Reaction of Thione S-*Imide* (*1*) *with Unsymmetrical Carbodiimides* (*11*). The reaction was carried out in the manner used for **8** (reaction time; **a** and **b**: 30 min, **c**: 15 h). The resultant reaction mixture was subjected to chromatography on silica gel, using chloroform as the eluent, to give **12** and **13**.[11]

12a: Colorless crystals (chloroform–hexane); mp 163—165 °C; IR (KBr) 3370, 3345 (N–H), 1590 (C=N), 1260 and 1145 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 0.9—2.1 (m, 10H, $(CH_2)_5$), 2.39 (s, 3H, CH_3 (Ts)), 2.80 (d, J=4.8 Hz, 3H, CH_3), 3.50 (broad s, 1H, CH), 5.3—6.6 (broad m, 2H, NH), 7.21 (d, J=7.8 Hz, 2H, arom), 7.76 (d, J=7.8 Hz, 2H, arom); MS (70 eV) *m/e* 309 (3, M^+), 162 (7), 154 (58), 98 (84), 91 (62), 28 (100). Found: C, 58.03; H, 7.45%. Calcd for $C_{15}H_{23}N_3O_2S$: C, 58.23; H, 7.49%.

12b: Colorless crystals (chloroform–hexane); mp 106—107 °C; IR (KBr) 3340 (N–H), 1580 (C=N), 1260 and 1140 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 0.8—2.1 (m, 11H, $(CH_2)_5CH$), 1.10 (t, J=7.0 Hz, 3H, CH_3), 2.38 (s, 3H, CH_3 (Ts)), 2.9—3.9 (m, 3H, CH_2, NH), 6.2 (broad, 1H, NH), 7.20 (d, 2H, J=8.0 Hz, arom), 7.73 (d, 2H, J=8.0 Hz, arom); MS (70 eV) *m/e* 323 (2, M^+), 225 (3), 168 (70), 155 (18), 98 (96), 91 (47), 44 (100). Found: C, 59.55; H, 7.81%. Calcd for $C_{16}H_{25}N_3O_2S$: C, 59.42; H, 7.79%.

12c: Colorless crystals (chloroform–hexane); mp 165—166 °C; IR (KBr) 3350 (N–H), 1625 (C=N), 1250 and 1140 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 0.7—2.2 (m, 10H, $(CH_2)_5$), 2.41 (s, 3H, CH_3 (Ts)), 3.8 (broad, 1H, CH), 5.0 (broad, 1H, NH), 7.0—7.5 (m, 6H, arom), 7.79 (d, 2H, J=8.2 Hz, arom), 8.66 (broad, 1H, NH); MS (70 eV) *m/e* 405 (2, M^+), 322 (2), 250 (10), 155 (13), 127 (100), 98 (24), 91 (31). Found: C, 59.22; H, 6.01%. Calcd for $C_{20}H_{24}N_3O_2SCl$: C, 59.18; H, 5.96%.

Reaction of Thione S-*Imide* (*1*) *with Ketenimines* (*14*). *A Typical Procedure*: To a partial suspension of **1** (0.92 g, 2.5 mmol) in 30 ml of 1,2-dichloroethane, a solution of **14a** (0.67 g, 2.5 mmol) in 10 ml of 1,2-dichloroethane was added dropwise at room temperature. The red suspension of **1** gradually disappeared within 2—4 h, but the mixture remained colored. The reaction mixture was stirred overnight

at room temperature to complete the reaction. The evaporation of the solvent gave the oily residue, which was subjected to column chromatography on silica gel with benzene as the eluent, followed by dichloromethane. The evaporation of the benzene elution gave **16** together with a trace amount of **14** and fluorenone (**13**). From the second dichloromethane elution, **15** (**17b**) was obtained. The crude **15**, **16**, and **17b** were recrystallized from the appropriate solvents as indicated below. In the case of **c** and **d**, the mixed elution solvent was used instead of the first benzene elution because of the low solubility of **15c**, **d** and **16c**, **d** into benzene (CH_2Cl_2/benzene; **c**: *ca.* 1, **d**: *ca.* 2).

15a: Yellow crystals (recrystallized from benzene-ether); mp 232—233.5 °C; IR (KBr) 1560 (C=N), 1320, 1150, and 1095 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 2.28 (s, 3H, CH_3 (Ts)), 6.8—7.8 (m, 25H, arom); MS (70 eV) *m/e* 632 (3, M^+), 477 (6, $M^+ - Ts$), 436 (12, $M^+ - Fl{=}S$), 281 (27, $M^+ - Ts - Fl{=}S$), 139 (100). Found: C, 76.17; H, 4.40; N, 4.53%. Calcd for $C_{40}H_{28}N_2O_2S_2$: C, 75.94; H, 4.46; N, 4.43%.

15b: Yellow crystals (benzene-ether); mp 267—269 °C; IR (KBr) 1560 (C=N), 1320, 1155, and 1100 cm^{-1} (SO_2); MS (70 eV) *m/e* 646 (4, M^+), 491 (3, $M^+ - Ts$), 450 (30, $M^+ - Fl{=}S$), 295 (78, $M^+ - Ts - Fl{=}S$), 255 (100), 139 (60). The Dehydrochlorination of *gem*-Dichloroalkane and the Formation of Dienes from the Reactions of Butenes and Cyclohexene with Chlorine through Molten Salt

Shōichi Kikkawa, Masakatsu Nomura,* and Michimasa Shimizu

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received January 5, 1980)

The dehydrochlorination of 1,1-dichloropropane and 1,1-dichloro-3-methylbutane was carried out over molten salt catalysts (mainly $ZnCl_2$-containing melts) using a conventional flow system. The *cis*/*trans* ratio (1.8) of the resulting olefins from 1,1-dichlorobutane was found to stand between the ratio (1.4) with 1,1-dichloro-3-methylbutane and the ratio (2.2) with 1,1-dichloropropane; this can be explained by considering the stereochemistry of the adsorbed carbonium ions. The detailed results of the reactions of three butene isomers with chlorine through molten salts were presented. The selective formation of butadiene was explained in terms of the thermally assisted attack of chlorine in the allylic positions of butene, followed by the 1,2- or 1,4-elimination of HCl from chlorobutenes, a process which is strongly assisted by the $ZnCl_2$-containing melts. The reaction of 2-methyl-2-butene and cyclohexene with chlorine through molten salts was also undertaken. The addition of Zn powder to $ZnCl_2$ melts in advance was found to improve the selectivity for the formation of isoprene and cyclohexadiene. Because the HCl evolved reacts instantly with Zn powder to afford $ZnCl_2$ and hydrogen, Zn powder substantially prohibits the addition of HCl to dienes yielding chlorobutenes and chlorocyclohexenes.

In a previous paper,[1] we explained the *cis*/*trans* ratio of the 1-chloro-1-butene produced in the dehydrochlorination of 1,1-dichlorobutane in contact with zinc chloride melts by considering the surface-adsorbed carbonium ion. The former part of this paper will present additional information to support this explanation, using 1,1-dichloropropane and 1,1-dichloro-3-methylbutane as reactants.

The reaction of butenes with chlorine through zinc chloride melts containing alkali chloride has been found to yield butadiene predominantly.[2] The dependence of this reaction on the reaction conditions has been discussed. The selective formation of isoprene and cyclohexadiene from the reaction of 2-methyl-2-butene and cyclohexene with chlorine was also examined. In these cases, the addition of zinc powder to zinc chloride melts improved the yield of these dienes.

Experimental

Catalysts and Reagents. The $ZnCl_2$, $SnCl_2$, CuCl, LiCl, NaCl, KCl, $NaNO_3$, and KNO_3 were all commercially available guaranteed reagents. The nitrogen, argon, chlorine, and hydrogen chloride were dried by passing each gas from commercial cylinders through concd H_2SO_4 and anhydrous calcium chloride. The 1,1-dichloropropane was prepared by the reaction of propionaldehyde with PCl_5 (bp 83—85 °C; 98% pure).[3] The 1,1-dichloro-3-methylbutane was prepared by the reaction of isopropyl chloride and vinyl chloride in the presence of $AlCl_3$ (bp 57 °C/66 mmHg; 99% pure).[4] The addition of HCl to isoprene afforded 3-chloro-3-methyl-1-butene (bp 32 °C/40 mmHg).[5] The 1-chloro-3-methyl-2-butene was obtained by the isomerization[5] of 3-chloro-3-methyl-1-butene in the presence of HCl [bp 61—62 °C/120 mmHg; NMR ($CDCl_3$) 1.70 (6H, CH_3, m), 3.96 (2H, $ClCH_2$, d), 5.34 (H, CH=C, t)]. The 3-chloro-2-methyl-1-butene and 1-chloro-2-methyl-2-butene were separated from a mixture of them obtained by the chlorination[6] of 2-methyl-2-butene using preparative gas chromatography; they were confirmed on the basis of their respective NMR spectra [the former NMR (CCl_4): 1.60 (3H, $ClCHCH_3$, d), 1.84 (3H, $=CCH_3$, s), 4.46 (1H, CHCl, q), 4.74 (1H, HC=, s), 4.92 (1H, HC=, s); the latter NMR (CCl_4): 1.70 (6H, $=CHCH_3$, $=CCH_3$, mc), 3.96 (2H, CH_2Cl, s), 5.34 (1H, $CHCH_3$, q)]. The 3-chlorocyclohexene was prepared by the photoirradiation of a mixture of cyclohexene and *t*-butyl hypochlorite (bp 52—53 °C/25 mmHg; 95% pure).[7] The 4-chlorocyclohexene was obtained by the dehydration[8] of 4-chlorocyclohexanol, which had been synthesized according to the literature (bp 56—57 °C/39 mmHg; 97% pure).[9]

General Procedure. The reaction through molten salts was carried out using an apparatus similar to that described in the previous paper.[1] The salts tested were two ternary mixtures, 60 mol% $ZnCl_2$–20 mol% KCl–20 mol% NaCl ($ZnCl_2$ melts) and 60 mol% CuCl–20 mol% KCl–20 mol% NaCl (CuCl melts), and a binary mixture, 60 mol% $SnCl_2$–40 mol% KCl and 60 mol% CuCl–40 mol% LiCl. The melt of 50 mol% KNO_3–50 mol% $NaNO_3$ was used as a reaction medium, through which chlorination may be supposed to reflect a purely thermal reaction. For the preparation of the anhydrous $ZnCl_2$ melts,[10] a stream of HCl gas was introduced, along with a N_2 stream, at the desired temperature; then dry N_2 was bubbled in in order to eliminate the excess HCl gas. For the other salts, dry N_2 was allowed to flow through the melts until no more H_2O was seen at the exit. A total of 40—70 g of material was used, and the melt height was 8 cm from the tip of the nozzle to the melt surface.

The duration of the reaction was 30 min. After the end of the reactant-feeding, N_2-bubbling was continued for about 1 h in order to recover the reaction mixture remaining in the system. The reaction products were collected at the exit in an ice–water trap. Analysis of the gaseous products was carried out by removing aliquots from the gas stream with the aid of a syringe (every ten minutes after the start of feeding). Both the HCl evolved and the unreacted Cl_2 (in the case of chlorination) were removed prior to sampling by passing the gas stream through a $Na_2S_2O_3$ solution.

Analysis of Reaction Products. The GC column materials used for products analysis were as follows: 1. 10% Pluronic L 84 on Neopak 1 A (60/80 mesh), 2. 30% Propylene Carbonate/Uniport C (30/60 mesh), 3. 15% Silicone DC 550/Celite 545 (60/80 mesh), 4. 20% PEG 20 M/Celite 545 (30/60 mesh), 5. Silica gel (60/80 mesh).

The columns and the operating temperature used for the analysis of the liquid and gaseous products obtained from the respective reaction systems are described below

for each reaction system. 1,1-Dichloropropane (liq: 1, 40 °C, Shimadzu GC-3BT; gas: 5, 145 °C, Shimadzu GC-3AH), 1,1-dichloro-3-methylbutane (liq: 1, 70 °C, Shimadzu GC-2C; gas; 5, 145 °C, Shimadzu GC-3AH), butene (liq: 1, 60 °C, Shimadzu GC-3BT; gas: 2, room temp, Shimadzu GC-2C), 2-methyl-2-butene (liq: 1, 50 °C, Shimadzu GC-3BT; gas: 3, 50 °C, Shimadzu GC-3BT), cyclohexene (liq: 4, 110 °C, Shimadzu GC-2C; gas: 5, 145 °C, Shimadzu GC-3AH).

Identification of Products. Both *cis*- and *trans*-1-chloro-1-propene and *cis*- and *trans*-1-chloro-3-methyl-1-butene were separated by preparative gas chromatography, and their structures were confirmed by a comparison of the chemical-shift difference[11] of the olefinic proton between CCl_4 and C_6H_6. Most of the products were confirmed by having the same retention time as that of the reference and by means of the mass spectra of each fraction, obtained using GC-MS (Hitachi-RMU-6 MG type). Table 1 shows the confirmed liquid products (arranged in the order of elution in a gas chromatography) for each reaction system.

