2.60 (3H, s, NCH_3), 2.75 and 2.80 (each 1H, do d, J=15 and 6 Hz, H_{6a} and H_{8a}), 3.58 (1H, d, J=11 Hz, H_{4e}), 3.65 (1H, do d, J=4 and 6 Hz, H_{2e}), 3.87 and 4.15 (each 1H, do d, J=4, 12 and 6, 12 Hz, CH_2OH), and 4.23 (1H, br d, J=11 Hz, H_{4a}). Found: C, 58.11; H, 8.23; N, 7.43%. Calcd for $C_9H_{15}O_3N$: C, 58.36; H, 8.16; N, 7.56%.

The isomeric acetate (**7b**, 240 mg) was converted into the alcohol (**7b′**, 130 mg), oil, in the same manner as described above, and showed the following spectra; MS, *m/e* 185 (M^+), 154, 128, and 110; IR ($CHCl_3$), ν_{max} 3330, 1710, 1100, and 1060 cm^{-1}; NMR, δ 2.22 and 2.25 (each 1H, br d, J=15 Hz, H_{6e} and H_{8e}), 2.62 (3H, s, NCH_3), 2.67 and 2.71 (each 1H, do d, J=15 and 6 Hz, H_{6a} and H_{8a}), 3.13 (2H, br d, J=6 Hz, 2H at C_1 and C_5), 3.60 (3H, m, H_{2a} and CH_2OH), 3.79 and 3.93 (each 1H, br d, J= 11 Hz, H_{4e} and H_{4a}).

2-Hydroxy-2,9-dimethyl-3-oxa-9-azabicyclo[3.3.1]nonan-7-one



23



24

(24). This compound was isolated in one run of the preceding Robinson-Schöpf condensation experiments, and the structure was confirmed by the hydration of **23** described below. Compound **23** (90 mg) in chloroform (30 ml) was treated with concd hydrochloric acid (2 ml) at room temperature for 20 min. After removal of the chloroform and subsequent addition of water (5 ml), the resulting aqueous solution was made basic with 6 M aq sodium hydroxide and extracted with chloroform (2×20 ml). The chloroform solution was worked up as usual to give crystalline alcohol (**24**, 71 mg), mp 97—99 °C; MS, *m/e* 185 (M^+) and 142; IR ($CHCl_3$), ν_{max} 3420, 1715, 1070, 1020, and 915 cm^{-1}; NMR, δ 1.30, (3H, s, $C\underline{H}_3$ at C_2), 2.19 (2H, br d, J=15 Hz $\underline{H}_{8e}$ and $\underline{H}_{6e}$), 2.52 and 2.63 (each 1H, br do d, J=15 and 6 Hz, $\underline{H}_{6a}$ and $\underline{H}_{8a}$), 2.55 (3H, s, $NC\underline{H}_3$), 2.99 (1H, d, J=11 Hz, $\underline{H}_{4e}$), 4.12 (1H, do do d, J=1, 2.5, and 11 Hz, $\underline{H}_{4a}$), and 4.95 (1H, br, O$\underline{H}$). An analytical sample of **24** was prepared by recrystallization from ether and hexane, mp 100—101 °C. Found: C, 58.14; H, 8.19; N, 7.69%. Calcd for $C_9H_{15}O_3N$: C, 58.36; H, 8.16; N, 7.56%.

cis-*3-Ethyl-2-hydroxymethyl-9-methyl-3-oxa-9-azabicyclo*[*3.3.1*]-*nonenes (10)*. A solution of **4a** (2.98 g) and tosylhydrazine (3.64 g) in THF (70 ml) containing a few drops of concd hydrochloric acid was heated under reflux for 12 h in a three-necked flask, fitted with a condenser and a magnetic stirring bar. After addition of benzene (250 ml) and removal of the condenser, the solution was concentrated to 70—80 ml, when the temperature of distillates had became near 80 °C, and then cooled in an ice-bath. To the concentrated solution was slowly added a solution of methyllithium, prepared from lithium (2.0 g) and methyl iodide (13 ml), in ether (210 ml). The whole mixture was stirred at room temperature for 20 h, and then washed with water. The aqueous washings were extracted with chloroform. All the organic (ether, benzene, and chloroform) solutions were combined, dried and evaporated to leave crude olefinic alcohol (3.1 g), most of which was used for the next reaction without further purification. A part of the crude sample of **10** was purified by preparative TLC (benzene : acetone=1 : 1) to give an almost pure sample, showing the following spectra; ν_{max} 3395, 1120, 1092, 1054, and 1040 cm^{-1}; NMR, δ 0.96 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 1.62 (2H, m, $CH_3C\underline{H}_2$), 2.40 and 2.42 (total 3H, each s, $NC\underline{H}_3$), and 5.75 (2H, br m, W_H=7 Hz, C$\underline{H}$=C$\underline{H}$).

cis-*2-Ethyl-8-hydroxymethyl- and* cis-*8-Ethyl-2-hydroxymethyl-3,4,7,8-dihydro-2*H-*oxocin-3-ones (13a and 13b), and Their Acetates (15a and 15b)*. 1) A solution of the crude olefinic alcohol (**10**, 3.0 g) in ethanol (80 ml) was refluxed with methyl iodide (62 ml) for 2 h and then evaporated to leave crystalline methiodides (3.65 g). Recrystallization from ethanol afforded a 1 : 8 mixture (crystals A, 1.33 g) of the methiodides (**11a** and **11b**), mp 213—124 °C, as the first crop; MS, *m/e* 197 (M^+-CH_3I), 142, 127, 108, and 94; IR (Nujol), ν_{max} 3330, 1200, 1172, 1140, 1108, 1045, and 995 cm^{-1}; NMR (D_2O), δ 1.28 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 2.05 (2H, m, $CH_3C\underline{H}_2$), 3.42 and 3.76 (each 3H, s, $2NC\underline{H}_3$), and 6.3 (2H, m, W_H=7 Hz, C$\underline{H}$=C$\underline{H}$). Found: C, 42.24; H, 6.56; N, 3.29; I, 37.19%. Calcd for $C_{12}H_{25}O_2NI$: C, 42.47; H, 6.48; N, 3.13; I, 37.45%.

An aqueous solution (20 ml) of crystals A (1.30 g) was passed through a column of Amberlite IRA-400 (basic form). The eluate was collected until it was no longer alkaline and evaporated under reduced pressure below 45 °C. The residual quaternary methohydroxides were decomposed by heating at 60—80 °C under reduced pressure for 45 min to give oil, which was extracted with ether (100 ml) and chloroform (100 ml). The solutions were combined, dried and evaporated to yield a 1 : 8 oily mixture (0.86 g) of *cis*-2-ethyl-8-hydroxymethyl-3-dimethylamino- and *cis*-8-ethyl-2-hydroxymethyl-3-dimethylamino-7,8-dihydro-2*H*-oxocins (**12a** and **12b**); IR, ν_{max} 3420, 1604 (dienamine), 1140, 1115, 1103, 1078, and 1043 cm^{-1}; NMR, δ 0.96 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 2.56 [6H, s, $N(C\underline{H}_3)_2$], 5.08 and 5.24 [total 1H (1 : 8), each d, J=4 Hz, $\underline{H}$ at C_4], 5.76 (1H, m, $\underline{H}$ at C_5), and 6.16 (1H, do d, J=4 and 10 Hz, $\underline{H}$ at C_6).

The mother liquors, obtained on removal of crystals A, were evaporated to give an 8 : 1 semi-crystalline mixture (crystals B, 2.20 g) of **11a** and **11b**, which was submitted to the same treatment as crystals A to yield an 8 : 1 oily mixtre (1.94 g) of **12a** and **12b**; IR, ν_{max} 3420, 1064 (dienamine), 1140, 1115, 1103, and 1078 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 1.72 (2H, m, $CH_3C\underline{H}_2$), 2.56 [6H, s, $2N(C\underline{H}_3)_2$], 5.08 and 5.24 [total 1H (8 : 1), each d, J=4 Hz, $\underline{H}$ at C_4], 5.70 (1H, m, $\underline{H}$ at C_5), and 6.18 (1H, do d, J=4 and 10 Hz, $\underline{H}$ at C_6).

2) An aqueous solution (7 ml) of the 1 : 8 mixture (0.85 g) of **12a** and **12b**, obtained from crystals A, was refluxed with 42% fluoroboric acid (1.5 ml) for 15 min. The reaction mixture was cooled, neutralized with saturated aq sodium hydrogencarbonate, and extracted with ether (2× 100 ml) and dichloromethene (2×200 ml). The combined organic solution was dried and evaporated to leave oil (601 mg), showing two spots on TLC (benzene : ethyl acetate=3 : 1). The oil was separated roughly into three fractions by column chromatography over silica gel (20 g, benzene : ethyl acetate=7 : 1). More mobile fractions gave **13b** (180 mg), oil, showing a single spots; MS, *m/e* 184 (M^+), 155, and 125; UV, λ_{max} 304 nm (ε 132) (sh), 312 (165), 321 (161), and 332 (95) (sh); IR; ν_{max} 3480, 1718, 1642, 1115, and 1055 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 1.62 (2H, m, $CH_3C\underline{H}_2$), 2.40 (3H, m, 2$\underline{H}$ at C_7 and O$\underline{H}$), 2.86 and 3.96 (each 1H, do d, J=12 and 6 Hz, 2$\underline{H}$ at C_4), 3.40 (1H, do do d, J=12, 6, and 2 Hz, $\underline{H}$ at C_8), 3.80 (2H, m, $C\underline{H}_2OH$), 4.00 (1H, do d, J=5 and 7 Hz, $\underline{H}$ at C_2), and 5.70 (2H, m, 2$\underline{H}$ at C_5 and C_6). An analytical sample of **13b** was obtained by rechromatography over silica gel. Found: C, 64.94; H, 8.65%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%. Middle fractions (99 mg) was found to be a 1 : 1 mixture of **13a** and **13b**. Less mobile fractions afforded **13a** (43 mg), showing a single spot, oil; MS, *m/e* 184 (M^+), 155, and 125; UV (the text); IR, ν_{max} 3480, 1720, 1645, 1115, 1095, and 1055 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 1.70 (2H, m, $CH_3C\underline{H}_2$), 2.30 (3H, m, 2$\underline{H}$ at C_3 and O$\underline{H}$), 2.82 and 3.86 (each 1H, do d, J=12 and 6 Hz, 2H at C_4), 3.62 (3H, m, $\underline{H}$ at C_8 and $CH_2O\underline{H}$), 3.82 (1H, do d, J=7 and 5 Hz, $\underline{H}$ at C_2), and 5.70 (2H, m, 2$\underline{H}$ at C_5 and C_6). The oil was rechromatographed over silica gel for analysis. Found: C, 65.33; H, 8.95%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

An aqueous solution (10 ml) of the 8 : 1 mixture (1.93 g), of **12a** and **12b**, obtained from crystals B, was likewise treated with 42% fluoroboric acid (2 ml) under reflux for 15 min. The reaction mixture was cooled, neutralized with saturated aq sodium hydrogencarbonate, and extracted with ether (2×200 ml) and then with chloroform (2×200 ml). The combined organic solution was worked up as usual to leave oil (954 mg), which was purified by repeated chromatography over silica gel (25 g) with benzene and ethyl acetate (8 : 1) to yield **13a** (181 mg) and **13b** (24 mg) in pure state with a 1 : 1 mixture (48 mg) of **13a** and **13b**.

3) Compound **13a** (62 mg) was treated with acetic an-

hydride (0.6 ml) and pyridine (1 ml) at room temperature overnight. The solution was poured into ice-water (5 ml) and extracted with ether (2×200 ml). The ether solutions were combined, washed with 2 M hydrochloric acid (2×10 ml) and water (2×10 ml), dried and evaporated to leave oil (15a, 69 mg), showing a single spot; IR, ν_{max} 1750, 1725, 1230, 1115, and 1040 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, CH_3CH_2), 1.64 (2H, m, CH_3CH_2), 2.10 (3H, s, $OCOCH_3$), 2.30 (2H, m, 2H at C_7), 2.80 (1H, do d, J= 12 and 6 Hz, H at C_3), 3.68 (1H, m, H at C_8), 3.76 (1H, do d, J=7 and 4 Hz, H at C_2), 3.84 (1H, do d, J=12 and 6 Hz, H at C_4), 4.15 (2H, m, CH_2OCOCH_3), and 5.75 (2H, m, 2H at C_5 and C_6).

Compound **13b** (104 mg) was likewise converted into the acetate (**15b**, 110 mg); IR, ν_{max} 1750, 1725, 1225, and 1115 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, CH_3CH_2), 1.56 (2H, m, CH_3CH_2), 2.05 (3H, s, $OCOCH_3$), 2.31 (2H, m, 2H at C_7), 2.84 (2H, do d, J=6 and 12 Hz, H at C_4), 3.34 (1H, m, H at C_8), 3.99 (1H, do d, J=6 and 12 Hz, H at C_4), 4.23 (3H, m, H at C_2 and CH_2OCOCH_3), and 5.78 (2H, m, 2H at C_5 and C_6).

*trans-2-Ethyl-8-hydroxymethyl-3,4,7,8-dihydro-2H-oxocin-3-one (**13c**).* The 2 : 2 : 1 mixture (16 g) of oxaazabicyclononanones **4a**, **4b**, and **4c**, described in the previous section, was transformed in almost the same manner as **4a** to give a mixture of tetrahydrooxocinones, from which **4a** (0.6 g), **4b** (0.3 g), and a new compound (**13c**, 0.2 g) were isolated by repeated chromatography. Compound **13c** showed the following spectra: MS, *m/e* 184 (M^+), 155, and 125; UV, λ_{max} 292 nm (ε 80), 303 (95), 313 (85), and 324 (40) (sh); IR, ν_{max} 3360, 1715, 1665, 1110, and 1050 cm^{-1}; NMR, δ 1.02 (3H, t, J=7 Hz, CH_3CH_2), 1.71 (2H, m, CH_3CH_2), 2.15 (3H, m, 2H at C_7 and OH), 3.08 and 3.44 (each 1H, do d, J=14, 5 and 14, 2 Hz, 2H at C_4), 3.52 and 3.76 (each 1H, do d and d, J=11, 7 and 11 Hz, CH_2OH), 3.93 (1H, m, H at C_8), 3.96 (1H, do d, J=5 and 7 Hz, H at C_2), and 5.65 (2H, m, 2H at C_5 and C_6). An analytical sample of **13c** was prepared by rechromatography over silica gel. Found: C, 64.92; H, 8.16%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

Compound **13c** (9 mg) was stirred with 5% potassium hydroxide in methanol (4 ml) at room temperature for 20 min. The solution was diluted with water (20 ml) and extracted with ether (2×30 ml). The ether solution, after being worked up as usual, afforded oil (8 mg), which was identical with **13a** in all respects (TLC, IR, and NMR).

*8-Acetoxymethyl-2-ethyl-3,4,7,8-tetrahydro-2H-oxocin-3-ol (**16**).* Compound **15a** (72 mg) in methanol (12 ml) was reduced with sodium borohydride (NBH, 50 mg) at 0 °C for 40 min. The solution was made acidic with 2 M hydrochloric acid, concentrated and extracted with ether. The ether solution, after usual work-up, left oil (65 mg), which was purified by chromatography over silica gel (2 g) with benzene and ethyl acetate (6 : 1) to give **16** (36 mg), oil, showing a single spot on TLC; MS, *m/e* 170, 168 (M^+—CH_3COOH), 125, and 116; IR, ν_{max} 3400, 1745, 2130, and 1035 cm^{-1}; NMR, δ 0.96 (3H, t, J=7 Hz, CH_3CH_2), 1.55 (2H, m, CH_3CH_2), 1.85 (1H, s, OH), 2.96 (3H, s, $OCOCH_3$), 2.29 (3H, br m, 3H at C_4 and C_7), 2.62 (1H, do d, J=12 and 8 Hz, H at C_4), 3.43 (1H, do do d, J= 8, 5, and 1.5 Hz, H at C_2), 3.67 (2H, m, 2H at C_3 and C_8), 4.08 (2H, m, CH_2OCOCH_3), and 5.78 (2H at C_5 and C_6). The sample was rechromatographed for analysis. Found: C, 63.25; H, 8.85%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

*2-Acetoxymethyl-8-ethyl-3,4,7,8-tetrahydro-2H-oxocin-3-ols (**17a** and **17b**).* Compound **15b** (120 mg) was reduced with NBH (68 mg) in methanol (15 ml) at 0 °C for 40 min. The reaction mixture was made acidic (pH 4—5) with 2 M hydrochloric acid, concentrated and extracted with ether (2×50 ml). The ether solution was worked up as usual to leave oil (114 mg), showing two spots on TLC, which was separated roughly into three fractions by column chromatography over silica gel (3 g, benzene : ethyl acetate =7 : 1). Fractions with higher R_f value gave **17b** (25 mg), oil, showing a single spot; MS, *m/e* 170, 168 (M^+—CH_3COOH), 125, and 116; IR, ν_{max} 3480, 1745, and 1235 cm^{-1}; NMR, δ 0.96 (3H, t, J=7 Hz, CH_3CH_2), 1.46 (2H, m, CH_3CH_2), 2.05 (3H, s, $OCOCH_3$), 2.06 (1H, s, OH), 2.26 (3H, br m, 3H at C_4 and C_7), 2.64 (1H, do d, J=12 and 8 Hz, H at C_4), 3.03 (1H, m, H at C_8), 3.78 (2H, m, 2H at C_2 and C_3), 4.16 (2H, m, CH_2OCOCH_3), and 5.76 (2H at C_5 and C_6). Rechromatography afforded an analytical sample of **17b**. Found: C, 62.91; H, 8.90%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%. Middle fractions (38 mg) were a 1 : 1 mixture of **17b** and **17a**.

Fractions (24 mg) with lower R_f value gave **17a** (24 mg), oil, showing a single spot: MS, *m/e* 170, 168 (M^+—CH_3COOH), 125, and 116; IR, ν_{max} 3480, 1740, and 1230 cm^{-1}; NMR, δ 0.96 (3H, t, J=7 Hz, CH_3CH_2), 1.47 (2H, m, CH_3CH_2), 2.07 (3H, s, $OCOCH_3$), 2.08 (1H, s, OH), 2.26 (3H, br m, 3H at C_4 and C_7), 2.81 (1H, do do d, J=3, 7, and 13 Hz, H at C_4), 3.30 (1H, m, H at C_8), 3.50 (1H, do d, J=4.5 and 9 Hz, H at C_2), 3.80 (1H, do t, J=9, 3, and 3 Hz, H at C_3), 4.24 (2H, d, J= 4.5 Hz, CH_2OCOCH_3), and 5.83 (2H, m, 2H at C_5 and C_6). An analytical sample of **17a** was prepared by rechromatography. Found: C, 63.25; H, 8.80%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

*cis-2-Ethyl-3,3-ethylenedioxy-8-hydroxymethyl-3,4,7,8-tetrahydro-2H-oxocin (**19**).* Compound **13a** (35 mg) in benzene (13 ml) was refluxed with ethylene glycol (30 mg) and *p*-toluenesulfonic acid (2 mg) for 18 h, water being removed by azeotropization. The solution was worked up as usual to give **19** (34 mg), oil; MS, *m/e* 228 (M^+), 130, and 125; IR, ν_{max} 3460, 1160, 1120, and 1022 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, CH_3CH_2), 1.46 (2H, m, CH_3CH_2), 2.00 (1H, do d, J=13 and 8 Hz, H at C_4), 2.32 (3H, m, 2H at C_7 and OH), 2.89 (1H, do d, J=13 and 8 Hz, H at C_4), 3.60 (2H, br s, CH_2OH), 3.63 (2H, m, 2H at C_2 and C_8), 3.98 (4H, m, W_H=10 Hz, OCH_2CH_2O), and 5.83 (2H, m, 2H at C_5 and C_6). An analytical sample was prepared by rechromatography. Found: C, 63.35; H, 8.75%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

*cis-2-Ethyl-3,3-ethylenedioxy-3,4,7,8-tetrahydro-2H-oxocin-8-carbaldehyde (**2**).* A viscous mixture, prepared by addition of chromium(VI) oxide (1.0 g) to anhydrous pyridine (1.6 g) in dichloromethane (25 ml) under stirring, was stirred at room temperature for 15 min. To the mixture was added a solution of **19** (0.40 g) in dichloromethane (5 ml), when a tarry black deposit separated immediately. The whole mixture was further stirred for 15 min at room temperature and then decanted. The supernatant solution thus obtained, was washed with 5% aq sodium hydroxide (3×10 ml) and 5% hydrochloric acid (20 ml), dried and evaporated to yield crystalline aldehyde (**2**, 0.39 g), mp 71—73 °C, which was recrystallized from ether and hexane to give **2** (0.35 g), mp 73—74 °C: MS, *m/e* 197 (M^+—CHO) and 168; IR (Nujol), ν_{max} 2820, 1735, 1160, 1140, 1110, and 1025 cm^{-1}; NMR, δ 0.99 (3H, t, J=7 Hz, CH_3CH_2), 1.55 (2H, m, CH_3CH_2), 2.20 and 2.88 (each 1H, do d, J=13, 6 and 13, 8 Hz, 2H at C_4), 2.41 (2H, m, 2H at C_7), 3.64 (1H, do d, J=8 and 5 Hz, H at C_2), 3.70 (1H, t, J=6 Hz, H at C_8), 3.99 (4H, m, OCH_2CH_2O), 5.83 (2H, m, 2H at

C_5 and C_6), and 9.76 (1H, s, CHO). Found: C, 63.88; H, 7.99%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*cis-2-Ethyl-8-(ethylenedioxymethyl)-3,4,7,8-tetrahydro-2H-oxocin-3-one (**20**), and Its 3,3-Ethylenedithio-(**21**) and 3,3-Ethylenedioxy-(**22**) Derivatives.* A solution of **2** (181 mg) and 1,2-ethanedithiol (74 mg, 1 equiv) in dichloromethane (30 ml) was treated with boron trifluoride etherate (74 mg) for 3 h at 0 °C, and then poured into 5% aq sodium hydrogencarbonate. The dichloromethane solution was washed with saturated brine (2×10 ml), dried and evaporated to leave oil, showing three spots on TLC. The oil was separated into three fractions by column chromatography over silica gel (5 g, benzene). Fractions with higher R_f value gave **21** (11 mg), oil, showing a single spot on TLC; MS, *m/e* 334 (M^+) and 305; IR, ν_{max} 1099, 1065, and 1025 cm^{-1}; NMR, δ 1.12 (3H, t, J=7 Hz, CH_3CH_2), 1.85 (2H, m, CH_3CH_2), 2.31 (1H, do d, J=12 and 8 Hz, H at C_4), 2.56 (2H, m, 2H at C_7), 3.24 and 3.28 (each 4H, br s, $2SCH_2CH_2S$), 3.31 (1H, do d, J=12 and 8 Hz, H at C_4), 3.51 (1H, m, H at C_8), 3.70 (1H, do d, J=9 and 2 Hz, H at C_2), 4.65 (1H, d, J=6 Hz, SCHS), and 5.88 (2H, m, 2H at C_5 and C_6). The compound was obtained from **2** in 80% yield, when 2 equiv of ethanedithiol was used.

Middle fractions gave **20** (122 mg), oil, showing a single spot on TLC; MS, *m/e* 258 (M^+) and 229; IR, ν_{max} 1720, 1645, 1100, and 1020 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, CH_3CH_2), 1.70 (2H, qui, J=7 Hz, CH_3CH_2), 2.45 (2H, do d, J=7 and 4 Hz, 2H at C_7), 2.86 (1H, do d, J=13 and 6 Hz, H at C_4), 3.21 (4H, s, SCH_2CH_2S), 3.34 (1H, do d, J=7 and 4 Hz, H at C_8), 3.80 (1H, t, J=7 Hz, H at C_2), 3.82 (1H, do d, J=13 and 6 Hz, H at C_4), 4.58 (1H, d, J=8 Hz, SCHS), and 5.70 (2H, m, 2H at C_5 and C_6).

Fractions with lower R_f value afforded **22** (30 mg), oil, showing a single spot; MS, *m e* 302 (M^+) and 273; IR, ν_{max} 1159, 1130, 1103, and 1020 cm^{-1}; NMR, δ 1.04 (3H, t, J=7 Hz, CH_3CH_2), 1.54 (2H, qui, J=7 Hz, CH_3CH_2), 2.15 (1H, do d, J=13 and 6 Hz, H at C_4), 2.45 (2H, m, 2H at C_7), 2.89 (1H, do d, J=13 and 9 Hz, H at C_4), 3.20 (4H, s, SCH_2CH_2S), 3.44 (1H, do do d, J=8, 6.5, and 3 Hz, H at C_8), 3.63 (1H, t, J=7 Hz, H at C_2), 3.95 (4H, m, OCH_2CH_2O), 4.62 (1H, d, J=7 Hz, SCHS), and 5.78 (2H, m, 2H at C_5 and C_6). The compound (**22**) was obtained from **20** in 65% yield by the procedure similar to that used for the conversion of **13a** into **19**.

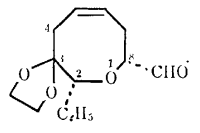
Synthetic Studies of Laurencin and Related Compounds. V.[1] Transformation of *cis*-2-Ethyl-8-formyl-3,4,7,8-dihydro-2*H*-oxocin-3-one 3-Ethylene Acetal into (±)-Laurencin

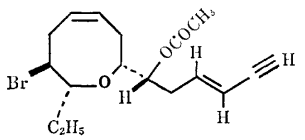
Tadashi MASAMUNE,* Hisashi MURASE, Hajime MATSUE, and Akio MURAI
Department of Chemistry, Faculty of Science, Hokkaido Uuiversity, Sapporo 060
(Received May 11, 1978)

Transformation of the title starting material into (±)-laurencin, which implies synthesis of the natural product, is described. The structure and configuration of synthetic intermediates are defined on the basis of the spectral evidence.

In the preceding paper[1] we reported the synthesis of *cis*-2-ethyl-8-formyl-7,8-dihydro-2*H*-oxocin-3(4*H*)-one 3-ethylene acetal (**1**). The present paper describes transformation of the aldehyde (**1**) into (±)-laurencin (±-**2**),[2a] which constitutes the first synthesis[2b] of a representative member of a group of naturally occurring halogeno compounds with (a) medium-sized cyclic ether skeleton(s) as well as an enyne moiety.[3]



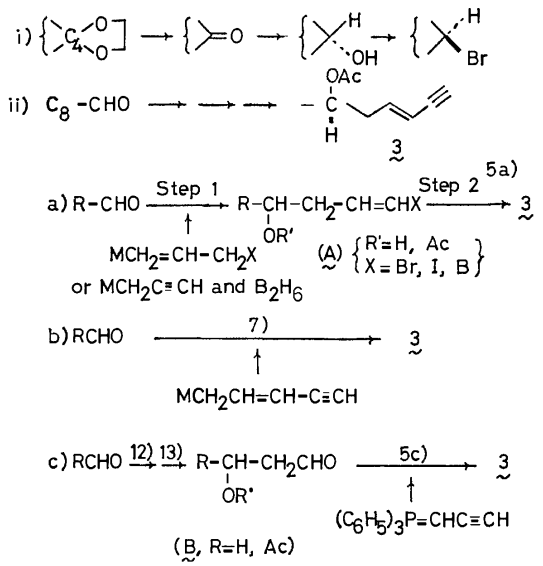
1



2

The transformation requires (i) conversion of the C_3-carbonyl group protected as the ethylene acetal in **1** into a bromine atom with the desired configuration (*trans* to the C_2-ethyl group), and (ii) that of the C_8-formyl into a 1-acetoxy-3-hexen-5-ynyl group (**3**). The former transformation (i) would probably proceed smoothly, apart from the yield, as had been illustrated in the synthesis of *t*-3-bromo-*r*-2,*c*-8-diethyl-3,4,7,8-tetrahydro-2*H*-oxocin[4] (**3**). On the other hand, many preparative methods for enyne units (-CH=CH-C≡CH) have recently been reported,[5] because the groups are characteristic of a number of natural products. A survey of literatures reveals that procedures applicable to the latter transformation (ii) are classified into three categories as shown in Scheme 1. The first route (iia) consists of at least two steps and involves groups of -CH(OR)CH_2CH=CHX (R=H or Ac, and X= Br, I, Cu, B, and so on) as the intermediates (**A**), which would be converted smoothly into the aimed group by various elegant methods[5a] (step 2). However, preparation of the intermediates (**A**), *e.g.*, by reaction of 3-halogeno-2-propenyl anions with the formyl group of **1** or by addition of 2-propynyl anion to the group followed by hydroboration, appeared to be considerably difficult owing to the possibility of allylic rearrangement or facile hydroboration to the *cis*-double bond in **1**.[6] This conceivable trouble led us to undertake syntheses by other routes.

The second route (iib) concerns the Grignard-type reaction of the formyl group with pentenynyl anions, obtained from 2-penten-4-ynyl halides and metals (Mg, Zn, and so on).[7] However, the reaction was reported to proceed with allylic rearrangement to give 2-ethynyl-1-hydroxy-3-butenyl groups, none of the products formed by expected addition of 2-penten-4-ynyl groups



Scheme 1. Possible routes from the aldehyde (**1**) into (±)-laurencin (±**2**).

being detected.[7] Nevertheless, in view of the fact that only a small amount of the starting aldehyde (**1**) is available, the route was very attractive in the sense of one-step synthesis of the aimed group, and the following model experiments were carried out. 2-Penten-4-yn-1-ol[8] (**4**) was converted into the pentenynyl phenyl sulfide (**5**) by reaction of the corresponding bromide[8] with sodium benzenethiolate, or into the 5-trimethylsilypentenynyl phenyl sulfide (**5a**) by bromination of 5-trimethylsilyl-2-penten-4-yn-1-ol[9] (**4a**) followed by reaction with sodium thiophenolate. Treatment of butanal with trimethylsilypentenynyl anions, prepared by reaction of **5a** with butyllithium (1 mol equiv) in tetrahydrofuran (THF) at −30 °C in the presence of 1,4-diazabicyclo[2.2.2]octane (Dabco),[10] at −50 °C for 1 h and subsequent removal of the trimethylsilyl group of the resultant addition products led to formation of a 1:5 (estimated by NMR) mixture of the expected alcohol, 5-phenylthio-6-nonen-8-yn-4-ol (**6**), and its rearranged isomer (**7**) in 26% yield from **5a**. On the other hand, the same treatment of butanal with pentenynyl anions, prepared from **5** and butyllithium (2 mol equiv) under almost the same conditions, produced a 1:1 mixture of **6** and **7** in 49% yield, from which *trans*-isomer (***t*-6**) and *cis*-isomer (***c*-7**) were isolated as the main products of the respec-

tive diastereoisomers. Compound ***t*-6** exhibited the following spectra as expected: UV, λ_{max} 217 nm (ε 16000); NMR, δ 2.96 (1H, d, 2 Hz, C≡C<u>H</u>), 5.32 and 6.10 (each 1H, do d, J=16 and 2 Hz, *trans*-C<u>H</u>=C<u>H</u>). The improved yield of **6** would be caused by *dianionic* character formed from the reactant (**5**). However, attempted selective reduction of the phenylthio group, *e.g.*, the Birch reduction, catalytic hydrogenation over Raney nickel, chemical treatment with aluminium amalgam or zinc and acetic acid, and so on, all failed; the reactions resulted in reduction of the triple bond or recovery of the starting material.

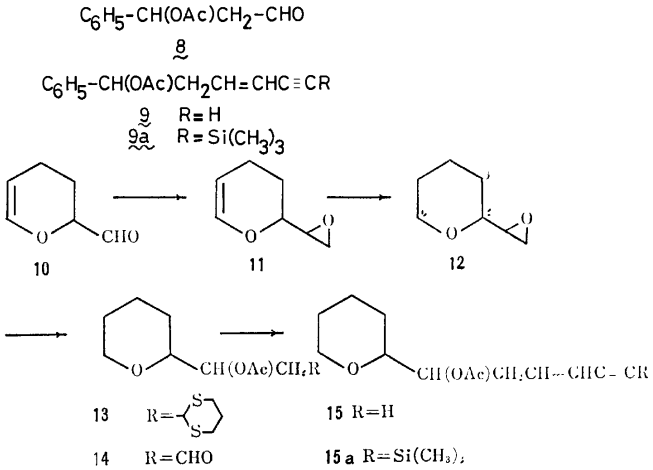
7

The desired transformation was achieved by the final route (iic), a stepwise synthesis by a modification of the Corey procedure.[5c] Before proceeding with the title aldehyde (**1**), several preliminary model experiments were carried out. The route (iic) in Scheme 1 involves β-acetoxy aldehydes as the key intermediates (**B**). Reaction of 3-acetoxy-3-phenylpropanal[11] (**8**), one of the β-acetoxy aldehydes, with triphenyl(3-trimethylsilyl-2-propynylidene)phosphorane at −78 °C in THF proceeded smoothly *without elimination of acetic acid* to give a trimethylsilyl enyne compound (**9a**) in 58% yield, which on treatment with sodium hydroxide followed by acetylation afforded acetoxy *trans*-hexenyne (**9**) in 77% yield. The NMR spectrum was consistent with the structure: δ 2.80 (1H, d, J=2 Hz, C≡C<u>H</u>), 5.50 and 6.10 (each 1H, do d and do t, J=16, 2 and 16, 7, 7 Hz, *trans*-C<u>H</u>=C<u>H</u>). The route (iic) also requires extension of a formyl group to 1-acetoxy-3-oxopropyl group(s), β-acetoxy aldehyde(s) (**B**). Treatment of 3,4-dihydro-2*H*-pyran-2-carbaldehyde ("acrylaldehyde dimer") (**10**), which possesses an ether oxygen atom at β-position to the formyl group and hence is suitable for a model compound of the title aldehyde (**1**), with dimethylsulfinylmethanide in dimethyl sulfoxide (DMSO) or with dimethylsulfonium methanide in DMSO and THF,[12] produced a mixture of diastereoisomeric 2-(epoxyethyl)-dihydropyrans (**11**) in 34 or 17% yield, respectively. The low yields would result from instability of the "acrylaldehyde dimer." Hydrogenation of **11** over platinum gave 2-(epoxyethyl)tetrahydropyrans (**12**), which on further treatment with 2-lithio-1,3-dithiane in THF at −50——20 °C[11,13] followed by acetylation afforded β-acetoxy aldehyde trimethylene dithioacetals (**13**) in 62% yield from **11**. The 1,3-dithiane (**13**) was smoothly hydrolyzed with mercury(II) oxide and boron trifluoride etherate to give β-acetoxy aldehydes (**14**) in 83% yield, which in turn was converted by the same treatment as described above into the corresponding acetoxy hexenynes (**15**) in 48% yield. The NMR spectrum indicated the *trans*-configuration of the double bond in question: δ 5.52 and 6.20 (each 1H, do d and do t, J=16, 2, and 16, 7, 7 Hz). The successful result of these model experiments led us to apply these methods for construction of the relevant side chain of laurencin (**2**).



Treatment of the title tetrahydrooxocincarbaldehyde (**1**) with dimethylsulfinylmethanide in DMSO at room temperature[12] afforded epoxyethyl hydrooxocin (**16**), mp 87—88 °C, showing a single spot by GLC and TLC, in 66% yield, as a sole isolable epoxide. In the NMR spectrum the epoxy protons appeared with the C_8-proton as two multiplets at δ 2.72 and 3.25. The epoxide (**16**), when treated with 2-lithio-1,3-dithiane in THF at −70——20 °C,[13] was converted into 2-(2-hydroxyalkyl)-1,3-dithiane (**17**), which was isolated as its acetate (**17a**), mp 161—162 °C, in 80% yield. Fortunately, the acetoxymethine proton was observed at δ 5.24 with almost the same splitting pattern (do t, J=9, 4, and 4 Hz) as that (δ 4.98, do t, J=8, 5, and 5 Hz) of laurencin[2a] (**2**), indicating that the relevant acetoxymethine carbon atom possesses the same relative configuration as the corresponding carbon in the natural product (**2**). Treatment of the dithiane (**17a**) with mercury(II) oxide and boron trifluoride etherate in 15% aqueous THF at room temperature[11] effected only hydrolysis of the 1,3-dithiano-2-yl group to yield β-acetoxy aldehyde (**18**), which was immediately submitted to the Wittig reaction with triphenyl(3-trimethylsilyl-2-propynylidene) phosphorane, prepared from triphenyl(3-trimethylsiliyl-2-propynyl)-phosphonium bromide and butyllithium (1 mol equiv) in THF.[5c] The reaction took place without elimination of acetic acid as expected to give acetoxy *trans*-trimethylsilylhexenyne (**19a**), which was converted readily into acetoxy *trans*-hexenyne (**19**), oil, in 94% yield, by treatment with ammonium fluoride in *N,N*-dimethylformamide (DMF) at room temperature.[5c,14] In good accord with the assigned structure and configuration, compound **19** exhibited parent and fragmentation peaks at *m/e* 334 and 274 in the mass spect-

rum and also absorption maxima at 223 and 230 nm (ε 13000 and 10500) and at 3300, 2110, 1740, 1645, 1247, 1160, 1105, 1027, and 960 cm^{-1} in the UV and IR spectra, respectively. The NMR spectrum confirmed the structure: δ 0.98 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 2.03 (3H, s, $OCOC\underline{H}_3$), 2.80 (1H, d, J=2 Hz, C≡C$\underline{H}$), 2.50 and 3.50 (6H and 2H, each m, $3C\underline{H}_2CH{=}CH$, and 2H at C_2 and C_8), 3.93 (4H, m, $OC\underline{H}_2C\underline{H}_2O$), 5.01 [1H, do t, J=9, 4, and 4 Hz, C$\underline{H}$(OAc)], 5.50 and 6.14 (each 1H, do d and do t, J=15, 2, and 15, 8, 8 Hz, *trans*-C$\underline{H}$=C$\underline{H}$), and 5.78 (2H, m, *cis*-C$\underline{H}$=C$\underline{H}$). A series of the reactions from the aldehyde (**1**) to the acetoxy hexenyne (**19**) *via* the epoxide (**16**) implies synthesis of the C_8-side chain (**3**) of laurencin (**2**).

The final stage of laurencin synthesis consists in introduction of a bromine atom at C_3 with the *trans*-configuration to the ethyl group at C_2. Deacetalization of the tetrahydrooxocinone ethylene acetal (**19**) with *p*-toluenesulfonic acid in aqueous acetone under reflux proceeded smoothly to give ketone (**20**), oil, in 74% yield, which displayed a new absorption maximum at 1720 cm^{-1} and also a one-proton double doublet (J=11 and 8 Hz) at δ 3.86 due to one of the two C_4-protons.[1,4] Reduction of the ketone (**20**) with sodium borohydride in methanol at 0 °C[1,4] produced a mixture of alcohols, from which a major alcohol (**21**), oil, with three *cis*-oriented substituents at C_2, C_3, and C_8 of the hydrooxocin ring, and a minor alcohol (**22**), oil, a C_3-epimer of **21**, could be isolated in 50 and 30% yields, respectively. The configurations of the hydroxyl groups at C_4 in the respective compounds (**21** and **22**) were deduced by analogy of the NMR data with those of the corresponding diethyltetrahydrooxocins[4] and related compounds;[1] namely, the hydroxymethine proton in question of the former (**21**) appeared as a broad signal with half-width of 20 Hz at δ 3.64, while the corresponding proton of the latter (**22**) was observed as a clear double triplet with J= 9, 3, and 3 Hz at δ 3.72.[1,4] Contrary to the expectation that the bromination would take place easily, the major alcohol (**21**), when treated with triphenylphosphine and tetrabromomethane in dichloromethane at room temperature,[4,15] gave a complex mixture. However, an aimed bromo compound, mp 45—47 °C, could be isolated after careful chromatography in 14% yield along with the starting material (**21**, 20%). The bromo compound exhibited the following spectra: MS, *m/e* 356, 354 (M^+), 296, and 294; IR, ν_{max} 3285, 2100, 1735, 1230, 1168, 1080, 1035, and 950 cm^{-1}; NMR, δ 0.98 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 2.03 (3H, s, $OCOC\underline{H}_3$), 2.83 (1H, d, J=2 Hz, C≡C$\underline{H}$), 4.07 (1H, do t, J=9, 3, and 3 Hz, C$\underline{H}$Br), 4.98 [1H, do t, J=8, 5, and 5 Hz, C$\underline{H}$(OAc)], 5.52 and 6.15 (each 1H, do d and do t, J=15, 2, and 15, 7, 7 Hz, *trans*-C$\underline{H}$=C$\underline{H}$), and 5.90 (2H, m, *cis*-C$\underline{H}$=C$\underline{H}$). These spectra were completely identical with those of natural laurencin (**2**), indicating completion of the synthesis of (±)-laurencin. The overall yield amounted to 1.1% from the tetrahydrooxocincarbaldehyde.

Experimental

All the mps and bps were uncorrected. The homogeneity of each compound was always checked by TLC over silica gel (Wakogel B-5) and/or GLC (Hitachi K-53) over 10% SE-30. Column chromatography was carried out over silicic acid (Merck, Kieselgel 60, 70—230 mesh) and/or alumina (Merck, Standard, Active I and II—III). The UV, IR, and NMR (100 MHz) spectra were measured in ethanol, in liquid state, and in chloroform-*d*, respectively, unless otherwise stated. The abbreviations "s, d, t, sex, m, br, do, and sh," in the NMR and IR spectra denote "singlet, doublet, triplet, sextet, multiplet, broad, double, and shoulder," respectively.

*2-Penten-4-ynyl Phenyl Sulfides (**5**) and Their Trimethylsilyl Derivatives (**5a**).* *a)*: Into a suspension of sodium thiophenolate in THF, prepared from sodium hydride (96 mg) and benzenethiol (424 mg) in THF (5 ml), was added a 1:1 mixture of *cis*- and *trans*-2-penten-4-ynyl bromides[8] (290 mg) in THF (1 ml) at 0 °C under stirring. The mixture was stirred at room temperature for 2 h, then mixed with water (10 ml) and extracted with ether (3×10 ml). The ether solution was washed with water, 5% aq potassium hydroxide and water, dried over sodium sulfate (or magnesium sulfate) and evaporated to leave yellow oil (466 mg). The oil was purified by chromatography over silica gel (20 g) with benzene and hexane (1:4) to give *cis*- and *trans*-pentenynyl phenyl sulfides (***c*-5**, 62 mg, and ***t*-5**, 86 mg) with the mixture (82 mg), bp 85—90 °C/2 Torr: ***c*-5**, MS, *m/e* 174 (M^+), 109, 77, and 65; IR, ν_{max} 3280, 2090, 1687, and 775 cm^{-1}: NMR, δ 3.13 (1H, d, J=2 Hz, C≡C$\underline{H}$), 3.79 (2H, d, J=8 Hz, $C\underline{H}_2$), 5.50 and 6.00 (each 1H, do d and do t, J=10, 2, and 10, 8, 8 Hz, *cis*-C$\underline{H}$=C$\underline{H}$), and 7.30 (5H, m, $C_6\underline{H}_5$): ***t*-5**, MS, *m/e* 174, 109, 77, and 65;

IR, ν_{max} 3286, 2096, 1687, and 954 cm^{-1}; NMR, δ 2.84 (1H, d, J=2 Hz), 3.55 (2H, d, J=7 Hz), 5.48 and 6.22 (each 1H, do d and do t, J=15, 2 and 15, 7, 7 Hz), and 7.30 (5H, m).

b): Into an ice-cooled solution of 5-trimethylsilyl-2-penten-4-yn-1-ol alcohol[9] (**4a**) in ether (3 ml) containing pyridine (0.2 ml) was added dropwise phosphorus tribromide (1.9 g) in ether (3 ml) during a period of 15 min. The mixture was stirred at room temperature for 75 min and then mixed with ether (50 ml). The whole solution was washed with water, 5% aq sodium hydrogen carbonate and saturated brine, dried over magnesium sulfate, evaporated and then distilled to yield the corresponding bromides (2.0 g, *cis*:*trans*=1 : 2), which were used for the next reaction without further purification.

Into a suspension of sodium benzenethiolate, prepared from sodium hydride (72 mg) and thiophenol (330 mg) in THF (7 ml), was added the bromide mixture (300 mg) in THF (1 ml). The mixture was stirred at room temperature for 2 h and then worked up as described in (a) to leave oil (396 mg), which was purified by chromatography over silica gel (20 g, hexane) to give *cis*- and *trans*-isomers (***c*-5a**, 77 mg and ***t*-5a**, 177 mg) with the mixture (28 mg), bp 98—100 °C/2 Torr: ***c*-5a**, MS, *m/e* 246 (M^+), 173, 137, 109, 73, and 59; IR, ν_{max} 2146, 1690, 1250, and 760 cm^{-1}; NMR, δ 0.22 [9H, s, $Si(C\underline{H}_3)_3$], 3.80 (2H, d, J=8 Hz, $C\underline{H}_2$), 5.52 and 5.94 (each 1H, do d and do t, J=10, 2 and 10, 8, 8 Hz, *cis*-$C\underline{H}$=$C\underline{H}$), and 7.20 (5H, m, $C_6\underline{H}_5$): ***t*-5a**, MS, *m/e* 246, 173, 137, 109, 73, and 59; IR, ν_{max} 2136, 1685, 1240, and 953 cm^{-1}; NMR, δ 0.18 (9H, s), 3.55 (2H, d, J=7 Hz), 5.54 and 6.18 (each 1H, J=16, 2, and 16, 7, 7 Hz), and 7.26 (5H, m).

*5-Phenylthio-6-nonen-8-yn-4-ols (**6**) and 1-Phenylthio-3-ethynyl-1-hepten-4-ols (**7**).* *a)* Into a solution of 1:1 mixture of ***c*-5** and ***t*-5** (870 mg, 5 mmol) in THF (50 ml) containg Dabco (560 mg, 5 mmol) was added butyllithium (12 mmol) in a 15% hexane solution (6.7 ml) at −30 °C under stirring. The mixture was further stirred for 1 h at −30—−20 °C, and cooled to −50 °C. Butanal (0.45 ml, excess) was added to the cooled solution and stirred at −50—−30 °C for 30 min and then at −30—−20 °C for 30 min. The reaction mixture was poured into water (200 ml) and extracted with ether (3×100 ml). The ether solution was washed with water and saturated brine, dried and evaporated to leave oil (1.2 g), which was purified by chromatography over silica gel (40 g, benzene) to give a 1:1 mixture (452 mg) of **6** and **7** with the starting material (**5**, 220 mg). A part (60 mg) of the mixture was further separated by preparative TLC (Wakogel B-5F, benzene) to yield a *trans*-isomer (***t*-6**, 25 mg) and a *cis*-isomer (***c*-7**, 5 mg) in pure state: ***t*-6**, MS, *m/e* 246 (M^+); UV, λ_{max} 217 nm (ε 16000); IR, ν_{max} 3400, 3280, 2090, 1600, and 958 cm^{-1}; NMR, δ 0.92 (3H, br s, $C\underline{H}_3$), 1.52 (4H, m, $C\underline{H}_2C\underline{H}_2$), 2.54 (1H, s, O$\underline{H}$), 2.86 (1H, d, J=2 Hz, C≡C$\underline{H}$), 3.6 (2H, br m, $C\underline{H}$(OH) and $C\underline{H}(SC_6H_5)$], 5.32 and 6.10 (each 1H, do d, J=16, 2, and 16, 10 Hz, *trans*-$C\underline{H}$=$C\underline{H}$), and 7.30 (5H, m, $SC_6\underline{H}_5$): ***c*-7**, MS, *m/e*, 246; UV, λ_{max} 266 nm (ε 10000); IR, ν_{max} 3420, 3096, 2114, and 1678 cm^{-1}; NMR, δ 0.94 (3H, br s), 2.56 (4H, m), 2.20 (1H, J=2 Hz), 3.66 (2H, br m), 5.80 and 6.30 (each 1H, do d and d, J=10, 10, and 10 Hz, *cis*-$C\underline{H}$=$C\underline{H}$), and 7.35 (5H, m).

b): Into a solution of a 1:2 mixture of ***c*-5a** and ***t*-5a** (492 mg, 2 mmol) in THF (20 ml) containing Dabco (224 mg, 2 mmol) was added butyllithium (2.4 mmol) in 15% hexane (1.36 ml) at −30 °C. The solution was stirred for 1 h at −30—−20 °C and cooled to −50 °C. Butanal (0.45 ml, excess) in THF (0.5 ml) was added to the cooled solution and stirred as described in (a). The reaction mixture was worked up as usual to leave oil (827 mg), which was purified by chromatography over silica gel (30 mg, benzene) to give acetylene compounds (307 mg). A part (80 mg) of the mixture in methanol (2.5 ml) was treated with 5 M aq sodium hydroxide (0.13 ml) at room temperature (25 °C) for 5 min. The reaction mixture was neutralized by addition of 2 M hydrochloric acid, evaporated and extracted with ether (2×50 ml). The ether solution was worked up as usual to leave oil (51 mg), which was separated by preparative TLC over silica gel with benzene and ethyl acetate (9 : 1) to yield a 1 : 5 mixture (by NMR) of **6** and **7** (30 mg) and **5** (10 mg). The mixture was not further purified.

*trans-1-Pheny-3-hexen-5-yn-1-yl Acetate (**9**) and Its 6-Trimethylsilyl Derivative (**9a**).* Into a suspension of triphenyl-(3-trimethylsilyl-2-propynyl)phosphonium bromide[5c] (305 mg, 0.67 mmol) in THF (5 ml) cooled at −78 °C was added butyllithium (0.78 mmol) in 15% hexane (0.5 ml) under stirring. The mixture was stirred at −45—−40 °C for 30 min and cooled to −78 °C. 3-Oxo-1-phenylpropyl acetate[11] (**8**, 87 mg, 0.45 mmol) in THF (0.8 ml) was added to the cooled mixture and stirred at ice-bath temperature for 1 h. On addition of hexane (20 ml) the reaction mixture formed precipitates, which were removed by filtration. The procedure was repeated three times to give brown oil (150 mg), which was separated by chromatography (1.5 g, benzene) to yield **9a** (78 mg), oil; MS, *m/e* 280 (M^+) and 226; IR, ν_{max} 2150, 1748, 1245, 1233, 1085, 1025, and 955 cm^{-1}; NMR, δ 0.16 [9H, s, $Si(C\underline{H}_3)_3$], 2.04 (3H, s, $OCOC\underline{H}_3$), 2.62 (2H, br t, J=7 Hz, $C\underline{H}_2$), 5.52 and 6.02 (each 1H, br d and do t, J=7 and 16, 7, 7 Hz, *trans*-$C\underline{H}$=$C\underline{H}$), 5.74 (1H, t, J=7 Hz, $C\underline{H}$(OAc)], and 7.26 (5H, s, $C_6\underline{H}_5$). The sample was rechromatographed for analysis. Found: C, 71.11; H, 7.71%. Calcd for $C_{17}H_{22}O_2Si$: C, 71.28; H, 7.74%.

Compound **9a** (43 mg) in methanol (1.5 ml) was stirred with 5 M sodium hydroxide (0.75 ml) at room temperature for 10 min. The mixture was acidified with 2 M hydrochloric acid, extracted with hexane repeatedly. The hexane solution was worked up as usual to give crude alcohol (25 mg). The alcohol (22 mg) was treated with acetic anhydride (0.2 ml) and pyridine 0.5 ml to give crude acetate, which was purified by preparative TLC (benzene) to yield **9** (22 mg), oil, in pure state: MS, *m/e* 154 (M^+−CH_3COOH); IR, ν_{max} 3300, 2100, 1748, 1230, and 958 cm^{-1}; NMR, δ 2.08 (3H, s, $OCOC\underline{H}_3$), 2.66 (2H, t, J=7 Hz, $C\underline{H}_2$), 2.80 (1H, d, J=1.5 Hz, C≡C$\underline{H}$), 5.50 and 6.10 (each 1H, br d and do t, J=16 and 16, 7, 7 Hz, *trans*-$C\underline{H}$=$C\underline{H}$), 5.77 [1H, t, J=7 Hz, $C\underline{H}$(OAc)], and 7.28 (5H, s, $C_6\underline{H}_5$). Found: C, 78.47; H, 6.50%. Calcd for $C_{14}H_{14}O_2$: C, 78.48; H, 6.58%.

*2-(Epoxyethyl)-3,4-dihydropyranes (**11**).* *a)*: A suspension of sodium hydride (0.06 mol) (50% mineral oil dispersion, 2.9 g) and trimethyloxosulfonium iodide (13.2 g, 0.06 mol) in dry DMSO (60 ml) was stirred at room temperature under sitrring for 10 min, when evolution of hydrogen stopped. A solution of 3,4-dihydro-2*H*-pyran-2-carbaldehyde (**10**, 5.6 g, 0.05 mol) in DMSO (5 ml) was added to the aforementioned dimethylsufinylmethanide solution during a period of 5 min and then stirred at room temperature for 1.5 h. The reaction mixture was mixed with water (130 ml) and extracted with ether (4×100 ml). The ether solution was washed with water and saturated brine, dried, evaporated and distilled to give **11** (2.16 g), bp 68—70 °C/15 Torr; MS, *m/e* 126 (M^+), 83, and 43; IR, ν_{max} 1646, 1237, and 1070 cm^{-1}; NMR, δ 2.00 (4H, br, m, 4H at C_3

and C_4), 2.80 and 3.25 (2H and 1H, each m, 3H in epoxyethyl), 3.65 (1H, m, H at C_2), 4.70 and 6.35 (each 1H, m, CH=CH). Found: C, 66.15; H, 7.99%. Calcd for $C_6H_8O_2$: C, 66.65; H, 7.99%.

b): Into a solution of sodium methylsulfinylmethanide, prepared by treatment of DMSO (60 ml) with sodium hydride (0.06 mol) (50% mineral oil dispersion, 2.9 g) at 80 °C for 1 h, was added THF (60 ml) and then a solution of trimethylsulfonium iodide (12.4 g, 0.06 mol) in DMSO at 0 °C during a period of 5 min under stirring. To the resultant dimethylsulfonium methanide solution was added **10** (5.6 g, 0.05 mol) in DMSO (5 ml), and the whole solution was stirred at room temperature for 1 h. The reaction mixture was poured into water and extracted with ether (4×200 ml). The ether solution was worked up as usual to give **11** (1.04 g), bp 64—68 °C/15 Torr. The NMR spectrum showed complex signals similar to those of **11** obtained in (a), indicating both the samples (**11**) to be a mixture of diastereoisomers. In the following experiments were used the sample (**11**) obtained in the section (a).

*2-(Epoxyethyl)-3,4,5,6-tetrahydropyrans (**12**).* Compounds **11** (2.1 g) were hydrogenated over platinum (60 mg as $PtO_2 \cdot H_2O$) for 14.5 h, when 430 ml (1.02 mol equiv) of hydrogen had been consumed. After removal of the catalyst, the solution was evaporated and distilled to give oil (**12**, 1.7 g), bp 70—74 °C, showing a single spot on TLC; MS, *m/e* 128 (M^+) and 85; IR, ν_{max} 1255, 1110, 1094, and 1050 cm^{-1}; NMR, δ 1.60 (6H, br m, 6H at C_3, C_4 and C_5), 2.80 and 2.95 (2H and 1H, each m, 3H at C_2 and C_6). Found: C, 65.22; H, 9.64%. Calcd for $C_7H_{12}O_2$: C, 65.60; H, 9.44%.

*3-Oxo-1-(2-tetrahydropyranyl)propyl Acetate (**14**) and Its 1,3-Trimethylene Dithioacetal (**13**).* *a)*: To a solution of 2-lithio-1,3-dithiane in THF, prepared from 1,3-dithiane (1.41 g, 11.7 mmol) and butyllithium (14 mmol) in THF (45 ml) at −30——20 °C for 2 h, was added **12** (1.5 g, 11.7 mmol) in THF (2 ml) under cooling at −60 °C. The mixture was stirred at −50——30 °C for 1 h, at −30——20 °C for 1 h, and then at −20 °C for 16 h, and mixed with ether (150 ml). The ether solution was worked up as usual to leave amorphous residue (3.1 g), which was purified by chromatography over silica gel (90 g, benzene) to yield white solid (2.2 g). A part (54 mg) was further purified by preparative TLC to give solid substance (43 mg), showing a single spot on TLC. The solid (43 mg) was converted under usual conditions into the acetate (**13**), oil; MS, *m/e* 290 (M^+), 230, 119, and 85; IR, ν_{max} 1742, 1240, and 1090 cm^{-1}; NMR, δ 1.50 (6H, m, 6H at C_3, C_4, and C_5), 2.20 (2H, m, $SCH_2CH_2CH_2S$), 2.11 (3H, s, $OCOCH_3$), 2.85 (4H, m, $SCH_2CH_2CH_2S$), 3.42 and 4.00 (each 2H, m, 3H at C_2 and C_6, and SCHS), and 5.18 [1H, m, CH(OAc)].

Into a suspension of mercury(II) oxide (0.6 g) and boron trifluoride etherate (0.35 ml) in 15% aq THF (4 ml) was added **13** (0.20 g, 6.9 mmol) in THF (0.2 ml) under stirring during a period of 15 min. The mixture was stirred at room temperature for 1 h. On addition of ether (10 ml) to the mixture, precipitates were separated and removed by filtration. The filtrate was washed with 10% aq sodium carbonate and saturated brine, dried and evaporated to give oil [crude **14** (0.115 g)], which was used for the next reaction without further purification: IR, ν_{max} 2760, 1746, 1240, 1095, and 1045 cm^{-1}; NMR, δ 2.08 (3H, s, $OCOCH_3$), 2.76 (2H, m, CH_2CHO), 5.30 [1H, do t, J=3, 6 and 6 Hz, CH(OAc)], 9.66 (1H, t, J=1.5 Hz, CHO).

*1-(2-Tetrahydropyranyl)-3-hexen-5-ynyl Acetate (**15**) and Its Trimethylsilyl Derivative (**15a**).* *a)*: Into a suspension of triphenyl(3-trimethylsilyl-2-propynyl)phoshonium bromide (0.34 g, 0.75 mmol) in THF (5 ml) cooled at −70 °C was added butyllithium (0.78 mmol) (15% hexane solution, 0.5 ml) under stirring. The mixture was stirred at −40——30 °C for 30 min and again cooled to −70 °C. Aldehyde **14** (0.11 g, 0.55 mmol) in THF (0.5 ml) was added to the cooled mixture, stirred at the temperature for 5 min and then at ice-bath temperature for 1 h. On addition of hexane (20 ml), precipitates were formed and removed by filtration. The procedure was repeated three times to yield oil (0.145 g), which was purified by chromatography over silica gel (4.5 g, benzene) to give **15a** (0.124 g), colorless oil; MS, *m/e* 294 (M^+), 234, and 85; IR, ν_{max} 2170, 1748, 1248, 1235, 1090, 1050, 1040, and 960 cm^{-1}; NMR, δ 0.16 [9H, s, $Si(CH_3)_3$], 2.04 (3H, s, $OCOCH_3$), 2.44 (2H, t, J=7 Hz, CH_2CH=CH), 4.80 [1H, m, CH(OAc)], 5.52 and 6.10 (each 1H, br d and do t, J=16 and 16, 7, 7 Hz, *trans*-CH=CH). Found: C, 64.92; H, 8.82%; Calcd for $C_{16}H_{28}O_3S$: C, 65.26; H, 8.90%.

b): A solution of **15a** (60 mg, 0.2 mmol) in methanol (2 ml) was stirred with 5 M aq sodium hydroxide (1 ml) at room temperature for 5 min. The solution was made acidic by addition of 2 M hydrochloric acid and extracted with hexane (4×2 ml). The hexane solution was worked up as usual to give alcohol (35 mg), oil. The oil was acetylated under usual conditions and purified by preparative TLC over silica gel to give **15** (39 mg), oil; MS, *m/e* 222 (M^+) and 162; IR, ν_{max} 3300, 2100, 1748, 1240, 1100, 1050, and 960 cm^{-1}; NMR, δ 1.52 (6H, m, $CH_2CH_2CH_2$), 2.03 (3H, s, $OCOCH_3$), 2.48 (2H, t, J=7 Hz, CH_2CH=CH), 2.82 (1H, d, J=2 Hz, C≡CH), 3.35 and 4.00 (2H and 1H, each m, CH_2OCH), 4.86 [1H, do t, J=12, 6, and 6 Hz, CH(OAc)], 5.52 and 6.20 (each 1H, do d and do t, J=16, 2 and 16, 7, 7 Hz, *trans*-CH=CH). Found: C, 69.97; H, 8.02%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

*cis-2-Ethyl-8-epoxyethyl-3,4,7,8-dihydro-2H-oxocin-3-one 3-Ethylene Acetal (**16**).* A suspension of sodium hydride (3.12 mmol) (50% mineral oil dispersion, 0.15 ml) and trimethyloxosulfonium iodide (690 mg, 3.12 mmol) in DMSO (15 ml) was stirred at room temperature under nitrogen. A solution of **1** (593 mg, 2.6 mmol) in DMSO (5 ml) was added dropwise to the dimethylsulfinylmethanide solution and stirred at room temperature for 1 h. The reaction mixture was mixed with water (50 ml) and extracted with ether (3×20 ml) and then with ethyl acetate (2×20 ml). All the organic solutions were combined, washed with water (3×20 ml) and saturated brine, dried and evaporated to leave oil (555 mg), which was purified by chromatography over silica gel (12 g, benzene:ethyl acetate=9:1) to give **16** (418 mg), white solid. A part (145 mg) was crystallized and recrystallized from hexane and ether for analysis to give a pure sample (128 mg), mp 87—88 °C; MS, 240 (M^+) and 211; IR (Nujol), ν_{max} 1648, 1380, 1252, 1162, 1107, and 1080; NMR, δ 1.00 (3H, t, J=7 Hz, CH_2CH_3), 1.44 (2H, m, CH_2CH_3), 2.72 and 3.25 (2H and 1H, each m, 3H in epoxyethyl), 2.94 (1H, do d, J=13 and 8.5 Hz, H at C_4), 3.60 (1H, do d, J=7 and 6 Hz, H at C_2), 4.00 (4H, m, OCH_2CH_2O), and 5.82 (2H, m, *cis*-CH=CH). Found: C, 64.98; H, 8.39%. Calcd for $C_{13}H_{20}O_4$: C, 64.86; H, 8.31%.

*cis-2-Ethyl-8-[1-hydroxy-2-(1,3-dithian-2-yl)ethyl]-3,4,7,8-tetrahydro-2H-oxocin-3-one 3-Ethylene Acetal (**17**) and Its Acetate (**17a**).* To a solution of 2-lithio-1,3-dithiane in THF, prepared from 1,3-dithiane (418 mg, 3.48 mmol) and butyllithium (4.2 mmol) (15% hexane solution, 2.8 ml) at −30——20 °C for 2 h under stirring, was added dropwise **16** (418 mg, 1.74 mmol) in THF (3 ml) at −70 °C. The mix-

ture was stirred at −20 °C for 14 h, and shaken with ether (50 ml) and saturated brine (20 ml). After separation of the ether solution, the aqueous solution was extracted with chloroform (3×20 ml). All the ether and chloroform solutions were combined, washed with saturated brine, dried and evaporated to leave oil (822 mg), which was purified by chromatography over silica gel (30 g, benzene) to give **17** (564 mg), viscous oil. The oil was treated with acetic anhydride (5.6 ml) and pyridine (12 ml) at room temperature overnight and then worked up as usual to give **17a** (557 mg), mp 145—150 °C. A part (66 mg) of the sample was recrystallized from benzene and hexane for analysis to yield **17a** (45 mg), mp 161—162 °C, in pure state; MS, *m/e* 402 (M^+), 373, and 342; IR (Nujol), ν_{max} 1740, 1640, 1230, 1125, 1110, and 1090 cm^{-1}; NMR, δ 1.00 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.38 (2H, m, $C\underline{H}_2CH_3$), 2.03 (3H, s, $OCOC\underline{H}_3$), 3.50 (2H, m, 2H at C_2 and C_8), 3.90 (5H, m, $OC\underline{H}_2C\underline{H}_2O$ and $SC\underline{H}S$), 5.24 [1H, do t, J=9, 4 and 4 Hz, $C\underline{H}$(OAc)], and 5.74 (2H, m, *cis*-$C\underline{H}$=$C\underline{H}$). Found: C, 56.79; H, 7.51%. Calcd for $C_{19}H_{30}O_5S_2$: C, 56.69; H, 7.51%.

cis-*8-(1-Acetoxy-3-oxopropyl)-2-ethyl-3,4,7,8-tetrahydro-2H-oxocin-3-one 3-Ethylene Acetal (**18**).* To a vigorously stirred mixture of mercury(II) oxide (387 mg, 1.79 mmol) and boron trifluoride etherate (0.22 ml, 1.79 mmol) in 15% aq THF (2.4 ml) was added **17a** (240 mg, 0.597 mmol) in THF (2 ml) at room temperature during a period of 10 min. The mixture was stirred for 15 min at room temperature and mixed with ether (10 ml). After removal of precipitates by filtration, the reaction mixture (filtrate) was washed with saturated aq sodium carbonate and then with saturated brine, dried and evaporated to leave oily substance (**20**, 111 mg), which was used for the next reaction without further purification; NMR, 2.08 (3H, s, $OCOC\underline{H}_3$), 4.00 (4H, m, $OC\underline{H}_2C\underline{H}_2O$), 5.54 [1H, do t, J=8, 4, and 4 Hz, $C\underline{H}$(OAc)], 5.86 (2H, m, *cis*-$C\underline{H}$=$C\underline{H}$), and 9.78 (1H, t, J=2 Hz, $C\underline{H}O$).

cis-*8-(1-Acetoxy-6-trimethylsilyl-3-hexen-5-ynyl)-2-ethyl-3,4,7,8-tetrahydro-2H-oxocin-3-one 3-Ethylene Acetal (**19a**).* Into a suspension of triphenyl (3-trimethylsilyl-2-propynyl)phosphonium bromide (242 mg, 0.534 mmol) in THF (2 ml) cooled at −78 °C was added butyllithium (0.543 mmol) (15% hexane solution, 0.33 ml). The mixture was stirred at −40 °C for 30 min and again cooled to −78 °C. A solution of **18** (111 mg, 0.356 mmol) in THF (1.5 ml) was added to the cooled mixture, and the whole mixture was stirred at ice-bath temperature for 1 h. After addition of ether, precipitates were formed and removed by filtration. The filtrate was evaporated to leave oil, which was separated by preparative TLC over silica gel (benzene:ethyl acetate=10:1) to give **19a** (99 mg), oil, showing a single spot on TLC; MS, *m/e* 406 (M^+), 391, 363, and 346; UV, λ_{max} 227 nm (ε 16600), 236 (22700), and 246 (17000); IR, ν_{max} 2160, 1740, 1248, and 960 cm^{-1}; NMR, δ 0.15 [9H, s, $Si(C\underline{H}_3)_3$], 2.05 (3H, s, $OCOC\underline{H}_3$), 3.50 (2H, m, 2H at C_2 and C_8), 3.94 (4H, m, $OC\underline{H}_2C\underline{H}_2O$), 5.02 [1H, do t, J=9, 4, and 4 Hz, $C\underline{H}$(OAc)], 5.45 and 6.08 (1H, br d and do t, J=15 and 15, 7, 7 Hz, *trans*-$C\underline{H}$=$C\underline{H}$), and 5.80 (2H, m, *cis*-$C\underline{H}$=$C\underline{H}$). Found: C, 64.55; H. 8.49%. Calcd for $C_{22}H_{24}O_5Si$: C, 64.98; H, 8.43%.

cis-*8-(1-Acetoxy-3-hexen-5-ynyl)-2-ethyl-3,4,7,8-tetrahydro-2H-oxocin-3-one 3-Ethylene Acetal (**19**).* A solution of **19a** (166 mg, 0.419 mmol) in DMF (17 ml) was treated with ammonium fluoride (1.7 g, excess) at room temperature under stirring. The reaction mixture was treated with water (40 ml) and extracted with ether (3×50 ml). The combined ether solution was worked up as usual to leave oil (190 mg), which was purified by preparative TLC (benzene:ethyl acetate=10:1) to give **19a** (130 mg), oil, showing a single spot on TLC; MS, UV, IR, and NMR, in the text. Found: C, 68.13; H, 7.87%. Calcd for $C_{19}H_{26}O_5$: C, 68.24; H, 7.84%.

cis-*8-(1-Acetoxy-3-hexen-5-ynyl)-2-ethyl-3,4,7,8-tetrahydro-2H-oxocin-3-one (**20**).* A solution of **19** (120 mg, 0.359 mmol) in acetone (50 ml) and water (8 ml) was heated with *p*-toluenesulfonic acid (90 mg, 0.474 mmol) under reflux for 24 h. After being cooled, the reaction mixture was treated with water (50 ml) and extracted with ethyl acetate (3×300 ml). The acetate solution was washed with 5% aq sodium hydrogencarbonate and saturated brine, dried and evaporated to leave oil (144 mg), which was purified by preparative TLC (benzene:ethyl acetate=10:1) to give **20** (31 mg), oil, and the starting acetal (**19**, 68 mg); MS, *m/e* 290 (M^+) and 230; UV, λ_{max} 322 nm (ε 194), 310 (279), 300 (300), 293 (323), 230 (sh) (11400), and 224 (14000); IR, ν_{max} 3310, 2110, 1740, 1720, 1236, and 960 cm^{-1}; NMR, δ 0.96 (3H, t, J=8 Hz, $CH_2C\underline{H}_3$), 2.06 (3H, s, $OCOC\underline{H}_3$), 2.81 (1H, d, J=2 Hz, C≡$C\underline{H}$), 3.44 (1H, m, H at C_8), 3.72 (1H, t, J=7 Hz, H at C_2), 3.86 (1H, do d, J=11 and 8 Hz, H at C_4), 5.00 [1H, do t, J=8, 5, and 5 Hz, $C\underline{H}$(OAc)], 5.52 and 6.14 (each 1H, do d and do t, J=15, 2, and 15, 7, 7 Hz, *trans*-$C\underline{H}$=$C\underline{H}$), and 5.64 (2H, m, *cis*-$C\underline{H}$=$C\underline{H}$). Found: C, 69.98; H, 7.91%. Calcd for $C_{17}H_{22}O_4$: C, 70.32; H, 7.64%.

r-*2*,c-*8-(1-Acetoxy-3-hexen-5-ynyl)-3,4,7,8-tetrahydro-2H-oxocin-3-ol and Its 3-Epimer (**22**).* Compound **20** (36 mg, 0.12 mmol) was treated with $NaBH_4$ (18 mg) in methanol (3 ml) at 0 °C for 20 min. The reaction mixture was made acidic with 2 M hydrochloric acid, concentrated and extracted with ethyl acetate (5×3 ml). The acetate solution was worked up as usual to leave oil (52 mg), showing two spots on TLC, which was separated by preparative TLC (benzene:ethyl acetate=4:1) to yield **22** (11 mg), oil, and **21** (18 mg), oil, as less and more polar fractions: **21**, MS, *m/e* 292 (M^+), 274, and 232; IR, ν_{max} 3440, 3300, 2120, 1740, 1645, 1235, 1130, 1075, 1048, 1030, and 960 cm^{-1}; NMR, δ 0.92 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.86 (1H, br s, O$\underline{H}$), 2.05 (3H, s, $OCOC\underline{H}_3$), 2.82 (1H, d, J=2 Hz, C≡$C\underline{H}$), 3.40 (2H, m, 2H at C_2 and C_8), 3.64 [1H, br, W_H=20 Hz, $C\underline{H}$(OH)], 4.98 [1H, do t, J=8, 5, and 5 Hz, $C\underline{H}$(OAc)], 5.52 and 6.16 (each 1H, do d and do t, J=16, 2, and 16, 7, 7 Hz, *trans*-$C\underline{H}$=$C\underline{H}$), and 5.74 (2H, m, *cis*-$C\underline{H}$=$C\underline{H}$): **22**, MS, *m/e* 292 (M^+), 274, and 232; IR, ν_{max} 3440, 3300, 2110, 1740, 1235, 1120, 1090, 1070, 1050, 1025, and 960 cm^{-1}; NMR, δ 0.98 (3H, t, J=7.5 Hz, $CH_2C\underline{H}_3$), 2.05 (3H, s, $OCOC\underline{H}_3$), 2.80 (1H, d, J=2 Hz, C≡$C\underline{H}$), 3.10 and 3.44 (each 1H, m, 2H at C_2 and C_8), 3.72 [1H, do t, J=9, 3, and 3 Hz, $C\underline{H}$(OH)], 4.98 [1H, do t, J=8, 5, and 5 Hz, $C\underline{H}$(OAc)], 5.52 and 6.16 (each, 1H, do d and do t, J=15, 2, and 15, 7, 7 Hz, *trans*-$C\underline{H}$=$C\underline{H}$), and 5.58 (2H, m, *cis*-$C\underline{H}$=$C\underline{H}$).

r-*2*,c-*8-(1-Acetoxy-3-hexen-5-ynyl)*-t-*3-bromo-3,4,7,8-tetrahydro-2H-oxocin Acetate [(±)-**2**].* Into a solution of **21** (15 mg, 0.05 mmol) and tetrabromomethane (125 mg, 0.375 mmol) in dichloromethane (4 ml) was added dropwise triphenylphosphine (65 mg, 0.25 mmol) in dichloromethane (6 ml, dried through Molecular Sieves 4A) at room temperature under stirring during a period of 3 h, and the whole solution was stirred at room temperature for 12 h. The reaction mixture was evaporated to leave resinous material, which was purified by preparative TLC (benzene) to yield (±)-**2** (2 mg), which crystallized spontaneously and had mp 45—47 °C, with the starting alcohol (**21**, 3 mg). The spectral data (described in the text) were com-

pletely identical with natural laurencin (MS, UV, IR, NMR, and TLC).

(Received May 31, 1978)

The reaction between (dimethylaminomethyl)ruthenocene with lithium tetrachloropalladate(II) in the presence of sodium acetate gave di-μ-chloro-bis[2-(dimethylaminomethyl)ruthenocenyl]dipalladium(II) (**2**). The σ-bonded structure of **2** has been confirmed by IR analysis and the reactions of **2** with triphenylphosphine, thallium(I) acetylacetonate, and lithium aluminum deuteride. The reactions of chloro[2-(dimethylaminomethyl)ruthenocenyl](triphenylphosphine)palladium(II) with carbon monoxide and **2** with methyl vinyl ketone, phenyl vinyl ketone, and styrene have been examined. 1, 2-Disubstituted ruthenocene derivatives have been obtained in higher yields than those of the corresponding ferrocene derivatives.

Cope has reported the first intramolecular *ortho*-palladation of azobenzene[1] and *N,N*-dimethylbenzylamine.[2] For the regiosclective syntheses of *ortho*-substituted aromatic compounds, there has been considerable interest in the intramolecular *ortho*-metalation by transition metals of aromatic compounds containing donor ligands such as nitrogen, phosphorus and sulfur.[3] In addition, the reactions of ferrocene derivatives with palladium(II) halides have been studied.[4] Generally, there have been few synthetic investigations of the ruthenocenes in contrast to those of the ferrocenes. This paper will deal with the intramolecular *ortho*-palladation of (dimethylaminomethyl)ruthenocene and the reactions of the palladium complexes.

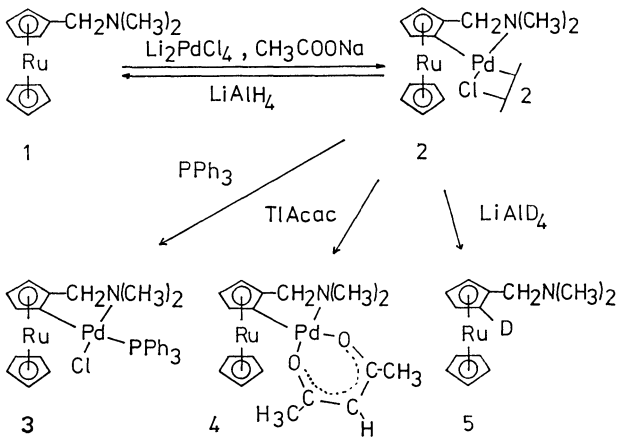

Fig. 1. Syntheses of palladium(II) complexes.

Results and Discussion

The reaction between (dimethylaminomethyl)-ruthenocene (**1**) with lithium tetrachloropalladate(II) in the presence of sodium acetate[5] gave di-μ-chloro-bis[2-(dimethylaminomethyl)ruthernocenyl]dipalladium(II) (**2**) in 78% yield. The complex **2** was shown to be an intramolecularly *ortho*-palladated complex on the basis of the reactions of **2** and the microanalytical and spectroscopic results. Measurement of the molecular weight using a vapor pressure osmometer was not conducted because of the low solubility of **2** in all common solvents. The treatment of **2** with triphenylphosphine and thallium(I) acetylacetonate afforded the monomeric triphenylphosphine (**3**) and acetylacetonate (**4**) complexes, respectively (Fig. 1). In the IR spectrum of **2**, the three bands at 323, 258, and 216 cm^{-1} have been assigned to the bridged Pd–Cl stretching absorption.[6] The single band at 357 cm^{-1} of **3** has been assigned to the terminal Pd–Cl stretching absorption. Thus, it has been confirmed that **2** is a typical chlorine-bridged binuclear complex. The low solubility of **2** in all common solvents precluded any NMR studies at room temperature. However, the ^1H NMR spectra of **3** and **4** clearly demonstrated that a palladium-carbon σ bond and a palladium-nitrogen coordinated bond existed in these complexes (Table 1). *N*-Methyl and *N*-methylene protons of **1** appear as a singlet, whereas the *N*-methyl protons appear as two broad singlets and the *N*-methylene protons as two doublets in **3** and **4**. The non-equivalence of the *N*-methyl and *N*-methylene protons in **3** and **4** can be explained in terms of a cyclic system in which the nitrogen is coordinated to the palladium and a palladium-carbon σ bond is involved.[7] To ascertain the formation of the σ-bond between pal-

ladium and the cyclopentadienyl ring in **2**, **3**, and **4**, **2** was reduced with lithium aluminum deuteride to give 1-(dimethylaminomethyl)ruthenocene-2-*d* (**5**) quantitatively. Again, the starting material (**1**) was obtained by the lithium aluminum hydride reduction of **2**. The presence of deuterium in **5** was established by a comparison of the ^1H NMR and mass spectra of **5** with those of the undeuterated sample (**1**). The intramolecular palladation of α-aryl nitrogen derivatives gave the *ortho*-palladated complexes.[3,4] It appears therefore that the deuterium exists at the *ortho*-position of the dimethylaminomethyl group in **5**.

The evidence indicates a five-membered chelate-ring exists between palladium and the ruthenocene moiety in **2**, **3**, and **4**. A simple model for **2**, **3**, and **4** suggests that the chelate-ring may be five-membered rather than six-membered. This conclusion has been unambiguously supported by the reactions of **2** and **3** with various reagents (Fig. 2). The reactions of *ortho*-palladation products from numerous α-aryl nitrogen derivatives with carbon monoxide,[8] halogens,[9] alkyllithium,[10] Grignard reagents,[10] and olefins[11] have been reported. Recently, the *ortho*-palladation complexes of ferrocene derivatives have been converted into a variety of 1,2-disubstituted ferrocenes.[4,12] Complexes **2** and **3** failed to react with bromine or butyllithium. However, **2** reacted with methyl vinyl ketone, phenyl vinyl ketone and styrene in the presence of triethylamine to readily give 1-alkenyl-2-(dimethylaminomethyl)ruthenocenes (**6**, **7**, **8**) in 89—94% yields. The yields of these ruthenocene derivatives were higher than those of the corresponding ferrocene derivatives.[12] 1-(Dimethylaminomethyl)-2-(ethoxycarbonyl)ruthenocene (**9**) was obtained by the carbonylation of **3** in ethanol; the carbonylation of **2** was unsuccessful. The ^1H NMR, IR, and mass spectra of these products were all consistent with those of the proposed structures.

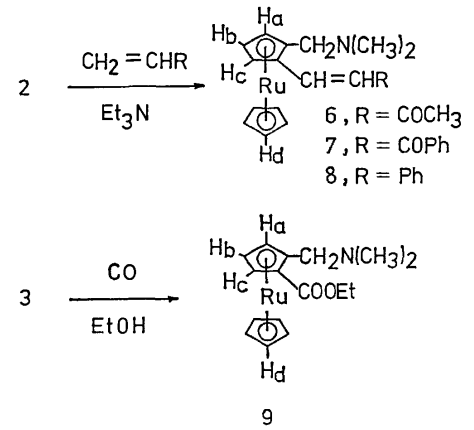

Fig. 2. Reactions of palladium(II) complexes.

1,2-Disubstituted ferrocenes exhibited one peak, while the 1,3-isomers showed two peaks in the region near 900 cm^{-1}, as the characteristic absorption band of

Table 3. Properties and analyses of 1,2-disubstituted ruthenocenes (**6**—**9**)

6	Pale yellow oil. Found: C, 57.18; H, 5.80; N, 3.74%. Calcd for $C_{17}H_{21}NORu$: C, 57.40; H, 5.92; N, 3.91%; mol wt, 356. IR(Nujol): 1655 (C=O); 1615, 965 cm^{-1} (*trans* -CH=CH-). MS: M^+ 356.
7	Pale yellow heavy oil. Found: C, 63.28; H, 5.41; N, 3.16%. Calcd for $C_{22}H_{23}NORu$: C, 63.52; H, 5.53; N, 3.34%; mol wt, 418. IR(Nujol): 1660 (C=O); 1605, 965 cm^{-1} (*trans* -CH=CH-). MS: M^+ 418.

the C–H out-of-plane bending mode on the ferrocene ring.[13] The IR spectra of compounds **6**, **7**, **8**, and **9** showed one peak at *ca.* 910 cm^{-1}. The infrared frequencies of the C–H bending modes of ruthenocene are similar to those of ferrocene.[14] Taking the evidences into account, it has been confirmed that **6**, **7**, **8**, and **9** are 1,2-disubstituted ruthenocenes. Furthermore, in the ^1H NMR spectra of **6**, **7**, and **8**, the *N*-methylene protons appear as doublets in contrast to those of **1** containing no substituent at the *ortho*-position of the dimethylaminomethyl group (Tables 1 and 2). This result, intimating the steric heterogeneity of the *N*-methylene protons in **6**, **7**, and **8**, supports the above conclusions. The coupling constnats of the doublets corresponding to olefinic protons are 16 Hz, and the absorption bands of the C=C linkage are located at *ca.* 1600 and 960 cm^{-1} in **6**, **7**, and **8** (Tables 2 and 3). This indicates that the olefinic protons occupy a *trans* position relative to each other.

Experimental

Materials. All the melting points are uncorrected. (Dimethylaminomethyl)ruthenocene (**1**) was prepared according to the method described by Hofer and Schlögl.[15]

Measurements. The ^1H NMR spectra were determined in $CDCl_3$ with a JEOL JNM-PMX-60 spectrometer (60 MHz) and a Hitachi R-22 spectrometer (90 MHz) at room temperature. All the chemical shifts are expressed in δ (ppm; downfield from the internal standard Me_4Si). The IR spectra were measured using KBr disks, Nujol mulls (4000—650 cm^{-1}) and Nujol mulls mounted on thin polythene windows (700—200 cm^{-1}) with Hitachi 215 and ÉPI-L spectrometers. The mass spectra were obtained on a JEOL JMS-07S mass spectrometer and a Hitachi RMU-6M mass spectrometer, using a direct insertion probe at an ionization energy of 70 eV. The molecular weight was determined in $CHCl_3$ with a Hitachi 115 vapor pressure osmometer.

Di-μ-chloro-bis[2-(dimethylaminomethyl)ruthenocenyl]dipalladium(II) (2). A mixture of lithium tetrachloropalladate(II) (2.28 g, 8.7 mmol) and sodium acetate trihydrate (1.18 g, 8.7 mmol) in ethanol (50 ml) was stirred for 20 min at room temperature. To the reaction mixture, a solution of (dimethylaminomethyl)ruthenocene (**1**) (2.5 g, 8.7 mmol) in ethanol (100 ml) was added, and the mixture was stirred for 5 min at room temperature. The yellow precipitate was filtered and dried, and the crude product was column-chromatographed on silica gel. The first band, eluted with chloroform, yielded di-μ-chloro-bis[2-(dimethylaminomethyl)-ruthenocenyl]dipalladium(II) (**2**) (2.9 g, 78%). The solid (**2**) was insoluble in all common solvents; mp 163—166 °C (dec). IR(Nujol): 323, 258, and 216 cm^{-1} (bridged Pd–Cl).

Chloro[2-(dimethylaminomethyl)ruthenocenyl](triphenylphosphine)-palladium(II) (3). A mixture of the complex **2** (1.9 g, 2.2 mmol) and triphenylphosphine (1.16 g, 4.4 mmol) in benzene (50 ml) was stirred for 12 h at room temperature. After removal of the solvent *in vacuo*, the column chromatography of the residue on silica gel (chloroform) gave chloro[2-(dimethylaminomethyl)ruthenocenyl](triphenylphosphine)palladium(II) (**3**) (2.7 g, 88%); mp 220—225 °C (dec) (chloroform). IR(Nujol): 357 cm^{-1} (terminal Pd–Cl). Found: C, 53.84; H, 4.39; N, 2.20%. Calcd for $C_{31}H_{31}ClRuPPd$: C, 53.85; H, 4.52; N, 2.03%; mol wt, 691.

Acetylacetonato[2-(dimethylaminomethyl)ruthenocenyl]palladium(II) (4). A suspension of the complex **2** (1.0 g, 1.16 mmol) and thallium(I) acetylacetonate (0.07 g, 2.3 mmol) in benzene (50 ml) was stirred for 3 h at room temperature, and filtered. The filtrate was evaporated *in vacuo*, and the residue was purified by column chromatography on silica gel (chloroform) to give acetylacetonato[2-(dimethylaminomethyl)ruthenocenyl]palladium(II) (**4**) (0.68 g, 60%); mp 162—165 °C(dec) (chloroform). IR(KBr): 1620 and 1550 cm^{-1} (acac group). Found: C, 43.66; H, 4.75; N, 2.91%. Calcd for $C_{18}H_{23}RuNPd$: C, 43.87; H, 4.70; N, 2.84%; mol wt, 493.

Reduction of Complex 2 with Lithium Aluminum Hydride. A mixture of the complex **2** (1.0 g, 1.16 mmol) and lithium aluminum hydride (0.044 g, 1.16 mmol) in dry ether (100 ml) was stirred for 4 h at room temperature. After the addition of moist ether and water, the reaction mixture was extracted three times with ether which had been washed with water and brine, and then dried over anhydrous sodium sulfate. The removal of the solvent gave **1** in 95% yield as brownish plates from petroleum ether; mp 38—41 °C (lit,[15] 39—42 °C). The ^1H NMR, IR, and mass spectra of **1** were consistent with those of an authentic sample.

Reduction of Complex 2 with Lithium Aluminum Deuteride. The reduction of the complex **2** (1.0 g) with lithium aluminum deuteride (0.044 g) in dry ether (100 ml) was conducted under the same conditions as in the proceeding experiment. After recrystallization from petroleum ether, the product (mp 39—42 °C) was identified as 1-(dimethylaminomethyl)ruthenocene-2-*d* (**5**) on the basis of the following evidence: ^1H NMR($CDCl_3$): δ 2.20 (s, 6H, $-N(CH_3)_2$); 3.10 (s, 2H, $-CH_2-$); 4.5—4.6 ppm (m, 8H, ruthenocene ring protons). MS: M^+ 289. Found: C, 54.08; H, 5.43; N, 4.91%. Calcd for $C_{13}H_{16}DRuN$: C, 53.96; H, 5.57; N, 4.84%; mol wt, 289.

General Procedure for the Reaction of Complex 2 with Olefins. In a closed vessel, a mixture of the complex **2** (1.0 g, 1.16 mmol) and an olefin (5 mmol) and triethylamine (0.30 g, 3 mmol) in toluene (50 ml) was stirred for 5 h at 80 °C under a nitrogen atmosphere. The reaction mixture was cooled and filtered to remove precipitated palladium, and the filtrate was evaporated *in vacuo*. The residue was dissolved in chloroform which had been washed with water and brine, and dried over anhydrous magnesium sulfate. After removal of the solvent, purification of the crude product by column chromatography (silica gel–chloroform) gave 1-alkenyl-2-(dimethylaminomethyl)ruthenocenes (**6**, **7**, **8**) in 91, 89, and 94% yields, respectively.

Carbonylation of Complex 3 in Ethanol. In an autoclave, a suspension of the complex **3** (1.3 g, 1.9 mmol) in ethanol (50 ml) was stirred for 50 h at 100 °C under a carbon monoxide pressure of 80 atm. The reaction mixture was filtered to remove precipitated palladium, and the filtrate was evaporated *in vacuo*. The residue was dissolved in chloroform and column chromatographed on silica gel (chloroform) to afford 1-(dimethylaminomethyl)-2-(ethoxycarbonyl)ruthenocene (**9**) (0.27 g, 40%). The structure of the 1,2-disubstituted ruthenocenes has been confirmed by elemental analysis and the ^1H NMR, IR, and mass spectra (Tables 2 and 3).

Trans-esterification Reaction Catalyzed by Alkoxo(triphenylphosphine)copper(I) Complexes

Minoru KUBOTA, Takakazu YAMAMOTO, and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received June 2, 1978)

Alkoxocopper and phenoxocopper complexes ROCu $(PPh_3)_n$ (PPh_3=triphenylphosphine; n=1 for R=n-C_3H_7 or i-C_3H_7; n=2 for R=CH_3, C_2H_5, CH_2=$CHCH_2$, $C_6H_5CH_2$, or C_6H_5) react with esters undergoing exchange of the RO group with carboxylic esters. The alkoxocopper and phenoxocopper complexes are found to be excellent catalysts for the trans-esterification of carboxylic esters, dimethyl carbonate, and trimethyl phosphite with alcohols and phenols. A comparison of the ability of the isopropoxocopper complex as trans-esterification catalyst with that of aluminum isopropoxide and titanium isopropoxide shows the superiority of the isopropoxocopper complex. The rate of trans-esterification between p-nitrophenyl acetate and phenol follows the second-order rate law $R=k$[p-nitrophenyl acetate][phenol], the activation energy of the reaction being estimated to be 12.4 kcal/mol. A mechanism comprising a nucleophilic attack on the copper-bound carbonyl group of the ester by alcohol is proposed.

Although metal alkoxides and phenoxides are widely utilized as reagents and catalysts for organic syntheses, reports on the utilization of copper alkoxides for organic syntheses are limited.[1] This seems to be due to the availability of only a few stable and well-characterized alkoxocopper and phenoxocopper compounds. In the preceding paper a report was given on the preparation of a series of stable alkoxocopper and phenoxocopper complexes formulated as ROCu-$(PPh_3)_n$ (PPh_3=triphenylphosphine) by the reaction of $CH_3Cu(PPh_3)_2(ether)_{0.5}$ with alcohols and phenol.[2]

In this paper we describe the utilization of the alkoxocopper and phenoxocopper complexes $ROCu(PPh_3)_n$ as the trans-esterification catalyst.

Results and Discussion

Alkoxo and Phenoxo Group Exchange Reactions between $ROCu(PPh_3)_n$ and Esters. Prior to exploration of the catalytic activities of the alkoxocopper and phenoxocopper complexes for trans-esterification, stoichiometric exchange reactions betweeen $ROCu(PPh_3)_n$ and esters were examined in order to find the general trend of the exchange reactions of the RO–Cu complexes against esters. The following exchange reactions were carried out between $ROCu(PPh_3)_n$ and acetic esters:

$$ROCu(PPh_3)_n + CH_3COOR' \xrightarrow{-5\,^\circ C} R'OCu(PPh_3)_n + CH_3COOR \quad (1)$$

R: CH_3(**1a**), C_2H_5(**1b**), n-C_3H_7(**1c**), allyl(**1d**), i-C_3H_7(**1e**), benzyl(**1f**), C_6H_5(**1g**), n=1 for **1c** and **1e**, n=2 for the others, **1a**, **1c**, and **1f** have diethyl ether as the solvent of crystallization. The results are summarized in Table 1.

Yields of the exchanged esters were determined by means of gas chromatography and those of R'OCu-

a) Reaction conditions: −5 °C for 12 h for complexes **1a**—**1f**: room temperature for 12 h for complex **1g**. b) Upper figures, %-yield of CH_3COOR; figures in parentheses, % yield of the isolated $R'OCu(PPh_3)_n$. c) C-Bonded acetoxyvinylcopper complex with formation of acetaldehyde. d) A mixture of the starting complex and produced complex was obtained but separation of the mixture was difficult. e) The starting $PhOCu(PPh_3)_2$ was recovered unreacted after 1—2 days.

$(PPh_3)_n$ were calculated from the weights of the isolated complexes. The starting alkoxocopper and phenoxocopper complexes are arranged in the increasing order of stability of the complexes, **1a**<**1b**<**1c**<**1d**<**1e**<**1f**<**1g**,[2] as judged by the decomposition points of the alkoxocopper complexes. Acetic esters are arranged in the decreasing order of the stability of the produced complexes $R'OCu(PPh_3)_n$.

It is seen that, in most cases, the RO group of $ROCu(PPh_3)_n$ can be exchanged with the R'O group of CH_3COOR' even at −5 °C and the yield of the product apparently depends on the relative stability of the complex $R'OCu(PPh_3)_n$ produced. The considerably high yields of products on employment of vinyl acetate seem to be due to high stability of the six-membered C-bonded acetoxyvinylcopper complex formed in the reaction.[2,3] When the starting complex is very stable such as the phenoxocopper complex **1g**, the exchange reaction with alkyl and alkenyl acetates scarcely proceeds. The reaction of **1c** and **1e** with phenyl acetate gave a new phenoxocopper complex containing only one PPh_3 ligand $C_6H_5OCuPPh_3$, whereas $C_6H_5OCu(PPh_3)_2$ has been obtained by the reaction of $CH_3Cu(PPh_3)_2 \cdot 0.5Et_2O$ with phenol.[2] The alkoxo and phenoxo group exchange reaction between $ROCu(PPh_3)_n$ and ester is not restricted to the esters of acetic acid. Employment of other various alkyl and aryl carboxylates also leads to the exchange reaction below room temperature indicating that the RO ligands bonded to copper have high lability toward the attack of esters.

The alkoxo and phenoxo group exchange reaction on copper may proceed through one of the concerted four center mechanisms as shown by Eqs. 2 and 3 or through an oxidative addition of esters to copper (Eq. 4).

$$CH_3COOR' + ROCuL_n \longrightarrow \text{(I)} \longrightarrow CH_3COOR + R'OCuL_n \quad (2)$$

$$CH_3COOR' + ROCuL_n \longrightarrow \text{(II)} \longrightarrow CH_3COOR + R'OCuL_n \quad (3)$$

$$CH_3COOR' + ROCuL_n \longrightarrow \text{(III)} \longrightarrow CH_3COOR + R'OCuL_n \quad (4)$$

The existence of carboxylic ester-coordinated metal complexes is well known and Lappert showed that the carbonyl group in esters is bonded to metal.[4] Equations 2 and 3 show that the ester coordination to the alkoxocopper complex facilitates the nucleophilic attack on the carbonyl group by the alkoxo group. Since esters can add oxidatively to transition metal compounds such as Ni(0)[5] and Mo(0)[6] complexes with the cleavage of the bond between acyl and alkoxyl groups, the mechanism expressed by Eq. 4 is also conceivable.

Trans-esterification Catalyzed by Alkoxocopper and Phenoxocopper Complexes. Alkoxocopper and phenoxocopper complexes catalyze trans-esterification of carboxylic esters, dialkyl carbonates, and trialkylphosphines under mild conditions. The results are summarized in Table 2.

When an equimolar amount of an ester and an alcohol is used and the free energy change in the trans-esterification is small, as in the ester interchange between methyl carboxylates and ethanol (Table 2, Nos. 1 and 4,), about half of the starting ester is interchanged with alcohol. The extent of ester interchange increases with increase in the amount of alcohol (Nos. 4, 5, and 19). An ester with a bulky alkyl group such as *t*-butyl acetate did not undergo the interchange reaction smoothly (No. 3).

The trans-esterification of alkenyl carboxylates presents a special case. Vinyl acetate and isopropenyl acetate were converted into alkyl acetate in high yields by the exchange reaction with alcohols. In these cases, however, alkenols which may be produced as intermediates are considered to have been converted into their stabler tautomers, acetaldehyde and acetone.

$$CH_2{=}CH(R')(OCOCH_3) + R''OH \xrightarrow{CuOR(PPh_3)_n} CH_2{=}CH(R')(OH) + CH_3COOR'' \quad (5)$$

$$CH_2{=}CH(R')(OH) \longrightarrow CH_3{-}C(=O){-}R'$$

Since the amount of acetaldehyde was much smaller than that of methyl acetate in No. 5, the major part of acetaldehyde seems to be further converted into polyaldols by copper complex.[7] When the starting ester has more than two alkoxyl groups as in dimethyl fumarate, dimethyl carbonate, and trimethyl phosphite, a mixture of partially and fully interchanged prodcuts was obtained, the ratio between the products depending upon the relative amount of alcohol to ester.

A comparison of the catalytic activity of i-$C_3H_7OCuPPh_3$ with that of typical trans-esterification catalysts at 0 °C is given in Table 3. We see that i-$C_3H_7OCuPPh_3$ has much higher activity than the corresponding aluminum and titanium alkoxides and an activity comparable to that of i-C_3H_7ONa which is a much stronger base than i-$C_3H_7OCuPPh_3$. Thus the present system is expected to provide synthetic utility specially when applied to systems which are susceptible to attack of strong base.

TABLE 2. TRANS-ESTERIFICATION OF CARBOXYLIC ESTERS

No.	Ester (mmol)	Alcohol	Molar ratio (alcohol/ester)	Catalyst[a]	Temp (°C)	Time (h)	Products (%-yield/starting ester)
1	CH_3COOCH_3 (20)	C_2H_5OH	1.0	**1b** (0.16)	−5	12	$CH_3COOC_2H_5$ (41)

TABLE 3. COMPARISON OF CATALYTIC ACTIVITIES OF i-$C_3H_7OCuPPh_3$ **1e** WITH THOSE OF $Al(O$-i-$C_3H_7)_3$, $Ti(O$-i-$C_3H_7)_4$, AND i-C_3H_7ONa FOR THE TRANS-ESTERIFICATION OF $CH_3COOCH_2C_6H_5$ WITH i-C_3H_7OH[a]

Catalyst	Yield of CH_3COO-i-C_3H_7 (%)
i-$C_3H_7OCuPPh_3$	70
$Ti(O$-i-$C_3H_7)_4$	20
$Al(O$-i-$C_3H_7)_3$	negligible
i-C_3H_7ONa	76

a) The reactions were carried out at 0 °C for 12 h using 0.32 mmol of the catalyst, 20 mmol of benzyl acetate and 60 mmol of isopropyl alcohol.

Figure 1 shows the time course of the trans-esterification of p-nitrophenyl acetate with phenol catalyzed by $C_6H_5OCu(PPh_3)_2$ under the conditions where the ratio of p-nitrophenyl acetate to phenol or that of phenol to p-nitrophenyl acetate was kept at 100. The data obtained under the two different situations fit the same curve. The first-order plot (log Co/C *vs.* t) of the data in Fig. 1 gives a straight line indicating that the rate of trans-esterification is proportional to both the concentration of p-nitrophenyl acetate and that of phenol:

$$R = k[p\text{-nitrophenyl acetate}][\text{phenol}] \quad (6)$$

When the molar ratio of p-nitrophenyl acetate to phenol is unity, the time course of conversion follows the second-order rate law supporting the validity of Eq. 6. From the temperature dependence of the second-order rate constant k (Table 4) the activation energy for trans-esterification was calculated to be E_a=12.4 kcal/mol. The rate of trans-esterification increases linearly with increase in the catalyst concentration.

Mechanism of Trans-esterification. A simple extension of the observation on stoichiometric exchange reactions between esters and the alkoxocopper complexes to catalytic trans-esterification promoted by the alkoxocopper complexes leads to the following mechanism comprising two steps, (1) the exchange between the ester and the alkoxocopper, and (2) the exchange between the alcohol used and the newly formed alkoxo-

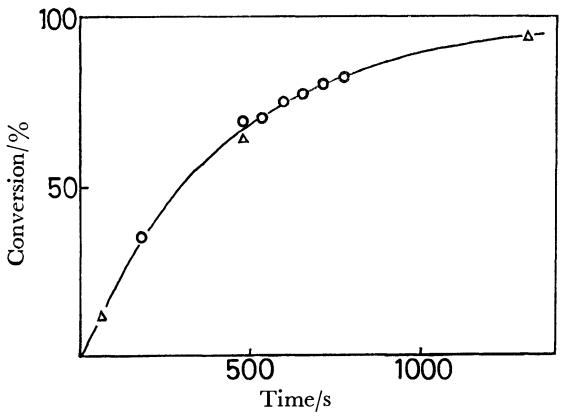

Fig. 1. Trans-esterification of *p*-nitrophenyl acetate with phenol catalyzed by $C_6H_5OCu(PPh_3)_2$. (a) ○, CH_3COO-*p*-$C_6H_4NO_2$ = 0.5 mmol (90 mg), C_6H_5OH = 50 mmol (4.70 g), catalyst = 85 mg, in this case the conversion is based on CH_3COO-*p*-$C_6H_4NO_2$. (b) △, CH_3COO-*p*-$C_6H_4NO_2$ = 50 mmol (9.00 g), C_6H_5OH = 0.5 mmol (47 mg), catalyst = 85 mg, in this case the conversion is based on C_6H_5OH. Solvent = toluene (10 ml) Temp = 50 °C.

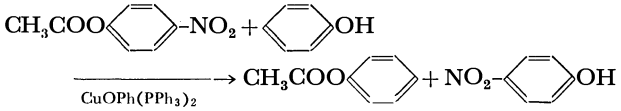

Table 4. Temperature dependence of the second-order rate constant k in the trans-esterification of CH_3COO-*p*-$C_6H_4NO_2$ with C_6H_5OH[a]

Temp (K)	$1/T$	k(l·mol^{-1}·s^{-1})
323	3.10×10^{-3}	0.8×10^{-4}
353	2.84×10^{-3}	4.0×10^{-4}
383	2.61×10^{-3}	17.0×10^{-4}
	E_a = 12.4 kcal/mol	

a) Catalyst = $C_6H_5OCu(PPh_3)_2$ (0.13 mmol). [CH_3COO-*p*-$C_6H_5NO_2$] = [C_6H_5OH] = 1.0 mol/l. Solvent = toluene.

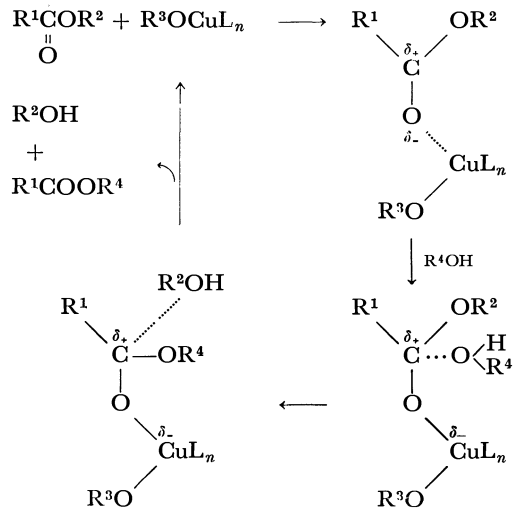
copper complex.:

$$R^1COOR^2 + R^3OCuL_n \longrightarrow R^2OCuL_n + R^1COOR^3$$
$$R^2OCuL_n + R^3OH \longrightarrow R^3OCuL_n + R^2OH$$

$$R^1COOR^2 + R^3OH \xrightarrow[ROCuL_n]{} R^1COOR^3 + R^2OH \quad (7)$$

Such a trans-esterification reaction does not seem to constitute the main mechanistic pathway for the following reasons. (a) The phenoxocopper complex **1g**, which undergoes exchange reaction with neither aliphatic esters nor alcohols, catalyzes the trans-esterification between methyl acetate and ethanol. (b) The exchange reaction between *p*-NO_2–$C_6H_4OCu(PPh_3)_2$ and phenol is extremely slow as compared to the relatively fast trans-esterification between *p*-nitrophenyl acetate and phenol catalyzed by **1g**. (c) The kinetic results expressed by Eq. 6 are not compatible with the stepwise mechanism shown by Eq. 7.

From the available experimental evidence we propose that the trans-esterification reaction proceeds through the copper-assisted nucleophilic replacement mechanism as shown below:



In view of the loosening of the carbonyl group in esters on their coordination to metal compounds as shown by infrared work by Lappert,[4c] the nucleophilic attack of the carbonyl carbon whose electron density decreases by coordination of the carbonyl group to metal is plausible. The mechanism is in line with the second-order rate equation, provided that the attack of alcohol on the metal-coordinated ester is the rate-determining step. According to the reaction mechanism the activation energy for the trans-esterification consists of the energy for the coordination of R^1COOR^2 to $R^3OCu(PPh_3)_n$ and that for the nucleophilic attack of R^4OH to the reaction intermediate.

Experimental

General. Preparation and the reaction of copper complexes were carried out in Schlenk type flasks under deoxygenated nitrogen or argon, or in a vacuum. Solvents were dried by the usual procedure, distilled, and stored in argon or nitrogen. IR spectra were recorded on a Hitachi Model 295 spectrophotometer. Microanalysis of carbon, hydrogen and nitrogen was carried out by Mr. T. Saito in our laboratory with a Yanagimoto CHN Autocorder Type MT-2.

Materials. Esters used in the reaction were sufficiently pure as checked by gas chromatography. Alkoxocopper and phenoxocopper complexes **1a**—**1g** were prepared as reported in the preceding paper.[2] *p*-Nitrophenoxocopper complex *p*-$O_2NC_6H_4OCu(PPh_3)_2$ was prepared similarly; yield = 90%. Found: C, 69.7; H, 4.69; N, 2.10%. Calcd for $C_{42}H_{34}CuNO_3P_2$: C, 69.5; H, 4.68; N, 1.93%. IR (KBr): 1580, 1505, 1307, 1280 cm^{-1}. NMR (C_6D_6): δ 6.48 (d, 2H), 7.0 (m, 18H), 7.4 (m, 12H), 8.04 (d, 2H).

Stoichiometric Exchange Reactions between $ROCu(PPh_3)_n$ and Carboxylic Esters. Phenyl acetate (64 mg, 0.47 mmol) was added to **1c** (200 mg, 0.47 mmol) suspended in 2 ml of diethyl ether at −5 °C. Stirring of the mixture at −5 °C for 12 h gave 0.41 mmol (87% per **1c**) of propyl acetate and a white precipitate. The white precipitate was recrystallized from toluene and dried in a vacuum to give a new phenoxocopper complex having one PPh_3 ligand, $C_6H_5OCuPPh_3$ (172 mg, 84% per **1c**). Found: C, 68.3; H, 4.50%. Calcd for $C_{24}H_{20}CuOP$: 68.8; H, 4.78%. IR(KBr): 1580, 1270 cm^{-1}. Other stoichiometric exchange reactions

of alkoxocopper and phenoxocopper complexes with carboxylic esters were carried out in a similar manner.

Catalytic Trans-esterification. Methyl acetate (1.48 g, 20 mmol) was added to an ethyl alcohol (0.92 g, 20 mmol) solution of **1c** (68 mg, 0.16 mmol) at −5 °C. Stirring of the solution at the temperature for 12 h afforded 8.2 mmol of ethyl acetate as determined by gas chromatography. Trans-esterification of carboxylic esters and trimethyl phosphite was carried out in a similar manner.

Kinetic Study. Kinetic study on the trans-esterification of CH_3COO-*p*-$C_6H_4NO_2$ by C_6H_5OH was carried out in a Schlenk type flask immersed in a thermostatted oil bath. The solvent, reactants, and catalyst were transferred in an atmosphere of nitrogen. The time-dependent conversion was measured by pipetting out each fraction of the solution at a set time and analyzing it by gas chromatography.

Reactions of Spiro[2.6]nona-4,6,8-triene Derivatives with Acids and Bases. Rearrangement to a Heptafulvene Derivative and Formation of Ether Linkage Compounds

Takashi TODA,* Katsuhiro SAITO,† and Toshio MUKAI

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

†*Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466*

(Received June 2, 1978)

Reaction of dimethyl *trans*-spiro[2.6]nona-4,6,8-trien-1,2-dicarboxylate with phenyllithium afforded *trans*-1,2-bis(hydroxydiphenylmethyl)spiro[2.6]nona-4,6,8-triene (**2**) in a good yield. Spirotriene **2** is very sensitive to acids and gave 8-(2,2-diphenylvinyl)heptafulvene accompanied with a quantitative amount of benzophenone by acid treatments. Although **2** is stable to basic reagents, upon treating with sodium hydride, **2** afforded 11-hydroxydiphenylmethyl-8-oxa-9-diphenyltricyclo[5.4.0.$0^{1,10}$]undeca-2,4-diene, and its double bond isomers. Mechanisms of the above reactions are discussed.

Spiro[2.6]nona-4,6,8-triene system is of interest from the view point of spiro conjugation.[1,2] Although some spiro[2.6]nonatriene derivatives have been synthesized,[3-9] chemical properties of this class of compounds have not been well known in detail.[7-11] We designed to introduce hydroxyl groups to this system and to investigate its properties to acids and bases. We wish to report here the results obtained and discuss about mechanisms of these reactions.

Reductions of dimethyl *trans*-spiro[2.6]nona-4,6,8-trien-1,2-dicarboxylate (**1**)[7,8] by lithium aluminium hydride gave several unidentified mixtures, and reactions of **1** with Grignard reagents (benzylmagnesium chloride or methylmagnesium iodide) also gave several intractable products which did not possess a cyclopropane moiety or a cycloheptatriene ring. Presumably skeletal rearrangements took place by the actions of the Grignard reagents or lithium aluminium hydride as Lewis acids. However, *trans*-1,2-bis(hydroxydiphenylmethyl)spiro[2.6]nona-4,6,8-triene (**2**) was obtained in 80% yield by reaction of **1** with excess phenyllithium.

Spirotriene **2** is very sensitive toward acidic reagents. When **2** was treated with organic or mineral acids, or even with silica gel, the colorless solution of **2** turned to dark red, and it gave a product (**3**) which possesses a strong absorption band at 385 nm in its UV spectrum, and is a very unstable entity. When **3** was allowed to stand at room temperature in neat, the color of **3** disappeared within one hour as shown in Fig. 1, and a mixture of resinous substances and one mole of benzophenone were obtained.

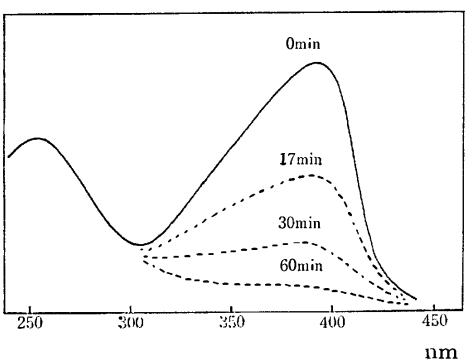

Fig. 1.

Considering that spiro[2.6]nonatriene derivatives have been known to give heptafulvene derivatives by acid treatments[3,4] and the UV spectrum of **3** is similar to those of heptafulvene derivatives,[12] structure of **3** was supposed to be 8-(2,2-diphenylvinyl)heptafulvene. Exhaustive catalytic hydrogenation of a freshly prepared reaction mixture of **2** with silica gel gave a hydrocarbon (**4**) in 75% yield and benzophenone in a good yield, after consumption of five mole of hydrogen. Hydrocarbon **4** shows the following spectral properties. Mass: *m/e*, 292 (9%, molecular ion peak, $C_{22}H_{28}$) and *m/e*, 167 (base peak, Ph_2CH^+). NMR (in CCl_4): δ ppm; 1.8—2.3 (multiplet, 17 H), 3.8 (triplet, 1 H, benzyl proton), and 7.2 (broad singlet, 10 H). These data suggest that the structure of **4** is 1-cycloheptyl-3,3-diphenylpropane, confirming the structure of **3** to be 8-(2,2-diphenylvinyl)heptafulvene. Scheme of these reactions is shown in Fig. 2.

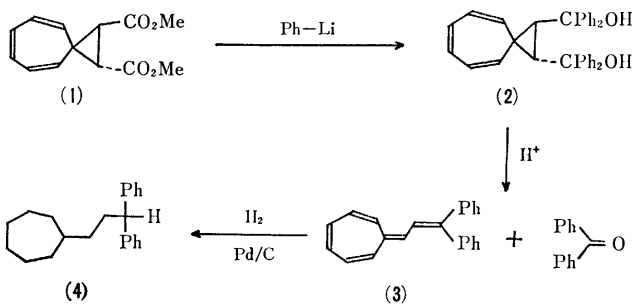

Fig. 2.

Spirotriene **2** is stable toward basic reagents. Reactions of **2** with refluxing pyridine, triethylamine, or 4 M sodium hydroxide in refluxing dioxane resulted in complete recovery of **2**. On the other hand, treatment of **2** with excess sodium hydride in dry dioxane afforded colorless crystalline substances (**5**, **6**, and **7**). Products ratios depended on the temperature and the reaction period as shown in Table 1.

Physical data of **5**, **6**, and **7** are summarized in Table 2—4. These products show the same elemental analyses ($C_{35}H_{30}O_2$) and molecular ion peaks in mass spectra (M^+, 482). Acid treatments of these products gave **3** and benzophenone, suggesting the structures of them to be analogous to that of **2**. The IR and NMR spectral studies in deuterium oxide cleared that each

Table 1.

Condition		Product yields (%) 2 (recv.)	5	6	7

Table 2.

	UV λ_{max}^{MeOH} nm (log ε)	IR ν^{KBr} cm^{-1}	Mass *m/e* (%)
5	255 (4.18)	3550 1600	482(M^+, 3), 269(9), 197(16), 196(100), 167(8), 105(40)
6	260 (4.07)	3595 1590	482(M^+, 2), 269(9), 196(100) 118(17), 105(78)
7	277 (4.10)	3600 1600	482(M^+, 5), 286(100), 105(84)

compound possesses one hydroxyl group and the other oxygen is in an ether linkage.

Structures of **5**, **6**, and **7** were determined to be 11-hydroxydiphenylmethyl-8-oxa-9,9-diphenyltricyclo-[5.4.0.0^{1,10}]undeca-3,5-diene, 2,4-diene, and 4,6-diene, respectively, as shown in Fig. 3, from their NMR spectra with double and triple resonance techniques. Assignment of the NMR spectra were deduced from their coupling patterns which clearly showed each proton's relations in the seven membered rings of them as shown in Tables 3 and 4. Investigation of their Dreiding model indicated that the chemical shifts of H_{11} should appear more lower fields than those of H_{10} by the different anisotropy effect of the phenyl groups at C_9 and C_{12}.

These structures could reasonably be explained also by their UV spectra. The absorption maxima of them shift to longer wavelength in the order of **5**, **6**, and **7**, being well coincident with that **5** has only one isolated diene chromophore, but **6** and **7** possess diene systems conjugated with a cyclopropane and a terminal vinyl ether linkage conjugated with a cyclopropane, respectively.

Thermal reactions of these three products under the basic conditions cleared the relation of them that the isomerization took place between **5** and **6**, and **5** isomerized to **7**, but **7** did not isomerized to **5** or **6** as shown in Fig. 3, and these facts confirmed the structures of them.

Although the best model compound α,α-diphenyl-β-(7-cycloheptatrienyl)ethyl alcohol could not be prepared in pure state, as models of the ether linkage formation of **2**, reactions of 7-cycloheptatrienylmethyl

alcohol (**8**),[13] β-(7-cycloheptatrienyl)ethyl alcohol (**9**),[14] α-phenyl-β-(7-cycloheptatrienyl)ethyl alcohol (**9a**), and *cis-endo*-1,2-bis(hydroxydiphenylmethyl)-bicyclo[2.2.1]hept-5-ene (**10**)[11] with sodium hydride under the same conditions as the case of **2** were investigated, but resulted in the complete recovery of the starting alcohols. Reactions of cycloheptatriene with benzyl alcohol or triphenylmethyl alcohol under the same conditions also resulted in the complete recovery of the starting substances.

Discussion

Mechanism of the rearrangement of **2** to **3** by acid treatments can be considered as shown in Fig. 5 by following reasons. First of all, ring creavage reactions of cyclopropane derivatives by acidic reagents are well known, and furthermore, a cycloheptatrienium ion (**11**) is a very stable ion. Secondary, dehydration reaction of **2** should proceed readily, because **2** is a benzyl alcohol. Finally, benzophenone is a stable compound: thus, elimination of benzophenone from **11** should not need high energy. From these reasons, the rearrangement of **2** to **3** seems to proceed readily.

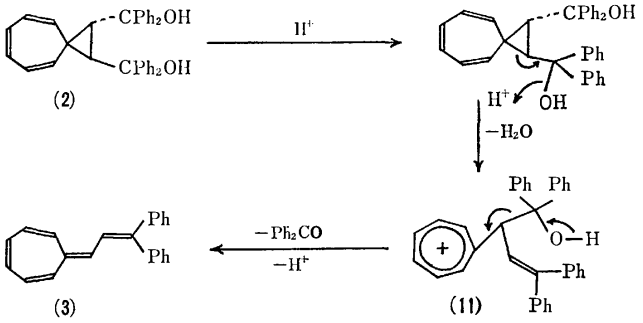

Fig. 5.

There are several plausible explanations about reaction mechanisms of the formation of **5** from **2**. The first one is direct alkoxide anion attack on double bonds. However, the reactions of **8**, **9**, and **10** did not give any ether compounds as described before. Steric requirements of **8**, **9**, and **10** are good enough for an ether linkage formation, because sterically analogous compounds such as α-(diazomethyl)-α'-(7-cycloheptatrienyl)methyl ketone gave a corresponding bond formation product by its decomposition reaction.[15] Also, it is well known that *endo*-bicyclo[2.2.1]hept-5-en-2-carboxylic acid afforded the lactone derivative by acid treatments. These results indicate that direct alkoxide anion attack on double bonds of **2** is not reasonable.

The second is an explanation by radical mechanisms. Color of the reaction mixture of **2** become deep blue during the reactions suggesting a formation of some radical species. ESR spectrum measurement of this reaction mixture did not show, however, any evidence of a radical formation. Also, if alkoxide radical or cycloheptatrienyl radical formed under the reaction conditions, the corresponding radicals would form in the reactions of **8**, **9**, and **10**, and some reactions should take place in these cases. So that radical mechanisms can not be negrected completely, but not very likely.

The third and the most probable one is a mechanism *via* norcaradiene intermediate. Valence tautomerism between cycloheptatriene and norcaradiene systems is well known phenomenon.[16,17] This tautomerism is also possible between **2** and its valence isomer (**2a**) which should be very strained one. Therefore, if once this strained tricyclic system formed in the reaction mixture, the intramolecular alkoxide anion attack takes place readily to give the ether compound **5**. The Dreiding model of **2a** indicates that the ether linkage formation is possible between alkoxide oxygen and C_1 (*ac.* 2.4 Å). Also, the most favorable conformer of **2a** is that the alkoxide oxygen comes nearby norcaradiene and the big phenyl groups stick to the outside of norcaradiene.

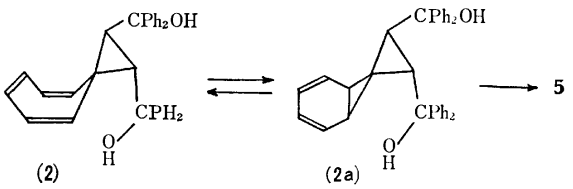

Fig. 6.

Recently, some examples of addition reactions of anionoid reagents with unsaturated or strained compounds have been reported.[18,19] Especially, addition reaction of amines to strained double bonds such as 9,9'-difluolenyridene[20] is a good example of this type of reaction.

The interconversions of **5**, **6**, and **7** are thermal 1,5-hydrogen shift reactions.[21] The diene system of **7** is conjugated with ether linkage constructing the vinyl ether skeletone, and therefore, **7** seems to be the most stable isomer of all of them.

Experimental

All melting and boiling points were uncorrected. IR spectra were measured in carbon tetrachloride solutions or potasium bromide disks, and UV spectra in methanol solutions. PMR spectra were measured with Varian T-60 or HA-100 spectrometer with deuteriochloroform or carbon tetrachloride as solvent and tetramethylsilane as internal

standard. Mass spectra were measured with Hitachi RMU 6D spectrometer at 70 eV by direct method.

*Reactions of **1** with Grignard Reagents and Lithium Aluminium Hydride.* (a) Reaction of **1** (468 mg, 2 mmol) with benzylmagnesium chloride (16 mmol) in anhydrous ether (30 ml) with ordinal method gave an yellow oil (1.436 g). Distillation of the oil afforded benzyl alcohol (50—60 °C/0.5 Torr, 300 mg), diphenylethane (65—70 °C/0.5 Torr, 85 mg), and an yellow oily residue (950 mg). Silica gel TLC (hexane, benzene, and methanol; 6 : 3 : 1) gave colorless oily mixtures (381 mg) which showed a broad absorption band at 1775 cm^{-1} in its IR spectrum. (b) Reaction of **1** (234 mg, 1 mmol) with methylmagnesium iodide (8 mmol) also gave none of clear products. (c) Reaction of **1** (300 mg, 1.3 mmol) with lithium aluminium hydride (1.2 g, 32 mmol) in boiling anhydrous tetrahydrofuran (30 ml) with ordinary method gave unidentified oily mixtures (162 mg) which still showed a broad carbonyl band at 1730 cm^{-1} in its IR spectrum.

*Reaction of **1** with Phenyllithium.* A solution of **1** (936 mg, 4 mmol) in anhydrous ether (30 ml) was added to a solution of phenyllithium (30 mmol) in anhydrous ether (20 ml) at 0 °C during 30 min with stirring. After further stirring for 13 h at room temperature, the reaction mixture was decomposed with water, and extracted with ether. Evaporation of the solvent and recrystallization of the residue from acetone gave **2** (1.58 g, 84%), mp 223—225 °C. Found: C, 87.16; H, 6.30%. Calcd for $C_{35}H_{30}O_2$: C, 87.06; H, 6.05%.

*Reactions of **2** with Acids.* A solution of **2** (1.0 g, 2.1 mmol) in 0.1 N sulfuric acid-dioxane (50 ml) was stirred for 1 h at 0 °C, and then added water (100 ml). The reaction mixture was extracted with benzene. A brown tarry material (1.0 g) obtained by evaporation of the solvent was chromatographed on alumina to give benzophenone (377 mg, 98%) by petroleum ether-benzene (9 : 1) and intractable unidentified tarry materials (600 mg). Treatments of **2** with hydrochloric acid, acetic acid, or silica gel gave the almost identical results with that of the case of sulfuric acid.

*Hydrogenation of **3**.* A mixture of **2** (1.0 g, 2.1 m mol), silica gel (10 g, 60—100 mesh), and benzene (70 ml) was stirred at room temperature for 1.5 h. Separation of the silica gel, and following hydrogenation of the filtrate with paradium carbon (10%, 400 mg) gave a pale yellow oil (1.0 g) after absorption of hydrogen (250 ml, 11 mmol). Alumina column chromatography of this oil gave a colorless oil (540 mg) by petroleum ether, benzophenone (278 mg, 74.5%) by petroleum ether-benzene (8 : 2), and diphenylmethyl alcohol (73 mg, 20%) by ether. Distillation of the colorless oil (bath temp 110 °C/0.2 Torr) gave **4** (454 mg, 74.7%). Found: C, 90.16; H, 9.63%. Calcd for $C_{22}H_{28}$: C, 90.35; H, 9.65%.

*Reactions of **2** with Sodium Hydride.* (a) A mixture of **2** (200 mg, 0.4 mmol), 55% sodium hydride (400 mg, 9 mmol), and anhydrous dioxane (10 ml) was stirred at room temperature for 330 h. The reaction mixture was filtered and the residual solid was decomposed with water and extracted with benzene. Combined organic layer was washed with water and dried over sodium sulfate. Evaporation of the solvent afforded an yellow oily material (335 mg). Purification of this oil with silica gel TLC (benzene) gave recovery of **2** (25 mg, 12%, R_f=0.5) and an yellow tarry material (156 mg, R_f=0.75). Crystallization of the tar from petroleum ether-benzene, and further recrystallization from ethyl acetate yielded pure **5** (125 mg, 63%), mp 115 °C. Found: C, 86.74; H, 6.54%. Calcd for $C_{35}H_{30}O_2$: C, 87.10; H, 6.27%. (b) A mixture of **2** (800 mg, 1.6 mmol), 55% sodium hydride (1.6 g, 37 mmol), and anhydrous dioxane (50 ml) was refluxed for 6.5 h. The same treatment as above afforded **5** (34 mg, 4.2%, R_f=0.75), colorless crystals of **6** (mp 150—155 °C, 351 mg, 44%, R_f=0.85), and **7** (mp 170—174 °C, 136 mg, 17%, R_f=0.9). Recrystallization of **6** and **7** from ethyl acetate raised their mps to 164 and 180 °C, respectively. Found: C, 87.10; H, 6.33% for **6**. Found: C, 86.76; H, 6.43% for **7**. (c) A mixture of **2** (1.0 g, 2.1 mmol), 55% sodium hydride (3.0 g, 70 mmol), and anhydrous dioxane (50 ml) was refluxed for 20 h. After the same treatment as above, the obtained yellow oil was chromatographed on alumina. An yellow oily resinous material (460 mg) which was eluted with benzene was recrystallized from ethyl acetate to give pure **7** (430 mg, 43%).

*Acid Treatments of **5**, **6**, and **7**.* A solution of **5** (10 mg, 0.02 mmol) in methanol (5 ml) containing a drop of conc sulfuric acid was allowed to stand at room temperature for 6 h. UV spectrum of this solution was identical with that of **3**, and gas chromatographic study showed existence of benzophonone. Treatments of **6** and **7** under the same conditions as above showed the identical results as the case of **5**.

*Interconversion of **5**, **6**, and **7**.* A solution of **5** (15 mg, 0.03 mmol) and 55% sodium hydride (30 mg, 7 mmol) in anhydrous dioxane (2 ml) was refluxed for 9 h. Silica gel TLC (benzene) showed three spots at the parts coincident with **5** (R_f=0.75), **6** (R_f=0.85), and **7** (R_f=0.9). By the same procedure, reaction of **6** showed the same three spots as the case of **5** on silica gel TLC, but reaction of **7** showed no other spot except one due to itself, and this spot diminished by prolonged refluxing (about one day).

*Reactions of **8**, **9**, and **10** with Sodium Hydride.* (a) A solution of **8** (1.34 g, 11 mmol) and 55% sodium hydride (2.4 g, 56 mmol) in anhydrous dioxane (10 ml) was stirred for 230 h at room temperature. The starting alcohol **8** (1.32 g, 98%) was recovered by the same treatment as the case of the reaction of **2** with sodium hydride. (b) Reaction of **9** (1.41 g) with sodium hydride under the same conditions as above resulted in recovery of the starting alcohol (1.34 g, 95%). (c) Reaction of **10** (500 mg) with sodium hydride under the same conditions as above resulted in recovery of the starting alcohol (485 mg, 97%).

Reactions of Cycloheptatriene with Benzyl Alcohol and Triphenylmethyl Alcohol. (a) A mixture of cycloheptatriene (1.8 g, 20 mmol), benzyl alcohol (16 g, 148 mmol), 55% sodium hydride (3.0 g, 70 m mol), and anhydrous dioxane (10 ml) was refluxed for 17 h. The starting alcohol was recovered quantitatively by the same treatments as above. (b) By the same procedure as above, reaction of cycloheptatriene with triphenylmethyl alcohol resulted in almost quantitative recovery of triphenylmethyl alcohol.

Preparation of α-Phenyl-β-(7-cycloheptatrienyl)ethyl Alcohol. To a solution of phenyl magnesium bromide prepared from 3.58 g of bromobenzene in 30 ml of ether, a solution of 2.0 g of (7-cycloheptatrienyl)acetaldehyde[22] in 20 ml of ether was added dropwise with stirring and under nitrogen atomsphere. After 5 h, an ordinal workup gave 1.40 g of the colorless needles of **9a**: mp 41—43 °C from hexane-ether. Found: C, 84.89; H, 7.64%. Calcd for $C_{15}H_{16}O$: C, 84.87; H, 7.60%.

We are indebted to Prof. Yusaku Ikegami for ESR spectrum measurements.

Direct Synthesis of 2,2-Diaryl-3-methyl-2,3-dihydrobenzothiazoles from 3-Methyl-2,3-dihydrobenzothiazole-2-thione and Some Mechanistic Aspects

Kin-ya AKIBA,* Hiroaki SHIRAISHI, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received June 9, 1978)

Reactions of 3-methyl-2,3-dihydrobenzothiazole-2-thione (**1**) and 3-methyl-2-(methylthio)benzothiazolium iodide with Grignard reagents gave 2,2-disubstituted 3-methyl-2,3-dihydrobenzothiazole (**2**) as a major product as well as 2,2′-disubstituted 3,3′-dimethyl-2,2′,3,3′-tetrahydrobi(2-benzothiazolyl) (**3**). Reactions of **1** with organolithiums gave **2** as a major product. The results demonstrate that the formation of **3** is due to the presence of transition metals as an impurity in magnesium.

As previously reported,[1] reactions of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles with Grignard reagents have been shown to give 2,2,3-trisubstituted 2,3-dihydrobenzothiazoles as well as other types of products.

It is known that Grignard reagents and organolithiums can react with thiocarbonyl group at sulfur atom.[2] On the other hand, Beak *et al.*[3] have reported that phenyllithium attacks on carbon atom of the thiocarbonyl group on *N*,*N*-dimethylthiobenzamide. Thus, occurrence of C-2 attack with Grignard reagents is expected in 3-methyl-2,3-dihydrobenzothiazole-2-thione (**1**) among other possibilities. On the other hand, reactions of 3-methyl-2-(methylthio)benzothiazolium salt (**8**) with Grignard reagents can be expected to give also 2,2-disubstituted 2,3-dihydrobenzothiazoles. This paper describes synthesis of 2,2-disubstituted 3-methyl-2,3-dihydrobenzothiazoles (**2**) from **1**, **8**, and related compounds.

The reaction of 3-methyl-2,3-dihydrobenzothiazole-2-thione (**1**) with excess Grignard reagents in refluxing benzene for 1.5—4 h under nitrogen afforded 2,2-disubstituted 3-methyl-2,3-dihydrobenzothiazole (**2**) together with 2,2′-disubstituted 3,3′-dimethyl-2,2′,3,3′-tetrahydrobi(2-benzothiazolyl) (**3**) as a minor product.

The presence of unchanged magnesium did not affect considerably the product ratio of **2** to **3** (see Table 1).

4 **5** **a**: R=Et **6**
b: R=Ph

The reaction of **1** with ethylmagnesium bromide gave also **2e** along with bis[*o*-(methylamino)phenyl] disulfide (**4**) and ethyl *o*-(methylamino)phenyl sulfide (**5a**). Refluxing of **1** with *t*-butylmagnesium bromide in benzene for 42 h gave 2-*t*-butyl-3-methyl-2,3-dihydrobenzothiazole (**6**) in 16% yield together with the recovered **1** (77%). Formation of the by-product (**3**) was encountered when phenyl and *p*-chlorophenyl Grignard reagents were employed.

Reactions of **1** with organolithiums proceeded at room temperature and gave mainly **2**. The results are summarized in Table 2. In the cases of phenyl- and butyllithiums, **5b**[1,4] and 2-butylidene 3-methyl-2,3-dihydrobenzothiazole (**7**) were also isolated. The formation of **7** is explained by deprotonation of an intermediate (*A*) by butyllithium[5] as mentioned later.

Table 3 summarizes the results of reactions of **8** with Grignard reagents.

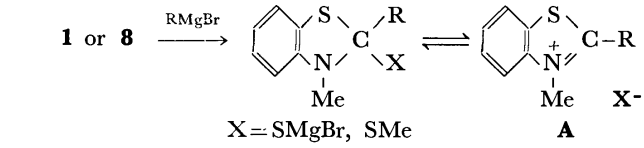
a) In the presence of unchanged magnesium.

The results reveal that the *para*-methoxyphenyl Grignard reagent bearing an electron-donating group tends to give **2** preferentially, whereas electron-withdrawing groups attached to the aromatic ring of Grignard reagents and also higher temperature would stimulate producing the compound **3**.

In the case of *t*-butylmagnesium bromide, **6** was obtained in 31% yield. The salt (**8**) can react with the Grignard reagents at room temperature, but the yield of **2** was less than those with reaction of **1** because of heterogeniety of the system.

Formation of **2** in the reactions of **1** or **8** can be rationalized by assuming the intermediacy of benzothiazolium salt (**A**) as follows.



Dimerized products have also been obtained by the reaction of 3-methylbenzothiazolium,[6] 2-substituted 1,3-benzoxathiolium,[7] and 1,3-benzodithiolium salts[8] with Grignard reagents. Thereupon, reactions of 3-methyl-2-phenylbenzothiazolium iodide (**9a**) with aryl Grignard reagents were examined. The results are summarized in Table 4.

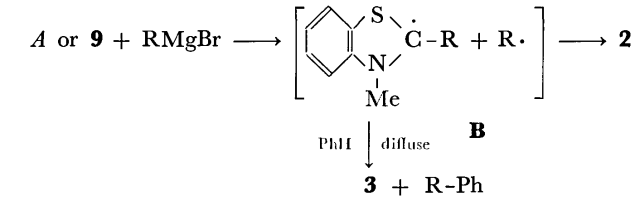
Ph	*p*-MeC_6H_4	r.t., 0.5 h; then 60 °C, 0.5 h	**2g**, 43	31	1.4

The yield of **3** also increased at a higher temperature.

A possible pathway for the formation of **3** would involve reduction of the intermediate **A** or **9** with an Mg–$MgBr_2$ complex in the reaction mixture. In fact, **9a** could be reduced to **3a** with the Mg–$MgBr_2$ complex in refluxing benzene in almost quantitative yield. Another possibility is that one-electron transfer from the Grignard reagent to *A* or **9** would provide the radical intermediate (**B**), which may give **2**, **3**, and the corresponding biphenyl derivative.



Indeed, the formation of biphenyl (21% after correction) was observed, when **9a** was treated with phenylmagnesium bromide in refluxing benzene. The interesting results from *p*-tolylmagnesium bromide solutions prepared from two kinds of magnesium metals [reagent grade: Mg-1 and 99.9% purity: Mg-2], which were treated with **9** and **10** in refluxing benzene, are summarized in Table 5.

Table 5. Effect of purity of magnesium on reactions of **9** or **10** with *p*-tolylmagnesium bromide

Mg	**9** or **10**	**2** (%)	**3** (%)	*Bis-p-tolyl* (%) [a]

	10c	**2i**, 86	**3d**, 2	0
	10c [b]	**2i**, 9	**3d**, 41	55

a) After correction of blank experiment. b) In the presence of a microspatula of anhydrous cobalt(II) chloride.

The results clearly showed that the pure magnesium (Mg-2) provided **2** preferentially and bis-*p*-tolyl was not detected. However, **3** could be obtained as a major product together with a significant amount of bis-*p*-tolyl when the reaction of **10** was carried out in the presence of a small amount of cobalt(II) chloride.

The fact that **3** is always accompanied by a significant amount of bis-*p*-tolyl using Mg-1 or Mg-2 plus cobalt(II) chloride shows that these two products are formed catalyzed by some transition metals present in magnesium as an impurity. This is supported by the fact that *p*-methylbiphenyl was not detected in the reaction mixture by careful gas chromatographic analysis which means that free *p*-toyl radical was not generated during the reaction, thus, in turn, eliminating one-electron transfer mechanism.

In the reaction of **10a** with *p*-tolymagnesium bromide prepared from Mg-2, the presence of an excess magnesium showed no effect, indicating that the reduction of *A* or **9** with the Mg–$MgBr_2$ complex to give **3** does not take place under the reaction conditions using pure magnesium.

In order to prepare 2,2-diaryl derivatives of **2**, the present reaction of **1** with aryl Grignard reagents is recommended and magnesium of higher purity should be used for selective formation of **2** and for suppression of **3** as a by-product.

Experimental

*3-Methyl-2,3-dihydrobenzothiazole-2-thione (**1**)*,[9] mp 92—94 °C (lit, 88—89 °C), 3-methyl-2-(methylthio)benzothiazolium

iodide (**8**),[10] mp 147—148 °C (lit, 148 °C (dec)), and 3-methyl-2-phenylbenzothiazolium iodide (**9a**),[11] mp 217—218 °C (lit, 218 °C (dec)), were prepared according to the reported methods.

*2-Aryl-3-methylbenzothiazolium Iodide (**9**).* *p*-Substituted benzaldehyde (80 mmol) was allowed to react with *o*-aminobenzenethiol (80 mmol) in ethanol (50 ml) for 1 h at 0 °C with stirring to afford 2-arylbenzothiazoline. The resulting thiazoline (60 mmol) was treated with dibenzoyl peroxide (60 mmol) in dichloromethane (250 ml) to give 2-arylbenzothiazole.[12] The benzothiazole (12 mmol) was heated with methyl iodide (40 mmol) at 100 °C in a sealed tube for 20 h to give 2-aryl-3-methylbenzothiazolium iodide (**9**) which was recrystallized from methanol; *p*-chloro derivative (**9b**), yield 80%, mp 253—256 °C (dec) (lit,[13] 224—225 °C) and *p*-methoxy derivative (**9d**), yield 87%, mp 197—198 °C (dec) (lit,[13] 199 °C).

*2-Aryl-3-methylbenzothiazolium Perchlorates (**10**).*[13] A solution of *o*-(methylamino)benzenethiol (69 mmol) and *p*-substituted benzoyl chloride (69 mmol) in benzene (60 ml) was stirred at room temperature for 0.1—1 h and then refluxed for 0.5 h. The resulting precipitates were collected; *p*-chloro chloride, mp 225 °C (dec) and *p*-methoxy chloride mp 191—196 °C (dec). To an aqueous solution of the chloride was added an excess amount of sodium perchlorate and the resulting precipitates were recrystallized from methanol; *p*-chloro (**10b**), yield 85%, mp 239—243 °C, and *p*-methoxy perchlorates (**10c**), yield 80%, mp 195.6—196.7 °C.

The following reactions were carried out under nitrogen.

*Reactions of 3-Methyl-2,3-dihydrobenzothiazole-2-thione (**1**) with Grignard Reagents. General Procedure.* An ethereal solution (20—30 ml) of the Grignard reagent (20—25 mmol), which was filtered through a glass filter, was added to a solution of **1** (905 mg, 5 mmol) in benzene (25—35 ml) and the mixture was refluxed for a time shown below. After addition of 10% aq ammonium chloride, the reaction mixture was extracted with dichloromethane, the extract was dried ($MgSO_4$), and the solvent was removed. The residue was submitted to dry column chromatography (DCC: SiO_2) to separate reaction products.

1) With Phenylmagnesium Bromide: The mixture was refluxed for 3 h. After addition of 10% aq sulfuric acid, evolved hydrogen sulfide was passe dthrough aq lead(II) acetate to give lead(II) sulfide (814 mg, 68%). Separation of the residue by DCC (CH_2Cl_2 : hexane=1 : 4) gave 3-methyl-2,2-diphenyl-2,3-dihydrobenzothiazole (**2a**; 1.021 g, 67%), mp 142—143 °C (from EtOH) (lit,[1a] 142—143 °C), and 3,3′-dimethyl-2,2′-diphenyl-2,2′,3,3′-tetrahydrobi(2-benzothiazolyl) (**3a**; 259 mg, 23%), mp 166—167 °C (from EtOH); NMR ($CDCl_3$): δ 2.24 (s, 6H) and 6.0—8.2 (m, 18H).

Found: C, 74.19; H, 5.26; N, 6.21%, Calcd for $C_{28}H_{24}N_2S_2$: C, 74.30; H, 5.34; N, 6.19%.

2) With p-Chlorophenylmagnesium Bromide: The mixture was refluxed for 4 h. Separation by DCC (CH_2Cl_2: hexane= 1 : 4) gave 2,2-di-*p*-chlorophenyl-3-methyl-2,3-dihydrobenzothiazole (**2b**; 1.079 g, 58%) and 2,2′-di-*p*-chlorophenyl-3,3′-dimethyl-2,2′,3,3′-tetrahydrobi(2-benzothiazolyl) (**3b**; 281 mg, 21%).

2b: did not solidify and was purified by molecular distillation; NMR ($CDCl_3$): δ 2.58 (s, 3H) and 6.3—7.5 (m, 12H).

Found: C, 64.76; H, 3.99; N, 3.63%. Calcd for $C_{20}H_{15}NCl_2S$: C, 64.52; H, 4.06; N, 3.70%.

3b: mp 203—204 °C (from PhH–EtOH); NMR ($CDCl_3$): δ 2.71 (s, 6H) and 6.0—8.1 (m, 16H).

Found: C, 64.33; H, 4.00; N, 5.37%. Calcd for $C_{28}H_{22}N_2Cl_2S_2$: C, 64.48; H, 4.25; N, 5.37%.

3) With p-Tolylmagnesium Bromide: The mixture was refluxed for 3 h. Separation by DCC (CCl_4) gave 3-methyl-2,2-di-*p*-tolyl-2,3-dihydrobenzothiazole (**2c**; 1.398 g, 84%), mp 143—144 °C (from EtOH) (lit,[1a] 141—141.5 °C).

4) With p-Methoxyphenylmagnesium Bromide: The mixture was refluxed for 1.5 h. Separation by DCC (CH_2Cl_2: hexane=1 : 1) gave 2,2-di-*p*-methoxyphenyl-3-methyl-2,3-dihydrobenzothiazole (**2d**; 1.532 g, 84%), mp 87—88 °C (from EtOH); NMR ($CDCl_3$): δ 2.61 (s, 3H), 3.85 (s, 6H), 6.3—7.2 (m, 4H), and 7.29 (ABq, $\Delta\delta$=32 Hz, J=9.5 Hz, 8H).

Found: C, 72.72; H, 5.86; N, 3.90%. Calcd for $C_{22}H_{21}NO_2S$: C, 72.70; H, 5.82; N, 3.85%.

5) With Ethylmagnesium Bromide: Filtration of the Grignard reagent was not carried out. The mixture was refluxed for 4 h. Separation by DCC (CH_2Cl_2 : hexane=1 : 4) and then preparative thin layer chromatography (PTLC) (SiO_2, CH_2Cl_2 : hexane=1 : 4) gave 2,2-diethyl-3-methyl-2,3-dihydrobenzothiazole (**2e**; 555 mg, 54%), bis[*o*-(methylamino)phenyl] disulfide (**4**; 133 mg, 19%), mp 66 °C (lit,[14] 64—68 °C), and ethyl *o*-(methylamino)phenyl sulfide (**5a**; 6 mg) (by IR and NMR[15]).

2e: oily material; NMR ($CDCl_3$): δ 0.95 (t, J=7.5 Hz, 6H), 1.3—2.2 (m, 4H), 2.70 (s, 3H), and 6.12—7.12 (m, 4H); MS: *m/e* 207 (M^+, 8%) and 178 (M^+ −Et, 100).

6) With t-Butylmagnesium Bromide: The mixture was refluxed for 42 h. Separation by DCC (CH_2Cl_2 : hexane= 1 : 4) gave recovered **1** (700 mg, 77%) and oily 2-*t*-butyl-3-methyl-2,3-dihydrobenzothiazole (**6**; 166 mg, 16%) (by NMR[1a]).

*Reaction of **1** with Organolithiums.* *1) With Phenyllithium*: Phenyllithium (40 mmol) in ether (30 ml) was added to **1** (905 mg, 5 mmol) in benzene (30 ml) and the mixture was stirred at room temperature for 15 min. After addition of 10% aq ammonium chloride and then usual work-up, the residue was submitted to DCC (SiO_2, CH_2Cl_2 : hexane= 1 : 4) and then PTLC (SiO_2, CH_2Cl_2 : hexane=1 : 4) to afford **2a** (635 mg, 42%) and oily *o*-(methylamino)phenyl sulfide (**5b**; 206 mg, 19%) (by IR and NMR[16]).

2) With Ethyllithium: To ethyllithium (20 mmol) in pentane (20 ml) was added **1** (905 mg, 5 mmol) in benzene (30 ml) and the mixture was stirred for 1 h. After usual work-up, **2e** (672 mg, 65%) was obtained by DCC (SiO_2, CH_2Cl_2 : hexane=1 : 4).

3) With Butyllithium: To butyllithium (50 mmol) in hexane (31 ml) was added **1** (1.812 g, 10 mmol) in benzene (30 ml) and the mixture was stirred for 1 h. After usual work-up, oily 2,2-dibutyl-3-methyl-2,3-dihydrobenzothiazole (**2f**; 1.536 g, 58%) (by IR and NMR[1c]) and oily 2-butylidene-3-methyl-2,3-dihydrobenzothiazole (**7**; 238 mg, 12%) were isolated by DCC (SiO_2, CH_2Cl_2 : hexane=1 : 1) and then PTLC (SiO_2, $CHCl_3$). **7** gradually changed to a solid on standing.

7: NMR ($CDCl_3$) : δ 0.6—1.9 (m, 7H), 3.01 (s, 3H), 4.65 (br s, 1H), and 6.9—7.4 (m, 4H); MS: *m/e* 205 (M^+, 100%) and 162 (M^+−Pr, 46).

*Reactions of 3-Methyl-2-(methylthio)benzothiazolium Iodide (**8**) with Grignard Reagents.* General procedure was almost the same as that for **1**.

1) With Phenylmagnesium Bromide: The mixture was stirred at room temperature for 1.5 h and then refluxed for 0.5 h. By DCC (CH_2Cl_2 : hexane=1 : 4), **2a** (818 mg, 54%) and **3a** (273 mg, 25%) were obtained.

2) With p-Chlorophenylmagnesium Bromide: The mixture was stirred overnight. By DCC (CH_2Cl_2 : hexane=1 : 4), **2b** (763 mg, 41%) and **3b** (86 mg, 7%) were obtained.

3) With p-*Tolylmagnesium Bromide*: The mixture was stirred overnight. By DCC (CCl_4), **2c** (823 mg, 50%) was obtained.

Similar reaction was carried out using **8** (808 mg, 2.5 mmol) and the Grignard reagent (10 mmol) under stirring for 0.5 h at room temperature and then refluxing for 0.5 h. **2c** (359 mg, 43%) and 3,3′-dimethyl-2,2′-di-*p*-tolyl-2,2′,3,3′-tetrahydrobi(2-benzothiazolyl) (**3c**: 166 mg, 28%), mp 163—165 °C (from EtOH); NMR (CCl_4): δ 2.29 (s, 6H), 2.94 (s, 6H), and 5.8—7.9 (m, 16H).

Found: C, 74.87; H, 5.86; N, 5.81%. Calcd for $C_{30}H_{28}N_2S_2$: C, 74.96; H, 5.87; N, 5.83%.

4) With p-*Methoxyphenylmagnesium Bromide*: The mixture was stirred overnight. By DCC (CH_2Cl_2: hexane=1 : 1), **2d** (1.515 g, 83%) was obtained.

5) With t-*Butylmagnesium Bromide*: The mixture was stirred overnight, and **6** (325 mg, 31%) was obtained by DCC (CH_2Cl_2 : hexane=1 : 4).

*Reactions of 3-Methyl-2-phenylbenzothiazolium Iodide (**9a**) with Grignard Reagents.* *1) With Phenylmagnesium Bromide*: Phenylmagnesium bromide (2 mmol) in ether (5 ml) was added to **9a** (353 mg, 1.0 mmol) in benzene (15 ml) and the mixture was stirred overnight. After usual work-up and PTLC (SiO_2, CCl_4), **2a** (93 mg, 31%), and **3a** (13 mg, 6%) were obtained.

Similar reaction was carried out using **9a** (883 mg, 2.5 mmol) and the Grignard reagent (5 mmol) under stirring at room temeperature for 0.5 h and then refluxing for 0.5 h, and **2a** (295 mg, 39%) and **3a** (289 mg, 51%) were obtained.

2) With p-*Tolylmagnesium Bromide*: *p*-Tolylmagnesium bromide (3 mmol) in ether (3 ml) was added to **9a** (353 mg, 1.0 mmol) in benzene (15 ml) and the mixture was stirred for 0.5 h and then refluxed for 0.5 h. After usual work-up and PTLC (SiO_2, CCl_4), 3-methyl-2-phenyl-2-*p*-tolyl-2,3-dihydrobenzothiazole (**2g**; 137 mg, 43%) and **3a** (70 mg, 31%) were obtained.

2g: mp 110.5—112.0 °C (from EtOH); NMR ($CDCl_3$); δ 2.30 (s, 3H), 2.52 (s, 3H), and 6.1—7.4 (m, 13H); MS; *m/e* 317 (M^+, 37%), 240 (100), and 226 (76).

Found: C, 79.46; H, 6.03; N, 4.33%. Calcd for $C_{21}H_{19}NS$: C, 79.45; H, 6.03; N, 4.41%.

*Reaction of **9a** with Mg–$MgBr_2$.* To a mixture of Mg and $MgBr_2$, prepared from magnesium (122 mg, 5 mmol) and 1,2-dibromoethane (470 mg, 2.5 mmol) in ether (10 ml), was added **9a** (883 mg, 2.5 mmol) in benzene (10 ml) and the mixture was stirred for 14 h and then refluxed for 1 h. After usual work-up, the residue was recrystallized from methanol to give **3a** (550 mg, 97%).

Determination of Biphenyl. An ethereal solution (10 ml) of phenylmagnesium bromide (8 mmol) was prepared. The Grignard solution (2.6 ml) and naphthalene as an internal standard were added to **9a** (353 mg, 1 mmol) in benzene (10 ml) and the mixture was refluxed for 49 min. Separately, the Grignard solution (2.6 ml), benzene (10 ml), and naphthalene were refluxed for 40 min. Based on gas chromatographic analysis (OV-1, 2m, 120 °C), the amount of biphenyl was 0.352 mmol and 0.142 mmol, respectively, indicating the net formation of biphenyl (0.210 mmol, 21%).

*Reactions of 2-Aryl-3-methylbenzothiazolium Salts (**9** or **10**) with* p-*Tolylmagnesium Bromide.* *General Procedure*: *p*-Tolylmagnesium bromide was prepared from magnesium (2.431 g, 0.1 mol) and *p*-bromotoluene (17.104 g, 0.1 mol) in ether (100 ml), using magnesium of reagent grade (Mg-1) and 99.9% magnesium (Mg-2), respectively, and filtered through glass wool.

To a suspension of **9** or **10** (2.5 mmol) in benzene (20 ml) was added the Grignard solution (5 mmol) at 78 °C and the mixture was heated as 76—80 °C for 1 h under stirring. A small aliquot was taken for gas chromatography. After addition of 1.5 M sulfuric acid, the reaction mixture was extracted with benzene, the extract was dired ($MgSO_4$), and evaporated. The residue was submitted to DCC (SiO_2, CH_2Cl_2: hexane=1 : 4; 1 : 1 for Mg-1 and **9c**). When the separation was incomplete, the yields were calculated based on the peak area of the NMR. The yields of bis-*p*-tolyl were determined by gas chromatography (OV-1, 120 °C) using biphenyl as an internal standard, and corrected by the amount produced after heating the Grignard solution in benzene without **9** or **10** under the same conditions. The results were listed in Table 5.

Physical data of new products are as follows.

2h: mp 145—146 °C (from MeOH–pentane); NMR ($CDCl_3$) : δ 2.27 (s, 3H), 2.51 (s, 3H), and 6.15—7.42 (m, 12H); MS : 353 (M^+ +2, 11%), 351 (M^+, 25), 262 (22), 260 (58), and 240 (100).

Found: C, 71.77; H, 5.19; N, 3.82%. Calcd for $C_{21}H_{18}NSCl$: C, 71.68; H, 5.16; N, 3.98%.

2i, mp 120.5—122.0 °C (from EtOH–pentane); NMR ($CDCl_3$): δ 2.33 (s, 3H), 2.59 (s, 3H), 3.75 (s, 3H), and 6.24—7.50 (m, 12H); MS : 347 (M^+, 46%), 256 (100), and 240 (92).

Found: C, 76.01; H, 6.19; N, 3.85%. Calcd for $C_{22}H_{21}NOS$: C, 76.05; H, 6.09; N, 4.03%.

3d: mp 182.0—183.5 °C (from MeOH–pentane); NMR ($CDCl_3$): δ 2.65 (s, 6H), 3.72 (s, 6H), and 5.90—7.95 (m, 16H); MS 512 (M^+, 0.8%), 256 (100), 241 (67), 226 (28), 198 (30), and 150 (16).

Found: C, 70.06; H, 5.54; N, 5.16%. Calcd for $C_{30}H_{28}N_2O_2S_2$: C, 70.28; H, 5.50, N, 5.46%.

Reactions of 4*H*-1-Benzothiopyran-4-ones and Related Compounds with Dimethyl Sulfate†

Hiroyuki NAKAZUMI* and Teijiro KITAO
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received June 9, 1978)

4*H*-1-Benzothiopyran-4-ones (thiochromones) and isomeric 2*H*-1-benzothiopyran-2-ones (thiocoumarins) have been allowed to react with dimethyl sulfate (DMS) to study the differences in reactivity on methylation. Methylation of 2-methyl(thiochromones) with DMS afforded the blue colored dimerization products, 4-(4-methoxy-1-benzothiopyran-2-ylidenemethyl)-2-methyl-1-benzothiopyrylium perchlorates, while that of 7-methoxy-4-methyl(thiocoumarin) gave the *O*-methylated yellow salt, 2,7-dimethoxy-4-methyl-1-benzothiopyrylium perchlorate. Methylations of oxa analogues (coumarins) and aza analogues (2-quinolones) of thiocoumarins with DMS have also been examined. It has been found that the ease of formation of methylation products is affected by the hetero atom and carbonyl group.

In a previous paper,[1] the spectral characterization of 4*H*-1-benzothiopyran-4-ones (thiochromones) was proposed to distinguish them from 2*H*-1-benzothiopyran-2-ones (thiocoumarins). However, it was very difficult to distinguish only on the basis of spectral data. The methylation of these compounds with dimethyl sulfate (DMS) is an attempt to distinguish them. Tolmachev *et al.*[2] reported the methylation of 2-methyl(thiochromone), however, the systematic study of the methylation of thiochromones, thiocoumarins and the oxa analogues (coumarins) and the aza analogues (2-quinolones) with DMS have not been reported. In this paper, the differences in methylation of these heterocyclic compounds with DMS will be reported.

Experimental

All the melting points are uncorrected. Infrared spectra were recorded on a Hitachi ESI-S2 spectrophotometer using KBr pellets. ^{1}H-NMR spectra were taken on a Hitachi R-24A spectrometer with tetramethylsilane as an internal standard. Elemental analyses were recorded on a Yanaco CHN recorder MT-2. DTA-TG analysis was taken on a Rigaku DTA-TG instrument at 10 °C/min under nitrogen.

*4-(4-Methoxy-1-benzothiopyran-2-ylidenemethyl)-2-methyl-1-benzothiopyrylium Perchlorate Derivatives (**2a**—**2c**).* 2-Methyl(thiochromone)[1] **1a** (3.5 g) was added to dimethyl sulfate (2 ml). The mixture was stirred at 70 °C for 5 h and after cooling, H_2O (2 ml) was added to the reaction mixture, followed by the addition of 60% $HClO_4$ (4 ml). The resulting solid was separated, and washed with MeOH, $CHCl_3$, and EtOH, and recrystallized from glacial acetic acid to give **2a** in 32% yield. From the first filtrate, starting material **1a** was recovered in 15% yield.

The other 1-benzothiopyrylium perchlorates (**2b** and **2c**) were similarly prepared in 30—40% yield together with the starting materials (**1b** and **1c**). **2a**(X=H): mp 225 °C; λ_{max} (acetone) 590 nm (ε 6.28×10^4); NMR(CF_3COOH)δ= 3.35 (3H, s), 4.65 (3H, s), 5.78 (2H, s), and 8.20—8.90 ($\approx$9H, m); Found: C, 56.19; H, 3.70%; Calcd for $C_{21}H_{17}O_5S_2Cl$: C, 56.19; H, 3.79%. **2b**(X=OCH_3): mp >300 °C; λ_{max} (acetone) 596 nm(ε 6.92×10^4); NMR(CF_3COOH) δ= 3.20, 4.05, 4.25, 4.65, 5.55, and 7.60—8.80 (integral values could not be measured due to the poor solubility of **2b**); Found: C, 54.49; H, 4.18%; Calcd for $C_{23}H_{21}O_7S_2Cl$: C, 54.28; H, 4.13%. **2c**(X=Cl): mp>300 °C; λ_{max} (acetone) 590 nm(ε 5.22×10^4); NMR(CF_3COOH) δ=3.35 (3H, s), 4.65(3H, s), 5.75 (2H, s) and 7.80—8.90 ($\approx$7H, m); Found: C, 48.12; H, 2.73%; Calcd for $C_{21}H_{15}O_5S_2Cl_3$: C, 48.70; H, 2.90%.

*4-(1-Benzothiopyran-2-ylidenemethyl)-2-methyl-1-benzothiopyrylium Perchlorate (**3**).* A suspension of $AlCl_3$ (2.6 g) in THF (40 ml) was added to a solution of $LiAlH_4$ (0.8 g) in THF. To the resulting solution, a solution of 2-methyl(thiochromone) (3.5 g) in THF (40 ml) was added dropwise at 25—30 °C. After standing for 30 min at 30 °C, H_2O (4 ml) and then 6M-H_2SO_4 (10 ml) was added to the reaction mixture. After filtration, the filtrate was condensed and extracted with ether. To the extract 70% $HClO_4$ (5 ml) and H_2O (10 ml) were added, and the resulting solid was washed with ether and methanol to give **3**: mp 250 °C; NMR(CF_3COOH) δ=2.85 (3H, s), 5.40 (2H, s), and 7.80—8.10 ($\approx$10H, m); λ_{max} (acetone) 616 nm(ε 6.14×10^4); Found: C, 57.47; H, 3.78%; Calcd for $C_{20}H_{15}S_2O_4Cl$: C, 57.35; H, 3.58%.

*2,7-Dimethoxy-4-methyl-1-benzothiopyrylium Perchlorate (**6**).* Compound **6** was prepared from **4**[1] by a method similar to that for compound **2a** and a reaction time of 10 h in 10% yield with the starting materials. Mp 166—168 °C; λ_{max} (acetone) 386 nm(ε 1.10×10^4); NMR(CF_3COOH) δ=3.09 (3H, s), 4.14 (3H, s), 4.60 (3H, s), 7.60—7.80 (3H, m), and 8.57 (1H, m); Found: C, 44.92; H, 4.12%; Calcd for $C_{12}H_{13}O_6SCl$: C, 44.93; H, 4.06%.

*4-Methoxy-2H-1-benzothiopyran-2-one (**7**).* Compound **7** was prepared from 4-hydroxy-2*H*-1-benzothiopyran-2-one **5**[3] by a method similar to that for compound **2a**: yield 33%; mp 126—128 °C; ν_{CO} 1635 cm^{-1}; MS(80 eV), *m/e*(rel intensity), 192 (100), 164 (64), 149 (85), and 136 (10); NMR ($CDCl_3$)δ=4.00 (3H, s), 6.10 (1H, s), 7.40—7.50 (3H, m), and 8.15 (1H, m); Found: C, 62.58; H, 4.12%; Calcd for $C_{10}H_8O_2S$: C, 62.50; H, 4.17%.

*2,7-Dimethoxy-4-methylquinolinium Perchlorate (**11**).* Compound **10**[4] (1.0 g) was added to dimethyl sulfate (8.4 g) with stirring. The mixture was heated at 70 °C for 4 h and after cooling, H_2O (7 ml) was added, followed by 60% $HClO_4$ (10 ml). The resulting solid was filtered after standing at room temperature for several hours. Recrystallization from EtOH gave quinolinium perchlorate **11**: yield 41%; dec 245 °C; NMR (CF_3COOH) δ=3.00 (3H, s), 4.10 (3H, s), 4.30 (3H, s), 7.20—7.55 (3H, m), and 8.30 (1H, m); Found: C, 47.15; H, 4.57; N, 4.25%; Calcd for $C_{12}H_{14}NO_6Cl$: C, 47.45; H, 4.61; N, 4.61%.

