(Received January 6, 1979)

The mechanism of uranium adsorption from sea water by hydrous titanium(IV) oxide was investigated. The uranium adsorption experiments were conducted using a solution containing NaCl, $NaHCO_3$, and uranium. Thermochemical calculation showed that the tris(carbonato)dioxouranate(VI) ion $[UO_2(CO_3)_3]^{4-}$ found in sea water existed in the solution at pH 8 and 25 °C. The uranium uptake varied with the pH of the solution, exhibiting a minimum value at pH 8. The enthalpy change, ΔH, and the activation energy, E, of the uranium adsorption were found to be 23.6 kJ mol^{-1} and 52.7 kJ mol^{-1} respectively. The analysis of carbonate in the adsorbent showed that the carbonate ion in $[UO_2(CO_3)_3]^{4-}$ was released into the solution during the uranium adsorption. On the basis of the present experimental results, the mechanism of uranium adsorption was discussed.

Many studies have been made on extracting uranium from sea water by adsorption on hydrous titanium(IV) oxide.[1-3] Previous investigations of the uranium adsorption have, however, dealt almost exclusively with the adsorption capacity. Only a few investigations have been carried out on the mechanism of uranium adsorption. Keen[4] reported that uranium was adsorbed by hydrous titanium(IV) oxide as the UO_2^{2+} cation. Ogata *et al.*[5] proposed that the uranium was adsorbed by a coordinate bond on hydrous titanium(IV) oxide.

In the present work, the enthalpy change, rate constant, and activation energy of the uranium adsorption by hydrous titanium(IV) oxide were determined, and the adsorption mechanism was discussed.

Experimental

Preparation of Hydrous Titanium(IV) Oxide. The hydrous titanium(IV) oxide was prepared in the following manner. Into 200 ml of a 0.6 mol dm^{-3} $TiCl_4$ solution under stirring and heating at 90 °C, a 7% NH_3 solution was added at a rate of 3.5 ml/min until the pH of the solution reached 5. After it had then aged for 1 h, the precipitate was filtered, washed several times with water, and dried for about a week at room temperature. The dried samples were crushed and sieved, a portion of 400—600 mesh being used in following experiments. The water content of the dried sample was determined by measuring the ignition loss at 800 °C and found to be 18%, which corresponds to that of $TiO(OH)_2$.

Adsorption Experiment. In the uranium adsorption experiments, 0.04 g of hydrous titanium(IV) oxide was introduced into 1000 ml of a solution containing 0.72 mol dm^{-3} NaCl, 0—5×10^{-3} mol dm^{-3} $NaHCO_3$, and 10—500 ppb of uranium. The concentration of NaCl was taken to be 0.72 mol dm^{-3} in order for it to have the same ionic strength as that of sea water. The concentration of $NaHCO_3$ was nearly equal to that of sea water. The solution was stirred vigorously by means of a vertical stirrer. After adsorption equilibrium has been attained, the solution was filtered and the uranium concentration was measured. The uranium uptake by the adsorbent was determined from the change in the uranium concentration in the solution. The pH of the solution was changed from 4 to 12 with an HCl or NaOH solution. The determination of carbonate uptake was carried out by the following procedure. One fifth of a gram of hydrous titanium(IV) oxide was equilibrated with 5000 ml of a 0.72 mol dm^{-3} NaCl+5×10^{-3} mol dm^{-3} $NaHCO_3$ solution containing 40—500 ppb of uranium at pH 8 and 25 °C. After 5 h adsorption, the hydrous titanium(IV) oxide was separated from the solution, and the carbonate adsorbed in the adsorbent was determined.

Analytical Method. The uranium in the sloution was determined spectrophotometrically with Arsenazo III as the indicator.[6] The determination of carbonate in the adsorbent was carried out by the following procedure. The carbonate was decomposed with an HCl solution, and the carbon dioxide thus produced was measured by coulomatic titration with a Kokusai Denki VK-l-type "Coulomatic C."

Results and Discussion

Adsorption Equilibrium. The uranium uptake as a function of the adsorption time with hydrous titanium(IV) oxide of different particle sizes is shown in Fig. 1. The smaller granules showed a faster rate of the uranium uptake than the larger granules. It was found that an adsorption equilibrium was attained within 3 h using the adsorbent smaller than 300 mesh. A portion of 400—600 mesh adsorbent was used, and the adsorption time of 5 h was chosen for the following

experiments.

Effect of pH. The effect of the pH on the uranium uptake by the hydrous titanium(IV) oxide is shown in Fig. 2. The uranium uptake is significantly influenced by the pH of the solution, showing a minimum at pH 8. The same adsorption curve as that in Fig. 2 was obtained in the adsorption experiment with sea water in the present work.

The variation in the uranium uptake with the pH is supposed to result from the fact that the species of uranyl(VI) ions changes with the pH. Under the present experimental conditions, the uranyl(VI) ion may exist in the form of *hydroxo-*, *chloro-*, and *carbonato-*complexes, the stability constants (K) of which are summarized in Table 1.[5] The distributions of the uranyl(VI) species in the NaCl–$NaHCO_3$ solution at various pH values, as calculated from the stability constants, are shown in Table 2. Tris(carbonato)-dioxouranate(VI) ion which is present in sea water is a predominant species at pH 8—10, while the uranyl and chloro complex ion in an acidic solution and the hydroxo complex ion in an alkaline solution are stable. The uranium uptake reaches its minimum at pH 8, where predominant uranyl(VI) species in the solution is $[UO_2(CO_3)_3]^{4-}$.

Effect of Carbonate Ions. In order to investigate the effect of carbonate ions in the solution, the uranium uptake was measured with a solution containing 0.72 mol dm^{-3} NaCl, 60 ppb uranium, and 0—5×10^{-3} mol dm^{-3} $NaHCO_3$ at pH 8. The results are shown in Fig. 3. The distribution of uranyl(VI) species in the NaCl–$NaHCO_3$ solution used in the experiments is summarized in Table 3. It may be found from Fig. 3 and Table 3 that the uranium uptake decreases with an increase in $[UO_2(CO_3)_3]^{4-}$. That is, the uranium uptake is larger from the tris(hydroxo)dioxouranate(VI) $[UO_2(OH)_3]^-$ solution than from the $[UO_2(CO_3)_3]^{4-}$ solution. It is considered that the

TABLE 2. DISTRIBUTION OF URANYL(VI) COMPLEXES WITH VARIOUS pH VALUES

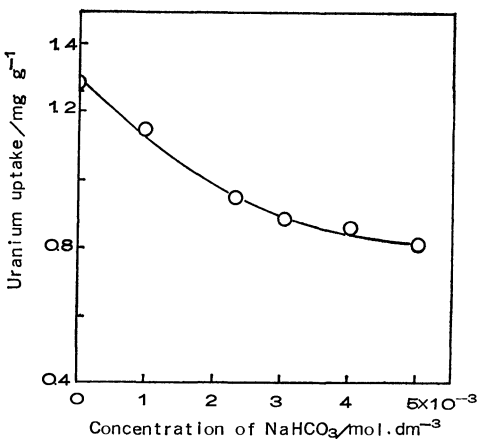

Fig. 3. Effect of carbonate ions on uranium uptake.
Adsorption temperature: 25 °C, pH of the solution: 8.0, NaCl: 0.72 mol dm^{-3}, uranium: 60 ppb.

Table 3. Distribution of uranyl(VI) complexes with various concentrations of $NaHCO_3$ (%)

Species	$[NaHCO_3]$/mol dm^{-3}			
	0	10^{-3}	2.3×10^{-3}	5×10^{-3}
$[UO_2(OH)_3]^-$	100	66.7	14.1	0
$[UO_2(CO_3)_3]^{4-}$	0	31	84.9	98.5

uranium uptake is reduced by the presence of $NaHCO_3$ because carbonate ions behave as a masking agent to uranium adsorption. The uranium uptake from a 5×10^{-3} mol dm^{-3} $NaHCO_3$ solution in which uranyl(VI) species is present in the form of $[UO_2(CO_3)_3]^{4-}$ (98.5%) is found to be 0.82 mg g^{-1} as is shown in Fig. 3. The results indicate that uranium adsorption takes place from the $[UO_2(CO_3)_3]^{4-}$ solution by means of hydrous titanium(IV) oxide.

Effect of Temperature. The effect of the temperature on the uranium uptake of hydrous titanium(IV) oxide is shown in Fig. 4. It is shown that the uranium uptake increases with the adsorption temperature. In order to obtain the enthalpy change of the adsorption, ΔH, the distribution coefficient, K_d, was calculated from the data. The distribution coefficient is defined as C_s/C_l, where C_s is the uranium adsorbed in the adsorbent per gram, and C_l the uranium in the solution per ml at equilibrium. The enthalpy change of the adsorption can be expressed as follows:[7]

$$\frac{d\ln K_d}{dT}=\frac{\Delta H}{RT^2}. \quad (1)$$

By integrating Eq. 1, we obtain

$$\log K_d = -\frac{\Delta H}{2.3R}\cdot\frac{1}{T}+\text{const}, \quad (2)$$

where T is the adsorption temperature, and R, the gas constant. As is shown in Fig. 4, the distribution coefficient increases markedly with the adsorption temperature. A plot of log K_d *versus* $1/T$ is shown in Fig.

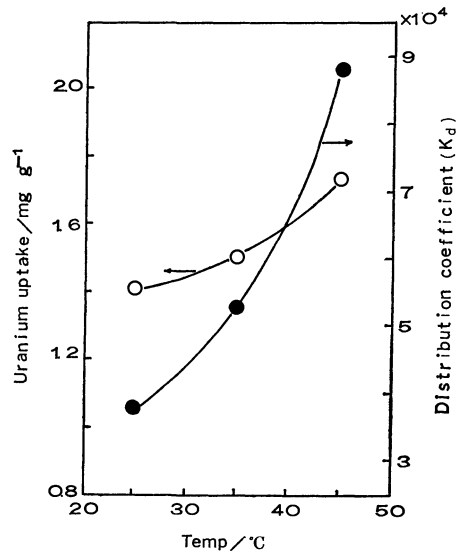

Fig. 4. Effect of temperature on uranium uptake.
pH of the solution: 8.0, NaCl: 0.72 mol dm^{-3}, $NaHCO_3$: 2.3×10^{-3} mol dm^{-3}, uranium: 90 ppb.

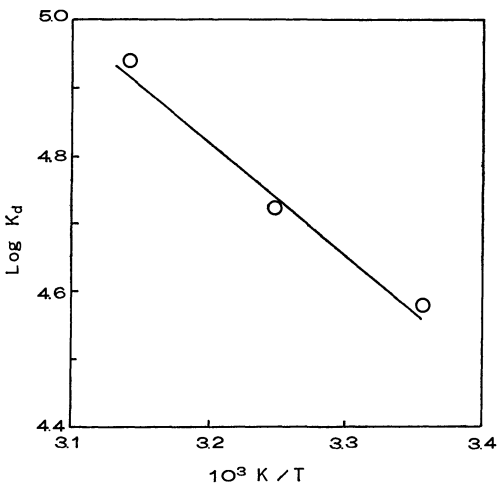

Fig. 5. Plot of log K_d *vs.* $1/T$.

5. The enthalpy change in the adsorption, ΔH, was found to be 23.6 kJ mol^{-1}. This value suggests that the uranium adsorption is neither physical adsorption nor an ion-exchange reaction. The physical adsorption is ordinarily exothermic, and the enthalpy change of the ion-exchange reaction is said to be -8.4—-12.6 kJ mol^{-1}.[7]

It may, therefore, be considered that the uranium adsorption proceeds *via* a certain complex chemical reaction.

Kinetics of Adsorption. The rate constant, k, and the activation energy, E, of the uranium adsorption were also determined. The variation in the uranium uptake with time is shown in Fig. 6. The rate of the uranium adsorption is larger at higher temperatures. The following equation is assumed:

$$\frac{dv}{dt}=k(v_e-v), \quad (3)$$

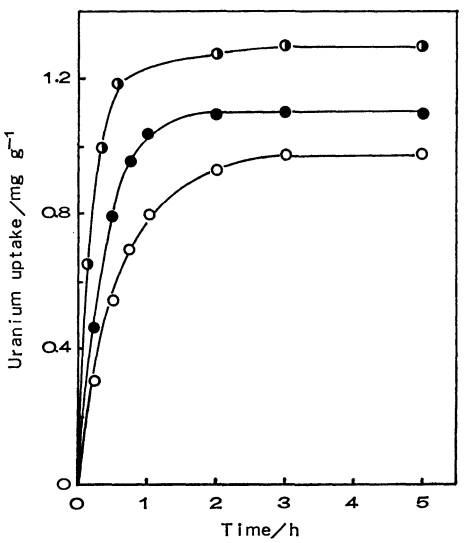

Fig. 6. Variation of uranium uptake with adsorption time.
pH of the solution: 8.0, NaCl: 0.72 mol dm^{-3}, $NaHCO_3$: 2.3×10^{-3} mol dm^{-3}, uranium: 60 ppb. Adsorption temperature, ○: 25 °C ●: 35 °C ◑: 45 °C.

where v_e is the adsorption capacity at equilibrium, and v, the adsorption capacity at time t. By integrating Eq. 3, Eq. 4 is obtained:

$$\ln\frac{1}{1-\theta} = kt, \quad (4)$$

where θ is the extent of adsorption (v/v_e). A plot of $\log 1/(1-\theta)$ *versus* t will give a straight line if the adsorption rate is represented by Eq. 3. As is shown in Fig. 7, the relation between $\log 1/(1-\theta)$ and t is nearly linear. The rate constants calculated from the slope were 0.0113 min^{-1} at 25 °C, 0.0217 min^{-1} at 35 °C, and 0.038 min^{-1} at 45 °C.

The activation energy, E, was determined by using the Arrhenius equation. A plot of $\log k$ *versus* $1/T$ is shown in Fig. 8, which gives an activation energy of 52.7 kJ mol^{-1}.

Mechanism of Adsorption. The adsorption mechanism of $[UO_2(CO_3)_3]^{4-}$ found in sea water will now

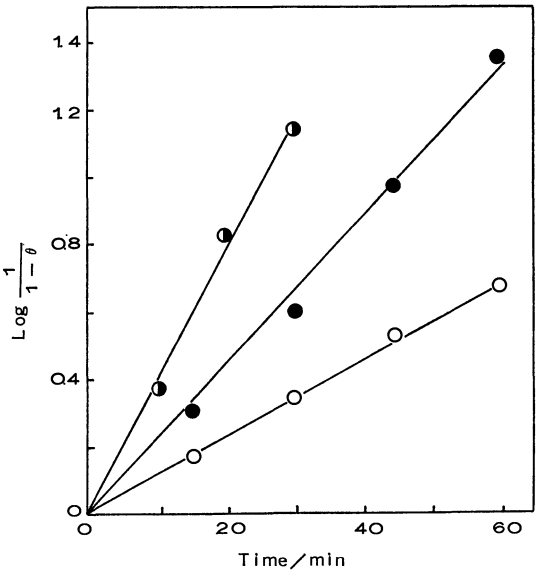

Fig. 7. Plot of $\log 1/(1-\theta)$ *vs.* t.

be discussed. Uranium adsorption takes place from the solution containing 0.72 mol dm^{-3} NaCl and 5×10^{-3} mol dm^{-3} $NaHCO_3$ by means of the hydrous titanium(IV) oxide mentioned before. In order to investigate the form of uranium adsorbed from the $[UO_2(CO_3)_3]^{4-}$ solution on the adsorbent, the uranium and carbonate uptake from the solution containing 0.72 mol dm^{-3} NaCl, 5×10^{-3} mol dm^{-3} $NaHCO_3$, and 40—500 ppb uranium are measured. The results are shown in Fig. 9. If the uranium form adsorbed on the adsorbent is $[UO_2(CO_3)_3]^{4-}$, the carbonate uptake should increase with the uranium uptake, as is shown by the broken line in Fig. 9. However, the carbonate uptake remains constant regardless of the uranium uptake. It is considered from the results that carbonate in $[UO_2(CO_3)_3]^{4-}$ is released into the solution, so that carbonate is not taken up by the adsorbent when uranium adsorption takes place from the tris(carbonato)dioxouranate(VI) solution.

In an alkaline solution, the surface hydroxo group [–Ti–OH] of hydrous titanium(IV) oxide dissociates into –Ti–O^-, which tends to undergo a cation exchange.[8] The amount of –Ti–OH in hydrous titanium(IV) oxide, as determined by the adsorption of fluoride ions, and that of –Ti–O^-, as determined by the ion-exchange reaction of potassium ions at pH 8, were found to be 1.7 mmol g^{-1} and 0.4 mmol g^{-1} respectively.[9] Although –Ti–OH and –Ti–O^- are present in the NaCl–$NaHCO_3$ solution at pH 8, it is unlikely that $[UO_2(CO_3)_3]^{4-}$ reacts with –Ti–O^- because they have the same electric charge. Therefore, the adsorption site of hydrous titanium(IV) oxide for the uranium is supposed to be –Ti–OH. Based on the present experimental results, the adsorption mechanism of $[UO_2(CO_3)_3]^{4-}$ is represented by

$$TiO(OH)_2 + [UO_2(CO_3)_3]^{4-} = TiO_3\cdot UO_2 + 2HCO_3^- + CO_3^{2-}. \quad (5)$$

The decrease in the concentration of $NaHCO_3$ in

the solution raises the uranium uptake, as is shown in Fig. 3. This may be attributable to the increase in $[UO_2(OH)_3]^-$, which shows a higher adsorbability than $[UO_2(CO_3)_3]^{4-}$. The adsorption mechanism of $[UO_2(OH)_3]^-$ is deduced to be as follows:

$$TiO(OH)_2 + [UO_2(OH)_3]^- = TiO_3 \cdot UO_2 + 2H_2O + OH^- . \quad (6)$$

It is considered that the competitive adsorption presented by the reaction of (5) and (6) takes place when $[UO_2(CO_3)_3]^{4-}$ and $[UO_2(OH)_3]^-$ coexist in the solution. However, with respect to the adsorption mechanism of $[UO_2(OH)_3]^-$, hydrolysis adsorption has been suggested by Katoh *et al.*[10] Therefore, further experiments will be made in the future with regard to the adsorption of $[UO_2(OH)_3]^-$.

In the present work, the mechanism of uranium adsorption from sea water, *i.e.*, a $[UO_2(CO_3)_3]^{4-}$ solution, was investigated. It is important to determine the adsorption mechanisms of all the uranyl(VI) species. However, the data for verifying the assumption of the adsorption mechanism cannot be obtained because various uranyl(VI) species coexist in the solutions of pH 4—8 under the present experimental conditions. Further study is required on this point.

The authors wish to thank Professor Shosuke Imoto of Osaka University for his many helpful discussions and suggestions.

Alkylation was carried out at room temperature over catalysts prepared by calcination of $FeSO_4$, Fe_2O_3, and $Fe(OH)_3$ in the air at various temperatures and subsequent exposure to HCl at room temperature for 20 min. The $FeSO_4$–HCl catalysts heat-treated at 700 and 750 °C showed very high activity and selectivity, the other catalysts except for the sulfate treated at 800 °C being almost inactive. The $FeSO_4$(700 °C)–HCl catalyst was found to consist of $FeCl_3$ and α-Fe_2O_3 by means of Mössbauer effect, the absorption peak areas being 14 and 86% for portions of iron based on the chloride and oxide, respectively. The results of DTA and TGA experiments suggest that the coordinate bond of water molecule on $FeCl_3$ of the $FeSO_4$(700 °C)–HCl catalyst is stronger than that on $FeCl_3$ of the $FeSO_4$ (600, 800, and 900 °C)–HCl and commercial $FeCl_3$. The $FeSO_4$(700 °C)–HCl catalyst showed a much higher activity than pure $FeCl_3$. The iron(III) chloride formed by reaction of HCl and α-Fe_2O_3 obtained by thermal decomposition of the sulfate at 700 or 750 °C was found to be a very strong Lewis acid catalyst.

t-Butylation and isopropylation of toluene and benzene with *t*-butyl and isopropyl chlorides are generally catalyzed by Lewis acids such as anhydrous aluminum chloride[2)] and boron trifluoride.[3)] This type of catalyst has been mostly used for the Friedel-Crafts reaction.[4)]

No data are available on the alkylation catalyzed by solid acids such as SiO_2–Al_2O_3 and metal sulfates at room temperature. We examined the reactions over heat-treated $FeSO_4$, which showed high catalytic activity and selectivity for benzylation and benzoylation of toluene with the corresponding chlorides in comparison with those of other solid acid catalysts, $NiSO_4$, SiO_2–Al_2O_3, *etc.*,[5)] although the catalyst was inactive for alkylation at room temperature. However, treatment with HCl remarkably promoted catalytic activity. The $FeSO_4$ catalyst prepared by calcination in the air at a certain temperature followed by treatment with HCl was found to show exceedingly high activity, its activity being higher than that of anhydrous $FeCl_3$.

Experimental

Materials and Catalysts. Toluene and benzene (guaranteed reagents) were purified by distillation over sodium metal. *t*-Butyl and isopropyl chlorides (guaranteed reagents, Tokyo Kasei Kogyo Co.) were used without further purification. Catalysts were prepared as follows: $FeSO_4 \cdot 7H_2O$ (guaranteed reagent, Kanto Chemicals Co.), Fe_2O_3 (Wako Pure Chemical Co.) and $Fe(OH)_3$ (Kokusan Chemical Works, Ltd.) were heated at 150 °C in the air for 1 h, and powdered below 100 mesh size. They were then calcined in Pyrex or quartz glass tubing at various temperatures in the air for 3 h and kept in sealed glass tubings. Catalysts thus prepared were exposed to a stream of mixed gas of N_2 (20 ml/min) and HCl (26 ml/min) for 20 min and finally to N_2 gas for 30 min. Hydrogen chloride gas was obtained by dropping concd hydrochloric acid into concd sulfuric acid, followed by passing the gas through concd sulfuric acid twice and cooling to −72 °C three times for drying. The catalyst thus prepared was sealed in an ampoule.

Procedure for Reaction. The reaction was carried out by stirring a mixture of weighed catalyst and 50 ml of 0.5 M toluene solution of *t*-butyl or isopropyl chlorides at room temperature. At appropriate time intervals, a small amount of the sample was taken out with a 1 ml syringe, separated from the catalyst, and analyzed by gas-liquid chromatography with a TCD detector using a 5 m column of tricresyl phosphate on Celite 545 (110 °C; He, 3.0 kg/cm^2). The yields of products were estimated on the basis of unreacted chloride and calculated by measurement of GLC peak areas (corrected). The competitive *t*-butylation of benzene and toluene was carried out with 0.5 M *t*-butyl chloride in equimolar amounts of benzene and toluene.

Physical Measurements. Differential thermal analysis (DTA) and thermal gravimetrical analysis (TGA) diagram were recorded at a heating rate of 10 °C/min from room temperature to 720 °C with a Rigaku CN8002. Infrared spectra were obtained with a Hitachi EPI-G2 spectrophotometer using Nujol and KBr tablets. Mössbauer spectra were recorded on an Elron Mössbauer effect radiation analyzer, using a ^{57}Co–Cu source at room temperature. The spectrum of the 90% ^{57}Fe-enriched iron foil was used for calibration of velocity scale.

Results and Discussion

No report seems to be available concerning the Friedel-Crafts *t*-butylation and isopropylation of aromatics with *t*-butyl and isopropyl halides as the alkylation reagents catalyzed by solid acids such as Al_2O_3 and SiO_2–Al_2O_3. No alkylation of toluene with *t*-butyl and isopropyl chlorides took place at room temperature over calcined $FeSO_4$, a solid acid. However, remarkable increase in the catalytic activity of $FeSO_4$ was caused by treatment with HCl, in which $FeSO_4$ was exposed to HCl gas at room temperature for 20 min after calcination. The catalytic activity and product distribution for the reactions at room temperature over catalysts prepared by calcination of $FeSO_4$ in the air at various temperatures, followed by treatment with HCl are given in Tables 1 and 2. The catalytic activity changed markedly with the calcination temperature of $FeSO_4$. The sulfates heat-treated at 700 and 750 °C showed strikingly high activity, $FeSO_4$ (800 °C)–HCl** being also highly active for *t*-butyla-

** This indicates a HCl-treated catalyst of $FeSO_4$ calcined at the temperature in parentheses.

tion. Figure 1 shows the time course of both reactions over these catalysts. In the case of *t*-butylation over $FeSO_4$ (700 °C and 750 °C)–HCl, the progress of reaction was linear with time up to over 50% completion,

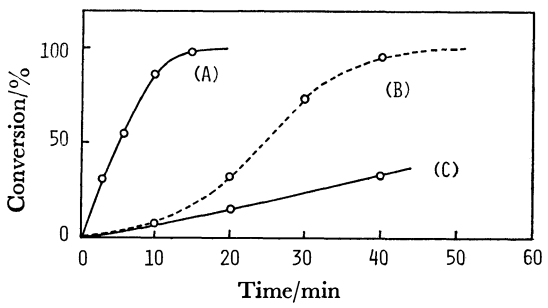

Fig. 1. *t*-Butylation and isopropylation of toluene over $FeSO_4$ treated with HCl at room temperature. *t*-Butylation (——), isopropylation (---). Heat-treatment of $FeSO_4$: 700 °C for (A) and (B); 800 °C for (C). Catalyst amount: 0.1 g for (A) and (C); 0.5 g for (B).

the reaction afterwards following first-order kinetics with respect to the *t*-butyl chloride concentration. Some of the reactions showed S-shaped curves, probably owing to the promotion effect of HCl formed by the reaction.

The reaction mixture after the 100% completion of the reaction was quite clear, no products other than listed in the Tables being detected. The isomer distributions of *t*-butyltoluenes and isopropyltoluenes did not change at 0 °C reaction temperature and were also the same as those observed for the general Friedel-Crafts Lewis catalysts such as $AlCl_3$[2)] and BF_3.[3)]

The activity of $FeSO_4$–HCl is low at 650 °C calcination as compared with the remarkable activity at 700 °C treatment. $FeSO_4$ decomposes completely to form α-Fe_2O_3 at temperatures in the range 675—700 °C, crystallization proceeding rapidly afterwards.[6)] Commercially available Fe_2O_3 and $Fe(OH)_3$ were calcined around 700 °C and treated with HCl, but the catalysts were almost inactive for both reactions (Tables 1 and 2).

The present catalysts were examined in the *t*-butyla-

tion and isopropylation of benzene with *t*-butyl and isopropyl chlorides at room temperature under the same reaction conditions, the following results being obtained: $FeSO_4$ (700 °C)–HCl and $FeSO_4$(800 °C)–HCl gave 94.3% *t*-butylbenzene in 10 min and 84.6% in 30 min, respectively, 85.5% isopropylbenzene being produced by $FeSO_4$(700 °C)–HCl in 5 min.[7] The sulfates–HCl heat-treated at 500, 600, and 900 °C showed conversion below 4% for *t*-butylation and isopropylation.

When a large amount of $FeSO_4$(700 °C)–HCl was used for *t*-butylation of toluene, isomerization of *t*-butyltoluene took place; *i.e.* isomerization from the *para*- to the *meta*-position up to the equilibrium composition of 64% *m*- and 36% *p*-*t*-butyltoluene.[2] The reaction with 1.0 g catalyst at room temperature gave 23.9% *m*- and 76.1% *p*-isomer at 5 min, 40.4 and 59.6 at 15 min, and 61.5 and 38.5 at 60 min, respectively. No isomerization was observed even over a period of 3 h when the catalyst amount was 0.1 g.

The competitive *t*-butylation of benzene and toluene at room temperature was carried out with 0.5 g of the above catalyst in equimolar amount. The secondary reactions such as transalkylation between *t*-butyltoluene and benzene and the isomerization of *t*-butyltoluene took place. The apparent k_T/k_B value (the relative rate of toluene to benzene, estimated from yields of *t*-butyltoluene and *t*-butylbenzene) decreased with time as was observed by Shimada.[8] The k_T/k_B value obtained was 14.7 at 1 min, 8.7 at 3 min, 4.8 at 10 min, and 1.5 at 60 min. The isomer distribution of *t*-butyltoluene was 6.6% *m*- and 93.4% *p*-form at 1 min and 52.7% *m*- and 47.3% *p*-form at 60 min.

On exposure to HCl at room temperature, the sulfates calcined at 700 and 750 °C evolved heat violently in 10 min, but $FeSO_4$ treated at 800 °C only slightly. The heat evolution seems to be related with the catalytic activity, since other materials except for the sulfates treated at 700, 750, and 800 °C evolved no heat. Even the $FeSO_4$(700 °C)–HCl was inactive when HCl treatment was stopped before heat generation. Figure 2 shows the catalytic activity of $FeSO_4$ (700 °C) with various periods of the HCl treatment for the isopropylation of benzene. The activity increases with duration of the treatment after the beginning of heat generation. The catalyst before the generation of heat was extremely low in activity even for the *t*-butylation of toluene, an easier reaction than isopropylation, though its activity was still high in comparison with that without any HCl treatment (Tables 1 and 2).

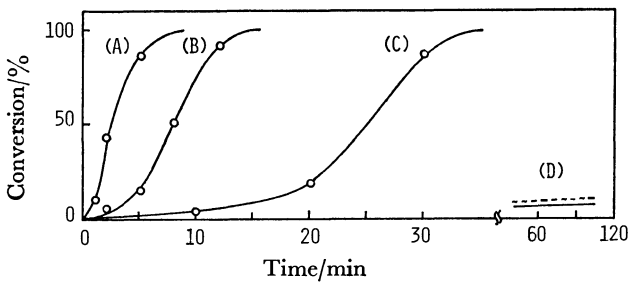

Fig. 2. Catalytic activity of $FeSO_4$ (700 °C) with different periods of the HCl treatment for the isopropylation of benzene at room temperature (catalyst: 1.1 g). The HCl treatment was ceased 10 min (A), 1 min (B), at once (C) after beginning of the heat generation and before (D) the generation. (---): *t*-butylation of toluene (catalyst: 0.1 g).

Heat generation by HCl treatment is considered to be due to the formation of $FeCl_3$ on the surface. In order to confirm the existence of $FeCl_3$, Mössbauer experiment on $FeSO_4$(700 °C)–HCl was carried out. The spectrum obtained is shown in Fig. 3. The spectrum consists of a single peak around zero velocity and other six peaks showing magnetic hyperfine splitting. The single peak is attributed to $FeCl_3$, the isomer shift 0.45±0.05 mm/s being close to 0.37 mm/s for commercial $FeCl_3$ and 0.36 mm/s for the value obtained by DeBenedetti *et al.*[9] The other six lines are attributed to α-Fe_2O_3,[5] indicating that $FeSO_4$ is decomposed to form Fe_2O_3 at 700 °C calcination. From absorption peak areas, the portions of iron based on $FeCl_3$ and α-Fe_2O_3 were found to be 14 and 86%, respectively.

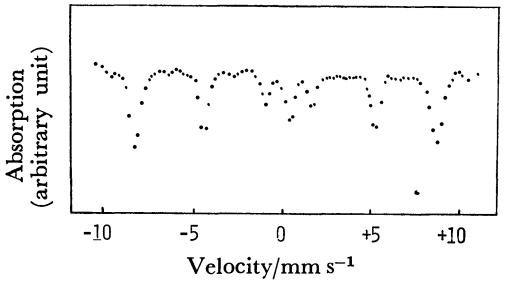

Fig. 3. Mössbauer spectrum of $FeSO_4$ (700 °C)–HCl. Isomer shift referred to metallic iron.

IR spectrum of $FeSO_4$(700 °C)–HCl showed an absorption band at 1600 cm^{-1}, which is assigned to a water molecule coordinated to $FeCl_3$.[10] The intensity of the band decreased when the substance was dried in the air at 150 °C for 2 h. The catalytic activity of the dried catalyst was higher than that of $FeSO_4$ (700 °C)–HCl, not subjected to drying, *viz.*, conversion for *t*-butylation of toluene at room temperature was 34.2% at 3 min, and 100% at 10 min (*cf.* Table 1).[11]

DTA and TGA of the catalysts were measured as shown in Fig. 4. The endothermic peaks appearing at 130—160 °C in all the samples are ascribed to the desorption of water molecule bonded coordinately to $FeCl_3$ formed by HCl treatment. A similar peak was observed around 140 °C in the case of pure anhydrous $FeCl_3$, a corresponding sharp decrease in weight being observed. Endothermic desorption of the water molecules is observed at much higher temperature, 160 °C for $FeSO_4$(700 °C)–HCl, and at a slightly higher one, 144 °C, for $FeSO_4$(800 °C)–HCl than that for other materials treated at 600 and 900 °C. The difference in temperature is connected with their catalytic activities (Table 1). The activity of the $FeSO_4$(700 °C)–HCl catalyst was much higher than that of anhydrous $FeCl_3$ (guaranteed reagent, Wako Pure Chemical Co.) for isopropylation, the activity

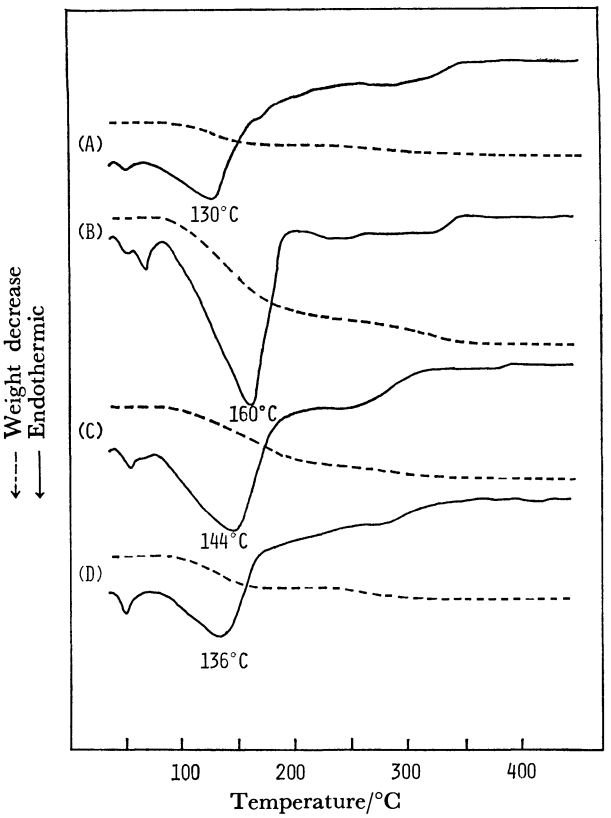

Fig. 4. DTA (——) and TGA (---) curves of $FeSO_4$ heat-treated at various temperatures, followed by treating with HCl. (A): 600 °C (21.7 mg), (B): 700 °C (25.3 mg), (C): 800 °C (30.0 mg), (D): 900 °C (30.0 mg).

ratio being greater than 10. The former also showed marked activity for the reaction of toluene with methanesulfonyl chloride at 100 °C, but not $FeCl_3$. It seems that the high temperature of desorption of water is based on the strong coordinate bond between water and the surface $FeCl_3$. Thus, the iron(III) chloride formed by reaction of HCl and α-Fe_2O_3, prepared by the thermal decomposition of the sulfate at 700 or 750 °C, could be a quite strong Lewis acid catalyst.

Gradual decrease in weight was observed in the temperature range 200—350 °C. This seems to be due to the sublimation of $FeCl_3$. The weight decrease was estimated as 1.6, 7.8, 3.5, and 2.0% for the 600, 700, 800, and 900 °C catalysts, respectively (adsorbed water observed up to 200 °C in TGA was not included in calculation).

11) The catalysts dried at 250 and 350 °C gave 21.7% conversion at 2.5 h and 17.2% at 3 h, respectively. The cause of low activities might be due to the sublimation of $FeCl_3$ on the surface, since some black-colored substance, seemingly $FeCl_3$, was observed on the upper wall of a test tube used for drying.

The Crystal Structure of (Acetylacetonato)bis(diethylamine)palladium(II) Acetylacetonate at −170 °C

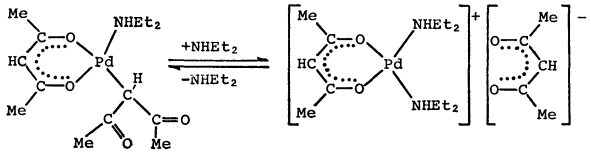
Shoji Kotake, Tsuyoshi Sei, Kunio Miki, Yasushi Kai, Noritake Yasuoka, and Nobutami Kasai*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received February 22, 1979)

The crystal structure of $[\{Pd(acac)(NHEt_2)_2\}^+(acac)^-]$ at −170 °C was determined by means of X-ray diffraction. The crystal belongs to monoclinic system: $a=13.905(3)$, $b=12.901(4)$, $c=12.205(3)$ Å, $\beta=96.28(2)°$, space group I2/c with $Z=4$. The structure was established by the heavy atom method and refined anisotropically by the least-squares procedure; $R=0.044$ for 1558 non-zero reflections. Both the $\{Pd(acac)(NHEt_2)_2\}^+$ cation and $(acac)^-$ anion lie on the crystallographic two-fold axis. The cation and anion lying on the same two-fold axis are bound together by two hydrogen bonds [N–H···O(2)=N′–H′···O(2′)=2.871(4) Å] to form an ion-pair. Two ion-pairs mutually related by the crystallographic center of symmetry make a packing unit of the crystal.

Okeya *et al.*[1] obtained (acetylacetonato)bis(diethylamine)palladium(II) acetylacetonate (**2**) by the reaction between (acetylacetonatoacetylacetonyl)(diethylamine)palladium(II) (**1**) and diethylamine. They observed that ligand exchange and Pd–C bond formation take place when the complex is dissolved in dichloromethane.



1 **2**

Crystals of **2** are unstable at room temperature, and by liberating a diethylamine molecule, Pd–C bond formation takes place in the solid state. Since the spatial disposition of anions and cations in the crystal seemed to be of interest in relation to ligand exchange and Pd–C bond formation reactions, the crystal structure analysis of the present complex was undertaken.

Experimental

The crystals are unstable at room temperature and easily decompose in a few days. A crystal, *ca.* 0.25×0.23×0.25 mm, was mounted on a Rigaku automated, four-circle single crystal diffractometer. The unit-cell parameters were determined at 20 and −170 °C, respectively. Crystal data are given in Table 1.

Intensity data were collected at −170 °C on the Rigaku diffractometer. Low temperature was attained by the gas flow method using liquid N_2. Graphite-monochromatized Mo $K\alpha$ radiation was used, the θ-2θ scan technique, with scan rate 4° min^{-1} and asymmetric scan width $\Delta(2\theta)=(2.0+0.7\tan\theta_c)°$, where θ_c is the calculated value of the Bragg angle using λ(Mo $K\alpha_1$)(=0.70926 Å), being employed. Background count was obtained by averaging the values measured for 7.5 s at both ends of a scan. For weak reflections with $|F|<3\sigma(F)$ the peak scan was repeated up to four times depending on their intensities. Four standard reflections (404, 640, 314, and 080) were measured after every 60 reflections, no intensity decrease being observed during the course of experiment. Numbers of reflections scanned ($2\theta\leqq48°$), observed, and unobserved were 1804, 1558, and 246, respectively. Correction for the usual Lp effect was made, the absorption correction being ignored (μ(Mo $K\alpha$)=8.61 cm^{-1}).

μ(Mo $K\alpha$)/cm^{-1}	8.61	8.30

Structure Determination and Refinement

The structure was solved by the heavy atom method. Since the space group is I2/c (No. 15) and the number of formula units per unit-cell is four, both the $\{Pd(acac)(NHEt_2)_2\}^+$ and $(acac)^-$ ions should lie on a two-fold axis. The coordinates of the Pd atom were determined from a three-dimensional Patterson function. Locations of all the remaining non-hydrogen atoms were determined by the Fourier synthesis. All the H atoms were located from the subsequent difference Fourier map.

The structure was refined by the block-diagonal least-squares procedure (*HBLS* V)[2] minimizing $\Sigma w\cdot(\Delta F)^2$. Anisotropic thermal parameters were considered for Pd, C, O, and N and isotropic ones for H. The final R value is 0.044 for 1558 observed (0.057 for all) reflections. The weighting scheme used was $w=(\sigma_{cs}+a|F_o|+b|F_o|^2)^{-1}$ for $|F_o|>0$ and $w=c$ for $|F_o|=0$, where σ_{cs} is the standard deviation obtained from the counting statistics, the values of a, b, and c used in the final refinement being −0.0162, 0.0037, and 2.7537, respectively. All the atomic scattering factors used were taken from International Tables for X-Ray Crystallography, Vol. IV.[3] The final atomic parameters are given in Table 2.†

TABLE 2. FINAL ATOMIC PARAMETERS (e.s.d.'s in parentheses)
Positional parameters in fraction of cell edges and anisotropic and isotropic thermal parameters in the form of $\exp\{-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)\}$ and $\exp\{-B(\sin\theta/\lambda)^2\}$, respectively.

Results and Discussions

An *ORTEP*[4] drawing of an ion-pair of the present complex and the numbering scheme of the atoms are shown in Fig. 1. The bond lengths and bond angles are given in Table 3. Some least-squares planes, deviations of atoms from the plane, and dihedral angles are given in Table 4. The most remarkable feature of the structure is that both the $\{Pd(NHEt_2)_2(acac)\}^+$ cation and $(acac)^-$ anion lie on the crystallographic two-fold axis.

In the cation the geometry around the Pd atom is square-planar. The Pd, N, O(1), N′, and O(1′) atoms lie on nearly the same plane, the maximum deviation being 0.054 Å. The Pd–O(1) distance [2.000(3) Å] is almost equal to that in $Pd(acac)_2$ at −170 °C [1.991(3) and 1.988(3) Å].[7] However, it is shorter than in mono-β-diketonate complexes.[5,6] The

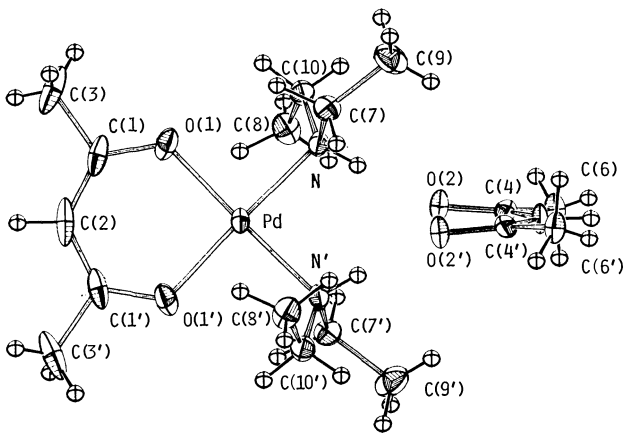

Fig. 1. An *ORTEP* drawing of the $\{Pd(acac)(NHEt_2)_2\}^+(acac)^-$ ion-pair with the numbering scheme of non-hydrogen atoms.
Non-hydrogen atoms are drawn as thermal ellipsoids with 50% probability level, and hydrogen atoms are drawn as spheres with 0.1 Å radius.

† The Tables of structure factors are kept in the Chemical Society of Japan as Document No. 8014.

Dihedral angles [ϕ/°]

between planes		
(1) & (2)	5.0
(1) & (3)	80.8
(2) & (3)	85.8

a) Δ: Deviations of atoms [l/Å] from the plane.

O(1)–Pd–O(1′) angle [94.0(2)°] is slightly smaller than that in $Pd(acac)_2$ [95.04(10)°]. The Pd–N bond length is 2.044(3) Å. The N–Pd–N′ and O(1)–Pd–N angles are 90.0(2)° and 88.2(2)°, respectively. All the bond lengths and bond angles for the acac ligand in the cation are equal within the limits of errors to the corresponding values in $Pd(acac)_2$ (Fig. 2).

Two diethylamines *cis*-coordinated to the Pd atom are mutually related by the two-fold axis. The N–C bond lengths are equal [1.497(5) and 1.498(7) Å], comparable with those in $RhCl(CO)(C_2H_4)(NHEt_2)$[8] [1.507 and 1.508 Å]. One of the methyl groups in a diethylamine group takes the most stable *trans* conformation, the other being in a *gauche* conformation. This seems to be caused by the steric hindrance between the $C(9)H_3$ and $C(8')H_3$ or the $C(8)H_3$ and $C(9')H_3$ methyl groups.

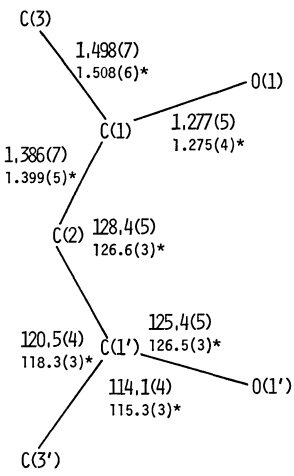

Fig. 2. Structure of the (acac) moiety *O,O′*-chelated to the Pd atom (−170 °C).
Average values the corresponding bond lengths and bond angles in $Pd(acac)_2$[7] are also given with asterisks.

In the $(acac)^-$ anion the O(2)–C(4) bond length of 1.246(5) Å is *ca.* 0.03 Å shorter than the corresponding length [1.277(5) Å] for the (acac)-*O,O′*-chelate. On the other hand, the C(4)–C(5) and C(4)–C(6) bond lengths [1.406(6) and 1.528(6) Å] are respectively equal to the corresponding lengths in the *O,O′*-chelate.

The cation and the anion lying on the same two-fold axis are bound together by hydrogen bonds, N–H···O(2) and N′–H′···O(2′) [both 2.871(4) Å], to form a ion-pair. The other two N–H···O(2′) and N′–H′···O(2) distances [both 3.213(4) Å] are rather short, and comparable with the largest value of the N–H···O hydrogen bond distances determined by means of neutron diffraction.[9]

An *ORTEP* drawing of the crystal structure is given in Fig. 3. Two ion-pairs mutually related by the crystallographic center of symmetry make a packing

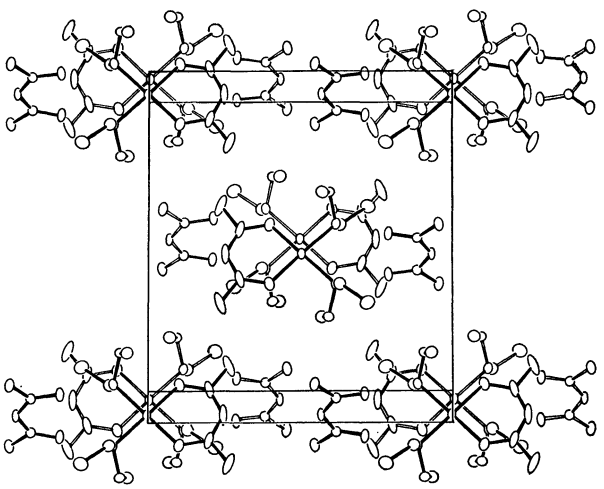

Fig. 3. Crystal structure of $[\{Pd(acac)(NHEt_2)_2\}^+(acac)^-]$ projected onto the ab plane.

unit of the crystal. No close atomic contact was found between these ion-pairs. No anion is located above or below the Pd atom of the cation. No explanation can be obtained for the ligand exchange reaction from **2** to **1**.

The authors wish to express their thanks to Prof. Shinichi Kawaguchi, Osaka City University, and Prof. Seichi Okeya, Wakayama University, for their valuable discussions and the supply of crystals. Computations were carried out on an ACOS Series 77 NEAC System 800 computer at Osaka University.

The Dissociation Rate of S_2 Produced from COS Pyrolysis

Tetsuo HIGASHIHARA, Ko SAITO,* and Ichiro MURAKAMI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received February 23, 1979)

The disappearance rate of S_2, which was produced from the pyrolysis of COS, was measured behind incident shock waves by monitoring the UV emission in the temperature range of 4500—6000 K and in the pressure range of 0.32—0.5 atm. It was found that two processes could possibly account for the disappearance of S_2:

$$S_2 + Ar \longrightarrow 2S + Ar \quad (3)$$

and

$$\begin{cases} S_2 + Ar \longrightarrow S_2^* + Ar & (4) \\ S_2^* + Ar \longrightarrow 2S + Ar & (5) \end{cases}$$

and the following rate equation was obtained:

$$-d[S_2]/dt = k_{II}[S_2][Ar] \text{ mol cm}^{-3} \text{ s}^{-1}$$

where

$$k_{II} = 10^{13.68} \exp(-77 \text{ kcal}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

The recombination of S atoms and the dissociation of the S_2 molecule play important roles in the combustion system of sulfur-containing compounds. Despite the importance of these reactions, there are no data for the rate of S_2 dissociation. At room temperature, some authors[1-3] have determined the rate constant for the recombination of S atoms, but the values determined were very different from one another. Fair and Thrush[1] generated ground-state sulfur atoms in a discharge-flow system by means of a rapid reaction between H and H_2S in order to observe the emission from the radiative recombination of S atoms; they determined the rate constant of S atom recombination from the emission intensity and the Franck-Condon factor as:

$$k_{-5} = 1 \times 10^{15} \text{ cm}^6 \text{ mol}^{-2} \text{ s}^{-1}.$$

This may be the most reliable data, since the rate constant of atom recombination is generally of the order of 10^{15} cm^6 mol^{-2} s^{-1} at room temperature.

The thermal decomposition of carbonyl sulfide was studied by Hay and Belford[4] and by Schecker and Wagner[5] in the temperature range of 1550—3200 K. The results of these studies showed that S_2 was mainly produced by these reactions:

$$COS + Ar \longrightarrow CO + S + Ar \quad (1)$$

$$COS + S \longrightarrow CO + S_2, \quad (2)$$

and that the rate constants for Reaction 1 determined by these two groups agreed with each other. Thus, the mechanism of COS pyrolysis is rather simple compared with those of the other sulfur-containing compounds and the concentration of S_2 formed during the reaction can be easily calculated under the conditions presently studied.

The purpose of this study is to investigate the behavior of the S_2 molecule at higher temperatures (above 4500 K). There are two spectrophotometric methods for monitoring the concentration change of S_2. The absorption method is preferable for the measurement of the ground-state sulfur molecules. However, this method was not successful because of the very strong interference of S_2 emission at temperatures above 4500 K. Therefore, in this study the concentration change of S_2 in the $B^3\Sigma_u^-$ state (S_2^*) was followed by monitoring the UV emission at 392.5 nm.

Experimental

The shock tube was 3.8 cm in internal diameter, with a 2.5-m test section and a 1.5-m driver section. The system was pumped off by means of an oil-diffusion pump to less than 1×10^{-4} Torr before each run. All experiments were performed behind incident shock waves which were generated by high-pressure hydrogen. The UV emission at 392.5 nm, selected by means of a grating monochromator, was detected by means of a photomultiplier through a quartz window which was placed at a position 2.1 m downstream from the diaphragm. Only the S_2 molecule has an emission band around this wavelength corresponding to the $B^3\Sigma_u^- \rightarrow X^3\Sigma_g^-$ transition.

Carbonyl sulfide obtained from a commercial cylinder was degassed at the temperature of liquid N_2–ethanol slash and purified by fractional distillations between this temperature and −197 °C. The gas mixtures studied were 0.5 and 1% COS in Ar. The post shock pressure and temperature were in the 0.32—0.5 atm and 4500—5800 K ranges, respectively. The temperature drop due to the pyrolysis of COS was estimated to be about 100 K for 1% COS and about 50 K for 0.5% COS in Ar mixture. The boundary-layer effects on the particle time, temperature, and density were estimated by the method of Mirels.[6] It was found that at $t_1 = 30$ μs (at the end of the observation time) the maximum time correction was 20%, the maximum temperature shift was 6.2%, and the maximum density increase was 9.4%.

Results and Discussion

At temperatures above 4500 K, the emission intensity reached a maximum value within 5 μs of laboratory time and then decreased exponentially to a steady value. A typical oscillogram is shown in Fig. 1 (a).

If S_2^* (the $B^3\Sigma_u^-$ state of S_2) was mainly produced by the recombination of S atoms, the emission intensity should maintain the equilibrium value observed by Bott and Jacobs[7] at relatively lower temperatures (2300—4800 K) and high pressures (10—20 atm), since the S atom concentration did not overshoot

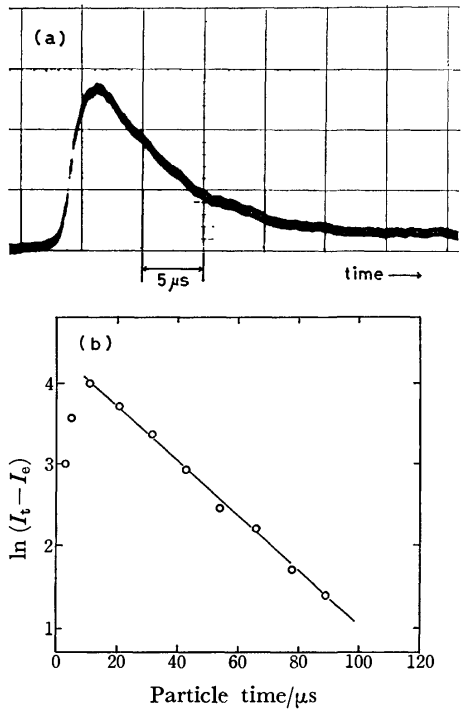

Fig. 1. (a): Typical oscilloscopic trace of S_2 emission at 392.5 nm, 0.5% COS in Ar mixture; post shock temperature=5507 K. (b): Plot of ln ($I_t - I_e$) *vs.* particle time.

behind the shock front, as is shown in Fig. 6. Therefore, the phenomenon shown in Fig. 1 (a) should be due to the thermal excitation from the ground electronic state of S_2. If so, the temperature dependence of the peak intensity per unit of S_2 concentration should give the energy difference between the ground and excited electronic states (90.6 kcal/mol). Figure 2 shows the Arrhenius plot of the peak intensity per unit of the initial concentration of COS. The apparent activation energy of this plot is 72.6 kcal/mol, smaller by about 20 kcal/mol than the energy difference of the two electronic states. This can reasonably be explained by considering that the yield of S_2 at the peak is temperature-dependent. If we plot the peak intensity per unit of S_2 concentration against $1/T$ (broken line of Fig. 2), where the S_2 concentration was calculated by using Reactions 1 and 2, the apparent activation energy becomes 114 kcal/mol, greater by about 20 kcal/mol than the energy difference of the two electronic states of S_2. However, if we use a value of $k_2=10^{13.92}$ exp (-27.2 kcal/RT) cm^3 mol^{-1} s^{-1} for the rate constant of Reaction 2, which was estimated by Kondratiev,[10] the apparent activation energy of the peak intensity becomes about 90 kcal/mol. Thus, the yield of S_2 (and the resulting apparent activation energy) is strongly influenced by the rate constants of Reactions 1 and 2. Unfortunately, since we have no reliable rate constants for these reactions at higher temperatures, we could not decide whether or not, at the peak, the thermal equilibrium between the $^3\Sigma_u^-$ and $^3\Sigma_g^-$ states of S_2 was maintained, but it may be reasonable to assume that the equilibrium was maintained. If such is the case, the

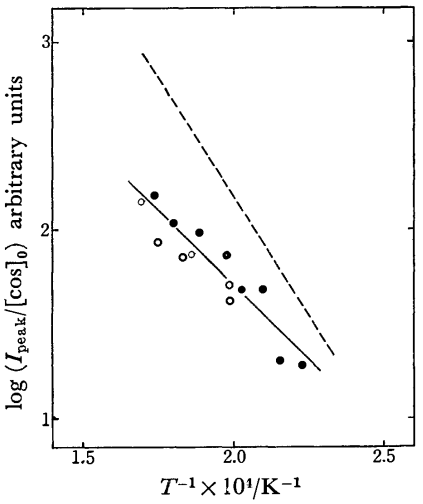

Fig. 2. ○ and ●: Arrhenius plot of peak intensity per unit initial concentration of COS, ○: 1% COS in Ar mixture; ●: 0.5% COS in Ar mixture. ----: Arrhenius plot of peak intensity per unit S_2 concentration.

decrease in the emission intensity after the peak corresponds to the dissociation rate of the S_2 molecule. Similar phenomena were observed for the emission of C_2 during the pyrolysis of CH_4, CCl_4, CF_4, and C_2H_2 by Fairbarn[8] and of C_2H_2 by Beck and Mackie.[9] In those studies, it was found that the thermal equilibrium between the electronically ground and excited states of C_2 was maintained.

The emission intensity is proportional to the concentration of S_2*. As is shown in Fig. 1 (b), since a semilogarismic plot of ($I_t - I_e$) *vs.* the time gives a straight line after the maximum, the variation in the S_2* concentration with the time is expressed by the following relation:

$$\ln (I_t - I_e) \propto \ln ([S_2^*]_t - [S_2^*]_e) = k_I t,$$

where the subscripts t and e denote the time t and the time needed to reach an equilibrium respectively. Although the emission intensity profile as experimentally recorded reflects the time variations in the gas temperature and density, in this study these corrections were not carried out and the mean temperature and density were used for the date reduction, since the observation time was very limited (from about 5 μs to about 20 μs laboratory time). Since COS decomposes almost completely at the time when the emission intensity reaches a peak (see Fig. 6), there is no need to consider the effect of S_2 formation on the rate of S_2 disappearance. Thus, the value of k_I gives a quasi-first-order rate constant of S_2 disappearance. Furthermore, taking into consideration the fact that S_2 disappears mainly as a result of the collision with Ar, the second-order rate constant of S_2 disappearance (k_{II}) is obtained from the $k_{II}=k_I/$[Ar] equation. The Arrhenius plot of k_{II} thus obtained is shown in Fig. 3 for 0.5 and 1% COS in Ar mixtures. The best-fitting line gives:

$$k_{II} = 10^{13.68} \exp (-77 \text{ kcal}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}.$$

The formation and disappearance of S_2 were considered to be governed by the reactions listed in Table

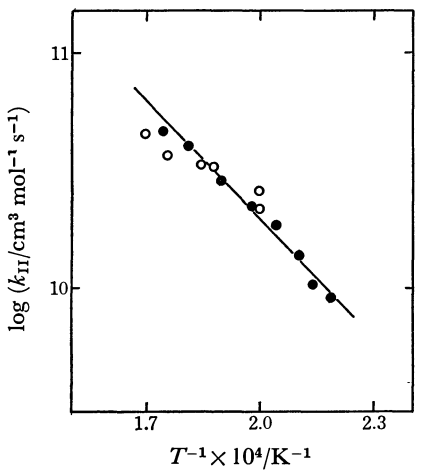

Fig. 3. Arrhenius plot of k_{II}, ○: 1% COS in Ar mixture; ●: 0.5% COS in Ar mixture.

1. In order to check the reliability of the assumption of the equilibrium between S_2 and S_2* and the resultant rate constant, k_{II}, for the S_2 disappearance, the concentration change of S_2* with the time was calculated at the temperatures of 5025 and 5753 K by using a reaction mechanism including the 11 elementary reactions listed in Table 1, and was compared with that obtained experimentally. The values of k_1,[4,5] k_2,[10] k_{-4}[1] at 298 K, k_{-5}[1] at 298 K, k_6[1] have been determined by other investigators, but there are no rate data for the rest. Therefore, the rate constants of these reactions were estimated in the following way. The rate constants of Reaction 4 were calculated from the simple collision theory, by assuming that the molecular diameters of S_2, S_2*, and Ar were 3.88, 4.47, and 3.42 Å respectively, as

$$k_4 = \lambda_4 \times 8.46 \times 10^{12}\, T^{1/2} \exp(-90.6\,\text{kcal}/RT)\ \text{cm}^3\,\text{mol}^{-1}\,\text{s}^{-1}$$

$$k_{-4} = \lambda_{-4} \times 9.89 \times 10^{12}\, T^{1/2}\ \text{cm}^3\,\text{mol}^{-1}\,\text{s}^{-1}.$$

The equilibrium constant for these reactions was expressed as

$$K_4 = k_4/k_{-4} = (Q_{S_2}*/Q_{S_2}) \exp(-90.6\,\text{kcal}/RT),$$

where Q_{S_2}* and Q_{S_2} are the partition functions of the electronically excited and ground states of S_2. The ratio of $Q_{S_2}*/Q_{S_2}$ can be calculated from the molecular constants; it is given as 2.15 at 5000 K. From this value, the λ_4/λ_{-4}=2.5 ratio was obtained. In general, the efficiency of electronic excitation is large; therefore, in this study λ_4=1 was assumed, and λ_{-4}=0.4 was thus obtained. Fair and Thrush[1] determined the value of k_{-4} at 298 K as

$$k_{-4} = 1.5\times10^{14}\ \text{cm}^3\,\text{mol}^{-1}\,\text{s}^{-1}.$$

The collision efficiency, λ_{-4}, was calculated from this value as λ_{-4}=0.88 at 298 K, in good agreement with that value obtained by assuming λ_4=1. Fair and Thrush also obtained values of k_{-5} at 298 K and k_6 as

$$k_{-5} = 10^{15}\ \text{cm}^6\,\text{mol}^{-2}\,\text{s}^{-1}$$

$$k_6 = 10^{7.48}\ \text{s}^{-1}.$$

Assuming that the rate constant of recombination reaction was inversely proportional to the temperature, k_{-5} was expressed as

$$k_{-5} = 10^{17.47}/T\ \text{cm}^6\,\text{mol}^{-2}\,\text{s}^{-1}.$$

The value of k_5 was obtained from k_{-5} by combining it with the equilibrium constant as

$$k_5 = 10^{13.95} \exp(-6\,\text{kcal}/RT)\ \text{cm}^3\,\text{mol}^{-1}\,\text{s}^{-1}.$$

The value of k_3 was assumed to be the same as that of k_{II}, and from the value of k_3 and the equilibrium constant, the value of k_{-3} was calculated. Now, we have all the rate constants needed to calculate the concentration changes in COS, CO, S, S_2, and S_2* with the time. Figures 4 and 5 present comparisons of the experimental (circle) and calculated histories of S_2* by using different sets of rate constants. As is shown in these figures, if a value of k_3 is set as equal to that of k_{II}(Case a), the calculated rate of S_2* disappearance becomes larger than that observed. This means that Reaction 4, followed by Reaction 5, contributes to the consumption of S_2. Therefore, the value of k_3 was changed to one-half the value of k_{II} and the concentration change of S_2* was recalculated (Case b). Although the agreement with the experiment seems to be improved, there remains some difference with regard to the equilibrium concentration of S_2*. Therefore, in order to check the influence of the values of k_4, k_{-4}, k_5, and k_{-5} on the

Table 1. Reaction mechanism

	Reaction	Rate expression[a]	Ref.
1)	$COS + Ar \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CO + S + Ar$	$k_1 = 10^{14.2} \exp(-61\,\text{kcal}/RT)$	5
2)	$COS + S \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CO + S_2$	$k_2 = 10^{12.23} \exp(-4.0\,\text{kcal}/RT)$	10

5)	$S_2* + Ar \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} 2S + Ar$	See text	
6)	$S_2* \xrightarrow{k_6} S_2 + h\nu$	$k_6 = 10^{7.48}$	1

a) Units: mol/cm^3 for concentration, s for time.

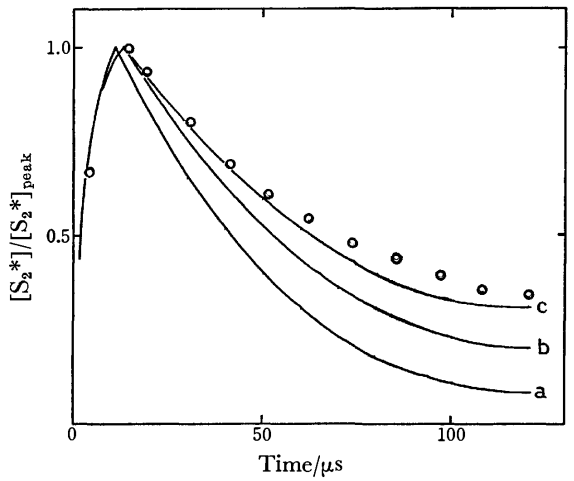

Fig. 4. Comparison of S_2* profils between the experiment (O) and the calculations (—), 1% COS in Ar mixture; post shock temperature=4851 K; mean temperature between 5 and 20 μs laboratory time=5025 K.

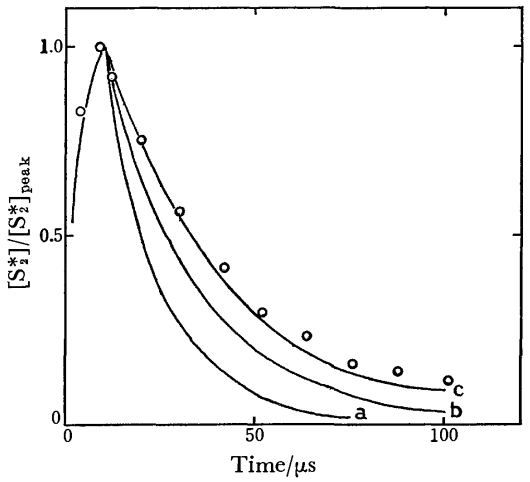

Fig. 5. Comparison of S_2* profiles between the experiment (O) and the calculations (—), 0.5% COS in Ar mixture; post shock temperature=5507 K; mean temperature between 5 and 20 μs laboratory time=5753 K.

equilibrium concentration of S_2*, the values of k_4 and k_{-4} were divided by 10, while those of k_5 and k_{-5} were multiplied by 10, leaving $k_3=1/2\ k_{II}$, and then the concentration change of S_2* was recalculated (Case c). The results of the calculations are shown in Figs. 4 and 5; the agreement is very satisfactory. Thus, if a set of proper rate constants was selected for Reactions 3, 4, and 5, the concentration change in S_2* could be reasonably reproduced, but the rate constant for Reaction 3 could not be determined precisely, since the exact values of k_4 and k_5 are not yet available. Therefore, we have the limiting relation, $k_{II}=k_3$, when the rates of Reactions 4 and 5 are negligibly small; we may conclude that the value of k_{II} is the upper limit of k_3.

Figure 6 shows the concentration profiles of COS, S, S_2, and S_2* with the time; these profiles were calculated by using the rate constants of Case c. As is

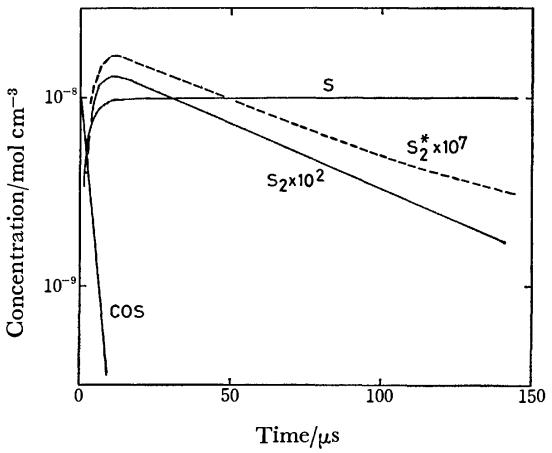

Fig. 6. Time dependent concentration changes of COS, S, S_2, and S_2*. Experimental conditions are the same as those of Fig. 4.

shown in this figure, although the equilibrium between the concentrations of S_2 and S_2* was not maintained precisely, it was found that the assumption of the equilibrium did not introduce many errors in estimating the disappearance rate of S_2 from the change in the emission intensity with the time.

The following three reactions are also possible in the decomposition of COS:

$$COS + S \longrightarrow CS + SO \quad (7)$$

$$COS + SO \longrightarrow CO_2 + S_2 \quad (8)$$

$$CS + SO \longrightarrow CO + S_2. \quad (9)$$

The influence of these reactions on k_{II} were examined. Since there are no rate data for Reaction 7, a value of 10^{12} cm^3 mol^{-1} s^{-1} was assumed for k_7. Using values of 10^{11} and 10^9 cm^3 mol^{-1} s^{-1} for k_8[10] and k_9[10] respectively, the history of S_2* was calculated. It was found from this calculation that the concentration of S_2* was slightly influenced by these reactions, but that the value of k_{II} so determined was not influenced.

Diffusion Coefficients of Bolaform Electrolytes. Part II.† Diffusion Coefficients of Magnesium 1,2-Ethanedisulfonate and Magnesium 1,4-Butanedisulfonate in Aqueous Solution

Hisashi UEDAIRA* and Hatsuho UEDAIRA

Research Institute for Polymers and Textiles, 1-1-4 Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received May 11, 1979)

The diffusion coefficients of magnesium 1,2-ethanedisulfonate and magnesium 1,4-butanedisulfonate in aqueous solutions have been measured at 25 °C. The concentration dependence of the diffusion coefficients of these salts was larger than those of the corresponding sodium salts. It has been shown that the 2:2 bolaform electrolyte behaves approximately like an ordinary 2:2 electrolyte. From these and previous results, it has been concluded that the diffusion behavior of bolaform electrolytes distinctively depend on the valency of the counterion.

In a previous report,[1] it was reported that diffusion of the 2:1 bolaform electrolyte, *i. e.*, the salt composed of a bolion[2] and two monovalent counterions, showed a peculiar behavior: the diffusion coefficients were significantly larger than that calculated according to the theory of diffusion of ordinary 2:1 electrolytes. The results were interpreted by assuming that the bolaform electrolyte behaves like an ordinary 1:1 electrolyte in the concentration range where the ionic atmosphere around each charged group is independent.

The spin-lattice relaxation time of ^{23}Na in aqueous solutions of sodium sulfonates has been reported.[3] The relaxation rate of ^{23}Na in ethanedisulfonate solution was reported to be smaller than that in butandisulfonate solution. If the both terminal sulfonic groups contribute to the relaxation rate of the Na^+ ion, the ^{23}Na relaxation rate in ethanedisulfonate solution should be larger. This result indicates that the Na^+ ions crowd separately around each sulfonic group and the electrostatic interaction between each crowd and the sulfonic group at one end is independent from the other terminal group.

In the case of the 2:2 bolaform electrolyte, the situation appears to be different. It is expected that the concentration dependence of the diffusion coefficients of 2:2 salts are larger than that of 2:1 salts. The diffusion coefficients of magnesium 1,2-ethanedisulfonate (MgEDS) and magnesium 1,4-butanedisulfonate (MgBuDS) in aqueous solution at 25 °C are presented and the effect of the valency of the counterion is discussed.

Experimental

MgEDS and MgBuDS (G. R., Tokyo Kasei Co.,) were recrystallized from water four times.

The diffusion experiments were performed at 25±0.01 °C using a Spinco Model H diffusion apparatus as Rayleigh interferometer. Details of the measurements are described elesewhere.[4]

Water, which was distilled after deionization, was used as the solvent. All the solutions were prepared by weight with the appropriate vacuum correction. The molar concentrations of the solutions were calculated from the densities, which were measured with a densimeter DMA O2C (Anton Paar Co.,) at 25±0.001 °C.

† For Part I in this series see Ref. 1.

Results and Discussion

The mean concentration in each diffusion experiment and the corresponding value of the diffusion coefficient are given in Table 1. The diffusion coefficient of each salt at infinite dilution was calculated from the

TABLE 1. DIFFUSION COEFFICIENTS OF BOLAFORM ELECTROLYTES IN WATER AT 25 °C

a; The limiting slope for Na_2EDS, b; the limiting slope for MgEDS.

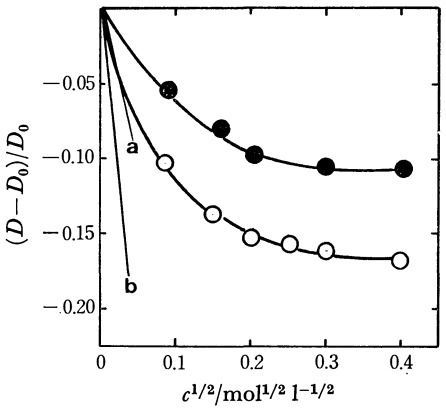

Fig. 2. Relative diffusion coefficients of MgBuDS and Na_2BuDS in aqueous solutions.
—●— Na_2BuDS, —○— MgBuDS.
a; The limiting slope for Na_2BuDS, b; the limiting slope for MgBuDS.

limiting mobilities of the relevant ions by the Nernst equation. The limiting mobilities of EDS^{2-}, $BuDS^{2-}$, and Mg^{2+} ions are 63.9[1] 63.1,[1] and 50.03[5] $cm^2\ \Omega^{-1}$ $equiv^{-1}$, respectively.

Figures 1 and 2 show plot of $(D-D_0)/D_0$ against $c^{1/2}$ for ethanedisulfonates and butanedisulfonates, respectively. The concentration dependence of the diffusion coefficients of the magnesium salts is larger than that of the sodium salts as expected. For the magnesium salts as well as the sodium salts, the dependence is smaller for butanedisulfonate than for ethanedisulfonate.

The diffusion coefficient of an electrolyte in aqueous solution may be given by

$$D = (D_0+\Delta_1)\left(1+c\frac{\mathrm{d}\ln y}{\mathrm{d}c}\right) \quad (1)$$

where D_0 is the Nernst limiting value of the diffusion coefficient, c the molarity and y the activity coefficient in molarity scale. Δ_1 is the first-order electrophoretic term.

The limiting equation for the diffusion coefficient may be obtained from the limiting mobilities of the cation and bolaform anion;[6]

$$D = D_0 - 3.63 \times 10^{-5}\sqrt{c} \quad (2)$$

for MgEDS, and

$$D = D_0 - 3.32 \times 10^{-5}\sqrt{c} \quad (3)$$

for MgBuDS.

In Figs. 1 and 2, the limiting slopes for 2:1 and 2:2 bolaform electrolyte are shown. The curves drawn through the experimental values approach asymptotically to the limiting slope only for the 2:2 bolaform electrolyte.

For 2:2 electrolytes, Δ_1 and the rational activity coefficient $f_\pm$ at 25 °C may be expressed by following relations, respectively.[5]

$$\Delta_1 = -8.07 \times 10^{-6}\frac{(\lambda_0^+-\lambda_0^-)^2}{\lambda_0^2}\cdot\frac{\sqrt{c}}{1+\kappa a} \quad (4)$$

$$\ln f_\pm = -\frac{9.42\sqrt{c}}{1+0.658a\sqrt{c}} + bc \quad (5)$$

where λ_0^+ and λ_0^- are the limiting mobilities of the cation and bolion, respectively. $\lambda_0=\lambda_0^++\lambda_0^-$. a and b are the constants adjustable to fit the experimental curve of the activity coefficient. κ has the usual meaning. The experimental data for the activity coefficients for MgEDS and MgBuDS are, however, not available at present. Consequently the values of a and b in Eq. 5 were estimated as follows.

In a previous report,[1] a was reported as 0.396 nm for Na_2EDS. Since a is related to the closest distance between the cation and the charged group of bolion, a is given as 0.553 nm for MgEDS by employing the Stokes radius for the cations.[5] The empirical relation given by Davis[5] $b=0.1\ |z_+z_-|$, was then employed, where z_+ and z_- are the valencies of the cation and anion, respectively.

The calculated diffusion coefficient for MgEDS is compared with the experimental value in Fig. 3. The decrease of the diffusion coefficient comes from that of the activity coefficient, since the Δ_1 value is of the order 10^{-8}—10^{-9} $cm^2\ s^{-1}$ and negligible compared with D_0. Similarly, the second-order electrophoretic term Δ_2 is of the order 10^{-9} $cm^2\ s^{-1}$ and of negligible contribution.

The density term of the activity coefficient $\ln y$ is small and contributes *ca.* 2% to the diffusion coefficient at 0.16 mol l^{-1}, becoming negligible below 0.07 mol l^{-1}.

The experimental and calculated values show greater agreement for MgEDS than for Na_2EDS, *i. e.*, at c=0.16 mol l^{-1}, the ratio of these values is 1.5 for Na_2EDS, but only 1.04 for MgEDS. The experimental determination of the activity coefficient of MgEDS will bring the calculated coefficient closer to the experimental one, since the correct value of b for MgEDS is probably larger than 0.4 as judged from 0.335 for Na_2EDS.[1]

A 2:1 bolaform electrolyte behaves approximately as a 1:1 electrolyte,[1] when the ionic atmosphere around each charged group is independent under the condition $\kappa R>1$, where R is the charge distance of the bolion. That is to say, a bolion behaves like two monovalent ions

If the 2:2 boalform electrolyte behaved like the 2:1 bolaform electrolyte under the conditions $\kappa R>1$, it would behave like an ordinary 1:2 electrolyte.

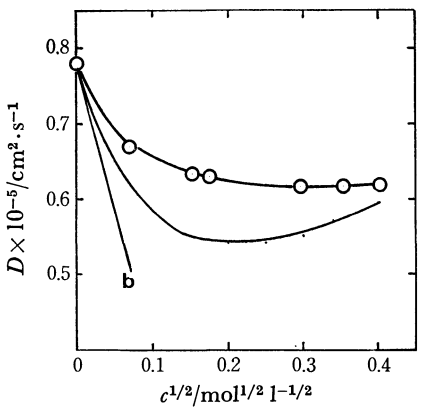

Fig. 3. Diffusion coefficients of MgEDS in aqueous solution.
—○— Experimental values, ——— calculated values, b; limiting slope.

From Figs. 1, 2, and 3, it is evident that the behavior of 2:2 bolaform electrolytes are quite different from that of the ordinary 1:2 electrolytes but resemble the ordinary 2:2 electrolytes. This is reasonable since the divalent counterion must contribute to the formation of the ionic atmospheres around the two charged groups of a bolion or bolions.

The motion of a charged group in a bolion is restricted by the other one connected to the skelton. In the diffusion process, the cation and anion move with the same velocity; hence a divalent counterion and two charged groups of two bolions or a counterion and a bolion move with the same velocity, *i.e.*, a counterion and a bolion move with the same velocty. That is, the 2:2 bolaform electrolyte behaves approximately like an ordinary 2:2 electrolyte.

There is a difference between the concentration dependence of the diffusion coefficient of the 2:2 bolaform electrolyte and that of the ordinary 2:2 electrolyte. The diffusion coefficient of the latter shows a minimum but that of the former shows a monotonical tendency to approach a constant value. Rice[7] pointed out that the assymmetry of the ion atmosphere leads to an additional retarding effect which will compensate for the increase in the diffusion coefficient by the thermodynamic term.

The concentration dependence of the diffusion coefficients of magnesium salts is larger than that of sodium salts. The explanation for this is that the concentration dependence of the activity coefficient of magnesium salts is larger than that of the sodium salts (compare Eq. 5 with Eq. 5 Ref. 1). And this is due to the ionic distribution which depends strongly on the valency of the counterion.

In the case of 2:1 bolaform electrolytes, Thomson *et al.*[8] found that the diffusion coefficients of potassium *p*-benzenedisulfonate and potassium 4,4'-biphenyldisulfonate in aqueous solution show no concentration dependence. The authors have shown that the sodium salts of several alkyl and aromatic disulfonic acids behave like 1:1 electrolytes rather than 2:1 electrolytes. The origin of this difference in diffusion has not yet been clarified. Such peculiar diffusion behavior probably only occurs in the case of 2:1 bolaform electrolytes with monoatomic counterions.

The authors would like to thank Dr. J. Komiyama (Tokyo Institute of Technology) for his interesting and helpful discussions.

The Crystal and Molecular Structure of γ-Metasantonin

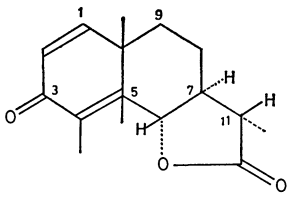
Hideo UEDA,** Chuji KATAYAMA, and Jiro TANAKA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

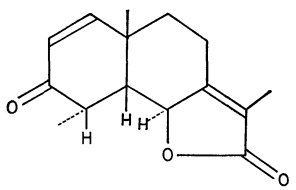
(Received April 4, 1979)

The crystal and molecular structure of γ-metasantonin has been determined by the X-ray method. The crystal is orthorhombic, $P2_12_12_1$, with lattice parameters $a=10.371(1)$, $b=7.904(1)$, $c=15.975(1)$ Å. The molecule has two independent α,β-unsaturated ketone chromophores which take a chiral configuration. The chromophores show good planarity. A/B ring fusion is *cis*.

Many investigations concerning the stereochemistry of santonin(I) and its related compounds have been made by the chemical methods,[1,2] NMR,[3,4] CD,[5,6] and X-ray analysis.[7-9] γ-Metasantonin, 6β-hydroxy-3-oxo-5β-eudesma-1,7(11)-dien-12-oic acid γ-lactone, is obtained by the reaction of concentrated sulfuric acid on santonic acid or metasantonic acid. Woodward and Yates[1] assigned the gross structure (II) to γ-metasantonin.



I



II

Hortman, Daniel, and Schaefer[3] and McMurry and Rane[4] confirmed the structure (II) by NMR. The conformation of this molecule, containing two separated α,β-unsaturated ketones, is interesting from the viewpoint of CD analysis. We determined the structure by X-ray analysis.

Experimental

The crystals are of transparent prismatic forms. The space group was determined as $P2_12_12_1$ from the oscillation and Weissenberg photographs. The density was measured by the flotation method with aqueous KI solution. The unit-cell parameters were determined by the least-squares methods, using twelve reflections measured on a Hilger & Watts four circle diffractometer with Zr-filtered Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). The intensity data were collected on the diffractometer with the 2θ-ω scanning mode ($2\theta \leqq 54°$). The size of the crystal used was $0.2\times0.3\times0.1$ mm. The crystal used for X-ray measurement was mounted in a glass capillary. The intensities of three standard reflections were monitored after every 50 reflections. They were stable to 1% from their mean values. Neither absorption nor extinction correction was made. The crystal data are given in Table 1.

Determination and Refinement of the Structure

The structure was determined by the direct method with the program MULTAN[10] using 201 reflections

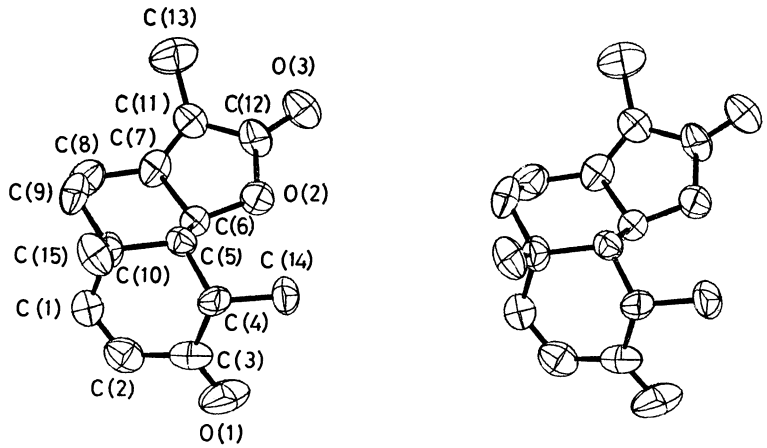

Fig. 1. The atomic labelings and a stereoscopic view of γ-metasantonin. Carbon and oxygen atoms are represented as thermal ellipsoids of a size such that the vibrating atoms have a 50% probability of being found within them. The absolute configuration of the molecule was drawn to be in conformity with the established configuration by a chemical correlation method.

** Present address: Central Research Laboratory, Ube Industries Ltd., Nishihon-machi, Ube, Yamaguchi 755.

with $|E| \geqq 1.30$. An E map computed from the phase set with the highest figure of merit ($FOM = 1.12$) revealed a partial structure containing a lactone ring. Other atoms were found by the succesive Fourier synthesis. Refinement of the structure was performed by the block-diagonal least-squares method with 752 independent reflections of $|F_o| \geqq 3\sigma$. R-index converged to 0.065 with an equal weight for each reflection. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[11] The program HBLS-IV coded by Ashida in UNICS was utilized for the refinement. The program ORTEP[12] was used for drawing Figs. 1 and 2. A part of computation was performed at the Nagoya University Computation Center. The observed and calculated structure factors are given in Table 2.[13]

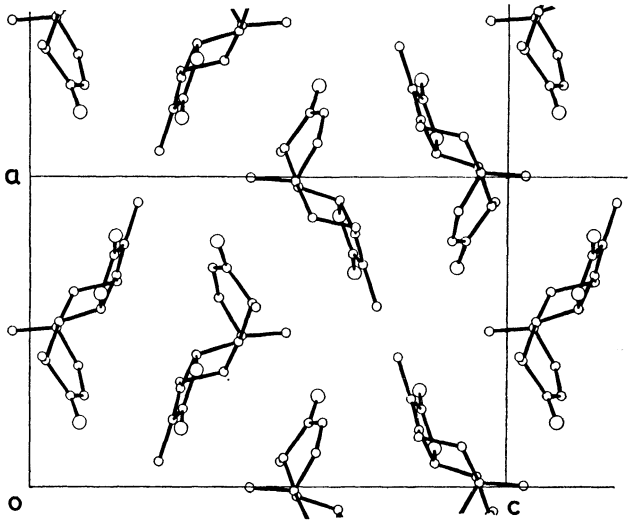

Fig. 2. The projection of the crystal structure along the b-axis. Carbon atoms are depicted as small circles and oxygen atoms as large circles. The configuration is the same as in Fig. 1.

Results and Discussion

The molecular structure, atomic labelings, and thermal ellipsoids are shown in Fig. 1. The positional and thermal parameters of non-hydrogen atoms with their standard deviations are given in Tables 3 and 4, respectively. The coordinates and isotropic thermal parameters of hydrogen atoms are given in Table 5.

are given in Tables 6 and 7, respectively. The various types of bond have lengths in good agreement with those reported for santonins.[7-9] The bond angles are all normal. The torsion angle O(1)–C(3)–C(2)–C(1) is −174°, and the maximum deviation from the least-squares plane containing these atoms is 0.031 Å at O(1), showing the good planarity of the α,β-unsaturated ketone group in the six-membered ring. The cyclohexenone ring A is puckered, C(5) being displaced by *ca.* 0.7 Å from the plane. The methyl group attached to C(4) is equatorial.

The molecule has a *cis* A/B ring fusion, and the ring B has a chair conformation. The mean endocyclic torsion angle for B is 54°, which is between santonins and *epi*-santonins,[9] and the value is similar to those for steroids.[14,18] The torsion angle C(6)–C(5)–C(10)–C(9) is −49° and the rotation around the bond C(5)–C(10) is in the opposite direction compared with the *epi*-santonins, the mean value being 47°.

The α,β-unsaturated lactone of γ-metasantonin is perfectly planar. The torsion angle O(3)–C(12)–C(11)–C(7) is −178°, the largest endocyclic torsion angle being 1.4°, and the maximum deviation from a least-squares plane of the conjugated double bond is 0.034 Å at O(2).

Some empirical rules[15,16] related to the sign of Cotton effect and the chirality of α,β-unsaturated lactones were reported. McMurry and his coworkers[17] investigated that the sign of $n\rightarrow\pi^*$ transition of the photolysis products of 4-hydroxysantonene, which had the same conformation as the lactone ring of γ-metasantonin, agreed with the rules. The CD spectrum of this molecule shows no peak due to $n\rightarrow\pi^*$ transition, presumably because of the planarity of the unsaturated ketone chromophore.[4] The CD spectrum shows a negative band around 230 nm and a positive one at 205 nm due to the coupled $\pi\rightarrow\pi^*$ transition.[19] Two independent chromophores, of which dihedral angle is 48°, take a chiral configuration, and the CD bands might appear owing to this configuration

(Received May 21, 1979)

Spherical particles of silica were prepared by passing fine silica material through the O_2–H_2 flame. Spherical particles obtained were amorphous, creviceless, and very large in size compared to those of the starting material which indicates that spheres are made by complete comelting of a large number of fine particles. Water adsorption measurements showed that the rate of rehydration of the dehydroxylated silica surface is very slow, especially at low water pressures, and that the spherical silica has a heterogeneous surface, this heterogeneity being enhanced when the sample is heated at elevated temperatures. The ratio of the number of water molecules adsorbed in the first physisorption layer to that of the underlying surface hydroxyls was found to be 1:1.

Particles of most powders employed in industry and surface chemical researches have irregular shapes and inhomogeneous surfaces. Since an ideally spherical particle of any solid substance, if available, will have a physically and chemically homogeneous surface, the usage of such a particle should simplify the surface phenomena and therefore permit exact theoretical treatment. Thus, spherical particles will represent the reference sample for the surface chemistry of powders.

The preparation of spherical particles can be carried out by two methods. The first is the reaction in the liquid phase, that is, the precipitaion of sparingly soluble salts,[1,2] hydrous metal oxides,[3–5] and polystyrene lattices.[6] The particles formed by this method usually contain reagents and by-products as impurities. The second method consists of melting of powders at elevated temperature and solidification on cooling at a lower temperature.[7,8] This procedure should give particles whose purity depends on the purity of the raw materials.

Silica is used in a variety of industrial fields as mixed catalysts, carriers of catalyst, fillers and drying materials, and has been extensively studied from the surface-chemical stand point. Generally, surface hydroxyls are present on metal oxides as the result of chemisorption of water in the atmosphere,[9–11] and it has been found that surface hydroxyls on silica show characteristic behavior[11] which differs from that of most oxides[10,11] in the following points: a small rate of hydroxylation, a small surface density of the hydroxyls, and the 1:1 ratio between the amounts of physisorbed water and the underlying hydroxyls. In the present work we have undertaken the preparation of spherical silica particles by passing fine silica powders through the O_2–H_2 flame in order to investigate the interaction of the surface with water.

Experimental

Preparation of Spherical Particles of Silica. The apparatus for preparing spherical particles is illustrated schematically in Fig. 1. Raw material of silica was melted by the O_2–H_2 flame in a cylindrical furnace tube made of high alumina, 30 mm in diameter and 250 mm in length, where O_2 and H_2 were introduced at the rate of 14 and 10 l min^{-1}, respectively. A sample bucket was vibrated electrically to permit the sample to fall through the 150 mesh sieve placed at the bottom of the bucket, and the sample was passed into the furnace by the O_2 stream. H_2 was emitted into the furnace at the entrance. After passing through the furnace, the sample was pumped out; the major part of spherical particles formed sedimented on the bottom of the ducts D_1, D_2, and D_3, of 1000 mm each in length, and a minor part was collected on the 100 mesh stainless steel net N and cotton gauze G.

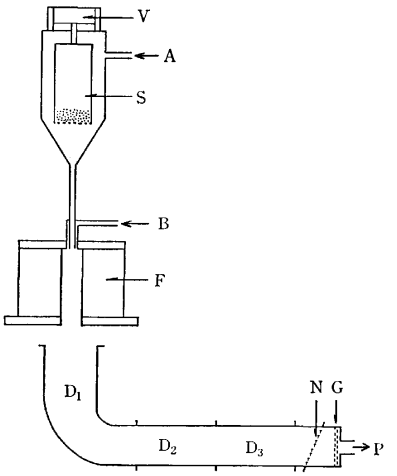

Fig. 1. Diagram of the apparatus for preparing spherical particles by fusion in the O_2–H_2 flame. A, O_2 inlet tube; B, H_2 inlet tube; V, vibrator; S, sample bucket (with 150 mesh net); F, furnace; D_1, D_2, D_3, ducts; N, stainless steel net (100 mesh); G, cotton gauze; P, pump.

Materials. The raw material of silica used in this study was Aerosil 200 made by Japan Aerosil Co., having a specific surface area of about 200 m^2 g^{-1}. Since the sample was too light to pass through the sieving mesh, it was sintered by heating it at 1220 °C for 3 h in an electric furnace; the particles formed had a specific surface area of about 31 m^2 g^{-1}, and could pass easily through the mesh.

Measurement of the Water Adsorption Isotherm and Surface Water Content. The adsorption isotherm of water on spherical silica was measured volumetrically by using a conventional adsorption apparatus equipped with an oil manometer. Prior to the adsorption measurement, the spherical sample was treated at 25, 300, 500, 900, and 1200 °C,

respectively for 4 h each in a vacuum of 10^{-6} Torr.† After the measurement of the water adsorption isotherm at 25 °C, the sample was exposed to the saturated water vapor for 12 h at room temperature in order to ensure the complete hydroxylation of the surface, followed by the evacuation at 40 °C to leave chemisorbed water on the surface. The second adsorption isotherm was then measured on the fully hydroxylated surface of silica. In order to obtain the isosteric heat of physisorption of water, the second adsorption isotherm was measured over a range of temperatures 10, 15, 20, and 25 °C. The time required of reaching the adsorption equilibrium was about 2 h and 30 min for the first and second adsorption, respectively.

The surface water content was measured by means of the successive-ignition-loss method,[12] and the N_2-BET method was used for the determination of surface area. Electron microscopes were Hitachi HU-11E and JEOL JSM-35.

Results and Discussion

Formation of Spherical Silica. Electron micrographs of sintered silica used as starting material and of spherical silica particles obtained are shown in Fig. 2. It is clear from Fig. 2 that the spherical particles obtained have smooth surfaces. Furthermore, observation of fracture of crushed particles of spherical silica under the field of a scanning electron microscope showed the inner part of the particle to have no crevices, in contrast to TiO_2.[13] X-Ray analysis proved the spherical particles of silica to be amorphous. The mean surface area of the particles obtained was 0.315 $m^2 g^{-1}$ as shown in Table 1, indicating that the size of the spherical particles is very much larger than that of the sintered sample. This fact manifests that a large number of sintered particles form a drop of melted silica in the flame, and the state of agglomeration of silica at the time when it enters the furnace determines the size of the silica sphere formed.

Adsorption Isotherm of Water and Isosteric Heat of Adsorption. The adsorption isotherm of water on spherical silica is given in Fig. 3. It can be seen from Fig. 3 that the isotherms belong to type II according to Brunauer's classification,[14] and that the second adsorption isotherms on the same sample almost coincide with each other when they are plotted against the relative pressure of water. Furthermore, Fig. 3 shows that the first adsorption isotherm lies above the second one except for the sample treated at 25.0 °C. In addition, the first and second adsorption isotherms measured at the same temperature do not go parallel, but deviate from each other with increasing relative pressure.

This can be explained by the idea that the rate of rehydration of the siloxane surface formed by dehydration of silanols is very slow at lower pressure and gradually increases with increasing relative humidity. This is in contrast to the behavior of most metal oxides where the two isotherms go parallel because of fast rehydration of the dehydrated surface

even at the initial pressure of water.[10]

For comparison, the water adsorption isotherms measured on the sintered silica are illustrated in Fig. 3. The results show that the adsorbed amounts for the second isotherm are almost equal to those in the case of spherical silica, but the first adsorption isotherm lies below that of the spherical silica. In other words, the extent of rehydroxylation differs from sample to sample, and the rehydroxylation rate is faster for the spherical sample than for the sintered one. This better hydrophilicity of spherical silica may be due to the history of the sample, *i.e.* the steam treatment by the O_2–H_2 flame at a very high temperature during the preparation.

As stated above, the first adsorption isotherm obtained includes physisorption and chemisorption of water, the latter of which is irreversible and increases in quantity with increasing pressure of water. This leads to a conclusion that the measurement of isosteric heat of adsorption q_{st} from the first adsorption isotherms by applying the Clausius-Clapeyron equation is unexpectable. On the other hand, the second adsorption isotherm measured on the fully hydroxylated surface of metal oxide has been found to be reversible and reproducible. Thus, we usually measure q_{st} values of water on the fully hydroxylated surface of metal oxide, though the surface heterogeneity discussed by the q_{st} values might be a little of quite different from that on the bare surface.

By applying the Clausius-Clapeyron equation to the second adsorption isotherm in Fig. 3, we can obtain the isosteric heat of adsorption q_{st} as given in

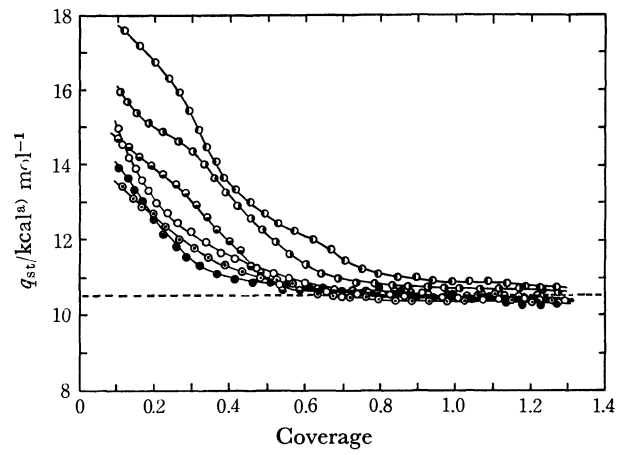

Fig. 4. Isosteric heat of adsorption of water on spherical SiO_2 pretreated at ○ 25 °C, ● 300 °C, ⊙ 500 °C, ◑ 900 °C, ◐ 1200 °C, and ◒ starting material of SiO_2 treated at 500 °C. Broken line represents the heat of liquefaction of water 25 °C. a) 1 cal (thermochemical)=4.184 J.

Fig. 4. The results reveal that the adsorption energy of water onto the hydroxylated surface of the original spherical silica decreases with the coverage of water indicating some heterogeneity of the surface, and that the extent of heterogeneity depends on the pretreatment temperature of the sample. The q_{st} curves change little until the pretreatment temperature of 500 °C is reached, but further increase in temperature raises the q_{st} values. Additional data of the q_{st} value of the sintered silica give an intermediate curve as shown in Fig. 4, which indicates that the surface heterogeneity of silica was clearly decreased by the formation of spheres. Thus, it is found that the surface activity and surface heterogeneity of fully hydroxylated surface of spherical silica for water adsorption were less than that of the raw material, though they were not so low as those expected. This can be elucidated as follows. When liquid spherical particles of silica melted in the O_2–H_2 flame are quenched, the solid particles formed will have surface state close to that of the liquid, including a small amount of water from the environment. Also on the fully hydroxylated surface of the spherical silica, there will exist the network of SiO_2 including Si atoms of the coordination number 4, which have at least one or two hydroxyls per Si atom. The variety of the direction and surface density of these hydroxyls can be considered to bring about the heterogeneity of hydroxylated spherical silica surface for water adsorption.

It is interesting to note that the surface becomes more active when spherical silica is treated at higher temperature *in vacuo*. The heat treatment at higher temperature naturally causes the migration of atoms in solid toward the direction of more stable state of the solid, *i.e.* toward crystallization, though it be very slow, accompanied by the evolution of bonded water molecules. This may produce more active sites such as corners and edges on the surface.

Surface Water Content on Spherical Silica. Figure 5 gives the surface water content on the spherical silica

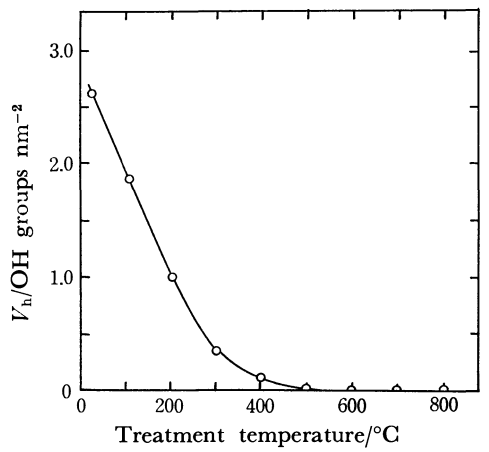

Fig. 5. Surface water content of spherical SiO_2.

which was obtained by the successive-ignition-loss method. The data obtained show that the surface water content at room temperature is almost the same as that reported on various other silica samples,[11] and very much smaller than that on most metal oxides.[10,11] The value 2.55 is almost one half of the calculated theoretical value.

Relation between the Amounts of Physisorbed Water and the Underlying Hydroxyls. The data obtained by the analysis of water adsorption isotherms of spherical silica are listed in Table 1. V_m and V_p are the monolayer capacities obtained by applying the BET method to the first and second isotherms, respectively. V_p contains only the physisorbed amount, but V_m both physisorbed and chemisorbed ones, and the difference between V_p and V_m therefore represents the amount of chemisorption V_c. We have another component of chemisorbed water, that is, the surface water content V_h which exists on the surface before the measurement of the first adsorption isotherm.

The sum V_c+V_h, therefore, represents the total amount of chemisorbed water. In the last column in Table 1, we can see the ratio of H_2O:OH to be 1:1, which shows a good agreement with the value obtained on fine silica particles.[11] In other words, a water molecule is physisorbed on a surface silanol group by hydrogen bonding on any kind of silica, contrary to the case of metal oxides, where a water molecule is adsorbed by two surface hydroxyls forming a tetrahedral coordination of the oxygen atom in an adsorbed water molecule. This interesting phenomenon of the silica surface may be attributed to a dilute population of surface silanols on the surface as was stated above, so that the neighboring two hydroxyls on silica are located too far apart for the bridging of a water molecule by two hydroxyls.

The present work was partially supported by a Grant-in-Aid for Development Research from the Ministry of Education.

Structure of α Form of L-Glutamic Acid. α-β Transition

Noriaki HIRAYAMA,* Kunikatsu SHIRAHATA, Yuji OHASHI,† and Yoshio SASADA†

Tokyo Research Laboratory, Kyowa Hakko Kogyo Co., Ltd., 3-6-6, Asahimachi, Machida, Tokyo 194

†*Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received May 22, 1979)

An X-ray analysis of the α form of L-glutamic acid, $C_5H_9NO_4$, has been carried out. The space group is $P2_12_12_1$ with $a=7.068(1)$, $b=10.277(1)$, $c=8.755(1)$ Å and $Z=4$. The structure was solved by the direct method, and least-squares refinement using 855 reflexions led to the final R value of 0.034. The molecule is in a zwitter ion form, and there is a strong OH···O intermolecular hydrogen bond with the O···O distance of 2.578(2) Å. The conformation of L-glutamic acid in the α form is quite different from that in the β form. The occurence frequency in various crystal structures containing glutamic acid residues shows that the conformation in the β crystal is more stable and favourable than that in the α crystal. The transition of the α form to the β form of L-glutamic acid in the mother liquor and the conditions for obtaining the α crystals are discussed based on the crystal and molecular structures of the two polymorphs.

L-Glutamic acid crystallizes in two polymorphic forms; they are designated α and β forms by Hirokawa.[1] In industrial processes, the α form is more advantageous to handle. The α crystal, however, is converted to the β when the α crystal is placed in solution for a long time. The β crystal is also obtained when it is grown slowly. Consequently, various kinds of investigations have been undertaken to find the conditions for crystallization of L-glutamic acid in the α form and to elucidate the mechanism of the α-β transition.[2-5] It was found empirically that addition of trace amount of some amino acids or other special compounds causes formation of the α form.[2,4,5] To clarify these problems, however, it is inevitable to know the difference in the crystal and molecular structure between the two polymorphs. While the refined crystal structure of the β form was obtained from neutron diffraction,[6] only crystal data for the α form has been reported by Bernal.[7] We have, therefore, undertaken an X-ray analysis of the α form of L-glutamic acid.

Experimental and Structure Determination

Prismatic crystals were obtained from an aqueous solution. A crystal, 0.5×0.4×0.3 mm in size, was used for data collection on a Rigaku four-circle automated diffractometer with graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Preliminary unit cell dimensions and space group were obtained from photographs. The space group was determined from the systematic absences ($h00$, $2n+1$; $0k0$, $2n+1$; 001, $2n+1$). Accurate cell dimensions were determined by the least-squares method using the 2θ values of 15 high angle reflexions, measured on the diffractometer. Crystal data are summarized in Table 1. All reflexions within the range of $2\theta \leqq 55°$ were collected by the use of the ω-2θ scan mode with a scanning rate of $4°(2\theta)$ min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. A total of 874 independent reflexions were obtained, of which 17 ($|F_o|<3.0\sigma(|F_o|)$) were considered as unobserved. A Lorentz-polarization correction was made as usual but absorption effect was neglected.

Table 1. Crystal data

$C_5H_9NO_4$	$V=637.5$ Å^3
$M.W.=147.13$	$D_x=1.533$ g·cm^{-3}
Orthorhombic	$Z=4$
$P2_12_12_1$	μ(Mo $K\alpha$) $=3.426$ cm^{-1}
$a=7.068(1)$ Å	
$b=10.277(1)$	
$c=8.775(1)$	

The phases for 191 reflexions with $|E_o|\geqq 1.2$ were assigned with MULTAN.[8] An E map computed with the phase set of the lowest R_k revealed the positions of 10 non-hydrogen atoms.** All hydrogen atoms were located from the difference synthesis. The structural parameters were refined by the block-diagonal least-squares method. The function minimized was $\sum w(|F_o|-|F_c|)^2$ with unit weight.

Table 2a. Final positional parameters multiplied by 10^4 for non-hydrogen atoms and by 10^3 for hydrogen atoms

Two strong reflexions, (2 1 0) and (1 2 1) were excluded because they seemed to suffer from secondary extinction. The final R value was 0.034 for 855 reflexions. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[10] The final positional and thermal parameters are given in Table 2.***

Description of the Structure

Hydrogen Bond. The crystal structure viewed along the a axis is drawn in Fig. 1, where the numbering of the atoms are shown. Here O(1) of α-carboxylate group is denoted to the oxygen atom whose torsional angle of O(1)–C(1)–C(2)–C(3) is negative. All of the hydrogen donors, OH and NH_3, participate in hydrogen bonds. The distances and angles of the hydrogen bonds are given in Table 3. A strong OH···O bond between the α- and γ-carboxyl groups links the molecules to form a chain along the b axis. The chains are interlinked by the three NH··· O hydrogen bonds to make a three-dimensional network. This scheme is similar, in general, to that of the β crystal. The difference is that in α O(2) accepts the hydrogen bonds from the γ-carboxyl and the NH_3^+ group and O(1) links to another NH_3^+ group while in β O(2) is the hydrogen bond acceptor from two NH_3^+'s and O(1) links to OH. The OH··· O distance in α is 0.06 Å longer than that in β, whereas the average of three NH···O distance in the former are 0.06 Å shorter than those of the latter.

Conformation. Figure 2 shows a stereoscopic drawing of the present molecule. The torsional angles are listed in Table 4. The conformations around the C(2)–C(3) and C(3)–C(4) bonds in the α form are both *gauche*, whereas those in the β form are *trans-gauche*. Such folded conformation of the molecule has

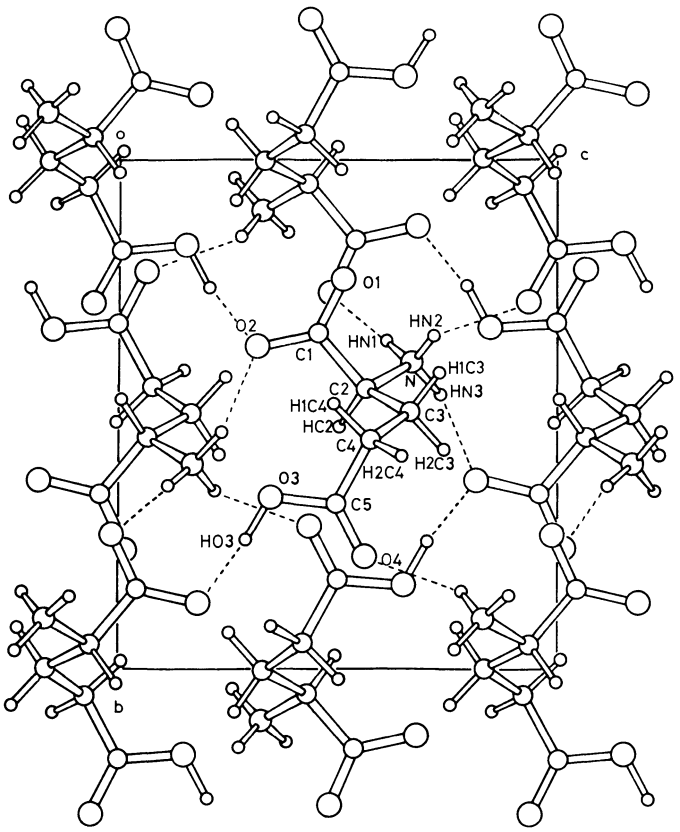

Fig. 1. A crystal structure viewed along the a axis with the numbering system of L-glutamic acid molecule.

***Lists of the observed and calculated structure factors are kept as Document No. 8002 at the Chemical Society of Japan.

not been observed in the crystal structures of the related compounds so far determined. Some torsional angles are compared with those of the related compounds in Table 5, in which the torsional angle nomenclature of IUPAC-IUB commission[11] are also given.

The conformation around the C(1)–C(2) bond in the α form is similar to that of the β form; the O(1)–C(1)–C(2)–N torsional angles for α and β are −50.3 and −42.3°, respectively. Similar negative values are usually observed in L-amino acids.[21] This would be brought about by the fact that both oxygen atoms of the α-carboxylate group should avoid C(3) and N which are bulky substituents. The torsional angles, χ^{31} and χ^{32}, in α are different from those in β, although the values in β are similar to those of the other compounds.

Table 3. INTERMOLECULAR HYDROGEN BOND LENGTHS (l/Å) AND ANGLES (ϕ/°)

I. $(1.0-x$	$0.5+y$	$0.5-z)$	
II. $(0.5-x$	$1.0-y$	$0.5+z)$	
III. $(1.0-x$	$-0.5+y$	$1.5-z)$	
IV. $(-0.5+x$	$0.5-y$	$1.0-z)$	

Bond Lengths and Angles. Bond lengths and angles are listed in Table 6, in which the corresponding values of the related compounds are also shown. As found in the β form, L-glutamic acid in the α form exists as a zwitter ion; a proton transfers from the α-carboxyl group to the amino group. The C(1)–O(1) and C(1)–O(2) distances of 1.242(3) and 1.275(3) Å, respectively, are the values of the ionized carboxyl group. The discrepancy of 0.03 Å between them can be attributed to differences of their intermolecular hydrogen bonds. As mentioned above, O(2) makes a very short hydrogen bond with the OH group and a NH···O hydrogen bond with the NH_3^+ group, while O(1) makes one NH···O bond with NH_3^+.

C(2)-C(3)-C(4)	114.1(2)	117.8(1)	115.8(4)				

Such a discrepancy is also found in the β form. The O(1) atom forms one OH···O hydrogen bond, whereas O(2) participates in two NH···O hydrogen bonds. The C(1)–O(1) bond is 0.02 Å longer than C(1)–O(2). This seems to indicate that the OH···O hydrogen bond is predominant in the L-glutamic acid crystals.

In the γ-carboxyl group, the lengths of C(5)–O(4) and C(5)–O(3), 1.214(3) and 1.327(3) Å, respectively, indicate that it is unionized. Other bond lengths and angles are normal.

The bond angles around C(2), C(3), and C(4) in the α form are significantly different from the corresponding ones in the β form. Such discrepancies may be resulted from the steric repulsions which are due to the conformational difference.

Discussion

In glutamic acid, χ^1 and χ^2 represent rotation about C(sp^3)–C(sp^3) bonds. Each of them is likely to have values in the neighbourhood of 60, 180, and $-60°$ which are designated by g, t, and $\bar{g}$, respectively. According to the conformational energy calculation,[22] favourable combinations χ^1 and χ^2 should be ($\bar{g}$, $\bar{g}$), (g, t), ($\bar{g}$, t), (t, t), and (t, g). The corresponding minimum conformational energies are 0.00, 0.21, 0.23, 0.40, and 0.43 kcal/mol. Judging from these values, glutamic acid in the β form is of the ($\bar{g}$, $\bar{g}$) conformer with the lowest energy, whereas that of the α form is of the (t, g) conformer with the highest energy. From the NMR study, Ham suggested that six conformers of L-glutamic acid can exist in solution.[23,24] Their populations are 0.27, 0.27, 0.18, 0.18, 0.06, and 0.04 for ($\bar{g}$, t), (g, t), ($\bar{g}$, g), (g, g), (t, t), and (t, g), respectively.

Six distinct conformations have been observed in the crystal structures so far reported as seen from Table 5. There are four, three, two, two, one, and one crystal structures containing conformers of ($\bar{g}$, t), ($\bar{g}$, $\bar{g}$), (g, t), (t, g), (g, $\bar{g}$), and (t, t), respectively. The occurence frequency in the crystal structures is in qualitative correspondence to the minimum conformational energy and the population in solution. This coincidence seems to indicate that the occurence frequency of each conformer is not biased to much extent by different crystalline fields or different substituents. Therefore, the occurence frequency may reflect the inherent relative stability of the conformations, and be used as a measure of the stability of the conformers if the considerable number of the related crystal structures can be obtained. These three measures suggest that the conformation in the β crystal is more stable and favourable than in the α crystal. The difference in conformational energy should be responsible for the transition from the α to β form.

Two types of chains or molecular arrangements, which are observed in the α and β crystals, are shown in Fig. 3, a and b, respectively. As mentioned above,

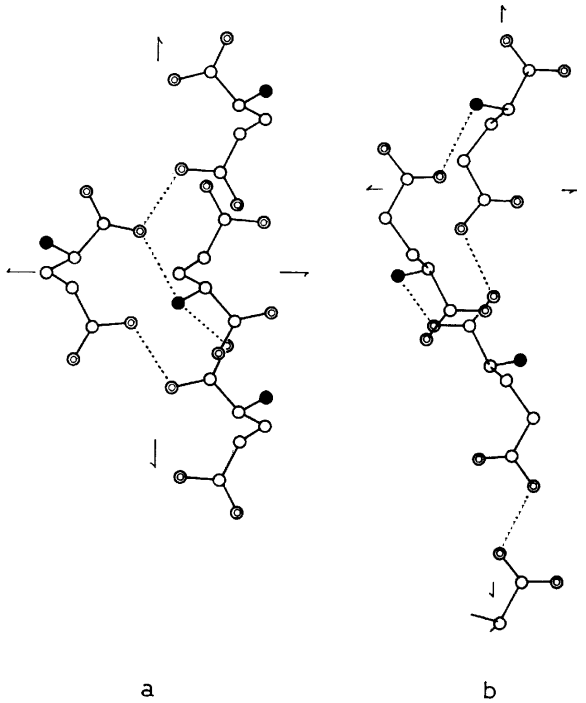

Fig. 3. A comparison of the hydrogen bond systems and the molecular arrangements in the α form (a) and the β form (b) crystals.

the OH···O bond seems to be most predominant among the four hydrogen bonds. Therefore, it is reasonable to assume that the considerable amounts of molecules are connected by the OH···O hydrogen bond to form chains in solution. The neighbouring chains can be connected by the NH···O hydrogen bonds and the conformation and the arrangement of the molecules are stabilized by these hydrogen bonds.

The α to β transition can be explained as shown in Fig. 4, in which the OH···O hydrogen bond is conserved. Here a and e correspond, respectively, to the initial α and the final β conformation. The b, c, and d conformers are hypothetical intermediates rotated stepwisely around the C–C single bonds. The

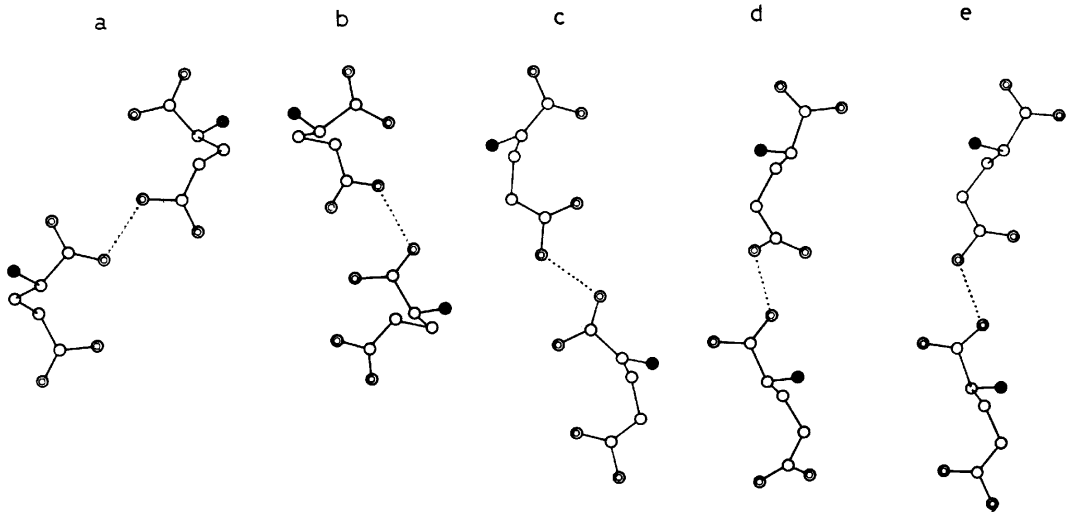

Fig. 4. A schematic drawing of the α to β transition.

actual conformational change might occur cooperatively. The α conformation would change to the β conformation, from a to e spontaneously rearranging the NH···O hydrogen bonds in solution.

Figure 4 also gives us an idea how the trace amount of the specific amino acids facilitates the crystallization of L-glutamic acid in the α form. Conformation of such amino acids would be suitable to make the NH···O hydrogen bonds with OH···O hydrogen bonded L-glutamic acid chains in the state a, and the nuclei generated in this way may trigger the initial stage of the crystallization to grow the α crystal.

The resonance Raman spectra of $TCNE^-M^+$ (M=Na, K, Rb, Cs) in MTHF solutions have been measured at 100 K by exciting radiations within the long wavelength absorption band characteristic of the dimer $(TCNE^-)_2$. Two remarkably resonant lines have been observed at about 180 cm^{-1} and 150 cm^{-1}, showing an obvious change of the relative intensity depending on the counter cation species. The resonance behavior definitely indicates that the stretching vibration of interradical bond is responsible for these lines. Formation of two different types of dimer salts has been proposed as the most probable interpretation of the observed spectral behaviors.

A number of aromatic radical ions have been known to form the dimers under appropriate conditions of temperature and concentration. The formation of dimers is manifested by the temperature dependence of ESR and electronic spectra, which have been quantitatively investigated in several systems to discuss the monomer-dimer equilibrium.[1-4] Recently we studied the vibrational spectra of the dimers of some Würster's cations[5] and of *p*-benzosemiquinone anion,[6] by taking advantage of the resonance Raman effect. The spectra were obtained by exciting radiations close to the new long wave absorption bands characteristic of the dimer formation. In each case, a new resonant Raman line was observed at a low frequency and was assigned to the stretching vibration of interradical bond of the dimer, because of its remarkable and exclusive resonance enhancement by the dimer's characteristic absorption.

Tetracyanoethylene radical anion($TCNE^-$) has been shown to form the dimer at low temperatures.[7] Itoh[4] carried out quantitative investigations of the ESR and electronic spectra, from which he obtained the heat of dimer formation for several counter alkali metal ions and for varied solvent compositions. He also measured the electronic spectra of solid salts, noticing the spectral similarity between the room temperature solids and low temperature solutions. Hinkel *et al.*[8] measured the resonance Raman spectra of $TCNE^-Na^+$ and $TCNE^-K^+$ solid films by exciting radiations within the broad low frequency absorption band. They observed a very broad and intense Raman band at about 170 cm^{-1} with the features sensitive to the condition of sample deposition. Making reference to the behavior of overtone progression, they assigned the band to several librational lattice modes, by assuming mixed formation of different crystal structures with changeable composition.

In this paper, we present the resonance Raman spectra of $TCNE^-$ dimers observed in the low temperature solutions, and discuss the results in connection with the existing experimental data mentioned above.

Experimental

$TCNE^-M^+$ (M=Na, K, Rb, Cs) was prepared by contacting 2-methyltetrahydrofuran(MTHF) solution of TCNE with an alkali metal film in an evacuated manifold. The Raman spectra were recorded for the solution at 100±2 K, where the sample was still kept fluid, by cooling with a regulated flow of cold nitrogen gas in a vacuum cell. The condition of spectroscopic measurement was almost equal to the previous studies.[5,6]

Results and Discussion

The Raman spectra of about 3×10^{-3} mol dm^{-3} $TCNE^-Rb^+$ solution in MTHF at 100 K are shown in Fig. 1 for some Ar^+ laser exciting radiations. These laser lines are located on the higher frequency side within the long wave absorption band characteristic of the dimer, as shown in Fig. 2. As the laser wavelength approaches the absorption maximum at about 540 nm, new Raman lines emerge at 180 cm^{-1} and 150 cm^{-1} with remarkable resonance enhancement, both showing the depolarization ratio of about 0.35. No monomer lines have appreciable intensity in the same conditions.

The aspect of things is essentially similar to the previous observations on Würster's cations[5] and *p*-

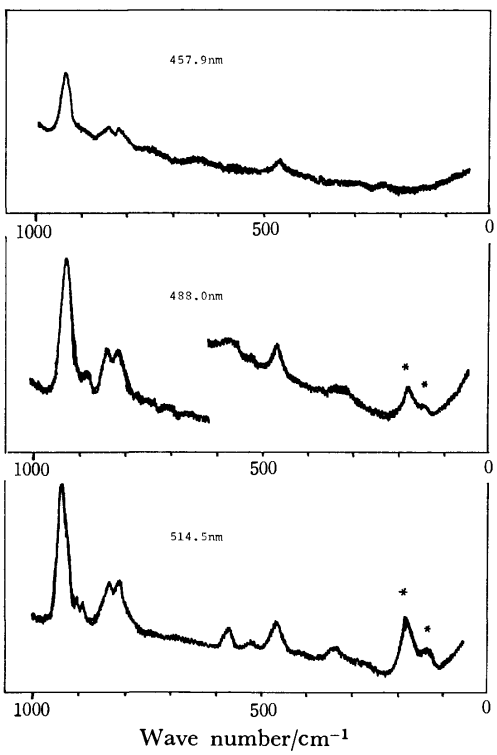

Fig. 1. Raman spectra of $TCNE^-Rb^+$ in MTHF solutions at 100±2 K. *Lines of the dimer.

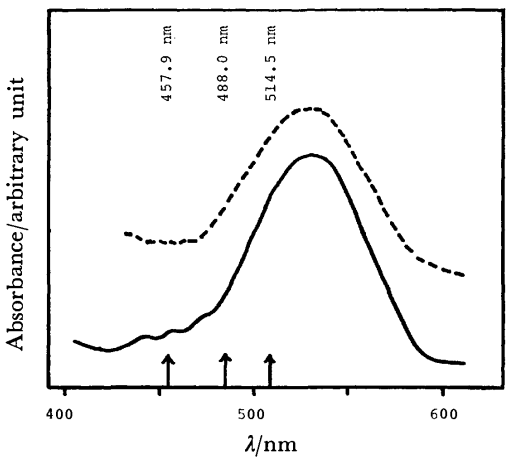

Fig. 2. Visible absorption spectra of $TCNE^-Na^+$ (solid line) and $TCNE^-Cs^+$ (broken line) in MTHF solutions at 100±2 K.

benzosemiquinone anion,[6] except that two well resolved new lines, instead of one, have been observed in the present spectra. Namely, it is little questionable that the 540 nm absorption band is attributed to the charge transfer type transition between $TCNE^-$ moieties of the dimer. The resonance Raman effect associated with this transition is most reasonably considered to originate in the Franck-Condon type term of the scattering tensor,[9] which is raised by the shift in the minimum position of interradical potential curves between the ground and excited states. Then, the strongly resonant low frequency lines obtained above are most likely associated with the stretching vibration of interradical bond. Here, we have tacitly assumed a parallel D_{2h} configuration of the dimer, by reason of the maximum overlap between the π-orbitals of both moieties. It may be noticed, however, that the electrostatic repulsion between the charge distributions on monomer ions is certainly against the D_{2h} structure, and the effect of attached counter cations brings further complexity.

Now, the appearance of two low frequency lines may possibly be due to the coupling of a low frequency dimer mode, composed of monomers' internal motion, with the strongly resonant interradical stretching mode. Such a coupling may be most probable for the symmetric combination of infrared active out-of-plane vibrations of monomers, and the Raman intensity of coupled modes is brought from the incorporated interradical motion. However, by measuring the spectra of other alkali metal salts under the same conditions, it has been found out that the intensity ratio of those two Raman lines changes remarkably depending on the counter cation species, as shown in Fig. 3. If we assume the coupled mode scheme as above, the observed intensity behavior signifies that the mixing ratio of internal and interradical mode amplitudes changes considerably by cation species, necessarily being attended by the corresponding frequency changes.

In the observed spectra, the higher frequency line is almost unchanged in the maximum position for different counter cation species, while a slight shift can be noticed for the lower frequency one, as shown

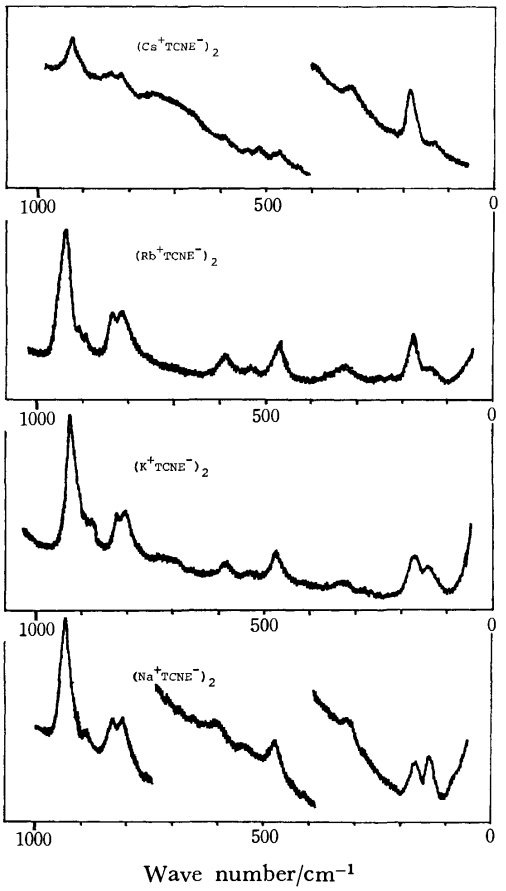

Fig. 3. Raman spectra of $TCNE^-M^+$ (M=Na, K, Rb, Cs) in MTHF solutions at 100±2 K with a 514.5 nm exciting radiation. The concentration is about 3×10^{-3} mol dm^{-3} for Na, K, and Rb salt and about 6×10^{-3} mol dm^{-3} for Cs salt.

in Fig. 4. A simple mechanical consideration shows that such a frequency behavior is rather unlikely in the above coupling scheme, and, even if admitted, cannot possibly be consistent with the observed intensity trend.

There may arise another argument that the two Raman lines are assigned to separate interradical modes with different origins of electronic resonance, so that the relative intensity changes due to the gradual shift of resonance origins from Na to Cs salts. However, this does not seem probable either, because the resonant 540 nm absorption band is essentially unchanged for different counter cations as observed in Fig. 2, and also because the relative intensity of two Raman lines hardly changes by altering the exciting radiation from 514.5 nm to 488.0 nm. The scarce sensitivity of the dimer's characteristic absorption to the counter cation species may be realized by the fact that the associated transition, illustrated in Fig. 5, gives rise to no substantial change in charge distribution, unlike the other transitions between different monomer orbitals.

Thus, we are led to conclude that the dimer molecules are distributed in two different forms, so that the observed intensity change may be interpreted as due to the population change in those forms effected by replacing the counter cation. In view of the ordinary and unchangeable features of 540 nm absorp-

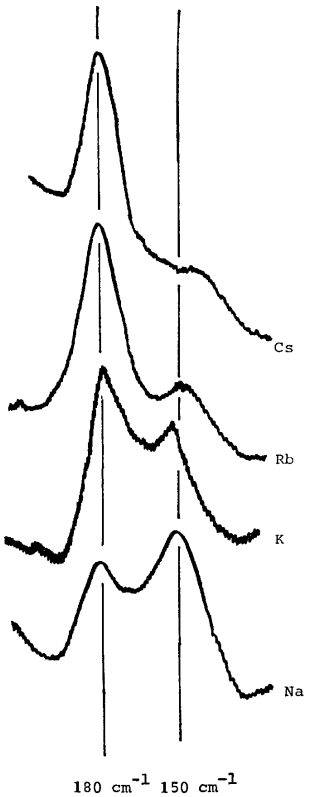

Fig. 4. Change of low frequency Raman features by counter cations in the spectra by 514.5 nm excitation.

tion band, the distinction between the two dimer forms may not consist in any notable difference in the interradical binding nature, but may be due to chemically less significant factors.

By investigating the temperature dependence of ESR and electronic absorption intensities, Itoh[4] showed that the heat of dimer formation($-\Delta H$) in MTHF solutions is appreciably dependent on counter cation species in the order $Na^+ > K^+ > Rb^+ > Cs^+$. He also showed that the $-\Delta H$ tends to be smaller for increasing solvation effect, from the same investigation by using THF/MTHF mixed solvents. The latter observation may be incorporated with the normally expected order of solvation strength, $Na^+ > K^+ > Rb^+ > Cs^+$, to suggest that the principal factor to give the above order of counter cation effect on $-\Delta H$ is not the solvation but more probably be ionic interactions. This is favorable for the supposition that two different modes of interaction between $(TCNE^-)_2$ and counter cations are responsible for the observed two Raman lines.

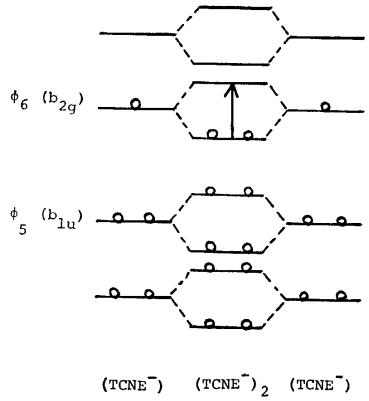

Fig. 5. MO scheme of $(TCNE^-)_2$ dimer formation. The arrow indicates the transition of 540 nm absorption.

Conceivable schemes may be the pair of $M^+(TCNE^-)_2$-M^+ and $M^+(TCNE^-)_2//M^+$, where // represents intervening solvent molecules, or two different geometrical arrangements in $M^+(TCNE^-)_2M^+$, *etc.*, but further investigations are required for discussing those schemes significantly.

On the other hand, it may be noticed that the observed low frequency Raman lines are in good correspondence to those of solid salts[8] in the frequencies and resonant behavior. Accordingly, it seems fairly probable that the solid lines have essentially the same origin as the present solution lines rather than the librational modes in the previous assignment[8]. This observation gives support to the formerly given suggestion that the structure unit of the crystal is the dimer[4].

(Received May 28, 1979)

The external magnetic field effects upon product yields in the singlet sensitized photolysis of dibenzoyl peroxide in toluene were studied. The observed field dependencies were classified into four types, and were interpreted in terms of the electronic Zeeman and hyperfine interactions in the intermediate radical pair. Especially large magnetic field effects were observed for the yields of dimethylbiphenyls, new products in this reaction.

Studies of external magnetic field effects upon intramolecular and intermolecular dynamical processes, have recently made much progress. New phenomena have been observed concerning intramolecular and intermolecular energy transfer[1] and also concerning chemical reactions[2-9] and their mechanisms have been clarified for some cases. Many problems, however, are still left unsolved in this field. The external magnetic field effect upon chemical reactions may be expected to be fruitful research field to be developed in future.

In a previous paper,[6] we first observed an external magnetic field effect upon the product yield of a photochemical reaction in solution, taking as an example the singlet sensitized photodecomposition reaction of dibenzoyl peroxide in the presence of magnetic field range, 1.0—4.3 T. We found the effect upon the yield of phenyl benzoate and interpreted the result in terms of the electronic Zeeman interaction in an intermediate radical pair. On the other hand, product yields and reaction intermediates for some other reactions through radical pairs have been found to be influenced by hyperfine interactions in low magnetic fields below 0.1 T.[7,8] Recently, we have published the theoretical study of external magnetic field effects on chemical reaction in solutions which occurs through radical pair formation,[10] and have classified them into three types.

In the present study, we have studied the photodecomposition reaction of dibenzoyl peroxide in the presence not only of high fields (4.3 and 6 T) but also of low fields below 78 mT. In the course of this study, we have found some new products and have succeeded in observing several different types of magnetic field effects on the product yields.[11]

Experimental

Toluene solutions (0.5 ml) of dibenzoyl peroxide (0.04 M) containing chrysene (0.002 M) as a singlet sensitizer[12] in Pyrex glass cells were degassed with the freeze-thaw technique, and were sealed under a nitrogen atmosphere. In the low magnetic field experiment below 78 mT the cells were placed in a hand-made coil which was cooled in a water bath, the temperature being kept 16.5±0.3 °C. The solution was irradiated with a 1 kW high pressure mercury lamp through a water filter and Pyrex glass. The decrease of dibenzoyl peroxide was monitored by iodometric titration of an aliquot and the half life under our experimental conditions was determined to be 11 min. Therefore the irradiation time was set to be 80 min in such a way that the dibenzoyl peroxide decomposed almost completely. In the high magnetic-field experiment, ternary solutions containing dibenzoyl peroxide and chrysene in toluene were irradiated in the presence of a magnetic field of 4.3 or 6 T induced by a superconducting magnet, and the details of the experiment were the same as described before.[6] The products were identified by GC-MS and VPC by comparing their retention times with those of the corresponding authentic samples. The yield, $P(H)$, of each product in the presence of an external magnetic field, H, was determined by VPC using 1,4-dicyanobenzene as an internal standard.

The viscosity dependence of the magnetic field effect upon the yield of phenyl benzoate was examined by changing the solvent viscosity. The viscosity was increased by the addition of polystyrene to the solvent. Polystyrene (Wako Pure Chemical Industries Ltd. polymerization degree 1600—1800) was purified by repeating twice precipitation from its toluene solution by methanol. The viscosity was measured by Ostwald's viscometer.

Results and Discussion

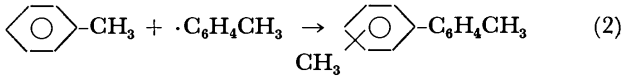
The singlet sensitized photolysis of dibenzoyl peroxide proceeds as follows:

$$\begin{aligned} &PhCO_2OCOPh^* \longrightarrow \\ &\quad \overline{PhCO_2\cdot + Ph\cdot} + CO_2 \longrightarrow \\ &\qquad \downarrow \qquad PhCO_2Ph \text{ (cage product)} + CO_2 \\ &PhCO_2\cdot + Ph\cdot \text{(escaping radicals)} + CO_2 \qquad (1) \\ &\qquad\qquad \downarrow \\ &\qquad\qquad \text{escape products} \end{aligned}$$

For this reaction in toluene, we identified 14 products the molecular weights of which are less than 212.[13] They are listed in Table 1 together with their yields. Among them *m,n'*-dimethylbiphenyls (**6**'s) were found in this study for the first time, although the others had already been detected.[14]

Phenyl benzoate (**2**) and biphenyl (**1**) are cage products[15] and the others in Table 1 are considered to be escape ones. From Table 1 we can see the following characteristic features of the yields of dimethylbiphenyls (**6**). Firstly, the dimethylbiphenyls with a methyl group on the 4-position are not observed. Secondly, the yield is larger for 3,3'-**6** than for 2,2'-**6** and 2,3'-**6**.

The simplest possible mechanism for the formation of dimethylbiphenyls in the present system is the tolylation of toluene which proceeds as follows;



(2)

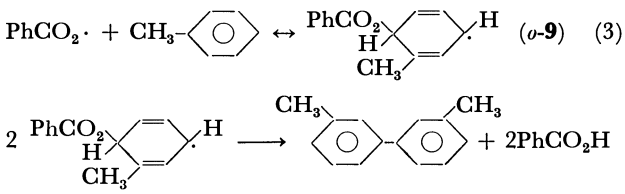
Table 1. Identified products and their yields in the presence of 0.3 mT

	Products	Yield[a)]
Cage products	biphenyl (**1**)	0.9
	phenyl benzoate (**2**)	11.6
Escape products	benzoic acid (**3**)	---[b)]
	o-methylbiphenyl (*o*-**4**)	6.4
	m-methylbiphenyl (*m*-**4**) *p*-methylbiphenyl (*p*-**4**) 1,2-diphenylethane (1,2-**5**)	18.9[c)]
	2,2′-dimethylbiphenyl (2,2′-**6**)	0.1
	2,3′-dimethylbiphenyl (2,3′-**6**)	0.8
	3,3′-dimethylbiphenyl (3,3′-**6**)	1.4
	o-tolyl benzoate (*o*-**7**)	2.6
	m-tolyl benzoate (*m*-**7**)	---[b)]
	p-tolyl benzoate (*p*-**7**)	---[b)]
	benzyl benzoate (**8**)	---[b)]

a) In mol% of dibenzoyl peroxide. b) --- indicates that their yields were not measured because of the incomplete separation between these compounds under our VPC conditions. c) Only the sum of the yields of these compounds was measured because they were not resolved from one another under our VPC conditions.

However, the partial rate factors (F_i) for this reaction determined by Ito *et al.*[16] ($F_o:F_m:F_p=3.3:1.0:1.3$) are completely different from the present results in Table 1. Thus the tolylation mechanism is disregarded.

Another possible mechanism for the formation of **6**'s is an assisted reaction[17] by $PhCO_2\cdot$ radicals. For example, 3,3′-**6** can be formed through (*o*-benzoyloxy)-methylcyclohexadienyl radical (*o*-**9**):



(*o*-**9**) (3)

The benzoyloxylation of toluene may preferably occur on the *o*-position through the hyperconjugation of the methyl group. The steric hindrance of the benzoyloxyl group is considered to disturb formation of the dimethylbiphenyls with a methyl group on the 4-position (2,4′-, 3,4′-, and 4,4′-dimethylbiphenyls). Thus, the assisted reaction scheme explains the observed yields of the dimethylbiphenyls. According to this mechanism, dimethylbiphenyls are escape products. This conclusion is also supported by the changes of the yields of dimethylbiphenyls due to dissolved oxygen and due to the excitation light intensity.[18]

From the magnetic field dependence of the measured $P(H)$ values listed in Table 1, the products can be classified into four groups.

[1] phenyl benzoate (**2**)

[2] 1,2-diphenylethane (1,2-**5**), *o*-, *m*-, and *p*-methylbiphenyls (*o*-, *m*-, and *p*-**4**'s) and biphenyl (**1**)

[3a] 2,2′-, 2,3′-, and 3,3′-dimethylbiphenyls (**6**'s)

[3b] *o*-tolyl benzoate (*o*-**7**)[19]

The observed relative change, $R(H)$, of the yield of the typical product in each group is plotted against log H in Fig. 1. Here $R(H)$ is defined

$$R(H) = [P(H)-P(0)]/P(0)$$

Here, $P(0)$ is the yield without an external magnetic field (in actuality, under the residual field (0.3 mT) of the magnets).

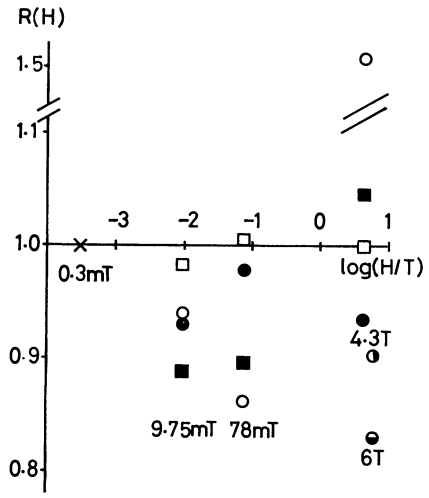


Fig. 1. $R(H)$-H plots in toluene and the viscosity dependence of R_2 (6 T): ● $R(H)$ for **2** (type 1); □ $R(H)$ for mixture of 1,2-**5**, *m*-**4**, and *p*-**4** (type 2); ○ $R(H)$ for 3,3′-**6** (type 3a); ■ $R(H)$ for *o*-**7** (type 3b); ◑ R_2 (6 T) for $\eta_r=3.6$; ◒ R_2 (6 T) for $\eta_r=8.8$. Here, $\eta_r=\eta_{solvent}/\eta_{toluene}$.

According to the theory of the external magnetic field effect on chemical reactions through a radical pair,[10] the field dependence of $P(H)$ for cage or escape products from Γ-precursors (Γ is singlet, triplet, or free radical) can be represented qualitatively as shown in Fig. 2.[20]

Case (a) in Fig. 2. can be applied to reactions in which the energy separation, $|2J|$, between the singlet, S, and triplet, T_m ($m=0, \pm1$), states of the intermediate radical pair is smaller than or comparable to the largest

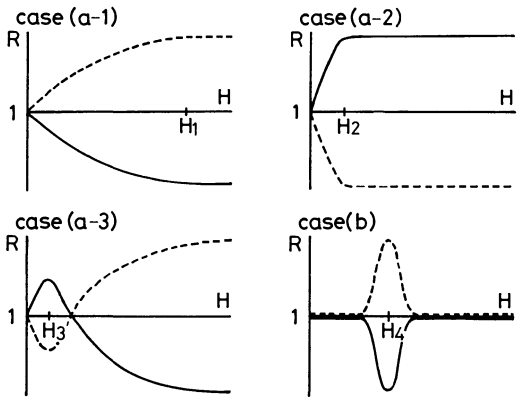

Fig. 2. Theoretical classifications of the magnetic field dependences on the product yields. The full curves indicate the magnetic field dependence of the cage (escape) product from a singlet (triplet or free radical) precursor; the broken curves indicate the magnetic field dependence of the escape (cage) product from a singlet (triplet or free radical) precursor. See text for H_1, H_2, H_3, and H_4.

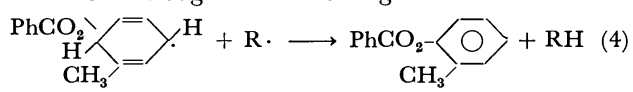
off-diagonal matrix element between S and T_m. Case (a) is further divided into three sub-groups according to the effective off-diagonal matrix elements: (a-1) electronic Zeeman interaction between S and T_0 (the first term in Eq. 2 of the previous paper[10]) is effective; (a-2) hyperfine interactions between S and T_m (the second and third terms in Eq. 2 and Eqs. 3 and 4 of the previous paper[10]) are effective; (a-3) both interactions are effective. Here we added a new situation (case (b)) which is applicable to reactions where $|2J|$ is larger than the largest off-diagonal matrix element.

Let us summarise the field dependence of $P(H)$ for the cage (escape) product from a singlet (triplet or free radical) precursor (full curves in Fig. 2). In case (a-1), $P(H)$ decreases with increasing magnetic field by the S-T_0 conversion through the electronic Zeeman term[10] and converges into a constant at a high magnetic field H_1. In case (a-2), $P(H)$ increases suddenly at a low field, H_2, and remains almost constant above H_2. In case (a-3), $P(H)$ first increases with the increasing magnetic field but begins to decrease from a fairly low magnetic field, H_3. In case (b), $P(H)$ suddenly decreases at a level-crossing field, $H_4=|2J|/(g\beta)$, through a sudden increase of the S-T_m ($m=1$ or -1) conversion in the radical pair.[2] Here g is the mean value of the isotropic g-factors of the component radicals. $P(H)$ for the cage (escape) product from a triplet or free radical (singlet) precursor can be represented as shown by the broken curves in Fig. 2.

Let us consider the $R(H)$ values observed in this study (Fig. 1) on the basis of the above-mentioned theoretical classification. We can see from Fig. 1 that $R(H)$ of **2** (group [1]) decreases with increasing magnetic field, and those of the products in group [2] are nearly constant independent of the applied field within the limits of experimental error. **2** is a cage product from the singlet radical pair containing Ph· and $PhCO_2$·, and the products in group [2] except for **1** are the escape products from the radical pairs shown in Eq. 1. The $R(H)$ values of **2**, *o*-**4**, *p*-**4**, and 1,2-**5** at the high field region, 1—4.3 T, were measured and analysed theoretically in the previous paper,[6] being classified to case (a-1). According to the present results at the low field region below 78 mT, no appreciable hyperfine effect (case (a-2)) could be detected for the products in groups [1] and [2]. Thus $R(H)$'s of **2** in the whole magnetic field region under the measurements are well explained in terms of the electronic Zeeman effect and **2** is regarded as one of the typical examples belonging to case (a-1).

1 is a cage product as **2**, but its $R(H)$ is independent of the applied field within the limits of experimental error. Thus **1** belongs to group [2]. The electronic Zeeman effect may be disregarded for this case because Δg is equal to zero for the radical pair containing the two phenyl radicals.

The $R(H)$ values of the products in groups [3a] and [3b] are smaller than 1.0 in the low field region and larger than 1.0 at the field of 4.3 T (Fig. 1). Actually $R_{3,3'\text{-}6}$ (78 mT) was determined to be as small as 0.86 and $R_{3,3'\text{-}6}$ (4.3 T) as large as 1.51. The latter is one of the largest external magnetic field effects upon the reaction yields observed so far. The above-mentioned field dependence of the $R(H)$ for the products of groups [3a] and [3b] clearly corresponds to the broken curve of case (a-3) in Fig. 2. Therefore they are regarded as escape products, since the present photodecomposition reaction occurs from the singlet precursor. This conclusion is supported by the following facts: (1) **6**'s are considered to be produced through dimerization of the **9** radical as is shown in Eq. 3. (2) According to Nakata *et al.*,[14] **7**'s are formed by the reaction between the **9** radical and the escaping (R·) radical. For example, *o*-**7** can be formed through the following reaction.



(4)

(3) The **9** radical is formed from the escaping benzoyloxyl radical as is shown in Eq. 3.

Thus, the magnetic field dependence of $R(H)$ for the products of groups [3a] and [3b] is explained in terms of the mixed effects of the electronic Zeeman and hyperfine interaction. Precisely speaking, the $R(H)$ value at 4.3 T is much smaller for *o*-**7** than for **6**'s, while in the low field region the values are similar to each other for *o*-**7** and **6**'s (see Fig. 1). This might be due to the fact that the yields of each **7** is proportional to the concentration of the corresponding(benzoyloxy)-methylcyclohexadienyl radical but that of *m*,*n*'-**6** is proportional to the product of the concentrations of *m*''- and *n*''-**9**.

We measured the viscosity dependence of $R(H)$ for **2**. The viscosity was increased by addition of polystyrene to the solvent (toluene). We can see from Fig. 1 that $R(6\text{ T})$ for **2** at $\eta_r=8.8$ was determined to be as small as 0.83, and the decrease in the yield of the cage product due to a magnetic field was proved to be enhanced by solvent viscosity.

The authors wish to express their sincere thanks to Prof. K. Tokumaru and Dr. H. Sakuragi, The University of Tsukuba and Prof. M. Yoshida, The University of Tokyo for helpful discussions and for supplying some of the authentic samples.

Picosecond Spectroscopy Studies of the Intersystem Crossing of Aromatic Carbonyl and Nitro Compounds in Solution

Hiroyuki OHTANI, Takayoshi KOBAYASHI,† Kaoru SUZUKI, and Saburo NAGAKURA*

Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo, 106

†*The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received July 16, 1979)

The build-up time constants of $T_n \leftarrow T_1$ transition bands were measured with 4-hydroxybenzophenone, Michler's ketone, 2-nitrofluorene, 1-nitropyrene, and 9-nitroanthracene in solution with the aid of picosecond spectroscopy. All the compounds exhibit fast build-up of the $T_n \leftarrow T_1$ absorption with the time constants smaller than 100 ps. The picosecond kinetics of these nonfluorescent compounds are interpreted in terms of the electronic structures of initial and final states relevant to radiationless transitions.

Aromatic carbonyl and nitro compounds are well known to be nonfluorescent.[1-3] Benzophenone exhibits strong phosphorescence, the quantum yield of the triplet formation being unity.[3] Therefore, the nonfluorescent property of benzophenone is caused by the fast S-T intersystem crossing. The quantum yields of the triplet formation are 0.63 and 0.83[4] for 1- and 2-nitronaphthalenes which are nonfluorescent and show weak phosphorescence, respectively.[2] Since the yield of fluorescence, $\Phi_F (=k_f/(k_f+k_{nr})$, $k_f=10^6$—$10^7\ s^{-1})$ is smaller than 10^{-4} for these molecules, the nonradiative rate constant, k_{nr}, is larger than $10^{10}\ s^{-1}$ and the nonradiative relaxation process occurs in the time scale of subnanosecond.

Nonradiative decay time constants of aromatic carbonyl compounds,[5-9] nitronaphthalene,[6] acridine,[10,11] and phenazine[10] have been measured so far by monitoring $T_n \leftarrow T_1$ absorption with picosecond time-resolved spectroscopy.

In a previous paper[7] we reported the intersystem crossing rate of anthrone and fluorenone. In anthrone the break-down of the El-Sayed rule was explained by the second order perturbation theory considering the vibronic interactions between appropriate states. In the present paper the nonradiative decay processes of excited singlet states have been studied for 4-hydroxybenzophenone, Michler's ketone (4,4'-bis(dimethylamino)benzophenone), 2-nitrofluorene, 1-nitropyrene, and 9-nitroanthracene.

Experimental

Picosecond Experiments. Figure 1 shows a picosecond time-resolved spectroscopy apparatus which is similar to the one described in the previous paper.[7] We used one OMA instead of two. The double-beam method[7,12] is effective for reducing deviations caused by the shot by shot change in spatial intensity distribution of the picosecond pulse. The frequency of a single pulse (694.3 nm, 30±3 ps pulse width, several giga watts) selected from a pulse train from a mode-locked ruby laser was doubled with a phase-matched ADP crystal. The frequency-doubled pulse (347.2 nm) was used for the excitation of samples through a pinhole (0.9 mm in diameter) of a sample cell holder. By passing the fundamental pulse through a phosphoric acid cell (20 mm in diameter, 100 mm in light path) a picosecond pulse of continuum light was generated. The pulse was divided into 14 pulses by an echelon with the time interval of 19.0 ps between the neighbouring pulses. These pulses were divided into two sets by a beam splitter.

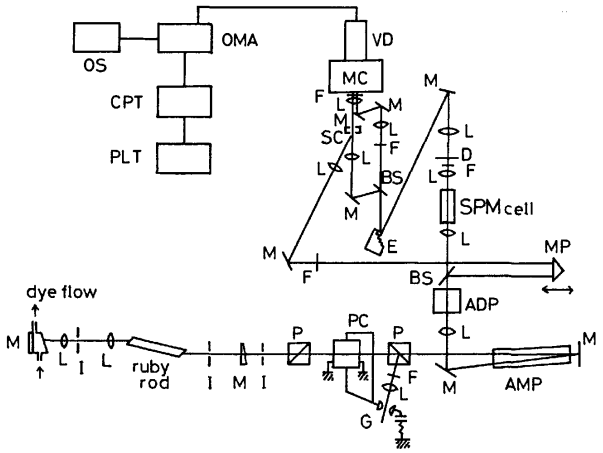

Fig. 1. The block diagram of the picosecond spectroscopy apparatus.
M: Mirror, L: lens, I: iris, P: polarizer, PC: Pockels cell, G: spark gap, BS: beam splitter, MP: movable prism, F: filter, SPM cell: self-phase modulation cell, D: diffuser, E: echelon, SC: sample cell, MC: monochromator, VD: vidicon, OMA: optical multichannel analyzer, OS: oscilloscope, CPT: computer, PLT: plotter.

One set passed through the Pyrex sample cell (light path 2.0 mm) and another set was used as reference. The observation wavelength was selected by a Shimadzu grating polychromator. Light intensities were detected by a vidicon head (PAR 1205 I) of an OMA (PAR 1205), digitized, and memorized in an OMA console (PAR 1205 A). The data were recorded in the digital cassette tapes and analyzed with a YHP 9825A desk-top computer. The results were printed out with the internal thermal printer of the computer or plotted with a YHP 9862A X-Y plotter.

Materials. 4-Hydroxybenzophenone (Tokyo Kasei), Michler's ketone (4,4'-bis(dimethylamino)benzophenone) (Tokyo Kasei), 2-nitrofluorene and 9-nitroanthracene (Aldrich) were purified by repeated recrystallizations and/or column chromatography. 1-Nitropyrene kindly supplied by Prof. T. Yamaoka, Chiba University was purified by repeated recrystallizations from ethanol. Ethanol (Wako, spectrograde) and benzene (Tokyo Kasei, UVIR grade) were used without further purification. Concentrations of samples were set in such ways that the absorbances at 337.1 nm were 1.0 in a 1 mm cell for nanosecond time-resolved spectroscopy experiments and those at 347.2 nm were at least 1.5 in a 1 mm cell for picosecond time-resolved spectroscopy experiments.

Results

Nanosecond Time-resolved Spectroscopy Experiments. Since the $T_n \leftarrow T_1$ spectra of 2-nitrofluorene, 9-nitroanthracene and Michler's ketone in benzene have never been reported, we measured their spectra with the nanosecond apparatus.[7] The strong absorption of Michler's ketone was observed between 420 nm and 600 nm in benzene solution. 2-Nitrofluorene exhibits strong absorption between 400 nm and 650 nm with a peak at 510—550 nm. The $T_n \leftarrow T_1$ absorption spectrum of 9-nitroanthracene resembles that of anthracene. All these transient absorption are assigned to $T_n \leftarrow T_1$ transitions, since the transient species are quenched by oxygen.

Picosecond Time-resolved Spectroscopy Experiments. Figures 2—6 show the time dependence of the $T_n \leftarrow T_1$ absorption intensity. Data of 7—14 shots are averaged for each point. Error bars in these figures represent standard deviations. The time constants were determined by the computer simulation on the assumptions described below. Before the measurement of the build-up of the $T_n \leftarrow T_1$ absorption of each sample we observed the build-up of the $S_n \leftarrow S_1$ absorption of coronene to determine the time resolution of the apparatus under the same monitoring wavelength and optical allignment. With the aid of formulas (1) and (2) we made computer simulation to determine the pulse width of the light source and the arrival time difference between the excitation pulse and the monitoring pulse train:

$$A(t) = -\log\left[\int_{-\infty}^{\infty} I(t-t')10^{-S(t')}\mathrm{d}t' \Big/ \int_{-\infty}^{\infty} I(t-t')\mathrm{d}t'\right] \quad (1)$$

$$S(t') = \Delta S \int_{-\infty}^{t'} I_{ex}(t''-t_0)\mathrm{d}t''$$

$$= \Delta S \int_{-\infty}^{t'} \frac{1}{\sqrt{\pi}G} e^{-(t''-t_0)^2/G^2}\mathrm{d}t'' \quad (2)$$

Here $A(t)$ is the absorbance for the $S_n \leftarrow S_1$ transition of coronene at time t, $I(t-t')$ is the monitoring pulse intensity at time t' which has the maximum at time t, ΔS is an experimentally determined parameter corresponding to the absorbance for the $S_n \leftarrow S_1$ transition of coronene at $t=\infty$, and $I_{ex}(t''-t_0)$ is the excitation pulse intensity at time t'' which has the maximum at time t_0. We assumed that excitation and monitoring pulses are gaussian and have the same pulse width (fwhm is $2 \ln G$). The time constant of the build-up of the $T_n \leftarrow T_1$ absorption (τ) and the contribution of $S_n \leftarrow S_1$ absorption (W) were obtained by the simulation of $A(t)$ to the observed curve by formulas (3) and (4),

$$A(t) = -\log\left[\int_{-\infty}^{\infty} I(t'-t)10^{-T(t')}\mathrm{d}t' \Big/ \int_{-\infty}^{\infty} I(t'-t)\mathrm{d}t'\right] \quad (3)$$

$$T(t') = \Delta A \int_{-\infty}^{t'} I_{ex}(t''-t_0)[W+(1-W)(1-e^{-(t-t'')/\tau})]\mathrm{d}t'' \quad (4)$$

where $T(t')$ is the transient absorption at time t' and consists of the $S_n \leftarrow S_1$ absorption and $T_n \leftarrow T_1$ absorption at the monitoring wavelength and ΔA is an experimentally determined parameter corresponding to the absorption for the transient absorption at $t=\infty$. The best-fit curve for each sample is shown in Figs. 2—6. The $T_n \leftarrow T_1$ build-up time constants thus determined are tabulated in Table 1. Error limits of

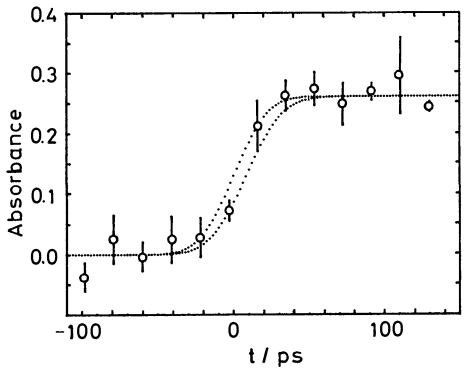

Fig. 2. Kinetics of $T_n \leftarrow T_1$ absorption at 550 nm for 4-hydroxybenzophenone in benzene. The time constants are 0 ps for •••• (upper) and 8 ps for •••• (lower).
The fraction of $S_n \leftarrow S_1$ absorption (W) is 0.0.

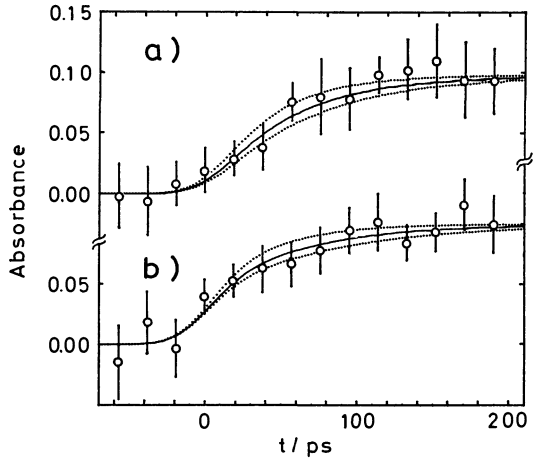

Fig. 6. Kinetics of $T_n \leftarrow T_1$ absorption for 9-nitroanthracene in benzene: a) observed at 450 nm where the $T_n \leftarrow T_1$ absorption is strong but the probing light intensity is reduced by the $S_1 \leftarrow S_0$ absorption tail: b) observed at 490 nm where the $T_n \leftarrow T_1$ absorption is weak the $S_1 \leftarrow S_0$ absorption intensity is negligibly small.
The time constants are 37 ps for •••• (upper), 50 ps for —, and 63 ps for •••• (lower) in a); 38 ps for •••• (upper), 58 ps for —, and 78 ps for •••• (lower) in b). The W value is 0.4 for both a) and b).

the time constants were determined in the following way. Simulation curves for the total absorbance of $T_n \leftarrow T_1$ and $S_n \leftarrow S_1$ absorptions were obtained with various build-up time constants of the triplet formation. The determined $\Delta\tau$ is the maximum of $\delta\tau$ which satisfies the following conditions; at least one of the two simulated curves with the time constants of $\tau+\delta\tau$ and $\tau-\delta\tau$ crosses all the error bars of absorbances at the respective steps of the echelon in the build-up part of the observed rising curves.

Discussion

The rate of the intersystem crossing depends on the matrix elements of the spin-orbit interaction between initial and final states. The selection rules for the radiationless transitions between electronic states with different spin-multiplicities were derived by El-Sayed.[13] The El-Sayed rule is applicable to the intersystem crossing process of many organic compounds. The break-down of this rule, however, has been observed for some cases: for example, benzophenone[14] and 9,10-diazaphenanthrene.[15] In the following we discuss the observed intersystem crossing rates in terms of the electronic structures of initial and final states relevant to the intersystem crossing.

Table 1. $T_n \leftarrow T_1$ build-up time constants at 347.2 nm excitation (room temperature)

Molecule	Solvent	λ_{obsd} / nm	τ [a] / ps	
			This work	Other authors
4-Hydroxy-benzophenone	Benzene	550	<8	
Michler's ketone	Benzene	550	18±8	
	Ethanol	550	18±8	
1-Nitronaphthalene	Benzene	533	—	12±5[b]
2-Nitronaphthalene	Benzene	533	—	10±2[b]
2-Nitrofluorene	Benzene	520	45±15	
1-Nitropyrene	Benzene	520	33±13	
9-Nitroanthracene	Benzene	450	50±13	
	Benzene	490	58±20	

a) τ is the $T_n \leftarrow T_1$ build-up time constant. b) λ_{ex} = 355 nm, λ_{obsd} = 533 nm.[6]

Aromatic Carbonyl Compounds. The intersystem crossing is a dominant deactivation process for benzophenone and 4-hydroxybenzophenone because its quantum yield, Φ_{ISC}, is unity and 0.9 for the former and the latter, respectively.[16] As for Michler's ketone, Φ_{ISC} is large in benzene (1.0) but small in ethanol (0.08).[17]

The $T_n \leftarrow T_1$ build-up time constant of benzophenone has been observed by several authors.[5,6,9] Recently, Hochstrasser and collaborators determined the value to be 12±2 ps in the benzene solution.[18] In the present study the $T_n \leftarrow T_1$ build-up time constant of 4-hydroxybenzophenone was found to be smaller than that of benzophenone, although the value was smaller than the time resolution of our apparatus. The energy level diagram of 4-hydroxybenzophenone is similar to that of benzophenone[19–23] and the lowest excited singlet state and the lowest triplet state have the n-π^* characters for both compounds. Therefore, 4-hydroxybenzophenone is another example deviating from the El-Sayed rule for the intersystem crossing rate. Its fast intersystem crossing may be explained, as in the cases of benzophenone and anthrone,[7] by the second order perturbation theory which considers vibronic couplings between the S_1 and S_2 states and also between the T_1 and T_2 states.[24,25]

The energy level diagram of Michler's ketone[26] in ethanol and in benzene are shown in Fig. 7; the diagram for the benzene solution is assumed to be the same as in hexane.[26] Since the yield of triplet formation is unity for Michler's ketone in benzene,[17] the observed time constant (18 ps) corresponds to the intersystem crossing rate constant. From the El-Sayed rule, we can expect the large spin-orbit coupling and the fast intersystem crossing for Michler's ketone in benzene,

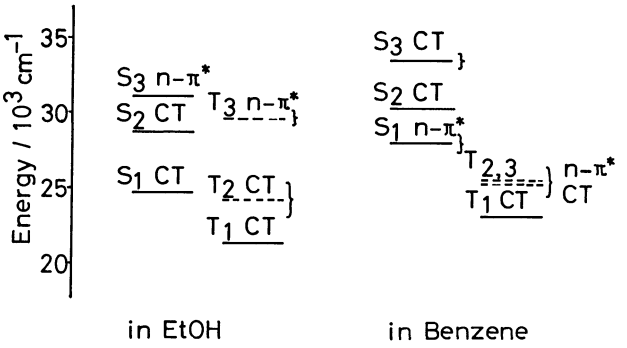

Fig. 7. Energy level diagrams of Michler's ketone in benzene and in ethanol.

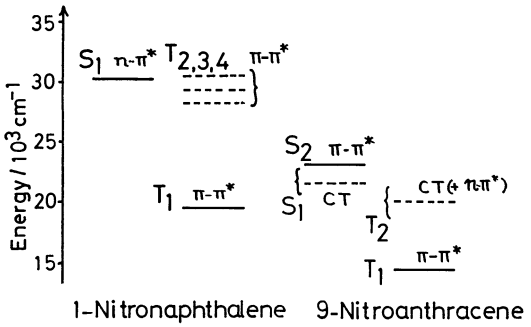

Fig. 8. Energy level diagrams of 1-nitronaphthalene and 9-nitroanthracene.
a) 1-Nitronaphthalene: S_1, determined from the absorption spectrum,[31] the triplet (π-π^*) states near S_1, estimated by the CNDO-CI calculation;[31] T_1 determined from the phosphorescence spectrum.[1,2]
b) 9-Nitroanthracene: S_1 and S_2, determined from the absorption spectrum.[32] The triplet state, determined from the $T \leftarrow S_0$ absorption spectrum.[33]
——: Experimentally determined level, ----: calculated level.

since the initial state is S_1(n-π^*) the final state is T_2 (CT).

Concerning Michler's ketone in ethanol the yield of triplet formation is 0.08[17] and the quantum yield of the photochemical reaction is below 10^{-4}.[17] This means that for this case the internal conversion to the ground state (S_0) is a main decay process of the lowest excited singlet state (S_1). The time constant of the intersystem crossing (k_{ISC}^{-1}) and that of the internal conversion (k_{IC}^{-1}) were determined to be 225 ps and 19 ps, respectively, by the use of the observed rate constant, $\tau^{-1}(=k_{IC}+k_{ISC})$ and the yield of triplet formation, $\Phi_T(=0.08)$.[17] The time constant of the intersystem crossing in ethanol (225 ps) is greater than that for benzene solution (18 ps). This fact is understandable, since the initial and final states are both of CT character in the ethanol solution (Fig. 7).

The rapid $S_1 \rightarrow S_0$ internal conversion (19 ps) of Michler's ketone in ethanol may be interpreted in terms of the proton transfer; the hydrogen bond is formed between Michler's ketone and ethanol in the ground state and the equilibrium position of hydrogen is changed in the excited state. Recently the proton-induced enhancement of the intersystem crossing[27] and the fluorescence quenching by proton transfer have been reported.[28,29]

Aromatic Nitro Compounds. The quantum yields of triplet formation are high for aromatic nitro compounds: 0.63 for 1-nitronaphthalene,[4] 0.83 for 2-nitronaphthalene,[4] and 0.6 for 1-nitropyrene.[30] These compounds exhibit strong $T_n \leftarrow T_1$ absorption. Therefore, the intersystem crossing is the important decay process of their singlet states. In aromatic nitro compounds the position of the CT state among other electronic states determines the rate of the intersystem crossing. Figure 8 shows the energy level diagrams of 1-nitronaphthalene[1,2,31] and 9-nitroanthracene.[1,2,32,33] Anderson *et al.*[6] reported the $T_n \leftarrow T_1$ build-up time constants of 1- and 2-nitronaphthalenes. Time constants of 1-nitronaphthalene in benzene and in ethanol are 10 ps and 12 ps, respectively. Using the quantum yields of triplet formation the time constants of the intersystem crossing for 1- and 2-nitronaphthalenes were determined to be 15.9 ps and 14.5 ps, respectively. Mikula *et al.*[31] calculated transition energies of 1-nitronaphthalene and reported that two π-π^* states and an n-π^* state are located 26300—37700 cm^{-1} corresponding to absorption band. The initial state of the intersystem crossing is the ^{1}n-π^*[2] state and the final state is the $^3\pi$-π^* states nearby.[31] The effective intersystem crossing causes the rapid build-up of the $T_n \leftarrow T_1$ absorption.

The ionization potential of naphthalene is 8.15 eV[34] and the CT state of 1-nitronaphthalene lies in the higher energy region. The CT state of 9-nitroanthracene lies under the ^{1}n-π^* states because the ionization potential of anthracene (7.47 eV)[35] is smaller than that of naphthalene. Thus the initial state of the intersystem crossing of 9-nitroanthracene is S_1(CT) and its final state is ^{3}CT or $^3\pi$-π^*. Since the yield of triplet formation may be less than unity for 9-nitroanthracene, the time constant of the intersystem crossing, k_{ISC}^{-1} is larger than the $T_n \leftarrow T_1$ build-up time constant, 50 ps. This time constant is larger than that of 1-nitronaphthalene and is reasonable for the intersystem crossing from ^{1}CT to $^3\pi$-π^* or ^{3}CT.

2-Nitrofluorene and 1-nitropyrene may be assumed to be intermediate cases between 1-nitronaphthalene and 9-nitroanthracene, since the ionization potentials of fluorene and pyrene (7.93 eV[36] and 7.53 eV,[37] respectively) lie between those of naphthalene and anthracene. The observed $T_n \leftarrow T_1$ build-up time constants of 2-nitrofluorene and 1-nitropyrene fall in between those of 1-nitronaphthalene and 9-nitroanthracene.

The authors wish to thank Professor Tsuguo Yamaoka, Chiba University for his kind gift of 1-nitropyrene.

Ab Initio Calculation of Force Constants of Hydroxylamine

Yoshiaki HAMADA, Masamichi TSUBOI,* and Hideaki UMEYAMA**

Faculty of Pharmaceutical Sciences, The University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo 113

(Received June 7, 1979)

Ab initio molecular orbital calculation has been applied to hydroxylamine molecule to reach a reliable set of force constants by the use of the 4-31G basis set. This approach was found to be an enlightening way to solve a problem of the so far undeterminable amino twisting frequency. For this, the value of 1250 ± 100 cm^{-1} was estimated. A few comments are also given on the theoretical and experimental values of force constants.

The amino group $-NH_2$ has three bending vibrational modes. They are scissoring, wagging, and twisting modes. The vibrational frequecies of the scissoring and wagging modes have been conclusively fixed in most of the primary amines. Figure 1 shows the established bending frequencies and approximate vibrational modes for three representative molecules. These are ammonia derivatives in each of which one of the hydrogen atoms is replaced by methyl, amino, or hydroxyl group. As are indicated in the figure, the twisting frequencies of methylamine and hydroxylamine have not been determined. In the twisting vibration, two XNH angles open and close alternately. Therefore, as long as the two NH bonds are equivalent to each other this vibration causes almost no change in the dipole moment, and only very weak absorption in the infrared spectrum. The twisiting modes of hydrazine give exceptionally strong absorptions, probably because the two NH bonds are not equivalent in this molecule.[1]

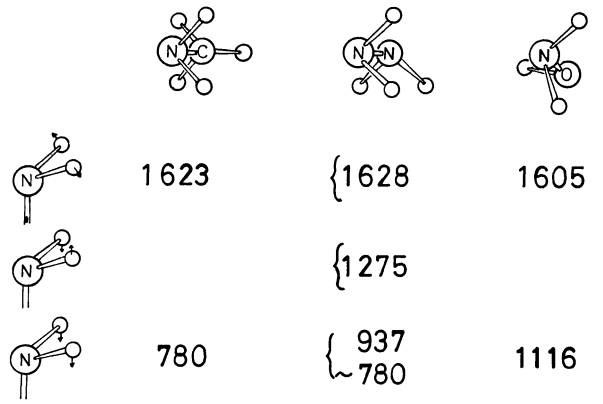

Fig. 1. Amino-scissoring, twisting, and wagging frequencies in cm^{-1}. Small circles indicate hydrogen atoms.

The weakness of the twisting bands of methylamine and hydroxylamine is one of the causes of a long-term debate[2–5] on the twisting frequency, whether it is in the vicinity of 1300 cm^{-1} or below 1000 cm^{-1}. Although there have been many normal coordinate treatments on the variety of assumptions, the results were not yet satisfactory. The off-diagonal elements of the potential energy matrix **F** for the XNH bending coordinates have never been determined on the basis of the experimental data. The infrared spectrum of hydroxylamine in gas phase was first observed by Giguere and Liu in 1952.[6] They assigned the perpendicular type band at 750 cm^{-1} to the amino twisting mode. However this band was shown later to be the first overtone of torsional vibration at 390 cm^{-1}.[7] Thus, the amino twisting frequency is now yet to be established.

The purpose of the present work is to fix the amino twisting frequency of hydroxylamine on the basis of *ab initio* molecular orbital calculation by the use of the 4-31 G basis set.[8]

Much effort has been made to obtain the meaningful set of force constants through various applications of molecular orbital theory. Unfortunately the semiempirical method such as the CNDO/2 method[9] has given the values two to three times as great as the experimental ones, and was scarcely fit for practical purpose, except for a work of estimating an order of magnitude of a vibrational frequency.[10] *Ab initio* molecular orbital calculations, on the other hand, have recently proved to be more reliable in estimating force constants of some small molecules. Particularly the "force method" developed by Pulay[11] seems to be the most useful in terms of both precision and computing time. The examples of its application are nicely reviewed by Duncan.[12]

Calculations of force constants using the 4-31 G basis set have been done by Bernhard-Schlegel *et al.*[13] The estimated error of the diagonal elements of stretching force constants is about 6%, and that of bending force constants is about 15% when the bonds involve hydrogen and second- or third-row elements. This means that the errors in frequencies are 3 and 8% for stretching and bending modes, respectively. In general, an advantage of application of *ab initio* calculation to a force field problem is that we can estimate the off-diagonal elements with the same precision as that for the diagonal elements. By experimental ways, off-diagonal elements of **F** matrix are often hard to evaluate even for small molecules.

Calculation

In this study, we used the 4-31 G split valence shell basis set in the Gaussian 70 program system.[14] The calculations were performed with a HITAC 8700/8800 in the computer center, University of Tokyo.

The internal coordinates are defined as shown in Fig. 2. There are six A′ modes and three A″ modes.

Starting from the experimental values determined by microwave spectroscopy,[15] one of the six internal coordinates belonging to the A′ symmetry species was changed, and we find the optimized point to

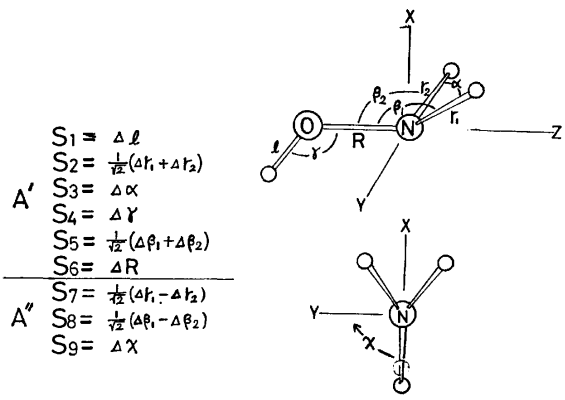

Fig. 2. Denotations of the bond lengths, bond angles, and internal rotation angle (χ); and definitions of symmetry coordinates **S** for the hydroxylamine molecule.

minimize the total energy. This procedure was repeated stepwise for other five coordinates to reach a calculated equilibrium structure (Process I).

From the process of geometry optimization we can estimate approximate values of diagonal force constants. To obtain off-diagonal force constants (or coupling constants), we need to calculate total energies at various combinations of six internal coordinates in question. A special attention was paid to have important coupling constants determined effectively (Process II).

Totally 77 sets of coordinates were chosen. Among them, the maximum deviations were ±0.04 Å in the bond lengths, and ±5° in the bond angles from the calculated equilibrium geometry. The 77 values of the total energy were used to obtain, by the least squares fit, the elements F_{ij} of the potential energy matrix in the expression,

$$V = V_0 + \sum_{i,j} \frac{1}{2} F_{ij}(R_i - R_i^0)(R_j - R_j^0), \qquad (1)$$

where R are internal coordinates (for which the total energy was calculated) and R^0 are those for the equilibrium geometry. By this procedure, we can obtain the minimum total energy (V_0), 6 parameters (R_j^0) of the "final" equilibrium geometry, and 21 force constants (F_{ij}) belonging to the A′ symmetry species.

A few comments will now be given below on the results of the calculations, so far described.

1) The total energy −130.791865(9) Hartrees at the equilibrium geometry is less than −130.78729 Hartrees obtained by Radom *et al.*[16] using the same computing program. This means that our optimization is better than theirs. (The figure given in the parenthesis gives the standard deviation in the unit corresponding to the last significant figures).

2) As shown in Table 1, the equilibrium geometry calculated by Process I is significantly different from that calculated by Process II. In the Process I, only one coordinate is changed with others fixed in finding the coordinate value that gives energy minimum. In the Process II, on the other hand, several coordinates are changed simultaneously with a proper assumption

Table 1. Equilibrium geometry of the NH_2OH molecule

	Calculated		Observed(r_0)
	Process I	Process II	
NO	1.4636(Å)	1.4432(4)[a]	1.453(2)[a]
OH	0.9528	0.9519(3)	0.962(5)

∠ONH	105.2	105.84(2)	103.25(50)

a) The figure in the parenthesis gives 1σ (standard deviation) in the unit corresponding to the last significant figure.

on the coupling among the coordinates. Probably, the most reliable geometry is reached by repeating the Process I in a systematic manner, but this will take a great amount of computer time.

3) The optimized structural parameters (Table 1) are found to be within the stated precision.[17,18] It should be realized that the calculated geometry is that for equilibrium or the geometry in which the total energy is minimized, while the experimental set of values determined by microwave spectroscopy, for example, are often that for vibrational ground state and for $J=K=0$ level. The former corresponds to the so-called r_e-structure, while the latter r_0-structure. Table 2 gives some examples, showing the differences of r_e- and r_0-structures. Taking probale differences between the r_e and r_0 structures of NH_2OH into account, it may be concluded that our *ab initio* calculations could reproduce the bond lengths quite satisfactorily, but the calculated bond angles are all larger than the experimental angles by about 5°.

Next, the internal symmetry coordinates belonging to the A″ symmetry species were subjected to our examination. After the equilibrium coordinates were determined, the three A″ internal coordinates were changed within the range of distortion where anharmonicities do not become influential. Six force constants were obtained from 15 data sets in a similar way to those of the A′ symmetry species.

Force Constants and Normal Frequencies

Table 3 shows the force constants obtained for the two symmetry species. Some off-diagonal elements are not found to be determinable from our 77 sets. All of these, however, are taken to be actually very small judged from their physical meanings. The coupling constant between S_3 and S_5 has been found to be as small as -0.03×10^{-11} dyne cm. The corresponding off-diagonal element of methylamine was once estimated to be as big as 0.123×10^{-11} dyne cm[2] (see Table 4). This should now be revised; an *ab initio* study on methylamine by Pulay and Török[19] also gave a very small value to this off-diagonal element.

In the process of experimental force-constant determination, the definitions of non-totally symmetrical coordinates are sometimes ambiguous. Particularly the physical meanings of off-diagonal elements and their signs are not usually the subject of investigation. On the other hand, in the case of calculation using molecular orbital theory as in this study, the definitions of coordinates and related force constants with their signs are determined unambiguously in principle. This is another merit of such a theoretical study.

The calculated normal frequencies, ω, are shown in Table 5, where experimental geometry was used to calculate **G**-matrix (inverse kinetic energy matrix). We have no data of experimental normal frequencies to compare, except for torsional oscillation. Here a rather nice agreement has been obtained, *i.e.* $\omega_{obsd}=407$ cm^{-1} [7] while $\omega_{calcd}=457$ cm^{-1}.

In comparing the observed and calculated frequencies, the frequency difference between the normal and fundamental frequencies, which is caused by anharmonicity, should be taken into account. For a correction, Pulay & Török[19] reduced 10% of diagonal stretching force constants and 20% of diagonal bending force constants, with off-diagonal force constants fixed. With this correction to include the anharmonicity effectively, they reproduced the observed frequencies within the deviation of 40 cm^{-1} for the fundamental frequencies below 2000 cm^{-1}. We adopted the same empirical way in changing the calculated normal frequencies into "calculated fundamental frequencies." The results are given in Table 5 (see also Table 4).

NH_2 stretching and wagging have deviations as much as 100—200 cm^{-1}. The anharmonicity for the former might be underestimated, and that for the latter overestimated. These discrepancies may be removed by including polarization functions and or by configura-

tion interaction calculation.

Now we can predict the twisting frequency in question. Estimating the maximum error, we predict that the frequency should be 1250±100 cm^{-1}. Giguére and Liu[6] observed, in their IR spectrum, a weak absorption at 1297 cm^{-1} on the shoulder of the OH bending band centered at 1350 cm^{-1}. They assigned this to $\nu_6+\nu_9$ combination band. In a solid state spectrum, a very weak absorption at 1287 cm^{-1} was assigned to $\nu_8+\nu_9$. It is possible, however, to assign these to the twisting mode. An *ab initio* MO study on methylamine by Pulay and Török[19] shows that NH_2 twisting mode and CH_3 rocking mode are so severely coupled to give positive combination of the two modes at 1335 cm^{-1}, and negative combination somewhere in the 880—1000 cm^{-1} region, with uncoupled original position around 1170 cm^{-1}. Therefore it is now certain that NH_2 twisting mode contributes to a band in the region of 1300 cm^{-1}.

The first order centrifugal distortion constants directly reflect the harmonic force field, and these were also calculated in our present study. The results are shown in Table 6. The most of the calculated values are in agreement with the experimental values at least in the order of magnitude.

a) Procedure II.

Dipole Moment Derivatives

The intensity of infrared fundamental band is represented by the formula,

$$A_i = \frac{N\pi g_i}{3c^2}\left|\frac{\partial^2 P}{\partial Q_i^2}\right|^2 \qquad (2)$$

where N is Avogadro's number, g_i the degeneracy of the i-th normal vibration, c the light velocity, P the dipole moment, and Q_i the normal coordinate of the i-th normal vibration. Therefore, $(\partial^2 P/\partial Q_i^2)^2$ is the experimentally determinable value. To investigate the physical meaning of the intensity we need to know $\partial P/\partial R_i$ which is related to $\partial P/\partial Q_i$ by the following formula,

$$\frac{\partial P}{\partial R_j} = \sum_i \left(\frac{\partial P}{\partial Q_i}\right) L_{ij}^{-1}, \qquad (3)$$

where $\boldsymbol{L}$ is the transformation matrix between internal (symmetry) coordinate R and normal coordinate Q, and can be obtained accurately when the vibrational analysis is completed.

Since it is difficult to determine the sign of $\partial P/\partial Q_i$ experimentally, and there is in general some ambiguity in the values of the off-diagonal elements $\boldsymbol{L}_{ij}$, the determination of the size of dipole moment derivative $\partial P/\partial R_j$ and its sign by *ab initio* calculations would have some significance. For example, near-Hartree-Fock calculation on NH_3[20] and CH_4[21] by Meyer and Pulay gave satisfactory results determining a set of signs of dipole moment derivatives. They stated that the dipole moment derivatives by *ab initio* calculations for bending coordinates are fairly stable for the choise of basis set, and estimated error is 20—30%.

7(NH_2 str.)	0.012(12)	−0.005(6)	0.268(5)	0.006(7)
8(NH_2 twist.)	0.017(6)	−0.005(3)	0.088(3)	0.012(4)
9(torsion)	0.011(8)	−0.015(4)	−1.195(4)	−0.004(5)

We present our results on NH_2OH in Tables 7 and 8. The dipole moment μ at various sets of coordinates were calculated, and by the use of an equation,

$$\mu = \mu_0 + \sum_i \left(\frac{\partial\mu}{\partial S_i}\right)\Delta S_i + \frac{1}{2}\sum_{i,j}\left(\frac{\partial^2\mu}{\partial S_i \partial S_j}\right)\Delta S_i \Delta S_j, \qquad (4)$$

the values of μ_0, $\partial\mu/\partial S_i$, and $\partial^2\mu/\partial S_i\partial S_j$ were determined by a least squares fit. The third term, with the second derivatives, was included (see Table 8) because some of them were determinable from our data set. The x, y, z axes were defined as in Fig. 2.

Strong intensities of OH bending and NH_2 wagging bands are obvious, and almost no intensity for NH_2 twisting is just as expected. It would be worthwhile to give the following two comments here:

1) The derivatives of the dipole components $\partial\mu_x/\partial S_i$, $\partial\mu_y/\partial S_i$,····· can be used to determine the band type —parallel or perpendicular—of each fundamental band, or, if it is a hybrid band, to determine the amount of contribution from each type.

2) When the amplitude of a stretching mode is set greater than 10^{-2} Å, the contribution from the second derivative is found to be appreciable. This can be accurate up to a few percent. This would allow us to estimate an intensity of some overtone and combination bands. To an intensity factor of overtone or combination transitions, the electrical anharmonicity (second derivative of dipole moment) and mechanical anharmonicity (anharmonicity of potential surface) are possible to contribute. So far,

TABLE 8. EXAMPLES OF SECOND DERIVATIVES OF DIPOLE MOMENT

$\frac{1}{2}\partial^2\mu_x/\partial S_i\partial S_j$

Light Scattering Study of Local Structure in Solutions. Importance of Temperature Dependency Measurements

Tadashi KATO, Katsuaki YANO, and Tsunetake FUJIYAMA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received June 26, 1979)

Light scattering spectra have been observed for binary solutions of acetic acid and carbon tetrachloride at several concentrations and temperatures. The Rayleigh intensities were reduced to concentration fluctuations. The observed concentration and temperature dependencies of concentration fluctuation were interpreted by assuming association equilibria involving both cyclic dimers and linear polymers. The simultaneous measurement of concentration and temperature dependencies of concentration fluctuation are necessary to determine local structures in solutions where different types of local structure coexist.

The local fluctuation of concentration can aid understanding the mixing of liquids from the molecular viewpoint. Based on this, studies on the temperature and concentration dependencies of concentration fluctuation through observations of light scattering spectra have been initiated.[1]

The relationship between concentration fluctuation and Rayleigh intensities have been theoretically established[2] and a method proposed for determining the local structures[3] existing in associated solutions from observed concentration fluctuation.[4,5] The validity of the method has been checked for the diethyl ether–chloroform system in which local structures of the (A-B)type (A and B represent diethyl ether and chloroform molecules, respectively) are expected. The method has been extended to the systems in which several types of local structures are formed. The use of infrared and light scattering spectra is complementary and useful to determine local structures for the system in which local structures of the A_l and A_lB types are expected (A_l represents an aggregate which is made up of l molecules of A, and A_lB represents an aggregate which is made up of l molecules of A and one molecule of B). The simultaneous use of microscopic and macroscopic information is necessary to understand the state of mixing in solutions. In certain cases, however, microscopic information such as infrared spectra cannot be obtained for solutions, particularly at high concentration.

In the present report, it will be shown that the simultaneous measurement of concentration and temperature dependnecies of concentration fluctuation can determine local structures in solutions where different types of local structures coexist. The acetic acid–carbon tetrachloride system was chosen because acetic acid molecules have been known to form both cyclic dimers and linear polymers in nonpolar solvents.[7]

Experimental

Light scattering spectra were observed at 22.5, 37, and 51 °C using a spectrometer designed and constructed in this laboratory.[1] The spectrometer is composed of a He–Ne gas laser source (NEC, GLG 108) and a pressure scanning Fabry-Perot interferometer. The temperature of the samples was controlled by a high temperature cell developed in this laboratory. A temperature constancy of ±0.1 °C was obtained with the apparatus. The refractive indicies of the samples were measured by an Abbe refractometer (Atago).

The samples used in the present study were commercial products and used without further purification. The binary solution of acetic acid and carbon tetrachloride was made dust-free by the use of a milipore filter FG of 0.2 μm pore size.

Results and Discussion

Light Scattering Spectra and Concentration Fluctuation. Figure 1 illustrates the observed light scattering spectra for the acetic acid–carbon tetrachloride system at 22.5 °C. After separating the Rayleigh part from the observed spectra, the Rayleigh intensity was expressed relative to the Rayleigh intensity of pure carbon tetrachloride. The concentration fluctuation, $N\langle(\Delta X_A)^2\rangle$, was calculated from the relation,[2]

$$N\langle(\Delta X_A)^2\rangle = \frac{N_A\rho}{M}\left(\frac{\lambda^4}{\pi^2}\right)\frac{1}{4n^2\left(\frac{\partial n}{\partial X_A}\right)^2}\{(R_{90})_R-(R_{90})_S\},$$

where N is the total number of molecules included in the field within which the concentration fluctuation is considered, N_A the Avogadro number, M the mean molecular weight, n the refractive index, ρ the density, λ the wavelength of the incident light, X_A the mole fraction of acetic acid, and $(R_{90})_R$ the Rayleigh ratio for a Rayleigh line. $(R_{90})_S$ is the Rayleigh ratio for entropy fluctuation and is expressed by the relationship:

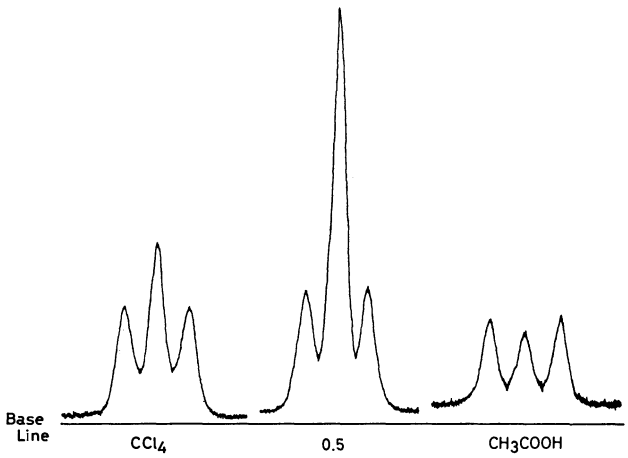

Fig. 1. Observed light scattering spectra for acetic acid-carbon tetrachloride system at 22.5 °C. Concentration is expressed in terms of mole fraction of acetic acid.

$$(R_{90})_S = \frac{\pi^2}{\lambda^4}\frac{4kn^2T^2}{C_{p_g}}\left(\frac{\partial n}{\partial T}\right)^2,$$

where k is the Boltzmann's constant, T the absolute temperature and C_{p_g} the isobaric heat capacity per gram. The values of $(R_{90})_S$ at each mole fraction were calculated from the physical quantities observed or obtained from the literature.[8]

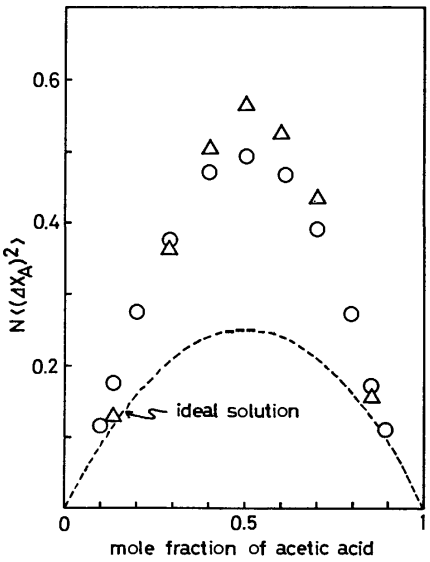

Fig. 2. Observed concentration fluctuation for acetic acid–carbon tetrachloride system at different temperatures: (○) 22.5 °C, (△) 51 °C.

In Fig. 2, the concentration fluctuations thus obtained are plotted against the mole fraction of acetic acid for different temperatures. The dashed line in Fig. 2 corresponds to the concentration fluctuation expected for an ideal solution. It is seen from the figure that the observed concentration fluctuation is larger than that of an ideal solution at all concentrations and the magnitude of concentration fluctuation increases with increasing temperature.

Analysis of Concentration Fluctuation. The method for determining local structures from the observed concentration fluctuation has been reported elsewhere.[4-6] In this method, an ideal associated complex model[9] was employed. This model assumes that the local structure can be treated as an associated complex and the solution regarded as an ideal solution whose components are free molecules and associated complex molecules.

As acetic acid molecules are associated with each other through hydrogen bonding, it may be assumed that associated molecules of the A_l type exist in the solution where A represents the acetic acid molecule and l is an association number. In this case, the concentration fluctuation is expressed by[6]

$$N\langle(\Delta X_A)^2\rangle = X_A(1-X_A)\{(1-X_A)\langle l\rangle + X_A\},$$
$$\langle l\rangle \equiv \frac{\sum_l l^2 n_{A_l}}{\sum_l l n_{A_l}}, \quad (1)$$

where n_{A_l} is the number of A_l molecules and $\langle l\rangle$ is the mean association number. Equation 1 qualitatively explains the present results in the sense that the concentration fluctuation is always larger than that of an ideal solution, $X_A(1-X_A)$. Therefore, the concentration and temperature dependencies of $\langle l\rangle$ may be determined by choosing an appropriate association equilibria model.

Acetic acid molecules are known to form both cyclic dimers and linear polymers. Therefore, $N\langle(\Delta X_A)^2\rangle$ will be calculated for the following types of model systems;

(a) cyclic dimer model,
(b) linear polymer model, and
(c) cyclic dimer-linear polymer model,

and calculated results will be compared with the observed values.

(a) Cyclic Dimer Model: It is assumed that the following species coexist in solutions;

$$A_1,\ A_2^c,\ B, \quad (2)$$

where A_1 and A_2^c represent a monomer and a cyclic dimer of acetic acid, respectively, and B represents a carbon tetrachloride molecule. In this model, the mean association number $\langle l\rangle$ is defined as

$$\langle l\rangle \equiv \frac{n_1+4n_2^c}{n_1+2n_2^c}, \quad (3)$$

where n_1 and n_2^c are the number of species A_1 and A_2^c, respectively. The mean concentrations of these species are related to each other by the equilibrium constant, K^c,

$$\frac{x_2^c}{x_1^2} = \frac{q_2^c}{q_1^2} \equiv K^c, \quad (4)$$

where q_i is a partition function of an i-th species,[6] which depends on temperature and not on concentration. x_i is the mole fraction of the i-th species, namely,

$$x_i = \frac{n_i}{n_1+n_2^c+n_B}, \quad (5)$$

where n_i is the number of carbon tetrachloride molecules. In the special case where $K^c=0$ and $K^c=\infty$, the mean association number may be written as

$$\langle l\rangle = 1 \quad \text{for } K^c = 0,$$
$$\langle l\rangle = 2 \quad \text{for } K^c = \infty. \quad (6)$$

In Fig. 3, the $N\langle(\Delta X_A)^2\rangle$ values calculated for $K^c=0$ and $K^c=\infty$ are compared with the observed values. In the case where $0<K^c<\infty$, the concentration fluctuation takes the values between the values calculated for $K^c=0$ and $K^c=\infty$. It is seen from the figure that the observed values are generally larger than the calculated values for $K^c=\infty$ except for in the low concentration range indicating the existence of a polymer whose association number is larger than two.

(b) Linear Polymer Model: The coexistence of the following species is assumed:

$$A_1,\ A_2,\ A_3,\ \ldots,\ A_l,\ldots$$
$$B \quad (7)$$

In this model, $\langle l\rangle$ is expressed as

$$\langle l\rangle = \frac{\sum_l l^2 n_l}{\sum_l l n_l} \quad (8)$$

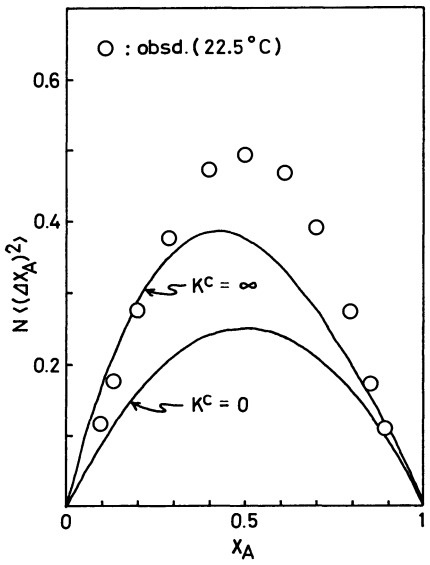

Fig. 3. Theoretical values of concentration fluctuation calculated from Eqs. 1, 3, and 4 for $K^c=0$ and $K^c=\infty$.

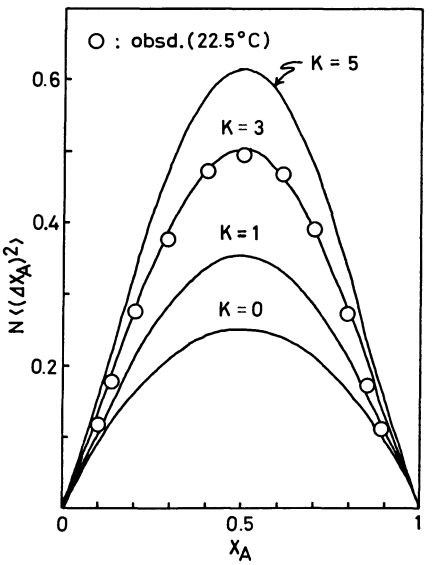

Fig. 4. Theoretical values of concentration fluctuation calculated from Eqs. 1 and 8—10 for $K=0$, 1, 3, and 5.

where n_l is the number of species A_l. The following equilibrium constants are thus defined;

$$\frac{x_3}{x_1^2}=\frac{q_2}{q_1^2}\equiv K_1,$$

$$\frac{x_3}{x_2x_1}=\frac{q_3}{q_2q_1}\equiv K_2,$$

$$\vdots \qquad \vdots \qquad \vdots$$

$$\frac{x_{l+1}}{x_lx_1}=\frac{q_{l+1}}{q_lq_1}\equiv K_l, \tag{9}$$

and it is assumed that

$$K_1=K_2=\ldots=K_l\equiv K. \tag{10}$$

In Fig. 4, the $N\langle(\Delta X_A)^2\rangle$ values calculated for different K values are compared with the observed values. From the figure it is apparent that the concentration fluctuation takes larger values for larger K. Therefore, the equilibrium constant, K, should increase with increasing temperature, since the observed concentration fluctuation increases as the temperature increases. This is inconsistent since the formation enthalpy of hydrogen bonding is negative. Therefore, this model cannot be applied to the present system, although the calculated values for $K=3$ agree well with the observed values at 22.5 °C.

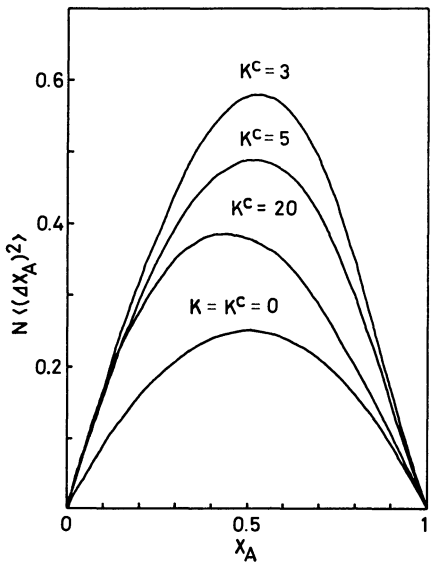

Fig. 5. Theoretical values of concentration fluctuation calculated from Eqs. 1, 12, and 13 for $K=10$ and various K^c values.

(c) Cyclic Dimer-Linear Polymer Model: It is assumed that cyclic dimers and linear polymers coexist in solution, that is, the following species:

$$\begin{matrix} A_2^c \\ A_1,\ A_2,\ A_3,\ \ldots,\ A_l,\ \ldots. \\ B \end{matrix} \tag{11}$$

The mean association number and equilibrium constants are

$$\langle l\rangle=\frac{4n_2^c+\sum_l l^2n_l}{2n_2^c+\sum ln_l}, \tag{12}$$

$$\frac{x_2^c}{x_1^2}=K^c,$$

$$\frac{x_2}{x_1^2}=\frac{x_3}{x_2x_1}=\ldots=\frac{X_{l+1}}{x_lx_1}=\ldots=K. \tag{13}$$

Figure 5 demonstrates the concentration dependencies of the concentration fluctuation calculated for $K=10$ and several K^c values. It is seen from the figure that the concentration fluctuation increases in magnitude with decrease in K^c. This suggests that the observed temperature dependence of concentration fluctuation arises from a difference in temperature dependencies of K and K^c. The best fit between the calculated and observed concentration fluctuation was obtained by setting $K=13$ and $K^c=90$ for 22.5 °C and $K=8$ and $K^c=20$ for 51 °C. The final results for the theoretical calculation are shown in Figs. 6 and 7.

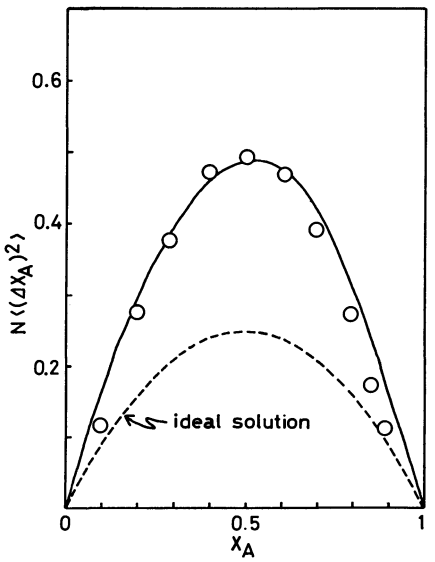

Fig. 6. Final results for theoretical calculations corresponding to experimental values at 22.5 °C.

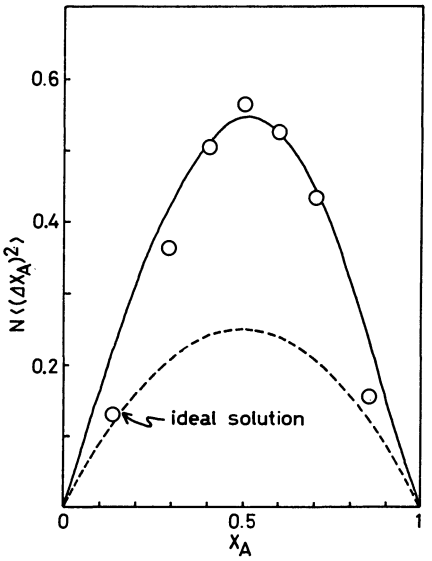

Fig. 7. Final results for theoretical calculations corresponding to experimental values at 51 °C.

The formation enthalpy of an associated complex may be calculated from the relationships;

$$\Delta H^{c} = RT^{2}\frac{\partial \ln K^{c}}{\partial T}, \qquad \Delta H = RT^{2}\frac{\partial \ln K}{\partial T}, \tag{14}$$

where ΔH^{c} and ΔH are the enthalpy change for the reaction, $A_1+A_1 \rightleftarrows A_2^c$ and $A_l+A_1 \rightleftarrows A_{l+1}$, respectively. The obtained values of ΔH^{c} and ΔH and the related entropy change, ΔS^{c} and ΔS, are given in Table 1.

The number ratio of the molecules forming an associated complex to the total acetic acid molecules,

$$\Phi_2^c = \frac{2n_2^c}{2n_2^c+\sum_l ln_l} \quad \text{(cyclic dimers)}$$

or (15)

$$\Phi_l = \frac{ln_l}{2n_2^c+\sum_l ln_l} \quad \text{(linear polymers)}$$

may be calculated from Eq. 13. Figure 8 illustrates the temperature and concentration dependencies of Φ_2^c and Φ_l. It is seen from the figure that almost all the acetic acid molecules form cyclic dimers at low concentrations. At higher concentrations, however, the number of molecules forming linear polymers ($l>2$) is larger than the number of molecules forming cyclic dimers. As the temperature increases, the number of molecules forming cyclic dimers decreases and the molecules forming linear polymers increase. The number of monomers increases with the increase of temperature.

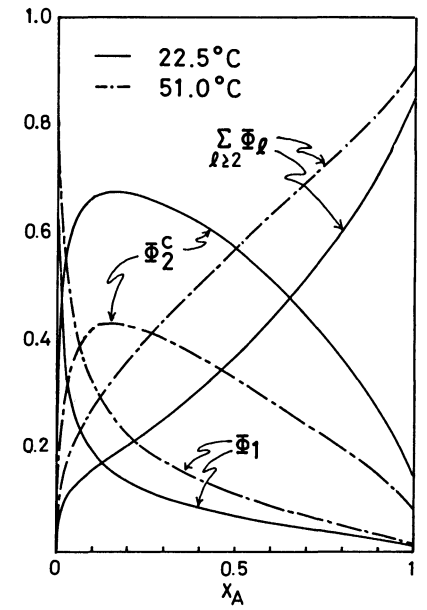

Fig. 8. Concentration and temperature dependencies of Φ^{c} and Φ_l calculated from Eq. 15.

TABLE 1. THE ENTHALPY AND ENTROPY CHANGES CALCULATED FROM EQ. 14

The equilibrium constants at the temperatures of 22.5, 37, and 51 °C have been used in the calculation.

Enthalpy/kcal mol^{-1}		Entropy/cal deg^{-1} mol^{-1}	
ΔH^{c}	10.1	ΔS^{c}	25.1
ΔH	3.2	ΔS	5.9

Goldman and Emerson[10] have quantitatively analyzed the NMR chemical shift of the acid proton of acetic acid in carbon tetrachloride solution at several concentrations and temperatures. The present results are consistent with their results qualitatively, although they used three equilibrium constants.

Conclusions. In the preceding paragraphs, the observed concentration fluctuation has been analyzed using three different models of association equilibria. Model(a) is excluded because it could not explain the observed concentration dependence of concentration fluctuation whereas Model (b) and (c) could explain the observed concentration dependence of concentration fluctuation. The observed temperature dependence of concentration fluctuation could not how-

ever be explained by model (b). Only model (c) explained the observed concentration and temperature dependencies of concentration fluctuation, simultaneously. It must be emphasized that the mean association number itself can be determined directly from Eq. 1. The introduction of the concept of association equilibria will furnish additional information about the concentration and temperature dependencies of the concentration fluctuation. In determining local structures in solutions where various types of local structures are expected, however, an appropriate model of association equilibria has to be selected from the various plausible models which give the same mean association number. The present results indicate the possibility of determining local structures uniquely by observing both concentration and temperature dependencies for concentration fluctuation.

The authors wish to express their sincere thanks to miss Masako Yudasaka for her helpful advice on the light scattering measurements.

a) Test solutions of the individual metal ions were prepared from their nitrate salts and were used in the test without the addition of any buffer agent. The figures in the parentheses beneath the analytical results indicate the pH values of the intact sample solution and the equilibrium solutions in each case. b) In this case, the Fe^{3+} ion in the red-colored sample solution was considered to have been partially hydrolysed and to exist as the colloidal state iron(III) nitrate hydroxide, it might be unable to diffuse into gel particles.

was no longer blue. The resulting blue particles of gel were preserved in water or dried.

The analytical results on the soluble Prussian blue in the system prepared are shown in Table 1. The high level of potassium content is considered to be proof of the fact that the majority of the blue is soluble Prussian blue. Under the conditions used in this work to prepare the system, among a variety of Sephadex gels (G-10, 15, 25, 50, 75, and 150) G-75 gel was the most suitable as a material for the preparation.

A microscopic photograph of the frozen slice of the Sephadex G-75 gel containing the soluble Prussian blue is shown in Fig. 1, from which it can be found that Prussian blue is well prepared in the network structure of gel. From the electron-microscopic photograph shown in Fig. 2, it is found that the Prussian blue is preserved as particles of 5 to 50 nm in size in the gel particle. In view of the fact that soluble Prussian blue is non-adsorptive to Sephadex gel,[4] these two photographs demonstrate that the soluble Prussian blue is caged in the gel particle.

When the system was swollen in water, a batch of it vividly captured various heavy metal ions. Tests of the ability of this system to capture the heavy metal ions in an aqueous solution in the batch procedure were carried out by using 0.1 g of each dry gel and 5 cm^3 of a solution containing the metal ions in the concentrations shown in Table 2. After having been allowed to stand overnight, the supernatants were taken for chemical analyses. The analytical results revealed a strong activity of the system in capturing heavy metal ions (Table 2).

Fig. 1. Microscopic photograph of the frozen slice of the Sephadex G-75 gel particles in which the soluble Prussian blue is caged.

Discussion

Our original expectation that a very soluble reagent of a large molecular size could be caged in the network structure of gel, and that it could be confined in the gel particle, was successfully realized in the preparation of this system.

On such a novel system in which intact soluble Prussian blue is caged, it had been further expected that the system would be an excellent capturer of heavy metal ions in an aqueous solution, since soluble Prussian blue reacts with ions of various heavy metals to form precipitates. The heavy metal ion in the solution would be able to diffuse into the gel particle through the network structure in the gel particle, and would then collide with the molecule of soluble Prussian blue residing there and react with the blue to be trapped. Thus, the heavy metal ion would not be able to return to the outside solution. This expectation as to the system was materialized, also, by the observation of its ability as a heavy-metal-ion capturer.

Recently, a way of combining two polymers to form such systems called "interpenetrating polymer network systems", has come to attract chemists' interest as a third possible way of combining two different types of polymers for the purpose of modifying the properties of individual polymers,[5] coming to supplement the conventional mechanical blending and copolymerization. This third way has, however, been used mostly to combine the elastomer-type polymer and the glassy-type polymer.

In the present work we accomplished the preparation of a new art of macromolecular system, in which the water soluble macromolecular electrolyte of an inorganic metal complex was confined within the swollen gel. The intriguing features of the structure and

nature, as well as the practical utility of the system, were also experimentally ascertained in this work.

The authors are very grateful for the aid of Dr. Ichiro Yamamoto, Professor of Pathology in Kitasato University, and Dr. Shinkichi Akao, Faculty of Medicine, Keio University, in preparing the electron-microscopic photographs of the gels.

Ab Initio Studies of the Hydrogen Atom Addition to Ethylene

Okio NOMURA,* and Suehiro IWATA

Institute of Physical and Chemical Research, Hirosawa 2-1, Wakoh, Saitama 351

(Received June 6, 1979)

The ethyl radical formation from hydrogen and ethylene was studied with *ab initio* open shell SCF and CI methods. At first, the minimal basis set (STO-6G) was used to determine a minimal energy path. The calculated exothermicity and the height of the barrier were 72.3 kcal/mol† and 16.9 kcal/mol, respectively. After the full geometry optimization with the double zeta basis set the calculated exothermicity became 38.3 kcal/mol, which is in agreement with the experimental value (40.1 kcal/mol), but the barrier height (16.5 kcal/mol) was no better than that obtained by the minimal basis set. After the extensive CI calculations along Sloane and Hase's path with the minimal basis set, the calculated height of the barrier became only 5.1 kcal/mol. The small but finite barrier height is important in this reaction. The successive hydrogenation to form ethane was also studied and no barrier was found in the reaction.

The addition of hydrogen to ethylene (1),

$$H\cdot + C_2H_4 \rightleftharpoons C_2H_5\cdot{}^* \longrightarrow C_2H_5\cdot \qquad (1)$$

has long been a concern to chemists as a fundamental model of addition reaction of alkyl to olefins. In recent years several powerful experimental techniques have been developed for studying free radical formation. The analysis of kinetic data clarifies the reaction mechanism and has made activation energy reliable in some important radical reactions within the error of a few kilocalories.[1-4] The experimental activation energy falls between 0.5 and 7 kcal/mol.[1,†] Sato and his collaborators[5] observed the isotopic effect and they suggested that there is a barrier, however small it might be. The exothermicity of the reaction is obtained experimentally as 40.1 kcal/mol,[6] which is equal to the theoretical value obtained by Lathan *et al.*[7] This agreement may be fortuitous, though the heat of formation is not difficult to estimate in the SCF (self-consistent field) calculation as demonstrated by Pople.[8] It is, however, difficult to evaluate the barrier height of radical reactions in which a bonded pair and an unshared electron are exchanged between reactants and products,[9] such as

$$A\text{-}B + C\cdot \longrightarrow A\cdot + B\text{-}C. \qquad (2)$$

The hydrogen exchange reaction H_2+H[10] and the reactions of hydrogen and fluorine, such as $H+F_2$, $H+HF$, and $F+H_2$[11] are among examples for which the barrier height is successfully evaluated by very extensive *ab initio* CI calculations. Another reaction studied theoretically is $H+N_2$,[12] in which three atoms are found not to lie on a line. In this case change of hybridization in the course of reaction plays a significant role.

A more complicated reaction may be an addition of hydrogen (H*) to ethylene. This can be regarded as a model of radical reaction of conjugated hydrocarbons. The reaction has characteristics in change of geometry as well as of hybridization along the reaction path. Bending the CH_2 moiety off the molecular plane is expected to be one of the most important changes in geometry to form a methyl moiety. The transfer of an unpaired electron occurs from the attacking hydrogen to the other side of carbon to which the hydrogen is not attached. Shih *et al.*[13] studied the reaction of $NH_2+C_2H_4$ from a similar point of view. The UHF method might be a convenient tool in discussing the reaction mechanism because it, in many cases, predicts proper dissociation products of a ground state in a single determinant approach at the cost of vitiating the spin symmetry. Sloane and Hase[14a] calculated the potential surfaces of the Reaction 1 using the UHF method with STO-3G and 4-31G. Though geometry optimization was made at each point, they could not find a barrier. Since experimentally the barrier is known to exist in the reaction, in the recent paper,[14b] they had to use the "experimental barrier height" (3.5 kcal/mol at r_{CH^*}= 2.0 Å) to derive the analytic potential energy surface. On the other hand, Nagase and Kern,[15a] and Kato and Morokuma[15b] found a very small barrier after careful geometry optimization with the 4-31 G UHF calculations. In the present paper the restricted open shell SCF and CI methods are used for the study of the Reaction 1. At first, several model reaction paths are examined to clarify the change of the electronic structure along the path, and then geometrical parameters are optimized. Finally careful CI calculations along the reaction path determined by Sloane and Hase are performed to compare with the UHF results. The barrier is found both in the restricted SCF and in the CI calculations.

Methods

Restricted SCF Method (RHF): The restricted SCF method for open shell (hereafter it is called RHF as traditionally is) used is essentially equivalent to the two-Hamiltonian method by Davidson.[16] The program written by one of the present authors (S. I.) was linked with GAUSSIAN 70 at the University of Rochester. Since it is also capable of solving the three-Hamiltonian method, the program can be applied to an excited singlet state belonging to an irreducible representation different from that of the closed shell ground state configuration. The closed shell SCF of a cation ($[C_2H_4]H^+$) is first solved to obtain an initial set of orbitals for determining the RHF MO of the radical ($[C_2H_4]H\cdot$). The set of doubly occupied orbitals (ϕ_i, $i=1,\cdots,7$) are first determined and then an electron is added to the vacant orbitals (ϕ_8 or ϕ_9) depending on the state of the radical. The matrix equations to be solved at the $(\nu+1)$th

† 1cal=4.184 J.

cycle are

$$G_C^{\nu} b_C^{\nu+1} \equiv \{F_C^{\nu} - (n_O/n_C)(P_O^{\nu} F_O^{\nu} + F_O^{\nu} P_O^{\nu})\} b_C^{\nu+1} = \varepsilon b_C^{\nu+1}, \quad (3)$$

$$(1-P_C^{\nu+1}) F_O^{\nu} (1-P_C^{\nu+1}) b_O^{\nu+1} = \varepsilon b_O^{\nu+1}, \quad (4)$$

where the occupation numbers, n_C and n_O, in this case, are equal to 2 and 1, respectively. Fock matrices F_C^{ν} of a closed shell and F_O^{ν} of an open shell are defined in terms of the ν-th cycle MO's $\{\phi_k^{\nu}\}$ as

$$(F_C^{\nu})_{jk} = \langle \phi_j^{\nu} | h + 2J_C - K_C + 2J_O - K_O | \phi_k^{\nu} \rangle, \quad (5)$$

$$(F_O^{\nu})_{jk} = \langle \phi_j^{\nu} | h + 2J_C - K_C | \phi_k^{\nu} \rangle, \quad (6)$$

respectively, where J_C and K_C, and J_O and K_O are the coulomb and exchange operators of the closed shell and of the open shell orbitals, respectively. The projection operators P_O^{ν} and $P_C^{\nu+1}$ are defined in the present case as

$$P_O^{\nu} = |\phi_s^{\nu}\rangle\langle\phi_s^{\nu}|, \quad P_C^{\nu+1} = \sum_{k=1}^{7} |\phi_k^{\nu+1}\rangle\langle\phi_k^{\nu+1}|. \quad (7)$$

The transformation of the operator F_O in Eq. 4 by the projection operator $(1-P_C)$ implies that the open shell orbital and the virtual orbitals are determined outside the space spanned by the closed shell orbitals. The orbital energies of both the closed shell and the open shell orbitals satisfy Koopmans' theorem. Generally speaking, convergence is slower than in the closed shell SCF procedure. The orbital set after about fifteen cycles is used as a basis for the MRBW and CI calculations; the energy convergence is about 10^{-4} hartree.

MRBW Method: Even for a system which can be satisfactorily described by a single Slater determinant around its stable geometry, several electronic configurations are required for correct description when the geometry changes to a transition state in a reaction path. The CI calculation may be the best way but it is time-consuming. To estimate the characteristics of the potential energy surface, the second order Brillouin-Wigner perturbation with several reference states is used. The essential idea has been proposed by Löwdin[17] by partitioning a full Hamiltonian matrix into reference (R) and its quotient (Q).

$$H_{\mathrm{eff}}(E) = H_{RR} + H_{RQ}(E - H_{QQ})^{-1} H_{QR} \quad (8)$$

A careful choice of a reference space, R, allows us to regard Eq. 8 as the effective Hamiltonian projected onto the space R. By neglecting the off-diagonal elements of H_{QQ}, the effective Hamiltonian reduces to a simple form,

$$H_{\mathrm{eff}}^{\mathrm{MRBW}}(E) = H_{RR} + H_{RQ}(E - E_Q^{\mathrm{diag}})^{-1} H_{QR}, \quad (9)$$

where H_{RR} and H_{RQ} are the Hamiltonian matrix among reference states and between the reference and the quotient states, respectively. E_Q^{diag} is the diagonal element of H_{QQ}. This perturbation expansion may be called the multi-reference Brillouin-Wigner (MRBW), which is equivalent to the B_k method of Gershgorn and Shavitt[18] and to the method proposed by Segal *et al.*[19] Obviously, in MRBW, the choice of the reference CSF's (configuration state function) is important to obtain the approximate results to the large CI calculation.

CI (Configuration Interaction): A CI program named EFCI[20] consists of six modules as follows.

Link 1. Reading a symmetry table of MO and transforming integrals from AO to MO basis.

Link 2. Generation of electronic configurations. A set of MO's are partitioned into four groups:

i) the fixed core orbitals (which are always doubly occupied),

ii) the core orbitals (hereafter abbreviated as $\{c\}$)

iii) the valence orbitals $\{v\}$, and

iv) the excited orbitals $\{e\}$.

The electronic configurations generated are grouped into nine types. (1) The "valence" CSF: First, all of $\{c\}$ are doubly occupied, and then, the rest of electrons are filled in $\{v\}$. All the possible CSF's are generated without filling electrons in $\{e\}$. The "valence" CSF's are usually the reference states for MRBW and for the configuration selection procedure. The dominant CSF's in the states which are being studied should be included in this type. The other eight types of CSF's are single and double excitations from the "valence" CSF's. (2) $v^2 \rightarrow e^2$ (3) $v \rightarrow e$ (4) $cv \rightarrow e^2$ (5) $c \rightarrow e$ (6) $c^2 \rightarrow e^2$ (7) $c \rightarrow v$ (8) $c^2 \rightarrow ve$ (9) $c^2 \rightarrow v^2$.

Link 3. Evaluation of matrix elements in H_{RR}, H_{RQ} and the diagonal of H_{QQ}, and selection of CSF's in Q using the second-order multi-reference Rayleigh-Schrödinger perturbation expansion (A_k method).[18]

Link 4. Performing MRBW and analysis of the result.

Link 5. Evaluation of off-diagonal matrix elements in H_{QQ}.

Link 6. Solving the eigenvalue problem and analysis of the electron correlation.[21] Davidson's method modified by S. I. is used.[22]

In some cases the type of excitations $c^2 \rightarrow e^2$, though inclusion of this type lowers the total energy considerably, can be neglected because this type of excitations contributes only to the pair correlation energy of the core electrons by shifting all the "valence" states almost uniformly.[21] Care should be taken of the choice of valence orbitals and the threshold value of configuration selection. On a similar account the size of CI is also paid attention to. Hereafter the size of CI calculation is denoted as $[M_{\mathrm{root}}/N_R, N_{\mathrm{Qsel}}/N_{\mathrm{Qgen}}]$, where N_R stands for the number of reference CSF's (which consist, in most cases, of the "valence" states) and M_{root} denotes the number of the eigenstates of H_{RR}, which are used for the CSF selection procedure. N_{Qgen} and N_{Qsel} are the numbers of CSF's generated for the Q space and of selected CSF's for the CI calculation, respectively. If the CSF selection procedure is not applied, the CI size is given by $[N_R, N_{\mathrm{Qsel}}]$.

A deliberate choice of valence orbitals is necessary to take into account a well-balanced correlation along the reaction path. Those orbitals (frontier orbitals) which play an important role in a bond formation or bond exchange should be taken into account in the valence orbitals $\{v\}$. It is necessary to include the antibonding orbitals which suffer considerable changes in the new bond formation, even if they lie much higher than the lowest vacant orbitals.

Results and Discussion

First the SCF calculations are performed along several model paths with a planar ethylene of fixed geometry as shown in Fig. 1. A hydrogen atom attacks an

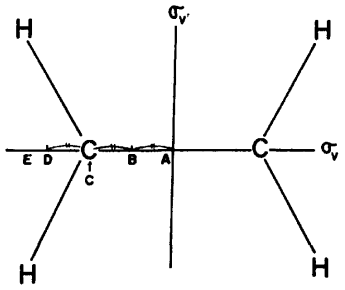

Fig. 1. Attacking points of a hydrogen on the planar ethylene (D_{2h} symmetry) in model calculations. (Only the attack on A has C_{2v} symmetry. Others have C_s symmetry.)

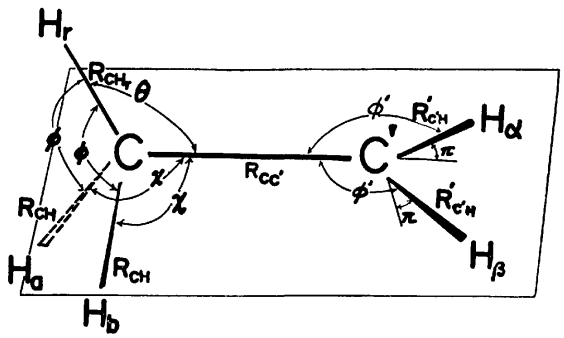

Fig. 2. Parameters of the ethyl for geometry optimization. (C_s symmetry is kept.)

ethylene vertically in the model paths. The vertical approach to the middle point of the C–C bond (path A in Fig. 1) has C_{2v} symmetry. In the paths, B to E, the hydrogen approaches the planar ethylene above the positions shown in Fig. 1. The partial geometry optimization is also performed for these models. These paths are useful for elucidating the origin of the barrier and change of the electron distribution in the course of reaction. Subsequently to the model calculations, the geometrical parameters which are critical to the reaction are optimized. In methyl formation, optimization of the angles ϕ and χ as well as θ defined in Fig. 2 is found to be important. This accounts for the change of hybridization of the carbon atom from sp^2 to sp^3. Sloane and Hase's path[14] is also examined to compare our RHF and CI results with their UHF's. In addition, careful optimization of geometries is made using the RHF method with the double zeta basis set for several important HC_1 distance.

Model A: The potential energy curves for Model A are shown in Fig. 3. In this model the repulsive $^2A_1$ state is dissociated to the ground state ethylene ($^1A_{1g}$) and hydrogen atom (^2S). The other state $^2B_2$ is correlated with the ionic products, $C_2H_4^+(^2B_{1u})+H^-$ in the RHF picture. If the UHF methode is used to describe the dissociation process, this state should be correlated with $C_2H_4(^3B_{2u})+H$. If the C–C bond length, R_{CC} is optimized along with the distance R_{HP} between H and the ethylene plane, the energy is lowered by 18.7 kcal/mol at $R_{HP}=1.1$ Å (see the curve b in Fig. 3). Even after the optimization of R_{CC} the energy minimum of the potential energy curve of $^2B_2$ in model A is found to be higher than the dissociation limit

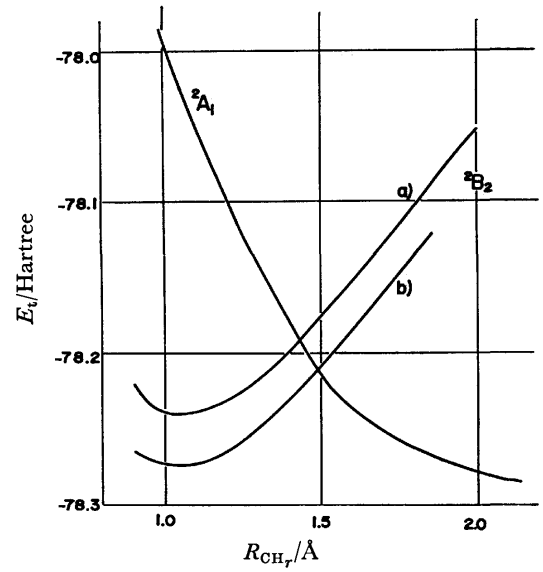

Fig. 3. Potential energy curves of the planar ethyl formation (model A).
a) In $^2B_2$, R_{CC} is fixed at 1.34 Å.
b) In $^2B_2$, R_{CC} is optimized with respect to R_{CH}.

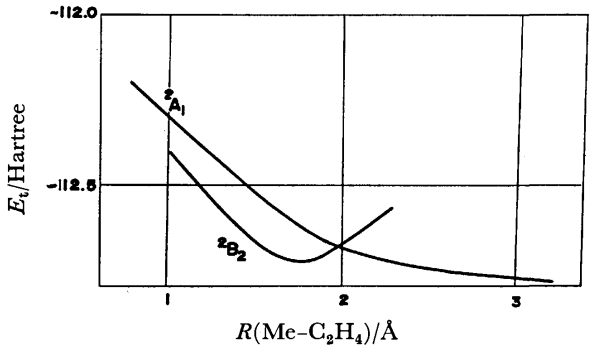

Fig. 4. Potential energy curves of $CH_3+C_2H_4\rightarrow C_3H_7$. Methyl radical approaches the planar ethylene perpendicularly to the middle of the C–C bond. $^2A'$ and $^2A''$ corresponds to the $^2A_1$ and $^2B_2$ in the C_{2v} $H+C_2H_4$ model system.

of C_2H_4+H. The optimization of the out-of-plane angles of CH_2 moieties does not change this conclusion. Although an experimental analysis suggests that CF_3 and CH_3 radicals might give rise to bridged adducts with substituted ethylenes,[23] no stable structures are found in bridged form (model A path) in our SCF calculation for $C_2H_4+CH_3$, as is shown in Fig. 4. This type of symmetric insertion is orbital-symmetry forbidden.[24–26]

Model B—E: In these models, because of the lower symmetry, the states $^2A_1$ and $^2B_2$ in model A can interact with each other. Consequently, at longer R_{HP}, the $^2A_1$ character is dominant in the lowest state while the bonding $^2B_2$ becomes a main component at shorter R_{HP}. At an intermediate R_{HP} the character of the lowest state suddenly changes. Around that distance a hump is expected to be found. The calculated potential energy curves are shown in Fig. 5. In models C, D, and E, C_2H_5 is more stable than the dissociation limit, C_2H_4+H. Among them, the most plausible path of the hydrogen to the planar ethylene is the

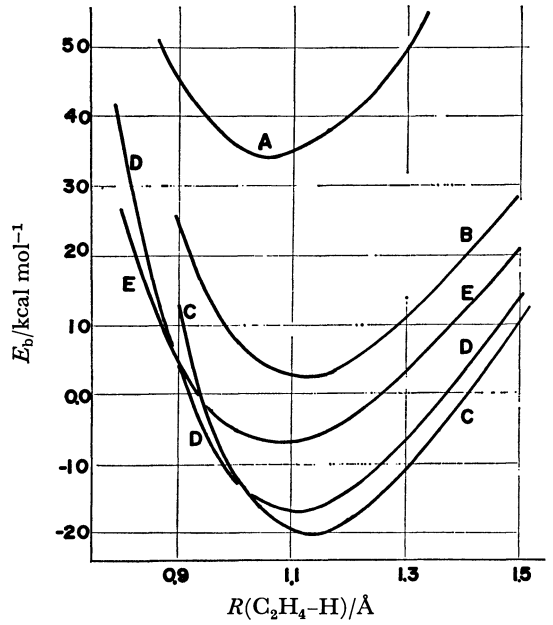

Fig. 5. Potential energy curves of $H+C_2H_4 \rightarrow C_2H_5$ model system (*cf.* Fig. 1). The energy is relative to the dissociation limit.

attack from above a carbon atom (path C). When a hydrogen atom attacks one of the carbon atom C_1, while a new H–C bond is formed, the C–C π bond breaks and an unpaired electron is localized at the other side of carbon C_2. The most stable R_{HC_1} is 1.15 Å; it is a little longer than a usual C–H bond length. As is expected, the hump is found at $R_{HC_1} \approx 1.8$ Å and its height is 20 kcal/mol, which is about several times larger than the experimentally estimated activation energy (see below).

Geometry Optimization: First, three geometry parameters (R_{CC}, θ, and χ) are optimized for each R_{HC_1} along the path C, using STO-6G and open shell RHF; the results are given in Table 1. It is notable that the C–C double bond is suddenly lengthened to become a single bond at the vicinity of the hump of the potential curve. As is mentioned above, at these R_{HC_1}, the main character of the ground state has changed. A similar feature is reported for R_{CN} in the reaction $C_2H_4+NH_2$.[13] Full geometry optimization is carried out using the double zeta basis set and the open shell RHF method at the bottom ($R_{HC_1}=1.1$ Å) and the hump (1.8 Å) determined above by the minimum basis set RHF calculations. The results are given in

Tables 2 and 3, and are compared with parameters determined by other workers. The angle π in Fig. 2 is the bending angle of nonreacting CH_2 moiety off the ethylene plane. The geometry of free ethylene with the same basis set is determined as $R_{CC}=1.342$ Å, $R_{CH}=1.084$ Å and $\angle CCH=121.7°$. Previously, Pacansky and Dupuis (PD),[27] Lathan *et al.* (LHP),[7] and Nagase and Kern (NK)[15a] optimized the structure parameters of the ethyl radical C_2H_5. PD used the triple zeta basis set for the RHF calculation and a larger set with polarization functions for the UHF calculation. They found no appreciable difference in the RHF and UHF structures. NK and LHP employed the 4-31G and STO-3G set, respectively and both used UHF method. Agreement between our parameter set and theirs is rather good except for the out-of-plane angle, π, for the $C_2H_\alpha H_\beta$, which is much smaller (4.8°) in ours, then increases in PD's and NK's, and is the largest in LHP's (22.9 °).

The exothermicity calculated by RHF with STO-6G is 72.3 kcal/mol; too large in comparison with the experimental value, 40±1 kcal/mol. The UHF method also overestimates the exothermicity (59.1 kcal/mol by Lathan *et al.*[7] and 76.1 kcal/mol by Sloane and Hase,[14a] if the minimal basis set is used. The use of the double zeta basis set improves this value substantially, which is 38.3 kcal/mol in our calculation and 40.1 kcal/mol in 4-31G UHF calculation by LHP and NK.

The calculated hump height is 12.76 kcal/mol at $R_{CH_1}=1.8$ Å for the STO-6G set and 16.5 kcal/mol at

the same bond length for the double zeta basis set, when the RHF method is applied. On the other hand, Sloane and Hase reported that they found no hump in their UHF potential energy curve.[14a] Very recently Kato and Morokuma,[15b] also using the UHF method and the 4-31G set, optimized the structure of C_2H_5 along the reaction path and found the hump with 2 kcal/mol at $R_{HC_1}=2.1$ Å, while NK obtained the same barrier at 2.015 Å.[15a] Experimentally, it has been known that the barrier exists in the reaction. Although the experimental activation energies reviewed by Teng *et al.*[1] are scattered from 7.2 to 0.5 kcal/mol, the most probable value may be *ca.* 3 kcal/mol. Our calculated heights are considerably higher than the experimental activation energy. Difficulty in calculating the hump height by RHF is not surprising, because the single electron configuration description such as RHF should fail at the hump region as model calculations (A—E) indicate. To obtain more reliable calculated hump height, the CI calculation is required.

CI Calculations: To compare Sloan and Hase (SH)'s UHF results, the CI calculations are performed along the reaction path determined by SH. The various schemes of the generation of the CSF list are examined. In this series of CI calculations, the STO-6G set is used. The molecular orbitals used are the open shell RHF MO's for the lowest state of ethyl radical. To test the MO set dependence, the closed shell SCF MO's for $C_2H_5^+$ are also used. The convergence is faster in the open shell MO-CI than in the closed shell MO-CI. Below, only the former results are discussed.

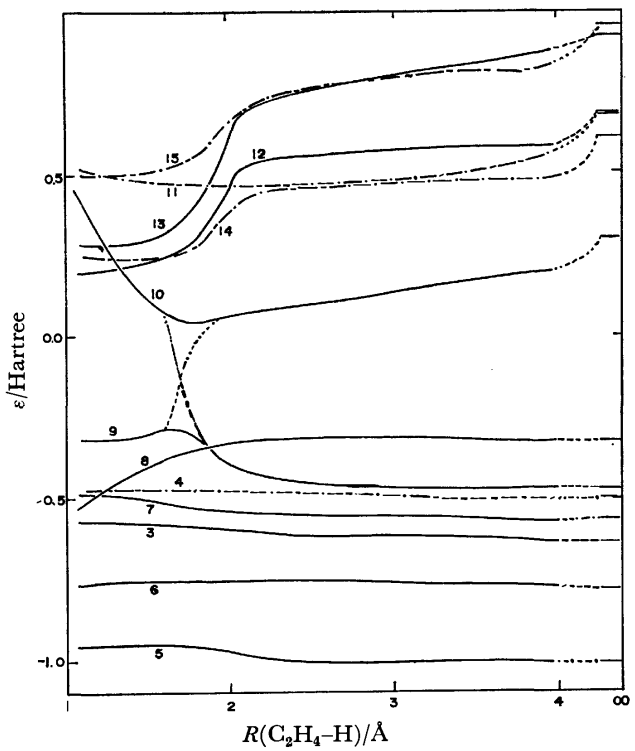

Fig. 6. Orbital correlation diagram for $H+C_2H_4\rightarrow C_2H_5$ (STO-6G RHF ground state), along the Sloane and Hase's path. Broken lines are for a″ and solid lines for a′.

To obtain even qualitatively correct potential energy surfaces in the CI calculations, it is very important how to generate the SCF list. In our terminology defined in the previous section, the CI results are dependent on the division of the set of MO's into $\{c\}$, $\{v\}$, and $\{e\}$. In Fig. 6 the change of the orbital energies is shown along the path. Note that the number given to each orbital is not the order of the orbital energy. For $R>1.9$ Å, the half filled orbital is the orbital 8, while at $R<1.9$ Å it switches to the orbital 9. Furthermore the character of the orbital 9 changes around the hump; at the shorter distance, the half filled orbital 9 becomes a localized π orbital on C_2. It is worth emphasizing the necessity of drawing the orbital correlation diagram before CI calculations for the potential energy surface. The MO coefficients in Table 4 show change of charracter of the frontier orbitals (ϕ_8, ϕ_9, and ϕ_{10}) as the hydrogen approaches. At $R_{HC_1}=4.079$ Å, the orbitals ϕ_8 and ϕ_{10} are the bonding and antibonding π of C_2H_4, and ϕ_9 is hydrogen ls. Just after the hump ($R_{HC_1}=1.7$ Å), where the bond formation between the hydrogen and the C_1 is almost completed, the half filled orbital ϕ_9 becomes localized on the $2p\pi$ lobe of the carbon C_2. The bonding π character of ϕ_8 disappears and the orbital becomes the $H-C_1$ bonding character. This is also reflected in the $H-C_1$ antibonding character in ϕ_{10}.

In PCI-1, ECI, and LCI shown in Table 5, the orbitals, 8, 9, and 10 are chosen as the "valence" orbitals, $\{v\}$, and the other occupied and vacant

a) see Ref. 16.

orbitals in the RHF electron configuration are the "core" $\{c\}$ and "excited" $\{e\}$ orbitals along the reaction path. Eight CSF's are constructed by filling three electrons in three "valence states". In LCI, all possible single and double electron excitations ($N_{Qgen}=4077$) from the "valence states" are taken into account. In ECI the CSF selection procedure are performed with a threshold value (10^{-4} h). These three CI potential curves agree qualitatively with each other as shown in Table 2, although the total electron energies in three calculations differ substantially. The MRBW calculations reproduce the ECI results except at $R_{HC_1}=4.079$ Å. There are several differences in the CI and RHF curves. The exothermicity and hump height are improved, and in addition, the hump position moves to a longer R_{HC_1}. Since our basis set used in CI is minimal, the calculated exothermicity (52 kcal/mol) and hump height (5 kcal/mol) may be satisfactorily in good agreement with the experiments. Surprisingly, the very small CI (PCI-1) among 8 CSF's can produce the qualitatively correct potential curve. This is because our choice of the "valence orbitals" are suitable for the potential curve calculations; in this sense, the orbitals, 8, 9, and 10, given in Table 2 can be called the "reaction orbitals".[25]

Our CI potential curves are differnt even qualitatively from the UHF curve obtained by Sloan and Hase, even though the reaction path is the same. As Yamaguchi[25] pointed out, the UHF (different orbitals for different spins, DODS) wavefunction for three electron-three orbital model, $|\psi_{1\alpha}\ \psi_{2\alpha}\ \overline{\psi}_{1\beta}|$ can be expanded in terms of four electron configurations, $|\chi_a\overline{\chi}_a\psi_{2\alpha}|$, $|\chi_b\overline{\chi}_b\psi_{2\alpha}|$, $|\chi_a\overline{\chi}_b\psi_{2\alpha}|$, and $|\chi_b\overline{\chi}_a\psi_{2\alpha}|$, where χ_a and χ_b are linear combinations of $\psi_{1\alpha}$ and $\psi_{1\beta}$, but the coefficients of these four Slater determinants are severely restricted in the UHF wavefunction. To compare the UHF results, the 3×3 CI calculations among $|\psi_8\overline{\psi}_8\psi_9|$, $|\psi_{10}\overline{\psi}_{10}\psi_9|$ and $1/\sqrt{2}[|\psi_8\overline{\psi}_{10}\psi_9|+|\psi_{10}\overline{\psi}_8\psi_9|]$ are carried out and the energies are shown as PCI-0 in Table 5. Again, the potential curve behaves correctly. These results clearly show that the CI or MCSCF calculations combined with an appropriate choice of the "reaction orbitals" are suitable for the study of the reaction potential curves. As another example of the importance of a careful selection of the "reaction orbitals", is given the PCI-2 calculations in Table 5, where 490 CSF's are created by filling nine electrons in seven orbitals (3a'—9a'). The potential curve thus obtained is absurd.