Results and Discussion

Dehydrochlorination of 1,1-Dichloropropane and 1,1-Dichloro-3-methylbutane. The results of the dehydrochlorination of 1,1-dichloropropane and 1,1-dichloro-3-methylbutane through $ZnCl_2$–KCl–NaCl, $SnCl_2$–KCl, and CuCl–LiCl are shown in Table 2 and Table 3 respectively. At 450 °C, the 1,1-dichloropropane conversion was approximately double the conversion at 400 °C through $ZnCl_2$ melts and $SnCl_2$ melts. The finding that the gaseous-product yield at 450 °C was more than twice the value at 400 °C suggests an increasing contribution of the thermal reaction at the higher temperature. Such a tendency was also observed in the dehydrochlorination of 1,1-dichloro-3-methylbutane. The dehydrochlorination with the $ZnCl_2$ melts afforded a relatively high conversion in comparison with that of the $SnCl_2$ melts.

The dehydrochlorination of alkyl halides through molten salts containing Lewis acid, such as $ZnCl_2$, $SnCl_2$, and CuCl, has been studied by Kenney,[12] Bailey,[10] and the present authors.[13] An E_1-elimination mechanism has been postulated. Since the carbonium ion formed by chloride abstraction from *gem*-dichlorides is stabilized through the conjugation with another chlorine atom, *gem*-dichloroalkanes also could proceed *via* E_1 elimination. The higher conversion of 1,1-dichloropropane and 1,1-dichloro-3-methylbutane

Table 1. The different kinds of liquid products for different reaction systems

Reaction system	Products
1,1-Dichloropropane	*cis*-1-chloro-1-propene, *trans*-1-chloro-1-propene, 3-chloro-1-propene, [1,1-dichloropropane], 1,2-dichloropropane
1,1-Dichloro-3-methylbutane	isoprene, *cis*-1-chloro-3-methyl-1-butene, *trans*-1-chloro-3-methyl-1-butene, monochloromethylbutenes (4 peaks), [1,1-dichloro-3-methylbutane]
Butene	2-chloro-1-butene, *trans*-2-chloro-2-butene, (*cis*-1-chloro-1-butene),[a] 3-chloro-1-butene, *cis*-2-chloro-2-butene(*trans*-1-chloro-1-butene),[a] 4-chloro-1-butene, 1-chloro-2-butene, *meso*-2,3-dichlorobutane, *dl*-2,3-dichlorobutane, 1,2-dichlorobutane, 3,4-dichloro-1-butene, polychloro compounds
2-Methyl-2-butene	2-methyl-1-butene, [2-methyl-2-butene], isoprene, 2-chloro-2-methylbutane and 3-chloro-3-methyl-1-butene, 3-chloro-2-methyl-1-butene, monochlorobutenes (3 peaks), 1-chloro-2-methyl-2-butene and/or 1-chloro-3-methyl-2-butene, polychloro compounds
Cyclohexene	[cyclohexene], 1,3-cyclohexadiene, 1,4-cyclohexadiene, benzene, monochloromethylcyclopentanes, chlorocyclohexane, 1-chlorocyclohexane, monochlorocyclohexadienes, 4-chlorocyclohexenene, 3-chlorocyclohexene, 1,2-dichlorocyclohexane

a) In the case of 1-butene as the starting material.

over the melts containing $ZnCl_2$ can easily be understood, because $ZnCl_2$ may be supposed to abstract chloride from the substrate forming the carbonium ion due to its relatively strong Lewis acidity.

In the case of 1,1-dichloropropane, the *cis/trans* ratio of the resultant 1-chloro-1-propene was observed in the region from 2.1 to 2.4 through three kinds of melts. On the other hand, the *cis/trans* ratio of 1-chloro-3-methyl-1-butene was between 0.9 and 1.4. We have reported on the dehydrochlorination[1] of 1,1-dichlorobutane through molten salts, where the quite large ratio of *cis/trans* of 1-chloro-1-butene (1.4—1.8 with $ZnCl_2$ melts) may be explained in terms of the resultant carbonium ion adsorbed on the surface of the melts [illustrated in Fig. 1 (R representing the methyl, ethyl, and isopropyl groups)].

The release of H_b from the carbonium ion (in Fig. 1)

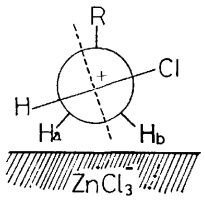

Fig. 1. Molten salts surface-adsorbed carbonium ion. Dotted line shows the vacant p orbital; R=CH_3, C_2H_5 and $(CH_3)_2CH$; Cl atom is linked to C_1, Both H_a and H_b are on C_2.

as a proton leads to the effective sharing of the free-electron pair at C_2 with the vacant p orbital at C_1. This process affords *cis*-olefin predominantly. If the alkyl group goes on from methyl to isopropyl, the location of the carbonium ion as in Fig. 1, becomes, however, somewhat unfavored because of the increasing steric repulsion between chlorine and isopropyl groups. This leads to the desorption of the carbonium ion from the melts surface, the *cis/trans* ratio of the resulting olefin nearing unity. The finding that *cis/trans* ratio with alkyl group=C_2H_5 (1.8) stands between the ratio with alkyl=CH_3 (2.2) and the ratio with alkyl=$(CH_3)_2CH$(1.4) under the same conditions is in good agreement with the explanation presented above.[14,15] The formation of isoprene from the reaction of 1,1-dichloro-3-methylbutane through $ZnCl_2$ can be explained by considering the rearrangement of the primary monochloro carbonium ion (in Fig. 1) to the more stable secondary and/or tertiary carbonium ion and the subsequent 1,4-dehydrochlorination of the 1-chloro-3-methyl-2-butene produced from the above rearranged carbonium ion.

Reaction of Butene with Chlorine. The reaction of butene with chlorine through the $ZnCl_2$ melts and the CuCl melts is shown in Tables, 4, 5, and 6. The substitution reaction by chlorine probably takes place at the allylic position of butenes (1-butene, *cis*-2-butene, *trans*-2-butene) *via* a radical mechanism whose operation was confirmed in the chlorination of cyclohexane[13]

through the $ZnCl_2$ melts and the CuCl melts. The subsequent dehydrochlorination of the resulting chlorobutenes could be assisted by the melts, yielding butadiene in a high selectivity. Using the $ZnCl_2$ melts, a butadiene selectivity of more than 93% is attained if one does not take account of the degree of isomerization among butenes. With the CuCl melts, considerable amounts of unreacted chlorobutene and dichlorobutane were observed. The effects of the reaction temperature and the Cl_2/butene ratio on the extent of reaction and the degree of selectivity to butadiene were examined with the $ZnCl_2$ melts (Tables 7 and 8). The reactions at 400 °C and 450 °C gave almost the same yields of butadiene in a good material balance. With a Cl_2/feed equal to 1.15, appreciable amounts of carbonaceous material were produced; this led to a poor material balance at a high concentration of chlorine. An inspection of Table 8 reveals that the Cl_2/butene ratio between 0.59 and 0.85 is desirable in view of the material balance and butadiene yield.

There have been reported several dehydrogenation processes of butene for butadiene production. One of them is to use metal oxide catalysts[16] in the presence of oxygen and chlorine-releasing compounds (yield 27%, selectivity, 43% at 700 °C). Another procedure[17] gives a 68.0% yield of butadiene with a 89.3% selectivity (temp 638 °C, HI/butene=0.2, over 5% CeO_2/Al_2O_3). The yield and selectivity of the process presented here compares fairly well with those of the latter process under less severe conditions.

and the $ZnCl_2$ melts containing a suspension of Zn powder in the reaction of 2-methyl-2-butene with chlorine are shown in Table 9.

Using the $ZnCl_2$ melts as catalysts, the reaction of 2-methyl-2-butene with chlorine gave small amounts of expected isoprene, along with great quatities of 2-chloro-2-methylbutane. The primary formation of the latter compound was supposed to be due to the addition of the HCl produced to an intermediate product, 2-methyl-2-butene, through the $ZnCl_2$ melts (at 400 °C, 76.9% yield of 2-chloro-2-methylbutane). In order to eliminate the HCl evolved during this reaction and to improve the yield of isoprene, we used $ZnCl_2$ melts containing a suspension of Zn powder instead of $ZnCl_2$ melts. As Table 9 shows, the use of those melts brough about a high yield of isoprene, as expected, and at the same time we found the formation of H_2 in an amount about the same as the quantities calculated on the basis of the following equation: $[H_2=(\text{isoprene})+(C_5H_9Cl)/2-(C_5H_{11}Cl)/2]$.

Based on these findings, this reaction may be outlined as follows:

$$2\text{C-C=C-C} + Cl_2 \longrightarrow \underset{\text{C}}{\text{C-C=C-CCl}} + \underset{\text{C}}{\text{C-C=C-CCl}} + 2HCl \quad (1)$$

$$Zn + 2HCl \longrightarrow ZnCl_2 + H_2 \quad (2)$$

$$\underset{\text{C}}{\text{ClC-C=C-C}} + \underset{\text{C}}{\text{C-C=C-CCl}} \longrightarrow 2\underset{\text{C}}{\text{C=C-C=C}} + 2HCl \quad (3)$$

TABLE 10. REACTION OF CYCLOHEXENE WITH CHLORINE[a]

Others	3.1	0.3	1.2	1.2

a) Cyclohexene : Ar=0.095 : 0.10 mol/h. b) $ZnCl_2$-KCl-NaCl=60 : 20 : 20 mol %. c) $ZnCl_2$-KCl-NaCl-Zn=46 : 15 : 15 : 24 mol %.

Appreciable amounts of 1-chloro-2-methyl-2-butene and/or 3-chloro-2-methyl-2-butene were produced with $ZnCl_2$ melts; this was confirmed by means of GC-MS analysis.

Reaction of Cyclohexene with Chlorine. The results of the reaction through the $ZnCl_2$ melts and the Zn-powder-suspended $ZnCl_2$ melts are presented in Table 10. The presence of Zn powder increases the selectivity to cyclohexadiene in the chlorination of cyclohexene. Therefore, in a way similar to the reaction of 2-methyl-2-butene, Zn powder can react with evolved HCl, which otherwise will add to cyclohexene or/and cyclohexadiene, yielding H_2 and $ZnCl_2$. The good agreement of the hydrogen amounts with the calculated value confirms this process to be correct. Under the same conditions, the dehydrochlorination of 3-chlorocyclohexene and 4-chlorocyclohexene (at 400 °C) proceeded with an 85 and 49% selectivity to cyclohexene respectively. Therefore, it may be suggested that the chlorination of cyclohexene proceeds as in the following reaction scheme:

A New Synthesis of Glutathione *via* the Thiazoline Peptide

Yoichi Ozawa, Toshiaki Tsuji, and Yasuo Ariyoshi*

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received January 18, 1980)

A convenient synthesis of glutathione (GSH) by the use of minimal protecting groups was investigated. *N*-Formyl-L-2-amino-4-cyanobutyric acid ethyl ester was condensed with ethyl L-cysteinylglycinate to give (4*R*)-2-[(3*S*)-3-ethoxycarbonyl-3-(formylamino)propyl]-4-(ethoxycarbonylmethylcarbamoyl)-2-thiazoline. This compound was saponified in aqueous acetone at −15——20 °C and subsequently treated with dilute H_2SO_4 (pH 4) to yield formylglutathione, whose formyl group was then hydrolyzed with 0.5 M (1 M=1 mol dm^{-3}) H_2SO_4 to give free GSH. For purification, this was changed to a copper thiolate, which was then decomposed with H_2S to afford pure GSH.

Glutathione (GSH) is a tripeptide with the sequence γ-L-Glu–L-Cys–Gly that occurs in many cells in a variety of species. It is currently used as a medicine for some diseases in several countries. GSH has thus been produced on a large-scale by means of both fermentation and chemical synthesis.

Although GSH is a small-sized peptide, a large-scale synthesis of it seems to be difficult because it has a free SH group that is susceptible to oxidation, and a γ-linkage in the molecule. A variety of methods[1] for synthesizing GSH have been reported so far, but only a few of them are applicable to a large-scale synthesis of GSH; in most of these reported syntheses, all the functional groups of the amino acids have been protected, and expensive benzyloxycarbonyl and benzyl groups have often been employed for protecting the amino and the mercapto groups, respectively. Moreover, in most of these methods, drastic conditions such as sodium in liquid ammonia have been used for removal of the protecting groups.

In order to find a more convenient synthetic method for GSH, we have investigated a new route which uses minimal protection. The distinctive feature of the present method is to form a tripeptide with a thiazoline ring as an intermediate peptide (**6**), which is subsequently hydrolyzed to give GSH. We concentrated our efforts on forming the thiazoline ring and opening it at the C–S bond to form a peptide linkage and a free SH group.