*2,7-Dimethoxy-4-methylquinoline (**12**).* Quinolinium

† A preliminary report of this work was presented at the 10th Congress of Heterocyclic Chemistry, Tsukuba, October 1977.

salt **11** (0.1 g) was dissolved in MeOH (5 ml), and 10% aqueous NaOH was added to this solution until the pH was 10. The resulting solid was collected and recrystallized from MeOH–H_2O solution to give 2,7-dimethoxy-4-methylquinoline **12**: mp 67—68 °C; NMR($CDCl_3$) δ=2.60 (3H, s), 3.95 (3H, s), 4.05 (3H, s), 6.63 (1H, s), and 7.20—7.80 (3H, m); Found: C, 70.68; H, 6.40; N, 6.47%; Calcd for $C_{12}H_{13}NO_2$: C, 70.94; H, 6.40; N, 6.90%.

*1,4-Dimethyl-2-methoxyquinolinium Perchlorate (**15**).* Compound **15** was prepared from **13**[5] by a method similar to that for compound **11**: yield 54%; mp 161—162 °C; NMR(CF_3COOH) δ=3.00 (3H, s), 4.30 (3H, s), 4.50 (3H, s), 7.45 (1H, s), and 7.80—8.45 (4H, m); Found: C, 50.01; H, 4.84; N, 4.73%; Calcd for $C_{12}H_{14}NO_5Cl$: C, 50.09; H, 4.87; N, 4.78%.

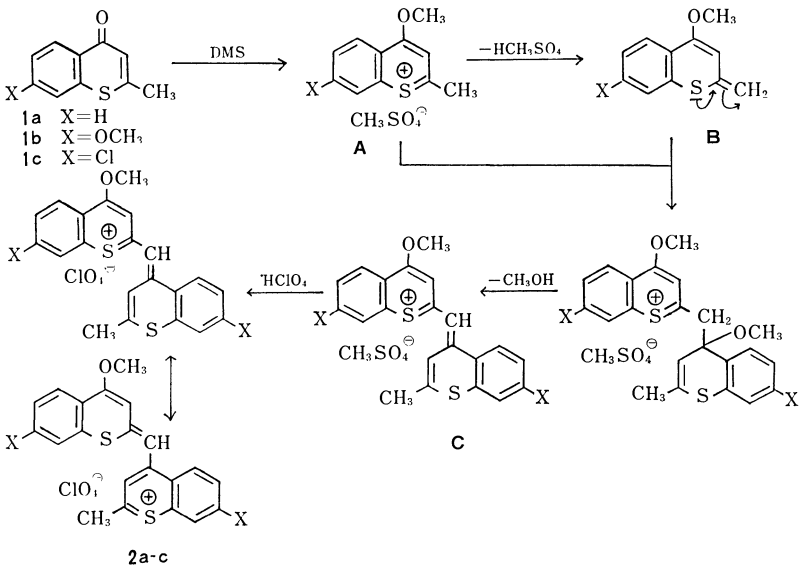
*4-Methyl-2-methoxyquinolinium Perchlorate (**16**).* Compound **14**[6] was allowed to react with DMS by a method similar to that for compound **11**. After treating with 60% $HClO_4$, the reaction mixture was allowed to stand overnight at room temperature. The resulting solid was separated by filtration, and recrystallization from MeOH afforded quinolinium perchlorate **15** (yield 11%). Another quinolinium perchlorate **16** was isolated by the evaporation of the filtrate of compound **15** and purified by repeated recrystallization from MeOH. It was found that compound **16** contained one molecule of water of crystallization by means of TG and DTA. Yield 50%; mp 157 °C; NMR(CF_3COOH) δ=3.05 (3H, s), 4.45 (3H, s) 7.45 (1H, s), and 7.70—8.40 (4H, m); Found: C, 45.79; H, 4.84; N, 5.27%; Calcd for $C_{11}H_{12}NO_5Cl\cdot H_2O$: C, 45.28; H, 4.80; N, 4.80%.

*4-Methyl-2-(methylthio)quinolinium Perchlorate (**17**) and 7-Methoxy-4-methyl-2-(methylthio)quinolinium Perchlorate (**18**).* Compound **17** was prepared by a method similar to that for compound **11** from 4-methylquinoline-2-thione:[7] yield 26%, mp 226—228 °C; NMR(CF_3COOH) δ=2.95 (6H, s) and 7.60—8.40 (5H, m); Found: C, 45.53; H, 4.30; N, 5.11%; Calcd for $C_{11}H_{12}NO_4SCl$: C, 45.60; H, 4.15; N, 4.84%. Compound **18** was similarly prepared from 7-methoxy-4-methylquinoline-2-thione (mp 240 °C; Found: C, 64.60; H, 5.44; N, 7.08%) which was obtained by the reaction of 7-methoxy-4-methyl-2-quinolone with P_2S_5 in benzene for 6 h under reflux: yield 38%; dec 250 °C; NMR (CF_3COOH) δ=2.95 (6H, s), 4.10 (3H, s), and 7.45—8.30 (4H, m); Found: C, 44.79; H, 4.46; N, 4.69%; Calcd for $C_{12}H_{14}NO_5SCl$: C, 45.07; H, 4.38; N, 4.38%.

*7-Methoxy-4-(7-methoxy-4-methylbenzopyran-2-ylidenemethyl)-2-(methylthio)benzopyrylium Perchlorate (**19**).* 7-Methoxy-4-methyl-2*H*-benzopyran-2-thione was obtained by the reaction of 7-methoxy-4-methyl(coumarin) with P_2S_5 in benzene: yield 64%; mp 135 °C; lit,[8] 136 °C. Treatment of the thiocarbonyl derivative with DMS at 70 °C and then with 60% $HClO_4$ gave a red product. Recrystallization from glacial acetic acid gave **19**: yield 23%; NMR(CF_3COOH) δ=3.10 (6H, s), 4.20 (6H, s), 5.20 (2H, s), and 7.50—8.50 ($\approx$7H, m); λ_{max}(acetone) 556 nm (ε 5.98×10^4); Found: C, 56.85; H, 4.46%; Calcd for $C_{23}H_{21}O_8SCl$: C, 56.04; H, 4.26%.

Results and Discussion

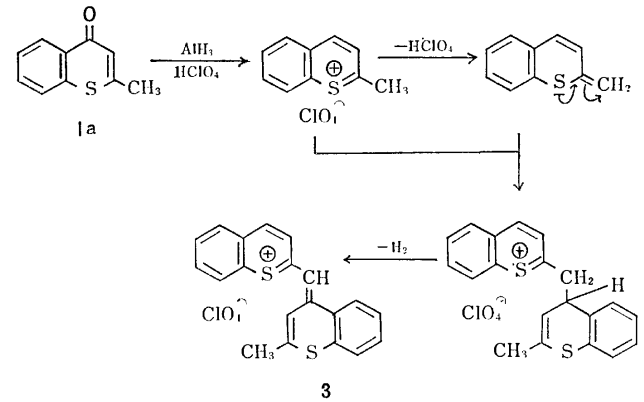
The Methylation of Thiochromones and Thiocoumarins. Traverso[9] has reported that 4-methoxythiopyrylium perchlorate, as the *O*-methylated product, was formed when 4*H*-thiopyran-4-one reacted with DMS followed by treatment with perchloric acid. In the case of 2-methyl(thiochromone) **1a**, a blue salt was found under the same conditions. The structure of this blue salt **2a** has been determined as 4-(4-methoxy-1-benzothiopyran-2-ylidenemethyl)-2-methyl-1-benzothiopyrylium perchlorate, on the basis of the NMR spectrum and elemental analyses. The structure has been also supported by ESCA.[10] The reactions of 7-methoxy-2-methyl- and 7-chloro-2-methyl(thiochromones) with DMS also gave blue 1-benzothiopyrylium salts **2b** and **2c**, respectively, with the starting materials. The blue 1-benzothiopyrylium salts have visible absorption maxima in the region 590—596 nm similar to that of a thiacyanine dye, which was prepared by the cyclodehydration of 4-(phenylthio)-2-butanone with polyphosphoric acid.[11] Tolmachev *et al.*[2] have reported that a similar 1-benzothiopyrylium salt was obtained by the reaction of 2-methyl(thiochromone) **1a** with methyl *o*-nitrobenzenesulfonate in toluene. A possible mechanism for the formation of **2a—c** is given in Scheme 1:



Scheme 1.

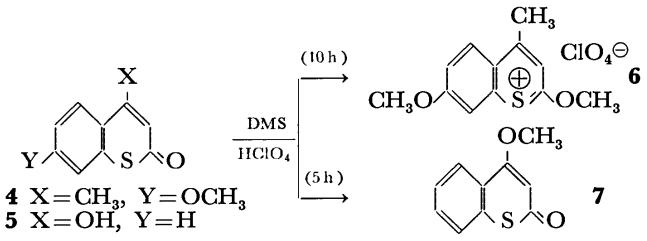
i.e. an initial attack of DMS to 2-methyl(thiochromone) derivatives leading to the *O*-methylated derivative **A**. Deprotonation could then occur to give **B**. The condensation of **B** with **A** would lead to **C**, and an anion exchange of ClO_4^- would afford the products **2a**—**c**.

Furthermore, 2-methyl(thiochromone) **1a** was reduced by aluminum hydride to 2-methyl-4*H*-1-benzothiopyran-4-ol, and the latter converted to the blue 1-benzothiopyrylium salt **3** with perchloric acid (Scheme 2). From these results, it appears that the methyl group at the 2-position of thiochromone derivatives has activated hydrogens.

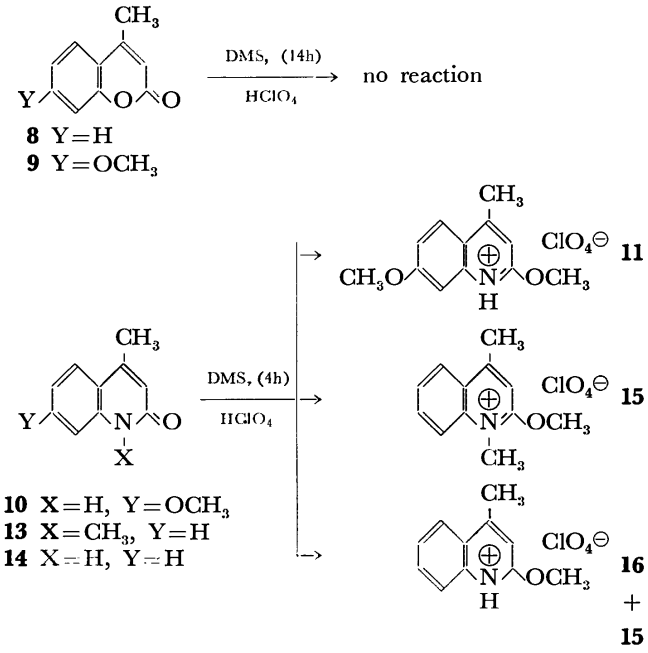


Scheme 2.

Methylation of 7-methoxy-4-methyl(thiocoumarin) **4**, the isomer of 7-methoxy-2-methyl(thiochromone) **1b**, with DMS gave a yellow salt. This yellow salt was identified with 2,7-dimethoxy-4-methyl-1-benzothiopyrylium perchlorate **6** as the *O*-methylated product of **4**. In the case of 4-hydroxy(thiocoumarin) **5**, 4-methoxy(thiocoumarin) **7** was isolated as the *O*-methylated product at the 4-position of **5** (Scheme 3). The different methylation mechanisms between 2-methyl(thiochromone) and 4-methyl(thiocoumarin) derivatives may be utilized to distinguish them.

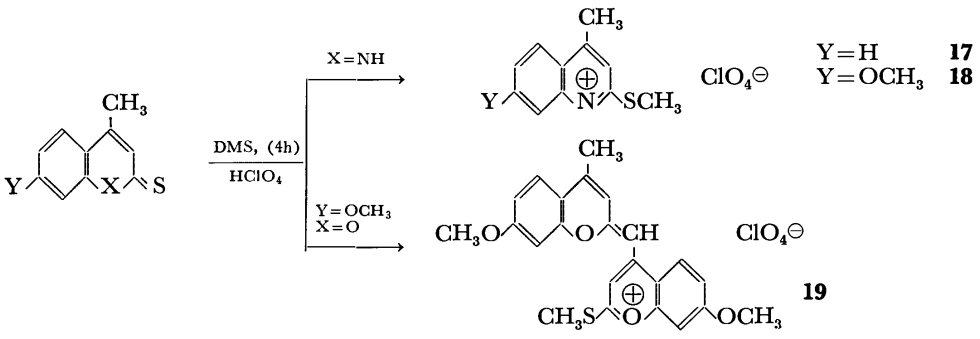


Scheme 3.



Scheme 4.

The Methylation of Oxa and Aza Analogues of Thiocoumarins with DMS. A comparison of the methylation of oxa analogues (coumarins) and aza analogues (2-quinolones) of 4-methyl(thiocoumarin) derivatives with DMS is summarized in Scheme 4. No methylation reaction occur, however, between coumarin derivatives (**8** and **9**) and DMS, even under the prolonged reaction time. In the cases of 2-quinolone derivatives (**10**, **13**, and **14**), *O*- and/or *N*-methylated products were obtained. The structures of quinolinium salts **11** and **16** could be identified by the treatment of **11** or **16** with base. For example, the 2-methoxyquinoline derivative **12** was obtained by the treatment of **11** with 10% aqueous NaOH. Similarly, 1,4-dimethyl-2-quinolone **13** gave the *O*-methylated 2-methoxy derivative **15**. In the case of 4-methyl-2-quinolone **14**, the 2-methoxy derivative **16** and the dimethylated quinolinium salt **15** were obtained. This result showed that the competitive *N*-methylation and *O*-methylation of **14** proceeded. From a comparison of the methylation of these heterocyclic compounds, it may be seen that methylation at the carbonyl group of heterocyclic compounds containing a nitrogen and/or sulfur atom readily occurs, but in the case of heterocyclic compounds containing an oxygen atom no methylation



Scheme 5.

occurs.

The Methylation of Heterocyclic Compounds Containing a Thiocarbonyl Group with DMS. Reactions of 2-quinolone and coumarin derivative(s) with phosphorus pentasulfide in benzene afforded the thiocarbonyl derivatives, which were subsequently treated with DMS (Scheme 5). In the cases of the quinoline derivatives, colorless *S*-methylated products **17** and **18** were obtained, respectively. While 7-methoxy-4-methyl-2*H*-benzopyran-2-thione afforded a red compound, 7-methoxy-4-(7-methoxy-4-methylbenzopyran-2-ylidenemethyl)-2-(methylthio)benzopyrylium salt **19**, the structure of which was assigned by analogy of **2a—c**, based on the NMR spectrum and elemental analyses. This observation shows that the formation of the benzopyrylium salt proceeds easier in the case of 2*H*-benzopyran-2-thione containing a thiocarbonyl group than in the case of coumarins containing a carbonyl group.

Dry Ozonation of Friedelane and Friedelin[1)]

Eri AKIYAMA, Masahiro TADA,† Takahiko TSUYUKI, and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

†*Laboratory of Bioorganic Chemistry, Tokyo University of Agriculture and Technology, Fuchu, Tokyo 183*

(Received June 16, 1978)

Dry ozonation of friedelane afforded 18β,19β-epoxyfriedelane, 19-oxofriedelane, 16-oxofriedelane, 21-oxofriedelane, friedelin, and a new compound, 15-oxofriedelane. Friedelin, on dry ozonation, gave 3,16-dioxofriedelane, 3,19-dioxofriedelane, and new compounds, 18β,19β-epoxyfriedelan-3-one and 3,15-dioxofriedelane. It was shown that the oxidation occurred at D and E rings regioselectively in the dry ozonation.

It has been known that ozone reacts slowly with saturated hydrocarbons in solution to give alcohols and ketones.[2)] Mazur *et al.*[3-6)] and Beckwith *et al.*[7,8)] have demonstrated that ozone adsorbed on silica gel reacts efficiently with saturated hydrocarbons,[3,4)] *t*-alcohols,[4)] bromides,[5)] acetates,[4,7,8)] bromo acetate,[6)] and ketone.[8)] This procedure, named dry ozonation, has been developed as a useful synthetic method for stereoselective hydroxylation of tertiary carbon atoms of organic compounds. Recently this dry ozonation reaction has been shown to be also applicable to oxidative conversion of primary amines to nitro compounds.[9)]

Hitherto only a few investigations on functionalization of unactivated carbon atoms in triterpene skeletons have been reported[10,11)] in contrast with investigations on the steroidal compounds.[12)] In connection with the studies on synthesis of friedelane derivatives, the dry ozonation reaction was applied to functionalization of an unactivated carbon atom of a friedelane skeleton. It is shown that friedelane (**1**) and its 3-oxo derivative, friedelin (**2**), on dry ozonation, gave 15-, 16-, and 21-oxo derivatives.

Friedelane (**1**)[13)] was adsorbed on silica gel (*ca.* 100 times weight of **1**). The silica gel was then cooled to −78 °C and saturated with ozone at this temperature. After warming to room temperature, the reaction products were eluted from the silica gel and examined by TLC. It was shown that the starting material was completely consumed and only a complex mixture of unidentified polar products with extremely low R_f value was detected. No spot corresponding to mono-oxygenated products such as tertiary alcohols or ketones was observed on the TLC. Beckwith *et al.*[7)] reported that a substrate adsorbed on silica gel was oxidized with ozone generated by desorption from the silica gel, and not directly with adsorbed ozone. And they pointed the importance of the maintenance of a high partial pressure of ozone during the warm-up period.

To obtain optimum conditions for the formation of the mono-oxygenated products, dependence of reaction temperature and ozone concentration on their yields was examined. The reaction at higher temperature increased in the conversion of friedelane and in the formation of the unidentified products, but decreased in the yields of the mono-oxygenated products. It was found that the following reaction temperature gave a fairly good result for the formation of the mono-oxygenated products, although the conversion yield of friedelane was less than 20%. The silica gel saturated with ozone at −78 °C was kept at −65 to −60 °C and ozone was desorbed gradually by sweeping with a slow stream of nitrogen at this temperature range, and then the silica gel was warmed up to room temperature. Ozone concentration was shown to be independent of the yields and silica gel (Wakogel C 200; 10 g) was saturated enough with a flow of 3% ozone in oxygen at flow rate of 50 ml/min for 1 h at −78 °C.

Under these conditions, friedelane (**1**; 100 mg) adsorbed on silica gel (10 g) was oxidized with ozone. The unchanged friedelane (**1**: 82 mg) was recovered and a mixture (*ca.* 19 mg; corresponding to 18% conversion) of mono-oxygenated products was obtained and was subjected to separation by preparative TLC, alumina column, and/or HPLC.

18β,19β-Epoxyfriedelane[14)] (**3**; yield[15)] 48%), 19-oxofriedelane[14)] (**4**; yield[15)] 2%), 16-oxofriedelane[16)] (**5**; yield[15)] 11%), and friedelin (**2**; yield[15)] 0.8%) were obtained and identified by comparison with their authentic samples, respectively. Two new carbonyl compounds (**6** and **7**) were also obtained in 11 and 1% yields,[15)] respectively.

The compound (**6**), $C_{30}H_{50}O$, mp 239—240 °C, showed a carbonyl absorption at 1700 cm^{-1} in the IR spectrum and an AB quartet signal at δ_A 2.15 and δ_B

2.50 (J_{AB}=18 Hz) in the PMR spectrum. These observations indicate the presence of a grouping ■–CO–CH_2–■ (■ refers to a quaternary carbon atom). The carbonyl group of this compound was inferred to be located either at C-15 or C-16 from the characteristic fragment peaks in the high resolution mass spectrum[17] (Fig. 1). The spectral data of the carbonyl compound (**6**) was different from those of 16-oxofriedelane (**5**).[16] Therefore, the ketone (**6**) was deduced to be 15-oxofriedelane.

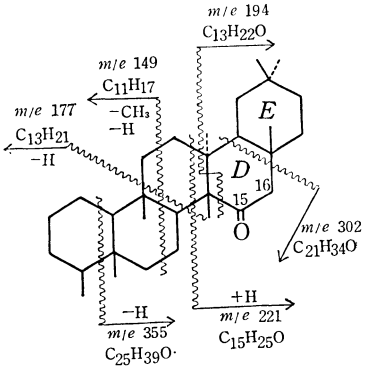

Fig. 1.

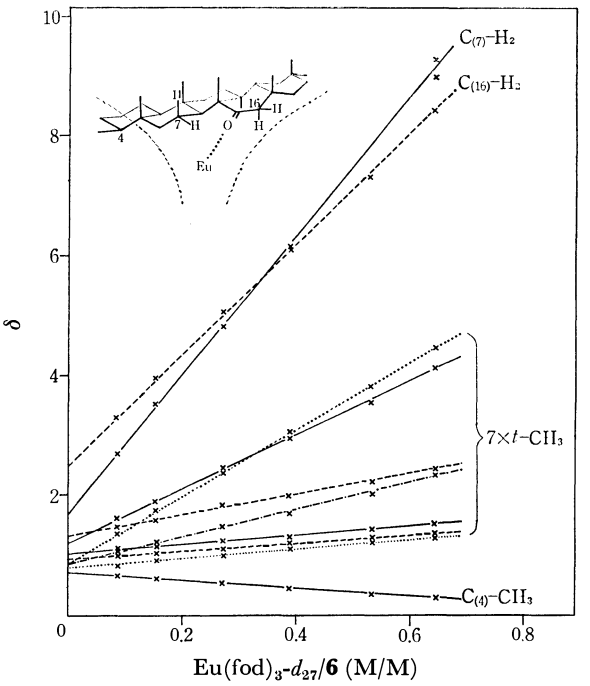

Fig. 2. Induced paramagnetic shifts for 15-oxofriedelane (**6**) in a 5% (w/v) in $CDCl_3$.

This conclusion was confirmed by spectral and chemical evidence. The intact friedelane-framework without skeletal rearrangement during the reaction was shown for **6** by its reduction under forced Wolff-Kishner conditions to afford friedelane (**1**). The carbonyl group at C-15 is so hindered that a half amount of **6** was left unchanged even though under these reduction conditions. On tretament with sodium deuterioxide, the compound (**6**) gave a deuteriated product (**6**-d_2), whose molecular ion peak was observed at *m/e* 428. In PMR measurement of **6** using Eu(fod)$_3$-d_{27} as a shift reagent, a doublet due to a secondary methyl group at C-4 suffered an upfield shift and a multiplet due to a methylene group caused condsierable downfield shift, which was much larger than that for the α-methylene protons (at C-16) adjacent to the carbonyl group (Fig. 2). Provided that the carbonyl group locates at C-15 and the shift reagent is associated with the carbonyl oxygen atom, these observations were reasonably expalined. The secondary methyl group at C-4 which would be placed outside of a cone area suffered upfield shift. The methylene group which caused downfield shift could be assigned to $C_{(7)}$–H_2 because of the nearest proximity of the shift reagent.

Oxidation with selenium dioxide, the compound (**6**) gave 15,16-dioxofriedelane (**8**), mp 280—281 °C, IR 1720 and 1700 cm^{-1}, MS *m/e* 440 (M^+). The dione (**8**) was shown to be identical with that obtained from 16-oxofriedelane (**5**) by the same treatment.

The other carbonyl compound (**7**), mp 237—240 °C, $[\alpha]_D$+117°, was shown to possess a grouping ■–CO–CH_2–■ based on the IR spectrum (1720 cm^{-1}) and on an appearance of a doublet as an H_A-part (δ 2.60, d, J=12 Hz) of an AB quartet in the PMR spectrum. In the PMR spectrum using Eu(fod)$_3$-d_{27} as a shift reagent, an H_B-part of the AB

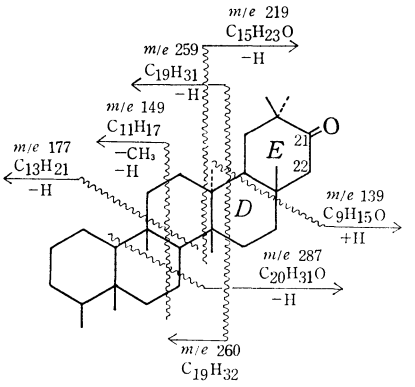

Fig. 3.

quartet was observed. The investigation on the fragmentation pattern in the high resolution mass spectrum revealed that the carbonyl group of **7** must locate on either D or E ring, that is, on either 15-, 16-, 19-, 21-, or 22 carbon atom[17] (Fig. 3). Thus the structure of **7** could be either 21- or 22-oxofriedelane, because the remaining three compounds had been already identified as the products of this reaction.

Courtney and Gascoigne isolated several friedelane derivatives from *Siphonodon australe* Benth.,[18] one of which was shown to be 3,21-dioxofriedelane.[19] In this structure determination, 21-oxofriedelane was prepared and the melting point (241—242 °C), $[\alpha]_D$ value (+152°), and the main fragment peaks (*m/e* 259, 177, and 149) were described.[18,20] On the other hand, 22-oxofriedelane has not been reported yet. Unfortunately direct comparison could not be made because no authentic 21-oxofriedelane left in Courtney's laboratory. However, the physical constants and mass fragmentation pattern were nearly

the same as those of the authentic 21-oxofriedelane. From these facts together with the spectral data, it is probable that the compound (**7**) would be 21-oxofriedelane (**7**), not 22-oxofriedelane.

Although 18β,19β-epoxyfriedelane (**3**) was obtained as the main product in the dry ozonation of friedelane (**1**), the epoxide (**3**) could be considered to be a secondary reaction product formed from friedel-18-ene (**9**) by oxidation with ozone. Initial attack of ozone to a methine hydrogen atom at C-18 would give unstable 18β-hydroxyfriedelane, which could be immediately dehydrated to form friedel-18-ene (**9**). It is known that the methine hydrogen atom at C-18 is susceptible to reaction with bromine to give friedel-18-ene (**9**)[13,21] through 18-bromofriedelane which could not be isolated, and that friedel-18-ene (**9**) in solution is easily epoxidized by ozone.[14,22]

Dry ozonation of friedel-18-ene (**9**) under the same conditions as above, gave the epoxide (**3**) in 53% yield together with the unchanged **9** (in 12% yield) and unidentified polar materials. 19-Oxofriedelane (**4**), however, could not be detected in the reaction mixture. This implies that 19-oxofriedelane (**4**) would be produced by direct insertion of ozone into $C_{(19)}$–H followed by oxidation, not through friedel-18-ene (**9**).

Friedelin (**2**) was then subjected to dry ozonation under the same conditions as above. However eaxmination of the reaction mixture by TLC showed that most of the starting material (**2**) remained unchanged. The low reactivity seems to be due to the presence of an electron-withdrawing carbonyl group at C-3.[4,5] After saturation with ozone at −78 °C, the silica gel was warmed to −15 °C and ozone was desorbed by sweeping with a stream of nitrogen at this temperature. The reaction mixture was separated as before.

Friedelin (**2**) was recovered in 32% yield. 3,16-Dioxofriedelane[16] (**12**; yield[15] 3%), a new epoxy ketone (**10**; yield[15] 12%), and a mixture of two diketones (**11** and **13**) were obtained. The epoxy ketone (**10**), $C_{30}H_{48}O_2$, mp 266—269 °C (with decomposition), showed a carbonyl absorption band at 1710 cm^{-1} and a singlet at δ 2.56 in the PMR spectrum, which could be easily assignable to a 19α-H by comparison with that (δ 2.56, s) of 18β,19β-epoxyfriedelane (**3**). The epoxy ketone (**10**) was subjected to the Birch reduction, the Jones oxidation, and then the Huang-Minlon reduction to afford 19-oxofriedelane (**4**). Thus the epoxy ketone (**10**) was shown to be formulated as 18β,19β-epoxyfriedelan-3-one.

The mixture of diketones (**11** and **13**), giving one spot on TLC, was separated by HPLC to afford **11** (yield[15] 1%), mp 264—266 °C, IR 1708 and 1680 cm^{-1} and **13** (yield[15] 3%), mp 280.5—281.5 °C, IR 1710 and 1700 cm^{-1}. On the Huang-Minlon reduction, the mixture (**11** and **13**) gave a mixture of 19-oxofriedelane (**4**) and 15-oxofriedelane (**6**). Therefore, the structutes of the diketones (**11** and **13**) were determined to be 3,19- and 3,15-dioxofriedelanes, respectively.

The dry ozonation of both friedeleane (**1**) and friedelin (**2**) resulted in the preferential introduction of a carbonyl group into hindered positions such as 15-, 16-, 19-, and 21-carbon atoms. These findings seem to be important and useful for synthesis of these carbonyl compounds hitherto unaccessible by other synthetic procedures. The reason why these sterically hindered ketones were produced is explained as follows.[7,8] If A ring moiety of friedelane (**1**) is preferentially adsorbed on the surface of silica gel due to sterical accessibility and a carbonyl group on A ring of friedelin (**2**) is apt to combine with the adsorbent, and if these molecules are ordered ideally in a close-packed array, it would be expected that the terminal moiety of these molecules, D or E ring, would be exposed for the attack by ozone.

Experimental

General Procedures. IR spectra were measured in KBr disk using a Hitachi EPI-G2 spectrometer. CD and ORD measurements were carried out on a JASCO Model J-20 spectrometer. Optical rotations were measured on a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer and high resolution mass spectra on a Hitachi RMH-2 mass spectrometer operating at 70 eV with a direct inlet system. The relative intensity observed in low resolution mass spectra was expressed in % in the parentheses. PMR spectra were measured using a JEOL 4H-100 (100 MHz) or a Hitachi R-20 (60 MHz) spectrometer. Chemical shifts were expressed in δ downfield from TMS as an internal standard, and coupling constants in Hz. HPLC analyses were carried out at room temperature using a Liquid Chromatograph Model ALC/GPC 202/401 (Waters Assoc.) with an RI detector (column: μ-Porasil 1/8(inch)×1(foot); pressure *ca.* 500 psi). GLC was carried out using a Shimadzu Gas Chromatograph 4APF equipped with a hydrogen flame ionization detector (column: OV-1 at 280 °C). Ozone was generated from an Ozonizer Model O-1-2 (Nippon Ozon) and silica gel (Wakogel C-200) was used for adsorbent. Analytical TLC was carried out on Kieselgel G (E. Merck, Darmstadt) and Alumina B-10-F (Wako) in 0.25 mm thickness, and preparative TLC on Kieselgel PF_{254} (E. Merck, Darmstadt) in 0.5 mm thickness. Wakogel C-200 (Wako) and Activated Alumina (Showa Chem.) were used for column chromatography. Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and were uncorrected.

*Dry Ozonation of Friedelane (**1**).* Silica gel (10 g) was mixed with a solution of friedelane (**1**; 100 mg) in hexane (20 ml) and shaken well. After the solvent was removed in a rotary evaporator, the silica gel was heated at 100 °C for 1 h and then deactivated with water (0.4 ml). The silica gel was placed in a reaction vessel, cooled to −78 °C and saturated with ozone at a flow rate of 50 ml/min for 1 h. The reaction vessel was maintained at −65 to −60 °C and a slow stream of nitrogen was passed through the silica gel for 1.5 h and then the vessel was warmed gradually to room temperature. The silica gel, on which the reaction products were adsorbed, was placed on the top of a column of silica gel (1 g), and hexane (200 ml) was eluted to afford the unchanged friedelane (**1**; 82 mg). Successive elution with benzene (150 ml) gave a mixture (*ca.* 19 mg) of monooxygenated friedelanes, which showed six spots on TLC (SiO_2). The mixture was further separated by preparative TLC (3 plates (20×20 cm), developed with hexane–benzene (1:1); detection: iodine) to give six components with R_f 0.7, 0.65, 0.5, 0.4, 0.25, and 0.2. The least polar fraction [9 mg; mp 268—271 °C; IR 1000, 940, and 920 cm^{-1}; PMR

δ 2.56 (1H, s); MS *m/e* (%) 426 (M^+; 33), 411 (11), 297 (17), 257 (28), 149 (78), and 135 (100)] was identified to be 18β,19β-epoxyfriedelane (**3**) by comparison with an authentic sample.[14] The structure of the second component was left undetermined because of paucity of the material. The third product [0.4 mg; mp 230—231 °C; IR 1675 cm^{-1}; PMR δ 2.17 (1H, s); MS *m/e* (%) 426 (M^+; 10), 411 (18), 259 (36), 217 (30), 139 (100), and 149 (28)] was shown to be 19-oxofriedelane (**4**).[14]

The fourth component with R_f 0.4 (**6**; 2 mg) was shown to be 15-oxofriedelane (**6**) based on spectral data and chemical conversion (*vide infra*). The fifth component (**5**) was found to contain a small quantity of unidentified material by TLC (Al_2O_3) and the mass spectrum. This dry ozonation was repeated seven times and the component with R_f 0.25 was collected. The combined material (23 mg) was subjected to separation by column chromatography on alumina (10 g). Elution with hexane–benzene (2:1) afforded 16-oxofriedelane[16] [**5**; 14 mg, mp 270—272 °C; IR 1680 cm^{-1}; PMR δ 0.78, 0.84, 0.95, 1.05, 1.17, 1.28 (each 3H, s; *t*-Me), 2.15 and 2.37 (2H, ABq, J=19 Hz; $C_{(15)}$-H_2); MS *m/e* 426 (M^+; 21), 411 (17), 274 (8), 259 (20), 149 (100), and 109 (75)] and a mixture of unidentified alcohols (7 mg).

Although the sixth component was inferred to be a mixture from the PMR spectrum, no separation could be attained by TLC (Al_2O_3). The HPLC examination (solvent system: 1.5% ether-hexane; flow rate: 0.9 ml/min) revealed that the fraction consisted of 21-oxofriedelane (**7**; 0.2 mg, R_t 17 min) and friedelin (**2**; 0.15 mg, R_t 20 min). The material (18 mg), obtained by repeating the dry ozonation of friedelane (each 250 mg, 12 times), was subjected to separation by HPLC under the same conditions as above to afford friedelin (**2**; 4 mg) and 21-oxofriedelane [**7**; 6 mg, mp 237—240 °C; $[\alpha]_D$ +117° (*c* 0.12, $CHCl_3$); ORD $[\alpha]_{280}$ −2320° and $[\alpha]_{325}$ +3490°; IR 1720 cm^{-1}; PMR δ 2.60 (1H, d, J=12 Hz; $C_{(22)}$–H); MS *m/e* (%) 426 (M^+; 3), 411 (7), 259 (22), 217 (16), 177 (15), and 149 (100); High resolution mass spectrum: *m/e* 426.3878 ($C_{30}H_{50}O$), 411.3646 ($C_{29}H_{47}O$), 287.2383 ($C_{20}H_{31}O$), 260.2483 ($C_{19}H_{32}$), 259.2420 ($C_{19}H_{31}$), 219.1835 ($C_{15}H_{23}O$), 177.1602 ($C_{13}H_{21}$), 149.1330 ($C_{11}H_{17}$), and 139.1115 ($C_9H_{15}O$). The fragmentation patterns were shown in Fig. 3].

*15-Oxofriedelane (**6**).* Mp 239—240 °C (recrystallized from ethyl acetate); $[\alpha]_D$ +38° (*c* 1.5, $CHCl_3$); CD $[\theta]_{300}$ −215 (*c* 0.1, dioxane); IR 1700 cm^{-1}; PMR δ 0.77, 0.86, 0.89, 0.95, 1.00, 1.20, 1.32 (each 3H, s, *t*-Me), 2.15 and 2.50 (2H, ABq, J=18 Hz; $C_{(16)}$–H_2); MS *m/e* (%) 426 (M^+; 19), 411 (90), 393 (64), 355 (10), 221 (54), 194 (100), 177 (20), and 149 (41); High resolution mass spectrum: *m/e* 426.3874 ($C_{30}H_{50}O$), 411.3681 ($C_{29}H_{47}O$), 355.2912 ($C_{25}H_{39}O$), 302.2569 ($C_{21}H_{34}O$), 221.1941 ($C_{15}H_{25}O$), 194.1646 ($C_{13}H_{22}O$), 177.1665 ($C_{13}H_{21}$), and 149.1343 ($C_{11}H_{17}$). Found: C, 84.73; H, 11.89%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%. The fragmentation patterns in the high resolution mass spectrum and PMR spectral data using Eu(fod)$_3$-d_{27} as a shift reagent were given in Figs. 1 and 2.

*Wolff-Kishner Reduction of 15-Oxofriedelane (**6**).* A mixture of sodium (100 mg) in diethylene glycol (5 ml) was heated at 180 °C under a nitrogen atmosphere. To the solution, anhydrous hydrazine (1 ml) and 15-oxofriedelane (**6**; 13 mg) were added and the mixture was refluxed overnight. After excess of hydrazine was removed by distillation, the reaction mixture was heated under reflux at 210 °C overnight. After usual treatment, the reaction product was subjected to separation by preparative TLC, developed with hexane-benzene (1:1) to afford friedelane (**1**; 2 mg), mp 248.5—249 °C together with the unchanged starting material (**6**; 2 mg).

*Treatment of 15-Oxofriedelane (**6**) with Sodium Deuterioxide.* A mixture of 15-oxofriedelane (**6**; 2 mg) and sodium deuterioxide prepared from sodium (10 mg) and deuterium oxide (0.5 ml) in dioxane (1 ml) was heated under reflux for 14 h under nitrogen. The reaction mixture was poured into water, extracted with benzene–ether, washed with dilute hydrochloric acid and successively with aqueous sodium hydrogencarbonate, and then dried over magnesium sulfate. This procedure was repeated twice to give deuteriated 15-oxofriedelane, which was found to consist of 15-oxofriedelane-d_2 (**6**-d_2; 90.2%), -d_1 (7.1%), and -d_0 (2.6%) by mass spectrometry.

*Conversion of 15-Oxofriedelane (**6**) into 15,16-Dioxofriedelane (**8**).* A mixture of 15-oxofriedelane (**6**; 5 mg) and selenium dioxide (17 mg) in acetic acid (5 ml) was heated under reflux for 6 h. Since TLC examination of the reaction mixture showed that a considerable amount of the starting material was left unchanged, heating was continued for 16 h after addition of selenium dioxide (5 mg). After cooling and removal of metallic selenium, the reaction mixture was extracted with ether and worked up as usual to give a residue, which was subjected to separation by preparative TLC (developed with benzene). The unchanged 15-oxofriedelane (**6**; *ca.* 1 mg) was recovered and 15,16-dioxofriedelane [**8**; 2 mg, mp 280—281 °C; IR 1720 and 1700 cm^{-1}; PMR δ 0.78, 0.86, 0.96, 1.02, 1.20, 1.39, and 1.54 (each 3H, s, *t*-Me); MS *m/e* (%) 440 (M^+; 94), 412 (70), 288 (98), 260 (100), and 177 (53)] was obtained.

*Conversion of 16-Oxofriedelane (**5**) into 15,16-Dioxofriedelane (**8**).* i) A mixture of 16-oxofriedelane (**5**; 4 mg) and selenium dioxide (17 mg) in acetic acid (5 ml) was heated under reflux (bath temperature 135 °C) for 6 h. After additional selenium dioxide (10 mg) was added, the reaction mixture was heated under reflux (bath temperature 150 °C) overnight. The same treatment and purification as above gave unchanged 16-oxofriedelane (**5**; *ca.* 1 mg) and 15,16-dioxofriedelane [**8**; 2 mg, mp 280—280.5 °C; IR 1720 and 1700 cm^{-1}; PMR δ 0.78, 0.86, 0.96, 1.02, 1.20, 1.39, and 1.54 (each 3H, s, *t*-Me); MS *m/e* (%) 440 (M^+; 94), 425 (9), 412 (70), 288 (98), 260 (100), and 177 (53)]. ii) A mixture of 16-oxofriedelane (**5**; 5 mg), selenium dioxide (18 mg), and dioxane (2 ml) in a sealed tube was heated at 180 °C for 4 h. After usual treatment, 15,16-dioxofriedelane (**8**) was obtained nearly quantitatively.

*Dry Ozonation of Friedel-18-ene (**9**).* Friedel-18-ene (**9**) was prepared from friedelane (**1**) according to the known procedures[13] and purified by passing through a column of silica gel impregnated with 30% silver nitrate. The purity of the friedel-18-ene (**9**) was examined by GLC, which confirmed the absence of friedelane (R_t 4.3 and 3.7 min for **1** and **9**, respectively).

Friedel-18-ene (**9**; 125 mg) was adsorbed on silica gel (13 g) and oxidized with ozone by the same procedures as above. The reaction product (127 mg), obtained from the silica gel-product mixture by elution with ethyl acetate, was subjected to separation by column chromatography of silica gel (15 g) and eluted with hexane (100 ml), hexane-benzene (3:1, 40 ml), benzene (100 ml), and then with ethyl acetate (100 ml). From the hexane fraction, friedel-18-ene (**9**; 15 mg) was recovered and the fraction eluted with hexane–benzene gave 18β,19β-epoxyfriedelane (**3**; 60 mg). A mixture (*ca.* 5 mg), obtained from the benzene fraction, showed three spots on TLC, but none of the products corresponding to these spots was identical with any one of the products obtained by the dry ozonation of friedelane (**1**).

Dry Ozonation of Friedelin (2). Friedelin (**2**; 420 mg) in chloroform (150 ml) was adsorbed on silica gel (50 g) and the solvent was removed in a rotary evaporator. The silica gel was cooled to −78 °C and saturated with ozone for 2 h under the same conditions as above. A slow stream of nitrogen was passed through the silica gel kept at −15 °C, and the temperature was raised to room temperature.

The reaction product (450 mg), eluted from the silica gel with ethyl acetate, was dissolved in benzene and passed through a column of silica gel (40 g). Elution was carried out with the following solvents: benzene (500 ml), benzene–ether (10:1, 500 ml), and ethyl acetate (500 ml). From the benzene fraction, friedelin (**2**; 70 mg) was recovered. The fraction (168 mg), eluted with benzene–ether, gave three spots on TLC (SiO_2) and subjected to separation by preparative TLC (15 plates (20×20 cm), developed with benzene–chloroform–ether (20:2:1), detection: iodine) to afford three fractions with R_f 0.45, 0.38, and 0.25.

The least polar fraction gave an epoxy ketone (**10**; 50 mg), mp 266—269 °C (with decomposition); $[\alpha]_D$ −6° (*c* 1.2, $CHCl_3$); IR 1710, 1115, 1080, 920, and 835 cm^{-1}; PMR δ 2.0—2.5 (3H, m, $-C\underline{H}_2-CO-C\underline{H}-$) and 2.56 (1H, s; $C_{(13)}$–H); MS *m/e* (%) 440 (M^+; 24), 425 (7), 368 (16), 311 (17), 154 (100), and 127 (99); Found: C, 81.65; H, 10.93%. Calcd for $C_{30}H_{48}O_2$: C, 81.76; H, 10.98%.

The second fraction with R_f 0.38 was shown to be a mixture of two components by HPLC (solvent system: 15% ether–hexane, flow rate: 0.5 ml/min) and separated into 3,19-dioxofriedelane (**11**; 4 mg, R_t 21 min) and 3,15-dioxofriedelane (**13**; 12 mg, R_t 24 min). *3,19-Dioxofriedelane (11)*: Mp 264—266 °C; IR 1708 and 1680 cm^{-1}; PMR δ 2.0—2.5 (3H, m; $-C\underline{H}_2-CO-C\underline{H}-$) and 2.20 (1H, br s; $C_{(18)}$–H); MS *m/e* (%) 440 (M^+; 9), 425 (11), 422 (5), 407 (3), 273 (25), 231 (16), 191 (11), and 139 (100). *3,15-Dioxofriedelane (13)*: Mp 280.5—281.5 °C; $[\alpha]_D$ +20° (*c* 0.67, $CHCl_3$); IR 1710 and 1700 cm^{-1}; PMR δ 2.16 and 2.55 (2H, ABq, J=19 Hz; $C_{(16)}$–H_2); MS *m/e* (%) 440 (M^+; 52), 425 (59), 422 (12), 407 (29), 355 (48), 201 (58), and 194 (100).

The third fraction with R_f 0.25 was identified to be 3,16-dioxofriedelane[16] (**12**; 13 mg), mp 294—295.5 °C; IR 1720 and 1690 cm^{-1}; PMR δ 0.73, 0.97, 1.05, 1.20, 1.29 (each 3H, s, *t*-Me), 0.90 (6H, s, 2×*t*-Me), and 1.8—2.6 (5H, m; $C_{(2)}$–H_2, $C_{(4)}$–H, and $C_{(15)}$–H_2); MS *m/e* (%) 440 (M^+; 48), 425 (52), 355 (36), 273 (29), 220 (43), 219 (33), 163 (31), and 109 (100).

Conversion of 18β,19β-Epoxyfriedelan-3-one (10) into 19-Oxofriedelane (4). A solution of 18β,19β-epoxyfriedelan-3-one (**10**; 19 mg) in ethylamine (30 ml) was placed in a flask equipped with a Dry Ice-condenser, and lithium (30 mg) and *t*-butyl alcohol (1 drop) were added with stirring. Blue color of the solution faded within 1 h and aqueous solution of ammonium chloride (300 mg) and then water were added. The reaction product was extracted with chloroform and washed with dilute hydrochloric acid, sodium hydrogencarbonate solution, and brine, and dried over sodium sulfate. Evaporation gave a residue (20 mg), which was dissolved in benzene–ether (10:1) and filtered through a column of silica gel to give a diol (19 mg).

A solution of the diol (19 mg) in acetone (50 ml) was cooled with ice-bath and the Jones reagent (0.2 ml) was added to the solution with stirring at 2 °C for 2 h and the stirring was continued at 20 °C for 3 h. Excess of the oxidizing reagent was destroyed by addition of methanol and the product was extracted with chloroform. The crude material, obtained by usual treatment, was purified by preparative TLC (2 plates (20×20 cm), developed with benzene–ether (10:1), detection:iodine) followed by recrystallization from ethyl acetate to give 3,19-dioxofriedelane (**11**; 14.5 mg), mp 255—257 °C; IR 1708 and 1680 cm^{-1}; PMR δ 2.20 (1H, br. s; $C_{(18)}$–H) and 2.0—2.5 (3H, m; $C_{(2)}$–H_2 and $C_{(4)}$–H).

A mixture of 3,19-dioxofriedelane (**11**; 13 mg), above obtained, hydrazine hydrate (2 ml), and sodium hydroxide (200 mg) in diethylene glycol (30 ml) was heated under reflux for 3 h. Excess of the hydrazine was removed by slow distillation until the temperature of the vapor reached to 205 °C, and the heating was continued for 4.5 h. After usual work-up, the product was dissolved in benzene and purified by passing through a column of alumina to afford 19-oxofriedelane (**4**; 4 mg), mp 230—231 °C; IR 1675 cm^{-1}; PMR δ 2.20 (1H, s; $C_{(18)}$–H); MS *m/e* (%) 426 (M^+; 9), 411 (18), 259 (36), 217 (29), 149 (27), and 139 (100).

Reduction of a Mixture of 3,19- and 3,15-Dioxofriedelanes (11 and 13). A mixture (6 mg) of 3,19- and 3,15-dioxofriedelanes (**11** and **13**), obtained as the second fraction with R_f 0.38 in the dry ozonation of friedelin (**2**) (*vide supra*), was heated under reflux with hydrazine hydrate (2 ml), potassium hydroxide (200 mg), and diethylene glycol (20 ml) for 2 h under a nitrogen atmosphere. Excess of the hydrazine was distilled off until the vapor temperature reached to 205 °C, and the mixture was refluxed for 4.5 h. Usual treatment and separation by preparative TLC (1 plate (20×20 cm), developed with hexane–benzene (1:1), detection: iodine) gave 19-oxofriedelane (**4**; 1 mg) and 15-oxofriedelane (**6**; 2 mg). *19-Oxofriedelane (4)*: Mp 230.5—232 °C; IR 1675 cm^{-1}; MS *m/e* (%) 426 (M^+; 10), 411 (17), 259 (36), 217 (30), 149 (30), and 139 (100). *15-Oxofriedelane (6)*: Mp 238—238.5 °C; IR 1700 cm^{-1}; MS *m/e* (%) 426 (M^+; 20), 411 (90), 393 (65), 355 (10), 221 (53), 194 (100), 177 (20), and 149 (39).

The authors are grateful to Professor Tohru Kikuchi, Toyama University for a gift of spectral chart copies of 16-oxofriedelane (**5**) and 3,16-dioxofriedelane (**12**).

Synthesis of 8- and 10-Methyl-substituted 8,9,10,11-Tetrahydro-7*H*-cycloocta[*de*]naphthalenes and Their 9-Oxo Derivatives

Toshihiro KAMADA

National Chemical Laboratory for Industry, 1-1-5 Honmachi, Shibuya-ku, Tokyo 151

(Received June 23, 1978)

A novel and convenient method for the synthesis of the 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene ring system is described. Reaction of diethyl acetonedicarboxylate and 1,8-bis(bromomethyl)naphthalene gave the eight-membered pericyclized compound, diethyl 9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10-dicarboxylate, which was then converted, through several steps, into various kinds of 8- and 10-methyl-substituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes and their 9-oxo derivatives, as well as the unsubstituted compounds, 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene and 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one. The hydrocarbon, 8,8,10,10-tetramethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]-naphthalene was prepared from 8,8,10,10-tetrakis(tosyloxymethyl)-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene.

Despite considerable current interest in the chemistry of peri-substituted naphthalenes,[1] few studies have been made on the eight-membered pericyclized naphthalene derivatives, 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (**1**). The only compound of this ring system so far known is the unsubstituted hydrocarbon **1a**, which was synthesized by Nelsen and Gillespie in five steps from acenaphthylene.[2] Recently, as a part of studies on the chemistry of pericyclic naphthalene derivatives, a report was given on the syntheses of some derivatives of **1a** starting from 1,8-naphthalenedicarboxylic anhydride.[3] A novel and convenient method was worked out for the synthesis of the tetrahydrocycloocta[*de*]naphthalene ring **1**, which can be applied to the syntheses of various substituted compounds of this ring system besides **1a**. This paper deals with the syntheses of several 8- and 10-methyl-substituted 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalenes (**2a**—**7a**) as well as some 9-oxo derivatives (**1b**—**7b**) which do not seem to have been reported.

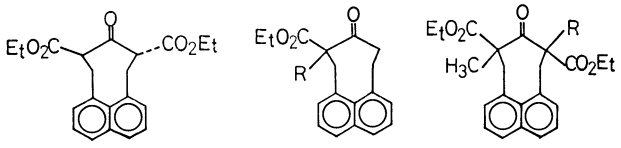
For the formation of the tetrahydrocycloocta[*de*]-naphthalene skeleton **1**, diethyl acetonedicarboxylate (**8**) was allowed to react with 1,8-bis(bromomethyl)-naphthalene (**9**) prepared from 1,8-naphthalenedicarboxylic anhydride.[3] By the reaction between equimolar amounts of **8** and **9** in refluxing ethanol, using sodium ethoxide as a condensing agent, diethyl 9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10-dicarboxylate (**10**) with the desired peri-eight-membered ring was obtained. Compound **10**, when treated with



10 **11** **12**

a; R=H, **b**; R=CH_3

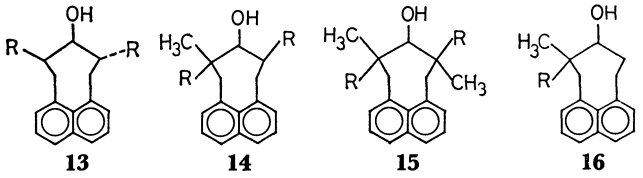
sodium ethoxide in ethanol, underwent deethoxycarbonylation to yield ethyl 9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8-carboxylate (**11a**). Alkaline hydrolysis of the β-keto esters **10** and **11a** was accompanied by decarboxylation to afford 8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one (**1b**). The Clemmensen reduction of ketone **1b** gave the parent hydrocarbon **1a** identical with that previously reported.[2]

Methylation of the β-keto ester **10** gave a mixture from which diethyl 8-methyl-9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10-dicarboxylate (**12a**) and diethyl 8,10-dimethyl-9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8,10-dicarboxylate (**12b**) were isolated by fractional crystallization in 60 and 22% yields, respectively. Repeated methylation of **10** with excess of the reagents afforded only **12b**. By alkaline hydrolysis and concurrent decarboxylation the monomethyl keto diester **12a** was converted almost in a quantitative yield into 8-methyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one (**2b**), which afforded the corresponding hydrocarbon **2a** on Clemmensen reduction.

On the other hand, alkaline treatment of dimethyl keto diester **12b** in boiling dioxane yielded a mixture of geometrical isomers, which was separated by recrystallization to give *cis*-8,10-dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-one (**3b**) and its *trans* isomer **4b** in 64 and 23% yields, respectively. **4b** was also prepared more efficiently from keto diester **10** having a *trans* structure by the following reaction. **10** was reduced by lithium aluminum hydride to give triol **13a**, which was converted by treatment with methanesulfonyl chloride in pyridine into dimesylate **13b**. Treatment of **13b** with excess lithium aluminum hydride in boiling ether afforded *c*-8,*t*-10-dimethyl-

8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-*r*-9-ol (**13c**), which, on Jones oxidation, gave the desired *trans*-8,10-dimethyl ketone **4b** in a 40% overall yield from **10**.

Monomethyl keto diester **12a** was then converted into 8,8,10-trimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta-[*de*]naphthalen-9-ol (**14c**) through the same steps as in the preparation of **13c** from the keto diester **10**. Reduction of **12a** with lithium aluminum hydride gave a triol **14a**, which, on treatment with 2 mol of methanesulfonyl chloride in pyridine, was converted into **14b**. Subsequent hydrogenolysis of **14b** with lithium aluminum hydride afforded a 59% overall yield of the trimethyl alcohol **14c**. Similarly, 8,8,-10,10-tetramethyl-8,9,10,11-tetrahydro-7*H*-cycloocta-[*de*]naphthalen-9-ol (**15c**) was derived from the dimethyl keto diester **12b** in a 78% yield by the successive reduction, mesylation and hydrogenolysis (**12b**→**15a**→**15b**→**15c**). On the other hand, methylation of the keto monoester **11a** gave ethyl 8-methyl-9-oxo-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene-8-carboxylate (**11b**), which was then converted, on reactions similar to the above through a diol **16a** and a monomesylate **16b**, into 8,8-dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalen-9-ol (**16c**) in only 12% overall yield from **11a**. Each of the methyl alcohols **14c**, **15c**, and **16c** was oxidized by Jones reagent to give the corresponding α-methyl ketones, **6b**, **7b**, and **5b**, respectively.

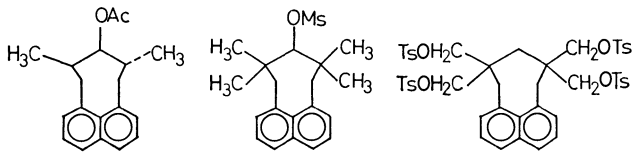


13 **14** **15** **16**

a; R=CH_2OH, **b**; R=CH_2OMs, **c**; R=CH_3

cis-8,10-Dimethyl ketone **3b** underwent Clemmensen reduction to give only the corresponding hydrocarbon **3a**, while the *trans*-dimethyl ketone **4b** gave, on Clemmensen reduction, a mixture of three compounds, which was isolated by chromatography on alumina to yield the desired *trans*-8,10-dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**4a**) (48% yield) along with the *trans*-dimethyl alcohol **13c** (8%) and its acetate **17** (26%), the acetoxyl group being derived from the solvent (acetic acid). The carbonyl groups of the *gem*-dimethyl ketone **5b** and the trimethyl ketone **6b** were smoothly reduced by Wolff-Kishner reactions to afford the corresponding hydrocarbons, 8,8-dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**5a**) and 8,8,10-trimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**6a**), respectively.

An attempt to transform **6b** into **6a** by Clemmensen reduction resulted in the formation only of intractable substances with a small amount of **6b**. On the other hand, Clemmensen reduction of the tetramethyl ketone **7b** produced only the tetramethyl alcohol **15c** instead of the hydrocarbon **7a**, while by the Wolff-Kishner procedure **7b** was recovered unchanged with a small amount of alcohol **15c**. Hydrogenolysis of



17 **18** **19**

the mesylate ester of the tetramethyl alcohol **15c** (**18**) using the same conditions as in the transformation of **13b** into **13c** caused only *O*-mesyl bond cleavage to regenerate **15c**. The great difficulty in effecting these reactions might be caused by steric hindrances,[4,5] expected to greatly increase in highly methylated compounds such as **6** and **7**, as compared to those in the lower homologs (**1**—**5**).

8,8,10,10-Tetrakis(tosyloxymethyl)-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**19**), which is expected as another precursor of compound **7a**, was prepared according to the method previously reported.[3] Treatment of the tosylate **19** with lithium aluminum hydride in ether led to hydrogenolysis of the tosyloxy groups to yield, with an unidentified compound, the desired hydrocarbon, 8,8,10,10-tetramethyl-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**7a**).

Experimental

All the melting points were uncorrected. The IR spectra were determined on a JASCO IR-G spectrometer calibrated with polystyrene. The proton NMR spectra were determined on a Varian HA-100D spectrometer (at 100 MHz) using chloroform-*d*, acetone-d_6 and pyridine-d_5 as solvents, and tetramethylsilane as an internal standard; the spectra of compounds **4a**, **4b**, and **10**, which changed markedly around or below room temperature, were measured under cooling, while other samples were measured at room temperature. Mass spectra were determined on a CEC 21-110B instrument.

*Diethyl 9-Oxo-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalene-8,10-dicarboxylate (**10**).* 1,8-Bis(bromomethyl)naphthalene (**9**) was prepared from 1,8-naphthalenedicarboxylic anhydride.[3]

To a stirred and cooled (at 0 °C) solution of sodium ethoxide in ethanol (prepared from 11.6 g of sodium and 1.14 l of absolute ethanol) was added quickly a solution of diethyl acetonedicarboxylate (**8**) (52 g) in dry dimethyl sulfoxide (0.14 l, distilled on calcium hydride) and absolute ethanol (0.14 l). After 8 min stirring a solution of the dibromide **9** (80 g) in dry dimethyl sulfoxide (0.86 l) was added over a period of 3 min and the mixture was stirred under reflux for 30 min. The reaction mixture was then poured into cracked ice and water (*ca.* 5 l) and the resulting cloudy solution was left at room temperature for 3 days. The precipitated solid was collected and crystallized from ethanol, giving the desired peri-eight-membered ring compound **10** as colorless fine needles (28 g, 31%); mp 146—147 °C; MS : *m/e* 354.146 (M^+ ($^{12}C_{21}{}^1H_{22}{}^{16}O_5$)=354.147); IR (Nujol): ν_{max} 1707 (ketone C=O), 1742 cm^{-1} (ester C=O); NMR ($CDCl_3$): δ 1.26 and 1.33 (each 3H, t, J=7.1 Hz, CH_3).
Found: C, 70.83; H, 6.15%. Calcd for $C_{21}H_{22}O_5$: C, 71.17 : H, 6.26%.

The crude keto diester **10** (20 g) was refluxed with a solution of sodium hydroxide (12 g) in ethanol (400 ml) and water (600 ml) for 30 h. After treatment with hydrochloric acid, the precipitated solid was collected and recrystallized from methanol to give *8,9,10,11-tetrahydro-7*H*-cycolocta*[de]*naph-*

*thalen-9-one (**1b**)* (10.8 g, 92%) as colorless needles; mp 195—196 °C; MS : *m/e* 210.103 (M^+ ($^{12}C_{15}{}^1H_{14}{}^{16}O_1$)= 210.103); IR (Nujol): ν_{max} 1695 cm^{-1} (C=O); NMR ($CDCl_3$): δ 2.80 (4H, t, J=7.1 Hz, 8,10-H), 3.77 (4H, t, J=7.1 Hz, 7,11-H).
Found: C, 85.80; H, 6.56% Calcd for $C_{15}H_{14}O$: C, 85.86; H, 6.71%.

Ethyl 9-Oxo-8,9,10,11-tetrahydro-7H-cycloocta[de]*naphthalene-8-carboxylate (**11a**).* 2.5 g of the keto diester **10** was treated with a solution of sodium ethoxide in ethanol (prepared by dissolving 7.0 g of sodium in 500 ml of absolute ethanol) and the mixture was stirred vigorously for 3 days. The reaction mixture was then acidified, diluted with water (*ca.* 2 l) and left at room temperature for 16 days. The crystals formed were removed by filtration and recrystallized from ethaonl to give the keto monoester **11a** (1.48 g, 75%) as colorless needles; mp 128—129 °C; MS : *m/e* 282.126 (M^+ ($^{12}C_{18}{}^1H_{18}{}^{16}O_3$)=282.126); IR (Nujol): ν_{max} 1705 (ketone C=O), 1744 cm^{-1} (ester C=O); NMR ($CDCl_3$): δ 1.32 (3H, t, J=7.0 Hz, CH_3), 4.28 (2H, q, J=7.0 Hz, $C\underline{H}_2CH_3$).
Found: C, 76.27; H, 6.33%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43%.

Diethyl 8-Methyl-9-oxo-8,9,10,11-tetrahydro-7H-cycloocta[de]*naphthalene-8,10-dicarboxylate (**12a**).* A solution of the crude keto diester **10** (18.5 g) in dry dimethyl sulfoxide (50 ml) was added to a solution of sodium ethoxide prepared by dissolving 1.44 g of sodium in 300 ml of absolute ethanol. To this mixture was added a solution of methyl iodide (6 ml) in absolute ethanol (40 ml) over a period of 5 min and the mixture was stirred overnight at room temperature. The reaction mixture was poured into water and the resulting solid was collected. Recrystallization of this solid from ethanol (500 ml) gave 11.2 g (60%) of the monomethyl compound **12a** as colorless needles; mp 129—130 °C; IR (Nujol): ν_{max} 1715 (ketone C=O), 1733, and 1738 cm^{-1} (ester C=O); NMR ($CDCl_3$): δ 1.01 (3H, s, CH_3), 1.20 and 1.28 (each 3H, t, J=6.7 and 7.1 Hz, respectively, CH_3).
Found: C, 71.80; H, 6.36%. Calcd for $C_{22}H_{24}O_5$: C, 71.72; H, 6.57%.

The mother liquor from the above was concentrated to yield 4.4 g (22%) of *diethyl 8,10-dimethyl-9-oxo-8,9,10,11-tetrahydro-7H-cycloocta*[de]*naphthalene-8,10-dicaroboxylate (**12b**).* The compound was prepared more efficiently (80%) by repeating the methylation procedure described above and obtained as colorless prisms by recrystallization from ethanol; mp 162—163.5 °C; IR (Nujol): ν_{max} 1709 (ketone C=O), 1734 cm^{-1} (ester C=O); NMR ($CDCl_3$): δ 0.95 and 1.76 (each 3H, s, CH_3), 1.22 and 1.31 (each 3H, t, J=6.8 and 7.1 Hz, respectively, CH_3).
Found: C, 72.50; H, 6.80%. Calcd for $C_{23}H_{26}O_5$: C, 72.23; H, 6.85%.

Ethyl 8-Methyl-9-oxo-8,9,10,11-tetrahydro-7H-cycloocta[de]*naphthalene-8-carboxylate (**11b**).* To a stirred solution of sodium ethoxide in ethanol (prepared by dissolving 0.18 g of sodium into 25 ml of absolute ethanol) was added a solution of the keto monoester **11a** (0.26 g) in dry dimethyl sulfoxide (10 ml) and the mixture was stirred for 2 h at room temperature. A solution of methyl iodide (2 ml) in absolute ethanol (10 ml) was then added and the mixture was stirred for 20 h at room temperature. The reaction mixture was concentrated, mixed with saturated salt solution and extracted with ethyl acetate. The extracts were washed with saturated salt solution and dried over sodium sulfate, the solvnet then being evaporated. The residue was chromatographed on alumina with hexane as eluant to give the monomethyl keto ester **11b** (0.26 g, 94%). This was recrystallized from ethanol for analysis (needles); mp 106—106.5 °C: IR (Nujol): ν_{max} 1705 (ketone C=O), 1728 and 1721 cm^{-1} (ester C=O); NMR ($CDCl_3$): δ 1.26 (3H, s, CH_3), 1.30 (3H, t, J=7.0 Hz, CH_3), 4.28 (2H, q, J=7.0 Hz, $OC\underline{H}_2CH_3$).
Found: C, 76.87; H, 6.50%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 8.43%.

8-Methyl-8,9,10,11-tetrahydro-7H-cycloocta[de]*naphthalen-9-one (**2b**).* Methyl keto diester **12a** (1.53 g) was refluxed with a solution of potassium carbonate (1.5 g) in dioxane (35 ml) and water (25 ml) for 3 days. The reaction mixture was treated with hydrochloric acid and the precipitated solid was collected. The solid was recrystallized from ethanol to give 0.93 g (99%) of the monomethyl ketone **2b** as colorless needles; mp 158—159 °C; IR (Nujol): ν_{max} 1694 cm^{-1} (C=O); NMR ($CDCl_3$): δ 1.20 (3H, d, J=6.8 Hz, CH_3).
Found: C, 85.79; H, 7.23%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%.

cis-*8,10-Dimethyl-8,9,10,11-tetrahydro-7H-cycloocta*[de]*naphthalen-9-one (**3b**).* Dimethyl keto diester **12b** (9.83 g) was refluxed with a solution of sodium hydroxide (6 g) in dioxane (0.5 l) and water (0.5 l) for 3 days. After treatment with hydrochloric acid the precipitated solid was collected and recrystallized from ethanol, giving 4.0 g (64%) of the *cis*-dimethyl ketone **3b** as colorless needles; mp 230—231 °C; IR (Nujol): ν_{max} 1694 cm^{-1} (C=O); NMR ($CDCl_3$): δ 0.97 (6H, d, J=6.8 Hz, CH_3).
Found: C, 85.70; H, 7.91%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%. On concentration of the above mother liquor, 1.43 g (23%) of the *trans* isomer **4b** was obtained. The compound was prepared more efficiently from the keto diester **10** as follows.

trans-*8,10-Dimethyl-8,9,10,11-tetrahydro-7H-cycloocta*[de]*naphthalen-9-one (**4b**).* Keto diester **10** (11 g) was stirred under reflux with lithium aluminum hydride (6 g) in dry ether (0.5 l) and dry benzene (0.1 l) for 12 days. The reaction mixture was treated with hydrochloric acid and the precipitated solid was collected and dried *in vacuo* to give 6.32 g (75%) of *8,10-bis(hydroxymethyl)-8,9,10,11-tetrahydro-7H-cycloocta*[de]*naphthalen-9-ol (**13a**)*; mp 165—166 °C; IR (Nujol): ν_{max} 3250 and 3420 (sh) cm^{-1} (OH); NMR (pyridine-d_5): δ 5.82 and 6.20 (br, OH).

To a stirred solution of triol **13a** (2.6 g) in pyridine (15 ml) was added dropwise a solution of methanesulfonyl chloride (1.5 ml) in pyridine (6 ml) over a period of 1 min. The mixture was stirred for 40 h at room temperature. The reaction mixture was then poured into ice water and the resulting solid was collected. Recrystallization of this solid from ethanol yielded 2.75 g (68%) of c-*8*,t-*10-bis(mesyloxymethyl)-8,9,10,11-tetrahydro-7H-cycloocta*[de]*naphthalen-r-9-ol (**13b**)* as a colorless microcrystalline solid; mp 167.5—169 °C; IR (Nujol): ν_{max} 3540 (OH), 1171 and 1350 cm^{-1} (mesyl ester); NMR (pyridine-d_5–$CDCl_3$ (2 : 1)): δ 6.14 (br, OH), 3.02 and 3.14 (each 3H, s, mesyl group).

To a stirred and boiled suspension of lithium aluminum hydride (*ca.* 6 g) in dry ether (0.3 l) was added a solution of the dimesylate **13b** (6.5 g) in dry benzene (0.1 l) over a period of 5 min. The mixture, after further addition of dry ether (0.1 l), was stirred under reflux for 14 days. The reaction mixture was then poured into ice-hydrochloric acid (*ca.* 4 l) and the mixture was allowed to stand at room temperature for 30 days. The precipitated solid was collected and chromatographed on alumina with benzene as eluant, yielding 2.65 g (73%) of c-*8*,t-*10-dimethyl-8,9,10,11-tetrahydro-7H-cycloocta*[de]*naphthalen-r-9-ol (**13c**).* The compound was further pruified by recrystallization from benzene-petroleum ether; mp 135—135.5 °C; IR (Nujol): ν_{max} 3440 and 3570 cm^{-1} (OH); NMR ($CDCl_3$) : δ 0.85 (3H, d, J=7.0 Hz, CH_3), 1.18 (3H, d, J=6.9 Hz, CH_3)

and 1.26 (s, OH).
Found: C, 84.80; H, 8.50%. Calcd for $C_{17}H_{20}O$: C, 84.95; H, 8.39%.

To a stirred and cooled (at 0 °C) solution of the dimethyl alcohol **13c** (0.747 g) in acetone (75 ml) was added dropwise the Jones reagent (prepared from 13.4 g of chromic anhydride in 25 ml of water and 12 ml of concentrated sulfuric acid) over a period of 5 min. The resulting mixture was stirred at 0 °C for 30 min. After addition of 2-propanol, the insoluble substance was removed by filtration and washed with acetone. The filtrate and washings were combined, concentrated, mixed with water and left to stand overnight. The solid precipitated was collected and chromatographed on alumina (deactivated on exposure to air) with benzene as eluant to give the *trans*-dimethyl ketone **4b** (0.59 g, 80%).

Ketone **4b** was recrystallized from aqueous ethanol to give colorless needles; mp 126—127 °C; IR (Nujol) : ν_{max} 1692 cm^{-1} (C=O); NMR ($CDCl_3$) : δ 0.94 and 1.45 (each 3H, d, J=6.5 Hz, CH_3).
Found: C, 85.60; H, 7.71%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

Using the same sequence of reactions as in the preparation of **4b** from **10**, compounds **6b**, **7b**, and **5b** were prepared from the corresponding keto esters **12a**, **12b**, and **11b**, through the steps, (**12a**→**14a**→**14b**→**14c**→**6b**), (**12b**→**15a**→**15b**→**15c**→**7b**), and (**11b**→**16a**→**16b**→**16c**→**5b**), respectively.

*8-Methyl-8,10-bis(hydroxymethyl)-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-ol* (**14a**) (Yield, 87%); mp 168—169 °C; IR (Nujol): ν_{max} 3220 and 1030 cm^{-1} (OH); NMR (pyridine-d_5): δ 1.58 (s, CH_3), 5.6 (br, OH). *8-Methyl-8,10-bis(mesyloxymethyl)-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen*-9-*ol* (**14b**) (Yield, 71%); mp 103—104 °C; IR (Nujol): ν_{max} 3560 (OH), 1344 and 1175 cm^{-1} (mesyl ester); NMR ($CDCl_3$): δ 1.22 and 1.21 (each s, CH_3), 2.77, 3.02, 2.98 and 3.06 (each s, mesyl group), the complex methyl signals indicate that **14b** is a mixture of isomers. *8,8,10-Trimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-ol* (**14c**) (Yield, 95%); mp 114.5—116 °C; IR (Nujol): ν_{max} 3335 cm^{-1} (OH); NMR ($CDCl_3$): δ 0.75, 1.05, 1.18, 1.21, and 1.27 (each s, CH_3), the unexpectedly complicated methyl proton signals of **14c** suggest that **14c** is a mixture of isomers; Found: C, 85.20; H, 8.69%. Calcd for $C_{18}H_{22}O$: C, 84.99; H, 8.72%. *8,8,10-Trimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-one* (**6b**) (Yield, 85%); colorless needles (from benzene–petroleum ether); mp 124.5—125 °C; IR (Nujol): ν_{max} 1696 cm^{-1} (C=O); NMR ($CDCl_3$): δ 0.99 (3H, d, J=6.8 Hz, CH_3), 0.92 and 1.43 (each 3H, s, CH_3). Found: C, 85.89; H, 8.09%. Calcd for $C_{18}H_{20}O$: C, 85.67; H, 7.99%.

*8,10-Dimethyl-8,10-bis(hydroxymethyl)-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-ol* (**15a**) (Yield, 93%); mp 171—172 °C; IR (Nujol): ν_{max} 3275 and 1030 cm^{-1} (OH); NMR (pyridine-d_5): δ 1.42 and 1.72 (each 3H, s, CH_3), 5.78 (br, OH). *8,10-Dimethyl-8,10-bis(mesyloxymethyl)-*8,9,10,11*-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-ol* (**15b**) (Yield, 92%); mp 155—156 °C; IR (Nujol): ν_{max} 3570 (OH), 1376 and 1174 cm^{-1} (mesyl ester); NMR (acetone-d_6): δ 1.12 and 1.34 (each s, CH_3), 3.01 and 3.15 (each s, mesyl group) and 4.08 (br, OH). *8,8,10,10-Tetramethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-ol* (**15c**) (Yield, 90%); mp 177—178 °C; IR (Nujol): ν_{max} 3460 and 3600 cm^{-1} (OH); NMR ($CDCl_3$): δ 0.90 and 1.21 (each 6H, s, CH_3) and 1.41 (s, OH); Found: C, 85.30; H, 9.23%. Calcd for $C_{19}H_{24}O$: C, 85.02; H, 9.01%. *8,8,10,10-Tetramethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-one* (**7b**) (Yield, 82%); colorless needles (from benzene–petroleum ether); mp 133—133.5 °C; IR (Nujol): ν_{max} 1683 cm^{-1}(C=O); NMR ($CDCl_3$): δ 0.92 and 1.48 (each 6H, s, CH_3); Found: C, 85.86; H, 8.27%. Calcd for $C_{19}H_{22}O$: C, 85.67; H, 8.33%.

*8-Methyl-8-hydroxymethyl-8,9,10,11-tetrahydro-7*H*-cycloocta-*[de]*naphthalen-9-ol* (**16a**) (Yield, 60%); mp 138—139 °C; IR (Nujol): ν_{max} 3330 cm^{-1}(OH); NMR ($CDCl_3$–pyridine-d_5 (2:1)): δ 1.34 (s, CH_3), 5.20 and 5.74 (each br, OH). Treatment of **16a** with 1 mol of methanesulfonyl chloride in pyridine under the same conditions as in the preparation of **13b** from **13a** afforded *8-methyl-8-mesyloxymethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-ol* (**16b**); IR (neat): ν_{max} 3530 (OH), 1340 and 1170 cm^{-1} (mesyl ester). *8,8-Dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-ol* (**16c**) (Yield, *ca.* 20% from **16a**); mp 114.5—115.5 °C; IR (Nujol): ν_{max} 3300 cm^{-1}(OH); NMR ($CDCl_3$): δ 0.92 and 1.09 (each 3H, s, CH_3), 1.24 (s, OH); Found: C, 84.70; H, 8.45%. Calcd for $C_{17}H_{20}O$: C, 84.95; H, 8.39%. *8,8-Dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalen-9-one* (**5b**) (Yield, 66%); mp 110—111 °C; IR (Nujol): ν_{max} 1695 cm^{-1} (C=O); NMR ($CDCl_3$): δ 0.93 and 1.42 (each 3H, s, CH_3); Found: C, 85.78; H, 7.80%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

*8,9,10,11-Tetrahydro-7*H*-cycloocta*[de]*naphthalene* (**1a**), *8-Methyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalene* (**2a**), cis-*8,10-Dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalene* (**3a**) and trans-*8,10-Dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalene* (**4a**). The compounds were prepared by Clemmensen reductions of the corresponding 9-ketones, **1b**, **2b**, **3b**, and **4b**, respectively, by the following procedure.

The ketone (1.0 g) in benzene (30 ml) was stirred under reflux for 30 h with amalgamated zinc (34 g), concentrated hydrochloric acid (100 ml) and acetic acid (150 ml). The mixture was cooled and extracted with ether repeatedly. The ether extracts were worked up as usual to leave a brown oil, which was purified by chromatography on alumina with hexane as eluant. The products were obtained as colorless needles by recrystallization from aqueous alcohol.

Compound **1a** (Yield, 92%); mp 57.5—58 °C (lit, mp 55—56 °C[2]); MS: *m/e* 196.126 (M^+($^{12}C_{15}{}^1H_{16}$)=196.125) (Found: C, 91.71; H, 8.26%); the compound showed spectral features similar to those reported by Nelsen and Gillespie.[2]

Compound **2a** (Yield, 74%); mp 40—41 °C; NMR ($CDCl_3$): δ 1.02 (CH_3); Found: C, 91.50; H, 8.60%. Calcd for $C_{16}H_{18}$: C, 91.37; H, 8.63%.

Compound **3a** (Yield, 63%); mp 116—117 °C; NMR ($CDCl_3$): δ 0.84 (6H, d, J=6.8 Hz, CH_3); Found: C, 90.80; H, 8.90%. Calcd for $C_{17}H_{20}$: C, 91.01; H, 8.99%.

Compound **4a** (Yield, 48%); mp 65—66 °C; NMR ($CDCl_3$): δ 0.80 (3H, d, J=6.7 Hz, CH_3) and 1.22 (3H, d, J=7.0 Hz, CH_3); Found: C, 91.30; H, 9.03%. Calcd for $C_{17}H_{20}$: C, 91.01; H, 8.99%. After **4a** had been obtained, further elution with benzene afforded the acetate ester of the *trans*-dimethyl alcohol **13c** (**17**) (Yield, 26%); mp 141.5—142 °C, whose IR spectrum (Nujol) showed absorptions at 1734 and 1241 cm^{-1} characteristic of the acetate ester group, and whose NMR spectrum [($CDCl_3$): δ 0.77 and 1.18 (each 3H, d, J=7.0 Hz, CH_3) and 1.85 (3H, s, acetyl CH_3)] was in line with the structure. Further elution with ethyl acetate gave the *trans*-dimethyl alcohol **13c** (Yield, 8%), whose melting point and spectral data were identical with those of the authentic sample prepared from **13b**.

*8,8-Dimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalene* (**5a**). *gem*-Dimethyl ketone **5b** (0.22 g), potassium hydroxide (0.4 g), hydrazine hydrate (0.5 ml) and diethylene glycol (7 ml) were combined and refluxed at 130—140 °C for 1.5 h. The condenser was then removed and the reddish

solution heated until the temperature reached 200 °C. After 15 h reflux at this temperature, the cooled reaction mixture was diluted with water, acidified and extracted with ethyl acetate. The organic extracts were washed with saturated brine solution, dried over sodium sulfate and finally concentrated to give a light brown solid. Chromatography on alumina using hexane as eluant yielded 0.18 g (86%) of the 8,8-dimethyltetrahydrocycloocta[*de*]naphthalene **5a**; mp 69—70 °C; NMR ($CDCl_3$): δ 0.80 and 1.16 (each 3H, s, CH_3). Found: C, 91.25; H, 8.80%. Calcd for $C_{17}H_{20}$: C, 91.01; H, 8.99%.

*8,8,10-Trimethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalene (**6a**).* Trimethyl ketone **6b** (0.3 g) was subjected to Wolff-Kishner reduction using the same procedure as in the preparation of **5a**. The crude product was chromatographed on alumina with hexane as an eluant to give 0.2 g (70%) of the hydrocarbon **6a**; mp 89—90 °C; NMR ($CDCl_3$): δ 0.80 (3H, d, J=6.8 Hz, CH_3), 0.81 and 1.16 (each 3H, s, CH_3). Found: C, 90.56; H, 9.46%. Calcd for $C_{18}H_{22}$: C, 90.70; H, 9.30%.

*8,8,10,10-Tetramethyl-8,9,10,11-tetrahydro-7*H*-cycloocta*[de]*naphthalene (**7a**).* 8,8,10,10-Tetrakis(tosyloxymethyl)-8,9,10,11-tetrahydro-7*H*-cycloocta[*de*]naphthalene (**19**) was prepared from tetraethyl 1,1,3,3-propanetetracarboxylate and 1,8-bis(bromomethyl)naphthalene (**9**).[3]

To a stirred and boiled slurry of excess lithium aluminum hydride in dry ether (0.3 l) was added a solution of the tosylate **19** (2.0 g) in dry ether (0.1 l) over a period of 5 min. The mixture, after further addition of dry ether (0.1 l), was stirred under reflux for 3 days and cooled. The reaction mixture was poured onto ice-hydrochloric acid and the mixture was extracted with ether. The ethereal extracts were combined, washed with saturated brine solution and dried over sodium sulfate. After removal of the solvent the residue was taken up in a small amount of hexane–benzene and chromatographed on alumina. Elution with hexane gave 0.24 g (44%) of the desired tetramethyltetrahydrocycloocta[*de*]naphthalene **7a**. Further elution with benzene yielded an unidentified compound (0.14 g), which, after recrystallization from hexane, melted at 160—161 °C. Hydrocarbon **7a** was recrystallized from aqueous ethanol to give colorless needles; mp 112—113 °C; NMR ($CDCl_3$): δ 0.74 and 1.29 (each 6H, s, CH_3). Found: C, 90.68; H, 9.34%. Calcd for $C_{19}H_{24}$: C, 90.41; H, 9.59%.

The author wishes to thank Dr. Yo-ichiro Mashiko, ex-director of this Laboratory, and Dr. Osamu Yamamoto for their encouragement and valuable discussions. The author also thanks Dr. Nobuhide Wasada for the measurements of high-resolution mass spectra.

Photochemical and Thermal Reactions of Cyclohexadienone Oximes

Renji OKAZAKI, Masako WATANABE, and Naoki INAMOTO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received July 1, 1978)

Photolysis of (*E*)-1-hydroxyimino-2,4,5-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**1**) and the corresponding (*Z*)-isomer in methanol, benzene, or pentane afford 1,3,5-tri-*t*-butyl-5-cyano-1,3-cyclohexadiene (**3**), 5-*t*-butyl-7-cyano-2,2,3,8,8-pentamethyl-3,4,6-nonatriene (**4**), 5-*t*-butyl-3-cyano-2,2,7,8,8-pentamethyl-3,4,6-nonatriene (**5**), 5-*t*-butyl-7-cyano-2,3,3,8,8-pentamethyl-1,4,6-nonatriene (**6**), 5-*t*-butyl-3-cyano-7-methoxy-2,2,7,8,8-pentamethyl-3,5-nonadiene (**7**), 5-*t*-butyl-7-cyano-7-methoxy-2,2,3,8,8-pentamethyl-3,5-nonadiene, and 2,4-di-*t*-butyl-6-cyano-7,7-dimethyl-1,3,5-octatriene (**9**). The presence of an oxaziridine in the reaction mixture has been confirmed by iodometry. The photoreaction in the presence of 1,3-pentadiene or oxygen gives essentially the same results, suggesting the involvement of the singlet excited state in these photoreactions. Thermal Beckmann rearrangement of **1** has been conducted for comparison to give only **6**, **7**, and **9**. The photochemical formation of **3**—**9** has been rationalized in terms of the "free" cyclopentadienyl cation formed by ionic α-cleavage of the oxime. Photoreaction of 1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadiene with one alkyl group at 6-position gives 5-*t*-butyl-7-cyano-2,3,8,8-tetramethyl-1,4,6-nonatriene, 5-*t*-butyl-3-cyano-8-methoxy-2,2,7,8-tetramethyl-4,6-nonadiene, 5-*t*-butyl-7-cyano-2-methoxy-2,3,8,8-tetramethyl-3,5-nonadiene, and 1,3-di-*t*-butyl-5-cyano-3-methoxy-6,6-dimethyl-1,4-heptadiene.

Since the first report on photo-Beckmann rearrangement by de Mayo in 1963,[1] there have been numerous reports on the photoreaction of oximes.[2] There are also many investigations concerning cyclohexadienones.[3,4] On the contrary, however, there has been no report on the photoreaction of cyclohexadienone oximes, probably because of the limited availability of the material.

Since we recently discovered the facile one-step synthesis of oximes of cyclohexadienones from the reactions of 2,4,6-tri-*t*-butylnitroso(or nitro)benzene with Grignard reagents,[5,6] we undertook the study on the photoreaction of these sterically hindered cyclohexadienone oximes[7] and a full account is described in this paper.

Reaction Products. Irradiation of (*E*)-1-hydroxyimino-2,4,6-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**1**) in solution (methanol, pentane, or benzene) (medium pressure mercury lamp, Pyrex-filter) afforded 1,3,5-tri-*t*-butyl-5-cyano-1,3-cyclohexadiene (**3**), 5-*t*-butyl-7-cyano-2,2,3,8,8-pentamethyl-3,4,6-nonatriene (**4**), 5-*t*-butyl-3-cyano-2,2,7,8,8-pentamethyl-3,4,6-nonatriene (**5**), 5-*t*-butyl-7-cyano-2,3,3,8,8-pentamethyl-1,4,6-nonatriene (**6**), 5-*t*-butyl-3-cyano-7-methoxy-2,2,7,8,8-pentamethyl-3,5-nonadiene (**7**), 5-*t*-butyl-7-cyano-7-methoxy-2,2,3,8,8-pentamethyl-3,5-nonadiene (**8**), and 2,4-di-*t*-butyl-6-cyano-7,7-dimethyl-1,3,5-octatriene (**9**) along with some recovered **1** and the isomer **2**. The yields of the products and the reaction conditions are shown in Table 1.

When (*Z*)-oxime (**2**) was irradiated under the identical conditions, isomerization into **1** was observed at first and the final products and their yields were essentially the same as those from **1**.

Formation of oxaziridine (**10**), which is considered to be an intermediate leading to an amide in photo-Beckmann rearrangement[2] and in some cases characterized in solution,[8] was also observed in the reaction of **1** in methanol; treatment of the reaction solution, after irradiation for 3.8 h, with sulfuric acid and potassium iodide, followed by titration of the liberated iodine and the subsequent titration of the consumption of the acid,[9] indicated the yield of the oxaziridine was about 6%.

The structural assignment of **3**, **7**, and **9** is straightforward from their analytical and spectral data, and it was confirmed by the chemical behavior as shown in Scheme 1.

Treatment of **7** with trifluoroacetic acid in benzene led to formation of **9** (95%), which was also obtained in irradiation of **1** in benzene for 4 h (14%). Triene (**9**) underwent cyclization to give **3** (96%) upon irradiation with Pyrex-filtered light for 6 h in methanol, suggesting that **3** is a secondary product formed *via* **9**.

Ether (**7**) is not a precursor of other products, be-

TABLE 1. YIELDS (%) OF PRODUCTS IN PHOTOREACTIONS OF **1** AND **2**

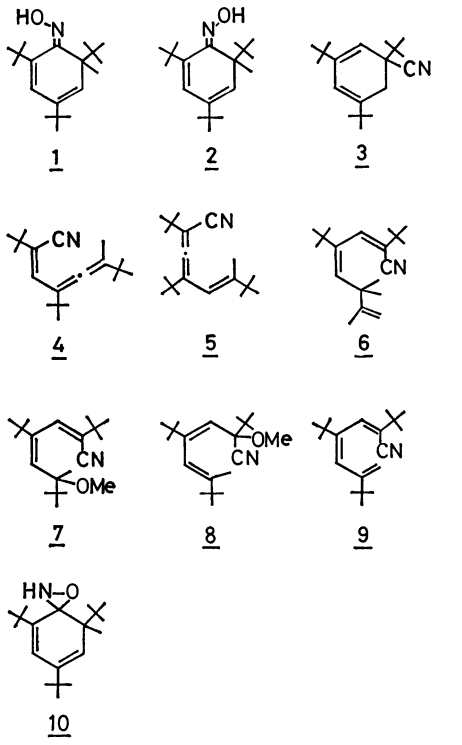
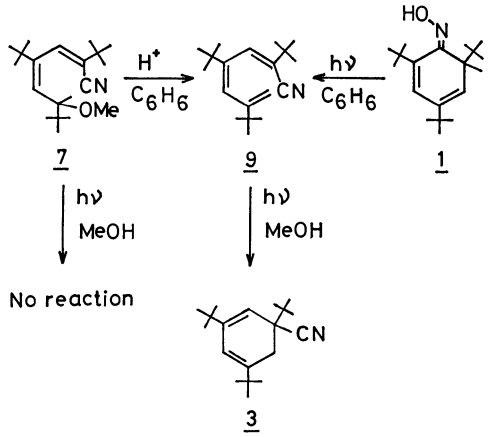
a) In the presence of 1,3-pentadiene. b) In the presence of oxygen.



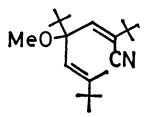


Scheme 1.

cause no change was observed in the irradiation of **7** for 7.5 h in methanol.

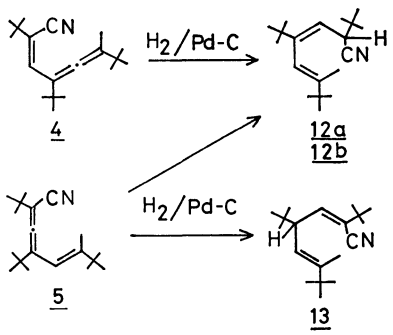
The NMR spectrum of **6** showed two *t*-butyl groups (δ 1.08 and 1.19), two methyl protons attached to the saturated carbon (1.19), methyl protons bound to the olefinic carbon (1.68) splitting with a small coupling constant, two equivalent olefinic protons (4.70) appeared as multiplet, and two olefinic protons (5.42 and 6.38) appeared as a doublet. The IR spectrum showed the presence of cyano (2235 cm^{-1}) and terminal methylene (889 cm^{-1}) groups. The UV spectrum of **6** had an absorption maximum at 257 nm which is consistent with the structure of a conjugated diene.

The NMR spectrum of **8** showed three *t*-butyl groups (δ 1.02 and 1.15 (1:2)), methyl protons bound to the olefinic carbon (1.83), methoxyl protons (3.35), and olefinic protons (5.04 and 5.42). The signal of the methyl protons shows a small coupling constant, suggesting that the methyl group may be attached to a fully substituted olefinic carbon. The IR spectrum showed the existence of a cyano group (2225 cm^{-1}), although absorption intensity was very week. This phenomenon suggests that the cyano group is located on the carbon to which an ether group attaches[10]. The UV spectrum of **8** had absorption maxima at 234(sh) and 262(sh) nm which indicated a conjugated diene and ruled out the structure (**11**).



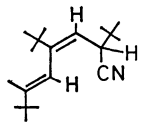
The long range coupling of two olefinic protons indicates the presence of a double bond between these protons and is consistent with this assignment.

The IR spectra of **4** and **5** indicated the existence of an allenic group (1950 cm^{-1}). Their ^{1}H-NMR spectra showed three *t*-butyl groups (δ 1.08 (18 H) and 1.21 (9 H) for **4**, δ 1.05, 1.10, and 1.28 for **5**), a methyl group on sp^2 carbon (δ 1.81 for **4**, 1.72 for **5**), and an olefinic proton (δ 6.36 for **4**, 6.56 for **5**). Since both of the methyl protons appeared as singlet and the coupling constant between the olefinic proton and the methyl protons was estimated to be very small, it is impossible from ^{1}H-NMR spectra to determine whether the methyl groups are bound to an olefinic carbon or an allenic carbon. The mass spectra of those products were similar to each other. The ^{13}C-NMR spectrum of **4** showed an allenic carbon at 198.5 ppm, a cyano group at 117.5 ppm, and a methyl group on sp^2 carbon at 14.4 ppm. Single resonance spectrum showed the signal of the cyano carbon splitted to doublet ($^3J_{CH}$=15.8 Hz). This coupling suggested the existence of β-proton, therefore, the cyano and methyl groups must be bound to olefinic and allenic carbons, respectively. These facts support the structure **4**. Therefore, **5** is considered to be an isomeric allene as shown, although satisfactory elemental analysis and ^{13}C-NMR spectrum could not be obtained because of paucity of the sample. That **4** and **5** have an allenic structure isomeric each other, was also established by catalytic hydrogenation.

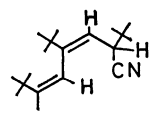


Thus, hydrogenation of **4** afforded conjugated diene **12a** as a result of the reduction of the allenic group followed by 1,5-hydrogen shift, while hydrogenation

of **5** afforded **12b** and **13**. The signal pattern of NMR spectra of **12a** and **12b** resembled each other but their chemical shifts were slightly different, suggesting they are geometric isomers having the same gross structure. They are probably (**12A**) and (**12B**), although the spectral data are insufficient to establish which is which.

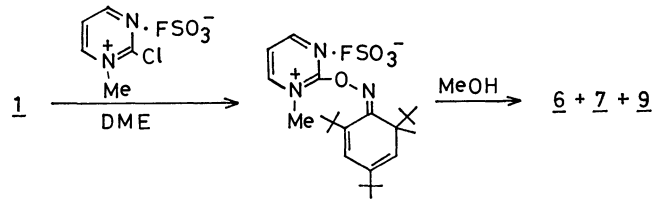


12 A



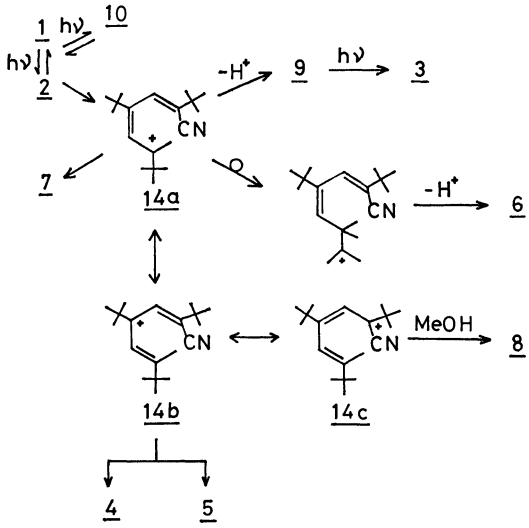
12 B

Thermal Beckmann Rearrangement. Reaction of **1** with 2-chloro-1-methylpyrimidinium fluorosulfate[11] followed by quenching with methanol, gave **6** (9%), **7** (6%), and **9** (46%).

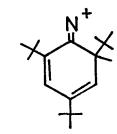


Reaction Mechanism. The products (**3**—**9**) are considered to be formed *via* heterolytically produced pentadienyl cation as depicted in Scheme 2. Since the photoreaction of **1** was not quenched by 1,3-pentadiene and oxygen, it probably proceeds *via* the singlet state.

Isomerization between oximes **1** and **2** occurs at first, as generally observed in the reaction of oximes. From this photochemical equilibrium mixture is formed oxaziridine (**10**), which probably reverts to the oxime mixture photochemically, thermally, and/or during the treatment with silica gel. Heterolytic α-cleavage and fission of the N–O bond of the oxime afford pentadienyl cation (**14**), with formal canonical structures (**14a**), (**14b**), and (**14c**). Whether these bond cleavages are simultaneous or stepwise could not be established experimentally, but involvement of nitrenium ion (**15**)



Scheme 2.



15

seemes unlikely in view of the known propensity of this kind of nitrenium ion to undergo intramolecular C–H insertion.[12] However, the possibility that oxaziridine (**10**) is a direct precursor of **14** can not be eliminated completely, although it appears quite unlikely.

The most obvious feature of this photoreaction is that all the products are formed *via* ionic processes. Contrary to frequent observations of nitrile formation in the ground state Beckmann rearrangement, photo-Beckmann fission is observed only rarely,[2] and more importantly the formation of nitriles in the excited state reaction has been explained by a homolytic process.[13,14]

The present reaction represents the first and unequivocal example of a heterolytic α-cleavage of an oxime. There seem two reasons for the facile heterolytic α-cleavage; one is that the carbonium ion formed is a stabilized pentadienyl cation with two alkyl groups on its terminal and the other is that oxaziridine, even if it is formed, would suffer strain by bulky *t*-butyl groups, thus reverting to the starting oxime.

The heterolytic pathway seems to be operative even in nonpolar solvent such as pentane, although the reaction is apparently more complex; the products identified were **3**, **4**, and **5** (Table 1).

The discrepancy in the products between the excited and ground state reactions is most likely due to the difference in nature of an intermediate in both reactions. The products of the thermal Beckmann fission are only those that are formally derived from canonical structure **14a**, suggesting the participation of the solvent (for **7**) and neighboring bonds (for **6** and **9**) in the product forming process. On the contrary, in the photoreaction, the pentadienyl cation **14** appears to be formed as a "free" carbonium ion without such assistance. The formation of the products (**4**, **5**, and **8**), characteristic of the excited state reaction, is reasonably explained in terms of canonical structures (**14b**) and (**14c**), that is, deprotonation from **14b** affords **4** and **5** and addition of methanol to **14c** gives **8**. This reactivity is most likely accounted for in the light of characteristics of a "free" (or "hot") carbonium ion[15] that reactions occur at a position(s) other than that where a carbonium ion is initially generated.

This sort of "free" carbonium ions have recently been invoked in the photoreactions of alkyl and vinyl halides in order to rationalize the difference in reactivity between the photochemical and solvolytic reactions.[16,17]

Photoreaction of 2,4-Cyclohexadienone Oxime with One Alkyl Group at 6-Position. In order to examine the relationship between structure and reactivity in the photoreaction of 2,4-cyclohexadienone oximes, the photoreaction of the oxime with only one alkyl group at the 6-position was carried out.

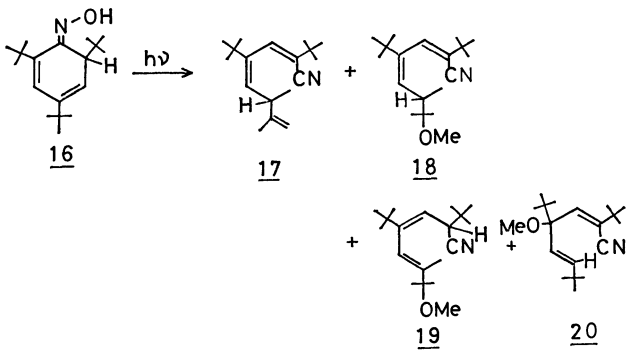
Irradiation of 1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-

cyclohexadiene (**16**) in methanol (medium pressure mercury arc, Pyrex-filter) for 17.5 h afforded 5-*t*-butyl-7-cyano-2,3,8,8-tetramethyl-1,4,6-nonatriene (**17**), 5-*t*-butyl-3-cyano-8-methoxy-2,2,7,8-tetramethyl-4,6-nonadiene (**18**), and recovered oxime **16**. When the reaction time was prolonged to 36.5 h products obtained were **17**, **18**, 5-*t*-butyl-7-cyano-2-methoxy-2,3,8,8-tetramethyl-3,5-nonadiene (**19**), and 1,3-di-*t*-butyl-5-cyano-3-methoxy-6,6-dimethyl-1,4-heptadiene (**20**).

The yield of the products and the reaction conditions are shown in Table 2.

Table 2. Yields (%) of products in photoreaction of **16**

Solvent	Reaction time (h)	Yields (%)				
		16	**17**	**18**	**19**	**20**
Methanol	17.5	6	20	18	—	—
Methanol	36.5	0	19	8	14	5



Irradiation (Pyrex-filtered light in methanol, 11.5 h) of **18** led to formation of **19** (94%). This suggests that **19** is a secondary product from **18** *via* photochemically allowed antarafacial 1,5-hydrogen shift.[18]

Elimination of methanol from **18** by trifluoroacetic acid in benzene, which converted **7** to **9**, was unsuccessful, probably because stabilization of carbonium ion formed is not sufficient in this case.

Although satisfactory elemental analysis could not be obtained, the structure of the products were confirmed by their spectral data.

The ^{1}H-NMR spectrum of **18** showed two *t*-butyl groups (δ 1.09 and 1.25), two methyl groups (1.00), methine proton with intricate splitting (1.85—2.46), methoxyl protons (3.08), and two olefinic protons (5.34 and 6.41), one methyl signal appearing as a doublet at δ 0.98.

The ^{13}C-NMR spectrum showed the presence of a cyano carbon at 117.4, three methyl carbons (δ 23.3, 21.6, and 14.2), a methoxyl carbon (48.8), and a tertiary carbon α to oxygen (77.1).

Molecular ion peak on the mass spectrum of **18** was not observed, but the fact that the base peak was *m/e* 73, assignable to $[(CH_3)_2(OCH_3)C]^+$, is consistent with the structure proposed in view of high stability of $[(CH_3)_2(OCH_3)C]^+$ and pentadienyl radical.

The easy 1,5-prototropy of **18** leading to **19** remains to be accounted for. Considering interactions between bulky *t*-butyl groups, configuration of **18** may be favorable for such a 1,5-hydrogen migration. It is interesting that similar phenomenon was observed in the hydrogenation of allene (**4**) as described before. The signal patterns of the NMR spectra of **12** and **19** resemble each other.

Formation of **20** can be explained formally by the reaction of methanol with pentadienyl cation with a canonical structure similar to **14b** shown in Scheme 2.

Therefore, the reaction of oxime (**16**) is essentially the same as that of **1** in the sense that it proceeds mainly *via* heterolytic α-cleavage, although the reaction is more complex.

Experimental

All melting points were not corrected. The IR and UV spectra were recorded with Hitachi EPI-G2 and EPS-3 spectrophotometers respectively. The ^{1}H-NMR and ^{13}C-NMR spectra were measured with Hitachi R-20B (60 MHz) and JEOL JNM-FX60 spectrometers using tetramethylsilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6L mass spectrometer. The photolyses were carried out using a 100 W medium pressure mercury lamp with a Pyrex filter, and nitrogen gas was passed through the solution before (about 15 min) and during irradiation unless otherwise noted. Gas chromatographic separation was performed using a JEOL-750 (versamide 900) unless otherwise noted.

Photolysis of (E)-1-Hydoxyimino-2,4,6-tri-t-butyl-6-methyl-2,4-cyclohexadiene (1) in Methanol. Oxime **1**[6] (450 mg, 1.55 mmol) in methanol (90 ml) was irradiated at 0—5 °C for 7.5 h. The solvent was removed under reduced pressure and the residue was subjected to preparative thin layer chromatography (TLC) (SiO_2, hexane-dichloromethane (4 : 1)) to be divided into five fractions.

The first fraction gave 28 mg (6%) of (*Z*)-isomer of (**1**).[6]

The second (white crystals) was a mixture of **4** (42 mg), **6** (16 mg), **8** (10 mg, 2%), and **9** (5 mg, 1%) according to the peak area on the gas chromatogram. Each product was isolated by means of gas chromatography (GLC) (in glass column at 135 °C). **4**: mp 54.0—55.0 °C (from methanol); IR (KBr) : 2220 (CN) and 1950 cm^{-1} (C=C=C); ^{1}H-NMR (CCl_4) : δ 1.08 (s, 18H), 1.21 (s, 9H), 1.81 (s, 3H), and 6.36 (s, 1H); ^{13}CNMR ($CDCl_3$) : 198.5 ppm, 136.4, 122.7, 117.5, 112.9, 109.9, 35.6, 34.3, 34.0, 29.5, 29.1, 28.8, and 14.4; λ_{max} (hexane) : 270.5 nm (ε 9060); MS : *m/e* 273 (M^+, 22%), 258 (17), 217 (40), 202 (100), 160 (29), and 57 (59). Found: C, 83.72; H, 11.71; N, 5.00%. Calcd for $C_{19}H_{31}N$: C, 83.45; H, 11.43; N, 5.12%. **6**: mp 48.5—49.5 °C (from methanol); IR (KBr) : 2235 (CN) and 889 cm^{-1} (C=CH$_2$); NMR (CCl_4) : δ 1.08 (s, 9H), 1.19 (s, 15H), 1.68 (d, J= 0.8 Hz, 3H), 4.07 (m, 2H), 5.42 (d, J=1.5 Hz, 1H), and 6.38(d, J=1.5 Hz, 1H); λ_{max} (hexane) : 257 nm (ε 1530); MS : *m/e* 273 (M^+, 6.7%), 258 (14), 216 (38), 202 (37), 160 (30), and 57 (100). **8** : oil; IR ($CHCl_3$) : 2225 cm^{-1} (CN); NMR (CCl_4) : δ 1.02 (s, 9H), 1.15 (s, 18H), 1.83 (d, J= 1.3 Hz, 3H), 3.35 (s, 3H), 5.04 (d, J=2.3 Hz, 1H), and 5.42 (m, 1H); λ_{max} (hexane) : 234(sh) (ε 4060) and 262(sh) nm (1500); MS : *m/e* 305 (M^+, 0.4%), 202 (13), 160 (12), and 57 (100). **9** : oil; IR (neat) : 2225 (CN), 1609, and 899 cm^{-1} (C=CH$_2$); NMR (CCl_4) : δ 1.09 (s, 9H), 1.13 (s, 9H), 1.18 (s, 9H), 4.68 (dd, J=1.5 Hz, 1H), 4.95 (d, J=1.5 Hz, 1H), 6.09 (dd, J=1.5 Hz, 1H), and 6.50 (d, J=1.5 Hz, 1H); λ_{max} (hexane): 262 nm (ε 6700); MS: *m/e* 273 (M^+, 1.5%), 217 (23), 160 (64), 57 (100), and 41 (46),

The third farction was a mixture of **3** (80 mg, 19%), **5**

(31 mg, 7%), **4** (3 mg, total yield 11%), and **6** (6 mg, total yield 5%) according to the peak area on the gas chromatogram, and they were purified by preparative GLC to give each product in a pure state. **3**: mp 137.1—137.8 °C (from methanol); IR (KBr) : 2235 cm^{-1} (CN); NMR (CCl_4) : δ 1.10 (s, 18H), 1.14 (s, 9H), 2.22 (d, J=2.4 Hz, 1H), 2.31 (s, 1H), 5.29 (d, J=1.7 Hz, 1H), and 5.95 (m, 1H); λ_{max} (hexane): 261 nm (ε 5950); MS : *m/e* 273 (M^+, <1%), 160 (13), and 57 (100). Found: C, 83.15; H, 11.67; N, 5.28%. Calcd for $C_{19}H_{31}N$: C, 83.45 : H, 11.43; N, 5.12%. **5** : oil; IR (neat) : 2225 (CN) and 1950 cm^{-1} (C=C=C); NMR (CCl_4) : δ 1.05 (s, 9H), 1.10 (s, 9H), 1.28 (s, 9H), 1.72 (s, 3H), and 6.56 (s, 1H); λ_{max} (hexane) : 258 nm (ε 14900); MS : *m/e* 273 (M^+, 6%), 217 (43), 202 (100), 160 (22), and 57 (80).

The fourth fraction (144 mg) was a mixture of **7** (78 mg, 16%) and recovered oxime **1** (48 mg, 11%) according to the signal intensity on the NMR spectrum. **7**: oil; IR (neat) : 2220 cm^{-1} (CN); NMR (CCl_4) : δ 0.88 (s, 9H), 1.12 (s, 9H), 1.18 (s, 3H), 1.22 (s, 9H), 3.16 (s, 3H), 5.55 (d, J= 1.8 Hz, 1H), and 6.50 (d, J=1.8 Hz, 1H); λ_{max} (hexane): 259(sh) (ε 3380), 306(sh) (1530), and 325(sh) nm (920); MS : *m/e* 273 (M^+-CH_3OH, <1%), 160 (16), and 57 (100).

*Photolysis of (Z)-1-Hydroxyimino-2,4,6-tri-t-butyl-6-methyl-2,4-cyclohexadiene (**2**) in Methanol.* Methanol solution (80 ml) of oxime (**2**) (394 mg, 1.35 mmol) was irradiated for 7.5 h under the same conditions as those of the photolysis of oxime **1**. After the removal of the solvent, the reaction products were analyzed by a combination of preparative TLC and GLC as described above for **1** (see Table 1).

*Photolysis of Oxime (**1**) in Pentane or Benzene.* Oxime **1** (450 mg, 1.55 mmol) in pentane or benzene (90 ml) was irradiated (9.3 h for the pentane solution and 4 h for the benzene solution) under the same conditions as those of the photolysis in methanol. The products were purified by TLC (see Table 1).

*Photolysis of Oxime (**1**) in the Presence of 1,3-Pentadiene.* Oxime (**1**) (450 mg, 1.55 mmol) and 1,3-pentadiene (608 mg, 8.9 mmol) in methanol (90 ml) was irradiated for 7.5 h. The reaction products were analyzed by TLC and GLC as above (see Table 1).

*Photolysis of Oxime (**1**) in the Presence of Oxygen in Methanol.* Oxime (**1**) (450 mg, 1.55 mmol) was dissolved in methanol (90 ml). After being flashed with oxygen, the solution was irradiated for 7.5 h at 0—5 °C, during which oxygen was passed through. The identification and determination of the yields of the reaction products were carried out by TLC and GLC (see Table 1).

*Determination of the Oxaziridine Concentration and "B.O. value" in the Photolysis of Oxime (**1**) in Methanol.* Oxime (**1**) (450 mg, 1.55 mmol) in methanol (90 ml) was irradiated under the same conditions as those of the photolysis in methanol. After irradiation for 3.8 h, a part of the solution (10 ml) was treated with sulfuric acid (0.01767 N, 50 ml) and potassium iodide (1 g), and then the liberated iodine was titrated with a standard solution of sodium thiosulfate (0.010029 N, 1.95 ml). Then the amount of the acid consumed to liberate iodine was determined by back titration with 0.009280 N potassium hydroxide. The amount of the species which liberated iodine was 0.00978 mmol (6%) and that of consumed acid was 0.036 mmol, thus the "B. O. value" being 3.68. This value suggested that the species was oxaziridine[9].

*Reaction of **7** with Trifluoroacetic Acid.* To a benzene solution (40 ml) of **7** (39 mg, 0.13 mmol), a drop of trifluoroacetic acid was added with stirring. After additional stirring for 26 h at room temperature, the solvent was removed under reduced pressure to give 33 mg (95%) of **9** as yellow tar (by NMR).

*Photoreaction of **9** in Methanol.* A mixture of trienes (**9**) and (**6**) (64.8 mg), which contained 57.6 mg (0.21 mmol) of **9** according to the GLC (DOS column, 180 °C) was dissolved in methanol (13 ml) in a Pyrex glass tube, flashed with nitrogen, and was externally irradiated for 6.3 h at 0—5 °C. TLC purification afforded 12 mg of **6** as white crystals and 55 mg (96%) of **3** (by NMR).

*Test for Photostability of **7** in Methanol.* Product **7** (99 mg, 0.32 mmol) in methanol (90 ml) was irradiated for 7.8 h under the same conditions as those of the photolysis of oxime **1** in methanol. Removal of the solvent resulted in almost complete recovery of **7** (97 mg) according to GLC. Some very small peaks other than that of **7** were observed by GLC, but they were not **3**, **4**, **5**, **6**, **8**, and **9**.

*Hydrogenation of **4**.* A solution of **4** (78 mg, 0.29 mmol) in ethanol (8 ml) and acetic acid (0.05 ml) was hydrogenated over 10% palladium on charcoal (30 mg) under atmospheric pressure for at room temperature. After the mixture was filtered and the catalyst was washed with ethanol, the solvent was evaporated from the combined filtrates under reduced pressure. The residue was chromatographed on alumina with carbon tetrachloride as eluent to give 51 mg of colorless tarry material, which was purified by preparative GLC to give 11 mg (14%) of **12a** as a colorless oil: NMR (CCl_4): δ 1.01 (s, 9H), 1.13 (s, 18H), 1.84 (d, J=1.6 Hz, 3H), 3.17 (d, J=10.8 Hz, 1H), 5.18 (dd, J=2.2 and 10.8 Hz, 1H), and 5.41 (m, 1H).

*Hydrogenation of **5**.* A solution of **5** (40 mg, 0.15 mmol) in ethanol (6 ml) containing a few drops of acetic acid was hydrogenated over a spatula of 10% palladium on charcoal under atmospheric pressure for 22 h at room temperature. After treatment similar to that mentioned above was obtained 26 mg of colorless tarry material, which was further purified by the preparative GLC to give 11 mg (27%) of **13** as colorless crystals and 8 mg (19%) of **12b** as colorless tar. **13**: NMR (CCl_4): δ 0.90 (s, 9H), 1.07 (s, 9H), 1.19 (s, 9H), 1.71 (d, J=1.5 Hz, 1H), 3.24 (dd, J=9.8 and 10.6 Hz, 1H), 5.09 (dd, J=1.5 and 9.8 Hz, 1H), and 5.86 (d, J=10.6 Hz, 1H); λ_{max} (hexane): 240(sh) nm (ε 8200); MS: *m/e* 275 (M^+, 1%). **12**: NMR (CCl_4): δ 0.99 (s, 9H), 1.08 (s, 9H), 1.15 (s, 9H), 1.62 (d, J=1.5 Hz, 3H), 2.94 (d, J=11.2 Hz, 1H), 5.25 (dd, J=1.5 and 11.2 Hz, 1H), and 5.61 (m, 1H); MS: *m/e* 275 (M^+, <1%).

*Reaction of Oxime (**1**) with 2-Chloro-1-methylpyrimidinium Fluorosulfate.* A mixture of 179 mg (0.62 mmol) of oxime (**1**) and 173 mg (0.68 mmol) of pyrimidinium salt in anhydrous 1,2-dimethoxyethane (6 ml) was stirred at room temperature under argon atmosphere. After 8.3 h, absolute methanol (20 ml) was added. After stirring for 17.4 h at room temperature, the reaction mixture was poured into water, and the mixture was extracted with dichloromethane. The extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent afforded 156 mg of yellow, partly crystalline material, which was subjected to preparative TLC (SiO_2, hexane–dichloromethane (5:1)) to give **9** (79 mg, 46%), **6** (15 mg, 9%), and **7** (12 mg, 6%).

*Photolysis of 1-Hydroxyimino-2,4,6-tri-t-butyl-2,4-cyclohexadiene (**16**) in Methanol.* a) Oxime (**16**)[19] (450 mg, 1.62 mmol) in methanol (90 ml) was irradiated at 0—5 °C for 17.5 h. The solvent was removed *in vacuo*, and the residue was subjected to preparative TLC (SiO_2, hexane–dichloromethane (4:1)) to give two fractions.

One fraction was 129 mg of yellow, partly crystalline material. According to the peak area on the GLC, it seemed

to be a mixture of **17** (85 mg, 20%), recovered oxime (**16**) (28 mg, 6%), and 16 mg of unidentified materials. **17** was isolated by GLC as colorless tarry material. **17**: IR (neat): 2220 (CN) and 889 cm^{-1} ($C=CH_2$); NMR (CCl_4): δ 1.10 (s, 9H), 1.19 (d, $J=7$ Hz, 3H), 1.26 (s, 9H), 1.63 (dd, $J=1.2$ Hz, 3H), 2.8 (m, 1H), 4.60 (m, 2H), 5.27 (dd, $J=9$ and 1.2 Hz, 1H), and 6.46 (d, $J=1.2$ Hz, 1H); MS: *m/e* 259 (M^+, 2.5%), 203 (21), 202 (21), 188 (36), 146 (23), and 57 (100).

Another fraction was 197 mg of brown tar, which was again purified with preparative TLC (SiO_2, hexane–dichloromethane (1:1)) to afford **18** (84 mg, 18%) as pale yellow tar; IR (neat): 2220 cm^{-1} (CN); ^{1}H-NMR (CCl_4): δ 0.98 (d, $J=7$ Hz, 3H), 1.00 (s, 6H), 1.09 (s, 9H), 1.25 (s, 9H), 1.85—2.46 (m, 1H), 3.08 (s, 3H), 5.34 (dd, $J=10.5$ and 2.2 Hz, 1H), and 6.41 (d, $J=2.2$ Hz, 1H); ^{13}C-NMR ($CDCl_3$): 143.9 ppm, 140.0, 128.5, 127.8, 117.4, 77.1, 48.8, 40.3, 36.6, 35.3, 29.3, 28.9, 23.2, 21.6, and 14.2; λ_{max} (hexane): 250 nm (ε 2580); MS: *m/e* 276 (M^+-CH_3, <1%), 73 (100), and 57 (31).

b) Oxime (**16**) (343 mg, 1.24 mmol) in methanol (80 ml) was irradiated as described in a) except that the reaction time was 36.5 h. Similar treatment gave 38 mg (19%) of **17**, 19 mg (5%) of **20**, 50 mg (14%) of **19**, and 29 mg (8%) of **18**. **19** was purified by GLC. **19**: IR (neat): 2225 cm^{-1} (CN); NMR (CCl_4): δ 0.99 (s, 9H), 1.12 (s, 9H), 1.29 (s, 6H), 1.81 (d, $J=2.4$ Hz, 3H), 3.08 (s, 3H), 3.17 (d, $J=10.2$ Hz, 1H), 5.13 (dd, $J=10.2$ and 2.4 Hz, 1H), and 5.55 (m, 1H); λ_{max} (hexane): 293(sh) nm (ε 970); MS: *m/e* 259 (M^+-CH_3OH, 6%), 244 (15), 202 (25), 188 (21), 146 (39), and 57 (100). **20**: IR (neat): 2220 cm^{-1} (CN); NMR (CCl_4): δ 0.99 (s, 9H), 1.14 (s, 9H), 1.25 (s, 9H), 3.27 (s, 3H), 5.24 (d, $J=14.4$ Hz, 1H), 5.75 (d, $J=14.4$ Hz, 1H), and 6.28 (s, 1H); MS: *m/e* 276 (M^+-CH_3, 1%), 234 (54), 202 (21), 193 (32), 188 (13), 178 (32), 146 (14), and 57 (100).

*Photoreaction of **18** in Methanol.* Diene (**18**) (56 mg, 0.19 mmol) in methanol (80 ml) was irradiated for 11.5 h under the same conditions as those of the photolysis of oxime (**16**). Removal of the solvent afforded 53 mg (94%) of **19** and a trace of recovered **18** (by GLC).

Studies on Biologically Active Pteridines. I. The Synthesis of 6-(1*R*)[and (1*S*)]-(1-Hydroxyethyl)- and 6-(1*S*)[and (1*R*)]-(1,2-Dihydroxyethyl)-2-amino-4-hydroxypteridines

Takashi SUGIMOTO* and Sadao MATSUURA

(Received July 4, 1978)

2-Amino-4-hydroxy-6-[(1*S*)-1, 2-dihydroxyethyl]pteridine has been synthesized by the condensation of 2, 4, 5-triamino-6-hydroxypyrimidine and D-threose phenylhydrazone, followed by oxidation of the intermediate carried out by adding the condensate to a mixture of $K_3[Fe(CN)_6]$, KI, and H_2O_2 in an acidic solution. The 6-(1*R*)-1, 2-dihydroxyethyl isomer and the 6-(1*R*)[and (1*S*)]-1-hydroxyethyl analogues have also been synthesized in a similar way. By applying the present method, biopterin has been obtained in 28% yield.

The 5,6,7,8-tetrahydro derivatives of various 2-amino-4-hydroxypteridines with an alkyl or polyhydroxyalkyl substituent at the 6-position act as a cofactor for tyrosine hydroxylase.[1,2] However, the cofactor activities of the pteridines vary depending on the structure of the side chain; tetrahydrobiopterin having an L-*erythro*-1,2-dihydroxypropyl side chain has been found to be the most active cofactor.[1,3,4] Indeed, tetrahydrobiopterin is the natural cofactor of phenylalanine hydroxylase[5] and is also thought to be the natural cofactor of tyrosine hydroxylase.[6] Recently the four stereochemical isomers of biopterin, *i.e.* 6-L-*erythro*-, 6-D-*erythro*-, 6-L-*threo*-, and 6-D-*threo*-1,2-dihydroxypropyl-2-amino-4-hydroxypteridines have been synthesized[7] and the cofactor activities of their 5,6,7,8-tetrahydro derivatives for tyrosine hydroxylase examined.[4] The L-*erythro* and D-*threo* isomers, both of which have the same configuration at the 1-position(C-1) of the side chain, exhibited similar cofactor characteristics. The D-*erythro* and L-*threo* isomers, both of which have the same, though reversed C-1 configuration compared to the others, behaved in a similar fashion as cofactor. However the latter pair were less active than the former pair. These results suggest that the cofactor activities are controlled to a fair extent by the configuration at C-1 of the side chain.[4] Consequently an examination of the cofactor characteristics of several tetrahydrobiopterin analogues having a side chain at the 6-position with an asymmetric carbon only at the 1-position(C-1) is required. This paper describes the synthesis of 6-[(1*S*)-1,2-dihydroxyethyl]- and 6-[(1*R*)-1,2-dihydroxyethyl]-2-amino-4-hydroxypteridines(**4a** and **4b**) and the 6-(1*R*)[and (1*S*)]-1-hydroxyethyl analogues(**4c** and **4d**).

Previously biopterin(**4e**) was prepared in 8% yield by the condensation of 2,4,5-triamino-6-hydroxypyrimidine(**1**) with 5-deoxy-L-arabinose phenylhydrazone (**2e**) and the subsequent oxidation of the intermediate tetrahydropteridine(**3e**).[7] This method has been one of the best methods for the synthesis of biopterin and its analogues. The first attempt to synthesize the required (1,2-dihydroxyethyl)pteridine(**4a**), in analogy to the above method, was by the condensation of **1** with D-threose phenylhydrazone(**2a**) and oxidation of the intermediate(**3a**). The main product was, however, the 6-unsubstituted 2-amino-4-hydroxypteridine(**4f**), formed by the loss of the 6-side chain during the oxidation of the tetrahydropteridine intermediate(**3a**), most probably, *via* a quinonoid dihydropteridine.[7-9] The same pteridine(**4f**) was also formed as the main product from **1** and 4-deoxy-D-erythrose phenylhydrazone (**2c**). These results suggested that the 1-hydroxyethyl or 1,2-dihydroxyethyl side chain of **3** is more susceptible to cleavage than the 1,2-dihydroxypropyl or 1,2,3-trihydroxypropyl group and hence the different oxidation conditions are required. By examining the oxidation conditions, it was found that cleavage could be reduced to a great exent by adding the solution of **3a** quickly into an aqueous acidic solution (pH 2—3) of $K_3[Fe(CN)_6]$, KI, and H_2O_2; a reverse addition, that is the addition of the oxidizing agents to the solution of **3a**, gave the 6-unsubstituted pteridine(**4f**) as the main product together with a small amount of **4a**.

Heating D-threose phenylhydrazone(**2a**) with **1** gave an orange red solution of, probably, the intermediate tetrahydropteridine(**3a**). Additional heating resulted in the development of a dark red solution, from which

b) Wavelength in nm measured in aqueous buffer of given pH.

the pteridine(**4a**) could be obtained only in a poor yield. Oxidation of the intermediate(**3a**) to **4a** was most effective by adding the solution of **3a** quickly into an acidic solution of the above oxidizing agents, followed by stirring under oxygen; paper chromatograms showed that **4a** was formed as the main product together with a trace of **4f**. Column chromatographic isolation on Florisil gave **4a** as ivory needles (27%), which were shown to be free from the possible 7-substituted isomer by oxidation to the known 2-amino-4-hydroxypteridine-6-carboxylic acid by potassium permanganate.[10] The structure of the product was confirmed to be **4a** from the pK_a values and UV spectra (Table 1), which were very similar to those of biopterin (**4e**).[7]

The other three pteridines(**4b**, **4c**, and **4d**) were similarly prepared from the pyrimidine(**1**) and a corresponding tetrose phenylhydrazone(**2b**, **2c**, or **2d**). The present method was applied to the synthesis of biopterin(**4e**) which was obtained in the pure crystalline state in 28% yield.

Experimental

The elemental analyses were conducted at the Analytical Section, Meijo University, Nagoya, The pK_a values were determined spectroscopically and the UV spectra measured on a Shimadzu UV-300 spectrophotometer.

*2-Amino-4-hydroxy-6-[(1S)-1,2-dihydroxyethyl]pteridine (**4a**).* To a solution of D-*threo*-5,5-bis(ethylsulfonyl)-4-pentene-1,2,3-triol[11] (5.0 g) in water (50 ml), concentrated aqueous ammonia (0.5 ml) was added. After stirring at pH 9—10 and at room temperature for 10 h, the resulting suspension was adjusted to pH 3—4 with formic acid and filtered. Phenylhydrazine (1.8 g) was added to the filtrate and the solution stirred at pH 2—3 and 25 °C for 1 h. The solution of the formed phenylhydrazone (**2a**) was added to a solution of 2,4,5-triamino-6-hydroxypyrimidine (**1**) dihydrochloride[12] (2.5 g) dissolved in a mixture of water (100 ml) and methanol (150 ml). The solution was stirred under nitrogen at 25 °C for 1 h and then under reflux for 20 min. The orange red solution, after being chilled in an ice bath, was poured into an ice chilled aqueous solution (150 ml) containing potassium hexacyanoferrate(III) (15 g), potassium iodide (2.5 g), 35% hydrogen peroxide (10 ml), and formic acid (5 ml). The mixture was stirred vigorously under bubbling oxygen at 5—10 °C for 1 h and at 25—30 °C for 3 h. The mixture was evaporated to dryness under reduced pressure and the residue extracted with 2% aqueous ammonia (500 ml). The extract was concentrated to about 200 ml under reduced pressure, adjusted to pH 2—3 with hydrochloric acid, and placed on a Florisil column (4.5×35 cm). The column was first eluted with 0.25 M formic acid (4 l) until the inorganic salts, blue colored materials, and small amount of blue fluorescent compounds were removed from the column. The column was then eluted with water (4 l). Evaporation of the eluate under reduced pressure gave a solid which was extracted with 2% ammonia (150 ml). The extract was evaporated to dryness under reduced pressure and the residue extracted with 2% ammonia (150 ml). Concentration of the extract to about 70 ml under reduced pressure and acidification with formic acid (pH 3—4) gave a solid, which crystallized from water to give ivory needles (710 mg) of **4a**, mp> 300 °C (Found: C, 41.98; H, 3.98; N, 30.85%. Calcd for $C_8H_9N_5O_3 \cdot 0.3H_2O$: C, 41.98; H, 4.24; N, 30.61%).

*2-Amino-4-hydroxy-6-[(1R)-1,2-dihydroxyethyl]pteridine (**4b**).* L-Arabinose diethyl dithioacetal[13] (5.0 g) was degraded to L-erythrose according to the method of Hough and Taylor[11] by oxidation to L-*erythro*-5,5-bis(ethylsulfonyl)-4-pentene-1,2,3-triol with aqueous peroxypropionic acid and by subsequent treatment with dilute ammonia. After treatment with phenylhydrazine, condensation of the resulting L-erythrose phenylhydrazone (**2b**) with **1** in a similar manner to that for **4a** gave the (1*R*)-1,2-dihydroxyethyl compound (**4b**) as ivory needles in 22% yield, mp>300 °C (Found: C, 41.98; H, 3.95; N, 30.77%. Calcd for $C_8H_9N_5O_3 \cdot 0.3H_2O$: C, 41.98; H, 4.24; N, 30.61%).

*2-Amino-4-hydroxy-6-[(1R)-1-hydroxyethyl]pteridine (**4c**).* 5-Deoxy-D-arabinose diethyl dithioacetal (5.5 g), prepared according to the method of Green and Rembold[13] by lithium aluminium hydride reduction of 5-tosyl-D-arabinose diethyl dithioacetal, was degraded to 4-deoxy-D-erythrose as above. The erythrose was treated with equimolar phenylhydrazine (2.4 g) and the resulting phenylhydrazone (**2c**; unisolated) was condensed with **1** (dihydrochloride, 4.5 g) and subsequently oxidized in the same way as that used for **4a** to give ivory needles (650 mg, 15% yield) of **4c**, mp>300 °C (from water)(Found: C, 43.33; H, 4.61; N, 31.82%. Calcd for

$C_8H_9N_5O_2 \cdot 0.8H_2O$: C, 43.35; H 4.87; N, 31.61%).

*2-Amino-4-hydroxy-6-[(1S)-1-hydroxyethyl]pteridine (**4d**).* By replacing 5-deoxy-D-arabinose diethyl dithioacetal by 5-deoxy-L-arabinose diethyl dithioacetal[13] in the foregoing procedure, the (1*S*)-1-hydroxyethyl compound (**4d**) was obtained as ivory needles in 9% yield, mp >300 °C (from water) (Found: C, 42.54; H, 4.48; N, 30.86%. Calcd for $C_8H_9N_5O_2 \cdot H_2O$: C, 42.66; H, 4.93; N, 31.10%).

*Biopterin (**4e**).* The condensation of 2,4,5-triamino-6-hydroxypyrimidine(**1**) dihydrochloride (5.0 g) and 5-deoxy-L-arabinose phenylhydrazone (**2e**) (5.5 g), followed by oxidation and chromatographic isolation in a manner similar to that used for **4a**, gave biopterin (1.56 g, 28% yield) as colorless needles.

The authors would like to thank Mrs. N. Nishioka for the measurement of pK_a values.

(Received July 3, 1978)

Allylic oxidation of methyl 2-alkenoates with chromium trioxide in a mixture of acetic anhydride and acetic acid afforded methyl 4-oxo-2-alkenoates.

The allylic oxidation of cycloalkenes to cycloalkenones with chromium trioxide in acetic acid has been reported.[1] However, the oxidation of methyl 2-alkenoates with the above reagent has not yet been reported.

We wish to report the allylic oxidation of methyl 2-alkenoates with a modified reagent prepared from chromium trioxide in a mixture of acetic anhydride and acetic acid. This reagent has the advantage that it is readily available and the reaction is rapid and efficient. The resulting product gave methyl 4-oxoalkanoates, which can be converted into cyclopentenones,[2] by reduction with zinc in acetic acid[3] or titanium trichloride.[4]

The methyl 2-alkenoates (**1a**—**f**) were prepared by a Wittig reaction using methoxycarbonylmethylenetriphenylphosphorane[5] of the corresponding aldehydes in good yields.

When methyl 2-decenoate (**1a**) was treated by the chromium trioxide–(p ridine)$_2$–dichloromethane s stem[6] or *t*-butyl chromate reagent[7] under several reaction conditions, the oxidation product was not obtained. On the other hand, **1a** was more slowly oxidized with chromium trioxide in acetic acid to give methyl 4-oxo-2-decenoate (**2a**). The addition of acetic anhydride to the above solution, however, resulted in a rapid oxidation. Consequently, the oxidation of **1a** was carried out in a mixture of acetic anhydride and glacial acetic acid (1:2) with chromium trioxide.

The oxidation of **1a** for 50 min with chromium trioxide in acetic anhydride and acetic acid (1:2) containing 1:1, 1.5:1, 3:1, 3.5:1, and 5:1 molar ratios of chromium trioxide to **1a** gave conversions to **2a** of 10, 20, 38, 57, and 80%, respectively. It is clear from the data that 5 mol equivalents of the reagent are required for complete conversion to ketone. With less than the 5:1 molar ratio extremely slow oxidation occurs.

Preparation of methyl 4-oxo-2-alkenoates (**2a**—**f**) was carried out by this method (Table 1).

The reagent was prepared by addition of chromium trioxide (50 mmol) in small portions to a mixture of acetic anhydride and glacial acetic acid under ice-cooling. Into the solution of the above reagent, methyl 2-alkenoates (**1a**—**f**) (10 mmol) were added with stirring. The optimal conditions for formation of methyl 4-oxo-2-alkenoates (**2a**—**f**) with minimum recovery of starting material were maintained by keeping a temperature at 15—25 °C for moderate times; if the temperature was allowed to rise to 30 °C, the desired product was obtained in a poor yield in the same reaction period. It was determined by gas chromatography that methyl 4-oxo-2-alkenoates (**2a**—**f**) were the sole reaction products.

Table 1. Allylic oxidation of methyl 2-alkenoates (**1**) with chromium trioxide

a) Isolated yields. b) The products were gas chromatographically pure (>99%).

In each case the product was the conjugated unsaturated ketone in which the double bond is located in its original position. Also, the fact that methyl 11-methoxycarbonyl-2-undecenoate (**1f**) gave only the corresponding 4-oxo-2-undecenoate (**2f**) [IR, 1740, 1710 cm^{-1}; NMR δ 3.63, 3.79 (each 3H, s), 2.24, 2.60 (each 2H, br t, J=7 Hz), 6.53, 7.02 (each 1H, d, J=16 Hz) ppm] shows that the methylene group next to the double bond is selectively oxidized.

On the other hand, the oxidation of 3-alkene-2-ones with chromium trioxide under the same conditions gave 3-alkene-2,5-diones in poor yields (26—34%) (n-C_7—n-C_{11}), along with aliphatic acids resulting from cleavage of the double bond in the original ketones.

The resulting **2a**—**f** were easily reduced with titanium trichloride[4] to give methyl 4-oxoalkanoates (**3a**—**f**) in good yields. They are key intermediates for the preparation of cyclopentenone derivatives.[2] From the above results, the syntheses of **3a**—**f** can be achieved in three steps from the corresponding aliphatic aldehydes in moderate yields.

a) All the semicarbazones were purified by recrystallization from methanol.

Experimental

Boiling points are uncorrected and melting points were determined on a Yanagimoto micro hot-stage and are uncorrected. The mass spectra were determined on a Hitachi RMS-4 mass spectrometer at 70 eV. The IR spectra were recorded with a Hitachi EPI-G3 grating spectrometer. All ^{1}H-NMR spectra were measured in a CCl_4 solution using a Varian T-60 NMR spectrometer with TMS as an internal standard. The GLC was carried out on a Shimadzu GC-4B, with SE-30 (2%) (3 mm×2 m) and at a temperature 140 °C, unless otherwise noted.

*Preparation of Methyl 2-Alkenoates (**1a—f**).* To a solution of methoxycarbonylmethylenetriphenylphosphorane[5] (22 mmol) in anhydrous benzene (*ca.* 60 ml), was added an appropriate aldehyde (20 mmol) in anhydrous benzene (*ca.* 5 ml) under nitrogen atmosphere. The solution was refluxed for 6 h and then cooled to room temperature. After evaporating the solvent in a reduced pressure, hexane was added to give precipitates. The precipitates were collected by filtration and washed with hexane. The combined solvents were evaporated and the resulting residue was distilled under reduced pressure. Yield; **1a**, 82% (bp 126—128 °C/14 Torr); **1b**, 91% (bp 63—65 °C/16 Torr); **1c**, 90% (bp 77—79 °C/16 Torr); **1d**, 78% (bp 103—104 °C/24 Torr); **1e**, 85% (bp 108—109 °C/12 Torr). The structures of **1a—e** were confirmed by examining their mass, IR, and NMR spectra.

*Methyl 11-Methoxycarbonyl-2-undecenoate (**1f**)*: Yield, 97% [from methyl 9-formylnonanoate (bp 122 °C/3 Torr)[8]]. Bp 152—154 °C/2 Torr; MS *m/e* 256(M^+), 225, 157, 87; IR 1745, 1735, 1665, 1180, 1145 cm^{-1}; NMR δ 1.33 (12H, br s), 1.98—2.45 (4H, m), 3.60, 3.65 (each 3H, s), 5.70 (1H, dt, J=16, 1.5 Hz), 6.84 (1H, dt, J=16, 7 Hz).

General Oxidation Procedure. The reagent was prepared by addition of chromium trioxide (50 mmol) in small portions to a mixture of acetic anhydride (12.5 ml) and glacial acetic acid (25 ml), followed by dilution with benzene (25 ml) under ice-cooling. Into the solution of the above reagent, **1** (10 mmol) in benzene (5 ml) was added dropwise with stirring. The reaction temperature was kept below 20 °C. The methyl 2-alkenoates were consumed in moderate times (the times required are shown in the Table 1) as confirmed by TLC. The reaction mixture was diluted with water, neutralized with aqueous sodium hydroxide solution, and extracted with ether. After being dried over anhydrous sodium sulfate, the extract was concentrated and the resulting residue was distilled under reduced pressure or crystallized from hexane to give **2** (Tables 1, 2, 3, and below).

*Methyl 11-Methoxycarbonyl-4-oxo-2-undecenoate (**2f**)*: Mp 54—55 °C (colorless needles from hexane); MS *m/e* 239 (M−31), 157, 128, 113; IR 1740, 1710, 1175 cm^{-1}; NMR δ 1.12—1.95 (10H, br s), 2.24, 2.60 (each 2H, br t, J=7 Hz), 3.63, 3.79 (each 3H, s), 6.53, 7.02 (each 1H, d, J=16 Hz). GLC: temperature program: 5 °C/min, from 150 to 200 °C. Found: C, 62.19; H, 8.40%. Calcd for $C_{14}H_{22}O_5$: C, 62.20; H, 8.20%.

*Reduction of Methyl 4-Oxo-2-alkenoates (**2a—f**).* Into a solution of **2** (3.5 mmol) in acetone (*ca.* 20 ml) cold titanium trichloride aqueous solution (20%, 8 mmol) was added under nitrogen atmosphere. The mixture was stirred for 40 min at room temperature, then poured into 50 ml of brine, and extracted with ether. The extract was concentrated and the residue was chromatographed on a silica gel column, eluting with ethyl ether–hexane (1 : 1). Yield, **3a**, 91% (M^+ *m/e* 200); **3b**, 88% (M^+ *m/e* 144); **3c**, 93% (M^+ *m/e* 158); **3d**, 90% (M^+ *m/e* 172); **3e**, 87% (M^+ *m/e* 186); **3f**, 87% (M^+ *m/e* 272). The structures of **3a—f** were confirmed by examining their IR and NMR spectra.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Conformational Effect on the Bridgehead Reaction of Bicyclo[3.3.1]nonan-2-ones. A Facile Bridgehead Deuteration of a Bicyclo[3.3.1]nonan-2-one Derivative with the Cyclohexanone Ring Locked in the Boat Conformation

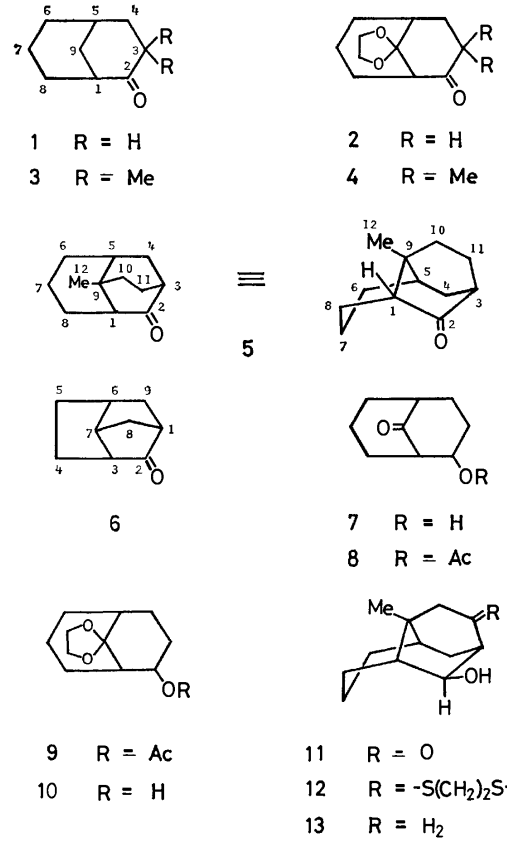
(Received July 3, 1978)

Five bicyclo[3.3.1]nonan-2-ones, two known (**1**, **3**) and three new ones (**2**, **4**, **5**) were prepared. The hydrogen-deuterium exchange reaction at the bridgehead position of the bicyclo[3.3.1]nonan-2-one system was examined under mild basic conditions (2 M NaOMe-MeOD, 33 °C, 22 h) using these five bicyclo[3.3.1]-nonan-2-ones. Virtually no deuteration took place at the bridgehead in each case of the bicyclic ketones (**1**, **2**, **3**, **4**), whereas one deuterium was incorporated into the bridgehead of the ketone (**5**). ^{13}C NMR spectroscopy was employed for the unambiguous determination of the site(s) of deuteration in all cases studied. The enhanced bridgehead acidity of (**5**) could be explained in terms of the locked boat conformation of the cyclohexanone ring contained in (**5**).

Schaefer and Lark[1] observed in 1965 that deuteration of the bridgehead position of bicyclo[3.3.1]nonan-2-one (**1**) occurred under basic conditions (*e.g.*, 77.2% deuteration: 0.1 M NaOD–D_2O, 95 °C, 40 days), and discussed the importance of the boat conformation of the ketone-bearing ring for stabilization of the bridgehead enolate. In 1975, Nickon and his coworkers[2] demonstrated that the bridgehead acidity of brendan-2-one (**6**) possessing the boat-locked bicyclo[3.2.1]-octan-2-one system was largely enhanced, resulting in the hydrogen-deuterium exchange at C-3 in **6** under mild conditions (92% deuteration: 4.84 M NaOD in MeOD, 25 °C, 69 h). Further they revealed that the enhanced bridgehead acidity of **6** was neither due to the "s" character of the carbon in the bridgehead C–H nor due to inductive stabilization of the carbanion by the carbonyl, but due to the facile formation of the corresponding enolate, which could be rationalized in terms of the Wiseman's postulate.[3]

We herein describe our results on the hydrogen-deuterium exchange reaction at the bridgehead position of the bicyclo[3.3.1]nonan-2-one system under the basic conditions milder than those[1] of Schaefer and Lark. The bicyclo[3.3.1]nonan-2-ones employed in the present studies are **1**, **2**, **3**, **4**, and **5**, among which the last one is a 4-homoisotwistane derivative and contains the cyclohexanone ring held rigidly in the boat conformation by the two-carbon bridge. The two known compounds, **1**[4] and **3**[6] were prepared by the modified procedures of Cope and his coworkers[5] and of Marvell and his colleagues,[6] respectively. Other three new compounds (**2**, **4**, **5**) were synthesized as follows. The acetal ketone (**2**) was synthesized from a diastereomeric mixture (*exo*-ol:*endo*-ol, 7:4) of the keto alcohol (**7**)[5] by the following sequence: (i) acetylation to give the keto acetate (**8**); (ii) acetalization affording the acetal acetate (**9**); and (iii) alkaline hydrolysis to yield the acetal alcohol(**10**) and subsequent oxidation (chromium trioxide–pyridine). Methylation of **2** with methyl iodide–sodium hydride in 1,2-dimethoxyethane gave the ketone (**4**). The tricyclic ketone (**5**) was synthesized from the keto alcohol (**11**),[7] which was converted to the corresponding thioacetal alcohol (**12**). Desulfurization of **12** with Raney nickel afforded the alcohol (**13**), oxidation of which with chromium trioxide in pyridine gave the tricyclic ketone (**5**) (The numbering system shown in **5**, although it differs from that based on the IUPAC rule, is used in the present paper for convenience of comparing ^{13}C chemical shifts with those of other bicyclo[3.3.1]nonan-2-ones).



Bridgehead Hydrogen Exchange. The hydrogen-deuterium exchange reaction for each of the bicyclo-[3.3.1]nonan-2-ones (**1**, **2**, **3**, **4**, **5**) was carried out in deuteriomethanol in the presence of sodium methoxide (2.0 M NaOMe–MeOD) at 33 °C for 22 h, and the extent of deuteration was determined by mass spectrometry.[8] The results are summarized in Table 1. The location of the deuterium(s) in each product was

Table 1. Deuterium incorporation by bicyclo-[3.3.1]nonan-2-ones

5	5	95		

a) Average of five mass spectral scans; corrected for ^{13}C.

proved by ^{13}C NMR spectroscopy (*cf.* Table 2). Most of the ^{13}C NMR chemical shift assignments for the bicyclo[3.3.1]nonan-2-ones, shown in Table 2, were made by the application of chemical shift theory[9–11] and single frequency off-resonance decoupling (sford) experiments, and further in some cases [in particular in **5**] with the aid of deuterium isotope shifts[12–15] and comparisons with structurally related compounds.[15,16] Although assignments of some signals remained uncertain for each compound (Table 2), there was no ambiguity as to the determination of the site(s) of deuteration.

Under the present exchange conditions the ketone (**2**) was shown to incorporate up to 2 equivalents of deuterium (**2**-d_1 44% and **2**-d_2 23%), the site of deuteration being shown to be C-3 as expected (*vide post*), and the incorporation of deuterium into the bridgehead position (C-1) was found to occur to an extremely small extent (3%). The site of deuteration in **2** was proved by the deuterium isotope effects in proton-noise decoupled ^{13}C NMR spectra:[12–14] on deuteration of **2** the singlet at δ 37.99 (C-3) was shifted upfield by 0.32 ppm to become a triplet due to ^{13}C–D coupling (J_{C-D}=19.6 Hz), and the singlet at δ 23.73 (C-4) was broadened and shifted upfield by *ca.* 0.06 ppm. The result on the deuteration of the ketone (**1**) was virtually the same as that of the ketone (**2**) (sce Table 1). The ketone (**3**), which possesses the gem dimethyl groups at C-3, was deduced to have the different conformation(s) regarding the cyclohexanone ring from that of the ketone (**1**). It was thus expected that the ketone (**3**) might exhibit reactivity at the bridgehead different from that of **1**. However, there was no significant incorporation of deuterium into the ketone (**3**) under the exchange conditions. No deuterium was incorporated into the bridgehead of the ketone (**4**) which has the gem dimethyl groups at C-3.

In contrast to the bicyclic compounds, **3** and **4**, the ketone (**5**) was found to be monodeuterated (95% d_1), and further it was established by ^{13}C NMR spectroscopy (*vide post*) that the deuterium was located at the bridgehead position (C-1) of **5**, excluding the possibility of deuteration by the mechanism of homoenolization.[13] It is known that homoenolization can only be effected under conditions (*e.g.*, *t*-BuOK–*t*-BuOH, 185 °C, 150 h) much more vigorous than those employed in the present studies. In the ^{13}C NMR spectrum of the monodeuterated compound (**5**-d_1) the signal at δ 52.28 assigned to the bridgehead (C-1) apparently disappeared. The ^{13}C chemical shift differences between **5**-d_1 and **5** [δ(**5**-d_1)−δ(**5**)] are shown in **5A**, and these magnitudes

a) Spectra taken in $CDCl_3$ at 20 MHz on a Varian CFT-20 spectrometer; chemical shifts are in parts per million relative to tetramethylsilane. b) The letter in parentheses refers to the signal multiplicity obtained from single frequency off-resonance decoupling experiments: s=singlet, d=doublet, t=triplet, q=quartet. c) Assignments may be interchanged among these signals in each vertical column.

of the upfield shifts for sp^3 carbons both geminal and vicinal to deuterium are in good agreement with those reported for deuterated 4-homoisotwistanes,[15] which has the same carbon skeleton as **5**, and for some bicyclic compounds[12c,12d,13,14] (*e.g.*, isotope shifts of carbons geminal to deuterium, 0.12 ± 0.04 ppm[12e]). Further some signals in the ^{13}C NMR spectrum of the deuterated ketone (**5**-d_1) were shown to be broadened by geminal (C-8 and C-9) and vicinal (C-5, C-7, C-10, and C-12) ^{13}C–D couplings. Thus the site of deuteration in **5** was proved to be C-1. It should be noted in this case that the ^1H NMR spectral analysis was not a reliable method of determining the deuterated site of **5**, because the signal due to H-1 could not unambiguously be identified.

Among the five bicyclo[3.3.1]nonan-2-ones (**1**, **2**, **3**, **4**, **5**) examined, the ketone (**5**) was a sole member that underwent deuteration at the bridgehead position under the exchange conditions of the present studies. As in the case of brendan-2-one (**6**),[2] the enhanced bridgehead acidity of **5** would be ascribed to the locked boat conformation of the cyclohexanone ring, in which the dihedral angle between the C(1)–H bond and the p-orbital of the carbonyl carbon is as small as *ca.* 30° from the examination of Dreiding models: this small value of the dihedral angle between the interacting orbitals would not only be favorable for removal of the proton at C-1 but result in the stabilization of the bridgehead enolate formed. On the other hand, the ketonic ring is conformationally flexible in each of the bicyclic analogs (**1**, **2**, **3**, **4**). Under the exchange conditions the flexible ketonic ring presumably can not assume the genuine boat conformation like that in **5** owing to the steric compression within the molecule, but exist as an another conformer such as a deformed boat (or as an equilibrium mixture of conformers other than boat), in which the dihedral angle discussed above is not so small as that (*ca.* 30°) in **5**, making removal of the bridgehead proton more difficult.

From the present studies it is concluded that the bicyclo[3.3.1]nonan-2-one system with the ketonic ring kept rigidly in the boat form shows the enhanced bridgehead acidity in comparison with that possessing the conformationally flexible ketonic ring.

Experimental

Melting points and boiling points are uncorrected. IR spectra were taken with a JASCO Model IRS or JASCO DS-402G spectrometer in $CHCl_3$. ^1H-NMR spectra were obtained in $CDCl_3$ using a Varian HA-100D (100 MHz) or NV-21 (90 MHz) instrument: chemical shifts (δ) are reported in ppm downfield from internal TMS. ^{13}C-NMR spectra were obtained in $CDCl_3$ (concentration, 0.3—0.4 mmol/ml) on a Varian CFT-20 spectrometer operating 20 MHz in the Fourier transform mode: chemical shifts are given in relative to internal TMS. Low resolution mass spectra were determined on a Hitachi RMU-6C mass spectrometer equipped with a heating inlet system as well as a direct inlet system and operating with an ionization energy of 70 eV. High resolution mass spectra were determined on a JEOLCO GMS-01SG mass spectrometer. Silica gel 60 F_{254} (No. 5715) and 60 PF_{254} (No. 7747) (E. Merck, A. G., Germany) were used for TLC: thickness employed was 1.50 mm for preparative TLC. Organic solutions were washed with saturated NaCl solution, dried over anhydrous Na_2SO_4, and evaporated by a vacuum rotary evaporator.

*Bicyclo[3.3.1]nonan-2-one (**1**).* A solution of a diastereomeric mixture (*exo*-ol:*endo*-ol, 4:7) of the keto alcohol (**7**)[5] (350 mg) and $BF_3\cdot OEt_2$ (0.15 ml, distilled from CaH_2) in *1,2*-ethanedithiol (5 ml) was stirred at room temperature for 40 min and diluted with ether (150 ml). The mixture was washed with 5 M NaOH (5×6 ml) and water (6 ml), and dried. On evaporation of the solvent there remained a colorless oil, which was purified by preparative TLC ($CHCl_3$–EtOAc, 3:1), giving 510 mg (98%) of a diastereomeric mixture of the thioacetal alcohol as a colorless liquid: IR 3460 cm^{-1}; ^1H-NMR (90 MHz) 3.10—3.50 (4H, complex m), 4.04 and 4.41 (total 1H, m each); MS 230 (M^+). To a solution of the diastereomeric mixture of the thioacetal alcohol (510 mg) in EtOH (12 ml) was added W-2 Raney nickel (*ca.* 8 g). The suspension was refluxed for 40 min and filtered. The filtrate was evaporated, affording a solid, which was purified by preparative TLC ($CHCl_3$–EtOAc, 3:1), affording a diastereomeric mixture of the alcohol (299 mg, 96%) as a colorless solid: IR 3650 cm^{-1}; ^1H-NMR (90 MHz) 3.60 and 3.90 (total 1H, m each); MS 140 (M^+). Found: *m/e* 140.1212. Calcd for $C_9H_{16}O$: 140.1201. A suspension of CrO_3 (420 mg) in dry pyridine (11 ml) was added to a cooled (0 °C) solution of the diastereomeric mixture of the alcohol (299 mg) in dry pyridine (3.6 ml) with stirring. The mixture was stirred at room temperature for 12 h and diluted with ether (250 ml). The precipitates were filtered through a pad of Super Cel and washed with ether thoroughly. The combined filtrates were washed with 2 M HCl and water, dried, and concentrated. Purification of the oily residue by preparative TLC ($CHCl_3$) gave **1** (160 mg, 54%) as colorless crystals: mp 127—132 °C (sealed tube) (lit, mp 135—137 °C[17] and 129—137 °C[4b]); IR 1695 cm^{-1}; ^1H-NMR (100 MHz) 2.40—2.70 (3H, complex m); MS 138 (M^+). Found: *m/e* 138.1052. Calcd for $C_9H_{14}O$: 138.1045.

*3,3-Dimethylbicyclo[3.3.1]nonan-2-one (**3**).* A solution of **1** (185 mg, 1.34 mmol) in dry 1,2-dimethoxyethane (DME, 1.1 ml) was added to a stirred suspension of NaH [250 mg of 55% mineral oil dispersion (*ca.* 4.5 mmol), three times washed with dry hexane and dried *in vacuo*] in dry DME (5.6 ml) under nitrogen. Methyl iodide (1.67 ml, 26.6 mmol) was added to the suspension, and the mixture stirred at room temperature for 26 h. After an excess amount of NH_4Cl was added, the mixture was concentrated, cooled (0 °C), diluted with water (4 ml), and extracted with $CHCl_3$ (3×10 ml). The combined $CHCl_3$ extracts were washed with water (3 ml), dried, and evaporated, giving a residue, purification of which by preparative TLC ($CHCl_3$) afforded **3** (104 mg, 47%) as a colorless liquid: IR 1686 cm^{-1}; ^1H-NMR (90 MHz) 1.12 (3H, s), 1.17 (3H, s), 2.44 (1H, m); MS 166 (M^+). Found: *m/e* 166.1361. Calcd for $C_{11}H_{18}O$: 166.1358.

*9-Oxobicyclo[3.3.1]non-2-yl Acetate (**8**).* A solution of a diastereomeric mixture (*exo*-ol:*endo*-ol, 4:7) of the keto alcohol (**7**)[5] (150 mg) in acetic anhydride (1.2 ml) and dry pyridine (2.9 ml) was stirred at room temperature for 12 h, and concentrated. The residue was purified by preparative TLC ($CHCl_3$–EtOAc, 5:1) to give the diastereomeric mixture of **8** (188 mg, 98%) as a colorless liquid: bp 178—181 °C/1 mmHg; IR 1733, 1723 cm^{-1}; ^1H-NMR (90 MHz) 2.01 and 2.06 (total 3H, s, each), 5.11 and 5.33 (total 1H, m each); MS 196 (M^+). Found: *m/e* 196.1085. Calcd for $C_{11}H_{16}O_3$: 196.1099.

9,9-Ethylenedioxybicyclo[3.3.1]non-2-yl Acetate (9). To a solution of the diastereomeric mixture of **8** (198 mg) in toluene (7 ml) were added *p*-toluenesulfonic acid monohydrate (7 mg) and ethylene glycol (0.9 ml). The stirred mixture was refluxed for 4 h using a Dean-Stark water separator to remove the water. After cooling, the mixture was washed with saturated $NaHCO_3$ solution (5 ml), dried, and concentrated. The residue was purified by preparative TLC ($CHCl_3$–EtOAc, 5:1), affording the diastereomeric mixture of **9** (234 mg, 97%) as a colorless liquid: IR 1723 cm^{-1}; ^{1}H-NMR (90 MHz) 2.04 (3H, s), 3.80—4.30 (4H, complex m), 5.01 and 5.25 (total 1H, m each); MS 240 (M^+). Found: *m/e* 240.1366. Calcd for $C_{13}H_{20}O_4$: 240.1362.

9,9-Ethylenedioxybicyclo[3.3.1]nonan-2-ol (10). To a solution of the diastereomeric mixture of **9** (234 mg) in tetrahydrofuran (THF, 5.8 ml) was added a mixture of H_2O (1.2 ml)–10% NaOH (1.6 ml)–MeOH (5.8 ml). The mixture was stirred at room temperature for 40 min and passed through a column of ion-exchange resin (H form, Amberlite CG-50 Type-I) (3.5 g). The column was further washed with MeOH (20 ml) for complete elution of the product. The combined mixtures were concentrated and the residue was dissolved in EtOH (30 ml). The solution was evaporated to give a residue, purification of which by preparative TLC ($CHCl_3$–EtOAc, 7:1) yielded the diastereomeric mixture of **10** (191 mg, 99%) as a colorless liquid: IR 3580, 3500 (broad) cm^{-1}; ^{1}H-NMR (90 MHz) 3.70—4.10 (4H, m, A_2B_2 type), 3.90 and 4.20 (total 1H, m each); MS 198 (M^+). Found: *m/e* 198.1247. Calcd for $C_{11}H_{18}O_3$: 198.1256.

9,9-Ethylenedioxybicyclo[3.3.1]nonan-2-one (2). To a stirred solution of the diastereomeric mixture of **10** (191 mg) in dry pyridine (2.9 ml) was added under cooling (0 °C) a suspension of CrO_3 (260 mg) in dry pyridine (7.1 ml) in one portion. The mixture was stirred at room temperature for 13 h, diluted with ether (150 ml), and filtered through a pad of Super Cel. The solid residue was washed with ether (40 ml). The combined filtrates were washed with water repeatedly until the washing became colorless, dried, and concentrated. The residue was purified by preparative TLC ($CHCl_3$–EtOAc, 7:1), giving **2** (160 mg, 85%) as a colorless liquid: IR 1700 cm^{-1}; ^{1}H-NMR (100 MHz) 3.95 (4H, s); MS 196 (M^+). Found: *m/e* 196.1108. Calcd for $C_{11}H_{16}O_3$: 196.1099.

9,9-Ethylenedioxy-3,3-dimethylbicyclo[3.3.1]nonan-2-one (4). To a stirred suspension of NaH [276 mg of 55% mineral oil dispersion (*ca.* 5 mmol), three times washed with dry hexane and dried *in vacuo*] in dry DME (6.1 ml) was added a solution of **2** (290 mg, 1.48 mmol) in dry DME (1.2 ml) under nitrogen. To the suspension MeI (1.84 ml, 29.3 mmol) was added, and the mixture stirred at room temperature for 29 h. An excess amount of NH_4Cl was added and, after 10 min, the mixture was concentrated. The residue was cooled, diluted carefully with water (5 ml), and extracted with $CHCl_3$ (4×10 ml). The combined $CHCl_3$ extracts were washed with water (5 ml), dried, and concentrated to afford an oily residue, purification of which by preparative TLC ($CHCl_3$) yielded **4** (164 mg, 50%) as colorless crystals: mp 54—56 °C; IR 1685 cm^{-1}; ^{1}H-NMR (90 MHz) 1.20 (3H, s), 1.24 (3H, s), 2.47 (1H, m), 3.93 (4H, s); MS 224 (M^+). Found: *m/e* 224.1408. Calcd for $C_{13}H_{20}O_3$: 224.1412.

Tricyclic Thioacetal Alcohol (12). A mixture of the crystalline keto alcohol (**11**)[7] (179 mg) and $BF_3 \cdot OEt_2$ (0.1 ml, distilled from CaH_2) in *1,2*-ethanedithiol (4 ml) was stirred at room temperature for 30 min, and diluted with saturated $NaHCO_3$ solution (5 ml) under cooling (0 °C). The mixture was extracted with $CHCl_3$ (4×10 ml). The combined $CHCl_3$ extracts were dried and concentrated. The residue was dissolved in toluene and the solution evaporated: this procedure was repeated for complete removal of *1,2*-ethanedithiol present in the residue. The resulting residue was purified by preparative TLC ($CHCl_3$–EtOAc, 8:1), giving the tricyclic thioacetal alcohol (**12**) (268 mg, 97%) as colorless crystals: mp 77—78 °C; IR 3400 (broad) cm^{-1}; ^{1}H-NMR (90 MHz) 0.90 (3H, s), 3.20—3.70 (4H, m, A_2B_2 type), 4.05 (1H, m); MS 270 (M^+). Found: *m/e* 270.1120. Calcd for $C_{14}H_{22}OS_2$: 270.1112.

Tricyclic Alcohol (13). A suspension of **12** (265 mg) and W-2 Raney nickel (*ca.* 4 g) in EtOH (25 ml) was refluxed for 45 min and filtered. The filtrate was concentrated to afford **13** (176 mg, 99%) as colorless crystals: mp 145—147 °C (sealed tube); IR 3660, 3440 (broad) cm^{-1}; ^{1}H-NMR (90 MHz) 0.87 (3H, s), 3.85 (1H, broad s); MS 180 (M^+). Found: *m/e* 180.1497. Calcd for $C_{12}H_{20}O$: 180.1514.