Ethane Formation: Addition of hydrogen to ethyl radical is studied to see the feature of the successive hydrogenation of ethylene,

$$C_2H_5 + H \longrightarrow C_2H_6^* \longrightarrow C_2H_6. \qquad (9)$$

Two curves are obtained in the SCF calculations. One (b in Fig. 7) is the result by the closed shell RHF which is correlated with the ethane formation. The other (a) is the curve obtained by the open shell RHF which leads to the dissociation product. The latter curve is already flat at the intersection of two curves. This implies that the dissociation is an almost complete at the bond length as short as 2 Å (Fig. 7) and that there may be no activation barrier in the ethane formation. In fact, the potential energy curve (c) obtained by CI shows no barrier. It is in conformity with the experimental facts that the rate of the ethane formation is hundred times as fast as that of the ethyl radical formation and that the abstraction of hydrogen by the ethyl easily occurs.

The MO basis set for CI at shorter C–H distance was obtained by the closed shell SCF. The ground electron configuration is $(1a')^2\cdots(5a')^2(1a'')^2(6a')^2(7a')^2(2a'')^2$. The next important configurations are a pair excitation to an antibonding orbital 8a' from the 7a' orbital with mixed character of C–H and C–C bonding, and the double excitation from 1a''

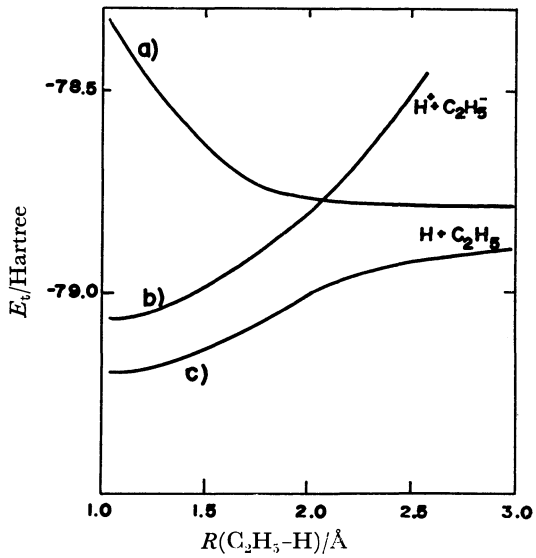

Fig. 7. Potential energy curves of ethane formation. a) Open shell SCF, b) closed shell SCF, c) CI.

and 2a'' to 3a'' and 4a''.These configurations are used as the reference states in the large CI calculation. At R_{HC_1}=2 Å the open shell SCF energy is slightly lower than that of the closed shell SCF. The highest occupied MO 7a' and the lowest vacant MO 8a' in the closed SCF MO are of the character of C–H bonding and C–H antibonding, respectively. Because of restriction of the double occupancy, the wavefuction is of too strong an ionic character. The open shell SCF makes it possible to localize electronic charge on each atom by a linear transformation of the orbitals. The frontier orbitals obtained by the open shell SCF take the form of hydrogen 1s orbital and unpaired pπ orbital on the carbon. The small energy difference between the two configurations suggests considerable configuration mixing. The CI based on the open shell SCF MO shows that the open shell electronic structure (i) $\Lambda_2(5a')^2(6a')^2(2a'')^2(7a')^1(8a')^1$ is dominant. The complementary ones are composed of closed shell structures (ii) $\Lambda_2(5a')^2(6a')^2(2a'')^2(7a')^2$ and (iii) $\Lambda_2(5a')^2(6a')^2(2a'')^2(8a')^2$, where $\Lambda_2=(1a')^2(2a')^2(3a')^2(4a')^2(1a'')^2$. The wavefunction can be approximated as: Ψ=0.90 (i) −0.29 (ii) −0.24 (iii). A linear transformation of the relevant orbitals among the major three configurations reduces to a single configuration wavefunction $\Psi=^1(\phi,\phi)$, with orbitals ϕ=0.97(pπ)−0.07 h and ϕ=1.02 h−0.05(pπ), where h and pπ denote the hydrogen ls orbital and the unpaired pπ on a carbon, respectively. On the other hand, the half filled orbitals determined by the open shell SCF are of the pure pπ and h character. Further decrease of the interaction between the hydrogen and the carbon changes the orbital character. At R_{HC_1}=3 Å the molecule can be regarded as a mixed system composed of a hydrogen atom and an ethyl radical, since 7a' and 8a' have characters of pure hydrogen ls orbital and of an unpaired pπ orbital, respectively. The orbital energy of the 7a' differs no more than 2 kcal/mol from the free hydrogen atom. The predominant configuration is $\Lambda_2(5a')^2(6a')^2(2a'')^2(7a')^1(8a')^1$. The complementary configurations are used to improve the other methyl moiety by promoting one or two electrons in the 6a' orbital (σ C–H) to the 11a' (σ^* C–C).

We wish to express our thanks to generous hospitality and suggestions given by Professor Keiji Morokuma and the members in his laboratory at the Institite of Molecular Science in Okazaki. Computation is performed with FACOM 230-75 (Fujitsu Co., Ltd.) in our Institute. Part of the work was supported by the Scientific Grant from Ministry of Education (No. 154144 and 254148).

(Received July 19, 1979)

Conductivities of HCl and KCl in methanol containing traces (0.12 to 0.40 mol%) of water have been measured in the concentration range of ≈0.4 to ≈5 mmol dm^{-3} at 25 °C up to 2000 kg cm^{-2}. The limiting equivalent conductance ($\Lambda°$) for HCl and KCl decreased with increasing pressure. The excess proton conductance due to the proton-jump mechanism has been measured by $\Lambda°$(HCl)—$\Lambda°$(KCl) and found to increase with increasing pressure in nearly and absolutely pure methanol. The acceleration of proton jumps by pressure indicates that the rotation of methanol molecules about the longer molecular axis becomes faster at higher pressure. This anomaly is attributed to distortion with pressure of hydrogen bonds in methanol and to an increase in the repulsive field exerted by the proton on the molecule to rotate.

It is one of the most interesting ionic transport phenomena that protons in hydrogen-bonded solvents have the anomalous (excess) conductance due to proton jumps in addition to the normal hydrodynamic one. Since the rotation of solvent molecules is regarded as the rate-determining step in the proton-jump mechanism,[1,2] the excess proton conductance can be used as a probe for a dynamic study of liquid structure of hydrogen-bonded solvents. Following this line, the effect of pressure on the reorientation of water molecules was investigated at various temperatures in our previous papers;[2,3] the water reorientation was promoted by pressure, and the larger the pressure effect, the lower the temperature. When a hydrogen atom in H_2O is replaced by a methyl group CH_3, the way of hydrogen bonding is simplified; methanol in the solid state contains linear chains of O–H···O hydrogen bonds,[4] while the various types of ice have three-dimensional networks of hydrogen bonds.[5] The present authors attempt here to elucidate the influence of pressure upon proton jumps in methanol hydrogen-bonded in a way simpler than water. Since proton jumps in methanol are markedly influenced by water contained in the solvent, it is to be clarified how the effect of pressure on proton jumps is varied with the content of water. After making it clear whether proton jumps in methanol are accelerated by pressure or not, the effect of pressure on the rotation of methanol molecules is discussed in view of hydrogen bonds in methanol.

Experimental

Methanol of guaranteed reagent grade (Nakarai Chemicals Co., Ltd.) was refluxed over sodium methoxide and silver nitrate and fractionally distilled. The central fraction collected was dried with aluminum amalgam and distilled again. By drying further with molecular sieves (3A, Nakarai) and distilling, methanol for conductivity measurements was prepared. Methanol just after the purification showed a water content of 0.02 mol % in the Karl Fischer test, but easily absorbed moisture from air without special care. The conductivity of methanol was less than 3×10^{-7} Ω^{-1} cm^{-1} in any case. Potassium chloride salt of high purity was obtained from Merck and dried above 150 °C. Methanol solutions of this salt were prepared by use of calibrated pipets and measuring flasks. The stock solution of HCl was obtained by allowing purified methanol absorb dry HCl gas; the HCl gas was generated by the addition of a concentrated aqueous HCl solution to a concentrated H_2SO_4, condensed at −90 °C to remove water, and then slowly evaporated. The concentration was determined by careful titration with carbonate-free NaOH solution standardized against potassium hydrogen phthalate (ultra-pure, Merck) solution.

The density (ρ)[6] and viscosity (η)[7] data of Bridgman for methanol at elevated pressures at various temperatures were interpolated to the required temperature and pressure. The dielectric constant (ε) was cited from Ref. 8. The properties of methanol at high pressure at 25 °C are listed in Table 1.

The high-pressure system for conductivity measurement is illustrated in Fig. 1. Pressure generated by the hand pump (1) was measured to ±1 kg cm^{-2} (1 kg cm^{-2}=0.9807 $\times10^5$ Pa) by a Heise Bourdon gage (3). The temperature of the oil bath (3) was kept constant at 25±0.03 °C. The conductivity cell (8) was put in the vessel (4) and resistances of methanol and solutions in the cell were measured by a commercially available instrument (Yanagimoto MY 7). The cell constant of the conductivity cell was determined at

Results

The equivalent conductances Λ of KCl and HCl in Tables 2 and 3 were obtained by subtracting the solvenct conductivity and assuming that densities of dilute KCl and HCl solutions were equal to the methanol density at each pressure. The Shedlovsky equation,[10]

$$1/\Lambda S(z) = 1/\Lambda^\circ + K_A C\Lambda S(z) f^2/\Lambda^{\circ 2},$$

where

$$S(z) = \{z/2+\sqrt{1+(z/2)^2}\}^2, \quad (2)$$

$$Z = 8.204\times10^5\,\Lambda^\circ/(\varepsilon T)^{3/2} + 82.50/\eta(\varepsilon T)^{1/2}\}\sqrt{C\Lambda/\Lambda^{\circ 3}}, \quad (3)$$

and

$$-\ln f^2 = 3.649\times10^6(\varepsilon T)^{3/2}\sqrt{C\Lambda S(z)/\Lambda^\circ}, \quad (4)$$

has been employed to obtain the limiting equivalent conductance Λ° from Λ; here, K_A, C, f^2, η, ε, and T are the association constant, concentration, Debye-Hückel limiting activity coefficient of the solute, the viscosity and dielectric constant of the solvent, and temperature, respectively. The present value of Λ° (KCl)/Ω^{-1} cm^2 equiv^{-1}, 104.4 at atmospheric pressure is comparable with the more accurate ones, 104.78[4] and 104.93[11] in literature.

As known well,[1,12,13] Λ(HCl) in methanol drops very sharply with the increase of the amount of water contained in contrast to Λ(KCl) insensitive to the impurity water, because protons bound to H_2O molecules (H_3O^+) will not tend to jump to neighboring CH_3OH molecules of lower dipole moment and the fraction of protons bound to CH_3OH molecules (CH_3OH^+) decreases on the addition of water to methanol. Hence, three sets of HCl solutions, which are different in the amount of water absorbed, were investigated. The mole fraction x[14] of water contained in methanol has been estimated at atmospheric pressure by means of Strehlow's equation,[13]

bound to CH_3OH, and Cl^- in nearly pure methanol. The parameters in Eq. 5 are determined at atmospheric pressure at 25 °C as

$$\Lambda_x°(HCl) = 198.5 - 1.39\times10^4 x/(1+138x). \quad (9)$$

The limiting equivalent conductances of KCl and HCl were divided into their ionic components as in Table 4, using the limiting transference numbers $t°(K^+)$ in KCl solution at atmospheric pressure[15] and those at high pressure which were obtained from Fig. 13 in Ref. 16. The ions decrease their mobilities with the rise in pressure as the methanol viscosity increases with increasing pressure, but initially increase in water qualitatively in parallel with the pressure dependence of the water viscosity.[2] In a quantitative sense, however, the pressure dependence of $\lambda°$ is not exactly parallel with that of the solvent fluidity η^{-1} because the Walden products of the ions $\lambda°\eta$ are not constant at high pressures as seen in Table 4. The effect of pressure on the Walden products of the ions is in the sequence,

$$H^+ > Cl^- > K^+.$$

Any of these ions has a much larger positive pressure coefficient of the Walden product in methanol than in water.[2,17]

The proton conductance in hydrogen-bonded solvents is due to the parallel series of the proton-jump and hydrodynamic processes.[1,18] However, no exact way to measure exclusively the anomalous conductance due to the proton-jump has been invented, and an empirical method is often used. The quantity,

$$\lambda_x°^{E} = \Lambda_x°(HCl) - \Lambda°(KCl), \quad (10)$$

is taken here as a measure of the anomalous conductance. Altough Li^+ and Na^+ are chosen elsewhere[1,19] instead of K^+ as a measure of the hydrodynamic conductance of the protonated species, H_3O^+ and CH_3OH^+, K^+ would be more appropriate because its ionic size is closer to H_3O^+ and CH_3OH^+ than the smaller ions.[20] The values of $\lambda_x°^{E}$ are plotted against pressure in Fig. 2. It is to be noted that $\lambda_x°^{E}$ increases with increasing pressure in methanol as $\lambda°^{E}$ in water.[2] The tendency is observed not only at infinite dilution but also at finite concentrations covered by the present work, while a decrease with pressure in the excess conductance measured at 2.5 mmol kg^{-1} by Λ(HBr)—Λ(NaBr) was reported[19] and later, an increase at infinite dilution was suggested.[21] The reason for the

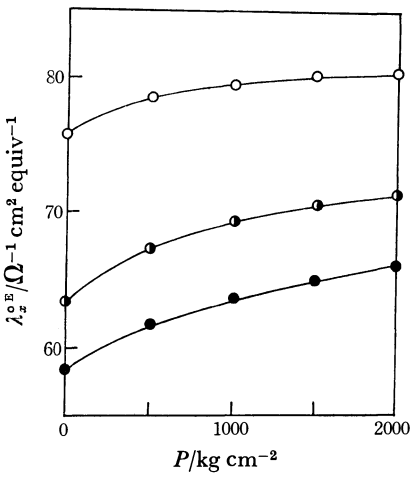

Fig. 2. Pressure dependence of excess proton conductances.
○, x=0.12 mol %; ◑, x=0.31 mol %; ●, x=0.40 mol %.

pressure-induced acceleration of proton jumps will be considered in the following section. On the other hand, the overall proton conductance decreases in methanol but increases in water.[2] The difference is explained in view of the facts that the contribution of the anomalous conductance to the overall proton conductance is much larger in the three-dimensionally hydrogen-bonded solvent (water) than in the one-dimensionally hydrogen-bonded solvent (methanol) and that the anomalous proton conductance is increased by pressure in both solvents but the hydrodynamic conductance is not initially promoted by pressure in methanol.

Discussion

It is important, first of all, to prove that the increase with pressure in the excess proton conductance at infinite dilution occurs in absolutely pure methanol as well as in methanol containing water. Using Eqs. 5 and 10 and assuming $\lambda°(H_3O^+)=\lambda°(K^+)$, We can derive the equation,

$$\lambda_x°^{E} = \lambda°^{E}(1-x)/\{1+(K-1)x\} \approx \lambda°^{E}/\{1+(K-1)x\}, \quad (11)$$

where the limiting excess proton conductance in pure methanol, $\lambda°^{E}$ is expressed as

$$\lambda°^{E} = \lambda°(CH_3OH_2^+) - \lambda°(K^+). \quad (12)$$

The differentiation of Eq. 11 with respect to pressure leads to the equation,

$$\partial\lambda°^{E}/\partial P = \{1+(K-1)x\}\partial\lambda_x°^{E}/\partial P + \lambda°^{E}\{1+(K-1)x\}^{-1}x\partial K/\partial P. \quad (13)$$

Since $\partial\lambda_x°^{E}/\partial P$ around 1 kg cm^{-2} is positive as seen in Fig. 2 and K at 1 kg cm^{-2} 139,[13] the first term in the right-hand side of Eq. 13 is positive. The second term is positive more or less because the equilibrium (7) is supposed to be shifted by pressure in some degree toward the right-hand side where the proton is bound to the stronger dipole and would have a smaller volume. Althogh the present data

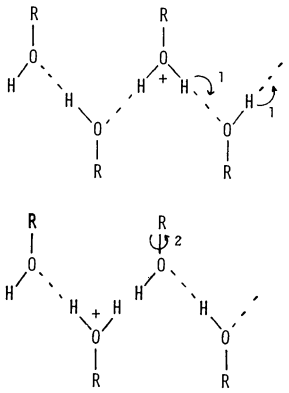

Fig. 3. Model for proton jump in methanol.
1, Proton transfer; 2, molecular rotation; R, methyl group.

are not enough to obtain quantitative information on $\partial\lambda^{\circ E}/\partial P$, they clearly exhibit through Eq. 13 that proton jumps in pure methanol are promoted by pressure to a larger extent than in methanol containing water.

The mechanism of proton jumps in alcohols has been proposed by Conway *et al.*[1] on the basis of the comparison between the excess proton conductance and the dielectric relaxation time in water and a few alcohols; there are two elementary processes, the proton transfer and the rotation of solvent molecules, the latter being the rate-determining step as in water. The same mechanism is assumed here and the molecular model is illustrated in Fig. 3. According to this mechanism, the increase with pressure in the excess proton conductance in methanol indicates that the rotation of methanol molecules about the longer molecular axis is promoted by pressure in spite of the increase in the density and the number of the hydrogen bonds.[22] When methanol is subjected to high pressure, the system is compressed to a denser state, irrespective of gain or loss in energy. For compression of the chain shown in the second row of Fig. 3, the following two factors are to be considered: (1) pushing the molecules above and below the plane of the chain so that the methyl groups may get closer, pressure distorts or bends the hydrogen bonds and weakens the strength; (2) keeping the molecules in the chain on the same plane, pressure decreases the intermolecular distance between the molecule to rotate and the hydrogen-bonded molecule (on the right side) and that between the molecule to rotate and the protonated molecule (on the left side). In the latter case, pressure gives more repulsive field to the molecule to rotate in favor of the rotation and at the same time, the strengthened hydrogen bond increases in some degree the potential barrier to the rotation. Although any conclusion on the relative importance of these factors must meet more straightforward studies, such as dielectric relaxation, NMR relaxation, and spectroscopic measurements at high pressure, at least, the factor (1) could not be neglected. As a matter of fact, the static dielectric constant of methanol increases and the Kirkwood correlation factor g decreases as methanol is compressed.[8] The increase in the dielectric constant is dominated by the density increase due to compression, but the decrease in the correlation factor suggests that such kind of distortion of the hydrogen bonds occurs that reduces the sum[23] of the average cosines of the angles between the dipoles of the correlated molecules in the hydrogen-bond chain.

A Conductance Study of Alkali Metal Ion–15-Crown-5, 18-Crown-6, and Dibenzo-24-crown-8 Complexes in Propylene Carbonate

Yasuyuki TAKEDA,* Hisao YANO, Masayuki ISHIBASHI, and Hiroshi ISOZUMI

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received July 23, 1979)

The formation constants, K_{ML^+}, for 1:1 complexes of 15-crown-5 (15C5), 18-crown-6 (18C6), and dibenzo-24-crown-8 (DB24C8) with alkali metal ions and the limiting ionic molar conductivities, $\lambda°$, of the complexed cations in propylene carbonate have been determined at 25 °C conductometrically. The K_{ML^+} value series about the same alkali metal ion among the crown ethers are given in the order 18C6 $\gg$ DB24C8 > 15C5. The K_{ML^+} sequences of the alkali metal ions with 15C5, 18C6, and DB24C8 are $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$, $K^+ > Na^+ > Rb^+ \gg Cs^+$, and $Na^+ > K^+ > Rb^+ \geq Cs^+$, respectively. The indication is that the ability of the alkali metal ions to form complexes with the three crown ethers is not always affected primarily by the relative sizes of the alkali metal ions and the crown ether cavity. In each case of 18C6 and DB24C8 the $\lambda°$ values of the alkali metal ions are nearly equal, while in the case of 15C5 there are considerably differences, suggesting that in the former case the charge of the alkali metal ion trapped in the crown ether cavity is effectively shielded. This is not true in the latter case.

It is known that crown ethers interact with certain cations, especially with alkali and alkaline earth metal ions, to form stable stoichiometric complexes. The stability of the complexes is governed by the solvent medium, the relative sizes of the cation and the crown ether cavity, the number of binding sites in the crown ether ring, and the flexibility of the crown ether.[1] The crown ether complexes in the crystalline state have been investigated by X-ray crystallography[2] and those in solution by spectroscopy[3] and conductimetry.[1h,4] The studies show that in many cases the cation is held in the crown ether cavity and surrounded by the oxygen atoms of the crown ether ring. The structure of the complex in solution is not always however the same as in the crystalline state.

The crown ethers used in this work are 15-crown-5 (15C5), 18-crown-6 (18C6), and dibenzo-24-crown-8 (DB24C8). The sizes, the cavity sizes, and the number of donor oxygen atoms of these three compounds are different from one another. Moreover, 15C5 and 18C6, whose oxygen atoms are coplanar and symmetrically distributed in the crown ether ring, are rigid crown ethers, while DB24C8, whose configuration is termed cylindrically symmetrical, is a flexible crown ether.[1a] In this paper, the formation constants for 1:1 complexes of 15C5, 18C6, and DB24C8 with alkali metal ions and the limiting ionic molar conductivities of the complexed cations in propylene carbonate (PC) have been determined conductometrically in order to study the factors influencing complex formation between crown ethers and alkali metal ions and the behavior of the complexed cations in PC, respectively. PC has a high dielectric constant (ε_r = 64 at 25 °C[5]) and moderate Lewis base and weak Lewis acid properties.[6] PC was used as the solvent since almost all univalent metal perchlorates are nearly completely dissociated in PC solution.[5,6b]

Experimental

Materials. 15C5, 18C6, and DB24C8 were obtained from Nisso Co., Ltd. 15C5 was purified by distillation under vacuum (bp 115—129 °C, 1.5 mmHg). 18C6 was recrystallized from acetonitrile and, prior to use, dried at 70 °C in a vacuum oven. The method of purification of DB24C8 was previously described.[7] Rubidium and caesium perchlorates were prepared by adding an equimolar perchloric acid solution to an aqueous solution of rubidium bromide and caesium hydroxide respectively. Lithium, sodium, and potassium perchlorates were purchased commercially. All perchlorates were recrystallized from water five times and, prior to use, dried at 150 °C in a vacuum oven. PC was distilled twice under nitrogen at approx. 12 mmHg. The middle 70% of the distillate was used. The water content of the finally purified PC determined by Karl Fischer titration was less than 0.01%. The conductivity of the final product was less than $5 \times 10^{-8}\ \Omega^{-1}\ cm^{-1}$.

Apparatus and Procedure. The conductance measurements were conducted on a Yanagimoto conductivity apparatus, model MY-7, in a water bath thermostated at 25.00±0.01 °C. Two cells were used with cell constants of 0.09317_1 and $0.2046_7\ cm^{-1}$.

The experimental procedure to obtain formation constants of crown ether complexes with alkali metal ions is as follows; a PC solution of the alkali metal perchlorate (4×10^{-4}—5×10^{-4} M, 200 cm^3) was placed in the cell (volume 300 cm^3) and the resistance of the solution measured. A step-by-step increase in the crown ether concentration was effected by a rapid transfer from the PC solution of the crown ether (5×10^{-3}—2×10^{-2} M) to the cell using a pipet, until the total concentration of the crown ether was approx. five times as large as that of the alkali metal perchlorate. The resistance of the solution in the cell was remeasured after each transfer.

The experimental procedure to obtain limiting ionic molar conductivities of the alkali metal ion–crown ether complexes was as follows; a PC solution of the crown ether (2×10^{-3} M, 200 cm^3) was placed in the cell and the resistance of the solution measured. Then a step-by-step increase in the alkali metal perchlorate concentration was effected by a rapid transfer from the PC solution of the alkali metal perchlorate (2×10^{-2} M) to the cell with a pipet, until the total concentration of the alkali metal perchlorate was approx. twice as large as that of the crown ether. The resistance of the solution in the cell was remeasured after each transfer.

Results

The molar conductivity, Λ, *vs.* $[L]_t/[M]_t$ plots in PC at 25 °C are given in Figs. 1—3, where $[L]_t$ and $[M]_t$ are the total concentrations of the crown ether

and the alkali metal ion respectively. Figures 1, 2, and 3 correspond to the cases of 15C5, 18C6, and DB24C8 respectively. The Λ *vs.* $[L]_t/[M]_t$ plots in Figs. 1—3 show a decrease of Λ with an increase in the crown ether concentration except for the 15C5-Li^+ and Na^+ and the Li^+–18C6 and DB24C8 systems. Those for the 15C5–Li^+ and Na^+ systems show an increase of Λ as the 15C5 concentration increases. In the Li^+–18C6 and DB24C8 systems, there is a negligible change in Λ in spite of an increase in the crown ether concentration, consequently the conductometric determination of the complex formation constant was impossible. The association between a cation, *i.e.*, an alkali metal ion and a tetraalkylammonium ion, and a perchlorate ion in PC is negligible,[5,6b] and therefore it is assumed on this basis that the association between the alkali metal ion–crown ether complex and the perchlorate ion in PC is also negligible under the highly dilute experimental conditions mentioned above. From Figs. 1—3, in the cases of the 15C5–Li^+ and Na^+, the 18C6–Na^+, K^+, Rb^+, and Cs^+, and the DB24C8–Na^+ systems, the slope of each curve changes sharply at the point when $[L]_t/[M]_t=1$, indicating that the crown ether forms a 1:1 complex with the alkali metal ion in PC under these experimental conditions.[8] For the 15C5 and DB24C8–K^+, Rb^+, and Cs^+ systems, no such clear breaking point was observed. From the literature[1b,1c,1f,1g] however, it is assumed that 15C5 and DB24C8 form 1:1 complexes with K^+, Rb^+, and Cs^+ in PC under these experimental conditions.

The equilibrium equation is given by

$$\begin{array}{ccccc} M^+ & + & L & \rightleftharpoons & ML^+ \\ \alpha[M]_t & & [L]_t-(1-\alpha)[M]_t & & (1-\alpha)[M]_t, \end{array} \quad (1)$$

where M^+, L, and α are the alkali metal ion, the crown ether, and the fraction of free alkali metal ions respectively. Accordingly, the complex formation constant, K_{ML^+}, is defined by

$$K_{ML^+} = \frac{[ML^+]}{[M^+][L]} = \frac{1-\alpha}{\alpha[L]}. \quad (2)$$

The observed conductivity, κ, is written as

$$\kappa = \kappa_{MClO_4} + \kappa_{MLClO_4}, \quad (3)$$

where κ_{MClO_4} and κ_{MLClO_4} are the conductivities of the alkali metal perchlorate and alkali metal crown ether perchlorate respectively. The molar conductivities are given by

$$\Lambda_{MClO_4} = \frac{\kappa_{MClO_4}}{[M^+]} = \frac{\kappa_{MClO_4}}{\alpha[M]_t}, \quad (4)$$

$$\Lambda_{MLClO_4} = \frac{\kappa_{MLClO_4}}{[ML^+]} = \frac{\kappa_{MLClO_4}}{(1-\alpha)[M]_t}, \quad (5)$$

where Λ_{MClO_4} and Λ_{MLClO_4} are the molar conductivities of the alkali metal perchlorate and alkali metal crown ether perchlorate respectively. Equation 3 may be transformed *via* Eqs. 4 and 5 to give

$$\Lambda = \frac{\kappa}{[M]_t} = \alpha\Lambda_{MClO_4} + (1-\alpha)\Lambda_{MLClO_4}. \quad (6)$$

Since the crown ether concentration was kept low ($<2.5\times10^{-3}$ M), corrections for viscosity changes were neglected. Substituting from Eq. 6 into Eq. 2 gives

$$K_{ML^+} = \frac{\Lambda_{MClO_4}-\Lambda}{(\Lambda-\Lambda_{MLClO_4})[L]}, \quad (7)$$

where

$$[L] = [L]_t - \frac{[M]_t(\Lambda_{MClO_4}-\Lambda)}{\Lambda_{MClO_4}-\Lambda_{MLClO_4}}.$$

Table 1. $\log (K_{ML^+}/mol^{-1}\,dm^3)$ values at 25 °C

	15C5		18C6		DB24C8	
	PC	H_2O[1b]	PC	H_2O[1b]	PC	70 wt% CH_3OH in H_2O[1c]
Li^+	4.2_6	—	—	—	—	—
Na^+	3.7	0.70	5.6_8	0.80	4.1_6	1.54
K^+	3.4_1	0.74	6.2_4	2.03	3.7_3	2.42
Rb^+	3.0_4	0.62	5.3_2	1.56	3.5_5	2.55
Cs^+	2.6_9	0.8	4.4_8	0.99	3.4_6	2.48

The procedure for obtaining the K_{ML^+} value is as follows. The Λ_{MLClO_4} value is estimated from the Λ values at the points of large $[L]_t$ to $[M]_t$ ratios. Using this Λ_{MLClO_4} value, the K_{ML^+} values in Eq. 7 is calculated. The actual K_{ML^+} and Λ_{MLClO_4} values are calculated by a nonlinear least-squares analysis.[1h] The log K_{ML^+} values are listed in Table 1.

The procedure for obtaining the limiting ionic molar conductivity, λ°, of the alkali metal ion–crown ether complex is as follows. The mass balances are

$$[M]_t = [M^+] + [ML^+], \quad (8)$$

$$[L]_t = [L] + [ML^+]. \quad (9)$$

From Eqs. 2, 8, and 9, the following quadratic equation follows;

$$K_{ML^+}[ML^+]^2 - \{1 + K_{ML^+}([M]_t + [L]_t)\}[ML^+] + K_{ML^+}[M]_t[L]_t = 0. \quad (10)$$

The $[M^+]$ value is obtained from Eq. 8 using the $[ML^+]$ value calculated from Eq. 10. The κ_{MClO_4} value in Eq. 3 at this $[M^+]$ point can be obtained from the previous $\Lambda_{MClO_4}-[MClO_4]^{1/2}$ plots in PC at 25 °C.[1i] Then, the Λ_{MLClO_4} value at this $[ML^+]$ point can be calculated from Eqs. 3 and 5 using this κ_{MClO_4} value. The limiting molar conductivity, Λ°, of the alkali metal crown ether perchlorate is determined by extrapolation of the calculated Λ_{MLClO_4} values from $\Lambda_{MLClO_4}-[MLClO_4]^{1/2}$ plots for ten-odd concentration points. From this Λ° value, the λ° value of the alkali metal ion–crown ether complex in PC at 25 °C is computed, using the λ° value of the perchlorate ion, $\lambda^\circ = 18.2_8\ \Omega^{-1}\,cm^2\,mol^{-1}$.[5] The λ° values of the alkali metal ion–crown ether complexes are given in Table 2, together with the λ° values of the alkali metal ions in PC at 25 °C.

Discussion

The log K_{ML^+} value series about the same alkali metal ion among the crown ethers in PC are from Table 1 in the order 18C6≫DB24C8>15C5. A complex is more stable the greater the number of oxygen atoms, provided the oxygens are coplanar and symmetrically distributed in the crown ether ring.[1a] 15C5 and 18C6 structurally obey these criteria and the log K_{ML^+} values of 15C5 and 18C6 in both PC and aqueous solutions (Table 1) show the same tendency as stated above. The log K_{ML^+} values of DB24C8 in PC (Table 1) are smaller than expected based on the greater number of donor oxygen atoms (eight) compared to those of 15C5 and 18C6 (five and six respectively), as found in the calorimetric titration study of the DB24C8 complexes with cations.[1c] This may be largely attributed to the entropy contribution due to the ring flexibility[1a] of DB24C8.

The log K_{ML^+} values of 15C5, 18C6, and DB24C8 for the alkali metal ions have been plotted as a function of the crystal ionic radius in Fig. 4. Figure 4 shows that the log K_{ML^+} values of these crown ethers for the same alkali metal ion are much larger for PC than for aqueous and 70 wt% CH_3OH solutions. This indicates that the alkali metal ions are more strongly solvated by water and methanol than PC. The data in Fig. 4 together with the fact that the dielectric constant, ε_r, value sequences of the three solvents are H_2O (ε_r=78 at 25 °C[1c])>PC (ε_r=64 at 25 °C[5c])> 70 wt% CH_3OH (ε_r=47 at 25 °C[1c]) indicates that the dielectric constant of the solvent is not always a

Table 3. Crystal ionic radii of alkali metals and cavity radii of crown ethers (Å)

Cation	Crystal ionic radius[9]	Crown ether	Cavity radius[10]
Li^+	0.60	15C5	0.85—1.1
Na^+	0.95	18C6	1.3—1.6
K^+	1.33	DB24C8	2.25—2.5
Rb^+	1.48		
Cs^+	1.69		

dominant factor in the alkali metal ion–crown ether complexing. The $\log K_{ML^+}$ series of 15C5 for the alkali metal ions in PC are in the order $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$ (Table 1), showing that the ability of the alkali metal ions to form complexes with 15C5 in PC is sensitive to the ratio of the ionic size to the cavity size except in the case of Li^+ (Table 3), while that in the aqueous solution is not (Fig. 4 and Table 3). The differences in the $\log K_{ML^+}$ values of 15C5 for the neighboring alkali metal ions increase from water to PC (Table 1). It is interesting that Li^+ forms a more stable complex with 15C5 than Na^+ in PC, although Li^+ is more strongly solvated by PC than Na^+[6a] and Na^+ fits more closely into the 15C5 cavity than Li^+ (Tables 1 and 3). From Table 1, the $\log K_{ML^+}$ sequences of the alkali metal ions with 18C6 in PC and aqueous solutions are $K^+ > Na^+ > Rb^+ \gg Cs^+$ and $K^+ > Rb^+ > Cs^+ > Na^+$ respectively, indicating that the selectivity of 18C6 for the alkali metal ions in PC and aqueous solutions primarily depends on the ratio of the ionic size to the cavity size of 18C6 (Table 3) and that the $\log K_{ML^+}$ sequences of the complex in PC differ from those in the aqueous solution. The $\log K_{ML^+}$ series of DB24C8 for the alkali metal ions in PC are given in the order $Na^+ > K^+ > Rb^+ \geq Cs^+$, although the more the size of the alkali metal ion decreases, the more strongly it is solvated by PC[6a] and as the size of the alkali metal ion increases, the crystal radius approaches the cavity radius of DB24C8 (Tables 1 and 3). The $\log K_{ML^+}$ sequences of the complex with DB24C8 in PC entirely differ from those in the 70 wt% CH_3OH solvent. It may be seen from Table 1 that in the case of each crown ether system an increase in $\log K_{ML^+}$ in moving from aqueous and 70 wt% CH_3OH solutions to PC increases with a decrease in the size of the alkali metal ion. Based on the above observations, both the stabilities and selectivities on complexation appear to reflect the competition between ligand coordination and solvation.

As can be seen from Table 2, the λ° value of the alkali metal ion is much larger than that of the corresponding alkali metal ion–crown ether complex except for the cases of 15C5-Li^+ and Na^+ systems, indicating that the size of the moving entity in PC is much larger for the alkali metal ion–crown ether complex than for the corresponding alkali metal ion. On the contrary the Li^+ and Na^+ ions are bulkier than the complexes of 15C5 with these ions in PC respectively. The λ° values of the alkali metal ion–crown ether complexes are larger for 18C6 than for DB24C8 and the size of DB24C8 is larger than that of 18C6. It thus appears that the relative sizes of the two crown ethers are the main factor influencing the mobilities. The λ° values of the complexes of 15C5 with Na^+ and Cs^+ are larger than those of 18C6 with Na^+ and Cs^+ respectively, which is the same tendency as that found in the 18C6 and DB24C8 systems. Those of 15C5 with K^+ and Rb^+ are smaller than those of 18C6 with K^+ and Rb^+ respectively, although the size of 15C5 is smaller than that of 18C6.

In each case of 18C6 and DB24C8 the λ° values of the alkali metal ions are nearly equal (Table 2), suggesting that the charge of the alkali metal ion trapped in the crown ether cavity is effectively shielded by the crown ether and that in each case of 18C6 and DB24C8 the complexes with the alkali metal ions are approximately equal to each other in size. That the λ° values of 15C5 for the alkali metal ions are considerably different from each other is in remarkable contrast to the cases of the 18C6 and DB24C8 systems (Table 2). A possible explanation for this is that it may be impossible for 15C5 to effectively screen the surface charge of the alkali metal ion held in its cavity because of its smaller size compared to 18C6 and DB24C8 (Table 3). Thus the 15C5 complexes with the alkali metal ions would more strongly undergo specific solvation by PC molecules than would 18C6 and DB24C8. It is of interest to note that in the cases of the 15C5 and 18C6 systems the Na^+ and K^+ complexes, where Na^+ and K^+ most closely fit into the cavities of 15C5 and 18C6 respectively (Table 3), have the largest mobilities of all the alkali metal ion complexes respectively (Table 2).

According to Lehn[11] and Boileau *et al.*,[4] the crystal ionic radii, $R_c(ML^+)$, of the alkali metal ion–15C5 and 18C6 complexes have been approximately evaluated from the crystal ionic radii $R_c(M^+)$, of the cations located within the central molecular cavity and from the ligand volume V_L:

$$R_c(ML^+) = \{R_c(M^+)^3 + 3V_L/4\pi\}^{1/3}$$

V_L may be approximated by summing the van der Waals volumes of the atoms or groups forming the ligand. Values of $R_c(ML^+)$ are given in Table 4 together with the calculated Stokes' radii, $R_s(ML^+)$, of the alkali metal ion-15C5 and 18C6 complexes from the equation $R_s(ML^+) = 0.819/\eta_0\lambda^\circ$, where η_0 is the viscosity of the pure solvent. Table 4 shows that the $R_s(ML^+)$ value about the same alkali metal ion in PC is much smaller than the $R_c(ML^+)$ one for 15C5 and 18C6, which is the same and opposite trends

Table 4. Stokes' radii, R_s, and crystal ionic radii, R_c, of alkali metal ion–crown ether complexes (Å)

Cation	15C5		18C6	
	R_s	R_c	R_s	R_c
Li^+	3.4_9	4.5	—	—
Na^+	3.2_1	4.6	3.8_0	4.8
K^+	3.7_4	4.6	3.6_3	4.9
Rb^+	3.8_7	4.6	3.6_5	4.9
Cs^+	3.4_3	4.6	3.6_9	4.9

for tetraalkylammonium ($R_s \ll R_c$) and alkali metal ions ($R_s \gg R_c$) in PC respectively.[5] The crystal ionic radii of the alkali metal ion–15C5 and 18C6 complexes are nearly identical with those of tetrapropylammonium (4.52 Å[12]) and tetrabutylammonium ions (4.94 Å[12]) respectively (Table 4). The λ° values of the alkali metal ion–15C5 and 18C6 complexes are however smaller than those of tetrapropylammonium (11.0_0[5]) and tetrabutylammonium ions (9.32_5[5]) respectively (Table 2).

Preparation and Stereochemistry of Cobalt(III) Complexes with Tetramines Derived from 1-(2-Pyridyl)ethylamine

Toshishige M. Suzuki,* Tetsuo Kimura, and Junnosuke Fujita†

Government Industrial Research Institute, Tohoku, Nigatake, Haranomachi, Sendai 983

†*Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464*

(Received May 14, 1979)

The optically active ligands, (2*S*,7*S*)-2,7-di(2-pyridyl)-3,6-diazaoctane (*S*,*S*-peaen) and (2*R*,8*R*)-2,8-di(2-pyridyl)-3,7-diazanonane (*R*,*R*-peatn) have been prepared. The dichlorocobalt(III) complexes of these ligands have been prepared and several isomers isolated. The ligand, *S*,*S*-peaen yielded one *cis*-α and two types of *cis*-β isomers, while the *R*,*R*-peatn gave only one *cis*-β isomer. Oxalato and dinitro derivatives of the *R*,*R*-peatn complexes have been isolated and characterized and the stereochemistry of the isolated complexes discussed.

Extensive investigations have been conducted on the stereochemistry of cobalt (III) complexes containing trien (triethylenetetramine) or its methyl substituted derivatives.[1] Tetramines derived from heteroaromatic ligands are quite limited however.[2–5] The quadridentate ligand, 1,6-di(2-pyridyl)-2,5-diazahexane (bispicen) is one of the representative tetramine ligands having pyridyl groups on the terminal arms. There are three topological ways for coordination of the tetramine type ligands to a cobalt(III) ion, *i.e.* *cis*-α, *cis*-β, and *trans*. Gibson and McKenzie isolated and characterized the *cis*-α and *cis*-β isomers of the dichlorocobalt(III) complex of bispicen for the first time.[2] Very recently Utsuno *et al.*, isolated the *cis*-α and two types of *cis*-β isomers of the cobalt(III) complex containing bispicen and ethylenedianime.[5]

Optically active centers may be introduced into the tetramine chain by methyl substitution on the skeletal carbons. The optically active derivatives of bispicen, $(+)_D$-1,6-di(2-pyridyl)-3-methyl-2,5-diazahexane (picpn)[3] and $(+)_D$-1,6-di(2-pyridyl)-3,4-dimethyl-2,5-diazahexane (bnpic)[4] are examples of such ligands having substituent(s) in the central bridge. Stereospecific coordination to a cobalt(III) ion giving a Δ-*cis*-β configuration has been found for these ligands.[3,4] The stereospecificity has been explained in relation to the restricted conformation of the central diamine chelate of picpn and bnpic.

The ligands prepared in the present study, (2*S*,7*S*)-2,7-di(2-pyridyl)-3,6-diazaoctane (*S*,*S*-peaen) and (2*R*,8*R*)-2,8-di(2-pyridyl)-3,7-diazanonane (*R*,*R*-peatn) derived from 1-(2-pyridyl)ethylamine (pea) have two methyl groups in the terminal arms as illustrated in Fig. 1. The terminal pea moiety has a structure intermediate between 1,2-propanediamine and 2,2′-bipyridine. It has been demonstrated that the *S*-pea chelate tends to assume a δ-conformation on complexation with the methyl group occupying an equatorial position.[6,7] Therefore on coordination both of the terminal chelate rings of *S*,*S*-peaen and *R*,*R*-peatn may be fixed giving a sterically prefered configuration about the metal ion.

The preparation and isolation of the isomers of cobalt(III) complexes containing *S*,*S*-peaen and *R*,*R*-peatn are given in this paper and the stereochemistry of the complexes discussed.

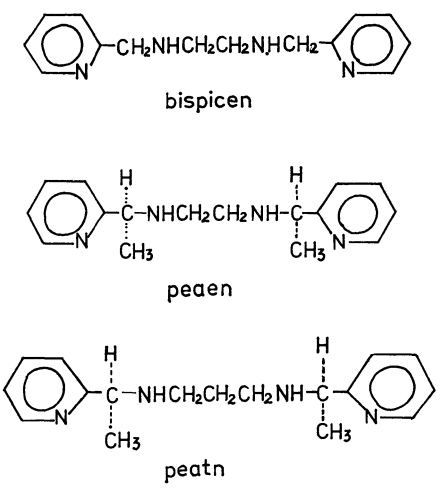

Fig. 1. Abbreviation and structure of ligands.

Experimental

Preparation of Ligands. Optically active 1-(2-pyridyl)-ethylamine (pea) used as the starting materials in the preparation of the tetramines were synthesized according to a method similar to that given by Michelsen.[8] The $(+)_D$-isomer of pea is known to have an *R* configuration.[9]

(2S,7S)-2,7-Di(2-pyridyl)-3,6-diazaoctane (S,S-peaen). To a vigorously stirred solution of *S*-pea (30.54 g, 0.25 mol) in ethanol (300 cm³) was added dropwise 1,2-dibromoethane (9.40 g, 0.05 mol) over a period of 2 h under nitrogen atmosphere at 50 °C. The mixture was heated to reflux with vigorous stirring under nitrogen for 18 h. The end point of the condensation was correlated with the disappearance of the 1,2-dibromoethane peak found from gas chromatography. The reaction mixture was subsequently cooled to room temperature. To the stirred solution was added granulated metallic sodium (2.3 g) in small portions. The mixture was stirred at 50 °C for a further 2 h and cooled to room temperature. After filtration, the ethanol and excess *S*-pea was removed by distillation under reduced pressure. The residue was purified by alumina column chromatography using hexane as an eluent. After removal of the solvent, a brown syrup (6.8 g) was obtained. Yield 50.3%. The tetramine was isolated as its hydrochloride by the addition of concd HCl (10 cm³) and ethanol (100 cm³). Yield 7.85 g.

Found: C, 46.33; H, 6.31; N, 13.56%. Calcd for $C_{16}H_{22}N_4 \cdot 4HCl$: C, 46.15; H, 6.25; N, 13.46%.

(2R,8R)-2,8-Di(2-pyridyl)-3,7-diazanonane (R,R-peatn). This ligand was prepared according to a method similar to that for *S*,*S*-peaen using *R*-pea and 1,3-dibromopropane and isolated as the hydrochloride. Yield 48.6%.

Found: C, 47.33; H, 6.82; N, 12.97%. Calcd for $C_{17}H_{24}N_4 \cdot 4HCl$: C, 47.45; H, 6.56; N, 13.02%.

cis-*β-I*-[*CoCl*$_2$(S,S-*peaen*)]*ClO*$_4 \cdot H_2O$. A stream of air was bubbled through a solution of the *S,S*-peaen·4HCl (2.08 g), $LiOH \cdot H_2O$ (0.65 g) and $CoCl_2 \cdot 6H_2O$ (1.2 g) in water (50 cm^3) for 3 h. To the solution was added concd HCl (8 cm^3) and 70% $HClO_4$ (2 cm^3). The resulting red solution was evaporated to 30 cm^3 on a water bath (60 °C) and stored in a refrigerator overnight. The violet crystals deposited were filtered, washed with water, ethanol and ether. Yield: 350 mg. The second crop of crystals which were identical with those of the first crop were obtained by evaporating the filtrate to 20 cm^3. Yield: 240 mg.

Found: C, 36.91; H, 4.86; N, 10.69%. Calcd for $C_{16}H_{24}N_4O_5Cl_3Co$: C, 37.17; H, 4.64; N, 10.82%.

cis-*β-II*-[*CoCl*$_2$(S,S-*peaen*)]*ClO*$_4 \cdot 1/2H_2O$. The filtrate from the separation of *cis-β*-I was stored in a refrigerator for 3 h. The reddish-purple crystals deposited were filtered, washed with a water–ethanol mixture (1:1), ethanol and ether, and air dried. Yield: 200 mg.

Found: C, 37.89; H, 4.60; N, 10.87%. Calcd for $C_{16}H_{22}N_4O_4Cl_3Co \cdot 1/2H_2O$: C, 37.73; H, 4.52; N, 11.01%.

cis-α-[*CoCl*$_2$(S,S-*peaen*)]*ClO*$_4 \cdot 3/2H_2O$. $CoCl_2 \cdot 6H_2O$ (1.2 g) in water (10 cm^3) and 30% H_2O_2 (1 cm^3) were mixed in an ice bath and added dropwise to a solution of $NaHCO_3$ (2.8 g in 50 cm^3 of water) at 0 °C for 30 min.[10] To the solution was added a mixture of *S,S*-peaen·4HCl (2.08 g) and $LiOH \cdot H_2O$ (0.63 g) in water (10 cm^3). The resulting red solution, concd HCl (10 cm^3) and 70% $HClO_4$ (1 cm^3) were added and heated at 80 °C for 20 min, and allowed to stand at room temperature overnight. The violet crystals deposited were filtered, washed with water, ethanol and finally ether. Yield: 300 mg. The crystals were identical with *cis-β*-I obtained by the air oxidation method. The filtrate from the separation of *cis-β*-I was poured onto a column of cation exchanger Dowex 50W-X8 (H^+ form) (ϕ 3.0× 20 cm). The column was washed with water, and the adsorbed product was eluted with 5 M HCl. The reddish-purple eluate was evaporated to dryness. The purple residue was dissolved in 5 M HCl (15 cm^3) and the solution filtered. After the addition of 70% $HClO_4$ (1 cm^3), the solution was stored in a refrigerator for three days. The purple crystals deposited were filtered, washed with a water–ethanol mixture (1:1), ethanol and finally ether. Yield: 240 mg.

Found: C, 36.63; H, 4.56; N, 10.64%. Calcd for $C_{16}H_{22}N_4O_4Co \cdot 3/2H_2O$: C, 36.49; H, 4.75; N, 10.63%.

cis-α-[*Co(ox)*(S,S-*peaen*)]*ClO*$_4 \cdot H_2O$. A mixture of *cis*-α-[$CoCl_2$(*S,S*-peaen)]$ClO_4 \cdot 3/2H_2O$ (0.5 g) and sodium oxalate (0.2 g) in water (30 cm^3) was heated at 80 °C for 30 min. The orange solution was evaporated to 10 cm^3 and stored at room temperature. The orange crystals deposited were collected and recrystallized from hot water.

Found: C, 40.58; H, 4.96; N, 10.39%. Calcd for $C_{18}H_{22}N_4O_8ClCo \cdot H_2O$: C, 40.43; H, 4.48; N, 10.48%.

cis-*β*-[*CoCl*$_2$(R,R-*peatn*)]*ClO*$_4 \cdot H_2O$. The procedure used here was analogous to the preparation of [$CoCl_2$(*S,S*-peaen)]$ClO_4 \cdot H_2O$. A stream of air was bubbled through a solution of *R,R*-peatn·4HCl (2.15 g), $LiOH \cdot H_2O$ (0.65 g) and $CoCl_2 \cdot 6H_2O$ (1.2 g) in water (50 cm^3) for 4 h. To the dark brown solution was added concd HCl (8 cm^3) and 70% $HClO_4$ (2 cm^3). The resulting solution was evaporated to 20 cm^3 on a water bath. On standing at room temperature for 1 h deep violet crystals deposited. The crystals were collected, washed with a small amount of water, acetone and air dried. Yield 1.64 g. The filtrate was poured onto a column of SP-Sephadex (ϕ 3.0×42 cm). The adsorbed band was eluted with 2 M HCl. The eluatant of the purple band was fractionated and the CD spectra recorded. All the fractions gave an identical CD spectra with that of the isolated complex. No indication of the presence of the other isomer was found. The so-called tricarbonato method[10] was also employed in the preparation of dichloro(*R,R*-peatn) complexes. The obtained complex was identical with that prepared by the air oxidation method.

Found: C, 38.28; H, 5.21; N, 10.37%. Calcd for $C_{17}H_{24}N_4Cl_3Co \cdot H_2O$: C, 38.40; H, 4.94; N, 10.53%.

cis-*β*-[*Co*(NO_2)$_2$(R,R-*peatn*)]*ClO*$_4$. Sodium nitrate (0.2 g) was added to a hot solution of *cis-β*-[$CoCl_2$(*R,R*-peatn)]ClO_4 (0.4 g) in water (10 cm^3). The solution was heated at 70 °C for 30 min. On cooling to room temperature for 1 h, the orange-yellow crystals were filtered and washed with water, ethanol and finally ether. Yield: 310 mg.

Found: C, 38.15; H, 4.54; N, 15.84%. Calcd for $C_{17}H_{24}N_6O_8ClCo$: C, 38.18; H, 4.52; N, 15.71%.

cis-*β*-[*Co(ox)*(R,R-*peatn*)]*ClO*$_4 \cdot 1/2H_2O$. A solution of *cis-β*-[$CoCl_2$(*R,R*-peatn)]ClO_4 (0.52 g) and sodium oxalate (0.2 g) in water (10 cm^3) was heated at 50 °C for 2 h. The cherry-red crystals deposited were collected and recrystallized from hot water. Yield: 220 mg.

Found: C, 42.06; H, 4.61; N, 10.38%. Calcd for $C_{19}H_{24}N_4O_8ClCo \cdot 1/2H_2O$: C, 42.27; H, 4.67; N, 10.38%.

Measurements. The visible and ultraviolet absorption were recorded with a Shimadzu Double 40-R spectrophotometer. The CD spectra were recorded on a JASCO J-20 spectropolarimeter. The spectra of the dichloro complexes were recorded in concd HCl, while those of the other complexes were recorded in water. The PMR spectra in DMSO-d_6 were obtained with a JNM-PMX60 spectrometer using tetramethylsilane (TMS) as an internal standard. All the measurements were conducted at room temperature.

Results and Discussion

Ligands. The quadridentate ligands, *S,S*-peaen and *R,R*-peatn were prepared from optically active 1-(2-pyridyl)ethylamine (pea) with 1,2-dibromoethane and 1,3-dibromopropane, respectively. The absolute configuration of the tetramine ligands is expected to be the same as that of the mother pea whose absolute configuration has been determined.[9]

S,S-*Peaen Complexes.* Dichlorocobalt(III) complexes of *S,S*-peaen were prepared according to the reaction scheme:

1) $Na_3[Co(CO_3)_3]$ + *S,S*-peaen

$$\xrightarrow[HClO_4]{HCl} \begin{cases} \textit{cis-α}\text{-}[CoCl_2(S,S\text{-peaen})]^+ \\ \quad \text{(purple)} \\ \textit{cis-β}\text{-I-}[CoCl_2(S,S\text{-peaen})]^+ \\ \quad \text{(violet)} \end{cases}$$

2) $Co(II)Cl_2 \cdot 6H_2O$ + *S,S*-peaen

$$\xrightarrow[HCl,\ HClO_4]{O_2} \begin{cases} \textit{cis-β}\text{-I-}[CoCl_2(S,S\text{-peaen})]^+ \\ \quad \text{(violet)} \\ \textit{cis-β}\text{-II-}[CoCl_2(S,S\text{-peaen})]^+ \\ \quad \text{(reddish-purple)} \end{cases}$$

Two types of stereoisomers were isolated by fractional crystallization from both reactions. The violet isomer (*cis-β*-I) was a major product in both reactions. Elemental analyses of the isomers are in good accord with the formulation and the geometrical configura-

tions were confirmed by visible absorption and PMR spectral data. No *trans*(Cl–Cl) isomer was obtained. The trans geometry of the peaen complex would be unstable presumably due to steric hindrance between the hydrogen atoms of the two terminal pyridine residues. The PMR spectra of the isolated isomers measured in deuterated DMSO are given in Fig. 2. The purple isomer which was obtained *via* tricarbonatocobaltate(III) showed a single methyl doublet at approximately 1.9 ppm, indicating that the two methyl groups of peaen are equivalent; the geometrical configuration is therefore *cis*-α. The violet (*cis*-β-I) and reddish-purple (*cis*-β-II) complexes gave signals for the two types of methyl groups. Thus, the geometries may be assigned as *cis*-β. For the *cis*-α isomer of the cobalt(III) complex of the trien type ligand, only one enantiomer is possible,

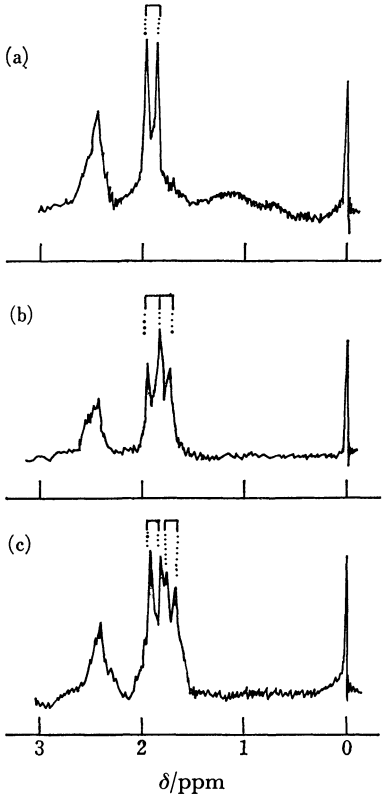

Fig. 2. PMR spectra of (a) *cis*-α-$[CoCl_2(S,S\text{-peaen})]^+$, (b) *cis*-β-I-$[CoCl_2(S,S\text{-peaen})]^+$ and (c) *cis*-β-II-$[CoCl_2(S,S\text{-peaen})]^+$ in DMSO(d_6).

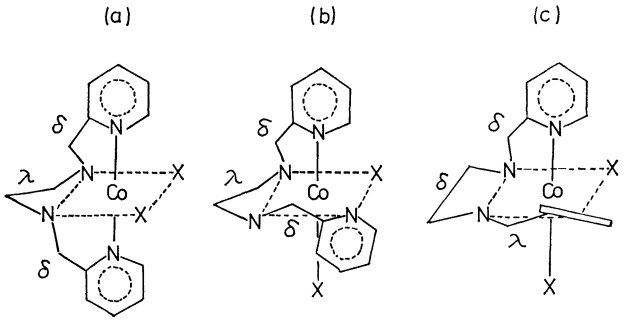

Fig. 3. Three diastereomers of *cis*-$[CoX_2(\text{bispicen})]^+$. (a) *Λ-cis*-α-($R_N$,$R_N$), (b) *Δ-cis*-β-($R_N$,$S_N$), (c) *Δ-cis*-β-($R_N$,$R_N$).

whereas two types of diastereomers are expected for the *cis*-β geometry. The two *cis*-β geometries arise from a combination of the configuration of the coordinated secondary nitrogen atoms.[11] Similar isomers are expected for the complexes of bispicen type ligands as shown in Fig. 3.[12]

According to a recent X-ray analysis of *Λ-fac*-$[Co(S\text{-pea})_3](ClO_4)_3\cdot H_2O$, the *S*-pea chelate has been shown to take a puckered δ-conformation with the C-methyl group occupying an equatorial position.[6] The terminal chelate rings of *S,S*-peaen in the present complex would also favour the δ-conformation in a similar manner to the chelate ring of the mother *S*-pea. A molecular model predicts that whenever the terminal chelates of *S,S*-peaen are fixed in a δ-conformation, the *cis*-α and *cis*-β geometries uniquely yield *Λ-cis*-α-(R_N,R_N) and *Δ-cis*-β-(R_N,S_N) configuration, respectively. Thus the present *cis*-α and one of the *cis*-β isomers are most likely to have the above configurations, respectively. Since two types of *cis*-β isomers were obtained in the present study, one must be either the *Δ-cis*-β-(R_N,R_N) or the *Λ-cis*-β-(S_N,S_N) (see Fig. 3-c). In these enantiomeric configurations, the two outer chelate rings should have opposed conformations, *i.e.*, one of the terminal chelate rings should take a λ-conformation in which the methyl group takes an axial position.

The electronic absorption and CD spectra of the *Λ-cis*-α dichloro(*S,S*-peaen) complex and its oxalato derivative are shown in Fig. 4. The *Λ-cis*-α dichloro-(*S,S*-peaen) complex shows a well defined shoulder at the longer wavelength side of the first absorption band. A similar feature in the first absorption band has been observed for the *cis*-α dichloro complex of trien[13] and methyl substituted trien.[14] The CD spectrum in the first absorption band region gives positive and negative components with nearly equal

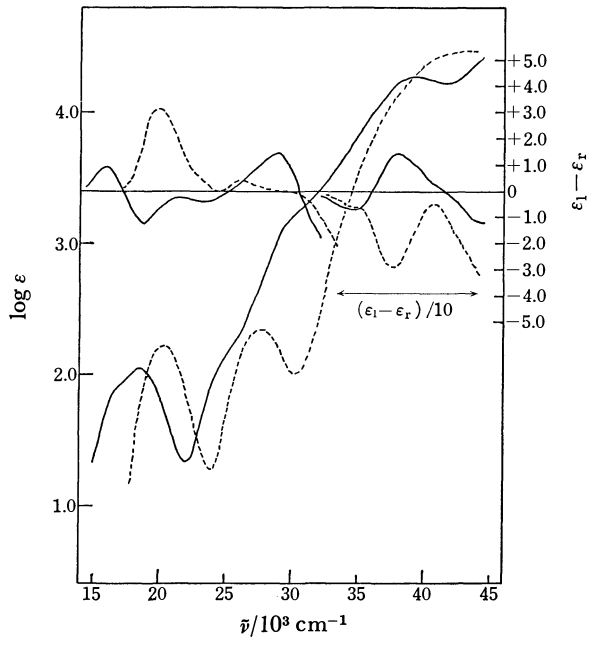

Fig. 4. Absorption and CD spectra of *cis*-α-$[CoCl_2(S,S\text{-peaen})]^+$ (——) in concd hydrochloric acid and *cis*-α-$[Co(ox)(S,S\text{-peaen})]^+$ (----) in water.

intensity from the longer to shorter wavelength. This CD pattern is vertually enantiomeric with that of *Λ-cis-α*-[$CoCl_2$(trien)]$^+$,[13] and *Λ-cis-α*-[$CoCl_2$(3*S*,8*S*-dimetrien)]$^+$ (3*S*,8*S*-dimetrien=(2*S*,7*S*)-2,7-dimethyl-3,6-diazaoctane-1,8-diamine).[14] The *cis-α* oxalato (*S*,*S*-peaen) complex which was obtained from the dichloro complex by a treatment with sodium oxalate in aqueous solution gave CD spectrum very similar to that of *Λ-cis-α*-[Co(ox)(trien)]$^+$.[15] The PMR spectrun of the oxalato complex showed a singel methyl doublet, indicating that the *cis-α* configuration is maintained in the course of reaction.

The absorption and CD spectra of the two types of *cis-β* isomers are shown in Fig. 5. Obviously these *cis-β* isomers give different absorption and CD spectra in the first absorption band region. The absorption maximum of *cis-β*-I appears at a longer wavelength than that of *cis-β*-II and the band has a well defined shoulder on the longer wavelength side. The CD associated with the first absorption band of *cis-β*-I gives two components, positive and negative Cotton effects from longer to shorter wavelength, while that of *cis-β*-II gives only one negative CD component. In contrast to the *S*,*S*-peaen complex only one *cis-β* isomer of structure *Λ-cis-β*-(R_N,S_N) has been obtained for the dichlorocobalt(III) complexes of 3*S*,8*S*-dimetrien and 2*S*,9*S*-dimetrien (2*S*,9*S*-dimetrien=(1*S*,8*S*)-1,8-dimethyl-3,6-diazaoctane-1,8-diamine).[14] The absorption and CD spectra in the first absorption band region for these *cis-β* complexes resembles those of the *cis-β*-II isomer rather than the *cis-β*-I isomer in the following points: (1) no shoulder of the first absorption band was detected; (2) only one negative CD peak was observed in the first absorption band region. Thus, the present *cis-β*-II isomer is most likely to have a *Λ-cis-β*-(R_N,S_N) configuration in which both of the two outer chelates have a *δ*-conformation.

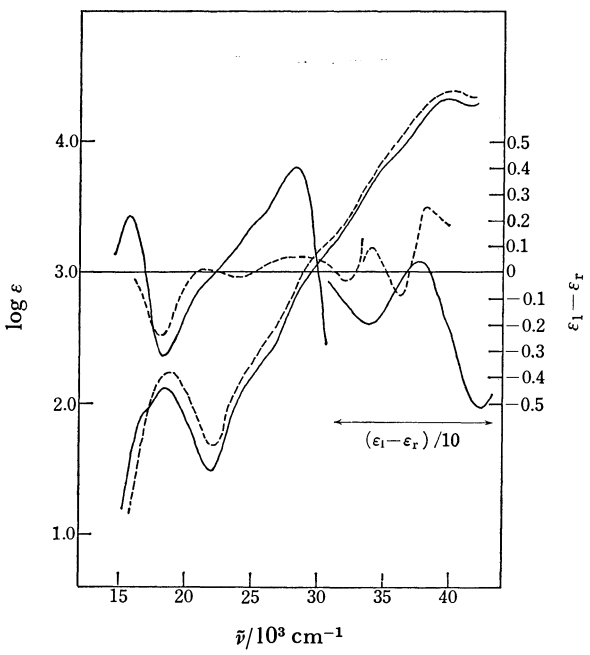

Fig. 5. Absorption and CD spectra of *cis-β*-I-[$CoCl_2$-(*S*,*S*-peaen)]$^+$ (——) and *cis-β*-II-[$CoCl_2$(*S*,*S*-peaen)]$^+$ (----) in concd hydrochloric acid.

The absorption spectra and CD pattern of the *cis-β*-I isomer resemble the *cis-α* more than the *cis-β* II, although the CD magnitude of the *cis-β*-I is smaller than that of *cis-α*. At present it is impossible to be unambiguous about the absolute configuration of the *cis-β*-I based on the CD pattern. Saburi *et al.*, have isolated a novel *cis-β* isomer of dinitro and carbonato (3*S*,8*S*-dimetrien)cobalt(III) complexes whose absolute configuration has been deduced to be *Λ-cis-β*-(S_N,S_N) on the basis of the PMR and CD spectra.[16] The molecular structure of *Λ-cis-β*-[Co(CO_3)(3*S*,8*S*-dimetrien)]-ClO_4 has been determined by the X-ray diffraction method[17] where it has been shown that the methyl group on the apically ligated chelate ring has an axial orientation. It is said that the apically ligated chelate ring inthe *cis-β*-(trien) complexes is less restricted than the side chelate ring coplanar with the central chelate.[1] Thus the structure of the present *cis-β*-I would also be in a *Λ-cis-β*-(S_N,S_N) configuration.

R,R-*peatn Complexes.* Dichlorocobalt(III) complexes with *R*,*R*-peatn were prepared according to the same method as those of the peaen complexes. In both methods, only one purple isomer was stereospecifically obtained. The PMR spectra of the dichloro complex shown in Fig. 6 gives two types of methyl doublets due to the terminal pea in the 1.8—2.0 ppm region, indicating that the complex has *cis-β* geometry.

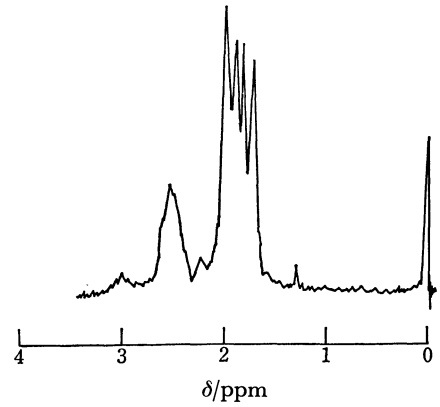

Fig. 6. PMR spectra of *cis-β*-[$CoCl_2$(*R*,*R*-peatn)]$^+$ in DMSO(d_6).

The central diamine moiety of *R*,*R*-peatn forms a six-membered chelate ring on complex formation. The conformational behavior of the six-membered chelate ring parallels that of cyclohexane. Among the three possible conformers of the six-membered chelate, *i.e.*, chair, skew and boat, the chair conformation is known to be most stable.[18–20] For the *cis-β* configuration of *R*,*R*-peatn complex, the following isomers are possible, *Λ-cis-β*-(S_N,S_N), *Λ-cis-β*-(R_N,R_N), *Λ-cis-β*-(R_N,S_N) and *Λ-cis-β*-(S_N,R_N). An examination of the molecular models indicates that for the *Λ-cis-β*-(S_N,S_N) configuration, the central six-membered ring can assume the chair conformation and at the same time both *R*-pea chelates take an *λ*-conformation with the methyl groups occupying equatorial positions. Accordingly, the most probable configuration of the *cis-β*-(*R*,*R*-peatn) complex is *Λ-cis-β*-(S_N,S_N).

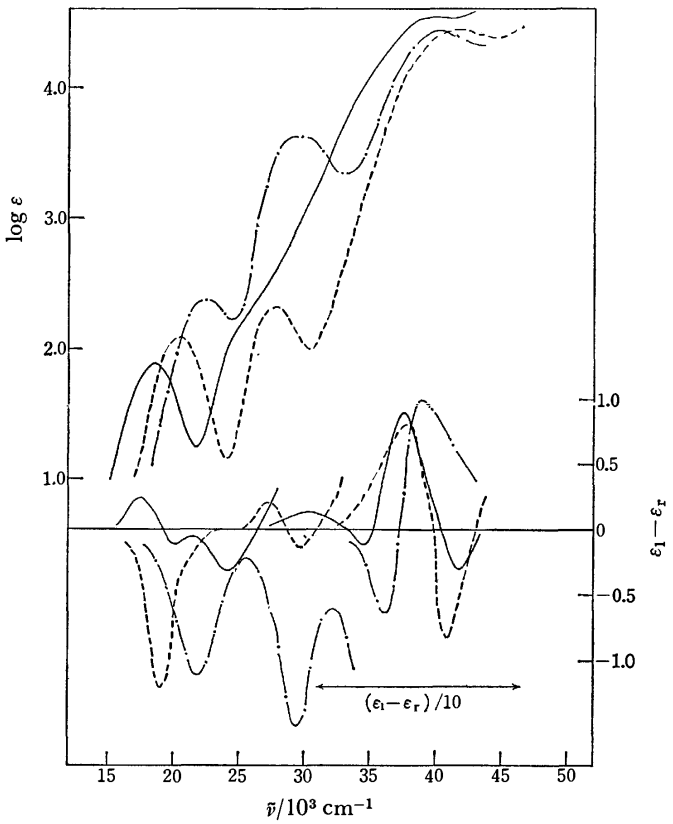

Fig. 7. Absorption and CD spectra of *cis*-β-[$CoCl_2$(*R*,*R*-peatn)]$^+$ (——) in concd hydrochloric acid, *cis*-β-[Co(ox)(*R*,*R*-peatn)]$^+$ (----) and *cis*-β-[$Co(NO_2)_2$-(*R*,*R*-peatn)]$^+$ (—·—·) in water.

The cis dinitro and oxalato complexes of *R*,*R*-peatn were prepared from *cis*-β-[$CoCl_2$(*R*,*R*-peatn)]ClO_4 by heating an aqueous solution of the complex with sodium nitrate or sodium oxalate, respectively. In all cases, absorption and CD spectra of the reacted solution were identical with those obtained for the isolated complexes and no other isomers were formed. Thus, it appears that the relative configurations of the dinitro and oxalato complexes are the same as that of the dichloro species.

The absorption and CD curves of dichloro, dinitro and oxalato complexes are shown in Fig. 7. The CD corresponding to the first absorption band of the dichloro complex gives two components, positive and negative signs from longer to shorter wavelengths. In contrast, the dinitro and oxalato complexes of *R*,*R*-peatn give one negative component in the first absorption band region. The Δ-configuration can be assigned for these complexes on the basis of the signs of the dominants CD peaks in the first absorption band region.[21] This assignment is in accord with that based on the stereomodels.

It has been revealed that the stereochemical behavior of the peaen and peatn complexes is very similar to the corresponding complexes of methyl substituted trien[14,16,22] and 2′,3,2′-tet ligands.[23] This indicates that the conformational effects of the terminal pea chelate moieties of peaen and peatn complexes are essentially the same as those of the chiral diamine chelates.

Kinetics and Mechanisms of Ligand Exchange Reactions of Tris(acetylacetonato)-chromium(III), -cobalt(III), -ruthenium(III), and -rhodium(III) in Acetylacetone

Hiroaki KIDO

Chemistry Department, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received May 15, 1979)

Tris(acetylacetonato[2-^{14}C])-cobalt(III), -chromium(III), -ruthenium(III), and -rhodium(III) undergo ligand exchange in acetylacetone(Hacac) at 85—190 °C without decomposition of the complexes. The exchange rate is proportional to the complex concentration, and the first-order rate constant k_0 decreases in the sequence Co(III) > Cr(III) > Ru(III) > Rh(III), $k_0/10^{-5}$ s^{-1} being 2.4 (93 °C), 5.6 (117 °C), 9.5 (158 °C), and 2.4 (185 °C), respectively. The activation enthalpies and entropies and deuterium isotope effect on k_0 are significantly different between the Co(III) and the Cr(III), Ru(III) and Rh(III) complexes. An intermediate involving an one-ended acetylacetonate and a solvent molecule(Hacac) is concluded to be formed in the rate-determining step. The S_N1 and the S_N2 mechanism are assigned to the exchange reactions of the Co(III) complex and the others, respectively, for the rate-determining steps.

The exchange reaction of solvo ligands with solvent molecules has been scarecely studied with bidentate ligands, although the reaction is profitable for the assignment of the substitution mechanisms. Pearson and Lanier[1] observed, as a unique example, the rate and the rate limits for the exchange of ethylene glycol coordinated to bivalent transition metal ions in ethylene glycol. In this work, the ligand exchange reactions of tris(acetylacetonato) complexes of tervalent transition metal ions(M(acac)$_3$; M(III)=Cr(III), Co(III), Ru(III), and Rh(III)) have been investigated in a reaction system consisting of only two components, the labelled complex as solute and acetylacetone (Hacac) as solvent.

In the previous papers, we have proposed the mechanisms of the ligand exchange reactions of Cr(acac)$_3$ and Co(acac)$_3$ in acetonitrile.[2,3] However, there remains an ambiguity in the mechanisms concerning participation of solvent molecule. In the present work, we have simplified the reaction system, confirmed the mechanisms of the reactions and suggested relative rates of individual steps in the substitution processes of the bidentate.

The ligand substitution kinetics of Co(III), Ru(III), and Rh(III) complexes containing O_6 core have been hardly studied,[3-5] although those of the N_5O type complexes represented by $[M^{III}(NH_3)_5H_2O]^{3+}$ containing the present metal ions have been systematically studied.[6,7] Therefore, we have also a unique opportunity of comparing the substitution mechanisms of the present exchange of the O_6 type complexes with those of the water exchange of the N_5O type complexes.[8-11]

Experimental

Materials. The labelled species, Hacac[2-^{14}C],[12] Hacac[*methylene*-$^2H_2$],[2] Co(acac[2-^{14}C])$_3$[3] and Cr(acac[2-^{14}C])$_3$[2] have been prepared and purified by the reported methods. The labelled complex, Ru(acac[2-^{14}C])$_3$, was prepared from ruthenium(III) chloride and Hacac[2-^{14}C] by the method of Wilkinson[13] and sublimed *in vacuo* (140 °C, 1 mmHg; 1 mmHg≒133 Pa). Both radioactive and non-active Rh(acac)$_3$ were prepared as follows; Hacac[2-^{14}C] or the ordinary Hacac (3 ml), and a few drops of water added to a mixture of rhodium(III) chloride trihydrate (0.5 g) and potassium hydroxide (0.3 g), and refluxed for 10 h at 110 °C and then for 2 h at 120 °C, with stirring. The Hacac and water were evaporated off from the resulting mixture, under a reduced pressure at room temperature. Light yellow crystals (0.3 g) were sublimed from the residue at 170 °C under 1 mmHg. Anal. (for the non-active Rh(acac)$_3$) Found; C, 44.71; H, 5.38%. Calcd for $RhC_{15}H_{21}O_6$; C, 45.01; H, 5.29%. Mp 262 °C for both the complexes (lit[14] 260 °C).

The deuterium content of Hacac[*methylene*-$^2H_2$] in the methylene moiety was determined to be 80% by PMR spectroscopy. Specific activities of Hacac[2-^{14}C] and the labelled complexes were *ca.* 10^4 and 10^3 dpm mg^{-1}, respectively. The solvent Hacac was dried over anhydrous sodium sulfate and distilled.

Kinetic Procedure. Aliquots of the solution of the labelled complex (0.003—0.009 M; 1 M=1 mol dm^{-3}) in Hacac or Hacac[*methylene*-$^2H_2$] containing 0.01—0.1 M water were sealed in 5 to 10 Pyrex glass tubes (10 mm in diameter, 50 mm in length) after degassing, and heated in a thermostated oil bath at 85—190 °C. The tubes were withdrawn one by one at appropriate time intervals and put into a cold water bath. From a given amount of the solution in each tube, the solvent was evaporated *in vacuo* at room temperature to recover the complex quantitatively in the original tube. The total amount of the recovered complex was dissolved in a given volume of acetonitrile and a given part of the solution was dissolved in toluene containing 0.1% *p*-terphenyl and 0.04% *p*-bis(5-phenyl-2-oxazolyl)benzene (POPOP) for scintillation pulse counting with a Nuclear Chicago Unilux IIA Liquid Scintillation Counter. The water content was determined for each portion of the solution by Karl Fischer titration.

Calculation of the Exchange Rate. The rates were calculated by the McKay equation

$$\text{Rate} = \frac{3[M][Hacac]}{3[M]+[Hacac]} \frac{\ln[(x_0-x_\infty)/(x_t-x_\infty)]}{t} \fallingdotseq 3[M]\ln(x_0/x_t)/t \quad ([Hacac] \gg [M],\ x_\infty \fallingdotseq 0) \qquad (1)$$

where [M] and [Hacac] stand for the concentration of the complex and acetylacetone, respectively. The x's are the specific counting rates of the complex for the time indicated by the subscripts.

Hacac is in tautomeric equilibrium between enol and keto forms, but the interconversion rate in neat Hacac is significantly greater[15] than the present exchange rates in the given temperature ranges; the tautomers are not kinetically distinguishable. Therefore, the overall concentration of

Hacac was used in the kinetic treatment.

Results

Verification of the Exchange Reactions. In the case of the Cr(III) and Co(III) complexes, the McKay plots gave straight lines up to at least 50—60% of the completion of exchange (Fig. 1) and the visible absorption spectra and the water content of the reaction mixture did not vary throughout the reaction. Hence, no other reaction than the exchange takes place.

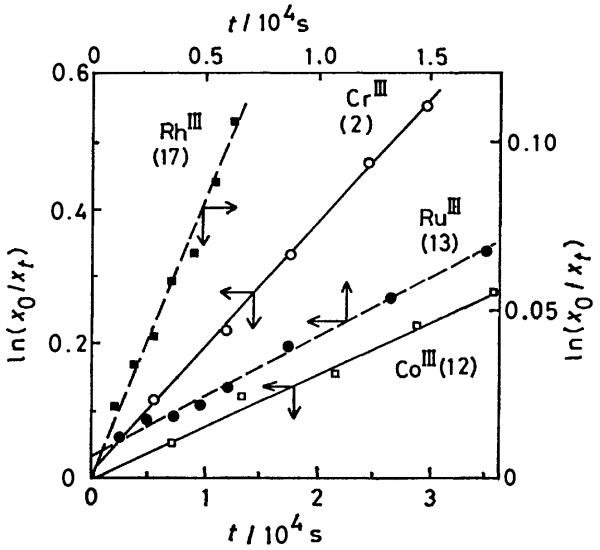

Fig. 1. Typical McKay plots for the ligand exchange of $M^{III}(acac)_3$ in acetylacetone. Numbers in parentheses stand for the experimental numbers in Table 1.

When the reaction mixture of the Ru(III) complex was heated at the given temperature, yellow substances were formed in the solution and water content increased gradually with time (Table 1). However, the visible absorption spectra of the solution did not change throughout the reaction. The linear McKay plots were obtained up to at least 50% of the completion of exchange. When the solvent was evaporated from 1 ml of the solution which had been heated for 3×10^4 s, a small amount of yellow oil (*ca.* a few mg at most) and the complex were left in the original tube. The oil was separated from the complex by vacuum distillation at 100 °C. The counting rate (^{14}C) of the oil was nearly zero. These facts show that the yellow substances should be formed not from the complex but from the solvent (probably, condensation polymerization of acetylacetone to give water as a by-product).

In the case of the Rh(III) complex, the similar changes in the color (the formation of the oil) and in the water content of the reaction mixture were observed as in the case of the Ru(III) complex. The counting rate of the oil recovered from the solution (heated for 10^4 s) was also nearly zero. The fact shows that the complex did not decompose. The McKay plots gave straight lines up to 10% of the completion of exchange and then the slopes of the plots increased steeply. The exchange rates were determined from the plots at the initial stage.

These facts show that the decrease of the specific counting rate of the complexes shown in Fig. 1 corresponds to the exchange of acetylacetonate between the complex and the solvent,

$$M^{III}(\overset{*}{acac})_3 + Hacac \rightleftharpoons M^{III}(acac)_3 + H\overset{*}{acac} \quad (2)$$

where asterisks denote ^{14}C labelling.

Kinetic Data. The exchange rate was proportional to the concentration of the complex, [M], (Table 1) and expressed by

$$\text{Rate} = k_o[M] \quad (3)$$

where k_o is the observed first-order rate constant.[16] The k_o values were independent of $[H_2O]$ for the Cr(III) and Co(III) systems (Table 1). For the Ru(III) and Rh(III) systems, the McKay plots gave straight lines, regardless of the increase in water concentration with the progress of the exchange (Fig. 1 and Table 1). Hence, the k_o values can be reckoned to be independent of $[H_2O]$.

When Hacac[*methylene-*$^2H_2$] was used as the solvent in place of the ordinary Hacac, the k_o values for the Cr(III) and Rh(III) systems decreased but those for the Co(III) system did not (Table 1). Ratio of the rate constants $k_o(H)/k_o(D)$ are calculated and given in Table 2, together with the activation parameters.

Discussion

Reaction Route of the Exchange. Since k_o was independent of $[H_2O]$, the chemical species participating in the rate-determining step should be only M(acac)$_3$ and Hacac. Consequently probable reaction routes are very much restricted. Equation 4 can be assumed almost exclusively as a common route for these exchange reactions,

$$\underset{I^*}{M(O,\overset{*}{O})} + Hacac \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{II^*}{M(acacH,O\text{–}\overset{*}{O})} \xrightarrow{k_2} \underset{II}{M(O\text{–}O,\overset{*}{acacH})} \xrightarrow{k_{-1}} \underset{I}{M(O,O)} + \overset{*}{Hacac} \quad (4)$$

where O–O and I* denote $acac^-$ and $M(\overset{*}{acac})_3$, respectively. (Two $acac^-$ chelates are omitted in these species.) The original complex I* and a solvent molecule(Hacac) produce an intermediate II*, which is converted into II through the proton transfer, and then II changes into I and $H\overset{*}{acac}$. The intermediate II* involves an one-ended bidentate and a solvent molecule as unidentates. Such a type of the intermediate is generally accepted as an intermediate for dissociation and formation reactions of chelates in octahedral complexes in coordinating solvents.[17–19] Acetylacetone, with a donor number *ca.* 17,[20] can be regarded as coordinating solvent. Therefore, the formation of II* is considered to be reasonable.

The k_1 step in Eq. 4 should be the rate-determining step. If k_2 were smaller than k_1, the proton transfer process would be the rate-determining step. However, such a mechanism does not interpret the different

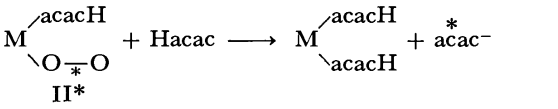
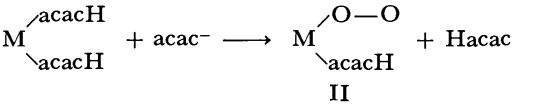
values of the kinetic parameters shown in Tables 1 and 2 among the complexes(*vide infra*).

Besides the k_2 process, an alternative route (Eqs. 5—7) containing the complete dissociation of the coordinated $\overset{*}{a}cac^-$ might be considered between II* and II in Eq. 4. (Notations are identical with those for Eq. 4.)



(5)

(6)



(7)

However, the route is not consistent with the observed k_o(H)/k_o(D) values for the Cr(III) and Rh(III) systems (Table 2), since it is unlikely that the k_o values are governed by the proton transfer process (Eq. 6) which is considered to be much faster than the dissociation process (Eq. 5). For the Co(III) complex, the complete dissociation of $acac^-$ (Eq. 5) has been suggested to be much slower than the exchange in acetonitrile.[3] Therefore, the k_2 process in Eq. 4 must be indispensable for the exchange to take place.

So far as k_1 is very small as compared with k_{-1} and k_2 and the stationary-state condition is assumed for II* in Eq. 4, k_o is expressed by Eq. 8,

$$k_o = k_1 \frac{k_2}{k_{-1}+k_2} \tag{8}$$

where k_1 is taken to be first-order ([M]≪[Hacac]). The k_1 process represents the rate-determining step, and the term $k_2/(k_{-1}+k_2)$ indicates a branching ratio for the accomplishment of the exchange from II*.

Substitution Mechanisms of the Rate-determining Step. Table 2 shows that the Co(III) complex gives different activation parameters and k_o(H)/k_o(D) values from those of the other complexes. The ΔH^* value for the Co(III) complex is distinctly higher than those for the others. The ΔH^* values for substitution processes of complexes containing the present tervalent metal ions are reported to be in similar ranges to one another.[6] The Co(III) complex has positive ΔS^*, whereas others have negative values. The difference reaches 24—38 cal K^{-1} mol^{-1}. These facts suggest the different mechanisms between the Co(III) and the other com-

plexes. Since the rate-determining step is reckoned to be the k_1 process, the acitivation parameters should reflect mostly those for this step. It is most likely that the intermediate II* in Eq. 4 is formed by the S_N1 and the S_N2 mechanism for the Co(III) and the other complexes, respectively.[21]

The difference in $k_o(H)/k_o(D)$ values in Table 2 is also interpreted on the basis of the same assignment of the mechanism. The Co(III) complex gives no isotope effect, whereas the Cr(III) and Rh(III) complexes have the ratio more than unity. If $k_{-1} \ll k_2$ in Eq. 8,

$$k_o = k_1 \quad (9)$$

If $k_{-1} \gg k_2$

$$k_o = k_1 k_2 / k_{-1} \quad (10)$$

Since the deuterium isotope effect on k_o must be attributable to that on k_2, Eqs. 9 and 10 should be applicable to the Co(III) and the other complexes with their inequalities, respectively. The rate constant k_{-1} can be assumed to be much more susceptible to the nature of M^{III} than k_2 is, since the k_{-1} process contains the dissociation and formation processes of M^{III}–O bonds, whereas the k_2 process does not. So far as k_2 for these metal complexes remains without big difference, the rate constant for the ring closure, k_{-1}, should be responsible for the difference in the inequalities [k_{-1}(for Co(III)) $\ll k_2 \ll k_{-1}$(for Cr(III) and Rh(III))]. The relatively high k_{-1} values assumed for the Cr(III) and Rh(III) complexes might be related to the labilization of cis position by the S_N2 action of unbound atom of a ligand (cis anchimeric effect).[22] Some fast substitution of Cr(III) complexes was interpreted by this effect. Therefore, an intermediate of S_N2 type (IV in Fig. 2) with a structure similar to that proposed for the effect[23] is suggested to be formed on going from I* to II*. On the contrary, such an effect is not expected for the S_N1 substitution. The relatively small k_{-1} assumed for the Co(III) complex is thus accounted for. An intermediate such as III in Fig. 2 may be present in the Co(III) system.

On the other hand, on the assumption that the proton transfer (k_2) in Eq. 4 is the rate-determining step, the following kinetic results are not interpreted; i) the different values of the activation parameters and $k_o(H)/k_o(D)$ for the Co(III) complex with those for the others and ii) a common sequence of the M(acac)$_3$ for the rates of the present exchange and the racemization in chlorobenzene (*vide infra*, the racemization cannot contain such a proton transfer process.)

The two unidentates in II* and II should be cis to each other, at least when the proton is transferred. The presence of trans isomer cannot be excluded, but it does not seem to play important role in the exchange reactions. It may be a dead end species, even if it is formed.

Therefore, the mechanisms illustrated in Fig. 2 can be proposed. The relatively slow and fast ring-closure processes (the k_{-1} step) compared with the proton transfer process (the k_2 step) are suggested for the Co(III) and the other complexes, respectively.

Comparison of Rates with Racemization. The Arrhenius plots for the exchange (k_o) and the racemization(k_{rac}, in chlorobenzene)[24] of the complexes are given in Fig. 3. The rates of both the reactions decrease in the sequence under the given conditions.

$$Co(III) > Cr(III) > Ru(III) > Rh(III)$$

The common sequence suggests that each M(acac)$_3$ has similar reactivities for both the inter- and intramolecular processes.

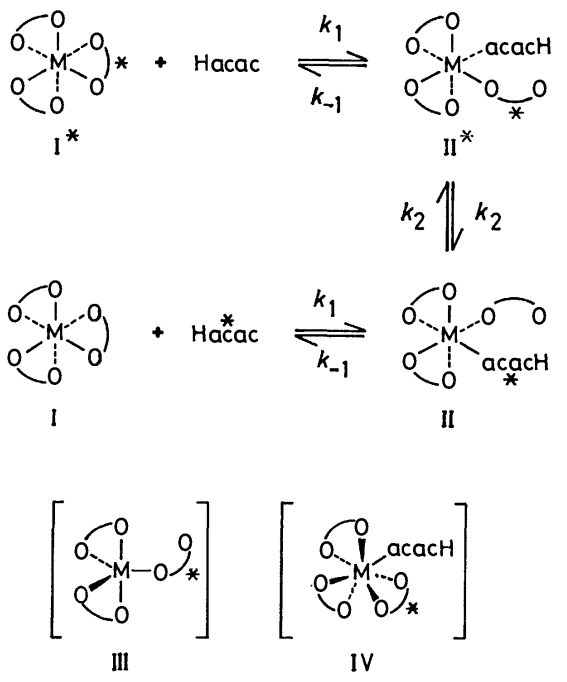


Fig. 2. Mechanisms of the ligand exchange of M^{III}(acac)$_3$ (I) in acetylacetone. The routes I*→III→II* (S_N1) and I*→IV→II*(S_N2) are proposed for the Co(III) and the Cr(III), Ru(III), and Rh(III) complexes, respectively. (The structures of III and IV are only provisional.)

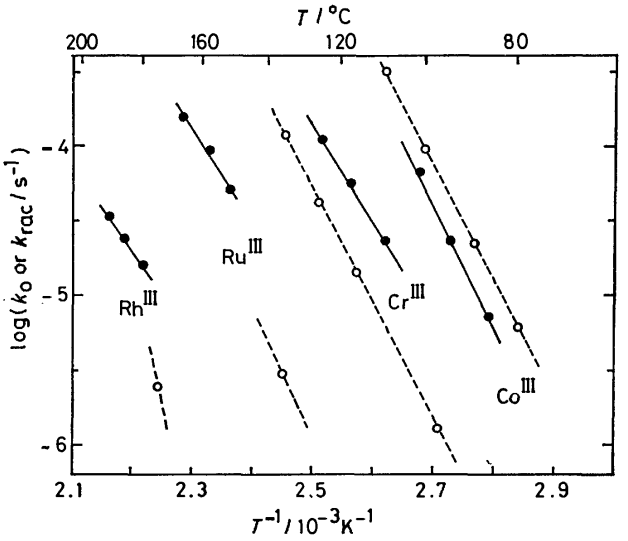

Fig. 3. Arrhenius plots for the reactions of $M^{III}(acac)_3$. Full circles with a solid line: the ligand exchange in acetylacetone (k_o). Open circles with a broken line: the racemization in chlorobenzene(k_{rac}, appoximate values for Ru(III) and Rh(III)[24]).

However, the correlation of the Arrhenius plots of both the reactions for the Co(III) complex is different from that for the other complexes; $k_o > k_{rac}$ and the less steep slopes for k_o in the Cr(III), Ru(III), and Rh(III) complexes, whereas $k_o \fallingdotseq k_{rac}$ (k_{rac} is rather slightly bigger than k_o) and similar gradient of the slopes for the Co(III) complex. A common S_N1 mechanism for both the exchange in acetonitrile and the racemization in chlorobenzene has been concluded for the Co(III) complex, despite of the difference of the solvent.[3] These facts and the conclusion support the difference in the proposed mechanisms for the exchange reactions, so far as the one-ended bond-rupture mechanism(S_N1)[25] opperates commonly in the racemization of these complexes.

Comparisons of the Mechanisms with Related Reactions. The substitution mechanisms for the present exchange reactions can be compared with those of the substitution reactions of unidentates in the tervalent metal complexes, since the rate-determining step of the former reactions is concluded to be the replacement of one of coordinated oxygen atoms in a chelate ring by an Hacac molecule and is comparably simple with that of the latter ones.

Comparison of Mechanisms with Those for Complexes Containing N_5O Core: The water exchange and the anation of various ligands to pentaammineaqua complexes of Co(III),[7,9] Cr(III),[7,10,26-28] Ru(III)[29,30] and Rh(III)[31-36] have been systematically studied in aqueous solutions. The S_N1 and the S_N2 mechanisms were predominantly assigned to the reactions of the Co(III) and the other complexes, respectively. Especially, the mechanisms assigned to the water exchange on the basis of ΔV^* values are generally accepted to be most convincing.[8-11] The Co(III) complexes have a rather exceptional mechanism[37] commonly in both the present and the reported exchange systems, despite of the difference in the charge of the complexes, the assortment of the coordinating atoms, the dentate number of the leaving and entering ligands and the property of the solvents. The ionic radius of M^{III} [11,38] (Co^{III}:52.5, Cr^{III}:61.5, Ru^{III}:68, Rh^{III}:66.5 pm)[41] seems to be commonly an important factor in determining the mechanisms of the exchange reactions of these complexes containing O_6 and N_5O cores.

Comparison of Mechanism among Complexes Containing O_6 Core: The S_N2 mechanism for the present exchange of $Cr(acac)_3$ is consistent with that for the solvent exchange of $Cr(H_2O)_6^{3+}$ [37], $Cr(dmf)_6^{3+}$ [38] and $Cr(dmso)_6^{3+}$ [39] (dmf=*N*,*N*-dimethyformamide, dmso=dimethyl sulfoxide) and for the anation of various ligands to hexaaqua complex ion.[40] The S_N2 mechanism is considered to commonly operate in these reactions of the $Cr^{III}O_6$ complex.

Little information is available concerning the substitution mechanism of the $M^{III}O_6$ type complexes of Co(III), Ru(III), and Rh(III). An S_N2 mechanism is concluded in the exchange of $Rh(acac)_3$, but an S_N1 mechanism was proposed for the water exchange and the bromide anation of $Rh(H_2O)_6^{3+}$.[4,5] The proposed mechanisms for the present Co(III) and Ru(III) complexes may be the first examples for O_6 type complexes of Co(III) and Ru(III), and should be compared with other examples in future.

The author wishes to thank Professor Kazuo Saito for helpful discussions. This work was supported by the Grant-in-Aid from the Ministry of Education.

A Nephelometric Analysis of Mercury(II) with Potassium Salt of α,α′-Bis(dithiocarboxyoxy)-*p*-xylene

Daijiro YAMAMOTO, Masamichi TSUKADA,* Yasuaki HIROTA,† and Haruo MIZUNO††

††*Department of Food Science and Technology, Tokyo University of Fisheries, 4, Konan, Minato-ku, Tokyo 108*

(Received May 15, 1979)

Potassium salt of α,α′-bis(dithiocarboxyoxy)-*p*-xylene (abbreviated as K_2-XDX) was synthesized as a chelating agent with *p*-xylene-α,α′-diol, carbon disulfide, and potassium hydroxide. Since a mercury(II)–XDX chelate complex suspension scattered pearl-blue light strongly because of the formation of a colloidal solution, the nephelometric analysis of small amounts of mercury(II) was undertaken. The calibration curve was found to be linear in the two ranges of 0.03—1.00 and 0.50—25.00 μg cm^{-3} of the mercury(II) ion respectively, but no suitable masking agents for interfering metal ions were found. The mole ratio of mercury(II) to XDX in the complex was found to be 1 to 1. These data for the complex suggested that XDX and mercury(II) combined alternately to form the $(-Hg-XDX-)_n$ complex. The molecular weight of this complex could be calculated as about 2×10^7 from the Zimm plot on the basis of the light-scattering method.

The formation of chelate complexes between a number of metals and dithiocarbonic acid derivatives is well known. Since the derivatives with a dithiocarboxyoxy group as a functional group can readily be prepared, and since they have a good reactivity with many metal ions, they have been used for other analytical studies as well as for absorptiometric analysis.[1–7] If the two hydrogen atoms of dihydroxy-compounds can be replaced by some functional groups, we can assume that the dithiocarbonic acid derivatives react with each of the different kinds of metal ions to form polynuclear metal complex salts in which a successive and alternate arrangement of metal and ligand is found. Provided that these chelate complexes become large and colloidal in form, those solutions may be used in the nephelometric determination of trace amounts of the metal ions.

According to the above-mentioned idea, potassium salt of α,α′-bis(dithiocarboxyoxy)-*p*-xylene, (K_2-XDX), was prepared from *p*-xylene-α,α′-diol. This derivative reacted with many ions and produced light-scattering colloidal solutions. Among these, the mercury(II)–XDX solution scattered very remarkable pearl-blue light. This colloidal solution was very stable for a long time. The substance could be extracted into 1-octanol and 3-heptanone, which were good solvents for some organic polymers. The solution was colloidal and scattered light as well as in the case of an aqueous solution. This colloidal solution was also very stable for a long time.

This solution could be used in the determination of mercury(II) by the nephelometric method, and the amount of the mercury(II) ion (from 0.03—25.00 μg cm^{-3}) was detectable. The molecular weight of the mercury(II)–XDX chelate was measured by the light-scattering method and found to be about 2×10^7. Therefore, a polynuclear chelate compound might be produced.

Although there have been reported several nephelometric methods for the determination of such metals as Ag, Ba, and Zn, nephelometry with a colloidal solution of polymeric polynuclear chelate has not yet been reported.[8] It should be emphasized that this analytical method may be a new tool for trace analysis.

Experimental

Reagents. Dust-free water was obtained by distilling deionized water with an all-quartz distillation apparatus and by then filtering it through a G-5 glass filter, it has been used throughout all the processes. Mercury(II) chloride was purified by sublimation. All the other reagents were of a chemically pure grade and were used without further purification. Each of the reagents was dissolved with the dust-free water until it became the desired concentration and then filtered through the G-5 glass filter.

Buffer Solution. Among many kinds of buffer solutions, the most rapid clearance of the reaction mixture was observed in the case of Walpole's buffer solution. At pH values of 3.8 or below, XDX^{2-} was decomposed rapidly, while above this pH, even in an alkaline solution, it was stable. This buffer solution was prepared by mixing hydrochloric acid and a sodium acetate solution. The maximum intensity of the scattering light from the chelate complex suspension was obtained at about pH 4.0.

Synthesis of K_2-XDX. This was synthesized according to the method given by Price.[9] The procedure was as follows: one gram of *p*-xylene-α,α′-diol (α,α′-dihydroxy-*p*-xylene) was dissolved in 6 cm^3 of a 15% potassium hydroxide solution, and then the mixture was added to 5 cm^3 of carbon disulfide. The mixture was stirred for 16 h, with the temperature kept at 5 °C. After the surplus carbon disulfide had been removed by filtration, ethanol was added to the solution until a slightly yellow crystalline was produced. The precipitate was filtered out, washed by ethanol, and recrystallized by dissolving them in a minimum amount of water and adding ethanol. The resulting product was filtered, washed with ethanol, and dried at room temperature under reduced pressure.

Properties of K_2-XDX. The K_2-XDX synthesized was not changed when kept for at least 50 days in a brown desiccator at reduced pressure. It is very soluble in water and acetone, and insoluble in carbon tetrachloride, ethanol, and benzene.

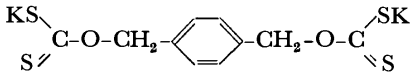
Some of its physicochemical properties were as follows.

† Present address: AMCO Co., Ltd., Iidabashi, Chiyoda-ku, Tokyo 102.

The ultraviolet spectrum of an aqueous solution of this compound in a neutral medium showed an absorption maximum at 303 nm. This is due to the replacement of a hydrogen atom by a carbodithioic group.[10]

The infrared spectra of the compound was measured in a KBr disc, and the bands were assigned (cm^{-1}) to the stretching vibrations of C=S (1150), and C–S (915, 870, and 650).[11,12] The ^1H NMR spectrum of a deuterium oxide solution of *p*-xylene-α,α'-diol (the starting material) showed a peak at 4.55 ppm by the existence of two protons of $-R-CH_2-O-$. In the case of this derivative, however, the identical peak was shifted to 5.48 ppm by substitution with the dithiocarboxyoxy group.

According to the data presented above, the structural formula was determined to be as follows:



The purity of this compound was determined to be over 99.7% by the method of JIS-K8269.

Stability of the Reagent Solution. The absorbance of the aqueous solution adjusted at pH 6.8 was measured at the wavelength of 303 nm. It showed little change for at least 120 min. After 24 h, however, it decreased 30%. On the basis of the results, all the measurements were designed to be completed within 30 min.

Apparatus. For the measurement of the intensity of the scattering light, a Hitachi EPS-3T recording spectrophotometer with an L-3 model fluorometer was used. As a light source, an ultra-high pressure lamp was used. Two monochromatic rays of 365 nm, through a ultraviolet filter, and 546 nm, through a green interference filter, were used in order to excite the sample. The intensity of the scattering light from the sample was measured perpendicular to the incident light. A greater intensity was always obtained in the case of 365 nm than in that of 546 nm.

For the estimation of the molecular weight, a Fica 4200 model light-scattering spectrophotometer was used.

Procedure for the Determination of Mercury(II). All the measurements were carried out at room temperature. The general procedure for the determination of mercury was as follows: 10-cm^3 portions of the sample solutions containing 0.06—50.00 μg cm^{-3} of the mercury(II) ion, which had been prepared from 100 μg cm^{-3} of the mercury(II) ion stock solution, were placed in a 30 cm^3-test tube fitted with a ground-glass stopper. 5 cm^3 of an acetate buffer solution (pH 4.0) and 5 cm^3 of an XDX^{2-} solution (150 mg dm^{-3} of K_2-XDX) were added. The XDX^{2-} solution was prepared afresh each time. The test tube was vigorously shaken and then allowed to stand for 10 min. The intensities of the scattering light were measured at 365 nm. The constant regulation of the slit width and the photomultiplier sensitivity was necessary in order to choose the best conditions between the concentration range of the mercury(II) ion and the intensity of the scattering light.

Results and Discussion

Reactions of XDX^{2-}. As is shown in Table 1, in the reactions between XDX^{2-} and various kinds of metal ions, the coloration was often similar to those which were observed in a reaction with the ethylxanthate ion. In an aqueous solution, however, XDX^{2-} differed from the ethylxanthate ion, in which turbidity or a precipitate more often appears when a kind of metal ion is mixed with it. The apparent values of the molar absorption coefficients, (ε), shown in the table might be slightly higher because of the influence of light scattering. They are, however, lower than those obtained by the use of ethylxanthate.[13] From the graph of the calibration curve prepared for each metal ion except Mo^{5+}, we obtained a straight line passing a point near to zero.

Calibration Curve. The two linear calibration curves were obtained for the concentration ranges of 0.03—1.00 μg cm^{-3} and of 0.50—25.00 μg cm^{-3}.

Solvent Extraction. Twenty-one kinds of generally available polar and nonpolar organic extractants were examined for the selective extraction of the mercury(II)–XDX chelate polymer. The polymer could be extracted into only 1-octanol and 3-heptanone, as is shown in Table 1. The light scattering was observed by this extracted sample, and the intensity of the scattered light was the same as in the aqueous solution. Other kinds of metal chelates, such as Co(II)–, Ni(II)–, Cu(II)–, and Cd(II)–XDX, were also extracted into both solvents.

Effect of Diverse Ions. For the study of the tolerance limits for diverse ions, 1 cm^3 of a 5.00 μg cm^{-3} mercury(II) ion solution was mixed with 1 cm^3

Table 1. Reactions of metal ions with XDX^{2-}

Ion	Color	λ_{max} / nm	ε / $dm^{-3}\,mol^{-1}\,cm^{-1}$	Extractant[a]
Fe^{2+}	Brown (unstable)	—	—	None
Co^{2+}	Pale-blue	360	1.5×10^4	3-Hept., 1-Oct.
Ni^{2+}	Brown-yellow	430	2.6×10^3	3-Hept., 1-Oct.
Cu^{2+}	Yellow	408[b]	3.5×10^3	3-Hept., 1-Oct.
As^{3+}	Colorless (precipitate)	—	—	None
Bi^{2+}	Yellow (precipitate)	—	—	None
Cd^{2+}	Pearl-blue	305	2.8×10^3	3-Hept., 1-Oct.
Hg^{2+}	Pearl-blue	295	2.8×10^3	3-Hept., 1-Oct.
Mo^{5+} [c]	Reddish-orange	521	5.8×10^3	None
V^{5+}	Yellow (precipitate)	—	—	None
UO_2^{2+}	Reddish-orange (precipitate)	—	—	None

a) 3-Hept. is 3-heptanone. 1-Oct. is 1-octanol. b) In the case of Cu^{2+}, undistinct peak of absorption was found.
c) Reduced MoO_4^{2-} with hydrazine sulfate.

of another ion solution in different concentrations. To each of these solutions 3 cm^3 of the buffer solution (pH 4.0), 2 cm^3 of the EDTA solution (3.7% of Na_2 edta) as a masking agent, and 3 cm^3 of the XDX^{2-} solution (150 mg dm^{-3} of K_2–XDX) were added. Then, in order to extract the mercury(II)–XDX chelate polymer, these were vigorously shaken with 10 cm^3 of 1-octanol.

According to the result, a large excess (300 $\mu g\ cm^{-3}$ each) of the following ions—Ag^+, Al^{3+}, Ba^{2+}, Be^{2+}, Ca^{2+}, Cr^{3+}, Mg^{2+}, Mn^{2+}, MoO_4^{2-}, and Sr^{2+}—had no effect on the intensity of the scattering light. Co^{2+}, Fe^{2+}, Fe^{3+}, Mo^{5+}, UO_2^{2+}, and Zn^{2+} did not interfere in concentrations 30 times or less that of the Hg^{2+}. Even if, in the same concentration as that of the Hg^{2+}, Cd^{2+} caused a positive interference, As^{3+}, Bi^{2+}, $Cr_2O_7^{2-}$, Cu^{2+}, Pb^{2+}, and V^{5+} showed a negative interference. The reason for the negative interference is probably that, in the case of Cu^{2+}, the solution formed with XDX^{2-} has a broad absorption band in the near-ultraviolet region, and the exciting and scattering lights are absorbed by the solution. In the cases of As^{3+}, Bi^{2+}, $Cr_2O_7^{2-}$, Pb^{2+}, and V^{5+}, they co-precipitate the Hg–XDX polymer. The addition of Na_2edta as a masking agent for these ions was not effective.

Composition of the Chelate. A continuous-variation method by means of nephelometry was carried out. Both mercury(II) and XDX ion solutions were adjusted to 5×10^{-3} mol dm^{-3} in concentration, (Hg:10 $\mu g\ cm^{-3}$), they were mixed in proper proportions, and a 4-cm^3 portion of a buffer solution (pH 4.0) was added. The total volume of this solution was finally made up to 14 cm^3, and then we measured the intensity of the scattering light. The results are shown in Fig. 1.

Since the maximum intensity was obtained with a concentration ratio of 0.5, the ratio of mercury(II) to XDX in this polymer was confirmed to be 1 to 1.

Estimation of the Molecular Weight of the Polymer. The molecular weight of the colloidal polymer can be determined by light-scattering spectrophotometry at the wavelength of 546 nm. The variation in the refractive index at various concentrations, (dn/dc), was

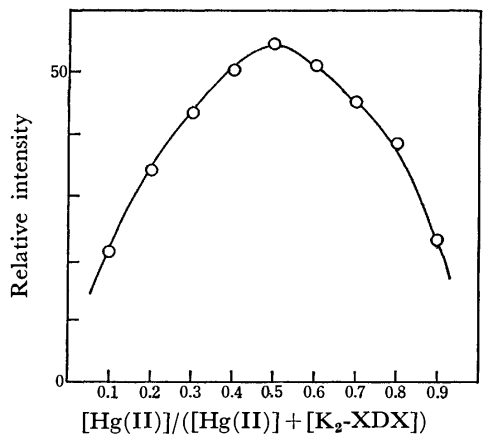


Fig. 1. Continuous variation method for Hg–XDX complex. This was obtained by means of nephelometry using the excitation at 365 nm. [Hg(II)]+[K_2-XDX]: 3.6×10^{-5} mol dm^{-3}.

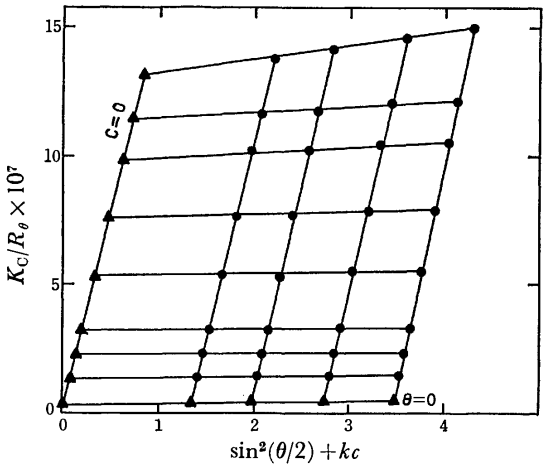

Fig. 2. Zimm plot for 1-octanol suspension of Hg–XDX complex.

obtained by using a differential refractometer (Narumi Co., Ltd.). To obtain a dust-free sample, pretreatment by centrifuging (10000 rpm) was necessary. Because the aqueous solution, however, had too low a viscosity to maintain the suspension, the sample extracted by high viscous 1-octanol was used.

From the measurements carried out on solutions ranging in concentration from 1.3×10^{-2} to 6.6×10^{-2} mg cm^{-3}, the dn/dc was calculated to be 1.65 $cm^3\ g^{-1}$. As is shown in Fig. 2, the molecular weight estimated by extrapolating into the Zimm plot was about 2×10^7. It is thus proved that the intense light scattering is due to the formation of a large molecule which can be considered to be a kind of colloid.

The authors wish to express their deep thanks to Assistant Professor Naomichi Iso of the Tokyo University of Fisheries for his many helpful discussions.

Formation and Spectral Properties of Some Bis(β-diketonato)-copper(II)–Diazole Complexes

Tamizo KOGANE* and Reiko HIROTA**

Industrial Research Institute of Kanagawa Prefecture, Showa-machi, Kanazawa-ku, Yokohama 236

***Faculty of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo 171*

(Received May 19, 1979)

The reactions of bis(β-diketonato)copper(II) with pyrazole and imidazole gave the diazole adducts Cu(β-dik)$_2$(Hdzl) (β-dik=β-diketonate anion; Hdzl=diazole) and/or the μ-diazolato complexes [Cu(β-dik)(dzl)]$_n$ (n=2,4,....). The complexation reactions are very sensitive to the nature of the diazole and to the reaction conditions, sometimes giving different products depending upon the solvent used. In chloroform, Cu(β-dik)$_2$–pyrazole and Cu(β-dik)$_2$–imidazole complexes exhibited characteristic absorption maxima at approximately 570 and 555 nm, respectively, which are much shorter than the λ_{max} values of the starting Cu(β-dik)$_2$ chelates.

Nitrogen heterocycles react with bis(β-diketonato)-copper(II) complexes in different solvents forming 1:1 or 1:2 adducts.[1] There have been several reports concerning the reactions of bis(β-diketonato)copper(II) with bidentate ligands containing similar nitrogen atoms. For example, the ethylenediamine complex with bis(2,4-pentanedionato)copper(II),[2] as well as the 2,2′-bipyridine,[3] pyrazine,[4] 1,5-naphthyridine,[5] and 1,10-phenanthroline[6] complexes with bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)copper(II), has been isolated and identified. Few papers have been published, however, on the reactions of bis(β-diketonato)copper(II) with heterocyclic bidentate ligands containing dissimilar nitrogen atoms.[7,8]

Pyrazole (Hpz) and imidazole (Him) are known to be versatile ligands which produce complexes with many metal ions or Lewis acids. These diazoles behave differently from pyridine and other six-membered nitrogen heterocycles in complex formation, since the NH protons are acidic and easily dissociate to give the corresponding anions.[9,10]

Diazole adducts of the bis(β-diketonato)copper(II) complexes, such as imidazole adducts of bis(fluorinated β-diketonato)copper(II)[7,8] and Cu$_2$(acac)$_2$(pz)$_2$ and Cu$_2$(acac)$_2$(OH)(pz) have been reported.[11] The reactions of diazoles with bis(β-diketonato)copper(II) in general, however, have not been studied systematically. The results of such studies and the behavior of the mixed complexes obtained, will be reported here.

Experimental

Materials. The β-diketonato chelates of copper(II) employed were Cu(dpm)$_2$, Cu(dibm)$_2$, Cu(dnbm)$_2$, Cu(dprm)$_2$, Cu(acac)$_2$, Cu(bzac)$_2$, Cu(tac)$_2$, Cu(fac)$_2$, and Cu(tfac)$_2$, where dpm, dibm, dnbm, dprm, acac, bazc, tac, fac, and tfac designate the anions of 2,2,6,6-tetramethyl-3,5-heptanedione, 2,6-dimethyl-3,5-heptanedione, 4,6-nonanedione, 3,5-heptanedione, 2,4-pentanedione, 1-phenyl-1,3-butanedione, 1-(2-thienyl)-1,3-butanedione, 1-(2-furyl)-1,3-butanedione, and 1,1,1-trifluoro-2,4-pentanedione, respectively. The chelates were prepared by mixing copper(II) acetate (1 mol) in aqueous solution with β-diketone (2 mol) in ethanol under stirring. The precipitate formed was filtered, dried, and recrystallized from chloroform or from a chloroform–ethanol mixture. Other materials and solvents were purified by standard procedures.

Syntheses of Pyrazolato and Imidazolato Mixed Complexes (Substitution Complexes). Cu$_2$(acac)$_2$(pz)$_2$, Cu$_2$(dprm)$_2$(pz)$_2$, and Cu$_2$(dnbm)$_2$(pz)$_2$ were obtained by reacting the β-diketonato complex with equimolar pyrazole in suitable solvents such as chloroform, acetone and ethanol. Cu(β-dik)(im) was obtained as a precipitate by the reaction of Cu(β-dik)$_2$ with an excess of imidazole in ethanol. The results of elemental analyses are given in Tables 1 and 3.

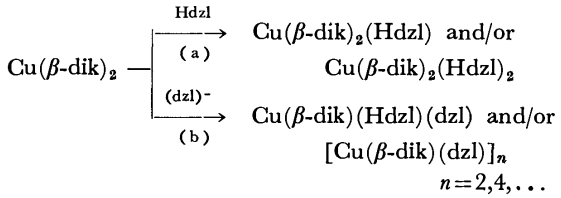
Synthesis of Pyrazole Adduct. Cu(bzac)$_2$(Hpz) and Cu(tfac)$_2$(Hpz): Cu(bzac)$_2$ or Cu(tfac)$_2$ was allowed to react with an equimolar quantity of pyrazole in cyclohexane under reflux for 5 min. After cooling, a light green or green precipitate was separated by filtration and dried *in vacuo*. Found: C, 60.88; H, 4.75; N, 5.95%. Calcd for $CuC_{23}H_{22}N_2O_4$: C, 60.85; H, 4.88; N, 6.17%. Found: C, 35.77; H, 2.62; N, 6.23%. Calcd for $CuC_{13}F_6H_{12}N_2O_4$: C, 35.67; H, 2.76; N, 6.40%.

Cu(tac)$_2$(Hpz) and Cu(fac)$_2$(Hpz): An equimolar mixture of pyrazole and Cu(tac)$_2$ or Cu(fac)$_2$ was dissolved in dichloromethane. The solvent was allowed to evaporate *in vacuo* and a green or light green solid was obtained as a residue. Found: C, 49.25; H, 4.04; N, 5.96%. Calcd for $CuC_{19}H_{18}N_2O_4S_2$: C, 48.97; H, 3.89; N, 6.01%. Found: C, 52.01; H, 4.09; N, 6.28%. Calcd for $CuC_{19}H_{18}N_2O_6$: C, 52.59; H, 4.18; N, 6.46%.

Spectra Measurement. The electronic absorption and diffuse reflectance spectra were recorded on a Hitachi Model 356 spectrophotometer and IR on a Hitachi Model 225 grating infrared spectrophotometer. ^{1}H-NMR spectra were obtained on a JEOL JNM C-60H spectrometer. Mass spectra were measured on a Hitachi RMU-6L mass spectrometer by introducing the sample through a direct inlet system.

Results and Discussion

The bis(β-diketonato)copper(II) complexes were treated with diazoles in solutions, and one or both of the reactions (a), (b) shown in Scheme 1 took place. Reaction (a) forms five or six coordinated bis(β-diketonato)copper(II) adducts, Cu(β-dik)$_2$(Hdzl) or Cu(β-dik)$_2$(Hdzl)$_2$, while (b) is a substitution reaction forming mononuclear Cu(β-dik)(Hdzl)(dzl) or polynuclear [Cu(β-dik)(dzl)]$_n$.[12]



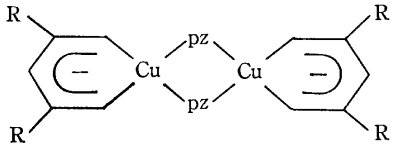
Scheme 1. Reaction paths of bis(β-diketonato)copper(II) with diazoles.

The complexation reactions are very sensitive to the nature of the solvent and to the reaction conditions, giving different products depending upon the solvent used. Hereafter, reactions (a) and (b) are referred to as addition and substitution reactions, respectively. The former proceeds *via* coordination of the neutral diazole molecules to the apical positions of the chelate, while the latter proceeds apparently by replacement of a β-diketonate anion of the chelate with one or two molecules of the diazolate anion.

The Pyrazole Complexes. Equimolar amounts of pyrazole and $Cu(acac)_2$ were mixed in chloroform, which gave $Cu_2(acac)_2(pz)_2$ (**1**) which was isolated as a light blue precipitate. The precipitate was identified by elemental analysis and spectroscopy, the results of which are in accordance with those previously reported by Barraclough *et al.*[11] who showed that it is a binuclear complex. The reaction of pyrazole with $Cu(dprm)_2$ and $Cu(dnbm)_2$ also gave the pyrazolato complexes **2** and **3**, respectively (Table 1).

TABLE 1. THE DIFFUSE REFLECTANCE SPECTRA AND CHEMICAL ANALYSES OF THE PYRAZOLATO COMPLEXES

Complex	λ_{max}/nm	Found (Calcd) (%)		
		C	H	N
$Cu_2(acac)_2(pz)_2$	630	41.72 (41.83)	4.37 (4.39)	12.37 (12.19)
$Cu_2(dprm)_2(pz)_2$	618	46.54 (46.59)	5.60 (5.47)	10.65 (10.87)
$Cu_2(dnbm)_2(pz)_2$	635	50.19 (50.43)	6.13 (6.35)	9.97 (9.80)



1 R=CH_3
2 R=C_2H_5
3 R=n-C_3H_7

The other bis(β-diketonato)copper(II) complexes examined gave no pyrazolato complexes of this type. Bis(β-diketonato)copper(II) complexes with bulky substituents such as isopropyl and *t*-butyl resist the formation of pyrazolato complexes, probably because of steric hindrance.

In order to investigate the substitution reactions further, the NMR spectra of ternary $Cu(\beta\text{-dik})_2$–diazole–chloroform-*d* system were measured. The signals of the OH and CH protons (*ca.* 16.0 ppm and 5.7 ppm, respectively) characteristic of the intramolecularly hydrogen-bonded enolic form of β-diketone are observed when diazole is added to $Cu(\beta\text{-dik})_2$ in chloroform. The signals are attributed to the β-diketone liberated during the reaction of $Cu(\beta\text{-dik})_2$ with diazole. The enolic CH and OH signals are also observed in cases when the substituents are bulky and the solid substitution products are not isolated. For example, the system $Cu(dpm)_2$–Hpz shows the following signals: ($CDCl_3$) δ=1.2 (s, *t*-butyl), 4.3 (br, ring), 5.73 (s, CH), and 16 (br, OH), suggesting that pyrazole, in solution, is coordinated in the anionic form even to the $Cu(\beta\text{-dik})_2$ chelates with bulky alkyl group, liberating the β-diketone.

The reaction of $Cu(bzac)_2$ with equimolar pyrazole in cyclohexane gave a light green precipitate, which was shown to be a 1:1 addition complex, $Cu(bzac)_2$-(Hpz).[13] The product undergoes extremely slow breakdown on standing for several months to give measurable amounts of $Cu(bzac)_2$ and pyrazole. $Cu(bzac)_2$(Hpz) exhibits a rather broad band at 3310 cm^{-1} which has been assigned to ν(N–H), showing that pyrazole is present as the neutral ligand in this complex. An analogous addition complex is also obtained by reacting pyrazole with $Cu(tfac)_2$ in cyclohexane. The diffuse reflectance spectra of the pyrazole complexes are shown Fig. 1. $Cu(bzac)_2$(Hpz) has a broad maximum at 675 nm, while that of $Cu(tfac)_2$-(Hpz) is broader and somewhat split, with the maximum at >700 nm. In general, the addition of a nitrogen base to bis(β-diketonato)copper(II) causes a shift in the visible absorption maximum of the original copper chelate to a longer wavelength, when the base is coordinated at an apical position.[14,15]

The electronic absorption spectrum of the ternary system, $Cu(tfac)_2$–pyrazole–chloroform, showed two isosbestic points at 597 and 483 nm, when the amount of pyrazole was altered. $Cu(tfac)_2$(Hpz) was also obtained from this ternary system. This addition complex has an absorption maximum at 700 nm in chloroform. The addition complex $Cu(bzac)_2$(Hzp), however, behaves differently from $Cu(tfac)_2$(Hzp) in the same solvent, having an absorption maximum at 568 nm (Fig. 2). In this case, no isosbestic point was

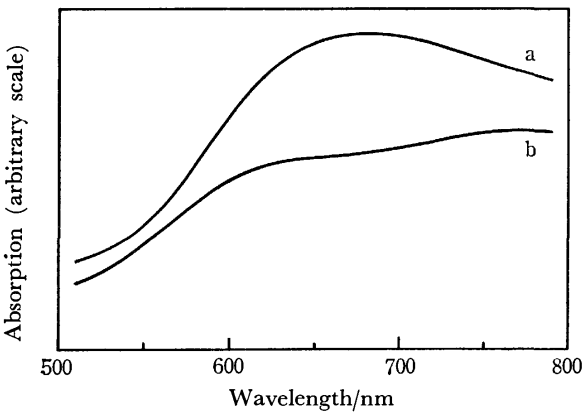


Fig. 1. The diffuse reflectance spectra of $Cu(bzac)_2$-(Hpz) (a) and $Cu(tfac)_2$(Hpz) (b).

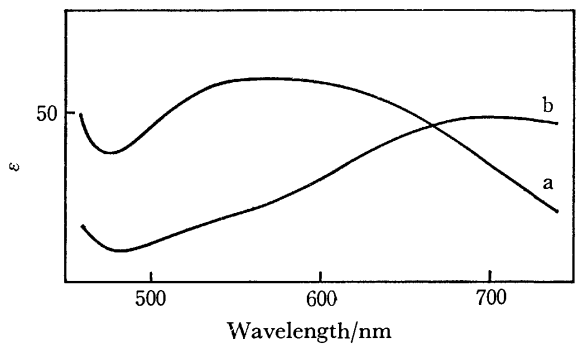

Fig. 2. The electronic spectra of $Cu(bzac)_2$(Hpz) (a) and $Cu(tfac)_2$(Hpz) (b) in chlorofrom.

observed with successive additions of pyrazole to a solution of $Cu(bzac)_2$. The spectral behavior suggests some structural change in the adduct, *e.g.* isomerization or partial dissociation, probably accompanied by apical-equatorial transfer of Hpz. Evaporation of chloroform, however, left a residue composed mainly of normal $Cu(bzac)_2(Hpz)$ and therefore the structural change in solution is apparently reversible.

As mentioned above, the adduct is obtained when the β-diketonato ligand is Hbzac and not when the ligands are aliphatic β-diketone. This suggests that the adduct $Cu(bzac)_2(Hpz)$ is more stable than the pyrazole adducts of bis(1,5-dialkyl-2,4-pentanedionato)-copper(II) chelates. This is in agreement with conclusions from the stability constants[15] of the $Cu(\beta\text{-dik})_2$(pyridine) and probably due to the contribution of phenyl group to the resonance stabilization of the adduct.[16]

Similarly, $Cu(tac)_2$ and $Cu(fac)_2$ formed stable 1:1 adducts with pyrazole. Equimolar quantities of pyrazole and either $Cu(tac)_2$ or $Cu(fac)_2$ were dissolved in dichloromethane. Evaporation of the solvent *in vacuo* left a green or light green residue, which was a 1:1 adduct of $Cu(tac)_2(Hpz)$ or $Cu(fac)_2(Hpz)$. The adducts lost pyrazole on standing for a long period in the atmosphere. The spectral data of the addition complexes are shown in Table 2, where it may be seen that the spectra are similar to that of $Cu(bzac)_2(Hpz)$, showing again characteristic absorption maxima at *ca.* 570 nm in solution.

The Imidazole Complexes. Using imidazole, 1:1 and 1:2 adducts of bis(fluorinated β-diketonato)copper-(II) have been isolated.[7] Those without fluorine substituents have, however, not been isolated because of their instability. An equimolar mixture of imidazole and $Cu(acac)_2$ in chloroform, when refluxed for 1 h, gave crystals which were isolated and shown to have a composition corresponding to Cu(acac)(im) by elemental analysis, IR and mass spectra. By the successive addition of imidazole to a solution of $Cu(acac)_2$ in chloroform, further displacement occurs. The product has not been identified, however. The displacement reaction in ethanol, however, gave Cu(acac)(im) exclusively. Consequently, $Cu(\beta\text{-dik})$(im) was prepared by the reaction of the bis(β-diketonato)copper-(II) complex with an excess of imidazole in ethanol. Characteristic data on the substitution complexes are given in Table 3.

Table 2. The electronic and IR spectra of the pyrazole adducts

Adduct	Electronic: Reflectance λ_{max}/nm	Electronic: In chloroform λ_{max}/nm	Electronic: In chloroform ε_a[a]	IR ν^{KBr}_{N-H}/cm^{-1}
$Cu(bzac)_2(Hpz)$	675	568	60	3310
$Cu(tac)_2(Hpz)$	673	567	56	3310
$Cu(fac)_2(Hpz)$	685	569	51	3300
$Cu(tfac)_2(Hpz)$	—	700	48[b]	3310

a) Apparent molar absorptivity. b) This value appears to correspond to the true molar absorptivity, since the addition complex is, probably, the only chemical species present in solution under the experimental conditions.

Cu(acac)(im) exhibits no N–H absorption band in the infrared spectra, and imidazole is shown to be present as the imidazolate anion. This complex has a magnetic moment of 1.59 BM which is less than the spin-only value of 1.73 BM for bivalent copper. The value of the magnetic moment is similar to that of a blue (1.57 BM) or a green (1.62 BM) modification of bis(imidazolato)copper(II).[17] The subnormal magnetic moment suggests the exsistence of spin interaction between the copper atoms through imidazole rings in the complex. The imidazolate anion thus acts as a bridging bidentate ligand linking two copper ions. Cu(acac)(im) was insoluble in ordinary solvents and is thus suspected to be polymeric, or tetranuclear as reported on a similar complex,[18] in structure rather than binuclear as in **1**.

The diffuse reflectance spectra of Cu(acac)(im) and **1** are shown in Fig. 3. The former complex has a maximum at 540 nm, while the latter has at 630 nm (Table 1). The binuclear complex $Cu_2(acac)_2(pz)_2$

Table 3. Characteristic data on the imidazolato complexes

Complex	Color	Found (Calcd) (%) C	H	N	Diffuse reflectance spectra λ_{max}/nm
Cu(acac)(im)	violet	41.74 (41.83)	4.41 (4.39)	12.28 (12.19)	540

was assumed to take a square-planar configuration.[11] The electronic spectra in Fig. 3 show that the coordination around the copper atom of the imidazolato complex is clearly different from that of the pyrazolato complex. Square-planar coordination around each copper atom with a coplanar arrangement of the two imidazole rings and one 2,4-pentanedionato ligand appears sterically difficult, and the coordination around the copper atom may be considerably distorted from square-planar towards a tetrahedral. The similarity of the spectra in the series of Cu(β-dik)(im) suggests similar structures. The spectra in chloroform solutions[19] (Fig. 4) are also similar to the corresponding solid spectra, so the arrangement of the ligands around the copper(II) ions in such solutions is assumed to be analogous to that in the solid complexes.

The reaction of $Cu(tfac)_2$ with diazoles gave the diazole adducts, and did not yield the μ-diazolato complexes under the experimental conditions described above. The introduction of a CF_3 group into β-diketone greatly increases the stability of Lewis base adducts of the chelates,[16,20] making it difficult to transform to the μ-diazolato complexes. 2-Methylimidazole and 3-methylpyrazole exclusively form addition

The electronic spectra of $Cu(\beta\text{-dik})_2$–pyrazole (4a) and $Cu(\beta\text{-dik})_2$–imidazole (4b) complexes in chloroform: $Cu(\beta\text{-dik})_2$ chelates are (1), $Cu(dpm)_2$; (2), $Cu(dibm)_2$; (3), $Cu(dnbm)_2$; (4), $Cu(dprm)_2$; (5), $Cu(acac)_2$; (6), $Cu(bzac)_2$; (7), $Cu(tac)_2$; (8), $Cu(fac)_2$.

complexes when reacted with $Cu(bzac)_2$. In these cases, the isomerization and the formation of substitution complex are prevented probably by steric hindrance.

In conclusion, the reactions of $Cu(\beta\text{-dik})_2$ with diazoles proceed differently depending upon the nature of the substitutions on the β-diketonato ligands and also on the nature of nitrogen bases. The investigated nitrogen bases (pyrazole and imidazole) have both pyridine-like and imino nitrogen atoms in the same molecule, which enable them to react through two alternate paths here referred to as the addition and substitution reactions (Scheme 1). In the case of a

fluorinated β-diketonato ligand, the addition complex is favored irrespective to the nature of the nitrogen base. The substitution complex is always produced, on the contrary, when the β-diketone is aliphatic. The structures of the complexes appear to be different, however, depending on the nature of the bases in cases when aroyl- or hetaroylacetonato chelates are allowed to react. Addition complexes are obtained from pyrazole and substitution complexes from imidazole (Table 4). The greater ease of formation of the addition complexes in the former cases may be due to the π-donating power of the neighboring imino group in pyrazole.[16)]

The authors are grateful to Mr. Katsuo Hara of Yokohama National University for the measurement of ^{1}H-NMR spectra.

19) Since the polymeric solid of Cu(β-dik)(im) is sparingly soluble in chloroform, the spectra were obtained with 1:1 mixtures of $Cu(\beta\text{-dik})_2$ and imidazole. The spectra did not change in the course of polymerization and final deposition of the solid. The differences in the solubilities of these complexes may thus be ascribed to the differences in the degree of polymerization in the solids.

(Received June 4, 1979)

Three modifications of dichloro[2-(hydroxymethyl)pyridine *N*-oxide]copper(II), $CuCl_2(2\text{-}CH_2OH\cdot pyo)$, were prepared and characterized by the temperature dependences of their magnetic susceptibilities and their IR spectra. The greenish-yellow modification shows ferromagnetic behavior (θ/K = +20), whereas both the yellow and deep-green modifications exhibit a dimer type of antiferromagnetism ($J/cm^{-1} = -585$ and -565). The hemi adducts with the empirical formula of $CuCl_2(2\text{-}CH_2OH\cdot pyo)\cdot 1/2L$, where $L = C_2H_5OH$ and H_2O, were also isolated. The structural assignments for the three modifications and the two adducts were made on the basis of the similarity of their magnetic and spectral properties to those of dimeric copper(II) pyridine *N*-oxide complexes, and the whole preparative scheme of these complexes was interpreted in terms of their structural features.

In a previous study of copper(II) halide complexes with substituted pyridine *N*-oxides,[1] we found that dichloro[2-(hydroxymethyl)pyridine *N*-oxide]copper-(II), $CuCl_2(2\text{-}CH_2OH\cdot pyo)$,[2] formed two magnetically different modifications: a greenish-yellow modification with a normal magnetic moment at room temperature and a yellow one with a subnormal moment. The normal moment is unusual, since many 1:1 complexes of copper(II) chloride with substituted pyridine *N*-oxides, including 3-and 4-(hydroxymethyl)pyridine *N*-oxides, exhibit antiferromagnetic interaction between the copper ions.[1]

This study was initiated in order to investigate the factors which cause such a difference in the magnetic properties. We have now prepared another modification and its hemi adducts with ethanol or water. A complex with the empirical formula of $Cu(2\text{-}CH_2OH\cdot pyo)_2(ClO_4)_2$ has also been prepared to help the investigation of the structural differences among the three modifications. We wish to report here the results of our preparative, IR spectral, and cryomagnetic studies of these complexes.

Results and Discussion

Preparation Scheme. The preparation scheme of the complexes studied in this work is shown diagrammatically in Fig. 1, together with the colors and the room-temperature magnetic moments. Compound **1** was easily converted into **2** either by keeping it over calcium chloride in a vacuum desiccator at room temperature for about one month[1] or by recrystallizing it from 1-butanol. On the other hand, attempts to convert **2** into **1** were unsuccessful. Compound **5** was readily converted into the hydrated form, **4**, on standing in the air at room temperature, whereas **1** and

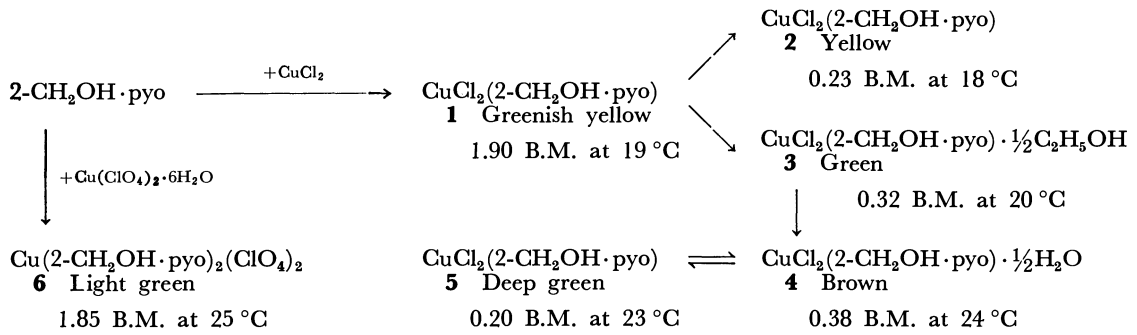

Fig. 1. Preparation scheme of complexes.

Table 1. Analytical data

	Complex	Found (%)				Calcd (%)			
		C	H	N	Cu	C	H	N	Cu
1	$CuCl_2(2\text{-}CH_2OH\cdot pyo)$	27.73	2.81	5.42	24.54	27.76	2.72	5.40	24.48
2	$CuCl_2(2\text{-}CH_2OH\cdot pyo)$	27.66	2.72	5.30	24.48	27.76	2.72	5.40	24.48
3	$CuCl_2(2\text{-}CH_2OH\cdot pyo)\cdot \frac{1}{2}C_2H_5OH$	27.72	2.66	5.45	22.46	29.75	3.57	4.96	22.48
4	$CuCl_2(2\text{-}CH_2OH\cdot pyo)\cdot \frac{1}{2}H_2O$	26.84	2.96	5.15	23.65	26.83	3.00	5.22	23.66
5	$CuCl_2(2\text{-}CH_2OH\cdot pyo)$	27.58	2.66	5.33	24.64	27.76	2.72	5.40	24.48
6	$Cu(2\text{-}CH_2OH\cdot pyo)_2(ClO_4)_2$	27.83	2.69	5.29	12.46	28.11	2.75	5.46	12.39

2 do not form such a hydrate under the same conditions.

In contrast with 2-(hydroxymethyl)pyridine *N*-oxide, 3- and 4-(hydroxymethyl)pyridine *N*-oxides form only one kind of 1:1 complex with copper(II) chloride; these complexes show subnormal magnetic moments.[1] This difference in the formation of 1:1 complexes may be due to the different ligand natures of the oxides: 2-(hydroxymethyl)pyridine *N*-oxide may coordinate to a metal ion by both the *N*-oxide and alcohol oxygens to form a six-membered chelate ring, whereas 3- and 4-(hydroxymethyl)pyridine *N*-oxides are not able to form such a chelate. This was confirmed by the observation that 2-(hydroxymethyl)pyridine *N*-oxide forms a 2:1 complex with copper(II) perchlorate (Compound **6**), unlike other aromatic amine *N*-oxides, which generally form 4:1 or 6:1 complexes with copper(II) perchlorate.[1,3-5]

The ethanol adduct, **3**, readily loses its ethanol and absorbs water in the air to give Compound **4**. As a consequence, the analytical data of carbon, nitrogen, and hydrogen for this compound were unsatisfactory. However, the copper analysis carried out immediately after the preparation indicated the formulation of **3**; the weight loss after the sample had stood in the air for 24 h at room temperature also agreed with that calculated on the basis of the structural change from **3** to **4** (*cf.* Table 1).

IR Spectra. The IR spectra of Compounds **1**, **2**, **4**, **5**, and **6** were measured in order to obtain information about the coordination mode of $2\text{-}CH_2OH\cdot pyo$ in these complexes. The IR frequencies pertaining to the alcohol- and *N*-oxide-oxygen atoms may be correlated with the geometric structures of the complexes and with the strength in the oxygen–metal coordination bond. The results for the O–H stretching vibration (νO–H), the N–O stretching vibration (νN–O), and the N–O bending vibration (δN–O) are shown in Fig. 2. For comparison, Fig. 2 also includes the IR spectrum of the copper(II) chloride complex with 2-ethylpyridine *N*-oxide, $CuCl_2(2\text{-}C_2H_5\cdot pyo)$, to which an oxygen-bridged binuclear structure has been assigned.[1]

These complexes can be classified into two groups based on the observed IR spectra and their magnetic moments: A) Compounds **2**, **4**, and **5**, which show subnormal magnetic moments, and B) Compounds **1** and **6**, which exhibit normal moments.

νO–H: In each of the complexes the strong band observed in the 3100—3500 cm^{-1} region may be assigned to the O–H stretching vibration of the CH_2OH group.[6,7] In support of this assignment, no band is observed in this region for the $CuCl_2(2\text{-}C_2H_5\cdot pyo)$ complex(*cf.* Fig. 2). There is a significant difference in the band position between the A and B groups; *i.e.*, the B compounds show the band at a frequency of less than 3300 cm^{-1}, whereas the A compounds exhibit it at *ca.* 3400 cm^{-1}(*cf.* Fig. 2). This fact suggests that the coordination mode of the OH group in the Group A complexes differs from that in the Group B complexes. The other band, at 3500 cm^{-1} in Compound **4**, may be due to the O–H stretching vibration of the water in this compound, because this band is absent in the spectrum of the anhydrous compound, **5**.

νN–O and δN–O: In the spectra of dimeric copper-

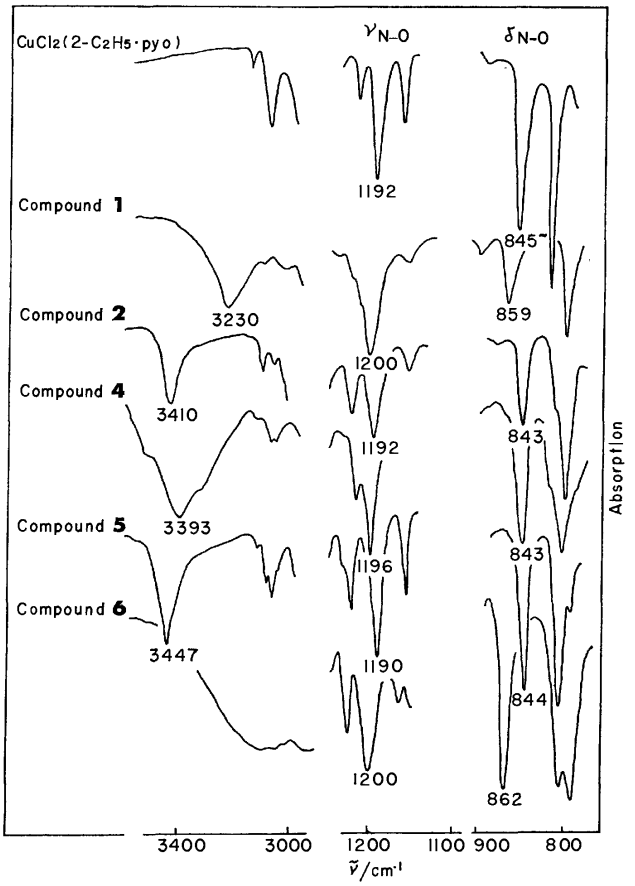

Fig. 2. IR spectra of complexes.

(II) halide complexes with aromatic amine *N*-oxides, a strong and sharp band at *ca.* 1200 cm^{-1} was assigned to the stretching vibration of the N–O group bridging two copper ions by the oxygen atom.[8,9] The present complexes exhibit the N–O band at 1190—1200 cm^{-1}. Figure 2 shows that the band frequencies in the Group A compounds (1190—1196 cm^{-1}) are lower than those in the Group B componds (1200 cm^{-1}). The lowering of νN–O is possibly due to a decrease in the N–O double-bond character,[9,10] resulting from stronger Cu–O–Cu bridging bonds formation for the A complexes than for the B complexes. The same trend was observed in the frequencies of the δN–O band of these complexes in the region of 840—860 cm^{-1}(*cf.* Fig. 2):[8] the band appeared at *ca.* 843 cm^{-1} for the A complexes and at *ca.* 860 cm^{-1} for the B complexes.

The IR spectrum of Compound **6** shows a broad and strong band around 1100 cm^{-1}, indicating the presence of an uncoordinated perchlorate ion.

For Compound **3**, accurate IR measurements could not be carried out because of its instability in the air.

Magnetic Susceptibility. The magnetic susceptibilities of Compounds **1**—**6** were measured in the temperature range of 80—300 K; the results are shown in Figs. 3 and 4. Their room-temperature magnetic moments, given in Fig. 1, were calculated from this expression:

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N\alpha)\cdot T} \qquad (1)$$

where χ_A is the molar magnetic susceptibility corrected

for the diamagnetism of the constituted atoms using Pascal's constants (2-CH_2OH·pyo, −70; C_2H_5OH, −34; H_2O, −13; Cu^{2+}, −11; Cl^-, −26; ClO^-_4, −34 in 10^{-6} cgs emu mol^{-1})[11] and, where $N\alpha$ is the temperature-independent paramagnetism per gram-ion of copper(II).** The $N\alpha$ values for Compounds **2**, **3**, **4**, and **5** were obtained from the analyses of their χ_A *vs.* T data (see below). For the other compounds, $N\alpha$ was assumed to be 60×10^{-6} cgs emu.[12]

The susceptibility data of Compound **1** follow the Curie-Weiss law in the temperature range studied(*cf.* Fig. 3). The positive Weiss constant, $\theta/K=+20$, estimated from the slope of the $(\chi_A-N\alpha)^{-1}$ *vs.* T plots, indicates the existence of a ferromagnetic interaction between the copper ions in this complex.

The susceptibilities of Compounds **2**—**5** over the temperature range are very low(*cf.* Fig. 4), indicating the existence of a very strong antiferromagnetic interaction in these complexes. Their cryomagnetic data are represented by the Bleaney-Bowers equation 2[13] for isotropic exchange in a copper(II) dimer (*cf.* Fig. 4):

$$\chi_A=\frac{N\beta^2g^2}{3kT}\left[1+\frac{1}{3}\exp\frac{-2J}{kT}\right]^{-1}(1-P)+\frac{N\beta^2g_1^2}{4kT}\cdot P+N\alpha \qquad (2)$$

where N is Avogadro's number, g is the average g factor of the binuclear complex, β is the Bohr magneton, k is the Boltzmann constant, J is the exchange integral, P is the mole fraction of the noncoupled Cu(II) impurity, and g_1 is the average g factor for the impurity. The second term in Eq. 2 was added to account for the presence of the small amount of a paramagnetic impurity, which was assumed to obey the Curie law.

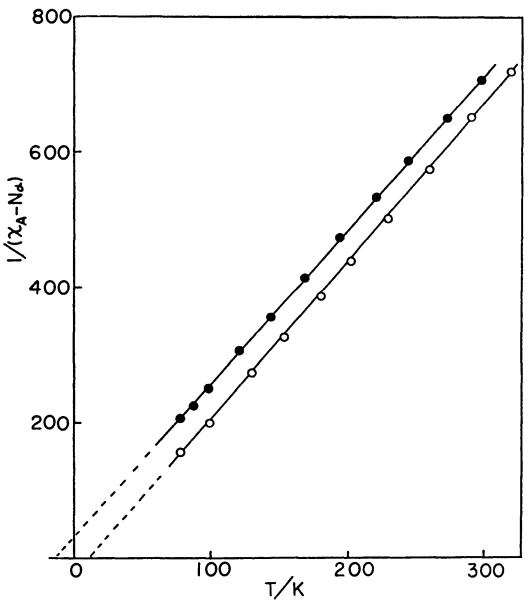

Fig. 3. Variation of reciprocal magnetic susceptibilities with temperature. ○=Compound **1**, ●=Compound **6**.

** The value of the molar magnetic susceptibility in m^3 mol^{-1} (SI) can be obtained by multiplying the value in cm^3 mol^{-1} (cgs) by $4\pi\times10^{-6}$.

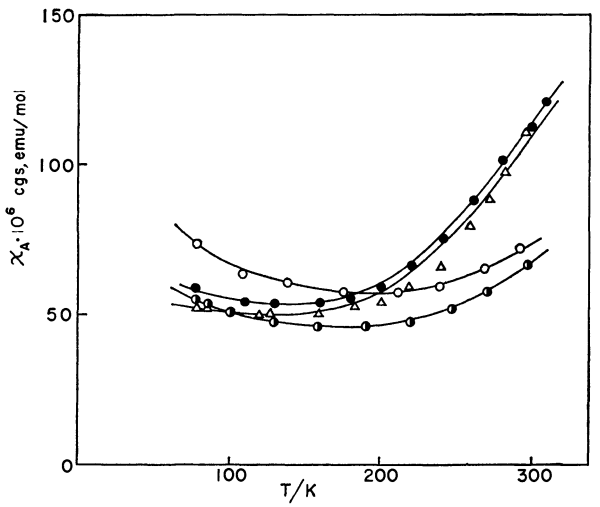

Fig. 4. Temperature dependence of magnetic susceptibilities of (○) Compound **2**, (●) Compound **3**, (△) Compound **4**, and (◑) Compound **5**.
The solid curves were calculated from Eq. 2 using the parameters listed in Table 2.

The J, $N\alpha$, and P values listed in Table 2 were estimated from the best fit of their cryomagnetic data to Eq. 2, assuming $g=g_1=2.20$. It is noteworthy that the values of $N\alpha(37\times10^{-6}$—46×10^{-6} cgs emu) are much smaller than that generally accepted in published works (60×10^{-6} cgs emu). However, it should also be pointed out that the magnitude of $N\alpha$ is dependent on the ligand-field strength, the stereochemistry around the metal ion, and the covalency of the bond between the metal ion and the ligand. The similarity of the magnetic properties of these complexes to those of a number of 1:1 aromatic amine *N*-oxide copper(II) halide complexes indicates that they are composed of binuclear structural units in crystals similar to that of dichloro(pyridine *N*-oxide)copper(II), $CuCl_2$(pyo).[14,15]

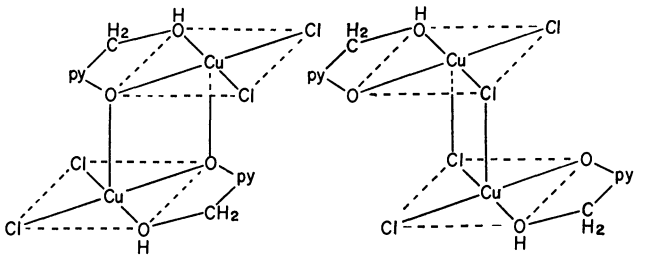
The χ_A *vs.* T data of Compound **6** follow the Curie-Weiss law with a small value of the Weiss constant, $\theta/K=-5$(*cf.* Fig. 3), indicating the absence of any appreciable antiferromagnetic interaction in this compound. It is thus probable that Compound **6** is composed of the monomeric structural units shown in (6). The IR spectral data are also consistent with this assignment.

Structure and Magnetism. On the basis of the experimental results and discussions described in the preceding sections, structural assignments for the three modifications(Compounds **1**, **2**, and **5**) may be made as follows. The most probable structure for Compound **1** is either (1) in which the monomeric $CuCl_2$(2-CH_2-OH·pyo) units are bridged by the Cu–O out-of-plane bonds or (2) in which the copper ions are bridged with chloride ions from the adjacent monomer moieties. The possible structures for both Compounds **2** and **5** are either (3) in which the pyridine rings are nearly perpendicular to the plane, in a manner similar to that in the $CuCl_2$(pyo) complex[14,15] or (4) in which the rings are parallel to the coordination

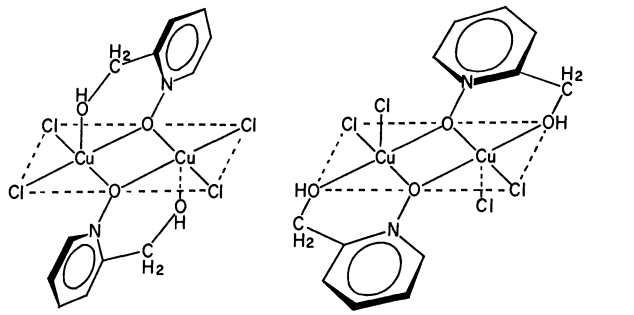
Table 2. Magnetic parameters

		J/cm^{-1}	$N\alpha$/cgs emu	P/mol
2	$CuCl_2(2\text{-}CH_2OH\cdot pyo)$	−585	44×10^{-6}	5×10^{-3}
3	$CuCl_2(2\text{-}CH_2OH\cdot pyo)\cdot\frac{1}{2}C_2H_5OH$	−470	46×10^{-6}	2×10^{-3}
4	$CuCl_2(2\text{-}CH_2OH\cdot pyo)\cdot\frac{1}{2}H_2O$	−475	46×10^{-6}	1×10^{-3}
5	$CuCl_2(2\text{-}CH_2OH\cdot pyo)$	−565	37×10^{-6}	3×10^{-3}

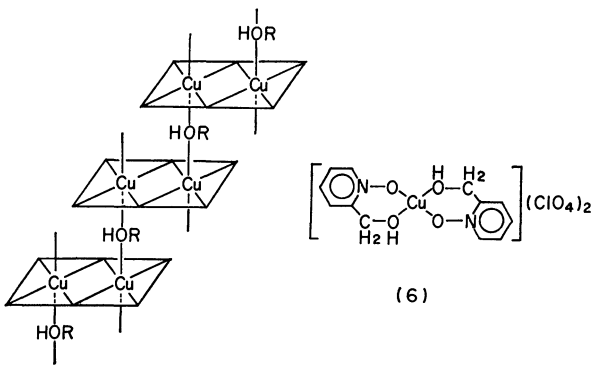
plane. However, a binuclear structure bridging copper ions with chloride ions is very unlikely for both Compounds **2** and **5**, since dimeric or polymeric copper(II) complexes containing a chloride bridge do not show any strong antiferromagnetism.[16,17] For Compound **1**, consequently, Structure (1) is considered to be more probable than (2), based on the ready conversion of **1** into **2**: the structural change from (1) to (3) or (4) is accompanied by no breaking of chemical bonds, while the change from (2) to (3) or (4) require a breaking and recombination of the coordinate bonds; thus, the former process may take place more easily than the latter. The ferromagnetism observed in Compound **1** may, therefore, be explained, as in the case



(1) (2)



(3) (4)

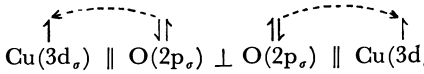


R=H or C_2H_5

(5)

(6)

of $[Cu(NO_3)_2(pyo)_2]_2$,[18] in terms of the 90° cation-anion-cation type of superexchange interaction discussed by Goodenough[19] and Kanamori.[20] The pathway is given by Ginsbergs' notation[21] as follows:



$Cu(3d_\sigma) \parallel O(2p_\sigma) \perp O(2p_\sigma) \parallel Cu(3d_\sigma)$

where $\parallel$ and $\perp$ indicate spin parallel and antiparallel interactions through orbitals in non-orthogonality and orthogonality respectively and, where the dashed arrows indicate partial electron transfer through the overlapping orbitals. The scheme represents the simultaneous partial electron transfer from a bridging oxygen atom to the pair of copper ions and the successive intra-atomic spin coupling on the oxygen atom. On the other hand, unambiguous structural assignments for Compounds **2** and **5** to either (3) or (4) are not possible on the basis of the present IR and magnetic data. However, the strong antiferromagnetism observed in these complexes may be interpreted on the basis of structure (3) or (4) in essentially the same manner as in the case of $CuCl_2(pyo)$, where we have previously emphasized the σ-type exchange pathway of $Cu(3d_\sigma)$-$O(2p_\sigma)$-$Cu(3d_\sigma)$.[1]

The bridging structure of the adducts, **3** and **4**, is considered to be essentially the same as that of the non-adducts with low magnetic moments, judging from their very similar magnetic behavior and the easy interconversion between Compounds **4** and **5**(*cf.* Fig. 1). The easy conversion of the ethanol adduct to the water adduct in the air suggests that the frameworks of the structures of the two compounds are the same; the adding molecules occupy the same position in each structure. The polymeric structure of type (5) can explain all these facts consistently since (a) this structure requires the one-adding-molecule—one-dimer relation, *i.e.*, the formation of hemi adducts, and (b) a water molecule of a higher coordinating ability replaces an ethanol molecule of a lower coordinating ability at the same coordination site of a dimer without destroying the framework of the whole polymeric structure. The **3** and **4** adducts exhibit a definitely weaker antiferromagnetic interaction than the two non-adducts, **2** and **5**, perhaps because the formation of an additional coordinate bond by a ligand at the fifth or sixth coordination site of Cu(II) weakens the in-plane coordinate bonds through which the spin coupling takes place, leading to a weaker antiferromagnetic interaction.

Experimental

Syntheses. *Compound 1*: A solution of $CuCl_2$ (1.57 g, 11 mmol) in ethanol (50 ml) was added to a solution of 2-

CH_2OH·pyo (1.25 g, 10 mmol) in ethanol (50 ml). The mixed solution was stirred at *ca.* 70 °C for 1/2 h. The greenish-yellow microcrystals thus produced were filtered off, washed with ethanol, and dried at 70—80 °C.

Compound **2**: This was obtained by recrystallizing compound **1** from 1-butanol.

Compound **3**: A solution of Compound **1** (1 g) in ethanol (500 ml) was allowed to stand for several days at *ca.* 5 °C in a freezer. After this period, green crystals were produced. The crystals separated were washed with ethanol and dried in a vacuum desiccator over calcium chloride at room temperature.

Compound **4**: This was obtained when Compound **3** was allowed to stand overnight in the air.

Compound **5**: This was obtained when the hydrate complex **4** was dehydrated in a vacuum desiccator at 70 °C over phosphorus pentaoxide.

Compound **6**: A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1.08 g, 3 mmol) in ethanol (30 ml) was added to a solution of 2-CH_2OH·pyo (0.75 g, 6 mmol) in ethanol (30 ml). After the mixed solution has been concentrated to a third of its volume, it was allowed to stand for few days at *ca.* 5 °C in a freezer. The green crystals thus precipitated were collected, washed twice with a small quantity of ethanol and once with ether, and dried at *ca.* 70 °C.

The results of the elemental analyses are given in Table 1.

Physical Measurements. The IR spectral measurements were made with a Hitachi EPI-G2 spectrophotometer in 400—4000 cm^{-1} region on Nujol mulls. The magnetic susceptibilities in the temperature range of 80—300 K were determined by the Gouy method for Compounds **1**, **2**, **4**, **5**, and **6** and by the Faraday method for Compound **3**.

The Proton-transfer Reactions of the Univalent Anions of *ortho*-Hydroxy Azo Compounds in Dioxane–Water Media†

Noboru YOSHIDA and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

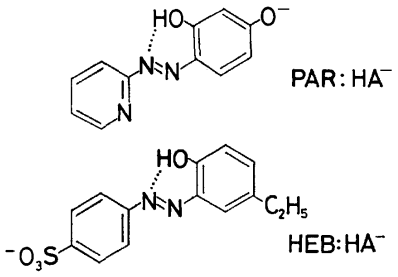
(Received June 13, 1979)

The proton-transfer reactions of the univalent anions of 4-(2-pyridylazo)resorcinol (PAR) and 4-(2-hydroxy-5-ethylphenylazo)benzenesulfonic acid (HEB) with hydroxide ion in dioxane–water media, $HA^- + OH^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} A^{2-} + H_2O$, were studied by means of temperature-jump method. The dependencies of the rate constants, k_f and k_r, on the solvent compositions were interpreted by a mechanism involving the breaking of an intramolecular hydrogen-bond.

In the previous papers we reported the proton-transfer reactions in mixed solvents of some anionic ortho-hydroxy azo compounds having a strong intramolecular hydrogen-bond.[1,2] These studies have brought us some important informations for the elucidation of mechanisms of proton-transfer reactions of these compounds in aqueous and/or in non-aqueous systems.

Recently Jost *et al.*[3] extensively studied the pressure effects on the proton-transfer reaction of 4-(*p*-nitrophenylazo)resorcinol (MAG) in aqueous solution; they gave the values of activation volumes, $\Delta\vec{V}^* = -(3.9 \pm 0.5)$ cm^3 mol^{-1} and $\Delta\overleftarrow{V}^* = -(3.1 \pm 1)$ cm^3 mol^{-1} for the forward and the backward reaction, respectively, and supported a mechanism involving the breaking of the intramolecular hydrogen-bond which will be discussed here.

In the present paper we studied the proton-transfer reactions between OH^- ion and the uninegative Brønsted acids, a slightly water-soluble acid PAR and a water-soluble acid HEB, in dioxane–water media by a temperature-jump method in order to clarify the difference of the behavior observed for PAR and HEB of the same charge-type. For kinetics of the proton-transfer reactions in dioxane–water media, the definite difference depending on the water-solubility of the reactant was observed. Although PAR and HEB behave as univalent anions, the dependence of the forward rate constant of PAR on the dielectric constant is considerably different from that of HEB.



Experimental

Measurements. Kinetic measurements were carried out at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3) with a Union Giken co-axial-cable temperature-jump apparatus Model RA-105 equipped with a pressurizing apparatus. The relaxation signal was recorded using a Tektronix oscilloscope Type 545B. The absorption spectra were measured with a Hitachi recording spectrophotometer Model EPS-3T. The pH-measurements in dioxane-water media were reported in a previous paper.[1]

Materials. Water was deionized and distilled. Dioxane was distilled and used without further purification. PAR was synthesized according to the literature[4] and recrystallized from hot ethanol–water. The purity was confirmed by elemental analysis. HEB was synthesized by the azo-coupling of *p*-ethylphenol and sulfanilic acid, and recrystallized from hot ethanol-water. Found: C, 49.31; H, 4.15; N, 8.18; S, 9.74; Na, 6.03%. Calcd for $C_{14}H_{13}N_2O_4SNa \cdot 0.5H_2O$: C, 49.85; H, 4.18; N, 8.30; S, 9.50; Na, 6.82%. Stock solutions of the dyes were prepared by dissolving a desired amount in water.

Results and Discussion

The overall equilibrium for the acid dissociation of the univalent anions of HEB and PAR, HA^-, is represented as follows:

$$HA^- \overset{K_a^c(s)}{\rightleftharpoons} A^{2-} + H^+. \quad (1)$$

The acid-dissociation constant, $K_a^c(s)$, is determined from the pH-dependence of the absorbance of HEB and PAR in solutions.[1] The values of $K_a^c(s)$ for HEB and PAR in various dioxane-contents are summarized in Table 1. The changes in the values of $pK_a^c(s)$ for

† Presented in part at the 1977 Winter Meeting in Hokkaido of the Chemical Society of Japan and the Japan Society for Analytical Chemistry, Sapporo, February 2, 1977, Abstract, p. 6.

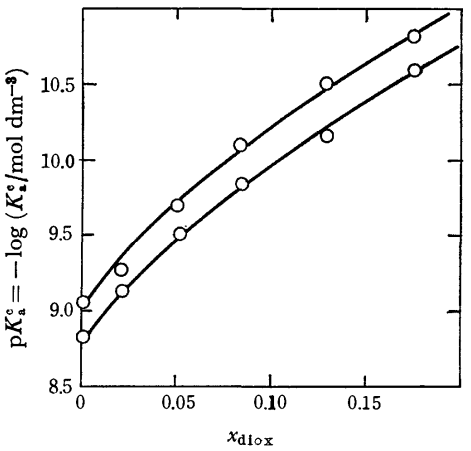

Fig. 1. Dependence of the acid-dissociation comstants, K_a^c, of HEB on the mole fractions of dioxane, x_{dlox}. At 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3). (a) The plot of pK_a^c(s) *vs.* x_{dlox}. (b) The plot of pK_a^c(k) *vs.* x_{dlox}.

the change in mole fractions of dioxane, x_{dlox}, from 0 to 0.174 are evaluated to be +1.77 and +1.83 for HEB and PAR, respectively. The corresponding values for the bivalent anions of *o*-hydroxy azo compounds, 7-hydroxy-8-phenylazo-1,3-naphthalenedisulfonic acid and 4-(2,4-dihydroxyphenylazo)benzenesulfonic acid, were reported to be +2.31 and +2.27, respectively.[2] In Fig. 1, the negative logarithms of the acid-dissociation constants of HEB ($pK_a^c(s) = -\log(K_a^c(s)/\text{mol dm}^{-3})$) are plotted as a function of x_{dlox}. Increasing dioxane content in the medium leads to a decrease in K_a^c(s) of HEB as expected. Similar tendency is observed in the pK_a^c(s) of PAR.

For the proton-transfer reactions between univalent anions of Brønsted acids and OH^- ion in dioxane–water media,

$$HA^- + OH^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} A^{2-} + H_2O, \qquad (2)$$

with the equilibrium constant $K_b^c = k_f/k_r' = \bar{C}_A/\bar{C}_{HA}\bar{C}_{OH}$, the relaxation time, τ, is expressed by

$$\tau^{-1} = k_f(\bar{C}_{OH} + \bar{C}_{HA}) + k_r', \qquad (3)$$

where k_r' equals $k_r[H_2O]$ and the bar over the concentration symbols denotes equilibrium concentrations. Table 2 shows the dependence of the reciprocal relaxation time on the analytical concentrations of HEB and pH*. Figure 2 shows the plots of τ^{-1} *vs.* $\bar{C}_{OH}$, giving k_f and k_r of PAR from the slope and the intercept, respectively. The values of k_f, k_r', pK_a^c(k), and K_b^c are summarized in Tables 3 (HEB) and 4 (PAR). In Fig. 1, pK_a^c(k)'s of HEB evaluated as $K_a^c(k) = K_b^c K_w^c$ from the kinetic data are plotted against x_{dlox}, where K_w^c denotes the apparent ionic product

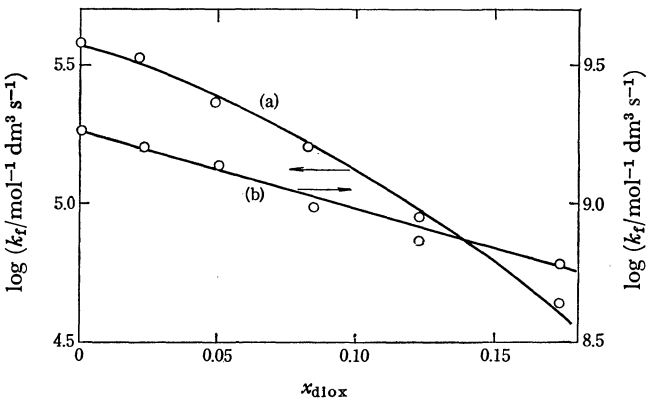

Fig. 3. Dependence of the recombination rate constants k_f on the x_{dlox} at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3) for PAR (a) and HEB (b).

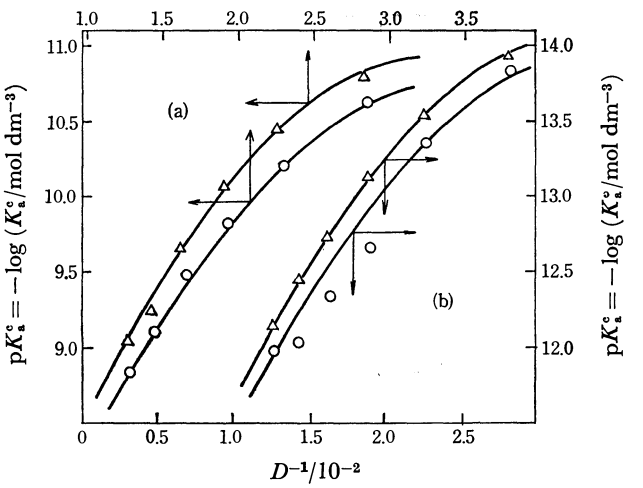

Fig. 4. Dependence of the acid-dissociation constants, K_a^c, of HEB (a) and PAR (b) on the dielectric constant of the medium at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3). ○: The plot of pK_a^c(k) *vs.* D^{-1}. △: The plot of pK_a^c(s) *vs.* D^{-1}.

of water. The differences in values between pK_a^c(k) and pK_a^c(s) of HEB and PAR are found to be small as compared with those of the bivalent anions of azo compounds. Figure 3 shows a dependence of log k_f on x_{dlox}. The recombination rate constants of HEB and PAR with OH^- ion decrease with increasing x_{dlox} (Fig. 3).

In Fig. 4 the values of pK_a^c(k) and pK_a^c(s) are plotted against the inverse macroscopic dielectric constant of medium, D^{-1}; the dependence is not linear. The simple electrostatic effect of the Born type is not observed.

The value of pK_a^c of HEB having no para O^--substituent with respect to the azo group is smaller by three orders of magnitude than that of PAR having a para O^--substituent. This is due to the difference in the stabilities of the acid form, HA^-, of HEB and PAR.

The recombination of OH^- ion and a univalent anion of HEB was found to proceed with the rate constants in the order of magnitude 10^9 mol^{-1} dm^3 s^{-1} (Table 3). However, the reaction of PAR proceeds considerably slowly, the rate constant k_f being in the order of magnitude 10^5 mol^{-1} dm^3 s^{-1}. These facts would be interpreted by the thermodynamic stability of the intramolecular hydrogen-bond and the increased double-bond character of a C–N bond between an azo nitrogen and the benzene ring owing to the resonance contribution from the para O^--substituent.[1]

A reaction mechanism

$$HA^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} HA^{*-} \tag{4}$$

$$HA^{*-} + OH^- \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} HA^{*-}\cdots(H_2O)_n\cdots OH^- \tag{5}$$

$$HA^{*-}\cdots(H_2O)_n\cdots OH^- \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} A^{2-} + H_2O \tag{6}$$

postulated previously[1] for the proton-transfer reactions in dioxane–water media is applicable also to that of HEB and PAR. Equation 4 suggests the equilibrium between two isomeric species of the acid form of *o*-hydroxy azo compounds, *viz.*, an HA^- species having an intramolecular hydrogen-bond and an intermediate species HA^{*-} having no intramolecular hydrogen-bond. The intermediate species can interact with the surrounding water molecules as the normal Brønsted acids do.

The relaxation time for the above reaction, τ, is given[1] by

$$\tau^{-1} = K_{12}k_{23}(\bar{C}_{OH} + \bar{C}_{HA}) + k_{32}/K_{34}. \tag{7}$$

The overall rate constants, k_f and k'_r, are shown by Eqs. 8 and 9.

$$k_f = K_{12}k_{23} = (k_{12}/k_{21})k_{23} \tag{8}$$

and

$$k'_r = k_{32}/K_{34} = k_{32}/(k_{34}/k_{43}) \tag{9}$$

Although no data on the equilibrium constant, $K_{12} = [HA^{*-}]/[HA^-]$, have been reported so far, the values of K_{12} can be estimated to be 10^{-5}—10^{-6} for PAR and 10^{-1}—10^{-2} for HEB provided that the rate constant k_{23} is in the order of magnitude 10^{10} mol^{-1} dm^3 s^{-1} (diffusion-controlled). Since the K_{12} is the equilibrium constant involving the step where HA^- interacts with the surrounding water molecules in the vicinity of reaction site, the larger value of K_{12} in the case of HEB indicates that the HA^- species of HEB can more easily interact with the surrounding water molecules than that of PAR.[5]

By neglecting the ionic-atmosphere term in Christiansen-Scatchard equation[7,8] we obtain

$$\ln (k_f/k_f^\circ) = -z_i z_j e^2/kTr^*D, \tag{10}$$

where z_i and z_j represent the charge of the reactants, D is the macroscopic dielectric constant of the medium, k the Boltzmann's constant, T the absolute temperature, r^* the reaction distance, e the elementary charge, and k_f° the rate constant at infinite dielectric constant. As shown in Fig. 5, the plot of log k_f *vs.* D^{-1} is linear. The forward rate constant k_f for the proton-transfer reaction is equal to $K_{12}k_{23}$ (see Eq. 8). Since, in the case of a sparingly water-soluble Brønsted acid, PAR, the value of K_{12} decreases with the decrease of the dielectric constant as observed in the case of 4-(*p*-

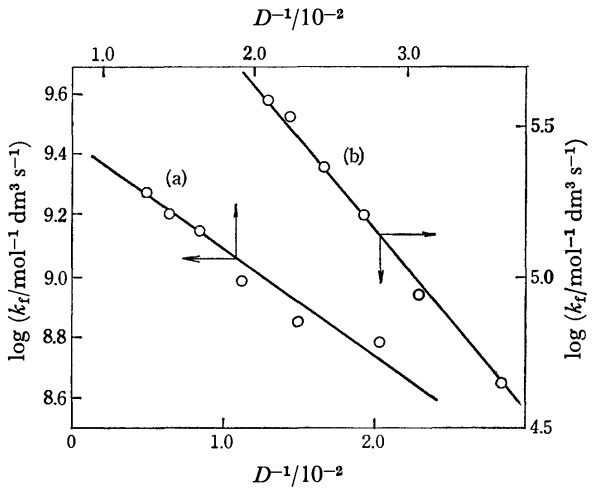

Fig. 5. Dependence of the log k_f of HEB (a) and PAR (b) on the dielectric constant, D, of the medium at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3).

nitrophenylazo)resorcinol,[1] we obtain an expectedly small value for r^* to be 3.8 Å (Fig. 5). Since in the case of a water-soluble Brønsted acid, HEB, the term K_{12} is assumed to be nearly constant, the slope in Fig. 5 is reduced to Eq. 11.

$$\begin{aligned} &\mathrm{d}\log(k_f/\mathrm{mol^{-1}\,dm^3\,s^{-1}})/\mathrm{d}\,D^{-1} \\ &= \mathrm{d}\log(k_{23}/\mathrm{mol^{-1}\,dm^3\,s^{-1}})/\mathrm{d}\,D^{-1} \\ &= -(z_i z_j e^2)/(kTr^*). \end{aligned} \tag{11}$$

From the slope for HEB in Fig. 5, we obtain the value of r^* to be 7.2 Å. The value of r^* was reported to be 8 Å for the neutralization reaction between hydrated proton $H_9O_4^+$ and hydrated hydroxide ion $H_7O_4^-$ in aqueous solution.[9,10] From the data mentioned above the intervening water molecules would be involved in the encounter complex, $HA^{*-}\cdots(H_2O)_n\cdots OH^-$.

Figure 6 leads to the linear relationships between log k_f and pK_a^c for HEB:

$$\log k_f = -0.27\mathrm{p}K_a^c(\mathrm{k}) + 11.65, \tag{12}$$

and

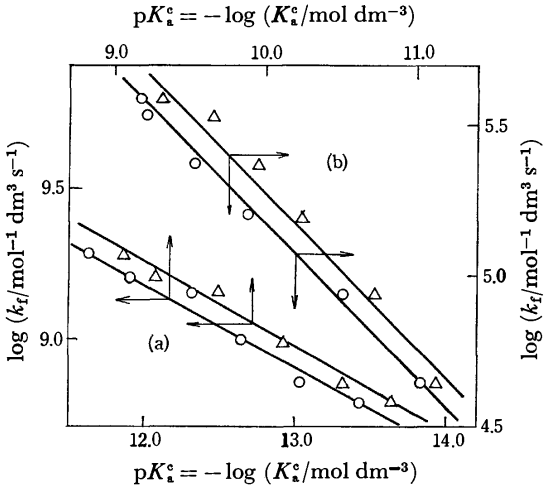

Fig. 6. Dependence of the log k_f on the pK_a^c of HEB (a) and PAR (b) in dioxane-water media at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3). ○: The plot of log k_f *vs.* pK_a^c(k). △: The plot of log k_f *vs.* pK_a^c(s).

$$\log k_f = -0.28\mathrm{p}K_a^c(\mathrm{s}) + 11.81, \tag{13}$$

and for PAR;

$$\log k_f = -0.51\mathrm{p}K_a^c(\mathrm{k}) + 11.70, \tag{14}$$

and

$$\log k_f = -0.51\mathrm{p}K_a^c(\mathrm{s}) + 11.80. \tag{15}$$

From the empirical equations 12, 13, 14, and 15, the following Brønsted type relation is found to hold between k_f and K_a^c upon changing the solvent composition:

$$k_f = G(K_a^c)^\alpha \tag{16}$$

and

$$0<\alpha<1. \tag{17}$$

Equations 16 and 17 indicates a correlation between the reactivity of HA^- with OH^- ion and the proton-donor strength of HA^- upon changing the solvent composition.

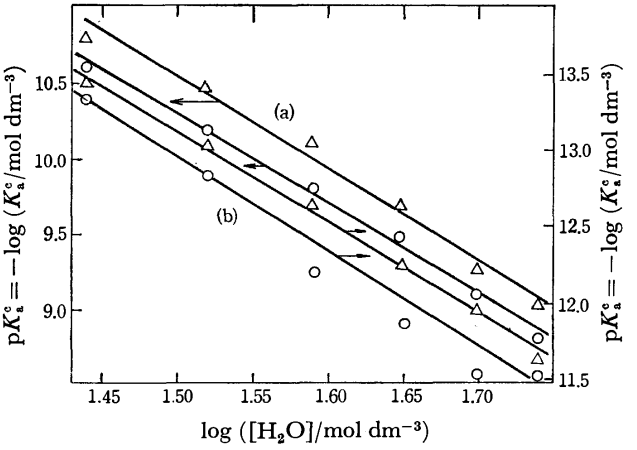

Fig. 7. Dependence of pK_a^c of HEB (a) and PAR (b) on the log [H_2O] in dioxane-water media at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3). △: The plot of pK_a^c(s) *vs.* log [H_2O]. ○: The plot of pK_a^c(k) *vs.* log [H_2O].

Figure 7 shows the linear relationship between pK_a^c and the logarithms of the concentrations of water, log[H_2O], for HEB:

$$\mathrm{p}K_a^c(\mathrm{k}) = -5.87\log[H_2O] + 19.08, \tag{18}$$

and

$$\mathrm{p}K_a^c(\mathrm{s}) = -6.13\log[H_2O] + 19.74, \tag{19}$$

and for PAR:

$$\mathrm{p}K_a^c(\mathrm{k}) = -6.27\log[H_2O] + 22.87, \tag{20}$$

and

$$\mathrm{p}K_a^c(\mathrm{s}) = -6.00\log[H_2O] + 22.74. \tag{21}$$

If the following simple acid dissociation of HA^- is postulated,

$$HA^- + n\ H_2O \overset{K}{\rightleftharpoons} H(H_2O)_x^+ + A(H_2O)_y^{2-} \tag{22}$$

with the equilibrium constant $K=[H^+_{aq}][A^{2-}_{aq}]/\{[HA^-]\cdot[H_2O]^n\}$, the acid-dissociation constant of HA^-, K_a^c, is defined as

$$K_a^c = [H^+_{aq}][A^{2-}_{aq}]/[HA^-] = K[H_2O]^n. \tag{23}$$

Therefore the following relationship could be expected:

$$\mathrm{p}K_a^c = -n\log[H_2O] + \mathrm{p}K. \tag{24}$$

From the empirical equations 18, 19, 20, and 21, the value of n is estimated to be 6 for the acid dissociation of the univalent anions, HA^-, of HEB and PAR.[11]

Solution Equilibria of Histidine-containing Ternary Amino Acid–Copper(II) Complexes in 20 v/v% Dioxane–Water

Osamu YAMAUCHI,* Toshikazu TAKABA, and Takeshi SAKURAI†

Faculty of Pharmaceutical Sciences, Osaka University, Yamadakami, Suita, Osaka 565

†*Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560*

(Received June 13, 1979)

Equilibria of histidine-containing ternary amino acid–copper(II) systems have been investigated by potentiometric titration in acid—neutral solution in 20 v/v% dioxane–water containing 0.1 M KNO_3 (1 M=1 mol dm^{-3}) at 25 °C. The stability constants of the binary complexes of histidine (his) and other amino acids (A) with a polar or a nonpolar side chain (A: serine, threonine, homoserine, asparagine, glutamine, citrulline, glycine, alanine, or valine) and the ternary complexes Cu(his)(A) have been calculated by the method of nonlinear least-squares. The overall stability constants for CuA, CuA_2, and Cu(his)(A) are higher than the values reported for the corresponding complexes in water, those for Cu(his) and $Cu(his)_2$ remaining unaffected. The stability constants (log β_{1110}) for Cu(his)(A) are in the range 17.4—18.0, no difference in stability being observed between the diastereomers Cu(L-his)(L-A) and Cu(D-his)(L-A). Species distribution as a function of pH reveals that Cu(his)(A) predominates in the neutral region. The stability constants have been compared with various theoretical values and found to be higher than the statistically estimated ones.

Copper(II) in human blood serum has been reported to form histidine-containing ternary complexes preferentially with threonine (thr), asparagine (asn), and glutamine (gln).[1] In fact a ternary complex, L-histidinato-L-threoninatocopper(II), has been detected by thin-layer chromatography using ^{64}Cu and ^{14}C as tracers.[2] Such low-molecular-weight copper(II) complexes are involved in the copper(II) transport in biological systems.[3,4] Computer simulation of the multimetal-multiligand equilibria in blood plasma indicates that copper(II) exists predominantly as binary and ternary complexes containing histidine (his),[5] supporting the reported involvement of histidine in copper(II) complex formation.

X-Ray crystal structure analysis of [Cu(L-his)(L-thr)(H_2O)]·H_2O shows that histidine coordinates to copper(II) through its amine and imidazole nitrogens with the carboxylate oxygen in the apical position and that threonine occupies the rest of the coordination plane with a glycine-like chelation in a *cis*-configuration with respect to the amino groups.[6]

On the basis of the molecular structure disclosed, the results of synthesis of ternary copper(II) complexes containing histidine and an amino acid with a polar side chain, such as asparagine and serine, and optical resolution of racemic histidine through ternary complex formation, we inferred that such a combination of ligands around copper(II) facilitates the crystallization of the ternary complexes probably owing to ligand-ligand interactions between the carboxylate oxygen of histidine and the polar side group of the other amino acid.[7,8] Very recently the structures of two modifications of L-asparaginato-L-histidinatocopper(II), isolated from water and from aqueous ethanol, have been revealed by X-ray analysis to have different side chain conformations of L-asparagine,[9] showing that the conformation is flexible and affected by the crystalline environment. Since the polar side groups of histidine and asparagine can have access to each other to within a hydrogen bond distance by the conformational change, the structures suggest that ligand-ligand interactions may take place under favorable conditions.

In order to obtain information on the ternary complex formation and ligand-ligand interactions in a medium with low polarity, we have investigated by potentiometric titration in 20 v/v% dioxane–water the equilibria of copper(II) complexes containing histidine and/or other amino acids (A) with a polar or a nonpolar side chain and compared the results with those reported for the systems in water. Comparison was also made between the stability constants for the diastereomers Cu(L-his)(L-A) and Cu(D-his)(L-A) and between the experimental and theoretical values for Cu(L-his)(L-A).

Experimental

Materials. L-Homoserine (L-hmser), L-glutamine, L-citrulline (L-cit), glycine (gly), L-alanine (L-ala), and L-valine (L-val) were obtained from Nakarai Chemicals, Ltd., and L- and D-histidine hydrochloride monohydrate, L-threonine, and L-serine (L-ser) from Ajinomoto Chemical Co. Dioxane (Nakarai Chemicals, Ltd.) was purified by distillation after refluxing for two hours over calcium hydride. All the materials were of analytical reagent grade or of highest grade available. Water was distilled and deionized.

Potentiometric Titrations. *Reagents*: Carbonate-free potassium hydroxide (0.1 M (M=mol dm^{-3})) was prepared by the method of Armstrong[10] and standardized against potassium hydrogen phthalate. Copper (II) nitrate (0.01 M) was standardized by chelatometric titration using EDTA with 1-(2-pyridylazo)-2-naphthol (PAN) as an indicator. Zinc (JIS primary standard) was used for standardization of 0.01 M EDTA.

Apparatus: Measurement of pH was made with an Orion Research 801A digital pH meter equipped with a 90-01-00 glass electrode and a 91-02-00 double junction reference electrode. The meter was standardized with Horiba standard buffer solutions (4.01, 6.86, and 9.18 at 25 °C).

Correction of pH *Meter Reading*: The pH meter readings in 20 v/v% dioxane–water were corrected according to Van Uitert and Haas[11] by titrating HNO_3 in 0.1 M KNO_3 (ionic strength (I)=0.1 M) with 0.1 M KOH. The correction factor C was calculated by means of the relation

$$-\log [H^+] = pH_M + C,$$

where $[H^+]$ and pH_M denote the analytical hydrogen ion concentration and the pH meter reading in 20 v/v% dioxane–

water, respectively. Thus, the hydrogen ion concentration was given by $10^{-pH_M}/0.66$. The ion product of water (pK_w') in this medium (I=0.1 M (KNO_3)) was determined to be 14.61 by varying the hydroxide ion concentration with 0.1 M KOH.

Determination of Equilibrium Constants: For determination of the acid dissociation constant (pK_a), a 4×10^{-3}M solution of an amino acid containing an excessive amount of nitric acid was titrated with 0.1 M KOH at 25±0.05 °C under a nitrogen atmosphere. The data for determination of the stability constants of the binary and ternary complexes were obtained by titrating 1:2 Cu(II)–amino acid systems and 1:1:1 Cu(II)–his–A systems, respectively, under the same conditions, the initial total concentration of copper(II) being 2×10^{-3} M. Dioxane was added at each addition of 0.1 M KOH to maintain the solvent composition. The pH value was measured after each addition of 0.1 M KOH and dioxane. Reproducibility of the titration was checked by multiplicate runs.

Calculations. The equilibria of the present systems in general are expressed by Eq. 1 and the equilibrium constant β_{pqrs} (Eq. 2):

$$pCu + q\text{his} + rA + sH \overset{\beta_{pqrs}}{\rightleftharpoons} Cu_p(\text{his})_q(A)_r(H)_s, \quad (1)$$

$$\beta_{pqrs} = \frac{[Cu_p(\text{his})_q(A)_r(H)_s]}{[Cu]^p[\text{his}]^q[A]^r[H]^s}, \quad (2)$$

where p, q, r, and s refer to the numbers of Cu(II), his, A, and H contained in the complex, respectively, and the charges are omitted. The β_{pqrs} values were calculated by the method of nonlinear least-squares by using the computer program SCOGS.[12] The acid dissociation constants were calculated by the usual method and refined by least-squares treatment when necessary.

Results

Acid Dissociation Constants. Typical titration curves for ligands alone are illustrated in Fig. 1, and the acid dissociation constants calculated from the data are summarized in Table 1, where pK_{COOH}, pK_{Im}, and pK_{NH_2}, referring to the pK_a's of the carboxyl, the imidazole, and the amino group, respectively, are compared with the corresponding values determined in water.[13] The pK_{COOH} values are less reliable owing to the low concentrations of the solutions, the standard deviations being *ca.* ±0.05 log unit. Whereas the constants for the amino groups, pK_{NH_2}, in aqueous dioxane are higher than those in water by 0.1—0.2 log unit,[13] the imidazole group exhibits a slightly lower pK_a value.

Stability Constants. Binary and ternary copper(II)–amino acid systems give the titration curves shown in Fig. 2, which reveals that coordination of the amino acids are nearly complete at neutral pH. The calculated stability constants ($\log\beta_{pqrs}$) for the binary and the ternary complexes are listed in Tables 2 and 3, respectively. In the computation we took into account the complex species, CuA, CuA_2, Cu(his), $Cu(his)_2$, Cu(his)(H), $Cu(his)_2(H)$, $Cu(his)_2(H)_2$, and Cu(his)(A). The stability constants thus determined reproduce the experimental curves satisfactorily (Fig. 3), with the standard deviations expressed in titer in the binary and ternary systems usually less than 0.5 and 1% of the total volume of 0.1 M KOH used,

L-cit	2.5_8 (2.43)		9.49 (9.41)
L-ser	2.4_4 (2.13)		9.16 (9.06)
L-thr	2.5_0 (2.21)		9.07 (8.97)
L-hmser	2.4_6 (2.27)		9.44 (9.28)
L-his	1.8 (1.70)	5.93 (6.02)[c]	9.23 (9.08)[c]

a) Standard deviations are <0.05 for pK_{COOH} and <0.01 for pK_{Im} and pK_{NH_2}. b) Corresponding values in water taken from Ref. 13 are shown in parentheses. c) We obtained the following values in water: pK_{Im}=6.03; pK_{NH_2}=9.11 (25 °C; I=0.1M (KNO_3)).

respectively. We see from Table 2 that the binary complexes, CuA and CuA_2, and the protonated complexes of histidine exhibit higher stability constants in aqueous dioxane than in water,[13,14] while Cu(his) and $Cu(his)_2$ remain equally stable in both media. The ternary complexes Cu(his)(A) have the $\log\beta_{1110}$ values of 17.4—18.0 (Table 3), which are also higher than the corresponding values in water.[8,14] The diastereomers Cu(L-his)(L-A) and Cu(D-his)(L-A) have $\log\beta_{1110}$ values which agree with each other to within experimental errors, apparently showing no stereo-

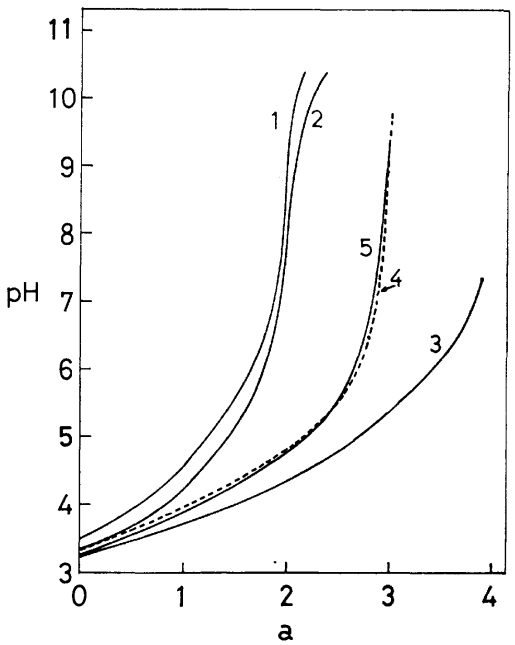

Fig. 2. Typical titration curves for binary and ternary copper(II)-amino acid systems (25°C; I=0.1 M (KNO_3)). Curves 1—5 correspond to the following systems: 1, 1:2 Cu(II)-L-hmser; 2, 1:2 Cu(II)-L-asn; 3, 1:2 Cu(II)-L-his; 4, 1:1:1 Cu(II)-L-his-L-hmser; 5, 1:1:1 Cu(II)-L-his-L-asn.
Initial total concentrations are as follows:
(i) Binary systems Cu(II)=0.002016 M; his or A=0.004000 M.
(ii) Ternary systems Cu(II)=0.002016 M; his=0.002000 M; A=0.002000 M.
a: Moles of KOH added per mole of Cu(II).

L-his[c]	10.13(10.10)	18.13(18.10)

a) Standard deviations are <0.01 for CuA and CuA_2 and 0.02—0.04 for the histidine complexes. b) Corresponding values in water taken from Ref. 13 are shown in parentheses. The values for the histidine complexes were taken from Ref. 14. c) $\log \beta_{1100}$ and $\log \beta_{1200}$ values. The stability constants for the protonated complexes are as follows: $\log \beta_{1101}$=14.31 (14.00); $\log \beta_{1201}$=24.07 (23.88); $\log \beta_{1202}$=27.83 (27.56).

selectivity in complex formation. In this connection, Freeman and Martin[15] and Brookes and Pettit[14] also reported that no stereoselectivity is observed between the diastereomers of Cu(his)(thr) in water, but the latter observed a small stability difference (0.06 log unit) between Cu(L-his)(L-val) and Cu(D-his)(L-val).

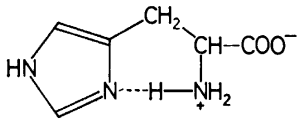
Discussion

Equilibrium Constants in 20 v/v% Dioxane-Water. *Binary Systems*: Depending on the structure of molecules involved, the polarity of the medium affects their behavior in different ways. The use of aqueous dioxane in place of water could approximate biological fluids, where the polarity may be lower because of proteins and other dissolved molecules and the difference in the stability of complexes could be more pronounced. The slightly lower pK_a value of the imidazole group of histidine as compared with the value in water may be explained by the result of a recent NMR study of histidine in aqueous solution,[16] which indicates that neutral histidine favors the struc-



1

ture with an intramolecular hydrogen bonding (**1**). Deprotonation from the imidazolium group of monoprotonated histidine is probably more favorable in aqueous dioxane and in hydrophobic regions in biological systems where the hydrogen bonding in **1** is more stabilized than in water. Analogously the higher log β_{1010} and log β_{1020} values of the complexes CuA and CuA_2 are interpreted as due to stabilization of the glycine-like mode of coordination involving a metal-carboxylate bonding with ionic character.

On the other hand, the copper(II)–histidine complexes behave differently; Cu(his) and $Cu(his)_2$ have approximately the same stability constants as those in water. This is what we expect for the two nitrogen–copper(II) bonds with covalent character through the amino group and the imidazole moiety. Formation of Cu(his)(H) and $Cu(his)_2(H)$ from Cu(his) and $Cu(his)_2$, respectively, is accompanied by stability enhancement (*ca.* 0.3 log unit) due to the solvent effect. This suggests that the carboxylate oxygen of histidine is involved in the coordination plane of copper(II).[17–20]

Ternary Systems: For the ternary complexes to have an intramolecular ligand-ligand interaction, the active complex Cu(L-his)(L-A) should assume a *cis*-configuration and the *meso* complex Cu(D-his)(L-A) a *trans*-configuration with respect to the amino groups, because of the steric requirement for the interaction. Lack of stereoselectivity may implicate either that the intramolecular interaction is too weak to affect the stability and/or *cis-trans* isomerism to an appreciable extent under the present conditions or that the proposed *cis*- and *trans*-isomers have the same stability. For the ternary systems with an acidic amino acid (Ac) and a basic amino acid (B) such as Cu(lys)(glu)(H), where lys and glu refer to lysine and glutamic acid, respectively, the difference log β_{1111} − log β_{1110} is larger than that for the system involving alanine instead of Ac.[21] This has been interpreted as due to the intramolecular electrostatic interaction between the oppositely charged groups of the side chains of Ac and B, because it makes the deprotonation from the ω-ammonium group of B more unfavorable than when Ac is replaced with alanine. However, no stereoselectivity has been detected between the diastereomers of Cu(Ac)(B)(H). Considering that the intramolecular hydrogen bonding proposed for Cu(his)(A) is weaker than the electrostatic interactions in Cu(Ac)(B)(H), it may not affect the stability constants appreciably even in 20 v/v% dioxane-water.

Information is lacking about the structures in solution of the ternary complexes, especially the *meso* complexes; they might exist as mixtures of geometric isomers. As regards the active complexes, however, the X-ray crystal structure analyses,[6,9] which have disclosed that all the three histidine-containing ternary copper(II) complexes have a *cis*-arrangement of the amino groups, may indicate their plausible structures in solution.[8]

Preferential Formation of Ternary Complexes. The species distributions as a function of pH, illustrated for Cu(L-his)(L-ala), Cu(L-his)(L-hmser), and Cu(L-his)(L-cit) in Fig. 4, show that the ternary complex Cu(his)(A) predominates in the neutral region.

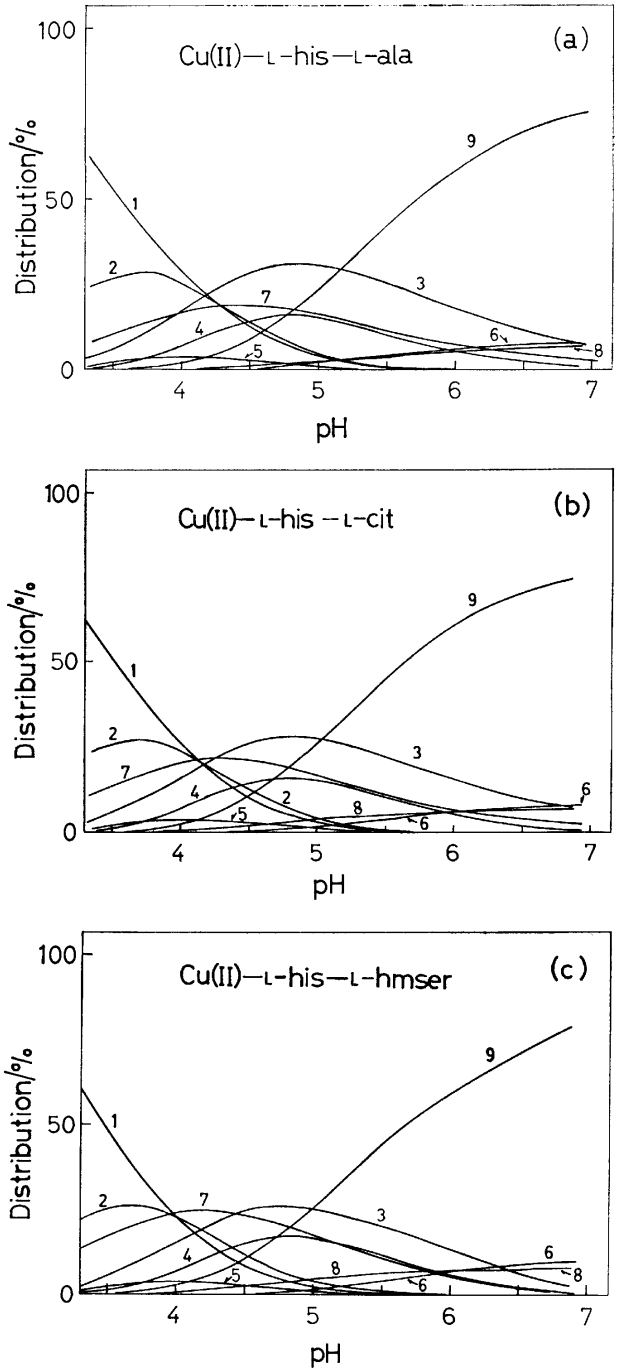


Fig. 4. Species distributions in the ternary systems as a function of pH(25 °C; I=0.1 M (KNO_3)).
(a) 1:1:1 Cu(II)–L-his–L-ala; (b) 1:1:1 Cu(II)–L-his–L-cit; (c) 1:1:1 Cu(II)–L-his–L-hmser.
Curves 1—9 correspond to the following species:1, Cu(II); 2, Cu(L-his)(H); 3, Cu(L-his); 4, $Cu(L\text{-his})_2(H)$; 5, $Cu(L\text{-his})_2(H)_2$; 6, $Cu(L\text{-his})_2$; 7, Cu(L-A); 8, $Cu(L\text{-A})_2$; 9, Cu(L-his)-(L-A).
Initial total concentrations: Cu(II)=0.002016 M; L-his=0.002000 M; L-A=0.002000 M.

Whether the formation of a ternary complex is favored or not as compared with that of binary complexes can be estimated in various ways. We use here log X and log β_{stat} defined by Eqs. 4 and 5, respectively:

$$Cu(his)_2 + CuA_2 \overset{X}{\rightleftharpoons} 2Cu(his)(A), \quad (3)$$

$$\log X = 2\log\beta_{1110} - (\log\beta_{1200} + \log\beta_{1020}), \quad (4)$$

$$\log\beta_{stat} = 1/2(\log\beta_{1200} + \log\beta_{1020}) + \log 2, \quad (5)$$

$$\Delta\log\beta = \log\beta_{1110} - \log\beta_{stat}. \quad (6)$$

We prefer the use of log X to $\Delta\log K$ ($=\log\beta_{1110} - (\log\beta_{1100} + \log\beta_{1010})$), because electrostatic factors cancel in the log X formulation for the present amino acid–copper(II) complexes where the charges of the two ligands are equal to each other.[22] The situation is regarded as the same in the log β_{stat} formulation. The observed values of log X and log β_{1110} can be compared with the statistical values of 0.6[23,24] and log β_{stat},[25] respectively. For all the systems investigated the values are larger than the statistical values (log $X>0.6$ and $\Delta\log\beta>0$) (Table 4). Thus, the formation of the ternary complexes with histidine is favored irrespective of the group contained in the side chain of A. This is partly ascribable to the favorable combination of the π-system of imidazole with a ligand with an oxygen donor.[26]

An interesting approach to the estimation of stability constants has been made by Tanaka,[27,28] who evaluated them on the basis of mechanistic considerations and by introduction of several parameters describing possible ligand-ligand interactions through the central metal ion. For copper(II) complexes with at least one neutral amine nitrogen as a ligand, the following relationship is derived:[28]

$$Cu(his) + A \overset{K}{\rightleftharpoons} Cu(his)(A), \quad (7)$$

$$\log K_{calcd} = \log\beta_{1010} + \sum^{I}\sum^{J}\delta_{ij}X_i(his)Y_j(A), \quad (8)$$

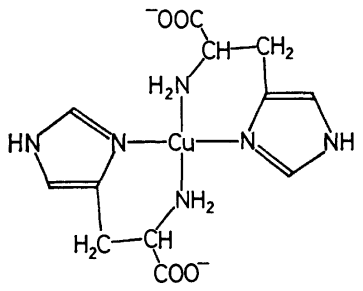
where δ_{ij} is the ligand interaction term allowing for the effect of the donor atom X_i of his on the donor atom Y_j of A, and X_i(his) and Y_j(A) are the numbers of donor atoms X_i and Y_j, respectively. Since log $K=\log\beta_{1110}-\log\beta_{1100}$, we have from Eq. 8

$$\log\beta_{1110\,calcd} = \log\beta_{1100} + \log\beta_{1010} + \sum^{I}\sum^{J}\delta_{ij}X_i(his)Y_j(A). \quad (9)$$

The δ_{ij} values have been determined by a detailed survey of reported stability constants.[28] For Cu(his)(A) with an aromatic nitrogen (N_{Im}) and an aliphatic nitrogen (N_{Am}) of histidine and an oxygen and an aliphatic nitrogen of A in the coordination plane, the expected values $\log\beta_{1110\,calcd}$ can be calculated by using $\delta_{N_{Im}N_{Am}}=-0.25$, $\delta_{N_{Im}N_{Im}}=-0.39$, $\delta_{N_{Im}O}=0.09$, $\delta_{N_{Am}N_{Am}}=-0.35$, and $\delta_{N_{Am}O}=-0.26$. Although these δ_{ij} values refer to the systems in water, we have calculated the $\log\beta_{1110\,calcd}$ values according to Eq. 9 by assuming that the δ_{ij} values are the same in 20 v/v% dioxane–water as in water because they are essentially the differences between the calculated and experimental stability constants. We see from Table 4 that the estimated values for Cu(his)(A) are in excellent agreement with the experimental ones, indicating that the δ_{ij} values hold in 20 v/v% dioxane–water and that the stability of these complexes could be affected by the electronic ligand-ligand interactions mediated by copper(II).

For the binary complexes, CuA_2, the values calculated by Eq. 10[28] are also close to those determined experimentally:

$$\log\beta_{1020\,calcd} = 2\log\beta_{1010} + \sum^{I}\sum^{J}\delta_{ij}X_i(A)Y_j(A) - \log 2. \quad (10)$$



2

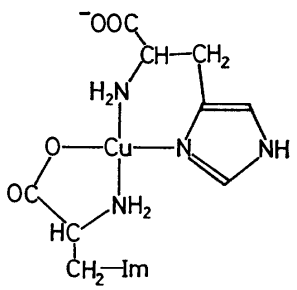
							19.19[h]

a) Calculated according to Eq. 9. b) Calculated according to Eq. 5. c) Calculated according to Eq. 6. d) Calculated according to Eq. 4. e) Calculated according to Eq. 10. f) $\log\beta_{1200}$ and $\log\beta_{1200\,calcd}$ values. g) Two (N_{Im})(N_{Am}) coordinations assumed. h) One (N_{Im})(N_{Am}) and one (N_{Am})(O) coordination assumed.



3

Interestingly $Cu(his)_2$ has a $\log \beta_{1200}$ value much smaller than the values estimated from $\log \beta_{1100}$ by Eq. 10 for two sets of donor atoms in the coordination plane, *i.e.*, two $(N_{Im})(N_{Am})$ coordinations (**2**) and one $(N_{Im})(N_{Am})$ and one $(N_{Am})(O)$ coordination (**3**). This suggests that the sterically and/or electronically unfavorable combination of donor groups in $Cu(his)_2$ contributes to the formation of ternary complexes.

We gratefully acknowledge the valuable suggestion and discussion by Prof. Motoharu Tanaka, Nagoya University. We wish to thank Profs. Akitsugu Nakahara and Yoshio Sasaki, Osaka University, for their helpful discussions, and the members of the Osaka University Computer Center for computation of the stability constants. This work was supported in part by a Grant-in-Aid from the Ministry of Education.

(Received June 29, 1979)

Polarographic behavior of the Brdička current (catalytic current produced by proteins in ammoniacal buffers containing cobalt ions) of cytochromes c from five sources (horse, chicken, and tuna hearts, *C. krusei* and *S. cerevisiae*) and of modified horse cytochromes (metal-substituted, metal-free, and heme-free cytochrome, and carboxymethylated cytochrome at methionyl residues) was investigated at dme and hmde. The results indicate that the heme group and its sixth ligand are important in determining the Brdička current-activity of cytochromes c. Replacement of the sixth heme ligand from Met to Lys reduced the Brdička current-activity by about one-half. Brdička current of *D. vulgaris* cytochrome c_3 was interpreted as due to four Lys-liganded heme groups.

Polarographic catalytic currents produced by cytochrome c in ammoniacal buffers containing cobalt ions have been studied by Carruthers[1] and Carruthers and Suntzeff[2] with a dropping mercury electrode (dme) and by Kuznetsov[3] with a hanging mercury drop electrode (hmde). They attributed the catalytic activity of cytochrome c to the cysteine residues in its molecule, as usually recognized with SS- and/or SH-containing proteins. In cytochrome c, however, the two residues of cysteine are linked to the heme group to form heme c and are not present as SS- or SH-groups. We have investigated the polarographic and voltammetric behavior of the catalytic currents, *i.e.* the Brdička currents, of cytochromes c from five sources (horse, chicken, and tuna hearts, *Candida krusei*, and *Saccharomyces cerevisiae*) and of modified horse heart cytochromes (metal-substituted, metal-free, and heme-free cytochrome, and carboxymethylated cytochrome at methionyl residues) and found that the heme group and its sixth ligand are important in the Brdička current-activity of cytochrome c. Brdička current-activity of *Desulfovibrio vulgaris* cytochrome c_3 was interpreted as due to four Lys-liganded heme groups.

Experimental

Materials. Horse heart cytochrome c (horse cyt-c), chicken heart cytochrome c (chicken cyt-c), tuna heart cytochrome c (tuna cyt-c), *Candida krusei* yeast cytochrome c (*C. krusei* cyt-c), and *Saccharomyces cerevisiae* yeast cytochrome c (*S. cerevisiae* cyt-c) were products of Sigma Chemicals Co. The purity of these cytochromes c was checked by means of cellulose acetate membrane electrophoresis. Stock solutions, usually 0.5% in cytochrome c were stored at 5 °C. The concentrations were checked spectrophotometrically.[4] Carboxymethylated cytochrome c (CM-cyt-c) was prepared by carboxymethylation of methionyl residues of horse cyt-c by the method of Babul and Stellwagen, identified by absorption spectroscopy, and its concentration determined spectrophotometrically with an absorbance coefficient 127 $mM^{-1}\,cm^{-1}$ at 406 nm.[5] Porphyrin cytochrome c (porphyrin cyt-c) was prepared by the method of Robinson and Kamen.[6] The product was further purified by the gel filtration method according to Dickerson and Chien.[7] The purified porphyrin cyt-c was identified by absorption spectroscopy, and its concentration determined spectrophotometrically with an absorbance coefficient 81 $mM^{-1}\,cm^{-1}$ at 404 nm.[8] Since porphyrin cyt-c is unstable,[7] freshly prepared porphyrin cyt-c was used for electrochemical measurements within the day. Cobalt cytochrome c (Co-cyt-c) was prepared by the method of Dickerson and Chien, identified by absorption spectroscopy, and its concentration determined spectrophotometrically with an absorbance coefficient 106 $mM^{-1}\,cm^{-1}$ at 426 nm.[7] Apocytochrome c (apo-cyt-c) was prepared by the method of Stellwagen and Rysavy.[9] The apoprotein exhibited no absorption in the visible region, indicating the absence of heme moiety. The concentration of apo-cyt-c was determined spectrophotometrically with an absorbance 0.92 ml $mg^{-1}\,cm^{-1}$ at 277 nm.[9] The purity of all these modified cytochromes was further checked by means of SDS-disk electrophoresis. *Desulfovibrio vulgaris* Miyasaki cytochrome c_3 (*D. vulgaris* cyt-c_3) supplied by T. Yagi was used. All other chemicals used were of reagent grade.

Instruments. Voltage sweep voltammograms and cyclic voltammograms at hmde were recorded on a Yanagimoto P8-MS6C polarograph and a Riken Denshi F42C X-Y recorder or a Yanagimoto PE21-TB2S potentiostat with a built-in sweep voltage generator and a Yokogawa 3077 X-Y recorder. A Metrohm E410 mercury drop electrode was used, its surface area being $0.0187\pm0.0003\ cm^2$. D.c. polarograms were recorded on a Yanagimoto P8 polarograph. In most cases a dme having the characteristics $m=1.43$ mg/s and $\tau=4.6$ s at open circuit in ammoniacal buffer at 74 cm height of mercury reservoir (h) was used. In some cases a dme having the characteristics $m=1.60$ mg/s and $\tau=6.3$ s at $h=70$ cm was used.

Electrochemical Measurements. All measurements were made in an H-type cell. All potentials were measured against a saturated calomel electrode (SCE). A buffer solution containing 0.1 M NH_3, 0.1 M NH_4Cl, and 0.1 M KCl (pH 9.4, ionic strength 0.2 mol/dm^3) was used as the base solution. 10 ml of the base solution was transferred to the cell and deaerated by passing nitrogen gas through the solution, which had been previously passed through a solution of the same composition as the base solution. An aliquot of each of the stock solutions of 0.05 M $Co(NH_3)_6Cl_3$ and 0.5% cytochromes c was then introduced into the base solution with a microsyringe under nitrogen atmosphere. In the measurements with hmde a mercury drop freshly formed at the tip of hmde was exposed to the test solution for a given period of time, referred to as exposure time (t_{exp}), during which the electrode potential was kept controlled at the initial voltage (E_i), voltammo-

grams being then run from $E_i = -0.1$ V with a sweep rate, $v = -0.2$ V/s. In determining the current intensities of the catalytic currents an extrapolated theoretical trace of degradating curve of the cobalt peak was subtracted from the current measured at the proper potential. In the measurements with dme, current intensities at the maximum growth of each mercury drop were taken and the catalytic currents measured from the cobalt limiting current. The measurements were carried out at 25 °C unless otherwise stated.

Results

Brdička Current of Horse Cyt-c. Horse cyt-c gave characteristic catalytic current, *viz.*, Brdička current in ammoniacal buffers containing hexaamminecobalt-(III) ion, Co(III), at both dme and hmde. Figure 1 shows d.c. polarograms of (a) 2×10^{-4} M Co(III) in the base solution (0.1 M NH_3, 0.1 M NH_4Cl, and 0.1 M KCl, pH 9.4) and (b—e) horse cyt-c at four different concentrations in (a) at the dme. Figure 2 shows cyclic voltammograms of (a) 2×10^{-4} M Co-(III) in the base solution and (b and c) 10^{-6} M horse cyt-c in (a) at two exposure times at the hmde. Detailed analysis of the polarographic and voltammetric

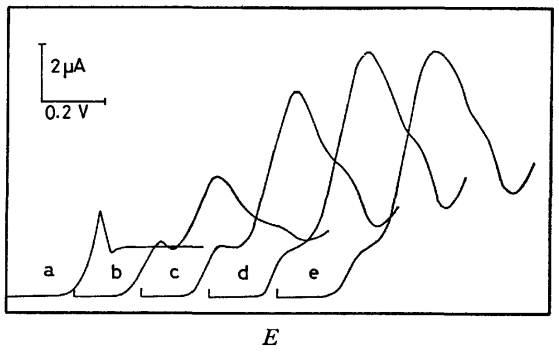

Fig. 1. D.c. polarograms of (a) 2.0×10^{-4} M Co(III) in the base solution and of horse cyt-c at (b) 4.0×10^{-7}, (c) 2.0×10^{-6}, (d) 4.0×10^{-6}, and (e) 5.7×10^{-6} M in (a). Polarograms are recorded from −0.9 V.

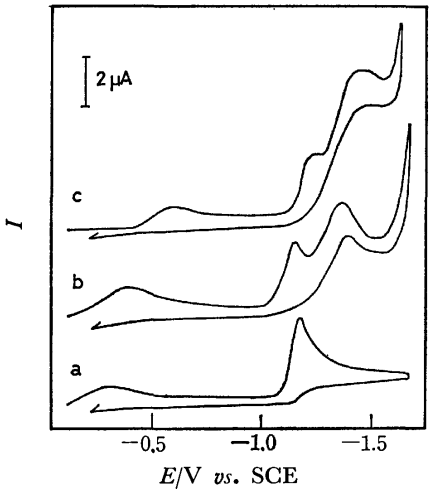

Fig. 2. Cyclic voltammograms of (a) 2.0×10^{-4} M Co(III) in the base solution and of (b and c) 1.0×10^{-6} M horse cyt-c in (a) exposuretim e: 4 s and 64 s, respectively, at the hmde.

behavior of the Brdička current produced by horse cyt-c at the dme and hmde has shown[10] that the dependence of the Brdička current-intensity at a given potential on various factors such as concentrations of the protein and Co(III), exposure time at hmde and drop time at dme is the same as that of the Brdička current produced by SS- and/or SH-containing proteins;[10,11] also that the Brdička current, i_B, at lower concentrations of Co(III), lower than 2×10^{-4} M in this case, can be expressed by

$$i_B = AFk_B\Gamma f_{Co} \quad (1)$$

where A is the electrode surface area, F Faraday constant, k_B a constant representing the Brdička current-activity of the protein studied, Γ the surface concentration of the protein adsorbed on the electrode surface, and f_{Co} the flux of cobalt ion at the electrode surface. It has also been shown[10,11] that the adsorption of protein on the mercury electrode surface at −1.4 V is controlled by diffusion and that Γ can be estimated by Koryta's equation.[12] The cobalt ion flux at the dme is given by Ilkovič theory. Thus the k_B value of horse cyt-c was determined by applying Eq. 1 to the Brdička current produced by horse cyt-c at −1.4 V, the diffusion coefficients of horse cyt-c and Co(III) being taken as 1.3×10^{-6} cm^2/s[13] and 7.5×10^{-6} cm^2/s,[11] respectively. The result is given in Table 1.

Figure 3 shows the temperature dependence of the polarograms of Brdička current produced by horse cyt-c from 10 °C to 25 °C. The current intensity at its maximum height (at −1.35 to −1.4 V) increased with rise in temperature. In contrast, it decreased at its shoulder at −1.5 V. The behavior is similar to that of SS- and/or SH-containing proteins.[10,14]

Brdička Current of Horse Cyt-c in the Presence of Other Metal Ions. In the presence of Co(II), cobaltous chloride, in place of Co(III), horse cyt-c gave a characteristic catalytic current practically the same in shape but slightly smaller in height than the catalytic current produced by horse cyt-c in the presence of Co(III). In the presence of Ni(II), nickel chloride,

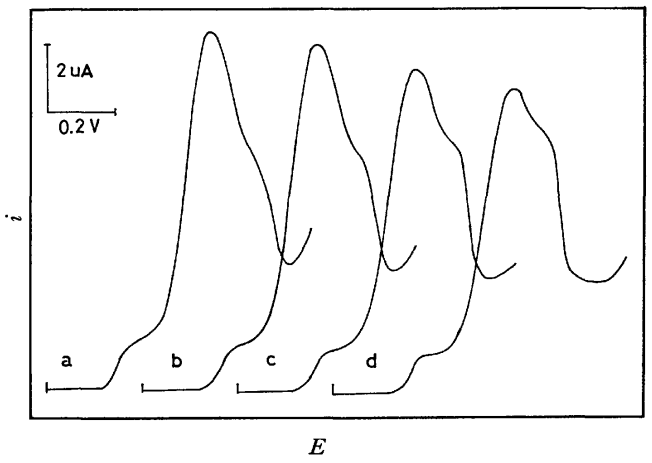

Fig. 3. Temperature dependence of d.c. polarograms of Brdička current of 4.0×10^{-6} M horse cyt-c in the base solution containing 2.0×10^{-4} M Co(III); temperature: (a) 25, (b) 20, (c) 15, and (d) 10 °C. Polarogramsa re recorded from −0.9 V.

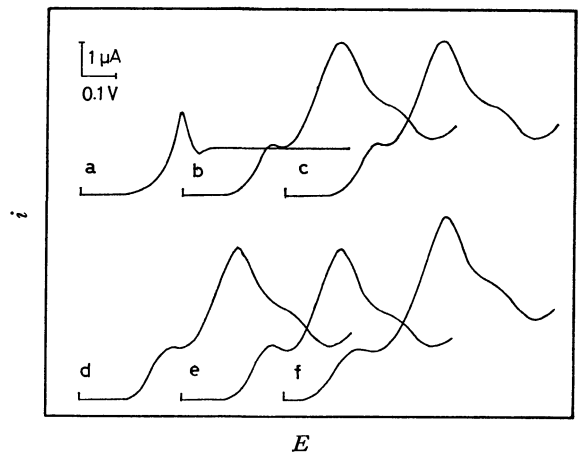

Fig. 4. D.c. polarograms of (a) 2.0×10^{-4} M Co(III) in the base solution and of 4.0×10^{-7} M cyt-c from (b) horse, (c) chicken, (d) tuna, (e) *C. krusei*, and (f) *S. cerevisiae* in (a). Polarograms are recorded from -0.9 V.

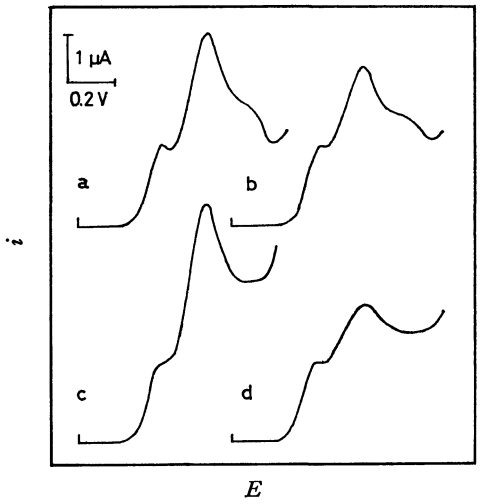

Fig. 5. D.c. polarograms of (a) native horse cyt-c, (b) CM-Cyt-c, (c) Co-cyt-c, and (d) porphyrin cyt-c each at 4.0×10^{-7} M in the base solution containing 2.0×10^{-4} M Co(III). Polarograms are recorded from -0.8 V.

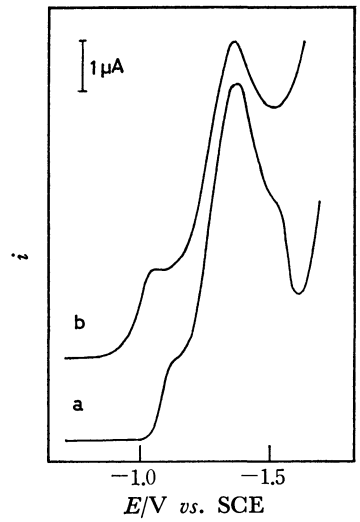

Fig. 6. D.c. polarograms of (a) 4.0×10^{-6} M native horse cyt-c and (b) 4.0×10^{-6} M apo-cyt-c in the base solution containing 2.0×10^{-4} M Co(III).

also catalytic current, though rather small, was produced. No catalytic current was observed when Co(III) was replaced by Cu(II), cupric nitrate, Zn(II), zinc chloride, and Mn(II), manganese chloride, each of 2×10^{-4} M.

Brdička Current of Cytochromes c from Other Sources. Figure 4 shows d.c. polarograms of cyt-c from five different sources at 4×10^{-7} M in a base soution containing 2×10^{-4} M Co(III). Chicken cyt-c and tuna cyt-c (Fig. 4, c and d) gave polarograms practically the same in both shape and height as horse cyt-c (Fig. 4b). *C. krusei* cyt-c also gave polarograms practically the same as horse cyt-c (Fig. 4e). At higher concentrations ($>2\times10^{-6}$ M), however, polarograms of *C. krusei* cyt-c were appreciably smaller in height as compared with those of horse cyt-c. *S. cerevisiae* cyt-c (Fig. 4f) gave polarograms which were different in shape and height from the four cytochromes mentioned above. The difference should be attributed to the existence of a free thiol group due to another cysteine residue.[15] k_B-values of these proteins determined by applying Eq. 1 to their Brdička currents at -1.4 V are given in Table 1.

Brdička Current of Modified Horse Heart Cytochromes. Figure 5 shows d.c. polarograms produced by (a) native horse cyt-c, (b) CM-cyt-c, (c) Co-cyt-c, and (d) porphyrin cyt-c each of 4×10^{-7} M in a base solution containing 2×10^{-4} M Co(III). The Brdička current of CM-cyt-c was very similar in shape to but smaller in height than that of native horse cyt-c. The Brdička currents of Co-cyt-c and porphyrin cyt-c differed more or less in shape and height from that of native horse cyt-c. Brdička currents of these modified proteins also have been found to follow Eq. 1. Their k_B values at -1.4 V are summarized in Table 1.

Apo-cyt-c gave Brdička current characteristic of denatured SS- and/or SH-containing proteins[10] (Fig. 6).

Brdička Current of D. vulgalis Cyt-c_3. Figure 7 and 8 show d.c. polarograms of *D. vulgaris* cyt-c_3 at four different concentrations in a base soution containing 2×10^{-4} M Co(III) at the dme and voltammograms of 4×10^{-7} M *D. vulgaris* cyt-c_3 at two exposure times at the hmde, respectively. Voltammograms of native cyt-c are also shown in Fig. 8. At lower surface concentration of adsorbed protein, *i.e.* at low bulk concentration with the dme or at smaller exposure time with the hmde, the polarograms (Fig. 7) and voltammograms (Fig. 8) of *D. vulgaris* cyt-c_3 were very similar in shape to but about double in height as compared with those of horse cyt-c. k_B-value of *D. vulgaris* cyt-c_3 determined at low protein concentrations at -1.4 V is given in Table 1. At high surface concentration of adsorbed protein, however, appreciable difference was observed especially at negative potential region (Figs. 1, 7, and 8).

Discussion

The polarograms of the Brdička current produced by Brdička current-active proteins are characteristic

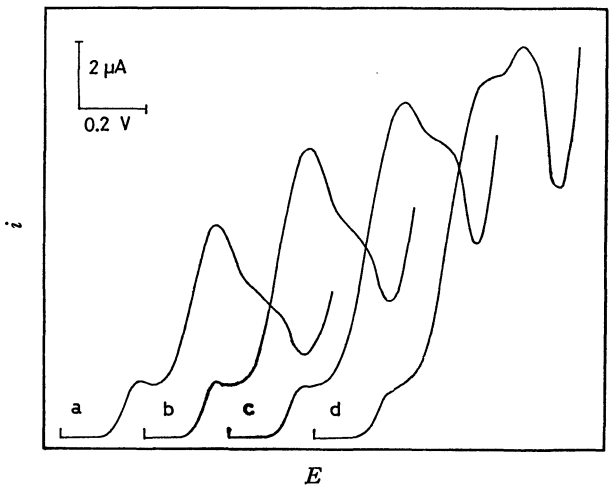

Fig. 7. D.c. polarograms of Brdička current of *D. vulgaris* cyt-c_3 at (a) 5.7×10^{-7}, (b) 1.7×10^{-6}, (c) 3.6×10^{-6}, and (d) 6.4×10^{-6} M in the base solution containing 2.0×10^{-4} M Co(III). Polarograms are recorded from −0.9 V.

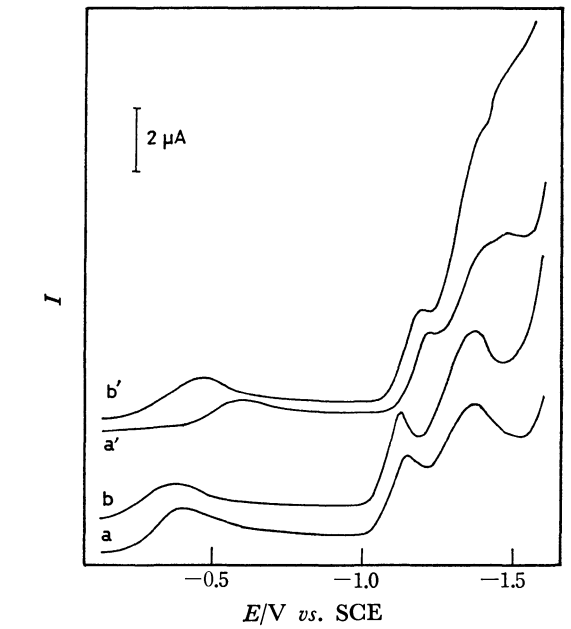

Fig. 8. Voltage-sweep voltammograms of (a and a') 4.0×10^{-7} M horse cyt-c at exposure time: 30 and 60 s, respectively and of (b and b') 4.0×10^{-7} M *D. vulgaris* cyt-c_3 at exposure time: 30 and 60s, respectively in the base solution containing 2.0×10^{-4} M Co(III) at the hmde.

of the proteins examined under specified conditions. Equation 1 predicts that the Brdička current is controlled by two factors, k_B and Γ. At and near −1.4 V the proteins we studied are very strongly adsorbed on the mercury electrode surface. At low bulk concentrations of the proteins, Γ at the dme surface can be evaluated by Koryta's equation, $\Gamma=(6/7)(D_p t_d/(3\pi/7))^{1/2}c_p$ *i.e.* as a function of the bulk concentration, c_p, and the diffusion constant, D_p, of the protein and the age of a mercury drop, t_d, at the dme. With increasing negative potential, however, the proteins become less strongly adsorbed on mercury electrode surface and Γ can no longer be evaluated by Koryta's equation. Evaluation of Γ, which is now a function also of the electrode potential, becomes very difficult.[10] In the following, quantitative analysis of the Brdička current-activities of the proteins is limited to k_B-values at −1.4 V, where Koryta's equation is valid to evaluate Γ. It is noted, however, the potential dependence of Γ and that of k_B are responsible for determining the polarographic wave-form of Brdička current characteristic of the proteins examined, especially at negative potential region.

Table 1. Polarographic catalytic activities at −1.4 V of cytochromes c at pH 9.4

Protein	n_H	n_S	k_B / 10^{12} cm^2 mol^{-1}	6th ligand
Cytochrome c				
horse	1	0	4.2	Met[15]
chicken	1	0	4.2	Met
tuna	1	0	4.2	Met
C. krusei	1	0	4.2	Met
S. cerevisiae	1	1	5.8	Met
Modified cytochrome (horse)				
CM-cyt-c	1	0	2.3	Lys[19]
Co-cyt-c	1	0	4.7	Met[21]
porphyrin cyt-c	1	0	1.4	—
apo-cyt-c	0	2	2.2	—
Cytochrome c_3				
D. vurgaris	4	0	8.8	Lys[22] or His[23]

k_B(−1.4 V)-values of various proteins are given in Table 1, in which n_H and n_S are the numbers of heme groups and SH (plus 2×SS) groups, respectively, in one protein molecule. D.c. polarograms (Fig. 4) and k_B(−1.4 V)-values of horse, chicken, and tuna cyt-c indicate that the Brdička current-activities of these mitochondrial cytochromes are the same in spite of a difference in amino acid composition among these proteins. This indicates that the Brdička current-activity with these cytochromes is primarilly due to the heme group in their molecules.

C. krusei cyt-c also has the same activity as that of mitochondrial cytochromes at lower surface concentration of the adsorbed proteins (Fig. 4 and Table 1). At high surface concentration, however, a difference in Brdička current-activity was observed between *C. krusei* cyt-c and the mitochondrial cytochromes. This might be due to the fact[15] that the amino acid composition of *C. krusei* cyt-c differs from that of mitochondrial cytochromes and is characterized by a high content of proline. When proteins are adsorbed on mercury electrode surface, their conformational states change more or less.[16,17] The conformational state of protein adsorbed on water-air interface is highly dependent on the concentration of protein in the bulk of solution, from which the adsorption of proteins takes place.[18]

The difference in amino acid composition between *C. krusei* cyt-c and mitochondrial cytochromes c may cause a difference in the conformation of the proteins adsorbed on mercury electrode surface. The Brdička current can be interpreted to be due to the catalytic action of Co(0)-protein complex formed on electrode surface. The k_B-value depends on the intrinsic catalytic activity and stability of the Co(0)-protein complex, which are determined by the conformational state of protein adsorbed on the electrode surface.

The Brdička current-activity of *S. cerevisiae* cyt-c should be interpreted as the sum of the activity of a heme group and that of an SH group. The average $k_B(-1.4\ V)/n_S$ value of five SS- and/or SH-containing proteins (bovine serum albumin, lysozyme, ribonuclease, trypsin, and pepsin) was determined to be $1.4\pm0.2\times10^{12}$ cm^2/mol.[10] Thus $k_B(-1.4\ V)=5.8\times10^{12}$ cm^2/mol of *S. cerevisiae* cyt-c can be interpreted as the sum of $k_B(-1.4\ V)=4.2\times10^{12}$ cm^2/mol of the heme group and $k_B(-1.4\ V)=1.6\times10^{12}$ cm^2/mol of the SH group.

In the presence of adsorbed SS- and/or SH-containing protein on the electrode surface the reduction step Co(II) to Co(0) shifts positively by 0.2 V.[11,14] An interesting feature of d.c. polarograms and voltammograms of the Brdička current of horse cyt-c is that the reduction potential of Co(II) to Co(0) is not or only slightly (less than ±30 mV) affected by the presence of the adsorbed protein on electrode surface. When SS and/or SH groups coexist, as in the case of *S. cerevisiae* cyt-c (Fig. 4), the reduction step Co(II) to Co(0) shifts a great deal to positive potential (Fig. 6). The results indicate that the Brdička current produced by the cytochromes is due to the heme group in them.

When the heme group of horse cyt-c was modified, the Brdička current-activities of the proteins were drastically changed as expected from the above conclusion. The removal of the central metal atom from the heme reduced the activity to about one-third and also changed the shape of the Brdička current. Replacement of the sixth ligand of the heme iron from Met to Lys[19] also reduced the activity to almost one-half of the original value. At the potential where Brdička current is produced ferricytochrome c is reduced to ferrocytochrome c on electrode surface. This was confirmed by potential-controlled electrolysis of horse ferricytochrome c at -1.4 V on mercury pool electrode, the electrolyzed solution showing an absorption spectrum characteristic of ferrocytochrome c.[4]

The sixth heme ligand of ferricytochrome c can change from Met to Lys, depending on the proton dissociation of ε-amino group of lysine with $pK=9.3$.[15] Upon reducing ferricytochrome c with dithionite or hydrated electron[15,20] in a basic solution (pH 11) a ferro-form having lysine as the sixth ligand is produced transiently, with a subsequent relaxation step to Met-liganded ferrocytochrome c within several hundred milliseconds. We may thus conclude that the Met-liganded ferrocytochrome c plays a dominant role in producing the Brdička current of native cytochromes in ammoniacal buffer of pH 9.4. Replacement of the central metal atom from iron to cobalt resulted in a slight increase in the Brdička current-activity of cytochrome. The sixth ligand is methionine for both cobalti- and cobalto-forms of Co-cyt-c.[21]

The fact that $k_B(-1.4\ V)$-value of CM-cyt-c is about one-half of $k_B(-1.4\ V)$-value of native cytochromes is of interest in view of the result that the $k_B(-1.4\ V)$-value of *D. vulgaris* cyt-c_3, 8.8×10^{12} cm^2/mol, is approximately equal to $4\times k_B(-1.4\ V)$-value of CM-cyt-c, $4\times2.3\times10^{12}$ cm^2/mol, indicating that the sixth ligands of four hemes of *D. vulgaris* cyt-c_3 are lysine. This is in line with the proposed sixth ligands of the four hemes on the basis of laser raman spectroscopy,[22] though a proposed His-liganded cytochrome c_3[23] is not excluded since the polarographic effect of replacement of the sixth ligand from Met to His is not clear at present. The observed difference between polarograms and voltammograms of cyt-c_3 and cyt-c at higher concentrations should be interpreted in a similar way to that discussed above on Brdička current of *C. krusei* cyt-c.

We are grateful to Prof. Seiyo Sano for his help in preparing porphyrin cyt-c, and to Prof. Tatsuhiko Yagi, Shizuoka University, for the supply of *D. vulgaris* cyt-c_3. This work was supported by a Grant-in-Aid from the Ministry of Education.

Halogenotriphenyltin(IV) Adducts of Tetrakis(*t*-butyl isocyanide)-rhodium(I) Perchlorate. Preparation and Kinetics

Ryosho KUWAE and Toshio TANAKA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received July 3, 1979)

$[Rh(t\text{-BuNC})_4]ClO_4$ undergoes oxidative addition reactions with Ph_3SnX (X=Cl, Br) to give *cis*-$[Rh(Ph_3Sn)X(t\text{-BuNC})_4]ClO_4$. The adducts partly dissociate in solution to exist as an equilibrium mixture with the Rh(I) substrate and the addendum. Kinetics of the equilibrium reactions in three different organic solvents were studied spectrophotometrically under pseudo-first-order conditions with excess Ph_3SnX. Rate constants for the forward reaction (k_f) are strongly dependent on the solvent polarity; k_f increases in the order of 1,2-dichloroethane<acetone<acetonitrile, whereas those for the backward reaction are little dependent on the solvents. Activation parameters also were obtained for the X=Cl system in acetonitrile; ΔS^* for the forward reaction is $-99.2\ J\ mol^{-1}\ K^{-1}$, while that for the backward reaction is $+24.9\ J\ mol^{-1}\ K^{-1}$. These results indicate that the addition reactions proceed *via* a three-center transition state formed by the nucleophilic attack of the Rh(I) ion to the tin atom.

Low-valent square planar rhodium(I) and iridium(I) complexes are known to undergo oxidative addition reactions with alkyl, aryl, and metal halides to afford octahedral rhodium(III) and iridium(III) complexes.[1-4] Some of these reactions have been studied kinetically.[5-11] As the results, the oxidative addition reactions may be classified mechanistically into the following three types; (i) a mechanism similar to the Menschutkin type reaction,[5-7] (ii) radical mechanisms,[8,9] and (iii) the mechanism involving a three-center transition state.[10] These reactions kinetically studied so far, however, were all irreversible. The present work was undertaken to study some reversible oxidative addition reactions, which will give more clear insight into transition states of the reactions.

This paper reports the preparation and configuration of chloro- and bromotriphenyltin(IV) adducts with tetrakis(*t*-butyl isocyanide)rhodium(I) perchlorate, and the kinetic study on the adduct formation

Experimental

Materials. $[Rh(t\text{-BuNC})_4]ClO_4$ was prepared as described elsewhere.[12] Chloro- and bromotriphenyltin(IV) were prepared and purified according to the literature methods, mp 105—106 °C (lit,[13] 104—106 °C) and 122—123 °C (lit,[14] 120—121 °C), respectively. Acetonitrile and acetone used as the solvents for kinetic measurements were dried over P_2O_5 and $CaSO_4$, respectively, followed by distillation. 1,2-Dichloroethane used for the same purpose was purified by the usual method.[15]

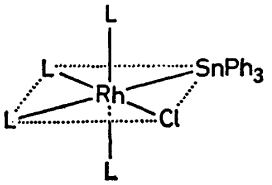
Isolation of $[Rh(Ph_3Sn)X(t\text{-BuNC})_4]ClO_4$ *(X=Cl, Br).* An acetone (7 cm^3) solution containing $[Rh(t\text{-BuNC})_4]ClO_4$ (0.75 mmol) and Ph_3SnCl (2.3 mmol) was stirred for 4 h at room temperature, followed by the addition of ligroin (*ca.* 15 cm^3). The solution was allowed to stand for 2 d in a refrigerator to afford white plates of $[Rh(Ph_3Sn)Cl(t\text{-BuNC})_4]ClO_4$, which were collected by filtration and dried *in vacuo*. From the filtrate, the adduct was further obtained by the addition of ligroin (*ca.* 15 cm^3), followed by the same procedure, 60% yield as a whole. ν(Rh–Cl), 301 cm^{-1}. Found: C, 49.47; H, 5.60; N, 6.08%. Calcd for $C_{38}H_{51}Cl_2N_4O_4RhSn$: C, 49.59; H, 5.59; N, 6.09%. The Ph_3SnBr adduct, $[Rh(Ph_3Sn)Br(t\text{-BuNC})_4]ClO_4$, was similarly obtained as white needles in a 65% yield by the reaction of $[Rh(t\text{-BuNC})_4]ClO_4$ with Ph_3SnBr at the mole ratio of 1:3. Found: C, 47.13; H, 5.36; N, 5.82%. Calcd for $C_{38}H_{51}BrClN_4O_4RhSn$: C, 47.31; H, 5.33; N, 5.81%.

Kinetic and Other Measurements. Kinetic measurements were performed using a Union Giken SM-401 spectrophotometer and a 10 mm quartz cell equipped with a Union Giken MX-7 mixing apparatus thermostated to ±0.2 °C. Two reactant solutions were rapidly introduced into the cell by the mixing apparatus. The initial concentration of the Rh(I) substrate was 8.0×10^{-5} mol dm^{-3}. All the reactions were carried out under pseudo-first-order conditions, using at least twenty-fold excess of Ph_3SnX. The rate of reaction was determined by following the decay of absorbances at 381 nm (absorption maximum of the Rh(I) substrate in acetonitrile) or at 383 nm (absorption maxima in acetone and in 1,2-dichloroethane) with time.