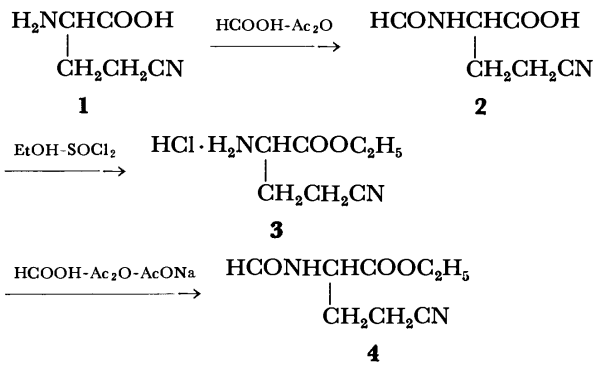
L-2-Amino-4-cyanobutyric acid (**1**),[2] which was prepared by dehydration of *Z*-L-Gln with *N*,*N*′-dicyclohexylcarbodiimide followed by hydrogenolysis, was employed as a starting material instead of L-Glu.

A partner peptide, L-Cys-Gly-OEt (**5**), was prepared by hydrolysis of (4*R*)-(3-formyl-2,2-dimethyl-4-ethoxycarbonylmethylcarbamoyl)thiazoline, which was prepared according to the method described in the synthesis of the corresponding methyl ester.[3]

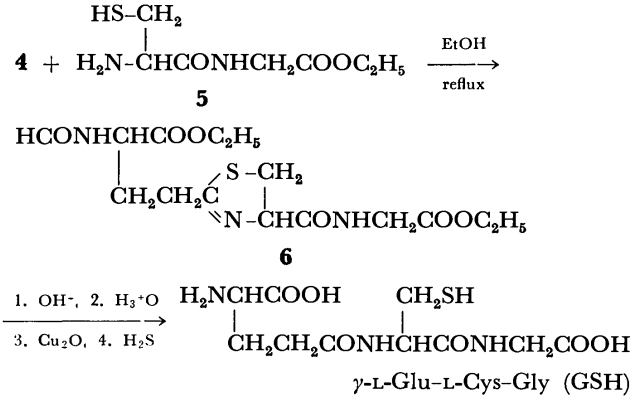
Esterification of **1** by a conventional method was always accompanied with a considerable amount of Glu formed by hydrolysis of the nitrile group. The amino acid (**1**) was successfully esterified with EtOH–$SOCl_2$ after blocking the amino group by a formyl group to give ethyl L-2-amino-4-cyanobutyrate hydrochloride (**3**). This compound was then treated with HCOOH–Ac_2O–AcONa for formylation because the formyl group of **2** was cleaved during the esterification (Scheme 1). An attempt to convert the nitrile group into an imidic ester failed. Treatment of *N*-formyl-L-2-amino-4-cyanobutyric acid ethyl ester (**4**) with EtOH–HCl was accompanied with a considerable amount of by-products, such as Glu and Glu ester, by concomitant cleavage of the formyl group and hydrolysis of the nitrile group. Therefore, we decided to form the thiazoline ring by direct condensation of **4** with L-Cys–Gly–OEt (**5**). Compound **4** was condensed with **5** in ethanol under reflux and in an atmosphere of nitrogen to give (4*R*)-2-[(3*S*)-ethoxycarbonyl-3-(formylamino)propyl]-4-(ethoxycarbonylmethylcarbamoyl)-2-thiazoline (**6**) in 62.5% yield (Scheme 2).

Care must be taken in treating **6** with alkali, since it is known that a thiazoline ring is susceptible to racemization.[4] No appreciable racemization occurred when **6** was treated with alkali at a low temperature of −15——20 °C.

Careful saponification of the ester group of **6** at −15——20 °C in aqueous acetone and subsequent mild



Scheme 1.



Scheme 2.

acid hydrolysis of the thiazoline ring gave *N*-formylglutathione. This was passed through a column of Diaion SK1B[5] (H^+ form) in order to remove the sodium ion which was found to cause the free SH group to change into an –S–S– bond at the final stage. Removal of the formyl group with dilute sulfuric acid gave free GSH, which was changed to a copper thiolate. Subsequent decomposition of the thiolate with hydrogen sulfide afforded pure GSH (Scheme 2).

This method shows considerable promise for large-scale syntheses of GSH.

Experimental

Melting points were measured in glass capillaries and are uncorrected. The UV-spectrum was recorded on a Shimadzu MPS-5000 spectrometer. The optical rotations were measured on a Perkin-Elmer 141 polarimeter.

N-Formyl-L-2-amino-4-cyanobutyric Acid Ethyl Ester (4). To an ice-cooled mixture of formic acid (55.2 g, 1.2 mol) and acetic anhydride (45.9 g, 0.60 mol) was added **1** (38.4 g, 0.30 mol) with stirring. After stirring for 3 h in an ice-bath, ether (500 ml) was added to the reaction mixture, and crystals (**2**) thus formed were collected by filtration; yield, 42.9 g (91.7%); mp 127—128 °C. To a suspension of **2** (42.1 g, 0.27 mol) in anhydrous ethanol (300 ml) was added dropwise thionyl chloride (21 ml) at −5——10 °C. After the addition was complete, the mixture was permitted to warm to room temperature. After the mixture was stirred at 40 °C for 40 min, the solvent was evaporated *in vacuo* at a bath temperature of 30 °C. The residue was dissolved in ethanol (140 ml) and filtered, and ether (300 ml) was added to the filtrate, which was then kept in a refrigerator overnight. Crystals (**3**) thus formed were collected by filtration and recrystallized from ethanol–ether; yield, 39.5 g (76.1%); mp 143—144 °C. To a mixture of formic acid (46.0 g, 1.0 mol) and sodium acetate (16.4 g, 0.2 mol) was added acetic anhydride (30.6 g, 0.3 mol) with cooling in an ice-bath. After stirring for 10 min, **3** (38.5 g, 0.2 mol) was added to the mixture, which was stirred with cooling in an ice-bath for 3 h. Ice water (30.6 g) was then added to the reaction mixture. After stirring at room temperature for 30 min, the reaction mixture was concentrated *in vacuo* to give an oily residue, which was dissolved in water (100 ml), adjusted to pH 6.0 with sodium carbonate, and extracted twice with 150-ml portions of chloroform. The chloroform layer was washed with water (100 ml), dried on anhydrous sodium sulfate, and evaporated *in vacuo* to give the desired compound (**4**) as an oil; yield, 30.4 g (82.6%).

L-Cys–Gly–OEt (5). (4*R*)-(3-Formyl-2,2-dimethyl-4-ethoxycarbonylmethylcarbamoyl)thiazolidine (mp 70—72 °C) prepared according to the method described for the corresponding methyl ester[3] was hydrolyzed in ethanolic hydrochloric acid to give L-Cys–Gly–OEt·HCl (83.5%; mp 135—137 °C), which was neutralized with Et_3N in ethyl acetate. The solvent was evaporated *in vacuo* to give **5** as an oil.

(4R)-2-[(3S)-3-Ethoxycarbonyl-3-(formylamino)propyl-4-(ethoxycarbonylmethylcarbamoyl)-2-thiazoline (6). A mixture of **4** (25.0 g, 0.136 mol) and **5** (33.6 g, 0.163 mol) in anhydrous ethanol (50 ml) was heated under reflux with stirring in an atmosphere of nitrogen for 16 h. After the reaction was complete, insoluble materials were filtered off, and the filtrate was concentrated *in vacuo*. The residue was taken up in chloroform (300 ml) and washed with a 20% aqueous citric acid solution (50 ml), and then twice with 100-ml portions of water. The chloroform layer was dried on anhydrous sodium sulfate and then evaporated *in vacuo* to give an oily residue, which was crystallized from ethyl acetate–petroleum ether to give **6** as crystals; yield, 31.7 g (62.5% based on **4**); mp 78—80 °C; UV (35% HCl): λ_{max} 268 nm (ε 4900); $[\alpha]_D^{18}$ +13.2° (*c* 1.0, ethanol). Found: C, 48.05; H, 6.19; N, 11.08; S, 8.69%. Calcd for $C_{15}H_{23}O_6N_3S$: C, 48.24; H, 6.21; N, 11.25; S, 8.59%.

Glutathione (GSH). To a stirred solution of **6** (70.0 g, 0.187 mol) in a mixture of acetone (617 ml) and O_2-free water (94 ml) was added dropwise 1 M (1 M=1 mol dm^{-3}) NaOH (374 ml) at −15——20 °C. After stirring at the same temperature for 1 h, the reaction mixture was acidified with 0.5 M H_2SO_4 (380 ml) to pH 4. In order to open the thiazoline ring, the mixture was stirred at room temperature for 30 min, and then the acetone was evaporated *in vacuo* from the mixture. The resulting solution, which contained formylglutathione, was passed through a column of Diaion SK1B (H^+ form) and the column was then washed with O_2-free water. The eluate and washings were combined and concentrated *in vacuo* to a small volume (336 ml), and then 5 M H_2SO_4 (37 ml) was added to the concentrate, which was stirred at 45—47 °C for 6 h in order to remove the formyl group. Copper(I) oxide (13.37 g, 0.0935 mol) was added to the reaction mixture, which was then stirred at the same temperature for 15 min. After storage in a refrigerator overnight, the copper thiolate thus formed was collected by filtration and washed thoroughly with water. The thiolate was suspended in water (500 ml) and H_2S gas was bubbled into the suspension. The copper sulfide thus formed was filtered off and the filtrate was concentrated *in vacuo* to give a syrupy residue, which was dissolved in O_2-free water (96 ml), and then ethanol (480 ml) was added to the solution at 40 °C. After standing at the same temperature for 15 min, a yellow oil was removed by decantation. Crystals of GSH (1.0 g) were added as seed to the solution, which was kept at room temperature for 2 d and then placed in a refrigerator overnight. Crude crystals along with a syrupy material were collected by filtration; yield, 20.0 g (34.7%; one gram (seed) is subtracted from the yield). The crystals (20.0 g) were dissolved in O_2-free water (60 ml) and 2-propanol (80 ml) was added at 40 °C. Crystals of GSH (1.0 g) were added as seed to the mixture, which was stirred at 40 °C for 2 h and kept at room temperature for 20 h, then kept in a refrigerator overnight. The crystals thus formed were collected by filtration; yield, 16.6 g (28.8%; one gram (seed) is subtracted from the yield). Mp 184—185 °C (dec); lit,[1] 186—190 °C (dec); $[\alpha]_D^{23}$ −21.9° (*c* 2.74, H_2O), lit,[1] $[\alpha]_D^{27}$ −21° (*c* 2.74, H_2O); Found: C, 38.88; H, 5.52; N, 13.75; S, 9.86%. Calcd for $C_{10}H_{17}O_6N_3S$: C, 39.08; H, 5.58; N, 13.67; S, 10.43%.

The authors are indebted to Mr. F. Kakizaki for his skillful technical assistance.

Electron Transfer Sensitization. II. Photo-cyclodimerization and -polymerization of *N*-Vinylcarbazole[1)]

Noboru KITAMURA and Shigeo TAZUKE*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received January 5, 1980)

Photoinduced ternary electron transfer reactions have been demonstrated in the system of perylene(Pe)-1,4-dicyanobenzene(DCB)-*N*-vinylcarbazole(VCZ) in acetone. Photoexcited perylene was recycled *via* two successive electron transfer reactions while VCZ-cyclodimer and/or -polymer were obtained in good yields. Quantum yields for VCZ-cyclodimer and -polymer formation were larger in the electron transfer sensitization system in comparison with the other reaction systems such as in the Pe–VCZ or the VCZ–DCB system. The photocatalytic effect of the electron transfer sensitization was clearly confirmed in the present system, by estimating the overall sensitizer efficiency as over 8000 although chain propagation steps of VCZ cation radical are involved in the present reaction processes.

The role of photosensitizer in photochemistry is unequivocally of primary importance. In the original meaning of photosensitizer(S), S is recycled by repeating photoabsorption and energy transfer to substrates.[2)] In view of utilizing low energy photons to initiate reactions *via* energy transfer processes, singlet sensitizers are by no means significant since the photoirradiation of sensitizers in a shorter wavelength region than the absorption of the substrates to be excited is required. Another category of photosensitization is the electron transfer sensitization consisting of at least two successive electron transfer processes. Although the number of examples are still limited, the most elegant example is the electron transport system in photosynthesis. It is consequently anticipated that the principle of the electron transfer sensitization will be widely applied to drive various one electron transfer redox reactions. Recently, some examples have been reported by several authors demonstrating such as dimerization of ethylenic compounds,[3)] photochemical addition of furans to electron-rich olefines,[4)] and photochemical cleavage of indene dimers,[5)] in addition to our preliminary report.[1)]

In the present article, we applied electron transfer sensitization to the Pe–DCB–VCZ system in polar media. Since VCZ cation radical is known to be the precursor of *trans*-1,2-di-9-carbazolylcyclobutane and the polymer,[6)] we expected that photo-cyclodimerization and/or -polymerization of VCZ were efficiently conducted in the electron transfer sensitization system while perylene was recycled as an electron carrier.