Tricyclic Ketone (5). Under cooling (0 °C) a suspension of CrO_3 (247 mg) in dry pyridine (6.2 ml) was added to a stirred solution of **13** (210 mg) in dry pyridine (2.8 ml) at one time. The mixture was stirred at room temperature for 13 h, diluted with ether (80 ml), and filtered through a pad of Super Cel. The solid residue was washed with ether repeatedly. The combined filtrates were washed with 1.5 M HCl (4×15 ml) and water (4×10 ml), dried, and concentrated. The resulting oily residue was purified by preparative TLC ($CHCl_3$) to yield the tricyclic ketone (**5**) (170 mg, 82%) as colorless crystals: mp 130—133 °C (sealed tube; sublimed at 40 °C/20 mmHg); IR 1714 cm^{-1}; ^{1}H-NMR (90 MHz) 1.01 (3H, s), 1.87 (1H, m), 2.34 (1H, m); MS 178 (M^+). Found: *m/e* 178.1353. Calcd for $C_{12}H_{18}O$: 178.1358.

Deuterium Exchange Reaction. In each run a ketone (0.05—0.5 mmol) was dissolved in a 2.0 M NaOMe solution in MeOD (≥99%, CEA, France) containing 9.4 molar equivalents of NaOMe and the solution was stirred at 33 °C for 22 h under nitrogen. The exchange reaction was repeated at least twice for each ketone, and it was confirmed that the extent of deuteration was reproducible. An example of the representative procedure follows. A solution of the ketone (**5**) (12.8 mg, 0.072 mmol) in 0.34 ml (0.68 mmol of NaOMe) of 2.0 M NaOMe in MeOD was stirred at 33 °C for 22 h under nitrogen, and then diluted with 1 ml of D_2O (≥99.75%, CEA, France). The mixture was extracted with hexane (4×8 ml). The combined organic extracts were washed with D_2O (5 ml), dried over anhydrous Na_2SO_4, and concentrated. The residue was purified by preparative TLC ($CHCl_3$), affording 9.4 mg (74%) of pure **5** as colorless crystals. The sample was analyzed for deuterium content by mass spectrometry.

Nitration of Hexamethylbenzene and Hexamethylbenzene-d_{18} in Acetic Acid. Deuterium Isotope Effect on the Product Distribution. Mechanism of Side-chain Substitution of Arenes[1)]

Hitomi SUZUKI,* Tadashi MISHINA, and Terukiyo HANAFUSA

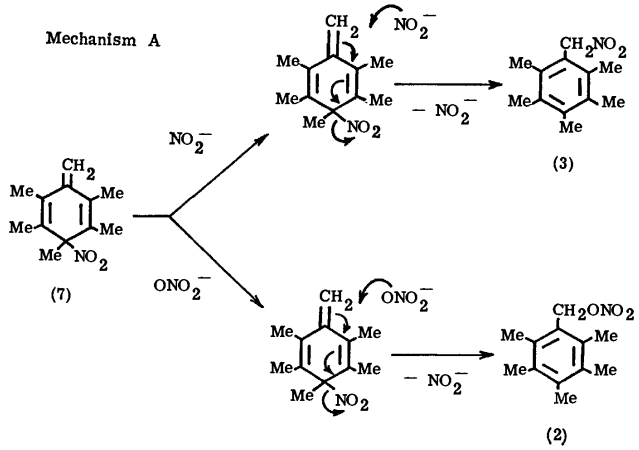
(Received July 4, 1978)

The reaction in acetic acid of hexamethylbenzene and hexamethylbenzene-d_{18} with nitric acid in the dark has been investigated under various conditions using a high-pressure liquid chromatographic method. Pentamethylbenzyl nitrate, pentamethylphenylnitromethane, pentamethylbenzyl acetate, and pentamethylbenzyl alcohol were formed immediately after the mixing of reactants; their relative amounts remained almost unchanged up to nearly 50% conversion. The addition of sodium nitrite gave little influence on the composition of the product mixture, while urea was found to depress somewhat the formation of nitromethane. In the presence of lithium nitrate, the reaction was modestly accelerated and the nitrate formation seems to be slightly favored over the nitromethane formation. Hexamethylbenzene-d_{18} reacted with nitric acid at the same rate as the non-labeled hydrocarbon did, but the benzyl nitrate/phenylnitromethane ratio in the product mixture was considerably higher in the former. Based on the quantitative data obtained, the mechanism for the side-chain substitution has been discussed in terms of the S_N1' pathway: nitronium ion makes an *ipso* attack on the substrate to form the arenium ion, which releases a proton from the activated methyl group *para* to the site of attack to give the 3-methylene-6-nitro-1, 4-cyclohexadiene intermediate (**7**). Heterolytic fission of the C–N bond in **7** will form a benzyl cation-nitrite anion pair, which recombines at the benzylic carbon atom *via* a C–N bond or *via* a C–O bond, giving benzyl nitrite or phenylnitromethane, respectively. Benzyl nitrite will be further converted into benzyl nitrate and benzyl alcohol, while benzyl acetate will arise from the incorporation of solvent molecules into the ion-pair.

When treated with an electrophile at low or room temperature, polyalkylated aromatic compounds often undergo substitution on a side-chain to yield benzylic compounds. The recent literature contains a variety of examples of such unusual substitution, which include chlorination,[2,3)] bromination,[4)] nitration,[5)] nitrooxylation,[5)] acetamidation,[6)] sulfonation,[7)] thiocyanation,[8)] and others.[9,10)] Although the first report on the side-chain nitration of polyalkylbenzenes under heterolytic conditions appeared nearly seventy years ago,[11)] the mechanistic aspect of this unique reaction had received little attention until very recently, probably because of the wide-spread misbelief that all the side-chain substitutions of arenes should proceed through the homolytic process. In the past decade, however, increasing attention has been focused on this aspect of non-conventional electrophilic substitutions. The accumulation of experimental evidence now provides substantial support for the view that alkylbenzenes may undergo side-chain substitution through a heterolytic mechanism involving a primary electrophilic attack at the aromatic ring: an *ipso* attack of an electrophile to form a benzenium ion is followed by a proton loss from the alkyl substituent to yield a methylenecyclohexadiene intermediate, which is then transformed into benzylic compounds. This type of reaction usually takes place in competition with the normal ring substitution and could be classified as a branched-off process of the ordinary S_E2 reaction.

Based on the product studies and kinetic evidence, several mechanistic propositions have been made for the side-chain substitution,[7,12,13)] but the actual mechanism is not yet fully understood. For *nitration*, the two propositions shown in Schemes 1 and 2, both referring to a methylenecyclohexadiene intermediate (**7**), appear to merit consideration:

Mechanism A:[14)] nucleophilic attack of nitrite or nitrate ions to the terminal methylene carbon atom in **7**, redistribution of electrons to regain the aromatic system, and departure of the nitro group as an anion.

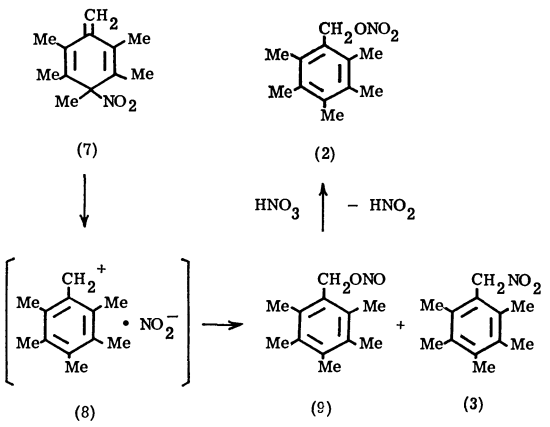


Scheme 1.

Mechanism B:[15)] heterolytic fission of the C–N bond in **7** to form a benzyl cation-nitrite anion pair (**8**) and subsequent recombination of these ions at the benzylic carbon atom either *via* a C–N bond or *via* a C–O bond.

In order to differentiate between these two possibilities, we have reinvestigated the nitration of hexamethylbenzene (**1**) and its perdeuterated derivative using the high-pressure liquid chromatographic method and now present the first quantitative data, which provide support for the mechanism B in which the side-chain substituted products are formed from the methylenecyclohexadiene intermediate through the intervention of an ion-pair.

Mechanism B



Scheme 2.

Experimental

All melting points were taken on a hot stage apparatus and are uncorrected. The IR, PMR, UV, and mass spectra were obtained using the same procedure and apparatus described in the previous paper[20] of this series, unless otherwise stated.

Acetic acid and nitric acid (d=1.5) of guaranteed grade were dried over phosphorus pentaoxide and carefully redistilled before use. Hexamethylbenzene (**1**; mp 163—164 °C),[21] pentamethylbenzyl nitrate (**2**; mp 95—97 °C),[22] pentamethylphenylnitromethane (**3**; mp 86—88 °C),[22] pentamethylbenzyl acetate (**4**; mp 84—86 °C),[23] and pentamethylbenzyl alcohol (**5**; mp 160—161 °C)[23] were prepared as described in the literature. Pentamethylbenzyl nitrite (**9**; mp 23.5—24 °C; bp 88 °C/3 mmHg)[24] was obtained by the reaction of alcohol **5** with nitrosyl chloride in pyridine.

Hexamethylbenzene-d_{18} was prepared according to the procedure of Koptyug and Shubin[25] with the indicated modification; a solution of 1,2,4,5,6,6-hexamethyl-3-methylene-1,4-cyclohexadiene (1.5 g)[26] in trifluoroacetic acid-*d* (10 ml) was allowed to stand at 70 °C for 15 min under nitrogen and then the solvent was removed under reduced pressure. A fresh 10 ml portion of trifluoroacetic acid-*d* was added to the solid residue and the solution was again worked up in a similar manner. This process was repeated until a total of seven exchanges had been performed. The progress of the isotopic exchanges was monitored by PMR spectroscopy. The solution was then diluted with deuterium oxide (6 ml) and kept under nitrogen for 72 h. The resulting oil was extracted with benzene and the organic layer was washed with saturated aqueous sodium carbonate and water, dried over sodium sulfate, and the solvent removed under reduced pressure. The crude solid obtained was placed on the top of an alumina column and eluted with light petroleum. Evaporation of the early eluate followed by recrystallization of the residue from methanol gave perdeuterated hydrocarbon as colorless plates, 0.16 g (10%). The deuterium content determined by mass spectroscopy was 99.3 atom %. Mp 165—166 °C. IR (Nujol): ν_{max} 2240, 2190, 2110, 2070, 1410, 1030, and 900 cm^{-1}.

Product analyses were performed with a high-pressure liquid chromatograph JASCO Model FLC A-700, equipped with a UV detector (Model UVIDEC-100) and a maximum 700 kg/cm^2 solvent delivery system with constant-flow capacities. The separations were made on a 500×2 mm stainless-steel column packed with JASCO-Pack SS-05 (available from Japan Spectroscopic Co., Hachioji, Tokyo). A computerized reporting integrator, Hewlett-Packard Model 3380-A, was used to estimate the concentration of each component. The eluting solvent was a water-saturated mixture of dichloromethane and hexane; the flow rate was 1.0 ml/min at a pressure of 180 kg/cm^2; the column temperature was ambient; and the injection volume was 2 μl. A 10 μl precision sampling pressure-lock syringe was used for sample injection. Determinations were made at 275 nm with UV units full scale. The difference in absorbance between the ordinary and fully deuterated compounds was negligible. Minor peaks which appeared at higher conversion were neglected.

All *kinetic measurements* were started by adding 10 ml of a solution of nitric acid (0.20 M) in acetic acid at 15 °C to 10 ml of a solution of hexamethylbenzene (0.02 M) and 3,5,6-trinitro-1,2,4-trimethylbenzene as internal standard (0.001 M) in the same solvent preequilibrated to the same temperature. The mixture was left at 15.0±0.1 °C for a suitable time which depended on the reaction rate. The products of reaction were identified by isolation and direct comparison with the authentic specimens. All products are known.

At predetermined times, each aliquot (5 ml) was drawn from the kinetic sample and transferred to a 50 ml separatory funnel containing ether (20 ml); the mixture was immediately washed with two 20 ml portions of cold distilled water, a suspension of calcium carbonate (*ca.* 0.5 g) in water (20 ml), and again distilled water (20 ml). The organic layer was separated and dried over anhydrous sodium sulfate, and the solvent was removed by flash rotary evaporation. The residual oil was dissolved in 4 ml of a 4:6 mixture of dichloromethane and hexane. An aliquot of the solution was withdrawn and injected immediately for analysis. This procedure should be carried out as quickly as possible to minimize errors arising from partial hydrolysis of the prod-

Table 1. Correction factors for the product determination

Compound	Relative molar extinction coefficient at 275 nm[a]	Relative extraction efficiency
Hexamethylbenzene	0.13	1.61
Pentamethylbenzyl nitrate	0.61	1.04
Pentamethylphenylnitromethane	0.67	1.05
Pentamethylbenzyl acetate	0.41	1.06
Pentamethylbenzyl alcohol	0.36	0.813
3,5,6,-Trinitro-1,2,4-trimethylbenzene[b]	1.00	1.00

a) In a water-saturated 4:6-mixture of dichloromethane and hexane. b) Of over fifty compounds examined, this compound was found to be best as the internal standard for liquid chromatography, since it satisfied the following requirements: to be soluble in reaction medium, extracting solvent, and eluant; to be stable throughout the reaction and work-up; to have no effect on the course of the reaction; to be well resolved from all the components of the product mixture on the chromatogram and have an elution order which promotes accuracy in the determination with two different solvent systems; and to have an appropriate intensity of UV absorption at the wavelength used for determination.

ucts. When a kinetic sample to be analyzed was first discharged into water and the products were extracted with ether from the aqueous layer, significant amounts of nitrate were hydrolyzed to alcohol. All the determinations were checked against the control experiments.

Appropriate corrections were made for the errors arising from the difference in loss of each component during the sample preparation, the correction factors being determined using the mixed standard solutions of authentic specimens. The relative molar extinction coefficient at 275 nm and the relative extraction efficiency of each component are shown in Table 1, with the internal standard as unity.

Results and Discussion

Before beginning our work, we made a systematic search for a substrate and an analytical method which could afford reliable quantitative data for side-chain nitrations of arenes. From the many alkyl aromatics examined, hexamethylbenzene (**1**) was chosen as the best, since it was found to give a clean, simple product mixture at low conversion. For the quantitative determination of the nitration product from **1**, the high-pressure liquid chromatographic method was found to be best; none of the other chromatographic procedures, such as GLC, TLC, and column, was found to give reliable and reproducible data, owing to the side reactions which inevitably took place during the separation.

Several reports have appeared on the nitration of **1**, but quantitative data are not yet available. Willstätter and Kubli treated **1** with benzoyl nitrate in carbon tetrachloride and obtained bis(pentamethylbenzyl) ether (**12**) and a bis(nitromethyl)tetramethylbenzene in an unspecified yield.[11] Smith and Harris carried out the nitration of **1** with fuming nitric acid in the presence of sulfuric acid and obtained as much as 22% yield of 5,6-dinitro-1,2,3,4-tetramethylbenzene (**14**).[27] A significant proportion of the starting material that had remained unaccounted for in their work was found by one of the present authors to be a complicated mixture of **2**, **3**, nitropentamethylbenzene (**13**), 6-nitro-2,3,4,5-tetramethylbenzyl nitrate (**14**), 5,6-bis(nitrooxymethyl)-1,2,3,4-tetramethylbenzene (**16**), pentamethylbenzaldehyde (**17**), and several other unidentified carbonyl compounds, nitrites, and aliphatic nitro compounds.[22] Illuminati and his coworkers nitrated **1** in acetic acid and obtained a mixture of **2**, **3**, and pentamethylbenzyl acetate (**4**).[28] Detsina and Koptyug reported the formation of 2,3,-4,5,6,6-hexamethyl-2,4-cyclohexadien-1-one (**18**) from the reaction of **1** with nitric acid in fluorosulfuric acid at −70 °C.[10] Fischer and his coworkers investigated the nitration of **1** in acetic anhydride at low temperature and obtained, besides various aromatic products, several extremely labile addition products, one of which was identified as 1,2,3,4,5,6-hexamethyl-3,6-dinitro-1,4-cyclohexadiene (**19**).[29]

The reaction of **1** with an excess of nitric acid was carried out in acetic acid at 15.0 °C in the dark. After aqueous work-up a mixture of nitrate **2**, nitromethane **3**, acetate **4**, and alcohol **5** was obtained as initial products. All these four products were formed immediately after the mixing of reactants and their relative amounts studied as a function of time remained almost unchanged up to nearly 50% conversion (Fig. 1). The sum of the concentration of **1** and these four products accounted for nearly all of the stoichiometric concentration, showing that even if some products other than **2** to **5** were formed, their concentrations were very small. The relative distribution of the products is given in Table 2. At higher conversions, these

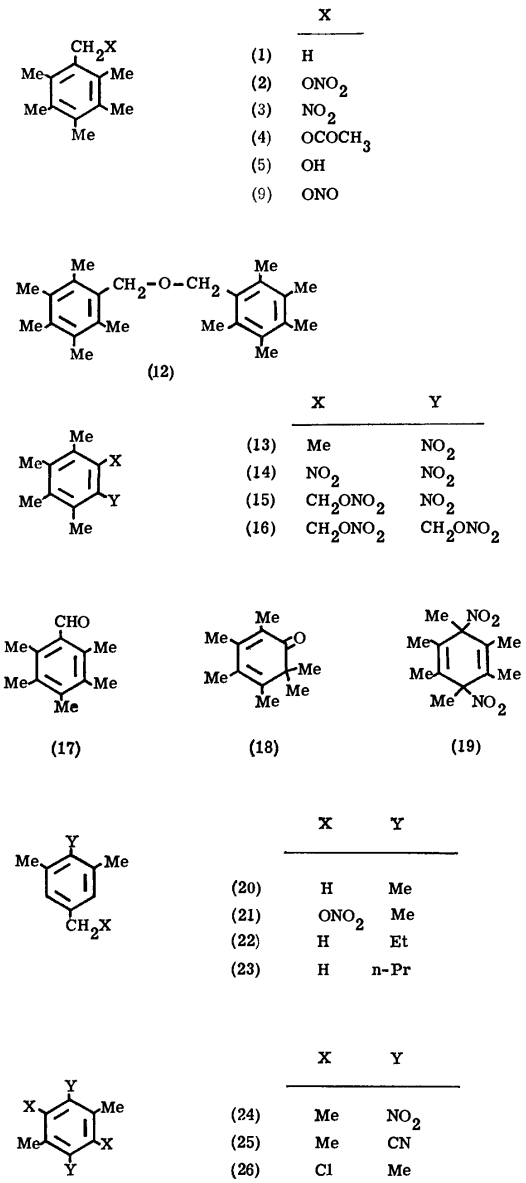
initial products gradually underwent further reaction with the reagent or solvent. Mechanism A requires that the nitro compound **3** be formed as the main product at sufficiently high nitrous acid concentration; that is, the amount of **3** would be multiplied during the progress of the reaction, as nitrous acid accumulates. According to Scheme 1, the increase in the concentration of nitrite ions in the reaction system is expected to favor the formation of nitromethane **3**. Added sodium nitrite, however, gave little influence on the composition of the product mixture. The role of urea as an added material was somewhat perplexing. Although the yellow coloration of the reaction mixture due to the liberated nitrogen dioxide was suppressed by the addition of small amounts of urea, the product composition remained little affected. However, in the presence of large amounts of urea, the nitrate formation seems to be favored, as shown in Table 2. Urea itself or its salt might be involved in the reaction process, but the situation is not clear at present.

Added lithium nitrate in low concentrations has little effect on the product composition. However, in the presence of large amounts of lithium nitrate (>0.1 M), the reaction was modestly accelerated and the nitrate formation seems to be favored over the nitromethane formation. These findings are not consistent with mechanism A, which assumes the reaction of triene intermediate **7** with external nitrate and nitrite ions for the respective formation of benzyl nitrate and phenylnitromethane. Mechanism B assumes the recombination of a benzyl cation with an ambident nitrite ion in the ion-pair. Thus, replacement of protium by deuterium in the cationic portion of the ion-pair is expected to increase the localized positive charge at the benzylic carbon atom due to the decrease in hyperconjugative electron release, as well as due to the more electronegative character of the perdeuteriomethyl group as compared to methyl group. Such an effect will favor the recombination at the oxygen atom of the ambident nitrite ions, leading to the preferential formation of benzyl nitrate or nitrite, while the secondary isotope effect would be of less significance in the product determination step in the mechanism A. In order to use the deuterium labeling as a probe into the ion-pair intermediate **8**, hexamethylbenzene-d_{18} was prepared from 1,1,2,3,4,5,6-heptamethylbenzenium chloride[26)] by the exchange of hydrogens with trifluoroacetic acid-*d* and subjected to nitration under the same conditions as applied to **1**. The perdeuterated hydrocarbon reacted with the reagent



Scheme 3.

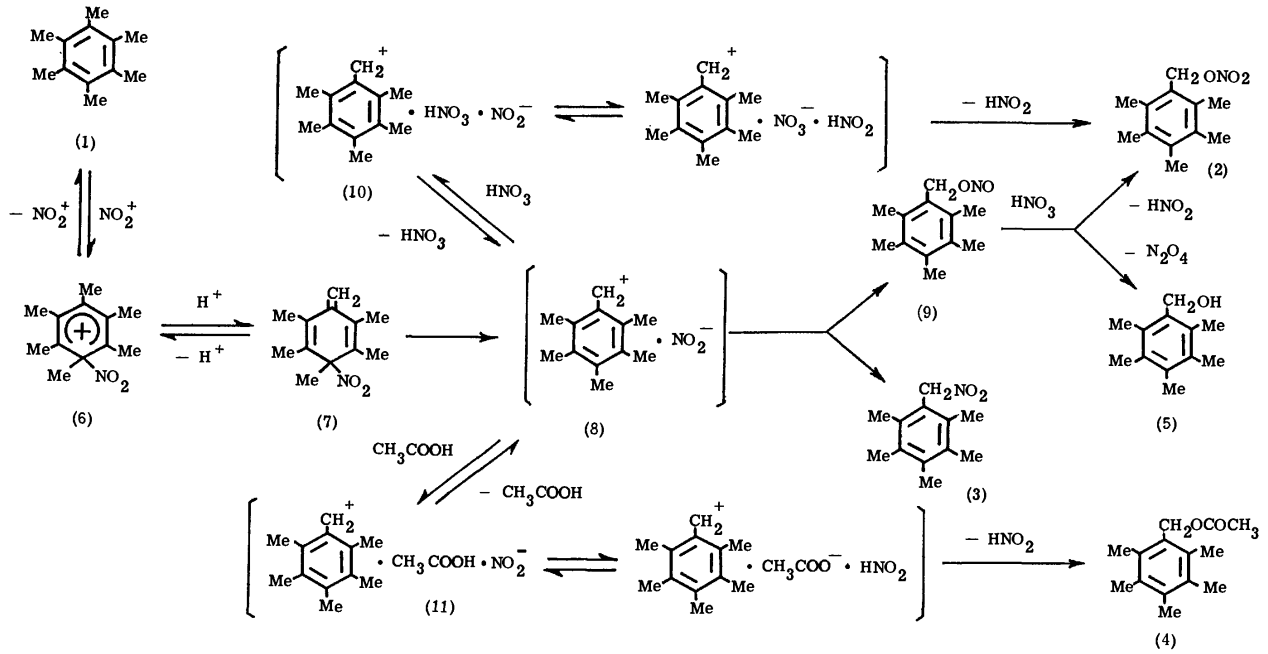
at the same rate as the non-labeled one did. In this case, however, the amount of nitrate was found to increase considerably at the expense of nitromethane, while the amount of acetate did not change very much (Table 2). These results are compatible with Scheme 2, but not with Scheme 1.

It is noteworthy that the molar ratio of acetate **4** to the sum of other three products (**2**+**3**+**5**) remains almost unaffected by the presence of sodium nitrite, urea, and lithium nitrate, as well as by the replacement of protium in **1** by deuterium. Similarly, the molar ratio of nitromethane **3** to the sum of nitrate and alcohol (**2**+**5**) is not very much affected. These trends may be taken to indicate that recombination of initially formed intermediates in **8** is a major pathway to nitrate and nitromethane, while acetate is formed through the nucleophilic capture of carbenium ion intermediate by solvent, possibly *via* a solvent-separated ion-pair (**11**). Pentamethylbenzyl nitrite (**9**) is known to be readily converted into a mixture of nitrate and alcohol in the presence of nitric acid.[24] Part of the nitrate may arise also from the reaction of ion-pair **8** with nitric acid, possibly *via* ion-pair (**10**), since the increase in the concentration of lithium nitrate was found to have a positive effect on the nitrate formation.[30] Alcohol **5** is probably formed partly from the reaction of **9** with nitric acid and partly from the hydrolysis of **2** and **9** during the aqueous work-up. Polymethylbenzyl nitrites are not highly stable and readily undergo hydrolysis to benzyl alcohols in aqueous media. However, they solvolyse quite slowly in anhydrous acetic acid.

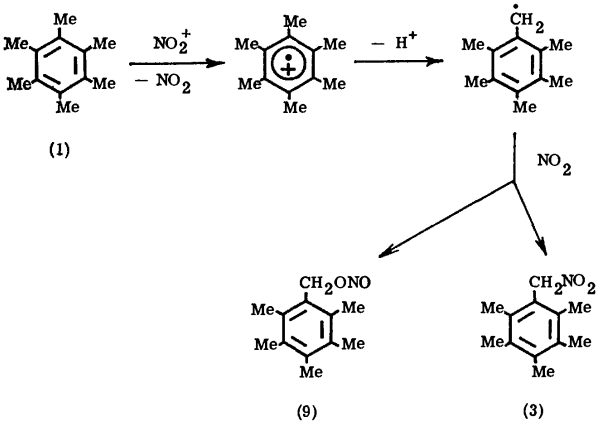
Generally speaking, the side-chain nitration and nitrooxylation of arenes in acetic acid are not sensitive to addenda such as sodium nitrite, urea, and lithium nitrate as long as their concentrations are not very high. In contrast, acetic anhydride exhibited a strong accelerating effect on the reaction and produced a profound effect on the product distribution. Even at the first stages of the reaction, liquid chromatograms of the product revealed a complicated pattern of composition, suggesting the occurrence of various competing side reactions. The addition of dichloromethane to the reaction system, as expected, depressed the acetate formation in favor to the formation of nitrate and nitromethane, leading to the increase in the molar ratio (**2**+**3**+**5**)/**4**. However, the ratio (**2**+**5**)/**3** remained unchanged again. Thus, all the results obtained in our study may be rationalized in terms of the heterolytic mechanism involving the formation of ion-pairs and their conversion to the benzylic compounds, as shown in Scheme 4.

Recently Kochi has made the suggestion of a possible intervention of radical cationic species in the side-chain chlorination of alkyl aromatics, on the basis of his observation of ESR signal during the chlorination of **1**.[13] He extended his idea to the side-chain nitration,[31] suggesting a mechanism in which one electron is transferred from the aromatic substrate to a nitronium ion to form an arene cation radical and nitrogen dioxide (Scheme 5). However, this scheme does not explain the results of our product study: the cation radical derived from 1,2,3,5-tetramethylbenzene (**20**) has a positive charge distribution on the ring carbons in the decreasing order: $C_2 \gg C_5 \gg C_1$, $C_3 > C_4$, C_6.[32] Thus, the proton loss should occur preferentially at the 2-methyl group to form 2,4,6-trimethylbenzyl radical and yield its descendents as major products. This is consistent with the result obtained by anodic oxidation of **20** to a mixture of heptamethyldiphenylmethanes,[32] and the results obtained by the reaction of **20** either with *N*-bromosuccinimide under homolytic conditions[33] or with cerium ammonium nitrate in acetic acid.[33] However, it is not consistent with the results obtained by the nitration of **20**, where the only side-chain substituted product was 3,4,5-trimethylbenzyl nitrate (**21**) or its derivative.[34] With 2-ethyl-1,3,5-trimethylbenzene (**22**) and 2-propyl-1,3,5-trimethylbenzene (**23**), side-chain substitution occurs exclusively at the 5-methyl group.[35]

3,6-Dinitro-1,2,4,5-tetramethylbenzene (**24**),[36] 1,2,-



Scheme 4.



Scheme 5.

4,5-tetramethylbenzene-3,6-dicarbonitrile (**25**),[20] and tetrachloro-*p*-xylene (**26**)[37] are all quite stable towards the action of transition metallic oxidizing agents which are thought to react *via* electron-transfer mechanism, but these compounds still undergo a smooth reaction with concentrated nitric acid at room temperature, giving the corresponding benzyl nitrates in good yields. The low efficacy of nitronium tetrafluoroborate to produce side-chain substituted products from **1** provides further evidence against the suggested scheme 5. Therefore, the electron-transfer mechanism does not seem to possess a sound ground on which the formation of a variety of side-chain nitration and nitrooxylation products should be rationalized.

The present findings are highly suggestive of a pathway involving an ion-pair intermediate; nitrate **2** and nitromethane **3** are formed from an intimate ion-pair **8**, and acetate **4** arises from a solvent-separated ion-pair **11**. Full discussion of this problem awaits more detailed data, in particular, direct evidence of isolating the triene intermediate.

We are grateful to the Ministry of Education and the Saneyoshi Scientific Foundation for financial support of this work.

Improved Synthesis of Antimycin A_3

Shimpei ABURAKI and Mitsuhiro KINOSHITA*
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 224
(Received July 8, 1978)

An improved synthesis of antimycin A_3 was accomplished by a suitable lactonization of 3-*O*-benzyl or 3-*O*-isovaleryl derivative (**10a** or **10b**) of (2*R*, 3*R*, 4*S*)-4-(*N*-benzyloxycarbonyl-L-threonyloxy)-2-butyl-3-hydroxypentanoic acid, which was synthesized by starting from the corresponding 3-*O*-benzyl or 3-*O*-isovaleryl derivative (**4a** or **4b**) of methyl 2-*C*-butyl-2, 5-dideoxy-β-L-arabinofuranoside, respectively. Acid hydrolysis of **4a** or **4b** followed by reduction with sodium borohydride afforded 3-*O*-benzyl or 3-*O*-isovaleryl-1, 3, 4-pentanetriol (**5a** or **5b**), respectively. Tritylation of **5a** or **5b** followed by succesive 4-*O*-acylation with *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine, detritylation, oxidation with chromium trioxide-acetic acid-pyridine, and de-*t*-butylation gave the hydroxy ester acid **10a** or **10b**, respectively. Lactonization of **10a** or **10b** through its 2-pyridinethiol ester **11a** or **11b** activated with silver perchlorate afforded the corresponding nine-membered dilactone derivative **12a** or **12b** in 33 or 13% yield, respectively. Removal of *N*,*O*-protecting groups of **12a** by hydrogenolysis, followed by successive *N*- and *O*-acylation gave the antimycin A_3 precursor, (3*S*, 4*R*, 7*R*, 8*R*, 9*S*)-3-(2-benzyloxy-3-nitrobenzoylamino)-4, 9-dimethyl-7-butyl-8-isovaleryloxy-1, 5-dioxonane-2, 6-dione derived from **12b**.

Antifungal antibiotic antimycin A complex has a unique nine-membered dilactone structure. In the first total synthesis[1,2] of antimycin A_3 (**1**), one of the major components of the complex, the dilactone intermediate, (3*S*,4*R*,7*R*,8*R*,9*S*)-3-benzyloxycarbonyl-amino-7-butyl-4,9-dimethyl-8-isovaleryloxy-1,5-dioxonane-2,6-dione (**12b**) was synthesized by lactonization of (2*R*, 3*R*,4*S*)-4-(*N*-benzyloxycarbonyl-L-threonyloxy)-2-butyl-3-isovaleryloxypentanoic acid (**10b**) prepared by the condensation of (±)-2,3-*threo*-3,4-*erythro*-2-butyl-4-hydroxy-3-isovaleryloxypentanoic acid *t*-butyl ester with *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine. The lactonization of **10b** was effected only with trifluoroacetic anhydride in hot benzene, but the yield of **12b** was extremely poor.[2]

We briefly communicated[3] the synthesis of deisovalerylblastmycin (**2**) which constitutes a new route for the stereospecific synthesis of antimycin A involving an improved lactonization step. We now describe in full the improved synthesis of antimycin A_3.[3] Since the first synthesis of antimycin A_3, studies have progressed in the field of macrolide synthesis, new lactonization methods being found to be effective for the synthesis of large lactone compounds.[4] It was expected that the yield of the medium lactone ring formation such as lactonization of the hydroxy ester acid **10b** would also be enhanced by appropriate modification in the structure of the reactant or by choice of a more suitable method for lactonization of the reactant.

The structural modification undertaken was an exchange of the 3-isovaleryloxy group of **10b** by benzyloxy group convertible into the former after lactonization. The modified hydroxy ester acid, (2*R*,3*R*,4*S*)-4-(*N*-benzyloxycarbonyl-L-threonyloxy)-3-benzyloxy-2-butylpentanoic acid (**10a**) was synthesized through the stereospecific route (Fig. 1) starting from the sugar derivative **3**.[5] The route was utilizable for the stereospecific synthesis of **10b**.

Lactonization of **10a** or **10b** through its 2-pyridinethiol ester **11a** or **11b** activated with silver perchlorate by the method of Gerlach and Thalmann[6] effectively afforded the corresponding dilactone intermediate **12a** or **12b** in 33 or 13% yield, respectively. The comparatively high yields are in contrast with the 0.8% yield[2] of **12b** obtained by the trifluoroacetic anhydride method. The dilactone derivative **12a** was converted into the 3-(2-benzyloxy-3-nitrobenzoylamino)-8-hydroxydilactone **15**, a synthetic precursor of the antibiotic deisovalerylblastmycin (**2**).[3] Isovalerylation of **15** afforded the antimycin A_3 precursor **16** which had been derived from **12b** *via* the amino dilactone derivative **13b**[2](Fig. 3). The synthesis of antimycin A_3 was thus improved through the route *via* **12a** effectively provided by suitable lactonization of the modified hydroxy ester acid **10a**. Moreover, the previous route *via* **12b** was also useful in the antimycin A_3 synthesis by the improved lactonization of **10b**.

Results and Discussion

Methyl 2-*C*-butyl-2,5-dideoxy-β-L-arabinofuranoside (**3**) was converted into the 3-*O*-benzyl derivative **4a** with benzyl bromide and sodium hydride in THF or into the 3-*O*-isovalerate **4b** with isovaleric anhydride in pyridine. Acid hydrolysis of **4a** followed by sodium borohydride reduction gave (2*S*,3*R*,4*S*)-3-*O*-benzyl-2-butyl-1,3,4-pentanetriol (**5a**) in 94% yield. Acid hydrolysis of **4b** followed by reduction with sodium borohydride in 70% ethanol at −10 °C afforded an 8:1 mixture of desired 3-*O*-isovaleryl triol (**5b**) and its positional isomer, 4-*O*-isovalerate (**5b'**)in a total yield of 97%. The formation of **5b'** was probably due to the 3→4 *O*-acylmigration proceeding under basic conditions in the borohydride reduction step.

Tritylation of **5a** with triphenylmethyl chloride in pyridine at 40 °C gave the 3-*O*-benzyl-1-*O*-trityl-1,3,4-pentanetriol (**6a**) quantitatively. Acylation of the 4-hydroxyl group of **6a** with excess *N*-(benzyloxycarbonyl)-*O*-*t*-butyl-L-threonine in the presence of dicyclohexylcarbodiimide (DCCI) and pyridine afforded the condensation product **7a** in 74% yield. Tritylation of the 8:1 mixture of **5b** and **5b'** at room temperature gave 3-*O*-isovaleryl-1-*O*-trityl-1,3,4-pentanetriol (**6b**) in

74% yield after being subjected to chromatography. However, when the reaction with **5b** was conducted at 40 °C, the major product was the isomer, 4-*O*-isovaleryl-1-*O*-trityl-1,3,4-pentanetriol (**6b'**), presumably formed from **6b** by the 3→4 *O*-acyl migration. Condensation of **6b** with the threonine derivative by the DCCI method afforded the ester **7b** in 65% yield.

Detritylation of **7a** and **7b** with 90% acetic acid gave the corresponding alcohols, **8a** and **8b** in 95 and 62.2% yields, respectively. Oxidation of **8a** and **8b** with a mixture of chromium trioxide, acetic acid and pyridine[7] afforded the corresponding ester acids, **9a** and **9b** in 76 and 96% yields, respectively.

The *t*-butyl groups of **9a** and **9b** were removed by treatment with trifluoroacetic acid to give (2*R*,3*R*,4*S*)-4-(*N*-benzyloxycarbonyl-L-threonyloxy)-3-benzyloxy-2-butylpentanoic acid (**10a**) and (2*R*,3*R*,4*S*)-4-(*N*-benzyloxycarbonyl-L-threonyloxy)-3-isovaleryloxy-2-butylpentanoic acid (**10b**), respectively.

In contrast with **10b**, the modified hydroxy ester acid **10a** afforded no cyclization product on treatment with trifluoroacetic anhydride in hot benzene by the same procedure as that for **10b**.[2] IR spectroscopy revealed that the major product of the reaction was the *O*-trifluoroacetyl derivative of **10a**.

The hydroxy acids **10a** and **10b** were converted into the corresponding 2-pyridinethiol esters, **11a** and **11b** by action of di-2-pyridyl disulfide and triphenylphosphine according to Mukaiyama *et al.*[8] in good yields after being subjected to chromatography. By the method of Gerlach and Thalmann,[6] the intramolecular cyclization of **11a** and **11b** was effected in about 0.01 M benzene solution with a 1.5 equivalent amount of silver perchlorate to yield the corresponding dilactone derivatives, **12a** and **12b** in 33 and 13.4% yields, respectively. In the cyclization of **11a** with silver perchlorate, no formation of intermolecular cyclization product was observed, the hydroxy ester acid **10a** being recoverd in good yield. Cyclization of **11a** carried out in a 0.00 M solution showed no improvement in the yield of **12a**.

According to the method of Corey and Nicolaou,[9] the crude 2-pyridinethiol ester **11a** was refluxed in a 0.005 M xylene solution to afford the sole intramolecular cyclization product in 13.7% yield. The product was distinguishable from **12a** in the ring coupling constants ($J_{7,8}$=4.0 and $J_{8,9}$=9.2 Hz), suggesting that the product might be **12a'**, the 7-epimer of **12a**.

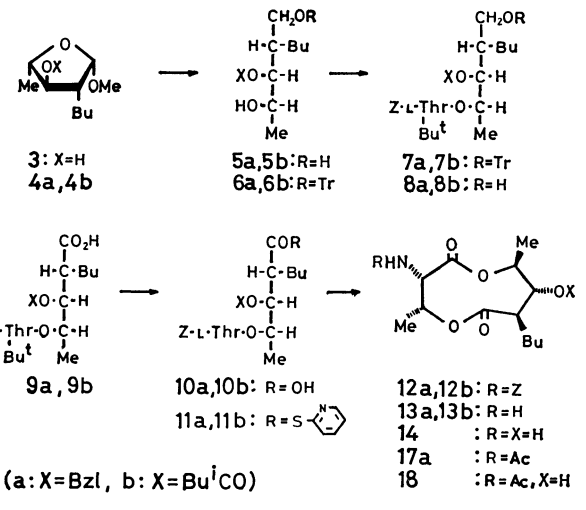

Fig. 1.

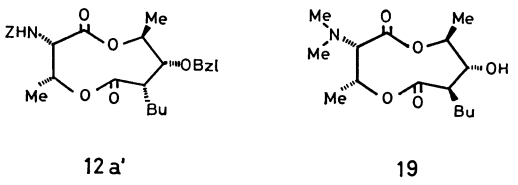

12a' 19

Fig. 2.

Hydrogenolysis of **12a** with palladium black in methanol under hydrogen atmosphere at 50 p.s.i. afforded the *N*-debenzyloxycarbonylated dilactone **13a**, *O*-debenzylation of which was effected *via* the *N*-acetyl derivative **17a** to afford **18**, the *N*-acetyl derivative of the amino hydroxy dilactone **14**. Hydrogenolysis of **12a** with palladium black in methanol containing a small amount of hydrogen chloride under hydrogen atmosphere at 50 p.s.i. gave the hydrochloride of **14**, which was selectively *N*-acylated with 2-benzyloxy-3-nitrobenzoic acid *N*-hydroxysuccinimide ester[10] to afford **15** in 72% yield. On the other hand, hydrogenolysis of **12a** with palladium black in methanol at 40 °C under hydrogen atmosphere at 50 p.s.i. yielded the dimethylamino hydroxy dilactone **19** whose structure was determined by its PMR and mass spectrum.

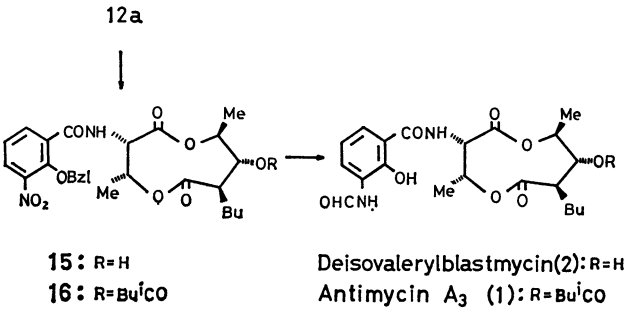

Fig. 3.

The *N*-acylamino hydroxy dilactone **15** was *O*-isovalerylated with isovaleric anhydride in pyridine to afford (3*S*,4*R*,7*R*,8*R*,9*S*)-3-(2-benzyloxy-3-nitrobenzoylamino)-4,9-dimethyl-7-butyl-8-isovaleryloxy-1,5-dioxonane-2,6-dione (**16**),[2] the antimycin A_3 precursor, in 88% yield.

Experimental

Melting points were determined on a micro hot stage and are uncorrected. IR spectra were taken on a Hitachi 225 Spectrophotometer, Mass spectra on a JMS-D-100, and PMR spectra on Varian A-60D and HA-100D Spectrometers using TMS as an internal standard. Optical rotations were measured with a Zeiss Photoelectroic Precision Polarimeter. CD spectra were taken on a JASCO J-20 Spectropolarimeter. TLC was carried out on Wakogel B-5 and silica gel column chromatography on Wakogel C-200 which was activated at 110 °C for 1 h. Concentration was carried out at reduced pressure below 40 °C.

*Methyl 3-O-Benzyl-2-C-butyl-2,5-dideoxy-β-L-arabinofuranoside (**4a**).* A suspension of 55% NaH (450 mg, 10.3 mmol) in THF(9 ml) was added to a solution of methyl 2-*C*-butyl-2,5-dideoxy-β-L-arabinofuranoside (**3**)[5] (1.29 g, 6.83 mmol) and stirred at room temperature for 2 h. Benzyl bromide (1.22 ml, 10.3 mmol) was added to the mixture and stirred at room temperature overnight. The reaction mixture was poured into cold water (50 ml) and extracted with ethyl acetate. The organic layer was washed with saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel(150 g) with benzene-ethyl acetate (30 : 1) to afford a colorless syrup of **4a** (1.54 g, 81%) : $[\alpha]_D^{21}$ −98°(*c* 1.1, $CHCl_3$); PMR($CDCl_3$) δ 1.32 (d, 4-CH_3, J=6.4 Hz), 3.44(s, OCH_3), 3.36 (dd, H-3, $J_{2,3}$= 4.0, $J_{3,4}$=6.1 Hz), 4.25 (dq, H-4), 4.68 (s, CH_2Ph), and 4.76 (d, H-1, $J_{1,2}$=1.8 Hz).

Found: C, 73.65; H, 9.27%. Calcd for $C_{17}H_{26}O_3$: C, 73.34; H, 9.41%.

*Methyl 3-O-Isovaleryl-2-C-butyl-2,5-dideoxy-β-L-arabinofuranoside (**4b**).* A mixture of **3** (1.08 g, 5.71 mmol), isovaleric anhydride (1.72 ml, 8.1 mmol) and pyridine (10 ml) was kept at room temperature for 2 days. The reaction mixture was poured into cold water (20 ml) and extracted with chloroform. The combined extracts were washed with saturated aqueous NaCl solution, dried, and evaporated. The residue was chromatographed on silica gel (150 g) with benzene-ethyl acetate(50 : 1) to afford an essentially pure sample of **4b** as a pale yellow syrup (1.52 g, 98%): PMR ($CDCl_3$) δ 0.97[d, 6H, $CH(CH_3)_2$, J=6.6 Hz], 1.33 (d, 3H, 4-CH_3, J=6.5 Hz), 3.40 (s, 3H, OCH_3), 4.08 (dq, H-4, $J_{3,4}$=5.9 Hz), 4.61 (dd, H-3, $J_{2,3}$=3.9 Hz), and 4.70 (d, H-1, $J_{1,2}$=1.8 Hz).

*(2S,3R,4S)-3-O-Benzyl-2-butyl-1,3,4-pentanetriol (**5a**).* A solution of **4a** (1.53 g) in a mixture of dioxane (44 ml) and 1 M HCl (11 ml) was kept at room temperature for 3 days. The reaction mixture was neutralized with solid $NaHCO_3$, the filtrate being evaporated. The residue was chromatographed on silica gel (150 g) with benzene-ethyl acetate (6 : 1) to give the free sugar (1.14 g). Unchanged **4a** recovered on chromatography was again subjected to hydrolysis and chromatography to afford an additional amount of the free sugar (260 mg). The total yield was 1.40 g (97%).

The free sugar (1.40 g, 5.30 mmol) was dissolved in 70% ethanol (28 ml), $NaBH_4$ (100 mg, 2.65 mmol) being added to the solution. The solution was stirred at room temperature for 2 h and then concentrated.The residue was taken in ethyl acetate (50 ml), and the mixture was washed with saturated aqueous NaCl solution, dried, and evaporated to afford a colorless syrup of **5a**(1.37 g, 94% overall yield based on **4a**). A portion of this product was chromatographed on silica gel with benzene-ethyl acetate (6 : 1) to give an analytical sample: $[\alpha]_D^{21}$ +1°, $[\alpha]_{365}^{21}$ −18° (*c* 0.4, $CHCl_3$); PMR ($CDCl_3$) δ 1.31 (d, 4-CH_3, J=6.4 Hz), 3.52 (dd, H-3, $J_{2,3}$= 3.4 and $J_{3,4}$=6.0 Hz), and 4.73 (s, CH_2Ph).

Found: C, 72.22; H, 9.77%. Calcd for $C_{16}H_{26}O_3$: C, 72.14; H, 9.84%.

*(2S,3R,4S)-2-Butyl-3-O-isovaleryl-1,3,4-pentanetriol (**5b**).* A solution of **4b** (1.55 g) in a mixture of dioxane (36 ml) and 2 M HCl (10.7 ml) was kept at 40 °C for 2 days. The reaction mixture was neutralized (pH 4) with solid $NaHCO_3$ and evaporated. The residue was extracted with ethyl acetate and the extract was evaporated. The residual syrup was chromatographed on silica gel (35 g) with benzene-ethyl acetate (15 : 1) to afford a colorless syrup of the free sugar (941 mg, 64%) and **4b** (395 mg, 25.5%). Free sugar: PMR ($CDCl_3$) δ 0.98[d, $CH(CH_3)_2$, J=6.8 Hz], 1.33 (d, 4-CH_3, J=6.3 Hz), 4.25 (dq, H-4, $J_{3,4}$=4.6 Hz), 4.65 (dd, H-3, $J_{2,3}$=3.2 Hz), and 5.22 (d, H-1, $J_{1,2}$=1.9 Hz). A solution of $NaBH_4$(124 mg, 2.17 mmol) in 70% ethanol (2.5 ml) was added under stirring to a solution of the free sugar (847 mg, 3.28 mmol) in 70% ethanol (17 ml) cooled at −10 °C. After being stirred at 0 °C for 1 h, the reaction mixture was neutralized with 2 M HCl and evaporated to dryness. The residue was extracted with ethyl acetate, the combined extracts being washed with saturated aqueous NaCl solution, dried, and evaporated to afford a crude syrup of **5b**(826 mg, 97%), which was used for subsequent synthesis. A portion of this sample (54.5 mg) was chromatographed on silica gel (5.5 g) with benzene-ethyl acetate (3 : 1) to give **5b**(R_f 0.12, 43.3 mg, 81%) and its positional isomer, 2-butyl-4-*O*-isovaleryl-1,3,4-pentanetriol (**5b'**) (R_f 0.26, 10 mg, 19%). **5b**: PMR($CDCl_3$) δ 0.98[d, $CH(CH_3)_2$, J=6.2 Hz], 1.21(d, 4-CH_3, J=6.3 Hz), 2.51(s, 2H, OH), *ca.* 3.6(m, 2H, H-1,1'), 4.00(dq, H-4, $J_{3,4}$=7.0 Hz), and 4.91(dd, H-3, $J_{2,3}$=3.8 Hz). Isomer of **5b**: PMR($CDCl_3$) δ 0.98[d, $CH(CH_3)_2$, J=6.5 Hz], 1.32(d, 4-CH_3, J=6.3 Hz), *ca.* 2.1 (m, 2H, OH), *ca.* 3.8(m, 3H, H-1,1',3), and 5.07(dq, H-4, $J_{3,4}$=5.9 Hz).

*(2S,3R,4S)-4-O-(N-Benzyloxycarbonyl-O-t-butyl-L-threonyl)-3-O-benzyl-2-butyl-1-O-trityl-1,3,4-pentanetriol (**7a**).* Triphenylmethyl chloride (1.68 g, 6.02 mmol) was added to a solution of **5a** (1.34 g, 5.03 mmol) in dry pyridine (6.7 ml) and the solution was allowed to stand at 40 °C overnight. Water (30 ml) was added to the reaction mixutre under cooling and the mixture was extracted with chloroform (20 ml×3). The combined extracts were washed with saturated aqueous NaCl solution, dried and evaporated to afford 1-*O*-tritylated product **6a** (2.56 g, 100%), which was used in the next reaction without purification. A solution of **6a** (2.56 g, 5.03 mmol) in dry ether (3.8 ml) and dry pyridine (0.43 ml) was added to a solution of DCCI (1.14 g, 5.54 mmol) in dry ether (3.1 ml) under ice-cooling. To this solution was added slowly a solution of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine (1.71 g, 5.52 mmol) in dry ether (3.1 ml) under cooling and stirred at 5 °C for 3 days. A solution of DCCI (1.14 g) and pyridine (0.43 ml) in dry ether (3.8 ml) and a solution of the threonine derivative (1.71 g) in dry ether (3.1 ml) were then added successively and the mixture was kept at 5 °C for 3 days. After removal of *N,N'*-dicyclohexylurea (DCU) by filtration, the filtrate was washed with saturated aqueous $NaHCO_3$ solution and saturated aqueous NaCl solution, dried, and evaporated. The residue (9 g) was chromatographed on silica gel (450 g) with benzene-ethyl acetate (50 : 1) to give a pure sample of the condensation product **7a**: colorless syrup (2.96 g, 74%); $[\alpha]_D^{21}$ +3°, $[\alpha]_{365}^{21}$ +26° (*c* 0.39, $CHCl_3$); PMR($CDCl_3$) δ 1.07 (s, OBu^t), 1.20(d, 4-CH_3, J=6.3 Hz), 1.29[d, CH_3 of threonine, J=6.7 Hz], 3.16(d, H-1, $J_{1,2}$=5.2 Hz), 3.72 (dd, H-3, $J_{2,3}$=5.5, $J_{3,4}$=2.8 Hz), 4.56 (ABq, CH_2Ph), 5.06(ABq, CH_2Ph of benzyloxycarbonyl), 4.54(dq, H-4), and 5.60(d, NH, J=9.2 Hz).

Found: C, 76.76; H, 7.78; N, 2.02%. Calcd for $C_{51}H_{61}NO_7$: C, 76.56; H, 7.69; N, 1.75%.

*(2S,3R,4S)-2-Butyl-3-O-isovaleryl-1-O-trityl-1,3,4-pentanetriol (**6b**).* a) A solution of the crude **5b**(796 mg, 3.05 mmol) and triphenylmethyl chloride (1.70 g, 6.10 mmol) in dry pyridine (8 ml) was kept at room temperature for 3 days. The reaction mixture was poured into water and extracted with chloroform. The extracts were washed with saturated aqueous NaCl solution, dried, and evaporated to afford a yellow syrup (1.7 g), which was chromatographed on silica gel (150 g) with benzene-ethyl acetate (50 : 1) to afford a homogeneous sample of **6b** [R_f 0.70 (6 : 1 benzene-

ethyl acetate), 1.13 g, 74%]: PMR ($CDCl_3$) δ 0.95[d, $CH(CH_3)_2$, J=6.8 Hz], 1.21 (d, 4-CH_3, J=7.5 Hz), *ca.* 3.1 (m, 2H, H-1,1'), 5.07(dd, H-3, $J_{2,3}$=4.7, $J_{3,4}$=6.3 Hz), and *ca.* 7.3(m, 15H, CPh_3).

Found: C, 78.48; H, 8.30%. Calcd for $C_{33}H_{42}O_4$: C, 78.85; H, 8.42%.

b) A homogeneous sample of **5b** (11.6 mg, 0.0445 mmol) was treated with triphenylmethyl chloride (49.6 mg, 0.178 mmol) in dry pyridine (0.23 ml) at 40 °C for 2 days and the mixture was worked up in the same manner as described above and chromatographed with the same solvent system to afford **6b**(R_f 0.70, 9.7 mg, 43.3%) and its isomer, 4-*O*-isovalerate **6b'**(R_f 0.80, 12.3 mg, 55%): PMR($CDCl_3$) δ 0.92[d, $CH(CH_3)_2$, J=6.4 Hz], 1.24(d, 4-CH_3, J=6.1 Hz), *ca.* 2.8(m, 1H, OH), *ca.* 3.3(m, 2H, H-1,1'), *ca.* 3.8(m, 1H, H-3), 4.97(dq, H-4, $J_{3,4}$=5.2 Hz), and *ca.* 7.3(m, 15 H, CPh_3).

(2S,3R,4S)-4-O-(N-Benzyloxycarbonyl-O-t-butyl-L-threonyl)-2-butyl-3-O-isovaleryl-1-O-trityl-1,3,4-pentanetriol (7b). A solution of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine (319 mg, 2.28 mmol) in dry ether (0.7 ml) was added dropwise under stirring to a cooled solution of DCCI (231 mg, 1.12 mmol), **6b** (471 mg, 0.937 mmol), and dry pyridine (0.075 ml, 2.07 mmol) in dry ether (0.62 ml). The mixture was stirred at 0 °C for 3 days, during which time the same amount of DCCI, pyridine, and the threonine derivative were added twice. The reaction mixture was worked up in the same manner as described in the preparation of **7a**. The crude product (5.11 g) was chromatographed on silica gel (80 g) with benzene-ethyl acetate (50 : 1) to afford **7b** (484 mg, 65%) as a syrup: PMR($CDCl_3$), δ 0.99 [d, $CH(CH_3)_2$, J=6.6 Hz], 1.09 (s, OBu^t), 1.19(d, CH_3 of threonine, J=6.5 Hz), 1.21 (d, 4-CH_3, J=7.6 Hz), 3.09 (m, 2H, H-1,1'), 4.1—4.2(m, 2H, H-2',3'), 5.15(ABq, CH_2Ph), 5.2—5.3(m, 3H, NH, H-3,4), and *ca.* 7.4(m, Ph).

(2R,3R,4S)-4-(N-Benzyloxycarbonyl-O-t-butyl-L-threonyloxy)-3-benzyloxy-2-butylpentanoic Acid (9a). A solution of **8a** (1.18 g, 2.11 mmol) in a chromium trioxide-acetic acid-pyridine reagent† (26.2 ml, 8.44 mmol) was kept at room temperature overnight. The reaction mixture was diluted with cold water (50 ml) and extracted with ether (20 ml×3). The combined extracts were washed with saturated aqueous NaCl solution, dried, and evaporated. The residual syrup (1.19 g) was chromatographed on silica gel (100 g) with hexane-benzene-acetone-acetic acid (40:20:1:2) to afford a pure sample of **9a**; colorless syrup (920 mg, 76%): $[\alpha]_D^{23}$ +3°, $[\alpha]_{365}^{23}$ +14° (*c* 2.4, $CHCl_3$), PMR($CDCl_3$) δ 1.09 (s, OBu^t), 1.19(d, 4-CH_3, J=6.5 Hz), 1.31(d, CH_3 of threonine, J=6.8 Hz), 3.78(dd, H-3, $J_{2,3}$=8.0, $J_{3,4}$=4.2 Hz), 4.66 (ABq, CH_2Ph), 5.10(dq, H-4), 5.11(ABq, CH_2Ph of benzyloxycarbonyl), and 5.62(d, NH, J=10.0 Hz).

Found: C, 67.27; H, 7.95; N, 2.32%. Calcd for $C_{32}H_{45}NO_8$: C, 67.23; H, 7.93; N, 2.45%.

(2R,3R,4S)-4-(N-Benzyloxycarbonyl-O-t-butyl-L-threonyloxy)-2-butyl-3-isovaleryloxypentanoic Acid (9b). A sample of **8b** (292 mg, 0.53 mmol) was oxidized with the chromium trioxide reagent (6.6 ml, 2.13 mmol) at room temperature for 1.5 h. Work-up of the product in the same way as in the preparation of **9a** afforded a brown syrup (299 mg), which was chromatographed on silica gel (30 g) with hexane-benzene-acetone-acetic acid (40:20:1:2) to give a pure sample of **9b**(287 mg, 96%) as a colorless syrup: $[\alpha]_D^{23}$ +5.1°(*c* 1.4, $CHCl_3$); PMR($CDCl_3$) δ 0.99[d, $CH(CH_3)_2$, J=6.5 Hz], 1.13(s, OBu^t), *ca.* 1.2(m, 6H, 4-CH_3, 3'-CH_3), *ca.* 4.2(m, 2H, H-2',3'), 5.19(s, CH_2Ph), 5.0—5.6(m, 3H, NH, H-3,4), 6.5(br, 1H, COOH), and 7.40(s, Ph).

Found: C, 63.59; H, 8.44; N, 2.61%. Calcd for $C_{30}H_{47}NO_9$: C, 63.69; H, 8.38; N, 2.48%.

Hydroxy Ester Acid (10a). A solution of **9a**(855 mg) in trifluoroacetic acid (10 ml) was allowed to stand at room temperature for 10 min and then evaporated below 10 °C to afford **10a** (770 mg, quantitative), which was used in the next reactions after being thoroughly dried at 0.01 Torr.

Hydroxy Ester Acid (10b). Treatment of **9b**(287 mg) with trifluoroacetic acid (3.5 ml) at room temperature for 10 min gave **10b** (248 mg, 96%) after evaporation: IR ($CHCl_3$) 3600—2800(COOH), and 1730 cm^{-1}(ester and amide); PMR($CDCl_3$) δ 1.03[d, $CH(CH_3)_2$, J=6.4 Hz], *ca.* 1.3(m, 6H, 4-CH_3, 3'-CH_3), 4.2—4.5(m, 2H, H-2',3'), 5.20 (s, CH_2Ph), 5.1—5.4(m, 2H, H-3,4), *ca.* 5.9(br, 1H, NH), 7.1—7.5(br, 1H, COOH), and 7.41(s, 5H, Ph).

(3S,4R,7R,8R,9S)-8-Benzyloxy-3-benzyloxycarbonylamino-7-butyl-4,9-dimethyl-1,5-dioxonane-2,6-dione (12a). A sample of **10a** (300 mg, 0.582 mmol) was dissolved in dry benzene (3 ml), triphenylphosphine (458 mg, 1.75 mmol) and di-2-pyridyl disulfide (385 mg, 1.75 mmol) then being added to the solution. After the mixture had been kept for 30 min at room temperature, the reaction mixture was evaporated and the residue (1.2 g) was chromatographed on silica gel (40 g) with benzene-acetone (10:1) to afford the 2-pyridinethiol ester **11a** (160 mg) as a yellow syrup. A solution of silver perchlorate†† (53.5 mg, 0.235 mmol) in dry benzene (0.5 ml) was added to a stirred solution of **11a** (143 mg, 0.235 mmol) in dry benzene (23.5 ml) and the mixture was stirred at room temperature for 1 h. The precipitates were filtered off and washed with benzene. The combined filtrate and washings were evaporated and the residue was chromatographed on silica gel (15 g) with benzene-ethyl acetate (50:1) to afford **12a** (38.6 mg, 33%) as colorless crystals and **10a** (94 mg, 66%). Analytical sample of **12a** was obtained by recrystallization from ethyl acetate as colorless needles: mp 118.5—119.5 °C; $[\alpha]_D^{23}$ +53°(*c* 0.73, $CHCl_3$); IR(CCl_4,

† The reagent consists of chromium trioxide (1 g), acetic acid (30 ml) and pyridine (1 ml).

†† The silver perchlorate used was thoroughly dried over P_2O_5 at 50—60 °C under reduced pressure (1 Torr) for 10 h.

Methylation of Pyrimidine 2′-Deoxynucleosides with Trimethyl Phosphate

Toshizumi TANABE,* Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received July 10, 1978)

The reactions of thymidine, deoxyuridine, and deoxycytidine with trimethyl phosphate (TMP) were studied in a homogeneous water solution at 37—60 °C and pH 7—10. Three pyrimidine deoxynucleosides were methylated mainly at the N-3 position to afford their 3-methyl derivatives. The methylation rate at the N-3 position was found to be dependent on the pH of reaction medium. At pH 10, thymidine and deoxyuridine were methylated much faster than deoxycytidine, the tendency being reversed at pH 7.

Most chemical carcinogens such as polycyclic aromatics, aromatic amines, and azo compounds have recently been found to be activated *in vivo* by oxidizing enzymes to alkylate nucleic acids, causing mutagenic or carcinogenic effects.[1] Since intrinsic alkylating agents such as dialkyl sulfates, alkyl alkanesulfonates, and diazo alkanes also have mutagenicity or carcinogenicity, many studies have been carried out on their actions on nucleic acids and their components.[2-7]

We reported the alkylation of five main nucleic acid-bases with trialkyl phosphates such as trimethyl,[8] triethyl,[9] and triallyl phosphates[10] (TMP, TEP, and TAP). From the results, TMP and TEP appear to be suitable for the alkylation of nucleic acids and their components because of their high solubility in water and moderate reactivity which enables the alkylating reactions to take place homogeneously in an aqueous phase. Methylation study with TMP seems to be worthy of further studies, since many methylated nucleosides are present in nucleic acids from various sources.

We have studied the methylation of pyrimidine deoxynucleosides such as thymidine (**1**), deoxyuridine (**2**), and deoxycytidine (**3**) with TMP in homogeneous aqueous phase of pH 7—12 at 37 and 60 °C.

The characterization of the products from these reactions is given in the following. The effect of pH of reaction mixtures on methylation rate is also discussed.

Results and Discussion

The reactions were carried out at 37 and 60 °C by stirring a mixture of a deoxynucleoside and TMP in water at an appropriate pH. The products were isolated by extraction and column chromatography and identified by means of UV and NMR spectra. Melting point and R_f value were also employed for the identification of products. The yields of the products were determined by means of UV spectra. The results are summarized in Tables 1 and 2.

*Thymidine (**1**) and Deoxyuridine (**2**).* Most methylation studies on thymidine (**1**) so far reported were conducted using diazomethane in water–ether[3] or methanol–ether[2,5] solution. The results indicate that diazomethane methylated **1** at the N-3 position chiefly to afford 3-methylthymidine (**4**) with co-formation of a small amount of O^4-methylthymidine. Treatment of DNA with *N*-methyl-*N*-nitrosourea, a possible source of diazomethane *in vivo*, has been reported to afford 3-

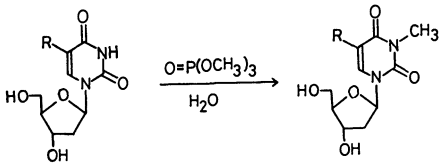
a) Reaction size: deoxycytidine (0.25 mmol) + TMP (3.8 mmol, 7.5 mmol, or 14.3 mmol) + H_2O (5.0 ml) at 37 or 60 °C. b) Spectroscopic yield.

methyl- and O^4-methylthymidines in addition to several methylated purine nucleosides.[11] On the other hand, little is known about the alkylation of deoxyuridine (**2**) which is present merely as the precursor of **1** in living systems.

The present reactions of **1** with TMP in an aqueous phase gave the results as shown in Table 1. Methylation occurs at the N-3 position of **1** to afford 3-methylthymidine (**4**) as the sole product at pH 7—11. However, when the pH is raised to 12, thin-layer chromatography of the reaction mixture shows two spots. One product (low R_f) was isolated and identified as **4**, the other product being assigned as 3,$O^{5'}$-dimethylthymidine by comparison of its UV spectrum and R_f value with those of an authentic sample.



1: R = CH_3
2: R = H

4: R = CH_3
5: R = H

The methylation rate of **1**, particularly the formation of **4**, was found to be dependent on the pH of reaction medium. In the pH region 7—11 at 37 °C, the higher the pH, the faster the methylation rate. For instance, **4** was produced quantitatively in the reaction at pH 11, while the reaction hardly proceeded at pH 7. However, when the pH of reaction mixture was raised from 11 to 12, no noticeable increase in methylation rate was observed at the N-3 position of **1**. The results suggest that methylation of **1** occurs most likely in a bimolecular fashion between the anionic form of **1** and TMP, since the dissociation of the N-3 proton of **1** (pK_a:9.8)[12] gradually increases in the pH range 7—11. At pH 11, the N-3 proton dissociates nearly completely, the methylation rate at the N-3 position under present conditions becoming maximum. The pH change from 11 to 12 might not affect the methylation rate at the N-3 position of **1**.

The formation of a small amount of 3,$O^{5'}$-dimethylthymidine in the reaction at pH 12 may also be attributed to the dissociation of 5'-OH group ($pK_a > 13$) to the oxido anion and its subsequent reaction with TMP.

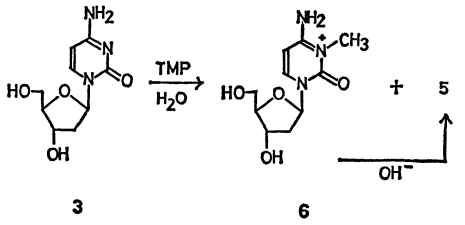
The rise in reaction temperature and increase in the mole ratio of TMP to **1** also accelerated the methylation rate (Table 1).

Methylation of deoxyuridine (**2**) with TMP gave almost the same result as that of methylation of **1**, **2** being methylated at the N-3 position to give 3-methyldeoxyuridine (**5**), whose yields increased gradually with the rise of pH of the reaction mixture. However, the reaction of TMP with a mixture of **1** and **2** at pH 10 showed that **2** is methylated at the N-3 position faster than **1**, probably because the pK_a value of the former is smaller, *e.g.* 9.2 and 9.8, respectively.[12]

*Deoxycytidine (**3**).* Several reports have appeared on the alkylation of cytidine and deoxycytidine (**3**).[3-7] Treatment of cytidine with diazomethane in water–ether[3] and dimethyl sulfate in DMF[4] caused methylation at the N-3 position of cytosine ring. However, **3** remains unchanged in the reaction with diazomethane in methanol–ether solution.[5] Sun and Singer studied methylation and ethylation of cytidine and **3** in detail using alkyl iodide, ethyl methanesulfonate, and diethyl sulfate, and observed the formation of 3-alkyl derivatives along with a small extent of alkylation at exocyclic 4-amino group of cytosine ring.[6]

In the present reactions, methylation took place smoothly at the N-3 position to afford 3-methyldeoxycytidine (**6**) at pH 7, while the reaction at pH 10 gave a mixture of **6** and 3-methyldeoxyuridine (**5**) (Table 2).

The production of **5** under alkaline conditions can be attributed to alkaline hydrolysis of **6**, since the analogous compound, 1,3-dimethylcytosine was trans-



formed into 1,3-dimethyluracil and the conversion of **3** into **2** was not observed under similar conditions. Since the deprotonation of the pyrimidine ring of **3**, established to exist in the amino form,[13] does not take place under the present conditions, the formation of **6** would occur most likely by the attack of TMP on the neutral N-3 position of the amino form of **3**.

The methylation rate at the N-3 position showed a slight dependence on the pH of reaction medium, which is, however, opposite to that observed in the methylation of **1**. That is, the methylation rate decreased with the increase of pH. Especially, at pH 12, methylation hardly occurred at the N-3 position of **3**, while deoxyribose moiety was methylated in a small amount. A similar trend of **3** or cytidine to resist methylation at the N-3 position under alkaline conditions has recently been reported by Kuśmierek *et al.*[7]

The above reactions thus reveal that **1** and **2** more easily undergo methylation than **3** under alkaline conditions, whereas **3** is methylated smoothly under neutral conditions. This remarkable dependence of the reactivity of **1**, **2**, and **3** on the pH of reaction mixture is useful in view of synthesis, allowing selective methylation of these deoxynucleosides (**1**, **2**, and **3**) by tretament with TMP at a suitable pH. Smooth methylation of **3** at the N-3 position at pH 7 is noteworthy from a biological point of view, since alkylation at the N-3 position of cytosine residues in nucleic acids is believed to be one of the most harmful reactions to result in mutagenicity or carcinogenicity on mice,[14] phage T4V[15] *etc.* Apparently, a Watson-Crick type of base pairing between cytosine bases and guanine bases is no longer possible by methylation of the former at the N-3 position.

Experimental

Melting points are uncorrected. UV spectra were measured with a Hitachi 3T spectrometer. NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 with a dilute solution in deuterioxide and tetramethylsilane as an outside standard or 3-(trimethylsilyl)propionic acid-d_4 sodium salt as an internal standard. Thin-layer chromatography was performed on silica gel [GF_{254} (type 60), Merck] or aluminum oxide [PF_{254} (type 150), Merck] using a mixture of chloroform and methanol. Column chromatography was carried out using silica gel (Merck, Art. 7734, 70—230 mesh) or aluminum oxide (Merck, Art. 1097).

Commercial thymidine (**1**), deoxyuridine (**2**), and deoxycytidine (**3**) as well as TMP were used without further purification.

Spectroscopic Determination of Yields. A mixture of deoxynucleoside (0.25 mmol) and TMP (1.9 mmol, 3.8 mmol, 7.5 mmol, or 14.3 mmol) in water (5.0 ml) was stirred at 37 or 60 °C at an appropriate pH maintained throughout the reaction by occasional addition of 2 M sodium hydroxide, with an error of about ±pH 0.3. At an appropriate reaction time, 4 μl of reaction mixture was spotted on a thin-layer chromatography plate, which was developed immediately with chloroform–methanol (5 : 1 for the reaction of **1** and **2**, and 5 : 2 for that of **3**).

The reaction mixture of **1** with TMP at pH 7—11 showed two spots (**1** and **4**) on TLC (R_f; **1** : 0.07, **4** : 0.23), and a new spot (R_f; 0.38) at pH 12. This was found to be 3,$O^{5'}$-dimethylthymidine by comparison of UV spectrum and R_f value of authentic sample; UV λ_{max} (H_2O) nm : pH 1, 266.0, pH 7, 267.0, pH 13, 267.0. In the reaction of **2** with TMP at pH 7—11, two spots corresponding to **2** and **5** were observed (R_f; **2** : 0.25, **5** : 0.46). Thin-layer chromatography of the reaction mixture of **3** with TMP at 37 °C showed two spots (**3** and **6**) at pH 7 and three spots (**3**, **6**, and **5**) at pH 10 (R_f; **3** : 0.22, **6** : 0.10, **5** : 0.79).

After each spot on TLC was scraped separately from the plate, the substance on the spot was extracted with 3 ml of water. From the absorbance of the solution, the yield of each product was calculated by means of a procedure similar to that described in a previous paper.[8]

Isolation of Products. *3-Methylthymidine (**4**)*: A mixture of **1** (1.20 g, 5.0 mmol) and TMP (10.5 g, 75.0 mmol) in water (15 ml) was stirred at 60 °C and pH 10. After 12 h, the spot of **1** disappeared on thin-layer chromatography of the reaction mixture. The reaction mixture was then neutralized with concentrated hydrochloric acid. After water had been removed from the reaction mixture, the residue was purified by silica gel column chromatography (2.5×35 cm). Elution with chloroform afforded unchanged TMP, **4** being obtained by subsequent elution with chloroform–methanol (7 : 1). Evaporation of the solvent afforded **4** as viscous liquid which crystallized on the addition of diethyl ether (1.13 g, 89.0%); mp 132—133.5 °C (from water) (when recrystallized compound was dried imperfectly, it melted at 84—86 °C) (lit,[16] 132.5—134.0 °C), NMR (D_2O) δ= 1.88 (3H, d, J=1.2 Hz, 5-C**H**$_3$), 2.33 (2H, complex m, 2′-C**H**$_2$), 3.28 (3H, s, N^3-C**H**$_3$), 3.81 (2H, complex m, 5′-C**H**$_2$), 4.03 (1H, complex m, 4′-C**H**), 4.45 (1H, complex m, 3′-C**H**), 6.31 (1H, t, J=7 Hz, 1′-C**H**), and 7.69 (1H, d, J=1.2 Hz, **H**^{6}); UV λ_{max} (H_2O) nm : pH 1, 265.5, pH 7, 266.0, pH 13, 266.0 (lit,[5] pH 1, 265.0, pH 7, 266.0, pH 13, 267.0).

*3-Methyldeoxyuridine (**5**)*: Compound **3** hydrochloride (0.52 g, 2.0 mmol) and TMP (4.2 g, 30.0 mmol) were stirred in water (20 ml, pH 10, NaOH) at 60 °C for 48 h. The reaction mixture was then neutralized with concentrated hydrochloric acid and extracted with chloroform to remove unchanged TMP. The water layer was concentrated to give a residue, which was then purified by silica gel column chromatography (2×33 cm). Elution with chloroform–methanol (7 : 1) provided **5** (120 mg, 25%); mp 109—110 °C (from ethyl acetate–hexane) (lit,[17] 98—100 °C), NMR (D_2O) δ=2.41 (2H, complex m, 2′-C**H**$_2$), 3.32 (3H, s, -C**H**$_3$), 3.85 (2H, complex m, 5′-C**H**$_2$), 4.10 (1H, complex m, 4′-C**H**), 4.45 (1H, complex m, 3′-C**H**), 6.03 (1H, d, J=8Hz, **H**^{5}), 6.39 (1H, t, J=7 Hz, 1′-C**H**), and 7.97 (1H, d, J=8 Hz, **H**^{6}); UV λ_{max} (H_2O) nm : pH 1, 262.5 (log ε 4.12), pH 7, 262.5 (log ε 4.12), pH 13, 263.0 (log ε 4.13).

*3-Methyldeoxycytidine (**6**)*: A mixture of deoxycytidine hydrochloride (1.30 g, 5.0 mmol) and TMP (18.8 g, 134 mmol) in water (50 ml, pH 7) was stirred for 100 h. Alumina thin-layer chromatography of the reaction mixture developed with methanol showed a faint spot of **3** (R_f : 0.12) and a distinct spot of **6** (R_f : 0.72). The reaction mixture was extracted with chloroform in order to remove unchanged

TMP. The water layer was concentrated to give a residue, which was then purified by alumina column chromatography (2.5×40 cm). Elution with methanol afforded the salt of 3-methyldeoxycytidine with dimethyl hydrogen phosphate. Since the phosphate salt was hygroscopic, it was converted into the hydrochloride salt according to the procedure of Furukawa *et al.*[18] (0.78 g, 57%); mp 250 °C (dec); NMR (D_2O) δ=2.55 (2H, complex m, 2′-C**H**$_2$), 3.67 (3H, s, -C**H**$_3$), 3.95 (2H, complex m, 5′-C**H**$_2$), 4.22 (1H, complex m, 4′-C**H**), 4.60 (1H, complex m, 3′-C**H**), 6.30 (1H, d, J=8Hz, **H**^{5}), 6.49 (1H, t, J=7 Hz, 1′-C**H**), and 8.26 (1H, d, J=8 Hz, **H**^{6}); UV λ_{max} (H_2O) nm: pH 1, 279.0, pH 7, 279.0, pH 13, 269.0. The free form of **6** was obtained by subsequent treatment of the hydrochloride salt with anionic exchange resin (Dowex 1×2, 100—200 mesh, OH form); mp 169—171 °C; Found: C, 49.94; H, 6.24; N, 17.29%. Calcd for $C_{10}H_{15}N_3O_4$: C, 49.78; H, 6.27; N, 17.42%.

A New Synthetic Method for Some Pyrazolo[4,3-*d*]pyrimidines[1]

Hisashi TAKEI,* Nobuyoshi YASUDA, and Hidetsugu TAKAGAKI

Departmentt of Life Chemistry, Tokyo Institute of Technology, Nagatsutacho, Midori-ku, Yokohama 227

(Received July 20, 1978)

3,7-Dihydroxy- and 3-substituted 7-hydroxypyrazolo[4,3-*d*]pyrimidines were synthesized from diethyl oxaloacetate and ethyl acylpyruvates *via* ethyl 4-amino-5-oxo-2-pyrazoline-3-carboxylate hydrochloride and ethyl 5-substituted 4-amino-3-pyrazolecarboxylates, respectively.

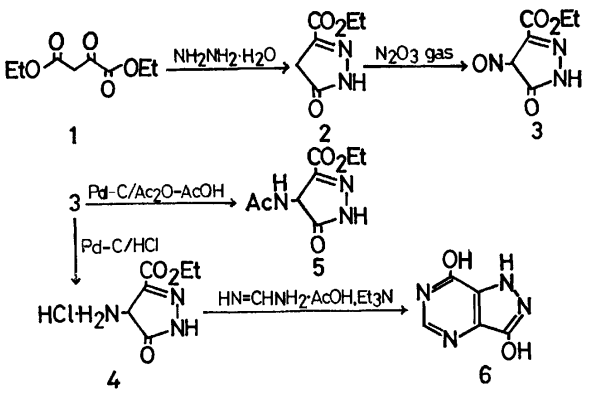
Purine antagonists have been shown to be chemotherapeutic agents against various tumors.[2] Some of pyrazolo[4,3-*d*]pyrimidine derivatives, which are purine analogue, have been also found to have this antagonism.[3] It thus seemed desirable to investigate the synthesis of the pyrazolo[4,3-*d*]pyrimidine ring system.

Recently, some carbon linked nucleoside antibiotics have been found in nature. Among these, formycin and formycin B[4] were characterized as 7-amino- and 7-hydroxy-3-β-D-ribofuranosylpyrazolo[4,3-*d*]pyrimidine, respectively. The structural characterization of the antibiotics has also regenerated a great interest in the synthesis of the pyrazolo[4,3-*d*]pyrimidine ring system.

The first reported sytnthesis of the ring system was that of Behrend,[5] who utilized 5-amino-6-methyluracil for the preparation of 5,7-dihydroxypyrazolo-[4,3-*d*]pyrimidine. Rose[6] has accomplished the synthesis of the ring system by diazotization of 4-alkyl-5-amino-6-methylpyrimidine followed by an intramolecular coupling. This method is quite satisfactory but definitely restricted to the substituent at position 7 of pyrazolo[4,3-*d*]pyrimidine, since 5-amino-6-methylpyrimidine substituted at position 4 with a hydroxyl, mercapto, or amino group upon diazotization couples to give the oxadiazole, thiadiazole, or triazole ring. Robins and his coworkers[7] synthesized the ring system from 4-nitro-3-pyrazolecarboxylic acid, and Townsend and his coworkers[8] have also synthesized 5,7-disubstituted 3-methylpyrazolo[4,3-*d*]pyrimidines from ethyl 5-methyl-4-nitro-3-pyrazolecarboxylate. But these nitropyrazole methods do not seem to be applicable for the synthesis of sugar derivatives, because nitration was performed in fuming sulfuric acid. The investigation of the synthesis of oxoformycin has appeared in the literature.[9] Formycin B was totally synthesized by Acton and his coworkers[10] in 1971 from 2,3,5-tri-*O*-benzyl-β-D-ribofuranosyldiazomethane as a key intermediate. Arabinosyl analogue was also synthesized by a similar method.[11]

In this paper, we describe a convenient synthesis of 3,7-dihydroxy- and 3-substituted 7-hydroxypyrazolo-[4,3-*d*]pyrimidines starting from diethyl oxaloacetate and ethyl acylpyruvates, respectively, under mild conditions in high yields.

Treatment of diethyl oxaloacetate (**1**) with hydrazine hydrate (1 equiv) in ethanol at room temperature gave ethyl 5-oxo-2-pyrazoline-3-carboxylate (**2**) in 88% yield. Introduction of N_2O_3 gas into an ethanol solution of **2** resulted in the formation of ethyl 4-nitroso-5-oxo-2-pyrazoline-3-carboxylate (**3**) in 95% yield. Catalytic hydrogenation of this nitroso compound **3** over 20% Pd–C in ethanol in the presence of hydrochloric acid at room temperature afforded ethyl 4-amino-5-oxo-2-pyrazoline-3-carboxylate hydrochloride (**4**) in 88% yield. When **3** was hydrogenated in acetic acid in the presence of acetic anhydride at room temperature, ethyl 4-acetamido-5-oxo-2-pyrazoline-3-carboxylate (**5**) was obtained in 75% yield. Treatment of the hydrochloride **4** with formamidine acetate (3 equiv) and triethylamine (5 equiv) in boiling 2-ethoxyethanol gave 3,7-dihydroxypyrazolo[4,3-*d*]pyrimidine (**6**) in 92% yield. The structure was confirmed by spectral data and elemental analysis.

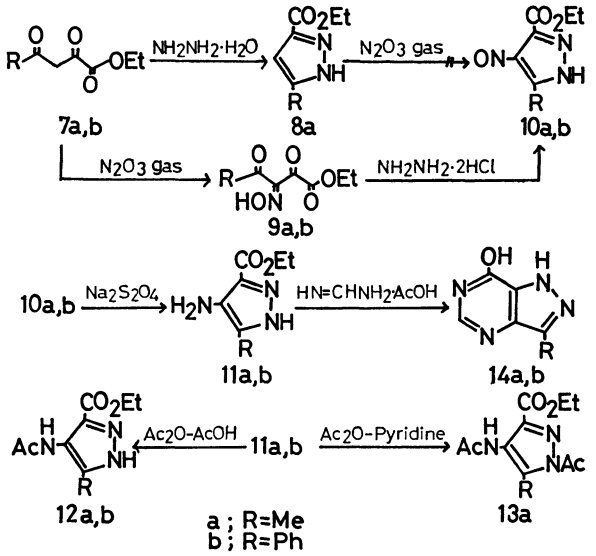


Scheme 1.

Ethyl 5-methyl-3-pyrazolecarboxylate (**8a**)[12] could not be nitrosated at position 4 of the pyrazole ring by the introduction of N_2O_3 gas. Therefore it was decided to introduce the nitroso group prior to the ring closure. Ethyl acetopyruvate (**7a**) was nitrosated to the corresponding hydroxyimino derivative (**9a**) with N_2O_3 gas in ethanol at room temperature. The reaction of this hydroxyimino derivative **9a** with hydrazine dihydrochloride (1 equiv) in water at 0 °C gave blue crystalline ethyl 5-methyl-4-nitroso-3-pyrazolecarboxylate (**10a**). By treatment with excess sodium dithionite in ethyl acetate and water at room temperature, this nitroso compound **10a** was readily reduced to ethyl 4-amino-5-methyl-3-pyrazolecarboxylate (**11a**) in 47% yield, based on ethyl acetopyruvate **7a**. Acetylation of this amino compound **11a** with acetic anhydride in pyridine gave ethyl 4-acetamido-1-acetyl-5-methyl-3-pyrazolecarboxylate (**13a**) in a quantitative yield. On the other hand, when acetylation was carried out in acetic acid, ethyl 4-acetamido-5-methyl-3-pyrazolecarboxylate (**12a**) was obtained in a quantitative yield. The reaction of the amino compound **11a** with formamidine acetate (3 equiv) in boiling 2-

ethoxyethanol afforded a quantitative yield of 7-hydroxy-3-methylpyrazolo[4,3-*d*]pyrimidine (**14a**).

Similarly, 7-hydroxy-3-phenylpyrazolo[4,3-*d*]pyrimidine (**14b**) was obtained as follows. Ethyl benzopyruvate (**7b**) was nitrosated to its hydroxyimino derivative (**9b**). This hydroxyimino derivative **9b** was converted to greenish blue crystalline ethyl 4-nitroso-5-phenyl-3-pyrazolecarboxylate (**10b**) by the reaction with hydrazine dihydrochloride (1 equiv). Reduction of the nitroso compound **10b** by excess sodium dithionite gave ethyl 4-amino-5-phenyl-3-pyrazolecarboxylate (**11b**) in 46% yield, based on ethyl benzopyruvate **7b**. Acetylation of **11b** with acetic anhydride in pyridine gave a complex result. When acetylation was carried out in acetic acid, however, ethyl 4-acetamido-5-phenyl-3-pyrazolecarboxylate (**12b**) was obtained in a quantitative yield. The reaction of the amino compound **11b** with formamidine acetate (3 equiv) in boiling 2-ethoxyethanol gave 7-hydroxy-3-phenylpyrazolo[4,3-*d*]pyrimidine (**14b**) in a quantitative yield. The structure was confirmed by spectral data and elemental analysis.



Scheme 2.

a) These compounds were unstable.

UV absorption data and elemental analyses of these pyrazoles and pyrazolo[4,3-*d*]pyrimidines are listed in Tables 1 and 2.

Experimental

All the melting points are uncorrected.

*Ethyl 5-Oxo-2-pyrazoline-3-carboxylate (**2**).* To a solution of diethyl oxaloacetate (**1**) (19.8 g, 0.1 mol) in 50 ml of ethanol, 80% hydrazine hydrate (6.25 g, 0.1 mol) in 50 ml of ethanol was added dropwise at room temperature. After the solution was stirred for 2 h, the solvent was removed under diminished pressure. The residual solid was recrystallized from ethyl acetate to yield 13.7 g (88%) of **2**. An analytical sample was obtained by an additional recrystallization from ethyl acetate, mp 183—184 °C.

*Ethyl 4-Nitroso-5-oxo-2-pyrazoline-3-carboxylate (**3**).* Into a solution of **2** (15.6 g, 0.1 mol) in 100 ml of ethanol, N_2O_3 gas generated by dropping concd hydrochloric acid to sodium nitrite was introduced at room temperature until the disappearance of **2** was confirmed by TLC. Then the solvent was removed under diminished pressure, and the residual yellow crystals of **3** were recrystallized from ethyl acetate, yield 17.6 g (95%). An analytical sample was obtained by two additional recrystallizations from ethyl acetate, mp 170—172 °C (dec).

*Ethyl 4-Amino-5-oxo-2-pyrazoline-3-carboxylate Hydrochloride (**4**).* The nitroso compound **3** (1.85 g, 0.01 mol) was dissolved in 50 ml of ethanol containing 2 ml of concd hydrochloric acid. A small amount of 20% Pd–C was added and stirred under hydrogen atmosphere. After 450 ml of hydrogen was absorbed, the solution was filtered and evaporated *in vacuo*. The residue was dissoved in a small amount of ethanol and 1.83 g (88%) of **4** was precipitated by the addition of ether. An analytical sample was obtained by an additional reprecipitation from ethanol and ether, mp 160 °C (dec).

*Ethyl 4-Acetamido-5-oxo-2-pyrazoline-3-carboxylate (**5**).* The nitroso compound **3** (3.70 g, 0.02 mol) was dissolved in 150 ml of acetic acid and 6 ml of acetic anhydride. A small amount of 20% Pd–C was added and stirred under hydrogen atmosphere. After 900 ml of hydrogen was absorbed, the solution was filtered and evaporated *in vacuo*. When ether was added to the residue, white crystals of **5** were precipitated, 3.20 g (75%). An analytical sample was obtained by recrystallization from water, mp 189.5—190 °C.

*3,7-Dihydroxypyrazolo[4,3-d]pyrimidine (**6**).* A mixture of **4** (519 mg, 2.5 mmol), formamidine acetate (780 mg, 7.5 mmol), and triethylamine (1.26 g, 12.5 mmol) in 10 ml of 2-ethoxyethanol was refluxed for 1 h under argon atmosphere. Crystals were precipitated when the solution was allowed to stand at room temperature. The precipitate was filtered and recrystallized from water to yield 350 mg (92%) of **6**. An analytical sample was obtained by an additional recrystallization from water, mp>300 °C.

*Ethyl α-(Hydroxyimino)acetopyruvate (**9a**) and Ethyl α-(Hydroxyimino)benzopyruvate (**9b**).* Into a solution of **7a** (15.8 g, 0.1 mol) in 100 ml of ethanol, N_2O_3 gas was introduced at room temperature until the disappearance of **7a** was confirmed by TLC. Then the solvent was removed under diminished pressure and water was added. The aqueous solution was extracted three times with ether and the combined organic layer was dried over anhydrous sodium sulfate. Evaporation of ether *in vacuo* gave a yellow oil of almost pure **9a**. The oily **9a** was used for the next step without further purification. The benzoyl derivative **9b** was obtained as an oil from ethyl benzopyruvate **7b** in a similar manner.

*Ethyl 5-Methyl-4-nitroso-3-pyrazolecarboxylate (**10a**).* To a solution of **9a** obtained from **7a** (3.16 g, 0.02 mol) in 50 ml of water, hydrazine dihydrochloride (2.08 g, 0.02 mol) in 50 ml of water was added dropwise and stirred at 0 °C until the disappearance of **9a** was confirmed by TLC. Then the solution was extracted with ether and the organic layer was dried over anhydrous sodium sulfate. When the solvent was removed under diminished pressure below 40 °C, blue crystals of **10a** were obtained. An analytical sample was obtained by using silica-gel column chromatography eluted with benzene–ethyl acetate (9 : 1), mp 95—98 °C (dec).

*Ethyl 4-Nitroso-5-phenyl-3-pyrazolecarboxylate (**10b**).* Greenish blue crystals of **10b** were obtained from **9b** in a manner similar to that described for **10a** when the removal of the solvent was carried out under an ice-cooled bath. An analytical sample was obtained by using silica-gel column chromatography eluted with benzene–ethyl acetate (5 : 1), mp 26 °C (dec).

*Ethyl 4-Amino-5-methyl-3-pyrazolecarboxylate (**11a**).* To a mixture of **10a** obtained from **7a** (3.16 g, 0.02 mol) in

50 ml of ethyl acetate and 50 ml of water, sodium dithionite was added to the mixture until the disappearance of **10a** was confirmed by TLC. Then the organic layer was separated and the aqueous layer was extracted with ethyl acetate. The combined organic layer was dried over anhydrous sodium sulfate and the solvent was removed under diminished pressure. The crude product was recrystallized from benzene to yield 1.60 g (47% from **7a**) of **11a**. An analytical sample was obtained by an additional recrystallization from benzene, mp 96—96.5 °C.

*Ethyl 4-Amino-5-phenyl-3-pyrazolecarboxylate (**11b**).* In a manner similar to that described for **11a**, **11b** was obtained from **7b** (2.20 g, 0.01 mol) and recrystallized from benzene to yield 1.06 g (46% from **7b**). An analytical sample was obtained by an additional recrystallization from benzene, mp 145—146 °C.

*Ethyl 4-Acetamido-5-methyl-3-pyrazolecarboxylate (**12a**).* A solution of **11a** (85 mg, 0.5 mmol) in acetic acid (5 ml) and acetic anhydride (26 mg, 2.5 mmol) was stirred at room temperature for 30 min. The solution was neutralized with aqueous sodium hydrogencarbonate solution and extracted with ethyl acetate. The organic layer was dried over anhydrous sodium sulfate and evaporated *in vacuo* to yield 106 mg (quantitative) of **12a**. An analytical sample was obtained by recrystallization from ethyl acetate, mp 176—177 °C.

*Ethyl 4-Acetamido-5-phenyl-3-pyrazolecarboxylate (**12b**).* In a similar manner, **12b** was obtained in a quantitative yield (137 mg) from **11b** (116 mg, 0.5 mmol). An analytical sample was obtained by recrystallization from ethyl acetate, mp 182.5—183 °C.

*Ethyl 4-Acetamido-1-acetyl-5-methyl-3-pyrazolecarboxylate (**13a**).* A solution of **11a** (169 mg, 1 mmol) in pyridine (5 ml) and acetic anhydride (510 mg, 5 mmol) was stirred at room temperature for 2 days and then the solvent was removed under diminished pressure. The crude product was recrystallized from benzene–hexane to yield 253 mg (quantitative) of **13a**, mp 152—153 °C.

*7-Hydroxy-3-methylpyrazolo[4,3-d]pyrimidine (**14a**).* A mixture of **11a** (338 mg, 2 mmol) and formamidine acetate (624 mg, 6 mmol) in 10 ml of 2-ethoxyethanol was refluxed for 1 h under argon atmosphere. Then the solvnet was removed under diminished pressure and the residue was recrystallized from water to yield 300 mg (quantitative) of **14a**. An analytical sample was obtained by an additional recrystallization from water, mp>300 °C (lit,[7] >300 °C).

*7-Hydroxy-3-phenylpyrazolo[4,3-d]pyrimidine (**14b**).* Crude **14b** was obtained from **11b** (231 mg, 1 mmol) in a similar manner. Recrystallization of crude **14b** from *N,N*-dimethylformamide gave 211 mg (quantitative) of **14b**. An analytical sample was obtained by an additional recrystallization from *N,N*-dimethylformamide, mp>300 °C.

This research was supported in part by a Kurata Research Grant.

A Simple Total Synthesis of (+)-Ferruginol, (+)-Sempervirol, and (+)-Podocarpa-8(14)-en-13-one

Takashi MATSUMOTO* and Shuji USUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received July 20, 1978)

The Wittig reaction of (*R*)-(−)-α-cyclocitral with (3-isopropyl-4-methoxybenzyl)-, (4-isopropyl-3-methoxybenzyl)-, and (3-methoxybenzyl)triphenylphosphonium chloride afforded the styryl derivatives which were partially hydrogenated to the corresponding dihydro derivatives (**18**, **26**, and **27**). Intramolecular cyclization of **18** and **26** with anhydrous aluminium chloride followed by demethylation with boron tribromide gave (+)-ferruginol and (+)-sempervirol. The similar cyclization of **27** gave (+)-13-methoxypodocarpa-8, 11, 13-triene. This was reduced with lithium in liquid ammonia in the presence of ethanol and then treated with dilute hydrochloric acid to give (+)-podocarpa-8(14)-en-13-one, a versatile intermediate for natural diterpene synthesis.

In previous papers,[1-3] we have reported the syntheses of highly-oxygenated tricyclic diterpenes, *i.e.* taxodione (**1**), royleanone (**2**), 7-oxoroyleanone (**3**), taxoquinone (**4**), horminone (**5**), 7α-acetoxyroyleanone (**6**), dehydroroyleanone (**7**), cryptojaponol (**8**), and inuroyleanol (**9**), using ferruginol (**10**) as an useful key intermediate. We also reported the synthesis of sempervirol (**11**), which is a rare tricyclic diterpene phenol possessing an isopropyl group at the C-12 position. All these syntheses started from natural (−)-abietic acid (**12**). To complete these previous works, we planned to devise a more efficient and general synthetic method for the optically active tricyclic diterpenes to achieve the total syntheses of the above natural products. This paper will describe the simple total syntheses of (+)-ferruginol (**10**), (+)-sempervirol (**11**), and (+)-13-methoxypodocarpa-8,11,13-triene (**13**),[4] which was easily converted into (+)-podocarpa-8(14)-en-13-one (**14**),[5-9] a versatile intermediate for naturally-occurring diterpenes.

(*R*)-(−)-α-Cyclocitral (**15**)[10] prepared from (±)-α-cyclogeranic acid was chosen as a starting material. The Wittig reaction of **15** with (3-isopropyl-4-methoxybenzyl)triphenylphosphonium chloride (**16**) in hexane in the presence of butyllithium gave 3-(3-isopropyl-4-ethoxystyryl)-2,4,4-trimethyl-1-cyclohexene (**17**). The stereochemistry of the newly formed double bond in **17** was assigned as the *trans*-configuration because of the vicinal coupling constant (J=15 Hz) between the olefinic protons in the NMR spectrum. The compound **17** in ethanol was submitted to partial catalytic hydrogenation over Pd–C at room temperature to give the corresponding phenethyl derivative (**18**). This was treated with anhydrous aluminium chloride in benzene and gave a mixture of two intramolecular cyclization products. The chromatographic purification of the mixture afforded ferruginyl methyl ether (**19**) and its *cis*-isomer (**20**) in a ratio of 1:1. The *cis*-configuration of the A/B ring junction in **20** was supported by its NMR spectrum, which showed a signal due to the $C_{4\beta}$ methyl group in the high field, δ 0.40 ppm, because of the shielding effect of the aromatic ring. The demethylation of **19** with boron tribromide in dichloromethane gave ferruginol (**10**). However, since the optical rotation ([α]$_D$+33.2°) was somewhat lower than that of the natural product,[2] this was further purified *via* the benzoate (**21**) to give the optically pure compound (**10**), [α]$_D$+55.0°.

ride (**22**) and (3-methoxybenzyl)triphenylphosphonium chloride (**23**) in the presence of butyllithium to afford the styryl derivatives (**24** and **25**), which were then hydrogenated in the presence of Pd–C to yield the corresponding phenethyl derivatives, **26** and **27**, respectively. The intramolecular cyclization of **26** with anhydrous aluminium chloride gave semperviryl methyl ether (**28**) and its *cis*-isomer (**29**).[3] The *trans*-compound (**28**) was demethylated with boron tribromide to give sempervirol (**11**), $[\alpha]_D$+38.0°. The purification of **11** *via* the acetate (**30**) gave the optically pure sample (**11**), $[\alpha]_D$+60.2°. The compound **27** was also cyclized with anhydrous aluminium chloride to give 13-methoxypodocarpa-8,11,13-triene (**13**),[4] which was purified by crystallization along with its *cis*-isomer (**31**). The conversion of racemic **13** into racemic podocarpa-8(14)-en-13-one (**14**) has already been reported by Barltrop and Rogers[11] and Church *et al.*[12] The synthetic optically-active **13** was similarly reduced with lithium in liquid ammonia in the presence of ethanol and then treated with dilute hydrochloric acid to give the α,β-unsaturated ketone (**14**), mp 61.5—62.5 °C, $[\alpha]_D$+40.4°, a degradation product of natural diterpenes, *e.g.* isophyllocladene (**32**)[5] and manool (**33**).[5,6,9] The optically-active ketone (**14**) has already been transformed into isophyllocladene (**32**),[13] manool (**33**),[7] phyllocladene (**34**),[13] hibaone (**35**),[14] sclareol (**36**),[7] manoyl oxide (**37**),[7] anticopalic acid (**38**),[15,16] *trans*-abienol (**39**),[17] and isoabienol (**40**).[17] Therefore, the present work can be regarded as the total syntheses of the above natural diterpenes.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as the internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. Column chromatography was performed using Merck silica gel (0.063 mm).

*(R)-(−)-α-Cyclocitral (**15**).*[10] (−)-α-Cyclogeraniol[10,18] (4.11 g, $[\alpha]_D$ −117° (EtOH)) prepared from (±)-α-cyclo geranic acid, and dicyclohexylcarbodiimide[19] (16.5 g) were dissolved in dimethyl sulfoxide (15 ml) and benzene (15 ml). Anhydrous phosphoric acid[20] (7 ml, 1 M solution in dimethyl sulfoxide) was added at 5 °C, and the mixture was stirred at this temperature for 4 h. Dry ether (50 ml) was added, followed by a solution of oxalic acid (6.72 g) in methanol (7 ml). After 30 min, the *N,N'*-dicyclohexylurea was removed by filtration and washed with ether. The filtrate was washed with water, dried over sodium sulfate, and then evaporated. The crude product was purified by column chromatography on silica gel using hexane–benzene (1:4) as the eluent to yield **15** (2.90 g: 72%), $[\alpha]_D$ −711° (EtOH), NMR: 0.89 and 0.97 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.60 (3H, d, J=1.5 Hz, $=\dot{C}CH_3$), 5.69 (1H, bs, $-CH=\dot{C}-$), 9.34 (1H, d, J=5 Hz, −CHO).

*(3-Isopropyl-4-methoxybenzyl)triphenylphosphonium Chloride (**16**).* A solution of 3-isopropyl-4-methoxybenzyl chloride[21] (5.71 g) and triphenylphosphine (7.54 g) in dry benzene (10 ml) was refluxed for 5 h and the precipitate (**16**) (7.80 g, mp 253—259 °C) was collected. The filtrate was further refluxed for 3 h to give some additional salt (1.20 g, mp 251—254 °C).

*3-(3-Isopropyl-4-methoxystyryl)-2,4,4-trimethyl-1-cyclohexene (**17**).* A solution of butyllithium in hexane (15%; 2.9 ml) was added at room temperature to a suspension of **16** (2.660 g) in hexane (13 ml) under a stream of nitrogen. The mixture was stirred for 1 h and a solution of **15** (549 mg) in hexane (2.0 ml) was added at 5 °C. After stirring at 5—10 °C for 4 h, the mixture was acidified with dilute hydrochloric acid, extracted with ether, and the extract was washed with brine, dried over sodium sulfate, and then evaporated. The residue was triturated with hexane, and the precipitated triphenylphosphine oxide was removed by filtration. The filtrate was evaporated and the residue (1.208 g) was purified by column chromatography on silica gel (50 g) using hexane as the eluent to give **17** (852 mg: 79%) as an oil, $[\alpha]_D$ −273°, NMR: 0.90 and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.63 (3H, bs, $=\dot{C}CH_3$), 3.27 (1H, m, $-C\underline{H}(CH_3)_2$), 3.79 (3H, s, $-OCH_3$), 5.40 (1H, m, $-CH=\dot{C}-$), 5.76 (1H, dd, J=8 and 15 Hz, $-\dot{C}H-C\underline{H}=CH-$), 6.25 (1H, d, J=15 Hz, $-\dot{C}H-CH=C\underline{H}-$), 6.63 (1H, d, J=9 Hz), 7.04 (1H, d, J=2 Hz), and 7.04 (1H, dd, J=2 and 9 Hz) (aromatic protons). Found: C, 84.62; H, 10.10%. Calcd for $C_{21}H_{30}O$: C, 84.51; H, 10.13%.

*3-(3-Isopropyl-4-methoxyphenethyl)-2,4,4-trimethyl-1-cyclohexene (**18**).* A suspension of **17** (852 mg) and 5% Pd–C (300 mg) in ethanol (8.0 ml) was stirred at room temperature in an atmosphere of hydrogen. After one equivalent of hydrogen had been absorbed (*ca.* 80 min), the mixture was filtered. The filtrate was evaporated and the residue (828 mg) was purified by column chromatography on silica

gel (80 g) using hexane as the eluent to afford **18** (790 mg: 92%) as an oil, $[\alpha]_D$ −89.3°, NMR: 0.88 and 0.99 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.19 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.68 (3H, bs, $=\dot{C}CH_3$), 3.26 (1H, m, $-C\underline{H}(CH_3)_2$), 3.77 (3H, s, $-OCH_3$), 5.28 (1H, m, $-CH=\dot{C}-$), 6.59 (1H, d, J=9 Hz), 6.83 (1H, dd, J=2 and 9 Hz), and 6.88 (1H, d, J=2 Hz) (aromatic protons). Found: C, 83.66; H, 10.73%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

Intramolecular Cyclization of ***18***. Anhydrous aluminium chloride (370 mg) was added at 30 °C to a solution of **18** (814 mg) in dry benzene (8.0 ml). The mixture was stirred at 30—33 °C for 30 min, decomposed with dilute hydrochloric acid, and then extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The crude product was chromatographed on silica gel (80 g) using hexane as the eluent to give the *cis*-isomer (**20**) (363 mg: 45%) as an oil, $[\alpha]_D$ −28.0°, NMR: 0.40 (3H, s, $C_{4\beta}$–CH_3), 0.93 (3H, s, $C_{4\alpha}$–CH_3), 1.14 (3H, s, C_{10}–CH_3), 1.16 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.19 (1H, m, $-C\underline{H}(CH_3)_2$), 3.78 (3H, s, $-OCH_3$), 6.63 and 6.69 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 84.21; H, 10.85%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%. Further elution gave the *trans*-isomer (**19**) (352 mg: 43%) as an oil, $[\alpha]_D$ +35.9°, NMR: 0.95 (6H, s, $-\dot{C}(CH_3)_2$), 1.16 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.19 (3H, s, C_{10}–CH_3), 3.18 (1H, m, $-C\underline{H}(CH_3)_2$), 3.74 (3H, s, $-OCH_3$), 6.55 and 6.67 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 84.24; H, 10.96%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

*Ferruginyl Benzoate (****21****).* A solution of **19** (384 mg) and boron tribromide (0.30 ml) in dichloromethane (4.0 ml) was allowed to stand at 0—5 °C for 2 h. The solution was then poured into water and extracted with ether. The extract was washed with brine, dried, and then evaporated to dryness. The crude product was purified by column chromatography on silica gel (40 g) using hexane–benzene (1:1) as the eluent to give ferruginol (**10**) (349 mg: 95%), $[\alpha]_D$ +33.2°, as an oil. The IR and NMR spectra were identical with those of an authentic sample.[2]

The above ferruginol (349 mg) was benzoylated at 50—55 °C for 3 h with benzoyl chloride (0.3 ml) in pyridine (3.5 ml). After the usual work-up, the crude product was chromatographed on silica gel (40 g) using hexane–benzene (1:1) as the eluent to give ferruginyl benzoate (**21**) (409 mg) which was recrystallized from ethanol, mp 154.5—156 °C, $[\alpha]_D$ +60.1°, IR: 1728 cm^{-1}, NMR: 0.96 (6H, s, $-\dot{C}(CH_3)_2$), 1.18 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.21 (3H, s, C_{10}–CH_3), 6.86 and 6.89 (each 1H and s, C_{11}–H and C_{14}–H), 7.3—7.7 (3H, m) and 8.1—8.3 (2H, m) (aromatic protons). The IR and NMR spectra were identical with those of authentic benzoate which was prepared from natural ferruginol. Found: C, 83.32; H, 9.02%. Calcd for $C_{27}H_{34}O_2$: C, 83.03; H, 8.78%.

*Ferruginol (****10****).* A mixture of **21** (134 mg) and lithium aluminium hydride (15 mg) in dry ether (2.0 ml) was refluxed for 1 h. After the usual work-up, the product was purified by column chromatography on silica gel (10 g) using hexane–benzene (1:1) as the eluent to give ferruginol (**10**) (93 mg: 94%) as an oil, $[\alpha]_D$ +55.0° (lit,[2] $[\alpha]_D$ +57.5°); IR: 3605, 3350 cm^{-1}; NMR: 0.91 (6H, s, $-\dot{C}(CH_3)_2$), 1.10 (3H, s, C_{10}–CH_3), 1.19 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.09 (1H, m, $-C\underline{H}(CH_3)_2$), 4.73 (1H, bs, –OH), 6.41 and 6.68 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 84.13; H, 10.49%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

*(4-Isopropyl-3-methoxybenzyl)triphenylphosphonium Chloride (****22****).* A solution of 4-isopropyl-3-methoxybenzyl chloride[22] (3.34 g) and triphenylphosphine (4.41 g) in dry benzene (5 ml) was refluxed for 6 h. The precipitate was collected and recrystallized from chloroform–benzene to give crystals (6.40 g: 82%), mp 222—225 °C.

*3-(4-Isopropyl-3-methoxystyryl)-2,4,4-trimethyl-1-cyclohexene (****24****).* A suspension of **22** (4.460 g) in hexane (22 ml) was treated with a solution of butyllithium in hexane (15%; 4.8 ml) under a stream of nitrogen and then with a solution of **15** (921 mg) in hexane (2.0 ml), as described for the preparation of **17**. The crude product was chromatographed on silica gel (100 g) using hexane as the eluent to give **24** (956 mg: 53%), $[\alpha]_D$ −320°, NMR: 0.89 and 0.95 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.63 (3H, bs, $=\dot{C}CH_3$), 3.25 (1H, m, $-C\underline{H}(CH_3)_2$), 5.42 (1H, m, $-CH=\dot{C}-$), 5.83 (1H, dd, J=8 and 15 Hz, $-\dot{C}H-C\underline{H}=CH-$), 6.28 (1H, d, J=15 Hz, $-\dot{C}H-CH=C\underline{H}-$), 6.69 (1H, overlap), 6.75 (1H, dd, J=2 and 8 Hz), and 7.02 (1H, d, J=8 Hz) (aromatic protons). Found: C, 84.71; H, 10.10%. Calcd for $C_{21}H_{30}O$: C, 84.51; H, 10.13%.

*3-(4-Isopropyl-3-methoxyphenethyl)-2,4,4-trimethyl-1-cyclohexene (****26****).* A mixture of **24** (956 mg), 5% Pd–C (300 mg), and ethanol (10 ml) was subjected to catalytic hydrogenation at room temperature for *ca.* 60 min as described for the preparation of **18**. After the usual work-up, the crude product was purified by column chromatography on silica gel (90 g) using hexane as the eluent, to afford **26** (765 mg: 80%) as an oil, $[\alpha]_D$ −98.7°, NMR: 0.88 and 0.99 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.16 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.69 (3H, bs, $=\dot{C}CH_3$), 3.22 (1H, m, $-C\underline{H}(CH_3)_2$), 3.78 (3H, s, $-OCH_3$), 5.27 (1H, m, $-CH=\dot{C}-$), 6.50 (1H, overlap), 6.58 (1H, dd, J=2 and 8 Hz), and 6.97 (1H, d, J=8 Hz) (aromatic protons). Found: C, 84.22; H, 10.66%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

Intramolecular Cyclization of ***26***. A mixture of **26** (395 mg), anhydrous aluminium chloride (180 mg), and dry benzene (4.0 ml) was treated at 30 °C for 30 min. After the usual work-up, the crude product was chromatographed on silica gel (40 g) using hexane as the eluent, to give the *cis*-isomer (**29**) (188 mg: 48%), $[\alpha]_D$ −24.7°, NMR: 0.37 (3H, s, $C_{4\beta}$–CH_3), 0.92 (3H, s, $C_{4\alpha}$–CH_3), 1.11 (3H, s, C_{10}–CH_3), 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.22 (1H, m, $-C\underline{H}(CH_3)_2$), 3.74 (3H, s, $-OCH_3$), 6.32 and 6.96 (each 1H and s, C_{14}–H and C_{11}–H). Found: C, 83.67; H, 10.84%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

Further elution gave semperviryl methyl ether (**28**) (151 mg: 38%), $[\alpha]_D$ +35.0°, NMR: 0.95 (6H, s, $-\dot{C}(CH_3)_2$), 1.15 (3H, s, C_{10}–CH_3), 1.16 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.19 (1H, m, $-C\underline{H}(CH_3)_2$), 3.73 (3H, s, $-OCH_3$), 6.32 and 6.94 (each 1H and s, C_{14}–H and C_{11}–H). Found: C, 83.92; H, 10.79%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

*Semperviryl Acetate (****30****).* A solution of **28** (283 mg) and boron tribromide (0.20 ml) in dichloromethane (3.0 ml) was allowed to stand at 0 °C for 2 h. The crude product was purified by column chromatography on silica gel (30 g) to give sempervirol (**11**) (249 mg: 92%), $[\alpha]_D$ +38.0°, which was treated at 50 °C for 2 h with acetic anhydride (0.20 ml) and pyridine (2.5 ml). The product was chromatographed on silica gel (25 g) using hexane–benzene (1:1) as the eluent and then recrystallized from ethanol to give the acetate (**30**), mp 92—94 °C, $[\alpha]_D$ +55.4° (lit,[23] mp 92—93 °C, $[\alpha]_D$ +51°), IR: 1750 cm^{-1}, NMR: 0.93 (6H, s, $-\dot{C}(CH_3)_2$), 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.18 (3H, s, C_{10}–CH_3),

2.21 (3H, s, $-OCOCH_3$), 6.52 (1H, bs, C_{14}–H), 7.04 (1H, s, C_{11}–H). Found: C, 80.41; H, 9.90%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%.

Sempervirol (11). A mixture of **30** (105 mg) and lithium aluminium hydride (15 mg) in dry ether (2.0 ml) was refluxed for 1 h. After the usual work-up, the product was purified by column chromatography on silica gel (10 g) using hexane–benzene (1:1) as the eluent, to afford sempervirol (**11**) (90 mg: 98%), $[\alpha]_D$ +60.2°; IR: 3605, 3340 cm^{-1}; NMR: 0.92 (6H, s, $-\dot{C}(CH_3)_2$), 1.13 (3H, s, C_{10}–CH_3), 1.19 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 3.10 (1H, m, $-CH(CH_3)_2$), 4.59 (1H, bs, –OH), 6.18 (1H, s, C_{14}–H), 6.92 (1H, s, C_{11}–H). Found: C, 83.78; H, 10.50%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

3-(3-Methoxystyryl)-2,4,4-trimethyl-1-cyclohexene (25). A solution of butyllithium in hexane (15%; 2.8 ml) was added to a suspension of (3-methoxybenzyl)triphenylphosphonium chloride (**23**)[24] (mp 159—165 °C, 2.39 g) in dry benzene (20 ml) under a stream of nitrogen and stirred at room temperature for 15 min. After the addition of a solution of **15** (434 mg) in dry benzene (2.0 ml), the mixture was stirred for 6 more hours and then treated as described for the preparation of **17**. The crude product was purified by column chromatography on silica gel (40 g) using hexane–benzene (4:1) as the eluent to give **25** (411 mg: 56%) as an oil, $[\alpha]_D$ −345°, NMR: 0.89 and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.63 (3H, bs, $=\dot{C}CH_3$), 3.76 (3H, s, $-OCH_3$), 5.42 (1H, m, $-CH=\dot{C}-$), 5.92 (1H, dd, J=8 and 15 Hz, $-\dot{C}H-CH=CH-$), 6.32 (1H, d, J=15 Hz, $-\dot{C}H-CH=CH-$). Found: C, 84.03; H, 9.29%. Calcd for $C_{18}H_{24}O$: C, 84.32; H, 9.44%.

3-(3-Methoxyphenethyl)-2,4,4-trimethyl-1-cyclohexene (27). A mixture of **25** (1090 mg), 5% Pd–C (600 mg), and ethanol (10 ml) was subjected to catalytic hydrogenation as described for the preparation of **18**. After the usual work-up, the product was purified by column chromatography on silica gel (100 g) using hexane–benzene (95:5) as the eluent to give **27** (785 mg: 71%) as an oil, $[\alpha]_D$ −113°, NMR: 0.88 and 0.99 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.68 (3H, bs, $=\dot{C}CH_3$), 3.73 (3H, s, $-OCH_3$), 5.28 (1H, m, $-CH=\dot{C}-$). Found: C, 83.72; H, 10.19%. Calcd for $C_{18}H_{26}O$: C, 83.66; H, 10.14%.

Intramolecular Cyclization of 27. A mixture of **27** (780 mg), anhydrous aluminium chloride (450 mg), and dry benzene (10 ml) was stirred at 30 °C for 30 min. After the treatment by a method similar to that used for **18**, the crude product was chromatographed on silica gel (80 g) using hexane–benzene (9:1) as the eluent to give the *cis*-isomer (**31**) (285 mg: 36%) as an oil, $[\alpha]_D$ −21.9°, NMR: 0.38 (3H, s, $C_{4\beta}$–CH_3), 0.92 (3H, s, $C_{4\alpha}$–CH_3), 1.11 (3H, s, C_{10}–CH_3), 3.70 (3H, s, $-OCH_3$), 6.44 (1H, overlap, C_{14}–H), 6.53 (1H, dd, J=2.5 and 8.5 Hz, C_{12}–H), 7.06 (1H, d, J=8.5 Hz, C_{11}–H). Found: C, 83.37; H, 10.23%. Calcd for $C_{18}H_{26}O$: C, 83.66; H, 10.14%.

Further elution gave the *trans*-isomer (**13**) (291 mg: 37%), $[\alpha]_D$ +41.4°, which was recrystallized from methanol to afford an optically pure sample (138 mg), mp 84.5—86 °C, $[\alpha]_D$ +53.9° (lit,[4] mp 86—88 °C, $[\alpha]_D$ +54°), NMR: 0.93 (6H, s, $-\dot{C}(CH_3)_2$), 1.13 (3H, s, C_{10}–CH_3), 3.67 (3H, s, $-OCH_3$), 6.40 (1H, overlap, C_{14}–H), 6.51 (1H, dd, J=3 and 8 Hz, C_{12}–H), 7.01 (1H, d, J=8 Hz, C_{11}–H). Found: C, 83.42; H, 10.18%. Calcd for $C_{18}H_{26}O$: C, 83.66; H, 10.14%.

(+)-Podocarpa-8(14)-en-13-one (14). According to the method of Church *et al.*,[12] the compound **13** (138 mg) in dry ether (7.0 ml) was reduced with lithium (110 mg) in liquid ammonia (*ca.* 20 ml) in the presence of ethanol (5.0 ml) and then treated with dilute hydrochloric acid. The crude product was purified by column chromatography on silica gel (5.0 g) using ether–benzene (3:97) as the eluent, followed by recrystallization from petroleum ether to afford the enone (**14**), mp 61.5—62.5 °C, $[\alpha]_D$ +40.4° (lit,[8] mp 62—65 °C, $[\alpha]_D$ +41°); IR: 1656, 1617 cm^{-1}; NMR: 0.83, 0.90, and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$ and C_{10}–CH_3), 5.73 (1H, bs, C_{14}–H). Found: C, 83.00; H, 10.78%. Calcd for $C_{17}H_{26}O$: C, 82.87; H, 10.64%.

A New Synthetic Method for Methyl Dihydrojasmonate from a Butadiene Telomer

Jiro Tsuji,* Kazuyuki Kasuga, and Takashi Takahashi
Tokyo Institute of Technology, Meguro, Tokyo 152
(Received July 19, 1978)

Ethyl 2-acetyl-4, 9-decadienoate, easily obtained by the palladium catalyzed telomerization of butadiene with ethyl acetoacetate, was selectively hydrogenated to ethyl 2-acetyl-9-decenoate using $RuCl_2(PPh_3)_3$ as a catalyst. Deacetylation, followed by hydrolysis produced 4-decenoic acid, which was converted into acid chloride. The $AlCl_3$-promoted cyclization gave 2-pentyl-2-cyclopentenone, from which methyl dihydrojasmonate was prepared.

Methyl dihydrojasmonate (**7**) is an important fragrant compound. A number of synthetic approaches for this ester have been reported.[1,2] We now wish to report a simple synthetic method for methyl dihydrojasmonate starting from an easily available butadiene telomer, which has functionality suitable for the synthesis of jasmonate. Palladium catalyzed telomerization of butadiene with various nucleophiles affords a variety of interesting telomers,[3] which can be used for syntheses of various natural products. We have already reported the syntheses of queen substance,[4] royal jelly acids,[5,6] civetone,[7] Matsutake alcohol,[8,9] pellitorine,[10] Recifeiolide,[11] and diplodialide[12] from various telomers. Butadiene and ethyl acetoacetate react readily using a palladium catalyst to give ethyl 2-acetyl-4,9-decadienoate (**1**) in a high yield.[13] This compound has the right carbon numbers and suitable functionality for a facile synthesis of 2-pentyl-2-cyclopentenone, an important precursor of dihydrojasmonate. Thus the compound **1** is a good starting compound for dihydrojasmonate.

Results and Discussion

The synthesis of methyl dihydrojasmonate using the butadiene telomer **1** was carried out by the following sequence of reactions.

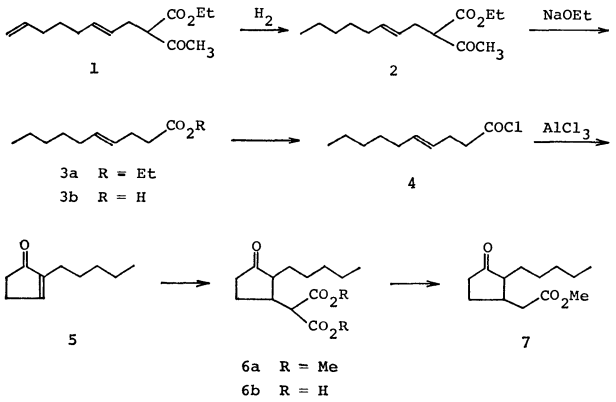

Fig. 1.

Regioselective hydrogenation of the terminal double bond of ethyl 2-acetyl-4,9-decadienoate (**1**) without attacking the internal double bond was achieved easily by homogeneous hydrogenation using $RuCl_2(PPh_3)_3$ as a catalyst under mild conditions.[14] The acetyl group of **2** was removed by the treatment with sodium ethoxide in ethanol to give ethyl 4-decenoate (**3a**) in 83% yield. Then the ester **3a** was hydrolyzed with a base to give 4-decenoic acid (**3b**) in 89% yield. The acid has a double bond at the position suitable for an acid catalyzed intramolecular cyclization to form a cyclopentenone ring. At first, the direct cyclization of the acid **3b** was attempted by using polyphosphoric acid, but the yield of the cyclopentenone was only 20%. In order to carry out the more efficient cyclization, the acid **3b** was converted to the more reactive acid chloride **4**. Then the intramolecular acylation of the double bond was carried out by using $AlCl_3$ in dichloromethane. By this method, the desired 2-pentyl-2-cyclopentenone (**5**) was obtained in 53% yield. The structure of **5** was confirmed by elemental analysis, and mass and NMR spectra. The conversion of **5** to methyl dihydrojasmonate (**7**) is the known reaction.[15] The Michael addition of dimethyl malonate (65.5% yield), followed by hydrolysis produced the diacid **6b**. Decarboxylation and methylation gave methyl dihydrojasmonate (**7**), which was identified by comparing its NMR and IR spectra with those of an authentic sample.

Experimental

NMR spectra were recorded by a Hitachi R-24A spectrometer at 60 MHz. Chemical shifts (δ) are given in ppm relative to an internal standard of TMS. IR spectra were recorded with a JASCO IRA-2 spectrometer. Ethyl 2-acetyl-4,9-decadienoate (**1**) was prepared according to the method of Hata *et al.*[13]

*Regioselective Hydrogenation of Ethyl 2-Acetyl-4,9-decadienoate (**1**).* A mixture of **1** (5.55 g, 23.3 mmol) and $RuCl_2(PPh_3)_3$ (87.6 mg, 0.09 mmol) in dry ethanol (15 ml) and dry benzene (15 ml) was pressured to 30 atm with hydrogen in a 100 ml autoclave and stirred at room temperature for 5 h. When the hydrogen pressure decreased to 19 atm, the autoclave was opened and the solvent was evaporated. Distillation of the residue afforded ethyl 2-acetyl-4-decenoate (**2**), bp 105—106 °C/1 Torr; 5.28 g (94% yield): IR (neat) 2920, 1740, 1718 cm^{-1}; NMR (CCl_4) 0.87 (t, J=4.8 Hz, 3H), 1.25 (t, J=7.2 Hz, 3H), 1.04—1.65 (m, 6H), 1.75—2.05 (m, 2H), 2.09 (s, 3H), 2.20—2.55 (m, 2H), 3.27 (t, J=7.2 Hz, 1H), 4.08 (q, J=7.2 Hz, 2H), 5.15—5.45 (m, 2H).

*Ethyl 4-Decenoate (**3a**).* Sodium metal (412 mg, 17.9 mmol) was dissolved in dry ethanol (50 ml) to which the ester **2** (8.62 g, 35.9 mmol) was added. The resulting mixture was refluxed for 6 h and neutralized with acetic acid. Ethanol was evaporated, and the residue was extracted

with ether. The extract was washed with brine and dried over sodium sulfate. After removal of ether, distillation of the residue gave **3a**, bp 114 °C/6 Torr; 5.9 g (83% yield): IR (neat) 2920, 1734 cm^{-1}; NMR (CCl_4) 0.87 (t, J=4.8 Hz, 3H) 1.05—1.50 (m, 6H), 1.22 (t, J=7.2 Hz, 3H), 1.55—2.13 (m, 4H), 2.13—2.33 (bs, 2H), 8.02 (q, J=7.2 Hz, 2H), 5.15—5.45 (m, 2H).

*4-Decenoic Acid (**3b**).* An aqueous KOH solution (2.51 g, 44.8 mmol in 20 ml) was added to a solution of **3a** (5.9 g, 29.8 mmol) in methanol (20 ml). The resulting mixture was stirred for 6 h at room temperature. The reaction mixture was washed with hexane and acidified with 6 M HCl. Methanol was evaporated and the aqueous phase was extracted with dichloromethane. The extract was dried over magnesium sulfate. The crude acid **3b** was obtained after evaporation of the solvent (4.1 g, 81% yield): IR (neat) 3000, 2930, 1705 cm^{-1}; NMR (CCl_4) 0.87 (t, J=4.8 Hz, 3H), 1.05—1.53 (m, 6H), 1.53—2.13 (m, 4H), 2.20—2.48 (bs, 2H), 5.24—5.53 (m, 2H), 10.84 (bs, 1H).

*Cyclization of **3b** with Polyphosphoric Acid.* A mixture of the acid **3b** (510 mg, 3 mmol) and polyphosphoric acid (1.6 g) was stirred at 95 °C for 4 h. Crushed ice and water were then added. The mixture was stirred until it became homogeneous and ether extraction was carried out. The extract was washed with saturated $NaHCO_3$ solution and brine, and dried over sodium sulfate. After evaporation of ether, the cyclized product was isolated by column chromatography (silica gel using hexane/ether as an eluent) (95 mg, 21% yield.

*4-Decenoyl Chloride (**4**).* A mixture of acid **3b** (1.5 g, 8.82 mmol) and thionyl chloride (1.26 g, 10.6 mmol) was heated at 60 °C under nitrogen for 5 h. The chloride **4** was obtained by distillation at 62.5 °C/1.5 Torr; (1.52 g, 91% yield): IR (neat) 2940, 1800 cm^{-1}; NMR (CCl_4) 0.88 (t, J=4.8 Hz, 3H), 1.07—1.75 (m, 6H), 1.77—2.65 (m, 4H), 2.74—3.07 (m, 2H), 5.26—5.55 (m, 2H).

*Cyclization of **4** by $AlCl_3$.* A mixture of **4** (600 mg, 3.18 mmol) and $AlCl_3$ (506 mg, 3.81 mmol) in dry dichloromethane (10 ml) was stirred at 0 °C for 2 h. Ice water (20 ml) was added and the aqueous phase was extracted with ether. The extract was washed sequentially with cold saturated $NaHCO_3$ and brine, and dried over sodium sulfate. The pure enone **5** was obtained by column chromatography (silica gel using hexane/ether as an eluent) after removal of ether (255 mg, 53% yield): IR (neat) 2920, 1700, 1630 cm^{-1}; NMR (CCl_4) 0.89 (t, J=4.8 Hz, 3H), 1.08—1.80 (m, 6H), 1.80—2.35 (m, 4H), 2.35—2.70 (m, 2H), 7.04—7.23 (m, 1H). Found: C, 78.56; H, 10.44%. Calcd for $C_{10}H_{16}O$: C, 78.90; H, 10.59%. MS *m/e* 152 (M^+).

*The Michael Addition of **5**.* Sodium metal (23.5 mg, 1.02 mmol) was dissolved in dry methanol (3 ml) and dimethyl malonate (261 mg, 1.98 mmol) was added under nitrogen at 0 °C. After 15 min, the enone **5** (171 mg, 1.13 mmol) in dry methanol (3 ml) was added dropwise during 15 min at −10 °C. After the addition, the reaction mixture was poured into a cold saturated NH_4Cl and the aqueous phase was extracted with ether. The combined organic layer was washed with brine and dried over magnesium sulfate. The addition product **6a** was isolated by column chromatography (silica gel using hexane/ether as an eluent) (209 mg, 65.5% yield): IR (neat) 2930, 1755, 1735 cm^{-1}; NMR (CCl_4) 0.90 (t, J=4.8 Hz, 3H), 1.05—1.58 (m, 8H), 1.80—2.30 (m, 6H), 3.40 (d, J=7.2 Hz, 1H), 3.71 (s, 6H).

*Methyl Dihydrojasmonate (**7**).* To aqueous NaOH (36.8 mg, 0.92 mmol) in 1 ml was added **6a** (125 mg, 0.44 mmol) in THF (2 ml). The resulting mixture was stirred for 1 h at room temperature. The solution was acidified with sulfuric acid, and refluxed for 3 h. Then, the product was extracted with ether. The extract was dried over sodium sulfate. After evaporation of ether, crude dihydrojasmonic acid was obtained. This crude acid was dissolved in dry methanol (2 ml) and the solution was heated at 40 °C for 3 h in the presence of a catalytic amount of sulfuric acid. Methanol was evaporated and the residue was extracted with ether. The ether extract was washed with cold saturated $NaHCO_3$ and brine, and dried over sodium sulfate. After evaporation of ether, pure methyl dihydrojasmonate **7** was isolated by column chromatography (silica gel using hexane/ether as an eluent) (70 mg, 70% yield): IR (neat) 2940, 1740, 1440, 1170 cm^{-1}; NMR (CCl_4) 0.88 (t, J=4.8 Hz, 3H), 1.07—1.60 (m, 8H), 1.85—2.65 (m, 8H), 3.60 (s, 3H). MS, *m/e* 226 (M^+). The IR and NMR spectra were identical with those of an authentic sample.

Continuous Removal of Heavy Metals by the Lime Sulfurated Solution (Calcium Polysulfide) Process

Toshiro ARATANI,* Shigeki YASUHARA,† Hitoshi MATOBA††
and Takeo YANO

Department of Chemical Engineering, College of Engineering, University of Osaka Prefecture, Mozu-Ume, Sakai, Osaka 591

(Received July 1, 1978)

A continuous wastewater treatment system was developed for the Lime Sulfurated Solution Process which had already been tested in a batch, stirred tank and ascertained to be an effective chemical precipitation process. The removability of heavy metals was investigated with the continuous treatment system, consisting of a plant composed of H_2S desorber, reactor, thickener, sand filter, and H_2S desorber. The sulfide ion dissolved in treated water was desorbed as H_2S by a mixed gas of air and CO_2 and recycled in the reactor to precipitate heavy metals. It has been found that: (1) by the recycling use of H_2S, the continuous treatment system can remove heavy metals with less coagulant than in the batch, stirred vessel, (2) desorption of the dissolved sulfide ion by the mixed gas decreases the sulfide ion concentration in the treated water below 0.2 ppb, and (3) the conditions for the removal of heavy metals can be detected immediately by a sulfide ion electrode meter.

The development of a continuous processing system is of great practical importance to economically treat wastewater. In previous work,[1-3] an effective heavy metal removal process, *i.e.*, the CaS_x process, which utilized the lime sulfurated solution as a single coagulant, had been proposed and investigated kinetically,[1] for the removal condition for heavy metals,[2] and the simultaneous removal of heavy metal, phosphate, and COD substances.[3] These investigations had, however, been conducted in a batch, stirred vessel. On the engineering scale, *i.g.*, the wastewater treatment plant, continuous operation has been desirable, since continuous processing reduces the operating costs. It is, therefore, necessary to devise a suitable continuous processing system for the CaS_x process. The removal of heavy metals from the system also needs investigation.

According to a previous work,[1] reaction scheme for the CaS_x process is represented by Eqs. 1 to 4.

$$CaS_x + 3/2\,O_2 \longrightarrow CaS_2O_3 + (x-2)S, \quad (1)$$

$$CaS_x + CO_2 + H_2O \longrightarrow CaCO_3 + H_2S + (x-1)S, \quad (2)$$

$$M^{2+} + CaS_2O_3 + H_2O \longrightarrow MS + CaSO_4 + 2H^+, \quad (3)$$

$$M^{2+} + H_2S \longrightarrow MS + 2H^+. \quad (4)$$

In the batch operation, the H_2S liberated by Eq. 2 is partly lost to the gas (air or CO_2) blown into the water to decompose the coagulant (CaS_x),[2] and so an amount of coagulant, more than the stoichiometric amount calculated from Eqs. 1 to 4 is required. In the present study, a continuous treatment system suited to the CaS_x process was realized on the bench scale. The plant was devised to recycle the H_2S in Eq. 2. In the plant, the H_2S liberated was scrubbed by the wastewater, and the dissolved sulfide ion recovered as H_2S from the treated water and re-used to precipitate heavy metals. The efficiency of the H_2S recycling plant was investigated with regard to the removal of heavy metals and the recycling of H_2S. The desorption of the dissolved sulfide ion from the treated water was also investigated.

Experimental

Continuous Processing Plant. Figure 1 shows the total system for the continuous CaS_x process. Simulated wastewater containing heavy metal was continuously fed to the top of the reactor. The reactor was made of a multistage vibrating disc column (MVDC) consisting of 15 stages (100 mm in height pet stage and 100 mm in inner diameter). The MVDC was used as the reactor, since it had excellent gas-liquid contacting ability even in the presence of suspended solid particles.[4] The coagulant, CaS_x solution was continuously injected into the 7th stage of the MVDC reactor. At the upstream stages from the injection point (1st to 7th stage), H_2S gas generated at the downstream stages (8th to 15th stage) was scrubbed by the wastewater and caught on reacting with the heavy metals in the wastewater. The CaS_x decomposed when it came into contact with the gas introduced from the bottom of the reactor. The precipitation of heavy metals by the decomposed CaS_x proceeded mainly at the downstream stages. The suspended solid particles were sedimented in the thickener of 300 mm both in diameter and height. The supernatant liquid was further clarified by a sand filter (150 mm diameter and 200 mm depth), packed with 120 mesh silica sand of 100 mm thickness. The clarified water was stripped of dissolved sulfide ions in the desorber, where the clarified water was contacted in countercurrent with the gas blown for the CaS_x decomposition. The gas used for the desorption was a mixture of air and CO_2 at predetermined volume ratio. The effluent water (treated water) from the desorber was removed as regards heavy metals and sulfide ions. The desorber was made up of an irrigated packed bed with 1/2″ Rasching ring.[5] The bed had a diameter of 150 mm and a height of 1 m. Air, according to a previous paper,[2] requires 60 to 90 min to decompose the CaS_x solution. The long processing time in the batch operation was known to require a large volume of the reactor for continuous operation. A mixed gas of air and CO_2 at various volume ratios was tested to determine the optimum conditions for heavy metal precipitation. The exit gas from the H_2S desorber was blown into the bottom of the reactor, and with this flow of gas, the H_2S, which was recovered by blowing gas into the desorber, was re-used to precipitate the heavy metals in the reactor. The other gas exiting from the top of the reactor was removed perfectly for H_2S, at the

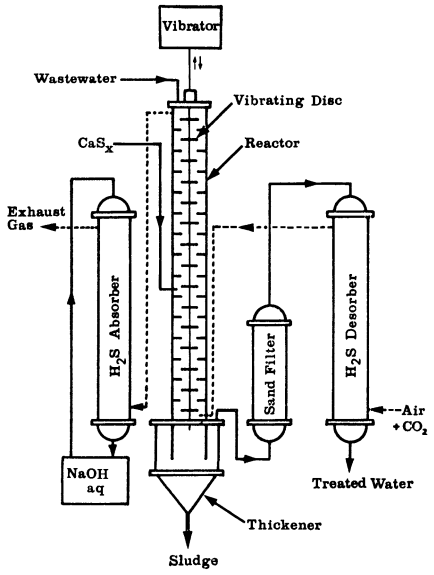

Fig. 1. Continuous heavy metal treatment system for the CaS_x process.

H_2S absorber (the same dimension of irrigated packed bed as the H_2S desorber was used). As the absorbing liquor, 5% NaOH aqueous solution was used.

Method. The simulated wastewater was prepared by dissolving the heavy metal nitrates into ordinary water, and stored in a tank (500 dm^3). The simulated wastewater was not temperature controlled, since the removal of heavy metals with the CaS_x process had already been found to be not severely affected by temperature.[2] First, the whole space of the plant, except the absorber and desorber, was filled with ordinary water. Continuous operation was started by the injection of the coagulant (CaS_x solution), followed by blowing of the gas for the CaS_x decomposition. Finally, the simulated wastewater was introduced. Samples were taken at predetermined time intervals from the outlets of the reactor, thickener, sand filter, and desorber. The samples from the reactor and thickener were filtered by membranes of various pore sizes, and the heavy metal concentrations were determined on an atomic absorption spectrophotometer. Samples from the sand filter and the desorber were directly determined for heavy metal concentrations. The sulfide ion concentration was measured by an ion meter with sulfide ion electrodes (Orion Research Inco., Model 94-16 and 90-02). Since the pH of the sample affects the detected sulfide ion concentration, the pH's of the samples were adjusted by adding a portion of 2 M-NaOH to give a pH of 10.0. The ion meter was calibrated with Na_2S of known concentration at pH=10.0. The flow rates of the wastewater and the blowing gas were set at 500 cm^3/min and 14 dm^3/min respectively. Liquid hold-up's in the reactor, thickner, sand filter, and desorber were measured to be 20, 20, 5, and 1 dm^3, respectively. With the base of these flow rates, the retention times of the reactor, thickener, sand filter, and desorber were calculated, respectively, as 40, 40, 10, and 2 min (the sum total was 92 min). The vibrating frequency of the disc in the MVDC reactor was set at 1.5 Hz with an amplitude of 19 mm, that is, at a vibrating speed of 2.85 cm/s, effective for the fine dispersion of the gas.[4]

Results and Discussion

The preliminary investigation was with simulated wastewater contaminated solely with Cd^{2+}. Figure 2 shows the change in Cd^{2+} concentration in the treated water from the start of the operation. Approximately four times the total retention time (92 min×4=368 min=6 h) was found sufficient for the steady state to be attained. In Fig. 3, the steady state concentration of Cd^{2+} has been plotted against the CO_2 vol % to air of the blowing gas. 8.5 vol % of CO_2 was found to be the optimum condition for the removal of Cd^{2+}, when R_m (the mole ratio of sulfur in the injected CaS_x per Cd^{2+} in the simulated wastewater) was 10 or 15, for C_{in} (the inlet concentration of Cd^{2+})=75 ppm. Consequently, the blowing gas containing 8.5 vol % of CO_2 was utilized in the following experiments. Figure 4 shows the steady state concentration of Cd^{2+} in the treated water plotted against R_m. The continuous plant can remove Cd^{2+}, even with R_m=5.0 for C_{in}=100 ppm, *i.e.*, closely at the stoichiometric amount of the coagulant (R_m=4.7 to 5.4).[2] This compares to the batch processing which needs more units of coagulant as shown by the dotted line in Fig. 4, for C_0=100 ppm. The economization of coagulant is mainly attributed to the recycling of H_2S.

Figure 5 shows the sulfide ion concentration detected by the ion meter against R_m. The keys in Fig. 5, *i.e.*, R_0, T_0, and *O* indicate the samples taken from the reactor, thickener, and desorber, respectively. The treated water (key: *O*) was found to be desorbed as

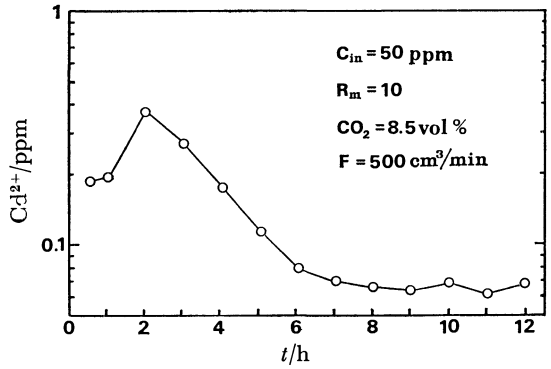

Fig. 2. Attainment to the steady state concentration with the continuous processing of Cd^{2+}.

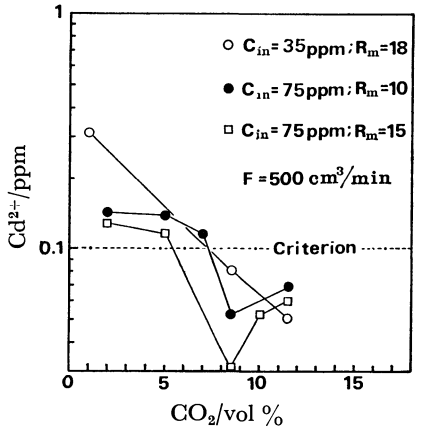

Fig. 3. Steady state concentration of Cd^{2+} *vs.* CO_2 vol % in the blowing gas.

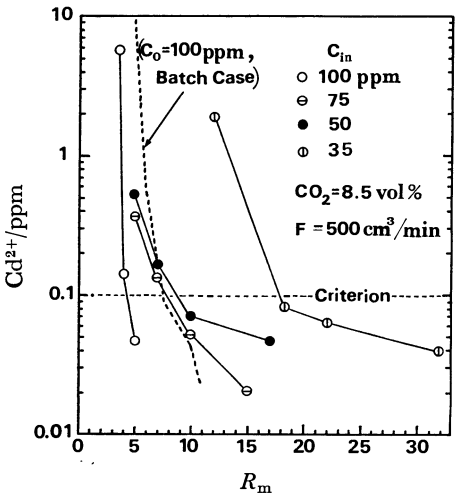

Fig. 4. Steady state concentration of Cd^{2+} *vs.* R_m.

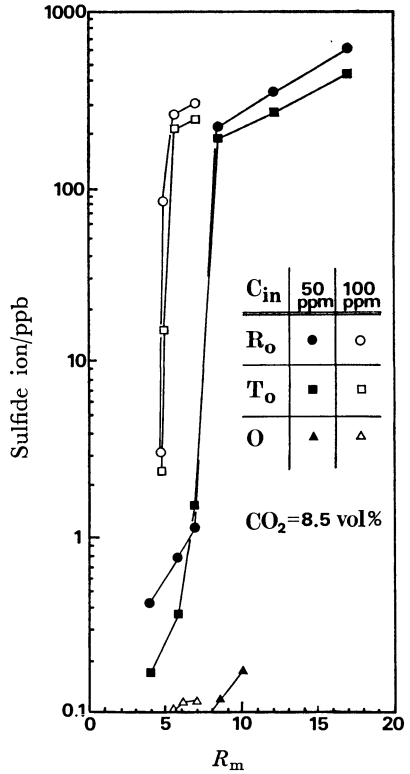

Fig. 5. Detected sulfide ion concentration by ion meter *vs.* R_m.
R_o: reactor outlet, T_o: thickener outlet, O: desorber outlet.

to have the sulfide ion concentration below 0.2 ppb. In water, H_2S is known to dissociate as shown by Eqs. 5 and 6, with dissociation constants of $K_1=[H^+][HS^-]/[H_2S]_{aq}=10^{-7.1}$ and $K_2=[H^+][S^{2-}]/[HS^-]=10^{-12.4}$ at 20 °C.[6]

$$(H_2S)_{aq} \overset{K_1}{\rightleftharpoons} HS^- + H^+, \quad (5)$$

$$HS^- \overset{K_2}{\rightleftharpoons} S^{2-} + H^+. \quad (6)$$

From Eqs. 5 and 6, the mole fractions of $(H_2S)_{aq}$, HS^-, and S^{2-} are represented as functions of pH;

$$[H_2S]_{aq}/C_{TDS} = 1/Q, \quad (7)$$

$$[HS^-]/C_{TDS} = 10^{-7.1+pH}/Q, \quad (8)$$

$$[S^{2-}]/C_{TDS} = 10^{-19.5+2pH}/Q, \quad (9)$$

where $Q=1+10^{-7.1+pH}+10^{-19.5+2pH}$ and C_{TDS} is the total molar concentration of the dissolved sulfides ($C_{TDS}=[H_2S]_{aq}+[HS^-]+[S^{2-}]$). The pH of the treated water with the blowing gas with 8.5 vol % of CO_2 was measured as 6.1. At pH=6.1, the mole fractions of $(H_2S)_{aq}$, HS^-, and S^{2-} calculated from Eqs. 7, 8, and 9 are 0.909, 0.09, and 10^{-7}, respectively. As reported by Ohkawa and Sakai,[7] H_2S in water can be desorbed better on the acidic side, since $(H_2S)_{aq}$ is more readily stripped than HS^- and S^{2-} which need to pass through the associating reaction to $(H_2S)_{aq}$ (Eqs. 5 and 6). 90.9% of C_{TDS} was found to be $(H_2S)_{aq}$ at pH=6.1; the low pH is a direct consequence of the acidity of the CO_2 gas. Thus, the use of CO_2 mixed gas for the CaS_x decomposition is desirable from the view point of H_2S desorption. The reason for the adjustment of the samples pH to 10.0 can be explained from Eqs. 7, 8, and 9 as follows. At pH=10.0, the mole fractions of $(H_2S)_{aq}$, HS^-, and S^{2-} are estimated as 0.001, 0.995, and 0.004, respectively. Therefore, the detected sulfide ion by a pair of electrodes can be said to be almost equal to C_{TDS}.

Figure 5 indicates that the R_m values crossing down the criterion for Cd^{2+} in Fig. 4 for C_{in}=50 and 100 ppm agrees closely with the R_m values of Fig. 5 when the sulfide ion concentration shows steep increase. This good agreement of R_m values suggests that the optimum conditions for Cd^{2+} removal can be detected immediately by measuring the sulfide ion concentration at the outlet of the reactor.

The agglomeration of precipitates is known to be accelerated by the solid particle concentration, or the number of particles existing in the water. To increase the solid particle concentration in the reactor, the precipitated sludge was recycled from the thickener to the top of the reactor by a peristaltic pump at 30 cm³/min. Figure 6 shows a result of Cd^{2+} removal with and without the sludge recycle. The sludge recycle was found to be effective in reducing the amount of coagulant as can be seen from Fig. 7. In Fig. 7, the abscissa is converted from R_m in Fig. 4 to $C_s=R_m\times C_{in}$, C_s being defined as the total sulfur atom concentration injected with the coagulant. Since the sulfur atoms added give rise to equivalent moles of metal sulfide and solid sulfur particles, as seen from Eqs. 1 to 4, C_s can be interpreted as the solid particle concentration generated by the CaS_x process. Since the Cd^{2+} concentration in Fig. 7 shows a single correlation with the solid particle concentration, C_s, the precipitation of heavy metals may depend solely on the solid particle concentration of the water. The recycling of the sludge will increase the solid particle concentration and may work effectively to precipitate heavy metals with less coagulant.

Figure 8 shows the result of the continuous processing of wastewater simultaneously contaminated with 25 ppm of Cd^{2+}, 100 ppm of Pb^{2+} and Zn^{2+}, 40 ppm of Cu^{2+}, and 5 ppm of Cr(VI) and Hg^{2+}. Figure 8 indicates that R_m=5.0, *i.e.*, nearly stoichiometric

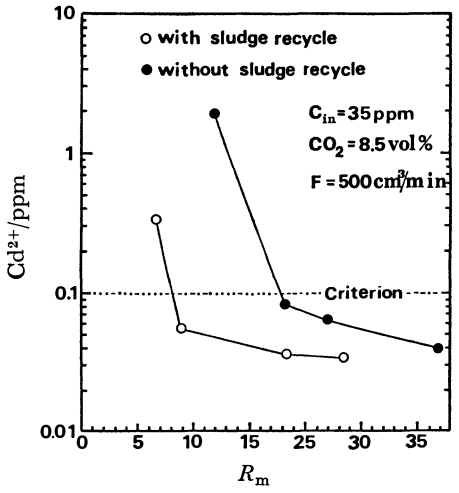

Fig. 6. Removal of Cd^{2+} with and without sludge recycle.

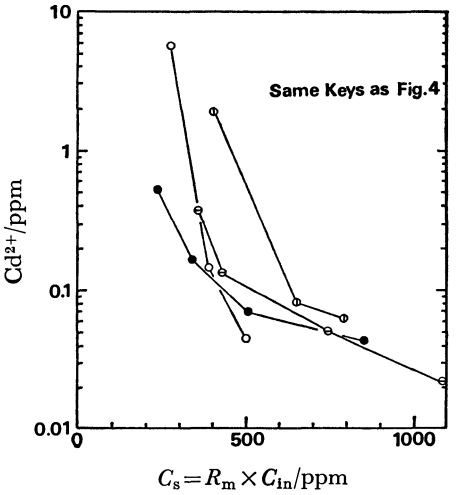

Fig. 7. Cd^{2+} *vs.* solids particle concentration or the sulfur atom concentration.

amount of coagulant is sufficient for the removal of contaminants. The removal concentrations are approximately proportional to the solubilities of the respective sulfides; 6.0×10^{-18} ppb for HgS, 1.62×10^{-10} ppb for CuS, 2.58×10^{-6} ppb for CdS, 2.0×10^{-6} ppb for PbS, 1.1×10^{-3} ppb for ZnS, and 8.3×10^{-2} ppb for $Cr(OH)_3$ at pH=7.0.[6] Cr(VI), Pb^{2+}, and Zn^{2+} show deviations from the order of solubility. The batch processing data shows a higher residual concentration for Zn^{2+}; the reason for this is not evident at present, but it is felt that the particle size of the precipitate may be concerned.

The samples taken from the outlets of the reactor and the thickener were filtered by membranes of various pore sizes, and the residual heavy metals concentrations were determined by atomic absorption, the results of which are shown in Fig. 9. Cr(VI) and Pb^{2+} are found to be finer in gain size. The growth of precipitates was shown to take place in the thickener. Figure 9 also shows that the precipitates grow to about 8 μm and this is thought sufficient for sand filtration.

Conclusion

Continuous CaS_x process study has lead to the following conclusions.

1) The amount of coagulant needed for the heavy metal removal can be lowered by recycling H_2S in the continuous operating plant.

2) The solid particle concentration in the reactor depends on the removability, which may explain the effective precipitation of Cd^{2+} by the recycling of the sludge.

3) The condition for removal of heavy metals can be detected by an electrode type ion meter. This simple method may enable the plant to be operated automatically with the least amount of coagulant.

4) The desorption of sulfide ions from the treated water can be effectively attained by the blowing gas or air containing CO_2.

The authors wish to thank Assoc. Prof. Kei Miyanami of the University of Osaka Prefecture, Prof. Ryuzo Ito of Osaka University, Profs. Takataro Suda, Yoshiki Sanoh, and Mr. Kiyochika Yahikozawa of Shinshu University for their useful discussions.

On the Mechanism of Formation of Furotropones from (4-Halogeno-2-butenyloxy)tropones

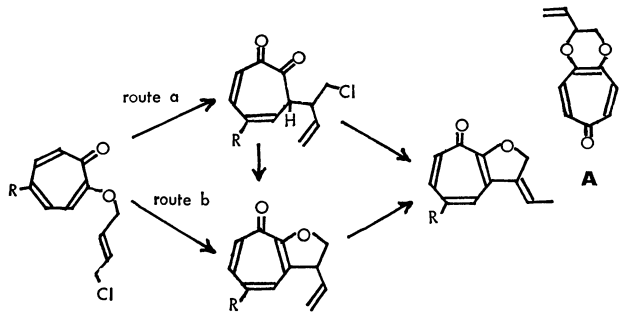
Hitoshi TAKESHITA,* Kozo TAJIRI, and Isao KOUNO

Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812

(Received July 21, 1978)

Synopsis. Pyrolysis of 2-[(*E*)-4-bromo-3-butenyloxy]-tropone and 2-[(*E*)-4-bromo-2-methyl-2-butenyloxy]tropone produced 3-methyl-3-vinyl-2,3-dihydro-8*H*-cyclohepta[*b*]-furan-8-one and 3-isopropylidene-2,3-dihydro-8*H*-cyclo-hepta[*b*]furan-8-one, which established the involvement of 3,3-sigmatropy for furotropone formation.

Previously, the one-step production of furotropones and difurotropones by application of the Claisen rearrangement to some bifunctional troponyl allyl ethers has been reported.[1,2] There are two possible mechanisms, *i.e.*, route a, 3,3-sigmatropy followed by dehydrohalogenation, and route b, a direct S_N2'-type elimination from the allyl ethers.[3]



R=H, OH or O-CH_2CH=H-CH_2Cl

Chart 1.

It is important to establish the mechanism to discover the synthetic versatility for furotropones. Using an unsymmetrical halogenide, (*E*)-1,4-dibromo-2-methyl-2-butene (**1**), route a was shown to be correct by the following experiments.[4]

1 was introduced into an anhydrous solution of potassium tropolonate, prepared from tropolone (**2**), potassium hydroxide and 18-crown-6-(CE) in benzene, and refluxed for 7 h to form the isomeric ethers, **3** and **4**. The ethers were separated by high-pressure liquid chromatography. The major product (**3**), a colorless liquid, 35%, was shown to be 2-[(*E*)-4-bromo-3-methyl-2-butenyloxy]tropone [$\delta^{5)}$:1.89(3H, d, J=1 Hz), 3.97(2H, s), 4.68(2H, d, J=6 Hz), 5.89(1H, tq, J=6, 1Hz), and 6.6—7.3(5H, m)] and **4**, a colorless liquid, 18% identified as 2-[(*E*)-4-bromo-2-methyl-2-butenyloxy]tropone [δ:1.83(3H, d, J=1 Hz), 4.01(2H, s), 4.57(2H, s), 5.91(1H, tq, J=8, 1 Hz), and 6.6—7.2 (5H, m)].

The *o*-dichlorobenzene solution of **3** when heated at 180 °C for 10 min gave product **5**, a colorless liquid, 13% yield other than the deallylation product, **2**. The NMR spectrum of **5**[δ:1.47(3H, s), 4.42(1H, d, J=13 Hz), 4.49(1H, d, J=13 Hz), 5.19(1H, d, J=17 Hz), 5.27(1H, d, J=10 Hz), 6.98(1H, dd, J=17, 10 Hz), and 6.8—7.2(4H, m)] was deduced as 3-methyl-3-vinyl-2,3-dihydro-8*H*-cyclohepta[*b*]furan-8-one. Similarly, **4** afforded **6**, a colorless liquid, 24%, together with 45% of deallylated **2**. The NMR spectrum of **6** [δ: 1.80(3H, t, J=2 Hz), 2.12(3H, t, J=3 Hz), 5.20 (2H, m), and 6.6—7.2(4H, m)] was compatible with 3-isopropylidene-2,3-dihydro-7*H*-cyclohepta[*b*]furan-8-one.

The specific formation of **5** from **3** and **6** from **4** established the involvement of 3,3-sigmatropy followed by dehydrobromination. Consequently the previous results may be interpreted in terms of a 3,3-process.

The absence of primary rearrangement products is thought to be a facile cyclization into the dihydrofuran derivatives. Kitahara *et al.*[6] observed the spontaneous cyclization of 3-allyltropolone when treated with bromine.

Experimental

potsasium salt of **2** (275 mg), the crown ether (CE, 450 mg) and **1**[7] (1.0 ml) were mixed in benzene (20 ml) and refluxed for 7 h. The mixture was, after removal of the solvent, fractionated on a silica gel column to give colorless liquids, **4**, 46 mg (10%) [Found: *m/e*, 268, 270 (M^+, double peaks for $C_{12}H_{13}O_2Br$). *ν*: 2980, 1625, 1595, 1580, 1490, 1285, 1190, 1090 cm^{-1}], from benzene–ether (80 : 20), and **3**, 170 mg (37%) [Found: 268, 270 (M^+). *ν*: 2980, 1625, 1595, 1580, 1490, 1290, 1195, 1092 cm^{-1}], from the same solvent. Analytical samples were obtained by high-pressure liquid chromatography (Micropolasil, hexane–ethyl acetate).

Thermal Reaction of ***3***: *Formation of* ***5***. An *o*-dichlorobenzene solution (5 ml) of **3** (35.8 mg) was heated on an oil bath and refluxed for 10 min. Silica gel column chromatography of the mixture produced **2**, 3.5 mg (37%), and subsequently a colorless oil, **5**, 1.9 mg (13%) [Found: C, 76.30; H, 6.59%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%. *ν*: 2900, 1615, 1565, 1480, 1430, 1000 cm^{-1}].

Thermal Reaction of ***4***: *Formation of* ***6***. Similarly, **4** (22 mg) was heated in *o*-dichlorobenzene (5 ml), and refluxed for 10 min. Silica gel chromatography of the mixture gave a colorless oil, **6**, 2.2 mg (24 %) [Found: *m/e*, 188.0722 (M^+). Calcd for $C_{12}H_{12}O_2$: 188.0769. *ν*: 2980, 1615, 1570, 1480, 1430 cm^{-1}], together with hydrolyzed **2**, 2.7 mg (45%).

Effect of Inorganic Additives on the Reactions of Isomeric Transition-Activated ^{80}Br and ^{82}Br in the Gaseous HBr–CH_4 System

Kenjiro KONDO* and Masuo YAGI

Laboratory of Nuclear Science, Tohoku University, Tomizawa, Sendai 982

(Received March 6, 1978)

Synopsis. The effects of various inorganic additives with and without dipole moments on the product yield distributions have been examined in the CH_4–$H^{80m}Br$ and CH_4–$H^{82m}Br$ systems. Indications were that the ion-clusters formed in the reactions of IT-activated ^{80}Br and ^{82}Br play an important role in determining individual product yield distributions.

It has been reported that isomeric transition (IT)-activated ^{80}Br and ^{82}Br undergo only thermal ionic reactions in the $H^{80m}Br$–CH_4 and $H^{82m}Br$–CH_4 systems, and that the large isotope effect observed can be explained in terms of the difference in decay schemes between ^{80m}Br and ^{82m}Br.[1,2] The γ-transition of ^{82m}Br to the ground state is attained in a single transition and fully converted. The ^{80m}Br has two successive transitions through the intermediate with a half-life of 7.4 ns, and the first stage is fully converted and the second is partially converted (61%). The organic yield of ^{80m}Br therefore can be classified into the following two types;[2] Processes A (39%): internal conversion (IC)+37 keV γ-ray emission; Process B (61%): IC+IC. The chemical effect due to Process A is essentially identical to that of ^{82m}Br. The above isotope effect has been explained by assuming that complex ions CH_4Br^+ or $HBrBr^+$ produced *via* the thermal ionic process interact with the surroundings to form an ion-cluster, and that the second IC in Process B occurs in such a cluster.[2] This has been qualitatively supported from the experimental results obtained in the condensed phase.[2] The aim of this paper is to confirm the presence of ion-clusters in the reactions of IT-activated ^{80}Br and ^{82}Br in the CH_4–$H^{80m}Br$ and CH_4–$H^{82m}Br$ systems by the addition of polar and/or nonpolar molecules, since the polarizability of molecules is one of the most important controlling factors in ion-cluster formation. The ratio of HBr to CH_4 and total pressure in all samples were kept constant at 0.1±0.01 and 660±30 mmHg respectively. Details of experimental procedures may be found elsewhere.[1–3]

Results and Discussion

The effects of inorganic additives (0.3 mf) on the yield distribution in both systems are shown in Table 1. Here, X and Y in the Table are CH_2BrCl and $CH_3CHBrCl$ respectively in the HCl additive experiment. In the case of the H_2S additive, X is thought to be CH_2BrSH. The minor products in low yields (≈0.1%) in other additive experiments have not been identified. CH_3Br yields were larger with ^{80m}Br than ^{82m}Br, while CH_2Br_2 yields with ^{82m}Br were much greater than with ^{80m}Br. Table 2 shows the normalized yields Y due to Process B, which have been calculated by the following equation:[2]

$$Y(\%) = \frac{100}{61}(^{80m}\text{Br-yield} - 0.39 \text{ of } ^{82m}\text{Br-yield}).$$

As previously reported, the isotope effect in both systems can be elucidated by comparing the yields due to Process B with ^{82m}Br yields.[2] The yield ratios of CH_3Br to CH_2Br_2 were 0.2—0.7 for ^{82m}Br and more than unity for Process B. CH_3Br yields in both systems were not affected by the addition of non-polar molecules without dipole moments, while a slight decrease in CH_3Br yields was observed in the system of polar ad-

ditives with dipole moments. CH_2Br_2 yields in both systems showed a sharp decrease by the addition of polar molecules, contrary to the results for non-polar additives.

The $^{80}Br^+$ and $^{82}Br^+$ ions formed by IT processes react with CH_4 and/or HBr to form collision complex ions, CH_4Br^+ and/or $HBrBr^+$ at first, as has been reported previously.[1,2] Further, these thermal ions are thought to have ample opportunity to form ion-clusters. Loeb has proposed the following equation indicating that an ion-cluster is formed when the potential energy between the ion and molecule is greater than the relative kinetic energy of the ion,[4]

$$\frac{(D-1)\beta}{8\pi Nr^4}/KE \geq 1,$$

where D is the dielectric constant of additive molecules, N, the number of molecules per cm^3, r, the distance between the ion and molecule, β, the statistical weight factor and KE, the relative kinetic energy of the ion. The ratio was found to be 3.4 for CH_4 at 660 mmHg ($D=1.00094$, $r=3\times10^{-8}$ cm[1]) and 0.5 assumed for β) and therefore it is reasonable to presume the formation of ion-clusters in the ^{82}Br and ^{80}Br reactions. Since the potential energies between the ion and nonpolar additives are smaller than for CH_4, and moreover the concentration of CH_4 is larger than those of the additives, the ion-cluster thus formed in the case of nonpolar additives contains mainly CH_4 and/or HBr molecules. In addition polar additives play an important role in cluster formation since the potential energies between the ion and additives are much greater than those for nonpolar additives. Consequently, the ion-cluster thus formed contains an appreciable number of additives as constituents.