Infrared and ^1H NMR spectra were recorded as described elsewhere.[12]

Results and Discussion

Configuration of the Adducts. The infrared spectrum of $[Rh(Ph_3Sn)Cl(t\text{-BuNC})_4]ClO_4$ in acetone (2.0×10^{-2} mol dm^{-3}) showed three ν(N≡C) bands at 2156, 2202, and 2230 cm^{-1}. The same spectrum was observed in an equimolar mixture (2.0×10^{-2} mol dm^{-3}) of $[Rh(t\text{-BuNC})_4]ClO_4$ with Ph_3SnCl in acetone. The 2156 cm^{-1} band was assigned to the Rh(I) substrate with a square planar configuration, on the basis of its coincidence with the ν(N≡C) frequency observed in an acetone solution containing $[Rh(t\text{-BuNC})_4]ClO_4$ alone. On the other hand, the 2202 and 2230 cm^{-1} bands are due to the adduct, because of their proximity in positions to the ν(N≡C) bands exhibited by the adduct in Nujol mulls(2205 and 2238 cm^{-1}). When one more equivalent Ph_3SnCl was added to the equimolar solution, the two high frequency bands were intensified at the expense of the low frequency one. It is therefore suggested that the adduct partly dissociates in acetone to exist as an equilibrium mixture with the Rh(I) substrate and the addendum. The appearance of the two ν(N≡C) bands assignable to the adduct indicates its *cis* configuration in an octahedral geometry around the rhodium ion, as shown in **1**. This configuration was confirmed also by ^1H NMR spectra. A chloroform-d_1 solution of $[Rh(t\text{-BuNC})_4]ClO_4$ (5.0×10^{-2} mol dm^{-3}) exhibited a triplet signal due to the *t*-BuNC protons at δ 1.58 ($J(H-^{14}N)=2$ Hz). Upon addition of excess Ph_3SnCl (5.0×10^{-1}



1: L=*t*-BuNC

mol dm^{-3}) to the solution, the triplet signal disappeared, instead three singlets[16] occurred at δ 1.27, 1.55, and 1.67 with the relative intensities of 2:1:1, which is compatible with the *cis* configuration of the adduct involving four *t*-BuNC placed in three magnetically different environments from one another. The same configuration is suggested also for the Ph_3SnBr adduct from its infrared and ^1H NMR spectra in acetone. Thus, the stoichiometry of the adduct formation is expressed as follow,

$$[Rh(t\text{-BuNC})_4]^+ + Ph_3SnX \rightleftharpoons [Rh(Ph_3Sn)X(t\text{-BuNC})_4]^+. \quad (1)$$

Kinetics and Mechanism. Figure 1 depicts the decay of the 381 nm band after mixing the Rh(I) substrate with Ph_3SnCl in acetonitrile. Plots of $\ln(A_t - A_\infty)$ *vs.* time, where A_t and A_∞ are absorbances at a time t and at the end of reaction respectively, showed a good linearity. Pseudo-first-order rate constants, k_{obsd}, were calculated by the least squares

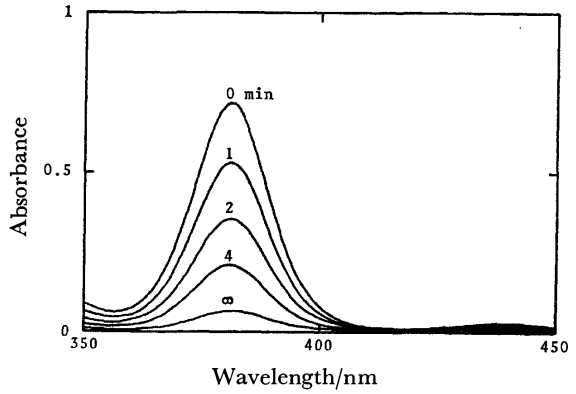


Fig. 1. Decay of the absorbance with time after mixing $[Rh(t\text{-BuNC})_4]ClO_4$ (8.0×10^{-5} mol dm^{-3}) with Ph_3SnCl (4.8×10^{-3} mol dm^{-3}) in acetonitrile at 25 °C, cell length = 10 mm.

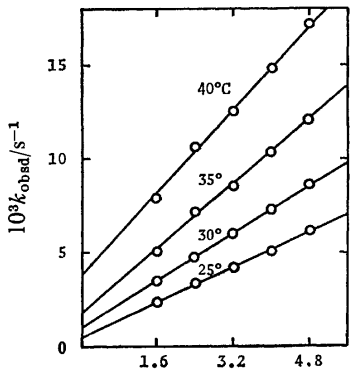

Fig. 2. Plots of k_{obsd} *vs.* $[Ph_3SnCl]$ for the reactions of $[Rh(t\text{-BuNC})_4]ClO_4$ (8.0×10^{-5} mol dm^{-3}) with Ph_3SnCl in acetonitrile at various temperatures.

method. As shown in Fig. 2, plots of k_{obsd} *vs.* the concentration of Ph_3SnCl at each temperature give a straight line with non-zero intercept which is characteristic of reversible reactions. In the presence of excess Ph_3SnCl, k_{obsd} is expressed as,[17]

$$k_{obsd} = k_f[Ph_3SnCl] + k_b \quad (2)$$

where k_f and k_b stand for the rate constants of forward and backward reactions of Eq. 1, respectively. The k_f and k_b values were obtained from the slope and intercept of the straight lines, respectively (Fig. 2). The rate constants for the $[Ph(t\text{-BuNC})_4]ClO_4$–$Ph_3SnCl$ system in acetone and 1,2-dichloroethane and for the $[Ph(t\text{-BuNC})_4]ClO_4$–$Ph_3SnBr$ system in three different solvents were similarly obtained. The results are listed in Table 1, which contains also equilibrium constants $K(=k_f/k_b)$. The ClO_4^- anion may not participate in the reactions, because the rate of reactions was little influenced by the presence of excess ClO_4^-. The reaction rate was hardly altered also by changing the slit width of the spectrophotometer. Thus, the light intensity has no appreciable effect upon the reaction rate, confirming that radical mechanisms may be ruled out for the present reactions.

The rate constant of forward reactions is strongly dependent on the solvent; k_f increases in the order 1,2-dichloroethane<acetone<acetonitrile in the two reaction systems. On the contrary, the rate constant of backward reactions is little dependent on solvent

Table 1. Rate and equilibrium constants for the reactions of $[Rh(t\text{-BuNC})_4]ClO_4$ with Ph_3SnX

X	Solvent	Temp °C	k_f[a] dm^3 mol^{-1} s^{-1}	10^3k_b[a] s^{-1}	K dm^3 mol^{-1}
Cl	Acetonitrile	25	1.18 ±0.01	0.502±0.014	2350± 70

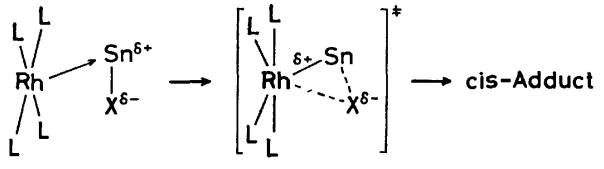
a) k_f and k_b stand for rate constants of the forward and backward reactions, respectively.

TABLE 2. ACTIVATION AND THERMODYNAMIC PARAMETERS FOR THE REACTION OF $[Rh(t\text{-BuNC})_4]ClO_4$ WITH Ph_3SnCl IN ACETONITRILE AT 25 °C

Reaction	E_a / kJ mol^{-1}	ΔH^* or ΔH° / kJ mol^{-1}	ΔS^* or ΔS° / J mol^{-1} K^{-1}	ΔG^* or ΔG° / kJ mol^{-1}
Forward	45.8±0.8	43.3±0.8	−99.2± 2.6	72.9± 2.3
Backward	102 ±3	99.5±2.5	24.9± 8.1	92.1±30.0
Equilibrium	—	−56.2±3.7	−124 ±12	−19.2± 2.2

polarity (Table 1). Accordingly, the equilibrium constant, K, undergoes the solvent effect to the same extent as k_f. This result suggests that an activated complex in the transition state has virtually the same polarity as the final product.

Table 2 lists activation and thermodynamic parameters for the $[Rh(t\text{-BuNC})_4]ClO_4$–$Ph_3SnCl$ system in acetonitrile at 25 °C. The entropy of activation, ΔS^*, for the forward reaction is large negative value, which implies that the activated complex is subjected to stereochemical restriction in the transition state. On the other hand, the ΔS^* value for the backward reaction is small, suggesting the activated complex may assume a structure which resembles that of the adduct. It is well known that low-valent transition metal complexes function as nucleophiles.[2] In the present reaction the Rh(I) ion of $[Rh(t\text{-BuNC})_4]ClO_4$ may initially attack the tin atom which is an electron deficient part of the addendum. In the Menschutkin-type oxidative addition reactions which have been suggested to proceed *via* a linear transition state $M^{\delta+}\cdots R\cdots X^{\delta-}$ (M=metal complex, RX=alkyl halide), the rate constant of the reaction for X=Br has been reported to be several hundred times larger than that for X=Cl.[6] In contrast to this, the k_f value in the present reactions is larger in Ph_3SnCl than in Ph_3SnBr in any solvents (Table 1), suggesting that the transition state may be different from that of the Menschutkin-type reactions. Thus, the oxidative addition of Ph_3SnX toward $[Rh(t\text{-BuNC})_4]ClO_4$ may proceed *via* a three-center (asymmetric) transition state which may involve deformation of the $[Rh(t\text{-BuNC})_4]^+$ moiety from a square planar configuration to some extent as follow.



L=*t*-BuNC

Similar transition states have been proposed for the reactions of $IrCl(CO)(PR_3)_2$ (R=alkyl, aryl) with MeI and $PhCH_2X$ (X=Cl, Br).[10]

Synthetic Inorganic Ion-exchange Materials. XXVI. Ion-exchange Properties of Crystalline Antimonic(V) Acid towards Noble Metals in Nitric Acid Media

Mitsuo ABE* and Mitsuo AKIMOTO**

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 7, 1979)

A study of the distribution coefficients on crystalline antimonic(V) acid (C-SbA) shows an unusual affinity series {Pt(IV) < Au(III) < Pd(II) ≪ Hg(I), Hg(II), Ag(I)} for microamounts of noble metal ions in nitric acid solution, as compared with ion-exchange resins in strong acid type. Extremely high adsorptive properties are found on the exchange system of Hg(II) and Ag(I), even in relatively high concentrations of nitric acid solution. The ion-exchange studies for macroamounts indicate that a solid solution forms for the system of the Ag(I) ions and hydrogen ions in C-SbA, while two solid phases are presented for the system of Hg(II) ions and hydrogen ions.

There has been a large amount of research on synthetic inorganic ion-exchange materials because of their thermal stability and resistance to radiation, and high selectivities for certain elements.[1-6]

Among these inorganic ion-exchangers, crystalline antimonic(V) acid (C-SbA) has been of interest in the last decade due to its high cation-exchange capacity and high selectivities for certain elements.[7-10] The increasing order of selectivities for microquantities show; $Li^+ < K^+ < Cs^+ < Rb^+ < Na^+$ for alkali metals,[8,10] $Mg^{2+} < Ba^{2+} < Ca^{2+} < Sr^{2+}$ for alkaline earth metals,[11] and $Ni^{2+} < Mn^{2+} < Zn^{2+} < Co^{2+} < Cu^{2+} < Cd^{2+}$ for transition metals[12] in nitric acid media. Extremely high absorptive ability was found for Na^+, Ca^{2+}, Sr^{2+}, and Cd^{2+} on C-SbA. The large differences in the distribution coefficients have been observed for several pairs of the elements. Some mutual separations can be achieved effectively for alkali metals,[8,10,13] Mg^{2+}–Ba^{2+}, Ba^{2+}–Sr^{2+}, Cs^+–Sr^{2+},[11] Ni^{2+}–Zn^{2+}, and Zn^{2+}–Cd^{2+} pairs[12] by using a relatively small C-SbA column.

Similar compounds to C-SbA have been reported, *e.g.* polyantimonic acid (PAA) by Lefebrve *et. al.*[14,15] and Baetsle and Huys,[16] and hydrated antimony pentoxide (HAP) by Girardi *et al.*[17]

This paper describes the ion-exchange properties of C-SbA for noble metal ions.

Experimental

Reagents. The antimony pentachloride (Yotsuhata Chemical Co., Ltd.) was used without further purification. The other reagents used were all analytical grade.

A solution of Ag(I), Hg(I), and Pd(II) was prepared by dissolving the corresponding nitrate salts with water and a solution of Hg(II) was prepared by dissolving the nitrate salt in 0.1 M (1 M = 1 mol dm^{-3}) nitric acid solution in order to prevent hydrolysis of Hg^{2+}. Tetrachloroauric(III) acid and hexachloroplatinic(IV) acid were used for preparing the solutions of Au(III) and Pt(IV).

Preparation of C-SbA as an Ion-exchange Material. C-SbA was prepared as described previously:[10,11] the precipitate obtained by the hydrolysis of antimony pentachloride was kept in the mother solution at 40 °C for more than 20 d. The precipitate was washed with cold demineralized water in a centrifuge (10000 rpm) until free from chloride ions, dried and the product ground and sieved (100—200 mesh size). The collected sample was rewashed with demineralized water in order to obtain a clear supernatant solution following batch equilibrium experiments and to improve the elution-flow rate.

Distribution Coefficients (K_d). The values for K_d for the noble metal ions were determined by batch operation as follows. C-SbA (0.250 g) was immersed in nitric acid solution (25.0 cm^3) containing 1×10^{-4} M of the metal ions at 30±0.1 °C with occasional shaking. The amount of metal ions adsorbed was determined from the changes in the concentration of the metal ions relative to the initial concentrations of the solution after equilibration. The concentrations of the metal ions were determined spectrometrically with *p*-diethylaminobenzalrhodanine for Ag(I), Hg(I), Hg(II), and Au(III), with tin(II) chloride for Pt(IV) and with sodium iodide and sodium sulfite for Pd(II).[18,19] The emf titration method was employed for determining the hydrogen ion concentration by means of a standardized sodium hydroxide solution.

Preparation of the Ion-exchanged C-SbA. The C-SbA ion-exchanged with Ag(I) in different degree was prepared by immersing C-SbA in 0.1 M $AgNO_3$ solution of which the volume contained amounts corresponding to 25, 50, or 80% of its theoretical capacity. The theoretical capacity (5.06 meq/g) may be estimated from the empirical formula $Sb_2O_5 \cdot 4H_2O$ assuming that one antimony atom gives one hydrogen ion available for ion-exchange.[20] In the case of C-SbA ion-exchanged with Hg(II), a solution containing 0.05 M $Hg(NO_3)_2$ in 0.1 M nitric acid solution was used. The fully ion-exchanged C-SbA with Ag(I) and Hg(II) was prepared by a breakthrough experiment as follows; a 0.1 M $AgNO_3$ was passed continuously through the C-SbA column of 0.5 g with a flow rate of 0.3 cm^3/min, and a 0.05 M $Hg(NO_3)_2$ solution containing 0.1 M HNO_3 was used for the fully ion-exchanged C-SbA. Injection was continued until the change in the concentration of metal ions between influent and effluent was negligible within the experimental error.

X-Ray Diffraction Analysis. The X-ray diffractions for the ion-exchanged C-SbA were determined using a JEOL X-ray Diffractometer Model, JDX-7E, with Ni-filtered Cu$K\alpha$ radiation.

Results and Discussion

The results of the TGA, DTA, and X-ray studies on C-SbA in the hydrogen ion form showed good

**Present address: Kugoh Middle School, 5-81, Kugoh-chō, Yokosuka-shi, Kanagawa 238.

agreement with earlier data.[10,20]

Adsorption of Noble Metal Ions. The time dependence on the adsorption of different metals was measured qualitatively in order to determine the equilibrium distribution coefficients (Fig. 1). Equilibrium was attained within 3, 4, and 7 d for Pd(II), Au(III), and Pt(IV) respectively. Complete adsorption (99—100%) was achieved for Ag(I), Hg(I), and Hg(II) within 24 h.

Distribution Coefficients. The equilibrium distribution coefficients of noble metal ions on C-SbA are shown in Fig. 2 as log-log plots of K_d *vs.* [HNO_3]. The slope, d log K_d/d log [HNO_3], for the Pd(II)–H^+ system is approximately 2 in the concentration range 0.5—2 M HNO_3 and approximately 1 in the range 0.05—0.5 M. Similar behavior has been found on Dowex 50W-X8, indicating the "ideal 2:1 ion-exchange reaction" of Pd^{2+}/H^+ at relatively high concentration of nitric acid solution. The reduction in slope may be explained in terms of the ion-exchange reaction of the $Pd(OH)^+$–H^+, since the $Pd(OH)^+$ species increases with decreasing concentration of hydrogen ions below 0.5 M HNO_3 from studies of the stability constant of the Pd(II)–OH^- system.[21] The slope was approximately 2 for the Pt(IV)–H^+ system, while the K_d value for Au(III) was independent of the concentration of nitric acid. It is known that in perchloric acid solution, the Pt(IV) ion is unaffected by cation-exchange resins such as Dowex 50, while in chloride solution the Pt(IV) ion gives stable chloride

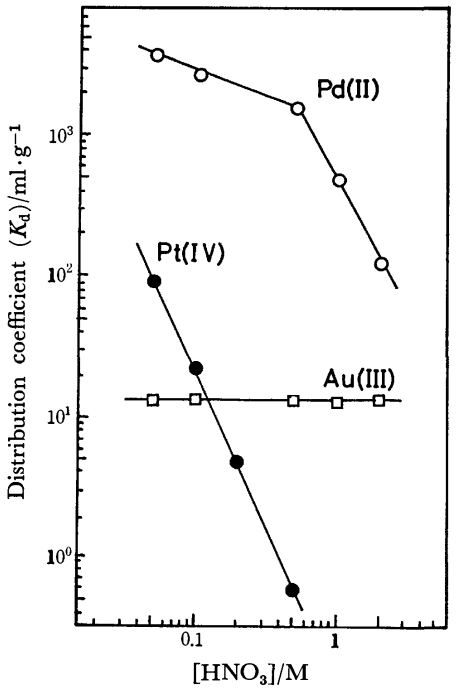

Fig. 2. Distribution coefficients of noble metals on C-SbA at different concentration of nitric acid solution. Initial concentration of the metals, $1.\times10^{-4}$ M. C-SbA, 0.250 g. Total volmue, 25.0 cm^3. Temperature, 30±0.1 °C.

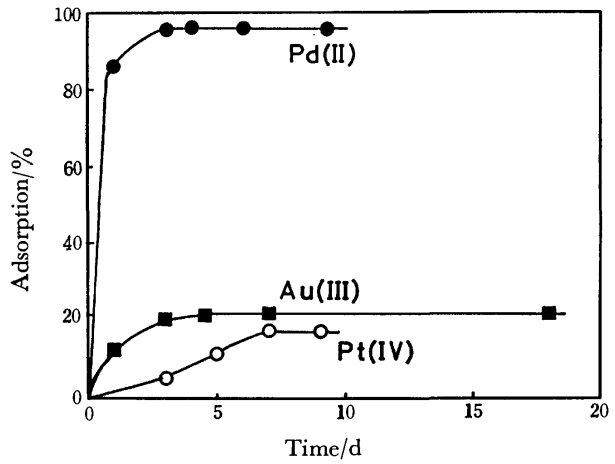

Fig. 1. Time dependence of the adsorption of noble metals on C-SbA in 0.2 M nitric acid solution. Initial concentration of metal ions, 1×10^{-4} M, C-SbA, 0.250 g. Total volume, 25.0 cm^3. Temperature, 30±0.1 °C.

complexes which can be retained quantitatively by anion-exchange resins.[22] On the ion-exchange system in aqueous solution, cationic species of Pt(IV) can not be found in the literature known so far. It has been reported that chloride and nitrate ions are unaffected by antimonic(V) acid in most media, but that phosphate ions can be adsorbed in phosphoric acid solutions.[23] The adsorptive behavior of Pt(IV) and Au(III) may be due to a difference in mechanism in the cation-exchange reaction.

The K_d values obtained are summarized in Table 1, the values on cation-exchange resin being included for comparison. The results obtained on Dowex 50W-X8 are in fairly good agreement with the results reported by Strelow *et al.*[24] Extremely high values of $K_d(>10^4)$ were observed for Ag(I), Hg(I), and Hg(II) on C-SbA in the concentration range 0.05—2 M HNO_3, compared with the ion-exchange resins. The following affinity series was found for C-SbA: Pt(IV)<Au(III)<Pd(II)≪Hg(I), Hg(II), Ag(I) in 0.5 M HNO_3 solution.

TABLE 1. DISTRIBUTION COEFFICIENTS FOR NOBLE METALS ON C-SbA IN 0.5 M HNO_3

Ion-exchanger	Pt(IV)	Au(III)	Pd(II)	Hg(I)	Hg(II)	Ag(I)

a) Data from Ref. 24.

Preparation of the Ion-exchanged C-SbA with Ag(I) and Hg(II). A solution containing Ag(I) or Hg(II) of macroamounts, corresponding to 25, 50, or 80% of the theoretical capacity when added to C-SbA, the liberated hydrogen ions were found to be equivalent to the metal ions added. This indicates that complete adsorption was achieved in both systems in the determination of metals and hydrogen ions within experimental error. In the batch system of Hg(II)–H^+, especially a very small quantity ($\simeq 10^{-6}$ M) of Hg(II) was observed in the supernatant solution equilibrated with C-SbA.

The breakthrough curves show that hydrogen ions are liberated quantitatively for an equivalent uptake of Hg(II) and Ag(I) ions (Fig. 3). The curves obtained are steep, indicating a reasonable rate of ion-exchange for the metal ions. The breakthrough capacities were found to be 4.95 meq/g for Ag(I) and 5.06 meq/g for Hg(II), which are in good agreement with the theoretical capacity for C-SbA. A similar result for Ag(I) has been reported; 5.0 meq/g by Lefebrve and Gaymard[15] and 5.1±0.5 meq/g by Baetsle and Huys.[16] The color of the C-SbA in the H^+ form changed from which to yellow on complete exchange of Ag(I) or Hg(II).

The addition of a 5 M nitric acid solution to the fully exchanged C-SbA with Hg(II) produced very small quantities ($\simeq 10^{-5}$ M) of Hg(II) which were found in the supernatant solution (50 cm^3).

X-Ray Analysis. The X-ray diffraction patterns of the C-SbA ion-exchanged with Hg(II) revealed two solid phases present on the C-SbA exchanged

Influent: Hg(II), 0.05 M $Hg(NO_3)_2$ in 0.1 M HNO_3, Ag(I); 0.1 M $AgNO_3$. -○-: H^+, -●-: Hg(II), -■-: Ag(I).

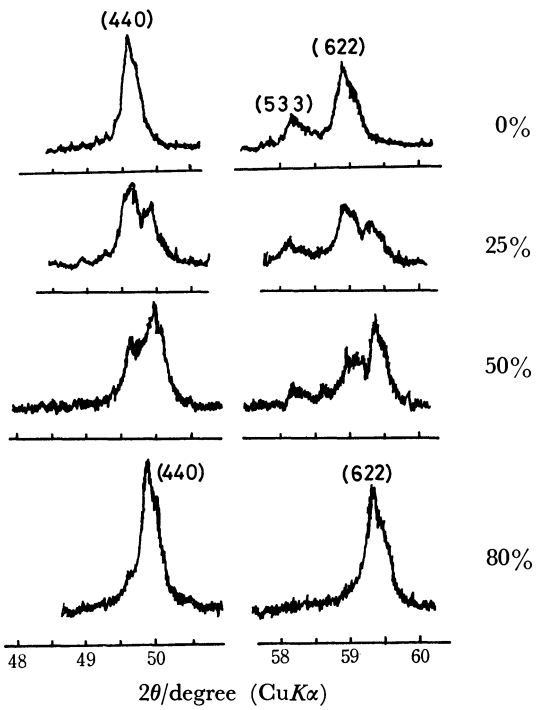

Fig. 4. Schmatic diagrams of X-ray diffraction patterns for (444), (533), and (622) planes of the C-SbA ion-exchanged with Hg(II) at different loading.

by approximately 10—80%. Typical patterns *viz.* (440), (533), and (622) are illustrated in Fig. 4. Both phases belong to the crystal system of Fd3m with a lattice constant of 10.37_5 and 10.31_4 Å. The former phase may be identified as the unexchanged C-SbA in the H^+ form. The diffraction intensities of the latter phase increase with increasing degree of ion-exchanging Hg(II) ions while those of the former decrease simultaneously. A single phase was observed for the C-SbA ion-exchanged by several metal ions, such as the alkali metals,[25] the alkaline earth metals,[26] and transition metals.[27] It has been established that the presence of two phases during ion-exchange is often observed in the system of ion-exchange on crystalline zirconium- or titanium-phosphate exchangers.[28–30] The presence of two solid phases is however the first case in the ion-exchange systems of C-SbA.

The calculated lattice constants for the C-SbA ion-exchanged with Hg(II) and Ag(I) are plotted against the loading of the ion-exchanging metal ions in Fig. 5. The lattice constants of the C-SbA ion-exchanged with Ag(I) decreased continuously with the degree of exchanging Ag(I) ions indicating that a solid solution forms for the ion-exchange system of the Ag^+ and hydrogen ions in the C-SbA. The X-ray diffraction data for the fully ion-exchanged C-SbA with Ag(I) and Hg(II) ions are summarized in Table 2. A remarkable decrease on the diffraction intensities of the (111) and (311) planes was observed for both ion-exchanged C-SbA, while the (222) plane increased simultaneously. Similar behavior was observed on the C-SbA ion-exchanged with relatively heavy metal ions sucn as Ag^+, Rb^+, Cs^+, Sr^{2+}, and Ba^{2+}.[25,26,31] Further ion-exchange studies Hg(II) with

Structural Study of Optical Resolution. VII. The Crystal Structure of $(-)_{589}$-Oxalatobis(ethylenediamine)cobalt(III) Hydrogen-*d*-tartrate Dihydrate and Comparison between the Crystal Structures of the More- and Less-soluble Diastereoisomers

Masahiro KURAMOTO, Yoshihiko KUSHI, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Hiroshima 730

(Received August 14, 1978)

The single crystals of the more-soluble diastereoisomeric salt including the hydrogen-*d*-tartrate anion as a resolving agent, $(-)_{589}$-[Co(ox)en_2]H-*d*-tart·$2H_2O$, have been newly obtained, and the crystal structure has been determined by three-dimensional X-ray analysis. The crystals are orthorhombic, space group $P2_12_12$, $Z=4$, $a=16.583(5)$, $b=14.186(5)$, and $c=7.403(2)$ Å. The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method to a conventional *R*-value of 0.044 for the 1907 independent reflections. One of the two ethylenediamine rings is of the *ob* form. The other ring has a conformational disorder, the proportion of the *ob* to the *lel* form being 50:50. The absolute configuration of the complex cation is denoted as $\Delta[(50\%\text{-}\delta, 50\%\text{-}\lambda)\delta]$. The framework of the crystal structure is built up of a stack of complex cations and H-*d*-tart anions along the c-axis in a "head-to-tail" arrangement. The shortest interatomic distance between the H-*d*-tart anions is 2.473 Å(O–H···O), while that between the complex cations is 2.995 Å (N–H···O). A comparison of the crystal structure of the more-soluble diastereoisomer with that of the less-soluble one revealed that the $\{\text{H-}d\text{-tart}\}_\infty$ chain is structurally different from that in the latter; the chain is spiral in the latter, but not in the former. The structural feature in the $\{\text{H-}d\text{-tart}\}_\infty$ chain is considered to play an important role in the discrimination of the chirality of the $[Co(ox)en_2]^+$ cation. The conformational disorder is discussed in connection with the dehydration of crystals.

Recently, we reported the crystal structure of the less-soluble diastereoisomeric salt, $(+)_{589}$-[Co(ox)en_2] H-*d*-tart·H_2O,[1] which is obtained as an intermediate in the course of the optical resolution of the $[Co(ox)en_2]^+$ cation using the hydrogen-*d*-tartrate anion (d-$C_4H_5O_6^-$, abbr. H-*d*-tart) as a resolving agent.[2] The optically active complex cation, Λ-$\delta\lambda$-$(+)_{589}$-$[Co(ox)en_2]^+$, was found to be locked in the right-handed spiral chains of $\{\text{H-}d\text{-tart}\}_\infty$.[1]

It has been thought that the comparison of a pair of crystal structures of less- and more-soluble diastereoisomeric salts would give valuable information on the mechanism of optical resolution. Therefore, we have attempted to determine the crystal structure of the more-soluble diastereoisomer, $(-)_{589}$-[Co(ox)en_2] H-*d*-tart·$2H_2O$, and to compare it with the structure of the less-soluble diastereoisomer, $(+)_{589}$-[Co(ox)en_2] H-*d*-tart·H_2O.

Experimental

The preparation of the more-soluble diastereoisomer, $(-)_{589}$-[Co(ox)en_2]H-*d*-tart·$2H_2O$, was reported in our earlier paper.[1] A red crystal with dimensions of $0.15\times0.15\times0.30$ mm³ was used for the X-ray analysis. The unit-cell dimensions were determined by the least-squares refinement of the angular settings of 25 reflections measured on a diffractometer. The crystal data are as follows: $C_{10}H_{25}O_{12}N_4Co$, orthorhombic, $P2_12_12$, $a=16.583(5)$, $b=14.186(5)$, $c=7.403(2)$ Å, $D_m=1.72$(by flotation in $CHCl_3$–$CHBr_3$), and $D_x=1.73(1)$ g cm^{-3} for $Z=4(\mu(\text{Mo }K\alpha)=11.0$ cm^{-1}).

The intensity data were measured on an automatic Rigaku AFC-5 four-circle diffractometer, equipped with a rotating anode(50 kV, 170 mA), using graphite-monochromated Mo-$K\alpha$ radiation ($\lambda=0.71069$ Å) and a monitor-counting technique. The ω-2θ scan mode with a scan rate of 16° min^{-1} employed. The θ scan range was $(1.0+0.45\tan\theta)°$. The intensity data of 2034 independent reflections were collected with $(\sin\theta)/\lambda\leq0.65$ Å^{-1}; of these, 1907 were measured with $|F_o|\geq3\sigma|F_o|$ and used in the present X-ray analysis. No absorption correction was applied.

Determination and Refinement of Crystal Structure

The position of the Co atom was determined from the Patterson map. Successive Fourier refinements with phases based initially on the Co atom revealed the locations of the remaining 27 nonhydrogen atoms. Block-diagonal least-squares refinement with anisotropic thermal parameters for these atoms converged to $R=0.101$ ($R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$). The different synthesis showed the "50%-*ob*, 50%-*lel*" type conformational disorder in one of the etylenediamine chelate rings.[3] The subsequent refinement for all the nonhydrogen atoms gave $R=0.063$. All the hydrogen-atom coordinates were found from the difference map; these 35 hydrogen atoms with fixed positional and isotropic thermal ($B=3.5$ Å^2) parameters were included in the final refinement. The convergence was attained at $R=0.044$. The final difference map showed no peaks higehr than 0.4 electron/Å^3. The quantity minimized was $\Sigma w(|F_o|-k|F_c|)^2$, where $w=1/(a+|F_o|+b|F_o|^2)$ with $a=16.0$ and $b=0.012$.[4] The atomic scattering factors from the International Tables for X-Ray Crystallography[5] were used. The effect of the anomalous dispersion of the Co atom was included in the calculation.[6] All the computations were carried out by a HITAC-8700 computer at the Hiroshima University Computer Center. The computer programs used were FOUR-MMM (Fourier synthesis)[7] and HBLS-IV (Least-square calculation), with a slight modification.[8] The final atomic parameters, the temperature factors (with their estimated standard deviations), and the occupation numbers are listed in Tables 1a, 1b, and 2 respectively. Complete lists of the $10|F_o|$ and $10|F_c|$ values have been

preserved by the Chemical Society of Japan (Document No. 8004).

Results and Discussion

Figures 1 and 2 show the projections of the crystal structure along the c- and b- axes respectively. The structure consists of discrete $(-)_{589}$-$[Co(ox)en_2]^+$ cations, H-*d*-tart anions, and water molecules. The bond distances and angles in the complex cation and the H-*d*-tart anion are listed in Table 3.

Cation and Anion Geometries. The absolute configuration of the $(-)_{589}$-$[Co(ox)en_2]^+$ cation is identified as Δ based on that of the H-*d*-tart anion.[9] This is in accordance with the absolute configuration of $(-)_{589}$-$[Co(ox)en_2]^+$ reported by Aoki *et al.*[10] and Toriumi *et al.*[11] However, in the present complex cation, one ethylenediamine ring is in the "50%-*ob*(N(1)–C(E1A)–C(E4A)–N(4)), 50%-*lel*(N(1)–C(E-1B)–C(E4B)–N(4))" form, as was described in the last section. The other ethylenediamine ring(N(2)–C(E2)–C(E3)–N(3)) is in the *ob* form. Thus, the absolute configuration should be denoted as $\Delta[50\%\text{-}\delta,50\%\text{-}\lambda)\delta]$. The structure is illustrated in Fig. 3.

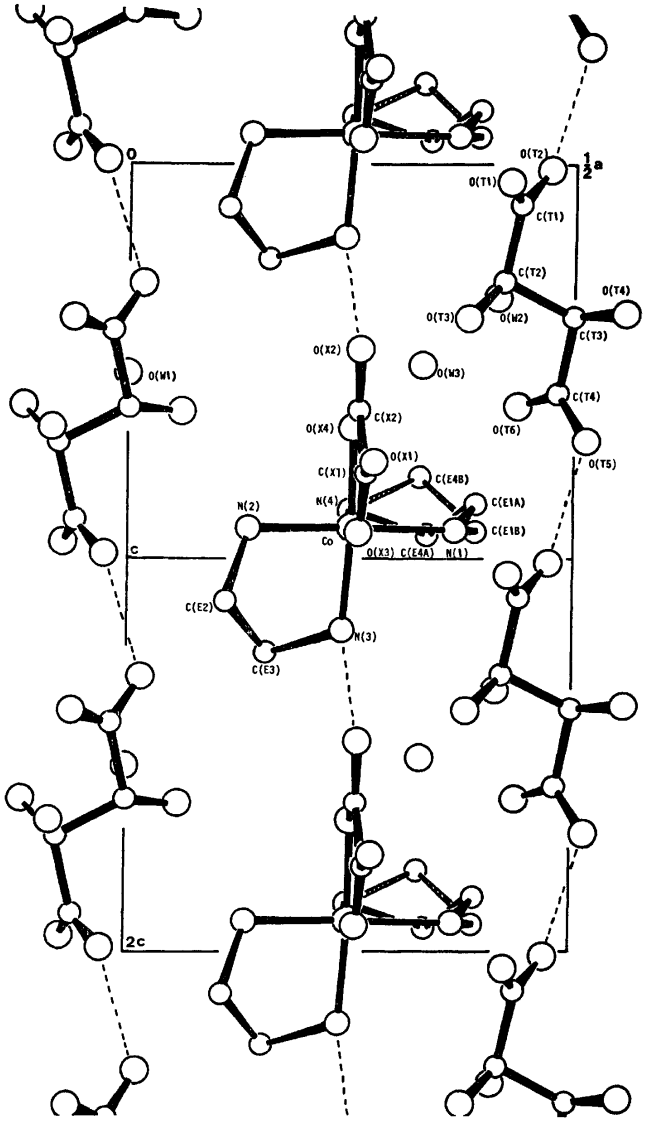

Fig. 2. A boundary projection of the crystal structure viewed along the b-axis.

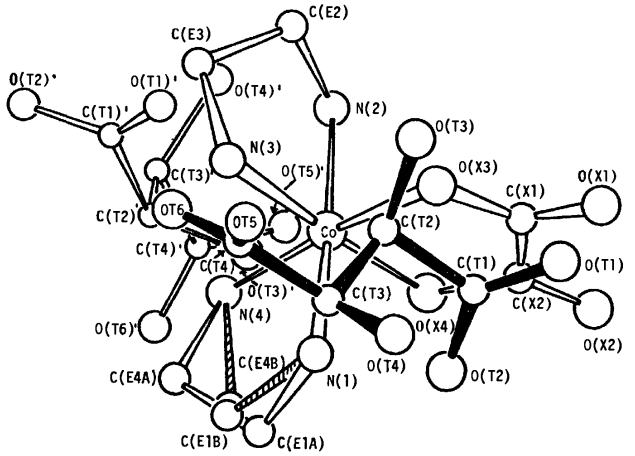

Fig. 3. The arrangement of the complex cation and H-*d*-tart anions projected down the quasi-threefold axis of the complex cation.

Crystal Packing. The intermolecular bond distances and angles are summarized in Table 4. The H-*d*-tart anions are arranged to make a "head-to-tail" chain structure in which two adjacent anions related by the translation along the c-axis (Fig. 2). The hydrogen-bond distance of $O(T2)^{II}\cdots O(T5)$ is 2.473 Å. This value is close to the corresponding one in $(+)_{589}$-$[Co(ox)en_2]$H-*d*-tart·H_2O(2.44 Å).[1] Along the c-axis, there is also a chain of complex cations which are joined by the $N(3)\cdots O(X2)^{II}$ hydrogen bond (2.995 Å). The chain of H-*d*-tart anions and that of the complex cations have the following short contacts: $N(1)\cdots O(T6)$, $N(2)\cdots O(T1)^{I}$, $N(4)\cdots O(T1)^{I}$, $O(X2)\cdots O(T3)$, $C(X2)\cdots O(T6)$, and $C(E2)\cdots O(T5)^{IV}$. Moreover, adjacent H-*d*-tart anions are connected through water molecules(O(W1) and O(W2)): $O(T3)^{V}\cdots O(W1)$, $O(T4)^{V}\cdots O(W1)$, and $O(T6)\cdots O(W2)$. There is no short contact between the complex cation and the water molecule lying on the twofold axis(O(W1)).

Figure 3 shows the relative arrangement of the $(-)_{589}$-$[Co(ox)en_2]^+$ cation and the H-*d*-tart anions projected down the quasi-threefold axis of the complex cation. The close contacts are: $N(1)\cdots O(T2)^{II}$, $N(4)\cdots O(T1)^{I}$, $N(4)\cdots O(T3)^{I}$, and $N(2)\cdots O(T1)^{I}$. In this case, the "face-to-face"-type close contact found in the $[CoXY(en)_2]^{n+}\cdots$*d*-bcs^{-}[15,16] and $[M(en)_3]^{3+}\cdots$*d*-$tart^{2-}$ systems[17–19] does not exist between any triangular face of the octahedral complex cation and the H-*d*-tart anion. This lack of any "face-to-face"-type close contact seems to be true of all salts containing the H-*d*-tart anion. In fact, the "face-to-face"-type close contact was not found in the structures of $(+)_{589}$-

[Co(ox)en$_2$]H-*d*-tart·H$_2$O[1] and the less- and more-soluble *trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·*n*H$_2$O.[20] In the case of the H-*d*-tart anion, the chiral discrimination is effected in a different way from the "face-to-face"-type compact fit.[1]

*Comparison between the Crystal Structures of the More-soluble Salt, $(-)_{589}$-[Co(ox)en$_2$]H-*d*-tart·2H$_2$O, and the Less-soluble Salt, $(+)_{589}$-[Co(ox)en$_2$]H-*d*-tart·H$_2$O.*[1] The crystal structures of more- and less-soluble diastereoisomers are shown schematically in Figs. 4 and 5, where the ions are represented simply by cylinders. It is noticeable that, in a broad sense, there are some resemblances in the packing features of the two structures in Fig. 4: (1) The H-*d*-tart anions in both crystals are stacked along the axis of the cylinder and make the {H-*d*-tart}$_\infty$ chain of the "head-to-tail" type.[1,12] (2) The complex cations are also stacked along the cylinder axis and form a chain parallel to the chain of the H-*d*-tart anion. (3) The effective lengths of the unit cylinders of the H-*d*-tart anion are quite similar: 7.403 Å for the more-soluble salt and 7.294 Å for the less-soluble salt. There are, however, some different features between the crystal structures: (1) The H-*d*-tart chain denoted as A is formed by the stacking of H-*d*-tart anions related by the translation along the c-axis, but the A′ chain is formed by the stacking of H-*d*-tart anions related by the twofold screw axis. (2) The chain of the *Δ*-$(-)_{589}$-complex cation in Fig. 4(a) is formed by the repetition of translations of the complex cation, but that of the *Δ*-$(+)_{589}$-complex cation in Fig. 4(b) is formed by the linkages of the complex cation along the twofold screw axis.

The projected views along the c-axis of the $(-)_{589}$-salt and along the b-axis of the $(+)_{589}$-salt are illustrated in Fig. 5. The column of complex cations in each structure is surrounded by four columns of H-*d*-tart anions. The parallelogramic frames shown by the broken and solid lines are depicted by connecting the four H-*d*-tart chains. The size of the parallelogram of the $(-)_{589}$-salt ($8.292\times7.196\times\sin(100.6°)$) is similar to that of the $(+)_{589}$-salt ($8.256\times7.009\times\sin(104.7°)$),[21] though the space groups are different. The water molecules in the more-soluble $(-)_{589}$-salt serve to connect the B and C chains or the A and D chains, but not the A and B chains or the C and D chains. This situation is quite similar to that with the less-soluble $(+)_{589}$-salt, though the number of water molecules different from that in the more-soluble salt.

The close contacts between the ions in both salts are summarized in Table 5. The $(+)_{589}$-salt has more short contacts than the $(-)_{589}$-salt. This suggests that the complex cation in the more-soluble $(-)_{589}$-salt is more loosely packed than that in the less-soluble $(+)_{589}$-salt. This situation is reflected in the difference between their densities (1.73(1) g cm^{-3} in the $(-)_{589}$-salt *vs.* 1.77(1) g cm^{-3} in the $(+)_{589}$-salt). The tight

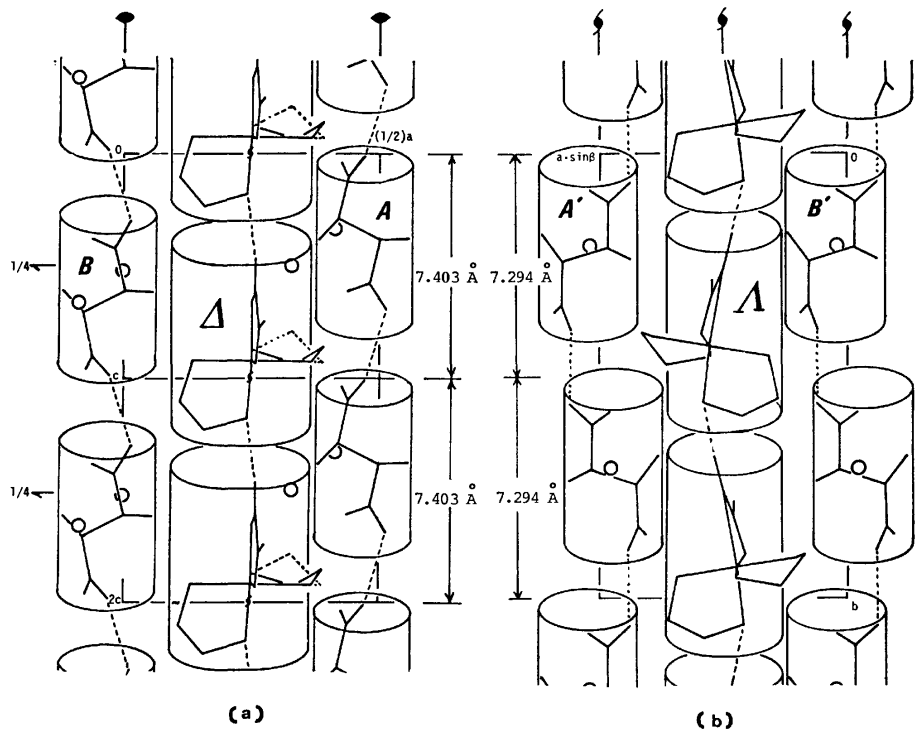

Fig. 4. A schematic drawing of the crystal structures of the more- and the less-soluble diastereoisomeric salts. Broken lines denote hydrogen bonds and disorder of the ethylenediamine ring. Circles indicate water molecules:
(a) $(-)_{589}$-[Co(ox)en_2]H-*d*-tart·$2H_2O$, (b) $(+)_{589}$-[Co(ox)en_2]H-*d*-tart·H_2O(all the *y* parameters in the less-soluble salt are shifted 3.10 Å along the b-axis from the reported values[1] for the purpose of the comparison).

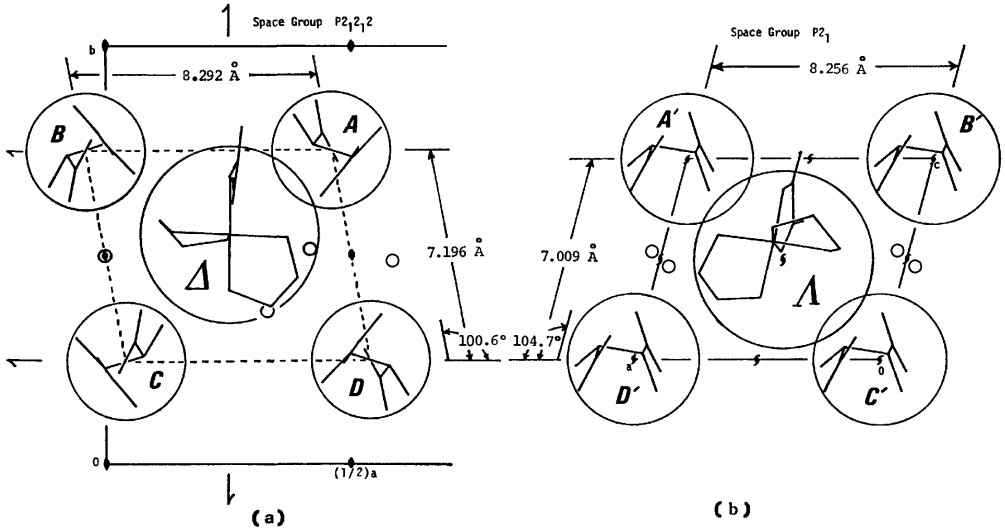

Fig. 5. A comparison of the arrangements of the H-*d*-tart anions and the complex cations.
(a) $(-)_{589}$-[Co(ox)en_2]H-*d*-tart·$2H_2O$, (b) $(+)_{589}$-[Co(ox)en_2]H-*d*-tart·H_2O.

packing in the less-soluble salt is thought to be caused by the twofold spiral chain of {H-*d*-tart}∞. Indeed, the spiral chains of {H-*d*-tart}∞ were always found in several less-soluble diastereoisomeric salt, $(+)_{589}$-*trans*(*O*)-[Co(gly)$_2$en]H-*d*-tart·$3H_2O$,[20] (−)-adrenalinium H-*d*-tart,[12] (+)-[(−)-1-methy-3-benzoylpiperidinium H-*d*-tart]H_2O,[13] and (−)-[(−)-1-methyl-3-ethyl-3-benzoylpiperidinium H-*d*-tart].[14] Although the present more-soluble salt also has a {H-*d*-tart}∞ chain, the chain is in a non-spiral form. The discrimination of the optically active $[Co(ox)en_2]^+$ cation by the H-*d*-tart anion is attributable to such a structural difference in the {H-*d*-tart}∞ columns.

Dehydration of the Water of Crystallization and Conformational Disorder. The water molecule O(W3) with a one-half weight is located at an unusually short distance (2.16 Å) from the C(E4B) (*lel* form) in the disordered ethylenediamine ring. On the other

hand, the distance from O(W3) to C(E4A) (*ob* form) is normal (3.12 Å). If this water molecule exists with weight one (this imaginary compound corresponds to 2.5 hydrate), the conformation of the ethylenediamine ring (N(1)–C(E1)–C(E4)–N(4)) is thought to be restricted to the *ob* form in order to avoid such an abnormal short contact between the O(W3) and C(E4B) atoms. In other words, the change in conformation from *ob* to *lel* seems to be related to the partial loss of this water(O(W3)) of crystallization. Shimura and Tsutsui[22] reported that the more-soluble $(-)_{589}$-salt contains 2.5 mol of the water of crystallization. If the crystal of $(-)_{589}$-salt·$2.5H_2O$ is isomorphous to the $(-)_{589}$-salt·$2H_2O$, the complex cation in the former crystal is confirmed to have the *ob-ob* form exclusively.

Recntly, Brouty *et al.* reported the crystal structures of (±)-$[Cr(en)_3](SCN)_3 \cdot 0.75H_2O$[23,24] and [(+)-Co(en)$_3$(−)-Cr(en)$_3$](SCN)$_3 \cdot nH_2O$[25] at 293 K and 133 K respectively. They found that, in both cases, one ethylenediamine ring in the $[Cr(en)_3]^{3+}$ cation is in conformational disorder at 293 K. They mentioned that the partial loss of the water of crystallization plays some role in causing the change in conformation from *lel* to *ob*. However, in $(-)_{589}$-$[Co(ox)en_2]$-H-*d*-tart·$2H_2O$, such a loss causes the confromational change from *ob* to *lel*. The reason for such a difference still remains unsolved.

We wish to thank the Hiroshima University Computer Center for its generous allocation of computer time and acknowledge a Grant-in-Aid for Scientific Research from the Ministry of Education.

Partition of Tris(acetylacetonato)chromium(III) and Its Temperature Dependence in the Systems of Dodecane/(Water–Organic Solvent Mixture)

Hiroshi Awano,** Hitoshi Watarai, and Nobuo Suzuki*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received July 31, 1979)

The partition constants $K_t^{\ominus}$ of tris(acetylacetonato)chromium(III) between dodecane and water–organic solvent mixtures have been measured. The organic solvents used as co-solvents were acetonitrile, *N,N*-dimethylformamide, methanol, ethylene glycol, and dimethyl sulfoxide which are all miscible with water but not with dodecane. From the temperature dependence of $K_t^{\ominus}$ the thermodynamic parameters for the transfer of the complex from dodecane to the mixed solvents have been determined. The dependences of the partition constants on solvent composition of the aqueous phase have been interpreted in terms of changes in the internal pressure and the volume upon mixing of water with the organic co-solvents. The standard transfer enthalpies have been correlated with the excess enthalpies of the mixed solvents.

The solvent extraction of metal chelates is one of the most useful methods for the separation or enrichment of metal ions. The effects of organic phases on the partition behavior of chelating reagents and their metal chelates have been interpreted in terms of the regular solution theory.[1] Quantitative interpretation of the effects of the aqueous phase on the partition behavior is however difficult. This is largely due to strong interactions such as hydrogen bonding or dipole-dipole interactions between solute and solvent molecules in the aqueous phase of the partition system. In spite of the important role of the aqueous phase in solvent extraction, few studies have been made on this subject. Yoshimura and Suzuki[2] examined the effects of some electrolytes on the standard chemical potential of benzoylacetone and benzoyltrifluoroacetone in aqueous solutions, and discussed the changes in the cohesive forces of water and the structure of water.

The present authors reported the partition equilibrium of acetylacetone complexes of chromium(III), cobalt(III), and rhodium(III)[3] in the heptane/(water–dimethyl sulfoxide (DMSO)) system. The dependence of the partition constants on the composition of the mixtures was discussed in terms of the extended McDevit-Long theory.[4] It was found that the partition constant variation with solvent composition was governed by the strong interactions between water and DMSO.

In this study, the partition constants of $[Cr(acac)_3]$ have been measured in the partition systems consisting of water–organic solvent mixtures and dodecane, which is less soluble in the polar solvents than heptane. Acetonitrile (AN), *N,N*-dimethylformamide (DMF), DMSO, methanol (MeOH), and ethylene glycol (EG) have been used as co-solvents in the aqueous mixtures. The temperature dependence of the partition constants have been examined, and the thermodynamic parameters for the transfer from dodecane to the solvent mixtures estimated. The partition constants and the standard transfer enthalpies are discussed in terms of the solvent-solvent interactions.

Experimental

Reagents. Tris(acetylacetonato)chromium(III) ($[Cr(acac)_3]$) was prepared by the method reported by Fernelius and Blanch.[5] Recrystallization from benzene and petroleum ether was repeated twice and the products sublimed under reduced pressure (*ca.* 10^{-3} mmHg, 100—150 °C). Mp, 214.0—215 °C; lit, 216 °C.[5] Found: C, 51,68; H, 6.02%. Calcd for $C_{15}H_{21}O_6Cr$: C, 51.81; H, 6.06%.

Dodecane (Tokyo Kasei, GR) was washed with a mixture of concd sulfuric acid and fuming sulfuric acid, an aqueous solution of sodium hydroxide, and water. After drying with calcium hydride, the dodecane was distilled under reduced pressure (less than 20 mmHg, 105 °C). Waste dodecane was recovered and purified by the same treatment. Acetonitrile (Wako, GR) was stirred with calcium hydride for 24 h and distilled in the presence of phosphorus pentaoxide under ambient pressure (61 °C). *N,N*-Dimethylformamide (Kanto, GR) was dried by stirring with molecular sieve 4A for 24 h, and distilled under reduced pressure under an atmosphere of N_2 (less than 20 mmHg, 62.5 °C). Dimethyl sulfoxide (Wako, GR) was stirred with calcium hydride overnight to dryness and distilled under reduced pressure (17 mmHg, 74 °C). Methanol (Kanto, GR) was distilled under ambient pressure. Ethylene glycol (Kanto, GR) was dried with molecular sieve 4A and distilled under reduced pressure (less than 20 mmHg, 106 °C). These very hygroscopic solvents were preserved in a desiccator over silica gel. Doubly distilled water was used throughout.

The water-organic solvent mixtures were prepared by weight.

Partition Measurements. A specified volume of a dodecane solution of $[Cr(acac)_3]$ ($1—4\times10^{-4}$ mol dm^{-3}) and a specified volume of mixed solvent were stirred for 30 min in a partition vessel which was equipped with a water jacket and thermostated at the desired temperature within $\pm$0.02 K. The partition constants in the system of dodecane/(water–acetonitrile), dodecane/(water-DMF), dodecane/(water-MeOH), and dodecane/(water-ethylene glycol) were measured at 278.15 K, 288.15 K, and 298.15 K, and those in dodecane/(water-DMSO system) were measured at 288.15 K, 293.15 K, and 298.15 K. The equilibrated dodecane phase was isolated, and the concentration at (298.15$\pm$0.2)K determined spectrophotometrically from the absorbance at 336 nm ($\varepsilon=1.715\times10^4$ dm^3 mol^{-1} cm^{-1}). The absorbance was measured by a Hitachi 356 or JASCO Uvidec 2 spectrophotometer. In this study, a partition constant is defined as an equilibrium

** Present address: The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980.

constant for the transfer process from the nonpolar phase to the polar phase. The partition constant was determined from the following relationship:

$$K_t\ominus = \frac{x_s^p}{x_s^n} = \frac{C_{s,\mathrm{init}}^n - C_s^n}{C_s^n}\frac{V^n}{V^p}\frac{v_p}{v_n}, \quad (1)$$

where x_s^n and x_s^p are the mole fractions of the solute in the nonpolar (dodecane) and polar (mixed solvent) phase, $C_{s,\mathrm{init}}^n$ and C_s^n are the initial and equilibrium concentrations in the dodecane phase, V^n and V^p are the volumes of the nonpolar and polar phases, and v_n and v_p are the molar volumes of the nonpolar and polar phases, respectively. Literature values[6] for v_n and v_p were used for the calculation $K_t\ominus$. More than five minutes' stirring made the ratio, $(C_{s,\mathrm{init}}^n - C_s^n)/C_s^n$, independent of the stirring time. The reversed partition experiment (a transfer of the solute from the mixed solvent phase to the dodecane phase) gave an equal value for $K_t\ominus$ with the normal partition experiment. Stirring for 24 h caused no change in spectra of both phases, and so it has been assumed that the decomposition

a) $K_t\ominus = x_s^p/x_s^n$. b) Estimated value (see text).

of $[Cr(acac)_3]$ is negligible. Thirty minutes' stirring was taken as sufficient to place the system into partition equilibrium. For each system at least three runs were conducted.

Results

Partition Constants. Table 1 illustrates the partition constants $K_t^{\ominus}$ of $[Cr(acac)_3]$ in dodecane/(water–organic solvent mixture) systems observed at several temperatures. All the values have a relative standard deviation within ±5%. Partition constants in the systems of $x_{DMF} \geq 0.8$ and $x_{MeOH} \geq 0.5$ at 298.15 K are the estimated values based on the quadratic regression for the experimental values at the lower temperatures given in the table, because of unsatisfactory phase separation at 298.15 K. For the system of $x_{DMSO}=1.0$ at 288.15 K, this is below the freezing point of DMSO 18.54 °C,[7] and so a hypothetical value was estimated by applying a linear regression for the observed values at 298.15 K and 293.15 K given in the table.

In Figs. 1(a) to 1(e), $-\log K_t^{\ominus}$ is shown as a function of the mole fraction of the organic co-solvent in the solvent mixture, x_2, in which the subscript 2 denotes the co-solvent. All the curves indicate that the partition constant decreases with increase in temperature and that the partition constant increases with an increase in x_2. In most systems, the curves have maxima in the water-rich regions.

The Thermodynamic Parameters. From the partition constants, the standard transfer chemical potential $\Delta_t\mu^{\ominus}$ of $[Cr(acac)_3]$ from dodecane to the water–organic solvent mixtures at different temperatures were calculated based on the following equation:

$$\Delta_t\mu^{\ominus} = -RT \ln K_t^{\ominus}. \quad (2)$$

From the expression for the temperature dependence of $\Delta_t\mu^{\ominus}$ as a quadratic function of temperature, the standard transfer enthalpy $\Delta_t h^{\ominus}$ and the standard transfer entropy $\Delta_t s^{\ominus}$ from dodecane to the solvent mixtures were calculated as follows:

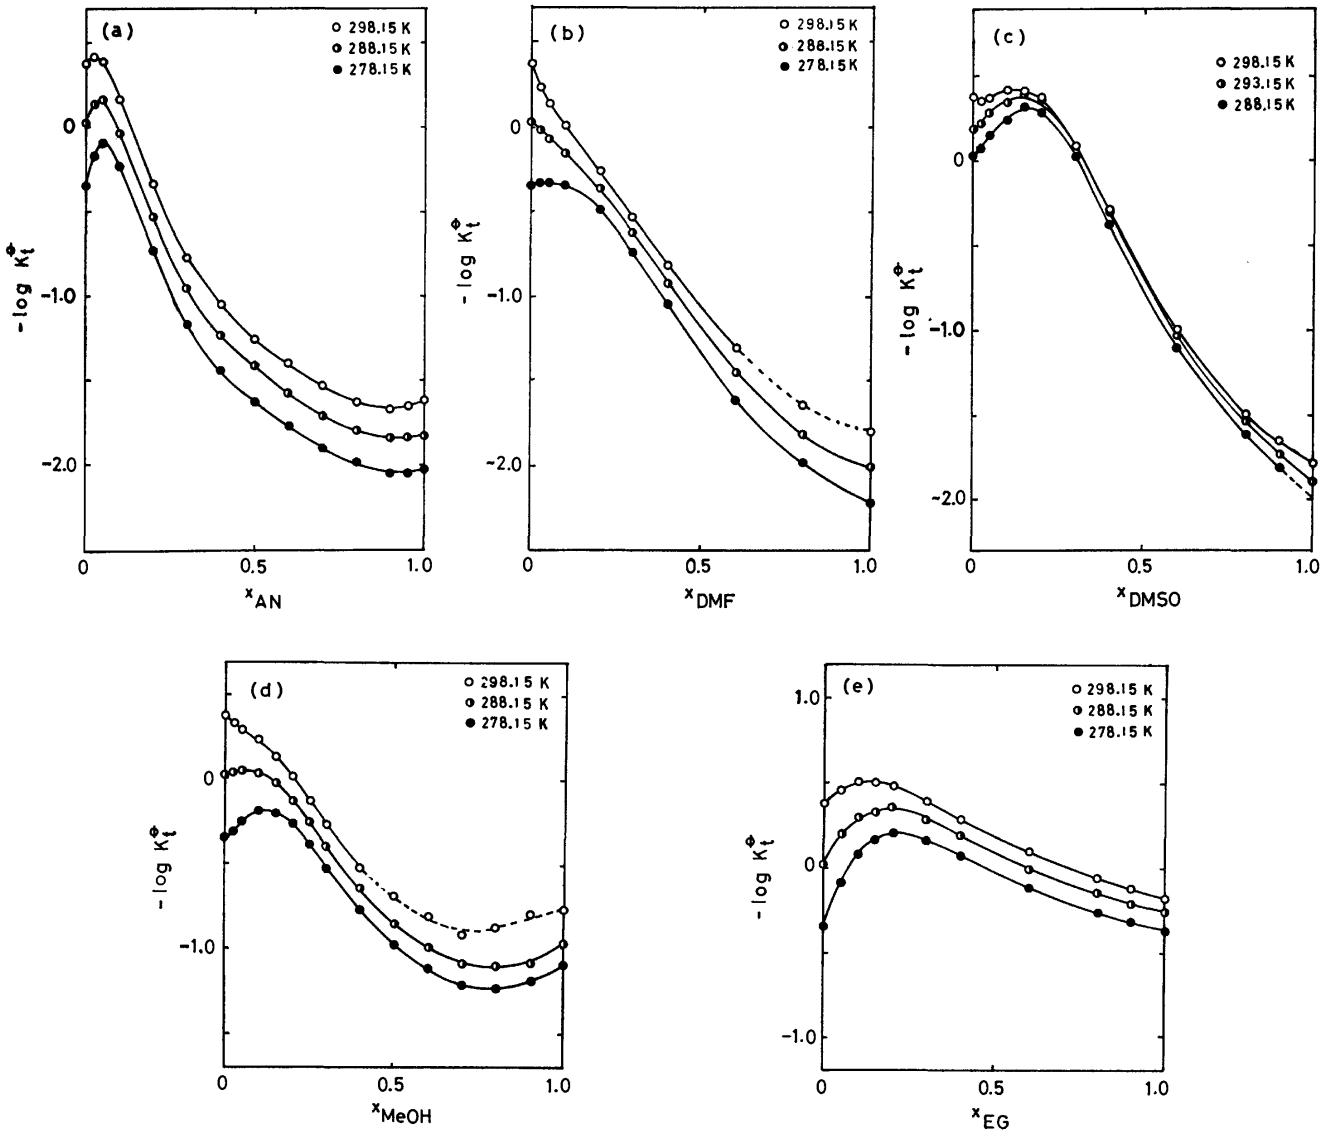

Fig. 1. Variation of the partition constants of $[Cr(acac)_3]$ in dodecane/(water–organic solvent mixtures) with mole fraction of the co-solvent; (a) acetonitrile, (b) dimethylformamide, (c) dimethyl sulfoxide, (d) methanol, (e) ethylene glycol.

$$\Delta_t h^{\ominus} = -T^2\left[\frac{\partial(\Delta_t\mu^{\ominus}/T)}{\partial T}\right]_p, \quad (3)$$

$$\Delta_t s^{\ominus} = -\left(\frac{\partial\Delta_t\mu^{\ominus}}{\partial T}\right)_p. \quad (4)$$

The calculated $\Delta_t h^{\ominus}$ and $\Delta_t s^{\ominus}$ at 298.15 K are shown in Figs. 2(a) to 2(e) as function of the mole fraction of the organic co-solvent. The standard transfer entropies are given in the term, $-T\Delta_t s^{\ominus}$.

The figures show that the transfer of $[Cr(acac)_3]$ from dodecane to water is accompanied by a very large decrease in the standard enthalpy (−55.0 kJ mol^{-1}), and that, in most systems variation in the thermodynamic values is remarkable in the water-rich regions. Cancellation of the large negative $\Delta_t h^{\ominus}$ with the large negative $T\Delta_t s^{\ominus}$ causes the small $\Delta_t\mu^{\ominus}$ values.

Discussion

Partition Constants in the Systems of Dodecane/Pure Solvent. The partition constant $K_t^{\ominus}$ in various systems of dodecane/pure solvent increases in the order: water<ethylene glycol<methanol<acetonitrile<DMSO≃DMF. Less work is needed for solute transfer into solvents with strong solute-solvent interactions and more work is required for solute transfer into solvents with strong solvent-solvent interactions. The dipole moment of solvent molecules is a measure of the electrostatic and polarization interaction between solute and solvent

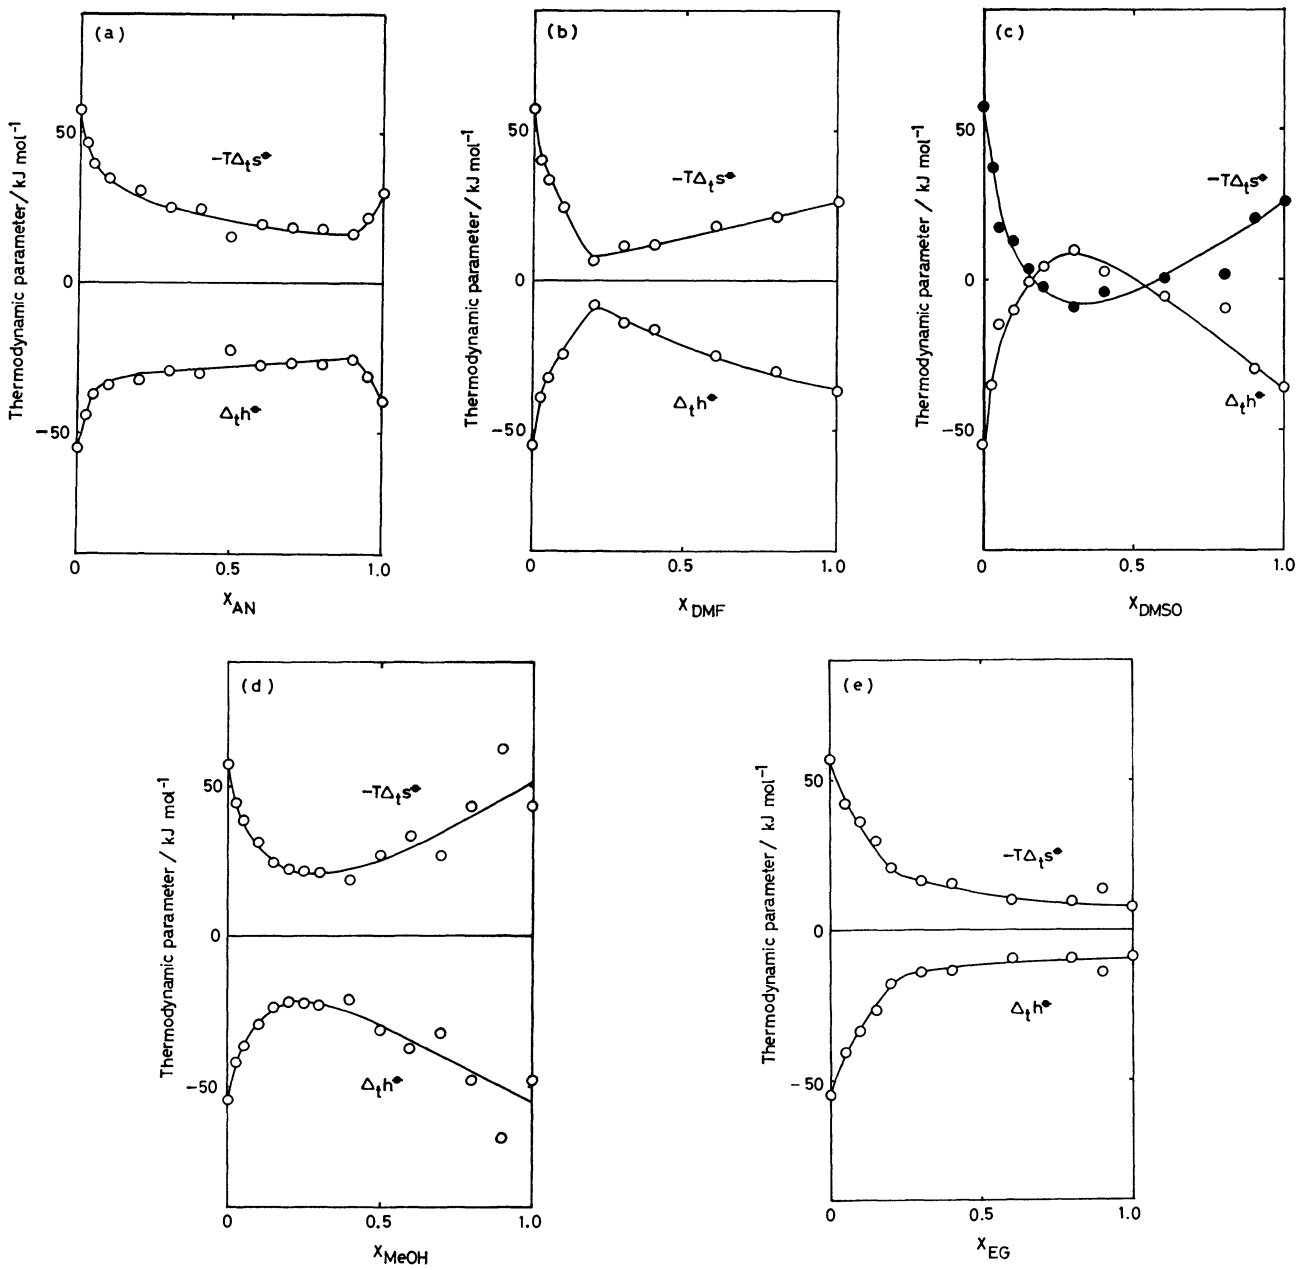

Fig. 2. Thermodynamic parameters for transfer of $[Cr(acac)_3]$ from dodecane to water-organic solvent mixtures at 298.15 K. Co-solvents are (a) acetonitrile, (b) dimethylformamide, (c) dimethyl sulfoxide, (d) methanol and (e) ethylene glycol.

Table 2. Dipole moment and cohesive energy density of the polar solvents studied[a)]

Solvent	Dipole moment D[b)]	Cohesive energy density MPa
Water	1.94	2302
Ethylene glycol	2.28	892
Methanol	2.87	874
Acetonitrile	3.44	582
DMSO	3.9	705
DMF	3.86	582

and cohesive energy density is a measure of the solvent-solvent interaction. It has been found that the increase in value of $K_t^{\ominus}$ or the decrease in value of $\Delta_t\mu^{\ominus}$ corresponds approximately to the increase in dipole moment of the solvent molecules and to the decrease in cohesive energy density of the solvent (see Table 2).

Dependence of the Partition Constant on the Composition of the Solvent Mixture. The pressure-volume approach has been previously proposed in order to interpret the solvent effect of water–organic mixture on the partition constants of acetone, acetylacetone,[4)] and several metal(III) acetylacetonates[3)] in heptane/(water–DMSO) systems. This approach is essentially an extension of the McDevit-Long theory,[7)] introduced to predict the activity coefficients of nonelectrolytes in water–organic solvent mixtures. The pressure-volume approach assumes that the non-ideal change in internal pressure and volume upon mixing two solvents causes a change in chemical potential or activity coefficient of the solute. According to this approach, the following relationship holds for a nonelectrolyte solute in a solvent mixture.[4)]

$$\ln f_s = -k\frac{P_i}{\alpha T}\frac{v^E}{v}, \qquad (5)$$

where f_s is the activity coefficient of the solute on the basis of the ideal mixing of the solvent mixture, and α, P_i, v, and v^E are the isobaric thermal expansivity, the internal pressure, the molar volume, and the excess molar volume of the solvent mixture, respectively. k is a proportional constant. In the partition systems studied here, it is acceptable to define the activity coefficient of the solute as

$$\ln f_s = -\ln K_t^{\ominus} + \phi_1 \ln K_{t,1}^{\ominus} + \phi_2 \ln K_{t,2}^{\ominus}, \qquad (6)$$

where $K_t^{\ominus}$, $K_{t,1}^{\ominus}$, and $K_{t,2}^{\ominus}$ are the partition constants in dodecane/mixed solvent, dodecane/solvent 1, and dodecane/solvent 2, respectively, and ϕ_1 and ϕ_2 are the volume fractions of the components 1 and 2. In this study, solvent 1 and solvent 2 refer to water and the organic co-solvent, respectively.

In dodecane/(water–DMSO) system, a plot of log f_s against the pressure factor $-(P_i/\alpha T)(v^E/v)$ gives reasonably good linearity as shown in Fig. 3. The observed partition behavior of [Cr(acac)$_3$], which is characterized by the minima of the partition constant (Fig. 1), is interpreted from the change in the internal

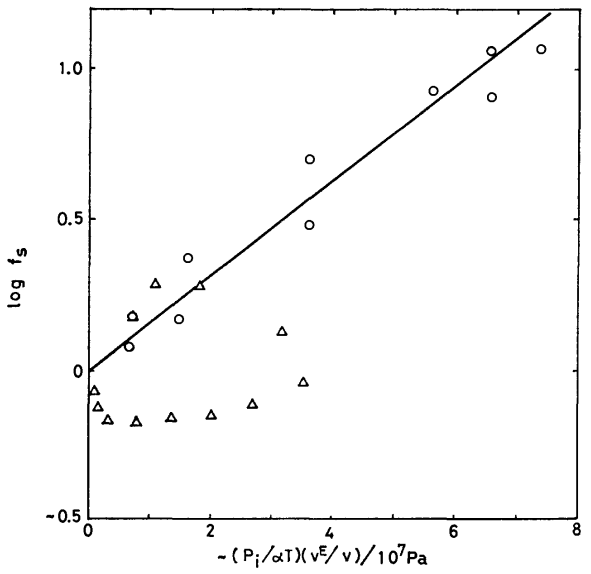

Fig. 3 Plot of logarithms of the activity coefficients of [Cr(acac)$_3$] against the pressure factors of the mixed solvent phase; ○, water–DMSO and △, water-AN.

pressure and the volume upon mixing which are caused by a strong interaction between water and DMSO, since the pressure-volume approach takes account of a solvent-solvent interaction as the only factor in the solvent effect.

In dodecane/(water–acetonitrile) system, a plot of log f_s against the pressure factor calculated from the internal pressure and density data reported by Grant-Taylor and Macdonald[8)] does not give a linear plot. In the region of $x_{AN} \leq 0.1$, however the slope of the best line is close to that for the water–DMSO system. A quite large scattering observed in the region $x_{AN} > 0.1$ may be due to the addition of acetonitrile to water causing not only an increase in the internal pressure but also destruction of the solvent structure. The destruction of the solvent structure causes an increase in the activity coefficient of water and acetonitrile. The abrupt increase in $K_t^{\ominus}$ in the region from $x_{AN} = 0.05$ to 0.4 or more corresponds to the abrupt structure-breaking of the polar phase upon mixing water and acetonitrile (h^E is positive in this region[9)]). The partition constant has a minimum in the region of $x_{AN} \leq 0.05$, which may be attributed to structure-making of the solvent upon mixing water and acetonitrile (h^E is negative in this region[9)]).

As shown in Fig. 1, a maximum in the $-\log K_t^{\ominus}$ *vs.* x_2 curve becomes remarkable as the temperature is lowered. As the temperature is lowered the interaction between water and the co-solvent becomes stronger, so that transfer of the solute from dodecane to the water-rich mixture becomes more unfavorable. It is expected that the interaction between water and the co-solvent affects the partition behavior of [Cr(acac)$_3$] in a similar fashion in every system except dodecane/(water–acetonitrile), because the h^E's of the mixed solvent have negative values in order of H_2O–EG> H_2O–MeOH> H_2O–DMF> H_2O–DMSO except for the water–acetonitrile system. The lack of data of

internal pressure and/or isobaric thermal expansivity, prohibits application of the pressure-volume approach to the other systems.

Dependence of the Standard Transfer Enthalpy of the Composition of the Solvent Mixture. It has been noted that a mixed solvent with a large negative value of h^E shows a large value of $\Delta_t h^\ominus$. A semi-quantitative formulation to represent this observation is developed by assuming that if 1 mol of the solute molecule is transferred from dodecane to the water–organic solvent mixture, then the interactions among the mixed solvent molecules included in volume V_s would be broken. The "excess" transfer enthalpy $\Delta_t h^{\ominus E}$ which is defined as

$$\Delta_t h^{\ominus E} = \Delta_t h^\ominus - x_1 \Delta_t h^\ominus(1) - x_2 \Delta_t h^\ominus(2), \quad (7)$$

where $\Delta_t h^\ominus(1)$ and $\Delta_t h^\ominus(2)$ are the standard transfer enthalpies from dodecane to solvent 1 and solvent 2, respectively will be proportional to the excess cohesive energy density, $-h^E/v$, *i.e.*,

$$\Delta_t h^{\ominus E} = V_s\left(-\frac{h^E}{v}\right), \quad (8)$$

where v refers to the mean molar volume of the solvent mixture. A plot of the calculated $\Delta_t h^{\ominus E}$ values against $(-h^E/v)$ gives a linear correlation, as shown in Fig. 4. From the slope the parameter V_s has been estimated as 616 $cm^3\ mol^{-1}$. This value is about 2.2 times larger than the molar volume of $[Cr(acac)_3]$ in the crystalline state, 275.3 $cm^3\ mol^{-1}$.[10] This observation may reflect the distance of closest approach of the solvent molecule to the complex molecule is larger than the radius of the complex molecule.

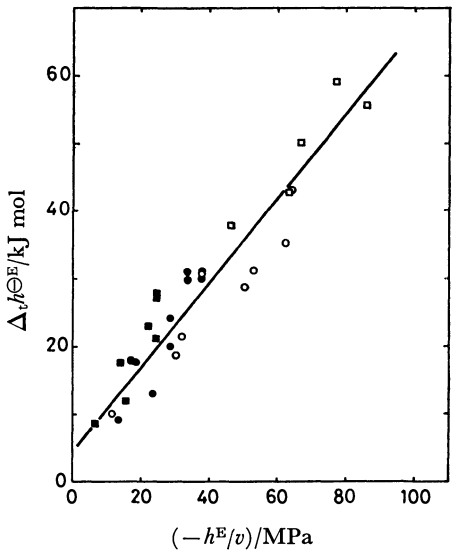

Fig. 4 Plot of the "excess" transfer enthalpy of $[Cr(acac)_3]$ against the excess cohesive energy density of water-organic solvent mixture; ○, water-DMF,[11] □, water-DMSO,[6,d] ●, water-methanol,[12] ■, water-ethylene glycol.[13]

Conclusion

In this study, it has been found that the activity coefficient derived from the partition coefficient may be correlated linearly with the pressure factor of the solvent mixture in Eq. 5 in the water–DMSO system, but not in the water–AN. This apparent discrepancy may be result from differences in the types of interactions, that is, the aqueous mixture is structure-making ($h^E<0$) or structure-breaking ($h^E>0$). It has been found that, in dodecane/aqueous mixtures with DMF, DMSO, MeOH, and EG, which are structure-making, the "excess" transfer enthalpy defined in Eq. 7 can be correlated linearly with the excess cohesive energy density. These findings show the importance of the solvophobic interaction between $[Cr(acac)_3]$ and polar solvent molecules in the aqueous mixed solvent phase.

Organonickel(II) Complexes Containing Carbon-bonded Heterocycles as a Ligand

Kiyoshi Isobe, Yukio Nakamura, and Shinichi Kawaguchi*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received August 14, 1979)

Oxidative addition reactions of 2- and 3-chloropyridines and of 2-chloropyrazine to tetrakis(triphenylphosphine)nickel(0) occurred in toluene at ambient temperature to afford dinuclear nickel(II) complexes containing carbon-bonded heterocycles as a ligand. They are quite stable and the bridging chloride was readily substituted by other halides and pseudohalides preserving the dinuclear structure. 8-Chloroquinoline yielded a mononuclear complex as an exception. These novel organonickel(II) complexes were characterized by analytical and molecular weight data together with IR, ^{1}H NMR, and ^{13}C NMR spectra. Di-μ-chloro-bis(2-pyridyl)bis(triphenylphosphine)dinickel(II) was found to be an excellent catalyst for selective cross coupling of 2-chloropyridine with methylmagnesium bromide.

Organonickel complexes have attracted interest of many investigators in coordination chemistry, synthetic chemistry, and other related fields.[1] The transition metal–carbon bond is not so unstable as was formerly considered. Thus the *trans*-NiX(aryl)$(PR_3)_2$ complexes, which are prepared conveniently by the oxidative addition reactions of aryl halides with tetrakis(tertiary phosphine)nickel(0),[2] are stable especially when the aryl ligand bears an *ortho*-substituent.[3] Benzyl,[4] vinyl, and acyl[5] halides also react with the nickel(0) complexes to afford similar square-planar organonickel(II) complexes which are isolable though they are less stable than the aryl complexes.

Cross coupling of alkyl, aryl, and alkenyl Grignard reagents with aryl and alkenyl halides was found by Kumada and his coworkers to be catalyzed by the dichlorodiphosphinenickel(II) complexes and the diorganonickel(II) complexes were presumed to be important intermediates.[6] The efficient method of carbon–carbon bond formation was successfully applied to halogenopyridines.[7] The σ-pyridyl nickel(II) complexes must be included in the catalytic turn-over in these reactions, although they have not yet been isolated.

Only a few examples of the carbon-bonded pyridyl complexes with transition metals have been reported. Stable (2-pyridyl)pentacyanocobaltate(III) was obtained by the reaction between 2-iodopyridine with pentacyanocobaltate(II).[8] Reactions of perfluoropyridine with several metal carbonyl compounds afforded the perfluoro-4-pyridyl complexes.[9] 2-Pyridylgold(I) was obtained by the reaction of chloro(triphenylarsine)gold(I) with 2-pyridyllithium and assumed to be a cyclic trimer.[10] 2-Methyl-, 2-phenyl-, and 2-vinylpyridines reacted with bis(η-cyclopentadienyl)methyltitanium(III) to give a 6-pyridyl complex, in which the nitrogen atom also interacts with the metal atom to form a three-membered titanocycle.[11] This paper reports very stable nickel(II) complexes containing carbon-bonded pyridines and two other nitrogen heterocycles as a ligand.

Experimental

Unless otherwise stated, air-sensitive materials were handled under a nitrogen atmosphere. Solvents were distilled under nitrogen and other reagents purged with nitrogen before use. Tetrakis(triphenylphosphine)nickel(0) and tetrakis(triphenyl phosphite)nickel(0) were prepared by the methods of Schunn,[12] and McLaughlin.[13] 2-Pyridyllithium was prepared according to Gilman and Spatz,[14] and sodium acetylacetonate by the reaction of acetylacetone with metallic sodium in methanol. Halopyridines, tertiary phosphines, and Grignard reagents were purchased and used without further purification.

*Preparation of Di-μ-halogeno-bis(2-pyridyl)bis(triphenylphosphine)dinickel(II) Complexes, $[NiX(C_5H_4N\text{-}C^2)(PPh_3)]_2$, where X=Cl (**1a**), Br(**1b**), and I(**1c**).* To a solution of tetrakis(triphenylphosphine)nickel(0) (2.5 g, 2.3 mmol) in toluene (100 ml) was added dropwise 2-chloropyridine (0.46 g, 4.0 mmol) or 2-bromopyridine (0.58 g, 3.7 mmol). The reaction proceeded quickly at ambient temperature to deposit an orange-red precipitate. After stirring for 3 h, the product was filtered, washed with methanol, and dried *in vacuo*. The yields were 60% for **1a** and 55% for **1b**. The crude product (*ca.* 0.4 g) of **1a** or **1b** was dissolved in dichloromethane (10 ml). After filtration, methanol (*ca.* 40 ml) was added slowly to the filtrate to precipitate glittery brownish yellow crystals, which were filtered, washed with diethyl ether, and dried *in vacuo*.

Compound **1c** was prepared by metathesis of **1a**. Compound **1a** (0.5 g, 0.6 mmol) was dissolved in dichloromethane (30 ml), and methanol (15 ml) was added slowly to the solution. A methanol solution (15 ml) of an excess amount (1.8 g, 12 mmol) of sodium iodide was then added slowly and the mixture was stirred for 2 h at room temperature. After evaporation of the solvent under reduced pressure, the concentrate (*ca.* 20 ml) was left standing for 2 h. An orange-red precipitate of **1c** was filtered and washed with methanol several times and with diethyl ether. The yield was 80%. Complex **1b** was also derived from **1a** by the same method in a 90% yield.

*Preparation of Di-μ-chloro-bis(6-chloro-2-pyridyl)- and Di-μ-chloro-bis(5-chloro-3-pyridyl)-bis(triphenylphosphine)dinickel(II) Complexes, $[NiCl(R)(PPh_3)]_2$, where $R=C_5H_3(6\text{-}Cl)N\text{-}C^2$ (**2a**) and $C_5H_3(5\text{-}Cl)N\text{-}C^3$ (**2b**).* The reaction of tetrakis(triphenylphosphine)nickel(0) (2.5 g, 2.3 mmol) with 2,6- or 3,5-dichloropyridine (1.5 g, 10 mmol) was carried out in toluene (140 ml) at ambient temperature in a similar manner as above. After stirring for 5 h, compound **2a** was obtained as an orange-red precipitate in a 90% yield. The reaction for **2b** was remarkably slow and allowed to proceed for 3 d to deposit a brown precipitate in a 70% yield.

*Preparation of Di-μ-chloro-bis(3-pyridyl)-, Di-μ-chloro-bis(2-pyrazinyl)-, and Di-μ-chloro-bis(6-methoxy-2-pyridyl)-bis(triphenylphosphine)nickel(II) Complexes, $[NiCl(C_5H_4N\text{-}C^3)(PPh_3)]_2$ (**3**), $[NiCl(C_4H_3N_2\text{-}C^2)(PPh_3)]_2$ (**4**), and $[NiCl(C_5H_3\text{-}(6\text{-}CH_3O)\text{-}N\text{-}C^2)(PPh_3)]_2$ (**5**).* Compounds **3**, **4**, and **5** were prepared by the method analogous to that for **1a**. The

reaction finished within 1 h in the case of **4** and **5**, but it took about 24 h for **3**. Yields of crude products were 40, 90, and 80% for **3**, **4**, and **5**, respectively. On recrystallization from dichloromethane–methanol **3** and **5** were obtained as orange-yellow crystals and **4** was orange-red. Compound **3** is less stable in air and prompt handling is necessary.

Preparation of Chloro(8-quinolyl)bis(triphenylphosphine)nickel(II), [NiCl(C_9H_6N-C^8)(PPh_3)$_2$]. A toluene solution (40 ml) of 8-chloroquinoline (1.6 g, 10 mmol) was added drop by drop to a solution of tetrakis(triphenylphosphine)nickel(0) (2.5 g, 2.3 mmol) in toluene (100 ml). After stirring for 3 h, a yellow precipitate was filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 90%.

*Preparation of Di-μ-pseudohalogeno-bis(6-substituted 2-pyridyl)-bis(triphenylphosphine)dinickel(II) Complexes, [NiX(R)(PPh_3)]$_2$, where R=C_5H_3(6-CH_3O)N-C^2, X=N_3 (**7a**), OCN (**7b**), SCN (**7c**), and SeCN (**7d**); R=C_5H_3(6-Cl)N-C^2, X=N_3 (**7a'**), OCN (**7b'**), and SCN (**7c'**).* Complex **5** or **2a** (0.4 g, 0.4 mmol) was dissolved in dichloromethane (40 ml) and methanol (15 ml) was added slowly to the solution. A methanol solution (15 ml) of sodium azide (0.3 g, 4 mmol), sodium cyanate (0.3 g, 4 mmol), sodium thiocyanate (0.3 g, 4 mmol), or potassium selenocyanate (0.6 g, 4 mmol) was added drop by drop to the complex solution. (Sodium cyanate was dissolved in 5 ml of water and then methanol was added to make up a 15 ml solution.) After stirring for 2 h, the reaction mixture was concentrated to about 20 ml by evaporation under reduced pressure to deposit an orange-yellow or orange-red precipitate in 65 (**7a**), 75 (**7b**), 90 (**7c**), 47 (**7d**), 70 (**7a'**), 75 (**7b'**), and 92% (**7c'**) yields, respectively. Glittery crystals of each complex were obtained by recrystallization from dichloromethane–methanol.

*Preparation of Bis(acetylacetonato)bis(6-chloro-2-pyridyl)dinickel(II), [Ni(C_5H_3(6-Cl)N-C^2)(acac)]$_2$ (**8**).* Complex **2a** (0.5 g, 0.5 mmol) was dissolved in dichloromethane (30 ml) and methanol (10 ml) was added slowly to it. A methanol solution (15 ml) of sodium acetylacetonate was added dropwise to the complex solution. After stirring for 7 h, the reaction mixture was concentrated to 20 ml by evaporation at ambient temperature under reduced pressure, and left standing for 30 min. A precipitate was separated by filtration and dissolved in dichloromethane (10 ml) and a blue insoluble residue was filtered off. Methanol (30 ml) was added to the filtrate and the solution was again evaporated to 20 ml to deposit yellow-orange crystals in a 60% yield. The blue residue was identified as sodium tris(acetylacetonato)-nickelate(II) (yield, 7%) on the basis of elemental analysis and IR spectrum.

*Reaction of Compound **8** with Triphenyl Phosphite.* Triphenyl phosphite (1.0 g, 3 mmol) was added to a suspension of compound **8** (0.3 g, 0.6 mmol) in methanol (40 ml) and the mixture was heated under reflux for 3 h. A precipitate was filtered off during hot and the filtrate was concentrated to 20 ml under reduced pressure and allowed to stand for 2 d to deposit a white precipitate of 6,6'-dichloro-2,2'-bipyridine. The product was dissolved in dichloromethane (5 ml) and methanol (20 ml) was added to the solution to separate out a less soluble contaminant. This procedure of purification was repeated several times to remove a small amount of tetrakis(triphenyl phosphite)nickel(0) (Found: C, 66.04; H, 4.81%. Calcd for $C_{72}H_{60}P_4O_{12}Ni$: C, 66.53; H, 4.65%). The yield of the coupling product was 60%. Found: C, 53.03; H, 2.66; N, 12.33%; parent mass peak (*m/e*), 223.90. Calcd for $C_{10}H_6N_2Cl_2$: C, 53.36; H, 2.69; N, 12.45%; *m/e*, 223.90.

*Cross Coupling of Methylmagnesium Bromide to 2-Chloropyridine Catalyzed by Compound **1a**.* Compound **1a** (0.7 g, 0.9 mmol) was added to a tetrahydrofuran (THF) solution (100 ml) of 2-chloropyridine (5.4 g, 48 mmol). To this solution was added dropwise a THF solution (60 ml) of methylmagnesium bromide (6.6 g, 60 mmol). The reaction proceeded quickly at ambient temperature, producing a precipitate of magnesium bromide chloride and color of the solution changing from yellowish brown to deep green. 2-Methylpyridine was yielded quantitatively and absence of unreacted 2-chloropyridine and other coupling products was confirmed by the gas-liquid chromatography.

Measurements. IR spectra were recorded in Nujol on JASCO IR-E (4000—650 cm^{-1}), Hitachi EPI-L (700—200 cm^{-1}) and FIS-3 (400—30 cm^{-1}) spectrophotometers. JEOL JNM C60-HL and PS-100 spectrometers were used to obtain ^1H NMR spectra at 60 and 100 MHz, respectively, in CD_2Cl_2 with tetramethylsilane as external reference. ^{13}C NMR spectra were taken in CD_2Cl_2 with a JEOL JNM-FX60 spectrometer at 15.0 MHz. Tetramethylsilane was used again as external reference. The molecular weight was determined by vapor pressure osmometry in dichloromethane at 25 °C with an instrument manufactured by Knauer in Berlin, Germany. Mass spectra were measured with a Hitachi GC-mass-spectrometer M-52 and gas chromatography was performed on a Varian Aerograph Model 920 through a column of Silicon OV 17 with helium as a carrier gas. The injection temperature was 100 °C.

Results and Discussion

Tetrakis(triphenylphosphine)nickel(0) has frequently been used as a starting material for preparation of the aryl and other organonickel compounds, and proved now to react readily with halogenated nitrogen heterocycles such as 2- and 3-halogenopyridines, 2,6- and 3,5-dichloropyridines, 2-chloro-6-methoxypyridine, 2-chloropyrazine, and 8-chloroquinoline. In each case the reaction occurred at room temperature and the time necessary for completion of reaction increased in the sequence of 2-bromopyridine<2-chloropyrazine ≈ 2-chloropyridine < 2-chloro-6-methoxypyridine ≈ 2,6-dichloropyridine < 3-chloropyridine < 3,5-dichloropyridine, indicating that the reactivity of pyridine at the C^2 position with nickel(0) is appreciably higher than at the C^3 position. 2-Chlorothiophene did not react with $Ni(PPh_3)_4$. 2-Chlorobenzothiazole did react, but gave no organonickel compound, producing dichlorobis(triphenylphosphine)nickel(II). The reaction of tetrakis(triphenyl phosphite)nickel(0) with 2-chloropyridine was examined, but refluxing in toluene for 10 h showed no sign of reaction.

Characterization of the Di-μ-halogeno-bis(σ-pyridyl)bis(triphenylphosphine)dinickel(II) Complexes. The analytical and molecular weight data of these complexes are collected in Table 1. The 3-pyridyl complex (**3**) is less stable than the 2-pyridyl complexes and decomposes gradually on exposure to air, thus giving unsatisfactory analysis. The complexes in Table 1 are all diamagnetic and have the square-planar structure, indicating the effect of π-bonding between the carbon-bonded pyridine ring and the nickel(II) ion, since dichlorobis(triphenylphosphine)nickel(II) has a tetrahedral structure.[15]

The molecular weight data indicate that all complexes except **6** are dinuclear. Characteristic IR data for these complexes are summarized in Tables 2 and

Table 1. Analytical data for the σ-pyridyl nickel(II) complexes

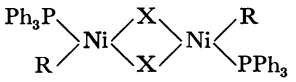
a) In dichloromethane at 25 °C.

3. As is seen in Table 2, two distinct ν(Ni–X) bands are observed for each complex and the frequencies are reasonable for the bridging halides.[16,17] The IR spectra in the lower frequency region also exhibit one band each at about 340 cm^{-1} which is assigned unambiguously to the ν(Ni–P) vibration. These IR-spectral patterns strongly support the following C_{2h} *trans* structure for the dinuclear complexes.[18]



Since the alkyl and aryl ligands are usually considered to exert a stronger *trans* influence than the tertiary phosphines,[19] the higher frequency one of the two ν(Ni–X) bands may be assigned to the vibration of the Ni–X bond *trans* to triphenylphosphine. The ν(Ni–Cl) frequencies (289 and 248 cm^{-1}) for **1a** are similar to but appreciably lower than those (302 and 280 cm^{-1}) for $[NiCl(CH_3)(PMe_3)]_2$,[17] probably indicating a stronger *trans* influence of the 2-pyridyl ligand than that of the methyl group. The ν(Ni–Cl):ν(Ni–Br):ν(Ni–I) ratio (1:0.67:0.53) for **1a**, **1b**, and **1c** is appreciably different from the values found for other halogenonickel(II) complexes, *e.g.* 1:0.83:0.70 for NiX_2(1,2-bis(diphenylphosphino)ethane).[20] The reason is not certain why the halogen-discriminating ability of nickel(II) is enhanced in the present complexes. As is expected from the order of *trans* influence of halide ions, the ν(Ni–P) frequencies slightly decrease in the sequence of **1a**>**1b**>**1c**.

Table 2. Decomposition temperatures and some FIR data

Complex	Dec. temp °C	ν(Ni–X) cm^{-1}		ν(Ni–P) cm^{-1}
1a	187	289 s	248 s	338 s
1b	170	191 s	170 m	337 s
1c	160	152 m	134 m	329 s
2a	194	305 m	250 m	355 m
2b	140	283 s	246 s	337 w
3	124	310 w	245 w	360 s
4	193	290 s	245 m	335 m
5	187	290 s	250 s	340 w
6	170	352 s		290 m

When 2,6- or 3,5-dichloropyridine is used as a reactant, it may be expected to react with two molecules of tetrakis(triphenylphosphine)nickel(0) to afford a dinuclear complex in which the pyridine links to nickel atoms *via* two ring carbons. In reality compounds **2a** and **2b** were obtained, which showed no sign of reaction with another nickel(0) compound. On coordination to a metal atom, electron density of the pyridine ring may be increased by the π-bonding so as to prevent the oxidative addition to another nickel(0).

All complexes listed in Table 2 except compounds **2b** and **3** are stable on long-time exposure to air and their decomposition temperatures are higher than that of *trans*-chloro(phenyl)bis(triphenylphosphine)nickel(II) (122—3 °C).[2b] The thermal stability diminishes in the sequence of Cl>Br>I and 6-chloro-2-pyridyl≈2-pyrazinyl>2-pyridyl≈6-methoxy-2-pyridyl>5-chloro-3-pyridyl>3-pyridyl. The former sequence suggests the operation of antisymbiotic effect,[21] increasing softness of the halide ions weakening the *trans* Ni–C bond. Similarly, the lowest π* level becomes higher[22] and the M→L π-bonding ability decreases in the sequence of pyrazinyl>pyridyl>phenyl. Instability of the 3-pyridyl complexes relative to the 2-pyridyl complexes may be caused by the larger electron density at the 3-position of pyridine than at the 2-position[23] which lowers the acceptor ability.

Data of ^1H NMR spectra for the chloro complexes are included in Table 4. In each case the ring protons

8	7.30 d	6.70 t	7.00 d				1.90 s, 2.00 s

s=singlet, d=doublet, t=triplet, m=multiplet
a) Masked by the signals of phenyl protons. b) Unassignable. c) H^2 and H^6 resonate at 8.82(m) and 6.75(m) ppm, respectively.

of triphenylphosphine resonate as two multiplets with the area ratio of 3:2 in the 7.30—7.50 and 7.88—8.16 ppm regions, respectively. The higher-field signal is assigned to the *meta* and *para* protons and the lower-field one to the *ortho* protons.[24)] The pyridine-ring protons of **1a** exhibit an ABCX-type signals at 6.27, 6.33, 6.79, and 8.57 ppm, showing large up-field shifts as compared with those at 7.18 (H^3), 7.55 (H^4), and 8.69(H^2) ppm for uncoordinated pyridine. The M→L π-bonding in the present complexes may be much more extensive than in *trans*-$NiBr(C_6H_5)(PEt_3)_2$, since the chemical shifts of the phenyl protons (6.90 and 7.40 ppm) in this complex are not so different from that of benzene (7.15 ppm).[25)]

When H^2 of pyridine is substituted by an electron-releasing group, similar up-field shifts of the ring proton signals are observed. Thus ring protons of 2-methylpyridine resonate at 6.92 (H^5), 7.00 (H^3), 7.43 (H^4), and 8.51 (H^6) ppm and those of 2-aminopyridine at 6.60 (H^5), 6.70 (H^3), 7.44 (H^4), and 8.11 (H^6) ppm.[26)] By reference to these data the pyridyl proton signals were assigned as shown in Table 4. A similar trend was also observed for $[Co(CN)_5(2\text{-pyridyl})]^{3-}$ but the up-field shifts are not so large as for the present complexes.[9)]

As is seen in Fig. 1, the pyridine-ring protons of **2a** show a triplet at 6.21 ppm and two doublets at 6.45 and 6.65 ppm. They are tentatively assigned to H^4, H^3, and H^5, respectively, on the assumption of

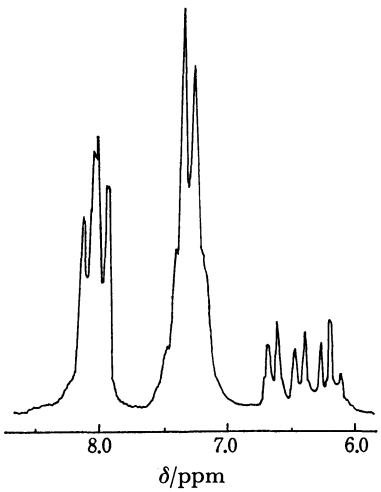

Fig. 1. The ^1H NMR spectrum of $[NiCl(C_5H_3(6\text{-Cl})\text{-}N\text{-}C^2)(PPh_3)]_2$ (**2a**) in CD_2Cl_2 with external TMS.

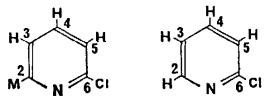
the first-order ABC spin system.[27)] In the case of uncoordinated 2-chloropyridine, signals for the corresponding protons are observed at 7.83, 7.39, and 7.49 ppm, respectively.[26)] A great deal of the up-field shifts of the ring-proton signals on coordination are again noted, the shift at H^4 (*meta* position from the metal) being the largest. Table 5 collects the ^{13}C NMR data for complex **2a** together with those for triphenylphosphine[28)] and 2-chloropyridine[29)] for

TABLE 5. ^{13}C NMR DATA



Compound	Chemical shift (δ/ppm)					Coupling constant/Hz
$P(C_6H_5)_3$	C^1 138.3	C^2 134.4	C^3 129.2	C^4 129.3		$J(P-C^1)=21$, $J(P-C^2)=20$ $J(P-C^3)=7$, $J(P-C^4)<1$
2-Cl-C_5H_4N[a]	C^2 151.1	C^3 123.9	C^4 138.5	C^5 122.4	C^6 149.7	
2a Phenyl carbon	C^1 134.2	C^2 135.7	C^3 128.5	C^4 130.5		$J(P-C^1)\simeq 20$, $J(P-C^2)=12$ $J(P-C^3)=10$, $J(P-C^4)=0$
2a Pyridyl carbon	C^2 131.8	C^3 118.8	C^4 128.7	C^5 128.1	C^6 130.5	

a) Ring carbons are numbered by reference to the complex as above.

comparison. Tentative assignments are given on the basis of the relative intensity and the J(P-C) value of each carbon and also by reference to the above literature data. In a similar manner as the proton resonances, the pyridine-ring carbons exhibit remarkable up-field shifts on coordination.

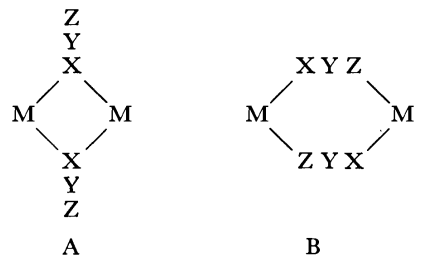
The pyridine-ring protons of compound **5** show two broad signals at 5.76 and 6.16 ppm, the methoxy protons resonating at 4.00 ppm. The corresponding proton signals for uncoordinated 2-methoxypyridine are observed at 6.62 (H^3), 7.40 (H^4), 6.70 (H^5), and 3.84 (CH_3) ppm. It is noteworthy that the methoxy protons show a down-field shift, while the pyridine-ring protons up-field shifts on coordination.

Properties of Chloro(8-quinolyl)bis(triphenylphosphine)-nickel(II) (6). As stated already only 8-chloroquinoline gave the mononuclear complex **6** on reaction with $Ni(PPh_3)_4$. Complex **6** exhibits a single ν(Ni–Cl) band at 350 cm^{-1} and a ν(Ni–P) band at about 290 cm^{-1}. The ν(Ni–Cl) frequency is quite similar to those observed for the *trans*-$NiCl(aryl)(PR_3)_2$ complexes,[2b,5] and the ν(Ni–P) frequency is a little higher than that observed for *trans*-$NiCl_2(PEt_3)_2$ (273.4 cm^{-1})[30] probably due to the weaker *trans* influence of PPh_3 as compared to PEt_3.[19] Thus complex **6** is considered to have the *trans* structure. It is stable in the air and the decomposition temperature (170 °C) is much higher than that of *trans*-$NiCl(C_6H_5)(PPh_3)_2$ (122—123 °C).[2b] The remarkable stability of **6** may be caused partly by the "*ortho* effect" [3] exerted by the fused pyridine ring in the 8-quinolyl ligand.

Proton NMR data for **6** are included in Table 4. In contrast with other dinuclear complexes, **6** exhibits a broad signal at about 7.50 ppm due to the phenyl protons. Of the quinoline-ring protons H^2 and H^6 resonate at 8.82 and 6.75 ppm, respectively, other proton signals being masked by those of the phenyl protons. Compared with the chemical shifts of H^2 (8.81 ppm) and H^6 (7.44 ppm) of uncoordinated quinoline,[26] the signal of H^6 which is in the *meta* position from the metal shows a remarkable up-field shift on ligation.

Characterization of the Di-μ-pseudohalogeno-bis(σ-pyridyl)-bis(triphenylphosphine)dinickel(II) Complexes. The bridging chloride ions in complexes **2a** and **5** were readily replaced by the azide, cyanate, thiocyanate, and selenocyanate ions to afford two series of compounds **7** in a mixture of dichloromethane and methanol at room temperature, the yields decreasing in the sequence of $SCN^- > OCN^- > N_3^-$ for both series. The analytical and molecular weight data listed in Table 1 together with the diamagnetic behavior indicate that the dinuclear square-planar structure is preserved in these complexes. Many dinuclear transition metal complexes containing pseudohalides as the bridging ligands have been prepared so far,[31–33] but no example of the square-planar nickel(II) complexes of this kind has been reported to our knowledge.

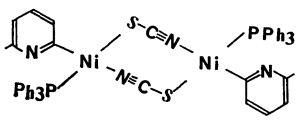
Of various bridging modes of the pseudohalide anions, the "one-end" bridge (A) and the "end-to-end" bridge (B) are most widely recognized. In the case



of the di-μ-azido complexes, X-ray analysis revealed that some complexes such as $[AsPh_4]_2[Pd_2(N_3)_6]$[34] and $NEt_4[Mn_2(N_3)_3(CO)_6]$[35] have the type A structure and the azide ion in $[Rh_2N_3(\eta^5\text{-}C_5Me_5)\text{-}(N_3C_4F_6)_3]$ is also one-end bridging,[36] while $[Cu(N_3)\text{-}(PPh_3)_2]_2$[37] and $[Cu_2(N_3)_2(Me_5dien)_2](BPh_4)_2$[38] have the type B structure. However both of the di-μ-azido structures have the local D_{2h} symmetry and it is impossible to distinguish between them only from the IR-spectral information. The cyanate ion usually coordinates to transition metals through the nitrogen atom,[31,33] and only one pair of linkage isomers has been reported in the solid state.[39] When the cyanate ion is involved in a dinuclear complex, one-end bridging at the nitrogen atom (type A) is common and the type B bridging has been found only in $[Ni_2(NCO)_2(tren)_2](BPh_4)_2$,[40] where tren is $N(CH_2\text{-}CH_2NH_2)_3$, and $(C_6H_5)_3TeNCO\cdot 0.5CHCl_3$.[41] In the case of thiocyanate and selenocyanate ions, however, the bridging mode of type B is usually preferred to type A,[31,33] although the one-end bridging both at

nitrogen[42] and sulfur[43] atoms has been exemplified.

Each of compounds **7a**—**7d** containing the 6-methoxy-2-pyridyl ligand exhibits a single sharp signal assignable to the methyl protons, indicating that neither geometrical nor linkage isomers are involved in each case. As is seen in Table 4 the pattern of ^{1}H NMR spectra for **7a**—**7d** and the chemical shifts of phenyl and pyridyl ring protons in these complexes show a striking resemblance to each other irrespective of the nature of the pseudohalide anions, suggesting the existence of a common bridging mode. We would like to tentatively assume the end-to-end bridging with the *trans* configuration (C). The IR spectral data in



C

Table 3 are not diagnostic but conform to the presumed structure.

Characterization of Compound **8**. The analytical and molecular weight data in Table 1 indicate that compound **8** is dinuclear. The ν(C=O) and ν(C=C=C) bands are observed at 1565 and 1514 cm^{-1}, respectively, resembling those of $Ni_3(acac)_6$ at 1598 and 1520 cm^{-1}. Figure 2 shows the ^{1}H NMR spectrum of **8** in CD_2Cl_2. Two kinds of methyl signals are observed at 1.90 and 2.00 ppm. The pyridyl protons resonate at 6.70, 7.00, and 7.30 ppm. The coupling constants to each other are equal to those for **2a**, but the down-field shifts of these signals are remarkable as compared with those of **2a** although they still exist in higher field than proton signals of uncoordinated 2-chloropyridine. All pieces of the spectral information well conform to the proposed structure. To our knowledge this is the first example of the square-planar NiO_3C-type complexes, although the NiO_2CP-type complexes such as $NiC_2H_5(acac)$-PPh_3[44] have been reported. Again the strong effect of

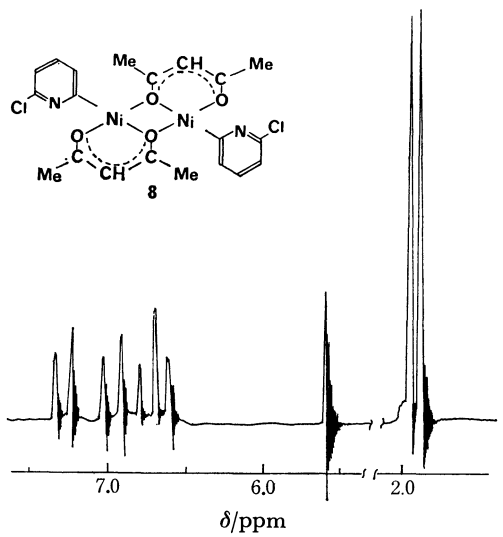


Fig. 2. The ^{1}H NMR spectrum of [Ni(acac)(C_5H_3-(6-Cl)N-C^2)]$_2$ (**8**) in CD_2Cl_2 with external TMS.

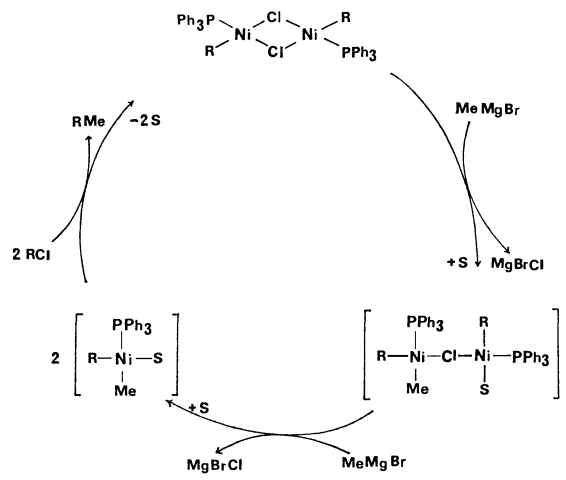
π-bonding between the pyridyl ligand and the nickel ion upon stabilizing the σ-carbon-bonded complex is noted.

Reactions of the σ*-Pyridyl Complexes.* Reactions of **1** with excess triphenylphosphine, thiourea, and pyridine were tried in vain at room temperature, ending in recovery of **1**. Refluxing of a solution of **1a** in neat pyridine for 2 h gave dichlorobis(pyridine)-nickel(II) in a 40% yield. Complex **6** reacted with acetylacetone to produce $Ni(acac)_2(C_9H_7N)_2$ in a 55% yield. Found: C, 64.78; H, 5.46; N, 5.19%. Calcd for $C_{28}H_{28}N_2O_4Ni$: C, 65.27; H, 5.48; N,5.44%. Presumably acetylacetone acted as an acid to split the nickel–quinolyl bond, the conjugate base (acac anion) replacing the chloride ion. It is noteworthy that bis(acetylacetonato)nickel(II) preferred quinoline to triphenylphosphine as a base in the adduct formation.

The reactions of bases such as pyridine and triphenylphosphine with **8** to break the dinuclear structure were unsuccessful at ambient temperature, but refluxing in a mixture of dichloromethane and methanol effected decomposition of **8** to yield unidentified products. When triphenyl phosphite was employed as a base, refluxing in methanol gave rise to 6,6′-dichloro-2,2′-bipyridine and tetrakis(triphenyl phosphite)nickel(0). Reductive elimination has occurred to yield a homocoupled product and the nickel(0) complex. The other product containing the acetylacetonate moiety has not been identified.

When Grignard reagents RMgBr (R=CH_3 or C_6H_5) and 2-pyridyllithium were reacted with **1a**, the diorganonickel complexes were not obtained, but instead 2-methylpyridine was yielded in the case of methylmagnesium bromide. On the contrary to the extraordinary stability of the σ-pyridyl nickel(II) complexes, the diorganonickel complex must be unstable, immediately undergoing a coupling reaction. As was described in the Experimental section, complex **1a** was found to be an excellent catalyst for the cross coupling of 2-chloropyridine with methylmagnesium bromide in THF at ambient temperature to produce 2-methylpyridine quantitatively. The pathway of the catalytic turn-over may be visualized by the proposed Scheme. The intermediates in brackets have not



Scheme.

been isolated but just presumed. A molecule S is used for bookkeeping of the coordination number and may be either the solvent or *N*-bonded 2-chloropyridine.

Morrell and Kochi[25] prepared *trans*-methylphenyl(and *o*-tolyl)bis(triethylphosphine)nickel(II) and determined the rates of reductive elimination to yield toluene and *o*-xylene, respectively. These rates were found to be too slow to allow for a catalytic process probably because of the *trans* structure. Oxidative addition of aryl halides to nickel(0) species usually affords trans products, showing no sign of isomerization to either a *cis* isomer or a tetrahedral species.[25] These results offer a trouble to understanding of the cross coupling mechanism. In the present case, on the other hand, the dinuclear structure of **1a** is quite favorable for the catalytic steps, allowing the *cis* arrangement of the two organic ligands as depicted in Scheme.

The authors wish to thank Mr. Junichi Gohda for the elemental analysis, and Drs. Kyo Abe and Takamasa Kinoshita for NMR measurements. They are also grateful to the Ministry of Education for the Grant-in-Aid for Special Project Research (No. 311706).

The Chemistry of 1,3-Glycol Derivatives. III. The Preparation of 1,1-Bis(1-hydroxyalkyl)cyclopropanes and Their Halogenation

Osamu Itoh,* Yoshiro Kohmura, Yasunori Ichikawa, Makoto Umezu, Tsutomu Okita, and Katsuhiko Ichikawa

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received December 27, 1978)

By the reduction of 1,1-diacylcyclopropanes and their related compounds, several kinds of 1,1-bis(1-hydroxyalkyl)cyclopropanes have been prepared. Some of the stereoisomers were separated, and their configurations were determined by the NMR study of the 1,3-dioxanes prepared by the acetallization of the diols. The diols were subjected to halogenation. Although the reactions of *meso*- and *dl*-bis(1-hydroxyethyl)cyclopropanes with thionyl chloride and phosphorus pentachloride gave normal dichlorides, accompanied by slight skeletal rearrangements, the stereospecificities were rather low. With $ZnCl_2$–HCl, the specificities were lost completely and large amounts of the homoallyl derivative were formed. The reaction mechanism is discussed.

Stereoisomers of several kinds of aliphatic 1,3-glycol and their derivatives, including cyclic orthoacetates, were prepared and their reactions reported previously.[1] In this paper, an extension of the study to 1,3-glycols, whose C-2 carbons are cyclopropane-ring carbons, will be reported, since the preparation of this type of compound has not yet been reported except for one case of 1,1-bis(hydroxymethyl)cyclopropane.[2]

The glycols have been prepared by the reduction of 1,1-diacylcyclopropanes. Some of the stereoisomers have been separated and their conformations have been determined by the ^1H and ^{13}C NMR study of the glycols and their corresponding acetals. The diols were subjected to halogenation under various conditions to examine the stereospecificities and the skeletal rearrangements.

The starting materials and the glycols obtained (including several kinds of related compounds) are listed in Table 1.

According to conventional methods, the reductions were carried out with lithium aluminium hydride in tetrahydrofuran at 0 °C, with sodium borohydride in methanol at room temperature, and with aluminium isopropoxide in 2-propanol under reflux. Normal results were obtained, and no unusual phenomena such as those observed in the case of spiro-diketone[3] were encountered.

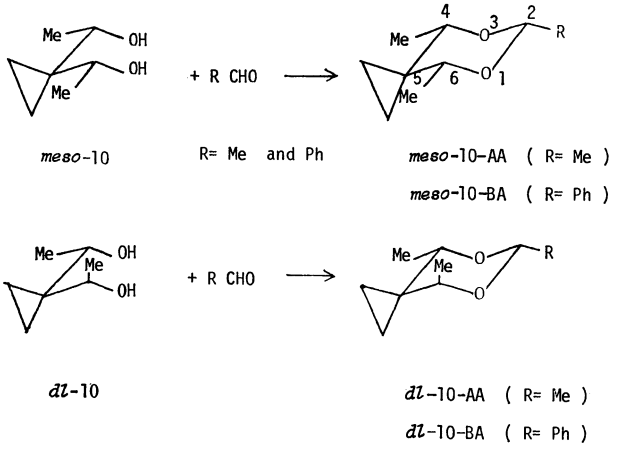
By reducing the reagent/substrate ratio, mono alcohols could be obtained. In the Meerwein-Pondorf-Verly reduction of the reference compound **6**, only glycol was obtained; no mono-alcohol could be isolated, not even with a smaller ratio of reagent/substrate (2/3) and with a shorter reaction time (0.5 h). No detectable amount of any by-product was obtained except 2-methyl-2,4-pentanediol, which was the aldol condensation product of acetone from the reducing reagent.[4] The results of the reduction are summarized in Table 2.

Since glycol **10** contains two asymmetric carbons, there should be *meso*- and *dl*-isomers. These were separated successfully by the following procedure. When a carbon tetrachloride solution of **10** was kept in a refrigerator at about −16 °C overnight, crystals (found to be *meso*-**10**, as will be described later) were formed. After filtration and evaporating the solvent, the liquid part of **10** (*dl*-**10**) was obtained. However, NMR analysis showed that the purity of the liquid part was as low as 70%. Since the solubility of *meso*-**10** was found to be slightly greater than that of the *dl*-form in water, the liquid portion was shaken with an ether–water mixture to remove the *meso*. After repeating the procedure, a *dl*-form with a purity of more than 80% was obtained.

Glycol **12** also has two asymmetric carbons and has *erythro*- and *threo*-forms. From crude **12**, crystals were formed after it had stood at room temperature for three months. Using the crystals as the seeds, a crystalline isomer of **12** (found to be *erythro*-**12**, as will be described later) were obtained from the ethereal solution of crude **12** at −30 °C. The residual part was *threo*-**12**, containing about 25% *erythro*-form.

Glycol **13** has *cis*- and *trans*-isomers in addition to *meso*- and *dl*-isomers, and all attempts at separation were unsuccessful. The isomer separation of *meso*- and *dl*-**15** was unsuccessful too, although the NMR assignments could be made in this case.

The structural assignments of the isomers of **10** and **12** were carried out by NMR analyses of the corresponding acetals obtained by the reactions with acetaldehyde and benzaldehyde (in the presence of calcium chloride and catalytic amounts of *p*-toluenesulfonic acid[5] in the same way as was reported previously.[1]



The physical properties of the acetals obtained are listed in Table 3.

The discussion of the NMR data of 1,3-dioxanes

which were obtained by the reactions of aliphatic 1,3-glycols with orthoacetate[1] can be applied to the present case without any change except that the cyclopropane ring anisotropy shifts the signals of equatorial hydrogens and methyl hydrogens at C^4 and C^6 to higher magnetic fields. The data in Table 3 can be explained reasonably in terms of the configurations described in the table. In the case of **8**, the NMR data showed that the acetallization gave a mixture of isomers due to axial and equatorial methyl derivatives in a ratio of 12:88.

Table 2. The results of the reduction

6	$Al(i\text{-}PrO)_3$ in *i*-PrOH 25/82	**15** (31%)

The following characteristic features of the NMR signals of benzaldehyde acetals can be pointed out. 1. Acetal-ring methylene protons give signals at about δ=4.21—4.31 for axial ones, and at δ=3.21—3.39 for equatorial ones. 2. Methine protons at C^4 and C^6 give signals at δ=4.16—4.54 for axial ones, and at δ=3.21—3.68 for equatorial ones. 3. Methyl protons at C^4 and C^6 give signals at δ=1.32—1.61 for axial ones, and at δ=0.90—1.05 for equatorial ones. These facts can be explained by the anisotropic effects of cyclopropane and phenyl rings.

The structures of *meso*- and *dl*-**10** were confirmed further by ^{13}C NMR. The *meso*-form gave signals at δ=4.4 and 9.0 (ring CH_2), 20.0 (CH_3), 29.5 (ring head C), and 71.2 (CHOH). The *dl*-form gave signals at δ=7.7 (ring CH_2), 18.9 (CH_3), 28.6 (ring head C), and 71.2 (CHOH) ppm downfield from the internal TMS. The major differences between the spectra of the two isomers are those due to the ring methylene carbons. The fact that the ring methylene carbons of *meso*-**10** gave two signals, while those of *dl*-**10** gave only one signal, shows that the former carbons are not equivalent, while the latter is equivalent, and that all can be well understood in terms of their structures.[6]

Among the physical properties of **10**, it should be

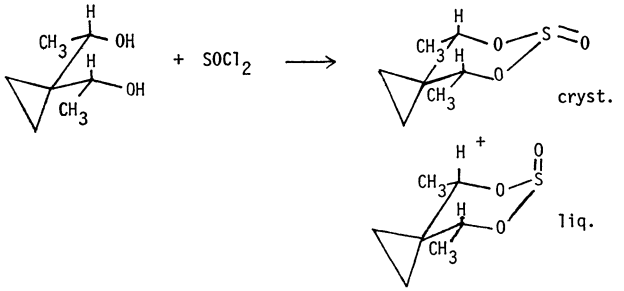
noted that the *meso*-form is crystalline and that the *dl*-form is liquid, while Pritchard reported that the crystalline form (mp 48—49 °C) was *dl* and the liquid one was *meso* in the case of 2,4-pentanediol.[7]

It is well known that the halogenation of cyclopropylalkanols is accompanied by skeletal rearrangements. For example, the reaction of cyclopropylmethanol with thionyl chloride gave cyclopropylmethyl chloride, cyclobutyl chloride, and homoallyl chloride.[8] We examined whether or not the behavior of bis(1-hydroxyalkyl)cyclopropanes is the same as that of mono-(1-hydroxyalkyl)cyclopropanes.

Thionyl chloride is the most frequently used reagent in the chlorination of a cyclopropylalkanol system. Therefore, the reaction with this reagent has been examined first.

Cyclic Sulfite Formation. Pritchard and his coworkers demonstrated that the reaction of 2,4-pentanediol with thionyl chloride gave a cyclic sulfite.[7] Similarly, **10** gave cyclic sulfites. In pyridine at 0 °C, *meso*-**10** formed two kinds of sulfite, crystalline and liquid (7:3).

Six-membered cyclic sulfites have stereoconformers, as in the case of cyclohexane derivatives. Since the C–O bonds of the glycol are not broken in the sulfite formation, the configurations of the carbons of C–O in the sulfites should be the same as those in the starting glycol. The two methyl groups at C-4 and C-6 of the cyclic sulfites from *meso*-**10** should both be equatorial or both axial. Apparently, the diaxial conformer should be much more unstable, and the product should have a di-equatorial conformation. The fact that the two kinds of product were obtained appears to have resulted from the axial and equatorial forms of S=O bond. Since the S=O bond shows an anisotropic effect,[9] NMR data can be used to clarify the structures. The axial S=O should shift the signals of the axial protons at C-4 and C-6 to lower fields, but not the equatorial S=O. All NMR data can be explained reasonably in terms of the structures depicted; they exclude the possibility of the twisted boat form.



There are two conflicting reports on the IR spectra of S=O. Pritchard and his coworkers assigned the absorptions of cyclic sulfite of 2,4-pentanediol at 1240 and 1188 cm^{-1} to axial and equatorial S=O respectively,[7] while Hellier and his coworkers assigned the absorptions of the same compound at 1230 and 1190 cm^{-1} to equatorial and axial respectively.[9,10] Our conclusion agreed with the latter assignment. *dl*-**10** gave only one cyclic sulfite, and the S=O bond was found to be axial from the NMR and IR data.

The cyclic sulfites obtained are listed in Table 4.

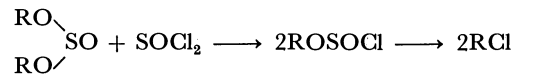
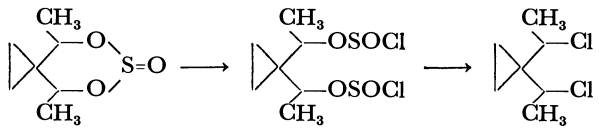
Diol **8** gave the sulfite containing two conformers.

Reaction of Cyclic Sulfite with Thionyl Chloride. The reaction of alkyl sulfite with thionyl chloride is believed to proceed according to the following equation.[11]



In the present case, the equation is as follows:



The configuration of the chloride is determined in the second step of the above equation, since the first step does not involve the breaking of the C–O bond.

The results of the reaction of sulfites with thionyl chloride are listed in Table 5.

The sulfite of *meso*-**10** (*meso*-**10-S**) reacted much slower than that of *dl*-**10**. Since the rates of the second step should be the same in both the stereoisomers, the difference must have resulted from the first step. The results can reasonably be explained by considering that the backsides of both O–SO bonds are blocked by two methyl groups to S_N2 attack on O in the case of the *meso*-isomer, while one of the backsides is open in the case of the *dl*-isomer.

The final dichloride (**10-Cl**) has stereoisomers of *meso* and *dl*, whose structural assignments will be described later. In a chloroform solution, *meso*-**10-S** gave *meso*-**10-Cl** and *dl*-**10-S** gave *dl*-**10-Cl** predominantly, but the stereospecificities were about 70%. If the reactions of the two C–O–SO groups are of the S_Ni type (which is believed to be the case in the absence of a base), the specificities should be 100%. The addition of pyridine changes the reaction to S_N2, but the results should be the same by double inversion. The formation of 5-chloro-3-(1-chloroethyl)-2-pentene (homoallyl-**Cl**), although the yields were very low, appears to show that the cyclopropylmethyl cation intervenes in the reaction, as in the chlorination of the usual cyclopropylmethanol. The addition of pyridine to the reaction system resulted in the further loss of the specificity and in the larger yield of homoallyl-**Cl**. These results will be discussed in the following section.

Halogenation of meso- *and* dl-***10*** *under Various Conditions.* The results of the halogenation of *meso*- and *dl*-**10** are listed in Table 6.

It is difficult to reach a clean-cut conclusion as to the steric course of the reactions with thionyl chloride and phosphorus pentachloride except that slight retentions of configuration were observed. It has been pointed out that the stereospecificity of the chlorination of alcohol with thionyl chloride depends on the experimental technique.[12] Therefore, we reexamined the reaction of *meso*-2,4-pentanediol reported by Pritchard[7] and confirmed that the reaction gave a product with a stereospecificity of more 98%, showing that the above results had not resulted from our experimental technique.

The formation of a homoallyl derivative, which indicates the intervention of the cyclopropylmethyl cation, was observed in all cases. Its yields were higher in a chloroform solution than in donor solvents such as benzene, dioxane, ether, carbon disulfide, and acetonitrile, but not pyridine. These results may be explained on the assumptions that the cyclopropylmethyl cation is stabilized by solvation with the basic solvent and that the rearrangement to the homoallyl derivative is suppressed. In the presence of pyridine, the hydrogen chloride formed reacts to form ionic pyridine hydrochloride, which may favor the formation of the cation and the rearrangement to the homoallyl

a) Pyridine was added to the chloroform.

derivative. The loss of the stereospecificity in the normal dichloride formation appears also to have resulted from the formation of the cation. Another possible reason for the loss of specificity might be that one of the two chlorine atoms is introduced by S_N2, and the other by S_N1. This possibility, however, appears to be excluded by the fact that the changes in the medium did not change the results appreciably.

In the case of the $ZnCl_2$–HCl system, the stereospecificity was lost almost completely and a large amount of the homoallyl product was formed, showing the formation of the cyclopropylmethyl cation.

The bromination of the same substrates resulted in further losses of specificity than in the case of chlorination and in larger yields of the homoallyl product.

Structural Assignments of meso- *and* dl-***10-X*** *and Homoallyl Chloride.* Attempts at the structural assignments of *meso*- and *dl*-**10** by PMR and IR were unsuccessful. However, ^{13}C NMR could clearly discriminate the two isomers by analogy with the case of diols mentioned in the early part of this paper. The cyclopropane-ring methylene carbons of the *dl*-isomer were equivalent (δ:11.3), but not those of the *meso*-isomer (δ:12.4 and 15.5).

The NMR data of homoallyl-**10-Cl** show that the structure should be the one depicted in Table 4. [δ: 1.60 (d, J=7.0, 3H, C^7H_3), 1.69 (d, J=7.0, 3H, C^1H_3), 2.66 (t, J=8.0, 2H, C^5H_2), 3.58 (m, 2H, C^4H_2), 4.59 (q, J=7.0, 1H, C^6H), and 5.73 (q, J=7.0, 1H, C^2H)]. Whether this compound has the structure of E or that of Z could not be determined, however.

Experimental

Materials. According to the method reported by Dox and Yoder,[13] **1** was prepared by the reaction of diethyl malonate with 1,2-dibromoethane in the presence of sodium ethoxide. The use of 2 M NaOH instead of the previously reported *n*-$BuNH_2$ to remove the unreacted diethyl molonate from the reaction product gave better results. Compounds **2**—**5** were prepared by the reaction of oxymercuration products of olefins with β-diketo compounds followed by demercuration, as had been reported previously.[14] Compound **6** was prepared from benzaldehyde and acetylacetone in the presence of picoline.[15]

Reduction. The reductions were carried out by the conventional methods;[3] no special technique was used except in the product isolations of **7**, **11**, and **14**. The reported poor yields of **7**[2] was greatly improved by the following procedure. After the hydrolysis of the reduction mixture, the aluminium hydroxide was filtered and washed

a) Very hygroscopic. b) Unstable to atmospheric moisture and light.

with water. When the water was removed from the filtrate by the use of rotatory evaporator, aluminium hydroxide precipitated again. After filtering again, the filtrate was distilled under reduced pressure. It appears that the second removal of aluminium hydroxide improved the isolation yield.

In order to isolate **11** (IR, $\nu_{C=O}$ at 1670 cm^{-1}), the distillate which had been obtained by the usual work-up was subjected to column chromatography (Wakogel C-200 $2\phi \times 20$ cm; 1. hexane–ethyl acetate (95 : 5), 2. hexane–ethyl ether (70 : 30), 3. ethyl ether). Similarly, **14** (IR, $\nu_{C=O}$ at 1680 cm^{-1}) was isolated by column chromatography (Silicic acid, Mallinckrodt, $2\phi \times 15$ cm; 1. hexane–ethyl ether (95 : 5), 2. hexane–ethyl ether (70 : 30), 3. ethyl ether).

Acetallization. The acetaldehyde acetal and benzaldehyde acetals were prepared by the method by Eliel and his coworkers.[16]

Cyclic Sulfite. The following example shows a typical experimental procedure. Into a pyridine (20 ml) solution of diol **10** (2.6 g, 20 mmol), we stirred thionyl chloride (4.76 g, 40 mmol), drop by drop in an ice bath. After 1 h, the crystalline pyridine hydrochloride formed was removed by filtration, and then pyridine was removed by distillation under reduced pressure. Ether was added to the residue, which was then washed with 6 M HCl, a saturated $NaHCO_3$ solution, and then with water, and dried over Na_2SO_4. After the ether had been removed, the residue (2.5 g, 71% yield) was recrystallized from CCl_4 to give crystalline *meso*-**10-S** (mp 80.8—81.2 °C). The liquid part was purified by column chromatography with Wakogel C-200, using $CHCl_3$ as the solvent (bp 112—120 °C). The ratio of the crystalline to the liquid part was 7 : 3. The same procedure gave the cyclic sulfite of **8** (bp 65 °C/24 mmHg).

Formation of Dihalides. The experimental procedure is shown by the following example. Into a chloroform (800 g) solution of diol **10** (29.6 g, 0.374 mol) we stirred a pyridine (29.6 g, 0.374 mol) solution of thionyl chloride (50.0 g, 0.42 mol) in an ice bath. After 10 h, the reaction mixture was washed with 2 M HCl, saturated $NaHCO_3$ and then water, and dried over Na_2SO_4. After the chloroform had then been removed, the residue was distilled under reduced pressure to give a mixture of *dl*- and *meso*-dichloride and homoallyl chloride (bp 84—86 °C/20 mmHg; yield, 90%), which was analyzed by GLC. Upon cooling in a dry ice–acetone bath, the mixture gave crystalline *meso*-**10-Cl**. The liquid part was *dl*-**10-Cl**, containing a small amount of homoallyl-**Cl**.

*Reaction of Diol-**10** with $ZnCl_2$–HCl.* Into concd hydrochloric acid (1 ml) containing $ZnCl_2$ (0.22 g) we stirred **10** (0.3 g) at 0. °C. After 5 h, the product was extracted with benzene, washed with saturated $NaHCO_3$ and water, dried over Na_2SO_4, and analyzed by GLC.

The analytical data are shown in Table 7.

The IR spectra were recorded on a HITACHI EPI-G2 apparatus. The NMR spectra (in deuteriochloroform, with TMS as the internal standard) were recorded on a Varian Associates HR-220 apparatus at 220 MHz at room temperature. The ^{13}C NMR spectra (in deuteriochloroform, with TMS as the internal standard) were obtained by the use of a JNM FX-100 spectrometer.

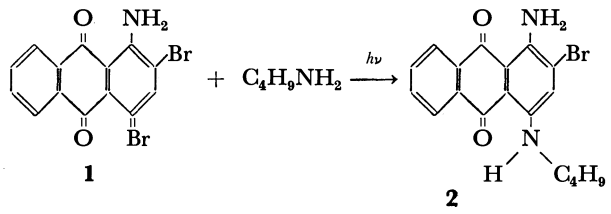
(Received February 17, 1979)

The photoamination of 1-amino-2,4-dibromoanthraquinone (**1**) by butylamine in ethanol was investigated. The reaction was accelerated under an air atmosphere ($\Phi_{air}=1.7\times10^{-3}$, $\Phi_{N_2}=2.3\times10^{-4}$, where [butylamine]$=5.00\times10^{-2}$ mol/dm^3). A detailed kinetic study indicated that, under nitrogen, the photoamination proceeded *via* the $T_1(^3CT)$ state populated by the intersystem crossing from the $S_1(^1CT)$ state, while under air it proceeded *via* both the $T_1(^3CT)$ and the $S_1(^1CT)$ states. The latter pathway under air included an interaction between the $S_1(^1CT)$ state and oxygen to form an exciplex or a collisional complex such as $[AQ^{\delta+}\cdots O_2^{\delta-}]$. The deactivation constant from the $T_1(^3CT)$ of **1** in ethanol was revealed to be one order of magnitude smaller than that in benzene and one order magnitude larger than that of 1-aminoanthraquinone in benzene. These results were discuessd in relation to the energy diagram in the excited state and the intramolecular heavy-atom effect of bromine in **1**.

It has long been emphasized that the excited triplet $n\pi^*$ state is reactive in almost all the photochemical reactions of anthraquinone derivatives, while the intramolecular CT state has little reactivity.[1] It has also been proved that the excited triplet $n\pi^*$ state is reactive even in the photoreduction of 2-piperidinoanthraquinone by an electron transfer from the hydroxide ion in aqueous 2-propanol,[2] which had been postulated to proceed *via* the intramolecular CT level.[3] However, we recently reported an interesting new photosubstitution reaction of aminoanthraquinones as the first example of a reaction actually demonstrated to proceed *via* the CT level.[4]

In the preceding paper we reported the striking solvent effects on the photoamination of 1-amino-2,4-dibromoanthraquinone (**1**) by butylamine.[5] In ethanol, 1) the dissolved oxygen promoted the photoamination of **1** and 2) the yield (%) of the aminated product (**2**) was not equivalent to the conversion (%) of **1** and the ratio (0.79) between them was unchanged during the photoreaction. The last result suggests that the photodecomposition of **1** and its photoamination took place simultaneously, as was previously observed in the photoamination of sodium 1-amino-4-bromoanthraquinone-2-sulfonate (**3**) in aqueous 2-propanol.[4] In benzene, 1) oxygen acted as a strong quencher to the reaction and 2) the yield of **2** was equal to the conversion of **1**, suggesting that the photoamination of **1** proceeded quantitatively.[5] On the basis of the postulated energy diagram of the excited **1** shown in Fig. 1, it was suggested that, in benzene, the photoamination proceeded through the $T_1(^3CT)$ level without the aid of oxygen because of a dominant population on the T_1 level by means of a close contiguity or an inversion in the disposition of $S_1(^1CT)$ and $T_2(^3n\pi^*)$ levels. In this paper we will report on our detailed kinetic analysis of the photoamination of **1** in ethanol and will propose a reaction mechanism with a dual mode from the $S_1(^1CT)$ and the $T_1(^3CT)$ levels of **1** in contrast with the single mode in benzene.



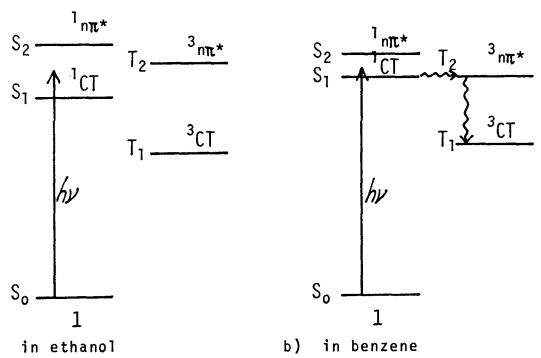


Fig. 1. Energy diagram of the excited state of **1**.

Experimental

The 1-amino-2,4-dibromoanthraquinone (**1**) was prepared and purified as reported in the preceding paper.[5] A Shimadzu UV-200 spectrophotometer and a Hitachi MPF-4 spectrofluorometer were used for the measurement of the UV and visible absorption spectra and the fluorescence emission spectra respectively. Irradiation was carried out by the use of a 500-W xenon lamp (USHIO UXL 500 DKO) through the following filter system: a soda glass for the irradiation of $\lambda>300$ nm, a Toshiba interference filter KL-40 for the monochromatic irradiation of $\lambda=400$ nm, a Toshida glass filter VY-42 for $\lambda>420$ nm, and VY-45 and KL-47 filters for the light of $\lambda=470$ nm. The amount of the aminated product (**2**) generated in the irradiated reaction mixture was determined by colorimetric analysis of the first absorption band of **2** ($\lambda_{max}=625$ nm, $\varepsilon=1.40\times10^5$ dm^2/mol). The number of photons absorbed by the reaction mixture was determined by the use of the chemical actinometer of potas-

sium tris(oxalato)ferrate(III). The amount of hydrogen peroxide in the irradiated reaction mixture was determined by colorimetric analysis of the absorption intensity at 357 nm, which is characteristic of the I_3^- generated by the addition of an aqueous solution of potassium iodide to an acidified reaction mixture.

Results and Discussion

The Photoamination of ***1*** *in Ethanol under a Nitrogen Atmosphere.* The photoamination of **3** in a 2-propanol–water (4 : 1 v/v) mixture proceeded through an exciplex formation between the excited **3** in its ^{1}CT state and the ground state oxygen; the reaction was hardly observed at all under a nitrogen atmosphere.[4] On the other hand, the photoamination of **1** in ethanol does proceed even under nitrogen, though the reactivity is about one-seventh of that under air ($\Phi_{air}=1.7\times10^{-3}$, $\Phi_{N_2}=2.3\times10^{-4}$, where [butylamine]$=5.00\times10^{-2}$ mol/dm^3). The previous study of the photoamination of **1** in benzene revealed that the ^{3}CT level of **1** is also responsible for the photoamination. Hence, the photoamination of **1** in ethanol under nitrogen may be explained by either of the following suggestions: 1) a direct photoamination proceeds *via* the ^{1}CT level of **1** without the aid of oxygen, or 2) the ^{3}CT level of **1** is responsible for the reaction.

In Table 1 the 0-0 level of the $S_1(^1CT)$ state and the relative fluorescence intensity of **1** in ethanol are compared with those of other aminoanthraquinones. Since the $S_1(^1CT)$ states of aminoanthraquinones (**3**—**5**) have much the same energy as that of **1**, and since the $n\pi^*$ levels of anthraquinones have been thought to be hardly affected by the introduction of substituents,[1] it may be accepted that the excited states of **3**—**5** have energy diagrams similar to that of **1**. On the other hand, the relative intensity of the fluorescence decreased with the increase in $\sum\zeta^2$, the sum of the squares of the spin-orbit coupling factors over all the atoms in the corresponding molecule. These results suggest that the intersystem crossing between the $S_1(^1CT)$ and the $T_1(^3CT)$ levels in **1** might be enhanced by the spin-orbit interaction promoted by the heavy-atom effect of the two bromine atoms as compared with those of other aminoanthraquinones. In order to make clear the multiplicity of the reactive excited state of **1** in the photoamination in ethanol under a nitrogen atmosphere, the effect of a triplet quencher, cyclooctatetraene (COT)($E_T=163$ kJ/mol), was investigated. As is shown in Fig. 2, a good linear Stern-Volmer plot was obtained with a slope of 54.0 dm^3/mol. This clearly indicated that the photoamination of **1** under nitrogen proceeded *via* only one pathway. Since COT was confirmed to act as a triplet quencher by the fact that the fluorescence intensity of **1** in ethanol was hardly affected at all by the presence of COT (5.0×10^{-2} mol/dm^3), it seems that the photoamination proceeded through the triplet ^{3}CT level of **1**.

A plot of the reciprocal of the quantum yield of the photoamination of **1** versus the reciprocal of the concentration of butylamine gave a fairly straight line (Fig. 3), indicating the presence of a collisional process between the excited **1** and butylamine in the photoamination in ethanol under a nitrogen atmosphere. The ratio of the slope to the intercept in Fig. 3 was 3.7×10^{-3} mol/dm^3. When the photoamination reac-

Aminoanthraquinones		0-0 level kJ/mol	Relative fluorescence intensity	$\sum\zeta^2$ cm^{-1}
	(**4**)	218	100	6.21×10^3
	(**5**)	216	49	6.11×10^6
	(**3**)	216	36	6.33×10^6
	(**1**)	218	18	1.22×10^7

a) The 0-0 levels of aminoanthraquinones were estimated from the intersections of the corresponding absorption and fluorescence spectra in a mirror image.

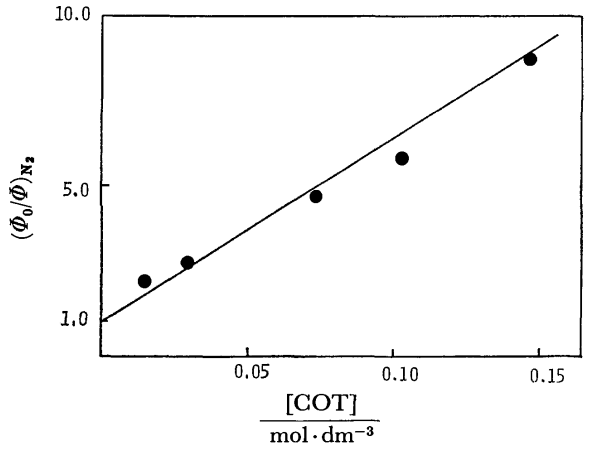

Fig. 2. Stern-Volmer plot for the quenching effect of cyclooctatetraene on the photoamination of **1** (1.00×10^{-4} mol/dm³) by butylamine (5.00×10^{-2} mol/dm³) in ethanol under nitrogen atmosphere by the irradiation of the light of $\lambda=470$ nm.

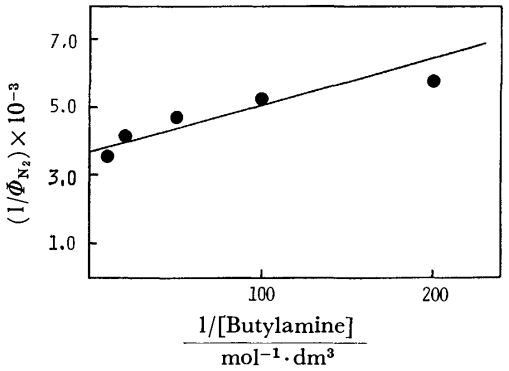

Fig. 3. Effect of the concentration of butylamine on the photoamination of **1** (1.00×10^{-4} mol/dm³) in ethanol under nitrogen atmosphere by the irradiation of the light of $\lambda=470$ nm.

tion of **1** (1.00×10^{-4} mol/dm³) was carried out in the presence of fluorenone ($E_T=226$ kJ/mol) (1×10^{-2} mol/dm³) as a triplet sensitizer under the irradiation of a light of $\lambda>300$ nm,[6] a good linear relationship was also found between the reciprocals of the quantum yield and the concentration of butylamine, with the value of the ratio of the slope to the intercept being 4.3×10^{-3} mol/dm³. The good agreement between these values obtained from the direct-irradiation experiment and the triplet-sensitizing experiment also strongly suggested that the photoamination proceeded through the $T_1(^3CT)$ level of **1** under a nitrogen atmosphere. When the fluorenone-sensitizing photoamination was carried out under air-saturated conditions, the reciprocals of the quantum yield and the concentration of amine also gave a good linear relationship. However, the ratio of the slope to the intercept, determined to be 39.1×10^{-3} mol/dm³, was much larger than that determined under a nitrogen atmosphere. Since the ratio of the slope to the intercept of the plot corresponds to the ratio of the rate constant of the deactivation to the reaction of the excited **1**, which is reactive to amine, the larger value of the ratio in

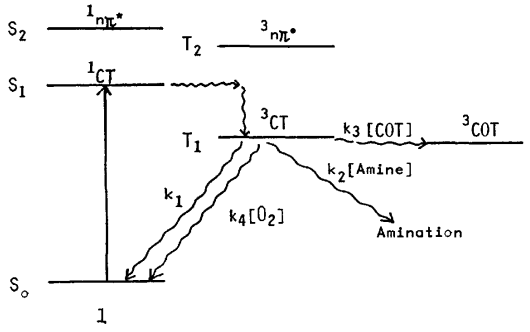

Fig. 4. Reaction scheme of the photoamination of **1** by butylamine under nitrogen atmosphere in ethanol.

the plot implies a larger deactivation from the excited **1** (^3CT) under air. This is in accord with the fact that the $T_1(^3CT)$ level of **1** was efficently quenched by the dissolved oxygen in benzene.[5]

The Reaction Mechanism of the Photoamination of ***1*** *in Ethanol under a Nitrogen Atmosphere.* On the basis of the above experimental results, the reaction scheme of the photoamination of **1** in ethanol under a nitrogen atmosphere may be depicted as in Fig. 4. The excited **1** in its $T_1(^3CT)$ state, populated by the intersystem crossing from the $S_1(^1CT)$ state, interacts directly with the amine to produce the aminated product, **2** (k_2). The $T_1(^3CT)$ state decays with the rate constant of k_1 and is quenched by COT (k_3). The reciprocal of the quantum yield of the photoamination under nitrogen *via* the $T_1(^3CT)$ level of **1**, $\Phi_{N_2}(^3CT)$, can be written as

$$1/\Phi_{N_2}(^3CT) = \frac{1}{\Phi_{isc}}\cdot\left(1+\frac{k_1}{k_2[A]}\right)\cdot\frac{1}{\alpha}, \quad (1)$$

where Φ_{isc}=the efficiency of the intersystem crossing of $S_1(^1CT)\rightarrow T_1(^3CT)$, α=the yield of the aminated product, **2**, for every collision between the amine and **1** in its $T_1(^3CT)$ level.

The Stern-Volmer plot with COT present under a nitrogen atmosphere is expressed by

$$(\Phi_0/\Phi)_{N_2} = 1 + \frac{k_3[COT]}{k_1+k_2[A]}. \quad (2)$$

Moreover, the reciprocal of the quantum yield, $\Phi^s_{N_2}(^3CT)$, of the photoamination in the fluorenone-sensitizing experiment under a nitrogen atmosphere can be written as

$$1/\Phi^s_{N_2}(^3CT) = \frac{1}{\Phi_{ET}}\cdot\left(1+\frac{k_1}{k_2[A]}\right)\cdot\frac{1}{\alpha}, \quad (3)$$

where Φ_{ET}=the triplet yield of **1** in the fluorenone-sensitizing experiment under a nitrogen atmosphere and under these conditions.

When the fluorenone-sensitizing experiment is carried out under air-saturated conditions, Eq. 3 is modified to Eq. 4 because of the quenching effect of oxygen on the $T_1(^3CT)$ level of **1**:

$$1/\Phi^s_{air}(^3CT) = \frac{1}{\Phi'_{ET}}\cdot\left(1+\frac{k_1+k_4[O_2]}{k_2[A]}\right)\cdot\frac{1}{\alpha}, \quad (4)$$

where Φ'_{ET}=the triplet yield of **1** in the fluorenone-sensitizing experiment under air-saturated conditions.

The value of the ratio of the slope to the intercept in Fig. 3 and Eq. 1, and the slope in Fig. 2 and Eq. 2 indicate the following relations:

$$k_1/k_2 = 3.7 \times 10^{-3}\ \text{mol/dm}^3,$$

$$k_3/(k_1+k_2[\text{A}]) = 54.0\ \text{dm}^3/\text{mol}.$$

The results of the fluorenone-sensitizing experiment under air-saturated conditions and Eq. 4 may also indicate that:

$$(k_1+k_4[\text{O}_2]_{\text{air}})/k_2 = 39.1 \times 10^{-3}\ \text{mol/dm}^3.$$

The concentration of the dissolved oxygen in air-saturated ethanol, $[\text{O}_2]_{\text{air}}$, was taken to be 2.07×10^{-3} mol/dm^3,[7] and $[\text{A}]=5.0\times 10^{-2}$ mol/dm^3. If the quenching rate constant of the $T_1(^3\text{CT})$ state by the dissolved oxygen is assumed to be $k_4=9.2\times 10^9$ dm^3 mol^{-1} s^{-1} (a diffusion-controlled one), the rate constants may be calculated as $k_1=2.0\times 10^6$ s^{-1}, $k_2=5.4\times 10^8$ dm^3 mol^{-1} s^{-1}, and $k_3=1.6\times 10^9$ dm^3 mol^{-1} s^{-1}. The value of the quenching rate constant (k_3) of the $T_1(^3\text{CT})$ state by COT coincides well with that obtained in a benzene solution (1.6×10^9 dm^3 mol^{-1} s^{-1}).[5]

The Photoamination of **1** *under an Air Atmosphere.* As has been stated before, the photoamination reaction in ethanol was remarkably accelerated under an air atmosphere. By comparison with the photoamination of **3** in a 2-propanol–water (4 : 1 v/v) mixture,[4] it might be immediately concluded that the reaction in ethanol proceeded through the interaction between **1** in its ^{1}CT state and the ground-state oxygen. However, our observation of the photoamination under a nitrogen atmosphere implies that the photoamination of **1** under air has a dual reaction mode: the reaction without the aid of oxygen through the $T_1(^3\text{CT})$ level of **1**, and the reaction *via* its $S_1(^1\text{CT})$ level with the aid of oxygen. Hence, the following kinetic treatment of the photoamination *via* the $S_1(^1\text{CT})$ level of **1** under an air atmosphere was developed for the quantum yield, $\Phi_{\text{air}}(^1\text{CT})$, calculated by Eq. 5:

$$\Phi_{\text{air}}(^1\text{CT}) = \Phi_{\text{air}} - \Phi_{\text{air}}(^3\text{CT}), \tag{5}$$

where Φ_{air} denotes the observed quantum yield of the photoamination under air, and $\Phi_{\text{air}}(^3\text{CT})$, the quantum yield of the reaction *via* the $T_1(^3\text{CT})$ level of **1** under air, which can be calculated by means of Eq. 6:[8]

$$\Phi_{\text{air}}(^3\text{CT}) = \Phi_{\text{isc}}\left(\frac{k_2[\text{A}]}{k_1+k_4[\text{O}_2]+k_2[\text{A}]}\right)\alpha. \tag{6}$$

As is shown in Fig. 5, a plot of the reciprocal of the quantum yield $\Phi_{\text{air}}(^1\text{CT})$ versus the reciprocal of the concentration of the dissolved oxygen gave a good straight line. This clearly indicated the presence of a collisional process between the excited **1** and the dissolved oxygen, leading to the aminated product, **2**. This is contrary to the case of the reaction *via* the $T_1(^3\text{CT})$ level of **1**, in which the dissolved oxygen acts as a strong quencher to the reaction. With respect to the fate of the oxygen, it was revealed that hydrogen peroxide was produced during the photoamination.[9] These results strongly suggested that the photoamination under air *via* the $S_1(^1\text{CT})$ proceeded through an exciplex or a collisional complex formation between the excited **1** in its ^{1}CT state and the ground-state

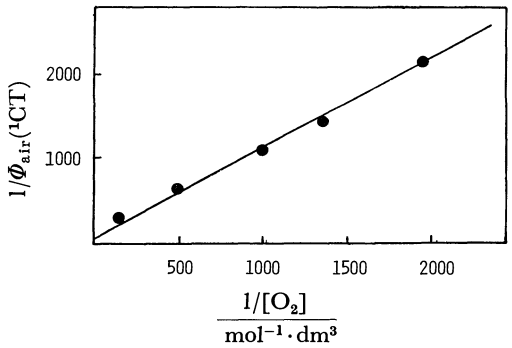

Fig. 5. Effect of the concentration of oxygen on the quantum yield $\Phi_{\text{air}}(^1\text{CT})$ calculated by Eq. 5; [1]: 1.00×10^{-4} mol/dm^3, [butylamine]: 5.00×10^{-2} mol/dm^3 in ethanol; irradiation light: $\lambda=470$ nm.

oxygen, designated $[\text{AQ}^{\delta+}\cdots\text{O}_2{}^{\delta-}]$. However, the intercept in Fig. 5 has a very small value, suggesting that the low quantum yield of the photoamination (in the order of 10^{-3}) is mainly due to the low efficiency of the reaction process between the excited **1** in its ^{1}CT state and oxygen. This is in accord with the fact that the fluorescence of **1** is not affected by the dissolved oxygen.

A double reciprocal plot between the quantum yield of the photoamination, $\Phi_{\text{air}}(^1\text{CT})$, and the concentration of butylamine also gave a good straight line, with the ratio of the slope to the intercept of 2.5×10^{-2} mol/dm^3 (Fig. 6), suggesting that, on the reaction pathway, butylamine collided with an intermediate which could be treated with the steady-state approximation. When COT was added to the reaction system, the photoamination was retarded and the Stern-Volmer plot gave a good straight line with a slope of 41 dm^3/mol (Fig. 7), indicating that COT also acted as a quencher molecule to the photoamination *via* the $S_1(^1\text{CT})$ level of **1** under air. Moreover, 1,3-cyclohexadiene (CHD), which has a higher triplet level ($E_T=226$ kJ/mol) than the $T_1(^3\text{CT})$ level of **1** ($E_T=163$—176 kJ/mol in benzene), also quenched the photoamination of **1** under air. Since COT and CHD hardly quenched the fluorescence of **1** at all, it appears that such olefins as COT and CHD did not interact with the excited **1** in its $S_1(^1\text{CT})$ state, but interacted

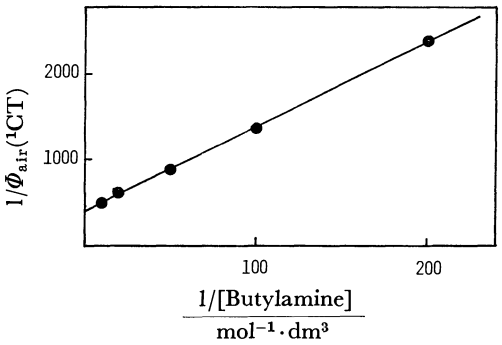

Fig. 6. Effect of the concentration of butylamine on the quantum yield $\Phi_{\text{air}}(^1\text{CT})$ calculated by Eq. 5; [1]: 1.00×10^{-4} mol/dm^3 in air-saturated ethanol; irradiation light: $\lambda=470$ nm.

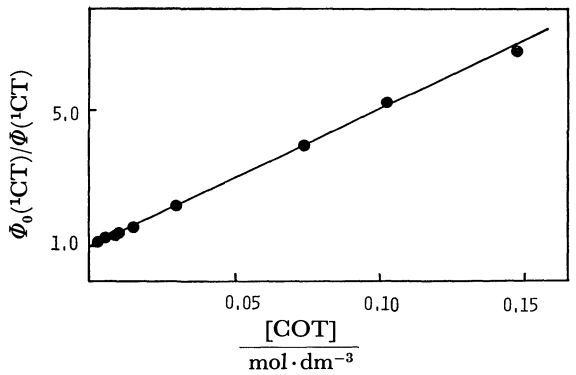

Fig. 7. Stern-Volmer plot for the quenching effect of cyclooctatetraene on the quantum yield of the photoamination under air; $\Phi_{air}(^1CT)$ was calculated by

$$\Phi_{air}(^1CT) = \Phi_{air} - \Phi_{isc}\cdot\left(\frac{k_2[A]}{k_1+k_3[COT]+k_4[O_2]+k_2[A]}\right)\cdot\alpha$$

[**1**]: 1.00×10^{-4} mol/dm^3, [butylamine]: 5.00×10^{-2} mol/dm^3 in air-saturated ethanol; irradiation light λ=470 nm.

with another intermediate on the reaction pathway of the photoamination *via* the $S_1(^1CT)$ level of **1** under air. Recently it has been reported that some exciplexes happen to be quenched by a third molecule (exciplex quenching).[10] The quenching effects of COT and CHD on the photoamination under air might be reasonably explained by assuming that these olefins interacted with the exciplex $[AQ^{\delta+}\cdots O_2^{\delta-}]$ to result in the quenching of the photoamination of **1** under air.

The Reaction Mechanism of the Photoamination of ***1*** *in Ethanol under Air.* The reaction scheme of the photoamination of **1** in ethanol under air may be depicted as in Fig. 8. The photoamination of **1** in ethanol has two possible reaction pathways. One is *via* the $S_1(^1CT)$ level of **1**. After being excited by the irradiation to the 1st absorption band of **1** (λ_{max}= 473 nm), **1** in its $S_1(^1CT)$ state interacts with the ground-state oxygen (k_5) to form an exciplex or a collisional complex, $[AQ^{\delta+}\cdots O_2^{\delta-}]$. The exciplex decays with the rate constant k_6 and is attacked by butylamine to produce the aminated product, **2** (k_7). The exciplex also interacts with such olefins as COT or CHD to be quenched (k_8; exciplex quenching). The quantum yield of the photoamination *via* the $S_1(^1CT)$, $\Phi_{air}(^1CT)$, can be written as Eq. 7:

$$\Phi_{air}(^1CT) = \left(\frac{k_5[O_2]}{1/\tau_s+k_5[O_2]}\right)\left(\frac{k_7[A]}{k_6+k_7[A]}\right)\beta, \quad (7)$$

where A=butylamine, τ_s=the lifetime of the $S_1(^1CT)$ state, and β=the yield of the aminated product, **2**, for every collision between the exciplex and the amine. The reciprocal of the quantum yield is thus expressed by

$$1/\Phi_{air}(^1CT) = \left(1+\frac{1}{\tau_s\cdot k_5[O_2]}\right)\left(1+\frac{k_6}{k_7[A]}\right)\frac{1}{\beta}. \quad (8)$$

When COT is present, the Stern-Volmer equation may be expressed by

$$\Phi_0(^1CT)/\Phi(^1CT) = 1 + \frac{k_8[COT]}{k_6+k_7[A]}. \quad (9)$$

Hence, the following values are estimated from the ratio of the slope to the intercept in the linear plot of Fig. 6 and Eq. 8, and from the slope in the Stern-Volmer plot of Fig. 7 and Eq. 9:

$k_6/k_7 = 2.5\times10^{-2}$ mol/dm^3, $k_8/(k_6+k_7[A]) = 41$ dm^3/mol,

where $A=5.0\times10^{-2}$ mol/dm^3.

Assuming the exciplex quenching rate constant, k_8, to be diffusion-controlled (9.2×10^9 dm^3 mol^{-1} s^{-1}), k_6 and k_7 may be calculated to be 7.5×10^7 s^{-1} and 3.0×10^9 dm^3 mol^{-1} s^{-1} respectively. Thus, the lifetime of the exciplex $[AQ^{\delta+}\cdots O_2^{\delta-}]$ was estimated to be about 13 ns. It may be significant that the lifetime of an exciplex such as $[AQ^{\delta+}\cdots O_2^{\delta-}]$ could be successfully estimated by means of this kinetic treatment, though in most cases the exsistence of a 'non-emmisive exciplex' on the reaction pathway is difficult to verify and its lifetime can hardly be estimated at all. The other reaction pathway is the photoamination *via* the $T_1(^3CT)$ level of **1**.[12] The quantum yield can be expressed by Eq. 6.

In Table 2 the rate constants obtained in this study are compared with those obtained in benzene, together with the rate constants in the case of 1-amino-4-bromo-

Table 2. Rate constants in the photoamination of **1** and **5** by butylamine

Anthraquinones		k_1 / s^{-1}	k_2 / dm^3/mol s	k_6 / s^{-1}	k_7 / dm^3/mol s
1	in ethanol	2.0×10^5	5.4×10^8	7.5×10^7	3.0×10^9
	in benzene	2.8×10^7	5.7×10^7	——	——
5	in ethanol	——	——	1.8×10^8	9.0×10^9
	in benzene	2.1×10^7	2.1×10^8	——	——

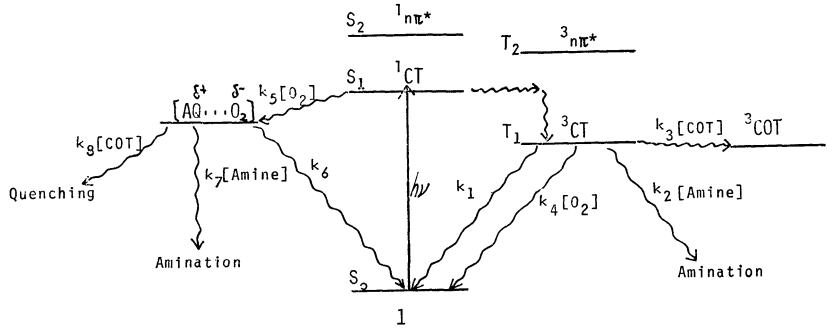

Fig. 8. Reaction scheme of the photoamiantion of **1** by butylamine under air atmosphere in ethanol.

anthraquinone (**5**) estimated by a similar kinetic treatment.

Contrary to the usual solvent effect, the deactivation constant, k_1, from the $T_1(^3CT)$ level is revealed to be one order of magnitude smaller in ethanol than that in benzene. This may be well correlated with the energy diagram of the excited state of **1** in ethanol and benzene shown in Fig. 1. In benzene, the $S_1(^1CT)$ state is supposed to interact more strongly with the $T_2(^3n\pi^*)$ state than in ethanol because of a close contiguity or a reversal of the disposition of $S_1(^1CT)$ and $T_2(^3n\pi^*)$, as is depicted in Fig. 1b). Hence, the $S_1(^1CT)$ state may interact more strongly with the $T_1(^3CT)$ state in benzene than in ethanol through the interaction among $S_1(^1CT)$, $T_2(^3n\pi^*)$, and $T_1(^3CT)$ states. The deactivation process (k_1) from the $T_1(^3CT)$ to the ground state, S_0, may borrow a part of the transition moment between the S_0 and the $S_1(^1CT)$ as a result of the mixing of the $S_1(^1CT)$ and $T_1(^3CT)$ states. Therefore, a larger deactivation from the $T_1(^3CT)$ may occur in benzene than in ethanol. It may also be noted that the deactivation constants, k_1, from the $T_1(^3CT)$ state of **1** and **5** in both ethanol and benzene are one or two orders of magnitude larger than that of 1-aminoanthraquinone (**4**) ($k_1=2\times10^5\ s^{-1}$),[11] which has no bromine atom in the molecule. These results clearly support the postulate that the heavy-atom effect on the spin-orbit interaction may be enhanced in **1**, which bears two bromine atoms. As has been reported in an earlier paper, the fluorescence intensity of **1** in benzene decreased by a factor of one-tenth as compared with that in ethanol.[6] This could also be successfully explained by the difference in the energy diagram with the alteration in the nature of the solvent (Fig. 1). On the other hand, the fluorescence intensity of **4** in benzene increased by a factor of 1.5 as compared with that in ethanol, in accordance with the usual solvent effect. Since **4** is supposed to have much the same energy diagram as that of **1** as has been stated before, this contradicting solvent effect on the fluorescence intensity may indicate that the close contiguity of the disposition of $S_1(^1CT)$ and $T_2(^3n\pi^*)$ and the spin-orbit interaction promoted by the intramolecular heavy-atom effect both play significant roles in the enhanced intersystem crossing between the $S_1(^1CT)$ and the $T_2(^3n\pi^*)$ of **1** in benzene.

Synthesis of (±)-Dihydrofomannosin Acetate[1)]

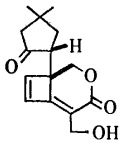
Hiroshi Kosugi* and Hisashi Uda

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-2, Sendai 980

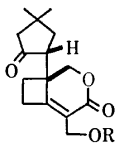
(Received April 19, 1979)

The synthesis of (±)-dihydrofomannosin acetate [5-acetoxymethyl-1-(4,4-dimethyl-2-oxocyclopentyl)-3-oxabicyclo[4.2.0]oct-5-en-4-one] is described. Photocycloaddition of 4-(2-acetoxy-4,4-dimethylcyclopentyl)-2(5*H*)-furanone to ethylene gave 5-(2-acetoxy-4,4-dimethylcyclopentyl)-3-oxabicyclo[3.2.0]heptan-2-one, which was converted into ethyl [2-acetoxymethyl-2-(2-acetoxy-4,4-dimethylcyclopentyl)cyclobutyl]glyoxylate by the reaction with 2-methylthio-1,3-dithiane, followed by acetylation and ethanolysis. Introduction of an additional one carbon unit to the glyoxylate was accomplished by the Wittig reaction, and the subsequent hydrolysis and lactonization afforded 1-(2-hydroxy-4,4-dimethylcyclopentyl)-5-methylene-3-oxabicyclo[4.2.0]octan-4-one, which was transformed into 5-acetoxymethyl-5-hydroxy-1-[4,4-dimethyl-2-(tetrahydropyranyloxy)cyclopentyl]-3-oxabicyclo[4.2.0]-octan-4-one. Mesylation followed by elimination and oxidation led to (±)-dihydrofomannosin acetate.

Fomannosin (**1**) is a biologically active sesquiterpene first isolated from the still culture of the wood-rotting fungus Basidiomycete *Fomes annosus* (Fr.) Karst[2)] and subsequently from *Fomitopsis insularis*,[3)] and has been found toxic toward *Pinus tadea* seedlings, *Chlorella pyrenoidosa*, and some bacteria.[4)] The unusual B-*seco*-protoilludane structure of fomannosin was determined by an X-ray study of the *p*-bromobenzoylurethane derivative of dihydrofomannosin (**2**).[2)] Recently, X-ray crystallography of the (−)-camphenate of **2** led to the establishment of its absolute configuration.[5)] The synthesis of fomannosin and its derivative seems to be of interest from structural and biological points of view. However, fomannosin is very unstable,[2)] and our initial efforts in synthetic studies have been directed towards the synthesis of dihydrofomannosin (**2**) or its acetate **3**. In view of the recent work on



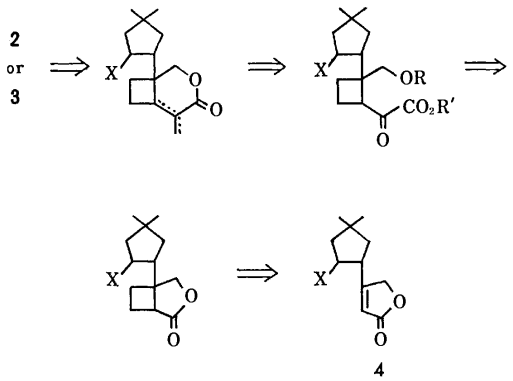
1



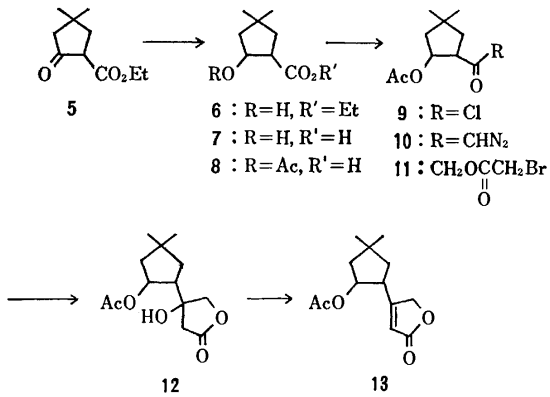
2 : R=H
3 : R=Ac

the photocycloaddition reaction of $\Delta^{\alpha,\beta}$-butenolides [2(5*H*)-furanones] with ethylene,[6)] we adopted Scheme 1 involving the photo-process on a suitably substituted butenolide **4** and the ring enlargement of a γ-lactonic photo-adduct to a δ-lactone system for construction of the fomannosin skeleton.[7)]

Our first step was to prepare the β-substituted $\Delta^{\alpha,\beta}$-butenolide **13** as a key intermediate. Three routes (Schemes 2—4) were examined for this purpose. Firstly, the intramolecular Reformatsky reaction of (bromoacetoxy)methyl ketones,[8)] a method for the synthesis of β-substituted butenolides, was applied. 2-Ethoxycarbonyl-4,4-dimethylcyclopentanone (**5**) was converted into the acetoxy carboxylic acid **8** by the usual procedure. The carboxyl group of **8** could be then transformed into the (bromoacetoxy)methyl ketone function through the standard steps[8)] to give the desired ketone **11** (Scheme 2). The Reformatsky reaction of **11** in the presence of ethyl bromoacetate[8)] followed by dehydration of the resulting hydroxy lactone **12** with alumina afforded the key butenolide **13** in 60% yield. In practice, however, this route appeared to be disadvantageous because of the low yield (<9.6% overall from **5**), requiring multistage operations and separation.

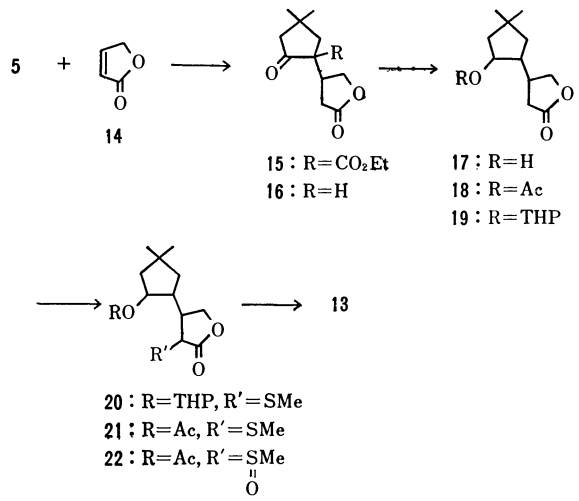


Scheme 1.



Scheme 2.

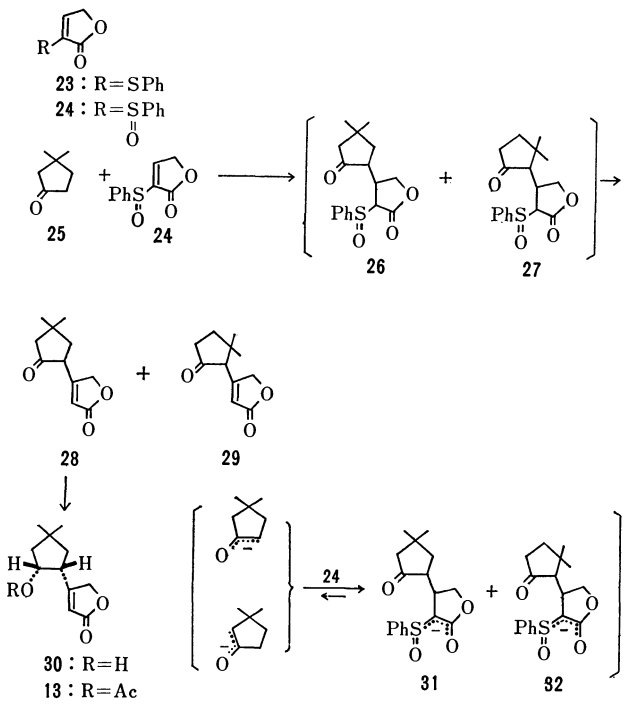
We adopted, as the second Scheme, introduction of the double bond at the α,β-position of a suitable γ-butyrolactone derivative such as **18** or **19**. The Michael reaction of **5** with γ-crotonolactone (**14**) afforded the adduct **15** in 66% yield, use of excess **14** being essential for a good yield of **15**. The adduct **15** was decarboxylated to give the keto lactone **16** in 74% yield, which was reduced to the hydroxy lactone **17**. Attempt to introduce unsaturation to the lactone moiety of the acetate **18** by the usual bromination-dehydrobromination was unsuccessful; bromination gave an intractable mixture. We examined the sulfenylation-dehydrosulfenylation procedure recently developed by Trost *et al.*[9)] Reaction of the enolate of the tetrahydropyranyl ether derivative **19** with



Scheme 3.

dimethyl disulfide afforded the α-methylthio lactone **20** in 60% yield. From the fact that a tetrahydropyranyloxy group is somewhat sensitive to UV irradiation (partial decomposition) at this stage, the protecting group was exchanged by an acetyl group. Oxidation of the acetoxy derivative **21** and subsequent pyrolysis of the resulting sulfoxide **22** gave **13** in 60% yield from **20** (Scheme 3). Thus, the desired compound **13** was available in moderate yield. However, the route also seems to be practically inconvenient for the preparation of **13** on a larger scale.

During the course of this study, it was found that α-phenylthio- (**23**) or α-phenylsulfinyl-$\Delta^{\alpha,\beta}$-butenolide (**24**) is an efficient carbanion acceptor in the Michael reactions and the use of **23** or **24** provides a high-yield and convenient method for the synthesis of butenolides having various substituents at the β-position.[10] The method should be applicable to the present case. Reaction of the enolate of **5** with either of **23** or **24** resulted in the formation of only self-polymerization product of **23** or **24**, indicating that the enolate of **5** acts as a base rather than the Michael addend.[10] This suggests that a much stronger nucleophilic enolate should be employed as an addend to achieve the Michael reaction. 3,3-Dimethylcyclopentanone (**25**) was chosen for this purpose. The Michael reaction of **24** with the lithium enolate of **25** proceeded smoothly at −68 °C, as expected, to produce the adduct **26** and **27**, which was dehydrosulfenylated, without separation, in refluxing toluene giving two separable keto butenolides **28** and **29** in 54 and 18% yields, respectively (Scheme 4). In the NMR spectra, the methine proton α to the keto group was observed as a broad triplet (J=10.5 Hz) at δ 3.45 in the major product **28**, but as a broad singlet at δ 3.40 in the minor one **29**, indicating that **28** is the desired compound and **29** the regioisomer. On the other hand, the reaction of the α-phenylthio lactone **23** with **25** gave a singel adduct (38% yield), which was confirmed to be the phenylthio analogue of **26** by transformation into **13** *via* **28**. The precursor **27** of the minor isomer **29** should be sterically less favorable than the major precursor **26**. The actual formation of **27** can be attributed to the formation of

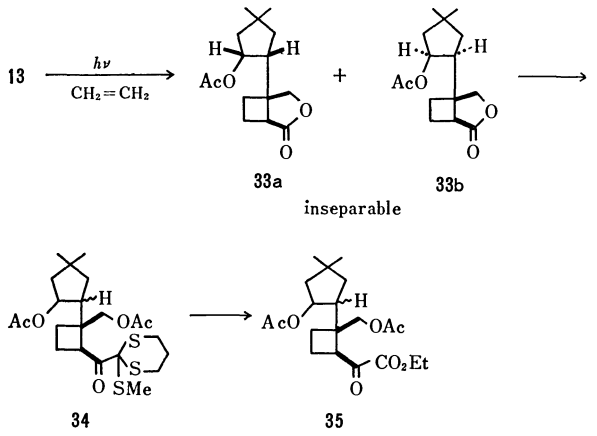


Scheme 4.

the relatively tight bonding between lithium cation and the effectively stabilized carbanion intermediate **32** together with **31**[10] from the equilibrated enolate of **25**. Such a tight bonding would prevent the reversible process (**32**→**24**+**25**) under the conditions employed, resulting in slight loss of the regioselectivity in the reaction. Reduction of **28** with sodium borohydride afforded the single crystalline hydroxy butenolide **30**, mp 36—37 °C, which was acetylated to give **13** in 74% yield. The spectral properties were compatible with the assigned structure **13**. Assignment of the *cis* configuration of two vicinal substituents on the cyclopentane ring of **13** follows from the steric course of the reaction and the NMR coupling pattern of the proton at the carbon atom bearing the acetoxyl group: doublet (J=6.0 Hz, *trans* coupling) of triplet (J=7.5 Hz, *cis* coupling) at δ 5.12.

According to the procedure of Kosugi *et al.*,[6] a solution of **13** in acetone with moderately rapid introduction of ethylene was irradiated at −50— −60 °C with a 500 W high-pressure mercury lamp without filter giving an 85% yield of the 1:1 photoadduct **33** (Scheme 5). From the NMR spectrum, the photoadduct was found to be a mixture of stereoisomers **33a** and **33b**. The ratio of **33a** and **33b** could not be determined at this stage, since the product was homogeneous on thin layer chromatography, and the NMR spectrum revealed no distinctly separated signals. Actual separation of the stereoisomers was carried out at a later stage.

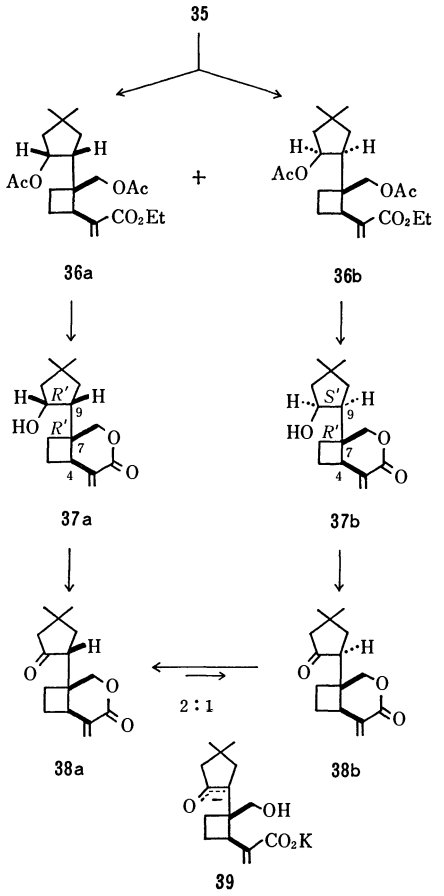
The next step to elaborate the fomannosin skeleton was one carbon elongation of the lactone-carbonyl position. Among a number of agents, 2-methylthio-1,3-dithiane[11] was chosen as a carboxyl equivalent. The photoadduct **33** was treated with lithiated 2-methylthio-1,3-dithiane, followed by acetylation giving the ring-opened product **34** in 74% yield. Mercury(II) ion-



Scheme 5.

catalyzed ethanolysis of **34** gave the glyoxylate **35** in high yield, which apparently consists of about equal amounts of two stereoisomers as detected by the NMR spectrum. The prominent peaks were observed as the pairs with about equal intensities. Although an α-methylene-δ-lactone structural unit has been found to a lesser extent than an α-methylene-γ-lactone unit in naturally occurring compounds, it is of growing importance from the viewpoint of its biological activities, *e.g.*, vernolepin. The glyoxylate **35** can be easily converted into an α-methylene-δ-lactone derivative **37**. The sequential reactions developed in the present study [(i) nucleophilic attack of the anion of 2-methylthio-1,3-dithiane, (ii) acetylation and ethanolysis, (iii) a Wittig reaction, and (iv) hydrolysis and lactonization] would provide a convenient method for the synthesis of α-methylene-δ-lactones from readily available γ-lactones.[12]

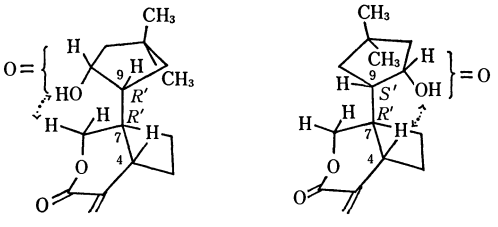
The next step was to extend the keto group of **35** by an additional one-carbon unit. A methylene function would be most suitable for leading to the final functionality, an allylic hydroxy- or acetoxymethyl grouping, of the synthetic targets, and would be introduced easily by the Wittig reaction.[13] However, it was found that the reaction of **35** with methylenetriphenylphosphorane in the standard way (generated by dimsylsodium in dimethyl sulfoxide or butyllithium in ether) is unsatisfactory because of very low yields of the product. Observation of the rapid consumption of the starting material **35** and of the low recovery after work-up in the above experiments suggests that the use of polar media probably caused further undesirable side reactions. A less polar medium, benzene, was employed as a co-solvent for the reaction. Inverse slow addition of a reagent solution in dimethyl sulfoxide to a solution of **35** in benzene afforded a high yield of the product **36**. At this stage, the stereoisomers could be separated by preparative thin layer chromatography to give the α-methylene esters **36a** and **36b** in 33 and 32% yields, respectively. Each isomer **36a** or **36b** was hydrolyzed with potassium hydroxide, and the resulting dihydroxy carboxylic acid was treated with *p*-toluenesulfonic acid in refluxing benzene giving, without double bond isomerization, the α-methylene-δ-lactone **37a** or **37b** in a high yield. The observed significant differences in the physical properties of



Scheme 6.

these isomers were the NMR coupling patterns of the lactonic methylene protons (–CH_2–O–CO–): an AB type quartet (J=12 Hz) at δ 4.20 in **37a** and a singlet at δ 4.07 in **37b**, and the chemical shift values of the allylic methine protons: δ 3.14 (dd) in **37a** and 3.43 (dd) in **37b**. Such characteristics were also observed in the corresponding keto lactones **38**: the lactonic methylene protons appeared as an AB type quartet (J=11 Hz) at δ 4.16 in **38a**, while a singlet at δ *ca.* 3.90 in **38b**, and the allylic methine protons appeared at δ 3.10 (br s) in **38a** and at δ *ca.* 3.80 (br s) in **38b**, respectively.

We now considered the stereochemical features of these isomeric lactone derivatives with Dreiding models, in order to establish whether the a-series or b-series lactone would possess the same stereochemistry as that of fomannosin. As shown in Scheme 6, one series has the same (7*R*′,9*R*′)[14] configuration as that of fomannosin,[16] the other having the (7*R*′,9*S*′) configuration. In both series, the conformations, in which the cyclopentane ring (especially the part of

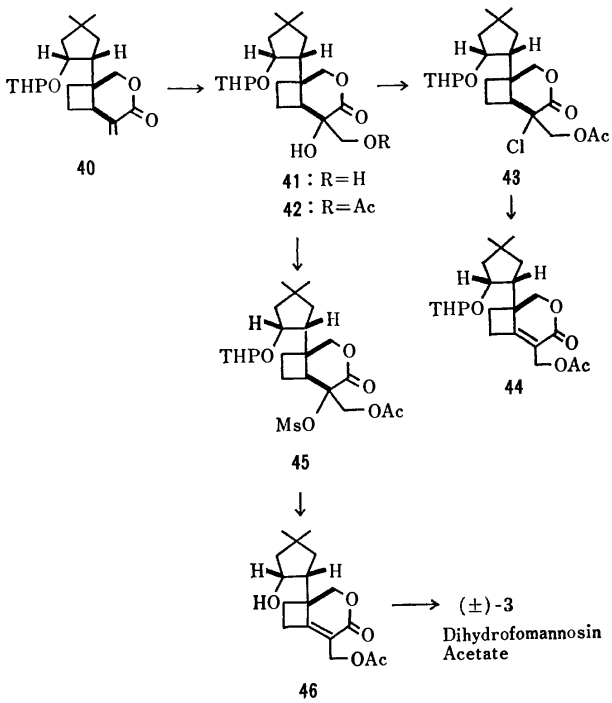


37a, 38a **37b, 38b**

the dimethyl groups) is so oriented as to be far from the bicyclic lactone ring system, the lactone ring being bisected by the methine hydrogen on the cyclopentane ring, could be postulated to be the sterically favorable conformations as shown by the stereoformulae. If so, in the (7*R*′,9*R*′)-series compounds the hydroxyl or carbonyl group on the cyclopentane ring is located close to the lactonic methylene group and apart from the allylic methine hydrogen at C-4, and therefore, the anisotropic effect of the oxygen-functions may cause a somewhat large difference in the chemical shifts of two methylene protons, resulting in the appearance as an AB type quartet. Almost no shift would be expected in the signal of the allylic methine proton upon conversion of the hydroxyl into the keto group. Contrary to the (7*R*′,9*R*′)-series, in the case of the (7*R*′,9*S*′)-series compounds the hydroxyl or carbonyl group on the cyclopentane ring should be far from the lactonic methylene group, approaching to the allylic methine hydrogen. Thus, lactonic methylene protons would appear as a singlet (alomost same chemical shifts), and the allylic proton signal at a lower field than that of the corresponding (7*R*′,9*R*′)-isomer, shifting markedly upon conversion of the hydroxyl into the keto group. The compounds (a-series) exhibiting an AB type quartet methylene signal should be the desired (7*R*′,9*R*′)-stereoisomers **37a** and **38a**. The assignment was confirmed by completion of the synthesis of dihydrofomannosin acetate from **37a**.[17] The spectral properties of the b-series compounds **37b** and **38b** were also in good agreement with expectation for the (7*R*′,9*S*′)-configuration.

At this point a remark regarding the relative stabilities between the stereoisomers is appropriate. After treatment of pure **38b** with excess potassium hydroxide in aqueous dioxane–methanol at room temperature overnight, the keto lactone **38** was recovered through acidification and lactonization. The recovered material was found to be a *ca.* 2:1 mixture of **38a** and **38b** as determined by a comparison of the NMR peak areas of the respective lactonic methylene protons. Thus, in the ring-opened state **39** the (7*R*′,9*R*′)-stereoisomer leading to **38a** was slightly more stable than the (7*R*′,9*S*′)-one.

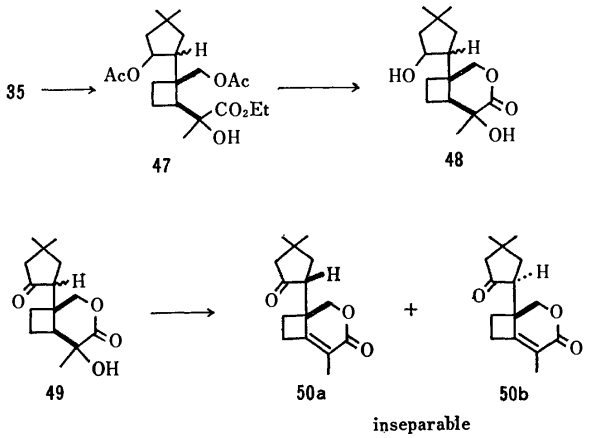
Of the compounds **37a** and **38a**, both having the proper stereochemistry and functionalities for the synthesis, **37a** appeared to be the better precursor, since the use of **38a** would cause some complexity (epimerization *etc.*) upon subsequent operations. For the remaining functional group manipulation,  ⟶  (R=H or Ac), allylic oxidation-rearrangement with singlet oxygen[18] or selenium dioxide[19] would be the most promising procedure. However, all attempts to achieve the allylic oxidation-rearrangement of **37a** or the acetate with singlet oxygen or selenium dioxide under various conditions were unsuccessful. Thus, a stepwise scheme (Scheme 7) was adopted.



Scheme 7.

The tetrahydropyranyl ether **40**, derived from **37a**, was hydroxylated with osmium tetraoxide-pyridine in ether, and the resulting dihydroxy lactone **41** was acetylated to the monoacetate **42** in 69% yield. Dehydration of **42** with the common agents (thionyl chloride or phosphoryl chloride in pyridine) was found to be quite troublesome. The reactions were extremely slow and the chloride **43** initially formed resisted subsequent dehydrochlorination enormously giving only a trace of the unsaturated lactone **44**. Compound **42** was then treated with methanesulfonyl chloride in the presence of triethylamine to give quantitatively the unstable mesylate **45**. Demesylation of crude **45** was accomplished by heating with lithium chloride-lithium carbonate in *N*,*N*-dimethylformamide, providing directly the unsaturated hydroxy lactone **46** along with several by-products. The Jones oxidation of **46**, without isolation, gave after chromatographic separation, (±)-dihydrofomannosin acetate (**3**), mp 102—103 °C, in 20% yield from **45**. The spectral [IR, NMR (60 and 100 MHz), and mass] and chromatographic behaviors were identical with those of the authentic sample prepared from dihydrofomannosin derived from natural fomannosin. Furthermore, we examined the preparation of (±)-dihydrofomannosin (**2**) itself. It was found that **3** and **2** seem to be base-sensitive; saponification of **3** resulted in the formation of a complex mixture.

An attempt to synthesize (±)-deoxydihydrofomannosin (**50a**) should be mentioned (Scheme 8). Treatment of the glyoxylate **35** with methyllithium gave the hydroxy ester **47**, which was converted into the dihydroxy lactone **48** through hydrolysis and lactonization in the same manner; there was no indication of cyclization to a tetrahydrofuran derivative. The Jones oxidation of **48** afforded the hydroxy keto lactone **49**. In the case of **49**, dehydration with thionyl chlo-



Scheme 8.

ride–pyridine proceeded well to give selectively the *endo*-unsaturated lactone. The product was apparently a *ca.* 1:1 mixture of the stereoisomers **50a** and **50b**, which were inseparable. In the NMR spectrum, the signals due to the lactonic methylene protons were observed as a set of an AB type quartet and a singlet. The isomer revealing an AB type quartet should be (±)-deoxydihydrofomannosin (**50a**).

Experimental

All melting points were taken on a Yamato melting point apparatus and are uncorrected. Small amounts of liquid products were purified by evaporative short-path distillation; oil-bath temperatures are recorded. IR spectra were obtained with a Hitachi EPI-S2 or G2 spectrophotometer, NMR spectra with a JEOL PMX-60 (60 MHz), C-60HL (60 MHz), or PS-100 (100 MHz) instrument with TMS as an internal standard, coupling constants being given in Hz, and mass spectra with a Shimadzu LKB-9000 spectrometer at 70 eV. Silica gel (Merck GF-254) was used for preparative and analytical thin-layer chromatography (TLC); solvent systems are indicated in parentheses. Microanalyses were carried out at this Institute.

*4-(2-Acetoxy-4,4-dimethylcyclopentyl)-2(5H)-furanone (**13**).* *Route a*: 2-Acetoxy-4,4-dimethylcyclopentyl (bromoacetoxy)-methyl ketone (**11**) was prepared from 2-ethoxycarbonyl-4,4-dimethylcyclopentanone (**5**)[20] in 16% overall yield through six steps by a procedure similar to that reported.[8] Activated zinc powder (1.56 g, 3 equiv) was added portionwise under stirring and gentle refluxing to a solution of **11** (2.65 g, 8 mmol), ethyl bromoacetate (1.0 g, 0.6 mmol), and iodine (a catalytic amount) in anhydrous benzene (40 ml). After vigorous reaction ceased, refluxing and stirring were continued for 2 h. Acetic acid (2 ml) and methanol (1 ml) were added in succession to the cooled reaction mixture, and the resulting mixture was diluted with water. The water layer was extracted with ether. The combined organic layers were washed with an aqueous solution of sodium hydrogencarbonate, water, and saturated brine, and dried over anhydrous sodium sulfate. After removal of the solvent, the oily residue (1.6 g) was dissolved in acetic anhydride (20 ml) and heated under reflux for 24 h. Concentration of the solution under reduced pressure and chromatography of the concentrate on silica gel (50 g) using $CHCl_3$ as an eluant gave **13** (437 mg, 48%).

Route b: To a slurry of potassium *t*-butoxide (4.93 g, 44 mmol) in anhydrous benzene (25 ml) was added dropwise a solution of **5** (7.4 g, 40 mmol) in anhydrous benzene (35 ml) at room temperature under nitrogen. After stirring at room temperature for 2 h, the solution was concentrated under reduced pressure, and the concentrated enolate was dissolved in DMSO (25 ml). To this solution was added dropwise a solution of γ-crotonolactone (**14**) (8.2 g, 0.1 mol, 2.5 equiv) in DMSO (25 ml) with ice-water cooling under nitrogen. After being stirred at room temperature for 12 h, the reaction mixture was poured into ice-water, neutralized with 10% sulfuric acid, and extracted with ether. The combined extracts were washed with water and brine, and dried. Evaporation of the solvent gave a stereoisomeric mixture of 4-(1-ethoxycarbonyl-4,4-dimethyl-2-oxocyclopentyl)tetrahydro-2-furanone (**15**) (6.06 g, 66%): bp 160—165 °C/1.5 Torr; IR ($CHCl_3$) 1780, 1750, 1720, 1180, and 1020 cm^{-1}; NMR ($CDCl_3$) δ 1.16 (6H, s) 1.28 (3H, t, J=7.0), 1.70—3.40 (7H, m), 4.20—4.75 (2H, m), and 4.25 (2H, q, J=7.0). Found: *m/e* 268 (M^+). Calcd for $C_{14}H_{20}O_5$: M 268.

A mixture of **15** (3.82 g) and an aqueous 20% perchloric acid solution was heated at 80—90 °C with vigorous stirring for 12 h and then at the refluxing temperature for 1 h. After cooling, the product was extracted with ether. The combined extracts were washed with water and brine, and freed from the solvent. Distillation of the oil remaining afforded 4-(4,4-dimethyl-2-oxocyclopentyl)tetrahydro-2-furanone (**16**): bp 135—145 °C/1.5 Torr; IR (CCl_4) 1780, 1740, 1170, and 1030 cm^{-1}; NMR ($CDCl_3$) δ 1.07 (3H, s), 1.20 (3H, s), and 3.90—4.90 (2H, m). Found: C, 67.21; H, 7.90%. Calcd for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

To a solution of **16** (2.0 g, 10 mmol) in methanol (80 ml) was added portionwise sodium borohydride (550 mg, 15 mmol) under cooling in an ice–water bath, and the reaction mixture was stirred at 0 °C for 1.5 h and at room temperature for 1 h. After the reaction was quenched by the addition of dilute hydrochloric acid (2 M), the solution was concentrated under reduced pressure. The residual semi-solid was dissolved in $CHCl_3$, the resulting solution being washed with brine. Evaporation of the solvent and distillation of the residue gave 4-(2-hydroxy-4,4-dimethylcyclopentyl)tetrahydro-2-furanone (**17**) (1.52 g, 77%): bp 145—155 °C/1.5 Torr; IR ($CHCl_3$) 3450 and 1760 cm^{-1}; NMR ($CDCl_3$) δ 1.02 (3H, s), 1.10 (3H, s), 2.40 (1H, s, OH), and 3.70—4.70 (3H, m). Found: C, 66.75; H, 8.95%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

A solution of tetrahydropyranyl ether **19** (2.83 g, 10 mmol), prepared from **17** by the standard method, in THF (6 ml) was added dropwise at −60 °C over a period of 10 min under nitrogen to a solution of lithium diisopropylamide (20 mmol) in anhydrous ether (14 ml) and THF (5 ml). After stirring at −60 °C to −40 °C for 1 h, the reaction mixture was added dropwise to a solution of dimethyl disulfide (2 ml, 20 mmol) in THF (6 ml) at −35 °C, and the resulting mixture was allowed to warm slowly to room temperature over a period of 2 h with stirring. A saturated aqueous solution of ammonium chloride was added, the water layer being separated and extracted with ether. The combined organic layers were washed with water and brine, dried, and freed from ether. Chromatography of the residue (3.26 g) on silica gel (75 g) using petroleum ether–ether (the amount of ether was gradually increased, the final ratio being 2:1.) as an eluant gave 4-[4,4-dimethyl-2-(tetrahydropyranyloxy)cyclopentyl]-3-(methylthio)tetrahydro-2-furanone (**20**) (1.88 g, 60%): IR ($CHCl_3$) 1760, 1025, and 1015 cm^{-1}; NMR (CCl_4) δ 1.04 and 1.10 (total 6H, each s), 2.15 and 2.25 (total 3H), and 3.00—4.80 (7H, m). Found: C, 62.44; H, 8.92%. Calcd for $C_{17}H_{28}O_4S$: C, 62.17; H, 8.59%.

A solution of **20** (3.1 g) and hydrochloric acid (1 M, 4 ml)

in methanol (50 ml) was allowed to stand at room temperature for 4 h. The reaction mixture subjected to the usual work-up (dilution with water and extraction with ether) gave 4-(2-hydroxy-4,4-dimethylcyclopentyl)-3-(methylthio)tetrahydro-2-furanone (1.95 g, 84%): bp 120 °C/0.5 Torr; IR ($CHCl_3$) 3400, 1760, 1160, and 1015 cm^{-1}; NMR ($CDCl_3$) δ 1.00 (3H, s), 1.07 (3H, s), 2.25 and 2.27 (total 3H, each s), and 3.80—4.70 (3H, m). Found: C, 59.02; H, 8.55%. Calcd for $C_{12}H_{20}O_3S$: C, 59.00; H, 8.25%.

The above hydroxy lactone was acetylated in the usual way with acetic anhydride and pyridine to afford 4-(2-acetoxy-4,4-dimethylcyclopentyl)-3-(methylthio)tetrahydro-2-furanone (**21**): IR ($CHCl_3$) 1770, 1725, and 1020 cm^{-1}; NMR (CCl_4) δ 1.07 (6H, s), 1.98 (3H, s), 2.22 (3H, s), 3.20 (1H, m), 3.90—4.70 (2H, m), and 5.00 (1H, m).

A solution of sodium periodate (1.7 g, 8 mmol) in water (15 ml) was added dropwise at 0 °C to a solution of **21** (1.94 g, 6.8 mmol) in methanol (15 ml), and the reaction mixture was stirred at room temperature overnight. After removal of inorganic material by filtration, the filtrate was extracted with $CHCl_3$ three times. The combined extracts were washed with water and brine, dried, and evaporated. The residual oil was dissolved in pyridine (20 ml), and the resulting solution was heated under reflux for 3 h and evaporated under reduced pressure. The residue was dissolved in ether, the ethereal solution being washed with dilute hydrochloric acid, water, and brine, and evaporated. The residue was passed through a short column of silica gel with the aid of 1:1 petroleum ether–ether and distilled to give **13** (1.23 g, 76% from **21**): bp 140 °C/1 Torr.

Route c: To a solution of lithium diisopropylamide (0.03 mol) in anhydrous THF (20 ml) and hexane (20 ml) was added dropwise a solution of 3,3-dimethylcyclopentanone (**25**)[21] (3.36 g, 0.03 mol) in anhydrous THF (10 ml) at −60 °C under nitrogen, and the reaction mixture was stirred at −60 °C for 1 h. A solution of 3-phenylsulfinyl-2(5*H*)-furanone (**24**)[10] (6.9 g, 0.03 mol) in anhydrous THF (35 ml) was added to the above solution at −78 °C with stirring. After stirring at this temperature for 2 h, a saturated aqueous solution of ammonium chloride was added. The resulting solution was then neutralized with dilute sulfuric acid and extracted with ether three times. The combined extracts were washed with water and brine, dried, and evaporated. The residue was dissolved in toluene (150 ml), and the solution was heated under reflux for 30 min. Evaporation of the solvent under reduced pressure and chromatography on silica gel (150 g) using 4:6 petroleum ether–ether as an eluant gave 4-(4,4-dimethyl-2-oxocyclopentyl)-2(5*H*)-furanone (**28**) (3.17 g, 54%, faster eluted fraction): IR ($CHCl_3$) 1790, 1758, 1750, and 1638 cm^{-1}; NMR ($CDCl_3$) δ 1.15 (3H, s), 1.26 (3H, s), 2.24 (2H, s), 1.80—2.50 (2H, m), 3.45 (1H, br t, J=10.5), 4.80 (1H, a part of AB type q, finely split, J=18.0), 5.12 (1H, a part of AB type q, finely split, J=18.0), and 5.88 (1H, q, J=2.2), and 4-(2,2-dimethyl-5-oxocyclopentyl)-2(5*H*)-furanone (**29**): IR ($CHCl_3$) 1785, 1765, 1745, and 1630 cm^{-1}; NMR ($CDCl_3$) δ 0.93 (3H, s), 1.30 (3H, s), 1.70—2.70 (4H, m), 3.40 (1H, br s), 4.76 (1H, a part of AB type q, finely split, J=18.0), 5.00 (1H, a part of AB type q, finely split, J=18.0), and 5.96 (1H, q, J=2.2). Both **28** and **29** were fairly unstable, decomposing on storage, giving no satisfactory analytical data.

To a solution of **28** (2.31 g, 12 mmol) in anhydrous methanol (60 ml) was added portionwise sodium borohydride (464 mg, 12 mmol) at −15 °C over a period of 30 min, and the reaction mixture was stirred at −15 °C for 30 min. A few drops of glacial acetic acid was added, and the resulting solution was concentrated under reduced pressure. The residue was dissolved in $CHCl_3$, and the solution successively washed with dilute sulfuric acid, water, and brine. Evaporation of the solvent left the single crystalline product, 4-(2-hydroxy-4,4-dimethylcyclopentyl)-2(5*H*)-furanone (**30**) (2.01 g, 89%). An analytical sample was purified by preparative TLC (1:1 $CHCl_3$–ether) and then by recrystallization from 4:1:1 CCl_4–ether–petroleum ether: mp 36—38 °C; IR ($CHCl_3$) 3450, 1780, 1745, 1630, and 1030 cm^{-1}; NMR ($CDCl_3$) δ 1.12 (3H, s), 1.19 (3H, s), 1.30—2.20 (4H, m), 2.97 (1H, m), 3.55 (1H, OH), 4.13 (1H, q, J=9.5), 4.92 (2H, t, J=2.5), and 5.85 (1H, q, J=2.5). Found: C, 66.90; H, 8.39%. Calcd for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22%.

Compound **30** (1.79 g) was treated with pyridine (20 ml) and acetic anhydride (20 ml), and the reaction mixture was allowed to stand at 0 °C overnight. The usual work-up and purification by chromatography on silica gel (50 g) using 1:1 petroleum ether–ether as an eluant gave **13** (1.78 g, 82%): bp 120—130 °C/1 Torr; IR (CCl_4) 1785, 1745, and 1640 cm^{-1}; NMR (CCl_4) δ 1.12 (3H, s), 1.15 (3H, s), 2.00 (3H, s), 3.16 (1H, dt, J=10.5 and 7.5), 4.77 (2H, d, J=2.2), 5.12 (1H, td, J=7.5 and 6.0), and 5.83 (1H, td, J=2.2 and 1.2). Found: C, 65.45; H, 7.64%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

*5-(2-Acetoxy-4,4-dimethylcyclopentyl)-3-oxabicyclo[3.2.0]heptan-2-one (**33**).* A solution of **13** (1.9 g) in freshly distilled acetone (600 ml) was irradiated with a 500 W high-pressure mercury lamp (immersed, no filter) at −50—−60 °C with continuous introduction of finely dispersed ethylene. On this scale, the reaction was essentially completed within 3—5 h. Evaporation of the solvent left the product (2.4 g) which was chromatographed on silica gel (70 g) using petroleum ether–ether (the amount of ether was gradually increased, the final ratio being 6:4.) as an eluant to give an inseparable stereoisomeric mixture of **33** (1.80 g, 85%): bp 110—120 °C/1 Torr; IR (CCl_4) 1775, 1732, 1233, and 1020 cm^{-1}; NMR (CCl_4) δ 1.08 and 1.12 (total 6H, each s), 2.00 (total 3H, two singlets), 4.10 (2H, m), and 5.00 (1H, m). Found: C, 68.03; H, 8.10%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

*Ethyl [2-Acetoxymethyl-2-(2-acetoxy-4,4-dimethylcyclopentyl)cyclobutyl]glyoxylate (**35**).* 2-Methylthio-1,3-dithiane was prepared according to the procedure given by Ellison *et al.*:[11] bp 130—150 °C/4—5 Torr; NMR (CCl_4) δ 2.10 (3H, s) and 4.75 (1H, s). To a solution of 2-methylthio-1,3-dithiane (1.80 g, 11 mmol) in anhydrous THF (10 ml) was added dropwise a solution of butyllithium in hexane (5.7 ml of 1.9 M solution, 11 mmol) at −60 °C under nitrogen, and the mixture was stirred at −60 °C for 0.5 h. A solution of **33** (850 mg, 3.2 mmol) in anhydrous THF (8 ml) was added dropwise to the above solution at −60 °C, and the reaction mixture was allowed to warm to 0 °C over a period of several hours with stirring. A saturated aqueous solution of ammonium chloride was added, and the product was extracted with ether. The combined extracts were washed with water and brine, and dried. Evaporation of the solvent left an oily material which was treated with a mixture of acetic anhydride (18 ml) and pyridine (18 ml) at room temperature overnight. The mixture was evaporated to dryness under reduced pressure. Chromatography of the oil remaining on silica gel (50 g) using 2:1 petroleum ether–ether as an eluant gave the ring-opened product **34** (1.08 g, 71%): IR ($CHCl_3$) 1725 cm^{-1}; NMR (CCl_4) δ 1.10 (6H), 1.87 (3H), 2.04 (3H), 4.05 (2H), and 4.30—5.50 (1H). Found: *m/e* 474 (M^+). Calcd for $C_{22}H_{34}O_5S_3$: M 474.

To a slurry of mercury(II) chloride (3.31 g, 12.2 mmol) and mercury(II) oxide (1.35 g, 6.2 mmol) in 95% ethanol

(50 ml)[11] was added a solution of **34** (1.43 g, 3.0 mmol) in 95% ethanol (20 ml), and the reaction mixture was vigorously stirred at 80—90 °C for 2 h. After cooling to room temperature, inorganic material was removed by filtration and the filtrate concentrated under reduced pressure. The residue was dissolved in ether, the ethereal solution being washed with water and brine. Evaporation of the ether gave colorless oily **35** (990 mg, 85%), which was sufficiently pure to be used for subsequent treatment. An analytical sample was purified by preparative TLC (6:4 petroleum ether–ether) and then distilled: bp 120—130 °C/0.5 Torr; IR ($CHCl_3$) 1730 (sh) and 1720 cm^{-1}; NMR ($CDCl_3$) δ 1.07, 1.13, and 1.18 (total 6H, each s), 1.38 and 1.41 (total 3H, each t, J=7.0), 1.95 and 2.12 (total 6H, each s), 3.60—4.20 (3H, m), 4.35 (2H, q, J=7.0), and 4.77 and 5.33 (total 1H, each m). Found: C, 62.76; H, 8.02%. Calcd for $C_{20}H_{30}O_7$: C, 62.81; H, 7.90%.

*Ethyl 2-[2-Acetoxymethyl-2-(2-acetoxy-4,4-dimethylcyclopentyl)-cyclobutyl]propenoate (**36**).* A solution of methylenetriphenylphosphorane in DMSO (2.8 ml of 0.5 M solution, 1.4 mmol), prepared according to the procedure given by Greenwald *et al.*,[22] was added to a solution of **35** (420 mg, 1.1 mmol) in anhydrous benzene (10 ml) at 0 °C under nitrogen. After stirring at room temperature for 1—2 h, the reaction mixture was poured into ice–water containing a few drops of 2 M sulfuric acid, and the product was extracted with ether. The combined extracts were washed with water and brine, dried and freed from ether. Preparative TLC (6:4 petroleum ether–ether) of the residue (710 mg) gave **36a** (R_f 0.58, 137 mg, 33%) and **36b** (R_f 0.67, 124 mg, 32%). The analytical samples were purified by distillation, bp 110—120 °C/0.5 Torr. Isomer **36a** had IR ($CHCl_3$) 1720, 1624, and 1035 cm^{-1}; NMR (CCl_4) δ 1.10 (3H, s), 1.13 (3H, s), 1.32 (3H, t, J=7.5), 1.85 (6H, s), 2.70 (1H, m), 3.30 (1H, br t, J=*ca.* 8.0), 3.84 (2H, s), 4.17 (2H, q, J=7.5), 4.63 (1H, m), 5.40 (1H, m), and 6.13 (1H, m). Found: C, 66.04; H, 8.73%. Calcd for $C_{21}H_{32}O_6$: C, 66.30; H, 8.48%. Isomer **36b** had mp 51—53 °C (crystallized sample); IR ($CHCl_3$) 1718, 1625, and 1030 cm^{-1}; NMR ($CDCl_3$) δ 1.05 (3H, s), 1.13 (3H, s), 1.33 (3H, t, J=7.0), 1.90 (3H, s), 1.97 (3H, s), 3.47 (1H, br t, J=7.5), 3.70 and 4.00 (1H each, AB type q, J=7.0), 4.22 (2H, q, J=7.0), 5.47 (2H, br s), and 6.13 (1H, br s). Found: C, 66.55; H, 8.44%.

*1-(2-Hydroxy-4,4-dimethylcyclopentyl)-5-methylene-3-oxabicyclo-[4.2.0]octan-4-one (**37**).* A solution of **36a** (221 mg) in a mixture of dioxane (4 ml), an aqueous solution of potassium hydroxide (200 mg in 4 ml of water), and methanol (1 ml) was allowed to stand at room temperature overnight. After acidification with dilute sulfuric acid, the product was thoroughly extracted with $CHCl_3$. The combined extracts were washed with brine, and evaporated. The residue was dissolved in benzene (5 ml) containing a catalytic amount of fused *p*-toluenesulfonic acid, and the resulting solution was heated under reflux for 1 h. The reaction mixture was diluted with ether and washed successively with an aqueous solution of sodium hydrogencarbonate, water, and brine, and dried. Evaporation of the solvent under reduced pressure gave **37a** (146 mg, quantitative). A pure sample was obtained by preparative TLC (1:4 petroleum ether–ether), but further purification by distillation caused decomposition. Compound **37a** had IR ($CHCl_3$) 3400, 1720, 1628, 1030, and 940 cm^{-1}; NMR ($CDCl_3$) δ 1.04 (3H, s), 1.18 (3H, s), 2.50 (1H, OH), 3.14 (1H, dd, J=9.0 and 6.0), 4.10 (1H, m), 4.02 and 4.38 (1H each, AB type q, J=10.0), 5.36 (1H, br s), and 5.95 (1H, br s). Found: *m/e* 250 (M^+). Calcd for $C_{15}H_{22}O_3$: M 250.

In the same manner, isomeric **37b** was obtained from **36b** and had IR ($CHCl_3$) 3400, 1720, 1625, 1030, and 940 cm^{-1}; NMR ($CDCl_3$) δ 1.05 (3H, s), 1.15 (3H, s), 2.42 (1H, OH), 3.43 (1H, dd, J=9.9 and 6.0), 4.07 (2H, s), 4.20 (1H, m), 5.43 (1H, br s), and 5.96 (1H, br s). Found: *m/e* 250 (M^+).

*1-(4,4-Dimethyl-2-oxocyclopentyl)-5-methylene-3-oxabicyclo-[4.2.0]octan-4-one (**38**).* The hydroxy lactone **37a** (90 mg) was oxidized with Jones reagent[23] in the standard way to afford **38a** (81 mg, 91%). Similarly, isomeric **38b** (74 mg, 90%) was obtained from **37b** (81 mg). The analytical samples were purified by preparative TLC (1:1 petroleum ether–ether) and by distillation, bp 130—140 °C/0.1 Torr. Isomer **38a** had IR ($CHCl_3$) 1730, 1725, 1640, 1625, 1140, 1040, and 950 cm^{-1}; NMR (CCl_4) δ 1.06 (3H, s), 1.23 (3H, s), 3.10 (1H, br s), 3.94 and 4.38 (1H each, AB type q, J=11.0), 5.26 (1H, br s), and 5.83 (1H, br s). Found: C, 72.77; H, 7.99%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%. Isomer **38b** had IR ($CHCl_3$) 1740, 1730, 1640, 1625, 1140, 1042, and 950 cm^{-1}; NMR (CCl_4) δ 1.03 (3H, s), 1.10 (3H, s), *ca.* 3.90 [total 3H, br, two singlets of 2H and 1H (centered at *ca.* 3.80) were overlapped], 5.30 (1H, br s), and 5.90 (1H, br s). Found: C, 72.47; H, 7.77%.

A solution of **38b** (50 mg, 0.2 mmol) in a mixture of dioxane (1 ml), methanol (2 ml), and water (2 ml) containing potassium hydroxide (56 mg, 1 mmol, 5 equiv) was left at room temperature overnight. Work-up and the subsequent lactonization of the acidic product (52 mg) in the same way as described in the preceding experiment gave a *ca.* 2:1 mixture of **38a** and **38b** [total product (50 mg) isolated by passing through a short column of silica gel with the aid of ether] as determined by the NMR spectrum.

*1-[4,4-Dimethyl-2-(tetrahydropyranyloxy)cyclopentyl]-5-methylene-3-oxabicyclo[4.2.0]octan-4-one (**40**).* A solution of **37a** (59 mg, 0.23 mmol), dihydropyrane (21 mg, 0.28 mmol), fused *p*-toluenesulfonic acid (a catalytic amount) in CH_2Cl_2 (2 ml) was stirred at 0 °C for 1 h. After addition of a few drops of pyridine, the usual work-up and purification by chromatography on silica gel with ether gave **40** (70 mg, 92%): IR ($CHCl_3$) 1720, 1630, 1150, 1130, and 1028 cm^{-1}; NMR (CCl_4) δ 1.07 and 1.12 (total 6H, each s), 4.47 (1H), 5.27 (1H, br s), and 5.83 (1H, br s). Found: *m/e* 334 (M^+). Calcd for $C_{20}H_{30}O_4$: M 334.

*(±)-Dihydrofomannosin Acetate (**3**).* To a solution of **40** (180 mg, 0.53 mmol) and pyridine (536 mg, 6.5 mmol) in ether (3 ml) was added dropwise a solution of osmium tetraoxide (165 mg, 0.65 mmol) in ether (1.5 ml) at 0 °C under nitrogen,[24] and the reaction mixture was stirred at room temperature overnight. Pyridine (2.5 ml) and then an aqueous solution of sodium hydrogensulfite (270 mg in 3.5 ml) were added to the stirred mixture at 0 °C, and the stirring was continued at room temperature for 1 h. Water was added, and the product was thoroughly extracted with a 1:2:1 mixture of $CHCl_3$–ether–ethyl acetate. The combined extracts were successively washed with dilute sulfuric acid, water, and brine, and dried. The solvent was evaporated to leave the diol **41** (225 mg): IR ($CHCl_3$) 3500—3200 and 1720 cm^{-1}; NMR ($CDCl_3$) δ 1.03 and 1.11 (total 6H, each s).

This crude diol **41**, without further purification, was dissolved in a mixture of acetic anhydride (0.6 ml) and pyridine (1 ml) at 0 °C, and the mixture was allowed to stand at the same temperature for 1 h. The usual work-up and purification by preparative TLC (2:3 petroleum ether–ether) gave 5-acetoxymethyl-5-hydroxy-1-[4,4-dimethyl-2-(tetrahydropyranyloxy)cyclopentyl]-3-oxabicyclo[4.2.0]octan-4-one (**42**) (148 mg, 68%) as a mixture of stereoisomers:

IR ($CHCl_3$) 3300 and 1735 cm^{-1}; NMR ($CDCl_3$) δ 1.03 and 1.12 (total 6H, each s), 2.10 (3H, s), and 3.20—5.50 (9H). Found: *m/e* 410 (M^+). Calcd for $C_{22}H_{34}O_7$: M 410.

To a solution of **42** (144 mg, 0.35 mmol) and triethylamine (54 mg, 0.53 mmol) in CH_2Cl_2 (2 ml) was added dropwise a solution of methanesulfonyl chloride (48 mg, 0.42 mmol) in CH_2Cl_2 (1 ml) at 0 °C, and the reaction mixture was stirred at 0 °C for 45 min. The mixture was poured into ice–water, and the water layer was extracted with a 2:1:1 mixture of ether–CH_2Cl_2–ethyl acetate. The combined organic layers were washed with water and brine, and dried. Removal of the solvent gave the unstable mesylate **45** (180 mg, quantitative): IR ($CHCl_3$) 1740 cm^{-1}; NMR ($CDCl_3$) δ 1.10 and 1.17 (total 6H), 2.13 (3H, s), and 3.17 (3H, s).

A mixture of **45** (187 mg, 0.38 mmol), lithium chloride (160 mg), and lithium carbonate (112 mg) in DMF (3.5 ml)[25] was heated with stirring at 110 °C for 1 h and then at 160 °C for 2 h. After cooling, the reaction mixture was poured into ice–water and acidified with dilute sulfuric acid, and the product was extracted with a 1:1 mixture of ether–ethyl acetate. The extracts were washed with water and brine, and dried. Removal of the solvent left an oily **46** (128 mg), which was immediately dissolved in acetone and treated with Jones reagene at 0 °C by the standard procedure. The reaction mixture was diluted with water and extracted with a 1:1 mixture of ether–ethyl acetate. The combined extracts were washed with water and brine, dried, and evaporated to dryness. Preparative TLC (4:6 petroleum ether–ether) of the residue gave (±)-**3** (23 mg, 20%): mp 102—103 °C. The IR, NMR, and mass spectra and chromatographic behavior were identical with those of the authentic sample, which was prepared by acetylation of dihydrofomannosin (2 mg), derived from natural fomannosin, with acetic anhydride (0.1 ml) and pyridine (0.1 ml) at room temperature for 4 h.

*Deoxydihydrofomannosin (**50a**) and the Stereoisomer (**50b**).* To a solution of **35** (413 mg, 1.04 mmol) in anhydrous ether (10 ml) was added dropwise a solution of methyllithium in ether (1.5 ml of 1.0 M solution, 1.5 mmol) at −60 °C under nitrogen. The reaction mixture was stirred at −60 °C for 1 h and the reaction was quenched by the addition of a saturated aqueous solution of ammonium chloride. After the usual work-up, the crude product **47** (400 mg) was dissolved in dilute methanol (75%, 4 ml) containing potassium hydroxide (290 mg), and the resulting solution was heated at 68—70 °C for 2 h. Acidification with 4 M sulfuric acid to pH 1—2 and the usual work-up gave an acidic product (280 mg). A solution of this product in benzene (10 ml) containing a catalytic amount of fused *p*-toluenesulfonic acid was heated under reflux for 2 h. The solution was diluted with ether and washed with an aqueous solution of sodium hydrogencarbonate, water, and brine. Evaporation of the solvent left the dihydroxy lactone **48** (243 mg): IR ($CHCl_3$) 3580, 3500, 1730, and 1160 cm^{-1}.

The total crude **48** was oxidized with Jones reagent by the standard procedure gave the hydroxy keto lactone **49** (240 mg). An analytical sample was purified by preparative TLC (1:3 petroleum ether–ether) and then by distillation: bp 160—170 °C/0.05 Torr; IR ($CHCl_3$) 3520, 1735, 1160, 1140, and 1035 cm^{-1}; NMR ($CDCl_3$) δ 1.03 and 1.10 (total 3H), 1.25 and 1.27 (total 3H), 1.42 and 1.46 (total 3H), 3.65 (1H, OH), and 4.00 (d, J=12.0), 4.25 (d, J=12.0), 4.57 (d, J=12.0), and 4.68 (d, J=12.0) [total 2H, two pairs of AB type q]. Found: C, 67.44; H, 8.45%; *m/e* 266 (M^+). Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.86%, M 266.

Thionyl chloride (0.2 ml) was added to a solution of **49** (227 mg) in pyridine (2 ml) and the reaction mixture was heated at 60 °C for 1 h. The usual work-up gave an inseparable stereoisomeric mixture (*ca.* 1:1) of **50** (171 mg, 81%). An analytical sample was purified by preparative TLC (1:2 petroleum ether–ether) and then by distillation: bp 130—140 °C/0.05 Torr; IR ($CHCl_3$) 1730 and 1030 cm^{-1}; NMR (CCl_4) δ 1.10 and 1.12 (total 3H, each s), 1.25 (3H, s), 1.72 (3H, br. s), and 4.10 and 4.72 (a pair of AB type q, J=10.5, isomer **50a**) and 4.10 (s, isomer **50b**) [total 2H]. Found: C, 72.35; H, 8.05%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

We are grateful to Dr. J. K. Kepler, Research Triangle Institute, for the supply of dihydrofomannosin derived from natural fomannosin. This work was supported by a Grant-in-Aid for Encouragement of Young Scientist No. 974158 (for HK) and a Grant-in-Aid for Scientific Research No. 147028 (for HU) from the Ministry of Education.

Abnormal Nazarov Reaction. A New Synthetic Approach to 2,3-Disubstituted 2-Cyclopentenones

Shigeo HIRANO, Seiji TAKAGI, Tamejiro HIYAMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received July 3, 1979)

Acid-catalyzed reaction of β,β′-disubstituted cross conjugated dienones or the corresponding ethylene acetals gives mainly 2,3-disubstituted 2-cyclopentenones in stead of the simple Nazarov cyclization products, 3,4-disubstituted 2-cyclopentenones. This transformation is explained in terms of electrocyclic ring-closure, addition of hydroxylic solvent(s), tautomerization of the resulting 2-hydroxycyclopentanone intermediates, followed by solvolysis and isomerization. Based on this working hypothesis a new route to jasmonoids is disclosed which involves acid-treatment of the acyloin disilyl ethers derived from substituted glutarates.

Conjugated cyclopentenones[1] are the key compounds for the synthesis of natural products such as jasmonoids,[2] prostanoids,[3] and muscone[4] as well as of [*n*]-metacyclophanes.[5] Among various kinds of approach[1] to 2-cyclopentenones the Nazarov reaction[6] seemed attractive with respect to its simple operation, ready availability of the starting material and also to the mechanistic view point. We have studied the acid-catalyzed cyclization of β,β′-disubstituted cross-conjugated dienones or their ethylene acetals and observed the cyclization accompanied by transposition of the carbonyl group.[7] This unusual Nazarov reaction led us to explore an additional route to 2,3-disubstituted 2-cyclopentenones from 2-hydroxycyclopentanones or their enol disilyl ethers.

Acid-catalyzed Cyclization of Cross-conjugated Dienones ***1*** *or Their Ethylene Acetals* ***2*** *to 2-Cyclopentenones* ***3***. The starting dienones **1a**, **1b**, **1d** were prepared by usual hydrolysis of the corresponding ethylene acetals **2**[8] obtained by dibromination[9] and duplicated dehydrobromination of the saturated ketone acetals. Upon exposure to acidic conditions either **1** or **2**[10] afforded 2,3-dialkyl-2-cyclopentenones **3** in good yield (Scheme 1). Two acid systems, namely (A) phosphoric acid–formic acid (1:1) and (B) hydrobromic acid–acetic acid (1:3), were studied and the results are summarized in Table 1. Depending on the conditions and the substrates the Nazarov products, 3,4-dialkyl-2-cyclopentenones **4**, were produced to some extent, whose formation is understood by deprotonation of the oxyallyl cation **6** (Scheme 2) which is derived from the oxypentadienyl cation **5**[11] by electrocyclic conrotatory ring closure. The formal "shift" of the carbonyl group in the production of **3** is rationalized by assuming the attack of the hydroxylic solvents, such as water or carboxylic acids, onto **6** to yield **7**, which is subsequently converted to acyloin (and/or equivalents) **8** by tautomerization. Elimination of hydroxyl group

and isomerization of the resulting oxyallyl cation **9** afford the most stable one **10**, deprotonation of which should give **3**. The driving force of this cyclopentenone formation is ascribed to the thermal cyclization of pentadienyl cation **5** to cyclopentenyl cation **6** and the subsequent isomerization to the most stable allylic cation **10**. Notably, when the reaction was carried out in less nucleophilic solvent or procedure B, the yield of the by-product **4** increased considerably. Hereby deprotonation of **6** is probably competing with the solvent attack. Previous study on the Nazarov reaction[6] has dealt only with α,β-disubstituted cross-conjugated dienone system wherein the cyclized form **6** is easily deprotonated to give a thermodynamically most favorable dienone of type **4**. The β,β'-disubstituted dienones studied here appear to have never been subjected to the acidic conditions before.[12] The proposed mechanism has been confirmed by the regioselective dehydration of alternatively synthesized **8** affording **3** as described below.

Regioselective Synthesis of 2-Cyclopentenones **3** via *Acid-catalyzed Dehydration of 2-Hydroxycyclopentanones.* In general, acyloins are hardly dehydrated to the corresponding α,β-enones. However, the proposed mechanism shown in Scheme 2 involves dehydration of the acyloin (and/or equivalents) **8**. In order to verify this 2,3-dialkylglutarates **11** were transformed to enediol disilyl ethers **12**, which were exposed to phosphoric acid. Both hydrolysis and dehydration[14] took place in one pot to give 2,3-dialkyl-2-cyclopentenones **3**. The results are summarized in Table 2. Disilyl ethers **12d** and **12e** were preferentially transformed to **3d** and **3e** respectively and their regioisomers **4d**, **4e**, were not isolated (entry 1, 2). This process gives dihydrojasmone (**3f**) in good yields. The substrates having olefinic appendage turned out rather unstable under these conditions and gave allethrone (**3g**) and *cis*-jasmone (**3h**) in somewhat lower yields.[15]

Experimental

All the temperatures are uncorrected. PMR spectra were taken on a JEOL JNM-PMX 60 or Varian EM 390 spectrometer and chemical shifts are recorded in ppm unit. IR spectra were recorded on a Shimadzu IR-27G spectrometer, and MS on a Hitachi RMU-6L spectrometer with 70 eV.

Dibromination of Ketone Ethylene Acetals. A General Procedure. Bromine (100 mmol) was added dropwise to a solution of the saturated ketone acetal (50 mmol) in dry ether (100 ml) under cooling with water bath. The mixture was neutralized with monosodium ethylene glycolate (prepared from sodium (2.5 g) and ethylene glycol (100 ml)) and worked up as usual. The yield and physical properties of α,α'-dibromo ketone ethylene acetals are given in the following order: R^1, R^2 of $R^1CHBrC(O_2C_2H_2)CHBrCH_2R^2$, yield(%), bp or mp, IR, PMR, elemental analysis. $R^1=R^2=Et$ (see Ref. 9). R^1, $R^2=-(CH_2)_7-$, 99%, mp 133—134 °C (ethyl acetate), IR (Nujol): 1185, 1047, 957 cm^{-1}, PMR ($CDCl_3$): δ 1.1—2.2 (m, 18H), 4.35 (s, 4H), 4.48 (t, 2H), (Found: C, 43.8; H, 6.4%. Calcd for $C_{14}H_{24}Br_2O_2$: C, 43.8; H, 6.3%). R^1, $R^2=-(CH_2)_5-$, 100%, mp 76—77.5 °C (ethyl acetate), IR (Nujol): 1045, 949 cm^{-1}, PMR ($CDCl_3$): 1.3—1.9 (m, 10H), 2.0—2.5 (m, 4H), 4.4 (s, 4H), 4.70 (t, $J=6$ Hz, 2H), (Found: C, 40.3; H, 5.7%. Calcd for $C_{12}H_{20}Br_2O_2$: C; 40.5; H, 5.7%). $R^1=n$-C_5H_{11}, $R^2=H$, *ca.* 96%, bp 135 °C/0.08 Torr, IR (neat): 1198, 1076, 954 cm^{-1}, PMR (CCl_4): 0.7—1.1 (m, 3H), 1.70 (d, $J=6.5$ Hz, 3H), 1.1—2.0 (m, 10H), 4.25 (s, 4H), 4.0—4.7 (m, 2H), (Found: C, 40.0; H, 6.5%. Calcd for $C_{12}H_{22}Br_2O_2$: C, 40.3; H, 6.2%).

Cross-conjugated Dienone Ethylene Acetals **2**. A solution of α,α'-dibromo acetal (30 mmol) dissolved in dry DMSO (120 ml) was admixed with finely powdered potassium *t*-butoxide (100 mmol) and the mixture stirred for 3 h at room temperature for acyclic bromides or at 50 °C for cyclic ones. The resulting dark-brown mixture was treated with water (200 ml) and the product extracted with benzene. Product, yield (%) were as follows: **2a**, 88; **2b**, 97; **2c**, 91; **2d**, 85 (based on the acetal). Physical properties of these are listed in Table 3.

Cross-conjugated Dienones **1**. Dienone acetal **2** (5 mmol) dissolved in THF (30 ml) was vigorously shaken with 10% sulfuric acid at room temperature for 2 h. The resulting mixture was saturated with sodium chloride and the product was extracted with ether. Product, yield (%): **1a**, 97; **1b**, 96; **1d**, 62. Physical properties are summarized in Table 3.

Acid-catalyzed Cyclization of Cross-conjugated Dienones **1** *or Their Ethylene Acetals* **2** *into 2-Cyclopentenones* **3**. *Procedure A*: A mixture of dienone **1** or its ethylene acetal **2** (1.0 mmol), 85% phosphoric acid (2.5 ml), and 90% formic acid (2.5 ml) was stirred at 90 °C for 2—3 h under a nitrogen atmosphere. The resulting brown solution was quenched with water (15 ml) and stirred for additional 0.5 h. After extraction with benzene the extract was washed with water, aq sodium hydrogencarbonate solution and brine, then dried over sodium sulfate. Preparative TLC on silica gel or GLC (SE 30 or Dowfax 9N9 on Chromosorb) gave pure **3** and **4** (Table 1). The structural assignment is based upon either comparison with the respective authentic samples or spectrometric analysis (see Table 4).

TABLE 2. 2-CYCLOPENTENONES *via* DEHYDRATION OF 2-HYDROXYCYCLOPENTANONE DERIVATIVES

Entry	Glutarate	2-Hydroxycyclopentanone enol disilyl ether Yield/%[a]	2-Cyclopentenone Yield/%[a]

Procedure B: Dienone **1** or its ethylene acetal **2** (1.0 mmol) was cyclized by treatment with a mixture of 47% hydrobromic acid (2 ml) and acetic acid (6 ml) at 80—90 °C for 2 to 3 h. Work-up and product analysis were carried out as described above.

*2-Cyclopentenone **3** from 2-Hydroxycyclopentanone Enol Disilyl Ether **12**.* A mixture of acyloin disilyl ether **12** (1.0 mmol) and 57% phosphoric acid (4.5 ml) was stirred at 50—60 °C for 1.5—3 h under a nitrogen atmosphere. Work-up followed by preparative TLC on silica gel gave analytically pure **3** (Tables 2 and 4).

Diethyl 2-Alkyl-2-ethoxycarbonyl-3-methylglutarate. Introduction of Allylic Group: Into a suspension of sodium hydride (22 mmol) in dry 1,2-dimethoxyethane (20 ml) diethyl 2-ethoxycarbonyl-3-methylglutarate[16] (5.48 g, 20 mmol) dissolved in the same solvent (10 ml) was added over a period of 10 min under cooling with a water bath. After 1 h allyl bromide or *cis*-2-pentenyl bromide (22 mmol) was added and the mixture was stirred overnight. Work-up gave the desired products: diethyl 2-allyl-2-ethoxycarbonyl-3-methylglutarate, 79% yield, bp 135 °C/5 Torr; IR (neat): 1739, 1635 cm^{-1}; MS *m/e* 269 (M^+—OEt); (Found: C, 61.1; H, 8.5%. Calcd for $C_{16}H_{26}O_6$: C, 61.1; H, 8.3%); diethyl 2-ethoxycarbonyl-3-methyl-2-(*cis*-2-pentenyl)glutarate, 86% yield, bp 130—135 °C/0.07 Torr, IR (neat): 1739, 1728, 1187, 860 cm^{-1}, MS *m/e* 297 (M^+—OEt). (Found: C, 63.2; H, 9.0%. Calcd for $C_{18}H_{30}O_6$: C, 63.1; H, 8.8%).

Reaction with 1-Iodopentane: The anion of the triester was prepared as above and to the anion solution hexamethylphosphoric triamide (30 ml) and successively 1-iodopentane (22 mmol) were added. Work-up gave diethyl 2-pentyl-2-ethoxycarbonyl-3-methylglutarate in 82% yield. Bp 150—160 °C/0.17 Torr; IR (neat): 1735, 1240, 1218, 1189, 1033 cm^{-1}; MS *m/e* 299 (M^+—OEt). Found: C, 62.6; H, 9.4%. Calcd for $C_{18}H_{32}O_6$: C, 62.8; H, 9.4%.

*Diethyl 2-Alkyl-3-methylglutarate (**11**).* A mixture of the above triester (10 mmol) and aqueous sodium hydroxide (50 mmol in 30 ml of water) was vigorously stirred at 100 °C for 10 h, the resulting clear solution being acidified (pH *ca.* 5) with 4 mol dm^{-3} hydrochloric acid and then subjected to thermal decarboxylation at bath temperature as high as 150—160 °C for 3—4 h under a nitrogen atmosphere. The reaction mixture was treated with 6 mol dm^{-3} hydrochloric acid and the separated free dicarboxylic acid was extracted with ether. The crude acid was esterified by treating with refluxing ethanol (50 ml) and benzene (60 ml) in the presence of a catalytic amount of *p*-toluenesulfonic acid under continuous removal of water with molecular sieves (3A). Product, % yield were as follows: **11f**, 84; **11g**, 85; **11h**, 81%. Physical properties of these are listed in Table 5.

*Diethyl 2-Pentylglutarate (**11d**).* Diethyl pentylmalonate[17] (400 mg, 2.0 mmol) was added to sodium hydride (3 mmol) suspended in dimethoxyethane (4 ml) and the resulting mixture was stirred for 30 min. Ethyl acrylate (300 mg, 3 mmol) dissolved in dimethoxyethane (2 ml) was added and the mixture stirred for an additional 30 min. Work-up followed by distillation afforded the recovered malonate (20 mg) and diethyl 2-pentyl-2-ethoxycarbonylglutarate (501 mg, 76% yield based on the consumed starting malonate), bp 120—122 °C/0.01 Torr, IR (neat): 1712 cm^{-1}. Found: C, 61.8; H, 9.3%. Calcd for $C_{17}H_{30}O_6$: C, 61.8; H, 9.2%. Decarboxylation of the triester to **11d** was performed as described above in 67% yield (see Table 5).

*3,4-Dialkyl-1,2-bis(trimethylsilyloxy)cyclopentene (**12**).* To sodium dispersion (276 mg, 12 mmol) stirred vigorously in dry toluene (25 ml) a mixture of glutarate **11** (2.0 mmol), chlorotrimethylsilane (1.30 g, 12 mmol) and toluene (10 ml) was added dropwise over a period of 20 min at 110 °C under an argon atmosphere. After 30 min the insoluble material was filtered off and solvent was evaporated *in vacuo*. Distillation gave the product listed in Table 5.

Regio- and Stereoselective Cross-aldol Reactions *via* Dialkylboryl Triflates

Tan INOUE and Teruaki MUKAIYAMA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Recieved April 25, 1979)

New borylating reagents, (Bu_2BOTf and 9-BBNOTf), were prepared in high yields. The triflates reacted with enolizable ketones in the presence of tertiary amines to generate selectively one of the regioisomers of vinyloxyboranes by the choice of the reagents (the dialkylboryl triflates and tertiary amines) under mild reaction conditions. Vinyloxyboranes thus generated showed remarkable reactivity toward aldehydes to give only one regioisomer of the corresponding cross-aldols in good yields. High stereoselectivity was also observed in these reactions.

Recently, attention is focussed on the cross-aldol reaction, a most useful means of organic synthesis, and various efficient intermediates such as enolates and their equivalents have been worked out.[1] Nevertheless, the methods so far reported are not generally feasible because of difficulties in regio- and stereoselective generation of the enolates from one of carbonyl compounds.

Vinyloxyboranes react easily with various carbonyl compounds to give corresponding β-hydroxy ketones and β-hydroxy esters under mild conditions.[2] Despite the synthetic use of vinyloxyboranes, no general and convenient methods for the direct formation of these key intermediates from ketones was reported until 1976.[3]

We prepared dialkylboryl triflates, a new class of borylation reagents, from borane derivatives and trifluoromethanesulfonic acid. The triflates (trifluoromethanesulfonates) react smoothly with various ketones in the presence of tertiary amines, giving the corresponding vinyloxyboranes. The reactions using these enolates represent new regioselective cross-aldol reactions under mild conditions.[3] In this paper, we wish to report on the extension of our works.

Results and Discussion

Design and Synthesis of Dialkylboryl Triflates. We prepared a new borylation reagent which has potential utility for the formation of vinyloxyboranes with enolizable ketones under mild conditions. Dialkylboryl carboxylates, derivatives of dialkylboric acids, were reported to be easily formed by the reaction of trialkylboranes with carboxylic acids.[4] This promoted us to prepare dialkylboryl triflate which has a better leaving group than dialkylboryl carboxylate by the reaction of equimolar amount of borane derivatives and trifluoromethanesulfonic acid.

$Bu_3B + TfOH \longrightarrow Bu_2BOTf$ 84%

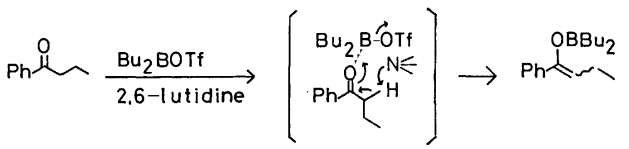
9-BBN + TfOH ⟶ 9-BBNOTf 85%

(9-Borabicyclo[3,3,1]nonane)

Scheme 1.

The reactions proceeded quite smoothly at room temperature, the corresponding dialkylboryl triflates being isolated in high yields by distillation.[5] We attempted to prepare anologous compounds by the combined use of borane derivatives or trialkylaluminum and various sulfonic acids (*e.g.* Bu_3B–$MeSO_3H$, Bu_3B–TsOH, Bu_3B–FSO_3H, Et_3B–TfOH, catecholborane–TfOH, 2,3-dimethylboracyclopentane–TfOH, Et_3Al–TfOH, *i*-Bu_3Al–TfOH). However, the desired boron and aluminum compounds were too unstable to be isolated in pure form for the generation of enolates.