Experimental

Materials. Perylene (Tokyo Kasei, G. R. grade) was used without further purification. 1,4-Dicyanobenzene (Tokyo Kasei, G. R. grade) and *N*-vinylcarbazole (Koch Light Co.) were purified by several recrystallization from ethanol and hexane, respectively. Acetone was refluxed over $KMnO_4$ for several hours followed by drying over $MgSO_4$, and then distilled. Tetrahydrofuran (THF), *N*,*N*-dimethylformamide (DMF), and dimethyl sulfoxide (DMSO) were dried over appropriate drying agents and then distilled before use.

Procedure. Absorption spectra were measured by a Hitachi Spectrophotometer EPS-III. The photoreactions were carried out in a quartz cell, under the conditions of monochromatic irradiation using a JASCO Spectroirradiator CRM-FA. After photoirradiation, the reaction mixture was evaporated to dryness under reduced pressure, and then 50 ml of methanol was added. The reaction mixture in methanol was stirred vigorously and insoluble precipitates were filtered off. The precipitates were dried *in vacuo* thoroughly and then weighed. The precipitates (VCZ-cyclodimer or -polymer) were analyzed by the usual accepted procedures (IR, mp, and NMR).[7)] The light intensities for quantum yield measurements were determined by a Hatchard-Parker actinometer.[8)]

Results and Discussion

Photodecomposition of Perylene. The absorption spectra of the reaction components are shown in Fig. 1. In the Pe–DCB–acetone system, perylene was photodecomposed readily when perylene was irradiated. However, if VCZ which did not participate in photoabsorption was added to the reaction system (*i.e.* Pe–DCB–VCZ system in acetone), photodecomposition of perylene was greatly retarded (Fig. 2a). The same phenomena have been observed in the systems of pyrene–diethyl terephthalate and of pyrene–diethyl terephthalate–*N*,*N*-dimethylaniline in polar media.[9)] Since photoinduced electron transfer processes in elec-

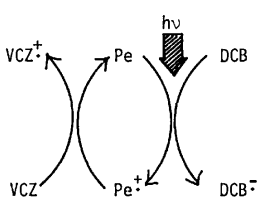
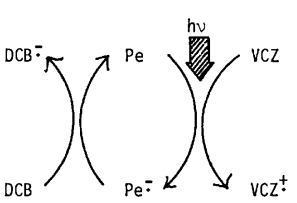
tron donor-acceptor systems in polar media are well established,[10] the results were interpreted by assuming two successive electron transfer reactions. In the present reaction system (Pe-DCB-VCZ), the reaction schemes are given as below. Namely, the successive electron transfer between perylene anion radical or cation radical and DCB or VCZ, respectively, brings about the recovery of perylene molecule, and then the photodecomposition of perylene is suppressed. In other words, perylene is recycled *via* two successive electron transfer reactions, and consequently perylene acts as an electron carrier. These mechanisms are called as "electron transfer sensitization" being contrasted to the conventional energy transfer sensitization.



Scheme 1.



Scheme 2.

The free energy change for the electron transfer between the excited singlet state of perylene (Pe*[1]) and DCB or VCZ, calculated from Eq. 1 ($E(D^+/D)$ and $E(A/A^-)$ are oxidation potential of an electron donor and reduction potential of an electron acceptor, respectively. $e^2/\varepsilon r$ is the Coulombic term and $\Delta E_{0\text{-}0}$ is the 0.0-band energy for the photoexcited species(Pe)),[11] is -38.5 or $+5.9$ kJ/mol, respectively.

$$\Delta G = E(D^+/D) - E(A/A^-) - e^2/\varepsilon r - \Delta E_{0\text{-}0} \quad (1)$$

These values suggest that the electron transfer between Pe*[1] and DCB proceeds with a nearly diffusion

controlled rate whereas that between Pe*[1] and VCZ is a rather slow process ($\approx 10^8$ dm^3 mol^{-1} s^{-1}); as being expected from the results reported by D. Rehm and A. Weller.[12] Consequently, Scheme 1 is considered as the main reaction path with a minor contribution of Scheme 2.

In the Pe–DCB system, the rapid photodecomposition of perylene is attributed to unstable perylene cation radical which is formed by the electron transfer between Pe*[1] and DCB. On the other hand, the result that perylene is scarcely photodecomposed in the course of photoirradiation in the Pe–VCZ system requires some comments. We consider that the electron transfer between Pe*[1] and VCZ occurs to produce perylene anion radical, since perylene is a weak but definite sensitizer for photoreactions of VCZ as shown in the next section. However, under aerobic conditions, perylene anion radical will be oxidized by oxygen to reproduce perylene molecule as shown below.

$$Pe^{\cdot-} + O_2 \longrightarrow Pe + O_2^{\cdot-} \qquad (2)$$

The elctron transfer from perylene anion radical to oxygen is a highly exothermic process so that we consider that the reaction in Eq. 2 occurs efficiently.[13]

The photodecomposition of perylene was also studied in THF, DMF, and DMSO (Figs. 2b, 2c, and 2d, respectively). Similar to the case in acetone, the fast photodecomposition of perylene in the Pe–DCB system was retarded or inhibited by the addition of VCZ. However, perylene was hardly photodecomposed in THF in the Pe–DCB system. Taking into account that the photodecomposition of perylene is induced by the electron transfer between Pe*[1] and DCB or VCZ, solvent polarity is suggested to be of primary importance. The finding that the free ion yield in photo-induced electron transfer reactions in electron donor-acceptor systems is nearly zero in a low polarity solvent such as THF would explain the stability of perylene in THF even in the presence of DCB.[14] On the other hand, the fact that the free ion is produced efficiently in polar solvents such as acetone, DMF, and DMSO, is in good agreement with the present results.[14]

Photo-cyclodimerization and -polymerization of VCZ. Since VCZ cation radical is known as the precursor of VCZ-cyclodimer and -polymer,[6] it is expected that VCZ-cyclodimer and/or -polymer are produced by irradiating the present ternary system. Indeed, photoirradiation leads to the formation of VCZ-cyclodimer and/or -polymer. Quantum yields for VCZ-cyclodimerization and -polymerization under various conditions are listed in Table 1. In the Table, the quantum yields over 1.0 indicate that the cyclodimerization or -polymerization of VCZ involves chain propagation processes which have been discussed by Ledwith in detail.[6] The mechanisms are as follows. The reaction path of VCZ cation radical as function of atmosphere and solvent is identical with the previous results.[15]

In the Pe sensitized systems (Pe–DCB–VCZ, Pe–VCZ) in acetone, VCZ-cyclodimer and -polymer were formed efficiently in air and *in vacuo*, respectively. The quantum yield is larger by a factor of ≈ 6 in the Pe–DCB–VCZ system than in the Pe–VCZ system

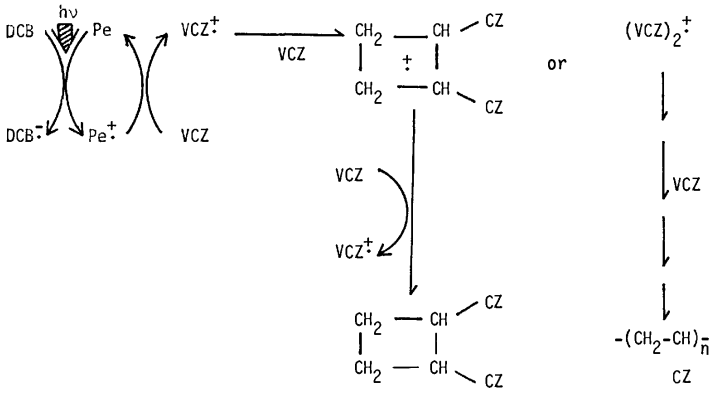


TABLE 1. QUANTUM YIELDS FOR VCZ-CYCLODIMER AND -POLYMER FORMATION

Solvent	$h\nu$ nm	Quantum yield in air (*in vacuo*)			
		Pe-VCZ-DCB	Pe-VCZ	VCZ-DCB	VCZ

Conditions; [Pe] = 2×10^{-5} mol dm^{-3}, [VCZ] = 0.2 mol dm^{-3}, monochromatic irradiation for 16 min at room temperature. a) 1,2-*trans*-Di-9-carbazolylcyclobutane, others are poly(*N*-vinylcarbazole).

either in air or *in vacuo*. Furthermore, in comparison with the quantum yield in the VCZ–DCB system or the system containing VCZ alone, the ternary system is twice as efficient as the others. The finding that the quantum yield is the highest in the ternary system indicates the suppression of the back electron transfer between ion radicals resulting in an increase in the steady state concentration of VCZ cation radical. Namely, an electron is transffered from VCZ to DCB by perylene and consequently, charge separation is most efficient in the ternary system, which brings about high quantum yields of cyclodimerization and/or -polymerization of VCZ. These results reveal the usefulness of the electron transfer sensitization system in respect of, i) the enhancement of quantum yield, and ii) the utilization of low enrgy photons. In the electron transfer sensitization system in air, we estimated the overall sensitizer efficiency which is defined as "product per consumed perylene," to be over 8000, although the mechanisms for VCZ-cyclodimer and -polymer formation involve chain propagation processes described above. Consequently, we conclude that the sensitizer (perylene) is reproduced *via* two successive electron transfer reactions, which is the same conclusion obtained in the previous section.

In THF, since the free ion yield in electron donor-acceptor systems is nearly zero, the absence of cyclodimerization or -polymerization of VCZ is quite reasonable. However, the features of the reactions in DMF and DMSO are more complicated. In perylene sensitized systems, VCZ-polymer was scarcely produced,[16] whereas the polymer was formed in the system of VCZ–DCB and of VCZ alone by irradiating VCZ. The reasons for these results are unclear at the present time. However, since it has been reported that viscous solvents such as DMF and DMSO promote geminate recombination of the ion radical pair,[17] we consider that the back electron transfer between perylene cation radical and DCB anion radical will suppress the polymerization or cyclodimerization from VCZ cation radical.

Conclusion

Although the quantitative information on the electron transfer sensitization was not obtained, it is concluded that perylene acts as an electron carrier to induce the cation radical initiated cyclodimerization and -polymerization of VCZ. The quantum yields for VCZ-cyclodimer and -polymer formation were enhanced in the presence of electron transfer sensitizer in comparison with other systems in which VCZ was directly excited. Furthermore, the effective absorption wavelength can be extended to longer wavelength region by the use of electron transfer sensitizer. The electron transfer sensitization is a useful tool for photo-redox reactions in general. Quantitative discussions on further examples of the electron transfer sensitization systems will be reported in near future.[18]

Electron Transfer Sensitization. III. A Kinetic Study of Oxidative Dye Formation from Leuco Crystal Violet

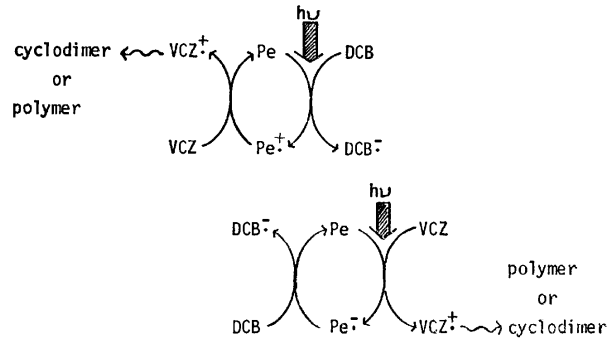
Noboru KITAMURA and Shigeo TAZUKE*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received January 5, 1980)

The action of electron transfer sensitization was quantitatively discussed by measuring photooxidative dye formation of leuco Crystal Violet (LCV) in the perylene(Pe)-1,4-dicyanobenzene(DCB)-LCV combination in polar media. Under the conditions of exclusive photoexcitation of perylene (λ_{ex} at 435 nm), the kinetic study revealed that the turn over number of perylene as a sensitizer was immeasurably large in the ternary system *in vacuo*. This is an indication that perylene is indeed recycled *via* two successive electron transfer processes. The turn over number decreased to 58 in air, probably due to instability of intermediate ion radicals. The quantum yield was larger for the ternary system than for the binary system(Pe–LCV) irradiated at 435 nm. Although the absolute quantum yield of photooxidation was in the order of 10^{-3} or less in both systems, the ternary electron transfer system was apparently advantageous since the efficiency of back electron transfer would be reduced when multiple electron transfer processes are linked. Furthermore, the concept of electron transfer sensitization enables spectral sensitization and utilization of low energy photons in singlet state photoredox reactions. Such systems would be considered as a model for the primary action of photosynthesis.

In the preceding articles, we have reported the electron transfer sensitization of Pe–DCB–*N*-vinylcarbazole(VCZ) system in polar media.[1] On selective irradiation of perylene, VCZ-cyclodimer and -polymer were obtained in good yields. Since the monomer cation radical is known to be the precursor of the VCZ-cyclodimer and -polymer,[2] we assumed the scheme described below. However, the formation of



VCZ-cyclodimer and -polymer involves chain propagation processes, and consequently the mean turn over number of perylene as a sensitizer could not be determined. In the present paper, we are presenting a kinetic study of oxidative dye formation from LCV sensitized by the electron transfer sensitizer (perylene).