The formation of $CH_3{}^{82}Br$ in the CH_4–$H^{82m}Br$ system has been explained energetically by the H^+ transfer reaction from $CH_4{}^{82}Br^+$ to CH_4 and/or HBr as previously reported.[2]

Similarly, the fact that $CH_3{}^{82}Br$ yields were almost constant in the present experiment can be explained on the basis of the exothermicity of the H^+ transfer reaction from $CH_4{}^{82}Br^+$ to CH_4 and/or additives. On the other hand, the $CH^{82}BrBr^+$ ion formed by the ion-molecule reaction of $CH_4{}^{82}Br^+$ with HBr is considered to be a precursor for $CH_2{}^{82}BrBr$. $CH^{82}BrBr$ formed by charge neutralization of $CH^{82}BrBr^+$ undergoes H-abstraction to give $CH_2Br^{82}Br$.[1,2] In the presence of polar additives, $CH_4{}^{82}Br^+$ is effectively surrounded by these molecules in the process of ion-cluster formation, therefore the concentration of HBr in the vicinity of $CH_4{}^{82}Br^+$ decreases, and eventually the above reaction leads to the $CH_2{}^{82}BrBr$ formation being hindered by the addition of polar molecules. Thus the remarkable decrease in $CH_2{}^{82}BrBr$ yields in polar additives can be explained qualitatively.

The second IC in Process B proceeds in an ion-cluster like a condensed phase. Therefore, the molecular explosion following the second IC is responsible for the chemical effect due to Process B. Although no precise information on the IT activated ^{80}Br reactions under such condition is available, both the ion-molecule reactions and primary radical recombinations in the clusters appear to be responsible for product formation. Previously it has been pointed out that radical reactions are not concerned with the formation of CH_3Br and CH_2Br_2.[1,2] This does not always mean however that the primary recombination involving ^{80}Br-radicals does not occur. In Process B that $CH_3Br>CH_2Br_2$ may be qualitatively interpreted by the above assumption since similar results were obtained in the solid CH_4–$H^{80m}Br$ system.[2] Furthermore, it is assumed that ion-molecule reactions also contribute to product formation, judging from the similarity of reaction products in both ^{82m}Br and Process B. The effect of additives on the CH_3Br and CH_2Br_2 yields in Process B may be explained in terms of the difference in concentration of polar and nonpolar molecules contained in the clusters in the same manner as ^{82m}Br. However the details of the reaction mechanisms must await until further experiments are conducted.

Far-infrared Absorption of Non-dipolar Liquid Mixtures

Kenji FUJIWARA,† Shun-ichi IKAWA,* and Masao KIMURA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 11, 1978)

Synopsis. Far-infrared absorptions of some non-dipolar liquid mixtures have been observed. The changes of the intensities with mixing ratio were examined on the basis of a formula derived for the difference between absorption intensities before and after mixing, to get information about the mixing state.

The far-infrared absorption of a non-dipolar liquid arises mainly from the bimolecular collisions and thus the absorption of a mixture of the non-dipolar liquids contains valuable information about the mixing state.[1,2] In the present study, the far-infrared absorptions were measured for benzene+cyclohexane, benzene+carbon disulfide, benzene+1,4-dioxane, and carbon disulfide+cyclohexane mixtures. The results were examined by means of a refined formula derived for the difference between the absorption intensities before and after mixing, to get information about the mixing state.

Experimental

The spectral measurements were performed at room temperature with the apparatus described previously.[3] The absorption coefficients were obtained by the equation:

$$\alpha(\nu) = \ln(I_1/I_2)/(l_2 - l_1), \quad (1)$$

where I_1 and I_2 are the transmitted intensities for the two sample thicknesses, l_1 and l_2, respectively. Thus the effects of the surface- and internal-reflection were minimized. The integrated intensities, $A=\int\alpha(\nu)\mathrm{d}\nu$, were estimated in a range from 10 to 220 cm^{-1}, except for samples containing 1,4-dioxane, for which integrations were performed over a range from 10 to 170 cm^{-1}. Spectroscopic grade samples were used for carobn disulfide, benzene, cyclohexane, and 1,4-dioxane. The observed spectra for pure liquids were consistent with the results previously reported.[1,2,4]

Theoretical

If the absorption arises from the bimolecular collisional process[1,2] in addition to the intramolecular process, the absorption intensity for a neat liquid is expressed as follows:

$$A = A_a/v_a + A_{aa}/v_a^2,$$

where v_a is the molar volume and A_a and A_{aa} denote the absorptions due to the intramolecular vibrations and the bimolecular collisions respectively. Let us consider the mixture of a and b components with volume ratio of $x/(1-x)$. The excess volume of mixing is ignored, since it is less than 1 vol % for ordinary organic liquids.[5] The absorption intensity before mixing is provided by the average of those of the neat liquids concerned as follows:

$$A_0 = x(A_a/v_a + A_{aa}/v_a^2) + (1-x)(A_b/v_b + A_{bb}/v_b^2), \quad (2)$$

where subscripts a and b indicate the two components. After mixing, the collision between the different species also takes part in the absorption and the intensity is expressed as follows:

$$A_m = x(A_a/v_a + \varphi_{aa}xA_{aa}/v_a^2) + (1-x)[A_b/v_b + \varphi_{bb}(1-x)A_{bb}/v_b^2] + 2x(1-x)\varphi_{ab}A_{ab}/v_av_b, \quad (3)$$

where φ_{aa}, φ_{bb}, and φ_{ab} are the relative ease of the three types of collision. These quantities represent the mixing state of the mixture. In the case of random mixing, all the three values are equal to unity. In general, however, these values are dependent upon the mixing ratio and are different from each other. They can probably be replaced by the probabilities of the intermolecular bond formation. Then the number ratio of the three types of bond, a–a, b–b, and a–b, is given by $f^2\varphi_{aa}:(1-f)^2\varphi_{bb}: 2f(1-f)\varphi_{ab}$, where f is the mole fraction of component a. According to Schulze,[6] these values are interrelated as follows:

$$\varphi_{ab} = \varphi, \quad \varphi_{aa} = \frac{1-\varphi+\varphi f}{f}, \quad \varphi_{bb} = \frac{1-\varphi f}{1-f}. \quad (4)$$

Since φ_{aa}, φ_{bb}, and φ are all positive, $0<\varphi<\min(f^{-1}, (1-f)^{-1})$. Besides, the limit of $\varphi(f)$ is unity as f approaches 0 or 1. The relationships among f, x, and the number of moles in unit volume, N, are $f=v_bx/[v_bx+v_a(1-x)]$, and $N=[fv_a+(1-f)v_b]^{-1}$. From Eqs. 2, 3, and 4 the difference between the absorption intensities before and after mixing is given by

$$\Delta A_m = A_m - A_0 = -N^2f(1-f)[(\varphi+v_b/v_a-1)A_{aa} + (\varphi+v_a/v_b-1)A_{bb}-2\varphi A_{ab}]. \quad (5)$$

Hereafter, ΔA_m is referred to as the absorption of mixing, by analogy with the heat of mixing.

In the case of random mixing, in which the φ value is unity, Eq. 5 becomes:

$$\Delta A_m = -Cf(1-f)[fv_a+(1-f)v_b]^{-2}, \quad (6)$$

where

$$C = (v_b/v_a)A_{aa} + (v_a/v_b)A_{bb} - 2A_{ab}.$$

If the molar volumes of the components are equal, *i.e.*, $v_a=v_b$, the f-dependence of ΔA_m is simply parabolic.

Results and Discussion

The integrated intensities obtained are plotted against the mole fraction f in the upper parts of Fig. 1(a—d). The standard errors for spectral measurements are indicated by the vertical bars. The solid line shows the intensity before mixing, A_o. For a mixture of two components with different molar

† Present address: Canon Inc., Torite, Ibaragi.

volumes, the mole fraction is nonlinear to the volume fraction. The molar volumes of benzene, cyclohexane, carbon disulfide, and 1,4-dioxane are 88.9, 108.1, 60.3, and 85.2 cm^3/mol, respectively. Then the A_0 curve for the benzene+1,4-dioxane mixture is almost straight, whereas that for the carbon disulfide+cyclohexane mixture shows the largest deviation from a straight line.

The absorptions of mixing, ΔA_m, are shown in the lower parts of Fig. 1(a—d) on an expanded scale. As may be seen in Eq. 5, the absorptions due to the monomolecular processes, A_a and A_b, are cancelled out in ΔA_m. Thus the intramolecular vibrational bands, such as the bands at 150 cm^{-1} of 1,4-dioxane and at 240 cm^{-1} of cyclohexane, contribute little to the values of ΔA_m. The broken lines in Fig. 1 show the values calculated from Eq. 6 with C values adjusted. For the benzene+cyclohexane and benzene+carbon disulfide mixtures, good fits were obtained between the observed and calculated values of ΔA_m. Therefore, the condition of random mixing may hold for these mixtures. The sign of ΔA_m for the benzene+cyclohexane mixture is negative, whereas that for the benzene+carbon disulfide mixture is positive. For the a+b mixture, the sign of ΔA_m is determined by the sign of C, *i.e.*, $(v_b/v_a)A_{aa}+(v_a/v_b)A_{bb}-2A_{ab}$. For the benzene+cyclohexane system, the molar volumes of the two components, v_a and v_b, are approximately equal and the benzene–benzene absorption, A_{aa}, is much stronger than the cyclohexane–cyclohexane absorption, A_{bb}. Therefore, the positive value of C shows that A_{aa} is the dominant absorption. For the benzene+carbon disulfide system, the negative value of C means that A_{ab} is larger than the average of A_{aa} and A_{bb}, which is approximately equal to that of $(v_b/v_a)A_{aa}$ and $(v_a/v_b)A_{bb}$. Davies and Chamberlain[2] considered that the positive sign of ΔA_m was due to a complex or sticky collision interaction between different species. However, as mentioned above, the sign of ΔA_m depends upon the magnitudes of the three types of binary absorption, A_{aa}, A_{bb}, and A_{ab}, which does not necessarily represent directly the strength of the intermolecular bondings.

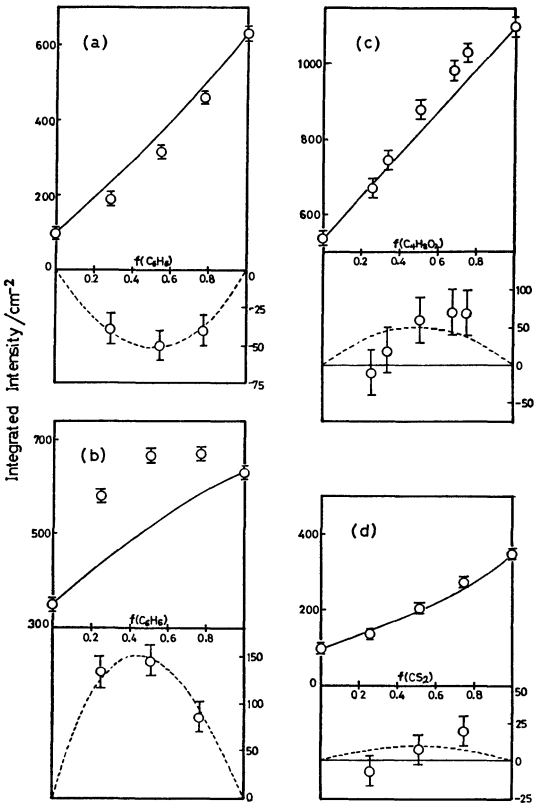

Fig. 1. The mole fraction dependency of the integrated absorption intensity (the upper part) and the absorption of mixing (the lower part) of liquid mixtures:
(a) benzene+cyclohexane,
(b) benzene+carbon disulfide,
(c) benzene+1,4-dioxane,
(d) carbon disulfide+cyclohexane.
The vertical bars indicate the standard errors. The solid lines represent the intensities before mixing. The broken lines represent the values calculated from Eq. 6 with the adjusted C values.

For the benzene+1,4-dioxane and carbon disulfide+cyclohexane mixtures, the observed values of ΔA_m seem to deviate from a symmetrical parabolic curve. Because of a moderately strong interaction between benzene and 1,4-dioxane,[7] the value of φ may change with mole fraction and cause the deviation from the random mixing model.[6] On the other hand, if the absorption due to trimolecular collisions is taken into account, the analytical form for the absorption of mixing will contain a term which has its maximum at $f=2/3$ or $1/3$. This term might also bring about the asymmetry of the ΔA_m curve. Although, at the present stage, it is not clear how much the trimolecular collision contributes to the absorption, it seems probable that the trimolecular absorption is considerably smaller than the bimolecular absorption[8] and that the main features of ΔA_m curve are governed by the latter. Then the deviation in the f-dependence of ΔA_m from Eq. 6 may be ascribed to the deviation in the mixing state from the random mixing. In order to get further insight into the mixing state, theoretical studies about the f-dependence of φ are needed.

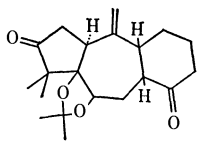
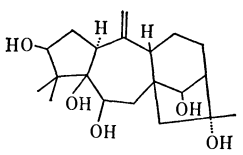
(Received June 13, 1978)

Synopsis. The molecular structure of the title compound has been determined by means of the X-ray method. The A, B, and C rings take half-chair, chair, and chair conformations, respectively, while the heterocyclic ring is of envelope form.

We report herewith on an X-ray study of the molecular structure of 5β,6β-isopropylidenedioxy-15,16,17-trinorgrayan-10(20)-ene-3,14-dione (**1**), obtained from the tetracyclic diterpene grayanotoxin II (**2**). Compound **1** was used as a link in the relay total synthesis of **2**.[1] The present study was undertaken in order to know the exact stereostructure and conformation of **1**.



1



2

Experimental

Single crystals of **1** were obtained as colorless plates or columns from an ethereal solution. A crystal with dimensions of $0.2\times0.2\times0.4$ mm^3 was used for the X-ray measurement. The crystal data are as follows: $C_{20}H_{28}O_4$, mp 208—211 °C; space group $P2_12_12_1$; $a=9.500(3)$, $b=21.524(4)$, $c=8.758(3)$ Å; $Z=4$, $D_c=1.233$ g·cm^{-3}. Both the cell dimensions and diffraction intensities were measured on a Rigaku four-circle diffractometer using Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) monochromatized with an LiF crystal. The intensities obtained were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ-values up to 140°, 1871 unique structure factor magnitudes above $\sigma(F_0)$ were selected for the structural study.

Structure Determination

The structure was determined by means of the Monte Carlo direct method.[2] The starting set was composed of the 10 strongest reflections given in Table 1. Tentative phase values for these reflections were derived from successively generated random numbers. In order to extend this tentative phase set, 10 cycles of the tangent procedure were performed using 380 E-values above 1.30. In this manner, the 40th phase set was extended to 367 phases, showing a low R_k-value of 23.5% ($R_k=\Sigma||E_o|-k|E_c||/\Sigma|E_o|$).[3] An E-map computed with these phases revealed the locations of all 24 non-hydrogen atoms.

It is of interest to compare the 40th random phase set with the correct phases calculated with the final atomic parameters. All the 10 reflections are not assigned phase values close to their correct phases (see Table 1). Great differences of 0.335π, π, and 0.434π can be seen for the (1 2 8), (3 0 7), and (2 19 3) reflections, respectively. It should be noted that, in spite of such great errors, this random phase set could lead to the correct structure. The structure thus obtained was refined by the block-diagonal-matrix least-squares method, first with isotropic temperature factors and then with anisotropic ones. The value $R=\Sigma||F_o|-k|F_c||/\Sigma|F_o|$ was reduced to 9.5%. After 28 hydrogen atoms had been found in a difference Fourier map, the least-squares refinement was repeated including these hydrogen atoms with isotropic temperature factors. For the refinement, the following weighting scheme was used:

$$W = 1/\{\sigma(F_0)^2 \exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. Coefficients A, B, C, D, and E were determined from $(\Delta F)^2$ values in each cycle. In this way, the R value reached 4.5%. The final parameters for the non-hydrogen atoms are given in Table 2.

Table 1. The 40th phase set and correct phases (in $10^{-3}\pi$)

	h	k	l	$\|E\|$	Correct	No. 40

The calculations for the present study were carried out on a FACOM 230-75 computer at the Computing Center of Hokkaido University, using our own programs. The atomic scattering factors were taken from International Tables for X-Ray Crystallography (1962), Vol. III. The tables of the observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 7911).

Results and Discussion

The molecular framework of **1** and the torsion angles for the tetracyclic system are shown in Figs. 1 and 2, respectively. Of the two five-membered rings, the A ring takes a somewhat distorted half-

chair form with an approximate two-fold rotation axis through the C(3) atom; the C(16) and O(2) atoms are equatorial and axial, respectively. On the other hand, the D ring takes an almost exact envelope form with an approximate mirror plane through the O(3) atom; the C(19) atom is axial. As a result of such ring conformations, the C(16) and C(19) atoms maintain a distance of 3.482(6) Å from each other. The seven-membered B ring takes a chair-like form and is nearly symmetrical with respect to a plane which runs through the C(9) atom, bisecting the C(5)–C(6) bond nearly perpendicularly. The six-membered C ring has a somewhat flattened chair form in which the axial positions in the C ring of the grayanane skeleton become equatorial and *vice versa*. All the observed bond distances and angles are normal; the average values for $C(sp^3)$–$C(sp^3)$, $C(sp^2)$–$C(sp^3)$, C=C, C–O, and C=O bond distances are 1.54, 1.51, 1.32, 1.43, and 1.21 Å, respectively.

The Principle of Corresponding States at Elevated Pressure

Kenji KUBOTA* and Kazuyoshi OGINO

Department of Pure and Applied Sciences, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received June 14, 1978)

Synopsis. The principle of corresponding states was examined at elevated pressure, and the validity of the assumption that the external degrees of freedom of the solution are given by linearity in the weight fraction of the components was examined without any model by use of the superposition method.

The principle of corresponding states[1,2] has been investigated extensively. Especially, the theory of moderately concentrated polymer solution thermodynamics[3,4] has shown newer development and made great success by the aid of the free volume theory.[5] In this theory, themodynamic quantities of the solution are represented by the characteristic parameters and the interaction energy parameter. This theory emphasizes the importance of the volume dependence of the free energy, and it is the elementary problem how the quantities characterizing the properties of the mixture are related to those of the respective components.[6] In this point, several model theories have been presented,[2-4] but, it is scarce that the characteristic parameters of the mixture are determined directly form P-V-T relations of it and are compared with those of respective components.[6,7] Moreover, it is of great importance that the volume dependence of the free energy should be examined from the pressure effect.[7] In this note, we examined the validity both of the principle of corresponding states at elevated pressure and of the assumption that the external degrees of freedom of the solution are given by linearity in the weight fraction of the components by use of the superposition method.

The examined systems are nitrobenzene,[8] aniline,[8] their mixture,[9] bromobenzene,[8] chlorobenzene,[8] *trans*-decalin,[10] and poly(dimethylsiloxane)[11] for the investigation of the principle of corresponding states at elevated pressure, and nitrobenzene-aniline,[9] poly(dimethylsiloxane)-benzene,[7] and poly(isobutylene)-benzene[12] for the investigation of the assumption for the external degrees of freedom.

According to the principle of corresponding states, the equation of states is represented by

$$f(\tilde{P},\ \tilde{V},\ \tilde{T}) = 0,\quad \tilde{P} = P/P^*,\quad \tilde{V} = V/V^*,\quad \tilde{T} = T/T^*, \tag{1}$$

where tilde and asterisk signify respectively the reduced quantities and the characteristic parameters. These characteristic parameters are related to each other by the relation

$$P^*V^* = T^*S^*, \qquad S^* = ck, \tag{2}$$

where c is the external degrees of freedom, and V^* and c are expressed in per gram.

Using these relations, thermal expansion coefficient and isothermal compressibility can be made to be dimensionless and reduced as follows:

$$\begin{aligned} \alpha T &= (\partial \ln V/\partial \ln T)_P = (\partial \ln \tilde{V}/\partial \ln \tilde{T})_{\tilde{P}} = \tilde{\alpha}\tilde{T}, \\ \beta P &= (\partial \ln V/\partial \ln P)_T = (\partial \ln \tilde{V}/\partial \ln \tilde{P})_{\tilde{T}} = \tilde{\beta}\tilde{P}. \end{aligned} \tag{3}$$

Accordingly, αT and βP are the universal functions of reduced quantities and should be expressed by a master curve. Since $\tilde{P} \simeq 0$ at atmospheric pressure, because P^* for these substances are few thousands bars, αT at atmospheric pressure plotted against $\ln T$ or $\ln V$ can be superposed by shifting along the abscissa. As $\beta P = \tilde{\beta}\tilde{P}$ gives $\ln\beta = \ln\tilde{\beta} - \ln P^*$, the curves of $\ln\beta$ *vs.* $\ln T/a_{T^*}$ can be superposed by shifting along the ordinate, since for the same value of T/a_{T^*}, $\tilde{T}$ is same each other. From these shift factors, a_{T^*} from αT *vs.* $\ln T$, a_{V^*} from αT *vs.* $\ln V$, and a_{P^*} from $\ln\beta$ *vs.* $\ln T/a_{T^*}$, the ratios of the characteristic parameters to those of the reference substance are obtained:

$$a_{P^*} = P^*/P_1^*,\quad a_{V^*} = V^*/V_1^*,\quad a_{T^*} = T^*/T_1^*, \tag{4}$$

where 1 implies the reference substance. The ratio of the external degrees of freedom are given from these by

$$c/c_1 = a_{P^*}a_{V^*}/a_{T^*}. \tag{5}$$

Moreover, at the same value of P/a_{P^*}, αT *vs.* $\ln T/a_{T^*}$ should give the well superposed one curve. By use of a_{T^*} and a_{V^*}, the universal relation of V/a_{V^*} *vs.* T/a_{T^*} is also obtained. This correspeonds to the intersection of $f(\tilde{P},\tilde{V},\tilde{T})$ with $\tilde{T}$-$\tilde{V}$ surface of $\tilde{P}$-$\tilde{V}$-$\tilde{T}$ space. In this way, without any model theory the characteristic parameter (ratio) is determined and the principle of corresponding states at elevated pressure is examined.

The superposed curves of αT *vs.* $\ln T/a_{T^*}$ at 1, 400, and 800 bar for nitrobenzene (reference substance)—P_1 in Figs. 1 and 2—are shown in Fig. 1. They are well superposed and show that a^*'s in Eqs. 4 determined at atmospheric pressure is proper even for elevated pressure and does not change with pressure. This is shown also in Fig. 2 for the relation between T/a_{T^*} and V/a_{V^*} at various pressures. Though it is not shown in Figs. 1 and 2 (since the range of αT is beyond that of these Figs.), the superposition is well performed for poly(dimethylsiloxane)-benzene and poly(isobutylene)-benzene mixtures. Therefore, at elevated pressure the principle of corresponding states is valid and the superposition is applicable.

The relation of the external degrees of freedom for nitrobenzene-aniline, poly(dimethylsiloxane)-benzene, and poly(isobutylene)-benzene mixtures determined as the above with the weight fraction could not be expressed by linearity. For example, c/c_1 *vs.* weight fraction of aniline for nitrobenzene-aniline mixture is shown in Fig. 3. In all cases, negative discrepancy

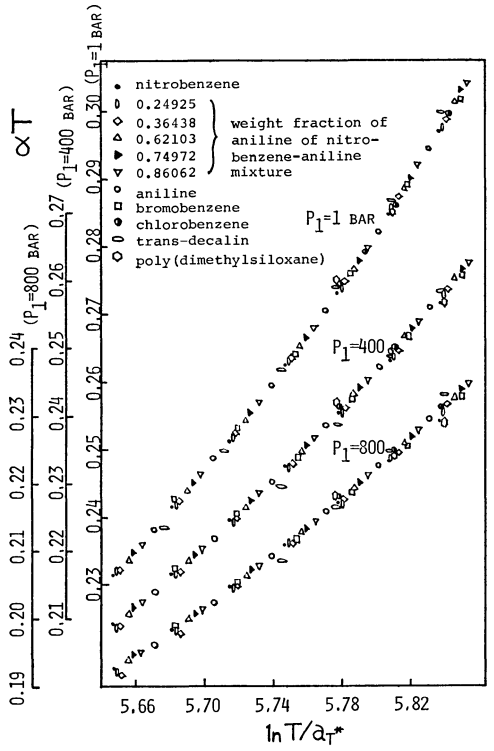

Fig. 1. The superposed curve of αT plotted against $\ln T/a_T*$. The indicated pressure, P_1, is for nitrobenzene (reference substance).

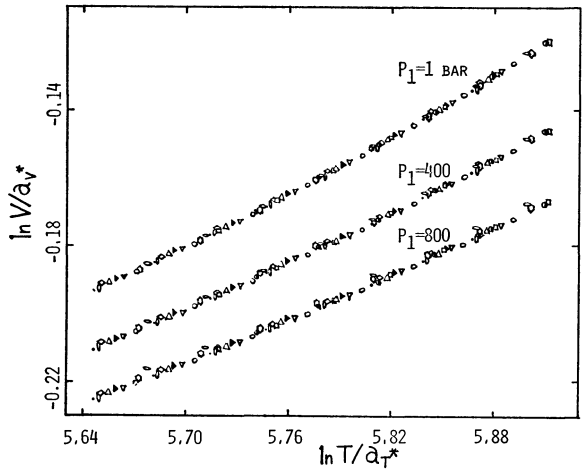

Fig. 2. The superposed curve of $\ln V/a_V*$ *vs.* $\ln T/a_T*$. The symbols for the substances are same as in Fig. 1.

was observed. In poly(dimethylsiloxane)–benzene the discrepancey is about 1.4% at 50% weight fraction and in poly(isobutylene)–benzene that is about 0.9% at 50%. This discrepancy corresponds to Q_{12}, entropy correction term of the new Flory theory.[3] This implies that the relation of the external degree of freedom with concentration much influences to the theoretical prediction for the solution thermodynamics, and the assumption of linearity is open to further consideration.

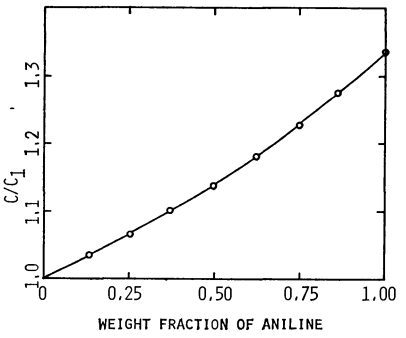

Fig. 3. The relation of the ratio of the external degrees of freedom of nitrobenzene–aniline mixture with weight fraction of aniline.

Table 1. Characteristic parameters at 30 °C and atmospheric pressure determined by use of the newer Flory theory

	$P*$ (Bar)	$V*$ (cm³/g)	$T*$ (K)
Nitrobenzene	7198	0.6898	5863
trans-Decalin	5063	0.9487	5726
Poly(dimethylsiloxane)	3390	0.8410	5563

For comparison, the characteristic parameters determined by the newer Flory theory for nitrobenzene, *trans*-decalin, and poly(dimethylsiloxane) are tabulated in Table 1. These are the values obtained at 30 °C and atmospheric pressure.

A Refinement of the Crystal Structure of Creatine Monohydrate

Yoshihiro KATO,* Yoshitaka HAIMOTO, and Kiichi SAKURAI
Department of Physics, Osaka Kyoiku University, Tennoji-ku, Osaka 543

(Received July 10, 1978)

Synopsis. The crystal structure of creatine monohydrate has been refined from three-dimensional X-ray data. This refinement introduces minor modifications to the positional and thermal parameters and confirmed the zwitter ion structure.

Mendel and Hodgkin[1] have determined the crystal structure of creatine monohydrate from three-dimensional X-ray data and inferred that the structure of the molecule corresponds to that of a zwitter ion. They calculated the *h0l* structure factors including hydrogen atoms placed at the probable positions, but the intensity data were not accurate enough to warrant the hydrogen atom positions. The present paper describes a refinement of the structure, which has determined the positions of the hydrogen atoms and confirmed that the molecule adopts a zwitter ion form.

Experimental

The intensities of 1411 independent reflections were measured visually from Cu $K\alpha$ Weissenberg photographs taken about b ($k=0$—4) and c ($l=0$). The cross-section of the crystal used was 0.35×0.35 mm. Corrections for Lorentz and polarization factors were applied in the usual way, but no correction for absorption was made. The lattice constants were determined from photographs taken with a Buerger's back-reflection Weissenberg camera calibrating the camera radius by using a silver wire. The crystal data are as follows: $a=12.510(6)$, $b=5.048(1)$, $c=12.191(1)$ Å, $\beta=108.9(3)°$, $P2_1/c$, $Z=4$.

Refinement of the Structure

Using the positional and thermal parameters taken from the previous determination,[1] the three-dimen-

a) The values given by Mendel and Hodgkin. The standard deviations in all bond lengths are 0.01 Å and those in bond angles are 4°. b) Hydrogen-bond distances.

sional refinements were carried out by the block-diagonal least-squares method for non-hydrogen atoms. The weighting scheme of the type $1-\exp(-15\,s^2)$ with $s=\sin\theta/\lambda$ was used. At a later stage of the refinement, hydrogen atoms were included in the calculations with a fixed thermal parameter ($B=3.5$ Å^2) and fixed positional parameters deduced from an F_o-F_c Fourier synthesis (Fig. 1). The final R value was 0.096. The final positional parameters are given in Table 1 together with those reported by Mendel and Hodgkin.[1] The thermal parameters are given in Table 2. A list of the observed and calculated structure factors are kept in the office of the Chemical Society of Japan (Document No. 7906).

The calculations were carried out on a NEAC SYSTEM 800 computer of the Computation Center of Osaka University using the program *HBLS V* written by Y. Okaya and T. Ashida for the least-squares refinement.

Description and Discussion of the Structure

The atoms N_1, N_2, C_1, and N_3 of the guanidine group are on the plane $0.2226X-0.6380Y+0.7371Z-1.6408=0$, and C_3, C_4, O_1, and O_2 are on the plane $0.3177X+0.6774Y+0.6634Z-6.3695=0$, where X, Y, and Z are referred to the orthogonal axes a, b, and c^* (Å). These planes intersect at an angle of 82.7° with each other. The interatomic distances and bond angles are listed in Table 3, which shows that these values are in good agreement with those reported by Mendel and Hodgkin.[1]

The F_o-F_c Fourier synthesis indicated clearly all the hydrogen atoms (Fig. 1). The four hydrogen atoms attached to the guanidine group are about 1 Å away from N_1 and N_2 atoms, while there appears no hydrogen peak around the carboxyl group, which shows that the hydrogen atom of the carboxyl group is transferred to the guanidine group. The molecule of creatine, therefore, corresponds conclusively to that of a zwitter ion in the crystal.

Radical-Ion Interaction. Diphenylmethyl and Triphenylmethyl Radicals Generated by the Dissociative Electron Attachment to Halogenated Compounds in Rigid Matrices

Tatsuo IZUMIDA, Yoshio TANABE, Tsuneki ICHIKAWA, and Hiroshi YOSHIDA*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received July 21, 1978)

Synopsis. Dissociative electron attachment to diphenylmethyl halides and triphenylmethyl halides in a γ-irradiated 3-methylhexane matrix at 77 K generates free radicals temporarily associated with a counterpart halide ion. The association is indicated by changes in the fluorescence and excitation spectra of the radicals as well as the charge-transfer excitation band of the radical-ion complexes.

Temporary radical-ion association has been indicated by the fluorescence spectrophotometric method for benzyl radicals[1-3] and the methyl-substituted derivatives (at the phenyl ring[2] and at the methylene position[4]) generated by the dissociative electron attachment to the corresponding halogenated compounds such as benzyl halides in organic glassy matrices γ-irradiated at 77 K. The radical-ion interaction causes the wavelength shift and the change in the vibration band structure of the benzyl spectra as well as the decrease in the fluorescence lifetime. The interaction has also been indicated by the charge-transfer band of the benzyl radical-halide ion complexes in nonpolar hydrocarbon matrices. The interaction is absent in a polar ethanol matrix probably because of the solvation of the halide ions. The temporary radical-ion association before complete dissociation appears as a general feature in solid state radiation chemistry and adds a new aspect to the molecular spectroscopy of radical intermediates. The study was extended to diphenylmethyl and triphenylmethyl radicals, because they show a similar absorption character to that of the benzyl radicals.[5-8] The triphenylmethyl radical shows an intense near-UV absorption due to the allowed $A_2''\leftarrow E''$ transition and a weak visible absorption due to the forbidden $A_1''\leftarrow E''$ transition. The assignment is based on the assumed D_{3h} symmetry of the radical. The forbidden transition is observable because of a slight deviation from the assumed planar configuration.[7] A similar assignment may be applicable to the diphenylmethyl radical.

Experimental

Diphenylmethane, dephenylmethyl chloride (Ph_2CHCl) and bromide (Ph_2CHBr), and triphenylmethyl chloride (Ph_3CCl) and bromide (Ph_3CBr), of analytical grade, were used as received. The solvents, 3-methylhexane (3MHx) and ethanol (EtOH), were purified as described elsewhere.[2] The solutions (10^{-2}—10^{-3} mol·dm^{-3}) were prepared under vacuum of *ca.* 10^{-5} Torr, sealed in quartz tubes (i.d. 4 mm), frozen by liquid nitrogen into the glassy state, and irradiated at 77 K with ^{60}Co γ-rays to a dose of *ca.* 5×10^4 rad or with unfiltered light from a high pressure mercury lamp. The fluorescence and fluorescence excitation spectra of the irradiated samples were recorded with a conventional fluorescence spectrophotometer (Hitachi, Model MPF-2A) at 77 K.

Results and Discussion

Diphenylmethyl Radical. When the diphenylmethyl (Ph_2CH) radical is generated by the dissociative electron attachment to Ph_2CHCl in the γ-irradiated EtOH matrix, the highest peak in the fluorescence spectrum is at 523 nm and the highest peak in the excitation spectrum is at 337 nm as shown in Fig. 1A. These spectra are essentially the same as those reported previously.[5-7] The excitation spectrum in the visible region is however too weak to be recorded. Although the vibration band structure is not well resolved, as is usually the case for glassy matrix samples, the peaks mentioned above indicate the wavelength of the 0-0 band for the electronic transitions in the near-UV and visible regions. The photolysis of Ph_2CH_2 gives also

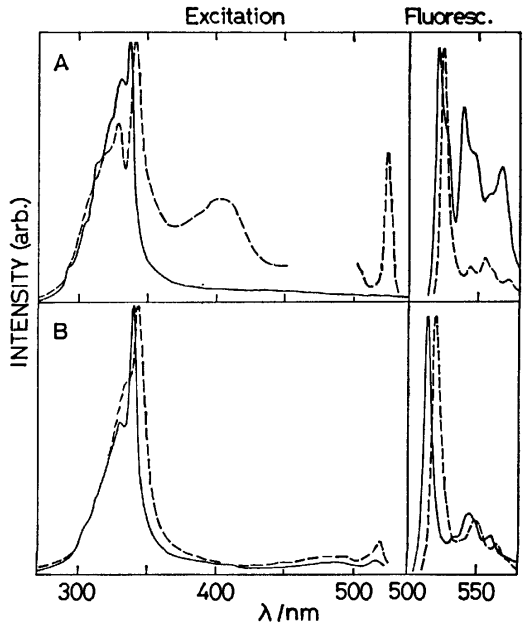

Fig. 1. Fluorescence and excitation spectra of (A) Ph_2CH radical generated from Ph_2CHCl and (B) Ph_3C radical generated from Ph_3CCl (——) in the EtOH matrix and (- - -) in the 3MHx γ-irradiated at 77 K. The spectral shape in the wavelength 460—500 nm shown by the dashed curve in A could not be determined because of the resonance lines of the Xe lamp used as a excitation source. Th excitation wavelengths and the monitoring one are generally at the highest peak of the fluorescence spectra and the excitation ones.

a) The 0-0 band of the fluorescence spectrum. b) The 0-0 band of the near-UV excitation spectrum. c) The peak of the CT excitation spectrum. d) The figures in parentheses give the wavelength after melting and refreezing of the irradiated samples. e) A satellite peak was observed at 395 nm.

the same spectra except that they overlap with the spectra of the benzyl radical attributed to the loss of a phenyl ring from the parent molecule. The Ph_2CH radical generated from Ph_2CHCl in the γ-irradiated 3MHx matrix gives a different spectra from those observed from the EtOH matrix (Fig. 1A): the spectra shift to the red, and the vibration band structure so changes that the 0-0 band comparatively increases in intensity. The visible excitation spectrum becomes intense enough to be recorded. These features are the same as those observed for the benzyl radicals and have been interpreted as the effect of the proximity of the halide ions to the radicals.[2] A similar phenomenon has been observed for the Ph_2CH radical from Ph_2CHBr, as representatively shown for the spectral red-shift in Table 1. In the EtOH matrix, the halide counter-ion is solvated with polar matrix molecules, so that the radical-ion interaction no longer affects the spectra of the Ph_2CH radical.

The radical-ion interaction has also been indicated by the presence of a broad unstructured excitation band at 405 nm observed from Ph_2CHCl in the 3MHx matrix (Fig. 1A). A similar band has been recorded for Ph_2CHBr at 460 nm with a satellite peak at 395 nm. Assignment has been made to the CT band of the Ph_2CH radical-halide ion complexes; the former having a large electron affinity acts as an electron acceptor, and the latter with a small ionization energy (the electron affinity of Cl and Br atom is 3.61 and 3.36 eV[9]) as an electron donor. The CT transition energy approximates to. $h\nu_{CT}=IP(X^-)-EA(R\cdot)+E_s(R\cdot\!-\!-X^-)-E_s(R^-\!-\!-X)$, where IP and EA represent the ionization energy and the electron affinity, and E_s is the solvation energy before and after the transition. $E_s(R\cdot\!-\!-X^-)$ can be expressed approximately by Born's formula, $E_s(X^-)=(e^2/2r)(1-1/D)$, where r is the effective radius of the halide ion and D is the dielectric constant of the matrix. The difference in the CT transition energy between 3.1 eV (405 nm) and 2.7 eV (460 nm) of 0.4 eV for Cl^- and Br^- as a counter-ion agrees well with 0.45 eV, the difference of $IP(X^-)+E_s(X^-)$ calculated from the dielectric constant, 2.0, for 3MHx[10] and the ionic radius, 0.164 and 0.180 nm for Cl^- and Br^-.[11] The energy difference between the main peak and the satellite one, 0.44 eV, observed for the Ph_2CH–Br^- complex may be interpreted as being due to the splitting of the CT excited state caused by the large separation between the $^2P_{3/2}$ and $^2P_{1/2}$ states of the bromine atom, 0.459 eV.

Triphenylmethyl Radical. Triphenylmethyl (Ph_3C) radicals generated from Ph_3CCl and Ph_3CBr in the γ-irradiated EtOH and 3MHx matrices give the spectra, as shown in Fig. 1B, of which the spectroscopic parameters are given in Table 1. The "free" Ph_3C radical in the EtOH matrix shows a visible fluorescence spectrum as well as a weak excitation spectrum in the visible region and an intense one in the near UV region. The Ph_3C radical in the 3MHx matrix shows a red-shift of the spectra (see Table 1) and an increase in spectral intensity in the visible region. The above observations indicate a radical-ion interaction for the Ph_3C radical.

Removal of the halide counter-ion produces further evidence for the interaction. The Ph_3C radical is so stable that it persists on melting the irradiated samples. The spectra of the Ph_3C radical in the 3MHx matrix changes and becomes identical with the spectra observed from the EtOH matrix, when examined after melting and refreezing. This change has been attributed to the removal of the counter-ion. The spectra observed from the EtOH matrix show no change upon melting and refreezing, since the radical is initially "effectively free" from the counter-ion in the matrix.

No CT band was recorded for the Ph_3C radical-halide ion complex in the 3MHx matrix. The intermolecular conformation adequate to the CT interaction is sterically inhibited for the bulky Ph_3C radical. However, the present investigation gives spectroscopic evidence for the temporary radical-ion association for the Ph_3C radical, as well as for the Ph_2CH radical, generated by the dissociative electron attachment in the irradiated nonpolar 3MHx matrix at 77 K.

Kinetics on the Formation and Transformation of Alkoxy-derived $SrSiO_3$

Osamu YAMAGUCHI,* Kenzo MATSUMOTO, and Kiyoshi SHIMIZU*

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received April 17, 1978)

Synopsis. A metastable modification of $SrSiO_3$ was formed at 850—910 °C from mixed powders prepared by the alkoxy-method. Crystallization isotherms were best described by the first-order equation and the activation energy was determined as 130 kcal/mol. The kinetics on the transformation of metastable to stable $SrSiO_3$ was also studied.

Though $SrSiO_3$ is known only in the pseudo-wollastonite modification,[1] Takahashi and Roy[2] reported that a new modification is obtained by heating the $SrSiO_3$ glass prepared by the splat-cooled method. It was found that this compound, apparently metastable, is formed during the course of heating of alkoxy-derived $SrSiO_3$. The present study is concerned with the kinetics on the formation of metastable $SrSiO_3$ and the transformation of metastable into stable $SrSiO_3$.

Experimental

Silicon ethoxide used was of guaranteed purity. Strontium methoxide was prepared by the reaction of strontium metal and dehydrated methyl alcohol. The purity of strontium metal used was 99%. A mixture of these alkoxides with the mole ratio $Sr^{2+}/Si^{4+}=1:1$ was prepared, and then poured into aqueous solution of ammonia at *ca.* 30 °C. The temperature was slowly raised up to 90 °C with stirring. The mixed powders hydrolyzed in this way were washed repeatedly with hot distilled water and dried at 40 °C under reduced pressure. The average particle size of the mixed powders is approximately 400—500 Å.

Results and Discussion

The TG of the mixed powders was carried out in the air from room temperature to 1000 °C(Fig. 1). The weight loss of 11% up to 650 °C is attributed to the loss of absorbed H_2O, NH_3(aq), and organic residue from the parent alcohol. DTA of the mixed powders was also performed. Two exothermic reactions were observed at 850—910 °C and 950—1020 °C. From the results of X-ray diffraction, the reactions were found to be the crystallization of metastable $SrSiO_3$ from an amorphous phase and the transformation of metastable into stable $SrSiO_3$, respectively.

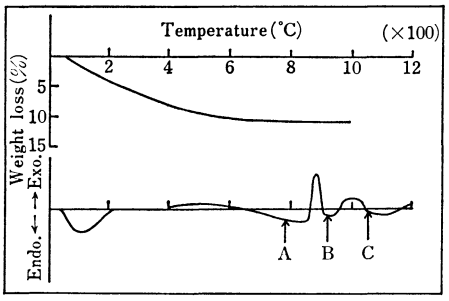

Fig. 1. TG and DTA curves of alkoxy-derived powder. Arrows show the temperatures at which the starting material was heated to obtain three specimens for X-ray diffraction.

Figure 2 shows the variation of X-ray diffraction patterns of $SrSiO_3$ with increasing temperature. The mixed powders as a raw material were amorphous, no significant changes being observed up to 820 °C. The peaks corresponding to metastable $SrSiO_3$[2] appeared after heat treatment at 850 °C for 20 min, and the intensity increased rapidly up to 900 °C. The specimen heated at 1050 °C showed an X-ray diffraction pattern of only stable $SrSiO_3$.[3]

Figure 3 shows the fraction of the metastable $SrSiO_3$

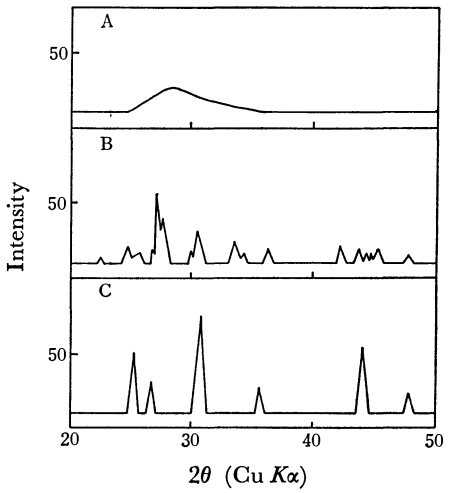

Fig. 2. X-Ray diffraction patterns for alkoxy-derived $SrSiO_3$ powder.

crystallization determined for 850, 870, and 890 °C. The mixed powders were pre-heated at 400 °C for 15 min. The fraction of crystallization of each specimen was determined from the height of $d=3.28$ Å($2\theta=27.2°$) which is the strongest line of the metastable $SrSiO_3$ spectrum. A well-crystallized specimen was obtained by heating the alkoxy-derived mixed powders at 900 °C for 30 min. Calcium fluoride was used as a standard material. Induction periods were observed, attempts being made to fit the results to kinetic laws by considering the induction periods. The data can be interpreted in terms of the first-order equation. Figure 4 shows the first-order plots of $-\ln(1-\alpha)$ against t, where α is the fraction of crystallization and t time. The rate constants were determined from the slopes of straight lines. The value of activation energy calculated from the Arrhenius plot was *ca.* 130 kcal/mol. This represents the activation energy employed for establishing active nucleation centers.[4]

Figure 5 shows the fraction of the transformation of metastable into stable $SrSiO_3$ as a function of time at different temperatures. The specimens heated at 900 °C for 30 min were used as starting material. The

fraction of transformation was established by determining the decrease of height of the strongest line($d=3.28$ Å) in the metastable diffraction pattern. Transformation isotherms were described by the zero-order equation $\alpha=kt$, where α is the fraction of transformation, t time and k the rate constant of propagation.[4] The result suggests that the transformation, which might take place in two processes(Fig. 5, broken line), is due to only a rearrangement of atoms or ions within the crystal, no penetration of a new phase from the surface being required. The values of activation energy were *ca.* 143 kcal/mol and 44 kcal/mol for initial and final stages, respectively.

Effect of Gelatin on the Reduction of Cobalt(II) in Thiocyanate Solutions at Mercury Electrodes

Eiki ITABASHI* and Kumiko TAKAYA
Miyagi University of Education, Aoba, Aramaki, Sendai 980

(Received May 19, 1978)

Synopsis. Reduction of cobalt(II) in thiocyanate solutions at mercury electrodes has been greatly accelerated in the presence of small amounts of gelatin. This accelerating effect results in an inhibition of the amalgamation of electrodeposited Co(0)SCN^-, which reacts chemically to yield CoS and CN^-. Both CoS and CN^- further stimulate the reduction of cobalt(II).

Recently, it has been shown that the reduction of cobalt(II) in thiocyanate solution at a hanging mercury drop electrode(HMDE) is accelerated by the reduction products of thiocyanate ions, cyanide and sulfide ions, produced by the chemical reduction of thiocyanate ion with the electroreduced metallic cobalt.[1] It is expected that the reduction rate of cobalt(II) in thiocyanate solution is further stimulated by the presence of surfactants, because the amalgamation of the electrodeposited cobalt is known to be inhibited by the presence of some surfactants.[2,3] It was indeed found that the reduction of cobalt(II) in thiocyanate solutions at dropping and stationary mercury electrodes was greatly accelerated in the presence of low concentrations of gelatin. This paper deals with the characteristics of the reduction wave of the above-mentioned system.

Experimental

The dropping mercury electrode(DME) had a flow rate of 0.95_6 mg s^{-1} at the controlled drop time of 4.95 s in deaerated 0.5 mol dm^{-3} $NaNO_3$ solution at −0.65 V *vs.* SCE for a mercury height of 60 cm. All the other experimental details were the same as previously described.[1] In Fig. 1, "current" means the maximum current observed just before the fall of the mercury drop.

Results and Discussion

The influence of gelatin on the dc polarograms is shown in Fig. 1. Cobalt(II) in dilute thiocyanate solution gave a pre-wave which was produced at potentials more negative than those for the usual hydrated cobalt(II) reduction wave. This pre-wave increased in height with increase in thiocyanate concentration up to *ca.* 0.1 mol dm^{-3}. The present experiments, however, were performed with dilute thiocyanate solution, because the most significant effect of gelatin has been observed at a thiocyanate concentration below 0.03 mol dm^{-3}. Upon the addition of gelatin to the solution, the pre-wave increased in height with increase in concentration of gelatin up to *ca.* 5×10^{-3} %. With further addition of gelatin above 1×10^{-2} %, the opposite effect was observed. When trace amounts of gelatin was added, the maximum wave accompanying the hydrated cobalt(II) reduction

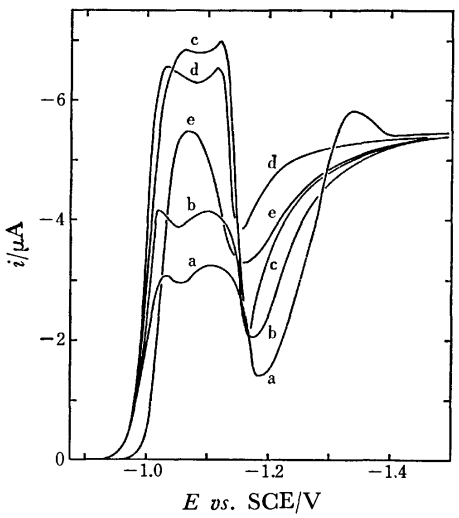

Fig. 1. Effect of concn of gelatin on the d.c. polarograms of 1 mmol dm^{-3} cobalt(II) in 0.01 mol dm^{-3} NaSCN and 0.49 mol dm^{-3} $NaClO_4$ at 25 °C. Gelatin concentration/%: (a), 0; (b), 1×10^{-3}; (c), 2×10^{-3}; (d), 5×10^{-3}; (e), 2×10^{-2}.

wave observed at potentials more negative than −1.20 V was completely suppressed, and the hydrated cobalt(II) reduction wave shifted to somewhat less negative potentials. Such a shift of the reduction potential appears to be generally characteristic of the hydrated cobalt(II) reduction wave. There have been several investigations on the positive shift of the hydrated cobalt(II) reduction wave in the presence of low con-

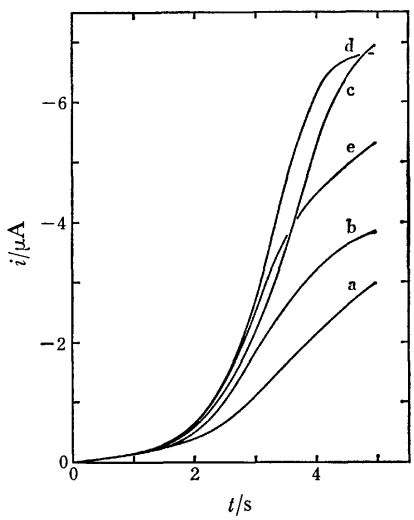

Fig. 2. Effect of concn of gelatin on the *i-t* curves with a DME at −1.05 V *vs.* SCE. Conditions are the same as Fig. 1.

centrations of some surfactants.[2,3]

The influence of gelatin on the current-time (*i-t*) curves for the pre-wave during the life of a mercury drop is shown in Fig. 2. The instantaneous current in a dilute thiocyanate solution in the absence of gelatin varies exponentially. This clearly indicates that the reaction mechanism of the pre-wave in dilute thiocyanate solution is autocatalytic in nature. The theoretical treatment of Laviron[4] predicts that the *i-t* curve varies exponentially for the catalytic polarographic wave involving a product of the electrode reaction. In the presence of gelatin, the *i-t* curves exhibit a sigmoid shape.

Figure 3 illustrates the influence of gelatin on the *i-t* curve obtained with a HMDE. In the potential region corresponding to the polarographic pre-wave, the *i-t* curves exhibited a maximum. With trace amounts of gelatin present, the diffusion-controlled current level is reached within several seconds. The falling portion after a maximum in the presence of gelatin follows an $i\text{-}t^{-1/2}$ relationship, indicating a diffusion-controlled mechanism.

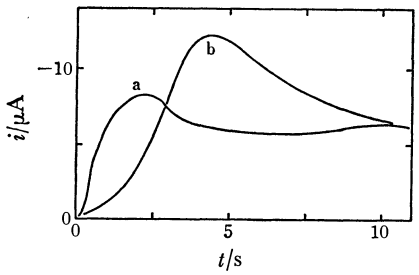

Fig. 3. *i-t* curves with a HMDE for the reduction of 1 mmol dm^{-3} cobalt(II) in 0.01 mol dm^{-3} NaSCN and 0.49 mol dm^{-3} $NaClO_4$ solutions in the absence (a) and presence (b) of 5×10^{-3}% gelatin. Electrode potential −1.05 V.

It has been recognized that the amalgamation of freshly deposited iron-group metals is inhibited by the presence of some surfactants.[2,3] The increase of the pre-wave height in the presence of small amounts of gelatin is accounted for by assuming an inhibition of the amalgamation of electrodeposited $Co(0)SCN^-$, which in part reacts chemically to yield CoS and CN^-. Cobalt sulfide as well as cyanide ion stimulates further reduction of cobalt(II). $Co(II)\text{–}CN^-$ complex is more easily reduced at the mercury electrode than the $Co(II)\text{–}SCN^-$ complex.[1] With large concentrations of gelatin present, the pre-wave becomes suppressed, gelatin then replacing the adsorbed thiocyanate ions from the surface of the electrode.

Dynamic Calibration and Memory Effect for Fluoride Ion Selective Electrode

Yoshio UMEZAWA,* Minoru NAGATA,† Katsuhiko SAWATARI, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 9, 1978)

Synopsis. The dynamic calibration of the F^- ion selective electrode was briefly evaluated in terms of the memory effect of the electrode by analyzing the NBS urine standard.

Liberti and Pinto[1] reported the "dynamic" calibration for the iodide ion selective electrode, where the electrode response after a selected time is compared with a calibration curve obtained by contacting the electrodes with standard solutions for the same time. Thus we can continuously monitor quickly changing concentrations, although the response is not necessarily rapid. For most of the solid membrane electrodes such as the fluoride ion electrode, the response time is less than 30 s when we define the response time as the time necessary to cover 95% of the equilibrium potential. The 95% attainment of the equilibrium potential involves about 30% error in the concentration at around 10^{-5} M of F^- ions. If we define the response time as the time to reach 0.2 mV pre-equilibrium potential, for example, the resulting error is 0.2% in terms of concentration, but causes much longer response time as shown in Table 1. This result implies that in the case of ordinary analysis, we are inherently using the dynamic calibration procedure, because final potentials are read in several minutes at longest. On the other hand, one of the main factors which affects the accuracy of results for ion selective electrodes at lower concentration range seems to be the "memory effect." Usually, the calibration curve is constructed by changing the concentration from low to high. In most cases, the concentration of the sample is located at around the middle of the calibration curve. This means one has to come back from higher concentration to lower one to measure the analyte concentration in the sample right after making calibration curves. Hence, the electrode inevitably remembers the higher concentrations of the previous runs causing an error in analysis even when the electrode surface is thoroughly rinsed after each run. This would also hold true for continuous analyses where the concentration could change up and down in a short time.

a) F^- ion selective electrode of DKK. b) Necessary time to reach 0.2 mV pre-equilibrium potential.

† Present adress: Denki Kagaku Keiki Co., Kichijoji-kitamachi 4-13-14, Musashino-shi, Tokyo 180.

In the present study, the dynamic calibration procedure was briefly evaluated in terms of the memory effect of the fluoride ion selective electrode by estimating the minimum time required for accurate F^- ion determination in the NBS human urine standard as illustrative example for natural samples. If the dynamic calibration works also satisfactorily for the natural systems, it would be extremely useful for clinical or environemental analysis where rapid and continuous measurements are highly desirable.

Experimental

In order to obtain precise and accurate hard copies of the potential *vs.* time profile of the ion selective electrodes, a special experimental set-up was made.[2] The analog output from the ion selective electrode is first converted into frequencies followed by counting, serialization, and finally data acquisition with a minicomputer. The precision of analog to digital conversion is 0.1 mV.

The dried urine fluoride standard sample (NBS SRM No. 2671) was dissolved in TISAB (Total ionic strength adjustment buffer) solution. The TISAB solution was prepared by dissolving 1 M NaCl, 0.25 M CH_3COOH, 0.75 M CH_3COONa, and 0.001 M sodium citrate in 1 litre of deionized and distilled water. The value recommended by NBS for the fluorine content in this solution is $(4.39\pm0.43)\times10^{-5}$ M (reliability 95%). The result of determination of fluoride ion in this NBS sample by fluoride ion selective electrode coincides with the value recommended by NBS. The total fluorine for the same solution by AlF molecular absorption spectrometry in carbon rod furnace[3] coincides with that of ion selective electrodes and of the NBS value within experimental error.[4] It seems that very little matrix effect exists and almost all fluorine containing species are of the form of free fluoride ion in the dissolved NBS standard sample. The magnitude of the error in the NBS value is rather large presumably due to the average of different lots. Thus, each bottle from the NBS probably contains a homogenous sample and the resulting analytical value should have higher precision. The response time of the fluoride ion selective electrode was examined with four electrode specimens, one from TOA and the other three from DKK. It was found that except for one from DKK which exhibited slightly slower response, three showed almost equal response time (Table 1). Therefore, the experiment concerning the memory effect was performed by using two electrode specimens from DKK, both of which gave virtually the same results (Tables 2 and 3).

Chemicals of analytical grade were used. Water was deionized and distilled. Fluoride ion selective electrodes from Denki Kagaku Keiki Co. (DKK) and TOA Dempa Co., Ltd., were used. An Ag/AgCl electrode of TOA Model HS 305 DP was used as a reference electrode. All fluoride ion selective electrodes were rinsed, excess water being wiped off before and after each run. For the dissolved NBS sample, the response time obtained is virtually equal to or slightly shorter than that of the ordinary F^- ion standard solution.

The measurement was performed in a constant temperature bath in a constant temperature room, both thermostated at 20±0.5 °C. The sample solution was stirred with a magnetic stirrer.

Results and Discussion

Table 2 shows the apparent concentration of F^- ions in the NBS standard urine sample obtained through the dynamic calibration curves at different waiting times. We deal with two cases: Analysis of the NBS sample is made after the measurements of 1) 1×10^{-4} M and 2) 1×10^{-5} M of the standard solutions for the calibration curves. The F^- ion concentrations for the NBS sample lies between these concentrations. The apparent concentration of F^- ions obtained in the NBS standard urine sample is initially higher than the NBS value for case 1) and gradually decreases to a nearly steady state value, C_1, in about 9 min. This value is consistent with the NBS value, indicating that the memory effect is completely removed. For actual analyses where the concentration of the analyte is not known, it is not clear whether the error from the memory effect is still involved in the C_1 value. Thus the following experiment corresponding to case 2) was performed. The apparent F^- concentration obtained in the NBS standard is initially lower than that of the NBS recommended value in contrast to case 1, increasing gradually to a steady state value, C_2, in about 6 min. The value is also consistent with the NBS value. From these results, it can be concluded that the most accurate method to remove the memory effect completely is to obtain the value C_0 which lies on the asymptotic line between the two concentration-time profiles, nearly equal to both C_1 and $C_2(C_1 \fallingdotseq C_2)$. This procedure may be called "double calibration." The memory free accurate result can be obtained when the waiting time exceeds 6—9 min. The lower the concentration of the analyte, the lower the accuracy (Table 3). However, even in the presence of the memory effect, we can still obtain fairly accurate results with a *ca.* 20 % error for 10^{-5} M NBS urine standard solution at a waiting time of 6 s.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 52 (1), 243—244 (1979)

Absorption and Circular Dichroism Spectra of Bis(ethylenediamine)-(1,3-diamine)cobalt(III) Complexes

Kazuo KASHIWABARA, Masaaki KOJIMA, Sumio ARAKAWA,[1] and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received June 30, 1978)

Synopsis. New bis(ethylenediamine)cobalt(III) complexes containing various 1,3-diamines have been prepared and resolved (or separated) into optical isomers. The preferred conformations of six-membered 1,3-diamine chelate rings in these complexes seem to be reflected on the absorption and circular dichroism spectra.

In the previous papers,[2,3] we reported that the stable conformations of flexible six-membered chelate rings in some tris(1,3-diamine)cobalt(III) complexes can be elucidated from their absorption and circular dichroism(CD) spectra in the region of the first absorption band. In this note, we have extended such studies to cobalt(III) complexes of the type, $[Co(en)_2(1,3\text{-diamine})]^{3+}$. The diamines used here are (*R,R*)- and (*R,S*)-2,4-pentanediamine(ptn), (*S,S*)- and (*R,S*)-1,3-diphenyl-1,3-propanediamine(dppn), (*S*)-1,3-butanediamine(bn), and (*S*)-1-phenyl-1,3-propanediamine(phtn).

Experimental

Ligands. 1,3-Diamines were prepared by the methods described previously; (*R,R*)- and (*R,S*)-ptn,[4] (*S,S*)- and (*R,S*)-dppn,[5] (*S*)-bn,[6] and (*S*)-phtn.[7]

Complexes. The $[Co(en)_2(1,3\text{-diamine})]^{3+}$ complexes were prepared from 1,3-diamine and *trans*-$[CoCl_2(en)_2]Cl$ in dimethyl sulfoxide according to a method similar to that for $[Co(en)_2(tn)]^{3+}$ (tn=trimethylenediamine).[8] The separation (or resolution) of diastereomers (or enantiomers) except the *R,S*-dppn complex were achieved by SP-Sephadex column chromatography using a 0.2 mol·dm^{-3} Na_2SO_4 or a 0.2 mol·dm^{-3} sodium $(+)_{589}$-tartrate solution as the eluent. The racemic $[Co(en)_2(R,S\text{-dppn})]Br_3\cdot 3H_2O$ complex was resolved with $K_3[Co(S\text{-cysu})_3]\cdot 6H_2O$(cysu=cysteinesulfinato(2−)-SN).[9] The addition of an aqueous solution (30 cm^3) of the resolving agent (1.4 g) to an aqueous solution (30 cm^3) of the complex(1.5 g) gave immediately orange precipitate, which was recrystallized from hot water several times. The product was suspended in water and 1 mol·dm^{-3} hydrobromic acid(20 cm^3) was added to the suspension. The solution became orange and insoluble material ([Co(*S*-Hcysu)$_3$]) was filtered off. The filtrate was evaporated to dryness and the residue was recrystallized from water to give Λ-$[Co(en)_2(R,S\text{-dppn})]Br_3\cdot 3H_2O$.

The results of elemental analysis are given in Table 1.

Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-20 Spectropolarimeter, respectively.

Table 1. Analytical data of the complexes

S-phtn	Λ(ch, λ)	20.94 (113)	20.37 (+1.08)

a) The conformations of L(1,3-diamine) are those with equatorially disposed substituents, and the λ and ch represent the λ-skew and the chair conformations, respectively. b) The absolute configuration of *S*-bn used in the Experiment was changed to its enantiomorph, *R*-bn, since the skew conformations of the other 1,3-diamine chelate rings studied here are all stabilized in the λ-form.

Results and Discussion

Table 2 shows that the peak positions of the first absorption bands for diastereomeric complexes of a given 1,3-diamine shift to higher energies in the order of the *meso*-diamine complex, Λ- and Δ-isomers of the optically active diamine. The *meso* and active diamine chelates listed in Table 2 will be stabilized in the chair and the λ-skew conformations, respectively, since these conformers have substituents disposed equatorially. The *R*-bn and *S*-phtn chelate rings can also take the chair conformation with an equatorial substituent (*vide infra*). The λ-skew conformers in the Δ- and Λ-configurations form the *lel* and the *ob* structures, respectively.[10] Thus, the order of the shift in the absorption bands corresponds to that of chair, $\Lambda(\lambda)$-(*ob*), and $\Delta(\lambda)$(*lel*) structures. This order agrees with the results obtained for some tris(1,3-diamine)cobalt-(III) complexes.[2,3] These findings will also be utilized for determining the absolute configuration of 1,3-diamine ligands.

The energy differences in the absorption bands between each pair of diastereomers of the *R*-bn and *S*-phtn complexes are smaller than those of cases of the ptn and dppn complexes. This fact suggests that the *R*-bn and *S*-phtn chelate rings are in equilibrium between the λ-skew and the chair conformations.

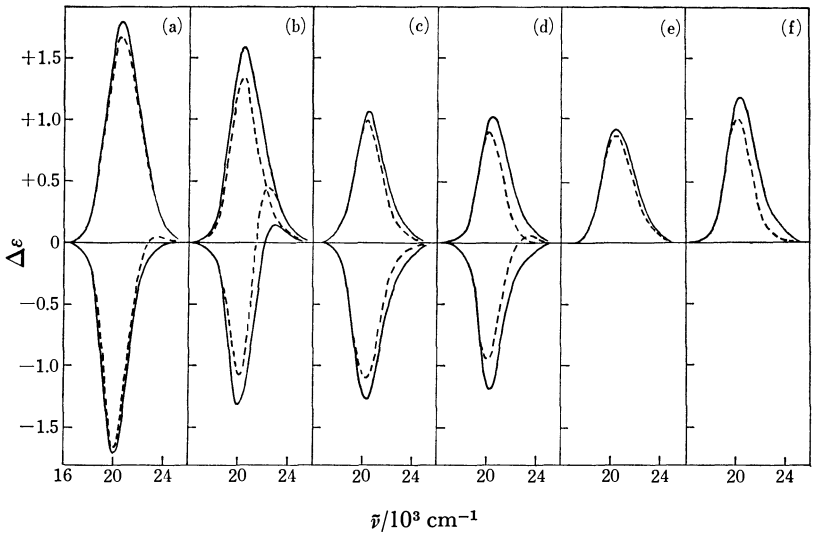

Fig. 1. CD spectra of $[Co(en)_2(L)]^{3+}$ in water (——) and in 0.2 mol·dm^{-3} Na_2SO_4 (----). L; (a) *S,S*-dppn, (b) *R,R*-ptn, (c) *S*-phtn, (d) *R*-bn, (e) *R,S*-dppn, and (f) *R,S*-ptn.

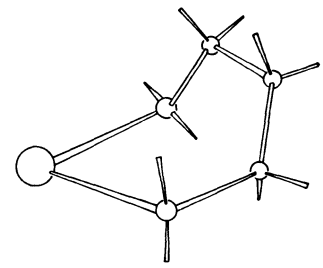

Fig. 2. The envelope conformation of a 1,3-diamine chelate ring.

As stated above, these chelate rings can also take the chair conformation. Molecular models suggest that the difference in the structure between the $\Delta(ch)$ and $\Lambda(ch)$ isomers is smaller than that between the $\Lambda(\lambda)(ob)$ and $\Delta(\lambda)(lel)$ isomers. Hence, the former two isomers give the first absorption bands with a small energy difference from each other.

In Fig. 1 are shown the CD spectra in water in the absence or the presence of sulfate ions. All the complexes show a typical CD pattern for a tris-diamine complex, and their absolute configurations can be assigned on the basis of the CD sign as shown in Table 2. In the presence of sulfate ions, all the complexes diminish the CD strength. Such a phenomenon is known to be caused by increase in the amounts of the $lel_3(\Delta(\lambda\lambda\lambda)$ or $\Lambda(\delta\delta\delta))$ conformer due to ion-association between a complex and a sulfate ion; the lel_3 conformer is the most effective structure in forming an ion-pair through hydrogen bonding between the amino protons and the sulfate ion,[11] and since the CD sign due to the vicinal effect of a λ ligand is positive opposite to that due to the configurational effect of a Δ isomer, the CD strength of the $lel_3(\Delta(\lambda\lambda\lambda))$ conformer should be smaller than those of other conformers such as lel_2ob $(\Delta(\lambda\lambda\delta))$ or $lelob_2(\Delta(\lambda\delta\delta))$.[2] For the present complexes of the optically active diamines, the Δ-isomers will be stabilized in the $\Delta(\lambda\lambda\lambda)(lel_3)$ conformer and reduced their CD strengths in the presence of sulfate ions. On the other hand, the Λ-isomers can form the $\Lambda(\delta\delta\delta)(lel_3)$ conformer with difficulty, since the δ forms of the present 1,3-diamine chelate rings involve axially disposed substituents. Similar conformers with one axial substituent are fomed for the *meso*-diamine complexes in the lel_3 form. These conformers will be unstable because of large steric interactions between the substituent and the ethylenediamine ligand. However, when these 1,3-diamine chelate rings take a conformation as shown in Fig. 2, the complex can have the same set of three N–H bonds as that in the lel_3 conformer, and can form a stable ion-pair with a sulfate ion. Such a conformer involves a *cis* form around a skeletal carbon-carbon bond (envelope type), and will be unstable compared with typical chair and skew forms. However, it seems to be much more stable than conformers with axial substituents in an octahedral complex. Although the vicinal contribution of this conformer to CD is unknown at present, the CD change of the Λ- and *meso*-diamine complexes caused by the addition of sulfate ions will also be related to such a conformational change of the 1,3-diamine chelate rings.

The authors wish to thank the Ministry of Education for Scientific Research Grant-in-Aid No. 243013.

Crystal Distortion and Cation Distribution in the System $La_{1/3}NbO_3$–WO_3

Yasuyoshi Torii

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received June 30, 1978)

Synopsis. It has been found that WO_3 is soluble in $La_{1/3}NbO_3$ up to *ca.* 35 mol %. The solid solutions showed an ordered perovskite structure. The orthorhombic distortion changes into a tetragonal one at 20 mol %. The temperature dependence of the tetragonality of typical samples has been examined and the nature of the tetragonal distortion discussed.

$La_{1/3}NbO_3$ is an orthorhombically distorted structure containing two perovskite subcells.[1] Iyer *et al.* reported that the perovskite-type unit cell contains a preferential distribution of La^{3+} ions on alternate c-planes, as shown in Fig. 1.[2] WO_3, on the other hand, is well-known to have a perovskite structure without A-site ions. A-site deficient perovskites with a wide range of non-stoichiometry, such as $La_{1-x}TiO_3$[3] (x=0.03—0.33) and $Sr_{1-x}NbO_3$[4] (x=0.05—0.30), have been reported to be of simple perovskite structure type. $La_{2/3}TiO_3$ is an exception and has the same ordered structure as $La_{1/3}NbO_3$.[5] It is of interest crystallographically to understand how solid solutions between $La_{1/3}NbO_3$ and WO_3 can be formed and whether such ordered arrangement is maintained. The present paper describes the structural properties of this system.

Experimental

The samples were prepared by conventional ceramic techniques, using La_2O_3, Nb_2O_5, and WO_3 as starting materials. Two-cycle firing was carried out in air at 1050—1270 °C for several hours, the samples being left to cool in the furnace. The products were analyzed by X-ray diffraction method, using Cu $K\alpha$ radiation. The lattice constants were determined from the best resolved lines of (004), (020), and (200), which appeared at 2θ=46—47°. Observed intensities were obtained from the diffractometer tracing by weighing the relative areas under the peaks. The theoretical intensities of the reflection lines were calculated according to a method previously reported.[6]

Results and Discussion

The $La_{1/3}NbO_3$–WO_3 system showed single-phase patterns similar to that for $La_{1/3}NbO_3$ up to a composition containing 35 mol % WO_3. In a 40 mol % WO_3 sample, a further phase appeared in small amounts besides the perovskite-like compound. The room temperature lattice constants are shown in Fig. 2. The crystal lattice became contracted by the partial substitution of W^{6+} ions for Nb^{5+} ions. The $c/2a$ ratio decreased with increasing amounts of WO_3. The orthorhombic distortion changed into a tetragonal one at 20 mol % WO_3 and the tetragonality decreased with further increase of WO_3, but the perovskite subcell did not become cubic. The decrease in crystal distortion is probably attributable to the size effect of B-site ions. The intensities of superstructure lines were also observed to decrease with increasing amounts of WO_3. The relative intensities of the typical lines of (001), (011), and (111) are shown by the solid lines in Fig. 3, the intensities of which depend on the La^{3+} ion concentration in this type of perovskite structure. It is impossible, however, to neglect the effect of high scattering power of the W^{6+} ion on intensity. In this respect the partial substitution of Mo^{6+} ions is more favored since the two scattering powers of the Nb^{5+} and Mo^{6+} ions are nearly equal. Unfortunately attempts to prepare solid solutions in the $La_{1/3}NbO_3$–MoO_3 system failed. In order to examine the cation distribution, the theoretical intensities of superstructure lines were calculated using Iyer's crystal data,[2] the results of which are shown by the broken lines in Fig. 3 in comparison with the observed values. Good agreement between the calculated and the observed intensities was obtained. Therefore, the ordered ar-

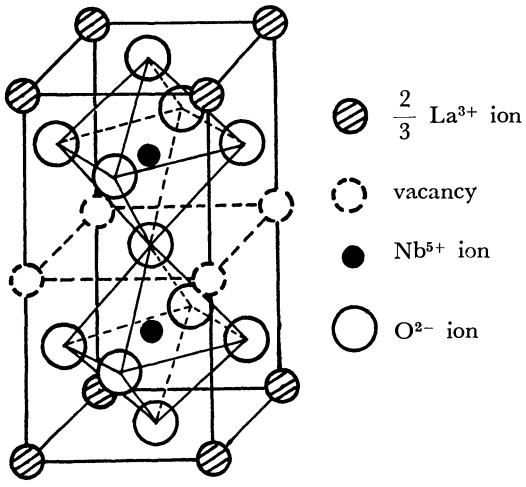

Fig. 1. Crystal structure of $La_{1/3}NbO_3$.

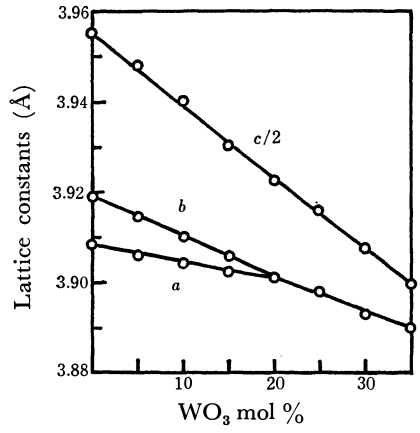

Fig. 2. Lattice constants in the $La_{1/3}NbO_3$–WO_3 system.

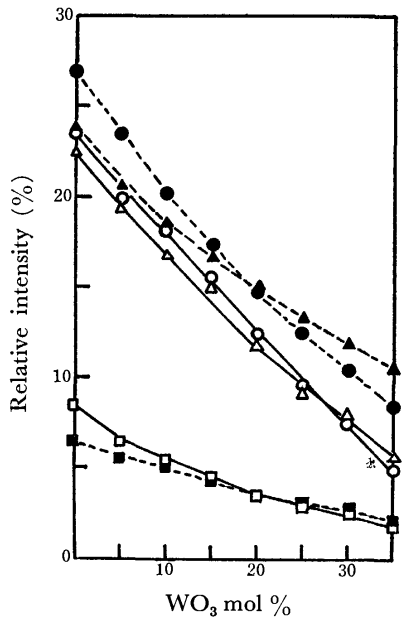

Fig. 3. Observed intensities *vs.* those caluculated for typical superstructure lines in this system.
○: $I_{obsd}(001)$, ●: $I_{calcd}(001)$,
△: $I_{obsd}(011)$, ▲: $I_{calcd}(011)$,
□: $I_{obsd}(111)$, ■: $I_{calcd}(111)$.
$I_{obsd}(001)$ represents observed intensity of (001) line, and $I_{calcd}(111)$ represents the sum of the calculated intensities of (111) and (003) lines which appeared at the nearly same value of 2θ.

rangement of La^{3+} ions as shown in Fig. 1 is completely maintained in the solid solution in the $La_{1/3}NbO_3$–WO_3 system. This is quite different from the situations showing simple perovskite phases of composition $La_{1-x}TiO_3$ (x=0.03—0.30), except $La_{2/3}TiO_3$ (x=0.33) with the ordered structure.

Figure 4 shows the variation of lattice constants of $La_{1/3}NbO_3$ with temperature. The orthorhombic subcell changes into a tetragonal one above *ca.* 190 °C. The $c/2a$ ratio is almost independent of temperature. For the 20 mol % WO_3 sample, the crystal lattice gradually expands with temperature, and the tetragonality remains almost unchanged. The superstructure lines for both samples did not disappear even at 1000 °C. Generally, the low symmetry of ordinary perovskites is expected to improve at high temperatures. It is likely that $La_{1/3}NbO_3$ and its solid solutions differ from ordinary perovskites in the nature of tetragonal distortion. In $La_{1/3}NbO_3$ two Nb^{5+} ions are located at $\pm(1/2, 1/2, z)$, z=0.262. The intensities of the superstructure lines are relatively sensitive to the atomic

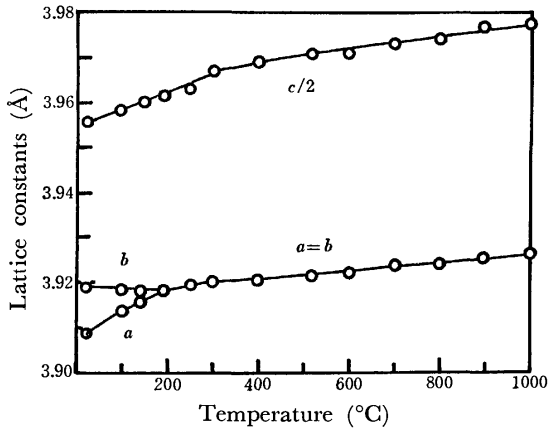

Fig. 4. Temperature dependence of lattice constants for $La_{1/3}NbO_3$.

z parameter from the structure factor. With increase in the z value, the (001) line tends to become weaker while the (011) line becomes stronger. For example, the calculated values of (001) and (011) lines for the 20 mol % WO_3 sample were 16.0 and 9.9 at z=0.25, and 14.7 and 14.9 at z=0.262, respectively. The corresponding observed values were 12.4 and 11.8, respectively. It becomes apparent that the differences between the calculated and observed intensities decrease by the deviation of Nb^{5+} and W^{6+} ions from the B positions of $\pm(1/2, 1/2, 1/4)$. In terms of charge balance, this antiparallel displacement of Nb^{5+} and W^{6+} ions with high valency is considered an important role for the formation of this type of superstructure, where the corner sites are occupied by corresponding amounts of La^{3+} ion and the vertical edge centre sites are vacant. It might be related to the origin of superstructure that the tetragonality in $La_{1/3}NbO_3$ and its solid solution remains nearly unchanged with temperature.

Electrode Reactions of Several Transition Metal Ions in Aqueous Polyelectrolyte Solutions as Studied by DC and Fourier Transform Polarography

Noboru IMAI,* Michio HIROTA, Yoshio UMEZAWA, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 2, 1978)

Synopsis. The kinetic parameters, k_s for several metal ions are decreased down to 1/10—1/50 in the presence of sodium polyacrylate, although the diffusion of metal ions in the same system differs little with and without sodium polyaclylate.

The electrochemical behavior of proteins and macromolecules has been gaining popularity in recent years.[1,2] In a preceding paper,[3] the diffusion coefficient of transition metal ions in polyelectrolyte solutions has been studied polarographically. However, due to the complexity of overall reactions involved, we could not discuss the following two effects separately; i) adsorption of polyelectrolytes on the surface of the mercury electrode, ii) complex formation of metal ions with polyelectrolytes.

In the present study, the effect of polyacrylate on the reduction process of transition metal ions at the surface of the dropping mercury electrode (DME) will be studied briefly in terms of the adsorption, complex formation with metal ions, and the influence on the kinetic parameters of metal ions.

Sodium polyacrylate (M.W. 2500—7500) purchased from WAKO Chemicals Co. was purified as reported previously.[3] In all cases, 1 M $NaClO_4$ was added to 5 mM polyacrylate aqueous solution in order to make the IR drop of the solution minimum. A saturated calomel electrode (SCE) was used as the reference electrode. The flow rate of mercury was 7.52 mg/s at a mercury column height of 40 cm in 1 M $NaClO_4$ solution at an open circuit. All measurements were performed at (25.0±0.5) °C. The standard rate constant (k_s) and the transfer coefficient (α) were determined using FT polarography, where details of the analysis were also described in the previous paper.[4] Two kinds of the AC potentials with the frequencies of 55.8 and 173.6 Hz and an amplitude (ΔE) of 5 mV were used. Simulations for obtaining k_s and α were performed on a HITAC 8700/8800 system at the Computer Center, The University of Tokyo, using the FORTRAN program written and kindly given by Prof. D. E. Smith.

Adsorption of Polyelectrolyte on DME. From the electrocapillary curves for 1 M $NaClO_4$ solutions with and without sodium polyacrylate, poly(acrylic acid) adsorbs on the DME only when the concentration of proton reaches a value of *ca.* 10 mM. The differential capacity of the interface with and without poly(acrylic acid) were obtained from the fundamental AC current measured by the Fourier Transform AC polarography using the equation

$$C = \frac{I}{f\Delta E},$$

where ΔE is the amplitude of the applied AC voltage, I the resulting fundamental AC current and f the frequency in Hz. The great decrease in the value of capacitance was observed in the presence of polyacrylic acid. This is interpretable in terms of the decrease in the double layer charge due to the adsorption of neutral poly(acrylic acid). No frequency dependence was observed from 55.8 to 173.6 Hz. This result implies that the adsorption equilibrium is fast enough as compared with the time scale of 0.02—0.006 s.

Diffusion Current. As shown in Table 1, the magnitude of diffusion currents of metal ions in 5 mM sodium polyacrylate is dependent on the proton ion concentration of the sample solution. When the value of pH decreases, the magnitude of diffusion currents increases to reach the value in 1 M $NaClO_4$ solution without sodium polyacrylate.

TABLE 1. pH DEPENDENCE OF DIFFUSION CURRENTS FOR METAL IONS WITH AND WITHOUT SODIUM POLYACRYLATE
(Diffusion current μA)

HNO_3 added	No polyacrylate		5 mM polyacrylate		
	0 mM	0 mM	1 mM	3 mM	10 mM
$MnCl_2$	8.2	6.3	7.1	8.3	N[a]
$CoCl_2$	9.4	5.3	6.3	8.1	N
$ZnSO_4$	9.6	N	N	N	9.3
$Pb(NO_3)_2$	11.0	N	N	N	10.8
$Cd(NO_3)_2$	9.8	N	N	N	9.6

a) N: The diffusion currents could not be measured due to the interference of the hydrogen wave and precipitation of hydroxides for Mn(II), Co(II) and Zn(II), Pb(II), Cd(II), respectively.

Possible mechanisms for change in diffusion currents in the presence of sodium polyacrylate are: i) decrease in diffusion coefficient of metal ions due to the complex formation with polyacrylate and/or ii) blocking effect of poly(acrylic acid) adsorbed layer on the diffusion of metal ions. Of these two, the mechanism ii) should be pronounced when the pH values decrease, because the formation of the adsorbed blocking layer, if any, is enhanced in lower pH ranges. However, the observed phenomenon is opposite to expectation from the mechanism ii). From these results, it is concluded that the increase in diffusion currents of metal ions with lower pH is explained in terms of the increase in the diffusion constant through dissociation

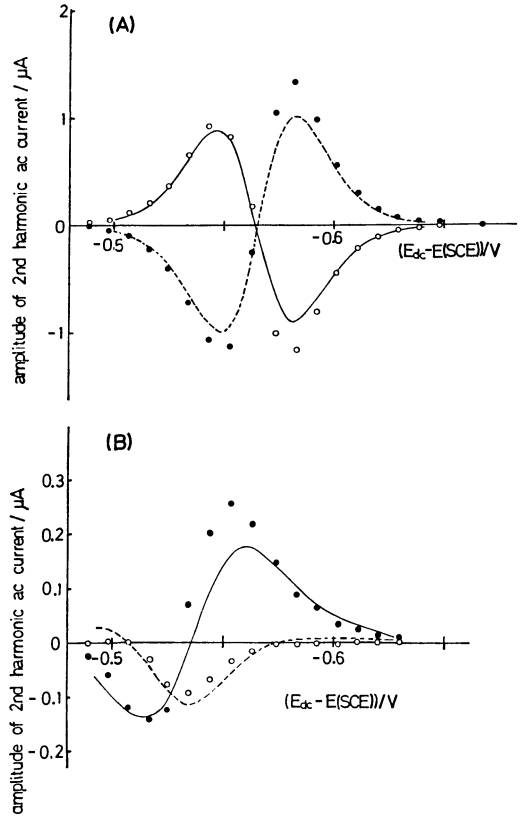

Fig. 1. The second harmonic AC polarogram of cadmium(II) ion with and without sodium polyacryate. ○: In-phase component, ●: quadrature component 2 mM Cd(II) and 1 M $NaClO_4$, (A) no sodium polyacrylate. (B) 5 mM sodium polyacrylate and 10 mM HNO_3.

of polyacrylate ligand from metal ions in acidic media.

Kinetics. Although the adsorbed layer of polyacrylic acid on the DME did not affect the diffusion current of metal ions at low pH regions (see preceding section), the kinetic parameters for the electrode reaction of these metal ions were greatly influenced by this adsorption layer. The kinetic parameters of electrode reactions with and without sodium polyacrylate was obtained through the second harmonic AC polarogram. Typical examples of the second harmonic polarogram for Cd(II) ion with and without sodium polyacrylate in acidic media are shown in Fig. 1, where the computer simulation were performed on these curves using the theoretical equation for the quasi-reversible 2nd harmonic polarogram.[7] The second harmonic polarograms with and without sodium polyacrylate differ appreciably each other.

Table 2. Kinetic parameters (k_s, α) with and without sodium polyacrylate

		α	k_s[c]/cm s^{-1}
$CdSO_4$	a)	0.15[d]	0.45[d]
	b)	0.30±0.02	0.0083±0.0005
$Pb(NO_3)_2$	a)	0.61[e]	10.2[e]
	b)	0.70±0.06	0.19±0.08
$Zn(NO_3)_2$	a)	0.30±0.04	$(3.0\pm1.0)\times10^{-3}$
	b)		$(4\pm2)\times10^{-4}$ [f]

a) No sodium polyacrylate. b) 5 mM sodium polyacrylate, $[HNO_3]=10$ mM. c) Observed rate constant. d) Values from Ref. 5. e) Values from Ref. 6. f) A well-defined second harmonic polarogram were not obtained. Therefore, k_s values roughly estimated from DC polarography.

The kinetic parameters obtained are summarized in Table 2. It is seen that in the presence of 5 mM polyacrylic acid, the value of k_s decreases down to 1/10—1/50 of those obtained without poly(acrylic acid). The shift of half-wave potential and the change in the slope for log $(i/(i_d-i))$ *vs.* E relation were obtained upon the addition of poly(acrylic acid). It is interesting to note that even if the value of kinetic parameters for Pb(II) and Cd(II) decreased upon adding poly(acrylic acid), the DC polarographic parameters such as $\Delta E_{1/2}$ and log $(i/(i_d-i))$ *vs.* E plot for those ions with and without sodium polyacrylate exhibit little change, indicating the electrode reaction for those system is still fast enough as compared with the DC polarographic time scale ($<5\times10^{-4}$ cm s^{-1}).

In conclusion, an electron transfer from the electrode to the metal ions becomes restricted appreciably in the presence of sodium polyacrylate, although the diffusion of metal ions in the same system differs little with and without sodium polyacrylate.

(Received August 28, 1978)

Synopsis. The titled compounds have been synthesized by a template reaction of aminoalkylphosphonic acids or glycylaminoalkylphosphonic acids and salicylaldehyde with copper(II) ion. The square-planar structures have been proposed by analogy with corresponding structures of *N*-salicyclideneglycine or *N*-salicylideneglycylglycine chelates. The deprotonated peptide nitrogen coordination was confirmed by IR-spectra for the phosphonopeptides chelates.

Since (2-aminoethyl)phosphonic acid has been discovered from some living organisms,[1-6] the aminoalkylphosphonic acids have attracted chemical and biological interest in the recent years. Several investigations have been reported for the syntheses of phosphonopeptides[7-9] and phosphonolipids[10] as well as aminoalkylphosphonic acids.[11-13]

It is well known that amino acids or peptides form Schiff bases with salicylaldehyde in the presence of a metal ion as a template and the stable copper(II) chelates have been isolated.[14] Because aminoalkylphosphonic acids and phosphonopeptides are phosphonic analogues of amino acids and peptides, similar metal chelate formation can be expected for these compounds. In the present investigation we have isolated salicylidene derivatives of (aminomethyl)phosphonic acid, (2-aminoethyl)phosphonic acid, (glycylaminomethyl)phosphonic acid, and [2-(glycylamino)-ethyl]phosphonic acid as a copper(II) chelate. This paper deals with synthesis of the copper(II) chelates and characterization of their structural similarity with those of amino acids and peptides by means of electronic and infrared spectroscopy.

Experimental

Reagents. (Aminomethyl)phosphonic acid,[12] (2-aminoethyl)phosphonic acid,[11] (glycylaminomethyl)phosphonic acid,[8] and [2-(glycylamino)ethyl]phosphonic acid[8] were prepared by slight modification of the previous reports.

Sodium [2-(N-Salicylideneamino)ethyl]phosphonatocuprate(II), Na[Cu(saepo)]. (2-Aminoethyl)phosphonic acid (0.63 g, 5 mmol) and salicylaldehyde (0.61 g, 15 mmol) were dissolved in 50 ml of 50% ethanol containing sodium hydroxide (0.6 g, 15 mmol) and powdered copper(II) acetate monohydrate (1.0 g, 5 mmol) was added. The mixture was heated on a water bath for a few minutes and bright green crystals were formed. They were recrystallized from hot water and air dried. Yield 0.4 g. Found: C, 31.45; H, 3.68; N, 4.16%. Calcd for $C_9H_{11}NO_5PCuNa \cdot H_2O$: C, 30.98; H, 3.76; N, 4.02%.

Sodium [(Salicylideneamino)methyl]phosphonatocuprate(II), Na[Cu(sampo)]. The procedure was the same as given for the preparation of Na[Cu(saepo)], using (aminomethyl)-phosphonic acid in place of (2-aminoethyl)phosphonic acid and bright green crystals were obtained in a yield of 0.5 g. Found: C, 30.12; H, 2.93; N, 4.34%. Calcd for $C_8H_7NO_4PCuNa \cdot H_2O$: C, 30.34; H, 2.87; N, 4.42%.

Barium [(N-Salicylideneglycylamino)ethyl]phosphonatocuprate(II), Ba[Cu(sgaepo)]. [2-(Glycylamino)ethyl]phosphonic acid (0.18 g, 1mmol) and salicylaldehyde (0.12 g, 1 mmol) were suspended in 20 ml of water and aqueous sodium hydroxide was added to give a clear solution. To this was added copper-(II) acetate monohydrate (0.2 g, 1 mmol) and the mixture was heated on a water bath, while aqueous sodium hydroxide was added to adjust a pH of 9. After ten minutes, the insoluble precipitate was filtered off and saturated barium chloride solution was added to the filtrate. The resulting blue-violet crystals were filtered and recrystallized from hot water and air dried. Yield 0.4 g. Found: C, 26.57; H, 2.67; N, 5.50%. Calcd for $C_{11}H_{11}N_2O_5PCuBa \cdot H_2O$: C, 26.36; H, 2.62; N, 5.59%.

Barium [(N-Salicylideneglycylamino)methyl]phosphonatocuprate-(II), Ba[Cu(sgampo)]. The procedure was the same as employed for the preparation of Ba[Cu(sgaepo)], but with (glycylaminomethyl)phosphonic acid in place of [2-(glycylamino)ethyl]phosphonic acid. Violet needles were obtained in a yield of 0.4 g. Found: C, 24.39; H, 2.51; N, 5.65%. Calcd for $C_{10}H_9N_2O_5PCuBa \cdot H_2O$: C, 24.66; H, 2.28; N, 5.75%.

Measurements. The infrared spectra were determined in potassium bromide disks by means of a Hitachi EPI-S2 spectrophotometer, while the electronic spectra were measured with a Hitachi EPS-3T spectrophotometer.

Results and Discussion

As described in the experimental section, copper(II) chelate formation is a typical template reaction and proceeded smoothly with equimolar aminoalkylphosphonic acid or glycylaminoalkylphosphonic acid, sali-

cylaldehyde, and copper(II) acetate in an alkaline medium. The probable structures of these chelates are formulated in Fig. 1 by analogy with the corresponding structures of the amino acid and peptide chelates. The elemental analyses also agreed with these formulations.

The electronic spectra of the copper(II) chelates exhibit one broad band due to d-d transition in the visible region. They are shown in Table 1 and compared with those of *N*-salicylideneglycinatocopper(II), Cu(sg) and sodium *N*-salicylideneglycylglycinatocuprate(II), Na[Cu(sgg)]. The close similarity in the absorption maximum and the intensity between the phosphonatocopper and the glycinatocopper clearly indicates the same geometry around the metal ion, *i.e.* square-planar as previously discussed.[14] It is interesting to note that the ligand field strength of the amine-phosphonate coordination is nearly equal to that of amine-carboxylate coordination. In the case of the phosphonopeptide chelates, Ba[Cu(sgampo)] and Ba[Cu(sgaepo)], the amide nitrogen coordinates to the metal ion by deprotonation. This conclusion is supported by the similarity of the ligand field strength to that of Na[Cu(sgg)] in which the coordination of the deprotonated amide nitrogen has been recognized.[14]

Kim and Martell[15] have studied infrared spectra of coordinated peptide in D_2O by varying pD, and assigned the carbonyl band at different solution conditions. The peptide carbonyl band of glycylglycine which exists as a zwitter ion appears at 1665 cm^{-1} and it shifts to 1625 cm^{-1} on coordination through the carbonyl oxygen to the copper(II) ion in acidic solution. The 1625 cm^{-1} band further shifts to 1610 cm^{-1} in alkaline solution and this was interpreted as direct evidence for the ionization of the peptide NH hydrogen. Similar spectral changes were observed in the solid state for the phosphonopeptide chelates as shown in Table 2, and peptide nitrogen coordination in these complexes is indicated. The amide I band (C=O stretching vibration) in the free ligands shifts to lower wave number and the amide II band (NH deformation vibration) disappears on metal chelate formation. This indicates the deprotonation of the amide nitrogen and the resulting delocalization of charge in the $N=C\diagup^{O}$ linkage. The P–O stretching bands of the monoanion in the free ligands also shift to lower wave number on metal chelate formation because of proton ionization to form the dianion.

It is concluded from the present investigation that aminoalkylphosphonic acids and their peptides with amino acids have properties that are similar to those of amino acids and peptides in metal chelate formation so far as copper(II) ion is concerned. Although aminophosphonate peptide derivatives have been described in this paper, there is another fundamentally different type of phosphonopeptide that may be formed; such as $H_2N(CH_2)_nP(O)(OH)NHCH_2COOH$ having a P–N linkage. Synthesis of such phosphonopeptides and investigation of their metal-chelating property are in progress at our laboratories.

Friedel-Crafts Reaction of Benzene with 2-Phenylpentanedioic Anhydride

Iwao HASHIMOTO

Department of Industrial Chemistry, Wakayama Technical College, Noshima, Nada-cho, Gobo 649-15

(Received December 21, 1977)

Synopsis. The reaction of benzene with 2-phenylpentanedioic anhydride in the presence of $AlCl_3$ afforded a mixture of 1,2,3,4-tetrahydro-4-oxo-1-naphthalenecarboxylic acid, 4-benzoyl-2-phenylbutanoic acid and the isomeric 4-benzoyl-4-phenylbutanoic acid. The relative yields among the products were markedly affected by a change in the polarity of the solvent.

In a previous paper[1] the $AlCl_3$-catalyzed acylation of benzene with 2-phenylbutanedioic anhydride (**1**) was reported. Competitive inter- and intramolecular acylations were reported in the above reaction system. It was also reported that either the oxonium compound or the acylium ion, which were derived from the interaction between **1** and $AlCl_3$, were the actual acylating agents. Therefore, in order to obtain more information on the actual acylating agent in the Friedel-Crafts reaction with the dibasic acid anhydride, it was necessary to investigate the Friedel-Crafts reaction with a higher dibasic acid anhydride.

Only a few works between benzene and 2-phenylpentanedioic anhydride (**2**) have so far been described[2,3] that **2** acylated intermolecularly benzene to give only 2-phenyl substituted keto acid under Friedel-Crafts conditions, although intramolecular reaction took place with sulfuric acid as catalyst.

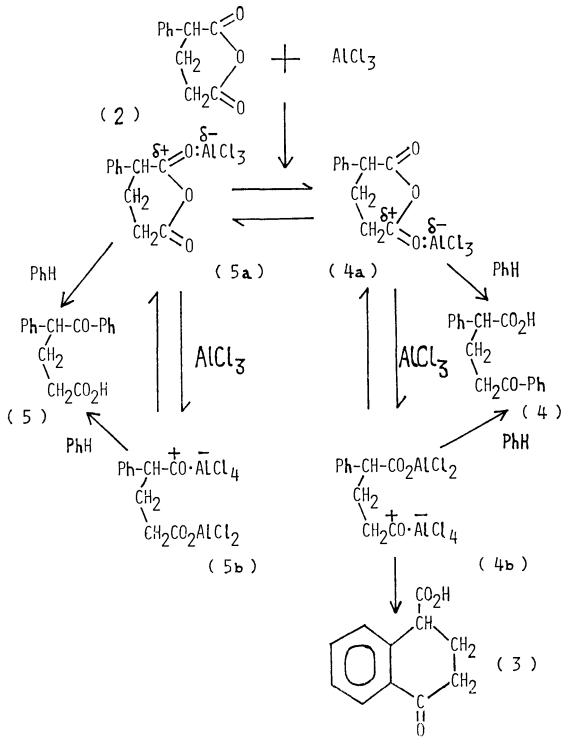
In the present study the Friedel-Crafts reaction of benzene with **2** was conducted in various solvents having different polarities, and the solvent effect examined in connection with the reaction mechanism.

The reaction of **2** with $AlCl_3$ in a large excess of benzene gave a mixture of 1,2,3,4-tetrahydro-4-oxo-1-naphthalenecarboxylic acid (**3**), 4-benzoyl-2-phenylbutanoic acid (**4**) and the isomeric 4-benzoyl-4-phenylbutanoic acid (**5**), as is shown in Table 1. However, the total yield of these keto acids was lower than that obtained from the acylation of benzene with **1** under similar reaction conditions, and the yield of **3** was always over the sum of those of **4** and **5**. This suggested that the intramolecular acylation of **2** with $AlCl_3$, even in a large excess of benzene, predominates over the intermolecular reaction of **2** on benzene in the presence of $AlCl_3$. A decrease in the amount of $AlCl_3$ from 20 to 10 mmol did not largely affect the distribution of products.

In more polar solvents such as 1,2-dichloroethane, the reaction of **2** with a limited amount of benzene predominantly gave **3** using 20 mmol of $AlCl_3$, accompanied by a small amount of **5** and a trace of **4**. Furthermore, in the case of 10 mmol of $AlCl_3$ on the reaction in 1,2-dichloroethane, **3** was exclusively obtained with a trace amount of **5**.

In nitrobenzene, the most polar solvent used, the reaction of **2** with benzene, in the presence of 30 mmol of $AlCl_3$, gave **3** almost exclusively. The intramolecular acylation of **2** with $AlCl_3$ in nitrobenzene overwhelmingly predominated over the intermolecular acylation of **2** on benzene in the presence of $AlCl_3$. The use of 30 mmol of $AlCl_3$ without benzene increased the yield of **3** to 79%.

These results imply that the solvent variations in the reaction of **2** with benzene in the presence of $AlCl_3$ markedly affect the relative yield among, **3**, **4**, and **5**; thus, an increase of polarity of solvent led to an increasing yield of **3** and the decreasing yields of **4** and **5**. From this, the following reaction paths may be formulated in consideration of the results obtained in the acylation of benzene with **1**.[1]



Scheme 1.

As delineated in Scheme 1, the oxonium compounds (**4a** and **5a**) possibly intermolecularly acylate benzene to give **4** and **5**, and also the acylium ions (**4b** and **5b**) afford **3**, **4**, and **5** by the intra- and intermolecular acylations. Since the above reaction gives **3** as the main product, which is obtained by way of **4b** and since the yield of **3** increases with increasing polarity of solvent, it may be assumed that the actual acylating agent in the reaction using **2** is a type of acylium ion. This is because the acylium ion bearing a more centered positive charge than the oxonium compound appears to be markedly influenced by a change of the polarity of solvent; hence, **4b** and **5b** reacted intermolecularly

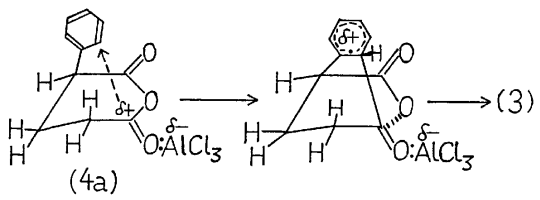
a) Calculated on the basis of the amount of 2-phenylpentanedioic anhydride used (10 mmol). b) The reaction was carried out at 60 °C, excess benzene being used as solvent.

with benzene to give **4** and **5**, respectively, although **4b** afforded **3** intramolecularly.

In nonpolar solvents such as benzene, the intermolecular acylations with **4b** and **5b** on the benzene molecule are possibly due to the low solvation of benzene, although the intramolecular acylation of **4b** predominates over the intermolecular acylations of **4b** and **5b** on benzene even in a large excess of benzene. In the intermolecular acylations, **5b** having an electron-attracting phenyl group closer to the acylium cation is preferred to **4b**. Hence the formation of **5** is more favored than **4**.

The highly charged acylium ions (**4b** and **5b**) may be strongly solvated by nitrobenzene to form a bulky acylating agent, and consequently the attack by such bulky agents upon benzene becomes intermolecularly difficult. Indeed, only the intramolecular acylation of **4b** occurred in nitrobenzene to give **3**, since the effect of solvent on the closely-located internal acylium ion and benzene ring is small.

If the phenyl group occupies a quasi axial position in **4a**, the formation of **3** should proceed with a direct intramolecular cyclization as follows:



Scheme 2.

However, the observed solvent effect can not be explained, because the effect of solvent upon the oxonium compound (**4a**) should be much less marked than for the acylium ion (**4b**). Moreover, the strained transition state, being caused by the intramolecular approach of $\overset{\delta+}{>}C{=}O{:}\overset{\delta-}{AlCl_3}$ to the benzene ring in **4a**, would have so high an energy that it would be improbable.

Since it is known[4] that trifluoromethanesulfonic acid is a very effective catalyst for the acylation of arenes, the reaction of **2** with a large excess of benzene in the presence of trifluoromethanesulfonic acid or concd sulfuric acid was attempted. However, only the intramolecular acylation of **2** occurred and the yield of **3** was considerably lower compared with the case using $AlCl_3$.

Experimental

Material. Compound **2** was prepared according to the method of Horning *et al.*

Acylation of Benzene with 2 in the Presence of $AlCl_3$. The procedure paralleled the acylation with **1** described in an earlier paper.[1]

Analyses of the Products. All keto acids were esterified with an ethereal solution of diazomethane and then analyzed by GLPC employing a Yanagimoto G-800T model on a 1.5 m × 3 mm column packed with Apieson Grease M (5 wt %) on Celite 545 of 80—100 mesh with a He flow of 40 ml/min at 228 °C. All methyl esters were identified by comparison of their retention times with those of authentic samples. The retention times of the methyl esters of **2**,[2] **3**,[2] **4**,[2,5] and **5**[5,6] were 1.0, 1.4, 4.2, and 5.6 min, respectively. 4-Chlorobenzophenone was used as the internal standard for the GLPC determination.

The author wishes to thank Professor Yoshiro Ogata, Nagoya University, for his valuable discussions.

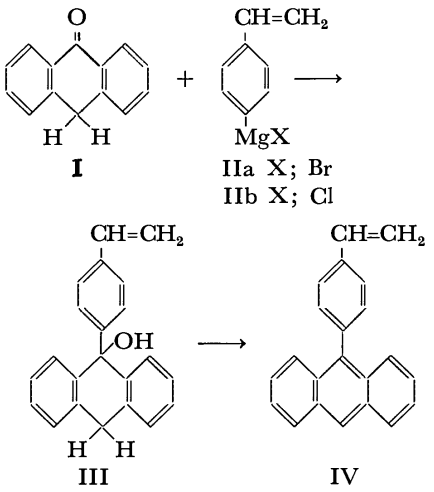
(Received March 7, 1978)

Synopsis. A novel vinyl monomer containing the polyaromatic ring, 9-(*p*-vinylphenyl)anthracene, was prepared by the Grignard reaction of anthrone and *p*-vinylphenylmagnesium halides which could be obtained either from *p*-bromostyrene or *p*-chlorostyrene. The results and the spectra of products are discussed.

Recently, many investigations of organic polymers[1] with polyaromatic rings in the side-chains have been carried out from the optical and electrical interests. 9-(*p*-Vinylphenyl)anthracene (IV) is a promising new vinyl monomer which can be used to prepare one such organic polymer. The authors wish to report on the preparation of IV by the Grignard reaction as follows.



p-Vinylphenylmagnesium halide (IIa) was synthesized by the Grignard reaction of *p*-bromostyrene and magnesium in accordance with Cazes' report.[2] A method using inexpensive *p*-chlorostyrene in place of *p*-bromostyrene was also investigated.

The results are given in Table 1. It was observed that *p*-vinylphenylmagnesium halides can be produced in yields of more than 80% either from *p*-bromostyrene or *p*-chlorostyrene. In the case of *p*-chlorostyrene the yield increased remarkably with the rises in the reaction temperature.

The reaction mixture of *p*-vinylphenylmagnesium halides with I was analyzed by thin layer chromatography(TLC) on alumina, and six spots were detected at R_f 0.94, 0.58, 0.49(main spot), 0.36, 0.25 and at the starting point. These spots were observed in the cases both chlorostyrene or bromostyrene was used. They were assigned to IV, anthraquinone (V), unreacted I, major product III, bianthrone-9-yl (VI) and the polymer of IV, respectively. TLC was presumed to produce V and IV by oxidation or hydration.[3] The spot at R_f 0.25 was identical with that which appeared when purified I was allowed to stand in a benzene solution for several days. It has been reported that I produces bianthrone-9-yl in benzene by photoreaction.[4] Bianthrone-9-yl (VI) was prepared by a known method,[5] and was found to be identical with the product (R_f 0.25) which formed in the reaction mixture. The spots at R_f 0.94 and at the starting point showed a strong blue fluorescence under UV irradiation (366 mm), and therefore, were characterized as polyaromatic compounds.

The overall yield of IV based on I was about 20% when III was separated, purified and then treated with phosphorus pentaoxide (Method A). On the other hand, when the reaction mixture from the reaction of I and *p*-vinylphenylmagnesium halide was directly treated with phosphorus pentaoxide without separating or purifying III, the yield of IV increased to about 40% (Method B). IV was also recrystallized from isopropyl alcohol after treatment with phosphorus pentaoxide without using column chromatography, and a high yield of IV was obtained as shown in Table 2 (the maximum overall yield 44%) (Method C). Table 2 shows the relation of the molar ratio of I to *p*-vinylphenylmagnesium halide and the yield of IV. The yield is maximum at a molar ratio of about 1.3.

In the NMR signals of IV quartet 1H at τ=3.24, doublet 1H at τ=4.29 and doublet 1H at τ=4.82 coincide well with the signals of the α,β-proton of the vinyl group of styrene. Further, the spin-spin coupling constants $J_{\alpha\beta}$=1.72, $J_{\alpha\beta'}$=10.8 and $J_{\beta\beta'}$=1.7 for the

vinyl group of IV also coincide well with the coupling constants of styrene.[6,7]

It is known that, when phenyl groups are introduced into anthracene rings, the overall ultraviolet absorption shifts to the longer wavelength region[8,9] and is scarcely affected by the position of the phenyl group or the kind of substitutes bonded to that group. As shown in Table 3, IV shows the same absorption as other 9-monophenylanthracene derivatives in the UV spectra.

Experimental

All compounds were shown to be pure by TLC with alumina B-5 or silica gel C-100 (Wako Pure Chemicals Co., Ltd., Tokyo) as absorbent on glass plates using benzene as the eluent, and with UV and iodine vapor for visualization. IR spectra were recorded using a Hitachi Model EPI-2 IR spectrometer. NMR spectra were recorded on Hitachi Model H-60 NMR spectrometer in deuteriobenzene.

p-Chlorostyrene and p-Bromostyrene[10]: *p*-Chlorostyrene and *p*-bromostyrene were synthesized by dehydration of *p*-hals-(α-hydroxyethyl)benzene with $KHSO_4$. *p*-Chlorostyrene was obtained in yield 67.9%: bp 50.5—51 °C/2 mmHg (lit, 65 °C/4 mmHg). *p*-Bromostyrene was obtained in yield 72.7%: bp 85—85.5 °C/11 mmHg (lit, 87—88 °C/12 mmHg).

9-(p-Vinylphenyl)-9-hydroxy-9,10-dihydroanthracene (III): A solution of 2.75 g of *p*-bromostyrene in 6 ml of THF was added dropwise during 1 h to a mixture of metal magnesium ribbon (0.37 g) and 10 ml of dry THF under mild refluxing. After the magnesium had disappeared, a solution of 2.91 g of I dissolved in 60 ml of dry THF was dropped into the above Grignard reagent (IIa) solution with stirring. The mixture was refluxed for 5 h, cooled and then hydrolyzed with 24 ml of 1.5 M HCl containing ice. An organic layer was extracted with ethyl ether and evaporated to dryness. Recrystallizations with methanol, and petroleum ether-benzene (9:1) in that order, gave 1.12 g (25.1%) of III: mp 132—135 °C; IR bands at 3300 and 1150 cm^{-1} (–OH), 907 and 990 cm^{-1} (–CH=CH_2). Calcd for $C_{22}H_{18}O$: C, 88.56; H, 6.08%. Found: C, 88.16; H, 6.74%.

9-(p-Vinylphenyl)anthracene (IV) Method A): Ten grams of phosphorus pentaoxide was added to a solution of 1.12 g of III dissolved in 22 ml of carbon tetrachloride with stirring at room temperature. Stirring was continued overnight. A solution was then extracted with ethyl ether was evaporated to dryness, taken up in toluene and chromatographed over a 2.5×30 cm column containing 42 g of silica gel. Elution of the column with isopropyl alcohol gave a crude product of IV, which was recrystallized twice with isopropyl alcohol, giving 0.77 g (73.2%) of IV: mp 166—168 °C; IR bands at 910 and 995 cm^{-1} (CH=CH_2), NMR signals (C_6D_6, internal TMS) τ: 1.67 (s, 1 anthracene ring C-10H), 1.99—2.20 (m, 4 anthracene ring C-1, C-4, C-5, and C-8H), 2.59—2.85 (m, 8 aromatic H), 3.24 (q, 1 vinyl α-H), 4.29 (d, 1 vinyl β-H), 4.82 (d, 1 vinyl β′-H). Calcd for $C_{22}H_{16}$: C, 94.25; H, 5.75%. Found: C, 94.26; H, 5.56%.

Method B): In the method described for III, a crude solid of III which was obtained by reaction IIa with I was dissolved in anhydrous benzene containing phosphorus pentaoxide (2% by weight of the benzene) and stirred overnight at room temperature. A solution was then extracted with ethyl ether and evaporated to dryness. The residue was chromatographed as in Method A, giving a crystalline of IV in yield of 40.5% which was recrystallized with isopropyl alcohol.

Method C): In the method described for III, 15.8 g of I in anhydrous benzene (125 ml) was added dropwise to Grignard reagent (IIb) prepared from 14.7 g of *p*-chlorostyrene in THF (50 ml). To the reaction mixture was added 7.6 g of phosphrous pentaoxide in 150 ml of anhydrous benzene with stirring overnight at room temperature. Subsequently, the addition of 332 ml of hexane and filtration left 13.5 g of a solid, which was insoluble in hexane. The filtrate was evaporated to dryness, giving a crude solid of IV which gave 10.0 g (43.7%) of pure product after recrystallization with isopropyl alcohol.

α-Chlorination of Long-chain Aliphatic Acids[1)]

Yoshiro OGATA,* Toshiyuki SUGIMOTO, and Morio INAISHI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 24, 1978)

Synopsis. Chlorination of long-chain aliphatic acids with a Cl_2–O_2 mixture in the presence of chlorosulfuric acid at 85 °C gave the corresponding α-chloro acids in good yields (*ca.* 90%) along with a little amount of aliphatic α-sulfo acids, but no α,α-dichloro acids.

Halogenation of aliphatic acids can occur *via* either a free-radical[2)] or a acid-catalyzed mechanism.[3,4)] The radical halogenation occurs at random positions, while the acid-catalyzed halogenation tends to give α-halo acid. Hell-Volhard-Zelinsky (H-V-Z) procedure using phosphorus tribromide gives exclusively α-bromo acid. However, the application of H-V-Z reaction to chlorination of long-chain aliphatic acids often gives α,α-dichloro acids along with α-chloro acids; the extent of α,α-dichlorination increases with the progress of reaction.[5,6)]

We have reported that aliphatic acids can be α-chlorinated by molecular chlorine in the presence of strong protic acids such as chlorosulfuric[7-9)] or fuming sulfuric acid[7)] and a radical trapper such as molecular oxygen. Here we wish to report the application of this chlorination method to higher fatty acids, *e.g.*, dodecanoic acid.

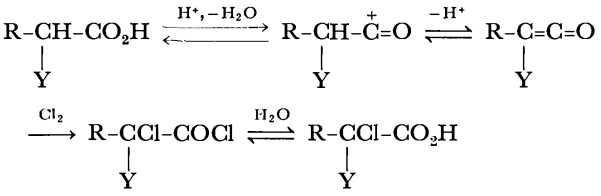
Results and Discussion

Dodecanoic acid was chlorinated in the presence of chlorosulfuric acid with a gaseous mixture of molecular chlorine and oxygen which acts as a radical trapper.[10)] The effect of reaction time on the yield is shown in Fig. 1. Within initial one hour, the yield of α-chlorododecanoic acid increased with progress of the reaction, but after one hour the yield was no more increased, but kept constant (*ca.* 90%). The substrate acid disappeared gradually until only a trace remained after 1 h.

The resulting mixture was extracted with ether and washed with water containing sodium chloride. The washing, after standing for a few days, afforded colorless crystals (0.1—0.6 g) of sodium 1-carboxy-1-undecanesulfonate, $[CH_3(CH_2)_9CH(SO_3Na)CO_2H]$, which is an expected product in view of the known formation of α-sulfo acid in the reaction of aliphatic acid with sulfur trioxide,[11-13)] fuming sulfuric acid,[11)] or chlorosulfuric acid.[11)]

Even the chlorination of dodecanoic acid for more than one hour gave α-monochlorododecanoic acid with no α,α-dichloro acid; further, no α,α-dichloro acid was detected in the attempted chlorination of α-chlorododecanoic acid as a substrate. Whereas, α,α-dichlorination occurs as easy as α-chlorination by H-V-Z procedure.[5,6)] Thus our procedure has the advantage that there is no contamination by dichloro acid, which is due to the low reactivity of α-chloro acid as well as gradual consumption of $ClSO_3H$ with the progress of reaction.

The mechanism may involve the addition of molecular chlorine to a ketene intermediate.[14)]



When Y=H and R=$C_{10}H_{21}$, alkyl substituted ketene is formed, while α-chloro acid (Y=Cl) gives chloro substituted ketene, which is less reactive to electrophilic chlorine addition; hence the reaction gives only α-monochlorination.

Figure 2 shows that the α-chlorination increases with increasing amount of catalyst acid, while the total yield of α-chlorinated product decreases, since there is a considerable amount of loss as α-sulfonated compound. In short, the optimum conditions for the highest yield and the lowest loss of the substrate are obtained with *ca.* 10 mmol of chlorosulfuric acid (1/5 equivalent of substrate).

The effect of reaction temperature on the yield is

less important (Fig. 3), probably because the favorable effect of increasing rate is compensated with the reverse effects of a decrease of chlorine solubility and an acceleration of α-sulfonation with increasing temperature.

This method can generally be applied to α-chlorination of other long-chain aliphatic acids with satisfactory yields. The optimum conditions for α-chlorination are as follows: A mixture of 50 mmol of substrate acid and 12.5 mmol of chlorosulfuric acid is heated at 85 °C for 60 min. The yields and physical properties for identification of α-chloro acids are listed in Table 1. Little effect of structure, *i.e.*, length of the chain, on the yield was observed.

The mechanism may involve the addition of molecular chlorine to a ketene intermediate.[14]

Experimental

Chlorosulfuric acid (1.45 g 12.5 mmol) was added gradually with stirring to substrate acid (50 mmol) and the mixture was heated slowly to 85 °C. The mixture of chlorine and oxygen in a molar ratio of 2:1 was bubbled into it for 60 min. After completion of the reaction chlorine was removed by introducing nitrogen, the mixture was cooled to room temperature, and extracted with ether (60 ml). The extract was washed with aqueous sodium chloride (20 ml) for three times. Ether was removed at 60 °C under reduced pressure. The residual material was cooled to freeze and dried *in vacuo*. The product was esterified with diazomethane[15] in ether and analyzed on a Yanagimoto G 180 gas chromatograph using a copper column packed with PEG 20 M 10% on Chromosorb WAW or Apiezon Grease L 15% on Celite 545.

The isolated α-chloro fatty acids (C_8—C_{16}) were identified by comparing the ^1H NMR and IR spectra with those of authentic samples. NMR and IR spectra were measured by means of a Hitachi R-24B NMR spectrometer and Perkin-Elmer Model 337 IR spectrophotometer, respectively.

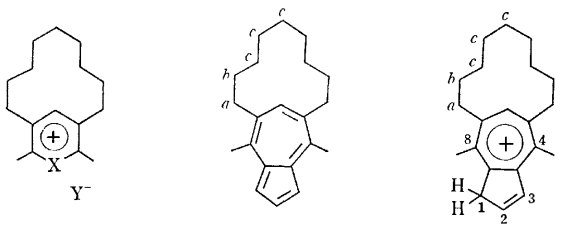
(Received April 10, 1978)

Synopsis. The title compound has been prepared from 2,6-dimethyl-3,5-nonamethylenepyrylium perchlorate and from 1,2,6-trimethyl-3,5-nonamethylenepyridinium iodide in low yield by reaction with sodium cyclopentadienide. The UV, visible and PMR spectra of the title compound are correlated with the structure.

Electrophilic substitution was used to prepare the intermediate for cyclization to a 1,3-meta-bridged azulene, 1,3-(5-cyano-6-oxoundecamethylene)azulene.[1] This route was not possible for the formation of a 5,7-bridge. The later synthesis of 3,5-bridged pyrylium perchlorate (**1**) and pyrydinium iodide (**2**)[2] made available compounds needed for a 5,7-bridged azulene by the Hafner route.



1: X=O, Y=ClO_4 **3** **4**
2: X=NMe, Y=I

Reaction of sodium cyclopentadienide with **1** or **2** gave a low (≤0.3%) yield of the title compound (**3**) as violet crystals. The PMR spectrum of **3** in trifluoroacetic acid corresponded well to the structure of the conjugate acid (**4**).

A molecular model of **3** did not show steric strain such that appreciable distortion of the azulene ring would occur. Distortion of the ring should cause a larger bathochromic shift of the ultraviolet absorption than is caused by the tetraalkyl substitution, and ring distortion would also probably cause lower intensity of absorption and loss of fine structure.[3] Comparison of the ultraviolet spectrum with those of the best model compounds in the literature (4,8-,[4] 4,5-,[5] and 4,7-dimethylazulenes[6]) showed a shift to longer wavelengths for **3**, but the principal maximum at 581 nm agreed well with 578 nm calculated by Plattner's rule.[6] The absence of ring distortion was also indicated by the high intensities (log ε 3.87 to 4.87) and the retention of fine structure.

The model of **3** showed the *c* methylenes over the pi-electron cloud of the aromatic ring in the sterically favoured conformations. The model also showed significant steric restrictions to rotational conversions from the many unsymmetric to the two symmetric conformations of the bridge. In agreement with the model, the PMR signal for the *c* methylenes (δ 1.25) is at higher field[7] than that for the *b* methylenes (δ 1.78) which are nearer to the plane of the azulene ring. Comparison with the spectrum of 5,7-dimethylazulene[8] showed a shift inversion for the 2- and 6-hydrogens: δ 7.48 and 7.61, respectively, for **3**, *vs.* δ 7.81 and 7.42. This may be explained by two factors: the very small concentration of **3** in the PMR solution would cause the 6-H signal to shift downfield, but would have little effect on the 2-H signal,[9] and the effective shielding of the 6-H would be decreased by the asymmetrical interaction with the bridge hydrogens.[10] The observed nonequivalence of 1-H and 3-H (δ 7.19 and 7.28) seems due to the asymmetrical magnetic anisotropy effect of the bridge. The small amount of material obtained did not permit experiments concerned with this point.

Experimental

PMR spectra (δ) were taken on a Hitachi R-22 spectrometer with TMS as internal standard, for **3**, with a Hitachi A-1600 signal averaging analyzer. MS were obtained at 70 eV on a Hitachi RMS-4 instrument. UV and visible spectra were recorded on a Hitachi 624 digital spectrometer with a Hitachi 056 recorder. IR spectra were taken on a JASCO A-3 spectrometer. Mps are uncorrected.

*2,6-Dimethyl-3,5-nonamethylenepyrylium Perchlorate (**1**).* This compound was prepared from cyclododecene [166 g (1 mol) purified by distillation; bp 111—116 °C/12 Torr] and acetic anhydride (511 g, 5 mol) in the presence of 70% perchloric acid[2] except that stirring was continued for 2 h at room temperature after addition of the acid. Recrystallization of the product from 1% perchloric acid gave 41.3 g (12.4%) of **1** as pale yellow crystals, mp 181—182 °C (lit,[2] 170 °C). IR (KBr) 3020, 2890—2940, 2855, and 1606 cm^{-1}. PMR (CF_3COOH) δ=2.94 (6H, s, CH_3), 3.02 (4H, t, *J*= 6.0 Hz, *a*), 2.00 (4H, symmetrical m, *b*), 1.28 (10H, unsymmetrical m, *c*), and 8.80 (1H, s, pyrylium H).

*1,2,6-Trimethyl-3,5-nonamethylenepyridinium Iodide (**2**).* Dry ammonia gas was bubbled into a suspension of 50.8 g (0.153 mol) of vacuum-dried **1** in 300 cm^3 of dry *t*-butyl alcohol for 2 h[2] to give 24.26 g (68.6%) of 2,6-dimethyl-3,5-nonamethylenepyridine, bp 140—142 °C/3 Torr; UV_{max} (cyclohexane) 197 (log ε 4.3), 217 (3.9), 273 (3.5) and 280^{sh} nm (3.5); IR (liquid film) 2930, 2855, and 1445 cm^{-1}; PMR ($CDCl_3$) δ=1.04 (10H, m, *c*), 1.64 (4H, m, *b*), 2.64 (4H, t, *J*=6.5 Hz, *a*), 2.41 (6H, s, CH_3) and 7.20 (1H, s, 4-H).

The pyridine [5.13 g (0.222 mol)] was mixed with 5 cm^3 (0.08 mol) of methyl iodide. After 12 h, an additional 5 cm^3 of methyl iodide was added. After 12 h, removal of excess methyl iodide (reduced pressure) left **2** as a yellowish hygroscopic crystalline mass.

*4,8-Dimethyl-5,7-nonamethyleneazulene (**3**). A. From **1**.* To sodium cyclopentadienide prepared from 4.6 g (0.07 mol) of cyclopentadiene and 2.9 g (0.06 mol) of sodium hydride in 30 cm^3 of THF under dry nitrogen, was added 6.7 g (0.02 mol) of **1** in 15 cm^3 of THF (30 min) and the mixture stirred

for 2 h. Two-thirds of the solvent was removed, 300 cm^3 of water was added, and the whole was extracted several times with petroleum ether. The solvent was evaporated and the residue chromatographed on 20 g of silica gel (petroleum ether eluant). Extraction of the blue-green fraction with 85% phosphoric acid, dilution of the extracts with ice water, extraction of the aqueous solution with petroleum ether, evaporation of the solvent, and chromatography with petroleum ether of the residue on 25 g of silica gel gave 16.7 mg (0.3%), mp *ca.* 89 °C.

The crude product (66.8 mg, 0.239 mmol) in petroleum ether was retreated with 85% phosphoric acid as described above. Chromatography on 25 g of silica gel (petroleum ether) and rechromatography on 7 g of silica gel (hexane–benzene, 9:1) gave 23.4 mg of **3** as blue-violet crystals. Passage over Amberlite IRC-50 (CG-50 type) (80% ethanol) gave 9.82 mg (0.04%) of violet plates from 80% ethanol, mp 109—110 °C; pure by GLC, UV_{max} (cyclohexane) 253 (log ε 4.71), 292 (4.87), 298 (4.85), 340 (3.97), 350 (4.06), and 365 nm (3.87); 565^{sh} (ε 829), 581 (875), 600 (816), 627^{sh} (666), 660^{sh} (361), and 690 nm (196). IR (CCl_4) 2920, 2850, and 1460 cm^{-1}. PMR (CCl_4, 90 MHz), δ= 1.25 (10H, broad s, *c*), 1.78 (4H, m, *b*), 2.88 (6H, s, CH_3), 3.05 (4H, m, J=6.0 Hz, *a*), 7.19 (1H, dd, J=4.0 and 1.5 Hz, 1- or 3-H), 7.28 (1H, m, overlapping 7.19 signal, 1- or 3-H), 7.48 (1H, q, J=4.0 Hz, 2-H) and 7.61 (1H, s, 6-H). MS *m/e* 280 (M^+ for $C_{21}H_{28}$, base peak) [M^+=280.218 ($C_{21}H_{28}$= 280.219)].

B. From **2**.[11] Sodium cyclopentadienide (from 3.8 g (0.078 mol) of sodium hydride and 7.4 cm^3 (0.09 mol) of cyclopentadiene) in 10 cm^3 of THF was added to the vacuum dried ($CaCl_2$) pyridinium iodide (**2**) from 0.222 mol of pyridine. The mixture was stirred for 2.5 h and the solvent was removed. A petroleum ether solution of the violet solid was washed (H_2O), dried (Na_2SO_4), separated from the solvent, and chromatographed on 80 g of silica gel (petroleum ether–benzene, 9:1). The green zone (86.23 mg) was purified as described for the crude product in *A* to give 2.12 mg (0.034%) of **3**.

A solution of **3** in trifluoroacetic acid showed PMR signals corresponding to **4**, δ=1.33 (10H, *c*), 2.10 (4H, *b*), 3.05 (6H, 4-CH_3 and 8-CH_3), 3.46 (4H, *a*), 4.20 (2H, 1-CH_2), 7.68 (2H, 2-H and 3-H), and 8.78 (1H, 6-H).

The authors wish to express their thanks to Professor Yuho Tsuno and Professor Hitoshi Takeshita of Kyushu University for kind measurements of FT-NMR spectra. Thanks are also due to Dr. Mitsuru Nakayama of Hiroshima University for kind measurements of mass spectra. The present work was partially carried out in the Department of Chemistry, University of Washington, and partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Allylation of Nucleic Acid-Bases with Triallyl Phosphate

Toshizumi TANABE,* Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received May 12, 1978)

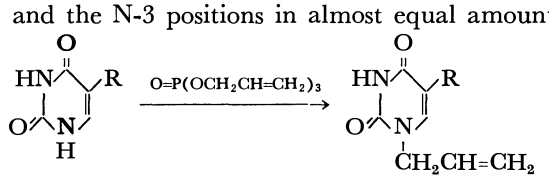
Synopsis. Triallyl phosphate alkylated uracil (N-1), thymine (N-1), cytosine (N-1), adenine (N-3 and N-9), and guanine (presumably N-1 or N-7) in a water solution at 60 °C (pH values were 10—10.5 for uracil, thymine, cytosine, and adenine, and 12 for guanine), giving the corresponding allyl derivatives in considerable yields.

Many modified nucleosides are present in various tRNAs and have been considered to play important roles in their biogenesis.[1] Since most of the modified nucleosides are methylated at nitrogen atoms of base moieties, methylation studies of nucleic acid-bases or nucleosides have been carried out using various alkylating agents, such as dimethyl sulfate,[2-4] diazomethane,[5] and methyl iodide.[6,7] Previously, we reported methylation[8] and ethylation[9] of nucleic acid-bases in an aqueous phase by means of trimethyl and triethyl phosphate (TMP and TEP).

In this paper, we wish to describe the reactions of nucleic acid-bases such as uracil (**1**), thymine (**2**), cytosine (**3**), adenine (**7**), and guanine (**10**) with triallyl phosphate (TAP) in an aqueous phase. These reactions may be interest since there is a class of nucleic acid components which are substituted by allyl or isopentenyl groups like triacanthine.[10] Moreover, the present reactions are considered to resemble the biosynthesis of cytokinin which involves a transfer of an allylic group from Δ^2-isopentenyl pyrophosphate to the 6-amino group of adenine ring.[11]

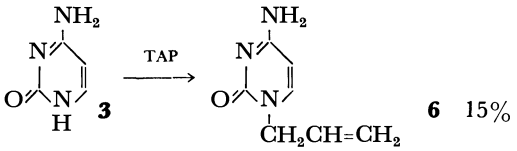
The reactions were carried out at 60 °C by stirring a mixture of a base and 2 molar excess of TAP in water. (The pH values were maintained at 10—10.5 for **1**, **2**, **3**, and **7**, and 12 for **10** throughout the reactions by the occasional addition of 4 M sodium hydroxide.)

Generally, **1** and **2** have been known to be alkylated with alkyl halides to give mainly 1-alkyl derivatives.[12,13] In the present reactions of **1** and **2** with TAP, 1-allyluracil (**4**) and 1-allylthymine (**5**) were obtained in 12 and 13% yields, respectively. The preference for the alkylation at the N-1 position was also observed in the ethylation of **1** and **2** with TEP,[9] while TMP methylated these two pyrimidine bases at both the N-1 and the N-3 positions in almost equal amounts.[8]



1: R=H
2: R=Me
4: R=H 12%
5: R=Me 13%

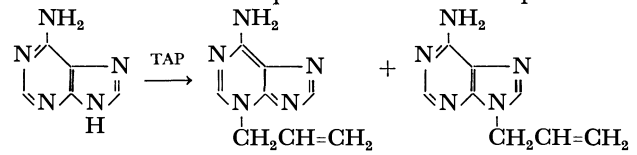
In cytosine (**3**), alkylation has been reported to take place mainly at the N-3 position in the reaction with dimethyl sulfate in DMF,[2] while TMP and TEP alkylated **3** at the N-1 position predominantly.[8,9] The present reaction of **3** with TAP occurred at the N-1 position to provide 1-allyl derivative (**6**) in 15% yield.



3 **6** 15%

Thus, triallyl phosphate was found to alkylate the above pyrimidines (**1**, **2**, and **3**) mainly at the N-1 position to give 1-allyl derivatives. The difficulty in alkylation at the N-3 position is attributed to the steric hindrance around the N-3 position of **1**, **2**, and **3** by two adjacent carbonyl or amino groups.

Meanwhile, adenine (**7**) was alkylated by TAP at the N-3 and the N-9 positions to afford 3-allyladenine (**8**) and 9-allyladenine (**9**) in 35 and 31% yields. Although **7** is generally known to be alkylated at the N-3 position under neutral conditions[3,4,14,15] and at the N-9 position under alkaline conditions,[7] alkylations with trialkyl phosphates such as TMP,[8] TEP,[9] and TAP in alkaline aqueous phase tend to take place at the N-3 and the N-9 positions in almost equal ratios.



7 **8** 35% **9** 31%

Most of guanine (**10**), on the other hand, remained unchanged in the reaction with TAP, because of the sparing solubility of **10** and TAP in water. (More than 70% of **10** was recovered.) But the reaction mixture, which was obtained after removing the unchanged **10**, showed eight product-spots on its thin-layer chromatography. Identification of these products, however, remained unsolved; the spectra of the isolated compounds did not resemble those of any known alkylated guanines.

Based on the above experiments, TAP was found to alkylate all five main nucleic acid-bases at various positions. This rather strong alkylating property of TAP may originate from its conjugated structure. The reactivity order of nitrogen atoms in each nucleic acid-base except **10**[16] toward TAP in weakly alkaline aqueous phase was found as follows; uracil, thymine, and cytosine: N-1>N-3; adenine:N-9, N-3>N-7, N-1.

Experimental

Melting points are uncorrected. The UV spectra were measured with a Hitachi EPS-3T spectrometer. The NMR spectra were recorded on a Hitachi 3T spectrometer, with a dilute solution in deuterium oxide, deuteriochloroform, or dimethyl-d_6 sulfoxide. Tetramethylsilane was used as the internal and outside standard. Mass spectra were obtained using a JEOL 01SG-2 spectrometer. Column chromatography was carried out using silica gel (Merck, Art. 7734, 70—230 mesh).

Commercially available uracil, thymine, cytosine, adenine,

and guanine were used without further purification. Triallyl phosphate was prepared by the procedure of Toy and Costello.[17]

*1-Allyluracil (**4**).* A mixture of **1** (1.23 g, 1.1 mmol) and TAP (5.10 g, 30.0 mmol) in water (15 ml) was stirred at 60 °C. The suspension was maintained at pH 9—10 throughout the reaction by the occasional addition of 4 M sodium hydroxide. After stirring for 48 h, the reaction mixture was neutralized with concentrated hydrochloric acid and extracted with chloroform. Unchanged **1** was recovered from the water layer (0.76 g, 63%). The organic layer was concentrated to give a residue which afforded crystalline 1-allyluracil (**4**, 0.20 g, 12%) by the addition of hexane; mp 106—108 °C; NMR ($CDCl_3$) δ=4.40 (2H, complex m, $-CH_2-CH=CH_2$), 5.08—5.57 (2H, complex m, $-CH_2-CH=CH_2$), 5.60—6.40 (1H, complex m, $-CH_2-CH=CH_2$), 5.78 (1H, d, J=7 Hz, **H**^{5}), 7.28 (1H, d, J=7 Hz, **H**^{6}), and 10.48 (1H, bs, N^3–**H**); UV, λ_{max} (H_2O) nm: pH 1, 266.0 (log ε 4.05), pH 7, 266.0 (log ε 4.00), pH 13, 265.0 (log ε 3.84); Found: C, 55.35; H, 5.04; N, 18.62%. Calcd for $C_7H_8N_2O_2$: C, 55.25; H, 5.30; N, 18.41%.

*1-Allylthymine (**5**).* A reaction of **2** (1.20 g, 10.0 mmol) with TAP (5.10 g, 30.0 mmol) in water (15 ml) at 60 °C for 48 h afforded **5** (0.20 g, 13%) after a procedure similar to that described above; mp 96—97 °C (from methanol); NMR ($CDCl_3$) δ=1.94 (3H, d, J=1.2 Hz, $-CH_3$), 4.35 (2H, complex m, $-CH_2-CH=CH_2$), 5.02—5.50 (2H, complex m, $-CH_2-CH=CH_2$), 5.50—6.30 (1H, complex m, $-CH_2-CH=CH_2$), 7.02 (1H, d, J=1.2 Hz, **H**^{6}), and 9.80 (1H, bs, N^3–**H**); UV, λ_{max} (H_2O) nm: pH 1, 272.0 (log ε 3.96), pH 7, 272.0 (log ε 3.95), pH 13, 272.0 (log ε 3.82); Found: C, 57.76; H, 5.98; N, 16.75%. Calcd for $C_8H_{10}N_2O_2$: C, 57.82; H, 6.07; N, 16.86%. Unchanged **2** was recovered in 67% yield (0.80 g).

*1-Allylcytosine (**6**).* A mixture of **3** (1.00 g, 0.9 mmol) and TAP (5.10 g, 30.0 mmol) was stirred in water (10 ml, pH 9—10, NaOH) at 60 °C for 48 h. The reaction mixture was then neutralized by concentrated hydrochloric acid and extracted with chloroform to remove the unchanged TAP. The water layer was concentrated to give a residue, which was then separated by silica gel chromatography (2×50 cm). Elution with chloroform–methanol (5:2) provided the salt of **6** with diallyl hydrogen phosphate (0.46 g) and unchanged **3** diallyl hydrogen phosphate (1.52 g, 59%). The salt of **6** was subsequently treated with an anionic exchange resin (Dowex 1×8, 200—400 mesh, OH form). Elution with water gave the free form of **6** (0.20 g, 15%); mp 245—247 °C (sublime); NMR (D_2O) δ=4.37 (2H, complex m, $-CH_2-CH=CH_2$), 4.85—5.48 (2H, complex m, $-CH_2-CH=CH_2$), 5.52—6.30 (1H, complex m, $-CH_2-CH=CH_2$), 5.99 (1H, d, J=7 Hz, **H**^{5}), and 7.48 (1H, d, J=7 Hz, **H**^{6}); UV, λ_{max} (H_2O) nm: pH 1, 282.0 (log ε 4.19), pH 7, 274.0 (log ε 4.01), pH 13, 274.0 (log ε 4.00); Found: C, 54.38; H, 5.76; N, 27.21%. Calcd for $C_7H_9N_3O\cdot 0.2H_2O$: C, 54.33; H, 6.08; N, 27.13%.

*3- and 9-Allyladenines (**8** and **9**).* Compound **7** (1.35 g, 10.0 mmol) and TAP (5.20 g, 31.0 mmol) was stirred in water (10 ml, pH 10, NaOH) at 60 °C for 48 h. After the reaction mixture was neutralized by hydrochloric acid, the resulting solution was concentrated to give a residue which was subsequently mixed with ethanol and separated from undissolved substances. The residue which was obtained after concentrating the ethanolic solution was then purified with a silica gel column (3×50 cm). Elution with chloroform–methanol (10:1) provided **9** (0.57 g, 31%); mp 162 °C (from benzene) (lit,[18] 163 °C); NMR ($CDCl_3$) δ=4.75—5.00 (2H, complex m, $-CH_2-CH=CH_2$), 5.05—5.53 (2H, complex m, $-CH_2-CH=CH_2$), 5.75—6.55 (1H, complex m, $-CH_2-CH=CH_2$), 6.32 (2H, bs, $-NH_2$), 7.88 (1H, s, **H**^{2}), and 8.46 (1H, s, **H**^{8}); UV, λ_{max} (H_2O) nm: pH 1, 259.5 (log ε 4.11), pH 7, 261.0 (log ε 4.11), pH 13, 261.0 (log ε 4.11). The subsequent elution with the same solvent afforded crude **8** contaminated with some phosphate, which was then treated with an anionic exchange resin (Dowex 1×8, 200—400 mesh, OH form). Elution with water gave **8** (0.64 g, 35%); mp 207—210 °C (from methanol) (lit,[15] 199—201 °C); NMR (D_2O) δ=4.40—5.06 (2H, complex m, $-CH_2-CH=CH_2$), 5.06—5.50 (2H, complex m, $-CH_2-CH=CH_2$), 5.58—6.50 (1H, complex m, $-CH_2-CH=CH_2$), 7.80 (1H, s, **H**^{2}), and 8.06 (1H, s, **H**^{8}); UV, λ_{max} (H_2O) nm: pH 1, 274.0 (log ε 4.22), pH 7, 274.0 (log ε 4.10), pH 13, 274.0 (log ε 4.06).

*Allylation of Guanine (**10**).* Compounds **10** (2.50 g, 16.6 mmol) was suspended in a mixture of TAP (10.2 g, 60.0 mmol) and water (100 ml, pH 12, NaOH) at 60 °C. After stirring for 48 h, undissolved **10** (1.83 g, 73%) was recovered by filtration and the resulting solution was extracted with toluene to remove unchanged TAP. The water layer was developed on silica gel [GF_{254} (type 60), Merck] thin-layer chromatography using chloroform–methanol (5:1), and showed eight unidentified spots. After concentrating the water solution, the residue was mixed with ethanol and separated from the undissolved substances. The residue which was obtained after concentrating the alcoholic solution was purified by silica gel chromoatography (3×55 cm). Two kinds of effluents were obtained, using chloroform–methanol (8:1) as the developing solvent. One of them showed a single spot on silica gel TLC, which turned out to be monoallylguanine from its mass spectrum (0.03 g, 1%); *m/e*: 191; UV λ_{max} (H_2O) nm: pH 1, 251, 275(s), pH 13, 280.0. The other effluent (0.01 g) seemed to be a mixture of monoallyl- and diallylguanines, since there were two spots on its silica gel TLC and its mass spectrum showed *m/e* 231 and 191.

Autoxidation of Thujopsene in Carboxylic Acid Media. Co-preparation of Mayurone and 3-Thujopsanone

Kazuo ABE* and Masaaki ITO

Chemistry Laboratory, Department of General Education, Higashi Nippon Gakuen University, Onbetsu, Hokkaido 088-01

(Received May 22, 1978)

Synopsis. *cis*-(−)-Thujopsene has been autoxidized by perculation molecular oxygen through carboxylic acid solution, giving mayurone and 3-thujopsanone in fair yields. An investigation on the reaction conditions is described.

In a previous paper,[1] the autoxidation of thujopsene (**1**) to mayurone and other carbonyl compounds was reported utilizing metal chelate catalysts in dioxane. The reaction of thujopsene however, with a bismuth-(III) sulfate catalyst in carboxylic acid media gave a neopentyl type ester (**2**),[2] which differed from the general reactions of olefins.[3] This paper reports the autoxidation of **1** in carboxylic acid media to give mayurone and 3-thujopsanone in fair yields.

Experimental

Melting points were determined with a Shimadzu micro melting point apparatus and are uncorrected. The NMR spectra were recored on a JEOL JNM-PMX spectrometer using TMS as the internal standard. The IR spectra were determined on a Shimadzu IR-400 spectrometer and optical rotations on a Shimadzu polarisacchari meter. GLC analyses were performed on a Shimadzu GC-4B apparatus with a 1.5 m glass column packed with 10% OV-17, at 200 °C. The thujopsene used was purified by distillation of Cedar H oil (Takasago Perfumery Co., Ltd.) through a concentric column; bp 120 °C/10 Torr. The organic acids used were commercial, extra-pure reagents.

*General Procedure for Autoxidation of Thujopsene (**1**) in Carboxylic Acid.* Into a stirred solution of **1** (4.09 g, 20 mmol) in an organic acid or dioxane (0.4 mol), was passed a stream of dry oxygen at a rate of 66 ml/min at 75 °C for 20 h, using a catalyst in some cases. After removal of the organic acid under reduced pressure, the solution of the resulting residue was washed with water, the ether layer dried over anhydrous sodium sulfate, and the solvent removed. The reaction mixture was analyzed by GLC. In the case of preparation of main products, the reaction mixture was distillated. The corresponding fractions were collected and subsequently recrystallized.

*Isolation of (−)-3-Thujopsanone (**4**).* Into a stirred solution of thujopsene **1** (30.7 g, 0.15 mol) in propionic acid (333 g, 4.5 mol), a dry stream of oxygen was passed at the rate of 200 ml/min at 75 °C for 30 h. After removal of propionic acid under reduced pressure, the reaction mixture was distilled through a concentric column to collect the distillate with a bp of 138—139 °C/8 Torr on chilling a crystalline matter deposited. Recrystallization of the crystals from pentane gave 2.6 g of **4** as colorless crystals, further purified by sublimation; mp 71.3—71.8 °C; $[\alpha]_D^{20}$ −85.5° (*c* 16.4, CCl_4); IR (CCl_4) 1712 cm^{-1} (C=O); NMR ($CDCl_3$) δ 0.61 (3H, s, CH_3), 1.10 (3H, s, CH_3), 1.23 (6H, d, $2CH_3$, J=6 Hz), 1.66 (1H, d, 4-$CH_2(\alpha)$, J=14 Hz), 2.22 (1H, d, 4-$CH_2(\beta)$, J=14 Hz), 2.45 (1H, q, 2-H, J=7 Hz). Found: C, 81.61; H, 10.88%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

Results and Discussion

The oxidation of *cis*-(−)-thujopsene (**1**) with molecular oxygen in a series of organic acids from acetic to isovaleric gave mayurone (**3**) and (−)-thujopsanone (**4**) in yields as shown in Fig. 1. The reactions always gave **3**, **4**, and **5**, regardless of the carboxylic acid used. The highest yields were obtained in propionic acid which has the highest pK_a value in the series of organic acid used. Addition of $CoCl_2 \cdot 6H_2O$ in the above reaction system (in $C_2H_5CO_2H$) did not influence the

yields of **3** and **5** but decreased the yield of **4**. Benzoyl peroxide did not give catalytic effect.

The autoxidation without catalyst in dioxane was significantly different from the same reaction in organic acid media. The addition of Co(II) complex catalyst in the system gave a higher yield of **3** and only a little of **4**,[1] the results of which are summarized in Table 1.

a) This work, *cf.* Ref. 1.

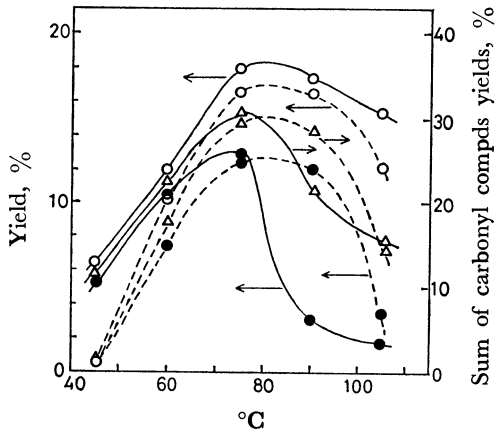

Fig. 2. Yield of carbonyl compounds—reaction temperature profiles for the autoxidation in carboxylic acid media.
Thujopsene 20 mmol, propionic acid 0.4 mol, O_2 or air 66 ml/min for 20 h.
○: Mayurone, ●: 3-thujopsanone, △: sum of carbonyl compds, ——: O_2, ----: air.

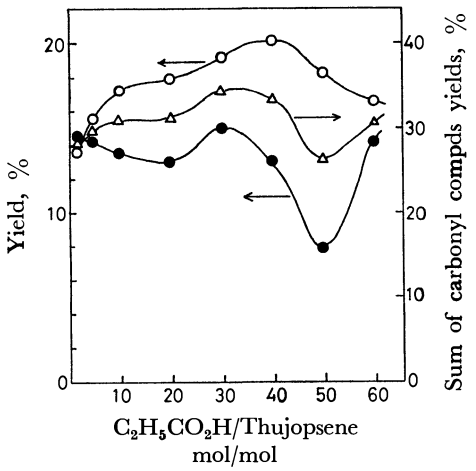

Fig. 3. Yield of carbonyl compounds—amount of carboxylic acid used profiles for the autoxidation in propionic acid media.
O_2 66 ml/min, at 75 °C for 20 h.
○: Mayurone, ●: 3-thujopsanone, △: sum of carbonyl compds.

The optimum conditions for autoxidation were found in propionic acid. To obtain higher yields of carbonyl compounds, the reaction must be conducted at 70 °C using 40—30 mole parts of thujopsene as shown in Figs. 2 and 3.

The GLC of the reaction product (propionic acid/thujopsene=40/1, oxygen 66 ml/min, 75 °C for 20 h) indicated that the main products were **3** and **4**. The IR and NMR spectra of products **3** and **5** were coincident with those of authentic samples. The structure of **4** was confirmed by analytical and spectral analysis and also by the LAH reduction of **4** which afforded (+)-3-neothujopsanol which have been prepared by the hydroboration of thujopsene.[4] It was found that an unidentified product of the autocatalytic oxidation[1] of thujopsene with metal chelate catalyst was identical with (−)-3-thujopsanone (**4**).

The authors wish to express their gratitude to Takasago Perfumery Co., Ltd., for the donation of crude thujopsene.

Reactions of 2-Hydroxyimino-3-methyl-2,3-dihydrobenzothiazole Derivatives with Grignard Reagents and Organolithiums

Kin-ya AKIBA,* Hiroaki SHIRAISHI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 9, 1978)

Synopsis. Reactions of 2-hydroxyimino-3-methyl-2,3-dihydrobenzothiazole derivatives (**1**) with Grignard reagents gave 2-hydroxyimino (**1e**) and 2-(substituted imino)-3-methyl-2,3-dihydrobenzothiazoles as major products, where **1e** was reduced by excess Grignard reagents to 2-imino derivative. On the other hand, reactions of **1** with organolithiums afforded *o*-(methylamino)phenyl sulfides as a major product.

As reported previously, reactions of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles with Grignard reagents[1] and organolithiums[2] give products through attacks on the C-2 and the sulfur atom in the ring and the nitrogen atom of the nitroso group, depending on the type of nucleophiles.[3] Therefore, it is interesting to examine reactions of 2-hydroxyimino-3-methyl-2,3-hydrobenzothiazole derivatives (**1**) with the same kind of nucleophiles, expecting to see whether these can be controlled to effect ring-expansion[4,5] by changing the nature of leaving groups.

Reactions of 2-hydroxyimino-3-methyl-2,3-dihydrobenzothiazole derivatives (**1**) with Grignard reagents gave 2-hydroxyimino- (**1e**), 2-imino- (**2**), and 2-(substituted imino)-3-methyl-2,3-dihydrobenzothiazoles (**3**), bis[*o*-(*N*-cyanomethylamino)phenyl] disulfide (**4**), bis[*o*-(methylamino)phenyl] disulfide (**5**), and *o*-(methylamino)phenyl sulfide (**6**), depending on the substituent of **1** and reaction conditions. The results are summarized in Table 1.

The tosyloxyimino (**1a**) and benzoyloxyimino derivatives (**1b**) reacted easily in ether–benzene at room temperature, whereas the trimethylsilyloxyimino (**1c**), methoxyimino (**1d**), and hydroxyimino derivatives (**1e**) reacted only in refluxing benzene.

The possible reaction centers in **1** are a) the nitrogen atom in the imino group, b) the α-atom in the X group, c) the sulfur atom, d) the C-2 atom on the ring.

The formation of **2** is due to *in situ* reduction of **1e** by excess Grignard reagent, which is formed through an attack on the X group (path b). The formation of **4** and **5** is attributable to the presence of ring-opening equilibrium of Grignard type reagent of **2**, which was established in a previous paper.[4] The sulfide **6** is formed through an attack on the sulfur atom in the ring (path c).

Thus, **1a** reacts mainly by path a showing high ability of *p*-toluenesulfonate as a leaving group,[6] **1b**, **1c**, and **1d** do almost exclusively by path b producing Grignard type reagent of **1e** *in situ*.

The interesting point in the reaction of **1** with organolithiums is that path c is observed in a comparable extent with paths a and b, respectively, in the cases of **1a** and **1c**, which was not the case with Grignard reagents.[2] Moreover, **1d** reacts exclusively by path c in dramatic contrast to the result with ethylmagnesium bromide which followed path b almost exclusively. The results are summarized in Table 2.

The high thiophilicity of organolithiums compared with Grignared reagents has been observed in the reaction of the nitrosoimino derivatives with these organometalloids[2] and also in that of thioketones.[7] Conversion of an intermediate, *o*-(*N*-cyanomethylamino)phenyl sulfide (**A**), in to **6** was confirmed by the formation of benzophenone of the corresponding amount in the reaction with phenyllithium.

Experimental

2-Hydroxyimino-3-methyl-2,3-dihydrobenzothiazole (**1e**) was prepared by the reported method,[9] mp 203—204 °C (lit, 202—203 °C).

3-Methyl-2-tosyloxyimino- (**1a**), 2-benzoyloxyimino-3-methyl- (**1b**), 3-methyl-2-trimethylsilyloxyimino- (**1c**), and 3-methyl-2-methoxyimino-2,3-dihydrobenzothiazole (**1d**) were prepared from **1e** and the corresponding halides with base (triethylamine or sodium methoxide) in yields of 80, 69, 87, and 59%, respectively, with correct elemental analyses.

1a: mp 167—169 °C (from benzene–hexane). NMR ($CDCl_3$): δ 2.44 (s, 3H), 3.34 (s, 3H), 6.65—7.95 (m, 8H).

1b: mp 140—142 °C (from methanol). NMR ($CDCl_3$): δ 3.55 (s, 3H), 6.90—7.55 (m, 7H), 8.10—8.25 (m, 2H).

1c: bp 152 °C/3.5 mmHg, mp 49—50 °C. NMR ($CDCl_3$): δ 0.15 (s, 9H), 3.39 (s, 3H), 7.4—7.6 (m, 4H).

1d: bp 125—127 °C/115 mmHg, mp 47—48 °C (from hexane). NMR (CCl_4): δ 3.30 (s, 3H), 3.82 (s, 3H), 6.62—7.30 (m, 4H).

The following reactions were carried out under nitrogen.

*Reaction of Tosyloxyimino Derivative (**1a**).* *1) With p-Tolylmagnesium Bromide*: *p*-Tolylmagnesium bromide (4.5 mmol) in ether (15 ml) was added dropwise to a solution of **1a** (1.00 g, 3.0 mmol) in benzene (15 ml) at room temperature, and the mixture was stirred for 0.5 h. The reaction mixture was treated with 10% aq ammonium chloride (25 ml), extracted with dichloromethane and the dried extract was evaporated. The residue was submitted to dry column chromatography (DCC) (SiO_2, hexane: CH_2Cl_2=1:1) to afford 3-methyl-2-*p*-tolylimino-2,3-dihydrobenzothiazole (**3a**), yield 523 mg, (69%), mp 92—93 °C (from MeOH). NMR ($CDCl_3$): δ 2.34 (s, 3H), 3.55 (s, 3H), and 6.80—7.42 (m, 8H); MS: *m/e* 254 (M^+, 100%).

The compound (**3a**) was identical in every data with the authentic sample prepared from p-toludine and 3-methyl-2-methylthiobenzothiazolium iodide.[10]

2) With Ethylmagnesium Bromide: Ethylmagnesium bromide (3.9 mmol) in ether (15 ml) was added dropwise to **1a** (1.00 g, 3 mmol) in benzene (30 ml) and the mixture was stirred for 1 h. After usual work-up and DCC (SiO_2, CH_2Cl_2:AcOEt-4:1), 274 mg of **1a** was recovered, and oily 2-ethylimino-3-methyl-2,3-dihydrobenzothiazole (**3b**) (302 mg, 72%) and bis[*o*-(*N*-cyanomethylamino)phenyl] disulfide (**4**) (42 mg, 12%), mp 141 °C (lit,[11] 140—141 °C), were isolated.

3b: NMR ($CDCl_3$): δ 1.30 (t, J=7 Hz, 3H), 3.25 (q, J=7 Hz, 2H), 3.40 (s, 3H), and 6.79—7.40 (m, 4H).

*Reaction of Benzoyloxyimino Derivative (**1b**) with p-Tolylmagnesium Bromide* in benzene at room temperature afforded, after usual work-up, **1e** in 78% yield.

*Reaction of Hydroxyimino Derivative (**1e**) with Ethylmagnesium Bromide.* Ethylmagnesium bromide (17 mmol) in ether (15 ml) was added to **1e** (500 mg, 2.8 mmol) in warm benzene (30 ml) and the mixture was refluxed for 3 h. After usual work-up and DCC (SiO_2, CH_2Cl_2:AcOEt=4:1) followed by preparative thin-layer chromatography (PTLC) (SiO_2, CH_2Cl_2:hexane=1:1), 40 mg of **1e** was recovered, and 2-imino-3-methyl-2,3-dihydrobenzothiazole (**2**) (357 mg, 85%) mp 122—123 °C (lit,[12] 123 °C), bis[*o*-(methylamino)phenyl] disulfide (**5**) (22 mg, 6%), mp 66—67 °C (lit,[13] 67—68 °C), and ethyl *o*-(methylamino)phenyl sulfide (**6b**) (24 mg, 6%) were obtained.

6b: IR (neat): 3350 cm^{-1}; NMR ($CDCl_3$): δ 1.18 (t, J=7 Hz, 3H), 2.72 (q, J=7 Hz, 2H), 2.85 (s, 3H), and 6.5—7.5 (m, 4H); MS: *m/e* 167 (M^+, 100%).

*Reaction of Trimethylsilyloxyimino Derivative (**1c**) with Ethylmagnesium Bromide* in refluxing benzene (1.5 h) gave, after the same procedure as the preceding one, **2** (78%), **3b** (4%), and **5** (3%).

*Reaction of Methoxyimino Derivative (**1d**) with Ethylmagnesium Bromide* in refluxing benzene (3 h) gave, after usual work-up, **2** (72%).

*Reaction of **1a** with Butyllithium.* Butyllithium (10 mmol) in hexane (6 ml) was added to **1a** (836 mg, 2.5 mmol) in benzene (35 ml) and the mixture was stirred for 2 h. After usual work-up, the residue was submitted to DCC (SiO_2, CH_2Cl_2) and then PTLC (SiO_2, CH_2Cl_2: AcOEt=10:1 and then CH_2Cl_2:hexane=1:1) to give **1e** (53 mg, 12%), butyl *o*-(methylamino)phenyl sulfide (**6d**) (165 mg, 34%), 2-butylimino-3-methyl-2,3-dihydrobenzothiazole (**3d**) (86 mg, 16%), and bis[*o*-(methylamino)phenyl] disulfide (**5**) (42 mg, 12%).

3d: oily material; NMR ($CDCl_3$): δ 0.8—1.8 (m, 7H), 3.20 (t, J=7 Hz, 2H), 3.39 (s, 3H), and 6.7—7.4 (m, 4H).

6d: oily material; IR (neat): 3360 cm^{-1}; NMR ($CDCl_3$): δ 0.7—1.0 (m, 3H), 1.2—1.7 (m, 4H), 2.71 (t, J=7 Hz, 2H), 2.89 (s, 3H), 4.80 (bs, 1H), and 6.5—7.5 (m, 4H).

*Reaction of **1c** with Phenyllithium.* Phenyllithium (36 mmol) in ether (20 ml) was added to **1c** (756 mg, 3.0 mmol) in benzene (30 ml) and the mixture was stirred for 1 h. After usual work-up, **1e** (225 mg, 42% after recrystallization from methanol) precipitated from the residue. DCC of the filtrate gave benzophenone (173 mg, 32%), mp 47 °C, and *o*-(methylamino)phenyl phenyl sulfide (**6c**)[2] (233 mg, 36%) (by IR and NMR[2]).

*Reaction of **1d** with Butyllithium* in benzene afforded, after usual work-up and DCC (SiO_2, CH_2Cl_2:hexane=1:4), butyl *o*-(methylamino)phenyl sulfide (**6d**) (90%).

*Reaction of **1d** with Phenyllithium* in benzene afforded, after usual work-up, benzophenone (89%) and **6c** (91%).

Carbon-13 Chemical Shifts of Retinal Isomers and Their Schiff Bases as Models of Visual Chromophores

Yoshio INOUE,* Yasuo TOKITÔ, Shigeki TOMONOH, and Riichiro CHÛJÔ

Department of Polymer Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received June 23, 1978)

Synopsis. Carbon-13 NMR spectra have been observed for 11- and 13-*cis*-retinals and their Schiff base linkage compounds with butylamine as a model compound of visual chromophore. The chemical shift changes on going from retinal to Schiff base. The changes in chemical shifts of polyene carbons were discussed in correlation with the changes of π-electron densities.

The visual mechanism in the vertebrate is mainly controlled by rhodopsin composed of the vitamin A_1 aldehyde isomer, 11-*cis*-retinal, and the lipoprotein, opsin. Absorption of the photon by a visual pigment induces immediate isomerization of the retinal from the 11-*cis*- to *all-trans*-isomer. This isomerization act as a trigger for stimulating the nerve.