Formation of Vinyloxyboranes from Ketones. 1-Pheny-1-butanone was treated with dibutylboryl triflate in the presence of 2,6-lutidine at room temperature. The NMR spectrum of the reaction mixture showed a signal at δ 5.4 assigned to a vinyl proton of dibutyl (1-phenyl-1-butenyloxy)borane, indicating that tertiary amine promotes the condensation reaction between ketones and dibutylboryl triflate and acts as the proton accepter (Scheme 2).



Scheme 2.

This is the first example for the formation of enolate from ketone by the combined use of Lewis acid and Lewis base.

The vinyloxyborane thus generated in situ was allowed to react with 3-phenylpropanal at room temperature for the formation of the cross-aldol (**1**) (Table 1).

Table 1. Effects of amines and solvents on the yield of 1,5-diphenyl-2-ethyl-3-hydroxy-1-pentanone[a]

Amine	Solvent	Yield of **1**/%
2,6-Lutidine	Hexane	83
	Diethyl ether	77
	Tetrachloromethane	70
N,*N*-Diisopropylethylamine	Hexane	74
Tributylamine	Hexane	65
Protonsponge	Hexane	38

a) The reactions were carried out at room temperature overnight.

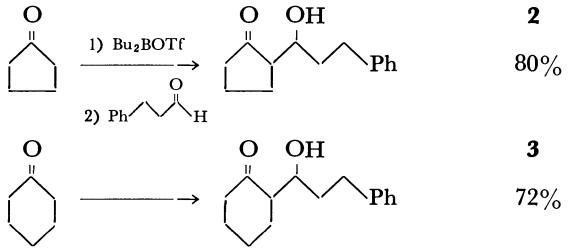
The combined use of 2,6-lutidine and hexane afforded the corresponding aldol in the highest yield. The reaction conditions were applied to the reactions of cyclic ketones such as cyclopentanone or cyclohexanone with 3-phenylpropanal. However, no corresponding cross-aldols could be obtained in satisfactory yield, presumably because of the self-aldol type reactions of starting ketones. In order to avoid such undesirable side reactions, preparation of the vinyloxyboranes and

Table 2. Synthesis of aldols using dibutylboryl triflate from ketones and aldehydes

	Ketone	Aldehyde	Product (Yield/%)	
4		PhCHO	 (84)	 (≈0)
5			 (82)	 (≈0)
6			 (70)	 (≈0)
7			 (65)	 (≈0)

the subsequent reaction with aldehydes were carried out at lower temperature (−78 °C).

This gave better results in the formation of the cross-aldols (Scheme 3).



Scheme 3.

Regioselectivity. In order to examine the regioselection of the new method, methyl ketones were allowed to react with aldehydes using dibutylboryl triflate under similar conditions. The results are given in Table 2.

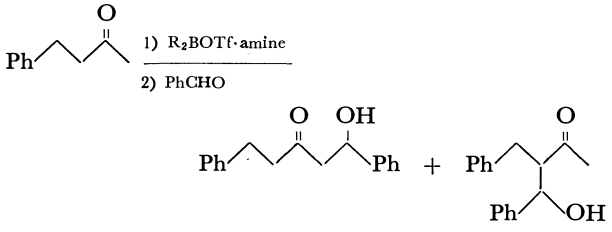
Only one of the regioisomers of cross-aldols was product without being accompanied by detectable amount of the other regioisomers. The results are interpreted by considering vinyloxyboranes to be generated through kinetically controlled steps.

The regioselectivity was examined by changing the combination of the triflates and amines in the reaction of 4-phenyl-2-butanone with benzaldehyde in ether at −78 °C (Table 3).

The results show that the ratio (**A**/**B**) of regioisomers great depends on the properties of the triflates and amines employed. The use of 9-BBNOTf and 2,6-lutidine afforded a remarkably high ratio (**A**/**B**=12/88) in contrast with the ratio of Bu_2BOTf and *N*,*N*-diisopropylethylamine (**A**/**B**=100/0).

Tertiary amines employed in the borylation also affected the yield and selectivity of the produced aldol greatly (Table 4).

Table 3. Ratios of regioisomers of the cross-aldol (**8**) by the combination of triflates and amines[a)]



Triflate	Amine	Ratio(**8A**:**8B**)
Bu_2BOTf	*N*,*N*-Diisopropylethylamine	100: 0
	2,6-Lutidine	69:31
9-BBNOTf	*N*,*N*-Diisopropylethylamine	38:62
	2,6-Lutidine	12:88

a) The reaction time for the generation of vinyloxyborane was 15 min and for the subsequent reaction with benzaldehyde 3 h at −78 °C.

Table 4. Ratio of regioisomers by the combination of 9-BBNOTf and amine[a)]

Amine	Temp/°C	Yield/%	Ratio(**8A**:**8B**)
2,6-Lutidine	−78	70	12:88
	−50	44	18:82
Tributylamine	−78	72	19:81
N,*N*-Diisopropylethylamine	−78	73	38:62
2,5-Lutidine	−78	34	56:44
Pyridine	−78	30	36:64

a) Reaction conditions the same as those in Table 3.

It was confirmed that the use of 2,6-lutidine at −78 °C gives a satisfactory yield and the highest ratio. For the formation of vinyloxyborane, the ef-

Table 5. The effect of time on the ratios of the regioisomers by the use of 9-BBNOTf at −78 °C[a)]

Time/h	Yield/%	Ratio(**8A**:**8B**)
0.25	70	12:88
2	80	6:94
3	90	2:98
4	92	1:99
16	96	0:100

a) Reaction conditions the same as those in Table 3.

fect of reaction time was studied in the same reaction (Table 5).

The synthetic yield and selectivity increased with increase in reaction time, complete reverse of selectivity being achieved in a different way from the case in which dibutylboryl triflate was used under kinetic controlled conditions. This revealed the fact that the vinyloxyborane kinetically formed isomerizes easily to the other more stable isomer. No such complete isomerization has been reported, though kinetically controlled enolates or enol ethers isomerize to thermodynamically stable ones in the presence of proton donor till two isomers equilibrate.[6)]

The method using 9-BBNOTf with 2,6-lutidine was applied to the reactions of other methyl ketones with various carbonyl compounds (Table 6).

The procedure provides an efficient method for the preparation of one regioisomer of cross-aldols from thermodynamically stable enolates of methyl ketones.

Stereoselectivity. The aldol reaction was subjected to kinetic stereoselection, with (*Z*)-enolate giving predominantly the erythro aldol, and (*E*)-enolate leading preferentially to threo isomer.[7)] This suggests that high stereoselection takes place in the present aldol reaction, since the key intermediate, vinyloxyborane, might be generated stereoselectively under suitable conditions. Thus, the reaction of 3-pentanone with benzaldehyde was taken as a model for examining selectivity. The results obtained under various conditions are summarized in Table 7.

It is apparent that reaction temperature is the most important factor to affect the selectivity. The reaction at lower temperature (−78 °C) gave rise to a remarkably high stereoselection (erythro/threo=96:4), and a fairly good selection at room temperature. The high selectivity of the reaction is explained by assuming that the initial generation of vinyloxyborane and subsequent reaction with benzaldehyde proceed in stereoselective manner at low temperature (Scheme 4).

Attempted Reactions of Vinyloxyboranes to Some Electrophiles.

The reactivity of vinyloxyboranes generated from

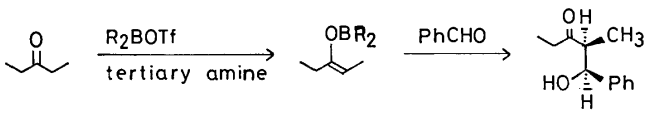
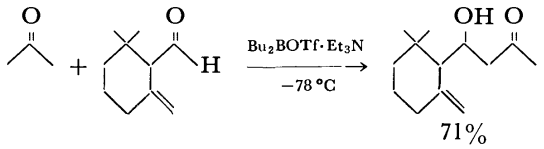


Scheme 4.

3-pentanone was examined for various electrophiles such as ethyl acetate, acetic anhydride, acetal, 1-phenyl-1-propanone and benzyl bromide. The electrophiles were recovered nearly quantitatively when the reactions were carried out by the two methods (Tables 2 and 6). The utility of the present procedure in the preparation of vinyloxyboranes is shown clearly in the difference of reactivity toward aldehydes and other electrophiles.

The reaction with γ-cyclocitral was achieved in 71% yield without any isomerization of the vinyl group (Scheme 5).[8]



Scheme 5.

In this case, use of alkali metal enolates or titanium tetrachloride with silyl enol ether of acetone on an acid or base sensitive double bond of γ-cyclocitral was unsatisfactory, the desired product not being obtained in satisfactory yield. The present methods might provide the mildest conditions among the procedures so far employed.

Summary. Various directed cross-aldols with high regio- and stereoselectivities were prepared in good yields starting from ketones with aldehydes by using dialkylboryl triflates and tertiary amines.

Experimental

Materials. Tributylborane was prepared from boron trifluoride etherate and butylmagnesium bromide in dry ether under argon. 9-BBN was prepared from borane–THF complex and 1,5-cyclooctadiene in dry THF under argon. Commercially available trifluoromethanesulfonic acid was distilled under argon before use.

Dibutylboryl Triflate.[5] Trifluoromethanesulfonic acid (12.51 g, 83.3 mmol) was added to tributylborane (15.16 g, 83.3 mmol) at room temperature under argon. After being stirred for 3 h, the reaction mixture was distilled *in vacuo* under argon. Bp 37 °C/0.12 mmHg, 19.15 g (84%). IR (CCl_4): 1405, 1380, 1320, 1200, 1150 cm^{-1}.

9-BBN Triflate. Trifluoromethanesulfonic acid (18.75 g, 125 mmol) was added to 9-BBN (15.33 g, 127 mmol) in hexane (100 ml) under argon. After being stirred overnight, the reaction mixture was concentrated and distilled *in vacuo* under argon. Bp 38 °C/0.03 mmHg, 28.84 g (85%). IR (CCl_4): 1400, 1240, 1080 cm^{-1}.

Reaction of 1-Phenyl-1-butanone with 3-Phenylpropanal Using Dibutylboryl Triflate (1). To a hexane solution (2 ml) of dibutylboryl triflate (0.253 g, 0.92 mmol) and 2,6-lutidine (0.099 g, 0.92 mmol) was added a hexane solution (1 ml) of 1-phenyl-1-butanone (0.137 g, 0.92 mmol) under argon at room temperature. After stirring for 10 min, a hexane solution (1 ml) of 3-phenylpropanal (0.124 g, 0.92 mmol) was added at room temperature and the reaction mixture was allowed to stand overnight. The mixture was added to phosphate buffer (pH 7.0) and extracted with ether. After removal of ether, the mixture was treated with 30% H_2O_2 (1 ml) in MeOH (3 ml) for 2 h and water was added. The mixture was concentrated *in vacuo* in order to remove most of the methanol and extracted with ether. The ethereal layer was washed with a 5% solution of $NaHCO_3$ and a saturated solution of NaCl, and dried over Na_2SO_4, the solvent being removed. The crude oil was purified by preparative TLC to give 1,5-diphenyl-2-ethyl-3-hydroxy-1-pentanone (0.233 g, 83%).

IR (neat); 1670 cm^{-1}: NMR (CCl_4) δ 7.20—8.10 (broad, 5H), 7.10 (s, 5H), 3.91 (m, 1H), 3.50 (m, 2H), 2.40—3.10 (broad, 2H), 1.40—2.10 (broad, 4H), 0.81 (t, 3H, J=6 Hz). The other reactions given in Table 1 were carried out according to the same procedure.

Reaction of 2-Methyl-4-pentanone with 3-Phenylpropanal Using Dibutylboryl Triflate (5). To an ether solution (1.5 ml) of dibutylboryl triflate (0.301 g, 1.1 mmol) and *N,N*-diisopropylethylamine (0.142 g, 1.1 mmol) was added dropwise an ether solution (1.5 ml) of 2-methyl-4-pentanone (0.100 g, 1.0 mmol) at −78 °C under argon. After being stirred for 30 min, an ether solution (1.5 ml) of 3-phenylpropanal (0.134 g, 1.0 mmol) was added at that temperature. The reaction mixture was allowed to stand for 1 h, then added to phosphate buffer (pH 7.0) at room temperature and extracted with ether. After removal of ether, the crude oil was treated as described above and purified by TLC to give 6-hydroxy-2-methyl-8-phenyl-4-octanone (0.192 g, 82%). IR (neat); 1695 cm^{-1}: NMR (CCl_4); δ 7.11 (s, 5H), 4.00 (m, 1H), 3.05 (broad, s, 1H), 2.06—2.92 (m, 6H), 1.70—2.00 (m, 3H), 0.86 (d, 6H), J=7 Hz.

The other reactions **2**, **3**, **4**, **6**, and **7** (Scheme 2 and Table 2), were carried out according to the same procedure (triethylamine was used as proton accepter in Reactions **4**, **6**, and **7** instead of *N,N*-diisopropylethylamine.), the physical and analytical data being given in Table 8. Absence of the regioisomers was determined by NMR or GLC (10% QF_1 at 130 °C).

Examination of Regioselectivity. Reaction of 4-Phenyl-2-butanone with Benzaldehyde (8). All the reactions (Tables, 3, 4, and 5) were carried out as follows: To a mixture of dialkylboryl triflate (2.00 mmol) and tertiary amine (2.00 mmol) in a solvent (3 ml) was added a solution (1.5 ml) of 4-phenyl-2-butanone (2.00 mmol) under argon. A solution (2 ml) of benzaldehyde (2.00 mmol) was added to the above mixture and allowed to stand for 3 h. The reaction mixture was added into phosphate buffer of pH 7.0 (5.0 ml), methanol (10 ml) and 30% H_2O_2 (5 ml) at 0 °C. After 15 min, the mixture was concentrated *in vacuo* in order to remove most of the methanol, extracted with dichloromethane and dried over $MgSO_4$, the solvent being then removed. The crude oil was purified by TLC, the regioisomers ((**8A**) and (**8B**)) being separated.

Reaction of 4-Phenyl-2-butanone with Benzaldehyde Using 9-BBN Triflate (8). To a solution of 9-BBN triflate (0.551 g, 2.04 mmol) and 2,6-lutidine (0.218 g, 2.04 mmol) in ether (6 ml) was added a solution of 4-phenyl-2-butanone (0.302 g, 2.04 mmol) in ether (3 ml) at −78 °C under argon. After the mixture had been stirred for 4 h, benzaldehyde (0.216 g, 2.04 mmol) in ether (3 ml) was added at the same temperature. The reaction mixture was left to stand for 3 h and worked up as described above. The resulting crude oil was purified by TLC to give 1-hydroxy-1,5-diphenyl-3-pentanone (**8A**) (0.006 g, 1%) and 3-benzyl-4-hydroxy 4-phenyl-2-butanone (**8B**) (0.476 g, 92%. (**8A**): IR (neat);

The Oxidation of (*E*)-α-Phenylcinnamic Acids with Manganese(III) Acetate

Kazuki Oishi and Kazu Kurosawa*

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received April 27, 1979)

The oxidation of eight (*E*)-α-phenylcinnamic acids with manganese(III) acetate in boiling acetic acid containing acetic anhydride gave 3-phenylcoumarins, 3-phenyl-1-oxaspiro[4.5]deca-3,7,9-triene-2,6-diones, 2-phenylbenzofurans, 3-(acetoxymethyl)-2-phenylbenzofurans, 3-formyl-2-phenylbenzofuran, 2-acetoxy-2-phenyl-3(2*H*)-benzofuranones, (*Z*)-α-acetoxystilbenes, 2-acetoxy-1,2-diphenylethanones, 5-acetoxy-4,5-diphenyl-2(5*H*)-furanones, and diphenylacetylene. The reaction pathways are discussed.

In the reaction of lead(IV) acetate and manganese(III) acetate with phenolic compounds in which a hydroxyl group and a double bond are located in spatially suitable positions, an oxidative cyclization has often been observed.[1-7] Davies *et al.* have reported that 2′-substituted biphenyl-2-carboxylic acid was oxidized with lead(IV) acetate to give 3,4-benzocoumarin as a cyclized product.[8] This result prompted us to examine the oxidation of α-phenylcinnamic acids with manganese(III) acetate, in the hope to obtain 3-phenylcoumarins.

(*E*)-α-Phenylcinnamic acids (**1a**—**h**) were prepared from the corresponding phenylacetic acid and benzaldehyde by the Perkin condensation; the (*Z*)-acid (**2f**) was also obtained in the reaction as a minor product. The structures of the new α-phenylcinnamic acids were confirmed by examining their NMR[9] and IR spectra, and by elemental analyses. The (*E*)-α-phenylcinnamic acids which were examined were (*E*)-2-methoxy-α-phenylcinnamic acid (**1a**), (*E*)-2,4-dimethoxy-α-phenylcinnamic acid (**1b**), (*E*)-2,3,4-trimethoxy-α-phenylcinnamic acid (**1c**), (*E*)-2-methoxy-α-(2-methoxyphenyl)-cinnamic acid (**1d**), (*E*)-2,4-dimethoxy-α-(2-methoxyphenyl)cinnamic acid (**1e**), (*E*)-2-methoxy-α-(4-methoxyphenyl)cinnamic acid (**1f**), (*E*)-2,4-dimethoxy-α-(4-methoxyphenyl)cinnamic acid (**1g**), and (*E*)-3,4-dimethoxy-α-(4-methoxyphenyl)cinnamic acid (**1h**). When the (*E*)-α-phenylcinnamic acids (**1a**—**h**) were oxidized with manganese(III) acetate, several products (**3**—**12**) were isolated. The structures of the products were determined again by examining their NMR, IR, and mass spectra, by elemental analyses, and by unambiguous syntheses.

The reactions of **1a**—**h** were carried out using two, four, and five equivalents of manganese(III) acetate in acetic acid containing acetic anhydride at the reflux temperature until the color of manganese(III) acetate disappeared (Fig. 1 and Table 1).

*3-Phenylcoumarins (**3**) and Spiro Lactones (**4**).* The manganese(III) acetate oxidation of methoxy-substituted (*E*)-α-phenylcinnamic acids (**1**), in which α- and β-phenyl groups are *cis*, afforded 3-phenylcoumarins (**3**) and spiro lactones (**4**), both with a *trans* double bond as to two phenyl groups in **3** and the six-menbered ring and a phenyl group in **4**. This indicates that the isomerization of **1** to **2** is involved and that then **2** is oxidized with manganese(III) acetate to give a carbonyloxy radical (I). Subsequently, the (I) radical cyclizes either at the 2-position with the elimination of a methoxyl radical, or at the 6-position with the elimination of hydrogen, while the attack at the 1-position yields **4** with the elimination of the methyl radical (Scheme 1). The pathway would be similar to that of the oxidation of 2′-substituted biphenyl-2-carboxylic acid with lead(IV) acetate.[8] It seems that the cyclization can occur when **1** possesses more than two methoxyl groups in the β-phenyl moiety (**1b**, **1c**, **1e**, and **1h**). An exception is **1g**.

*2-Phenylbenzofurans (**5**), 3-(Acetoxymethyl)-2-phenylbenzofurans (**6**), 3-Formyl-2-phenylbenzofuran (**7**), and 2-Acetoxy-2-phenyl-3(2H)-benzofuranone (**8**).* These compounds were obtained in the reaction of **1** substances which have a methoxyl group at the 2-position in the β-phenyl ring (**1a**, **1b**, **1d**, **1e**, **1f**, and **1g**). An exception is **1c**. Thus, the reaction may proceed through the pathway shown in Scheme 2. The vinylic radical (II), which is formed on the oxidative decarboxylation of the parent acid (**1**), is further oxidized to give a vinylic cation (III). The 2-methoxyl group in **1** attacks the cationic center of III intramolecularly, and then **5** is formed by the removal of the methyl cation. A similar reaction has been known to occur in the solvolysis of 1-aryl-2,2-bis(2-methoxyphenyl)vinyl halides.[10] In the oxidation of **1f**, the yield of **5f** decreased from 34 to 15%, and that of **6f** increased from 2 to 14%, where the amount of manganese(III) acetate was increased, and **7** and **8f** were isolated in the reaction in a molar ratio of 1:5 (Table 1, entries 8 and 9). This suggests that **6f**, **7**, and **8f** can be formed *via* the oxidation of **5f**. In fact, when 2-phenylbenzofuran (**5a**) was oxidized with manganese(III) acetate, 3-(acetoxymethyl)-2-phenylbenzofuran (**6a**, 30%) and 2-acetoxy-2-phenyl-3(2*H*)-benzofuranone (**8a**, 25%) were obtained. Therefore, the reaction may proceed as shown in Scheme 2. **7** can be formed by the further oxidation of **6**, followed by hydrolysis during the work-up. Acetoxymethylation has been reported to occur in the reaction of aromatic compounds with manganese(III) acetate.[11-15]

*(Z)-α-Acetoxystilbenes (**9**), 2-Acetoxy-1,2-diphenylethanones (**10**), and 5-Acetoxy-4,5-diphenyl-2(5H)-furanone (**11**).* The structures of **9** were elucidated by a comparison of their UV spectra with those of (*E*)- and (*Z*)-α-acetoxystilbenes.[16] (*Z*)-α-Acetoxy-3′,4,4′-trimethoxystilbene (**9h**) was synthesized from the corresponding benzyl aryl ketone and was found to be identical. The reaction which gave **9** may proceed through one of the following pathways: a) an acetoxyl radical attacks the vinylic radical (II) to form **9**, or b) the vinylic cation (III) reacts with acetic acid to yield **9**, with the elimination of a proton. The absence of dimeric compounds and stilbenes, which could be

formed from II, in the products suggests that the b pathway is preferable to the a pathway. As to the formation of **10**, again two pathways can be considered: c) the oxidation of **9** gives **10**, or d) the oxidation of benzyl aryl ketone, which might be formed *via* the solvolysis of **9**, gives **10**. In order to distinguish the c and d pathways, **9h** was oxidized with two equivalents of manganese(III) acetate. 2-Acetoxy-1-(4-methoxyphenyl)-2-(3,4-dimethoxyphenyl)ethanone (**10h**) was obtained in a good yield (67%), together with unchanged **9h** (22%) (Table 2, entry 1). However, when **9h** was heated without the oxidant, **9h** was recovered quantitatively. The fact that 3,4-dimethoxybenzyl 4-methoxyphenyl ketone, which might be formed by the solvolysis of **9h**, was not found in the products of these reactions, even though a substantial amount of **9h** was recovered, leads to the conclusion that the 2-acetoxy-1,2-diphenylethanones (**10**) were formed through the c pathway. It is worth noting that the acetoxyl group in 2-acetoxy-1,2-diphenylethanone (**10**) obtained in the reaction of (*E*)-α-phenylcinnamic acid was located at the α-position in the parent acids and that the yield of **10i** was much improved in the reaction of **9i** in acetic acid (Table 2, entry 4). This suggests that the manganese(III) acetate oxidation of **1** can be utilized as a regiospecific synthesis of 2-acetoxy-1,2-diphenylethanones which have different aryl groups from (*E*)-α-phenylcinnamic acids (**1**), although the formation of α-acetoxy ketones from enol acetates by lead(IV) acetate[17] and by anodic oxidation[18] have been reported.

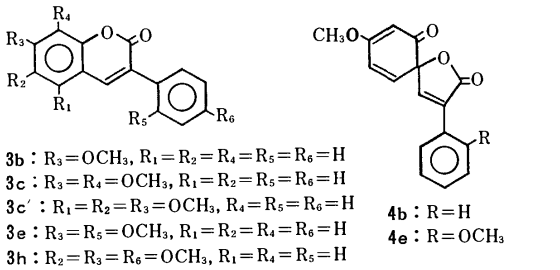

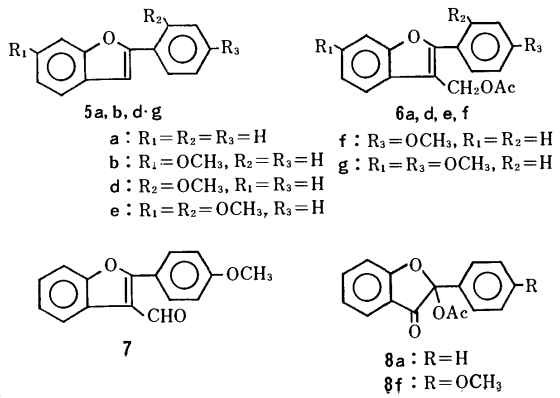

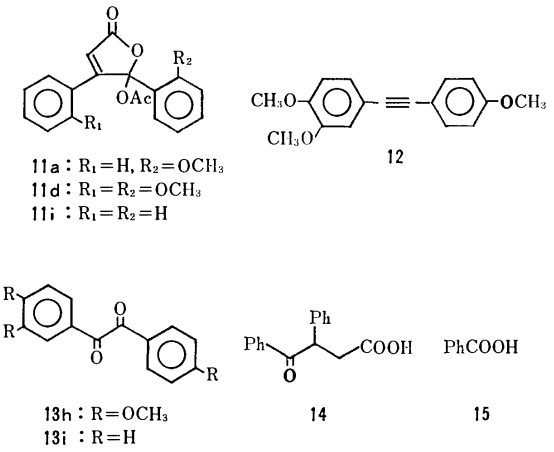

Fig. 1.

When **9h** was oxidized with five equivalents of manganese(III) acetate, 3,4,4′-trimethoxybenzil (**13h**) was obtained, together with **10h** (Table 2, entry 2). Two reaction pathways (e and f) which could give **13h** may be envisaged: e) the oxidation of **9h** gives **13h**, or f) the oxidation of 2-acetoxy-1-(4-methoxy-

4	**9i**	1 : 3	AcOH	95	**10i** (43) **11i** (2) **15** (7)	

a) The reactions were carried out at reflux temperature. b) The yield is based on the amount of the substrate used.

phenyl)-2-(3,4-dimethoxyphenyl)ethanone (**10h**) gives **13h**. In order to establish the true pathway, 2-acetoxy-1,2-diphenylethanone (**10i**) was oxidized with manganese(III) acetate to give **13i** in a 15% yield. The result showed that 3,4,4′-trimethoxybenzil (**13h**) was formed through the f pathway.

The formation of 5-acetoxy-4,5-diphenyl-2(5*H*)-furanones (**11**) from **1** is very interesting, as it may be formed by another reaction of (*Z*)-α-acetoxystilbene (**9**) with manganese(III) acetate. The reaction of (*Z*)-α-acetoxystilbene (**9i**) with manganese(III) acetate did give 5-acetoxy-4,5-diphenyl-2(5*H*)-furanone (**11i**), along with 3,4-diphenyl-4-oxobutanoic acid (**14**) (Table 2, entry 3). The reaction pathway could be explained as follows. The reaction of **9** with the carboxymethyl radical would give a radical. This radical is oxidized to a cation, V, which gives a γ-lactone (VI). The VI would then be oxidized to give **11** via acetoxylation at the 4-position of VI, followed by the elimination of acetic acid. The V cation also reacts with acetic acid and then eliminates acetic anhydride, giving **14** (Scheme 2). It has been mentioned earlier that the yield of **10i** was increased when **9i** was oxidized in acetic acid, but that of **11i** decreased (Table 2, entry 4). This may suggest that diacetoxylation took place[2b] under the present reaction conditions and that the carboxymethyl radicals were produced in smaller amounts. It has previously been reported that the reaction of olefins with manganese(III) acetate under anhydrous conditions gave γ-lactones.[19]

*1-(3,4-Dimethoxyphenyl)-2-(4-methoxyphenyl)acetylene (**12**).* This compound may be formed either from the vinylic radical (II) with a loss of hydrogen or from the vinylic cation (III) with the removal of the proton (Scheme 2).

In conclusion, it was shown that the reactions of (*E*)-α-phenylcinnamic acid (**1**) with manganese (III) acetate could be explained by assuming two radicals, I and II, two cations, III and V, and the lactone VI as the reaction intermediates.

Experimental

All the ^1H NMR spectra were recorded with a Hitachi Perkin-Elmer R-24 spectrometer, with tetramethylsilane as the internal reference. The IR spectra were taken on a JASCO IRA-1 grating spectrometer, while the UV spectra were recorded for the methanol solution with a Hitachi EPS-3T spectrophotometer. The mass spectra were recorded with JMS-01 SG-2 and Hitachi RMU-7M 002CPU mass spectrometers. The melting points were determined with a Yanagimoto micro-melting point apparatus and were not corrected.

*Preparation of α-Phenylcinnamic Acids (**1a—h**).* The general procedure for the preparation of α-phenylcinnamic acids was as follows. A mixture of a benzaldehyde (45 mmol), a phenylacetic acid (36 mmol), triethylamine (30

ml), and acetic anhydride (60 ml) was heated under reflux for 4 h. The reaction mixture was acidified with concd hydrochloric acid (40 ml) and extracted with benzene. This solution was washed with water and then extracted several times with 2 M aqueous sodium hydroxide. The combined extract was then acidified to a pH of 5.9 (the pH adjustment was checked with a Hitachi-Horiba F-5 pH meter) with concd hydrochloric acid. The precipitate was collected by filtration. The crude acid was purified by recrystallization to give (*E*)-α-phenylcinnamic acid. The (*Z*)-isomer was precipitated by the further addition of concd hydrochloric acid to the filtrate. The crude (*Z*)-acid was collected by filtration and recrystallized.

*(E)-2,4-Dimethoxy-α-(2-methoxyphenyl)cinnamic Acid (**1e**)*: Mp 177.5—179 °C (benzene); 20% yield; IR (KBr) 2950 and 1697 cm^{-1} (COOH); UV λ_{max} (log ε) 239^{sh} (4.09), 294 (4.08), and 331 nm (4.23); NMR ($CDCl_3$) δ=3.71 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 6.11 (1H, dd, J=9 and 2.5 Hz, $H_{(5)}$), 6.37 (1H, d, J=2.5 Hz, $H_{(3)}$), 6.74 (1H, d, J=9 Hz, $H_{(6)}$), 6.7—7.5 (4H, m, $H_{(3'-6')}$), 8.24 (1H, s, =CH), and 9.9—11 (1H, br, COOH). Found; C, 68.60; H, 5.82%. Calcd for $C_{18}H_{18}O_5$; C, 68.78; H, 5.77%.

*(Z)-2-Methoxy-α-(4-methoxyphenyl)cinnamic Acid (**2f**)*: Mp 129.5—131 °C (benzene–light petroleum); 0.3% yield; IR (KBr) 2960 and 1705 cm^{-1} (COOH); UV λ_{max} (log ε) 236^{sh} (4.12), 290^{sh} (4.22), and 321 nm (4.25); NMR ($CDCl_3$) δ=3.82 (6H, s, 2×OCH_3), 6.89 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.46 (2H, m, $H_{(2')}$ and $H_{(6')}$), 6.7—7.6 (4H, m, $H_{(3-6)}$), 7.19 (1H, s, =CH), and 10.57 (1H, br s, COOH). (Found; C, 71.67; H, 5.73%. Calcd for $C_{17}H_{16}O_4$; C, 71.82; H, 5.67%.

*(E)-2,4-Dimethoxy-α-(4-methoxyphenyl)cinnamic Acid (**1g**)*: Mp 217.5—220.5 °C (EtOH); 27% yield; IR (KBr) 2940 and 1680 cm^{-1} (COOH); UV λ_{max} (log ε) 240 (4.17), 295 (4.07), and 336 nm (4.23); NMR (DMSO-d_6) δ=3.72 (3H, s, OCH_3), 3.76 (3H, s, OCH_3), 3.86 (3H, s, OCH_3), 6.20 (1H, dd, J=9 and 2.5 Hz, $H_{(5)}$), 6.54 (1H, d, J=2.5 Hz, $H_{(3)}$), 6.59 (1H, d, J=9 Hz, $H_{(6)}$), 6.90 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.07 (2H, m, $H_{(2')}$ and $H_{(6')}$), 7.93 (1H, s, =CH), and 11.5 (1H, br, COOH). Found; C, 68.62; H, 5.81%. Calcd for $C_{18}H_{18}O_5$; C, 68.78; H, 5.77%.

*Oxidation of (E)-α-Phenylcinnamic Acids (**1a—h**) with Manganese(III) Acetate.* The general procedure for the oxidation of (*E*)-α-phenylcinnamic acids was as follows. To a hot solution of an (*E*)-α-phenylcinnamic acid (2 mmol) in acetic acid (35 ml) containing acetic anhydride (5 ml), we added manganese(III) acetate dihydrate.[26] The solution was then heated under reflux until the dark color of the Mn(III) ions disappeared. After the removal of the solvent *in vacuo*, the resulting mixture was triturated with water and extracted with chloroform. The chloroform solution was washed with aqueous sodium carbonate, dried over sodium sulfate, and evaporated under reduced pressure. The products were chromatogrammed on TLC (Wakogel B-10) with chloroform and then ether as developing solvents, and recrystallized. The yields are summarized in Table 1. The aqueous sodium carbonate solution was acidified with concd hydrochloric acid and extracted with ethyl acetate. The ethyl acetate solution was dried and evaporated. The IR spectrum of the resulting substance was superimposible on that of the (*E*)-α-phenylcinnamic acid. The acid was also recovered on TLC. The recovery of the (*E*)-α-phenylcinnamic acid in Table 1 was the sum of them.

*Oxidation Products of **1a**. 2-Phenylbenzofuran (**5a**)*: Mp 120—121 °C (EtOH) (lit,[27] mp 120 °C).

*3-(Acetoxymethyl)-2-phenylbenzofuran (**6a**)*: Liquid; IR ($CHCl_3$) 1750 cm^{-1} (OAc); NMR (CCl_4) δ=2.03 (3H, s, OAc), 5.32 (2H, s, $-CH_2-$), and 6.9—8.0 (9H, m, aromatic). Found; *m/e* 266.0921. Calcd for $C_{17}H_{14}O_3$; M, 266.0943.

*2-Acetoxy-1-phenyl-2-(2-methoxyphenyl)ethanone (**10a**)*: Liquid; IR ($CHCl_3$) 1752 (OAc) and 1715 cm^{-1} (C=O); NMR (CCl_4) δ=2.08 (3H, s, OAc), 3.84 (3H, s, OCH_3), 6.6—7.5 (8H, m, >CH– and aromatic), and 7.7—8.0 (2H, m, $H_{(2)}$ and $H_{(6)}$). Found; *m/e* 284.1041. Calcd for $C_{17}H_{16}O_4$; M, 284.1049.

*5-Acetoxy-4-(2-methoxyphenyl)-5-phenyl-2(5H)-furanone (**11a**)*: Mp 150—152 °C (aq MeOH); IR ($CHCl_3$) 1770 cm^{-1} (α,β-unsaturated γ-lactone[28]); UV λ_{max} (log ε) 236^{sh} (4.03), 283 (4.19), and 334 nm (3.89); NMR ($CDCl_3$) δ=2.12 (3H, s, OAc), 3.89 (3H, s, OCH_3), 6.5—7.9 (9H, m, aromatic), and 7.13 (1H, s, $H_{(3)}$); MS *m/e* 324 (M^+), 282, 265, 254, 237, 177, 132, 105, and 77. Found; C, 70.20; H, 4.96%. Calcd for $C_{19}H_{16}O_5$; C, 70.36; H, 4.98%.

*Oxidation Products of **1b**. 7-Methoxy-3-phenylcoumarin (**3b**)*: Mp 122—123 °C (EtOH) (lit,[29] mp 124 °C).

*8-Methoxy-3-phenyl-1-oxaspiro[4.5]deca-3,7,9-triene-2,6-dione (**4b**)*: Mp 135—137.5 °C (benzene–light petroleum); IR (KBr) 1770 (γ-lactone) and 1675 cm^{-1} (C=O); UV λ_{max} (log ε) 225 (4.38) and 276 nm (4.26); NMR ($CDCl_3$) δ=3.75 (3H, s, OCH_3), 5.73 (1H, s, $H_{(7)}$), 6.38 (2H, s, $H_{(9)}$ and $H_{(10)}$), 7.25 (1H, s, $H_{(4)}$), 7.3—7.6 (3H, m, $H_{(3'-5')}$), and 7.7—8.1 (2H, m, $H_{(2')}$ and $H_{(6')}$); MS *m/e* 268 (M^+). Found; C, 71.51; H, 4.50%. Calcd for $C_{16}H_{12}O_4$; C, 71.63; H, 4.51%.

*6-Methoxy-2-phenylbenzofuran (**5b**)*: IR and NMR spectra of **5b** separated on TLC were identical with those of an authentic sample.[4]

*2-Acetoxy-1-phenyl-2-(2,4-dimethoxyphenyl)ethanone (**10b**)*: Mp 112—113 °C (benzene–light petroleum); IR (KBr) 1753 (OAc) and 1715 cm^{-1} (C=O); UV λ_{max} (log ε) 239 (4.23), 283 (3.75) and 289^{sh} nm (3.71); NMR ($CDCl_3$) δ=2.18 (3H, s, OAc), 3.77 (3H, s, OCH_3), 3.89 (3H, s, OCH_3), 6.3—6.6 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.1—7.6 (5H, m, >CH– and aromatic), and 7.8—8.1 (2H, m, $H_{(2)}$ and $H_{(6)}$). Found; C, 68.83; H, 5.86%. Calcd for $C_{18}H_{18}O_5$; C, 68.78; H, 5.77%.

*Oxidation Products of **1c**. 7,8-Dimethoxy-3-phenylcoumarin (**3c**)*: Mp 135.5—136 °C (EtOH) (lit,[30] mp 142—144 °C).

*5,6,7-Trimethoxy-3-phenylcoumarin (**3c'**)*: Mp 143—143.5 °C (MeOH); IR ($CHCl_3$) 1730 cm^{-1} (C=O); UV λ_{max} (log ε) 232^{sh} (4.32), 251^{sh} (4.04), and 351 nm (4.33); NMR ($CDCl_3$) δ=3.85 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 4.04 (3H, s, OCH_3), 6.64 (1H, s, $H_{(8)}$), 7.2—7.8 (5H, m, Ph), and 8.01 (1H, s, $H_{(4)}$). Found: C, 69.02; H, 5.15%. Calcd for $C_{18}H_{16}O_5$; C, 69.22; H, 5.16%.

*Oxidation Products of **1d**. 2-(2-Methoxyphenyl)benzofuran (**5d**)*: Mp 78.5—80 °C (EtOH) (lit,[31] mp 82—83 °C).

*3-(Acetoxymethyl)-2-(2-methoxyphenyl)benzofuran (**6d**)*: Liquid; IR ($CHCl_3$) 1748 cm^{-1} (OAc); NMR (CCl_4) δ=1.93 (3H, s, OAc), 3.69 (3H, s, OCH_3), 5.12 (2H, s, $-CH_2-$), and 6.7—7.7 (8H, m, aromatic). Found; *m/e* 296.1059. Calcd for $C_{18}H_{16}O_4$; M, 296.1049.

*2-Acetoxy-1,2-bis(2-methoxyphenyl)ethanone (**10d**)*: Mp 101—102 °C (cyclohexane) (lit,[32] mp 102 °C).

*5-Acetoxy-4,5-bis(2-methoxyphenyl)-2(5H)-furanone (**11d**)*: Mp 143.5—146 °C (MeOH); IR ($CHCl_3$) 1770 cm^{-1} (α,β-unsaturated γ-lactone[28]); UV λ_{max} (log ε) 281 (4.21) and 330 nm (3.89); NMR ($CDCl_3$) δ=2.11 (3H, s, OAc), 3.61 (3H, s, OCH_3), 3.85 (3H, s, OCH_3), 7.06 (1H, s, $H_{(3)}$), 6.6—7.6 (7H, m, aromatic), and 7.79 (1H, dd, J=7.5 and 2 Hz, $H_{(6')}$); MS *m/e* 354 (M^+), 312, 295, 253, 177, 135, 132, 92, 89, and 77. Found; C, 67.81; H, 5.12%. Calcd for $C_{20}H_{18}O_6$; C, 67.79; H, 5.12%.

Oxidation Products of ***1e****.* *7-Methoxy-3-(2-methoxyphenyl)-coumarin (**3e**)*: Mp 134—135 °C (benzene–light petroleum) (lit,[33] mp 136 °C).

*8-Methoxy-3-(2-methoxyphenyl)-1-oxaspiro[4.5]deca-3,7,9-triene-2,6-dione (**4e**)*: Mp 171—172 °C (CCl_4); IR ($CHCl_3$) 1775 (γ-lactone) and 1680 cm^{-1} (C=O); UV λ_{max} (log ε) 224 (4.40), 240^{sh} (4.30), 277 (4.19), and 311^{sh} nm (3.88); NMR ($CDCl_3$) δ=3.72 (3H, s, OCH_3), 3.89 (3H, s, OCH_3), 5.68 (1H, s, $H_{(7)}$), 6.38 (2H, s, $H_{(9)}$ and $H_{(10)}$), 6.8—7.5 (3H, m, $H_{(3'-5')}$), 7.59 (1H, s, $H_{(4)}$), and 8.40 (1H, dd, J=8 and 2 Hz, $H_{(6')}$); MS *m/e* 298 (M^+). Found; C, 68.25; H, 4.70%. Calcd for $C_{17}H_{14}O_5$; C, 68.45; H, 4.73%.

*6-Methoxy-2-(2-methoxyphenyl)benzofuran (**5e**)*: Mp 87—88 °C (aq EtOH); IR (KBr) 1555, 947, and 910 cm^{-1} (C=C); NMR (CCl_4) δ=3.79 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 6.5—7.5 (6H, m, aromatic), 7.13 (1H, s, $H_{(3)}$), and 7.96 (1H, dd, J=7.5 and 2.5 Hz, $H_{(6')}$). Found; C, 75.42; H, 5.58%. Calcd for $C_{16}H_{14}O_3$; C, 75.57; H, 5.55%.

*3-(Acetoxymethyl)-6-methoxy-2-(2-methoxyphenyl)benzofuran (**6e**)*: Liquid; IR ($CHCl_3$) 1745 cm^{-1} (OAc); NMR (CCl_4) δ=1.97 (3H, s, OAc), 3.79 (6H, s, 2×OCH_3), 5.10 (2H, s, $-CH_2-$), and 6.6—7.7 (7H, m, aromatic). Found; *m/e* 326.1166. Calcd for $C_{19}H_{18}O_5$; M, 326.1154.

*2-Acetoxy-1-(2-methoxyphenyl)-2-(2,4-dimethoxyphenyl)ethanone (**10e**)*: Mp 111.5—112 °C (ether); IR ($CHCl_3$) 1745 (OAc) and 1698 cm^{-1} (C=O); UV λ_{max} (log ε) 236^{sh} (4.05), 253 (3.94), 288 (3.65), and 313 nm (3.58); NMR ($CDCl_3$) δ= 2.14 (3H, s, OAc), 3.67 (3H, s, OCH_3), 3.71 (6H, s, 2× OCH_3), 6.2—6.5 (2H, m, $H_{(3')}$ and $H_{(5')}$), 6.6—7.5 (4H, m, aromatic), 7.14 (1H, s, >CH–), and 7.69 (1H, dd, J= 8.5 and 2 Hz, $H_{(6)}$). Found; C, 66.34; H, 5.58%. Calcd for $C_{19}H_{20}O_6$; C, 66.27; H, 5.85%.

Oxidation Products of ***1f****.* *2-(4-Methoxyphenyl)benzofuran (**5f**)*: Mp 146—147 °C (EtOH) (lit,[4] mp 146 °C).

*3-(Acetoxymethyl)-2-(4-methoxyphenyl)benzofuran (**6f**)*: Mp 72—73 °C (light petroleum); IR ($CHCl_3$) 1740 cm^{-1} (OAc); UV λ_{max} (log ε) 305 nm (4.47); NMR ($CDCl_3$) δ=2.09 (3H, s, OAc), 3.84 (3H, s, OCH_3), 5.38 (2H, s, $-CH_2-$), 6.98 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.74 (2H, m, $H_{(2')}$ and $H_{(6')}$), and 7.0—7.8 (4H, m, $H_{(4-7)}$). Found: C, 72.85; H, 5.45%. Calcd for $C_{18}H_{16}O_4$; C, 72.96; H, 5.44%.

*3-Formyl-2-(4-methoxyphenyl)benzofuran (**7**)*: Mp 114.5—115.5 °C (cyclohexane); IR ($CHCl_3$) 1678 cm^{-1} (CHO); UV λ_{max} (log ε) 251 (4.28) and 331 nm (4.26); NMR ($CDCl_3$) δ=3.88 (3H, s, OCH_3), 7.08 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.2—7.7 (3H, m, $H_{(5-7)}$), 7.83 (2H, m, $H_{(2')}$ and $H_{(6')}$), 8.2—8.5 (1H, m, $H_{(4)}$), and 10.25 (1H, s, CHO); MS *m/e* 252 (M^+). Found; C, 76.19; H, 4.84%. Calcd for $C_{16}H_{12}O_3$; C, 76.18; H, 4.80%.

*2-Acetoxy-2-(4-methoxyphenyl)-3(2H)-benzofuranone (**8f**)*: Mp 112.5—113.5 °C (benzene–light petroleum); IR ($CHCl_3$) 1770^{sh} (C=O) and 1747 cm^{-1} (OAc); UV λ_{max} (log ε) 225^{sh} (4.32), 259 (4.11), 283^{sh} (3.58), and 330 nm (3.69); NMR ($CDCl_3$) δ=2.15 (3H, s, OAc), 3.74 (3H, s, OCH_3), 6.83 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.10 (2H, m, aromatic), 7.48 (2H, m, $H_{(2')}$ and $H_{(6')}$), and 7.3—7.8 (2H, m, aromatic); MS *m/e* 298 (M^+). Found; C, 68.49; H, 4.74%. Calcd for $C_{17}H_{14}O_5$; C, 68.45; H, 4.73%.

*2-Acetoxy-1-(4-methoxyphenyl)-2-(2-methoxyphenyl)ethanone (**10f**)*: Mp 81.5—83.5 °C (hexane); IR ($CHCl_3$) 1745 (OAc) and 1705 cm^{-1} (C=O); UV λ_{max} (log ε) 222 (4.25) and 286 nm (4.27); NMR ($CDCl_3$) δ=2.17 (3H, s, OAc), 3.80 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 6.83 (2H, m, $H_{(3)}$ and $H_{(5)}$), 6.7—7.5 (4H, m, aromatic), 7.36 (1H, s, >CH–), and 7.97 (2H, m, $H_{(2)}$ and $H_{(6)}$). Found; C, 68.89; H, 5.87%. Calcd for $C_{18}H_{18}O_5$; C, 68.78; H, 5.77%.

Oxidation Products of ***1g****.* *6-Methoxy-2-(4-methoxyphenyl)-benzofuran (**5g**)*: Mp 156.5—158 °C (EtOH) (lit,[4] mp 159 °C).

*(Z)-α-Acetoxy-2',4,4'-trimethoxystilbene (**9g**)*: Mp 105.5—108.5 °C (benzene–light petroleum); IR ($CHCl_3$) 1762 cm^{-1} (OAc); UV λ_{max} (log ε) 237^{sh} (4.05), 300^{sh} (4.33), and 325 nm (4.41); NMR ($CDCl_3$) δ=2.24 (3H, s, OAc), 3.80 (9H, s, 3×OCH_3), 6.4—6.7 (2H, m, $H_{(3')}$ and $H_{(5')}$), 6.87 (1H, s, =CH), 6.92 (2H, m, $H_{(3)}$ and $H_{(5)}$), 7.48 (2H, m, $H_{(2)}$ and $H_{(6)}$), and 7.56 (1H, m, $H_{(6')}$). Found; C, 69.58; H, 6.27%. Calcd for $C_{19}H_{20}O_5$; C, 69.50; H, 6.14%.

*2-Acetoxy-1-(4-methoxyphenyl)-2-(2,4-dimethoxyphenyl)ethanone (**10g**)*: Liquid; IR ($CHCl_3$) 1750 (OAc) and 1705 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.16 (3H, s, OAc), 3.74 (3H, s, OCH_3), 3.77 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 6.2—6.6 (2H, m, $H_{(3')}$ and $H_{(5')}$), 6.81 (2H, m, $H_{(3)}$ and $H_{(5)}$), 7.21 (1H, m, $H_{(6')}$), 7.23 (1H, s, >CH–), and 7.89 (2H, m, $H_{(2)}$ and $H_{(6)}$). Found; *m/e* 344.1235. Calcd for $C_{19}H_{20}O_6$; M, 344.1260.

Oxidation Products of ***1h****.* *6,7-Dimethoxy-3-(4-methoxyphenyl)coumarin (**3h**)*: Mp 172—173 °C (EtOH); IR ($CHCl_3$) 1730 cm^{-1} (C=O); UV λ_{max} (log ε) 230 (4.42), 249^{sh} (4.15), and 370 nm (4.36); NMR ($CDCl_3$) δ=3.84 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 6.7—7.1 (4H, m, aromatic), 7.67 (2H, m, $H_{(2')}$ and $H_{(6')}$), and 7.68 (1H, s, $H_{(4)}$). Found; C, 69.10; H, 5.26%. Calcd for $C_{18}H_{16}O_5$; C, 69.22; H, 5.16%.

*(Z)-α-Acetoxy-3',4,4'-trimethoxystilbene (**9h**)*: Mp 108.5—109 °C (benzene–light petroleum); IR ($CHCl_3$) 1760 cm^{-1} (OAc); UV λ_{max} (log ε) 320 nm (4.48); NMR ($CDCl_3$) δ=2.28 (3H, s, OAc), 3.82 (3H, s, OCH_3), 3.89 (6H, s, 2×OCH_3), 6.52 (1H, s, =CH–), 6.88 (2H, m, $H_{(3)}$ and $H_{(5)}$), 6.7—7.2 (3H, m, $H_{(2')}$, $H_{(5')}$, and $H_{(6')}$), and 7.46 (2H, m, $H_{(2)}$ and $H_{(6)}$). Found; C, 69.21; H, 6.20%. Calcd for $C_{19}H_{20}O_5$; C, 69.50; H, 6.14%.

*2-Acetoxy-1-(4-methoxyphenyl)-2-(3,4-dimethoxyphenyl)ethanone (**10h**)*: Liquid; IR ($CHCl_3$) 1750 (OAc) and 1705 cm^{-1} (C=O); NMR (CCl_4) δ=2.07 (3H, s, OAc), 3.66 (6H, s, 2×OCH_3), 3.69 (3H, s, OCH_3), 6.68 (2H, m, $H_{(3)}$ and $H_{(5)}$), 6.5—7.0 (4H, m, >CH– and aromatic), and 7.77 (2H, m, $H_{(2)}$ and $H_{(6)}$). Found; *m/e* 344.1238. Calcd for $C_{19}H_{20}O_6$; M, 344.1260.

*1-(3,4-Dimethoxyphenyl)-2-(4-methoxyphenyl)acetylene (**12**)*: Mp 107—107.5 °C (EtOH); IR ($CHCl_3$) 2840 cm^{-1} (OCH_3); UV λ_{max} (log ε) 247^{sh} (4.04), 298 (4.49), 310 (4.46), and 319 nm (4.46); NMR ($CDCl_3$) δ=3.78 (3H, s, OCH_3), 3.86 (6H, s, 2×OCH_3), 6.83 (2H, m, $H_{(3')}$ and $H_{(5')}$), 6.7—7.3 (3H, m, $H_{(2)}$, $H_{(5)}$, and $H_{(6)}$), and 7.41 (2H, m, $H_{(2')}$ and $H_{(6')}$); MS *m/e* 268 (M^+). Found; C, 75.90; H, 6.12%. Calcd for $C_{17}H_{16}O_3$; C, 76.10; H, 6.01%.

*Oxidation of 2-Phenylbenzofuran (**5a**).* A mixture of 2-phenylbenzofuran (**5a**)[27] (194 mg), manganese(III) acetate dihydrate (2.68 g), acetic acid (30 ml), and acetic anhydride (2 ml) was heated under reflux for 2.5 h. After the removal of the acetic acid *in vacuo*, the resulting mixture was triturated with chloroform and filtered. The filtrate was concentrated and separated on TLC, giving **5a** (25 mg), 3-(acetoxymethyl)-2-phenylbenzofuran (**6a**) (86.7 mg, 30%), and 2-acetoxy-2-phenyl-3(2*H*)-furanone (**8a**) (67.7 mg, 25%); mp 128—129 °C (light petroleum); IR ($CHCl_3$) 1770 (C=O) and 1748 cm^{-1} (OAc); UV λ_{max} (log ε) 257 (4.11) and 329 nm (3.55); NMR ($CDCl_3$) δ=2.14 (3H, s, OAc) and 6.9—7.8 (9H, m, aromatic) (Found: C, 71.80; H, 4.41%. Calcd for $C_{16}H_{12}O_4$; C, 71.63; H, 4.51%).

*Preparation of (Z)-α-Acetoxy-3',4,4'-trimethoxystilibene (**9h**).* A mixture of 3,4-dimethoxybenzyl 4-methoxyphenyl ketone[34] (1.8 g), freshly fused potassium acetate (3.6 g), and acetic anhydride (60 ml) was heated under reflux for 5 h. After

the removal of the acetic anhydride *in vacuo*, the residue was extracted with chloroform. The chloroform solution was washed with aqueous sodium hydrogencarbonate, dried, and evaporated. The crude product was purified on TLC, using chloroform as the developing solvent, and by recrystallization, giving colorless needles (900 mg, 44%), mp 108.5—109 °C (MeOH).

Oxidation of (Z)-α-Acetoxystilbene (9). The general procedure for the oxidation of (*Z*)-α-acetoxystilbene (**9**) was as follows. A mixture of **9** (1 mmol), manganese(III) acetate dihydrate (2—5 mmol), and a solvent (20 ml) was heated under reflux for the time shown in Table 2. After being worked-up in a manner similar to that used in the oxidation of (*E*)-α-phenylcinnamic acids (**1**), the following products were obtained (the yields are summarized in Table 2): (*Z*)-α-Acetoxy-3′,4,4′-trimethoxystilbene (**9h**) gave **10h** and 3,4,4′-trimethoxybenzil (**13h**); mp 123—124 °C (EtOH); IR ($CHCl_3$) 1670 cm^{-1} (C=O); UV λ_{max} (log ε) 228 (4.29), 295 (4.36), and 322^{sh} nm (4.23); NMR ($CDCl_3$) δ=3.87 (3H, s, OCH_3), 3.93 (6H, s, 2×OCH_3), 6.89 (1H, d, J=7.5 Hz, $H_{(5)}$), 6.95 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.3—7.6 (2H, m, $H_{(2)}$ and $H_{(6)}$), and 7.92 (2H, m, $H_{(2')}$ and $H_{(6')}$) (Found; C, 68.05; H, 5.48%. Calcd for $C_{17}H_{16}O_5$; C, 67.99; H, 5.37%). (*Z*)-α-Acetoxystilbene (**9i**)[35] yielded 2-acetoxy-1,2-diphenylethanone (**10i**); mp 81.5—82.5 °C (benzene–hexane) (lit,[36] mp 83 °C); 5-acetoxy-4,5-diphenyl-2(5*H*)-furanone (**11i**); liquid; IR ($CHCl_3$) 1770 cm^{-1}; NMR ($CDCl_3$) δ=2.16 (3H, s, OAc), 6.61 (1H, s, $H_{(3)}$), and 7.2—7.7 (10H, m, 2×Ph); MS *m/e* 294 (M^+), 252, 235, 147, 105, 102, and 77, and 3,4-diphenyl-4-oxobutanoic acid (**14**); mp 148—149 °C (benzene–light petroleum) (lit,[37] mp 161 °C); IR ($CHCl_3$) 1705 (C=O), 1735 (COOH), and 2400—3600 cm^{-1} (COOH); NMR ($CDCl_3$) δ=2.72 (1H, dd, J=18 and 6 Hz, -CH-), 3.41 (1H, dd, J=18 and 9 Hz, -CH-), 5.05 (1H, dd, J=9 and 6 Hz, >CH-), 7.0—7.6 (8H, m, aromatic), 7.90 (2H, m, aromatic), and 9.95 (1H, br, s, COOH), and benzoic acid (**15**).

Oxidation of 2-Acetoxy-1,2-diphenylethanone (10h). A mixture of **10h** (254 mg), manganese(III) acetate dihydrate (536 mg), acetic acid (20 ml), and acetic anhydride (0.4 ml) was heated under reflux for 3 h. After the removal of the solvent, the resulting mixture was extracted with chloroform. The chloroform solution was concentrated and the resulting substance was chromatogrammed on TLC by developing with chloroform, giving **13i** (31 mg, 15%) and unchanged **10i** (173 mg, 68%).

The authors wish to thank Mr. Shuichi Ueda at the Taiho Pharmaceutical Co., Ltd., Tokushima, and Dr. Shinzaburo Hishida at Hitachi, Ltd., Katsuda, for their measurements of the mass spectra.

Molecular Dynamical Studies on Nitrobenzene in Solutions of Tetraethyl and Tetrabutylammonium Bromides

Hiroyasu NOMURA,* Yoshiaki TSUKAMOTO, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received May 15, 1979)

The concentration and temperature dependences of the reorientational correlation times of nitrobenzene in solutions of tetraethyl(TEABr) and tetrabutylammonium bromides(TBuABr) have been determined by Raman line shape analysis. Pure liquid nitrobenzene was evaluated for comparison. The reorientational correlation times of nitrobenzene in solutions decreased with increasing concentration of the salts and the apparent activation enthalpy of τ_{or} of nitrobenzene in solutions was larger than in that pure nitrobenzene. From the experimental results, the solution structure of TEABr and TBuABr in nitrobenzene are discussed.

It the studies of ionic association in nonaqueous solvents, nitrobenzene has an important role, because of its high viscosity and high dielectric constant. In these studies, the ionic association constant and the kinetic parameters have been determined by means of various techniques, such as electrical conductance[1-3] and ultrasonic absorption measurements.[4] It has been shown that the association of ions in nitrobenzene type was of the solvent-separated type.

Hyne proposed a model for the specific solvation of the n-$Bu_4N^+Br^-$ ion pair in nitrobenzene.[5] Considering the relative dimensions and the charge distributions of the n-$Bu_4N^+Br^-$ ion-pair and nitrobenzene molecule, it was concluded that it was not improbable that the nitrobenzene acts as a "template for the absorption" of n-$Bu_4N^+Br^-$ ion-pairs and this was comfirmed by NMR studies.

Recently, several molecular dynamical studies of liquid nitrobenzene have been reported using nuclear magnetic resonance[6,7] and depolarized Rayleigh scattering.[7,8] In these studies, the reorientational correlation times of nitrobenzene have been determined and the liquid structure of nitrobenzene discussed.

One of the most powerful tools in determining the reorientational correlation times is Raman spectroscopy. It is expected that the reorientational correlation times of the nitrobenzene molecule is a sensitive measure of the solute-solvent interaction, especially the local structure, in solutions.

In this paper, the temperature dependence of the reorientational correlation time of nitrobenzene and the concentration dependence in tetraethyl and tetrabutylammonium bromides–nitrobenzene solutions will be reported. In addition, in order to discuss the effects of viscosity and molecular volume on reorientational motion, the viscosity and partial molar volumes of tetraethyl and tetrabutylammonium bromides in nitrobenzene have been evaluated.

Experimental and Data Analysis

Sample. Nitrobenzene was a commercial product (extra-pure-grade reagent) and was distilled under reduced pressure, after drying by molecular sieves. Tetraethylammonium bromide and tetrabutylammonium bromide, hereafter abbreviated TEABr and TBuABr, respectively, were of extra-pure-grade.

Viscosity and Density Measurements. The density and viscosity were measured, respectively, with an Ostwald type pycnometer and viscometer at 30 °C.

Raman Spectroscopy. The apparatus used consisted of an argon ion laser (800 mW 488 nm) produced by the Coherent Radiation Co., Ltd., and a Laser Raman Spectrometer of JRS-Ul type, JEOL Ltd., Japan.

In order to obtain the reorientational correlation times, the Raman line shape of the ν_{12} (a_1) fundamental mode of ring-stretching,[9] 1004 cm^{-1}, was analyzed. The Raman spectrum was observed at 90° scattering with respect to the linearly polarized incident light. The intensities $I_{isot}(\omega)$ and $I_{anis}(\omega)$ may be determined from the spectra obtained by polarizing the scattered beam parallely, $I_{\parallel}(\omega)$ and perpendicularly, $I_{\perp}(\omega)$ to the electric field vector E of incident light:

$$I_{isot}(\omega) = I_{\parallel}(\omega) - 4/3 I_{\perp}(\omega) \quad (1)$$

$$I_{anis}(\omega) = I_{\perp}(\omega) \quad (2)$$

$I_{isot}(\omega)$ represents the intrinsic vibrational line shape and $I_{anis}(\omega)$ is a convolution of the vibrational line shape and the reorientational spectrum.

The Raman bands measured are broadened by the instrumental slit width and the spectrum obtained is a convolution of the true Lorentzian spectrum and the slit function, $S(\omega)$. The spectral slit function is well approximated by a Gaussian function,[10] and thus:

$$I'(\omega) = N\int_{-\infty}^{\infty} \frac{1}{\beta_L{}^2 + (\omega-\omega')^2} \exp\left\{-\left(\frac{\omega'}{\beta_G}\right)^2\right\} d\omega', \quad (3)$$

where β_L is the true half-width and $\beta_G = S/2\sqrt{\ln 2}$, where, S is the spectral slit width.

An approximate analytical expression for $I'(\omega)$ in Eq. 3, has been proposed by Kielkopf.[12] It is preferable to estimate the apparent spectral line-width as a function of mechanical slit width by means of the direct calculation of Eq. 3 for each β_L value.

For example, the Raman line shape of the $\nu_{12}(a_1)$ band of nitrobenzene is shown in Fig. 1. The spectral half-width of the Raman line of the $\nu_{12}(a_1)$ band of nitrobenzene was measured as a function of the mechanical slit width S. Figure 2 shows a plot of the apparent spectral line width obatined *vs.* the mechanical slit width of the spectrometer used. In Fig. 2, the solid line shows the relation between the apparent spectral line width calculated by Eq. 3 and the mechanical slit width, $\beta_G = S/2\sqrt{\ln 2}$, assuming the true half-width, β_L, of Lorentzian spectrum. As seen in Fig. 2, the agreement between the values observed and those calculated is extremely good. This indicates that the isotropic and anisotropic line shapes of Raman scattering of the $\nu_{12}(a_1)$ fundamental mode of nitrobenzene is adequately described by the Lorentzian function and the slit function, $S(\omega)$, of the spectrometer used may be well approximated by the Gaussian function. The true half-width, β_L, by fitting the observed spectrum with one calculated from Eq. 3 using the

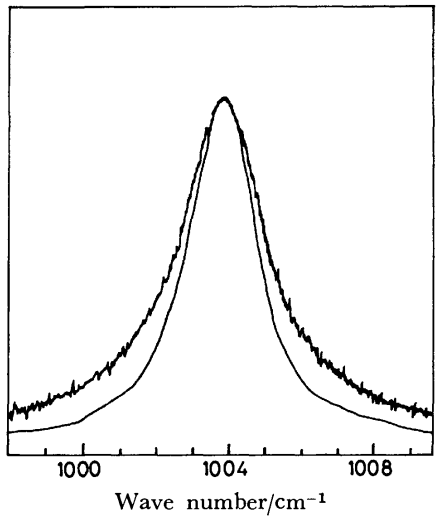

Fig. 1. Raman line shape of isotropic (∥) and anisotropic (⊥) parts of $\nu_{12}(a_1)$ mode (1004 cm^{-1}) of nitrobenzene in tne solution of TBuABr, 0.025 mol/l. (the intensities were normalized each other.)

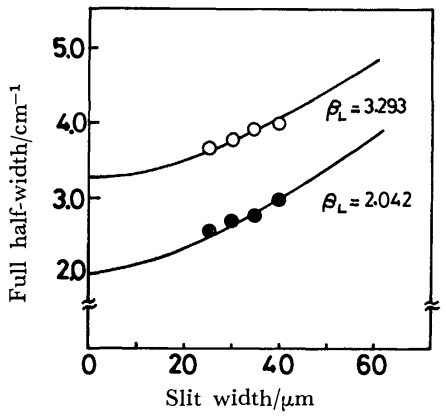

Fig. 2. Plots of apparent spectral slit-width *vs.* mechanical slit-width of the spectrometer used. Solid lines show the calculated ones from Eq. 4. (0.05 mol/l; TBuABr-nitrobenzene solution).
○; Anisotropic, ●; isotropic.

spectral slit width, β_G, under the conditions of measurement. Hereafter, instead of β_L, $\omega_{isot}(1/2)$ and $\omega_{anis}(1/2)$ refer to the true half-width of isotropic and anisotropic Raman line shape.

Thus, the vibrational and reorientational correlation times may be estimated from the half-width of anisotropic and isotropic Raman line shape as follows;

$$\tau_v = (\pi c \omega_{isot}(1/2))^{-1}, \quad (4)$$

$$\tau_{or} = (\pi c \omega_{or}(1/2))^{-1}, \quad (5)$$

where, $\omega_{or}(1/2) = \omega_{anis}(1/2) - \omega_{isot}(1/2)$.

Results

The polts of $\omega_{isot}(1/2)$ and $\omega_{anis}(1/2)$ against the concentration of TEABr and TBuABr are shown in Fig. 3. The differences in these values of TEABr and TBuABr can not be observed. The values of $\omega_{anis}(1/2)$ increase with increasing concentration, but at higher concentration, the increment increase of $\omega_{anis}(1/2)$ with concentration becomes small. The

values of $\omega_{isot}(1/2)$ are however independent of concentration, indicating that the solute molecules, TEABr and TBuABr, do not contribute to the vibrational correlation times of the $\nu_{12}(a_1)$ mode of nitrobenzene in the solutions.

The temperature dependence of $\omega_{anis}(1/2)$ and $\omega_{isot}(1/2)$ of nitrobenzene and nitrobenzene in solutions of TEABr are shown in Fig. 4. As seen, the differences in value of $\omega_{isot}(1/2)$ in pure nitrobenzene and in the solutions could not be observed in the temperature ranges, but at the transition point from solid to liquid phases, the values of $\omega_{isot}(1/2)$ change drastically. This line broadening is thought due to a molecular dephasing process accompanied by molecular collisions in the liquid and/or solution. This mechanism is independent of the solute ions in solutions. The values of $\omega_{anis}(1/2)$ in the liquid phase increase with increasing temperature.

In Table 1, the partial molar volumes and the viscosity *B* coefficients of TEABr and TBuABr in nitrobenzene, obtained from density and viscosity measurements, are summarized together with those in aqueous solutions.

Table 1. Partial molar volumes and B coefficient of TEABr and TBuABr in nitrobenzene

Discussion

The molecular symmetry of nitrobenzene belongs to the class C_{2v}. In the present work, the $\nu_{12}(a_1)$ mode of nitrobenzene, the ring stretching mode, was used to determine the reorientational correlation time of nitrobenzene by line shape analysis. As clearly indicated by Nafie and Peticolas,[13] the normalized correlation function obtained from the Raman line shape analysis of this mode may be expressed as follows;

$$C(t) = (a^2+b^2+c^2-ac-ab-bc)^{-1} \times \{(b-a)^2\boldsymbol{P}_2[\boldsymbol{u}^y(0)\boldsymbol{u}^y(t)] + (c-a)^2\boldsymbol{P}_2[\boldsymbol{u}^z(0)\boldsymbol{u}^z(t)] + (b-a)(c-a)\boldsymbol{P}_2[\boldsymbol{u}^z(0)\boldsymbol{u}^y(t)] + \boldsymbol{P}_2[\boldsymbol{u}^y(0)\boldsymbol{u}^z(t)]\}, \quad (6)$$

where $\boldsymbol{u}^z(0)$ is unit vector indicating the direction of the molecular z axis at time $t=0$, $\boldsymbol{u}^z(t)$ indicates the direction of the same axis at time t and a, b, and c refer to the Raman tensors of α_{xx}, α_{yy}, and α_{zz}, respectively. Therefore, at this stage, the reorientational correlation time, τ_{or}, obtained from the Raman line shape analysis of the ν_{12} mode of nitrobenzene can not explicitly assigned to a rotational diffusion tensor. Bauer *et al.* concluded by comparison with NMR measurements that the reorientation about the z axis is at least twice as fast as reorientation about the other axis.[7,8] The reorientational motion of nitrobenzene is mainly concerned with motion about the z axis and the τ_{or} obtained, here, is a measure of the local motion of nitrobenznene in the liquid and solutions.

Influence of TEABr and TBuABr on the Molecular Motion of Nitrobenzene. As seen in Fig. 3, the values of $\omega_{isot}(1/2)$, which are related to the vibrational correlation times of nitrobenzene, are independent of the concentration of tetraalkylammonium bromide and its chain length. This indicates that the solute molecules do not affect the molecular vibrational correlation times of nitrobenzene as a solvent.

The plots of reorientational correlation time against the concentration of TEABr and TBuABr are shown in Fig. 5. The reorientational correlation time of nitrobenzene, τ_{or}, as a solvent decreases with increasing concentration of solute, indicating that the interaction between nitrobenzenes is stronger than that between nitrobenzene and TEABr and/or TBuABr. As seen in Table 1, the partial molar volumes of TEABr and TBuABr in nitrobenzene do not greatly differ from in aqueous solutions. This indicates that the molecular diameter and volumes of the tetraalkylammonium ion in nitrobenzene are comparable to those in aqueous solutions. The viscosity B coefficients of both solutions

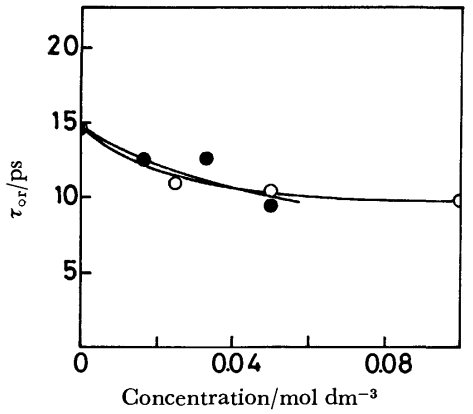

Fig. 5. Plots of τ_{or} *vs.* concentration of salts in solutions.
●; τ_{or} of nitrobenzene in TEABr,
○; τ_{or} of nitrobenzene in TBuABr.

○; τ_{or} of nitrobenzene in 0.0333 mol/l TEABr solution.
●; τ_{or} of neat nitrobezene.

are positive.

The values of $(B-\phi_{ion}^\circ)$ which are a measure of the ion-solvent interactions do not differ indicating that the ion-solvent interactions remain in TEABr and TBuABr–nitrobenzene solutions. The results mentioned above do not agree with the model proposed by Hyne for specific solvation of n-$Bu_4N^+Br^-$ ion-pairs and nitrobenzene.

Temperature Dependence of Reorientational Correlation Times of Nitrobenzene in the Pure and Solution States. The relationships between the reorientational correlation times of nitrobenzene in the pure and solution states, τ_{or}, and $1/RT$ are shown in Fig. 6. As seen in Fig. 6, τ_{or} can be expressed by the equation

$$\tau_{or} = \tau_{or}^\circ \exp(U/RT), \quad (7)$$

TABLE 2. REORIENTATIONAL RELAXATION TIMES DETERMINED BY VARIOUS TECHNIQUES

T/°C	τ_{or}(Raman)	τ_{1s}	$\tau_{NMR,p}(C^{13})$	$\tau_{NMR,o,m}(C^{13})$	$\tau_{NMR}(N^{14})$
10	14.8[a]				
20	17.6[e]	40.83[e]			
24		36.0[b]	12.5[b]	8.1[b]	
30	13.1[a]				3.45 (25 °C)[d]
38			9.6[c]	6.6[c]	
50	8.0[a]				
70	5.7[a]				

a) This work. b) Ref. 7. c) G. C. Levy, J. D. Cargioli, and F. A. L. Anet, *J. Am. Chem. Soc.*, **95**, 1527 (1973). d) Ref. 6. e) A. M. Amorim, D. Costa, M. A. Norman, and J. H. Rclarke, *Mol. Phys.*, **29**, 191 (1975).

where U refers to the apparent activation energy. The apparent activation energies, U, estimated from the plots of τ_{or} *vs.* $1/RT$ are 3.5 kcal/mol and 2.2 kcal/mol in the pure and solution states, respectively. The value of U, 3.5 kcal/mol, for pure liquid nitrobenzene is in good agreement with those obtained from the temperature dependence of "quadrupolar" correlation times for the molecular reorientation of liquid nitrobenzene by means of nuclear relaxation experiment of N^{14} [6] and are also comparable to those obtained from the temperature dependence of viscosity of nitrobenzene.

The reorientational correlation times of nitrobenzene in the solution of TEABr (0.0333 mol/l) are shorter than that in the pure liquid state in the temperature ranges and the apparent activation energy of τ_{or} in the solution state is smaller than that in pure liquid state. This indicates that the molecular motion of nitrobenzene is easier in solution than in the pure liquid state.

Bauer *et al.*[8] considered that nitrobenzene forms a "weak" dimer which hinders rotation. The addition of TEABr and/or TBuABr in nitrobenzene breaks the "weak" dimer and consequently nitrobenzene molecule can rotate more freely.

Comparison with Other Relaxation Times. The reorientational relaxation time obtained from the depolarized light scattering spectrum, τ_{LS}, relates to the single particle reorientational relaxation time, τ_s, which can be determined directly by means of Raman line shape analysis:[8]

$$\tau_{LS} = \left(\frac{1+fN}{1+gN}\right)\tau_s, \qquad (8)$$

where the parameter, fN and gN, refer to the static and dynamic orientational pair correlation terms, respectively.

The relaxation times determined by several techniques are summarized in Table 2. Alms *et al.*[8] estimated the values of fN and gN as 1.30 ± 0.05 and 0.1 ± 0.0 for neat nitrobenzene. Using the value of τ_{LS}, 36.0 ps, and these values of fN and gN, the single particle relaxation time, τ_s, has been estimated to be 15.8 ± 0.5 ps. This value is in good agreement with those of τ_{or} obtained from the Raman line shape analysis.

Branched-chain Sugars. XIX. On the Application of ^{13}C NMR Spectroscopy to the Configurational Assignment of 3-*C*-Substituents of Aldohexopyranose Derivatives[1)]

Ken-ichi SATO, Masafumi MATSUZAWA, Katsumi AJISAKA,† and Juji YOSHIMURA*

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received May 18, 1979)

It was found that ^{13}C NMR spectroscopy is applicable to the unequivocal configurational assignment at the quarternary carbon in seven pairs of 3-*C*-substituted-hexopyranose derivatives. The configuration of methyl 4,6-*O*-benzylidene-3-*C*-nitromethyl-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside reported by Jordaan *et al.* is revised to D-*allo* by a chemical method.

Determination of the configuration of a branching carbon atom in branched-chain sugars having no hydrogen atom at the branching point is difficult, no simple and reliable method being available. In our work on the subject, chemical derivations, cuprammonium complex formation,[1)] and the chemical shift of tertiary acetoxyl protons[3)] have been used. However, some exceptions in ^1H NMR method have been found in the case of branched-chain sugars.[4-6)]

Recently, lanthanoid-induced changes in the chemical shifts of ^1H NMR[7)] and the ^{13}C chemical shift differences between axial and equatorial carbons[8)] have been used to elucidate the configuration of tertiary alcoholic centers of several branched-chain sugars.

In the lanthanoid method, the magnitude of the shift gradient (proportional shift of the concentration to shift reagent) for each identifiable proton resonance of a tertiary alcoholic derivative is compared with that of the corresponding secondary alcohol of known stereochemistry. The uniform correspondence of the entire set of shift gradients is taken as evidence of their same relative configuration.[7)] However, during the course of examination of the method for branched-chain sugars synthesized in our laboratory, we found that it is ambiguous in a few instances; the configuration of methyl 4,6-*O*-benzenzylidene-3-*C*-nitromethyl-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (**1**)[9)] assigned by this method[6)] has been revised to D-*allo* (**2**).

More data seemed necessary to establish the ^{13}C NMR method. In this paper, the above structure revision and consistent results in the examination of the ^{13}C NMR method for seven pairs of 3-*C*-substituted hexopyranose derivatives having various functional groups at the branching point are described.

Results and Discussion

Methyl 4,6-*O*-benzylidene-3-*C*-(benzoylaminomethyl)-α-D-allopyranoside (**3**) was obtained by the reaction of methyl 4,6-*O*-benzylidene-2-*O*-benzoyl-α-D-*ribo*-hexopyranosid-3-ulose with nitromethane, followed by hydrogenation which was accompanied by O→N benzoyl migration.[10)] The configuration of **3** was confirmed by comparison of the rotational change in cuprammonium solution with that of its 3-epimer synthesized from the same 3-ulose by the successive reactions; spiro-epoxidation with diazomethane, epoxy-ring opening with ammonia, and then *N*-benzoylation. From the results, the assignment of D-*gluco* configuration to a 3-*C*-nitromethyl derivative from nitromethane and 2-*O*-*p*-tolylsulfonyl analogue of the above 3-ulose was highly doubtful. From the reaction conditions the 3-*C*-nitromethyl derivatives were considered to be thermodynamically stable products. Consequently, **1** preparaed according to the method of Jordaan *et al.*[9)] was hydrogenated in the presence of well-washed Raney nickel and then subjected to *N*-benzoylation with benzoic anhydride to give the corresponding 3-*C*-(benzoylaminomethyl) derivative (**4**). Treatment of **3** in pyridine with equimolar *p*-toluenesulfonyl chloride also gave **4**. Thus, the D-*gluco* configuration of **1** assigned by shift reagent method was revised to D-*allo* (**2**) by the chemical method.

The fact that equatorially oriented branching carbons are deshielded with respect to axially oriented carbons in ^{13}C NMR for the configurational assignment of branched-chain pyranoses has been shown by examination of three epimeric pairs of 4-*C*-methyl,[11)] two pairs of 3-*C*-hydroxymethyl,[8)] one pair of 3-*C*-methyl derivatives[8)] possessing an hydroxyl group at the quarternary carbon, and one pair of 2-deoxy-2-*C*-methyl derivatives.[11)] We have examined seven epimeric pairs of 3-*C*-substituted derivatives: methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-*C*-methyl-α-D-allo- (**5**) and -glucopyranoside (**6**),[10)] their 3-*O*-acetyl derivatives (**7** and **8**),[10)] methyl 4,6-*O*-benzylidene-3-*C*-methyl-2-*O*-methyl-α-D-allo- (**9**) and glucopyranoside (**10**),[4a)] methyl 4,6-*O*-benzylidene-3-*C*-methyl-2-*O*-methyl-α-D-altro- (**11**) and -mannopyranoside (**12**),[4a)] methyl 2-*O*-acetyl-3-*C*-(benzoylaminomethyl)-4,6-*O*-benzylidene-α-D-allo- (**13**)[10)] and -glucopyranoside (**14**), methyl 3-acetylamino-2,3,6-trideoxy-3-*C*-methyl-4-*O*-methyl-α-L-*ribo*- (**15**) and -*arabino*-hexopyranoside (**16**),[1)] 2,3,6-trideoxy-3-*C*-methyl-4-*O*-methyl-3-nitro-L-*ribo*- (**17**) and -*arabino*-hexose (**18**),[1)] and one pair of 2-*C*-methyl derivatives; methyl 4,6-*O*-benzylidene-2-*C*-methyl-3-*O*-methyl-α-D-altro- (**19**) and -allopyranoside (**20**).[4b)] Among these compounds, only **14** was newly synthesized by acetylation of the 3-epimer of **3**[10)] in pyridine with acetic anhydride.

Chemical shifts of the chain carbons and 3-*C*-branching carbon of hexopyranoses and shift differences between axially and equatorially oriented carbons at C_3 in **5**—**18** and at C_2 in **19** and **20** are summarized in Table 1. The carbon shifts were distinguished

† Present address: Ajinomoto Co., Inc., Central Research Laboratories, 1-1 Suzuki-cho, Kawasaki-ku, Kawasaki 210.

from other carbon shifts in phenyl, methine, methoxyl, and acetyl groups on the basis of their position, multiplicity and consistency.[7,8,11-13] The methyl signals of the same chemical shift in a pair of 3-epimers were assigned to confusing methyl carbons in acetyl groups.

Of the carbon shifts given, C_1, C_6, quarternary carbon atoms and branching carbon atoms were identified

from their chemical shifts and single frequency off-resonance decoupled spectra, the other carbons being assigned from their chemical shifts. The effect of acetylation of the tertiary hydroxyl group[14] was observed on the chemical shifts of C_3 and branching carbons in **7** and **8**, as compared with those in **5** and **6**. The deshielding effect[12] by *O*-methylation is also prominent in the chemical shifts of C_2 in **9**—**12**, C_4 in **15** and **17**, and C_3 in **19** and **20**, but very small in the cases of **16** and **18**. The lower field shifts from the usual position of branching carbons in **13** and **14**, and of C_3 in **15**—**18** are attributed to the deshielding effects of the groups attached to them; the chemical shifts of C_2 and C_5 in **15**—**18** are reasonable for the deoxy carbon atoms of 2,6-dideoxy-4-*O*-methylhexoses.[13] Data of **17** and **18** support the ^1H NMR spectra which show that **17** exists almost completely in the β-form, whereas **18** exists in an α,β-mixture of nearly equal amounts.

The resonance due to the equatorial carbon atoms of 3-*C*-branching chains is always at a field lower than that of the axial carbons for the seven pairs of 3-*C*-substituted sugars examined (Table 1). Consistent results were also obtained for the sugars containing a benzoylaminomethyl group or a nitro group at quar-

TABLE 1. ^{13}C CHEMICAL SHIFTS OF CHAIN CARBON ATOMS AND BRANCHING CARBON ATOMS OF BRANCHED-CHAIN SUGARS AND THE CHEMICAL SHIFT DIFFERENCES BETWEEN AXIALLY AND EQUATORIALLY ORIENTED CARBON ATOMS (ppm from Me_4Si in $CDCl_3$)

a) Assignments may be reversed although those given here are preferred.

ternary carbon. It was established for seven pairs of 3-*C*-substituted sugars that the $\Delta(e-a)$ values in the ^{13}C NMR spectra permit the configurational assignment at the 3-*C* position. Inconsistent results for the 2-*C*-methyl derivatives **19** and **20** seem to be related to their conformations. At present only a somewhat flattened configuration can be deduced from the $J_{3,4}=2.0$ Hz value for **20**, more data being needed for 2-*C*-branching sugars.

Experimental

^{13}C NMR spectra of branched-chain sugars, **5**, **6**, **9**—**12**, **19**, and **20** were obtained at 30 °C on a JEOL JNM FX-100 spectrometer in pulse Fourier transform/proton noise decoupled mode at 25.15 MHz in deuteriochloroform. The corresponding spectra of **7**, **8**, and **13**—**18** were similarly recorded 32 °C on a Varian XL-100-15-FT spectrometer. Each spectrum was obtained after 1000 transients with a spectral width of 5000 Hz, a computer data memory size for the free induction decay of 8 K, an acquisition time of 0.8 s, a pulse delay of 0.8 s, and pulse angle of 45°. ^1H NMR spectra were measured on a JEOL PS-100 spectrometer with a CW mode. All measurments were carried out in a $CDCl_3$ solution containing a drop of TMS as an internal standard. Optical rotations were measured in 0.2-dm tubes in a Carl Zeiss LEP-A1 polarimeter. IR spectra were recorded with a Hitachi Model EPI-G2 spectrometer.

Chemical shifts and coupling constants in ^1H NMR were recorded in δ(ppm) and Hz, respectively, and IR frequencies in cm^{-1}.

Methyl 3-C-(benzoylaminomethyl)-4,6-O-benzylidene-2-O-p-tolylsulfonyl-α-D-allopyranoside (4). *a)*: Methyl 4,6-*O*-benzylidene-3-*C*-nitromethyl-2-*O*-*p*-tolylsulfonyl-α-D-allopyranoside [300 mg, mp 143—145 °C, $[\alpha]_D$ +39.5° (*c* 1.01, $CHCl_3$)] prepared by the method of Jordaan *et al.* [lit,[9] mp 143—144 °C, $[\alpha]_D^{24}$ +41.6° (*c* 1, $CHCl_3$)] was hydrogenated in ethanol in the presence of well-washed Raney nickel at room temperature, and then filtered. The filtrate was evaporated under reduced pressure. The residue was *N*-benzoylated with benzoic anhydride (150 mg) in ethanol to give **4** (121 mg) in 35% yields. Mp 184—185 °C (from ethanol), $[\alpha]_D^{22}$ +13.3° (*c* 1.8, $CHCl_3$), IR: 3450 (NH), 3340 (OH), 1636 (NHBz), NMR: 8.00—7.24 (Ph:m), 7.10 (NH), 5.57 (PhCH), 4.74 (H_1: d, $J_{1,2}=4.0$), 4.61 (H_2: d), 4.36 (H_6: q, $J_{5,6}=4.0$), 4.28—3.95 (CH_2: m), 3.95 ($H_{6'}$: t, $J_{5,6'}=J_{6,6'}=9.0$), 3.38 (H_5: m), 3.35 (OMe), 2.43 ($PhCH_3$).

Synthesis of a Partial Sequence of Proinsulin Using the A-Chain of Natural Insulin. II.[1] Synthesis of a Peptide Corresponding to Positions 53—81 of Bovine Proinsulin

Hiroko AIBA and Yasutsugu SHIMONISHI*

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 23, 1979)

For the synthesis of bovine proinsulin, the *S*-sulfonate of the A-chain of bovine insulin was elongated by two single-step reactions using Boc-Arg(Tos)-ONSu and Boc-Leu-Glu(OBu^t)-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-N_3. The *S*-sulfonate of the Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain, corresponding to positions 53—81 of bovine proinsulin, was obtained after removal of the protecting groups. The *S*-sulfonates of the elongated derivatives of the A-chain were shown to be very soluble not only in water, but also in organic solvents such as DMF and DMSO in the presence of water. Therefore, these *S*-sulfonates could react with protected peptides in homogeneous solution. Furthermore, the *S*-sulfonates could easily be purified by ion-exchange chromatography. The *S*-sulfonates of the A-chain and its elongated derivatives are thus useful intermediates for the synthesis of proinsulin.

Weinert *et al.*[2] proposed that the *S*-sulfonate of the des-Gly^1-A-chain, prepared by the Edman degradation of the A-chain of natural insulin, can be used as starting material for the synthesis of proinsulin. The procedure has the advantage that the des-Gly^1-A-chain can be coupled by various methods with protected peptides which have a glycine residue at the carboxyl end. However, the procedure is complicated, since the des-Gly^1-A-chain must be prepared from the A-chain by a laborious degradation process. One of the authors (Y.S.)[1] reported the synthesis of a partial sequence of proinsulin using the *S*-sulfonate of the A-chain[3,4] prepared by sulfitolysis of natural insulin. The procedure merits special attention as a method for direct elongation of the A-chain.

We are working on further elongation of the peptide chain of the A-chain of bovine insulin using our procedure for the synthesis of proinsulin. This paper describes the synthesis of a partial sequence corresponding to positions 53—81 of bovine proinsulin[5] (Fig. 1). First, Boc-Leu-Glu(OBu^t)-Gly-Pro-Pro-Gln-Lys-[Z(2-Cl)]-N_2H_3[6] (X) was synthesized (Fig. 2), two fragments, Boc-Leu-Glu(OBu^t)-Gly-OH (IV) and Boc-Pro-Pro-Gln-Lys[Z(2-Cl)]-OMe (VIII), being synthesized separately and coupled together to give the heptapeptide methyl ester (IX), which was then converted to the corresponding hydrazide (X). The tripeptide (IV) was synthesized by two routes. (a) Z-Glu(OBu^t)-ONSu[7] was coupled with H-Gly-OEt to give Z-Glu(OBu^t)-Gly-OEt (I). The dipeptide ethyl ester (I) was then catalytically hydrogenated. The resulting dipeptide ester was not isolated, but coupled directly with Boc-Leu-ONSu[8] to give Boc-Leu-Glu(OBu^t)-Gly-OEt (II). The resulting tripeptide ester was converted to the corresponding acid (IV) by saponification. (b) Z-Glu(OBu^t)-ONSu[7] was condensed with H-Gly-OBzl to give Z-Glu(OBu^t)-Gly-OBzl (III). The dipeptide benzyl ester (III) was catalytically hydrogenated and the resulting dipeptide was condensed with Boc-Leu-ONSu[8] to give IV.

The synthesis of the tetrapeptide, Boc-Pro-Pro-Gln-Lys[Z(2-Cl)]-OMe (VIII), was started by condensing Boc-Gln-ONp[9] with H-Lys[Z(2-Cl)]-OMe (V) to give Boc-Gln-Lys[Z(2-Cl)]-OMe (VI). VI was then treated with TFA and the resulting dipeptide ester was coupled with Boc-Pro-Pro-ONSu (VII) prepared by condensing Boc-Pro-Pro-OH[10] with HONSu using DCC, to give Boc-Pro-Pro-Gln-Lys[Z(2-Cl)]-OMe (VIII). The tetrapeptide (VIII) thus synthesized was treated with TFA and the resulting tetrapeptide ester was condensed with the tripeptide (IV) using DCC in the presence of HOBt.[11] The isolated Boc-Leu-Glu(OBu^t)-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-OMe (IX) was converted to the corresponding hydrazide (X) by the usual method of hydrazinolysis.

The *S*-sulfonate of the Arg-A-chain[2] was synthesized by coupling the *S*-sulfonate of the A-chain with Boc-Arg(Tos)-ONSu and removing the protecting group of the arginine residue of the *S*-sulfonate of the Boc-Arg(Tos)-A-chain with anhydrous liquid hydrogen fluoride.[12] In the preceding work,[1] the *S*-sulfonate of the protected Arg-A-chain, Boc-Arg(NO_2)-A-chain, was used directly without removal of the guanidino protecting group of the arginine residue. However, when Boc-Arg(Tos)-ONSu was used for acylation of the *S*-sulfonate of the A-chain, no quantitative coupling of the A-chain could be attained. Thus, in this work the protecting group of the arginine residue was removed from the *S*-sulfonate of the crude Boc-Arg(Tos)-A-chain, the *S*-sulfonate of Arg-A-chain[2] being purified by chromatography on DEAE-Sephadex A-25[13] (Fig. 3).

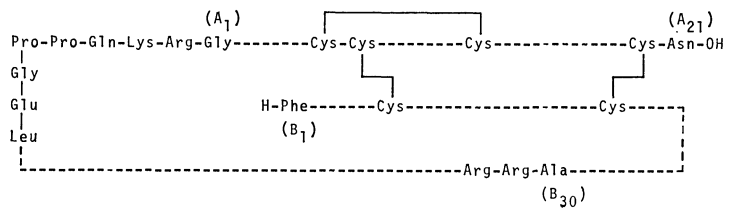

Fig. 1. Structural model of bovine proinsulin.[5]

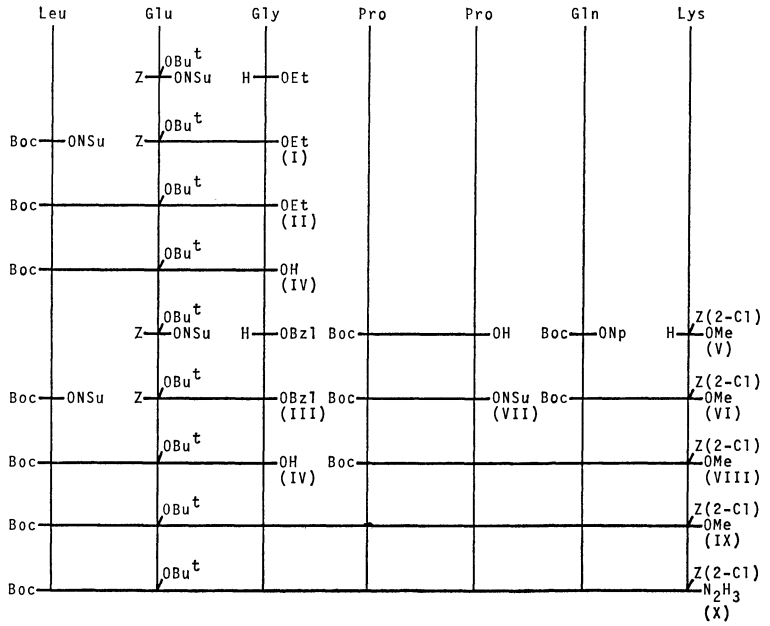

Fig. 2. Scheme for synthesis of protected heptapeptide (sequence corresponding to positions C_{21} to CA_1 in bovine proinsulin).

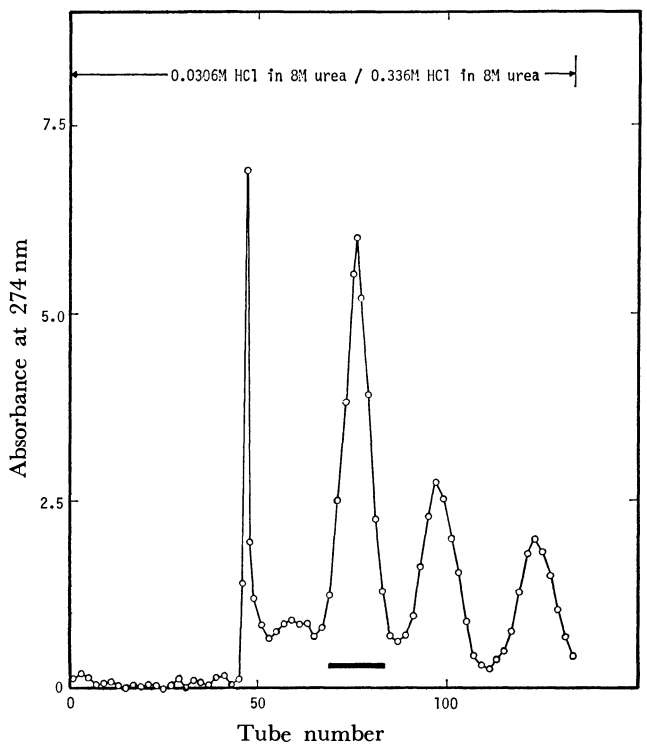

Fig. 3. Chromatogram of the *S*-sulfonate of Arg-A-chain on DEAE-Sephadex A-25 under the conditions described in the text.

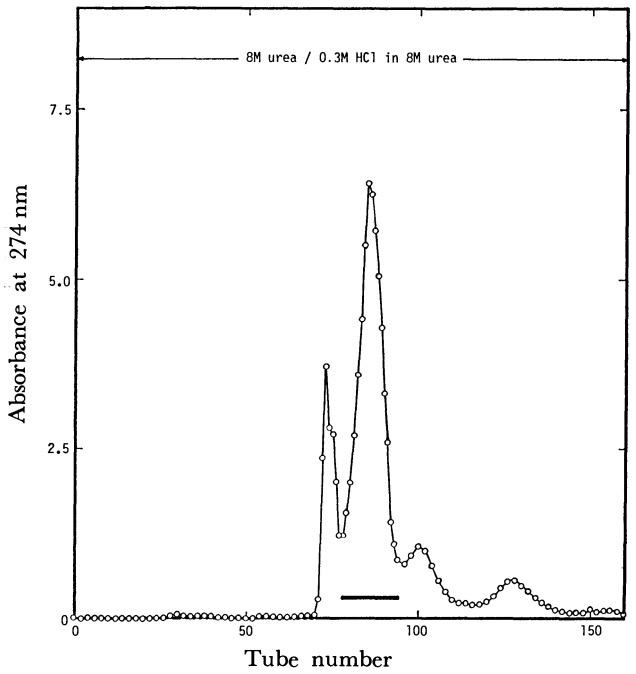

Fig. 4. Chromatogram of the *S*-sulfonate of Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain on DEAE-Sephadex A-25 under the conditions described in the text.

The *S*-sulfonate of Arg-A-chain was acylated by protected peptide azides with the sequence, Leu-Glu-Gly-Pro-Pro-Gln-Lys. The *S*-sulfonate of the Arg-A-chain was coupled with Boc-Leu-Glu(OBu^t)-Gly-Pro-Pro-Gln-Lys(Z)-N_3, prepared from the corresponding hydrazide. Considerable cleavage of the N$^\varepsilon$-Z group from the lysine residue occurred when the isolated *S*-sulfonate of the Boc-Leu-Glu(OBu^t)-Gly-Pro-Pro-Gln-Lys(Z)-Arg-A-chain was treated with TFA to remove the Boc group at the amino terminus. The *S*-sulfonate of the Arg-A-chain was then condensed with Boc-Leu-Glu(OBu^t)-Gly-Pro-Pro-Gln-Lys-[Z(2-Cl)]-N_3 protected at the lysine residue with the Z(2-Cl) group,[14] which is more stable than the Z group. The condensation reaction was examined using ratios of 5, 7.5 and 10 equivalents of the protected peptide azide to the *S*-sulfonate of the Arg-A-chain under the conditions described below. The resulting

TABLE 1. AMINO ACID CONTENTS OF DERIVATIVES OF THE A-CHAIN[a]

Amino acid	I[b]	II[b]	III[b]
Lys			1.00 (1)
Arg		1.01 (1)	1.00 (1)
Asp	1.99 (2)	1.96 (2)	1.94 (2)
Ser	1.82 (2)	1.58 (2)	1.79 (2)
Glu	4.35 (4)	4.23 (4)	6.73 (6)
Pro			2.09 (2)
Gly	1.02 (1)	0.99 (1)	1.95 (2)
Ala	1.00 (1)	1.00 (1)	1.00 (1)

Val	1.59 (2)	1.80 (2)	1.59 (2)
Ile	0.60 (1)	0.84 (1)	0.63 (1)
Leu	2.03 (2)	2.00 (2)	2.96 (3)
Tyr	2.12 (2)	1.94 (2)	1.94 (2)

a) Molar ratios of individual amino acid are shown relative to that of alanine. Numbers in parentheses are theoretical values. b) Compounds I, II, and III are the *S*-sulfonates of the A-chain, Arg-A-chain and Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain, respectively. c) Cystine was not determined.

S-sulfonate of Boc-Leu-Glu(OBu^t)-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain was treated with TFA and the *S*-sulfonate obtained was subjected to chromatography on DEAE-Sephadex A-25[13] (Fig. 4). The best result was obtained with use of 7.5 equivalents of the protected peptide azide.

The N-terminal amino acid residues of the purified *S*-sulfonates of the Arg- and Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chains were detected as arginine and leucine, respectively, by dinitrophenylation.[15] Amino acid analyses of acid hydrolysates of the purified *S*-sulfonates gave satisfactory results (Table 1).

Thus, the *S*-sulfonate of the A-chain of bovine insulin was elongated by reactions with acylamino acid active ester and acylpeptide azides. During the procedure it became clear that the *S*-sulfonates of the elongated derivatives of the A-chain thus synthesized are very soluble in buffers and organic solvents such as DMF and DMSO containing water, and can react with acylpeptide in homogeneous solution and be purified by chromatography on ion-exchange resin. These *S*-sulfonates seem to be useful intermediates for synthesis of proinsulin. Results on the further elongation of the derivatives obtained will be described in subsequent papers.[16,17]

Experimental

Crystalline bovine insulin was obtained from the Chemical Research Laboratories, Takeda Chemical Industries, Ltd. (Osaka), by courtesy of Dr. M. Fujino. Sephadex was purchased from Pharmacia Co. (Uppsala). All chemicals were of reagent grade and used without further purification. Thin layer chromatography was performed on silica gel G (Merck) using the following solvent systems (volume ratios); $CHCl_3$: MeOH : AcOH (95 : 5 : 3), *n*-BuOH : AcOH : H_2O (4 : 1 : 1), $CHCl_3$: MeOH : AcOH : H_2O (10 : 10 : 1 : 10, lower phase). Peptide samples were hydrolyzed in 6 M HCl in sealed tubes at 105 °C for 48 h, amino acids in the hydrolysates being analyzed in a Hitachi KLA-5 analyzer by the method of Moore *et al.*[18] Optical rotations were determined with a Perkin-Elmer Model 241 polarimeter. Melting points were measured by the capillary method and are given as uncorrected values. 1 M = 1 mol dm^{-3}.

Z-Glu(OBu^t)-Gly-OEt (I). H-Gly-OEt·HCl (7.50 g, 53.6 mmol) and TEA (7.6 ml) were dissolved in a mixture of DMF (100 ml) and $CHCl_3$ (100 ml), and then Z-Glu (OBu^t)-ONSu[7] (19.5 g, 44.9 mmol) was added to the solution. The solution was stirred at room temperature for a day and then concentrated to a syrup *in vacuo*. The syrup was dissolved in AcOEt, and the solution was washed successively with 0.1 M HCl and 5% aqueous $NaHCO_3$ and then dried over Na_2SO_4. The dried solution was concentrated to a syrup *in vacuo*; crystals formed on storage in a refrigerator. The crude crystals were collected by filtration with hexane; wt 18.2 g (95.8%). The crude material was recrystallized from AcOEt and hexane; wt 15.6 g (82.1%), mp 76.5—78 °C, $[\alpha]_D^{20}$ −7.3° (*c* 2.0, DMF).

Found: C, 59.63; H, 7.15; N, 6.78%. Calcd for $C_{21}H_{30}O_7N_2$: C, 59.70; H, 7.16; N, 6.63%.

Boc-Leu-Glu(OBu^t)-Gly-OEt (II). Compound I (8.45 g, 20.0 mmol) was dissolved in EtOH (100 ml) and hydrogenated over 5% palladium-charcoal catalyst under atmospheric pressure for 2.5 h. The catalyst was filtered off and washed with EtOH. The filtrate and washings were combined and concentrated to a solid under reduced pressure. The solid was dissolved with Boc-Leu-ONSu[8] (7.20 g, 22.0 mmol) in a mixture of DMF (50 ml) and CH_2Cl_2 (50 ml). The solution was stirred at room temperature for 1 h and then concentrated to a semi-solid residue. The residue was dissolved in $CHCl_3$ and the solution was washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water. The washed solution was dried and then concentrated to a solid. The solid was collected by filtration with hexane; wt 9.00 g. The crude material was recrystallized from AcOEt and hexane; wt 6.70 g (67.0%), mp 128—130 °C, $[\alpha]_D^{20}$ −22.6° (*c* 1.0, DMF).

Found: C, 57.37; H, 8.94; N, 8.33%. Calcd for $C_{24}H_{43}O_8N_3$: C, 57.46; H, 8.64; N, 8.38%.

Z-Glu(OBu^t)-Gly-OBzl (III). H-Gly-OBzl·TosOH (12.1 g, 35.9 mmol) was suspended in THF (200 ml) and mixed with TEA (5.0 ml). The clear solution thus obtained was mixed with Z-Glu(OBu^t)-ONSu[7] (13.0 g, 30.0 mmol). The mixture was stirred at room temperature for 4 d and then concentrated to a syrupy residue, and the residue was dissolved in AcOEt. The solution was washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water. The washed solution was dried and then concentrated to an oil. The oil was triturated in AcOEt and hexane; wt 13.5 g. The crude product was recrystallized from AcOEt and hexane; wt 12.0 g (82.2%), mp 59.5—61.5 °C, $[\alpha]_D^{19}$ −6.0° (*c* 2.0, DMF). (lit,[19] mp 45—47 °C, $[\alpha]_D^{25}$ −15.9° (*c* 1.01, MeOH)).

Found: C, 64.46; H, 6.65; N, 5.82%. Calcd for $C_{26}H_{32}O_7N_2$: C, 64.45; H, 6.66; N, 5.78%.

Boc-Leu-Glu(OBu^t)-Gly-OH·DCHA (IV). a) Compound II (6.52 g, 13.0 mmol) was dissolved in dioxane (100 ml). To the solution was added 1 M NaOH (15.6 ml) dropwise under cooling with ice-water. The solution was stirred at room temperature for 2 h and then neutralized with 1 M HCl and the dioxane was evaporated off. The residue was mixed with 5% aqueous $NaHCO_3$ and AcOEt. The aqueous layer was separated from the organic layer and acidified with 1 M HCl. The product was extracted several times with AcOEt. The extracts were combined,

dried and concentrated to a syrup; wt *ca.* 5.5 g.

b) Compound III (12.1 g, 24.9 mmol) was dissolved in MeOH (300 ml) and hydrogenated over 5% palladium–charcoal catalyst at 35 °C for 2.5 h. The catalyst was filtered off and the filtrate was concentrated to a solid. The solid was mixed with Boc–Leu–ONSu[8] (9.00 g, 27.4 mmol) and TEA (3.5 ml) in $CHCl_3$ (200 ml), and then stirred at room temperature for 3 d. The reaction mixture was concentrated to a residue, which was dissolved in AcOEt. The solution was washed with 0.1 M HCl and water, dried and concentrated to a syrupy residue. The residue was dissolved with DCHA (5.0 g) in AcOEt. Hexane was added to the soultion and the precipitate formed was collected by filtration; wt 16.0 g. The crude product was crystallized from AcOEt and hexane; wt 13.5 g (82.8%), mp 137—140 °C, $[\alpha]_D^{15.5}$ −13.5° (*c* 1.0, DMF).

Found: C, 62.04; H, 9.78; N, 8.42%. Calcd for $C_{34}H_{62}O_8N_4$: C, 62.35; H, 9.54; N, 8.56%.

H–Lys[Z(2-Cl)]–OMe·HCl (V). Thionyl chloride (8.7 g) was added dropwise in MeOH below −10 °C. To the solution was added H–Lys[Z(2-Cl)]–OH[14] (22.0 g, 69.8 mmol). The mixture was stirred at room temperature for 3 d and concentrated to a syrup, which was crystallized from MeOH and ether; wt 22.5 g. The crude material was recrystallized from MeOH and ether; wt 18.0 g (70.6%), mp 119—121 °C, $[\alpha]_D^{19}$ +12.0° (*c* 2.0, DMF).

Found: C, 49.19; H, 6.04; N, 7.90; Cl, 19.64%. Calcd for $C_{15}H_{22}O_4N_2Cl_2$: C, 49.32; H, 6.07; N, 7.67; Cl, 19.41%.

Boc–Gln–Lys[Z(2-Cl)]–OMe (VI). Compound V (1.80 g, 4.93 mmol) was dissolved in DMF (30 ml) and mixed with TEA (0.7 ml). The mixture was stirred with Boc–Gln–ONp[9] (2.00 g, 5.45 mmol) at room temperature for 1 d and then concentrated to dryness. The residue was dissolved in AcOEt and washed successively with 0.1 M HCl, 1 M Na_2CO_3 and water. The washed solution was dried and then concentrated to a syrup, which was crystallized from AcOEt and hexane; wt 2.33 g. The crude material was recrystallized from AcOEt and hexane; wt 2.30 g (83.6%), mp 95.5—97.5 °C, $[\alpha]_D^{19}$ −7.6° (*c* 2.0, DMF).

Found: C, 53.91; H, 6.93; N, 9.87; Cl, 6.40%. Calcd for $C_{25}H_{37}O_8N_4Cl$: C, 53.90; H, 6.70; N, 10.06; Cl, 6.37%.

Boc–Pro–Pro–ONSu (VII). A solution of Boc–Pro–Pro–OH[10] (25.0 g, 80.1 mmol) and HONSu (10.0 g, 87.0 mmol) in THF (400 ml) was cooled to −10—−20 °C, DCC (16.5 g, 80.1 mmol) then being added. The solution was stirred at the same temperature for 1 h and at room temperature overnight and the resulting precipitate was filtered off. The filtrate was concentrated to a syrup, which was dissolved in AcOEt. The solution was washed with 5% aqueous $NaHCO_3$ and water saturated with NaCl, dried, and concentrated to a syrup, which was crystallized from AcOEt and hexane; wt 24.6 g. The crude material was recrystallized from 2-propanol; wt 23.5 g (71.6%), mp 147.5—149.5 °C, $[\alpha]_D^{19}$ −90.0° (*c* 2.0, DMF).

Found: C, 55.72; H, 6.63; N, 10.33%. Calcd for $C_{19}H_{27}O_7N_3$: C, 55.73; H, 6.65; N, 10.26%.

Boc–Pro–Pro–Gln–Lys[Z(2-Cl)]–OMe (VIII). Compound VI (11.1 g, 19.9 mmol) was dissolved in TFA (30 ml). The solution was stirred at room temperature for 40 min and concentrated to a syrup, which was washed with ether and dried over NaOH. The dried material was dissolved in THF (100 ml), mixed successively with TEA (3.4 ml) and compound VII (9.0 g, 22.0 mmol), and stirred at room temperature for 1 d. The mixture was stirred with TEA (1.2 ml) and compound VII (4.0 g, 9.8 mmol) at room temperature for 2 d and then concentrated to an oil. The oil was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water. The washed solution was dried and concentrated to a syrup, The syrup was solidified in a mixture of AcOEt and hexane, and reprecipitated from AcOEt and hexane; wt 12.5 g (83.9%), mp 70.5—72.5 °C, $[\alpha]_D^{16.5}$ −55.2° (*c* 1.0, DMF).

Found: C, 55,65; H, 6.96; N, 10.88; Cl, 4.63%. Calcd for $C_{35}H_{51}O_{10}N_6Cl$: C, 55.95; H, 6.84; N, 11.19; Cl, 4.72%.

Boc–Leu–Glu(OBu^t)–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–OMe (IX). Compound VIII (2.25 g, 3.00 mmol) was dissolved in TFA (7 ml). The solution was stirred at room temperature for 60 min and then concentrated to a syrup. The syrup was solidified in ether and dried over NaOH. The dried solid was dissolved in THF (80 ml) with Boc–Leu–Glu(OBu^t)–Gly–OH, which was prepared from compound IV (2.00 g, 3.05 mmol). The solution was mixed with *N*-methylmorpholine (0.64 ml) and cooled to 0 °C. To the solution were added HOBt (0.60 g, 4.44 mmol) and DCC (0.68 g, 3.30 mmol). The mixture was stirred at 0 °C for 1 h and at room temperature for 1 d and then HOBt (0.2 g) and DCC (0.3 g) were added. The precipitate formed was filtered off after 3 d, and the filtrate was concentrated to dryness. The residue was dissolved in AcOEt, washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, and concentrated to a residue, which was crystallized from AcOEt and hexane; wt 2.81 g. The crude product was recrystallized from AcOEt and hexane; wt 2.57 g (77.4%), mp 96—98 °C, $[\alpha]_D^{16.5}$ −53.6° (*c* 1.0, DMF). Amino acid ratio in the acid hydrolysate: Glu, 2.22 (2); Gly, 1.00 (1); Pro, 2.21 (2); Leu, 0.99 (1); Lys, 1.10 (1).

Found: C, 56.21; H, 7.49; N, 11.19; Cl, 3.23%. Calcd for $C_{52}H_{80}O_{15}N_9Cl$: C, 56.43; H, 7.29; N, 11.39; Cl, 3.20%.

Boc–Leu–Glu(OBu^t)–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–N_2H_3 (X). Compound IX (5.53 g, 5.00 mmol) was dissolved in MeOH (50 ml) and mixed with $NH_2NH_2 \cdot H_2O$ (2.5 g). The solution was stirred at room temperature for 3 d and concentrated to a residue, which was collected with ether; wt 5.76 g. The crude material was reprecipitated from $CHCl_3$ and ether; wt 3.82 g (67.0%), mp 114.5—117.5 °C.

Found: C, 53.83; H, 7.36; N, 13.61; Cl, 3.66%. Calcd for $C_{51}H_{80}O_{14}N_{11}Cl \cdot 2H_2O$: C, 53.79; H, 7.44; N, 13.18; Cl, 3.11%.

S-Sulfonate of the A-Chain. The *S*-sulfonate of the A-chain was prepared by the method of Zahn and Drechsel[4] with some modifications. Bovine insulin (1.0 g) was suspended in a solution of 0.05 M NaOAc (36 ml) and dioxane (26 ml). To the suspension was added EDTA·2Na (0.08 g) to give a clear solution, which was adjusted to pH 7.6 with NaOH. Then a solution (10.4 ml) containing Na_2SO_3 (2.3 g) at pH 7.6 and a solution (10.4 ml) containing $Na_2S_4O_6$ (5 g) at pH 7.6 were added at 37—38 °C alternately over a period of 30 min. The *S*-sulfonate of the A-chain was separated from the *S*-sulfonate of the B-chain as follows: The solution was stirred at 37—38 °C for 2 h and at room temperature for 1 d. The resulting precipitate, mainly consisting of the *S*-sulfonate of the B-chain, was removed by centrifugation, and the upper phase, mainly containing the *S*-sulfonate of the A-chain, was desalted on a column of Sephadex G-25 using 0.1 M NH_4HCO_3. The eluate with absorption at 274 nm was lyophilized; wt 493 mg. The lyophilized powder was charged on a column of Dowex 50×2 (1.7×11 cm) equilibrated with 10% HCOOH and 10% AcOH in 8 M urea, and the *S*-sulfonate of the A-chain was eluted with the same buffer. The eluate with absorption at 274 nm was desalted on a column of Sephadex G-25 and lyophilized; wt 361.1 mg. The *S*-sulfonate of the A-chain was also recovered from the precipitate consisting mainly of the *S*-sulfonate of the B-chain during purification of the

latter on a column of carboxymethylcellulose;[20] wt 88.1 mg. For amino acid ratio in the acid hydrolystae, see Table 1.

S-Sulfonate of Arg-A-Chain. *a) Boc-Arg(Tos)-ONSu.* Boc-Arg(Tos)-OH[21] (8.75 g, 20.4 mmol) was dissolved with HONSu (2.80 g, 24.3 mmol) and DCC (4.10 g, 19.9 mmol) in THF (350 ml) below 0 °C. The solution was stirred at the same temperature for 1 h and at room temperature for 3.5 h. The precipitate formed was filtered off and the filtrate was concentrated to a syrup, which was crystallized from AcOEt; wt 6.70 g (62.6%). Although the product contained some impurities, it was used without further purification.

b) S-*Sulfonate of Arg-A-Chain.* The *S*-sulfonate of the A-chain (546 mg) was dissolved in a mixture of DMF (3 ml) and DMSO (3 ml). The solution was mixed with TEA (0.14 ml) and then with a solution of Boc-Arg(Tos)-ONSu (1.10 g) in DMF (4 ml) and DMSO (1 ml). The mixture was stirred at room temperature for 1 d and then mixed with TEA (0.1 ml) and a solution of Boc-Arg(Tos)-ONSu (0.50 g) in DMSO (2 ml). The mixture was stirred at room temperature for 3 d and then mixed with 0.1 M NH_4HCO_3. The precipitate formed was removed by centrifugation and the upper phase was charged on a column of Sephadex G-25 equilibrated with 0.1 M NH_4HCO_3. The column was eluted with 0.1 M NH_4HCO_3 and the eluate with absorption at 274 nm was collected and lyophilized; wt 517.1 mg. Amino acid ratio in the acid hydrolysate: Asp, 1.97 (2); Ser, 1.75 (2); Glu, 4.29 (4); Gly, 1.01 (1); Ala, 1.00 (1); Val, 1.64 (2); Ile, 0.62 (1); Leu, 2.01 (2); Tyr, 2.30 (2); Arg, 0.83 (1). The lyophilized powder and anisole (0.64 ml) were put into the Daiflon-cylinder of an HF-reaction apparatus.[12] Anhydrous hydrogen fluoride (15 ml) was distilled into the cylinder cooled to −78 °C. The mixture was stirred at 0 °C for 90 min and then hydrogen fluoride was evaporated off. The residue was dissolved in 8 M urea (40 ml) with Na_2SO_3 (1.6 g), $Na_2S_4O_6$ (1.6 g) and EDTA·2Na (24 mg) and the solution was adjusted to pH 8 and stirred at room temperature for 3 d. It was then charged on a column (3×77 cm) of Sephadex G-25 equilibrated with 0.1 M NH_4HCO_3, and the column was eluted with 0.1 M NH_4HCO_3. The eluate with absorption at 274 nm was collected and lyophilized; wt 455.1 mg. The lyophilized powder (449.4 mg) was charged on a column (1.6×21 cm) of DEAE-Sephadex A-25 (acetate cycle) previously equilibrated with 8 M urea, and fractionated with a liner gradient of 0.0306 M HCl in 8 M urea (250 ml) to 0.336 M HCl in 8 M urea (250 ml) (Fig. 3). The fraction with absorption at 274 nm (shown by a bar) was collected, desalted on a column (3×57 cm) of Sephadex G-25, and lyophilized; wt 252.7 mg. For amino acid ratio in the acid hydrolysate, see Table 1.

S-Sulfonate of Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-Chain. Compound X (2.01 g, 1.76 mmol) was dissolved in DMF (7.5 ml) and cooled to below −40 °C. The cooled solution was mixed with 4.0 M HCl in dioxane (2.25 ml) and isopentyl nitrite (0.25 g, 2.11 mmol), and then stirred at the same temperature for 75 min. To the mixture were added *N*-methylmorpholine (1.10 ml) and a solution of the *S*-sulfonate of Arg-A-chain (0.68 g) in a mixture of DMSO (10 ml) and water (3.3 ml). The mixture was stirred at 2—3 °C in a refrigerator for 5 d and then 0.1 M NH_4HCO_3 was added. The resulting syrupy material was centrifuged and the supernatant was charged on a column of Sephadex G-25 equilibrated with 0.1 M NH_4HCO_3. The eluate with absorption at 274 nm was lyophilized; wt 848 mg. Amino acid ratio in the acid hydrolysate: Asp, 1.96 (2); Ser, 1.81 (2); Glu, 6.64 (6); Pro, 1.94 (2); Gly, 1.94 (2); Ala, 1.00 (1); Val, 1.63 (2); Ile, 0.62 (1); Leu, 2.89 (3); Tyr, 1.94 (2); Lys, 0.96 (1); Arg, 0.97 (1). The lyophilized powder was dissolved in TFA (20 ml) under cooling in an ice-water bath. The solution was stirred at room temperature for 60 min and then concentrated to a syrup. The syrup was dissolved in 0.1 M ammonium water at pH 8.0, and the solution was lyophilized. The resulting powder was dissolved in 8 M urea (50 ml) with Na_2SO_3 (2.0 g), $Na_2S_4O_6$ (2.0 g) and EDTA·2Na (0.04 g). The solution was stirred at room temperature for 2 d and then desalted using a column of Sephadex G-25 in 0.1 M NH_4HCO_3. The eluate with absorption at 274 nm was lyophilized; wt 770 mg. The lyophilized powder (329 mg) was charged on a column (1.6×15 cm) of DEAE-Sephadex A-25 (acetate cycle) equilibrated with 8 M urea, and the column was eluted with a linear gradient of 8 M urea (250 ml) to 0.3 M HCl in 8 M urea (250 ml) (Fig. 4). The fraction shown by a bar was collected, desalted and lyophilized; wt 213 mg. For amino acid ratio in the acid hydrolysate, see Table 1.

Synthesis of a Partial Sequence of Proinsulin Using the A-Chain of Natural Insulin. III.[1] Synthesis of a Peptide Corresponding to Positions 41—81 of Bovine Proinsulin

Hiroko AIBA and Yasutsugu SHIMONISHI*

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 23, 1979)

For the synthesis of bovine proinsulin, the *S*-sulfonate of the Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain, which was synthesized using the *S*-sulfonate of the A-chain of natural bovine insulin and which corresponds to positions 53—81 of bovine proinsulin, was coupled with Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-N_3. After removal of the protecting groups from the resulting material the *S*-sulfonate of the Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain, corresponding to positions 41—81 of bovine proinsulin, was purified by chromatography on QAE-Sephadex A-25.

In the preceding paper[1] we reported the synthesis of a peptide corresponding to positions 53—81 of bovine proinsulin,[2] the *S*-sulfonate of the Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain,[3] using the *S*-sulfonate of the A-chain of natural bovine insulin. The synthesis has the merit that the *S*-sulfonates not only of the A-chain but also of its elongated derivatives can react with acylpeptides in homogeneous solution, since they are very soluble in organic solvents such as DMF and DMSO in the presence of water. The solubility of the reaction products makes it easy to purify them, and pure products can be obtained free from starting materials and side-reaction products by chromatography. The present paper reports the synthesis of a 41-amino acid sequence corresponding to positions 41—81 of bovine proinsulin by this procedure, as a step in the synthesis of the prohormone.

In the synthesis of this partial sequence of the prohormone, shown in Fig. 1, the *S*-sulfonate of the Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain[1] was allowed to react with a protected peptide azide with the sequence, Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly. Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-OBzl (X) was synthesized, according to the scheme shown in Fig. 2. Before synthesis of this protected dodecapeptide, its two building fragments, Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-OH (V) and Boc-Gly-Pro-Gly-Ala-Gly-Gly-OBzl (IX) were synthesized separately. The synthesis of the former hexapeptide (V) was started by coupling Boc-Ala-OH[4] with H-Gly-OBzl by DCC to give Boc-Ala-Gly-OBzl (I). The protecting group on the amino terminus was removed by TFA and the peptide chain was elongated further by two single-reactions using Boc-Leu-ONSu[5] and Z-Glu(OBu^t)-ONSu[6] for acylation. The tetrapeptide, Z-Glu(OBu^t)-Leu-Ala-Gly-OBzl (III), thus synthesized was catalytically hydrogenated and the resulting free tetrapeptide was condensed *in situ* with Z-Leu-ONSu[5] to give Z-Leu-Glu(OBu^t)-Leu-Ala-Gly-OH (IV). The protected pentapeptide (IV) was once again catalytically hydrogenated and the resulting peptide was allowed to react with Boc-Ala-ONSu[5] to give the hexapeptide (V), Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-OH.

The hexapeptide (IX), Boc-Gly-Pro-Gly-Ala-Gly-Gly-OBzl, was synthesized by the condensation of Boc-Gly-Pro-OH[7] with the tetrapeptide benzyl ester, which was prepared by treatment of Boc-Gly-Ala-Gly-Gly-OBzl (VIII) with TFA, by DCC. The tetrapeptide (VIII) was synthesized from Boc-Gly-Gly-OBzl (VI), which was prepared by coupling Boc-Gly-OH[4] with H-Gly-OBzl by DCC, by a stepwise elongation procedure using Boc-amino acid *N*-hydroxysuccinimide ester. The hexapeptide (IX) thus synthesized was treated with TFA. The resulting peptide was not isolated, but coupled directly with the hexapeptide (V) by DCC in the presence of HOBt.[8] The crude material was purified on a column of LH-20 to give pure Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-OBzl (X).

The *S*-sulfonate of Leu-Glu-Gly-Pro-Pro-Gln-Lys-[Z(2-Cl)]-Arg-A-chain[1] was coupled with a protected peptide with the sequence Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly. The dodecapeptide benzyl ester (X) was converted to the corresponding acid (XI) by catalytic hydrogenation. Attempts were made to couple the dodecapeptide acid (XI) thus obtained with HONSu in the presence of DCC in order to obtain the corresponding active ester. However, pure active ester could not be obtained. The dodecapeptide ester (X) was converted to its corresponding

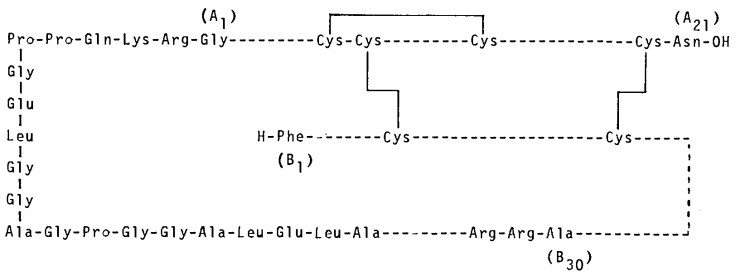

Fig. 1. Strutural model of bovine proinsulin.[2]

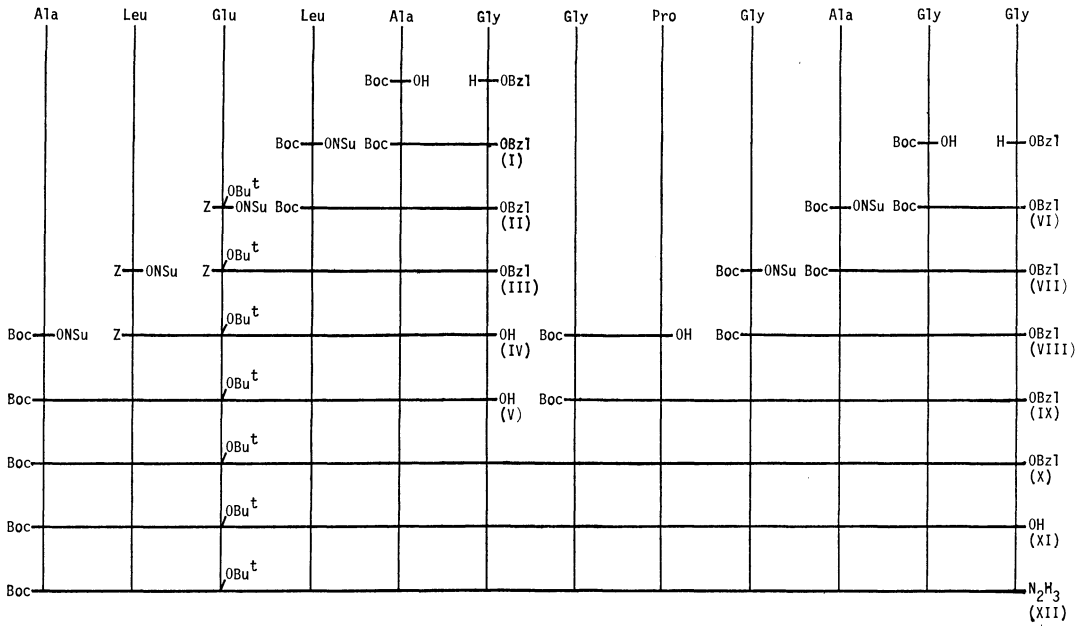

Fig. 2. Scheme for synthesis of protected dodecapeptide (sequence corresponding to positions C_9 to C_{20} in bovine proinsulin).

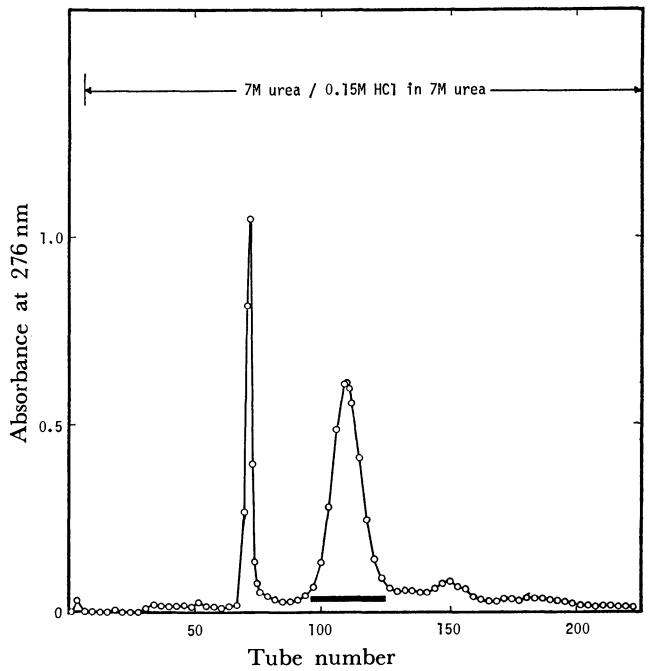

Fig. 3. Chromatogram of the *S*-sulfonate of the Ala–Leu–Glu–Leu–Ala–Gly–Gly–Pro–Gly–Ala–Gly–Gly–Leu–Glu–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–Arg–A-chain on QAE-Sephadex A-25 obtained under the conditions described in the text.

hydrazide (XII) by the usual method of hydrazinolysis, and the hydrazide (XII) was converted to the corresponding azide by Rudinger's method[9]. The peptide azide was allowed to react *in situ* with the *S*-sulfonate of the Leu–Glu–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–Arg–A-chain. The resulting *S*-sulfonate of the Boc–Ala–Leu–Glu(OBu^t)–Leu–Ala–Gly–Gly–Pro–Gly–Ala–Gly–Gly–Leu–Glu–Gly–Pro–Pro–Gln–Lys[Z-(2-Cl)]–Arg–A-chain was treated with TFA and then

TABLE 1. AMINO ACID RATIO OF PEPTIDES SYNTHESIZED[a]

Amino acid	Protected [41—53]	*S*-Sulfonate of [53—81][b]	*S*-Sulfonate of [41—81]
Lys		1.00 (1)	1.00 (1)
Arg		1.00 (1)	1.00 (1)
Asp		1.94 (2)	2.09 (2)
Ser		1.79 (2)	1.98 (2)
Glu	1.03 (1)	6.73 (6)	8.39 (7)
Pro	1.06 (1)	2.09 (2)	3.04 (3)
Gly	4.85 (5)	1.95 (2)	7.40 (7)
Ala	3.00 (3)	1.00 (1)	4.00 (4)
Cys		nd[c]	nd[c]
Val		1.59 (2)	1.60 (2)
Ile		0.63 (1)	0.55 (1)
Leu	1.92 (2)	2.96 (3)	5.09 (5)
Tyr		1.94 (2)	1.86 (2)

a) Molar ratios of individual amino acids are shown relative to that of alanine. Numbers in parentheses are theoretical values. b) Values are cited from Ref. 1. c) Cystine was not determined.

subjected to chromatography on QAE-Sephadex A-25 (Fig. 3). The amino acid ratio of the acid hydrolysate of the *S*-sulfonate synthesized is given in Table 1. The N-terminal amino acid residue of the purified *S*-sulfonate was identified as alanine by dinitrophenylation.[10]

Thus, the *S*-sulfonate of a peptide corresponding to positions 41—81 of bovine proinsulin was synthesized and purified. Studies on the further elongation of this peptide will be described in the subsequent paper.[11]

Experimental

The general experimental and analytical methods used were described in the preceding paper.[1]

Boc–Ala–Gly–OBzl (I). H–Gly–OBzl·TosOH (40.4 g,

120 mmol) and TEA (16.8 ml) were dissolved in a mixture of DMF (100 ml) and THF (200 ml). The solution was mixed with Boc-Ala-OH[4] (18.9 g, 100 mmol) and cooled to −5 °C—−10 °C. DCC (20.6 g, 100 mmol) was added to the cooled mixture. The mixture was stirred at the same temperature for 1 h and at room temperature for 1 d. The precipitate formed was filtered off and the filtrate was concentrated to a syrup under reduced pressure. The syrup was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water. The washed solution was dried over Na_2SO_4 and concentrated to a syrup *in vacuo*. The syrup was crystallized from AcOEt and hexane; wt 26.0 g (77.4%). The crude material was recrystallized from AcOEt and hexane; wt 21.5 g (64.0%), mp 86—88 °C, $[\alpha]_D^{18}$ −11.7° (*c* 2.2, DMF).

Found: C, 60.75; H, 7.34; N, 8.65%. Calcd for $C_{17}H_{24}O_5N_2$: C, 60.70; H, 7.19; N, 8.33%.

Boc-Leu-Ala-Gly-OBzl (II). Compound I (20.2 g, 60.1 mmol) was dissolved in TFA (40 ml). The solution was stirred at room temperature for 90 min and then concentrated to a syrup. The syrup was washed with ether and redissolved with TEA (8.4 ml) and Boc-Leu-ONSu[5] (21.0 g, 64.0 mmol) in THF (200 ml). The solution was stirred for 2 d and then concentrated to a syrup. The syrup was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water. The washed solution was dried and concentrated to an oily residue, which was crystallized from a mixture of AcOEt, ether and hexane; wt 26.5 g. The crude material was recrystallized from ether; wt 20.5 g (75.9%), mp 83—86 °C, $[\alpha]_D^{18}$ −19.2° (*c* 2.0, DMF).

Found: C, 61.24; H, 7.88; N, 9.52%. Calcd for $C_{23}H_{35}O_6N_3$: C, 61.45; H, 7.85; N, 9.35%.

Z-Glu(OBu^t)-Leu-Ala-Gly-OBzl (III). Compound II (18.0 g, 40.0 mmol) was dissolved in TFA (50 ml), stirred at room temperature for 90 min and then concentrated to a syrup. The syrup was solidified in ether, dissolved with TEA (5.6 ml) and Z-Glu(OBu^t)-ONSu[6] (18.4 g, 42.4 mmol) in $CHCl_3$ (300 ml), and stirred at room temperature for 2 d. The solution was diluted with $CHCl_3$, washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, dried, and then concentrated to a solid. The solid was crystallized from AcOEt and hexane; wt 23.5 g. Recrystallization of the crude product from AcOEt and hexane gave 23.0 g of material (85.8% yield), mp 162—164 °C, $[\alpha]_D^{18}$ −17.5° (*c* 2.0, DMF).

Found: C, 62.68; H, 7.25; N, 8.52%. Calcd for $C_{35}H_{48}O_9N_4$: C, 62.85; H, 7.24; N, 8.38%.

Z-Leu-Glu(OBu^t)-Leu-Ala-Gly-OH (IV). Compound III (6.70 g, 10.0 mmol) was dissolved in hot MeOH (150 ml), cooled to room temperature and mixed with AcOH (50 ml). Catalytic hydrogenation was carried out over 5% palladium-charcoal catalyst at atmospheric pressure. The catalyst was filtered off and the filtrate was concentrated to a solid. The solid was suspended with TEA (2 ml) and Z-Leu-ONSu[5] (4.32 g, 11.9 mmol) in a mixture of DMF (100 ml) and THF (50 ml), and dissolved gradually during the course of stirring. The solution was stirred overnight at room temperature and concentrated to a solid, which was suspended in AcOEt and washed with 0.1 M HCl and water. The organic layer was concentrated to a solid, which was crystallized from EtOH; wt 5.10 g. The crude material was recrystallized from EtOH; wt 4.58 g (66.2%), mp 226—228 °C (dec), $[\alpha]_D^{20}$ −26.0° (*c* 2.0, DMF).

Found: C, 58.90; H, 7.84; N, 10.18%. Calcd for $C_{34}H_{53}O_{10}N_5$: C, 59.03; H, 7.72; N, 10.12%.

Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-OH (V). Compound IV (4.15 g, 6.00 mmol) was dissolved in hot MeOH (150 ml), cooled to room temperature, and hydrogenated in the presence of AcOH (50 ml) and 5% palladium-charcoal catalyst. AcOH (100 ml) was added to dissolve the solid formed during the course of hydrogenation. The catalyst was filtered off and the filtrate was concentrated to a solid. The solid was suspended with Boc-Ala-ONSu[5] (2.00 g, 6.99 mmol) in DMF (300 ml) and stirred at room temperature for 3 d. The solution thus obtained was concentrated to a gelatinous solid, which was collected by filtration with $CHCl_3$. The crude material was recrystallized from MeOH; wt 3.52 g (79.5%), mp 230 °C (dec), $[\alpha]_D^{20}$ −34.2° (*c* 2.0, DMF). Amino acid ratio in the acid hydrolysate: Glu, 1.10 (1); Gly, 1.00 (1); Ala, 2.00 (2); Leu, 2.00 (2).

Found: C, 55.07; H, 8.25; N, 11.38%. Calcd for $C_{34}H_{60}O_{11}N_6 \cdot 1/2H_2O$: C, 55.34; H, 8.33; N, 11.39%.

Boc-Gly-Gly-OBzl (VI). H-Gly-OBzl·TosOH (24.3 g, 72.1 mmol) was dissolved with TEA (10.1 ml) and Boc-Gly-OH[4] (10.5 g, 60.0 mmol) in THF (300 ml). The solution was cooled to 0 °C, mixed with a solution of DCC (12.4 g, 60.2 mmol) in THF (50 ml), and stirred overnight at room temperature. The precipitate formed was filtered off and the filtrate was concentrated to an oily residue. The residue was dissolved in AcOEt, washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, dried, and concentrated to a syrup. The syrup was crystallized from a mixture of AcOEt and hexane; wt 16.5 g. The crude material was recrystallized from AcOEt and hexane; wt 16.0 g (82.9%), mp 83—84.5 °C.

Found: C, 59.78; H, 7.02; N, 8.84%. Calcd for $C_{16}H_{22}O_5N_2$: C, 59.61; H, 6.88; N, 8.69%.

Boc-Ala-Gly-Gly-OBzl (VII). Compound VI (13.0 g, 40.4 mmol) was dissolved in 3.55 M HCl in dioxane (113 ml) and stirred at room temperature for 1 h. The crystalline material formed was collected by filtration with ether and dissolved with TEA (5.4 ml) and Boc-Ala-ONSu[5] (13.7 g, 47.9 mmol) in a mixture of $CHCl_3$ (200 ml) and DMF (100 ml). The solution was stirred at room temperature for 1 d and then concentrated to a syrup. The syrup was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, dried and then concentrated to an oil. The oil was triturated in a mixture of AcOEt and hexane; wt 14.0 g. The crude material was recrystallized from AcOEt and hexane; wt 13.9 g (87.4%), mp 108.5—110.5 °C, $[\alpha]_D^{17}$ +0.2° (*c* 2.0, DMF).

Found: C, 58.21; H, 6.70; N, 10.69%. Calcd for $C_{19}H_{27}O_6N_3$: C, 58.00; H, 6.92; N, 10.68%.

Boc-Gly-Ala-Gly-Gly-OBzl (VIII). Compound VII (9.80 g, 24.9 mmol) was dissolved in 3.90 M HCl in dioxane (47.5 ml), stirred at room temperature for 60 min and concentrated to an oily residue. The oil was triturated in ether and dissolved with TEA (3.5 ml) and Boc-Gly-ONSu[5] (8.20 g, 30.1 mmol) in a mixture of DMF (100 ml) and $CHCl_3$ (100 ml). The solution was stirred overnight at room temperature and concentrated to a syrup. The syrup was dissolved in AcOEt, washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, dried, and concentrated to a crystalline solid. The solid was collected by filtration with a mixture of AcOEt and hexane; wt 9.00 g. The crude material was recrystallized from AcOEt and hexane; wt 8.54 g (76.3%), mp 126—128 °C, $[\alpha]_D^{17}$ −1.0° (*c* 2.0, DMF).

Found: C, 55.74; H, 6.84; N, 11.96%. Calcd for $C_{21}H_{30}O_7N_4$: C, 55.99; H, 6.71; N, 12.44%.

Boc-Gly-Pro-Gly-Ala-Gly-Gly-OBzl (IX). Compound VIII (4.05 g, 9.00 mmol) was dissolved in 4.0 M HCl in dioxane (25 ml), stirred at room temperature for

60 min and then concentrated to a crystalline residue. The residue was collected by filtration with ether and dried over NaOH. The crystalline material was dissolved with *N*-methylmorpholine (1.0 ml), Boc-Gly-Pro-OH[7] (2.45 g, 9.01 mmol) and HOBt (2.02 g, 15.0 mmol) in DMF (40 ml). The mixture was cooled to 0 °C, mixed with DCC (2.30 g, 11.2 mmol), and then stirred at the same temperature for 1 h and at room temperature overnight. The precipitate formed was filtered off and the filtrate was concentrated to dryness. The residue was dissolved in $CHCl_3$, washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, dried, and concentrated to a syrup. The syrup was crystallized from AcOEt, EtOH, and hexane; wt 5.17 g. The crude product was recrystallized from AcOEt, EtOH, and hexane; wt 4.73 g (86.8%), mp 164 °C, $[\alpha]_D^{18}$ −21.0° (*c* 2.0, DMF). Amino acid ratio in the acid hydrolysate: Gly, 3.84 (4); Ala, 1.00 (1); Pro, 1.02 (1).

Found: C, 55.67; H, 6.78; N, 13.83%. Calcd for $C_{28}H_{40}O_9N_6$: C, 55.62; H, 6.67; N, 13.90%.

Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-OBzl (X). Compound IX (3.00 g, 4.96 mmol) was dissolved in TFA (10 ml), stirred at room temperature for 30 min and concentrated to a syrup, which was triturated with ether. The solid was dissolved with *N*-methylmorpholine (0.85 ml), compound V (3.70 g, 5.01 mmol) and HOBt (1.00 g, 7.41 mmol) in DMF (300 ml) and cooled below 0 °C. The solution was stirred with DCC (1.00 g, 4.85 mmol) at the same temperature for 1 h and at room temperature for 1 d. The solution was stirred with HOBt (0.30 g, 2.2 mmol) and DCC (0.5 g, 2.4 mmol) at room temperature for 3 d. The precipitate formed was filtered off and the filtrate was concentrated to dryness. The residue was taken up in DMF and water and purified on a column (3×50 cm) of LH-20 using DMF as a solvent. The fractions containing the product were collected and concentrated to a solid, which was filtered with hot AcOEt; wt 4.09 g (67.4%), mp 210 °C (sintered) and 227 °C (dec), $[\alpha]_D^{20}$ −31.0° (*c* 2.0, DMF). Amino acid ratio in the acid hydrolysate: Glu, 1.03 (1); Pro, 1.06 (1); Gly, 4.85 (5); Ala, 3.00 (3); Leu, 1.92 (2).

Found: C, 55.86; H, 7.64; N, 13.68%. Calcd for $C_{57}H_{90}O_{17}N_{12}\cdot 1/2H_2O$: C, 55.91; H, 7.49; N, 13.73%.

Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-OH (XI). Compound X (1.22 g, 1.00 mmol) was dissolved in DMF (100 ml) by gentle heating and hydrogenated over 5% palladium-charcoal catalyst in a water bath at 35 °C. The catalyst was filtered off and the filtrate was concentrated to a solid, which was collected with AcOEt by filtration; wt 1.14 g. The crude product was reprecipitated from DMF and AcOEt; wt 1.12 g (97.4%), mp 217 °C (dec), $[\alpha]_D^{16.5}$ −25.9° (*c* 1.0, DMF).

Found: C, 52.16; H, 7.43; N, 14.51%. Calcd for $C_{50}H_{84}O_{17}N_{12}\cdot 3/2H_2O$: C, 52.11; H, 7.61; N, 14.59%.

Boc-Ala-Leu-Glu(OBu^t)-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-N_2H_3 (XII). Compound X (2.79 g, 2.28 mmol) was dissolved in *N*-methylpyrrolidone (20 ml) by gentle heating. The solution was cooled to room temperature, mixed with hydrazine hydrate (1.2 ml) and stirred at room temperature overnight. The precipitate formed was filtered and dried; wt 2.26 g (81.0%), mp 222—224 °C (dec).

Found: C, 51.89; H, 7.62; N, 16.79%. Calcd for $C_{50}H_{86}O_{16}N_{14}\cdot H_2O$: C, 51.89; H, 7.66; N, 16.95%.

S-Sulfonate of the Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-Chain. Compound XII (1.68 g, 1.38 mmol) was suspended in *N*-methylpyrrolidone (20 ml), cooled to −20 °C—−30 °C and mixed with 3.0 M HCl in dioxane (2.3 ml). The solution thus obtained was mixed with isopentyl nitrite (0.19 g, 1.66 mmol) and stirred at −15 °C—−20 °C for 60 min. The *S*-sulfonate of the Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain (510 mg) in water (2 ml) was added and its solution was stirred at 2 °C—3 °C in a refrigerator for 5 d and then poured into 0.1 M NH_4HCO_3 (100 ml). The precipitate formed was centrifuged, dissolved in DMSO, mixed with 0.1 M NH_4HCO_3 and filtered through a column of Sephadex G-25 (3×60 cm). The supernatant was also filtered through a similar Sephadex G-25 column. The eluates with absorption at 280 nm were pooled and lyophilized; wt 639 mg. Amino acid ratio in the acid hydrolysate: Lys, 1.00 (1); Arg, 1.00 (1); Asp, 2.09 (2); Ser, 1.98 (2); Glu, 8.39 (7); Pro, 3.04 (3); Gly, 7.40 (7); Ala, 4.00 (4); Cys, not determined; Val, 1.60 (2); Ile, 0.55 (1); Leu, 5.09 (5); Tyr, 1.86 (2). The powder (325 mg) was dissolved in TFA (10 ml) in an ice-water bath, stirred at room temperature for 60 min and concentrated to a syrup. The syrup was dissolved in 0.1 M NH_4HCO_3 (pH *ca.* 8.0) and lyophilized. The powder was dissolved with Na_2SO_3 (0.5 g), $Na_2S_4O_6$ (0.5 g) and EDTA·2Na (0.01 g) in 8 M urea (12.5 ml). The solution was adjusted to pH 8.0 and stirred at room temperature for 2 d. Then it was charged on Sephadex G-25 (3×60 cm) and the material was eluted with 0.1 M NH_4HCO_3. Fractions with absorption at 280 nm were collected and lyophilized; wt 287 mg. The lyophilized powder (49.1 mg) was charged on a column (0.9×8 cm) of QAE-Sephadex A-25 (acetate cycle) equilibrated with 7 M urea, and the material was eluted with a linear gradient of 7 M urea (250 ml) to 0.15 M HCl in 7 M urea (250 ml), as shown in Fig. 3. The fraction with an absorption at 276 nm, shown by a bar in Fig. 3, was collected and desalted on a column (3×60 cm) of Sephadex G-25 using 0.1 M NH_4HCO_3 and lyophilized; wt 38.3 mg.

Synthesis of a Partial Sequence of Proinsulin Using the A-Chain of Natural Insulin. IV.[1] Synthesis of a Peptide Corresponding to Positions 31—81 of Bovine Proinsulin

Hiroko AIBA and Yasutsugu SHIMONISHI*

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 23, 1979)

For the synthesis of bovine proinsulin, the *S*-sulfonate of the Ala–Leu–Glu–Leu–Ala–Gly–Gly–Pro–Gly–Ala–Gly–Gly–Leu–Glu–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–Arg–A-chain, which corresponds to positions 41—81 of bovine proinsulin, was coupled with Boc–Arg(Tos)–Arg(Tos)–Glu(OBu^t)–Val–Glu(OBu^t)–Gly–Pro–Gln–Val–Gly–N_3. The *S*-sulfonate of the Arg(Tos)–Arg(Tos)–Glu–Val–Glu–Gly–Pro–Gln–Val–Gly–Ala–Leu–Glu–Leu–Ala–Gly–Gly–Pro–Gly–Ala–Gly–Gly–Leu–Glu–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–Arg–A-chain, correspoding to positions 31—81 of bovine proinsulin, was obtained in a pure form by removal of the protecting groups from the coupled product and chromatography on QAE-Sephadex A-25.

In preceding papers[1-3] we reported the synthesis of the *S*-sulfonates of the Arg–A-chain,[2] Leu–Glu–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–Arg–A-chain[3] and Ala–Leu–Glu–Leu–Ala–Gly–Gly–Pro–Gly–Ala–Gly–Gly–Leu–Glu–Gly–Pro–Pro–Gln–Lys[Z(2-Cl)]–Arg–A-chain,[1] which correspond to positions 60—81, 53—81, and 41—81 respectively, of bovine proinsulin,[4] using the *S*-sulfonate of the A-chain of natural bovine insulin as a starting material. In the conventional procedure, the low solubility of larger polypeptides protected with hydrophobic groups causes serious problems not only in their reactivity in solution but also in purification. Attempts have been made to find protecting groups that increase the solubility of larger protected polypeptides. The Bunte-salt[2,5] was found to be suitable as both a protecting group for cysteine residues in the A-chain of insulin, as well as for increasing the solubility of the A-chain and its elongated derivatives in buffers and organic solvents such as DMF and DMSO[6] in the presence of water. It was found feasible to carry out the elongation reaction of the A-chain in homogeneous solution and purification of the product by ion-exchange chromatography. In the present work, the procedure was applied to the synthesis of the *S*-sulfonate of the sequence corresponding to positions 31—81 of bovine proinsulin (Fig. 1). The synthesis was carried out as a step in the synthesis of the prohormone.

The synthesis was performed by the reaction of the *S*-sulfonate of sequence 41—81 of bovine proinsulin[1] with a protected peptide azide with the sequence, Arg–Arg–Glu–Val–Glu–Gly–Pro–Gln–Val–Gly, which corresponds to positions 31—40 of the prohormone. Boc–Arg(Tos)–Arg(Tos)–Glu(OBu^t)–Val–Glu(OBu^t)–Gly–Pro–Gln–Val–Gly–OBzl[6] (IX) was synthesized (Fig. 2), the protected decapeptide being constructed from two appropriately protected smaller fragments (V) and (VIII). The synthesis of (V), Boc–Arg(Tos)–Arg(Tos)–Glu(OBu^t)–Val–Glu(OBu^t)–Gly–OH, was started by condensing Z–Val–ONSu[7] with H–Glu(OBu^t)–Gly–OH, obtained by catalytic hydrogenation of its corresponding Z derivative[3] and used directly without isolation. The tripeptide (I) Z–Val–Glu(OBu^t)–Gly–OEt, thus synthesized, was catalytically hydrogenated. The resulting tripeptide ester was not isolated, but coupled directly with Z–Glu(OBu^t)–ONp[8] to give Z–Glu(OBu^t)–Val–Glu(OBu^t)–Gly–OEt (II). The Z group of the protected tetrapeptide (II) was then removed by catalytic hydrogenation, and the resulting tetrapeptide ester was acylated with Z–Arg(Tos)–OH[9] by means of DCC to give Z–Arg(Tos)–Glu(OBu^t)–Val–Glu(OBu^t)–Gly–OEt (III). The protected pentapeptide (III) was once again catalytically hydrogenated and allowed to react with Boc–Arg(Tos)–ONSu[3] to give the protected hexapeptide (IV), Boc–Arg(Tos)–Arg(Tos)–Glu(OBu^t)–Val–Glu(OBu^t)–Gly–OEt. IV was saponified under the usual conditions to give the corresponding acid (V). Synthesis of the latter fragment (VIII), Boc–Pro–Gln–Val–Gly–OBzl, was started by coupling Boc–Val–OH[10] with H–Gly–OBzl by DCC. The dipeptide derivative (VI) thus synthesized was treated with TFA. The resulting dipeptide ester was not isolated, but directly elongated by two further single-reactions using Boc–Gln–ONp[11] and Boc–Pro–ONSu[7] for acylation. The protected tetrapeptide (VIII), Boc–Pro–Gln–Val–Gly–OBzl, thus obtained was treated with TFA. The resulting peptide ester was not isolated, but directly coupled with the

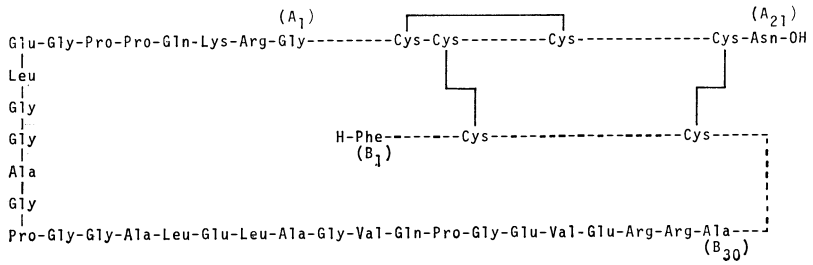

Fig. 1. Structural model of bovine proinsulin.

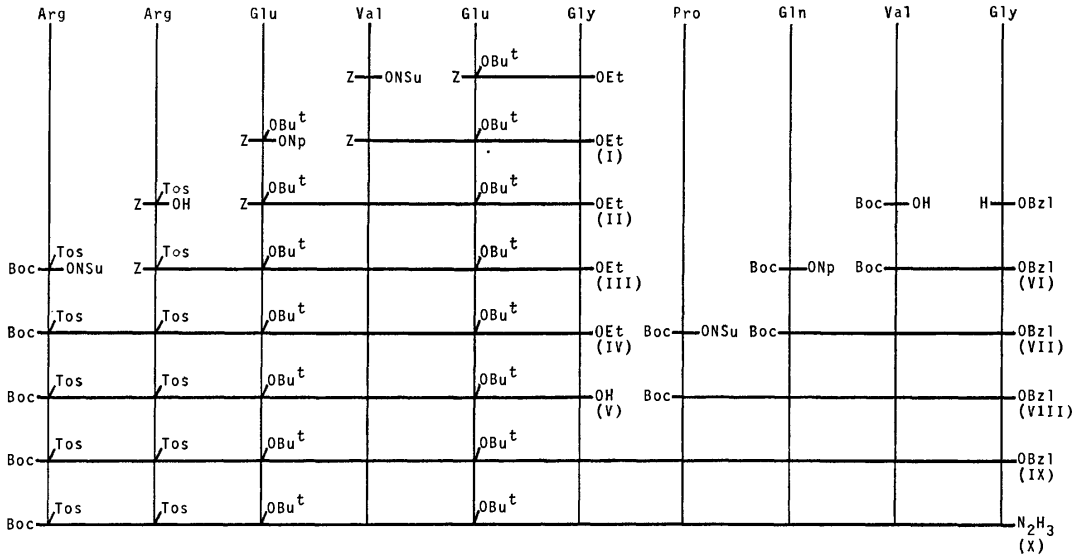

Fig. 2. Scheme for synthesis of protected decapeptide (sequence corresponding to positions BC_1 to C_8 in bovine proinsulin).

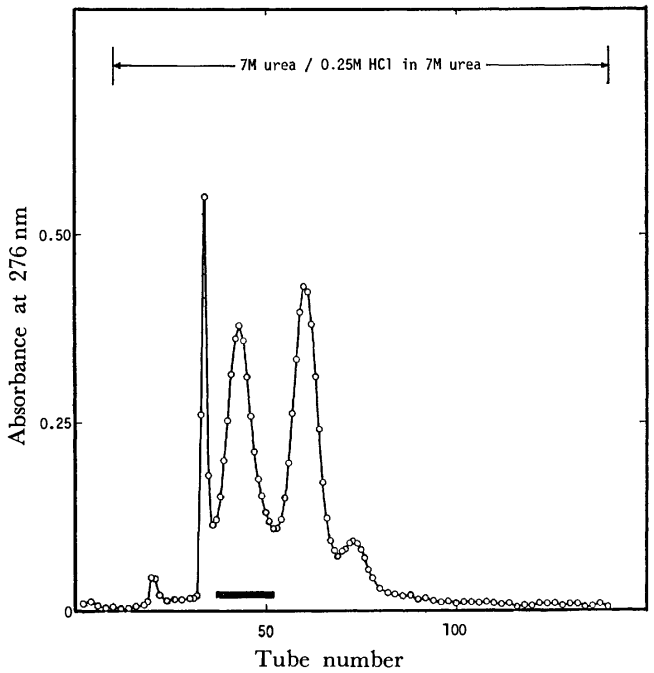

Fig. 3. Chromatography of the *S*-sulfonate of the Arg(Tos)-Arg(Tos)-Glu-Val-Glu-Gly-Pro-Gln-Val-Gly-Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain on QAE-Sephadex A-25 under the conditions described in the text.

hexapeptide acid V by DCC in the presence of HOBt[12] to give the protected decapeptide ester (IX), Boc-Arg(Tos)-Arg(Tos)-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-Pro-Gln-Val-Gly-OBzl, which was then converted to its corresponding hydrazide (X) by the usual method.

Boc-Arg(Tos)-Arg(Tos)-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-Pro-Gln-Val-Gly-N_3, prepared from its corresponding hydrazide (X) by Rudinger's method[13] without being isolated, was coupled with the *S*-sulfonate of the Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-cahin.[1] Azide couplings in the synthesis of peptides corresponding to positions 53—81[3] and 41—81[1] of bovine proinsulin mainly gave the target material, leaving only a little unchanged starting material. On the other hand, on azide coupling starting material remained considerably unreacted, even though the coupling reaction was performed under similar conditions to those described in the preceding papers.[1,3] However, the target product ,the *S*-sulfonate of a peptide corresponding to positions 31—81 of bovine proinsulin, Arg(Tos)-Arg(Tos)-Glu-Val-Glu-Gly-Pro-Gln-Val-Gly-Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain, could be easily separated from the starting material and the side-reaction product by ion-exchange chromatography on QAE-Sephadex A-25 after treatment of the reaction product with TFA (Fig. 3). The amino acid ratio of the acid

Table 1. Amino acid ratios of peptides synthesized[a]

Amino acid	Protected [31—40]	*S*-Sulfonate of [41—81][b]	*S*-Sulfonate of [31—81]
Lys		0.92(1)	1.00(1)
Arg	1.87(2)	1.00(1)	2.76(3)
Asp		1.96(2)	2.04(2)
Ser		1.94(2)	1.99(2)
Glu	3.14(3)	7.62(7)	11.27(10)
Pro	1.02(1)	2.88(3)	4.40(4)
Gly	2.00(2)	7.10(7)	9.15(9)
Ala		4.00(4)	4.00(4)
Cys		nd[c]	1.39(2)
Val	2.09(2)	1.67(2)	3.52(4)
Ile		0.55(1)	0.60(1)
Leu		5.00(5)	5.23(5)
Tyr		1.72(2)	1.98(2)

a) Molar ratios of individual amino acids are shown relative to that of glycine or alanine. Numbers in parentheses are theoretical values. b) Cited from Ref. 1. c) Cystine was not determined.

hydrolysate of the purified *S*-sulfonate is given in Table 1. Edman-degradation[14] of the purified material released the phenylthiohydantoin derivative of ω-tosylarginine as the N-terminal amino acid residue, which was identified on polyamide thin-layer by comparison with an authentic sample.

Thus a peptide with 51 amino acid residues, which shares a little over 62% of the 81 amino acid residues of bovine proinsulin, could be prepared in a homogeneous reaction system and purified easily by chromatography on an ion-exchanger.

Experimental

The general experimental and analytical methods are the same as reported.[3] UV-Absorption spectra were recorded on a Hitachi-spectrophotometer, type-124 and ^{1}H-NMR spectra on a JEOL PFT-100 pulse Fourier transform NMR spectrometer locked in deuterium and equipped with an FT-1a pulse control system. Chemical shifts were measured with TMS as an internal reference.

5-[3-[3-(p-Tolylsulfonyl)guanidino]propyl]-3-phenyl-2-thiohydantoin Hydrochloride (PTH-derivative of H-Arg(Tos)-OH). The title compound was prepared from H-Arg(Tos)-OH,[9] as reported[14]; mp 139—141 °C; $[\alpha]_D^{20}$ −9.7° (*c* 0.6, EtOH); UV (EtOH): λ_{max} 269.5 nm ($\varepsilon=15.1\times10^3$), λ_{min} 252 (8.6×10^3); ^{1}H-NMR (D_2O in DMSO-d_6): CH_2-CH_2(1, 2) δ 1.47—1.75 (4H, m), CH_3(aromatic) 2.32 (3H, s), CH_2(3) 3.11 (2H, t), CH(ring) 4.41 (1H, t), H(aromatic) 7.23—7.68 (9H, m); (DMSO-d_6): NH(ring) 10.57 (1H, s) ppm. Found: C, 49.47; H, 4.80; N, 14.50; S, 13.57; Cl, 7.05%. Calcd for $C_{20}H_{23}O_3N_5S_2\cdot HCl$: C, 49.83; H, 5.02; N, 14.53; S, 13.30; Cl, 7.36%.

Z-Val-Glu(OBu^t)-Gly-OEt (I). Z-Glu(OBu^t)-Gly-OEt[3] (16.5 g, 39.1 mmol) was dissolved in EtOH (250 ml) and hydrogenated over 5% palladium-charcoal catalyst. The catalyst was filtered off and the filtrate was concentrated to an oil under reduced pressure. The oil was dissolved with Z-Val-ONSu[7] (13.0 g, 37.4 mmol) in $CHCl_3$ (150 ml), stirred at room temperature for 2 d and then concentrated to a syrup. The syrup was dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, dried and then concentrated to a crystalline solid, which was collected with AcOEt and hexane; wt 17.5 g. The crude material was recrystallized from EtOH; wt 16.2 g (83.1%), mp 141—143 °C, $[\alpha]_D^{27}$ −31.6° (*c* 2.2, EtOH).

Found: C, 59.89; H, 7.75; N, 8.09%. Calcd for $C_{26}H_{39}O_8N_3$: C, 59.87; H, 7.54; N, 8.06%.

Z-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-OEt (II). Compound I (13.0 g, 24.9 mmol) was suspended in EtOH (250 ml), and hydrogenated over 5% palladium-charcoal at 40 °C. The catalyst was filtered off and the filtrate was concentrated to an oil. The oil was dissolved with Z-Glu(OBu^t)-ONp[8] (12.0 g, 26.2 mmol) in $CHCl_3$ (150 ml) and stirred at room temperature for a day, The solution was washed successively with 0.1M HCl, 5% aqueous $NaHCO_3$ and water, dried and then concentrated to a syrup. The syrup was triturated with hexane; wt 14.3 g. The crude material was recrystallized from AcOEt and hexane; wt 14.1 g (80.1%), mp 149—150 °C, $[\alpha]_D^{27}$ −8.8° (*c* 2.0, DMF).

Found: C, 59.33; H, 7.95; N, 7.83%. Calcd for $C_{35}H_{54}O_{11}N_4$: C, 59.47; H, 7.70; N, 7.93%.

Z-Arg(Tos)-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-OEt (III). Compound II (2.80 g, 3.96 mmol) was dissolved in hot MeOH (150 ml), and hydrogenated over 5% palladium-charcoal catalyst at room temperature. The catalyst was filtered off and the filtrate was concentrated to a solid. The solid was dissolved in THF (100 ml) with Z-Arg(Tos)-OH, which was prepared from its cyclohexylammonium salt[9] (2.50 g, 4.45 mmol), cooled to −5 °C— −10 °C and mixed with HOBt (0.8 g, 5.93 mmol) and DCC (0.9 g, 4.37 mmol). The mixture was stirred at the same temperature for 1 h and at room temperature for 1 d. The precipitate formed was filtered off and the filtrate was concentrated to a syrup. The syrup was dissolved in AcOEt, washed successively with 0.1M HCl, 5% aqueous $NaHCO_3$ and water, dried and concentrated to a crystalline residue; wt 3.60 g. The crude product was recrystallized from EtOH and hexane; wt 3.48 g (86.4%), mp 179.5—181.5 °C, $[\alpha]_D^{21}$ −7.5° (*c* 2.0, DMF).

Found: C, 56.51; H, 7.13; N, 10.95; S, 3.44%. Calcd for $C_{48}H_{72}O_{14}N_8S$: C, 56.67; H, 7.14; N, 11.02; S, 3.15%.

Boc-Arg(Tos)-Arg(Tos)-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-OEt (IV). Compound III (5.10 g, 5.01 mmol) was dissolved in hot MeOH (200 ml) and hydrogenated over 5% palladium-charcoal catalsyt at 35 °C. The catalyst was filtered off and the filtrate was concentrated to a solid. The solid was dissolved with Boc-Arg(Tos)-ONSu[3] (3.90 g, 7.41 mmol) in DMF (50 ml), stirred at room temperature for 1 d and then concentrated to a residue. The residue was dissolved in $CHCl_3$ and washed successively with 0.1M HCl, 5% aqueous $NaHCO_3$ and water, dried, and concentrated to a residue. The residue was collected from $CHCl_3$ and ether; wt 6.06 g. The crude product was reprecipitated from $CHCl_3$ and ether; wt 4.69 g (70.4%), mp 141—142 °C, $[\alpha]_D^{21}$ −8.1° (*c* 2.0, DMF). Amino acid ratio in the acid hydrolysate: Glu, 2.13 (2); Gly, 1.00 (1); Val, 1.04 (1); Arg, 1.95 (2).

Found: C, 52.30; H, 7.15; N, 12.80; S, 4.91%. Calcd for $C_{58}H_{92}O_{17}N_{12}S_2\cdot 2H_2O$: C, 52.39; H, 7.28; N, 12.64; S, 4.82%.

Boc-Arg(Tos)-Arg(Tos)-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-OH (V). Compound IV (1.30 g, 0.977 mmol) was dissolved in MeOH (30 ml) and 1 M NaOH (3 ml) was added to the solution. The solution was stirred at room temperature for 2 h and then neutralized with 1 M HCl. MeOH was evaporated from the solution and the residue was mixed with 0.1 M HCl. The precipitate formed was filtered and reprecipitated from MeOH and ether; wt 1.20 g (94.5%), mp 136—139 °C, $[\alpha]_D^{21}$ −7.5° (*c* 2.0, DMF).

Found: C, 51.46; H, 6.81; N, 12.86; S, 5.04%. Calcd for $C_{56}H_{88}O_{17}N_{12}S_2\cdot 2H_2O$: C, 51.67; H, 7.12; N, 12.92; S, 4.93%.

Boc-Val-Gly-OBzl (IV). Boc-Val-OH prepared from its dicyclohexylammonium salt[10] (20.0 g, 50.1 mmol) was added to a solution of H-Gly-OBzl·TosOH (20.2 g, 59.9 mmol) and TEA (8.4 ml) in THF (200 ml). The solution was cooled below 0 °C, mixed with a solution of DCC (11.3 g, 54.9 mmol) in THF (50 ml) and stirred at the same temperature for 1 h and at room temperature for 1 d. It was then concentrated to a syrupy residue, dissolved in AcOEt and washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water. The washed solution was dried and then concentrated to a syrup, which was crystallized from hexane; wt 16.0 g. The crude material was recrystallized from EtOH and hexane; wt 10.5 g (57.7%), mp 74.5—76.5 °C, $[\alpha]_D^{20}$ −8.3° (*c* 2.0, DMF).

Found: C, 62.78; H, 7.97; N, 7.75%. Calcd for $C_{19}H_{28}O_5N_2$: C, 62.62; H, 7.74; N, 7.69%.

Boc-Gln-Val-Gly-OBzl (VII). Compound VI (8.40 g, 23.1 mmol) was dissolved in 3.65 M HCl in dioxane (63 ml) and stirred at room temperature. After 1 h the solution was mixed with 3.65 M HCl in dioxane (10 ml) and stirred at room temperature for 30 min. The solution then was

concentrated to a syrup, which was solidified in ether. The solid was dissolved with TEA (3.2 ml) and Boc-Gln-ONp[11] (8.40 g, 22.9 mmol) in DMF (200 ml), stirred at room temperature for 2 d and then concentrated to dryness. The residue was suspended in $CHCl_3$, washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, filtered, and then dried; wt 10.0 g. The crude material was crystallized from a mixture of EtOH and MeOH; wt 9.50 g (84.1%), mp 203.5—204.5 °C, $[\alpha]_D^{20}$ −17.3° (*c* 2.0 DMF).

Found: C, 58.68; H, 7.35; N, 11.48%. Calcd for $C_{24}H_{36}O_7N_4$: C, 58.52; H, 7.37; N, 11.38%.

Boc-Pro-Gln-Val-Gly-OBzl (VIII). Compound VII (9.40 g, 19.1 mmol) was dissolved in 3.65 M HCl in dioxane (52 ml), stirred at room temperature for 60 min and then concentrated to a syrup. The syrup was triturated in ether, dissolved with TEA (2.7 ml) and Boc-Pro-ONSu[7] (7.10 g, 22.8 mmol) in DMF (150 ml), stirred at room temperature for 2 d and then concentrated to a solid. The solid was suspended in $CHCl_3$, washed successively with 0.1 M HCl, 5% aqueous $NaHCO_3$ and water, filtered, and dried over P_2O_5; wt 9.71 g. The crude material was reprecipitated from DMF, EtOH, and water; wt 8.66 g (76.7%), mp 210 °C (sintered) and 216—217 °C (decomp), $[\alpha]_D^{20}$ −38.2° (*c* 2.0, DMF). Amino acid ratio in the acid hydrolysate: Glu, 1.12 (1); Pro, 0.99 (1); Gly, 1.00 (1); Val, 1.04 (1).

Found: C, 59.02; H, 7.33; N, 11.89%. Calcd for $C_{29}H_{43}O_8N_5$; C, 59.07; H, 7.35; N, 11.88%.

Boc-Arg(Tos)-Arg(Tos)-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-Pro-Gln-Val-Gly-OBzl (IX). Compound VIII (1.95 g, 3.31 mmol) was stirred in TFA (7 ml) at room temperature for 60 min. The solution was concentrated to a syrupy residue, which was triturated in ether. The material was dissolved wtih compound V (3.88 g, 2.98 mmol), *N*-methylmorpholine (0.43 ml) and HOBt (0.6 g) in DMF (50 ml). The solution was cooled below 0 °C, mixed with a solution of DCC (0.68 g, 3.30 mmol) in DMF (20 ml) and stirred at the same temperature for 1 h and at room temperature for 1 d. The mixture was stirred with HOBt (0.2 g), *N*-methylmorpholine (0.25 ml) and DCC (0.3 g) at room temperature for 2 d. The precipitate formed was filtered off and the filtrate was concentrated to dryness. The residue was collected with DMF and water and reprecipitated from MeOH and AcOEt; wt 4.54 g (86.0%), mp 201.5—203.5 °C (melt and dec), $[\alpha]_D^{20}$ −30.8° (*c* 1.0, DMF).

Found: C, 54.31; H, 7.02; N, 13.07; S, 3.74%. Calcd for $C_{80}H_{121}O_{22}N_{17}S_2 \cdot 2H_2O$: C, 54.19; H, 7.10; N, 13.43; S, 3.62%.

Boc-Arg(Tos)-Arg(Tos)-Glu(OBu^t)-Val-Glu(OBu^t)-Gly-Pro-Gln-Val-Gly-N_2H_3 (X). Compound IX (1.42 g, 0.802 mmol) was dissolved in DMF (10 ml) and mixed with 100% hydrazine hydrate (0.5 g). The solution was stirred at room temperature for 4 h and concentrated to a syrup, which was triturated in ether; wt 1.35 g (100%), mp 207.5—209.5 °C (dec).

Found: C, 52.07; H, 7.34; N, 16.07; S, 4.01%. Calcd for $C_{73}H_{117}O_{21}N_{19}S_2 \cdot H_2O$: C, 52.22; H, 7.14; N, 15.85; S, 3.82%.

S-Sulfonate of the Arg(Tos)-Arg(Tos)-Glu-Val-Glu-Gly-Pro-Gln-Val-Gly-Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-Chain. Compound X (0.83 g, 0.5 mmol) was dissolved in *N*-methylpyrrolidone (8 ml) and mixed with 3.0 M HCl in dioxane (1 ml) and then isopentyl nitrite (70 mg) in *N*-methylpyrrolidone (1 ml) at −20 °C. The solution was stirred at −20 °C——25 °C for 75 min, mixed with *N*-methylmorpholine (0.4 ml) and the *S*-sulfonate of the Ala-Leu-Glu-Leu-Ala-Gly-Gly-Pro-Gly-Ala-Gly-Gly-Leu-Glu-Gly-Pro-Pro-Gln-Lys[Z(2-Cl)]-Arg-A-chain[1] (236 mg, *ca.* 50 μmol), and stirred at 2—3 °C for a week in a refrigerator.

The solution then was mixed with 0.1M NH_4HCO_3 (20 ml) and subjected to gel-filtration on Sephadex G-25 (3×60 cm) in 0.1M NH_4HCO_3. The eluate with absorption at 280 nm was collected and lyophilized. The lyophilized material was dissolved in TFA (10 ml) in an ice-water bath, stirred at room temperature for an hour and concentrated to a syrup. The syrupy material was dissolved in 0.1 M NH_4HCO_3 (50 ml) with a small amount of ammonia water, lyophilized and redissolved with Na_2SO_3 (0.4 g), $Na_2S_4O_6$ (0.4 g) and EDTA·2Na (0.01 g) in 8 M urea (10 ml) at pH 8.0. The solution was stirred at room temperature for 2 d and then charged on a column (3×60 cm) of Sephadex G-25 in 0.1 M NH_4HCO_3. The eluate with absorption at 280 nm was collected and lyophilized. The lyophilized material was charged on a column (9×140 mm) of QAE-Sephadex A-25 (acetate cycle), equilibrated with 7 M urea, and material was eluted with a linear gradient of 7 M urea (250 ml) to 0.25 M HCl in 7 M urea (250 ml) (Fig. 3). The fraction (shown by a bar), with an absorption at 276 nm, was desalted on a column (3×60 cm) of Sephadex G-25 using 0.1 M NH_4HCO_3 and lyophilized; 87.6 mg.

Chemistry of *N*-Thiosulfinylanilines. V.[1] Reactions of *N*-Thiosulfinylanilines with Nucleophilic Reagents

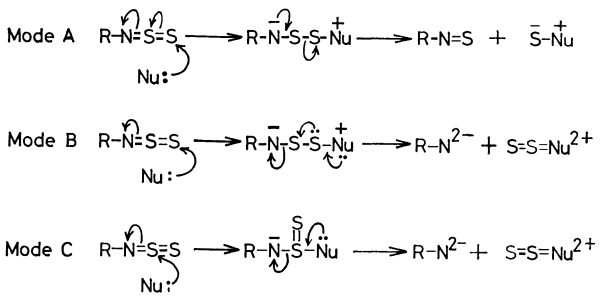
Yoshio Inagaki, Takeo Hosogai, Renji Okazaki, and Naoki Inamoto*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 24, 1979)

2,4-Di-*t*-butyl-6-methyl-*N*-(thiosulfinyl)aniline (**1**) gave 2,4-di-*t*-butyl-6-methylaniline in the reactions with such reagents as alkylamines, thiourea, butyllithium, alkylmagnesium halides, 1-(1-pyrrolidinyl)cyclopentene, and hydrogen sulfide. Triphenylphosphine reacted with **1** to give (2,4-di-*t*-butyl-6-methylphenylimino)triphenylphosphorane and bis(2,4-di-*t*-butyl-6-methylphenyl)sulfur diimide. Reaction of triphenylphosphine with 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene afforded 2,4,6-tri-*t*-butylaniline, bis(2,4,6-tri-*t*-butylphenyl)-sulfur diimide, and 2,4,6-tri-*t*-butyl-*N*-sulfinylaniline (**7**). The sulfur diimide was considered to be formed *via* intermediary 2,4,6-tri-*t*-butylthionitrosobenzene, which was trapped by oxygen to give the *N*-sulfinyl derivative **7**.

It is an interesting subject which atom of a thiocumulene of the type X=S=Y is attacked by a nucleophile. Some thiocumulenes are attacked on the central sulfur atom (*e.g.* sulfur dioxide,[2] sulfinylamines,[3] sulfur diimides,[4] and sulfines[5]), while some others are attacked on the terminal atom, X or Y (*e.g.* thiocarbonyl imines[6] and sulfines[7]). The latter type of reaction is known to occur when the difference in electronegativity between the two ligand atoms, X and Y, is small.[8] We became interested in the attacking point of a nucleophile in the case of an *N*-thiosulfinyl group. There seem three conceivable modes as depicted in Scheme 1, and the formation of Nu=S and Nu=S=S is of interest from the standpoint of utilization of thiosulfinylamino compounds as thiotransfer reagents.



Scheme 1.

This paper describes the reactions of *N*-thiosulfinylanilines with various nucleophilic reagents in relation to these problems.

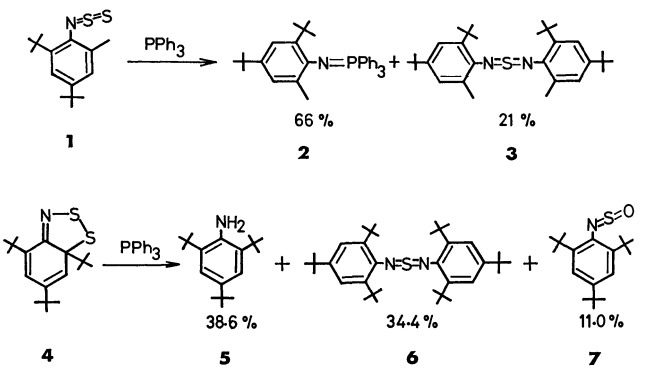
Results and Discussion

Reactions with Triphenylphosphine. We described previously[9] that one of the possible decomposition pathways of a thiosulfinylamino compounds was extrusion of one sulfur atom leading to sulfur diimide *via* thionitroso intermediate and that this explained the instability of the thiosulfinylamino group.

$$\mathrm{Ar{-}N{=}S{=}S} \xrightarrow{-S} \mathrm{Ar{-}N{=}S} \xrightarrow{-S} 1/2\,\mathrm{Ar{-}N{=}S{=}N{-}Ar}$$

It is conceivable, therefore, that elimination of one sulfur atom from thiosulfinylamino group by phosphines would also afford sulfur diimide. In order to examine such a possibility, desulfurization of *N*-thiosulfinylanilines with triphenylphosphine was investigated.

Reactions of 2,4-di-*t*-butyl-6-methyl-*N*-thiosulfinylaniline (**1**) or 2,4,6-tri-*t*-butyl-7,8-dithia-9-azabicyclo-[4.3.0]nona-2,4,9-triene (**4**) with an equimolar amount of triphenylphosphine proceeded even at −78 °C to give products shown in Scheme 2. Since about 50% of **1** or **4** was recovered in these reactions, the yields of the products were calculated based on the consumed **1** or **4**.



Scheme 2.

Reaction of **4** with trimethyl phosphite proceeded very slowly even at room temperature; reaction with 3.9 molar excess of trimethyl phosphite at room temperature for 3 days afforded the phosphoramidate (**8**) in 56% yield.

$$\mathbf{4} \xrightarrow{\mathrm{P(OMe)_3}} \mathrm{Ar^1NHP(O)(OMe)_2} \quad \mathbf{8}$$

$\mathrm{Ar^1 = 2,4,6\text{-}(t\text{-}Bu)_3C_6H_2}$

The reactivity of the *N*-thiosulfinylanilines is in striking contrast to that of *N*-sulfinylanilines, which do not react with trivalent phosphorus compounds; for example, 2,4,6-tri-*t*-butyl-*N*-sulfinylaniline (**7**) reacted with neither triphenylphosphine nor trimethyl phosphite.

When the reaction of **4** with triphenylphosphine was carried out under a stream of oxygen, the sulfur diimide (**6**) was not produced, but the yield of the *N*-sulfinylaniline (**7**) increased up to 38.6% instead. Since **4** did not react with oxygen under the reaction conditions, this result suggests

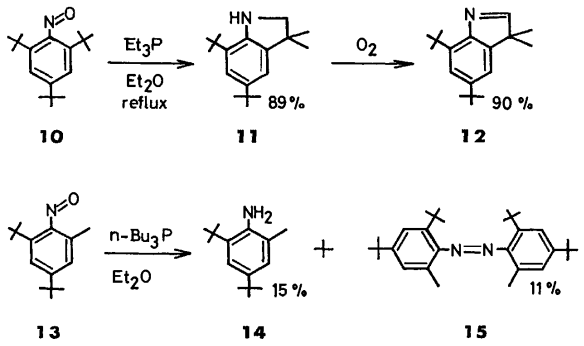
$$\mathbf{4} \xrightarrow[-78\,^\circ\mathrm{C}]{\mathrm{Ph_3P,\ O_2}} \mathrm{Ar^1{-}NH_2} + \mathrm{Ar^1{-}N{=}S{=}O}$$

5, 35.4% **7**, 38.6%

that the sulfur diimide (**6**) and the *N*-sulfinylaniline

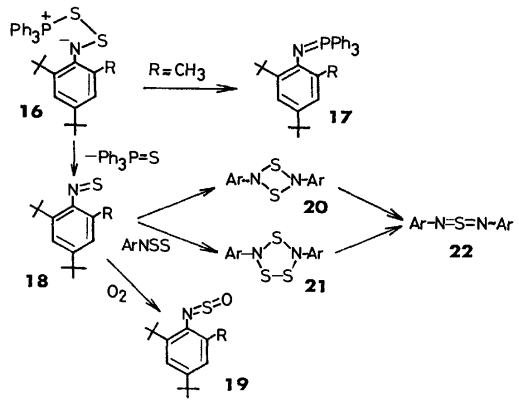
(**7**) were produced *via* a common intermediate, thionitrosobenzene (**9**) (Ar^1–N=S), which could be trapped by oxygen.

Reactions of sterically hindered nitrosobenzenes (**10** and **13**) with trialkylphosphines afford products which are considered to be formed *via* nitrene[10,11] (Scheme 3).



Scheme 3.

Absence of **11** or **15** in the prodcuts obtained by the reaction of **1** or **4** with triphenylphosphine excludes the nitrene formation. Therefore, the probable reaction mechanism can be depicted as in Scheme 4. Nucleophilic attack of triphenylphosphine on **1** or **4** affords zwitterion **16**, which gives the iminophosphorane **17** when R is methyl. When R is more bulky *t*-butyl, elimination of triphenylphosphine sulfide from **16** to give the thionitrosobenzene (**18**) is a predominant pathway. The thionitroso derivative gives **22** *via* cyclization into **20** or **21** followed by extrusion of sulfur. Formation mechanism of 2,4,6-tri-*t*-butylaniline (**5**) is not clear but one possible route is hydrolysis of the zwitterion **16**.



Scheme 4.

Reactions with Amines. A sulfinyl group of a sulfinylamine has been reported to be transferred to a primary amine.[12]

$$R\text{-}N{=}S{=}O + R'\text{-}NH_2 \longrightarrow R\text{-}NH_2 + R'\text{-}N{=}S{=}O$$

In the hope that a similar transfer might occur in the case of thiosulfinylamino compounds, the reactions of the *N*-thiosulfinylaniline (**1**) with amines were attempted. Reactions of **1** with alkylamines afforded 2,4-di-*t*-butyl-6-methylaniline (**14**) together with other products which could not be identified because of difficulty in purification. The results are summarized in Table (see also Experimental).

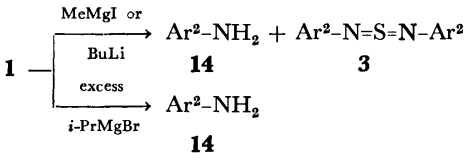
Table 1. Yields of **14**

R-NH_2	Reaction time	Solvent	Molar ratio R-NH_2/**1**	Yield of **14** %
n-$BuNH_2$	88 h	EtOH	1.08	41.1
t-$BuNH_2$	22 h	Et_2O	1.39	30.6
1-$AdNH_2$[a]	11 days	CH_2Cl_2	1.01	81.1
$PhNH_2$	1 week	Et_2O	0.94	no reaction
Pyrr.[b]	2.5 h	CH_2Cl_2	2.23	63.7

a) 1-Ad denotes 1-adamantyl. b) Pyrr. stands for pyrrolidine.

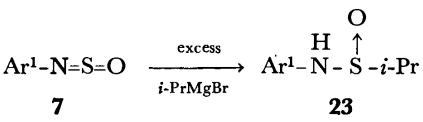
Similar reduction of **1** also took place with thiourea in ethanol for a day at room temperature in 87.7% yield.

Reactions with Organometallic Compounds. Reaction of **1** with an equimolar amount of methylmagnesium iodide afforded the aniline (**14**) (65.2%) and the sulfur diimide (**3**) (8.5%). In the reaction with an equimolar amount of butyllithium the products were also **14** (54.1%) and **3** (23.6%). Reaction of **1** with excess isopropylmagnesium bromide gave **14** in 59.6% yield. These reactions proceeded smoothly and **1** was almost completely consumed. In contrast to



Ar^2 = 2,4-(*t*-Bu)$_2$-6-MeC_6H_2

these reactions, reactions of 2,4,6-tri-*t*-butyl-*N*-sulfinylaniline (**7**) with isopropylmagnesium bromide afforded 63.0% of *N*-(2,4,6-tri-*t*-butylphenyl)-1-methylethanesulfinamide (**23**),



the structure of which was established by hydrolysis giving the aniline (**5**) as well as its spectral and analytical data.

Reaction with an Enamine. Reaction of **1** with 1-(1-pyrrolidinyl)cyclopentene was carried out in the hope of obtaining 1 : 1 cycloadduct. Although the reaction proceeded immediately even at −78 °C to give the aniline (**14**) (57.7%), the reaction mechanism is not clear at present. Absence of the cycloadduct may be attributable to steric hindrance around the nitrogen atom of **1** and to lability of the N–S bond against nucleophilic attack.[13]

Reaction with Hydrogen Sulfide. Reaction of **1** with hydrogen sulfide in benzene followed by chromatographic treatment on silica gel afforded 50.8% of the aniline (**14**) and another compound which was unstable to decompose into **14** on further chromatographic treatment on alumina.

Conclusion. In all these reactions described above, 1:1 adducts appeared too unstable to be isolated. Since any product containing sulfur atom(s) could

not be isolated except for the case of triphenylphosphine, the detailed reaction mechanism remains to be determined. However, it is clear that the thiosulfinylamino group has thiotransfer ability judging from the formation of the corresponding reduced compounds.

Experimental

All melting points were uncorrected. The IR and UV spectra were recorded with Hitachi EPI-G2 and EPS-3 spectrophotometers, respectively. The NMR spectra were measured with a Hitachi R-20B (60 MHz) spectrometer using tetramethylsilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6L mass spectrometer (70 eV). Chromatographic treatment was carried out using dry column chromatography (Woelm silica gel for dry column chromatography) unless otherwise stated.

*Reaction of 2,4-Di-t-butyl-6-methyl-*N*-(thiosufinyl)aniline (**1**) with Triphenylphosphine.* To an ethereal solution (25 ml) of **1** (634 mg, 1.90 mmol)[14] was added an ethereal solution (15 ml) of triphenylphosphine (498 mg, 1.90 mmol) at −78 °C under nitrogen. After the mixture was stirred for 4 h at −78 °C, the temperature was raised gradually up to −5 °C over a 13.5 h period. Removal of the solvent followed by treatment with hexane gave white precipitates. They were recrystallized once from ethanol to give triphenylphosphine sulfide (mp 166.5—167.0 °C), which was identified by means of IR. Hexane-soluble part was subjected to dry column chromatography (DCC) (silica gel, hexane) to give three fractions. From the first fraction was recovered 287 mg (53.7%) of **1**. The second fraction gave 51 mg of orange tar, which was purified by DCC to give 43 mg (21.0% based on consumed **1**) of bis(2,4-di-*t*-butyl-6-methylphenyl)sulfur diimide (**3**) (NMR and IR).[9] The third fraction afforded 278 mg (66.0% based on consumed **1**) of (2,4-di-*t*-butyl-6-methylphenylimino)triphenylphosphorane (**2**) as pale yellow crystals, which were recrystallized five times from hexane to give colorless crystals, mp 171—172.5 °C; IR (KBr): 1110 (P–Ph) cm^{-1}; NMR (CCl_4): δ 1.24 (s, 9H), 1.31 (s, 9H), 1.61 (s, 3H), 6.6 (broad, 1H), 7.01 (broad, 1H), and 7.13—7.93 (m, 15H); MS: *m/e* 479 (M^+, 31.5%), 464 (43.5), 262 ($Ph_3P^{+\cdot}$, 50.0), 252 (45.4), and 185 (Ph_2P^+, 100). Found: C, 82.42; H, 8.14; N, 2.84%. Calcd for $C_{33}H_{38}NP$: C, 82.64; H, 7.99; N, 2.92%.

*Reaction of 2,4,6-Tri-t-butyl-7,8-dithia-9-azabicyclo[4.3.0]nona-2,4,9-triene (**4**) with Triphenylphosphine.* To an ethereal solution (20 ml) of **4** (426 mg, 1.32 mmol)[14] was added an ethereal solution (12 ml) of triphenylphosphine (351 mg, 1.34 mmol) at −78 °C under nitrogen. The mixture was stirred for 1.5 h at −78 °C, for 2 h at 0 °C, and 3 h at room temperature. Removal of the solvent followed by treatment with hexane afforded triphenylphosphine sulfide (mp 161—163 °C), which was identifical by means of IR. The hexane-soluble part was chromatographed (silica gel, hexane) to give four fractions. The first fraction afforded recovered **4** (225 mg, 52.8%). The second fraction was rechromatographed (silica gel, CCl_4) to give 59 mg (34.4% based on consumed **4**) of bis(2,4,6-tri-*t*-butylphenyl)sulfur diimide (**6**) and 21 mg (11.0% based on consumed **4**) of *N*-sulfinyl-2,4,6-tri-*t*-butylaniline (**7**). These products were identified by comparing the IR and NMR spectra with those of authentic samples.[9] The third fraction gave 63 mg (38.6% based on consumed **4**) of 2,4,6-tri-*t*-butylaniline (**5**) which was identified by IR and NMR. The fourth fraction gave 21 mg of pale yellow tarry material, which could not be purified.

*Reaction of **4** with Triphenylphosphine under a Stream of Oxygen.* After oxygen was bubbled into 40 ml of ether at −78 °C for 30 min, 804 mg (2.49 mmol) of **4** was dissolved. To this solution was added an ethereal solution (39 ml) of triphenylphosphine (652 mg, 2.49 mmol). The reaction mixture was stirred under an oxygen stream for 5 h at −78 °C, for 2 h at 0 °C, and similar work-up to the preceding experiment gave **4** (409 mg, 50.9% recovery), **7** (145 mg, 38.6% based on consumed **4**) and **5** (113 mg, 35.4% based on consumed **4**).

*Reaction of **4** with Trimethyl Phosphite.* A solution of **4** (560 mg, 1.73 mmol) and trimethyl phosphite (332 mg, 8.04 mmol) in ether (45 ml) was stirred for 3 days at room temperature. After ether and excess trimethyl phosphite were removed under reduced pressure, the resulting residue was treated with hexane to give 357 mg (56%) of *O,O*-dimethyl *N*-(2,4,6-tri-*t*-butylphenyl)phosphoramidate (**8**) as colorless needles, which were recrystallized six times from hexane and once from methanol, mp 182 °C; IR (KBr): 3170 (broad, NH), 1140 (PO), and 825 cm^{-1} ($POCH_3$); NMR (CCl_4): δ 1.31 (s, 9H), 1.52 (s, 18H), 3.56 (d, J= 11 Hz, 6H), 4.35 (broad, 1H), and 7.33 (s, 2H); MS: *m/e* 369 (M^+, 20.6%), 298 (41.3), 242 (40.0), 57 (100), and 41 (87.0). Found: C, 64.74; H, 10.03; N, 3.73%. Calcd for $C_{20}H_{36}NO_3P$: C, 65.02; H, 9.82; N, 3.79%.

*Reaction of 2,4,6-Tri-t-butylnitrosobenzene (**10**) with Triethylphosphine.* To an ethereal solution (50 ml) of **10**[15] (8.43 g, 27 mmol), was added triethylphosphine (6.4 g, 54 mmol) dissolved in 50 ml of ether under nitrogen. The solution was then refluxed for 18 h. The solvent and the remaining triethylphosphine were removed under reduced pressure. Crude 3,3-dimethyl-5,7-di-*t*-butylindoline (**11**) was obtained by DCC on silica gel. The yield was 6.2 g (89%). The crude material dissolved in petroleum ether was shaken with aq hydrochloric acid. The precipitated hydrochloride salt was washed with petroleum ether. The free indoline (**11**) was obtained by treatment of the salt with aq sodium carbonate. The above purification was repeated four times to yield pure **11** (2.6 g, 34%), mp 100—102 °C; NMR (CCl_4): δ 1.25 and 1.31 (24H), 3.20 (2s, H), 3.69 (br, 1H), 6.77 (d, J=4 Hz, 1H), and 6.92 (d, J=4 Hz, 1H); IR (KBr): 3300 cm^{-1} (NH). Found: C, 83.10; H, 11.43; N, 5.50%. Calcd for $C_{18}H_{29}N$: C, 83.33; H, 11.27; N, 5.40%. This compound was also purified by recrystallization from ethanol. The dihydroindole (**11**) (0.41 g, 1.6 mmol) dissolved in 25 ml of 90% ethanol was heated at reflux for 11 h in the presence of active charcoal (1 g) under a stream of oxygen. The active charcoal was filtered off from the warm solution and then the crude 3*H*-indole (**12**) (0.36 g, 90%) was obtained by removal of the solvent. The pure material was obtained by repeated recrystallization from 80% ethanol. The yield was 0.2 g (50%), mp 128—129 °C; NMR (CCl_4): δ 1.29 and 1.35 (s, 15H), 1.50 (s, 9H), 7.04 (d, J=4 Hz, 1H), 7.17 (d, J=4 Hz, 1H), and 7.77 (s, 1H); IR (KBr): 1590 cm^{-1} (C=N); UV_{max} (C_2H_5OH): 224 (log ε 4.2), 231 (4.1), and 266 nm (3.9). Found: C, 83.86; H, 10.51; N, 5.28%. M^+ 257. Calcd for $C_{18}H_{27}N$: C, 83.99; H, 10.57; N, 5.44%. M^+ 257.

*Reaction of 2,4-Di-t-butyl-6-methylnitrosobenzene (**13**) with Tributylphosphine.* To an ethereal solution (20 ml) of tributylphosphine (2 g, 9.9 mmol) was added an ethereal solution (15 ml) of **13** (0.996 g, 4.27 mmol).[15] The mixture was stirred for 70 min at room temperature, and then stirred with sulfur (170 mg) for 40 min. After removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene afforded a red fraction (Fraction A) and a yellow one (Fraction B). Fraction A was chromatographed

on silica gel with CCl_4 as eluent to afford 97.5 mg (0.224 mmol, 10.5%) of 2,2′,4,4′-tetra-*t*-butyl-6,6′-dimethylazobenzene (**15**), which was recrystallized from aq methanol; mp 156—158 °C. NMR (CCl_4): δ 1.37 (s, 36H), 2.24 (s, 6H), 7.04 (d, J=2 Hz, 2H), and 7.32 (d, J=2 Hz, 2H); UV_{max} (hexane): 238 (ε 9040), 247 (sh) (8570), 312 (15650), and 486 nm (1750); MS: *m/e* 434 (M^+, 5.4%), 217 (35), and 57 (100).

Fraction B was chromatographed on alumina with hexane as eluent to give 140 mg (0.638 mmol, 15.0%) of 2,4-di-*t*-butyl-6-methylaniline (**14**).

Reactions of **1** *with Amines.* Reactions were carried out under nitrogen or argon.

Reaction with Butylamine: A mixture of **1** (400 mg, 1.42 mmol) and butylamine (112 mg, 1.53 mmol) in 10 ml of ethanol was stirred for 88 h at room temperature. The reaction mixture was filtered to give 62 mg of colorless crystals, which melted at 107.5—108.5 °C after twice recrystallization from ethanol; IR (KBr): 3420, 870, 725, 605, and 590 cm^{-1}; NMR (CCl_4): δ 1.27 (s, 9H), 1.48 (s, 9H), 2.42 (s, 3H), and 7.05 (ABq, J=2 Hz, $\Delta\delta$=0.09, 2H); MS: *m/e* 267 (3.6%), 233 (3.6), 225 (17.2), 220 (17.5), and 205 (100). Found: C, 59.90; H, 8.44; N, 4.54; S, 26.58%, which requires $C_{15.4}H_{25.8}NS_{2.6}$, but the structure was not determined.

The filtrate was treated with DCC (silica gel, CCl_4). A reddish fraction gave 116 mg of tarry mixture, which could not be purified and identified; IR (neat): 3430 and 3340 cm^{-1} (broad); NMR (CCl_4): δ 1.26 (s, *ca.* 18H), 1.44 (s, 18H), 2.35 (s, *ca.* 3H), 2.41 (broad s, *ca.* 3H), 5.24 (broad, 1H), 5.37 (broad, 1H), 6.92 (m, 2H), and 7.07 (m, 2H). A colorless fraction gave 128 mg (41.1%) of **14**.

Reaction with t-*Butylamine*: A mixture of **1** (399 mg, 1.42 mmol) and *t*-butylamine (145 mg, 1.98 mmol) in 5 ml of ether was stirred for 22 h at room temperature. Removal of the solvent followed by treatment with hexane afforded 62 mg of colorless precipitates; IR (KBr): 2600—2500 (broad band), 1200, 1110, and 640 cm^{-1}; NMR ($CDCl_3$): δ 1.31 (s, 9H), 1.47 (s, 18H), 2.50 (s, 3H), 5.62 (broad s, 1H), 6.05 (broad s, 4H), 7.15 (m, 1H), and 7.33 (m, 1H). The hexane-soluble part was treated with DCC (silica gel, hexane) to give 117 mg (29.3%) of **1**, 116 mg of tarry mixture, which could not be purified, and 95 mg (30.6%) of **14**.

Reaction with 1-Adamantylamine: A solution of **1** (565 mg, 2.01 mmol), 380 mg (2.03 mmol) of 1-adamantylammonium chloride, and triethylamine (255 mg, 2.52 mmol) in dichloromethane (15 ml) was stirred for 11 days at room temperature. The reaction mixture was washed with water and dried over $MgSO_4$. Removal of the solvent followed by treatment with pentane afforded 110 mg of sparingly soluble colorless powder, which sublimed at 315—350 °C; IR (KBr): 3345 (NH), 3250—2500 (broad band), 1210, 1190, 1025, and 640 cm^{-1}; NMR (acetone-d_6): δ 1.55—1.92 (m) and 2.00—2.25 (m), the intensity ratio was 12:3; MS: *m/e* 264 (2.6%), 330 (1.1), 307 (1.1), 297 (0.9), 284 (0.9), 213 (2.2), 204 (4.8), 197 (3.0), 151 (1-$AdNH_2^{+\cdot}$, 100), 135 (Ad^+, 62), and 108 (32).

Found (recrystallized once from acetone): C, 52.00; H, 7.15; N, 5.82; S, 22.31%, which requires $C_{10.4}H_{17.0}N_{1.0}O_{1.9}S_{1.7}$, but the structure could not be identified.

The pentane-soluble part was treated with DCC (silica gel, hexane) to give 72 mg (12.7%) of **1** in a purple fraction, and 357 mg (81.1%) of **14**. The other products could not be isolated, but a tarry mixture (104 mg) obtained from a fraction next to an orange-yellow fraction exhibited following spectral data; IR (neat): 3410 (sharp), 3475, and 3300 cm^{-1} (broad); NMR (CCl_4): δ 1.18 (s, 9H), 1.38 (s, 9H), 1.46—1.88 (m, 11—12H), 1.82—2.20 (m, 3H), 2.36 (s, 3H), 3.46 (broad, 1H), 5.40 (broad, 1H), 6.39 (d, J=2 Hz, 1H), and 7.15 (d, J=2 Hz, 1H); MS: *m/e* 380 (trace), 352 (trace), 330 (trace), 262 (trace), 247 (6.6%), 232 (23.8), 219 (18.9), 204 (100), 151 (13.9), 148 (7.8), 94 (86.9), and 64 (75.4).

Reaction with Pyrrolidine: A solution of **1** (302 mg, 1.07 mmol) and pyrrolidine (170 mg, 2.39 mmol) in dichloromethane (5 ml) was stirred for 2.5 h at room temperature to give a yellowish orange solution, which was washed with water and dried over $MgSO_4$. Removal of the solvent followed by DCC (silica gel, hexane) gave 150 mg (63.7%) of **14**. The other products could not be isolated.

Reaction of **1** *with Thiourea.* Ethanol solution (10 ml) of 404 mg (1.44 mmol) of **1** and 109 mg (1.44 mmol) of thiourea was stirred for 24 h at room temperature. The reaction mixture was filtered to give 83 mg (2.58 mg-atom) of sulfur and reddish brown solution. After removal of the solvent, the residue was treated with hexane to give colorless crystals which seemed to be a mixture containing thiourea mainly on the basis of the IR spectrum, but could not be purified. The hexane-soluble part was subjected to DCC (silica gel, hexane) to give 276 mg (87.7%) of **14**.

Reaction of **1** *with Organometallic Compounds.* Reactions were carried out under nitrogen. Concentration of organometallic reagents were determined by titration with 2-butanol in xylene using 1,10-phenanthroline as an indicator.[16]

Reaction of **1** *with Methylmagnesium Iodide.* To an ethereal solution (10 ml) of **1** (440 mg, 1.56 mmol) cooled to *ca.* 0 °C was added an ethereal solution (1.63 ml) of CH_3MgI (0.98 M). After being stirred for 30 min at 0 °C, the reaction mixture was treated with aq NH_4Cl (5 ml) to give orange solution, which was washed with water and dried over $MgSO_4$. Removal of the solvent followed by DCC (silica gel, hexane) afforded 23 mg (5.3% recovery) of **1** in a purple fraction. The subsequent fraction gave 25 mg of slightly colored tarry material, which partly decomposed into purple substance (probably **1**) on treatment with TLC (silica gel). This tarry material afforded following spectral data; IR (neat): 3420 cm^{-1}; NMR (CCl_4): δ 1.28 (s, 9H), 1.49 (s, 9H), 1.94 (s, 3H), 5.46 (broad s, 1H), 7.00 (d, J=2 Hz, 1H), and 7.15 (d, J=2 Hz, 1H); MS: *m/e* 247 (3%), 232 (13), 219 (19), and 204 (100).

The orange fraction gave 118 mg of orange crystalline material, which was recrystallized once from acetone to give 31 mg (8.5%) of the sulfur diimide **3**.

The most polar fraction gave 224 mg (65.2%) of **14**.

Reaction of **1** *with Isopropylmagnesium Bromide.* To an ethereal solution of the Grignard reagent prepared from 871 mg (7.08 mmol) of isopropyl bromide and cooled with an ice bath, 160 mg (6.59 mmol) of magnesium, and 11 ml of ether, was added an ethereal solution (11 ml) of **1** (198 mg, 0.703 mmol) dropwise over a period of 10 min. After being stirred for 1 h at 0 °C, the reaction mixture was hydrolyzed by aq NH_4Cl. After the usual work up, the residue was treated with DCC (silica gel, hexane) to give 32 mg of orange tar, which gave 15 mg of **14** on purification by TLC (silica gel, CCl_4–hexane; 4:1), and 112 mg of pale yellow tar, which was treated with DCC (silica gel, CCl_4). From a colorless fraction, 77 mg of **14** was obtained. Thus the yield of **14** was 92 mg (59.6%).

Reaction of **1** *with Butyllithium.* To a pentane solution (5 ml) of **1** (501 mg, 1.78 mmol) was added 1.15 ml of hexane solution of butyllithium (1.55 M) at 0 °C over a 5 min period. After being stirred for 1 h at 0 °C, the reaction mixture was hydrolyzed by 5 ml of aq NH_4Cl, washed with water, dried over $MgSO_4$. After the solvent was removed, the residual orange tar was washed with 3 ml of methanol to give 98 mg (23.6%) of **3** as orange crystals. The methanol-soluble part

was treated with DCC (silica gel, hexane) to give 211 mg (54.1%) of **14**.

Reaction of 2,4,6-Tri-t-butyl-N-sulfinylaniline (7) with Isopropylmagnesium Bromide. To the Grignard reagent prepared from 391 mg (16.1 mmol) of magnesium, 2.00 g (16.3 mmol) of isopropyl bromide, and 25 ml of ether and cooled with an ice bath, was added an ethereal solution (10 ml) of **7** (501 mg, 1.63 mmol) dropwise with stirring. After additional stirring for 40 min, the reaction mixture was hydrolyzed by aq NH_4Cl, washed with water, and dried over $MgSO_4$. Removal of the solvent gave 569 mg of colorless crystals, which were recrystallized once from aq methanol to give 261 mg (63.0%) of the sulfinamide **23** (mp 100.5—101 °C (dec)), which was recrystallized three times from hexane to give colorless needles, mp 101 °C (dec); IR (KBr): 3290 (broad, νNH) and 1075 cm^{-1} (νSO); NMR ($CDCl_3$): δ 1.33 (s, 9H), 1.45 (d, J=7 Hz, 6H), 1.50 (s, 18H), 3.21 (sep, J=7 Hz, 1H), 6.12 (broad s, 1H), and 7.39 (s, 2H); MS: *m/e* 261 ($M^+ - (CH_3)_2C{=}S{=}O$, 16.3%) and 246 (100). Found: C, 71.87; H, 10.84; N, 3.92; S, 8.94%. Calcd for $C_{21}H_{37}NOS$: C, 71.74; H, 10.61; N, 3.98; S, 9.12%.

A solution of **23** (42 mg, 0.12 mmol) in 10 ml of methanol containing 1 drop of trifluoroacetic acid was allowed to stand for 3 days at room temperature. Removal of the solvent followed by preparative TLC purification (silica gel, CCl_4) gave 17 mg (54%) of **14**.

Reaction of 1 with 1-(1-Pyrrolidinyl)cyclopentene. To a CH_2Cl_2 solution (15 ml) of **1** (880 mg, 3.13 mmol) was added a solution of the enamine[12] (4.38 mg, 3.19 mmol) in 10 ml of CH_2Cl_2 at −78 °C. The color of **1** (red-purple) disappeared immediately. After removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene afforded 396 mg (57.7%) of **14**.

Reaction of 1 with Hydrogen Sulfide. Hydrogen sulfide was bubbled into a benzene solution (15 ml) of **1** (306 mg, 1.09 mmol) at *ca.* 10 °C for 3.5 h. Removal of the solvent followed by preparative TLC (silica gel, CCl_4) gave two fractions. The first fraction was rechromatographed (TLC, silica gel, hexane) to give 131 mg of brown tar, which gave **14** (57 mg) on treatment with TLC (alumina, hexane). The second fraction gave 121 mg (50.8%) of **14** (mp 33.5—35.5 °C).

10) Under similar conditions, such reagents as triethyl phosphite, triphenylphosphine, and phosphorus trichloride did not react with **10**. When **10** and an excess amount of triethylphosphine were mixed in ether under nitrogen at 0 °C, the solution gradually turned red with concomitant appearance of a set of persistent ESR signals (g=2.004, a_N=9.7 G, $a_H(2)$=2.2 G; a triplet of triplet). When the solution was shaken under air, the red color as well as the ESR signals disappeared with concurrent recovery of the green color due to **10**. The same phenomena were observed when tributylphosphine was used in place of triethylphosphine. When the nitrosobenzene **13** was allowed to react with tributylphosphine, strong ESR signals were also observed, albeit they were less stable than that observed for **10**, bearing much complex features presumably due to the presence of some species.

The Transformation of Jervine into 18-Functional *C*-Nor-*D*-homosteroids[1)]

Hiroshi SUGINOME,* Norihisa YONEKURA, and Tadashi MASAMUNE*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 2, 1979)

N,O-Diacetyldeoxojervine, obtained by the Wolff-Kishner reduction of jervine followed by acetylation, has been catalytically hydrogenated to (22*S*,25*S*)-*N*,3-*O*-diacetyl-5α-veratranine-3β,23β-diol. Irradiation in benzene containing mercury(II) oxide and iodine afforded 20-formyl-17β-ethyl-12α-etiojervan-3β-ol 3-acetate which was converted into 17β-ethyl-3β-hydroxy-12α-etiojervan-20-one 3-acetate by dye-sensitized photo-oxygenation of the corresponding morpholine enamine. Reduction to 17β-ethyl-12α-etiojervane-3β,20β-diol 3-acetate with sodium borohydride followed by irradiation in benzene in the presence of mercury(II) oxide and iodine afforded an 18-functional *C*-nor-*D*-homosteroid, (20*R*)-18,20-epoxy-17β-ethyl-12α-etiojervane-3β,20β-diol. The configuration of the methyl group on the tetrahydrofuran ring has been shown to be α on the basis of the NMR spectrum, confirming a previous assignment.

In a previous paper, the transformation of deoxojervine, a jerveratrum alkaloid, into an 18-functional *C*-nor-*D*-homosteroid was reported.[2)] The transformation involved the catalytic hydrogenolysis of deoxojervine[3)] to a veratranin-23β-ol (**5**), removal of the piperidine ring by a procedure devised by Franck and Johnson to afford 17β-ethyl-3β-hydroxy-12α-etiojervan-20-one, reduction to 17β-ethyl-12α-etiojervane-3β,20β-diol 3-acetate (**10**) with sodium borohydride, and a functionalization of the inactive 13β-methyl group by an intramolecular radical process.

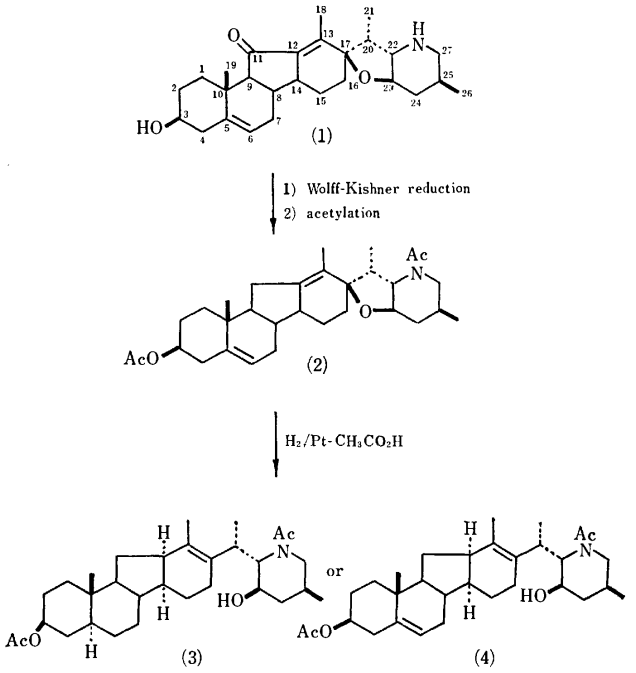
In this paper, an alternative method for the transformation of deoxojervine derived from jervine into the 18-functional *C*-nor-*D*-homosteroid (**11**) is described which utilizes photo-induced reactions as the key steps.

Results

Jervine (**1**), an abundantly available jerveratrum alkaloid, was used as the starting material. The previous severe conditions for the removal of the hindered 11-oxo group[3)] was found to be unnecessary and the 11-oxo group was smoothly removed either by the Huang-Minlon or by the Nagata-Itasaki[4)] modification of the Wolff-Kishner reduction to yield deoxojervine (approximate yield 50%).

In previous experiments, the transformation of deoxojervine into (22*S*,25*S*)-5α-veratranine was achieved in a rather poor yield by catalytic hydrogenation of deoxojervine itself.[2)] This has now been significantly improved by the use of the *N,O*-diacetyl derivative (**2**). Thus, catalytic hydrogenation of the diacetate **2**[3)] in glacial acetic acid in the presence of Adams platinum oxide (25% weight of the substrate) afforded an amorphous product which showed a single spot on TLC and which was identified as (22*S*,25*S*)-*N*,3-*O*-diacetyl-5α-veratr-13(17)-enine-3β,23β-diol (**3**) by NMR analysis (see Experimental). Hydrogenation conducted with less catalyst (10% weight of the substrate) gave (22*S*,25*S*)-*N*-3-*O*-diacetylveratr-5,13(17)-dienine-3β,23β-diol (**4**) as the major product; the product was identified by NMR analysis.

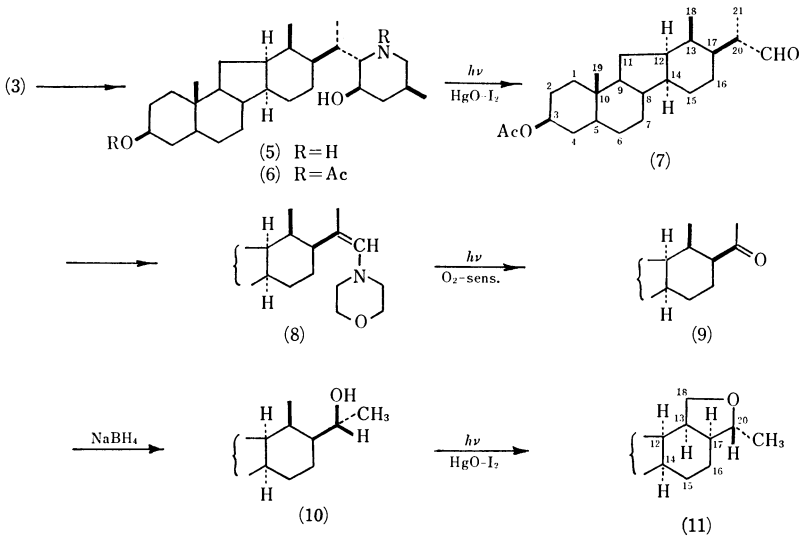
The hindered tetrasubstituted double bond of the 23β-ols **3** or **4** was hydrogenated catalytically using a rhodium–platinum catalyst as reported in a previous paper[2)] to yield an amorphous perhydro derivative (**6**) as the exclusive product. The stereochemistries at the C-13 and the C-17 were identified by its transformation into 17β-ethyl-3β-hydroxy-12α-etiojervan-20-one 3-acetate obtained in previous experiments.[2,5)]



Scheme 1.

The removal of a heterocyclic ring of veratranine **6** was executed by a method involving a radical fragmentation developed by the authors.[6)] Thus, (22*S*,25*S*)-*N*,3-*O*-diacetyl-5α-veratranine-3β,23β-diol (**6**) in benzene containing mercury(II) oxide and iodine was irradiated for 13 h with a high pressure Hg arc. The product was passed through a column of silica gel and the most mobile fraction collected to afford crystalline 20-formyl-17β-ethyl-3β-hydroxy-12α-etiojervan-20-one 3-acetate **7** in 35% yield. As noted previously, this fragmentation reaction is considered to be a radical counterpart of an ionic fragmentation[7)] and is useful in removing the piperidine ring from *N*-acetylveratranine at room temperature under neutral conditions.

The transformation of the aldehyde into 17β-ethyl-3β-hydroxy-12α-etiojervan-20-one 3-acetate (**9**) was conducted by a photochemical method. The aldehyde **7**, obtained as above, was converted into a morpholine enamine (**8**) which was immediately subjected to dye-sensitized photo-oxygenation as reported by Huber[8)]



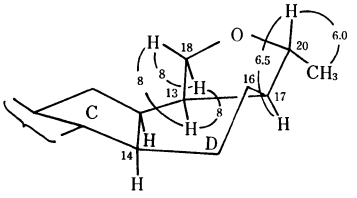
Scheme 2.

and Foote.[9] Irradiation of a benzene solution of the enamine **8** containing Rose Bengal with a 100-W high pressure Hg arc for 10 h with oxygen bubbling slowly through afforded 17β-ethyl-3β-hydroxy-12α-etiojervan-20-one 3-acetate (**9**), identical with a specimen obtained by a nonphotochemical procedure[2] as a single product in 83% yield. As previously reported,[2] reduction of the methyl ketone **9** with sodium borohydride afforded nearly a single alcohol (**10**). The configuration of the 20-hydroxyl group of this compound was assumed to be β on the basis of the consideration of the steric course of the reduction with complex metal hydrides.[2]

Irradiation of 20β-ol **10** in benzene containing mercury(II) oxide and iodine[10] gave an amorphous 18-functional *C*-nor-*D*-homosteroid **11** in 47% yield after purification by column chromatography. The yield was much greater than that in the previous experiments in which lead tetraacetate was used instead of mercury-(II) oxide.

An analysis of the NMR spectrum of the cyclic ether **11** with the aid of spin-decoupling confirmed the structure to be (20*R*)-18,20-epoxy-17β-ethyl-12α-etiojervane-3β,20β-diol acetate **11**, confirming the β-configuration of the C-20 hydroxyl of the starting C-20-ol **10**. Thus, the epoxide **11** showed a 3H singlet at τ 9.27 (19-H), a 3H doublet centered at τ 8.79 (J=6.0 Hz, C-20-methyl), a 3H singlet at τ 8.01 and a broad signal centered at τ 5.34 due to 3α-H. Besides these signals, the spectrum exhibited signals attributable to a methine and methylene protons adjacent to the oxygen of a tetrahydrofuran ring. The methine proton appeared as a 1H broad octet centered at τ 6.39 and the methylene proton as two triplets at τ 6.06 (J= 8 Hz) and 6.58 (J=8 Hz). Irradiation at the center of the doublet at τ 8.79 due to C-20 methyl caused a collapse of the broad octet to a doublet (J=6.5 Hz). Inspection of the Dreiding molecular model indicated that the dihedral angle between the 17α-H and the 20β-H is approximately 130° in epoxide (**11**) having 20 (*R*) configuration. The observed coupling constant is in agreement with this configuration.

Irradiation at τ 7.42 corresponding to a signal due to 13α-H caused a collapse of two triplets into two doublets with J=8 Hz. This decoupling defines the couplings between 13α-H and 18β-H as well as 13α-H and 18α-H to be approximately the same and 8 Hz. These results are summarized in a formula (**12**).



(**12**)

Experimental

All melting points were determined with a hot-plate apparatus (Yanagimoto micro melting point apparatus) and are uncorrected. Unless stated otherwise, IR spectra were determined in Nujol with a JASCO model IR-E spectrophotometer. NMR spectra were determined with a JEOL PS-100 high-resolution spectrometer (solvent $CDCl_3$; Me_4Si as internal reference). TLC was conducted on Wakogel B-5. Mass spectra and elemental analyses were taken by the staff of the Faculty of Pharmaceutical Sciences of this University, the MS with a Hitachi RMU-6E spectrometer.

Reduction of Jervine **1** *to Deoxojervine. i) By Nagata-Itazaki Procedure*:[4] Jervine (30 g) in triethylene glycol (900 ml) containing hydrazine hydrochloride (54 g) and 80% hydrazine hydrate (216 ml) was refluxed for 3 h and the solution cooled to room temperature. To this solution, potassium hydroxide (81 g) was added and the solution concentrated and refluxed for a further 3 h (bath temp 240—260 °C) and poured into water. The crystals, collected by filtration, were dissolved in chloroform and the chloroform solution washed with water and dried (Na_2SO_4). The residue was recrystallized from methanol to yield deoxojervine (14.4 g, 49%) in three crops.

ii) By Huang-Minlon Procedure: Jervine **1** (2 g) in triethylene glycol (60 ml) containing hydrazine hydrate (12 ml) and potassium hydroxide (5.4 g) was refluxed for 1 h (bath temp

120 °C). To the solution, triethylene glycol (100 ml) was added and the solution refluxed for 1 h. The solution was concentrated at bath temperature 200 °C and refluxed for 3 h. The solution was poured into water and extracted with chloroform and the chloroform solution worked up in the usual way. The residue was recrystallized from methanol to yield deoxojervine (0.98 g, 51%) in three crops.

Catalytic Hydrogenation of N,O-*Diacetyldeoxojervine* **2** *in the Presence of Adams Platinum Oxide.* i) *N*,3-*O*-Diacetyl-11-deoxojervine (1 g) in acetic acid (10 ml) containing platinum oxide (250 mg) was hydrogenated under atmospheric pressure until absorption of hydrogen gas ceased. After removal of the catalyst and the solvent, the residue was neutralized with aq sodium hydrogencarbonate and extracted with chloroform. The chloroform solution was washed with water and dried (Na_2SO_4). The residue (1.01 g) showed a single spot on TLC. Crystallization could not be induced and the solution was immediately used for the next step. IR 3387 (OH), 1740 (OAc), 1620 (NAc), 1239, 1027, and 762 cm^{-1}; NMR 9.29 (1H, s, 19-H), 8.94 (3H, d, J=6.8, 26-H), 8.79 (3H, d, J=6.8, 21-H), 8.34 (3H, s, 18-H), 7.98 and 7.93 (each 3H, s, NAc and OAc), 7.03 (1H, m, 2-H), 6.74 (2H, br. s, 27-H), 5.92 (1H, br. s, $W_{1/2}$=8.4, 23β-H), 5.33 (1H, d, J=10.5, 22β-H) and 5.33 (1H, br. overlapped with 22α-H).

ii) *N*,3-*O*-Diacetyl-11-deoxojervine **2** (1 g) in acetic acid (10 ml) containing platinum oxide (100 mg) was hydrogenated as described above until absorption of hydrogen gas ceased. Work-up of the solution afforded (22*S*,25*S*)-*N*,3-*O*-diacetylveratr-5,13(17)-dienine-3β,23β-diol **4**. Crystallization of the diol was not possible. IR 3394 (OH), 1743 (OAc), 1618 (NAc), 1239, and 1029 cm^{-1}. NMR τ 9.08 (3H, s, 19-H), 8.95 (3H, d, J=7.5, 26-H), 8.65 (3H, d, J=7.5, 21-H), 8.32 (3H, s, 18-H), 7.98 (6H, s, NAc, and OAc), 6.74 (2H, s, br. s, 27-H), 5.93 (1H, br. s, $W_{1/2}$= 9.0, 23β-H), 5.34 (1H, d, J=11.9, 22β-H), and 4.64 (1H, br. s, 6-H).

This diacetate was immediately used for the next step.

*Catalytic Hydrogenation of (22S,25S)-*N-*3-*O-*Diacetylveratr-13-(17)-enine-3β,23β-diol* (**3**) *in the Presence of Rhodium–Platinum Catalyst.* The rhodium–platinum catalyst (800 mg) in glacial acetic acid (10 ml) was hydrogenated until approximately 200 ml of hydrogen gas were absorbed. To this solution, 400 mg of (22*S*,25*S*)-*N*,3-*O*-diacetylveratr-13(17)-enine-3β,23β-diol (**3**) was added and the solution hydrogenated for 91 h under atmospheric pressure. The usual work-up of the solution afforded an amorphous (22*S*,25*S*)-*N*,3-*O*-diacetyl-5α-veratranine-3β,23β-diol (**6**) (410 mg). IR 3367 (OH), 1739 (OAc), 1617 (NAc), 1238, 1025, and 775 cm^{-1}; NMR 9.26 (3H, s, 19-H), 9.26 (3H, d, J=6.9), 9.10 (3H, d, J=6.0), and 8.92 (3H, d, J=6.9) (three secondary methyl groups at C-13, C-20, and C-25), 8.03 (3H, s, NAc), 7.91 (3H, s, OAc), 6.80 (1H, d, 22β-H), 6.00 (1H, br. s, 23α-H), and 5.47 (1H, br. 3α-H).

Preparation of 20-Formyl-17β-ethyl-12α-etiojervan-3β-ol Acetate by Irradiation of 23β-ol **6** *in Benzene in the Presence of Mercury(II) Oxide and Iodine.* (22*S*,25*S*)-*N*,3-*O*-Diacetyl-5α-veratranine-3β,23β-diol (**6**) (1 g) in dry benzene (50 ml) containing mercury(II) oxide (1.3 g) and iodine (2.4 g) was placed in a Pyrex vessel and the solution irradiated with a 100-W high pressure Hg arc under an atmosphere of argon for 13 h. After removal of the inorganic materials by filtration, the solvent was evaporated and the residue subjected to column chromatography (Wakogel C-200). Elution with benzene afforded a residue which was dissolved in dichloromethane. The solution was washed with aq sodium thiosulfate and water successively and dried (Na_2SO_4). Evaporation of the solvent left the crystalline aldehyde **7** (259 mg). NMR 9.19 (3H, s, 19-H), 9.21 (3H, d, J=6.9, 18-H), 8.98 (3H, d, J=7.2, 21-H), 7.99 (3H, s, OAc), 5.34 (1H, broad signal, 3α-H), and 0.49 (1H, d, J=4.1, CHO). In this reaction, a tarry polymerized material accompanied the aldehyde.

Morpholine Enamine **8** *of Aldehyde* **7**. The aldehyde **7** as obtained above (210 mg) together with morpholine (0.5 ml) and *p*-toluenesulfonic acid (10 mg) in benzene (40 ml) were refluxed for 3 h in a vessel equipped with a Dean-Stark apparatus. The solvent was removed by a rotary evaporator and the residue dissolved in dichloromethane. The solution was washed with 5% aq sodium hydrogencarbonate solution and water successively and dried (Na_2SO_4). Evaporation of the solvent by a rotatory evaporator left an amorphous enamine **8** (250 mg) which was immediately used for the next step. NMR 9.38 (3H, d, J=7.5, 18-H), 9.26 (3H, s, 19-H), 8.41 (3H, s, CH_3–C=C–N), 8.07 (3H, s, OAc), 7.35 (4H, m, $-CH_2-O-CH_2-$), 6.36 (4H, m, $-CH_2-N-CH_2-$), 5.38 (1H, broad signal, 3α-H), and 5.79 (1H, d, J=2.7, C=CH–N–).

Preparation of 17β-Ethyl-3β-hydroxy-12α-etiojervan-20-one Acetate from Enamine **8** *by Dye-sensitized Oxygenation.* Morpholine enamine **8** (250 mg) in dry benzene (35 ml) containing Rose Bengal (6 mg) in a Pyrex vessel was irradiated with a 100-W high pressure Hg arc through a Pyrex filter for 10 h while oxygen was bubbled slowly though. After removal of the solvent, the residue was dissolved in dichloromethane and the solution worked up in the usual way. The residue was subjected to column chromatography (alumina) to remove the Rose Bengal. Elutions with a 6:1 mixture of benzene and diethyl ether afforded a crude 17β-ethyl-3β-hydroxy-12α-etiojervan-20-one acetate (**9**) which was recrystallized from methanol to afford the pure acetate (171 mg). This was identical with the specimen obtained by a non-photochemical procedure.

Reduction of 17β-Ethyl-3β-hydroxy-12α-etiojervan-20-one Acetate (**9**) *with Sodium Borohydride.* 17β-Ethyl-3β-hydroxy-12α-etiojervan-20-one acetate **9** (1.56 g) and sodium borohydride (640 mg) in ethanol containing ethyl acetate (6 ml) were stirred for 4 h at room temperature. After the addition of acetic acid, the solvent was evaporated and the residue extracted with dichloromethane. The solution was washed with water and dried to afford an amorphous alcohol (1.44 g) which was virtually a single compound. This was recrystallized from a hexane–diethyl ether mixture.

The Hypoiodite Reaction of 17β-Ethyl-12α-etiojervane-3β,20β-diol 3-Acetate (**10**) *with Mercury(II) Oxide and Iodine.* Etiojervan-20β-ol **10** (550 mg) in dry benzene (100 ml) containing mercury(II) oxide (825 mg) and iodine (1.1 g) was irradiated with a high pressure mercury arc generated by Rayonet RPR-208 preparative photochemical reactor through Pyrex for 3 h under an argon atmosphere with stirring. The solution was filtered and a further amount of benzene added. The solution was washed with 5% sodium thiosulfate and water successively and dried. The amorphous residue (575 mg) was subjected to column chromatography (silica gel). Elution with a 20:1 mixture of benzene and diethyl ether afforded an amorphous 18,20-epoxide **11** (260 mg) identical with a specimen obtained previously.[2] It had mp 80.5—81.5 °C after recrystallization from methanol. For NMR spectrum see text.

The authors would like to thank Mrs. Tomoko Okayama of this laboratory for the NMR measurements and spin-decoupling.

Homogeneous Hydroformylation of Methyl Acrylate Catalyzed by $Co_2(CO)_8$–Di(tertiary phosphine) Complexes

Kazuhisa MURATA* and Akio MATSUDA

National Chemical Laboratory for Industry, 1-1, Higashi, Yatabe-Machi, Tsukuba-Gun, Ibaraki, Japan

(Recieved June 7, 1979)

Some complexes prepared *in situ* from $Co_2(CO)_8$ and various di(tertiary phosphine)s as ligands have been found to be more active than $Co_2(CO)_8$ for the hydroformylation of methyl acrylate. The activity decreased in the order; $Ph_2P(CH_2)_2PPh_2 > Ph_2PC{\equiv}CPPh_2 >$ *cis*-$Ph_2PCH{=}CHPPh_2 > Ph_2P(CH_2)_3PPh_2 >$ none $> Ph_2PCH_2PPh_2 > Ph_2P(CH_2)_4PPh$. The most active catalyst (I) was obtained when a molar ratio of $Ph_2P(CH_2)_2PPh_2$ to $Co_2(CO)_8$ was *ca.* 0.5. The catalyst (I) is also active even at low pressure, where the decomposition of $Co_2(CO)_8$ occurs.

Many efforts have been made to enhance the catalytic activity in the hydroformylation of olefin using $Co_2(CO)_8$ catalyst.[1] It is well known that the presence of small amounts of organic amines such as pyridine increases the rate of cobalt-catalyzed hydroformylation.

From the reaction of cyclohexene in methylcyclohexane as solvent, for example, Wender *et al.* found a small rate increase for pyridine/$Co_2(CO)_8$ ratios between 0.15 and 1.2, the maximum being around 0.15.[2] For the hydroformylation of methyl acrylate in benzene, Iwanaga reported that the relative rate increased up to 3.14 times at 100 °C using pyridine/Co ratios of 10.[3]

On the other hand, recently, it has been reported by Sanger that the rate of hydroformylation of 1-hexene with $RhH(CO)(PPh_3)_3$ was enhanced by the addition of a small amount of a di- or tri(tertiary phosphine) to this system.[4] In the case of cobalt catalyst, however, the presence of phosphines such as PPh_3, PBu_3, $Ph_2P(CH_2)_nPPh_2$ (n=2,4,5) drastically decreased the rate, although a slight increase in product linearity was observed.[5]

We have found for the first time that complexes prepared *in situ* from $Co_2(CO)_8$ and some di(tertiary phosphine)s are more active catalysts for the homogeneous hydroformylation of methyl acrylate than $Co_2(CO)_8$. Now we would like to report on some of the interesting findings that have been obtained.

Experimental

Materials. Methyl acrylate, phosphines and toluene were obtained commercially and used with no further purifications. Cobalt carbonyl cluster ($CH_3CCo_3(CO)_9$) was prepared from $Co_2(CO)_8$, according to a procedure based on that given by Pályi.[6]

Reaction Procedure. The hydroformylation reactions were carried out in the 100 ml stainless-steel autoclave, in which methyl acrylate, $Co_2(CO)_8$, toluene, and phosphine were placed. After the vessel was sealed, a mixture of hydrogen and carbon monoxide (*ca.* 1/1 ratio) was introduced. The system was then brought to the desired reaction temperature and pressure by the additional charging of the same gas under heating. Stirring was begun and the reaction took place. The total pressure was kept constant during the reaction by supplying the gas from a 100 ml pressure storage vessel through a pressure regulator, and the reaction temperature was controlled within a range of ±1 °C. The amount of syn-gas supplied at constant pressure during the reaction was calculated from pressure drop in the storage.

Analysis of the Products. Liquid products were analyzed by gas chromatography. A gas chromatograph, equipped with a 6 m column of squalane was used at 100 °C. The IR spectra of catalyst solutions were recorded on a Hitachi-215 type spectrometer.

Determination of Molar Ratios of CO to Co, CO/Co, in Complexes Formed in the Catalytic System. Aliquat samples of catalyst solutions were withdrawn at definite times through a stainless-steel tube into a glass reciever in ice. After nitrogen of a high purity had been bubbled through these samples to purge the dissolved CO, the sample was heated with 3.6 M-H_2SO_4. The gas thus liberated was measured in volume and analyzed for CO by gas chromatography, while the resulting cobalt ions was determined by an EDTA-titration method.

Results

Effect of Some Diphosphorus Ligands. A hydroformylation catalyst was prepared *in situ* from $Co_2(CO)_8$ and a complementary diphosphine. As shown in Table 1, where the initial rate of gas consumption was taken, remarkable ligand effects on the activity were observed; 1,2-bis(diphenylphosphino)ethane (hereafter, abbreviated as diphos) was found to be the most effective ligand, and in this case the activity was *ca.* 3 times that in $Co_2(CO)_8$ (Run 1, 3).

For comparison, the use of bis(2-diphenylphosphinoethyl) phenylphosphine results in the slight increase in the activity (Run 9), but triphenylphosphine is an unfavorable ligand (Run 10). A cobaltcarbonyl cluster ($CH_3CCo_3(CO)_9$) instead of $Co_2(CO)_8$ appears to be undesirable as a catalyst precursor (Run 4).

The results of analysis of the products are also listed in Table 1. The competitive hydrogenation to give methyl propionate occurred very little (Run 3), and little difference between Run 1 ($Co_2(CO)_8$) and Run 3 ($Co_2(CO)_8$–diphos) was observed in the α/β ratio.

Effect of Diphos to $Co_2(CO)_8$ Ratio on the Activity. The results tested under standard conditions are illustrated in Fig. 1, where the amount of $Co_2(CO)_8$ was kept constant at 0.25 mmol. The maximum activity was achieved when the molar ratio was *ca.* 0.5 and subsequent addition of diphos drastically decreased the activity. (Thereafter, the complex showing the maximum activity will be called 'cobalt–diphos catalyst'.)

Another feature of the cobalt–diphos catalyst is that it is active even under lower pressure than $Co_2(CO)_8$; as shown in Table 2, for instance, at 110 °C under 30 kg/cm² of total pressure (CO/H_2=1) aldehyde($\alpha+\beta$) is produced in *ca.* 77% yield after 107 min-reaction

Table 1. Hydroformylation of methyl acrylate catalyzed by $Co_2(CO)_8$ with some diphosphines
$Co_2(CO)_8$ 0.25 mmol, phosphine 0.125 mmol, toluene (solvent) 50 ml
methyl acrylate 50 mmol, $H_2/CO=1$, 50 kg/cm² (const.), temp 120 °C.

$Co_2(CO)_8$ 0.25 mmol, diphos 0.125 mmol (Run 1, 2), toluene 50 ml, methyl acrylate 50 mmol, temp 110 °C.

Run No.	Pressure kg/cm² CO	Pressure kg/cm² H_2	Time / min	α+β[b] yield/%	Methyl propionate yield/%
1	25	10	168	86	0.6
2	15	15	107	77	0.2
3[a)]	25	10	553	45	—
4[a)]	15	15	372	34	—

a) Without diphos. b) See footnotes in Table 1.

with the resulting catalyst solution remaining homogeneous (Run 2), whereas confined yield in aldehyde is significantly low in $Co_2(CO)_8$ under the same conditions, because the catalyst decomposition occurs completely during the course of the reaction (Run 4).

Effect of Reaction Parameters. Using both cobalt-diphos and $Co_2(CO)_8$ catalysts kinetic properties were examined, the purpose of which is to shed light on the reasons for the promoting effect of diphos in this cobalt-catalyzed hydroformylation.

For the calculation of the reaction rate, the correlation between the amount of reacted methyl acrylate (MA) and that of the gas ($CO/H_2=1$), which was supplied during the reaction, must be known. In order to obtain information on change in the amount of aldehyde formation with time, the reactions at 100—110 °C under 50 kg/cm² (const., $CO/H_2=1$) were carried out and aliquot samples were withdrawn from autoclave at several reaction times and analyzed.

As can be seen from a comparison of Fig. 2A(○) with Fig. 2B(○), the amount of total aldehydes ([TA]) was approximately equal to one-half that of the corresponding gas uptake ([C]), indicating that the hydroformylation (but not hydrogenation) principally occurs under these conditions. Also, [TA] increases with time with a first order behavior with respect to the concentration of (MA), similar to [C], according to Eq. 1,

$$r = -\mathrm{d}[\mathrm{MA}]_t/\mathrm{d}t = k[\mathrm{MA}]_t, \quad (1)$$

where r, k, and [MA] stand for the overall rate, apparent rate constant and the concentration of (MA) at time 't', respectively. These observations on cobalt-diphos catalyst allow us to assume that [TA]=[C]/2. Thus $[\mathrm{MA}]_t$ in Eq. 1 can be expressed as follows;

$$[\mathrm{MA}]_{\mathrm{initial}} = 50(\mathrm{mmol}) = [\mathrm{MA}]_t + [\mathrm{C}]/2. \quad (2)$$

Good linear plots of $\ln(50/[\mathrm{MA}]_t)$ *vs.* time are provided in Fig. 2B(●, ▲), apparent rate constant, k, being calculated from the slope.[7]

In case of $Co_2(CO)_8$, on the other hand, Figs. 2A(△), C(○, △) show rather zero order behavior with respect to the concentration of (MA), though the hydroformylation predominantly occurs. Thus, apparent rate constant, k', was calculated from the slope, according to Eq. 3;

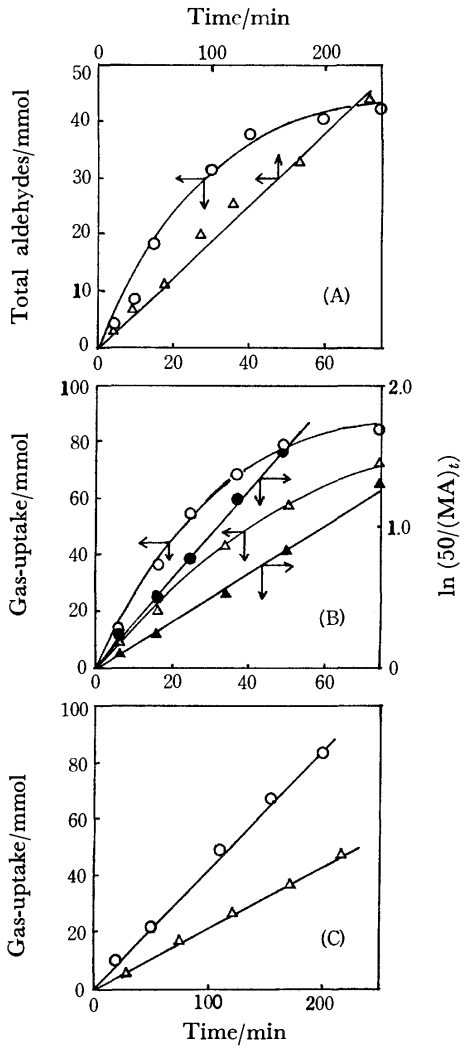

Fig. 2. Results plotted against time.
$Co_2(CO)_8$ 0.25 mmol, diphos 0.125 mmol (A,B), toluene 50 ml, $CO/H_2=1$, 50 kg/cm^2(const.), methyl acrylate 50 mmol.
(A) Total aldehydes (mmol), temp 110 °C.
—○—: Cobalt-diphos, —△—: $Co_2(CO)_8$.
(B) Cobalt-diphos
—○—, —●—: 110 °C; —△—, —▲—: 100 °C.
(C) $Co_2(CO)_8$
—○—: 110 °C, —△—: 100 °C.

$$k't = ([MA]_{initial} - [MA]_t) = [C]/2. \quad (3)$$

Good Arrhenius plots of the rate constants, k or k', provide the apparent activation energies, respectively; the values obtained when the reactions were carried out in the temperature range from 90 to 120 °C were 23.0 kcal/mol with respect to k, 26.7 kcal/mol to k'.