X=H OR CN

Since the photoreactions of leuco triphenylmethane derivatives in the presence or the absence of an electron acceptor are well established,[3] quantitative information on the action of electron transfer sensitization is expected.

Experimental

Materials. Perylene(Aldrich) was used without further purification. 1,4-Dicyanobenzene and leuco Crystal Violet (both Tokyo Kasei, guaranteed reagent) were recrystallized from ethanol several times. 9-Cyanoanthracene (CNA) was prepared according to literature,[4] and was purified by column chromatography, followed by recrystallization from ethanol and finally sublimed *in vacuo* before use. Acetonitrile was refluxed over phosphorus pentaoxide for several hours and then distilled. Benzene, tetrahydrofuran (THF), and *N*,*N*-dimethylformamide (DMF) were dried over appropriate drying reagents (CaH_2, Na and $LiAlH_4$, and CaH_2, respectively) and then distilled. Acetone was treated over $KMnO_4$ and $MgSO_4$ successively, and then distilled.

Procedure of Photoreactions. Photoreactions in air were carried out in a Teflon capped quartz cell (optical length 1 cm). Degassed samples were prepared by several freeze-pump-thaw cycles and then sealed off at the constriction of a Pyrex branch of a quartz cell. Monochromatic light source was obtained by a JASCO Spectroirradiator CRM-FA equipped with a 2-kW xenon lamp. Absorption and fluorescence spectroscopy were made by a Shimadzu UV-200S spectrophotometer and a Hitachi MPF-4 spectrofluorometer, respectively. For fluorescence quenching experiments, samples were thoroughly deaerated by argon bubbling. Light intensity for the quantum yield measurements were determined by a Hatchard-Parker actinometer (0.15 mol dm^{-3} potassium trioxalatoferrate(III) in a 0.1 mol dm^{-3} aqueous sulfuric acid solution).[5]

Results and Discussion

Oxidative Dye Formation of LCV and Photodecomposition of Perylene. Figure 1 shows the absorption spectra of the components in this electron transfer sensitization system in acetonitrile. Perylene is an electron transfer sensitizer (a photoabsorber), DCB and CNA are electron acceptors, and LCV is an electron donor. It

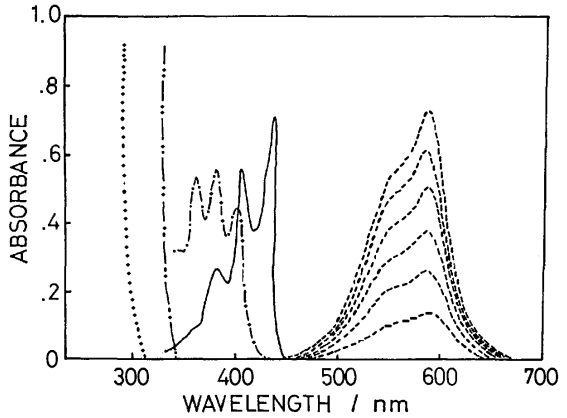

Fig. 1. Absorption spectrum of the components for the present reaction system in acetonitrile.
[Pe]$=1.7\times10^{-5}$ mol dm^{-3} (——); [CNA]$=1.0\times10^{-3}$ mol dm^{-3} (—·—·—); [DCB]$=1.0\times10^{-3}$ mol dm^{-3} (·····), [LCV]$=1.0\times10^{-3}$ mol dm^{-3} (—··—··—); CV^+ (----).

is clear from these spectra that LCV and DCB have no absorption at the absorption maximum of perylene (435 nm). CNA is also transparent at 435 nm under our experimental conditions ([CNA]$=1\times10^{-4}$ mol dm^{-3}) as manifested by the fact that the fluorescence from CNA on excitation at 435 nm is not observed at all. Hence, the selective excitation of perylene is attained in this system.

On excitation of perylene in the Pe–CNA–LCV system, the development of violet color showing an absorption maximum around 590 nm was observed. This new absorption band is identical to that observed upon direct excitation of LCV. Since LCV is easily photooxidized to give its violet colored carbonium ion, and the spectrum in Fig. 1 agrees with the reported one,[6] we identified the violet species as Crystal Violet cation (CV^+) which is one of the triphenylmethane dyes ($\lambda_{max}=590$ nm, $\varepsilon=1.1\times10^5$ dm^3 mol^{-1} cm^{-1}).[7] The dye was stable within the time scale of our experimental conditions. As the absorption intensity at 590 nm due to the dye formation increases, the absorption around 435 nm also increases and the conditions of selective excitation of perylene are no longer sustained. However, since the extinction coefficient around 435 nm is negligibly small compared with the value at 590 nm and also with the value for perylene, the inner filter effect due to the increase in the absorption at 435 nm is negligible if the dye absorbance at 590 nm is less than 0.8.

Figure 2 shows the time conversion curves of the dye formation in the Pe–CNA–LCV and the Pe–LCV systems in acetonitrile. It is obvious that the rate of the dye formation is faster in the ternary system than in the binary one, and the reactions seem to be favored in air than *in vacuo*. The photodecomposition of perylene shown in Fig. 3 indicated that the fast decomposition of perylene in the aerated system of Pe–CNA was retarded by the addition of LCV which did not concern with the light absorption. In a similar manner, the fast decomposition of perylene in the Pe–LCV system was completely inhibited in

the ternary system *in vacuo*. The same results were also obtained using DCB as an electron acceptor instead of CNA.

Proposed Mechanism. Either energy transfer or electron transfer should be responsible for the primary processes. However, energy transfer mechanism is excluded because the energy of the excited state of perylene is lower than the energy of LCV or the acceptors either in the excited singlet or the triplet state (see Table 1). On the other hand, the negative free

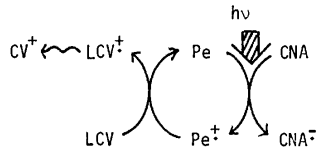
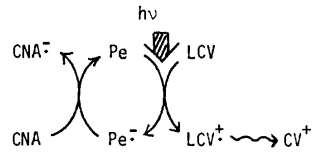
energy change (ΔG listed in Table 1) for the electron transfer between the excited singlet state of perylene (Pe*[1]) and LCV or the electron acceptors (CNA and DCB), calculated from Eq. 1,[8] indicate that electron transfer from Pe*[1] to the electron acceptor or from

$$\Delta G = E(D^+/D) - E(A/A^-) - e^2/\varepsilon r - \Delta E_{0\text{-}0} \quad (1)$$

LCV to Pe*[1] is the primary key step for the subsequent reactions. Consequently, we assumed the following ion radical mediated reaction schemes. In Scheme 1, electron transfer takes place between



Scheme 1.



Scheme 2.

Pe*[1] and CNA in the first step, and then in the second, an electron is transferred from LCV to perylene cation radical to bring about the recovery of perylene molecule. On the other hand, Scheme 2 indicates that the first electron transfer occurs between Pe*[1] and LCV, and then the second electron transfer occurs between perylene anion radical and CNA. Since Schomburg *et al.* have also reported such electron transfer reactions in the system of pyrene–*N*,*N*-dimethylaniline–DCB in acetonitrile,[9] and the free energy change for the electron transfer between Pe*[1]–LCV or Pe*[1]–CNA (or DCB) has a negative value,[10] we considered that these schemes are plausible. Furthermore, by assuming these schemes, the retardation or the inhibition of perylene decomposition in the ternary system compared with the binary one is well interpreted.

The mechanism of Crystal Violet dye formation from LCV cation radical has been reported by MacLachlan for the system of leuco Ethyl Crystal Violet–carbon tetrachloride, based on ESR and flash photolysis study, as follows;[6]

$$LCV^{\cdot+} \overset{K}{\rightleftharpoons} CV\cdot + H^+ \quad (2)$$

$$LCV^{\cdot+} + CV\cdot \xrightarrow{k_r} LCV + CV^+ \quad (3)$$

where K denotes the equilibrium constant

$$K = [CV\cdot][H^+]/[LCV^{\cdot+}].$$

The dye is yielded by disproportionation between LCV cation radical and Crystal Violet radical (CV·) which is formed by the equilibrium Eq. 2. The participation of equilibrium is supported by the results from the temperature effects on the dye formation. The Arrehnius plots and the activation energies are shown in Fig. 4 and Table 2, respectively. The activa-

tion energies for the dye formation were +33.5 kJ/mol under aerated conditions, while the nearly zero or slightly negative temperature dependence was observed *in vacuo*. We consider that such temperature dependence indicates the participation of equilibrium Eq. 2 in the dye formation, corresponding the positive and the negative (or zero) temperature dependence, for the forward and the backward reactions in the equilibrium, respectively.

Kinetics. The reaction Schemes 1 and 2, and the CV^+ dye formation processes from LCV cation radical lead to kinetic expressions as follows.

$$Pe \xrightarrow{I} Pe^{*1} \tag{4}$$

$$Pe^{*1} \xrightarrow{\tau^{-1}} Pe \text{ or } Pe^{*3} \tag{5}$$

Equation 5 expresses the sum of the decay processes of the excited singlet state of perylene by internal conversion to the ground state (rate constant: k_d), radiative decay (k_f), and intersystem crossing (k_{isc}) to the excited triplet state (Pe^{*3}). In the presence of an electron acceptor or LCV, we take the non-electron transfer quenching processes into account (Eqs. 6 and 7). The elementary reactions in the schemes are

$$Pe^{*1} + A \xrightarrow{k_{qa}} Pe + A \tag{6}$$

$$Pe^{*1} + LCV \xrightarrow{k_{qd}} Pe + LCV \tag{7}$$

expressed as below (Eqs. 8—11). The quantum yield

Scheme 1

$$Pe^{*1} + A \xrightarrow{k_1} Pe^{+\cdot} + A^{-\cdot} \tag{8}$$

$$Pe^{+\cdot} + LCV \xrightarrow{k_2} Pe + LCV^{+\cdot} \tag{9}$$

Scheme 2

$$Pe^{*1} + LCV \xrightarrow{k_3} Pe^{-\cdot} + LCV^{+\cdot} \tag{10}$$

$$Pe^{-\cdot} + A \xrightarrow{k_4} Pe + A^{-\cdot} \tag{11}$$

of the CV^+ dye formation (ϕ_{CV}) is expressed as Eq. 12.

$$\phi_{CV} = \frac{k_r[LCV^{+\cdot}][CV\cdot]}{I}, \tag{12}$$

where I indicates the absorbed photoenergy. Now assuming the stationary concentration for Pe^{*1}, CV radical, LCV cation radical, and perylene cation radical, we obtained the Stern-Volmer equation for the dye formation (Eq. 13).

$$\phi_{CV} = Z\left(1+\frac{k_{qa}[A]+k_{qd}[LCV]}{k_1[A]+k_3[LCV]}+\frac{1}{\tau(k_1[A]+k_3[LCV])}\right), \tag{13}$$

where

$$Z = ([H^+]+Kk_r)/K.$$

Varying the concentration of DCB or LCV (1.0×10^{-3}—1.0×10^{-4} mol dm^{-3}) while keeping the concentration of LCV or DCB constant at 1.0×10^{-4} mol dm^{-3}, respectively, the change in ϕ_{CV} was spectroscopically determined and presented in a form of Stern-Volmer plot in Fig. 5. It is shown that the slopes depend upon the concentration of DCB or LCV. Under two extreme conditions, namely [DCB] $\gg$[LCV] and [DCB]$\ll$[LCV], Eq. 13 can be simplified as Eqs. 14 and 15, respectively.

$$\phi_{CV} = Z\left(1+\frac{k_{qa}}{k_1}+\frac{1}{\tau k_1[DCB]}\right) \tag{14}$$

$$\phi_{CV} = Z\left(1+\frac{k_{qd}}{k_3}+\frac{1}{\tau k_3[LCV]}\right) \tag{15}$$

The concentration dependent terms in Eqs. 14 and 15 correspond to the initial slopes in Fig. 5 (*i.e.* the high concentration limits of DCB and LCV, respectively) and Eq. 13 to the low concentration region. Consequently, the slopes in the high concentration regions give the values $Z/\tau k_1$ and $Z/\tau k_3$ relevant to the electron transfer processes Eqs. 8 and 10, respectively. From the ratio of these slopes, we obtained $k_1/k_3=2.5$. Namely, the electron transfer between Pe^{*1} and DCB is faster than that between Pe^{*1} and LCV. These results suggest that the perylene cation radical intermediate mechanism (Scheme 1) is more plausible, although Scheme 2 participates to a lesser extent.