When the 11-*cis*-retinal, which has an absorption maximum at 380 nm, forms the visual pigment by combination with opsin, a large bathochromic shift is observed.[1] In order to understand the origin of this spectral shift, it is necessary to know the electronic structure of polyene chain of retinal. Since experimental results suggest that the retinal is bonded through a Schiff base linkage to the ε-amino group of a lysine residue in a opsin,[2–5] the Schiff base compound of retinal with butylamine, *N*-retinylidenebutylamine (NRB), have been used as a model for the rhodopsin. The change in carbon-13 chemical shifts of the conjugated polyene carbon atoms on going from *all-trans*-retinal to *all-trans*-NRB can be correlated quite well with that in π-electron density.[6,7]

We have investigated the changes in the π-electron densities of polyene carbon atoms on going from 11-*cis* and 13-*cis*-retinals to their Schiff base linkage compounds with butylamine by observing the carbon-13 NMR chemical shifts. The polyene aldehyde 13-*cis*-retinal is considered the chromophores of the membrane protein, bacteriorhodopsin.[8]

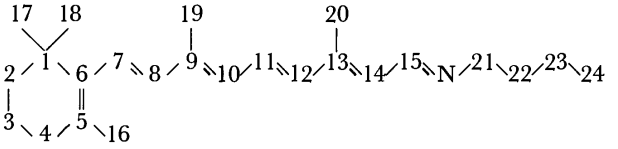
Experimental

11- and 13-*cis*-retinals were prepared by the photoisomerization of *all-trans*-retinals in ethanol in the sunlight. The resulting mixture of retinal isomers was fractionated on a column of sodium aluminosilicate by eluting with petroleum ether. Each crude isomer was purified by repeated crystallization from petroleum ether at −15 °C. Details of the methods of preparation for the *all-trans*-retinal and the Schiff base compound of retinal isomer have been reported.[7]

Carbon-13 NMR spectra were observed on a JEOL JNM PS-100 spectrometer linked with a PFT-100 Fourier transform system at 25.14 MHz. All measurements were carried out immediately after dissolution of sample in CCl_4 in 8 mm o.d. glass tubes in the dark. Chemical shifts were measured as downfield shifts from internal tetramethylsilane. The carbon-13 NMR spectra of 11- and 13-*cis*-retinals were assigned according to the results published.[9,10] All peaks in the carbon-13 NMR spectra of NRB have been assigned by use of various techniques.[7]

Results and Discussion

The chemical shifts of the conjugated polyene chain carbons in *cis*-retinal isomers and their Schiff base linkage compounds are given in Table 1 together with the data of *all-trans*-retinal and *all-trans*-NRB for the sake of comparison. The chemical shifts of the NRB are expressed as the chemical shift differences $\Delta\delta$, the differences between chemical shifts of retinal and those of corresponding NRB, in which the positive and negative signs indicate the downfield and upfield shifts, respectively. The numbering of the carbons, for example in *all-trans*-NRB, is given as shown in the following.



For all isomers the peaks assigned to the odd-numbered carbons show large upfield shifts and the peaks assigned to the even-numbered carbons show small downfield shifts by formation of the Schiff base com-

TABLE 1. THE CARBON-13 CHMICAL SHIEFTS OF CONJUGATED CHAIN CARBONS ON RETINAL ISOMERS AND THEIR SCHIFF BASE COMPOUNDS (NRB)

Carbon No.	11-*cis*		13-*cis*		*all-trans*[c]	
	Retinal[a]	NRB[b]	Retinal[a]	NRB[b]	Retinal[a]	NRB[b]
5	131.5	−0.7	131.7	−0.6	131.7	−1.0
6	139.8	0.1	139.4	0.5	139.8	−0.1
7	130.9	−1.9	130.9	−1.6	130.9	−2.2
8	139.8	0.5	139.8	0.2	139.4	0.3
9	142.6	−2.6	142.3	−2.9	142.1	−3.6
10	128.0	1.3	131.8	0.8	131.7	0.6
11	132.6	−3.8	134.5	−4.0	133.5	−4.9
12	132.6	1.8	129.0	1.0	137.1	1.4
13	155.5	−10.5	154.2	−10.4	154.7	−10.6
14	131.9	0.9	129.8	1.0	131.2	1.1
15	191.5	−30.8	190.2	−30.7	191.5	−31.3

a) Chemical shifts were measured as downfield shifts from internal tetramethylsilane and are expressed in terms of ppm. The estimated error in chemical shifts is less than 0.1 ppm. b) Chemical shifts of NRB are expressed as downfield (plus) and upfield (minus) shifts from the corresponding carbon of retinal. c) The chemical shifts of *all-trans*-retinal and *all-trans*-NRB were taken from Refs. 6 and 7.

pounds. Table 1 also indicates the presence of the gradients in the chemical shifts differences $\Delta\delta$ along the polyene chain from $C(15)$ to $C(5)$.

The carbon-13 chemical shifts of conjugated π-electron systems are generally dominated by the contribution from the paramagnetic term, being related to the π-electron density and π-bond order.[11] According to the data of X-ray analysis[12] and resonance-enhanced Raman spectra,[13] and the results of CNDO/2 MO calculation,[7] there are neither collapse of the bond alternation nor remarkable difference of the π-bond order between *all-trans*-retinal and *all-trans*-NRB. The constancy of the π-bond order may be also valid in the *cis*-isomers. Thus the changes of the chemical shifts can be explained by those of π-electron densities on the polyene chain.[7,11]

When the terminal atom of the polyene chain changes from oxygen to nitrogen, the total π-electron density of the conjugated polyene carbons of NRB increases due to the decrease in electronegativity at the polyene terminal. The carbon-13 chemical shifts differences show that an increase in total π-electron density leads to the increase in π-electron density at the odd-numbered carbons of NRB. It is noticeable that the chemical shifts in the conjugated polyene carbons of NRB are distributed in a relatively narrow range of approximately 30 ppm, whereas those of corresponding retinal isomers are in a range of 60 ppm. The decrease in the chemical shift range indicates that the delocalization of π-electron on the polyene chain is induced by the formation of Schiff base linkage.

The chemical shift differences $\Delta\delta$ of the odd-numbered polyene carbons of *all-trans*-NRB are slightly larger than those of the corresponding carbons in 11- and 13-*cis*-NRB's. This result may reflect the fact that the changes in π-electron density induced by the formation of the Schiff base are slightly larger on the *all-trans* polyene chain than on the *cis*-chain.

The authors are grateful to Dr. Yasuhiro Miyoshi of the Department of Botany, The University of Tokyo, for his valuable discussion.

A Convenient Synthesis of α-(2-Benzothiazolylthio)alkanoates by Cleavage of β-Keto Esters with 2-Benzothiazolesulfenamides

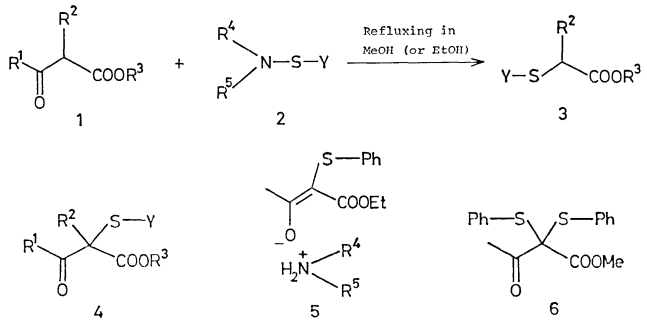
Sigeru TORII,* Hideo TANAKA, and Hiroshi OKUMOTO

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received June 26, 1978)

Synopsis. α-(2-Benzothiazolylthio)alkanoates were prepared by the reaction of β-keto esters with 2-(morpholinothio)benzothiazole in refluxing alcohols. Sulfenylating cleavage of α-methoxycarbonylcycloalkanones afforded the corresponding ω-alkoxycarbonyl- and/or ω-carbamoyl-α-(2-benzothiazolylthio)alkanoates.

In a previous paper, it has been shown that the direct cross-coupling reaction of disulfides with amines by an electrochemical procedure provides a variety of sulfenamides **2** in high yields.[1] Several investigations demonstrate that the sulfenamides **2** and their related compounds can be used for sulfenylation of active hydrogen compounds.[2,3] It was previously reported that sulfenylation of ethyl acetoacetate (**1**, R^1=Me, R^2=H, R^3=Et) with sulfenamides **2** (Y=Ph, R^4, R^5=alkyl) in CH_2Cl_2 gives ethyl α-(phenylthio)acetoacetate (**4**, R^1=Me, R^2=H, R^3=Et, Y=Ph) *via* the intermediate **5**.[3] However, sulfenylating cleavage of β-keto esters **1** with **2** into the corresponding α-sulfenyl esters **3** has not yet been realized. In this paper, we wish to report an efficient synthesis of α-sulfenylalkanoates **3** from β-keto esters **1** by the action of 2-benzothiazolesulfenamides **2**.



The reaction of equimolar amounts of methyl acetoacetate (**1a**, R^1=R^3=Me, R^2=H) with sulfenamide **2a** (Y=Ph, R^4, R^5=$(CH_2CH_2)_2O$) in refluxing methanol for 7 h afforded methyl (phenylthio)acetate (**3a**) along with disulfenylated product **6** (8%) (Table 1, entry 1). On the other hand, the reaction of **1a**

a) Isolated yield.

with various 2-benzothiazolesulfenamides **2b—d** (Y= 2-benzothiazolyl (BT)) furnished **3b** (Y=BT, R^2=H) as a sole product in high yields (entries 2—4). In contrast, thiocarbamoylsulfenamide **2e** (entry 5) afforded only 21% of the desired α-sulfenyl ester **3c** as well as complex materials. In entry 6, most of *N*-(phenylthio)phthalimide (**2f**) was recovered.

Above all, it was found that 2-benzothiazolesulfenamide **2b** is the most effective reagent for the conversion of **1a** into the corresponding α-sulfenylacetates **3**. The results of sulfenylation of α-substituted β-keto esters **1** (R^1, R^2=alkyl) with **2b** in refluxing alcohols are shown in Table 2. Thus, α-alkoxycarbonylcycloalkanones **1** afforded the corresponding ω-alkoxycarbonyl-α-sulfenylalkanoates **3** (R^2=$(CH_2)_n$COOMe (or COOEt)) (entries 8, 9, 12, 13, and 14), indicating that regioselective nucleophilic attack with alcohols, providing the ω-ester groups, was encountered.

When the reaction of 2-methoxycarbonylcyclopentanone (**1c**) with **2b** was carried out in benzene or CH_2Cl_2, the corresponding methyl 5-morpholinocarbonyl-2-sulfenylpentanoate **3g** was isolated in good yields (entries 10 and 11). This result demonstrates that nucleophilic attack of morpholine provided by the sulfenylation to the ketonic carbonyl of **4** [Y=BT, R^1, R^2=$(CH_2)_3$, R^3=Me] would occur preferentially in aprotic solvent.

Experimental

All the melting and boiling points are uncorrected. IR spectra were determined with a JASCO IRA-I infrared spectrometer. NMR spectra were obtained at 100 MHz with a JEOL MH-100 spectrometer.

*Methyl (Phenylthio)acetate (**3a**).* A MeOH solution (3 ml) of $AcCH_2COOMe$ (70 mg, 0.6 mmol) and **2a** (110 mg, 0.6 mmol) was heated to reflux for 7 h. The solution was concentrated *in vacuo* and the residue was chromatographed (SiO_2, benzene–hexane–AcOEt, 10/10/1). The first coming elute gave **6** (16 mg, 8%): bp 119—123 °C/0.003 Torr; IR (neat) 3060, 3030 (HC=C), 1723, 1712 cm^{-1} (C=O); NMR ($CDCl_3$) δ 2.30 (s, 3, CH_3), 3.59 (s, 3, CH_3O), 7.10—7.82 (m, 10, HC=C). Found: C, 61.50; H, 4.99%. Calcd for $C_{17}H_{16}O_3S_2$: C, 61.42; H, 4.85%.

The second fraction afforded **3a** (67 mg, 61%): bp 38—40 °C/0.007 Torr (lit,[4a] bp 87—90 °C/0.3 Torr); IR (neat) 3046 (HC=C), 1734 cm^{-1}; NMR ($CDCl_3$) δ 3.70 (s, 2, CH_2), 3.76 (s, 3, CH_3O), 7.30—7.72 (m, 5, HC=C).

*Methyl (2-Benzothiazolylthio)acetate (**3b**).* A MeOH solution (3 ml) of $AcCH_2COOMe$ (116 mg, 1.0 mmol) and **2b** (252 mg, 1.0 mmol) was heated to reflux for 7 h. Evaporation of the solvent followed by column chromatography (SiO_2, benzene–hexane–AcOEt, 10/10/1) gave **3b** (219 mg, 92%): mp 74—75 °C (Et_2O–hexane, 1/2); IR (Nujol) 3050 (HC=C), 1743 cm^{-1} (C=O); NMR ($CDCl_3$) δ 3.70 (s, 3, CH_3O), 4.12 (s, 2, CH_2), 7.06—7.86 (m, 4, HC=C). Found: C, 50.20; H, 3.81%. Calcd for $C_{10}H_9NO_2S_2$: C, 50.19; H, 3.79%.

The reaction of β-keto esters **1** with **2b—c** was carried out in a similar manner to that above (Tables 1 and 2). Physical properties and spectral data of the products **3c—j** are as follows.

*Compound **3c**:* Bp 64—68 °C/0.006 Torr; IR (neat) 1734 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.72 (br, 6, CH_2), 3.75 (s, 3, CH_3O). 3.92—4.40 (m, 4, CH_2N), 4.18 (s, 2, CH_2S). Found: C, 46.14; H, 6.23%. Calcd for $C_9H_{15}NO_2S_2$: C, 46.32; H, 6.48%.

*Compound **3d**:* Bp 123—126 °C/0.005 Torr; IR (neat) 3053 (HC=C), 1739 cm^{-1}; NMR ($CDCl_3$) δ 0.87 (t, 3, J=6 Hz, CH_3), 1.05—2.19 (m, 10, CH_2), 3.72 (s, 3, CH_3), 4.61 (t, 1, J=7 Hz, CH), 7.11—7.91 (m, 4, HC=C). Found: C, 59.38; H, 6.42%. Calcd for $C_{16}H_{21}NO_2S_2$: C, 59.41; H, 6.54%.

*Compound **3e**:* Bp 124—126 °C/0.008 Torr; IR (neat) 3050 (HC=C), 1732 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.58—2.27 (m, 4, CH_2), 2.35 (t, 2, J=7 Hz, CH_2CO), 3.61 (s, 3, CH_3O), 3.72 (s, 3, CH_3O), 4.66 (t, 1, J=7 Hz, CH), 7.14—7.90 (m, 4, HC=C). Found: C, 53.03; H, 4.87%. Calcd for $C_{15}H_{17}NO_4S_2$: C, 53.08; H, 5.05%.

*Compound **3f**:* Bp 121—123 °C/0.009 Torr; IR (neat) 3050 (HC=C), 1732 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.22 (t, 3, CH_3), 1.62—2.26 (m, 4, CH_2), 2.35 (t, 2, J=7 Hz, CH_2CO), 3.73 (s, 3, CH_3O), 4.07 (q, 2, CH_2O), 4.66 (t, 1, J=7 Hz, CH), 7.09—7.94 (m, 4, HC=C). Found: C, 54.32; H, 5.41%. Calcd for $C_{16}H_{19}NO_4S_2$: C, 54.37; H, 5.42%.

*Compound **3g**:* Bp 147—150 °C/0.006 Torr; IR (neat) 3060 (HC=C), 1733, 1640 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.65—2.31 (m, 4, CH_2), 2.40 (t, 2, J=7 Hz, CH_2CO), 3.28—3.78 (m, 8, NCH_2CH_2O), 3.79 (s, 3, CH_3O), 4.76 (t, 1, J=7 Hz, CH), 7.24—8.06 (m, 4, HC=C). Found: C, 54.64; H, 5.52%. Calcd for $C_{18}H_{22}N_2O_4S_2$: C, 54.80; H, 5.62%.

*Compound **3h**:* Bp 124—126 °C/0.009 Torr; IR (neat) 3065 (HC=C), 1735 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.25 (t, 3, CH_3), 1.63—2.25 (m, 4, CH_2), 2.37 (t, 2, J=7 Hz, CH_2CO), 3.62 (s, 3, CH_3O), 4.19 (q, 2, CH_2O), 4.63 (t, 1, J=7 Hz, CH), 7.11—7.95 (m, 4, HC=C). Found: C, 54.24; H, 5.59%. Calcd for $C_{16}H_{19}NO_4S_2$: C, 54.37; H, 5.42%.

*Compound **3i**:* Bp 124—126 °C/0.006 Torr; IR (neat) 3050 (HC=C), 1730 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.24 (t, 3, CH_3), 1.26 (t, 3, CH_3), 1.67—2.28 (m, 4, CH_2), 2.38 (t, 2, J=7 Hz, CH_2CO), 4.14 (q, 2, CH_2O), 4.26 (q, 2, CH_2O), 4.70 (t, 1, J=7 Hz, CH), 7.24—8.03 (m, 4, HC=C). Found: C, 55.65; H, 5.86%. Calcd for $C_{17}H_{21}NO_4S_2$: C, 55.56; H, 5.76%.

*Compound **3j**:* Bp 125—128 °C/0.006 Torr; IR (neat) 3058 (HC=C), 1739 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.32—2.22 (m, 6, CH_2), 2.31 (t, 2, J=7 Hz, CH_2CO), 3.63 (s, 3, CH_3O), 3.73 (s, 3, CH_3O), 4.64 (t, 1, J=7 Hz, CH), 7.08—8.04 (m, 4, HC=C). The Photo-Beckmann Rearrangement of A-Nor-5α-cholestan-3-one Oxime[1)]

Hiroshi SUGINOME,* Hiroshi TAKEDA, and Tadashi MASAMUNE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 3, 1978)

Synopsis. The photo-Beckmann Rearrangement of A-nor-5α-cholestan-3-one oxime affords 4-aza-5α-cholestan-3-one and 3-aza-5α-cholestan-4-one as the only lactams.

In previous papers,[2)] we reported the photo-Beckmann rearrangement of some cholestanone oximes and A-nor-5β-cholestan-3-one oxime.

In this paper, we report on an investigation of the photo-Beckmann rearrangement of A-nor-5α-cholestan-3-one oxime (**3**) which is complementary to the previous communications.[2)]

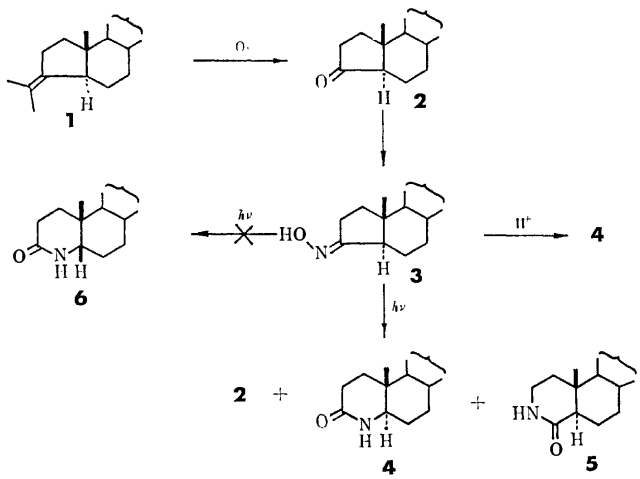
The parent ketone, A-nor-5α-cholestan-3-one (**2**),[2b,6)] has been prepared either by oxidative decarboxylation of 3-hydroxy-A-nor-5α-cholestane-3-carboxylic acid,[4)] prepared *via* three steps from cholest-4-en-3-one, with sodium bismuthate[5)] or by ozonization of 3-isopropylidene-A-nor-5α-cholestane (**1**) prepared *via* 4 steps from cholest-4-en-3-one.[6)] In the present experiment, the 3-one (**2**) was prepared by the latter method which afforded a significantly better overall yield from cholest-4-en-3-one. We have found that the reported yield for the ozonization step (12%) could be significantly improved by a modified procedure (64%, see Experimental).

The new oxime (**3**), prepared by the standard method, exhibited no deshielded proton signal due to the 2-H or the 5-αH at *ca.* τ 6.6 in the ^{1}H NMR spectrum as for the 5β-isomer.[2b)] This is expected since no proton eclipsed by the C=N bond of the hydroxyimino group is present in the oxime (**3**). The Beckmann rearrangement with thionyl chloride afforded 4-aza-5α-cholestan-3-one (**4**) as the sole product, indicating the configuration of the hydroxyimino group as depicted.

The photo-Beckmann rearrangement of the oxime (**3**) in methanol was carried out under the same procedure as for the photo-Beckmann rearrangement of cholestanone oxime previously reported.[2b)] As in the case of A-nor-5β-cholestan-3-one-oxime, irradiation of the oxime led to a mixture of products from which 4-aza-5α-cholestan-3-one (**4**) (6%) and 3-aza-5α-cholestan-4-one (**5**) (4%) were isolated as the only lactams together with A-nor-5α-cholestan-3-one (**2**) (4%) and unchanged oxime (**3**) (9%) by careful preparative TLC. Examination by TLC proved that no 5β isomers of the lactams (**4**) or (**5**) [*e.g.*,(**6**)] were formed.

Thus, it was again proved that the chirality of the migrating group in the oxime is retained during the photo-rearrangement.[2,7)]

The lactam (**5**) has been prepared by a method[3)] which involved 5 steps from 3,4-secocholest-5-ene-3,4-dioic acid. The present result may provide another route for this rather inaccessible lactam.



Scheme.

Experimental

For instruments used and general procedure see Ref. 2b. The mass spectra were taken with a Hitachi JMS-D 300 spectrometer using a direct inlet system (source temperature *ca.* 180 °C) in the Faculty of Pharmaceutical Sciences. Only fragment peaks of the relative intensities of over 20% are described. The infrared spectrum was taken with a model 260-10 Hitachi infrared spectrophotometer.

A-Nor-5α-cholestan-3-one (2).[2b,6)] This ketone was prepared either by the procedure of Camerino *et al.*[5)] or by the procedure of Biellmann and Ourisson.[6)] A modified procedure for ozonization of 3-isopropylidene-A-nor-5α-cholestane by Biellmann afforded a better yield of the ketone. Namely,

TABLE 1. NMR PARAMETERS (100 MHz) FOR THE KETONE, THE OXIME AND THE LACTAMS IN $CDCl_3$ SOLUTION
[Chemical shifts (τ) and splittings (Hz; in parentheses)]

Compound	18-H	19-H	2-CH_2	5-αH	Others

a) Unassignable.

3-isopropylidene-A-nor-5α-cholestane (2 g) in a mixed solvent of dichloromethane and methanol was ozonized at −72 °C. The temperature of the solution was raised to room temperature without adding sodium borohydride. After removal of the solvent, the residue (2.2 g) was subjected to column chromatography (silica gel, Wako C-200, 150 g). Elution with hexane afforded the starting material (41 mg). Further elutions with a 3 : 1 mixture of benzene and hexane afforded the ketone (1.21 g, 64%). This was recrystallized from methanol (1.12 g). Mp 103—106 °C (lit,[6] mp 106 °C). Biellmann[6] reports a yield of 12% for this ozonization step.

A-Nor-5α-cholestan-3-one Oxime (3). The 3-ketone (**2**) (270 mg), hydroxylamine hydrochloride (193 mg) and sodium acetate trihydrate (386 mg) in methanol (35 ml) and water (5 ml) were stirred for 3h. The solution was neutralized with 10% sodium hydrogencarbonate and was extracted with ether. The ethereal solution was worked up in usual way. The residue was recrystallized from methanol to yield the oxime (265 mg). Mp 167—168 °C; $[\alpha]_D^{22}$ +18.4 (*c* 1.0 $CHCl_3$); Found: C, 80.17; H, 11.87; N, 3.31%. Calcd for $C_{26}H_{45}NO$: C, 80.56; H, 11.70; N, 3.61%; IR 3288 (OH), 970, 934, and 905 cm^{-1}; MS (70 eV), *m/e* (rel. intensity), 41 (24.2), 43 (32.0), 55 (33.1), 109 (21.4), 112 (42.0), 217 (24.8), 233 (35.8), 356 (21.7), 370 (100), 371 (32.9), 372 (28.0), 387 (32.4, M^+).

The Beckmann Rearrangement of the Oxime (3). A stirred solution of the oxime (200 mg) in dioxane (6 ml) and ether (2 ml) was cooled to 5 °C. To this solution was added thionyl chloride (1 ml) and the solution was stirred for 1 min. The crystals which appeared in the solution were collected by filtration to afford the crude lactam (112 mg). The filtrate was extracted with ether-water. The ethereal solution was washed with aq sodium hydrogencarbonate solution and with water and dried (Na_2SO_4). The crude product was subjected to preparative TLC with a 4 : 1 mixture of dichloromethane and diethyl ether to afford the crude lactam (53 mg) as a least mobile fraction. The combined crude lactam (**4**) (165 mg, 83%) was recrystallized from methanol. Mp 252—255 °C (lit,[3] 253—255 °C); $[\alpha]_D^{22}$ +43.1 (*c*, 1.0 $CHCl_3$). MS (70 eV), *m/e* (rel. intensity), 41 (20.2), 43 (32.1), 55(28.3), 56 (40.5), 57 (24.0), 98 (37.4), 112 (26.0), 232 (82.4), 233 (50.9), 234 (23.3), 248 (21.3), 372 (24.3), 387 (100, M^+), 388 (30.2).

The Photo-Beckmann Rearrangement of the Oxime (3). The oxime (570 mg) in methanol (500 ml) was irradiated with a 15-W low pressure mercury arc in an atmosphere of nitrogen for 68 h. After removal of the solvent, the residue was extracted with ethyl acetate and the solution was worked up as usual. The TLC has shown the products to be a complex mixture. The crude photolyzate was subjected to preparative TLC (Wakogel B-5F) with a 4 : 1 mixture of dichloromethane and diethyl ether. Seven fractions A, B,C,D,E,F and G were obtained in order of decreasing mobility. The fraction A (37 mg) was the crude parent ketone and this was purified by preparative TLC (a 4 : 1 mixture of benzene and diethyl ether)followed by two recrystallizations to yield pure ketone (20 mg, 4%). The fractions B (20 mg), D (28 mg), E (23 mg), and G (164 mg) were an intractable mixture and they were not identified. The crystalline fraction C (90 mg) was recrystallized to yield the recovered oxime (50 mg, 9%). The fraction F (209 mg) was a mixture of two lactams and this was again subjected to preparative TLC with a 1 : 1 mixture of ethyl acetate and diethyl ether. Developments were made twice. The more mobile crystalline lactam (30 mg, 5%) was recrystallized from methanol to yield the lactam (**5**), (20 mg) in two crops. Mp 225 °C. (lit,[3] 225—227 °C). The less mobile crystalline lactam (34 mg, 6%) was recrystallized from methanol to yield the lactam (**4**) (25 mg). Mp 252—255 °C (lit,[3] mp 253—255 °C); $[\alpha]_D^{22}$ +43.1 (*c* 1.0 $CHCl_3$); MS (70 eV), *m/e* (rel. intensity). 41 (19.7), 43(27.0), 55 (28.1), 57 (20.1), 99 (25.5), 112 (42.3), 125 (42.2), 232 (78.5), 233 (34.0), 234 (23.1), 372 (21.9), 287 (100, M^+), and 388 (30.3).

We thank Mrs. T. Okayama and Miss H. Maki for H^1 NMR measurements.

The Selective Elimination of Secondary Alkyl Group from Trialkylborane by the Successive Treatments with Anisole and Dimethyl Sulfoxide. A Supply of the Synthetic Intermediate for Primary Alkyl Derivatives

Yuzuru MASUDA, Masayuki HOSHI and Akira ARASE*

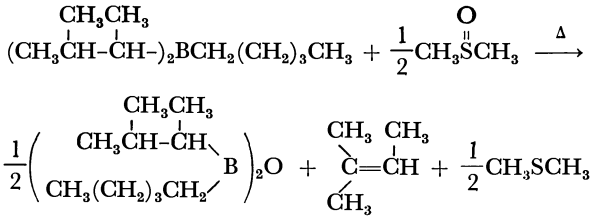
Department of Applied Chemistry, Kitami Institute of Technology, Kitami, Hokkaido 090

(Received July 7, 1978)

Synopsis. Secondary alkyl group of trialkylborane, derived from terminal olefin and borane, was selectively eliminated by the successive treatments with anisole and dimethyl sulfoxide. By the use of the resulting trialkylborane as the synthetic intermediate for primary alkyl derivatives, the contaminations of secondary alkyl derivatives were greatly reduced.

In the hydroboration of simple straight-chain terminal olefins, boron atom is placed on the terminal carbon atom, 95%, and on the internal carbon atom, 5%,[1] giving a mixture of trialkylboranes. For example, 1-pentene gives a mixture of tripentylborane (91%), dipentyl(1-methylbutyl)borane (6%), and pentylbis(1-methylbutyl)borane and tris(1-methylbutyl)borane (3%).[2] Accordingly, when these trialkylboranes are used as the synthetic intermediates, in some cases, contamination of the secondary alkyl derivative to the primary alkyl derivative is unavoidable.[3]

The authors previously reported that the mixed trialkylborane, which contained the primary and the secondary alkyl groups on the same boron atom, eliminated the secondary alkyl group preferentially to the primary alkyl group on heating in dimethyl sulfoxide (Eq. 1).[4]



(1)

The present work was undertaken with a view to obtain trialkylboranes in which the amount of the secondary alkyl group was considerably small by the selective elimination of the secondary alkyl group of the trialkylboranes, prepared from terminal olefins by the hydroboration with borane.

To achieve the selective and effective elimination of the secondary alkyl group from the mixed trialkylborane, several reaction procedures were examined by using the reaction of trihexylborane, prepared from 1-hexene, with dimethyl sulfoxide. After the reaction, the amounts of hexyl and 1-methylpentyl group were estimated from the amounts of hexanols obtained by the alkaline hydrogen peroxide oxidation of the reaction mixture.

By the direct reaction only with dimethyl sulfoxide, it was not able to obtain a satisfactory result (Table 1). This insufficient result seemed to be caused by the progress of the isomerization of the primary alkyl group to the secondary alkyl group in nearly neat trihexylborane during the elimination reaction with dimethyl sulfoxide.[5] Accordingly, anisole, which had a significant effect on the migration of the boron atom from the terminal carbon atom to the internal carbon atom,[5] was used as shown in Scheme 1. Thus, trihexylborane was heated in anisole followed by the reaction with dimethyl sulfoxide.

Table 1. Residual hexyl groups after the reaction with dimethyl sulfoxide[a]

Anisole[b] (ml)	DMSO / R_3B (mmol) / (mmol)	Temperature, °C (treatment with DMSO)	Residual hexyl group (%)	Hexyl/1-Methylpentyl
None	0.5 / 4	160	87.1	95 / 5
None	1 / 4	160	85.1	95 / 5

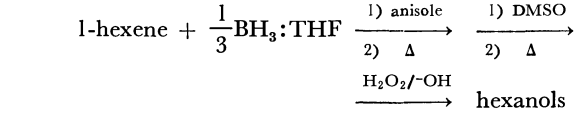
2	0.2 / 4	170	97.5	99 / 1
2	0.5 / 4	170	84.3	99 / 1

a) Carried out for 2 h. b) Pretreatment with anisole was carried out at 170 °C for 2 h.



Scheme 1.

By this procedure, the ratio of hexyl group and 1-methylpentyl group was greatly improved to 99:1, and 97.5% of hexyl group remained on the boron atom (Table 1).

By the same procedure, high proportions of the primary alkyl group were also realized in the reactions of trialkylboranes derived from other terminal olefins. The results are listed in Table 2.

Actually, the 1-alkanols thus formed by the oxidation with alkaline hydrogen peroxide, could be separated from the reaction mixtures effectively by column chromatography. For example, 1-octanol was obtained in 89% yield accompanied by only 0.5% of 2-octanol.

On the other hand, neat trialkylboranes could be distilled from the reaction mixtures. For example, essentially pure tripentylborane was distilled from the reaction mixture in 85% yield (75—76 °C/12 mmHg).

Then we undertook another reactions to confirm the usefulness of this procedure. Thus, after the treatments with anisole and dimethyl sulfoxide, trihexylborane was allowed to react with aqueous iron(III) chloride, aqueous copper(II) bromide and aqueous

Table 2. Residual alkyl group of some trialkylboranes after the successive treatments with anisole[a] and dimethyl sulfoxide[b]

Methyl vinyl ketone (6)	2-Decanone	2.41	98 / 2
	5-Methyl-2-nonanone	0.05	

a) 4 mmol of trihexylborane was used. b) The reaction was carried out at 55 °C for 48 h. c) The reaction was carried out at 55 °C for 48 h. d) The reaction was carried out at 20 °C for 2 h. e) The treatments were carried out by using 2 ml of anisole at 170 °C for 2 h, and then by using 0.2 mmol of DMSO at 170 °C for 2 h.

methyl vinyl ketone. The results are presented in Table 3.

As previously reported, the reactions of trialkylboranes with these reagents provide simple and convenient synthetic methods for chloroalkane,[3b] bromoalkane[3b] and 2-alkanone[3a] from various types of olefins. These reactions have a characteristic that the secondary alkyl group reacts with these reagents preferentially to primary alkyl group when both alkyl groups are on the same boron atom. Accordingly, in the direct reactions of these reagents with trialkylborane, prepared from terminal olefin and borane, appreciable amounts of secondary alkyl derivatives were involved in the reaction mixtures, that is, 8% of 2-chlorohexane, 5% of 2-bromohexane and 15% of 5-methyl-2-nonanone in the respective reactions. However, after the treatments with anisole and dimethyl sulfoxide, the proportions of the secondary alkyl derivatives were greatly reduced in the reactions with the same reagents.

We have not fully examined how trialkylboranes changed by the treatment with anisole. However, this procedure seems to have a practical value when trialkylboranes, derived from terminal olefins, are used as the synthetic intermediates for primary alkyl derivatives.

Experimental

Materials. Commercial 1-butene, 1-pentene, 1-hexene, 1-octene, 1-dodecene, anisole and dimethyl sulfoxide were dried over molecular sieve-5A and distilled before use. Commercial iron(III) chloride and copper(II) bromide were used without any purification.

Successive Treatments of Trialkylborane with Anisole and Dimethyl Sulfoxide. The following procedure is representative. A dry 50-ml flask, equipped with a magnetic stirring bar, a septum inlet and a reflux condenser, was flushed with argon. In the flask, 12 mmol of 1-hexene was hydroborated with 4 mmol of borane in tetrahydrofuran in the usual procedure.[6] After the addition of a 2 ml portion of anisole, tetrahydrofuran was removed under reduced pressure. Then the solution was heated at 170 °C for 2 h, followed by the reaction with 0.2 mmol of dimethyl sulfoxide at 170 °C fro 2 h. Then 4 ml of tetrahydrofuran was added to the solution and the solution was oxidized with alkaline hydrogen peroxide. The lower aqueous layer was separated and extracted with ethyl ether. The combined extracts and upper layer were analyzed by GLC, demonstrating that 11.6 mmol of 1-hexanol (96.7%) was obtained accompanied by 0.10 mmol of 2-hexanol (0.8%).

Isolation of 1-Octanol. From the organic layer, derived from 24 mmol of 1-octene in a similar manner as above, tetrahydrofuran and ethyl ether were removed. Then the reaction mixture was put on a dry silica gel column (Wako Q-50). Anisole was first eluted by benzene and then octanols were eluted by ethyl ether. Thus, 21.4 mmol of 1-octanol and 0.12 mmol of 2-octanol were obtained.

Reactions of Trihexylborane with Iron(III) Chloride, Copper(II) Bromide and Methyl Vinyl Ketone. After the treatments of trihexylborane with anisole and dimethyl sulfoxide as above, the aqueous solutions of these reagents were added to the solution respectively, and the reactions were carried out in similar manners as described in the previous reports.[3] The amounts of the reaction products were estimated by GLC.

Simple and Practical Routes to 4,5-Benzocycloheptenone. Ring Enlargement of 3,4-Dihydro-2-ethoxynaphthalene and 2-Alkoxynaphthalenes with Dichlorocarbene

Tadao, UYEHARA,* Akio ICHIDA, Makoto FUNAMIZU,† Hirofumi NANBU, and Yoshio KITAHARA††

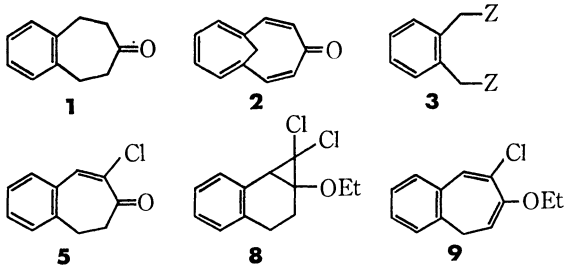
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received August 15, 1978)

Synopsis. An addition of dichlorocarbene generated by a phase-transfer reaction, to 3,4-dihydro-2-ethoxynaphthalene gave 7,7-dichloro-6-ethoxy-2,3-benzobicyclo[4.1.0]-hept-2-ene, from which 4,5-benzocycloheptenone was derived in preparative yield. 2-Methoxy- and 2-ethoxynaphthalene were converted into 2-chloro-4,5-benzotropone in 33 and 66% yield, respectively, by treatment with large excess of ethyl trichloroacetate and sodium methoxide.

4,5-Benzo-4-cyclohepten-1-one (**1**) is an important compound to obtain 4,9-methano[11]annulenone (**2**),[1] a ten-pi-electron analog of tropone. During investigation of polycondensed novel aromatics containing a methano-eleven-membered ring, we were in need of large amount of **1**.

Standard synthetic methods of **1** are intramolecular acylations of diethylbenzene derivatives (**3**, Z= CO_2R,[2] CN,[3] and $CO_2^-M^{+4}$), derived from *o*-xylene *via* once or twice of elongation of the side chains, under the basic conditions followed by decarboxylation. The other procedure is ring enlargement of β-tetralone enamine (**4**) using dichlorocarbene, generated from sodium trichloroacetate, to give 2-chloro-4,5-benzo-2,4-cycloheptadien-1-one (**5**), from which the ketone **1** is derived by catalytic hydrogenation.[5] The latter is relatively simple to handle, but the yield of the crucial compound **5** is not high enough. Parham *et al.* have reported that 2-chloro-4,5-benzo-2,4,6-cycloheptatrien-1-one (**6**) is obtained from 2-methoxynaphthalene by the treatment with ethyl trichloroacetate and sodium methoxide.[6] The benzotropone **6** should be converted into the desired ketone **1**, easily. However, the optimum conditions to obtaine **6** were not established. We wish to describe a simple route to the ketone **5** in a practical yield and a reaction to give **6** more than 65% yield.



1 **2** **3** **5** **8** **9**

In order to use dichlorocarbene generated from inexpensive reagents: chloroform, 50% aqueous sodium hydroxide and a phase-transfer catalyst: and to avoid multiple additions of the carbene to a 1:1 adduct, we chose 2-ethoxy-3,4-dihydronaphthalene (**7**) as the substrate. The addition of dichlorocarbene to the enol ether **7**, which was derived easily from β-tetralone, proceeded smoothly to give the adduct (**8**), as colorless oil, which decomposed slowly on silica gel TLC. An attempt of purification of the adduct by distillation *in vacuo* was not successful: elimination of hydrogen chloride proceeded under the conditions to form 1,2-benzo-4-chloro-5-ethoxy-1,3,5-cycloheptatriene (**9**). Compound **9** was obtained cleanly in 86% yield (from **7**), when a solution of the adduct **8** in pyridine was heated under reflux for 90 min under a nitrogen atmosphere. Conversion of the enol ether **9** into the ketone **5** was performed with heating under reflux for 90 min in a mixture of methanol and hydrochloric acid. Catalytic hydrogenation of **5** in the presence of potassium acetate gave 4,5-benzo-4-cyclohepten-1-one **1** in an excellent yield.[5]

It has been reported that a treatment of 2-methoxynaphthalene with 0.75 equiv of the carbene source (ethyl trichloroacetate) and sodium methoxide gives the benzotropone **6** in 13% yield with recover of 73% of the naphthalene.[6] In order to know synthetic utility of the ring enlargement, we changed the ratios of the carbene source and the base to the substrate. When 7 equiv of the carbene source and sodium methoxide were used, **6** was obtained in 33% yield with unexpected by-products (**10**, **11** and **12**; in 6.0, 23.0 and 0.2%, respectively).[7] Replacement of the substrate to 2-ethoxynaphthalene (**13**) gave better results. The yield of **6** was increased to 66%, when **13** was treated with 7 equiv of ethyl trichloroacetate and 8 equiv of sodium methoxide. Catalytic hydrogenation of the tropone **6** gave the ketone **1** in 97% yield.

Experimental

Instruments. Melting points were determined on Thomas Hoover MP Apparatus using an uncorrected thermometer. NMR spectra were recorded with a JEOL JNM-PMX-60 spectrometer or a Varian Model A-60 spectrometer using tetramethylsilane as an internal standard. IR spectra were measured with a Hitachi Model 215 grating infrared spectrophotometer.

*2-Ethoxy-3,4-dihydronaphthalene (**7**).*[8] A solution of β-tetralone (15.2 g, 0.104 mol), ethyl orthoformate (41.6 g, 0.312 mol) and *p*-toluenesulfonic acid (50 mg) in ethanol (60 ml) was heated under reflux for 40 min. Removal of the solvent followed by distillation gave **7** (16.95 g, 93.7%) : bp 84—86 °C/0.2 Torr; NMR (CCl_4) δ=1.34 (3H, t, J=7.0 Hz), 2.21—3.0 (4H, m), 3.89 (2H, q, J=7.0 Hz), 5.63 (1H, s) and 6.72—7.02 (4H, m).

*1,2-Benzo-4-chloro-5-ethoxy-1,3,5-cycloheptatrine (**9**).* To a solution of **7** (16.54 g, 95 mmol) and benzyltrimethylammonium chloride (262 mg) in chloroform (38.7 ml) was added dropwise 50% aqueous sodium hydroxide (38.4 g) at 0 °C under an inert atmosphere (N_2). The mixture was allowed to warm to room temperature and stirred for 14 h. The mixture was diluted with dichloromethane and water, and the organic layer was separated. After dried over magnesium sulfate, evaporation of the solvent to dryness *in vacuo* (0.06 Torr, 4 h) gave **8** (24.03 g) as brown oil: NMR (CCl_4) δ=1.24 (3H, t, J=7.0 Hz), 2.15—2.94 (4H, m), 2.64 (1H, s), 3.74 (1H, q, J=7.0 Hz), 3.77 (1H, q, J=7.0 Hz) and 6.95—7.26 (4H, m). A mixture of **8** (24 g, 93.5 mmol) and dry pyridine (36.5 ml) was heated under reflux for 90 min. Pyridinium hydrochloride was removed by filtration and the filtrate was diluted with water and extracted with three portions of ether (60 ml each). The extract was washed successively with 10% hydrochloric acid, water and brine, and dried over magnesium sulfate. Evaporation of the solvent followed by distillation gave **9** (17.8 g, 86.4%) as pale yellow oil: bp 113 °C/0.05 Torr; IR (neat) 1684 (m), 1630 cm^{-1} (s); NMR (CCl_4) δ=1.20 (3H, t, J=7.0 Hz), 2.85 (2H, d, J=7.4 Hz), 3.60 (2H, q, J=7.0 Hz), 4.88 (1H, t, J=7.4 Hz), 7.08—7.19 (4H, m), 7.23 (1H, s).

*2-Chloro-4,5-benzo-2,4-cycloheptadien-1-one (**5**).* A suspension of **9** (17.6 g, 80.1 mmol) in a mixture of concd hydrochloric acid (0.143 ml), methanol (20 ml) and water (5.7 ml) was heated under reflux for 90 min. White precipitate was formed, after addition of ice (30 g) followed by vigorous stirring. The product was filtered, washed with water, dried over calcium chloride *in vacuo* and recrystallized from hexane (13.66 g, 88.6%). **5**: mp 66.5—67.5 °C (lit,[5] 63—65 °C)

*2-Chloro-4,5-benzo-2,4,6-cycloheptatrien-one (**6**).* To a mixture of dry sodium methoxide (21.6 g, 0.4 mol), 2-ethoxynaphthalene (8.6 g, 0.05 mol) and dry ether (50 ml) was added dropwise with vigorous stirring a solution of ethyl trichloroacetate (62.76 g, 0.35 mol) in ether (50 ml) under a nitrogen atmosphere below 0 °C. The reaction mixture was kept at 0 °C for an additional hour, and then allowed to stand over night at room temperature, whereupon water was added and extracted with ether. The extract was dried over sodium sulfate, concentrated and chromatographed on a dry column of silica gel (240 g, Wako C-200). Elution with hexane gave a mixture of 2-ethoxynaphthalene, ethyl trichloroacetate and less polar products (*ca.* 10 g). 2-Chlorobenzotropone **6** was eluted with hexane–benzene (2 : 1) and benzene, and recrystallized from hexane (6.3 g, 66%). **6**: mp 103—104 °C (lit,[6] 105—106 °C).

*4,5-Benzo-4-cyclohepten-1-one (**1**). Hydrogenation of **5**:* The chloro ketone **5** (25 g, 0.130 mol) and potassium acetate (14 g, 0.143 mol) were suspended in ethanol (150 ml) and hydrogenated at atmospheric pressure over 5% Pd on charcoal (0.9 g). After 20 h the catalyst was filtered, the solvent was removed *in vacuo* and the residue was dissolved in ether. The etherial solution was washed with water, aqueous sodium hydrogencarbonate and brine, and dried over sodium sulfate. Evaporation of the ether to dryness gave white solid (20.2 g, 97%). **1** : mp 41—42 °C (lit,[4] 41—42 °C).

*Hydrogenation of **6**:* A mixture of **6** (3.2 g, 16.6 mmol), potassium acetate (2.1 g, 21.4 mmol) and methanol (50 ml) was hydrogenated over 5% Pd–C (0.1 g) for 96 h. The product **1** was obtained as colorless needles (2.6 g, 98%) from hexane.

The Reaction of Copper(I) Methyltrialkylborates with 1-(1-Pyrrolidinyl)-6-chloro-1-cyclohexene

Kinji YAMADA, Takashi YANO, Norio MIYAURA, and Akira SUZUKI*
Faculty of Engineering, Hokkaido University, Sapporo 060

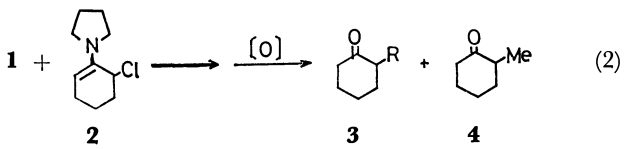
(Received August 3, 1978)

Synopsis. The reaction between copper(I) methyltrialkylborates readily obtainable from organoboranes and 1-(-1-pyrrolidinyl)-6-chloro-1-cyclohexene was found to give corresponding alkylation products which are readily hydrolyzed to alkylated cyclohexanones.

Recently, we have reported that lithium methyltrialkylborates readily undergo cation exchange reaction by copper(I) halides to give copper(I) methyltrialkylborates, which in turn successfully add to acrylonitrile, ethyl acrylate, 1-acyl-2-vinylcyclopropane[1] and ethyl propiolate.[2] These borate complexes also react with benzylic bromides,[3] aroyl chlorides,[4] allylic chlorides, propargylic bromides,[5] and ethyl β-bromoacrylates.[6] In an attempt to develop the reaction of such borate complexes, we examined the possibility of a coupling reaction with 1-(1-pyrrolidinyl)-6-chloro-1-cyclohexene.

To a solution of copper(I) methyltripropylborate obtained from lithium methyltripropylborate and copper(I) iodide (Eq. 1), 1-(1-pyrrolidinyl)-6-chloro-1-cyclohexene was addde at 0 °C and stirred at room temperature. After the reaction was complete, the residual organoborane was oxidized with alkaline hydrogen peroxide under the usual conditions. VPC analysis revealed the formation of 2-propylcyclohexanone (**3**) and 2-methylcyclohexanone (**4**) in 31 and 11% yields, respectivley (Eq. 2). Although the

$$R_3B + MeLi \rightarrow (R_3BMe)Li \xrightarrow{CuX} \underset{\mathbf{1}}{(R_3BMe)Cu} \qquad (1)$$



2 **3** **4** (2)

formation of an undesirable by-product, 2-methylcyclohexanone (**4**) formed by attack of methyl group in the borate was observed, it was found that such yields are markedly dependent upon copper(I) halides and solvents employed, as shown in Table 1. The reaction using copper(I) cyanide and 1,2-dimethoxyethane (DME) as a solvent was effective for the circumvention of formation of the by-product. This reaction is applicable to other representative organoboranes. In each case, the desired alkylated cyclohexanones were obtained in good yields (Table 1).

It is well known that enamines formed from cyclanones react with reactive alkyl halides at the β-carbon atom to afford an immonium salt, which is readily hydrolyzed to the monoalkylated ketone. Allylic, propargylic and benzylic halides as well as α-halo ketones, α-halo esters, and α-halo nitriles give good results, but yields are only fair with saturated alkyl halides[7]. On the other hand, the present reaction overcomes such a difficulty, which makes possible to introduce saturated alkyl groups at the α-carbon atom of cyclohexanones.

Table 1. Reaction of copper(I) methyltrialkylborates with 1-(1-pyrolidinyl)-6-chloro-1-cyclohexene

R_3B	CuX	Solvent	R'X	Yield (%)[a] of **3** or **6**
Propyl	CuI	THF		31 (11)
	CuBr	THF		32 (10)
	CuCl	THF		29 (7)
	CuCN	THF		53 (6)
	CuCN	DME		60 (13)
Butyl	CuCN	DME		81 (n. a.)[b]

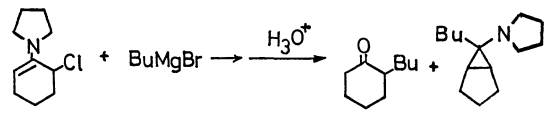
	CuCN	DME	Benzyl bromide	59 (n. a.)[b]
	CuCN	DME	Dimethyl sulfate	37 (n. a.)[b]

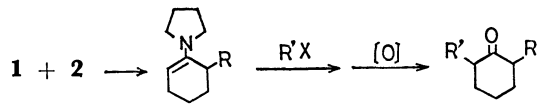
a) Based on the chloroenamine (**2**) employed and the yields of methylcyclohexanone are shown in parentheses.
b) Not analyzed.

Recently, Cantacuzene *et al.*,[8] reported the alkylation of 1-(1-pyrrolidinyl)-6-chloro-1-cyclohexene (**2**) with Grignard reagents, For example, 2-butylcyclohexanone and 6-butyl-6-(1-pyrrolidinyl)bicylo[3.1.0]hexane were obtained in the ratio of 30:70: the ratio varied with different Grignard reagents (Eq. 3). However, any formation of such a cyclopropane derivative was not observed in the present reaction of copper(I) borates.



2 (3)

The present reaction, although the mechanism is still unknown, appears to proceed through the enamine (**5**) as an intermediate, because treatment of the reaction mixture, without alkaline hydrogen peroxide oxidation, with relatively active alkyl halides such as allylic and benzylic bromides or dimethyl sulfate pro-



5 **6** (4)

duced the corresponding disubstituted cyclohexanone (**6**) (Eq. 4).

Combination of these two reactions, namely, the reaction of borate complexes with chloroenamine (**2**) and subsequent alkylation by alkyl halides, provides a convenient synthetic procedure for disubstituted cyclohexanones from organoboranes.

Experimental

Materials. Commercial copper(I) halides and alkyl halides were used. The solvents were purified by distillation before use. 1-(1-Pyrrolidinyl)-6-chloro-1-cyclohexene was prepared from 2-chlorocyclohexanone and pyrrolidine by the Blazejenski's method.[8] Trialkylbroanes were prepared from diborane and olefins *via* hydrobroation.[9]

The IR and NMR spectra were taken on a Hitachi-Perkin Elmer Model 125 spectrophotometer and a Hitachi R-22 spectrometer at 90 MHz using tetramethylsilane as an internal standard.

General Procedure. The following procedures for the preparation of 2-propylcyclohexanone and 2-allyl-6-propylcyclohexanone are representative.

A dry 100 ml-flask equipped with a septum inlet and a magnetic stirring bar was flushed with dry nitrogen. The flask was charged under dry nitrogen atmosphere with 0.89 g (9 mmol) of copper(I) cyanide and 12 ml of dry 1,2-dimethoxyethane. To this mixture was added lithium methyltripropylborate[1] (9 mmol in THF) at 0 °C and stirred for 5 min. Then 0.84 ml (6 mmol) of 1-(1-pyrrolidinyl)-6-chloro-1-cyclohexene was gradually added and the mixture was stirrred for 2 h at room temperature. After the reaction was complete, the residual organoborane was oxidized with 3 ml of 3 M aqueous NaOH and 3 ml of 30%-H_2O_2 at room temperature for 2 h. The products were extracted with ether. The combined extracts were washed with saturated NaCl solution and dried over anhydrous sodium sulfate. The ether solution thus obtained was analyzed by VPC, revealing the formation of 2-propylcyclohexanone (5.4 mmol, 60%).

The procedure for the preparation of 2-allyl-6-propylcyclohexanonone is as follows: To the reaction mixture obtained by the same procedure described above was added allyl bromide (3.06 g, 18 mmol), followed by refluxing for 3 h and allowed to stand over night at room temperature. Analysis by VPC after alkaline hydrogen peroxide oxidation indicated the presence of 3.54 mmol (59% yield) of 2-allyl-6-propylcyclohexanone. Although 2-allyl-6-methylcyclohexanone formed as a by-product was not analyzed, the quantity was little.

Identification of the Products. In all cases analytically pure samples were obtained by preparative VPC with Varian autoprep Model-2800 and characterized by NMR, IR, and mass spectra, refractive indices, and elemental analyses.

Correlation between Electron Capture Response and Chemical Structure for Benzyl Chlorides

Tsugio KOJIMA,* Masaru SATOUCHI,† and Yasukazu TANAKA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

†*Department of Industrial Chemistry, Shiga Prefectural Junior College, Hikone, Shiga 522*

(Received March 6, 1978)

In the dissociative electron capture reaction of benzyl chlorides, all the substituents in the para position except for *t*-butyl group tend to decrease the activation energy, those in the meta position having no influence on the activation energy. This can be explained in terms of the contribution of a para substituent to the stabilization of the incipient radical in the transition state resulting from the delocalization of the odd electron. The resonance effect of the para substituent was compared with that obtained in the phenylation of substituted benzenes with phenyl radical, where phenylcyclohexadienyl radical is formed as an intermediate. The resonance effects in these two reactions agree, supporting the reaction mechanism proposed.

The principle of electron capture detection is based on the electron attachment to a molecule. Since an electron capture detector (ECD) gives data concerning only the probability of electron attachment to a molecule, the information obtained is not useful. However, if the temperature dependence of the electron capture coefficient is measured and analyzed, we can obtain useful information on the chemical structure of the molecule.[1-3]

Wentworth and coworkers studied the electron attachment phenomenon on kinetics using the steady-state approximation, giving the electron capture response to the concentration of a capturing species in terms of electron capture coefficient K.[4-6] According to Wentworth's theory, the molecular electron affinity or activation energy for an electron attachment accompanying a bond dissociation is obtained from K.

We proposed that the dissociative electron capture reaction of alkyl and aryl halides proceeds by a mechanism similar to that of S_N2 reaction.[1-2] In the case of alkyl halides the magnitude of the activation energy is determined by the stability of the transition state, which depends upon the extent to which the odd electron on the α-carbon atom is delocalized by resonance. Although reports have appeared on the relative electron attachment coefficients for different organic compounds, little is known about the electron capture reaction in view of nucleophilic reaction. It is interesting to test this reaction model with various classes of compounds.

In the present paper, the results of measurements of activation energy in the electron capture reaction of benzyl chlorides are given, the substituent effect on the activation energy being discussed in terms of the reaction mechanism proposed for alkyl halides.[1]

Experimental

A modified Shimadzu GC-2C model gas chromatograph was used. The ECD employed was of a concentric type with 15 mCi nickel-63 as radioactive source. Applied voltage was supplied as a pulse through a pulse generator with an amplitude of 28 V, a pulse period of 3200 μs, and a pulse width of 3.2 μs; the electron capture reaction proceeded under field free conditions.

Glass columns (0.4 cm × 100 cm and 0.4 cm × 40 cm) were packed with Durapak (Carbowax 400/Porasil C), temperature being maintained at 70 or 100 °C. Nitrogen was used as a carrier gas. The oxygen in the carrier gas was removed by passing the gas through a tube packed with copper(I) chromate pellets. Another tube packed with Molecular Sieve 5A was used for the removal of moisture. The tubes were inserted between the cylinder of the carrier gas and the GC inlet.

Reagents except for commercial ones were synthesized. *m*-Methoxybenzyl chloride and *p*-*t*-butylbenzyl chloride: *m*-Methoxy- and *p*-*t*-butylbenzoic acids were reduced to the corresponding benzyl alcohols with lithium aluminum hydride in ether solution. They were converted into benzyl chlorides by chlorination with concd hydrochloric acid at 80 °C for 2 h. Alkylbenzyl chlorides were synthesized by the chlorination of alkyltoluenes with chlorine gas or sulfinyl chloride.

The compounds synthesized were identified by GC-MS technique. The sample solution was prepared by dilution with benzene to a concentration such that the detector current decreases to about a half of the back ground current.

The electron capture coefficient K was calculated by the following equation derived by Wentworth and Chen:[5]

$$\frac{F}{S}\int\frac{(I_b-I_e)}{I_e}dx = Kn, \qquad (1)$$

where F is the flow rate of the carrier gas in l/min, S the chart speed in cm/min, n the amount of sample injected in moles. I_b and I_e are the detector current without and with a capturing species in the detector, respectively. Since the detector signal proportional to (I_b-I_e) was converted into the signal proportional to $(I_b-I_e)/I_e$ through an analog convertor,[3] the integral term of the above equation corresponds to the peak area on the chromatogram.

Results and Discussion

The mode of the electron capture reaction for a halogen compound depends upon the organic group bonding to the halogen atom. An aklyl halide captures a free electron dissociatively (Eq. 2), while an aryl halide dose so before the bond dissociation of the carbon-halogen bond (Eq. 3).[2,4]

$$RX + e^- \longrightarrow R\cdot + X^- \qquad (2)$$

$$ArX + e^- \longrightarrow ArX^{\cdot-} \longrightarrow Ar\cdot + X^- \qquad (3)$$

The type of reaction can be judged by means of the Arrhenius plot of ln K. According to Wentworth's theory,[5] the temperature dependence of K is expressed by the following equations:

$$\ln K = \ln Z - E^*/RT \quad \text{(dissociative)}, \qquad (4)$$

$$\ln KT^{3/2} = \ln Z + EA/RT \quad \text{(nondissociative)}, \qquad (5)$$

where E^* and EA are activation energy and molecular electron affinity, respectively; R is the gas constant, T the absolute temperature of the detector and Z the pre-exponential factor. The Arrhenius plot of ln K might be linear with a negative slope of E^*/R for the dissociative case and with a positive slope of EA/R for the nondissociative case.

In a previous paper,[1] it was proposed that the dissociative electron capture reaction of an alkyl halide can be assumed to be similar to the S_N2 reaction in solution and the sp^3 orbital on the α-carbon atom changes to an sp^2 orbital with the approach of a free electron to an alkyl halide. The linear relationship observed between the activation energy and the change in internal energy was explained.

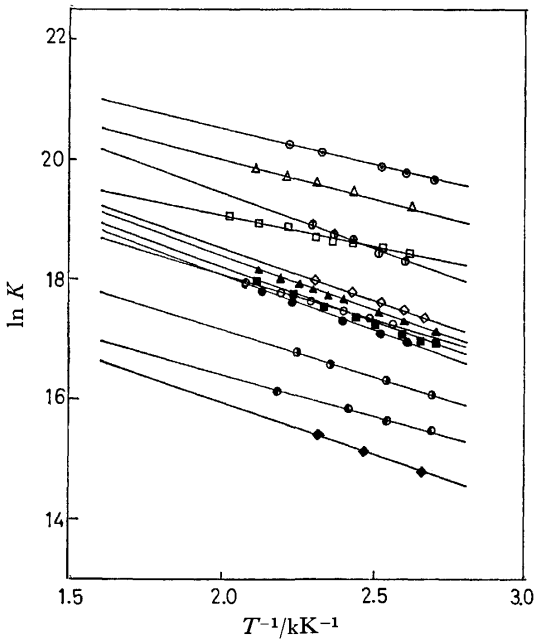

Fig. 1. Arrhenius plots of electron capture coefficients for benzyl chlorides.
● Benzyl chloride, ◆ *m*-methylbenzyl chloride, ○ *p*-methylbenzyl chloride, ▲ *p*-*t*-butylbenzyl chloride, △ *m*-chlorobenzyl chloride, ◑ *p*-chlorobenzyl chloride, ■ *m*-methoxybenzyl chloride, ◐ *p*-methoxybenzyl chloride, ⊙ *p*-phenylbenzyl chloride, △ *p*-cyanobenzyl chloride, ⓘ *m*-nitrobenzyl chloride, □ *p*-nitrobenzyl chloride.

It is of interest to see if this reaction model is adequate in the electron capture reaction of benzyl chlorides. It will be useful if the variation of activation energies for benzyl chlorides with various substituents is explained.

The Arrhenius plots of ln K for benzyl chlorides with various substituents in the aromatic ring are shown in Fig. 1. Since all the plots are linear with negative slopes, benzyl chlorides capture free electron dissociatively as in the case of alkyl halides. The activation energies E^* calculated by the least-squares method are given in Table 1.

A question may be raised whether the α-carbon atom is the reaction center, or the α-carbon atom is attacked

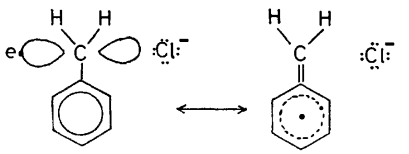
a) Activation energy. b) Standard deviation.

by a free electron. The activation energy of 8.6 kcal/mol[2] or 9.25 kcal/mol[7] observed for chlorobenzene corresponds to the energy of the barrier for electron attachment to the benzene nucleus of the compound. When the benzene nucleus is substituted by a more electron-withdrawing group, the electron attachment to the benzene nucleus occurs more easily.[2] Therefore, when a free electron attacks the benzene nucleus of benzyl chloride, the activation energy should be greater than 8.6 kcal/mol. However, the activation energy of benzyl chloride is only 3.6 kcal/mol (Table 1). It can be concluded that in analogy with alkyl halides, the α-carbon atom is attacked by a free electron in the electron capture reaction of benzyl chloride.

All the activation energies of benzyl chlorides in Table 1 are smaller than those of alkyl chlorides by 6—8 kcal/mol. A comparison of K shows that benzyl chloride reacts with a free electron faster than alkyl chlorides by a factor of 1000—3000. The enhanced reactivity of benzyl chloride over the corresponding alkyl chloride has also been observed in S_N2 reaction in solution.[8]

It seems that the transition state of the dissociative electron capture reaction for benzyl chloride has a



Scheme A.

structure as shown in Scheme A. It is expected from the structure that the accepted odd electron on the α-carbon atom is delocalized by the overlapping of the π orbital on the benzene ring with the p orbital on the α-carbon atom and the stabilization of the transition state due to such resonance affords the enhanced reactivity for benzyl chloride.

In the substituted benzyl chlorides, it is necessary to take into account the contribution of substituents to the resonance through the benzene ring. The substituent effect in the electron capture reaction can be illustrated

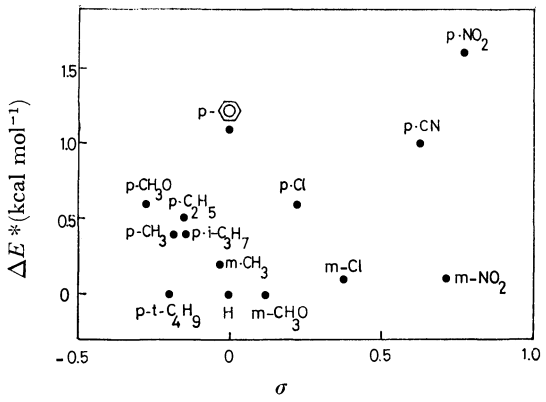


Fig. 2. Relationship between activation energy and Hammett substituent constant.

by a plot, ΔE^* $(=E_H^*-E_X^*)$ *vs.* the Hammett σ constant, where the subscripts H and X are used to represent benzyl chloride and the benzyl chloride substituted by a group X, respectively (Fig. 2). The relationship between the electron capture coefficient K and the rate constant k in the dissociative electron capture reaction is given by

$$\ln K = \ln k_{12} - \ln k_D, \tag{6}$$

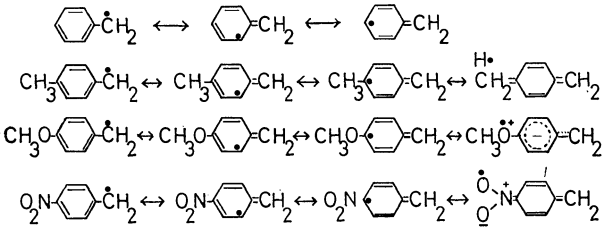
where k_D is the rate constant of the reaction between a positive ion produced from a molecule of the carrier gas and a free electron, k_{12} is the rate constant of the dissociative process of benzyl chlorides as given by Eq. 2.[5-7] Using the Arrhenius equation, we have

$$\ln k_{12} = \ln Z' - \frac{E^*}{RT}. \tag{7}$$

k_D is almost temperature independent as pointed out by Wentworth and Chen.[5] Hence, $\ln(K_X/K_H)$ is nearly equal to $\ln(k_{12,X}/k_{12,H})$. Since it is reasonable to presume that the pre-exponential factor Z' is nearly equal for all the benzyl chlorides investigated, ΔE^* (ordinate, Fig. 2) is approximately equal to the difference in $\ln k_{12}$ between the benzyl chloride substituted by a group X and benzyl chloride. Thus, Fig. 2 can be considered to be Hammett plot which enables us to evaluate the substituent effect in the electron capture reaction.

We see that the plots for meta-substituted benzyl chlorides are linear with a slope near to zero. This can be explained as follows. In the transition state for benzyl chlorides, the negative charge is localized on the chlorine atom as shown in Scheme A. Consequently, a group in meta position does not contribute to the stabilization of the transition state by the inductive effect. The odd electron can conjugate only with the π electrons in the aromatic ring and the conjugative system can not be extended to meta substituents. The resonance effect, therefore, for all meta-substituted benzyl chlorides should be equal to that for benzyl chloride itself.

On the other hand, no simple relation exists between ΔE^* and the Hammett σ constant for para-substituted benzyl chlorides. The plot is concave downward. Both electron releasing groups except for *t*-butyl group and electron withdrawing groups tend to decrease the activation energy. This indicate that, in the transition state of para-substituted benzyl chlorides, the odd electron accepted on the α-carbon atom can conjugate not only with the π electrons in the aromatic ring, but with the electrons in the para substituent through the π electron system of the aromatic ring. Consequently, para substituents contribute to the stabilization of the transition state through hydrogen atom hyperconjugation and electron donating or electron accepting resonance as shown in Scheme B. The resonance effect of the para



Scheme B.

substituents decreases in the order: NO_2>CN, C_6H_5 >CH_3O, Cl>*iso*-C_3H_7, C_2H_5, CH_3>H. As *t*-butyl group has no hydrogen atom capable of participating in the hyperconjugation, the resonance effect for *t*-butylbenzyl chloride is equal to that for benzyl chloride itself. The order is in line with that of the substituent effect found in polarographic reduction of benzyl halides.[9,10]

A similar substituent effect has been reported in the phenylation of substituted benzenes with phenyl radical. Ito and coworkers observed that for all benzene compounds the ortho and para positions are more reactive than the meta position. The relative reactivity of the para position does not satisfy the Hammett relation, being usually larger than that expected from the Hammett equation by an increment of τ_p as expressed by

$$\log (k_{X(p)}/k_H) = \rho\sigma_p + \tau_p, \tag{8}$$

where $k_{X(p)}/k_H$ is the partial rate constant of the para position of the benzene substituted by a group X in phenylation, ρ is the Hammett reaction constant for the phenylation estimated from the Hammett plot for the meta substituent and σ_p is the Hammett substituent constant for para position.[11] τ_p is regarded as a measure of the conjugative effect.

The value of τ_p for a substituent is approximately constant for each substituted benzene irrespective of the nature of attacking radical. It is accepted that the homolytic phenylation proceeds through the rate determining step of the addition of a phenyl radical to the aromatic ring, a phenylcyclohexadienyl radical being formed as an intermediate. When the substitution occurs in the para position to a substituent, the odd electron in the transition state can conjugate with the electrons in the substituent. Consequently, the value of τ_p indicates the extent to which the incipient radical in the transition state of the addition of a phenyl radical to a substituted benzene is stabilized by resonance.

Thus, ΔE^* and τ_p can be considered to show identical character, and the validity of our proposal on the mechanism of the dissociative electron capture reaction for benzyl chlorides should be judged by a comparison of ΔE^* and τ_p. As shown in Table 2, the conjugative effect expressed in energy term $2.3RT\tau_p$ is almost equal

TABLE 2. COMPARISON OF THE CONJUGATIVE EFFECT OF PARA-SUBSTITUENTS OBSERVED IN ELECTRON CAPTURE REACTION OF BENZYL CHLORIDES WITH THAT OBSERVED IN PHENYLATION OF SUBSTITUTED BENZENES BY PHENYL RADICAL

Substituent	ΔE^{*} [a] / kcal mol^{-1}	τ_p [b]	$2.3RT\tau_p$ [c] / kcal mol^{-1}
CH_3	0.4	0.09	0.2
Cl	0.5	0.16	0.3
CH_3O	0.6	0.14	0.3
NO_2	1.6	0.9	1.8

a) The conjugative effect of para substituents observed in electron capture reaction of benzyl chlorides. b) Values taken from Ref. 11. c) $T=423$ K.

to ΔE^{*} at 423 K, the average temperature of ECD. The agreement between ΔE^{*} and τ_p shows that our proposal is valid. Thus, the substituent effect is explained by assuming the reaction mechanism of the electron capture reaction for benzyl chlorides analogous to that of alkyl halides.

Conclusion

An extensive study has been made on the substituent effect on the electron capture reaction of benzyl chlorides. We concluded that the electron capture reaction of benzyl chlorides is a kind of S_N2 reaction in analogy with alkyl halides. The enhanced reactivity of a para-substituted benzyl chloride over the corresponding meta isomer and benzyl chloride itself can be explained on the basis of a mechanism similar to the S_N2 reaction. Our proposal on the mechanism of the electron capture reaction will be useful for understanding the relationship between the activation energy measured and the chemical structure of the sample molecule and for identifying peaks on the chromatogram for separation of halogen compounds by GC-ECD system.

Effect of Pressure on Iodine Complexes. I. Absorption Spectra of the Visible Iodine Bands with Diethyl Ether, Diethyl Sulfide, and Diethyl Selenide in Heptane

Seiji SAWAMURA, Yoshihiro TANIGUCHI, and Keizo SUZUKI*

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received April 13, 1978)

Absorption spectra of the visible I_2 band of I_2 complexes with Et_2O, Et_2S, and Et_2Se in heptane have been measured up to 3300 bar at 25 °C. The equilibrium constants and volume changes accompanying complex formation, the molar extinction coefficients and the absorption maxima have been estimated. The volume changes were found comparable with those estimated from the X-ray data of the I_2 complexes in the crystalline state. The enhancement of the molar extinction coefficient and the blue shift of the visible I_2 band with increasing pressure have been established. The results suggest a decrease in the bond distance between an n-donor and I_2, compared with the spectroscopic properties of the I_2 complex at 1 bar. The decrease has been estimated as 0.008 nm with increasing pressure up to 3300 bar.

There have been several investigations of iodine (I_2) complexes as examples of charge transfer (CT) complexes from both the experimental and theoretical point of view.[1] Pressure effects on the I_2 complexes with π-donors such as benzene, toluene, and mesitylene have been studied by Ham,[2] and Kwun and Lentz,[3] where it was concluded that the equilibrium constants accompanying complex formation increased with increasing pressure. There has yet been no investigation of I_2 complexes with n-donor such as ether or amines under high pressure.

In the study of the I_2 complex at 1 bar, not only a CT band but also a I_2 band in the visible region (visible I_2 band) has been reported.[1] The I_2 band shifts to blue (to shorter wavelength) very largely with complex formation, and the shift is larger with stronger n-donors. Thus the blue shift in the visible I_2 band has been a useful indication of CT interaction. Furthermore, the molar extinction coefficients of the visible I_2 bands increase with stronger n-donors. Consequently the investigation of the visible I_2 bands of the I_2 complexes with n-donors under high pressure has been interesting. Recently by measuring the visible absorption spectra pressure effect on I_2 complex with diethyl ether (Et_2O) in heptane has been studied.[4] The present report is an extention of the work using diethyl sulfide (Et_2S) and diethyl selenide (Et_2Se) as n-donors in heptane.

Experimental

The purification of I_2 and heptane has been described in a preceding paper.[4] Et_2S (Wako Pure Chemical Co., Ltd.) was dried with calcium chloride and fractionally distilled, bp 91—92 °C (lit,[5] bp 92 °C). Et_2Se was synthesized by the method of Bird and Challenger,[6] n_D^{20} 1.4790, bp 107—108 °C (lit,[7,8] n_D^{20} 1.4768, bp 108 °C). The method of measuring the absorption spectra under high pressure has been described in a preceding paper.[4]

Results and Discussion

The absorption spectra of the Et_2S–I_2 complex in Fig. 1 show an isosbestic point at 490 nm. The absorption band at 522 nm decreases and at 438 nm increases with increasing pressure. The former band has been ascribed as free I_2 (I_2 in heptane) and the latter the complexed I_2 with Et_2S.[6] In the Et_2Se–I_2 complex absorption spectra similar to Fig. 1 were observed with an isosbestic point at 470 nm. The absorption spectra of the Et_2O–I_2 complex have been described previously.[4]

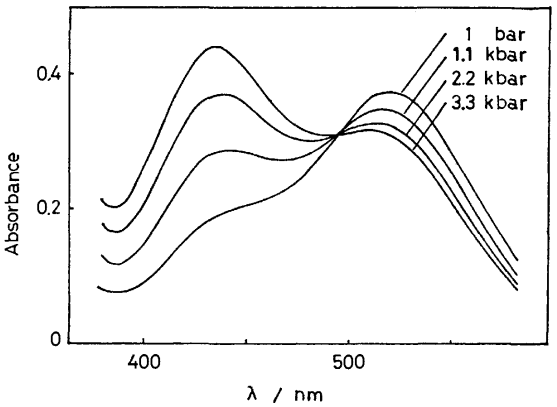

Fig. 1. Visible I_2 absorption spectra of mixed solution of Et_2S and I_2 in heptane at 25 °C and various pressures. Et_2S: 1.4×10^{-3} mol dm^{-3}, I_2: 5.0×10^{-4} mol dm^{-3}. The absorptions are not corrected for compression.

Equilibrium Constants. The equilibrium constants accompanying complex formation and the molar extinction coefficients have been estimated by the Benesi-Hildebrand equation[10]

$$\frac{X_A}{A} = \frac{V}{K\varepsilon l}\frac{1}{X_D} + \frac{V}{\varepsilon l}, \quad (1)$$

where K is the equilibrium constant in mole fractions accompanying complex formation, A the absorbance of the mixed solution of I_2 and donor, ε the molar extinction coefficient of the complex, l the path length, X_A and X_D the initial mole fractions of I_2 and donor, respectively, and V the molar volume of the solution which has been assumed to be equal to that of the solvent under each pressure.[11] The value of the initial concentration of I_2 in units of mol dm^{-3} ($[I_2]$) used by Benesi and Hildebrand[10] depends on the pressure. The value in mole fraction units (X_A) has been utilized in Eq. 1 with the following relation:

$$X_A = [I_2]V. \quad (2)$$

The values of K and ε have been evaluated from the intercept and the slope of the plot of X_A/A *vs.* $1/X_D$, the results of which are shown in Table 1 together with the spectroscopic data.

The volume changes, ΔV, accompanying formation of the I_2 complexes have been calculated from the following equation and the slopes of the ln K *vs.* P plot as shown in Table 2:

$$\left(\frac{\partial \ln K}{\partial P}\right)_T = -\frac{\Delta V}{RT}. \quad (3)$$

TABLE 2. VOLUME CHANGES (ΔV) ACCOMPANYING THE FORMATION OF I_2 COMPLEXES AT 25 °C (cm^3 mol^{-1})

ΔV_{theor}[b]	−6.4[c]	−8.9	−9.8

a) From visible I_2 band and Eq. 3. b) From Eq. 4. c) Ref. 4.

In the preceding paper[4] the volume change accompanying the formation of the Et_2O–I_2 complex was estimated from Eq. 4, assuming that the I_2 complex is formed along the axis of cylinder having a radius equal to the van der Waals radius for the iodine atom:

$$\Delta V = (\pi r^2 \Delta d) N_A, \quad (4)$$

where N_A is Avogadro's number, r the radius of the cylinder, and Δd the contraction of the cylinder accompanying complex formation estimated by the following equation:

$$\Delta d = d_X - (d_D + d_A), \quad (5)$$

where d_X is the bond distance of the complex estimated from the X-ray data of the crystal, and d_D and d_A are van der Waals radii for the donor atom (O) and the acceptor atom (I), respectively. In the same manner the volume changes for the Et_2S–I_2 and Et_2Se–I_2 complexes have been estimated with the bond distance for 1,4-dithiane–I_2[14] and 1,4-diselenane–I_2[15] complexes in the crystal for d_X, van der Waals radii[16] of the sulfur and selenium atoms for d_D, and van der Waals radius of the iodine atom for d_A and r, the results of which are shown in Table 2. These values are comparable with those estimated from the pressure dependence of the equilibrium constants.

Spectroscopic Properties. Absorption maxima (λ_{max}) of the visible I_2 band are shown in Table 1. The values of λ_{max} for free I_2 were determined directly from the observed absorption. In the Et_2S–I_2 and Et_2Se–I_2 complexes, these were determined from the observed absorptions under the condition that $X_D \gg X_A$, where the absorption of free I_2 could be neglected. The λ_{max} values of the Et_2O–I_2 complex have been estimated from the observed absorption by subtracting the absorption of the free I_2 calculated from the equilibrium constant of the Et_2O–I_2 complex and the molar extinction coefficient of free I_2. All of the λ_{max} values shifted to blue with increasing pressure; Ham failed to observe any blue shift in the visible absorption spectra of I_2 in heptane up to 2000 bar.[2] The molar extinction coefficients (ε_{max}) of the visible I_2 band at λ_{max} increased with increasing pressure in Et_2S–I_2 and Et_2Se–I_2 complexes (Table 1). In the Et_2O–I_2 complex and free I_2, however, ε_{max} was not enhanced.

The pressure effect of the increase in ε_{max} accompanying the blue shift of λ_{max} is similar to the property of I_2 complexes with n-donors at 1 bar as shown in Fig. 2, where the value of ε_{max} is larger in the I_2 complex whose λ_{max} is at shorter wavelength. Mulliken and Person explained this as follows.[1] The visible I_2 band corresponds to the excitation of an electron from the π_g MO to the σ_u MO of I_2 molecule. Since the latter MO is strongly antibonding, the size of the σ_u MO must be larger than that of the π_g MO. When the I_2 molecule, coupled with a donor in a I_2 complex, is excited by absorption of visible light, its suddenly swollen size ($\sigma_u \leftarrow \pi_g$) increases the repulsion energy between I_2 and the donor, which causes the blue shift of the visible I_2 band. The shift should be greater, the more compact the I_2 complex. The enhanced intensity of the visible I_2 band is presumably explained in terms of the increased mixing of the excited state of the visible I_2 band with the higher excited states of the I_2 complex, as a result of the shift of the excited state of the visible I_2 band to higher energy. Such a explanation may be suited for the pressure effects on the I_2 complex, that is, the blue shift of λ_{max} and the enhancement of ε_{max} of the visible I_2 band, implying a decrease in the bond distance between I_2 and the n-donor.

The values of the slope in Fig. 2 have been estimated to be 0.01, 0.12, 0.81, and 0.95 mol^{-1} dm^3 cm^{-1}/cm^{-1} at band maxima of free I_2, Et_2O–I_2, Et_2S–I_2, and Et_2Se–

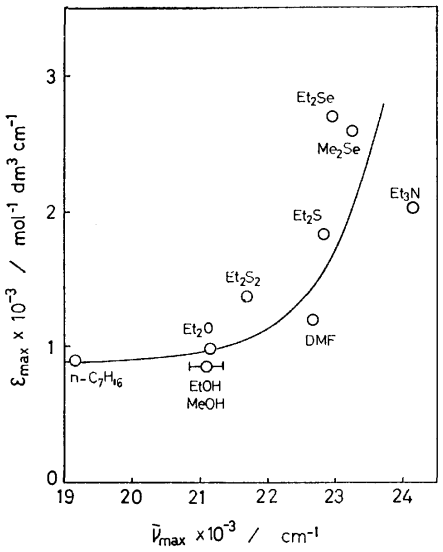

Fig. 2. Relation between ε_{max} and $\tilde{\nu}_{max}$ at visible I_2 band of I_2 complexes with n-donors at 1 bar. References 1 and 17 were utilized. $\tilde{\nu}_{max}=1/\lambda_{max}$.

TABLE 3. THE INCREASES IN THE MOLAR EXTINCTION COEFFICIENTS AT λ_{max} OF VISIBLE I_2 BANDS WITH INCREASING PRESSURE UP TO 3300 bar (mol^{-1} dm^3 cm^{-1})

	Free I_2	Et_2O–I_2	Et_2S–I_2	Et_2Se–I_2
$\Delta\varepsilon_{obsd}$	0	0	300	290
$\Delta\varepsilon_{est}$	1.4	36	267	285

$\Delta\varepsilon=\varepsilon_{max}$ (at 3300 bar) $-\varepsilon_{max}$ (at 1 bar). The subscripts "obsd" and "est" represent the observed value in Table 1 and the estimated one from Fig. 2, respectively.

I_2 complexes, respectively. The blue shifts of the visible I_2 bands with increasing pressure up to 3300 bar have been estimated as 140 cm^{-1} for free I_2, 300 cm^{-1} for Et_2O–I_2 and Et_2Se–I_2 complexes, and 330 cm^{-1} for Et_2S–I_2 complex from Table 1. The amount of increase in ε_{max} corresponding to the blue shift of the visible I_2 band with increasing pressure up to 3300 bar may be estimated from the slope of the curve in Fig. 2. These values shown in Table 3 are comparable with the observed ones. This result may support that Mulliken's explanation is suited for the pressure effect on I_2 complexes.

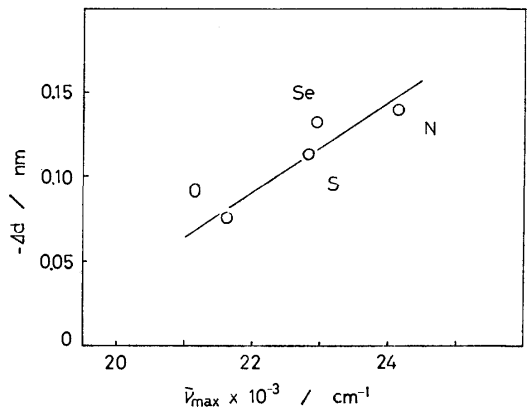

Fig. 3. Relation between $-\Delta d$ and $\tilde{\nu}_{max}$ of visible I_2 bands with several n-donors at 1 bar. O: Et_2O–I_2, S: Et_2S–I_2, Se: Et_2Se–I_2, N: Me_3N–I_2, Δd: see Eq. 5. For the estimation of Δd, van der Waals radii[16] of O, S, Se, N, and I atoms and X-ray data of 1,4-dioxane–I_2 (O),[18] 1,4-dithiane–I_2 (S),[14] 1,4-diselenane–I_2 (Se),[15] and Me_3N–I_2 (N)[19] complexes in their crystals were utilized.

In I_2 complexes with n-donors at 1 bar, it has been found that the decreases in distance between the n-donors and I_2 accompanying complex formation are larger with stronger n-donors.[14,15,18,19] These values are also related to the absorption maxima of the visible I_2 bands in Fig. 3, suggesting the blue shift of the visible I_2 band by the increase in the repulsion force between a n-donor and I_2. The value of $-\Delta d$ in Fig. 3 represents a decrease in the interatomic distance between an n-donor atom and an iodine atom accompanying formation of the I_2 complex (refer to Eq. 5). A linear relation between $-\Delta d$ and the absorption maxima ($\tilde{\nu}_{max}$) of the visible I_2 band has been obtained, and the slope has been estimated to be 2.7×10^{-5} nm/cm^{-1}. The blue shift of 300 cm^{-1} in the visible I_2 band of Et_2Se–I_2 complex with increasing pressure up to 3300 bar has been observed. The value of $-\Delta d$ corresponding to this blue shift may be estimated as 0.008 nm from the slope in Fig. 3.

We wish to thank Professor H. Tsubomura of Osaka University for his useful discussion and advice.

Effect of Pressure on Iodine Complexes. II. Absorption Spectra of the Charge Transfer Bands with Diethyl Ether, Diethyl Sulfide, and Diethyl Selenide in Heptane

Seiji SAWAMURA, Yoshihiro TANIGUCHI, and Keizo SUZUKI*

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received April 13, 1978)

Absorption spectra of the CT bands of I_2 complexes with Et_2O, Et_2S, and Et_2Se in heptane have been measured up to 4400 bar at 25 °C. The equilibrium constants and the volume changes accompanying complex formation, and the molar extinction coefficients and absorption maxima have been estimated. The volume changes were comparable with those estimated by the visible I_2 bands and by the X-ray data of the I_2 complexes in the crystalline state. In the CT bands of Et_2S–I_2 and Et_2Se–I_2 complexes inversion of shift from red to blue has been observed with increasing pressure though the CT band of Et_2O–I_2 complex shifted only through red. This inversion appears to be characteristic of the strong CT complex. Enhancement of the molar extinction coefficient of the CT band has been found with increasing pressure suggesting enhancement of the CT interaction between I_2 and the n-donor.

In previous papers[1,2] I_2 complexes with diethyl ether (Et_2O), diethyl sulfide (Et_2S), and diethyl selenide (Et_2Se) have been studied as an example of a n-σ complex under high pressure measuring the visible I_2 band. Enhancement of the molar extinction coefficient and the blue shift of the visible I_2 band have been observed with increasing pressure, and the decrease in bond distance between the n-donor and I_2 with increasing pressure up to 3300 bar was estimated as 0.008 nm. The I_2 complex has not only a visible I_2 band but also a charge transfer (CT) band. Then information about the pressure effect on the I_2 complex can be also found by measuring the latter band. The pressure effect on the CT band of the I_2 complexes with Et_2O, Et_2S, and Et_2Se in heptane has consequently been studied.

Experimental

The purification of reagents and the method of measuring the absorption spectra under high pressure are the same as described previously.[1,2]

Results and Discussion

Equilibrium Constants. The CT absorption spectra of the Et_2S–I_2 complex are shown in Fig. 1, and as can be seen the absorption spectra are free from component bands. Similar distinct CT absorption spectra have been observed in the Et_2Se–I_2 complex. The equilibrium constants (K) accompanying complex formation and the molar extinction coefficients (ε_{max}) of these CT bands have been estimated from the Benesi-Hildebrand equation.[2] The CT band of the Et_2O–I_2 complex overlaps the I_2 band in the ultraviolet region (Fig. 2). For the estimation of K and ε_{max} of the Et_2O–I_2 complex, a modified Benesi-Hildebrand equation has been used as previously described.[1] These results are shown in Table 1 together with the spectroscopic data.

The volume changes, ΔV, accompanying complex formation have been calculated from the pressure dependence of $\ln K$.[1,2] These are shown in Table 2. The volume changes estimated from the CT band of the I_2 complex in the present work is comparable with that previously estimated from the visible I_2 band in each complex[2] and furthermore comparable with that estimated from the X-ray data of the I_2 complex.[2]

Spectroscopic Properties. The absorption maxima (λ_{max}) of the CT bands of several I_2 complexes are

shown in Table 1. In Et_2O–I_2 complex the λ_{max} values of the CT band have been estimated from the observed absorption by subtracting that of the free I_2, which has been calculated from the equilibrium constant of this complex and the molar extinction coefficient of free I_2. In Et_2O–I_2 complex λ_{max} showed a red shiftt with increasing pressure. The red shift has been generally observed in π-π complexes.[6-11] Two explanations have been proposed for the red shift of the CT band with increasing pressure. One is the enhancement of the dielectric constant of the solvent by compression.[6,11,12] This effect stabilizes the excited state of the CT complex rather than the ground state as the dipole moment of the former state is much larger than that of the latter. The other reason is the decrease in the bond distance between a donor and an acceptor,[8,9] supposing that the distance between a donor and an acceptor at the potential minimum of the ground state is larger than that of the excited state.

In Et_2S–I_2 and Et_2Se–I_2 complexes the λ_{max} of the CT band shifted to red with increasing pressure, and then to blue (Table 1). Such an unusual pressure shift from red to blue has been observed only in CT complex between hexamethylbenzene (HMB) and tetracyanoethylene (TCNE).[7,8,11] Gott and Maisch attributed the blue shift in the HMB–TCNE complex under high pressure to the onset of steric hindrance between the nitrogen atoms of TCNE and the methyl groups of HMB.[7] This explanation does not appear to be valid for Et_2S–I_2 and Et_2Se–I_2 complexes because of the absence of steric hindrance. The bond energies of these complexes in nonpolar solvents are 33, 41, and 32 kJ mol^{-1} for Et_2S–I_2,[4] Et_2Se–I_2,[5] and HMB–TCNE complexes,[13] respectively. These values are larger than those of other CT complexes (≈20 kJ mol^{-1}) which indicate normal red shifts of the CT bands with increasing pressure.[6-11] Therefore the unusual pressure shift, namely the inversion of shift with increasing pressure up to several thousand bars may be a character of the complex with strong CT interaction.

The increases in ε_{max} of the CT bands up to 3300 bar are shown in Table 3 as $\Delta\varepsilon_{obsd}$. The same magnitude of $\Delta\varepsilon_{obsd}$ value has been generally observed in π-π complexes.[7-11] The enhancement of ε_{max} of the CT band may be ascribed to the decrease in the bond distance between a donor and an acceptor with increasing pressure as the overlap integral increases due to the decrease in bond distance as expected by Mulliken,[14] implying enhancement of the CT interraction. This explanation supports the preceding conclusion, that is, a decrease in the bond distance of 0.008 nm between I_2 and an n-donor with increasing pressure up to 3300 bar.[2] Furthermore the amount of increase in the overlap integral accompanying decrease in the bond distance is expected to be larger in the stronger CT complex since the overlap integral

Table 3. The increases in the molar extinction coefficients at the CT absorption maxima with increasing pressure up to 3300 bar (mol^{-1} dm^3 cm^{-1})

	Et_2O–I_2	Et_2S–I_2	Et_2Se–I_2
$\Delta\varepsilon_{obsd}$	100±1200	1000±1200	3000±1000
$\Delta\varepsilon_{est}$	2200	2400	2200

$\Delta\varepsilon=\varepsilon$ (at 3300 bar) $-\varepsilon$ (at 1 bar), where ε is the molar extinction coefficient at the CT absorption maximum. The subscripts "obsd" and "est" represent the observed value in Table 1 and the estimated value from Fig. 3, respectively.

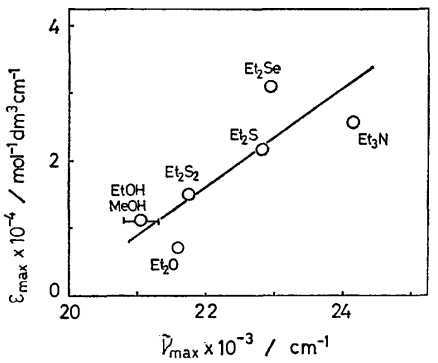

Fig. 3. Relation between ε_{max} of CT band and $\tilde{\nu}_{max}$ of visible I_2 band of I_2 complexes with n-donors at 1 bar. References 15 and 16 were utilized. $\tilde{\nu}_{max}=1/\lambda_{max}$.

increases exponentially with decrease in bond distance. This may explain the $\Delta\varepsilon_{obsd}$ values in Table 3 being larger with stronger n-donors (O<S<Se).

A relation between ε_{max} of the CT bands and λ_{max} (or $\bar{\nu}_{max}$) of the visible I_2 bands of the I_2 complexes with n-donors is expected at 1 bar since it is established that the former values are larger and the latters are at shorter wavelengths with stronger n-donors.[15] This relation is shown in Fig. 3 with a straight line of slope 7.3 mol^{-1} dm^3 cm^{-1}/cm^{-1}. From this slope we can estimate the increases in ε_{max} of the CT bands corresponding to the previously observed blue shifts of the visible I_2 bands, that is, 300 cm^{-1} for Et_2O–I_2 and Et_2-Se–I_2 complexes and 330 cm^{-1} for Et_2S–I_2 complex with increasing pressure up to 3300 bar.[2] These blue shifts suggest enhancement of the CT interaction with increasing pressure. The results are shown in Table 3 as $\Delta\varepsilon_{est}$ and compared with the observed values. The values of $\Delta\varepsilon_{est}$ appear to be the same order of magnitude as the $\Delta\varepsilon_{obsd}$ values and this supports the hypothesis that the increase in ε_{max} of the CT band with increasing pressure is due to the enhancement of the CT interaction between I_2 and the n-donor.

We wish to thank Professor H. Tsubomura of Osaka University for his useful discussion and advice.

A Molecular Orbital Approach to the Electrophilicity of H and OH Radicals

Akira IMAMURA* and Kimihiko HIRAO

Department of Chemistry, Shiga University of Medical Science, Setatsukinowa-cho, Otsu, Shiga 520-21

(Received April 28, 1978)

We tried to explain the electrophilicity of radical reagents such as H and OH radicals in the aromatic substitution reaction by using the molecular orbital theory. The delocalization energy of π electrons was decomposed into two parts: one is the energy due to the delocalization from a substrate to a reagent and another is that from a reagent to a substrate. The former was considered to be a measure of the electrophilicity and the latter of the nucleophilicity. The decomposition of the delocalization energy into two parts was carried out by modifying the relevant core resonance integrals as appropriate. The result indicated that the delocalization energy for the electrophilicity was much larger than that for the nucleophilicity for both radicals. Thus, H and OH radicals should be electrophilic in nature, in good agreement with the experimental facts. Finally, the origin of the electrophilicity was discussed in connection with the height of the relevant energy levels by following a perturbational approach.

Chemical reactivities of OH and H radicals have been extensively studied in connection with the radiobiological reaction mechanism.[1-6] In many studies of the reaction mechanisms of OH and H radicals, it has been shown that OH and H radicals are electrophilic in nature.[1,2] A beautiful proof for the electrophilicity of the OH radical was published by Anbar *et al.*:[2] they measured the relative rates of reaction of OH radicals with many benzene derivatives and substituted benzoate ion, and found that a plot of the reaction rate against Hammett's σ value is nearly linear, with $\rho = -0.41$, indicating the electrophilicity of the OH radical.

Molecular orbital studies of the reaction mechanism of the OH radical have also been carried out by many researchers.[10-12] In these studies, the electrophilicity of the OH radical was indicated by the electron transfer quantity from the substrate to the OH radical. This quantity, however, can only be used as a qualitative measure of the electrophilicity, since this quantity should be the difference of two electron transfer quantities, from substrate to OH radical and *vice versa*.

In the present paper, we used the unrestricted SCF method in the INDO approximation and calculated, separately, the stabilization energies due to the delocalization of electrons from radical reagent to substrate and those due to the delocalization of electrons from substrate to radical reagent. Obviously, the former can be considered to be a measure of the nucleophilicity of the radical reagent and the latter a measure of the electrophilicity. From the results obtained, OH and H radicals were found to have much more electrophilicity than nucleophilicity, in good agreement with the experimental data.[1,2]

Method of Calculations

First of all, we assumed that the transition state of the reaction between benzene and the radical reagent is the tetrahedral intermediate, as shown in Fig. 1. This model for the transition state has been used in many theories for the chemical reactivity, especially in the frontier electron theory of Fukui *et al.*[7,8] The geometry of the tetrahedral intermediate was tentatively assumed at follows: C–C bond = 1.397 Å, C–H bond = 1.084 Å, C–O bond = 1.360 Å, O–H bond = 0.967 Å, all bond angles except for those including the tetrahedral carbon = 120°, bond angles including tetrahedral carbon = 109°28′, ∠COH = 107°18′, and the H atom of the OH group and the H atom of the CH bond are assumed to be in the trans form. Although the C–O and C–H bond lengths of the tetrahedral carbon atom in the transition state may be different from those used in the present article, it is difficult to determine the bond lengths in the transition state. However, the relative magnitude of the stabilization energies for delocalization of electrons from the substrate to the reagent and *vice versa* can probably be estimated by using the above-mentioned geometry.

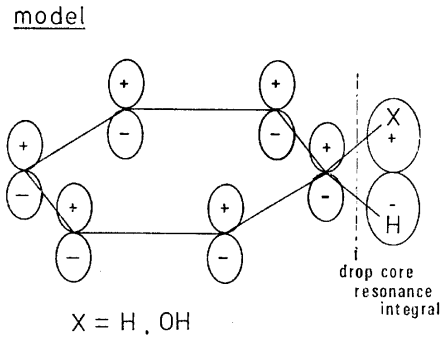

Fig. 1. The model for the tetrahedral intermediate. The orbital at the most right is the pseudo π orbital.

It has been well known that the chemical reactivity of aromatic substitution is mainly governed by the magnitude of the stabilization energy due to the delocalization of π electrons between benzene π orbitals and the pseudo π orbital which is formed from the attacking radical reagent and the remaining hydrogen atom.[7,8] In order to estimate the delocalization energy of π electrons, first, the total energy of the molecule was calculated by using the unrestricted SCF method with INDO approximation[9] after dropping all core resonance integrals between π atomic orbitals on the benzene moiety and the pseudo π orbital. This gives the total energy without the delocalization of π electrons. Next, the total energy of the molecule was calculated after partially including the core resonance integrals between π atomic orbitals and the pseudo π^* orbital, so as to include only the effect of the delocalization of π electrons from the substrate to the radical reagent, and not from

the radical reagent to the substrate. The difference between these two total energies can be considered to be a measure of the electrophilicity of the radical reagent in question:

$$E_{\text{electrophilicity}} = E(\text{including the delocalization from the substrate to the radical reagent}) - E(\text{without the delocalization of } \pi \text{ electrons}), \quad (1)$$

where E is the total energy calculated under the restriction described in the parentheses. In a similar manner, we can obtain a measure of the nucleophilicity of the radical reagent by the following equation:

$$E_{\text{nucleophilicity}} = E(\text{including the delocalization from the radical reagent to the substrate}) - E(\text{without the delocalization of } \pi \text{ electrons}). \quad (2)$$

In calculating a measure of the electrophilicity as well as the nucleophilicity, the core resonance integrals between π atomic orbitals on the benzene moiety and the pseudo π orbital should be modified in order to include the delocalization of π electrons from the substrate to the radical reagent or *vice versa*. That is, for a measure of the electrophilicity, the core resonance integrals between atomic orbitals in question should be modified so that the core resonance integrals between the occupied π molecular orbitals on the benzene moiety and the vacant pseudo π^* molecular orbitals have the same value as those obtained by using the usual core resonance integrals between atomic orbitals, and the resonance integral between other molecular orbitals is always zero. Of course, the molecular orbitals which are used for calculating the core resonance integral have to be those obtained without the effect of the delocalization of π electrons, namely, by dropping the core resonance integrals between π and pseudo π atomic orbitals. The values of the core resonance integrals required can be calculated by the procedure described below.

Molecular orbitals obtained by dropping all the core resonance integrals between π atomic orbitals on benzene and pseudo π orbitals can be classified into two groups: one is those containing only π atomic orbitals on a benzene moiety and the other, the pseudo π orbitals as well as σ atomic orbitals of benzene. Thus, the molecular orbitals can be represented as follows:

$$\phi_{\pi i} = \sum_r C_{\pi i,r}\chi_r, \quad (3)$$

$$\phi_{\sigma j} = \sum_s C_{\sigma j,s}\chi_s, \quad (4)$$

where $\phi_{\pi i}$ denotes a molecular orbital containing only π atomic orbitals on the benzene ring, and $\phi_{\sigma j}$ denotes that containing pseudo π orbitals as well as σ atomic orbitals of benzene. From Eq. 3, an atomic orbital, χ_r, can be represented by a linear combination of molecular orbitals $\phi_{\pi i}$, as shown in the following. Equation 3 is multiplied by the coefficient $C_{\pi i,r_1}$ and the resulting equations are added for all i:

$$\sum_i C_{\pi i,r_1}\phi_{\pi i} = \sum_r\sum_i C_{\pi i,r_1}C_{\pi i,r}\chi_r = \sum_r \chi_r \sum_i C_{\pi i,r_1}C_{\pi i,r} = \sum_r \chi_r \delta_{rr_1} = \chi_{r_1}, \quad (5)$$

where r_1 designates one of the π atomic orbitals $\{\chi_r\}$. Thus, we have

$$\chi_r = \sum_i C_{\pi i,r}\phi_{\pi i}. \quad (6)$$

Similarly,

$$\chi_s = \sum_j C_{\sigma j,s}\phi_{\sigma j}. \quad (7)$$

By using Eqs. 6 and 7, we can represent a core resonance integral between atomic orbitals χ_r and χ_s as the sum of core resonance integrals between molecular orbitals $\phi_{\pi i}$ and $\phi_{\sigma j}$:

$$I_{rs} = \int \chi_r h^\circ \chi_s d\tau = \sum_i\sum_j C_{\pi i,r}C_{\sigma j,s}\int \phi_{\pi i} h^\circ \phi_{\sigma j} d\tau = \sum_i\sum_j C_{\pi i,r}C_{\sigma j,s}I_{ij}, \quad (8)$$

where I_{rs} and I_{ij} are the core resonance integral between the atomic orbitals χ_r and χ_s, and that between the molecular orbitals $\phi_{\pi i}$ and $\phi_{\sigma j}$, respectively, and h° means the one electron Hamiltonian. By modifying Eq. 8, we can obtain the value of the core resonance integral between atomic orbitals which gives the core resonance integrals between any specified molecular orbitals $\phi_{\pi i_1}$ and $\phi_{\sigma j_1}$ correctly and gives zero for the core resonance integrals between other molecular orbitals. That is,

$$I_{rs} = \sum_{(i_1-j_1)} C_{\pi i_1,r}C_{\sigma j_1,s}I_{i_1 j_1}, \quad (9)$$

where (i_1-j_1) means that the summation should cover only some specified molecular orbitals $\phi_{\pi i_1}$ and $\phi_{\sigma j_1}$. It is proved below that the core resonance integrals, I_{rs}, in Eq. 9 give the core resonance integrals between molecular orbitals $\phi_{\pi i_1}$ and $\phi_{\sigma j_1}$ correctly and give zero values for others. Consequently, when the vacant molecular orbitals localized in the radical moiety and the occupied molecular orbitals are chosen for i_1 and j_1, respectively, we can calculate the delocalization energy for the electrophilicity given by Eq. 1. The proof is as follows:

$$\begin{aligned} I_{ij} &= \sum_r\sum_s C_{\pi i,r}C_{\sigma j,s}\int \chi_r h^\circ \chi_s d\tau = \sum_r\sum_s C_{\pi i,r}C_{\sigma j,s}I_{rs} \\ &= \sum_r\sum_s C_{\pi i,r}C_{\sigma j,s}\sum_{(i_1-j_1)} C_{\pi i_1,r}C_{\sigma j_1,s}I_{i_1 j_1} \\ &= \sum_{(i_1-j_1)} I_{i_1 j_1}\left(\sum_r C_{\pi i,r}C_{\pi i_1,r}\right)\left(\sum_s C_{\sigma j,s}C_{\sigma j_1,s}\right) \\ &= \sum_{(i_1-j_1)} I_{i_1 j_1}\delta_{ii_1}\delta_{jj_1}. \end{aligned} \quad (10)$$

Equation 10 indicates that I_{ij} is equal to the correct value only when $i=i_1$ and $j=j_1$ and is zero otherwise. Consequently, when molecular orbitals $\phi_{\pi i_1}$ cover all occupied orbitals, and $\phi_{\sigma j_1}$ cover all vacant pseudo π^* orbitals, the SCF calculations with the core resonance integrals of Eq. 9 should give a measure of the electrophilicity. On the other hand, when molecular orbitals $\phi_{\pi i_1}$ cover all vacant orbitals, and $\phi_{\sigma j_1}$ cover all occupied pseudo π orbitals, a measure of the nucleophilicity must be given.

The procedure of the calculations can be summarized as follows. (i) The total energy of the molecule in the transition state is calculated with the unrestricted SCF method in the INDO approximation after dropping all the core resonance integrals between the π atomic orbitals on the benzene moiety and the pseudo π orbital. (ii) By using the molecular orbitals obtained in step (i), the core resonance integrals between π atomic orbitals and pseudo π atomic orbitals are modified according to

Eq. 9 in order to take the electrophilic or the nucleophilic nature into account. (iii) The modified core resonance integrals are employed to calculate the total energy of the molecule in the transition state with the delocalization of π electrons, which corresponds to the electrophilic or the nucleophilic nature. (iv) A measure of the electrophilicity or the nucleophilicity of the radical reagent can be obtained by calculating the difference between energies obtained in steps (i) and (iii).

Results and Discussion

The electrophilicity of H and OH radicals was studied according to the procedure described. However, the procedures for H and OH radicals are slightly different owing to the symmetrical character of the pseudo π orbital; that is, in the case of the H radical, the pseudo π orbital is antisymmetric with respect to the reflection in the plane containing the benzene ring, but is lacking in the symmetry for the OH radical. Consequently, the results for H and OH radicals will be shown separately in the following.

H Radical. The unrestricted SCF method is applied to the tetrahedral intermediate of the benzene attacked by the H radical (see Fig. 1) in the INDO approximation. The obtained energy levels are as indicated in Fig. 2 when the delocalization of π electrons is prohibited. As is clearly shown in Fig. 2, the energy level of the pseudo π orbital for α-spin is much lower than that for β-spin owing to the effect of the spin polarization. The delocalization energy for the measure of the nucleophilicity of the H radical is obtained when the core resonance integrals are retained only between the pseudo π orbital and the vacant π^* molecular orbitals on the benzene moiety for α-spin, as shown by arrows in Fig. 2. On the other hand, the measure of the electrophilicity can be calculated by retaining the core resonance integrals between the pseudo π^* orbital and the occupied π molecular orbitals on the benzene moiety for β-spin.

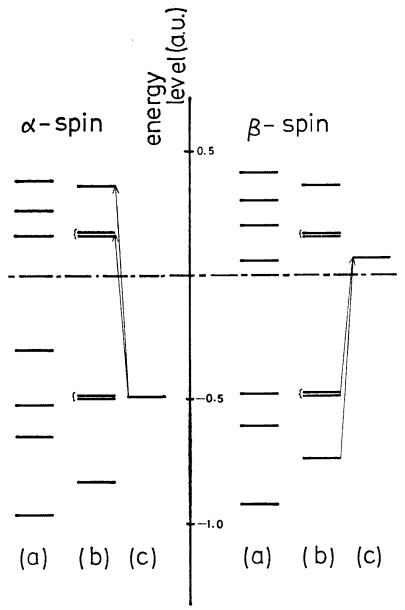

Fig. 2. Energy level diagrams of π molecular orbitals for the tetrahedral intermediate attacked by H radical. (a) The energy levels obtained by the usual UHF calculation. (b) The energy levels of benzene π molecular orbitals obtained by the UHF calculation after dropping core resonance integrals shown in Fig. 1. (c) The energy levels of pseudo π orbital obtained by the procedure in (b). The arrows in the figure indicate the direction of electron delocalization.

Table 1. Total energies of tetrahedral intermediate attacked by H radical with various types of delocalization effects

Interacting MO[a] (α-spin)	Interacting MO[a] (β-spin)	Total energy[b]	Delocalization energy[b]
all	all	−46.312	0.315

none	$\begin{matrix}\text{all } \pi \\ \text{all } \pi^*\end{matrix}$-pseudo π	−46.180	0.182

a) Interacting MO means molecular orbitals which retain the core resonance integrals between themselves.
b) In a.u.

The obtained results are listed in Table 1. The third line indicates the nucleophilicity and the fourth line the electrophilicity of the H radical. Obviously, the delocalization energy for the electrophilicity is much larger than that for the nucleophilicity. Consequently, it should be concluded that the H radical is electrophilic in nature for the radical reaction with benzene, in accordance with the experimental fact that the H radical behaves like an electrophilic reagent in the abstraction reaction[1] (although this reaction is somewhat different from the model used in the present article). The fifth line of Table 1 includes the delocalization energy obtained by retaining core resonance integrals for the electrophilicity as well as the nucleophilicity. The delocalization energy in the fifth line is nearly equal to the sum of the delocalization energies in the third and the fourth lines, that is, the delocalizations of α-spin and β-spin electrons affect each other only slightly. The delocalization energy in the sixth line was obtained by including the core resonance integrals between the pseudo π orbital and all the π molecular orbitals on benzene moiety for α-spin, that is, the effect of the nucleophilicity as well as the redistribution of α-spin electrons were included in the value of the delocalization energy. Similarly, the delocalization energy in the seventh line includes the effect of the electrophilicity as well as the redistribution of the β-spin electrons. By comparing the values in the sixth and the seventh lines with those in the fourth and fifth lines, the redistribution effect is found not to be negligibly small, although the delocalization energy corresponding to the nucleophilicity and the electrophilicity are somewhat larger than those for the redistribution effect. In conclusion, for the H radical the delocalization energy for the electrophilicity was found to be the most important contribution to the total delocalization energy.

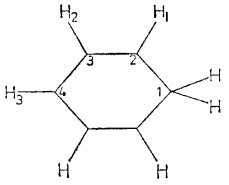
a) The numbering of the atom is as below: b) The meaning of "Interacting MO" is given in Table 1.



In Table 2, charge distributions of the tetrahedral intermediate were given for the various cases corresponding to the calculations in Table 1. It is obvious that the charges on the hydrogen atoms bonded to the tetrahedral carbon atom can help in determining the direction of the electron delocalization. The charge on the hydrogen atom in the third line is positive, in accordance with the fact that the calculations of the third line give a measure for the nucleophilicity. Similarly, the negative charge on the hydrogen in the fourth line corresponds with the calculations for the electrophilicity. The charges listed in the sixth and the seventh lines indicate that the inclusion of the redistribution effect makes the positive hydrogen more positive and the negative hydrogen more negative. As a result, the sum of the charges of the hydrogen atom in the sixth and seventh lines leads to a slightly negative charge, which corresponds to the value of the charge in the first line.

OH Radical. For the calculation of the electrophilicity of the OH radical, the tetrahedral intermediate of the benzene attacked by an OH radical (see Fig. 1) was subjected to the unrestricted SCF calculations in the INDO approximation. However, this intermediate has no symmetry for the reflection in the plane containing the benzene ring. In other words, the pseudo π and π^* orbitals don't localize in the parts of the H atom and OH group attached to the tetrahedral carbon atom, but these orbitals spread over the σ skeleton of the whole molecule. Because of the delocalizing character of the pseudo π and π^* orbitals, it becomes rather difficult to discriminate the pseudo π and π^* orbitals from other orbitals. In addition to this, the core resonance integrals between the $2p\pi$ atomic orbitals and the other 2s or 2p atomic orbitals of the same atom are apparently non-zero, using Eq. 9, since the values of $C_{\sigma j,s}$ for a pseudo π or π^* orbital are non-zero because of the spreading character of the pseudo π or π^* orbital.

In order to overcome these undesirable developments, the molecular orbitals $\psi_{\sigma j}$ given by Eq. 4 were transformed into the localized molecular orbitals according to the procedure of Edmiston and Ruedenberg.[13] After this procedure, it becomes quite easy to pick up the pseudo π or π^* orbital. Furthermore, if the transformed orbital is localized completely, the core resonance integral between $2p\pi$ and 2s or $2p\sigma$ atomic orbitals, which is apparently non-zero if one uses canonical molecular orbitals, becomes completely zero if one uses localized molecular orbitals, since the value of $C_{\sigma j,s}$ in Eq. 9 vanishes. Usually, transformed orbitals don't localize completely, and hence the undesirable development cannot be completely excluded, but its contribution is expected to be significantly diminished. Therefore, the degree of localization given by Eq. 11 was calculated to check the validity of the calculations.

$$\text{Degree of localization} = \sum_{\substack{r \\ (\text{OH.H})}} C_{ir}^2, \qquad (11)$$

where r in the summation covers all atomic orbitals on the OH group and H atom attached to the tetrahedral carbon atom.

a) The meaning of "interacting MO" is the same as that in Table 1. b) In a.u.

The degree of the localization for some transformed molecular orbitals is listed in Table 3, and compared with that for the corresponding canonical molecular orbitals. Obviously, the degree of localization increases remarkably by the transformation of the molecular orbital. The measure of the electrophilicity of the OH radical was calculated in a similar manner to that of the H radical by using the transformed molecular orbitals. The results thus obtained are collected in Table 4. It is clearly indicated that the OH radical is quite electrophilic in nature, in agreement with the experimental data.[1,2] In order to investigate the effect of the localization of molecular orbitals, the same calculations were carried out by using canonical molecular orbitals. Table 5 contains the results which indicate the essential features of the electrophilicity of the OH radical. That is, by comparing Tables 4 and 5, the delocalization energy for the measure of the electrophilicity is much larger than that for the nucleophilicity, regardless of the degree of the localization. In other words, the conclusion that the OH radical is electrophilic in nature is valid independently of the degree of the localization for the molecular orbitals in question. In Table 6, charge distributions corresponding to the calculations of Table 4 are listed. This indicates that the electrophilicity of the OH radical is reflected in the negative charges of the H atom and OH group attached to the tetrahedral carbon atom. That is, when the conjugation of π electrons is completely prohibited between pseudo π or π^* orbital and benzene π molecular orbitals, the charge on the tetrahedral group is somewhat negative (−0.110). When the effect of the nucleophilicity is taken into account, it becomes slightly positive (+0.003), and when the effect of the electrophilicity is taken into account, it becomes quite negative (−0.352). As a sum of these two effects, the considerable negative charge on the group results. This feature for OH radicals is quite similar to that for H radicals.

Concluding Remarks. In the present article, the electrophilicity of H and OH radicals was quantitatively evaluated by separating the delocalization energy in the nucleophilic and the electrophilic ones. The obtained result is in good agreement with the experimental fact that H and OH radicals are electrophilic in nature. In the present paragraph, we will discuss briefly the origin of the electrophilicity of H and OH radicals. Since the measure of the electrophilicity is a kind of delocalization energy, it should be very effective for the analysis of the electrophilicity of H and OH radicals to use the concept of the perturbation method.

In Figs. 2 and 3, the energy levels for zero-th order wave functions are given for H and OH radicals. As is well known, the delocalization energy is approximately proportional to the core resonance integral between pseudo π or π^* orbital and benzene π molecular orbitals, and is inversely proportional to the energy difference between pseudo π and benzene unoccupied π^* molecular orbitals or pseudo π^* and benzene occupied π orbitals. The above-metioned reasoning is applicable only when the uncoupled approximation[14,15] in the SCF perturbation method is valid. The present approach has its

special characteristics in the feature of the distribution of energy levels: that is, by using the unrestricted SCF method the energy level for an odd electron splits into two different values, for occupied α-spin and unoccupied β-spin levels. Thus, the dependence of the delocalization energy upon the height of the energy levels should be classified into two factors; one is the average height of the two split levels for an odd electron and the other is the magnitude of splitting of these two levels. This situation is schematically shown in Fig. 4. As is evident from this figure, the lower the average height of the two energy levels is, the more electrophilic the radical reagent is. On the other hand, a large magnitude of splitting of the two energy levels results in large values for the measures of both the electrophilicity and the nucleophilicity.[16] From the heights of the energy levels in Figs. 2 and 3, H and OH radicals can be inferred to be electrophilic in nature, although the quantitative evaluation of the delocalization energy is not accessible, owing to the contribution of the core resonance integral between pseudo π or π^* orbital and benzene π molecular orbitals. In conclusion, the electrophilicity of the radical reagent may qualitatively be predicted by the average of the two energy levels of pseudo π and π^* orbitals and the magnitude of their splitting. As to other radical reagents, analysis will soon be carried out in order to investigate whether the above-mentioned conclusion holds or not. Furthermore, the abstraction reaction of a hydrogen atom, as well as a halogen atom, by the reagent was subjected to an analysis similar to that in the present article and was published.[17]

The authors are very grateful to Prof. T. Masuda of Tokyo Metropolitan University for suggesting this problem and for stimulating discussion. We are also grateful to Dr. T. Minato for his considerable assistance with the computer program of localized molecular orbitals. The numerical calculations were carried out on the FACOM 230-75 at the Computer Center of Kyoto University. This research was supported in part by a Scientific Grant from the Ministry of Education.

Liquid Structure of Carbon Tetrachloride and Long-range Correlation

Keiko NISHIKAWA* and Yoshitada MURATA†

Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received May 20, 1978)

The diffraction of liquid CCl_4 was measured by using the energy-dispersive X-ray diffractometer. The fine structure was observed for the first time in the present study. The existence of the fine structure in the diffraction pattern shows the long-range correlation "directly." The bcc cluster model for liquid CCl_4 is presented on the basis of the long-range correlation. The calculated intensity of the model is in good agreement with the observed one.

We constructed an energy-dispersive X-ray diffractometer using a solid state detector for the determination of liquid structure. The details were reported in a previous paper.[1)]

The energy-dispersive method has various merits in comparison with the traditional angle-dispersive method. First, a higher resolution of the s-value ($s=4\pi \sin\theta/\lambda$, λ: wavelength, 2θ: scattering angle) can be obtained. The resolution of the s-value is determined by the following equation:

$$\Delta s/s = \Delta E/E + \cot\theta \cdot \Delta\theta. \quad (1)$$

In the energy-dispersive diffractometer, the first term on the right side of Eq. 1 is nearly 0.01 and much larger than in a conventional angle-dispersive one. The second term in the angle-dispersive one, on the other hand, is several times as large as that in the energy-dispersive one. Since $\cot\theta \cdot \Delta\theta$ is less than 0.01 in our apparatus, the resolution $\Delta s/s$ is consequently a half of that in the conventional angle-dispersive diffractometer. Second, in the energy-dispersive method the scattering intensity is hardly affected by fluctuation in the primary beam intensity. Thirdly, it is possible to expand the observable region of the s-value, and hence the intensity data over the range of $s=0.15$—30 Å^{-1} can be obtained by our energy-dispersive X-ray diffractometer. Fourth, such accessories as a sample holder operated at high or low temperature can be mounted easily, since the design of the diffractometer is simple.

The scattering intensity from liquid CCl_4 was measured by taking advantage of the energy-dispersive method. Carbon tetrachloride has been studied well by the angle-dispersive method,[2–7)] and several models for liquid CCl_4 have been proposed by Narten *et al.*,[5)] Egelstaff *et al.*,[9)] Reichelt *et al.*[6)] and Narten.[7)] We reported the scattering intensity of liquid CCl_4 and its electron radial distribution function in a previous paper,[1)] but the analysis of the data obtained by energy-dispersive method was described mainly. In the present study it is shown that liquid CCl_4 has a long-range correlation at room temperature. A new model which explains the observed scattering intensity and the long-range correlation is presented.

Scattering Intensity and Radial Distribution Function

Details of the measurement and data analysis were described elsewhere.[1)] The absorption and Compton correction are more difficult in the energy-dispersive method than in the angle-dispersive one and these may be thought to be a demerit in energy-dispersive diffractometry, but these difficulties were resolved.[1)] The reduced intensity $i(s)$ was obtained in electron units after these corrections. The weighted structure function $si(s)$ is shown in Fig. 1 and agrees fairly well with the recent data for CCl_4 obtained by Narten[7)] except for the fine structure.

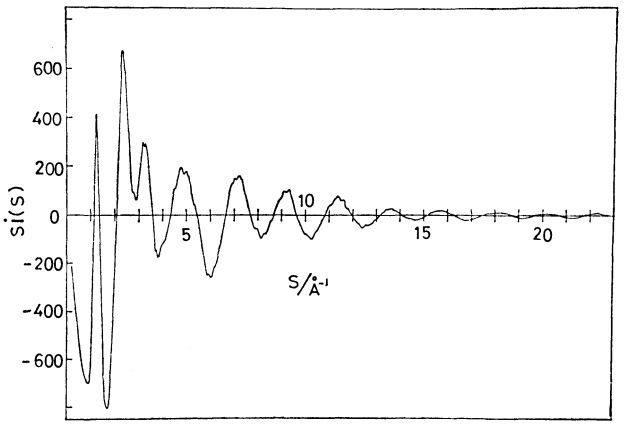

Fig. 1. Weighted structure function $si(s)$ for liquid CCl_4 at room temperature.

The electron radial distribution function from which the bulk density is subtracted, $4\pi r^2(\rho-\rho_0)$, is obtained by the Fourier transformation of $si(s)$,

$$4\pi r^2(\rho-\rho_0) = \frac{2r}{\pi \sum_j Z_j^2} \sum_s si(s) \cdot \sin(sr) \cdot \Delta s, \quad (2)$$

where ρ is the radial distribution function, ρ_0 the bulk density and Z_j the atomic number of a component atom j. The radial distribution function derived from Eq. 2 includes the distribution of the electron cloud. The

electron radial distribution function of CCl_4 at room temperature is shown in Fig. 2.

The intramolecular parameters of CCl_4 were obtained by the least-squares fit of the calculated intensity of the free molecule to the observed intensity of the liquid at s-values larger than 8 Å^{-1}. These parameters are listed in Table 1 with those obtained by other experiments.[5-8] The interatomic distances are in good agreement with each other within experimental errors.

The Fine Structure in the Scattering Intensity and the Long-Range Correlation

Figure 2 shows that liquid CCl_4 at room temperature has long-range correlation. The information on the long-range correlation in liquid is confined in the region of $s<2$ Å^{-1}, but it is also recognized elsewhere. Figure 1 shows that the intensity curve has fine structure of short periodicity at small s-values.†† The fine structure near the top and the bottom of the halos at $s=3.2$ and 4.7 Å^{-1} was reproducible not only in repeated measurements but also in measurements at different scattering angles. The separation between the peaks in this fine structure were 0.2—0.3 Å^{-1}, which was larger than the estimated resolution in the s-value ($\Delta s=0.14$ Å^{-1} at those s-values) in our experiment. The difference between the collected counts at the top and the bottom of these small waves was about 500 counts, which were larger than the statistical random error ($\sqrt{n}=170$, where total counts $n=3\times10^4$). In the energy-dispersive method, the scattering intensity is hardly affected by fluctuations of the incident beam intensity. Therefore, the statistical random error given by the square root of the total counts at each position is the main origin of the noise.

To examine the relation between the fine stricture and the long-range correlation in liquid CCl_4, the inverse Fourier transformation of the experimental data was conducted. Each peak in the observed radial distribution function was expressed approximately by

$$G(r) = A\exp[-4(\ln 2)(r-r_0)^2/w^2] - B, \quad (3)$$

where A is the peak height measured from the average values at the minimum points, w the full width at half maximum, and B the difference between the zero line and the average minimum values. Figure 3 shows the curve for the inverse Fourier transformation for each Gaussian function $G(r)$. The curve (1), (2), (3), (4), (5), and (6) in Fig. 3(a) correspond to the peaks at the maximum positions $r_0=3.8$, 6.3, 8.3, 11.4, 16.3, and 21.5 Å, respectively. The summation of these curves is

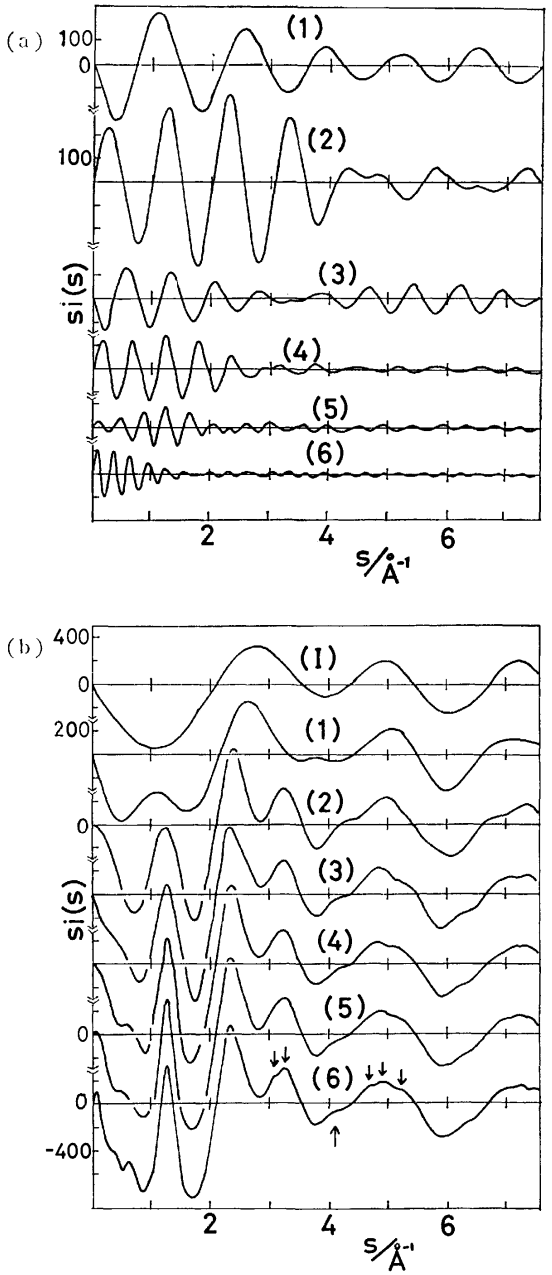

Fig. 3. (a) The inverse Fourier transformation function of the Gaussian function given by Eq. 3. Curves (1), (2), (3), (4), (5), and (6) correspond to the functions with $r_0=3.8$, 6.3, 8.3, 11.4, 16.3, and 21.5 Å, respectively. (b) The uppermost curve (I) is the inverse Fourier transformation function of the intramolecular part. Curve (n) is the sum of curves (1), (2)—(n) of Fig. 3(a) and curve (I).

†† The fine structure at large s-values is random noise, since the ratio of the reduced intensity $i(s)$ to the total scattering intensity is small.

shown in Fig. 3(b). The uppermost curve (I) is the inverse Fourtier transformation of the intramolecular contribution. Curve (n) in Fig. 3(b) represents the sum of curves (1), (2),$\cdots$(n) of Fig. 3(a) and curve (I). The fine structure indicated by the small arrows is in good agreement with the experimental intensity (Fig. 1), *e.g.*, the shoulder peak on the left side of the fourth halo, at $s \simeq 4$ Å^{-1}, appears due to the peaks at $r_0 = 6.3$ and 8.3 Å. The two small waves on the top of the third halo at $s \simeq 3.2$ Å^{-1} may be due to the scattering intensities corresponding to peaks at $r_0 = 16.3$ and 21.5 Å.

It has been concluded that the long-range correlation is not caused by experimental error nor by errors in the data analysis and this is supported by the following consideration. The electron radial distribution function, $4\pi r^2(\rho - \rho_0)$, computed using the intensity data obtained by Narten[7] shows a long-range correlation similar to Fig. 2. However, fine structure was not been observed in the intensity data. The fine structure represents "directly" that the molecules in the liquid phase have a long-range order in the arrangement. The presence of this fine structure had never been detected until the energy-dispersive method was applied to liquids in the present experiment.

Structure of Liquid CCl_4

The molecular arrangement in liquid CCl_4 was drawn on the basis of the following experimental results; (1) the small peak around 3.8 Å in the electron radial distribution function shows the nearest neighbor distance between chlorine atoms belonging to different molecules, and (2) the peaks with respect to the long-range correlation of molecular arrangement appear at integral multiples of about 5.7 Å, *i.e.* $r_0 = 11.4$, 16.3, and 21.5 Å. The peak at 3.8 Å is assigned to the Cl–Cl pair in the partial distribution function derived from X-ray and neutron diffractions by Narten.[7] That the peaks appear in equal intervals may show that CCl_4 molecules are arranged linearly. Consequently it is assumed that the three-fold axes of the CCl_4 molecules are linear. A chlorine atom of one molecule lies in the hollow formed by the three off-axis chlorine atoms of the other molecules. The distance between chlorine atoms belonging to different molecules is 3.8 Å, as shown in Fig. 4(a). Moreover, it is assumed that the average orientation is set in the eclipsed form for the chlorine atoms. In this arrangement, molecules form a body-centered cubic lattice, hereafter called a bcc cluster model. Since the nearest neighbor distance between chlorine atoms is 3.8 Å, the nearest neighbor distance referred to the molecular centers, *i.e.* the carbon atoms, is given by 5.77 Å and the second nearest neighbor distance is 6.77 Å, which corresponds to the lattice constant of the bcc lattice. Figure 4(b) shows the bcc cluster containing 15 CCl_4 molecules. The packing shown in Fig. 4(a) is similar to the "Apollo model" presented by Egelstaff *et al.*[9] They assumed that both molecules were freely oriented about the three-fold axes. However, neither the scattering intensity nor the distribution function was calculated for this model.

Of course, the liquid can never be the crystal. The

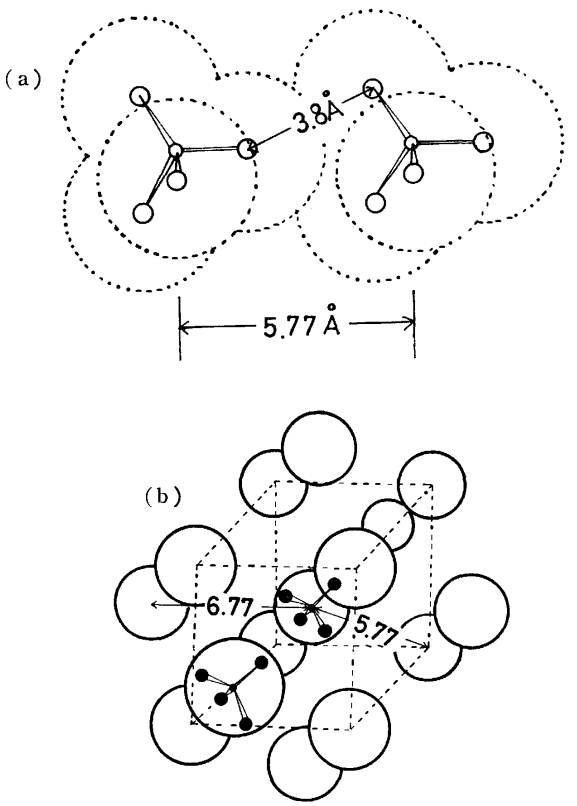

Fig. 4. (a) Packing model for liquid CCl_4. Small circles denote carbon atoms and large circles chlorine atoms. Van der Waals spheres of chlorine atoms are shown by dotted circles. (b) The bcc cluster model for liquid CCl_4 with 15 molecules. CCl_4 molecules are shown by circles. The orientation of all molecules is same as that described in the circles. The cube shown by broken lines forms the bcc unit cell.

molecule in the liquid phase lies around the equilibrium position, which forms the cluster. The cluster must have the same density as the actual liquid. We never mean that clusters with a density different from uniform medium exist actually—here "cluster" means a representation of the region where one molecule "feels" the "structure." The cluster is not rigid, but the structure becomes gradually loose as the molecules separate from the center of the cluster, *i.e.* the distance between molecules in the cluster is smeared as they are separated from each other. The smearing effect is treated with the increase of the root mean-square amplitude l_{ij} of the interatomic distance r_{ij}. The structure outside the cluster is a uniform medium.

The reduced intensity function may be computed from the equation,

$$i(s) = \frac{1}{N}\sum\sum_{i \neq j} f_i f_j \frac{\sin(sr_{ij})}{sr_{ij}} \exp(-l_{ij}^2 s^2/2) + i_c, \quad (4)$$

where N is the number of CCl_4 molecules contained in the cluster. In the cluster model, the first term series in Eq. 4 must be terminated at the end of the cluster. The second term in Eq. 4 complements a fault due to this termination. This correction corresponds to placing a uniform and structureless medium outside the cluster. This is depicted in Fig. 5. The sphere surrounded by

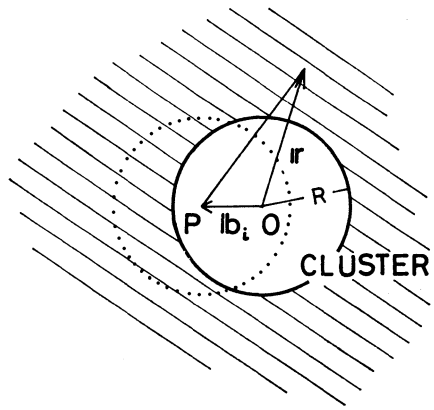

Fig. 5. A schematic illustration of the model used for the calculation of the correction term i_c in the reduced intensity $i(s)$.

the solid line is the cluster, in which the structure exists and the stripped region is the uniform medium. The continuous medium of the unit volume has a scattering factor $\langle F\rangle\rho_0$, where ρ_0 is the number density of CCl_4 in the liquid and $\langle F\rangle$ is the average scattering factor of CCl_4 in the continuous medium. The scattering intensity due to interference between the cluster and the continuous medium becomes,

$$i_c = \frac{1}{N}\sum_i\{f_i\langle F\rangle\rho_0 \exp(-l_i^2s^2/2)\int\exp(i(\boldsymbol{s}\cdot\boldsymbol{r}-\boldsymbol{b}_i))\mathrm{d}v_r\}, \quad (5)$$

where the origin is taken at the center of the cluster, $\boldsymbol{b}_i$ is the position vector of the i-th atom with a scattering factor f_i and l_i is the root mean-square amplitude of b_i. The integration in Eq. 5 is performed beyond the sphere of the cluster to infinity, that is over the stripped region of Fig. 5. The average scattering factor $\langle F\rangle$ is given by

$$\langle F\rangle = f_C + 4f_{Cl}\frac{\sin(sr_{C-Cl})}{sr_{C-Cl}}. \quad (6)$$

In Eq. 5 the atom around the periphery of the cluster effectively "feels" a much smaller cluster size than the atom at the center. On the other hand, the cluster means the representation of the region where one molecule "feels" the "structure." All molecules in the liquid must sit at the center of the cluster, when the second term of Eq. 4 is estimated. The surrounding of a molecule in a liquid is spherically symmetric except for near positions, and then the cluster radius R should be the same for all molecules. When the i-th atom is located at P (Fig. 5), the second term of Eq. 4 is integrated over the continuous medium beyond the dotted sphere. Therefore, it is reasonable to modify Eq. 5:

$$\begin{aligned} i_c &= \frac{1}{N}\sum_i f_i\langle F\rangle\rho_0\langle\exp(-is\cdot b_i)\rangle\exp(-l_i^2s^2/2) \\ &\quad\times\int_R^\infty\exp(is\cdot r)\mathrm{d}v_r \\ &= -\frac{1}{N}\sum_i f_i\langle F\rangle\rho_0\frac{\sin(sb_i)}{sb_i}\exp(-l_i^2s^2/2) \\ &\quad\times\frac{4\pi}{s^3}[\sin(sR)-sR\cos(sR)]. \end{aligned} \quad (7)$$

This equation is an extension of the formula derived by Warren.[10]

With a cluster radius R equal to 8.4 Å, the best agreement between the calculated and experimental intensities was obtained. This value, 8.4 Å, is reasonable, since the effective radius of the cluster containing 15 CCl_4 molecules, namely, the distance between the center of the cluster and the farthest chlorine atom is 8.54 Å. The weighted structure function, $si(s)$, with respect to the bcc cluster model with 15 CCl_4 molecules was calculated and is shown over the range from s=0—6

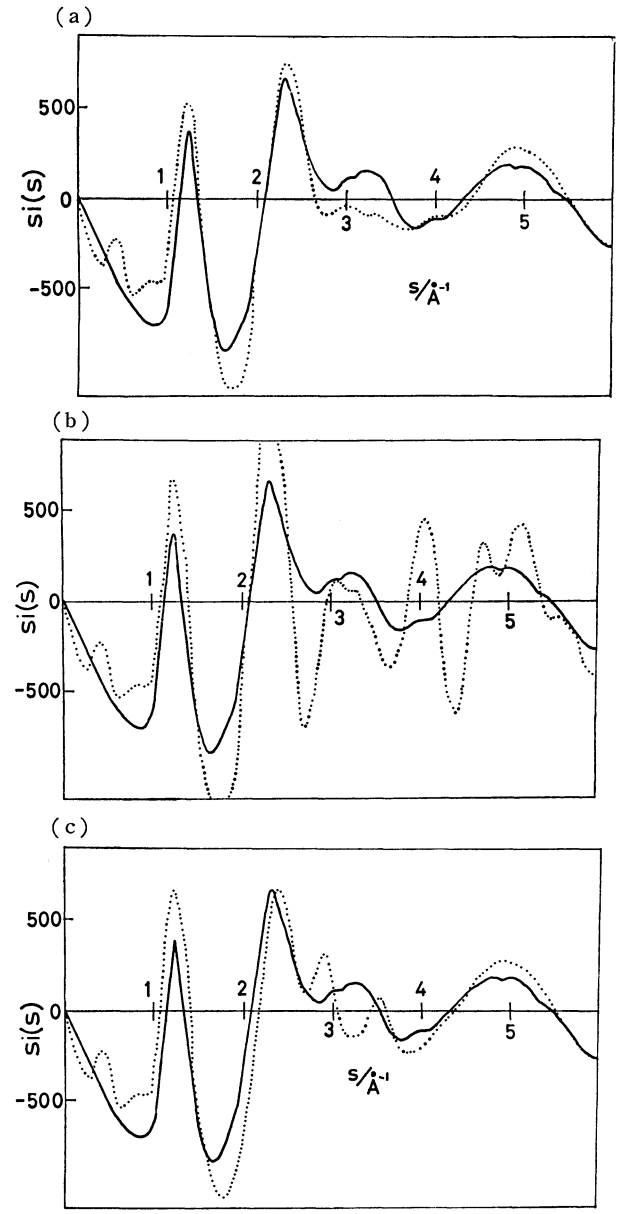

Fig. 6. Weighted structure function $si(s)$ for liquid CCl_4. (a) Solid line: experimental intensity. Dotted line: calculated intensity for the bcc cluster model with 15 CCl_4 molecules. (b) Solid line: experimental intensity. Dotted line: calculated intensity for the bcc cluster model neglecting the root mean square amplitude. (c) Solid line: experimental intensity. Dotted line: calculated intensity for the bcc model modified by the freely rotating molecules.

Table 2. Root mean-square amplitudes assumed for the calculated intensity of Figs. 6(a) and (c)

r_{ij}(Å)	l_{ij}(Å)
1.77 (C-Cl, intramolecule)	0.069
2.89 (Cl-Cl, intramolecule)	0.086
3—4	0.25
4—6	0.30
6—8	0.35
over 8	0.40

Å^{-1} in Fig. 6(a). The intensity curve in s-values larger than 6 Å^{-1} is almost the same as that of the free molecule of CCl_4. The full line is the observed intensity, and the dotted line shows the calculated intensity, where the root mean-square amplitude l_{ij} used is listed in Table 2. The fine structure on the fourth halo does not appear in the dotted line in Fig. 6(a). However, if the smearing effect is neglected, that is, l_{ij} is assumed to be zero in Eq. 4, the fine structure appears as shown in Fig. 6(b). The periodicity in the calculated intensity agrees well with the fine structure of the experimental intensity indicated by the full line. Therefore, the molecular arrangement of the bcc cluster explains the fine structure in the scattering intensity.

The dotted line in Fig. 6(c) corresponds to the bcc cluster model modified by the freely rotating molecules. In the model of the free rotation, the halo at 3.3 Å^{-1} splits into two peaks at 2.9 and 3.6 Å^{-1}, which differs from the experimental intensity. The possibility of a free rotation model is excluded by the distance between the nearest neighbor molecules, 5.77 Å, which is smaller than the van der Waals diameter of CCl_4, 7 Å. Consequently the barrier is too high for the molecule to rotate independently.

In the calculated intensity two small peaks appear at s=0.4 and 0.9 Å^{-1} as shown by the dotted line in Fig. 6(a) and this represents a discrepancy between the calculated and observed intensities. These peaks are, however, not significant. The intensity calculated by use of only the first term of Eq. 4 agrees well with the dotted line of Fig. 6(a) in the region of $s>1$ Å^{-1}. On the other hand, the second term of Eq. 4 dominates the region of s=0—1 Å^{-1}. In this region the weighted intensity curve without i_c has a strong peak, as shown by the solid line in Fig. 7. The dotted line in Fig. 7 shows the correction term, $-si_c$. These large values were subtracted in the calculation of the reduced intensity in the region of s=0—1 Å^{-1}.

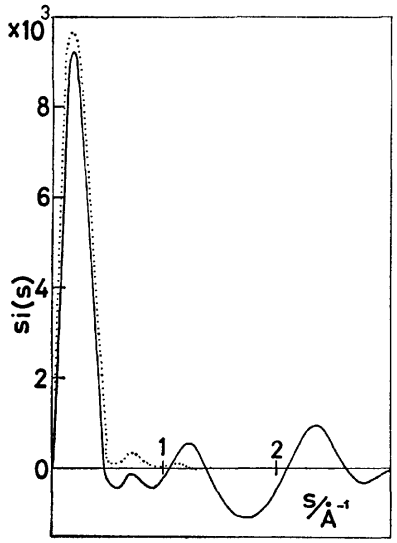

Fig. 7. The effect of the correction of Eq. 7. The full line is the weighted intensity neglecting the correction term i_c. The dotted line shows the correction term, $-si_c$.

The calculated intensity of the bcc cluster model is in good agreement with the observed intensity, not only in the main peaks at $s\simeq 1.2$ and 2.3 Å^{-1} but also in the fine structure around s=3—4 Å^{-1} (Fig. 6(a)). However disagreement in the intensity around s=3 Å^{-1} was observed. This discrepancy may be caused by the analysis, since it is difficult to derive the reduced intensity $i(s)$ from the total scattering intensity in this region.[1] Further possible source of the discrepancy may be the small cluster size and the large root mean-square amplitude assumed in this model.

In the present model, the peak in the radial distribution at 6.3 Å consists of two kinds of radial distances refering to the molecular centers, 5.77 and 6.77 Å, in which 8 and 6 molecules are contained, respectively. The equal interval in the peak in the radial distribution, *i.e.* 5.77, 11.4, 16.3, and 21.5 Å, is explained from the bcc cluster model.

The first and second nearest neighbor distances of the molecular center, 5.77 and 6.77 Å, happen to coincide with the model presented by Narten *et al.*,[5] as shown in Table 3 in spite of a different model. Narten *et al.* assumed at first the "crystal" of the space group Pa3,

Table 3. The distance between molecular centers r and the number of the pair n in the two models of liquid CCl_4

bcc cluster model		Pa3 model	
r(Å)	n	r(Å)	n
5.77	8	5.77	6
6.77	6	6.13	1
		6.77	6

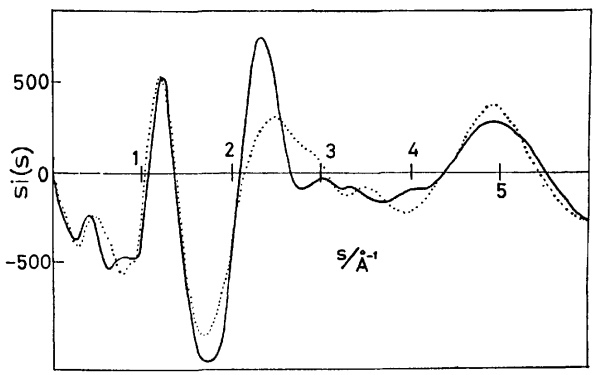

Fig. 8. Weighted structure function for liquid CCl_4. Solid line: bcc cluster model with 15 CCl_4 molecules. Dotted line: Pa3 model with 14 CCl_4 molecules.

which is the space group in the close-packing structure of Group IV halides *e.g.* SnI_4.[11] Next, the "ideal structure" was distorted by the least-squares fit to the observed diffraction data of the liquid. In order to compare the bcc cluster model with the distorted close-packing model, $si(s)$ of the close-packing model (Pa3 model) was calculated using Eq. 4 and the parameters given by Narten *et al.* The result is shown in Fig. 8 together with the intensity calculated from the bcc model. The agreement between both intensities fairly well in the positions of the main peaks, but differences exist in the region $s \simeq 2.5$—3.5 Å^{-1} and in the fine structure. Therefore, the long-range correlation demonstrated by the present study is important for estimating the liquid structure, and the measurements including the fine structure are necessary. For this purpose the energy-dispersive method is superior to the angle-dispersive one.

We are indebted to Prof. T. Iijima of Gakushuin University for helpful disscussions and reading of the manuscript. The present work was partially supported by Grant-in-Aid for Scientific Research from the Ministry of Education.

The γ-Ray Induced Oxidation of Cyclohexene in the Liquid Dinitrogen Oxide at −18 °C

Shun-ichi HIROKAMI,† Laszlo WOJNAROVITS,†† and Shin SATO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 6, 1978)

The γ-radiolysis of a cyclohexene–dinitrogen oxide mixture in the liquid phase at −18 °C has been studied and the results compared with that of the radiolysis of a cyclohexene–carbon dioxide mixture in the liquid phase.[5] The oxidation reaction initiated by oxygen atoms produced in the direct radiolysis of dinitrogen oxide or carbon dioxide is common for both solutions, the products being cyclohexene oxide, cylohexanone, and cyclopentanecarbaldehyde. In the dinitrogen oxide solution, however, two other oxidation processes have to be considered in order to interpret the material balance of products and the formation of other oxygenated compounds: cyclohexanol, 2-cyclohexenol, and 2-cyclohexenone. A possible reaction mechanism is discussed.

Recently the liquid phase γ-radiolysis of the carbon dioxide solution of hydrocarbons has been extensively investigated.[1–6] It is now believed that the liquid phase γ-radiolysis of carbon dioxide provides a conventional source of oxygen atoms. However, in this system, the formation of a small amount of cyclohexanol with a G-value of 0.2 has been observed under optimum conditions. This compound has not been observed in the gas phase reaction of oxygen atoms with cyclohexene. There has been much speculation on the precursor of cyclohexanol, one of which is the O^- ion.

Dinitrogen oxide is a well-known electron scavenger, widely used in radiation chemistry and O^- or N_2O^- ions are believed to be formed by electron scavenging.[7] Since dinitrogen oxide, like carbon dioxide, is a good solvent for hydrocarbon, the γ-radiolysis of a cyclohexene–dinitrogen oxide mixture at −18 °C has been studied and compared with the results obtained with a carbon dioxide solution.[5]

Experimental

The experimental procedure is the same as that described in a previous paper.[5] Impurities in cyclohexene (Tokyo Kasei Co.) were less than 0.5%, estimated by gas chromatography with a 2-m PEG-600 column of 20% w/w on celite. Dinitrogen oxide (Takachiho Shoji Co.) contained no detectable impurities, confirmed by gas chromatography with a 5 m dimethyl sulfolane column of 20% w/w on celite. In order to calculate the G-value, the absorbed dose was estimated by Fricke dosimetry assuming a proportionality between the absorbed dose and the electron density of the solution.

Results

The G-values of the noncondensable products, nitrogen and hydrogen, are shown in Fig. 1 as a function of the electron fraction ε of N_2O. The result is similar to that of the radiolysis of mixtures of various hydrocarbons and dinitrogen oxide.[1,8]

Figure 2 shows the G-values of cyclohexene oxide, cyclohexanone, and cyclopentanecarbaldehyde. In the γ-radiolysis of a cyclohexene–CO_2 mixture, the three products were explained in terms of the addition reaction of oxygen atoms to cyclohexene. The electron fraction dependence of G(cyclohexene oxide) in Fig. 2 is very similar to that obtained with a cyclohexene–CO_2 mixture;[5] however, G(cyclohexanone) deviates from the

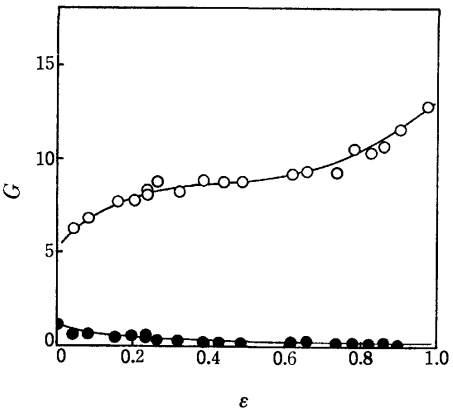

Fig. 1. The G-values of nitrogen (○) and hydrogen (●) from a cyclohexene–dinitrogen oxide mixture as a function of the electron fraction ε of dinitrogen oxide.

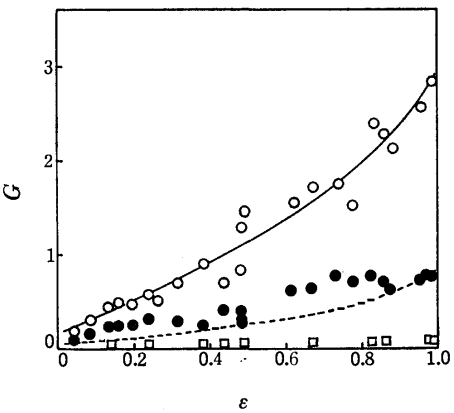

Fig. 2. The G-values of cyclohexene oxide (○), cyclohexanone (●), and cyclopentanecarbaldehyde (□) as a function of the electron fraction of dinitrogen oxide. The dashed curve was drawn by assuming G(cyclohexanone)/G(cyclohexene oxide+cyclohexanone)=0.2, the ratio which was obtained in the radiolysis of a cyclohexene–carbon dioxide mixture.

†† Present address: Institute of Isotopes of the Hungarian Academy of Sciences, H-1525, Budapest, P. O. B. 77.

curve drawn on the assumption that G(cyclohexanone)/G(cyclohexene oxide+cyclohexanone)=0.2, the ratio obtained in the γ-radiolysis of a cyclohexene–CO_2 mixture. The deviation suggests that there is another process for the formation of cyclohexanone.

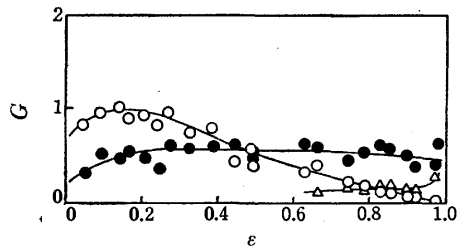

Fig. 3. The G-values of cyclohexanol (○), 2-cyclohexenol (●), and 2-cyclohexenone (△) as a function of the electron fraction of dinitrogen oxide.

Figure 3 shows the G-values of other oxygen containing compounds: cyclohexanol, 2-cyclohexenol, and 2-cyclohexenone, the yields of which were very small in the radiolysis of the carbon dioxide solution.

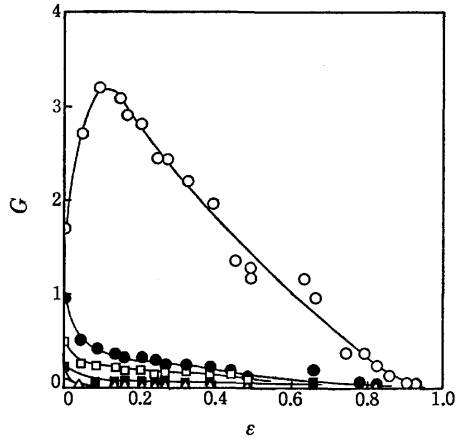

Fig. 4. The G-values of bi(2-cyclohexenyl) (○), cyclohexane (●), 2-cyclohexenylcyclohexane (□), bicyclohexyl (■), and 2-cyclohexenyl-1-cyclohexene (△) as a function of the electron fraction of dinitrogen oxide.

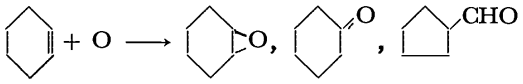
Figure 4 shows the G-values of hydrocarbon products. Bi(2-cyclohexenyl) shows a peculiar dependence on the electron fraction of N_2O; at low concentration of N_2O, the G-value increases with increase in the electron fraction of N_2O until it reaches a maximum at ε=0.1 after which it decreases.

Discussion

Oxygen Atom Reactions. The dependence of G(cyclohexene oxide) on the electron fraction of N_2O (Fig. 2) is similar to that for the G-value of this compound on the electron fraction of CO_2 obtained in the γ-radiolysis of a cyclohexene–CO_2 mixture. On the other hand, cyclohexene oxide is known to be one of the main products in the gas phase reaction of oxygen atoms with cyclohexene.[5] The formation of cyclohexene oxide in the present experiment, therefore, may be ascribed to the reaction of oxygen atoms produced in the direct radiolysis of N_2O with cyclohexene.

$$N_2O \rightsquigarrow N_2 + O \quad (1)$$



(2)

Cyclopentanecarbaldehyde is a minor product among the three compounds.

At high electron fractions, above 0.6, of N_2O, a slight deviation is observed from the linearity between G-(cyclohexene oxide) and ε. This deviation may be due to another process for the formation of oxygen atoms which is interrupted by the presence of cyclohexene:

$$N_2O^+ + N_2O^- \longrightarrow N_2 + O + N_2O, \quad (3)$$

$$N_2O^+ + \text{cyclo-}C_6H_{10} \longrightarrow N_2O + \text{cyclo-}C_6H_{10}^+. \quad (4)$$

A similar process has been discussed in the case of the cyclohexene–CO_2 mixture.[5]

Reactions of N_2O^- (or O^-) Ions. Dinitrogen oxide is a well-known scavenger. Nitrogen molecules are produced as the consequence of electron scavenging. However, the detailed mechanism for the formation of nitrogen has not been established.[9–11]

According to the discussion of Wakeford and Freeman,[12] the main reactions initiated by ionization in the γ-radiolysis of cyclohexene may be described as follows:

$$\text{cyclo-}C_6H_{10} \longrightarrow \text{cyclo-}C_6H_{10}^+ + e^- \quad (5)$$

$$\text{cyclo-}C_6H_{10}^+ + e^- \longrightarrow \cdot + H \quad (6)$$

$$H + \text{cyclo-}C_6H_{10} \longrightarrow \cdot \quad (7)$$

$$2 \cdot \longrightarrow \quad (8)$$

$$\longrightarrow + \quad (9)$$

$$\cdot + \cdot \longrightarrow \quad (10)$$

$$\longrightarrow + \quad (11)$$

$$2 \cdot \longrightarrow \quad (12)$$

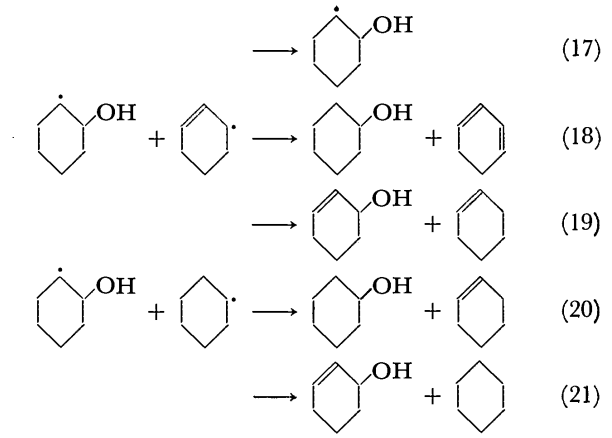
$$\longrightarrow + \quad (13)$$

When a small amount of N_2O is present in this system, N_2O interrupts the neutralization reaction. According to the mechanism proposed by Sambrook and Freeman for the radiolysis of hydrocarbons containing N_2O,[8] the succeeding reactions may be written as follows:

$$e^- + N_2O \longrightarrow N_2O^- \text{ (or } N_2 + O^-) \quad (14)$$

$$N_2O^- + \text{cyclo-}C_6H_{10} \longrightarrow N_2 + OH^- + \cdot \quad (15)$$

$$OH^- + \text{cyclo-}C_6H_{10}^+ \longrightarrow H_2O + \text{C}_6\text{H}_9\cdot \quad (16)$$



(17)–(21)

The increase of G(bi(2-cyclohexenyl)) and the decrease in G-values of other hydrocarbon products upon addition of N_2O can be explained by this reaction mechanism. However, the increase of $G(N_2)$ with the increase in ε is too great to be explained by the above mechanism.[10] The neutralization reaction which does not lead to the formation of any products,

$$\text{cyclo-}C_6H_{10}^+ + e^- \longrightarrow \text{cyclo-}C_6H_{10}, \quad (22)$$

may play an important role in the present reaction system. The fraction of the neutralization reaction not leading to the formation of any products has not been determined even in the radiolysis of cyclohexane for which numerous studies have been published. There is some evidence to show that this fraction is negligibly small.[13]

When ε is larger than 0.1, N_2O suppresses the formation of bi(2-cyclohexenyl) (Fig. 4). This suggests that the N_2O^- or O^- ions are reactive to N_2O molecules. For this reaction, two processes are energetically possible;[9]

$$N_2O^- + N_2O \longrightarrow N_2 + NO + NO^-, \quad (23)$$

$$\longrightarrow 2N_2 + O_2^-. \quad (24)$$

In mass spectrometry,[14] Reaction 23 is the main process and if the same is true here, then the G-value of the electrons from cyclohexene should be of the order of $G(N_2)$; *i.e.*, about 5—7, since one nitrogen molecule corresponds to one electron captured by N_2O. On the other hand, if Reaction 24 is the main process, the G-value of the electrons should be in the range 2.5—3.5. The latter value is consistent with the W-value obtained in the gas phase,[15] Reaction 22 not being necessarily involved in the reaction mechanism. From the present experiment it is impossible to determine which Reaction, 23 or 24, is more dominant. However, in order to explain the deviation of G(cyclohexanone) from the dashed curve (Fig. 2), Reaction 24 has been tentatively used as follows:

$$\text{cyclo-}C_6H_{10}^+ + O_2^- \longrightarrow \text{C}_6\text{H}_9\cdot + HO_2\cdot \quad (25)$$

$$\text{C}_6\text{H}_9\cdot + HO_2\cdot + C_6H_{10} \longrightarrow \text{C}_6\text{H}_9\text{OH} + \text{C}_6\text{H}_8\text{O} \quad (26)$$

At present, no completely self-consistent reaction scheme for the formation of all oxygen containing products can be proposed.

Material Balance. Since the origin of oxygen atoms in the present system is dinitrogen oxide, the G-value of nitrogen should be equal to the sum of the G-values of oxygen containing products. However, the observed G-value of oxygen containing products does not reach 20% of the G-value of nitrogen. Sambrook and Freeman suggested that most of the oxygen containing product is water.[8] The G-value of water in the present experiment could not be measured because of experimental difficulties. However, if the rest of the oxygen containing products is water, hydrocarbon products such as bi(2-cyclohexenyl) should not decrease with an increase in ε, since two hydrogen atoms in water molecule should be supplied from cyclohexene. No material balance was given by Sambrook and Freeman for hydrocarbon products in their experiments.

In conclusion, the γ-ray induced oxidation of cyclohexene in liquid dinitrogen oxide occurs through three processes. The precursor in the first process is the oxygen atom produced by the direct radiolysis of dinitrogen oxide. The second process proceeds by the reaction of N_2O^- or O^- ions, produced by the electron scavenging of the N_2O molecule. The third process is not clear; the precursor may be produced in the reaction of N_2O^- or O^- ions with N_2O. It might be O_2^- ions.

A Kinetic Study of the Simultaneous Dealkylation and Disproportionation of Cumene over Silica-Alumina[1]

Jun-ichiro TAKE,* Yoichi TOZAWA, and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 8, 1978)

Cumene has been passed over a silica–alumina bed at low temperature (210 to 254 °C) and at cumene pressures of 0.003 to 0.023 atm. Both dealkylation and disproportionation occurred simultaneously and independently of each other. The disproportionation/dealkylation ratio increased with decrease in temperature and/or an increase in cumene pressure. The dealkylation and disproportionation reactions followed a Langmuir-Hinshelwood model with inhibition by the reactant. The dealkylation has been interpreted in terms of a unimolecular surface reaction, while the disproportionation reaction in terms of a bimolecular surface reaction. The heat of adsorption of cumene and the entropy loss of cumene on adsorption were much larger for the dealkylation sites than for the disproportionation sites. These results indicated that dealkylation was catalyzed by strong acid sites, while disproportionation by weak acid sites. The dealkylation had a much higher activation energy than the disproportionation reaction. The activation energy for dealkylation (33.5 kcal mol^{-1}) was in good agreement with that predicted on the assumption that the previously reported LFER (linear free-energy relationship) in the alcohol dehydration holds for alkylbenzene dealkylation.