Effects of catalyst concentrations on k or k' were examined under total pressure of 50 kg/cm^2 ($CO/H_2=1$) with the diphos/$Co_2(CO)_8$ molar ratio kept constant at 0.5 in the case of cobalt-diphos catalyst. Figure 3 reveals first order dependence of k as well as k' on the catalyst concentration over this range.

Effects of partial pressure of hydrogen (carbon monoxide) on k or k' were examined, where carbon monoxide (hydrogen) partial pressure in each run was adjusted to 25±2 kg/cm^2 and syn-gas ($CO/H_2=1$) was supplied during the reaction. The rate constants, k or k', were calculated from the slopes as mentioned above. As shown in Fig. 4, these constants increase with the increase in hydrogen pressure. Also, Figure 5 shows that k value tends to decrease more greatly with the increased CO pressure than does k', in the range from 25 to 77 kg/cm^2.

Change in the CO/Co Molar Ratio with Time. The CO/Co molar ratio, which was determined by withdrawing samples from the vessel at definite time, may give some hints to discuss the promoting effect of diphos on the reaction. Interestingly, the ratio for the cobalt-diphos catalyst slightly increases from a value of *ca.* 1.5 to 2, as the reaction proceeds, and it is apparently lower than that for $Co_2(CO)_8$ (from 3 to 4).

Discussion

By numerous workers effects of different phosphines on the rate of $Co_2(CO)_8$-catalyzed hydroformylation have been already investigated, and the general conclusion obtained was that the addition of phosphorus ligands always decreases the rate, though certain ligands such as PBu_3 are favorable for high product linearity.[1,5] Of all these reports, that published by Slaugh and Mullineaux is interesting to us, since $Co_2(CO)_8$ complex with diphos ligand has been used as a catalyst for the hydroformylation of 1-pentene.[5a] The catalytic features of both our system(A) and Slaugh(B) may be summarized as in Table 3.

Our catalyst system (cobalt–diphos) is relatively favorable for the measurement of the hydroformylation rate, because little hydrogenation of methyl acrylate occurs under the conditions employed. As shown in Figs. 2—5, cobalt–diphos catalyst gave similar kinetic behavior to $Co_2(CO)_8$, except for first order with respect to the concentration of (MA).

However, these do not always appear to mean the participation of active species such as $HCo(CO)_x$ (x= 3 or 4),[8] since the CO/Co molar ratio obtained for this catalyst is apparently lower than that for $Co_2(CO)_8$, and since different IR spectral patterns during the reaction were observed for these catalyst solutions.[9] This view may be also supported by the finding that cobalt-diphos catalyst is active even under lower pressure than $Co_2(CO)_8$. (Table 2).

Thus, $HCo(CO)_2$(P–P), (**A**), which is responsible for the increase in the activity, may be postulated as one of principal active catalysts. Though attempts to isolate the species **A** and to identify it were not successful, following two facts would prompt us greatly;

1) The treatment of $Co_2(CO)_8$ with trialkylphosphine(PR_3) under the hydroformylation reaction conditions leads to the formation of $HCo(CO)_3(PR_3)$, which is an active catalyst for the reaction.[5b,c,10]

2) Apparently, diphos acts as a bidentate ligand.[11,12] In fact, Ikariya and Yamamoto have reported the preparation and properties of **A**, $HCo(CO)_2$(P–P), which has been characterized by elemental analysis and IR spectrum.[13]

A speculative reaction scheme and rate equation containing the species **A** is given in *Appendix*, where a rate law of the form in Eq. 7 is derived. According to Eq. 7, r is first order in [MA] and decreases as the CO pressure is increased (Fig. 5). Also, according to Eq. 7, the overall rate, r, is closely related to the concentration of both $HCo(CO)_2$(P–P) and $HCo(CO)$-(P–P). Namely, the mean ratio of CO coordinated to cobalt atom, (CO/Co), should be of the value between 1 and 2 so long as a steady state is reached, and should approach to 2 at the end of the reaction, since steps [1], [7] are still present.; these are in accordance with the foregoing results.

Equation 7, however, does not necessarily justify the first order behavior in catalyst concentration (Fig. 3) and in hydrogen pressure (Fig. 4). Therefore, these facts reveal that cobalt–diphos system is very complex, and that more than one active species or other reaction schemes are probably involved.

The reason for the drastic decrease in the activity, which is shown in Fig. 1, cannot be explained by paths [1]—[7]. Therefore, another paths leading to, probably, the formation of inactive catalyst species consisting of $Co_2(CO)_8$ and diphos, would be also present.[11,14]

Appendix

Overall possible reaction scheme may be postulated as follows;

$$Co_2(CO)_8 + H_2 + 2P\text{-}P \longrightarrow \underset{\mathbf{A}}{2HCo(CO)_2(P\text{-}P)} + 4CO \qquad [1]$$

Table 3. Comparison of our catalyst system(A) with Slaugh(B)

		(A)	(B)
1)	Olefin	Methyl acrylate	1-Pentene
2)	Diphos/$Co_2(CO)_8$ ratio	0—1.0 (0.5 for the most active catalyst, Fig. 1)	4.0
3)	Temperature	90—120 °C	150—200 °C
4)	Catalytic activity in comparison with $Co_2(CO)_8$	*ca.* 3 times active (Table 1, Fig. 1)	Less active by a factor of, at least, 100
5)	Main products	Aldehydes (Table 1, 2)	Alcohols
6)	Thermal stability	Active at 110 °C under 30 kg/cm² (CO/H_2=1) (Table 2)	Active at 150—200 °C under 7—20 kg/cm²

$$HCo(CO)_2(P\text{-}P) + H_2C{=}CH\text{-}COOMe \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} HCo(CO)(P\text{-}P) + CO \quad [2]$$

$$H_2C{=}CH\text{-}COOMe$$

1

$$\mathbf{1} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} MeOOC\text{-}CH_2\text{-}CH_2\text{-}Co(CO)(P\text{-}P) \quad [3]$$

2

$$\mathbf{2} + CO \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} MeOOC\text{-}CH_2\text{-}CH_2\text{-}\overset{O}{\overset{\|}{C}}\text{-}Co(CO)(P\text{-}P) \quad [4]$$

3

$$\mathbf{3} + H_2 \xrightarrow{k_5} MeOOC\text{-}CH_2\text{-}CH_2\text{-}CHO + HCo(CO)(P\text{-}P) \quad [5]$$

$$HCo(CO)(P\text{-}P) + H_2C{=}CH\text{-}COOMe \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \mathbf{1} \quad [6]$$

$$HCo(CO)(P\text{-}P) + CO \xrightarrow{k_7} HCo(CO)_2(P\text{-}P), \quad [7]$$

where P-P stands for diphos.

An active species **A** is formed by step [1], and the step is not probably rate determining, because no induction period was observed at the beginning of the reaction (Fig. 2A) and rate constant, k, is first order in [MA] (Fig. 2B).

Subsequent steps [2]—[7] are similar to that presented previously by Heck.[8] That the reversal of step [5] is negligible under the conditions employed has been already confirmed by an additional experiment.[9] Also, if the reversal of step [7] is present, the CO/Co molar ratio would be still of the value between 1 and 2 at the end of the reaction; our result is not consistent with this. Thus, steps [5], [7] are proposed as irreversible steps.

The overall rate, r, is expressed as in Eq. 4;

$$r = k_5[\mathbf{3}]P_{H_2}, \quad (4)$$

where [**3**] stands for the concentration of an intermediate ***3***. A rate law of the form in Eq. 5 would be obtained, provided that steady state concentrations for intermediates ***1***, ***2***, ***3*** are assumed, respectively;

$$r = \frac{k_3k_4P_{CO}(k_2[HCo(CO)_2(P\text{-}P)] + k_6[HCo(CO)(P\text{-}P)]) \cdot [MA] \cdot k_5P_{H_2}}{(k_{-2}k_{-3}k_{-4}P_{CO} + k_{-3}k_{-4}k_{-6}) + k_5P_{H_2}[k_{-3}k_{-6} + (k_{-2}k_{-3} + k_3k_4 + k_4k_{-6} + k_{-2}k_4P_{CO})P_{CO}} \quad (5)$$

where $[HCo(CO)_2(P\text{-}P)]$, $[HCo(CO)(P\text{-}P)]$ stand for the concentrations of species $HCo(CO)_2(P\text{-}P)$, $HCo(CO)(P\text{-}P)$, respectively. Here, if the second term in the denominator is assumed to be much larger than the first one, Eq. 6 is obtained;

$$r = \frac{k_3k_4P_{CO}(k_2[HCo(CO)_2(P\text{-}P)] + k_6[HCo(CO)(P\text{-}P)]) \cdot [MA]}{k_{-3}k_{-6} + (k_{-2}k_{-3} + k_3k_4 + k_4k_{-6} + k_{-2}k_4P_{CO})P_{CO}}. \quad (6)$$

Furthermore, if $k_{-3}k_{-6} \ll (k_{-2}k_{-3} + k_3k_4 + k_4k_{-6} + k_{-2}k_4P_{CO})P_{CO}$, the overall rate, r, is expressed as Eq. 7;

$$r = \frac{k_3k_4[MA](k_2[HCo(CO)_2(P\text{-}P)] + k_6[HCo(CO)(P\text{-}P)])}{(k_{-2}k_{-3} + k_3k_4 + k_{4-6}) + k_{-2}k_4P_{CO}}. \quad (7)$$

Photo-induced Alkoxybromination of Olefins by *N,N'*-Dibromo-2,5-piperazinedione

Akira Sera,* Hiroshi Yamada, and Kuniaki Itoh

Department of Chemistry, Faculty of Science, Kobe University, Kobe 657

(Received June 28, 1979)

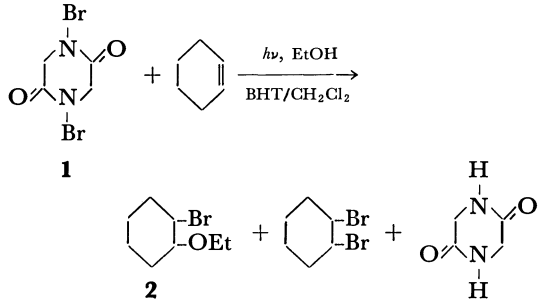
Irradiation of *N,N'*-dibromo-2,5-piperazinedione in dichloromethane in the presence of an alcohol induced alkoxybromination of cyclohexene to give *trans*-1-bromo-2-alkoxycyclohexane in a good yield. The reaction was thought to proceed through an ionic mechanism.

N-Bromosuccinimide(NBS) and related active *N*-halogeno compounds have been prepared and their reactivity has been thoroughly examined.[1] They have been employed as the versatile allylic brominating and oxidizing reagents in many organic syntheses. Although reactions of NBS with simple olefins in water or in acetic acid gave corresponding bromohydrins or bromoacetoxylated compounds, photoreactions of NBS with olefins in aprotic solvents gave exclusively allylic brominated products, 1,2-addition products, and in some instances rearranged products, which were all produced through the well established free radical reaction mechanism. Related reactions of *N*-halogenated amines or imides,[1] sulfoximides,[2,3] have been examined, however, nothing has been investigated on the reaction of *N*-halogeno derivatives of 2,5-piperazinedione, a cyclic anhydride of glycine. This paper concerns with some particular reactions of *N,N'*-dibromo-2,5-piperazinedione (NBP, **1**).

Results and Discussion

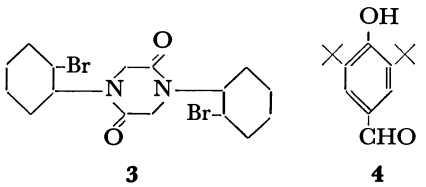
Bromination of 2,5-piperazinedione gave NBP in a good yield. NBP showed free radical reactivities similar to those of NBS. For example, a benzoyl peroxide induced reaction of NBP with cyclohexene in boiling carbon tetrachloride gave 3-bromocyclohexene (70—75%) and a small amount of 1,2-dibromocyclohexane. No *N*-(2-bromocyclohexyl)-2,5-piperazinedione was obtained in this case, while quite recently Skell[4] reported the formation of the corresponding free radical adducts,[5] *N*-(2-halocyclohexyl)succinimide, in a similar reaction of *N*-halosuccinimide with cyclohexene.

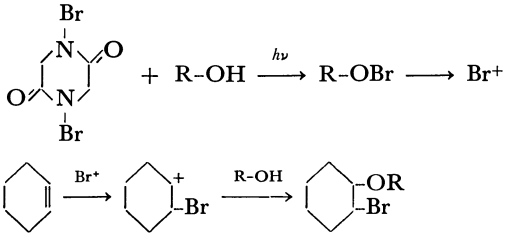
Irradiation of NBP with cyclohexene in dichloromethane[6] gave neither photo-decomposition product nor substitution product in an appreciable amount. In the presence of added ethanol (5 mol equivalent to NBP), however, the reaction gave 3-bromocyclohexene (12%) and *trans*-1-bromo-2-ethoxycyclohexane (37%, **2**). No *cis* isomer was detected (NMR). The stereochemistry of **2** was determined by comparison of its spectral characteristics with those of authentic specimen.[7] An increased yield of **2** was achieved by adding a small amount of a free radical inhibitor, 2,6-di-*t*-butyl-*p*-cresol (BHT, 0.1 mol equivalent to NBP). The free radical inhibitor depressed the formation of 3-bromocyclohexene which was thought to be produced by the free radical mechanism as was observed for the allylic bromination by NBS. Instead, 1,2-dibromocyclohexane was obtained in a considerable yield. This dibromide could be resulted from an addition of bromine which was produced from NBP through an ionic process.[8]



The reaction was examined using variable sets of alcohol–olefin or –vinyl ether pair. The reactivity of the photoalkoxybromination decreased in the order of primary, secondary, and tertiary alcohols (see Table 1). With an increased amount of added ethanol (or by the use of an ethanol as the solvent), **2** was obtained in a nearly quantitative yield. Although the alkoxybromination of olefins was observed in dark conditions,[9] the reaction was actually accelerated by a UV irradiation. A representative case was the bromo-*t*-butoxylation of cyclohexene by NBP–*t*-butyl alcohol, where the irradiation gave a nearly 20-fold yield of 1-bromo-2-*t*-butoxycyclohexane in comparison with that in the dark reaction.

In the cases of less reactive alcohols, isopropyl and *t*-butyl alcohols, small amounts of *N,N'*-bis(2-bromocyclohexyl)-2,5-piperadinedione (**3**) and 2,6-di-*t*-butyl-4-formylphenol (**4**) were isolated in addition to alkoxybromides. The former is one of the free radical reaction products,[10] while the latter is considered to be produced by the oxidation of the free radical inhibitor, BHT.





1-Hexene and 3,4-dihydro-2*H*-pyran were also ethoxy-

TABLE 1. ALKOXYBROMINATION OF OLEFINS BY NBP[a]

Olefins (2 mmol)	ROH, added mmol		Product yields/% Br OR -C-C-	Br Br -C-C-	Others

a) Irradiation with 1 mmol of NBP in 5 ml of dichloromethane containing 0.1 mmol of 2,6-di-*t*-butyl-*p*-cresol for 30 min. b) Without 2,6-di-*t*-butyl-*p*-cresol. c) 1-Bromo-2-ethoxyhexane. d) *trans*-3-Bromo-2-ethoxytetrahydropyran. e) 2-Bromo-1-ethoxy-3,3-dimethylbutane. f) 2-Bromo-1-ethoxy-1-butoxyethane.

brominated in the same conditions to give 1-bromo-2-ethoxyhexane and 3-bromo-2-ethoxytetrahydropyran, respectively. These two products were undoubtedly the Markovnikov addition products, and hence the formation of these two products indicated that the reaction should proceed through an ionic mechanism.[11] Accordingly one can assume that the photoreaction of NBP with an alcohol gives an alkyl hypobromite intermediate[12] which in turn decomposes to give bromine cation. An addition of bromine cation to cyclohexene yields a new carbon centered cation. Following reaction of the cation with alcohol finally produces the alkoxybrominated product. Intervention of the alkyl hypobromite or bromine cation in the reaction can rationalize the formation of **4** as a by-product, because Cohen[13] reported that **4** was obtained from 2,6-di-*t*-butyl-*p*-cresol by treatment with bromine in *t*-butyl alcohol or acetic acid. The photoethoxybromination of *t*-butylethylene gave 2-bromo-1-ethoxy-3,3-dimethylbutane which was seemingly an *anti*-Markovnikov adduct. However, this observation implied the intervention of an intermediate bridged bromonium cation[14] on which a nucleophilic attack of ethanol occurred from less hindered site.[15] Photoreactions with electron poor olefins (methyl acrylate, stilbene *etc.*) gave little or no alkoxybromides, but yielded dibromides exclusively. In the photo-induced ionic addition of alcohols, Marshall[16] reported that cyclohexenes and cycloheptenes showed marked reactivities to give Markovnikov addition products. As seen in the Table, cycloolefins (cyclohexene and 3,4-dihydro-2*H*-pyran) gave alkoxybromides in higher yield than corresponding acyclic olefins (1-hexene and vinyl ether) did. All of these results agree the proposed ionic addition mechanism where the electrophilic attack of bromine cation plays a key role in determining regioselectivity of the reaction.

Experimental

The olefins used were dried over Molecular Sieves 4A and distilled over copper chloride(I) prior to use. Alcohols were dried over Molecular Sieves 4A and distilled. Dichloromethane was washed successively with sulfuric acid, sodium hydroxide solution and water, dried over calcium chloride and distilled. IR and NMR spectra were measured on a JASCO IRA-1 and a JEOL JNN-PMX 60 spectrometers, respectively. GLC analysis was carried out by a Hitachi Model 063; column (1 m×3 mm); A, 10% Carbowax 20 M on 60—80 mesh Shimalite W; B, 15% Diethylene Glycol Succinate Polyester on 60—80 mesh Chromosorb W. All irradiations were conducted through a Pyrex filter using an Ushio Model UI-501e high-pressure mercury lamp (500 W).

Preparation of NBP:[17] To a solution of 3.5 g of sodium carbonate in 100 ml of water was added 3.3 g of 2,5-piperazinedione. The mixture was stirred as bromine was added dropwise. After the reaction mixture had been stirred for 2 h, the pale yellow solid was collected by filtration, washed with water, and dried under vacuum. Yield, 5.7 g, white powder, recrystallizable from hot pyridine; insoluble in carbon tetrachloride, dichloromethane, acetone, benzene; slightly soluble in ethanol, acetonitrile, DMF and DMSO.

NBP–Cyclohexene–Ethanol Reaction. The typical experimental procedure employed in all the reactions is described. Irradiation of a mixture[6] containing 272 mg (1 mmol) of NBP, 164 mg (2 mmol) of cyclohexene, 461 mg (10 mmol) of ethanol, 22 mg (0.1 mmol) of BHT in 5 ml of dichloromethane was carried out under stirring at ambient temperature for 30 min. The products were determined by GLC using methyl benzoate as the internal standard. The reaction mixtures (3—4 runs) were combined, and after removal of solvent, the products were separated on a silica-gel column (benzene→benzene:ethyl acetate/4 : 1). 1,2-Dibromocyclohexane: liquid; NMR (CCl_4) δ=4.40 (2H, s), 1.0—2.8 ppm (8H, m); IR, ν_{C-Br} 680 cm^{-1}. *trans*-1-Bromo-2-ethoxycyclohexane: MS, *m/e*, 208 and 206 (M^+), 127, 81 57; NMR (CCl_4) δ=1.14 (3H, t), 3.48 (2H, q),

3.1—3.5 (1H, m), 3.6—4.1 (1H, m), 1.0—2.5 ppm (8H, m): IR, ν_{C-O} 1110, ν_{C-Br} 690 cm^{-1}. The stereochemistry of the products was determined to be *trans* judging from comparison with the authentic specimen.

NBP–Cyclohexene–t-BuOH Reaction. Irradiation of a mixture[6] containing 272 mg (1 mmol) of NBP, 164 mg (2 mmol) of cyclohexene, 741 mg (10 mmol) of *t*-butyl alcohol, 22 mg (0.1 mmol) of BHT in 5 ml of dichloromethane was carried out as above. The products: 1-Bromo-2-*t*-butoxycyclohexane: NMR (CCl_4) δ=1.20 (9H, s), 3.1—3.5 (1H, m), 3.7—4.0 (1H, m), 1.0—2.5 ppm (8H, m); IR, ν_{C-O} 1100, ν_{C-Br} 690 cm^{-1}. *N,N'*-Bis(2-bromocyclohexyl)-2,5-piperadinedione: mp 211.2—211.5 °C; NMR ($CDCl_3$) δ= 1.1—2.6 (16H, m), 3.90 (4H, s), 3.9—4.5 (4H, m); IR, $\nu_{C=O}$ 1680, ν_{C-N} 1080, ν_{C-Br} 680 cm^{-1}. 2,6-Di-*t*-butyl-4-formylphenol: mp 191.5—192.5 °C (Ref.[18] mp 189—190 °C); NMR (CCl_4) δ=1.50 (18H, s), 5.72 (1H, s), 7.60 (2H, s), 9.71 (1H, s); IR, ν_{O-H} 3440, ν_{C-H} 2810 and 2730, $\nu_{C=O}$ 1665, ν_{C-O} 1100 cm^{-1}.

Products from Other Reactions: *trans*-1-Bromo-2-methoxycyclohexane: NMR (CCl_4) δ=3.35 (1H, s), 3.1—3.5 (1H, m), 3.7—4.1 (1H, m), 1.0—2.5 ppm (8H, m); IR, ν_{C-O} 1110, ν_{C-Br} 690 cm^{-1}.

trans-1-Bromo-2-isopropoxylcycloxane: NMR(CCl_4) δ= 1.12 (6H, dd), 3.67 (1H, m), 3.1—3.5 (1H, m), 3.7—4.0 (1H, m), 1.0—2.5 ppm (8H, m); IR, ν_{C-O} 1110, ν_{C-Br} 680 cm^{-1}.

trans-1-Bromo-2-butoxycyclohexane: NMR (CCl_4) δ=0.95 (3H, t), 1.0—2.5 (4H, m), 3.44 (3H, t), 3.1—3.5 (1H, m), 3.7—4.1 (1H, m), 1.0—2.5 ppm (8H, m); IR, ν_{C-O} 1110, ν_{C-Br} 690 cm^{-1}.

1-Bromo-2-ethoxyhexane: NMR (CCl_4) δ=1.13 (3H, t), 3.45 (2H, q), 3.2—3.4 (2H, m), 3.5—4.0 (1H, m), 1.03 (3H, t), 0.6—2.1 ppm (6H, m); IR, ν_{C-O} 1100, ν_{C-Br} 670 cm^{-1}.

trans-3-Bromo-2-ethoxytetrahydropyan: NMR (CCl_4) δ= 1.18 (3H, t), 3.63 (2H, q), 3.7—4.1 (1H, m), 4.50 (1H, d), 3.2—4.1 (2H, m), 1.2—2.7 ppm (4H, m); IR, ν_{C-O} 1100, ν_{C-Br} 670 cm^{-1}.

2-Bromo-1-ethoxy-3,3-dimethylbutane: NMR (CCl_4) δ= 1.17 (3H, t), 3.42 (2H, q), 3.62 (2H, dd), 3.82 (1H, t), 1.07 ppm (9H, s); IR, ν_{C-O} 1110, ν_{C-Br} 660 cm^{-1}.

(2-Bromo-1-ethoxyethyl)benzene: NMR (CCl_4) δ=1.16 (3H, t), 3.30 (2H, q), 3.28 (2H, d), 4.30 (1H, t), 7.08 ppm (5H, s); IR, ν_{C-O} 1120, ν_{C-Br} 690 cm^{-1}.

2-Bromo-1-ethoxy-1-butoxyethane: NMR (CCl_4) δ=1.16 (3H, t), 3.48 (2H, q), 3.22 (2H, d), 4.53 (1H, t), 1.06 (3H, t), 0.7—2.1 ppm (6H, m); IR, ν_{C-O} 1120, ν_{C-Br} 680 cm^{-1}.

The present work has been supported in part by a Grant-in-Aid for Scientific Research (No. 247021, 1977) from the Ministry of Education.

The Use of Grignard Reagents in the Synthesis of Carbohydrates. I.[1] The Synthesis of Deoxy and Branched-chain Deoxy Sugars

Masajiro KAWANA* and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 2, 1979)

Two branched-chain deoxy sugars, methyl 5,6-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-β-D-*arabino*-hexofuranoside and its α-D-*ribo* isomer, were easily prepared by the one-step reaction of methyl 5,6-*O*-cyclohexylidene-3-*O*-mesyl-β-D-allofuranoside (**3a**) with methylmagnesium iodide. Similarly, the corresponding α-mesylate (**4a**) gave methyl 5,6-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-α-D-*ribo*-hexofuranoside. It was demonstrated that these reactions involved 1,2-hydride shifts. The reaction of **3a** and **4a** with *t*-butylmagnesium bromide yielded two deoxy sugars, methyl 5,6-*O*-cyclohexylidene-3-deoxy-β-D-*arabino*-hexofuranoside and the corresponding α-D-*ribo* isomer, respectively. Under certain reaction conditions with the Grignard reagents, the sulfonate (**3a**) afforded dimeric compounds, in which two furanose rings were directly bound with a carbon–carbon bond. A convenient method for the preparation of the sulfonates (**3a** and **4a**) is also reported.

The synthesis of deoxy and branched-chain sugars has recently received increased attention because these sugars are found in nature as glycoside-components of an important class of antibiotics.[2] We would like to describe here the details of a new method previously reported in only preliminary form[3] for the one-step synthesis of deoxy and branched-chain deoxy sugars starting from sugar sulfonates with Grignard reagents; we will also report some observations made during this work.

The starting point for the present work was our finding of a convenient method for the preparation of the starting sulfonates, methyl 5,6-*O*-cyclohexylidene-3-*O*-mesyl-β-D-allofuranoside (**3a**) and the corresponding α-anomer (**4a**), in good yields. Thus, a methanolic solution of a 3-*O*-mesyl derivative (**2** in Fig. 1) prepared from 1,2:5,6-di-*O*-cyclohexylidene-α-D-allofuranose[4a] (**1**) was refluxed in the presence of an acid, after which the mixture was diluted with benzene. In order to complete this reaction, a large amount of the methanol was evaporated to give a mixture (92%) of **3a** and **4a** in a ratio of 2:1; those anomers were easily separated by fractional crystallization.

The structures of both mesylates were established by means of their elemental analyses and spectrocsopic data (see Experimental). Their mass spectra showed strong peaks at *m/e* 141 characteristic of the dioxolane ring at C-4, thus indicating the furanose structures of these mesylates.[5]

The branched-chain deoxy sugars were obtained very easily when these mesylates were treated with an excess of methylmagnesium iodide (MeMgI). Thus **3a** was added to an ethereal solution of a 3-molar excess of MeMgI to give, in one step, methyl 5,6-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-β-D-*arabino*-hexofuranoside (**6a**) and the corresponding *ribo* isomer

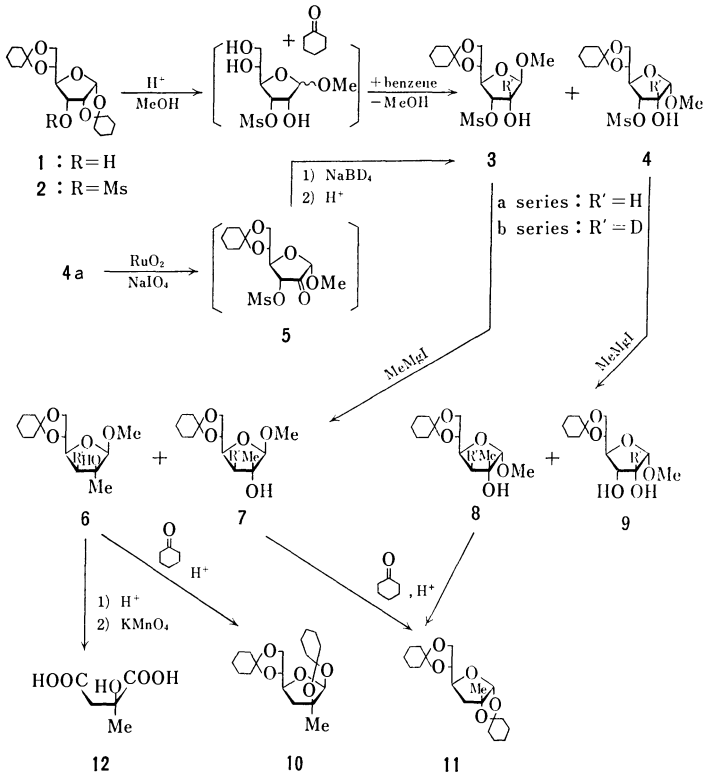

Fig. 1.

(**7a**) in 86 and 4% yields respectively. When **4a** was treated with MeMgI, methyl 5,6-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-α-D-*ribo*-hexofuranoside (**8a**) was obtained in a 29% yield, besides methyl 5,6-*O*-cyclohexylidene-α-D-allofuranoside (**9a**) in a 37% yield, the cleavage of the mesyl group in **4a** being predominant in this case.

The structures of the newly synthesized branched-chain deoxy sugars were established on the basis of their analytical and spectroscopic data and the chemical conversion. The ^{1}H NMR spectrum of each sugar derivative (**6a**—**8a**) showed a singlet due to the anomeric proton and a pair of quartets characteristic of the AB parts of an ABX system; these phenomena were assignable to H_{3a} (A), H_{3b} (B), and H_4 (X).[6] The relatively large values (8.6—6.4 Hz) of the coupling constants for H_{3a}–H_4 and H_{3b}–H_4 in **6a**—**8a** suggested that these sugars most probably existed in C_3-*endo* conformations.[7] For example, the C_3-*endo* conformation of **6a** can be depicted as in Fig. 2, in which H_{3a} and the methyl group at C-2 as well as H_{3a} and H_4 consititute an axial-quasi axial pair. Spin-spin decoupling experiments demonstrated that the methyl protons in the former pair were coupled to H_{3a} (J=0.8 Hz) because of their W-shaped arrangement.

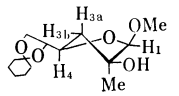

Fig. 2. C_3-*endo* conformation of **6a**.

The ^{13}C NMR spectra of **6a**—**8a** were also taken (Table 1). The signal due to the methyl carbon at C-2 of **7a** appeared at fields higher by 2.7 and 4.6 ppm than those for **6a** and **8a** respectively. This indicated that the methyl group at C-2 in **7a** was located vicinal to the methoxyl group at C-1 in a *cis* manner.[8] These ^{1}H and ^{13}C NMR spectral data are consistent with the proposed structures for **6a**, **7a**, and **8a**.

Both compounds, **7a** and **8a**, gave 1,2:5,6-di-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-α-D-*ribo*-hexofuranose (**11**) when they were treated with cyclohexanone in the presence of an acid. Similarly, the corresponding β-D-*arabino* isomer (**10**) could be obtained from **6a**. The mass spectra of **10** and **11** showed strong peaks at *m/e* 141 attributable to the dioxolane ring at C-4, thus indicating the furanose structures of these compounds.[5] Their anomeric configurations were also assigned on the basis of the sign of the optical rotation; **10** had a negative sign, whereas **11** had a positive one.[9] From these results, it was concluded that **7a** and **8a** were a pair of anomers, and that the configurations at C-2 for these anomers were different from that for **6a**.

Furthermore, the absolute configuration of the branching point at the C-2 position of **6a** was determined by chemical degradation. Thus, **6a** was treated with an acid to hydrolyze the acetal protecting group and the glycoside, after which the resulting free sugar was oxidized with potassium permanganate to yield the known 2-methylmalic acid (**12**), which had the *S* configuration at its asymmetric center.[10a]

Salaün and Conia[11] have reported that when 2-tosyloxycyclobutanone was treated with MeMgI, the resulting Grignard adduct, 1-methyl-2-*O*-tosyl-1,2-cyclobutanediol, underwent a skeletal rearrengement of the cyclobutane ring to give cyclopropyl methyl ketone. Sasaki *et al.*[12] have obtained 3-deoxy-2-keto sugar-nucleosides by the reaction of 3′-*O*-sulfonates of nucleosides with sodium benzoate in *N*,*N*-dimethylformamide; they assumed that these reactions proceeded *via* the 1,2-elimination of the sulfonyloxyl group at C-3′ and of the proton at C-2′. In the present reactions, it was considered that the 3-deoxy-2-keto sugars (**B** in Fig. 3) were formed as intermediates from **3a** and **4a** by the elimination of the mesyloxyl groups at C-3 concomitant with the 1,2-hydride shifts from C-2 to C-3.

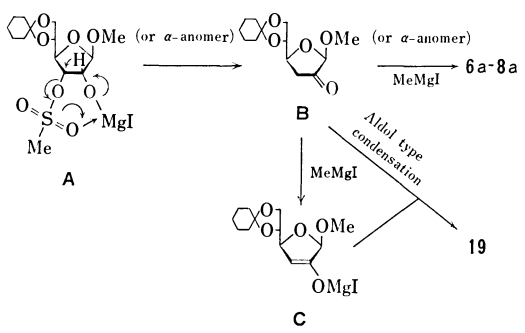

Fig. 3.

In order to demonstrate the hydride shifts in our case, the C-2 deuterated analogs of **3a** and **4a** were prepared. The oxidation of **4a** with ruthenium dioxide-sodium metaperiodate gave an ulose (**5**), which, without purification, was then reduced with sodium borodeuteride to give the C-2 deuterated analog (**4b**). The corresponding β-anomer (**3b**) was obtained by the anomerization of **4b** with an acid.

The deuterated analogs (**3b** and **4b**) thus obtained were subjected to the same Grignard reactions to give the corresponding deuterated products (**6b**—**8b**). The mass spectra of these products showed that the deuterium contents of the starting materials were almost entirely retained in the products. Their ^{1}H NMR spectra indicated that the deuteriums at C-2 in the starting materials had been transferred to the C-3 position of the products. As the ^{1}H NMR analysis distinguished between H_{3a} and H_{3b} in **6a**, the *S* configuration could be assigned to the C-3 position of **6b**. Therefore, the 1,2-deuteride shift in **3b** occurred stereoselectively by way of the intramolecular S_N2 displacement of the mesyloxyl group at C-3.

On the basis of these observations it can be assumed that the present Grignard reactions proceed through a postulated intermediate (**A** in Fig. 3) in which the oxygen atom of the sulfone moiety is coordinated to the magnesium atom to form a cyclic seven-membered ring. The formation of the keto group, the 1,2-hydride shift, and the elimination of the mesyloxyl group then occurs in a concerted manner to give the 3-deoxy-2-keto sugar (**B**), which, in turn, reacts with another MeMgI, mainly from the opposite side of the methoxyl group at C-1, to yield the branched-chain deoxy sugars.

TABLE 1. THE ^{13}C NMR CHEMICAL SHIFTS OF DEOXY AND BRANCHED-CHAIN DEOXY SUGARS[a]

Product	Carbon positions[b]											
	C_1	C_2	C_3	C_4	C_5	C_6	C-Me	O-Me	$C_{1'}$	$C_{2',6'}$	$C_{3',4',6'}$	
6a	106.56	77.60	41.18	78.66[c]	78.78[c]	66.72	23.80	54.90	109.88	34.84 36.51	23.80 24.00	25.14
7a	109.81	80.51	41.39	79.87	79.05	67.20	21.10	54.54	109.81	34.98 36.52	23.86 24.02	25.16
8a	107.38	77.51	40.66	78.00	76.94	66.72	25.73	55.43	110.06	34.74 36.20	23.78 23.94	25.16
13a	101.82	72.33	35.02	78.08[c]	78.59[c]	66.65	—	54.86	109.67	34.78 36.42	23.77 23.97	25.09
14a	102.56	71.69	33.60	77.03[c]	77.69[c]	66.43	—	55.24	110.13	34.62 36.17	23.74 23.98	25.14

a) The spectra were run in $CDCl_3$ and were completely decoupled. The shifts are given in parts per million relative to the internal tetramethylsilane. b) C_1-C_6 refer to the carbon atoms of the sugars, while $C_{1'}$-$C_{6'}$ refer to the cyclohexylidene carbon atoms. c) The assignment of the signals to C_4 and C_5 may be reversed.

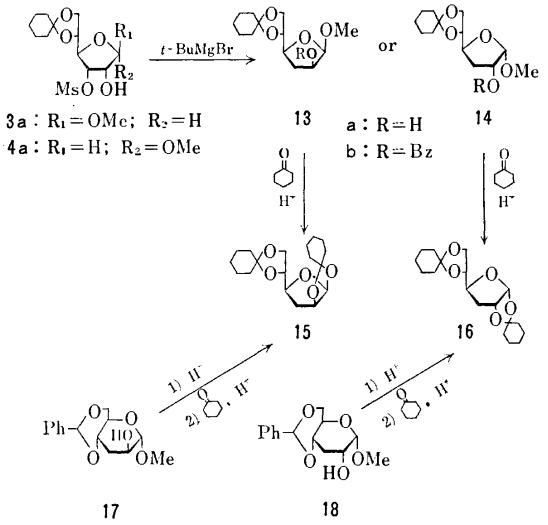

Fig. 4.

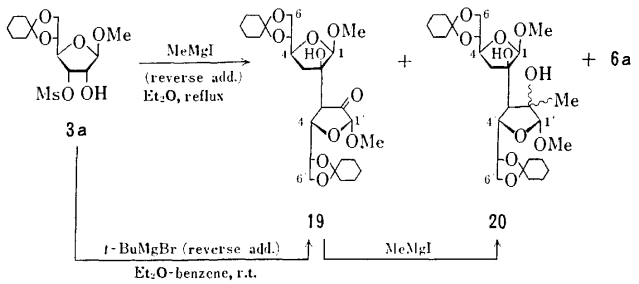

Fig. 5.

With the hope of obtaining exclusively the 3-deoxy-2-keto sugars in the present reactions, we attempted to use sterically bulky *t*-butylmagnesium bromide (*t*-BuMgBr) instead of MeMgI. However, the reaction of **3a** or **4a** with *t*-BuMgBr did not stop at the stage of the formation of the desired sugar derivative, but proceeded further to afford methyl 5,6-*O*-cyclohexylidene-3-deoxy-β-D-*arabino*-hexofuranoside (**13a**) or the corresponding α-D-*ribo* isomer (**14a**) in an 87 or 75% yield respectively after column chromatography (Fig. 4). The Grignard reduction by *t*-BuMgBr was effective in this case. An attempt to reduce 1,2:5,6-di-*O*-cyclohexylidene-α-D-*ribo*-hexofuranos-3-ulose[4b] with *t*-BuMgBr under similar conditions gave a mixture (91:9) of the corresponding *allo*- and *gluco*-furanose in a 78% yield.

The structures of **13a** and **14a** as well as their monobenzoates (**13b** and **14b**) were characterized by their elemental analyses and spectroscopic data, including the ^{13}C NMR spectra (Table 1). Furthermore, the treatment of **13a** and **14a** with cyclohexanone in the presence of an acid gave 1,2:5,6-di-*O*-cyclohexylidene-3-deoxy-β-D-*arabino*-hexofuranose (**15**) and the corresponding α-D-*ribo* isomer (**16**) respectively, their furanose structures being tentatively assigned. However, the physical properties of **15** and **16** were identical with those of the specimens prepared from known compounds, methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*arabino*-hexopyoranoside[13] (**17**) and the corresponding α-D-*ribo* isomer[14] (**18**) respectively.

When an ethereal solution of MeMgI was very gradually added to a refluxing solution of **3a** in ether, it gave two dimeric compounds, **19** and **20**, in 3 and 44% yields respectively, besides **6a** (29%)(Fig. 5). Using *t*-BuMgBr, we obtained **19** in a moderate yield, upon subsequent treatment with MeMgI, this gave **20**.

The structures and the stereochemistry of the binding sites of the two furanose rings for **19** and **20** were deduced to be as is shown in the scheme on the basis of their spectral data as well as an inspection of the CPK molecular model, but the configuration of the methyl and hydroxyl groups in **20** is not clear at this time. These reactions are considered to be Aldol-type condensations of the ketone (**B**, β-anomer) and its enolate (**C**) (Fig. 3); the slow addition of MeMgI to a solution of **3a** would result in the survival of a relatively large amount of unreacted ketone (**B**), some of which would be isomerized with MeMgI to **C**. Similar reactions have been reported by Horton and Just[15a] and others.[15b,c]

Experimental

The boiling and melting points are uncorrected. The optical rotations were measured with a Perkin-Elmer Model 141 polarimeter. The IR spectra were recorded on a Shimadzu IR-27 instrument. The mass spectra were obtained

with a Japan Optics Lab. Model JMS-01SG instrument. The ^{1}H NMR spectra were recorded on a Varian HA-100D apparatus, with tetramethylsilane as the internal standard. The proton noise-decoupling ^{13}C NMR spectra were obtained on a JEOL FX-60 FT.

Merck silica gel 60 (0.063—0.20 mm) was used for the column chromatography, and silica gel GF_{254} was used for the analytical TLC; visualization was effected by the use of a methanol–sulfuric acid–*p*-methoxybenzaldehyde (85:10:5, v/v) spray, followed by heating. The elemental analyses were performed by this Institute. The sodium borodeuteride (98% min deuterium content) was purchased from Merck.

1,2:5,6-Di-O-Cyclohexylidene-3-O-mesyl-α-D-allofuranose (2). Mesyl chloride (5.5 ml) was added to a stirred solution of I[4a] (17 g, 0.05 mol) in a mixture of dry pyridine (30 ml) and benzene (30 ml) at 0—5 °C (bath temperature). The mixture was then stirred at room temperature overnight. After cooling, iced water was added and the mixture was extracted with chloroform. The extract was washed with water, dried ($MgSO_4$), and concentrated. The pyridine was removed by co-evaporation with xylene. The residue was diluted with methanol to give **2** (88%) as crystals. An analytically pure sample was obtained by recrystallization from methanol: mp 119.5—121.5 °C; $[\alpha]_D^{23}$ +82.2° (*c* 1.3, $CHCl_3$). IR (KBr): 1358 (S=O), 1179 (S=O) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 1.0—2.0 (20H, m, CH_2 of the cyclohexylidene groups), 3.8—4.4 (4H, m), 4.7—4.9 (2H, m), 5.82 (1H, dd, J=3.8 Hz, J=0.8 Hz, H-3).

Found: C, 54.68; H, 6.98; S, 7.67%. Calcd for $C_{19}H_{30}O_8S$: C, 54.53; H, 7.23; S, 7.66%.

Methyl 5,6-O-Cyclohexylidene-3-O-mesyl-β-D-allofuranoside (3a) and Its α-Anomer (4a). A mixture of **2** (16.8 g, 0.04 mol) and concd sulfuric acid (0.2 ml) in dry methanol (120 ml) was stirred at 75—80 °C (bath temperature) for 3 h. The methanol was then removed below 35 °C *in vacuo* until crystals appeared. Dry benzene (60 ml) was added, and the mixture was concentrated to *ca.* 30 ml. This procedure (the addition of benzene and the concentration of the mixture) was repeated once again. Calcium hydroxide (4 g) was then added, and the mixture was diluted with chloroform. After the crystalline materials had been removed by filtration, the chloroform solution was washed successively with aqueous sodium hydrogencarbonate and water, and dried ($MgSO_4$). The removal of the solvent gave crude products, the ^{1}H NMR spectrum of which showed that the ratio of **3a** and **4a** was approximately 2:1. The products were triturated with hot hexane (80 ml). After the mixture had been cooled, the crystalline compounds were collected and washed with hexane. Recrystallization from benzene–diisopropyl ether gave **3a** (8.1 g, 57%). The mother liquor was concentrated, and the residue was submitted to fractional crystallization from diisopropyl ether, giving **4a** (3.95 g, 28%) and another crop of **3a** (0.98 g, 7%).

The recrystallization of the crude **3a** from methanol gave an analytically pure sample as needles: mp 138—140 °C; $[\alpha]_D^{24}$ −44.6° (*c* 1, $CHCl_3$). IR (KBr): 3470 (OH), 1353 (S=O), 1173 (S=O) cm^{-1}. MS: *m/e* 352 (M^+), 141 (the dioxolane ring at C-4). ^{1}H NMR ($CDCl_3$): δ 1.2—1.8 (10H, m, CH_2 of the cyclohexylidene groups), 2.50 (1H, br s, OH), 3.16 (3H, s, SCH_3), 3.35 (3H, s, OCH_3), 3.9—4.2 (4H, m), 4.31 (1H, dd, $J_{1,2}$=1.4 Hz, $J_{2,3}$=4.6 Hz, H-2), 4.87 (1H, d, $J_{1,2}$=1.4 Hz, H-1), 5.10 (1H, m, H-3).

Found: C, 47.73; H, 6.84; S, 9.00%. Calcd for $C_{14}H_{24}O_8S$: C, 47.72; H, 6.78; S, 9.10%.

The recrystallization of the crude **4a** from benzene–diisopropyl ether gave an analytically pure sample as prisms: mp 118—119 °C; $[\alpha]_D^{22}$ +97.7° (*c* 1, $CHCl_3$). IR (KBr): 3500 (OH), 1353 (S=O), 1172 (S=O) cm^{-1}. MS: *m/e* 352 (M^+), 141 (the dioxolane ring at C-4). ^{1}H NMR ($CDCl_3$): δ 1.2—2.0 (10H, m, CH_2 of the cyclohexylidene groups), 3.12 (3H, s, SCH_3), 3.47 (3H, s, OCH_3), 3.7—4.4 (5H, m) 4.93 (1H, d, $J_{1,2}$=4.8 Hz, H-1), 5.0 (1H, m, H-3).

Found: C, 47.53; H, 6.83; S, 9.13%. Calcd for $C_{14}H_{24}O_8S$: C, 47.72; H, 6.87; S, 9.10%.

Methyl 5,6-O-Cyclohexylidene-3-O-mesyl-β-D-allofuranoside-2-d (3b) and Its α-Anomer (4b). A mixture of **4a** (2.27 g, 6.45 mmol), sodium metaperiodate (6.8 g), ruthenium dioxide (400 mg), and potassium carbonate (720 mg) in alcohol-free chloroform (80 ml) and water (80 ml) was vigorously stirred at room temperature for 8 h.[16] After the excess of ruthenium tetraoxide had then been decomposed with 2-propanol, the undissolved materials were filtered through a Celite pad and washed with chloroform. The filtrate was dried ($MgSO_4$) and concentrated to give a syrupy ketone (**5**, 1.85 g) which was almost pure, judging from its TLC analysis, and IR and ^{1}H NMR spectral data; this product was found to be converted to almost pure **4a** by reduction with sodium borohydride under conditions similar to those described below.

Sodium borodeuteride (200 mg) was added to a stirred solution of this crude **5** (1.75 g) in methanol (15 ml) at 0—5 °C (bath temperature) over a period of 5 min. After 1 h, the mixture was diluted with ether, and the solution was washed with water and dried ($MgSO_4$). The evaporation of the solvent gave a crystalline product, which was triturated with hot diisopropyl ether to give **4b** (1.48 g, 69% from **4a**); the deuterium content was found to be 91% on the basis of the mass spectrometric analysis. MS: *m/e* 353 (M^+). ^{1}H NMR ($CDCl_3$): δ 1.1—1.8 (10H, m, CH_2 of the cyclohexylidene group), 3.11 (3H, s, SCH_3), 3.46 (3H, s, OCH_3), 3.9—4.3 (4, 1H, m), 4.92 (1H, s, H-1), 4.97 (1H, m, H-3).

A stirred mixture of **4b** (1.3 g) and concd sulfuric acid (0.03 ml) was refluxed at 80—85 °C (bath temperature) for 3 h. The solution was treated in a manner to that described for the synthesis of **3a** to give a mixture (1.2 g) of **3b** and **4b** in a ratio of 2:1, from which **3b** (500 mg, 38%) was isolated. Recrystallization from benzene–diisopropyl ether gave **3b**; the deuterium content was found to be 87% on the basis of the mass spectrometric analysis. MS: *m/e* 353 (M^+). ^{1}H NMR ($CDCl_3$): δ 1.1—1.9 (10H, m, CH_2 of the cyclohexylidene group), 3.16 (3H, s, SCH_3), 3.36 (3H, s, OCH_3), 3.8—4.2 (4H, m), 4.3 (0.1H, m, H-2), 4.87 (1H, s, H-1), 5.1 (1H, m, H-3).

Methyl 5,6-O-Cyclohexylidene-3-deoxy-2-C-methyl-β-D-arabino-hexofuranoside (6a) and Methyl 5,6-O-Cyclohexylidene-3-deoxy-2-C-methyl-β-D-ribo-hexofuranoside (7a). To a stirred solution of MeMgI (6 mmol) in ether (20 ml) we added **3a** (705 mg, 2 mmol) at 0—5 °C (bath temperature) under a dry nitrogen atmosphere over a period of 5 min, after which the mixture was stirred at room temperature for 2 h. After the mixture had been cooled, aqueous ammonium chloride was added. The mixture was then extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated to give crystalline products, which were recrystallized from water–ethanol on seeding to afford **6a** (262 mg, 48%): mp 69—70 °C; $[\alpha]_D^{25}$ −69.4° (*c* 1, $CHCl_3$). IR (KBr): 3500 (OH) cm^{-1}. MS: *m/e* 272 (M^+). ^{1}H NMR[6] ($CDCl_3$): δ 1.2—1.7 (10H, m, CH_2 of the cyclohexylidene group), 1.32 (3H, d, $J_{3a,Me}$=0.8 Hz, C-CH_3), 1.88 (1H, q, $J_{3a,3b}$=11.5 Hz, $J_{3a,4}$=8.0 Hz, H-3a), 2.09 (1H, q, $J_{3a,3b}$=11.5 Hz, $J_{3b,4}$=6.5 Hz, H-3b), 2.72 (1H, br s, OH), 3.40 (3H, s, OCH_3), 3.7—4.2 (4H, m), 4.35 (1H, s, H-1).

Found: C, 62.00; H, 8.70%. Calcd for $C_{14}H_{24}O_5$: C,

61.74; H, 8.88%.

The mother liquor was concentrated, and the residue was chromatographed on a silica-gel column with hexane–ether (2:1) to give a ketonic compound (11 mg) which was not characterized, another crop of **6a** (209 mg, 38%), and the C-2 epimer (**7a**, 22 mg, 4%) as crystals: mp 90—92 °C; $[\alpha]_D^{20}$ −80.2° (*c* 0.3, $CHCl_3$). IR (KBr): 3280 (OH) cm^{-1}. MS: *m/e* 272 (M^+). ^1H NMR[6] ($CDCl_3$): δ 1.1—1.7 (10H, m, CH_2 of the cyclohexylidene group), 1.36 (3H, s, C-CH_3), 1.91 (1H, q, $J_{3a,3b}=13.1$ Hz, $J_{3a,4}=8.6$ Hz, H-3a), 2.09 (1H, q, $J_{3a,3b}=13.1$ Hz, $J_{3b,4}=6.6$ Hz, H-3b), 2.23 (1H, br s, OH), 3.32 (3H, s, OCH_3), 3.8—4.4 (4H, m), 4.51 (1H, s, H-1).

Found: C, 61.96; H, 8.97%. Calcd for $C_{14}H_{24}O_5$: C, 61.74; H, 8.88%.

*Methyl 5,6-*O*-Cyclohexylidene-3-deoxy-2-*C*-methyl-α-*D*-ribo-hexofuranoside (**8a**) and Methyl 5,6-*O*-Cyclohexylidene-α-*D*-allofuranoside (**9a**).* A solution of MeMgI (18 mmol) in ether (15 ml) was gradually added to a stirred suspension of powdered **4a** (1.06 g, 3 mmol) in ether (20 ml) at −3—0 °C (bath temperature) under a dry nitrogen atmosphere over a period of 30 min; when powdered **4a** was added to the solution of MeMgI under conditions similar to those described for the synthesis of **6a**, gummy materials were formed to decrease the yield of **8a**. After the mixture had then been stirred at room temperature for 7 h, it was poured into a cold solution of ammonium chloride (1 g) in water (30 ml) and extracted with ether (250 ml). The extract was washed with water (40 ml×8), dried ($MgSO_4$), and concentrated. The residue was chromatographed on a silica-gel column with hexane–ether to give **8a** (240 mg, 29%) as a syrup. An analytically pure sample was obtained by distillation: bp 128—130 °C (bath temperature)/2 mmHg; $[\alpha]_D^{21}$ +75.2° (*c* 1, $CHCl_3$). IR (neat): 3530 (OH) cm^{-1}. MS: *m/e* 272 (M^+). ^1H NMR[6] ($CDCl_3$): δ 1.2—1.7 (10H, m, CH_2 of the cyclohexylidene group), 1.37 (3H, s, C-CH_3), 1.93 (1H, q, $J_{3a,3b}=12.4$ Hz, $J_{3a,4}=6.4$ Hz, H-3a), 2.11 (1H, q, $J_{3a,3b}=12.4$ Hz, $J_{3b,4}=7.0$ Hz, H-3b), 2.74 (1H, br s, OH), 3.47 (3H, s, OCH_3), 3.8 (1H, m), 3.9—4.3 (3H, m), 4.53 (1H, s, H-1).

Found: C, 61.86; 8.89%. Calcd for $C_{14}H_{24}O_5$: C, 61.74; H, 8.88%.

The aqueous ammonium chloride and washings were combined and concentrated. The residue was triturated with chloroform, and the undissolved materials were removed by filtration. The chloroform was evaporated to give a syrup, which was then chromatographed on a silica-gel column with chloroform–methanol (98:2) to afford **9a** (304 mg, 37%) as a syrup: $[\alpha]_D^{21}$ +100° (*c* 1, $CHCl_3$). IR (neat): 3450 (OH) cm^{-1}. MS: *m/e* 274 (M^+). ^1H NMR ($CDCl_3$): δ 1.1—2.0 (10H, m, CH_2 of the cyclohexylidene group), 2.85 (2H, s, two hydroxyl protons), 3.48 (3H, s, OCH_3), 3.7—4.3 (6H, m), 4.9 (1H, m, H-1); (benzene-d_6) δ 3.11 (3H, s, OCH_3), 4.60 (1H, d, $J_{1,2}=4.2$ Hz, H-1).

Found: C, 56.90; H, 7.95%. Calcd for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08%.

*Methyl 5,6-*O*-Cyclohexylidene-3-deoxy-2-*C*-methyl-β-*D*-arabino-hexofuranoside-3-*d* (**6b**) and Its C-2 Epimer (**7b**).* The deuterated analog (**3b**, 300 mg, 0.85 mmol) was treated with MeMgI (5.1 mmol) in a manner similar to that described for the synthesis of **6a** to give, after chromatography, **6b** (192 mg, 83%) and **7b** (5 mg, 2.2%). The mass spectra of these products indicated that their deuterium contents were 87%.

6b. MS: *m/e* 273 (M^+). ^1H NMR[6] ($CDCl_3$): δ 1.34 (3H, s, C-CH_3), 1.2—1.8 (10H, m, CH_2 of the cyclohexylidene group), 1.9 (0.15H, m, H-3a), 2.1 (1H, m, H-3b), 2.79 (1H, s, OH), 3.42 (3H, s, OCH_3), 3.8—4.2 (4H, m), 4.36 (1H, s, H-1).

7b. MS: *m/e* 273 (M^+). ^1H NMR[6] ($CDCl_3$): δ 1.1—1.8 (10H, m, CH_2 of the cyclohexylidene group), 1.34 (3H, s, C-CH_3), 1.9 (0.15H, m, H-3a), 2.1 (1H, m, H-3b), 3.30 (3H, s, OCH_3), 3.8—4.3 (4H, m), 4.50 (1H, s, H-1).

*Methyl 5,6-*O*-Cyclohexylidene-3-deoxy-2-*C*-methyl-α-*D*-ribo-hexofuranoside-3-*d* (**8b**) and Methyl 5,6-*O*-Cyclohexylidene-α-*D*-allofuranoside-2-*d* (**9b**).* The deuterated analog (**4b**, 282 mg, 0.8 mmol) was treated with MeMgI (4.8 mmol) in a manner similar to that described for the synthesis of **8a**. After the reaction had been completed, a small amount of cold aqueous ammonium chloride was added to the cooled reaction mixture and the products were extracted with ether and dried ($MgSO_4$). The residue was chromatographed on a silica-gel column with hexane–ether (1:1) to give **8b** (63 mg, 29%) and **9b** (59 mg, 27%). The mass spectra of **8b** and **9b** indicated that their deuterium contents were 86 and 90% respectively.

8b. MS: *m/e* 273 (M^+). ^1H NMR[6] ($CDCl_3$): δ 1.2—1.8 (10H, m, CH_2 of the cyclohexylidene group), 1.36 (3H, s, C-CH_3), 1.9 (0.15H, m, H-3a), 2.1 (1H, m, H-3b), 2.94 (1H, s, OH), 3.46 (3H, s, OCH_3), 3.7—3.9 (1H, m), 4.0—4.2 (3H, m), 4.52 (1H, s, H-1).

9b. MS: *m/e* 257 (M^+). ^1H NMR ($CDCl_3$): δ 1.1—1.8 (10H, m, CH_2 of the cyclohexylidene group), 2.79 (1H, br d, $J=7.4$ Hz, OH at C-3), 3.01 (1H, br s, OH at C-2), 3.47 (3H, s, OCH_3), 3.7—4.3 (5.1H, m), 4.91 (1H, s, H-1).

*1,2:5,6-Di-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-β-*D*-arabino-hexofuranose (**10**).* A mixture of **6a**, cyclohexanone (0.4 ml), and concd sulfuric acid (*ca.* 40 mg) in dry benzene (2 ml) was vigorously stirred at room temperature for 30 h. During this reaction time, the following procedure was repeated several times: the mixture was concentrated below 30 °C *in vacuo*, followed by the addition of dry benzene in order to remove the methanol and water produced. The mixture was then diluted with dry benzene and neutralized with calcium hydroxide. The undissolved material was filtered and washed with chloroform. The chloroform solution was washed successively with aqueous sodium hydrogencarbonate and water, and then dried ($MgSO_4$). The subsequent evaporation of the solvent gave a syrup, which was chromatographed on a silica-gel column with hexane–ether (8:2) to give **10** (180 mg, 58%). An analytically pure sample was obtained by distillation: bp 167—170 °C (bath temperature)/1 mmHg; $[\alpha]_D^{23}$ −21.0° (*c* 1, $CHCl_3$). IR (neat): no OH absorption. MS: *m/e* 338 (M^+), 141 (the dioxolane ring at C-4). ^1H NMR[6] ($CDCl_3$): δ 1.1—1.9 (10H, m, CH_2 of the cyclohexylidene group), 1.48 (3H, s, C-CH_3), 2.09 (1H, q, $J_{3a,3b}=13.8$ Hz, $J_{3a,4}=7.8$ Hz, H-3a), 2.34 (1H, q, $J_{3a,3b}=13.8$ Hz, $J_{3b,4}=6.8$ Hz, H-3b), 3.6—4.4 (4H, m), 5.35 (1H, s, H-1).

Found: C, 67.59; H, 8.70%. Calcd for $C_{19}H_{30}O_5$: C, 67.43; H, 8.94%.

*1,2:5,6-Di-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-α-*D*-ribo-hexofuranose (**11**).* *From **8a***: A mixture of **8a** (130 mg, 0.48 mmol), cyclohexanone (0.4 ml), and concd sulfuric acid (*ca.* 40 mg) in dry benzene (2 ml) was vigorously stirred at room temperature for 2.5 h; the benzene was then removed below 30 °C *in vacuo*. The residue was treated in a manner similar to that described for the synthesis of **10** to afford, after column chromatography, **11** (140 mg, 86%). An analytically pure sample was obtained by distillation: bp 173—175 °C (bath temperature)/1.5 mmHg; $[\alpha]_D^{22}$ +10.3° (*c* 1, $CHCl_3$). IR (neat): no OH absorption. MS: *m/e* 338 (M^+), 141 (the dioxolane ring at C-4). ^1H NMR ($CDCl_3$): δ 1.1—1.9 (10H, m, CH_2 of the cyclohexylidene group),

1.50 (3H, s, C-CH_3), 2.1—2.5 (2H, m, H-3a and H-3b), 3.7—4.3 (4H, m), 5.48 (1H, s, H-1).

Found: C, 67.63; H, 8.75%. Calcd for $C_{19}H_{30}O_5$: C, 67.43; H, 8.94%.

From **7a**. The compound (**7a**, 5 mg, 0.018 mmol) was treated with cyclohexanone in a manner similar to that described for the synthesis of **11** from **8a**, giving a syrupy **11** (5 mg, 82%). The physical properties (IR, ^1H NMR, and the specific rotation) of this material were identical with those of the specimen prepared from **8a**.

(S)-(+)-2-Methylmalic Acid (12). Dowex 50W-X8 (H^+ form, 6 ml) was added to a solution of **6a** (1.32 g, 4.85 mmol) in a mixture of dioxane (10 ml) and water (16 ml), after which was stirred at 90 °C (bath temperature) for 1 h. The resin was removed by filtration and washed with water. The combined filtrate and washings were concentrated. The residue was chromatographed on a silica-gel column with chloroform–methanol (8:2) to give a syrupy product (740 mg). To a solution of this syrup (350 mg) and potassium hydroxide (200 mg) in water (50 ml), there was added powdered potassium permanganate (1.3 g) at 4—5 °C over a period of 1 h. After the mixture had been stirred at this temperature for another 1 h, 15% hydrogen peroxide (*ca.* 5 ml) was added to decompose the excess potassium permanganate. The mixture was then diluted with water and treated with charcoal. The undissolved materials were removed by filtration through a Celite pad and washed with water. The combined filtrate and washings were acidified with Dowex 50W-X8 (H^+ form). After the removal of the resin, the solution was concentrated. The residue was chromatographed on a column of Dowex-X8 (H^+ form, 100—200 mesh, 300 ml, 2.8×66 cm) with water; a 6-ml fraction was thus collected. Fractions No. 31—38 were combined and concentrated to give a syrup, which was taken up in ethyl acetate. A small amount of the undissolved material was filtered, and the filtrate was concentrated. The water which remained in the residue was removed by repeated co-evaporation with ethyl acetate–benzene to give, after drying (P_2O_5) at 57 °C *in vacuo* for 4 h, **12** as a syrup (190 mg, 56% from **6a**): $[\alpha]_D^{27}$ +21.2° (*c* 1.2, H_2O) [lit,[10b] $[\alpha]_D^{22}$ +23° (*c* 6.316, H_2O)]; $[\alpha]_D^{27}$ +1300° [*c* 0.1, in a mixture of H_2O (2.5 ml), 0.25 M sodium citrate (2.5 ml), 29% ammonium molybdate (4.5 ml), and acetic acid (0.5 ml)] [lit,[10c] $[\alpha]_D^{18}$ −1335°: This optical rotation was measured in a mixture of 0.01 M (−)-2-methylmalic acid (2.5 ml), 0.25 M sodium citrate (2.5 ml), 29% ammonium molybdate (4.5 ml), and acetic acid (0.5 ml)]. The ^1H NMR spectrum of **12** was completely identical with that of an authentic sample of racemic **12**.

A solution of the syrupy **12** (47 mg) and brucine (136 mg) in water (0.3 ml) was allowed to stand at 3 °C overnight to give an analytically pure brucine salt of **12** as crystals (67 mg, 41%): mp 216—217 °C (dec under rapid heating) [lit,[10b] 222 °C (dec)]; $[\alpha]_D^{26}$ −7.3° (*c* 0.44, 50% MeOH). The IR spectrum of this salt was completely identical with that of an authentic sample.

*Methyl 5,6-O-Cyclohexylidene-3-deoxy-β-*D-arabino-*hexofuranoside (13a)*. Into a solution of *t*-BuMgBr (24 mmol) in a mixuter of ether (20 ml) and benzene (10 ml) we stirred **3a** (704 mg, 2 mmol) at room temperature under a dry nitrogen atmosphere over a period of 30 min. The mixture was stirred for another 30 min and then cooled to 5 °C. Cold aqueous ammonium chloride was added, and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and then concentrated. The residue was chromatographed on a silica-gel column with benzene–ethyl acetate (9:1) to give **13a** (447 mg, 87%) as a syrup: $[\alpha]_D^{25}$ −86.0° (*c* 0.8, $CHCl_3$). IR (neat): 3480 (OH) cm^{-1}. MS: *m/e* 258 (M^+). ^1H NMR ($CDCl_3$): δ 1.2—1.9 (10H, m, CH_2 of the cyclohexylidene group), 2.2—2.6 (2H, m, H-3a and H-3b), 3.39 (3H, s, OCH_3), 3.8—4.4 (5H, m), 4.71 (1H, d, $J_{1,2}$=4.3 Hz, H-1).

Found: C, 60.27; H, 8.55%. Calcd for $C_{13}H_{22}O_5$: C, 60.44; H, 8.59%.

*Methyl 5,6-O-Cyclohexylidene-3-deoxy-α-*D-ribo-*hexofuranoside (14a)*. To a stirred solution of *t*-BuMgBr (24 mmol) in a mixture of ether (20 ml) and benzene (10 ml) we added **4a** (704 mg, 2 mmol) at 60—65 °C (bath temperature) under a dry nitrogen atmosphere over a period of 15 min. The stirring was continued at this temperature for another 25 min. The usual work-up gave a syrupy product, which was chromatographed on a silica-gel column with hexane–ether (6:4) to give **14a** (387 mg, 75%) as a syrup: $[\alpha]_D^{25}$ +93.6° (*c* 1, $CHCl_3$). IR (neat): 3500 (OH) cm^{-1}. MS: *m/e* 258 (M^+). ^1H NMR ($CDCl_3$): δ 1.1—1.9 (10H, m, CH_2 of the cyclohexylidene group), 1.7—2.4 (2H m, H-3a and H-3b), 2.46 (1H, d, J=8.6 Hz, OH), 3.43 (3H, s, OCH_3), 3.72 (1H, m), 3.9—4.5 (4H, m), 4.83 (1H, d, $J_{1,2}$=4.5 Hz, H-1).

Found: C, 60.48; H, 8.55%. Calcd for $C_{13}H_{22}O_5$: C, 60.44; H, 8.59%.

*Methyl 2-O-Benzoyl-5,6-O-cyclohexylidene-3-deoxy-β-*D-arabino-*hexofuranoside (13b)*. Benzoyl chloride (0.3 ml) was stirred into a cold (0—5 °C) solution of **13a** (147 mg, 0.57 mmol) in dry pyridine (1.5 ml). The mixture was stirred at room temperature for 10 min and then cooled. Iced water was added, and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and then concentrated to give a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (9:1) to give **13b** as crystals in a quantitative yield: mp 86.0—86.5 °C; $[\alpha]_D^{25}$ −88.4° (*c* 1.2, $CHCl_3$). IR (KBr): 1724 (C=O) cm^{-1}. MS: *m/e* 362 (M^+). ^1H NMR ($CDCl_3$): δ 1.1—1.9 (10H, m, CH_2 of the cyclohexylidene group), 2.0—2.8 (2H, m, H-3a and H-3b), 3.32 (3H, s, OCH_3), 3.8—4.3 (4H, m), 5.0—5.3 (2H, m, H-1 and H-2), 7.2—7.7 (3H, m, the phenyl protons), 7.9—8.2 (2H, m, the phenyl protons).

Found: C, 66.38; H, 7.17%. Calcd for $C_{20}H_{26}O_6$: C, 66.28; H, 7.23%.

*Methyl 2-O-Benzoyl-5,6-O-cyclohexylidene-3-deoxy-α-*D-ribo-*hexofuranoside (14b)*. Benzoyl chloride (0.3 ml) was stirred into a cold (0—5 °C) solution of **14a** (160 mg, 0.62 mmol) in dry pyridine (1.5 ml). The mixture was then stirred at room temperature for 10 min. The usual work-up gave a syrup, which was subsequently chromatographed on a silica-gel column with hexane–ether (8:2) to afford **14b** (185 mg, 83%) as a syrup: $[\alpha]_D^{25}$ +96.0° (*c* 1, $CHCl_3$). IR (neat): 1721 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.2—1.8 (10H, m, CH_2 of the cyclohexylidene group), 2.2—2.5 (2H, m, H-3a and H-3b), 3.36 (3H, s, OCH_3), 3.78 (1H, m), 4.0—4.3 (3H, m), 5.1—5.3 (2H, m, H-1 and H-2), 7.2—7.7 (3H, m, the phenyl protons), 7.9—8.2 (2H, m, the phenyl protons).

Found: C, 66.30; H, 7.27%. Calcd for $C_{20}H_{26}O_6$: C, 66.28; H, 7.23%.

*The Reaction of 1,2:5,6-Di-O-cyclohexylidene-α-*D-ribo-*hexofuranos-3-ulose with* t-*BuMgBr*. To a stirred solution of *t*-BuMgBr (6 mmol) in ether (8 ml) and benzene (4 ml), there was added a solution of the title compound[4b] (172 mg, 0.51 mmol) at room temperature under a dry nitrogen atmosphere over a period of 5 min. The mixture was then stirred for 15 min. The usual work-up gave crystalline products, which were recrystallized from ligroin to give a mixture (154 mg, 89%) of 1,2:5,6-di-*O*-cyclohexylidene-α-D-allofuranose and the corresponding gluco isomer in a ratio of approximately 91:9, judging from the ^1H NMR

spectroscopy.

*1,2:5,6-Di-O-cyclohexylidene-3-deoxy-β-D-arabino-hexofuranose (**15**).* *From **13a***: A mixutre of **13a** (100 mg, 0.39 mmol), cyclohexanone (0.3 ml), and concd sulfuric acid (*ca.* 40 mg) in dry benzene (1.5 ml) was stirred at room temperature for 4 h. Calcium hydroxide was then added, and the undissolved material was filtered off and washed with methanol. The combined filtrate and washings were treated with sodium borohydride at 0—5 °C (bath temperature) to reduce the excess cyclohexanone. The mixture was then extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated to give a syrup, which was subsequently chromatographed on a silica-gel column with hexane–ether (9:1) to afford **15** (80 mg, 63%) as a syrup: $[\alpha]_D^{24}$ +6.1° (*c* 1.4, $CHCl_3$). IR (neat): no OH absorption. MS: *m/e* 324 (M^+). ^1H NMR ($CDCl_3$): δ 1.2—1.9 (20H, m, CH_2 of the cyclohexylidene groups), 2.0—2.5 (2H, m, H-3a and H-3b), 3.7—4.5 (4H, m), 4.72 (1H, m), 5.75 (1H, d, $J_{1,2}$=4.0 Hz, H-1).

Found: C, 66.58; H, 8.59%. Calcd for $C_{18}H_{28}O_5$: C, 66.64; H, 8.70%.

*From **17***: A mixture of **17**[13] (500 mg, 1.9 mmol) and Dowex 50W-X8 (H^+ form, 4 ml) in dioxane (10 ml) and water (4 ml) was stirred at room temperature for 23 h. The resin was removed by filtration through a Celite pad, and washed successively with dioxane and water. The combined filtrate and washings were concentrated. The residue was chromatographed on a silica-gel column with chloroform–methanol (9:2) to give a syrupy product (350 mg). A stirred mixture of this product (100 mg), cyclohexanone (0.35 ml), and concd sulfuric acid (*ca.* 80 mg) was heated at 65—70 °C (bath temperature) for 30 min. After cooling, calcium hydroxide was added, and the undissolved material was removed by filtration and washed with methanol (6 ml). The combined filtrate and washings were cooled (0—5 °C) and treated with sodium borohydride (230 mg) for 5 min to reduce the excess of cyclohexanone. The mixture was then diluted with ether. The solution was washed with water, dried ($MgSO_4$), and concentrated to give syrup, which was subsequently chromatographed on a silica-gel column with hexane–ether (9:1), thus affording **15** (74 mg, 41% from **17**). An analytically pure sample was obtained by distillation: bp 172—175 °C (bath temperature)/1 mmHg. This product was identical in all respects (IR, ^1H NMR, and the specific rotation) with a specimen prepared from **13a**.

*1,2:5,6-Di-O-cyclohexylidene-3-deoxy-α-D-ribo-hexofuranose (**16**).* *From **14a***: A mixture of **14a** (63 mg, 0.24 mmol), cyclohexanone (0.3 ml), and concd sulfuric acid (*ca.* 40 mg) in dry benzene (1.5 ml) was stirred at room temperature for 1.5 h and then treated in a manner similar to that described for the synthesis of **15** from **13a**, thus giving **16** (75 mg, 95%) as a syrup: $[\alpha]_D^{26}$ +1.4° (*c* 1.2, $CHCl_3$). IR (neat): no OH absorption. MS: *m/e* 324 (M^+). ^1H NMR ($CDCl_3$): δ 1.1—2.0 (20H, m, CH_2 of the cyclohexylidene groups), 2.0—2.4 (2H, m, H-3a and H-3b), 3.6—4.3 (4H, m), 4.72 (1H, m) 5.80 (1H, d, $J_{1,2}$=3.7 Hz, H-1).

Found: C, 66.64; H, 8.67%. Calcd for $C_{18}H_{28}O_5$: C, 66.64; H, 8.70%.

*From **18a***: The sugar derivative (**18**,[14] 500 mg, 2 mmol) was treated with Dowex 50W-X8 (H^+ form, 4 ml) at room temperature for 20 h in a manner similar to that described for the synthesis of **15** from **17** to yield a syrupy product (300 mg) after chromatography. This product (100 mg) was treated with cyclohexanone (0.35 ml) in dry benzene (1.5 ml) in the persence of concd sulfuric acid at 70 °C (bath temperature) for 5 min. Subsequent reduction with sodium borohydride, followed by column chromatography, gave analyticaly pure **16** (104 mg, 49% from **18**). The physical properties (IR, ^1H NMR, and the specific rotation) of this product were identical with those of a specimen prepared from **14a**.

*The Dimer (**19**).* To a stirred solution of **3a** (352 mg, 1 mmol) in a mixture of ether (10 ml) and benzene (10 ml) we added, drop by drop, a solution of *t*-BuMgBr (6 mmol) in a mixture of ether (10 ml) and benzene (5 ml) at room temperature under a dry nitrogen atmosphere over a period of 1 h; the mixture was then stirred for another 1 h. After cooling, cold aqueous ammonium chloride was added and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated. The residue was chromatographed on a silica-gel column with hexane–ether (6:4) to give **19** (143 mg, 56%) as crystals. An analytically pure sample was obtained by recrystallization from hexane–benzene: mp 151—153 °C; $[\alpha]_D^{20}$ −49.6° (*c* 0.8, $CHCl_3$). IR (KBr): 3480 (OH), 1773 (C=O) cm^{-1}. MS: *m/e* 512 (M^+). ^1H NMR ($CDCl_3$): δ 1.1—1.9 (20H, m, CH_2 of the cyclohexylidene groups), 1.90 (1H, m, H-3a), 2.53 (1H, m, H-3b), 2.65 (1H, d, $J_{3',4'}$=3.0 Hz, H-3′), 2.83 (1H, br s, OH), 3.41 and 3.43 (each 3H, s, OCH_3), 3.6—4.3 (7H, m), 4.3—4.6 (1H, m, H-4′), 4.68 and 5.31 (each 1H, s, H-1 and H-1′).

Found: C, 61.08; H, 7.71%. Calcd for $C_{26}H_{40}O_5$: C, 60.92; H, 7.87%.

*The Dimer (**20**).* *From **3a***: To a refluxing suspension of **3a** (1.06 mg, 3 mmol) in ether (25 ml) we added, drop by drop, a solution of MeMgI (12 mmol) in ether (20 ml) under a dry nitrogen atmosphere over a period of 1 h. The mixture was further refluxed for another 10 min and then treated with aqueous ammonium chloride and extracted with chloroform. The extract was washed with water, dried ($MgSO_4$), and concentrated. The resulting crystalline products were triturated with a small amount of hexane. The undissolved crystals were collected by filtration, washed with cold hexane, and dried.

The hexane-insoluble crystals were recrystallized from benzene to give **20** (350 mg. 44%) as crystals. An analytically pure sample was obtained by silica-gel column chromatography with chloroform–ether (9:1): mp 155—156 °C; $[\alpha]_D^{25}$ −83.2° (*c* 1, $CHCl_3$). IR (KBr): 3460 (OH) cm^{-1}. MS: *m/e* 528 (M^+). ^1H NMR ($CDCl_3$): δ 1.2—1.9 (20H, m, CH_2 of the cyclohexylidene groups), 1.36 (3H, s, C-CH_3), 1.76 (1H, q, $J_{3a,3b}$=12.0 Hz, $J_{3a,4}$=7.8 Hz, H-3a), 2.22 (1H, d, $J_{3a',4'}$=4.0 Hz, H-3a′), 2.92 (1H, q, $J_{3a,3b}$=12 Hz, $J_{3b,4}$=6.4 Hz, H-3b), 3.30 and 3.44 (each 3H, s, OCH_3), 3.8—4.5 (8H, m), 4.58 and 5.10 (each 1H, s, H-1 and H-1′).

Found: C, 61.53; H, 8.19%. Calcd for $C_{27}H_{44}O_{10}$: C, 61.34; H, 8.39%.

The mother liquor, from which **20** had been isolated, was concentrated, and the residue was chromatographed on a silica-gel column with chloroform–ether (9:1), thus giving **19** (26 mg, 3%).

The hexane-soluble material was chromatographed on a silica-gel column with hexane–ether (4:6) to afford **6a** (240 mg, 29%).

*From **19***. The dimer (**19**, 50 mg, 0.098 mmol) was added to a stirred solution of MeMgI (1 mmol) in ether (4 ml) at room temperature under a dry nitrogen atmosphere, after which the mixture was stirred for 30 min. After cooling, cold aqueous ammonium chloride was added, and the mixture was extracted with chloroform. The extract was washed with water, dried ($MgSO_4$), and concentrated. The residue was chromatographed on a silica-gel column with chloroform–methanol (99.5:0.5) to give **20** (45 mg, 87%). The

IR spectrum of this material was completely identical with that of a sample prepared from **3a**.

We wish to thank Dr. Haruo Homma and his staff for the elemental analyses, Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for measuring the NMR spectra, and Mr. Yasuaki Ezumi and Miss Kyoko Sugita for their measurment of the mass spectra. We are also grateful to Drs. Hiroyoshi Kuzuhara and Hiroshi Ohrui for their valuable discussions.

The Use of Grignard Reagents in the Synthesis of Carbohydrates. II.[1] The Cleavage of Acetal Protecting Groups in Sugar Derivatives

Masajiro KAWANA* and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

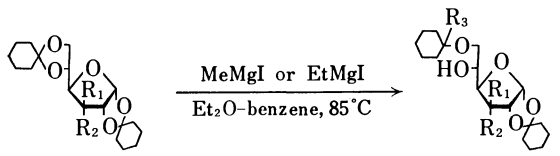
(Received July 2, 1979)

The selective reaction of acetal protecting groups in sugars with Grignard reagents is described. The treatment of 1,2:5,6-di-*O*-cyclohexylidene-α-D-glucofuranose (**1**) with methylmagnesium iodide in benzene–ether at about 85 °C gave 1,2-*O*-cyclohexylidene-6-*O*-(1-methylcyclohexyl)-α-D-glucofuranose. When isopropylmagnesium iodide or *t*-butylmagnesium bromide was used instead of methylmagnesium iodide, **1** gave 1,2-*O*-cyclohexylidene-6-*O*-(cyclohex-1-enyl)-α-D-glucofuranose and the corresponding 6-*O*-cyclohexyl derivative. The selective cleavage of the acetal protecting groups in some other sugars with the Grignard reagents is also described.

It is considered that acetals are generally stable under Grignard reaction conditions. However, when benzene was used as a solvent, the Grignard reagent formed a complex with the acetal, resulting in the cleavage of the acetal carbon–oxygen bond.[2] For example, the treatment of 1,4-dioxaspiro[4.5]decane (cyclohexanone ethylene acetal) with methylmagnesium iodide (MeMgI) in a benzene solution at 75 °C gave 2-(1-methylcyclohexyloxy)ethanol in a 91% yield.[2a] In the course of our work on the synthesis of sugar derivatives with Grignard reagents, we found that the acetal protecting groups in the sugar derivatives were also cleaved by these reagents to be transformed into *O*-alkyl or -alkenyl protecting groups. Independently, Fischer and Horton[3] have found a similar phenomenon in the carbohydrate field. They treated 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose with phenylmagnesium bromide under usual Grignard reaction conditions to obtain two normal Grignard adducts, along with a small amout of the 5,6-*O*-isopropylidene ring-opening product. In this paper we wish to describe our results concerning the cleavage of cyclohexylidene and isopropylidene groups in the sugars with several kinds of Grignard reagents.

When a mixture of 1,2:5,6-di-*O*-cyclohexylidene-α-D-glucofuranose[4] (**1**) and 4 molar equivalent of MeMgI in benzene–ether was heated under reflux at about 85 °C (Method A, Table 1) for 20 h, the 5,6-*O*-cyclohexylidene group of **1** was selectively cleaved and the methyl group of the Grignard reagent was introduced into the cyclohexyl moiety to form 1,2-*O*-cyclohexylidene-6-*O*-(1-methylcyclohexyl)-α-D-glucofuranose (**3**) in a 58% yield (Fig. 1); under these reaction conditions, the ether had very gradually been evaporated through a refluxing condenser. Its reaction time was shortened to about 1 h when the reaction mixture in a flask without a refluxing condenser was heated at the same temperature and the ether was allowed to evaporate (Method B).

The structural assignment of **3** was done on the basis of its elemental analysis and spectral properties (Tables 2 and 3). The ^{1}H NMR spectrum of **3** in dimethyl-d_6 sulfoxide showed a singlet at δ 1.04 due to the methyl protons and two doublets at δ 4.50 and 5.07 due to two secondary hydroxyl protons. The signals due to the methylene protons at C-6 for **3** shifted by *ca.* 0.3 ppm to a higher field than those for **1**. This shift was diagnostic for the *O*-alkylation at C-6 of the aldohexofuranoses prepared in the present work. On the other hand, the chemical shifts and coupling constants of the anomeric and C-2 protons of **3** were



1 : R_1=OH; R_2=H

a) Anhydrous solvents were used. b) A: A reaction mixture in a flask equipped with a condenser was refluxed at 80—85 °C for the given reaction time. B: A reaction mixture was heated at the same temperature without a refluxing condenser to remove the ether by distillation. c) Crude products were purified by chromatography on a silica-gel column with the given solvent system. d) This product was not isolated, acetylated to **7** (see Experimental).

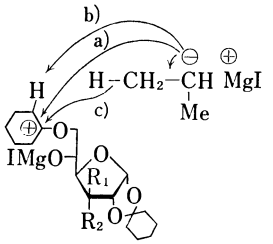
almost the same as those for **1**, thus indicating that the 1,2-*O*-cyclohexylidene moiety of **1** was unchanged in this product. These observations were consistent with the proposed structure for **3**.

The reaction of **1** with ethylmagnesium iodide similarly gave a 1-ethylcyclohexyl derivative (**4**). Using isopropylmagnesium iodide (*i*-PrMgI), however, we obtained 6-*O*-cyclohexenyl and -cyclohexyl[5] derivatives (**6** and **9**) in 60 and 11% yields respectively, along with a small amount of a 6-*O*-(1-isopropylcyclohexyl) derivative (**12**).

The compound (**6**), with the enol group, could not be purified because of its instability at room temperature. When *t*-butylmagnesium bromide (*t*-BuMgBr) was used in this reaction, **6** was also produced; it was later acetylated to give the corresponding diacetyl derivative (**7**) in an 87% overall yield. The ^1H NMR spectrum of **7** showed a multiplet at δ 4.60 due to a vinyl proton at C-2′. On catalytic hydrogenation, **7** was converted into 3,5-di-*O*-acetyl-6-*O*-cyclohexyl-1,2-*O*-cyclohexylidene-α-D-glucofuranose (**10**), which was identical with the specimen prepared from **9** by acetylation.

Similarly, 1,2:5,6-di-*O*-cyclohexylidene-α-D-allofuranose[6] (**2**) reacted with MeMgI to yield a 6-*O*-(1-methylcyclohexyl) derivative (**5**). When **2** was treated with *i*-PrMgI, a 6-*O*-cyclohexenyl derivative (**8**) was obtained in a good yield as crystals, which could be purified by recrystallization.

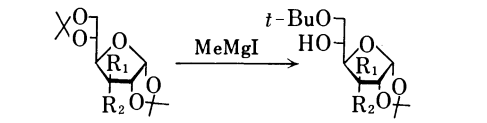
The formation of 6-*O*-alkyl and -alkenyl derivatives can be explained by means of a postulated intermediacy (**A**), which involves a cyclohexyl cation[2b] formed



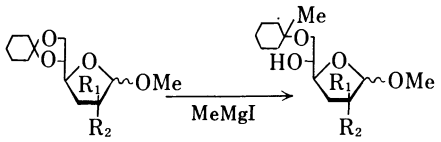
A

by the ring-opening of the 5,6-*O*-cyclohexylidene group. The attack of the alkyl anion of the Grignard reagent on the center of this cation (Path a) gave the 1-alkylcyclohexyl derivatives (**3**—**5** and **12**). When a sterically bulky reagent, such as *i*-PrMgI or *t*-BuMgBr, was used in this reaction, the direct attack of the bulky alkyl group of this reagent on the center of the cyclohexyl cation was largely prevented, so that the abstraction of a proton α to the cation (Path b) and the reduction of this cation (Path c) by the reagent preferably occurred to afford the cyclohexenyl compounds (**6** and **8**) and the cyclohexyl compounds (**9** and **11**) respectively.

The isopropylidene groups also reacted with the Grignard reagents. Thus, the treatment of 1,2:5,6-



13 : R_1=OH; R_2=H 15 : R_1=OH; R_2=H
14 : R_1=H; R_2=OH 16 : R_1=H; R_2=OH



17 : R_1=OH; R_2=Me; (β) 19 : R_1=OH; R_2=Me; (β)
18 : R_1=Me; R_2=OH; (α) 20 : R_1=Me; R_2=OH; (α)

Fig. 2.

di-*O*-isopropylidene-α-D-gluco-[7] and -allofuranose[8] (**13** and **14**) with MeMgI gave the corresponding 6-*O*-*t*-butyl derivatives (**15** and **16** respectively) (Fig. 2). Here again, the 1,2-*O*-isopropylidene group remained intact, but the one at the 5,6-position was selectively cleaved, while the secondary hydroxyl group at C-5 was freed. This selectivity was the same as that observed by Fischer and Horton.[3]

Branched-chain deoxy sugars, [1a,9] methyl 5,6-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-β-D-*arabino*-hexofuranoside (**17**), and the corresponding α-D-*ribo* isomer (**18**) yielded, upon treatment with MeMgI, the corresponding 6-*O*-(1-methylcyclohexyl) derivatives, **19** and **20** respectively.

The same reaction was applied to an acetal protecting aldopentose; 1,2:3,5-di-*O*-cyclohexylidene-α-D-xylofuranose[10] (**21**) reacted with MeMgI to give 1,2-*O*-cyclohexylidene-3-*O*-(1-methylcyclohexyl)-α-D-xylofuranose (**22**) in a 58% yield (Fig. 3). The cleavage of the carbon–oxygen bond between O-5 and the cyclohexyl carbon in **21** was confirmed by means of ^{1}H NMR spectroscopy. On the treatment of **21** with *i*-PrMgI, 3-*O*-(cyclohex-1-enyl)-1,2-*O*-cyclohexylidene-α-D-xylofuranose (**23a**) was obtained as the main product (52%), but with *t*-BuMgBr the corresponding 3-*O*-cyclohexyl derivative (**24a**) was the major one (71%). The former product was characterized as its acetate (**23b**); thus, it was hydrogenated to give 5-*O*-acetyl-3-*O*-cyclohexyl-1,2-*O*-cyclohexylidene-α-D-xylofuranose (**24b**), which was identical with the sample prepared by the acetylation of **24a**.

In all cases of the aldohexofuranoses tested in the present experiments, their 5,6-*O*-acetal protecting groups were selectively cleaved and the secondary hydroxyl groups at C-5 were selectively freed. The latter selectivity is, however, different from that observed for the previously reported experiments with a steroidal derivative (**25**), in which the acetal ring was opened to form the primary hydroxyl group.[2b] It has been assumed that, in this case, the Grignard reagent would predominantly attack the sterically less hindered primary hydroxyl oxygen of the acetal ring. This is the case for the reaction of the pentofuranose (**21**). One possible explanation for the observed selectivity in the hexofuranose is as follows.

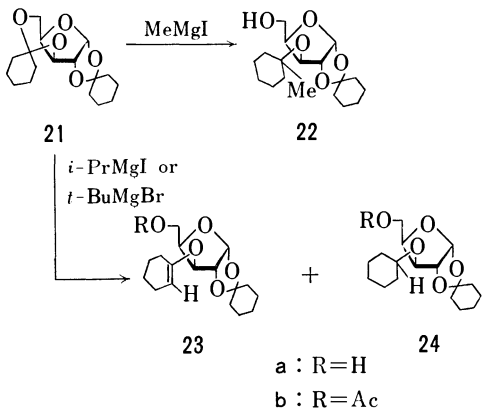


Fig. 3.

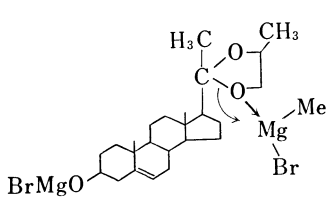
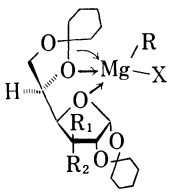
The magnesium atom of the Grignard reagent would be coordinated with both oxygen atoms of C-5 and the furanose ring (see **26**);[11] these oxygens were, therefore, activated to cleave the bond between O-5 and the cyclohexyl carbon in this case.[12] The same chelation as in **26** would also be possible for **21** to explain the observed selectivity.



25



26

Experimental

The melting points are uncorrected. The optical rotations were determined with a Perkin-Elmer 241 MC polarimeter. The IR spectra were recorded on a Shimadzu IR-27 instrument. The mass spectra were obtained with a Japan Optics Lab. Model JMS-OlSG instrument. The ^{1}H NMR spectra were recorded on a Varian HA-100D apparatus, with tetramethylsilane as the internal standerd. Merck silica gel GF_{254} was used for the TLC, and the compounds were detected by heating after spraying them with a methanol–sulfuric acid–*p*-methoxylbenzaldehyde (85:10:5, v/v) mixture. Merck silica gel 60 (0.063—0.29 mm) was used for column chromatography. The elemental analyses were performed by this Institute.

The results of the elemental analysis and the physical properties of the compounds obtained are summarized in Tables 2 and 3.

General Method for the Reaction of the Acetal Protecting Sugars with the Grignard Reagents. Some of the reaction conditions are described in Table 1. A crystalline sugar derivative or a solution of a syrupy sugar derivative in a small amount of dry benzene was added to a solution of the Grignard reagent in dry benzene–ether in a flask equipped with a condenser (Method A) or without a condenser (Method B) at room temperature under a dry nitrogen atmosphere. The mixture was then heated at 80—85 °C (bath temperature) for a given period; in the case of Method B, the ether was distilled out. After cooling, aqueous ammonium chloride was added, and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and con-

centrated. The crude product was purified by silica-gel column chromatography using a given solvent system.

3,5-Di-O-acetyl-6-O-(cyclohex-1-enyl)-1,2-O-cyclohexylidene-α-D-glucofuranose (7). A powdered sugar derivative (**1**,[4] 340 mg, 1 mmol) was stirred into a solution of MeMgI (8 mmol) in benzene (15 ml)–ether (10 ml) under a dry nitrogen atmosphere, after which the mixture was heated at 80—85 °C (bath temperature) for 35 min to remove the ether. After the mixture had been cooled, dry pyridine (0.2 ml) was added, followed by the addition of aqueous ammonium chloride. The mixture was then extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated below 35 °C *in vacuo*. The water was removed by co-evaporation with benzene below 35 °C *in vacuo*. The residue was then taken up in dry pyridine (5 ml) and cooled to about 5 °C. To this cold solution, we added acetic anhydride (1.5 ml), after which the mixture was stirred at room temperature for 6 h. After the usual work-up, the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated. The pyridine was removed by co-evaporation with xylene. The residue was chromatographed on a silica-gel column with benzene–ethyl acetate (9:1) to give **7** (370 mg, 87%).

3,5-Di-O-acetyl-6-O-cyclohexyl-1,2-O-cyclohexylidene-α-D-glucofuranose (10). *From* ***9***: Acetic anhydride (0.3 ml) was added to a cold (0—5 °C) solution of **9** (95 mg, 0.28 mmol) in dry pyridine (1 ml), and the mixture was stirred at room temperature overnight. The usual work-up gave a crude product, which was chromatographed on a silica-gel column with benzene–ethyl acetate (9:1) to give **10** (112 mg, 95%) as crystals.

From ***7***: The sugar derivative (**7**, 130 mg, 0.3 mmol) was hydrogenated in methanol (20 ml) in the presence of 10% Pd on charcoal (80 mg) with a Parr apparatus at 2.8 kg/cm^2 at room temperature for 7 h. The catalyst was removed by filtration through a Celite pad and washed with methanol. The combined filtrate and washings were concentrated below 35 °C. The residue was chromatographed on a silica-gel column with benzene–ethyl acetate (95:5) to give **10** (80 mg, 61%) as crystals. The physical properties (mp, IR, MS,

(Received July 2, 1979)

The sensitized photooxidation of 7-methoxycycloheptatriene (7-methoxytropilidene) afforded [4+2] cycloadduct (**2**), tropone, benzaldehyde and their 2-methoxy derivatives. Thermal isomerization of **2** followed by the treatment with alumina yielded 4-methoxytropone. The photooxidation of 1-methoxytropilidene gave 4-hydroxytropone and *o*-methoxybenzaldehyde, and the photooxidation of 3-methoxytropilidene followed by the treatment with triethylamine afforded 3-methoxytropone, tropone, and *o*-methoxybenzaldehyde. Characterization of the products and the mechanisms of the reactions are discussed.

Recently, we have reported that the oxidation of cycloheptatriene (tropilidene) by photochemically generated singlet oxygen afforded [4+2] cycloadduct, and other products derived from [6+2] cycloadduct, and that tropone can be efficiently obtained *via* the photooxidation of tropilidene.[3]

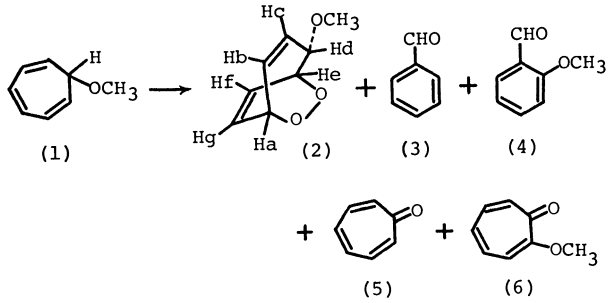
Mori and Takeshita have also reported on the photooxidation of tropilidene, methoxytropilidene, and bitropyl sensitized by α-dicarbonyl compounds to isolate [4+2] and [6+2] cycloadducts.[4]

More recently, Adam and Balci have isolated [6+2] cycloadduct and two kinds of [4+2] cycloadducts derived from norcaradiene and cycloheptatirene by the separation of photooxidation product of tropilidene at low temperature.[5]

We have studied the photooxidation of three kinds of methoxytropilidenes to isolate and characterize the oxidation products and to derive to hydroxytropones, especially to 3- and 4-hydroxytropones (β- and γ-tropolones, respectively) which have been prepared with some difficulty. The results are reported in this paper.

Results and Discussion

Photooxidation of 7-Methoxytropilidene. The photooxidation of 7-methoxytropilidene (**1**) was performed in acetone with visible light (60 W×3) at room temperature in the presence of hematoporphyrin as sensitizer, and the products were separated by silica gel chromatography to afford five products; [4+2] cycloadduct (**2**, 40—50%), benzaldehyde (**3**, 10%), *o*-methoxybenzaldehyde (**4**, 5%), tropone (**5**, trace), and 2-methoxytropone (**6**, trace). The compounds (**3**—**6**)



were characterized by direct comparison of their spectroscopic data with those of the authentic samples. The compound (**2**) was obtained as colorless oil, shows a parent ion peak at 154 in the mass spectrum, and strong IR absorption bands (neat) at 1085, 970, and 750 cm^{-1}. ^{1}H-NMR spectrum of **2** in $CDCl_3$ is shown in Fig. 1 and the each signal and coupling constant can be assigned with the help of double resonance

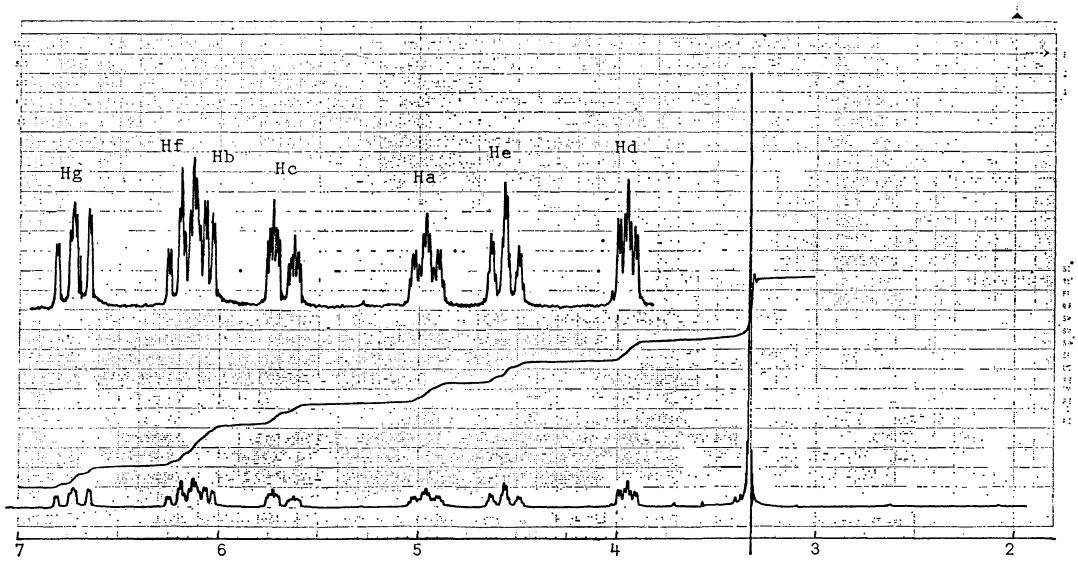


Fig. 1. ^{1}H-NMR spectrum of 2 in $CDCl_3$ (100 MHz).

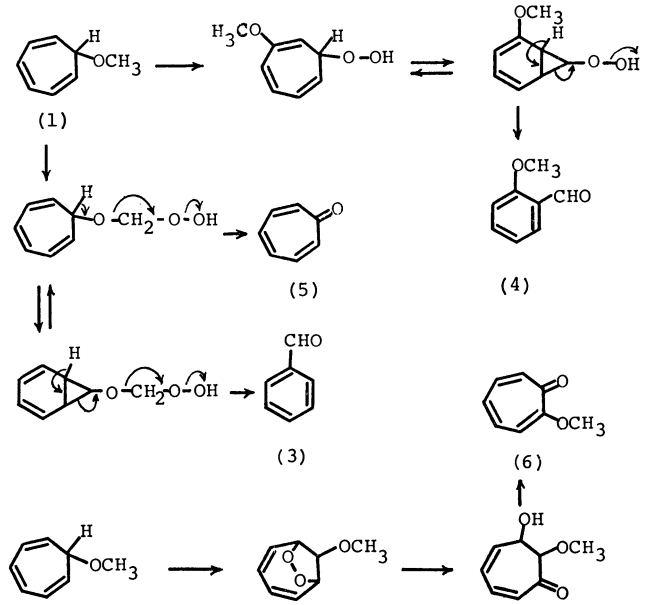
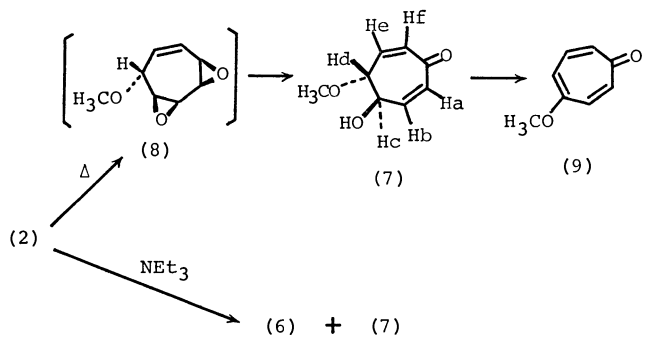
experiments, and the parameters are shown in Table 1. From these data the structure of the compound (**2**) was determined as [4+2] cycloadduct, 4-methoxy-6,7-dioxabicyclo[3.2.2]nona-2,8-diene, shown in scheme including a stereochemistry of methoxyl group.

We tentatively proposed the mechanisms, involving peroxides and [6+2] cycloadduct as intermediates, of the formation of the products (**3**—**6**) as follows.

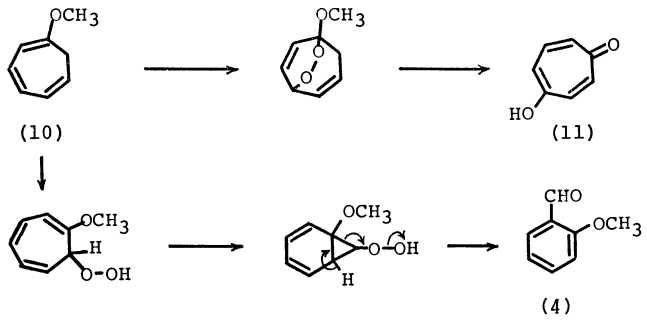


The adduct (**2**) was thermally isomerized in xylene to give 4-hydroxy-5-methoxy-2,6-cycloheptadien-1-one (**7**) in 60% yield, whose structure including a stereochemistry was determined by ^{1}H-NMR spectrum data shown in Table 1. The compound (**7**) is considered to be formed *via* diepoxide (**8**) which could not be isolated in this case.[6] The treatment of **7** with alumina afforded 4-methoxytropone (**9**)[7,8] in 58% yield. Furthermore, the treatment of **2** with triethylamine afforded **7** (34%) and 2-methoxytropone (**6**) (34%).

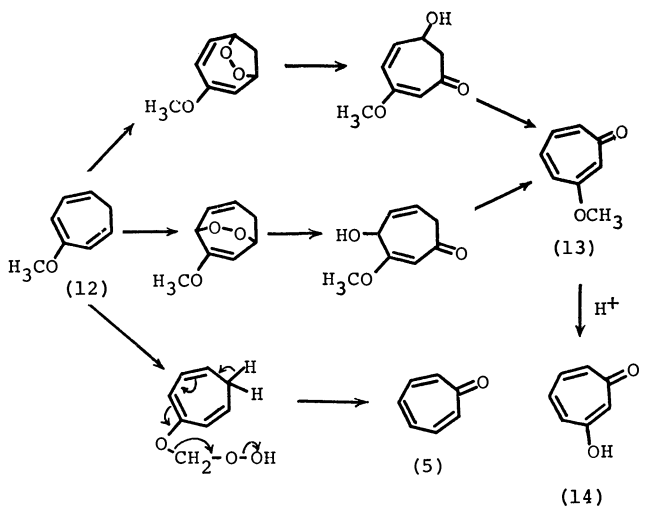
From these results, it was found that 4-methoxytropone (**9**) can be effectively synthesized in moderate yield starting from 7-methoxytropilidene *via* photooxidation.



Photooxidation of 1-Methoxytropilidene. The photooxidation of 1-methoxytropilidene (**10**)[9] was performed in a similar manner to 7-methoxytropilidene in acetone in the presence of hematoporphyrin. The removal of the solvent just after the oxidation was completed caused explosion, and no clear product was obtained. However, working up after the solution of the oxidation was allowed to stand at room temperature for a week, gave two products; 4-hydroxytropone (γ-tropolone) (**11**)[7,8] and *o*-methoxybenzaldehyde (**4**) in 34% and 12% yields, respectively by chromatographic separation, and any *endo*-peroxides could not be isolated. The mechanisms of the formation of these compounds were tentatively proposed as follows.



Photooxidation of 3-Methoxytropilidene. The photooxidation of 3-methoxytropilidene[9] in methanol in the presence of Methylene Blue afforded only *o*-methoxybenzaldehyde after the direct separation using silica gel chromatography. However, the treatment of the crude photooxidation products with triethylamine afforded 3-methoxytropone (**13**),[8,10] tropone (**5**), and *o*-methoxybenzaldehyde in 16%, 24%, and 5% yield, respectively. 3-Methoxytropone (**13**) can be easily hydrolyzed by acids to give 3-hydroxytropone (β-tropolone) (**14**).[10a] The mechanism of the formation of the tropones was tentatively considered as follows which involves the formation of [4+2] or [6+2] cycloadduct and peroxide at methoxyl carbon as intermediates.



Experimental

The mp values are uncorrected. The IR spectra were recorded with Hitachi EPI 510 and Hitachi 215 grating spectrophotometer. The mass spectra were obtained with Hitachi RMU 60 mass spectrometer. The NMR spectra were recorded on Varian HA-100, A-60, and Hitachi R-20 spectrometers.

Sensitized Photooxidation of 7-Methoxytropilidene. A solution of 7-methoxytropilidene (10.0 g, 0.082 mol) and hematoporphyrin (132 mg) in acetone (400 ml) was irradiated by visible light (60 W×3) for 6 days at below 30 °C by cooling with water while oxygen was slowly passed through the solution. The solvent was removed under reduced pressure, the residue was submitted to column chromatography on silica gel and eluted with chloroform. From the effluents, benzaldehyde (869 mg, 8.2 mmol, 10%), *o*-methoxybenzaldehyde (558 mg, 4.1 mmol, 5%), an adduct (**2**, 5.44 g, 34.3 mmol, 43.5%), tropone (trace), and 2-methoxytropone (trace) were obtained by the order of the effluents. **2**; Colorless oil, IR (neat) 1085, 970, 750 cm^{-1}; MS *m/e* 154 (M^+, 18), 122 (57), 94 (100), 84 (71), 81 (52), 68 (73), 66 (73); Found: C, 62.42; H, 6.46%. Calcd for $C_8H_{10}O_3$: C, 62.32; H, 6.54%.

Thermal Reaction of 2. A solution of **2** (600 mg, 3.9 mmol) in anhydrous xylene (30 ml) was refluxed under nitrogen atmosphere for 15 h. The solvent was removed under reduced pressure, the residue was submitted to column chromatography on silica gel and eluted with chloroform, and keto alcohol (**7**, 360 mg, 2.34 mmol, 60%) was obtained. **7**; Colorless oil, IR (neat) 3450, 1660, 1618 cm^{-1}; MS *m/e* 154 (M^+, 2.9), 122 (47.1), 109 (35.3), 95 (35.3), 94 (100). 2,4-Dinitrophenylhydrazone; reddish crystals, mp 156—157 °C, Found: C, 50.17; H, 4.14; N, 16.71%. Calcd for $C_{14}H_{14}O_6N_4$: C, 50.30; H, 4.22; N, 16.76%.

Treatment of 7 with Alumina. A solution of **7** (200 mg, 1.3 mmol) in chloroform was adsorbed on alumina column (10 g). After 2 h, the column was eluted with ethyl acetate to give 4-methoxytropone (102 mg, 0.75 mmol, 58%), colorless crystals, mp 28—29 °C, which was identified by direct comparison of spectroscopic data with those of the authentic sample.

Reaction of 2 with Triethylamine. A solution of **2** (429 mg, 3.2 mmol) in dichloromethane (30 ml) was refluxed for 25 h in the presence of triethylamine (5 drops). The solvent was removed under reduced pressure, a solution of the residue in chloroform was submitted to chromatography on silica gel and eluted with chloroform–methanol (2%). From the effluents, keto alcohol (**7**, 158 mg, 1.1 mmol, 34.4%) and 2-methoxytropone (138 mg, 1.1 mmol, 34.4%) were obtained.

Sensitized Photooxidation of 1-Methoxytropilidene. A solution of 1-methoxytropilidene (1.0 g, 8.2 mmol) and hematoporphyrin (30 mg) in acetone (100 ml) was photochemically oxidized for 2 days in a similar manner to 7-methoxytropilidene. After the oxidation, the solution was allowed to stand at room temperature for a week. The solvent was removed under reduced pressure and 4-hydroxytropone (**11**, 382 mg, 34.1%), mp 211 °C (dec) was obtained as crystalline substance. The residue was separated by chromatography on silica gel and *o*-methoxybenzaldehyde (137.5 mg, 12.3%) was obtained. 4-Hydroxytropone (**11**) was identified by direct comparison of the physical data with those of the authentic sample.

Photooxidation of 3-Methoxytropilidene. A solution of 3-methoxytropilidene (**12**, 1.0 g, 8.2 mmol) and Methylene Blue (50 mg) in methanol (100 ml) was photochemically oxidized for 2 days in a similar manner to 7-methoxytropilidene. The solvent was removed under reduced pressure. A solution of the residue in methanol (70 ml) was added triethylamine (1.5 ml) and allowed to stand at room temperature for 10 h. The solvent was removed under reduced pressure, the residue was submitted to chromatography on alumina and eluted with chloroform. From the effluents, *o*-methoxybenzaldehyde (55.8 mg, 5%), tropone (213 mg, 24%), and 3-methoxytropone (**13**, 210.5 mg, 16%), colorless oil, were obtained. 3-Methoxytropone (**13**) was identified by the comparison of the spectroscopic data with those of the authentic sample.

The Temperature Dependence of Carbon-13 Chemical Shifts of Retinal Isomers and Their Related Compounds

(Received April 25, 1979)

The temperature dependence of carbon-13 chemical shifts has been studied for retinal isomers, *N-all-trans*-retinylidenebutylamine(*all-trans*-NRB) and *N-all-trans*-retinylidenebutylammonium chloride(*all-trans*-NRB·HCl). The change in the chemical shift was discussed in terms of the temperature dependences of the polarizability and conformation of the polyene-chain. In 11-*cis*-retinal, the coplanarity between the two parts of polyene-chain separated by the cis bond increases with a lowering of the temperature. The equilibrium between 12-*s*-*cis* and 12-*s*-*trans* conformers in 11-*cis*-retinal was studied and it was shown the latter conformer is preferable at low temperatures. In *all-trans*-NRB and *all-trans*-NRB·HCl, the temperature dependences of the chemical shifts are similar to those in *all-trans*-retinal. The extents of the chemical shift changes are in the following order: NRB·HCl<NRB <retinal. This trend can be correlated with the order of the red shifts of the absorption spectra.

The carotenoid compound, 11-*cis*-retinal, acts as a photoreceptor in a visual system. The primary event in the visual process in vertebrate retinas is the photochemical isomerization of the bound 11-*cis*-retinal to the *all-trans* form (Fig. 1). Other succeeding transformations in the retina are known to occur in the dark.[1,2]

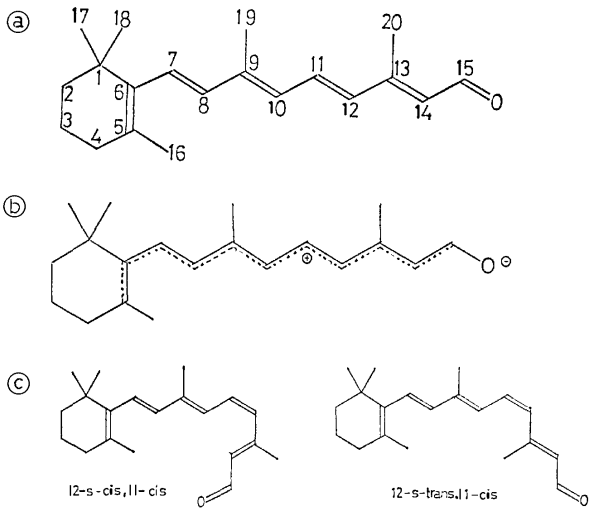

Fig. 1. a) Structural formula of *all-trans*-retinal.
b) Resonance structure of *all-trans*-retinal.
c) Structural formulas of 12-*s*-*cis* and 12-*s*-*trans* conformers in 11-*cis*-retinal.

The conformations of retinal isomers and related compounds have been studied by means of the UV spectra at lower temperatures because of the instability of the transient intermediates in the visual process at ambient temperatures. The absorption maxima of the retinal isomers and their Schiff bases reveal a red (bathochromic) shift upon the lowering of the temperature.[2-4]

The conjugated polyene-chain of 11-*cis*-retinal twists around the C12–C13 single bond as a result of the severe steric hindrance, while that of *all-trans*-retinal is planar. The 11-*cis*-retinal may exist as an equilibrium mixture of distorted 12-*s*-*cis* and 12-*s*-*trans* conformers as is shown in Fig. 1c; this indicates much larger absorption and intensity changes in the UV spectra than in the cases of the other retinal isomers for the same range of temperatures and solvent polarity.[3] Such a conformational equilibrium is a possible key to interpreting the temperature dependence of the spectroscopic parameter in the molecular level. We will study the temperature dependence of the carbon-13 NMR spectra of retinal and its related compounds. Both proton and carbon-13 NMR spectra of these compounds have been widely studied by many including the present authors.[5-10] Rowan *et al.*[7] have investigated the temperature dependence of the proton NMR spectrum of 11-*cis*-retinal; they concluded the 12-*s*-*trans* to be the preferred conformer in the 11-*cis* isomer in acetone at lower temperatures. Since the carbon-13 chemical shift is related to the electron density of the corresponding carbon atom, it makes possible a study of the charge delocalization in conjugated polyene carbons of the retinal Schiff base.[8,10]

In this investigation, the carbon-13 chemical shifts of retinal isomers and their Schiff bases were observed in the temperature range from −50 °C to +30 °C. The temperature dependences of the chemical shifts will be discussed in terms of the changes in the electronic structure. The degree of the delocalization of the positive charge (Fig. 1b) will be related with the conformational changes in the conjugated polyene-chain of 11-*cis*-retinal at lower temperatures. This relation will be used to explain the degree of the red shift of the absorption maximum in the absorption spectra of corresponding compounds at lower temperatures. It has been widely accepted that, in the rhodopsin, a protonated Schiff-base linkage exists between the retinal chromophore and the protein opsin *via* an ε-amino group of the lysin residue.[11] Therefore, the protonated Schiff base with *n*-butylamine was chosen as a pertinent model for the rhodopsin.

Experimental

All of the retinal compounds used were prepared by a procedure described elsewhere.[9]

The UV spectra were observed in methanol with a Beckman-25 spectrometer. The carbon-13 NMR spectra were measured in the dark, using a JNM JEOL PS-100 spectrometer equipped with a PFT-100 Fourier transform system at 25.15 MHz and in the temperature range of −50 °C—+30 °C. The 90°-pulse recycle times were chosen to be at least five times the longest spin-lattice relaxation time of the carbon atoms. The number of accumulations were chosen to be 128—1024. The concentrations of the retinal

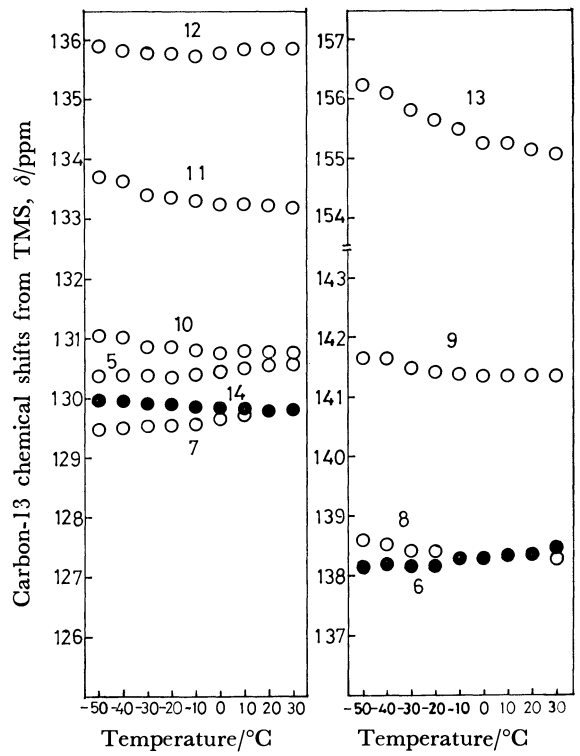

Fig. 2. Temperature dependence of chemical shifts for each of conjugated polyene-chain carbons of *all-trans*-retinal in acetone.

compounds were 0.3—0.5 mol dm^{-3} in a solution of acetone-d_6 and chloroform-*d*. The chemical shifts were expressed in ppm as downfield shifts from internal tetramethylsilane (TMS). The maximum experimental error of the chemical shift was within ±0.06 ppm.

Results

The carbon-13 NMR spectra have been assigned by the use of various techniques shown in previous papers.[6,9,10] Figure 2 shows the temperature dependence of the chemical shift for each of the conjugated polyene-chain carbons in *all-trans*-retinal in an acetone solution. Similar temperature dependences were also obtained for the same isomer in a chloroform solution and for the 11-*cis* isomer in acetone and chloroform solutions. The carbon atoms are numbered as is shown in Fig. 1a; the numbers indicated in Fig. 2 correspond to this numbering.

Tables 1 and 2 are tabulated the chemical shifts at room and lower temperatures and the differences, $\Delta\delta$, between the chemical shifts at these two temperatures for identical carbons. The plus and minus signs in $\Delta\delta$ indicate the downfield and upfield shifts respectively upon a lowering of the temperature. According to the UV analysis[3,4] and solvent theory,[12] the conformational change of the retinal isomer increases with an increase the polarity of the solvent. Therefore, acetone and chloroform were used in this work as representative polar and non polar solvents respectively.

From these two tables, a general trend was observed for downfield shifts to be observed with a lowering of the temperature for the conjugated polyene-chain carbons of both *all-trans*- and 11-*cis*-retinal. This trend

is clear in acetone, though it is rather ambiguous in chloroform. The β-ionone-ring carbons indicate a upfield shift with a lowering of the temperature in both solvents. The relatively large upfield shift of C2 is remarkable. Among conjugated polyene-chain carbons, the downfield shifts are remarkable for the odd-numbered carbons, while they are not so clear for the even-numbered carbons. The same experimen-

tal result, that the chemical-shift changes of polyene-chain carbons can be classified into two types according to whether the numbering on the carbon is even or odd, is also found in the chemical-shift changes on going from retinal isomers to their Schiff bases and from Schiff bases to protonated Schiff bases.[9,10]

Table 2 also shows the chemical-shift changes, $\Delta\delta$, of the conjugated polyene-chain carbons of *all-trans*-NRB and *all-trans*-NRB·HCl in chloroform. The chemical shift changes in the carbons of *all-trans*-NRB are generally smaller than those in the carbons of *all-trans*-retinal, while those of *all-trans*-NRB·HCl are smaller than those of *all-trans*-NRB.

Discussion

Origin of the Temperature Dependence of Chemical Shifts. Several contributions can be pointed out as the causes of the temperature dependences of chemical shifts. Firstly, the effect of the temperature-dependent polarizability of the solvent must be examined, since the changes in the carbon-13 chemical shifts of polyene carbons of retinal are connected with the changes in electron density.[8-10] Wyman[13] has reported that the dielectric constant and the polarizability of the solvent increase with a lowering of the temperature. An increase in the polarizability of the solvent induces an increase in that of the retinal carbonyl group.[14] As has been shown in previous papers,[9,10] the positive charge at the polyene-chain-end atom tends to be distributed onto the polyene-chain carbons(Fig. 1b); this delocalization of the positive charge results in the downfield shifts for these carbons. Thus, the downfield shifts(Table 1) of the odd-numbered polyene carbons in *all-trans*- and 11-*cis*-retinal with a lowering of the temperature may be attributed to the delocalization of the positive charge at the polyene-chain end resulting from an increase in the polarizability of the retinal carbonyl group. Such downfield shifts are especially clear in the C13 and C15. The large $\Delta\delta$'s of the C9 and C11 in 11-*cis*-retinal imply a larger delocalization of the positive charge compared with that of the same carbons in *all-trans*-retinal.

The overall decrease in the electron density of the polyene-chain can be explained in terms of the intramolecular polarizability, which produces an increase in the electron density in the β-ionone-ring carbons. These carbons show upfield shifts. Thus, at least a part of the origin of the chemical-shift changes, $\Delta\delta$'s, can be explained by the changes in polarizability. However we have to consider other factors besides polarizability, since the polyene carbons of 11-*cis*-retinal show very different $\Delta\delta$'s from those of *all-trans*-retinal, as is indicated in Fig. 3. The peculiarity of $\Delta\delta$ of 11-*cis*-retinal can be explained by the conformational changes of its conjugated polyene-chain.

The following two conformational changes can be induced by lowering the temperature. One is due to a decrease in the skewness in the conjugated polyene-chain, while the other is due to the rotation around the C12–C13 single bond.

In 11-*cis*-retinal, the steric hidrance between the C10-hydrogen and C20-methyl group is relieved by a skew geometry around the C12–C13 single bond at

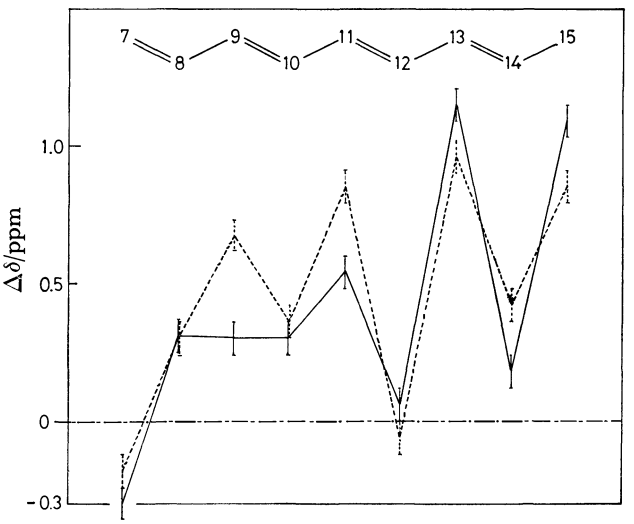

Fig. 3. The plot of the chemical-shift differences $\Delta\delta$ *vs.* carbon number of *all-trans*-retinal (—) and 11-*cis*-retinal (---) in acetone.

room temperature.[5,7] Patel[5] suggested that it is more difficult to distribute the positive charge in 11-*cis*-retinal than in *all-trans*-retinal, judging from the proton chemical-shift differences in the two retinal isomers at room temperature. In Table 1, the $\Delta\delta$'s in acetone of the C9 and C11 in 11-*cis*-retinal are +0.67 and +0.85 ppm respectively, while those in *all-trans*-retinal are +0.30 and +0.54 ppm. The $\Delta\delta$'s of the C15 and C13 in *all-trans*-retinal are about 1.1 ppm, while those in 11-*cis*-retinal are about 0.9 ppm. These trends indicate an increase in the degree of the delocalization of the positive charge on C15 upon a lowering of the temperature. The decrease in the skewness produces an increase in planarity(an increase in the resonance structure) of the 11-*cis* polyene-chain and results in an increase in the delocalization of the positive charge. Therefore, the larger downfield shitfs of C9 and C11 of 11-*cis*-retinal as compared with those of *all-trans*-retinal may be due to a decrease in the skewness of the conjugated polyene-chain upon a lowering of the temperature. This explanation is consistent with that of UV analysis at lower temperatures.[3,15]

The other origin of chemical-shift change is the change in equilibrium between the 12-*s-cis* and 12-*s-trans* conformers of 11-*cis*-retinal. It has been reported that the relative stabilities of the two conformers in 11-*cis*-retinal change with temperature[7] and the kind of solvent.[12] The chemical shifts of sterically perturbed carbon atoms are generally found at higher magnetic fields than those of similar carbons which are not spatially crowded. This steric perturbation of the carbon-13 chemical shifts is known as the γ-effect.[16] The chemical shifts of C10, and C20 may be affected by the γ-effect resulting from the steric hindrance between the C10-hydrogen and C20-methyl or C14-hydrogen, depending on the equilibrium between the two conformers. As is shown in Table 1, the $\Delta\delta$ of C10 in 11-*cis*-retinal in acetone is nearly equal to that of *all-trans*-retinal. The 14 and 20 carbons of 11-*cis*-retinal show a downfield shift of 0.42 ppm and an upfield shift of 0.18 ppm respectively, while those of

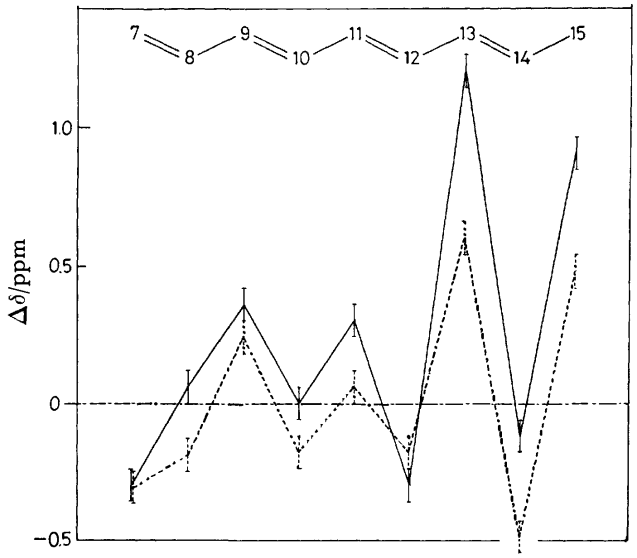

Fig. 4. The plot of the chemical shift differences $\Delta\delta$ *vs.* carbon number of *all-trans*-retinal(—) and *all-trans*-NRB(---) in chloroform.

all-trans-retinal remain in nearly the same positions. These results reveal that, in 11-*cis*-retinal, the 12-*s-trans* conformer is preferred over the 12-*s-cis* one in acetone at low temperatures. These results are consistent with the proton-NMR analysis,[7] which indicates a higher population of the 12-*s-trans* conformer in acetone at −52 °C. At present, however, we can not evaluate the population of each conformer.

In *all-trans*-NRB, the smaller downfield shifts for C13 and C15 as compared with those of *all-trans*-retinal might be due to a decrease in the delocalization of the positive-charge density induced by a decrease in the electronegativity of the terminal group,[9] because $\Delta\delta$'s of the β-ionone ring carbons are approximately equal to those of *all-trans*-retinal(Table 2 and Fig. 4).

Correlation between the UV Red Shift and the Carbon-13 Chemical Shift. It has previously been reported that the blue shift with a magnitude of about 20 nm on going from *all-trans*-retinal to *all-trans*-NRB is due mainly to the delocalization of the π-electron density,[9] and that the large red shift (about 80 nm) by the N-protonation on NRB is due mainly to the collapse of the bond alternation[9] and the delocalization of the positive charge.[9,17,18] Schaffer *et al.*[4] have indicated that 11-*cis*-retinal shows a larger red shift than other retinal isomers and that the magnitudes of the red shifts of retinal isomers are somewhat larger than those of the corresponding Schiff bases on going from room to lower temperatures. These phenomena are explained by the carbon-13 NMR analysis as follows.

The red shifts in retinal compounds at lower temperatures may be due to an increase in the degree of delocalization of the positive charge as a result of an increase in the degree of polarizability. The difference in the magnitude of the red shift in *all-trans*-retinal and 11-*cis*-retinal can be related to the magnitude of the chemical-shift changes of C9 and C11 resulting from the delocalization of the positive charge induced by an increase in planarity in the conjugated polyene-chain of 11-*cis*-retinal upon a lowering of the temperature.

The small chemical-shift changes of *all-trans*-NRB as compared with those of *all-trans*-retinal explain why *all-trans*-retinal shows a larger red shift than does *all-trans*-NRB on going from room to lower temperatures. For *all-trans*-NRB·HCl, the smaller red shift[4] corresponds to the smaller chemical-shift changes. Thus, the chemical-shift changes are correlated with the UV red shift.

From the present work, it is clear that the temperature dependences of the carbon-13 chemical shifts of the retinal isomers and related compounds are explainable in terms of the changes in the polarizability and conformation of the polyene chain, although this explanation is more or less qualitative. To give a quantitative explanation of the experimental results, a theoretical investigation by means of CNDO calculation is now in progress and will be reported elsewhere.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education(No. 311809).

12,13-Epoxy-*C*-nor-*D*-homosteroids. VI.[1] Reaction of 17-Oxygenated 12,13-Epoxyetiojervanes with Boron Trifluoride Etherate[2]

Akio MURAI, Noriaki IWASA, Masami TAKEDA, and Tadashi MASAMUNE*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 11, 1979)

17-Oxygenated 12,13-epoxyetiojerv-5-en-3-one 3,3-ethylene acetals (**1A—10A**) were treated with boron trifluoride etherate in benzene at room temperature. The epoxy ring cleavage reactions proceeded slowly with increase of electronegativity of the 17-substituents without and/or with deacetalization to give a variety of compounds including rearranged products (**23A** and **23B**). The results summarized in Table 1 indicated that the reactions produced compounds formed by initial cleavage at less electronegative C-12 rather than at C-13 except several compounds (**11A**, **20A**, **20B**, and **34A**). Formation of the latter compounds was attributed by hydride shift or neighboring participation of the 17-acetoxyl groups.

In a previous paper[3] we reported the synthesis and stereochemistry of 17-oxygenated 12,13-epoxyetiojervanes. As a continuing study on the reactions of 12,13-epoxy-*C*-nor-*D*-homosteroids, involving formation of novel rearranged products,[4] we have examined reactions of 17-oxygenated 12α,13α- and 12β,13β-epoxyetiojervanes with boron trifluoride etherate, keeping in mind that the epoxy ring cleavage of the 11-oxygenated 12,13-epoxides varied, depending on electronegativity of the 11-substituents rather than conformation of the epoxy groups.[4] In this paper we describe the results, including interesting participation of neighboring groups.

The reactions of 17α-hydroxy-[3] (**1A**), 17α-acetoxy-[3] (**2A**), 17β-hydroxy-[3] (**3A**), 17β-acetoxy-[3] (**4A**), and 17-oxo derivatives of 12α,13α-epoxyetiojerv-5-en-3-one 3,3-ethylene acetals[3] (**5A**), and the corresponding 12β, 13β-epoxides[3] (**6A—10A**) with boron trifluoride etherate were carried out in benzene at room temperature, and the results are summarized in Table 1. The structure of each product was assigned on the basis of the chemical and spectral evidence. The functional groups in the A and B rings, Δ^5-3,3-ethylenedioxy ($S=S_A$) and Δ^4-3-oxo groups ($S=S_B$), the latter being formed by deacetalization of the former under the acidic conditions, were defined clearly on the spectral grounds: (i) S_A, δ ≈3.94 (4H, s, $OC\underline{H}_2C\underline{H}_2O$) and ≈5.40 (1H, br, W_H=8 Hz, 6-H): S_B, λ_{max} 235 nm (ε ≈10000); ν_{max} ≈1660 and ≈1615 cm^{-1}; δ ≈5.78 (1H, s, 4-H), and (ii) difference in chemical shift of 19-methyl protons of several pairs of compounds differing only in these functional groups, $\Delta\delta_{obsd}$ 0.14—0.18; $\Delta\delta_{calcd}$ 0.16.[5]

Table 1. Reaction results of 17-oxygenated 12α,13α-epoxy- (**1A—5A**) and 12β,13β-epoxy-13-epietiojerv-5-en-3-one 3,3-ethylene acetals (**6A—10A**) with boron trifluoride etherate[a]

Compound **11A**, mp 132—134 °C, a major product of **1A**, had a molecular formula $C_{21}H_{28}O_3$ corresponding to a dehydration product of **1A**. The IR (ν_{max} 1720 cm^{-1}) and NMR spectra [δ 1.21 (3H, d, J=7 Hz, 18-H)] suggested the presence of a $\Delta^{12(14)}$-17-carbonyl moiety on the six-membered *D* ring. Indeed, compound **11A**, when treated with base (KOH in aq CH_3OH, room temp, 1 h), was converted quantitatively into a known compound, etiojerva-5,12-diene-3,17-dione ethylene acetal[3] (**12A**). The configuration of the 13-methyl group was deduced from the negative Cotton effect (a=+15°) as illustrated in Fig. 1. All these facts establishes that the compound is represented by formula **11A**. The deshielding effect ($\Delta\delta$ 0.12) of a double bond at C-12–C-14 to the chemical shift of the 19-methyl protons [δ_{obsd} 1.10 for **11A**; δ_{calcd} 0.98 and 1.03 for 12β- and 12α-etiojerv-4-en-3-one ethylene acetals[5] (**13A** and **14A**)] was in good accord with the corresponding difference (0.11) between 12β,13α-dihydroacetyljervine[6] (**15**) (δ 1.02) and "diacetyl-Δ^{13}-jervine"[6,7] (**16**) (δ 1.13).

The structure of compound **17A** ($C_{21}H_{26}O_2$), mp 116—118 °C, was based on the spectral data, which gave indications of an aromatic *D* ring: λ_{max} 273 nm

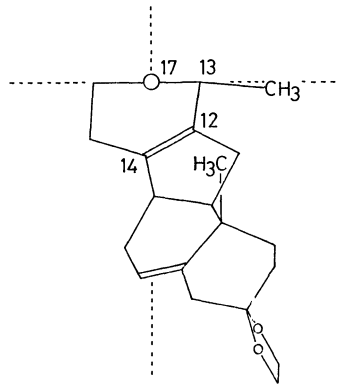

Fig. 1

(ε 300) and 264 (300); δ 2.26 (3H, s, 18-H) and 6.96 (3H, m, W_H=5 Hz, 15-, 16-, and 17-H). The compound (**17A**), on treatment with acid (p-TsOH in a 3:1 mixture of acetone and water, reflux, 4 h) afforded its deacetalization product, Δ^4-3-ketone (**17B**), mp 129—130 °C, in good yield. Naturally, the chemical shifts (δ 1.16 and 1.30) of 19-methyl protons of **17A** and **17B** coincided with those (δ 1.17 and 1.31) of the related veratramine derivatives,[5,8] indicating the deshielding effect of an aromatic D ring to be $\Delta\delta$ 0.17 [1.16 (δ_{obsd} of **17A**)—0.98 (δ_{calcd} of **13A**) or 1.30 (δ_{obsd} of **17B**)—1.14 (δ_{calcd} of **13B**)].

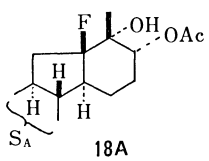
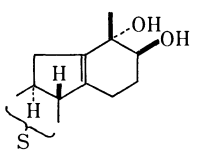
17A S=SA
17B S=SB

The reaction of 17α-acetoxy-12α,13α-epoxide (**2A**) afforded fluorohydrin (**18A**), mp 186—189 °C, as a minor product besides the two aromatic compounds (**17A** and **17B**). The molecular formula $C_{23}H_{33}O_5F$ suggested that **18A** would be a compound formed by simple cleavage of the epoxy ring by a fluoride anion.[9] A 12β-fluoro-13α-hydroxyetiojervane formula (**18A**) was assigned to the compound by analogy of the NMR spectra of the related compounds: 13β-fluoro-12α-hydroxyetiojervanes[10] and the corresponding *C*-nor-*D*-homospirostanes[10,11] exhibited three-proton singlets due to the 18-methyl protons at δ 1.47—1.58, while 12β-fluoro-13α-hydroxyetiojervane,[12] the corresponding spirostan,[11,12] and the relevant compound (**18A**) displayed the singlets at higher fields, δ 1.27, 1.29, and 1.25, respectively.



18A



19A S=SA
19B S=SB

Compound **19A**, mp 201—203 °C, obtained as a major reaction product of 17β-hydroxy-12α,13α-epoxide (**3A**), had the same molecular formula $C_{21}H_{30}O_4$ as **3A**. The NMR spectrum revealed a broad singlet (1H, W_H=7 Hz) due to a proton on the carbon (probably C-17) bearing an axial secondary hydroxyl group at δ 3.93 and two singlets (each 3H) due to the 19- and 18-methyl protons at δ 1.08 and 1.35, respectively. In view of the absence of evidence supporting any skeletal rearrangement (no absorption maxima in the carbonyl region), the appearance of the 19- and 18-methyl protons at such low fields indicated the presence of the afore-mentioned double bond at C-12–C-14 (δ_{calcd} 1.10[5] for 19-H). Hence the remaining oxygen atom would have to constitute a tertiary hydroxyl group most probably at C-13. Since the compound did not form the acetonide under the conditions described later, it was formulated as structure **19A**. On the other hand, a minor product, mp 174—177 °C, was readily assigned the corresponding Δ^4-3-ketone formula (**19B**) from the spectral data (Experimental).

The acid treatment of 17β-acetoxy-12α,13α-epoxide (**4A**) gave two compounds (**20A** and **20B**) as major products. The former (**20A**), mp 204—206 °C, had a molecular formula $C_{23}H_{34}O_6$ corresponding to a hydration product of **4A**, suggesting formation of two new hydroxyl groups. Compound **20A**, formulated as monoacetate [δ 2.06 (3H, s, OCOCH$_3$) and 5.00 (1H, br, W_H=9 Hz, 17-H)], resisted mild acetylation and oxidation with periodic acid. Hydrolysis of **20A** with base (K_2CO_3 in aq CH_3OH, room temp, 3 h) gave triol (**21A**), mp 197—199 °C [δ 3.82 (1H, br, W_H=10 Hz, 17-H)], in 80% yield, which on treatment with acetone and acid ($HClO_4$, room temp, 4 h) underwent acetonide formation with concomitant deacetalization, giving Δ^4-3-oxo triol 13β,17β-acetonide (**22B**), amorphous, in 70% yield [δ 1.44 (9H, s, 18-H and acetonide CH$_3$) and 4.19 (1H, m, W_H=12 Hz,

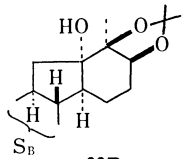
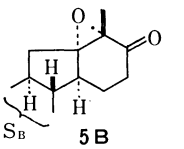
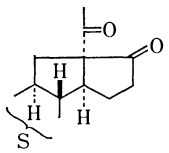
21B S=SB, R=H



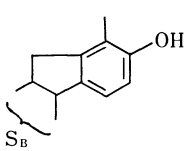
22B



5B



23A S=SA
23B S=SB

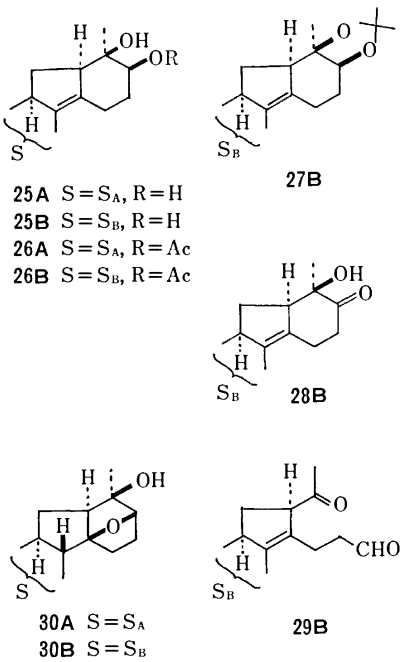


24B

17-H)]. All these facts indicate that the compound is represented favorably by formula **20A**. The latter compound (**20B**), mp 182—184 °C, was also formulated as monoacetate [δ 2.07 (3H, s, $OCOCH_3$) and 5.01 (1H, br, W_H=9 Hz, 17-H)] and was converted under the afore-mentioned basic conditions into triol (**21B**), mp 217—218 °C, in 90% yield, which formed the corresponding acetonide by the same treatment as **21A** in 80% yield. This acetonide was identical with that (**22B**) derived from **20B**, and hence formula **20B** was assigned to the compound. The β-configurational assignment to the 13-hydroxyl group in **20A** and **20B** was understood reasonably by neighboring participation[13] of the *trans*-17β-acetoxyl group adjacent to the relevant α-epoxy group, as discussed later.

Prolonged treatment of 17-oxo-12α,13α-epoxide (**5A**) with the acid produced four compounds. The first compound (**5B**), mp 185—187 °C, was identified easily as a deacetalization product of **5A** by comparison of the spectral data. The second (**23A**), mp 124—125 °C, had the same molecular formula $C_{21}H_{28}O_4$ as **5A**. The spectra revealed that acetyl [ν_{max} 1715 cm^{-1}; δ 2.20 (3H, s)] and five-membered ring carbonyl groups (ν_{max} 1734 cm^{-1}) were newly formed, suggesting cleavage of the C-12–O bond and contraction of the D ring. These data, combined with analogous examples,[4,11] led to assignment of formula **23A** to the compound. The configuration of the acetyl group was deduced from recently reported mechanism on rearrangement of epoxy ketones,[14] as discussed later. The third compound (**23B**), mp 112—113 °C, was identified as a deacetalization product of **23A** on the spectral ground. The fourth compound, mp 289—291 °C, was assigned formula **24B** on the basis of the spectral data indicating the presence of a phenol ring: λ_{max} 285 nm (sh) (ε 900) and 279 (1100); δ 2.15 (3H, s, 18-H), and 6.58 and 6.79 (each 1H, ABq, J=8 Hz, 16- and 15-H).

One (**25A**), mp 102—104 °C, of two major products in the reaction of 17β-hydroxy-12β,13β-epoxide (**6A**) had the same molecular formula as **6A** and gave its monoacetate (**26A**), mp 232—234 °C. The IR and NMR spectra of **25A** and **26A** revealed the presence of secondary (equatorial) and tertiary hydroxyl groups at C-17 and C-13, respectively: **25A**, δ 1.23 (3H, s, 18-H) and 3.41 (1H, br m, W_H=25 Hz, 17-H): **26A**, ν_{max} 3507, 1719, and 1260 cm^{-1}; δ 1.13 (3H, s, 18-H) and 4.77 (1H, do d, J=10 and 5 Hz, 17-H). Compound **25A**, when treated with acid (*p*-TsOH in aq acetone, reflux, 2 h), underwent deacetalization to give another major product (**25B**), mp 185—187 °C, in 80% yield, which also formed its monoacetate (**26B**), mp 123—124 °C. Further treatment of **25B** with acetone and acid ($HClO_4$, room temp, 0.5 h) afforded the corresponding 13β,17β-acetonide (**27B**), oily, though in low yield: δ 1.33 and 1.40 (each 3H, s, acetonide CH_3), and 4.14 (1H, br m, 17-H). Mild oxidation of **25B** with chromium(VI) oxide in pyridine afforded the corresponding 17-ketone (**28B**), mp 178—180 °C, in low yield together with a major product, amorphous, assigned tentatively formula **29B** on the spectral ground (Experimental): **28B**, ν_{max} 3370 and 1717 cm^{-1}. All these facts indicated the presence of 13β- and 17β-hydroxylgroups in **25A** and **25B**. Contrary to the expectation that the remaining double bond would be located at C-12–C-14 as in the case of **19A**, the 19-methyl protons of **25A** and **26A** appeared at abnormally high fields, δ 0.91 and 0.92, compared with those of other usual etiojervanes: δ_{obsd} 1.04, 1.10, 1.08, and 1.02 for **6A**, **11A**, **19A**, and **18A**; δ_{calcd} 0.98 and 1.03 for **13A** and **14A**. The chemical shifts in question were consistent with disposition of a double bond at C-8–C-14, since the shielding effect ($\Delta\delta$ −0.12= 0.91–1.03) of a $\Delta^{8(14)}$-system to the relevant chemical shift has been demonstrated for normal[15] ($\Delta\delta$ 0.117) and *C*-nor-*D*-homosteroids.[11] It is also emphasized that the absorption maximum due to the double bond in question was observed at 208 nm (ε 10000).[16] Hence the compound is represented reasonably by formula **25A**, in which the configuration at C-12 was assigned from the mechanistic ground (hydride shift from C-14 as well as by analogy of the related reactions,[11] as discussed later).

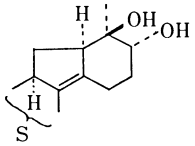


Two minor products, **30A**, mp 207—208 °C, and its deacetalization product (**30B**), mp 136—138 °C, were assigned hydroxy oxolane structures. The former (**30A**), with the same molecular formula $C_{21}H_{30}O_4$ as **6A**, resisted acetylation and oxidation with periodic acid under the usual conditions. While the spectra revealed the presence of a $-CH_3(C)(OH)-$ moiety, in which (C) denotes a quaternary carbon [*m/e* 346 (M^+), 331, and 328; ν_{max} 3580 cm^{-1}; δ 1.30 (3H, s, 18-H)], a one-proton doublet (J=5 Hz) was observed at a relatively low field, δ 4.06. This signal could be ascribed to a proton on the carbon (probably C-17) bearing an ether oxygen atom because of the absence of absorption maxima at 205—210 nm and also at the carbonyl region in the UV and IR spectra. In view of the splitting pattern of the 17-proton (*cf.*, W_H=25 Hz for 17-H of **25A**), the *D*-ring would be deformed considerably and the 17-oxygen atom would constitute an ether bond between C-17 and either one of C-12, C-14, and C-8. The formation of an

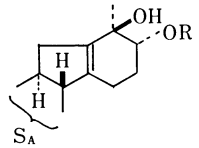
oxetane or an oxane ring (C-12 or C-8) would be eliminated by examination of the Dreiding model and also by inertness to hydride reduction of **30A** ($LiAlH_4$ in THF–dioxane, reflux, 4 h).[17] The compound is therefore be represented favorably by formula **30A**. In view of the fact that interconversion between **25A** and **30A** did not take place under the acidic conditions, compound **30A** would presumably be formed by cleavage of the C-12–O bond, hydride shift of the 14α-hydrogen to C-12, and subsequent intramolecular attack of the 17β-hydroxyl group to the relevant 14-carbenium ion.

Two reaction products of 17β-acetoxy-12β,13β-epoxide (**7A**) were identified as the above-described $\Delta^{8(14)}$-13β,17β-diol 17-acetate (**26A**) and its deacetalization compound (**26B**), respectively, by direct comparison. Naturally, compounds corresponding to **30A** and **30B** could not be detected.

Two major products, **31A**, mp 174—175 °C, and its deacetalization product (**31B**), amorphous, in the reaction of 17α-hydroxy-12β,13β-epoxide (**8A**) were assigned $\Delta^{8(14)}$-13β,17α-diol formulas as follows. The former (**31A**), with the same molecular formula $C_{21}H_{30}O_4$ as **8A**, displayed essentially the same mass and UV spectra as **25A** with the $\Delta^{8(14)}$-13β,17β-dihydroxy moiety: λ_{max} 207 nm (ε 9000). The NMR spectrum also resembled that of **25A**, except a signal due to the 17-proton [δ 3.70 (1H, br, W_H=8 Hz)], indicating that **31A** differed from **25A** only in configuration of the 17-hydroxyl group. The same situation held for the relation between **31B** and **25B**. Indeed, compound **31B**, when oxidized with chromium(VI) oxide in pyridine (room temp, 0.6 h) afforded the afore-mentioned hydroxy ketone (**28B**), mp 178—180 °C, confirming the assigned structures to compounds **31A** and **31B**. A minor product (**32A**), mp 169—171 °C, with the same molecular formula as **8A**, gave its monoacetate (**33A**), mp 119—121 °C, which still showed an absorption maximum at 3440 cm^{-1} due to a hydroxyl group. These facts, coupled with the mass spectrum [**32A**, *m/e* 346 (M^+), 331, 328, 302 (M^+—$CH(OH)CH_2$), and 234], suggested that **32A** would probably possess a partial formula of –(CH_3)(C)(OH)CH(OH)CH_2– on the D ring. However, the UV (no absorption maximum above 205 nm) and NMR spectra [δ 1.12 and 1.29 (each 3H, s, 19- and 18-H)] differed clearly from those of **31A** [δ 0.90 and 1.20 (each 3H, s, 19- and 18-H)]. These spectra were consistent with disposition of a double bond at C-12–C-14: δ_{calcd} 1.10 and 0.91 for 19-H of **32A** and **31A**. Hence the $\Delta^{12(14)}$-13β,17α-diol structure (**32A**) was assigned to the minor compound.



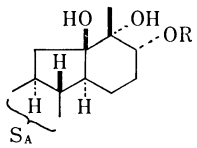
31A S=S_A
31B S=S_B



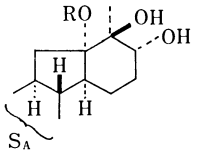
32A R=H
33A R=Ac

The reaction of 17α-acetoxy-12β,13β-epoxide (**9A**) with the acid gave rise to a complex mixture, from which two compounds (**34A** and **35A**) were isolated with a mixture of the respective deacetalization products. The former (**34A**), mp 217—219 °C, had a molecular formula $C_{23}H_{34}O_6$ corresponding to that of a hydration product of **9A**. The NMR spectrum exhibited a three-proton singlet due to 18-methyl protons at δ 1.22 and a broad multiplet (1H, W_H= 17 Hz) due to a proton on the 17-carbon bearing an equatorial acetoxyl group at δ 5.14. Compound **34A**, when hydrolyzed with base (KOH in CH_3OH, room temp, 5 h), yielded triol (**36A**), mp 207.5—208.5 °C, showing no carbonyl band in the IR spectrum. This triol (**36A**), on treatment with acetone and acid under the same conditions as described above, gave Δ^4-3-oxo triol 13α,17α-acetonide (**37B**), amorphous, whose spectra (Experimental) were in good accord with the assigned structure. All these facts, combined with the formation of **20A** from **4A**, led to assignment of formula **34A** to the compound. On the other hand, compound **35A**, amorphous, had the same molecular formula as **34A** and displayed three three-proton singlets at δ 1.02, 1.18, and 2.08 and a broad multiplet (1H, W_H=22 Hz) at δ 3.72, which were attributed to 19-, 18-, acetoxyl methyl protons and a proton at C-17, respectively. The compound (**35A**) was hydrolyzed by base treatment to give triol (**38A**), mp 199.5—201.5 °C [δ 2.60, 2.66, and 2.71 (each 1H, s, 3OH) and 3.68 (1H, br, W_H=14 Hz, and 6 Hz on addition of D_2O, 17-H), which on treatment with acid (*p*-TsOH in aq acetone, reflux, 2 h) gave the corresponding Δ^4-3-ketone (**38B**), mp 197—198 °C. Oxidation of **38B** with chromium(VI) oxide in pyridine afforded 17-ketone (**39B**), mp 171.5—173 °C: ν_{max} 3605, 3510, and 1715 cm^{-1}; δ 1.58 and 3.66 (each 1H, s, 2OH). The same 17-ketone was also obtained by oxidation of **21B** (12α,13β,17β-triol) under the same conditions as that of **38B**, establishing the presence of a 12α,13β,17α-trihydroxy moiety in compound **38B**. These facts, coupled with neighboring participation of the 17α-acetoxyl group, indicated that the compound is represented favorably by formula **35A**.

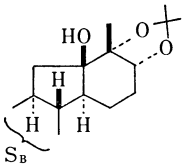
The epoxy cleavage reaction of 17-oxo-12β,13β-epoxide (**10A**) with the acid proceeded rather slowly with concomitant deacetalization to give ketone, mp 178—180 °C, in 80% yield as a sole product, which



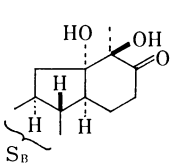
34A R=Ac
36A R=H



35A S=S_A, R=Ac
38A S=S_A, R=H
38B S=S_B, R=H



37B

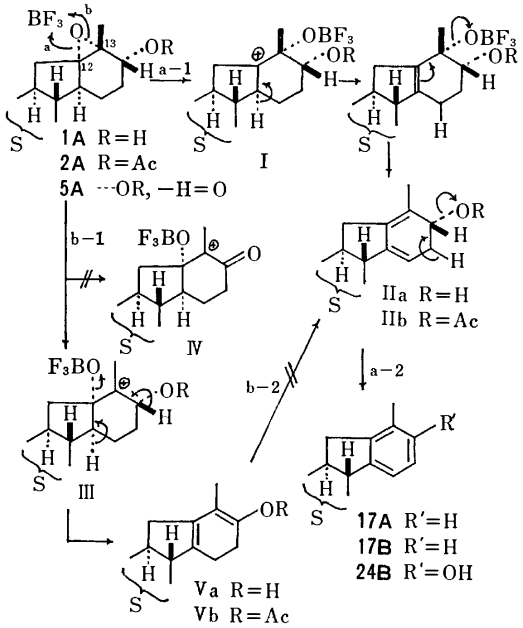


39B

was identified as the afore-mentioned $\Delta^{8(14)}$-13β-hydroxy-17-ketone (**28B**).

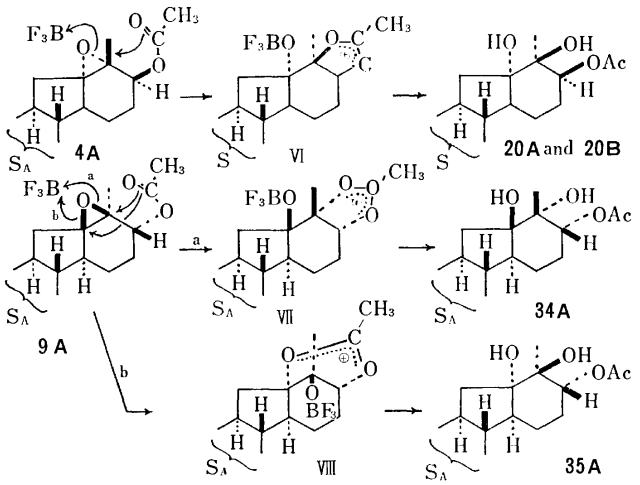
The results in Table 1 are summarized as follows. The reactions gave rise to products resulting from the epoxy ring cleavage at C-12 rather than C-13 for all the starting epoxides (**1A**—**10A**) except those **11A**, **20A**, **20B**, and **34A**. The preferential C-12–O bond cleavage, combined with the previously reported analogous results on acid treatment of 11-oxygenated 17α-aceytl-12,13-epoxides,[4] is understood well by the difference in stability of incipient carbenium ions at C-12 and C-13 formed by the epoxide opening. The fact that the reactions proceeded slowly with increase of electronegativity of the 17-substituents is also in good accord with the preferential cleavage of the C-12–O bond. These results are discussed in more details in the following.

(i) The formation of aromatic compounds (**17A**, **17B**, and **24B**) is rationalized well by assuming the initial cleavage of the C-12–O bond (Scheme 1). The route a (initial cleavage of the C-12–O bond) would give a 12-carbenium ion (I) (step a-1), which would be transformed smoothly *via* diene alcohol (IIa) or its acetate (IIb) into the aromatic compounds (step a-2). The reaction of 17α-acetate (**2A**) leading to the predominant formation of **17A** and **17B**, compared with the formation of **17A** from 17α-alcohol (**1A**) as a minor product, is ascribed to facile removal of the acetoxyl function as a leaving group (step a-2). On the other hand, the route b (initial cleavage of the C-13-O bond) must involve relatively unstable 13-carbenium ions (III) or (IV) (step b-1). Moreover, conversion of dienol (Va) or dienol acetate (Vb), formed from III, into IIa or IIb (step b-2) would not easily proceed under the acidic conditions.



Scheme 1. Pathway for formation of **17A**, **17B**, and **24B**.

(ii) The reaction results of **4A** and **9A**, in which the 17-acetoxyl groups are oriented *trans* to the 12,13-epoxy groups, are explained reasonably on the basis of participation of the acetoxyl groups to epoxy bond cleavage leading to formation of acetoxonium ion intermediates (VI—VIII) (Scheme 2). While we have a few of analogous precedents[13] regarding the relevant participation controlling epoxy ring opening, the formation of **35A** from **9A** is very noteworthy in the sense that a 1,3-diaxial acetoxonium ion (VIII) is required as an intermediate, resulting from attack of the 17β-acetoxy function to an alternate, not adjacent, epoxy carbon atom (C-12). Moreover, the difference in reactivity between **4A** and **9A** would be attributed to that between conformations of the respective 17-acetoxyl groups, as suggested by the Dreiding model and demonstrated by the NMR spectra (17-H, W_H=6 Hz for **4A** and 14 Hz for **9A**).



Scheme 2. Pathways for formation of **20A**, **34A**, and **35A**.

(iii) The reaction of 17α-hydroxy-12α,13α-epoxide (**1A**). especially the formation of β,γ-unsaturated ketone (**11A**), was examined in more detail. Reduction of 12α,13α-epoxy-17-ketone (**5A**) with sodium borodeuteride (>98%) afforded alcohol-17-*d* (**40A**), mp 169—171 °C, and its 17-epimer (**41A**), mp 154.5—157 °C, in 79 and 20% yields, respectively. These alcohols showed almost the same parent peaks at *m/e* 347 (0.59 and 0.66%) in the mass spectra and the same R_f values on TLC as **1A** and **3A**, respectively. Naturally, these alcohols (**40A** and **41A**) were reconverted by oxidation with chromium(VI) oxide in pyridine into the original ketone (**5A**). Reaction of **40A**, a 17-*d* derivative of **1A**, under the same acidic conditions as that of **1A** resulted in isolation of two deuterated compounds (**42A** and **43A**), mp 133—135 °C and 116—118.5 °C, which were corresponding to **11A** and **17A**, respectively. In accordance with the assigned structures, the former (**42A**) (isotope content, >75% by MS and NMR) exhibited a parent peak at *m/e* 329 (1.73%) and a singlet due to the 18-methyl protons at δ 1.21 in the mass and NMR spectra, while the latter (**43A**) (>98%) displayed a parent peak at *m/e* 311 (2.48%) and an AB type quartet (J=8 Hz) due to the 15- and 16-protons at δ 6.97 and 7.06. Furthermore, compound **42A**, when treated with base under the afore-mentioned conditions, was transformed into the undeuterated α,β-unsaturated ketone (**12A**).

These results established that (i) formation of **11A** resulted from cleavage of the epoxy ring at more electronegative C-13 and hydride shift of the 17β-hydrogen to C-13 in a concerted manner,[18] and (ii) reaction of **1A** to the aromatic compound (**17A**) proceeded *via* route a but not route b (Scheme 1).

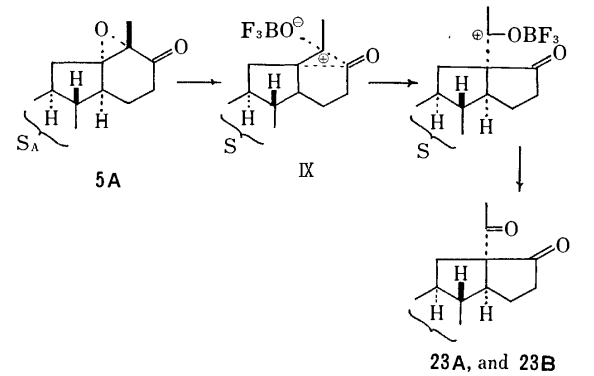
41A R=−OH, ···D

42A

43A

(iv) The reaction of 17-oxo-12α,13α-epoxide (**5A**) gave rise to rearranged products (**23A** and **23B**), which evidently resulted from migration of the C-17–C-13 bond (acyl) to C-12 *via* an intermediate (IX) formed by cleavage of the C-12–O bond (Scheme 3). It has been reported that the acyl migration[19] is preferred over a hydrogen or a primary alkyl shift[19b] and occurs in aprotic solvents in a concerted manner with inversion of the configuration at the migration terminus.[14] The configuration of **23A** and **23B** was deduced from these mechanistic grounds. The fact that no rearranged product was obtained in the reaction of 17-oxo-12β,13β-epoxide (**10A**) would probably be ascribed to difficult formation of *trans*-fusion of two five-membered (*C*/*D*) rings.



5A IX **23A**, and **23B**

Scheme 3.

In summary we again emphasize that all the reactions, except those involving the hydride shift and neighboring participation of the acetoxyl groups, were initiated by the epoxy ring cleavage at the less electronegative C-12. It is also noteworthy that the products with a double bond at C-12–C-14 were isolated only from the 12β,13β-epoxides.

Experimental

All the melting points were uncorrected. The homogeneity of each compound was always checked by TLC on silica gel (Wakogel B-5) with various solvent systems, and the spots were developed with cerium(IV) in dil sulfuric acid and/or iodine. Column chromatography was carried out over silica gel (Merck, Kieselgel 60, 70—230 mesh) or over alumina (Merck, Aluminiumoxid G. Type E), and preparative TLC over silica gel (Wakogel B-5F, 20×20 cm^2), unless otherwise stated. The optical rotations, UV, and IR spectra were measured in chloroform, ethanol, and Nujol, respectively, unless otherwise stated. The NMR spectra were obtained in chloroform-*d* at 100 MHz, TMS being used as an internal reference. The abbreviations, "s, d, q, m, br, do, and sh," in the NMR and IR spectra denote "singlet, doublet, quartet, multiplet, broad, double, and shoulder," respectively.

Reaction of 12α,13α-Epoxy-17α-hydroxyetiojerv-5-en-3-one 3,3-Ethylene Acetal (1A) with Boron Trifluoride Etherate (BF_3). To a benzene solution (100 ml) of **1A** (450 mg) was added rapidly BF_3 (0.2 ml) in benzene (3 ml) under stirring, and the resulting dark-blue solution was stirred at room temperature for 30 s. The reaction was ceased by rapid addition of ether (70 ml) and 5% aq sodium hydrogencarbonate ($NaHCO_3$, 70 ml), when the mixture became yellow. The benzene-ether solution was washed with 5% aq $NaHCO_3$ (3×80 ml) and water (3×100 ml), dried over anhydrous sodium sulfate and evaporated to dryness to leave resinous substance (430 mg), which was separated by chromatography over silica gel (25 g), benzene-ether mixtures being used as solvents. Fractions eluted with benzene–ether (10:1) gave etiojerva-5,12,14,16-tetraen-3-one 3,3-ethylene acetal (**17A**, 25 mg), mp 116—118 °C (from ether) and $[\alpha]_D$ −84.7°; MS, *m/e* 310 (M^+); UV, λ_{max} 273 nm (ε 300), 264 (300), 220 (sh) (5000), 215 (sh) (6300), and 205 (9000); IR, ν_{max} 1108 and 1095 cm^{-1}; NMR, δ 1.16 and 2.26 (each 3H, s, 19- and 18-H), 3.94 (4H, s, OC_2H_4O), 5.47 (1H, br, W_H=10 Hz, 6-H), and 6.96 (3H, m, W_H=5 Hz, 15-, 16-. and 17-H). Found: C, 80.81; H, 8.57%. Calcd for $C_{21}H_{26}O_2$: C, 81.25; H, 8.44. Fractions eluted with benzene–ether (10:2) gave 13-epietiojerva-5,12(14)-diene-3,17-dione 3,3-ethylene acetal (**11A**, 118 mg), mp 132—134 °C (from ether) and $[\alpha]_D$ −55.6°; ORD (dioxane), $[\phi]_{322}^{trough}$ −1540°, $[\phi]_{293}^{peak}$ 0°, and a=+15°, MS, *m/e* 328 (M^+), 313, 300, and 286; IR, ν_{max} 1720, 1113, and 1101 cm^{-1}; NMR, δ 1.10 (3H, s, 19-H), 1.21 (3H, d, J=7 Hz, 18-H), 3.97 (4H, s, OC_2H_4O), and 5.41 (1H, br, W_H=10 Hz, 6-H). Found: C, 76.49; H, 8.80%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%. Fractions eluted with benzene-ether (2:1) afforded α,β-unsaturated ketone (22 mg), mp 162—164 °C, which was identical with an authentic sample of etiojerva-5,12-diene-3,17-dione 3,3-ethylene acetal[3] (**12A**) (UV, IR, NMR, and TLC).

Compound **11A** (25 mg) was treated with 5% potassium hydroxide (KOH) in methanol (1 ml) at room temperature for 1 h. After removal of the solvent, the residue was mixed with water and 2M hydrochloric acid (pH≈6) and extracted with chloroform (4×10 ml). The chloroform solution was washed with 5% aq $NaHCO_3$ (2×20 ml) and water (2×20 ml), dried and evaporated to leave amorphous substance (23 mg), showing a single spot, which was purified by preparative TLC (1 plate) over silica gel with benzene-ether (3:1) to yield **12A** (14 mg), which had mp 164—165 °C on trituration with isopropyl ether.

Reaction of 12α,13α-Epoxy-17α-hydroxyetiojerv-5-en-3-one 17-Acetate 3,3-Ethylene Acetal (2A) with BF_3. A solution of **2A** (250 mg) in benzene (25 ml) was stirred with BF_3 (0.25 ml) at room temperature for 30 s. After addition of ether (50 ml) and 5% aq $NaHCO_3$ (50 ml), the benzene-ether solution was worked up as mentioned above to leave resinous substance, showing several spots on TLC, which was separated into three fractions by chromatography over silica gel (15 g) as usual. Most mobile fractions gave **17A** (32 mg), mp 114—116 °C (from ether). Middle fractions afforded etiojerva-4,12,14,16-tetraen-3-one (**17B**, 27 mg), mp 129—130 °C (from ether) and $[\alpha]_D$ +75.6°; MS, *m/e* 266 (M^+);

UV, λ_{max} 272 nm (ε 300), 237 (8400), and 219 (7600); IR, ν_{max} 1665 and 1613 cm^{-1}; NMR, δ 1.30 and 2.26 (each 3H, s, 19- and 18-H), 5.79 (1H, s, 4-H), and 6.97 (3H, s, W_H= 5 Hz, 15-, 16-, and 17-H). Found: C, 85.79; H, 8.19%. Calcd for $C_{19}H_{22}O$: C, 85.67; H, 8.33%. Least mobile fractions gave 12β-fluoro-13α,17α-dihydroxyetiojerv-5-en-3-one 17-acetate 3,3-ethylene acetal (**18A**, 15 mg), mp 186—189 °C (from ether) and $[\alpha]_D$ −53.0°; MS, *m/e* 408 (M^+), 388 (M^+−HF), and 364; IR, ν_{max} 3500, 1718, 1260, and 1110 cm^{-1}; NMR, δ 1.02, 1.25, and 2.10 (each 3H, s, 19- and 18-H, and OCOCH_3), 3.94 (4H, s, OC_2H_4O), 4.94 (1H, br, W_H=20 Hz, 17-H), and 5.36 (1H, br, W_H=10 Hz, 6-H). Found: C, 67.89; H, 8.16%. Calcd for $C_{23}H_{33}O_5F$: C, 67.62; H, 8.08%.

*Reaction of 12α,13α-Epoxy-17β-hydroxyetiojerv-5-ene-3,17-dione 3,3-Ethylene Acetal (**3A**) with BF_3.* Compound **3A** (110 mg) was treated with BF_3 (0.04 ml) in benzene (27 ml) at room temperature for 30 s under stirring. The reaction mixture was worked up as mentioned above to leave amorphous substance (130 mg), showing two main spots on TLC, which was separated by preparative TLC (6 plates) over silica gel with benzene–ether (1:3). A fraction with higher R_f value gave 13α,17β-dihydroxyetiojerva-5,12(14)-dien-3-one 3,3-ethylene acetal (**19A**, 60 mg), mp 201—203 °C and $[\alpha]_D$ −50.8°; MS, *m/e* 346 (M^+) and 303; IR, ν_{max} 3535, 3380, and 1095 cm^{-1}; NMR, δ 1.08 and 1.35 (each 3H, s, 19- and 18-H); 3.93 (5H, br s, W_H=7 Hz, 17-H and OC_2H_4O), and 5.36 (1H, br, W_H=10 Hz, 6-H). Found: C, 72.95; H, 8.85%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. A fraction with lower R_f value afforded 13α,17β-dihydroxyetiojerva-4,12(14)-dien-3-one (**19B**, 23 mg), mp 174—177 °C (from ether) and $[\alpha]_D$ +57.2°; MS, *m/e* 302 (M^+) and 259; UV, λ_{max} 237 nm (ε 9600); IR, ν_{max} ($CHCl_3$) 3640, 3460, 1662, 1613, 1110, 1010, and 960 cm^{-1}; NMR, δ 1.24 and 1.36 (each 3H, s, 19- and 18-H), 3.96 (1H, br, W_H=7 Hz, 17-H), and 5.75 (1H, s, 4-H). Found: C, 75.38; H, 8.77%. Calcd for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67%.

*Reaction of 12α,13α-Epoxy-17β-hydroxyetiojerv-5-en-3-one 17-Acetate 3,3-Ethylene Acetal (**4A**) with BF_3.* To a benzene solution (80 ml) of **4A** (320 mg) was added BF_3 (0.2 ml) in benzene (2 ml) under stirring. The resulting dark-green mixture was stirred at room temperature for 20 min. The reaction was ceased by addition of 5% aq $NaHCO_3$ (80 ml), when the mixture became yellow. The benzene solution was worked up as usual to leave resinous substance (320 mg), which was separated into three fractions by chromatography over silica gel (90 g) with benzene–ether mixtures. Initial fractions eluted with benzene–ether (1:1) gave the unreacted epoxide (**4A**, 43 mg). Early fractions eluted with benzene–ether (1:1) afforded 12α,13β,17β-trihydroxy-13-epietiojerv-5-en-3-one 17-acetate 3,3-ethylene acetal (**20A**, 115 mg), mp 204—206 °C (from ether–acetone) and $[\alpha]_D$ −25.4°; MS, *m/e* 406 (M^+), 388, 370, and 346; IR, ν_{max} 3530, 3460, 3350, 1730, 1267, 1105, 1090, and 1020 cm^{-1}; NMR, δ 1.02, 1.20, and 2.06 (each 3H, s, 19- and 18-H, and OCOCH_3), 3.93 (4H, s, OC_2H_4O), 5.00 (1H, br, W_H=9 Hz, 17-H), and 5.34 (1H, br, W_H=10 Hz, 6-H). Found: C, 67.59; H, 8.68%. Calcd for $C_{23}H_{34}O_6$: C, 67.95; H, 8.43%. Later fractions eluted with benzene–ether (1:1) gave 12α,13β,17β-trihydroxy-13-epietiojerv-4-en-3-one 17-acetate (**20B**, 140 mg), mp 182—184 °C (from ether–acetone) and $[\alpha]_D$ +124°; MS, *m/e* 362 (M^+), 344, 302, 284, and 266; UV, λ_{max} 239 nm (ε 9700); IR, ν_{max} 3490, 3400, 1712, 1668, 1610, 1263, and 1024 cm^{-1}; NMR, δ 1.17, 1.20, and 2.07 (each 3H, s, 19- and 18-H, and OCOCH_3), 5.01 (1H, br, W_H=9 Hz, 17-H), and 5.74 (1H, s, 4-H). Found: C, 69.83; H, 8.35%. Calcd for $C_{21}H_{30}O_5$; C, 69.58; H, 8.34%.

Compound **20A** (20 mg) was treated with potassium carbonate (K_2CO_3, 8 mg) in water (2 ml) at room temperature for 3 h under stirring. The reaction mixture was mixed with saturated brine (40 ml) and extracted with chloroform (3×10 ml). The chloroform solution was washed with water (3×20 ml), dried and evaporated to leave amorphous residue, showing a single spot on TLC, which was purified by preparative TLC (1 plate) over silica gel with ether, giving 12α,13β,17β-trihydroxy-13-epietiojerv-5-en-3-one 3,3-ethylene acetal (**21A**, 14 mg), mp 197—199 °C (from acetone) and $[\alpha]_D$ −33.2°; MS, *m/e* 364 (M^+), 346, and 328; IR, ν_{max} 3460, 3360, 1117, 1100, 1023, and 990 cm^{-1}; NMR, δ 1.05 and 1.29 (each 3H, 19- and 18-H), 3.82 (1H, br, W_H=10 Hz, 17-H), 3.94 (3H, s, OC_2H_4O), and 5.37 (1H, br, W_H=10 Hz, 6-H). Found: C, 69.23; H, 8.84%. Calcd for $C_{21}H_{32}O_5$: C, 69.20; H, 8.85%.

Compound **20B** (20 mg) in methanol (8 ml) was treated with K_2CO_3 (8 mg) in water (2 ml) in the same manner as **20A**. The reaction mixture was worked up as described above to yield 12α,13β,17β-trihydroxy-13-epietiojerv-4-en-3-one (**21B**, 13 mg), mp 217—218 °C (from acetone) and $[\alpha]_D$ +79.4°; MS, *m/e* 320 (M^+), 302, 284, and 266; UV, λ_{max} 239 nm (11000); IR, ν_{max} 3470, 1638, and 990 cm^{-1}; NMR, δ 1.20 and 1.30 (each 3H, s, 19- and 18-H), 3.82 (1H, br, W_H =11 Hz, 17-H), and 5.76 (1H, s, 4-H). Found: C, 70.87; H, 8.88%. Calcd for $C_{19}H_{28}O_4$: C, 71.22; H, 8.81%.

A solution of **21A** (37 mg) in acetone (8 ml) was stirred with 60% aq perchloric acid ($HClO_4$, 0.5 ml) at room temperature for 4 h. The solution was mixed with 5% aq $NaHCO_3$ (2 ml) and saturated brine (2 ml), and extracted with chloroform (4×10 ml). The chloroform extracts were washed with water (3×10 ml), dried and evaporated to yield amorphous residue, which was purified by preparative TLC (2 plates) over silica gel with ether–ethyl acetate (5:1) to give 12α,13β,17β-trihydroxy-13-epietiojerv-4-en-3-one 13β,17β-acetonide (**22B**, 25 mg), showing a single spot, amorphous and $[\alpha]_D$ +88.0 °; MS, *m/e* 360 (M^+), 345, 327, 302 (M^+−C_3H_6O), 284, and 267; UV, λ_{max} 239 nm (ε 12000); IR, ν_{max} ($CHCl_3$) 3580, 3440, 1660, 1615, 1380, 1376, and 1071 cm^{-1}; NMR, δ 1.17 (3H, s, 19-H) and 1.44 (9H, s, 18-H and acetonide CH_3), 4.19 (1H, br, W_H=12 Hz, 17-H), and 5.76 (1H, s, 4-H). Found: C, 72.99; H, 9.39%. Calcd for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95%.

Compound **21B** (8 mg) in acetone (2 ml) was stirred with 60% aq $HClO_4$ (0.1 ml) in the same manner as **21A**. The reaction mixture was worked up as usual to give the amorphous acetonide (7 mg) identical with **22B** (UV, IR, NMR, and TLC).

*Reaction of 12α,13α-Epoxyetiojerv-5-ene-3,17-dione 3,3-Ethylene Acetal (**5A**) with BF_3.* Compound **5A** (400 mg) in benzene (100 ml) was treated with BF_3 (0.36 ml) in benzene (3 ml) at room temperature for 1 h under stirring, when a small spot of **5A** was still detected on TLC. After addition of ether (50 ml) and 5% aq $NaHCO_3$, the mixture was separated into the benzene–ether and aqueous solutions. The former was worked up as usual to a resinous mixture, which was separated and purified by chromatography over silica gel (25 g) with benzene–ether mixtures. Initial two fractions eluted with benzene–ether (6:1) afforded the unchanged epoxide (**5A**, 24 mg) and 13α-acethyl-18,*C*-dinorcholest-5-ene-3,17-dione 3,3-ethylene acetal (**23A**, 20 mg), mp 124—125 °C (from ether) and $[\alpha]_D$ −72.1°; MS, *m/e* 344 (M^+) and 301; IR, ν_{max} 1734, 1715, 1361, and 1105 cm^{-1}; NMR, δ 0.96 and 2.20 (each 3H, s, 19-H and $COCH_3$), 3.94 (4H, s, OC_2H_4O), and 5.38 (1H, br, W_H=11 Hz, 6-H). Found: C, 73.08; H, 8.31%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%. Next two fractions eluted with benzene–ether (6:

1) gave 17-hydroxyetiojerva-4,12,14,16-tetraen-3-one (**24B**, 60 mg), mp 289—291 °C (from $CHCl_3$) and $[\alpha]_D$ +48.4°, and 12α,13α-epoxyetiojerv-4-ene-3,17-dione (**5B**, 90 mg), mp 185—187 °C and $[\alpha]_D$ +82.9°. **24B**, MS, *m/e* 282 (M^+) and 160; UV, λ_{max} 285 nm (sh) (ε 900), 279 (1100), and 234 (9000); IR ν_{max} 3280, 1648, 1600, and 830 cm^{-1}; NMR, δ 1.28 and 2.15 (each 3H, 19- and 18-H), 5.78 (1H, s, 4-H), 6.58 and 6.79 (each 1H, ABq, J=8 Hz, 16- and 15-H). Found: C, 80.60; H, 7.72%. Calcd for $C_{19}H_{22}O_3$: C, 80.81; H, 7.85%. **5B**, MS, *m/e* 300 (M^+), 285, 257, and 214; UV, λ_{max} 237 nm (ε 9500); IR ν_{max} 1716, 1673, and 1613 cm^{-1}; NMR, δ 1.20 and 1.36 (each 3H, s, 19- and 18-H), and 5.80 (1H, s, 4-H). Found: C, 75.68; H, 8.16%. Calcd for $C_{19}H_{24}O_3$: C, 75.94; H, 8.05%. Fractions eluted with benzene-ether (4:1) afforded 13α-acetyl-*C*,18-dinorcholest-4-ene-3,17-dione (**23B**, 90 mg), mp 112—113 °C (from ether) and $[\alpha]_D$ +74.0°; MS, *m/e* 300 (M^+), 285 and 257, UV, λ_{max} 237 nm (ε 10000), IR, ν_{max} 1733, 1700, 1679, 1615, and 1365 cm^{-1}; NMR, δ 1.14 and 2.20 (each 3H, s, 19-H and $COCH_3$), and 5.73 (1H, s, 4-H). Found: C, 75.82; H, 8.06%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%.

*Reaction of 12α,13β-Epoxy-17β-hydroxy-13-epietiojerv-5-en-3-one 3,3-Ethylene Acetal (**6A**) with BF_3.* To a benzene solution (50 ml) of **6A** (200 mg) was added rapidly BF_3 (0.06 ml) in benzene (2 ml) under stirring, and the dark-blue solution was stirred at room temperature for 30 s, when the solution became brown. The reaction was ceased by addition of ether (50 ml) and 5% aq $NaHCO_3$ (50 ml). The benzene-ether solution was worked up as mentioned above to leave amorphous substance, which was separated roughly by chromatography over silica gel (8 g) with a 2:1 mixture of benzene and ether. Early eluates contained two compounds, which were separated by preparative TLC (6 plates) over silica gel with ether to give 14β,17β-epoxy-13β-hydroxy-12α,13-epietiojerv-5-en-3-one 3,3-ethylene acetal (**30A**, 29 mg), mp 207—208 °C and $[\alpha]_D$ −45.2°, and 13β,17β-dihydroxy-12α,13-epietiojerva-5,8(14)-dien-3-one 3,3-ethylene acetal (**25A**, 90 mg), mp 102—104 °C (from ether-hexane) and $[\alpha]_D$ −37.2°. **30A**, MS, *m/e* 346 (M^+), 331, 328, and 303; IR, ν_{max} 3580, 1200, 1140, 1130, 1100, 1080, 1060, 1040, 970, and 940 cm^{-1}; NMR, δ 1.08 and 1.30 (each 3H, s, 19- and 18-H), 3.95 (4H, s, OC_2H_4O), 4.06 (1H, d, J=5 Hz, 17-H), and 5.38 (1H, br, W_H=10 Hz, 6-H). Found: C, 72.84; H, 8.71%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. **25A**, MS, *m/e* 346 (M^+), 331, 328, and 313; UV, λ_{max} 208 nm (ε 10000); IR, ν_{max} 3420, 1095, and 1018 cm^{-1}; NMR, δ 0.91 and 1.23 (each 3H, s, 19- and 18-H), 3.41 (1H, br, W_H= 25 Hz, 17-H), 3.94 (4H, s, OC_2H_4O), and 5.34 (1H, br, W_H=8 Hz, 6-H). Found: C, 73.15; H, 8.32%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. Later eluates also consisted of at least two compounds, from which the following were isolated by preparative TLC (3 plates over silica gel with ether. 13β,17β-Dihydroxy-12α,13-epietiojerva-4,8(14)-dien-3-one (**25B**, 49 mg), mp 185—187 °C and $[\alpha]_D$ +83.3°; MS, *m/e* 302 (M^+) and 284; UV, λ_{max} 234 nm (ε 12000) and 208 (10000); IR, ν_{max} 3530, 3380, 1650, 1618, 1120, 1060, and 1002 cm^{-1}; NMR, δ 1.07 and 1.24 (each 3H, s, 19- and 18-H), 3.45 (1H, br, W_H=22 Hz, 17-H), and 5.82 (1H, s, 4-H). Found: C, 74.99; H, 8.57%. Calcd for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67%. 14β,17β-Epoxy-13β-hydroxy-12α,13-epietiojerv-5-en-3-one (**30B**, 13 mg), mp 136—138 °C (from ether-hexane) and $[\alpha]_D$ +60.2°; MS, *m/e* 302(M^+), 287, 284, and 259; UV, λ_{max} 237 nm (ε 11000); IR, ν_{max} 3460, 1660, 1610, 1010, 990, 952, and 912 cm^{-1}; NMR, δ 1.23 and 1.31 (each 3H, s, 19- and 18-H), 4.07 (1H, d, J=5 Hz, 17-H), and 5.75 (1H, s, 4-H). Found: C, 75.81; H, 8.60%. Calcd for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67%.

Compounds **25A** (12 mg) and **25B** (12 mg) were treated with acetic anhydride (0.6 ml) and pyridine (0.12 ml) at room temperature for 20 h under stirring. The respective reaction mixtures were mixed with cold water (5 ml) and extracted with chloroform (3×10 ml). The extracts were washed with 5% aq $NaHCO_3$ to give the corresponding monoacetates (**26A**, 9 mg, and **26B**, 10 mg), which were identical with the reaction products of **7A** described later.

Compound **25A** (42 mg) was refluxed with *p*-toluenesulfonic acid (*p*-TsOH, 22 mg) in acetone (13 ml) and water (2 ml) for 2 h under stirring. The mixture was evaporated to leave amorphous residue, which was treated with 5% aq $NaHCO_3$ and chloroform. The chloroform extracts were worked up as usual to leave crystalline residue (41 mg), which was purified by preparative TLC (1 plate) over silica gel with ether–benzene (1:1) to yield a crystalline substance (32.5 mg), which was identical with an authentic sample of **25B** in all respects.

Compound **25B** (32 mg) was treated with acetone (5 ml) and 60% aq $HClO_4$ (0.05 ml) at room temperature for 30 min under stirring. The mixture was evaporated below 30 °C, made alkaline with 6 M aq ammonia, and extracted with dichloromethane (4×10 ml). The extracts were worked up as usual to leave oily residue (22 mg), containing **25B** regenerated during work-up, which was submitted to chromatography over alumina (3 g). Less polar fractions eluted with benzene gave an oily material (2.3 mg), showing a single spot on TLC, which was identified as the corresponding acetonide (**27B**), oily; MS, *m/e* 342 (M^+), 327, 284, and 269; IR, ν_{max} ($CHCl_3$) 1665 and 1618 cm^{-1}; NMR, δ 1.07 and 1.26 (each 3H, s, 19- and 18-H), 1.33 and 1.40 (each 3H, s, acetonide CH_3), 4.14 (1H, br, W_H=14 Hz, 17-H), and 5.81 (1H, s, 4-H). Eluates with chloroform afforded the unchanged glycol (**25B**, 17 mg).

To a suspended mixture of chromium(VI) oxide (CrO_3, 27 mg) in dichloromethane (0.3 ml) and pyridine (2 drops) was added **25B** (6.3 mg) in dichloromethane (0.3 ml). The mixture was stirred at room temperature for 30 min and then diluted with ether (10 ml). The ether-dichloromethane solution was washed 5% aq sodium hydroxide, 2M hydrochloric acid (HCl), 5% aq $NaHCO_3$, and saturated brine, dried and evaporated to leave oily residue (6.7 mg), showing 3 spots on TLC. The mixture was separated by preparative TLC (10×20 cm^2, 1 plate) with benzene–ether (1:1). A less polar fraction gave a crystalline substanec (0.4 mg), which was identical with the reaction product (**28B**) of **10A** described later. A more polar fraction yielded formyl ketone (**29B**, 2.0 mg), oily, showing a single spot on TLC, which exhibited the following spectra; MS, *m/e* 300 (M^+), 257, 256, and 213; IR, ν_{max} ($CHCl_3$) 2700, 1723, 1710, 1668, and 1620 cm^{-1}; NMR, δ 1.02 and 2.20 (each 3H, s, 19-H and CH_3CO), 3.65 (1H, br, W_H=12 Hz, 12-H), 5.85 (1H, s, 4-H), and 9.74 (1H, d, J=5 Hz, CHO). A most polar fraction gave the starting glycol (**25B**, 1.3 mg).

*Reaction of 12β,13β-Epoxy-17β-hydroxy-13-epietiojerv-5-en-3-one 17-Acetate 3,3-Ethylene Acetal (**7A**) with BF_3.* Compound **7A** (100 mg) was treated with BF_3 (0.03 ml) in benzene (40 ml) at room temperature for 30 s under stirring, when the spot of **7A** had disappeared on TLC. The reaction mixture was worked up as described above to leave amorphous residue, which was separated roughly into two fractions by chromatography over silica gel (5 g) with benzene–ether mixtures. Fractions eluted with benzene–ether (3:1) were further purified by preparative TLC (3 plates) over silica gel with benzene–ether (2:1) to give 17-acetate (**26A**, 51 mg) of **25A**,

mp 232—234 °C (from ether) and $[\alpha]_D$ +19.2°; MS, 388 (M^+), 373, 370, 355, 328, and 313; UV, λ_{max} 205 nm (ε 6000); IR, ν_{max} 3507, 1719, 1260, 1105, 1088, 1028, and 1019 cm^{-1}; NMR, δ 0.92, 1.13, and 2.09 (each, 3H, s, 19- and 18-H, and OCOCH$_3$), 3.94 (4H, s, OC$_2$H$_4$O), 4.77 (1H, do d, J=10 and 5 Hz, 17-H), and 5.30 (1H, br, W_H=8 Hz, 6-H). Found: C, 70.82; H, 8.21%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%. Fractions eluted with benzene–ether (2:1 and 1:1) were purified in the same manner as mentioned above to give 17-acetate (**26B**, 20 mg) of **25B**, mp 123—124 °C (from ether) and $[\alpha]_D$ +88.0°; MS, *m/e* 344 (M^+), 326, 284, and 266; UV, λ_{max} 232 nm (ε 12000) and 210 (12000); IR, ν_{max} 3400, 1748, 1673, 1250, 1050, and 1040 cm^{-1}; NMR, δ 1.09, 1.15, and 2.08 (each 3H, s, 19- and 18-H, and OCOCH$_3$), 4.78 (1H, do d, J=10 and 5 Hz, 17-H), and 5.77 (1H, s, 4-H). Found: C, 72.89; H, 8.12%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

Reaction of 12β,13β-Epoxy-17α-hydroxy-13-epietiojerv-5-en-3-one 3,3-Ethylene Acetal (8A) with BF_3. To a benzene solution (50 ml) of **8A** (150 mg) was added BF_3 (0.05 ml) in benzene (2 ml) under stirring. The solution was stirred at room temperature for 30 s, when the starting alcohol (**8A**) had disappeared on TLC. After addition of ether (25 ml) and 5% aq $NaHCO_3$ (25 ml), the benzene–ether mixture was worked up as usual to leave resinous material, which was submitted to chromatography over silica gel (8 g) with benzene–ether mixtures. Early fractions eluted with benzene–ether (2:1) gave 13β,17α-dihydroxy-12α,13-epietiojerva-5,8(14)-dien-3-one 3,3-ethylene acetal (**31A**, 50 mg), mp 174—175 °C (from ether) and $[\alpha]_D$ −45.8°; MS, *m/e* 346 (M^+), 331, 328, 313, and 284; UV, λ_{max} 207 nm (ε 9000); IR, ν_{max} 3550, 3480, 1100, 1075, 1032, and 1022 cm^{-1}; NMR, δ 0.90 and 1.20 (each 3H, s, 19- and 18-H), 3.70 (1H, br, W_H=8 Hz, 17-H), 3.94 (4H, s, OC$_2$H$_4$O), and 5.34 (1H, br, W_H=8 Hz, 6-H). Found: C, 72.83; H, 8.97%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. Later fractions eluted with benzene–ether (2:1) afforded 13β,17α-dihydroxy-13-epietiojerva-5,12(14)-dien-3-one 3,3-ethylene acetal (**32A**, 30 mg), mp 169—171 °C (from acetone–ether) and $[\alpha]_D$ −3.7°; MS, *m/e* 346 (M^+), 331, 328, 313, 302, and 234; IR, ν_{max} 3400, 1095, and 1058 cm^{-1}; NMR, δ 1.12 and 1.29 (each 3H, s, 19- and 18-H), 3.58 (1H, br, W_H=5 Hz, 17-H), 3.95 (4H, s, OC$_2$H$_4$O), and 5.44 (1H, br, W_H=7 Hz, 6-H). Found: C, 72.68; H, 8.90%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. Fractions eluted with benzene–ether (1:1) gave 13β,17α-dihydroxy-12α,13-epietiojerva-4,8(14)-dien-3-one (**31B**, 42 mg), showing a single spot on TLC, amorphous and $[\alpha]_D$ +59.7°; MS, *m/e* 302 (M^+), 284, and 266; UV, λ_{max} 234 nm (ε 11000) and 208 (9000); IR, ν_{max} 3400, 1650, 1070, and 1018 cm^{-1}; NMR, δ 1.08 and 1.25 (each 3H, s, 19- and 18-H), 3.76 (1H, br, W_H=7 Hz, 17-H), and 5.84 (1H, s, 4-H). Found: C, 75.89; H, 8.34%. Calcd for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67%.

Compound **31A** (6 mg) was treated with *p*-TsOH (2 mg) in acetone (2 ml) and water (0.5 ml) under reflux for 2 h. The mixture was worked up as usual to give an amorphous substance, showing a single spot on TLC, which was identical with a sample of **31B** (MS, IR, NMR, and TLC).

Compound **32A** (8 mg) was treated with acetic anhydride (0.05 ml) and pyridine (0.1 ml) at room temperature for 24 h under stirring. The mixture was worked up as usual to give 17-acetate (**33A**, 6 mg), mp 119—121 °C (ether) and $[\alpha]_D$ −15.2°; MS, *m/e* 388 (M^+), 373, and 310; IR, ν_{max} 3440, 1735, 1248, and 1100 cm^{-1}; NMR, δ 1.13, 1.20, and 2.05 (each 3H, s, 19- and 18-H, and OCOCH$_3$), 3.96 (4H, s, OC$_2$H$_4$O), 4.77 and 5.44 (each 1H, br, W_H=7 Hz, 17- and 7-H).

To a suspended mixture of CrO_3 (20 mg) in dichloromethane (0.3 ml) and pyridine (2 drops) was added **31B** (6 mg) in dichloromethane (0.4 ml) under stirring. The mixture was stirred vigorously at room temperature for 40 min and diluted with ether. The whole mixture was worked up as described before to leave crystalline residue (5.4 mg), which was purified by preparative TLC (10× 20 cm^2, 1 plate) over silica gel with benzene–ether (1:1). A major fraction gave hydroxy ketone (2.3 mg), mp 176—179 °C, which was identical with a sample of **28B** described before in all respects.

Reaction of 12β,13β-Epoxy-17α-hydroxy-13-epietiojerv-5-en-3-one 17-Acetate 3,3-Ethylene Acetal (9A) with BF_3. Compound **9A** (140 mg) was treated with BF_3 (0.04 ml) in benzene (50 ml) at room temperature for 1 min under stirring, when the solution became violet. After addition of ether (25 ml) and 5% aq $NaHCO_3$ (25 ml), the mixture was separated into the benzene–ether and aqueous solutions. The former was washed with 5% aq $NaHCO_3$ (50 ml) and water (3× 50 ml), dried and evaporated to leave a complex mixture, which was separated roughly into two fractions by chromatography over silica gel (5 g) with a 1:1 benzene–ether mixture. Early and later eluates (33 and 65 mg) were further purified by preparative TLC (2 and 4 plates) over silica gel, respectively, giving 12α,13β,17α-trihydroxy-13-epietiojerv-5-en-3-one 12-acetate 3,3-ethylene acetal (**35A**, 33 mg) and 12β,13α,17α-trihydroxyetiojerv-5-en-3-one 17-acetate 3,3-ethylene acetal (**34A**, 24 mg). **35A**, amorphous and $[\alpha]_D$ −14.6°; MS, 406 (M^+), 388, 346, and 328; IR, ν_{max} ($CHCl_3$) 3640, 3510, 1708, 1280, 1100, 1010, and 980 cm^{-1}; NMR, δ 1.02, 1.18, and 2.08 (each 3H, s, 19- and 18-H, and OCOCH$_3$), 3.72 (1H, br, W_H=22 Hz, 17-H), 3.95 (4H, s, OC$_2$H$_4$O), and 5.38 (1H, br, W_H=8 Hz, 6-H). Found: C, 67.40; H, 8.77%. Calcd for $C_{23}H_{34}O_6$: C, 67.95; H, 8.43%. **34A**, mp 217—219 °C (from ether) and $[\alpha]_D$ −22.5°; MS, *m/e* 406 (M^+), 388, 346, and 328; IR, ν_{max} 3608, 3550, 1728, 1260, 1110, 1023, and 990 cm^{-1}; NMR, δ 1.03, 1.22, and 2.09 (each 3H, s, 19- and 18-H, and OCOCH$_3$), 3.95 (4H, s, OC$_2$H$_4$O), 5.14 (1H, br, W_H=17 Hz, 17-H), and 5.41 (1H, br, W_H=8 Hz, 6-H). Found: C, 67.92; H, 8.55%. Calcd for $C_{23}H_{34}O_6$: C, 67.95; H, 8.43%.

Compound **34A** (6 mg) was treated with 5% KOH in methanol (1 ml) at room temperature for 5 h under stirring. The reaction mixture was worked up as usual to leave crystalline residue (4.8 mg), which was recrystallized from ether to give the corresponding triol (**36A**), mp 207.5—208.5 °C; MS, *m/e* 364 (M^+), 346, 328, and 99; IR, ν_{max} ($CHCl_3$) 3605, 3470, 1101, 1017, and 987 cm^{-1}; NMR, δ 1.02 and 1.32 (each 3H, s, 19- and 18-H), 3.87 (1H, br m, W_H= 24 Hz, 17-H), 3.94 (4H, s, OC$_2$H$_4$O), and 5.39 (1H, br, W_H=8 Hz, 6-H). The triol (**36A**, 4.8 mg) was then treated with acetone (2 ml) and 60% aq $HClO_4$ (2 drops, 0.035 ml) at room temperature for 20 h under stirring. The reaction mixture was worked up as usual to give the corresponding 13α,17α-acetonide (**37B**, 4.6 mg), amorphous; MS, *m/e* 360 (M^+), 320, 302, 284; IR, ν_{max} ($CHCl_3$) 3690, 3480, 1661, and 1614 cm^{-1}; NMR, δ 1.14 (3H, s, 19-H), 1.24 and 1.29 (6H, and 3H, each s, 18-H and acetonide CH$_3$), 4.22 (1H, br, W_H=20 Hz, 17-H), and 5.77 (1H, s, 4-H).

Compound **35A** (36 mg) was hydrolyzed with 5% KOH in methanol (2 ml) at room temperature for 20.5 h to give the corresponding triol (**38A**, 26 mg), mp 199.5—201.5 °C (from benzene) and $[\alpha]_D$ −51.7°; MS, *m/e* 364 (M^+), 346, 328, and 99; IR, ν_{max} 3460, 3425 (sh), 1084, 1013, and 985 cm^{-1}; ν_{max} ($CHCl_3$) 3615, 3490, 1105, 1088, 1059, 1019, and 997 cm^{-1}; NMR, δ 1.04 and 1.36 (each 3H, s, 19- and 18-H), 2.60, 2.66, and 2.71 (each 1H, s, 3OH), 3.68 (1H,

br, W_H=14 Hz, and 6 Hz on addition of D_2O, 17-H), 3.94 (4H, s, $OC_2\underline{H}_4O$), and 5.36 (1H, br, W_H=9 Hz, 6-H). The triol (**38A**, 13 mg) was also treated with *p*-TsOH (3 mg) in acetone (2 ml) and water (0.5 ml) under reflux for 2 h. The mixture was worked up as described already to leave crystalline residue (12 mg), which on recrystallization from benzene-diisopropyl ether gave 12α,13β,17α-trihydroxy-13-epietiojerv-4-en-3-one (**38B**, 5.0 mg), mp 197—198 °C and $[\alpha]_D$ +76.6°; MS, *m/e* 320 (M^+), 302, 284, 266, and 84; IR, ν_{max} ($CHCl_3$) 3645, 3455, 1667, 1617, 1060, 1016, and 937 cm^{-1}; NMR, δ 1.14 and 1.37 (each 3H, s, 19- and 18-H), 3.03 (1H, br s, OH), 3.68 (1H, br, W_H=21 Hz, and 9 Hz on addition of D_2O, 17-H), and 5.73 (1H, s, 4-H).

To a suspended mixture of CrO_3 (30 mg) in dichloromethane (0.3 ml) and pyridine (3 drops) was added **38B** (10 mg) in pyridine (0.5 ml). The mixture was stirred at room temperature for 40 min. After addition of ether (50 ml) the reaction mixture was worked up as described before to leave oily residue (6 mg), which was submitted to prepararive TLC (20×10 cm^2, 1 plate) over silica gel to give the starting alcohol (**38B**, 1.3 mg) and 12α,13β-dihydroxy-13-epietiojerv-4-ene-3,17-dione (**39B**, 1.7 mg), mp 171.5—173 °C (from benzene-diisopropyl ether); MS, *m/e* 318 (M^+) and 300; IR, ν_{max} ($CHCl_3$) 3605, 3510, 1715, 1669, and 1619 cm^{-1}; NMR, δ 1.08 and 1.47 (each 3H, s, 19- and 18-H), 1.58 and 3.66 (each 1H, s, 2OH), and 5.79 (1H, s, 4-H). Compound **21B** (9.2 mg) was likewise oxidized with CrO_3 (25 mg) in dichloromethane (0.6 ml) and pyridine (0.2 ml) at room temperature for 45 min under stirring. The reaction mixture was worked up as usual and purified by preparative TLC (1 plate) over silica gel with ether to give the starting alcohol (**21B**, 0.5 mg) and hydroxy ketone, mp 168.5—170 °C, which was identical with a sample of **39B** (MS, IR, NMR, and TLC).

*Reaction of 12β,13β-Epoxy-13-epietiojerv-5-ene-3,17-dione 3,3-Ethylene Acetal (**10A**) with BF_3.* Compound **10A** (50 mg) was treated with BF_3 (0.02 ml) in benzene (20 ml) at room temperature for 20 min under stirring, when the spot of **10A** had disappeared on TLC. The reaction was ceased by addition of ether (10 ml) and 5% aq $NaHCO_3$ (10 ml), and the mixture was worked up as mentioned above to leave amorphous residue, showing essentially a single spot on TLC, which was purified by preparative TLC (3 plates) over silica gel with a 6:4:1 mixture of benzene, ether, and chloroform to give 13β-hydroxy-12α,13-epietiojerva-4,8(14)-diene-3,17-dione (**28B**, 35 mg), mp 178—180 °C and $[\alpha]_D$ +178.2°; MS, *m/e* 300 (M^+), 282 and 214; UV, λ_{max} 232 nm (ε 10000) and 206 (8000); IR, ν_{max} 3370, 1717, 1650, 1610, 1112, and 1083 cm^{-1}; NMR, δ 1.14 and 1.27 (each 3H, s, 19- and 18-H), and 5.83 (1H, s, 4-H). Found: C, 75.69; H, 7.85%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%. The compound (**28B**) was identified as the aforementioned oxidation product of **25B** by direct comparison of both the samples.

*Reduction of **5A** with Sodium Borodeuteride ($NaBD_4$).* Compound **5A** (1.12 g) was treated with $NaBD_4$ (Merck, D-content 98%, 160 mg) in methanol (100 ml) at room temperature for 30 min under stirring. After addition of acetic acid to decompose excess of the $NaBD_4$, the mixture was made alkaline with 6 M aq ammonia, evaporated below 30 °C, mixed with water and extracted with chloroform. The chloroform extracts were worked up as usual to leave foamy residue (1.27 g), showing two spots on TLC, which was submitted to chromatography over silica gel (80 g) with benzene-ether mixtures. Less polar fractions (220 mg) eluted with benzene-ether (2:1) afforded 12α,13α-epoxy-17β-hydroxyetiojerv-5-en-3-one-17-*d* 3,3-ethylene acetal (**41A**, 161 mg), mp 154.5—157 °C (from benzene-diisopropyl ether) and $[\alpha]_D$ −75.2°; MS, *m/e* 348 (0.25%), 347 (M^+, 0.66%), 329 (0.27%), and 99 (base); IR, ν_{max} 3470, 1115, 1100, 1028, 997, and 963 cm^{-1}; NMR, δ 1.00 and 1.37 (each 3H, s, 19- and 18-H), 1.60 (1H, s, OH), 3.95 (4H, s, $OC_2\underline{H}_4O$), and 5.38 (1H, br, W_H=11 Hz, 6-H). More polar fractions eluted with benzene-ether (2:1 and 1:1) gave a 17β-epimer (α-OH) (**40A**, 890 mg), mp 169—171 °C (from benzene-diisopropyl ether) and $[\alpha]_D$ −57.8°; MS, *m/e* 348 (0.24%), 347 (M^+, 0.59%), 329 (0.33%), and 99 (base); IR, ν_{max} 3480, 1136, 1090, 1070, 1047, 961, and 946 cm^{-1}; NMR, δ 1.00 and 1.39 (each 3H, s, 19- and 18-H), 1.68 (1H, s, OH), 3.95 (4H, s, $OC_2\underline{H}_4O$), and 5.38 (1H, br, W_H=10 Hz, 6-H). The R_f values of **40A** and **41A** on TLC were identical with those of **1A** and **3A**, respectively.

Compound **40A** (20 mg) was oxidized with CrO_3 (242 mg) in pyridine (5.1 ml) at room temperature for 17 h under stirring. The reaction mixture was worked up as mentioned above to leave oily residue (21 mg), showing two spots on TLC, which was separated by chromatography over silica gel (1.5 g) with benzene–ether (2:1). Less polar fractions gave a crystalline substance (6.7 mg) on trituration with diisopropyl ether, which had mp 143.5—144 °C and was identified as **5A** by direct comparison of both the samples. More polar fractions afforded the unchanged alcohol (**40A**, 12.3 mg). Compound **41A** (15 mg) was likewise oxidized with CrO_3 (173 mg) in pyridine (4.5 ml) at room temperature for 17 h to give **5A** (8.2 mg), mp 143.5—144 °C, and the unchanged alcohol (**41A**, 6 mg).

*Reaction of **40A** with BF_3.* To a benzene solution (100 ml) of **40A** (452 mg) cooled with ice-water was added rapidly BF_3 (0.2 ml), freshly distilled over calcium hydride, in benzene (3 ml) under stirring. The mixture was stirred at room temperature for 30 s. The reaction was ceased by addition of 5% aq $NaHCO_3$ (50 ml). The whole mixture was separated into the benzene and aqueous layers, and the latter was shaken with ether (2×50 ml). The benzene and ether solutions were combined, washed with 5% aq $NaHCO_3$ (3×30 ml) and saturated brine (3×30 ml), dried and evaporated below 30 °C to leave foamy residue (437 mg), showing two major spots on TLC, which was separated by chromatography over silica gel (30 g) with benzene–ether (19:1). Less polar fractions afforded a crystalline substance (51 mg) on trituration with diisopropyl ether–hexane, which on recrystallization from ether gave a 17-*d* derivative (**43A**, 13 mg) of **17A**, mp 116—118.5 °C and $[\alpha]_D$ −81.0°; MS, *m/e* 312 (0.87%), 311 (M^+, 2.48%), 310 (0.20%), and 99 (base); IR, ν_{max} ($CHCl_3$) 1104 and 1094 cm^{-1}; NMR, δ 1.16 and 2.27 (each 3H, s, 19- and 18-H), 3.95 (4H, s, $OC_2\underline{H}_4O$), 5.49 (1H, br, W_H=10 Hz, 6-H), 6.97 and 7.06 (each 1H, ABq, J=8 Hz, 15- and 16-H). More polar fractions afforded a crystalline substance (79 mg) on trituration with diisopropyl ether, which was recrystallized from ether to give a 13-*d* derivative (**42A**, 24 mg) of **11A**, mp 133—135 °C and $[\alpha]_D$ −63.2°; MS, *m/e* 330 (0.67%), 329 (M^+, 1.73%), 328 (0.50%), and 99 (base); IR, ν_{max} 1722, 1109, and 1096 cm^{-1}; NMR, δ 1.09 and 1.21 (each 3H, s, 19- and 18-H), 3.96 (4H, s, $OC_2\underline{H}_4O$), and 5.43 (1H, br, W_H=10 Hz, 6-H).

Compound **42A** (25 mg) was treated with 5% KOH in methanol (1 ml) at room temperature for 1 h. The reaction mixture was evaporated, diluted with water, acidified to pH 6 with 2 M aq HCl, and extracted with chloroform (4×10 ml). The chloroform extracts were worked up as usual to leave amorphous residue (23 mg), which was purified by preparative TLC over silica gel (1 plate) with benzene-ether (3:1). Major fractions gave a crystalline substance

(13 mg) on trituration with diisopropyl ether, which had mp 164.5—166 °C and was identical with a sample of **12A** (MS, IR, NMR, and TLC).

12,13-Epoxy-*C*-nor-*D*-homosteroids. VII.[1] Reaction of 11-Oxygenated 17α-Acetyl-12β,13β-epoxy-13-epietiojervanes with Boron Trifluoride Etherate and Potassium Hydroxide[2]

Akio MURAI, Hiroshi SASAMORI, and Tadashi MASAMUNE*

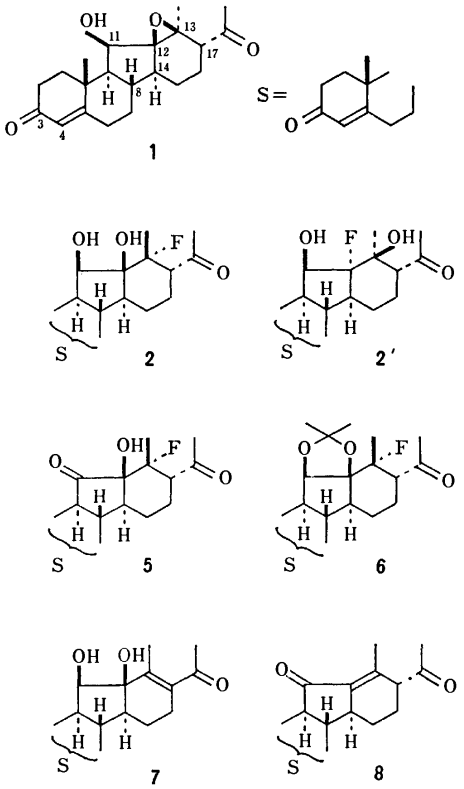
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 11, 1979)

The title compounds were treated with boron trifluoride etherate in benzene at room temperature. 11β-Hydroxy- and 11-oxo-12β,13β-epoxides (**1** and **14**) underwent cleavage of the epoxy group at C-13 by the acid treatment to give the corresponding fluorohydrins (**2** and **5**) as the respective major products, while the former (**1**) also afforded a 13β-pregnane derivative (**3**) with a normal steroid skeleton. On the other hand, several 11-oxygenated 12α,13α- and 12β,13β-epoxides (**17**, **17a**, **19**, **21**, **1**, and **23**) were treated with potassium hydroxide in aqueous methanol at room temperature. All epoxides gave the corresponding $\Delta^{13(17)}$-20-ketones, and only 11-hydroxy- and 11-acetoxy-12α,13α-epoxides (**17**, **19**, and **17a**) were further transformed into a 13α-pregnane derivative (**12**).

In a previous paper[3] we reported the synthesis and stereochemistry of 17α-acetyl-12,13-epoxyetiojervanes. As a continuing study aimed at the preparation of normal steroids from jervine, we have examined reactions of 11-oxygenated 17α-acetyl-12β,13β-epoxy-13-epietiojervanes[3] with boron trifluoride etherate and potassium hydroxide, considering the reaction of the corresponding 12α,13α-epoxyetiojervanes.[4] In the present paper we describe the result, which involves transformation into a compound with a pregnane skeleton.

Acid Treatment. Treatment of 17α-acetyl-12β,13β-epoxy-11β-hydroxy-13-etiojerv-4-en-3-one[3] (**1**) with boron trifluoride etherate (BF_3) in benzene at room temperature for 30 s produced a mixture, from which three compounds (**2**—**4**) were isolated after careful chromatography in 38, 16 and 10% yields, respectively. The major product (**2**), mp 228—230 °C, was assigned on the basis of the following evidence. The mass [*m/e* 364 (M^+), 344 (M^+-HF), and 301 (344—$COCH_3$)] and NMR spectra [δ 2.22 (3H, s, 21-H), 3.29 (1H, d, J=6 Hz, 11-OH), 3.72 (1H, s, OH)] revealed the presence of one fluorine atom, one acetyl (at C-17) and two hydroxyl groups. These spectra, coupled with the UV [λ_{max} 239 nm (ε 11000)] and IR spectra (ν_{max} 1702 cm^{-1}), indicated that the A ring and 17-side chain remained unchanged. The NMR spectrum also exhibited two three-proton singlets at δ 1.40 and 1.42 (19- and 18-H or *vice versa*) and one-proton doublet (J=8 Hz) due to a proton on the carbon atom (at C-11) bearing the hydroxyl group at δ 4.57. Compound **2**, when oxidized with the Jones reagent, was converted into hydroxy ketone (**5**), mp 198—200 °C, in 75% yield, which showed a strong absorption maximum at 1748 cm^{-1} in the IR spectrum, indicating the secondary hydroxyl group is located on a five-membered (C) ring. Compound **2** also formed the acetonide (**6**), oil, by prolonged treatment (42 h) with acetone and acid ($HClO_4$) in 47% yield, with the recovered fluorohydrin (**2**, 50%), indicative of the presence of a *cis*-glycol moiety. Moreover, the fluorohydrin (**2**) underwent dehydrofluorination by treatment with base (KOH in aq CH_3OH, room temp, 3.5 h) to give $\Delta^{13(17)}$-20-ketone (**7**), mp 154—156 °C, showing an absorption maximum at 245 nm (ε 17000) and two three-proton singlets at δ 1.39 and 1.86 (19- and 18-H) in the UV and NMR spectra. This compound (**7**), when treated with BF_3 at room temperature for 30 s, was transformed into a known Δ^{12}-11,17-dione[3] (**8**) in 40% yield. All these facts indicate that the major compound should be assigned formula **2**, excluding an alternate structure (**2'**). The configuration of the fluorine atom at C-13 was assigned by analogy of *trans*-fluorohydrin formation[4] resulting from the epoxide cleavage by the S_N2 type of nucleophilic attack of a fluoride anion.[5]



The second product (**3**), oil, had the same molecular formula $C_{21}H_{28}O_4$ as the starting epoxide (**1**), and its spectra revealed the presence of hydroxyl, acetyl, and Δ^4-3-carbonyl groups: OH, *m/e* 344 (M^+) and 326 (M^+-H_2O); ν_{max} 3483 cm^{-1}; δ 3.80 (1H, d, J=4 Hz, OH): CH_3C=O, ν_{max} 1713 cm^{-1}; δ 2.18 (3H, s, 21-H): Δ^4-3-C=O, λ_{max} 239 nm (ε 13000); ν_{max} 1664

and 1616 cm^{-1}; δ 5.72 (1H, s, 4-H). Hence the remaining oxygen atom would consititute a carbonyl group on a six-membered ring, whose absorption maximum might overlap with that of the acetyl carbonyl group (1713 cm^{-1}),[6] or an ether oxygen function. The possibility of the latter was excluded by the following facts. Compound **3**, when oxidized with the Jones reagent, was converted into diosphenol (**9**), mp 142—144 °C, in 75% yield. The diosphenol structure was characterized by the spectra of **9** and its acetate (**9a**): **9**, λ_{max} 284 nm (ε 7000);[7] ν_{max} 3400, 1664, and 1620 cm^{-1}; δ 6.91 (1H, s, OH) and no signal due to a proton at C-11: **9a**, λ_{max} 243 nm (ε 20000) ($\Delta^{9(11)}$-12-C=O and Δ^{4}-3-C=O); ν_{max} 1766, 1621, and 1225 cm^{-1}; δ 2.28 (3H, s, $OCOCH_3$), 1.12 and 1.53 (each 3H, s, 18- and 19-H), and 3.55 (1H, do d, J=12.5 and 6 Hz, 17-H). The formation of diosphenol **9** suggested strongly that an α-ketol group is located in a six-membered ring in **3** and hence the compound (**3**) must possess a normal steroid skeleton. In order to confirm the structure, compound **3** was treated with base (KOH in aq CH_3OH, room temp, 16 h) with expectation that **3** would be transformed into a known steroidal compound[8] (**10**). However, the treatment led to formation of hemiacetal (**11**). oil, in 40% yield, whose structure was deduced from the spectral data; ν_{max} 3600, 3430, 1718, 1667, and 1614 cm^{-1}; δ 1.13, 1.32 and 1.41 (each 3H, s, 18-, 19- and 21-H, or *vice versa*), 4.22 and 5.72 (each 1H, s, 12- and 4-H). The spectra were similar to but not identical with those of the corresponding 13α-pregnane[4] (**12**). The compound (**3**) is therefore represented by the 13β-pregnane formula (**3**) most favorably. The formation of hemiacetal **11** rather than **10** would probably result from facile epimerization of the α-ketol system under the basic conditions, compared with that of the 17-acetyl group.

12

The third product (**4**), mp 188—190 °C, was tentatively assigned formula **4**. The molecular formula $C_{21}H_{30}O_5$ [(**1**) $C_{21}H_{28}O_3+H_2O$], coupled with the spectral data, suggested that the compound would be formed by hydrolysis of the epoxy group and formulated by **4** or **4'**: OH, *m/e* 362 (M^+), 344 (M^+-H_2O) and 326 (M^+-2H_2O); ν_{max} 3360 cm^{-1}; δ 4.46 (1H, d, J=6 Hz, 11-H) and 1.34 (3H, s, 18-H): 17-$COCH_3$, ν_{max} 1693 cm^{-1}; δ 3.15 (1H, br, W_H=18 Hz, 17-H) and 2.26 (3H, s, 21-H): Δ^{4}-3-C=O, λ_{max} 239 nm (ε 13000); ν_{max} 1661 and 1613 cm^{-1}; δ 1.38 (3H, s, 19-H) and 5.70 (1H, s, 4-H). Oxidation of **4** with chromium(VI) oxide gave a five-membered hydroxy ketone (**13**), mp 198—200 °C, showing an absorption maximum at 1747 cm^{-1} in the IR spectrum. The compoumd (**4**) was then treated with periodic acid (aq dioxane, room temp, 18 h), when none of the acid had been consumed. Moreover, it did not give the acetonide under the same conditions as **2**. These results are in good accord with formula **4** with two *trans*-glycol systems for the third compound. The formation of **4** would probably take place in acidic media during the work-up.

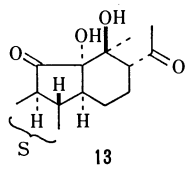
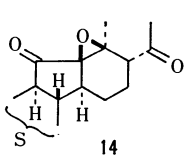
4'

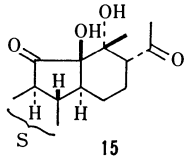


13

Similar and slightly prolonged (10 min) treatment of 17α-acetyl-12β,13β-epoxy-13-epietiojerv-4-ene-3,11-dione[3] (**14**) with BF_3 producted two compounds in 63 and 18% yields. The major product, mp 198—200 °C, was identified as fluorohydrin **5** described already. The minor product (**15**), mp 221—223 °C, had a molecular formula $C_{21}H_{38}O_4$ [(**14**) $C_{21}H_{26}O_3+H_2O$] and displayed the mass, UV, and IR spectra (except the finger print region) similar closely to those of compound **13**. However, the NMR spectrum revealed the presence of two hydroxyl groups at δ 4.20 and 7.24 (each 1H, s) and differed clearly from that of **13**. These data led to tentative assignment of formula **15** to the compound. It is beyond our comprehension that 12β,13β-epoxyetiojervanes (**1** and **14**) gave compounds formulated by simple hydrolysis products (**13** and **15**) though in low yield, while such compounds were not isolated from 12α,13α-epoxyetiojervanes.[4] In summary, the reactions of 12β,13β-epoxyetiojervanes with the acid resembled those of the corresponding 12α,13α-epimers as far as the predominant formation of fluoro-



14



15

hydrins concerns, but differed definitely in the one-step transformation into the 13β-pregnane derivative (**3**).

Base Treatment. We previously reported that base treatment of 17α-acetyl-13β-fluoro-11α,12α-dihydroxy-13-epietiojerv-4-en-3-one (**16**), a major product obtained by the BF_3 treatment of the corresponding 12α,13α-epoxide (**17**), gave rise to a 13α-pregnane derivative (**12**) *via* 11α,12α-dihydroxy-$\Delta^{13(17)}$-20-ketone (**18**).[4] In connection with the interesting rearrangement, we examined reactions of several 11-oxygenated 17α-acetyl-12,13-epoxyetiojervanes with base. The results (Table 1) are summarized as follows.

Table 1. The reaction of 11-oxygenated 17α-acetyl-12,13-epoxyetiojervanes with base[a]

Starting 12,13-epoxide	Reaction time/h	Products (isolated yield/%) $\Delta^{13(17)}$-20-ketone		13-pregnane

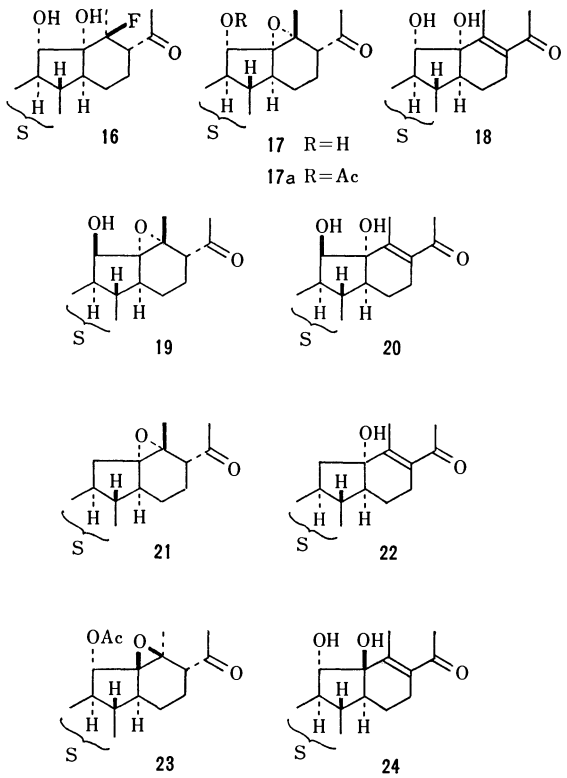
11α-OAc, β-epoxide (**23**)	19	(**24**)	70		0

a) KOH in aq CH_3OH, room temp.

(i) The base treatment of 11α-hydroxy-12α,13α-epoxide[3] (**17**) and its 11-acetate[3] (**17a**) afforded **18** and **12**. Likewise, 11β-hydroxy-12α,13α-epoxide[3] (**19**) was converted into the corresponding 11β,12α-dihydroxy-$\Delta^{13(17)}$-20-ketone (**20**) and **12**. However, (ii) the reaction of 11-unsubstituted 12α,13α-epoxide[3] (**21**) resulted in formation of only the corresponding $\Delta^{13(17)}$-20-ketone (**22**). Moreover, 11β-hydroxy-12β,13β-epoxide (**1**) and its 11α-acetoxy isomer[3] (**23**) produced only 11β,12β- and 11α,12β-dihydroxy-$\Delta^{13(17)}$-20-ketones (**7** and **24**) under almost the same conditions, no 13β-pregnane derivatives (**3** and **11**) being isolated. The structure of these new compounds (**20**, **22**, and **24**) were deduced from their spectral data. Compounds **20**, mp 221—223 °C, **22**, mp 169.5—171.5 °C, and **24**, mp 212—214 °C, exhibited the same absorption maximum at 245 nm (ε 17000) as the known $\Delta^{13(17)}$-20-ketones (**7** and **18**) and also three three-proton singlets at δ 1.36, 1.91, and 2.29 (19-, 18- and 21-H), δ 1.07, 1.90, and 2.25, and δ 1.21, 1.97, and 2.25, respectively. The configuration of 11-hydroxyl groups in **20** and **24** were drawn from the chemical shifts of the respective 19-methyl protons (δ_{calcd} 1.36 for **20** and 1.17 for **24**), the contribution of 12-hydroxyl groups being neglected.[9]

Detailed examination of Table 1 reveals the following points. (i) All the epoxides (**17**, **17a**, **19**, **21**, **1**, and **23**) readily gave the respective $\Delta^{13(17)}$-20-ketones (**18**, **18**, **20**, **22**, **7**, and **24**) by base treatment, and the former



two (**18** and **20**) were intermediates for the formation of the 13α-pregnane (**12**). (ii) The reaction of 11α-acetoxy-12α,13α-epoxide (**17a**) proceeded slowly than that of 11α-hydroxy-12α,13α-epoxide (**17**), because the former involved hydrolysis of the 11α-hydroxyl group as the first step. (iii) It should be noted that (a) the formation of 13α-pregnane **12** required the presence of not only a 12α-hydroxyl group but also a hydroxyl group at C-11, whatever the configuration was, and (b) the rearrangement of *cis* (11α,12α)-glycol (**18**) took place more rapidly than *trans* (11β,12α)-glycol (**20**), indicative of serious participation of the 11-hydroxyl group in the rearrangement. The fact that only the compounds possessing 11- and 12α-hydroxyl groups were transformed into the rearranged product (**12**) would be interpreted by assuming that the cleavage of the C-12–C-14 bond and formation of the C-13–C-14 bond would occur from the β-side of the molecule in a concerted manner. We again emphasize that the 13β-pregnane (**3**) was produced from the 11β-hydroxy-12β,13β-epoxide (**1**) only by acid treatment but not by base treatment, while the 13α-pregnane (**12**) from the 11-hydroxy-12α,13α-epoxides (**17** and **19**) only by base treatment.

Experimental

All the melting points were uncorrected. The homogeneity of each compound was always checked by TLC on silica gel (Wakogel B-5) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid and/or iodine. The optical rotations, UV, and IR spectra were measured in chloroform, ethanol, and chloroform, respectively, unless otherwise stated. The NMR spectra were obtained in chloroform-*d* at 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. The abbreviations "s, d, t, br, and

do" in the NMR and IR spectra denote "singlet, doublet, broad, and double," respectively.

Treatment of 17α-Acetyl-12β,13β-epoxy-11β-hydroxy-13-epietiojerv-4-en-3-one (1) with Boron Trifluoride Etherate (BF_3). A solution of **1** (90 mg) in anhydrous benzene (9 ml) was stirred with BF_3 (0.18 ml), freshly distilled over calcium hydride, at room temperature for 30 s. The solution was mixed with ether (5 ml), washed with 5% aq sodium hydrogencarbonate and water, dried over anhydrous sodium sulfate, and evaporated to leave amorphous residue (100 mg), which was separated into three fractions by preparative TLC over silica gel (Wakogel B-5F, 10 plates) with ether. A most mobile fraction gave a crystalline substance, which was recrystallized from ether to yield 17α-acetyl-13α-fluoro-11β,12β-dihydroxyetiojerv-4-en-3-one (**2**, 35 mg), mp 228—230 °C and $[\alpha]_D$ +156°; MS, UV, IR, and NMR, in the text. Found: C, 69.35; H, 8.20%. Calcd for $C_{21}H_{29}O_4F$: C, 69.20; H, 8.02%. A middle fraction afforded 11β-hydroxy-17-epipregn-4-ene-3,12,20-trione (**3**, 14 mg), oil, $[\alpha]_D$ +45°; MS, UV, IR, and NMR, in the text; NMR, δ 1.51 and 1.21 (each 3H, s, 19- and 18-H), 3.80 and 4.08 (each 1H, d, J= 4 Hz, OH and 11-H). Found: C, 73.03; H, 8.40%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%. A least mobile fraction gave 17α-acetyl-11β,12α,13β-trihydroxy-13-epietiojerv-4-en-3-one (**4**, 10 mg), mp 188—190 °C (from diisopropyl ether–acetone) and $[\alpha]_D$ +129°; MS, UV, IR, and NMR, in the text.

17α-Acetyl-13α-fluoro-12β-hydroxy-etiojerv-4-ene-3,11-dione (5). A solution of **2** (20 mg) in dry acetone (4 ml) was stirred with the Jones reagent (0.24 ml) for 1 h under cooling with ice. After addition of ethanol, the solution was evaporated and shaken with water and chloroform. The chloroform solution was worked up as usual to leave a crystalline substance, showing a single spot, which was recrystallized from acetone-hexane to give **5** (15 mg), mp 198—200 °C and $[\alpha]_D$ −5.5°; ORD, $[\phi]_{344}^{trough}$ −3900°, $[\phi]_{300}^{peak}$ +4250°, a= −82°; MS, *m/e* 362 (M^+), 344 (M^+-H_2O), 342 (M^+−HF), and 299 (342−$COCH_3$); UV, λ_{max} 235 nm (ε 10000); IR, ν_{max} 3400, 1748, 1707, 1664, and 1614 cm^{-1}; NMR, δ 1.21, 1.50 and 2.20 (each 3H, s, 19-, 18- and 21-H), and 5.80 (1H, s, 4-H).

11,12-Acetonide (6) of 2. A solution of **2** (40 mg) in acetone (8 ml) was stirred with 60% aq perchloric acid (0.4 ml) for 42 h. The solution was made alkaline with 5% aq sodium hydrogencarbonate, evaporated and extracted with chloroform. The chloroform solution, after being worked up as usual, left an oily residue (50 mg), showing two spots, which was separated into two fractions by preparative TLC over silica gel (Wakogel B-5F, 2 plates) with ether. A less polar fraction gave **6** (20 mg), oil; IR, ν_{max} 1705, 1664, 1615, 1384, and 1373 cm^{-1}; NMR, δ 1.39 and 2.17 (6H and 3H, each s, 19-, 18- and 21-H), 1.47 and 1.55 (each 3H, s, acetonide 2CH_3), 3.00 (1H, br, W_H=20 Hz, 17-H), 4.74 (1H, d, J=4 Hz, 11-H), and 5.71 (1H, s, 4-H). Found: C, 71.33; H, 8.07%. Calcd for $C_{24}H_{33}O_4F$: C, 71.26; H, 8.22%. A more polar fraction (20 mg) was identified as the starting fluorohydrin (**2**).

17-Acetyl-11β,12β-dihydroxyetiojerva-4,13(17)-dien-3-one (7). a) A solution of **2** (10 mg) in methanol (2.5 ml) containing 5% potassium hydroxide was stirred at room temperature for 3.5 h. The solution was made neutral with 10% aq acetic acid, evaporated below 40 °C, and shaken with water and chloroform. The chloroform solution gave a crystalline substance, showing a single spot, which was recrystallized from diisopropyl ether–acetone to yield **7**, (8 mg), mp 154—156 °C; MS, *m/e* 344 (M^+), 326, and 311; UV, λ_{max} 245 nm (ε 17000); IR, ν_{max} 3624, 3450, 1680 (br), 1658, and 1612 cm^{-1}; NMR, δ 1.39, 1.86, and 2.25 (each 3H, s, 19-, 18-, and 21-H), 3.36 (1H, d, J=9 Hz, OH), 4.33 (1H, t, J= 9 Hz, 11-H), and 5.67 (1H, s, 4-H).

b) A solution of **7** (20 mg) in anhydrous benzene (2 ml) was stirred with freshly distilled BF_3 (0.04 ml) at room temperature for 30 s. The solution was worked up as usual to leave an oily residue (19 mg), which was separated by preparative TLC over silica gel (Wakogel B-5F, one plate) with ether. A major fraction was crystallized on trituration with diisopropyl ether–acetone and recrystallized from the same solvent mixture to give Δ^{12}-11,20-dione (**8**, 7 mg), which was identified as the known compound.[3]

11-Hydroxy-17-epipregna-3,11-diene-3,12,20-trione (9) and Its 11-Acetate (9a). a) A solution of **3** (8 mg) in dry acetone (1.5 ml) was stirred with the Jones reagent (0.05 ml) for 1 h under cooling with ice. The reaction mixture was worked up as described before to leave an oily substance, which was purified by preparative TLC to yield diosphenol (**9**, 6 mg), mp 142—144 °C; UV, λ_{max} 237 nm (ε 12000) and 284 (7000); IR, ν_{max}3400, 1712, 1664, 1620, and 1613 cm^{-1}; NMR, δ 1.11, 1.53, and 2.14 (each 3H, s, 18-, 19-, and 21-H), 5.77 (1H, s, 4-H), and 6.91 (1H, s, OH). Found: C, 73.41; H, 7.86%. Calcd for $C_{21}H_{26}O_4$: C, 73.66; H, 7.66%.

b) Compound **9** (6 mg) was stirred with acetic anhydride (0.2 ml) and pyridine (0.4 ml) at room temperature for 12 h. The reaction mixture was worked up as usual to give enol acetate (**9a**, 6.4 mg), oil; UV, IR, and NMR, in the text.

12α-Hydroxy-17-epipregn-4-ene-3,11,20-trione 12,20-Hemiacetal (11). A solution of **3** (10 mg) in methanol (2.5 ml) containing 5% potassium hydroxide was stirred at room temperature for 16 h. The reaction mixture was made neutral, evaporated, and shaken with water and chloroform. The chloroform solution was worked up as usual to leave an oily substance, which was purified by preparative TLC to give hemiacetal (**11**, 4 mg), oil and $[\alpha]_D$ +96°; MS, *m/e* 344 (M^+), 326, 311, 301, 284, 283, and 256; UV, λ_{max} 237 nm (ε 10000); IR and NMR, in the text.

17α-Acetyl-12α,13β-dihydroxy-13-epietiojerv-4-ene-3,11-dione (13). To a stirred suspension of chromium(VI) oxide (15 mg) in dry dichloromethane (0.4 ml) and pyridine (0.025 ml) was added a solution of **4** (8 mg) in dichloromethane (0.1 ml). The mixture was stirred at room temperature for 15 min and filtered, then precipitates were washed with ether. The filtrate and ether washings were combined, washed with 5% aq sodium hydroxide and saturated aq sodium chloride, dried and evaporated to leave a crystalline substance (7 mg), which was recrystallized from ether to yield **13** (4 mg), mp 198—200 °C; MS, *m/e* 360 (M^+), 342, 318, 300, and 285; UV, λ_{max} 238 nm (ε 12000); IR, ν_{max} 3440, 1747, 1710, 1665, and 1612 cm^{-1}; NMR, δ 1.23, 1.46, and 2.20 (each 3H, s, 19-, 18- and 21-H), 4.20 (1H, s, OH), 5.76 (1H, s, 4-H), and 7.24 (1H, s, OH).

Treatment of 17α-Acetyl-12β,13β-epoxy-13-epietiojerv-4-ene-3,11-dione (14) with BF_3. Compound **4** (30 mg) in benzene (3 ml) was treated with BF_3 (0.07 ml) at room temperature for 10 min. The reaction mixture was worked up as described before to give oily residue (34 mg), which was separated into two fractions by preparative TLC over silica gel (Wakogel B-5F, 2 plates) with ether. A less polar fraction gave 11-oxo fluorohydrin (20 mg), mp 198—200 °C (from acetone–hexane), which was identified as **5**. A more polar fraction afforded 17α-acetyl-12β,13α-dihydroxyetiojerv-4-ene-3,11-dione (**15**, 6 mg), mp 221—223 °C and $[\alpha]_D$ −2.2°; MS, *m/e* 360 (M^+), 342, 318, 300, and 285; UV, λ_{max} 238 nm (ε 12000); IR, ν_{max} 3443, 1743, 1713, 1664, and 1614 cm^{-1};

NMR, δ 1.18, 1.46, and 2.20 (each 3H, s, 19-, 18- and 21-H), 4.20 (1H, s, OH), 5.76 (1H, s, 4-H), and 7.24 (1H, s, OH).

*Base Treatment of 11-Oxygenated 17α-Acetyl-12,13-epoxyetiojervanes (**17**, **17a**, **19**, **21**, **1**, and **23**).* The results are summarized in Table 1, and a few representative examples are described below. a) A solution of 11α-hydroxy-12α,13α-epoxide[3] (**17**, 20 mg) in methanol (5 ml) containing 5% potassium hydroxide was stirred at room temperature for 2.5 h. The reaction mixture was made neutral with 10% aq acetic acid under cooling, evaporated below 40 °C, and shaken with water and chloroform. The chloroform solution was worked up as usual to leave oily residue, showing two spots on TLC, which was separated into two fractions by preparative TLC over silica gel (Wakogel B-5F, one plate). A less polar fraction (13 mg) was identified as a known 13α-pregnane derivative[4] (**12**) by direct comparison with the sample (MS, NMR, IR, and TLC). A more polar fraction (3 mg) was also identified as 11α,12α-dihydroxy-$\Delta^{13(17)}$-20-ketone[4] (**18**).

b) Treatment of 11β-hydroxy-12α,13α-epoxide[3] (**19**, 20 mg) with potassium hydroxide under the same conditions (2.5 h) as mentioned above afforded **12** (5 mg) and 11β,12α-dihydroxy-$\Delta^{13(17)}$-20-ketone (**20**, 11 mg) after preparative TLC, mp 221—223 °C; MS, *m/e* 344 (M^+); UV, λ_{max} 245 nm (ε 16000); IR, ν_{max} 3540, 3380, 1690 (br), 1655, and 1608 cm^{-1}; NMR, δ 1.36, 1.91, and 2.29 (each 3H, s, 19-, 18-, and 21-H), 4.10 (1H, d, J=4 Hz, 11-H), and 5.71 (1H, s, 4-H).

c) Treatment of 11-unsubstituted 12α,13α-epoxide[3] (**21**, 20 mg) and 11α-acetoxy-12β,13β-epoxide[3] (**23**, 20 mg) were treated with potassium hydroxide under the same conditions (19 h) as described above. The respective reaction mixture was worked up as usual to give 12α-hydroxy- (**22**, 13 mg) and 11α,12β-dihydroxy-$\Delta^{13(17)}$-20-ketones (**24**, 13 mg), 13α- and 13β-pregnane derivatives being not detected on TLC: **22**, mp 169.5—171.5 °C; MS, *m/e* 328 (M^+); UV, λ_{max} 245 nm (ε 17000); IR, ν_{max} 3610, 3444, 1680 (br), 1660, and 1614 cm^{-1}; NMR, δ 1.07, 1.90, and 2.25 (each 3H, s, 19-, 18-, and 21-H), and 5.73 (1H, s, 4-H): **24**, mp 212—214 °C; MS, *m/e* 344 (M^+), 326, 311, and 301; UV, λ_{max} 245 nm (ε 17000); IR, ν_{max} 3624, 3444, 1680 (br), 1660, and 1610 cm^{-1}; NMR, δ 1.21, 1.97, and 2.25 (each 3H, s, 19-, 18-, and 21-H), 3.97 (1H, br, W_H=10 Hz, 11-H), and 5.75 (1H, s, 4-H).