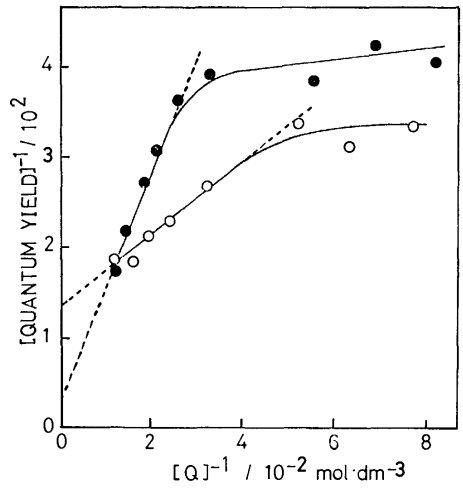

Fig. 5. Stern-Volmer plots for the dye formation. The concentration of perylene was fixed at constant (2×10^{-5} mol dm^{-3}), while the concentration of DCB (○) or LCV (●) was varied from 1×10^{-3} mol dm^{-3}—1×10^{-4} mol dm^{-3}. The reactions were carried out under air saturated conditions at 23.0 °C. Irradiation at 435 nm.

When $[Q]^{-1}$ in Fig. 5 increases, the assumptions on which the deviation of Eqs. 14 and 15 is based are no longer valid. Under the conditions of [LCV] $=1\times10^{-4}$ mol dm^{-3}, [DCB] being variable, Eq 13 indicates that ϕ_{CV}^{-1} should approach a constant value of $Z\left(1+\frac{k_{qd}}{k_3}+\frac{1}{\tau k_3[LCV]}\right)$ at the low concentration limit of DCB. Similarly, when [LCV] is variable, [DCB] being fixed, the limiting ϕ_{CV}^{-1} at [LCV]$\rightarrow$0 corresponds to $Z\left(1+\frac{k_{qa}}{k_1}+\frac{1}{\tau k_1[DCB]}\right)$. Deviation of Stern-Volmer plots in Fig. 5 with decreasing the quencher concentration is the manifestation of these.

The value of k_1/k_3 can be also estimated from the fluorescence quenching experiments of Pe*[1] as shown in Fig. 6. Since quenching of fluorescence in electron donor-acceptor systems in polar media is known to proceed *via* electron transfer process,[11] the Stern-Volmer quenching constants, K_q(DCB) and K_q(LCV), determined for DCB and LCV, respectively, will represent the relative rate of the electron transfer processes (Eqs. 8 and 10). The ratio of K_q therefore provides the value of k_1/k_3,

$$K_q(DCB)/K_q(LCV) = k_1/k_3 = 2.7.$$

Good agreement of the values obtained by reaction kinetic analysis and fluorescence quenching study strongly supports the validity of the present kinetic treatments.

It is worth noting that the electron transfer between Pe*[1] and DCB is faster than that between Pe*[1] and LCV, whereas, the values of ϕ_{CV} obtained by extraporating [LCV] to the infinite concentration, [DCB] being kept constant, is larger than the value at the infinite concentration of DCB with a fixed [LCV]. The difference between the ϕ_{CV} values is explained by the fact that two successible electron transfer processes (Eqs. 8 and 9) are necessary for the dye formation in the latter case, whereas the dye is formed directly by single electron transfer reaction (Eq. 10) in the former case. In other words, fast electron transfer between Pe*[1] and DCB does not necessarily bring about an increase in the quantum yield by Scheme 1, since another electron transfer between perylene cation radical and LCV is necessary. If the second electron transfer is slow, the overall quantum yield turns to be smaller, probably due to competing back electron transfer processes, Eqs. 16, 17, and 18. The back

$$Pe^{+\cdot} + DCB^{-\cdot} \longrightarrow Pe + DCB \quad (16)$$

$$LCV^{+\cdot} + DCB^{-\cdot} \longrightarrow LCV + DCB \quad (17)$$

$$LCV^{+\cdot} + Pe^{-\cdot} \longrightarrow LCV + Pe \quad (18)$$

electron transfer processes involving perylene cation radical (Eq. 16) would be more efficient than those involving LCV cation radical since LCV cation radical dissociates to CV radical. For the reaction to proceed by Scheme 1 at high DCB concentration, Eq. 9 has to compete with Eq. 16 at a fixed LCV concentration at 1×10^{-4} mol dm^{-3}. Apparently, the efficiency of reaction by Scheme 1 at infinite concentration of LCV is higher than that by Scheme 1 at infinite concentration of DCB in which the overall effciency is reduced by the ion recombination (Eq. 16) and also by the limited probability of Eq. 9 to occur within the lifetime of perylene cation radical at [LCV] $=1\times10^{-4}$ mol dm^{-3}. These discussions, however, could not be expressed by a kinetic treatment. Including these back electron transfer processes in the kinetic expression, the rate equation is far too complicated to be graphically presented. As a compromise, all factors reducing overall efficiency are attributed to Eqs. 6 and 7 in our present kinetic treatment. Phenomenalogically, participation of Eq. 16 is equivalent to increasing k_{qa} in Eq. 6.

Quantum Yield Measurements. The quantum yields for the dye formation (ϕ_{CV}) and perylene photodecomposition (ϕ_{Pe}) were measured in various conditions and shown in Table 3. The values of f in Table 3 confirm the turn over number of perylene by Scheme 1 or Scheme 2. In fact, the f value is about 58 in air and immeasurably large *in vacuo* in the ternary system. The finding that perylene is recycled even

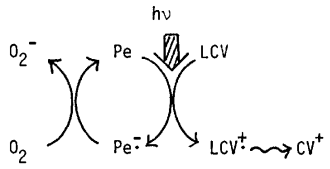
Irradiated at absorption maximum of perylene(435 nm) at 23.0 °C ([Pe]$=2\times10^{-5}$ mol dm^{-3}, [DCB]$=$[LCV]$=2\times10^{-3}$ mol dm^{-3} in acetonitrile). a) Irradiated on LCV directly at 304 nm. b) Turn over number of perylene as an electron carrier, which is defined as $f=2\times\phi_{CV}/\phi_{Pe}$. c) Immeasurably large.

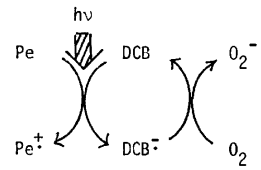
in the Pe–LCV system ($f=14$) in air requires comments. In this system, O_2 will act as an electron acceptor so that Pe anion radical formed by Eq. 10 will be oxidized to reproduce the Pe molecule by Eq. 19. Although the detection of superoxide ion (O_2^-)

$$Pe^{\cdot-} + O_2 \longrightarrow Pe + O_2^- \quad (19)$$

was not carried out, the participation of O_2 is confirmed by the facts that perylene is not recycled *in vacuo* ($f=0.5$) and Eq. 19 is a highly exothermic process ($\Delta G=-100.4$ kJ/mol).[12] Recently, the similar electron transfer reaction between O_2 and 9,10-dicyanoanthracene anion radical has been reported as an elementary process of non-singlet oxygen photooxygenation of alkenes or sulfides *via* superoxide ion.[13] We conclude that the electron transfer sensitization is also attained in this system, O_2 being an electron acceptor, as described below (Scheme 3).



Scheme 3.



Scheme 4.

In a similar manner, a large quantum yield of perylene photodecomposition in Pe–DCB system in air is understandable by assuming Scheme 4, where DCB acts as an electron carrier instead of perylene. DCB anion radical is reproduced by the electron transfer from DCB anion radical to O_2 ($\Delta G=-100.4$ kJ/mol),[12] whereas perylene cation radical must escape from the cycle to decompose. Although the product analysis has not been carried out, perylene cation radical will be decomposed by oxygenation with superoxide ion as Eriksen *et al.* have reported.[13] The participation of oxygen (superoxide ion) in the perylene decomposition is confirmed by the difference in quantum yields of perylene photodecomposition in air and *in vacuo* (ϕ_{Pe} (in air) $=20.8\times10^{-3}$ and ϕ_{Pe} (*in vacuo*) $=0.3\times10^{-3}$, in Table 3).

The larger quantum yield of dye formation in air relative to the value *in vacuo* will be also explained by assuming the participation of superoxide ion. Superoxide ions produced by the electron transfer from acceptor anion radicals to O_2 reduce the proton concentration according to Eq. 20 and consequently

$$H^+ + O_2^{\cdot-} \longrightarrow HO_2\cdot \quad (20)$$

shift the equilibrium (Eq. 2) towards right to increase the quantum yield of dye formation. Such assumption is supported by the fact that the activation energy for the dye formation in air has a positive value whereas the rate of the dye formation *in vacuo* shows negative dependence on temperature. The negative temperature dependence of the rate is explainable only by considering equilibrium in the course of the dye formation.

In comparison with the unimolecular photodissociation of Crystal Violet leuconitrile (X=CN) to the dye which proceeds with a quantum yield close to unity,[3] the quantum yields given in Table 3 are very much smaller. ϕ_{CV} in the LCV–DCB system on direct irradiation of LCV at 304 nm is almost the same as the values in the ternary system in air. The quantum yields of these electron transfer sensitization systems are small in general, because the presence of back electron transfer between ion radicals diminishes the efficiency. The merit of electron transfer sensitization is to shift the effective absorption wavelength towards longer wavelength regions in comparison with the direct excitation of a redox pair. Singlet state sensitization by means of energy transfer is obviously impossible. The same principles of electron transfer sensitization will be applicable to redox reactions in which the excited triplet state participates.

Solvent Effects. The solvent effects on the dye formation are shown in Table 4. The free ion yields determined by the laser photolysis of electron donor-acceptor (EDA) systems are nearly zero in low polarity solvents. The threshold of the solvent polarity to promote photo-ionic dissociation of EDA systems *via* electron transfer seems to be around ≈10, which is confirmed by transient spectroscopy or photocurrent

Table 4. Solvent effect

	Solvent properties			$\phi_{CV}/10^{-3}$			
		DN	AN	Pe–LCV–DCB[a]	Pe–LCV[a]	LCV–DCB	LCV

Irradiated under air saturated solution at 23.0 °C ([Pe] $=2\times10^{-5}$ mol dm^{-3}, [DCB] = [LCV] $=2\times10^{-3}$ mol dm^{-3}). ε and η indicate solvent polarity and solvent viscosity, respectively. Irradiation wavelength is as follows, a) 435 nm(Pe), b) 304 nm(LCV), c) 334 nm(LCV).

measurement in the pyrene–*N*,*N*-dimethylaniline system.[14] As anticipated from the preceeding discussions, the electron transfer between EDA pairs is an essential requirement for the dye formation. Consequently, the present results that ϕ_{CV} is nearly zero in benzene or THF whereas the efficient dye formation takes place in acetone, acetonitrile, and DMF are well understandable. Furthermore, the largest ϕ_{CV} in acetonitrile is in agreement with the finding that the relative free ion yield is the largest in this solvent. In addition to solvent polarity, solvent viscosity seems to influence the efficiency of the dye formation. While DMF is as polar as acetonitrile, the value of ϕ_{CV} in DMF is about half of that in acetonitrile. This difference would be attributed to the high viscosity of DMF. Recently, Schulten and Schulten have reported that ion radical recombination processes are largely affected by solvent viscosity.[16] Namely, viscous solvent like DMF, compared with acetonitrile, will promote the back electron transfer reactions between the ion radicals in geminate ion pair which will diminish the dye formation yield. Furthermore, since carbonium ions are stable and cationic reactions are favored in the solvent having a high acceptor number(AN) and a low donor number(DN) as Gutmann has suggested,[17] the high DN of DMF is also unfavorable factor for the formation of Crystal Violet cation dye.

In contrast to the case in acetonitrile or DMF, the electron transfer sensitization was not achieved in acetone, in which the ϕ_{CV} value was smaller in the ternary system than in the binary one. For electron transfer sensitization to be effective, highly polar solvent and sufficient lifetime of free ion are required. To satisfy these conditions, acetone is neither polar enough nor sufficiently electrophilic to stabilize the cations. The finding that ϕ_{CV} of Pe–LCV system in acetone is comparable to that in acetonitrile whereas the efficiency of the dye formation in the ternary system is low in acetone would indicate the participation of Scheme 1 to be inefficient. This is understandable since perylene cation radical intermediate will be unstable in acetone. From these discussions, it is a reasonable consequence that Crystal Violet dye cation formes efficiently in acetonitrile, having high polarity and low viscosity as well as having the highest AN and the lowest DN among the solvents examined.

Conclusion

On the basis of a kinetic investigation, we have shown that LCV is oxidized to Crystal Violet dye cation *via* electron transfer sensitization mechanism. Under a limited conditions, the turn over number of perylene used as the primary photoabsorber is measurably large. From the view point of singlet state sensitization, the principle of spectral sensitization of redox reactions *via* singlet state has been established. Furthermore, these systems can be considered as a kinetic model for the electron transport system in photosynthesis, which have been also reported by the present authors demonstrating the photoreduction of carbon dioxide to oxalic acid or formic acid using water as a hydrogen source,[18] or the primary action of chlorophyll using polymer bound or micellar electron transfer sensitizers to facilitate energy migration among the chromophores like in antena pigments.[19]

(Received January 25, 1980)

γ-Hydroxy-DL-ornithine was obtained from an alkaline hydrolysate of 2,5-diamino-4-pentanolide synthesized according to the method of Talbot *et al.*[1] The amino acid preparation was found to be a racemic mixture composed of 34% *erythro* and 66% *threo* isomers by a new chromatographic assay. This assay is based on the conversion of the basic amino acid to a neutral amino acid by acetylation of the δ-amino group and the analysis of the resulting N^{δ}-acetyl derivative with an automatic amino acid analyzer by the ordinary method. Two diastereoisomers of γ-hydroxy-DL-ornithine were separated by column chromatography on Dowex 50 and isolated as their crystalline hydrochlorides. Guanidination of the separated racemic diastereoisomers gave the corresponding diastereoisomeric γ-hydroxyarginines, hydrolysis of which with arginase yielded *erythro*- and *threo*-γ-hydroxy-L-ornithines.