The catalytic dealkylation of cumene has been employed as a standard test for characterizing acidic cracking catalysts. The kinetics have been investigated in detail at high temperatures (above 300 °C) by Prater and Lago,[2] Horton and Maatman,[3] and Wojciechowski and coworkers.[4,5] Under the conditions where the reverse reaction is negligible, the accepted kinetic scheme of this reaction is

$$C + S \rightleftharpoons CS \longrightarrow \text{products}, \quad (1)$$

where C represents cumene, S, an active site, and CS, cumene adsorbed on an active site. It has been shown that the bond-breaking step, CS→products, is the rate-determining step.[2,6,7]

Cumen is known to undergo disproportionation to benzene and diisopropylbenzenes in the presence of a Friedel-Crafts catalyst.[8,9] Therefore, under favorable conditions, cumene disproportionation may take place on acidic cracking catalysts. However, little attention has been paid hitherto to this reaction over acidic cracking catalysts. The present study intends to obtain kinetic data on the nature of the active sites for cumene dealkylation and disproportionation, as well as about the nature of the two reactions, under the conditions where both reactions take place simultaneously.

Recently, it has been reported that the activation energy for the bond-breaking step in the catalytic dehydration of alkanols (ROH) on silica–alumina has a linear relationship with the heterolytic bond dissociation energy for the C–O bond in alcohols, $D(R^+OH^-)$.[10] Mochida and Yoneda[7] reported that the apparent activation energy for the dealkylation of monoalkylbenzenes (RPh, where R=alkyl and Ph=phenyl) over silica–alumina had a linear relationship with the enthalpy change of the hydride abstraction from the corresponding paraffin, $\Delta H_c^+(R)$. This enthalpy change, in its turn, linearly correlates with $D(R^+Ph^-)$ for RPh. Therefore, the present study also intends to establish whether the LFER (linear free-energy relationship) obtained in the alcohol dehydration holds in the catalytic dealkylation of monoalkylbenzenes.

Experimental

Materials. The silica–alumina (SA-1, 13% Al_2O_3) was obtained from the same source.[6,7,10] Cumene of GR grade from Tokyo Kasei was percolated through two columns packed with silica gel and active alumina, and stored over a mixture of active alumina and Molecular Sieve 4A under nitrogen. Gas-chromatographic analysis of the cumene indicated a purity of 99.2 mol%; the impurities were *m*- and *p*-xylenes which did not affect the reactions to any detectable extent. Hydrogen, used as a diluent gas, was purified by passing it through a Deoxo column and then a Dry Ice–ethanol temperature trap.

Apparatus and Procedures. Experiments were conducted in a continuous flow-type reactor, the details of which have been given in a previous paper.[10] Catalyst charges of 0.19—0.26 g were used depending mainly on the reaction temperature. The catalyst was activated in a hydrogen stream with a flow rate of 40 STP ml min^{-1} for 2 h at 450 °C. The temperature was then lowered to the reaction temperature (210—254 °C) and additional hydrogen was admitted from another inlet. After the total flow rate of hydrogen had been adjusted to about 300 STP ml min^{-1}, cumene was introduced from a microfeeder. The desired partial pressure was attained about 30 min later.

Subsequently, a portion of the effluent gas was led through a 6-way sampling-valve to a gas-liquid chromatograph with a flame ionizing detector for analysis at intervals of 5—10 min. An analysing column of Silicone DC-11 (2-m long) was used at 140 °C. In some experiments, a column of VZ-7 (6-m long) was also used at 0 °C for analysis of lighter hydrocarbon products.

A total of five kinetic runs were made at 210—254 °C. In each run lasting for 7—8 h at constant temperature, the run was divided into several periods in which the partial pressure of cumene was altered over the range of 0.003—0.023 atm (by changing the feed rate). Each period lasted for 60—80 min, including an initial 30 min period for the attainment of steady-state conditions (no samples taken). In the subsequent period of 30—50 min, the effluent gas was analysed at least four times.

Treatment of Data. A plot of the cumene conversion to each product against the reciprocal space velocity was linear through the origin in the region of total conversion below 8%, indicating that the differential-reactor conditions were met.

Since the total conversion of cumene was kept below this level in all runs, the rate of formation of the i product, v_i, was calculated by

$$v_i = x_i F/W, \quad (2)$$

where x_i is the fractional conversion to the i product, F, the feed rate of cumene (mol min^{-1}) and W, the catalyst weight(g).

Slow catalyst aging occurred during the run, necessitating correction of the data on a common basis. The bracketing sequence of Sinfelt[11] was adopted for this purpose: periods at a chosen standard condition were repeated between periods at other conditions. The rates of formation of the dealkylation and disproportionation products were plotted separately as a function of run time. Smooth curves were drawn through the data of the standard periods to obtain the aging curves. Intermediate run periods were then corrected to a common reference time using the following relationships, since the aging curves were linear as will be stated below:

$$\alpha = (v_r^s - v_t^s)/v_r^s,$$
$$v_r = v_t/(1-\alpha),$$

where α is the degree of catalyst aging, v_r^s and v_t^s, the reaction rates for standard conditions at reference time r and another time t, respectively, and v_r and v_t, the reaction rates for other conditions at times r and t, respectively.

Sample analyses in each period consistently gave the same product composition, implying that the catalyst aging was negligible in that period. Therefore, each period was represented by the reaction rates and run time averaged over that period. Typical plots of the rates of formation as a function of run time are presented in Fig. 1. Other temperature conditions gave a similar catalyst aging pattern, indicating that the catalyst activity declined slowly and linearly with increasing run time. The standard periods were operated at a cumene pressure of 0.003—0.004 atm. The reference time was t/min= 50 in Fig. 1.

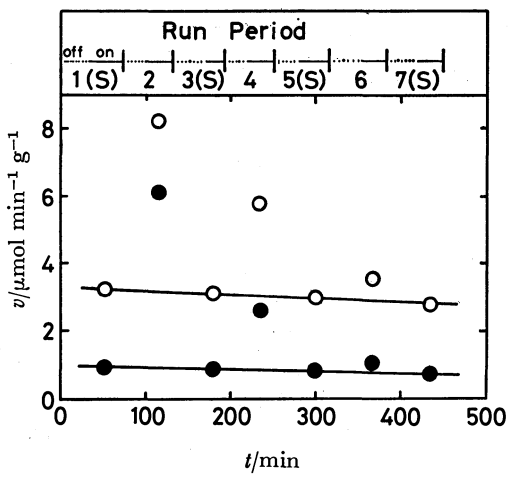

Fig. 1. Catalyst aging for run at 220 °C.
○ and ● denote the rates of dealkylation and disproportionation, respectively, (s), the standard period.

Results

Diffusion Effects. The mass transfer effects were assessed by running at constant partial pressure (0.023 atm) and temperature (250 °C) and by varying the total flow rate of the diluent gas over the range of 100 to 400 STP ml min^{-1}. The reaction rates for dealkylation and disproportionation did not change when the total flow rate was higher than 180 STP ml min^{-1}, indicating that the external diffusion effects were negligible under such conditions. The diluent gas has therefore been passed at a flow rate of about 300 STP ml min^{-1} in all kinetic runs.

The internal diffusion effects have been examined using the Weisz formula,[12]

$$\Phi = \frac{dN}{dt}\frac{1}{C_0}\frac{R^2}{D_{eff}},$$

where dN/dt is the reaction rate in mol s^{-1} cm^{-3}, C_0, the reactant concentration in mol cm^{-3}, R, the catalyst particle radius in cm, and D_{eff}, the effective diffusion constant in cm^2 s^{-1}. In the present study, the limits for these coefficients are as follows: $dN/dt = 5\times10^{-7}$ mol s^{-1} cm^{-3} as the total reaction rate of cumene, $C_0 = 1\times10^{-7}$ mol cm^{-3}, $R = 5\times10^{-3}$ cm, and $D_{eff} = 10^{-3}$ cm^2 s^{-1} for the system of silica–alumina and cumene.[12] These values give a Φ of 1.3×10^{-1}, from which the effectiveness factor is evaluated to be very close to 1 for zero- to second-order reactions.[12] Consequently, the internal diffusion effects on the reaction rates have been concluded to be negligible.

Table 1. Product composition from cumene on silica–alumina

t °C	p[a] atm	Molar ratios of products[b,c] P	DPB	P+DPB	B	DPB/P
210	0.02	0.59	0.39	0.98	1.00	0.66
230	0.02	0.70	0.33	1.03	1.00	0.47
254	0.02	0.80	0.19	0.99	1.00	0.24
254	0.01	0.85	0.12	0.97	1.00	0.14

a) Cumene partial pressure. b) P=propene, DPB=*m*- and *p*-diisopropylbenzenes, B=benzene. c) Normalized to benzene=1.00.

Reaction Products. The reaction products were propene (P), benzene (B), and *m*- and *p*-diisopropylbenzenes (DPB); *o*-diisopropylbenzene was not formed to any detectable extent. Table 1 presents typical data on the product composition. Other temperature and partial pressure conditions gave a similar product composition. On the basis of these data, the following points emerge: (a) propene is consistently smaller in the amount of formation than benzene, indicating reactions other than dealkylation, (b) the amount of propene plus diisopropylbenzenes is equal to that of benzene, (c) the DPB/P ratio changes depending upon the temperature and cumene pressure, *i.e.*, the lower-temperature and/or higher-cumene pressure conditions favor the formation of diisopropylbenzenes.

The formation of propene undoubtedly results from the dealkylation of cumene. The possible reactions which form diisopropylbenzenes are the disproportionation of cumene, the alkylation of cumene with propene, and the alkylation of benzene with propene. The existence of one of the three reactions, in addition to that of dealkylation, accounts for observation (b), P+DPB=B. As mentioned in Experimental, a plot of the cumene conversion to each product against the residence time

was linear through the origin, indicating that the two isomers of diisopropylbenzene are primary products. Therefore, the last two of the three reactions are unimportant for the formation of diisopropylbenzenes under these experimental conditions. The rates of formation of diisopropylbenzenes and propene thus give the rates of disproportionation, v_D, and dealkylation, v_C, respectively. In some experiments, the difference in the amounts of benzene and propene was taken as the amount of diisopropylbenzenes formed. The ratio of the meta to the para isomers was 1.3—1.6 for all runs.

Kinetics. The rate data were first subjected to a simple power low rate equation. The plots of log v_C and log v_D *versus* log p(cumene pressure) indicated that the kinetic expressions were more complex than a simple first- or second-order reaction.

Subsequently, the data was analysed using the Langmuir-Hinshelwood theory. Best fits were found when dealkylation was assumed to be controlled by a single-site surface reaction, namely,

$$v_C = \frac{k_C K_C p}{1+K_C p}, \quad (3)$$

and disproportionation by a dual-site surface reaction,

$$v_D = k_D\left(\frac{K_D p}{1+K_D p}\right)^2, \quad (4)$$

TABLE 2. RATE AND ADSORPTION-EQUILIBRIUM CONSTANTS FOR CUMENE DEALKYLATION AND DISPROPORTIONATION

t / °C	Dealkylation k_C / μmol min⁻¹ g⁻¹	Dealkylation K_C / atm⁻¹	Disproportionation k_D / μmol min⁻¹ g⁻¹	Disproportionation K_D / atm⁻¹
210	5.33	175	7.31	114
220	12.7	93.5	12.7	88.9
230	20.4	84.0	16.6	79.0
240	40.6	54.0	25.0	71.4
254	105	27.4	39.1	53.3

where k_C and k_D are the rate constants for dealkylation and disproportionation, respectively, K_C and K_D, the adsorption equilibrium constants of cumene for the dealkylation and disproportionation sites, respectively. Figures 2 and 3 show typical plots for these equations. The proposed fit to the equations is good and the values for the rate and adsorption-equilibrium constants obtained from each plot are given in Table 2. The plots of log k and log K *versus* $1/T$ were ideally linear. The activation energies (E_A), the pre-exponential factors (A), the heats of adsorption (Q_a), and the entropies of adsorption (ΔS_a) were calculated from the plots, the results of which are included in Table 3.

TABLE 3. ARRHENIUS PARAMETERS, HEATS OF ADSORPTION, AND ENTROPIES OF ADSORPTION FOR CUMENE DEALKYLATION AND DISPROPORTIONATION[a)]

	Dealkylation	Disproportionation
E_A/kcal mol⁻¹	33.5	19.4
log (A/μmol min⁻¹ g⁻¹)	15.9	9.67
Q_a/kcal mol⁻¹	20.1	8.1
ΔS_a/cal K⁻¹ mol⁻¹	−31.4	−7.4

a) E_A is the activation energy, A, the pre-exponential factor, Q_a and ΔS_a, the heat and entropy of adsorption, respectively.

Discussion

The Nature of the Dealkylation, Disproportionation, and Active Sites. The kinetic model which best correlates the rate data on the dealkylation at low temperatures is identical with that which has generally been accepted for the same reaction at higher temperatures (Eq. 1). This implies that the low-temperature dealkylation of cumene is rate-determined by a unimolecular surface reaction of cumene adsorbed on an active site. The disproportionation of cumene has kinetically been shown to be rate-determined by a bimolecular surface reaction of the adjacent, absorbed molecules of cumene. The cumene disproportionation is therefore the same in the kinetic model as the disproportionation of toluene[13)] and mesitylene[14)] over acidic solid catalysts. The reactions are clearly different from each other in the number of cumene molecules which participate in the respective rate-determining steps. This difference gives rise to an increase of the disproportionation/dealkylation ratio with an increase in the partial pressure of cumene. In addition, the dealkylation has a higher activation energy

than the disproportionation, as shown in Table 3 and the disproportionation/dealkylation ratio, therefore, decreases steeply with increase in temperature (Table 1).

For the dealkylation, the adsorbed cumene has generally been supposed to be a σ-complex with the proton attached at the substituted position. Accordingly, the rate-determining step in the kinetic model corresponds to a break of the C(phenyl)–C(isopropyl) bond in the σ-complex. Previous LFER studies on the dealkylation of monoalkylbenzenes[6,7] has shown that bond-breaking in the rate-determining step is heterolytic. The alkylbenzene disproportionation in the presence of Friedel-Crafts catalysts has been accepted as rate-determined by the nucleophilic attack of an arene on an arene cation.[8,9,15] The nature of the arene cation does not seem to have been established: a σ-complex[8] of the same type as proposed for the alkylbenzene dealkylation and a π-complex[9] have been suggested; a benzyl cation has also been proposed for the disproportionation of primary alkylbenzenes.[15]

Since the adsorption equilibrium constant measures the strength of the interactions of an adsorbing molecule with an active site, the nature of active sites should be reflected in the constant. If the dealkylation and disproportionation occurred, respectively, *via* a unimolecular and a bimolecular reaction of the surface species present on the same active sites, the same adsorption equilibrium constant would kinetically be observed for the two reactions. The data in Table 2 clearly shows that the adsorption equilibrium constants for the two reactions are different in magnitude. This difference in the adsorption equilibrium constant is emphasized by the data in Table 3, where the Q_a and ΔS_a values are clearly different for the two reactions. The heat of adsorption of cumene is notably smaller for the disproportionation sites than for the dealkylation sites. These results, therefore, indicate that the active sites differ in nature, probably in acidic nature. Dealkylation is catalyzed by strong acid sites, while disproportionation by weak acid sites.

The difference in the heat of adsorption also suggests that the surface species on the disproportionation sites are more mobile than those on the dealkylation sites and this is confirmed by a comparison of the entropy data in Table 3. As shown, cumene in the gas phase has an entropy loss of about 31 cal K^{-1} mol^{-1} when it is adsorbed on the dealkylation sites, while the entropy loss markedly decreases when cumene is adsorbed on the disproportionation sites. An entropy loss of 31 cal K^{-1} mol^{-1} is comparable to that for immobile adsorption, which has been estimated to be 39 cal K^{-1} mol^{-1} under the present experimental conditions.[16] It has therefore been deduced that cumene molecules adsorbed on the disproportionation sites are, probably, relatively free on the surface. This viewpoint is in line with the nature of the disproportionation reaction, since a bimolecular surface reaction necessitates mobile adsorbed molecules.

Finally, it must be said that the correct kinetics for disproportionation were not obtained assuming the following two possible mechanism: a Rediel-type mechanism with the rate-determining step involving reaction between an adsorbed cumene molecule and another cumene molecule in the gas phase, a Langmuir-Hinshelwood mechanism with the rate-determining step in which a cumene molecule chemisorbed on the dealkylation site reacts with another cumene molecule chemisorbed on the adjacent site which differs in nature from the dealkylation sites.

Activation Energy for Dealkylation. Recently, it has been found that, in the catalytic dehydration of alkanols over silica–alumina, the activation energy for the bond-breaking step has a linear relationship with the heterolytic bond dissociation energy for the C–O bond in the alcohols, $D(R^+OH^-)$.[10] The activation energy for the bond-breaking step in the cumene dealkylation has consequently been determined. The silica–alumina catalyst used for both dehydration and dealkylation was from the same batch and was activated in the same way. The alcohol dehydration and the alkylbenzene dealkylation belong to an olefin-forming elimination reaction catalyzed by acids. Therefore, it is necessary to establish whether the LFER obtained in the alcohol dehydration holds in the alkylbenzene dealkylation. The $D(R^+Ph^-)$ value for cumene has been calculated to be 220 kcal mol^{-1} using the reported values for the standard heats of formation of cumene, the isopropyl cation, and the phenyl anion, as shown in Table 4. This $D(R^+Ph^-)$ value is equal in magnitude to the $D(R^+OH^-)$ value for *s*-butyl alcohol. The assumption that the LFER in the alcohol dehydration holds in the alkylbenzene dealkylation predicts an activation energy of 32 kcal mol^{-1} for the bond-breaking step in the cumene dealkylation. The predicted value is very close to the observed one (33.5 kcal mol^{-1}, Table 3).

The apparent activation energies for the monoalkylbenzene dealkylation have been reported by Mochida

and Yoneda,[7] under the conditions where the reaction was nearly first-order in the reactant using silica–alumina taken from the same batch as used in the present work. The numerical values of the apparent activation energies reported in Ref. 7 are as follow (in kcal mol^{-1}): 17 ± 4 (ethylbenzene); 14.5 ± 2 (propylbenzene); 14.5 ± 1.5 (butylbenzene); 11 ± 3.5 (cumene); 11 ± 2 (*s*-butylbenzene); 10 ± 1 (*t*-butylbenzene). The assumption[6] that the heat of adsorption is approximately the same for all the alkylbenzenes used has been used here. Using the observed value for the heat of adsorption of cumene on the dealkylation sites (Table 3), the activation energies for the zero-order dealkylation, namely, for the bond-breaking step in the dealkylation may be calculated as the sum of the apparent activation energies and the heat of adsorption of cumene. The calculated values and the values predicted from the LFER in the alcohol dehydration and the $D(R^+Ph^-)$ values shown in Table 4 are (given in kcal mol^{-1} as the calculated, the predicted): 37 ± 4, 37 (ethylbenzene); 35 ± 2, 35 (propylbenzene); 35 ± 1.5, 35 (butylbenzene); 31 ± 3.5, 32 (cumene); 31 ± 2, 31 (*s*-butylbenzene); 30 ± 1, 28 (*t*-butylbenzene). The activation energy calculated for the cumene dealkylation is in good agreement with that observed in the present study. Also, the agreement between the calculated and the predicted values is excellent for all the alkylbenzenes used, though the equality in the heat of adsorption has been assumed as above. Therefore, it is likely that the LFER observed in the alcohol dehydration holds, at least approximately, in the alkylbenzene dealkylation, as shown in Fig. 4.

NQR and NMR Studies of Boron Trihalide-Trimethylamine Complexes

Tsutomu OKUDA,* Hideta ISHIHARA, Koji YAMADA, and Hisao NEGITA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received June 9, 1978)

The character of the B–X bond (X=Cl, Br, and I) in BX_3–TMA complexes (TMA=trimethylamine) has been studied on the basis of the results of the nuclear quadrupole resonance (NQR). The ionic character of the B–X bond decreased in the order as expected from the electronegativity of the halogen atoms. The temperature dependence of the halogens on the NQR frequencies has been examined for BBr_3– and BI_3–TMA. For BBr_3–TMA, all the observed resonance lines faded out far below the melting point and this has been attributed to the hindered rotation of the BBr_3 group about the B–N bond, as with BCl_3–TMA.

The crystal structure of BX_3–TMA complexes has been recently determined by X-ray analysis[1] and the atomic arrangement about the boron atom is shown to be approximately tetrahedral and that the B–N bond distance decreases with increasing atomic weight of the halogen atom. It is of interest to examine the character of the B–X and B–N bonds in these complexes. Furthermore, for BCl_3–TMA, the reorientation of the methyl and trimethylammonio groups is known to affect the temperature dependence of the ^{35}Cl NQR frequencies[2] and consequently a study of the temperature dependence of the NQR frequencies for BBr_3– and BI_3–TMA will elucidate dynamic properties of the crystals.

Experimental

BCl_3 and BBr_3 were prepared by heating a mixture of potassium tetrafluoroborate with aluminum(III) chloride or bromide, respectively, up to 140—170 °C.[3] BI_3 was prepared from sodium hydroborate and iodine according to the method of Schumb *et al.*[4] The complexes BCl_3– and BBr_3–TMA were prepared by the dropwise addition of a dichloromethane solution of BX_3 to a dichloromethane solution of TMA under dry nitrogen. For the complex BI_3–TMA, a similar procedure was conducted using benzene as a solvent. BCl_3– and BBr_3–TMA were recrystallized from ethanol and BI_3–TMA from benzene. The compound obtained was dried in a vaccum desiccator. The elemental analyses of these complexes agreed well with theoretical values. Found: C, 20.47; H, 5.26; N, 7.75%. Calcd for $C_3H_9NBCl_3$: C, 20.44; H, 5.14; N, 7.94%. Found: C, 11.86; H, 3.01; N, 4.56%. Calcd for $C_3H_9NBBr_3$: C, 11.64; H, 2.93; N, 4.52%. Found: C, 7.96; H, 2.05; N, 3.09%. Calcd for $C_3H_9NBI_3$: C, 8.00; H, 2.01; N, 3.10%.

NQR spectra were observed on an oscilloscope using a super-regenerative oscillator with frequency modulation. NMR were observed using a broad line NMR spectrometer, JES-ME 1 from JEOL Co., Ltd.

Results and Discussion

NQR of BX_3–TMA. The NQR frequencies of boron trihalides and their complexes are listed in Table 1. Each NQR line for BBr_3, BI_3, and their complexes was split into a doublet by the boron isotope, ^{10}B and ^{11}B.[6] However, the frequencies are listed only for the halogen atoms linked to the ^{11}B atom. Each complex has two resonance lines with an intensity ratio of 1 to 2 and this is consistent with the X-ray analysis.[1] The weaker resonance line in each complex is due to the halogen atom on the symmetry plane and the stronger to the two halogen atoms symmetrically located with respect to this plane.

It has been established that the B–X bond in BX_3 has a considerably large double bond character.[5,6] When BX_3 forms a complex with TMA, the BX_3 molecule is deformed from a planar to a pyramidal configuration. As a direct consequence most of the double bond character of the B–X bond is lost *i.e.*, the asymmetry parameter of the halogen atoms becomes very small as shown in BI_3–TMA. For ^{35}Cl and ^{81}Br atoms, the quadrupole coupling constant, e^2Qq/h, is obtained from the equation,

$$\nu = (1/2)(e^2Qq/h)(1+\eta^2/3)^{1/2}, \quad (1)$$

where ν is the resonance frequency and η the asymmetry parameter. For BCl_3– and BBr_3–TMA, the asymmetry parameter has been assumed to be zero. For ^{127}I atom,

Table 1. NQR parameters at 77 K

Compound	Nucleus	Frequency(MHz)	Intensity ratio	η	e^2Qq/h (MHz)
BCl_3[a]	^{35}Cl	21.582		0.54	41.208
BCl_3–TMA[b]	^{35}Cl	21.532	1		43.064
		21.779	2		43.558
BBr_3[c]	^{81}Br	146.43		0.45	283.45
BBr_3–TMA	^{81}Br	144.28	1		288.56
		147.20	2		294.40
BI_3	^{127}I	ν_1 214.00		0.453	1186.3
		ν_2 342.95			
BI_3–TMA	^{127}I	ν_1 186.65	2	0.066	1238.4
		ν_2 371.19			
		ν_1 190.48	1	0.066	1263.9
		ν_2 378.84			

a) Ref. 5. b) Ref. 2. c) Ref. 6.

the quadrupole coupling constant and asymmetry parameter can be derived from the frequency ratio, ν_1/ν_2 (ν_1 and ν_2 are the frequencies corresponding to the $\pm1/2\leftrightarrow\pm3/2$ and $\pm3/2\leftrightarrow\pm5/2$ transitions, respectively). The quadrupole coupling constants thus obtained are listed in Table 1.

The Character of the B–X Bond. The amount of the unbalanced p-electron, U_p, is given by[7]

$$U_p = |e^2Qq/e^2Qq_0|, \quad (2)$$

where e^2Qq_0/h is the quadrupole coupling constant for the free halogen atom (−109.746, 643.032, and −2292.712 MHz for ^{35}Cl, ^{81}Br, and ^{127}I, respectively). Assuming that the B–X bond is represented by the resonance between B–X, $B^-{=}X^+$, and B^+X^-, U_p is then related to the ionic character, i, and the double bond character, f, expressed by[6,8]

$$U_p = (1-i)(1-s)-(f/2)\{1-(1-2s)\varepsilon\}, \quad (3)$$

where s is the fractional s character of the B–X bond and ε the correction for the increase in field gradient attributed to the positive fractional charge at the halogen atom.[8] In addition, the double bond character is related to the asymmetry parameter expressed by

$$\eta = (3/2)f(1+\varepsilon)/U_p. \quad (4)$$

Thus, U_p, i, and f can be deduced from Eqs. 2—4, by selecting s=0.15 and ε to be 0.14, 0.13, and 0.12 for Cl, Br, and I, respectively,[9] the results of which are listed in Table 2.

TABLE 2. THE NATURE OF THE B–X BOND

Compound	U_p	i(%)	f(%)
BCl_3	0.376	50	12
BCl_3–TMA[a)]	0.395	54	0
BBr_3	0.441	42	12
BBr_3–TMA[a)]	0.455	47	0
BI_3	0.517	32	14
BI_3–TMA[a)]	0.544	35	2

a) For each complex, the weighted-mean value of the two resonance lines is listed.

In each complex, U_p is greater than that of the halogens in BX_3 caused largely by the loss of double bond character upon complex formation. In addition, the ionic character of the complexes decreases in the order, chloride>bromide>iodide which is consistent considering the electronegativity of the halogen atoms.

Attempts to obtain the quadrupole coupling constant of the ^{11}B atom at 13 MHz in each complex gave neither first-order nor second-order splitting. The quadrupole coupling constant of the ^{11}B atom in each complex was however estimated to be less than 500 kHz from the line-width of the polycrystalline sample. This value was far less than *ca.* 2.5 MHz for BX_3.[10] Consequently, in the complex, the B–N bond and the three B–X bonds are arranged almost tetrahedrally and thus each bond may be regarded as equivalent.

The Temperature Dependence of the NQR Frequencies. For BCl_3–TMA, it has been established that the reorientation of the methyl and trimethylammonio groups affects the ^{35}Cl NQR line, *i.e.*, the temperature coefficient of the NQR frequency varied at 100 and 204 K, respectively.[2] A similar phenomenon was however not observed for both BBr_3– and BI_3–TMA.

For BBr_3–TMA, the resonance lines faded out in the noise level at about 285 K, which far below the melting point, 511 K, as seen for BCl_3–TMA. The resonance lines became increasingly broad from 260 K, although the accurate evaluation of line-widths could not be made, since each NQR line was a doublet. The disappearance of the NQR line may be caused by the hindered rotation of the BBr_3 group. It is known that the activation energies of the reorientation of trimethylammonio group in BCl_3– and BBr_3–TMA are greater than those of BH_3– and BF_3–TMA.[11] This suggests that in BCl_3– and BBr_3–TMA, the molecule rotates as a whole, that is, the triemethylammonio and BX_3 groups do not rotate independently. For BBr_3–TMA, the frequency of this motion or the rotation of the BBr_3 group reaches 10^4—10^5 Hz in the vicinity of 285 K and approaches the NQR frequency.[12] Therefore, rotation of the BBr_3 group or the whole molecule is thought to induce broadening of NQR lines. Moreover, at a particular rate of rotation, averaging of the field gradient will occur along the axis of rotation reducing the NQR frequency to[13]

$$\nu_T = \nu_Q(3\cos^2\theta-1)/2, \quad (5)$$

where ν_T is the averaged NQR frequency, ν_Q the NQR frequency of the stationary molecule, and θ the angle between the B–Br bond and the axis of rotation. An attempt to observe the resonance lines above room temperature however was unsuccessful.

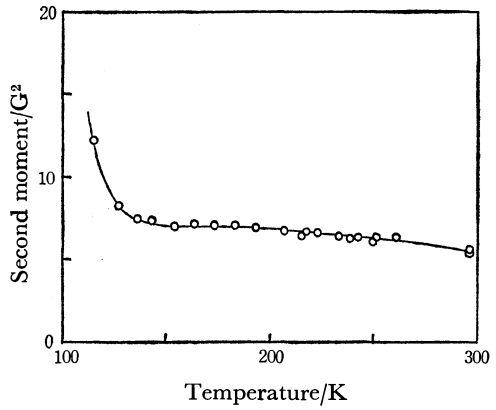

Fig. 1. Temperature dependence of the second moment of ^1H NMR spectrum for BI_3–TMA.

TABLE 3. CALCULATED SECOND MOMENTS FOR BI_3–TMA

Group		Second moment (G^2)
CH_3	$N(CH_3)_3$	
Static	Static	28.6
Rotating	Static	9.7
Rotating	Rotating	1.6

For BI_3–TMA, the resonance lines could be observed up to 353 K at which time the sample began to turn brown. For this complex, the second moment of ^1H NMR spectrum was approx. 7.5 G^2 from 113 to 300 K

as shown in Fig. 1. The theoretical second moment was calculated on the basis of the crystal structure[1] based on the same assumptions for the hydrogen position as for Ref. 11, the results of which are listed in Table 3. The reorientation of the trimethylammonio group is not expected in this temperature range, from a comparison of the observed with the calculated values.

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita 565

(Received June 10, 1978)

Magnetic susceptibilities, χ, of $Cu_2AsO_4(OH)$, $Cu_2(OH)PO_4$, and Cu_2OSO_4 have been measured from 4.2 to 360 K to establish the role of the OH^- and O^{2-} ions in the magnetic superexchange interaction. The former two compounds showed a broad maximum for χ at 118 and 110 K, respectively. Although the crystal structure is three-dimensional, only a tetramer model with two parameters can explain the temperature dependence of χ, since the hydroxide anion causes a strong magnetic interaction which is limited to four copper atoms between which the anion is intermediary. The magnetic susceptibility of Cu_2OSO_4 obeyed the Curie-Weiss law above 140 K with a Weiss constant of -56 K. At 16 K the compound transformed into a ferrimagnetic phase, the effective megneton number of which is 0.11 at 4.2 K. A canted ferrimagnetic structure has been proposed and the canting angle estimated. In the superexchange interaction, only hydroxide and oxide anions are significant and both anions behave similarly.

Copper oxide compounds are a group of substances whose magnetic behavior has been widely studied. The magnetic properties of many oxoacid copper salts have also drawn much interest and have been examined theoretically and magnetochemically. However, little work has been published on hydroxide compounds. Escoffier and Gauthier published the Curie and the Weiss constants for 15 basic copper salts.[1] Diot *et al.* studied copper hydroxide and found its transition to an antiferromagnetic phase at about 20 K from measurements of magnetic susceptibility and specific heat.[2] Abrahams *et al.* reported that $CuIO_3(OH)$ showed signs of a phase transition into an antiferromagnetic state at 162 K.[3] Hatfield and coworkers found a linear relationship between the exchange energy $2J$ and the bridging angle of the OH^- anion for a series of di-μ-hydroxo-copper(II) complexes.[4] The observed correlation was explained quantitatively[5] as well as qualitatively[6] by means of MO's. All experiments indicated that the hydroxide anion has the potential to bring about a stronger magnetic interaction between copper(II) spins.

In order to elucidate the superexchange interaction *via* the hydroxide anion, the magnetic susceptibilities of three basic salts of copper, $Cu_2AsO_4(OH)$, $Cu_2(OH)PO_4$, and Cu_2OSO_4, have been measured from 4.2 to 360 K. The compounds have similar chemical compositions, and contain, as a common structural feature,[7,8] a trigonal bipyramid and an octahedron of oxygen atoms around a central copper atom. They were chosen as a suitable series of compounds to establish the magnetic behavior of the hydroxide and the oxide anions.

Experimental

Preparation. Samples of $Cu_2AsO_4(OH)$ and $Cu_2(OH)PO_4$ were prepared hydrothermally at 130—140 °C[9] and identified by X-ray diffraction.[7] Dicopper oxide sulfate, Cu_2OSO_4, was obtained by the thermal decomposition of $CuSO_4 \cdot 5H_2O$ at 650 °C over 10 h.[10] During this process the reacting material was removed from the furnace, ground and re-heated several times. This technique was found necessary because, otherwise, the decomposition reaction proceeded only at the reagent surface owing to sintering of the product, Cu_2OSO_4, resulting in a mixture of $CuSO_4$, Cu_2OSO_4, and CuO. The product was identified by powder X-ray diffraction.[8] The reagent used are of superpure grade (Wako Pure Chemical Industries, Ltd.). Found: Cu, 44.89; As, 26.03%. Calcd for $Cu_2AsO_4(OH)$: Cu, 44.90; As, 26.47%. Found: Cu, 53.00; P, 12.88%. Calcd for $Cu_2(OH)PO_4$: Cu, 53.16; P, 12.96%.

Magnetic Measurements. The magnetic susceptibility was measured from 4.2 to 360K using powder samples. A Faraday balance was employed and calibrated for $CoHg(SCN)_4$.[11] Susceptibility values were corrected for diamagnetism; the values were -1.18, -1.02, and -0.93 mm^3 mol^{-1} for the arsenate, phosphate, and sulfate, respectively.[12] The temperature of the sample was measured by a calibrated 0.03% Co: Au or constantan *vs.* Cu thermocouple.

Results and Discussion

Crystal Structures.[7,8] The crystal structures of $Cu_2(OH)PO_4$ and Cu_2OSO_4 are projected in Fig. 1. As a common structural feature, they contain two kinds of oxygen polyhedra coordinating to the copper atoms; a trigonal bipyramid and an octahedron. In this paper the center of the trigonal bipyramid will be designated

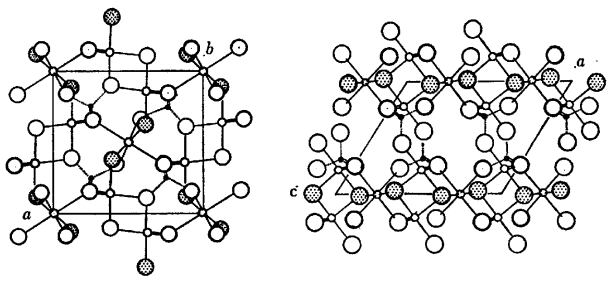

Fig. 1. Projection of the crystal structures of (a) $Cu_2(OH)PO_4$ and (b) Cu_2OSO_4. Symbols are Cu: middle circle, O: large circle and P or S: small solid circle. Oxygen atoms belonging to the hydroxide or the oxide anions are shaded. The octahedron in $Cu_2(OH)PO_4$ has the diad axis along the c axis, while that in Cu_2OSO_4 has a center of symmetry. They form a linear chain perpendicular to the projection plane.

† Present address: Mitsui Aluminum Co., Ltd., 80 Yotsuyama-cho, Omuta 836.

†† Emeritus professor of Osaka University.

as site A and that of the octahedron as site B. The octahedron shares two opposite edges with two neighboring octahedra to form a linear chain. The two trigonal bipyramids constitute a dimer by sharing an edge. The dimeric unit, the linear chain of the octahedra, and the anion tetrahedra share corners thereby forming a three-dimensional network.

An oxide anion has the tendency to form tetrahedral bonds with four metallic cations.[13] Consequently, the oxide anion in Cu_2OSO_4 can occupy the position which lies on the shared edge of the linear chain and simultaneously on that of the dimer. The dimeric unit connects two linear chains by the oxide anions. Since other oxygen corners of the dimer are shared with the same linear chains, the two kinds of coordination polyhedra construct a two-dimensional network. This network is joined with neighboring ones only by the tetrahedra of an SO_4^{2-} anion, and as a result, each copper atom has 5 or 6 copper neighbors through the intermediate oxide anions.

In contrast, the hydroxide anion can make bonds with, at most, three metal atoms.[14] This limitation brings about a remarkable difference in the manner of linkage of the polyhedra between $Cu_2(OH)PO_4$ and Cu_2OSO_4. The hydroxide anion in $Cu_2(OH)PO_4$ lies on a shared edge of the linear chain, but in the dimer it is located on a corner not belonging to the shared edge. The dimer joins two linear chains by the hydroxide anions and two more chains by other oxygen atoms. In this case, therefore, a three-dimensional network is built of the coordination polyhedra, independent of the phosphate tetrahedra. Also in the phosphate the copper atom has 5 or 6 copper neighbors, two or three of which are connected with the copper atoms by the hydroxide anions.

The crystal structure of $Cu_2AsO_4(OH)$ is isomorphous with that of $Cu_2(OH)PO_4$.[15] The phosphate, however, belongs to the space group Pnnm and the arsenate to $P2_1nm$,[16] a subgroup of Pnnm, and so it appears necessary to take into account some deformation of the coordination polyhedra in $Cu_2AsO_4(OH)$.

Magnetic Properties of $Cu_2AsO_4(OH)$ and $Cu_2(OH)PO_4$. The magnetic susceptibilities, χV_m, of $Cu_2AsO_4(OH)$ and $Cu_2(OH)PO_4$ have been plotted as a function of temperature in Figs. 2 and 3. The two compounds exhibit a similar temperature dependence on χV_m; a broad maximum around 110 K accompanied by a large decrease below that temperature. The sharp increase of χV_m with decreasing temperature below 10 K has been attributed to paramagnetic impurities. There was, however, a distinct difference between the maximum susceptibilities, $\chi_{max} V_m$, for the arsenate and the phosphate, which were 39.8 and 49.7 $mm^3\,mol^{-1}$, respectively. The temperature, T_{max}, at which the susceptibility is a maximum, was 118 K for $Cu_2AsO_4(OH)$ and 110 K for $Cu_2(OH)PO_4$. Such large values of T_{max} indicate that the magnetic interaction between copper(II) spins is very strong in these compounds. Since the two values of T_{max} are similar, the large difference in $\chi_{max} V_m$ has been attributed to differences in the magnetic interaction and the g-factor.

The susceptibility obeyed the Curie-Weiss law, $\chi V_m = C/(T-\theta)$, above 200 K. However, in the course of the analysis given below, the temperature of measurement was found so low that only formal values of the Curie and the Weiss constants were obtained.

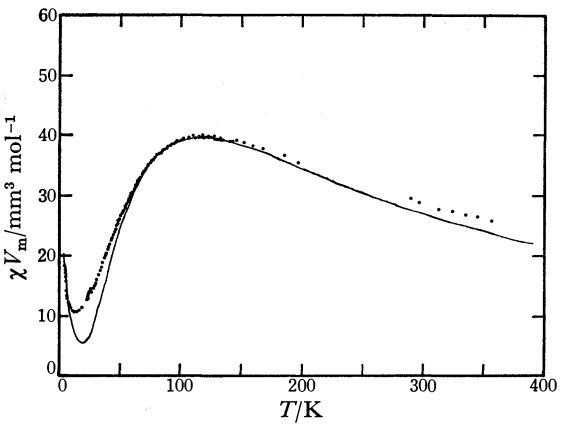

Fig. 2. Temperature dependence of the magnetic susceptibility of $Cu_2AsO_4(OH)$. The solid line shows the calculated susceptibility for the tetramer model with parameters of $g=2.02$, $J=-68$ K and $J'/J=-3.0$ plus a contribution from paramagnetic impurities.

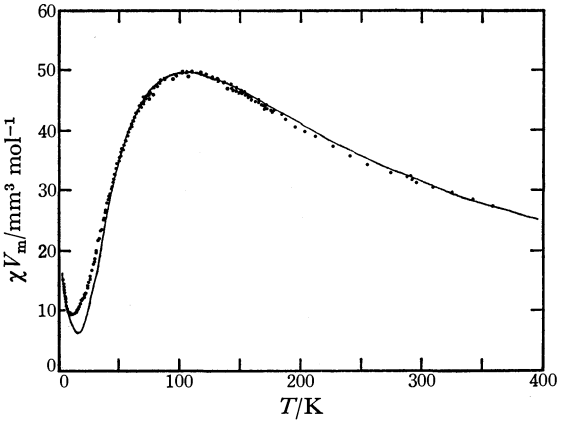

Fig. 3. Temperature dependence of the magnetic susceptibility of $Cu_2(OH)PO_4$. The solid line shows the calculated susceptibility for the tetramer model with parameters of $g=2.16$, $J=-62$ K and $J'/J=-2.4$ plus a contribution from paramagnetic impurities.

Several magnetic models have been tested in order to investigate the magnetic interaction in these hydroxide compounds. However, since the susceptibility below T_{max} decreases significantly, only cluster models containing an even number of copper(II) spins are admissible. Furthermore, the possible models has been confined to the following two cases taking into account the symmetry relationship between the copper atoms.

(1) The tetramer model in which two copper atoms at site A and two at site B are connected by two hydroxide anions as depicted in Fig. 4. The interaction energy for this spin system may be written as follows:

$$H = -2J(\boldsymbol{S}_1\boldsymbol{S}_2+\boldsymbol{S}_2\boldsymbol{S}_3+\boldsymbol{S}_3\boldsymbol{S}_4+\boldsymbol{S}_4\boldsymbol{S}_1)-2J'(\boldsymbol{S}_1\boldsymbol{S}_3). \quad (1)$$

Solving the equation for the case of $S=1/2$ for all spins, the magnetic susceptibility is given by Eq. 2:[17]

$$\chi V_m = \frac{Lg^2\mu_B^2}{kT} \times \frac{\exp(x)+\exp(2x-x')+\exp(2x)+5\exp(3x)}{1+3\exp(x)+4\exp(2x-x')+3\exp(2x)+5\exp(3x)}, \quad (2)$$

where $x=2J/kT$ and $x'=2J'/kT$.[18]

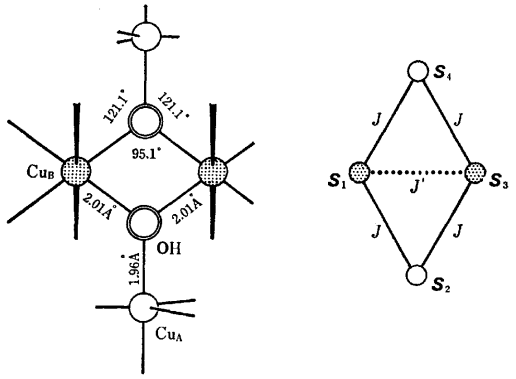

Fig. 4. Schematic drawing of the tetramer unit (left), and interaction scheme in it (right). The unit has a point symmetry of C_{2h} with the diad axis passing through the Cu_B atoms.

(2) Two kinds of dimers. One of the dimers is composed of two copper atoms on site A and the other on site B. The susceptibility for this system is obtained by adding the two Bleaney-Bowers equations with the respective values for the g-factor and J.[17,18]

$$\chi V_m = (L\mu_B^2/3kT)\sum_{i=A,B} g_i^2\left[1+\frac{1}{3}\exp(-2J_i/kT)\right]^{-1} \quad (3)$$

The former model gave good agreement between the calculated and observed values, whereas in the latter $Cu_2(OH)PO_4$ gave an unreasonable value for the g-factor and $Cu_2AsO_4(OH)$ poorer agreement than in the tetramer model. Consequently the tetramer model has been thought suitable for these compounds. The values of g, J, and J'/J, which gave the best fit to the observed susceptibility, are 2.02 ± 0.04, -68 ± 1 K and <-1.5 for the arsenate, and 2.16 ± 0.04, -62 ± 2 K and -2.4 ± 1.5 for the phosphate. The susceptibilities calculated from these parameters are shown in Figs. 2 and 3. The large standard deviation of J'/J arises from Eq. 2 in that χV_m shows low sensitivity to J'/J when this parameter is less than -1. In the case of Cu_2AsO_4-(OH) the small g value further diminished the sensitivity to J'/J, which prevented the absolute value of this parameter being found.

As the large values of T_{max} suggest, the deduced values of J are very large. Such strong magnetic interaction must be brought about by a superexchange interaction *via* intermediate anions, since the separation between copper atoms exceeds 2.96 Å. It is also noteworthy that J and J' have opposite signs; the interaction between a copper spin on site A and that on site B is antiferromagnetic, whereas the interaction between two copper spins on site B is ferromagnetic (Fig. 4). It is widely recognized that there is a correlation between the parameter J and interatomic angle relevant to the superexchange interaction. The angle of Cu_B–OH–Cu_B' is 95.1° and that of Cu_A–OH–Cu_B is 121.1° in $Cu_2(OH)PO_4$ (Fig. 4), and consequently the signs expected from this correlation are consistent with those obtained from the present study.

As described earlier, the coordination polyhedra form a three-dimensional network and no isolated clusters are found in the crystal structure. Nevertheless, only the tetramer model could explain the temperature dependence of the magnetic susceptibility. This indicates that the hydroxide anion, which joins three copper atoms in the tetramer unit, makes the main contribution to the magnetic interaction between copper(II) spins, whereas the phosphate oxygen atoms have a negligible effect on the interaction. It is surprising that the difference between the roles is very large, because the interatomic distances and angles relevant to the superexchange interaction are similar for both types of oxygen atoms.

The susceptibility of $Cu_2AsO_4(OH)$ can be explained on the basis of the tetramer model. The magnitude of the obtained J value is similar to that of the phosphate and the signs of both J and J' are the same as those of the phosphate. This supports the assertion that the two compounds are isomorphous. Agreement between the observed and calculated susceptibility values was poorer for $Cu_2AsO_4(OH)$ than for $Cu_2(OH)PO_4$. Introduction of the anisotropic parameters, $J_\parallel$, $J_\perp$, $J_\parallel'$, and $J_\perp'$, into Eq. 1 proved no appreciable improvement. It appears, therefore, that the superexchange interaction through an arsenate oxygen atom makes some contribution to the magnetic behavior of $Cu_2AsO_4(OH)$.

In contrast with the values of J and J', the values of the g-factor differ from each other and this difference largely accounts for the difference in $\chi_{max}V_m$ between the two compounds. This indicates that the local environment at the copper site, and thus at the sites of the intermediary oxygen atoms in $Cu_2AsO_4(OH)$ vary considerably from those in $Cu_2(OH)PO_4$. This may explain the different effects of the arsenate and the phosphate oxygen atoms on the magnetic interaction. Further structural study is both necessary and desirable.

Magnetic Properties of Cu_2OSO_4. The magnetic susceptibility of Cu_2OSO_4 is shown in Figs. 5 and 6. It may be seen that as the temperature decreases, the

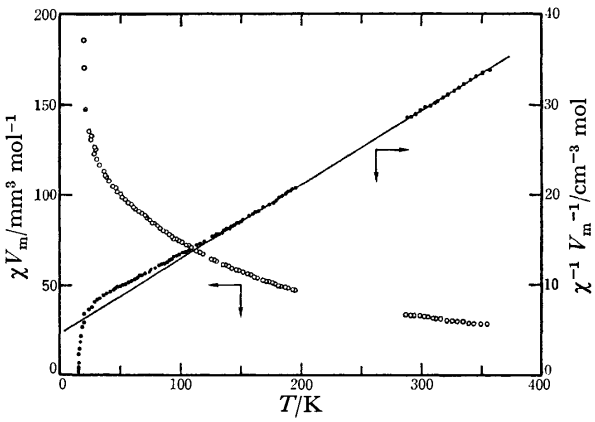

Fig. 5. Temperature dependence of the magnetic susceptibility (○) and its inverse (●) of Cu_2OSO_4 in the paramagnetic region. The solid line shows the Curie-Weiss relation obtained by the least-squares fit.

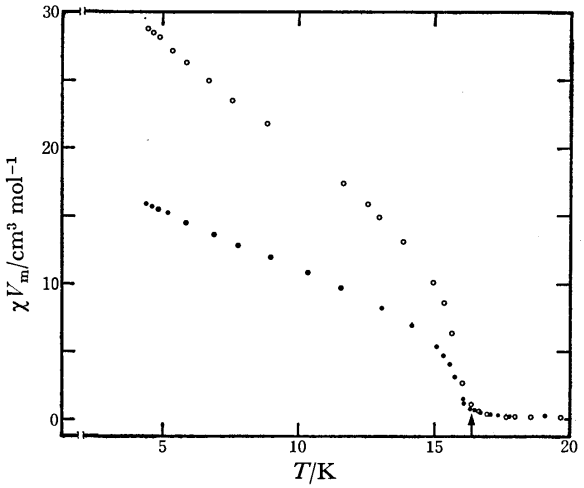

Fig. 6. Temperature dependence of the apparent magnetic susceptibility of Cu_2OSO_4 in the ordered phase. The arrow shows the transition temperature. ○: 22 kA m^{-1}, ●: 55 kA m^{-1}.

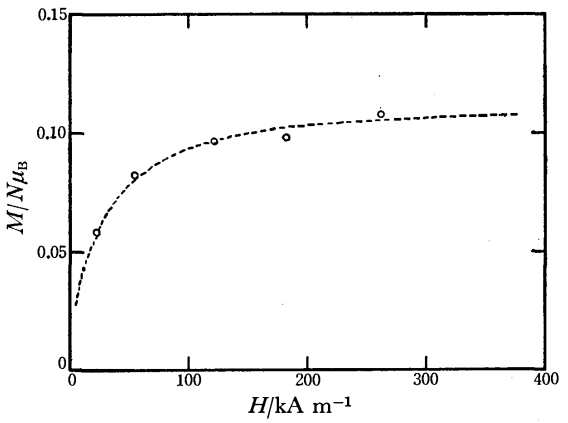

Fig. 7. Magnetization as a function of the magnetic field strength. Quantity N is a number of copper atoms per unit volume.

susceptibility increases monotonically and the Curie-Weiss law is obeyed above 140 K. The effective number of Bohr magnetons, p, and the Weiss constant, θ, have been deduced to be 1.96 ± 0.01 and -56 ± 2 K. Below 30 K the susceptibility increases rapidly and finally becomes dependent on the magnetic field strength, indicating a transition to an ordered phase with spontaneous magnetization. The transition temperature was found to be 16 ± 1 K. In Fig. 7 the magnetization, M, at 4.2 K is plotted as a function of the magnetic field strength, H, and from this plot the effective magneton number, n_B, has been evaluated as 0.11 ± 0.01.

The small value of n_B and the negative value of θ indicate that the spin-ordered state is ferrimagnetic. In order to determine the ferrimagnetic structure, it has been assumed that the magnetic space group of Cu_2OSO_4 can be obtained by changing each element of the crystallographic space group, C2/m, for a primed or unprimed magnetic symmetry element. Thus the spontaneous magnetization can only arise in the magnetic space groups of C2/m and C2′/m′.[19] In Fig. 8 the

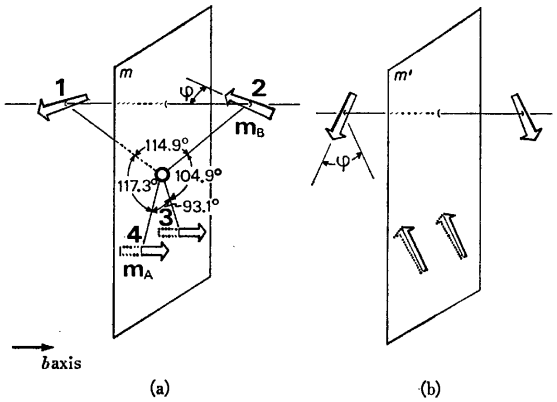

Fig. 8. Arrangement of the magenetic moments in the two possible magnetic space groups of (a) C2/m and (b) C2′/m′. Angles are the interatomic ones about the intermediary oxide anion.

arrangement of the magnetic moments is shown for the two space groups. In the case of C2/m, the moments of the copper cations on sites A, $\boldsymbol{m}_A$, are all parallel to the b axis. Those on sites B, $\boldsymbol{m}_B$, are divided into two sublattices. The components perpendicular to the b axis compensate for each other, whereas the components along the b axis remain unchanged. The net moment from $\boldsymbol{m}_B$ must be antiparallel to $\boldsymbol{m}_A$ so that the compound is ferrimagnetic. From the observed n_B the canting angle, φ, has been estimated as 38.7°, assuming that both m_A and m_B are equal to one μ_B. The discussion also holds in the case of C2′/m′, except for the direction of the spontaneous magnetization and the value of φ (Fig. 8b).[20] Therefore this compound probably has a canted ferrimagnetic structure.[21]

As cited earlier, the coordination polyhedra in Cu_2OSO_4 form a two-dimensional network. In this network layer the copper atoms form a kagomé-like lattice and the oxide anion is intermediate in every pair of adjacent copper atoms. The magnetic interaction can extend through the layer, as expected from the presence of the ordered state, assuming the oxide anion plays an important role. Since the interatomic distance between copper atoms exceeds 2.9 Å, the superexchange interaction governs the magnetic behavior of Cu_2OSO_4. The sulfate oxygen atoms afford interaction paths with long Cu–O separations of 2.14 and 2.52 Å. On the other hand, the interatomic distances of Cu–O (oxide anion) are short; 1.87(×2), 1.91, and 2.01 Å. In addition, judging from the Cu–O distances in the coordination polyhedra, three copper atoms with a half-filled 3d orbital direct their lobes towards the oxide anion. For the magnetic interaction in Cu_2OSO_4, therefore, the oxide anion assumes important role, whereas the sulfate oxygen atoms contribute a negligible effect.

Since the four Cu–O (oxide anion) distances are similar, the sign and magnitude of the superexchange interaction appears to mainly depend on the interatomic angles Cu–O–Cu′. Then the following relations hold among the parameters, J_{ij}:

$$|J_{12}| > |J_{13}| = |J_{23}|,\quad J_{12} \approx J_{14} = J_{24},$$
and J_{12}, J_{13}, $J_{23} < 0$, and $J_{34} > 0$

where the suffixes, i and j, refer to the numbering given in Fig. 8a. The statement that the interaction between copper(II) spins on sites B, J_{12}, is strong and antiferromagnetic appears, at first sight, to be conflicting with the ferrimagnetic structure discussed above, in which the main components of the $\boldsymbol{m}_B$'s are arranged ferromagnetically. However, this ferrimagnetic structure is a direct result of competing antiferromagnetic interactions. If the magnetic moments $\boldsymbol{m}_B$ are ordered antiferromagnetically, the interaction of $\boldsymbol{m}_A$ with two $\boldsymbol{m}_B$'s cancels out. Canting of $\boldsymbol{m}_B$'s brings the moment $\boldsymbol{m}_A$ some energy gain, which accompanies some energy loss for a pair of $\boldsymbol{m}_B$'s. The canting angle is thus determined by delicate balancing between energy loss and gain. The following simple formalism explains the canting angle quantitatively and supports the arguments made above. On the basis of the ferrimagnetic structure in Fig. 8 and including the interaction between the four copper moments, the interaction energy of the system, E, is given as a function of the angle, φ_{ij}, between the moments $\boldsymbol{m}_i$ and $\boldsymbol{m}_j$.

$$E = 2(N_{13}+N_{14})m^2 \cos(180°-\varphi) + N_{12}m^2 \cos(2\varphi) + N_{34}m^2 \quad (4)$$

The parameter, N_{ij}, is proportional to J_{ij}. The relationship of $N_{13}=N_{23}$ and $N_{14}=N_{24}$ holds on the basis of the symmetry, and $m_1=m_2=m_3=m_4=m$ is assumed. Setting $\partial E/\partial\varphi=0$, the canting angle is obtained.

$$\varphi = \cos^{-1}\{(N_{13}+N_{14})/2N_{12}\} \quad (5)$$

Substituting $\varphi=38.7°$, deduced from the magnetic space group of C2/m, and $N_{14}\approx N_{12}$, ratio of N_{13}/N_{12} is calculated to be 0.5. In the case of C2′/m′ it is in the range from 0.95 to 0.5 depending on the value of φ.[20] These values are comparable with the value of 0.5, obtained by application of the relationship between $2J$ and the bridging angle for the di-μ-hydroxo-copper(II) complexes.[4,6] The calculated values mean that both J_{12} and J_{13} have the same sign and that the interaction J_{12} is stronger than J_{13}.

Comparison of the Hydroxides and the Oxide. The magnetic behavior of the hydroxides, $Cu_2AsO_4(OH)$ and $Cu_2(OH)PO_4$, and the oxide, Cu_2OSO_4, are remarkably different; the former behaves like a cluster, whereas the latter like an ordered phase. This difference does not stem from the different roles in the magnetic behavior between the hydroxide and the oxide anions. On the contrary, the magnetic interaction induced by both anions has been explained qualitatively on the same principle. Rather the different magnetic behavior has its origin in the following: (1) mainly hydroxide or oxide anions contribute to the magnetic interaction, and (2) they are arranged in a different manner in the coordination polyhedra. The oxide anions occupy the trans positions in the octahedron and participate in every shared edge. Thus the interaction path extends infinately in the layer parallel to the (001) plane. The hydroxide anions occupy the cis positions in the octahedron and participate in every two shared edges. Moreover, it makes three bonds with copper atoms. Since other oxygen atoms give no appreciable effect, the magnetic interaction is localized within the four copper atoms bridged by two hydroxide anions. This explains the success of the tetramer model in spite of the three-dimensional network structure.

Adsorption of Water on FeOOH as Studied by Electrical Conductivity Measurements

Katsumi KANEKO* and Katsuya INOUYE

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 280

(Received June 12, 1978)

Changes in the electrical conductivity of synthetic α-, β-, and γ-FeOOH crystals with the amount of adsorbed water were measured at 30 °C and various frequencies (dc, 100—10 MHz). The conductivity variations of water-adsorbed FeOOH with temperature were also examined over the range from −140 to 140 °C. For the adsorption coverages between 0 and 0.5, the electronic conduction increased with the coverage due to the transfer of electrons from chemisorbed water molecules to the FeOOH crystal. The decrease in activation energy for conduction with chemisorption was observed. The conductivity increase due to the chemisorption is related to the characteristic surface structure of each FeOOH polymorph. In the coverage range 0.7—2, protons in the adsorbed water layer transport electrical charges. The linear relationships between the logarithm of conductivity and the logarithm of the relative pressure of water vapor suggest the presence of clusters of physisorbed water molecules on FeOOH surfaces. A steep change in protonic conductivity by a factor of 10^2—10^4 was observed at a temperature close to −5 °C. The change seems to be caused by an order-disorder transition of protons in the adsorbed water layer.

Both O and OH on the surfaces of semiconductors and metal oxides play an important role in chemisorption.[1,2] Iron hydroxide oxide (FeOOH) crystal containing O and OH offers an ideal system for investigating the mechanism of chemisorption, since the geometrical positions of the surfaces O and OH can be derived by X-ray diffraction[3-5] and neutron diffraction[6-8] in crystallographic studies. α-, β-, and γ-FeOOH are found as minerals and as the main components in atmospheric corrosion products of iron. Electronmicroscopic observation reveals the presence of the predominant plane for each FeOOH, the index of which has been determined by selected-area electron diffraction.[9] With reference to these results, the surface characteristics of each FeOOH can be discussed by examining the structure of the predominant plane. It is anticipated that the adsorption sites for gaseous molecules are the characteristic O and OH on the predominant planes.

FeOOH is produced through an electrochemical process on the iron surface in the atmospheric environments, when water film of necessary thickness exists. The rust formed further promotes the adsorption of water on the iron surface. There is no doubt that water exhibits a particular activity to the FeOOH surface.

Kaneko *et al.* examined the adsorption process of water molecules on synthetic α-, β-, and γ-FeOOH by dielectric measurements.[10] They postulated that water molecules are adsorbed on two kinds of OH in (100) planes for α-FeOOH, OH and tunnels for β-FeOOH, and OH in (010) planes for γ-FeOOH; the adsorbed water layer forms a regular structure. The adsorption process was supported by thermodynamic study.[11] However, they were unable to discuss the electronic factors in the water adsorption. In the present work, the changes in electrical conductivity of synthetic FeOOH crystals with the amount of adsorbed water have been measured in order to elucidate the mechanism of chemisorption and the structure of adsorbed water.

Experimental

α-, β-, and γ-FeOOH were synthesized by procedures similar to those described in an earlier paper.[12] The X-ray diffraction of the samples gave patterns of pure, well-crystallized crystals. The BET surface areas obtained by use of N_2 adsorption at liquid nitrogen temperature were 69, 34, and 66 m^2/g for α-, β-, and γ-FeOOH, respectively.

Adsorption of Water and Electrical Conductivity. Sample disks made by applying a pressure of 150 kg/cm^2 were set between silver-plated brass electrodes in a glass cell of 215 cm^3. The sample disk was evacuated under a pressure of 10^{-5} Torr at 100 °C for 14 h prior to the adsorption measurement. The amount of adsorbed water was measured at 30 °C with use of a conventional volumetric apparatus with a silicone-oil manometer in the range of relative pressure 0—0.7. The water vapor was evolved from $BaCl_2 \cdot 2H_2O$. It took an hour to reach the adsorption equilibrium. Variations of electrical conductivity with the amount of adsorption at 30 °C and various frequencies (dc, 100—10 MHz) were measured by the same method as reported previously.[13] The conductivity of water-adsorbed FeOOH was also examined at different temperature in the range −140—140 °C. For the dc conductivity measurements, voltage in the range 0.1—100 V was applied. The current-voltage relationship for samples with submonolayer-adsorbed water obeyed Ohm's law, while that for samples with adsorbed water exceeding the monolayer deviated from the law.

Results and Discussion

FeOOH crystals exhibit an n-type electronic conduction *in vacuo*,[14,15] *i.e.*, the negative sign in Seebeck voltage and a conductivity decrease caused by introducing oxygen. The conductivity of samples with adsorbed H_2O of the coverage below 0.5 decreased by more than 25% of the initial value within a minute after the introduction of oxygen. The decrease is an evidence of electronic conduction. On the other hand, the exposure of samples with H_2O coverage above 0.7 to the oxygen gas brought about an instantaneous increase in conductivity. A fact of particular interest is that the water-adsorbed β-FeOOH (coverage 1.0) evolved hydrogen gas by applying dc 100 V at 30 °C for 265 h, which was detected by a mass spectrometer (Hitachi RMU-7M). No hydrogen gas was evolved from the water-adsorbed γ-FeOOH under the same conditions as those for the above-mentioned β-FeOOH specimen. No evolution of H_2 seems to be due to the progress of the reductive

reaction of γ-FeOOH to Fe_3O_4 consuming the protons at the specimen-electrode interface.[16] Thus, the protonic conduction is assumed for water-adsorbed FeOOH of coverage above 0.7. In view of the facts mentioned above as well as the dependence of conductivity on frequency, temperature, and adsorption of water described later, it is suggested that the electrical transport in the water-adsorbed FeOOH consists of electronic and protonic conductions. The total electrical conductivity of the specimen is assumed to be the sum of the electronic conducitivity σ_{el} and the protonic one σ_p.

$$\sigma = \sigma_{el} + \sigma_p. \quad (1)$$

σ is nearly equal to σ_{el} for the samples of adsorption coverage less than 0.5. In the coverage range 0.7—2, σ is close to σ_p. In the range 0.5—0.7, σ_{el} is comparable to σ_p.

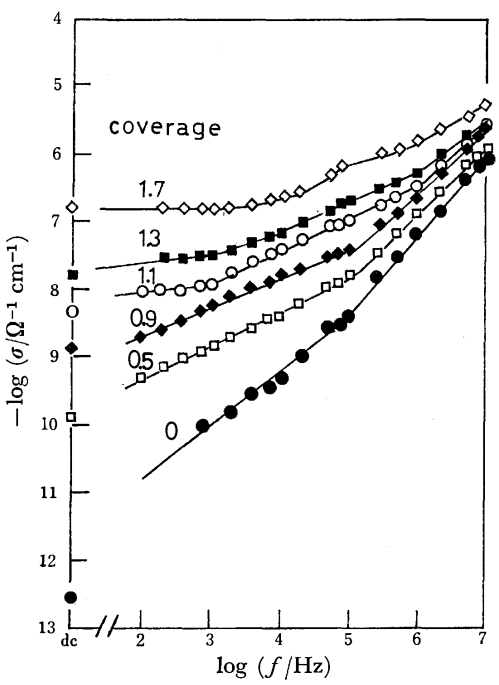

Fig. 1. Frequency dependence of electrical conductivity of γ-FeOOH at 30 °C at various coverages of adsorbed water (●: θ=0, □: θ=0.5, ◆: θ=0.9, ○: θ=1.1, ■: θ=1.3, and ◇: θ=1.7).

The frequency dependence of conductivity of γ-FeOOH measured at 30 °C for different values of coverage θ of adsorbed water is shown in Fig. 1. The logarithm of conductivity of pure γ-FeOOH (θ=0) shows linear dispersion with the logarithm of frequency, suggesting the hopping of d-electrons in the t_{2g}-orbital of Fe^{2+} to that of adjacent Fe^{3+}.[17,18] In the coverage range 0.5—1, it appears that the more water is adsorbed, the more vague is the dispersion in the lower frequency range, probably because of the contribution of the protonic conduction to the dc conduction. The dispersion of conductivity in the lower frequency range disappeared for samples with adsorbed water exceeding the monolayer; dc protonic conduction through adsorbed water layer overwhelms the dc electronic conduction. Water molecules seem to be partly chemisorbed in the coverage range 0—0.5, and physisorbed in the coverage range 0.7—2. Discussion is given in two parts, chemisorption and physisorption.

Chemisorption

Change of Physisorption to Chemisorption. The excess d-electrons of Fe^{2+} in pure FeOOH crystals move in a hopping process with mobility proportional to $\exp(-W_H/kT)$, where W_H is the hopping energy. The activation energy E for conduction of pure FeOOH crystals is nearly equal to the hopping energy W_H, if the Fe^{2+} concentration n does not change with temperature. Taking into account the interaction between Fe^{2+} ions, E can be given by

$$E \approx W_H = W_H^\circ - c\frac{e^2}{d}, \quad (2)$$

where W_H° is the hopping energy in the case where there is no interaction between carriers, e the electronic charge, c a constant, and d the average Fe^{2+}–Fe^{2+} distance. The value d is approximately given by[14]

$$d = 2\left(\frac{3}{4\pi n}\right)^{1/3}. \quad (3)$$

It is accepted that the water molecule with negative electron affinity is apt to give an electron to the oxide surface.[19,20] A portion of water molecules physisorbed on the FeOOH crystals by hydrogen bonding can be chemisorbed through a charge-transfer interaction.[21] The chemisorbed water molecule donates an electron to the t_{2g} orbital of Fe^{3+} according to the thermal excitation process:

$$H_2O \text{ (chemisorbed)} \longrightarrow H_2O^+ \text{ (chemisorbed)} + e(t_{2g}), \quad (4)$$

where $e(t_{2g})$ denotes the electron in the t_{2g} orbital. The ionization energy of the chemisorbed water molecule is denoted by E_i hereafter. The electron-transfer from water to the FeOOH surface results in an increase of the carrier concentration n; the activation energy for conduction decreases with increase in the amount of chemisorption owing to shallowing of the polarization-well of the carrier. The Fe^{2+}–Fe^{2+} distance d (Eq. 2) changes with the chemisorption of water. When the initial number of carriers, n_0, is much larger than the number of electrons donated from chemisorbed water, the hopping energy for the water-chemisorbed FeOOH is given by

$$W_H = W_H^\circ - \frac{ce^2}{2}\left(\frac{4\pi n_0}{3}\right)^{1/3} - \frac{ce^2}{6}\left(\frac{4\pi}{3n_0^2}\right)^{1/3} N_m\theta \exp(-E_i/kT), \quad (5)$$

where N_m is the number of adsorbed water molecules in monolayer at 30 °C. Equation 5 can be simplified to

$$W_H = W_H(\text{none}) - g\theta, \quad (6)$$

where W_H(none) is the hopping energy for FeOOH without water-chemisorption,

$$W_H(\text{none}) = W_H^\circ - \frac{ce^2}{2}\left(\frac{4\pi n_0}{3}\right)^{1/3}, \quad (7)$$

and g is given by

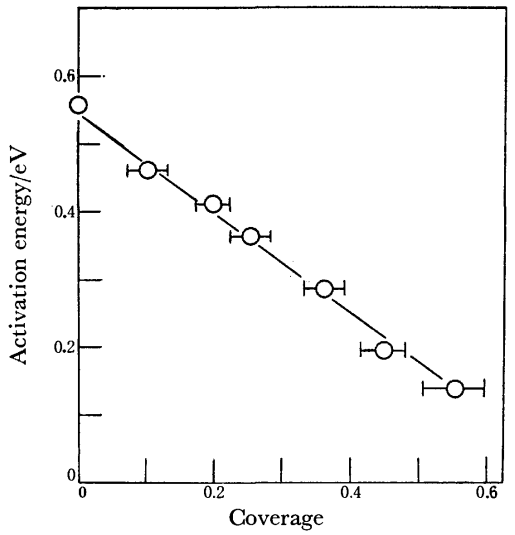

Fig. 2. Relationship between the activation energy and the coverage of adsorbed water for γ-FeOOH.

$$g = \frac{ce^2}{6}\left(\frac{4\pi}{3n_0^2}\right)^{1/3} N_m \exp(-E_i/kT). \quad (8)$$

Equation 6 shows that the hopping energy decreases in proportion to the coverage θ at a certain temperature.

Equation 6 holds for γ-FeOOH (Fig. 2); the activation energy for dc conduction at 30 °C decreases linearly with coverage; the slope of the straight line gives a g value of 0.71 eV. Taking the values $c=0.6$, $n_0=2\times10^{20}$ cm^{-3}, and $N_m=7\times10^{14}$ cm^{-2} in Eq. 8 we obtain $E_i=0.03$ eV. Thus, it is concluded that water molecules less than 15% of monolayer give electrons to γ-FeOOH at 30 °C, since the factor of $\exp(-E_i/kT)$ is about 0.3 and the upper limit of coverage for the chemisorption is 0.5.

Effect of the Surface Structure. Equation 6 requires a linear relationship between the logarithm of conductivity, log σ, and coverage θ, since log σ is proportional to the activation energy E ($\log\sigma \propto (W_H - g\theta)/kT$). Figures 3—5 show the linear relationships between log σ at dc and θ for γ-, α-, and β-FeOOH. The linear relationships

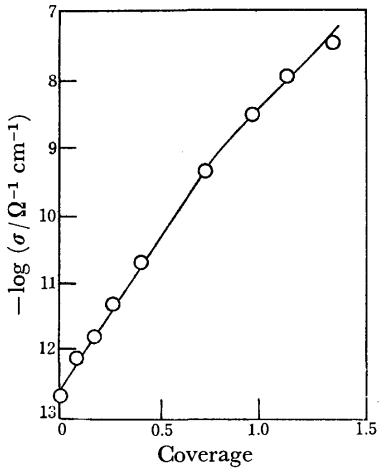

Fig. 3. Relationship between dc electrical conductivity and the coverage of adsorbed water at 30 °C for γ-FeOOH.

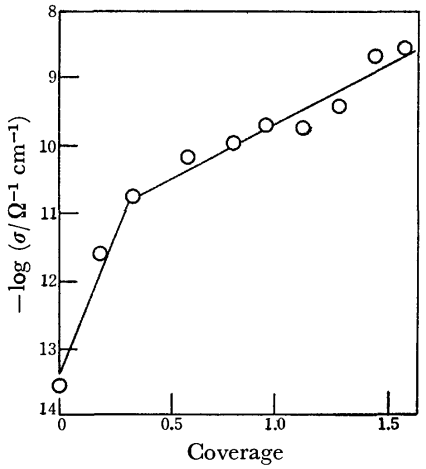

Fig. 4. Relationship between dc electrical conductivity and the coverage of adsorbed water at 30 °C for α-FeOOH.

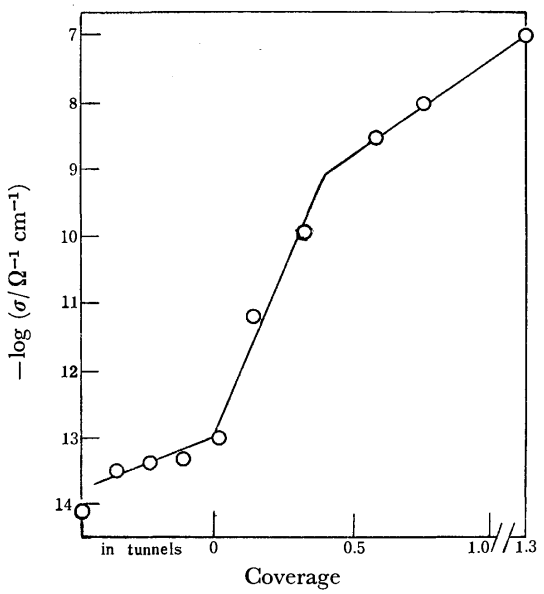

Fig. 5. Relationship between dc electrical conductivity and the coverage of adsorbed water at 30 °C for β-FeOOH.

break at an inherent coverage for each FeOOH, which can be ascribed to the change in E_i. The coverage at which the line breaks relates to the number of the particular adsorption sites on the crystal surface.

Ewing[3] postulated that the crystal structure of γ-FeOOH is built up of layers parallel to the (010) plane, each layer being made up of octahedra embracing iron atoms at centers of octahedra and linked together by sharing corners (Fig. 6(A)); the layers are joined to each other by hydrogen bonds. The linear relationship for γ-FeOOH (Fig. 3) in a wide range of coverage up to 0.8 is in line with the fact that the predominant (010) plane of γ-FeOOH has only one kind of OH as the water-adsorption site. However, the linearity breaks at the coverage of 0.8, since the protonic conduction through the bilayer of adsorbed water prevails over the electronic conduction.

The surface structure of α-FeOOH is shown in Fig. 6 (B).[4] Water molecules up to a coverage of 0.3 are

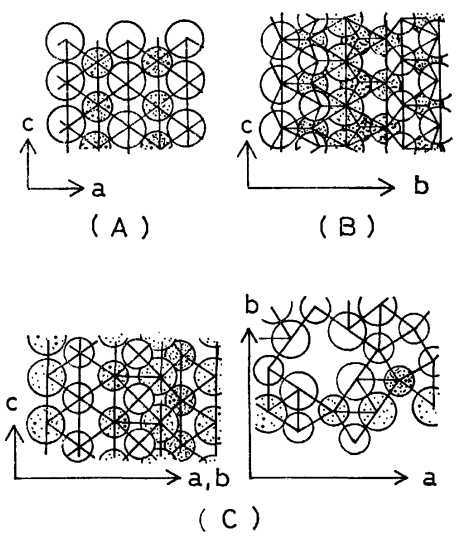

Fig. 6. Structure of the predominant surface of γ-FeOOH (A), α-FeOOH (B), and β-FeOOH (C). Large circle denotes OH^- and small circle O^{2-}.

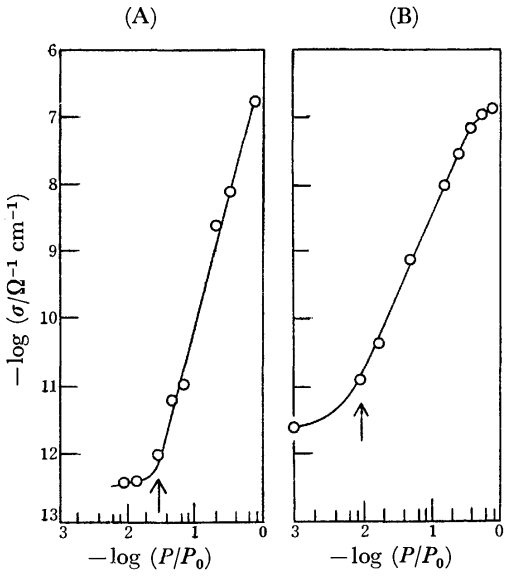

Fig. 7. Proportionality between log σ at dc and log (P/P_0) for β-FeOOH (A) and γ-FeOOH (B).

adsorbed on the hydroxyls in the groove of the (100) plane of α-FeOOH; the line in Fig. 4 breaks at 0.3.

Mackay[5] showed that β-FeOOH has a hollandite structure having tunnels parallel to the c-axis, in which Cl^- and H_2O can be occluded (Fig. 6(C)). The vacant part in the tunnel, produced by the removal of Cl^-, is the most active site for water adsorption, and the number of the adsorption site can be determined by the Cl^- content in the tunnel. The adsorption begins when water molecules enter the tunnels. The abscissa in Fig. 5 represents the coverage of the sites in tunnels and that of the outer surface (coverage: 0—1.3). We see that the conductivity-increase of β-FeOOH due to the adsorption in the tunnel is less conspicuous than that due to the adsorption on the outer surface. The linear relationship between log σ and θ in the coverage range from 0 to *ca.* 0.5 is ascribed to the transformation of physisorbed water molecules with bifurcated hydrogen bonding to chemisorption.

When water is desorbed from each FeOOH sample at 30 °C under a pressure of 10^{-5} Torr for several hours, the conductivity is reduced to the order of the original value for the sample without adsorbed water; the chemisorption of water appears to be reversible. It seems that the chemisorbed water molecules are connected to the FeOOH surface by both hydrogen bonds and weak charge-transfer bonds.

Physisorption

Clusters of the Physisorbed Water Molecules. The protonic conduction through the physisorbed water layer seems to predominate over the d-electron conduction in a restricted coverage range. In the coverage range 0.7—2, log σ is proportional to the logarithm of relative pressure, $\log(P/P_0)$, at 30 °C, where P and P_0 are the vapor pressure and the saturated one, respectively. Figure 7 shows the relationship between log σ at dc and $\log(P/P_0)$ for β- and γ-FeOOH. The lines on the right side of the bending point (indicated by an arrow, Fig. 7) correspond to the region of protonic conduction. When the linear relationship is expressed by

$$\sigma \propto (P/P_0)^s, \tag{9}$$

s values obtained from the slope of each line are: α-FeOOH, 1.1; β-FeOOH, 4.1; and γ-FeOOH, 2.2.

The adsorbed water layer is supposed to consist of solid-like two-dimensional clusters of water molecules. The relation given by Eq. 9 is interpreted by the presence of the clusters of adsorbed water molecules. The protonic conduction in the adsorbed water layer requires the production of protons by the ionic dissociation of water molecules. The dissociation of H_2O is determined by two bonding states, *i.e.*, the bonding between an adsorbed molecule and the surface, and that between adsorbed molecules. The proton formation from associated water molecules should differ from that of a single molecule. The association of m molecules on the FeOOH surface can be expressed by

$$m\mathrm{H_2O(g)} = m\mathrm{H_2O(ads)};\quad K_{\mathrm{ads}}, \tag{10}$$

$$m\mathrm{H_2O(g)} = (\mathrm{H_2O(ads)})_m;\quad K_{\mathrm{ass}}. \tag{11}$$

The number of association, m, is determined by the field strength of the surface. The dissociation equilibrium of a proton can be written as

$$(\mathrm{H_2O(ads)})_m = \mathrm{H^+} + (\mathrm{H_2O(ads)})_{m-1}\mathrm{OH^-};\quad K_{\mathrm{dis}}, \tag{12}$$

where (g) and (ads) denote gaseous water molecule and adsorbed one, respectively. The equilibrium constants for Eqs. 10, 11, and 12 are denoted by K_{ads}, K_{ass}, and K_{dis}, respectively. From Eqs. 10—12 the concentration of protons, p, is given by

$$p = \sqrt{K_{\mathrm{ads}}K_{\mathrm{ass}}K_{\mathrm{dis}}}P^{m/2}. \tag{13}$$

We see that σ_p is proportional to $P^{m/2}$, the mobility changing slightly with the adsorption of water. m is found to be $2s$ from a comparison of Eqs. 13 and 9.

The number of association m suggests a model of the cluster on the surface of each FeOOH, as shown in Fig. 8. For α-FeOOH (Fig. 8(A)), two molecules in the b-axis direction (dark circles) tend to form a dimer (m=2). When all grooves exposed on the β-FeOOH

surface are filled with H_2O at a coverage of 0.3, H_2O molecules can come into contact with the six nearest neighbors; in this case m equals 7 (Fig. 8(C)). The adsorbed water molecules on γ-FeOOH surfaces (Fig. 8(B)) are connected to each other by tetrahedral hydrogen bonding (Fig. 11), the m value approaching 5.

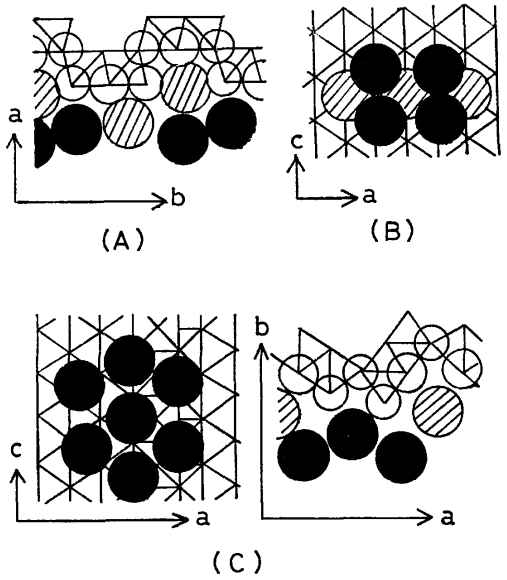

Fig. 8. Associated structures of water molecules physisorbed on α-FeOOH (A), γ-FeOOH (B), and β-FeOOH (C). Large and small circles denote OH^- and O^{2-}, respectively. Hatched circle and dark one denote the adsorbed water molecule contributing to the electronic conduction and to the protonic conduction, respectively.

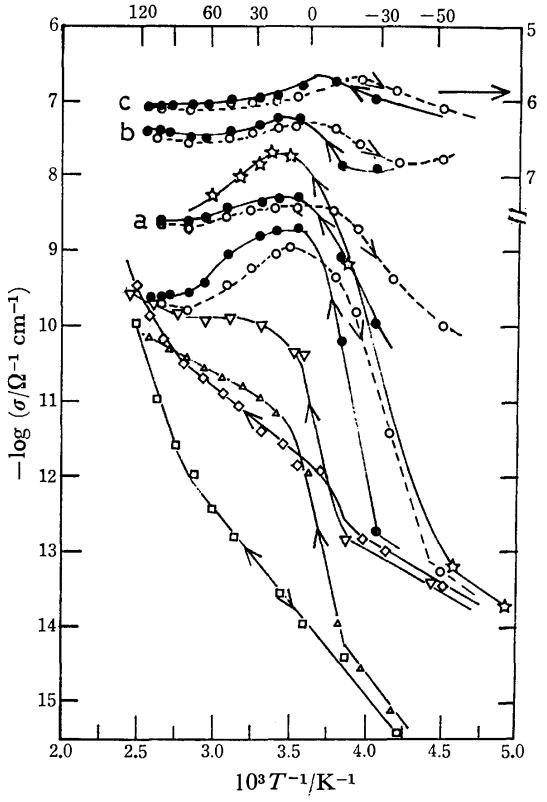

Fig. 9. Temperature dependence of electrical conductivity of γ-FeOOH with adsorbed water of various coverages.
dc: $\theta=0$ (□), $\theta=0.3$ (◇), $\theta=0.5$ (△), $\theta=0.7$ (▽), $\theta=1$ (●,○), and $\theta=1.5$ (☆). $\theta=1$ (●,○): 1 kHz (a), 100 kHz (b), and 7 MHz (c).

Phase Transition of Adsorbed Water Layer. The proton conduction through the adsorbed layer shows characteristic temperature dependence. Figure 9 shows the temperature dependence of the dc electrical conductivity of γ-FeOOH with adsorbed water of different coverages ($\theta=0$—1.5 at 30 °C). The coverage determined at 30 °C increases with a lowering in temperature due to the condensation of vapor on the samples below 30 °C. It decreases with rise in temperature due to the desorption above 30 °C. The linear $\log\sigma$ *vs.* $1/T$ relationships for the coverage above 0.5 become nearly vertical in the range from −40 to −5 °C. The higher the coverage, the lower the temperature at which conductivity jumps. The $\log\sigma$ *vs.* $1/T$ relationships of water-adsorbed samples ($\theta=1$ and 1.5) have maxima at 10 °C. The $\log\sigma$ *vs.* $1/T$ relationships of γ-FeOOH ($\theta=1$ at 30 °C) at different frequencies are also shown in Fig. 9. The higher the frequency, the smaller the change in conductivity with temperature. The conductivities at 1 and 10 kHz reach maxima at 10 °C with rise in temperature. On the other hand, the conductivity at 7 MHz has no maximum at 10 °C, but at -7 ± 3 °C, where dc and lower frequency conductivities increase vertically with rise in temperature. The hysteresis of conductivity-temperature change was observed at all frequencies.

The steep change in conductivity in the temperature range from −40 to −5 °C may be due to a phase transition of the adsorbed water layer. All the phenomena observed appear to be similar to a solid-liquid transition of water in porous solids, which shows freezing-point depression.[23–25] However, the phase transition does not seem to be the solid-liquid transition for two reasons: (1) The adsorbed water layer of

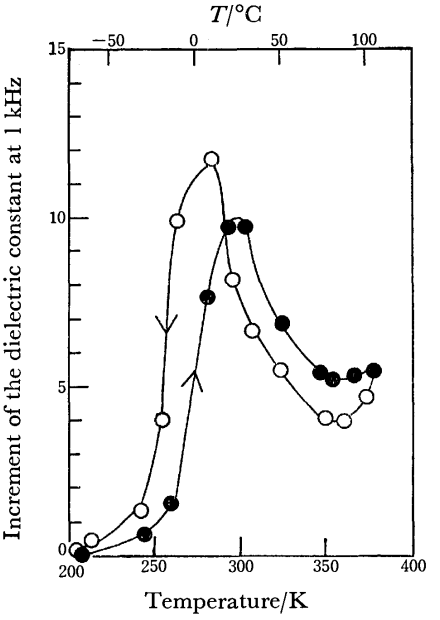

Fig. 10. Temperature dependence of the increment of the dielectric constant at 1 kHz of γ-FeOOH covered with adsorbed water ($\theta=1$ at 30 °C).

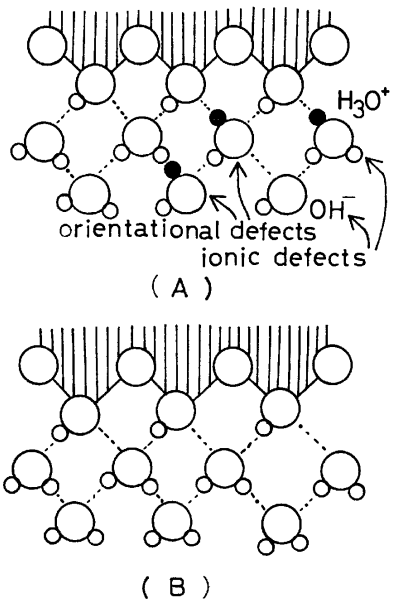

Fig. 11. Hydrogen-disordered (A) and hydrogen-ordered (B) structures of bilayer of water adsorbed on γ-FeOOH. Small, open circle denotes a hydrogen atom. Small, black circle denotes the misplaced hydrogen atom (or ion). Large circle denotes an oxygen atom (or ion).

thickness less than three molecular layers can not be regarded as a liquid phase. (2) The phase transition between ice I and liquid water causes no significant conductivity changes, since the electrical conductivity of ice I at -20 °C is 10^{-8}—10^{-10} Ω^{-1} cm^{-1} [26] and that of liquid water 10^{-9} Ω^{-1} cm^{-1}.[27] The variations of dielectric constant with temperature should also be taken into consideration. Figure 10 shows the temperature dependence of the dielectric constant for γ-FeOOH at 1 kHz ($\theta=1$ at 30 °C). The results are referred to the dielectric studies on polymorphs of ice by Whalley *et al.*,[28,29] who argued that an order-disorder transition of the position of hydrogen atoms affects the dielectric constant. It seems that the phase transition of the adsorbed water layer on the FeOOH surface is not a solid-liquid transition but an order-disorder transition of hydrogen atoms. A model of the order-disorder transition of hydrogen atoms in the adsorbed water layer on γ-FeOOH is shown in Fig. 11. The disordered adsorbed-water layer containing many orientational and ionic defects would result in high dielectric constant and high conductivity. The electrical conduction at dc and that at frequencies higher than 100 kHz arise from the migration of ionic (protonic) defects and the formation of orientational defects, respectively.[30] Most orientational defects appear at the temperature of order-disorder transition; the conductivity at 7 MHz reaches maximum at the transition temperature. The fact that H_2O-adsorbed FeOOH ($\theta=1$ or 1.5) has the highest protonic conductivity at 10 °C might be related to the maximum of the adsorbed water in the disordered state at the temperature. The hysteresis observed can be attributed to a strong interaction between the adsorbed water and the FeOOH surface. The strong interaction also promotes the dissociation of water. Gallagher and Phillips[31,32] observed the hydrogen-exchange between hydroxyls of FeOOH and water.

ESR Study of SeO_2^- Radical in an Irradiated Single Crystal of Triglycine Selenate in the Vicinity of Phase Transition Temperature

Yashige KOTAKE* and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 12, 1978)

Detailed observations of the angular dependence of ESR spectra of SeO_2^- radicals formed by X-ray irradiation of a single crystal of ferroelectric triglycine selenate were carried out. Two kinds of SeO_2^- radicals were produced due to the difference in manner of selenium-oxygen bond scission. In spite of the difference in stability of radicals in TGSe and those in TGS, the behavior of SeO_2^- radicals in the phase transition region is in line with that expected from the result of X-ray diffraction study of TGS.

Various aspects of ferroelectric phase transition have been clarified by ESR technique with use of paramagnetic probes such as radiation damage and doped metal ions. As regards triglycine sulfate (TGS), X- or γ-ray irradiation has been effective for producing paramagnetic probes which are stable up to the transition temperature.[1-7] However, the stability of the resulting radicals in TGS and isomorphous triglycine selenate differs a great deal. In TGS, radicals from glycines II and III are stable while in TGSe those from acid ions are stable, indicating that the environments of radicals differ from each other. It is interesting to see whether the difference influences the behavior of radicals upon phase transition, resulting in a behavior differing from that expected from the result of X-ray diffraction study on TGS.

In view of the fact that the radicals are good probes for watching microscopic behavior of phase transition, the difference in the behavior of yielded radicals in isomorphous crystals might supply useful information.

In the mechanism of the phase transition in TGS, Hoshino *et al.*[8] postulated that acid ions change their structure and orientation at the phase transition point, and that they are located on the mirror planes at $b=1/4$ and 3/4 in the paraelectric phase. In isomorphous triglycine fluoberyllate (TGBe) the behavior of fluoberyllate ion has been studied by making use of ^{9}Be quadrupole perturbed NMR in deuterated crystals.[9] The results were in line with those of the X-ray diffraction study, the fluoberyllate ions being on the mirror planes at $b=1/4$ and 3/4 in the paraelectric phase.

No ESR study using paramagnetic probes has been reported for such behavior of acid ions mainly because of the lack of suitable probes.

The objective of this work is to clarify whether the stable radical produced from acid ions in TGSe reflects the general behavior of acid ions in TGS and its isomorphous crystals.

Experimental

Single crystals of TGSe were grown from aqueous solutions by slow cooling. After being irradiated by X-ray at room temperature for 1 h, the crystal was aged at room temperature for several weeks in order to reduce the unstable radicals produced from glycines.

The ESR spectrometer employed was operated at X-band, the second derivative signal being recorded. The position of the absorption line was determined by using DPPH as a standard. The temperature of the sample was controlled by a nitrogen gas stream and measured by a copper-constantan thermocouple attached to the crystal.

Results and Discussion

Stability of Radicals. In TGS two radical species are observed immediately after irradiation at room temperature.[3] They are assigned to $\dot{C}H_2COO^-$ produced from glycine I and $NH_3^+\dot{C}HCOO^-$ from glycines II and III. $\dot{C}H_2COO^-$ radicals have a half life of about one week at room temperature, while $NH_3^+\dot{C}HCOO^-$ is stable for a long period of time. In the case of TGSe, SeO_2^- radicals are formed from selenate ions in addition to radicals from glycines. The yield of the radicals from glycines is low, and they have a half life of several weeks. SeO_2^- radicals are quite stable, no decrease in signal intensity being observed. The difference in the stability of radicals formed from acid ions might be ascribed to the reactivity of the radical. However, the difference in the stability of the $NH_3^+\dot{C}HCOO^-$ radical indicates that the hydrogen-bonded network which stabilizes the radical is different. The radicals located in the network might give microscopic information on the difference in the surrounding which cannot be obtained from macroscopic properties such as Curie temperature and transition entropy.

Angular Dependence of SeO_2^- Radicals. The stable radical species produced in irradiated TGSe has been assigned to SeO_2^- radicals by Suzuki and Abe[10] by comparison of the principal values of hf-tensors of ^{77}Se with those of various oxy radicals of selenium. However, the structure and alignment of the radical has not been clarified in connection with the crystal structure.

The present results of angular dependence show that there are two major radicals which give eminent peaks in all of the three perpendicular planes. Figure 1 shows the observed angular dependence of the two species denoted by S1 and S2 in both the para- and ferroelectric phases. Weaker signals appear in certain directions.

The results of the tensor analysis with repect to a'bc orthogonal coordinate are given in Table 1, where $a' \perp c$ lies in the ac plane. Both species S1 and S2 change the alignment upon phase transition. However, the principal values remain unchanged. Though there is a considerable discrepancy in the direction cosines, the principal values coincide with those of Suzuki and Abe.[10] In view of the difference in the angular dependence in

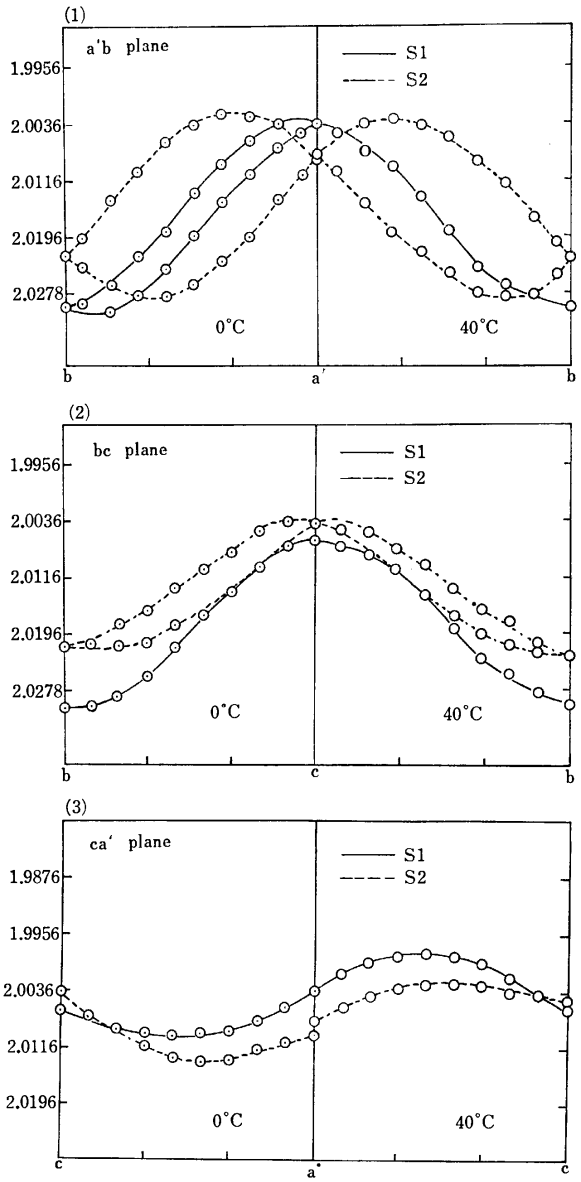

Fig. 1. Angular dependence of the ESR spectra of SeO_2^- radicals in the para- (40 °C) and ferroelectric (0 °C) phases. The magnetic field is applied parall to the crystallographic planes: (1) a'b plane, (2) bc plane, and (3) ca' plane.

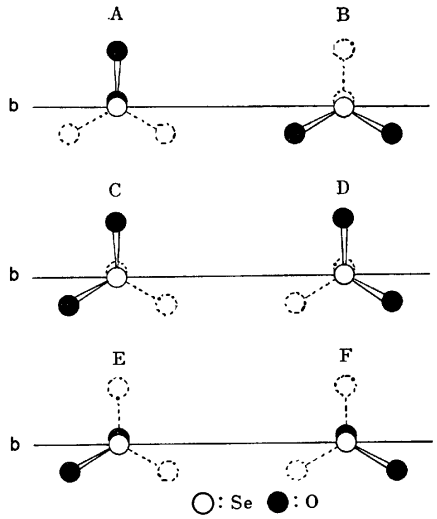

Fig. 2. Possible spatial configurations of SeO_2^- radicals produced from SeO_4^{2-} ion in TGSe crystals. The horizontal line shows the b-axis. S1 was assigned to B and S2 to E or F.

both the para- and ferroelectric phases, the most striking feature is that the site splitting of S1 in the ferroelectric phase disappears in the paraelectric phase.

There are six possible spatial configurations for SeO_2^- radicals in the paraelectric phase of TGSe crystals as shown in Fig. 2. Two of them (A, B) have mirror planes perpendicular to the b-axis. From the fact that the direction of the maximum principal value of the *g*-tensors in SeO_2^- corresponds to the direction combining two oxygen atoms[11,12] S1 is assigned to SeO_2^- of configuration B. The direction cosines of S2 have no such characteristics of S1 (Table 1) and are ascribed to configurations E and F in Fig. 2. The two configurations are crystallographically equivalent in the paraelectric phase. In the ferroelectric phase ESR spectra of configurations E and F should give a slightly different angular dependence caused by the different bond lengths of the two selenium-oxygen bonds, but this was not shown by experimental results.

The direction cosines of S1 and S2 show that S1 almost exactly keeps the configurations of the mother selenate ions even after the loss of two oxygen atoms. The direction cosines of SeO_2^- radicals calculated on the X-ray diffraction data for configurations B and F are given in Table 2. There is a considerable displacement of S2 from the site of the mother selenate ions as compar-

TABLE 2. CALCULATED DIRECTION COSINES FOR CONFIGURATIONS B AND F

Configuration	*a'*	*b*	*c*	Difference[a] (degree)
B g_{max}	0	1	0	0
B g_{int}	−0.44	0	0.89	11
B g_{min}	0.89	0	0.44	11
F g_{max}	0.39	±0.53	0.76	24
F g_{int}	−0.89	±0.44	0.15	41
F g_{min}	0.24	±0.72	0.63	34

[a] The angular deviation of the observed direction of S1 from B and that of S2 from F.

ed with the case of S1. This is reasonably explained by the fact that S1 has mirror symmetry but not S2. The selenate ions are stabilized by a network having a mirror symmetry because of the symmetry of the crystal. After the loss of two oxygen atoms S2 is forced to have asymmetric hydrogen bond system possibly causing displacement to seek a stable position.

Scission of Selenium–Oxygen Bonds. According to the crystal structure determined by X-ray diffraction[8] and neutron diffraction,[13] glycine I and one of the oxygen atoms in a sulfate ion are bonded by a short hydrogen bond (0.254 nm) in the TGS crystal. This is the shortest hydrogen bond connecting sulfate ion and neighboring glycines, the involved sulfur–oxygen bond having the longest bond length (0.148 nm) in a sulfate ion. In TGSe one of the lost oxygen in SeO_2^- corresponds to the oxygen atom with the longest sulfur–oxygen bond. The scission behavior of the selenate ion is in line with the fact that in a single crystal the breakage of the bond by irradiation tends to occur along the shortest hydrogen bond.[14]

Behavior of SeO_2^- Radical upon Phase Transition. As shown by the angular dependence of the *g*-value of the SeO_2^- radical, the orientations of radicals in the para- and ferroelectric phases differ. Particularly in the case of S1 disappearance of the site splitting was clearly observed in the a'b plane. In the bc plane the site splitting was too small as compared with linewidth even in the ferroelectric phase.

In the ferroelectric phase, the direction combining two oxygen atoms in SeO_2^- of configuration B has a finite angle with the b-axis, due to the lack of mirror symmetry. X-Ray diffraction study has shown that in TGS the sulfate ions do not have tetrahedral symmetry in the ferroelectric phase. In isomorphous TGSe, two selenium-oxygen bonds in SeO_2^- are thought to have a different bond length, causing the slightly different configurations of B in the ferroelectric phase. On the other hand, in the paraelectric phase the change of the structure makes the angle zero, resulting in mirror planes perpendicular to the b-axis. The result of tensor analysis shows the behavior to be consistent with that predicted by the result of X-ray diffraction study.[8] It should be noted that the behavior of radicals shows no influence expected from the difference in the stability of radicals. The magnitude of the site splitting gradually tends to zero without line broadening. It is hard to explain the absence of the line broadening in terms of the dynamic order-disorder mechanism.[15] It this system, the dynamic order-disorder mechanism assumes the interchange of two sites of S1 by thermal motion. When the interchange rate becomes greater, the site splitting should become smaller with exchange broadening.

The magnitude of the site splitting of S1 is not large enough as compared with the linewidth in the phase transition region. It was found that the alignment of S1 and S2 has a suitable relation for the observation of the change of the spectral feature in the critical region. In a certain direction, *i.e.* when the external field is slightly off from the b- and c-axis, each component of the signals from S1 and S2 completely collapses in the paraelectric phase because of the different temperature dependence of the alignment. The doublet splitting in this direction is sufficiently large in the ferroelectric phase to observe the temperature dependence. Figure 3 shows the difference between the resonance fields of the signals of S1 and S2 as a function of temperature. The plot shows that the change has a second order nature, the behavior of the radicals being in line with that of TGS.[16]

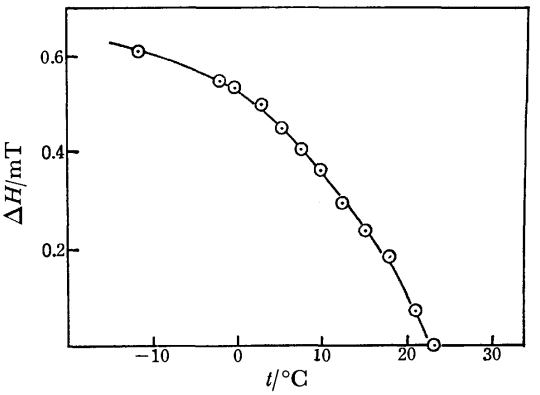

Fig. 3. Temperature dependence of the separation of ESR signals of S1 and S2. The magnetic field is applied slightly off from the b- and c-axis.

The Crystal Structures of Methylammonium Hexachlorostannate(IV) in the High- and Low-temperature Phases Studied by X-Rays

Katsuki KITAHAMA,* Hideko KIRIYAMA, and Yoshihisa BABA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 28, 1978)

The title compound crystallizes in the trigonal space group $R\bar{3}m$ with $a=7.171$, $c=21.952$ Å, and $Z=3$ at 298 K. The crystal structures at 298 and 120 K, as well as the lattice parameters in the temperature range 113—298 K, have been determined by X-rays, in order to elucidate the mechanism of the phase transition occurring at $T_t=156$ K. The structure of the high-temperature phase is essentially the same as that determined by Wyckoff, except for the discrimination between C and N atoms. No change in the space group nor in the basic structure was detected over the temperature range studied, in spite of a strong suggestion from previous ^{35}Cl-NQR measurements. A small but significant anomaly associated with the transition is recognized in the c axis, which retains almost the same length near and below T_t. As a result, the lattice shrinkage below T_t becomes increasingly anisotropic as the temperature is lowered, whereas the thermal expansion above it is relatively isotropic.

In a series of hexahalo complexes of quadrivalent metal ions, A_2MX_6, the compounds of methylammonium cations, $A=CH_3NH_3^+$, are of much interest, because dumbell-like cations and octahedral anions co-exist in their structures. According to Wyckoff, a crystal of methylammonium hexachlorostannate(IV) has an anti-fluorite type structure which is deformed by elongation of the cubic unit-cell parallel to [111].[1] A phase transition in this compound was found at 156 K from an anomaly in the frequency of chlorine-35 NQR (nuclear quadrupole resonance) measured by Kume *et al.*[2] In our laboratory, molecular motions of both cation and anion have been studied by means of magnetic resonance of ^{1}H and ^{35}Cl nuclei. The results of PMR (proton magnetic resonance) revealed that the total cations are rapidly reorienting about their three-fold axes even at very low temperatures.[3] It was also suggested that the motion of cations makes a minor contribution to the occurrence of the phase transition. On the other hand, the ^{35}Cl-NQR spin-lattice relaxation time, T_1, showed a distinct reduction in the vicinity of the phase transition temperature, T_t.[4] This anomalous behavior of ^{35}Cl-T_1 has been explained in terms of the softening of some rotary lattice mode of anion octahedra, $[SnCl_6]^{2-}$, in analogy with K_2PtBr_6.[5]

The present X-ray study was undertaken to make clear the change in crystal structure and/or in lattice constants on passing through the phase transition and to check the transition mechanism suggested from the NQR results. Discrimination between C and N atoms of the cation will be accomplished as well.

Experimental

Polycrystalline $(CH_3NH_3)_2SnCl_6$ was prepared by the same method as in the previous paper.[3] Single crystals were obtained as hexagonal plates by the slow cooling of a 6 mol/dm^3 HCl solution.

All single crystals used were sealed in glass capillary tubes to protect them from moisture. Cooling was achieved by blowing a stream of cold nitrogen gas over a crystal. The temperature of a sample was stabilized within ±0.5 K during measurements of the lattice constants and within ±1.0 K during exposure of X-ray photographs and also throughout the intensity data collection at 120 K.

A single crystal with dimensions $0.3\times0.3\times0.15$ mm was used throughout the measurements described below. The crystal was mounted on a Rigaku four-circle diffractometer with the a-axis along the ϕ-axis of the goniostat. Intensity data at 120 and 298 K and the lattice parameters from 113 to 298 K were measured with graphite monochromatized Mo $K\alpha$ radiation. Diffraction peaks were centered automatically in the measurement of the cell constants. The lattice parameters at a given temperature were refined by a least-squares method based on the setting angles (2θ, ω, χ, and ϕ) of nine reflections. The results are summarized in Table 1.

Table 1. Lattice parameters for $(CH_3NH_3)_2SnCl_6$ at various temperatures

T/K	a/Å	c/Å	V/Å^3
298	7.171	21.952	977.6
293	7.169	21.944	976.7
233	7.137	21.859	964.3
213	7.130	21.828	961.0
193	7.119	21.810	957.2
173	7.108	21.790	953.4
153	7.098	21.790	950.7
133	7.090	21.791	948.6
120	7.082	21.790	946.5
113	7.077	21.789	945.1

e.s.d.'s for a and c are less than 0.004 and 0.009 Å, respectively. Space group : $R\bar{3}m$ (throughout the temperature range). $Z=3$, $F.W.=395.54$ g mol^{-1}, $F(000)=570$ e cell^{-1}, $\rho_{obsd}=1.989$ g cm^{-3} (at 293 K), $\rho_{calcd}=2.018$ g cm^{-3} (at 293 K).

The intensity data at the two temperatures were collected in a 2θ range of 0—60° by using the 2θ-ω scan technique. Of 402 independent reflections at 298 K and of 392 ones at 120 K, 383 reflections at 298 K and 364 ones at 120 K were observable ($F_o>3\sigma_{CS}$); these were used in the present analysis and refinement. No correction was made for absorption (μ for Mo $K\alpha=31.3$ cm^{-1}).

Structure Determination and Refinement

Weissenberg and precession photographs of zero- and upper-layers showed that the space group is either R32, R3m, or $R\bar{3}m$ at both 120 and 298 K, and that no change in crystal symmetry occurs on passing through the phase transition. By judging from the solutions of the structure, the space group was determined to be $R\bar{3}m$

for both phases.

The positional parameters of the Cl atom reported by Wyckoff,[1] together with the isotropic thermal parameters of the Sn and Cl atoms, were refined by least-squares methods with the intensity data collected at 298 K. Using the intensity data phased with these coordinates, three-dimensional electron density maps were calculated. The position of the C atom was clearly distinguished from that of the N atom; the peaks assigned to C and N atoms were as high as 8.0 and 11.0 e/Å^3, respectively. Successive difference Fourier syntheses did not yield any hydrogen position. The block-diagonal least-squares refinement with anisotropic thermal parameters was continued until the maximum shift of any parameter was less than one-fifth of its associated e.s.d. The structure in the low-temperature phase was determined at 120 K by almost the same procedure as described above.

The atomic scattering factors for Sn^{4+}, Cl^-, C, and N and the anomalous dispersion corrections f' and f'' for Sn and Cl were taken from the International Tables for X-Ray Crystallography, Vol. IV.[6] The quantity minimized in the refinement was $\sum w(|F_o|-k|F_c|)^2$ with unit weight for all reflections. The final residual values, $R[=\sum||F_o|-|F_c||/\sum|F_o|]$, of 0.052 and 0.062 were obtained at 298 and 120 K, respectively. The final positional and thermal parameters of non-hydrogen atoms at the two temperatures are presented in Table 2. The coordinates for all H atoms were calculated by assuming their existence on the crystallographic mirror planes, the staggered conformation of the $CH_3NH_3^+$ ions, and the bond lengths and angles: N–H=1.03 Å, C–H=1.09 Å, C–N–H=109.47°, and N–C–H=109.47°. Thus the assumed positions are also included in Table 2. The main interatomic distances and angles are given in Table 3. A list of the observed and calculated structure factors at 120 and 298 K has been deposited with the Chemical Society of Japan (Document No. 7904).

All computations were made on a NEAC 2200/700 at the computer center, Osaka University, using local modifications of RSSFR-5, HBLS-IV, and RSDA-4 in the UNICS program system,[7] and the stereoscopic drawing program ORTEP.[8]

Table 2. Positional (x_j) and thermal parameters (B_{ij}/Å^2) for $(CH_3NH_3)_2SnCl_6$ in hexagonal coordinate system

Estimated standard deviations are given in parentheses. The anisotropic thermal factors are of the form: $T=\exp[-1/4(h^2a^{*2}B_{11}+\ldots+2klb^*c^*B_{23})]$.

Results and Discussion

Crystal Structure. The structure described by Wyckoff[1] was confirmed to be essentially correct. The present study showed that there is no change in the basic structure in moving between the high- and low-temperature phases. This finding is an important piece of structural information about the phase transition which will be discussed later.

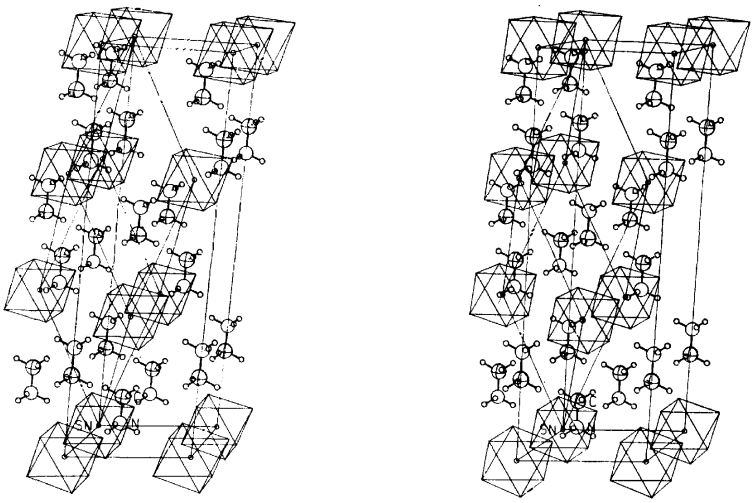

Fig. 1. Stereoscopic drawings of the crystal structure of $(CH_3NH_3)_2SnCl_6$.

The crystal consists of dumbell-like $CH_3NH_3^+$ ions and octahedral $[SnCl_6]^{2-}$ ions. These ions are arranged, in principle, in an antifluorite-type structure like K_2PtCl_6, but the real unit cell is deformed rhombohedrally by elongation along one body-diagonal of the cube. The C–N axes of cations are parallel to the hexagonal c-axis thus obtained. The packing of both ions and the relation between the unit cell in the hexagonal coordinate system ($Z=3$) and that in the rhombohedral coordinate system ($Z=1$) are illustrated in Fig. 1. It is clear that each ion species forms separate layers parallel to the hexagonal basal plane. The octahedron layer seems to be stabilized by electrostatic interaction between the negatively charged octahedra and the positively charged NH_3^+ groups of cations. Then the layers of octahedra are held together by van der Waals interactions between CH_3 residues and Cl atoms. Because the locations of the Cl atoms do not deviate largely from a close-packing of Cl atoms, the stacking sequence of chlorine sheets can be regarded as ABCABC along the hexagonal c-axis.

In the crystal lattice, each cation is tetrahedrally surrounded by four complex anions, while each anion has eight cation neighbors. The CH_3 group of a cation faces the triangle of Cl atoms coming from the same octahedron. The equivalent three C···Cl distances (3.70 Å) are shorter than the van der Waals distance (2.0+1.8=3.8 Å), and much shorter than the corresponding value (3.90 Å) found in CH_3NH_3Cl.[9] However, a reasonable assumption of tetrahedral angles around a methyl carbon atom leads us to speculate that the C–H bond should deviate greatly from the C···Cl direction; the C–H···Cl angle is estimated to be 129° from the coordinates given in Table 2. Therefore, the methyl group of a cation only has contact with three Cl atoms, and can scarcely form C–H···Cl type hydrogen bonds.

The other end of the cation, *i.e.* the NH_3 group, has nine Cl neighbors, three from each of the three $[SnCl_6]^{2-}$ ions. The nine N···Cl distances (three 3.46 and six 3.59 Å) are rather long compared with those in such chloride compounds as: CH_3NH_3Cl (N···Cl=3.18 Å),[9] NH_4Cl (3.35 Å),[10] $NH_4HgCl_3\cdot H_2O$ (3.31—3.41 Å),[11] $C_4N_2O_3H_9Cl\cdot H_2O$ (3.18—3.30 Å),[12] and $C_5H_{10}O_4N\cdot C$ (3.16—3.21 Å).[13] On the other hand, the N···Cl distances in the present $(CH_3NH_3)_2SnCl_6$ are comparable to the 3.55 Å reported for $(NH_4)_2SnCl_6$.[14] As evidenced by the Sn–Cl distance of 2.417 Å at 298 K, as well as the ^{35}Cl-NQR frequency of 15.815 MHz at 300 K,[2] the Sn–Cl bond nature is far less ionic and, consequently the effective charge on the Cl^- ion may be appreciably reduced. Furthermore, each hydrogen atom of an NH_3 group is probably pointed toward nearly the center of a triangle of Cl atoms, forming a trifurcated hydrogen-bond. However the average H···Cl distance (2.75 Å) is too large, and also the average N–H···Cl angle (134°) is too small, for a significant hydrogen-bond interaction. Such an arrangement of the H atoms or a very weak hydrogen-bonding scheme is supported by the PMR results described previously.[3] Thus, the $CH_3NH_3^+$ ion can exhibit the reorientation about its three-fold axis as a whole, instead of the individual or uncorrelated motions of CH_3 and NH_3 groups with different activation energies which are recognized in typical CH_3NH_3Cl and other related compounds.[15,16]

The C–N distances were determined to be 1.49 and 1.52 Å at 298 and 120 K, respectively. Each value, especially the room temperature one, is quite usual for normal single-bond lengths between carbon and quaternary nitrogen atoms, in comparison with those in $(CH_3NH_3)_2MnCl_4$,[17] $(CH_3NH_3)_2ZnCl_4$,[18] and CH_3NH_3Cl.[9] It may be noted that the C–N distance in the high-temperature phase is a little shorter than in the low-temperature one. Such a tendency has been established in chloride perovskite-layer-compounds and interpreted in terms of a change in motion of methylammonium ions.[17,19] But a tilting motion of the C–N bond relative to the c-axis expected above T_t cannot be confirmed by the present study, because the difference in C–N distance is only twice the associated e.s.d. (Table 3).

Thermal Expansion. The lattice constants and the unit-cell volumes are plotted against temperature in Fig. 2, where the ordinate scales are normalized to the

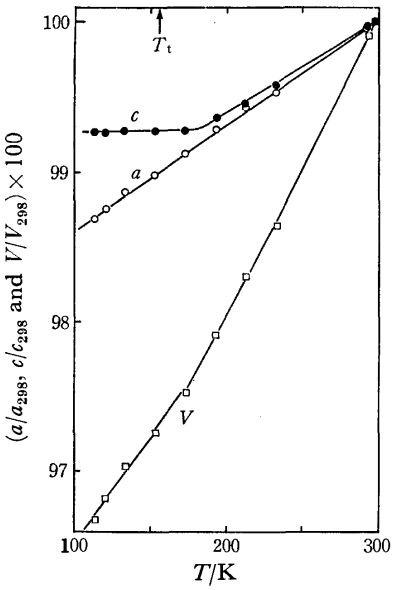

Fig. 2. Variation of a/a_{298}, c/c_{298} and V/V_{298} with temperature, where a_{298} *etc.* stand for the lattice constants at 298 K.

respective values at 298 K. The a-axis length increases steadily with a thermal expansion coefficent $(1/a)da/dT$ of 0.7×10^{-5} over the whole temperature range. On the other hand, the c-axis remains at almost the same length between 120 and 180 K (across T_t), above which it starts to increase with a linear coefficient $(1/c)dc/dT$ of 0.6×10^{-5}. Although this anomaly should be reflected in the volume change, its effect may be largely masked by the more effective expansion of the a-axis. Consequently the unit-cell volume appears to change continuously near T_t, indicating that the phase transition is approximately of a higher order. It is therefore concluded that the detectable change in structure on the phase transition is only the anomaly of the c-axis length. This finding may help us to understand the mechanism of the phase transition.

Very recently, we have found a similar structural phase transition in the trigonal phase of the tellurium(IV) complex, $(CH_3NH_3)_2TeCl_6$, which is isomorphous with the tin(IV) complex.[20]

Phase Transition. The present X-ray work showed that the basic structures are identical above and below T_t. Among the three space groups allowed for a diffraction symmetry of $\bar{3}$m, only R$\bar{3}$m was preferred for both phases. The ^{35}Cl-NQR results, however, suggested the softening of some rotary phonon of the anion octahedra as a mechanism of the phase transition.[2,4] If this is the case, the appearance of a superstructure and/or a small deviation from the space group R$\bar{3}$m would be expected in the low-temperature phase. The first possibility was easily excluded because no extra spot nor superstructure spot was detected on the X-ray photographs in spite of long exposure. On the other hand, the second possibility is likely to happen if the rotary mode of $[SnCl_6]^{2-}$ octahedra about the c-axis, *i.e.* their three-fold axes, softens at the Γ point of the Brillouin zone.

Hence, this possibility was checked by permitting the lowering of the diffraction symmetry. It is evident that all the Cl atoms are equivalent even below T_t, because a single ^{35}Cl-NQR line is observable in the low-temperature phase.[2] Accordingly, the diffraction symmetry should be $\bar{3}$ and then the space group is limited to R$\bar{3}$. Actually the refinement of the low-temperature structure in R$\bar{3}$ yielded a rather poor *R*-value of 0.066. In this trial, however, the Cl atom is displaced only by 0.004 Å, which corresponds to a 0.13° rotation of the $[SnCl_6]^{2-}$ octahedra about the c-axis. Such a very small displacement is of no significance, since it is less than twice of its associated e.s.d. Additionally, taking into account the thermal ellipsoid of the Cl atom, which was rather spherical in the low-temperature phase, we cannot pick out the rotation of $[SnCl_6]^{2-}$ octahedra, at least positively.

In this connection, there arose a new question of whether or not the single crystal might be twinned when it was cooled down below T_t. The shift of the Cl position to either side of the mirror plane in R$\bar{3}$m will produce the identical structure, regardless of its orientation. If such twinning occurs, both individual crystals must be related to each other by a 180° rotation about the [210] direction, followed by a 180° rotation about the c-axis. The diffraction intensity in this case can be expressed by $xF^2(hkl)+yF^2(\bar{k}\bar{h}l)$ instead of the usual $F^2(hkl)$, where x and y stand for the volume fractions of both individuals. Therefore, when the twin effect is neglected, the refinement of the low-temperature structure may lead us to unreasonable positional parameters or incredible thermal parameters, especially for the Cl atom. However, as described previously, the results refined in R$\bar{3}$m (Table 2) as well as the electron density maps are good enough to exclude the occurrence of any twinning.

In conclusion, the X-ray study cannot provide any evidence to support the transition mechanism which has been ascribed to a softening of some rotary lattice mode of the anion octahedra. It is therefore conceivable that the rotation angle of the $[SnCl_6]^{2-}$ ion expected for the low-temperature phase is too small to be detected by the present X-ray experiments. On the other hand, an alternative mechanism was proposed from the structural anomaly in the c-spacing. That is, the phase transition in this compound may be primarily triggered by softening of some acoustic mode at the zone center, because it is accompanied by the bulk deformation but not by any change in the structure.

The authors wish to express their thanks to Professor Emeritus Ryôiti Kiriyama for his continuous encouragement and fruitful discussion. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 154141).

The Low-Energy π,π^* S-S Absorption Spectra of 1,4-Dimethyl- and 1,4-Dichloroanthraquinones

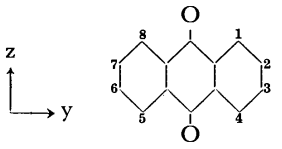
Akira KUBOYAMA

National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151

(Received July 6, 1978)

The very broad absorption band of 1,4-dichloroanthraquinone, which corresponds to the allowed $^1B_{2u}\pi,\pi^*$ band of anthraquinone (AQ), is shown to consist of two π,π^* bands with comparable intensities. The band which corresponds to the ^1A_g forbidden band of AQ is at longer wavelengths than the band corresponding to the $^1B_{2u}$ band of AQ. MO calculations were made, and MCD spectra and 77 K absorption spectra were measured. The very broad absorption band of 1,4-dimethyl-AQ can probably be similarly interpreted. The strong visible π,π^* bands of 1,4- and 1,5-disubstituted AQ's are shown to arise from the ^1A_g and $^1B_{2u}$ bands of AQ respectively.

In the π,π^* S-S absorption spectrum of anthraquinone (AQ) the $^1B_{2u}$ band near 330 nm is the only one so far found in the wavelength region longer than 300 nm.[1-3] According to the P-P-P method[4] calculations,[2,3] a forbidden ^1A_g level is predicted to be located close to this allowed $^1B_{2u}$ level. However, few experimental facts about this ^1A_g forbidden state have been reported.[5] Recently, we noticed that 1,4-dimethyl-AQ seems to show a rather intense band corresponding to the ^1A_g band on the longer wavelength side of the band corresponding to the $^1B_{2u}$ band, and that the P-P-P method calculations support this interpretation. We have therefore studied the π,π^* S-S absorption spectra of various symmetrically substituted dimethyl-AQ's and dichloro-AQ's in this wavelength region.



(AQ)

Experimental

Measurements. The absorption spectra were measured with a Cary 14 M recording spectrophotometer, using cyclohexane as solvent. A Dewar vessel and 1 mm-path cells[6] were used to obtain the absorption spectra at 77 K, using heptane as solvent. The magnetic circular dichroism (MCD) spectra were obtained by a J-40 circular dichroism spectrometer of the Japan Spectroscopic Co., Ltd.,[7] with a magnetic field of 3500 Gauss, using cyclohexane as solvent.

Materials. Commercially-available AQ was zone-refined (mp 286.6—287.2 °C). Commercially-available 1,4-dimethyl-AQ and 1-chloro-AQ were purified by vacuum sublimation (mp 141.0—142.0 °C and 159.0—160.5 °C). Commercially-available 2,3-dimethyl-AQ and 1,5-dichloro-AQ were twice recrystallized, from a toluene and cyclohexane (1:2) mixture and from acetic acid respectively (mp 207.5—208.8 °C and 243.3—244.0 °C). According to the method described in the literature,[8] 1,4-dichloro-AQ was synthesized, purified by liquid chromatography on alumina using toluene as developer, and obtained as yellow crystals[9] (mp 190.5—191.0 °C). Commercially-available heptane and cyclohexane of spectrograde quality were used.

Results. The absorption and MCD spectra obtained are shown in Figs. 1—4. The wavelengths and molar absorption coefficients of the absorption maxima in these absorption spectra are shown in Table 1. The MCD spectra were obtain-

carbon atoms was taken as −9.00 eV, considering only the inductive effect of the methyl group, as in the previous work.[3] The core Coulomb integral and two-center electron repulsion integral of chlorine atoms and the core resonance integral of the C–Cl bonds were taken as −25.00, 14.30, and −0.75 eV respectively.[10] In the calculations, the lowest thirty singly-excited configurations were included. The dimension of the AQ skeleton in the AQ derivatives was that of AQ.[3] The bond length of the C–Cl bonds was assumed to be 1.75 Å.

Results. The calculated results for the three lowest-energy singlet excited states of AQ and the symmetrically substituted dimethyl-AQ's are shown in Table 2: the first column indicates the numbering of the states in order of increasing excitation energies (calculated). In Fig. 5, the calculated results for 1,4-dichloro-AQ, taking −0.75 and −1.50 eV for the core Coulomb integral values of the C–Cl bonds, are shown together with that for AQ.

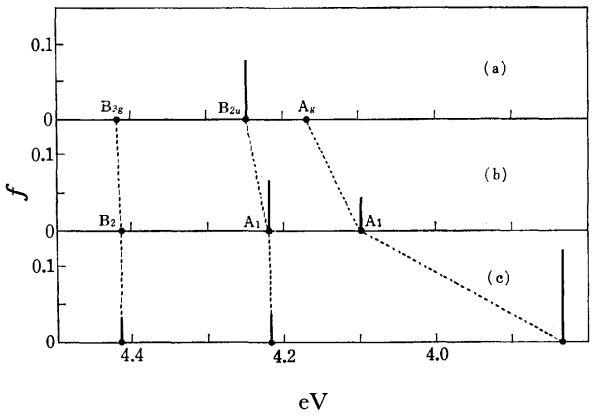

Fig. 5. Comparisons of the calculated excitation energies and oscillator strengths of the low-energy π,π^* states of AQ and 1,4-dichloro-AQ.
a) AQ, b) 1,4-dichloro-AQ (β(C–Cl) = −0.75 eV), c) 1,4-dichloro-AQ (β(C–Cl) = −1.50 eV).

Discussion

The absorption band of AQ in Fig. 1 has been theoretically and experimentally assigned to the $^1B_{2u}$ band by many authors.[1-3] In the absorption band of 1,4-dimethyl-AQ in Fig. 1, the absorption maximum is at far longer wavelengths than those for AQ and 2,3-dimethyl-AQ, and the half-width (5170 cm^{-1}) is far larger than those for the latter (3850 and 4210 cm^{-1} respectively). In Fig. 2, the absorption spectrum of 1,4-dichloro-AQ, which is far broader than that of 1,5-dichloro-AQ, is similar to that of 1,4-dimethyl-AQ in position and shape. The absorption spectra of 1,8-dichloro-AQ[11] and 2,6-dichloro-AQ[12] reported by other authors in this wavelength region are similar to those of 1,5-dichloro-AQ and AQ respectively in position and shape. From these facts, it may be considered that in 1,4-dimethyl-AQ and 1,4-dichloro-AQ, a band corresponding to that ^1A_g band appears with a considerable intensity on the longer wavelength side of the band corresponding to the $^1B_{2u}$ band.

In Table 2, the three lowest-energy π,π^* states, the Nos. 1—3 states, of all the dimethyl-AQ's correspond to the Nos. 1—3 states of AQ: the ^1A_g, $^1B_{2u}$, and $^1B_{3g}$ states respectively. As may be seen in Table 2, only in 1,4-dimethyl-AQ does the No. 1 state have a relatively large oscillator strength; there its energy is considerably lower than that of the ^1A_g state of AQ. Similar calculated results were obtained for 1,4-dichloro-AQ. These calculated results support the above assignment of the π,π^* spectra of 1,4-dimethyl-AQ and 1,4-dichloro-AQ. In these two AQ's, on the basis of the calculated results, it has been proved that the excitations to the Nos. 1 and

2 states have the character of a charge-transfer from the carbon atoms of the 1- and 4-positions and the 5- and 8-positions, respectively, to the carbonyl groups.

In the absorption spectra of 1,4-dimethyl-AQ and 1,5-dichloro-AQ, the two $^1A_1$ bands corresponding to the excitations to the Nos. 1 and 2 states can not be discriminated by the usual dichroism measurements. In this work, therefore, their MCD spectra and that of AQ[13] in this wavelength region have been measured. Since these compounds have no electronic degenerate states, all the MCD spectra obtained are B-type.[13,14] In Fig. 3, the MCD spectrum of 1,4-dichloro-AQ consists of a negative and a positive band in the longer and shorter wavelength regions, respectively, while those of AQ and 1,4-dimethyl-AQ show only a positive spectrum. On the basis of these results, the absorption spectrum of 1,4-dichloro-AQ may be concluded to consist of two absorption bands, one of which is at longer wavelengths than the other. This result proves the previous assignment of the spectrum of 1,4-dichloro-AQ to be correct. On the other hand, the sign of the MCD in the longer wavelength region of the absorption spectrum of 1,4-dimethyl-AQ is opposite to that for 1,4-dichloro-AQ. In general, the MCD for originally forbidden bands may be expected to depend strongly on the substituents, as in the case of the L_b bands of benzene derivatives.[15] In 1,4-dimethyl-AQ, the calculated results show that the electron-donative inductive effect of the two methyl groups plays an important role in the intensity enhancement of the longer wavelength $^1A_1$ band. On the other hand, in 1,4-dichloro-AQ, the calculated results show that the electron-attractive resonance effect of the two chlorine atoms does so. Therefore, this difference of the electronic property between these two substituents may be expected to bring about the above mentioned difference of the MCD sign.

In the absorption spectra of 1,4-dichloro-AQ (Fig. 2) and 1-chloro-AQ (Fig. 4) in the heptane solutions at 77 K, four sharp peaks[16] are observed in the longer wavelength region; they may be assigned to the $^1A_1$ band corresponding to the ^1A_g band of AQ. In the absorption spectrum of 1-chloro-AQ in the heptane solution at room temperature (Fig. 4), therefore, the shoulder on the longer wavelength side may also be assigned in the same way. In the absorption spectrum of 1,4-dimethyl-AQ at room temperature (Fig. 1), a small but relatively sharp shoulder is observed near 330 nm on the broad absorption curve; this may be considered to belong to the $^1A_1$ band corresponding to the $^1B_{2u}$ band of AQ. This peak may correspond to Peak III in the 77 K spectrum (Fig. 1), and the sharp Peak I in the latter spectrum may be considered to belong to the $^1A_1$ band corresponding to the ^1A_g band of AQ, as in the case of 1,4-dichloro-AQ. On the basis of the theoretically and experimentally obtained results for the absorption spectrum of 1,4-dimethyl-AQ, it may be considered that the assignment of that spectrum is also likely to be correct.

In Fig. 5, an increase of the absolute value of the core Coulomb integral of the C–Cl bonds means an increase of the electron-donative power of the chlorine atoms. In 1,4-dichloro-AQ (Fig. 5), the lower $^1A_1$ level (the No. 1 level) drops significantly and its oscillator strength becomes strikingly larger, with an increase in the absolute value of that integral, while the higher $^1A_1$ level (the No. 2 level) shows almost no change and its oscillator strength becomes considerably smaller. On the other hand, in 1,5-dichloro-AQ, the ^1A_g levels are the forbidden levels, and the ^1B_u level drops considerably and its oscillator strength becomes markedly larger with an increase in the absolute value of that integral. On the basis of these calculated results, the strong π,π^* bands of 1,4-dihydroxy-AQ[17] and 1,4-diamino-AQ[18,19] and 1,5-dihydroxy-AQ[17] and 1,5-diamino-AQ[18] in the visible range may be concluded to arise from the $^1A_g \leftarrow {}^1A_g$ and $^1B_{2u} \leftarrow {}^1A_g$ transitions of AQ respectively, and the relatively weak π,π^* bands of 1,4-dihydroxy-AQ and 1,4-diamino-AQ near 330 nm to arise from the $^1B_{2u} \leftarrow {}^1A_g$ transition of AQ. This conclusion about the spectra of these 1,4-disubstituted AQ's is consistent with the polarized absorption spectra of 1,4-diamino-AQ reported by Inoue *et al.*[19] and Labhart.[20]

The author is grateful to Mr. A. Takakuwa of the Japan Spectroscopic Co., Ltd., and to Prof. M. Miwa and Dr. T. Komiyama of Seikei University for their helpful cooperation in obtaining the MCD spectra.

Ab initio LCAO MO SCF CI Calculations on the Electronic Structure of the Cyclopropenyl Cation

Toshikazu TAKADA* and Kimio OHNO

Department of Chemistry, Faculty of Science, Hokkaido University, Kita-ku, Sapporo 060

(Received July 14, 1978)

Ab initio LCAO MO SCF and limited CI calculations are carried out on the electronic structure of the $C_3H_3^+$ ion. Two kinds of basis sets are used, namely the minimal STO's and the minimal STO's plus 3d orbitals on each carbon atom. With the latter basis, the equilibrium C–C distance is calculated to be 1.389 Å. It is predicted that the C–C bond distance of $C_3H_3^+$ is shorter than that of C_6H_6. The calculated C–C stretching force constant is 7.92 mdyn/Å and is close to the experimental value 6.59 mdyn/Å. Contour diagrams of the charge distribution of valence electrons are drawn and it is revealed that the calculated C–C bonds are bent and have two maxima in charge density. In terms of population analysis of localized MO's, it is shown that the C–H bond in this molecule has a higher s-character than the C–H bonds in C_2H_4 and C_6H_6 and is close to an sp hybrid. This is in accord with a very large NMR coupling constant $J_{^{13}C-H}$. From CI calculations of low lying excited states, singlet σ-π^* states ($^1A_1''$, $^1E''$, $^1A_2''$) are calculated to be lower than the singlet π-π^* state ($^1E'$).

The cyclopropenyl cations are the smallest ring systems which have two π-electrons and satisfy the Hückel $4n+2$ rule. Their electronic structures are of great interest since the molecules are highly strained. The simplest one, $C_3H_3^+$, has been synthesized by Breslow and Groves.[1] The D_{3h} configuration of the ion is indicated on the basis of the IR and NMR spectra.[1] One might think that the C–C bonds in this system would be weaker than the usual C–C bonds such as those in C_6H_6 and thus the equilibrium C–C bond distance would be longer and the C–C stretching force constant smaller. Apparently, this is not the case. X-Ray diffraction shows that trisdimethylaminocyclopropenyl cation has a regular triangle cyclopropenyl ring with a C–C bond length of 1.363 Å[2] and that the C–C bond length of triphenylcyclopropenyl cation is 1.373 Å.[3] These values are significantly smaller than the C–C bond distance of 1.397 Å[4] in C_6H_6. From IR spectra, the Urey-Bradley force constant of the ring C–C stretching of $C_3H_3^+$ has been estimated to be 6.590 mdyn/Å,**,[5] which is larger than the C_6H_6 value of 5.78 mdyn/Å.[6]

In spite of these immense theoretical interest, there have been only three *ab initio* all-electron calculations on $C_3H_3^+$ as far as the authors are aware. Clark carried out *ab initio* LCAO SCF MO calculations on both $C_3H_3^+$ and $C_3H_3^-$ and discussed the aromaticity and antiaromaticity.[7] Ha, Graf and Günthard reported an extensive *ab initio* LCAO SCF MO investigation on $C_3H_3^+$, C_3H_3, and $C_3H_3^-$ and discussed the geometry and stability of these species.[8] Their basis set consists of Gaussian lobe functions and is approximately of the double zeta quality. Radom, Hariharan, Pople, and Schleyer also carried out *ab initio* LCAO SCF MO calculation on $C_3H_3^+$ using STO-3G and 6-31G and obtained the equilibrium structure of the ion.[9]

In this paper, the results of *ab initio* LCAO MO SCF CI calculations on $C_3H_3^+$ are reported. The C–C bond distance is varied and the equilibrium C–C distance and the C–C stretching force constant are calculated and are compared with experiment. The occupied MO's are transformed into localized MO's and the nature of the C–C and C–H bonds is discussed in terms of the contour diagrams of the charge distribution and the population analysis of these localized MO's. CI calculations of the low lying excited states are carried out for the first time and the character of these states is discussed.

Method of Calculations

The wave functions of $C_3H_3^+$ are obtained by *ab initio* LCAO MO SCF and CI calculations. Two kinds of basis sets are used. One is the minimal STO's. The other is the minimal STO's plus 3d orbitals on each carbon atom. One reason for adding the 3d orbitals is to hope for a better description of the bent C–C bonds. The former basis is called Min. and the latter Min.+C3d, hereafter. The orbital exponents adopted are shown in Table 1. The values of H1s and C1s, 2s and 2p orbitals are optimized for C_6H_6 by Hehre, *et al.*[10] The exponents of C3d orbitals are optimized for CO by Nesbet.[11] In the evaluation of molecular integrals, these STO's are expanded in terms of GTO's; the H1s and C1s, 2s and 2p orbitals are expanded by five GTO's and the C3d orbitals by three GTO's, respectively. The expansion coefficients are those given by Stewart.[12]

Table 1. Orbital exponents

H1s	1.21
C1s	5.67
2s, $2p_v$,[a] $2p_h$,[b] $2p_z$	1.71
$3d_{z^2}$, $3d_{h^2-v^2}$, $3d_{hv}$	1.895
$3d_{hz}$, $3d_{vz}$	1.429

a) The v axis is pointing towards the partner H atom.
b) The h axis is in the molecular plane and perpendicular to the v axis.

In the CI calculations, configuration state functions are constructed as follows. All single and double excitations are considered from $2a_1'$, $2e'$, $3a_1'$, $3e'$, and $1a_2''$ to $1e''$, $1a_2'$, $4e'$, $4a_1'$, $2e''$, $2a_2''$, $5e'$, $5a_1'$, and $3e''$ orbitals (These orbitals are indicated by * in Table 2 in Section 3.). Other molecular orbitals are excluded, that

** This value is obtained by assuming that the C–C bond distance of $C_3H_3^+$ is equal to that of triphenylcyclopropenyl cation.

is, $1a_1'$ and $1e'$ as core and the orbitals whose energies are greater than 1.0 a.u. This is called occupation Scheme I. In another choice, occupation Scheme II, only single and double excitations from the four highest occupied MO's $3a_1'$, $3e'$, and $1a_2''$ to the six lowest unoccupied MO's $1e''$, $1a_2'$, $4e'$, and $4a_1'$ are taken into account. The method of the first order interacting space proposed by McLean and Liu[13] is employed in order to reduce the number of configuration state functions without sacrificing the accuracy too much.

The D_{3h} configuration is assumed in the present calculations. This configuration is indicated on the basis of the IR and NMR spectra[1] and is supported theoretically by Ha and others.[8] The C–H internuclear distance is fixed at 1.09 Å which is the observed C–H distance in C_6H_6.[14] The calculation is repeated for the following six C–C distances, 1.300, 1.350, 1.375, 1.400, 1.425, and 1.500 Å. The calculated energy curve is expressed as a fifth degree polynominal of the C–C distance and the minimum energy, the equilibrium C–C distance and the C–C stretching force constant are determined.

In order to investigate the nature of C–C and C–H bonds of the system, the resulting MO's are transformed into localized MO's by a unitary transformation. The measure of localization proposed by Hall[15] and applied extensively by Edmiston and Ruedenberg[16] is adopted. This is to maximize the total self-energy of the orbitals. The unitary transformation is applied only to the valence MO's. Namely the three lowest MO's, $1a_1'$ and $1e'$, are omitted since, in our opinion, the distinction between valence electrons and inner-shell electrons is more fundamental than the requirement of "localization."

Results and Discussion

The calculated potential curves are illustrated in Fig. 1. In the ground state CI calculations, the occupation Scheme I is used. The orbital energies are given in Table 2. The values in the parentheses are those

for the C–C bond distance of 1.400 Å, which is used by Ha and others.[8] Although their absolute values are larger than our values by 0.08—0.23 a.u., the order is the same and the relative positions are very similar between the two calculations.

Equilibrium C–C Bond Distance and the C–C Stretching Force Constant. By using the results shown in Fig. 1, the equilibrium C–C bond distance R^e_{C-C} and the stretching force constant k_{C-C} are determined. First, R^e_{C-C} and $k_{A_1'}$ (stretching force constant of totally symmetric vibrational mode) are calculated by expanding the potential curves in terms of a polynominal of fifth degree. Next, if we neglect the cross terms such as $\Delta r_1 \Delta r_2$ in the expansion, k_{C-C} is one third of $k_{A_1'}$. By using this relation, k_{C-C} is estimated. The R^e_{C-C} and k_{C-C} are given in Table 3 with the results of the previous calculations. It is noted that the C–C bond distance becomes larger and the C–C stretching force constant smaller by the CI calculation in comparison with the SCF results. The calculated C–C distance by CI with the Min.+C3d basis is close to the observed values at the substituted cyclopropenyl cations.[2,3] The equilibrium C–C distance of C_6H_6 is calculated to be 1.39 Å in the SCF calculation by Newton and others.[17] Since the calculated value of R^e_{C-C} of $C_3H_3^+$ at the SCF level is smaller than this value, the equilibrium C–C distance of $C_3H_3^+$ is expected to be smaller than that of C_6H_6. The C–C bond distance of $C_3H_3^+$ has not been determined experimentally so far.

The calculated C–C stretching force constants are improved by CI and the CI results are in fair agreement with experiment. However, it is difficult to say whether the C–C stretching force constant of $C_3H_3^+$ would be greater than that of C_6H_6, or not. One will have to calculate the stretching force constant of C_6H_6 in the same manner and to compare the result with that of $C_3H_3^+$.

Charge Distribution and Localized Molecular Orbitals. The σ-bonds of three membered ring molecules would have the maxima of charge distribution outside the ring, that is, the bonds are bent. X-Ray diffraction showed that cyclopropane has such bent bonds.[18] In order to examine whether the calculated C–C bonds of $C_3H_3^+$ are bent or not, the contour diagrams of the charge distribution of the valence electrons are drawn, using the ground state wave functions obtained by the Min. and Min.+C3d SCF calculations and are shown in Figs. 2 and 3, respectively. The contributions of the three lowest molecular orbitals, $1a_1'$ and $1e'$, are excluded since they consist of mainly carbon core orbitals. According to these figures, the C–C bonds of

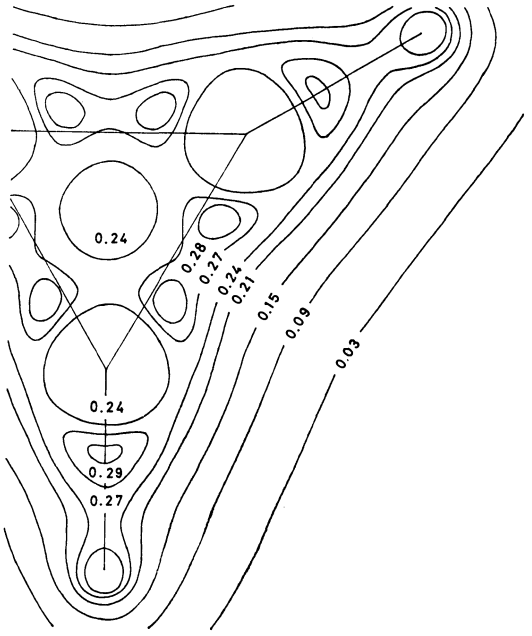

Fig. 2. Valence electron density (e/a.u.^{3}) in $C_3H_3^+$ obtained from Min. SCF.

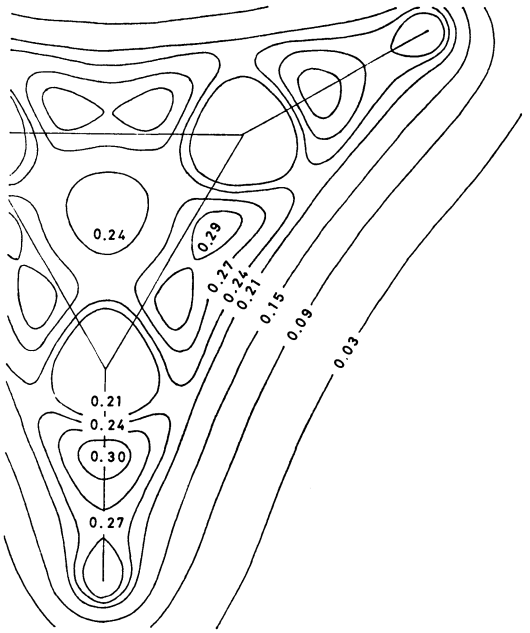

Fig. 3. Valence electron density (e/a.u.^{3}) in $C_3H_3^+$ obtained from Min.+C3d SCF.

$C_3H_3^+$ are bent having the two maxima of charge density. Ha and others also reported a similar diagram of $C_3H_3^+$.[8] However, because of the existence of the inner-shell electrons, the positions of the maxima of C–C and C–H bonds and the degree of the bending were not so clear. It is interesting to note that the charge density in the C–C and C–H bond regions increases by the addition of 3d orbitals, as is clear from Figs. 2 and 3.

The localized MO's have certain advantages over cannonical MO's in describing a bond. The occupied MO's are thus transformed into the localized MO's by the Edmiston and Ruedenberg procedure.[16] This is carried through with the Min. basis. The contour diagrams of charge distribution of the localized MO's

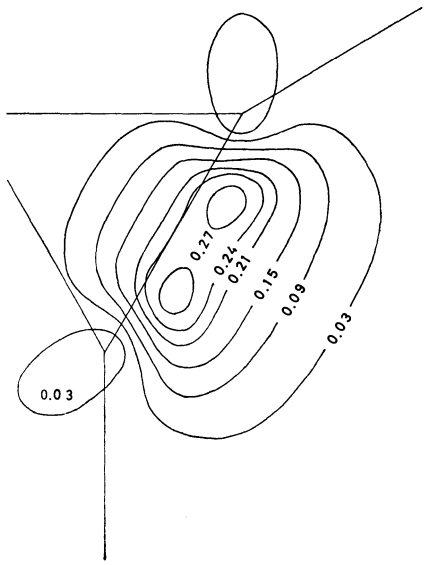

Fig. 4. Electron density (e/a.u.^{3}) of two electrons in a localized C–C orbital in $C_3H_3^+$.

	sp^x		$J_{^{13}C-H}$(Hz)
	C–C	C–H	
C_2H_4	1.74	1.85[a]	157[b]
C_6H_6	1.73	1.87[a]	159[b]
$C_3H_3^+$	2.28	0.99	265[c]

a) See Ref. 20. b) See Ref. 21. c) See Ref. 1.

corresponding to the C–C and C–H bonds are illustrated in Figs. 4 and 5, respectively.

The ratio of 2s and 2p orbitals in a hybrid sp^x is estimated by the coefficients of these localized MO's. The values of x are given by $(C_{2ph}^2+C_{2pv}^2)/C_{2s}^2$, where C_{2s}, C_{2ph}, and C_{2pv} are the coefficients of STO's in the localized MO's. Newton and others reported the ratio for several molecules determined by the same procedure.[19,20] The ratio for $C_3H_3^+$ is compared with their results of C_2H_4 and C_6H_6 in Table 4. It is seen that the localized MO's of C_2H_4 and C_6H_6 are rather similar to the sp^2 hybrid orbitals in the region around the carbon nuclei. In the same region, the C–H bond orbital of $C_3H_3^+$ has a higher s-character than C_2H_4 and C_6H_6 and is closer to an sp hybrid. Breslow pointed out that the ^{13}C–H coupling constant $J_{^{13}C-H}$ of NMR spectra of $C_3H_3^+$ is quite large.[1] The values of coupling constant of C_2H_4, C_6H_6,[21] and $C_3H_3^+$ are also included in Table 4. As was shown by Ramsey,[22] the Fermi contact term which gives a dominant contribution to the constant, is proportional to the density of s-electrons at the two nuclei. In Table 4, this relation is seen to hold approximately, namely, $1/3: 1/2 \simeq 159: 265$.

Low Lying Excited States. The electronic structure

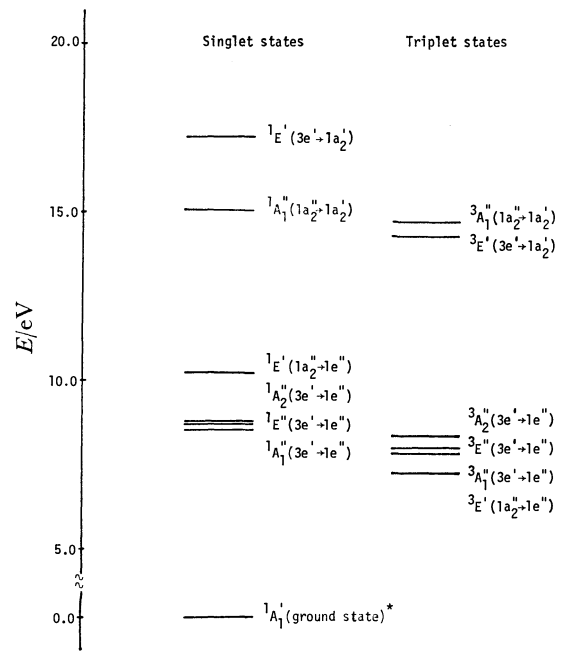

Fig. 6. Excitation energies of $C_3H_3^+$.
* -114.8003 a.u. obtained by CI calculation with occupation II basis. Dimension of CI is 140 in C_{2v} symmetry.

of excited states in highly strained molecules is of considerable experimental and theoretical interest. The excitation energies of $C_3H_3^+$ has never been measured, probably because of its instability. CI calculations of the low lying excited states of $C_3H_3^+$ are carried out for the geometry with the C–C bond distance of 1.400 Å and the results are given in Fig. 6. In these calculations, the occupation Scheme II is used. The values in Fig. 6. are the excitation energies of the π-$\pi^*(1a_2'' \rightarrow 1e'')$, π-$\sigma^*(1a_2'' \rightarrow 1a_2')$, σ-$\pi^*(3e' \rightarrow 1e'')$, and σ-$\sigma^*(3e' \rightarrow 1a_2')$ states. It should be noted that the singlet σ-π^* states ($^1A_1''$, $^1E''$, $^1A_2''$) are lower than the singlet π-π^* state ($^1E'$). All excited states are represented well by a single configuration except for the singlet σ-σ^* state ($^1E'$) and in these states the weights of the leading configurations are as big as 82—96%. In the singlet σ-σ^* state ($^1E'$), the weight of leading configuration is 47% and that of $(3a_1')^2(3e')^3(1a_2'')^2(4e')^1$ is 36%.

Conclusions

The LCAO MO SCF and CI calculations are carried out on the electronic structure of $C_3H_3^+$ and the following conclusions are obtained.

1. The calculated C–C bond distance of $C_3H_3^+$ is 1.389 Å. This is close to the experimental values of the substituted cyclopropenyl cations. The C–C distance of $C_3H_3^+$ is expected to be shorter than that of C_6H_6. The C–C stretching force constant is calculated to be 7.92 mdyn/Å, and is close to the experimental value of 6.59 mdyn/Å.

2. The contour diagram of the charge distribution of valence electrons indicates that the σ-bonds of $C_3H_3^+$ are bent outwardly.

3. The ratio, x of a hybrid orbital sp^x to be found in $C_3H_3^+$ is estimated by the coefficients in the localized MO's. The value x of the C–H bond is 0.99 reflecting that the bond has a larger s-character, compared with the C–H bonds in C_2H_4 and C_6H_6. This is in accord with the very large NMR coupling constant J^{13}_{C-H} of the ion.

4. The low lying excited states of $C_3H_3^+$ are calculated by the CI calculations. The singlet σ-π^* state ($^1A_1''$, $^1E''$, $^1A_2''$) are lower than the singlet π-π^* state ($^1E'$).

We wish to thank Professor Fukashi Sasaki, Professor Hiroshi Kashiwagi, Dr. Kiyoshi Tanaka, and Dr. Hiroshi Tatewaki for helpful suggestions and discussions. Thanks are also due to Dr. Kiyoshi Tanaka, Dr. Hiroshi Tatewaki, Mr. Tsutomu Nomura, and Dr. Takeshi Noro for making their CI program package COMICAL available. The calculations reported in this paper were carried out on the FACOM 230-75 computer at the Hokkaido University Computing Center.

Molecular Motion in Ammonium Hydrogendifluoride Studied by Pulsed NMR

Yoshihiro FURUKAWA* and Hideko KIRIYAMA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 17, 1978)

The proton and fluorine-19 spin-lattice relaxation times, T_1 and $T_{1\rho}$, in polycrystalline ammonium hydrogendifluoride were measured in the temperature range 142—345 K to elucidate the molecular motion of cation and anion. Below 200 K, the relaxation rates of both nuclei can be accounted for by dipolar interactions modulated *via* the isotropic reorientation of NH_4^+ ions. The log $T_{1\rho}$ *versus* $1/T$ curves above 200 K exhibit two distinct minima, suggesting that two crystallographically nonequivalent HF_2^- ions undergo 180°-flips about their two-fold axes with different correlation times. The activation energy of the NH_4^+ reorientation was determined to be 25.5 ± 1.0 kJ/mol from the T_1 data, while those of the 180°-flips were estimated from the $T_{1\rho}$ data to be about 40 and 60 kJ/mol for the two types of anions. These relaxation mechanisms have been confirmed by further experiments on a partially deuterated sample.

A series of alkali-metal hydrogendifluorides have occasioned much interest in the very short, nearly symmetric hydrogen-bond of the $[F\text{–}H\text{–}F]^-$ ion and in the motional state of such a dumbbell-like anion. The hydrogendifluorides of heavy alkali-metals, such as K, Rb, and Cs, transform to cubic phases at high temperatures because rapid, random reorientations of linear HF_2^- ions give rise to an effectively cubic symmetry.[1] It was also recognized from the previous NMR measurements that the HF_2^- ions are 180°-flipping in the low-temperature phase.[2,3] On the other hand, the compounds of light alkali-metals such as Li and Na, and of NH_4^+, have no phase transitions, suggesting that even if the 180°-flip motion takes place, it persists up to their melting points. The NH_4^+ ion has some freedom of reorientation and a possibility of forming another type of hydrogen bond between $N(NH_4^+)$ and $F(HF_2^-)$ in addition to the hydrogen bond in an $[F\text{–}H\text{–}F]^-$ ion just described. It is therefore worthwhile to investigate the ionic motions of nearly spherical NH_4^+ and dumbbell-like HF_2^- ions in NH_4HF_2 crystals and to compare the results obtained with those in potassium hydrogendifluoride.[3]

The crystal structure of NH_4HF_2 contains four chemical formula units in its orthorhombic cell; the HF_2^- ions are distinguished between two crystallographically nonequivalent $HF_2^-(1)$ and $HF_2^-(2)$, whereas the ammonium ions are all equivalent.[4] The crystal structure can be described as a superstructure of the caesium chloride type, although it is distorted by the presence of rod-shaped HF_2^- ions and by interionic hydrogen bonds.

In this paper, the results of pulsed NMR of both ^1H and ^{19}F nuclei in NH_4HF_2 are reported, and models of the isotropic reorientation of the NH_4^+ ion and the two types of 180°-flipping of the HF_2^- ions are proposed.

Experimental

Powdered NH_4HF_2 was prepared from an aqueous solution of NH_4F and a slight excess of HF acid; it was then recrystallized twice from the aqueous solution. The sample used was identified from its X-ray powder diffraction pattern.[4]

A Bruker B-KR 322s frequency-variable, pulsed NMR spectrometer was employed to determine the magnetic relaxation times, T_1 and $T_{1\rho}$, of ^1H and ^{19}F nuclei. The spin-lattice relaxation time, T_1, was measured by use of the 180°-t-90° pulse sequence at 60 and 20 MHz for ^1H and at 56.442 and 18.814 MHz for ^{19}F nuclei. The relaxation time in the rotating frame, $T_{1\rho}$, was determined by the spin-locking method. The temperature of the sample was controlled to within ±0.5 K by using an Ohkura EC 61 temperature controller and was measured with a copper-constantan thermocouple calibrated before measurements.

Results

Figure 1 shows the temperature dependences, as a semilogarithmic plot *versus* inverse temperature, of proton $T_1(H)$ and fluorine-19 $T_1(F)$ obtained at 60 and 56.442 MHz respectively, together with the $T_{1\rho}(H)$ at the r.f. field strength 10 G. The $T_{1\rho}(F)$ could not be measured because of its poor signal, resulting from a very short free-induction-decay (FID). Below about 200 K, the magnetization-recovery curve for the T_1 process of either nucleus became markedly non-exponential, owing to heteronuclear H–F dipole interaction.[5] The recovery curve was, therefore, resolved into two exponential terms, according to the equation $<I_0-I_z>/2I_0=A\exp(-t/T_1')+B\exp(-t/T_1'')$; here I_z and I_0 are the z-components of the I-spin (^1H or ^{19}F) magnetization at time t and at thermal equilibrium, respectively, A and B are constants, and T_1' and T_1'' denote the short and long relaxation times, respectively.[3] Above 200 K, although the recovery curve was slightly non-exponential, the T_1 value as well as the $T_{1\rho}$ one was approximated by a single relaxation time, which was defined as the time necessary for the $<I_0-I_z>/2I_0$ to fall to $1/e$ of its initial value. The frequency dependence of the T_1 value was examined by additional measurements at 20 MHz for ^1H and 18.814 MHz for ^{19}F nuclei; these plots were omitted from Fig. 1 for simplicity.

The log $T_1(H)$ *vs.* $1/T$ curve at 60 MHz exhibits a deep T_1 minimum at $kK/T\approx4.4$; the corresponding $T_{1\rho}$ minimum occurs at $kK/T\approx6.6$. Two additional $T_{1\rho}$ minima are recognized at $kK/T\approx3.0$ and 4.0, indicating that the molecular motions of NH_4^+ and/or HF_2^- ions are rather complex within the crystal lattice.

In order to uncover further details of the ionic motion in the high-temperature region, the measurements of the $T_1(F)$ and $T_{1\rho}(F)$ were extended to a sample of partially deuterated NH_4HF_2. The results are shown as

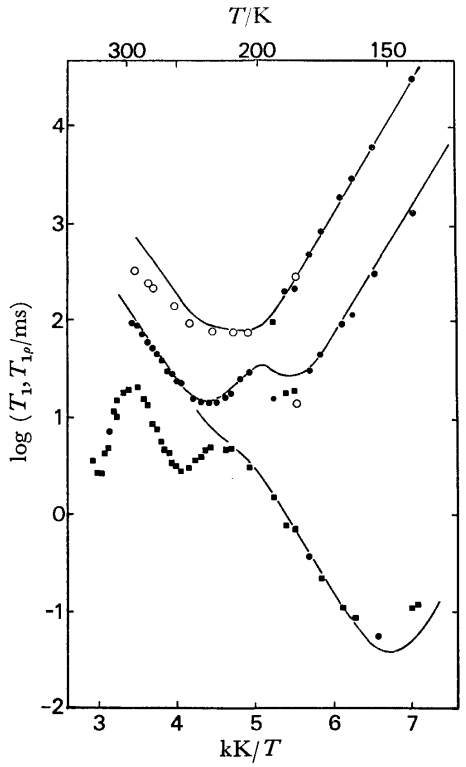

Fig. 1. Temperature dependences of spin-lattice relaxation times in NH_4HF_2: (●) T_1(H) at 60 MHz, (○) T_1(F) at 56.442 MHz, and (■) $T_{1\rho}$(H) at 10 G. The solid lines indicate the calculated temperature dependences of T_1 and $T_{1\rho}$(H) for randomly reorienting NH_4^+ ions.

experimental points in Fig. 2. The deuterium content was estimated to be about 65% from the ratio of the T_1(F) minimum value for the nondeuterated sample to that for the partially deuterated one; these minima will be assigned to the NH_4^+ isotropic reorientation later.