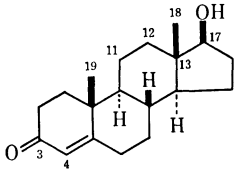
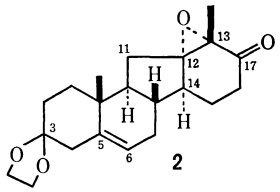
(Received July 11, 1979)

Transformation of the title epoxy ketone (**2**) into testosterone (**1**), which implies synthesis of the hormone **1** from jervine, is described. Irradiation of **2** by a low-pressure lamp in dioxane afforded an androstane-12,17-dione derivative, which was reduced regioselectively with lithium tri-*t*-butoxyaluminium hydride to give 12β-hydroxy ketone (**5**). The compound **5** was transformed *via* a four-step process into androstan-4-ene-3,17-dione, which was converted into **1** by a known procedure. The overall yield amounted to 1.8% from jervine.

In a recent preliminary communication[3] we reported the synthesis of testosterone (**1**) from jervine *via* the title epoxy ketone (**2**) as a result of continuing studies on the preparation of biologically active steroid hormones from jervine, one of the most readily available veratrum alkaloids. In the present paper we describe the details of the transformation from **2** into **1**, since the preparation of **2** had already been reported.



1



2

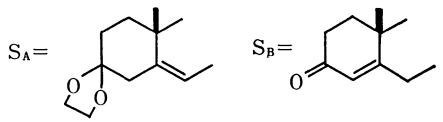


Photo-transformation of α,β-epoxy ketones has been investigated extensively and demonstrated to give a variety of products including rearranged 1,3-diketones.[5] With the expectation that the title 12α,13α-epoxy 17-ketone (**2**) would be transformed into an androstane-12,17-dione derivative, we examined the photolysis of **2** under various conditions (Experimental, Table 1). It was found that irradiation of **2** by a low pressure lamp in dioxane produced two isomeric 1,3-diketones (**3**), mp 253—254 °C, and (**4**), mp 181—183 °C, in 14 and 10% yields, respectively, a considerable amount (67%) of the starting material (**2**) being recovered unchanged. In accordance with the assigned structures, the respective compounds (**3** and **4**) had the same molecular formula $C_{21}H_{28}O_4$ as **2** and exhibited two absorption maxima at the carbonyl region and two three-proton singlets at high field in the IR and NMR spectra: **3**, ν_{max} 1756 and 1707 cm^{-1}; δ 1.13 and 1.23 (19- and 18-H): **4**, ν_{max} 1745 and 1708 cm^{-1}; δ 0.97 and 1.23. The calculated δ-values (1.167 and 1.293) for 19- and 18-methyl protons[6] and mechanistic considerations[5] indicated that a normal steroid skeleton could be assigned to the former (**3**), while a bicyclo-[3.3.1]nonane-2,9-dione partial structure to the latter (**4**). The former was then obtained in 40% yield by the repeated photo-transformations.

Table 1. Photolysis of **2**[a]

Solvent	Time	Products (yield/%)						
		2	**3**	**4**	**15**	**17**	**18**	**19**
Dioxane	1 d	67	14	10	—	—	—	—
Ether	1 d	76	5	5	—	—	—	—
DME[b]	1 d	67	10	6	—	—	—	—
Cyclohexane	1 d	75	4	3	—	—	—	—
THF	1 d	70	7	4	—	—	—	—
CH_3CN	10 h	35	6	5	18[d]	—	—	—
CCl_4[c]	3.5 h	84	—	—	4[d]	—	—	—
CCl_4+O_2[e]	20 h	27	—	—	38	—	—	—
Benzene[d]	10 h	24	—	—	—	19	8	22

a) Carried out by a 15-W low pressure mercury lamp at room temperature. b) DME, 1,2-dimethoxyethane. c) By a 100-W high pressure lamp. d) Formation of **15** would be attributed to the presence of oxygen gas contaminated in the solvents. e) Carried out in stream of oxygen.

Transformation of the 12,17-diketone (**3**) into **1** was carried out by two usual routes. Reduction of **3** with lithium tri-*t*-butoxyaluminium hydride in tetrahydrofuran (THF) proceeded regioselectively to give 12β-hydroxy 17-ketone (**5**), mp 195—197 °C [ν_{max} 1736 cm^{-1}; δ 3.81 (1H, do d, J=10 and 5 Hz, 12-H)], in 96% yield, which was converted readily into the corresponding 12β-mesylate (**6**), mp 156—158 °C. Attempted reductive elimination of the mesyl group by treatment with lithium aluminium hydride resulted in the S–O bond cleavage of the group to give only 12β,17β-diol (**7**), mp 186—188 °C [δ 3.52 (1H, do d, J=10 and 5 Hz, 12-H) and 3.88 (1H, t, J=8 Hz, 17-H)]. The diol (**7**) was also obtained by direct reduction of **3** with the hydride reagent in 94% yield.[7] Partial acetylation of **7**, however, led to formation of a 3:2 mixture of the 17β- and 12β-monoacetates (**8a** and **8b**), which without further purification was oxidized with chromium(VI) oxide (CrO_3) in pyridine to yield a 1:1 mixture of the corresponding 17-oxo 12-acetate (**9a**) and 12-oxo 17-acetate (**9b**). The mixture was then submitted to the Wolff-Kishner reduction followed by purification by preparative TLC to give 17β-hydroxyandrost-5-en-3-one 3,3-ethylene acetal[8] (**10**) in low (12%) yield from **3**. This compound (**10**) underwent deacetalization by a known procedure[8] to yield testosterone (**1**).

An alternate and improved transformation of **3** into **1** was commenced by acetalization of 12β-hydroxy 17-ketone (**5**) with ethylene glycol and acid (p-TsOH). The resulting acetal (**11**), mp 219—220 °C, was oxidized by the usual procedure (CrO_3 in Py) to 12,17-diketone 17-acetal (**12**), mp 215—216 °C, in 66% yield from **5**. The Wolff-Kishner reduction of **12** produced 3,17-diacetal (**13**), mp 175—176 °C, which on deacetalization with the acid in aqueous acetone gave androst-4-ene-3,17-dione[8] (**14**), mp 175—176 °C, in 85% yield from **12**. This diketone (**14**) was transformed by a known procedure[8] into testosterone (**1**). The overall yield amounted to 35% from the photolysis product (**3**) and 1.8% from jervine.

Experimental

All the melting points were uncorrected. The homogeneity of each compound was always checked by TLC on silica gel (Wakogel B-5) with various solvent systems, and the spots were developed with cerium(IV) in dil sulfuric acid and/or iodine. Column chromatography was carried out over silica gel (Merck, Kieselgel 60, 70—230 mesh) and preparative TLC over silica gel (Wakogel B-5F, 20×20 cm^2). The optical rotations, UV, IR, and NMR (100 MHz) spectra were measured in chloroform, ethanol, Nujol, and chloroform-*d*, respectively, unless otherwise stated. The abbreviations "s, d, t, m, br, and do" in the NMR spectra denote "singlet, doublet, triplet, multiplet, broad, and double," respectively.

Photolysis of 12α,13α-Epoxyetiojerv-5-ene-3,17-dione 3,3-Ethylene Acetal (2). The photolysis was examined under various conditions and the results were summarized in Table 1. A few representative examples were described below. i) Compound **2** (1.12 g) in dioxane (200 ml) was irradiated by a 15-W low-pressure mercury lamp at room temperature for 2 d under nitrogen. The reaction mixture was evaporated to leave resinous material (1.10 g), which was separated by chromatography over silica gel (35 g) with benzene-ether mixtures. Elution with benzene-ether (5:1) led to recovery of **2** (750 mg). Early fractions eluted with benzene-ether (2:1) afforded semi-crystalline substance, which was purified by preparative TLC (6 plates) over silica gel with benzene–ether (3:2) to give a bicyclo [3.3.1]nonane-2,9-dione derivative (**4**, 120 mg), mp 181—183 °C (from ether) and $[\alpha]_D$ −24.2°; MS, *m/e* 344 (M^+); IR, ν_{max} 1745, 1708, 1275, and 1095 cm^{-1}; NMR, δ 0.97 and 1.23 (19- and angular CH$_3$), 3.94 (4H, s, OC_2H_4O), and 5.42 (1H, br, W_H=10 Hz, 6-H). Found: C, 73.19; H, 7.98%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%. Later fractions eluted with benzene–ether (1:1) gave a crystalline substance, which was also purified by preparative TLC (8 plates) under the same conditions as mentioned above to give androst-5-ene-3,12,17-trione 3,3-ethylene acetal (**3**, 157 mg), mp 242—243 °C and 253—254 °C (from acetone) and $[\alpha]_D$ +68.4°; MS, *m/e* 344 (M^+) and 149; IR, ν_{max} 1756, 1707, 1291, and 1095 cm^{-1}; NMR, δ 1.13 and 1.23 (each 3H, s, 19- and 18-H), 3.94 (4H, s, OC_2H_4O), and 5.41 (1H, br, W_H=10 Hz, 6-H). Found: C, 73.00; H, 8.38%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

ii) An acetonitrile solution (20 ml) of **2** (200 mg) was irradiated for 10 h under the same conditions. The mixture

was worked up as usual to leave amorphous residue (190 mg), which was submitted to chromatography over silica gel (15 g) to give **2** (70 mg), **4** (10 mg), a new compound (**15**, 35 mg), and **3** (12 mg) as benzene–ether eluates (5:1, 10:3, 10:4, and 1:1), respectively. The new compound (**15**), 5β,6β:12α,13α-diepoxyetiojervane-3,17-dione 3,3-ethylene acetal, mp 129—130 °C (from diisopropyl ether) and $[\alpha]_D$ −37°; MS, *m/e* 360 (M^+); IR, ν_{max} 1720, 1125, 1104, 1075, and 1015 cm^{-1}; NMR, δ 0.98 and 1.30 (each 3H, s, 19- and 18-H), 3.14 (1H, d, J=2 Hz, 6-H), and 3.92 (4H, s, OC_2H_4O). This diepoxide was obtained by oxidation of a known compound, 5β,6β:12α,13α-diepoxy-17α-hydroxyetiojervan-3-one 3,3-ethylene acetal[4] (**16**) as follows. To a suspended mixture of CrO_3 (1.0 g) in pyridine (10 ml) was added **16** (100 mg) in pyridine (1 ml) under stirring. The mixture was stirred at room temperature for 4 h. After addition of ether (20 ml), the mixture was worked up as usual to leave amorphous residue, which was purified by passing through a silica gel column (6 g) to give **15** (70 mg), mp 129—130 °C. This was identical with one of the photolysis products in acetonitrile (MS, IR, NMR, and TLC).

iii) Compound **2** (170 mg) was irradiated in benzene (thiophene-free, 30 ml) under the afore-mentioned conditions for 10 h. The mixture, after being worked up as usual, left a complex mixture (205 mg), which was separated by chromatography over silica gel (7.0 g) with benzene–ether mixtures. While eluates with benzene–ether (20:1) gave **2** (40 mg), those with benzene–ether (10:1, 5:1, and 5:2) were further purified by preparative TLC (each 2, plates) over silica gel with a 3:2 mixture of benzene–ether, respectively, to yield three new compounds (**17**, 34 mg), (**18**, 16 mg), and (**19**, 37 mg), respectively. These compounds were tentatively assigned the respective formulas on the basis of the following spectral data: **17**, amorphous; MS, *m/e* 344 (M^+−18), 316, 301, 288, and 256; UV, λ_{max} 237 nm (ε 6500); IR, ν_{max} (neat) 3440, 1673, 1115, 1095, and 1020 cm^{-1}; NMR, δ 1.06 and 1.76 (19-H and CH_3), 3.92 (4H, s, OC_2H_4O), 5.36 (1H, br, W_H=9 Hz, 6-H), and 6.43 (1H, br, W_H=10 Hz, $CH(OH)_2$]; **18**, amorphous, MS, *m/e* 344 (M^+); IR, ν_{max} ($CHCl_3$) 1749, 1714, 1265, 1162, and 1110 cm^{-1}; NMR, δ 1.00 and 1.70 (each 3H, s, 19-H and CH_3), 3.95 (4H, s, OC_2H_4O), and 5.34 (1H, br, W_H=10 Hz, 6-H): **19**, amorphous, MS, *m/e* 344 (M^+), 316, 300, and 272; UV, λ_{max} 244 nm (ε 10000); IR, ν_{max} ($CHCl_3$), 2725, 1731, 1663, 1615, and 1097 cm^{-1}; NMR, δ 1.07 and 1.84 (each 3H, s, 19-H and CH_3), 3.97 (4H, s, OC_2H_4O), 5.46 (1H, br, W_H=10 Hz, 6-H), and 9.78 (1H, s, CHO).

12β-Hydroxyandrost-5-ene-3,17-dione 3,3-Ethylene Acetal (5). A THF solution (12 ml) of **3** (100 mg) was stirred with lithium tri-*t*-butoxyaluminium hydride (160 mg) at room temperature for 8 h. The reaction was ceased by addition of aq ammonium sulfate, and the mixture was filtered. The filtrate was concentrated, mixed with water, and extracted with chloroform (3×30 ml). The chloroform solution was washed with water, dried over anhydrous sodium sulfate and evaporated to leave a crystalline substance, which was recrystallized from acetone to yield **5** (97 mg), mp 195—197 °C and $[\alpha]_D$ +2.8°; MS, *m/e* 346 (M^+), IR, ν_{max} 3500, 1736, 1133, 1119, and 1100 cm^{-1}; NMR, δ 0.98 and 1.07 (each 3H, s, 18- and 19-H), 3.81 (1H, do d, J=10 and 5 Hz, 12-H), 3.95 (4H, s, OC_2H_4O), and 5.37 (1H, br, W_H=10 Hz, 6-H). Found: C, 72.61; H, 8.77%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

12β,17β-Dihydroxyandrost-5-en-3-one 3,3-Ethylene Acetal (7). i) To a dichloromethane solution (4 ml) of **5** (60 mg) cooled at −8 °C (ice-water-NaCl) was added dropwise triethylamine (0.07 ml) and then methanesulfonyl chloride (0.02 ml) under stirring. The mixture was stirred at the temperature for 2 h and then diluted with dichloromethane (20 ml). The solution was washed with water (20 ml), 2 M hydrochloric acid (HCl, 20 ml), 5% aq sodium hydrogencarbonate ($NaHCO_3$, 2×20 ml), and water (3×20 ml), dried and evaporated to leave a crystalline substance (50 mg), which was purified by passing through a silica gel column (3 g) to give the 12β-mesylate (**6**, 32 mg) of **5**, mp 156—158 °C (from ether): NMR, δ 1.04 and 1.07 (each 3H, s, 18- and 19-H), 3.22 (3H, s, CH_3SO_2), 3.95 (4H, s, OC_2H_4O), 4.40 (1H, do d, J=10 and 5 Hz, 12-H), and 5.38 (1H, br, W_H=10 Hz, 6-H).

To a suspended mixture of lithium aluminium hydride (LAH, 26 mg) in THF (10 ml) cooled with ice-water was added **6** (30 mg) in THF (10 ml) under stirring, and the mixture was refluxed for 3 h under nitrogen and then cooled. After dropwise addition of water (4 ml) and 4 M aq sodium hydroxide (1 ml) under cooling with ice-water, the mixture was filtered. The filtrate was concentrated, mixed with water and extracted with chloroform (4×50 ml). The extracts were worked up as usual to leave a crystalline substance, which was purified by passing through a silica gel column (2.0 g) to yield **7** (23 mg), mp 186—188 °C (from diisopropyl ether) and $[\alpha]_D$ −31.9°; MS, *m/e* 348 (M^+); IR, ν_{max} 3400, 1140, 1102, 1062, and 1025 cm^{-1}; NMR, δ 0.82 and 1.06 (each 3H, s, 18- and 19-H), 3.52 (1H, do d, J=10 and 5 Hz, 12-H), 3.88 (1H, t, J=8 Hz, 17-H), 3.95 (4H, s, OC_2H_4O), and 5.32 (1H, br, W_H=10 Hz, 6-H). Found: C, 70.33; H, 9.11%. Calcd for $C_{21}H_{32}O_4 \cdot 1/2H_2O$: C, 70.55, H, 9.31%.

ii) To a mixture of LAH (40 mg) in THF (8 ml) cooled with ice-water was added **3** (50 mg) in THF (30 ml) under stirring, and the whole mixture was refluxed for 3 h. The reaction mixture was worked up and purified as described above to give **7** (45 mg), mp 186—188 °C, which was identical with a sample of the afore-mentioned diol (**7**) (IR, NMR, and TLC).

17β-Hydroxyandrost-5-en-3-one 3,3-Ethylene Acetal (10). A benzene solution (3 ml) of **7** (55 mg) was treated with acetic anhydride (0.1 ml) and pyridine (0.1 ml) at room temperature for 31 h. The solution was diluted with ether (100 ml) and worked up as usual to give a mixture of the 12β- and 17β-monoacetates (**8a** and **8b**, total 34 mg) of **7**; amorphous; NMR, δ 0.80 and 0.86 (total 3H, 3:2, each s, 18-H), 1.06 (3H, s, 19-H), 2.09 and 2.07 (total 3H, 3:2, each s, $OCOCH_3$), 3.58 (2/3H, do d, J=10 and 5 Hz, 12-H), 3.96 (≈4H, s, OC_2H_4O and 17-H), 4.75 (1H, br m, W_H=24 Hz, 12- and 17-H), and 5.36 (1H, br, W_H=10 Hz, 6-H).

The mixture (**8a** and **8b**, 34 mg) in pyridine (2 ml) was treated with CrO_3 (340 mg) in pyridine (3.4 ml) at room temperature for 1.5 h under stirring. The reaction mixture was worked up as usual to give a 1:1 mixture of 17- and 12-ketones (**9a** and **9b**), amorphous: **9a**, 0.97 and 1.06 (each 1.5H, s, 18- and 19-H), 2.09 (1.5H, $OCOCH_3$), and 4.96 (0.5H, br, W_H=16 Hz, 12-H); **9b**, 1.14 and 1.19 (each 1.5H, s, 19- and 18-H), 2.04 (1.5H, s, $OCOCH_3$), and 5.06 (0.5H, br, W_H=20 Hz, 17-H); **9a** and **9b**, 3.94 (3H, s, OC_2H_4O) and 5.37 (1H, br, W_H=10 Hz, 6-H).

To a solution of the mixture (**9a** and **9b**, 24 mg) in ethylene glycol (6 ml) was added 85% aq hydrazine hydrate (0.18 ml) and powdered potassium hydroxide (KOH, 0.32 g). The solution was heated at 100—110 °C for 1.5 h and then refluxed at 180—190 °C for 18.5 h. The reaction mixture was cooled, poured into ice-water, and extracted with chloroform (3×40 ml). The chloroform solution was washed with 2 M HCl (2×50 ml) and water (4×80 ml), dried and evaporated

under reduced pressure to leave amorphous residue (23 mg), which was separated by preparative TLC (2 plates) over silica gel with benzene–ether (2:1). A fraction with the highest R_f value gave a crystalline substance, which was recrystallized from acetone to yield **10** (7.1 mg), mp 188—189 °C and $[\alpha]_D$ −45.6°; MS, *m/e* 332 (M^+); IR, ν_{max} 3260, 1136, 1097, 1055, and 1025 cm^{-1}; NMR, δ 0.76 and 1.05 (each 3H, s, 18- and 19-H), 3.65 (1H, t, J=8 Hz, 17-H), 3.96 (4H, s, OC_2H_4O), and 5.34 (1H, br, W_H=10 Hz, 6-H). This sample was identical with an authentic specimen[8] obtained by acetalization of **1**.

*12β-Hydroxyandrost-5-ene-3,17-dione 3,3-Ethylene Acetal (**11**).* Compound **5** (42 mg) was dissolved in benzene (20 ml) and ethylene glycol (2 ml) containing *p*-toluenesulfonic acid (*p*-TsOH, 3 mg), and the solution was refluxed (oil-bath temperature, 100±5 °C) for 16 h under stirring, water being removed under a Dean-Stark apparatus. The mixture was washed with 5% aq $NaHCO_3$ (3×50 ml) and water (3×40 ml), dried and evaporated to leave a crystalline substance, which was purified by passing through a silica gel column (1.8 g) to give **11** (31 mg), mp 219—220 °C (from ether) and $[\alpha]_D$ −70.8°; MS, *m/e* 390 (M^+) and 372; IR, ν_{max} 3540, 1105, 1028, 995, and 945 cm^{-1}; NMR, δ 0.93 and 1.05 (each 3H, s, 18- and 19-H), 3.96 (8H, br, s, $2OC_2H_4O$), and 5.35 (1H, br, W_H=10 Hz, 6-H). Found: C, 70.56; H, 8.75%. Calcd for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78%.

*Androst-5-ene-3,12,17-trione 3,3:17,17-Bis(ethylene acetal) (**12**).* To a suspended mixture of CrO_3 (300 mg) in pyridine (3 ml) was added **11** (30 mg) in pyridine (2 ml) under stirring. The mixture was stirred at room temperature for 1.5 h, cooled and then filtered. The filtrate and precipitates were washed with ethyl acetate (4×50 ml and 50 ml), respectively. All the ethyl acetate solutions were worked up as described above to leave a crystalline substance, which was purified by passing through a silica gel column (1.5 g) to give **12** (21 mg), mp 215—216 °C (from ether) and $[\alpha]_D$ +10.5°; MS, *m/e* 388 (M^+); IR, ν_{max} 1715, 1100, 1025, and 990 cm^{-1}; NMR, δ 1.08 and 1.11 (each 3H, s, 18- and 19-H), 3.94 (4H, s, 3-OC_2H_4O), 4.02 (4H, m, 17-OC_2H_4O), and 5.39 (1H, br, W_H=10 Hz, 6-H). Found: C, 71.06; H, 8.32%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%.

*Androst-5-ene-3,17-dione 3,3:17,17-Bis(ethylene acetal) (**13**) and Androst-5-ene-3,17-dione 3,3-Ethylene Acetal (**14**).* i) An ethylene glycol solution (3 ml) of **12** (9 mg) was heated with 85% aq hydrazine hydrate (0.08 ml) and KOH (0.08 g) at 100—110 °C (bath temp) for 1 h and then refluxed (bath temp, 180—200 °C) for 20 h. After being cooled, the mixture was poured into ice–water (20 ml) and then extracted with chloroform (4×40 ml). The chloroform extracts were worked up as mentioned above to yield amorphous residue (9 mg), which was purified by passing through a silica gel column (0.5 g) and crystallized on trituration with ether. Recrystallization from ethanol–ether afforded **13** (7.4 mg), mp 174—176 °C and $[\alpha]_D$ −64.0°; MS, *m/e* 374 (M^+); IR, ν_{max} 1100, 1037, 1025, and 990 cm^{-1}; NMR, δ 0.86 and 1.04 (each 3H, s, 18- and 19-H), 3.89 and 3.94 (each 4H, s, 17- and 3-OC_2H_4O). Found: C, 73.62; H, 9.17%. Calcd for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15%.

Compound **13** (45 mg) was heated with *p*-TsOH (15 mg) in acetone (15 ml) and water (3 ml) under reflux for 17 h. After being cooled, the mixture was evaporated, mixed with water and then extracted with chloroform (4×20 ml). The chloroform extracts were worked up as mentioned above to leave amorphous residue (59 mg), which was purified by passing through a silica gel column (3 g) and crystallized on trituration with ether. This was recrystallized from ether to give **14** (29 mg), mp 175—176 °C and $[\alpha]_D$ +198.8°; MS, *m/e* 286 (M^+) and 244; UV, λ_{max} 239 nm (ε 12000); IR, ν_{max} 1740, 1662, and 1613 cm^{-1}; NMR δ 0.93 and 1.23 (each 3H, s, 18- and 19-H), and 5.74 (1H, s, 4-H). Found: C, 79.49; H, 9.28%. Calcd for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15%. This compound (**14**) was identical with an authentic sample obtained by oxidation of **1** (MS, UV, IR, NMR, TLC, and mixed mp), and was converted into **1** by a known procedure.[8]

The Catalytic Reactions on Hafnium Dioxide

Yoshito Onishi,* Yasuo Iizuka, and Takuya Hamamura
Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606

(Received May 18, 1979)

Synopsis. The mechanisms of the catalytic oxidations of carbon monoxide and hydrogen on hafnium dioxide are similar to those on titanium dioxide (anatase and rutile) and zirconium dioxide, and the activation energies of these reactions have been correlated with the oxygen bond energies of these four oxides.

In previous papers, the catalytic reactions on zirconium dioxide were reported in comparison with those on titanium dioxide. There exist however little data on the catalytic reactions on hafnium dioxide.[1,2] This paper will report the catalytic reactions on hafnium dioxide in connection with those on titanium dioxide and zirconium dioxide.

Experimental

The procedure and apparatus employed were almost the same as those used previously.[3] Hafnium dioxide obtained from Ventron Alfa Products Corporation was employed as the catalyst. The sample was of spectroscopic grade and free from zirconia. From X-ray powder analysis, the specimen was shown to exist in the monoclinic form. The BET surface area was 0.66 m^2/g (N_2 at −196 °C). Hafnium dioxide (9.5 g) was used as the catalyst.

Prior to measurement, the sample in the reaction tube was evacuated to 10^{-6} mmHg** and subsequently heated at 870 °C in oxygen (75 mmHg) for 3 h to clean the surface. A mixture of carbon monoxide and oxygen or a mixture of hydrogen and oxygen when introduced to the heated hafnium dioxide produced cataytic oxidation giving carbon dioxide or water, which then condensed into the liquid nitrogen cooled traps. The reaction rate was determined by measuring the decrease in the total pressure.

Results and Discussion

Kinetic studies of the carbon monoxide oxidation on hafnium dioxide were conducted using a mixed gas of carbon monoxide and oxygen in the temperature range 400—550 °C and in the pressure range 10^{-3}—100 mmHg. The oxidation rate was proportional to the carbon monoxide pressure and independent of the oxygen pressure. Therefore, the reaction rate may be expressed by the following equation:

$$d(CO_2)/dt = k_{CO_2} \cdot P_{CO}, \quad (1)$$

where k_{CO_2} is the oxidation rate constant of carbon monoxide on hafnium dioxide.

The oxidation rate of hydrogen on hafnium dioxide was measured using a mixed gas of hydrogen and oxygen in the temperature range 450—600 °C and in the pressure range 10^{-3}—10^{-1} mmHg. The reaction rate may be expressed as follows:

$$d(H_2O)/dt = k_{H_2O} \cdot P_{H_2}, \quad (2)$$

where k_{H_2O} is the oxidation rate constant of hydrogen on hafnium dioxide.

The catalyst pretreated in oxygen (75 mmHg) at 870 °C for 3 h was cooled to the reaction temperature and evacuated. Carbon monoxide or hydrogen, at a pressure of approximately 10^{-2} mmHg, was introduced into the reaction system, whereby it reacted with the active oxygen of the catalyst and the formed carbon dioxide or water was caught in the traps. The rate of the formation of carbon dioxide and water was found to be proportional to P_{CO} or P_{H_2}, respectively:

$$d(CO_2)/dt = k_{CO} \cdot P_{CO}, \quad (3)$$

$$d(H_2O)/dt = k_{H_2} \cdot P_{H_2}, \quad (4)$$

where k_{CO} and k_{H_2} are the rate constants of the reductions of hafnium dioxide by carbon monoxide and hydrogen, respectively. The Arrhenius plots of k_{CO} and k_{H_2} are shown in Fig. 1 together with those of the oxidation rate constants k_{CO_2} and k_{H_2O}. It may be seen that k_{CO} reasonably agrees with k_{CO_2}, and k_{H_2} with k_{H_2O} at each corresponding temperature.

The catalyst was reduced by carbon monoxide at approximately 40 mmHg for 1 h. Oxygen at approximately 10^{-2} mmHg was then introduced to measure the oxidation rate of the reduced hafnium dioxide by oxygen. The oxidation rates were 1100—5300 times as large as the reduction rates of hafnium dioxide by carbon monoxide and hydrogen in the temperature range 450—600 °C.

Thus the mechanism of the oxidation of carbon monoxide on hafnium dioxide may be expressed by the following equations:

$$CO(g) + O(s) \xrightarrow{h\nu} CO_2(g) + (s), \quad (5)$$

$$(s) + 1/2\,O_2(g) \longrightarrow O(s), \quad (6)$$

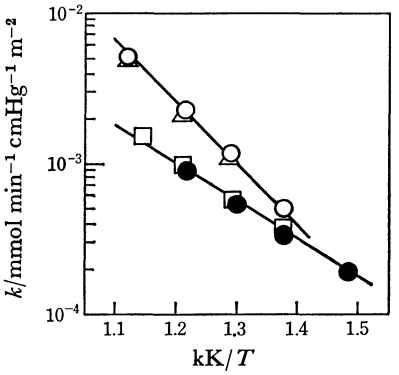

Fig. 1. Effect of temperature on the rate constant. ●: k_{CO_2}, ○: k_{H_2O}, □: k_{CO}, △: k_{H_2}.

**1 mmHg=133.322 Pa.

where O(s) refers to the active oxygen of the catalyst and (s) the oxygen defect on the surface. Step (6) is much faster than step (5), so that step (5) becomes the rate-determining step of the overall reaction. This mechanism is closely analogous to those for titanium dioxide[3] and zirconium dioxide.[4]

The oxidation of hydrogen on hafnium dioxide may be expressed as follows:

$$H_2(g) + O(s) \xrightarrow{\text{slow}} H_2O(g) + (s), \quad (7)$$

$$(s) + 1/2\,O_2(g) \longrightarrow O(s), \quad (8)$$

and similar mechanisms have been published on titanium dioxide[5] and zirconium dioxide.[6]

The thermodesorption rate of oxygen from hafnium dioxide was measured by a procedure described in previous papers.[3,4]

The activation energies of the two oxidation reactions and that of the thermodesorption of oxygen from hafnium dioxide are summarized in Table 1 together with those on anatase, rutile, and zirconium dioxide. It may be seen from Table 1 that hafnium dioxide agrees well with zirconium dioxide in the activation energies not only on the oxidations of carbon monoxide and hydrogen but also on the thermodesorption of oxygen. This is possibly a direct result of the remarkable resemblances between hafnium dioxide and zirconium dioxide in crystal structures.[7]

There have been several studies to elucidate the correlations between the strength of the metal oxygen bond of the oxidation catalysts and their activities in the several types of oxidation reaction. According to Seiyama,[8] the reactivity of oxygen on the metal oxide catalyst may be estimated by determining the equilibrium oxygen pressures of the oxide at several temperatures. Sachtler *et al.*[9,10] studied the catalytic oxidation reactions on several metal oxides, and concluded that the activity of the oxide is related to its ability to release oxygen. Boreskov *et al.*[11–15] investigated the catalytic properties of Period IV transition metal oxides, and stated that the rates of the catalytic oxidations of carbon monoxide depend upon the surface oxygen bond energies of these oxides estimated by the thermodesorption method and that a linear correlation is established between the oxygen bond energies and the activation energies of the catalytic oxidations of hydrogen and methane.

Table 1. Activation energies (E/kcal$_{th}$ mol^{-1})[a] for the oxidations of CO and H_2 and those for the thermodesorption of oxygen

Catalyst	Oxidation of CO	Oxidation of H_2	Thermodesorption of oxygen
Hafnia	11.7	19.8	42.8
Zirconia	12.5	22.6	44.0
Anatase	16.0	29.2	57.8
Rutile	6.7	17.8	38.4

a) 1 cal$_{th}$=4.184 J.

From Table 1, it may be seen that the four oxides can be arranged in the same order anatase zirconia hafnia rutile with respect to their activation energies in the catalytic oxidations of carbon monoxide and hydrogen and the thermodesorption rate of oxygen. Consequently, the activation energies of the oxidations of carbon monoxide and hydrogen on anatase, rutile, zirconium dioxide, and hafnium dioxide may be correlated with the oxygen bond energies of these four oxides.

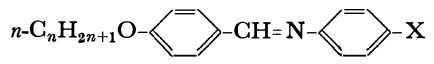
Liquid Crystalline Properties of *N*-(4-Alkoxybenzylidene)-4-halogenoanilines

Sakumitsu SAKAGAMI* and Minoru NAKAMIZO
National Industrial Research Institute of Kyushu, Tosu, Saga 841

(Received July 3, 1979)

Synopsis. *N*-(4-Alkoxybenzylidene)-4-halogenoanilines have been synthesized, and the phase transitions determined using a differential scanning calorimeter and a polarizing microscope. Smectic and nematic phases have been observed for fluoro and chloro derivatives whereas bromo and iodo derivatives exhibit only a smectic phase.

A number of investigations have been conducted on the relationship between molecular structure and liquid crystallinity.[1-4] The vast majority of compounds exhibiting a liquid crystalline phase may be regarded as consisting of a rigid central group and a flexible end group.[4] In order to understand the relationship between liquid crystallinity and terminal substituents, the homologous series of *N*-(4-alkoxybenzylidene)-4-halogenoanilines has been synthesized. The members of this homologous series having the generallized structural formula have been given the



abbreviation *n*-O-X, in which the value of *n* ranges from 1 to 8 and X denotes a halogen atom.

Experimental

Materials. The *N*-(4-alkoxybenzylidene)-4-halogenoanilines were prepared by condensing 4-halogenoaniline with an equimolar amount of 4-alkoxybenzaldehyde in absolute ethanol. The reaction mixture was refluxed for one hour after which the product was collected as a solid crystalline precipitate. The product was recrystallized two or three times from ethanol and benzene.

Measurements. The liquid crystalline texture and the transition temperatures were determined by a Nikon polarizing microscope equipped with a Mettler FP 52 microfurnace and control unit. Checks on the transition temperatures and the measurement of enthalpies of transitions were made using a Rigaku differential scanning calorimeter.

Results and Discussion

The transition temperatures and the heats of transition in the case of the homologous series *n*-O-F are given in Table 1. In this series the only methoxy member shows no mesomorphic property, all the other higher members exhibiting a smectic II phase. The pentyloxy and hexyloxy members of this series show an enantiotropic smectic II phase although the smectic II phases of the other members occur monotropically. With increasing alkoxyl chain another feature is found on the appearance of the smectic phase, *i.e.*, a smectic I phase is enantiotropically observed for the hexyloxy to octyloxy members. On cooling the nematic state of the hexyloxy member, focal conic or fan texture may be observed for the smectic I phase. In addition, the focal conic or fan textures are easily changed to a pseudo-isotropic texture (homeotropic alignment) by cover slip displacement. The characteristic behavior of the textures indicates that the smectic I phase can be identified as smectic A.[5] In the phase transition from smectic I to smectic II transition bars are temporarily formed. On further cooling the transition bars disappear, and mosaic or fan-shaped textures similar to those observed for the smectic I phase are found. It should be emphasized that on cooling the smectic I phase with homeotropic alignment, the homeotropic alignment is also maintained in the smectic II phase. From these characteristic changes in microscopic textures, it follows that the smectic II phase can be classified as smectic B.[5] Smectic polymorphism is not unusual, and has been frequently observed as the alkoxyl chain length increases in other homologous series of liquid crystalline materials.[4]

Table 1. Thermodynamic data for the homologous series, *n*-O-F

n	Smectic B(II)	Smectic A(I)	Nematic	Isotropic
1				63.0 4800
2	(56.0) (1800)		(62.5) (140)	72.2 4900
3	(55.0) (1800)			62.1 5400
4	(58.0) (1700)		(59.6) (130)	64.5 6300
5	51.5 3800			57.4 1900
6	52.3 5200	55.0 640	59.3 770	61.1 150
7	(56.4) (640)	57.0 7200		61.6 1100
8	(54.3) (590)	60.0 7700		63.6 1000

The upper value indicates the transition temperature (°C) and the lower value the heat of transition (cal/mol). 1 cal=4.184 J. The parentheses show the monotropic transition.

Furthermore, it should be noted that a nematic phase occurs only for ethoxy, butoxy, and hexyloxy members. That the nematic phase can only be observed for homologues with even numbers of carbon atoms in alkoxyl chain is not surprising, and can be explained by considering the chain-order parameter of the end alkoxyl group with respect to the molecular axis.[6]

The phase transition temperatures of the homologous series *n*-O-Cl are given in Table 2. In this series the appearance of liquid crystalline phases is similar to that observed for *n*-O-F as stated above. As the length of the alkoxyl chain is increased, two smectic phases, *i.e.*, smectic A and B phases are found. It should be emphasized however that the nematic phase is monotropically observed for only ethoxy member. This indicates that increasing the ionic radius of the terminal substituent tends to destroy the parallel orientation of the molecules. This observation is more

Table 2. Thermodynamic data for the homologous series, *n*-O-Cl

n	Smectic B	Smectic A	Nematic	Isotropic
1				90.2 8300
2			(85.0) (151)	94.0 6500
3	(81.5) (1900)			82.0[a]
4	83.5 5000	88.6 900		89.4 1200
5	58.5 4400	90.7 840		92.8 1300
6	56.5 5200	88.7 750		96.3 1300
7	59.4 6500	89.4 770		97.5 1300
8	61.0 6100	87.7 740		98.5 1300

a) The heat of transition could not be determined due to complex crystal-to-crystal transitions.

Table 3. Thermodynamic data for the homologous series, *n*-O-Br

n	Smectic B	Smectic A	Isotropic
1			115.0 5000
2			103.1 4100
3	(92.2) (2200)		94.1 4500
4	78.5 4500		99.1 2300
5	71.9 5100	100.5 850	103.2 1500
6	72.1 5100	100.4 830	103.3 1400
7	64.5 6600	100.7 870	103.8 1600
8	65.4 6100	100.1 860	104.9 1600

readily demonstrated in Tables 3 and 4 which show the phase transition temperatures for *n*-O-Br and *n*-O-I, respectively. In both homologous series the nematic phase is no longer found. In the homologous series, *n*-O-I, the smectic B phase alone is observed

Table 4. Thermodynamic data for the homologous series, *n*-O-I

n	Smectic B	Isotropic
1		149.5 6800
2		132.8 5100
3		117.0 4300
4	78.0 3000	111.4 2600
5	72.7 4300	108.5 2500
6	85.7 5400	110.3 2600
7	80.1 6300	110.7 2600
8	79.0 6500	110.8 2700

while in the series *n*-O-Br both the smectic A and B phases are exhibited depending on the length of the alkoxyl chain.[7]

7) Vora has recently studied the phase transitions of the series *n*-O-Br. There is an essential discrepancy between his and the present data besides the slight difference in transition temperatures. According to Vora the smectic B phase may be observed only for the hexyloxy member which is in contrast with the results reported here. This discrepancy could be ascribed to the fact that the authors determined the phase transitions from both the DSC measurements and microscopic observations while Vora employed only an optical microscope to identify the smectic phases. On the Nature of the 5,10-Dimethyl-5,10-dihydrophenazine–Tetracyanoquinodimethane

Isao FUJITA and Yoshio MATSUNAGA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 18, 1979)

Synopsis. The 5,10-dimethyl-5,10-dihydrophenazine–tetracyanoquinodimethane appears to be largely ionic at room temperature. The results of various physical measurements of this compound can be explained without the reversible nonionic-to-ionic transition proposed by Soos *et al.*

The 1:1 compound between 5,10-dimethyl-5,10-dihydrophenazine (DMPH) and tetracyanoquinodimethane (TCNQ) has been prepared by Melby by the treatment of $DMPH^+I^-$ in hot absolute ethanol with a boiling solution of Li^+TCNQ^- dissolved in the same solvent.[1] He has suggested that the solid compound is represented as a pi-complex rather than as an ion-radical salt. The structure and the packing arrangement of this compound have been studied by Goldberg and Shmueli.[2] The structure consists of stacks in which the DMPH and TCNQ molecules alternate along the c axis. On the basis of the intrastack contacts and the molecular geometry of TCNQ, these authors have postulated the presence of rather strong charge transfer interactions.

Recently, Soos *et al.* have reported measurements of the ESR spectrum.[3] At room temperature, DMPH–TCNQ powder exhibits a very weak ESR signal at $g=2.0026$. An additional exchange-narrowed signal at $g=2.0035$ appears on heating. The intensity of the latter increases rapidly with a rise in the temperature. They have considered the compound to be largely neutral and diamagnetic at 300 K and to undergo an unusual reversible transition to a paramagnetic state at 390 K. The same group has reported an increase in the activation energy for semiconduction around 360 K.[4] Earlier, one of the present authors isolated two differently-colored forms of 7-methylbenzo[*a*]phenazinium–TCNQ.[5] The violet form is largely ionic, while the green form is not. Although the transformation of the green form to the violet one was observed in the presence of a solvent, the crystals were found to be stable once they were isolated. As it seemed unlikely to us that the nonionic-to-ionic transition proposed by Soos *et al.* occurs without hysteresis, a further study of this compound was undertaken.

5,10-Dimethyl-5,10-dihydrophenazine was prepared by means of the method described by Gilman and Dietrich[6] and was subsequently purified by sublimation in a vacuum. By the treatment of the phenazine with one equivalent of TCNQ separately dissolved in hot acetonitrile, dark violet DMPH–TCNQ crystals were precipitated. Found: C, 75.54; H, 4.37; N, 20.07%. Calcd for $C_{14}H_{14}N_2$–$C_{12}H_4N_4$: C, 75.28; H, 4.38; N, 20.28%.

The temperature dependence of the ESR signals examined at the X band exactly reproduced the observation described by Soos *et al.* Furthermore, three pairs of resonance lines characteristic of triplet-spin excitons could be recorded with the polycrystalline sample. The zero-field splitting parameters, $|D/g\beta|$ and $|E/g\beta|$, are 149 and 21 G (1 G=10^{-4}T) at 327 K. As the temperature is increased, the lines are broadened and the splittings become less, the values at 380 K being 135 and 18 G. Our observation reasonably agrees with the results reported by Nöthe *et al.*, namely, 144 and 20 G at 339 K[4]. The room temperature resistivity of polycrystalline compactions measured by a four-probe method is in accord with the value of 6×10^6 ohm cm reported by Melby. The activation energy for semiconduction is 0.51 eV below 350 K and 0.65 eV in the higher-temperature region. The former value is in good agreement with the value of 0.50 eV obtained by two-probe single crystal measurements.[4] Consequently, we suppose that our DMPH–TCNQ sample is identical with that prepared by Soos *et al.*

The vibrational spectrum of TCNQ is known to be considerably modified by the addition of an extra electron;[7] therefore, it is not difficult to distinguish between the nonionic and ionic complexes by examining the spectrum. In Fig. 1, the spectrum of DMPH–TCNQ is compared with those of TCNQ and K^+-$TCNQ^-$, all examined as Nujol mineral oil mulls at room temperature. As the bands appearing at 1580, 1520, 1320, 1167, 844, and 710 cm^{-1} approximately constitute the pattern of the $TCNQ^-$ ion, the compound appears to be largely ionic under the conditions ex-

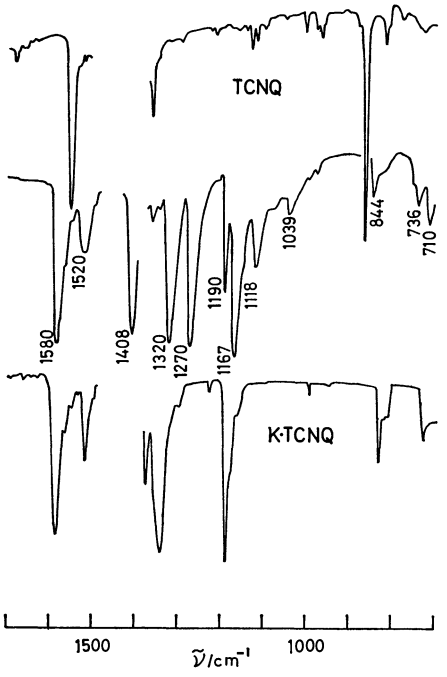

Fig. 1. Vibrational spectrum of the 5,10-dimethyl-5,10-dihydrophenazine–tetracyanoquinodimethane compared with those of TCNQ and K^+TCNQ^-.

amined. The measurements were performed at several temperatures up to 410 K; however, no change could be observed except for slight shifts to the lower-energy side.

As a distinct difference in the electronic spectrum has been seen between the nonionic and ionic forms of 7-methylbenzo[*a*]phenazinium–TCNQ, some changes may be expected in the specrtum of DMPH–TCNQ if the proposed transition takes place upon an increase in the temperature. The spectrum recorded as Nujol mineral oil mulls at room temperature shows absorption maxima at 6.8×10^3, about 16×10^3, and 27.5×10^3 cm^{-1}, with a shoulder around 23×10^3 cm^{-1}. These spectral features could be reproduced by diffuse-reflectance measurements of a sample diluted with sodium chloride. The maxima are located at 6.8×10^3, 17.2×10^3, and 27.5×10^3 cm^{-1}, with a shoulder around 24×10^{-3} cm^{-1}. By means of the latter technique, we examined the spectrum at several temperatures up to 473 K; nonetheless, no change could be detected in the spectral pattern.

The Seebeck coefficient, as measured with a polycrystalline compaction, is negative throughout the range from room temperature to 385 K, as is shown in Fig. 2. The open and shaded circles indicate points taken in the processes of increasing and decreasing the temperature respectively. A broad minimum of about -100 μV K^{-1} is located near 350 K. Such a change in the slope is commonly found when the contribution of impurities or imperfections cannot be ignored in the lower-temperature region.[8] If this interpretation is correct, the change in the activation energy of semiconduction may be attributed to the extrinsic conduction dominant below 350 K rather than to the nonionic-to-ionic transition around that temperature.

Differential scanning calorimetric measurements carried out up to 420 K showed that no enthalpy change takes place, at least not in a relatively narrow temperature range. Moreover, the X-ray diffraction pattern of the polycrystalline sample recorded at about 390 K was found to be the same as that recorded at room temperature.

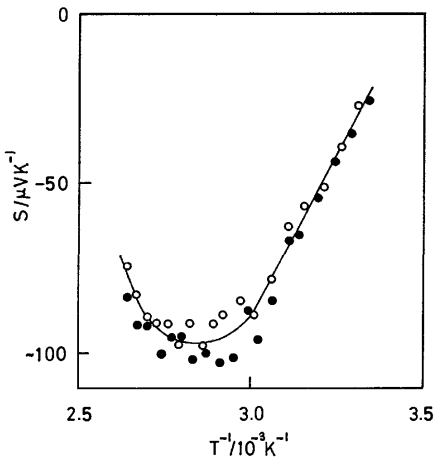

Fig. 2. Seebeck coefficient of the 5,10-dimethyl-5,10-dihydrophenazine-tetracyanoquinodimethane.

The newly obtained results lead to the conclusions that, basically, the DMPH–TCNQ is ionic at room temperature and that the nonionic-to-ionic transition does not occur in this solid complex. The former conclusion seems, though, to be inconsistent with the number of electrons per TCNQ molecule (0.30) estimated by Flandrois and Chasseau based on the bond lengths in the TCNQ molecule determined by Goldberg and Shmueli.[9] The ground state of the DMPH–TCNQ is supposed to be singlet because of an antiferromagnetic exchange interaction, as has been found for a number of ionic charge-transfer complexes. A change in the weak ESR signals appearing near $g=2.00$ with the temperature is not unknown for such complexes. Faucher and Robert have examined the ESR spectrum of powder and single crystals of the *p*-phenylenediamine–*p*-chloranil and have found two magnetic species in it.[10] One of them has an isotropic *g*-factor of 2.0035, and its intensity varies following the classic Curie law. The other species exhibits temperature-dependent *g*-factor splittings, and the spin density shows an exponential dependence with an activation energy of 0.22 eV. Because of this complication, the powder spectrum is markedly dependent on the temperature.

The observations described above were supplemented with some measurements of a related compound; that is, the 5,10-diethyl-5,10-dihydrophenazine–TCNQ is largely ionic, judging from the vibrational spectrum. Triplet-spin excitons can also be found in this compound. The zero-field splitting parameters are 147 and 19 G at 310 K and 141 and 18 G at 380 K. In this case, too, a weak signal in the $g=2.00$ region at room temperature is reversibly replaced by a rapidly growing signal with a little larger *g*-value when the temperature is increased. The zero-field splitting parameters obtained here compare well with those observed for the ionic form of 7-methylbenzo[*a*]-phenazinium–TCNQ and also with those reported for a number of simple TCNQ salts.

Reaction between Aluminium Trichloride and Oxygen in the Vapor Phase and Properties of the Aluminium Oxide Formed

Yuichi SHOJI, Kimikazu TATSUMI, Ryoko MATSUZAKI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received April 23, 1979)

Synopsis. The reaction between gaseous $AlCl_3$ and oxygen occurs at above *ca.* 400 °C and proceeds appreciably above *ca.* 800 °C to form Al_2O_3 and chlorine. The Al_2O_3 formed is amorphous Al_2O_3 at 800 °C, γ-Al_2O_3 containing amorphous Al_2O_3 at 900 and 950 °C, and γ-Al_2O_3 at 1000 °C. The phase transition of the Al_2O_3 formed is discussed.

There is limited data on the reaction between gaseous aluminium trichloride($AlCl_3$) and oxygen. Kato *et al.*[1] have studied the modification and the particle size distribution of the aluminium oxide(Al_2O_3) prepared by the reaction between gaseous $AlCl_3$ and oxygen mainly at 1100 °C and the thermal transition of δ-Al_2O_3 formed. In this paper, the reaction between gaseous $AlCl_3$ and oxygen at temperatures below 1000 °C, and the products formed have been examined by X-ray analysis, thermogravimetry(TG), differential thermal analysis(DTA), and electron microscopy.

Experimental

The $AlCl_3$ used was prepared by the reaction between pure aluminium (Al: 99.99%) and chlorine at 400 °C, and confirmed as $AlCl_3$ by X-ray analysis.[2] Found: Al, 20.2; Cl, 79.8%. Calcd for $AlCl_3$: Al, 20.24; Cl, 79.76%.

A transparent quartz reaction tube (1000 mm length) with an inner concentric tube was used. Gaseous $AlCl_3$ was formed by heating $AlCl_3$ placed in the inner tube at 150 °C, and was carried by a stream of argon (40 cm^3/min) to the reaction zone (27 mm i.d. and 250 mm length) held at a specified temperature. In the meantime, pre-dried oxygen was introduced through a separate tube into the reaction zone at a flow-rate of 100 cm^3/min. The mean flow-rate of the $AlCl_3$ was approximately 3.8 cm^3 Al_2Cl_6(g)/min. The reaction was allowed to proceed for 2 h.

The amount of chlorine formed during the reaction was determined by iodometry after being absorbed in potassium iodide solution.

The unreacted $AlCl_3$ which was deposited together with the Al_2O_3 formed was separated by heating the mixture in an argon stream at 250 °C, a temperature higher than the sublimation point of $AlCl_3$ (180 °C).[3] Removal of the $AlCl_3$ adsorbed on Al_2O_3, which could not be removed by the above heating procedure, was conducted as follows: The Al_2O_3 (0.5—1.0 g) was washed with ethanol (100 cm^3) in an Erlenmeyer flask with a reflux condenser at boiling point for 2 h with stirring. The Al_2O_3 was separated from the ethanol phase by a centrifuge. The washing was repeated until no chlorine could be detected in the ethanol phase. The aluminium content in the ethanol phase was determined by chelatometric titration,[4] and the chlorine content by a Corning-ELL Chloride Meter Model 921.

Throughout this work, $AlCl_3$ was handled in an argon atmosphere to prevent any contamination with moisture in the air.

X-Ray analysis of the solid product was performed with an X-ray powder diffractometer, equipped with a proportional counter, using Ni filtered Cu radiation. TG and DTA were performed in an argon stream and a heating rate of 5 °C/min was employed. The sensitivity of the quartz helix used for TG was approximately 71 mm/g. α-Al_2O_3 was used as a reference for DTA.

The percentage of the reacted $AlCl_3$ was calculated from the amount of chlorine formed, the value also being evaluated from the amount of Al_2O_3 formed. Both values showed good agreement with each other.

Results and Discussion

The formation of chlorine by the reaction between gaseous $AlCl_3$ and oxygen was observed above 400 °C. The percentages of the reacted $AlCl_3$ at various temperatures are shown in Fig. 1. The percentage of reacted $AlCl_3$ was very low below 700 °C (less than 2.5%), and the reaction between gaseous $AlCl_3$ and oxygen proceeded appreciably above 800 °C.

The products formed above 800 °C were examined by X-ray analysis and TG after removal of the unreacted $AlCl_3$.

The products formed at 800 and 900 °C could not be identified by X-ray analysis, because the former gave no diffraction line and the latter gave a faint and diffuse diffraction line (2θ=67°) alone. The products obtained at 950 and 1000 °C gave diffraction lines corresponding to γ-Al_2O_3.[5,6]

The products formed at 800, 900, and 950 °C gradually lost weight in the temperature range 350—900 °C, and the final weight losses were 18, 10, and 5%, respectively. It was observed that a white powder was deposited on a cooler part during the weight loss. The product formed at 1000 °C showed no weight change. The white powder mentioned above was identified as $AlCl_3$ by chemical analysis in a sub-

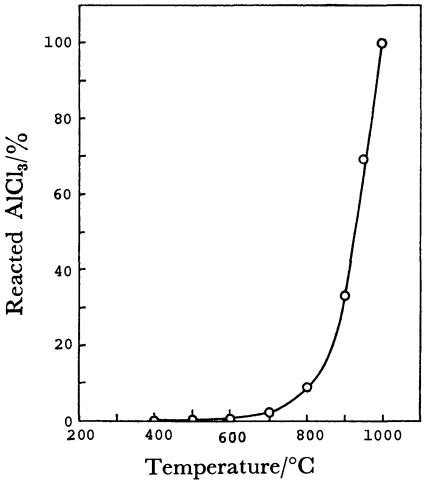

Fig. 1. Reaction rates of $AlCl_3$ with oxygen at various temperatures.

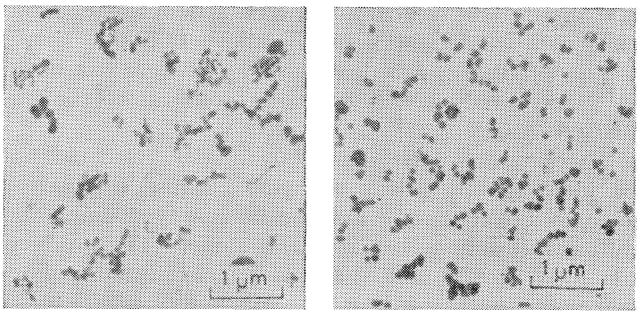
sequent experiment. From the results, it may be assumed that the $AlCl_3$ adsorbed on the fine powders of Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and oxygen vaporized when the Al_2O_3 was heated above approximately 350 °C.

The removal of the $AlCl_3$ adsorbed on the products formed at 800—950 °C was conducted by washing the products with ethanol, in order to prepare the sample for examination. From the chemical analysis of the Al and Cl contents in the ethanol phase, it was confirmed that $AlCl_3$ was dissolved in the ethanol phase. The X-ray diffraction patterns of the products after the washing showed no change in comparison with those of the products before the washing. The products freed from $AlCl_3$ were examined by TG. All prodcuts showed no weight change.

The Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and oxygen at various temperatures were examined by electron microscopy. The Al_2O_3 formed was found to be an ultrafine powder with diameters of the order of 1/100 μm. Electron micrographs of the Al_2O_3 formed at 900 and 1000 °C are shown in Fig. 2.



(a) (b)

Fig. 2. Electron micrographs of the Al_2O_3 formed. (a): 900 °C, (b): 1000 °C.

The Al_2O_3 formed at various temperatures were examined by DTA. The DTA curves of the Al_2O_3 formed at 800, 900, and 950 °C showed a weak exothermic effect in the vicinity of 820 °C. The sample after heating the Al_2O_3 formed at 800 °C up to 900 °C was found by X-ray analysis to be χ-Al_2O_3.[5,7] The samples after heating the Al_2O_3 formed at 900 and 950 °C were found to be a mixture of χ-Al_2O_3 and γ-Al_2O_3. The Al_2O_3 formed at 1000 °C showed no thermal effect in the DTA cuvre, and gave no change in X-ray diffraction pattern (γ-Al_2O_3) on heating.

The Al_2O_3 obtained by heating the Al_2O_3 formed at 800—1000 °C at a specified temperature for 2 h was examined by X-ray analysis. The results are summarized in Table 1.

From the experimental results above, the Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and oxygen at 800 °C is amorphous Al_2O_3. On heating the amorphous Al_2O_3, the amorphous→χ→κ→α transition occurs. The Al_2O_3 formed by the reaction at 1000 °C is γ-Al_2O_3. On heating the γ-Al_2O_3, the γ→δ→θ→α transition occurs.

Table 1. Thermal transitions of Al_2O_3 formed at various temperatures

Heating temp/°C	Formation temperature of Al_2O_3			
	800 °C	900 °C	950 °C	1000 °C
Room temp	Amorphous	γ	γ	γ
600	Amorphous	γ	γ	—
700	χ	χ, γ	$\gamma>\chi$	—
800	$\chi>\kappa$	$\chi>\gamma>\kappa$	$\gamma>\chi\gg\kappa$	—
900	χ, κ	$\chi>\gamma$, κ	$\gamma>\chi$, κ	γ
1000	$\kappa>\alpha$	κ, $\delta>\alpha$	$\delta>\alpha$, κ	γ, δ
1100	$\alpha>\kappa$	α, $\theta>\delta$	δ, θ, α	δ, $\theta\gg\alpha$
1200	α	$\alpha>\theta$	α, θ	$\theta>\alpha$
1300		$\alpha>\theta$	$\alpha>\theta$	α, θ

Amorphous=amorphous Al_2O_3, γ=γ-Al_2O_3, χ=χ-Al_2O_3, κ=κ-Al_2O_3,[5,8] α=α-Al_2O_3,[9] δ=δ-Al_2O_3,[5,10] θ=θ-Al_2O_3.[11]

As mentioned before, the Al_2O_3 formed at 900 °C gave a faint and diffuse diffraction line (2θ=67°; corresponding to the strongest line of γ-Al_2O_3) alone. The Al_2O_3 formed at 950 °C showed diffraction lines corresponding to γ-Al_2O_3. The DTA curves of both the Al_2O_3 formed at 900 and 950 °C showed a weak exothermic effect due to the crystallization of amorphous Al_2O_3 to χ-Al_2O_3. As shown in Table 1, on heating the Al_2O_3 formed at 900 and 950 °C, the both amorphous→χ→κ→α and γ→δ→θ→α transitions occurred. Thus the Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and oxygen at 900 °C comprises amorphous Al_2O_3 and γ-Al_2O_3 and the Al_2O_3 formed by the reaction at 950 °C is γ-Al_2O_3 containing amorphous Al_2O_3.

The thermal transition of amorphous Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and oxygen differs from the thermal transition of amorphous Al_2O_3 prepared by the thermal decomposition of $Al(NO_3)_3\cdot 9H_2O$, $AlCl_3\cdot 6H_2O$, and $Al(CH_3COO)_3$ in which the transition has been reported to be the amorphous→γ→δ→θ→α.[12]

Electron Spin Resonance Spectra of Square Planar Cobalt(II) Complexes with Various N_4-Macrocyclic Ligands

Yuzo NISHIDA,* Kazuki HAYASHIDA, Akira SUMITA, and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received May 18, 1979)

Synopsis. ESR spectra of square planar cobalt(II) complexes with various N_4-macrocyclic ligands were measured, the results being discussed in relation to the π-basicity and π-conjugation of the macrocyclic ligands.

Square planar low-spin cobalt(II) complexes can be classified into complexes of the $(d_{xy})^2(d_{z^2})^1$ ground state(Type I) and those of the $(d_{xy})^2(d_{yz})^1$ ground state(Type II).[1-5] The diagnosis of the compounds can be carried out by means of ESR spectra; $|A_3|$ (g_3 is the ESR peak observed at the highest field) is always larger than 100×10^{-4} cm^{-1} in Type I complexes but much smaller than this in Type II compounds. A number of compounds were subjected to analysis on this basis. From the results, it was found that complexes with electrically neutral ligands, phthalocyanine and porphyrins belong to Type I, and those with dinegatively charged ligands to Type II. This is interpreted as Type I complexes being formed with π-neutral or very weak π-basic ligands, and Type II complexes with fairly strong π-bases.[6]

In this study, we have measured the ESR spectra of square planar cobalt(II) complexes with tetraaza-macrocyclic ligands (Fig. 1 (e)—(j)) in order to confirm this view.

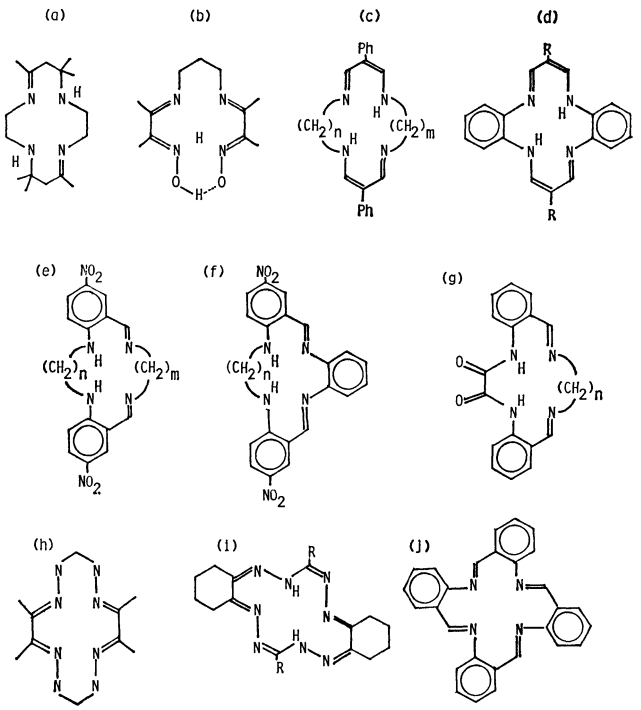

Fig. 1. N_4-Macrocyclic ligands cited in this paper. Abbreviations are: (a); (a-14), (b); H(b-14), (c); H_2(c-14), $n=m=2$, H_2(c-15), $n=2$, $m=3$, (d); H_2(d-14), R=phenyl, H_2(d-14′), R=*p*-tolyl, (e); H_2(e-14), $n=m=2$, H_2(e-15), $n=2$, $m=3$, H_2(e-15′), $n=3$, $m=2$, (f); H_2(f-14), $n=2$, H_2(f-15), $n=3$ (g); H_2(g-14), $n=2$, H_2(g-15), $n=3$, (h); (h-14), (i); H_2(i-14), R=CH_3, H_2(i-14′), R=C_2H_5, (j); (j-16).

Experimental

Preparation. The ligands and their metal complexes were prepared according to the methods reported. ((e),[7] (f),[7] (g),[8] (h),[9] (i),[10] and (j)[11]). New compounds were prepared as follows.

[Co(i-14)]: To a methanol solution (20 ml) of cobalt(II) acetate (0.001 mol) was added a benzene solution (10 ml) of the ligand, H_2 (i-14) (*cf.* Fig. 1, R=CH_3) (0.001 mol) under an atmosphere of nitrogen, and the resulting solution was warmed at 60 °C for 1 h. After the solution had been cooled, violet crystals deposited.

H_2 (f-14) and H_2 (f-15): A DMF solution (100 ml) of $[Mn(py)_4(NCS)_2]$[12] (0.001 mol), *N,N′*-bis(2-formayl-4-nitrophenyl)ethylenediamine[7] (0.001 mol) (or its 1,3-propanediamine derivative) and *o*-phenylenediamine (0.002 mol) was refluxed for several hours. After the solution had beed cooled, yellow crystals deposited. Analytical data of the compounds are given in Table 1.

Table 1. Analytical data of the new compounds

Compound	Found (Calcd) (%)		
	C	H	N
H_2(f-14)	61.19(61.39)	4.18(4.22)	19.47(19.52)
H_2(f-15)	61.89(62.16)	4.50(4.54)	18.90(18.90)
[Co(f-14)][a]	53.76(53.79)	3.32(3.35)	17.32(17.11)
[Co(f-15)][a]	55.02(54.58)	3.62(3.59)	16.79(16.63)
[Co(i-14)]	50.10(49.87)	5.92(5.75)	29.53(29.08)
[Co(i-14′)]	52.81(52.30)	6.43(6.34)	27.44(27.11)

a) Obtained by the use of free ligands obtained in this study, and not a new complex.

Measurements. ESR spectra were obtained with a JEOL ESR apparatus model MEX-3X at liquid nitrogen temperature. For ESR measurements, all the cobalt(II) complexes were diluted in the corresponding nickel(II) complexes. The diluted samples were obtained by the use of template reactions except for [Co(f-14)] and [Co(f-15)]. For the latter complexes, the free ligands we prepared were used for obtaining diluted samples.

Results and Discussion

The ESR parameters are summarized in Table 2 together with some related data.[2-4] It is seen that the complexes are satisfactorily classified into Types I and II by their $|A_3|$ values. The results are completely in line with our view that all the complexes with dinegatively charged ligands belong to Type II.

In some Type II pairs of compounds, [Co(c-14)] and [Co(d-14)], [Co(e-14)], and [Co(f-14)], and [Co(e-15)] and [Co(f-15)], π-conjugation is assumed to be

a) This work. b) Accurate values not obtained.

more developed in the latter than in the former, because ethylenediamine-ring is substituted for *o*-phenylenediamine-ring in the latter complexes. g_1 and $|A_1|$ (the ESR peak observed at the lowest field) of the latter complexes are larger than those of former complexes. This can be explained by the theoretical interpretation of g and $|A|$ values for square planar cobalt(II) complexes.[3] We showed that g_1 (and also $|A_1|$) corresponds to g_x ($|A_x|$) in Type II complexes, increasing considerably with decrease in Δ_{z^2}, which denotes the energy difference between $(d_{xy})^2(d_{z^2})^1$ and $(d_{xy})^2(d_{yz})^1$ states (*cf.* Fig. 2 in Ref. 3). From the results of X-ray crystal structure determination on analogous complexes,[13] it can be expected that all the 14-membered macrocyclic metal complexes such as [Co(c-14)], [Co(d-14)], [Co(f-14)], and [Co(i-14)], have essentially a planar structure. Thus, the present ESR results suggest that the increase of π-conjugation brings about the decrease of the energy difference between $(d_{xy})^2(d_{z^2})^1$ and $(d_{xy})^2(d_{yz})^1$, *i.e.*, the ground state of Type II compound approaches the cross-over region between Type I and Type II, when π-conjugation of the ligand increases.

Induced Circular Dichroism Spectra of Some Racemic *cis*-Bis(ethylenediamine)cobalt(III) Complexes in Aqueous (*R,R*)-Tartrate and (*R,R*)-Tartratoantimonate(III) Solutions and Their Optical Resolution by Ion-exchange Chromatography

Hiroshi NAKAZAWA, Chang Eon OH, Katsuhiko MIYOSHI, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received June 25, 1979)

Synopsis. Induced circular dichroism (induced CD) was measured for some racemic cobalt(III) complexes in aqueous (*R,R*)-tartrate and (*R,R*)-tartratoantimonate(III) solutions, and correlation was examined between the sign of their induced CD spectra and their elution order in ion-exchange chromatography.

In a previous paper,[1] it was demonstrated that relatively weak circular dichroism (CD) induced in the first d-d transition region for a series of racemic tervalent cobalt(III) complexes of the type *cis*-[Co(RNH$_2$)$_2$(en)$_2$]$^{3+}$ in aqueous (*R,R*)-tartrate (*d*-tart^{2-}) and (*R,R*)-tartratoantimonate(III) (Sb$_2$*d*-tart$_2^{2-}$) solutions owes its origin to the differential CD change between the two enantiomers of each complex upon the addition of these chiral anions. It was proposed that the induced CD spectrum serves as a measure of chiral discrimination effected by *d*-tart^{2-} or Sb$_2$*d*-tart$_2^{2-}$. An attempt was made to correlate the sign of the induced CD spectrum of a racemic complex with the elution order in its chromatographic resolution on an ion-exchange column with *d*-tart^{2-} or Sb$_2$*d*-tart$_2^{2-}$ as an eluent. In the present study, a similar attempt was made for some bi- and univalent bis(ethylenediamine)cobalt(III) complexes whose absolute configurations were established by X-ray diffraction and/or assigned on the basis of their CD spectra.

Experimental

Metal Complexes. Metal complexes [Co(tn)$_3$]$^{3+}$,[2] [Co(gly)(en)$_2$]$^{2+}$,[3] [Co(β-ala)(en)$_2$]$^{2+}$,[3] [Co(acac)(en)$_2$]$^{2+}$,[4] [Co(ox)(en)$_2$]$^{+}$,[5] [Co(mal)(en)$_2$]$^{+}$,[5] *cis*-[Co(CN)$_2$(en)$_2$]$^{+}$,[6] *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^{+}$,[6,7] *cis*-[Co(NCS)$_2$(en)$_2$]$^{+}$,[7] and *cis*-[Co(N$_3$)$_2$(en)$_2$]$^{+}$,[6,7] were prepared as appropriate salts and, when necessary resolved by pertinent methods. They were found to be chromatographically pure and were identified by their absorption and/or CD spectra.

Chromatographic Resolution and Measurements. Chromatographic resolution was carried out in the same way as reported,[1,3] and found incomplete for most of the complexes. Since partial resolution is often attained on an SP-Sephadex column even with achiral eluents owing to the chirality of the resin,[8] Dowex 50W-X2 resin was used to confirm that the resulting elution order was not determined by the chirality of SP-Sephadex resin. Induced CD spectra were recorded for racemic complexes (0.01 mol dm^{-3}) in aqueous solutions containing sodium (*R,R*)-tartrate (0.1 mol dm^{-3}) or sodium (*R,R*)-tartratoantimonate(III) (0.1 mol dm^{-3}) at ambient temperature.

Results and Discussion

Figure 1 shows the induced CD spectra in the first d-d transition region obtained for all the racemic complexes in aqueous *d*-tart^{2-} and Sb$_2$*d*-tart$_2^{2-}$ solutions. Only one CD component is induced for all of the tris-chelate complexes. Their Λ-enantiomers except for [Co(tn)$_3$]$^{3+}$ have in common a positive main CD component[3-6] in the first d-d transition region, its magnitude being diminished upon the addition of *d*-tart^{2-} or Sb$_2$*d*-tart$_2^{2-}$. Thus negative and positive induced CD obtained for these complexes indicates that the Λ- and Δ-enantiomers, respectively, are subjected to a greater CD change upon addition of *d*-tart^{2-} or Sb$_2$*d*-tart$_2^{2-}$.[1] The enantiomer for which the eluent has a stronger affinity should be eluted faster in ion-exchange chromatography. It is thus possible to predict the elution order from the sign of the induced CD if stronger interaction of these chiral anions with the complex leads to a greater change in its natural CD spectrum.

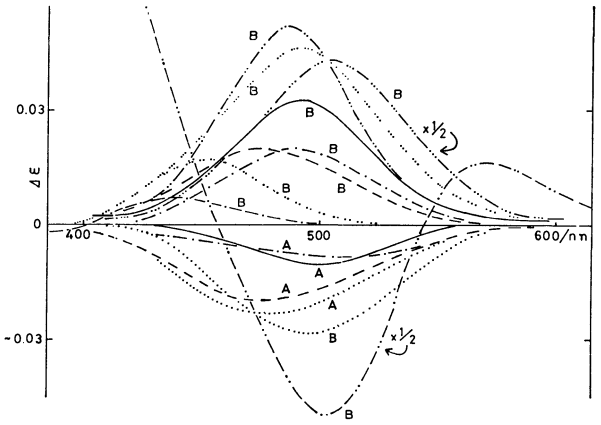

Fig. 1. Induced CD spectra in the first d-d transition region for racemic complexes in aqueous *d*-tart^{2-} (A) and Sb$_2$*d*-tart$_2^{2-}$ (B) solutions; [Co(tn)$_3$]$^{3+}$(———), [Co(gly)(en)$_2$]$^{2+}$ (·····), [Co(β-ala)(en)$_2$]$^{2+}$ (— — —), [Co(acac)(en)$_2$]$^{2+}$ (—·—·), [Co(ox)(en)$_2$]$^{+}$ (—···—···), [Co(mal)(en)$_2$]$^{+}$ (—··—··), *cis*-[Co(CN)$_2$(en)$_2$]$^{+}$ (— —·— —), *cis*-[Co(NO$_2$)$_2$(en)$_2$]$^{+}$ (·· ·· ·· ··), *cis*-[Co(NCS)$_2$(en)$_2$]$^{+}$ (··· ··· ··· ···), and *cis*-[Co(N$_3$)$_2$(en)$_2$]$^{+}$ (— —·· — —).

In Table 1 are summarized the sign of the induced CD spectra and the absolute configurations of the enantiomers for which *d*-tart^{2-} or Sb$_2$*d*-tart$_2^{2-}$ is expected to have a greater affinity as judged from the signs of the corresponding induced CD spectra for tris-chelate complexes. Also given in Table 1 are the absolute configurations of the enantiomers eluted faster in ion-exchange chromatography with *d*-tart^{2-} or Sb$_2$*d*-tart$_2^{2-}$ as an eluent. It is confirmed that, when *d*-tart^{2-} is used, the elution order[3] is in complete agreement with the prediction from the sign of the induced CD spectrum for all the tris-chelate complexes. On the other hand, when Sb$_2$*d*-tart$_2^{2-}$ is used, the induced

a) Absolute configuration of the enantiomer eluted faster. b) No resolution. c) Absolute configuration assigned not by its CD spectrum. See Ref. 8. d) Absolute configuration of the enantiomer expected to have a greater affinity for the eluent. e) Very weak. f) No induced CD detected. g) See Fig. 1.

CD exceptionally fails to predict a correct elution order for $[Co(\beta\text{-ala})(en)_2]^{2+}$ and $[Co(acac)(en)_2]^{2+}$ only. A similar apparent discrepancy was observed for *cis*-$[Co(NH_3)_2(en)_2]^{3+}$ with Sb_2*d*-$tart_2^{2-}$ as an eluent.[1] It seems that Sb_2*d*-$tart_2^{2-}$ associates more easily with the *Λ*-enantiomers of the two complexes, their CD spectra not being so affected in comparison with those of the *Δ*-enantiomers, *i.e.*, the stronger interaction with Sb_2*d*-$tart_2^{2-}$ does not lead to a greater CD change for the two complexes.[1] This suggests that the discriminating interaction with these cobalt(III) complexes essentially differs for *d*-$tart^{2-}$ and Sb_2*d*-$tart_2^{2-}$.[9,10]

In the case of $[Co(tn)_3]^{3+}$ (Table 1) its *Λ*-enantiomer has a *negative* main CD component in the first d-d transition region unlike other tris-chelate complexes. However, its magnitude is enhanced upon addition of *d*-$tart^{2-}$ or Sb_2*d*-$tart_2^{2-}$, so that negative and positive induced CD suggest stronger interaction of *d*-$tart^{2-}$ or Sb_2*d*-$tart_2^{2-}$ with the *Λ*- and *Δ*-enantiomers, respectively. Thus the induced CD also correctly predicts the elution order[11] for $[Co(tn)_3]^{3+}$.

The induced CD spectra of bis-chelate complexes of the type *cis*-$[Co(X)_2(en)_2]^{+}$ are complicated (Fig. 1 and Table 1). Their natural CD spectra are enhanced in magnitude for some complexes and are diminished for others upon the addition of *d*-$tart^{2-}$, Sb_2*d*-$tart_2^{2-}$, or oxoanions.[6,12] It is impossible to predict the elution order from the induced CD spectra for *cis*-$[Co(X)_2(en)_2]^{+}$ complexes.

On the other hand, there seems to be a general trend in the elution order (Table 1) in the present chromatographic resolution. When *d*-$tart^{2-}$ is used, the *Λ*-enantiomers are eluted faster for all the bis(ethylenediamine) complexes including the tervalent complexes[1] and $[Co(tn)_3]^{3+}$. When Sb_2*d*-$tart_2^{2-}$ is used, the *Λ*- and *Δ*-enantiomers are eluted faster for the bivalent and univalent bis(ethylenediamine) complexes, respectively, except for the diazido complex. The exceptional chromatographic behavior of the diazido complex has been discussed separately.[8] However, it is not possible at present to interpret the elution order obtained for *cis*-$[Co(X)_2(en)_2]^{+}$ complexes.

Formation of Sr_2SiO_4 and $SrSiO_3$ from Strontium Silicate Hydrate Prepared by the Alkoxy Method

Osamu YAMAGUCHI,* Yoshifumi ITO, and Kiyoshi SHIMIZU*

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received August 1, 1979)

Synopsis. Sr_2SiO_4 and metastable $SrSiO_3$ were formed directly at low temperatures from $3SrO \cdot 2SiO_2 \cdot 3H_2O$ prepared by the alkoxy method. The transformation of metastable into stable $SrSiO_3$ was observed at 900—980 °C. A kinetic study was made on the formation of Sr_2SiO_4.

Strontium silicon oxide exists in three forms, $SrSiO_3$ (monoclinic), Sr_2SiO_4(monoclinic), and Sr_3SiO_5(tetragonal). Though $SrSiO_3$ has been known only in the pseudo-wollastonite modification,[1] Takamori and Roy[2] obtained a compound of new modification by heating $SrSiO_3$ glass. Yamaguchi *et al.*[3] found that the metastable compound is formed from an amorphous substance prepared by the alkoxy method, and carried out kinetic studies on the formation of metastable $SrSiO_3$ and the transformation of metastable into stable $SrSiO_3$. Their studies on the solid state reaction of an equimolar mixture between strontium carbonate and amorphous silica showed that stable $SrSiO_3$ is formed *via* two processes: (a) transformation of metastable into stable $SrSiO_3$; (b) solid state reaction between Sr_2SiO_4 and SiO_2.[4] This study was undertaken to elucidate the reaction mechanism in the heating process of the alkoxy-derived $3SrO \cdot 2SiO_2 \cdot 3H_2O$ and the kinetics of formation of Sr_2SiO_4.

Experimental

Silicon ethoxide of guaranteed purity was used. Strontium methoxide was synthesized by heating strontium metal, purity 99.9%, in an excessive amount of dehydrated methanol at 65 °C for 5 h. A mixture of these alkoxides with mole ratio $Sr^{2+}/Si^{4+}=3:2$ was prepared, and then poured into aqueous ammonia solution at 30 °C. The temperature was slowly raised up to 85 °C with stirring. The resulting mixed powder was washed repeatedly with hot water and dried at 65 °C under reduced pressure. The product was identified as $3SrO \cdot 2SiO_2 \cdot 3H_2O$[1] by X-ray diffraction analysis using nickel filtered copper $K\alpha$.

Results and Discussion

DTA was carried out at a heating rate of 10 °C/min. A large endothermic peak corresponding to dehydration was observed at 270—410 °C. The specimen turned amorphous after the completion of dehydration. Three exothermic reactions were observed at 700—815 °C, 815—860 °C, and 900—980 °C. X-Ray diffraction analysis confirmed that the first exothermic peak (700—815 °C) is due to the formation of Sr_2SiO_4, the second (815—860 °C) to that of metastable $SrSiO_3$, and the third (900—980 °C) to the transformation of metastable into stable $SrSiO_3$. The result is in line with that reported, *viz.*, Sr_2SiO_4 is always the first product obtained in solid state reaction,[4-7] regardless of the Sr/Si ratio.

Figure 1 shows the results of X-ray diffraction analysis of the specimens heated at 870 °C with various reaction times. The specimen was pre-heated at 450 °C for 30 min. The fractions of Sr_2SiO_4, metastable $SrSiO_3$, and stable $SrSiO_3$ were determined from heights d=2.80 Å, d=2.68 Å, and d=3.57 Å, respectively, in comparison with those of the well-formed products obtained by heating the specimens at 900 °C 1 h for Sr_2SiO_4, 860 °C 30 min for metastable $SrSiO_3$, and 1000 °C 1 h for stable $SrSiO_3$. The fractions of Sr_2SiO_4 and metastable $SrSiO_3$ attained a constant value in a short time. This suggests that both products are formed directly from the starting substance. No change was observed in the fraction of Sr_2SiO_4. On the other hand, the transformation of metastable into stable $SrSiO_3$ was observed with lapse of time. From the results as well as DTA data, the reaction mechanism can be postulated as shown in Fig. 2. More than one compound were observed during the course of solid state reaction in silicate systems; the final product can be predicted from the initial composition by referring to the equilibrium phase diagram. Results of the solid state reaction between strontium carbonate

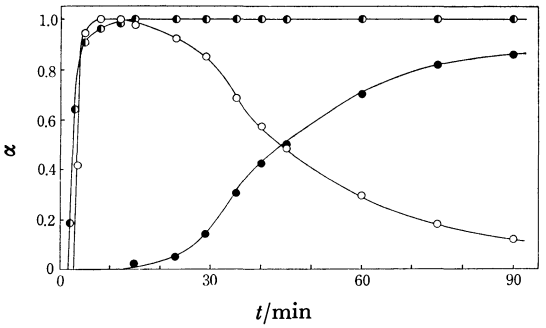

Fig. 1. Results of X-ray diffraction analysis during the reaction at 870 °C.
○: Metastable $SrSiO_3$, ●: stable $SrSiO_3$, ◐: Sr_2SiO_4.

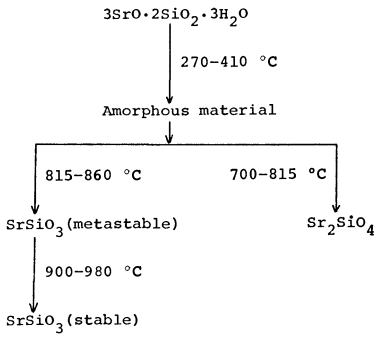

Fig. 2. Reaction scheme to the formation of $SrSiO_3$ and Sr_2SiO_4 from $3SrO \cdot 2SiO_2 \cdot 3H_2O$ as a raw material.

and amorphous silica (Sr/Si=3:2), mixed by ball-milling for 20 h, showed that metastable and stable $SrSiO_3$, Sr_2SiO_4, Sr_3SiO_5, and free SrO are formed during the course of heating. The discrepancy in the two results should be attributed to the difference in the contact between reactant between particles.

The fraction of Sr_2SiO_4 formation was determined by the lapse of time, since it is a function of time at different temperatures. The starting powder was pre-heated under the same conditions as mentioned above. The fraction of formation of each specimen was determined from the height d=2.80 Å (2θ=31.9°), the strongest line of the Sr_2SiO_4 spectrum as observed by X-ray diffraction. Alpha-crystobalite was used as an internal standard. Short induction periods were observed, attempts being made to fit the results to kinetic laws by considering the induction periods. As shown in Fig. 3, formation isotherms are best described by the first-order equation $-\ln(1-\alpha)=k(t-t_0)$, where α is the fraction of formation, t time and t_0 induction period. The rate constants were determined from the slopes of the straight lines. Activation energies calculated from the Arrhenius plot were 142 kJ/mol and 113 kJ/mol for initial and final stages, respectively. They might represent activation energies employed for establishing a nucleation process and a propagation process, respectively.[8]

N-Alkylation of Cytosine and Its Nucleosides with Trialkyl Phosphates

Masahiro HAYASHI,* Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received March 22, 1979)

Synopsis. Cytosine has been readily alkylated with trialkyl phosphates to give the corresponding *N*-alkyl derivatives, trimethyl phosphate being especially useful for the *N*-methylation of the base moiety of cytosine nucleosides.

The alkylation of nucleic acid components has been the subject of deep interest in organic and biological fields because of the induced physiological effects of alkylated products. The conventional alkylating agents used have been diazomethane,[1] dimethyl sulfate,[2] and alkyl halides.[3]

The alkylation of purines, pyrimidines, imidazole analogs, and pyridones with the alkyl esters of oxoacids of phosphorus,[4] have been reported where it was found that these agents were useful for the alkylation of nitrogen-containing heterocyclic compounds. This paper deals with an application of the method to the alkylation of cytosine and its nucleosides using trialkyl phosphates.

Results and Discussion

The reaction conditions and results are shown in Table 1. Upon heating cytosine (I) with trimethyl phosphate(TMP), I went gradually into solution to give three products, 1-methylcytosine (IIa), 3-methylcytosine (IIIa), and 1,3-dimethylcytosine (IVa, main). Triethyl and triallyl phosphate also converted I into a mixture of the corresponding 1-alkyl-, 3-alkyl-, and 1,3-dialkylcytosines. In general, the reactivity of trialkyl phosphates as alkylating agents appeared in the following order; methyl>allyl>ethyl.

In methylations using *N*,*N*-dimethylformamide (DMF) as the solvent in the presence of triethylamine, the reaction time was considerably reduced and the yield of IIa increased. The employment of protic solvents such as ethanol resulted in decreasing yields of alkylated products, in spite of the addition of triethylamine.

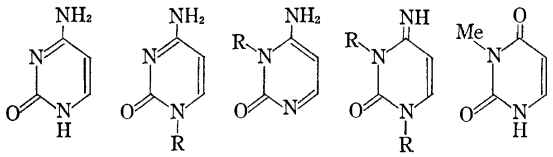
The methylation of I with dimethyl sulfate has been reported to produce only IIIa (25%) and IVa (5%);[2a] the authors have found however this reaction afforded IIa (9%) in addition to IIIa (42%) and IVa (15%) under the same conditions described in the literature[2a] (100 °C, 1 h, sulfate/I=2). The product distribution observed is somewhat different from that in the reaction with TMP (see Table), suggesting that TMP more readily methylates *N*-1 of I than dimethyl sulfate does.

Table 1. Alkylation of cytosine (I) with trialkyl phosphates[a]

R in $(RO)_3PO$	Time h	Temp °C	Solvent	Products yield/% II	III	IV	V
Me	27	100	—	6	10	74	0
	31	80	EtOH	4	20	11	10
	12	90	DMF	18	8	22	0
	12	88	DMF Et_3N	36	4	38	0
	34	100	DMF[b]	16	10	53	0
Et	37	130	—	13	3	71	0
Allyl	56	100	—	16	11	44	0
	17	110	DMF	21	8	36	0

a) Phosphate/I=4, b) Phosphate/I=8.

In the formation of IVa, two pathways (I→IIIa→IVa and I→IIa→IVa) are possible and this was examined briefly. The time-course of the reaction of I with TMP in DMF is depicted in Fig. 1. Figure 2 shows the reactions of IIa or IIIa with TMP under conditions similar to that used for reactions described in Fig. 1, indicating that IIIa is converted to IVa faster than IIa. Since IIa and IIIa are produced in similar yields in the reaction mixture of I and TMP (see Fig. 1), IVa should be produced largely *via* IIIa rather than IIa.



I IIa—c IIIa—c IVa—c V
a: R=Me, b: R=Et, c: R=allyl.

The *N*-1 of IIIa, which exists in the form of a 4-amino-2-oxo structure, is known to be more basic and less sterically hindered than the *N*-3 of IIa,[5] suggesting the former site is more reactive than the latter. The faster rate of formation of IVa from IIIa than from IIa (Fig. 2) may be attributable to these factors.

The methylation of cytidine (VIa) and 2'-deoxycytidine (VIb) was examined using TMP, which appeared to be the most reactive alkylating agent of the trialkyl phosphates studied.

Under neutral conditions in water or anhydrous solvent, alkylating agents such as diazomethane, benzyl

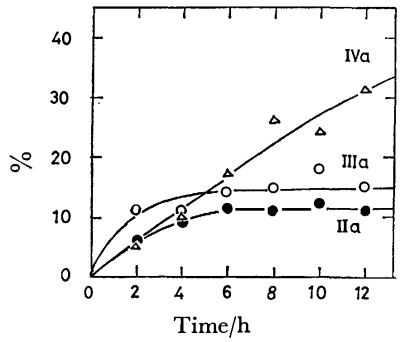


Fig. 1. The reaction of cytosine (I) with trimethyl phosphate (TMP) in DMF at 100 °C. TMP/I=8.

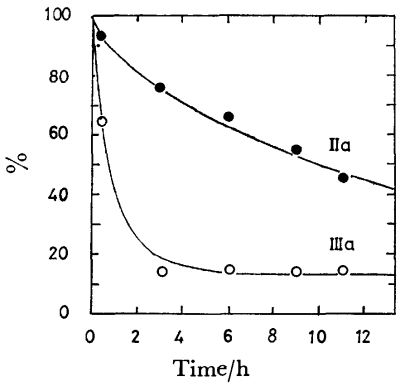

Fig. 2. The reaction of 1-methylcytosine (IIa) and 3-methylcytosine (IIIa) with trimethyl phosphate (TMP) in DMF at 100 °C. TMP:IIa:IIIa=8:1:1.

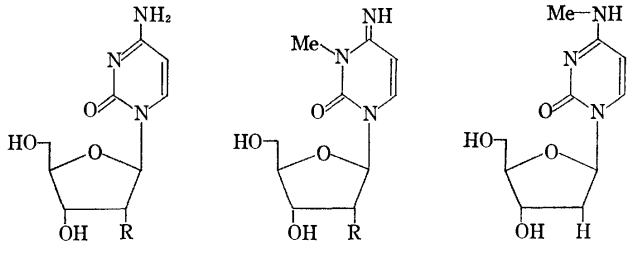
iodide, dimethyl sulfate, and nitrogen mustard have been shown to give the *N*-3-alkylated derivatives.[1,2a,3a,3b,6] Under alkaline conditions these alkylating agents predominantly alkylate the carbohydrate hydroxyls.[2b,7]

In the reaction with TMP (10 mol-equiv.) in DMF (70 °C; 32 h), compound VIa was smoothly methylated only at the *N*-3 position to give 3-methylcytidine (VIIa) in 81% yield. Under similar conditions, VIb was converted to 3-methyl-2′-deoxycytidine (VIIb; 52 %), but unlike the 4-amino group of VIa, VIb was also methylated to generate N^4-methyl-2′-deoxycytidine (VIII; 11%) as a by-product.[8] Under the present conditions, TLC analysis of the reaction mixture did not show any products which were methylated at the carbohydrate hydroxyls of VIa and VIb.



VIa,b VIIa,b VIII

a: R=OH, b: R=H.

The methylation of VIa with dimethyl sulfate gave VIIa in a yield comparable with that of TMP. Methylations with diazomethane and methyl iodide have been known to be less efficient than dimethyl sulfate or TMP. Thus, the present method would be useful particularly for the *N*-methylation of cytosine and its nucleosides.

Experimental

Commercial reagents were used without further purification. Triallyl phosphate was prepared by the procedure of Toy *et al.*[9] The reaction procedures and product isolations were in a manner similar to that of previous work.[4c] The yields of the reaction products were obtained spectroscopically similarly to that used in the former study.[4d] Results and reaction conditions are given in Table 1.

The majority of the products isolated agreed with the literature values (mp, UV, and NMR).[2a,3b,10,12,13,14]

Effect of Polyether Linkages on the Carboxylation of Sodium Phenoxide

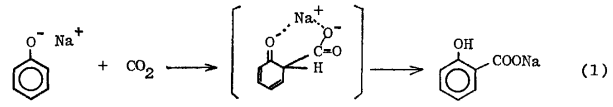
Tsutomu SAKAKIBARA* and Kazuyo HARAGUCHI
Institute of Chemistry, College of Liberal Arts, Kagoshima University, Korimoto, Kagoshima 890

(Received April 23, 1979)

Synopsis. In the carboxylation of sodium phenoxide under mild conditions, the crown compound or polyethers with three to five ether linkages caused carboxylation to give *o*- and *p*-hydroxybenzoic acids, but not ethers with one or two linkages. The chelation of sodium phenoxide with polyethers changed the formation ratio of isomers.

It is well known that various polyethers have properties in which a neutral molecule encircles metal ions or related cation, and changes the chemical or physical charactor of metal ion or the paired anion, such as reactivity, solubility, or catalytic activity.[1] With potassium phenoxides, chelation with crown ethers achieves conversion of phenols into their chalcones,[2] the chelation increasing the reactivity of potassium phenoxide.

In the Kolbe-Schmitt reactions, sodium phenoxide exclusively gives *o*-hydroxybenzoic acid (salicylic acid).[3] Preferential formation of *o*-isomer is explained in terms of intramolecular chelation in the intermediate (**1**) (Eq. 1).



(1)

1

So far, only a few reports have appeared on the effect of polyethers on the carboxylation of sodium phenoxide. In this report, we will show how the chelation with polyethers influences the reaction of sodium phenoxide with carbon dioxide under mild conditions.

In a typical experiment, 0.03 mol of sodium phenoxide in dry diglyme (1.0 mol) was stirred under carbon dioxide atmosphere at 80 °C for 10 h. After work-up of the reaction mixture, pure *o*-hydroxybenzoic acid was isolated in 5% yield as the sole product. Similar reactions were carried out in some polyether solvents. The results are summarized in Table 1.

The conversion of the reactant was low due to the mild reaction conditions. However, the results indicate that the number of ether linkages in solvent molecule influences the carboxylation of sodium phenoxide. A solvent with three to five ether linkages in a molecule gave rise to carboxylation of aromatic ring, but not a solvent with one or two. Use of tetraglyme in the reaction resulted in the formation of *p*-hydroxybenzoic acid, in spite of the preferential formation of *o*-isomer under the usual Kolbe-Schmitt conditions, *i.e.*, under high temperature and high pressure of carbon dioxide.[3]

Sodium phenoxide in monoglyme solvent gives no aromatic acids (Table 1). However, in the presence of a small amount of dibenzo-18-crown-6, carboxylation

TABLE 1. EFFECT OF POLYETHERS ON THE CARBOXYLATION OF SODIUM PHENOXIDE

Polyethers	Yield/%		
	Yield of hydroxybenzoic acid[a]	Composition	
		o-isomer,	*p*-isomer

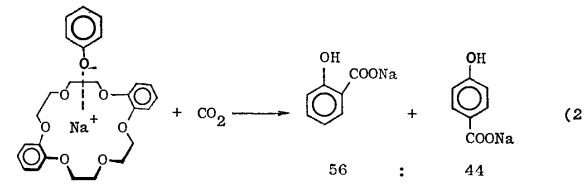
3	5	80	20
4	4	20	80
4	3	25	75

a) Based on the amount of sodium phenoxide.

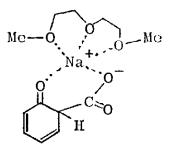
slowly proceeds in monoglyme to give a mixture of *o*-hydroxybenzoic acid and the *p*-isomer. Thus, a mixture of sodium phenoxide (0.03 mol) and dibenzo-18-crown-6 (0.005 mol) was stirred in monoglyme (1.0 mol) at 80 °C for 10 h under carbon dioxide atmosphere. After neutralization of the reaction products, a mixture of aromatic acids was isolated in a 3.5% yield, which contained *o*- (56%) and *p*-acid (44%). The 1:1 formation of *o*- and *p*-isomers is in line with the expected reactivity at *o*- and *p*-positions of free phenoxide ion.[4] This shows that the carboxylation may proceed *via* a phenoxide ion separated from the paired sodium ion by chelation with crown ether (Eq. 2).



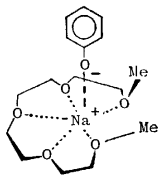
(2)

2

The results of reactions in noncyclic polyethers are also explained in terms of the chelation of sodium phenoxide with polyethers. Diglyme and triglyme may activate sodium phenoxide to react with carbon dioxide, but cannot form free phenoxide ion because of their weak chelation ability. The formation of probable intermediate (**3**) may lead to *o*-isomer. On the other hand, tetraglyme completely binds sodium ion to form an analogous intermediate (**4**) to **2**. The complex (**4**) might have a less coplanar chelating ring as compared with that in **2** due to the terminal methyl groups. The preferential formation of *p*-isomer might show the steric effect at *o*-position by methyl groups.



3



4

Experimental

Materials. Sodium phenoxide and dibenzo-18-crown-6 were prepared according to the methods described by Mori *et al.*,[5] and Pedersen,[6] respectively. 2,2'-Bi(tetrahydrofuranyl) was prepared in a 24% yield by the photoreduction of acetone in tetrahydrofuran (molar ratio of acetone/THF; 1/10): n_D^{23} 1.4572 (lit,[7] n_D^{20} 1.4512), Mass (*m/e*); 142 (M^+), 71 ($M^+/2$). The IR and NMR were identical with those of authentic material. Commercially available monoglyme, diglyme, triglyme, and tetraglyme were distilled on sodium under reduced pressure before use.

Carboxylation of Sodium Phenoxide in Diglyme. A mixture of 3.48 g of sodium phenoxide (0.03 mol) and 134 g of diglyme (1.0 mol) was stirred at 80 °C for 10 h bubbling with dried carbon dioxide in a dried four necked flask, equipped with a stirrer sealed by liquid paraffin, a Dimroht condenser with calcium chloride tube, a thermometer, and an introducing tube of carbon dioxide. After the reaction, 40 ml of 15% aqueous sodium hydroxide was added to the reaction mixture and the organic solvent was separated in a separating funnel. The aqueous layer was washed with a small amount of diethyl ether and afterwards was acidified with concd HCl, followed by extraction with diethyl ether. After the ether solution had been dried on anhydrous sodium sulfate, evaporation of ether gave 207 mg of pure salicylic acid, which was identified with the authentic material by mp measurement, IR, and NMR.

Similar reactions using tri- or tetraglyme, or dibenzo-18-crown-6 gave a mixutre of organic acids, in which the formation ratio of *o*- and *p*-isomers was determined by GLC using OV-101 column (182 °C, carrier gas; H_2).

The authors wish to express their thanks to Prof. T. Hase, Kagoshima University, for his valuable aid.

4) When benzyl anion is considered as a model of phenoxide ion, the total π-electron density at *p*-position is somewhat larger than that at *o*-position (*o*/*p*=1.142/1.144), the Frontier electron densities being almost equal at both positions. Thus, the reaction of phenoxide ion with carbon dioxide, known as a hard acid, should give a considerable large *o*/2*p* ratio when the steric effect is neglected. In the present reaction. the *o*/2*p* ratio was 0.63; see I. Fleming, "Frontier Orbitals and Organic Chemical Reactions," Japanese Edition (translated by K. Fukui *et al.*), Kodansha Co., Ltd., (1978), pp. 40—77.

Preparation of Methoxy-substituted Diaryl Ketone Anils *via* Phenyliminodimagnesium Intermediate

Masao Ōkubo* and Sonoko Ueda

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received May 18, 1979)

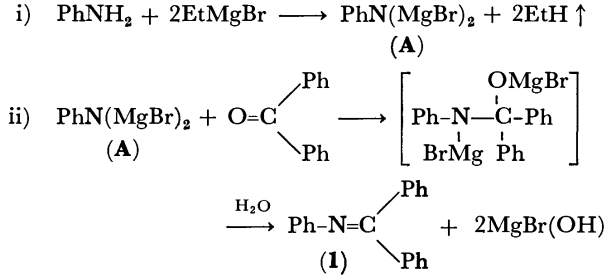
Synopsis. Phenyliminodimagnesium reagent ($PhN(MgBr)_2$) and its *o*- and *p*-methoxy derivatives, prepared in THF by treatment of anilines with EtMgBr, were found to be effective for condensation with benzophenones and fluorenone. The corresponding anils (*N*-(diarylmethylene)-anilines) were prepared in good yields.

In the course of studies on the Grignard reaction with a carbon-nitrogen double bond, it was found necessary to prepare the unknown *o*-methoxybenzophenone anil (*N*-(phenyl-2-methoxyphenylmethylene)-aniline) as a model compound for examining the S_{RN}-type reaction of the methoxyl group with phenylmagnesium bromide.[1] While benzaldehydes can be condensed with anilines without any catalyst,[2] the condensation of ketones with amines requires a catalyst such as $ZnCl_2$,[3,4] HBr,[5] $POCl_3$,[6] BF_3,[7] $TiCl_4$,[8] or molecular sieves.[9] The first four catalysts have been used for the condensation of diaryl ketones with anilines, but they can cause side reactions such as cleavage of ether linkage, making their applicability to the desired condensation of *o*-methoxybenzophenone with aniline impracticable.

The three catalytic methods gave anils in poor yields (Table 1). The very high yield of anil **4** obtained by the condensation of fluorenone with *p*-methoxyaniline(c-4)[7] might show the effectiveness of BF_3, which, however, gave no satisfactory results in other cases. None or only trace amounts of the expected anils were detected by TLC in experiments b-2, c-2, c-6, and c-7. From the results and from successful BF_3-catalysis reported on the condensation of nitro-substituted fluorenones with anilines,[7] it is apparent that the strongly electron-donating methoxyl group especially at *ortho*-position of both benzophenones and anilines is unfavorable for catalytic condensation. Since benzaldehyde and *o*-methoxybenzaldehyde can be condensed respectively with *o*-methoxyaniline and aniline,[10] the bulkiness of the carbonyl component is another obstructive factor.

In our search for some other method involving a procedure to activate the NH-bond of aniline molecule, the anilinomagnesium (PhNHMgBr) and phenyliminodimagnesium($PhN(MgBr)_2$) reagents supplied us with a clue. The former reagent and its *N*-methyl derivative have been used as catalysts for aldol condensation;[11] the latter has been used as the intermediate for preparing trimethylsilylated amino compounds[12] and for converting carboxylic esters into amides.[13] The dimagnesium intermediate seems effective for achieving dehydrative condensation. The expected reaction is shown in Scheme 1.

Phenyliminodimagnesium reagent(**A**) and its *o*- and *p*-methoxy derivatives were prepared according to step i) and subsequently condensed with benzophenones and fluorenone (Table 1, d-1 to d-7). The yields



Scheme 1.

of anils **1**[3] and **2**[5] were markedly improved though the reaction conditions were not optimized. However, the desired preparation of *o*-methoxybenzophenone anil was not successful even by this method(d-6), since the methoxyl group was replaced by the PhN(MgBr)-group leading to the formation of **6**. This is apparently due to a S_{RN}-type reaction similar to that proposed for the Grignard reaction of hindered benzophenone derivatives.[1] The low yield of **6** is due to the consumption of two molar equivalents of **A**. The successful preparation of **7** by the condensation of 4,4'-bis(dimethylamino)benzophenone with *p*-methoxyaniline(d-7), both of which have strongly electron-donating substituents, shows the usefulness of the method. The *ortho*-effect of the methoxyl group on the aniline component was substantially overcome as indicated by the fair yields of **3** and **5**. The anils **3**, **5**, **6**, and **7** are new compounds.

The reaction conditions of the method are much milder compared to those of the previous ones requiring higher temperature for the fusion of the reaction mixtures or for the removal of the formed water. The THF solution of **A** is extremely air-sensitive, the solution turning reddish purple rapidly by only a slight intrusion of air. The mechanism of step ii) remains equivocal, since there is another possibility that the $O(MgBr)_2$ species leaves directly from the addition complex prior to treatment with water. Since it is not applicable to nitro-substituted diaryl ketones and aniline, this method and BF_3-catalysis[7] are complementary to each other.

Experimental

Procedures. The phenyliminodimagnesium reagent (**A**, 0.03 mol) in THF (35 ml) was prepared under nitrogen by the addition of aniline to a solution of ethylmagnesium bromide (0.06 mol) at room temperature. The mixture was stirred at 50—55 °C for 30 min to complete the evolution of the latter half equivalent of ethane. Slight heat evolution took place with the subsequent addition of equimolar benzophenone (0.03 mol in 10 ml THF). The reaction mixture turned yellow and then reddish brown. The colored mixture was stirred at 50—55 °C for 30 min and at room temperature overnight, and then treated with saturated aqueous NH_4Cl.

Table 1. Yields of methoxy-substituted ketone anils

Anils No.	Structure	Ketones	Anilines	Yields of anils (a) $ZnCl_2$	(b) $POCl_3$	(c) BF_3	(d) $ArN(MgBr)_2$
1				28	27	—	68
2				10.1 1.3 7.5	not isolated	not isolated	72
3				—	3.6	—	36
4				—	—	81	82
5				—	—	10.2	54
6				—	—	not isolated	39
7				—	—	not isolated	59

Extraction of the resulting mixture with diethyl ether or benzene, drying of the combined extracts with $MgSO_4$, and evaporation of the solvent under reduced pressure afforded a dark yellow crystalline mass. Recrystallization from methyl alcohol afforded 5.0 g (68%) of **1** in a pure form.

The other anils were prepared similarly. Anils **3** and **6** were isolated from the respective product mixture by column chromatography on silica gel (Wakogel C-200, petroleum ether:diethyl ether:benzene=10:1:1).

Melting points (uncorrected), NMR data for methyl and NH protons, and results of the elemental analysis (for only new anils) are given below. All the aromatic protons in NMR appear in the range 6.40—7.95 ppm.

Anil **1**. Mp 116 °C (lit,[3] 116 °C), —.

Anil **2**. Mp 70—72 °C (lit,[4] 70 °C), δ=3.62(s).

Anil **3**. Mp 61—62 °C, δ=3.52(s). Found: C, 83.81; H, 5.85; N, 4.67%. Calcd for $C_{20}H_{17}NO$: C, 83.60; H, 5.96; N, 4.87%.

Anil **4**. Mp 135—138 °C (lit,[4,7] 135—136 °C), δ=3.80(s).

Anil **5**. Mp 141—142 °C, δ=3.70(s). Found: C, 83.97; H, 5.28; N, 4.81%. Calcd for $C_{20}H_{15}NO$: C, 84.19; H, 5.30; N, 4.91%.

Anil **6**. Oil, δ=10.02(s, NH). Found: C, 86.23; H, 5.76; N, 8.07%. Calcd for $C_{22}H_{20}N_2$: C, 86.18; H, 5.79; N, 8.04%.

Anil **7**. Mp 174—175 °C, δ=3.64 (3H, s) and 3.90 (12H, d). Found: C, 77.15; H, 7.31; N, 11.22%. Calcd for $C_{24}H_{27}N_3O$: C, 77.18; H, 7.29; N, 11.26%.

From the control experiments for measuring the volume of evolved ethane, the yield of intermediate **A** was estimated to be 85—92%.

Studies on 2-Aziridinecarboxylic Acid. III. Reaction of 1-Acyl-2-aziridinecarboxylic Acid Peptide with Amines

Kiichiro NAKAJIMA, Takumi TANAKA, Kaoru MORITA, and Kenji OKAWA*

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

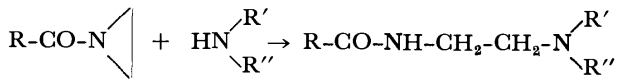
(Received June 6, 1979)

Synopsis. The reaction of Z-Gly-Azy-Gly-OBzl with amines was studied. With primary amines, the 1-acyl group (Z-Gly) of the aziridine peptide mainly migrated to the reactant amine with cleaving of the amide bond between glycine and aziridine, whereas aniline and diethylamine gave diaminopropionic acid derivatives *via* the ring opening reaction.

The present study is a part of an investigation of the reactivity of 1-acylaziridine peptides. It was shown that 1-acylaziridine peptides afford the *O*-esters as a result of the ring opening reaction with carboxylic acids.[1]

In this communication, we wish to give the results of a study of the reactivity of Z-Gly-Azy-Gly-OBzl(**1**)[2] with amines. Ammonia, benzylamine, ethylenediamine, amino acid esters, aniline, and diethylamine were used as the amines.

1-Acylaziridine derivatives generally undergo the ring opening reaction with primary or secondary amine, giving the following ethylenediamine derivatives.[3]



All amines examined, however, caused migration of the 1-acyl group (Z-Gly) from **1** to the reactant amines except aniline and diethylamine. Consequently, the fragment peptides (Z-Gly-NH-R(**2**) and Azy-Gly-OBzl(**3**)) were obtained in quantitative yields (Scheme 1 and Table 1). The results indicate that the reactivity of 1-acylaziridine peptide is independent of both the amount of amine and the reaction temperature. Evidently, the carbonyl carbon of the acyl group on 1-acylaziridine peptide is more positive than that of ordinary amides. The aziridine ring has an electron withdrawing or quasi-aromatic character.[4] A similar property is recognized in a nitrogen-containing heterocyclic ring system as amide component, such as pyrazolides, imidazolides and triazolides. The competitive reaction between migration and the ring opening reaction occurred to give the fragment peptides (**2**, **3**) and diaminopropionic acid derivative (A_2pr; **4**) in aniline. In contrast, only diaminopropionic acid derivative (**5**) was obtained *via* the ring opening reaction in the case of diethylamine. It seems that the reaction is specific for secondary amine.

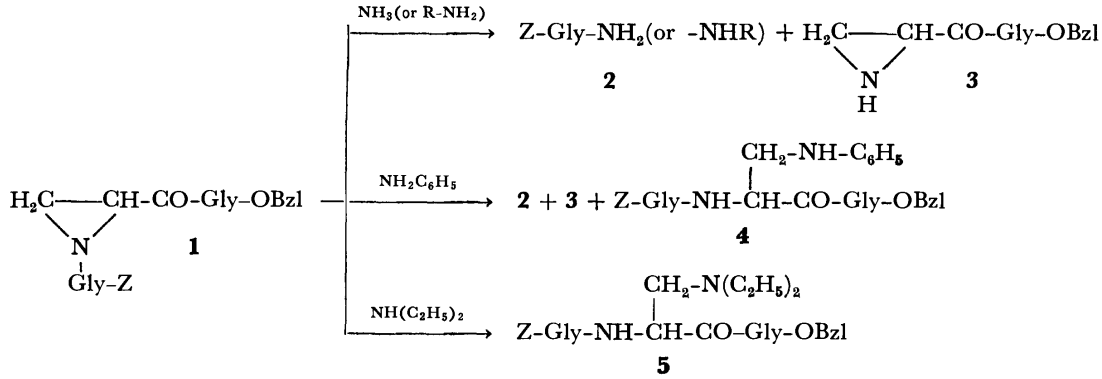
a) Total yield of both products Azy-Gly-OBzl and Ary-Gly-$NHCH_2Ph$.

Experimental

All melting points are uncorrected. NMR spectra were compatible for all products isolated. The purity of products was confirmed by thin layer chromatography on silica gel G.

Z-Gly-Azy-Gly-OBzl (1). Compound **1** prepared from serine derivative[5] was crystallized from THF–ether; mp 118—119 °C, $[\alpha]_D^{23}$ −52.2° (*c* 1.0, MeOH). NMR (acetone-d_6): δ 2.38 (1H q, J=1.5, 2.9 Hz, aziridine β-proton), 2.52 (1H, q, J=1.5, 5.9 Hz, aziridine β-proton), 3.29 (1H, q, J=2.9, 5.9 Hz, aziridine α-proton), 4.01 (2H t, J=5.0, -NH-CH_2-CO-). Found: C, 61.92; H, 5.57; N, 10.07%. Calcd for $C_{22}H_{23}O_6N_3$: C, 62.16; H, 5.45; N, 9.88%.

Reaction of 1 with Amines. *By Ammonia (a)*: Dry ammonia gas was bubbled into a solution of **1** (106 mg, 0.25 mmol) in CH_2Cl_2 (3 ml) at −5 °C until saturation. After being kept at the same temperature for 1 h, the solvent was removed. Dry ether was added to the residual product.



Scheme 1.

Crystals which appeared were collected by filtration, and identified as Z-Gly-NH_2; 52 mg (94.5%), mp 135—136 °C (lit,[6] mp 138—139 °C). From the filtrate, Azy-Gly-OBzl was isolated as crystals from $CHCl_3$-ether-hexane; 54.3 mg (92.8%), mp 118—119 °C, $[\alpha]_D^{23}$ −21.0° (*c* 1.0, $CHCl_3$). Found: C, 61.48; H, 5.97; N, 11.83%. Calcd for $C_{12}H_{14}O_3N_2$: C, 61.52; H, 6.02; N, 11.96%.

By Ammonia (b): Dry ammonia gas was bubbled into a solution of **1** (100 mg, 0.23 mmol) in CH_2Cl_2 (3 ml) at room temperature. After 1 h, the products were isolated as described for (a). Z-Gly-NH_2; 54.3 mg (95.1%). Azy-Gly-OBzl; 56 mg (92.2%).

By Benzylamine (c): Benzylamine (0.56 ml, 5.2 mmol) was added with stirring to a solution of **1** (110 mg, 0.26 mmol) in CH_2Cl_2 (3 ml) at room temperature. After 24 h, ether was added to the reaction mixture. Crystals which appeared were collected by filtration, and identified as Z-Gly-NH-CH_2-C_6H_5; 58 mg (77.7%), mp 118—119 °C (lit,[7] mp 119—120 °C). The filtrate was concentrated *in vacuo*, the residual product being crystallized from MeOH-ether-hexane. The first crop of crystals was Azy-Gly-NH-CH_2-C_6H_5; 53.6 mg (91.6%), mp 140—141 °C, $[\alpha]_D^{23}$ −22.0° (*c* 1.0, MeOH). Found: C, 61.98; H, 6.48; N, 17.87%. Calcd for $C_{12}H_{15}O_2N_3$: C, 61.78; H, 6.48; N, 18.02%. The second crop was Azy-Gly-OBzl; 4.4 mg (7.9%).

By Benzylamine (d): Compound **1** (106 mg, 0.25 mmol) and benzylamine (0.14 ml, 1.25 mmol) were reacted in CH_2Cl_2 (3 ml) at room temperature for 24 h. The products were isolated as described for (c). Z-Gly-NH-CH_2-C_6H_5; 67 mg (90.4%), Azy-Gly-NH-CH_2-C_6H_5 and Azy-Gly-OBzl; 57 mg (79.0%).

By Benzylamine (e): Compound **1** (212 mg, 0.5 mmol) and benzylamine (0.27 ml, 2.5 mmol) were reacted in CH_2Cl_2 (3 ml) at 45 °C for 24 h. The products were isolated as described for (c). Z-Gly-NH-CH_2-C_6H_5; 148.2 mg (99.4 %), Azy-Gly-NH-CH_2-C_6H_5 and Azy-Gly-OBzl; 61 mg (41.6%).

By Ethylenediamine (f): Ethylenediamine (12.4 mg, 0.21 mmol) was added with stirring to a solution of **1** (176 mg, 0.4 mmol) in CH_2Cl_2 (3 ml) at room temperature. After 24 h, crystals which appeared were collected by filtration, and identified as (Z-Gly-NH-CH_2-)$_2$; 71.1 mg (77.7%), mp 206 °C (dec). Found: C, 59.65; H, 5.88; N, 12.47%. Calcd for $C_{22}H_{26}O_6N_4$: C, 59.72; H, 5.92; N, 12.66%. From the filtrate, Azy-Gly-OBzl was obtained; 65.8 mg (64.6%).

By Gly-OBu^t (g): Gly-OBu^t (525 mg, 4 mmol) was added to a solution of **1** (212 mg, 0.5 mmol) in CH_2Cl_2 (3 ml) at room temperature. After 24 h, the solvent was removed *in vacuo*. The residual oily product was subjected to silica gel column chromatography with ethyl acetate-$CHCl_3$ (1:1 v/v). Z-Gly-Gly-OBu^t; 135 mg (84.8%), oil. Found: C, 59.48; H, 6.98; N, 8.72%. Calcd for $C_{16}H_{22}O_5N_2$: C, 59.61; H, 6.88; N, 8.69%. Azy-Gly-OBzl; 125 mg (100%).

By D-Gly(ph)-OBu^t (h): D-Gly(ph)-OBu^t (72 mg, 0.35 mmol) was added to a solution of **1** (106 mg, 0.25 mmol) in CH_2Cl_2 (3 ml) at room temperature. After 72 h, the products were isolated as described for (g). Z-Gly-D-Gly-(ph)-OBu^t; 99.6 mg (100%), oil, $[\alpha]_D^{23}$ −88.8° (*c* 1.0, $CHCl_3$). Found: C, 66.09; H, 6.96; N, 7.40%. Calcd for $C_{22}H_{26}O_5N_2$: C, 66.39; H, 7.09; N, 7.04%. Azy-Gly-OBzl; 62.5 mg (100%).

By Aniline (i): Aniline (0.88 ml, 10 mmol) was added to a solution of **1** (212 mg, 0.5 mmol) in CH_2Cl_2 (3 ml) at room temperature. After 24 h, the solvent was removed *in vacuo*. Ether was added to the residue, and crystals which appeared were collected by filtration. The crystals were identified as Z-Gly-NH-C_6H_5; 40.5 mg (14.1%), mp 144.5—146.5 °C (lit,[8] mp 145—146 °C). The filtrate was subjected to silica gel column chromatography with ethyl acetate-$CHCl_3$ (1:1 v/v). Azy-Gly-OBzl; 38.7 mg (15.0%). Z-Gly-A_2pr(NHph)-Gly-OBzl; 71.5 mg (27.8%), mp 80—81.5 °C, $[\alpha]_D^{23}$ +6.5° (*c* 0.25, MeOH). Found: C, 64.75; H, 5.84; N, 10.51%. Calcd for $C_{28}H_{30}O_6N_4$: C, 64.85; H, 5.84; N, 10.80%.

By Aniline (j): Compound **1** (212 mg, 0.5 mmol) and aniline (0.22 ml, 2.5 mmol) were reacted in CH_2Cl_2 (3 ml) at room temperature for 72 h. The products were isolated as described for (i). Z-Gly-NH-C_6H_5; 104 mg (36.2%), Azy-Gly-OBzl; 72.2 mg (28.0%), and Z-Gly-A_2pr(NHph)-Gly-OBzl; 112 mg (43.7%).

By Aniline (k): Compound **1** (212 mg, 0.5 mmol) and aniline (0.22 ml, 2.5 mmol) were reacted in CH_2Cl_2 (3 ml) at 45 °C for 24 h. The products were isolated as described for (i). Z-Gly-NH-C_6H_5; 33 mg (11.5%), Azy-Gly-OBzl; 49 mg (19.0%), and Z-Gly-A_2pr(NHph)-Gly-OBzl; 134 mg (51.9%).

By Diethylamine (l): Diethylamine (1.02 ml, 10 mmol) was added to a solution of **1** (212 mg, 0.5 mmol) in CH_2Cl_2 (3 ml) at room temperature. After 72 h, the solvent was removed *in vacuo*. The residual oily product was subjected to silica gel column chromatography with MeOH-$CHCl_3$ (1:20 v/v). Z-Gly-A_2pr(NEt_2)-Gly-OBzl was obtained as oil; 221 mg (88.5%), $[\alpha]_D^{23}$ −5.1° (*c* 0.4, MeOH). Found: C, 61.67; H, 6.76; N, 10.14%. Calcd for $C_{26}H_{34}O_6N_4 \cdot 1/2H_2O$: C, 61.52; H, 6.95; N, 10.15%.

Kinetics of the Tungstate-catalyzed H_2O_2 Oxidation of Amines in Aqueous Methanol. Acidity Effect[1)]

Yoshiro OGATA,* Kohtaro TOMIZAWA, and Hirokazu MAEDA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 13, 1979)

Synopsis. Oxidation of *N,N*-dimethylaniline and benzylamine with H_2O_2 catalyzed by Na_2WO_4 has been kinetically studied in buffered 50% aqueous methanol at 25 °C. The rates with a catalytic amount of Na_2WO_4 fit Eq.: $v=k[\text{amine}]_t[Na_2WO_4]_t[H_2O_2]^0$ and the pH profile of rate constant shows no dissociation of peroxotungstate at pH 5—10. *N,N*-Dimethylaniline gives *N*-oxide (73%) and benzylamine gives benzaldehyde oxime (65%) under the present kinetic conditions.

The oxidation reactions with hydrogen peroxide catalyzed by metallic salts (*e.g.*, molybdate, tungstate and vanadate) have been reported with epoxidation of fumaric[2)] and maleic[3)] acids and allyl alcohol[4)] and also oxidation of amines.[5,6)] The tungstate-catalyzed oxidation of primary and secondary amines gives the corresponding oximes, hydroxylamines and hydroxamic acids, while the same oxidation of tertiary amines gives the corresponding *N*-oxides. Russian workers reported that the rate expression was shown as: $k_{obsd}=k[\text{amine}]^1[WO_4^{2-}]^1[H_2O_2]^0$, which was discussed mainly as to the steric effect of amines.[5,6)] The present paper summarizes our kinetic data and probable mechanisms based on the acidity effect on the oxidation of *N,N*-dimethylaniline forming *N*-oxide and that of benzylamine forming benzaldehyde oxime in aqueous methanol.

Results and Discussion

The Na_2WO_4-catalyzed H_2O_2 oxidation of *N,N*-dimethylaniline gave *N*-oxide in a yield of 73%. The same reaction of benzylamine gave benzaldehyde oxime in a yield of 65%. These reactions do not occur without the catalyst, hence the active oxidant, peroxotungstate, may be formed by the reaction of Na_2WO_4 and H_2O_2.

The rates were measured with various initial concentrations of amines and H_2O_2 (*i.e.*, $[PhMe_2N]_0=3.95-7.89\times10^{-3}$ M, $[H_2O_2]_0=9.21-18.6\times10^{-3}$ M, $[Na_2WO_4]_0=1.00\times10^{-3}$ M at pH 5.80 and $[PhCH_2NH_2]_0=4.53-18.3\times10^{-3}$ M, $[H_2O_2]_0=9.10-17.8\times10^{-3}$ M, $[Na_2WO]_0=1.00\times10^{-3}$ M at pH 9.40; all data for difinite molar ratio of reactants fit the rate equation (1) previously reported,[5)] where $[\ ]_t$ means the stoichiometric concentration.

$$v=k_{obsd}[\text{amine}]_t[Na_2WO_4]_t \quad (1)$$

The values of k_{obsd} were $1.20\pm0.1\times10^{-2}$ M^{-1} s^{-1} for $PhMe_2N$ and $5.90\pm0.2\times10^{-2}$ M^{-1} s^{-1} for $PhCH_2NH_2$ in 50% aq MeOH at 25 °C.

The rates were measured at various initial concentrations of Na_2WO_4 and H_2O_2 for the oxidation of *N,N*-dimethylaniline and thus the rate is practically independent of the concentration ($4.60-27.6\times10^{-3}$ M) of H_2O_2 in this range of $0.20-3.20\times10^{-3}$ M Na_2WO_4; *i.e.*, at initial molar ratio $[Na_2WO_4]_0/[H_2O_2]_0$ below 1/9; but as the ratio approaches to unity, the rate deviates from the first-order dependence on $[Na_2WO_4]_0$. The similar result was obtained for the oxidation of benzylamine. This deviation may be attributed to the decrease of rate of reproducing peroxotungstate with decreasing concentration of H_2O_2.

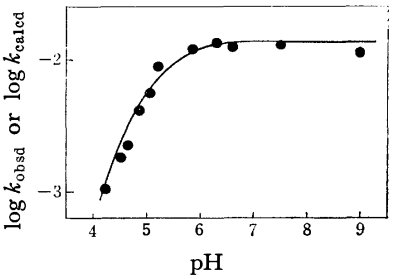

Fig. 1. pH profile for the Na_2WO_4-catalyzed H_2O_2 oxidation of *N,N*-dimethylaniline in 50% aq MeOH at 25 °C. $[PhMe_2N]=7.00\times10^{-3}$ M, $[H_2O_2]=18.1\times10^{-3}$ M, $[Na_2WO_4]=1.00\times10^{-3}$ M.
● $\log k_{obsd}$, $-\log k_{calcd}$.

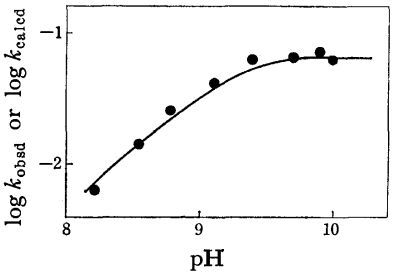

Fig. 2. pH profile for the Na_2WO_4-catalyzed H_2O_2 oxidation of benzylamine in 50% aq MeOH at 25 °C. $[PhCH_2NH_2]=9.61\times10^{-3}$ M, $[H_2O_2]=13.5\times10^{-3}$ M, $[Na_2WO_4]=1.00\times10^{-3}$ M.
● $\log k_{obsd}$, $-\log k_{calcd}$.

The effects of acidity of solution on the second-order rate constant k_{obsd} are shown in Figs. 1 and 2. As apparent from the figures, the rate constants decrease with increasing acidity at pH below 5 for *N,N*-dimethylaniline and at pH below 9 for benzylamine. Since the basicity constants, $K_H=[BH^+]/([B][H^+])$, are 1.15×10^5 for *N,N*-dimethylaniline[7)] and 2.19×10^9 for benzylamine,[7)] the decrease of k_{obsd} is ascribed to the deactivation of amines by protonation of amino nitrogen.

These results suggest a mechanism for *N,N*-dimethylaniline oxidation, where T means WO_3^-, WO_4^-, or WO_6^-. ($m=1$, 2, 4, $n=0$, 1, 3)[8)]

$$Na_2WO_4 \underset{\text{fast}}{\rightleftharpoons} 2Na^+ + WO_4^{2-} \quad (2)$$

$$WO_4^{2-} + mH_2O_2 \underset{\text{fast}}{\rightleftharpoons} T\text{-}OOH + OH^- + nH_2O \quad (3)$$

$$PhMe_2N + H^+ \underset{\text{fast}}{\overset{K_H}{\rightleftharpoons}} PhMe_2\overset{+}{N}H \quad (4)$$

$$PhMe_2N + T\text{-}OOH \xrightarrow[\text{slow}]{k_1} PhMe_2\overset{+}{N}OH + T\text{-}O^- \quad (5)$$

$$PhMe_2\overset{+}{N}OH \underset{\text{fast}}{\rightleftharpoons} PhMe_2N{\rightarrow}O + H^+ \quad (6)$$

Since the rate is determined by step 5 as in the case of analogous oxidation of amines, the rate is expressed as

$$v = k_1[PhMe_2N][T\text{-}OOH]. \quad (7)$$

Here,

$$[PhMe_2N] = [PhMe_2N]_t/(1+K_H[H^+]). \quad (8)$$

$[PhMe_2N]_t$ means stoichiometric or total concentration, *i.e.*, $[PhMe_2N]_t=[PhMe_2N]+[PhMe_2\overset{+}{N}H]$. Sodium tungstate reacts rapidly with excess H_2O_2 giving quantitatively peroxotungstate, T–OOH, whose structure is still ambiguous, *i.e.*, T–OOH may be HWO_5^-, HWO_6^-, HWO_8^-, *etc.*[8] Hence, Eq. 7 can be transformed into

$$v = \frac{k_1}{1+K_H[H^+]}[PhMe_2N]_t[Na_2WO_4]_t. \quad (9)$$

Introduction of the value of $K_H=1.15\times10^5\ M^{-1}$ and an average observed value of $k_1=1.25\times10^{-2}\ M^{-1}\ s^{-1}$ at pH independent region ($6\leq pH\leq8$) gave the value of $k_1/(1+K_H[H^+])$ or k_{calcd}. A plot of log k_{calcd} *vs.* pH is shown as a solid line in Fig. 1, on which lies the values of log k_{obsd} and this supports the mechanism.

Analogously, a mechanism for benzylamine is proposed as follows:

$$PhCH_2NH_2 + T\text{-}OOH \xrightarrow[\text{slow}]{k_2} PhCH_2\overset{+}{N}H_2OH + T\text{-}O^- \quad (10)$$

$$PhCH_2\overset{+}{N}H_2OH \underset{\text{fast}}{\rightleftharpoons} PhCH_2NHOH + H^+ \quad (11)$$

$$PhCH_2NHOH + H_2O_2 \xrightarrow[\text{fast}]{} PhCH{=}NOH + 2H_2O \quad (12)$$

Although benzylhydroxylamine cannot be isolated in the oxidation of benzylamine, the rapid uncatalyzed oxidation of prepared benzylhydroxylamine to benzaldehyde oxime with rate constant $k_{obsd}\approx10^{-2}\ s^{-1}$ at 25 °C was confirmed. Therefore, the rate for the rate-determining step is expressed as

$$v = \frac{k_2}{1+K_H[H^+]}[PhCH_2NH_2]_t[Na_2WO_4]_t. \quad (13)$$

Here, K_H is $1.2\times10^9\ M^{-1}$ and an average k_2 value was calculated to be $7.24\times10^{-2}\ M^{-1}\ s^{-1}$, which is comparable to that in water ($8.4\times10^{-2}\ M^{-1}\ s^{-1}$).[5] By the similar treatments as above, it was found that the observed values of k_{obsd} lie on the calculated solid line in Fig. 2, hence the above mechanism is supported.

In conclusion, the present reaction involves a rate-determining electrophilic attack of HO– (or $\begin{matrix}O\\|\\O\end{matrix}$) from peroxotungstate on neutral amino nitrogen of amine. The rate for *N,N*-dimethylaniline (log $k_{obsd}=-1.9$) is smaller than the rate with H_2SO_5 oxidation (log $k_{obsd}=1.5$)[9] and the rate with H_3PO_5 (log $k_{obsd}=-0.7$).[10] *N,N*-Dimethylaniline is less reactive than benzylamine, which is expected from the lower basicity of *N,N*-dimethylaniline ($K_H=1.15\times10^5\ M^{-1}$) compared with that of benzylamine ($K_H=2.19\times10^9\ M^{-1}$).

Experimental

Materials. *N,N*-Dimethylaniline, bp 192—194 °C, and benzylamine, bp 185 °C, used were of guaranteed grade. Sodium tungstate was also of guaranteed grade. Benzylhydroxylamine was prepared by the reaction of benzyl chloride with hydroxylamine hydrochloride in alkaline aqueous ethanol, mp 54—56 °C (lit,[11] 57 °C).

Aqueous hydrogen peroxide for kinetic experiments was prepared by dilution of guaranteed 90% H_2O_2 purchased from Mitsubishi Gas Chem. Co.

Products. *N,N*-Dimethylaniline was oxidized with 3 equivalents of 90% H_2O_2 in the presence of catalytic amount of Na_2WO_4 in 50% aqueous MeOH to yield *N,N*-dimethylaniline *N*-oxide, λ_{max}^{MeOH} 254 nm (log ε 2.40), mp 150—152 °C (lit,[12] mp 151—152 °C). Benzylamine, λ_{max}^{MeOH} 253 nm (log ε 2.38) was oxidized with 3 equivalents of 90% H_2O_2 in the presence of Na_2WO_4 at below 20 °C, yielding benzaldehyde oxime, bp 78—79 °C/1 mmHg (lit,[5] 104 °C/5 mmHg). Benzylhydroxylamine was oxidized analogously to give quantitative yield of benzaldehyde oxime, bp 78—79 °C/1 mmHg. These products were identified by comparison of NMR peaks with those of authentic specimen.

Kinetics. The kinetic experiments were conducted in buffered 50% aqueous MeOH at 25 °C. The reaction was started by the addition of aqueous methanol solution of H_2O_2 (5 ml) to thermostated aqueous methanol Na_2WO_4 solution (45 ml). The rate was followed by iodometric titration of H_2O_2 and also by UV spectrophotometry of the pipetted out aliquots. The rates observed by both methods agreed satisfactorily. In the UV spectrophotometry, the decrease of absorption of *N,N*-dimethylaniline at λ_{max}^{MeOH} 251 nm (log ε 4.10) and the increase of absorption of benzaldehyde oxime at λ_{max}^{MeOH} 250 nm (log ε 4.14) were measured. The buffer solutions were made of AcONa–HCl, AcONa–AcOH, or KH_2PO_4–Na_2HPO_4.

Reaction of Bis(dimethylglyoximato)(pyridine)styrylcobalt(III) Derivatives with Arenesulfenyl Chloride

Masaru TADA,* Hiraku SHINOZAKI, and Kyo MIURA
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received June 25, 1979)

Synopsis. *cis*-Styryl and *trans*-styryl-type cobaloximes, having a *para*-substituent on the styrene moiety, give the corresponding *cis*- and *trans*-(styrylthio)benzene derivatives in excellent yields by the reaction with 2,4-dinitrobenzenesulfenyl chloride. The substitution proceeds stereospecifically with retention of configuration except for the case of *cis*-(*p*-cyanostyryl)cobaloxime.

Bis(dimethylglyoximato)(pyridine)cobalt(III) derivatives (the conventional name styryl-type cobaloxime is used hereafter) are converted to styryl-type halides and mercurials by reaction with bromine and mercury(II) acetate, respectively. The substitution proceeds stereospecifically with retention of configuration.[1,2] In this report the substitution of styryl-type cobaloximes with 2,4-dinitrobenzenesulfenyl chloride will be discussed. The reaction gives styryl-type sulfides, which may be utilized as a synthetic intermediate.[3] This reaction is an addition to the new synthetic routes for sulfides,[4-8] and the preparation of styryl-type cobaloxime is relatively simple.

cis- and *trans*-Styryl-type cobaloximes (**1**, **2**, and **3**) were synthesized from the corresponding styryl-type halides and the cobaloxime anion prepared *in situ* from dimethylglyoxime, pyridine, cobalt(II) chloride, and sodium borohydride.[1] Treatment of one of the *cis*-(**1c**, **2c**, and **3c**) or *trans*-styryl-cobaloximes (**1t**, **2t**, and **3t**) with 2,4-dinitrobenzenesulfenyl chloride in dichloromethane gave *cis*- (**4c**, **5c**, and **6c**) and *trans*-2,4-dinitro-1-(styrylthio)benzene (**4t**, **5t**, and **6t**), respectively, in excellent yields (see Table 1). The structures of the products were detected by elemental analyses and spectroscopy. The stereochemistry of the products was readily assigned by the coupling constants of vinyl hydrogens in the NMR spectra (J=11 Hz for *cis*-isomers and J=16 Hz for *trans*-isomers). The displacement of the cobaloxime moiety with 2,4-dinitrobenzenesulfenyl group proceeds with retention except in the reaction of *cis*-(*p*-cyanostyryl)cobaloxime (**1c**), in which a mixtures of *cis*- and *trans*-2,4-dinitro-1-(*p*-cyanostyrylthio)benzene (**4c** and **4t**) was obtained. As reported in an earlier paper,[1] the reaction of *cis*-(*p*-cyanostyryl)cobaloxime (**1c**) with bromine gave *cis*- and *trans*-styryl bromides. The formation of *trans*-styryl bromide was shown to be due to the isomerization of the *cis*-*p*-cyanostyryl bromide formed initially. The non-stereospecificity of the reaction of **1c** in the present study, therefore, is thought due to the isomerization of *cis*-2,4-dinitro-1-(*p*-cyanostyrylthio)benzene (**4c**) to the *trans*-isomer (**4t**) under the reaction conditions.

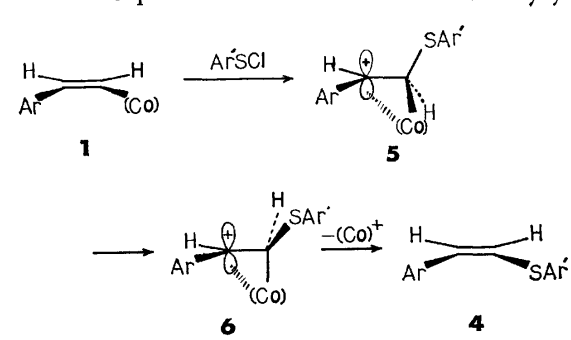
The basic nature of the present reaction is thought to be the same as that of bromination. The steric consequence of bromination has been discussed in some detail[1] in which the interaction between the benzylic cation and cobalt(III) by p_π-d_π[9] or σ-π conjugation[10] was important. Bond rotation is hindered in the intermediates **5** and **6** in the reaction scheme due to this type of interaction. The mechanistic feature of the present sulfenylation, therefore, can be shown correctly by the scheme shown here. The reaction of **1**, **2**, and **3** with benzenesulfenyl chloride gave (styrylthio)benzenes in the same manner but with less stereospecificity.

In the experiments it was found that styryl-type



Scheme 1.

cobaloximes do not react with hard electrophiles[11] such as isoamyl nitrite and ethyl chloroformate. Soft but weak electrophiles, such as diphenyl disulfide and *N*-(phenylthio)succinimide, again do not react with styryl-type cobaloximes. This property of styryl-type cobaloximes can be attributed to the soft nature and p_π-d_π interaction of cobalt(III). The olefinic carbon of styryl-type cobaloxime, therefore, must acquire a more soft and less nucleophilic property, a property stemming from p_π*-d_π back-donation from cobalt(III) which diminishes the reactivity of the olefinic carbon towards electrophiles.

In conclusion, soft and strong electrophiles, such as bromine, mercury(II) acetate, and arenesulfenyl chloride, smoothly substitute the cobaloxime group of styryl-type cobaloximes *via* an addition-elimination mechanism as shown in the scheme.

Experimental

Styryl-type cobaloximes (**1**, **2**, and **3**) were prepared by the methods reported[1] and 2,4-dinitrobenzenesulfenyl chloride was prepared by the method of Kharasch and Langford[12] from 2,4-dinitrochlorobenzene. Melting points are not corrected and IR spectra were measured using KBr disks. The NMR spectra were measured in DMSO-d_6 and chemical shifts have been expressed by δ values using sodium 3-(trimethylsilyl)propanoate-d_4 as an internal standard.

Reaction of Cobaloximes with 2,4-Dinitrobenzenesulfenyl Chloride. To a solution of one of the styryl-type cobaloximes (0.25×10^{-3} mol) in dichloromethane (10 ml) was added dropwise 2,4-dinitrobenzenesulfenyl chloride (0.28×10^{-3} mol) dissolved in dichloromethane (2 ml) with magnetic stirring. The reaction mixture was stirred for 1 h after addition of the reagent under nitrogen at ambient temperature (*ca.* 27 °C). The reaction mixture was passed through an alumina column (Merck act. II—III) and the column further eluted by chloroform. Condensation of the combined eluates gave 2,4-dinitro-1-(styrylthio)benzenes (Table 1). Recrystallization of the products from DMF–ethanol gave the pure sulfides. In the case of **1c** the product was a mixture of isomers, which was separated into **4c** and **4t** by chromatography on silica gel eluted by chloroform and recrystallization from DMF–ethanol. **4c**: Mp 149—151 °C. (Received June 28, 1979)

Synopsis. In connection with studies on the structure of carthamin (**1**), two analogous compounds of **1**, 3-(*p*-hydroxycinnamoyl)-5-methylfilicinic acid and dehydro-3,3′-diacetyl-5,5′-methylenedifilicinic acid have been synthesized.

The structure for carthamin **1**, the red coloring matter of the flowers of Safflower (*Carthamus tinctorius* L.) has recently been proposed on the basis of spectroscopic evidence and hydrolytic behavior.[1)] In this paper, the synthesis of two compounds, 3-(*p*-hydroxycinnamoyl)-5-methylfilicinic acid (**3**) and dehydro-3,3′-diacetyl-5,5′-methylenedifilicinic acid (**6**), will be reported. These compounds have been offered as the analogs of **1** in a previous communication.[1)]

3-(*p*-Hydroxycinnamoyl)-5-methylfilicinic acid (**3**) was synthesized by the condensation of 3-acetyl-5-methylfilicinic acid (**2**),[2)] obtained by the methylation of phloroacetophenone, with *p*-hydroxybenzaldehyde in the presence of piperidine[3)] by reference to the synthesis of ceroptene. Dehydro-3,3′-diacetyl-5,5′-methylenedifilicinic acid (**6**) was prepared by the condensation of 3-acetyl-5-formylfilicinic acid (**4**), obtained by the methylation of formylphloroacetophenone,[4)] with acetylfilicinic acid (**5**)[2)] and 1% aqueous potassium hydroxide solution at −10— −15 °C. The structures of **3** and **6** were confirmed by IR, PMR, and mass spectra, and elemental analysis.

Compounds **3** and **6** both showed a characteristic enol proton signal at very low field (19.30 and 18.38 ppm) in the PMR spectra, which have been observed in other enolized 1,3,5-triketone structure.[5)] Hydrogenation of **6** gave 3,3′-diacetyl-5,5′-methylenedifilicinic acid (**7**), which was identical to the specimen obtained by the condensation of **5** with formaldehyde.

Compound **6**, light yellow crystals, exhibited an absorption maximum at 350 nm in chloroform solution, but shifted to the long-wavelength region, 490 nm, in ethanol solution. The unusual red shift has been ascribed to the formation of the stable enol anion of **6** in ethanol.

Experimental

All melting points are uncorrected. The UV and IR spectra were recorded on a Hitachi 135 and a Hitachi EPI-S2 spectrophotometer, respectively. The PMR spectra were measured with a Hitachi R-22 spectrometer (90 MHz), using tetramethylsilane as an internal standard. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer.

3-(p-Hydroxycinnamoyl)-5-methylfilicinic Acid (3). A mixture of 3-acetyl-5-methylfilicinic acid (**2**) (2.0 g), *p*-hydroxybenzaldehyde (6.0 g), and piperidine (2 ml) was heated on a water bath for 1 h. The reaction mixture was poured into dilute hydrochloric acid and extracted with ethyl acetate. The ethyl acetate solution was washed with water, dried over anhydrous Na_2SO_4, and evaporated *in vacuo*. The residue was chromatographed on a silica-gel column with benzene–ethyl acetate (4:1) to give crude crystals, which were further chromatographed with a benzene–ethyl acetate–acetic acid mixture (80:20:1). Recrystallization from methanol gave **3** (380 mg, 13%) as yellow needles, mp 215—216 °C. UV_{max} (EtOH) 350 and 415 nm; IR (KBr) 1600, 1624, and 1663 cm^{-1}; PMR (acetone-d_6) δ 1.39 (6H, s, $C_{3'}$-Me×2), 1.87 (3H, s, $C_{5'}$-Me), 6.90 (2H, d, J=8.5 Hz, $C_{3,5}$-H), 7.58 (2H, d, J=8.5 Hz, $C_{2,6}$-H), 7.80 (1H, d, J=16 Hz, C_α-H), 8.22 (1H, d, J=16 Hz, C_β-H), 19.30 (s, OH). Found: C, 68.55; H, 5.80%; M^+, 314. Calcd for $C_{18}H_{18}O_5$: C, 68.78; H, 5.77%; M, 314.

Diacetate, mp 152—153 °C; IR (KBr) 1673, 1662, 1650, and 1600 cm^{-1}. Found: C, 66.32; H, 5.63%; M^+, 398. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%; M, 398.

3-Acetyl-5-formylfilicinic Acid (4). To a solution of formylphloroacetophenone (4.9 g)[4)] in dried methanol (25 ml) was added a sodium methylate solution, which was prepared from sodium (1.8 g), methanol (40 ml), and methyl iodide (21 g). The reaction mixture was allowed to stand for 3 days in the dark at room temperature. Removal of the solvent *in vacuo* gave a residue. The residue, after the addition of 1 M hydrochloric acid, was extracted with ethyl acetate. The ethyl acetate solution was washed with water, dried over anhydrous Na_2SO_4 and evaporated *in vacuo* to yield a viscous oil, which on crystallization from ligroin, gave compound **4** (1.85 g, 33%), mp 56—58 °C; IR (KBr) 1675 and 1625 cm^{-1}. Found: C, 58.94; H, 5.45%; M^+, 224. Calcd for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40%; M, 224.

Dehydro-3,3′-diacetyl-5,5′-methylenedifilicinic Acid (6). A

mixed solution of 3-acetylfilicinic acid (**5**)[2] (600 mg) and **4** (860 mg) in 1% aqueous potassium hydroxide solution (17 ml) was allowed to stand for 12 h at −10—−15 °C. The reaction mixture was acidified with 2 M hydrochloric acid and extracted with ether. Removal of the solvent from the ether solution gave a residue, which was extracted with ethyl acetate. The ethyl acetate, on removal of the solvent *in vacuo*, gave a residue. The residue gave **6** (550 mg, 44%) as yellow needles, which on recrystallization from benzene showed a mp 173—174.5 °C. UV_{max} ($CHCl_3$) 350 nm (log ε=4.33), UV_{max} (EtOH) 300 and 490 nm (log ε= 4.17 and 4.85); IR (KBr) 1670, 1648, and 1628 cm^{-1}; PMR (DMSO-d_6) δ 1.28 (12H, s, $-CH_3\times4$), 2.57 (6H, s, $-COCH_3\times2$), 7.95 (1H, s, -CH=), 18.38 (2H, br s, $-OH\times2$). Found: C, 62.73; H, 5.59%; M^+, 402. Calcd for $C_{21}H_{22}O_8$: C, 62.68; H, 5.51%; M, 402.

*3,3'-Diacetyl-5,5'-methylenedifilicinic Acid (**7**).* To a solution of 3-acetylfilicinic acid[2] (100 mg) in 1% aqueous potassium hydroxide solution (0.4 ml) was added paraformaldehyde (25 mg) under cooling with ice–water and the mixture allowed to stand for 30 min. The reaction mixture was acidified with 2 M hydrochloric acid and extracted with ether. The ether solution was evaporated and the residue was recrystallized from methanol to give **7** (40 mg, 19%), mp 170—172 °C. IR (KBr) 1640 cm^{-1} (C=O); PMR (pyridine-d_5) δ 1.53 (12H, s, $-CH_3\times4$), 2.72 (6H, s, $-COCH_3\times2$), 3.96 (2H, s, $-CH_2-$), 18.47 (2H, s, $-OH\times2$). Found: C, 62.16; H, 6.13%; M^+, 404. Calcd for $C_{21}H_{24}O_8$: C, 62.37; H, 5.98%; M, 404.

*Reduction of **6**.* Compound **6** (80 mg) was hydrogenated in methanol (8 ml) with 4% aqueous palladium chloride solution (1.5 ml) for 5 h. The reaction mixture was filtered and the filtrate cooled to give a small amount of colorless prisms, mp 170—172 °C. The IR spectrum of this reduction product was identical with that of a synthetic sample of **7**.

The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

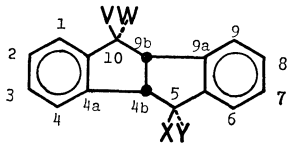
Synthesis, Absolute Configuration, and Chiroptical Property of (+)-*cis*-4b,5,9b,10-Tetrahydroindeno[2,1-*a*]indene-5,10-dione

Fumio OGURA,*,** Akio NAKAO, and Masazumi NAKAGAWA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received June 30, 1979)

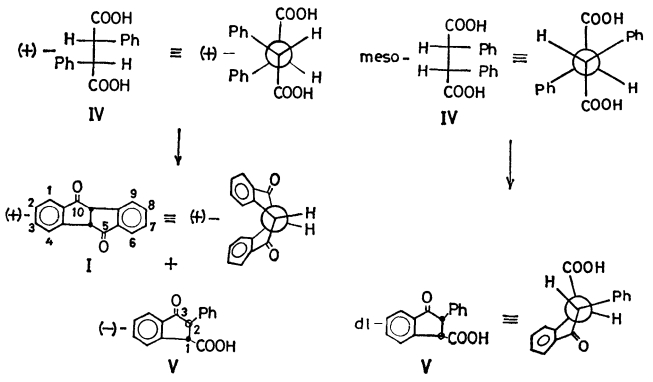
Synopsis. The title compound having the (4b*S*,9b*S*) configuration was prepared from (2*S*,3*S*)-(+)-2,3-diphenylsuccinic acid, and the circular dichroic property was discussed.

The title compound (I) has a fairly rigid *cis*-bicyclo-[3.3.0]octane skeleton and holds two 1-indanone chromophores in a twisted spacial position. This paper deals with the synthesis, determination of the absolute configuration, and the chiroptical property of (+)-I.



I, V+W = X+Y = O
II, V = W = H, X+Y = O
III, V = W = X = Y = H

The route of synthesis was outlined in Scheme 1. (2*S*,3*S*)-(+)-2,3-Diphenylsuccinic acid (IV)[1,2] was converted to the dichloride, which was subjected to the Friedel-Crafts reaction to yield (+)-I. Thus, the absolute configuration of (+)-I was determined to be (4b*S*,9b*S*). As a by-product of the cylization, (−)-keto acid (V) was obtained. The keto acid was subjected again to the same cyclization reaction, but virtually recovered unchanged. Under the more drastic condition using hot polyphosphoric acid, (−)-V afforded (+)-I having somewhat low optical purity. The only product isolated from the same Friedel-Crafts reaction of *meso*-IV was *rac*-V. On the basis of these facts, (−)-V was tentatively assigned to be (1*S*,2*S*)-(−)-3-oxo-2-phenyl-1-indancarboxylic acid, in which the configuration between the phenyl and carboxyl groups would be trans, being unable to proceed to further cyclization. The trans isomer seemed to be thermodynamically more stable than the cis one and to be produced from (+)-IV during the course of transformation (not before but after the half cyclization) by epimerization at the C-2 chiral center α to both phenyl and carbonyl groups. The Clemmensen reduction of (+)-I gave monoketone (II) and hydrocarbon (III), both of which had (4b*S*,9b*S*) configuration.



Scheme 1.

The UV and CD spectra of (+)-I are shown in Fig. 1. A negative CD band with fine structure and a positive one were observed in the n-π* and $^1B_{2u}$ regions, respectively. A typical negative couplet centered at near 40000 cm^{-1} was attributed to an exciton couplet due to the interaction of so-called intramolecular CT band of two benzoyl chromophores. From a consideration using the Dreiding molecular model with the (4b*S*,9b*S*)-configuration, the negative and positive peaks could be assigned to the transitions from the ground to the excited states with A and B symmetry, respectively. The transition moment of the monomeric indanone chromophores was assumed to lie in the center of the benzene ring and to be directed to the oxygen atom. This interpretation was supported by UV intensity distribution *versus* wavelength in the band, and with the lack of a CD couplet in the same absorption region of monoketone II.[3]

Thus, the absolute configuration deduced from the CD analysis was in accord with the chemically established (4b*S*,9b*S*) configuration.

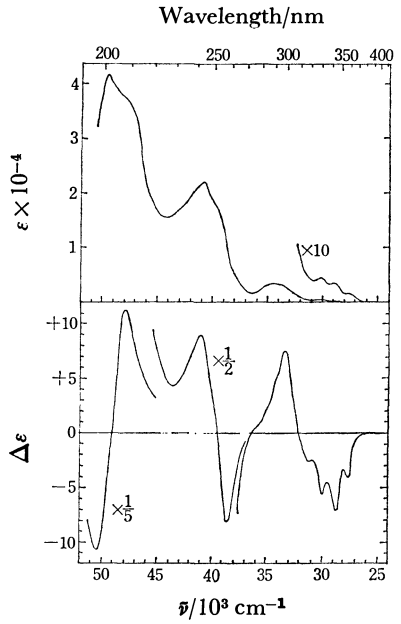


Fig. 1. UV (top) and CD (bottom) spectra of (4b*S*,9b*S*)-(+)-*cis*-4b,5,9b,10-tetrahydroindeno[2,1-*a*]-indene-5,10-dione (I) in 99% EtOH.

** Present address: Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Hiroshima 730.

Experimental

Melting points were measured on a Mettler FP2 apparatus and were uncorrected. IR spectra (Nujol mull) were obtained on a Hitachi EPI-2, EPI-G_3, or a JASCO DS-301 spectrometer, and UV spectra on a Hitachi EPS-3T spectrometer. ^{1}H-NMR spectra of $CDCl_3$ solutions were obtained on a Varian XL-100 or A-60D spectrometer, and chemical shifts from internal TMS are given in δ-unit. Optical rotations were measured on a Union Giken Polarimeter PM-71 at 20 °C, and CD spectra on a JASCO J-20 spectrometer. Shoulders and inflections are denoted by an asterisk.

2,3-Diphenylsuccinic Acid (IV): *dl*-Form,[1] recrystallized from water, melted once at 184—185 °C, immediately resolidified and melted again at 233—236 °C, and had IR: 1700 ($\nu_{c=o}$)cm^{-1}, ^{1}H-NMR: 4.38 (s, 2H, methine), 7.27 (s, 10H, aromatic), 7.40 (s, 2H, COOH). *meso*-Form,[1] recrystallized from 99% EtOH, melted at 248—252 °C, and had IR: 1690 ($\nu_{c=o}$)cm^{-1}, ^{1}H-NMR (DMSO-d_6): 4.26 (s, 2H, methine), 7.20—7.54 (m, 10H, aromatic), 12.22 (br s, 2H, COOH).

The racemate was resolved *via* bis-brucine salt.[1] An optically pure salt melted at 154.5—155.5 °C. Found: C, 64.59; H, 6.92; N, 4.69%. Calcd for $C_{62}H_{66}N_4O_{12}\cdot 5H_2O$: C, 64.79; H, 6.67; N, 4.87%. (*S*)-(+)-Form,[1,2] recrystallized from water, melted once at 170—180 °C, resolidified immediately and melted again at 210—220 °C. The hygroscopic acid was analysed immediately after drying at 100 °C for 17 h *in vacuo*, and had $[\alpha]_D$ +361.0° (*c* 1.457, 99% EtOH). Found: C, 70.82; H, 5.29%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%.

*(4bS,9bS)-(+)-*cis*-4b,5,9b,10-Tetrahydroindeno[2,1-*a*]indene-5,10-dione (I) and (−)-3-Oxo-2-phenyl-1-indancarboxylic Acid (V)*: A mixture of (*S*)-(+)-IV (0.655 g, 2.34 mmol) and PCl_5 (1.2 g, 5.8 mmol) was warmed on a boiling water bath for 30 min. After removal of $POCl_3$ *in vacuo*, the residue was dissolved in CS_2 (65 ml) and cooled in an ice bath. Freshly powdered $AlCl_3$ (1 g) was added at once, and the mixture was heated under reflux for 30 min with stirring. The reaction was quenched carefully by addition of ice water and 3M-HCl, and the product was extracted with ether. The combined organic layers were washed three times with aq 5% $NaHCO_3$ and dried over Na_2SO_4. The solvents were removed under reduced pressure to afford crude crystals (0.277 g) of (+)-I, which were recrystallized from EtOH. (*S*)-(+)-Diketone (I) sublimed at *ca.* 240 °C, melted at 253.5—254.5 °C, and had $[\alpha]_D$ +51.1°, $[\alpha]_{405}$ −600° (*c* 0.0572, 99% EtOH); IR: 1710 ($\nu_{c=o}$) cm^{-1}; UV: $\lambda_{max}^{99\%\ EtOH}$ (ε) 364 (164), 346 (346), 332.5 (392), 297* (3220), 291 (3310), 253* (17000), 245.5 (21300), 237* (23500), 210* (36800), 202 (42500) nm; CD: $\lambda_{max}^{99\%\ EtOH}$ ($\Delta\varepsilon$) 362 (−4.00), 348 (−7.12), 333 (−5.42), 320 (−2.60), 299 (+7.29), 258.5 (−16.8), 243.5 (+18.9), 209 (+56.8), 198 (−54.8) nm. Found: C, 81.96; H, 4.27%. Calcd for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%. The combined $NaHCO_3$ washings were acidified with concd HCl, and light yellow solid (0.273 g) thus obtained was recrystallized from CCl_4 to yield (−)-V; mp 138—139 °C; $[\alpha]_D$ −150.3°; $[\alpha]_{405}$ −496.9° (*c* 0.192, 99% EtOH); IR: 1725 ($\nu_{c=o}$, ketone), 1690 ($\nu_{c=o}$) cm^{-1}; ^{1}H-NMR (DMSO-d_6): 4.26 (d, J=4.5 Hz, 1H, methine), 4.42 (d, J=4.5 Hz, 1H, methine), 7.10—7.94 (m, 9H, aromatic); UV: $\lambda_{max}^{99\%\ EtOH}$ (ε) 335* (110), 293 (1820), 287* (1800), 244 (9500), 208 (24200) nm; CD: $\lambda_{max}^{99\%\ EtOH}$ ($\Delta\varepsilon$) 345* (−0.76), 331 (−1.06), 318 (−0.96), 292.5 (−0.86), 285 (−0.78), 269 (−0.35), 244 (−6.12), 220 (+7.58), 210 (+6.66) nm. Found: C, 76.07; H, 4.76%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80%.

(−)-Keto acid (V, 110 mg) was converted to the acid chloride with $SOCl_2$ in benzene and subjected again to the same cyclization. Only a minor amount (11 mg) of (+)-I was isolated, and almost all of (−)-V was recovered.

Polyphosphoric acid (5 g) was mixed with (−)-V (50.3 mg) and heated on a boiling water bath for 15 h. After ordinary work up, (+)-I (40.3 mg, optical purity *ca.* 40%) was obtained as a neutral product.

rac-*3-Oxo-2-phenyl-1-indancarboxylic Acid (V)*: By the essentially same cyclization reaction of *meso*-IV as in the case of (*S*)-(+)-IV, *dl*-V was obtained, mp 124—126 °C. Neither *dl*-I nor its *trans*-isomer was isolated.

*(4bS,9bS)-*cis*-4b,5,9b,10-Tetrahydroindeno[2,1-*a*]indene (III) and -5-one (II)*: (*S*)-(+)-Diketone (I, 200 mg) was dissolved in benzene (5 ml) and added to a mixture of water (1 ml), concd HCl (1 ml), and amalgamated Zn, which was prepared by the standard procedure from granules of Zn (1 g). The reaction mixture was refluxed for 6 h with stirring, and the product was extracted with CH_2Cl_2 after dilution with water. After usual work up, the solvent was removed *in vacuo*, and the residue was chromatographed on a column of silica gel (20 g) using benzene as an eluant. Hydrocarbon III (30 mg), monoketone II (55 mg), and recovered I (90 mg) were eluted successively. Both of II and III were purified by vacuum sublimation and then recrystallization from EtOH. Hydrocarbon III showed mp 140 °C; ^{1}H-NMR: 2.9—4.2 (m, 6H, aliphatic), 7.0—7.7 (m, 8H, aromatic); UV: $\lambda_{max}^{99\%\ EtOH}$ (ε) 273.5 (3880), 267 (2970), 261 (1780), 254 (890), 217.5 (17200), 212.5 (18900), 209 (20200), 196 (64800) nm; CD: $\lambda_{max}^{99\%\ EtOH}$ ($\Delta\varepsilon$) 272.5 (−1.7), 265 (−1.4), 260 (−1.0), 220.5 (+12), 197 (+67.4) nm. Found: C, 93.24; H, 6.81%. Calcd for $C_{16}H_{14}$: C, 93.16; H, 6.84%.

Monoketone II melted at 120 °C, and had ^{1}H-NMR: 3.0—4.1 (m, 4H, methylene and methine), 7.0—7.4 (m, 8H, aromatic); UV: $\lambda_{max}^{99\%\ EtOH}$ (ε) 332 (295), 294 (2200), 286 (2160), 276 (3100), 269 (2630), 247 (12400), 208.5 (29500) nm; CD: $\lambda_{max}^{99\%\ EtOH}$ ($\Delta\varepsilon$) 362 (+0.15), 346 (+0.39), 331 (+0.50), 316 (+0.46), 305 (+0.37), 291 (+1.2), 285* (+0.98), 275 (−3.4), 268 (−3.9), 251 (−7.2), 230* (+1.4), 206 (+38.1) nm.

2) R. Buchan and M. B. Watson, *J. Chem. Soc., C*, **1968**, 2465; N. D. Berova and B. J. Kurtev, *Tetrahedron*, **25**, 2301 (1969).

3) A positive couplet was anticipated for an exciton interaction of the short axis polarized transition of two 1-indanones. The strongest positive couplet observed at near 49000 cm^{-1} and the positive peak in $^1B_{2u}$ band might be attributed to the coupling of this nature. However, further interpretation of CD is reserved until the exact molecular structural parameters and nature of the electronic transition are clarified.

Synthetic Studies *via* Arene-Metal Compounds. An Application to the Regioselective Synthesis of a Natural Phthalide

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received July 3, 1979)

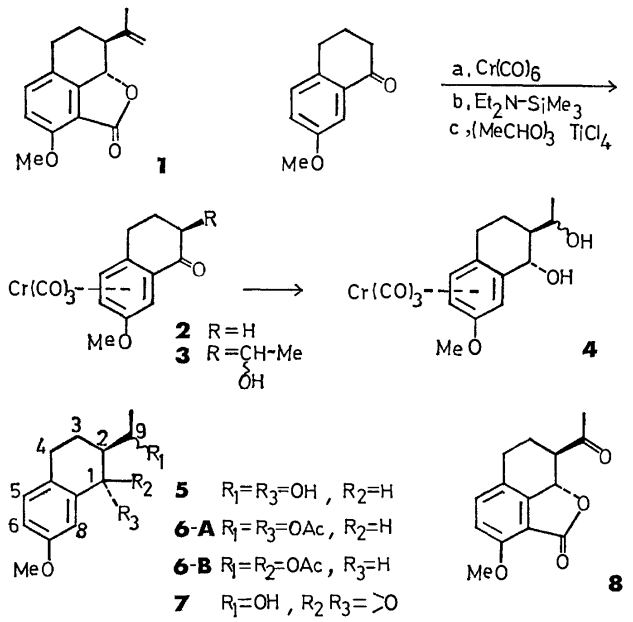
Synopsis. A naturally occuring methoxyphthalide derivative, a constituent of *Othonna Cylindrica Dc*, was synthesized by employing stereoselective carbonyl reduction of (η-arene)tricarbonylchromium complex and regioselective lithiation of 7-methoxy-2-(1-hydroxyethyl)-1-tetralol.

The 3-methoxybenzyl alcohol derivatives and related compounds were lithiated mostly at 2-position of the aromatic ring on the basis of coordination between the lithium cation and the two proximal oxygen atoms.[1] In case of such a molecule that the benzylic hydroxyl group is fixed by a rigid conformation as in 7-methoxy-1-tetralol, this selective metallation is more facilitated by further stabilization of the cyclic lithio compound. This paper reports an application of this reaction to the synthesis to (**1**),[2] a constituent of *Othonna Cylindrica Dc*, combined with the stereoselective carbonyl reduction of tricarbonyl (2-substituted 7-methoxy-1-tetralol) chromium complex.

Refluxing of 7-methoxy-1-tetralone with hexacarbonylchromium in heptane and dibutyl ether gave a red colored (η-arene) tricarbonylchromium complex (**2**) in a 65% yield. The reaction of the complex **2** with *N*-trimethylsilyldiethylamine in the presence of *p*-toluenesulfonic acid,[3] followed by cross-aldol condensation[4] with paraldehyde and titanium tetrachloride, afforded a mixture of diastereomeric keto alcohols (**3**).[5] The compound **3** was reduced with diisobutylaluminum hydride (Dibal) to give the chromium complex (**4**) of *trans* substituted diol. No trace of the corresponding *cis* isomer was detected. In this reaction, the hydroxyethyl and hydride addition selectively took place from the other side of the tricarbonylchromium group.[6] Decomplexation of the chromium metal (by exposure to sunlight) gave the *trans* diol (**5**), which was chracterized as a diacetyl compound (**6-A**).

When the carbonyl reduction of the trimethylsilyl ether of the keto alcohol (**7**), prepared from 7-methoxy-1-tetralone by an analogous procedure, was performed without complexation by $Cr(CO)_3$ group, the product (80% yield) was a mixture of *trans* and *cis* alcohols in an approximate ratio of 12:88. The stereochemistry (C-1 and C-2) of both compounds was elucidated by the comparison of the ^{1}H-NMR spectra of the corresponding diacetates, **6-A** and **6-B**, derived by deprotection of trimethylsilyl group and acetylation. In this reduction, the *cis* isomer was formed predominantly, in contrast to the reduction of the (η-arene) tricarbonylchromium complex.

Treatment of the *trans* compound **5**[5] with butyl lithium and tetramethylethylenediamine (TMEDA) in hexane, followed by carboxylation with solid carbon dioxide, gave a hydroxy γ-lactone, which, without purification, was oxidized with Collins reagent to a



trans keto lactone (**8**)[7] as a sole isolable product in a 20% overall yield, unaccompanied with any other carboxylated products. Reaction of the *trans* keto lactone (**8**) with methylenetriphenylphosphorane gave **1**, which exhibited the same spectral data as those of the reported natural product.[2]

Experimental

Tricarbonyl(η-7-methoxy-1-tetralone)chromium Complex (2). A mixture of 7-methoxy-1-tetralone (1 g, 3.67 mmol), $Cr(CO)_6$ (2 g, 5.87 mmol), α-picoline (0.54 g, 5.87 mmol), heptane (20 ml) and dibutyl ether (100 ml) was refluxed under nitrogen for 24 h in a Strohmeier type apparatus. After filtration and evaporation *in vacuo*, a crude product was chromatographed on silica gel. Elution with ether–petroleum ether (1 : 4) gave a 1.15 g (65%) of **2**. IR ($CHCl_3$): 1975, 1920—1880, 1683 cm^{-1}. NMR ($CDCl_3$)δ: 3.66 (s, 3H, OMe), 5.36(d, J=6 Hz, 1H), 5.49 (dd, J=2, 6 Hz, 1H), 5.66 (d, J=2 Hz, 1H).

Tricarbonyl[η-7-methoxy-2-(1-hydroxyethyl)-1-tetralone]chromium Complex (3). A mixture of **2** (997 mg, 3.2 mmol), *N*-trimethylsilyldiethylamine (1.856 g, 12.8 mmol) and catalytic amount of *p*-TsOH was stirred at 35 °C in dry dichloromethane (15 ml) for 24 h. After evaporation at a reduced pressure, a residue was triturated with dry pentane. Evaporation of the pentane solution gave an oily enolsilyl ether (811 mg, 66%), which was used for next step without further purification. IR(neat): 1955, 1885—1855, 1640, 1605 cm^{-1}. NMR($CDCl_3$)δ: 0.19(s, 9H, $SiMe_3$), 3.68(s, 3H, OMe), 4.96—5.44(m, 4H). A solution of the crude enolsilyl ether (811 mg) in dry dichloromethane (10 ml) was added dropwise into a mixture of paraldehyde (169 mg, 0.84 mmol) and titanium tetrachloride (480 mg, 2.52 mmol) in dry dichlo-

romethane (10 ml) under argon atmosphere at −78 °C, and the reaction mixture was stirred for 7 h at the same temperature. After hydrolysis with water, the reaction mixture was extracted with dichloromethane. The extract was washed with brine and dried over Na_2SO_4. The solvent was evaporated under reduced pressure, and the residue was purified by silica gel chromatography. Elution with ether–petroleum ether (1 : 3) afforded a diastereomeric mixture of **3** (428 mg, 57% yield). IR ($CHCl_3$): 3440, 1970, 1910, 1890, 1660 cm^{-1}. NMR ($CDCl_3$)δ: 1.23 (d, J=7 Hz) and 1.26 (d, J=7 Hz) (2 : 3 ratio, 3H, CHMe), 3.66 (s, 3H, OMe), 5.39 (d, J=6 Hz, 1H), 5.55 (dd, J=2, 6 Hz, 1H), 5.72 (d, J=2 Hz).

trans-*7-Methoxy-2-(1-hydroxyethyl)-1-tetralol (**5**).* Diisobutylaluminum hydride in toluene (0.186 M solution, 3.0 ml, 5.28 mmol) was added to a solution of **3** (510 mg, 1.43 mmol) in dry THF (10 ml) under argon atmosphere at −78 °C. After stirring for 3 h, acetone (1 ml) and then, water (10 ml) were added, After filtration and evaporation of the organic solvents under reduced pressure, the reaction mixture was extracted with ether. The extract was worked up as usual to leave *trans* compound **4** as a yellow oil which was used for next step without further purification. A solution of the *trans* compound **4** in ether (10 ml) was exposed to sunlight for 2 h. The precipitate was filtered and washed with ether. The ether solution was concentrated *in vacuo*, leaving a crude product which was purified by silica-gel chromatography (elution with ether–petroleum ether; 1:3) to give **5** as a colorless oil (250 mg, 79% from **3**). IR(CCl_4): 3210, 1610, 1580, 1505 cm^{-1}. NMR(CCl_4)δ: 1.18(d, J=7 Hz) and 1.21(d, J=7 Hz) (2 : 3 ratio, 3H, CHMe), 3.77(s, 3H, OMe), 6.76(dd, J=3, 7 Hz, 1H,) 7.03(d, J=7 Hz, 1H), 7.16(d, J=3 Hz, 1H).

trans *Keto Lactone (**8**).* A solution of the *trans* diol **5** (730 mg, 3.29 mmol) in dry ether (3 ml) was added into a mixture of butyllithium (1.3 M in hexane solution, 8.0 ml, 10.4 mmol), TMEDA (1.206 g, 10.4 mmol) in dry hexane (10 ml) under nitrogen, and the reaction mixture was heated at 60 °C for 5 h. The resulting dark red reaction mixture, after cooling to −78 °C, was treated with large excess of Dry Ice (in small pieces). After standing overnight, the reaction mixture was acidified with 2 M-HCl, heated at 50 °C for 30 min, and extracted with ethyl acetate. The extract was washed with brine, and dried over Na_2SO_4. Evaporation of the solvent gave an oily product, which was used for next oxidation step without purification. A solution of the product in dry dichloromethane (2 ml) was added to stirred Collins reagent (prepared from 1.2 g of chromium trioxide, and 1.9 g of pyridine in 25 ml of dry dichloromethane) at 0 °C. After stirring at that temperature for 3 h, ether (10 ml) was added. The solution was filtrated from the residue, which was washed with ether. The combined organic solution was washed with 2M-HCl, saturated aq $NaHCO_3$, and brine and then, dried over Na_2SO_4. Evaporation of the solvent at reduced pressure afforded 290 mg of an oily product, which was purified over silica gel column chromatography to give a crystalline compound **8** (159 mg, 20% from **5**). Recrystallization from ether–petroleum ether gave colorless needles; mp 148—149 °C. IR($CHCl_3$): 1750, 1710, 1640, 1605, 1510 cm^{-1}. NMR($CDCl_3$)δ: 2.32(s, 3H, COMe), 3.92(s, 3H, OMe), 5.22(d, J=10 Hz, CHOC=O), 6.82(d, J=8 Hz, 1H), 7.31(d, J=8 Hz, 1H). Found: C, 68.23; H, 5.76%. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73%.

*Wittig Reaction of **8**.* Butyllithium (1.3 M in hexane solution, 0.29 ml, 0.382 mmol) was added to a mixture of methyltriphenylphosphonium bromide (151 mg, 0.42 mmol) in dry THF (2 ml) at 0 °C under nitrogen atmosphere. After stirring for 1 h, a solution of **8** (77 mg, 0.313 mmol) in dry THF (5 ml) was added to the above Wittig reagent, and the reaction mixture was stirred for 3 h at 0 °C. After addition of 2M-HCl, the product was extrated with ether as usual. The crude product was purified by silica gel column chromatography to give crystalline compound **1** (25 mg). MS *m/e*: 244, 176. IR($CHCl_3$): 2940, 1750, 1660, 1605, 1510 cm^{-1}. NMR($CDCl_3$)δ: 1.86(s, 3H, MeC=), 3.97(s, 3H, OMe), 4.94(broad s, 2H, H_2C=C), 5.12(d, J=10 Hz, 1H, O=COCH–), 6.85(d, J=8 Hz, 1H), 7.32(d, J=8 Hz, 1H). UV(EtOH) max: 215, 241, 305 nm. These data were well consistent to the spectral data reported for the natural product.[2]

trans-*Diacetate (**6-A**).* This acetate was prepared with acetic anhydride and pyridine by usual method. IR (CCl_4): 1740, 1615, 1505, 1245 cm^{-1}. NMR(CCl_4)δ: 1.25(d, J=7 Hz) and 1.29(d, J=7 Hz) (3:2 ratio, 3H, CHMeOAc), 1.97(s) and 2.01(s) (2:3 ratio, 3H, OAc), 2.13(s, 3H, OAc), 4.80—5.10(m, 1H, MeCHOAc), 5.95(d, J=8 Hz, 1H, CHOAc), 6.63(d, J=3 Hz, 1H), 6.77(dd, J=3, 8 Hz, 1H), 7.01(d, J=8 Hz, 1H).

cis-*Diacetate (**6-B**).* A mixture of **7** (110 mg, 0.5 mmol) and hexamethyldisilazane (242 mg, 1.5 mmol) was heated at 50 °C for 24 h. Evaporation at reduced pressure gave an oily silylated product in a quantitative yield. IR(neat): 1680, 1610, 1500 cm^{-1}. NMR($CDCl_3$)δ: 0.21(s) and 0.18(s) (2:3 ratio, 9H, $OSiMe_3$), 1.18(d, J=7 Hz) and 1.32(d, J=7 Hz) (3:2 ratio, 3H, CHMe), 3.88(s, 3H, OMe), 4.70(m, 1H, MeCHO–), 7.08(dd, J=2, 7 Hz, 1H), 7.20(d, J=7 Hz, 1H), 7.54(d, J=2 Hz, 1H). The keto silylated product was reduced with Dibal (THF, −78 °C), to giva a hydroxy silylated compound, which was converted to a diacetylated product by deprotection of silyl group (aq AcOH, THF, rt) and then acetylation (acetic anhydride, pyridine, rt) in a 80% yield. Pure *cis* isomer was obtained by preparative TLC. IR(CCl_4): 1740, 1615, 1505, 1245 cm^{-1}. NMR (CCl_4)δ: 1.26(d, J=7 Hz, 3H, CHMeOAc), 1.91(s) and 1.98(s) (3:2 ratio, 3H, OAc), 1.95(s) and 2.00(s) (3:2 ratio, 3H, OAc), 3.74(s, 3H, OMe), 4.80—5.05(m, 1H, MeCHOAc), 6.05(d, J=7 Hz, 1H, CHOAc), 6.70—6.82(m, 2H), 6.97 (broad d, J=8 Hz, 1H).

A Novel Synthesis of 2-(1-Imidazolyl)benzophenones

Yasutaka KAYAMA, Takeshi HARA,* and Tamiko SUNAMI
Teijin Institute for Bio-medical Research, Asahigaoka, Hino, Tokyo 191

(Received July 5, 1979)

Synopsis. 2-(1-Imidazolyl)benzophenones were prepared from 3-(2,2-dialkoxyethyl)-3,4-dihydro-4-hydroxy-4-phenylquinazolines and a corresponding 4-alkoxy derivative by heating in formic acid or in sulfuric acid–ethanol.

2-(1-Imidazolyl)benzophenones with appropriate substituents are themselves pharmacologically active compounds[1,2] or important intermediates for the synthesis of 6-phenyl-4*H*-imidazo[1,2-*a*][1,4]benzodiazepines[3] or 6-phenyl-4*H*-imidazo[1,5-*a*][1,4]benzodiazepines.[4] This type of compounds have so far been prepared by nucleophilic reaction of imidazolide anions with 2-halobenzophenones,[2] oxidation of 1-(2-benzylphenyl)-1*H*-imidazoles[5] or seven-membered ring cleavage of 6-phenyl-4*H*-imidazo[1,2-*a*][1,4]benzodiazepines.[1,4,6] We now wish to report a novel synthesis of 2-(1-imidazolyl)benzophenones.

When 3-(2,2-dialkoxyethyl)-3,4-dihydro-4-hydroxy-4-phenylquinazolines **3a**, **c** prepared by the reaction[7] of aminoacetaldehyde dialkyl acetals (**2**) with 2-(1-alkoxyethylideneamino)benzophenones (**1**) were heated with formic acid, ring opening and recyclization occured to afford the 2-(1-imidazolyl)benzophenones **5a**, **b** in good yields (Table 1).

The conversion of **3c** to **5b** could also be carried out with sulfuric acid, but in a decreased yield. As we previously reported,[7] the 4-hydroxydihydroquinazolines **3** formed by refluxing an ethanolic solution of **1** and **2** are converted to the corresponding 4-ethoxy derivatives **4** under the reaction conditions, and the latters can be isolated as such avoiding acidic treatment such as silica gel chromatography; the chromatography converted **4** to **3**. So, next we examined the conversion of **4** to **5**. Treatment of **4b** with formic acid also afforded **5b** in 81% yield. The 2-(1-imidazolyl)benzophenones **5a**, **b** thus obtained gave satisfactory elemental analysis and IR and NMR spectral properties. Ring opening and recyclization of dihydroquinazolines to yield 2-(4*H*-1,2,4-triazol-4-yl)benzophenones, a reaction similar to the one reported herein, was previously reported.[8]

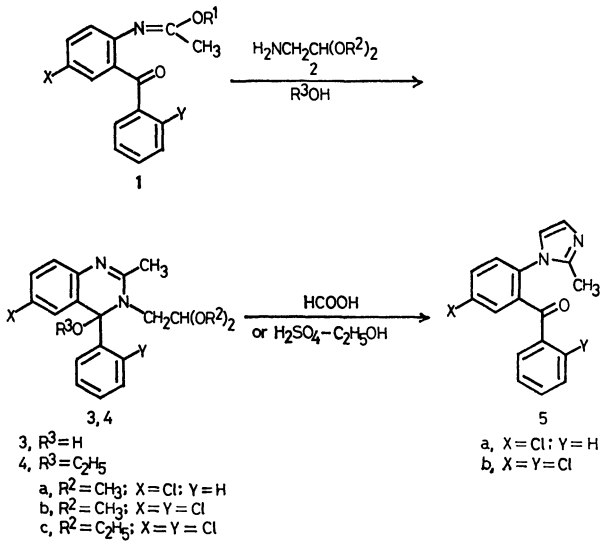

TABLE 1. CONVERSION OF QUINAZOLINES (**3**, **4**) TO IMIDAZOLYLBENZOPHENONES (**5**)

Run	Starting material	Catalyst-solvent	Refluxing period/h	Product	Yield/%
1	**3a**	80% HCO_2H[a]	3	**5a**	83
2	**3c**	99% HCO_2H[a]	1	**5b**	85
3	**3c**	H_2SO_4–C_2H_5OH	3	**5b**	55
4	**4b**	85% HCO_2H[a]	3	**5b**	81

a) Formic acid was employed as solvent as well as catalyst.

Experimental

Melting points were taken with a Yanagimoto hot-stage apparatus and are uncorrected. Combustion analyses were carried out by the Analytical Chemistry Laboratory of Central Research Institute, Teijin Limited. IR spectra were measured on a Hitachi EPI-S2 spectrophotometer. NMR spectra were obtained on a JEOL JNM-MH-100 spectrometer, and chemical shifts are expressed in parts per million (δ) relative to TMS as an internal standard.

*5-Chloro-2-(2-methyl-1-imidazolyl)benzophenone (**5a**).*

A solution of 6-chloro-4-hydroxy-3-(2,2-dimethoxyethyl)-2-methyl-4-phenyl-3,4-dihydroquinazoline (**3a**) (2.03 g, 5.62 mmol) in 80% formic acid (10 ml) was refluxed for 3 h. The formic acid was evaporated. Ice–water (10 g) was added to the residue, and the mixture was made alkaline with 4 M (1M=1 mol dm^{-3}) NaOH and extracted with dichloromethane (40 ml). The extract was washed with brine, dried (Na_2SO_4), and evaporated. The residue was crystallized with ether and triturated after addition of a small amount of hexane. The crystals were collected on a filter, washed with ether–hexane, and dried to give 1.40 g (83%) of **5a** as colorless crystals. Recrystallization from ether–hexane gave colorless plates: mp 115.5—117.0 °C; IR (KBr) 1656, 1596, 1485, 1414, 1303, 1284, 1242, 827, 737, 711; NMR ($CDCl_3$) δ 2.18 (s, 3H), 6.73 (s, 2H), 7.24—7.67 (m, 8H).

Found: C, 68.51; H, 4.24; N, 9.60%. Calcd for $C_{17}H_{13}N_2OCl$: C, 68.80, H, 4.42; N, 9.44%.

*2',5-Dichloro-2-(2-methyl-1-imidazolyl)benzophenone (**5b**).*

a) Compound **5b** isolated by silica gel column chromatography [eluent; dichloromethane–ethyl acetate (2:1)] of the product mixture in Run 2 of Table 1 was recrystallized from dichloromethane–hexane to give colorless prisms: mp 112—113.5 °C; IR (KBr) 1665, 1591, 1482, 1415, 1298, 1258, 1238, 837, 747; NMR ($CDCl_3$) δ 2.12 (s, 3H), 6.69 (m, 2H), 7.20—7.34 (m, 5H), 7.61 (dd, J=8.0 and 2.5 Hz, 1H), 7.71 (d, J=2.5 Hz, 1H).

Found: C, 61.65; H, 3.48; N, 8.43%. Calcd for $C_{17}H_{12}N_2OCl_2$: C, 61.65; H, 3.65; N, 8.46%.

b) A mixture of 6-chloro-4-(2-chlorophenyl)-3-(2,2-diethoxyethyl)-3,4-dihydro-4-hydroxy-3-methylquinazoline (**4b**) (1.00 g, 2.36 mmol), ethanol (5 ml), and 9 M H_2SO_4 (5 ml) was refluxed for 3 h. To the reaction mixture, after evapora-

tion of ethanol, was added ice–water (10 g) and dichloromethane (30 ml), and the resulting mixture was made alkaline with 4 M NaOH. The layers were separated, and the organic layer was washed with brine, dried (Na_2SO_4), and evaporated. The residue was chromatographed on silica gel with benzene–ethyl acetate (2:1 to 0:1) as eluent to give 0.427 g (55%) of **5b** as yellowish crystals. Recrystallization from dichloromethane–hexane gave colorless prisms of mp 112.5—113 °C, showing identical IR and NMR spectra with those of **5b** prepared in Run 2 of Table 1.

The authors wish to thank Miss A. Mineo for NMR spectral measurement. Particular appreciation is expressed to Dr. T. Noguchi for his encouragement during the course of this work.

New Routes to the Pyrrolo[2,1-*a*]isoquinoline System

Masatomo Iwao* and Tsukasa Kuraishi

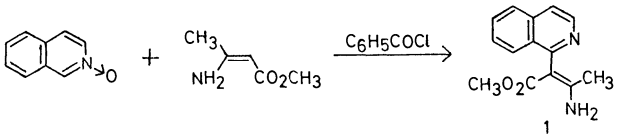
Department of Chemistry, Faculty of Liberal Arts, Nagasaki University, 1-14 Bunkyo-machi, Nagasaki 852

(Received July 12, 1979)

Synopsis. Some derivatives of the title ring system were prepared from methyl α-(1-isoquinolyl)-β-aminocrotonate and ethyl α-(1-isoquinolyl)-β-amino-β-ethoxyacrylate in moderate to good yields *via* their quaternary salts.

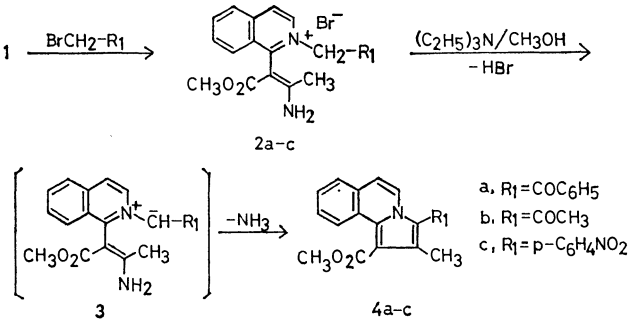
Although several methods for the preparation of pyrrolo[2,1-*a*]isoquinoline system have been reported, the yields of the products are usually poor.[1)]

In the course of our recent study of the convenient synthesis of heteroarylacetic esters, methyl α-(1-isoquinolyl)-β-aminocrotonate (**1**) was prepared in a moderate yield (58%) as an intermediate compound for methyl 1-isoquinolylacetate, from isoquinoline 2-oxide and methyl β-aminocrotonate in the presence of benzoyl chloride.[2)] The ready availability of **1** and its unique

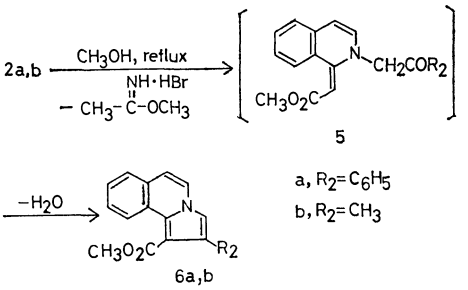


structure, possessing a reactive enaminic substituent at the 1-position of the isoquinoline ring, prompted us to determine the utility of this compound for the synthesis of fused isoquinoline systems. In this paper, we wish to describe the efficient synthesis of pyrrolo-[2,1-*a*]isoquinoline system from **1**. In addition, a related synthesis of the same system from ethyl α-(1-isoquinolyl)-β-amino-β-ethoxyacrylate(**7**) will also be described.

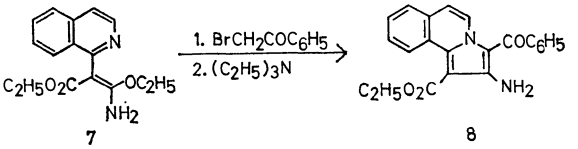
Compound **1** was allowed to react with phenacyl bormide or bromoacetone in chloroform under reflux for 1 h to give quaternary salts **2a**, **b** in about 90% yields. When these salts were treated with excess triethylamine in methanol in order to generate the ylides, **3**, a successive cyclization occurred and two pyrrolo[2,1-*a*]isoquinoline derivatives, **4a** and **4b**, were obtained in 93% and 77% yields respectively. This cyclization can be well explained in terms of the intramolecular nucleophilic attack of the ylidic carbanion on a β-carbon atom in the crotonate moiety, followed by the elimination of ammonia. The intermediacy of the ylides was shown by the development of a deep-red color at the initial stage of the reactions. Although the yield was not satisfactory (23%), Compound **4c** was obtained in a similar manner from **1** and *p*-nitrobenzyl bromide without isolating the intermediate quaternary salt, **2c**.



On the other hand, when quaternary salts **2a** and **2b** were heated in methanol under the reflux temperature for an appropriate time, pyrrolo[2,1-*a*]isoquinoline derivatives of another type, **6a** and **6b**, were obtained in 85% and 92% yields respectively. The structures of these unexpected compounds were fully supported by the results of microanalyses and the spectral data. In addition, the Compound **6b** thus obtained was completely identical with an authentic sample prepared from methyl 1-isoquinolylacetate and bromoacetone using Bragg's method.[3)] Although we have not conducted experiments to establish the reaction mechanism, it is reasonable to assume that the reaction is initiated by the nucleophilic attack of methanol on a β-carbon of **2**, which causes the elimination of methyl acetimidate. The intermediate enamine, **5**, thus formed gives **6** by spontaneous dehydrative cyclization.



Recently, Yamanaka *et al.* reported the synthesis of ethyl α-(1-isoquinolyl)-β-amino-β-ethoxyacrylate(**7**).[4)] The structural resemblance of **7** to **1** suggested that the above cyclization methods are also applicable to this compound. In fact, the quaternization of **7** with phenacyl bromide and subsequent treatment with triethylamine afforded 2-aminopyrrolo[2,1-*a*]isoquinoline derivative **8** in a 66% yield. In this case, the elimination of ethanol occurred in preference to that of ammonia.



Experimental

All the melting points are uncorrected. The NMR spectra were recorded on a Hitachi R-20B spectrometer for a solution in deuteriochloroform, using TMS as the internal standard. The IR spectra were obtained in Nujol mulls with a Hitachi EPI-2 spectrometer. The UV spectra were determined for solutions in 95% ethanol with a Hitachi 323 spectrometer.

*Preparation of Quaternary Salts (**2a, b**). General Procedure*: A solution of 2.51 g (10 mmol) of hemihydrate of **1** and the appropriate α-bromoketone (10 mmol) in 25 ml of chloroform was refluxed for 1 h. The precipitated yellow solid of **2** was collected by filtration, washed with ether, and then recrystallized from methanol–ether. If the quaternary salt was not precipitates from the reaction mixture, the chloroform was removed by evaporation and the residual oil was crystallized by trituration with ether. The quaternary salt **2a** was thus obtained in a 92% yield; mp 190.5 °C (dec). IR: 3330, 3230, and 3160 cm^{-1} (NH_2), 1692 and 1672 cm^{-1} (C=O). The quaternary salt **2b** was obtained in a 90% yield; mp 148—149 °C (dec). IR: 3350, 3240, and 3160 cm^{-1} (NH_2), 1723 and 1672 cm^{-1} (C=O).

*Methyl 3-Benzoyl-2-methylpyrrolo[2,1-a]isoquinoline-1-carboxylate (**4a**).* Triethylamine (2 ml) was added to a solution of 1.00 g of **2a** in 20 ml of chloroform. The solution turned a deep red and was gradually decolorized. After several minutes, a crystalline compound began to precipitate. After having been allowed to stand overnight, the precipitates were collected by filtration, giving 0.72 g (94%) of **4a** as pale yellow needles. An analytical sample was purified by recrystallization from ethanol; mp 151.5—152.5 °C. IR: 1695 and 1612 cm^{-1} (C=O). UV max: 216^{sh} (log ε 4.40), 273 (4.60), 320 (4.13), 368^{sh} (4.12), and 382 nm (4.18). NMR; δ 2.07 (s, 3H, CH_3), 3.95 (s, 3H, $COOCH_3$), 7.01 (d, 1H, H-6, J=7.5 Hz), 7.3—7.9 (m, 5H arom, 3H, H-7, H-8, H-9), 8.6—8.9 (m, 1H, H-10), and 8.94 ppm (d, 1H, H-5, J=7.5 Hz). Found; C, 77.02; H, 4.92; N, 4.11%. Calcd for $C_{22}H_{17}NO_3$: C, 76.95; H, 4.99; N, 4.08%.

*Methyl 3-Acetyl-2-methylpyrrolo[2,1-a]isoquinoline-1-carboxylate (**4b**).* This compound was prepared from **2b** in a 77% yield in a manner similar to that described above; colorless prisms; mp 124.5—125.5 °C. IR: 1702 and 1623 cm^{-1} (C=O). UV max: 224^{sh} (log ε 4.19), 249 (4.30), 274 (4.57), 284 (4.48), 323 (4.11), 340 (3.91), 357 (4.15), and 375 nm (4.12). NMR: δ 2.51 (s, 3H, CH_3 or $COCH_3$), 2.53 (s, 3H, $COCH_3$ or CH_3), 3.96 (s, 3H, $COOCH_3$), 6.94 (d, 1H, H-6, J=7.5 Hz), 7.35—7.6 (m, 3H, H-7, H-8, H-9), 8.2—8.5 (m, 1H, H-10), and 9.52 ppm (d, 1H, H-5, J=7.5 Hz). Found: C, 72.43; H, 5.32; N, 5.07%. Calcd for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.37; N, 4.98%.

*Methyl 2-Methyl-3-(p-nitrobenzyl)pyrrolo[2,1-a]isoquinoline-1-carboxylate (**4c**).* A mixture of 2.51 g (10 mmol) of hemihydrate of **1**, 2.16 g (10 mmol) of *p*-nitrobenzyl bromide, and 25 ml of chloroform was refluxed for 3 h. The chloroform was then removed by evaporation, and the residual oil was dissolved in 20 ml of methanol. Triethylamine (4 ml) was added to the solution, and the reaction mixture was allowed to stand at room temperature for 2d. The precipitated orange prisms were collected by filtration to give 0.72 g of **4c**; mp 192.5—193.5 °C. The filtrate was evaporated, and the residue was passed through a colum of silica gel, using chloroform as the eluent. From the first orange band, an additional 0.09 g of **4c** was obtained; mp 189—192.5 °C. The total yield was 0.81 g (23%). An analytical sample was purified by recrystallization from ethanol; mp 192.5—193.5 °C. IR: 1682 cm^{-1} (C=O), 1510 and 1346 cm^{-1} (NO_2). UV max: 253^{sh} (log ε 4.42), 269^{sh} (4.55), 277 (4.65), 332 (4.11), and 388 nm (4.00). NMR: δ 2.30 (s, 3H, CH_3), 3.96 (s, 3H, $COOCH_3$), 6.80 (d, 1H, H-6. J=7.5 Hz), 7.3—7.7 (m, 2H arom, 4H, H-5, H-7, H-8, H-9). 8.31 (near d, 2H arom) and 8.9—9.1 ppm (m, 1H, H-10). Found: C, 70.15; H, 4.50; N, 7.77%. Calcd for $C_{21}H_{16}N_2O_4$: C, 69.99; H, 4.48; N, 7.77%.

*Methyl 2-Phenylpyrrolo[2,1-a]isoquinoline-1-carboxylate (**6a**).* A solution of 0.5 g of **2a** in 20 ml of methanol was refluxed for 2 d. The solution was then evaporated, and the residue was extracted with chloroform. The extract was washed with water, dried over sodium sulfate, and evaporated. The residue was recystallized from methanol to give 0.29 g (85%) of **6b** as colorless plates; mp 91.5—92.5 °C. IR: 1690 cm^{-1} (C=O). UV max: 253^{sh} (log ε 4.42), 274^{sh} (4.62), 281 (4.68), and 329 nm (4.08). NMR: δ 3.65 (s, 3H, $COOCH_3$), 6.62 (d, 1H, H-6, J=7.5 Hz), 7.03 (s, 1H, H-3), 7.1—7.7 (m, 5H arom, 4H, H-5, H-7, H-8, H-9), and 8.7—8.95 ppm (m, 1H, H-10). Found: C, 79.62; H, 4.90; N, 4.69%. Calcd for $C_{20}H_{15}NO_2$: C, 79.71; H, 5.02; N, 4.65%.

*Methyl 2-Methylpyrrolo[2,1-a]isoquinoline-1-carboxylate (**6b**).* A solution of 0.5 g of **2b** in 20 ml of methanol was refluxed for 17 h and then worked up in a manner similar to that described for **6a**. Recrystallization from methanol afforded 0.29 g (92%) of **6b** as colorless needles; mp 139—140 °C. IR: 1675 cm^{-1} (C=O). UV max; 223 (log ε 4.44), 243 (4.15), 272^{sh} (4.45), 281 (4.62), and 331 nm (4.06). NMR: δ 2.30 (s, 3H, CH_3), 3.88 (s, 3H, $COOCH_3$), 6.64 (d, 1H, H-6, J=7.5 Hz), 6.80 (s, 1H, H-3), 7.3—7.6 (m, 4H, H-5, H-7, H-8, H-9), and 9.15—9.4 ppm (m, 1H, H-10). Found: C, 75.56; H, 5.50; N, 5.93%. Calcd for $C_{15}H_{13}NO_2$: C, 75.30; H, 5.48; N, 5.85%.

Unequivocal Synthesis of Methyl 2-Methylpyrrolo[2,1-a]isoquinoline-1-carboxylate. A solution of 2.24 g (11 mmol) of methyl 1-isoquinolylacetate and 0.77 g (5.5 mmol) of bromoaceone in 10 ml of acetone was refluxed for 17 h. The solution was then evaporated, and the residue was extracted with chloroform. The extract was washed with water, dried over sodium sulfate, and evaporated. The residue was subsequently recrystallized from methanol, giving 0.67 g (50%) of methyl 2-methylpyrrolo[2,1-*a*]isoquinoline-1-carboxylate; mp 138—140 °C. This compound was shown to be identical with Compound **6b** by a comparison of the IR spectra and by a mixed-melting-point determination.

*Ethyl 2-Amino-3-benzoylpyrrolo[2,1-a]isoquinoline-1-carboxylate (**8**).* A solution of 2.86 g (10 mmol) of **7** and 1.99 g (10 mmol) of phenacyl bromide in 25 ml of chloroform was refluxed for 1 h. The solution was then evaporated, and the residual oil was dissolved in 20 ml of methanol. After triethylamine (4 ml) has been added to this solution, the reaction mixture was allowed to stand overnight at room temperature. The yellow needles thus precipitated were collected by filtration to give 2.38 g (66%) of **8**; mp 155—156 °C. An analytical sample was purified by recrystallization from ethanol; mp 155—156 °C. IR: 3450 and 3300 cm^{-1} (NH_2), 1683 cm^{-1} (C=O). UV max: 214^{sh} (log ε 4.46), 228^{sh} (4.40), 287 (4.62), and 362 nm (4.30). NMR: δ 1.39 (t, 3H, $COOCH_2C\underline{H}_3$, J=7 Hz), 4.38 (q, 2H $COOC\underline{H}_2CH_3$, J=7 Hz), 5.97 (broad s, 2H, NH_2), 6.80 (d, 1H, H-6, J=7.5 Hz), 7.3—7.7 (m, 5H arom, 3H, H-7, H-8, H-9), 8.56 (d, 1H, H-5, J=7.5 Hz) and 9.0—9.25 ppm (m, 1H, H-10). Found: C, 73.93; H, 5.06; N, 7.90%. Calcd for $C_{22}H_{18}N_2O_3$: C, 73.73; H, 5.06; N, 7.82%.

(Received December 19, 1978)

The reaction of cyclohexene oxide over solid acids and bases at 108 °C gave five main products, 1,3-cyclohexadiene (**1**), cyclohexanone (**2**), cyclohexanol (**3**), 2-cyclohexen-1-one (**4**), and 2-cyclohexen-1-ol (**5**). SiO_2–TiO_2 and SiO_2–TiO_2–MgO were highly active for the isomerization, giving a large amount of **1**. TiO_2–ZrO_2 mainly showed selectivity for the formation of **5**, and other catalysts formed both **2** and **5**. Of the alumina prepared in four different ways, two were highly active, giving **5** predominantly. The results were discussed in comparison with those for an oxide containing a methyl group on the oxide ring, 1-methylcyclohexene oxide. By the experiment using the deuterated epoxide, 1,2-epoxycyclohexane-3,3,6,6-d_4, isotope effects for the formation of **2**, **3**, **4**, and **5** over Al_2O_3's, SiO_2–TiO_2 and solid H_3PO_4 were observed. It has been concluded that the epoxide is adsorbed on both acidic and basic sites, and that allyl alcohol is formed when both the opening of the epoxide ring and the hydrogen abstraction take place simultaneously, while ketone is formed when the former precedes the latter.

Studies on the rearrangement of cyclohexene oxide have been made. Nagvi and his coworkers reported for the first time that the oxide undergoes rearrangement in the presence of magnesium bromide etherate to *trans*-2-bromocyclohexanol and cyclopentanecarbaldehyde, a ring-contracted aldehyde.[2)] The aldehyde formation from the oxide has been demonstrated using molten salts, low-melting binary or ternary eutectic salts as catalysts, *i.e.*, in the presence of lithium bromide or perchlorate with tributylphosphine oxide or hexamethylphosphoric triamide as reported by Rickborn and Gerkin,[3)] or over lithium bromide–rubidium bromide eutectic supported on firebrick similar to the gas chromatography column reported by Kennedy and Buse.[4)]

The isomerization of cyclohexene oxide to the uncontracted products has also been reported. Cyclohexanone was readily formed in alcoholic solutions of octacarbonyldicobalt(0),[5)] 2-cyclohexenol being predominantly given by various lithium monoalkylamides and dialkylamides as strong bases.[6,7)] The oxide was also converted into both cyclohexanone and 2-cyclohexenol by thermal gas-phase isomerization over the temperature range 407—464 °C under pressures 1.6—6 Torr (1 Torr=133.322 Pa).[8)]

In contrast to the above observations on the homogeneous system, Al_2O_3 was used as a catalyst in the heterogeneous system.[9)] However, diols or hydrated dimers were obtained instead of the isomerized products, probably owing to the incomplete dehydration of Al_2O_3 or adsorption of moisture caused by careless treatment.[10)] Use of solid catalysts under heterogeneous conditions has the advantage of allowing easy separation of products from catalyst.

We have recently studied the isomerization of 1-methylcyclohexene oxide and *d*-limonene oxide catalyzed by solid acids and bases in a heterogeneous solid–liquid system, and observed the markedly different selectivities which depend on the type of catalyst.[11)] Since only alumina has been investigated for the isomerization of cyclohexene oxide, the epoxide has now been isomerized over several solid acids and bases in order to see how the activity and selectivity differ according to the type of catalyst.

Experimental

Cyclohexene oxide (Tokyo Kasei Kogyo Co.) was more than 98% pure and toluene (guaranteed reagent) used as solvent was purified by distillation over sodium metal. 1,2-Epoxycyclohexane-3,3,6,6-d_4 (supplied by Dr. M. C. Flowers) was used. Purity of the epoxide was 99.5%, and isotopic purity was about 90% $C_6H_6D_4O$.

Standard Procedure for Reaction. The reaction was carried out at 108 °C in the presence of toluene as a solvent. A mixture of 0.5 ml of the epoxide, 2.5 ml of toluene, and about 0.3 g of catalyst, ground to below 100 mesh, was stirred in a reaction vessel with a magnetic stirrer. At appropriate time intervals, a small amount of the sample was taken out with a 1 ml syringe, separated from the catalyst by means of centrifuge, and analyzed by gas-liquid chromatography with a TCD detector using a 3-m column of 20% polyethylene glycol 20 M on Celite 545 SK (180 °C, He 1.0 kg/cm²). The yields of products were based on the epoxide and calculated by measurement of GLC areas (uncorrected). The competitive isomerization of the deuterated and undeuterated cyclohexene oxide was carried out with a mixture of 0.1 ml of both oxides in equivalent amount, 0.5 ml of toluene and 60 mg of catalyst. The products were analyzed by combined gas chromatography-mass spectrometry (Hitachi RM50GC) with a 2-m column of PEG 20M.

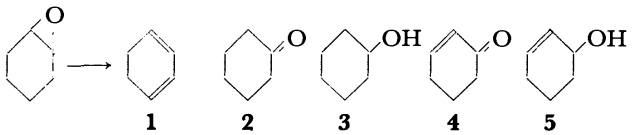
Catalysts. SiO_2–Al_2O_3 [N361(L)(Al_2O_3; 15 wt %) of Nikki Chemical Co.] was calcined at 500 °C. SiO_2–TiO_2 (molar ratio=1:1) was prepared by coprecipitation of a mixed solution of ethyl orthosilicate and titanium tetrachloride with aqueous ammonia. The precipitate was aged over a water bath for 1 h, washed with distilled water until no chloride ion was detected, dried at 100 °C for 20 h and calcined at 500 °C. SiO_2–TiO_2–MgO (molar ratio=1:1:1) was prepared by kneading SiO_2–TiO_2 (1:1) and magnesium hydroxide together with an appropriate amount of water for 2 h, followed by drying at 120 °C for 1 d and calcining at 500 °C. Magnesium hydroxide was prepared by hydrolysis of magnesium chloride with aqueous ammonia, followed by washing and drying as above. $LiClO_4 \cdot 3H_2O$ (guaranteed reagent, Nakarai Chemical Co.) was dried at 120 °C for 3 d. H_2SO_4/SiO_2 was prepared as follows: 10 g of granular silica gel was immersed in 12 ml of 0.5 M H_2SO_4, evaporated, dried and then calcined at 150 °C. $FeSO_4$ and $NiSO_4$ were prepared by calcining their heptahydrates (guaranteed) at 500 and 350 °C, respectively. Solid phosphoric acid (N501, Nikki Chemical Co.) was calcined at 300 °C. TiO_2–ZrO_2

(molar ratio= 1 : 1) was prepared by thermal decomposition, at 500 °C, of H_4TiO_4–$Zr(OH)_4$, which was precipitated by heating a mixed aqueous solution of titanium tetrachloride, zirconium dichloride oxide, and an excess amount of urea on a boiling water bath, followed by washing thoroughly with distilled water until no chloride ions were detected in the filtrate and drying in the air at 110 °C. Al_2O_3 A (KAT 6, Nishio Chemical Co.) was heat-treated at 500 °C. Al_2O_3 B, C, and D, Albes FF, Albes FE and Albes C, respectively, (Showa Tansan Kaisha, Ltd.) were calcined at 500 °C. All the catalysts were heat-treated in air for 3 h and stored in sealed ampoules.

Identification of Products. Reaction products were identified by the observed gas-chromatographic retention time and their mass spectra, obtained by combined gas chromatography-mass spectrometry, by comparison with authentic samples. A mixture of cyclohexene oxide (0.1 ml) and toluene (0.4 ml) was reacted over 60 mg of Al_2O_3 A at 110 °C for 2 h. The products were 5% of **1**, 2% of **2**, 6% of **3**, 30% of **5**, and 8% of **4** as the order of elution on a GLC PEG 20 M column at 180 °C. Their mass spectra at 70 eV of ionization voltage are as follows: important ions at *m/e* of **1**: 80 (M^+), 79 (100 %), 40 (78%), 80 (61%), 77 (36%), 78 (14%); **2**: 98 (M^+), 41 (100%), 55 (98%), 69 (82%), 42 (76%), 70 (35%); **3**: 100 (M^+), 57 (100%), 40 (51%), 82 (49%), 44 (38%), 67 (23%); **4**: 96 (M^+), 68 (100%), 40 (46%), 96 (42%), 39 (19%), 42 (10%); **5**: 98 (M^+), 70 (100%), 98 (50%), 97 (34%), 83 (30%), 39, (23%), 41 (22%).

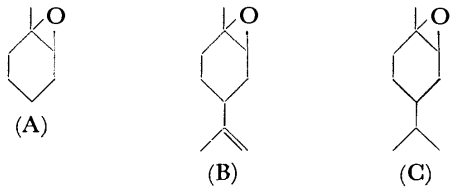
Results and Discussion

The reaction of cyclohexene oxide catalyzed by solid acids and bases gave 1,3-cyclohexadiene (**1**), cyclohexanone (**2**), cyclohexanol (**3**), 2-cyclohexen-1-one (**4**) 2-cyclohexen-1-ol (**5**), and other compounds.



1 **2** **3** **4** **5**

The products are substances expected from studies on the rearrangement of 1-methylcyclohexene oxide (A).[11a] Cyclopentanecarbaldehyde, a ring-contacted aldehyde, which was formed as the main product over molten salts or binary eutectic salts,[3,4] could not be detected, though the corresponding aldehydes were observed on the rearrangements of *d*-limonene (B) and carvomenthene oxides (C) over some of the present catalysts under the same reaction conditions.[11c,g]



(A) (B) (C)

The catalytic activity and selectivity of several solid acids and bases at 108 °C are given in Table 1. The catalysts were chosen on the basis of activity and selectivity for isomerization of 1-methylcyclohexene[11a,b] and carvomenthene oxides.[11g] The isomerization of 1-methylcyclohexene oxide was suggested to proceed *via* a carbonium ion intermediate.[2] Thus, cyclohexene oxide is considered to require a longer reaction time for the formation of secondary carbonium ions by cleavage of carbon–oxygen bond than 1-methylcyclohexene oxide which forms tertiary carbonium ions on carbon atoms bearing methyl groups. The results meet this expectation.

The time of reaction was so selected that appropriate conversion levels could be achieved. An example of

Al_2O_3 D	0.20	4	39	3	10	1	8	16	1

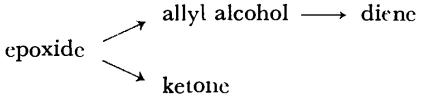
time-variation of the products is shown in Fig. 1, where the catalyst is TiO_2–ZrO_2. The yields of all products increased almost parallel to each other during the course of reaction. A similar time-variation was observed for the other catalysts.

Cyclohexanol (**3**) was presumably formed by a hydrogen transfer from **4**, since the corresponding alcohol and α,β-unsaturated ketone were observed with approximately the same yield in the case of 1-methylcyclohexene oxide.[11b] **3** was formed with less yield in comparison with **4** in every case and at any time of reaction. **3** was probably converted into cyclohexene by its readsorption and dehydration on the catalyst surface during reaction periods. However, trace amount of cyclohexene was detected on GLC analysis. The olefin having a lower boiling point (82 °C) as compared with reaction temperature might have evaporated out of the reaction vessel.

In the case of 1-methylcyclohexene oxide, ketone was predominantly formed over SiO_2–Al_2O_3, H_2SO_4/SiO_2, $FeSO_4$, solid H_3PO_4, $LiClO_4$, SiO_2–TiO_2, and SiO_2–TiO_2–MgO, and allyl alcohol over TiO_2–ZrO_2 and Al_2O_3 A, the selectivities being more than 80% in both groups.[11a,b,f] $NiSO_4$ gave both products in the same amount. In the present work, the former catalysts produced unexpectedly large amounts of allyl alcohol, while the three latter catalysts, TiO_2–ZrO_2, Al_2O_3 A, and $NiSO_4$, showed catalytic actions analogous to the case of 1-methylcyclohexene oxide. Allyl alcohol formation is explained by an acid-base bifunctional mechanism.[11b] Strong acid sites are active for the selective formation of ketone,[11a] SiO_2–Al_2O_3,[12] SiO_2–TiO_2,[13] and SiO_2–TiO_2–MgO[11f] being known to have acid sites stronger than $pK_a = -8.2$ on their surfaces. In the present reaction, basic sites on these catalysts seem to play an important role. The slow reaction rate of the epoxide is due to the greater difficulty in formation of secondary carbonium ion intermediates on acid sites than that of the tertiary one for the case of 1-methylcyclohexene oxide. It is likely that the basic sites cause hydrogen abstraction during the course of cleavage of a carbon–oxygen bond by acid sites, even though the basic sites are weak.

In the case of *d*-limonene oxide,[11e] of the fibrillar aluminas Al_2O_3 B, C, and D, Al_2O_3 B predominantly formed allyl alcohols and Al_2O_3 D carbonyl compounds (ring-contracted aldehyde and ketone), both selectivities exceeding 75%, while Al_2O_3 C formed both products in the same amount. In the present case, however, Al_2O_3 D produced a considerable amount of allyl alcohol which can be understood by the above mechanism explaining the formation of allyl alcohol. The selectivities of Al_2O_3 B and C are comparatively close to those expected from the results on *d*-limonene oxide. Al_2O_3 A and B were extremely active for the present isomerization.

A large amount of diene **1** was formed over SiO_2–TiO_2 and SiO_2–TiO_2–MgO, and also in the isomerization of cyclohexene oxide catalyzed by solid acids and bases in gas phase, the diene formation being interpreted by the dehydration of 2-cyclohexen-1-ol.[11d] The results on cyclohexene oxide differ from those on 1-methylcyclohexene oxide. The difference might be caused by the easier readsorption of the present allyl alcohol on the catalyst surface to form the diene as compared with the case of the allyl alcohols formed from 1-methylcyclohexene oxide, because of the steric hindrance of the methyl group for readsorption of the hydroxyl group of the allyl alcohol. The interpretation leads to the observation of a smaller yield of **3** than that of **4**, *viz.*, easy dehydration of **3** on the catalyst surface. The reaction of cyclohexene oxide seems to occur in the following series of parallel and consecutive steps,

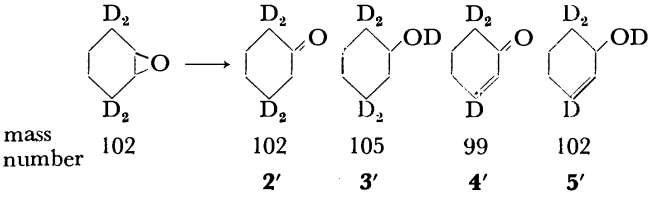


In order to obtain further information on the reaction mechanism, the isomerization of cyclohexene oxide deuterated at the 3 and 6 positions, 1,2-epoxycyclohexane-3,3,6,6-d_4, was performed over Al_2O_3 A and the products were analyzed by combined gas chromatography-mass spectrometry. The product distribution and parent mass number of products are given in Table 2, the reaction scheme being as follows.

Table 2. Isomerization of 1,2-epoxycyclohexane-3,3,6,6-d_4 over Al_2O_3 A[a] and mass number of parent peak of products

Product	**2′**	**3′**	**4′**	**5′**
Yield/%	2	7	10	22
Mass number of parent peak	102	104	99	101

a) The reaction was carried out with 0.1 ml of the epoxide in toluene (0.4 ml) over the catalyst (60 mg) at 108 °C for 2 h. b) 2% of 1,3-cyclohexadiene was observed.



The mass numbers 104 and 101 shown for **3′** and **5′**, respectively, seem to be due to the alcoholic proton D^+ of **3′** and **5′** being exchanged with outer proton H^+ during the course of reaction and analysis. Al_2O_3 A consists of Lewis acid sites.[14] Thus, the exchange of proton between the epoxide and the catalyst surface could be excluded. **3′** and **4′** are considered to be formed by hydrogen (HD) transfers between two molecules of the oxide. Therefore, the above reaction scheme seems to be reasonable.

In order to obtain isotope effects for isomerization over catalysts, the competitive isomerization of deuterated and undeuterated cyclohexene oxide in equiamount was carried out over several catalysts, the products being analyzed by GLC-MS (Table 3). The d_0/d value was taken as the isotope effect for the isomerization of cyclohexene oxide. The primary isotope effect

TABLE 3. COMPETITIVE ISOMERIZATION OF 1,2-EPOXYCYCLOHEXANE AND 1,2-EPOXYCYCLOHEXANE-3,3,6,6-d_4 OVER SEVERAL SOLID ACID AND BASE CATALYSTS AT 108 °C FOR 1 h

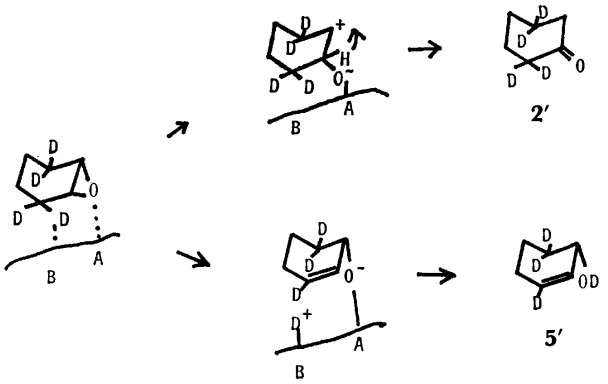
of the 3 or 6 position of cyclohexane ring can be seen for the formation of **2**, **4**, and **5**.

The allyl alcohol formation was interpreted in terms of the correlation between activity and acid-base property of catalyst by an acid-base bifunctional mechanism, where an oxygen of epoxide is adsorbed on an acidic site and a hydrogen atom of the methylene group on a basic site.[11] The present isotope effect for **5** supports the reaction mechanism. The isotope effect for dehydration of isobutyl alcohol over Al_2O_3 by acid-base bifunctional mechanism determined to be 2.55 at 170 °C[15] is close to our value.

Ketone formation, however, showed an unexpected primary isotope effect, indicating interaction between a hydrogen at the 3 or 6 position and a basic site on the catalyst surface. The formation of ketone is explained by the isomerization on strong acid sites in consideration of correlation between acid and base properties of catalyst and its selectivity.[11] The cleavage of the oxygen bond takes place by adsorption of oxygen on a strong acid site with a subsequent shift of a hydrogen attached to a carbon atom bearing another oxygen bond. However, the isotope effect decreases in the order Al_2O_3 A, Al_2O_3 D, SiO_2–TiO_2, and solid H_3PO_4 with increase in the selectivity for ketone (Table 3). It can be concluded that ketone is formed selectively when acid sites play a more important role as compared with basic sites. In other words, a molecule of epoxide adsorbs on both an acid and a basic site, the extent of both adsorptions determining the selectivity. When both modes of adsorption are such that both the opening of the epoxide ring and the hydrogen abstraction take place simultaneously, allyl alcohol would be formed, while the cleavage of oxygen bond prior to the hydrogen abstraction would occur to form ketone if the acid is too strong.

Values of the isotope effect for **2** over Al_2O_3 A and D are comparatively large. These catalysts, especially Al_2O_3 A, probably affect the strong interaction between a hydrogen at the 3 or 6 position and a relatively strong basic site on the surface, together with the weak one between an oxygen and a weak acid site. Consequently, the anion formed on carbon would facilitate cleavage of the oxygen bond. However, this case seems to be limited, judging from the low yield of **2** on both aluminas. Since MgO and CaO catalysts, which have a stronger basic character than alumina, were inactive for the isomerization of 1-methylcyclohexene and *d*-limonene oxides,[11] it seems that the oxide ring can not be opened by a basic site only without the effect of an acid site.

The reaction mechanism for the isomerization of cyclohexene oxide over solid acid and base catalysts is shown in the following.



The fact that the isotope effect for **4** is large but that for **3** is small seems to be reasonable in view of the deuterium distributions of products **3'** and **4'** which indicate the HD migration from a molecule of the oxide to another. The products of **3** and **4** were observed over the catalysts giving preferential formation of allyl alcohol. Thus, the intermediate species is considered to be related with the formation of both products.

The authors are indebted to Dr. M. C. Flowers, The University of Southampton, England, for the supply of the sample of 1,2-epoxycyclohexane-3,3,6,6-d_4.

Isomeric Transition-activated ^{80}Br and ^{82}Br Reactions in the Gaseous CH_3Br–HBr System

Kenjiro KONDO** and Masuo YAGI*

Laboratory of Nuclear Science, Faculty of Science, Tohoku University, Mikamine 1, Sendai 982

(Received February 9, 1979)

The isomeric transition(IT)-activated ^{80}Br and ^{82}Br reactions in the gaseous $H^{80m}Br$–CH_3Br and $H^{82m}Br$–CH_3Br systems have been compared and the roles of the charge and kinetic energy imparted to ^{80}Br and ^{82}Br in recombina tion reactions studied using a Kr moderator. The products CH_3Br, CH_2Br_2, $CHBr_3$, and CH_3CH_2Br in both reactions are only formed *via* thermal ionic processes. This differs from the $^{82m}BrBr$–CH_3Br system, in which the reaction products are only formed through excess kinetic energy processes. The difference between the two reactions has been explained on the basis of the cross sections for charge neutralization and ion molecule reactions of Br^+ ions as a function of the kinetic energy initially imparted to the ^{80}Br or ^{82}Br atoms. An isotope effect has been observed between the IT-activated ^{80}Br and ^{82}Br reactions with CH_3Br, and attributed to the difference in the decay modes of ^{80m}Br and ^{82m}Br. Furthermore, the analysis of product yields due to the successive internal conversion process in ^{80m}Br suggested that the second Auger process from the excited ^{80}Br occurs in a liquid-like condition such as ion-clusters.

Generally, the radioactive bromine atoms produced by a variety of nuclear transformations have an appreciable recoil kinetic energy and charges. Many investigations have been made in order to evaluate and interpret the kinetic energy and charges in the recombination reactions of radioactive bromine atoms in the gas phase.[1-11] It has been demonstrated that the formation of the C–*Br bond by the reactions of (n,γ)[11-13] and/or fission[14] activated energetic bromine with CH_4 proceeds principally through kinetic energy processes, and that not only kinetic energy but also the charges of IT-activated ^{80}Br and ^{82}Br in the $^{80m}Br_2$ and/or $^{82m}Br_2$–CH_4 system play important roles in determining the chemical reactions of these atoms.[5-9] Furthermore the authors have recently reported that IT-activated ^{80}Br and ^{82}Br in the $H^{80m}Br$–CH_4 and $H^{82m}Br$–CH_4 systems undergo only thermal ionic reactions (kinetic energy independent).[1-4] Since the kinetic energy imparted to the ^{80}Br and ^{82}Br by molecular explosion processes following the internal conversion in HBr molecule is 0.75 eV on average,[15] being very small compared with that (40.3 eV)[16] for the IT in $^{80m}Br_2$ and/or $^{82m}Br_2$, this indicates that the organic yields by thermal ionic processes are largely dependent on the kinetic energy of the positively charged $*Br^+$ ion.

This paper will report the contribution of the charge and kinetic energy of IT-activated ^{80}Br and ^{82}Br to the organic product yields in the $H^{80m}Br$–CH_3Br and $H^{82m}Br$–CH_3Br systems, by comparing the results previously reported for the reactions of CH_3Br with *Br activated by (n,γ)[11] and IT[11,17,18] in Br_2. An isotope effect between thermal ionic ^{80}Br and ^{82}Br reactions has been found in the $H^{80m}Br$–CH_4 and $H^{82m}Br$–CH_4 systems,[1] and a similar isotope effect between the IT-activated ^{80}Br and ^{82}Br reactions with CH_3Br using HBr as a source molecule will be reported.

Experimental

Materials. The listed purities of gaseous reagents, supplied by Takachiho Chemical Co., were 99.95% for Kr and 99.5% for CH_3Br. Krypton gas was used without further purification and CH_3Br was purified by a vacuum distillation technique so that the impurity was reduced below less than 0.1% for gas chromatographic analysis. The ^{80m}Br and ^{82m}Br labeled HBr were prepared by procedures described previously.[1,2,4]

Sample Preparation. The gaseous samples were prepared in the same manner as reported elsewhere.[1,2,4] The reaction mixtures were sealed in cylindrical Pyrex glass ampoules or breakable glass tubes using a vaccum line. The ratio of HBr to CH_3Br and the total pressure were maintained constant at 0.1 ± 0.01 and 660 ± 30 mmHg,† respectively, throughout the series of gas phase experiments. In the solid phase experiments, the reaction gases of HBr (^{80m}Br-labeled) (200 mmHg) and CH_3Br (700 mmHg) were mixed thoroughly by the freeze-thaw method and solidified at liquid nitrogen temperature.

Product Analysis and Yield Determination. The details concerning product analysis and yield determination have been reported elsewhere.[1,2,4]

The experimental errors due to the standard deviation for counting statistics and chemical procedures were estimated as 5—9% for the organic yields in the ^{80m}Br-experiments and less than 10% for those in the ^{82m}Br-experiments.

Results and Discussion

Role of Charge and Kinetic Energy of IT-Activated ^{80}Br and ^{82}Br in Product Formation. The conventional method for discriminating between the charge contribution and the kinetic energy of bromine in the reactions of product formation is the addition of an inert gas to the system. The yield of products formed through kinetic energy processes is expected to decrease by the addition of an inert gas due to the removal of Br kinetic energy by the moderation effect. Hence, a yield which is insensitive to the addition of an inert gas is considered to be due to thermal ionic processes.

Krypton was used as the moderator which has an ionization potential of 13.99 eV, (Br (11.84 eV)), and a mass almost equal to that of Br. Kr therefore appears to be the most effective moderator for energetic Br atoms and appropriate for distinguishing between the yields

from kinetic processes and thermal ionic processes.

The effect of Kr as an additive on the product yield distributions in the $H^{80m}Br$–CH_3Br and $H^{82m}Br$–CH_3Br systems is summarized in Tables 1 and 2, and also illustrated in Figs. 1 and 2. The ^{80}Br and ^{82}Br labeled CH_3Br, CH_2Br_2, C_2H_5Br, and $CHBr_3$ were identified as the reaction products in both systems. The products

were similar to those found previously for (n,γ)-[11] and IT-[17,18] activated ^{80}Br and ^{82}Br reactions in the Br_2–CH_3Br system. The C_2H_5Br and $CHBr_3$ yields are listed as the other product yield (the 4th column) in the Tables. The $C_2H_5{}^{82}Br$ yields were less than 0.1% in most cases, while the $CHBr_2{}^{80}Br$ yields were approximately 60 to 80% of the other yield. As is shown in Figs. 1 and 2, the product yield distributions was not altered by the addition of Kr in the range 0—0.5 mole fraction indicating that the reaction products in both systems are formed only through thermal ionic processes, similar to the results observed in the $H^{80m}Br$–CH_4[1] and $H^{82m}Br$–CH_4[2] systems. The thermal ionic yields of CH_3Br and CH_2Br_2 at 0 mole fraction of Kr were 3.8% and 1.3% for the ^{82m}Br system, and 2.4% and 1.5% for the ^{80m}Br system, respectively.

Oate *et al.*,[17] and Okamoto and Tachikawa[18] have reported that the IT-activated ^{82}Br in the $^{82m}BrBr$–CH_3Br system undergoes only kinetic energy dependent reactions. Similarly, Spicer and Gordus[11] have pointed out that the (n,γ)-activated ^{80}Br in the same system reacts to give the products through kinetic energy processes. The present results are however largely different from the above earlier findings. The present

a) HBr or $Br_2/CH_3Br=0.1\pm0.01$. b) Present work. c) Ref. 17. d) Ref. 18. e) Ref. 11, $Br_2=0.0254$ mole fraction.

authors have pointed out that the product yields due to both kinetic and thermal ionic processes largely depend on the Br kinetic energy acquired initially as results of a nuclear event.[1,2] The maximum kinetic energies (E_{max})[15] of Br for (n,γ) and IT in HBr and Br_2 are shown in Table 3. In contrast to the present results, there is no contribution of thermal ionic reaction to the product formation in both (n,γ)[11] and IT[17,18] in Br_2 because of the large values of E_{max}. This difference suggests that there is a close relationship between the kinetic energy of Br and the yields due to both thermal ionic and kinetic energy processes. The yields due to thermal ionic reactions are largely dependent on the number of Br^+ ions reaching the thermal energy region by escaping from the charge neutralization.[1-4] Therefore it is of paramount importance to estimate the cross sections for charge neutralization and ion-molecule (capture collision) reactions as a function of the kinetic energy of Br^+ in the present systems. These relationships are shown in Fig. 3. The cross sections (σ) for capture collision between Br^+ and CH_3Br were calculated from the following equation,[20] which is applicable for ions with a kinetic energy <1 eV.

$$\sigma = (2\pi e/v)(\alpha/\beta) + (2\pi e/v^2)(\mu/m)$$

where v is the relative velocity of Br^+, e the charge on the ion, α the polarizability of CH_3Br (2.8×10^{-24} cm^3/mol),[21] m the mass of Br^+, β the reduced mass of collision pair, and μ the dipole moment of CH_3Br (1.45×10^{-18} esu. cm).[22] The cross sections for resonant charge transfer reaction between Br^+ and Br, which are the highest of several types of charge neutralization concerning Br^+, were obtained by interpolating the resonant charge transfer cross sections at intermediate impact velocity (10^5—10^8 cm/s) as calculated by Rapp and Francis using the semi-classical impact-parameter method.[23] Furthermore, V_{max}, giving the maximum cross sections for asymmetric charge transfer reactions of ground state Br^+ with CH_3Br, Kr, and HBr, were calculated from the "adiabatic rule."[24] V_{max} for CH_3Br is 2.2×10^7 cm/s, 3.5×10^6 for HBr, and 3.6×10^7 for Kr. The threshold velocity (V_{th})[25] of Br^+ for endo-energetic charge transfer reaction with Kr was obtained as 2.3×10^5 cm/s. The dotted line in Fig. 3, showing the velocity dependence of cross sections for the charge transfer reactions of Br^+ with Kr, is drawn on the basis of values of V_{max} and V_{th}, assuming that the asymmetric charge transfer cross section is close to that for the resonance charge transfer at velocities above V_{max}.[23] The charge transfer reactions of the ground state Br^+ with HBr and CH_3Br are exothermic, 0.2 and 1.3 eV respectively. In consideration of the vibrationally excited states of those molecules, it is expected that the charge neutralization of Br^+ takes place effectively, and its cross section is close to that of the resonant charge transfer between Br^+ and Br. The thus formed neutral Br cannot however enter into chemical combination *via* kinetic energy processes because the kinetic energy is not sufficient to substitute for H and/or Br in the CH_3Br molecule. The values of E_{max} for (n,γ) and IT in HBr and Br_2 are shown by arrows in the upper abscissa of the Fig. 3.

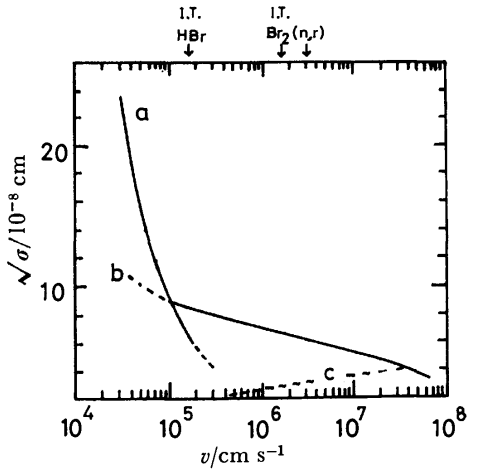

Fig. 3. Relationship between the velocity of $*Br^+$ and cross sections for capture collision and charge neutralization.
a: Capture collision; $*Br^+ + CH_3Br \rightarrow CH_3Br*Br^+$, b: resonant charge transfer; $*Br^+ + Br \rightarrow *Br + Br^+$, c: $Br^+(^3P_2) + Kr \rightarrow Br + Kr^+$.

Figure 3 indicates that the charge transfer reactions occur predominantly in the energy range >1 eV, while the formation of the capture collision complex is favoured at energies <1 eV. It is readily seen therefore that the Br atoms produced by (n,γ) and IT in Br_2 undergo charge neutralization before reaching the reaction range because of the large values of E_{max}. The average kinetic energy of Br in the case of IT in HBr is only 0.75 eV,[15] which is very small compared with that for (n,γ) and IT in Br_2. It is presumed therefore that the formation of the capture collision complex competes with the charge neutralization under the present experimental

systems using HBr as a source molecule, and a part of $*Br^+$ which escapes charge neutralization reacts with CH_3Br to form the capture collision complex, CH_3Br*Br^+. This complex ion is thought to be a precursor for product formation *via* a thermal ionic process as will be described in the following section.

Isotope Effect in the Reactions of IT-Activated ^{80}Br and ^{82}Br with CH_3Br. As Figs. 1 and 2 illustrate, the organic yields were a little larger in the $H^{82m}Br$–CH_3Br system than in the $H^{80m}Br$–CH_3Br system. An outstanding difference between the results in both systems was found in the yield distribution of individual products. The yield ratios of CH_3Br to CH_2Br_2 were 3.0±0.5 for ^{82m}Br and 1.8±0.2 for ^{80m}Br at 0 mole fraction of Kr. Evidently there is an isotope effect between the thermal ionic reactions of IT-activated ^{80}Br and ^{82}Br in the gaseous HBr–CH_3Br system. The mass difference between ^{80}Br and ^{82}Br cannot be considered to be responsible for the above isotope effect and therefore the isotope effect may be attributed to the differences in the decay modes of ^{80m}Br and ^{82m}Br.[19]

The de-excitation of ^{82m}Br to the ground state occurs in a single step and is fully converted. The ^{80m}Br however is de-excited in two successive steps through an intermediate state with a half-life of 7.4 ns; the first step is fully converted and the second, partially converted (61%). Since the first de-excitation step of ^{80m}Br is essentially the same as that of ^{82m}Br, the charge and kinetic energy distribution on the excited ^{80}Br should be identical with those on the ^{82}Br. Furthermore, the excited ^{80}Br undergoes successive de-excitation to the ground state; 61% of the excited ^{80}Br is de-excited through the second internal conversion process, while the remaining 39% is directly de-excited to the ground state by means of a 37 keV gamma-ray emission. The chemical effect due to this gamma-emission is however considered to be negligible since the kinetic energy achieved on the ^{80}Br is of the order of 10^{-2} eV. On the basis of the foregoing the reaction processes of IT-activated ^{80}Br may be classified into two types:[1,3]

Process (A); 39%, internal conversion (IC)
+ 37 keV gamma-ray emmission

Process (B); 61%, IC + IC

The chemical effects due to process (A) are essentially identical with those of the ^{82m}Br, and therefore the yields due to process (A) are equal to 39% of those obtained in the ^{82m}Br. Hence the normalized yields due to process (B) may be calculated by the following equation.

Yield/% due to process (B) = 100/61(^{80m}Br-yield − 39% of ^{82m}Br-yield)

and are depicted in Fig. 4. The isotope effect in both systems may be elucidated by comparing the yields due to process (B) with those due to the ^{82m}Br.

As Fig. 4 shows, the $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ yields were constant in the range 0—0.6 mole fraction of Kr, indicating that the products due to process (B) are also formed through kinetic energy independent processes. The yield ratio of CH_3Br to CH_2Br_2 was between 0.9

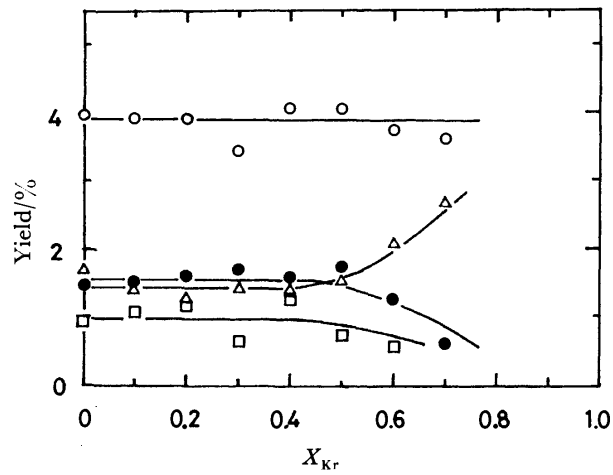

Fig. 4. Effect of Kr additive on the product yield distributions due to process (B).
○: Organic yield, ●: $CH_3{}^{80}Br$, △: $CH_2{}^{80}BrBr$, □: other.

and 1.3 for 0.6 mole fraction of Kr, being largely different from that due to the ^{82m}Br (3.0). The other product yields due to process (B) were much higher compared to those due to the ^{82m}Br.

Assuming the excited ^{80}Br does not react within its life time (1.1×10^{-8} s), and/or assuming that the excited ^{80}Br forms chemical combinations, such as $H*Br$, H_2*Br, $H*Br^+$, *etc.*, the chemical effect due to the successive IC (process B) should also be identical to that due to the ^{82m}Br because the following IC leads to an additional build-up of the charge on the free atom, and/or the kinetic energy of ^{80}Br resulting from the molecular explosion in such a species is very small. In this case, an isotope effect will be absent.

Assuming the excited ^{80}Br reacts with the surroundings to form a C–*Br and/or Br–*Br combination prior to the second IC, the resulting ^{80}Br by successive IC acquires an appreciable kinetic energy and undergoes kinetic energy dependent reactions. As Fig. 4 illustrates, the experimental results show that there is no contribution to the yield by excess kinetic energy processes, *i.e.*, these chemical species will not be present in process (B). The existence of an isotope effect suggests that the life-time of the excited $^{80}Br^+$ (1.1×10^{-8} s) is sufficiently long to form some chemical species containing the excited $^{80}Br^+$. The environment surrounding the excited ^{80}Br is thought to be different from those for the ions present as single species. Accordingly, it has been concluded that the $^{82}Br^+$ and excited $^{80}Br^+$ undergo capture collision complex formation (Reactions 1a and 2). Typically this type of ion-molecule reaction does not require any activation energies.[1,2]

$$*Br^+ + CH_3Br \longrightarrow CH_3Br*Br^+ \quad (1a)$$

$$*Br^+ + HBr \longrightarrow HBr*Br^+ \quad (2)$$

Furthermore, the thermal complex ions have an ample opportunity to interact with the surroundings within the life-time of the excited ^{80}Br[26] since the life-time is relatively long compared to the collision time under the present experimental conditions.[27]

It is generally known that at high pressure thermal ions preferentially form ion-clusters by electro-static forces.[28-30] The authors have demonstrated that the isotope effect observed in the $H^{80m}Br$–CH_4 and $H^{82m}Br$–CH_4 systems may be explained by introducing the above cluster model.[1,3] The complex ions formed by the above reactions undergo successive attachment reactions with surrounding molecules to form ion-clusters, and the second IT in process (B) proceeds in a liquid-like condition such as ion-clusters. Thus the chemical effect due to process (B) is expected to be very similar to that in the condensed phase. Table 4 shows the results obtained in the solidified $H^{80m}Br$–CH_3Br system. The yield ratio of CH_3Br to CH_2Br_2 was 0.8, which compare favourably with the values of 0.9–1.3 for process (B). This indicates that the chemical effect due to process (B) is very similar to that in the solid phase, which qualitatively supports the above cluster model. The large amount of energy evolved from the second molecular explosion in process (B) is dissipated to the rigid sphere of the cluster and used in the formation of ions, radicals and excited species, which contribute directly or indirectly to individual product formation.

TABLE 4. THE YIELD RATIO OF INDIVIDUAL PRODUCTS RELATIVE TO CH_3Br IN THE SOLIDIFIED $H^{80m}Br$–CH_3Br SYSTEM

Product	CH_3Br	C_2H_5Br	CH_2Br_2	$C_2H_4Br_2$	$CHBr_3$
Relative yield ratio	1	<0.1	1.3	0.2	0.4

There is little precise information on the ion-molecule reactions leading to the $CH_3{}^*Br$ and $CH_2Br{}^*Br$ in process (A) because of a lack of knowledge concerning the chemical behaviour of the complex ion ($CH_3Br{}^*Br^+$) under high pressure. The following reactions are considered to be possible reaction routes for the formation of the above products from thermodynamics.

$$CH_3Br{}^*Br^+ \longrightarrow CH_3{}^*Br^+ + Br \qquad (1b)$$

$$CH_3Br{}^*Br^+ + HBr \longrightarrow CH_2Br{}^*Br + H_2Br^+ \qquad (3)$$

$$CH_3Br{}^*Br^+ + CH_3Br \longrightarrow CH_2Br{}^*Br + CH_4Br^+ \qquad (4)$$

The heat of reaction for the above reactions has been calculated approximately as 29, 65, and 87 $kcal_{th}$††/mol (exothermic) for Reactions 1a, 1b, 3, and 4, respectively.[32]

The second IC in process (B) proceeds *via* an ion-cluster, so that the molecular explosion following the second IC is responsible for the chemical effect due to process (B). Although no information on the IT-activated ^{80}Br reactions under such specific conditions is available, both ion-molecule reactions and the reactions concerning radicals and excited species produced in the clusters appear to be responsible for product formation in analogy with the results previously obtained in the $H^{80m}Br$–CH_4 system.[1,3] The details of such reactions must however await further analysis.