γ-Hydroxyornithine is a diamino monocarboxylic acid which, by virtue of its two asymmetric centers, may exist as four optically active stereoisomers or two racemic diastereoisomers (Scheme 1). Since this amino acid was first synthesized in 1916 by Hammarsten,[2] several synthetic attempts, leading to racemic mixtures in varying proportions of the two possible diastereoisomers of 2,5-diamino-4-pentanolide (**2**), have been studied by several researchers.[3–5] Although the synthesis of the two diastereoisomers of this amino acid from L-histidine and the establishment of the stereochemistry of γ-carbon, to which the secondary hydroxyl group is attached, have been achieved in 1956 by Witkop and Beiler,[5] none of the four optically active isomers has been characterized. Several years later an optically active γ-hydroxyornithine was isolated from an enzymatic hydrolysate of the natural γ-hydroxyarginine and the overall configuration of the amino acid was determined to be *erythro*-γ-hydroxy-L-ornithine by Fujita.[7,8] The occurrence of this amino acid in a plant was also reported.[9] However, none of the optically active isomers, other than the *erythro* L-isomer, has hitherto been characterized, nor has any description for the separation of the two diastereomeric racemates appeared. This paper is primarily concerned with the preparative separation of these diastereomeric racemates, and the resolution of each racemic pair to yield *erythro* and *threo* isomers of γ-hydroxy-L-ornithine.

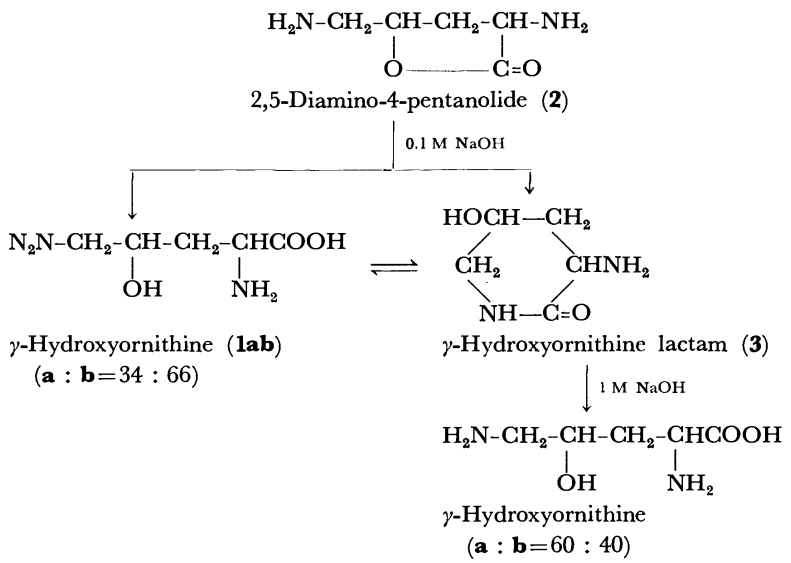
Results and Discussion

*Preparation of γ-Hydroxy-DL-ornithine (**1ab**).* Compound **2** was prepared according to the directions of Talbot *et al.*[1] The preparation started from diethyl allylmalonate and involved treatment with sulfuryl



Scheme 2. Alkaline hydrolysis of 2,5-diamino-4-pentanolide.

† Present address: Sumitomo Chemical Co., Ltd., 2-40 Tsukahara, Takatsuki 569.

chloride, followed by hydrolysis and distillation to yield 2,5-dichloro-4-pentanolide. Condensation of this with potassium phthalimide gave 2,5-diphthalimido-4-pentanolide. Talbot *et al.* reported that the latter compound, on hydrolysis by a mixture of glacial acetic acid and concentrated hydrochloric acid, yielded γ-hydroxy-DL-ornithine, which was isolated as a crystalline dihydrochloride monohydrate of the corresponding **2** in a good yield (95%), mp 239 °C. But acid hydrolysis of the diphthalimido derivative in the present work gave a crude diamino lactone hydrochloride as a gummy residue. This crystallized on repeated trituration with ethanol but the crystalline product had an indistinct melting point. Additional recrystallization was impossible, and the lactone was unstable. The crude lactone hydrochloride was subjected to alkaline hydrolysis (Scheme 2). Paper chromatographic analysis of the hydrolysate in 1-butanol–acetic acid–pyridine–water system revealed many spots upon spraying with ninhydrin. Therefore, the hydrolysate neutralized with acid was freed from contaminated acidic and neutral amino acids by passage down a column of Dowex 50 (NH_4^+ form). The basic amino acid were eluted with aqueous ammonia. Further purification was performed by ion exchange chromatography on a column of Dowex 50 equilibrated with pyridinium acetate buffer of pH 4.8. The component that appeared as the first major peak was confirmed to be **lab** by the chromatographic and electrophoretic behavior on paper. From the fractions comprising the peak, a mixture of the two racemic diastereoisomers of γ-hydroxyornithine was isolated as its hydrochloride (**lab**·HCl) (see Experimental section). The isomeric composition of the sample of **lab**·HCl was estimated to be 66% *threo* and 34% *erythro* forms by the assay with an amino acid analyzer, as described below. The next major peak was found to be principally composed of a derivative of γ-hydroxyornithine. From the fractions comprising the peak, a product that gave a characteristic brown-gray color with ninhydrin on paper was isolated as the crystalline hydrochloride. The compound was identified as γ-hydroxyornithine lactam (3-amino-5-hydroxy-2-piperidone) (**3**) by elementary analysis. The characteristic amide bond (lactam) of **3** was well defined by the band at 1670 cm^{-1} in the IR spectrum. Another γ-hydroxyornithine preparation was also recovered from **3** hydrochloride by treatment with alkali. This preparation was composed of 40% *threo* and 60% *erythro* isomers. If γ-hydroxyornithine hydrochloride was treated with warm aqueous ammonia or the free base with refluxing water, a fraction of the amino acid was converted into the lactam. In the same manner, ornithine lactam (3-amino-2-piperidone) was formed from ornithine hydrochloride. Fischer and Zemplen[10] have reported that piperidone was formed from 5-aminovaleric ester and 3-amino-2-piperidone from ornithine ester as a result of spontaneous cyclization. Taking into account the isomeric compositions of the two γ-hydroxyornithine preparations, we can assert that *erythro* isomer is liable to cyclize more easily than *threo* isomer.

*Preparative Separation of Two Diastereoisomers of γ-Hydroxyornithine (**lab**).* The successful separation of the diastereoisomers of hydroxylysine on a column (3.4×115 cm) of Dowex 50 (Na^+ form) was reported by Hamilton and Anderson.[11] For the separation of the two racemic diastereoisomers of **lab**, we also tried this technique, but only partial separation was obtained. Upon passage through a long column (3.8×275 cm) of Dowex 50, a good separation of the diastereoisomers into two peaks resulted. A typical elution pattern is shown in Fig. 1. The component of the first major peak was confirmed to be **lb** and that of the second peak to be **la** by the assay with an amino acid analyzer. From the combined peak fractions, **la** and **lb** were isolated as their crystalline hydrochlorides, respectively. Their stereoisomeric purity was ascertained by the assay with an amino acid analyzer.

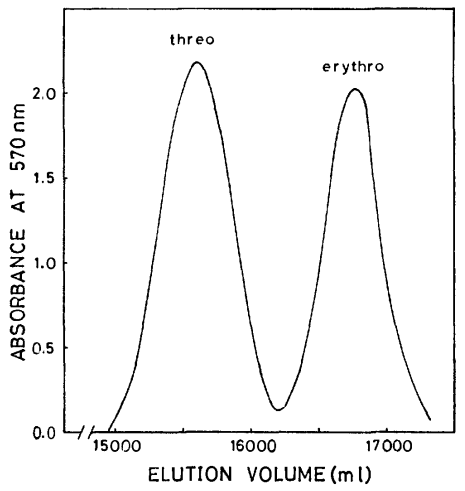


Fig. 1. Elution pattern of γ-hydroxyornithine diastereoisomers on a column (3.8×275 cm) of Dowex 50.

Assay with an Automatic Amino Acid Analyzer. The analytical separation of the diastereoisomers of γ-hydroxyornithine on a Dowex column (0.9×100 cm) by the method of Hirs *et al.*[12] as modified by Piez[13] was reported by Witkop and Beiler.[6] However, the procedure involves many time-consuming operations. A new attempt was made to assay the diastereoisomeric composition of γ-hydroxyornithine with an automatic amino acid analyzer after transformation of this basic amino acid into a neutral amino acid by acetylation of the δ-amino group. As a standard we used "natural" *erythro*-γ-hydroxy-L-ornithine, obtainable by enzymatic hydrolysis of natural γ-hydroxy-L-arginine with arginase. The elution profiles of some N^δ-acetyl derivatives of γ-hydroxyornithine are shown in Fig. 2. The separation of the two isomers was not complete, but was sufficient to allow us to estimate their compositions. The elution times were 40 min for the *threo* and 45 min for the *erythro* isomers. This is a suitable method for routine analysis of the stereochemical purity and of the composition of the diastereoisomers of γ-hydroxyornithine preparations.

Epimerization of erythro-*γ-Hydroxy-L-ornithine by Treatment with Acid and Alkali.* Hamilton and An-

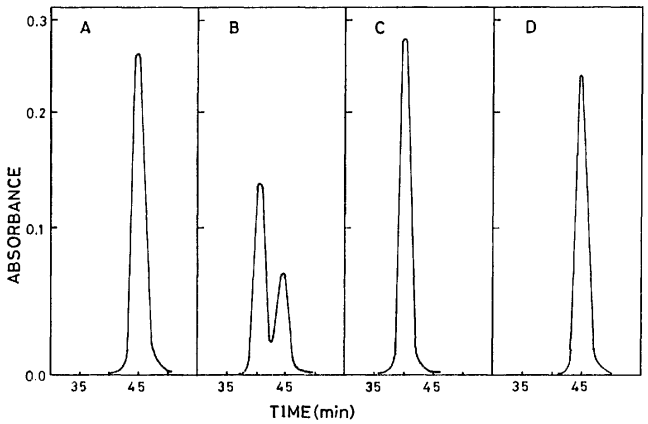

Fig. 2. Elution pattern of N^{δ}-acetyl-γ-hydroxyornithine on a long column (0.8×50 cm) of an amino acid analyzer. A: N^{δ}-Acetyl derivative of γ-hydroxyornithine derived from natural γ-hydroxyarginine, B: N^{δ}-Acetyl derivative of diastereoisomeric γ-hydroxy-DL-ornithine (**lab**), C and D: N^{δ}-Acetyl derivatives of *threo* L- and *erythro* L-isomers obtained in this study.

Table 1. Epimerization of *erythro*-γ-hydroxyornithine on refluxing in acid and alkali

Conditions time (h)	6 M HCl			0.5 M $Ba(OH)_2$	
	0	24	72	0	2
erythro Isomer, %	100	90	78	100	80
threo Isomer, %	0	10	22	0	20

derson[11] have reported that refluxing solutions of δ-hydroxy-L-lysine with 6 M (1 M=1 mol dm^{-3}) hydrochloric acid for 72 h led to epimerization at the α-carbon; a nearly equal mixture of δ-hydroxy-L-lysine and allo-δ-hydroxy-D-lysine resulted. A "natural" γ-hydroxyornithine preparation was refluxed with 6 M hydrochloric acid or 0.5 M barium hydroxide and the extent of epimerization was determined by the assay with an amino acid analyzer. The results are presented in Table 1. Epimerization of *erythro*-γ-hydroxy-L-ornithine was shown to take place more slowly in boiling 6 M hydrochloric acid than that of δ-hydroxy-L-lysine. On the other hand, after refluxing of natural γ-hydroxyarginine in 0.5 M barium hydroxide for 2 h, the content of the diastereoisomers of the resulting γ-hydroxyornithine was found to be 20% *threo* and 80% *erythro* isomers.

Preparation of γ-Hydroxy-DL-arginine. Compounds **1a** and **1b** obtained above were guanidinated with 1-amidino-3,5-dimethylpyrazole nitrate to give γ-hydroxyarginines in the usual manner.[14] After column chromatography of the reaction mixture, γ-hydroxyarginine and unchanged γ-hydroxyornithine were isolated as their hydrochlorides. Assays with an amino acid analyzer of each isomer of the unchanged γ-hydroxyornithine showed that no racemization occurred under the conditions of guanidination.