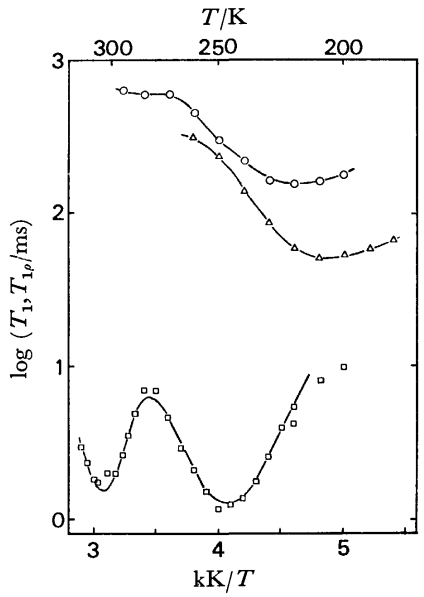

Fig. 2. Temperature dependences of spin-lattice relaxation times in 65% *d*-NH_4HF_2: (○) T_1(F) at 56.442 MHz, (△) T_1(F) at 18.814 MHz, and (□) $T_{1\rho}$(F) at 6.5 G. The lines are drawn to guide the eye.

Isotropic Reorientation of NH_4^+ Ions. The relaxation process for T_1 below room temperature is ascribable to NH_4^+ isotropic reorientation, because such a short T_1(H) minimum as 14 ms is characteristic of NH_4^+ reorientation. In this case, the ^1H relaxation rate is governed mainly by the intraionic H–H dipolar interaction and partially by the interionic dipolar interactions, $H(NH_4^+)$–$H(NH_4^+)$ and $H(NH_4^+)$–$H(HF_2^-)$, and the heteronuclear $H(NH_4^+)$–$F(HF_2^-)$ one. Among these, the contribution of the homonuclear H–H interaction to the ^1H relaxation rate is expressed as follows:

$$T_1(\mathrm{HH})^{-1} = (2/3)\gamma_H^2 \Delta M_{HH} f(\omega_H, \tau_H), \quad (1a)$$

$$f(\omega, \tau) = \tau/(1+\omega^2\tau^2) + 4\tau/(1+4\omega^2\tau^2). \quad (1b)$$

The quantity ΔM_{HH} is the reduction in the second moment of the ^1H absorption spectrum due to the H–H dipolar interaction associated with the NH_4^+ reorientation; τ_H stands for the correlation time for the NH_4^+ motion; the other symbols have their usual meaning.

On the other hand, the relaxation due to heteronuclear dipole interaction between ^1H and ^{19}F nuclei can be expressed by the following pair of coupled equations:[5]

$$\mathrm{d}\langle I_z\rangle/\mathrm{d}t = -\langle I_z - I_0\rangle/T_1(\mathrm{IS}) - \langle S_z - S_0\rangle/T_1'(\mathrm{IS}), \quad (2a)$$

$$\mathrm{d}\langle S_z\rangle/\mathrm{d}t = -\langle I_z - I_0\rangle/T_1'(\mathrm{SI}) - \langle S_z - S_0\rangle/T_1(\mathrm{SI}), \quad (2b)$$

where I and S stand for H and F, respectively. Each relaxation time in Eq. 2 can be calculated in the same manner as with $(NH_4)_2BeF_4$.[5] Thus,

$$T_1(\mathrm{FH})^{-1} = (3/16)\gamma_F^2 \Delta M_{FH} g(\omega_F, \omega_H, \tau_H), \quad (3a)$$

$$T_1'(\mathrm{FH})^{-1} = (3/16)\gamma_F^2 \Delta M_{FH} g'(\omega_F, \omega_H, \tau_H), \quad (3b)$$

$$g(\omega_I, \omega_S, \tau) = \tau/[1+(\omega_I-\omega_S)^2\tau^2] + 3\tau/(1+\omega_I^2\tau^2) + 6\tau/[1+(\omega_I+\omega_S)^2\tau^2], \quad (3c)$$

$$g'(\omega_I, \omega_S, \tau) = -\tau/[1+(\omega_I-\omega_S)^2\tau^2] + 6\tau/[1+(\omega_I+\omega_S)^2\tau^2]. \quad (3d)$$

The ΔM_{FH} is again the reduction in the ^{19}F second moment due to the F–H dipolar interaction *via* the NH_4^+ reorientation. By taking into account the abundances of ^1H and ^{19}F nuclei in the crystal,[5] the ^1H relaxation rates due to the heteronuclear H–F interaction, $T_1(\mathrm{HF})^{-1}$ and $T_1'(\mathrm{HF})^{-1}$, can be easily related to Eq. 3. The $T_1(\mathrm{FF})^{-1}$ of course, need not be considered because the F–F dipole interaction is not modulated *via* the NH_4^+ reorientation. The observed relaxation rates are given by the eigenvalues of the relaxation matrix:

$$\begin{pmatrix} T_1(\mathrm{HH})^{-1} + T_1(\mathrm{HF})^{-1} & T_1'(\mathrm{HF})^{-1} \\ T_1'(\mathrm{FH})^{-1} & T_1(\mathrm{FH})^{-1} \end{pmatrix}.$$

The ΔM_{HH} value was first evaluated from the atomic positions as determined by X-rays.[4] It was too large to explain the observed T_1(H) minimum, because of the rather short N–H distance (0.88 Å) used. So the values of ΔM_{HH} and ΔM_{FH} were recalculated by taking the r(N–H) distance as 1.059 Å (corresponding to 1.73 Å for the r(H···H) distance in a tetrahedral NH_4^+ ion)[6] and the two nonequivalent r(F–F) distances as 2.297 and 2.291 Å in both hydrogen-centered $[F\text{–}H\text{–}F]^-$ ions.[7] For the rigid lattice model, the theoretical second moments thus obtained are M_{HH}=41.80, M_{HF}=30.01 G^2 for ^1H and M_{FF}=4.18, M_{FH}=84.97 G^2 for ^{19}F nuclei. On the other hand, a model of the NH_4^+

isotropic reorientation yields $M_{HH}=5.55$, $M_{HF}=26.56$, $M_{FF}=4.18$, and $M_{FH}=75.20$ G^2. By substituting the calculated second moments into Eqs. 1 and 3 and by diagonalizing the relaxation matrix, one can calculate the following T_1 minimum values for the two nuclei: $T_1(H)_{min}=14.3$ and $T_1(F)_{min}=79.5$ ms. The experimental values to be compared with these T_1 minima were 13.5 and 73 ms, respectively. The good agreement between the calculated and experimental values indicates that the NH_4^+ isotropic reorientation is responsible for the relaxation process in this temperature region. The activation energy, E_a, of the NH_4^+ reorientation was determined to be 25.5 ± 1.0 kJ/mol from the slope of the log T_1' (or T_1'') *vs.* $1/T$ line on its low-temperature side, by assuming that $\tau=\tau_0\exp(E_a/RT)$. The solid lines for T_1(H) and T_1(F) in Fig. 1 were calculated from Eqs. 1 and 3 with the relaxational parameters, τ_0 and E_a, listed in Table 1.

Table 1. Relaxational parameters in NH_4HF_2

	E_a/kJ mol^{-1}	τ_0/s	Motion
NH_4^+	25.5 ± 1.0	2.5×10^{-15}	isotropic
HF_2^-(1)	≈60	$\approx10^{-15}$	180°-flip
HF_2^-(2)	≈40	$\approx10^{-14}$	180°-flip
HF_2^- in KHF_2[a]	50.5	6.4×10^{-15}	180°-flip

a) Ref. 3.

In the weak collision limit, $T_{1\rho}$(H) is given by the equation corresponding to Eqs. 1 and 3 for T_1(HH), *etc*:[5]

$$T_{1\rho}(H)^{-1} = (1/3)\gamma_H^2\Delta M_{HH}f_\rho(\omega_H, \tau_H) + (3/32)\gamma_H^2\Delta M_{HF}g_\rho(\omega_H, \omega_F, \tau_H), \quad (4a)$$

$$f_\rho(\omega_I, \tau) = 3\tau/(1+4\omega_{1I}^2\tau^2) + 5\tau/(1+\omega_I^2\tau^2) + 2\tau/(1+4\omega_I^2\tau^2), \quad (4b)$$

$$g_\rho(\omega_I, \omega_S, \tau) = 4\tau/(1+\omega_{1I}^2\tau^2) + \tau/[1+(\omega_I-\omega_S)^2\tau^2] + 9\tau/(1+\omega_I^2\tau^2) + 6\tau/[1+(\omega_I+\omega_S)^2\tau^2]. \quad (4c)$$

Although our experimental condition ($H_1=\omega_{1H}/\gamma_H=10$ G) wasn't sufficient for the weak collision limit, we tried to approximate the problem by this limit. Thus, the theoretical log $T_{1\rho}$(H) *vs.* $1/T$ curve was calculated from Eq. 4 with the same relaxational parameters as those in the T_1 calculation. As compared in Fig. 1, the overall agreement between the calculation and the observation is good, except for the temperature range above 200 K.

180°-Flipping of HF_2^- Ions. The relaxational behavior above 200 K is rather complicated. The $T_{1\rho}$ data in Figs. 1 and 2 clearly suggest the presence of other relaxational processes. The FID signals of both nuclei show no lengthening due to self-diffusion of the NH_4^+ or HF_2^- ions, even at the highest temperature of measurement (345 K). Hence, the 180°-flip motion of the HF_2^- ion becomes of much interest, because it can contribute to the relaxation rates of both nuclei in the high temperature region, as evidenced in the low-temperature phase of potassium hydrogendifluoride.[2,3]

If that is the case, at temperatures higher than 200 K the $T_{1\rho}$(H) in NH_4HF_2 may be governed by the H–F dipolar interaction modulated *via* the 180°-flips of the HF_2^- ions. The two crystallographically nonequivalent HF_2^- ions may have different correlation times, τ_1, and τ_2, for their individual 180°-flips. If these correlation times are greatly different from each other, then the two corresponding $T_{1\rho}$ minima would be well separated, as can be seen in Fig. 1. The ^{1}H relaxation rate due to the H–F dipolar interaction *via* the 180°-flip is given in a spatial average form as follows:[3]

$$T_{1\rho}(HF)^{-1} = \gamma_H^2\gamma_F^2\hbar^2/80\sum_F[r_{HF}(\beta)^{-6}+r_{HF}(\delta)^{-6} - r_{HF}(\beta)^{-3}r_{HF}(\delta)^{-3}(3\cos^2\Delta_{\beta\delta}-1)]g_\rho(\omega_H, \omega_F, \tau_i), \quad (5)$$

where τ_i stands for τ_1 and τ_2, β and δ denote two positions of a given F atom, $r_{HF}(\beta)$ is the distance between the hydrogen and the fluorine atom at a β-site, and $\Delta_{\beta\delta}$ is the angle between two H–F internuclear vectors. In the actual calculation based on Eq. 5, four hydrogen atoms of a rapidly rotating NH_4^+ ion were located at the center of the ion, in the usual manner.

On the other hand, the $T_{1\rho}$(F) in the 65% *d*-NH_4HF_2 may be governed by the homonuclear F–F dipolar interaction. The relaxation rate due to 180°-flipping of water molecules has been derived by Look and Lowe.[8] In order to apply the Look and Lowe equation to the present case, the equation was modified to hold for two independent correlation times. The results are presented only in the $T_{1\rho}^{-1}$ form for a single crystal:

$$T_{1\rho}(FF)^{-1} = 3\gamma_F^4\hbar^2I_F(I_F+1)/64N\sum_{i\neq j}[\zeta^{(0)}J(2\omega_{1F}, \tau_i) + 10\zeta^{(1)}J(\omega_F, \tau_i)+\zeta^{(2)}J(2\omega_F, \tau_i) + \xi^{(0)}J(2\omega_{1F}, \tau_j)+10\xi^{(1)}J(\omega_F, \tau_j) + \xi^{(2)}J(2\omega_F, \tau_j)+\eta^{(0)}J(2\omega_{1F}, \tau_{ij}) + 10\eta^{(1)}J(\omega_F, \tau_{ij})+\eta^{(2)}J(2\omega_F, \tau_{ij})], \quad (6a)$$

$$\zeta^{(q)} = |\chi_{ij}^{(q)}(\beta_i, \beta_j)+\chi_{ij}^{(q)}(\beta_i, \delta_j)-\chi_{ij}^{(q)}(\delta_i, \beta_j) -\chi_{ij}^{(q)}(\delta_i, \delta_j)|^2, \quad (6b)$$

$$\xi^{(q)} = |\chi_{ij}^{(q)}(\beta_i, \beta_j)-\chi_{ij}^{(q)}(\beta_i, \delta_j)+\chi_{ij}^{(q)}(\delta_i, \beta_j) -\chi_{ij}^{(q)}(\delta_i, \delta_j)|^2, \quad (6c)$$

$$\eta^{(q)} = |\chi_{ij}^{(q)}(\beta_i, \beta_j)-\chi_{ij}^{(q)}(\beta_i, \delta_j)-\chi_{ij}^{(q)}(\delta_i, \beta_j) +\chi_{ij}^{(q)}(\delta_i, \delta_j)|^2, \quad (6d)$$

$$\tau_{ij}^{-1} = \tau_i^{-1} + \tau_j^{-1}, \quad (6e)$$

$$J(\omega, \tau) = \tau/(1+\omega^2\tau^2), \quad (6f)$$

where $\chi_{ij}^{(q)}$ ($q=0$, 1, and 2) is the usual orientation function.[8] When $\tau_i=\tau_j$, of course, Eq. 6 is identical with the Look and Lowe equation. As a powdered sample was used in this study, Eq. 6 was spatially averaged before use.[9]

In addition, the interionic F–H dipolar interaction also contributes to $T_{1\rho}$(F). This contribution can be estimated from Eq. 5, taking into account the extent of the deuteration. The contribution from ^{2}H nuclei was neglected because γ_F is very large compared with γ_D.

The summations in Eqs. 5 and 6 were carried out up to six or eight neighboring ions around a central HF_2^-(1) or HF_2^-(2) ion, respectively. By using the parameters thus obtained, and Eqs. 5 and 6 for $T_{1\rho}$'s, the minimum values of $T_{1\rho}$ were evaluated. In this calculation, the correlation time for the 180°-flip of the HF_2^-(2) ions was assumed to be shorter than that of the HF_2^-(1) ions, for a reason to be described later. These values

Table 2. Calculated and experimental values of $T_{1\rho}$ minima due to the 180°-flips of the HF_2^- ions

$T_{1\rho}$(H) was measured at 10 G in NH_4HF_2 and $T_{1\rho}$(F) was at 6.5 G in the 65% *d*-NH_4HF_2.

	$T_{1\rho}(H)_{min}$/ms		$T_{1\rho}(F)_{min}$/ms	
	Calcd	Exptl	Calcd	Exptl
$HF_2^-(1)$	2.4	2.2	1.2	1.7
$HF_2^-(2)$	2.5	1.9	1.1	1.2

are compared with the experimental ones in Table 2. The agreement is fairly good, supporting the idea that the 180°-flip motions of the nonequivalent, linear HF_2^- ions are separately excited at high temperatures. The values of E_a and the pre-exponential factor τ_0 were roughly estimated in a conventional way; these results are included in Table 1 together with those for the NH_4^+ ions.

Discussion

The T_1 observed at all temperatures and the $T_{1\rho}$ in the low-temperature region were well explained by the random reorientation of the NH_4^+ ion, rather than by its C_2 reorientation predicted from the site symmetry (2) of the ammonium nitrogen. An activation energy E_a of 25.5 kJ/mol in the present NH_4HF_2 suggests that the hydrogen-bonds between N(NH_4^+) and F(HF_2^-) atoms are rather strong, as was anticipated from the short N–F distances (2.797 Å twice and 2.822 Å twice)[4] and also from the highly ionic charge on the F atom ($-0.83e$).[10] The values of E_a and the N(H)···F distance in NH_4HF_2 are intermediate between those found in NH_4F (42 kJ/mol, 2.71 Å)[11] and NH_4BF_4 (6.3 kJ/mol, 2.92 Å);[12] an E_a value of 3—5 kJ/mol in NH_4PF_6 is the lowest one,[13] but the N···F distance (2.4 Å) seems to be too small to compare with the above three, possibly owing to the highly disordered structure.[14] These comparisons indicate that the activation energy for the NH_4^+ reorientation strongly depends on the NH···F hydrogen-bond distance as well as on the dimensions of a combined anion.

On the other hand, the $T_{1\rho}$ data above 200 K could be interpreted in terms of the stepwise 180°-flip motions of the two nonequivalent HF_2^- ions. According to the X-ray results, the intraion F–(H)–F bond distances in both HF_2^- ions are nearly the same within the experimental errors, whereas the interionic hydrogen-bond distances F···(H)N significantly differ from each other (2.797 for $HF_2^-(1)$ and 2.822 Å for $HF_2^-(2)$ ions).[4] It was therefore expected that the latter $HF_2^-(2)$ ion would be more mobile and be characterized by a lower activation energy, *i.e.* a shorter correlation time. The preceding analysis of the $T_{1\rho}$ data based on this assumption yielded approximate E_a values of 60 for $HF_2^-(1)$ and 40 kJ/mol for $HF_2^-(2)$, both of which are roughly comparable to the 50 kJ/mol obtained in KHF_2 (Table 1).[3] However, the difference of E_a in the ammonium salt seems to be too large to arise from the difference in the hydrogen-bond strength alone. This finding leads us to point out that the different HF_2^- ions take different pathways of flipping. For an isolated molecular ion, the two-fold (C_2) axis of flip cannot be defined uniquely on the molecular mirror plane, because the symmetry of the ion is ∞/m ($D_{\infty h}$). Furthermore, the X-ray results, especially the strongly anisotropic temperature factors, provided valuable information on the ionic motion. That is, the maximum amplitude of either fluorine atom due to ionic libration is observed perpendicular to the mean plane of the three hydrogen-bonds, one of which is intraionic and the other two interionic.[4] As can be seen in Fig. 3, both types of HF_2^- ions locate at the sites of the same symmetry 2/m, but the ionic axis of $HF_2^-(1)$ is perpendicular to the mirror plane (100), while the axis of $HF_2^-(2)$ ion lies on this mirror plane. Under these circumstances, the $HF_2^-(2)$ ion may rotate about the ionic and crystallographic C_2 axis, *i.e.* on the plane (100), without destroying any initial site symmetry. In contrast to this, the flipping pathway of the $HF_2^-(1)$ ion about the C_2-axis, which lies on the hydrogen-bonded plane, does break down the site symmetry and then the motion is highly hindered by the repulsion from the neighboring fluorine atoms, when the linear anion goes across the crystal mirror plane. Although this explanation is only a simple and tentative one, it seems likely that such a steric hindrance contributes to the difference in the activation energies.

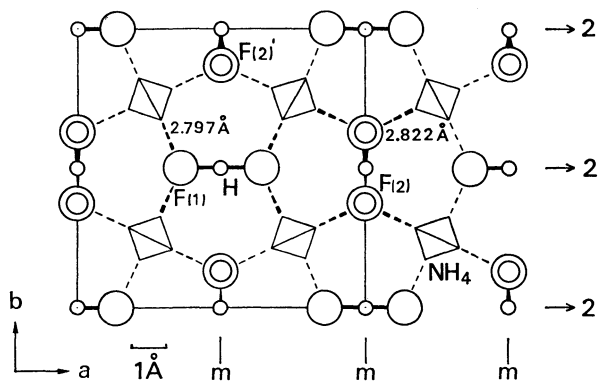

Fig. 3. The crystal structure of NH_4HF_2 projected along the c axis after McDonald.[4]

Vibrational Spectra and Rotational Isomerism of 2-Chloro- and 2-Bromoethyl Methyl Sulfides

Hiroatsu MATSUURA,* Nobuyuki MIYAUCHI, Hiromu MURATA, and Masaaki SAKAKIBARA†

(Received July 17, 1978)

The Raman and infrared spectra of 2-chloro- and 2-bromoethyl methyl sulfides $CH_3SCH_2CH_2X$ (X=Cl and Br) were measured for the liquid and crystalline solid states. The vibrational frequencies of these molecules were calculated by the use of the force constants transferred from unbranched alkyl sulfides and alkyl halides. The rotational isomerism was studied on the basis of the spectral observations and the calculations, and the following conclusions were obtained. (1) In the crystalline solid state, both the chloride and the bromide take the molecular form with the *gauche* conformation about the (C)S–C(C) axis and the *trans* conformation about the (S)C–C(X) axis. (2) In addition to this form (GT), three other forms (TG, GG, and TT) coexist in the liquid state, the GT form being the most stable. (3) The sulfur atom is suggested to lower the energy of the *trans* conformation of the (S)C–C(X) axis.

The vibrational spectra of unbranched alkyl halides have been studied extensively by many investigators. The rotational isomerism of these molecules was thoroughly examined in recent studies[1,2] by analyzing the spectra in conjunction with the systematic calculations of normal coordinates. These studies provided us with essential knowledge on the conformational stability of the halide molecules. In the present study, we deal with 2-halogenoethyl methyl sulfides $CH_3SCH_2CH_2X$ (X=Cl and Br), in which halogen and sulfur atoms are simultaneously involved, in order to examine the effect of the sulfur atom on the conformation of the halide part. Another interest is the reversed effect, namely the effect of the halogen atom on the conformation of the sulfide part. The rotational isomerism of alkyl sulfides has also been investigated systematically in a series of recent studies.[3–5]

Experimental

2-Chloroethyl methyl sulfide was purchased from Tokyo Kasei Kogyo Co., Ltd. and was distilled prior to the Raman and infrared measurements. 2-Bromoethyl methyl sulfide was prepared from 2-methylthioethanol (Tokyo Kasei Kogyo Co., Ltd.) and phosphorus tribromide and was distilled under reduced pressure (bp 64 °C at 25 mmHg).

The measurements of Raman spectra were made on a JEOL JRS-400D spectrophotometer with a Coherent Radiation CR-2 or CR-3 argon ion laser. The Raman spectra were obtained for the liquid state at various temperatures and the crystalline solid state at liquid nitrogen temperature. The infrared spectra were recorded on a Perkin-Elmer 621 spectrophotometer and Hitachi EPI-G2 and EPI-L spectrophotometers. The crystalline solid sample for the infrared measurements was obtained by depositing vapor of the substance onto a cooled window and annealing it repeatedly.

Normal Coordinate Treatment

The calculations of the normal coordinates for 2-chloro- and 2-bromoethyl methyl sulfides were carried out by an MVIB system,[6] which is a program system consisting of various program units combined functionally with one another to calculate vibrational frequencies, modes and other information on the normal vibrations from minimal input data of only a name of the molecule and its conformation. This program system is adapted for a HITAC 8800/8700 Computing System at the University of Tokyo.

The force constants associated with the sulfur and halogen parts were transferred from the unbranched alkyl sulfides[6] and alkyl halides.[7] The force constants for the (S)C–C(X) stretching and the methylene-methylene interactions were transferred from the corresponding alkyl halides. No further adjustment of the force constants was made. The transferred values were found to be accurate enough for determining the existing rotational isomers from their vibrational frequencies. Structural parameters used in the calculations were the same as those of the corresponding parts of the sulfides and halides.[6,7]

Results

The Raman spectra of 2-chloro- and 2-bromoethyl methyl sulfides are shown in Figs. 1—4, and the observed and calculated frequencies and the vibrational assignments based on the potential-energy distributions are listed in Tables 1 and 2. Considering possible molecular forms to be in the staggered conformations, we have for a 2-halogenoethyl methyl sulfide molecule five rotational isomers, TT, TG, GT, GG, and GG′, where the first and second conformation symbols in each isomer designation are those for the (C)S–C(C) and (S)C–C(X) axes, respectively. The symbols T and G imply *trans* and *gauche*, respectively, in accordance with the convention generally accepted.[8]

The following general spectral features are observed for the two halogeno sufildes. (1) As expected, the spectra have combined features of alkyl halides and sulfides. (2) The number of the bands observed in the crystalline solid state is less than that in the liquid state. The former corresponds to what is expected for one molecular form. (3) The relative intensities in the liquid-state Raman spectra vary with the change of temperature.

The rotational isomers existing in each state of aggregation and their relative stabilities will be considered below. The results are summarized in Table 3.

2-Chloroethyl Methyl Sulfide. The key bands for studying molecular conformations of this molecule are the bands due to the S–CH_2 stretching, C–Cl stretching and skeletal deformation vibrations.[1,4,5] The C–S stretching (CH_3–S and S–CH_2) and C–Cl stretching frequencies are expected to be in the range between 800 and 600 cm^{-1}, where the CH_2 rocking frequencies are also likely to be.

a) VS: very strong, S: strong, M: medium, W: weak, VW: very weak, sh: shoulder. b) All the calculated frequencies for the individual rotational isomers are given in parentheses except for those of the CH stretching and torsional vibrations and the lowest skeletal deformation frequency for the TT form (133 cm^{-1}, SCC deform) which are not included in the table. c) The infrared spectra in the region below 250 cm^{-1} were not measured.

The Raman and infrared spectra of the crystalline solid state exhibit four distinct bands at 763, 745, 703, and 680 cm^{-1}, the fourth being a doublet in the infrared spectrum. Since a single molecular form exists in this state as is evident from the number of the bands observed in the whole region, the four bands are assigned to the CH_3–S, S–CH_2, and C–Cl stretching, and one of the two CH_2 rocking vibrations. The least strong Raman band at 745 cm^{-1} is assignable to the CH_2 rocking vibration by considering that Raman intensities for the C–S or C–Cl stretching vibration are generally stronger than those for the rocking vibration. Previous studies indicated that the C–S stretching frequencies for the P_C conformation (the sulfur atom is *trans* to a carbon atom) and the P_H conformation (the sulfur atom is *trans* to a hydrogen atom) are 745—760 and 645—670 cm^{-1}, respectively,[9] and that the C–Cl stretching frequencies for the P_C conformation (the chlorine atom is *trans* to a carbon atom) and the P_H conformation (the chlorine atom is *trans* to a hydrogen atom) are 720—730

and 650—660 cm^{-1}, respectively.[10,11] These frequency-conformation correlations show that the 763 cm^{-1} band of 2-chloroethyl methyl sulfide corresponds definitely to the C–S stretching of $P_{C'}$, and therefore is assigned to the C–S stretching of P_{Cl}. Thus, the (S)C–C(Cl) axis in this molecule is determined to be in the *trans* conformation and the molecular conformation is either TT or GT. No observation of the C–Cl stretching band of P_H also suports this conformation. The band at 703 cm^{-1} (710 cm^{-1} in the liquid state) is assigned to the C–Cl stretching of the P_S conformation with reference to the P_C frequency of 720—730 cm^{-1}. The remaining band at 680 cm^{-1} is then assigned to the CH_3–S stretching vibration. All of these vibrational assignments are confirmed by the normal coordinate calculations as shown in Table 1.

The conformation about the (C)S–C(C) axis is found to be in *gauche* in the solid state by examining the skeletal deformation vibrations as mentioned below. The Raman bands are observed in this state at 333, 274, and 228 cm^{-1} between 500 and 180 cm^{-1} (the corresponding frequencies in the liquid state are 332, 265, and 223 cm^{-1}). On the other hand, the normal coordinate calculations give the frequencies of 335 and 288 cm^{-1} in the same range for the TT form and 337, 257, and 204 cm^{-1} for the GT form. The number of the observed bands and their frequencies are explained only by the GT form. The Raman band at 282 cm^{-1}, which is observed in the liquid state but disappears on solidification, is in fact assigned to the TT form.

Close examinations of the observed Raman and infrared spectra, incorporated with the results of the normal coordinate calculations (Table 1), indicate that the TG, GG, and TT forms coexist in the liquid state in addition to the GT form. The frequencies of the observed bands which are assigned only to a single molecular form are 863, 663, and 422 cm^{-1} (TG form), 845, 632, and 412 cm^{-1} (GG form), and 282 cm^{-1} (TT form). The existence of the GG′ form is not certain but this conformation is quite unlikely to exist as suggested from the expected large steric repulsions.

The liquid-state Raman spectra were measured at higher and lower temperatures in order to study the relative conformational stabilities among the existing rotational isomers (Fig. 2). Although most of the individual Raman bands are more or less overlapped by other bands, it is evidently shown that the bands due to the GT form increase at lower temperature as compared with the bands due to the other forms. The GT form is thus found to be the most stable in the liquid state. The relative conformational stability for the other forms is not definitive from the present spectral measurements.

2-Bromoethyl Methyl Sulfide. The S–CH_2 and C–Br stretching frequencies are useful in determining the conformation about the (S)C–C(Br) axis, similarly to the case of 2-chloroethyl methyl sulfide for which the S–CH_2 and C–Cl stretching frequencies have been used.

In the crystalline solid state, the distinct bands are observed at 750, 741, 695, and 601 cm^{-1} in the range between 800 and 500 cm^{-1}. The 601 cm^{-1} band (613 cm^{-1} in the liquid state) is assigned to the C–Br stretching vibration of the P_S conformation, since the C–Br stretching frequencies for the P_C and P_H conformations of alkyl bromides are 635—645 and 555—565 cm^{-1}, respectively,[12] and the corresponding frequency for the P_S conformation is expected to be lower than the P_C frequency on account of a heavier atom of sulfur. The P_H frequencies of the C–Br stretching vibration is observed, in fact, at 565 and 557 cm^{-1} in the liquid state. Thus, the (S)C–C(Br) axis is determined to be in the *trans* conformation and the molecular conformation in the solid state is either TT or GT. The 741 cm^{-1} band, which is the least strong of the four Raman bands and corresponds to the 745 cm^{-1} band of the chloride, is assigned to the CH_2 rocking vibration. The band at 750 cm^{-1} is associated with the S–CH_2 vibration of the P_{Br} conformation in accord with the P_C frequency of 745—760 cm^{-1}, and the band at 695 cm^{-1} is assigned to the CH_3–S stretching vibration. It is noted that the

Table 3. Rotational isomers of 2-halogenoethyl methyl sulfides

	$CH_3SCH_2CH_2Cl$	$CH_3SCH_2CH_2Br$
Liquid[a]	GT, TG, GG, TT	GT, TG, GG, TT
Crystalline solid	GT	GT

a) For both 2-chloro- and 2-bromoethyl methyl sulfides, the GT form is the most stable in the liquid state.

C–Br stretching Raman band is stronger than the C–S stretching Raman band. For the chloride, a similar observation is also made that the C–Cl stretching vibration gives rise to a stronger Raman intensity than the C–S stretching vibration.

In the solid-state spectra, the bands are observed at 320, 242, and 207 cm^{-1} in the region between 500 and 180 cm^{-1}.[13] The TT form gives two calculated frequencies of 329 and 235 cm^{-1} in this region and the GT form three calculated frequencies of 318, 216, and 200 cm^{-1}. The comparison of the observed and calculated frequencies readily leads to the conclusion that the molecular conformation in the solid state is the GT form. Thus, the normal coordinate calculation is shown to be important in determining the conformation about the (C)S–C(C) axis in both cases of the chloride and the bromide.

In the liquid-state spectrum, there appear several bands which are not found in the solid-state spectrum. These are reasonably assigned to the rotational isomers other than the GT form on the basis of the spectral analyses and the results of the normal coordinate calculations. Of the bands observed only in the liquid state, the following bands are associated exclusively with a single rotational isomer: 960 cm^{-1} (TT form), 896, 675, 565, 401, and 218 cm^{-1} (TG form), and 828, 718, 655, 555, and 392 cm^{-1} (GG form). The GT, TG, GG, and TT forms are thus found to coexist in the liquid state, but the GG′ form is again unlikely to exist. If the GG′ form existed, the Raman spectrum would exhibit a band around 270 cm^{-1}, since the normal coordinate calculation on this form gives this frequency for a quasi-totally symmetrical deformation of the molecular skeleton.

The Raman spectra in the liquid state at higher and lower temperatures (Fig. 4) show the relative intensities of the bands assigned to the GT form are stronger at lower temperature than those assigned to the other forms. Accordingly the GT form is the most stable in the liquid state similarly to the case of the chloride.

Discussion

The rotational isomerism of 2-chloroethyl methyl sulfide has been studied by Hayashi[14] and the molecular form in the solid state has been reported to be either GT or TT.

In the present study, the following results on the rotational isomerism have been obtained for 2-chloro- and 2-bromoethyl methyl sulfides in common. (1) The molecular form in the crystalline solid state is the GT form. (2) The GT, TG, GG, and TT forms coexist in the liquid state, the GT form being the most stable.

For both 2-chloro- and 2-bromoethyl methyl sulfides, the GT form is the most stable in the liquid state, the (C)S–C(C) and (S)C–C(X) axes being in the *gauche* and *trans* conformations, respectively. The previous studies on unbranched alkyl sulfides indicated that the *gauche* conformation about the (C)S–C(C) axis is slightly more stable than the *trans* conformation[3–5,15,16] and for ethyl methyl sulfide the enthalpy difference between the *trans* and *gauche* conformation was shown to be $\Delta H_{T-G}=140\pm50$ cal mol^{-1} in the liquid state.[15] Accordingly, the conformational stability of the (C)S–C(C) part in the halogeno sulfides is in line with that for other sulfides.

The most stable isomer of the halogeno sulfide molecules takes the *trans* conformation about the (S)C–C(X) axis. For unbranched alkyl halides, the *gauche* (C)C–C(X) axis was found to be slightly more stable than the *trans* axis.[1] The conformational stability of the (O)C–C(X) axis in halogeno ethers was also studied and the *gauche* conformation was found to be more stable than the *trans* conformation.[17] Accordingly, the stability of the (S)C–C(X) axis is different from that of the (C)C–C(X) or (O)C–C(X) axis.

The Raman spectrum of 2-bromoethyl methyl sulfide in the liquid state (Fig. 3) shows that the C–Br stretching band at 613 cm^{-1} due to the *trans* (S)C–C(Br) conformation is much stronger than the corresponding bands at 565 and 555 cm^{-1} due to the *gauche* conformation.[18] For 2-bromoethyl methyl ether, however, the C–Br stretching Raman band of the *trans* (O)C–C(Br) conformation at 668 cm^{-1} is weaker than that of the *gauche* conformation at 571 cm^{-1} (Fig. 4 of Ref. 17) in contrast with the case of 2-bromoethyl methyl sulfide. This spectral difference for the two molecules suggests the difference of the conformational stability of the (S)C–C(Br) and (O)C–C(Br) axes as mentioned above, on the assumption that the ratio of the Raman intensity, per molecule, of the *trans* conformation to that of the *gauche* conformation does not change for these molecules. The validity of this assumption may be diagnosed in part by examining the coupling of these C–Br stretching vibrations with other vibrations. The calculated potential-energy distributions indicate that the bands assigned to the C–Br stretching have contributions from other vibrations less than 20% in any case of 2-bromoethyl methyl sulfide and 2-bromoethyl methyl ether. Accordingly, the assumption can be approximately valid for discussing the relative conformational stability.

For 1-bromobutane, the C–Br stretching Raman band of the *trans* (C)C–C(Br) conformation is weaker than the corresponding band of the *gauche* conformation (Fig. 11 of Ref. 1), similarly to the case of 2-bromoethyl methyl ether, but the intensity ratio of the *trans* to *gauche* band is larger than that of 2-bromoethyl methyl ether. Hence, the *gauche* conformation of the (O)C–C(Br) axis is shown to be more stabilized than the *gauche* conformation of the (C)C–C(Br) axis on the assumption of the constant Raman intensity ratio. The spectral observations on the above-mentioned molecules give a suggestion that a sulfur atom lowers, as compared with a carbon atom, the energy of the *trans* conformation but an oxygen atom lowers the energy of the *gauche* confor-

mation of the (A)C–C(X) axis, where A is S or O and X is a halogen atom.

Part of the Raman and infrared measurements for 2-chloroethyl methyl sulfide was made on the spectrometers in the laboratory of Professor Mitsuo Tasumi, the University of Tokyo, to whom the authors wish to express their gratitude.

The Photochemical Reaction of Benzo[*c*]cinnoline. II. Photo-reduction in Acidic 2-Propanol

Hiroyasu INOUE,* Yukimi HIROSHIMA, and Norio MAKITA

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received July 22, 1978)

The photochemical reduction of benzo[*c*]cinnoline in strongly acidic 2-propanol (4 M HCl) has been studied using light of wavelength longer than 400 nm. The photoproduct has been identified as 5,6-dihydrobenzo[*c*]-cinnoline. The quantum yields for product formation, which are the same as that for the disappearance of the reactant, have been measured under various conditions. In contrast to the poor phosphorescent property of benzo[*c*]cinnoline, the protonated species has been found to phosphoresce with significant efficiency. The lowest triplet state energy has been estimated to be 51 kcal/mol. The results of the quenching showed that the photo-reduction was attributed to the lowest excited triplet state of protonated benzo[*c*]cinnoline. The pK_a value in the reactive state is lower than that in the ground state.

Several nitrogen heterocyclic compounds in electronically excited states have been shown to undergo hydrogen atom abstraction from solvent molecules. The photo-reductions of acridine and phenazine, for example, have been extensively studied, and the reactive states in the photo-reduction shown to be the lowest excited $n\pi^*$ singlet states.[1,2] The photo-reduction of phenazine has also been studied in acidic media, and the $n\pi^*$ singlet state mechanism proposed.[3] For quinoline and pyrimidine derivatives in acidic alcohol solutions, however, photoalkylation has been observed.[4,5]

In a previous paper[6] it was reported that the photo-irradiation of benzo[*c*]cinnoline in strongly acidic (4M HCl) alcoholic solution led to the formation of 2,2′-diaminobiphenyl or carbazole as the final product depending on the excitation wavelength and the alcohol used as the solvent. In both reactions the final products are formed by the subsequent reactions of the initially formed intermediate which is characterized by absorption bands at 240, 270, and 316 nm. In the case of benzo[*c*]cinnoline in acidic 2-propanol, irradiation with light of a wavelength longer than 400 nm gives the intermediate compound, but no subsequent reaction occurs.[7]

In this paper, the initial photoreaction of benzo[*c*]-cinnoline under certain conditions will be reported. Although some results indicate that the photoproduct is 5,6-dihydrobenzo[*c*]cinnoline, further evidence will be given for the identification of the product. This will be followed by a discussion of the reactive state of the reactant on the basis of the quantum yields for the reaction under various conditions.

Experimental

Materials. Benzo[*c*]cinnoline was obtained from Aldrich Chemical Co. and recrystallized from ethanol; mp 155 °C (lit,[8] 156 °C). 2-Propanol, a Kokusan Works reagent, was purified by refluxing in sodium hydroxide solution and subsequent distillation. Purified 2-propanol was shown to be free from aldehydes by GLC analysis.[9] Anthracene, pyrene, fluoranthene, *trans*-1,3-pentadiene, and naphthalene, which were used in quenching experiments, were purified by recrystallization or distillation.

Light Source and Irradiation. A 500 W high pressure mercury arc lamp (Ushio USH-500) was used as the visible light source with a Corning glass filter (CS3-73) which cut off light shorter than 400 nm. All irradiations were carried out at room temperature. The solution of the reactant was flushed with nitrogen passed through a pyrogallol solution for 30 min prior to and during the irradiation. Acidities of the solution were adjusted with HCl.

Actinometry and Analysis. The intensities of light transmitted by the sample solution and solvent respectively were measured to determine the quantum yields of the photoreaction using a potassium ferrioxalate solution as actinometer.[10] Two cylindrical cells (diameter: 4.5 cm, length: 3 cm) were used in the actinometry. The disappearance of benzo[*c*]-cinnoline and the appearance of the product were determined spectrophotometrically. The molar extinction coefficients of the ultraviolet absorption bands of the photoproduct have been determined previously.[6]

Measurements. Ultraviolet absorption spectra were taken with a Shimadzu UV-200 spectrophotometer using 1 cm quartz cells. Emission spectra were recorded on a Shimadzu RF-500 spectrofluorimeter.

Chemical Reduction of Benzo[c]*cinnoline with Lithium Aluminium Hydride.* Benzo[*c*]cinnoline was chemically reduced by a large excess of lithium aluminium hydride in tetrahydrofuran under nitrogen at room temperature. After 30 min the solution was acidified by the addition of HCl and the absorption spectrum of the reduced compound was measured.

Results and Discussion

Photoproduct in Acidic Aqueous 2-Propanol. Figure 1 shows the spectral change caused by irradiation of the reactant (6.7×10^{-5} M) in acidic (4 M HCl) aqueous 2-propanol. The photo-reaction was completed in 140 min giving rise to a photoproduct having bands at 240, 270, and 316 nm. The existence of three isosbestic points at 235, 270, and 324 nm and the quantitative recovery of benzo[*c*]cinnoline by aeration of the irradiated solution indicate the absence of a side reaction.

In order to identify the product as 5,6-dihydrobenzo-[*c*]cinnoline (monoprotonated form in strongly acidic solution), the chemical hydrogenation of the reactant was attempted. The hydrogenation was performed by treating the tetrahydrofuran solution of benzo[*c*]-cinnoline with lithium aluminium hydride. The solution of the resulting reduced compound was acidified and the absorption spectrum determined. The observed spectrum is presented in Fig. 2. The chemically reduced compound has been considered to be 5,6-dihydrobenzo-

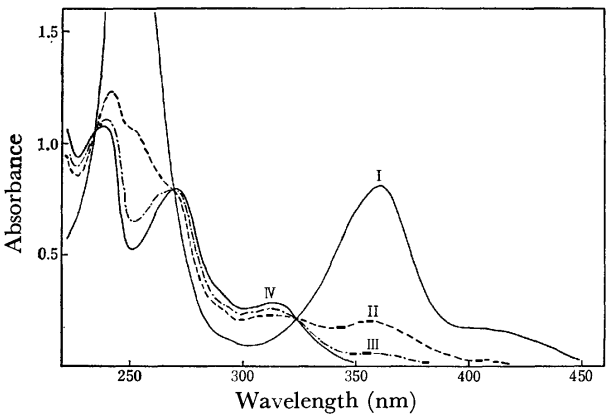

Fig. 1. Spectral change of the 4 M HCl 2-propanol solution of benzo[*c*]cinnoline (6.7×10^{-5} M) caused by irradiation with light longer than 400 nm. Irradiation time (min); I: 0, II: 30, III: 60, IV: 140.

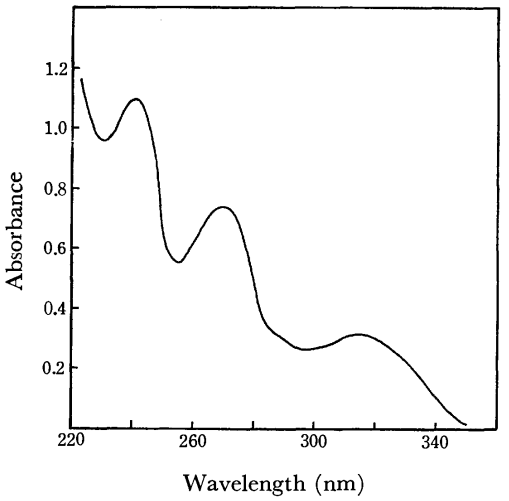

Fig. 2. Absorption spectrum of the acidified tetrahydrofuran solution of the compound prepared by reduction of benzo[*c*]cinnoline with $LiAlH_4$.

[*c*]cinnoline. As seen from Figs. 1 and 2, the absorption spectra of the products formed by the two methods show good agreement. Consequently, the photoproduct has been identified as 5,6-dihydrobenzo[*c*]cinnoline.

Quantum Yields for the Photo-reduction under Various Conditions. The quantum yield for the disappearance of the reactant coincides with that for product formation, thus indicating that 5,6-dihydrobenzo[*c*]-cinnoline is the only photoproduct from the reactant in the present experimental conditions. As seen from Fig. 3, the quantum yield remained constant with variation in the irradiation time (15—120 min) and in the initial concentration of the reactant (4.0×10^{-5}—5.2×10^{-4} M). The average quantum yield has been determined to be 5.5×10^{-3}. For the photo-reduction of phenazine in alcoholic solution, the concentration dependence of the quantum yield has been established and interpreted in terms of self quenching.[11] However, the result shown in Fig. 3b indicates that such self-quenching is absent in the present photo-reduction in the concentration range studied here.

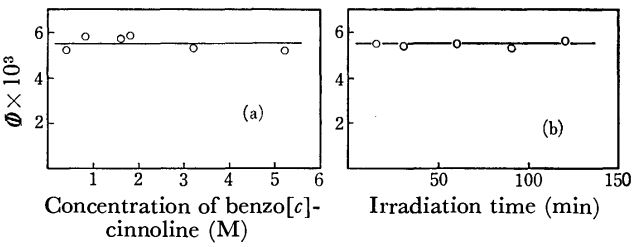

Fig. 3. Dependence of quantum yields for the photoreduction: (a) on the initial concentration of the reactant; (b) on irradiation time.

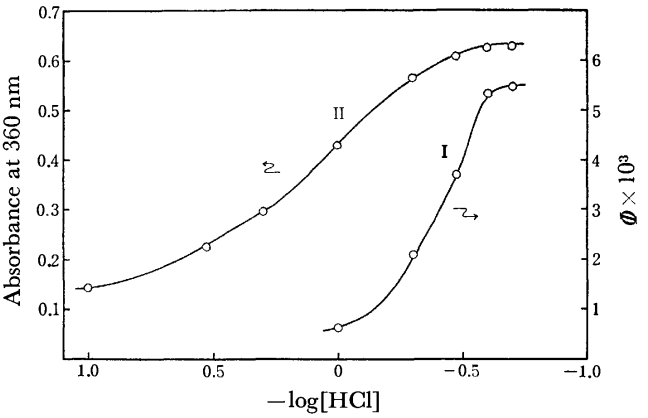

Fig. 4. Quantum yields for the photoreduction (I) and absorption intensity of the 360 nm band (II) at various concentrations of HCl.

It has been found that the quantum yield changes with variation in the acidity of the solution. Curve I in Fig. 4 shows the quantum yield at various concentrations of hydrochloric acid. In Fig. 4 the absorbances of protonated benzo[*c*]cinnoline at 360 nm have also been plotted against the acid concentration (curve II). From this curve the apparent pK_a of the conjugate acid of benzo[*c*]cinnoline in the ground state has been determined to be 0.1 in a mixed solvent of 2-propanol and water (1 : 1) at 20 °C. Since only the protonated species of the reactant can be excited with visible light, curve I may be regarded as reflecting the equilibrium situation of the protonation at the reactive state in the photo-reduction. From curve I the pK_a at the reactive state, which can be assigned as the lowest triplet state as described below, has been estimated to be −0.4. Therefore, the basicity of the reactant in the lowest triplet state is considered to be lower than that in the ground state and this behavior is in contrast to that for other nitrogen heterocyclic compounds which have higher pK_a values in the lowest triplet states than in the ground states.[12–14]

Since hydrochloric acid was used to acidify the solution the quenching effect of chloride ion needs to be examined in view of the fact that in some cases halide ions act as fluorescence quenchers[15] and exibit a quenching effect as in the photo-reduction of acridine.[16] In the present case, the quantum yield has been found to be unaffected on addition of sodium chloride in the concentration range up to 0.05 M.

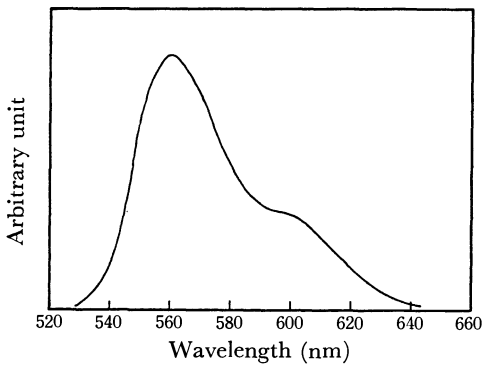

Fig. 5. Phosphorescence spectrum of protonated benzo[c]cinnoline in 4 M HCl aqueous 2-propanol at 77 K. Excitation wavelength 420 nm.

Therefore, it is not necessary to correct the results concerning the effect of acid concentration on the quantum yield presented in Fig. 4 for changes in chloride ion concentration.

Emission Spectra of Protonated Benzo[c]*cinnoline.* It has been established that benzo[*c*]cinnloine exibits fluorescence, but does not phosphorescence with a significant quantum yield.[17] The lowest triplet state has been assigned as of the $\pi\pi^*$ type and the energy determined to be 52.0 kcal/mol from the $S_0 \rightarrow T_1$ absorption spectrum.[18] On the other hand, little is known concerning the excited states of the protonated species. In order to study the behavior of protonated benzo[*c*]cinnoline in electronically excited states, the emission spectra have been measured. In contrast to the non-phosphorescent property of the unprotonated species, the phosphorescence emission could be observed for the protonated species by means of a conventional spectrofluorimeter at 77 K, the observed phosphorescence band is shown in Fig. 5. On the other hand, the intensity of the fluorescence band at 490 nm decreased with increasing acid concentration. Since the phosphorescence band has no fine structure, the position of the 0-0 transition can not be determined precisely. Nevertheless, the wavelength of the peak (560 nm) may indicate the approximate energy of the lowest triplet state (E_T), that is, E_T has been estimated to be 51 kcal/mol. Recently, Lin *et al.*[19] have observed the enhanced phosphorescence band in isopentane solution containing fluorinated alcohols which can form hydrogen bonds with benzo[*c*]cinnoline. The spectra have fine structure and the shortest wavelength peaks are at approximately 550 nm.

Quenching in the Photo-reduction. In order to investigate the reactive state of the reactant in the photoreduction, quenching experiments were conducted. Quenching during the photo-reduction has been studied quantitatively through measurements of the quantum yields. In consideration of the estimated value of the lowest triplet state of the reactant (E_T=51 kcal/mol), the following compounds have been employed in the quenching experiments, naphthalene (E_T=60.9 kcal/mol), *trans*-1,3-pentadiene (E_T=59.2 kcal/mol), fluoranthene (E_T=52.9 kcal/mol), pyrene (E_T=48.2 kcal/mol), and anthracene (E_T=42.7 kcal/mol).[20] Under the present experimental conditions, none of these compounds can absorb the irradiated light.

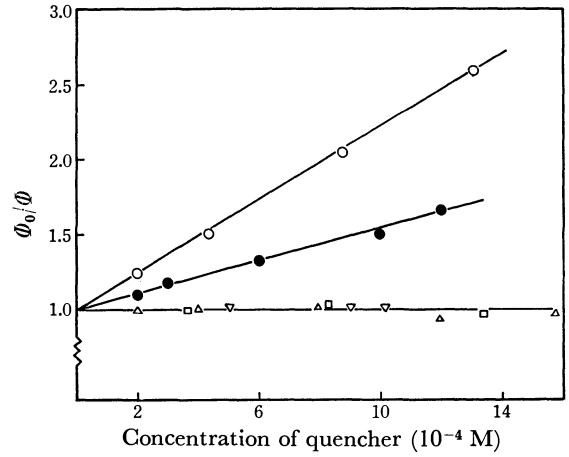

Fig. 6. Stern-Volmer plots for the photoreduction.
○: Anthracence, ●: pyrene, ▽: fluoranthene, △: *trans*-1,3-pentadiene, □: naphthalene.

The quenching experiments were performed using a fixed concentration of the reactant and variations in the quencher concentration. The quenching data are presented in Fig. 6, where Φ_0/Φ have been plotted against the quencher concentrations. The quantities Φ and Φ_0 are the quantum yields with and without quencher, respectively. As can be seen from Fig. 6, pyrene and anthracene act effectively as quenchers for the photo-reduction and the Stern-Volmer plots give straight lines, thus indicating that a single excited state participates in the photo-reduction. Fluoranthene, *trans*-1,3-pentadiene, and naphthalene exibited no influence on the quantum yield. Taking into account the lowest triplet state energies of the reactant and the quenchers, the triplet-triplet energy transfers from the protonated benzo[*c*]cinnoline donor to the pyrene and anthracene acceptors are considered possible, whereas such energy transfer are impossible in other cases. These situations reflect the results obtained here. Therefore, the observed quenching effects have been interpreted in terms of the triplet-triplet energy transfer. This is also indicated by the phosphorescence quenching data as shown in Fig. 7, where I_0/I has been plotted against the concentration of pyrene acceptor. The quantities I and I_0 are phosphorescence intensities at 560 nm with and

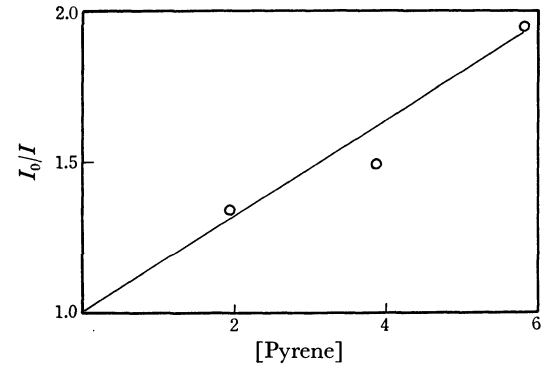

Fig. 7. Phosphorescence quenching plots of protonated benzo[*c*]cinnoline by the pyrene acceptor.
Excitation wavelength: 362 nm. Concentration of benzo[*c*]cinnoline: 1.04×10^{-4} M.

without pyrene. It is evident that pyrene acts as a triplet quencher.

The lowest excited singlet state energy of the protonated benzo[*c*]cinnoline has been estimated to be 68 kcal/mol from the longest wavelength absorption band at 420 nm. This value is lower than that of any compound used in the quenching experiments,[20] and therefore, the singlet-singlet energy transfer may be dismissed as responsible for the observed quenching. From the absorption and emission spectra, no evidence was obtained for the ground state complexing and the exciplex formation between the reactant and the quenchers.

Consequently, the results suggest that the reactive state in the photo-reduction in strongly acidic aqueous 2-propanol is the lowest excited triplet state of protonated benzo[*c*]cinnoline.

CNDO/2 Parametrizations and the Applications to Some Organo-sulfur Molecules: $(CH_2SH)_2$, $(CH_2SCH_3)_2$, CH_3SCH_2SH, and $CH_3SCH_2SCH_3$[1]

Masaru OHSAKU,* Norihisa BINGO, Wataru SUGIKAWA, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received July 31, 1978)

The CNDO/2 spd′ parametrizations of K_d, β_C, ζ_S, and β_S have been performed. Some of the valence and torsional angles of 1,2-ethanedithiol $(CH_2SH)_2$, 1,2-bis(methylthio)ethane $(CH_2SCH_3)_3$, methanethiol, ethanethiol, (methylthio)methanethiol CH_3SCH_2SH, and bis(methylthio)methane $CH_3SCH_2SCH_3$ have been optimized. In order to obtain further information on the rotational isomerism, CNDO/2 spd′ and sp calculations have been conducted for the molecules with variations in torsional angle.

Recently semi-empirical MO calculations have been widely applied and subsequently modified, *e.g.*, to the molecules including 2nd- and 3rd-row elements.[2,3] The authors have previously investigated the vibrational spectra of 1,2-ethanedithiol $(CH_2SH)_2$,[4] 1,2-bis(alkylthio)ethane $RSCH_2CH_2SR$ (R=Me, Et, *n*-Pr, and *n*-Bu),[5,6] bis(alkylthio)methane $RSCH_2SR$ (R=Me, Et, *n*-Pr, and *n*-Bu),[7-9] and (methylthio)methanethiol CH_3SCH_2SH.[10] With $(CH_2SH)_2$, electron diffraction[11] and EHMO[12] studies have been reported. The molecular structure of ethanethiol EtSH has appeared recently,[13-16] while for methanethiol MeSH and EtSH, the MINDO/3 calculations were performed;[17] however the MINDO/3 calculations do not always faithfully reproduce the experimental geometries. With oxygen analogs such as dimethoxymethane $CH_3OCH_2OCH_3$, the experimental structural analysis[18] and the theoretical conformational analyses by the semi-empirical and non-empirical methods have been attempted.[19]

In the present paper, to avoid the complexity of *ab initio* calculations, several of the CNDO/2 parameters have been reasonably optimized and the CNDO/2 method applied to examine the stable geometries of the molecules concerned. The CNDO/2 calculations have also been conducted on the oxygen analogs, 1,2-ethanediol $(CH_2OH)_2$, 1,2-dimethoxyethane $(CH_2OCH_3)_2$, and 1-methoxy-2-methylthioethane $CH_3OCH_2CH_2SCH_3$. The results of the CNDO/2 calculations will be compared with the observed values.

Optimization of Parameters

The Fock matrix[20] in the CNDO/2 method[21,22] can be expressed by

$$F_{\mu\mu} = -(1/2)(I_\mu + A_\mu) + [(P_{AA} - Z_A) - (1/2)(P_{\mu\mu} - 1)]\gamma_{AA} + \sum_{B \neq A} (P_{BB} - Z_B)\gamma_{AB} \quad (\mu \text{ on A}),$$

$$F_{\mu\nu} = (1/2)KS_{\mu\nu}(\beta_A + \beta_B) - (1/2)P_{\mu\nu}\gamma_{AB} \quad (\mu \text{ on A}, \nu \text{ on B}),$$

where the notations are the same as those used by Pople *et al.*[21] The constant K of the off-diagonal core matrix element has been given by Pople *et al.*[21] as unity in relation to the first-row elements, and 0.75 in the 2nd-row elements. In this paper, hereafter K_d will replace K in relation to the 2nd-row elements. The constant β is the bonding parameter, and this will be estimated reasonably. The orbital exponent ζ is included in the radial distance r multiplied by a decaying exponential $\exp(-\zeta r)$.

SCF calculations using the parameters of Pople *et al.*[21] (POPLE) sometimes diverge for certain molecules having more than two 2nd-row elements. Moreover the POPLE method gives the organo-sulfur molecules rather larger dipole moments and higher energy barriers for internal rotation than observed. In order to overcome the first difficulty, the density matrix method,[23-25] and others have been used, but suffer from the disadvantage of requiring a lot of computation time. Consequently the value of the constant K_d has been varied. With reference to previous works,[26-28] K_d has been assumed to be 0.492 on the basis of the smoothness of the SCF using the molecular geometry of $(SiH_3)_2O$.[29] The ζ and β values have been optimized in relation to carbon and sulfur atoms. In the course of the parametrizations, the molecular geometry of T-EtSH,[13] and initial parameters reported[21] have been adopted. The optimizations have been made in the order:

i) β_C has been estimated using ζ_C as the Slater value to reproduce the observed r(C–C) of ethane.[30]

ii) ζ_S was then deduced using the revised β_C to fit the observed r(C–S) of T-EtSH.[13]

iii) β_S was optimized using the revised ζ_S to reproduce the observed ϕ(CSH) of T-EtSH.[13]

iv) Steps ii) and iii) were repeated until the two parameters, ζ_S and β_S, did not vary very much. In the present case, nine cycles were repeated. The parameters finally obtained are summarized in Table 1 together with those reported,[3,21] and the relation between ζ_S and β_S is shown in Fig. 1. The orbital exponents previously estimated by Clementi *et al.*[31] and Burns[32] are included. The ζ_S obtained here is larger than that

used by Pople *et al.*[21] and smaller than that used by Clementi *et al.*[31] For β_S, a fairly small value was obtained. Hereafter, the method with the revised parameters will be employed as the MCNDO method. The method with K_d set at 0.492 and the others as the original ones[21] is named the KCNDO method. These methods have been applied to some of organo-sulfur molecules, and an attempt has been made to obtain information on the molecular conformations of these molecules.

Results and Discussion

Molecular geometries used were as follows: for $(CH_2SH)_2$— the geometry reported[11] except ϕ(CSH), for $(CH_2SCH_3)_2$, CH_3SCH_2SH, and $CH_3SCH_2SCH_3$, r(C–H)=1.09 Å, r(C–S)=1.82 Å, r(C–C)=1.54 Å, r(S–H)=1.335 Å. The angles around the carbon atom have been assumed as tetrahedral, and for MeSH[33] and EtSH[13,15] those observed. The dihedral angles were 180° and 60° for the T and G forms, respectively. The angles calculated and observed, and the stability of the molecules are summarized in Tables 2 and 3.

$(CH_2SH)_2$ and $(CH_2SCH_3)_2$. Using the molecular geometry reported above, optimizations were made on ϕ(CSH) of $(CH_2SH)_2$ and ϕ(CSC) of $(CH_2SCH_3)_2$. The calculated ϕ(CSH) are 95.5 and 96.5° for the MCNDO and POPLE methods respectively. The observed ϕ(CSH) has been reported as 90.5°[11] which is much smaller than those of the other thiols; MeSH: ϕ(CSH)=96.5°,[33] and T-EtSH: 96°13′.[13] With the ϕ(CSC) of

Small figures indicate the energy difference, in kcal/mol. —, stable form in the crystalline solid state. a) From Ref. 36. b) From Ref. 4a. c) From Ref. 4b. d) From Ref. 37. e) From Ref. 38. f) From Ref(s). 5 (and 38). g) From Ref. 6. h) From Ref. 10. i) From Ref. 7. j) From Ref. 8. Geometries; $(CH_2OH)_2$: from Ref. 12, $(CH_2OCH_3)_2$ and $CH_3OCH_2CH_2SCH_3$: r(C–O)=1.41 Å, ϕ(COC)=111°49′, referred from M. Hayashi and K. Kuwada, Preprint of the 32nd National Meeting of the Chemical Society of Japan, Vol. 1, (1975) p. 121, and assumed r(C–H)=1.09 Å, r(C–C)=1.54 Å, r(C–S)=1.82 Å, ϕ(CSC)=99°, angles around carbon atom=tetrahedral.

$(CH_2SCH_3)_2$, 115.5° was obtained which corresponds well to the 115.4° of MeSMe and 115.6° of MeSEt estimated by the MINDO/3 method.[17] However, the calculated value 115.5° is somewhat larger than that observed for poly(ethylene sulfide) (PES) 109.5°[34] and poly(thiomethylene) (PTM) 106°52′.[35]

The calculations were conducted for each of six typical forms with ϕ(CSH)=95.5° in $(CH_2SH)_2$ and ϕ(CSC)=115.5° in $(CH_2SCH_3)_2$. The stability from the calculated energy is in the order, TGG>GGG>TGT>GTG>TTT>GTG′ for $(CH_2SCH_3)_2$. It had been previously concluded[6] that the conformation about the C–C bond in the crystalline state is the G conformation. From the CNDO/2 calculations (KCNDO) assuming the four typical forms, TGT, GGG, TTT, and GTG′, the conclusion drawn is that the TGT form is the best form to explain the stable crystalline solid state.[6] The main reason for the difference in stability between the present and previous calculations is due to the difference in geometry used. For $(CH_2SH)_2$ nearly the same order to that of $(CH_2SCH_3)_2$ was obtained. The sp calculations[22] have also been conducted for these molecules. With $(CH_2SH)_2$, the CNDO/2 spd′ or sp calculation suggests that the most stable form is the TGT form. From this, it appears that the previous conclusion,[4a] in which mainly the TTT and TGT molecular forms exist in the gaseous and liquid states and the TTT form alone persists in the solid state, is of doubtful validity. As a result, it may be concluded that the stable form in the crystalline solid state is the TGT form.

With $(CH_2SCH_3)_2$, if the observed spectra demon-

strate[5,38] the mutual exclusion rule between the IR and Raman spectra, the actual molecular form in the crystalline solid state should be either the TTT or the GTG′ form. However, the CNDO/2 spd′ calculation does not support this conclusion, although the TTT form has been shown to be the fairly stable form from the sp calculation.

$(CH_2OH)_2$, $(CH_2OCH_3)_2$, and $CH_3OCH_2CH_2SCH_3$. The vibrational spectra, normal coordinate treatments, and conformational analyses of $(CH_2OH)_2$[36] and $(CH_2OCH_3)_2$[37] have been studied extensively. Recently, the vibrational spectra and rotational isomerism of $CH_3XCH_2CH_2YCH_3$ (X, Y=O or S) have been published.[38] The CNDO/2 calculations for these molecules have been conducted assuming the typical forms, the results of which are summarized in Table 3. The stability, determined with the aid of the CNDO/2 calculations for $(CH_2OCH_3)_2$ agree excellently with the observed, TGT>TTT>TGG>TTG,[38] although the present calculation was not performed on the TTG form. With $CH_3OCH_2CH_2SCH_3$, the observed frequencies[38] in the crystalline solid state can be well explained by the GGT form—the most stable form calculated from the MCNDO method—as well as by the TTG form, which was concluded as the stable form in the crystalline solid state.[38]

MeSH and EtSH. The relations between the bond order, bond lengths, and force constants have been reported by Coulson.[39,40] It has been previously shown that a linear relationship exists between the bond length r(X–H) and the X–H stretching frequency and the bond order matrix elements, $P_{1sH,nSX}$ calculated by the POPLE method, where n is 2 or 3, and X is C, N, or Si.[41] The same is true in this case as shown in Fig. 2. These results, therefore, imply that most of the X–H stretching force constant K(X–H) can be explained in terms of the relation between the 1s AO of hydrogen and the ns AO of the X atom.

The angles ϕ(CSH), ϕ(HSH), and ϕ(SSH) of the molecules having the S–H bond are excellently reproduced, both by the POPLE and MCNDO methods (Table 2). The torsional angle is also fairly well reproduced. However, the sp calculations, in general, do not agree with the observed ones very well. With EtSH, the energy difference has been found and is summarized in Table 4. The experimental value obtained from the calorimetric data gives the stability G>T and the difference 0.3 kcal/mol,[42] and recent microwave data[14] the value 0.406 kcal/mol. The observed values are well explained by the calculations. The MCNDO method is refined a little in the energy difference.

Geometries; 1: TGT, 1′: TTT, 2: from Ref. 33, 3: from Ref. 13 in T, 3′: from Ref. 15 in G, 4: e of Table 2 with r(S–H)=1.3362 Å, 5: g of Table 2 in T, 6: see geometry listed in Table 2, 7: TT. $(CH_2SH)_2$: we have at first carried out the calculations using r(S–H)=1.4 Å then we have obtained an extraordinarily low value of $P_{1sH.3sS}$: 0.2554. On the other hand the infrared frequency does not lie off the ordinary value. Therefore, we have assumed r(S–H)=1.335 Å only in these calculations (bond order calculations).

CH_3SCH_2SH and $CH_3SCH_2SCH_3$. The optimized angles are shown in Table 2 along with the observed values for dimethyl ether (MeOMe),[43] dimethyl sulfide (MeSMe),[44] $CH_3OCH_2OCH_3$,[18] poly(oxymethylene) (POM),[45] PES,[34] and PTM.[35] For the ϕ(CSC) of the molecules now of interest, it can be expected that the value is larger than that of MeSMe[44] and smaller than that of PTM.[35] The sp calculations reproduce the values as expected except for the τ(C–S) of CH_3SCH_2SH, but the spd′ calculations are somewhat too large. The CNDO/2 calculations were then performed with variations in the torsional angle. From the analyses of the vibrational spectra it has been concluded that for CH_3SCH_2SH only one form exists, the GG form in the crystalline solid state as compared with five

forms, GG, GT, TG, GG′, and TT, which coexist in the liquid and gaseous states.[10] With $CH_3SCH_2SCH_3$, the order of the stability has been reported as: GG>TG>TT≫GG′.[7,8] By the MCNDO method using the assumed geometry $\phi(CSC)=99°$ and $\phi(CSH)=96.5°$, the order for CH_3SCH_2SH has been established as: GT>GG>GG′>TG>TT, and for $CH_3SCH_2SCH_3$ as: GG>TG>TT≫GG′. With $CH_3SCH_2SCH_3$, the most stable form GG is well explained by the MCNDO method, the stable structure corresponding with that of the oxygen analog, $CH_3OCH_2OCH_3$.[18,19] With CH_3SCH_2SH, however, the most stable form has been calculated as GT by the MCNDO method, but this does not agree perfectly with the observed one.[10] In the course of the analyses of the IR spectra of this molecule, the most stable form expected was the GG or GT form. From the frequency shift of the S–H stretching vibration by D substitution it has been concluded that the most stable form is the GG. In the molecule CH_3SCH_2SH, the conformation about the bond CH_3SCH_2–SH is indeed very difficult to explain, since hydrogen is a very light and small atom. It may be concluded that the conformation about the bond CH_3S–CH_2SH is reproduced by the spd′ calculations. In the case of $CH_3SCH_2SCH_3$, it has been previously stated that the GG′ form is not the stable form even in the liquid state.[7,8] On the other hand the GG′ form has been taken into consideration for CH_3SCH_2SH.[10] These situations are well reproduced by the CNDO/2 method.

The sp calculations explain fairly well the geometries of CH_3SCH_2SH and $CH_3SCH_2SCH_3$ as reported above, but do not explain the stability. In the case of two sulfur atoms in a molecule, the interactions between the d-orbitals may play an important role in the conformational stability. Therefore, it is better to use the spd′ calculation for the molecules having more than two sulfur atoms in a molecule than the sp calculation.

The conclusions drawn are that the use of the POPLE and MCNDO parameters give fairly good ϕ(CSH) and internal rotation angles for simple aliphatic thiols. The present calculations also show that the molecular geometry reported for $(CH_2SH)_2$[11] appears ambiguous, in particular in ϕ(CSH) and r(S–H). The energy barrier is better reproduced by the MCNDO method than by the POPLE one (Table 4). The dipole moment in general decreases in the order: POPLE>MCNDO>KCNDO and in these respects, the MCNDO method is better than the original CNDO/2 method. The angle ϕ(CSH) for RSH is better reproduced by the CNDO/2 spd′ method than by the MINDO/3 method.[17]

The CNDO/2 method now used, however, may not reproduce the energy difference itself between the rotational isomers which is very important in the analysis of rotational isomerism. Therefore in the CNDO/2 parameters there may be still some ambiguities, in particular relating to the 2nd-row elements. Generally, from the vibrational data and normal coordinate treatment, it is very difficult to determine which rotational isomer is more stable when the calculated frequencies of the rotational isomers are almost identical. In order to overcome this difficulty, the CNDO/2 method is helpful.

The authors wish to thank Prof. Akira Imamura of Shiga University of Medical Science for his kind advice. All calculations were performed at the Computing Center of Hiroshima University.

Conformational Transition of Poly(L-glutamic acid) in Aqueous Decylammonium Chloride Solution

Iwao SATAKE,* Takeshi GONDO,† and Hideo KIMIZUKA†

Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890

†*Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812*

(Received August 5, 1978)

The cooperative binding of decylammonium chloride to poly(L-glutamic acid) (PLG) was studied by the potentiometric measurement of the binding isotherm at pH 7.9. Circular dichroism spectra were also measured as a function of the degree of binding of surfactant ion (x). It was shown that the coil to α-helix transition of PLG-surfactant complex takes place with a change in x. PLG did not undergo an appreciable conformational change in the range of x below 0.55. But the helical content increased suddenly with further increase in x. An abrupt increase in the helical content of PLG-surfactant complex can be well interpreted in terms of the hydrophobic interaction among bound surfactant ions. On the basis of the theoretical analysis of the cooperative binding isotherm, it was concluded that the formation of a micelle-like cluster consisting of at least eight surfactant ions is required for the stabilization of a surfactant induced helical structure.

The conformational transition of polypeptide in surfactant solution is of special interest in connection with the effect of surfactant on protein structure. Although most studies so far reported have been confined to the conformational changes of poly(L-ornithine) (PLO) homologs with side chain R=$-(CH_2)_nNH_2$, some interesting features of such transition have been clarified.

PLO (n=3)[1,2] and its homologs (n=5—7)[3] adopt helical conformation in neutral solution of sodium dodecyl sulfate (SDS). The coil to helix transition of PLO is also noted in solution of sodium n-alkyl sulfate with 8 to 16 carbon atoms.[2] In contrast, however, poly(L-lysine)(PLL, n=4) assumes β-structure in neutral solutions of sodium decyl sulfate (SDeS) and its longer chain homologs,[2,4-8] while it assumes helical structure in sodium octyl sulfate solution.[2] Upon raising the pH of SDS solution, PLL undergoes a reversible β to helix transition.[7-9] These conformational changes occur even in the concentration of SDS much lower than the critical micelle concentration (CMC), suggesting a highly cooperative binding of surfactant ions to polypeptide.[2,7,8,10] An acidic solution of SDS causes poly(L-arginine) to undergo a coil to helix transition and poly(L-histidine) to change from a coil to β-structure.[11] In view of these observations, it is likely that the hydrophobic interaction between electrostatically bound surfactant ions plays a predominant role in the conformational change of charged polypeptide in surfactant solution. However, little is known about the factors which influence the type of a resulting conformation.

One might expect a similar conformational change of anionic polypeptide in cationic surfactant solution. The purpose of the present paper is to determine the binding isotherm of decylammonium ion to poly(L-glutamic acid)(PLG) and to find a correlation between the degree of binding and a resulting conformational change as inferred from circular dichroism (CD) spectra.

Experimental

Materials. PLG (Miles-Yeda Ltd., molecular weight 50000) was converted to sodium salt by dissolving it into dilute sodium hydroxide solution and then dializing against distilled water. The polypeptide concentration was determined by micro-Kjeldahl nitrogen analysis. Decylammonium chloride (DeAC) was prepared from 99% decylamine (Nakarai Chemicals Ltd.) according to a method described by Kolthoff and Strickes.[12] The pK_a of DeAC in 10^{-2} mol/dm³ KCl solution was determined from pH titration to be 10.4 at 25 °C.

Binding Isotherm Measurement. Since PLG is a typical polyelectrolyte, the apparent dissociation constant (K) depends not only on the degree of dissociation (α), but on added salt concentration. For instance, in 5×10^{-3} mol/dm³ NaCl, the pK value varies from 4.45 at α=0 to 6.0 at α≈0.9.[13] This means that about 10% of carboxylic acid groups remain still undissociated even at pH 7. In order to secure the complete dissociation of PLG, therefore, all experiments were performed with buffered solution at pH 7.9, which contains 4.32×10^{-3} mol/dm³ sodium borate and 7.36×10^{-3} mol/dm³ hydrochloric acid. The binding isotherm of DeAC to PLG was determined potentiometrically at 25 °C, using a poly(vinyl chloride)(PVC) plastic electrode which had been shown to respond to tetraalkylammonium ions.[14] The cell constructed was as in the following.

Reference electrode (Ag-AgCl)|1 mol/dm³ NH_4NO_3 Agar bridge|Reference solution (DeAC, 5.238×10^{-4} mol/dm³)|PVC membrane|Sample solution ($C_p=3.18\times10^{-4}$ residue mol/dm³; DeAC, C_t; Borate buffer)|1 mol/dm³ NH_4NO_3 Agar bridge| Reference electrode (Ag-AgCl),

where, C_p denotes the concentration of PLG in residue mol/dm³ and C_t, the total concentration of DeAC, respectively. The PVC membrane was prepared by dissolving 0.6 g of PVC into mixed solution of 2.4 cm³ of bis(2-ethylhexyl) phthalate and 2.4 cm³ of 10^{-4} mol/dm³ DeAC in tetrahydrofuran. The solution was then poured onto a covered glass dish and allowed tetrahydrofuran to evapolate slowly. A resulting film 0.30 mm thick was fixed to a PVC tube of 9 mm diameter by the use of a tetrahydrofuran solution of PVC. The electromotive force (EMF)(E) of the cell was measured with a Corning Digital 112 Research pH Meter with an accuracy of ±0.1 mV. Prior to the measurements on PLG solutions, the PVC membrane was calibrated with solutions of DeAC. Figure 1 shows the semilogarithmic plots of EMF *vs.* DeAC concentration. A linear relation with a slope of 57.9 mV suggests that the PVC membrane responds to surfactant ion exclusively in the concentration range studied. The concentration of PLG was

kept constant throughout a series of experiments.

Circular Dichroism. The CD spectra were obtained at 25 °C with a JASCO Automatic Recording Spectropolarimeter J-40A, using 1 cm path length cell equipped with water-circulating jacket. The spectra were recorded 3.5—4 h after mixing, because an appreciable time dependence was found during first 2—3 h.

Results and Discussion

In order to estimate the degree of binding (x) of decylammonium ion to PLG, it is necessary to assume that the polypeptide ions in an excess salt solution do not affect appreciably the activity coefficient of free surfactant ion.[10] On this assumption, which is compatible with a theoretical prediction,[15] x may be given as

$$x = C_b/C_p = (C_t - C_f)/C_p, \quad (1)$$

where, C_b represents the bound surfactant ion concentration and C_f, the free surfactant ion concentration which can be determined from Fig. 1.

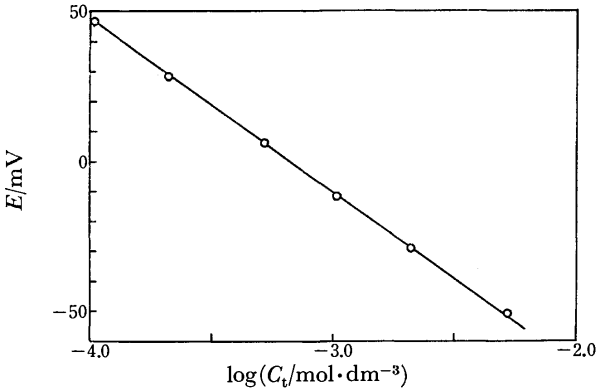

Fig. 1. Plots of EMF (E) of the cell *vs.* the logarithm of decylammonium chloride concentration in the absence of PLG at 25 °C.

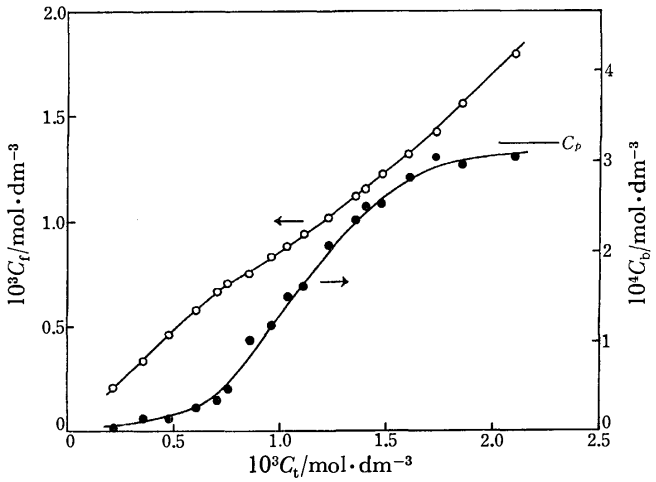

Fig. 2. Plots of C_f and C_b *vs.* C_t at 25 °C. C_p=3.18 $\times 10^{-4}$ residue mol/dm³. Arrows indicate the ordinate to be applied.

In Fig. 2, C_f and C_b observed with constant PLG concentration of 3.18×10^{-4} residue mol/dm³ are plotted against the total concentration of DeAC, C_t. Through a broad kink at about 7×10^{-4} mol/dm³, C_t first increases

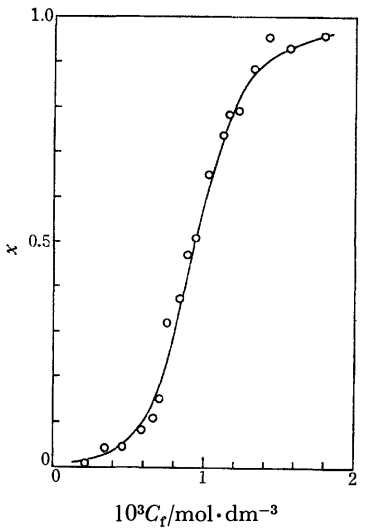

Fig. 3. The binding isotherm of decylammonium chloride to PLG at 25 °C.

almost linearly with increasing C_t and then increases gradually with further increase in C_t. In accordance with the change in C_f, C_b shows a sigmoidal increase with C_t and approaches eventually to PLG concentration, C_p. Figure 3 shows the binding isotherm of DeAC to PLG calculated from Fig. 2. Since the carboxylic acid groups of PLG are completely ionized at pH 7.9, decylammonium ion can interact electrostatically with carboxylate group, giving rise to an ion pair. As was pointed out by Satake and Yang,[10] however, the binding process of surfactant ion to polypeptide ion becomes cooperative because of an additional hydrophobic interaction among bound surfactant ions. In these circumstances, the bound surfactant ions will cluster side by side onto polypeptide chain even in small degree of binding and cause the binding isotherm to rise steeply in narrow range of C_f. This is indeed the case for the present result shown in Fig. 3, where x increases more rapidly than predicted by simple statistical binding model. In this connection, it is interesting to compare the present binding isotherm with those of sodium decyl sulfate to PLL and PLO.[10] In the case of PLL, the binding isotherm was found to rise almost vertically at a certain value of C_f, indicating a highly cooperative binding of decyl sulfate ion. This in turn results in a micellar clustering on the polypeptide chain similar to the micelle formation process of the surfactant alone above its CMC. On the other hand, the binding isotherm for PLO is not so sharp as for PLL,[10] but is still sharp as compared with the present result. These facts imply that the cooperativity in surfactant ion binding to polypeptide depends virtually on the total alkyl chain length of the complex species, *i.e.*, the sum of alkyl chain length of bound surfactant ion and polypeptide side group. The type of ionic group seems to play, if any, a minor role.

On the basis of Zimm-Bragg theory[16] for helix-coil transition, Satake and Yang[10] derived the following expression for the cooperative binding of small ions to polymer;

$$2x - 1 = (y-1)/[(1-y)^2 + 4yu^{-1}]^{1/2}, \quad (2)$$

where

$$y = C_f/(C_f)_{x=0.5}. \quad (3)$$

In Eqs. 2, and 3, u denotes a parameter, which is a measure of cooperativity, defined by

$$u = \exp[(2E_{01}-E_{11}-E_{00})/kT], \quad (4)$$

where, E_{ij} represents the interaction energy between neighboring i-j pairs, and suffix 0 and 1 refer to an unbound and a surfactant-bound polypeptide side chain respectively. The estimation of u can easily be attained by using a relation,

$$(dx/d\ln C_f)_{x=0.5} = u^{1/2}/4. \quad (5)$$

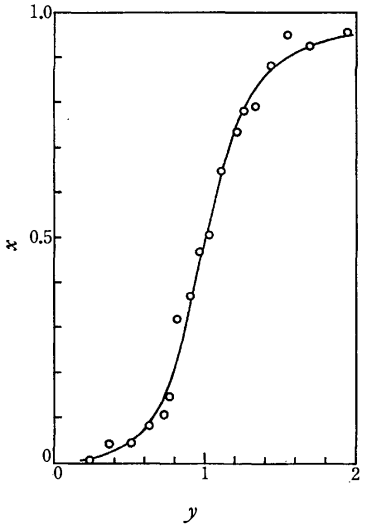

Fig. 4. Comparison of calculated and observed binding isotherm for PLG at 25 °C. ○, observed; solid line, calculated isotherm from Eq. (2) with $u=40$.

The most reliable value of u for the present system was found to be 40, reflecting well the cooperative nature of the binding process. The value of $u=40$ corresponds to an interchange energy $(2E_{01}-E_{11}-E_{00})$ of 9.12 kJ at 25 °C. Figure 4 shows the comparison of the calculated binding isotherm from Eq. 2 with $u=40$ with the observed one. The agreement is quite satisfactory over nearly whole range of x. As would be anticipated, the value of u obtained above is considerably small as compared with that of 77 for SDeS–PLO system.[10] This may reasonably be ascribed to a change in hydrophobic interaction between neighboring groups, arising from a difference in the alkyl chain length of polypeptide side group. According to a foregoing treatment,[10] the average cluster size ($\bar{m}$) of bound surfactant ions, *i.e.*, the average number of bound surfactant ions which constitute a one-dimensional micellar cluster on the polypeptide chain, is given as

$$\bar{m} = 2x(u-1)/[\{4x(1-x)(u-1)+1\}^{1/2}-1]. \quad (6)$$

In Table 1, the calculated values of $\bar{m}$ from Eq. 6 with $u=40$ are given as a function of x. It should be noted

Table 1. The calculated value of $\bar{m}$ as a function of x

x	0.1	0.2	0.3	0.4	0.5	0.55	0.6	0.7	0.8	0.9
$\bar{m}$	2.7	3.8	4.9	6.0	7.3	8.1	9.0	11.4	15.2	24.4

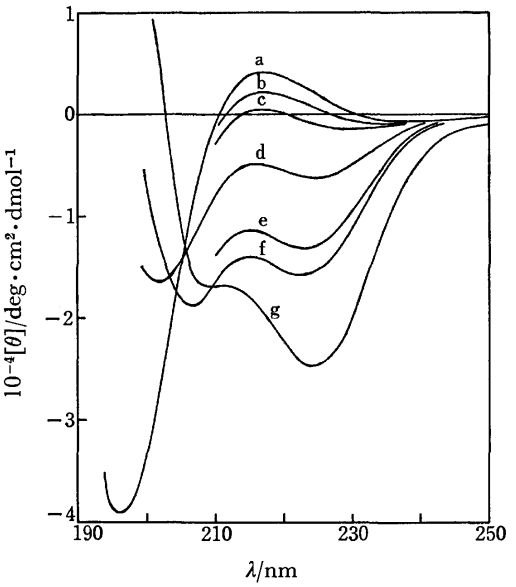

Fig. 5. The change in CD spectrum of PLG with respect to x at 25 °C.
a, 0; b, 0.35; c, 0.56; d, 0.64; e, 0.72; f, 0.80; g, 1 (C_t=0.1515 mol/dm³).

that the cluster size of bound surfactant ions increases rapidly with increasing x.

It is of great interest to find an interrelation between the degree of binding (x) or the average cluster size ($\bar{m}$) and the conformational change induced by surfactant ion binding. To this end, CD spectra were measured under the same experimental conditions as for binding isotherm measurement. Figure 5 shows the change in CD spectrum with respect to x. In the absence of surfactant, the CD spectrum of PLG is characterized by two extrema, a maximum centered at 217 nm with mean residue ellipticity, $[\theta]_{217}$, of 4300 and a deep minimum at 196 nm with $[\theta]_{196}$ of −39000. An additional shallow minimum is also observed at around 235 nm. These features agree well with the CD spectra observed for PLG[17] and PLL[18,19] in their random conformations. With increasing degree of binding, the CD spectrum of PLG tends to approach progressively to a typical spectrum which has a double minimum characteristic of α-helical conformation. A similar change in CD spectrum with surfactant concentration has been found for PLL in SDS solution[2,7] as well as for PLO in solutions of SDS[2] and SDeS.[10] At a concentration above CMC, where x may virtually be regarded as unity, the CD spectrum shows a deep minimum centered at 224 nm with $[\theta]_{224}$ of −25000 and a well defined shoulder located at 209—210 nm with $[\theta]_{209}$ of −17000. Hence, the ordered conformation of PLG in DeAC solution can reasonably be identified as an α-helical structure. It must be kept in mind, however, that the CD spectrum of surfactant induced helical conformation is somewhat different in shape and magnitude from those of helical PLG and PLL in water.[1,2,11] In the absence of surfactant, a double minimum of helical PLG or PLL has been found to locate at 221—222 nm with $[\theta]_{222}$ of −(32000—40000) and at 207—209 nm with $[\theta]_{207-209}$ of −(33000—39000).[17-20] Unfortunate-

ly, there is no conclusive evidence that accounts for the observed decrease in CD minima of helical polypeptide in surfactant solution. Grourke and Gibbs[1] have assumed that the environment produced by the bound surfactant ions affects the rotatory strengths of n-π^* and π-π^* transitions. Nevertheless, it seems equally probable that the surfactant induced helical structure contains small amounts of random conformation. It is true that the above situation makes it difficult to estimate the precise percentage of helix in PLG–DeAC complex, but $[\theta]_{222}$ is still available for a measure of helix content.

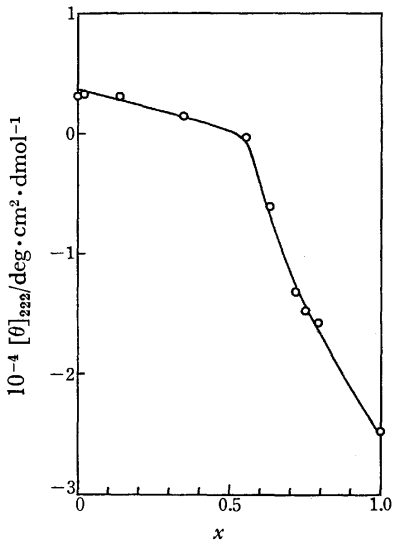

Fig. 6. Plots of $[\theta]_{222}$ *vs.* x at 25 °C. Value at $x=1$ is that in 0.1515 mol/dm³ decylammonium chloride solution.

In Fig. 6, $[\theta]_{222}$ is plotted as a function of x. A clear kink occurs at $x\approx0.55$, through which the magnitude of $[\theta]_{222}$ increases sharply with further increase in x. This implies that PLG does not undergo an appreciable coil to helix transition unless more than 50% of carboxyl groups are bound to decylammonium ions and that a helical structure of the complex become stable only when x exceeds this critical value. An abrupt increase in $[\theta]_{222}$ with x was also observed by Satake and Yang[10] for PLO in SDeS solution. In this case, however, the kink point locates at $x=0.3$—0.4, which corresponds to the average cluster size ($\bar{m}$) of bound decyl sulfate ions of 7—8.[10] This, in turn, corresponds to the number of residues included in two helical turns of α-helical structure. On the basis of these observations, they assumed that the hydrophobic interaction of each bound surfactant ion with another one locating one turn above or below is essential for the formation of a stable helical structure. If this is also valid for PLG–DeAC system, the kink point in $[\theta]_{222}$ *vs.* x plot should appear at x which corresponds to $\bar{m}=7$—8. In addition, the critical x value for the present system will be slightly large as compared with that for PLO–SDeS system, since the binding process is less cooperative in the former than in the latter. The estimation of $\bar{m}$ given in Table 1 supports well the above predictions. As would be expected, the critical value of $x=0.55$ corresponds to $\bar{m}\approx8$.

The authors wish to thank Prof. M. Tanaka and Prof. G. Sugihara, both of Fukuoka University and also to Prof. T. Inaba of Saga University for their helping in CD measurements.

The Crystal and Molecular Structure of Benzanilide

Setsuo KASHINO,* Kuniaki ITO,† and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received August 7, 1978)

The crystal structure of benzanilide has been determined from Weissenberg photographs using Cu $K\alpha$ radiations and refined to an R value of 0.075 for 766 independent reflections. The crystals are monoclinic, space group C2/c, $Z=4$, with $a=24.34(4)$, $b=5.325(3)$, $c=8.012(8)$ Å, $\beta=107.2(3)°$, $D_m=1.32$ and $D_x=1.321$ g cm^{-3}. Dihedral angle between the benzene rings is 62.6°, and each benzene ring makes dihedral angle of 31.3 and 31.6° with the plane of amido group as found in Kevlar and Nomex polymers. The molecules related by a ***b***-translation are linked together by N-H···O hydrogen bond [N···O 3.112(6), H···O 2.03 Å, N-H···O 157°] to form a chain along ***b***. The chains are held together primarily by dipole forces of carbonyl groups of the molecules related by inversion centers to form a sheet parallel to the *bc* plane. The sheets are stacked along ***a*** with disorder by van der Waals interactions.

The present work forms a part of studies on the relationship between molecular conformation and crystal structure of aromatic compounds containing amido group.[1] One particular interest is in a comparison of the compounds in which two benzene rings are separated by two bonding atoms. Another aspect is of a model compound of the polymer chains in poly(*p*-phenyleneterephthalamide) (Kevlar) and poly(*m*-phenyleneisophthalamide) (Nomex). Their conformations have been explained to be governed primarily by torsion about the exocyclic bonds.[2-4]

Experimental

Crystals were grown from an ethanol solution by slow evaporation as hexagonal plates with developed (100) and bounded by {001} and {011}. Systematic absences were *hkl* with $h+k$ odd, and *h0l* with l odd, hence the space group was Cc or C2/c. During the analysis Cc was ruled out. The density was measured by flotation in aqueous KI solution.

Crystal Data: Benzanilide, $C_{13}H_{11}NO$, $Mr=197.2$, mp 161—162 °C, monoclinic, space group C2/c, $a=24.34(4)$, $b=5.325(3)$, $c=8.012(8)$ Å, $\beta=107.2(3)°$, $V=992(3)$ Å^3, $D_m=1.32$, $D_x=1.321$ g cm^{-3}, $Z=4$, μ(Cu $K\alpha$)$=6.89$ cm^{-1}, $F(000)=416$.

Intensity data were collected on Weissenberg photographs for the layers *h0l* to *h4l* by using a specimen of dimensions 0.3 × 2.0 × 0.4 mm. The intense reflections, particularly 002, were accompanied by diffuse streaks elongated along a^*. Intensities of 766 independent reflections were visually estimated and corrected for Lorentz and polarization factors and for spot shape. Inter-layer scaling was made according to the exposure time (about 40 h for each layer). Wilson's plot gave $B=6.99$ Å^2. Distribution of E-values preferred to centrosymmetrical space group.

Structure Determination and Refinement

The structure was solved from a Patterson map and refined by block-diagonal least-squares calculations. Analysis based on the space group Cc gave extraordinary values of bond lengths and angles even at the stage of R value of 0.087. Therefore the space group C2/c was adopted by assuming the disorder with occupancy factor 0.5 about the twofold rotation axis. A difference Fourier map (Fig. 1) at the stage of $R=0.10$ revealed the H atoms. For further refinements the H atoms were included with their thermal parameters ($B=6.99$ Å^2) and fixed positional parameters deduced from the geometry of the molecule. The weighting scheme used was: $w=1.0$ for $0<|F_o|\leq 5.0$, $w=(5.0/|F_o|)^2$ for $|F_o|>5.0$. The final R value was 0.075 for 766 non-zero reflections.

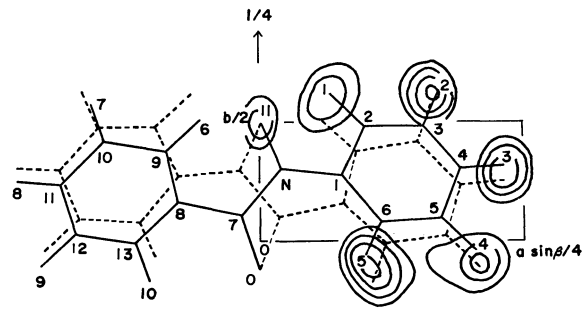

Fig. 1. Difference Fourier map at the stage of $R=0.10$. Contours are depicted for positive x region, at intervals of 0.1 e Å^{-3} starting at 0.1 e Å^{-3}. The molecular frames are based on the final positional parameters.

TABLE 1. THE FINAL POSITIONAL PARAMETERS (×10^4) OF THE NON-HYDROGEN ATOMS WITH STANDARD DEVIATION IN PARENTHESES

For all the atoms the occupancy factor is 0.5.

Atomic scattering factors were taken from International Tables for X-Ray Crystallography.[5] The computations were carried out on an NEAC 2200-500 computer at the Okayama University Computer Center. The programs used were HBLS-5 and DAPH.[6] The final atomic parameters are listed in Tables 1 and 2.[7]

Results and Discussion

Molecular Structure. Bond lengths and angles are given in Fig. 2. The least-squares planes of the benzene rings and the amido group and the displacement of the atoms from the planes are listed in Table 3. The dihedral angles of two benzene ring-planes with respect to the amido group plane are 31.3 and 31.6°. These values are close to those in Kevlar and Nomex and consistent with the value calculated from the π-bond energy and the steric interaction.[4]

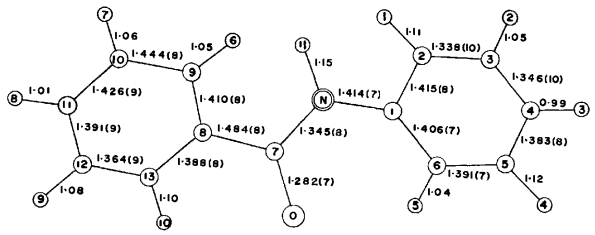

Fig. 2. The molecular structure: (a) bond lengths (Å) and numbering of atoms, (b) bond angles (°).

It is interesting to compare the competitive interactions between the resonance effect of the benzene ring and the steric hindrance of attached atoms to the ring. Table 4 lists the torsion angles about the exocyclic

bonds in the series of compounds, *p*-R–Ph–XY–Ph–R′-*p*, where the central part XY is such as CH=N, N=N, CH=CH (these are isoelectronic), and so on, and the substituents R and R′ are confined to relatively small groups for the sake of brevity A survey of the crystal structures of this series shows that the molecules in the crystals are classified into either centrosymmetrical or non-centrosymmetrical group, the present one belonging to the latter The former is visualized only when X and Y are identical or isoelectronic and R and R′ are also identical. The torsion angles are in general very small, suggesting the electronic delocalization extended over the central part between benzene rings. Large torsion angles occur only when X and Y are attached by bulky substituents (*e.g.* CN) or of sp^3 hybrid type missing conjugation. Even in this case parallelism of two benzene rings is maintained.

On the other hand, when X and Y or R and R′ are different the two benzene rings lose the parallelism and make in general large dihedral angle near 60°. In the non-centrosymmetrical group the torsion angles about each exocyclic bond differ greatly from each other in general. The disordered structure is, however, observed only when these torsion angles are similar to each other as in the present compound.

It is of interest to note that *N*-(*p*-chlorobenzylidene)-*p*-chloroaniline shows dimorphism where the Pccn form[8] belongs to the non-centrosymmetrical group while $P\bar{1}$ form[9] belongs to the centrosymmetrical one. They are conformational dimorphs, showing disorder about twofold rotation axis and inversion center respectively.

Crystal Structure. The crystal structure viewed along **c** is illustrated in Fig. 3. The four possible cells

Table 4. Molecular conformations of the series of compounds, *p*-R–Ph–XY–Ph–R′-*p*

The torsion angles (°) about X–C (aromatic) and Y–C (aromatic) bonds are denoted by $\widehat{\text{XPh}}$ and $\widehat{\text{YPh}}$ respectively, and the dihedral angles (°) between the benzene rings are by $\widehat{\text{PhPh}}$. The values were calculated based on the atomic coordinates in the literatures

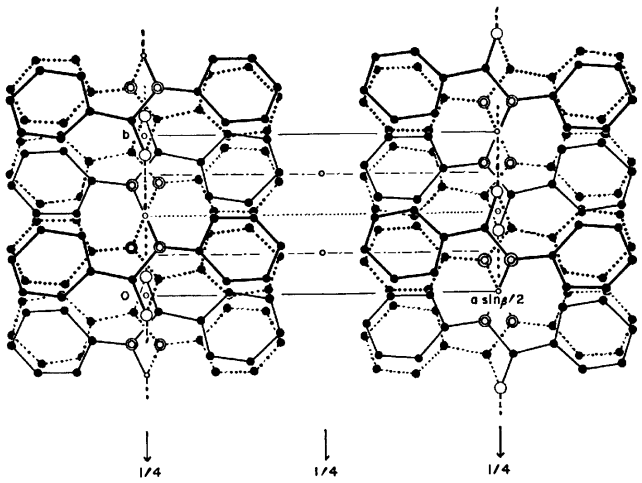

Fig. 3. The crystal structure viewed along ***c***. Arrangement of the molecules shown by solid lines corresponds to that in the $P2_1/n$ cell. The disordered molecules about twofold rotation axis are shown by dotted lines.

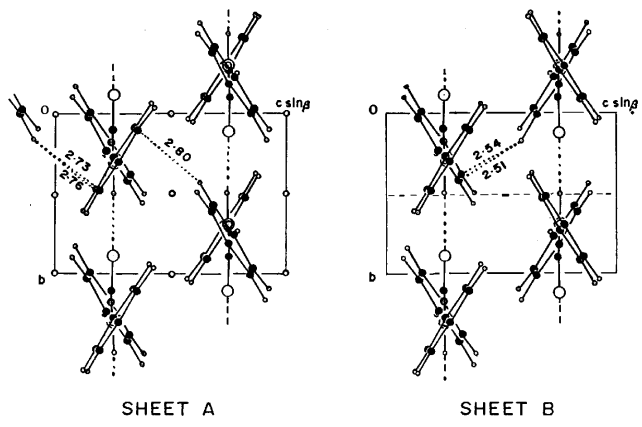

Fig. 4. Two possible arrangements of the chains in the sheets. Short intermolecular contacts are shown by dotted lines, and hydrogen bonds by broken lines.

which generate the apparent space group C2/c by adding the symmetry operation 2 for disordering are listed in Table 5. In the cells, the molecules related by a ***b***-translation are linked together by N–H···O hydrogen bond [N···O 3.112(6), H···O 2.03 Å, N–H···O 157, H···O=C 161°] to form a chain along ***b***. The chains are held together primarily by dipole interactions of the carbonyl groups of the molecules related by inversion centers or c-glide plane to form a sheet A or B parallel to the bc plane. Packing arrangement of the chains in the sheets is illustrated in Fig. 4. The sheets are stacked along ***a*** by van der Waals forces.

As seen from Table 5 and Fig. 4, the sheet A seems to prefer to the sheet B from the viewpoint of the molecular interactions. Concerning to the inter-sheet interactions, there are no significant differences among the stacking modes.

Disordered Structure. Disordering in the chain is not plausible, because it would result in an unexpectedly short intermolecular C···C contact of 3.03 Å. The disorder can be explained by a random stacking of the sheets A by two kinds of operations, 2_1 and $\bar{1}$, with an equal probability. In fact, the continuous streaks are elongated along a^* and no doubling of cell dimension a is observed.

The disordering of the present compound and the Pccn form of *N*-(*p*-chlorobenzylidene)-*p*-chloroaniline is similar in the axis about which disorder occurs, and the torsion angles around the central bond, but in the latter the disordering occurs by random arrangement of the molecular units.

Comparison of the Crystal Structure with the Related Compounds. The chains of amido groups related by a translation have been observed also in the related compounds as shown in Table 6. The dimension of the axis along which the chain extends becomes smaller with increasing the dihedral angle between the amido group and benzene ring. It is noted that the arrangement of the chains in the sheet (Fig. 4) is similar to that of Kevlar,[4)] irrespective of the difference in the symmetry operation relating the chains.

Chemical Reactivity of Würster's Salts at Very High Pressure

Akifumi ONODERA,* Tadayoshi SAKATA,† Hiroshi TSUBOMURA, and Naoto KAWAI

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 9, 1978)

The electrical and chemical properties of some Würster's salts have been studied under the static pressure of up to 250 kbar. In most cases the resistances of the salts decreased to the respective minima and then rose irreversively with increasing pressure. Spectral observations on the recovered specimens revealed that such behavior is associated with chemical reaction induced by the pressure. This reaction takes place more readily in the salts of *p*-phenylenediamine cation radical than in those of Würster's red or Würster's blue radicals.

Recent high-pressure studies on organic solid materials have shown that a number of charge transfer complexes[1-5] and ion radical salts[6-9] cause chemical changes above one hundred kilobars†† or so. The occurrence of chemical reaction is unequivocally indicated by the peculiar behavior in electrical resistance of the specimen showing a minimum on the way of increasing pressure and monotonic rise on the way of decreasing pressure. The samples recovered after the application of pressure were chemically analysed and the reaction mechanisms were elucidated.[2-4]

In a previous paper[4] we reported the pressure-induced chemical reactions in three charge transfer (CT) complexes of *p*-chloranil with aromatic diamines. In the crystalline state of CT complexes the donor and acceptor molecules are generally stacked alternately in columns. The crystals of ion radical salts, on the other hand, are made up of columns of ion radicals. The interactions between adjacent molecules within a column are strong while the interaction between columns are much weaker. Therefore, the chemical reactivities of ion radical salts would be different from those in CT complexes.

The present investigation was undertaken to see chemical reactivity at very high pressure in a series of ion radical salts derived from *p*-phenylenediamine (PD), *N*,*N*-dimethyl-*p*-phenylenediamine and *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine The counter ions were iodide, bromide and perchlorate. The electrical resistance measurements of the radical salts were carried out under various pressures and the reaction products recovered after the application of high pressure were analysed spectroscopically.

Experimental

Materials. *p*-Phenylenediamine bromide (PDB) and *p*-phenylenediamine iodide (PDI) were prepared by the reaction of *p*-phenylenediamine with the respective halogens in methanol. Würster's red bromide (WRB) and Würster's red iodide (WRI) were obtained by the reaction of *N*,*N*-dimethyl-*p*-phenylenediamine with the respective halogens in methanol. *p*-Phenylenediamine perchlorate (PDP), Würster's red perchlorate (WRP) and Würster's blue perchlorate (WBP) were prepared by the oxidation of dissolved amine perchlorate and sodium perchlorate with bromine in ethanol.[10] The radical salts were submitted for elementary analyses on formation and were compressed within a week.

† Present address: Institute for Molecular Science, Olazaki, Aichi 444.

†† 1 bar=10^5 Pa.

High-pressure System. The materials described above were compressed in a split sphere-type apparatus.[11] The apparatus is composed of cube, sphere and cylinder, all split up and assembled in a layered structure as shown in Fig. 1. A sphere made of hardened steel is equally divided into six segments, each with a square face at the front. Three out of the six segments are placed in a hemispherical space on the upper part of a cylinder. Similarly, the second assemblage is constructed using the remaining three segments. The two assemblages are set opposed and joined so that a cubic cavity whose ⟨111⟩ direction is parallel to the axis of cylinders is formed in the center of the join.

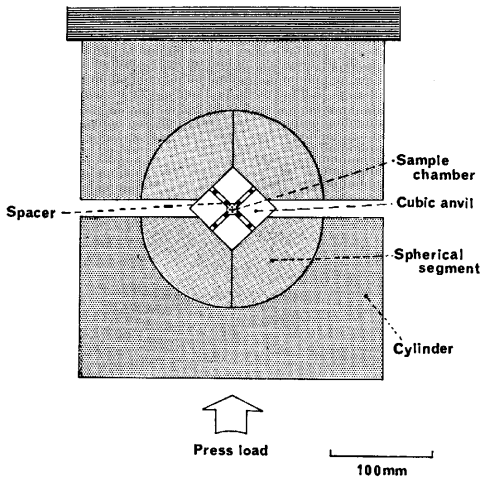

Fig. 1. A schematic drawing of the high-pressure apparatus.

An assemblage of eight cubic anvils made of cemented tungsten carbide is placed in the cubic cavity. A corner of each cubic anvil is truncated to form a triangular face. When the eight cubic anvils are put together an octahedral hollow space is formed in the center of the assemblage. Into this space is placed an octahedral pressure-transmitting medium made of pyrophyllite ($Al_2O_3 \cdot 4SiO_2 \cdot H_2O$). Crushable spacers made of cardboard are sandwiched in the gaps among the eight cubic anvils. When the two cylinders containing a split sphere and cubes are compressed in a uniaxial press, the thickness of the spacers decreases and quasi-hydrostatic high pressure is generated in the octahedral chamber. The pressures are calibrated by measuring the sharp resistance changes at the phase transitions of Bi (Bi_{I-II} at 25 kbar, Bi_{V-VI} at 74 kbar), ZnTe (127 kbar), Pb (132 kbar), ZnS (153 kbar), GaAs (177 kbar) and GaP (222 kbar).[12-16]

As shown in Fig. 2 the sample is enclosed within a Teflon capsule which is inserted into a hole drilled from a face to face of the ocatahedral chamber. Two platinum electrodes

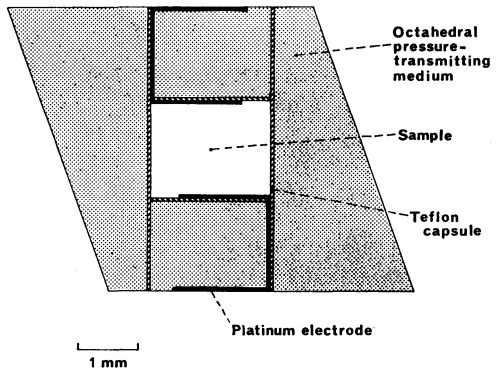

Fig. 2. A cross section of the octahedral pressure chamber.

for resistance measurements are taken out of the octahedron and are in contact with the top faces of the two of the eight cubic anvils. Electrical insulation between the anvils is provided by cardboard spacers and also by thin sheets of mica.

Measurements. The electrical resistance of the samples under pressure is measured *via* two cubic anvils with a Keithley 160B digital multimeter. The resistance of the cubic anvils is low enough to be neglected. On the other hand, the resistance of the pressure-transmitting medium is higher than that of any of the present samples by more than one order of magnitude. Thus the observed resistance reflects substantially the behavior of the sample. For the recovered samples after the application of pressure, the electronic spectra are obtained on the KBr disks with a Shimadzu Model MPS-50L multipurpose spectrometer. The vibrational spectra are obtained on a JASCO JRA-1 type diffraction grating infrared spectrometer using a similar KBr method.

Results

PD Cation Radical Salts. In Fig. 3 the electrical resistance of PDP is plotted on a logarithmic scale as a function of pressure. The resistance drops rapidly with pressure up to about 130 kbar. At higher pressure the resistance begins to rise. A noticeable upward drift of the resistance continues while the pressure is kept fixed. Beyond 200 kbar the resistance begins to decrease slowly. The resistance changes on the unloading process as shown by a dotted line in the diagram.

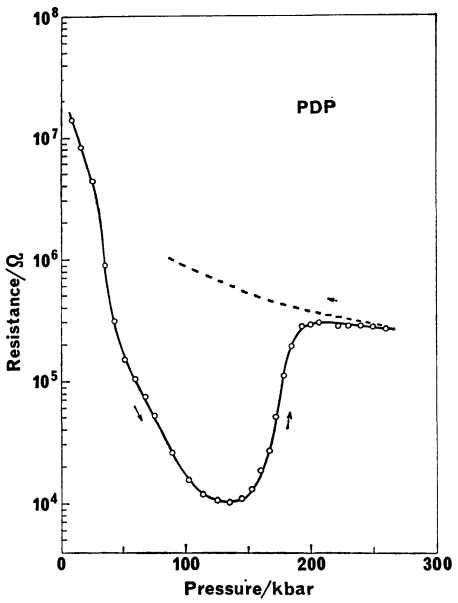

Fig. 3. Electrical resistance *versus* pressure for PDP.

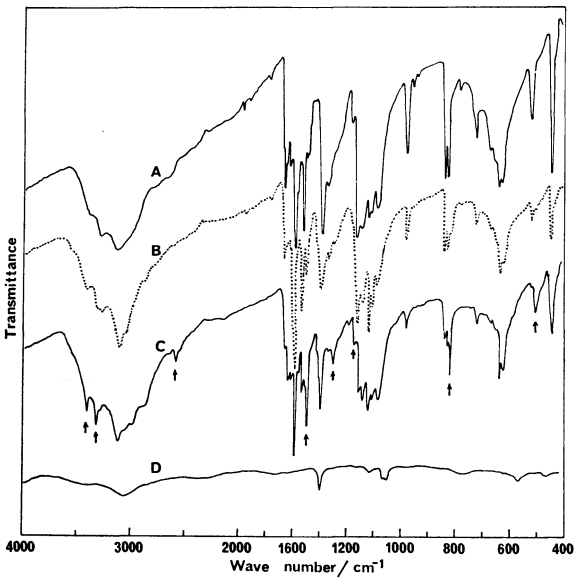

Fig. 4. Infrared spectra.
A: PDP at 1 bar, B: the sample recovered after the application of 140 kbar, C: the sample recovered after the application of 180 kbar, D: the sample recovered after the application of 220 kbar.

Figure 4 shows the infrared (IR) spectra of PDP before and after the compression. It should be noted that there was no appreciable change in the spectrum for the specimen compressed to pressures lower than 130 kbar, where a minimum appears in the electrical resistance. At 140 kbar new bands become to appear on the IR spectrum B, and at 180 kbar they become stronger as shown by the spectrum C. The bands indicated by arrows in Fig. 4, at 3420, 3330, 2590, 1505, 1300, 1195, 820, and 505 cm^{-1}, are assigned to 4-aminophenylammonium perchlorate, [PDH$^+$][ClO_4^-]. This was confirmed by the comparison of the bands with those in the IR spectrum of the synthesized authentic sample. The spectrum D is quite simple, suggesting that the product at higher pressure is polymeric. In the spectra of the high-pressure products in Fig. 4, there remain the bands responsible for the starting material, showing that the reaction in this system is rather slow.

Figure 5 shows the electronic absorption spectra of PDP and its reaction products recovered after the application of pressure, all specimens containing equal amounts of PDP in each of the KBr pellets. In the spectrum of PDP at 1 bar, the band at 13000 cm^{-1} is assigned to the charge transfer between cation radicals, whereas the peaks at 28800 and 35500 cm^{-1} are due to the local excitation between cation radicals.[17] As seen in Fig. 5 the band at 13000 cm^{-1} becomes weaker and shifts to blue with increasing pressure. The intensities of the peaks at 28800 and 35500 cm^{-1} decrease and the peaks shift to red with increasing pressure. The spectrum

The weight concentration of the above samples are epual to each other.

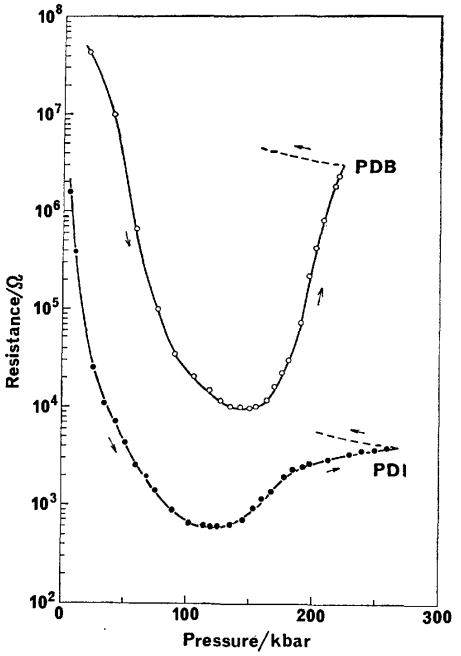

Fig. 6. Electrical resistance *versus* pressure for PDB and PDI.

C in Fig. 5 is well accounted for by a formation of $[PDH^+][ClO_4^-]$. In coincidence with the IR spectrum D in Fig. 4, the spectrum D in Fig. 5 is quite simple.

Figure 6 shows the electrical resistance *versus* pressure curves for PDB and PDI. The resistance of PDI is lower than that of PDB by about one order of magnitude throughout the pressure range covered. The resistance of PDB decreases by approximately four orders of magnitude when pressurized to 150 kbar, where a minimum appears. Above this pressure the electrical resistance of PDB begins to increase. As the pressure is released the resistance increases monotonously, suggesting that chemical reaction takes place in PDB above 150 kbar. The electrical resistance of PDI decreases by compression to about 120 kbar, above which it begins to rise. The behavior is irreversible on unloading process. This again suggests that chemical reaction takes place. The recovered PDI specimens were inspected after the application of pressures up to 200 kbar. Both the IR and electronic absorption spectra of compressed PDI were quite similar to those of compressed PDP. This shows that the high-pressure product of PDI is $[PDH^+][I^-]$.

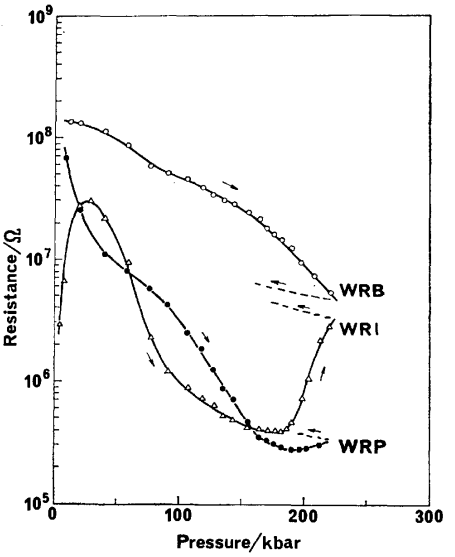

Fig. 7. Electrical resistance *versus* pressure for WRP, WRB, and WRI.

WR Cation Radical Salts. Figure 7 shows the electrical resistance of WRP, WRB, and WRI as a function of pressure. The resistance of these WR radical salts at high pressure are higher than those of PD radical salts. For WRP there appears a broad minimum around 190 kbar. The electrical resistance of WRP changes on unloading process in a different way from that shown on compression, indicating chemical reaction. The resistance of WRB decreases monotonously up to the highest pressure applied in this work. There might be a minimum in resistance at higher pressure. The resistance of WRI first increases to about 40 kbar, then decreases and after a broad minimum it increases again. The first increase of resistance is not well understood at present. From the resistance-pressure curve, the solid-state reaction in WRI seems to take place at a pressure of 180 kbar. No attempt was made to recover the specimen after the application of pressure and to carry out its spectral inspection.

WB Cation Radical Salt. Figure 8 shows the change of electrical resistance of WBP as a function of pressure. There appear two minima, the first at about 25 kbar, and the second around 220 kbar. WBP transforms at ambient pressure from the orthorhombic to monoclinic structure near 190 K. The pressure dependence of this transition temperature is reported to be 10 deg/kbar.[18] The linear extrapolation to room temperature locates the transition pressure at about 11 kbar, which is much less than the first minimum pressure. It is not certain whether or not the first

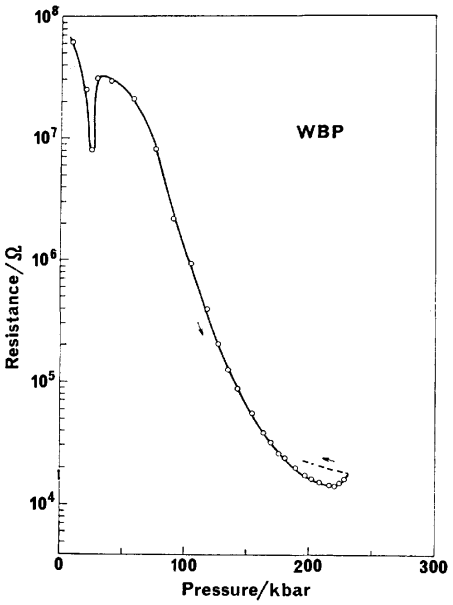

Fig. 8. Electrical resistance *versus* pressure for WBP.

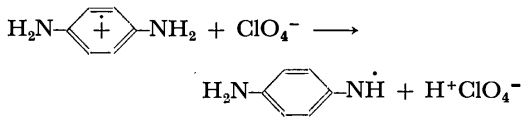
minimum reflects the phase transition. Since the resistance drifts upward after the second minimum and increases irreversibly on decreasing pressure, the second minimum is attributable to chemical reaction, as in the case of PD radical salts, WRP and WRI.

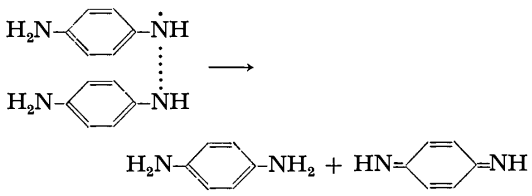
Discussion

The product of the high-pressure reaction in PDP is, as described earlier, $[PDH^+][ClO_4^-]$. A possible scheme for the reaction to $[PDH^+][ClO_4^-]$ from PDP is as follows.

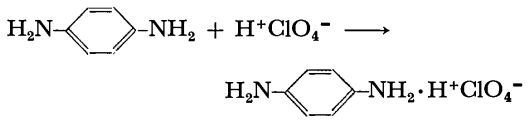
i) Proton transfer between ClO_4^- and PD cation radicals, yielding semi-quinone type radical and $HClO_4$.



ii) Disproportionation between two radicals to form neutral PD and *p*-benzoquinone diimine.



iii) Addition of $HClO_4$ to PD.



When PDP crystal is heated at 120 °C under vacuum, a solid-state reaction takes place within several hours. The products are PD, 4,4′-diaminoazobenzene (AZ), N^1, N^4-bis(*p*-aminophenyl)-2,5-diamino-1,4-benzoquinone diimine (Bandrowski's base, BB) and its polymer, among which BB-polymer and PD are predominant.[19] These materials are not recognized in the spectra of the high-pressure product of PDP. In order that BB[20] be produced by the linkage of three adjacent PD molecules in the crystalline state, the PD molecule to be centered should rotate to a certain amount because they are stacked in parallel face to face positions. This rotation will be facilitated in solids at higher temperature in vacuo, while it will be rather retarded under high pressure. BB is also synthesized by the reaction of PD cation radical with the parent molecule in ethanol solution.[21] The requisite linkage of three molecules for the formation of BB would be much easier in the solution than in the solid state.

Table 1. Pressure at which a minimum appears in the electrical resistance of respective Würster's salts

Cation radical	Counter ion		
	ClO_4^-	Br^-	I^-
	P_{min}/kbar		
PD^+	130	150	120
WR^+	190	>230	180
WB^+	25 220	a)	a)

a) Not measured.

Table 1 lists P_{min}, the pressure at which the electrical resistance shows minimum. As described earlier, P_{min} reflects the commencement of solid-state reaction. In PD radical salts P_{min} increases with the order; iodide, perchlorate and bromide. The reactivity[19] of the PD radical salt in the thermal reaction at ambient pressure becomes lower in the same sequence, indicating that the chemical reactivity in PD radical salts at high pressure is similar to the thermal reaction at 1 bar, although the products and hence the mechanisms are different. In the WR radical salts, the chemical reactivity at high pressure decreases with the order; WRI, WRP and WRB, in coincidence with the salts of PD radical. The counter ions are, therefore, very effective in the chemical reactivity in PD and WR radical salts at high pressure.

For PDP, WRP, and WBP, on the other hand, the chemical reactivity decreases at high pressure as the cation radical changes in the order PD, WR, and WB. The order holds also for salts of bromide and iodide. This sequence of chemical reactivity may be attributed to the difference in the number of active protons in PD, WR, and WB molecules, respectively.

In some of the present radical salts the interplanar spacing of cation radicals is quite short with respect to that calculated from the van der Waals distances. The separation is 3.105 Å in WRB[22] and 3.550 Å in WBP,[23] respectively, which is to be compared with that of tetrathiafulvalenium (TTF) cation radical in TTF salts. The spacing of TTF molecules is 3.57 Å in $TTFBr_{0.8}$,[24] 3.56 Å in TTF_7I_5[25] and 3.48 Å in TTF-TCNQ (tetracyanoquinodimethane),[26] respectively. These TTF cation radical salts undergo chemical reactions at pressures below 50 kbar,[8,9] whilst much higher

pressures are required for the reactions in Würster's salts. Therefore, the short spacing of the cation radicals does not necessarily facilitate the chemical reactivity of the compressed radical salts. Partial charge transfer, prevailing in the TTF cation radical salts,[24,27] seems to be more effective in causing the chemical changes at high pressure. This is evidenced by the pressure-induced chemical reaction of TCNQ anion radical salts[7-9] in which is also observed partial charge transfer.

Magnetic Susceptibility and Low-field ESR of an Organic Ion-radical Salt, Tri-*p*-tolylaminiumyl Chloroantimonate

Toshio YOSHIOKA†

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received August, 9, 1978)

The static magnetic susceptibility and the low-field ESR spectra (33.6 and 135 MHz) of powder samples of tri-*p*-tolylaminiumyl chloroantimonate were measured above 1.7 K. A broad maximum in the susceptibility, which indicates an antiferromagnetic interaction, was observed at 6.0 K; this is consistent with the results of the proton NMR measurements. In the low-field ESR spectra, broadening of the $g=2$ absorption line and distinct appearance of the $g=4$ absorption line were observed in the temperature region below T_m, the temperature at which the susceptibility is maximum. The results are interpreted by assuming that the magnetic behavior is due to antiferromagnetic Heisenberg linear chains. An abrupt decrease in the $g=2$ absorption intensity and a rapid increase in the $g=2$ absorption linewidth were also found in the temperature range from 3.5 to 2.5 K, while a slight rise in the susceptibility was observed below 2.5 K. These anomalies may imply a magnetic-phase transition in the vicinity of 2.5 K.

There have been many investigations regarding the magnetic properties of the stable organic free radicals. A deviation from the Curie-Weiss law and a broad maximum in the susceptibilities of some ion-radical salts with plate-like structures have been observed above the temperature of liquid nitrogen.[1] The anomalous behavior arises from the strong interaction between adjacent radicals and has been interpreted in terms of the exchange-coupled pair model or the linear Ising model. The mechanism of such a strong interaction is considered to be the charge-transfer stabilization. However, the magnetic behavior of ion-radical salts which have small Weiss constants had never been studied in the low-temperature region.

In triarylaminiumyl radical salts, the cations are considered to have propeller-like structures similar to those of triarylmethylium salts,[2] so that the exchange interaction between adjacent radicals is expected to be small compared with that of plate-like ion-radical salts. The static magnetic susceptibilities from 77 to 300 K and the proton NMR spectra from 1.5 to 77 K have been measured on powder samples of some triarylaminiumyl radical salts by the present author and his co-workers.[3] The static magnetic susceptibilities of tri-*p*-tolylaminiumyl chloroantimonate (TTA·$SbCl_5$) obeyed the Curie-Weiss law, with a Weiss constant of $\theta=-10$ K, and a broad maximum in the paramagnetic shift of its proton NMR spectra was found in the vicinity of 6.0 K. The broadening of the shifted lines was also observed below 4.2 K. This behavior cannot be explained by the anisotropic broadening.[3,4] In order to clarify the magnetic behavior of TTA·$SbCl_5$ at low temperatures, the static magnetic susceptibility and low-field ESR (33.6 and 135 MHz) measurements were carried out for temperatures above 1.7 K. Precise and absolute values of susceptibility can be obtained from the static magnetic measurements. Information concerning the dynamical behavior of the spin system near the zero field can be obtained from the low-field ESR (LF-ESR) measurements. In this paper the author will report the results of these measurements and discuss the exchange interaction, spin correlation, and abnormal ESR behavior in the TTA·$SbCl_5$ salt. The tri-*p*-tolylaminiumyl cation, TTA, has the molecular structure shown in Fig. 1.

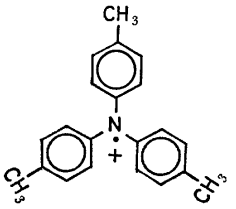

Fig. 1. Molecular structure of the tri-*p*-tolylaminiumyl cation, TTA.

Experimental

The tri-*p*-tolylamine was prepared by the method of Walter and was purified by repeated recrystallization.[5] The TTA·$SbCl_5$ was prepared according to the method of Wieland.[6] To a solution of the tri-*p*-tolylamine in benzene was added a chloroform solution of $SbCl_5$ under cooling. By addition of benzene a deep blue crystalline product with a metallic luster was obtained from the solution. After filtration, the product was quickly washed with benzene and dried *in vacuo*, mp 114—116 °C. The results of the elementary analysis were described in the previous paper.[3]

The static magnetic susceptibilities were measured for powder samples of 70—90 mg in a field of 8.8 kG from 1.7 to 100 K by means of the torsion balance described elsewhere.[7] No ferromagnetic impurities were found in samples by checking the field dependence of magnetization up to 12 kG at 4.2 K. The temperatures were measured with an AuCo–Cu thermocouple and a carbon resistor calibrated by measuring not only the magnetic susceptibility of Mn-Tutton salt, but also the vapor pressures of liquid helium, liquid hydrogen, and liquid nitrogen. The LF-ESR spectra (33.6 and 135 MHz) were observed using a Robinson type spectrometer[8] and a Benedek-Kusida type spectrometer,[9] respectively. Details of the apparatus for the LF-ESR measurements have been described elsewhere.[10] The sensitivity of the Robinson type spectrometer with respect to temperature variations was checked by measuring the absorption intensity of the proton NMR, which is inversely proportional to the temperature. A conventional cryostat was used, and tem-

peratures were determined using an Allen-Bradley carbon resistor calibrated against the vapor pressures of liquid helium, hydrogen, and nitrogen.

Results and Discussion

Susceptibility. The diamagnetic correction was made using Pascal's constant. The diamagnetic susceptibility, χ_d, is listed in Table 1. In the temperature range above 15 K, the paramagnetic susceptibility, χ_p, of TTA·$SbCl_5$ follows the Curie-Weiss law, with a Weiss constant of $\theta=-10$ K and a spin concentration of $p=0.94$. As the temperature is lowered below 15 K, it deviates from the Curie-Weiss law and reaches a broad maximum at 6.0 K, as is shown in Fig. 2. After passing through the maximum, it decreases comparatively slowly down to 2.5 K. However, below 2.5 K it increases slightly as the temperature is lowered. In the region from 3.0 to 77 K, the behavior of the susceptibility is consistent with that of the relative susceptibility obtained from the proton paramagnetic shift.[3]

The *g*-value of TTA·$SbCl_5$ is nearly isotropic, so that it is not appropriate to discuss its magnetic properties on the basis of the linear Ising model. Therefore, the susceptibility data have been analyzed using the pair model and the one-dimensional Heisenberg model based on Bonner and Fisher's calculation.[11] The kT_m/J ratio is 1.28 for the one-dimensional Heisenberg model and 1.25 for the pair model, where T_m is the temperature at which the susceptibility reaches its maximum value and J is the exchange coupling constant. The J value for each model can be estimated from the T_m value

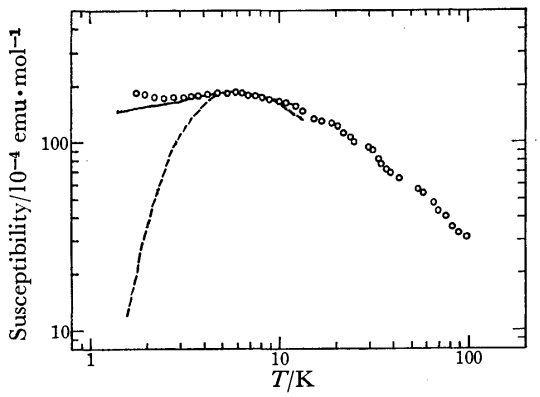

Fig. 2. Magnetic molar susceptibility of TTA·$SbCl_5$. The open circles represent the experimental values. The solid line and the dashed line are the theoretical curves for the one-dimensional Heisenberg model of $J=-4.7$ K and for the pair model of $J=-4.9$ K, respectively, which are fitted at $T_m=6.0$ K.

obtained experimentally. In Fig. 2, the paramagnetic susceptibility is compared with the theoretical curves for the one-dimensional Heisenberg model of $J=-4.7$ K and for the pair model of $J=-4.9$ K, which are fitted at the temperature T_m. It can be seen from Fig. 2 that the observed value above 2.5 K fits the one-dimensional Heisenberg model better than the pair model. However, the maximum value of the observed susceptibility, $\chi_m=188\times10^{-4}$ emu/mol, is 20% lower than the former theoretical $\chi_m=225\times10^{-4}$ emu/mol; it is 40% lower than the latter theoretical $\chi_m=296\times10^{-4}$ emu/mol. The difference between the experiment and the theory is not due to a poor spin concentration, but to the some other effect, for the spin concentration is equal to 0.94 in the temperature range above 15 K. The one-dimensional Heisenberg interaction has not been observed in ion-radical salts. It is interesting that the ion-radical salt, TTA·$SbCl_5$, studied here exhibits a one-dimensional Heisenberg interaction. In the crystalline state, the cation radicals with a propeller-like configuration may form chain-like arrays of molecules. The propeller-like structure of the cation radical, TTA, may restrict pairing of electron spins and dimerization of molecules in the crystalline state compared with a plate-like structure. The resulting parameters are summarized in Table 1, together with those of one-dimensional Heisenberg antiferromagnets typical of organic neutral radicals, 2,2,6,6-tetramethyl-4-hydroxy-1-piperidinyloxyl (TANOL) and 9-(α-fluorenylidene-*p*-chlorobenzyl)-9-fluorenyl (*p*-Cl-BDPA).[12] The exchange parameter J for TTA·$SbCl_5$ is as large as that for the organic neutral radicals. The mechanism of such a weak interaction may be attributable to the overlap of π-orbitals occupied by the unpaired electron rather than to the charge-transfer stabilization. The slight rise in the susceptibility below 2.5 K may be attributable to a magnetic-phase transition rather than to paramagnetic impurities. Such a slight rise in the susceptibility has also been found near a magnetic-phase transition into an antiferromagnetic state in the case of some organic neutral radicals.[12,13] This will be discussed below on the basis of the LF-ESR results.

LF-ESR. The LF-ESR absorption spectra of TTA·$SbCl_5$ exhibit a single line which has an exchange-narrowed Lorentzian shape at room temperature. The temperature dependences of the 33.6 MHz ESR and 135 MHz ESR spectra are shown in Figs. 3 and 4, respectively. The linewidth, which was taken to be the peak-to-peak linewidth of the first derivative of the $g=2$ absorption spectrum, started to increase as the temperature was decreased below T_m, where the susceptibility went through a broad maximum. The

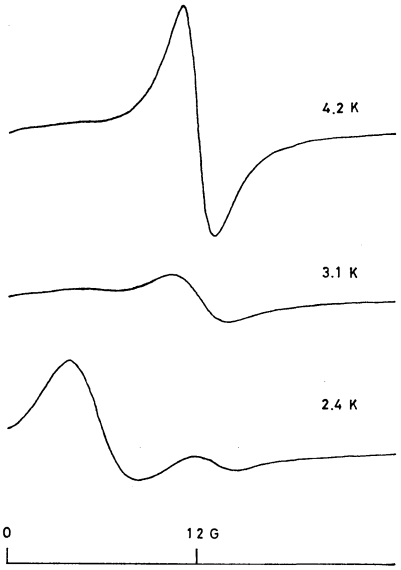

Fig. 3. The LF-ESR spectra of TTA·$SbCl_5$ measured at 33.6 MHz. The 2.4 K signal is amplified thirty three times compared with the 4.2 and 3.1 K signals.

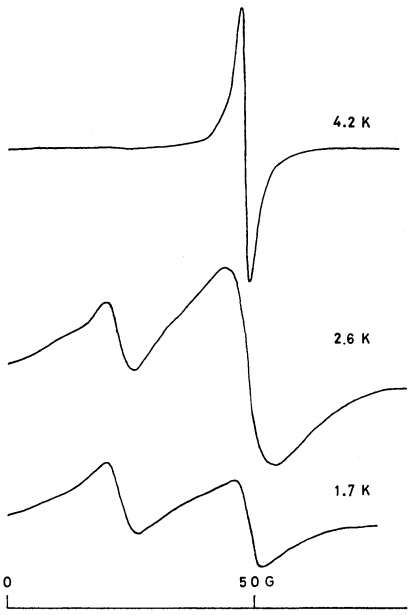

Fig. 4. The LF-ESR spectra of TTA·$SbCl_5$ measured at 135 MHz.

signal intensity, which was defined as the product of the square of the linewidth and the amplitude of the first derivative of the $g=2$ absorption line, measured at 33.6 MHz, was almost constant in the region from 4.2 to 3.5 K. In the temperature range from 3.5 to 2.5 K, an abrupt decrease in the signal intensity and a rapid increase in the linewidth were found. The temperature dependence of the linewidth and signal intensity measured at 33.6 MHz is shown in Fig. 5. Below 2.5 K the linewidth measured at 135 MHz decreased rapidly, as is shown in Fig. 6. The $g=4$ absorption could not be observed at room temperature or at liquid nitrogen temperature. Below the temperature at which the susceptibility deviated from the Curie-Weiss law, the

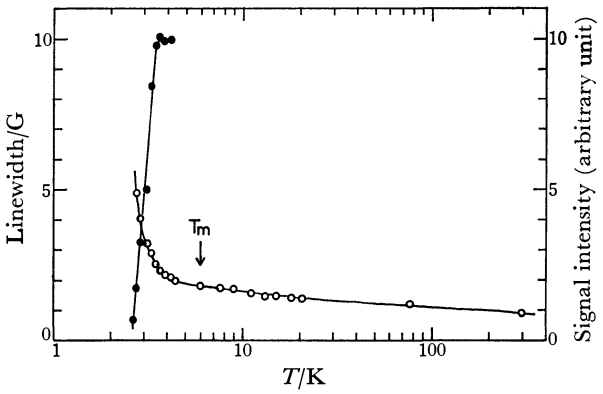

Fig. 5. Temperature dependence of the LF-ESR linewidth (-○-) and signal intensity (-●-) measured at 33.6 MHz.

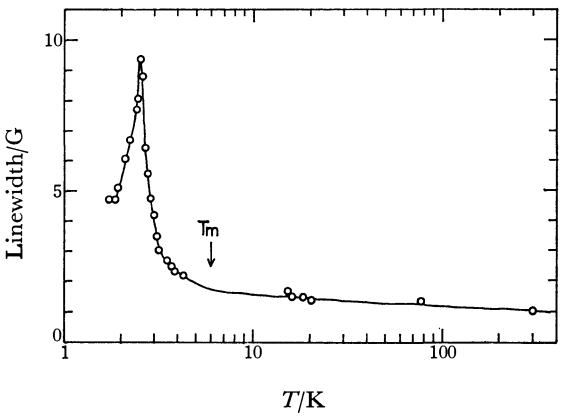

Fig. 6. Temperature dependence of the LF-ESR linewidth measured at 135 MHz.

$g=4$ absorption was detected as the temperature was lowered. At fixed temperature, the ratio of the intensity of the $g=4$ resonance absorption to that of the $g=2$ absorption was larger in the 33.6 MHz ESR spectrum than in the 135 MHz ESR spectrum.

It is well-known that the signal intensity of the ESR absorption line is proportional to the magnetic susceptibility in the paramagnetic state. The relative susceptibility, obtained from the signal intensity, agrees qualitatively with the static magnetic susceptibility for temperatures above 3.5 K. In Fig. 7, the relative susceptibility, obtained from the signal intensity, is compared with the static magnetic susceptibility and the theoretical curves for the one-dimensional Heisenberg model of $J=-4.7$ K and the pair model of $J=-4.9$ K, which are normalized at 4.2 K. In a one-dimensional Heisenberg system, a rapid decrease in the signal intensity is not observed below the temperature of maximum susceptibility.[14] In a pair-like system, the signal intensity decreases in direct proportion to the static magnetic susceptibility below the temperature of maximum susceptibility. The observed deviation from the static magnetic susceptibility below 3.5 K, consisting in an abrupt decrease in the signal intensity of the ESR line, indicates the occurrence of a reorganization of the energy spectrum involving a decrease in the number of

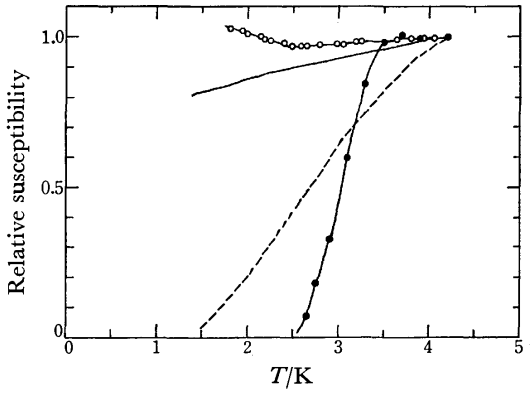

Fig. 7. Comparison between the static magnetic susceptibility (-○-) and the relative susceptibility obtained from the LF-ESR signal intensity (-●-). The solid line and the dashed line represent the theoretical curves for the one-dimensional Heisenberg model of $J=-4.7$ K and the pair model of $J=-4.9$ K, respectively. The experimental plots and the theoretical curves are normalized at 4.2 K.

spins possessing a paramagnetic property. Recent magnetic resonance measurements revealed that some organic neutral radicals go into a long-range ordered antiferromagnetic state in a sufficiently low temperature region.[15] The abrupt decrease in the signal intensity of the ESR line of TTA·$SbCl_5$ may imply a magnetic-phase transition from the short-range ordered state to the long-range ordered state in the vicinity of 2.5 K. In the temperature range from 3.8 to 3.2 K, such an abrupt decrease in the signal intensity of 33.6 MHz ESR line has also been observed for *p*-Cl-BDPA,[16] which undergoes a magnetic-phase transition to an antiferromagnetic state at 3.25 K.[17] Delocalization of the unpaired electron on the three *p*-tolyl rings or the chloroantimonate anion with a diamagnetic formula[3] may play some role in an exchange interaction leading to a long-range ordered state, such as the interchain exchange interaction.

In the case of LF-ESR, precise linewidth data can be obtained even in powder samples, because any contribution to the linewidth from the anisotropy of the *g*-values is excluded. The LF-ESR line is narrowed by the strong exchange interaction in the high-temperature region. It has been reported that, in several organic neutral radicals, the LF-ESR linewidth *versus* temperature below T_m of maximum susceptibility can be fitted to the following empirical relation:[14]

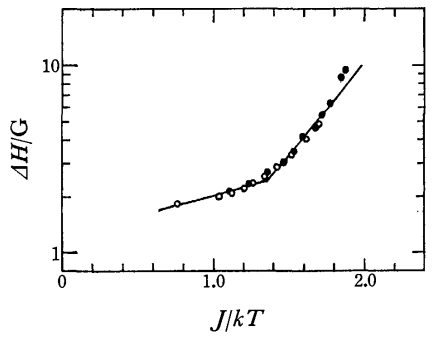

Fig. 8. LF-ESR linewidth (ΔH) *versus* J/kT. ○: 33.6 MHz, ●: 135 MHz.

$$\Delta H = \alpha \exp(\beta J/kT), \quad (1)$$

where α and β are constant and where J means the absolute value of the exchange coupling constant. The parameters of temperature dependent LF-ESR linewidth for TTA·$SbCl_5$ are summarized in Table 2, together with those for some organic neutral radicals.[14,16] The β values for TTA·$SbCl_5$ were determined to be 0.50 in the region from 6.0 to 3.5 K and to be 2.30 in the region from 3.5 to 2.5 K, by plotting the linewidth against the reciprocal of the temperature, as is shown in Fig. 8. The β value is considered to be associated with the correlation mechanism of exchange motion, which may be related to the magnetic interaction of the system. It is interesting that the first β value for TTA·$SbCl_5$ is nearly equal to the β value for TANOL, which has a one-dimensional Heisenberg interaction.[12] The broadening of the resonance with the first β value is attributable to an increase in the correlation for exchange motion because of short-range magnetic ordering below the temperature of maximum susceptibility. Such a broadening was not found above 1.7 K in tri-*p*-tolylaminiumly perchlorate (TTA·ClO_4); its susceptibility obeyed the Curie-Weiss law with a Weiss constant of $\theta=-0.5$ K.[3] The second β value for TTA·$SbCl_5$ is much larger than the β values for the radicals with one-dimensional Heisenberg or pair-like interaction. The rapid increase in linewidth with the second β value may be the result of the critical fluctuation of electron spins in the vicinity of the transition temperature, which may simultaneously cause the abrupt decrease in the signal intensity in the range from 3.5 to 2.5 K. It may be appropriate to use one parameter in place of $\beta J/k$ in Eq. 1, because the J parameter is considered to be insignificant in this temperature

Table 2. Parameters for temperature dependent LF-ESR linewidth and magnetic interaction

	α / G	β	J/k / K	Magnetic interaction
TTA·$SbCl_5$[a] 2.5—3.5 K	0.1	2.30	4.7	——

range. The behavior of the $g=2$ resonance can be related to the broadening of the shifted lines in the proton NMR spectra below 4.2 K. The residual resonance measured at 135 MHz below 2.5 K is probably due to paramagnetic impurities.

In the high-temperature region, the $g=4$ resonance, which is probably caused by a forbidden transition due to dipolar interaction, cannot be detected,[14,19] for the strong exchange interaction averages the dipolar coupling.[20] The appearance of the $g=4$ resonance at low temperatures can be explained by an increase in the correlation time for exchange motion, as is expected from the linewidth of the $g=2$ resonance and the susceptibility data. Below 3.5 K the behavior of the $g=4$ resonance was independent of the temperature in spite of the anomalies of the $g=2$ resonance. This cannot be explained now.

Conclusions

1. The static magnetic susceptibility of TTA·$SbCl_5$, as well as the relative susceptibility obtained from the paramagnetic shift, can be described by the one-dimensional Heisenberg model of $J/k=-4.7$ K in the temperature range above 2.5 K, although the maximum value of the observed susceptibility is 20% lower than the theoretical value.

2. The broadening of the $g=2$ absorption line and the distinct appearance of the $g=4$ absorption line in the LF-ESR spectra are attributable to the effects of short-range magnetic ordering below the temperature of the susceptibility maximum.

3. The following anomalies may imply a magnetic-phase transition in the vicinity of 2.5 K: 1) the rise of the susceptibility below 2.5 K, 2) the abrupt decrease in the $g=2$ absorption intensity and the rapid increase in the $g=2$ absorption linewidth in the temperature range from 3.5 to 2.5 K, 3) the broadening of the shifted lines in the proton NMR spectra below 4.2 K.

The author would like to express his appreciation to Professor Yasuo Deguchi for his continuous encouragement throughout this work. He also wishes to thank Drs. Hiroaki Ohya-Nishiguchi and Jun Yamauchi for their illuminating discussions and Dr. Kohji Watanabe for his advice on the preparation of the samples.

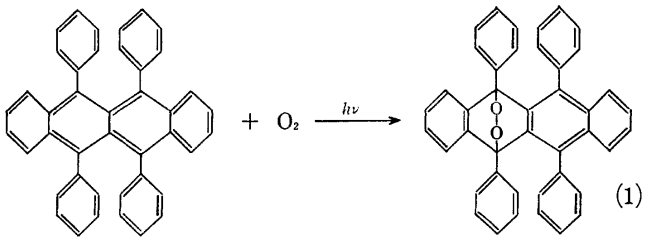
(Received August 24, 1978)

The gas and solid phase UV photoelectron spectra of rubrene were measured. In the molecule there is little conjugation of π-electrons between four substituent phenyl groups and the naphthacene skeleton owing to the effect of the steric hindrance of the phenyl groups. Therefore, the lower IP bands in the gas phase spectrum could be correlated to the π-bands in the photoelectron spectra of benzene and naphthacene. The features of the solid phase spectrum are similar to those of the gas phase one except for a large peak due to inelastically scattered electrons. The polarization energy due to the molecular ion in the solid, the peak to peak difference between the gas and solid phase spectra, was observed to be 0.6 eV, which is about half the polarization energy for naphthacene. This means that rubrene molecules are loosely packed in the solid as a result of the steric hindrance of four phenyl groups.

The compound 5,6,11,12-tetraphenylnaphthacene (rubrene) has aroused considerable chemical interest, since Moureu *et al.*[1] observed that its solution became colourless when irradiated in the presence of air. Subsequently, it was established that the change in colour is due to the formation of a transannular compound:[2]



rubrene (1) rubrene peroxide

Recently we have studied the photooxidation process (1) in solid phase by ultraviolet photoelectron spectroscopy.[3] In the course of the study, it was necessary to assign the bands in the photoelectron (PE) spectrum of rubrene.

We therefore present the PE spectra of rubrene for gas and solid phases, and a subsequent analysis of the electronic structure in comparison with that of the unsubstituted compound, naphthacene.

Experimental

Rubrene was purified by vacuum sublimation. The gas phase He I spectrum was recorded on a Perkin-Elmer PS-18 photoelectron spectrometer. The temperature of the sample was kept at 280 °C during the experiment.

The He I spectrum of solid rubrene was measured using an ultra high vacuum spectrometer constructed at our laboratory (the University of Tokyo), the details of which will be described elsewhere.[3] A 180° hemispherical analyzer of 5 cm mean radius was used for electron energy analysis. The solid phase photoelectron spectrum was also obtained with 7.75 eV† monochromatic light which was provided by a 0.5 m Seya-Namioka type monochromator fitted with a hydrogen discharge lamp. In this case a spherical retarding type analyzer was used with an ac-modulation method. Rubrene films were prepared by vacuum sublimation *in situ* onto copper substrates. The thickness of the films was controlled by means of a quartz osicillator monitor and was about 15 nm.

Results and Discussion

Gas Phase Spectrum. Figure 1 shows the gas phase spectrum of rubrene. The observed lower ionization potentials (*IP*'s) are listed in the first column of Table 1. Since four substituent phenyl groups in the rubrene molecule are considered to be rotated out of the molecular plane owing to the effect of steric hindrance,†† little conjugation of π-electrons between the phenyl groups and the naphthacene skeleton is expected. Therefore, bands in the lower *IP* region of the rubrene spectrum can be correlated to the π-bands in the photoelectron spectra of benzene[4,6] and naphthacene.[5]

The correlation is listed in Table 1 for the bands 1 to

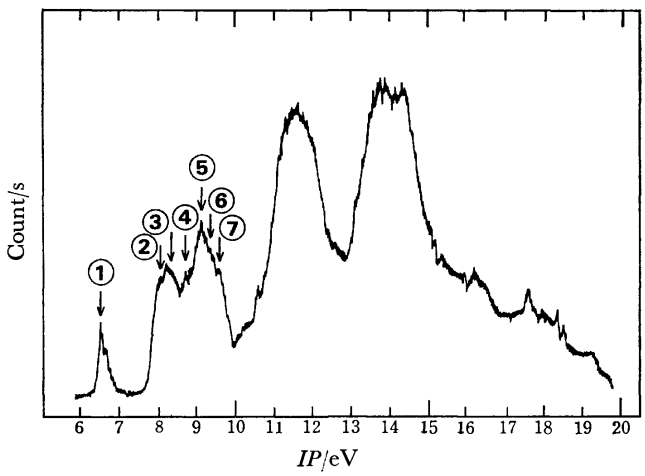


Fig. 1. Gas phase He I photoelectron spectrum of rubrene.

† Throughtout this paper 1 eV = 1.62×10^{-19} J.

†† The conformation of rubrene has not been determined experimentally.

Table 1. Vertical ionization potentials of rubrene and related compounds with assignment

Rubrene	Vertical *IP*/eV: Benzene[c]	Vertical *IP*/eV: Naphthacene[d]	ΔIP/eV[a]	Partial electron density[b]
① 6.52		6.97($2a_u\pi$)	0.45	0.148
② 8.0_5		8.41($3b_{1u}\pi$)	0.3_8	0.048
③ 8.3_0		8.41($2b_{2g}\pi$)	0.1_1	0.000
④ 8.7_5	9.24 ($1e_{1g}\pi_3$)			
⑤ 9.15	9.24 ($1e_{1g}\pi_2$)	9.56($1a_u\pi$)	0.41	0.044
⑥ 9.4		9.70($2b_{3g}\pi$)	0.3	0.034
⑦ 9.6		10.25($1b_{2g}\pi$)	0.6_5	0.112

a) The difference between the IP value of naphthacene and that of rubrene b) partial π-electron density due to the orbital of naphthacene at one of the substituted positions (5-, 6-, 11-, and 12-positions). c) Refs. 4 and 6. d) Ref. 5.

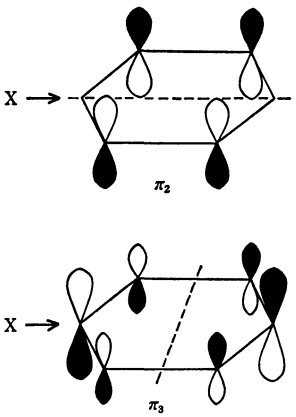

Fig. 2. The $1e_{1g}$ π-orbitals of benzene. X represents a substituent.

7 in Fig. 1. The 9.24 eV band of benzene has been assigned to the degenerate π_2 and π_3 orbitals.[6] At the point of substitution, the π_2 orbital has a node, while the π_3 has its maximum electron density (Fig. 2). Accordingly, on substitution, the π_2 orbital may be relatively unaffected, whereas the π_3 may have its energy lowered relative to the π_2. Thus, in Table 1 we assign the bands at 8.7_5 and 9.15 eV of rubrene to the π_3 and π_2 orbitals, respectively. This assignment is supported by the fact that the bands ascribable to the π_2 and π_3 orbitals are also found in the *IP* region 8.8—9.3 eV of the photoelectron spectrum of 5,10-diphenylanthracene.[7] Moreover, it has been observed that the bands corresponding to the 8.7_5 and 9.15 eV bands of rubrene remain in the photoelectron spectrum of a rubrene peroxide film (*cf.* Eq. 1).[3] Although the intensities of the bands ④ and ⑤ involving the ionization of four benzene rings are much stronger than those of the bands ⑥ and ⑦, they are not strong enough in comparison with the intensities of the bands ① to ③. The transmission coefficient ($\propto \Delta E/E$; E, the energy of photoelectrons) of the energy analyzer used may partly account for this effect.

When the naphthacene molecule is substituted by phenyl groups, similar effect as above can be expected; the shift of the π-orbital energy may become greater, the larger the partial π-electron density due to the orbital at the position of substitution.††† In Table 1 the differences between the *IP* values of naphthacene and those of rubrene (π-orbital energy shifts) are shown in comparison with the π-electron densities of naphthacene at one of the substituted positions (5-, 6-, 11-, and 12-positions). The electron densities were calculated on the basis of the Pariser-Parr-Pople method. It can be seen from Table 1 that the correlation of the *IP* shift with the π-electron density is satisfactory. This supports the present assignment of the bands in the lower *IP* region of the rubrene spectrum.

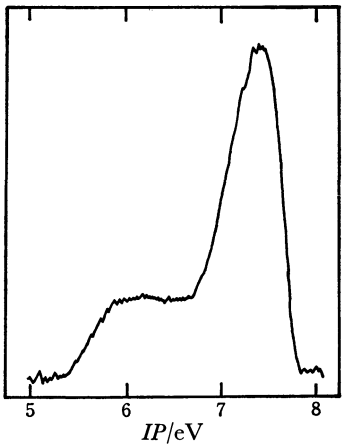

Fig. 3. Solid phase photoelectron spectrum of rubrene for $h\nu$=7.75 eV.

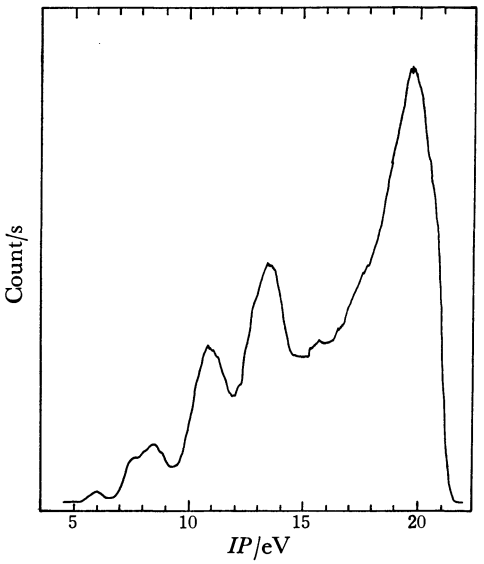

Fig. 4. Solid phase photoelectron spectrum of rubrene for $h\nu$=21.22 eV.

††† When a π LCAO MO, $\phi_i=\sum_k C_{ik}\chi_k$, is perturbed by a substituent X, the first-order perturbation energy of the MO is expressed by $\Delta E_i=\int \phi_i^* \hat{H}' \phi_i dv=\sum_{k,l} C_{ik}^* C_{il} H'_{kl}$, where $\hat{H}'$ is the perturbation operator and $H'_{kl}=\int \chi_k^* \hat{H}' \chi_l dv$. Let s be the number of the carbon atom substituted by X, H'_{ss} is considered to be much larger than the other H'_{kl}'s. Neglecting them, we have $\Delta E_i \fallingdotseq |C_{is}|^2 H'_{ss}$; the MO energy shift is proportional to the partial π-electron density $|C_{is}|^2$ due to ϕ_i at the position of substitution.

Solid Phase Spectrum. Figures 3 and 4 show the photoelectron spectra of solid rubrene for photon energies of 7.75 and 21.22 eV, respectively. The numbers on the abscissas indicate the ionization potential, which could be obtained by a spherical retarding type analyzer for $h\nu=7.75$ eV. In Fig. 3 only the first band located at 6.0 eV appears in the spectrum because of the small photon energy. The value of its adiabatic *IP* (threshold energy) is 5.3 eV. As can be seen from Figs. 1 and 4, the appearance of the solid phase spectrum for 21.22 eV is similar to that of the gas phase one except for a large peak due to inelastically scattered electrons. This behaviour means that the features of the solid phase spectrum are mostly associated with the valence bands. Further, it is found from Figs. 1 and 4 that the peak positions of the solid phase spectrum are lowered by *ca.* 0.6 eV relative to those of the gas. The shift corresponds to the polarization energy due to the molecular ion left in solid after a photoelectron is removed. In the case of naphthacene the polarization energy is observed to be around 1.1 eV,[8] which is about twice as large as that for rubrene. Being non-planar as a result of the steric hindrance of four phenyl groups, rubrene molecules are considered to be loosely packed in solid. This seems to be the reason for the small polarization energy for rubrene.‡

The authors are grateful to Dr. Koichi Ohno, the University of Tokyo, for his helpful discussion. The π-electron densities of the naphthacene molecule were calculated by him.

‡ The values of the polarization energy for benzene, naphthalene and anthracene are 1.15, 1.1, and 1.2 eV, respectively (W. D. Grobman and E. E. Koch, "Photoemission in Solids I," ed by M. Cardona and L. Ley, Springer, Berlin (1978)). Thus the polarization energy is fairly constant for the aromatic molecules, benzene to naphthacene, which suggests that its value depends on the molecular packing in the crystal, irrespective of the size of the molecule.

High Resolution Infrared Spectrum of Chlorine Dioxide: The v_2 Fundamental Band

Yoshiaki HAMADA and Masamichi TSUBOI*

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 26, 1978)

Fourier transformed infrared absorption spectrum of gaseous ClO_2 has been obtained with the resolution of 0.06 cm^{-1}. The rotational structure of the bending fundamental band ($v_2=1\leftarrow0$) was analyzed. Rotational constants determined were in good agreement with previous microwave results. The band center was now fixed at 447.675 ± 0.030 cm^{-1}, and five centrifugal distortion constants for the $v_2=1$ state were also newly determined.

Extensive spectroscopic and kinetical studies have been started on photochemically produced molecules originating from chlorofluorocarbons, since it was disclosed that they are partially on charge of destruction of ozone in the upper atmosphere.[1] ClO_2 is one of the reaction products which appears in the final step in the Cl and O chain, and is considered to exist in the lower layer of the stratosphere, but has never been detected yet.[2]

It is thought to be important to study ClO_2 spectroscopically in the various regions of radiation in the laboratory system to give more detailed understanding of stratospheric reactions. Curl *et al.* have intensively studied the microwave spectrum, and determined a number of molecular parameters involving spin-rotation interaction constants.[3–8] Since infrared spectrum had first been observed by Bailey and Cassie,[9] some infrared works[10–12] were reported without any high resolution. The higher vibrational levels of the electronic ground state were mainly obtained by means of the electronic absorption spectrum[13] or fluorescence spectrum.[14]

We have recently observed the infrared spectrum by a Fourier transform spectrometer and partially by a diode laser spectrometer. This is a report of an analysis of the bending fundamental band ($v_2=1\leftarrow0$) in the 415—510 cm^{-1} region. 8 rotational transitions of $v_2=1$ state were observed in the microwave spectrum by Mariella and Curl.[8] The results of our infrared analysis will be compared with the microwave results.

Experimental

ClO_2 was prepared by the reaction of oxalic acid and potassium chlorate in dilute sulfuric acid at 60 °C.[15] The product was condensed in a dry ice bath, and then distilled in vacuum. The sample with the vapour pressure (about 1 mmHg) at dry ice temperature was introduced into a multiple reflection cell, whose optical path length was 10 m.

The spectrum was obtained by a Nicolet 7199 Fourier transform spectrometer. 128 scans of interferometer were accumulated (38 sec per scan) to construct an interferogram, and this was Fourier-transformed (it took about 30 min.) into an ordinary spectrum of 4000—400 cm^{-1} region. The maximum distance of the moving mirror is 8 cm, and by the use of Happ-Genzel apodization function to remove the ripple of the spectral curve the actual width (full width at half miximum) was found to reach 0.07 cm^{-1}. The peak separation of 0.05 cm^{-1} was found to be recognizable. To confirm the accuracy of the wavenumber scale, some of the atmospheric CO_2 and H_2O lines overlapped on the ClO_2 spectrum were compared with the standard spectral data.[16] The wavenumber precision was found to be better than ±0.02 cm^{-1}.