The authors would like to thank the staff of the Hot Laboratory, Research Reactor Institute, Kyoto University, who assisted in the neutron irradiations and provided the research facilities.

The Isomerization of *cis*-2-Butene over SO_2-adsorbing $Mg(OH)_2$ and MgO

Kiyoshi Otsuka,* Kimiaki Tanaka, and Akira Morikawa

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 18, 1979)

The reaction of butenes caused by the surface compounds formed from SO_2 on $Mg(OH)_2$ or MgO has been studied. It has been shown that the cis-trans isomerization of 2-butene is selectively induced by the sulfur compounds. This specific isomerization has been explained by the previously proposed mechanism that the reaction is accompanied by the copolymerization of 2-butene and SO_2. The infrared spectroscopic study on the sulfur compounds formed on $Mg(OH)_2$ or on MgO has demonstrated the presence of SO_3^{2-}, SO_4^{2-}, or sulfinato complexes. The formation of these surface species may cause a strong electrostatic field on the surface, resulting in the polarization of reactant molecules, which is necessary for the initiation of the copolymerization or of the cis-trans isomerization. It has been shown, however, that the presence of weakly adsorbed SO_2 is essential for determining the catalytic activities of the solids in the SO_2-induced isomerization.

The need to understand gas-aerosol reactions in the atmosphere stems from the potential impact of such reactions on atmospheric chemistry, as well as their contribution to atmospheric haze formation and health effects attributable to aerosols in the respirable size range. Heterogeneous reactions of SO_2 and the contribution of the reactions to atmospheric sulfate aerosol are considered to be important to the over all pollution problem.[1-4] There are many reports which relate to the reactions between SO_2 and various solid particulates likely to be found in the polluted atmosphere.[5-12] However, very little is known about the possible, thermal reactions of SO_2 with hydrocarbons over solid particulates.

Preliminary experiments showed that the addition of SO_2 onto such solids as SiO_2, Al_2O_3, Fe_2O_3, CaO, $Ca(OH)_2$, MgO, or $Mg(OH)_2$, all of which are likely to be found in urban aerosols, causes the isomerization of butene. The most active solids to the reaction were MgO and $Mg(OH)_2$. Hence, we intend to report here the reaction over $Mg(OH)_2$ and MgO in the presence of the sulfur compounds on their surfaces formed from SO_2, which were confirmed by infrared spectroscopic measurement. The reaction mechanism and the nature of the active sites will also be discussed.

Experimental

Materials. The $Mg(OH)_2$ used in these experiments was reagent-grade powder from the Kanto Chemical Co., Inc. The reagent SO_2 gas, of anhydrous grade and supplied by the Matheson Chemical Co., and *cis*-2-butene gas, a high-purity product of the Phillips Petroleum Co., were purified by the freeze-pump technique.

Procedure. In the infrared spectroscopic experiments, a self-supporting $Mg(OH)_2$ wafer was made by pressing powder (about 15 mg) in 2-cm-diameter stainless steel discs at 2.7 t/cm^2. The wafer was then placed into the IR-cell for pretreatment and spectroscopic measurements. The sample wafer was degassed in a vacuum with increasing temperature to a required value between 100 and 600 °C. The rate of heating was 10 °C/min. Evacuation was further kept at the fixed temperature for 2 h. After the base-line spectrum of the wafer had been recorded at 20 °C, a known amount of SO_2 was adsorbed onto the wafer at the same temperature. Then the wafer was degassed in a vacuum for 3 min through a cold trap immersed in liquid nitrogen. After these procedures, the spectra of the sulfur compounds on the wafer were recorded. The amount of SO_2 remaining on the solid was calculated by the mass valance of the amount of SO_2 introduced and the amount of collected in a liquid nitrogen trap. A Shimadzu IR-430 grating spectrometer was used for all the infrared measurements.

The relative absorbance of the sulfur compounds, OD_s, on an unit surface area of the wafer was calculated by assuming the following, modified Lambert-Beer law equation,

$$OD_s = \left(\log \frac{I_0}{I}\right) \Big/ A = \varepsilon CW/A \qquad (1)$$

where I_0 represents the light intensity transmitted through the wafer of W in weight with a surface area of A (cm^2/g) in the absence of SO_2, I is the intensity of light transmitted through the wafer which contains the sulfur compounds of the concentration C (mol/g), and ε is the molar extinction coefficient.

The adsorption experiments were carried out volumetrically using a conventional closed system 119 cm^3 in volume. The BET surface area of the $Mg(OH)_2$ pretreated at different temperatures were determined by means of the nitrogen adsorption. The molecular cross sections of N_2 and SO_2 were taken as 16.2 and 19.2 Å^2 respectively.[13]

The isomerization of *cis*-2-butene in the presence or absence of SO_2 was carried out in a gas-circulation system with a volume of 210 cm^3. After the pretreatment of $Mg(OH)_2$ ($\approx$0.20 g), the reaction was started at 20 °C by feeding and circulating *cis*-2-butene gas at the pressure of 85 Torr, through the catalyst bed. A small amount of the reactant gas was periodically sampled and analyzed by gas chromatography. The initial rates of the isomerization were calculated from the concentration of the butene isomers formed in the initial 3 min. In the case of the SO_2-induced isomerization, a required amount of SO_2 was preadsorbed on the solid at 20 °C after the pretreatment of $Mg(OH)_2$. The solid was then evacuated slightly for 3 min before the addition of the reactant gas.

Results and Discussion

The State of the Catalyst after the Pretreatment. The state of the $Mg(OH)_2$ after evacuation pretreatment for 3 h at different temperatures has been examined by X-ray analysis. The results are summarized in Table 1, together with the surface areas of the samples. The

Table 1. The form of the solid and the BET surface area after the pretreatment

Pretreatment temperature/°C	Surface area $m^2\ g^{-1}$	The form of solid from X-ray analysis
100	21.4	$Mg(OH)_2$
200	27.4	$Mg(OH)_2$
300	295.0	MgO
400	282.0	MgO
500	251.0	MgO
600	221.0	MgO

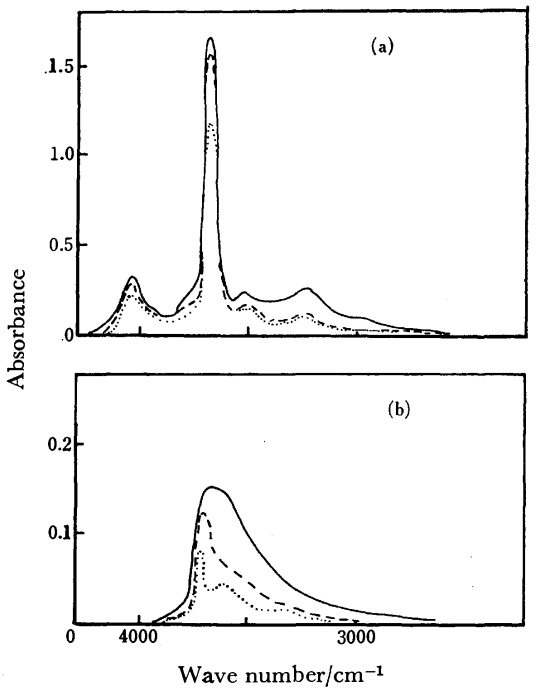

Fig. 1. Infrared spectra of hydroxyl groups for the samples pretreated at different temperatures.
The pretreatment temperatures: (a) —100 °C, ---200 °C, ···300 °C, (b) —400 °C, ---500 °C, ···600 °C.

X-ray data have shown that the $Mg(OH)_2$ dehydrated at the temperatures higher than 300 °C were converted into MgO face-centered cubic crystals. The surface areas were also drastically changed above 300 °C. Figure 1 shows the infrared spectra for the sample wafers in the wave number range of the stretching bands of hydroxyl groups. Only a slight decrease in the intensities of the hydroxyl bands was observed when the pretreatment temperature was increased from 200 to 300 °C, as is indicated in Fig. 1-a. These facts from the X-ray and infrared data imply that, under the dehydration conditions at 300 °C, only a part of the individual $Mg(OH)_2$ grains has been converted to MgO, while the $Mg(OH)_2$ grains are covered by MgO layers at the surface. The information from the X-ray analysis is limited to these surface MgO layers. A decrease in the intensity of hydroxyl groups is obvious at temperatures higher than 400 °C, suggesting that a further dehydration progresses into bulk $Mg(OH)_2$.

The SO_2-induced Cis-Trans Isomerization of cis*-2-Butene.* The catalytic activity of $Mg(OH)_2$ at 20 °C for the isomerization of *cis*-2-butene emerged when the sample was pretreated at temperatures above ≈400 °C. The steep increase in the catalytic activity as raising the activation temperatures above ≈400 °C is a general observation for the isomerization of olefin catalyzed by MgO[14–16] or CaO.[15,16] The catalytically active centers for the reaction, presumably the strongly basic O^{2-} ions, are considered to be created as a result of the removal of H_2O and/or CO_2 as raising the pretreatment temperatures for the catalysts.[14–16]

For the $Mg(OH)_2$ pretreated at the temperatures lower than 400 °C, the addition of SO_2 onto the surface induced the cis-trans isomerization of *cis*-2-butene without causing any double-bond migration to 1-butene. The absence of the double-bond migration has been confirmed using 1-butene as the starting olefin. The addition of SO_2 to the MgO prepared from $Mg(OH)_2$ by dehydration at 500 and 600 °C rather retarded the two isomerizations which proceeded with an appreciable rate in the absence of SO_2. The addition of SO_2 (5.4×10^{-10} mol/cm^2) to a sample pretreated at 600 °C stopped the progress of both the isomerizations. Further addition of SO_2, however, enhanced the rate of cis-trans isomerization selectively.

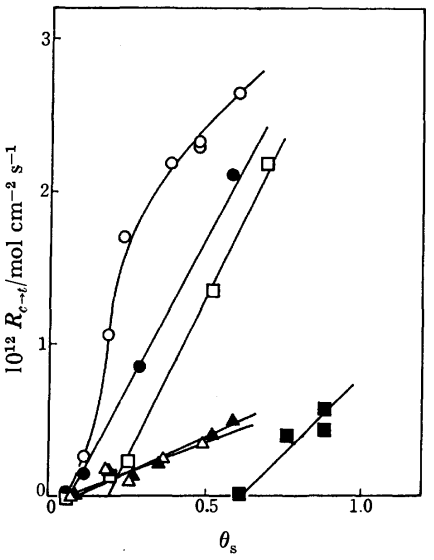

Fig. 2. The rate of SO_2-induced isomerization as a function of θ_s. The samples were pretreated at the following temperatures; (▲) 100 °C, (△) 200 °C, (●) 300 °C, (○) 400 °C, (□) 500 °C, (■) 600 °C.

The rates of SO_2-induced cis-trans isomerization on the catalysts pretreated at 100—600 °C have been plotted in Fig. 2 as a function of the apparent surface coverage of SO_2, θ_s.[17] The specific isomerization did not proceed until a critical amount of SO_2 had been preadsorbed. These values in θ_s are ≈0.1, ≈0.2, and ≈0.6 for the samples pretreated at 100—400 °C, at 500 °C, and at 600 °C, respectively. Beyond the critical θ_s, the rates of the reaction increased sharply.

The temperature effects on the rates of the SO_2-induced isomerization for the samples activated at 100 and 400 °C have been examined under the initial pressures of 85 and 49 Torr for *cis*-2-butene and SO_2 respectively. For both samples, the rates increased as

the reaction temperatures were raised until 25 °C, but decreased above this temperature. The addition of a small amount of NO (less than 10% of the amount of SO_2) strongly inhibited the cis-trans conversion. These results suggest that the reaction proceeds by means of the polysulfone-accompanying mechanism proposed previously:[18-20]

cis- or *trans*-2-butene + $\cdot SO_2[CH(CH_3)CH(CH_3)SO_2]_n$
$\rightleftarrows \cdot CH(CH_3)CH(CH_3)\text{-}SO_2[CH(CH_3)CH(CH_3)SO_2]_n$ (2)

The specific cis-trans isomerization proceeds *via* the addition and elimination of 2-butene molecules at the terminal of the polymer formed in the adsorption layer. The attempt to confirm the polysulfone production at 20 °C by infrared spectroscopic measurement was unsuccessful because the ceiling temperature for the copolymerization lies at about 25 °C.[19] The formation has, however, been confirmed using MgO in the reaction at −10 °C under 280 Torr of the *cis*-2-butene and SO_2 (1: 1) gas mixture. The infrared spectra of the water of this sample have exhibited the two characteristic absorption bands ascribed to the polysulfone from *cis*-2-butene, one at 1300 cm^{-1} and the other at 1105—1140 cm^{-1}, attributable to the symmetrical and asymmetrical stretching vibrations of the sulfone groups respectively.[21]

Surface Sulfur Compounds from SO_2. Figure 3 shows the infrared spectra of the sulfur compounds on the samples pretreated at 100—600 °C, where OD_s was calculated by means of Eq. 1. At least eleven bands are apparent in the (b)-spectrum of Fig. 3. As the pretreatment temperature is raised from 300 to 600 °C, these resolved bands are diminished, but at least three broad bands, at 1030, 950, and 800 cm^{-1} are observed.

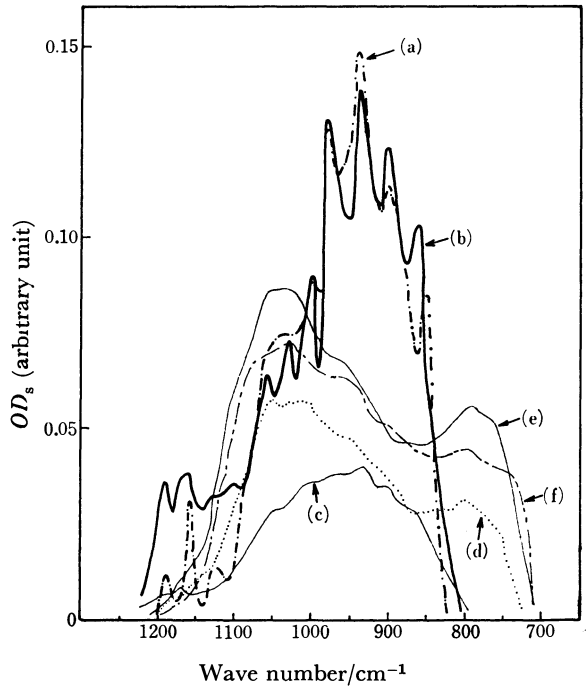

Fig. 3. The infrared spectra of the surface sulfur compounds on the samples pretreated at 100—600 °C. (a) Pretreatment temperature (T_p) 100 °C, θ_s=0.26, (b) T_p 200 °C, θ_s=0.26, (c) T_p 300 °C, θ_s=0.23, (d) T_p 400 °C, θ_s=0.17, (e) T_p 500 °C, θ_s=0.17, (f) T_p 600 °C, θ_s=0.19. SO_2-preadsorption at 20 °C.

Some bands from $Mg(OH)_2$ can be identified with reference to the work on MgO.[6,8] Schoonheydt and Lunsford have observed two different SO_3^{2-} species on MgO pretreated at 500 °C, one is an unidentate sulfito complex coordinated through an oxygen atom and the other a bidentate sulfito complex coordinated through its sulfur and oxygen atoms.[8] The former has absorption bands at 895, 925, and 975 cm^{-1}, and the latter, at 975, 1040, and 1070 cm^{-1}. The frequencies of the pair bands at 900, 940, and 980 cm^{-1} and those at 980, 1030, and 1060 cm^{-1} for the (a)- and (b)-spectra agree reasonably well with those of the pair bands observed by Schoonheydt and Lunsford. Thus, the bands between 900—1100 cm^{-1} in the (a)- and (b)-spectra can be assigned to the SO_3^{2-} species.

SO_3 species, including the sulfito complex, free SO_3^{2-} ions and free SO_3, do not exhibit absorption bands in 1100—1200 cm^{-1} region. The bands observed at this region and at 850—860 and 1000 cm^{-1} for Spectrum(a) or (b) may be ascribed to the formation of various SO_4^{2-} species which have been proposed by Goodsel *et al.*[6] and by Schoonheydt and Lunsford,[8] on MgO. Although the exact assignment of these surface sulfato complexes on $Mg(OH)_2$ cannot be verified from our experiments, the production of the SO_4^{2-} species at room temperature is a surprising observation, since the higher temperatures than 500 °C are usually needed for the formation of SO_4^{2-} species on alkaline earth metal oxides.[5,6,8]

In the case of the samples evacuated at high temperatures (>400 °C) (MgO), the broad bands between 700—1200 cm^{-1} do not allow the identification of the possible sulfur compounds. Schoonheydts and Lunsford speculated that SO_2 is present in the form of a sulfinato complexes on MgO at room temperature.[8] Goodsel and coworkers suggested the formation of unidentate- and bidentate-like sulfito complexes on the surface.[6] The broad bands in the (c)—(f) spectra may be attributed to these surface complexes.

Drastic changes in the spectra such as was shown in Fig. 3 when the pretreatment temperature was increased from 200 to 300 °C imply that the surface reactive species responsible for the SO_2—surface reactions may change in their nature between $Mg(OH)_2$ and MgO. Electron-donor centers associated with OH^- groups for $Mg(OH)_2$ or strongly basic O^{2-} ions for MgO may be necessary for the generation of the surface sulfur complexes described above.[14,22] The poisoning effect of SO_2 at low θ_s on the butene isomerizations observed on the samples activated at 500 and 600 °C can be ascribed to the consumption of the active centers, *i.e.*, the basic O^{2-} ions, by SO_2, producing sulfinato or SO_3^{2-} species.

Contribution of the Weakly Adsorbed SO_2 to the Isomerization of cis*-2-Butene.* It has been suggested that the polysulfone-accompanying cis-trans isomerization of 2-butenes (Eq. 2) is initiated through the strong polarization of the butene–SO_2 charge-transfer complexes

under the influence of the electrostatic field on the catalyst surface.[19,20] The charge-transfer complex necessary for the reaction is formed from the butene and SO_2 molecules physisorbed. Therefore, knowledge about the sulfur compound remaining on the surface in the form of SO_2 is required to explain the peculiar feature of the reaction rates as a function of θ_s as is indicated in Fig. 2.

Goodsel *et al.* have observed the bands due to chemisorbed SO_2 on MgO at 1140 (ν_1) and 1322 cm^{-1} (ν_2), and those of the physisorbed SO_2 at 1149 and 1336 cm^{-1}.[6] In the present work the bands at 1140 and 1330 cm^{-1} becomes observable when θ_s increases beyond 0.50 in the case of the samples pretreated at 500 and 600 °C. For the samples pretreated at the temperature below 400 °C, the bands due to adsorbed SO_2, however, were not detected, probably because the weak band around 1140 cm^{-1} was hidden in the bands of SO_4^{2-} species and the band around 1330 cm^{-1} was obscured by the broad, strong band at 1290—1340 cm^{-1} attributable to carbonated species contained in $Mg(OH)_2$ as an unavoidable impurity.

Since the information about the sulfur compound in the form of SO_2 derived from infrared spectroscopic experiments was scarce, a volumetric study has been carried out. The amount of SO_2 desorbed at 50 °C in 30 min from a surface with a fixed value of θ_s was measured by collecting the desorbed SO_2 by cold trap at 77 K. The amount of the weakly adsorbed SO_2 thus measured, $[SO_2]_a$, has been plotted as a function of θ_s in Figs. 4 and 5 for the samples activated at 100 and 400 °C respectively. The rates of the SO_2-induced isomerization of *cis*-2-butene are also shown by dotted curves in the figures. It is noticeable that the reaction rate and the amount of the weakly adsorbed SO_2 depend on θ_s in very similar ways. The correlation between the rate of the SO_2-induced isomerization and the amount of weakly adsorbed SO_2 has been examined

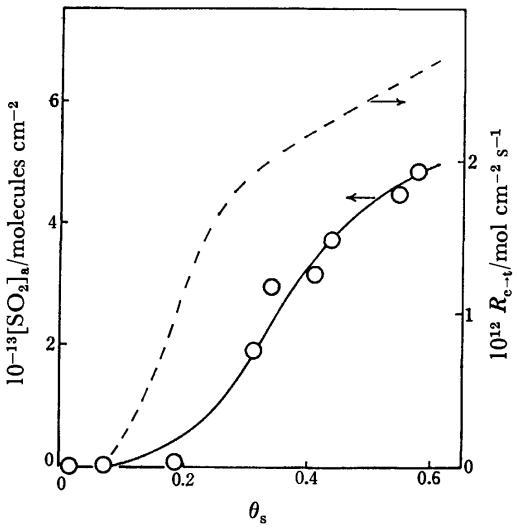

Fig. 5. The amount of weakly adsorbed SO_2 and the rate of isomerization of *cis*-2-butene over MgO as a function of θ_s: The sample was activated at 400 °C. —; The amount of weakly adsorbed SO_2, ---; the rate of cis-trans isomerization.

at the fixed θ_s of 0.57. The results are shown in Figs. 6 and 7 for $Mg(OH)_2$ and MgO respectively. Here also a good correlation between the rate and the amount of weakly adsorbed SO_2 has been demonstrated.

The ratios of the amount of weakly adsorbed SO_2 to that of the total sulfur compounds at θ_s of 0.57, on the basis of the sulfur atoms, are 0.25 and 0.015 for the samples pretreated at 100 and 600 °C respectively. Most of the sulfur compounds remaining on the surface after desorption treatment must be in the form of the SO_3^{2-}, SO_4^{2-}, or sulfinato complexes described previously. At a low θ_s the added SO_2 must have been converted to these sulfur compounds as a result of the reaction with the solid, leaving no physisorbed SO_2 necessary for the specific isomerization. The absence

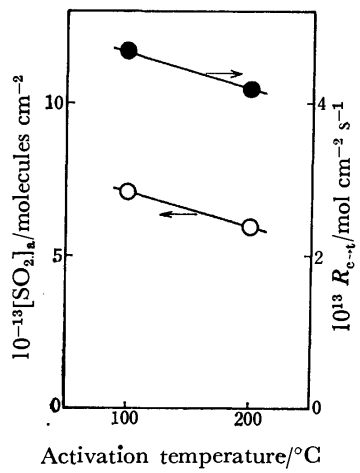

Fig. 6. The amount of weakly adsorbed SO_2 and the rate of isomerization of *cis*-2-butene on $Mg(OH)_2$ as a function of pretreatment temperatures: (●); the rate of cis-trans isomerization, (○); the amount of weakly adsorbed SO_2. θ_s=0.57.

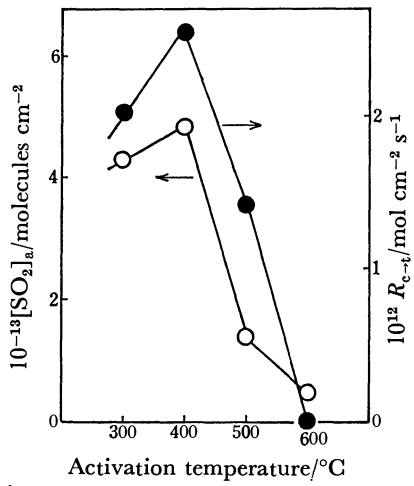

Fig. 7. The amount of weakly adsorbed SO_2 and the rate of isomerization of *cis*-2-butene on MgO as a function of pretreatment temperatures: (●); The rate of cis-trans isomerization, (○); the amount of weakly adsorbed SO_2. θ_s=0.57.

of the reaction at the θ_s less than the critical values shown in Fig. 2 can be ascribed to the absence of the weakly adsorbed SO_2, as has been described above.

The amount of *cis*-2-butene adsorbed per unit of the surface area did not change with the θ_s for the samples activated at 100—600 °C; for example, it was $20.0\pm 1.2\times10^{13}$ molecules/cm^2 for the samples activated at 300—600 °C over the range of θ_s of 0.05—0.60. Therefore, the change in the rate of the cis-trans isomerization shown in Figs. 2, 6, and 7 cannot be ascribed to that in the amount of the adsorbed *cis*-2-butene. A good correlation between the isomerization rate and the amount of weakly adsorbed SO_2 (Figs. 4—7) indicates that the activities of the solids for the polysulfone-accompanying isomerization are determined by the concentration of the weakly adsorbed SO_2 remaining on the surface.

The picture of the initiation step of the copolymerization, and accordingly of the cis-trans isomerization, that we have in mind is the polarization of the SO_2–butene charge-transfer complex under the influence of electrostatic field due to exposed surface ions.[20] As a consequence of the formation of the SO_3^{2-}, SO_4^{2-} species or sulfinato complexes, the surface magnesium will be positively charged due to electron transfer from the surface to these ionic species, and a strong electrostatic field would be formed. The concerted action of the negatively charged sulfur complexes—magnesium cation pairs may promote the strong polarization of the charge-transfer complex, causing the initiation of the copolymerization.

On the Excimer Formation of Pyrene in Electrochemiluminescenece

Takeshi SUMINAGA and Sohachiro HAYAKAWA*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 20, 1979)

Temperature effect in electrochemiluminescenece (ECL) of pyrene was investigated in order to clarify the formation of excimers. The ratio of intensity of excimer to monomer emission was measured on solutions of pyrene in *N,N*-dimethylformamide (DMF) at various temperatures from the decay curves of excimer emission due to pulse excitation with a nitrogen laser. The temperature change of concentration dependence of the ratio was derived from the rate equations for the respective direct and indirect formation of excimers. The mechanism of direct excimer formation was confirmed in ECL of pyrene more clearly by analysis of the temperature effect than by that of the concentration effect at a certain temperature.

Electrochemiluminescence (ECL) from pyrene has been studied by several workers since Hercules[1] first recognized the blue emission in *N,N*-dimethylformamide (DMF). Fleet *et al.*[2] reported on ECL spectra containing an excimer emission. Kihara *et al.*[3] proposed the formation of the excited state of pyrene *via* anion-cation annihilation in acetonitrile, but carried out measurements only at room temperature. Very few measurements have been made on the temperature effect on ECL. Recently, we reported on the temperature dependence of the red emission in ECL of pyrene.[4] The temperature effect in ECL of pyrene from monomer and excimers does not seem to have been measured.

This paper deals with the excimer formation process by the temperature effect in emission intensity and relevant rate constants. The rate constants can be analyzed from the decay curves of the excited state of pyrene in DMF under pulse excitation with a nitrogen laser.

Experimental

Pyrene was recrystallized carefully from benzen solution. Tetrabutylammonium bromide (TBAB) used as a supporting electrolyte was recrystallized from ethyl acetate solution. The ECL was observed in a pyrex glass cell equipped with two Pt wire electrodes. The cell was cooled by cold N_2 gas through a copper tube around the cell. ECL spectrum was measured with a fluorescence spectrophotometer (Hitachi MPF-2A) at room temperature and a Hamamatsu T.V. R375 photomultiplier and a photon counting system through interference filter (center wavelength: 386 nm, half width: 13 nm) at low temperatures. The decay curve of excimer emission by nitrogen laser excitation was measured with an oscilloscope, the result being analyzed following the method of Birks.[5] The measurement was performed under the same conditions as those for ECL measurements, a solution degassed by N_2 gas and containing 1×10^{-2} mol dm^{-3} supporting electrolyte being used. Transmittance of the interference filter was compensated by the spectrum measured with MPF-2A at room temperature.

Results and Discussion

The relationship between ECL emission and the formation of anion-cation was investigated by means of a double potential step and/or triangular potential sweep. Emission with steady intensity was obtained with applied voltage DC 4 V, the solution being stirred.

Figure 1 shows the ECL spectrum and the fluorescence spectra. The concentration dependence of the emission

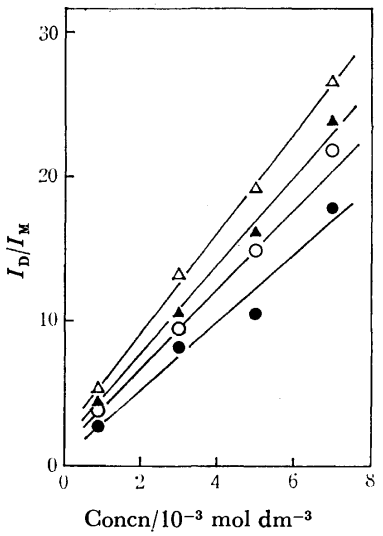

Fig. 2. Concentration dependence of the ratio excimer to monomer emission in ECL at various temperatures.
●: 20 °C, ○: 0 °C, ▲: −10 °C, △: −30 °C.

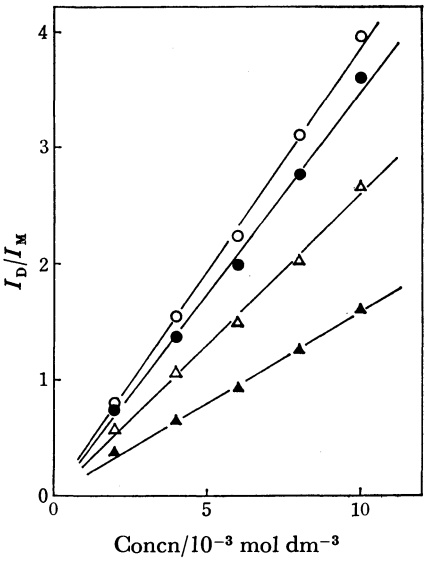

Fig. 3. Concentration dependence of the ratio of excimer to monomer emission in case of photoexcitation at various temperatures.
○: 20 °C, ●: 0 °C, △: −20 °C, ▲: −40 °C.

intensity ratio of excimer to monomer (I_D/I_M) on temperature is shown for ECL and emission by photoexcitation in Figs. 2 and 3, respectively. The results show linearity as regards concentration. The results were analyzed assuming the following reaction scheme:[3]

$$M^+ + M^- \xrightarrow{k_A} M^* + M, \quad (1)$$

$$M^+ + M^- \xrightarrow{k_B} D^*, \quad (2)$$

$$M^* \xrightarrow{k_{FM}} M + h\nu \qquad M^* \xrightarrow{k_{GM}} M, \quad (3)$$

$$D^* \xrightarrow{k_{FD}} 2M + h\nu' \qquad D^* \xrightarrow{k_{GD}} 2M, \quad (4)$$

$$M^* + M \underset{k_{MD}}{\overset{k_{DM}}{\rightleftharpoons}} D^*, \quad (5)$$

where M, M^+, M^-, and D^+ denote the pyrene molecule, its cation, anion, and excimer, respectively, and k denotes the rate constants of each reaction.

In the steady state we have

$$\frac{d[M^*]}{dt} = 0, \qquad \frac{d[D^*]}{dt} = 0. \quad (6)$$

Thus

$$\frac{I_D}{I_M} = \frac{k_{FD}}{k_{FM}} \frac{ak_M + (1+a)k_{DM}[M]}{k_D + (1+a)k_{MD}} \equiv K + K'[M], \quad (7)$$

where

$$\frac{I_D}{I_M} = \frac{k_{FD}[D^*]}{k_{FM}[M^*]},$$

and

$$k_M = k_{FM} + k_{GM},\ k_D = k_{FD} + k_{GD},\ k_B/k_A = a. \quad (8)$$

On the other hand, k_B is zero in the case of photoexcitation, since excited states are given by the following process instead of processes (1) and (2):

$$M + h\nu \longrightarrow M^*.$$

Thus

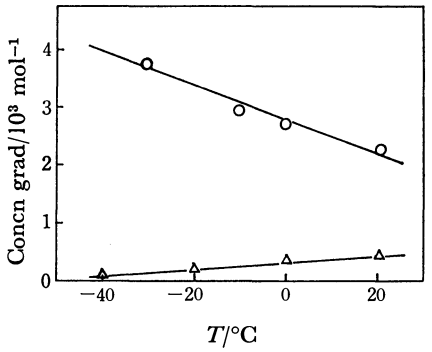

Fig. 4. Temperature dependence of concentration gradient obtained from Figs. 2 and 3.
○: ECL, △: photoexcitation.

$$\frac{I_D}{I_M} = \frac{k_{FD}}{k_{FM}} \frac{k_{DM}[M]}{k_D + k_{MD}} \equiv K''[M]. \quad (9)$$

From Eqs. 7 and 9 and experimental results (Figs. 2 and 3), the formation of the excited state *via* anion-cation annihilation is suggested. Plots of the gradient of I_D/I_M *vs.* temperature from data in Figs. 2 and 3 are shown in Fig. 4. The gradient increases in the case of ECL with fall in temperature but decreases in the case of photoexcitation.

From Eqs. 7 and 9, Kihara *et al.*[3] put

$$K'/K = (1+a^{-1})k_{DM}k_M, \quad (10)$$

$$K'/K'' = 1 + 1/[a^{-1} + (1+a^{-1})k_{MD}k_D], \quad (11)$$

and evaluated a from the data of k_M, k_D, k_{DM}, k_{MD} of pyrene in cyclohexane or 95% ethanol in substitution for them in acetonitrile. The value of K was estimated by extrapolation. The estimation seems erroneous for the following reasons: estimation of k values from the solutions different from the actual ones of ECL, and the erroneous extrapolation from the relationships I_D/I_M *vs.* concentration.

We postulate the following process for excimer formation in order to analyze the temperature effect on the concentration dependence of I_D/I_M.

From Eqs. 3, 4, 5, and 8, we have

$$\frac{d[M^*]}{dt} = k_{MD}[D^*] - (k_M + k_{DM}[M^*])[M^*]$$

$$\frac{d[D^*]}{dt} = k_{DM}[M][M^*] - (k_D + k_{MD})[D^*].$$

Let us consider the case in which the initial state is a monomer-state. Putting $[M^*]=[M^*]_0$, $[D^*]=0$ at $t=0$, we get

$$[M^*] = \frac{[M^*]_0}{\lambda_2 - \lambda_1}(c_1 e^{-\lambda_1 t} + c_2 e^{-\lambda_2 t}),$$

$$[D^*] = \frac{k_{DM}[M][M^*]_0}{\lambda_2 - \lambda_1}(e^{-\lambda_1 t} - e^{-\lambda_2 t}),$$

where

$$\lambda_1 = \frac{1}{2}\{k_M + k_{DM}[M] + k_D + k_{DM} - \sqrt{s}\},$$

$$\lambda_2 = \frac{1}{2}\{k_M + k_{DM}[M] + k_D + k_{MD} + \sqrt{s}\},$$

$$s = (k_D + k_{MD} - k_M - k_{DM}[M])^2 - 4k_{MD}k_{DM}[M],$$

$$c_1 = \lambda_2 - k_M - k_{DM}[M],$$
$$c_2 = k_M + k_{DM}[M] - \lambda_1.$$

Substituting them into the equation

$$\frac{I_D}{I_M} = \frac{k_D \int [D^*]dt}{k_M \int [M^*]dt},$$

we get

$$\frac{I_D}{I_M} = \frac{k_D k_{DM}[M]}{k_M(k_D + k_{MD})}. \quad (12)$$

Putting $[M^*]=0$, $[D^*]=[D^*]_0$ at $t=0$, we get

$$[M^*] = \frac{[D^*]_0(\lambda_2 - y)(y - \lambda_1)}{k_{DM}[M](\lambda_2 - \lambda_1)}(e^{-\lambda_1 t} - e^{-\lambda_2 t}),$$

$$[D^*] = \frac{[D^*]_0}{\lambda_2 - \lambda_1}[(\lambda_2 - y)e^{-\lambda_1 t} + (y - \lambda_1)e^{-\lambda_2 t}],$$

and

$$\frac{I_D}{I_M} = \frac{k_D(k_M + k_{DM}[M])}{k_M k_{MD}}, \quad (13)$$

where

$$y = k_D + k_{MD}.$$

The decay parameters λ_1 and λ_2, obtained experimentally are given Figs. 5 and 6. The values of the rate constants k_M, k_D, k_{DM}, and k_{MD} can be obtained by use of the parameters. The constants in DMF at 20 °C, 0 °C, −20 °C, and −40 °C are given in Table 1. The temperature dependence of $k_D k_{DM}/k_M(k_D + k_{MD})$ and

Table 1. Rate constants obtained by pulse excitation of the DMF solution of pyrene at various temperatures

Temp/°C	k_M / 10^{-7} s^{-1}	k_D / 10^{-7} s^{-1}	k_{DM} / 10^{-9} M^{-1} s^{-1}	k_{MD} / 10^{-7} s^{-1}
20	0.5	1.4	3.8	0.4
0	0.4	1.2	2.6	0.4
−20	0.35	1.1	2.1	0.2
−40	0.25	0.7	1.4	0.1

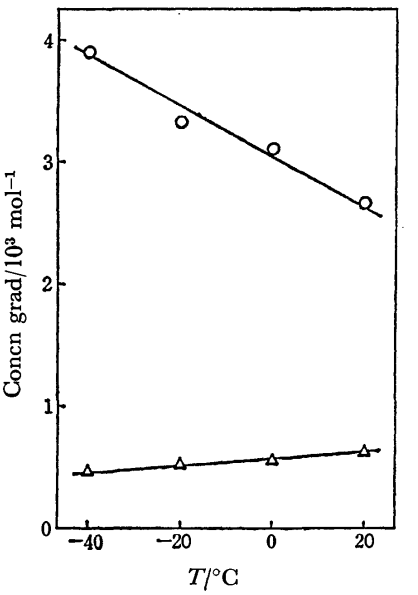

Fig. 7. Temperature dependence of concentration gradient calculated from Eqs. 12, 13, and Table 1.
○: Initial conditions $[M^*]=0$, △: initial conditions $[D^*]=0$.

$k_D k_{DM}/k_M k_{MD}$ is calculated by means of Eqs. 12 or 13 and the values given in Table 1. The results are shown in Fig. 7. By comparison of the curves in Figs. 4 and 7,

we see that the curves for photoexcitation and for ECL (Fig. 4) correspond respectively to the curves for Eqs. 12 and 13. $[D^*]=0$ at $t=0$ in case of photoexcitation, and $[M^*]=0$ at $t=0$ (excimers are directly generated from anion-cation annihilation) in case of ECL. Mechanism of direct excimer formation is confirmed in ECL of pyrene through analysis of temperature and concentration dependence of I_D/I_M. The present approach is more advantageous than the conventional one, utilizing the value K of I_D/I_M at $[M]=0$, which is often erroneous.

The authors wish to express their sincere thanks to Mr. Tadamasa Akutagawa and Mr. Katsuhiko Abe for their valuable advice and help in the course of the study.

The Crystal and Molecular Structure of Palythine Trihydrate

Akio FURUSAKI,* Takeshi MATSUMOTO, Isami TSUJINO,† and Isao SEKIKAWA††

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

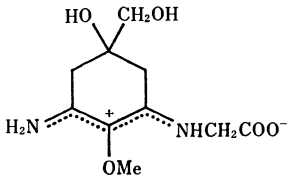
†*Department of Chemistry, Faculty of Fisheries, Hokkaido University, Hakodate 041*

††*Institute of Immunological Science, Hokkaido University, Sapporo 060*

(Received May 1, 1979)

The molecular structure of palythine, $C_{10}H_{16}N_2O_5$, has been confirmed by means of an X-ray crystal analysis of its trihydrate. The crystals are monoclinic, with two formula units in a unit cell with dimensions of $a=10.499$, $b=12.812$, $c=5.322$ Å, and $\beta=98.53°$; the space group is $P2_1$. 1377 unique intensity data were collected on a four-circle diffractometer with LiF-monochromated Cu $K\alpha$ radiation. The structure was solved by the Monte Carlo direct method, using the 20 strongest reflections as a starting set, and was refined by the block-diagonal least-squares method. The final R value was 3.1%. The molecular structure thus obtained corresponds to that proposed by Tsujino *et al.* and Takano *et al.* on the basis of the chemical evidence. Palythine exists as a zwitter ion in the crystal. The palythine and water molecules are connected by twelve types of hydrogen bonds, forming a three-dimensional hydrogen-bonded structure.

Palythine is a new amino acid isolated from the red alga *Chondrus yendoi* and the zoanthid *Palythoa tuberculosa*.[1,2] On the basis of the chemical evidence, the **1** structure has been proposed for this compound. However, because of the remarkable lability of palythine, there was some doubt about the proposed structure. Therefore, in order to confirm **1**, we have now undertaken an X-ray crystallographic study of palythine trihydrate.



1

Experimental

Colorless, single crystals of palythine trihydrate were obtained from an aqueous solution. A crystal with dimensions of about $0.1\times0.3\times0.4$ mm³ was used for the X-ray measurement. The crystal data are summarized in Table 1. The cell dimensions and diffraction intensities were measured on an automatic, four-circle diffractometer using Cu $K\alpha$ radiation ($\lambda=1.5418$ Å) monochromatized with an LiF crystal. The intensity measurement was made by using an ω-2θ continuous scan at a rate of about 1°(ω)/min; the background was measured for 20—30 s at each end of the scan range. The intensities thus obtained were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 140°, 1377 unique structure factor magnitudes above $2\sigma(F)$ were selected for the structure determination.

Structure Determination

At the early stage of the structure determination, attempts were made to solve the structure by the symbolic-addition method.[3] Although a phase set which showed a low R_K value of 32.8% ($R_K=\Sigma||E_o|-k|E_c||/\Sigma|E_o|$) gave an E-map which contained a six-membered ring, it did not lead to the elucidation of the whole structure. It was found afterwards that the six-membered ring in the E-map deviated from its correct position, nearly perpendicular to the ($\bar{2}$ 0 1) plane by

a) Phase values obtained from the starting phase set, different from the 54th set only in the phase of $\bar{1}0$ 0 2.

about 1.1 Å. The structure was finally elucidated by the Monte Carlo direct method.[4] The 20 strongest reflections given in Table 2 were chosen as members of a starting set. The tentative phase values for the starting reflections were derived from successively-generated random numbers. In order to extend this tentative phase set, 10 cycles of the tangent procedure were performed using 331 $|E|$ values above 1.20; during the first 5 cycles, the phases of the starting reflections were kept constant. Since the 54th phase set showed a low R_K value of 28.2%,** 6 additional cycles of the tangent procedure were carried out. Consequently, the R_K value was reduced to 18.8%. An E-map based on 329 phases clearly revealed the locations of all 20 non-hydrogen atoms.

The 54th random phase set and the correct phases calculated with the final atomic parameters are given in Table 2. The two corresponding phase values are in substantial agreement with each other except for the $\bar{1}0\ 0\ 2$, $\bar{5}\ 4\ 5$, and $\bar{5}\ 1\ 4$ reflections. However, it should be noted that the phase value assigned to the strongest $\bar{1}0\ 0\ 2$ reflection is different from the correct phase by π. It was ascertained that, when this phase value was replaced by the correct one in the initial stage of the tangent procedure, the 54th random phase set no longer led to the correct solution. Of the phase values calculated in such a way, those for the starting reflections are given in the last column of Table 2. Especially great deviations from the correct phases can be seen for the $3\ 0\ 5$, $\bar{3}\ 4\ 1$, $\bar{1}\bar{1}\ 6\ 2$, and $\bar{1}0\ 1\ 2$ reflections, those derivations being π, $0.422\,\pi$, $0.524\,\pi$, and $0.621\,\pi$ respectively. Since none of the 24 most probable phase relationships ($\kappa=2\sigma_3\sigma_2^{-3/2}|E_hE_kE_{h-k}>3.5$) associated with the $\bar{1}0\ 0\ 2$ reflection contain errors greater than

Table 3. The final atomic parameters and estimated standard deviations

(1) The non-hydrogen atoms

The positional and thermal parameters are multiplied by 10^4 and 10^5 respectively. The latter ones are defined as $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$.

** The second lowest of the R_K values for the 54 sets was 30.7%.

$\pi/3$, such serious deviations may be due to the accidental accumulation of rather large errors produced by these phase relationships.

The structure thus obtained was refined by the block-diagonal-matrix least-squares method, first with isotropic and then with anisotropic temperature factors. After all the 22 hydrogen atoms had been located in a difference Fourier map, further least-squares refinement including these hydrogen atoms with isotropic temperature factors was carried out. For this refinement, the following weighting scheme was used:

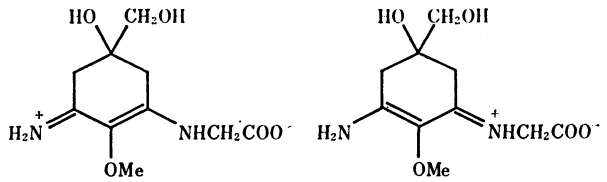
$$W = 1/\{\sigma(F)^2 \exp(AX^2+BY^2+CXY+DX+EY)\}$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients are constants which were determined from the $(\Delta F)^2$ values in each cycle of the refinement. In this manner, the R value reached 3.1%. The atomic parameters thus obtained are listed in Table 3. The tables of the observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8003).

All the calculations were performed on a FACOM 230-75 computer at the Hokkaido University Computing Center, using our own programs. Random numbers were generated by calling a function RANDOM which existed in a program library of the Computing Center. The atomic scattering factors were taken from the International Tables.[5]

Results and Discussion

Molecular Structure. The molecular structure of palythine is illustrated in Fig. 1, where each atom is represented as a thermal ellipsoid enclosing a 50% probability. As can be seen in Fig. 1, the molecular framework obtained corresponds to the structure **1**. Since the proton of the carboxyl group is transferred to the nitrogen atom, in the crystalline state palythine exists as a zwitter ion which is stabilized by resonance between the two nearly-equivalent structures, **2a** and **2b**. The bond distances and angles and the dihedral angles are listed in Tables 4 and 5 respectively. If the H(N1a) atom and the CH_2COO^- group are excluded,



2a **2b**

TABLE 4. THE BOND DISTANCES (l/Å) AND ANGLES (ϕ/°), WITH THEIR STANDARD DEVIATIONS

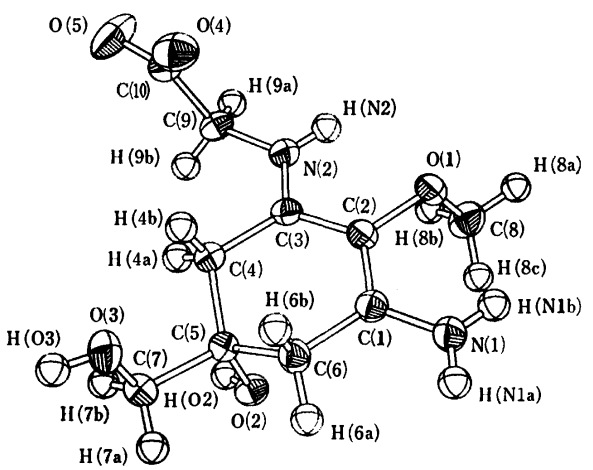

Fig. 1. A perspective view of the palythine molecule. For hydrogen atoms, a B value of 2 Å^2 was used.

the zwitter ion is almost symmetrical with respect to the plane determined by the C(2), C(5), and O(2) atoms.

The six-membered ring takes an envelope-like form in which the C(5) atom is 0.579 Å apart from the least-squares plane for the other five atoms. The deviations of the other atoms from this plane are as follows: C(1), 0.039 Å; C(2), −0.031 Å; C(3), 0.006 Å; C(4), 0.009 Å; C(6), −0.023 Å; N(1), 0.117 Å; N(2), 0.038 Å; O(1), −0.097 Å. All the bond distances in the ring are normal. The average of the C(1)-N(1) and C(3)-N(2) bond distances is 1.322 Å, which is somewhat small compared with the C–N distances (1.334 Å) in pyrazine[6] and 1,2,4,5-tetrazine,[7] and almost equal to the lengths of amide linkages, CO–NH.[8] This bond shortening may be related to the cationic nature of the conjugated system, since the C–NH part in amides also carries a considerable positive charge.

In a crystalline state, a carbon atom of a methoxyl group attached to an aromatic ring usually lies nearly on the ring plane. However, since the present molecule has amino or imino groups at both of the two positions *ortho* to the methoxyl group, the C(8) atom deviates remarkably from the C(1)-C(2)-C(3) plane in the same direction as the O(2) atom. The H(N1b) and H(N2) atoms are situated at distances of 2.42 and 2.37 Å from the O(1) atom respectively. An NMR study of 2-substituted 1,3-phenylenediamines and their *N,N'*-diacyl derivatives has revealed that, for the 2-methoxy compound in a deuterochloroform solution, a weak, but still effective, dual intramolecular hydrogen bonding is formed.[9] Accordingly, the N(1)···O(1) and N(2)···O(1) contacts in the palythine molecule can be taken as intramolecular hydrogen bonds.

Of the two groups bonded to the C(5) atom, the larger, CH_2OH group occupies the equatorial position, and the smaller, OH group, the axial. Although, from the standpoint of steric repulsion, a structure in which the O(3)H group takes a *trans* conformation with one of the two bulky methylene groups around the C(5)-C(7) bond can be expected to be the most stable, in fact,

Table 5. The dihedral angles (ϕ/°)

the O(3)H group has *gauche* relations with both of the methylene groups. The preference of the present conformation may be due not only to the electrostatic repulsion between the negatively-charged atoms, O(2) and O(3), but also to the hydrogen-bond formation of the O(3)H group with adjacent molecules.

The carboxylate ion group is placed on the opposite side of the mean plane for the N(1)–C(1)–C(2)–C(3)–N(2) conjugated system to the $C(8)H_3$ group. The carboxylate plane is approximately perpendicular to the C(3)–N(2)–C(9) plane, and the O(4) atom nearly eclipses the N(2) atom around the C(9)–C(10) bond. As a result, the H(4a) and H(9b) atoms are very close to each other, the distance between them being only 2.10 Å.

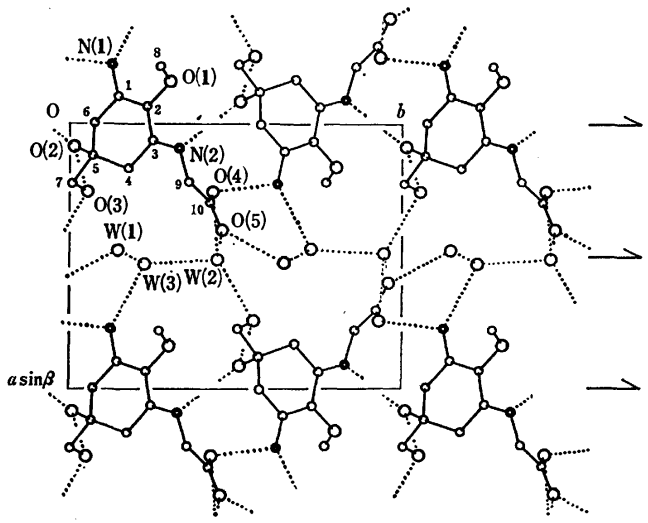

Fig. 2. The crystal structure viewed along the c axis.

TABLE 6. THE HYDROGEN BONDS, X–H···Y

O(W3)	O(W2)[a]	2.831(3)	2.07(6)	178(5)

The symmetry codes are: a) x, y, z (given in Table 3); b) $-x, -1/2+y, -z$; c) $-x, 1/2+y, -z$; d) $-x, 1/2+y, 1-z$; e) $x, y, 1+z$; f) $1-x, -1/2+y, 1-z$; g) $1-x, 1/2+y, 1-z$; h) $1-x, -1/2+y, -z$.

Crystal Structure. The projection of the crystal structure viewed along the c axis is shown in Fig. 2, while the details of the hydrogen bonds are given in Table 6. The palythine and water molecules are joined together into a three-dimensional hydrogen-bonded structure by twelve types of hydrogen bonds. Three groups, N(1)–H(N1b), N(2)–H(N2), and O(W2)–H(W2a), take part in bifurcated hydrogen bonds.[10] The first two make intermolecular hydrogen bonds with the O(W3)[c] and O(2)[d] atoms respectively, besides intramolecular ones with the O(1) atom. The last group donates its proton, H(W2a), to both of the two oxygen atoms in the same carboxylate group, O(4)[h] and O(5)[h]. Although the O(W2)···O(4)[h] and O(W2)···O(5)[h] distances are somewhat different, the O(W2)–H(W2a)···O(4)[h] and O(W2)–H(W2a)···O(5)[h] angles are nearly equal to each other, 149 and 154° respectively.

(Received May 4, 1979)

The reactivity and mobility of the lattice oxygen of iron oxide, in particular γ-Fe_2O_3, has been investigated by ^{18}O-exchange with CO_2 and CO oxidation by $^{18}O_2$. The low mobility of the lattice oxygen is in agreement with the reduction-oxidation mechanism of γ-Fe_2O_3 bulk, which proceeds by Fe ion migration without diffusion of the lattice oxygen. The rapid diffusion of the Fe ion makes the redox cycles of γ-Fe_2O_3 easy and explains, together with the cation deficient structure, the high reactivity and selectivity of lattice oxygen. Thus, γ-Fe_2O_3 may be regarded as a new prototype of selective catalyst for allylic oxidation.

Iron oxide catalyst is widely used either as a single metal oxide or as a mixed oxide in industrial processes such as dehydrogenation (*e.g.* ethylbenzene to styrene and methanol to formaldehyde), the water gas shift reaction, and the reduction of nitrogen monoxide.[2] Among the oxides of the first transition metals, iron oxide exhibits intermediate activity in the complete oxidation of methane, carbon monoxide, and isotopic equilibration of oxygen,[3] but is not a good catalyst in the partial oxidation of hydrocarbons.[4,5]

It has been demonstrated that iron oxide becomes very active and selective in the oxidative dehydrogenation of butenes, when the structure of iron oxide is transformed from the α-form (hematite; a corundum structure) to the γ-form (maghemite; an inverse spinel).[6] This high activity and selectivity of γ-Fe_2O_3 was confirmed in catalytic reactions in both pulse and flow reactors at 250—300 °C.[6c] This temperature range is considerably lower than that employed for Bi_2O_3–MoO_3 catalysts.[7]

The importance of structural factors and the oxidation state of iron oxide catalysts may be inferred from the following. In the dehydrogenation of ethylbenzene, the addition of alkali metal to or the pre-reduction of iron oxide increases the selectivity significantly. It has been suggested that this effect is not only electronic but also structural.[8] In this reaction, the oxidation state of iron oxide has been reported to be important.[9] Changes in structure under the reaction conditions of oxidative dehydrogenation of butenes was observed by Sazonova *et al.*,[10] who attributed this change to the reduction of α-Fe_2O_3 to Fe_3O_4. This change is probably however a transformation to γ-Fe_2O_3 based on our results. In ferrite catalysts, distribution of metal ions into tetrahedral (Td) sites and octahedral (Oh) sites appears to be connected to the catalytic activity for the dehydrogenation of butenes.[11]

In a previous report the catalytic activity of iron oxide in the oxidation of butene was investigated as a function of the structure and oxidation state, the results of which are summarized as follows:

(i) The activity for butadiene formation varies markedly with the bulk structure and the oxidation state, *i.e.* γ-$Fe_2O_3 > \alpha$-$Fe_2O_3 \gg Fe_3O_4$.[6]

(ii) Lattice oxygen is the reactive oxygen species and the redox mechanism which comprises reduction-oxidation cycles of iron oxide is operative.[6]

(iii) The allylic species is probably the reaction intermediate in view of the substituent effect of the reactant.[6b]

The last two facts apparently coincide with those reported for Bi_2O_3–MoO_3.** In Bi_2O_3–MoO_3, oxygen tracer studies coupled with kinetic studies have revealed that oxidation proceeds by redox cycles of catalyst and the lattice oxygen is directly involved in the reaction.[7,12] The importance of the high mobility of oxygen in the bulk oxide has been pointed out in this oxide and also for other related mixed oxides.[13] These mixed oxides form one group of oxidation catalysts, in which Bi_2O_3–MoO_3 may be considered a prototype.

The aim of the present study has been to investigate the reactivity and mobility of the lattice oxygen of iron oxide, particularly in γ-Fe_2O_3, and to elucidate the redox process which is pertinent to the catalytic oxidation. Stress has been placed on the similarity and contrasts of iron oxide to Bi_2O_3–MoO_3, to provide a new prototype of oxidation catalyst, comprising a single metal oxide.

Experimental

Apparatus. A conventional pulse reactor and a closed circulation reactor were used for the reactions. The pulse technique used was the same as described elsewhere.[6] Oxygen impurities in the He carrier gas were removed by a molecular-sieve trap kept at the temperature of liquid-nitrogen. The closed circulation system, equipped with a mercury manometer, a magnetic circulation pump, and a gas-sampling valve for the measurement of mass spectra, had a volume of *ca.* 200 cm^3 and was readily evacuated to 10^{-3} Pa by a rotary pump and an oil diffusion pump.

Catalysts and Reagents. α-Fe_2O_3 (BET surface area: 10 $m^2\,g^{-1}$) was prepared from $Fe(NO_3)_3$ (Kishida Chemical Co.) as described previously.[6] γ-Fe_2O_3 was prepared from α-Fe_2O_3 by two methods. In the pulse reactor, α-Fe_2O_3 was reduced

** Both iron oxide and Bi_2O_3–MoO_3 are selective catalysts for butene oxidation, but the former is not a selective catalyst for the oxidation of propene to acrolein. This difference may be attributed to the low activity of iron oxide in the reaction step of oxygen addition to the allylic intermediate. Both oxides are however very similar for the allyl formation (abstraction of an allyl hydrogen by oxygen on metal oxides). This step is often considered the key reaction of allylic oxidation.

by CO pulses to Fe_3O_4 and then re-oxidized by O_2 or N_2O pulses to γ-Fe_2O_3 at 200—300 °C. The structures of α- and γ-Fe_2O_3 prepared by this procedure were confirmed by X-ray powder diffraction patterns and Mössbauer spectra. γ-Fe_2O_3 was also prepared in the closed circulation system by reducing α-Fe_2O_3 to Fe_3O_4 with pure CO or mixtures of CO and CO_2, followed by re-oxidation with O_2. As described in the following section the reduction of iron oxide by CO in a closed system appeared to partially form Fe metal and Fe carbide.

O_2 enriched in ^{18}O(^{18}O: 20 or 70 atom %) was purchased from Japan Radioisotope Association. $C^{18}O_2$(^{18}O: 10 or 35 atom %) was prepared by oxidizing CO with ^{18}O-enriched O_2 over iron oxide at 300 °C and used without further treatment.

Procedures. Both ^{18}O-exchange between CO_2(or O_2) and iron oxide and CO oxidation over iron oxide using $^{18}O_2$ were conducted in the closed circulation reactor. Prior to reaction, the iron oxide samples (300 or 600 mg) were evacuated in the closed system for 1 h at 300 °C, treated with pure O_2 (13 kPa) at 300 °C (with circulation and a liquid nitrogen trap), and finally evacuated for 1 h at the reaction temperature. ^{18}O distributions in CO, O_2, and CO_2 in the gas phase was analyzed by a mass spectrometer (Hitachi Co, Ltd.) after intermittent sampling. After the run, the catalyst was subjected to X-ray powder diffraction analysis by a Geigerflex ECP-TG (Rigaku Denki Co.) with Cu $K\alpha$ irradiation. Analysis showed that the structure of the catalyst did not change before and after the run.

Results

Oxygen-18 Exchange between CO_2 or O_2 and Iron Oxide. The reactivity of the lattice oxygen of the iron oxide was investigated by ^{18}O-exchange between ^{18}O-labeled CO_2 (10 Torr) and iron oxide (600 mg). Figure 1 illustrates the changes of ^{18}O content (atomic fraction) in CO_2 with reaction time, where the ^{18}O contents relative to the initial ^{18}O content are given. The reaction temperature was raised in steps from 150 °C to 300 °C as indicated in the figure. The times required to raise the temperature from 150 to 220 °C and from 220 to 300 °C were 10—15 min each.

From Fig. 1 it may be seen that the ^{18}O content became constant within 5 min after the introduction of CO_2 over both α- and γ-Fe_2O_3 at 150 °C. In all runs, the ^{18}O distributions in CO_2 in the gas phase were always in equilibrium, *i.e.* $[C^{16}O^{18}O]^2/\{[C^{18}O_2]\times[C^{16}O_2]\}=4$. In the case of α-Fe_2O_3, a small decrease of the ^{18}O content in CO_2 with reaction time was observed at 220 and 300 °C (Fig. 1), but this decrease was very small and negligible compared with the total change of the ^{18}O content in CO_2.

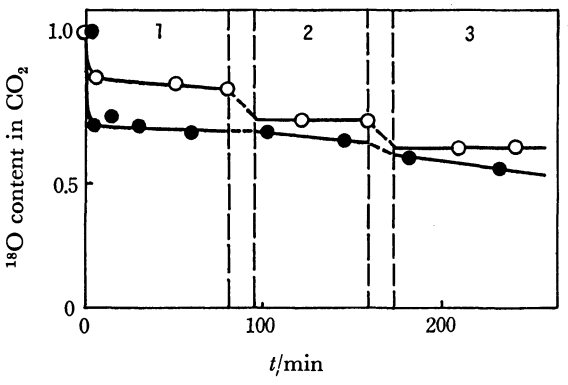

Fig. 1. Isotopic exchange of oxygen between $C^{18}O_2$ and Fe_2O_3.
React. temp (°C), 1: 150, 2: 220, 3: 300.
○: γ-Fe_2O_3, ●: α-Fe_2O_3, Fe_2O_3: 0.6 g, P_{CO_2}: 1 cmHg. ^{18}O content is relative to the initial content.

The indication is that oxygens of the iron oxides exchange rapidly with CO_2, but the degree of exchange is very small: 1.4 cm^3 NTP g^{-1} (0.5) for α-Fe_2O_3 and 0.9 cm^3 NTP g^{-1} (0.3) for γ-Fe_2O_3 at 150 °C. At 300 °C, the values are 3.5 (1.3) and 2.7 cm^3 NTP g^{-1} (1.0) for α- and γ-Fe_2O_3, respectively. The numbers in parentheses are the amounts of exchangeable oxygen in terms of surface layers, calculated by assuming the number of oxygen in one layer to be 1.5×10^{19} atom m^{-2} (see Discussion). Consequently, the amounts of exchangeable oxygen are comparable to or smaller than one surface layer.

Oxygen exchange between $^{18}O_2$ and iron oxide was very slow, *e.g.* 0.6 cm^3 NTP g^{-1} (0.2 surface layer) exchanged after 4 h at 300 °C and the isotope distributions in O_2 remained far from equilibrium, indicating that isotopic equilibration of O_2 was also very slow. Therefore, the activation of molecular oxygen on iron oxides in the fully oxidized state is a slow process.

CO Oxidation by $^{18}O_2$. CO oxidation by $^{18}O_2$ was conducted at 150 °C, to determine the amount of oxygen atoms in iron oxide participating in catalytic oxidation. The ^{18}O contents in CO, O_2, and CO_2 are plotted in Fig. 2 as a function of the amount of CO_2 produced, where the ^{18}O contents are all normalized to the initial ^{18}O content in O_2. Over both α- and γ-Fe_2O_3, the ^{18}O content in CO_2 produced at the initial stage was low and then gradually increased with reaction time as shown in Fig. 2. The ^{18}O distributions in CO_2 were always in equilibrium during the reaction. In contrast to CO_2, ^{18}O-exchange between CO or O_2 and iron oxide did not occur at all, as seen from the constant ^{18}O contents in O_2 and CO during the reaction. Isotopic equilibration in O_2 was also absent.

From these data, it is possible to calculate the amount

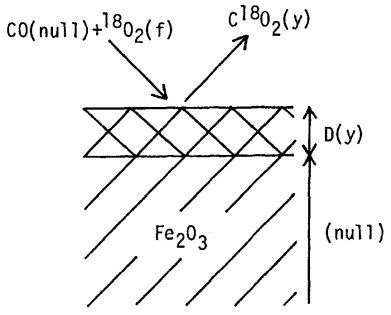

Fig. 3. Model for calculation of the amount of lattice oxygen participating in CO oxidation by $^{18}O_2$.
( ): ^{18}O content (%)
D: the amount of lattice oxygen participating in CO oxidation (see text).
f and y are ^{18}O% in O_2 and CO_2, respectively.

of oxygen atoms in iron oxide, which participate in the CO oxidation. Since the ^{18}O-exchange between CO_2 and iron oxide was very rapid as shown in Fig. 1, the amount of oxygen atoms calculated here includes those which participated only in the ^{18}O-exchange between CO_2 and iron oxide, in addition to the lattice (or surface) oxygen atoms which were incorporated into CO_2 directly by the oxidation reaction. In other words, only the upper limit of the lattice (or surface) oxygen atoms which have participated directly in CO oxidation can be determined. The calculation was conducted in the following manner. Since the oxygen exchange between the surface and CO_2 is rapid, it is reasonable to place the ^{18}O content in the catalyst surface equal to the ^{18}O content in CO_2 at each reaction time. The model for CO oxidation by $^{18}O_2$ over iron oxide is shown in Fig. 3. It was assumed that the surface layer of the catalyst which participates equally in the reaction has a uniform ^{18}O concentration to a depth of D (expressed in $cm^3\,NTP\,g^{-1}$) and that the lattice oxygen in the bulk deeper than this layer (depth$>D$) does not participate in the reaction (^{18}O: 0%). The method reported by Miura *et al.*[14] was subsequently applied for the calculation, where the contribution from ^{18}O-exchange between CO_2 and catalyst surface was additionally taken into account. In Fig. 3, p, y, and f represent the amount ($cm^3\,NTP\,g^{-1}$) of CO_2 produced, the ^{18}O content (%) in CO_2 at reaction time t (min), and the ^{18}O content (%) in O_2, respectively. The mass balance of the ^{18}O in the catalyst surface layer D at reaction time t is represented by Eq. 1.

$$D\mathrm{d}y = f\mathrm{d}p - 2\mathrm{d}(py) \quad (1)$$

$$p = D\cdot y/(f-2y) \quad (2)$$

Integration of Eq. 1 at the initial conditions of $p=0$ and $y=0$ gives Eq. 2. Equation 2 shows that a plot of p against $y/(f-2y)$ gives a slope ($=D$) which represents the amount of oxygen in the catalyst participating in CO oxidation (oxygen atom, $cm^3\,NTP\,g^{-1}$). The results in Fig. 2 are plotted in Fig. 4, according to Eq. 2. From the slopes of the linear plots in this figure, the amounts of oxygen at 150 °C have been calculated as 3.3 (1.2) and 2.0 $cm^3\,NTP\,g^{-1}$ (0.7 surface layers) for α- and γ-Fe_2O_3, respectively (numbers in parentheses are in terms of surface layers). These values are comparable with the amount of exchangeable oxygen with

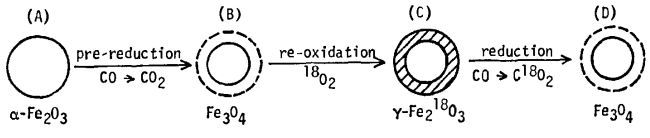
f and y are the same as in Fig. 3.

CO_2 and demonstrate that the amount of oxygen participating directly in the reaction is at most one or two surface layers even during the CO oxidation.

Reduction-Oxidation (Redox) Mechanism of γ-Fe_2O_3. The reduction and re-oxidation of the bulk of iron oxide was very rapid, and this rapid redox process appeared connected with the high activity and selectivity observed for oxidative dehydrogenation.[6] The results indicate however that the lattice oxygen has low mobility in the bulk. Therefore, an attempt was made to determine which ion (O^{2-} or Fe^{3+}) diffused during the redox process. The method is schematically drawn in Scheme 1. γ-$Fe_2{}^{18}O_3$ prepared by the re-oxidation of Fe_3O_4 by



Scheme 1. Changes of one sample particle are schematically drawn. Shaded area is the layer formed by re-oxidation, which is eliminated by subsequent reduction.

$^{18}O_2$ (Scheme 1, A→B→C) was gradually reduced by CO (Scheme 1, C→D), in which the ^{18}O contents of CO_2 produced were measured as a function of the degree of reduction, x in γ-Fe_2O_{3-x}. The degree of reduction, x, has been evaluated from the amount of CO_2 produced (x of Fe_3O_4=0.33). The ^{18}O recovery is defined as

$$^{18}O\text{ recovery} = 2\times[^{18}O\%\text{ in }CO_2\text{ produced during the reduction by CO}]/[^{18}O\%\text{ in }O_2\text{ used for the re-oxidation}] \quad (3)$$

The ^{18}O recovery is expected to be as follows, depending on the rate of oxygen diffusion. (1) If lattice oxygen does not migrate during the $^{18}O_2$ re-oxidation and the subsequent CO reduction, ^{18}O should be uniformly contained only in the surface layer formed by the re-oxidation, the ^{18}O content in this layer being identical

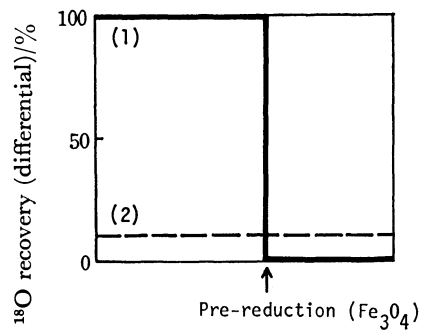


Fig. 5. ^{18}O recovery (differential) expected for the process C→D in Scheme 1 for two extreme cases.
(1) No oxygen diffusion,
(2) rapid oxygen diffusion.

to that in $^{18}O_2$ used for the re-oxidation. Therefore, the differential ^{18}O recovery, which is defined as the ^{18}O recovery for a small increment of CO_2 formation, should be 100% until the γ-$Fe_2{}^{18}O_3$ is reduced to the state of the pre-reduction (Scheme 1, B), and nil (zero) on further reduction (Fig. 5, full line). (2) If lattice oxygen diffuses very rapidly (complete mixing of lattice oxygens), the differential ^{18}O recovery is constant and equal to the amount determined by the reaction stoichiometry: 11% for γ-Fe_2O_3 in the present experiment (Fig. 5, broken line). Thus the ^{18}O recovery reflects the change in the ^{18}O concentration from the surface to the center and, therefore, the rate of diffusion of the oxide ion (Fig. 6).

In Exp. 1, both the CO reduction and $^{18}O_2$ re-oxidation were performed in a closed circulation system at 250 °C. The ^{18}O recovery was 66% after corrections for the ^{18}O-exchange between iron oxide and CO_2. The migration of lattice oxygen was slow but not negligible. This rather low recovery of ^{18}O may be attributed to a diffusion of lattice oxygen accelerated by the increase of temperature caused by the exothermic re-oxidation step. Therefore, the reaction temperature of the re-oxidation step was lowered from 250 °C to 150 °C in Exp. 2, but there was only a small increase in ^{18}O recovery (65—71%). Another possible explanation for the low ^{18}O recovery is the formation of iron metal or iron carbide in the reduction step ($CO+Fe_2O_3 \rightarrow CO_2+Fe$, FeC_n). In Exp. 3, reduction was carried out with a mixture of CO and CO_2. The ^{18}O recovery increased slightly (72—73%) but the formation of iron metal and iron carbide was still indicated since the reduction-oxidation was not completely stoichiometric and a small amount of CO_2 was formed on re-oxidation. Finally, CO reduction (both pre-reduction and final reduction) was performed with the pulse method and re-oxidation by $^{18}O_2$ with the closed circulation system (Exp. 4), by transferring the sample between the two systems without exposing it to air. In this method, the reduction and subsequent re-oxidation of α-$Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow \gamma$-$Fe_2O_3$ was confirmed at each step stoichiometrically and by X-ray diffraction analysis and Mössbauer spectroscopy. Further, there was no change in surface area.

As shown in Fig. 6, by using γ-$Fe_2{}^{18}O_3$ thus prepared the ^{18}O recovery increased to 91% at the reduction stage of $x=0.25$ and was 83% at $x=0.33$ (reduction to Fe_3O_4). Therefore, it may be assumed that little diffusion of lattice oxygen took place during the redox cycle.

Discussion

Mobility of Lattice Oxygen in Iron Oxide. As shown by the isotopic exchange of oxygen with CO_2 (Fig. 1) and the CO oxidation by $^{18}O_2$ (Figs. 2—4), the amount of lattice (surface) oxygen of iron oxide, which participates in these reactions was 0.9—3.5 cm^3 NTP/g-Fe_2O_3. This amount is equivalent to 0.4—1.4% of the total lattice oxygen and is very small compared with Bi_2O_3–MoO_3, for which the amount of oxygen participating in CO oxidation was about 20% of total lattice oxygen.[14] A remarkable contrast exists, therefore, between iron oxide and Bi_2O_3–MoO_3, although both catalysts are very similar.

Although iron oxide is not very active for the activation of the O_2 molecule below 300 °C, as seen from the very small rate observed in the ^{18}O-exchange with O_2, the ^{18}O-exchange between surface oxygen and CO_2 was rapid and equilibrium was reached almost instantaneously. The agreement of the amounts of exchangeable oxygen calculated for CO_2 exchange (Fig. 1) and CO oxidation (Fig. 4) may be due to the fact that both were determined by the same reaction, that is, the ^{18}O-exchange between CO_2 and iron oxide surface. This reaction is generally considered to proceed *via* a surface carbonate complex.[15] Over iron oxide the formation of surface carbonate from CO_2 has actually been detected

by infrared spectrometry.[16]

The amount of exchangeable oxygen of iron oxide calculated from the ^{18}O concentration of CO_2 after a long period of the reaction was 3.5 and 2.7 cm^3 NTP/g-Fe_2O_3 at 300 °C for α- and γ-Fe_2O_3, respectively. These values may be represented in terms of the number of surface layers and compared with those reported in the literature. Assuming the surface of iron oxide is composed of the maximum packing of oxide ion, the surface density is thus 1.5×10^{19} atom m^{-2} for the (111) surface (radius of O^{2-}; 1.40 Å). The actual surface density of oxide ion may be lower than this value, since the metal oxide surface is not fully covered with oxide ion. In general, the surface atom density is given as $1—2\times10^{19}$ atom m^{-2}.[17] Assuming the value of 1.5×10^{19} atom m^{-2}, the exchangeable oxygen at 300 °C obtained in the present work corresponds to 1.3 and 1.0 surface layers for α- and γ-Fe_2O_3, respectively. Based on the work of Nováková using Winter's data,[18] the amount of oxygen exchangeable with O_2 is 1.5—4 layers for α-Fe_2O_3 at 260—400 °C, the surface oxide density being assumed 0.6×10^{19} atom m^{-2}.[15] Boreskov *et al.* reported that 1.8 surface layers were exchangeable with O_2 at 350 °C (surface oxide density; 1.28×10^{19} atom m^{-2}).[19] The present results are in reasonable agreement with those reported values and demonstrate that the diffusion of the lattice oxygen of iron oxide between the surface layer (1—2 layers) and inner bulk is a very slow process during both CO_2-oxygen isotopic exchange and CO oxidation. It is thus concluded that the mobility of the lattice oxygen is small in the bulk of iron oxide under the conditions of catalytic oxidation.

Mechanism of CO Oxidation over Iron Oxide. The oxidation state of the iron oxide catalyst may be regarded as in the fully oxidized state (Fe_2O_3) when CO oxidation is taking place, on the basis of the following. The re-oxidation process of partially reduced iron oxide by O_2 was much faster than the reduction of iron oxide by CO when measured in the circulation system. Furthermore, the rate of CO oxidation was of zero order with respect to O_2 pressure. The iron oxide catalyst under the working conditions was also found to be Fe_2O_3 (α- or γ-) in the case of the oxidative dehydrogenation of butenes in the flow reactor and the reaction was of zero order in O_2 pressure.[6c]

The reactive oxygen species on the surface of iron oxide does not desorb into the gas phase unless reaction occurs with CO to form CO_2, *i.e.* the adsorption of oxygen is irreversible and probably dissociative. In Fig. 2 neither ^{18}O-exchange between O_2, CO, and the catalyst nor the equilibration of the oxygen isotope in gaseous O_2 was observed during the CO oxidation by $^{18}O_2$. Reversible and molecularly adsorbed oxygen that might explain the facts in Fig. 2 does not seem sufficiently reactive to participate directly in the CO oxidation, even if it exists. The irreversible adsorption process of oxygen can be the oxidation of the bulk to form lattice oxygen as discussed below.

From the agreement of the reactions of butene pulses with and without O_2 it was concurred that the lattice oxygen of iron oxide is the oxygen species responsible for oxidative dehydrogenation of butenes below 300 °C.[6a] The lattice oxygen is also probably the main oxygen species involved directly in the CO oxidation. The reactivity of γ-Fe_2O_3 with CO (non-catalytic) was examined and found independent of the oxidation state from γ-Fe_2O_3 to $Fe_2O_{2.8}$. This relationship between the reactivity and the extent of reduction was very similar to that observed for the oxidative dehydrogenation of butenes. Over γ-Fe_2O_3 however the rate of oxidation of CO pulsed together with O_2 was 1.6 times greater than that without O_2, indicating that the contribution of adsorbed oxygen to the activity can not be neglected. Therefore, both the lattice oxygen and adsorbed oxygen, although these are sometimes difficult to distinguish, must be considered in the mechanism of CO oxidation. The amount of adsorbed oxygen on α-Fe_2O_3 measured by thermal desorption was approx. 2.0% of one surface layer.[20]

The CO oxidation necessitates the transfer of two electrons. In the case that lattice oxygen is the active species, a two-centered mechanism which involves two Fe^{3+} ions operates. This is a typical redox mechanism of catalytic oxidation:

$$CO + 2Fe^{3+} + O^{2-}(\text{lattice}) \longrightarrow CO_2 + 2Fe^{2+}, \quad (4)$$

$$1/2O_2 + 2Fe^{2+} \longrightarrow 2Fe^{3+} + O^{2-}(\text{lattice}). \quad (5)$$

A one-centered mechanism is for an adsorbed O^- and a Fe^{3+} ion, *i.e.* the mechanism proposed for butene dehydrogenation over ferrite catalysts:[23]

$$CO + Fe^{3+} + O^- \longrightarrow CO_2 + Fe^{2+}, \quad (6)$$

$$1/2O_2 + Fe^{2+} \longrightarrow Fe^{3+} + O^-. \quad (7)$$

In both mechanisms, CO_2 is formed by the reaction of CO and the surface oxygen species to form vacant sites which are reoccupied by the oxygen from the gas phase. The second step, (5) or (7), is always instantaneous and irreversible. The two-centered mechanism, which is probably responsible for the major part of the reaction, occurs readily, since the electron exchange in iron oxide must be very easy owing to its high electric conductivity. The ease of the electron transfer or exchange must be an important factor in some catalytic oxidations.

Reduction-Oxidation Mechanism of Bulk Iron Oxide and Catalytic Activity. In this section, the catalytic activity and the reduction-oxidation (redox) mechanism of γ-Fe_2O_3 is discussed in terms of structural characteristics, particularly the similarity of its crystal structure to Fe_3O_4. While α-Fe_2O_3 has a corundum-type structure (oxide ions form a hexagonal close-packed array with Fe^{3+} ions occupying octahedral (Oh) interstices), both γ-Fe_2O_3 and Fe_3O_4 have an inverse-spinel structure (cubic close-packed array (ccp) of oxide ion).[24] For Fe_3O_4, two-thirds of the iron cations are Fe^{3+} ions which are distributed at Td sites and Oh sites. For γ-Fe_2O_3, one-ninth of the total cation sites are vacant, probably in Oh sites.[25] The dimension of the unit cell of γ-Fe_2O_3 is 8.350 Å, which is slightly smaller than that of Fe_3O_4 (8.390 Å).

The structural characteristics suggest the following redox process between γ-Fe_2O_3 and Fe_3O_4, in which the packing structure of oxide ion remains unchanged.

The oxidation of Fe_3O_4 to γ-Fe_2O_3 proceeds by the addition of oxygen atoms on the surface to form new oxide layers which have the same packing structure as in Fe_3O_4 (ccp). This process is accompanied by the migration of iron cations from the bulk into the newly formed oxide layer to compensate for the charge, forming cation vacancies. The reduction of γ-Fe_2O_3 to Fe_3O_4 may be exactly the reverse process: removal of the oxide layer and migration of iron cations inward to fill the vacancies in the bulk. Thus, in the case of γ-Fe_2O_3, only iron cation diffuses during the reduction-oxidation of the bulk.

Experimentally this was confirmed by Exp. 4 shown in Fig. 6. The redox model of γ-Fe_2O_3, discussed above, is shown schematically in Fig. 7. The redox mechanism of γ-Fe_2O_3 bulk without the diffusion of lattice oxygen is in agreement with the results shown in Figs. 1—4, which demonstrate the very slow diffusion of lattice oxygen. Therefore, the ready interconversion between Fe^{2+} and Fe^{3+}, and the comparatively rapid diffusion of iron cations between bulk and surface layer perhaps make the redox cycles of γ-Fe_2O_3 easy. In addition to the easy redox cycles, the high energetic lattice oxygen induced by cation vacancy (low coordination number of iron)[21] may also be responsible for the high reactivity of lattice oxygen in γ-Fe_2O_3.

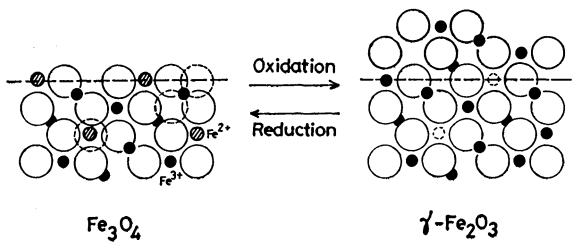

Fig. 7. Redox model of iron oxide for selective oxidation.

As discussed above, the oxidative dehydrogenation of butenes over γ-Fe_2O_3 resembles that over Bi_2O_3–MoO_3. The rapid diffusion of lattice oxygen in Bi_2O_3–MoO_3 originating from its layered structure[22] was however not observed for γ-Fe_2O_3. In the case of γ-Fe_2O_3 rapid diffusion of iron cations makes the redox cycles easy. Although the high reactivity and selectivity of both γ-Fe_2O_3 and Bi_2O_3–MoO_3 is attributed to the easy redox cycles of bulk and the high reactivity of lattice oxygen for allyl-type oxidation, their origin is quite different. Thus, γ-Fe_2O_3 may be regarded as another catalysts prototype for selective allylic oxidation.

A Kinetic Study of the Reaction of 1-Propyl-1,4-dihydronicotinamide with Hexacyanoferrate(III)

Tadashi Okamoto,* Atsuyoshi Ohno, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Gokasho, Uji 611
(Received May 15, 1979)

The reaction of 1-propyl-1,4-dihydronicotinamide with hexacyanoferrate(III) in 20% aqueous methanol follows a second-order rate law with first order with respect to each reactant concentration. Kinetic parameters are $\Delta H^{\neq}$: $(8.8\pm0.4)\times10^3$ J mol^{-1} and $\Delta S^{\neq}$: -1.8×10^2 J mol^{-1} K^{-1}, the observed kinetic isotope effect, k_H/k_D, being 1.51. The mechanism of the reaction is discussed.

The reaction of unsaturated organic compounds by *N*-substituted dihydronicotinamide has been extensively investigated as a model of reduction by coenzymes NADH and NADPH.[1] The formation of an intermediate complex(es) during the course of the reaction has been reported for various systems.[2] The facility of electron-transfer mechanism for such a net hydride-transfer reaction in biological systems was suggested.[3]

However, the mechanism of this apparent hydride-transfer reaction has not yet been clarified: an initial electron-transfer followed by a hydrogen (as a hydrogen atom, or a proton and an electron) on one hand and a hydride-transfer on the other.[1a] Argument was given as to the single- or multi-step character of the reduction.[4]

In the present paper, we would like to report the details of a kinetic study of the electron-transfer reaction of 1-propyl-1,4-dihydronicotinamide (PNAH) with hexacyanoferrate(III),[5] showing the mechanism of a simplified reduction by PNAH together with some parameters of the reaction.

Experimental

Materials. PNAH-4,4-d_2 was prepared by the repeated reduction of 1-propyl-3-carbamoylpyridinium salt with alkaline dithionite in D_2O and re-oxidation of the resulting dihydronicotinamide with ethyl benzoylformate three times. The deuterium content was estimated by the integral ratios of NMR signals (deuterium purity; 94±5%). Solvents for spectroscopic measurement were Dotait spectro-grade reagents and used after distillation under nitrogen. Inorganic reagents (analytically pure reagents, Nakarai Chem. Co.) were used.

Kinetic Measurement. The solution for kinetic measurement was prepared by injecting 10 μl of a 1.00×10^{-2} M-methanol solution of PNAH into a 4.0 ml portion of 20% aqueous methanol containing $2.00—8.00\times10^{-4}$ M of $K_3Fe(CN)_6$ and $0.75—1.00\times10^{-2}$ M of K_2CO_3 in a serum-capped optical cuvett under nitrogen. Solutions of Li_2CO_3 and KCN, or solid $K_4Fe(CN)_6$ were added when necessary. Reaction rates were measured by the spectroscopic method monitoring the absorbance change at 356 nm on a thermostatted Union Giken SM 401 spectrophotometer. The concentration of potassium ion was adjusted by using potassium chloride.

Results

Stoichiometry. The stoichiometry of the reaction was determined by titration of a 4.0 ml portion of the solution of $K_3Fe(CN)_6$ (2.00×10^{-3} M) and K_2CO_3 (1.00×10^{-2} M) with 1.25×10^{-4} M equivalents of PNAH in 20% aqueous methanol (Fig. 1). Two moles

of hexacyanoferrate(III) were consumed by 1 mol of PNAH giving rise to the product solution, the spectrum of which was identical with that of the authentic sample of 1-propyl-3-carbamoylpyridinium salt (PNA^+) and hexacyanoferrate(II).

$$PNAH + 2Fe(CN)_6^{3-} \longrightarrow PNA^+ + 2Fe(CN)_6^{4-} + H^+ \quad (1)$$

Kinetic Study. A good pseudo-first-order kinetics (correlation coefficient: $\gamma>0.999$) was observed throughout the experiments for over 90% of the reaction with an excess of hexacyanoferrate(III). However, the reproducibility of the rates of different batches was not very good, suggesting the presence of some impurity which affects the reaction rate. The results are given in Table 1. The apparent rate constants thus obtained are linearly correlated with the concentration of hexacyanoferrate(III) by a straight line that passes through the origin ($\gamma=0.9994$) indicating the second-order rate law with the rate constant (k) of $(6.68\pm0.08)\times10$ M^{-1} s^{-1} ($[K^+]$ of 1.80×10^{-2} M, $[CO_3^{2-}]$ of 0.750×10^{-2} M, and pH of 10.92). The change of basicity of the solution, and the addition of hexa-

cyanoferrate(II) or some alkali-metal ions[6)] affected the reaction rate. Slight retardation took place by addition of cyanide ion, but not by that of other anions such as chloride and perchlorate. Ionic strength had almost no effect either.[6,7)] Linear relationship holds between the reciprocal of the rate constant and the concentration of hexacyanoferrate(II) (Fig. 2). The dependence of rate on basicity was measured with the use of lithium carbonate, since lithium ion does not affect the reaction rate, in contrast to other alkali-metal ions.[6)] The rate was accelerated by increasing basicity (Fig. 3).

Kinetic Parameters. Kinetic parameters measured in the temperature range 298 K—318 K were ΔH^*: $(8.8\pm0.4)\times10^3$ J mol^{-1} and ΔS^*: -1.8×10^2 J mol^{-1} K^{-1} (γ=0.997) at pH of 10.97 and potassium ion concentration of 2.15×10^{-2} M.

The kinetic deuterium isotope effect observed by using PNAH-4,4-d_2 at 298 K was 1.51 ± 0.03.[8)]

Discussion

Only a hydride ion, a hydrogen atom, and an electron give rise to the reducing equivalent of the reduction by PNAH. However, the mechanism is complicated. The hydride-transfer mechanism is simple; the reduction itself should be a single-step reaction no matter whether there is a step for the complex-formation preceding the reduction. A single-step transfer of hydrogen and a reducing equivalent, however, does not necessarily indicate the hydride-transfer mechanism (*vide infra*). The electron-transfer mechanism, in contrast, has many possibilities. The reducing equivalent could be transferred to a substrate at the initial step or after a certain modification of the reductant in a slow step

or in an equilibrium preceding the slow step. Even when an electron is transferred at the initial slow step, the hydrogen at the C_4-position of PNAH could be transferred as a hydrogen atom or a proton in the succeeding step. These elementary steps might occur simultaneously at different reaction sites.

Since hexacyanoferrate(III) is inert for substitution reaction in the ordinary time scale,[9] the possibility of direct hydride-transfer yielding an iron hydride is eliminated. A certain retarding effect by cyanide ion is observed but it is too small for a mass law effect on a reactive intermediate existing in very low concentration. A mechanism with the initial fast equilibrium generating a hydride ion, which reduces hexacyanoferrate(III) in a slow step, is unlikely in the light of hydride chemistry. Since the rate increases with the basicity of solution, one might expect a process of deprotonation of PNAH preceding the net reduction. This mechanism is discarded by the absence of deuterium exchange between PNAH and D_2O under basic conditions and also by the small deuterium isotope effect. The difficulty of deprotonation from such an electron-rich compound would be easily expected.

The above discussion leads to the initial electron-transfer mechanism as the only reasonable possibility for the present reaction shown in the following.

$$\mathrm{PNAH} + \mathrm{Fe(CN)_6^{3-}} \xrightarrow[\text{slow}]{k} \mathrm{PNAH^{\cdot+}} + \mathrm{Fe(CN)_6^{4-}} \quad (3)$$

$$\mathrm{PNAH^{\cdot+}} \longrightarrow \mathrm{PNA^{\cdot}} + \mathrm{H^+} \quad (4)$$

$$\mathrm{PNA^{\cdot}} + \mathrm{Fe(CN)_6^{3-}} \xrightarrow[\text{fast}]{} \mathrm{PNA^+} + \mathrm{Fe(CN)_6^{4-}} \quad (5)$$

The linear dependence of the reciprocal of the rate constant on the concentration of hexacyanoferrate(II) suggests that Eq. 3 is reversible at high concentrations of hexacyanoferrate(II). However, under the usual reaction conditions with no extra hexacyanoferrate(II), the ratio of the rate of the back reaction of Eq. 3 to that of Eq. 4, calculated from the slope of Fig. 2, is 2×10^{-2} even at the end of the reaction. So the net reaction under the usual reaction conditions proceeds according to the reaction sequences presented above. The good correlation coefficient for the pseudo-first order kinetics observed throughout the experiments supports the conclusion.

The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ lie within the region of outer-sphere electron-transfer reaction,[10] which could be taken as evidence of the mechanism presented. The reaction of radical species with hexacyanoferrate(III), corresponding to Eq. 5, is fast.[11]

The acceleration of the reaction by increasing basicity suggests that the deprotonation step also participates in the rate-determining step. In this context, the work of electrochemical oxidation of dihydronicotinamide presents an important evidence.[12] The oxidation potential of dihydronicotinamide is slightly lowered in the presence of a base, indicating the assistance of a base for the initial electron-transfer step. A possible picture of the transition state of the electron-transfer reaction is shown in Fig. 4. Expectation of the base working

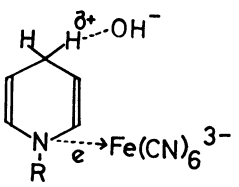

Fig. 4. A possible sketch of the transition state.

only in the step of Eq. 4 which competes with the back reaction of Eq. 3 is not in line with our result quantitatively.

The observed value of the kinetic deuterium isotope effect is too large to be accounted for by the normal secondary isotope effect, and too small to be the rate-determining deprotonation. However, it should be noted that a similar value (1.4) of deuterium isotope effect was reported for the oxidation of tetracyanodiamineferrate(III) into diimine complex,[13] which proceeds through the rate-determining electron-transfer reaction followed by the loss of hydrogen.

The present study has revealed that the reduction by PNAH under weakly basic conditions proceeds through a mechanism with an electron-transfer followed by a proton-transfer and that the transfer of a proton participates in the initial rate-determining electron-transfer step, though slightly. The transfer of the second electron is fast.

An Investigation of the Power Characteristics in Heterogeneous Electrochemical Photovoltaic Cells for Solar-energy Utilization

Tooru INOUE,* Claude WEBER, Akira FUJISHIMA, and Kenichi HONDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113

(Received May 23, 1979)

A heterogeneous electrochemical photovoltaic cell was constructed using the system of cadmium sulfide(CdS)/sulfides reducing agents//oxidizing agents/platinum. The output power characteristics were investigated focusing upon the redox potentials of the oxidizing agents in the cathodic half-cell and then discussed from the point of view of the solution-electrode junction. Though this type of cell intrinsically has a negative free energy for redox reactions of redox agents in an anodic and a cathodic compartment, it has a characteristic point that a larger open-circuit output than the intrinsical electromotive force determined by a redox couple was obtainable in operation under illumination. For example, in the CdS/S^{2-}/S//$Fe^{2+/3+}$/Pt system we found the open-circuit photovoltage of *ca.* 2.0 V, which is *ca.* 83% of a band gap (2.4 eV) of CdS. These measurements showed that a larger open-circuit photovoltage was obtained, though, of course, it was smaller than the band-gap energy of CdS, when the oxidizing agent of the more positive redox potential was dissolved in the cathodic compartment.

The conception of solar-energy conversion to chemical energy and/or electrical energy has been actualized by the use of such electrochemical photocells as photoelectrolytic cells[1-8] and regenerative photovoltaic cells.[9-11] As these photocells have a Schottky-type junction of a semiconductor/solution interface, photoinduced electron-hole pairs are separated by the electric field in the space-charge layer and react with redox agents in an electrolyte solution. For the efficient conversion of solar energy, much information has been presented on the reactions at semiconductor electrodes under illumination.[12] The stabilization of a photoelectrode with a small bandgap is a key problem and is attained by the competitive reaction of redox agents in an electrolyte solution.[12-16] For a regenerative photovoltaic cell after it has been stabilized by a strong reducing agent, its output photovoltage was small with respect to the bandgap value of the semiconductor employed. In order to obtain good output-power characteristics in a regenerative photovoltaic cell, a variety of combinations of semiconductors and solution species have been employed and then discussed, focusing upon the solar-conversion efficiency.[17-19]

Cadmium sulfide (CdS) is a promising material because its bandgap (2.4 eV) is suitable for the conversion of solar light and because its flatband potential (E_{fb}) is sufficiently negative, in particular in a sulfide solution.[14,20-22] However, the output voltage of the regenerative photovoltaic cell constituted by the single compartment of the CdS/redox species/Pt system is limitted to about 600 mV,[18] as determined by the potential difference between the flatband potential of CdS and the reduction potential of the oxidized species. When the low value of the photovoltage is compared with the CdS bandgap of 2.4 eV, one can understand that it limits the electric-output power efficiency.

In order to increase the electric-output power, it may be advantageous to employ a photovoltaic cell constructed by two separated half cells: CdS/sulfide solution//oxidizing solution/Pt. In this case, such a cell can be expected to overcome the photovoltage limitation (*ca.* 600 mV) by means of the positive reduction potentials of the oxidizing agent dissolved in the cathodic compartment, while stabilizing the CdS photoanode by means of the sulfide solution. The evaluation of the power characteristics of such systems is the subject of the present study.

Experimental

The cadmium sulfide electrode was an n-type single crystal (Teikoku Tsushin Kogyo Co., Ltd.) with a resistivity of 0.26 Ω·cm and a carrier density of 8×10^{16} cm^{-3} (as determined by the company). The irradiated face (001) had an area of 0.85 cm^2. This face was polished by alumina powder and etched in concentrated HCl for 10 s. Ohmic contact for a copper wire was made by means of indium and silver paste, and the electrode was isolated on a glass rod by means of epoxy resin. As a cathode, platinum foil (1.7 cm^2) was used. Before the experiment, the platinum electrode was treated with concentrated HNO_3. The solution for stabilizing CdS was 0.5 M Na_2S+0.1 M NaOH (M=mol/cm^3). The aqueous solutions in the cathode compartment were as follows: (1) 0.1 M NaOH+0.5 M Na_2S+0.01 M S; (2) 0.2 M Na_2SO_4; (3) 0.5 M $K_3Fe(CN)_6$; (4) 0.5 M $Fe(NO_3)_3$; (5) 0.5 M KI +0.1 M I_2+0.2 M Na_2SO_4. All the chemicals used were reagent-grade. The light source was a 500-W Xe lamp (Ushio Electric UXL Type). The incident light was filtered by means of a UV-D2 (Toshiba Kasei) glass filter, which lets the wavelengths of 300—400 nm pass through and which has a peak transmittance of 80% for the wavelength of 360—370 nm. The power output characteristics were measured by using a compensated electrometer (Kowa Electronics VM-208) and an ammeter (Nikko Keisoku NZ-1). The anode and cathode compartments were separated with an agar-agar salt bridge containing saturated KCl.

Results and Discussion

Figure 1 shows the current-potential curves at the illuminated CdS electrode and at the platinum electrode obtained under potentiostatic conditions. The anodic photocurrent (Curve 1) appears at a potential more positive than −1.13 V *vs.* NHE at the CdS photoelectrode in the electrolyte solution containing sulfide ions. When the platinum counter electrode is set in an electrolyte solution containing oxidizing agents ($K_3Fe(CN)_6$), the cathodic current appears at the

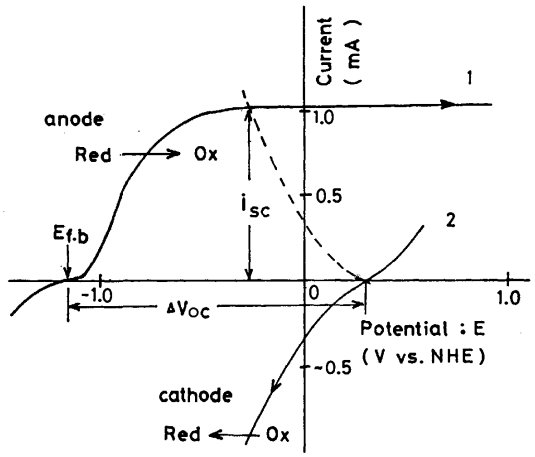

Fig. 1. Current-potential curves at a CdS photoanode and a platinum cathode.
Solid line 1: at CdS in 0.5 M Na_2S+0.1 M NaOH+0.01 M S aqueous solution, solid line 2: at Pt in 0.5 M $K_3Fe(CN)_6$+0.2 M Na_2SO_4 aqueous solution, dashed line: rewriting of a negative part of a solid line 2 with absolute values

potential of *ca.* 0.37 V *vs.* NHE. This cathodic onset potential is more positive than the onset potential of the cathodic current which appears at the Pt electrode in the solution containing sulfides. Considering the limitation of the open-circuit photovoltage determined by the potential difference between anodic and cathodic onset potentials, one can see that the larger electric-output power will be obtained when the cathode is set in the solution with the stronger oxidizing agent.

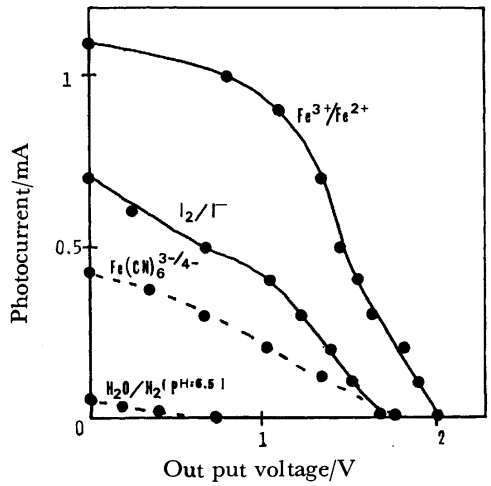

Fig 2. Output power characteristics (current-voltage curves) in heterogeneous photovoltaic cells of CdS/0.5 M+0.1 M NaOH/0.5 M oxidizing agent/Pt systems. Oxidizing agents: 1, H_2O (pH=6.5); 2, $K_3Fe(CN)_6$; 3, I_3^-; 4, $Fe_2(SO_4)_3$.

In Fig. 2 we present some output power characteristics for [a CdS/0.5 M Na_2S+0.01 M S+0.1 M NaOH aqueous solution//solution containing oxidizing agents/Pt] photovoltaic cell. The actual output power was in the order of $Fe^{3+}>I_2(I_3^-)>Fe(CN)_6^{3-}>H_2O$, so the maximum of the open-circuit photovoltage was about 2.0 V, which was *ca.* 83% of the bandgap (2.4 eV) of CdS. This suggests that the output power increases with the more positive shift of the redox potential of an oxidizing agent.

We examined the open-circuit output voltages in the dark and under illumination when various oxidizing agents were introduced in the solution. The results are shown as functions of their redox potentials in Fig. 3.

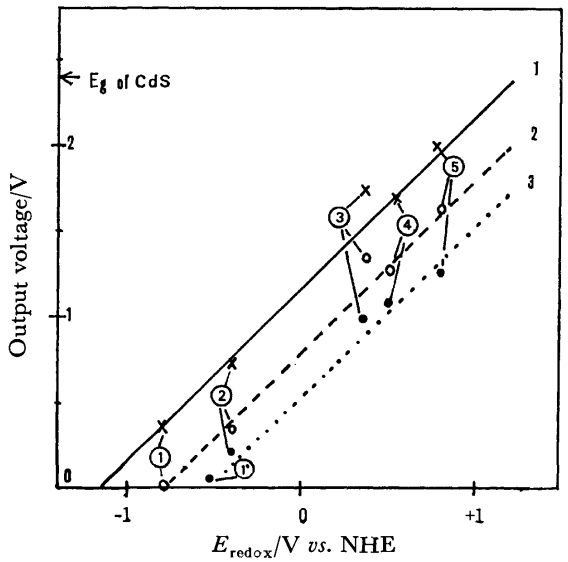

Fig. 3. Open-circuit voltage in heterogeneous photovoltaic cells as a function of the redox potentials of oxidizing agents in cathodic compartments.[25]
1: H_2O/H_2 (pH=13.5), 1′: S^{2-}/S_2^{2-}, 2: H_2O/H_2 (pH=6.5), 3: $Fe(CN)_6^{3-/4-}$, 4: I_2/I^-, 5: $Fe^{3+/2+}$.
×, Solid line 1; output photovoltage between CdS and Pt, ○, dashed line 2; output voltage (dark) between CdS and Pt ●, dotted line 3; output voltage between Pt and Pt.

The dashed line 2 represents the output voltages in dark conditions, its slope is *ca.* 1.0. The intersection of this line with the abscissa is at the potential of −0.8 V *vs.* NHE, which is close to the water reduction potential (hydrogen evolution) at this pH value (13.5). The solid line 1 represents the output voltages obtained under irradiation. The value of its slope is also 1.0, and the intersection of the line with the abscissa is at the potential of −1.16 V *vs.* NHE, corresponding to the flatband potential of the CdS electrode under these conditions. As for the flatband potential (E_{fb}), Minoura *et al.*[20] have reported $E_{fb}\fallingdotseq-1.13$ V *vs.* NHE for a 0.1 M Na_2S+1 M Na_2SO_4 solution, Ginley and Butler[21] have reported $E_{fb}\fallingdotseq-1.05$ V *vs.* NHE for a 0.9 M Na_2S+0.05 M KOH solution, while we ourselves[22] have presented $E_{fb}\fallingdotseq-1.09$ V *vs.* NHE for a 0.1 M Na_2S+0.2 M Na_2SO_4 solution. The dotted line 3 in Fig. 3 represents the relation between the open-circuit output voltage and the redox potentials of the oxidizing agents when we employed the Pt electrode instead of the CdS electrode in the anodic compartment (pH=13.5). The intersection of this line with the abscissa is at the potential ($E_{redox,1}=-0.52$ V *vs.*

NHE) of a S^{2-}/S system.

The open-circuit output voltage (ΔV_{oc}) of the electrochemical photovoltaic cell arises from the difference between the flatband potential of the semiconductor photoanode and the redox potential ($E_{redox,2}$) of an oxidizing agent (O_x) at a cathode:

$$\Delta V_{oc} = |E_{fb} - E_{redox,2}| \quad (1)$$

$$2S^{2-} \longrightarrow S_2^{2-} + 2e^- \text{ (at an anode)} \quad (2)$$

$$O_x + ne^- \longrightarrow \text{Red (at a cathode)} \quad (3)$$

Some investigations have also reported as the output characteristics in the electrochemical photovoltaic cell determined using a CdS electrode, as are shown in Table 1. The upper four electrochemical photovoltaic cells are composed of a single compartment with a redox couple, so they are regenerative. The last two electrochemical photovoltaic cells are similar to ours and are not regenerative. From the data in Fig. 3 and Table 1, we can conclude that the relation (Eq. 1) is applicable to the output voltage in the electrochemical photovoltaic cell.

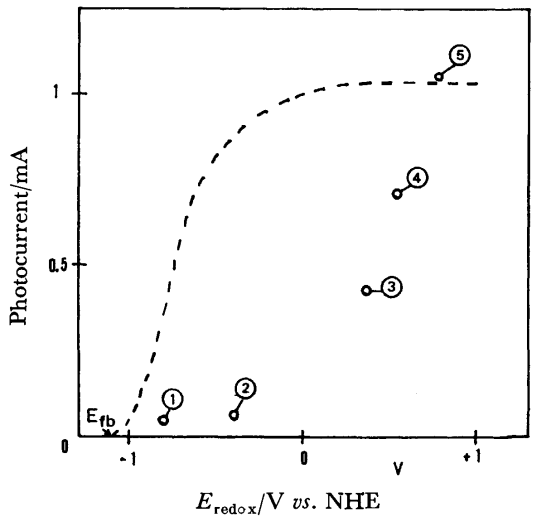

Fig. 4. Short-circuit currents in heterogeneous photovoltaic cells as a function of the redox potentials of oxidizing agents in cathodic compartments.[25] A dashed line shows a current-potential curve of a CdS photoanode. All numbers are the same as those in Fig. 3.

Figure 4 shows the short-circuit output currents as functions of the redox potentials of oxidizing agents dissolved in the cathodic compartment. The dashed curve represented the anodic photocurrent at a CdS electrode obtained under potentiostatic conditions. The currents actually obtained are smaller than the CdS anodic photocurrent observed under the potentiostatic conditions. The difference in photocurrents between the value from this dashed curve and that from the experimental results may come from polarization losses in an operation. Therefore, if the redox couples in the cathodic half-cell are infinitely reversible, and also if all losses in the semiconductor bulk and surface can be neglected, these plots will lie on the ideal dashed curve. The fact that the losses diminish with an increase in the redox potential can be explained the fact that the increase in the cell electromotive force advantageously affects the polarization characteristics of both electrode reactions. It can be assumed that the limited photocurrent determined by the light absorption of CdS can be obtained in this cell when an oxidizing agent with a redox potential more positive than a $Fe^{2+/3+}$ couple is dissolved in the cathodic compartment.

Figure 5 shows the output power in the electrochemical photovoltaic cells as functions of the redox potentials of the oxidizing agents. The dashed line represents the maximum output power (P_{max}) obtainable for a particular redox system, it is calculated by the following procedure:

$$P_{max} = i[E_F](E_{redox} - E_F) \quad (4)$$

where E_F denotes the semiconductor Fermi level, *i.e.*, the electrode potential in an operation; E_{redox}, the redox potential of an oxidizing agent in a cathodic compartment; and $i[E_F]$, the output current determined from the photocurrent at the potential of E_F. Figure 6 explains the calculation procedure of P_{max} schematically, where the magnitude of the current is determined by means of the polarization of CdS. The output power observed is plotted in Fig. 5 and is reflected in the

characteristics shown in Fig. 4. The calculated power, P_{max}, increases with the variation in the redox potential and will be saturated at the potentials near the valence-band potential (*ca.* 1.4 V *vs.* NHE) of CdS.

In conclusion, we have shown the power characteristics in the heterogeneous electrochemical photovoltaic cell. This type of photovoltaic cell has two kinds of redox systems. Sulfides as a reducing agent shift the flatband potential of CdS and are oxidized at the CdS photoanode. Oxidizing agents are reduced at the Pt electrode. The characteristic point is that a large open-circuit voltage is obtainable with respect to the bandgap (2.4 V) of CdS. For the elucidation of the

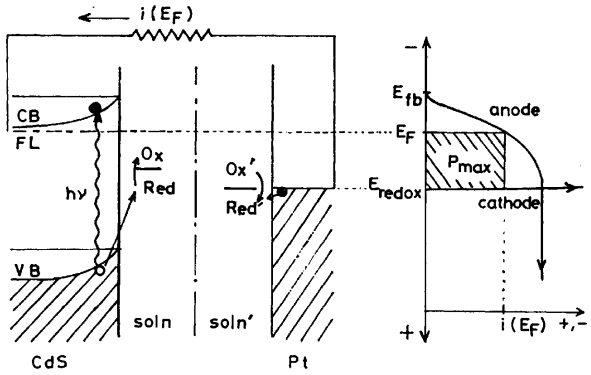

Fig. 6. Schematic explanation for calculation of P_{max} according to Eq. 4.

heterogeneous photovoltaic cell, we show in Fig. 7 a schematic illustration of the potential variations in the solution-electrode junctions in comparison with other types of electrochemical photocells. We can classify the electrochemical photocells into three types from the point of view of the difference (ΔE) in redox potentials at an anode and a cathode:

$$\Delta E = E_{redox,1} - E_{redox,2} \quad (5)$$

First, when the value of ΔE is positive, the electrochemical photocell works as a photoelectrolytic cell which can convert the light energy to chemical and/or electrical energy and also store the chemical energy. Second, when the value of ΔE is zero, it works as a regenerative photovoltaic cell which can convert the light energy only to electrical energy. Third, when the value of ΔE is negative, it works as a heterogeneous photovoltaic cell which can convert both the light and the chemical energy to electrical energy and which can generally give the largest output photovoltage of these three electrochemical photocells.

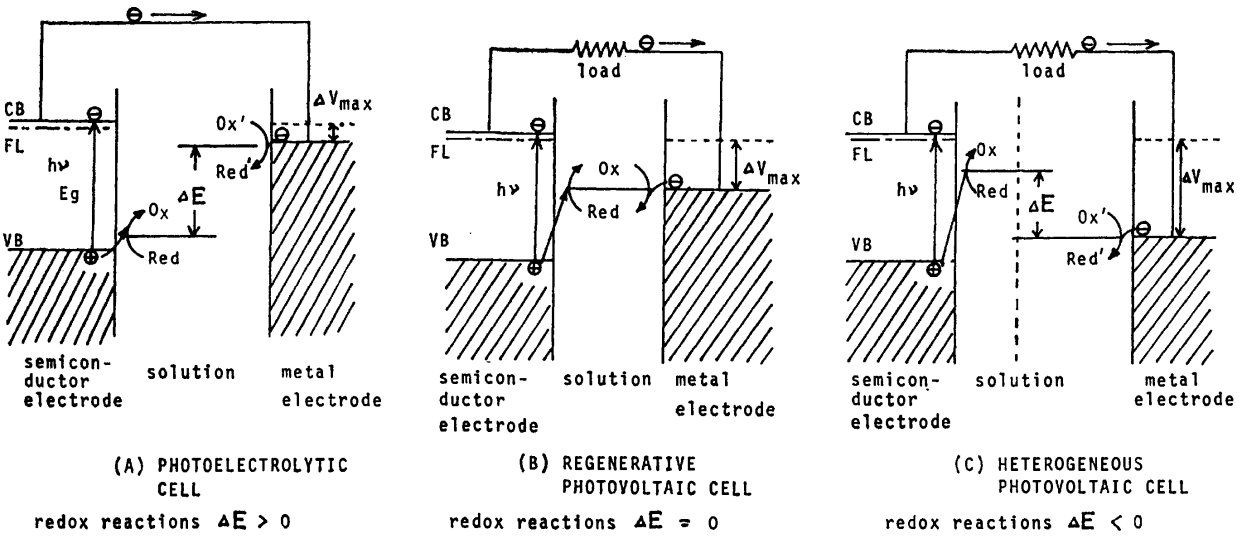

Fig. 7. Schematic illustrations of the semiconductor electrode-solution junctions for three typesof electrochemical photocells.
(A) Photoelectrolytic cell (Refs. 4, 6, 7, 8), free energy of a redox reaction is positive.
(B) Regenerative photovoltaic cell (Refs. 7—11), free energy of a redox reaction is zero.
(C) Heterogeneous photovoltaic cell (this study), free energy of a redox reaction is negative.

Formation of Chiral Aggregates of Acylamino Acids in Solutions

Kazutami SAKAMOTO* and Masahiro HATANO**

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki, Kanagawa 210

***The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira 2-2-1, Sendai, Miyagi 980*

(Received May 29, 1979)

An alcoholic solution of optically active acylamino acid (AAA) was found to show a circular dichroism (CD) band at 212 nm. The CD band should be inherent to the solution system, since AAA and alcohol *per se* have no absorption band at this wavelength. The CD band intensity decreased on addition of urea and rise in temperature. This is attributed to the formation of chiral aggregate through hydrogen bonds among AAA molecules. Hydrophobic interaction seems to be of minor importance for the formation of the chiral aggregate in alcoholic solution, since the variation of the chain length in the acyl group or addition of myristic acid did not affect the magnitude of profile of the CD band. In aqueous solutions, salts of optically active AAA formed micelles with hydrophobic interactions among the molecules, and only in the case of optically active monosodium salt of *N*-acylglutamic acid (AGS) showed a CD band at 220 nm resulting from the formation of chiral hydrogen bonds at concentrations above the critical micelle concentration (CMC). This type of chiral aggregation may be caused by the existence of free carboxyl group in the optically active AGS molecule.

New lyotropic cholesteric liquid crystals consisting of *N*-acyl-L-glutamic acid (L-AGA) and aromatic solvents were found recently,[1] and a discussion was given on the origin of the circular dichroism (CD) and the iridescent color observed in these liquid crystals.[2] It was deduced that optically active acylamino acids (AAA's) can form lyotropic cholesteric liquid crystals when they are suspended in the solvents in which the acids do not dissolve but undergo swelling. During the course of swelling in some solvents, the optically active AAA molecules are oriented to form a helix.

On the other hand, when L-AGA was completely dissolved in methanol, no iridescent color or CD band around 300—400 nm was observed. However, a new CD band around 200—250 nm was observed for the isotropic solution. Since L-LGA and methanol *per se* have no absorption in this wavelength region, the new CD band should be inherent to the solution systems. The CD band indicates the formation of a chiral aggregate of L-AGA molecules in alcoholic solution, which might result from the asymmetrical interaction between molecules and have a correlation with the formation of cholesteric liquid crystals of L-AGA.

AGA is somewhat similar to protein, having an acyl group neighboring an asymmetric carbon of amino acid and being sufficiently amphiphilic to interact with both hydrophobic and hydrophilic surroundings. Thus an investigation of the chiral aggregate of AGA would be of interest as regards the structure and function of protein.

The function of protein depends on its stereochemical structure, the local structure of proteins, such as α-helix or β-sheet, being determined essentially by their sensitivity toward molecular environments. Some local structures exhibit optical activity similar to that of AAA aggregates by the formation of chiral hydrogen bonding between amino acid residues.

Tachibana and Oda showed that the chirality of the amino acid residue in the polyglutamate determines the asymmetric structure of higher ordered aggregates such as fibrous aggregates[3] and cholesteric films.[4] Saeva and Olin reported that the helical sense of the cholesteric liquid crystals consisting of polyglutamate also depends on the chirality of glutamic acid residue.[5] The higher ordered structures of polyglutamate also result from the hydrogen bond formation among chiral amino acid residues. AGA forms higher ordered chiral structures such as cholesteric liquid crystals[1,2] and chiral aggregates, similar to polyglutamates. They might result from the hydrogen bond formation among molecules since AGA has the same glutamic acid residue which can form hydrogen bond as in polyglutamates. Parthasarthy *et al.* reported the formation of a hydrogen bond among AAA molecules in crystals by means of X-ray diffraction but gave no discussion in view of chirality.[6–8]

We have analysed the CD spectrum of the aggregates of optically active acylamino acids (AAA's) and their salts in isotropic reaction in terms of chiral hydrogen bonding. The results are given in this paper.

Experimental

The AAA's we used are the same as those reported by Takehara *et al.*[9] Their sodium salts can be prepared through neutralization of the corresponding AAA's by the addition of an equivalent quantity of sodium hydroxide.[10] The CD spectra of samples were recorded on a JASCO J-20A spectropolarimeter. Spectral measurements were carried out at constant temperature, the temperature being adjusted by circulation of thermostated water. Solvents used were of spectral grade and used without further purification.

Results and Discussion

Formation of Chiral Aggregate in Alcoholic Solutions. Optically active *N*-lauroylglutamic acid (L- or D-LGA) dissolved in methanol shows a CD band at 212 nm (Fig. 1). The CD band should be inherent to the mixture, since LGA and methanol have no absorption at around 212 nm. L-Enantiomer (L-LGA) and D-enantiomer (D-LGA) have opposite signs and their CD bands should thus be due to the different chiral configuration of LGA. CD bands were also obtained for L-LGA in other solvents such as 1-propanol or 1-octanol, in which L-LGA was apparently completely dissolved (Table 1). Similar CD bands around 212 nm were

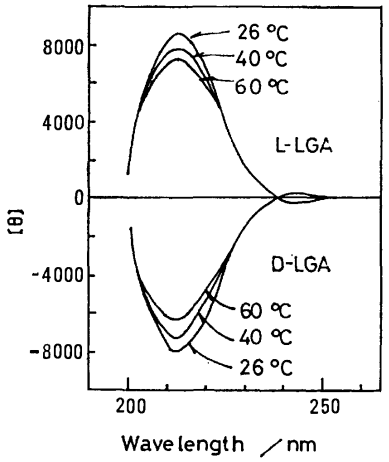

Fig. 1. The CD spectra of optically active *N*-lauroyl-glutamic acid (LGA) in methanol; concentration is 1.0×10^{-2} M.

TABLE 1. EFFECT OF SOLVENTS OR ADDITIVES ON $[\theta]_{212}$ OF L-LGA, 6.1×10^{-3} M, AT 26° C

Solvent	Additive		$[\theta]_{212}$
Methanol	—		8.9×103
	Urea	6.0×10^{-1} M	6.9
	Myristic acid	8.8×10^{-3} M	9.2
1-Propanol	—		9.3
1-Octanol	—		8.8

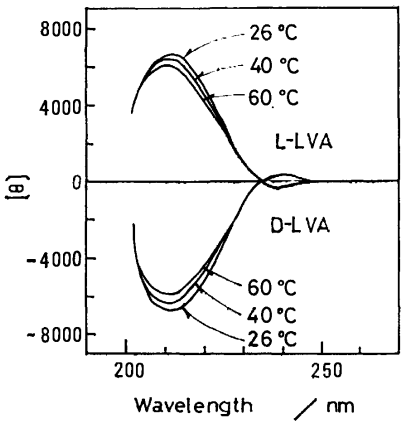

Fig. 2. The CD spectra of optically active *N*-lauroyl-valine (LVA) in methanol; concentration is 1.0×10^{-2} M.

observed in the alcoholic solutions of optically active *N*-lauroylvaline (L- or D-LVA) (Fig. 2). They differ entirely from those of the lyotropic cholesteric liquid crystals consisting of optically active AAA's and solvents,[2] since the wavelengths of the CD band maxima and the spectral profiles differ a great deal in the two cases.[11] The alcoholic solutions showed no birefringence toward the polarized light. The CD bands at 212 nm disappeared at a concentration below 1×10^{-4}, indicating a chiral structure through aggregation. We therefore examined in detail the concentration effect on the CD bands of LGA in alcohols.

Effect of Concentration. The magnitude of the CD band at 212 nm was found to be independent of the concentration of L-LGA or L-LVA in methanol at concentrations higher than 1×10^{-4} M (Fig. 3). This indicates that the number of molecules per aggregate is independent of the concentration of AAA. A concentrated solution of L-LGA (>*ca.* 1×10^{-1} M) in methanol showed birefringence together with a CD band at 212 nm due to the formation of liquid crystaline phase.[12]

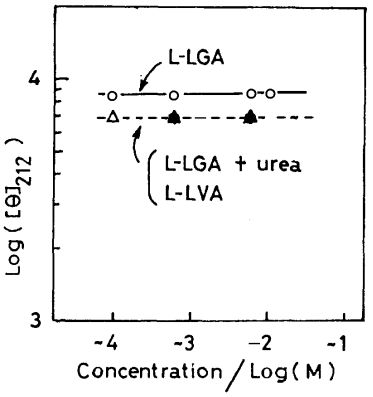

Fig. 3. Relation between concentration of *N*-acyl-L-amino acid and the magnitude of CD in methanol solution at 26 °C.
○: L-LGA, ●: L-LGA+0.6 M urea, △: L-LVA.

Since alcohols have higher affinity to both hydrophobic and hydrophilic parts in the solute molecule, most amphiphilic substances can not form any micelle in alcohols. AAA's have amphiphilic structure in themselves, and the aggregates of AAA's in alcohols do not seem to be micelle.

TABLE 2. $[\theta]_{212}$ IN METHANOL SOLUTION OF *N*-ACYL-L-AMINO ACIDS (L-AAA), 1×10^{-2} M, AT 26 °C

L-AAA	Amino acid residue	Carbon number in the acyl group	$[\theta]_{212}$
L-LGA	Glutamic acid	12	8.5×10^{3}
L-MGA		14	8.5
L-PGA		16	8.0
L-P_3VA	Valine	3	6.7
L-LVA		12	6.7
L-MVA		14	7.9
L-PVA		16	5.9

Hydrophobic Interactions among the Acyl Long Chains. Since AAA has amphiphilic structure, we examined the effect of hydrophobic counterpart in an AAA molecule on the CD spectral profile. In both cases of L-AGA and *N*-acyl-L-valine (L-AVA) the magnitude of CD band at 212 nm ($[\theta]_{212}$) was almost independent of the chain length of acyl groups in each series (Table 2). In the case of L-AVA, chiral aggregation occurred even for *N*-propionyl-L-valine which seems to have a too short acyl chain to form micelle by the hydrophobic interaction between its acyl side chains. Addition of myristic acid to the methanol solution of L-LGA, by which

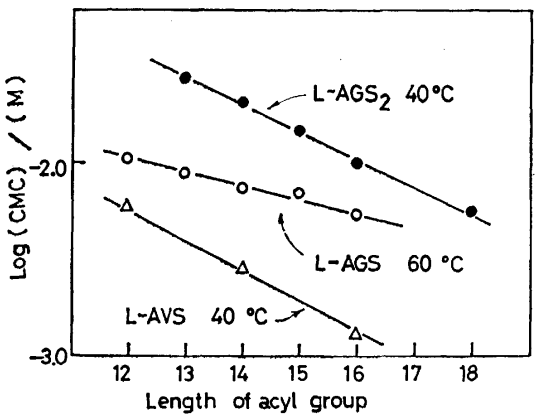

Fig. 4. Relation between log CMC and number of carbon atoms in acyl-group.

perturbation of the hydrophobic interaction between the acyl groups was expected to take place, showed no effect on the value of $[\theta]_{212}$ (Table 1).

The results suggest that hydrophobic interaction is less important for the formation of chiral aggregates. On the other hand, values of critical micelle concentration (CMC) in aqueous solutions of AAA were dependent on the lengths of acyl groups (Fig. 4)[10,13] and hydrophobic interaction was essential for the micelle formation. The structure of the chiral aggregates in alcoholic solutions should be quite different from the micelle structure in aqueous solutions.

Aggregation by Hydrogen Bonding. On addition of urea, which tends to break hydrogen bonds in the proteins,[14] the values of $[\theta]_{212}$ for the alcoholic solutions of AAA decreased (Table 1 and Fig. 3). L-LGA and L-LVA showed no CD band at 212 nm in trifluoroacetic acid, a hydrogen bond breaker stronger than urea. The formation of chiral aggregates of optically active AAA in alcohols may be caused by the hydrogen bond formation between AAA molecules themselves. The decrease in the value of $[\theta]_{212}$ at higher temperatures may be caused by hydrogen bonds rupture in the aggregates (Figs. 1 and 2).

Proteins form second order structure with the hydrogen bond between NH-group and CO-group in the molecule[15] and its helical sense is partially determined by the asymmetric carbon in the amino acid residue. The α-helical conformation, including the hydrogen bonds, results in the appearance of CD bands at 191, 209, and 222 nm.[16] From these properties of proteins, it was assumed that the CD band at 212 nm in alcoholic solutions of optically active AAA indicates the formation of the intermolecular chiral hydrogen bond.

Two possible hydrogen donors in AAA, NH in amide group and OH in carboxyl group, can be considered. The latter may have no contribution to the hydrogen bond formation, since a similar CD band at 212 nm was observed in the methanol solution of

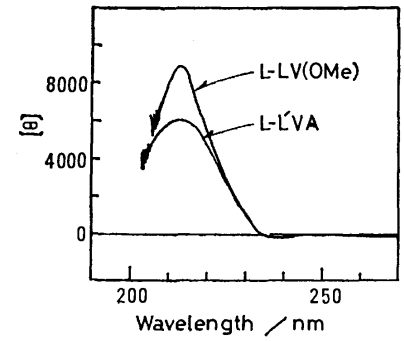

Fig. 5. CD spectra of *N*-lauryl-L-valine (L-L'VA) and methyl ester of *N*-lauroyl-L-valine(L-LV(OMe)) in methanol; at 40 °C and 1.0×10^{-2} M.

methyl ester of L-LVA (Fig. 5). We can also expect two types of hydrogen acceptor in AAA, amide carbonyl and carbonyl of carboxylic group. CO in the amide group may have no participation for the hydrogen bond formation, since the CD band at 212 nm could not be detected for the methanol solution of *N*-lauryl-L-valine(L-L'VA), an *N*-alkylated amino acid without amide group (Fig. 5). An intermolecular chiral hydrogen bond may occur between NH in amide group and CO in carboxyl group of AAA. Mutual orientation between the NH and CO groups is determined by the configuration of the asymmetric carbon being adjacent to both. In the case of racemic mixture of AAA in methanol, no CD band could be detected. Thus, the aggregation of optically active AAA in alcoholic solution occurrs through the chiral hydrogen bonds among AAA molecules.

CD of Optically Active AAA in Aqueous Solution. The sodium salts of optically active AAA's form micelles in aqueous solutions at concentrations above their CMC (Table 3).[10] If the chiral aggregation occurrs together with micelle formation, the existence of a CD band and its concentration dependence are expected for the aqueous solutions of the sodium salts of optically active AAA's. Only monosodium salt of *N*-acylglutamic acid (L- or D-AGA) shows a CD band at 220 nm (Fig. 6). The concentration dependency of this CD magnitude was found to be correlated with its CMC (Fig. 7 and Table 3). For example, the magnitude of CD band at 220 nm, $[\theta]_{220}$, observed for the aqueous solution of monosodium salt of *N*-lauroyl-L-glutamic acid (L-LGS)

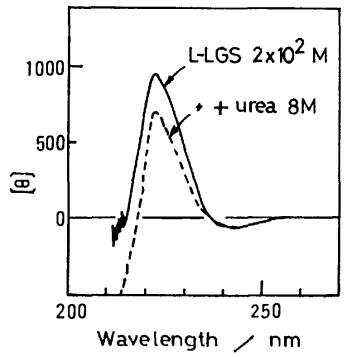

Fig. 6. The CD spectra of monosodium *N*-lauroyl-L-glutamate (L-LGS) in water at 40 °C.
Solid line: L-LGS, 2×10^{-2} M.
Broken line: L-LGS, 2×10^{-2} M and urea, 8 M.

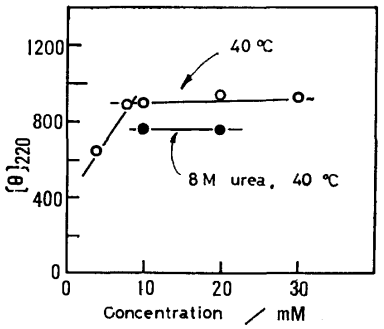

Fig. 7. Relation between $[\theta]_{220}$ and concentration of monosodium *N*-lauroyl-L-glutamate(L-LGS) in water, at 40 °C.

increased with increase in the concentration of L-LGS upto about 1×10^{-2} M which corresponds to its CMC. At concentrations above 1×10^{-2} M, $[\theta]_{220}$ was approximately constant (Fig. 7). Addition of urea to the aqueous solution of L-LGS decreased the CD magnitude in a similar way to that in the case of alcoholic solution (Figs. 4, 6, and 7). Thus, the CD band at 220 nm observed for optically active AGS in aqueous solutions suggests the occurrence of micelle formation together with the formation of chiral hydrogen bond.

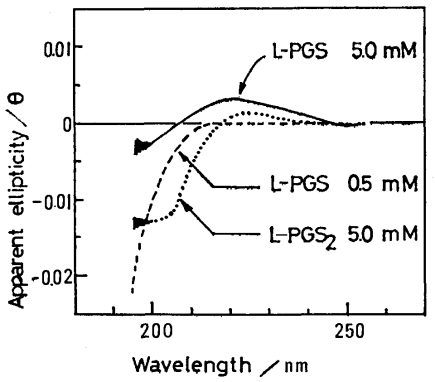

Fig. 8. The CD spectra of sodium and disodium *N*-palmitoyl-L-glutamate (L-PGS and L-PGS_2).
Solid line: L-PGS, 5.0 mM (above CMC), at 60 °C.
Broken line: L-PGS, 0.5 mM (below CMC), at 60 °C.
Dotted line: L-PGS_2, 5.0 mM (below CMC), at 40 °C.

At concentrations lower than CMC, L-AGS shows another CD band at *ca.* 200 nm with the opposite sign to that of the CD band at *ca.* 220 nm (Fig. 8). On the other hand, the aqueous solutions of optically active disodium *N*-acylglutamates (L- or D-AGS_2) and optically active sodium *N*-acylvalinates (L- or D-AVS) show a CD band only at *ca.* 200 nm irrespective of their concentration. From the results, the CD band at 200 nm is attributable to the asymmetric structure of the optically active AGS, AGS_2, and AVS themselves. Since CMC's of these surfactants are dependent on the length of acyl groups (Fig. 4 and Table 3), the micelle formation might be caused by the hydrophobic interaction among acyl chains. On the surface of micelles, amino acid residues of these surfactants can not be brought close enough to form hydrogen bonds because of the repulsive interaction among the carboxylate anions. In the case of L-AGS the decrease in CMC with increase of the acyl chain length is a little smaller than in the case of L-AGS_2 and L-AVS (Fig. 4). This suggests that the hydrophobic interaction is less in L-AGS than in L-AGS_2 and L-AVS. The mutual repulsion between amino acid residues on the surface of L-AGS micelles might be relaxed by the existence of a free carboxyl group. The free carboxyl group in L-AGS is assumed to form chiral hydrogen bond, which may be correlated to the CD band at 220 nm.

The structure of the aggregates of optically active AAA's or their salts are determined by solvent. In alcoholic solutions, AAA's form a different aggregate from micelle through the chiral hydrogen bonding among AAA molecules. However, in aqueous solutions, salts of optically active AAA's form micelles by the hydrophobic interaction among their side chains; the hydrophobic interaction induces hydrogen bond formation in the parts of the hydrophilic moiety of L-AGS.

Conclusion

A CD band at 212 nm was found in alcoholic solutions of optically active AAA's. Hydrophobic interaction among the long chains of acyl groups of AAA molecules is of minor importance to the formation of their aggregates, since the spectral profile and magnitude of the CD bands are independent of the lengths of the acyl groups in the AAA molecules and of their concentrations. Hydrogen bonds might break under certain conditions. The addition of urea and rise in temperature decrease the magnitude of the CD bands, and thus the aggregate may result from the chiral hydrogen bond formation among AAA molecules.

On the other hand, in aqueous solutions, salts of optically active AAA's form micelles with hydrophobic interaction among the molecuels, and show a CD band at 220 nm at concentrations above its CMC only in the case of optically active AGS. The CD band at 220 nm corresponds to the formation of chiral hydrogen bond caused by the existence of a free carboxyl group.

AAA's have a certain similarity to proteins, having acyl group juxtaposition to the asymmetric carbon and becoming amphiphilic to interact both with hydrophobic and hydrophilic surroundings. Proteins em-

bedded in biological membranes reveal two different features. Inside membranes where hydrophobic environment is predominant, the embedded proteins behave like a polar solute in lipid, being forced to form intramolecular hydrogen bonding inside the proteins. In contrast, at the surface of membranes where hydrophilic environment is predominant, the buried proteins are hydrated and seem to be suppressed to form a chiral hydrogen bond. The chiral aggregation or micelle formation of AAA's, which reflects the interaction of AAA's with environmental solvents, may help us to understand the behavior of proteins embedded in membranes.

Adsorption of Alkaline Earth Cations on Mercury as Studied with the Perbromate Kinetic Probe

Tetsuya OSAKA*,** and Robert DE LEVIE
Department of Chemistry, Georgetown University, Washington, D. C., 20057, U. S. A.
(Received June 8, 1979)

Reduction of perbromate was used as a kinetic probe of double layer parameters for weak specific adsorption of double layer parameters for weak specific adsorption of alkaline earth cations at the mercury/electrolyte solutions interface. The results are interpreted as evidence for weak specific adsorption of Sr^{2+} and particularly Ba^{2+} in 10 mM solutions at negative electrode charge densities. The limitation of the use of an anionic probe for the quantitation of cation specific adsorption is discussed.

The weak specific adsorption of alkali metal cations at the interface between mercury and aqueous electrolyte solutions has given rise to controversy because of the seemingly conflicting results obtained from various experimental methods.[1-10] Damaskin[11] showed that such results are, in fact, quite to be expected for subequivalent specific adsorption of ions, for which the usual thermodynamic method is not sufficiently sensitive. A similar situation applies to alkaline earth cations, for which Frumkin and Nikolaeva-Fedorovich[12] reported a slight increase in the rate of peroxydisulfate reduction in going from Ca^{2+} to Ba^{2+}, whereas Parsons *et al.*[13,14] observed approximate agreement between experimental data and double layer calculations assuming the absence of specific adsorption for both Mg^{2+} and Ba^{2+}. In the present communication, we report results similar to those of Frumkin and Nikolaeva-Fedorovich, using perbromate as a kinetic double layer probe.

Experimental

The dc, ac, and pulse polarograms were obtained on an instrument described earlier[15-17] which features phase-resolved ac polarograms, IR compensation and a simple integral pulse circuit based on the 60 Hz line frequency. Chemicals of reagent grade were used without further purification. The rate constants $k_c^\ominus$'s were calculated from dc polarograms using the Koutecký formalism[18-21] and from integral pulse polarograms using an equivalent method based on the relations of Brinkman and Los.[22] Polarographic maxima of the first kind in the dc polarograms were avoided by using low perbromate concentrations ($\leqslant$0.1 mM), and maxima of the second kind by using low mercury flow rates ($\approx$0.15 mg s^{-1}); maxima on the integral pulse polarograms such as reported by Fonds *et al.*[23] were initially observed, but were eliminated by proper IR compensation. Charge densities were obtained by integration of capacitance data from IR-compensated quadrature ac polarograms at 159 Hz ($\omega = 10^3$ rad s^{-1}). The potentials of zero charge required as integration constants were taken at the diffuse layer minima in the capacitance curves. Comparison with electrocapillary measurements in 10 mM LiCl and 10 mM $MgSO_4$ showed agreement within 1 and 2 μC cm^{-2}, respectively. All potentials are referred to a saturated calomel electrode (SCE), measurements being made at 25.0 °C.

Results and Discussion

The dc polarograms of perbromate in 10 mM alkali halide solutions exhibit pronounced minima, but the corresponding minima in 10 mM solutions of alkaline earth halides or sulfates are too shallow to allow accurate numerical evaluation. Thus, integral pulse polarograms were used instead to provide sufficiently accurate rate parameters. Figure 1 shows the dependence of the ratio i/i_l on the reaction rate constant $k_c^\ominus$ for the dc and integral pulse polarograms. Heterogeneous rate constants up to *ca.* 0.05 cm s^{-1} could be obtained with reasonable accuracy from pulse-polarographic i/i_l ratios. Where the pulse-polarographic limiting current was not directly observable, and its value was calculated from the dc limiting current and the known ratio of dc and pulse-polarographic limiting currents in our instrument as determined with Cd^{2+} and Zn^{2+} ions. The results for 10 mM alkaline earth chlorides and for 10 mM $MgSO_4$ are shown in Fig. 2, and compared with rate constants calculated for a 2,2-electrolyte such as $MgSO_4$ on the basis of measured rate constants for 10 mM LiCl assuming the absence of specific adsorption

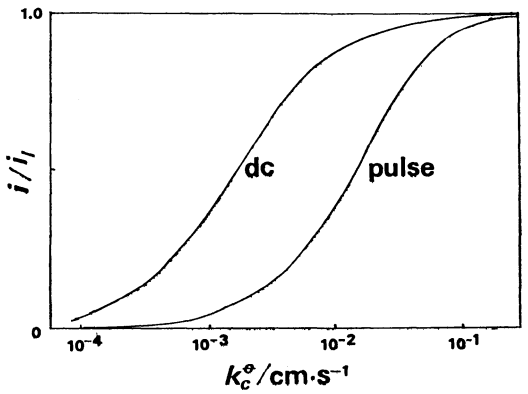

Fig. 1. The ratio of current i to limiting current i_l as a function of rate constant $k_c^\ominus$ for an irreversible reduction or oxidation in dc and integral pulse polarography respectively. The curves were calculated with the following specific parameter: $D = 2.5 \times 10^{-5}$ cm^2 s^{-1}, sampling time (for dc and pulse) 4.2 s after drop birth, sampling interval from 16.7 to 33.3 ms after application of the pulse.

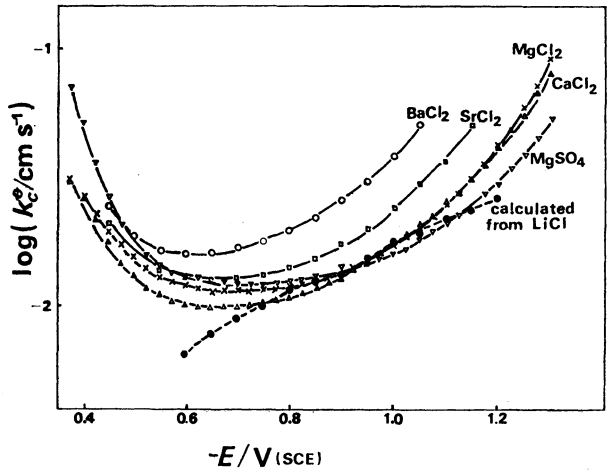

Fig. 2. Rate constants calculated from the integral pulse polarograms of 0.06 mM $KBrO_4$ in 10 mM aqueous alkaline earth electrolytes.

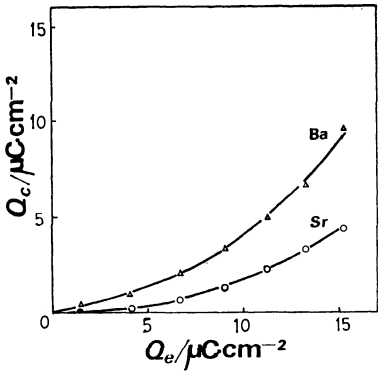

Fig. 3. Specifically adsorbed charge density Q_c as a function of electronic charge density Q_e, calculated from the data of Fig. 2 for 10 mM $SrCl_2$ and $BaCl_2$ on the assumptions that the Gouy-Chapman-Stern theory and simple Frumkin correction apply and that Mg^{2+} is not at all specifically adsorbed from 10 mM aqueous $MgCl_2$.

of both Li^+ and Mg^{2+}.† At potentials more negative than −0.8 V *vs.* SCE, the data for $MgSO_4$ coincide with those calculated from LiCl within experimental error. Comparison of the results for $MgSO_4$ and $MgCl_2$ indicates that the nature of the anion is not very important at sufficiently negative potentials, where the double layer predominantly contains cations. Coincidence of the curves for $MgCl_2$ and $CaCl_2$ suggests that Ca^{2+} is not specifically adsorbed to any appreciable extent from 10 mM aqueous halide solutions either. However, Sr^{2+} and particularly Ba^{2+} appear to be specifically adsorbed. Estimation of such specific adsorption can be made on the assumption that $MgCl_2$ is not specifically adsorbed at all. The results are shown in Fig. 3. Calculation of the specifically adsorbed charge densities Q_c of Sr^{2+} and Ba^{2+} from the difference of their measured rate constants was made by assuming complete absence of specific adsorption of Mg^{2+} as follows.

$$\Delta\phi_0 = \frac{RT}{(1+2\alpha)F} \ln \Delta k_c^\circ \quad (1)$$

$$Q_d = \left\{A\sum_i c_i \left\{\exp\left(-\frac{Z_i F}{RT}\phi_0\right) - 1\right\}\right\}^{1/2} \quad (2)$$

$$Q_c = -(Q_d + Q_e) \quad (3)$$

where Q_d and Q_e are the diffusion double layer and electronic charge densities, respectively. Since the charge transfer coefficient α is potential-dependent, each value was determined graphically with the use of k_{corr} *vs.* $(E-\phi_0)$ curve of perbromate reduction.†† In both cases of Sr^{2+} and Ba^{2+}, the estimates indicate weak specific adsorption, considerably less than in amount equivalent to the electronic charge density Q_e.

In an earlier work with perbromate,[9] quite good agreement with data reported was obtained for specifically adsorbed anions. However, the estimates for alkali ion adsorption were a factor of two higher than those obtained with the mixed-electrolyte approach.[6-8] Damaskin[11,24] reported a similar discrepancy with MnO_4^-, $S_4O_6^{2-}$, $S_2O_8^{2-}$, PtF_6^{2-}, and $Fe(CN)_6^{3-}$ in studying alkali ion adsorption, but good agreement when H^+ was used. It appears that the probe ion is attracted electostatically by the specifically adsorbed ion, and preferentially reduced close to the latter if the two have charge of opposite sign. The probe ion would undergo stronger specific adsorption than accounted for by the Frumkin correction. Because of this dynamic discreteness-of-charge effect, the data in the present communication should be qualitative.

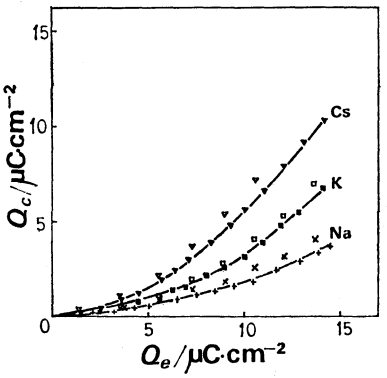

Fig. 4. Specifically adsorbed charge density Q_c as a function of electronic charge density Q_e, calculated from dc and integral pulse polarograms in 10 mM and 0.1 M aqueous alkali halide solutions respectively, based on Gouy-Chapman-Stern theory, Frumkin correction and the absence of specific adsorption of Li^+. Symbols used: +, ■ and ▼: 10 mM NaF, KCl, and CsCl respectively; ×, □ and ▽: 0.1 M NaCl, KCl, and CsCl respectively.

† The rate constants calculated for a 2,2-electrolyte such as $MgSO_4$ were derived from the rate constant with the Frumkin correction $k_{corr}(\log k_{calcd} = \log k_{corr} + (F/2.3RT)\phi_0$, *cf.* Ref. 9) in 10 mM LiCl, and the double layer potential ϕ_0 (mean potential of OHP) was calculated by means of Gouy-Chapman-Stern theory using the electronic charge density in 10 mM LiF and 10 mM $MgSO_4$ obtained by integrating capacitance.

†† A more detailed discussion is given in Ref. 9. The value of α is sufficiently small to justify this procedure.

The same applies to the slight extension of the work of de Levie and Nemes on alkali cations (Fig. 4), where the earlier dc-polarographic results for 10 mM solutions are combined with new pulse-polarographic data for 0.1 M. The amount of specific adsorption is approximately independent of the ten-fold increase in concentration, in agreement with the observations of Damaskin and Ivanova[8] and with the buffering effect of the double layer on weak specific adsorption of cations.[11,25] The results appear to be qualitatively correct, although the specific values obtained are likely to be too high in view of the dynamic discreteness-of-charge effect. Other possible sources of systematic error, of cource, result from all other assumptions in the Gouy-Chapman-Stern theory and the Frumkin correction, specifically the assumption that the average potential at the reaction plane coincides with that of the outer Helmholtz plane.

The authors thank Mr. James F. Garvey for construction of the pulse-polarographic attachment, Drs. Srinivasan Sarangapani and Paul F. Seelig for their help in the calculations, and Dr. E. H. Appelman, Argonne National Laboratories, for the supply of $KBrO_4$. The work was carried out with Grants 76-3027 and GM 2296-03 from AFOSR and NIH, respectively.

The Micelle-promoted Selective Hydrolysis of Anionic and Nonionic Ester Substrates by Hydroxamic Acids and Histidine Derivatives

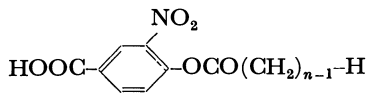
Ryuichi UEOKA,* Hidehiko MATSUURA, Syuji NAKAHATA, and Katsutoshi OHKUBO**

Department of Industrial Chemistry, Kumamoto Institute of Technology, Kumamoto 860
***Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860*

(Received June 11, 1979)

The hydrolyses of anionic 3-nitro-4-acyloxybenzoic acid (S_2^-–S_{16}^-) and nonionic *p*-nitrophenyl carboxylate (S_2—S_{16}) substrates catalyzed by hydroxamic acids (C_6—C_{12}) and histidine derivatives (AcetHis and LauHis) were performed with and without alkyltrimethylammonium (DTAC, CTAB, and OTAC) surfactants at pH 7.45. The present reaction was characterized by the selectively efficient hydrolysis of the same substrate of S_6^- or S_{10} by the comicellar C_m (m=8, 10, or 12)–CTAB (or OTAC) or LauHis–CTAB (or OTAC) catalysts. Relevant factors to such a selective hydrolysis of a specific substrate by the comicellar catalysts were discussed by taking notice of the electrostatic-charge-attraction force, steric hindrance, and hydrophobic interaction. The investigation of the binding constants in the present micellar reaction system demonstrated the importance of an appropriate hydrophobic interaction between a substrate and micelles for the selective rate enhacement of ester-hydrolysis.

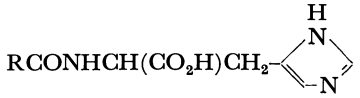
The contribution of hydrophobic (apolar) forces and micellar effects to the rate enhancement of enzyme-model reactions has recently received considerable attention, especially in connection with the hydrolysis of ester substrates by synthetic catalysts involving the hydroxamate group (a model of the Ser-195 part in chymotrypsin),[1–11] imidazolyl group (a model of the His-57 part in chymotrypsin),[12–24] both of them (bifunctional catalysts),[6,25–27] or with *N*-alkylamines,[28–30] amino acids,[31] polyelectrolytes,[32] surfactants,[33–38] and surfactants having imidazole derivatives.[39–43] The magnitude of the hydrophobic interaction between a substrate and a catalyst is well kown to be directly dependent on their apolar alkyl-chain lengths and on the micellar effects of the species participating in the reaction. In this regard, the micellar effects of catalysts, surfactants, and/or substrates on the rate enhancement of ester-hydrolyses have no yet been treated systematically by changing the hydrophobic alkyl-chain length in the above species, even though the micellar effects on the ester-hydrolyses have been discussed in many of the ealier investigations.[44]



S_n^- (n=2, 4, 6, 10, 12, and 16)

S_n (n=2, 4, 6, 10, 12, and 16)

C_m (m=6, 8, 10, and 12)



AcetHis (R=CH_3) and LauHis (R=$C_{11}H_{23}$)

DTAC CTAB

OTAC

The present work has been undertaken in an attempt to investigate how the systematic change in hydrophobic chain lengths in substrates, catalysts, and surfactants influences the hydrolyses of anionic 3-nitro-4-acyloxybenzoic acids (S_n^-) and nonionic *p*-nitrophenyl carboxylates (S_n) by hydroxamic acids (C_m) or L-histidine derivatives (AcetHis and LauHis) with and without cationic-surfactant (DTAC, CTAB, or OTAC) micelles.

Experimental

Material. 3-Nitro-4-acyloxybenzoic acids (S_2^-—S_{16}^-) were prepared in accordance with the method of Overberger *et al.*[18] Satisfactory elementary analyses were obtained for S_n^- (n=2—16), and those for new compounds are shown below: S_4^-: mp 113—114 °C. Found: C, 52.47; H, 4.25; N, 5.64%. Calcd: C, 52.17; H, 4.35; N, 5.53%. S_6^-: mp 75.0—76.0 °C. Found: C, 54.86; H, 5.29; N, 4.94%. Calcd: C, 55.51; H, 5.38; N, 4.98%. S_{10}^-: mp 70.1—72.0 °C. Found: C, 60.29; H, 6.79; N, 4.10%. Calcd: C, 60.52; H, 6.87; N, 4.15%. S_{16}^-: mp 87.1—89.0 °C. Found: C, 65.24; H, 8.21; N, 3.66%. Calcd: C, 65.53; H, 8.37; N, 3.32%.

p-Nitrophenyl acetate (S_2) was prepared by the acylation of *p*-nitrophenol with acetic anhydride, while the other *p*-nitrophenyl carboxylates (S_2—S_{12}) were obtained by the condensation of the corresponding acid chloride with *p*-nitrophenol. *p*-Nitrophenyl hexadecanoate (S_{16}) was commercially available and was used without further purification, because the elementary analysis of S_{16} gave satisfactory results. The results of the elementary analyses of synthetic S_n (n=2—12) were as follows: S_2: Found: C, 52.85; H, 3.66; N, 7.65%. Calcd: C, 53.00; H, 3.86; N,7.74%. S_4: Found: C, 57.74; H, 5.32; N, 6.90%. Calcd: C, 57.50; H, 5.32; N, 6.72%. S_6: Found: C, 60.75; H, 6.37; N, 5.90%. Calcd: C, 60.90; H, 6.32; N, 5.93%. S_{10}: Found: C, 65.65; H, 7.77; N, 4.68%. Calcd: C, 65.50; H, 7.85; N, 4.78%. S_{12}: Found: C, 67.71; H, 8.69; N, 4.41%. Calcd: C, 67.26; H, 8.47; N, 4.36%.

N^{α}-Lauroyl-L-histidine (LauHis) was obtained by the reaction of L-histidine and lauroyl chloride:[14] mp 162 °C (lit,[31] mp 160—161 °C). Found: C, 64.03; H, 9.27; N, 12.11%. Calcd: C, 64.06; H, 9.26; N, 12.45%. The N^{α}-acetyl-L-histidine (AcetHis) used in the present work was supplied by the Sigma Chemical Company.

The hydroxamic acids (C_6—C_{12}) were prepared from H–$(CH_2)_{m-1}$–$CO_2C_2H_5$ (m=6—12) and hydroxylamine, and

satisfactory elementary analyses were obtained: C_6: mp 45—47 °C. Found: C, 55.53; H, 9.78; N, 10.40%. Calcd: C, 54.94; H, 9.99; N, 10.68%. C_8: mp 75.6—77.2 °C. Found: C, 60.55; H, 10.52; N, 8.58%. Calcd: C, 60.34; H, 10.76; N, 8.80%. C_{10}: mp 85.9—86.7 °C. Found: C, 64.96; H, 11.10; N, 7.41%. Calcd C, 64.13; H, 11.30; N, 7.48%. C_{12}: mp 96—97 °C. Found: C, 67.13; H, 11.53; N, 6.26%. Calcd for: C, 66.98; H, 11.63; N, 6.51%.

Commercially available dodecyltrimethylammonium chloride (DTAC), hexadecyltrimethylammonium bromide (CTAB), and octadecyltrimethylammonium chloride (OTAC) were recrystallized from an anhydrous ethanol–ether mixture.

Hydrolysis. The hydrolyses of anionic S_n^- and nonionic S_n substrates ($(2—5)\times10^{-5}$ M; 1 M=1 mol dm^{-3}) by the C_m and LauHis (and/or AcetHis) catalysts ($(1—5)\times10^{-4}$ M) with or without a surfactant of DTAC (3.3×10^{-2} M), CTAB (5×10^{-3} M), or OTAC (5×10^{-3} M) were carried out at 31.0 °C, pH 7.45, in a 0.083 M tris(hydroxymethyl)aminomethane buffer (Tris) involving 0.083 M KCl (μ=0.083) in 10%(v/v) CH_3CN–H_2O; the reactions were followed spectrophotometrically by means of the phenolate-anion formation at 410 nm (for S_n^-) and 400 nm (for S_n). In the above procedure, the concentrations of the surfactants are higher than their critical micelle concentrations (CMC).

Determination of Critical Micelle Concentration (CMC). The CMC values for the substrates (S_n^-), the catalysts (C_m or LauHis), or the surfactants were measured by means of the usual conductivity method; a remarkable change in the conductivities of the above species upon an increase in their concentrations was found in the cases of S_n^- (n=12 and 16), C_m (m=8, 10, and 12), and all of the surfactants (DTAC, CTAB, and OTAC) employed for the present work. The CMC values obtained under the present reaction conditions are summarized below: $S_{12}^-=(1—3)\times10^{-4}$ M, $S_{16}^-=2\times10^{-5}$ M, $C_8=1\times10^{-4}$ M, $C_{10}=(1.3—2.0)\times10^{-5}$ M, $C_{12}=1\times10^{-5}$ M, LauHis=5×10^{-5} M, DTAC=1.5×10^{-2} M, CTAB=1×10^{-3} M, and OTAC=1.3×10^{-4} M at 31 °C, pH 7.45, in a 0.083 M Tris–KCl buffer in 10%(v/v) CH_3CN–H_2O.

Results and Discussion

Pseudo-first-order Hydrolysis. The hydrolysis of the S_n^- or S_n (n=2—16) substrates by the C_m (m=6—12) or LauHis (and/or AcetHis) catalysts, with and without the surfactants, obeys the usual pseudo-first-order rate law, which is substantiated by the linear relationship between log $(A_\infty-A_t)$ and the reaction time (t), where A_∞ and A_t denote the absorbances of the phenolate anion formed at an infinite time and at t respectively. The second-order rate constant (k_{cat}) for the deacylation of the ester substrates was evaluated as an average value obtained from the reactions repeated three times under identical conditions:

$$k_{cat} = (k_{total}-k_{spont})/[Cat]_0,$$

where k_{total} and k_{spont} (less than 5% of the k_{total}[45]) indicate, respectively, the first-order rate constant for the S_n^- (or S_n) hydrolysis with or without the catalyst, and where $[Cat]_0$ indicates the initial catalyst concentration. The catalytic efficiency of mixed catalysts was, then, compared on the basis of the k_{cat} values obtained at a fixed surfactant concentration (DTAC=3.3×10^{-2} M, CTAB=5×10^{-3} M, and OTAC=5×10^{-3} M).

Hydrolysis of Anionic S_n^- by C_m. The effects of the hydrophobic acyl- or alkyl-chain lengths of substrates, catalysts, or surfactants on the ester-hydrolysis reaction will first be discussed by comparing the rate constants obtained in the S_n^- (n=2—16) hydrolysis by C_m (m=6—12) with or without the surfactant (DTAC, CTAB, or OTAC); since the pK_a values of the hydroxamic acids (C_m) tested are around 9.5,[46] the hydrolyzing activity of the C_m catalyst is weaker in a neutral region (pH≈7) than in a basic solution.

In the absence of the surfactant micelles, an increase in the alkyl-chain length in the C_m catalyst from m=6 to m=10 results in a monotonous rate-enhancement for the S_n^- (n=2—16) hydrolysis because of the increase in the hydrophobic interaction between S_n^- and C_m; such a rate enhancement came to be especially great when the catalyst was changed from C_{10} to C_{12}.

On the other hand, the change in the acyl-chain length of the substrates also influenced the rate of S_n^- (n=2—16) hydrolysis by C_m (m=6—12). The increase in the acyl-chain length in S_n^- (n=2—16) for the S_n^- hydrolysis by C_6, which has no CMC, retarded the hydrolysis rate monotonously, probably because of the steric hindrance of the long acyl chain (in S_n^-);[18,19] this trend was also observed in the cases of the S_n^- (n=2—6) hydrolysis by the C_m (m=8—12) catalysts. However, in the hydrolysis of S_n^- (n=10—16), which possesses a relatively long acyl-chain length, by the C_{10} and C_{12} (especially by C_{12}), the contribution of the hydrophobic forces to the hydrolysis acceleration can be recognized (Table 1).

Table 1. k_{cat}(M^{-1} s^{-1}) values for the hydrolyses of S_n^- by C_m at pH 7.45

Catalyst	S_2^-	S_4^-	S_6^-	S_{10}^-	S_{12}^-	S_{16}^-

In the presence of the surfactant micelles, the comicellar catalysis was recognized in the S_n^- (n=2—16) hydrolysis, which was fairly much accelerated by condensing the anionic S_n^- substrates on the cationic micelles through electrostatic and hydrophobic forces. In this respect, the extent of the rate acceleration by the surfactant micelles, which was the most remarkable in the S_n^- (n=2—16) hydrolysis by the mixed micelles of the C_m (m=10 or 12)–CTAB (or OTAC) system,

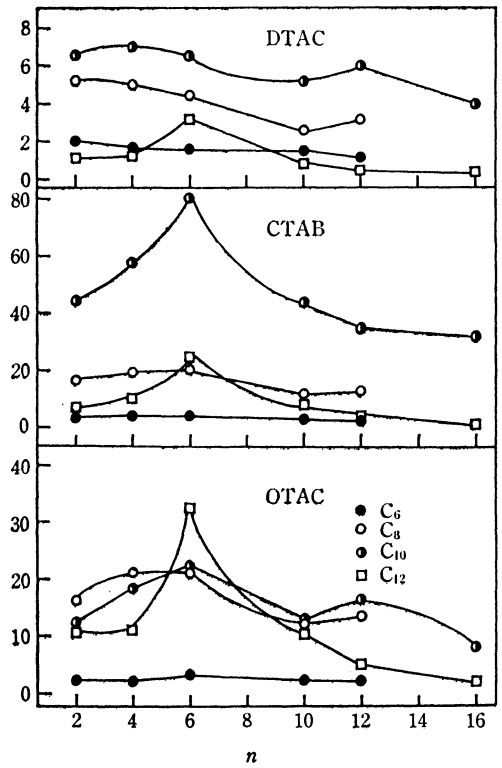

Fig. 1. Dependence of r value on the acyl chain length (n) in S_n^-.

was not monotonously increased by lengthening the hydrophobic acyl or alkyl chain in the catalyst, substrate, or surfactant (Table 1). Here, we can notice the magnitude of the micellar influence of the surfactant on the hydrolysis acceleration, which can be measured by the ratio (r) of the k_{cat} value in the presence of the surfactant to that in its absence, and the dependence of the r value on the acyl-chain length in S_n^- is shown in Fig. 1. As Fig. 1 indicates, a remarkable enhancement of the hydrolysis rate by the comicellar catalyst was realized in the S_6^- hydrolysis by C_{10}–CTAB or C_{12}–OTAC; that is, the hydrolyzing activities of C_{10} and C_{12} in the S_6^- hydrolysis are elevated by the respective surfactants (CTAB and OTAC) to *ca.* 80 and 32 times as great as those of C_{10} and C_{12} themselves. Such a selective enhancement of S_6^- hydrolysis by the above comicellar catalysts has also been observed in the S_n^- hydrolysis at pH 9.06.[10] The efficient activities of the mixed micelles of C_m (m=8, 10, and 12) –CTAB (or OTAC) for the selective enhancement in the hydrolysis of the same specific substrate (S_6^-) might result from the cooperative forces appearing in the following factors, in view of the fact that the alkyl-chain lengths in CTAB and OTAC are not so very different: (a) a favorable arrangement of the active nucleophilic group in C_m on the micellar surface for selectively accelerating the hydrolysis of a substrate possessing an appropriate acyl chain length and/or (b) a balance between the steric hindrance and the hydrophobic forces of the acyl-chain length (in S_n^-) in the condensation of S_n^- by the comicellar catalysts. Since the C_{10}–CTAB (or C_{12}–OTAC) catalyst showed great activity for the rate

The values in parentheses are those for the S_n hydrolyses.

enhancement in all the hydrolyses of S_n^-, the latter factor (b) seems to play a predominant role in such a selective enhancement of S_6^- hydrolysis.

Hydrolysis of S_n^- and S_n by AcetHis and LauHis. In order to investigate the effects of different substrates and catalysts on the above-mentioned selective hydrolysis acceleration, the hydrolyses of the anionic S_n^- and nonionic S_n (n=2—16) substrates by an AcetHis (with no CMC) or micellar LauHis catalyst were performed with or without surfactants.

Although the relatively small activity of AcetHis, as compared with that of LauHis, was considerably diminished by the addition of the surfactant (DTAC, CTAB, or OTAC), the micellar or comicellar catalysis for the hydrolysis acceleration was also recognized in the S_n^- (or S_n) hydrolysis by a LauHis or LauHis-surfactant system (Table 2). The LauHis catalyst hydrolyzed both kinds of substrates (S_n^- and S_n) more easily, as the hydrophobic acyl-chain length in the substrates varied from n=4 in S_n^- (or n=6 in S_n) to n=16 through the hydrophobic forces. The extent of the change in the hydrolysis rates by lengthening the acyl chain in S_n (or S_n^-) is different between LauHis–DTAC and LauHis–CTAB (or OTAC); that is, the former comicellar catalyst increases the rate of S_n or S_n^- (n=10—16) hydrolyses monotonously, in parallel with the increase in the acyl-chain length (n), but the latter one results in a rate decrease in the S_n (n=10—16) or S_n^- (n=6—16) hydrolyses. Such a difference in catalysis between LauHis–DTAC and LauHis–CTAB (or OTAC) is also reflected in the following observations: the latter catalyst brought about a rate enhancement for the hydrolysis of anionic S_6^- and nonionic S_{10} selectively (this is probably due to the force expressed by the (b) factor mentioned before, even though such a selective rate enhancement was not realized by the former one. At any rate, it is worthy of notice that the same selective rate enhancement of S_n^- (especially S_6^-) hydrolysis by LauHis–CTAB and C_{10}–CTAB catalysts was observed in spite of the different functional groups between LauHis and C_{10}.

Binding Constants for the Selective Hydrolysis of S_n.

The present selective hydrolysis of a substrate possessing an appropriate acyl-chain length by the comicellar catalysts will be briefly discussed by taking notice of the binding constants obtained for the present hydrolyses of S_n (n=2, 6, 10, and 16) by the LauHis–OTAC comicelles at pH 7.45. The present micellar reactions can be given the following steps:

$$S_n + M \overset{K_b}{\rightleftharpoons} MS_n \overset{k}{\longrightarrow} P$$

(on the miceller surface)

$$S_n \overset{k_{spont}}{\longrightarrow} P$$

(in the bulk solution)

where M=comicelles of LauHis–OTAC; MS_n=micelle-substrate complex; P=*p*-nitrophenol; K_b=binding constant.

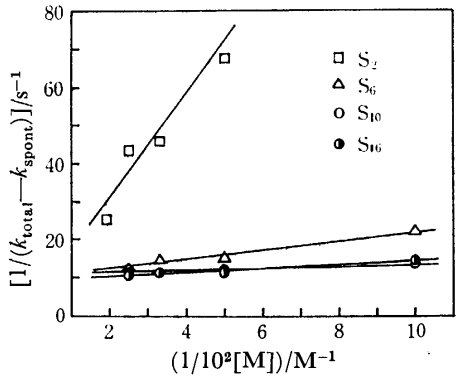

Fig. 2. Linear relationships between the reciprocal values of (k_{total}—k_{spont}) and [M] in the hydrolyses of S_n by LauHis in the presence of OTAC.

In the present study, the experiments were carried out under the following conditions: [OTAC]≫CMC, and [OTAC]>[LauHis]>[S_n], at 31 °C, pH 7.45, in a 0.083 M Tris-KCl buffer in 10%(v/v) CH_3CN–H_2O. The linear relationships between the reciprocal value of ($k_{total}-k_{spont}$) and [M] ([M]=[OTAC]+[LauHis]−[OTAC]$_{CMC}$; [OTAC]$_{CMC}$ is 1.3×10^{-4} M) were obtained as is indicated in Fig. 2. The K_b/N and k values were, then, evaluated from the following equation according to the previous techniques:[31,34]

$$1/(k_{total}-k_{spont}) = N/K_b(k-k_{spont})[M] + 1/(k-k_{spont})$$

where N=aggregation number.

In estimating the K_b/N and k values listed in Table 3, the monotonous increase in the former value with an increase in the acyl-chain length in S_n from n=2 to n=16 suggests that the formation of MS_n by the condensation of S_n by the comicelles is favored in the hydrolysis of S_n with a longer hydrophobic acyl-chain length. However, no appreciable change in the k value with an increase in the acyl-chain length in S_n was observed.

It may be deduced, therefore, that the selective S_{10} hydrolysis by the LauHis+OTAC comicelles cannot be explained well by only the binding constant, and the present selective hydrolysis of a specific substrate with an appropriate acyl chain can be understood as a result of the approximation effect which makes the nucleophile and the substrate come close to each other.

Table 3. Estimated constants for the binding system in the hydrolysis of S_n by a comicellar catalyst (LauHis+OTAC)

	S_2	S_6	S_{10}	S_{16}
$(K_b/N)M^{-1}$	52.8	811	1829	2772
k/min^{-1}	0.149	0.100	0.106	0.099

45) In the case of the S_n^- (or S_n) hydrolysis by AcetHis with or without the surfactant, the k_{spont} value comes to be about 20% of the k_{total} value because of the low activity of AcetHis.
46) See Refs. 3 and 7. In our experiments, the pH dependence of the k_{cat} value in the C_m (m=6—12)-CTAB (or OTAC) system indicated a pK_a value of *ca.* 9 for the C_m catalysts.

A Development in Polarization Experiments; Emission Spectra of Anthracene, Dibenzothiophene, and Xanthone in Stretched Polyethylene Films[1)]

Tomoyuki TERADA, Motohiko KOYANAGI,* and Yoshiya KANDA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received June 15, 1979)

The polarized emission spectra of anthracene, dibenzothiophene, and xanthone have been studied in stretched polyethylene films at 77 and 4.2 K. Applicability and advantage of this method are examined by virtue of conventional polarization technique and modulation technique. The latter leads us to finding of an important role of a nontotally symmetric vibration, the b_{3g} ring vibration at 1655 cm^{-1}, in the fluorescence spectrum of anthracene. An assignment for several prominent vibrational bands in the phosphorescence spectrum of dibenzothiophene is proposed from detailed analysis of the modulation polarization spectrum at 77 K. The phosphorescence properties of xanthone are also investigated.

A number of polarization measurements of electronic transitions of molecules have been carried out mainly in crystal systems[2–5)] and in glasses[6–10)] using the single crystal technique and the photoselection technique, respectively. During the present decade another polarization technique has been developed through the measurements of the absorption[11–15)] and emission[16,17)] spectra of oblate or prolate organic molecules oriented in stretched polymer films.

Main advantages of the emission polarization measurements in the stretched polyethylene film over conventional photoselection and mixed-crystal methods are in wider range of the degree of polarization and less ambiguous environmental effects. In the present work a modulation polarization technique is applied to these film systems and its applicability and advantage are shown in several examples of emission spectra. An application of the similar techniques to the single crystal systems has been reported elsewhere.[18,19)]

Experimental

Materials. Commercial extra-pure-grade heptane and zone refined anthracene, both obtained from Tokyo Kasei Co. Ltd., were used without further purification. Dibenzothiophene and xanthone, products of the same company, were purified by zone-refining after several vacuum sublimations. Commercial polyethylene films of 0.15 mm in thickness were swollen in heptane for a few days before measurements. The films treated in this way showed no background emission at 77 K.

Apparatus. The optical arrangement employed in this work is schematically shown in Fig. 1. Light from a 500 W xenon arc lamp (**1**) passed through a condensing lens (**2**) and a combination filter system (**3**), *i.e.*, a Corning glass of type 7—54 of 3 mm in thickness and a 30% $NiSO_4$ aqueous solution of 30 mm in pathlength. The sample film (**4**) was set in a Dewar (**5**) with an aluminum cell holder. The direction of the stretching axis of the film was then inclined by 45° from the vertical axis of the Dewar for possible diminution of the systematic error of polarization coming from the curvature of the Dewar wall. The emission from the sample film passed through a lens (**6**), a standing polarizer (**7**) (and, if necessary, a rotating polarizer system (**8**) according to two different methods of polarization measurements as mentioned below), and a slit of a 3/4 m Czerny-Turner Nalumi grating spectrometer (**9**) in order. The polarization emission spectra were

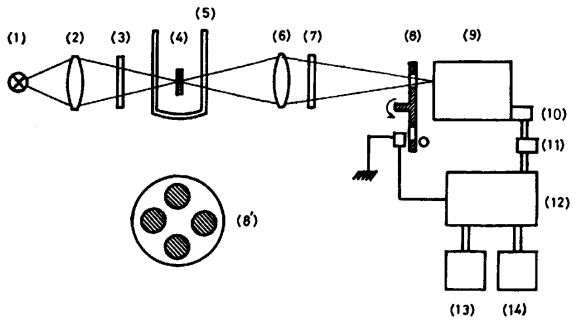

Fig. 1. Optical arrangement. For the notations (**1**)—(**10**) see descriptions in the Experimental section of this paper. Other notations are: (**11**), preamplifier; (**12**), lock-in-amplifier; (**13**), Iwatsu Dual beam oscilloscope type DS-5016; and (**14**), Hitachi recorder type 056. The drawing (**8'**) shows the front view of (**8**).

recorded on the spectrometer in the first order with an HTV R-375 photomultiplier tube (**10**). An HN 22 polaroid sheet employed in the polarizer systems (**7** and **8**) showed transmittance of about 8% at 375 nm and 28% at 500 nm.

Measurements. Two kinds of techniques were employed for polarization measurements. One is the same as given by Dekkers *et al.*:[16)] Two intensities $I_{//}$ and $I_{\perp}$ are measured independently and compared each other against wavelength. Here $I_{//}$ and $I_{\perp}$, respectively, refer to the intensity of an emission with the electric vector parallel to the direction of the stretching axis of the sample film and that perpendicular to it. We shall call this type of experiment *the DP method* and the spectrum *the DP spectrum* hereafter. The other method is an application of the modulation technique to the polarization experiments. The rotating-polarizer system (**8**) consists of a 120 mmϕ aluminum chopper with four holes (20 mmϕ) to which one each HN 22 polarizer sheet was fixed in such a way that the axis of the analyzing polarizer appears alternatively either parallel to or perpendicular to the stretching axis of the film. The emission signals were thus modulated at 100 Hz and fed to a lock-in-amplifier type NF model-LI-572B. If an appropriate phase relation is selected between the sample and reference signals, the output voltage of the lock-in-amplifier will be proportional to the difference between two intensities of interest, *i.e.*, $I_{//}-I_{\perp}$. This method will be called *the MP method* after its modulation polarization technique. The spectrum obtained by this method will also be *the MP spectrum.*

There is a problem in the case of analysis of the MP spectrum. The extremum of the MP spectrum does not always signify the existence of a band ! An apparent maximum is

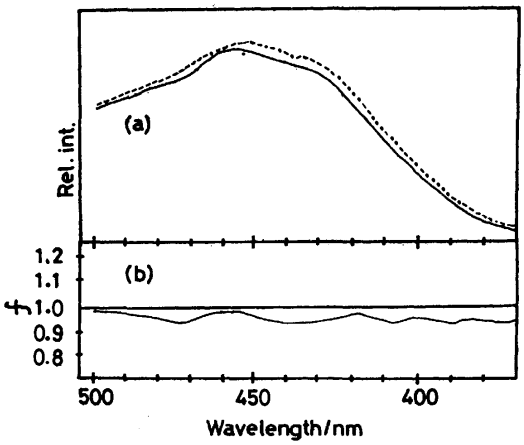

Fig. 2. (a) The self-polarization of the optical system employed. The solid curve denotes the polarization parallel to the stretching direction of polyethylene films and the dotted one that perpendicular to the film direction. (b) The dispersion curve of the correction factor f $(=I_{//}/I_{\perp})_{\text{system}}$ against wavelength.

formed among overlapping bands on rare occasions. A maximum appears sometimes near a minimum position between two emission bands, while another occurs in a region where the $I_{//}-I_{\perp}$ signal of a certain band competes with those of neighboring bands. Therefore, it is very meaningful to compare the MP spectrum with a well-resolved spectrum such as that in a Shpolskii matrix.[20]

Correction. In polarization experiments we sometimes encounter a problem of instrumental self-polarizations; in this work these come largely from a Dewar, lenses, and a spectrometer. The correction for the self-polarizations was carried out according to a conventional method.[21] As shown in Fig. 2, the correction factor in our system was found to vary little over a wide range of wavelength and to be nearly equal to 0.95 on an average. The correction factor of 0.95 was thus adopted for the DP experiments.

In principle, of course, the MP spectrum should also be corrected through 5% attenuation of $I_{\perp}$-component intensity. However, the actual correction of the MP spectrum leads to only a little increase in intensity toward the (+) parity direction and, accordingly, a little change in the band feature. Consequently, no correction was applied for the MP spectra in this work.

Sample Preparation. Swollen in heptane for a few days, a polyethylene film of 3×6 cm^2 was immersed in a solution of sample of 10^{-3} M in heptane. After natural evaporation of the solvent in the atmosphere, it was fixed on a stretching machine and extended by 500% in length at room temperature. Then the stretched sample film was set on an aluminum cell-holder.

Results and Discussion

Anthracene. The fluorescence and its polarization spectra of anthracene in polyethylene film systems are shown in Fig. 3, together with the fluorescence spectrum in heptane matrix. The spectroscopic data are also given in Table 1. The DP spectra shown in Fig. 3a are in good agreement with those reported by Dekkers *et al.*[16] It should be noted that the minima of bands shown in Fig. 3c just correspond to the band locations of the short-molecular-axis polarized spectrum (see also the dotted curve in Fig. 3a); and that the MP spectral line crosses the base line at the same wavelength position as the $I_{//}$ curve does the $I_{\perp}$ one in the DP spectra. This means that there is a one-to-one correspondence between the DP and MP spectra. The MP spectrum shows several extrema at 386.4 (α in Fig. 3c), 406.4 (γ),

a) Results obtained with the MP method. b) The sign "+" means a maximum peak of $I_{//}-I_{\perp}$ signal in the MP spectrum and the "−" a minimum one. Band designations to the figures are given in parenthesis by greek letters. c) Deviation in cm^{-1} units from the first fundamental combinations is given in parenthesis.

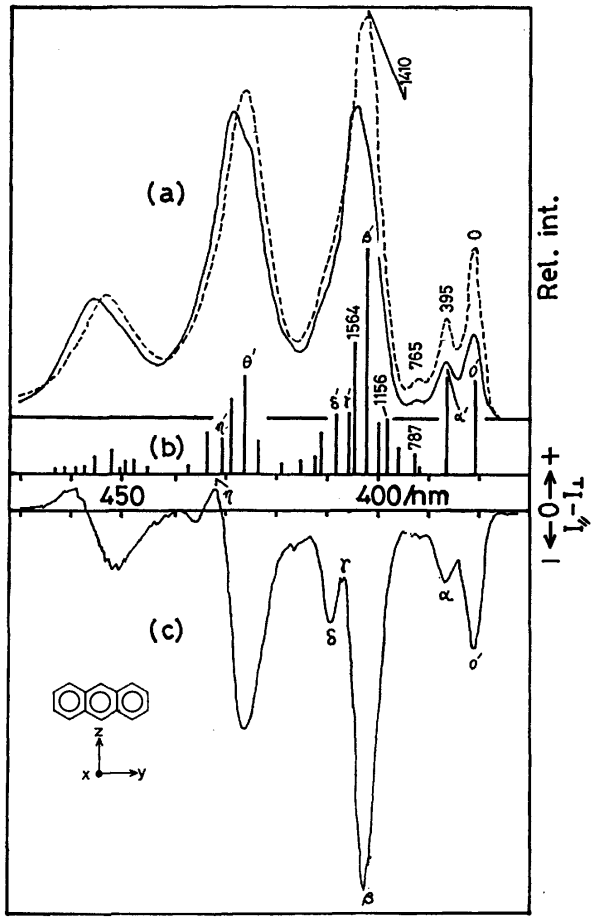

Fig. 3. The fluorescence and its polarization spectra of anthracene at 77 K. (a) The DP spectra in stretched polyethylene film systems; the solid curve denotes the polarization parallel to the stretching direction of polyethylene films and the dotted one that perpendicular to the film direction. (b) The fluorescence spectrum in heptane matrix (schematic). (c) The MP spectrum. Band notations are defined in Table 1.

and 409.0 nm (δ). These extrema are difficult to be identified in the DP spectra because of the band broadness. Among them the first two extrema in the MP spectrum are attributed to several vibrational bands in comparison with the spectrum in a Shpolskii solvent, heptane (see Fig. 3b). In view of concentrations employed a considerable weakness of the origin band in intensity is ascribed to the reabsorption effect of the 0—0 band.[22,23]

The DP and MP spectra show that the origin band of the fluorescence spectrum of anthracene is polarized along the short axis of the molecule under an assumption of *nice* molecular orientations in stretched polymer systems. This result is in good agreement with those from other experimental[24-26] and theoretical[27-29] works.

The band at 386.4 nm in the DP spectra, *i.e.*, the 0—395 cm^{-1} ($\pm$15 cm^{-1}) band in Table 1 and Fig. 3a, is assigned to be of an a_g-vibration, based on the band behavior in the MP spectrum. Dekkers *et al.* reported $P=-0.39$ for the 0—0 band and $P=-0.30$ for the 0—395 cm^{-1} band from their DP spectra and inferred that the latter came from accidental overlapping of a totally symmetric a_g-mode and a nontotally symmetric b_{3g}-mode. The MP spectrum also supports such an assignment from the intensity consideration.

The weak band at 392.0 nm, *i.e.*, the 0—765 cm^{-1} band in Fig. 3a, is ascribed to an a_g-fundamental vibration or an overtone of the a_g-vibration at 394 cm^{-1}.[25] Although the corresponding band also appears in the MP spectrum, it is too weak to discriminate between these assignments.

The strong band at 402.2 nm in the DP spectrum, *i.e.*, the 0—1410 cm^{-1} band, consists of several overlapping bands as can be seen from the broad band feature. Therefore, detailed discussion for the "band" is not possible with the DP spectra. However, it is an experimental fact that $I_{//}$ (max) appears at a longer wavelength than $I_{\perp}$ (max) does. Through the vibrational analysis of the fluorescence spectrum in heptane matrix (see Table 1), $I_{\perp}$ (max) is attributed mainly due to the band of 0—1405 cm^{-1} ($\pm$5 cm^{-1}) and $I_{//}$ (max) due to those of 0—1564 cm^{-1} ($\pm$5 cm^{-1}), 0—1637 cm^{-1} ($\pm$5 cm^{-1}), and 0—1799 cm^{-1} ($\pm$5 cm^{-1}) as Dekkers *et al.* suggested.[16]

On the other hand, the MP spectrum clearly discriminates among three bands of 0—1410 cm^{-1} ($\pm$15 cm^{-1}), 0—1655 cm^{-1} ($\pm$15 cm^{-1}), and 0—1820 cm^{-1} ($\pm$15 cm^{-1}) which are designated as β, γ, and δ in Fig. 3c and correspond to those of 0—1405 cm^{-1}, 0—1637 cm^{-1}, and 0—1799 cm^{-1} in the fluorescence spectrum in heptane matrix, respectively. From their polarization behaviors we attribute these bands to a_g, b_{3g}, and a_g fundamentals, respectively, in good correspondence with suggestions inferred from the experiments in the crystal systems.[30] The band of 0—1564 cm^{-1} in heptane matrix does not correspond to any maximum or minimum position in the MP spectrum. However, it is suggested that this band would be based on an a_g fundamental mode from viewpoints of the band shape of the MP spectrum.

Although the fluorescence polarization spectrum of anthracene has been studied in naphthalene crystals at 4.2 K, no positive evidence has been found for the existence of long-molecular-axis polarized bands, possibly due to strong crystal effects.[24] We also confirmed this in our mixed crystal systems at 4.2 K. Only one report has been given for observation of the long-molecular-axis polarized fluorescence spectrum of anthracene in fluorene at 20 K.[25] However, the band system is complicated reflecting site emissions and no precise data concerning polarization intensities is available. Thus it should be noted that the present work gives a clear-cut evidence for a participation of the b_{3g} vibration in the $S_1 \rightarrow S_0$ fluorescence process. This observation is in good agreement with finding of the band intensification observed in the pre-resonance Raman effect of anthracene by Ohta and Ito.[31]

Dibenzothiophene. The phosphorescence spectrum of dibenzothiophene (DBTH in abbreviated form) in heptane at 77 K is shown in Fig. 4, together with the DP spectra in stretched polyethylene film systems. A considerable polarization of the origin band observed in the DP spectra establishes that DBTH molecules are sufficiently oriented in the systems in such a way that

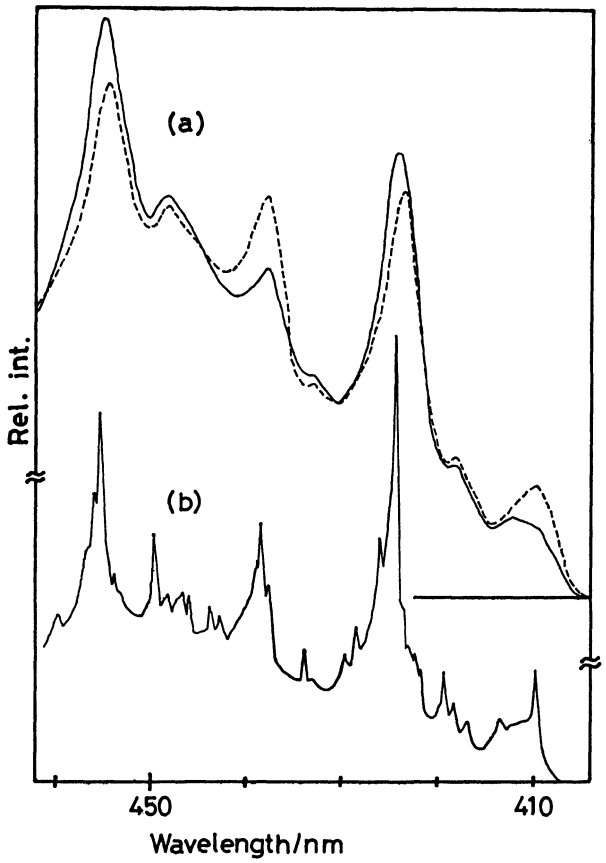

Fig. 4. (a) The phosphorescence polarization spectrum of DBTH in stretched polyethylene film systems at 77 K with the DP method; the solid curve represents the spectrum polarized parallel to the stretching direction of the films and the dotted one that perpendicular to the film direction. (b) The phosphorescence spectrum of DBTH in heptane at 77 K.

the long-molecular-axis is parallel to the stretching axis of the film.

The MP spectrum is compared with the phosphorescence spectrum in heptane matrix in Fig. 5, where the

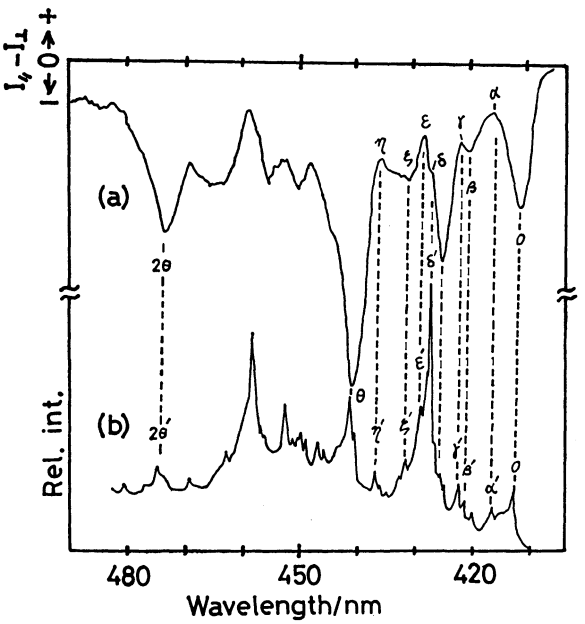

Fig. 5. (a) The MP phosphorescence spectrum of DBTH in polyethylene film systems at 77 K and (b) the phosphorescence spectrum of DBTH in heptane at 77 K. Band notations are given in Table 2.

positions of the origin bands are adjusted to be identical. A tentative vibrational assignment for the first main bands is also given in Table 2. As shown in Fig. 5a, the origin band (designated as *o* in the figure) is polarized normal to the long axis of the molecule, *i.e.*, along the x- or z-axis in the molecular coordinates shown in Fig. 6. Since the emission is certainly ascribed to be of $\pi\pi^*$ in the nature from the long lifetime of 0.5 s, the origin band is assumed to be polarized along the out-of-plane axis of the molecule, *i.e.*, the x-axis, on the basis of the predominant first-order spin-orbit coupling mechanism illustrated schematically in Fig. 6a.

As shown in Fig. 5a, the 0—240 cm^{-1} (± 15 cm^{-1}) band (α) in the MP spectrum is polarized along the

a) For brevity we list only the assignment of bands sufficient enough to show the vibronic pattern. b) See Table 1, footnote a. c) See Table 1, footnote b. d) Data taken from Ref. 32.

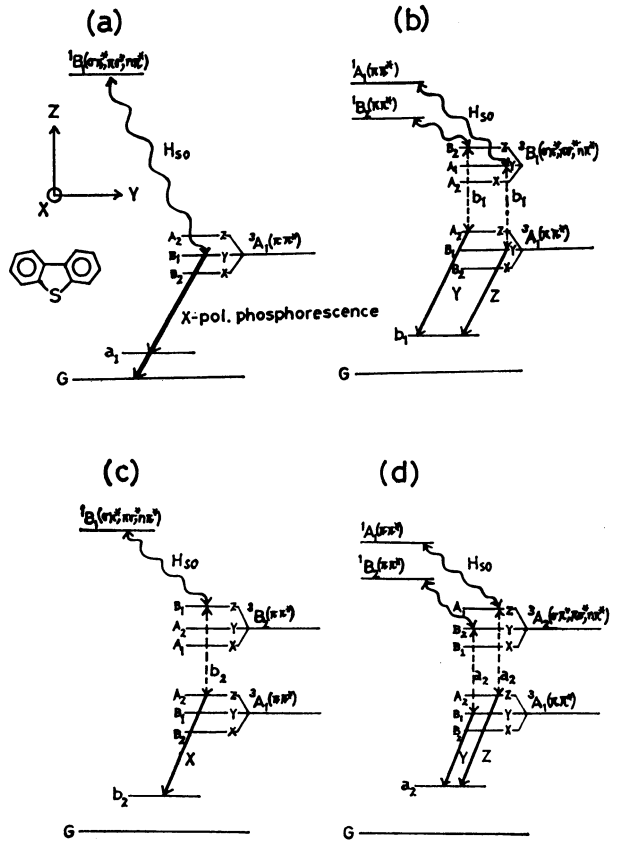

Fig. 6. Main coupling mechanisms in the phosphorescence process of DBTH. (a): 1st-order spin-orbit coupling. (b), (c), and (d): 2nd-order spin-orbit-vibronic couplings due to b_1, b_2, and a_2 vibrations, respectively. Here are described only vibronic couplings between triplet manifold for the saving of the space. Similar schemes, of course, hold for singlet manifold.

y-axis. It is evident from the coupling schemes given for triplet manifold (see Figs. 6b and 6d) and from the similar ones for singlet manifold that the y-axis polarized transition is caused by nontotally symmetric b_1 and/or a_2 vibrations through the second-order spin-orbit-vibronic coupling mechanisms under the assumption that the first-order spin-orbit-vibronic couplings are negligibly small.[32] The spacing of 0—240 cm^{-1} observed in the MP spectrum is found to correspond to a b_1-fundamental vibration of 226 cm^{-1} assigned from the observed IR and Raman spectra.[33]

The 0—500 cm^{-1} (± 15 cm^{-1}) band (β) in the MP spectrum is polarized perpendicular to the long axis of the molecule. This band is close in wavenumber to the 0—502 cm^{-1} (± 5 cm^{-1}) band in the phosphorescence in heptane matrix (see also Table 2). Several coupling schemes are possible for such transitions that are polarized perpendicular to the long axis, as shown in Fig. 6. According to the vibrational analysis, a band at 498 cm^{-1} in the IR spectrum of crystalline DBTH has been assigned as an a_1 fundamental.[33] If this vibration is employed, the 0—500 cm^{-1} band in the MP spectrum is to be polarized along the x-axis. Similarly, many other bands are assigned on the basis of the IR and Raman data.

The vibrational assignment for most of the bands are in accord with that given by Bree and Zwarich (hereafter referred to BZ).[32] However, several prominent bands are assigned here in a different way: They are the bands of 0—229 cm^{-1} (α' in Fig. 5b), 0—565 cm^{-1} (γ'), 0—851 cm^{-1} (δ'), and 0—1351 cm^{-1} (η') in the phosphorescence spectrum in heptane matrix at 77 K, as designated by greek symbols in Fig. 5b. In an energy region of 200—300 cm^{-1} from the origin band of the phosphorescence of DBTH in heptane at 15 K, BZ observed two main bands at 210 cm^{-1} and 221 cm^{-1} and assigned as (a_1) and (a_1+phonon) modes, respectively, in comparison with the assignment to the X-trap emission of DBTH in the crystal at the same temperature. We also studied the phosphorescence spectrum in heptane at 4.2 K and obtained a similar band pattern to that reported by BZ. We find that the band system contains several site emissions and that the 0—210 cm^{-1} band reported by BZ is ascribed to an emission from a different site. On the other hand, the phosphorescence of DBTH in heptane at 77 K is found to be mainly due to one site as shown in Fig. 5b, although it is not clear at present what is the origin of those sites in heptane matrix at low temperatures. The 0—229 cm^{-1} band (α') in heptane matrix at 77 K, *i.e.*, the main band between 200 and 300 cm^{-1} from the origin band (o') should thus correspond to a maximum position in the MP spectrum (α in Fig. 5a) which is here ascribed to a b_1 fundamental vibration as mentioned above.

The 0—565 cm^{-1} band (γ') in heptane matrix was attributed to a b_2 symmetry mode by BZ. However, the corresponding MP band is found at 570 cm^{-1} from the origin peak (o) and has a nature of the (+) parity polarization. This property is in contrast with the predicted (—) polarization if the BZ's b_2-assignment would be accepted for the band (*e.g.*, see Fig. 6c). The coupling schemes (**b**) and/or (**d**), however, suggest such (+) polarization behaviors. Thus we assign this band as due to an a_2 mode which is only out-of-plane fundamental vibration predicted in a wavelength region of 500—650 cm^{-1}.[33]

The 0—851 cm^{-1} band (δ') is the strongest one in the phosphorescence system of DBTH. Observing an IR active b_2 vibrational band at 868 cm^{-1}, BZ attributed this phosphorescence band to the b_2 mode. However, the result of the MP spectrum indicates that the band should be out-of-plane vibration from the same reason as mentioned in the case of the 0—565 cm^{-1} band. In a wavenumber region of 800—900 cm^{-1} only one out-of-plane vibration was observed at 859 cm^{-1} (b_1) by BZ! The b_1 assignment is thus preferable. This revised assignment leads us to another prediction that the 0—1351 cm^{-1} band (η'), which can be assigned here as a combination band of 851+502 cm^{-1} ($b_1 \times a_1 = B_1$) in accord with the assignment by BZ, might manifest a similar polarization behavior to that of the 0—851 cm^{-1} band. The MP spectrum shown in Fig. 5a endorses this prediction.

Xanthone. The phosphorescence spectrum of xanthone (hereafter XTH) in 3-methylpentane and EPA has been reported to be very sensitive to temperature.[34,35] This is also confirmed to be the case

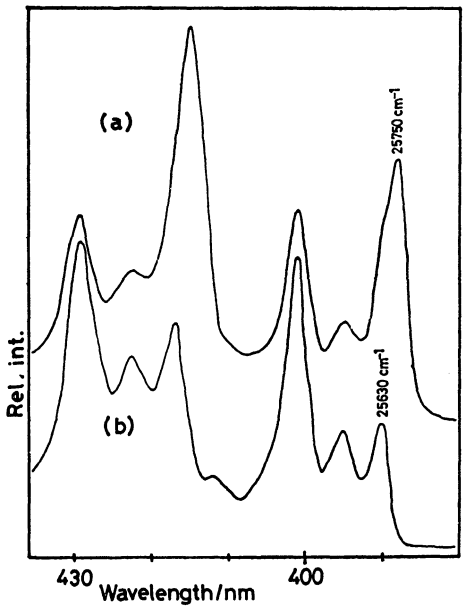

Fig. 7. The phosphorescence spectrum of XTH in polyethylene polymer systems (a) at 77 K and (b) at 4.2 K.

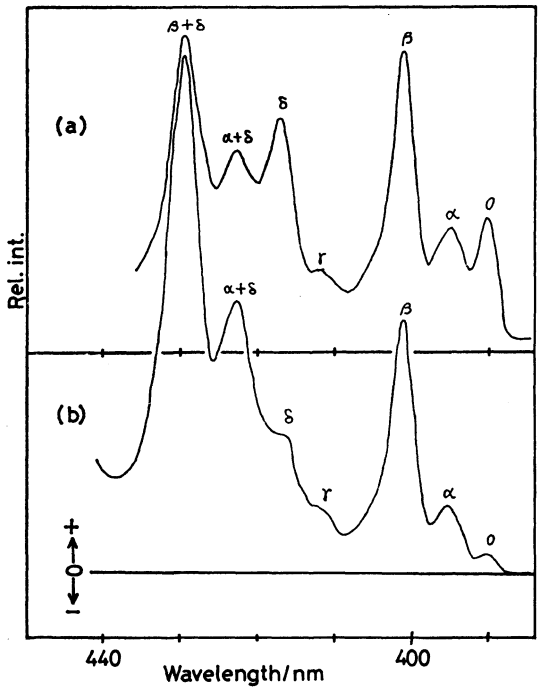

Fig. 8. (a) The phosphorescence spectrum of XTH in polyethylene polymer systems at 4.2 K. (b) The phosphorescence polarization spectrum of XTH with the MP method at 4.2 K. Band notations are given in the Text.

in polyethylene matrix; *e.g.*, the spectra at 4.2 and 77 K as illustrated in Fig. 7. On account of a small energy separation between $^3\pi\pi^*$ and $^3n\pi^*$ levels and a general existence of molecules at different sites the phosphorescence spectrum of XTH in aliphatic hydrocarbons has generally been found to manifest complicated band-patterns.[34-36] Especially, a statistical distribution of emission sites in polyethylene film systems seems to increase the complication of the spectrum, as can be seen in too much deviation from an exponential decay relationship of the phosphorescence lifetime at 77 K.

On the other hand, the phosphorescence at 4.2 K is observed to decay nearly exponentially and to show little change in intensity with a decrease in temperature to 1.5 K. The strong activeness of several out-of-plane vibronic bands and the rather long lifetime of the order of $\approx 10^{-1}$ s are manifestations that the lowest excited triplet state of almost all the emission sites in polyethylene matrix is of $\pi\pi^*$ type. These features resemble those reported in the spectra of XTH in the crystal and in diphenylmethane matrix at 1.5 K by Chakrabarti and Hirota,[37] although there is a big difference in the T_1-T_2 energy separation between their systems and ours, possibly based on environmental difference (*e.g.*, $\Delta E(T_2\text{-}T_1) \approx 1680\ cm^{-1}$ in their diphenylmethane matrix and $\Delta E(T_2\text{-}T_1) \approx 140\ cm^{-1}$ in the present work). Thus, we confine ourselves to the spectrum at 4.2 K in this paper. The phosphorescence spectrum of XTH in polyethylene film systems and its MP spectrum are shown in Fig. 8. Except for some combination bands, the band system consists mainly of the origin band (band notation *o* in Fig. 8) and several fundamental bands such as $0-320\ cm^{-1}$ ($\pm 20\ cm^{-1}$) (α), $0-700\ cm^{-1}$ ($\pm 20\ cm^{-1}$) (β), $0-1320\ cm^{-1}$ ($\pm 20\ cm^{-1}$) (γ), and $0-1670\ cm^{-1}$ ($\pm 20\ cm^{-1}$) (δ). It is found that the bands α, β, γ, $\alpha+\delta$, and $\beta+\delta$ are strongly polarized along the long axis of the molecule (P: 0.40—0.50). The origin band itself and the $0-\nu(C{=}O)$ band (δ) are also polarized along the long-molecular-axis, but their degrees of polarization are considerably small (P=0.10). The great degrees of polarization along the long-molecular-axis observed in the bands α, β, γ, $\alpha+\delta$, and $\beta+\delta$ support a large contribution to the overall phosphorescence system through the second-order spin-orbit-vibronic mixings *via* the magnetic z-sublevel.[37] However, it is difficult to mention from only the present work which coupling scheme plays a predominant role in the phosphorescence process for such a close-energy-system *via* singlet manifold or *via* triplet manifold. As has been suggested in the case of the phosphorescence spectrum of *p*-methoxybenzaldehyde in *p*-dimethoxybenzene,[19] remarkable degrees of the depolarization of the bands *o* and δ may be attributed to the existence of the competitive processes of the environmental direct coupling between $^3\pi\pi^*$ and $^3n\pi^*$ and the first-order spin-orbit coupling between $^3\pi\pi^*$ and $^1\sigma\pi^*$.

Concluding Remarks

The DP method in stretched polymer film systems has extensively been employed for absorption and emission polarization measurements. The method is attractive certainly in simplicity of the experiment, but it is unfortunately subject to a limitation in its applicability. In general the wide band-width originating from a statistical distribution of emission sites in those polymer film systems prevents us from finding out a weak band near a strong band and from discriminating a band from the overlapping bands. Despite the

unavoidable problem of the band broadness in stretched polyethylene film systems, the MP method is found to improve the band resolution remarkably. The high S/N ratio in the MP method promises a future development in the application to other molecules.

The Molecular Structure of 1-Phenoxy-1,2,2a,8b-tetrahydrocyclobuta[*a*]naphthalene-8b-carbonitrile

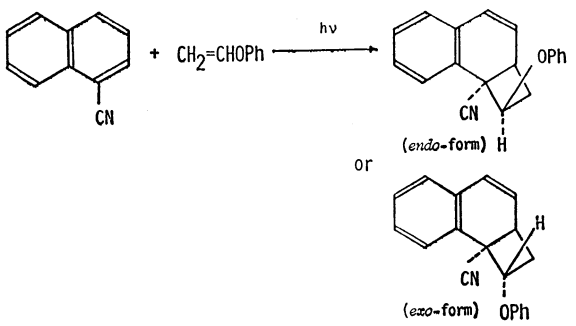
Hideaki MATSUURA,† Yasushi KAI, Noritake YASUOKA,†† and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 16, 1979)

The molecular structure of the sole photocycloaddition product of α-naphthonitrile with phenyl vinyl ether, $C_{18}H_{15}ON$ was determined by means of X-ray diffraction. The crystals are monoclinic, space group $P2_1/c$, unit-cell dimensions are $a=11.563(2)$, $b=9.826(1)$, $c=14.324(2)$ Å, $\beta=113.46(1)°$, $Z=4$. The structure was solved by the direct method, the final R value being 0.042 for 2022 non-zero reflections. The molecule has an *endo*-configuration, and the cyclobutane ring is puckered.

Recently, Pac and co-workers found that the photoreaction of α-naphthonitrile with alkyl vinyl ethers (CH_2=CHOR, R: Me or Et) affords both the *endo*- and *exo*-cycloadducts,[1] whereas the (4+4) photocycloaddition of furan to α-naphthonitrile is highly stereoselective and remarkably dependent on solvent used.[2] These facts suggested the enhanced stereoselectivity on the photocycloaddition of α-naphthonitrile with phenyl vinyl ether.



A sole cycloadduct has been obtained by the phtoreaction in question.[3] However, spectroscopic studies failed to characterize the cycloadduct to have *endo*- or *exo*-form (Scheme), and X-ray crystal structure analysis of the cycloadduct has been carried out in order to determine the exact configuration.

Experimental

Crystal Data. $C_{19}H_{15}ON$, mp 115.5—116.5 °C, *F.W.* 273.3, $F(000)=576$, monoclinic, space group $P2_1/c$, $a=11.563(2)$, $b=9.826(1)$, $c=14.324(2)$ Å, $\beta=113.46(1)°$, $V=1493.1(3)$ Å^3, $D_m=1.22$ g cm^{-3} (25 °C, aqueous solution of potassium tartarate), $Z=4$, $D_c=1.22$ g cm^{-3}.

Unit-cell dimensions and reflection intensities were measured on a Rigaku automated, four-circle diffractometer using graphite monochromatized Cu $K\alpha$ radiation. A parallelepiped, transparent crystal with dimensions of *ca.* $0.2\times0.3\times0.1$ mm^3 was used.

The θ-2θ scan technique was employed for the intensity data collection at a 2θ rate of 2° min^{-1}. Backgrounds were measured for 7.5 s before and after the scan of each peak. In total 2209 independent reflections were collected up to $2\theta\leqq120°$, of which 184 were considered unobserved. Intensity data were corrected for Lp effect but not for absorption [μ(Cu)=6.08 cm^{-1}].

Solution and Refinement of the Structure

The structure was solved by the direct method. From the Wilson plot average temperature factor and scale factor were obtained. A set of 284 $|E|$'s($|E|\geqq1.5$) were used with the *MULTAN* program[4] to establish the phase relationship. From the E map (ABSFOM 1.2422) all the non-hydrogen atoms could be located. The positional and isotropic thermal parameters of these atoms were refined by the block-diagonal least-squares procedure (*HBLS* V[5]). After eight cycles of refinement ($R=0.158$), anisotropic thermal parameters were introduced; five cycles of refinement reduced the R to 0.094. All the H atoms were located on a difference Fourier map. The refinement was continued including these H atoms with isotropic thermal parameters. The function minimized was $(\sum w|F_o|-k|F_c|)^2$, where k is a single scale factor and $w=\{\sigma_{cs}(F_o)+a|F_o|+b|F_o|^2\}^{-1}$ (σ_{cs}: standard deviation determined from the counting statistics). The R value converged to 0.053. However, in the range $7.0\leqq|F_o|\leqq20.0$ the quantity minimized showed an anomaly. The $30\bar{2}$, 111, and 402 reflections which have extraordinarily large $|F|$'s were then excluded, and the weights of Hughes,[6] $w=(F_{max}/|F_o|)^{-2}$ for $|F_o|>F_{max}$ and $w=1$ for $|F_o|\leqq F_{max}$ ($F_{max}=15.0$ in the present study), were introduced in the next stage. The refinement converged normally to $R=0.042$ ($R_w=0.052$). Atomic scattering factors for C, N, and O were taken from those of Hanson and coworkers,[7] and that of H from Stewart and coworkers.[8] The final atomic parameters are given in Table 1.†††

Results and Discussion

Figure 1 shows an *ORTEP* plot[9] of the molecule. Bond lengths and bond angles are given in Fig. 2.

The remarkable feature of the structure is that the photocycloadduct of α-naphthonitrile with phenyl vinyl ether has the *endo*-configuration (Scheme). This result suggests an existence of the exciplex of the phenyl vinyl ether as a photoreaction intermediate.[3]

Fig. 1. A stereoscopic drawing of the molecule.
Non-hydrogen atoms are drawn as thermal ellipsoids with 30% probability and H atoms are circles with $B=1.2$ Å^2

The cyclobutane ring C is puckered, dihedral angle between the plane defined by C(6), C(1), and C(8) and the plane of C(6), C(7), and C(8) being 31.3°. A significant lengthening of C(1)–C(6) [1.565(3) Å] and C(1)–C(8) bonds [1.577(2) Å] is clearly observed. On the other hand C(7)–C(8) bond shows a shortening [1.516(3) Å]. As a result of the cyclobutane ring formation, ring B of the naphthonitrile moiety is no more planar, the C(1) and C(6) atoms are deviated by 0.10 and −0.14 Å out of the mean plane, respectively. Both rings A and D are planar within 0.002 Å and have normal structures. Concerning the ether

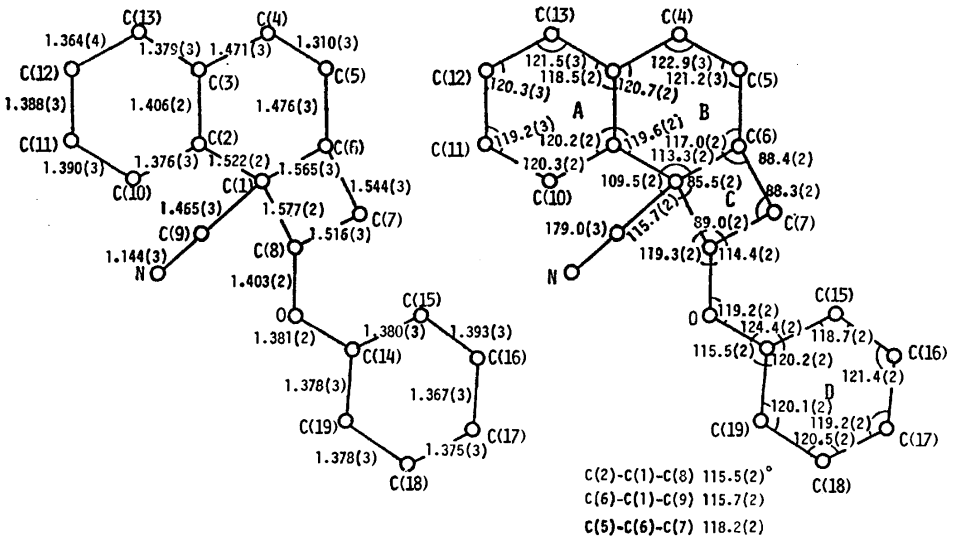

Fig. 2. Bond lengths and bond angles with e.s.d's in parentheses.

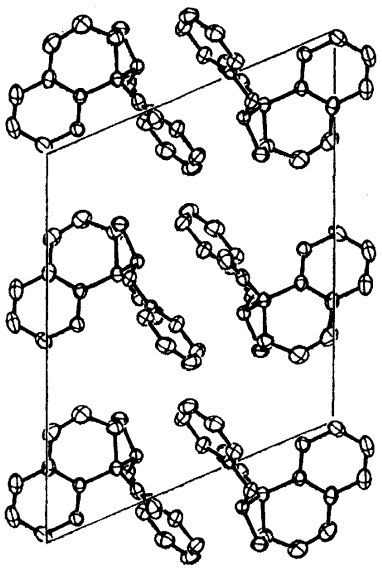

Fig. 3. Crystal structure projected along the b axis.

bond, the C(8)–O bond length [1.403(2) Å] is longer than the C(14)–O [1.381 (2) Å]. The torsion angle C(8)–O–C(14)–C(15) is −10.9°. This is considered as due to the steric interaction between H(8) and H(15) [H(8)···H(15)=2.13(3) Å].

Figure 3 shows the crystal structure projected along the b axis. No close intermolecular contact less than usual van der Waals distance is observed.

The authors wish to express their deep thanks to Professor Hiroshi Sakurai and Dr. C.-J. Pac of the Institute of Scientific and Industrial Research, Osaka University for crystals. Thanks are also due to Mr. Kunio Miki for his helpful discussions. All the numerical computations were done on a NEAC 2200-700 computer at the Osaka University.

Direct Measurement of the Interaction Energy between Solids and Gases. V. Change of the Differential Heats of Adsorption of Ammonia with Specific Poisoning on Silica-Alumina

Hitofumi TANIGUCHI,* Tatsuo MASUDA, Kazuo TSUTSUMI, and Hiroshi TAKAHASHI
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received June 18, 1979)

Heats of adsorption of ammonia on specifically poisoned silica–alumina were measured by use of a twin-conduction-type calorimeter in order to elucidate the adsorption energy and acid strength distributions for both Brönsted (hereafter referred to as B) and Lewis (L) acid sites. Infrared spectra of adsorbed pyridine and cumene cracking activity for the poisoned sample were also examined. Sodium alcoholate–alcohol solution was used as the reagent poisoning only B sites. The use of sodium 2-propanolate–2-propanole dilute solution of which sodium contents was approximately equal to the expected amount of proton on silica–alumina surface caused a large portion of B sites to be poisoned without the decrease in the number of L sites. The following conclusions could be drawn from the experimental results that i) above 115 kJ/mol of the differential heat of adsorption of ammonia no B acid sites were present but only L acid sites, and ii) B acid sites existed chiefly in the vicinity of the adsorption energy distribution of 110 kJ/mol.

The acid strength distribution of dehydrated silica–alumina was determined by amine titration using Hammett indicators[1] or by gas adsorption calorimetric titration[2] and the relation between these two methods was clarified.[3] However, bases such as butylamine and ammonia are adsorbed on both L and B acid sites so that the acid strength distribution of one kind of acid sites has been still uncertain.

On the basis of the inference that B acid sites are generated by the addition of water to L acid sites,[4,5] heats of adsorption of ammonia on the latter may be higher than that on the former. However, a number of other models of acid sites of silica–alumina have been proposed[4–7] and the real silica–alumina surface seems to be more complex.

In this study, heats of adsorption of ammonia on specifically poisoned sample were calorimetrically determined in order to evaluate the acid strength distribution of only L acid sites or B sites. An ion exchange method has been mainly adopted so as to poison B acid sites. Since the exchange technique using aqueous solution such as aq sodium acetate is unsuitable for the specific poisoning of B sites because of the new generation of B sites accompanied by the addition of water molecules to L sites, sodium alcoholate–alcohol solution was used as exchange reagent of proton. Sodium alcoholate reacts easily with the hydroxyl group and has been known as the reagent for the determination of active hydrogen content on the surface. Triphenylchloromethane–hexane solution was used as the reagent poisoning L acid sites.[8,9]

Experimental

Materials. Commercial FCC silica–alumina (Catalysts & Chemicals Ind. Co., Ltd.: alumina 13 wt%) was used as a starting material. Sodium exchanged silica–aluminas (NaSA series) were obtained by impregnation of a starting material into sodium alcoholate–alcohol solutions after pretreatment at 400 °C under 10^{-3} Pa for 5 h. Silica–alumina of which L acid sites were poisoned (TSA) was prepared by impregnation of pretreated original silica–alumina into triphenylchloromethane–hexane solution. The poisoned samples were washed with corresponding alcohol or hexane and subsequently freed from the solvent by the evacuation at 400 °C.

Apparatus and Procedure. Heats of adsorption were determined by a twin-conduction-type microcalorimeter (Tokyo Riko Co., Ltd.) with a conventional vacuum system.[10] In order to measure the differential heat of adsorption, about 0.5 g of the sample was weighed into the sample cell which was evacuated at 400 °C under 10^{-3} Pa for 5 h and placed in the calorimeter. The heat of adsorption of ammonia was measured at 25 °C.

Cumene cracking activity tests were performed by use of a micro pulsereactor connected to a conventional gas chromatography assembly. One hundred and fifty milligrams of the sample was packed in a stainless steel tube and pretreated at 400 °C for 3 h in a stream of helium gas as a carrier. The helium flow rate was 30 cm^3/min. Catalytic activity was given in terms of the conversion ratio of cumene to propylene and benzene during the first pulse reaction.

Infrared spectra of the adsorbed pyridine were measured in an *in situ* quartz cell connected to a vacuum system. Twenty milligrams of sample was pressed to a thin wafer and set in the cell. After evacuation at 400 °C under 10^{-3} Pa for 3 h, pyridine was adsorbed with an equilibrium pressure of 1.3 kPa at room temperature. Then the sample was evacuated at 150 °C for 1 h in order to remove physisorbed pyridine. The spectral measurement was carried out at room temperature.

Specific surface area was determined by the BET nitrogen adsorption method.

Results and Discussion

Silica–alumina was treated with sodium methanolate, sodium 2-propanolate and sodium 2-methyl-2-propanolate in order to clarify the effect of the chain length and the steric conformation of the alkyl group on the amount of sodium exchange. The properties of NaSA series samples were shown in Table 1. NaSA(I), (III), and (IV) were obtained by the impregnation of pretreated silica–alumina into the concentrated sodium alcoholate–alcohol solutions in which sodium contents were in large excess in relation to the expected proton contents of silica–alumina surfaces. On the other hand, NaSA(II) was obtained by treatment with sodium 2-propanolate–2-propanole dilute solution in which

Table 1. Samples

Sample	Specific surface area, $S/m^2\ g^{-1}$	Na content / mmol g^{-1}	Treatment[b]
SA-13[a]	410	0	none
NaSA(I)	374	0.25	$(CH_3)_3CONa$–$(CH_3)_3COH$, concn
NaSA(II)	404	0.52	$(CH_3)_2CHONa$–$(CH_3)_2CHOH$, dilute
NaSA(III)	361	0.97	$(CH_3)_2CHONa$–$(CH_3)_2CHOH$, concn
NaSA(IV)	390	1.64	CH_3ONa–CH_3OH, concn

a) Commercial FCC silica-alumina. b) Each poisoned sample was obtained by impregnation with sodium alcoholate–alcohol solution at room temperature.

sodium content was nearly equal to the expected proton content. The amount of sodium exchange was maximum in case of NaSA(IV) which was treated with sodium methanolate and decrease with an increase in the steric hindrance of the alkyl group. Since no remarkable reduction of specific surface area with the treatment of sodium alcoholate was observed for each sample, the surface structure of the original silica–alumina remained unchanged after the treatment.

Figure 2 shows the differential heats of adsorption of ammonia on sodium exchanged samples. With an increase in sodium content, the heat of adsorption of ammonia decreased. The initial heats of adsorption of ammonia on NaSA(I) and (II) were approximately equal to that on original silica-alumina, however, those on NaSA(III) and (IV) were remarkably reduced. Ammonia gas adsorption energy distributions are shown in Fig. 3. In cases of NaSA(I) and (II), the distribution around 110 kJ/mol of the heat of adsorption became markedly lower with an increase in sodium content, while that above 115 kJ/mol remained unchanged compared with original silica-alumina. In cases of NaSA(III) and (IV), however, the adsorption sites distribution became lower in a whole range above 80 kJ/mol. It is noteworthy that this range for original silica-alumina was also influenced by the heat treatment as shown in Fig. 1. The effect of the treatment with sodium 2-methyl-2-propanolate–2-methyl-2-propanol solution or sodium 2-propanolate–2-propanol dilute solution differed from that with sodium methanolate–methanol solution or sodium 2-propanolate–2-propanol concentrated solution.

Infrared spectra of pyridine adsorbed on sodium exchanged samples were shown in Fig. 4. Both absorption peaks for B acid sites (1540 cm^{-1}) and for L acid sites (1450 cm^{-1}) were observed on original silica-alumina. However, the former was remarkably reduced for NaSA(I) and disappeared for other exchanged samples, which suggests that B acid sites almost or completely disappeared by the treatment with sodium alcoholate. On the other hand, the reduction of the latter peak occurred particularly for NaSA(IV). This fact suggests that sodium methanolate reacted not only with surface active proton but was coordinated with L acid sites. The formation of the coordinative bond must require the small steric hindrance and the strong basicity of the coordinated species. Therefore it is

reasonable that the larger the alkyl group of sodium alcoholate is, the more difficult the formation of the coordinative bond with L acid site becomes. On the sample treated with sodium 2-methyl-2-propanolate, even a part of B sites still remained besides L sites.

The adsorbed amount of ammonia having the heat of adsorption below 115 kJ/mol, chiefly in the vicinity of 110 kJ/mol, decreased by sodium exchange. When the coordination of sodium alcoholate with L acid sites occurred besides sodium exchange, even the adsorbed amount of ammonia above 115 kJ/mol decreased together with the reduction of initial heat of adsorption. Hence, B acid sites seem to distribute mainly in the adsorption energy region below 115 kJ/mol.

In Fig. 5 the differential heat of adsorption of ammonia on silica-alumina poisoned with triphenylchloromethane (TSA) is shown together with those on SA-13 and on NaSA(II). The initial heat of adsorption of ammonia on TSA, 115 kJ/mol, was much lower than that on original silica-alumina, while that on NaSA(II) was approximately equal to that on original sample. Furthermore, as shown in Fig. 6, ammonia adsorption sites on TSA existed below 115 kJ/mol of the differential heat of adsorption, which was markedly different from the case of NaSA(II). This supports the above-mentioned suggestion that only L acid sites exist above 115 kJ/mol of the differential heat of adsorption. The number of ammonia adsorption sites above 115 kJ/mol for NaSA(III) or (IV) was smaller than that for NaSA-(II) or original silica-alumina, as a result of a decrease in the number of L acid sites.

It is possible to consider that L acid sites are stronger

than B sites in silica–alumina from the finding[11] that pyridine adsorbed on B sites was completely removed by evaculation at 300 °C while pyridine on L sites remained after evacuation even at 400 °C. As shown in Fig. 1, the adsorbed amount of ammonia above 115 kJ/mol on silica–alumina pretreated at 600 °C was about twice as much as that on the sample pretreated at 400 °C, which can therefore be ascribed to the increase in the number of L acid sites. The results are similar to those found in Y type zeolites.[12]

Table 2. Relations among cumene conversion ratio, sodium content and calorimetrically determined *acidity*

Sample	*Acidity* mmol g^{-1}	Na content mmol g^{-1}	Cumene conversion ratio/%
SA-13	0.35	0	87
NaSA(I)	0.31	0.25	78
NaSA(II)	0.22	0.52	31
NaSA(III)	0.21	0.97	23
NaSA(IV)	0.08	1.64	0

Cumene cracking activity of the catalyst has been known to arise from B acidity and its dependence on the calorimetrically determined surface acidity was reported previously in detail.[13] We now define the adsorbed amount of ammonia between 80 and 115 kJ/mol as *acidity* which seems to be the difference between total acidity and a large portion of L acidity. In Table 2 the relations among *acidity*, sodium content and cumene cracking activity are shown. With an increase in sodium content, both *acidity* and activity decreased. This fact suggests that the treatment with sodium alcoholate reduced B acidity.

The conclusions based on the above experiments are that B acid sites of silica–alumina studied here are distributed below 115 kJ/mol of the differential heat of adsorption of ammonia, mainly in the vicinity of 110 kJ/mol, and above 115 kJ/mol only L acid sites exist. A part of L acid sites may be present below 115 kJ/mol.

Considering a poisoning technique, it was shown that ion exchange in aq solution was unsuitable for the purpose of poisoning only B acid sites. Because the shape of q-N curve and the adsorption energy distribution curve of silica–alumina treated with aq sodium acetate solution were close to those of NaSA(IV); the amount of L sites of the latter decreased to about one-third of that of original silica–alumina.

This work was partly supported by a Grant-in-Aid for Science Research from the Ministry of Education.

High Temperature Hard Anodizing with Tartaric Acid-Oxalic Acid-Triethanolamine Bath

Yoshio FUKUDA* and Toshiro FUKUSHIMA

Corrosion Division, National Research Institute for Metals, 2-3-12, Nakameguro, Meguro-ku, Tokyo 153

(Received July 9, 1979)

Tartaric acid does not produce uniform films on A6063 alloy (Al–Mg–Si). Uniform films are formed when oxalic acid is added to the tartaric acid bath, but hardness above Hv 400 cannot be obtained at a voltage below 100 V. When 1 mol dm^{-3} tartaric acid–0.4—0.6 mol dm^{-3} oxalic acid baths were adjusted with triethanolamine (0.26—0.54 mol dm^{-3}) to pH 1.00 and 1.25, crack-free films with hardness above Hv 430 were formed at 40 °C in the range 65—85 V. The hardness of the film is independent of the anion content of the film, increasing with increase in the thickness of cell wall and lowering in porosity.

In general, hard anodizing of aluminum has been carried out in sulfuric acid at low temperatures below 10 °C.[1] It is considered that compact films can be obtained at low temperatures because of high formation voltages and that thick films can be obtained because of the low rate of dissolution of porous layers during the course of anodization. However, this process requires special facilities for refrigeration, and the films are cracked. A process operating at moderate temperatures is desirable.

For this purpose, (a) dilute sulfuric acid or (b) organic acid whose solvent action on the oxide film is weak above ordinary temperatures, are suitable as electrolyte, because hard films which possess large cells and a small number of pores can be formed on account of high voltage. (a) is liable to produce pitting,[2] and (b) to produce uniform films.[3,4] However, study on hard anodizing above ordinary temperatures has seldom been reported. Although malonic acid yields hard films at temperatures 40—60 °C,[5] it is liable to decompose into CH_3COOH and CO_2 at high temperatures.[6]

Recently, it was found[7,8] that crack-free films with hardness above Hv 500 are formed in tartaric or malic acid baths at temperatures above 60 °C. However, the acids have the disadvantages that the bath voltage is too high (above 150 V for high purity aluminum) and uniform films cannot be formed on alloys such as A6063 (Al–Mg–Si). Additives for overcoming the difficulty were investigated.[9] By addition of 0.2 mol dm^{-3} oxalic acid to 1 mol dm^{-3} tartaric or malic acid, films with hardness Hv 300—420 were obtained on A6063 alloy at 40—50 °C.[10] However, the bath voltage was still high (105—140 V at 5.65 A dm^{-2}).

The bath voltage can be lowered by further addition of oxalic acid, but the dissolution of the cell wall during anodization is accelerated, leading to a decrease in the hardness of the film. Simultaneous attainment of the increase in hardness and decrease in bath voltage is impossible.

With the aim of producing film with hardness above Hv 400 at voltages below 100 V, tartaric–oxalic acid electrolyte was improved. The dependence of the hardness on the anion content and porous structure of the film was also investigated.

Effect of pH and Oxalic Acid Concentration

The rise in the pH of electrolyte is necessary to reduce the rate of chemical dissolution of the porous layer during the course of anodization above room temperature. However, the rise in bath voltage, which follows the rise in pH and induces burning, should be suppressed as much as possible. There are two means for raising the pH, dilution of acid and addition of a base without dilution. In a dilute oxalic acid bath of high pH, the bath voltage is so high that burning is liable to occur, whereas in a bath with high oxalic acid concentration, adjusted to the same pH, the voltage is lower than in the dilute acid bath.[11,12] The lower the pH and the higher the oxalic acid concentration, the more the oxalate is involved in the film. The chemical dissolution rate of the film is independent of the oxalate concentration of the bath, and the film becomes soluble when the oxalate content of the film is higher and the pH of the bath lower. It seems that the barrier layer formed in a bath with concentrated oxalic acid, adjusted to a high pH, contains more oxalate than that formed in a dilute acid bath of the same pH so that the electrochemical dissolution of the layer is accelerated, lowering the bath voltage at a constant current density. This might occur also in the case of oxalic acid mixed with tartaric or malic acid. In a tartaric or malic acid bath with high oxalic acid concentration, adjusted to a high pH, the bath voltage would be lower than that in a bath with low oxalic acid concentration. Even if the bath voltage is decreased, the rate of dissolution of the cell wall is relatively low because of a high pH so that the hardness of the film would not decrease remarkably.

Experimental

Plates of extruded aluminium alloy A6063-T5,[13] 3 mm thick and 40 mm wide, were cut into 100 mm lengths (surface area $=88.4$ cm^2). Each of them was racked to a holder made of pre-anodized tantalum wire, 1 mm diam., and treated with an aqueous solution of 1.25 mol dm^{-3} NaOH at 80 °C for 30 s. They were then successively rinsed, neutralized with 15% HNO_3, rinsed and anodized. A 5 dm^3 beaker was used as an electrolytic cell, cathodes being made of two plates of carbon ($250\times 50\times 10$ mm).

Tartaric acid which can produce film at lower voltage than malic acid was used as the primary ingredient of the electrolyte

Table 1. Composition and pH of electrolytes

Tartaric acid / mol dm^{-3}	Oxalic acid / mol dm^{-3}	Triethanolamine / mol dm^{-3}	pH (at 25 °C)
1	0.2	0	0.80
1	0.2	0.13	1.00
1	0.2	0.22	1.25
1	0.4	0	0.67
1	0.4	0.26	1.00
1	0.4	0.34	1.25
1	0.6	0	0.60
1	0.6	0.43	1.00
1	0.6	0.54	1.25
1	0	0	1.28

and was mixed with oxalic acid or oxalic acid and triethanolamine[14] (Table 1). The bath temperature was kept at 30, 40, and 50±1 °C. While the solution was stirred with a propeller at about 330 min^{-1}, galvanostatic anodization using a three-phase full-wave rectifier was carried out at 2.26 A dm^{-2} for 50 min and at 5.65 A dm^{-2} for 20 min. Current was controlled to a specified value within 15 s after switching on.

The hardness was measured on the surfaces of two anodized specimens at three points each, using a micro Vickers hardness tester with a load of 100 g. The average of six readings was taken. The microstructure of the anodized surface was observed with an electron microscope using a one-step carbon replica at an accelerated voltage of 50 kV. The carbon content of the film was determined by analysis of CO_2 gas produced by combustion (1300 °C, carrier gas O_2) of the film.[12] The film was isolated by the cathodic reduction method.

Results

States of the Anodized Surface. When anodizing was carried out in a bath with 0.2 mol dm^{-3} oxalic acid, adjusted to pH 1.00 and 1.25, at 5.65 A dm^{-2}, burning occurred. Under all other conditions uniform films were formed. The thickness of each film was about 35 μm. Films were colored, no cracks being observed. The color of the films formed at 2.26 A dm^{-2} was grayish yellow and that of the films formed at 5.65 A dm^{-2} reddish dark yellow. The lightness of the color increased with increase in oxalic acid concentration and rise in temperature.

Bath Voltage. The time dependence of the bath voltage is shown in Fig. 1. The voltage dropped after

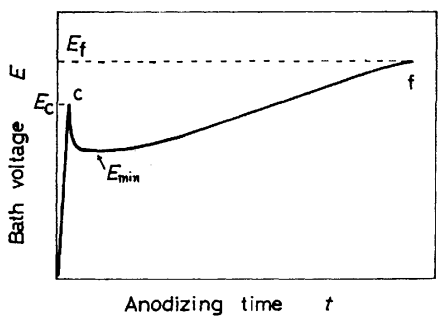

Fig. 1. Time dependence of bath voltage under galvanostatic anodizing.

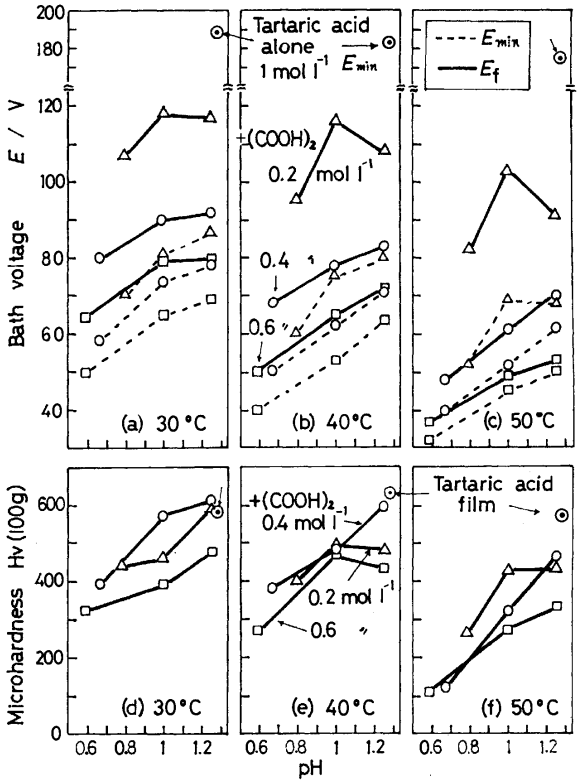

Fig. 2. Dependence of bath voltage and hardness of films on pH of electrolytes at various temperatures and oxalic acid concentrations(2.26 A dm^{-2}, 50 min, A6063 alloy).

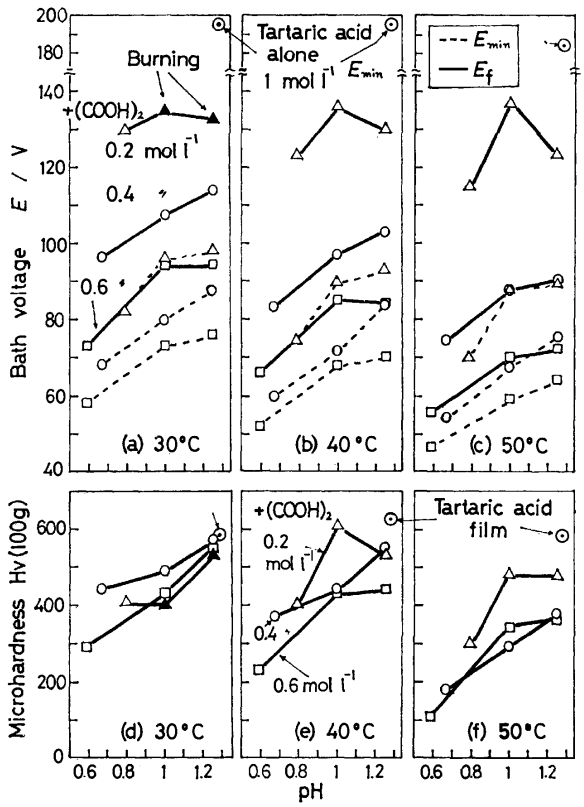

Fig. 3. Dependence of bath voltage and hardness of films on pH of electrolytes at various temperatures and oxalic acid concentrations(5.65 A dm^{-2}, 20 min, A6063 alloy).

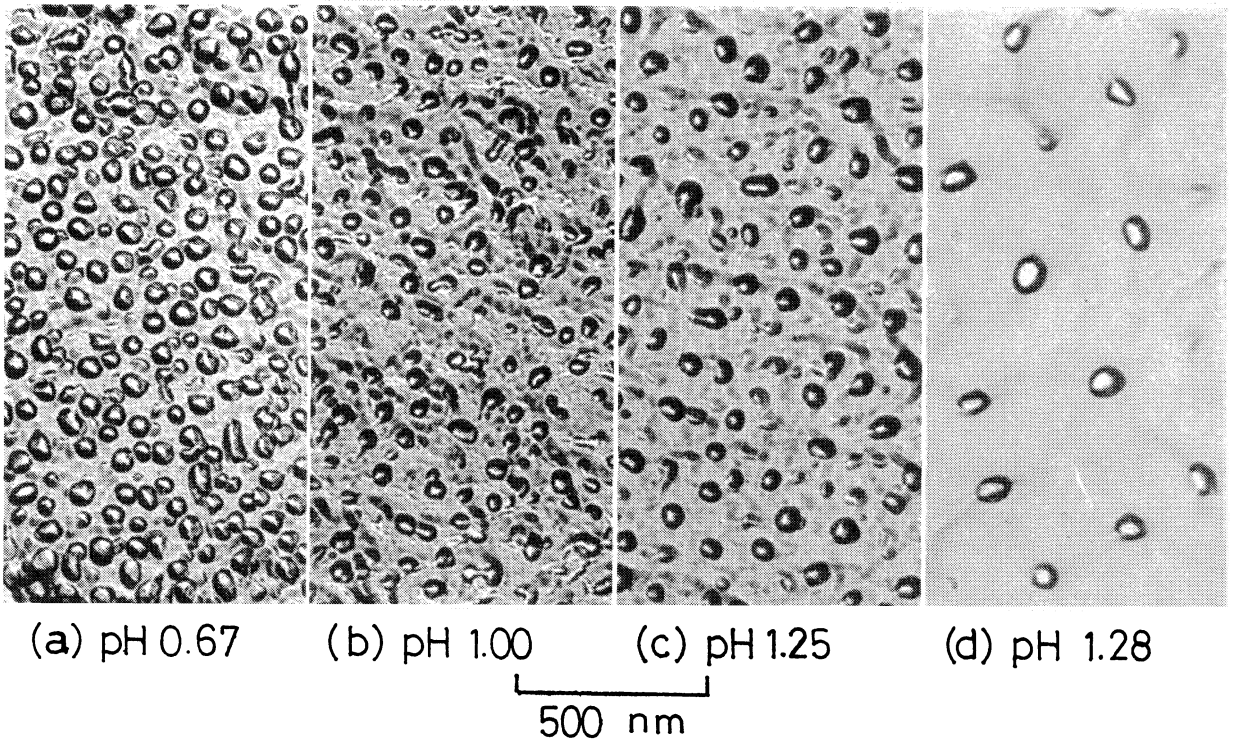

Fig. 4. Replica electron micrographs of film formed in (a) 1 mol dm^{-3} tartaric acid -0.4 mol dm^{-3} oxalic acid, (b) (a) $+0.26$ mol dm^{-3} triethanolamine, (c) (a) $+0.34$ mol dm^{-3} triethanolamine and (d) 1 mol dm^{-3} tartaric acid at 40 °C and 2.26 A dm^{-2} for 50 min.

the critical point "c" and then rose gradually. The slope of the voltage-time curve after point "c" decreased with increase in oxalic acid concentration, rise in temperature and lowering in current density.

The minimum bath voltage immediately after the critical point (E_{min}) increased with increase in pH and decreased with increase in oxalic acid concentration (broken line, Figs. 2a—c and 3a—c). The tendency was recognized also in the case of the final voltage (E_f, solid line). However, when oxalic acid concentration was 0.2 mol dm^{-3}, the E_f at pH 1.25 was lower than that at pH 1.00. The bath voltage decreased with rise in temperature and increased with increase in current density.

Hardness of the Film. As shown in Figs. 2d—f and 3d—f, the hardness increased with increase in pH and decreased with rise in temperature. At constant pH and temperature, the hardness decreased with

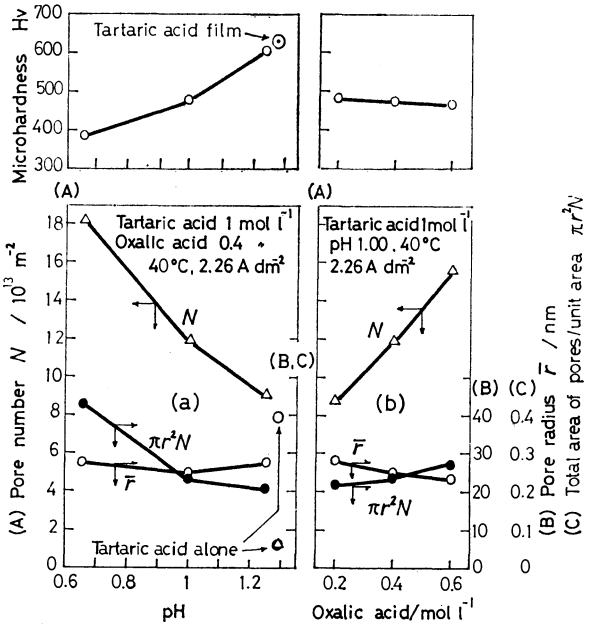

Fig. 5. Dependence of number, radius and total area of pores on pH and oxalic acid concentration of electrolytes.

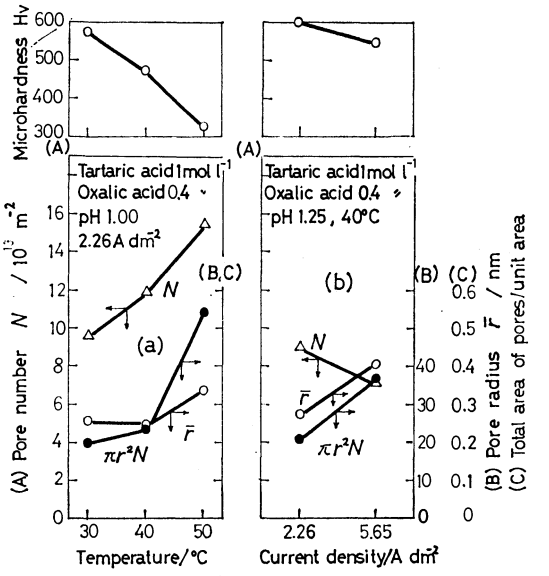

Fig. 6. Dependence of number, radius and total area of pores on temperature and current density.

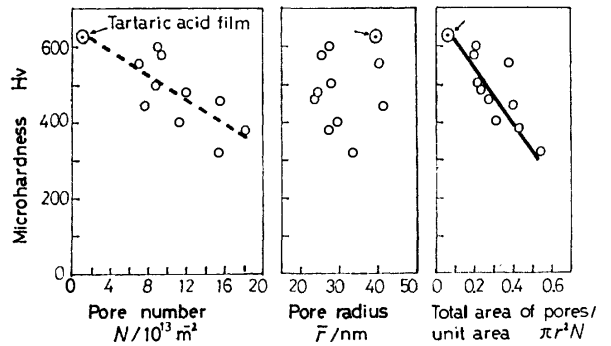

Fig. 7. Dependence of hardness of films on number, radius and total area of pores.

oxalic acid concentration. There was little change in the hardness with current density. By comparing the hardness with bath voltage, it was found that films with hardness above Hv 430 are formed in 1 mol dm^{-3} tartaric acid–0.4—0.6 mol dm^{-3} oxalic acid baths of pH 1.00 and 1.25 with voltage 65—85 V at 40 °C.

Carbon Content and Hardness of the Film. The carbon content of the film was determined in order to examine the effect of electrolyte anions on the hardness of the film. The hardness was independent of the carbon content of the film.

Microstructure and Hardness of the Film. Replica images of the film surface are given in Fig. 4. The number of pores in the films formed with mixed baths (a—c) is larger than that of pores in the film formed with tartaric acid alone (d). There is a difference in the number and radius of pores among the films shown in Figs. 4a—c. The number (surface density, m^{-2}) and radius (nm) of pores were measured on the photographs and the total area of pores was calculated. The parameters are plotted against the anodizing variables (Figs. 5 and 6) and the hardness of the film (Fig. 7). The hardness increased with decrease in the number and area of pores, but was not correlated with the radius of pores.

Discussion

When the pH of tartaric–oxalic acid electrolyte is raised by addition of triethanolamine, the electrochemical dissolution of the barrier layer is so suppressed that the bath voltage generally increases to maintain the current flow constant. The role of triethanolamine in this case is considered to be only the suppression of dissolution of the film by reducing the acidity of the tartaric–oxalic acid electrolyte as in the oxalic acid–triethanolamine bath.[12]

Porous layer contains a considerable amount of electrolyte anions,[15] the anion content of the phosphoric,[16] oxalic,[11] or sulfuric[17] acid film becoming maximum at a point between the wall/solution interface and the cell boundary. Electrolyte anions are considered to migrate through the barrier layer. Assuming that electrolyte anions are immobile, the porous layer arising from the barrier layer formed only by anion (O^{2-} and OH^-) migration[18] would contain no electrolyte anions.

The radius of oxalate ions seems to be smaller than that of tartrate ions. Thus oxalate ions are more mobile in the barrier layer than tartrate ions. The solvent action of oxalic acid on the oxide film is stronger than that of tartaric acid. The bath voltage rises gradually with anodizing time (Fig. 1). As the porous layer grows, the supply of oxalic acid by diffusion from the bulk of the solution to the surface of the barrier layer is retarded[19] and the dissolution of the barrier layer is suppressed and the layer becomes thick gradually, leading to gradual rise in bath voltage. In baths with 0.2 mol dm^{-3} oxalic acid, the E_f at pH 1.25 is lower than that at pH 1.00. At pH 1.25, a local rise in temperature of the anode might occur[20] owing to uneven current distribution. However, apparently uniform films were formed.

According to the theory of ionic equilibria,[21] in the pH range 0—1.25, little tartaric acid dissociates, while 5—48% of the oxalic acid dissociates to $HC_2O_4^-$ ions. For instance, at pH 1.00, 99% of the tartaric acid remains undissociated, while 65% of the oxalic acid remains undissociated and 35% of the oxalic acid is present as $HC_2O_4^-$ ions. Even if this mixed acid has the same pH value, undissociated oxalic acid concentration increases with the addition of oxalic acid, causing the decrease in bath voltage.

No cracks were observed in the films obtained by high temperature process. From the fact[22] that cracks increase as the anode warms up to room temperature after withdrawal, the film formed by the low temperature process may easily be cracked under the influence of tensile stress caused by expansion of the anode. On the other hand, in the case of the high temperature process, when the anode is cooled to room temperature after withdrawal, the film undergoes compressive stress by contraction of the anode but it can withstand the stress.

The hardness of the film is controlled by the geometrical structure of the film, but not the carbon or anion content of the film. The hardness of the film is closely related to its porosity,[23] but the porosity varies with the number and radius of pores. Hardness seems to be related to the wall thickness. The relation between these parameters and the hardness was examined in detail.

Higher pH gave a harder film with a smaller number of pores and smaller area of pores, or lower porosity (Fig. 5a). The distance between the pores, or wall thickness, increases with increase in pH (Fig. 4). Lower oxalic acid concentration gave a harder film with a smaller number of pores and lower porosity (Fig. 5b), the cell wall becoming thick. Lower temperature also gave a harder film with a smaller number of pores and lower porosity (Fig. 6a). The cell wall became thick with fall in temperature, the parameters changing with current density (Fig. 6b). When the current density was high, the number of pores was small but the porosity was high and the hardness value small. In this case, the relation between the number of pores and the hardness was opposite to that obtained in the other cases. The bath voltage at 5.65 A dm^{-2} was higher than at 2.26 A dm^{-2} so that the cell wall near the pore base should be thicker. However, the thicknesses of the walls near

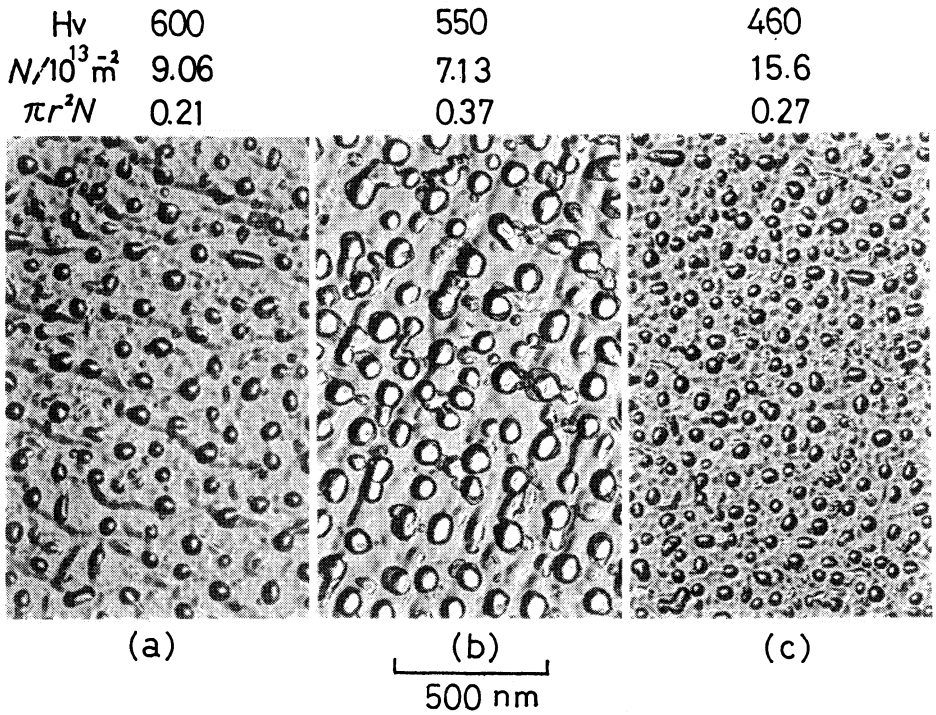

Fig. 8. Porous structure (replica image) and hardness of film.
(a) 1 mol dm^{-3} tartaric acid —0.4 mol dm^{-3} oxalic acid —0.34 mol dm^{-3} triethanolamine, pH 1.25, 40 °C, 2.26 A dm^{-2}, 50 min.
(b) The same bath as (a), 5.65 A dm^{-2}, 20 min.
(c) 1 mol dm^{-3} tartaric acid—0.6 mol dm^{-3} oxalic acid—0.43 mol dm^{-3} triethanolamine, pH 1.00, 40 °C, 2.26 A dm^{-2}, 50 min.

the surface were nearly the same as those of the walls of the film formed at 2.26 A dm^{-2} (Fig. 8b). When the current density is high, considerable heat is generated from the anode, making heat transmission insufficient and causing easy dissolution of the film. No definite relation exists between hardness and the radius of pores (Fig. 7).

When the bath voltage was raised, the cell wall as well as the barrier layer became thick and the number of pores decreased (Fig. 9), leading to a decrease in porosity and increase in hardness. Thus, in many cases, hardness was related to pore number, wall thickness and porosity. However, the number of pores is not closely related to hardness (Fig. 7). As shown in Fig. 8, film (a) is harder than film (b), while (a) has a larger number of pores than (b). This is due to the lower porosity of (a). Film (b) is harder than film (c), while (b) has a higher porosity than (c). This is due to the thicker wall of (b).

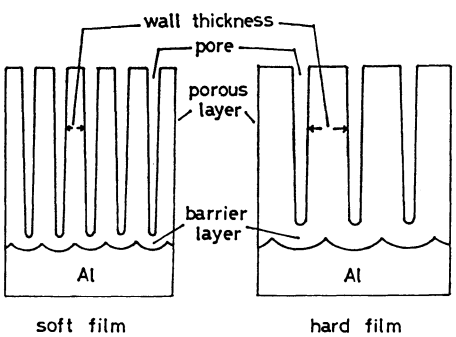

Fig. 9. Porous structure (cross section) and hardness of film.

The hardness of the film is controlled by wall thickness and porosity of the film, but not the anion content of the film; the thicker the wall and the lower the porosity, the harder the film.

Conclusions

High temperature hard anodizing of A6063 alloy was tested in 1 mol dm^{-3} tartaric acid–0.2—0.6 mol dm^{-3} oxalic acid–0—0.54 mol dm^{-3} triethanolamine baths at temperatures 30—50 °C and current densities 2.26 and 5.65 A dm^{-2}. The results are as follows:

1) In tartaric–oxalic acid baths, the films formed by addition of 0.2 mol dm^{-3} oxalic acid gave hardness above Hv 400, but the bath voltage was too high (above 100 V). When oxalic acid concentration was increased to 0.4—0.6 mol dm^{-3}, the hardness of film as well as the bath voltage decreased.

2) When 1 mol dm^{-3} tartaric acid–0.4—0.6 mol dm^{-3} oxalic acid baths were adjusted with triethanolamine (0.26—0.54 mol dm^{-3}) to pH 1.00 and 1.25, crack-free films with hardness above Hv 430 were formed at 40 °C with voltage 65—85 V.

3) The hardness of the film is independent of the anion content of the film, increasing with increase in the thickness of cell wall and decrease in porosity.

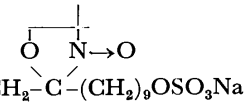
(Received July 20, 1979)

Nitroxide spin labeled surfactant, sodium salt of 2-ethyl-2-[9-(hydroxysulfonyloxy)nonyl]-4,4-dimethyloxazolidin-3-yloxyl, was synthesized and some properties of the compound were studied by means of ESR and conductivity measurements. From conductivity measurements it was found that the critical micelle concentration of the compound was 21.6 mmol kg^{-1} at 25.0±0.1 °C and the micelle consisted of a small number of labeled surfactant ions. The ESR spectra of the labeled surfactant were measured as a function of concentration and temperature. These spectra showed a typical pattern interpreted in terms of spin exchange. Regarding spin exchange as chemical reaction, second order rate constant was determined from the analysis of line width and compared with the values obtained by diffusion controlled model.

Spin label method[1] developed by Ohnishi and McConnell[2] has become more important because the ESR spectrum reflects sensitively the rotational motion in the wide range, *i.e.*, 10^{-11}—10^{-3} s,[3] the local environment, and the orientation of labeled compound. In particular, the application to biological system has offered many valuable information concerning the dynamic properties.[4]

In general, it is well known that surfactant molecules form the ordered aggregates known as micelles. Since a dynamic study of micellar solution by means of ESR was first attempted by Waggoner *et al.*,[5] many studies of micellar solution have been examined.[6-8] However, most of the studies have been performed by spin probe method. In order to obtain more detailed information on micelle, it is desirable to use the sample of micellar solution which consists of the spin labeled surfactant molecules only. So, a nitroxide spin label compound,[9] sodium salt of 2-ethyl-2-[9-(hydroxysulfonyloxy)nonyl]-4,4-dimethyloxazolidin-3-yloxyl (SL-SDS)



$CH_3CH_2-C-(CH_2)_9OSO_3Na$ (SL-SDS)

was synthesized and examined whether this compound is able to form micelle, characteristic of surface active molecule, or not.

In this paper, the results of a study of SL-SDS solution by means of ESR and conductivity measurements will be presented.

Experimental

Materials. Preparation of SL-SDS.[9] Dimethyl decanedioate was prepared by refluxing a mixture of 202 g (1 mol) of decanedioic acid, 800 ml of methanol, and 80 ml of concentrated sulfuric acid for 3 h. The reaction mixture was diluted with water of 3 times volume and the diester was extracted with 2000 ml benzene. After the removal of benzene under reduced pressure, the residue was transferred to a flask containing 85.6 g (0.5 mol) of anhydrous barium hydroxide in 1000 ml methanol. The flask was quickly closed with a soda-lime tube and the mixture was allowed to stand for 24 h with stirring at room temperature. The white barium salt collected by filtration was washed with two 200 ml portions of methanol and was shaken with a mixture of 1000 ml of 4 M HCl and 1000 ml of ether in a separatory funnel. The ether extract was washed with three 1000 ml portions of water. The ether was removed by evaporation and the residue was distilled under reduced pressure. The yield of methyl hydrogen decanedioate was 130 g (60%).

In a flask were placed 130 g (0.6 mol) of methyl hydrogen decanedioate and 143 g (1.2 mol) of thionyl chloride. The solution was gently warmed at 30—40 °C for 3 h and allowed to stand for 12 h at room temperature. The excess thionyl chloride was removed under reduced pressure and the residue was distilled, yielding 127 g (70%) of 9-(methoxycarbonyl)-nonanoyl chloride.

A solution of ethyl bromide 30.2 g (0.2 mol) in 100 ml of anhydrous ether was added to the 100 ml ether solution containing a 0.2 g atom of magnesium turnings and the mixture was refluxed for 30 min longer. To the mixture was portion-wise added 18.3 g (0.1 mol) of anhydrous cadmium chloride at 0 °C. The mixture was refluxed until a Gilman test[10] for the Grignard reagent was negative. The ether was completely removed and 200 ml of anhydrous benzene was added. The mixture in benzene was refluxed for 1 h. A solution of acid chloride, 9-(methoxycarbonyl)nonanoyl chloride 47 g (0.2 mol), dissolved in 50 ml anhydrous benzene was slowly added to the solution of the organo-cadmium compound and refluxed with stirring for an additional hour. The reaction product was cooled in an ice bath and decomposed by dropping of 50 ml of ice water, followed by an addition of 20% sulfuric acid sufficient to produce two transparent layers. The benzene solution was washed successively with 100 ml of water, 100 ml of 5% sodium hydrogencarbonate, 100 ml of water, and 50 ml of saturated sodium chloride. Then, the benzene solution was dried on anhydrous sodium sulfate. After removal of benzene, the reaction product was distilled (bp 115—117 °C/399 Pa), yielding 32 g (70%) of methyl 10-oxododecanoate; IR 1710 (C=O) and 1735 cm^{-1} (ester C=O); NMR (CCl_4) δ=0.99 (3H, t, J=7.6 Hz, CH_3).

To 500 ml of toluene were dissolved 22.8 g (0.1 mol) of the methyl 10-oxododecanoate, 89 g (1.0 mol) of 2-amino-2-methyl-1-propanol, and 100 mg (0.5 mmol) of *p*-toluenesulfonic acid monohydrate. The mixture was refluxed for 3 days using a Dean-Stark trap for continuous water removal. The toluene solution was washed 6 times with 200 ml portions of saturated sodium hydrogencarbonate solution and 4 times with 200 ml portions of water and dried through a column of anhydrous sodium sulfate. The toluene was then removed with a rotary evaporator. The residue containing the oxazolidine derivative was directly used to the following reaction for oxidation. Identification of oxazolidine was as

follows: NMR (CCl_4) δ=3.43 (2H, s, CH_2O); IR 1080—1190 cm^{-1} (triplet bands).[11]

A 15 g of the mixture containing the oxazolidine was dissolved in 300 ml of anhydrous ether and cooled at 0 °C in an ice bath. A cold solution of 100 ml ether containing 9 g (0.05 mol) of *m*-chloroperbenzoic acid was added drop-wise to the oxazolidine solution over a period of 2 h. The mixture was allowed to stand for 48 h with stirring at room temperature. The ether solution was then washed 4 times with 200 ml portions of saturated sodium hydrogencarbonate solution and water successively, and dried on anhydrous sodium sulfate. After removing ether under reduced pressure, a yellow oil was eluted with hexane–ether (7: 3) through a column of activated alumina. The yield of 2-ethyl-2-[8-(methoxycarbonyl)octyl]-4,4-dimethyloxazolidin-3-yloxyl based on methyl 10-oxododecanoate was 40%.

10 ml anhydrous ether solution containing 17.5 mg (0.46 mmol) of $LiAlH_4$ was cautiously added to 20 ml anhydrous ether solution of 144 mg (0.46 mmol) of 2-ethyl-2-[8-(methoxycarbonyl)octyl]-4,4-dimethyloxazolidin-3-yloxyl at −15——20 °C and the mixed solution was allowed to stand for 30 min at 0 °C. Then, to the solution were carefully added 5 ml of cold water and 10 ml of 5% sulfuric acid at −15——5 °C. After separation of the ether layer, the aqueous layer was extracted with two 30 ml portions of ether. The ether solutions were dried over anhydrous sodium sulfate. After removing the ether, a yellow oil was eluted with hexane–ether (1: 1) through a column of activated alumina. The nitroxide alcohol, 2-ethyl-2-(9-hydroxynonyl)-4,4-dimethyloxazolidin-3-yloxyl, was obtained in 70% yield after eluting the nitroxide ester. Found: C, 66.90; H, 11.30; N, 4.70%. Calcd for $C_{16}H_{32}O_3N$: C, 67.09; H, 11.26; N, 4.88%; mol wt 286.4.

In a 10 ml flask equipped with a magnetic stirrer were placed 100 mg (0.35 mmol) of nitroxide alcohol, 1 ml of anhydrous dioxane and 0.02 ml of anhydrous pyridine. The solution was stirred and sulfur trioxide-pyridine,[12] 55.5 mg (0.35 mmol), was portion-wise added over a period of 5—10 min at 20—25 °C. Thereafter, the mixture was allowed to stand for 24 h with stirring at 30—40 °C, then cooled, neutralized with 10% sodium hydroxide and poured into 10 ml of cold methanol. After filtration, solvents were evaporated under reduced pressure. A paste-like residue was washed many times with 2 ml portions of ether, dissolved in the ethanol of 10 ml, and filtered. Removing the ethanol, SL-SDS was obtained as the yellow solid in 25% yield. Found: C, 48.88; H, 8.07; N, 3.50%. Calcd for $C_{16}H_{31}O_6NSNa$:C, 49.46; H, 8.04; N, 3.60%; mol wt 388.4.

Sodium dodecyl sulfate (SDS), sodium decyl sulfate (SDeS), and Würster's blue perchlorate were prepared by conventional methods.

3-Carbamoyl-2,2,5,5-tetramethyl-3-pyrrolin-1-yloxy (CTMPY) was purchased from Aldrich Chemical Co.

Measurement of ESR and Conductivity. The samples for ESR measurement were carefully deoxygenated by the repetitive freeze-thaw technique and then substituted by dry nitrogen gas. ESR spectra were recorded on JEOLCO model PE-1X spectrometer equipped with a variable temperature accessory. The temperature control was checked with a copper-constantan thermocouple and found to be stable within ±0.5 °C. The magnetic field sweep was calibrated by a Würster's blue perchlorate sample.[13] The measurements of electrolytic conductivity were carried out by means of Yokogawa-Hewlett-Packard (YHP) model 4255A conductivity outfit connecting 4440B decade capacitor (YHP) at 25.0±0.1 °C.

Results and Discussion

The relations of conductivity against concentration for SL-SDS and SDS are shown in Fig. 1. The kink point in the conductivity curve indicated that the critical micelle concentration (CMC) of SL-SDS was 21.6 mmol kg^{-1} at 25.0±0.1 °C. The CMC of SL-SDS lies between those of SDS (8.3 mmol kg^{-1}) and SDeS (33.2 mmol kg^{-1}). It is found at first sight that the slope of a straight line below the CMC of SL-SDS is almost the same as that of SDS, but above CMC the slope of the line for SL-SDS is greater than that for SDS. The difference in the slope of conductivity *vs.* concentration for these surfactants above CMC may be largely dependent on the strength of hydrophobic interaction among the surfactant ions. That is, the smaller slope for SDS will be attributed to the strong hydrophobic interaction which gives rise to the rigid micelle with larger aggregation number, while the greater slope for SL-SDS will represent the weak hydrophobic interaction which produces the soft micelle with smaller aggregation number. The weak hydrophobic interaction of SL-SDS may be ascribed to hydrophilic oxazolidine ring introduced into the hydrocarbon chain.

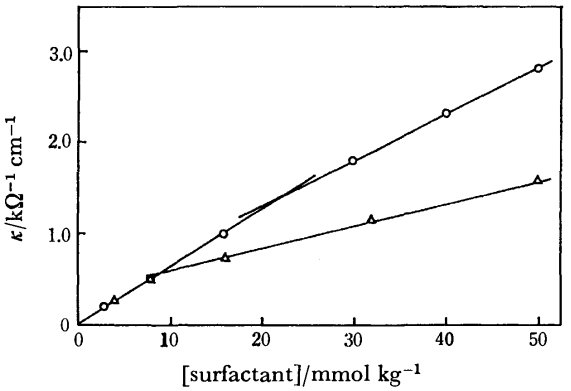


Fig. 1. Relation of specific conductivity *vs.* concentration for SL-SDS(○) and SDS(△) at 25.0±0.1 °C.

Kimizuka and Satake[14] presented the equation for estimating aggregation number from conductivity data as follows:

$$\left(\frac{\Lambda_0-\Lambda}{\Lambda_0-\Lambda_m}\right)^2 = \left\{(z_d-z_c)+(z_d+z_c)\frac{m}{m_m}\right\}\Big/(z_g+z_d), \quad (1)$$

where Λ_0 and Λ_m are the equivalent conductivities at infinite dilution and CMC, respectively. Further, z_g and z_d denote the charges of gegen and detergent ions, respectively, m, the concentration in the gram formula weight per kilogram, m_m, critical micelle concentration, and z_c, the aggregation number of micelle. For SL-SDS, Λ_0=69.4, Λ_m=63.6, $|z_g|=|z_d|=1$ and m_m=21.6 mmol kg^{-1} were obtained respectively. The aggregation number of SL-SDS micelle, $z_c\simeq 6$, was evaluated by inserting these values in Eq. 1. This value is very small as compared with the aggregation number ($z_c\simeq 60$) of SDS. The increase in CMC and the decrease in micellar aggregation number of SL-SDS compared with SDS indicate that the micelles are formed under the influence

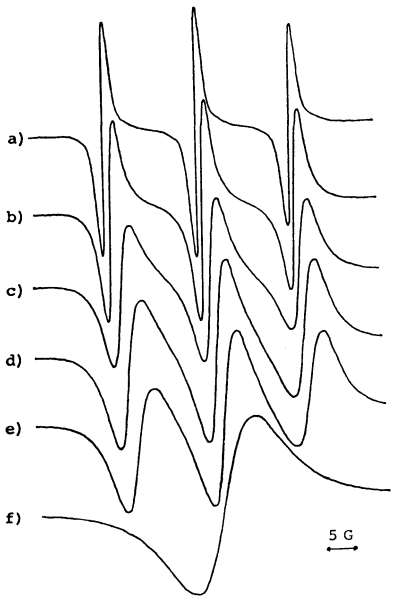

Fig. 2. ESR spectra of SL-SDS in a) 8, b) 16, c) 30, d) 40, e) 50, and f) 250 mmol kg^{-1}, respectively, at 25 °C.

of the weak hydrophobic interaction as well as the steric hindrance due to oxazolidine ring.

Figure 2 represents the ESR spectra of SL-SDS as a function of concentration at 25 °C. As the concentration of SL-SDS increases, each line width of nitroxide radical becomes broader and two side bands ($M=\pm 1$ lines, where M is the nuclear spin quantum number) shift gradually to the center of the spectrum so that the individual lines coalesce into one broad line at about 250 mmol kg^{-1}. These phenomena can be well interpreted in terms of spin exchange which results from the collision among the radical molecules.[15]

Above CMC, the ESR spectrum of micellar solution with both large aggregation number and low CMC may indicate the superposition of the three sharp lines and single broad line caused by singly dispersed and micellar surfactants, respectively.[16] However, in the case of SL-SDS the superposed monomer-micelle signal was not observed. On the other hand, the ESR spectrum of SL-SDS solution containing 1 mol kg^{-1} NaCl gave rise

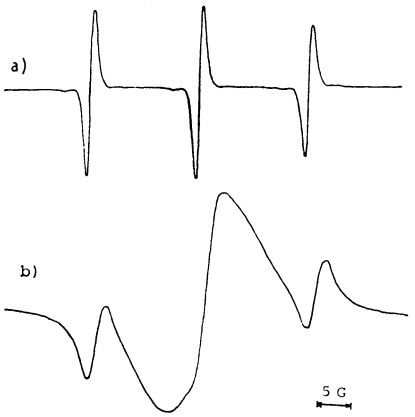

Fig. 3. ESR spectra of SL-SDS solution containing 1 mol kg^{-1} NaCl in a) 8 and b) 100 mmol kg^{-1} at 25 °C.

to the superposed signal as shown in Fig. 3. This implies that the aggregation number of the micelle increases by the added salt. Therefore, the fact that the superposed signal is not observed in SL-SDS solution may be ascribed to a small aggregation number of SL-SDS micelle in agreement with the result of the conductivity measurement. Taking account of the results mentioned above, the observed spectra in (c)—(f) of Fig. 2 are explained as the effect of spin exchange caused by the interaction between the singly dispersed surfactant ions and the surfactant ions of a soft micelle with a small aggregation number.

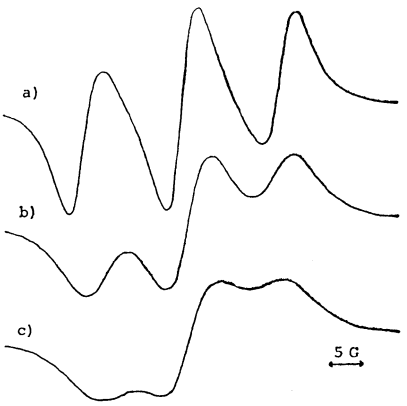

Fig. 4. ESR spectra of 50 mmol kg^{-1} SL-SDS solution at a) 25 °C, b) 55 °C, and c) 70 °C.

The ESR spectra recorded at various temperature are shown in Fig. 4. The broadening of the line width and the shift reflect mainly the effect of spin exchange due to the rise in temperature.

Generally, the analysis of line width offers the important information on the dynamic state of the molecule. In SL-SDS solution, the variation of line width as a function of temperature and concentration may be mainly dependent on spin rotation,[17] dipolar interaction, spin exchange, and monomer-micelle exchange effect.

Foremost spin rotational relaxation is caused by the interaction between the rotational magnetic moment of a paramagnetic molecule and its spin magnetic moment. In order to examine the contribution to the line width of spin rotational relaxation, the line width was plotted against a function T/η, where η is the viscosity of the medium and T is the absolute temperature. For this system, the solution of 5×10^{-5} mol kg^{-1} was used so that the other relaxation effects except spin rotation could be ignored. As shown in Fig. 5, the relation between line width ($M=+1$ line) and T/η exhibits a small contribution to line width of spin rotational relaxation. In Fig. 5, in order to inquire the effect of small spherical molecule, the line width of CTMPY is also plotted against T/η. Clearly, the relaxation due to spin rotation of the latter was more dominant as compared with the former. However, it can be said that the effect of spin rotation of SL-SDS, is slightly dependent upon radical concentration.

Secondly, when radical concentration increases, it

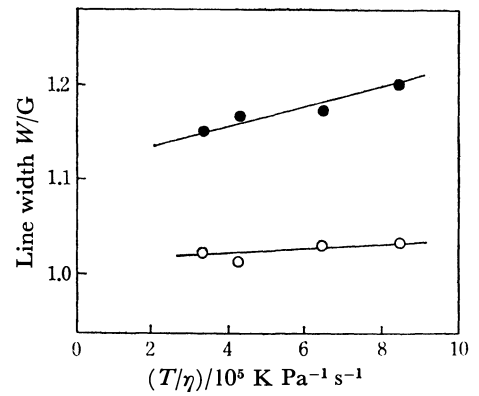

Fig. 5. Width of the $M=+1$ line *vs.* T/η for SL-SDS(○) and CTMPY(●) at each 5×10^{-5} mol kg^{-1} solution.

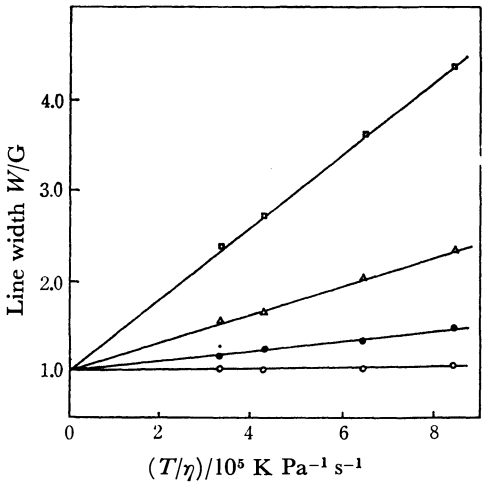

Fig. 6. Width of the $M=+1$ line *vs.* T/η for SL-SDS in 0.05 (○), 4 (●), 8 (△), and 18 mmol kg^{-1} (□), respectively.

will be necessary to consider the contribution to the line width by electron spin dipolar interaction and spin exchange.[18,19] Electron-electron intermolecular dipolar interaction should be proportional to η/T, while spin exchange interaction should be proportional to T/η. The observed line width in the concentration range from 0.05 to 20 mmol kg^{-1} showed the dependence on T/η and the intercept in each concentration coincides with each another, as shown in Fig. 6. This indicates that the relaxation by spin exchange is predominant in this concentration range. As a result, it may be concluded that the dipolar interaction would not exist in the above concentration range. Furthermore, the fourth effect, *i.e.*, monomer-micelle exchange is taken into consideration for the analysis of line width indicated below.

In Fig. 7, widths of $M=+1$ line *vs.* concentration of SL-SDS for each temperature are given, in which the line width is given by subtracting the line width ($W(0)$) due to spin rotation at 5×10^{-5} mol kg^{-1} SL-SDS from the observed line width (W). The line width ($W-W(0)$) remains almost constant below about 2 mmol kg^{-1} but increases linearly with concentration in the range of 2—20 mmol kg^{-1} due to spin exchange effect. Spin exchange effect is also dependent on temperature and the width increases with the rise in temperature. Above

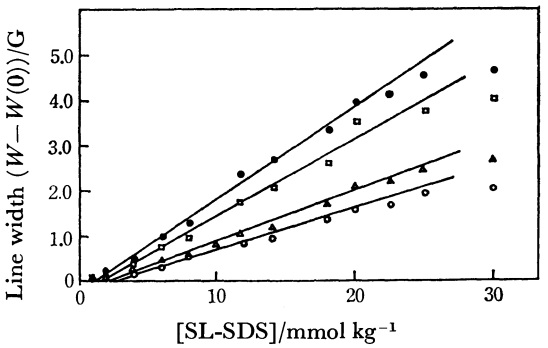

Fig. 7. Width of the $M=+1$ line *vs.* concentration of SL-SDS at 25 °C (○), 35 °C (△), 55 °C (□), and 70 °C (●).

about 20 mmol kg^{-1}, which corresponds to CMC of SL-SDS obtained from the conductivity measurement, the plot of line width *vs.* concentration deviates from a straight line. The effect of monomer-micelle exchange on the line width is not clear because of the signal distortion above 20 mmol kg^{-1} and the small aggregation number of the micelle.

In order to understand the behavior of the surfactant ions at molecular level, it is desirable and valuable to know the rate constant of spin exchange. Here, provided that spin exchange is regarded as a second order chemical reaction, a second order rate constant can be obtained from the line width.[19] Therefore, according to the method of Eastman *et al.*,[19] the rate constant was estimated and was compared with that obtained from the treatment of the diffusion controlled model.[20]

According to their theory, the second order rate constant k_2 is given as follows:

$$k_2 = \frac{3\sqrt{3}}{4}|\gamma_e|h, \qquad (2)$$

where γ_e is a magnetogyric ratio of a free electron, and h is the slope of a linear plot of the line width *vs.* concentration at a constant temperature in Fig. 7. The values of k_2 at various temperatures were obtained from Eq. 2 and are given in Table 1.

Table 1. Values of second order rate constant for spin exchange

T / K	$k_2\times10^{-9}$ / kg mol^{-1} s^{-1}	$k_2'\times10^{-9}$ / kg mol^{-1} s^{-1}
289	2.2	3.6
308	2.7	4.7
328	4.0	7.1
343	5.0	9.3

On the other hand, when the probability of spin exchange between two spins during an encounter is close to unity, the reaction limited by the rate of encounters is described as diffusion controlled.[20] Under these conditions, the second order rate constant k_2' is determined by the collision frequency among the radicals. On using the Stokes-Einstein relation for the Brownian diffusion of SL-SDS molecules in the solution, the following equation for collision frequency ν can be

obtained,

$$\nu = \frac{4kT}{3\eta} n^2, \quad (3)$$

where n is equal to the radical concentration, η, solvent viscosity, and k, Boltzmann constant. In this case the second order rate constant k_2' is given by

$$k_2' = \frac{N_A}{1000\rho} \frac{4kT}{3\eta}, \quad (4)$$

where N_A is the Avogadro number and ρ, density of the solution. The calculated values using Eq. 4 are also represented in Table 1.

In Table 1, the values of k_2 and k_2' at various temperatures are summarized. The dependence of these values on temperature is accounted as the increase of collision between spin molecules. These orders of k_2 and k_2', 10^9 kg mol^{-1} s^{-1}, are well consistent with the spin exchange rates for several free radicals in solution.[19,21] This consistency indicates that spin exchange between SL-SDS molecules in this study also can be regarded as diffusion controlled process. However, though k_2 and k_2' are of the same order, the values of the latter are approximately twice as large as those of the former. The fact that k_2 is not exactly in accord with k_2' may be ascribed to the approximation in which SL-SDS molecule is assumed as small spherical one. In the case of long chain molecule such as SL-SDS, it is a problem whether Stokes-Einstein relation can be simply applied to the system or not. It is probable that diffusion constant of SL-SDS is slightly smaller than that of the simple spherical molecule. On the other hand, regarding SL-SDS molecule as a spherical one in using Stokes-Einstein relation, diffusion constant of SL-SDS becomes more or less larger than true diffusion constant. Therefore, the difference of k_2 and k_2' may be ascribed to the incorrect estimation of diffusion constant. Considering the crudeness of the relation described above, the agreement would be satisfactorily good. In the end, it is concluded that the spin exchange for SL-SDS molecules is the same bimolecular reaction as that for small organic free radicals interpreted by diffusion controlled model.[21]

The authors wish to thank Dr. Junji Inanaga of Kyushu University for his helpful suggestions for SL-SDS preparation. We are also grateful to Dr. Sunao Tokii of Saga University for permitting us to use an ESR apparatus.

Infrared and ESR Spectra of Reaction Intermediates Formed from 1,1-Diphenylethylene Adsorbed on Oxides

Noriko TANI, Asako KAWAMORI, and Haruka YAMADA*

Faculty of Science, Kwansei Gakuin University, Nishinomiya, Hyogo 662

(Received July 26, 1979)

When 1,1-diphenylethylene (DPE) was adsorbed on porous Vycor glass (PVG) or silica–alumina, some unstable reaction intermediates, blue, green, and yellow species, were formed. The blue species produced on the silica–alumina showed a characteristic band at 1525 cm^{-1}, assigned to the shifted C=C stretching band, which disappeared in the green and yellow samples; it also showed an ESR signal. This indicates that the unstable blue species is probably a cation radical $\left[\begin{matrix}\Phi\\ \Phi\end{matrix}\!\!>\!C\!-\!CH_2\right]^+$. The infrared spectra of the green and yellow species on the silica–alumina showed new bands, ascribed to the $-CH_3$ and $-CH_2-$ vibrations, which were in good agreement with the resonance Raman bands of the carbonium ions formed on the PVG. The green and yellow intermediates, therefore, should be two kinds of carbonium ions. The structures, formation mechanisms, and surface coverages of these intermediates are discussed.

We first applied the resonance Raman technique to the study of a small amount of surface species; the resonance Raman spectra could be successfully obtained for halogens adsorbed on silicas,[1] reaction intermediates on porous Vycor glass,[2] dye adsorbed on a working ZnO electrode[3] and pyridines adsorbed on various oxides.[4]

When 1,1-diphenylethylene (DPE) was adsorbed on porous Vycor glass (PVG) treated at 500 °C, two carbonium ions, reaction intermediates, were detected by means of the resonance Raman spectra.[2] In the present work, the infrared and ESR spectra of the reaction intermediates formed from DPE adsorbed on oxides have been studied in order to obtain more precise information about the vibrational spectra of the reaction intermediates and also about the adsorption mechanism. As adsorbents PVG treated at a higher temperature (800 °C) and silica–alumina were used in this study; they had more Lewis or Brönsted acid sites than the PVG treated at 500 °C.

On the other hand, reaction intermediates produced by the adsorption of DPE on silica–alumina were studied by measuring the ESR and electronic spectra.[5–10] The structures of the intermediates, however, are still in question. Some radical species were really found on silica–alumina by observing the ESR signal. However, it is uncertain whether the radical is produced directly from the DPE adsorbed or whether it is concerned with any impurity involved.

Experimental

The porous Vycor glass used was obtained from Corning Glass Works, No. 7930; 1 mm thick transparent sheet, containing 96.3% SiO_2 and 2.9% B_2O_3. It was cut into 20×10 mm sections. Then it was pretreated in the same way as that for the resonance Raman measurements;[2] it was heated at 500 °C in 500 Torr** oxygen for 4 h and then degassed at 800 °C for 10 h. The surface area was 130 m^2/g,[11] compared with 170 m^2/g[1] for the PVG treated at 500 °C.

The silica–alumina was obtained from the Catalysts and Chemicals Ind. Co.; it was 13.8% Al_2O_3 and 85.9% SiO_2 and consisted of particles 60 μm in diameter. It was pressed into disks (10 or 20 mm in diameter) whose optical thickness was about 10 mg/cm^2. This was heated at 500 °C in 500 Torr** oxygen and then degassed at 400 °C (or 500 °C) for 3 h.

The 1,1-diphenylethylene used was obtained from Nakarai Chemicals (99.8%) and also from Wako Chemicals and Tokyo Chemicals (99%). This DPE was used after having been degassed by alternate freezing and thawing. The infrared spectra of these three DPE's did not show any difference from one another, and the 99% DPE did not show any appreciable OH stretching band.

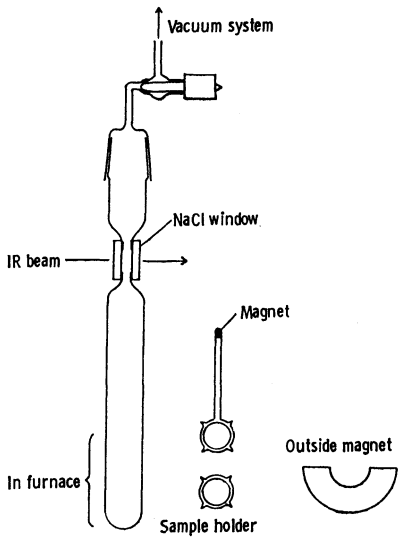

Fig. 1. Infrared absorption cell made of quartz. Sample was fixed in the holder with platinum wire and placed into the cell tube.

An infrared cell made of quartz was specially designed, as is shown in Fig. 1; it consisted of a tube and a sample holder. There were NaCl windows where infrared light passed through. The distance between these two plates was only 5 mm, so that atmospheric vapors could hardly interfere at all with the spectra obtained. A small magnet was enclosed in the tip of the holder, so a sample fixed in the holder could be moved up to the window for the infrared measurement. Greaseless stopcocks and a connector were used.

The infrared spectra were measured with a JASCO DS-402

** 1 Torr ≃ 133.3 Pa.

G infrared spectrophotometer and a modified JASCO DS-3 0 1 infrared spectrophotometer especially designed for the use with small samples.[12] The ESR measurements were carried out with a JEOL-JES 3B-type X-band spectrometer using 100 kHz modulation.

Results and Discussion

PVG. When the vapor of DPE was adsorbed onto PVG, some unstable intermediates were produced. First, a blue species was found, and then it gradually changed to a green species and then to a yellow species. Finally, the sample became reddish brown. The blue, green, and yellow species, therefore, might be reaction intermediates. The color development observed was the same for both DPE's; 99.8% and 99%. Since the PVG (1 mm) absorbed infrared light strongly in the region below 2000 cm^{-1}, only the >2000 cm^{-1} region could be used for the measurements of the reaction intermediates. When a disk (*ca.* 0.1 mm thick) made of PVG powder was used instead of 1 mm PVG, it was fairly transparent in the <2000 cm^{-1} region. However, no band assigned to the unstable species adsorbed on that disk could be detected, so the number of surface species adsorbed on it must be quite small.

The infrared spectra for the blue, green, and yellow samples are shown in Fig. 2. (a) shows the spectrum of PVG pretreated at 800 °C as a background. The two bands at 3747 and 3703 cm^{-1} are assigned to the free surface OH groups.[13] The spectra for the colored samples are shown in (b), (c), and (d). For comparison, the liquid spectrum of DPE is also given in Fig. 2.

A new OH band at 3610 cm^{-1} appeared in these (b), (c), and (d) spectra. This is a shifted OH band due to the interaction of surface OH groups with the π-electrons of DPE. Further, these spectra showed new bands at 2966 and 2926 cm^{-1}; these bands increased in intensity in the order of (b), (c), and (d). An additional band at 2865 cm^{-1} appeared in the (c) and (d) spectra. These three new bands can be assigned to the CH stretching vibrations of $-CH_3$ and $-CH_2-$ groups. On the other hand, the olefinic band at 3083 cm^{-1} decreased. That is to say, the bond order of the olefinic C=C decreased upon adsorption, while new surface species with aliphatic $-CH_3$ and $-CH_2-$ groups were formed on the PVG. In Table 1 the absorption peak frequencies observed for the DPE adsorbed on PVG

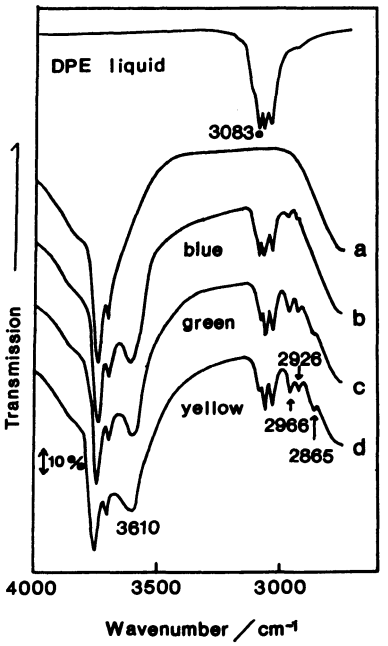

Fig. 2. Infrared spectra of DPE adsorbed on PVG pretreated at 800 °C for 10 h; (a) background, (b) blue, (c) green, and (d) yellow samples.

are listed, with the relative intensities in parentheses. The amounts of the intermediates produced on the PVG are rather small, so only the bands in the 3 μm region can be detected by using the 1 mm thick PVG. The blue species is probably a kind of radical, because the ESR signal was observed for the blue sample.[2]

Silica–Alumina. When the 99.8% DPE was adsorbed on the silica–alumina pretreated at 400 °C for 3 h, the sample appeared blue or blue-green immediately and then changed to a deeper color as the amount of adsorbed species increased. After the sample had been kept at 80 °C for 20 h, it turned green and then to yellow (after several days), and finally it became brown. Much more reaction intermediates were produced on the silica–alumina than on the PVG. When the 99.8% DPE was adsorbed on the silica–alumina pretreated at 500 °C for 3 h, the sample showed a rather green color at first, while when the 99% DPE was used instead of the 99.8% DPE on the silica–alumina pretreated at 500 °C, the sample appeared rather blue at first. All the blue samples gradually changed in

color in the order of green, yellow, and brown when they were kept at room or a higher temperature. Thus, the blue, green, and yellow species formed on the silica-alumina must be reaction intermediates, though there was a little difference in the color development of the samples. Dollish and Hall[10] reported that lemon yellow appeared on the silica-alumina pretreated at 540 °C for 24 h; they pretreated the silica-alumina at a higher

temperature and for a longer period than in the present work.

Figure 3 shows the observed spectra for the colored samples on the silica–alumina pretreated at 500 °C. The spectrum of the yellow sample was similar to (d). The spectra observed for the adsorbed species differed from that of liquid DPE as follows: Three new bands appeared at 2966, 2930, and 2866 cm^{-1}; they were assigned to the aliphatic CH stretching bands. On the other hand, the olefinic CH band of DPE at 3083 cm^{-1} decreased in intensity in the 3 μm region. In the region below 1700 cm^{-1} the blue sample showed a characteristic new band at 1525 cm^{-1} (b). This band was also found for the blue-green sample (c), but it disappeared for the green sample (d). The (c) and (d) spectra showed distinct bands at 1476 and 1376 cm^{-1} which could be assigned to the aliphatic CH bending vibrations. On the other hand, the 1611 and 1331 cm^{-1} bands of DPE almost disappeared for the adsorbed species. The 1611 and 1331 cm^{-1} bands can be assigned to the olefinic C=C stretching and CH deformation vibrations respectively. Since these bands disappear in (b), (c), and (d), it follows that the double bond might vanish for the adsorbed species. In Table 2 the absorption peak frequencies observed for the DPE adsorbed on the silica–alumina are listed, with the relative intensities in parentheses.

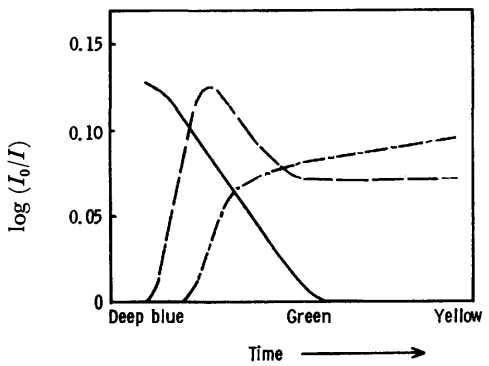

Fig. 4. Intensity changes accompanied with color development; (——) 1525 cm^{-1} band ascribed to radical species, (-•••-) 1476 cm^{-1} band assigned to $-CH_2-$ bending vibration and (----) 1376 cm^{-1} band assigned to $-CH_3$ bending vibration.

The relationship between the color development of the sample and the infrared band intensities can be seen in Fig. 4. The abscissa shows the color change with the time after the DPE has been adsorbed, while the ordinate shows the relative peak height of each band. As the blue species decreased, the 1525 cm^{-1} band rapidly dropped, while the 1476 cm^{-1} band increased in intensity. The 1476 cm^{-1} band could be assigned to the $-CH_2-$ deformation, and the 1376 cm^{-1} band, to the $-CH_3$ deformation. These two bands (1476 and 1376 cm^{-1}) must be ascribed to the unstable reaction intermediates. The present infrared spectra observed for the blue-green, green, and yellow samples are in good harmony with the results of the resonance Raman spectra for DPE adsorbed on the PVG. The reaction intermediates, therefore, must be the carbonium ions;[2]

where A represents the adsorbent.

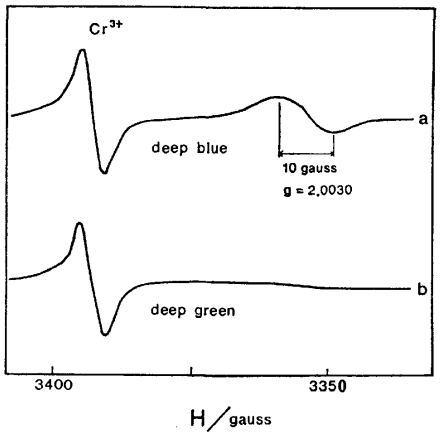

Fig. 5. ESR spectra of DPE adsorbed on silica–alumina pretreated at 500 °C for 3 h (9 GHz); (a) deep blue and (b) deep green samples.

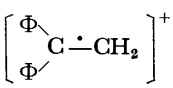
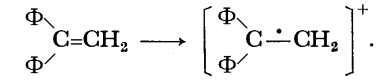
In order to ascertain whether the reaction intermediates were paramagnetic or not, we measured the ESR spectra for these samples. Figure 5 shows the ESR spectra obtained for the blue and green samples with the signal belonging to the Cr^{3+} ion (g=1.9800) doped in MgO added as a standard material. The blue sample had a broad signal centered at g=2.0030, whose half-width was about 10 G,*** while the green sample did not show any ESR signal. Consequently, it is found that the blue sample certainly included some radical. The ESR signal observed for the blue sample was also observed for the deep blue or blue-green samples, but not for the green sample. This ESR signal coincides well with that observed by Leftin *et al.* for the blue sample on silica–alumina.[7]

Since the infrared 1525 cm^{-1} band characteristic of the blue species was observed, the 1525 cm^{-1} band must be ascribed to a radical which showed the ESR signal. For this radical the following structure must be considered;



which is consistent with the results of the observed infrared and ESR spectra. When the DPE changes to this radical, the C=C band has to shift to the lower-frequency side. The band observed at 1525 cm^{-1} is lower than the 1611 cm^{-1} band by 90 cm^{-1}; this shift corresponds well to this change:

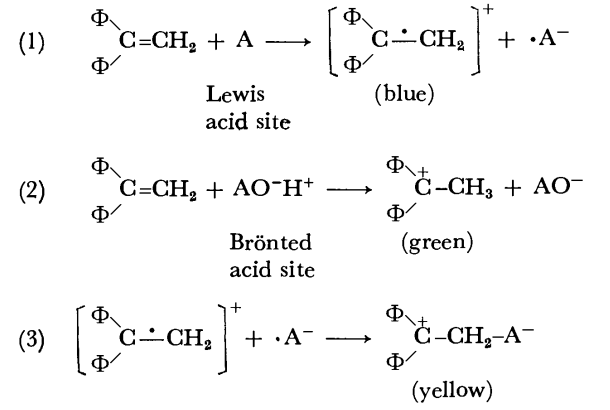


It is the first time that the vibrational spectrum of this unstable radical has been detected.

Now we have actually found these three reaction intermediates formed on the silica–alumina, a cation

*** 1 G = 10^{-4} T.

radical, and two carbonium ions. We shall now proceed to consider the formation mechanism of these reaction intermediates. When DPE was adsorbed on the Lewis acid site, the cation radical could be formed. If the proton was accepted by the DPE on the Brönsted acid site, the carbonium ion, $\Phi\diagdown\atop\Phi\diagup$C$^+$–CH$_3$, could be formed. The cation radical combined with the Lewis acid site changes to the carbonium ion, $\Phi\diagdown\atop\Phi\diagup$C$^+$–CH$_2$–A. More



blue species were formed when the silica-alumina was pretreated at a lower temperature or for a shorter period. Therefore, it seems likely that the surface OH groups play an important role in the formation of the blue species. However, it is not clear whether or not this role of the OH groups is catalytic. For the cation radical, a modified C=C stretching vibration was observed, while for the carbonium ions, $-CH_3$ and $-CH_2-$ stretching and deformation vibrations were observed. The CH stretching bands for the carbonium ions are in good agreement with those of the resonance Raman spectra of the carbonium ions formed on the PVG.

Now we would like to consider the coverage of the intermediates. When DPE was adsorbed on PVG or silica-alumina, the reaction intermediates with physically adsorbed DPE were formed. The CH stretching vibration of the phenyl group at 3061 cm^{-1} is supposed to be hardly changed when the DPE is changed to the three intermediates described above or a physically adsorbed species. Therefore, if the absorption intensities of the 3061 cm^{-1} bands for all the adsorbed species are the same as that of the liquid DPE, the total amount of the adsorbed species can be estimated from the observed intensities; 0.05 molecule/nm^2 for the PVG treated at 800 °C and $\approx$1.4 molecule/nm^2 for the silica-alumina treated at 500 °C. The intensity decrease of the olefinic band at 3083 cm^{-1} may be proportional to the amount of the intermediates. For the DPE on the PVG, this decrease was $\approx$10% for the blue sample, $\approx$20% for the blue-green sample, and 30—40% for the green or yellow sample. The intensity of the 3061 cm^{-1} band was almost constant during this color changing of the sample. For the DPE on the silica-alumina, the intensity decrease of the 3083 cm^{-1} band was found to be $\approx$70% for all the samples (blue to yellow). Therefore, the coverage of the intermediates and products should be 0.005—0.02 molecule/nm^2 on the PVG and $\approx$1 molecule/nm^2 on the silica-alumina in Table 3, judging from the surface areas of 130 m^2/g on the PVG and $\approx$500 m^2/g on the silica-alumina.[14]

Table 3. Coverage of surface intermediates formed from DPE

(molecules/nm^2)

Adsorbent	θ (total)	θ (intermediates and products)
PVG(800 °C)	0.05	0.005—0.02
Silica-alumina (500 °C)	$\approx$1.4	$\approx$1

Table 4. Numbers of Lewis and Brönsted acid sites obtained from the adsorbed pyridine

(molecules/nm^2)

Adsorbent	Lewis acid site	Brönsted acid site
PVG (800 °C)	0.05	Not observed
Silica-alumina (500 °C)	0.2	0.04

Let us now compare these coverages with the numbers of Lewis and Brönsted acid sites[15] which could be found from the experiments on adsorbed pyridines (Table 4). The numbers of Lewis acid sites were estimated by comparing the intensities of the 1629 cm^{-1} (on the PVG) and 1452 cm^{-1} (on the silica-alumina) bands with those of the 1610 cm^{-1} (ν_{8a}) and 1450 cm^{-1} (ν_{19a}) bands[16] of pyridine respectively in the (pyridine)$_2$–$ZnCl_2$ complex. Also, the number of Brönsted acid sites on the silica-alumina was obtained by comparing the intensity of the 1545 cm^{-1} band of adsorbed pyridine with that of the 1528 cm^{-1} (ν_{19b}) band[16] of pyridine in the pyridine-HCl complex. The coverage of the intermediates on the PVG is comparable to the number of Lewis acid sites, while the coverage on the silica-alumina seems much more than that of the Lewis or Brönsted acid sites.

Structures and Properties of 5-Substituted Cytosines. II.** The Crystal Structure of 5-Methylcytosine Hemihydrate

Akio TAKENAKA,* Masuhiro KATO, and Yoshio SASADA*

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received July 30, 1979)

The crystal structure of 5-methylcytosine hemihydrate has been determined by an X-ray analysis to investigate the substitution effect on the cytosine moiety. The space group is C2/c, with unit-cell dimensions $a=17.832(4)$, $b=8.261(2)$, $c=10.641(3)$ Å, $\beta=125.12(1)°$, and $Z=8$. The hydrogen bonding scheme is quite different from that of cytosine, its monohydrate, 5-bromocytosine, and its dioxane hemi-solvate. This is ascribed to the packing effect of the methyl group. A comparison with the cytosine structure indicates some deviations in bond lengths and angles, which are due to the steric and electronic effects caused by methylation. The similar values of the C(2)–N(3)–C(4) angle in cytosine and 5-methylcytosine can be related to a resemblance of their pK_a values.

In the course of the studies on the protein: nucleic acid interaction, we have found two different interaction modes of acidic amino acids with cytosine and 5-bromocytosine.[1-4] To interpret this in terms of the molecular structure of the component, crystal structures of 5-substituted cytosines have been determined by X-ray analyses.

Previously it was revealed that the geometrical change of cytosine upon bromination at C(5) is related to its physico-chemical property in solution.[5] The present paper deals with the crystal structure of 5-methylcytosine. Since its substituent has almost the same van der Waals radius[6] as bromine but electronically opposite effect, the comparison of their structures will give some additional supports to the view mentioned in the previous paper.[5]

Experimental and Structure Determination

5-Methylcytosine was purchased from Aldrich Chemical Co. Crystals were obtained from an aqueous solution. Density was measured by flotation in a mixture of cyclohexane and carbon tetrachloride. Weissenberg photographs showed the systematic absences, hkl for $h+k=2n+1$ and $h0l$ for $l=2n+1$, indicating the space group to be C2/c or Cc. A crystal $0.3\times0.3\times0.4$ mm was used for data collection on a Rigaku four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). The unit-cell dimensions were determined with 24 high angle reflexions. Intensities were measured in the ω-2θ scan mode with a scan width of 1.25° (in ω) plus α_1-α_2 divergence and a scan speed of 4° (in 2θ) min^{-1}. Four reference reflexions showed no significant intensity deterioration throughout the data collection. The intensities were corrected for Lorentz and polarization factors but not for absorption effects. Of 850 independent reflexions in the range $2<2\theta<55°$, 93 reflexions with F_o less than $3\sigma_P(F_o)$ were considered zero reflexions, where $\sigma_P(F_o)$ is evaluated by counting statistics; the observational threshold value, F_{llm}, was 3.70. The standard deviations were estimated by the equation of $\sigma^2(F_o)=\sigma_P^2(F_o)+qF_o^2$, where q, 3×10^{-5}, was derived from the variations of the monitored reflexions.[7] Crystal data are summarized in Table 1.

Normalized structure factor statistics strongly indicated the space group to be centrosymmetric, C2/c. The structure was solved by the direct method and its parameters were refined by the full-matrix least-squares method. All the hydrogen atoms, found on a difference map, were included. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, with $w=1/\sigma^2(F_o)$. The zero reflexions were included in least-squares calculation by assuming $F_o=F_{llm}$ and $w=w(F_{llm})$; those for which $|F_c|<F_{llm}$ were omitted. The final R was 0.066 ($R=0.056$ for $F_o>3\sigma(F_o)$); the maximum shift of parameters in the last cycle was 0.02σ for C, N, and O, and 0.18σ for H atoms. Atomic scattering factors used were taken from International Tables for X-ray Crystallography.[8] Atomic parameters are listed in Table 2, and observed and calculated structure factors in Table 3.[9]

$\beta=125.12(1)°$	
$U=1282.1(6)$ Å^3	

Results and Discussion

Crystal Structure. Figure 1 shows the crystal structure. Hydrogen bond distances and angles are given in Table 4 (as for atomic numbering, see Fig. 2). Two N(4)–H(4A)···N(3) hydrogen bonds between molecules related by the inversion at (1/4, 1/4, 1/2) constitute a cytosine dimer. This pattern is similar to the dimer component of the cytosine ribbon found in 5-bromocytosine: *N*-tosyl-L-glutamic acid and 5-bromocytosine: *N*-phthaloyl-DL-glutamic acid complexes.[1,2] The carbonyl oxygen, O(2), is an acceptor of hydrogen bond from the remaining N(4)–H(4B) group of the adjacent molecule to form a layer of the dimers. The water molecule, the oxygen, O(W), of which is located on the two-fold axis, links the cytosine layers with two O(W)–H(W)···O(2) and two O(W)···H(1)–N(1) hydrogen bonds in tetrahedral disposition.

The hydrogen bonding scheme found in the present crystal is quite different from that of cytosine,[10] its monohydrate,[11] 5-bromocytosine,[5] and its hemi-dioxane solvate,[12] in which cytosines form a ribbon by the two hydrogen bonds, N(4)–H···O(2) and N(3)···H–N(1), along the 2_1 axis. This difference is ascribed to the

steric effect of methyl group at C(5) atom. A hypothetical model of 5-methylcytosine crystal was constructed using the parameters of 5-bromocytosine crystal by an interactive computer graphics,[13] and intermolecular atomic distances were calculated by rotating the methyl group around the C(5)–C(7) bond. Such an examination showed that the hydrogen atoms of the methyl group could be put considerably far from the surrounding atoms by an appropriate rotation, owing to the shorter C–CH_3 bond distance than C–Br bond, though van der Waals radii of bromine and methyl group are nearly the same.[6] In this crystal, therefore,

the packing of 5-methylcytosine molecules is thought to be looser than that of 5-bromocytosine.† Such a hypothetical loose packing of 5-methylcytosine is actual-

† Crystal structure of 5-bromocytosine closely resembles that of cytosine. In both crystals, the molecules form ribbons with hydrogen bonds along the two-fold screw axis. The only difference is the lacking of inter-ribbon hydrogen bonds in the former due to bromine substituents.[5] It is argued, therefore, that the former crystal is less stable than the latter one. This is supported by the fact that recrystallization of 5-bromocytosine from a water–dioxane mixture gives a complex with dioxane, in which the dioxane molecule links the 5-bromocytosine ribbons.[12] The screwed ribbon structure is thought to be barely allowed to be taken in the 5-bromocytosine crystal which was the basis of the present simulation.

ly forbidden and replaced by a different hydrogen-bond network involving the water in order that the molecules pack more effectively.

Molecular Structure. Bond lengths and angles are shown in Fig. 2 together with those of cytosine[14] and its monohydrate[14] for comparison. The bond lengths and angles involving the hydrogen atoms are given in Table 5. The deviations from the cytosine values may be attributed to the steric and electronic effects caused by methylation. After an interpretation of benzene ring deformation on the basis of the valence-shell electron-pair repulsion theory,[15] the electron-releasing group attached to C(5) atom makes the C(4)–C(5)–C(6) angle smaller. In addition, the lengthening of C(5)–C(4) and C(5)–C(6) bonds, which are due to repulsions between C(7) and C(4) or C(6) atoms, may allow to narrow the C(4)–C(5)–C(6) angle accompanied by the slight expansions of C(5)–C(4)–N(3) and C(5)–C(6)–N(1) angles. Although the distance between the C(7) and N(4) atoms looks rather short, there are no abnormal contacts between their hydrogen atoms. Steric hindrance between the methyl and amino groups is relieved by an appropriate rotation of the former around the C(5)–C(7) bond, so that the deviation of C(5)–C(4)–N(4) angle becomes small. The steric effect of the methyl group thus is buffered and does not extend to N(3), while that of bromine in 5-bromocytosine makes the C(2)–N(3)–C(4) angle slightly expand. The C(2)–N(3)–C(4) angle, which is varied little by the methyl substitution, suggests no significant change of the effective charge of lone-pair lobe at N(3), and this seems to be related to similar pK_a values of cytosine and 5-methylcytosine [4.58 and 4.6, respectively].[16] Table 6 shows the atomic net charges calculated by CNDO approximation[17] for cytosine and its 5-methyl derivative. Invariant charge at N(3) upon methylation supports the above interpretation.

As compared with cytosine structure, the shortening of the C(2)–N(3) and C(4)–N(4) bonds, and the lengthening of the C(2)–O(2) bond accompanied by the increase of N(1)–C(2)–N(3) angle are observed. These changes, though small, suggests the increase of the contribution from the canonical formula in which the amino nitrogen and the carbonyl oxygen carry positive and negative charges, respectively. Such an increase may be induced by the strong hydrogen bond from water molecule to the carbonyl oxygen. Similar trend is also observed in cytosine monohydrate, in which the water molecule participates in the same way.[11,14]

TABLE 6. NET CHARGE DISTRIBUTION

Cytosine		5-Methylcytosine

H(1)	0.031	H(1)	0.134
H(4A)	0.135	H(4A)	0.147
H(4B)	0.136	H(4B)	0.135
H(6)	0.001	H(6)	0.002
		H(7A)	0.009
		H(7B)	0.013
		H(7C)	0.014

TABLE 7. LEAST-SQUARES PLANE FOR PYRIMIDINE RING
X, Y, and Z are in Å along a^*, b, and c, respectively. Asterisks denote atoms defining the plane. Standard deviations are given in parentheses.

Equation

$$-0.0110(13)X+0.96519(33)Y+0.2613(12)Z-1.2394(54)=0$$

Deviations (l/Å) of atoms from the plane			
N(1)*	0.012	C(7)	−0.035
C(2)*	0.005	H(1)	−0.05
N(3)*	−0.016	H(6)	−0.08
C(4)*	0.011	H(4A)	0.03
C(5)*	0.006	H(4B)	0.17
C(6)*	−0.017	H(7A)	−0.02
O(2)	0.005	H(7B)	0.73
N(4)	0.016	H(7C)	−0.83

The least-squares plane of 5-methylcytosine together with the deviations of atoms from the plane is listed in Table 7. Although the pyrimidine ring with amino nitrogen N(4) and carbonyl oxygen O(2) is planar within 0.017 Å, the small deviations of atoms show the slight bending of the ring around the N(3)–C(6) axis. The methyl C(7) atom deviates on the opposite side of the plane to the amino group. This deviation is rather small as compared with that of bromine in 5-bromocytosine because of the relief of short contacts by an appropriate rotation of the methyl group mentioned above.

Figure 1 was drawn by TSD: XTAL, which is a computer-graphics interactive modelling programme for the NOVA 3 computer.[13]

Effect of Ultraviolet Ray on Graphite Fluoride in Organic Solvents

Nobuatsu WATANABE* and Kazuo UENO

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received March 16, 1979)

Graphite fluoride, $(CF)_n$, was photolyzed in alcohols and hydrocarbons. Hydrogen fluoride was formed in each case. Alcohols were partially converted into the corresponding carbonyl compounds by the reaction $2(C\text{–}F)+RR'CHOH \xrightarrow{h\nu} 2(C)+2HF+RR'C{=}O$. ESCA measurement revealed that the fluorine at the surface decreases more rapidly than that of the inner region of $(CF)_n$ particle, the inner region being also photolyzed. Results of DTA measurement indicate that the irradiation reduces the thermostability of $(CF)_n$.

Graphite fluoride, $(CF)_n$, is prepared by the reaction of fluorine gas with various carbon materials at high temperature. The crystalline structure consists of condensed cyclohexane-like carbon rings with fluorine atoms occupying the fourth coordination site of the sp^3-hybridized carbon atom.[1–3] Recently, the compound has been used as a superior lubricant[4–6] under extreme conditions of high temperature and high vacuum. It has also been found to be a cathodic depolarizer in high energy density batteries.[7–9] However, little is known about its chemical reactivity towards organic compounds. This paper deals with the effect of ultraviolet irradiation on graphite fluoride in various hydrocarbons and alcohols.

Experimental

Graphite fluoride with a F/C molar ratio of 1.16 was prepared by the direct fluorination of petroleum coke,[10] fine white powder with particle size greater than 400 mesh being obtained. All organic solvents were of reagent grade and used without further purification. Graphite fluoride dispersed in the solvent was irradiated at room temperature in a 500 ml photochemical reactor (Ushio Denki Co.) with a high pressure mercury lamp of 100 W (UM-102) put into a water cooling jacket made of Pyrex glass. The lamp emits ultraviolet rays (the output is indicated in parentheses) 3132 Å (2.10 W), 3650—3663 Å (3.08 W), 4047—4078 Å (1.26 W), and other rays with smaller power. The suspension was stirred with a magnetic stirrer during the course of irradiation. The oxygen dissolved in the solvent was removed by bubbling nitogen for half an hour before irradiation. After the irradiation, $(CF)_n$ was separated from the solvent by centrifugation, and then dried in a vauum. The sample was analyzed by means of X-ray photoelectron spectroscopy (ESCA), X-ray diffraction, and differential thermal analysis (DTA). The content of carbon, hydrogen and fluorine was determined by the usual method.[11]

Results and Discussion

Photochemical Decomposition of $(CF)_n$. The F/C molar ratio of $(CF)_n$, which was allowed to stand in MeOH without irradiation for more than six months remained almost unchanged. On the other hand, by ultraviolet irradiation for several hours, the color of $(CF)_n$ in organic solvent turned black or brown from white, the F/C ratio decreasing with increasing irradiation time. Thus, the decomposition of $(CF)_n$ by ultraviolet irradiation would proceed only in a solvent, considering the fact that $(CF)_n$ is photochemically stable in the air.

Since the F/C ratio decreased by irradiation, the photolysis of $(CF)_n$ may lead to the cleavage of a C–F bond rather than a C–C bond. In thermal decomposition of $(CF)_n$ in a vacuum or in inert gas, the initial step of the reaction may be the rupture of C–C bonds rather than C–F bonds.[12]

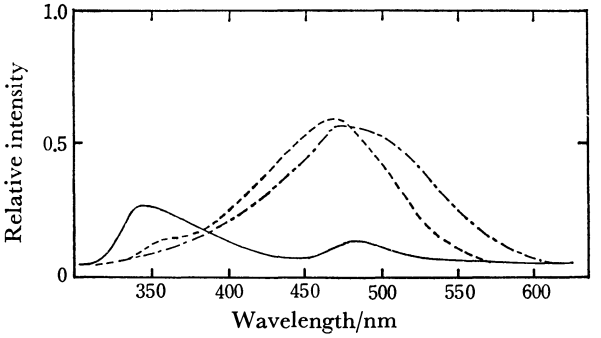

Fig. 1. Emission spectra of $(CF)_n$. Exciting wavelength is 290 nm. ——: in air, ——: in paraffin, –·–: in MeOH.

Figure 1 shows the emission spectra of $(CF)_n$ in the air, MeOH, and in liquid paraffin. The peak areas of the spectra both in MeOH and in paraffin were 3 times greater than those in the air. The coloration of $(CF)_n$ turns slightly dark when it is put into MeOH and paraffin, *viz.* solvatochromism takes place. The absorption spectrum of a solution changes with solvent without chemical reaction between solute and solvent. In the case of $(CF)_n$, the main peak in its emission spectra shifted to lower wavelength with increasing solvent polarity. Compounds which show such bathochromic effect are, in general, more polar in excited state than in the ground state.

Parry[13] calculated the band structure of $(CF)_n$ on the basis of the self-consistent semi-empirical LCMO method, and found that the direct band gap at the center of the Brillouin zone for a layer of $(CF)_n$ is 8.4 eV, *viz.*, 147.6 nm. The emission spectra were not in line with his results. This may be attributed to the $(CF)_n$ we prepared which has mechanical distortions and crystal defects such as exfoliation and crack, being far from Parry's ideal crystal.

The F/C ratio and decomposition ratio (α) of $(CF)_n$ after photolysis in various alcohols and hydrocarbons for 24 h are given in Table 1. The decomposition ratio,

Table 1. F/C ratio and decomposition ratio of graphite fluoride photolyzed for 24 h in various alcohols and hydrocarbons

Solvent	F/C[a)]	Decomposition ratio/%	Dielectric constant
MeOH	0.94	7.3	32.6
n-PrOH	0.97	6.3	20.1
i-PrOH	0.99	5.5	18.3
n-BuOH	1.01	4.9	17.8
t-BuOH	1.08	2.5	10.9
Hexane[b)]	1.09	2.3	1.9
Cyclohexane[b)]	1.07	2.8	2.0

a) Value of original $(CF)_n$ 1.16. b) Irradiation time 20 h.

α, is defined by

$$\alpha = \frac{F_0 - F}{F_0} \times 100,$$

where F_0 and F are the fluorine content of original sample and that of the sample photolyzed, respectively. Graphite fluoride was decomposed to a greater extent in alcohols than in hydrocarbons. α is proportional to the dielectric constant of the solvent. Thus, $(CF)_n$ seems to be polar at the transition state of the reaction. This is supported by the solvent effect of the emission spectra, if the excited state is the transition state of the reaction.

Photochemical Reaction in Alcohols. When photolysis was carried out for a longer time, the reaction mixture became acidic by the formation of hydrogen fluoride. When it was neutralized with aqueous sodium hydroxide, precipitation of sodium fluoride took place. This was confirmed by means of X-ray diffraction. The amount of hydrogen fluoride coincided with the net decrease of fluorine in $(CF)_n$.

The solvent was subjected to gas chromatography with Porapak R (Water Associates Inc.) as a separating packing. In *i*-PrOH and *n*-BuOH, the corresponding carbonyl compounds, acetone and butyraldehyde, respectively, were detected. From the results, photochemical decomposition of $(CF)_n$ in alcohols can be presented by

$$2(C\text{–}F) + RR'CHOH \xrightarrow{h\nu} 2(C) + 2HF + RR'C{=}O,$$

where R and R′ are either hydrogen or alkyl group.

ESCA Measurement. ESCA measurement was made on $(CF)_n$ photolyzed in MeOH for 27, 72, and 96 h (Fig. 2). The spectra show, in addition to the main peak at 290 eV (A_1), a broad shoulder at 292.4 eV (A_2) and a low intensity tail at *ca.* 294.4 eV (A_3), which are assigned to the carbon having $>CF$, $>CF_2$, and $-CF_3$ bonds, respectively.[14,15] After photolysis, the peaks became smaller, while a new peak appeared at *ca.* 286 eV (A_4), which may be the carbons having no C–F bond.[16] The peak at 285 eV is due to hydrocarbon contamination, and regarded to have approximately the same intensity in each run.

The relative peak area of these peaks, the F/C ratio calculated from above relative peak area, and that determined by elemental analysis are given in Table 2.

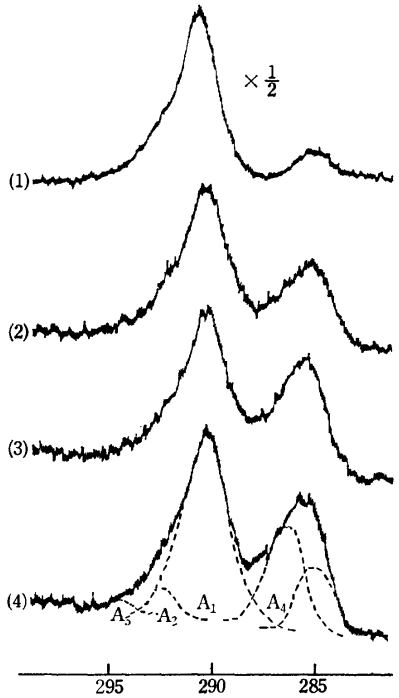

Fig. 2. The change in ESCA spectra of C_{1s} photoelectron of $(CF)_n$ photolyzed for various times in MeOH. (1) Original sample, (2) 27 h, (3) 72 h, (4) 96 h.

Table 2. Influence of time on the relative peak area of C_{1s} and F/C ratio of $(CF)_n$ photolyzed in methanol

Irradiation time h	C_{1s} peak/%				F/C ratio	
	A_1	A_2	A_3	A_4	(a)	(b)
0	79.4	16.0	4.6	0	1.33	1.16
27	67.3	5.0	4.6	23.1	0.91	0.93
72	59.5	4.4	3.8	32.3	0.80	0.86
96	60.9	3.6	2.7	32.8	0.76	0.84

a) Determined by means of ESCA spectrum. b) Determined by chemical analysis.

In the original $(CF)_n$, the F/C ratio calculated from the ESCA spectrum is higher than that from elemental analysis. This indicates that there are many $>CF_2$ and $-CF_3$ groups at the surface of the $(CF)_n$ particle. Since the electron escape depth for C_{1s} photoelectron is *ca.* 10 Å,[17] and the $(CF)_n$ particle has a diameter of several micrometers, only the surface region of solid can be examined by ESCA. By photolysis, the amount of fluorine at the surface decreased more rapidly than that of the inner region of the particle (Table 2). However, after photolysis for even 96 h, many fluorine atoms remained undecomposed at the surface as shown in Fig. 2, the F/C ratio at the surface no differing from that of the total particle. The reaction may proceed not only at the surface but also in the inner region of the solid, especially at cracks and mechanically distorted parts where the solvent can permeate.

Effects on the Structure of $(CF)_n$. No remarkable changes of the structure of $(CF)_n$ due to photolysis

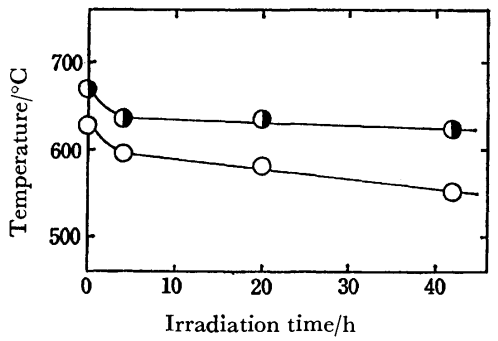

Fig. 3. The variation of the starting temperature, T_s, and of the peak maximum temperature, T_m, with the irradiation time.
○: T_s, ◑: T_m.

were observed by means of X-ray diffraction. A DTA curve of $(CF)_n$ prepared from flaky natural graphite showed an exothermic peak at *ca.* 670 °C. Figure 3 shows variation of the peak starting temperature, T_s, and of the peak maximum temperature, T_m, with irradiation time. Photolysis was carried out in MeOH, the DTA being measured in a vacuum. Both T_s and T_m decreased linearly, the peak being broadened with increasing irradiation time. The irradiated sample undergoes thermal decomposition at lower temperature as compared with the original one. The thermostability of $(CF)_n$ is reduced by irradiation.

Photoacoustic Spectrometry of Solid Samples. III. Microdetermination of Mercury as Hg Diphenylcarbazone Complex

Seiji KAWAMOTO, Yu YOKOYAMA,* and Shigero IKEDA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received April 12, 1979)

Photoacoustic spectrometry was applied to the determination of michroamount of Hg diphenylcarbazone complex. The photoacoustic spectrum and diffuse reflectance spectrum almost agree with each other, showing an absorption maximum at 560 nm, as in the absorption spectrum of the complex in benzene solution. Determination of Hg was performed by measuring the intensity of photoacoustic signal at 560 nm. The normalized signal intensity increased linearly with the amount of mercury ion up to 100 ng, deviating from linear relationship downwards above 100 ng. The photoacoustic signal saturation caused by strong absorption of radiation was investigated.

Photoacoustic spectrometry of solid substances was applied to the determination of Ni, Cu, and Al as Ni dimethylglyoxime complex, Cu thiooxine complex, and Al quinalizarin lake, respectively.[1,2] The complex or lake was formed on filter paper according to the procedure of spot test and the signal intensity by the photoacoustic effect of colored substances was measured. As the amount of the colored substance increased beyond a certain limit, the relation between the amount of substance and normalized signal intensity was no longer linear and the intensity deviated from linear relationship downwards.

Mercury ion forms a strongly colored insoluble complex with diphenylcarbazone. The complex shows violet to blue color and is contrasted with reagent blank in acidic medium. It has been used as a color reagent of mercury in both extraction spectrophotometric determination and spot test. Dithizone is also a very sensitive color reagent, but the reagent itself is intensely colored. The present work was undertaken for a study on the determination of microamount of mercury with diphenylcarbazone and the photoacoustic signal saturation.

Experimental

Apparatus. The photoacoustic spectrometer assembly for this work was the same as previously reported.[1,2] Absorption spectra and diffuse reflectance spectra were measured with a Hitachi 124 type spectrophotometer and a Hitachi 323 type recording spectrophotometer with integrating sphere, respectively.

Reagent. The stock solution of mercury was prepared by dissolving distilled mercury metal in concentrated nitric acid and by diluting the solution with deionized water. The concentration of mercury and nitric acid were adjusted to 1150 ppm and 0.1 mol dm^{-3}, respectively. Standard solutions were prepared by diluting the stock solution and by adjusting the concentration of nitric acid to 0.02 mol dm^{-3}.

Diphenylcarbazone solution was prepared by dissolving 100 mg of diphenylcarbazone in 10 cm^3 ethanol immediately before use.

Other reagents were of reagent grade and were used without further purification. Water was deionized through ion exchange resin after distillation. Carbon black paper was prepared by smoking benzene soot on filter paper.

Procedure. Diphenylcarbazone test paper was prepared by impregnating filter paper with alcoholic solution of diphenylcarbazone. Hg diphenylcarbazone complex was formed by dropping 5 mm^3 of mercury standard solution on a diphenylcarbazone test paper of 10 mm in diameter. The test paper was immediately mounted on the sample holder by use of transparent double-sided adhensive tape and then photoacoustic signal intensity was measured.

Acidity. The sensitivity of mercury determination with diphenylcarbazone depends on the acidity of solution, decreasing with increasing acidity. However, in neutral or weakly acidic solution, other heavy metals also give colored compounds with diphenylcarbazone. With increasing acidity, interference of other ions decreases, and in 0.2 mol dm^{-3} nitric acid solution the diphenylcarbazone reaction is almost specific for mercury.[3] The acidity of solution should be chosen according to the circumstances, especialy in consideration of foreign ions. In the case of high acidity, Hg diphenylcarbazone complex formed on filter paper gradually decomposed to decolorize because of concentration of acid due to evaporation of water. In addition nitric acid vapor attacks the diaphragm of the microphone. Therefore in the present study, the concentration of nitric acid in mercury solution was adjusted to 0.02 mol dm^{-3} and the signal intensity was measured immediately after complex formation.

When sulfuric acid was used, the photoacoustic signal intensity of blank was higher and Hg diphenylcarbazone complex was less stable than in nitric acid medium.

Results and Discussion

Photoacoustic Spectrum of Hg Diphenylcarbazone Complex. The photoacoustic spectrum was obtained by calculating the normalized intensity (I_n) at each wavelength and by plotting the value against wavelength.[1,2] The photoacoustic spectrum of Hg diphenylcarbazone complex thus obtained is shown in Fig. 1. The absorption maximum appears at *ca.* 560 nm and the photoacoustic spectrum of benzene solution of the complex except for broadening of the absorption band. It also agrees with

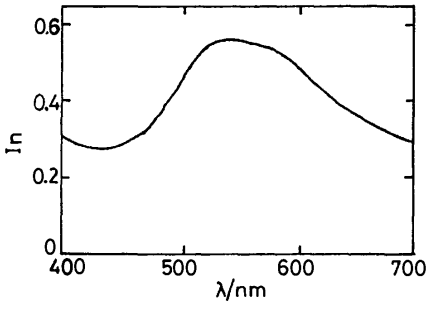

Fig. 1. Photoacoustic spectrum of Hg diphenylcarbazone complex.

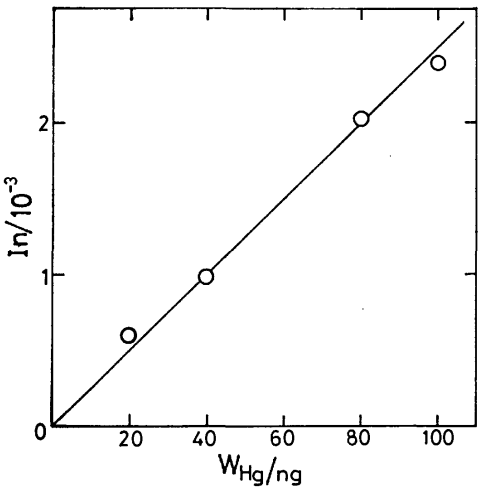

Fig. 2. Calibration curve for mercury. Wavelength: 560 nm.

the diffuse reflectance spectrum.

Determination of Microamounts of Mercury by Photoacoustic Spectrometry. Hg diphenylcarbazone complex was formed by the analytical procedure on diphenylcarbazone test paper. A blank diphenylcarbazone test paper was prepared by dropping 5 mm^3 of 0.02 mol dm^{-3} nitric acid. The photoacoustic signal intensity of sample, blank and carbon black were measured at 560 nm, and the normalized signal intensity was calculated. The calibration curve obtained by plotting the normalized signal intensity against mercury amount was linear from 20 to 100 ng as shown in Fig. 2. The detection limit for mercury (20 ng) was lower than for diffuse reflectance spectrometry of the complex (40 ng),[4] and that for extraction photometry of the complex in benzene (5 μg).[5]

TABLE 1. DETERMINATION OF Hg

Taken W_{Hg} / ng	Found W_{Hg} / ng		
20	26	22	26
40	38	37	42
80	84	84	76
100	100	92	92

By use of the calibration curve, determination of Hg was carried out. The results are summarized in Table 1. Samples containing 20 ng of Hg showed comparatively higher results. The error was within ±8% for samples containing Hg from 40 to 100 ng.

Saturation of Photoacoustic Signal. The photoacoustic effect of solid sample was analyzed theoretically by Rosencwaig and Gersho.[6] The expression giving the amplitude of pressure fluctuation by photoacoustic effect in a cell is simplified, when the thermal diffusion length of the sample (μ_s) and the optical absorption length ($\mu_\beta = 1/\beta$) are appreciably larger than the sample thickness (l). Thus the amplitude of pressure fluctuation in the cell is given by

$$Q = A[1-\exp(-\beta l)], \quad (1)$$

where A is a constant which depends on thermal property of the sample cell and of the filler gas, geometrical structure of the cell, intensity of the incident monochromatic light and the ambient pressure and volume, and β denotes the optical absorption coefficient of the solid sample (in cm^{-1}) for the wavelength λ, and is $2.3\times\varepsilon C$ where ε is the molar extinction coefficient of the sample and C is the sample concentration. Since the exponential term of Eq. 1 is approximated by $1-\beta l$ for a very small value of βl, Eq. 1 becomes

$$Q \cong A\beta l = 2.3A\varepsilon Cl. \quad (2)$$

It is obvious from Eq. 2 that the calibration curve obtained by plotting the signal intensity against sample amount is linear for a small amount of sample. For a higher value of βl, however, the higher order terms of expantion terms of $\exp(-\beta l)$ can be ignored. When $\exp(-\beta l)$ is developed up to the second order term, Eq. 1 becomes

$$Q = A\beta l\left(1-\frac{\beta l}{4}\right). \quad (3)$$

When βl increases infinitely and the sample absorbs most part of the incident light, $\exp(-\beta l)$ nearly equals zero and therefore Eq. 1 becomes

$$Q = A. \quad (4)$$

It is obvious from Eqs. 3 and 4 that, as the absorption coefficient increases or sample thickness becomes larger, saturation of the signal intensity occures. As a result, the signal intensity approaches gradually to a constant value independent of the absorption coefficient and the sample thickness.

Since carbon black might be assumed to be an approximately black body absorbing visible light perfectly, the normalized signal intensity (I_n) obtained by taking the ratio of the signal intensity of the sample to that of carbon black is given as follows by means of Eqs. 1 and 4.

$$I_n = \frac{S_s}{S_b}[1-\exp(-\beta l)], \quad (5)$$

where the coefficient S_s/S_b is a correction term introduced by considering that the photoacoustic signal intensity is proportional to surface area of the substance, and S_s and S_b are surface areas of samples and carbon black, respectively.

Since Eq. 5 was derived on the assumption that $\mu_s > l$, it is necessary to examine the validity of assumption. Experiments were carried out with Hg diphenylcarbazone complex formed on filter paper. Rosencwaig and Gersho[6] showed that in the case of $\mu_s > l$ and $\mu_\beta > l$, the photoacoustic signal intensity (I) is proportional to the reciprocal of chopping frequency of the incident light (ω^{-1}), but the signal intensity is proportional to $\omega^{-3/2}$ in the case of $\mu_s < l$ and $\mu_\beta > l$. Thus the dependence of the photoacoustic signal intensity of Hg diphenylcarbazone complex on the chopping frequency was investigated. The relation between photoacoustic signal intensity (in μV) and ω^{-1} is shown for the range of the chopping frequency from 17—125 Hz in Fig. 3. In this chopping frequency range the signal intensity is proportional to ω^{-1}. It is concluded that Hg diphenylcarbazone complex prepared in this way satisfies $\mu_s > l$.

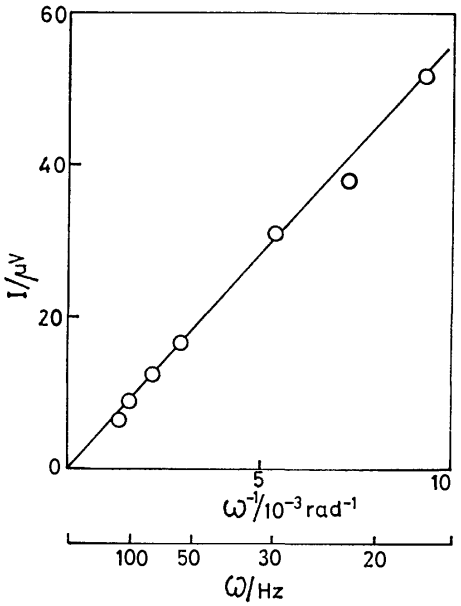

Fig. 3. Photoacoustic signal intensity of Hg diphenylcarbazone complex *versus* reciprocal of the chopping frequency.

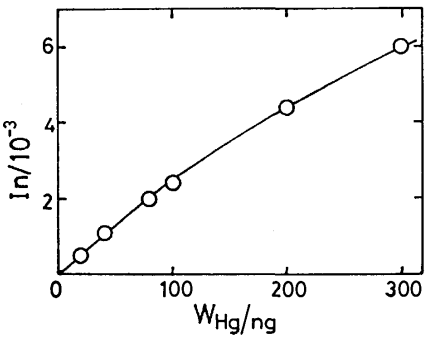

Fig. 4. Observed normalized signal intensity of Hg diphenylcarbazone complex *versus* weight of Hg in complex.

The relation between the photoacoustic signal intensity and mercury amount dropped onto filter paper was linear for 20—100 ng of Hg, as shown in Fig. 2. In order to examine the relation above 100 ng of Hg, measurements were extended up to 300 ng of Hg. The results are shown in Fig. 4. The normarized signal intensity of sample containing Hg above 100 ng deviates from linear relationship downwards. The normalized signal intensity was calculated from Eq. 5 by substituting the following values; the molar extinction coefficient ($\varepsilon=4.5\times10^4$), which was determined on benzene extract of the Hg complex, S_s which was measured on the spot of complex, $S_b=0.785$ cm^2, the concentration of complex in filter paper (C), which was calculated from mercury amount dropped onto test paper and the volume of spot [$S_s\times$thickness of filter paper (l)]. The normalized signal intensity calculated by use of these parameters is plotted against the mercury amount in Fig. 5. Figures 4 and 5 almost agree with each other except for the scale of the ordinate. And it is understood that the saturation of normalized signal

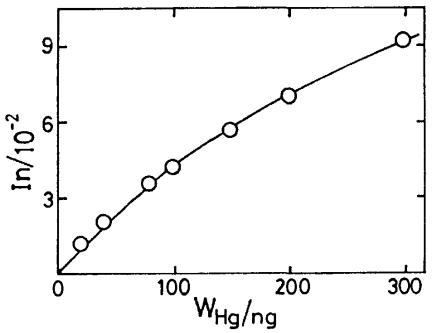

Fig. 5. Calculated normalized signal intensity of Hg diphenylcarbazone complex *versus* weight of Hg

intensity is mainly due to the terms of higher order of $[1-\exp(-\beta l)]$ in Eq. 5.

Disagreement between the calculated and the observed intensities might be explained by some of the following factors: 1) Validity of the assumption that carbon black paper used is a black body, 2) estimation of the term βl, and 3) estimation of the effective particle size of solid samples.

When the black standard is not a perfectly black body, it is expected that the observed value is larger than the calculated value. Since this is not the case, the experimental results can not be explained by this factor. A light absorber having a microscopically heterogeneous distribution in a dispersed system should show apparently a smaller absorption coefficient than that shown in a homogeneous system. The value of ε measured in homogeneous solution would be too high to used in Eq. 5, giving a higher calculated photoacoustic intensity. In fact the calculated intensity is one order higher than the observed one. On the other hand, since the incident beam reflects repeatedly within texture of filter paper before passing through it, the effective optical path length would be greater than the sample thickness (l). Therefore lowering of I_n caused by decrease in apparent absorption coefficient would be cancelled partially by increase in effective optical path length.

Absorption by particles is largely affected by particle size, the smaller the particle size, the higher the photoacoustic intensity. Usually the particle size of soot produsd by burning is approximately 50—500 nm. Crystals (approximately 1—30 μm) of Hg diphenylcarbazone complex formed in filter paper can be observed by microscopy. Effective surface area of benzene soot seems to be at least one order larger than that of the complex. This might be the principal cause for the difference between the observed and the calculated intensities.

Saturation of the photoacoustic signal should influence the shape of photoacoustic spectrum as well as calibration curve. As is obvious from Eq. 2, the photoacoustic spectrum can reflect wavelength dependency of β for a small value of βl. However, when the photoacoustic intensity is beyond the range of proportionality around the absorption maximum, the center of the absorption band should be flattened for saturation of absorption. Therefore in measurement of the photoacoustic spec-

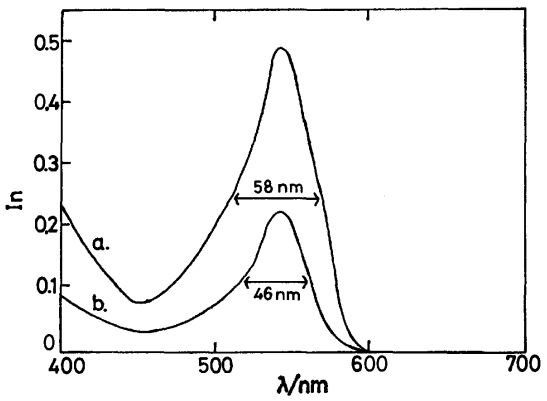

Fig. 6. Photoacoustic spectra of Ni dimethylglyoxime complex.
(a) $W_{Ni}=3$ μg, (b) $W_{Ni}=0.7$ μg.

trum, it is desirable to restrict the value of βl within the proportionality range by reducing the concentration of absorber and/or the thickness of samples. The phenomenon of saturation could easily be demonstrated by photoacoustic spectra of Ni dimethylglyoxime complex. Figure 6 show the spectra of samples containing 0.7 and 3 μg of Ni. The former belongs to the linear part of calibration curve for nickel and the latter to the saturation part. The half maximum width of the absorption band at 545 nm was 46 and 58 nm for the former and the latter samples, respectively. The absorption band is broadened due to saturation of photoacoustic signal.

Metal Complexes Coordinating Pyridine Derivatives. I. Preparation and Circular Dichroism Spectra of *cis*-α Isomers of [(*S*)-*N*,*N*′-Bis(2-pyridylmethyl)propylenediamine]dihalogenochromium(III) and -cobalt(III) Complexes

Yukihiro YAMAMOTO* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 23, 1979)

Several chromium(III) and cobalt(III) complexes with (*S*)-*N*,*N*′-bis(2-pyridylmethyl)propylenediamine (*S*-picpn) were prepared and their structures assigned. The $[CoCl_2(S\text{-picpn})]^+$ complex was reassigned to have *cis*-α configuration. The *Δ* and *Λ* diastereomers of $[CrX_2(S\text{-picpn})]^+$ of *cis*-α configuration were obtained (X=Cl^- and Br^-) and their absorption and circular dichroism spectra were discussed.

The structural assignment of $[CoX_2(S\text{-picpn})]^+$ complexes, where *S*-picpn is the abbreviation for (*S*)-*N*,*N*′-bis(2-pyridylmethyl)propylenediamine and X^- stands for an aniono ligand such as Cl^- or Br^- has been the subject of controversy. In 1967 Bosnich prepared several complexes and discussed their circular dichroism (CD) spectra in terms of *cis*-α configuration (Fig. 1).[1] Cragel and Brubaker[2] studied the stereospecific formation of such complexes from racemic or resolved picpn ligand, and concluded that in contrast most of the cobalt(III) complexes have *cis*-β configuration. Studies on strain energy minimization and conformational analysis[3] of six possible isomers of $[Co(ox)(S\text{-picpn})]^+$ have shown that the strain energy of a *cis*-α isomer is the lowest of the six isomers, although the strain energy of some *cis*-β isomers differs from that of the lowest α-isomer by only a few percent.

The corresponding ethylenediamine analogue ligand, *N*,*N*′-bis(2-pyridylmethyl)ethylenediamine (abbrev. picen), also forms several cobalt(III) complexes.[4] The structures of two isomers of dichloro complex $[CoCl_2(picen)]^+$, a purple and a cherry-red one, were definitely assigned by Gibson and McKenzie to *cis*-α and *cis*-β configurations, respectively, from their PMR spectra.[4a] Michelsen[5] prepared the *cis*-α and *cis*-β isomers of dichloro chromium(III) complexes, and also studied chromium(III) complexes of some analogous bidentate ligands, *i.e.*, 2-pyridylmethylamine[6] and 1-(2-pyridyl)ethylamine.[7]

The present paper deals with the preparation of several dianiono *S*-picpn chromium(III) and cobalt(III) complexes, their structures being discussed along with the absorption and CD spectra.

Experimental

Ligands. The ligands *S*-picpn and picen were prepared from (*S*)-propylenediamine or ethylenediamine and 2-pyridinecarbaldehyde by the method of Goodwin and Lions.[8]

Cobalt(III) Complexes. $(+)^{CD}_{600}$-$[CoCl_2(S\text{-picpn})]Cl\cdot H_2O$: A portion of $Na_3[Co(NO_2)_6]$ was dissolved in water, and an equimolar amount of *S*-picpn was added with stirring. A yellowish orange precipitate was formed. This is supposed to be $[Co(NO_2)_2(S\text{-picpn})]NO_2$. After cooling in an ice bath, the product was collected and washed with ether; this was suspended in a small amount of concd hydrochloric acid and evaporated to dryness on a steam bath. The violet residue was dissolved in warm dilute hydrochloric acid (*ca.* 6 M (1 M= 1 mol dm^{-3})) and cooled in an ice bath. Violet crystals were obtained; $\Delta\varepsilon_{600}=+1.67$. Found: C, 41.29; H, 4.84; N, 12.85%. Calcd for $CoC_{15}H_{20}N_4Cl_3\cdot H_2O$: C, 40.98; H, 5.04; N, 12.74%. The CD spectrum in the region of 15000—50000 cm^{-1} was the same as that of a $[CoCl_2(S\text{-picpn})]^+$ complex which was erroneously assigned to *cis*-β configuration by Cragel and Brubaker.[2]

$(+)^{CD}_{600}$-$[CoCl_2(S\text{-picpn})]ClO_4$: The violet residue mentioned above was dissolved in water to which was added sodium perchlorate. After the solution had been left to stand overnight in a refrigerator, violet crystals were obtained. Recrystallization was performed from a small amount of warm dilute hydrochloric acid; $\Delta\varepsilon_{600}=+1.67$. Found: C, 36.89; H, 4.20; N, 11.55%. Calcd for $CoC_{15}H_{20}N_4O_4Cl_3$: C, 37.10; H, 4.15; N, 11.54%.

cis-α-$[CoCl_2(picen)]Cl$: The complex, prepared by the method of Michelsen[5] and for which the *cis*-α configuration has been confirmed,[4a] was partially resolved on an SP-Sephadex C-25 column when eluted with a 0.25 M sodium antimony(III) $(+)_{589}$-tartrate aqueous solution. The CD spectrum of the former fractions of the eluted band is opposite in the sign to that of $(+)^{CD}_{600}$-$[CoCl_2(S\text{-picpn})]Cl$, showing a negative band at 16670, positive ones at 19230 and 23810, and a negative one at 30300 cm^{-1} (Fig. 3). The latter fractions exhibited the same CD pattern of opposite sign.

Chromium(III) Complexes. $(-)^{CD}_{600}$-$[CrF_2(S\text{-picpn})]Br\cdot LiBr\cdot 3H_2O$: *S*-picpn (2.5 g, 9.9 mmol) was dissolved in a solution of *trans*-$[CrF_2(py)_4]Br\cdot 2H_2O$[9] (5.17 g, 9.9 mmol) and 20 cm^3 of 2-methoxyethanol. The solution was heated on a water bath with occasional stirring until it became sticky. To the resulting solution were added a small amount of water, an ethanol solution (20 cm^3) of 10 g LiBr, and then 50 cm^3 of an ethanol–ether mixture (1:1). After standing the solution overnight in a refrigerator, a violet precipitate was filtered, the precipitate mainly consisting of the starting complex, *trans*-$[CrF_2(py)_4]Br$. To the filtrate were added 20 cm^3 of methanol and 400 cm^3 of acetone, and an oily material obtained by decantation was dissolved in 10 cm^3 of water; then an ethanol solution (20 cm^3) of 10 g LiBr and 150 cm^3 of acetone were added. By scratching with a glass rod and cooling, the desired violet crystals were precipitated, the precipitate showing a CD spectrum. The violet crystals were washed with acetone and dried in the air. The substance was adsorbed on an SP-Sephadex C-25 column ($\phi 10\times 200$ mm) and eluted with a 0.1 M sodium chloride aqueous solution in order to confirm the purity of the complex; all fractions showed the same CD spectra: $\Delta\varepsilon_{600}=-1.61$. Found: C, 31.78; H, 4.71; N, 9.84%. Calcd for $CrC_{15}H_{20}N_4F_2Br\cdot LiBr\cdot 3H_2O$: C, 31.77; H, 4.62; N, 9.88%.

$(-)^{CD}_{600}$-$[CrCl_2(S\text{-picpn})]Cl\cdot 0.5NaCl$: In dimethyl sulfoxide

(10 cm³) was suspended anhydrous chromium(III) chloride (3.2 g, 20 mmol), and *S*-picpn (5.07 g, 20 mmol) was added to it with stirring at room temperature. After 1 h, the unreacted chromium(III) chloride was filtered off and washed with a small amount of water. The filtrate and washings were adsorbed on an SP-Sephadex C-25 column (ϕ45×600 mm) and eluted with a 0.1 M sodium chloride aqueous solution acidified with hydrochloric acid (0.12 M). Four colored bands, (i) violet, (ii) red-violet, (iii) blue-violet, and (iv) dirty violet, were eluted in this order. A dark green band appearing between bands (i) and (ii) turned red after being eluted from the column. Eluate (i) was condensed to a small volume with a vacuum rotary evaporator below 40 °C, red-violet crystals being separated. They were filtered and washed with cold water and ether: $\Delta\varepsilon_{600}=-1.26$. Found: C, 40.13; H, 4.54; N, 12.54%. Calcd for $CrC_{15}H_{20}N_4Cl_3\cdot 0.5NaCl$: C, 40.58; H, 4.54; N, 12.62%. The CD spectrum of the latter half of eluate (i) showed the opposite sign to that of the former half, indicating that the band contains two diastereomers. However, the crystals obtained above showed the same CD spectrum as that of the former half of eluate (i). Eluate (ii) was condensed to a small volume. The crystals obtained were collected but no pure crystals obtained in spite of repeated recrystallization. Their absorption spectrum indicates that band (ii) contains $[Cr(OH)(H_2O)(S\text{-picpn})]^{2+}$ ions. Eluate (iii) and (iv) were adsorbed so tightly to the Sephadex column that they could not be eluted with a 0.1 M sodium chloride aqueous solution. They were eluted with a 0.25 M sodium chloride aqueous solution, but broadened through the column. They may be some polynuclear complexes.

(−)$^{CD}_{600}$-[CrCl$_2$(S-picpn)]ClO$_4$: (−)$^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl·0.5NaCl was dissolved in water, and sodium perchlorate was added to the solution. A dark violet precipitate was soon formed. After filtering and washing with ethanol and ether, the product was air-dried: $\Delta\varepsilon_{600}=-1.26$. Found: C, 37.44; H, 4.21; N, 11.61%. Calcd for $CrC_{15}H_{20}N_4O_4Cl_3$: C, 37.64; H, 4.21; N, 11.70%.

(−)$^{CD}_{600}$-[CrCl$_2$(S-picpn)]I: (−)$^{CD}_{600}$-[CrF_2(*S*-picpn)]Br·LiBr·3H$_2$O was dissolved in a small volume of concd hydrochloric acid in a flask (50 cm³). The mixture was saturated with gaseous hydrogen chloride below −13 °C, and the flask was stoppered tightly and left to stand at room temperature for 3 d. After cooling, the flask was opened. Sodium iodide was added to the red-violet solution with stirring, the violet precipitate being filtered promptly and washed with acetone. Recrystallization was carried out by dissolving it in hot water (70 °C): $\Delta\varepsilon_{600}=-1.26$. Found: C, 35.31; H, 3.94; N, 11.08%. Calcd for $CrC_{15}H_{20}N_4Cl_2I$: C, 35.59; H, 3.98; N, 11.07%.

(+)$^{CD}_{600}$-[CrCl$_2$(S-picpn)]I·0.5H$_2$O: One gram of chromium shot (19.2 mmol) was dissolved in a 50 cm³ flask containing 15 cm³ of concd hydrochloric acid under a current of nitrogen. The resulting solution was evaporated and heated to dryness in a vacuum rotary evaporator to obtain chronium(II) chloride. To the flask was added *S*-picpn (4.9 g, 19.4 mmol, in 20 cm³ pyridine) and the mixture was heated, a solution of iodine (2.4 g, 9.5 mmol, in 8 cm³ pyridine) being added. The reaction was carried out by refluxing for 20 min. After cooling, the violet precipitate was filtered and washed with ethanol. The crude product (0.78 g) was suspended in 10 cm³ of water, and 0.2 g of freshly prepared silver chloride was added with stirring. The silver salt precipitated was filtered off. The filtrate was adsorbed on an SP-Sephadex C-25 column (ϕ20×300 mm) and eluted with a 0.1 M sodium chloride aqueous solution acidified with hydrochloric acid (0.1 M), only one band being eluted. The band was collected in 15 fractions, all fractions except for the last two showing the same CD pattern. The first 13 fractions were combined and condensed with a rotary evaporator below 40 °C. To the concentrated solution was added sodium iodide. On cooling, violet crystals were obtained. They were recrystallized from water: $\Delta\varepsilon_{600}=+0.89$. Found: C, 33.87; H, 3.94; N, 10.55%. Calcd for $CrC_{15}H_{20}N_4Cl_2I\cdot 0.5H_2O$: C, 34.97; H, 4.11; N, 10.88%.

(+)$^{CD}_{600}$-[CrCl$_2$(S-picpn)]Cl·0.5H$_2$O: The dichloro iodide, (+)$^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]I, was suspended in water and silver chloride was added to it. The silver salt was filtered. Concd hydrochloric acid was added to the filtrate and the solution was cooled in an ice bath. Violet crystals were obtained. $\Delta\varepsilon_{600}=+0.89$. Found: C, 42.61; H, 4.87; N, 13.12%. Calcd for $CrC_{15}H_{20}N_4Cl_3\cdot 0.5H_2O$: C, 42.52; H, 5.00; N, 13.22%.

(−)$^{CD}_{600}$-[CrBr$_2$(S-picpn)]Br·0.5LiBr·0.5H$_2$O: The difluoro bromide, (−)$^{CD}_{600}$-[CrF_2(*S*-picpn)]Br·LiBr·3H$_2$O (1.15 g), was suspended in a small amount of 47% hydrobromic acid in a flask. Gaseous hydrogen bromide was bubbled into the mixture below −13 °C for 5 min, and the flask was stoppered tightly and left to stand at room temperature for 3 d. After cooling, the violet precipitate was filtered and washed with ethanol and ether. By adding a mixture of ethanol–ether (1:1) to the filtrate, more crystals were obtained. Recrystallization was carried out by dissolving the combined precipitate in hot water (70 °C) acidified with 47% hydrobromic acid (1 M). The bromide salt was sparingly soluble in water: $\Delta\varepsilon_{600}=-1.10$. Found: C, 29.94; H, 3.48; N, 9.22%. Calcd for $CrC_{15}H_{20}N_4Br_3\cdot 0.5\ LiBr\cdot 0.5H_2O$: C, 30.00; H, 3.52; N, 9.33%.

(+)$^{CD}_{600}$-[CrBr$_2$(S-picpn)]I·0.25H$_2$O: One gram (19.2 mmol) of chromium shot was dissolved in a 50 cm³ flask containing a mixture of 47% hydrobromic acid (3 cm³) and water (2 cm³) under a current of nitrogen. The resulting solution was evaporated in a vacuum rotary evaporator to give chromium(II) bromide which was heated to dryness. To the flask was added *S*-picpn (4.8 g, 19.2 mmol, in 30 cm³ pyridine) and the mixture was heated and then a solution of iodine (2.4 g, 9.5 mmol, in 8 cm³ pyridine) was added. The reaction was carried out by refluxing for 20 min. After cooling, the red violet precipitate was filtered. This was mainly "diol complex," $[\{Cr(OH)(S\text{-picpn})\}_2]I_4$, which was characterized by elemental analysis, absorption, and CD spectrum.[5] Found: C, 29.21; H, 3.84; N, 9.10%. Calcd for $Cr_2C_{30}H_{42}N_8O_2I_4\cdot 2.5H_2O$: C, 29.94; H, 3.94; N, 9.31%.

To the filtrate was added *ca.* 30 cm³ of ethanol, a small amount of violet precipitate being obtained. This was (−)$^{CD}_{600}$-[$CrBr_2$(*S*-picpn)]I. More ethanol was added and the precipitate obtained was filtered. After standing the filtrate for a month, violet powder less soluble in water than the (−)$^{CD}_{600}$-[$CrBr_2$(*S*-picpn)]I complex was precipitated. The crude product was washed on a glass filter with a small amount of water (70 °C), the residue being extracted with a large amount of hot water (70 °C). To the extracted solution was added sodium iodide and the resulting solution was cooled in an ice bath. The violet crystals obtained were washed with ethanol–ether (1:1) and then air-dried: $\Delta\varepsilon_{600}=+0.78$. Found: C, 29.48; H, 3.35; N, 9.19%. Calcd for $CrC_{15}H_{20}N_4Br_2I\cdot 0.25H_2O$: C, 30.05; H, 3.45; N, 9.35%.

(−)$^{CD}_{600}$-[Cr(NCS)$_2$(S-picpn)]SCN: The dichloro chloride, (−)$^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl (0.5 g), and an excess potassium thiocyanate were dissolved in water, and the solution was heated to boiling. The original violet solution turned red. After cooling, the precipitate was filtered and recristallized twice from water; $\Delta\varepsilon_{600}=-0.08$. Found: C, 44.97; H, 4.20; N, 20.48%. Calcd for $CrC_{18}H_{20}N_7S_3$: C, 44.80; H, 4.18; N, 20.32%.

cis-α-[*CrCl*$_2$*(picen)*]*Cl*: The complex prepared by the method of Michelsen[5] was partially resolved by the same method as for *cis*-α-[CoCl$_2$(picen)]Cl. The CD spectrum of the former part of the eluted band showed a negative value at 17150, a positive one at 19420, a negative one at 36360, and a negative one at 37310 cm^{-1} (Fig. 4); this is similar to the spectra of $(-)_{589}$-[CrCl$_2$(picen)]ClO$_4$[7] and $(-)^{CD}_{600}$-[CrCl$_2$(*S*-picpn)]Cl.

cis-α-[*CrCl*$_2$*(trien)*]*Cl*: The complex[10] was partially resolved by the same method as for *cis*-α-[CoCl$_2$(picen)]Cl. The complex was adsorbed on an SP-Sephadex C-25 column (ϕ15×300 mm) and eluted with a 0.25 M sodium antimony(III) $(+)_{589}$-tartrate aqueous solution. The CD spectrum of the former fractions was opposite in sign to that of the latter fractions (Fig. 4).

Measurements. The visible and ultraviolet absorption spectra were obtained with a Shimadzu UV-200 spectrophotometer and the CD spectra with a JASCO MOE-1 spectropolarimeter. The absorption and CD spectra were measured in 0.1 M hydrochloric acid for the dichloro and dibromo complexes, and in water for the other complexes. The X-ray powder patterns were measured with Cu *K*α radiation for the chromium(III) complexes and with Co *K*α radiation for the cobalt(III) complexes. The IR spectra were run as nujol mulls on a JASCO DS-402G spectrophotometer.

Results and Discussion

Structural Assignments. $(+)^{CD}_{600}$-[*CoCl*$_2$*(S-picpn)*]$^+$: Three geometrical configurations, *cis*-α, *cis*-β, and *trans* (Fig. 1)[11] are possible in general for an octahedral

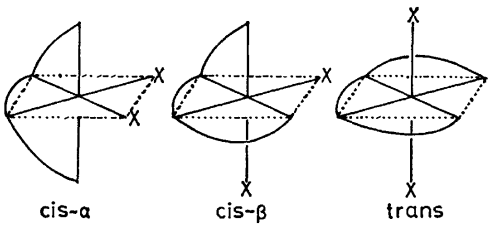

Fig. 1. Three geometrical isomers of [MX$_2$(linear tetradentate)]$^+$.

complex coordinating a linear tetradentate ligand. Both *cis*-α and *cis*-β configurations have several optically active isomers and their classifications is made in two steps. (1) In a [MX$_2$(picen)]$^+$ complex, *Δ* and *Λ* configurations exist for each of the *cis*-α and *cis*-β isomers. (2) Chirality of the coordinated secondary amine nitrogens should be considered for each configuration, *viz.*, only one (*R*,*R*) pair of asymmetric nitrogen is possible for the *Δ*-*cis*-α configuration and only one (*S*,*S*) for the *Λ*-*cis*-α. In the *cis*-β configuration, the two nitrogen atoms differ from each other and are distinguished by numbering N$_1$ and N$_2$ for those located at the center of N–N–N moieties coordinated facially and meridionally, respectively. Thus (R^1,R^2) and (R^1,S^2) isomers exist for the *Λ*-*cis*-β configuration, and (S^1,S^2) and (S^1,R^2) for the *Δ*-*cis*-β. For the case of [CoCl$_2$(*S*-picpn)]$^+$, the number of possible isomers of the *cis*-β configuration doubles the above number because of non-symmetrical disposition of the methyl substituent. Thus two structures are possible for the *cis*-α configuration and eight for *cis*-β. It is well established that the

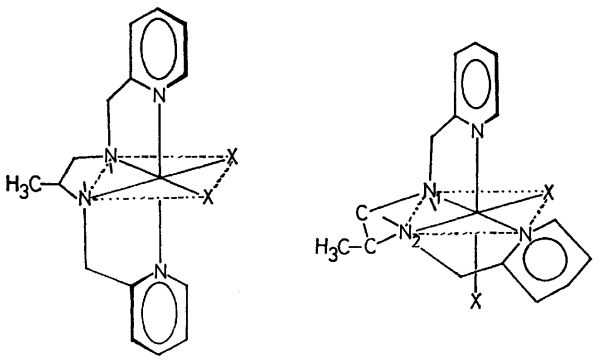

Fig. 2. Two configurations of [MX$_2$(*S*-picpn)]$^+$ (a) *Λ*-*cis*-α-(*SR*): this corresponds to the (*S*,*S*) isomer of picen complex. (b) *Δ*-*cis*-β-(S^1,R^2): this corresponds to the (S^1,S^2) isomer of picen complex.

methyl substituent of propylenediamine type moiety prefers the equatorial orientation in octahedral complexes.[12] Two of the ten possible isomers are shown in Fig. 2.

The CD spectrum of $(+)^{CD}_{600}$-[CoCl$_2$(*S*-picpn)]Cl prepared in the present study (Fig. 3) is in good agreement with the data of Cragel and Brubaker on their "*cis*-β" form.[2] On the other hand, the *cis*-α-[CoCl$_2$(picen)]$^+$ complex, assigned to this configuration,[4a] was resolved by SP-Sephadex column chromatography, and the CD spectrum (dotted line) is very similar in pattern to that of the $(+)^{CD}_{600}$-[CoCl$_2$(*S*-picpn)]Cl complex. Thus, the $(+)^{CD}_{600}$-[CoCl$_2$(*S*-picpn)]Cl complex is considered to take the *cis*-α configuration. The "*cis*-β" assignment by Cragel and Brubaker for this complex seems to be incorrect.

The CD spectrum of $(+)^{CD}_{600}$-[CoCl$_2$(*S*-picpn)]Cl shows a positive (longer wavelength) and a negative (shorter wavelength) extremum in the first absorption band region. In order to assign the absolute configuration

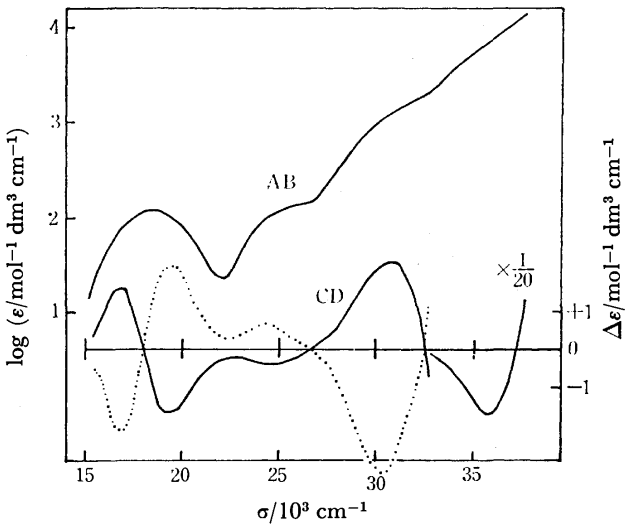

Fig. 3. The absorption (AB) and CD spectra of $(+)^{CD}_{600}$-[CoCl$_2$(*S*-picpn)]Cl (——), and the qualitative CD spectrum of former fraction of [CoCl$_2$(picen)]$^+$ eluted with sodium antimony(III) $(+)_{589}$-tartrate (···).

a) Abbreviations of ligands: (3*S*,8*S*)-dimetrien= (2*S*,7*S*)-2,7-dimethyl-3,6-diazaoctane-1,8-diamine; (2*S*,9*S*)-dimetrien= (1*S*,8*S*)-1,8-dimethyl-3,6-diazaoctane-1,8-diamine; bnpic= (2*S*,3*S*)-*N*,*N*′-bis(2-pyridylmethyl)-2,3-butanebiamine. b) This work; sh=shoulder. c) Values taken from the figure in the paper. d) Given in mol^{-1} dm^3 cm^{-1} unit.

of this complex, the CD spectrum was compared with those of the *cis*-α-[$CoCl_2$(dimetrien)]$^+$ (dimetrien= dimethyl derivative of triethylenetetramine) complexes (Table 1). The *Λ*-*cis*-α-[$CoCl_2$(dimetrien)]$^+$ complexes show a negative and then a positive CD extremum from the lower energy side in the first absorption band region, while the corresponding *cis*-β complex show no such dispersion type pattern.[13,14] Thus, it is confirmed that the $(+)^{CD}_{600}$-[$CoCl_2$(*S*-picpn)]$^+$ complex has *Λ*-*cis*-α configuration. Bosnich and Kneen prepared the *Λ*-*cis*-β-[$CoCl_2$(bnpic)]Cl complex,[15] which shows no dispersion type CD pattern (bnpic=(2*S*,3*S*)-*N*,*N*′-bis(2-pyridylmethyl)-2,3-butanediamine). Gibson and McKenzie,[4a] and Michelsen[5] prepared the *cis*-β dichloro complex with the picen ligand, but the *cis*-β complex of the *S*-picpn ligand was not formed by our methods. The reason why the *cis*-β complex could not be prepared for this ligand is unknown.

$(+)^{CD}_{600}$- and $(-)^{CD}_{600}$-[$CrCl_2$(S-picpn)]Cl: The CD spectrum of $(+)^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl shown in Fig. 4 (broken line) is quite enantiomeric to the qualitative CD spectrum (dotted line) of *cis*-α-[$CrCl_2$(picen)],[5]

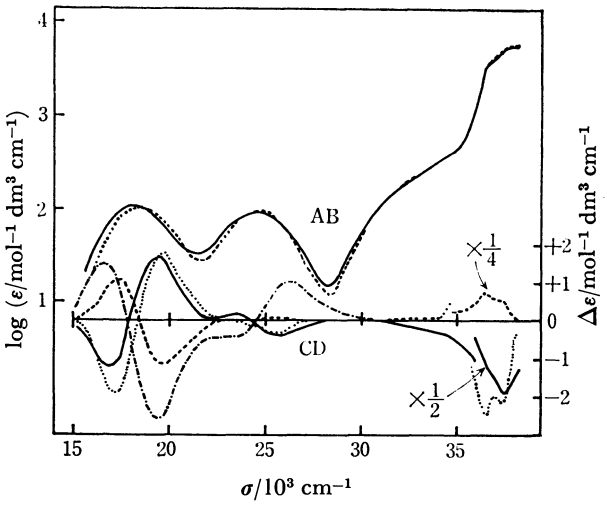

Fig. 4. The absorption (AB) and CD spectra of $(+)^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl (----), and $(-)^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl (——); and the qualitative CD spectra of *cis*-α-[$CrCl_2$(picen)]$^+$ (····) and *cis*-α-[$CrCl_2$(trien)]$^+$ (latter fraction) (-·-·-).

TABLE 2. INFRARED ABSORPTION OF [MCl_2(*S*-picpn)] Cl COMPLEXES (M=Co and Cr)

	$(+)^{CD}_{600}$-Co	$(+)^{CD}_{600}$-Cr	$(-)^{CD}_{600}$-Cr

which was resolved by a chromatographic method. Thus, the $(+)^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl complex is assigned to the *cis*-α configuration. The IR spectra of the two complexes, $(+)^{CD}_{600}$-[$CoCl_2$(*S*-picpn)]Cl and $(+)^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl, were measured, and the wave numbers of the absorption bands corresponding to the CH_2-rocking and -twisting are given in Table 2. The peak positions of the two complexes almost agree. The IR data of another complex, $(-)^{CD}_{600}$-[$CrCl_2$(*S*-picpn)]Cl, also given in Table 2, differ from those of the former two

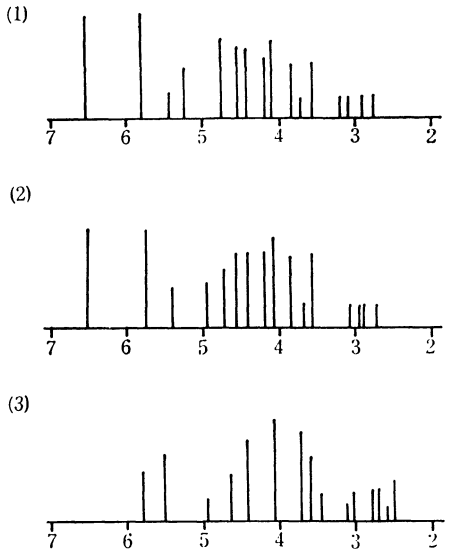

Fig. 5. The X-ray powder patterns: The *d*-spacings (in Å) of the complexes, $(+)^{CD}_{600}$-$[CoCl_2(S\text{-picpn})]ClO_4$ (1), $(+)^{CD}_{600}$-$[CrCl_2(S\text{-picpn})]ClO_4$ (2), and $(-)^{CD}_{600}$-$[CrCl_2(S\text{-picpn})]ClO_4$ (3).

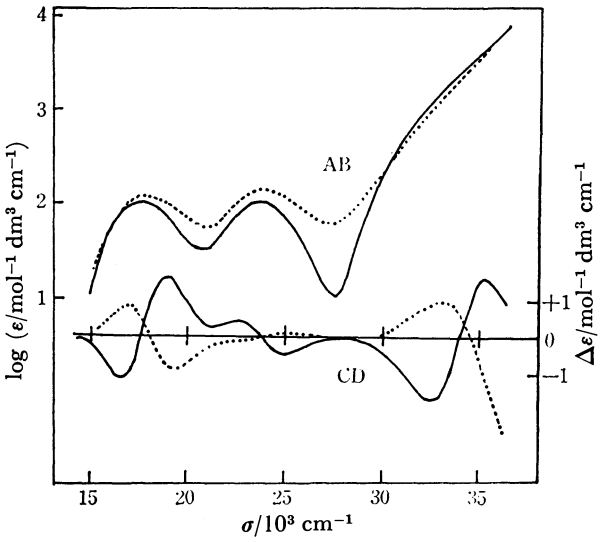

Fig. 6. The absorption (AB) and CD spectra of $(+)^{CD}_{600}$-$[CrBr_2(S\text{-picpn})]I$ (——) and $(-)^{CD}_{600}$-$[CrBr_2(S\text{-picpn})]Br$ (——).

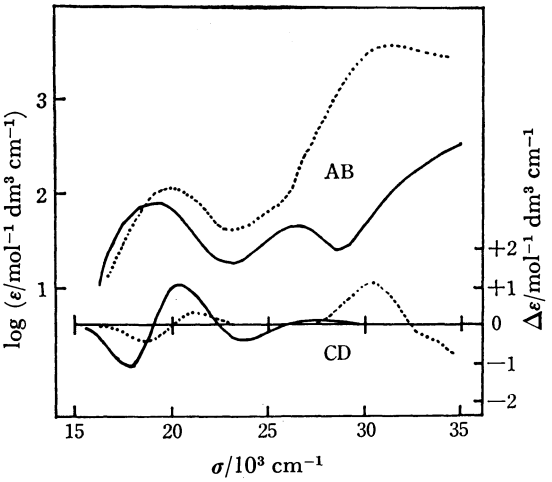

Fig. 7. The absorption (AB) and CD spectra of $(-)^{CD}_{600}$-$[CrF_2(S\text{-picpn})]Br$ (——) and $(-)^{CD}_{600}$-$[Cr(NCS)_2(S\text{-picpn})]SCN$ (——).

$(+)^{CD}_{600}$ complexes. Results of measurement of X-ray powder patterns of the three complexes (perchlorate salts) are shown in Fig. 5. The patterns of the cobalt(III) and the $(+)^{CD}_{600}$ chromium(III) complexes are very similar but that of the $(-)^{CD}_{600}$ chromium(III) complex is different. The CD spectra of the *Δ-cis-α*-$(+)^{CD}_{600}$-$[CoCl_2(S\text{-picpn})]Cl$, $(+)^{CD}_{600}$-$[CrCl_2(S\text{-picpn})]Cl$, and *cis-α*-$[CrCl_2(trien)]^+$ (latter fractions) complexes show a similar pattern (a positive and then a negative sign from the lower energy side) in the first absorption band region but that of the $(-)^{CD}_{600}$-$[CrCl_2(S\text{-picpn})]Cl$ complex shows the opposite dispersion type pattern (Fig. 4). It can be concluded that the former three complexes have the same *Δ-cis-α* configuration and the latter one *Λ-cis-α*. The latter *Λ-cis-α* configuration has been expected to be more unstable than the *Δ-cis-α* configuration from a strain energy minimization calculation.[3] This trend is reflected on the observed positions of the first absorption bands, *viz.*, the first absorption band (18180 cm^{-1}) of the *Λ* complex is in the slightly lower energy side than that (18520 cm^{-1}) of the *Δ* complex.

The Other Complexes: Absorption and CD spectra are shown on Figs. 6 and 7; the data are given in Table 3. Since the fluoro, chloro, bromo, and isothiocyanato ligands lie in the same (weaker) side on the spectrochemical series as compared with organic amine ligands,[16] the CD patterns of the fluoro, bromo, and isothiocyanato complexes are expected to resemble those of the corresponding chloro complexes in the first absorption band region, as seen in Table 3. All the complexes are assigned to the *cis-α* configuration, and the complexes which show a positive and then a negative CD extremum from the lower energy side in the first absorption band region to the *Δ-cis-α* configuration. The complexes with the inverse sign can be assigned to the *Λ-cis-α* configuration.

Spectral Properties: The wave number of the first absorption band maximum of the *Λ-cis-α*-$[CrBr_2(S\text{-picpn})]^+$ complex is slightly smaller than that of the *Δ-cis-α*-$[CrBr_2(S\text{-picpn})]^+$ complex (Table 3). The same trend was observed between the corresponding dichloro complexes, suggesting that the *S*-picpn ligand is strained to a greater extent in the *Λ-cis-α* configuration than in the *Δ-cis-α* one. The CD strength in the first absorption band region increases in the order NCS< F<Br<Cl.

The complexes $[CrCl_2(S\text{-picpn})]^+$ and $[CrF_2(S\text{-picpn})]^+$ show a broad absorption band of low intensity (log ε=1.2—2.6) in the region 30000—35000 cm^{-1}, where weak CD bands are observed. The low intensity absorption band might correspond to the third d-d band due to two electron excitation. An alternative explanation is to assign it to a d→π^* transition.[17] A similar band was observed in the $[Ni(phen)_3]^{2+}$ and $[Ni(bpy)_3]^{2+}$ complexes[18] in the region 22200—28600 cm^{-1} (phen=1,10-phenanthroline and bpy=2,2′-bi-

a) Given in mol^{-1} dm^3 cm^{-1} unit.

pyridine). The bands in the present chromium(III) complexes seem to correspond to the "Ir(III)–pyridine band."[17] No such band is observed in the [$CrBr_2$(*S*-picpn)]$^+$ and [$CoCl_2$(*S*-picpn)]$^+$ complexes, in which the band is covered by charge transfer bands due to the bromo or chloro ligands.[19]

In the [CrX_2(*S*-picpn)]$^+$ complex, three kinds of chiralities should be considered: configurational (*Δ* and *Λ*), asymmetric carbon atoms (*S*), and conformational of the central chelate ring (*δ* and *λ*). Since the chiralities of the secondary amine nitrogen atoms in the *cis*-α complex depend on configurational chirality, the contributions of these two chiral nitrogen atoms are combined with that of the chirality *Δ* or *Λ*.

By applying the additivity rule,[20] CD contributions for the three complexes, *Λ*-*cis*-α-[$CrCl_2$(*S*-picpn)]$^+$ (1), *Λ*-*cis*-α-[$CrCl_2$(*S*-picpn)]$^+$ (2), and *Λ*-*cis*-α-[$CrCl_2$-(picen)]$^+$ (3), are written as follows.

$$\Delta\varepsilon(1) = \Lambda + \delta + S \quad \text{(i)}$$

$$\Delta\varepsilon(2) = \Lambda + \delta + S \quad \text{(ii)}$$

$$\Delta\varepsilon(3) = \Lambda + \lambda \quad \text{(iii)}$$

The vicinal contribution ($\delta+S$) of the ligand *S*-picpn is calculated by 1/2{(1)+(2)}:

$$\frac{1}{2}\{\Delta\varepsilon(1)+\Delta\varepsilon(2)\} = \delta + S$$

The configurational contribution (*Λ*) is calculated by 1/2{(1)−(2)}:

$$\frac{1}{2}\{\Delta\varepsilon(1)-\Delta\varepsilon(2)\} = \Lambda \quad \text{(iv)}$$

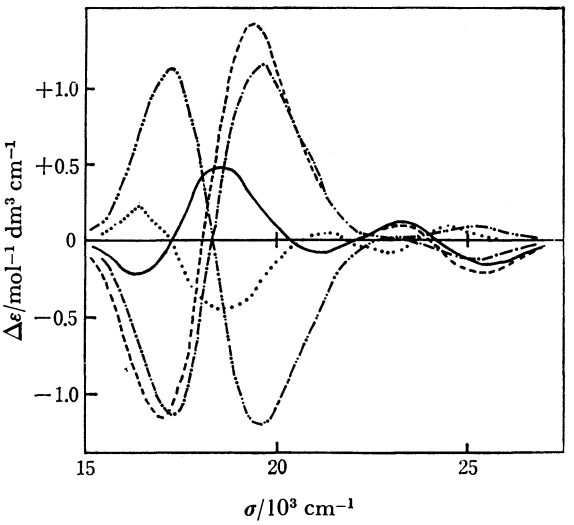

Fig. 8. Configurational and vicinal CD curves: configurational *Λ* (——), vicinal $\delta+S$ (——), and conformational *λ* (····). The observed CD curves of *Λ*-*cis*-α-[$CrCl_2$(*S*-picpn)]$^+$ (-·-·-·-) and *Λ*-*cis*-α-[$CrCl_2$(picen)]$^+$ (-····-) are also shown for comparison.

The calculated curves are shown in Fig. 8. We then obtain from (iii) and (iv) the conformational contribution (*λ*) (dotted line) of the central chelate ring,

$$\Delta\varepsilon(3) - \frac{1}{2}\{\Delta\varepsilon(1)-\Delta\varepsilon(2)\} = \lambda$$

This is nearly enantiomeric to the $\delta+S$ vicinal curve, indicating that the contribution of asymmetric atoms (*S*) is negligibly small. This is also substantiated by the fact that the observed CD curve of the *Λ*-*cis*-α-[$CrCl_2$(*S*-picpn)]$^+$ is almost identical to that of the *Λ*-*cis*-α-[$CrCl_2$-(picen)]$^+$ (Table 3). Similar CD curves for the vicinal and the configurational contributions can be calculated for the dibromo complexes.

We are grateful to Dr. Shinichi Kikkawa and Mr. Hideo Kusuyama for measuring the X-ray powder patterns.

Adsorption of Orthophosphate on a Synthetic Silica-Alumina

Shuzo TOKUNAGA* and Jiro SHIOKAWA**

National Chemical Laboratory for Industry, Yatabe, Ibaraki 305

***Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565*

(Received April 25, 1979)

The characteristics and mechanism of the adsorption of orthophosphate on a commercial synthetic silica–alumina, Neobead D, were studied. The adsorption rate increased with decrease in pH and increase in the dose of silica–alumina below the concentration of 4 g dm^{-3}. The adsorption almost terminated in 24 h, but a very slow reaction was observed even after 3 d. The adsorption isotherm follows the Freundlich equation, the inflection in the log-log plot indicating difference in the adsorption mechanism between low and high phosphate concentrations. The adsorption capacity increased with decrease in pH, being the highest at an initial pH of 3.0. The silica–alumina exhibited buffer action, phosphate-free solutions of pH 4—10 showing pH of *ca.* 6 after 24 h. In coincidence with and in proportion to the adsorption, release of hydroxide, sulfate and silicate ions occurred in the reaction of initial pH of 4.7. The sum of the equivalents of the three anions released could well account for the moles of phosphate adsorbed. The adsorption thus proceeds mainly through the ion-exchange process between phosphate in solution and the anions on the solid, univalent phosphate ions taking part in the reaction.

Recently eutrophication of enclosed water areas has caused problems in fishery, agriculture and other industries, and development of effective methods for removal of nutrients has become necessary.

In order to remove phosphate from water, coagulation, chemical and biological methods have been utilized conventionally. Ion-exchange is also effective for removal of phosphate, but does not seem advantageous since ordinary organic anion-exchange resins remove not only phosphate ions but also other anions. Yee[1] proposed a selective ion-exchange process using a packed bed of acid-treated alumina, with which orthophosphate, pyrophosphate, triphosphate, and hexametaphosphate can be removed efficiently. Regeneration of the alumina consumed was conducted with small amounts of sodium hydroxide and nitric acid. Columnar studies[2-4] made on the activated alumina process have shown that it has advantages such as high selectivity for phosphate, simplicity in operation, easy regeneration and production of small amounts of solid waste.

The phosphate adsorption capacity of alumina is increased by addition of silica, which suppresses crystallization of alumina and increases its surface area, mechanical strength and heat resistance. Takimoto *et al.*[5] showed that silica–alumina containing 10% silica by weight exhibits the highest phosphate adsorption capacity.

In order to study the removal of phosphate from aqueous solution, we used a commercial synthetic silica–alumina. Useful information was obtained about the characteristics and mechanism of adsorption of phosphate.

Experimental

Synthetic Silica–Alumina. Neobead D (Mizusawa Industrial Chemicals Ltd.) was pulverized to 105—250 μm in diameter. This is an X-ray amorphous hydrogel having the composition 79.4% Al_2O_3, 11.5% SiO_2, 1.1% SO_4, and 8.0% ignition loss, and a specific surface area of *ca.* 330 $m^2\ g^{-1}$.

Phosphate Solution. Potassium dihydrogenphosphate, KH_2PO_4 (reagent grade) was dissolved in water, the pH being adjusted with hydrochloric acid or sodium hydroxide.

Orthophosphate was chosen as a model phosphate, since other forms of phosphates proved to be also adsorbed on alumina,[1] and readily converted into orthophosphate in natural water through chemical and biological reactions.

Analysis. JIS K 0102† was applied to the determination of phosphate, sulfate (the barium–chromate colorimetric method) and aluminum ions, and JIS K 0101†† to that of silicate (the molybdenum blue method). Sulfate and silicate were determined after removing phosphate as calcium phosphate in order to avoid its interference which became appreciable from a phosphate concentration of *ca.* 0.03 mmol dm^{-3} in the sulfate determination and *ca.* 2 mmol dm^{-3} in the silicate determination.

Adsorption Rate. 3—12 g of the silica–alumina was added to 3 dm^3 of 1.05-mmol dm^{-3} phosphate solution, and stirred at 25 °C. An aliquot was taken at intervals and centrifuged, phosphate, sulfate, silicate, aluminum, and pH being determined for the supernatant.

Adsorption Equilibrium. Eighty cm^3 of 0—8.42-mmol dm^{-3} phosphate solution was placed in a 100-cm^3 glass-stoppered Erlenmeyer flask, to which 0.2 g of the silica–alumina was added. This was shaken in a 25 °C water bath for 24 h and centrifuged, and then phosphate, sulfate, silicate, aluminum, and pH were determined for the supernatant.

Results and Discussion

Adsorption Rate. Since adsorption of phosphate on silica–alumina is a solid-liquid reaction, the adsorption rate is strongly dependent on the total surface area of the solid, or solid concentration. Figure 1 shows decrease of phosphate concentration in solution at an initial pH of 5.0 with addition of 1.0—4.0 g dm^{-3} of the silica–alumina. The adsorption rate was extremely great immediately after the addition of the silica–alumina. The reaction seemed to almost terminate in 24 h, but the phosphate concentration decreased very slowly even after 3 d. Such a slow reaction was observed in the reaction between phosphate ions and alumina or kaolinite by Chen *et al.*[6] who postulated that it follows the first-order reaction rate law and

† Japanese Industrial Standard, "Testing Methods for Industrial Waste Water."

†† Japanese Industrial Standard, "Testing Method for Industrial Water."

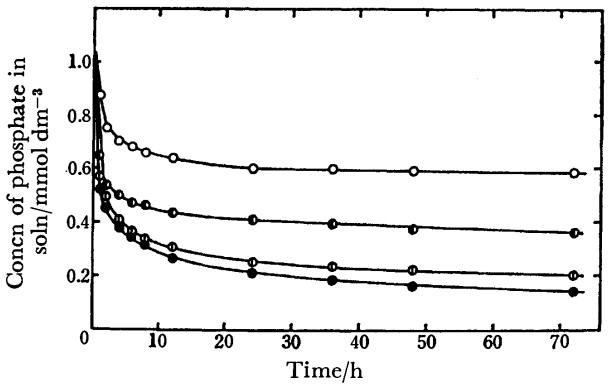

Fig. 1. Relation between adsorption rate and concentration of the silica–alumina.
Initial phosphate concentration: 1.05 mmol dm^{-3}, initial pH: 5.0, temperature: 25 °C, concentration of the silica–alumina (g dm^{-3}); ○: 1.0, ◐: 2.0, ⓘ: 3.0, ●: 4.0.

continues as long as for 60 d. The initial adsorption rate increased with increase in solid concentration, but this tendency became unappreciable with addition of a large amount of solid, indicating that diffusional effects become significant.

Effects of initial pH on the adsorption rate are shown in Figs. 2 and 3. The adsorption rate decreased considerably with increase in the initial pH value from 5.0 to 8.5. The pH variation and release of sulfate, silicate and aluminum ions were determined with the progress of phosphate adsorption. The release of sulfate rapidly reached a plateau possibly due to depletion of sulfate group on the solid. The release of the other ions was almost in line with the adsorption of phosphate. The pH variation in the alkaline solution seems independent of phosphate adsorption.

Adsorption Isotherm. Though phosphate concentration decreased very slowly even after 3 d, the adsorption rate was much higher at the initial stage, the greater part of the reaction having proceeded in several hours.

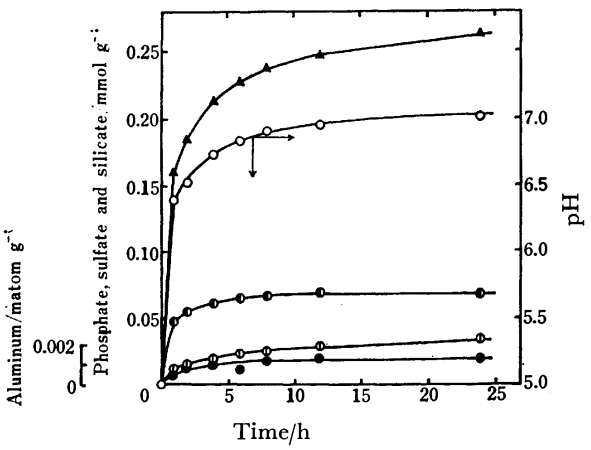

Fig. 2. Release of sulfate, silicate, and aluminum ions and pH variation concomitant with the adsorption of phosphate at an initial pH of 5.0.

Adsorption isotherms at 25 °C at initial pH 2.0—10.0 are shown in Fig. 4. The amount of phosphate adsorbed is plotted against the equilibrium concentration of phosphate in solution in logarithmic scale. A linear relationship was obtained. There is an inflection at a phosphate concentration of 0.38—2.58 mmol dm^{-3}. The linear relationship indicates that the adsorption reaction is of Freundlich type:

$$\log x/m = 1/n \log c + k,$$

where

x/m = quantity of phosphate adsorbed per unit mass of silica–alumina, mmol g^{-1},
c = equilibrium concentration of phosphate in solution, mmol g^{-1}, and
k and $1/n$ = constants.

The inflection in the isotherms indicates the difference in the adsorption mechanism between low and high

Table 1. Isotherms of phosphate adsorption on silica–alumina

Initial pH	Inflection point (mmol dm^{-3})	Low concn		High concn	
		$1/n$	$-k$	$1/n$	$-k$
2.0	2.58	0.217	0.350	0.387	0.420
3.0	1.75	0.050	0.033	0.264	0.085
4.0	0.70	0.152	0.310	0.307	0.286

8.5	0.59	0.092	0.776	0.417	0.701
10.0	1.31	0.130	0.783	0.509	0.828

Freundlich's adsorption equation: $\log x/m = 1/n \log c + k$.

phosphate concentrations. The values of the slope ($1/n$), intercept (k) and inflection of each isotherm are given in Table 1. The higher values of $1/n$ at higher phosphate concentrations indicate greater increase in phosphate adsorption value with increase in phosphate concentration. On the other hand, the lower values of $1/n$ and the higher values of intercepts at lower concentrations indicate that relatively high phosphate adsorption still takes place at lower concentrations of phosphate.

The quantity of phosphate adsorbed per unit mass of the silica–alumina was very small in alkaline solutions. It increased with decrease in pH value, becoming the greatest (>1 mmol g^{-1}) at an initial pH of 3.0. However, it was very low at an initial pH of 2.0.

The effects of pH in this system seem to change with the species of phosphate in solution and the adsorption reaction. The pH of the solutions varied during the course of reaction, the initial pH values 3.0, 4.0, and 4.7, at which high adsorption values were attained, finally increasing up to 4.2—5.5, 6.3—7.0, and 6.3—7.0, respectively, depending on adsorption values. The dissociation constants of orthophosphoric acid††† indicate that the univalent phosphate species, $H_2PO_4^-$, predominates in this range of pH. It can thus be said that univalent phosphate ion is most easily adsorbed, while molecular phosphoric acid and ionic species of higher valence are adsorbed with difficulty or not at all. Acidic condition seems to favor the adsorption of phosphate, since the highest adsorption values were obtained at an initial pH of 3.0.

Release of Hydroxide, Sulfate, Silicate, and Aluminum Ions. Increase in pH and release of sulfate, silicate, and aluminum ions were observed coincidently with the adsorption of phosphate. This is discussed for the case of initial pH of 4.7, where $H_2PO_4^-$ is the predominant form of phosphate and high adsorption values were obtained, and for that of initial pH 8.5 for comparison.

At zero phosphate-adsorption where the silica–alumina was added to phosphate-free water, the initial pH values 4.0, 4.7, 7.2, 8.5, and 10.0 turned to 5.7, 5.8, 6.0, 6.2, and 6.2, respectively ater 24 h. Sacconi[7] reported such surface buffer action for pure activated alumina in acid or salt solution and explained that it is due to displacement of Al^{3+} ions with H^+ ions in the solution. However, we found no such evidence in our silica–alumina study. The phenomenon can be explained in terms of adsorption and desorption of hydroxide ions on and from the silica–alumina, *i.e.*, desorption of hydroxide ions in acidic solution causes increase in pH, adsorption in alkaline solution a decrease.

††† $pk_1=2.2$, $pk_2=7.2$, and $pk_3=12.3$.

a) Increment of (OH equivalent: PO_4 mole) ratio corresponding to difference in pH, obtained on the titration curve. b) Equals $\frac{(A+B)}{2} \times C \times 0.08 \div 0.2$ (volume of sample solution=0.08 dm^3, and amount of the silica–alumina added=0.2 g).

In the phosphate solutions, the final pH increased with the adsorption of phosphate, indicating that hydroxide ions were released. Due to the buffer action

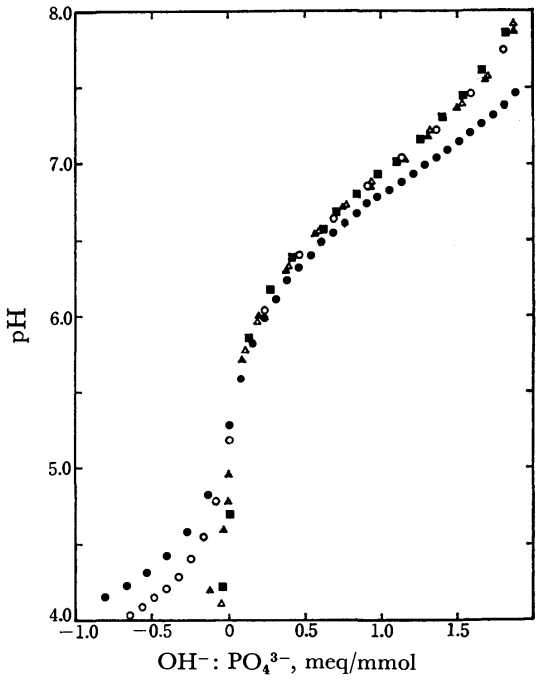

Fig. 5. Titration curves of dihydrogenphosphate solutions. (The positive and negative abscissae correspond to the titration with NaOH and HCl, respectively.) Phosphate concentration (mmol dm^{-3}); ●: 0.15, ○: 0.25, ▲: 1.00, △: 4.00, ■: 8.00.

of phosphate solution and decrease in phosphate concentration during the course of reaction, the amount of hydroxide ions released can not be calculated only from the initial and final pH values. If phosphate concentration remains constant during the course of reaction and pH increases, the amount of hydroxide ions released can be calculated using a titration curve of phosphate solution. The actual amount of hydroxide ions released should be between the value calculated from the initial phosphate concentration and that from the final concentration. We have calculated the approximate values of the hydroxide-ion release as follows (Table 2). The arithmetical mean value of the initial and final phosphate concentrations $((A+B)/2)$ was chosen to represent phosphate concentrations during the course of adsorption. This was multiplied by the increment of the ratio of hydroxide-ion equivalent and phosphate-ion mole $((C))$ corresponding to the difference between the initial and final pH values on the titration curves (Fig. 5). The curve was prepared by means of titration, adding sodium hydroxide or hydrochloric acid stepwisely to dihydrogenphosphate solutions of various concentrations. The shapes of the curves are almost the same in the pH range 5—8 and phosphate concentrations 0.25—8.0 mmol dm^{-3}.

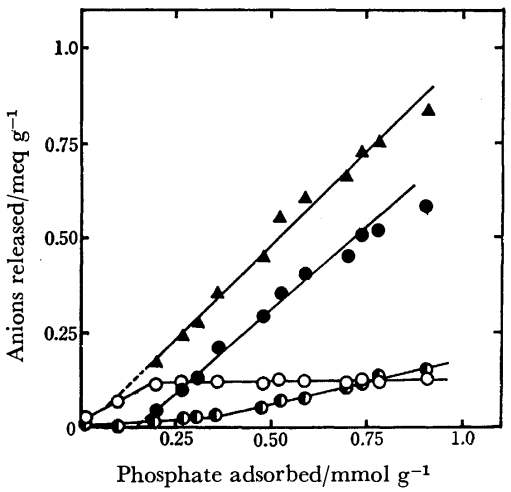

Fig. 6. Relation between adsorption of phosphate and release of hydroxide, sulfate and silicate ions at an initial pH of 4.7.
Amount of anions released (meq g^{-1}); ●: hydroxide ion (approximate value), ○: sulfate ion, ◐: silicate ion, ▲: sum of the equivalents of the three anions.

The calculated values together with the amounts of sulfate and silicate released* are plotted in Fig. 6 against the amounts of phosphate adsorbed. From an adsorption value of *ca.* 0.2 mmol g^{-1}, the release of hydroxide ions is in a linear relation with the adsorption of phosphate, indicating that phosphate ions in solution were exchanged with hydroxide group on the solid. However, at high adsorption values, it deviated downward from the linear relation, suggesting the existence of weakly and strongly bonded hydroxide groups on the silica–alumina, as reported by Takimoto *et al.*[5]

The silica–alumina originally contains *ca.* 0.2 meq g^{-1} of sulfate derived from aluminum sulfate. When it was brought into contact with neutral phosphate-free solution, *ca.* 0.06 meq g^{-1} of sulfate ions was released. In alkaline solution, sulfate release increased up to 0.2 meq g^{-1}, the total amount of sulfate contained in the silica–alumina. In acidic phosphate solutions, sulfate ions are released in proportion to the adsorption of phosphate, the release becoming constant as the sulfate on the solid is depleted. Thus the exchange process with sulfate ions is significant only at low phosphate adsorption values less than *ca.* 0.2 mmol g^{-1}. In alkaline phosphate solutions, on the other hand, a constant amount of sulfate ions, *ca.* 0.2 meq g^{-1}, was brought into solution irrespective of the phosphate adsorption, the sulfate ions undergoing exchange only with hydroxide ions.

The release of silicate ions was insignificant in alkaline phosphate solutions. In acidic phosphate solutions, it was very small in quantity at low adsorption values, but increased in proportion to the adsorption of phosphate above an adsorption value of *ca.* 0.2 mmol g^{-1}. In general, silicate tends to polymerize in aqueous solution, making determination by the molybdenum blue procedure impossible.[8] However, silicate determination before and after the sodium-carbonate fusion on the same sample gave almost the same results, indicating that the silicate exists in the monomeric state. Silicate groups at the terminal of the structure of the silica–alumina seem to be easily exchangeable with phosphate ions in solution, and consequently released as univalent anions such as $H_3SiO_4^-$.

From the coincidence of the release of the three anions with the adsorption of phosphate and the proportionality between the amounts of phosphate adsorbed and the three anions released, it is certain that the adsorption reaction involves an ion-exchange process between phosphate ions in solution and the three anions on the solid.

In consideration of the contribution of the three anions to the adsorption reaction, we see that the sulfate group plays the greatest role in the ion-exchange reaction for adsorption values less than *ca.* 0.2 mmol g^{-1}, while the contribution of sulfate rapidly decreases with increase in adsorption value due to depletion of the effective sulfate group on the solid. The contribution of hydroxide and silicate ions to the exchange reaction increases at higher adsorption values.

For a better understanding of the process of phosphate adsorption on silica–alumina, we should consider the species of phosphate adsorbed on the solid. By X-ray study Cole and Jackson[9] found that crystalline aluminum dihydroxide dihydrogenphosphate, $Al(OH)_2H_2PO_4$, is obtained by the reaction between aluminum oxide and potassium dihydrogenphosphate in acidic solution. It was suggested that phosphatized silica–alumina contains the H_2PO_4 group. However, we found no decisive evidence for the formation of crystalline material by means of X-ray diffraction.

We made stoichiometrical discussion on the basis of the release of the anions. The sums of the equivalents

* Blank values for phosphate-free solution were subtracted from individual measured values for phosphate solutions.

of the three anions released are plotted against moles of phosphate adsorbed (Fig. 6). These plots give a straight line with a 1.0 slope almost passing through the origin, indicating that the sum values can account for the moles of phosphate adsorbed. It can be concluded that the adsorption of phosphate on the silica–alumina proceeds mainly through the ion-exchange reaction between phosphate ions in solution and hydroxide, sulfate and silicate ions on the solid, and that the phosphate ions adsorbed should be univalent, the latter conclusion being supported by the results obtained from a similar study with an ion-exchange resin, Amberlite IRA-410 in the Cl^--form, in pH 4.0 solutions. The exchange ratio of phosphate and chloride ions was 1 : 1, indicating that phosphate ions taking part in the exchange reaction are univalent.

The amount of the release of aluminum ions was small, *ca.* 1/5—1/10 that of silicate ions. Aluminum ions were determined also by the atomic absorption method, which gave almost identical results with those obtained by the colorimetric method, indicating that the values obtained represent the total amount of aluminum ions which may be present in solution in various species. It tended to increase with the adsorption of phosphate and was greater in alkaline solutions, but was at most less than 0.08% of the total aluminum of the silica–alumina. It seems that the solubility of alumina hydrogel increases with increase in the concentration of phosphate.

(Received May 21, 1979)

The lifetimes of *ortho*-positronium (*o*-Ps) have been measured in benzene solutions of β-diketonates of iron(III) and cobalt(III). A trend in substituent effect on the acceleration of *o*-Ps decay has been found. A substituent such as trifluoromethyl, that tends to withdraw electrons from the chelate ring, greatly accelerated *o*-Ps decay; the greatest rate constant observed was 33.8×10^9 M^{-1} s^{-1} for tris(hexafluoroacetylacetonato)iron(III). An electron-releasing substituent such as *t*-butyl accelerated *o*-Ps decay to a lesser extent, *e.g.* 10.5×10^9 M^{-1} s^{-1} for tris(dipivaloylmethanato)iron(III). The extent to which a complex accelerated *o*-Ps decay was largely related to the redox potential, which was observed by cyclic voltammetry. Complexes with phenyl substituents in the ligand showed slightly smaller effects than that suggested by their redox potentials.

Chemical reactions of *ortho*-positronium (*o*-Ps) in aqueous solutions have been investigated by many workers,[1–9] who have shown that the reactions of *o*-Ps with solute species can be characterized essentially as one or the other type: oxidation of *o*-Ps, and spin-conversion of *o*-Ps to *para*-positronium (*p*-Ps) and *vice versa*. Highly oxidizing ions such as MnO_4^- and CrO_4^{2-} oxidized *o*-Ps, resulting in a decrease in the lifetime and intensity of *o*-Ps.[2,3] Bartal and Ache[7] reported that the reactions of *o*-Ps show some similarities to those of the hydrogen atom in aqueous solutions of Werner-type cobalt(III) complexes. In nonaqueous systems, however, the interaction of *o*-Ps has not been systematically investigated. In nonaqueous solvents such as benzene, positrons and positronium as well as solute species are solvated to a lesser extent than in aqueous solutions. There is no evidence to prove whether positrons and positronium in benzene are solvated or not, but molecular orbital calculations have shown that the positron is barely bound to benzene.[10,11] Thus *o*-Ps will react with solute species in a way more characteristic of dissolved species. In a previous paper,[12] it was shown that *o*-Ps is oxidized by acetylacetonates and dipivaloylmethanates of iron(III) and manganese(III), and that the decay rate constant strongly depends on the redox potential of the solute. The reaction of *o*-Ps with solutes may however be influenced by the outer constituent of the solute molecule and the reaction mechanism may not be so simple. Thus, it is of interest to study the reaction of *o*-Ps with a series of complexes which are identical in the first coordination sphere but differ in the periphery.

A series of β-diketones form chelates of similar structure with a variety of metal ions. Among them, iron(III) forms tris chelates of high-spin ($S=5/2$) type, while cobalt(III) forms chelates of low-spin ($S=0$) type. In the present study, the lifetimes of positrons and positronium decaying in benzene solutions of β-diketonates of iron(III) and cobalt(III) have been measured. These complexes have different electronic densities at the metal center with different substituents in the ligands, thus showing different redox potentials. Another type of acceleration of *o*-Ps decay, due to spin-conversion mechanism, may occur in the presence of unpaired electrons. A comparison of the reaction rates for diamagnetic cobalt(III) and paramagnetic iron(III) complexes will enable the mechanism of *o*-Ps decay to be elucidated.

Experimental

Preparation of β-Diketonates. The following chemicals of reagent grade were used for the preparation of iron and cobalt complexes without further purification: acetylacetone (Hacac), dipivaloylmethane (Hdpm), trifluoroacetylacetone (Htfa), hexafluoroacetylacetone (Hhfa), 2-thenoyltrifluoroacetone (Htta), benzoyltrifluoroacetone (Hbta), dibenzoylmethane (Hdbm), benzoylacetone (Hbza), and 3-phenylacetylacetone (Hpaa).

Tris(β-diketonato)iron(III) complexes were prepared by the reaction of iron(III) sulfate or nitrate with the corresponding β-diketones.[13,14] $Fe(hfa)_3$, $Fe(tfa)_3$, $Fe(acac)_3$, and $Fe(dpm)_3$ were purified by repeated vacuum sublimations. $Fe(tta)_3$, $Fe(dbm)_3$, $Fe(bta)_3$, $Fe(bza)_3$, and $Fe(paa)_3$ were recrystallized from a benzene–hexane mixture. The preparation of aluminium complexes was essentially the same as that for the corresponding iron compounds. $Co(acac)_3$ was synthesized by the method of Moeller,[13] and $Fe(dpm)_3$ by Hammond *et al.*[14] $Co(tfa)_3$ and $Co(bza)_3$ were prepared from $Na_3[Co(CO_3)_3]3H_2O$, and purified on an alumina column.[15]

Lifetime Measurements. A specified amount of each complex was dissolved in benzene, and the solution was kept in a Pyrex-glass tube which contained a positron source of nearly 6 μCi of ^{22}Na(NaCl) of high specific activity. The ^{22}Na(NaCl) was sealed with aluminium foil, such that annihilation of positrons in the foil was negligibly small. The sample solution was degassed by repeated vacuum freeze-thaw treatments. The lifetime of positrons and positronium was measured with a fast-slow coincidence system constructed by the authors, the details of which were reported elsewhere.[16] The time resolution of the system was determined to be 750 ps (full width at half maximum) with prompt γ-rays of ^{60}Co under the same condition as that for positron measurements. The lifetime of *o*-Ps was obtained from the slope in the lifetime spectrum.

Cyclic Voltammetry. Cyclic-voltammetric measurements were made on β-diketonates of iron(III) and cobalt(III) in *N,N*-dimethylformamide (DMF), using 0.1 M tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. The measurement was conducted in a three-necked cell at room temperature. A platinum inlay electrode (Beckman 32273) was used as the working electrode; the counter electrode was a piece of platinum wire. A saturated Ag/AgCl

electrode as reference was connected to the cell by the two salt bridges: saturated KCl in water, and 0.1 M TBAP in DMF. A Hokuto Denko Model HA-101 potentiostat and a Hokuto Denko Model HB-107 function generator were used. Voltammograms were recorded on a Rikadenki X-Y recorder Model BW-133.

Results and Discussion

Benzene–Acetylacetone System. The lifetime spectra of positrons and positronium were measured in mixture of benzene and acetylacetone (Hacac). The lifetime (τ_2) of *o*-Ps in the mixture was essentially the same irrespective of the molar fraction of acetylacetone, whereas the *o*-Ps intensity (I_2) decreased with increasing molar fraction of Hacac (from 34.4% for pure benzene to 10.4% for pure acetylacetone), as shown in Fig. 1. The ionization and UV spectroscopy data suggest that no remarkable difference in the Oré gap model exists between benzene and acetylacetone, and thus the observed trend in I_2 values is not explainable by a simple Oré model.

Assuming the compounds of the mixture behave additively in the formation of *o*-Ps, the I_2 value for a mixture containing acetylacetone at a molar fraction of x may be expressed by

$$I_2 = \frac{\lambda_{pb}(1-x)+\lambda_{pa}x}{(\lambda_{pb}+\lambda_{qb})(1-x)+(\lambda_{pa}+\lambda_{qa})x}, \quad (1)$$

where λ_{pb} and λ_{qb} are respectively the average rate of *o*-Ps formation and that of annihilation without forming *o*-Ps in pure benzene, and λ_{pa} and λ_{qa} are those in pure acetylacetone. The curve in Fig. 1 shows the I_2 values calculated from Eq. 1, assuming $\lambda_{qb}/\lambda_{pb}=2$, $\lambda_{pa}/\lambda_{pb}=4$, and $\lambda_{qa}/\lambda_{pb}=34$. Within the experimental error, the curve fits the results except for one data point. This indicates that acetylacetone is ten times more reactive against positrons compared with benzene. The probability of *o*-Ps formation is however lower in the former case.

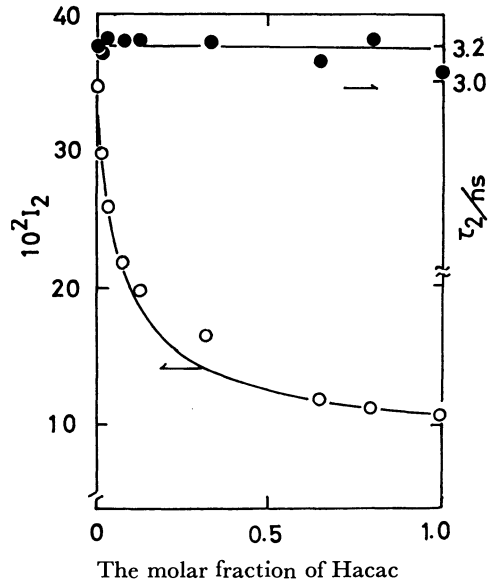

Fig. 1. Dependence of the lifetime(τ_2) and intensity(I_2) of *o*-Ps on the molar fraction of acetylacetone in acetylacetone–benzene mixture.

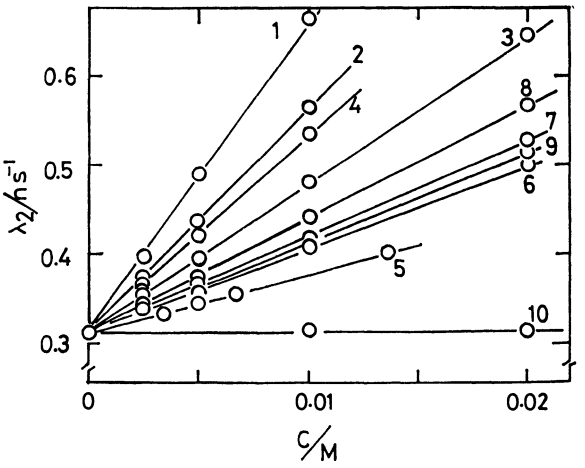

Fig. 2. Decay constant, $\lambda_2(\tau_2^{-1})$ of *o*-Ps in benzene solutions of β-diketonates of iron(III) as a function of the chelate concentration: (1) $Fe(hfa)_3$, (2) $Fe(tta)_3$, (3) $Fe(bta)_3$, (4) $Fe(tfa)_3$, (5) $Fe(dbm)_3$, (6) $Fe(bza)_3$, (7) $Fe(paa)_3$, (8) $Fe(acac)_3$, (9) $Fe(dpm)_3$, (10) $Al(bta)_3$ (as reference).

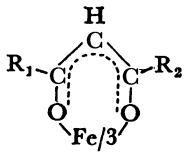
Effects of Ligating β-Diketonate Anion on the Lifetime of o-Ps. As reported in a previous paper,[12] $Al(dpm)_3$ and $Al(acac)_3$ do not affect the lifetime of *o*-Ps. Neither phenyl nor trifluoromethyl substituents changed the lifetime of *o*-Ps at 0.06 M, which was proved by the use of $Al(bza)_3$ and $Al(tfa)_3$. Therefore, the change in the lifetime of *o*-Ps in solutions of their complexes may be attributed to the effect of the central metal ions.

Lifetimes in Benzene Solutions of β-Diketonates of Iron(III) and Cobalt(III). The lifetime spectra of positrons and positronium were measured in benzene solutions of β-diketonato complexes at several concentrations. Figure 2 shows the plot of the observed decay constant, $\lambda_2(=\tau_2^{-1})$ against the solute concentration. For each compound, the following linear relationship was observed

$$\lambda_2 = 0.313 + k[C],$$

where 0.313 is the pick-off rate constant of *o*-Ps in pure benzene, [C] the molar concentration of the complex, and k the rate constant for *o*-Ps decay induced by the solute. The observed rate constants are given in Table 1. Apparently, the acceleration of *o*-Ps decay is greatest for compounds which have the trifluoromethyl group in the ligands. The trend is clearly shown in Fig. 3, where the rate constants of β-diketonates with different substituents are compared. For a series of β-diketonates with one common substituent, the acceleration of *o*-Ps decay increased in the same sequence of the other substituents. The sequence is closely related to the electron attracting or releasing properties of the substituents. For a more quantitative estimation of the latter property, the cyclic voltammograms were measured in DMF. Typical voltammograms are shown in Fig. 4. The voltammogram of $Fe(dbm)_3$ showed an almost reversible wave, whereas those of the other iron(III) compounds were found to be irreversible; the



Common substituent	The sequence of the other substituent with regard to the acceleration of the *o*-Ps decay
CF_3	CF_3>thenoyl>CH_3>phenyl
phenyl	CF_3>CH_3>phenyl
CH_3	CF_3>CH_3>phenyl

Fig. 3. Schematic drawing of the molecular structure of tris(β-diketonato)M(III) (M=Co, Fe) and the sequence of the substituents with respect to the effects on the *o*-Ps decay.

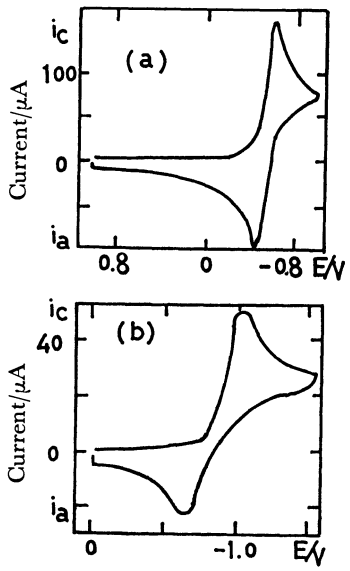


Fig. 4. Cyclic voltammograms for 5 mM β-diketonates of Fe(III) in *N*,*N*-dimethylformamide with 0.1 M tetrabutylammonium perchlorate: (a) $Fe(bza)_3$, (b) $Fe(dpm)_3$. Scan rate was 100 mV/s and the potential was measured against a saturated Ag/AgCl electrode.

irreversibility was highest for the wave of $Fe(dpm)_3$ among the iron(III) compounds studied, the results of which are summarized in Table 1. Figure 5 gives a plot of log *k* against *E*, the redox potential (the average of the peak potentials of the reduction and oxidation waves) of the complex. As expected, a greater acceleration of *o*-Ps decay was in general observed for a complex of less negative redox potential. The trifluoromethyl group tends to withdraw σ-electrons from the chelate ring, and therefore makes the reduction of the complex easier, both at the electrode and by *o*-Ps. Dipivaloylmethane has electron-releasing methyl substituents, and thus the increased electron density at the iron(III) atom of the dipivaloylmethanate makes the addition of an electron less easy. As seen in Fig. 5, exceptions were found for those compounds with phenyl substituents. In spite of the more positive or less negative redox potentials, the values of the rate constants were lower for $Fe(bta)_3$ and $Co(bta)_3$ than for $Fe(tfa)_3$ and $Co(tfa)_3$, respectively. The compounds, $Fe(dbm)_3$, $Fe(bza)_3$,

Table 1. Rate constants of *o*-Ps reaction and the cathodic and anodic potentials of cyclic voltammograms for β-diketonates of iron(III) and cobalt(III)

	$10^{-9}\,k/M^{-1}\,s^{-1}$	E_{pc}/V[a]	E_{pa}/V[a]
$Fe(hfa)_3$	33.8±0.8	0.50	0.72

$Fe(bta)_3$	19.6±0.5	0.07	0.21
$Fe(tfa)_3$	22.1±0.7	0.00	0.19
$Fe(dbm)_3$	7.1±0.4	−0.55*	−0.49*
$Fe(bza)_3$	9.6±0.3	−0.61	−0.47
$Fe(paa)_3$	10.1±0.4	−0.69	−0.55
$Fe(acac)_3$	15.6±0.6	−0.68	−0.55
$Fe(dpm)_3$	10.5±0.4	−1.16	−0.66
$Co(bta)_3$	16.6±0.7	−0.07	1.12
$Co(tfa)_3$	17.0±0.6	−0.05	1.10
$Co(bza)_3$	0.5±0.1	−0.93	0.53
$Co(acac)_3$	1.1±0.2	−1.04	0.47
$Co(dpm)_3$	0.0±0.1	—[b]	—[b]

a) The scan rate was 100 mV/s except for the data with an asterisk for which the scan rate was 500 mV/s, and the reproducibility of the potential was within±0.04 V on each sample. b) No reliable data were obtained because of the limited solubility of $Co(dpm)_3$.

$Fe(paa)_3$, and $Co(bza)_3$ also contain phenyl groups and showed lower *k* values than expected from the reduction potentials.

The *o*-Ps decay was also accelerated by most cobalt(III) complexes, but to a lesser extent than by the iron(III) analogues. This can primarily be attributed to the more negative reduction potentials of the cobalt(III) complexes. The reduction potential however cannot fully explain the very slow rate of reaction between *o*-Ps and the complex, and the electronic structure of the cobalt(III) complex may be partly responsible for the slow rates. Unlike the iron(III) β-diketonate of the high-spin type ($S=5/2$), all the cobalt(III) complexes investigated are of low-spin type ($S=0$). In the reduced state, however, the high-spin configuration should be preferred by the cobalt complexes ($S=3/2$) as well as the iron complexes ($S=2$). Thus, an extra activation energy will be required in the reduction of the cobalt complexes. Activation energy is essential in a kinetic process such as the reaction of *o*-Ps, but rarely important in the equilibrium. Voltammetry measures an equilibrium property rather than a kinetic one, although the latter is to some extent involved when irreversible waves occur. Thus the extra activation energy required in the reduction of cobalt(III) complexes will make the rate of the reaction with *o*-Ps considerably lower than expected from the redox potential.

An approximately linear relationship was observed between log *k* and *E* (Fig. 5); however, the slope or the value of $\Delta\log k/\Delta E$ was unusally small. A linear free energy relationship is often observed between logarithms of the rate and equilibrium constants of interrelated reactions, with a coefficient of $\Delta\log k_A/\Delta\log K_{A'}$, usually ranging from 0.3 to 0.9.[17] The $\Delta\log k/\Delta E$ value of 0.33

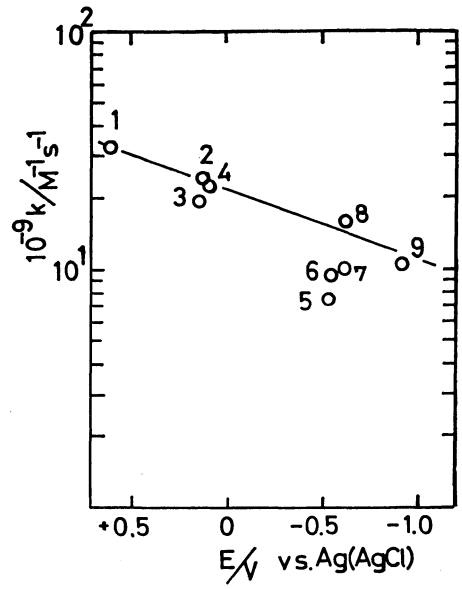

Fig. 5. Rate constants for the reactions of *o*-Ps with *β*-diketonates of iron(III) *vs.* the half-wave potentials measured with cyclic voltammetry in *N,N*-dimethylformamide with 0.1 M tetrabutylammonium perchlorate: (1) $Fe(hfa)_3$, (2) $Fe(tta)_3$, (3) $Fe(bta)_3$, (4) $Fe(tfa)_3$, (5) $Fe(dbm)_3$, (6) $Fe(bza)_3$, (7) $Fe(paa)_3$, (8) $Fe(acac)_3$, (9) $Fe(dpm)_3$.

observed here corresponds to a $\Delta\log k/\Delta\log K$ value of approx. 0.02.

No definite explanation can be made at present for this unusually small value. A possible explanation is that the rate constants were observed in a region where the rate is close to diffusion controlled. Assuming this to be the case, the $\Delta\log k/\Delta E$ value can be unusually small, but cannot be constant over such a wide range as covered in Fig. 5. Another possibility is that the difference between activation energies for the reactions of *o*-Ps and the iron(III) complexes is much less than that between the free energy changes for the electrode reactions of the complexes. This may occur if the structure of the complex undergoes only slight changes during the process of the reaction with the *o*-Ps atom, a very soft atom, from the initial to the transition state. A third possibility cannot be excluded, *i.e.* that the observed linear relationship is incidental and results from a mixing of the various effects including the steric effect of the substituent groups.

The acceleration of *o*-Ps decay can also occur through the spin-conversion mechanism in the presence of unpaired electrons. In the present case, this mechanism may not be important, since it has been previously shown that *o*-Ps decay by way of spin-conversion process makes only a minor contribution when both spin-conversion and oxidation processes are possible.[18]

The authors wish to thank Prof. I. Motoyama for his valuable advice on cyclic voltammetry.

The Precipitation of Traces of Copper, Cadmium, and Lead with 6-Anilino-1,3,5-triazine-2,4-dithiol and Its Application to X-Ray Fluorescence Spectrometry

Hiroto WATANABE* and Takashi UEDA

Department of Applied Chemistry, Muroran Institute of Technology, Mizumoto-cho, Muroran 050

(Received June 15, 1979)

A selective enrichment procedure for copper, cadmium, and lead is described. This method is based on precipitating the three elements with 6-anilino-1,3,5-triazine-2,4-dithiol (ATD) or with a combination of ATD and benzyldimethyltetradecylammonium chloride (BMTAC), filtering the precipitates to form a suitable X-ray sample, and then analyzing the sample by means of X-ray fluorescence. Microgram amounts of the three elements were precipitated quantitatively with ATD from 50 cm^3 or less of aqueous solutions of pH 7. Several to several tens mg amounts of such other elements as aluminium, iron(III), vanadium(V), zinc, arsenic(III, V), nickel, cobalt, and manganese(II) do not form any precipitates in the presence of citrate. Quantitative recoveries of the three elements from aqueous solutions ranging from 200 to 500 cm^3 were also possible when BMTAC was present as a coagulant aid. ATD was used for the determination of the three elements in reference materials (Orchard Leaves and Pepperbush Leaves). The results agreed with the certified values and with those obtained by isotope-dilution mass-spectrometry, and the precisions were satisfactory. The three elements in hot-spring water at levels from several to several tens ppb were determined by using a combination of ATD and BMTAC.

Various 6-substituted 1,3,5-triazine-2,4-dithiols react with relatively limited numbers of metal ions to give precipitates which are sparingly soluble in water.[1] One of the most remarkable properties of the dithiols is their extraordinary stability. They are not readily oxidized on exposure to air and are stable in either an alkaline or an acid solution.[1] This is quite different from the properties of other sulfur-containing ligands, such as dithiocarbamates, which react rather nonspecifically with a wide variety of metal ions. The dithiols have proved to be very effective in precipitating copper(II), cadmium(II), lead(II), and mercury(II) in industrial waste waters.[2]

Precipitation has long been used for the concentration and separation of trace elements in aqueous samples. Recently emphasis has been placed on the use of polymeric precipitating reagents. Muzzarelli[3] used a naturally occurring chelating polymer, chitosan, and Buono *et al.*[4] employed poly(5-vinyl-8-hydroxyquinoline). However, there has been little mention of utilizing organic ligands which give rise to polynuclear complexes. It is well known that dithiooxamide (DTO) reacts with copper to form a bridged polymer consisting of a series of five-membered rings.[5] Unfortunately, DTO is unstable and readily undergoes hydrolysis to hydrogen sulfide, so that metal ions, such as zinc, cadmium, lead, and mercury, are precipitated as their sulfides.[6] In this respect, the dithiols seem to be potential precipitants. As has been reported by Chudy and Dalziel[7] and by Mori *et al.*,[8] the dithiols are also capable of forming polymeric complexes with metal ions.

Of the commercially available dithiols, 6-anilino-1,3,5-triazine-2,4-dithiol (ATD) was chosen in this study because it gave the most insoluble precipitates. This report will deal with the application of ATD as a precipitant for the determination of copper, cadmium, and lead in conjunction with X-ray fluorescence (XRF) spectrometry.

Experimental

Materials. A 1.0% (w/w) ATD solution was prepared by dissolving 1.0 g of the compound (sodium hydrogen 6-anilino-1,3,5-triazine-2,4-dithiolate tetrahydrate; Sankyo Kasei Co., Ltd., Osaka) in 50 cm^3 of 2 mol dm^{-3} aqueous sodium hydroxide and by then diluting the mixture to 100 g with water.

A 0.001 mol dm^{-3} aqueous solution of benzyldimethyltetradecylammonium chloride (BMTAC) was prepared by using a commercial material (Dojindo Co., Ltd., Kumamoto).

Standard solutions containing 1 g dm^{-3} portions of a number of elements were prepared by dissolving weighed quantities of the high-purity metal, oxide or salt in a minimum amount of acid and then diluting the mixtures to known volumes. Working solutions containing the cations at concentrations of from 1 to 100 $\mu g\ cm^{-3}$ were prepared by dilution.

A buffer solution of pH 7.0 was made by mixing 0.5 mol dm^{-3} of sodium dihydrogenphosphate and 0.5 mol dm^{-3} of disodium hydrogenphosphate.

A 0.5 mol dm^{-3} portion of sodium citrate was prepared by dissolving the compound in water.

The citrate and the buffer solutions were cleansed of metal contaminants by precipitation with ATD, as in Method A described below.

The other reagents, such as nitric, hydrochloric, hydrofluoric, and perchloric acids, were purified by sub-boiling distillation.[9]

Apparatus. A Rigaku model SX X-ray fluorescence spectrometer with a tungsten target tube, a LiF(200) crystal, and a NaI(Tl) scintillation counter was used. However, in the determination of cadmium, it was necessary to use a chromium target tube, an EDDT crystal, and a flow proportional counter. The X-ray tubes were operated at 40 kV and 35 mA. Both sample and spectrometer chambers were evacuated to a pressure of less than 13.3 Pa.

Procedure. Precipitation of Copper, Cadmium, and Lead with ATD (Method A): To a test solution (usually 25 cm^3) containing 10 μg or less of the respective element, 1 cm^3 of a 1.0% ATD solution and 1 cm^3 of 0.5 mol dm^{-3} sodium citrate were added. Then the pH was adjusted to 7.0 with 2 cm^3 of the phosphate buffer and, if necessary, with an appropriate amount of ammonium hydroxide or hydrochloric

acid. The resulting mixture was allowed to stand for 20 min at room temperature and then filtered under suction through a Millipore filter disk (25 mm diameter, 0.45 μm pore size). The precipitate on the filter disk was washed with a small amount of water and subsequently allowed to dry at 60 °C for 10 min. The XRF specimens thus prepared were placed between 6 μm Mylar films in an XRF sample holder. A titanium disk was inserted into the holder to keep the filter flat. The XRF intensities were then measured at the *Kα* line of copper (45.02°) and the *Lα* lines of cadmium (53.38°) and lead (33.92°). The counting times were 40 s except in the case of cadmium, for which the counting time was 100 s. The background counts were measured at the following 2θ values: copper (44.52°, 45.52°), cadmium (52.38°, 54.38°), lead (33.72°, 34.12°).

Precipitation of the Three Elements with a Combination of ATD and BMTAC (Method B): To a test solution (usually 200 cm^3) containing 10 μg or less of the respective element, 1 cm^3 of a 1.0% ATD solution, 1 cm^3 of 0.5 mol dm^{-3} sodium citrate, 1 cm^3 of 0.001 mol dm^{-3} BMTAC, and 2 cm^3 of the phosphate buffer were added successively. Precipitation and XRF sample preparation were then performed as in Method A, but the time of precipitation was extended to 25 min. These methods were selected in view of the results of the optimization study to be described in the next section.

Throughout the present study, the recovery yields of the three elements (5.0 μg each) were expressed as ratios of the net counts of samples prepared under various conditions to that of a reference sample. The reference sample was prepared by applying Method A to a 25 cm^3 aqueous solution containing 5.0 μg of the respective element. For the reference sample, the recoveries of the three elements were confirmed to be quantitative by determining the three elements remaining in the filtrates. Atomic absorption spectrometry was used for this purpose.

Results and Discussion

Effect of the pH *on the Precipitation of Various Elements.* The recovery yields of various elements from 25 cm^3 of aqueous solutions were examined as a function of the pH in the absence of BMTAC. This procedure was practically the same as Method A except that no buffer was used and filtration was done 60 min after precipitation. Copper was precipitated over the pH range of 4—9, while the range for cadmium and lead was 6 to 9, as is shown in Fig. 1. Thus, a pH value of 7 was chosen in Method A. The precipitates thus formed were easily filtered and did not adhere to glass.

Ten micrograms of other elements, such as cobalt, nickel, arsenic(III, V), manganese(II), vanadium(V), zinc, aluminium, iron(II, III), bismuth, calcium, and magnesium, gave no precipitates over the entire pH range studied. In the absence of citrate aluminium, iron(III) and bismuth were precipitated, but their precipitates seemed to be hydroxides because the precipitation of these elements was also observed for solutions from which ATD was omitted. When the pH was adjusted to 7 by using the phosphate buffer in the presence of citrate, the other elements did not form any precipitates.

Although it has been pointed out that mercury(II) forms a highly insoluble precipitate with ATD,[1,2] the sensitivity of XRF for mercury is low, thus precluding its determination in the present study. ATD itself

○: Cu, ●: Cd, ◐: Pb.
Counting time: 40 s for Cu and Pb, 100 s for Cd. Total volume of aqueous solutions: 200 cm^3. Amount of each of the three elements: 5.0 μg.

did not precipitate at pH 7, but it was precipitated below pH 4. This is due to the insolubility of the protonated form of ATD.

Figure 2 shows the effect of the pH on the collection of the three elements from 200 cm^3 portions of aqueous solutions containing BMTAC. For this purpose, Method B, from which the phosphate buffer had been omitted, was used. The recoveries of the three elements were quantitative over the pH range of 6—9. Working at pH values greater than 9 appeared to be time-consuming for filtration (>30 min): thus, no further studies were carried out. For the filtration of 200 cm^3 portions of the

aqueous solutions prepared over the pH range of 6—9, a period of 5 min was required. For experimental convenience, a pH value of 7 was also chosen in Method B.

ATD itself did not form any precipitates with BMTAC. This was verified by the fact that no intensities due to sulfur $K\alpha$ line were observed for samples from which the three elements had been omitted.

Effect of ATD. Ten-μg amounts of the three elements were precipitated from 25 cm³ (Method A) or 200 cm³ (Method B) of test solutions containing various amounts of ATD. The recoveries were independent of the amounts of the ATD solution in the range >0.8 cm³. Thus, 1 cm³ of the ATD solution was used for both methods.

Effect of Time. The minimum time required to obtain quantitative precipitation was determined by varying the time of precipitation. Method A was used for several 25 cm³ solutions, filtration being done for a specified period of time ranging from 5 min to 24 h. It was found that filtration should be performed after 20 min in Method A.

Method B was applied to several 200 cm³ portions of test solutions. After the addition of the ATD solution and the phosphate buffer to the test solutions, the mixtures were allowed to stand for from 5 to 60 min. Twenty-five min was found to be adequate for the completion of the precipitation of the three elements.

Table 1. Effect of sample volume on the recovery yields of the three elements[a] at pH 7

Method A				Method B			
Volume cm³	Recovery yield Cu	Pb	Cd	Volume cm³	Recovery yield Cu	Pb	Cd
10	1.00	1.00	1.00	200	1.00	1.00	1.00
25	1.00	1.00	1.00	300	0.99	0.98	0.99
50	1.00	1.00	1.00	400	1.01	0.99	1.00
100	1.00	0.98	0.81	500	1.00	1.00	0.99
150	0.74	0.66	0.51				

a) A 5-μg portion of the respective element was used.

Effect of Sample Volume. Method A was applied to various volumes (10—150 cm³) of test solutions. The results, shown in Table 1, indicate that the influence of the sample volume is significant. It is thus recommended that the sample volume should be made up to 50 cm³ or less for the simultaneous determination of the three elements.

On the other hand, when BMTAC was present, the recovery yields were essentially independent of the sample volume, as is shown in Table 1. A 5 μg portion of the respective element was precipitated quantitatively even from 500 cm³ of aqueous solutions. This fact makes it possible to determine the three elements present in water at levels of from several to several tens ppb. This marked effect of BMTAC is probably due to the formation of a large anionic polynuclear complex of ATD. This interpretation seems to be consistent with the failure of a usual organic solvent such as *N,N*-dimethylformamide to dissolve the precipitates prepared by Method A. Working with sample volumes larger than 500 cm³ was not done, but it appeared to be too time-consuming to be practical.

Effect of BMTAC. The three elements were collected from 200 cm³ portions of aqueous solutions containing various amounts of BMTAC. When the amount of the BMTAC solution added was 1 cm³ or larger, the recoveries were quantitative. However, a longer period (>30 min) was required for filtration because of the dispersing action when 3 cm³ or more of the BMTAC solution was added. When 1 cm³ of the BMTAC solution was added to test solutions ranging from 200 to 500 cm³, a period of 5 to 10 min was required for filtering off the precipitates. Thus, in Method B a 1 cm³ portion of the solution was employed.

Table 2. Effect of foreign ions on the determination of the three elements[a]

Foreign ion	Added mg	Method A Cu	Pb	Cd	Method B Cu	Pb	Cd
Fe(III)	1.0				0.97	0.98	0.96
	10	1.01	1.03	0.97

	40	1.00	1.01	0.99			
Zn(II)	2.0				1.00	1.01	1.01
	10	1.00	0.98	1.02			
Co(II)	2.0				0.99	0.99	0.98
	10	0.98	0.97	0.96			
Ni(II)	2.0				1.01	1.02	1.00
	10	1.00	0.99	0.98			
V(V)	5	0.98	0.97	0.96			
Bi(III)	0.3	1.03	1.02	1.01			
Al(III)	1.0				0.96	0.97	0.98
	20	0.99	0.98	0.99			
Ca(II)	20				1.00	1.01	1.00
	30	0.97	0.97	0.98			
Mg(II)	20				1.00	1.00	1.01
	50	0.97	0.98	0.98			

a) A 5-μg portion of the respective element was used.

Effect of Foreign Ions. Test solutions containing 5.0 μg of the respective element and various amounts of a foreign ion were analysed. The results are summarized in Table 2. Lower results were obtained when foreign ions other than calcium, magnesium, and arsenic(III, V) were present in amounts higher than those indicated in Table 2. In Method A, several to several tens mg of foreign ions do not interfere with the determination of the three elements. It is well known that arsenic interferes seriously with the determination of lead because of mutual line interference. However, ATD does not react with arsenic(III, V), so the interference for lead is thus eliminated. At least 1 mg of arsenic was tolerable for the determination of 5 μg of lead.

In Method B the tolerance limits of foreign ions are lower than those in Method A. This is due to the precipitation of foreign ions to such an extent that the

XRF intensities of the three elements are lowered significantly. For example, when 1 mg of iron(III) was added about 10 μg portions of iron were found on the filter disk by measuring the XRF intensity of the iron $K\alpha$ line. The precipitation of iron(III) becomes more significant as the quantities of iron(III) exceed 1 mg. This precipitation of iron(III) may be caused by the reaction between a citrate complex of iron(III) and BMTAC, for a similar tendency was observed on samples prepared by Method B from which the ATD solution and the buffer had been omitted. The precipitate of iron(III) has a very small grain size; hence, filtration is made more time-consuming (>30 min). Though it was not shown in Table 2, the recoveries of the three elements were quantitative from test solutions (200—500 cm^3) of any salinity up to that of seawater.

Mutual interferences among the three elements must also be taken into account. When one of the three elements was present in an amount higher than 100 μg, the XRF intensities for the other two elements were reduced. The total amounts of the three elements in an aliquot should be below 100 μg for both methods.

TABLE 3. SENSITIVITY AND PRECISION

	Cu	Pb	Cd
Sensitivity (counts/s)/μg	253	42.1	38.7
Background counts/s	1100	1113	19.9
95% confidence limit[a] μg	5.05±0.10[b]	5.05±0.11[b]	5.02±0.05[b]
	5.03±0.20[c]	5.02±0.24[c]	5.03±0.13[c]
Limit of detection μg	0.04	0.24	0.03

a) Confidence limit (95%) for the median of the eleven samples used for the preparation of the calibration curves. The median sample contains 5.00 μg of the respective element. b) Method A. c) Method B.

Calibration Curve. Linear calibration functions were obtained for the three elements in the concentration range of up to 10 μg. Table 3 lists the sensitivity of the XRF measurements; the background counts; the confidence limits (95%), C, for the median of the eleven samples used for the preparation of the calibration curves, and the limit of detection, D. The limit of detection at the 95% confidence level was calculated from the $D=3C\sqrt{B}M^{-1}$ relationship, where M is the slope of the calibration curves, and B, the background counts, based on a 40 s counting period for copper and lead or a 100 s counting period for cadmium. From this table it may be seen that the precision of the two methods is satisfactory.

Application of the Present Methods. Method A was applied to the determination of the three elements in NBS Orchard Leaves (National Bureau of Standards, U.S.A., Standard No. 1571). A weighed sample (3.0896 g) was placed in a Teflon beaker, together with 30 cm^3 of 14 mol dm^{-3} nitric acid, 5 cm^3 of 26 mol dm^{-3} hydrofluoric acid, and 4 cm^3 of 8 mol dm^{-3} perchloric acid. This mixture was warmed until a clear solution was obtained. The solution was then gently evaporated to dryness. The residue was dissolved in 5 cm^3 of 1 mol dm^{-3} hydrochloric acid and finally diluted to 100 cm^3 with water. A 15 cm^3 aliquot of this solution was used for the determination of the three elements. The confidence limits (95%) for the average of five determinations are shown in Table 4. In the table the present results are also compared with the values obtained by Murozumi[10] by isotope-dilution mass-spectrometry and those given by the NBS.[11] The data indicate a very satisfactory agreement between the present results and the others.

Method A was also used for the determination of the three elements in a reference sample, NIES Pepperbush Leaves (*Clethra barbinervis Sieb. et Zucc.*), distributed by the National Institute for Environmental Study, Japan. The sample (0.9788 g) was decomposed in the same manner as the Orchard Leaves. The results are presented in Table 4, in which the values given by Murozumi[10] are also included. They are in acceptable agreement.

The three elements in a sample of hot-spring water were also determined by Method B. Two 150 g aliquots of the sample, both alone and with 2.0 μg of the respec-

tive element added, were analysed. The samples were placed in a polyethylene bottle (1 dm^3) containing 1 g of 6 mol dm^{-3} hydrochloric acid, and the mixture was allowed to stand overnight prior to the determination. It is apparent from Table 5 that from several to several tens ppb level of the three elements in water can be determined with fairly satisfactory precision.

Conclusion

Sodium diethyldithiocarbamate,[12,13] ammonium 1-pyrrolidinecarbodithioate,[14,15] 1-(2-pyridylazo)-2-naphthol,[13,16,17] and sodium dibenzyldithiocarbamate[18] are currently used in the preparation of suitable XRF samples. These organic reagents ordinarily react with a wide range of metal ions. Therefore, as has been reported by Hellman,[19] it is necessary to select certain masking conditions if a limited number of elements are to be precipitated by means of a nonspecific reagent. In this respect, the specificity of ATD toward copper, cadmium, and lead can be useful for separating μg amounts of the three elements from large amounts of other elements. Especially, there are few simple and selective methods for the separation of cadmium and lead, so ATD will be one of the most suitable reagents for their enrichment from multicomponent solutions.

Takemoto *et al.*[20] were the first to introduce a coagulant aid for the precipitation of heavy metal ions as dithiocarbamates. Microgram amounts of heavy metal ions were rapidly and quantitatively precipitated in the presence of dibenzylidene-D-sorbitol. Recently Panayappan *et al.*[21] have reported that a combination of poly(*N*-vinylpyrrolidone) and *N*-(2-naphthyl)mercaptoacetamide was excellent in precipitating heavy metal ions rapidly and forming insoluble compounds. These methods are convenient for the simultaneous precipitation of a variety of metal ions. The combination of ATD and BMTAC proposed in this study is particularly suited for the selective enrichment of the three elements from large volumes of aqueous samples containing considerable amounts of other elements. A number of coagulant aids currently used for water and waste-water purification, in combination with ATD, were tested, but they did not show any promise of being as effective as the ATD-BMTAC combination.

The authors wish to thank Professor Masayo Murozumi of this laboratory for his offer of reference materials (Orchard Leaves and Pepperbush Leaves) and for his kindness in letting us use a part of his analytical results obtained on the samples by means of isotope-dilution mass spectrometry. The XRF measurements were made on the spectrometer in the laboratory of Mr. Katsumasa Yabe, the Goverment Industrial Development Laboratory, Hokkaido, to whom the authors wish to express their gratitude. We also would like to thank Mr. Akira Umehara, Sankyo Kasei Co., Ltd., for kindly supplying a sample of ATD.

(Received June 16, 1979)

A selective and sensitive method is presented for the determination of cadmium(II), based on polarography after salting-out extraction into acetonitrile. The effect of nonaqueous solvents, salting-out agents, and the concentration of reagents has been studied. Under the conditions established, the cadmium(II) iodide complex extracted into the solvent gives a well-defined d.c. wave and a sharp a.c. peak, with $E_{1/2}$ and $E_p = -0.72$ V *vs.* SCE respectively. Down to 0.50 ppm of cadmium(II) in the original aqueous solution can be determined by the proposed method. Lead(II) and In(III) do not interfere up to a 1000-fold amount relative to Cd(II). Interference from Fe(III) and Tl(III) can be eliminated by the addition of ascorbic acid.

The polarographic behavior of metal complexes in nonaqueous solvents has been reported in various papers.[1,2] As for analytical applications, the polarographic analysis of methods after extraction have been studied using chloroform,[3] 4-methyl-2-pentanone (MIBK),[4] and benzyl alcohol,[5] in which cases the extract has been diluted with other polar solvents, such as water, methyl cellosolve, or methanol, to obtain a higher conductivity of the medium. Recently, Kitagawa and Ichimura[6] have reported the d.c. polarographic determination of metals in the MIBK extract. These methods, however, still seem insufficient with respect to the sensitivity and selectivity of the determination.

The salting-out effect is useful for analytical purposes in order to increase the extractability of species and to facilitate phase separation in the liquid-liquid extraction. Matkovich and Christian[7] have used the salting-out phenomenon in the separation of acetone from an aqueous solution and have determined the cobalt(II) in the extract by means of atomic-absorption spectrophotometry. Kawamoto and Akaiwa[8] have also studied a spectrophotometric determination of iron(III) after extraction into 2-propanol by the salting-out method.

In a previous paper,[9] an attempt has been made to utilize the salting-out technique for the extraction-polarographic method of analysis, in which both extraction and polarography have been carried out with acetonitrile. In the present paper, the phase separation of various organic solvents from an aqueous solution has been investigated and has been used for the polarographic determination of cadmium(II) after the salting-out extraction of the iodide complex. Acetonitrile as the solvent has a relatively low viscosity (0.345 cP) and a high dielectric constant (37.5), and it dissolves many ion-pair compounds, particularly tetraalkylammonium salts as supporting electrolytes; the resulting solution has a high conductivity. Further, the solvent is easily salted-out from an aqueous solution with various inorganic compounds. With ammonium sulfate as the salting-out, cadmium(II) in an aqueous solution can be extracted quantitatively into the acetonitrile phase as the ion-pair of tetrabutylammonium tetraiodocadmate, $NR_4[CdI_4]$; tetrabutylammonium iodide (TBAI) has been added not only as the reagent to form the tetraiodocadmate(II) complex, but also as the supporting electrolyte for the polarographic measurements. The present method constitutes a useful means of solving some problems in polarographic analysis.

Experimental

Reagents. Standard cadmium(II) solution (100 ppm): 0.247 g of cadmium(II) nitrate was dissolved in 20 cm^3 of 0.1 mol dm^{-3} nitric acid, after which the solution was diluted to 1 dm^3 with water. The acetonitrile was purified by distillation once from phosphorus pentaoxide. The ammonium sulfate (Wako Junyaku Co., Ltd.) for atomic-absorption spectrometry, the TBAI (Tokyo Kasei Co., Ltd.), and the Karl Fisher reagent (Mitsubishi Kasei Co., Ltd.) were used without further purification. The other chemicals were of guaranteed grade. Redistilled water was used throughout this study.

Apparatus. Two Yanagimoto polarographs, Model P8-D with a three-electrode system and PA-102, were used for the d.c. and a.c. polarographic measurements. In the a.c. polarographic measurements, a capacitor of 100 μF was inserted between the platinum wire counter electrode and the aqueous saturated calomel reference electrode. The DME had the following characteristics at a mercury head of 60 cm: $m = 0.783$ mg s^{-1}, $t = 3.98$ s in acetonitrile with an open circuit. A Toa Denpa pH meter, Model HM-5A, was used for the pH measurements.

Salting-out Experiment. Aliquots of water and an organic solvent were placed in a 50.0-cm^3 stoppered volumetric cylinder which had been calibrated before use. After a salting-out agent had been added to the mixture, the volume of the two phases was measured and the amount of the water present in the organic phase was determined by the Karl Fisher titration method.

Procedure. An aliquot of the standard cadmium(II) solution was placed in a 50.0-cm^3 stoppered centrifuge tube, and the volume was adjusted to 20.0 cm^3 with water. After 10.0 cm^3 of a 0.1 mol dm^{-3} TBAI solution in acetonitrile had then been added to it, the mixture was shaken with 10.0 g of ammonium sulfate for 1 min and then allowed to stand for 1 min. A portion of the extract was placed in a polarographic cell and deaerated for 3 min. The d.c. and a.c. polarograms were recorded against SCE at (25±0.1) °C.

Results and Discussion

Solvent for Polarographic Use. The phase separation of various organic solvents suitable for the polarography after salting-out extraction was investigated with ammonium sulfate. Table 1 summarizes the salting-out

Table 1. Salting-out data with ammonium sulfate for water-miscible solvents

Solvent	Organic phase-volume recovered/cm³	Water content of organic phase/(v/v %)	Dielectric constant	Viscosity/cP
Acetonitrile	10.2	9.8	37.5	0.325
Acetone	12.2	29.1	20.7	0.304
Dioxane	10.0	35.6	2.2	1.087
Tetrahydrofuran	10.0	6.2	7.5	0.460
Ethanol	14.5	50.6	24.6	1.078
1-Propanol	12.5	19.5	20.3	2.004
1-Butanol	10.3	7.7	17.5	2.271
2-Methoxyethanol	15.5	44.3	29.6	1.85
2-Buthoxyethanol	10.4	10.6	9.3	3.12
1,2-Dimethoxyethane	13.7	43.4	7.2	0.455
Propylene carbonate	9.9	4.7	64.4	2.53

The initial volumes of the water and the non-aqueous solvent were 10.0 cm³ each. The phase separations were carried out from a saturated ammonium sulfate solution.

data: the volume and the water content of the organic phase after phase separation, together with the dielectric constant and the viscosity of the pure solvents. In the polarography after extraction, it is considered preferable for the solvent to have such properties as a low mutual solubility with water, a high dissociation constant of extracted species, and a high conductivity. Acetonitrile was found to be the most useful among the solvents examined. Propylene carbonate and 1-butanol seem fairly useful, provided a suitable salting-out agent is present. Methanol, *N,N*-dimethylformamide, dimethyl sulfoxide, and pyridine did not cause any phase separation.

Salting-out Agent. Various inorganic salts were investigated as possible salting-out agents for the phase separation of acetonitrile from aqueous solution. Table 2 summarizes the minimum salt quantities required to cause phase separation, and also the volume and the water content of the acetonitrile phase after saturation with the salt. It may be concluded from Table 2 that the phase separation takes place more easily with the salt of multivalent ions than with that of univalent ions. The water content of the acetonitrile phase decreased in this order: alkali ion>alkaline earth ion> aluminum ion, with respect to their chloride salts. Among the inorganic salts tested, all the sodium and ammonium salts showed a water content of about 10%, except for sodium acetate. Ammonium sulfate as a salting-out agent is useful for the polarographic determination of cadmium(II) because of the high extractability of the complex.

Volume Ratio after Phase Separation. The initial volume of water was varied from 10.0 to 50 cm³ against 10.0 cm³ of acetonitrile. The aqueous and acetonitrile phase-volumes were measured after the mixture was saturated with ammonium sulfate. The results are shown in Table 3, from which it may be found that the acetonitrile phase-volume recovered decreased with an increase in the volume of the aqueous solution and that the water content remained almost constant under the conditions studied; this can be presumed from the fact that the amount of acetonitrile dissolved in the aqueous phase increases with the volume of the aqueous solution taken initially. The addition of TBAI to this system

Table 2. Salting-out data for inorganic compounds causing phase separation in the acetonitrile–water system

Compound	Minimum quantity causing phase separation/mmol	Acetonitrile phase-volume recovered from sat. salt solution/cm³	Water content of acetonitrile phase/(v/v %)
$AlCl_3$	2.48	7.52	0.81
$SrCl_2$	3.23	7.70	1.37
$BaCl_2$	3.36	6.69	1.32

The initial volumes of the water and the acetonitrile were 10.0 cm³ each.

Table 3. Effect of initial volume ratio on phase separation

Initial volume ratio (V_w/V_o)	Acetonitrile phase-volume recovered/cm³	Aqueous phase-volume recovered/cm³	Water content of acetonitrile phase/(v/v %)
1	10.2	13.0	9.87
2	9.7	27.2	9.32
3	9.2	40.5	10.0
4	8.5	54.3	10.0
5	7.7	68.3	9.32

The initial volume of the acetonitrile was 10.0 cm³. The phase separations were carried out from a saturated ammonium sulfate solution.

Table 4. Effect of amount of ammonium sulfate on phase separation

$(NH_4)_2SO_4$/g	Acetonitrile phase-volume recovered/cm³	Water content of acetonitrile phase/(v/v %)
1.5	9.9	24.2
2.0	10.1	20.5
2.5	10.2	18.0
3.0	10.2	16.6
3.5	10.3	15.0
4.0	10.1	14.6
4.5	10.2	13.8
5.0	10.3	11.5
5.5	10.1	10.6
6.6	10.2	9.8

The initial volumes of the water and the acetonitrile were 10.0 cm³ each.

caused a slight increase in the final acetonitrile phase-volume because of a salting-in effect.

Varying amounts of ammonium sulfate (1.5—6.0 g) were added to a mixture of acetonitrile (10.0 cm³) and water (10.0 cm³), and the phase-volumes were measured after the phase separation. According to the results shown in Table 4, the phase separation was initiated by the addition of 1.2 g of the ammonium salt, while the final acetonitrile phase-volume became almost constant (10.2 cm³) with a salt amount of more than 1.5 g. The content of water present in the acetonitrile phase decreased with an increase in the salt amount added. In this extraction system, the addition of a large amount of a salting-out agent is desirable to accelerate the phase separation and to increase the extractability of the species, provided no significant contamination with the coexisting impurities results. The volumes of the two phases were measured under varying experimental conditions. On the basis of the results, a ternary-phase diagram composed of acetonitrile, water, and ammonium sulfate was obtained, as is shown in Fig. 1. The solid lines of 1—4 in Fig. 1 represent the volume ratio of the two phases recovered

0.200	0.463	180	−0.86	10.2

d.c. wave and a.c. peak heights were obtained in the case of the acetonitrile extraction; this suggests that acetonitrile is the best solvent to obtain a good sensitivity. Under the conditions established, the cadmium(II) complex gave a well-defined d.c. wave and a sharp a.c. peak usable for the polarographic determination, as can be seen in Fig. 2. The available potential range was from −0.53 to −1.47 V *vs.* SCE, between which potentials no metal except for cadmium(II) gave polarographic waves. The half-wave potential of the cadmium(II) complex varied with the solvent; this is presumably a result of the difference in the liquid junction potential between SCE and the organic solvent, or to that in the electrode reaction.

Effect of pH. Extractions were carried out at varying pH values, while the other experimental conditions were kept constant. It was found that the d.c. wave and the a.c. peak heights were approximately constant at pH values between 1.7 and 6.8, in which range there was no shift of the half-wave potential. Beyond this pH range, the final acetonitrile phase-volume was decreased somewhat by salting-out with added hydrochloric acid or sodium hydroxide.

Effect of TBAI Concentration. Hitherto, TBAI has often been used as a complexing agent[10] for the formation of metal iodides in acetonitrile, a supporting electrolyte[11] for the polarographic measurement in the solvent, and an extraction reagent[5] after ion-pairing with anions. In the present study, it was examined whether or not TBAI simultaneously played the three roles over the concentration range from 0.03 to 2.00 mol dm^{-3}. The results in Table 6 show that a well-defined d.c. polarogram and a sharp a.c. polarogram of cadmium(II) were observed at all the TBAI concentrations studied. The d.c. wave and the a.c. peak heights decreased gradually with an increase in the TBAI concentration above 0.05 mol dm^{-3}, probably because of the increase in the final volume and in the viscosity of the acetonitrile phase. As the TBAI concentration was increased, the half-wave potential shifted toward negative values and the content of water in the acetonitrile phase increased. The negative shift may be interpreted as resulting from the increase in the concentrations of the complexing agent and the supporting electrolyte. The extractability of TBAI into acetonitrile in the absence of cadmium(II) was determined by the titration method[12] to be 98.9%. The electrolytic conductivity and the viscosity of the acetonitrile extract obtained under the conditions of the procedure were 1.07×10^{-2} S cm^{-1} and 0.439 cP respectively. A 0.1

mol dm^{-3} TBAI solution in acetonitrile was used in the present investigation.

Effect of Amount of Ammonium Sulfate. Preliminary experiments indicated that ammonium sulfate was effective in obtaining a high extractability of the cadmium(II) complex, in addition to being a good salting-out agent for the phase separation. Table 7 shows the polarographic data obtained with varying amounts of ammonium sulfate. The d.c. wave and the a.c. peak heights decreased linearly with an increase in the salt concentration. This is mainly caused by the increase in the final volume of the extract. The half-wave potential shifted toward more negative values with an increase in the salt concentration. The amount of the ammonium sulfate involved in the acetonitrile extract was determined to be below 0.1 mg cm^{-3} after evaporating under reduced pressure and drying at 110 °C. Approximately constant heights of the d.c. wave and the a.c. peak were obtained when ammonium sulfate was added in the range between 8.0 and 12.0 g; 10.0 g of the salt was chosen for the determination of cadmium(II).

Effect of Volume of Aqueous Solution. The initial volume of the aqueous solution was varied from 10.0 to 30.0 cm^3 against 10.0 cm^3 of acetonitrile, while the other conditions were kept constant. As can be seen from Table 8, the d.c. wave and the a.c. peak heights of the cadmium(II) complex increased as the initial volume of the aqueous solution was increased; in the volume range, the degree of extraction is quantitative. The extracted cadmium(II) complex is enriched at a higher concentration as the acetonitrile phase-volume recovered is decreased. A slight shift of the half-wave potential was observed. The initial volume of the aqueous solution was adjusted to a constant volume of 20.0 cm^3.

Calibration Curves. Under the established procedure, the d.c. wave and the a.c. peak heights were determined at varying amounts of cadmium(II). The calibration curves constructed were linear over the concentration range from 0.05 to 10.0 ppm cadmium(II) in the original aqueous solution. The sensitivity of the proposed method was about twice as much as that obtained in a 1.0 mol dm^{-3} KI solution.[13] The relative standard deviation for 100 μg of cadmium(II) were 1.8% and 1.5% in the d.c. and a.c. methods respectively. The extractability of cadmium(II) was >99% over the working range. The polarographic parameters were determined to be 30 mV for the slope of the plot of $\log [i/(i_d-i)]$ *vs.* E and 5.20 $\mu A \cdot dm^3 \cdot mmol^{-1} \cdot mg^{-2/3} \cdot s^{1/2}$ for the diffusion-current constant; this indicates that the cadmium(II) complex extracted into acetonitrile is reduced by two-electron transfer.

Effect of Diverse Ions. The interference from coexisting ions was studied for the a.c. polarographic determination of 100 μg of cadmium(II). The results are summarized in Table 9. Each ten-fold amount of Bi(III), Hg(II), Fe(II), Cu(II), and Tl(III) did not interfere; Fe(III) and Tl(III) were tolerable up to 100 mg in the presence of 1 g of ascorbic acid. Indium(III) and Pb(II), both non-extractable into acetonitrile, had no effect up to 100 mg, but interfered on the addition of 0.5 g of KI. None of the metals such as Mn(II), Co(II), Ni(II), and Zn(II) interfered. Of the anions examined, MoO_4^{2-}, $S_2O_4^{2-}$, and EDTA showed a serious interference, even with the same amount of cadmium(II).

Benzo-15-crown-5-Aluminium Chloride Complexes of Unusual Stability

Fumio WADA* and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received June 25, 1979)

Among twelve crown ethers of 12, 15, 18, and 21 rings only benzo-15-crown-5 and those with an electron-releasing substituent formed the complexes with aluminium chloride which were stable in methanol.

The halides of group III elements, such as boron trifluoride and aluminium chloride, are typical Lewis acids and known to form stable adducts with ether and tertiary amine in nonpolar solvents. The common feature of the ether adducts so far known is easy exchange of the donated ether molecule(s) with other donative molecule (Eq. 1) or substitution of the halide ion by protic molecule such as methanol (Eq. 2).[1] Though the extent of the processes depends on the nature of

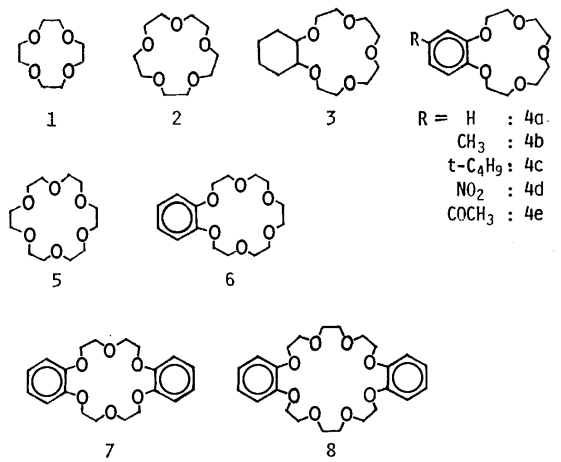
$$R_2O{\rightarrow}AlX_3 + R_2'O \longrightarrow R_2'O{\rightarrow}AlX_3 + R_2O \quad (1)$$

$$R_2O{\rightarrow}AlX_3 + R'OH \longrightarrow R'OAlX_2 + HX + R_2O \quad (2)$$

the halide and the donating molecule, there is no ether–aluminium halide adduct (or complex) which is stable in protic solvent as far as we know.

In the course of our study to introduce various substituents into the benzene ring of benzocrown ethers, attempted Friedel-Crafts acylation catalyzed by aluminium chloride was proved to be unpractical. The failure of the reaction can be reasonably explained in terms of the formation of a stable crown ether adduct with the aluminium chloride, and resulting deactivation of the catalyst.[2] However, this study led us to a novel finding that a complex containing aluminium chloride was obtained even after usual hydrolysis of the reaction mixture and successive recrystallization from methanol. The unusual feature of the complex has prompted us to study behavior of typical Lewis acids to various crown ethers (**1** to **8**). It should be noted that despite of a large number of studies on the chemistry of the crown ether complexes with group I and II element cations as well as ammonium-type ions there have been few papers concerned with those of group III element halides.[3]

This paper described a specific feature of benzo-15-crown-5 and some of its derivatives with an electron-releasing group, those ethers which afford stable 1 : 1 complexes with aluminium chloride in methanol. Though elucidation of the relationship between their structures and the unusual stability has to await X-ray crystallography, the present observations would shed light to the study for the crown ether complexes with neutral Lewis acids.



Results and Discussion

Slow addition of benzo-15-crown-5 (**4a**) (3 mmol) in benzene into an ethereal aluminium chloride (6 mmol) produced white precipitates (**9**) in a quantitative yield (>95%), which proved to be an 1 : 2 adduct of the crown ether and aluminium chloride (Eq. 3). The same adduct was obtained even when the ratio of the starting materials was changed to 1 : 1. The reaction in more donative solvent, THF or nitromethane, afforded viscous oil, which offered difficulty for further treatment. The adduct **9** was sparingly soluble in methanol, and attempted recrystallization from the solvent gave a complex (**10**), white powders, mp 147—148 °C, in 77% yield (Eq. 4). Longer heating of **9** in methanol brought about slow decomposition to liberate the crown ether. The interaction between

the ether oxygens and aluminium in both **9** and **10** was shown by bathochromic shift in the IR absorptions of ether linkages (Fig. 1). The adduct **9** was also proved to be transformed easily into **10** on dissolution in methanol, and thus **9** and **10** gave the same NMR spectrum in methanol-d_4 (Fig. 2). The larger down-field shift in methylene signals ($\Delta\delta$ 0.4—0.6 ppm) than those of aromatic protons ($\Delta\delta$ *ca.* 0.32 ppm)

is indicative of the preferential coordination of aluminium with the ether oxygens. The fact that the similar treatment of **9** with ethanol gave **10** (NMR and EA; Found: C, 41.55; H, 5.00%) reasonably ruled out the possibility that **10** was one of the products derived by substitution of the chloride ion(s) by the alcohols. The complex **10** is insoluble in most solvents but shows a small solubility in methanol (*ca.* 6×10^{-3} mol/l). Molecular weight determination by means of vapor pressure depression technique gave an average value of 403 ± 10 (calcd for $C_{14}H_{20}O_5AlCl_3$: 401.3), indicating that **10** was monomeric in methanol. None of useful information was obtained in MS analysis. The reactions of **4a** with boron trifluoride etherate, aluminium bromide and indium chloride under the similar conditions gave white precipitates, but on dissolution in methanol they liberated the crown ether. Thus, the following experiments were conducted with use of aluminium chloride. Aluminium chloride adducts of **1**, **5**, **6**, and **8** were again proved to decompose in methanol and **7** did not afford any solid adduct. Although **2** and **3** seem to be favorable ligands than **4a** in terms of their increased basicity of the ether oxygens, the methanol-d_4 solutions of their 1:2 adducts showed the NMR spectra coincided with those of the free crown ethers.

Since these experiments led us to the presumption that the ability of forming stable complex with aluminium chloride was limited to benzo-15-crown-5 structure, we proceeded to examine whether the feature was common among substituted benzo-15-crown-5 ethers. The adducts obtained from **4d** and **4e** bearing an electron-withdrawing group were found to liberate the corresponding crown ether in methanol-d_4, even when the amount of aluminium chloride was increased to 10 molar excess taking account of possible donation of the substituent to the halide. **4b** and **4c** with an electron-releasing group gave semi-solid and viscous oil, respectively, in the reaction with 2 equivalents of aluminium chloride. White powders were obtained by evaporation of the solvent, and their NMR spectra in methanol-d_4 demonstrated the formation of the complexes which showed the similar signals to that of **10**. However, attempts to isolate them as crystals failed. The down-field deviation of ^{1}H signals in the three complexes in the solvent at room temperature are summarized in Table 1. From these data it could be

deduced that the aluminium atom in the complexes does not equally interact with the five ether oxygens, but preferentially does with the three located remote from the benzene ring. The deduction is also in line with the less basicity of the phenol ether oxygens than other aliphatic ones.

It is noteworthy that the formation of the crown ether–aluminium chloride complexes which are stable in methanol is limited only to benzo-15-crown-5 and

those with an electron-releasing group. Moreover, there is no precedent of such peculiar properties among known ether–aluminium chloride adducts (or complexes). The stability of various crown ether complexes with cation is known to be determined principally by the basicity of crown ethers and matching of their cavities with the size of a guest cation. The present results, however, seem to indicate that the similar generalization does not necessarily hold for the aluminium chloride complex, a complex with neutral species, in view of the behaviors that the adducts of **2** and **3** are more susceptible to the decomposition. The presence of the benzo moiety might be one of the reasons for the increased stability of **10** and the complexes of **4b** and **4c**, leading to increased conformational rigidity of the crown ether ring and the resulting steric hindrance toward the attack by methanol.

Experimental

Materials. 12-Crown-4, 15-crown-5, and 18-crown-6 were of commercial origin (Bokusuy Brown Co.). 4′-Acetobenzo-15-crown-5 (mp 94.2—95.4 °C) was obtained by acetylation of **4a** with acetic anhydride in polyphosphoric acid–acetic acid mixture. Other crown ethers were prepared according to the published procedures[4] (lit, 5 for **4d**). Indium chloride (extra pure) was used as received, and other Lewis acids used were purified by the known procedure: sublimation for aluminium chloride and distillation for aluminium bromide and boron trifluoride etherate. Solvents were dehydrated over sodium–potassium alloy and distilled under nitrogen.

General Procedure. The preparations of the adducts and the complex (**10**) were carried out in a closed system and under nitrogen. ^{1}H NMR spectra in methanol-d_4 were recorded using Brucker WH 90 FT spectrometer (90 MHz) at room temperature. The following procedure for the preparation of **9** and **10** was also used in the other combinations of the Lewis acid and the crown ether. To a solution of **4a** (3 mmol) in benzene (6 ml) aluminium chloride (6 mmol) in ether (3 ml) was slowly added. The adduct (**9**) precipitated was collected and thoroughly washed with ether, and dried under vacuum. The treatment of **9** with methanol (or ethanol) gave **10**.

Kinetics and Mechanism of Ligand Exchange of Tris(acetylacetonato)-iron(III) in Acetylacetone

Hiroaki KIDO* and Kazuo SAITO*

Chemistry Department, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received August 9, 1979)

Tris(acetylacetonato[2-^{14}C])iron(III) undergoes ligand exchange in acetylacetone at 4—16 °C without side reactions. The exchange rate is expressed by Rate$=(k_a+k_b[H_2O])$[complex]([complex]$\approx$0.01 M, [H_2O]$\approx$0.05 M), and the rate constant (10.2 °C) and activation parameters are $k_a=(8.9\pm1.2)\times10^{-4}$ s^{-1}, $\Delta H^{\ddagger}=14.4\pm0.9$ kcal mol^{-1}, $\Delta S^{\ddagger}=-22\pm3$ cal K^{-1} mol^{-1} and $k_b=(2.22\pm0.20)\times10^{-2}$ M^{-1} s^{-1}, $\Delta H^{\ddagger}=16.9\pm0.4$ kcal mol^{-1}, $\Delta S^{\ddagger}=-6.1\pm1.3$ cal K^{-1} mol^{-1} (1 cal$=$4.18 J, 1 M$=$1 mol dm^{-3}). No deuterium isotope effect on the rate. The rate-determining steps seem to correspond to the formation of intermediates containing a one-ended acac$^-$ and an Hacac molecule (the k_a path), and the anion and a water molecule (the k_b path), by the S_N2 mechanism.

Although numerous studies of ligand substitution reactions of Fe^{III} complexes have been reported,[1] almost all the studies are concerned with $[Fe(H_2O)_6]^{3+}$ and $[Fe(dmso)_6]^{3+}$ (dmso=dimethyl sulfoxide). These complexes undergo labile solvent exchange and anation reactions with various ligands, and both the S_N1 and the S_N2 mechanism have been proposed to these substitution processes. However, little information is available concerning the kinetics of Fe^{III} complexes containing bidentate ligands. Recently, the rate of the ligand substitution of tris(acetylacetonato)iron(III) with 2-thenoyltrifluoroacetone has been reported in organic solvents such as carbon tetrachloride and benzene, but the mechanism was not definitely proposed.[2]

The reaction systems consisting of two components, tris(acetylacetonato)complexes of Cr^{III}, Co^{III}, Ru^{III}, or Rh^{III} as solute and acetylacetone (Hacac) as solvent, are suitable for understanding the mechanism of the ligand exchange between the two species.[3] On extending of the kinetic studies of these systems, we have found a slow exchange of $Fe(acac)_3$ in Hacac at 10 °C. This paper deals with the kinetics and the mechanism of this exchange reaction examined by the isotopic labelling method.

Experimental

Materials. The labelled acetylacetone, Hacac[2-^{14}C][4] and Hacac[*methylene*-$^2H_2$] (the deuterium content in the methylene moiety: 80%)[5] were prepared and purified by the reported methods. Tris(acetylacetonato)iron(III), $Fe(acac)_3$, was prepared from ammonium iron(III) sulfate dodecahydrate (1.9 g), acetylacetone (1.5 ml) and sodium hydrogencarbonate (1.3 g) in water (40 ml) at room temperature. The labelled complex, $Fe(acac[2\text{-}^{14}C])_3$, was prepared from Hacac[2-^{14}C] and $Fe(acac)_3$ by the ligand exchange method. The solution of $Fe(acac)_3$ (300 mg) in a mixed solvent of Hacac[2-^{14}C] (1 ml) and acetonitrile (0.5 ml) was heated at 80 °C for 1 h and evaporated to dryness under reduced pressure at room temperature to give orange crystals (*ca.* 300 mg of $Fe(acac[2\text{-}^{14}C])_3$), which were recrystalized from benzene–petroleum ether. Its UV and visible absorption spectra in acetonitrile coincided with the reported data.[6] The specific activity of the complex was 0.005 μCi/mg.

The solvents, Hacac and acetonitrile, were purified by the reported method.[5] Guaranteed grade of hexane was used without purification.

Kinetic Procedure. The free Hacac was separated from the complex in the reaction mixtures by the solvent extraction with hexane. The labelled complex (*ca.* 12 mg) and the solvent (6 ml of Hacac, Hacac[*methylene*-$^2H_2$] or Hacac diluted with acetonitrile) were placed separately in the two sections of a glass-stoppered flask with a branched bottom. The flask was kept in a thermostat (4.4±0.1, 10.2±0.1, or 16.2±0.1 °C) for *ca.* 30 min and rotated to unite the contents of the two sections. The complex dissolved within 10 s. Portions (0.5 ml) of the solution were taken out at appropriate time intervals and swiftly (<10 s) poured into a chilled (−30 °C) hexane layer (10 ml), which floated on a pure acetonitrile layer (1 ml) in a glass-stoppered thin test tube. The tube was shaken vigourously for 10 s and allowed to stand for *ca.* 1 min at −30 °C. A 1 ml portion of the acetonitrile layer was taken out and washed twice with hexane (10 ml) at −30 °C in a similar manner to be made free from Hacac. The complex is insoluble in hexane and present only in the acetonitrile layer. This acetonitrile solution contained sufficient amount of $Fe(acac)_3$ for kinetic analysis (*ca.* 70% of that in the original Hacac solution) and a negligible amount of Hacac. Spectrophotometry at 434 nm and the liquid scintillation counting of this acetonitrile solution gave the specific counting rate of the recovered complex. The exchange rate R was calculated by the McKay equation

$$R=\frac{3[Fe][Hacac]}{3[Fe]+[Hacac]}\frac{\ln[(x_0-x_\infty)/(x_t-x_\infty)]}{t}$$
$$\approx 3[Fe]\ln(x_0/x_t)/t \quad ([Hacac]\gg[Fe],\ x_\infty\approx0) \qquad (1)$$

where [Fe] and [Hacac] stand for the concentration of the complex and acetylacetone, respectively. The x's are the specific counting rates of the recovered complex at the times indicated by the subscripts.

The water contents (0.2—0.8 M; 1 M$=$1 mol dm^{-3}) of the reaction mixture were determined by the Karl Fischer titration.

Results

The visible absorption spectra of the reaction mixture containing the given amount of H_2O remained unchanged throughout the reaction, and were identical with those of the complex in anhydrous Hacac and in anhydrous acetonitrile ([H_2O]<0.01 M) within experimental errors at room temperature ($\lambda_{max}=434\pm0.5$ nm, log $\varepsilon=3.55\pm0.02$). The water content also remained unchanged. The McKay plots gave straight lines up to at least 50% completion of the exchange (Fig. 1). No significant zero-time exchange was observed. Therefore, the decrease of the specific counting rate of

the recovered complex corresponds exclusively to the exchange reaction (2).

$$Fe(\overset{*}{acac})_3 + Hacac \rightleftharpoons Fe(acac)_3 + H\overset{*}{acac} \quad (2)$$

The R in neat acetylacetone was proportional to the concentration of the complex (Table 1) and is given by

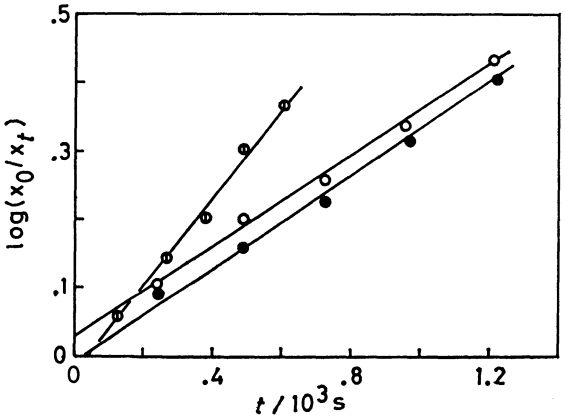

Fig. 1. Typical McKay plots for the ligand exchange of $Fe(acac)_3$ in acetylacetone (○, ⓘ) and in acetylacetone[*methylene*-$^2H_2$](●) at 10.2(ⓘ) and 16.2(○,●) °C ([Fe]≈0.006 M).

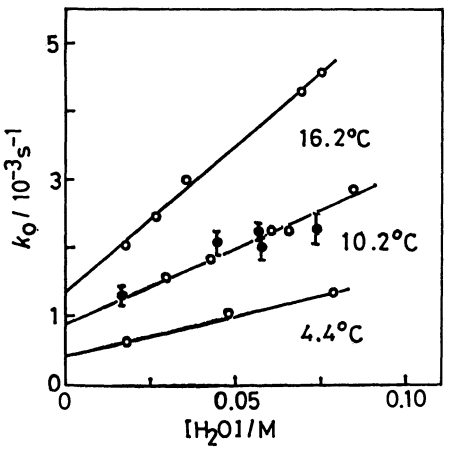

Fig. 2. Influence of the water concentration and the deuterium isotope effect on the exchange rate constant (k_o) of $Fe(acac)_3$ in acetylacetone(○) and in acetylacetone[*methylene*-$^2H_2$](●)([Fe]≃0.006 M).

Table 1. Ligand exchange rate of Fe(acac-[2-$^{14}C_3$])$_3$ in acetylacetone at 4.4 °C

[Fe] / 10^{-3} M	[H_2O] / M	R / 10^{-6} M s^{-1}	k_o / 10^{-4} s^{-1}
5.78	0.018	3.7±0.1	6.4±0.2
9.75	0.021	6.5±0.2	6.7±0.2

$$R = k_o[Fe] \quad (3)$$

where k_o is the observed first-order rate constant. The k_o value was dependent on [H_2O] (Fig. 2), and expressed by Eq. 4 in the given concentration range,

$$k_o = k_a + k_b[H_2O]. \quad (4)$$

The k_a and k_b values were obtained from the intercepts and the slopes of the lines in Fig. 2, respectively, and are shown in Table 2, together with the activation parameters.

When Hacac[*methylene*-$^2H_2$] was used as the solvent at 10.2 °C in place of the ordinary Hacac, the k_o values coincided with those in Hacac within the experimental errors (Fig. 2).

The k_o value increased linearly with the increase in concentration of Hacac in the mixed solvent with acetonitrile up to 9.7 M (in neat acetylacetone) under a given concentration of the complex and water (Fig. 3). The k_o *vs.* [Hacac] plot has a very small intercept.

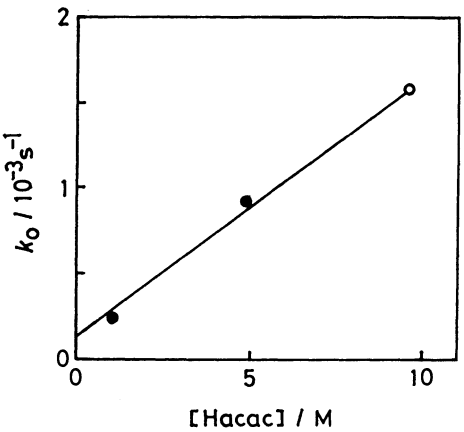

Fig. 3. Influence of the free ligand concentration on the exchange rate constant (k_o) of $Fe(acac)_3$ in acetylacetone(○) and in acetonitrile(●)([Fe]≃0.006 M, [H_2O]=0.03 M, 10.2 °C).

Discussion

Equation 4 indicates that the exchange in Hacac (Eq. 2) proceeds by two paths (the k_a and k_b path) in the presence of water. The linear plot of k_o *vs.* [Hacac] (Fig. 3) suggests that the exchange reactions in Hacac and in the mixed solvent are essentially the same and expressed by Eq. 5 in the concentration region from 1 to 9.7 M of Hacac,

$$k_o = k_o'[Hacac]. \quad (5)$$

If either k_a or k_b in Eq. 4 were independent of [Hacac], the k_o *vs.* [Hacac] plot would not have such a small intercept shown in Fig. 3, because the k_a and k_b terms give comparable contributions to k_o under the given

Table 2. Kinetic data for the ligand exchange of Fe(acac[2-^{14}C])$_3$ in acetylacetone

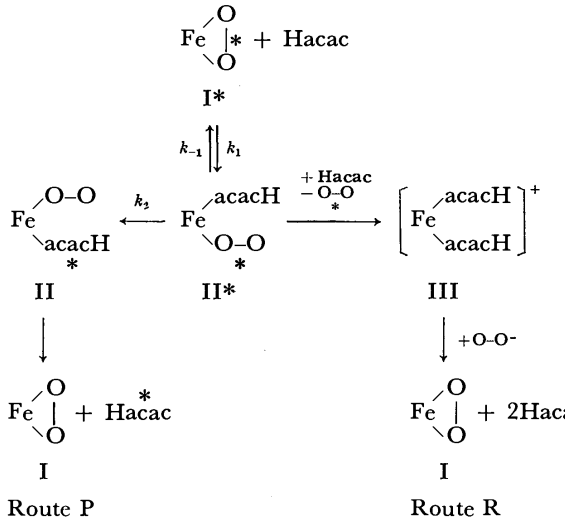
Parameters	Rate constants 4.4 °C	10.2 °C	16.2 °C	$\Delta H^{\ddagger}$ / kcal mol^{-1}	$\Delta S^{\ddagger}$ / cal K^{-1} mol^{-1}
k_a/10^{-3} s^{-1}	0.44±0.04	0.89±0.12	1.35±0.10	14.4±0.9	−22±3
k_b/10^{-2} M^{-1} s^{-1}	1.16±0.08	2.22±0.20	4.24±0.19	16.9±0.4	−6.1±1.3

conditions (*cf.* Fig. 2, $[H_2O] \simeq 0.03$ M). Hence Eq. 6 holds at least in the vicinity of [Hacac]=9.7 M (in Hacac),

$$k_o \approx (k_a' + k_b'[H_2O])[\text{Hacac}]. \quad (6)$$

Equations 3 and 6 suggest that one $Fe(acac)_3$ and one Hacac molecule participate in the k_a and k_b paths and one H_2O molecule also does in the k_b path.

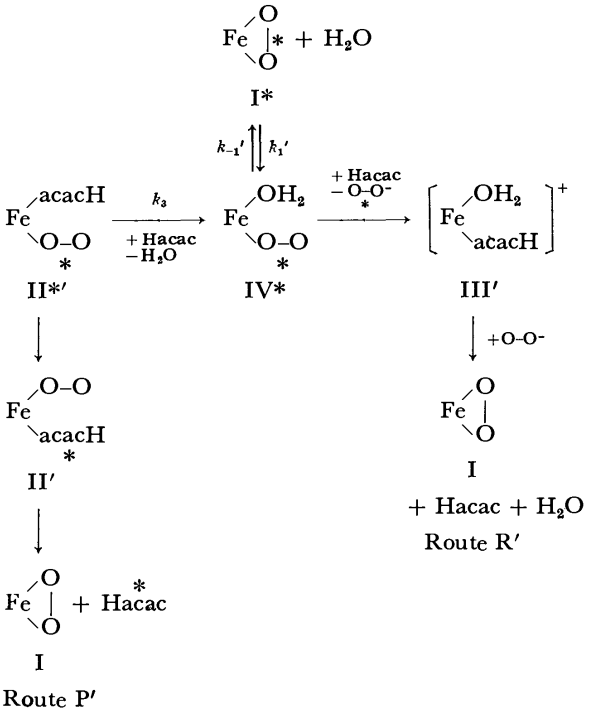
Possible Reaction Routes of the k_a and k_b Paths. Varieties of probable reaction routes for the k_a path are very much limited, since the reaction system is very simple and the chemical species participating in the rate-determining step should be only $Fe(acac)_3$ and Hacac. Scheme 1 can be assumed almost exclusively as possible routes for the k_a path,[3]



Scheme 1.

where O–O and I* denote $acac^-$ and $Fe(acac)_3$, respectively, and two $acac^-$ chelates are omitted from each species. The intermediate II* is formed from I* and Hacac. (II* corresponds to an intermediate containing a one-ended bidentate and a solvent molecule; such a type of intermediate is generally accepted in substitution processes of bidentates.[3]) In the Route P, II* is converted into II through the proton transfer between the unidentate ligands, $O^*\text{–}O^-$ and Hacac, and II turns to I and Hacac*. In the Route R, II* changes into another cationic intermediate III by the replacement of unidentate $O^*\text{–}O^-$ by free Hacac (III corresponds to a bis-chelate-type intermediate containing two solvent molecules, $[Fe(acac)_2(solvent)_2]^+$), and III produces I by the ligation of $O^*\text{–}O^-$ which is formed by the proton exchange between $O^*\text{–}O^-$ and Hacac in the bulk or in the second coordination sphere of the complex.

Similar routes are possible for the k_b path shown in Scheme 2. I* and a water molecule produce an intermediate IV*. When H_2O or the unidentate $O^*\text{–}O$ in IV* is replaced by the free Hacac, II*′ or III′ is formed, respectively. The intermediates II*′ and III′ undergo similar changes as in the P and R Routes in Scheme 1, to turn to I through the P′ and R′ Routes, respectively.



Scheme 2.

Reaction Mechanism. The activation enthalpies and entropies for k_a and k_b can be reckoned to have similar tendency to each other (Table 2). Hence both the paths are suggested to have similar reaction routes and rate-determining steps to each other. If the similar routes are P and P′ and the k_1 and the k_1' step are the slowest in each path, stationary-state conditions to II* and IV*, can be reasonably assumed to give Eqs. 7 and 8,

$$k_a = k_1[\text{Hacac}]\frac{k_2}{k_{-1}+k_2} \quad (7)$$

$$k_b[H_2O] = k_1'[H_2O]\frac{k_3[\text{Hacac}]}{k_3[\text{Hacac}]+k_{-1}'} \quad (8)$$

Concentrations of the intermediates should be negligible as compared with those of I* and I, since the visible absorption spectra of the complex in the reaction mixture, in Hacac and in acetonitrile are almost identical to one another (*vide supra*). On the assumptions, $k_{-1} \ll k_2$ and $k_{-1}' \gg k_3[\text{Hacac}]$, Eqs. 7 and 8 are further converted into Eqs. 9 and 10, respectively.

$$k_a = k_1[\text{Hacac}] \simeq k_a'[\text{Hacac}] \quad (9)$$

$$k_b[H_2O] = k_1'[H_2O]\frac{k_3[\text{Hacac}]}{k_{-1}'} \simeq k_b'[H_2O][\text{Hacac}] \quad (10)$$

These assumptions are not unreasonable. The proton transfer process(k_2) can be much faster than the ring-closure process(k_{-1}). On the contrary, if k_2 were much smaller than k_{-1}, k_a should be affected by k_2 (*cf.* Eq. 7) and deuterium isotope effect on the exchange rate should be observed as in the exchange of $Cr(acac)_3$ in Hacac.[5] Moreover, replacement of H_2O in IV* by the free end of one-ended acetylacetonate ligand (k_{-1}', intramolecular) can be much faster than that by the free Hacac (k_3[Hacac], intermolecular).

Equations 9 and 10 are consistent with Eq. 6. The k_1 and k_1' steps correspond to the rate-determining steps and the term $k_3[Hacac]/k_{-1}'$ represents a branching ratio for the accomplishment of the exchange from IV*.

On the contrary, the combination of the R and R' Routes does not seem adequate. When the first steps, I*→II* and I*→IV*, are considered to be the rate-determining steps, the first-order dependency of [Hacac] in the k_b term in Eq. 6 cannot be interpreted. On the other hand, when the second steps (II*→III, IV*→III', *i.e.*, replacement of acetylacetonate unidentate by Hacac or H_2O) are assumed to be rate-determining or to be concerned in determining the rate as in the P' Route mentioned above, the k_a term must have the second-order dependency with respect to [Hacac], which conflicts with the observation (Eq. 6). Such a type of one-ended acetylacetonate in II* and IV* has been claimed to be stablized towards replacement by free ligands such as Hacac, H_2O and acetonitrile in the exchange of $Co(acac)_3$ in acetonitrile. The stability has been attributed to the conjugated structure of the ligand, *i.e.*, concentration of negative charge on the coordinated oxygen (Co–O–C(CH_3)=CH–C(CH_3)=O).[7]