Analysis

Neglect of the Spin-Rotation Interaction. The spin-rotation constants for the $v_2=1$ state are known to be almost the same as those for the ground state.[8] In Fig. 1, the spin splitting patterns in the ground state are shown, on the basis of the following equations:

$$F_1 = \left\{\left[a-a_0\pm\frac{1}{2}b\delta_{1,K}\right]N(N+1)-3aK^2 + 9a^2K^2\left[1-\frac{K^2}{(N+1)^2}\right]\Big/4\bar{B}\right\}\Big/2(N+1), \quad (1)$$

$$F_2 = -\left\{\left[a-a_0\pm\frac{1}{2}b\delta_{1,K}\right]N(N+1)-3aK^2 + 9a^2K^2\left[1-\frac{K^2}{N^2}\right]\Big/4\bar{B}\right\}\Big/2N, \quad (2)$$

where

$$a_0 = -\frac{1}{3}(\varepsilon_{aa}+\varepsilon_{bb}+\varepsilon_{cc}),$$

$$a = -\frac{1}{6}(2\varepsilon_{aa}-\varepsilon_{bb}-\varepsilon_{cc}),$$

$$b = -\frac{1}{2}(\varepsilon_{bb}-\varepsilon_{cc}),$$

and

$$\bar{B} = \frac{1}{2}(B+C).$$

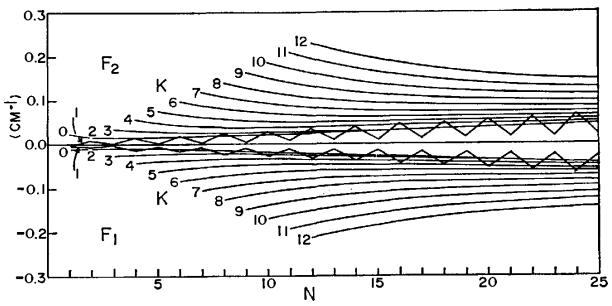

Fig. 1. Spin splitting pattern of $^{35}ClO_2$ in the ground state. Deviations, F_1 and F_2, caused by the spin rotation interaction, from pure rotational levels are shown. F_1 is for $N=J-S$, and F_2 for $N=J+S$, where N is the quantum number of rotational angular momentum, S is the quantum number of electron spin angular momentum, and J is the quantum number of total angular momentum. The calculations were made on Eqs. 1 and 2, where it was assumed that $a_0=0.017798$, $a=0.014262$, and $b=0.003679$ cm^{-1}.

ε's are spin-rotation interaction constants defined by

$$\mathcal{H}_{s.r.} = \varepsilon_{aa}N_aS_a + \varepsilon_{bb}N_bS_b + \varepsilon_{cc}N_cS_c, \quad (3)$$

where $\mathcal{H}_{s.r.}$ is the Hamiltonian for the spin-rotation interaction. As may easily be seen in Fig. 1, the spin-splitting should reach as much as 0.1 cm^{-1}, for lines of ^{P}R- and ^{R}P-branches if K is as high as 10 or so. These lines, however, have practically no intensity to be detected. The next largest spin-splitting is expected to occur in the lines of ^{R}Q- and ^{P}Q-branches, but these are so badly overlapped on one another. Absorption lines in the ^{R}R- and ^{P}P-branches are well separated from one another and intense enough. The spin-splittings for these lines are, however, always less than 0.05 cm^{-1} (our resolution). We, therefore, neglect the spin-rotation interaction in our present analysis.

Assignments of the Observed Peaks. The assignments were made on the basis of a comparison of the observed and calculated spectra. In the calculation, rotational matrices were trancated so as to include the elements with the K value which is higher by three than the maximum K we need. This makes the eigenvalues significant at least for 7 decimal digits. The ground state energy levels were calculated with the constants given by the microwave spectroscopy.[18] In an early stage of the analysis, the rotational constants A, B, and C of the $v_2=1$ state given by Mariella and Curl[8] were used to predict the J structures of low K sub-branches. Here essentially no single lines were detected, but most of the strong transitions were reasonably assigned to the observed peaks. In Fig. 2, part of the calculated spectrum is shown along with the observed spectrum.

At first sight, we can see ^{R}Q- and ^{P}Q-branches that make clusters: especially, $^{P}Q_K$ with $K\geqq 7$ give narrow and intense absorption peaks. These confirm the K-numbering. We can next recognize the strong absorptions formed by the turning head of the progressions in the $^{P}Q_2$, $^{P}Q_3$, $^{R}Q_1$, and $^{R}Q_2$ branches. The J-numbering for these progressions is of great merit for the following assignments in the low K region, because this allows us to fix the size of asymmetry, $B-C$. The absorption lines with $J=10$—30 in the $^{R}R_0$ and $^{P}R_1$ branches in the higher frequency region than the band center, and those in the $^{P}P_1$ and $^{R}P_0$ branches in the lower frequency region than the band center are the most intense ones in the whole band. They form progressions with nearly equal spacings.

Towards the high frequency end of the band, some of the ^{R}R branch lines are piled up to construct a progression with fairly regular spacing of about 0.6 cm^{-1}. From this we can determine the $\bar{B}'=1/2(B'+C')$ value. The J-numbering of this progression is rather straightforward, because we can use the ground state combination differences with the ^{P}P branch lines located in the other end of the band. The assignments are proceeded to reach reasonable intensity pattern.

We used the sample of ClO_2 with isotopes of natural abundance. This means that $^{35}ClO_2$ is mixed with $^{37}ClO_2$ with the ratio 3: 1. Hence difficulty was that not all absorption lines should necessarily be assigned to any transition of $^{35}ClO_2$. Also it happened that some fairly strong absorption was buried behind the $^{37}ClO_2$ absorption and made no apparent peak. No attempt was made to analyze $^{37}ClO_2$ spectrum in our present work.

Determination of the Molecular Constants. Upper state term values were calculated by adding the ground state rotational levels to the observed frequencies. The ground state rotational and centrifugal constants were fixed, as given in Table 1, in this work. Then, the term values were used for the least squares fitting to obtain the parameters of the following Hamiltonian:[17]

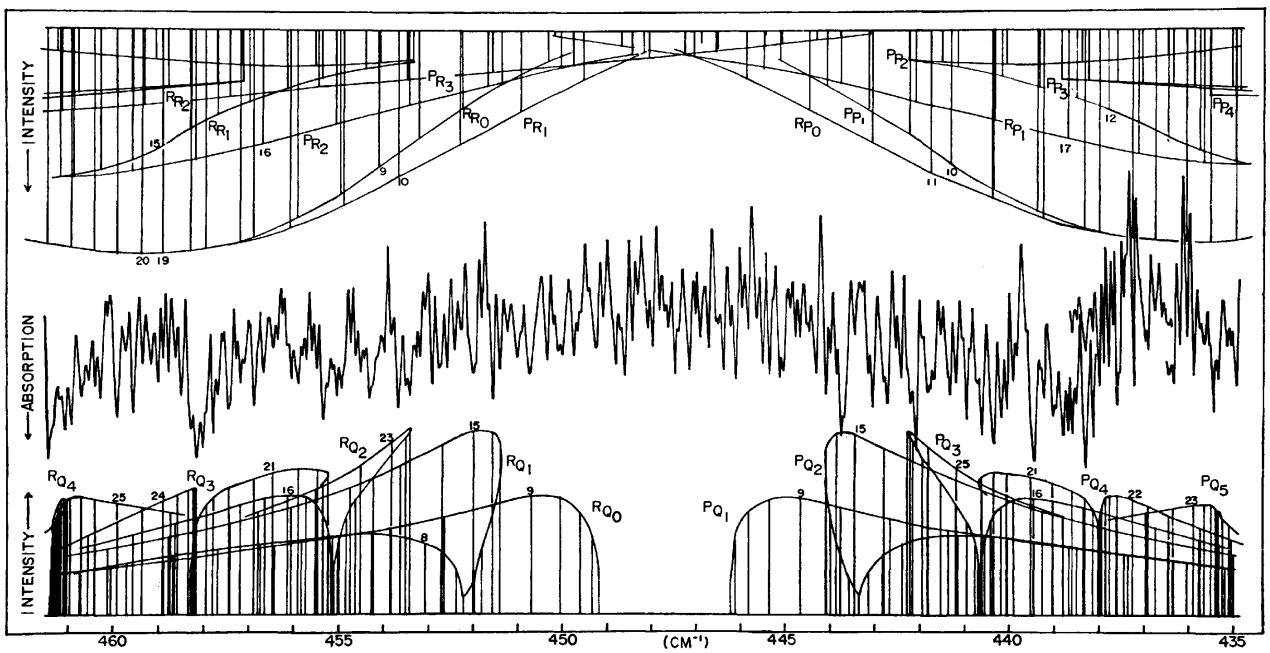

Fig. 2. The infrared absorption spectrum of ClO_2 in the 461—435 cm^{-1} region. Upper is the calculated pattern of R- and P- branches. Lower is the calculated pattern of Q-branches. The observed spectrum is shown in the middle.

Table 1. Molecular constants of $^{35}ClO_2$[a]

	(000)[b]	This work(010)	Previous data
ν_0		447.675(11)	447.3[c]/447.9[d]

Δ_J	$2.335(334)\times10^{-7}$	$1.127(224)\times10^{-7}$	
Δ_{JK}	$-4.003(1000)\times10^{-6}$	$-2.714(222)\times10^{-6}$	
Δ_K	$6.905(300)\times10^{-5}$	$7.580(107)\times10^{-5}$	
δ_J	$7.67(100)\times10^{-8}$	$-2.714(222)\times10^{-9}$	
δ_K	$5.67(300)\times10^{-7}$	$-4.72(1365)\times10^{-6}$	

a) Units are in cm^{-1}. Uncertainties (3σ) in parentheses are in units of the last significant figure. b) The higher order centrifugal distortion constants $H_J=7\times10^{-7}$, $H_{JK}=2\times10^{-5}$, $H_{KJ}=-1\times10^{-4}$, $H_K=1\times10^{-3}$, $h_J=3\times10^{-7}$, $h_{JK}=-3\times10^{-4}$, in units of MHz, were used to calculate the ground state rotational energies, and the same values were assumed for $v_2=1$ state. c) Ref. 11 from IR spectrum. d) Ref. 11 from UV spectrum. e) Ref. 8.

$$\begin{aligned}\mathscr{H} = {} & \nu_0 + AP_a^2 + BP_b^2 + CP_c^2 - \Delta_J P^4 - \Delta_{JK}P^2P_a^2 \\ & - \Delta_K P_a^2 - 2\delta_J P^2(P_b^2-P_c^2) - \delta_K[P_a^2(P_b^2-P_c^2) \\ & + (P_b^2-P_c^2)P_a^2] + H_J P^6 + H_{JK}P^4P_a^2 + H_{KJ}P^2P_a^4 \\ & + H_K P_a^6 + 2h_J P^4(P_b^2-P_c^2) + h_{JK}P^2[P_a^2(P_b^2-P_c^2) \\ & + (P_b^2-P_c^2)P_a^2] + h_K[P_a^4(P_b^2-P_c^2) \\ & + (P_b^2-P_c^2)P_a^4]. \qquad (4)\end{aligned}$$

From totally 452 term values, ranging J up to 47, and K up to 15, first 9 parameters were determined. The parameters of P^6-term were fixed to the ground state values. There could not seen any systematic deviation in the residuals (observed-calculated) in the final least squares fit. Therefore, it has been concluded that the higher centrifugal distortion constants are not necessary to be included as variables.

Discussion

In Table 1, the final set of parameters are compared with the previous results. As described in the preceding chapter, the precision of the observed line position is better than ±0.02 cm^{-1}. Therefore, (in combination with the calculated error ±0.01 cm^{-1}), the standard error is estimated to be ±0.03 cm^{-1} for the band center.

The rotational constant B has a meaningful discrepancy between the microwave and our infrared analysis. This may be attributed to the fact that, in microwave analysis, Curl *et al.* assumed the same centrifugal distortion constants in $v_2=1$ state as in the ground state, and used only 4 rotational transitions of low J's of $K=0$ and 1 in their least squares fit.

As was pointed by Pliva and Telfair,[19] the term values of the upper state are strongly correlated with the ground state parameters. We should realize, therefore, that from an infrared term value analysis, such as what we have done in the present work, the differences ΔA, ΔB, ΔC, *etc.* of the parameters in the upper and ground states are determined rather than their absolute values of the parameters themselves. Even if the ground state parameters are revised in future, ΔA, ΔB, ΔC,···values fixed here will remain significant.

The authors wish to express their deep appreciation to Dr. S. Saëki and Dr. S. Kondo for their kindness in affording us their Fourier transform infrared facilities in the National Chemical Laboratory for Industry. Their thanks are also due to Dr. T. Nakagawa for his computer program in calculating the absorption intensities.

Interdiffusion of Zinc Ions in Aluminium Cobalt(II) Oxide and Aluminium Nickel(II) Oxide

Kunihito KOUMOTO,* Takao MATSUBARA, Masasuke TAKATA, and Hiroaki YANAGIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 5, 1978)

The interdiffusion coefficients $\tilde{D}$ of Zn^{2+} ions in aluminium cobalt(II) oxide (cobalt aluminate) and aluminium nickel(II) oxide (nickel aluminate) were measured. In the former $\tilde{D}$ is independent of the concentration of the composition-dependent cation vacancies, while in the latter it decreases with increase in the concentration of cation vacancies. The difference in the distribution of cations and cation vacancies in the spinel lattice has a great effect on the interdiffusion coefficients of Zn^{2+} ions. The results were interpreted by means of the vacancy mechanism for Co^{2+} and Ni^{2+} ions and the interstitial or interstitialcy mechanism for Zn^{2+} ions. The activation energy is independent of the concentration of Zn^{2+} ions or cation vacancies; 355 kJ mol^{-1} for cobalt aluminate and 364 kJ mol^{-1} for nickel aluminate.

The vaporization rate of ZnO from the spinel solid solution of the ZnO–CoO–Al_2O_3 system was more pronounced than from that of the ZnO–NiO–Al_2O_3 system above 1300 °C in air.[1] It was suggested that the diffusion of Zn^{2+} ions in the spinel phase might be a rate determining process during the course of vaporization of ZnO. Thus the measurements of the diffusivity of Zn^{2+} ions and its dependence on the concentration of the composition-dependent cation vacancies in aluminium cobalt(II) oxide (cobalt aluminate) and aluminium nickel(II) oxide (nickel aluminate) were undertaken in the present work.

When $(A_x^{2+}B_{1-x}^{2+})O\cdot M_2^{3+}O_3$ forms a solid solution of $(A_xB_{1-x})O\cdot nM_2O_3$ with M_2O_3, the concentration of the composition-dependent cation vacancies is $(n-1)/(9n+3)\times 100$ cation site percent, increasing with the increase of n up to the solubility limit.

Studies have been carried out on the ionic diffusion in spinels. However, most of them are concerned with perfect spinels having no composition-dependent cation vacancies. Only a few studies on the defective spinels have appeared. Ando and Oishi[2] reported that the self-diffusion coefficients of oxygen ions in $MgO\cdot 1.2Al_2O_3$ and $MgO\cdot 2.2Al_2O_3$ single crystal spinels are close to those in $MgO\cdot Al_2O_3$ spinel. Morkel and Schmalzried[3] found for various kinds of spinels that the self-diffusion coefficients of cations in perfect spinels differ from those in defective spinels. Dieckmann and Schmalzried[4] measured the dependence of self-diffusion coefficient of iron ions in magnetite on oxygen partial pressure and found that the diffusion mechanism changes with the change in P_{O_2}. Yamaguchi *et al.*[5] proposed a vacancy mechanism of Ni^{2+} ion diffusion in magnesium aluminate on the basis that the interdiffusion coefficient of Ni^{2+} ions increases in proportion to the increase in the concentration of the composition-dependent cation vacancies.

The dependence of interdiffusion coefficients of Zn^{2+} ions on the concentration of the composition-dependent cation vacancies was found to differ in the two systems investigated in the present study. The mechanism of cation diffusion is also discussed.

Experimental

Material. The spinel powders of compositions $(Zn_xCo_{1-x})O\cdot nAl_2O_3$ and $(Zn_xNi_{1-x})O\cdot nAl_2O_3$ ($x=0$, 0.2; $n=1.0$—1.2) were synthesized from basic zinc carbonate, basic cobalt carbonate, basic nickel carbonate, and gibbsite of reagent grade. The pellets, diam. 10 mm and thickness 2—4 mm, were obtained by hot-pressing the spinel powders in a carbon mold under the pressure 260 kg/cm^2 at 1000 °C for 2 h. The pellets were further sintered densely for 1—2 h at 1700 °C to give the relative density colse to that of a single crystal. They were polished with SiC abrasives and diamond paste, and the diameters and thicknesses were measured with a micrometer. The sintering degrees, apparent density/theoretical density, calculated for a cation vacancy model, were 80—85%.

Diffusion Measurements. Interdiffusion between pure polycrystalline cobalt aluminate (or nickel aluminate) ($x=0$) and the spinel solid solution containing Zn^{2+} ions ($x=0.2$) was studied, the concentration of the composition-dependent cation vacancies being the same in both compositions (n is equal). The diffusion couple, made by giving the polished surfaces an intimate contact, was interposed between alumina plates. Annealing was carried out in the air in a vertical tube furnace with a SiC heating element. Temperature was measured with a calibrated Pt–Pt 13% Rh thermocouple. Although ZnO vaporized from the diffusion couples during the course of annealing, its amount was almost negligible in the diffusional zone near the interface. Annealing was carried out at 1320—1540 °C over a period of 24—96 h. After annealing, the diffusion couple was embedded in epoxy resin and cut perpendicular to the diffusion interface with a diamond cutter. The cut surface was polished carefully with SiC grains and diamond paste and then coated with gold by vacuum sputtering. The specimens were mounted on the sample holder and analyzed by an electron probe microanalyzer. They were moved perpendicular to the diffusion interface at 50 μm/min while the electron beam was kept fixed; the intensity profile of Zn $K\alpha$ radiation was then obtained. The microprobe was calibrated using standard samples having compositions $(Zn_xCo_{1-x})O\cdot Al_2O_3$ and $(Zn_xNi_{1-x})O\cdot Al_2O_3$, where $x=0.05$, 0.1, and 0.2. The standards were mounted and polished following the procedure for the diffusion couples. The relative intensity of Zn $K\alpha$ radiation to that of Al $K\alpha$ radiation showed good linearity as regards the concentration of Zn^{2+} ions in both cases.

Results and Discussion

The intensity profile of Zn $K\alpha$ radiation obtained by electron microprobe analysis was smoothed so as to average the statistical fluctuations. The curve thus obtained was considered to represent the concentration distribution of Zn^{2+} ions in the diffusion couple as the intensity of Al $K\alpha$ radiation was constant throughout the diffusional zone. A typical profile is shown in Fig. 1. The concentration curves were not apparently

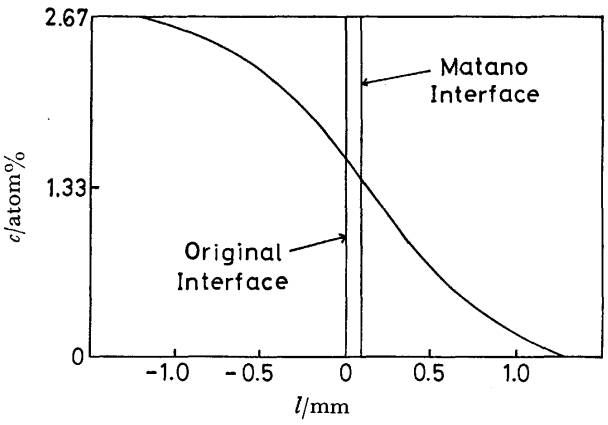

Fig. 1. Concentration profile of Zn^{2+} ions in $CoO \cdot 1.1\text{-}Al_2O_3$ annealed at 1540 °C for 48 h.

symmetrical as regards the original interface, and the Matano interface in all cases was determined graphically. The concentration-dependent diffusion coefficients were calculated by the Boltzmann-Matano solution:

$$D(c') = (-1/2t)(dx/dc)_{c=c'} \int_0^{c'} x dc,$$

where t is the annealing time, x the distance, and c, c' the concentration of Zn^{2+} ions. When Matano's method is used, the molar volume change caused by diffusion should be taken into acount as pointed out by Prager[6] and Balluffi.[7] In the present diffusion couples, however, the maximum molar volume changes due to the diffusion of Zn^{2+} ions were 0.14 and 0.48% for cobalt aluminate and nickel aluminate, respectively, as calculated from the lattice constants reported by Romeijn.[8] The changes were not significant and the effect of the molar volume change on diffusion coefficients was negligible.

Cobalt Aluminate. Interdiffusion coefficients $\tilde{D}$ of Zn^{2+} ions in cobalt aluminate are plotted against the concentration of Zn^{2+} ions in Fig. 2. The coefficient decreased with the increase in the concentration of Zn^{2+} ions in the perfect spinel which has no composition-dependent cation vacancies, while that of Zn^{2+} ions in the defective spinels turned out to be approximately independent of the concentration of Zn^{2+} ions. The value remained almost unchanged with the change in the concentration of cation vacancies.

Morkel and Schmalzried[3] found that the self-diffusion coefficient of Co^{2+} ions in $Co_{0.85}Al_{2.10}O_4$ ($\fallingdotseq CoO \cdot 1.235\text{-}Al_2O_3$) is larger than that in $CoAl_2O_4$ ($=CoO \cdot Al_2O_3$). This suggests the vacancy mechanism for the diffusion of Co^{2+} ions in cobalt aluminate. If the diffusion of Zn^{2+} ions were also to occur by the vacancy mechanism in

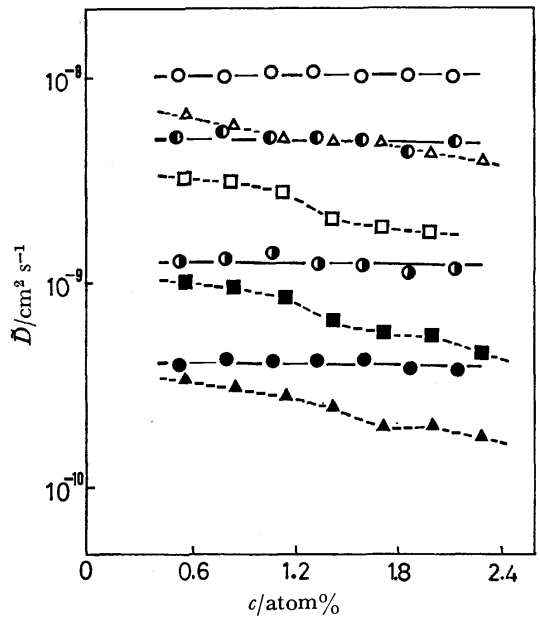

Fig. 2. Interdiffusion coefficients of Zn^{2+} ions in $CoO \cdot nAl_2O_3$ as a function of the concentration of Zn^{2+} ions. $n=1.0$: △ (1540 °C), □ (1470 °C), ■ (1400 °C), ▲ (1320 °C); $n=1.1$: ○ (1540 °C), ◐ (1470 °C), ◑ (1400 °C), ● (1320 °C).

cobalt aluminate, the interdiffusion coefficients would increase with the increase in the concentration of the composition-dependent cation vacancies, but this was not the case.

According to Darken's binary diffusion equation, when two kinds of ions interdiffuse, the effect of diffusion of the first ions on the interdiffusion coefficient increases with the increase in the concentration of the second ions. Thus, the diffusion of Zn^{2+} ions comes to play an important role as the concentration of Zn^{2+} ions decreases

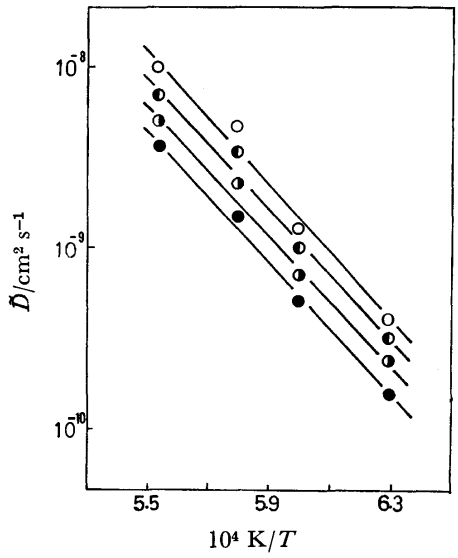

Fig. 3. Arrhenius plots of interdiffusion coefficients of Zn^{2+} ions for $CoO \cdot nAl_2O_3$.
○: $\varepsilon_{Zn} < 2.5$ ($n=1.1$, 1.2), ◐: $c_{Zn}=0.0$ ($n=1.0$), ◑: $c_{Zn}=1.0$ ($n=1.0$), ●: $c_{Zn}=2.0$ ($n=1,0$), where c_{Zn} is the concentration of Zn^{2+} ions in atomic percent.

(the concentration of Co^{2+} ions increases). The so-called impurity diffusion coefficients of Zn^{2+} ions for both perfect and defective spinels obtained by extrapolating interdiffusion coefficients to zero concentration of Zn^{2+} ions were the same within experimental errors. The Arrhenius plot shown in Fig. 3 is expressed as follows:

$$D_i = 2.1 \times 10^2 \exp(-355000/RT) \quad (cm^2/s),$$

where D_i is the impurity diffusion coefficient, R the molar gas constant, and T the absolute temperature. These results give no evidence for the vacancy mechanism of Zn^{2+} ion diffusion.

In general, the spinel structure consists of cubic close-packed oxygen ions with 1/8 of tetrahedral and 1/2 of octahedral interstices occupied by cations. The rest of the interstices are vacant as no-cation sites or interstitial sites. The structural formula for $(Zn_{0.5}Co_{0.5})O \cdot 2Al_2O_3$ spinel can be written as[1]

$$[Zn_{0.28}Co_{0.28}Al_{0.44}](Al_{1.86}\square_{0.14})O_4,$$

where $\square$ denotes cation vacancies, and [ ] and ( ) tetrahedral and octahedral sites, respectively. Thus, even though the concentration of the composition-dependent cation vacancies increases as $n>1.0$, the cation vacancies tend to occupy octahedral sites having little influence on the diffusion of Zn^{2+} ions on tetrahedral sites. The above formula represents only approximate distribution of cations and cation vacancies in the spinel lattice. There still remains the possibility of the existence of interstitial cations (especially Zn^{2+} ions) and octahedral Co^{2+} ions which could not be detected by the X-ray diffraction method. Consequently, the present result in which the interdiffusion coefficient is essentially independent of the concentration of the composition-dependent cation vacancies in cobalt aluminate could be explained on the assumption that Zn^{2+} ions diffuse through the spinel lattice *via* interstitial sites and not *via* octahedral sites.

Nickel Aluminate. Interdiffusion coefficients $\tilde{D}$ of Zn^{2+} ions in nickel aluminate obtained at 1470 °C are plotted as a function of the concentration of Zn^{2+} ions in Fig. 4. The interdiffusion coefficient is strongly dependent on the concentration of Zn^{2+} ions in each spinel with different concentration of cation vacancies. This is also the case for other annealing temperatures.

As is clear from Fig. 4, the interdiffusion coefficient decreases with increase in the concentration of the composition-dependent cation vacancies within the range of at least 1.45 cation site percent (corresponding to $n=1.2$) at low concentration of Zn^{2+} ions. It should be considered, as Yamaguchi *et al.*[5] reported, that the diffusion of Ni^{2+} ions in nickel aluminate occurs by the vacancy mechanism. The fact that $\tilde{D}$ increases with the increase in the concentration of Zn^{2+} ions in the cases of $n=1.15$ and 1.2 may support this suggestion. However, the present results deny the vacancy mechanism for the diffusion of Zn^{2+} ions in nickel aluminate.

The approximate structural formula of $(Zn_{0.5}Ni_{0.5})O \cdot 2Al_2O_3$ spinel is given by[1]

$$[Zn_{0.28}Ni_{0.14}Al_{0.44}\square_{0.14}](Ni_{0.14}Al_{1.86})O_4.$$

This indicates that both Zn^{2+} ions and cation vacancies prefer tetrahedral sites in nickel aluminate. Thus, when the concentration of the composition-dependent cation vacancies increases in nickel aluminate, they predominantly occupy tetrahedral sites causing the decrease in the interdiffusion coefficient of Zn^{2+} ions on tetrahedral sites. The decrease in the interdiffusion coefficient of Zn^{2+} ions should correspond to the decrease in the concentration of interstitial Zn^{2+} ions which are considered to be mobile as compared to those at normal cation sites, if the interstitial or interstitialcy mechanism for the diffusion of Zn^{2+} ions is assumed.

The activation energy obtained from the Arrhenius plots in Fig. 5 is nearly independent of the concentration of Zn^{2+} ions and the composition-dependent cation

vacancies, the average value calculated being 364 kJ mol^{-1}.

Contribution of Grain Boundary Diffusion. The contribution of grain boundary diffusion to the diffusion coefficients should be considered when polycrystalline specimens are used for diffusion measurements. The contribution can be detected by measuring the difference in diffusion coefficients between a single crystal and a polycrystal in an experiment on the coupling of two crystals. By this method, Yamaguchi *et al.*[5] found no contribution for the diffusion of Ni^{2+} ions in magnesium aluminate. In the present work, it was difficult to obtain single crystals of aluminates containing Zn^{2+} ions because of the high vapor pressure of ZnO at high temperatures, so that the contribution of grain boundary diffusion could not be made clear.

Enhancement of anion diffusion at grain boundaries has been reported for Al_2O_3,[9] MgO,[10] and alkali halides.[11] However, no evidence has been found for grain boundary enhancement of cation diffusion in spinels. The contribution of grain boundary diffusion was not taken into consideration in interpreting the present results.

The authors wish to thank Messrs. T. Ohta and T. Akiba of Chichibu Cement Co., Ltd. for their assistance in the electron microprobe analysis.

The Crystal and Molecular Structure of Dichloro[1,3-bis(di-*t*-butylphosphino)propane]platinum(II) Chlorobenzene Solvate

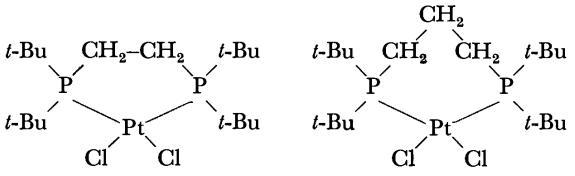
Masahiro HARADA, Yasushi KAI, Noritake YASUOKA, and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received September 9, 1978)

X-Ray crystal structure analysis of $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_3P(t\text{-}Bu)_2\}]\cdot 0.5C_6H_5Cl$ has been carried out. Crystals belong to monoclinic system: $a=11.532(2)$, $b=14.984(5)$, $c=16.455(4)$ Å, $\beta=106.96(2)°$, space group $P2_1/c$ with $Z=4$. The structure, solved by the heavy-atom method, has been refined anisotropically by least-squares procedure to $R=0.056$ for 5019 non-zero reflections. The coordination around the platinum atom is approximately square-planar, however, it showed a slight deviation toward the tetrahedral geometry; Pt–P=2.281(3) and 2.282(3), Pt–Cl=2.359(3) and 2.362(3) Å, P–Pt–P=99.05(9) and Cl–Pt–Cl=83.18(11)°.

In co-operation with the studies on a series of bis(di-substituted phosphino)alkaneplatinum complexes by Sei Otsuka and his coworkers,[1] we have carried out the determination of X-ray molecular structures of these complexes. Recently, we have reported the crystal and molecular structures of dichloro[1,2-bis(di-*t*-butylphosphino)ethane]platinum(II) (**1**) and its chlorobenzene solvate.[2] We report here the crystal structure analysis of dichloro[1,3-bis(di-*t*-butylphosphino)propane]platinum(II) (**2**) chlorobenzene solvate.



Experimental

Crystals of $[PtCl_2\{(t\text{-}Bu)_2P(CH_2)_3P(t\text{-}Bu)_2\}]\cdot 0.5C_6H_5Cl$ were kindly provided by Professor Sei Otsuka and co-workers. The space group was uniquely determined as $P2_1/c$ from the preliminary Weissenberg photographs. Accurate unit-cell dimensions were determined at 20 °C by a least-squares fit of 2θ values of high order reflections measured on a Rigaku automated, four-circle diffractometer. The crystal data are given in Table 1.

TABLE 1. CRYSTAL DATA OF $[PtCl_2(\{(t\text{-}Bu)_2PC(H_2)P(t\text{-}Bu)_2\})]\cdot 0.5C_6H_5Cl$

$C_{14}H_{26.5}P_2Cl_{2.5}Pd$	*F.W.* 654.77
Monoclinic	Space group $P2_1/c$
$a=11.532(2)$ Å	$D=1.61$ g cm^{-3}
$b=14.984(5)$	$Z=4$
$c=16.455(4)$	$D=1.599$ g cm^{-3}
$\beta=106.96(2)°$	μ(Mo $K\alpha$)=57.94 cm^{-1}
$U=2719.8(12)$ Å^3	

A crystal with dimensions of *ca.* $0.2\times 0.2\times 0.3$ mm, sealed in a thin-walled glass capillary tube, was mounted on the diffractometer for the intensity data collection. Graphite-monochromatized Mo $K\alpha$ radiation was used. The θ—2θ scan technique was employed. The integrated intensity was determined by scanning over the peak at a rate of 4° min^{-1}, and substracting the background obtained by averaging the two values measured for 6 s at both ends of a scan. The scan width was calculated by the equation: $\Delta(2\theta)=(2.4+0.69\tan\theta_c)°$, where θ_c is the calculated value of the Bragg angle using λ (Mo $K\alpha_1$)=0.70926 Å. The starting angle of the scan was $(2\theta_c-1.2)°$. Usual Lorentz and polarization corrections were applied, but absorption correction was ignored. Throughout the data collection four standard reflections were measured after every 60 reflections, which remained constant within the error limits. A total of 5936 independent reflections was measured out to a 2θ value of 54°, and of these 917 reflections were less than $3\sigma(F)$ and they were recorded as $F_o=0$.

Solution and Refinement of the Structure

The structure was solved by the heavy atom method and was refined by the block-diagonal least-squares procedure. HBLS V program was used,[3] the function minimized being $\sum w(|F_o|-k|F_c|)^2$. Starting from isotropic temperature factors, anisotropic thermal parameters were introduced in the refinement. When the R value decreased to 0.086 the Fourier map calculated revealed an existence of the chlorobenzene molecule disordered near a crystallographic center of symmetry, and they were then included in the refinement. How-

ever, peaks assigned for Cl(S), C(S2), C(S4), and C(S6) (or C(S4)′, C(S6)′, Cl(S)′, and C(S2)′) could not be resolved (Fig. 1), and the unresolved Cl(S)/C(S4)′ (or C(S4)/Cl(S)′) and C(S2)/C(S6)′ (or C(S6)/C(S2)′) atoms were treated as peaks of a hypothetic (Cl+C)/2 and a single carbon atoms, respectively.

The final R value is 0.080 (0.056 for non-zero reflections). The weighting scheme employed was: $w=(\sigma(F)^2+0.03289|F_o|+0.00159|F_o|^2)^{-1}$ for $|F_o|>0$ and $w=0.06036$ for $|F_o|=0$. The atomic scattering factors used were those of neutral atoms given in International Tables for X-Ray Crystallography, Vol. IV,[4] and those for the hypothetic (Cl+C)/2 atom were assumed as the mean value of those for Cl and C. The effect of the anomalous dispersion of Pt, Cl, and P atoms was included in the calculation: the values of $\Delta f'$ and $\Delta f''$ being also taken from the International Tables for X-Ray Crystallography.[5]

The final positional and thermal parameters are listed in Table 2.†

Results and Discussion

Molecular Structure. A stereoscopic drawing of the molecule is given in Fig. 2. Bond lengths and bond angles are listed in Table 3. Selected bond lengths and

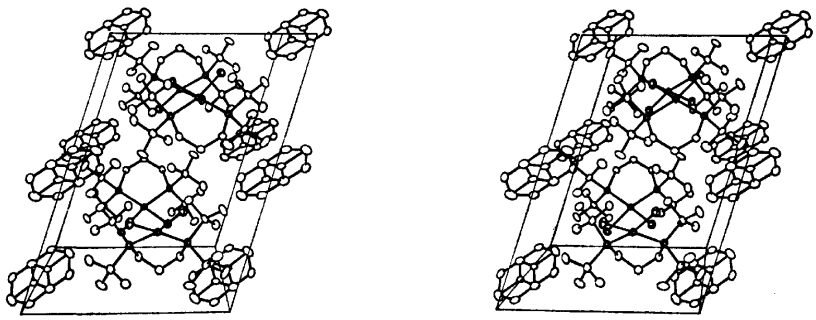

Fig. 4. Stereoscopic drawing of molecular packing in the unit cell. Disordered chlorobenzene molecules are shown.

bond angles are compared with those of **1**[2] in Fig. 3.

The co-ordination around the platinum atom can be described as approximately square-planar, however, the remarkable feature is that, different from **1**, there observed a slight distortion towards the tetrahedral geometry (Table 4). The dihedral angle between two planes defined by P(1), Pt, and P(2) and Cl(1), Pt, and Cl(2) is 12.0°.

The Pt–P bond lengths [2.281(3) and 2.282(2) Å] are significantly longer, whereas the Pt–Cl bond lengths [2.359(3) and 2.362(3) Å] are slightly shorter than those observed in **1** (Fig. 3). The shortening of the Pt–Cl lengths in the present complex indicates that the *trans*-influence of the phosphorus atoms is somewhat less than that in **1** because of the distortion of the $5d6s6p^2$ hybrid orbitals of the platinum atom.[6]

The P(1)–Pt–P(2) angle [99.05(9)°] is considerably greater than the corresponding angle in **1** [89.42(2)°], and other three angles around the platinum atom are smaller than the corresponding angles in **1**. This widening of the P–Pt–P angle in the present complex is probably due to an increased number of methylene groups in bis(di-*t*-butylphosphino)alkane ligand, which results in a distortion of dsp^2 hybrid orbitals of the platinum atom. Similar coordination geometry is observed in $[cis\text{-}PtCl_2(PMe_3)_2]$,[7] in which there seems to exist a steric repulsion between *cis*-PMe_3 groups.

As is found in **1** two P–C(CH_2) bond lengths [1.853(12) and 1.850(11) Å] are shorter than four P–C(*t*-Bu) bonds [1.919(12), 1.898(11), 1.900(12) and 1.914(13) Å].

The Pt–P–C(CH_2) angles [115.5(4) and 115.7(4)°] are about 10° larger than the corresponding angles in **1**. This is also probably affected by the increased number of methylene groups.

In the central propane moiety, the C(1)–C(2) and C(2)–C(3) bonds [1.50(2) and 1.52(2) Å] have normal single bond length, and bond angles around the C(1), C(2), and C(3) show slight deviations from the tetrahedral angle, however these are not significant except the P(1)–C(1)–C(2) [116.9(8)°]. The conformations about the C(1)–C(2) and C(2)–C(3) bonds are both nearly gauche. The torsion angles P(1)–C(1)–C(2)–C(3) and P(2)–C(3)–C(2)–C(1) are −75.7 and 80.3° respectively. The displacements of three methylene carbon atoms, C(1), C(2), and C(3) from the plane defined by Pt, P(1), and P(2) are 0.01, −0.67, and 0.13 Å, respectively.

Bond lengths and bond angles in *t*-butyl groups are normal values [1.55 Å and 109.4°]. Two *t*-butyl groups attached to the same phosphorus atom are mutually in a staggered position.

Solvated Chlorobenzene Molecule. In the crystal 0.5 chlorobenzene molecule per one platinum complex is contained. There observed a disorder of chlorobenzene molecules: a pair of molecules with 0.5 occupancy being related by a crystallographic center of

symmetry. Figure 1(b) shows a drawing of a disordered molecular pair. Owing to the difficulty resolving each of the overlapped peaks in two (Fig. 1(a)), the Cl(S)/C(S4)′ (or C(S4)/Cl(S)′) and C(S2)/C(S6)′ (or C(S(6)/C(S2)′) atoms are drawn as a single hybrid (Cl+C)/2 and single carbon atoms. Consequently, bond lengths and bond angles shown in Fig. 1(b) are less satisfactory.

Crystal Structure. The crystal structure is shown in Fig. 4 as a stereoscopic drawing. Pairs of disordered chlorobenzene half molecules are also shown on the center of symmetry. All the intermolecular atomic contacts are the usual van der Waals distances.

Computations throughout the present study were carried out on a NEAC 2200-700 computer at Osaka University. Figures 2, 4, and 5 were drawn on a NUMERICON 7000 systems at Osaka University with a local version of ORTEP.[8]

The authors wish to express their deep thanks to Professor Sei Otsuka and his coworkers for providing crystals and helpful discussions.

Thermodynamic Studies on Phase Transitions of Potassium Thiocyanate and Ammonium Thiocyanate Crystals

Yoshio KINSHO,† Natsuo ONODERA,†† Minoru SAKIYAMA, and Syûzô SEKI*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received September 16, 1978)

Heat capacities of KSCN and NH_4SCN crystals were measured by adiabatic calorimetry in the temperature range between 13 K and the melting points. Molar volume of NH_4SCN was also determined above room temperature. Entropy change for the II-I transition of KSCN (414.54 K, essentially higher order but accompanied with the first order component) is 6.26 J K^{-1} mol^{-1} (=1.09 R ln 2), which is of similar magnitude with our previous value (*Bull. Chem. Soc. Jpn.*, **36**, 1025 (1963)). Entropy change for the III-II transition of NH_4SCN (360.1 K, first order) is 10.01 J K^{-1} mol^{-1} and apparent entropy change for the II-I transition of NH_4SCN (392.8 K, higher order) is 2.85 J K^{-1} mol^{-1} (=0.49 R ln 2) in spite of possibly similar nature of the transition with the II-I transition of KSCN. A possibility has been suggested that the entropy change might be approximately R ln 2 if the transition was not interfered with the III-II trasition and the premelting.

In the previous paper,[1] thermodynamic studies were reported which had been carried out on potassium thiocyanate (KSCN) crystal by use of a conduction calorimeter above room temperature in combination with the infrared studies and its apparently higher order transition at 414.5 K was interpreted in terms of orientational disorder of thiocyanate ions in the higher temperature phase††† of the crystal. In parallel with these studies X-ray diffraction study was also reported by Yamada and Watanabé.[2]

In the present paper we have studied the thermodynamic behavior of NH_4SCN crystal and reinvestigated that of KSCN crystal. Ammonium thiocyanate crystal, which consists of two kinds of polyatomic ions, undergoes two phase transitions below the melting point.††† A significant volume decrease on heating was observed for the III-II transition by Bridgman in his high pressure experiments.[3] X-Ray diffraction study on phase III showed that the crystal is monoclinic with four pairs of ions per unit cell (β=97.4°, a=0.43 nm, b=0.72 nm, c=1.30 nm) arrayed in a layered structure.[4] A thermoanalytical study on the system KSCN–NH_4SCN showed that both compounds formed solid solution in phases I and II over the entire composition range.[5] Hence, both crystals are possibly isomorphous with each other in these phases and the II-I transitions in these crystals are possibly of similar nature. Pressure dependence of the II-I transition temperature for these crystals were studied and its thermodynamic implication was discussed.[6,7]

Heat capacity measurements for ammonium thiocyanate crystal above room temperatures by conduction calorimetry and for ammonium thiocyanate and potassium thiocyanate crystals below 300 K by adiabatic calorimetry had been completed before 1969.[8] Heat capacities obtained by conduction and adiabatic methods for the both compounds showed discrepancies at 300 K. Subsequently, Vanderzee and Westrum reported the results of heat capacity measurements below 340 K for both salts.[9] Their results also showed discrepancies with our results obtained by conduction calorimetry. Further measurements of heat capacities above ordinary temperature were carried out by adiabatic calorimetry for these crystals, in order to examine the validity of our previous conclusion on the phase transition of potassium thiocyanate and to elucidate the mechanism of phase transitions of ammonium thiocyanate. In this paper, heat capacities of these crystals at temperatures above 13 K and below the melting points and molar volumes of ammonium thiocyanate above room temperatures are reported.

Experimental

Materials. Commercial potassium thiocyanate (Wakō, special grade) was purified by repeated recrystallization from methanol solutions followed by drying under vacuum (≈0.1 Pa) at 373 K and loaded into the calorimeters under dry nitrogen atmosphere. The nitrogen was exchanged with helium, when helium was used as heat exchange gas.

Commercial ammonium thiocyanate (Wakō, special grade) used for calorimetry and dilatometry was purified by repeated crystallization from 50% aqueous methanol solution and methanol solutions. The crystal was dried under vacuum (≈0.1 Pa) through heating and cooling cycles around the III-II transition temperature. In spite of the precaution, examination of the heat capacity behavior indicated the presence of a small amount of methanol occluded in the crystals by showing an excess heat capacity at 176 K with magnitude similar to that observed by Vanderzee *et al.*[9] The anomaly was attributed to the melting of CH_3OH–NH_4SCN eutectic mixture by them. Loading into the calorimeters and substitution of nitrogen with helium were carried out as for the potassium salt.

Calorimetric Procedures. Measurements between 13 and 300 K for both compounds were carried out by adiabatic calorimetry using a cryostat, a gold calorimeter cell, and a control system described elsewhere.[10] The calorimetric sample of potassium thiocyanate had a mass corrected to buoyancy of 30.141 g and its heat capacity ranged from 35% of the total at 13K to 59% at 300 K. The contribution from nitrogen (heat exchange gas except in series IV of Table 1) including the effects of its melting and vaporization or that from helium (heat exchange gas in series IV) was subtracted properly. The mass of the calorimetric sample of ammonium thiocyanate corrected to buoyancy was 22.227 g and contri-

† Present address: Kurosaki Plant, Mitsubishi Chemical Industries Ltd., Yahata-nishi-ku, Kitakyushu, Fukuoka 806.

†† Present address: Japan Information Center of Science and Technology, Chiyoda-ku, Tokyo 100.

††† Crystalline phases are denoted as I, II, (and III) from higher temperature side for both crystals.

bution of its heat capacity to the total ranged from 44% at 13 K to 66% at 298 K. Contribution of helium packed in the calorimeter was corrected properly. The original heat capacities for both compounds, determined in 1968 in terms of NBS-55 temperature scale below 90 K and in terms of International Temperature Scale of 1948 (IPTS-48) between 90 and 300 K, were converted to the values in terms of IPTS-68 in this paper.[11,12]

Measurements above 300 K for both compounds were performed by adiabatic calorimetry using a calorimetric system described elsewhere,[13] and a gold calorimeter-cell equipped with eight internal radial vanes and two silver shields. Temperature was measured by a Tinsley type 5187-L platinum resistance thermometer calibrated in terms of IPTS-68 against a Leeds-Northrup type 8163 platinum resistance thermometer. Lead wires in the calorimetric system were replaced with copper wires (0.2 mm in diameter) covered with glass-fiber. The mass of calorimetric sample (corrected for buoyancy) was 32.799 g for the potassium salt and 23.485 g for the ammonium salt. Contribution of the heat capacity to the total was 46—50% for the former and 52—55% for the latter in the temperature range where no heat capacity anomaly was observed. Contribution from helium enclosed in the calorimeter was corrected properly.

Dilatometry. A glass dilatomer with internal volume of *ca.* 10 cm^3 was used. Confining liquid was mercury. The mass of ammonium thiocyanate crystal packed in the dilatometer was 6.262 g. Temperature of the dilatometer was detected by a copper-constantan thermocouple. Molar volume for phase III was calculated on the basis of the molar volume at 295 K obtained from X-ray diffraction data.[15] For other phases X-ray diffraction data[15] at 362 K was employed for the calculation.

Results and Discussion

Potassium Thiocyanate. Enthalpy increase per 1 K is presented in Tables 1 and 2 for temperatures below and above 300 K, respectively. Molar heat capacity was obtained by applying curvature correction and shown in Fig. 1 over the entire temperature range. The curves for both temperature ranges are smoothly connected with each other at 300 K. The molar heat capacity below 330 K is in agreement with the values reported by Vanderzee *et al.*[9] within 1%.

Relative enthalpy $[H°(T)-H°(400\ K)]$ plotted against temperature is shown in Fig. 2. Enthalpies from the three series of measurements are in good agreement with each other except for those above 414.5 K for Series VI, in which temperature increments around 414.5 K were small. A small but distinct discontinuity is observed at 414.54 K, which was assigned to the transition temperature as given in Table 3. A small discontinuity (0.20 $cm^3\ mol^{-1}$) is found at the same temperature also in the molar volume *vs.* temperature curve as shown in Fig. 7. These findings indicate unambiguously that the transition is a higher order transition accompanied with the first order component as suggested by Klement.[7] The transition was interpreted as a higher order transition previously by the present authors[1] and by Yamada and Watanabé[2] and as a first order one with a small volume change by Bridgman.[3] Both conclusions are partly correct in view of the present findings.

As shown in Fig. 1, a straight line connecting the points at 300 and 438 K on the heat capacity curve was drawn for the estimation of a "normal" heat capacity in the transition region.[1] Vanderzee and Westrum showed that the difference between experimental and calculated heat capacities of potassium thiocyanate crystal deviates from ±1% limits above 310 K.[9] This fact is in harmony with the present selection of 300 K as the lower temperature limit of the transition region. Transition enthalpy and entropy thus determined are given in Table 3 together with contributions from the

first order component of the transition. The total entropy change of 6.26 J K^{-1} mol^{-1} is equal to 1.09 R ln 2. The previous conclusion of the present authors[1] that the transition entropy may be interpreted principally in terms of two-fold orientational disorder of thiocyanate ions in phase II need not be altered at all.

Volume thermal expansion coefficient was calculated from the dilatometric data given in Appendix. Plots of the heat capacity below the transition temperature against the thermal expansion coefficient is shown in Fig. 3. The plots below 412.2 K was approximated with a straight line as shown in the figure. Pressure dependence of transition temperature $(dT/dp)_{tr}$ was

a) Contribution from the first order component.

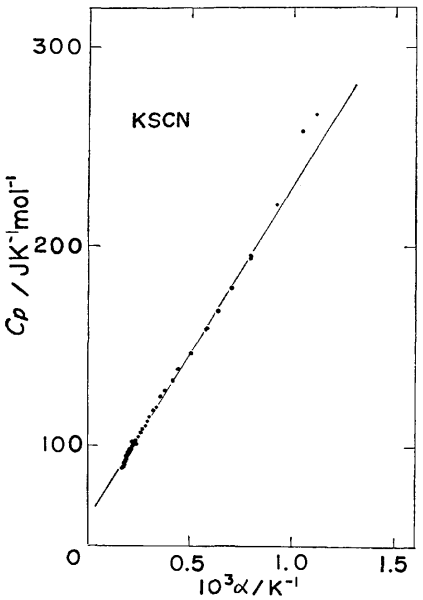

Fig. 3. Molar heat capacity *vs.* thermal expansion coefficient plot of potassium thiocyanate crystal below 414.5 K.

calculated from the slope of the straight line on the basis of the Pippard's relation,[14]

$$C_p = \left(\frac{dp}{dT}\right)_{tr} V_m T_{tr} \alpha + \text{const},$$

where C_p, the molar heat capacity, V_m, the molar volume, α, the thermal expansion coefficient and T_{tr}, the transition temperature. The calculated value for $(dT/dp)_{tr}$ is 0.134 K MPa^{-1}, while the observed value[6] is 0.172 K MPa^{-1}.

For the first order component of the transition, the Clausius-Clapeyron equation was applied with the volume change of 0.20 cm^3 mol^{-1} and the entropy change of 1.21 J K^{-1} mol^{-1}. The calculated value for $(dT/dp)_{tr}$ is 0.165 K MPa^{-1}, which is rather in good agreement with the observed value.[6]

Ammonium Thiocyanate. Plot of the molar volume against temperature is shown in Fig. 4. Molar volumes calculated from the X-ray diffraction data by Pistorius[15] is also shown in the figure. As stated above, the dilatometric values were calculated with reference to the X-ray diffraction data at 295.2 and 361.7 K. Agreement is especially good for the temperature dependence of molar volume in phase II. Part of the molar volume *vs.* temperature curve around the II-I transition temperature is enlarged and presented in the enclosed portion. It is not clear whether a discontinuity in molar volume is present at the transition temperature or not. In the III-II transition, a discontinuous volume decrease (*ca.* 6% of the molar volume) took place on heating. Significant superheating and supercooling were also observed as will be explained below.

Changing topics to the discussion of heat capacity data, the effect of thermal decomposition upon the heat capacity values will be given. One of the principal reactions which ammonium thiocyanate crystal undergoes at higher temperatures may be the dissociation reaction into gaseous ammonia and gaseous isothiocyanic acid:

$$NH_4SCN(c) \longrightarrow NH_3(g) + HNCS(g). \quad (1)$$

The dissociation pressure comes up to 101.325 kPa at 443 K.[16] Now, for the dissociation effect molar heat capacities were corrected approximately by using the following equation:

$$\Delta C_p = \Delta H_r^\circ(T) \cdot \frac{MV_g}{2mRT}\left(\frac{dp}{dT} - \frac{p}{T}\right), \quad (2)$$

where ΔC_p is the correction to molar heat capacity, m, the mass of the sample in the calorimeter, M, the molar mass, V_g, the volume available for the gaseous species in the calorimeter, and $\Delta H_r^\circ(T)$, the standard enthalpy of reaction. In the derivation of the equation, the gases were assumed to be ideal and only the direct effect of the dissociation was taken into account. Here, V_g was found to be 18.0 cm^3. $\Delta H_r^\circ(T)$ for each of the phases

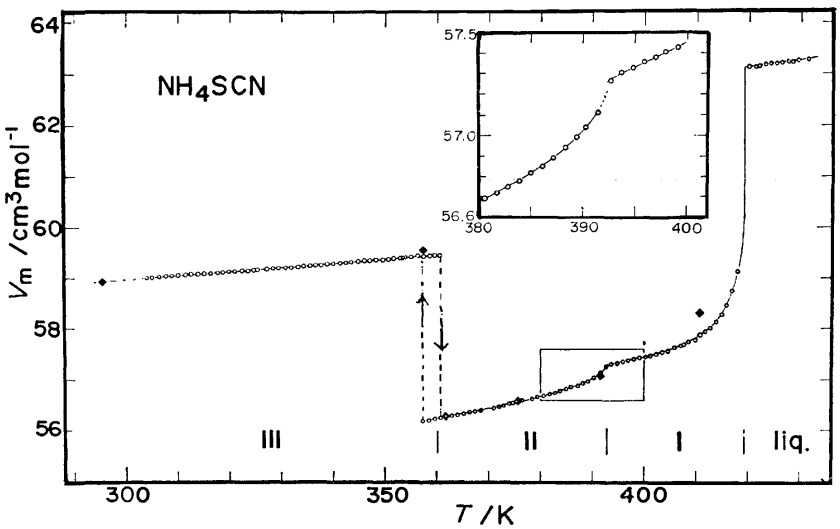

Fig. 4. Molar volume of ammonium thiocyanate in the crystalline and liquid phases.
○: Dilatometric data, ◆: X-ray diffraction data.[15]

was assumed to be independent of temperature for simplicity, *i.e.* 140 kJ mol^{-1} for the liquid phase, 149, 152, and 160 kJ mol^{-1} for the phases I, II, and III, respectively. These values were evaluated from standard enthalpies of formation at 298.15 K of the relevant species,[17] relative enthalpy $[H°(T)-H°(298.15\ K)]$ of ammonium thiocyanate, and molar heat capactites of the gaseous species.[17] The relative enthalpy of ammonium thiocyanate was calculated from the observed (uncorrected) molar heat capacities for the crystal below 400 K, while the molar heat capacities of the crystal above 400 K and of the liquid phase were assumed to be 130 J K^{-1} mol^{-1}. The observed enthalpies of transition as will be given below, and the enthalpy of melting (9.2 kJ mol^{-1}) determined by conduction calorimetry[8] were also utilized to estimate ΔH_r°. Dissociation pressure and its temperature dependence given in Eq. 2 were derived with reference to the dissociation pressure of 101.325 kPa at 443 K on the basis of the Van't Hoff's equation,

$$\ln p = -\frac{\Delta H_r^\circ(T)}{2RT} + \text{const.} \qquad (3)$$

The correction term to molar heat capacity, ΔC_p, amounted to 0.10, 0.29, 0.61, and 1.21 J K^{-1} mol^{-1} at 360, 378, 393, and 407 K, respectively. Enthalpy increase per 1 K of the crystal corrected as above for the dissociation effect are tabulated for temperatures below 300 K and above 278 K in Tables 4 and 5, respectively. No correction was made upon the data of Table 4 for the effect of eutectic melting of NH_4SCN–CH_3OH mentioned above. Molar heat capacities were calculated by applying curvature correction for the

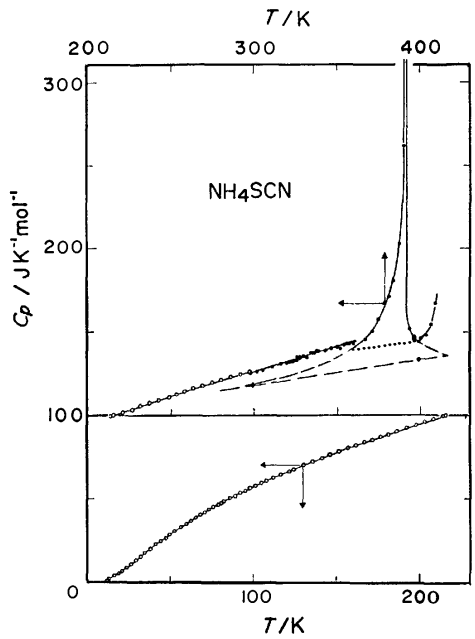

Fig. 5. Molar heat capacity of ammonium thiocyanate crystal. Experimental values are shown by empty and filled circles for the regions 13—300 K and 300—410 K, respectively. Estimated normal molar heat capacities at 300 and 400 K for phase II are shown by filled squares. For dotted and broken lines, see the text.

enthalpy increments and shown in Fig. 5 for the entire temperature range.

Another reaction to be taken into consideration will be the decomposition of ammonium thiocyanate in the solid state. The decomposition reaction in the liquid state was studied above 423 K by Kodama *et al.* in some detail.[24] The equilibrium composition of the reaction product at 423 K was 67% in ammonium thiocyanate, 30% in thiourea and 3% in other products. In the following discussion, only the isomerization

$$NH_4SCN \longrightarrow (NH_2)_2CS$$

will be considered. This reaction is exothermic at 298.15 K with the standard enthalpy of reaction of $-9.6\,kJ\,mol^{-1}$, which has been calculated from enthalpies of formation of the both compounds in the solid states.[17] In the present study, the significant increase of temperature drift of the calorimeter in the cooling direction was observed above 402 K, which brought about difficulty in the precise measurement of molar heat capacity. Two molar heat capacity data above 402 K tabulated in Table 3 were obtained under the abnormal condition and would be influenced significantly with the isomerization reaction.

Increase in molar heat capacity above 402 K may be interpreted in the following way. Molar heat capacity of thiourea crystal at 298.15 K ($108.91\,J\,K^{-1}\,mol^{-1}$)[19] is considerably lower than that of ammonium thiocyanate crystal (*ca.* $125\,J\,K^{-1}\,mol^{-1}$) at the same temperature and the former crystal shows no phase transition between 298 and 400 K, while the latter undergoes two phase transitions in the same temperature range. Accordingly, the above-mentioned isomerization reaction as a solid state reaction would certainly continue to be exothermic up to 400 K. However, the system NH_4SCN-$(NH_2)_2CS$ shows a eutectic point at 373 K with the mole fraction of thiourea of 0.3.[5] Thus a small amount of crystalline thiourea formed by the solid-state isomerization would melt immediately together with ammonium thiocyanate to give a melt rich in ammonium thiocyanate. From the analysis of equilibria between ammonium thiocyanate and thiourea in the liquid phase, enthalpy of reaction for the isomerization in the liquid state was determined to be $-9.1\,kJ\,mol^{-1}$.[24] A thermochemical cycle involving both the species in the liquid and solid states shows that net change in enthalpy from ammonium thiocyanate crystal to thiourea liquid *via* thiourea crystal is almost neutral. On the other hand, ammonium thiocyanate in the liquid state would be converted to thiourea more rapidly than in the solid state, but the conversion is only of the order of 1% after 1 h even at 413 K.[18] Although the enthalpies of melting of ammonium thiocyanate and of isomerization in the liquid state into thiourea are of similar magnitude with opposite sign, realized net result would be the predominance of endothermic effect due to the melting of ammonium thiocyanate. Summerizing, the increase in molar heat capacity above 402 K may be interpreted in terms of premelting of ammonium thiocyanate crystal, triggered and accelerated by the isomerization into thiourea.

Transition temperature for III-II transition was determined to be $360.1_5 \pm 0.1$ K by monitoring the temperature of the calorimeter under the adiabatic condition when the crystal transformed partially. Superheating and supercooling of the crystal were observed, when the crystal was heated up or cooled down through the transition range by a small temperature head between the calorimeter and the adiabatic jacket. Transition enthalpy and entropy are given in Table 3. The above-mentioned findings together with the discontinuous volume change in this transition reveal that the transition is of the first-order type. In phases I and II, the crystal forms mixed crystal with potassium thiocyanate crystal over the entire composition range[5] and they are possibly isomorphous. The crystal of ammonium thiocyanate in phase III is characterized with open structure with hydrogen bonding between essentially stationary ammonium ions and thiocyanate ions. In phase II, the orientation of the ammonium ions would be statistically disordered so that the crystal may be isomorphous with the potassium salt.

Application of the Clausius-Clapeyron equation for the III-II transition with the volume change of $3.42\,cm^3\,mol^{-1}$ (from X-ray diffraction[15]) and the entropy change of $10.0\,J\,K^{-1}\,mol^{-1}$ (the present study) gave $-0.342\,K\,MPa^{-1}$ for $(dT/dp)_{III\text{-}II}$, which agreed with the observed value of Bridgman,[3] $-0.334\,K\,MPa^{-1}$.

Transition temperature of the II-I transition of the ammonium salt was determined to be 392.8 ± 0.1 K from the plot of relative enthalpy $[H^\circ(T) - H^\circ(361\,K)]$ against temperature. It is not certain from the relative enthalpy plot whether the transition is accompanied with a first-order component as observed for the potassium salt. Thermal expansion coefficient α of ammonium

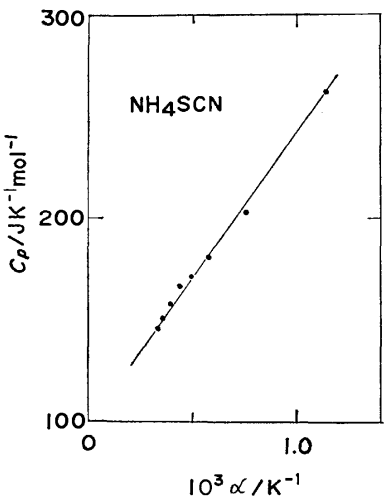

Fig. 6. Molar heat capacity *vs.* thermal expansion coefficient plot of ammonium thiocyanate crystal below 392.8 K in phase II.

thiocyanate crystal in phase II was calculated from the dilatometric data in Fig. 7 and the heat capacities were plotted against the thermal expansion coefficient as shown in Fig. 6. The plots below 385 K was approximated with a straight line. The value of $(dT/dp)_{II-I}$ calculated from the slope of the straight line with the value of V_m of 57.0 $cm^3\,mol^{-1}$ on the basis of the Pippard's relation[14] is 0.155 K MPa^{-1}, while the observed value[7] is 0.126 K MPa^{-1}.

It is difficult to draw a reasonable "normal" molar heat capacity curve for phase II in Fig. 5. An obvious but tentative solution is to draw a straight line between the points at 360 and 398 K on the smoothed curve as shown by a dotted line in the figure. Transition enthalpy and entropy thus obtained are tabulated in Table 3. As stated above, the II-I transition in potassium thiocyanate and ammonium thiocyanate crystals should be similar in nature. Although the II-I transition of the ammonium salt is of essentially higher-order type as indicated in the heat capacity curve, the transition entropy 0.49 R ln 2 calculated as above is considerably lower than the expected value, R ln 2.

One possible interpretation of the apparent smallness of this transition entropy is that the crystal transforms from phase III into phase II which has been disordered to some extent with respect to the orientation of thiocyanate ions. A support to this is that thermal expansion coefficient of the ammonium salt at the lowest temperature in phase II is considerably higher than the corresponding value for the potassium salt at 300 K (see Figs. 3 and 6). The entropy change for the III-II transition is 10.0 J $K^{-1}\,mol^{-1}$, which is of sufficient magnitude to include a part of the contribution from the disordering process of thiocyanate ions in addition to the entropy change related with the orientational disorder of ammonium ions. In this respect, the adoption of the normal heat capacity as given above is in conflict with the supposition that orientation of thiocyanate ions has been disordered to some extent even at the lowest temperature in phase II.

This supposition leads to the suggestion that hypothetical heat capacity for phase II below the III-II transition temperature is lower than the one observed for phase III. Furthermore it is to be recalled that normal heat capacities have not been determined adequately for phase I by the interference with the premelting described above. Thus, the normal heat capacities for phase I should be lower than the observed values above 402 K.

Application of the Kopp's law using ("normal") heat capacities of ammonium chloride,[20] potassium thiocyanate, and potassium chloride[20] gave 125 and 153 J $K^{-1}\,mol^{-1}$ for heat capacities at 300 and 400 K, respectively, which agree rather well with heat capacities of phase III observed at 300 K and extrapolated to 400 K and are therefore higher than expected for phase II.

Chihara and Nakamura[21] showed that heat capacity of ammonium chloride at 300 K was anomalously higher than the value calculated as a sum of Debye heat capacity and contributions from internal vibrations and harmonic (or anharmonic) vibration of ammonium ions. The anomaly had been pointed out earlier by Sakamoto.[22] Linear extrapolation of heat capacities of ammonium chloride at 500 and 600 K,[20] where the crystal is in the higher temperature phase, to 300 and 400 K gives 80 and 82 J $K^{-1}\,mol^{-1}$ for heat capacities of ammonium chloride, respectively. Adoption of these values leads to 118 and 133 J $K^{-1}\,mol^{-1}$ at 300 and 400 K, respectively, for ammonium thiocyanate.

Potassium and ammonium thiocyanate crystals are of cesium chloride type structure, while potassium and ammonium chloride crystals are of sodium chloride structure, in the relevant phases. This fact seems to lend support to the latter estimation of "normal" heat capacities.

A possible hypothetical "normal" heat capacity curve is thus drawn in Fig. 5 by a broken line, which is obtained by assuming that "normal" heat capacities are 118 and 133 J $K^{-1}\,mol^{-1}$ at 300 and 400 K as shown by filled squares, respectively, and that it changes linearly between these temperatures. Anomalous heat capacities are also extrapolated smoothly to lower and higher temperatures as shown in the figure with broken lines. Hypothetical total entropy of transition for II-I transition thus obtained is 5.22 J $K^{-1}\,mol^{-1}$, which is equal to 0.91 R ln 2. Klement discussed the apparent entropy decrease with increasing polarizability of the cation observed for corresponding transitions of KSCN, RbSCN, NH_4SCN, and TlSCN.[7] However, the present analysis suggests a possibility that transition entropy for the ammonium salt would be compatible with the value of the isomorphous potassium salt, if the transition was not interfered with the III-II phase transition and the premelting.

Appendix

The molar volume of potassium thiocyanate crystal from 300 to 460 K has been reported only briefly in a previous paper.[23] Temperature dependence of the molar volume around 415.5 K (II-I transition temperature) is shown in detail in Fig. 7. Obviously, a small discontinuity of the molar volume can be observed in the small interval of 415.5—415.7

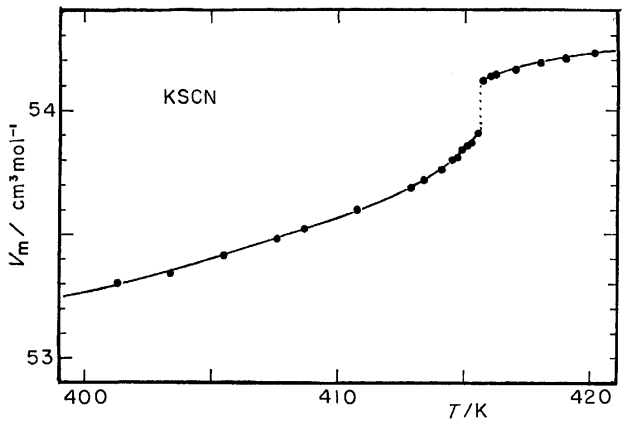

Fig. 7. Molar volume of potassium thiocyanate crystal around the II-I transition temperature.

K. Magnitude of the discontinuity amounts to 0.20 cm^3 mol^{-1}, which corresponds to 0.39% of the molar volume. The presence of the discontinuity had been shown implicitly as ΔV_t in Table 1 of the previous paper[23] before Klement pointed out from an analysis of molar volume data supplied by the authors.[7] However, the values of $\Delta V_t/V_t$, ΔV_t and t.p. given in the Table[23] are not correct and should read 0.39%, 0.20 cm^3 mol^{-1}, and 141.4 °C, respectively.

The Crystal Structure of *fac*(*N*)-*Δ*-Tris(L-asparaginato)-cobalt(III) Trihydrate

Masao SEKIZAKI

College of Liberal Arts, Kanazawa University, Marunouchi, Kanazawa 920

(Received May 9, 1978)

The crystal structure of tris(L-asparaginato)cobalt(III) trihydrate, $[Co(L\text{-}H_2NCOCH_2CHNH_2COO)_3]\cdot 3H_2O$, has been determined by the X-ray diffraction method, and refined by a block-diagonal least-squares method to give $R=0.055$ for 1302 non-zero reflections. The crystals are orthorhombic with a space group $P2_12_12_1$, $a=39.082(4)$, $b=7.523(2)$, $c=6.643(2)$ Å, and $Z=4$. The complex molecule has a slightly distorted octahedral coordination with *fac*(*N*)-*Δ* geometry. The three bidentate ligand ions form five-membered planar chelate rings with coordination through amino nitrogen and carboxyl oxygen atoms. The amide groups of the two side-chains approach the central atom, and the oxygen atoms are connected through intramolecular hydrogen bonds. Another amide group is, however, far from the central atom. The complex molecules are hydrogen-bonded to one another to form layers parallel to the (100) plane. These layers are piled up through hydrogen bonds to complete a three-dimensional network.

Transition metal complexes of L-asparaginate ion (L-2-aminosuccinamate ion, $L\text{-}H_2NCOCH_2CHNH_2COO^-$) have been widely investigated,[1–5] and it has been concluded that the ligand ion is terdentate or bidentate. The terdentate ligand occupies the *facial* positions of the octahedron and the amide group is of *N*-[3] or *O*-coordination.[4] The coordination modes of the bidentate ligand are various.[2,5] According to the spectroscopic investigation by Takenaka and Shibata[2] on the stereochemistry of trivalent cobalt complexes, the bidentate ligand may coordinate through amino nitrogen and carboxyl oxygen atoms forming a five-membered chelate ring, and the amide group may remain free. If this assumption is correct, the bulky side-chain including the amide group is expected to have considerable effects on the neighboring molecules in the crystal. To ascertain these effects and to confirm the assumed structure, a single-crystal structure analysis of tris(L-asparaginato)cobalt(III) trihydrate has been carried out.

Experimental

The crystals which were prepared by Professor Muraji Shibata of Kanazawa University were dark pink needles. A crystal was shaped into a ball with the diameter of *ca.* 0.05 mm, and the intensities were measured on a Philips PW1100 four-circle diffractometer with Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) monochromated by a graphite plate. The θ-2θ scan technique was used at a scan rate of 0.0666°/s in θ with a scan width of $(1.20+0.20\tan\theta)°$. The intensities of the three reference reflections were monitored every 2 h and remained constant within experimental error during data collection. Of 1392 independent reflections measured up to $\theta=65°$, 1302 with $|F|>3\sigma$ were used for the structure analysis. No corrections were made for absorption and extinction effects ($\mu r=0.2$). Cell dimensions were obtained by a least-squares method based on 17 2θ values measured by diffractometry.

Crystal data:
$Co(H_2NCOCH_2CHNH_2COO)_3\cdot 3H_2O$. *F.W.*=506.31. $a=39.082$ (4), $b=7.523$ (2), and $c=6.643$ (2) Å. $U=1953$ (2) Å^3. $Z=4$. $D_x=1.722$ g cm^{-3}. Orthorhombic. Space group $P2_12_12_1$. $\mu=78$ cm^{-1} (Cu $K\alpha$ radiation, $\lambda=1.5418$ Å).

Determination and Refinement of the Structure

The coordinates of the cobalt atom were determined from a Patterson map; successive Fourier syntheses gave the approximate skeletal structure. The block-diagonal least-squares refinement was carried out based on 1302 reflections with a unit weight. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[6]

After several cycles of refinement with isotropic temperature factors the *R*-value became 0.077. At this stage the oxygen and nitrogen atoms of each amide group could be distinguished by interatomic distances. Anisotropic temperature factors were, then, introduced for all the non-hydrogen atoms with the anomalous scattering factor of the cobalt atom for Cu $K\alpha$ radiation ($f'=-2.464$, $f''=3.608$).[6] The *R*-value was reduced to 0.064. Of all 27 hydrogen atoms, 23 appeared in a difference Fourier map. Their positional parameters were refined with isotropic temperature factors of 4.0 Å^2. Four hydrogen atoms attached to C(3) and O(1w) could not be found. The final *R*-value was 0.055. The final atomic parameters are listed in Table 1, and a list of the observed and calculated structure amplitudes has been deposited with the Chemical Society of Japan (Document No. 7903).

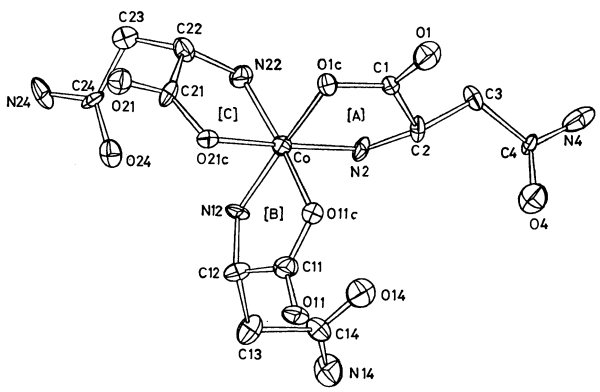

Fig. 1. The molecular structure and the absolute configuration with the anisotropic thermal ellipsoids of the atoms at 50% probability level.

The absolute configuration of the complex was determined by a comparison of the absolute configuration of the coordinated ligand ion with that of the free ligand molecule, and by a comparison of the *R*-values between the correct structure (0.055) and the mirror image (0.116). To confirm the result, another set of reflections ($\bar{h}\bar{k}l$) was measured by diffractometry with Cu $K\alpha$ radiation. All 363 Friedel pairs satisfying $|F(hkl)|/|F(\bar{h}\bar{k}l)| < 0.9$ or > 1.1 gave coincident intensity relations with those calculated, except for 14 weak pairs.

The refinement of the structure and the drawing of thermal ellipsoids were carried out with HBLS-IV[7] and ORTEP[8] programs, respectively. Other calculations were carried out with programs written by the author. A FACOM 230-35 computer at the Data Processing Center of Kanazawa University and a

Description of the Structure and Discussion

The molecular structure is shown in Fig. 1, together with the thermal ellipsoids of the non-hydrogen atoms. The bond distances and angles are listed in Table 2. The projections of the crystal structure on the (010) and (100) planes are shown in Figs. 2 and 3, respectively. The hydrogen bonds are shown in these figures and in Table 3.

The three ligand ions act bidentately through amino nitrogen and carboxyl oxygen atoms forming three five-membered chelate rings in the *Δ* configuration. The cobalt atom is, thus, surrounded by three nitrogen atoms and three oxygen atoms in *fac*(*N*) geometry. This structural feature agrees with the assumption based on the spectroscopic investigation by Takenaka and

Shibata.[2]

The Co–N bond lengths are 1.94—1.95 Å, which are longer than the Co–O bond lengths (1.89—1.91 Å). The coordination bond angles of the chelate rings are 85—86°. Thus the octahedron is slightly distorted. Each of the three five-membered chelate rings is nearly planar within 0.15 Å. Two side-chains of chelate rings **[B]** and **[C]** turn their amide groups toward the central atom, so that O(14) and O(24) are connected with N(2) and N(12), respectively, through intramolecular hydrogen bonds (Fig. 2 and Table 3). The side-chain of ring **[A]** is far from the central atom, and N(4) is hydrogen-bonded with O(14) of the neighboring molecule v.

The molecules i and ii are connected with one another through several hydrogen bonds to form columns parallel to the c axis. These columns are combined with each other by hydrogen bonds between molecules i and iii (Fig. 3), thus forming layers along the (100) plane. A three-dimensional network is completed by piling up of an infinite number of these layers through hydrogen bonds.

The author is grateful to Professor Muraji Shibata of Kanazawa University for the supply of crystals, and also to Professor Seiji Sugiura, Department of Mineralogy, Kanazawa University, for the use of the diffractometer.

Stereochemistry of Cobalt(III) Complexes with Sulfur-containing Amino-carboxylate. Mixed Cobalt(III) Complexes with L-Methioninate or *S*-Methyl-L-cysteinate and L- or D-Aspartate

Takashi ISAGO, Kozo IGI,† and Jinsai HIDAKA*

Department of Chemistry, University of Tsukuba, Ibaraki 300-31

(Received May 29, 1978)

Four kinds of $[Co(N)_2(O)_3(S)]$ type mixed complexes, (L- or D-aspartato)(L-methioninato), and (L- or D-aspartato) (*S*-methyl-L-cysteinato)cobalt(III) complexes have been prepared and chromatographically separated into their three geometrical isomers, *trans(N)*, *trans(SO)* and *trans(SN)*, respectively. The isomers were identified from their electronic absorption and PMR spectra. The absolute configurations of sulfur atoms in the ligands after coordination were suggested on the basis of their PMR spectra. The circular dichroism spectra of the isomers were considered in relation to their geometrical configurations.

Bis(terdentate) type Co(III) complexes containing α-amino-carboxylates have been extensively investigated during the past several years.[1-9] However, the relationship between their geometrical configurations and CD spectra remains unsolved because of the peculiarity of configurational chirality. For example, $[Co(L\text{-asp})_2]^-$ (L-asp=L-aspartate) was prepared and separated into their three geometrical isomers,[1] but their configurational assignments on the basis of their CD spectra were unsuccessful.[1,10,11] As for the isomers of $[Co(L\text{-met})_2]^+$ and $[Co(L\text{-smc})_2]^+$ (L-met=L-methioninate and L-smc=*S*-methyl-L-cysteinate),[3,12,13] which have biochemically important functions and quite similar frameworks to those of $[Co(L\text{-asp})_2]^-$, their three isomers have been assigned on the basis of their absorption spectral behavior due to the coordinated sulfur atom of the ligand, though the sulfur atom takes *R* or *S* configuration after coordination. Recently, Yamanari *et al.*[14] reported the preparation and separation of the isomers of two kinds of mixed type cobalt(III) complexes, [(2-aminoethylthio)acetato](L-methioninato) and [3-(2-aminoethylthio)propionato](L-methioninato)cobalt-(III), and suggested the vicinal CD contribution due to the chiral sulfur atom of L-methioninate by applying an additivity rule for the CD curves of their diastereomeric pairs. In these circumstances, it is significant to investigate the properties of the mixed Co(III) complexes with L- or D-aspartate and L-methioninate or *S*-methyl-L-cysteinate. In the present work, the mixed Co(III) complexes, [Co(L-asp)(L-met)], [Co(D-asp)(L-met)], [Co(L-asp)(L-smc)], and [Co(D-asp)(L-smc)], have been prepared and chromatographically separated into their three geometrical isomers, respectively. The isomers have been characterized from their electronic absorption and PMR spectra. The absolute configurations of sulfur atoms after coordination were also suggested on the basis of their PMR spectra. Their CD spectra were discussed mainly in relation to the geometrical configurations of the isomers.

Experimental

Preparation and Separation of Isomers. *(L-Aspartato)(L-methioninato)cobalt(III)*, *[Co(L-asp)(L-met)]*: A solution containing 0.9 g of L-aspartic acid and 1.1 g of L-methionine in 20 cm³ of water was adjusted to pH 8 by the addition of sodium hydroxide aqueous solution. This was added to a a hot solution (*ca.* 65 °C) containing 1.6 g of cobalt(II) chloride hexahydrate in 30 cm³ of water. 3.0 g of lead dioxide and 0.5 g of activated charcoal were gradually added to the solution, which was then stirred at 65 °C for 30 min, the color of the solution turning violet. The mixture was filtered in order to remove the excess of lead dioxide and charcoal after cooling to room temperature. The filtrate was passed through an anion-exchange column of Dowex 1-X8 (Cl^- form, 200—400 mesh, 4.5×20 cm) and successively through a cation-exchange column of Dowex 50W-X8 (Na^+ form, 100—200 mesh, 4.5×20 cm) in order to obtain a solution containing the neutral species which are the isomers of [Co(L-asp)(L-met)]. The eluate was concentrated to 5—10 cm³. Chromatographic seapration was then carried out through a cation-exchange column of Dowex 50W-X8 (Na^+ form, 200—400 mesh, 3.0×120 cm). The adsorbed band was eluted with water at a rate of 0.4 cm³/min. Three colored bands, dark violet (F-1), purple (F-2) and reddish violet (F-3) were eluted in succession. Here the F-2 isomer followed closely after the F-1 isomer. The three eluates were separately concentrated to dryness in a rotary evaporator below 30 °C. The F-2 isomer was recrystallized from hot water, and the F-1 and F-3 isomers were recrystallized from as little water as possible by adding ethanol. The F-2, isomer was less soluble in water. The F-1 isomer formed needle crystals, the F-2 isomer flaky crystals and the F-3 isomer hexagonal crystals. Found for F-1: C, 28.21; H, 5.25; N, 7.31%. Calcd for $[Co(L\text{-asp})(L\text{-met})]\cdot 2.5H_2O = CoC_9H_{15}N_2O_6S\cdot 2.5H_2O$: C, 28.20; H, 5.26; N, 7.31%. Found for F-2: C, 31.57; H, 4.52; N, 8.24%. Calcd for $[Co(L\text{-asp})(L\text{-met})] = CoC_9H_{15}N_2O_6S$: C, 31.96; H, 4.42; N, 8.24%. Found for F-3: C, 30.24; H, 4.85; N, 7.85%. Calcd for $[Co(L\text{-asp})(L\text{-met})]\cdot H_2O = CoC_9H_{15}N_2O_6S\cdot H_2O$: C, 30.34, H, 4.81; N, 7.86%.

(D-Aspartato)(L-methioninato)cobalt(III), *[Co(D-asp)(L-met)]*: Preparation was carried out according to a method similar to that for [Co(L-asp)(L-met)] by using an anion-exchange column (Dowex 1-X8, Cl^- form) and a cation-exchange column (Dowex 50W-X8, Na^+ form). Chromatographic separation was carried out through a column of QAE-Sephadex A-25 (Cl^- form, 3.3×250 cm) instead of Dowex 50W-X8 (Na^+ form, 200—400 mesh, 3.0×120 cm). The adsorbed band was eluted with water at a rate of 0.3 cm³/min. Three colored bands, gray-violet (G-1), reddish violet (G-2), and pink-violet (G-3) were eluted in succession. The G-2

† Present address: Department of Chemistry, Washington State University, Pullman, Washington 99164.

isomer followed colsely after the G-1 isomer. The three eluates were separately concentrated to dryness in a rotary evaporator below 30 °C. The G-1 and G-3 isomers were recrystallized from hot water and the G-2 isomer was recrystallized from as little water as possible by adding ethanol. The G-1 and G-3 isomers were sparingly soluble in water and the G-2 isomer was very soluble in water. The G-1 isomer formed needle crystals and the G-3 isomer rod crystals whereas the G-2 isomer was powdery. Found for G-1: C, 30.51; H, 4.95; N, 7.80%. Calcd for [Co(D-asp)(L-met)]·H_2O=$CoC_9H_{15}N_2O_6S\cdot H_2O$: C, 30.34; H, 4.81; N, 7.86%. Found for G-2: C, 26.78; H, 4.85; N, 6.92%. Calcd for [Co(D-asp)(L-met)]·$2H_2O$·0.5NaCl = $CoC_9H_{15}N_2O_6S\cdot 2H_2O\cdot 0.5NaCl$: C, 26.79; H, 4.75; N, 6.94%. Found for G-3: C, 28.82; H, 4.68; N, 7.49%. Calcd for [Co(D-asp)(L-met)]·$2H_2O$=$CoC_9H_{15}N_2O_6S\cdot 2H_2O$: C, 28.88; H, 5.12; N, 7.49%.

(L-Aspartato)(S-methyl-L-cysteinato)cobalt(III), *[Co(L-asp)(L-smc)]*: A solution containing 1.2 g of L-aspartic acid and 1.2 g of *S*-methyl-L-cysteine in 20 cm^3 of water was adjusted to pH 6 by the addition of sodium hydroxide aqueous solution. This was added to a hot solution (*ca.* 65 °C) containing 2.0 g of cobalt(II) chloride hexahydrate in 30 cm^3 of water. 3.0 g of lead dioxide and 0.5 g of activated charcoal were gradually added to the solution which was then stirred at 65 °C for 30 min, the color of the solution turning violet. After the mixture had been filtered, the filtrate was passed through an anion-exchange column and then a cation-exchange column in order to obtain a solution containing the neutral species which are the isomers of [Co(L-asp)(L-smc)]. Chromatographic separation was carried out by a method similar to that for [Co(D-asp)(L-met)], using a column of QAE-Sephadex A-25 (Cl^- form, 3.3×250 cm). Three colored bands, purple (H-1), dark violet (H-2), and light purple (H-3) were eluted in succession. The H-2 isomer followed closely after the H-1 isomer. The three eluates were separately concentrated to dryness in a rotary evaporator below 30 °C. Each crude product was recrystallized from as little water as possible by addition of ethanol. The H-3 isomer formed needle crystals whereas the H-1 and H-2 isomers were powdery. Found for H-1: C, 25.42; H, 4.69; N, 7.30%. Calcd for Co(L-asp)(L-smc)]·$3H_2O$=$CoC_8H_{13}N_2O_6S\cdot 3H_2O$: C, 25.40; H, 5.06; N, 7.41%. Found for H-2: C, 24.76; H, 4.68; N, 7.27%. Calcd for [Co(L-asp)(L-smc)]·$3.5H_2O$=$CoC_8H_{13}N_2O_6S\cdot 3.5H_2O$: C, 24.81; H, 5.20; N, 7.23%. Found for H-3: C, 26.27; H, 4.76; N, 7.64%. Calcd for [Co(L-asp)(L-smc)]·$2H_2O$=$CoC_8H_{13}N_2O_6S\cdot 2H_2O$: C, 26.67; H, 4.76; N, 7.78%.

(D-Aspartato)(S-methyl-L-cysteinato)cobalt(III), *[Co(D-asp)(L-smc)]*: The preparation was carried out according to a method similar to that for [Co(L-asp)(L-smc)]. Chromatographic separation was accomplished according to a method similar to that for [Co(L-asp)(L-met)], using a column of Dowex 50W-X8 (Na^+ form, 200—400 mesh, 3.0×120 cm). Three colored bands, purple (I-1), gray-violet (I-2), and light purple (I-3) were eluted in succession. The I-2 isomer followed closely after the I-1 isomer. The three eluates were separately concentrated to dryness in a rotary evaporator below 30 °C. The I-2 and I-3 isomers were recrystallized from hot water and the I-1 isomer was recrystallized from as litlte water as possible by adding ethanol. The I-2 isomer was sparingly soluble in water. The I-2 isomer formed needle crystals and the I-3 isomer cubic crystals whereas the I-1 isomer was powdery. The yields of the I-1 and I-2 isomers were rather small. Found for I-1: C, 26.50; H, 4.90; N, 7.72%. Calcd for [Co(D-asp)(L-smc)]·$2H_2O$=$CoC_8H_{13}N_2O_6S\cdot 2H_2O$: C, 26.67; H, 4.76; N, 7.78%. Found for I-2: C, 29.31; H, 4.08; N, 8.57%. Calcd for [Co(D-asp)(L-smc)]=$CoC_8H_{13}N_2O_6S$: C, 29.64; H, 4.04; N, 8.64%. Found for I-3: C, 27.78; H, 4.58; N, 8.22%. Calcd for [Co(D-asp)(L-smc)]·H_2O=$CoC_8H_{13}N_2O_6S\cdot H_2O$: C, 28.08; H, 4.42; N, 8.19%.

Measurements. Electronic absorption spectra were measured with a JASCO UVIDEC-1 spectrophotometer in aqueous solution. CD spectra were recorded with a JASCO J-20 spectropolarimeter. Proton magnetic resonance spectra were recorded in deuterium oxide or trifluoroacetic acid (CF_3COOH) on a JEOL JUM-MH-100 NMR spectrometer with DSS as an internal reference. All measurements were carried out at room temperature.

Results and Discussion

Absorption Spectra and Configurational Assignment. Three geometrical isomers are possible for the present $[Co(N)_2(O)_3(S)]$ type complex because of the stereospecific regulation by the coordinated terdentate ligands. The three isomers for each of [Co(L-asp)(L-met)], [Co(D-asp)(L-met)], [Co(L-asp)(L-smc)], and [Co(D-asp)(L-smc)] are shown in Fig. 1. The isomers are designated as *trans(N)*, *trans(SO)*, and *trans(SN)* with respect to the coordinated atoms, N, O, and S. The absorption spectra of the isomers of [Co(L- or D-asp)(L-met)] are shown in Fig. 2 and their data are summarized in Table 1. For all the isomers the first absorption bands are located at around 19000 cm^{-1} and the charge transfer bands due to the coordinated sulfur atoms at around 33000 cm^{-1}. The second absorption bands appear as shoulders on the lower energy side of the thioether charge transfer bands. The shape of the first absorption band for each of the isomers can be expected from the semi-empirical calculation[15] on the basis of the ligand field order N>S>O.[16–18] The first absorption band of the *trans(N)* isomer is expected to show a well separated minor component on the lower energy side of the major one, that of the *trans(SN)* isomer a broad band, and the *trans(SO)* isomer a sharp band. As seen in Fig. 2 and Table 1, the F-1 isomer of [Co(L-asp)(L-met)] shows an explicit shoulder on the lower energy side of the major peak (19600 cm^{-1}), and the G-1 isomer of [Co(D-asp)(L-met)] a peak on the lower energy side of the major one (19600 cm^{-1}). Thus F-1 and G-1 isomers are assigned to *trans(N)* form. The similar splitting pattern was also observed for the *trans(N)* isomers of $[Co(L\text{-met})_2]^+$,[3] $[Co(L\text{-smc})_2]^+$,[12] and $[Co(L\text{-asp})_2]^-$.[1] The F-2 isomer of [Co(L-asp)(L-met)] shows a broad band and the G-2 isomer of [Co(D-asp)(L-met)] a broad band with a vague shoulder on the higher energy side, while the F-3 isomer of [Co(L-asp)(L-met)] and the G-3 isomer of [Co(D-asp)(L-met)] show apparently a sharp band. These absorption patterns indicate that the F-2 and G-2 isomers are *trans(SN)* form and the F-3 and G-3 ones *trans(SO)* form in accordance with the expected splittings which were estimated semiempirically.[15] A similar treatment was successfully applied to the isomers of bis[(2-aminoethylthio)acetato]cobalt(III) complex.[18] The present assignment is in line with that based on the PMR spectra (*vide post*). The absorption spectra of the isomers of [Co(L- or D-asp)(L-smc)] are shown in Fig. 3 and their

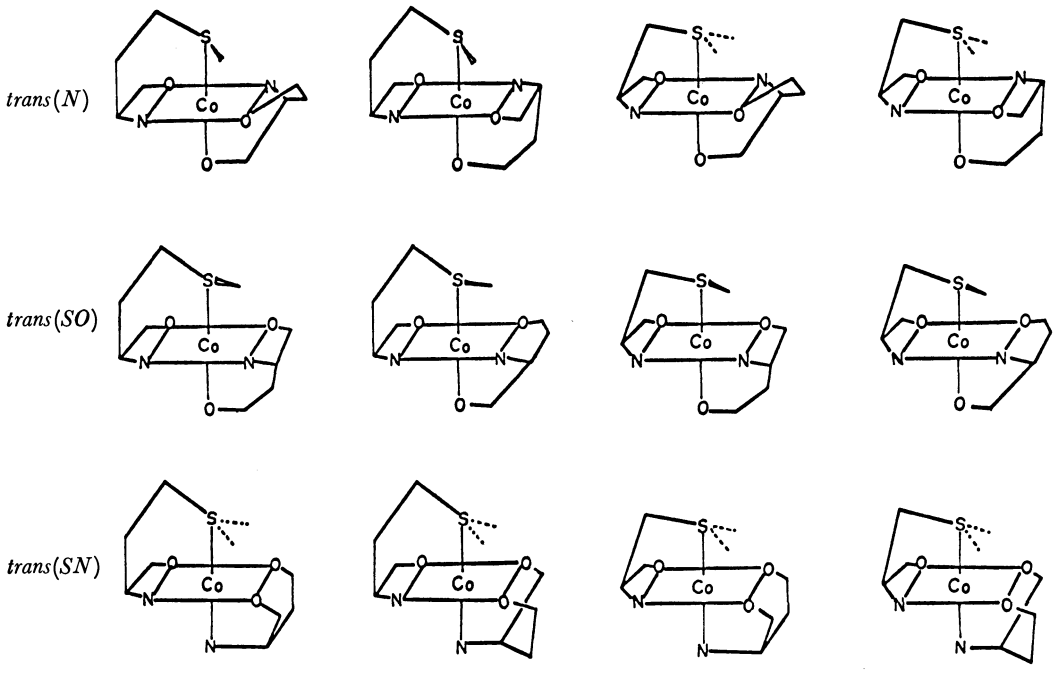

Fig. 1. Three geometrical isomers of [Co(L-asp)(L-met)] (a), [Co(D-asp)(L-met)] (b), [Co(L-asp)(L-smc)] (c) and [Co(D-asp)(L-smc)] (d).

a) A shoulder.

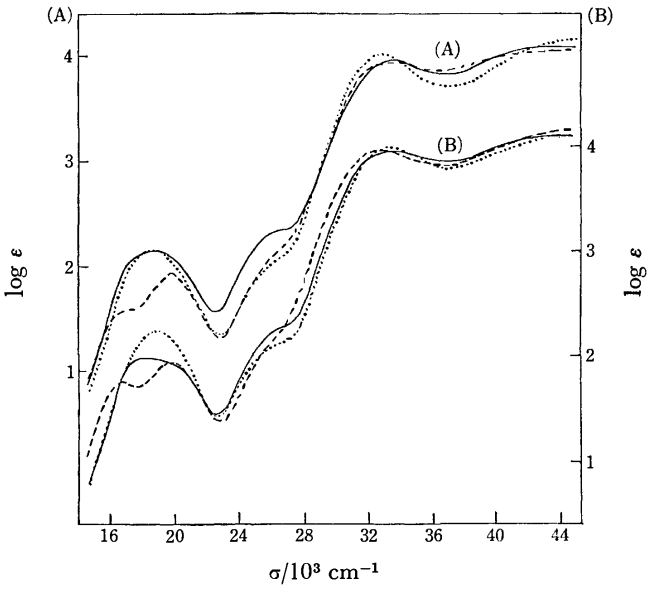

Fig. 2. Absorption spectra for the isomers of [Co(L-asp)-(L-met)] (A); F-1 (——), F-2 (——), and F-3 (·····) and [Co(D-asp)(L-met)] (B); G-1 (——), G-2 (——), and G-3 (·····).

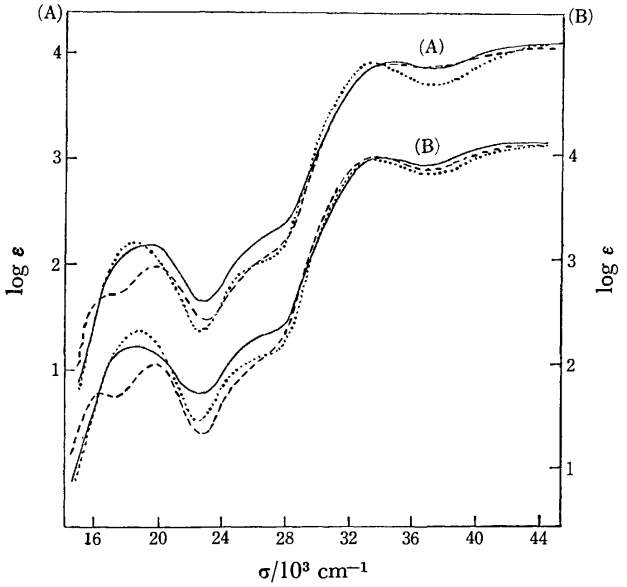

Fig. 3. Absorption spectra for the isomers of [Co(L-asp)-(L-smc)] (A); H-1 (——), H-2 (——) and H-3 (·····) and [Co(D-asp)(L-smc)] (B); I-1 (——), I-2 (——), and I-3 (·····).

data are summarized in Table 1. The splitting behavior of their first absorption bands is very similar to that of the corresponding isomers of L-methioninato complex. Thus the H-1, H-2, and H-3 isomers of [Co(L-asp)(L-smc)] are assigned to *trans(SN)*, *trans(N)*, and *trans(SO)* forms, respectively. As for the [Co(D-asp)(L-smc)], the I-1, I-2, and I-3 isomers are assigned to *trans(SN)*, *trans(N)*, and *trans(SO)* forms, respectively.

Proton Magnetic Resonance Spectra. Proton magnetic resonance spectra of the isomers isolated were measured in D_2O or trifluoroacetic acid. Representative spectra are shown in Fig. 4. The sulfur atom of a thioether

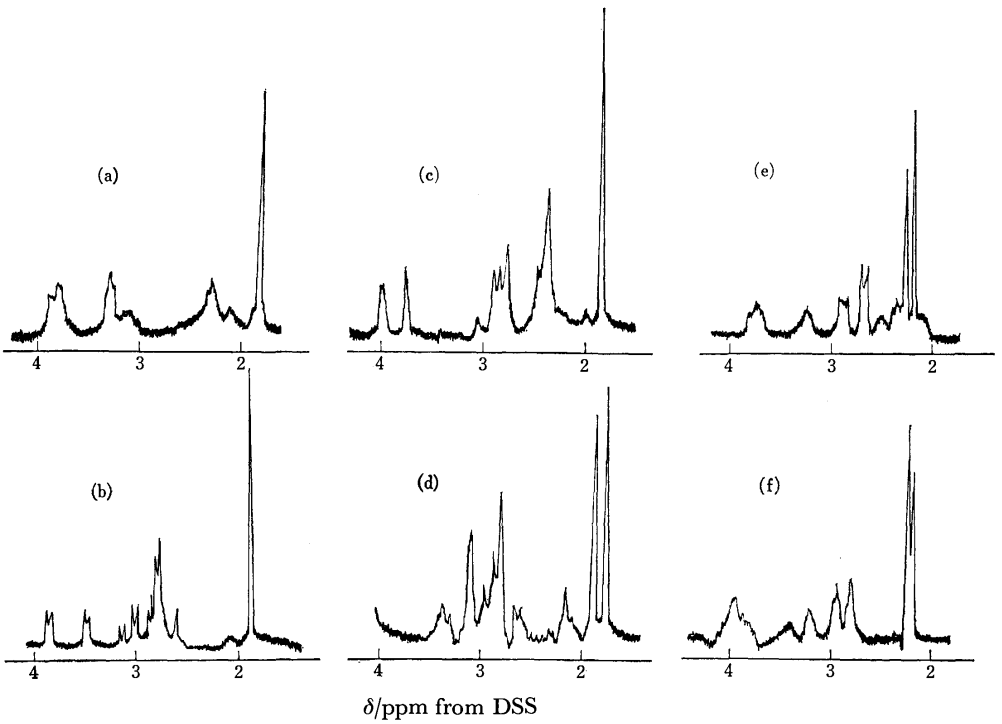

Fig. 4. The representative PMR spectra for the isomers of [Co(L- or D-asp)(L-met)] and [Co(L- or D-asp)(L-smc)]: (a) *trans(SO)*-[Co(L-asp)(L-met)] in CF_3COOH, (b) *trans(SO)*-[Co(L-asp)(L-smc)] in D_2O, (c) *trans(N)*-[Co(L-asp)(L-met)] in D_2O, (d) *trans(N)*-[Co(L-asp)(L-smc)] in D_2O, (e) *trans(SN)*-[Co(D-asp)(L-met)] in D_2O and (f) *trans(SN)*-[Co(D-asp)(L-smc)] in D_2O.

ligand becomes chiral by coordination, leaving on itself a single lone-pair which can give a fixed configuration for the donor center at ordinary temperature.[14] The sulfur atom of L-methioninate or *S*-methyl-L-cysteinate should take *R* or *S* configuration after coordination. Taking the chiral sulfur atom into consideration, two isomers of another type are expected for each of the three geometrical isomers. Each reacted solution was separated chromatographically into three bands (*trans*-(*N*), *trans*(*SN*), and *trans*(*SO*) isomers), the detailed fractions of each separated band showing similar CD spectra. This suggests that the isomers due to the configuration *R* or *S* of the chiral sulfur atom are not separable from each other by the present procedure or the sulfur atom is coordinated stereoselectively. As seen in Figs. 4 and 5, the F-3, G-3, H-3, and I-3 isomers assigned to *trans*(*SO*) from their absorption spectra show a single peak (1.87[1.88] ppm for F-3, [2.00] ppm for G-3, 1.90 ppm for H-3 and 1.98 ppm for I-3. Chemical shifts in trifluoroacetic acid are shown in the brackets) in the *S*-methyl proton region, respectively. It seems that sulfur atoms of these isomers selectively take either *R* or *S* configuration. Molecular model constructions indicate that the *S*-methyl group of *trans*(*SO*) isomer has a significant steric interaction with the amino group of L- or D-aspartate chelate when the sulfur atom takes *R* configuration, while no interaction arises for *S* configuration. A similar result was obtained for the sulfur atoms of *trans*(*S*)-[Co(L-smc)$_2$]$^+$ [12,13] which has a similar framework to the present *trans*(*SO*) isomers. On the other hand, the F-2, G-2, H-1, and I-1 isomers assigned to *trans*(*SN*) show two peaks (2.27, 2.16 ppm for F-2; 2.13, 2.25 ppm for G-2; 2.19, 2.33 ppm for H-1, and 2.21, 2.26 ppm for I-1) in the *S*-methyl proton region, respectively (Figs. 4 and 5). The results indicate that each of the isomers contains the sulfur atoms of both *R* and *S* configurations. Molecular models reveal that the sulfur atoms of *trans*(*SN*) isomers can easily coordinate in both configurations *R* and *S* (Fig. 1). The F-1 and G-1 isomers assigned to *trans*(*N*) show a single peak (1.82 ppm for F-1 and 1.79 ppm for G-1) due to the *S*-methyl protons of L-methioninate, respectively. These *trans*(*N*) isomers seem to take *R* configuration, since the *S*-methyl group is *S* configuration interacts with the amino group of L- or D-aspartate (Fig. 1). However, the H-2 and I-2 isomers assigned similarly to *trans*(*N*) show two peaks (1.91, 1.80 ppm for H-2 and 1.90, 1.78 ppm for I-2) due to the *S*-methyl protons of *S*-methyl-L-cysteinate, respectively (Figs. 4 and 5). This indicates that both of the isomers contain the sulfur atoms of both *R* and *S* configurations. The difference between the *trans*(*N*)-L-methioninato and *S*-methyl-L-cysteinato isomers is attributed to the situation in which the steric interaction between the *S*-methyl group in *S*-configuration and the adjacent amino group of aspartate is more serious in orientation of *S*-methyl group for the six-membered chelate ring of L-methioninato isomers than for the five-membered ring of *S*-methyl-L-cysteinato isomers (Fig. 1). The consideration on the basis of their PMR spectra and molecular model constructions is in line with the structural arguments from their first absorption band patterns.

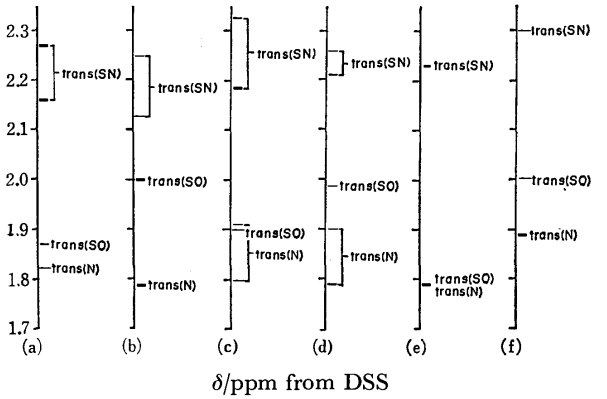

Fig. 5. The distribution of the *S*-methyl protons' chemical shifts: (a) [Co(L-asp)(L-met)], (b) [Co(D-asp)(L-met)], (c) [Co(L-asp)(L-smc)], (d) [Co(D-asp)(L-smc)], (e) [Co(ida)(L-met)], and (f) [Co(ida)(L-smc)].

The chemical shifts of *S*-methyl protons of the twelve isomers isolated are summarized in Fig. 5 with those of six isomers of (iminodiacetato)(L-methioninato) and (iminodiacetato)(*S*-methyl-L-cysteinato)cobalt(III).[20] The PMR spectra were measured in D_2O except for *trans*(*SO*)-[Co(D-asp)(L-met)] which was measured in trifluoroacetic acid because of its low solubility in D_2O. The values can be arranged in order in accordance with their geometries (Figs. 1 and 5). The chemical shifts of the *trans*(*N*) isomers (F-1, G-1, H-2, and I-2) and *trans*(*SO*) isomers (F-3, G-3, H-3, and I-3) appear in a higher magnetic field (1.7—2.0 ppm) than those of the *trans*(*SN*) isomers (F-2, G-2, H-1, and I-1) (2.1—2.4 ppm). The chemical shifts of *trans*(*SO*) isomers are similar to those of *trans*(*N*) ones, though the former has a tendency to a slightly lower field (Fig. 5). This is understandable from the fact that the oxygen atom occupies the trans position to the sulfur atom for the *trans*(*N*) and *trans*(*SO*) isomers, whereas the nitrogen

a) A shoulder.

atom occupies the trans position for the *trans*(*SN*) isomers. The results are in line with the PMR spectra for the isomers of (L- or D-aspartato)(L-2,4-diaminobutyrato)cobalt(III) complexes.[19] In these complexes, the carbon proton adjacent to the coordinated nitrogen atom resonates at a higher magnetic field when oxygen atom occupies trans position to the nitrogen atom than when nitrogen atom occupies the same position.

Circular Dichroism Spectra. The CD curves of *trans*(*N*)-[Co(L- or D-asp)(L-met)] and [Co(L- or D-asp)-(L-smc)] are shown in Fig. 6 and their data are summarized in Table 2. In the first absorption band region, the two L-aspartato complexes, [Co(L-asp)(L-met)] and [Co(L-asp)(L-smc)], show two positive CD bands which correspond to their absorption components (Table 1). This CD pattern is similar to that of *trans*(*N*)-[Co(L-asp)$_2$]$^-$ [1] and of *trans*(*N*)-[Co(L-met)$_2$]$^+$ [3] The replacement of the ligand L-aspartate by D-aspartate reveals a negative CD component at the higher energy side, though the positive CD band at the lower energy side remains unchanged. A similar CD behavior was observed for the curves of *trans*(*SN*) isomers (Fig. 7 and Table 2). In this isomer, however, the replacement of the D-aspartate to L-aspartate reveals a positive CD component at the lower energy side in contrast with the case of *trans*(*N*) isomers, the CD band at the higher energy side remaining unchanged. The CD curves of *trans*(*SO*) isomers show a similar CD pattern (+ and − from the lower energy) to each other in the corresponding region,

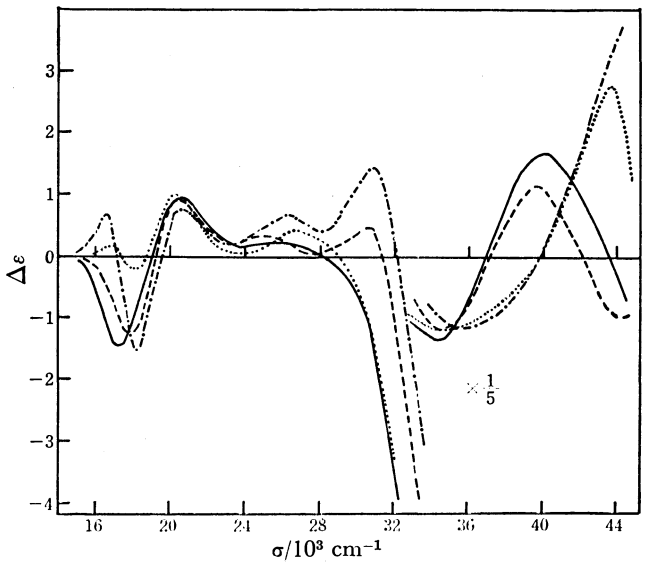

Fig. 7. CD spectra of *trans*(*SN*) complexes: [Co(L-asp)-(L-met)](-•-•-), [Co(D-asp)(L-met)](——), [Co(L-asp)-(L-smc)](·····), and [Co(D-asp)(L-smc)] (——).

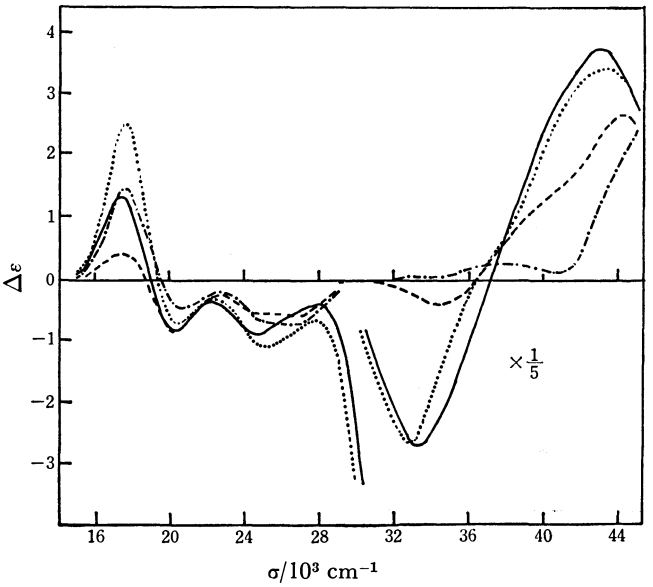

Fig. 8. CD spectra of *trans(SO)* complexes: [Co(L-asp)-(L-met)](-·--·-), [Co(D-asp)(L-met)](——), [Co(L-asp)-(L-smc)](·····), and [Co(D-asp)(L-smc)](——).

though the positive CD band intensities significantly differ from each other (Fig. 8 and Table 2). This pattern might be related to the situation where the first absorption components of *trans(SO)* isomer are close to each other. These observations approximately suggest that the LL mixed or DL mixed type complexes of each of three isomers show a similar CD pattern regardless of L-methioninate coordination or *S*-methyl-L-cysteinate one, the CD pattern depending mainly on the L- or D-aspartate coordination in the first absorption band region.

The three isomers of [Co(L-asp)(L-met)] are very similar in framework to the corresponding isomers of $[Co(L\text{-}asp)_2]^-$ or $[Co(L\text{-}met)_2]^+$. As an example, the *trans(N)* isomer of the mixed complex corresponds to *trans(N)*-$[Co(L\text{-}asp)_2]^-$, the *trans(SN)* isomer to *trans*-(O_5)-$[Co(L\text{-}asp)_2]^-$ and the *trans(SO)* isomer to *trans*(O_6)-$[Co(L\text{-}asp)_2]^-$, respectively. The *trans(SN)* and *trans(SO)* isomers of [Co(L-asp)(L-met)] are quasiantipodal in framework as in the case of the *trans*(O_5) and *trans*(O_6) isomers of $[Co(L\text{-}asp)_2]^-$. In fact, the CD curves of the *trans(SN)* and *trans(SO)* isomers reflect their antipodal relationship in the first and second absorption band region, though the *trans(SN)* isomer shows a positive CD band (16500 cm^{-1}), which suggests a lowering of molecular symmetry or the vicinal CD contributions (Fig. 9). A similar consideration is also applicable to each pair of the *trans(SO)* and *trans(SN)* isomers of [Co(D-asp)(L-met)] or [Co(L- or D-asp)(L-smc)] (Figs. 7 and 8). The quasiantipodal relationship in framework and CD curve is better for the DL mixed complexes than for the LL mixed ones, being especially good for the *trans(SO)* and *trans(SN)* isomers of [Co(D-asp)(L-met)]. From these observations in the first and second absorption band regions, it seems that the CD patterns of the complexes are understandable in relation to their frameworks so far as the present terdentate ligands are concerned. It was suggested that the sulfur chirality of

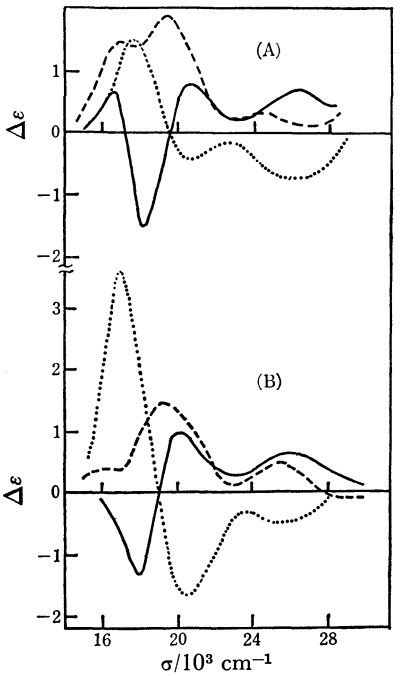

Fig. 9. The CD spectra for isomers of [Co(L-asp)(L-met)] (A), [*trans(N)*(——), *trans(SN)*(——), and *trans(SO)* (·····)] and $[Co(L\text{-}asp)_2]^-$ (B), [*trans(N)*(——), *cis(N)*-*trans*(O_5)(——), and *cis(N)trans*(O_6)(·····)].

the coordinated L-methioninate has large vicinal CD contribution in the first absorption band region.[14] In the present case, however, the CD curves of *trans(N)*-[Co(L-asp)(L-met)], in which the coordinated sulfur atom is assigned to *R* configuration, are similar to those of *trans(N)*-[Co(L-asp)(L-smc)] which contains two kinds of chiral sulfur atoms, *R* and *S* configurations (Fig. 4 and Table 2). It seems that in the present mixed complexes the framework of isomer determines dominantly the CD pattern in the first absorption band region. In the thioether charge transfer band region (30000—35000 cm^{-1}), the CD curves of the twelve isomers are classified apparently into two groups. L-Methioninato complexes show a positive CD band regardless of L- or D-aspartate coordination, though it is only a trend for the *trans(SO)* isomers. In contrast, no CD band appears for the *S*-methyl-L-cysteinato complexes (Figs. 6—8). The sulfur atoms of *trans(N)*-L-methioninato complexes take *R* configuration and *trans(N)*-*S*-methyl-L-cysteinato one contain two kinds of chiral sulfur atoms, *R* and *S* configurations. The *trans(SN)* isomers contain the sulfur atom of both *R* and *S* configurations for both the L-methioninato and *S*-methyl-L-cysteinato complexes. The *trans(SO)* isomers take only *S* configuration. From the information on their PMR spectra, it is assumed that the CD spectra in this region apparently depend mainly on L-methioninate coordination or *S*-methyl-L-cysteinate one, though the influence of the CD bands in the highest energy region (35000—44000 cm^{-1}) should be taken into consideration.

X-Ray Diffraction Studies on the Structures of Tetra- and Higher-ammine Complexes of Copper(II) Ion in Aqueous Solution

Toshio YAMAGUCHI and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received June 11, 1978)

From X-ray scattering measurements on ammoniacal aqueous solutions of copper(II) chloride at the NH_3/Cu mole ratios of 4.8 and 5.0, four ammonia molecules at the equatorial position and other two water molecules at the axial one were found to be coordinated to a copper(II) ion at the distance of 2.03 and 2.33 Å, respectively. The radial distribution curve obtained for an aqueous solution of copper(II) chloride saturated with ammonia ($NH_3/Cu=11.2$) showed that a higher ammine copper(II) complex than the tetraamminecopper(II) ion is formed in the solution. The complex has a distorted octahedral form in which the equatorial Cu–N bond distance is 1.93 Å. The axial apices of the octahedron at the distance of 2.30 Å are occupied by either an ammonia molecule and a water molecule or two ammonia molecules. The present study shows that the structures of the tetra- and higher-ammine copper(II) complexes in solution are different from those in crystal.

A number of methods have been applied for investigating the formation of ammine complexes of copper(II) ion. For a long time the tetraamminecopper(II) ion has been believed to have a square planar structure. In 1968 Tomlinson and Hathaway[1] studied the structures of pentaammine- and hexaamminecopper(II) salts in the solid state by means of electronic, ESR, and infrared spectra, together with magnetic moment measurements, and they suggested that the configuration of the pentaammine complex of copper(II) ion is a tetragonal pyramid and that the hexaammine complex has also the pentaammine moiety so that the complex should be described as $Cu(NH_3)_5X_2\cdot NH_3$ having a free ammonia molecule in the lattice. Romano and Bjerrum[2] also proposed the tetragonal pyramid form for the pentaammine complex in aqueous solution.

While numerous crystal structures have been reported for the tetraammine complexes of copper(II) ion,[3–6] no structural data have been reported for the complex in solution. For penta- and hexaamminecopper(II) complexes, many powder X-ray data have been reported,[7,8] but few crystallographic data are available because of low stability of the crystals.

The present X-ray diffraction study for ammoniacal aqueous solutions of copper(II) chloride with the NH_3/Cu mole ratios of 4.8 and 5.0 has been undertaken in order to clarify the structure of the tetraamminecopper(II) complex in solution. An aqueous solution of copper(II) chloride saturated with ammonia has also been examined to determine the structure of a higher-ammine complex of copper(II).

Experimental

Preparation and Analysis of Sample Solutions. The tetraammine copper(II) chloride solutions were prepared by dissolving recrystallized copper(II) chloride (Wako Pure Chemicals. Co., reagent grade) into concentrated ammoniacal aqueous solutions (Wako Pure Chemicals. Co., reagent grade) and by adding gaseous ammonia (99.99%) to the solutions (A and B) in order to obtain prescribed stoichiometric ratios of NH_3/Cu, in which the tetraaminecopper(II) ion is expected to be predominant in the solutions according to the formation constants of ammine copper(II) complexes.[9] The distribution of the ammine complexes of copper(II) ion is shown in Fig. 1. An ammoniacal copper(II) chloride solution (C) of a high ammonia concentration was also prepared by introducing gaseous ammonia into a tetraammine copper(II) chloride solution to saturation (the NH_3/Cu mole ratio was about 11).

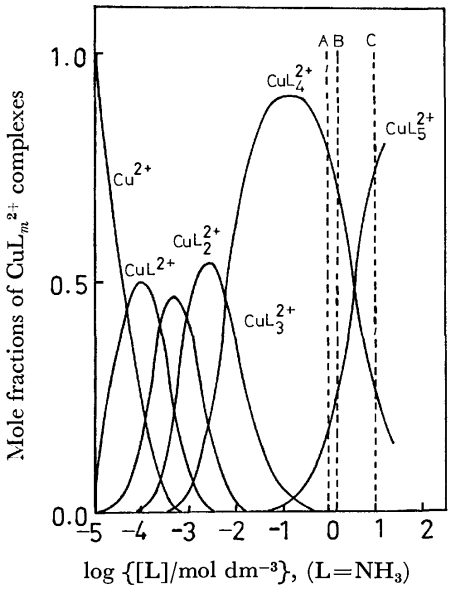

Fig. 1. The distribution of copper(II) ammine complexes as a function of the free ammonia concentration by assuming the formation constants in the literature[16] to be valid.

The concentration of the copper(II) ion was determined both by EDTA titration using a BT indicator and by electrogravimetry as metallic copper on a platinum gauze. The results of the two different methods agreed each other within 0.2%. The concentration of total ammonia was determined by the Kjeldahl method. The concentration of the chloride ion was determined from the stoichiometry of copper(II) chloride.

The density of the solutions was determined pycnometrically.

The compositions of the solutions are given in Table 1.

X-Ray Scatterings. The X-ray diffractometer used, methods of measurements and data treatment have been previously described.[10–12] Mo $K\alpha$ radiation ($\lambda=0.7107$ Å) was used for the measurements. The measurements were

TABLE 1. THE COMPOSITION (g-atoms/dm^3) AND THE STOICHIOMETRIC VOLUME V PER COPPER ATOM IN THE SOLUTIONS

Solution	Cu	Cl	N	O	H	$\frac{NH_3}{Cu}$	$\frac{V}{Å^3}$	Density / g cm^{-3}

carried out over the range of $1°<\theta<70°$ (2θ is the scattering angle), corresponding to the range 0.31 Å$^{-1}<s<16.6$ Å^{-1} ($s=4\pi \sin\theta/\lambda$). Times required to accumulate 40000 counts at each angle were recorded. The whole angle range was scanned twice. The scattered intensities were corrected for background, polarization, absorption and Compton modified radiation, and then scaled to absolute units by conventional ways.[10-12] The values of coherent, incoherent and anomalous scatterings were the same as those used in previous papers.[11,12] The reduced intensities $i(s)$ obtained by subtraction of independent atomic scatterings from the scattered intensities thus deduced, were Fourier transformed into radial distriction functions, $D(r)$, after smoothing correction.[12] Residual systematic errors appearing in the small r region of the $D(r)$ curves were also corrected. The theoretical peak for a given atom pair i-j was calculated in the previous manner.[12]

Results and Discussion

The scaled coherent intensity curves, the observed $s\cdot i(s)$ values, the $D(r)$, and $(D(r)-4\pi r^2\rho_0)$ curves where ρ_0 is the bulk electron density obtained for solutions A, B, and C are shown in Figs. 2—5, respectively.

Solutions A and B. As can be seen in Fig. 1, the tetraamminecopper(II) ion is the predominant species in solutions A and B. The $D(r)$ and $(D(r)-4\pi r^2\rho_0)$ curves obtained for the both solutions are very similar except for $r>5$ Å and show four peaks around 1.0, 2.1, 3.3, and 4.3 Å. The smallest broad peak around 1 Å is attributed to both O–H and N–H bonds within water and ammonia molecules, respectively. The peak centered at 3.3 Å is mainly attributed to the interaction between chloride ions and water molecules.[13]

The location of the second major peak at about 2.1 Å is consistent with interatomic distances between Cu(II) and nitrogen atoms within the square-planar tetraamminecopper(II) ion in the crystalline state.[3-6] However, the area under the peak was found to be larger than the area calculated from only four Cu–N bonds. Therefore, it is expected that the copper complex may have an octahedral structure and the axial copper–ligand bond within the octahedral coordination may also contribute to the area under the peak. By assuming that the equatorial Cu(II)–N bonds are the same as those in the crystalline state, the interactions due to the four Cu–N bonds were subtracted from the $D(r)$ and $(D(r)-4\pi r^2\rho_0)$ curves. The values of 2.03 Å for the Cu–N distance and 0.0020 Å^2 for the temperature factor calculated from spectroscopic data[14] were adopted for the calculation. The result is shown in Fig. 6 (fine solid line). A hump still remaining around 2.3 Å may be due to the axial copper(II)–ligand bonds. The location of this hump ruled out the possibility of axial Cu(II)–Cl bonding, since the Cu–Cl distance was reported to be about 2.6 Å.[15] It is therefore assumed that water molecules occupy the axial sites of Cu(II). The Cu–OH_2(axial) distance, as well as the Cu–NH_3(equatorial) one, within the tetraamminecopper(II) complex were determined by the trial-and-error method so that subtraction of the calculated peaks of the assumed structure of the tetraamminecopper(II) complex from the $D(r)$ and $(D(r)-4\pi r^2\rho_0)$ curves led to a smooth background curve with no indication of any other intramolecular interactions in the first coordination sphere of copper(II) ion. From the analysis, we found that two water molecules should coordinate to the tetraamminecopper(II) ion in solutions A and B.

Table 2 gives the final values estimated from the

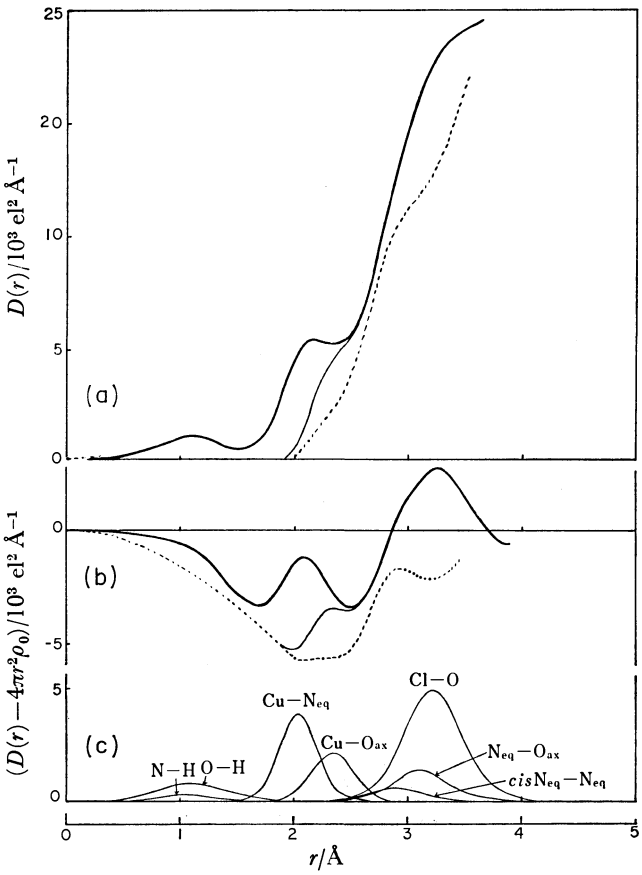

Fig. 6. (a). The $D(r)$ curve for solution A (NH_3/Cu= 4.8). The fine solid line shows the residual curve obtained subtraction of theoretical peak shape for four Cu-N_{eq} bonds from the $D(r)$ curve and the broken curve the difference between the $D(r)$ curve and theoretical peak shapes shown in (c). (b). The corre sponding $(D(r)-4\pi r^2\rho_0)$ curve. (c). The theoretical peak shapes with the parameters given in Table 2.

shape of the $D(r)$ curve in Fig. 6. The broad peak at around 2.9 Å still left in the residual radial distribution curve (broken line) may be ascribed to the O–O bonds of bulk water. The maximum at 4.3 Å in the $D(r)$ and $(D(r)-4\pi r^2\rho_0)$ curves (Figs. 4 and 5) may include the interaction between Cu(II) and water molecules within the secondary hydration shell,[16] as well as the interaction of *trans*-N···N.

TABLE 2. THE FINAL PARAMETER VALUES FOR THE DISTORTED OCTAHEDRAL STRUCTURE OF THE TETRAAMMINE COPPER(II) COMPLEX. THE VALUES IN PARENTHESES ARE THEIR ESTIMATED ERRORS

	r_{ij}/Å	b_{ij}/Å^2	n_{ij}
$Cu(NH_3)_4(OH_2)_2^{2+}$			
Cu–N_{eq}	2.03(±0.02)	0.003	4
Cu–O_{ax}	2.33(±0.03)	0.005	2
cis-$N_{eq}\cdots N_{eq}$	2.87(±0.05)	0.01	4
$N_{eq}\cdots O_{ax}$	3.09(±0.05)	0.01	8
$Cl(H_2O)_6^-$			
Cl–O	3.20(±0.05)	0.01	6

Solution C. Figure 1 shows that the predominant species is a pentaamminecopper(II) ion in solution C. As can be seen in Figs. 4 and 5, the $D(r)$ and $(D(r)-4\pi r^2\rho_0)$ curves for solution C show double peaks in the range of r=2.0—2.5 Å. The double peaks may be easily resolved into a peak with the maximum at about 1.95 Å and another one at about 2.3 Å. Other peaks at 3.3 Å and 4.2 Å also appeared in the curve C.

The first small peak located at 1.0 Å is due to the O–H bonds within water molecules and partly due to the N–H bonds within ammonia molecules. The peak at about 1.95 Å may be ascribed to the Cu(II)–N bond in the square-plane and the peak at about 2.3 Å may be ascribed to the interaction between Cu(II) and the ligands at the axial sites. The peaks located at 3.3 Å and 4.2 Å are mainly related to the Cl–O and to the Cu–OH_2 (in the second coordination layer) interactions, respectively, as previously described.

After subtracting the appropriate intramolecular interactions within the tetraamminecopper(II) ion present, as well as O–H and N–H interactions in solution C, the second and third peaks of the residual curves (fine solid line in Fig. 7) were analyzed for determining the structure of a higher-ammine complex of copper ion as illustrated in Fig. 7. The clearly defined peak at 1.93 Å was assigned to the equatorial Cu–N distance and the area under this peak gave four Cu–N bonds per Cu(II). The distance and the number of the axial copper(II)–ligand bonds were estimated after subtraction of the four equatorial Cu–N interactions from the $D(r)$ curve. The resulting curve is drawn by the chain line (—·—) in Fig. 7. The area under the peak at 2.3 Å corresponded to the Cu–NH_3 and Cu–OH_2 bonds with an equal distance (see Fig. 7c), if it is assumed that the pentaamminecopper complex is formed. However, it must be noted that another assumption of the formation of the hexaamminecopper complex can equally well explain the data. The final parameter values thus determined are summarized in Table 3. The residual radial distribution curve after subtraction of all the intramolecular interactions of the

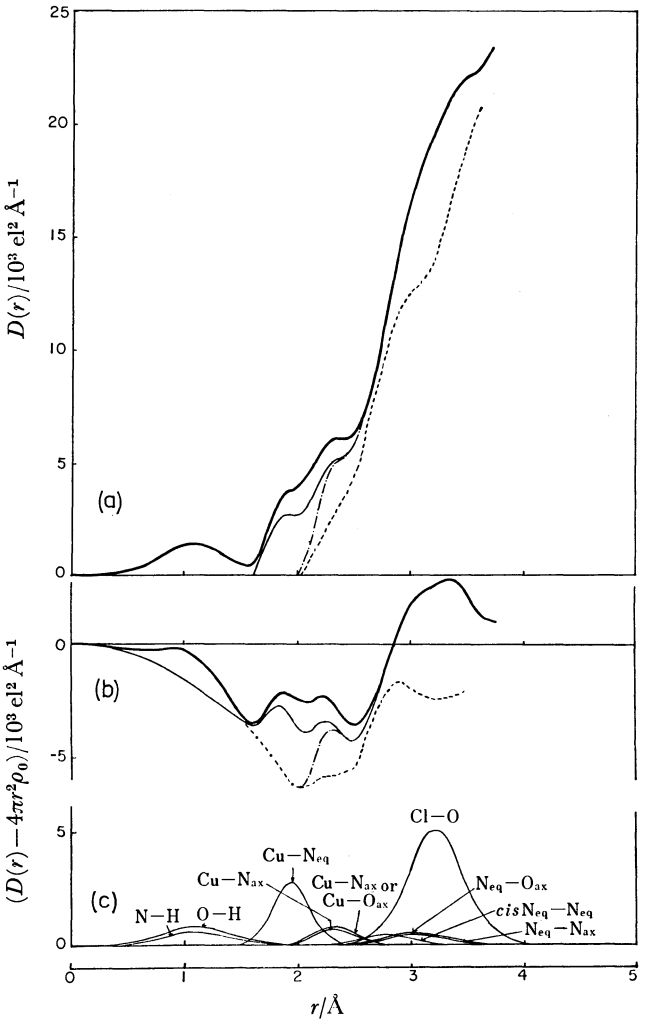

Fig. 7. (a). The $D(r)$ curve for solution C (NH_3/Cu= 11.2). The fine solid line (——) shows the residual curve obtained by subtracting the contribution of the tetraamminecopper(II) ion from the $D(r)$ curve, the chain line (-·-·-) gives the difference between the residual curve and the calculated peak shape for four Cu–N_{eq} bonds and the broken line (----) the residual curve obtained by subtraction of the theoretical peak shapes shown in (c) from the residual curve.
(b). The corresponding $(D(r)-4\pi r^2\rho_0)$ curve. (c). The theoretical peak shapes with the parameters given in Table 3.

TABLE 3. THE FINAL PARAMETER VALUES FOR THE DISTORTED OCTAHEDRAL STRUCTURE OF THE $Cu(NH_3)_5X^{2+}$ (X=NH_3 or H_2O) THE VALUES IN PARENTHESES ARE THEIR ESTIMATED ERRORS

	r_{ij}/Å	b_{ij}/Å^2	n_{ij}
$Cu(NH_3)_5X^{2+}$			
Cu–N_{eq}	1.93(±0.02)	0.003	4
Cu–N_{ax}	2.30(±0.03)	0.005	1
Cu–X_{ax}	2.30(±0.03)	0.005	1
cis-$N_{eq}\cdots N_{eq}$	2.73(+0.05)	0.01	4
$N_{eq}\cdots N_{ax}$	3.00(±0.05)	0.01	4
$N_{eq}\cdots X_{ax}$	3.00(±0.05)	0.01	4
$Cl(H_2O)_6^-$			
Cl–O	3.20(±0.05)	0.01	6

species is shown in Fig. 7 with dashed lines. The broad peak remaining at about 2.9 Å in the residual radial distribution curve may be due to the O–O interactions within bulk water. The maximum at 4.3 Å in the $D(r)$ curve (Fig. 4, curve C) may be attributable to the interaction between Cu(II) and water molecules within the secondary hydration shell.

Although it is not conclusive whether the copper(II) ion combines with five ammonia molecules and a water molecule or with six ammonia molecules in solution C, it is obvious that the complex present in the solution has not a tetragonal-pyramidal form, but a distorted octahedral structure.

In the hexaaquacopper(II) ion the Cu–OH_2-(equatorial) distance is 1.94 Å[17] and the Cu–NH_3-(equatorial) one within the tetraamminecopper(II) complex is 2.03 Å. However, we observed that the Cu–NH_3(equatorial) distance is shortened to 1.93 Å by further combination of ammonia molecules with the tetraamminecopper(II) complex. Although the reason of the change in the bond distance is not clear yet, it may be due to the lowering of the symmetry of the complex ion. The electron density of the bonds between the central copper(II) ion and the ammonia molecules at the equatorial position may also be changed with varying ligand molecules at the axial position. This may reflect to the change in the bond distances between the copper(II) ion and ligand molecules.

Single Crystal Growth of Zirconium Nitride by Modified Filament-Method

Kohzo SUGIYAMA, Kunio WATANABE, Seiji MOTOJIMA,* and Yasutaka TAKAHASHI

Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Kakamigahara, Gifu 504

(Received June 2, 1978)

Single crystals of zirconium nitride (ZrN) have been grown by the modified filament-method from a gas mixture of $ZrCl_4$, N_2, H_2, and Ar. The cubic crystals grew at 2000—2200 °C with a gas flow ratio $2N_2/ZrCl_4$ of 2—6, and evaporation of ZrN took place above 2400 °C. Linear growth rates along the <100> direction have been measured in terms of sequential micrographs, and attained a maximum of 60—75 μm/min at 2100—2200 °C. The atomic ratio N/Zr of grown crystals increased with an increase of the flow ratio $2N_2/ZrCl_4$, and reached a constant of 0.93 above the flow ratio of 3.

Zirconium nitride, a representative interstitial compound of NaCl-type structure, has desirable properties such as high melting point (2982 °C,[1] 3700 ±70 °C at P_{N_2} 60 atm[2]), high hardness (≈2500 kg/mm²),[3] metallic conductivity and high resistivity at high temperature.

The preparation of single crystals of refractory compounds is difficult because of the high melting point. Crystal growth using a floating zone technique[4] is the only way by which single crystals have been successfully grown. Single crystals of the nitride,[5] diboride,[6] and carbide[7] of titanium have been grown by the authors using a modified filament-method, which has the advantages of simple procedure and apparatus. In this paper, the single crystal growth of zirconium nitride by the modified filament-method will be described.

Experimental

Apparatus and Growth Procedure. The apparatus is analogous to that used in previous experiments on titanium nitride crystal growth.[5] A tungsten filament (99.0% pure) 30 mm long and 0.3 mm thick was tightly bound to iron electrodes 5.8 mm thick. Another short tungsten wire of 0.3 mm diameter was twisted around the tungsten filament (one and a half turns) and the tips cut slantwise with a separation of 0.3—1.0 mm from the filament and pointing towards the gas inlet. The filament was located in a horizontal reaction tube (24 mm in i.d.) which was heated to 400 °C by a nichrome heater thereby keeping zirconium tetrachloride in the vapor phase. Zirconium tetrachloride was prepared by the chlorination of zirconium sponge (99.9% pure) at 550 °C, and carried into the reaction zone by argon gas. The flow rate of zirconium tetrachloride was calculated assuming quantitative chlorination to the tetrachloride. Hydrogen and nitrogen were mixed with the zirconium tetrachloride stream near the filament. The surface temperature of the growing crystals was measured by an optical pyrometer through an observation window.

Measurement of Linear Growth Rate. The growing crystals were photographed using a stereoscopic microscope every 10—20 s. A series of sequential micrographs is shown in Fig. 1. The linear growth rate along the <100> direction was obtained as the gradient from the plot of edge length versus growth time.

Atomic Ratio (N/Zr) in Crystals and the Lattice Constant. A collection of zirconium nitride crystallites was pulverized, and oxidized to zirconium dioxide at 1000 °C for 5 h in an oxygen flow. The atomic ratio N/Zr was calculated from the weight of zirconium nitride crystallites W_{ZrN} and zirconium dioxide W_{ZrO_2} using the following equation;

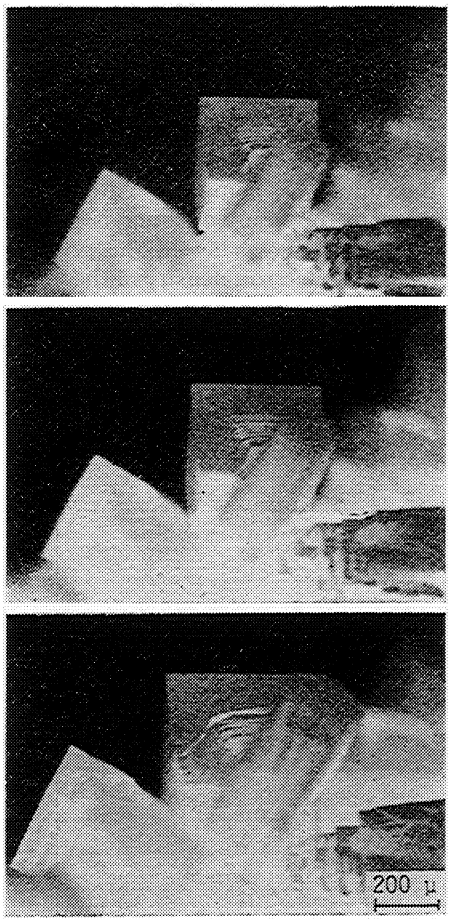

Fig. 1. Sequential micrographs of the growing crystals. Temperature: 2000 °C, $2N_2/ZrCl_4$: 5.4, $2H_2/ZrCl_4$: 10, total flow rate: 3.0 cm³/s, growth time: (A) 0 min (starting of measurement), (B) 4 min, (C) 15 min.

$$N/Zr = 8.7972(W_{ZrN}/W_{ZrO_2}) - 0.7403. \quad (2)$$

The lattice constant was determined by X-ray diffraction using annealed silicon powder as internal standard.

Micro-hardness. Micro-hardness was measured by a Vickers micro-hardness tester (Akashi, MVK-C) on the (100) and (111) facets of cubic and tetragonal pyramid crystals, respectively.

Results and Discussion

Crystal Morphology. The effect of growth temperature and source gas flow ratio $2N_2/ZrCl_4$ ("N/Zr ratio" hereafter) on crystal morphology is shown in Fig. 2, in which the sum of the flow rates of zirconium tetra-

chloride and nitrogen was kept at 0.1 cm^3/s and the gas flow ratio $2H_2/ZrCl_4$ ("H/Zr ratio" hereafter) kept at 3. The crystal morphology varied with increase in growth temperature in the following order; polycrystallite or fine crystal, tetragonal pyramid, cubic, and arrow-like or dendritic. Cubic crystals grew in the temperature range of 2000—2200 °C and at a N/Zr ratio of 2—6. Above 2400 °C, the crystals did not grow and crystallites which had been deposited at a lower temperature gradually disappeared. Concerning the evaporation of zirconium nitride, Hoch *et al.*[8] have investigated the evaporation in the temperature range of 2236—2466 K. Extrapolating the data of Hoch *et al.* to 2400 °C, the evaporation rate is given by the curve B in Fig. 8, and is as fast as 85 μm/min at 2400 °C. This evaporation temperature is 200 °C higher than that of titanium nitride.[5]

The effect of growth temperature and H/Zr ratio on crystal morphology is shown in Fig. 3, in which the N/Zr ratio was kept constant at 4. The growth regions of the pyramidal and arrow-like or dendritic crystals spread to the hydrogen-rich region (Fig. 3, regions B and D). Cubic crystals grew in the temperature range of 2100—2300 °C under a H/Zr ratio below 40.

In Figs. 4 and 5, the representative morphologies of zirconium nitride crystals are shown. Large cubic or

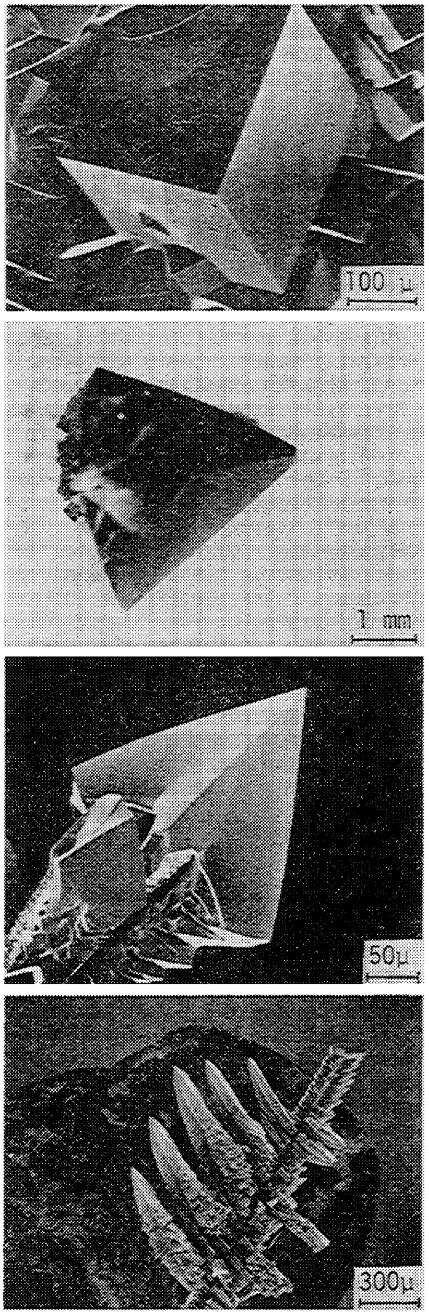

Fig. 4. Representative morphologies of zirconium nitride crystals. (A) cubic crystal, temperature: 2000 °C; $2N_2/ZrCl_4$: 4, (B) tetragonal pyramid crystals, (C) tetragonal pyramid crystal, temperature: 1800 °C; $2H_2/ZrCl_4$: 4, (D) arrow-like and dendritic crystals, temperature: 2300 °C; $2N_2/ZrCl_4$: 4.

tetragonal pyramidal crystals grew from the tips of the tungsten wire, after initial deposition of a few nuclei (Fig. 5). The largest single crystals obtained in this work were 3 mm in edge length for cubic crystals and 3.5 mm for tetragonal pyramids for 90 min growth under a condition of C- and B-regions in Fig. 2, respectively. Square pillar crystals of 10 μm thickness and 1 mm length, on which short pillar crystals branched perpendicularly, were obtained by chance on the filament close to the bound point of the electrodes (Fig. 6). X-Ray diffraction profiles of the pillar crystals are

shown in Fig. 7D, together with those of pulverized crystallites (Fig. 7B) and the square facet of a cubic crystal (Fig. 7C). The pillar crystal was suspended in a

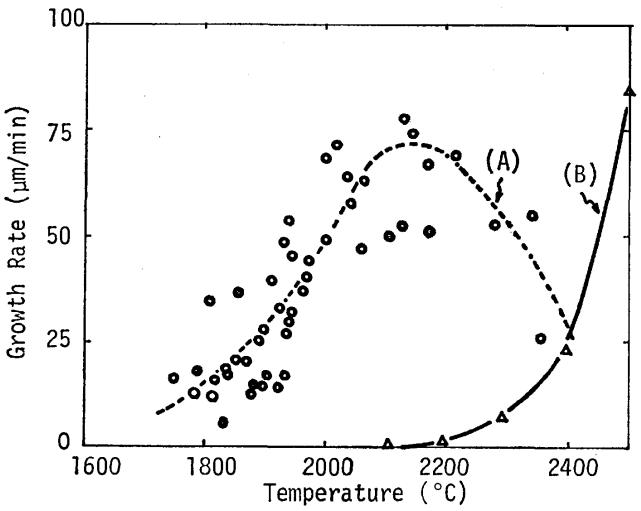

Fig. 8. (A) Effect of the temperature on the linear growth rate in <100> direction. Total flow rate: 3.0 cm^3/s, $2N_2/ZrCl_4$: 4, $2H_2/ZrCl_4$: 15. (B) Evaporation rate.[8]

drop of water, poured on to a holder plate and dried. Thus, the growth axis of the pillar crystals may be regarded as parallel to the holder plate. The two strong peaks in Fig. 7D have been assigned as (200) and (220) of the cubic lattice and thus, the growth direction is considered to be <100>.

Linear Growth Rate. Dependence on Temperature: The linear growth rate along the <100> direction of a cubic crystal was measured in the temperature range of 1700—2400 °C as shown in Fig. 8, in which the N/Zr and H/Zr ratios were kept constant at 4 and 15, respectively. The growth region for tetragonal pyramid crystals is below 1900 °C and for arrow-like crystals above 2250 °C, as seen in Fig. 2. The linear growth rate along the <100> direction in the temperature range was measured as follows; a few small cubic crystals were deposited on the tip in the temperature range C in Fig. 2, followed by decreasing or increasing the temperature to that of measurement. The growth rate increased with the increase of temperature and reached a maximum (about 75 μm/min) in the temperature range 2100—2200 °C, and decreased above 2200 °C. Dispersion of the data may be attributed to fluctuation of the nucleation site, the size and the orientation of the crystals, and the temperature of the growing crystals.

Dependence on N/Zr Ratio: The effect of the N/Zr ratio on the linear growth rate along the <100> direction was examined, where the sum of the flow rates of zirconium tetrachloride and nitrogen, and the H/Zr ratio were kept constant at 0.1 cm^3/s and 10, respectively. The maximum growth rates of 60 and 35 μm/min were measured under a N/Zr ratio of 2—3 at 2100 °C and 1.5—2.5 at 1900 °C, respectively. These values are in agreement with that of the polycrystalline growth of zirconium nitride from the same gas mixture at 1150 °C.[9]

Dependence on H/Zr Ratio: The effect of the H/Zr ratio on the linear growth rate was examined, where the N/Zr ratio was kept constant at 4. The linear growth rate increased with increase of the H/Zr ratio and the maximum was at a ratio as high as 15—18 at 2100 °C, the rate decreasing abruptly above these ratios. At a H/Zr ratio above 40, that is, a low flow ratio of zirconium tetrachloride, the growth rate along the <111> direction predominated resulting in arrow-like or dendritic growth.

Dependence on the Total Flow Rate: The effect of the total flow rate on the growth rate along the <100> directions was examined, where N/Zr and H/Zr ratios were kept constant at 4 and 10, respectively, and the temperature at 2000 °C. The growth rate increased with increase of the total flow rate approaching a constant value of 45 μm/min above a flow rate of 3 cm^3/s which corresponds to a linear velocity at the growth temperature of about 5 cm/s.

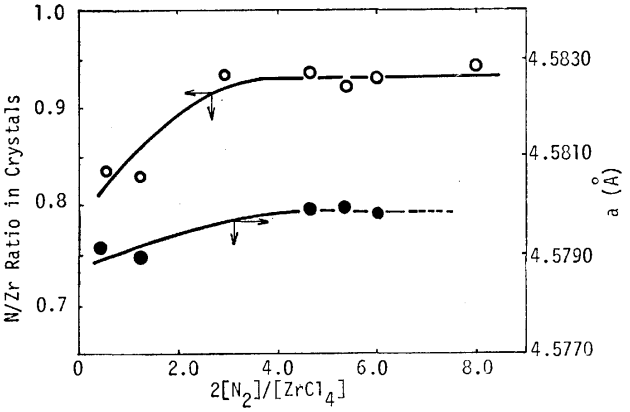

Fig. 9. Effect of flow ratio ($2N_2/ZrCl_4$) on the atomic ratio (N/Zr) and the lattice constant in ZrN crystals. Temperature: 2000—2100 °C, total flow rate: 3.0 cm^3/s, $2H_2/ZrCl_4$: 15.

The Atomic Ratio N/Zr in Crystals and Lattice Constant. The influence of the N/Zr ratio in input gas on the atomic ratio N/Zr in crystals and the lattice constant are shown in Fig. 9, in which the crystals were grown in the temperature range of 2000—2100 °C and with a H/Zr ratio of 15. The atomic ratio N/Zr in crystals increased with the increase of N/Zr ratio in input gas attaining a constant value of 0.93 at a flow ratio above 3. Zirconium nitride exists over a broad composition range corresponding to $ZrN_{0.55-1.0}$[10] and $ZrN_{1.54-1.0}$ at 1500 °C.[11] The stoichiometric composition of ZrN could not be obtained in the present work and the lowest atomic ratio N/Zr was about 0.83.

The lattice constants of zirconium nitride crystals were 4.579 Å for a sample of N/Zr=0.83 and 4.580 Å for that of 0.93. These values are slightly larger than those reported in the literature; *i.e.* 4.5755 Å (N/Zr=0.89),[12] 4.564 Å (N/Zr=1.0),[13] and 4.5755 Å (N/Zr=0.93).[14] The deviations of the constants from the literature may arise from the presence of oxygen in the crystal lattice,[15] although the presence of oxygen in the crystal was below the detectable limit of electron probe microanalysis.

Micro-hardness. Micro-hardness was measured on the (100) and (111) facets of cubic and tetragonal pyramid crystals, respectively. The hardness varied from 1500 to 1600 kg/mm^2, irrespective of the crystal

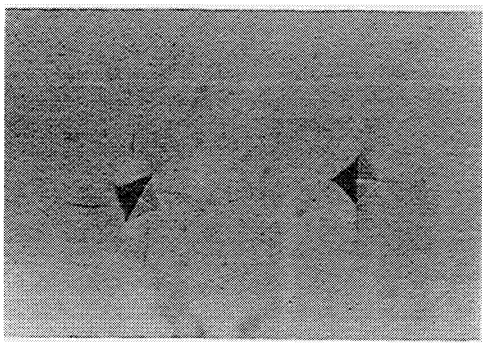

Fig. 10. Typical marks impressed on the (100) facet of a cubic crystal by a pyramidal diamond indenter in Vickers microhardness tester.

facets. These values are somewhat smaller than that reported by Hill *et al.*[3] Typical marks impressed on the (100) facet of cubic crystals by a pyramidal diamond indenter are shown in Fig. 10. Slip lines can be seen in the <110> direction irrespective of the orientation of the indenter, which is in agreement with the slip direction of titanium nitride.[16]

Polysoap as a New Titrant for the Determination of Sodium Dodecylbenzenesulfonate by Colloid Titration

Toshiro Ono, Haruo Miyata, and Kyoji Tôei*

Department of Chemistry, Faculty of Science, Okayama University, Tsushima-naka 3-1-1, Okayama 700

(Received June 12, 1978)

A colloid titration method for the determination of sodium dodecylbenzenesulfonate (LAS) with poly(4-vinyl-1-pentylpyridinium bromide) (polysoap) is described. The end-point detection is based on the measurement of turbidity, the transmittance at 420 nm or 680 nm being used for the determination. The most successful results were obtained by titrating LAS ($1—7.5\times10^{-4}$ N) with 2.5×10^{-3} N polysoap solution. The purity of commercial LAS was found to be 81—84%.

Colloid titration is widely used for the determination of polyelectrolytes. Usually, Cat-Floc (poly(diallyldimethylammonium chloride)) and PVSK (potassium poly(vinyl sulfate)) are used as polycationic and polyanionic titrants, respectively.[1] Anionic surfactants, however, can not be titrated with Cat-Floc, since Cat-Floc can not form polyion complexes with anionic surfactants stoichiometrically.

When a long aliphatic chain is introduced into the polycation to enhance the bonding strength of polycationic titrants with sodium dodecylbenzenesulfonate, the chain is combined firmly with the dodecyl group of the surfactant by hydrophobic bonding. An attempt was made to synthesize a cationic titrant by introducing methyl, ethyl, propyl, butyl, pentyl, hexyl, or octyl group into poly(4-vinylpyridine) in order to form poly(4-vinyl-1-alkylpyridinium halide). The longer the chain, the stronger the bonding strength, the solubility in water decreasing. No standard solution of hexyl and octyl derivatives (2.5×10^{-3} N) can be prepared since they are hardly soluble in water. Thus, poly(4-vinyl-1-pentylpyridinium bromide)(polysoap), synthesized by Menschutkin's reaction,[2] was used as a new cationic titrant. It can combine with sodium dodecylbenzenesulfonate (LAS) stoichiometrically. For the titration of LAS, turbidimetry[3] was used to observe the end-point at wavelengths 420 or 680 nm. Titration was carried out slowly near the end-point.

Experimental

Synthesis of Polysoap. Poly(4-vinyl-1-pentylpyridinium bromide) was synthesized as follows: An equimolecular mixture of pentyl bromide(3 M) and 4-vinylpyridine(3 M) in nitrobenzene was refluxed at 100 °C for several hours. After steam distillation to remove the nitrobenzene and the unreacted reagents, polysoap was obtained as a solid.

Apparatus. Turbidity was measured with a Metrohm Spectrocolorimeter E 1009 equipped with a titration cylinder cell(diameter 35 mm), titration curve being recorded with a Metrohm Potentiograph E 336. pH was measured with a Hitachi-Horiba M 5 pH meter.

Reagents. PVSK solution. Potassium poly(vinyl sulfate) (Wako Pure Chemical Industries Ltd., degree of esterification 92.6%) was dissolved in distilled water to prepare a 2.5×10^{-3} N solution. The factor of the PVSK solution was determined by titrating a standard solution of 2.5×10^{-3} N hexadecylpyridinium chloride monohydrate,[4] stored for several days over a silica gel desiccator, using Toluidine Blue as an indicator.

Polysoap solution. Poly(4-vinyl-1-pentylpyridinium bromide) was dissolved in distilled water to prepare a 2.5×10^{-3} N solution. The solution (10 ml) was diluted to 50 ml with distilled water in a 100 ml cylinder cell and titrated automatically with the standardized PVSK solution using Toluidine Blue as an indicator. The titration speed was 0.37 ml min^{-1}. The end-point was indicated by the inflection point of the transmittance at 630 nm.

Sample Solutions. Standard LAS solution. Standard LAS (Wako Pure Chemical Industries Ltd., purity>99%) was dried *in vacuo* at about 50 °C, and weighed. The standard LAS solution was prepared by dissolving the LAS in distilled water to a constant volume.

Other LAS sample solutions were prepared in the same way as described above.

Titration Procedure of LAS. LAS solution was titrated directly with 2.5×10^{-3} N polysoap solution. A sample solution (2.5×10^{-3} N, 10 ml) in a 100 ml cylinder cell was diluted to 50 ml with distilled water, and titrated with the polysoap solution under mechanical stirring. In order to follow the course of titration, the transmittance at 420 or 680 nm was measured and recorded automatically. It is important to maintain a titration speed of 0.37 ml min^{-1} near the end-point.

Results and Discussion

Standardization of Polysoap. Figure 1 shows the influence of pH on the titration of polysoap with a standard solution of PVSK. The values of meq g^{-1} are constant (3.77 meq g^{-1}) in the pH range 5.0—9.5, decreasing gradually above 9.5. Since the polysoap is quaternary ammonium salt, the values of meq g^{-1} should be constant over the whole pH range 0—14. Actually, however, the pH range is restricted. This

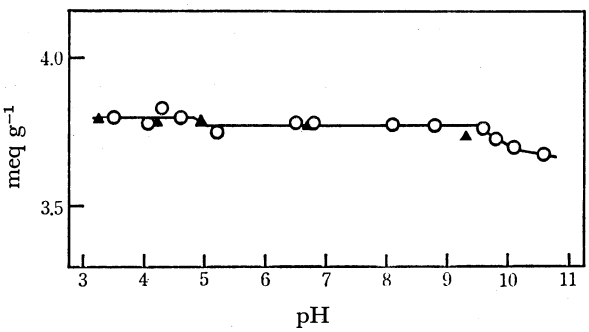

Fig. 1. Colloid titration results of polysoap. Titrant: 1×10^{-3} N PVSK. Titrating solution: 2×10^{-4} N polysoap. ○ Colorimetric, ▲ conductometric.

Table 1. Titration values of standard LAS solution

LAS total concn	Polysoap normality ($N \times 10^3$)					
	2.5	1.25	1	0.5	0.25	0.125
75×10^{-5} N	2.84 meq g^{-1} ($99._1$%)					
50	2.85($99._1$)					
25	2.85($99._5$)	2.78($97._1$)				
20			2.76($96._4$)			
15	2.85($99._2$)

7.5		2.77($96._5$)		2.74($95._5$)		
5		2.79($97._2$)		2.72($94._8$)	2.68($93._5$)	
2.5						2.69($93._5$)

Standard LAS (Wako Pure Chemical Industries, Ltd.; purity: more than 99%).

suggests that the quaternarized reaction is incomplete, the titration results of 3.77 meq g^{-1} corresponding to 96.7% of the expected value, 3.90 meq g^{-1}. The results obtained by the conductometric method[4] with platinum electrodes coincide with those of the photometric method as shown in Fig. 1.

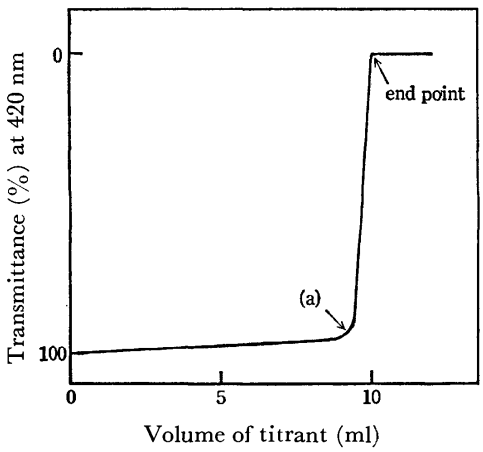

Fig. 2. Turbidimetric titration curve. Titrant: 1×10^{-3} N polysoap. Titrating solution: 2×10^{-4} N LAS(purity: more than 99%).

Turbidimetric Titration of LAS. Figure 2 shows a titration curve for LAS (50 ml of 2×10^{-4} N) titrated with polysoap solution (1×10^{-3} N). The turbidity measured at 420 nm increases gradually with the progress of titration. Near the end-point the transmittance decreases abruptly. The end-point was determined by the point where the reaction between polysoap and LAS finishes completely and the transmittance becomes zero. The titration curve is reproducible. The titration speed is 0.55 ml min^{-1} until point (a) in Fig. 2, and subsequently, 0.37 ml min^{-1}. When the titration speed is faster than 0.37 ml min^{-1} near the end-point, the results are not reproducible since the rate of reaction between polysoap and LAS is slow. When the concentration of LAS is above 2.5×10^{-3} N LAS, the wavelength 680 nm is preferable.