Hydrolysis of γ-Hydroxy-DL-arginine with Arginase. The optical resolution of racemic γ-hydroxyarginine into γ-hydroxy-L-ornithine and γ-hydroxy-D-arginine was performed by the L-directed hydrolytic action of beef liver arginase. Thus *threo*-γ-hydroxy-L-ornithine and *threo*-γ-hydroxy-D-arginine were obtained from the hydrolysate of *threo*-γ-hydroxy-DL-arginine, and *erythro*-γ-hydroxy-L-ornithine and *erythro*-γ-hydroxy-D-arginine from *erythro*-γ-hydroxy-DL-arginine, respectively. Two optically active isomers of γ-hydroxy-L-ornithine were isolated in crystalline state as their hydrochlorides. The *erythro* isomer obtained here was found to be optically identical with "natural" *erythro*-γ-hydroxy-L-ornithine obtained from natural γ-hydroxy-L-arginine. Rivard and Carter[15] have reported that L- and D-ornithines were obtained from L- and D-arginines, respectively, by hydrolysis with barium hydroxide and careful crystallization with ethanol. Refluxing natural γ-hydroxy-L-arginine with 0.5 M barium hydroxide for 2 h led to complete conversion to γ-hydroxyornithine, but partial epimerization in the product occurred as described above. Therefore, no attempt was made to prepare the isomers of γ-hydroxy-D-ornithine.

Experimental

All melting points are uncorrected. The amino acid analyses were carried out using a JEOL-6AS amino acid analyzer. The optical rotations were measured with a Union high sensitivity polarimeter PM-71. Paper chromatography was done by the ascending technique on Toyo Roshi No. 52 paper with 1-butanol–acetic acid–pyridine–water (4:1:1:2, v/v). Paper electrophoresis was carried out at 300 V for 2.5 h on Toyo Roshi No. 52 paper in a buffer solution of pyridine–acetic acid–water (20:10:970, v/v). The spots were made visible with ninhydrin and Sakaguchi reagents.

Preparation of 2,5-Diphthalimido-4-pentanolide. This compound was prepared from 2,5-dichloro-4-pentanolide (52 g, 30.8 mmol) and potassium phthalimide (122 g, 67.8 mmol) according to the method reported by Talbot *et al.*[1] Yield of crude product, 108 g (27.7 mmol). Recrystallization from a large volume of glacial acetic acid gave crystals, mp 261—263 °C (lit,[1] 263 °C).

Found: C, 64.14; H, 3.71; N, 7.07%. Calcd for $C_{21}H_{14}O_6N_2$: C, 64.62; H, 3.61; N, 7.18%.

*Preparation of γ-Hydroxyornithine (**1ab**) and Its Lactam (**3**).* The crude 2,5-diphthalimido-4-pentanolide (10 g, 25.6 mmol) was hydrolyzed by a mixture of glacial acetic acid (50 ml) and concentrated hydrochloric acid (100 ml) according to the literature.[1] The filtrate was evaporated to dryness *in vacuo* after the phthalic acid had been removed from the cold solution. The residue was dissolved in water and the solution was decolorized with Norit, concentrated to a small volume, and crystallized by repeated trituration with ethanol. The crystalline product was hygroscopic and had an indistinct melting point. The product (2.1 g) was dissolved in 0.1 M sodium hydroxide (30 ml); the solution was refluxed for 3 h and subsequently neutralized with dilute hydrochloric acid. The solution was washed onto a column (2×15 cm) of Dowex 50 (H^+ form); the column was washed with water and then eluted with 2 M aqueous ammonia (200 ml). The eluate was evaporated to dryness *in vacuo*. The residue taken up in a small volume of water was applied to a column (2×15 cm) of Dowex 50 (NH_4^+ form). The column was washed with water and then eluted with 2 M aqueous ammonia (200 ml), and the eluate was evaporated to dryness. The residue dissolved in a small volume of 0.3 M pyridinium acetate buffer, pH 4.8, was placed on a Dowex 50 column (3×54 cm) equilibrated with the same buffer. The column

was developed with the same buffer at a flow rate of about 10 ml/h and the effluent was collected in 5 ml fractions. The position and shape of the resulting peaks were established by ninhydrin spot test on paper of 10 μl samples taken from alternate fractions. Two major peaks appeared on the chromatogram. The component of the first major peak was proved to be **lab** and that of the second to be **3**, by means of paper chromatography and electrophoresis.

*γ-Hydroxy-*DL*-ornithine Hydrochloride (**1ab**·HCl)*: The first major peak fractions were pooled and evaporated to dryness *in vacuo*. The residue dissolved in water was passed through a column (2×10 cm) of Dowex 50 (H^+ form) and the column was washed with water. The amino acid was eluted with 2 M aqueous ammonia (100 ml) and the evaporated eluate was dissolved in water (5 ml). The solution was adjusted to pH 5.0 with 1 M hydrochloric acid, decolorized with charcoal, and concentrated to a syrup. The syrup dissolved in a small volume of 50% ethanol was subjected to crystallization in the cold with the addition of absolute ethanol; yield, 806 mg (4.4 mmol); mp 180—181 °C; *erythro*:*threo*=34:66.

Found: C, 32.77; H, 7.29; N, 15.04%. Calcd for $C_5H_{12}O_3N_2$·HCl: C, 32.53; H, 7.10; N, 15.17%.

*γ-Hydroxy-*DL*-ornithine Lactam Hydrochloride (**3**·HCl)*: The next major peak fractions were pooled and evaporated to dryness. The residue was dissolved in 2 M hydrochloric acid and the solution treated with charcoal, filtered, and evaporated to a syrup. Ethanol was added to the syrup and triturated in the cold to yield crystals. Recrystallization from water–ethanol gave 268 mg (1.6 mmol) of pure **3**·HCl; mp 217—218 °C (dec). This compound gave the characteristic brown-gray color on paper with ninhydrin reagent. IR (KBr): 3200, 1670, and 1580 cm^{-1} (lactam).

Found: C, 35.96; H, 6.66; N, 16.80%. Calcd for $C_5H_{10}O_2N_2$·HCl: C, 36.01; H, 6.60; N, 16.81%.

The combined mother liquors of the crystallization of **3**·HCl were evaporated to dryness. The residue dissolved in 1 M sodium hydroxide (30 ml) was refluxed for 3 h. After neutralization with 1 M hydrochloric acid, the solution was passed through a column (2×11 cm) of Dowex 50 (H^+ form) and the column was washed with water. The amino acid was eluted with 2 M aqueous ammonia (150 ml) and the eluate was evaporated to dryness. From the residue, racemic γ-hydroxyornithine was crystallized as its hydrochloride as described for **lab**·HCl. Yield, 486 mg (2.6 mmol); mp 168—169 °C; *erythro*:*threo*=60:40.

*Separation of Two Diastereoisomers of γ-Hydroxy-*DL*-ornithine (**1ab**).* A preparation of **lab**·HCl (600 mg) was dissolved in a small volume of water and the solution was applied to a column (3.8×275 cm) of Dowex 50 equilibrated with 0.2 M acetate buffer, pH 3.4. The column was developed at room temperature with 0.1 M phosphate buffer, pH 7.8, at a flow rate of 20 ml/h. The first 15 liters of effluent were discarded and the next 2.5 liters were collected in 20 ml fractions. The position and shape of the resulting peaks were established by the colorimetric ninhydrin analysis[16] of 0.2 ml aliquots taken from each fraction. Figure 1 shows a typical chromatogram. The component and the degree of overlap were confirmed by the assay with an amino acid analyzer of 1—2 ml aliquots of the peak fractions. Fractions comprising the fore and after peaks were found to be composed of **1b** and **1a**, respectively, and fractions that overlapped were discarded.

threo-*γ-Hydroxy-*DL*-ornithine Hydrochloride (**1b**·HCl)*: The fractions of 15100—15940 ml were collected and adjusted to pH 5.0 with 2 M hydrochloric acid. The solution was passed through a column (3.8×20 cm) of Dowex 50 (H^+ form) and the column was washed with 50% ethanol. The amino acid was eluted with 2 M aqueous ammonia (900 ml) and the eluate was treated as described for **lab**·HCl; yield of crystals, 300 mg (76%), mp 193—194 °C (dec). The stereochemical purity of the compound was ascertained by the assay with an amino acid analyzer, as shown in Fig. 2.

Found: C, 32.05; H, 7.15; N, 15.15%. Calcd for $C_5H_{12}O_3N_2$·HCl: C, 32.53; H, 7.10; N, 15.17%.

erythro-*γ-Hydroxy-*DL*-ornithine Hydrochloride (**1a**·HCl)*: The fractions of 16460—17120 ml were treated as described for **lb**·HCl; yield of crystals, 153 mg (75%), mp 175—175.5 °C (dec).

Found: C, 32.44; H, 7.04; N, 15.15%. Calcd for $C_5H_{12}O_3N_2$·HCl: C, 32.53; H, 7.10; N, 15.17%.

*Preparation of N^δ-Acetyl-γ-hydroxy-*L*-ornithine.* *erythro*-γ-Hydroxy-L-ornithine hydrochloride (92.3 mg, 0.5 mmol) obtained from natural γ-hydroxy-L-arginine hydrochloride was dissolved in a small volume of water; the solution was brought to 90 °C and copper(II) carbonate was added. Excess copper carbonate was filtered off and the filtrate chilled. With stirring in an ice–water bath, 2 M lithium hydroxide (0.5 ml, 1 mmol) and acetic anhydride (0.1 ml, 1 mmol) were added alternately in portions. After standing for 30 min at room temperature, the solution was acidified with glacial acetic acid and poured onto a column (1×3 cm) of Dowex 50 (H^+ form). After washing with water, the N^δ-acetyl derivative was eluted with 2.5 M pyridine (20 ml) and the eluate was evaporated to dryness *in vacuo*. The residue was triturated in ethanol, filtered off, and washed with ethanol and ether. The product was recrystallized from water–ethanol; yield 49.2 mg (52%); mp 211 °C (dec).

Found: C, 44.02; H, 7.38; N, 14.39%. Calcd for $C_7H_{14}O_4N_2$: C, 44.21; H, 7.37; N, 14.73%.

Amino Acid Analysis of N^δ-Acetyl-γ-Hydroxyornithines. A small amount of γ-hydroxyornithine preparation (1—2 mg) was transformed into its N^δ-acetyl derivative, as described above, on a small scale. Without crystallization, the product was dissolved in 0.2 M sodium citrate buffer (5 ml) of pH 3.25 (the first buffer). A sample of the solution was applied to a long column (0.8×50 cm) and the column was eluted with the first buffer in the usual way.

Epimerization of erythro-*γ-Hydroxy-*L*-ornithine with Strong Acid.* *erythro*-γ-Hydroxy-L-ornithine hydrochloride (9.3 mg) was refluxed in 6 M hydrochloric acid (10 ml). Two milliliter aliquots of the reaction mixture were taken out and evaporated to dryness. The product was converted to N^δ-acetyl derivative as described above and subjected to amino acid analysis. The results of the samples refluxed for 24 and 72 h are presented in Table 1.

Degradation of erythro-*γ-Hydroxy-*L*-arginine with Weak Alkali.* Natural γ-hydroxyarginine hydrochloride (12 mg) was refluxed in 0.5 M barium hydroxide (2 ml) for 2 h. The reaction mixture was no longer positive to a Sakaguchi reaction. Then it was neutralized with 0.25 M sulfuric acid and centrifuged. The concentrated supernatant was treated with copper(II) carbonate. This was followed by acetylation with acetic anhydride and alkali, as described above. N^δ-Acetyl derivative of the possible reaction product (γ-hydroxyornithine) was subjected to amino acid analysis. The result is presented in Table 1.

Preparation of γ-Hydroxyarginine from γ-Hydroxyornithine. Guanidination of γ-hydroxyornithine with 1-amidino-3,5-dimethylpyrazol nitrate and chromatographic separation of the product and unchanged amino acid on a Dowex 50 column were carried out essentially according to the literature.[14]

erythro-*γ-Hydroxy*-DL-*arginine Hydrochloride*: Compound **1a**·HCl (203 mg, 1.1 mmol) was guanidinated with 1-amidino-3,5-dimethylpyrazol nitrate (443 mg, 2.2 mmol) and the reaction mixture subjected to chromatography on a Dowex 50 column (2×16 cm). From the afterpeak fractions, the product was crystallized as its hydrochloride. The yield of hygroscopic crystals was 160 mg (64%). The homogeneity of this compound was confirmed by ninhydrin and Sakaguchi reagents by paper electrophoresis and chromatography. A small amount of **1a**·HCl was recovered from the forepeak fractions.

threo-*γ-Hydroxy*-DL-*arginine Hydrochloride*: Guanidination of **1b**·HCl (277 mg, 1.5 mmol) with the guanidinating reagent (604 mg, 3 mmol), followed by column chromatography, gave hygroscopic crystals; yield 140 mg (41%).

Optical Resolution of Racemic γ-Hydroxyarginine by Arginase. The partially purified arginase preparation was obtained as reported by Schmike.[17] Racemic γ-hydroxyarginine hydrochloride (120—140 mg) and the arginase (50 mg) were dissolved in 0.025 M Tris-Cl buffer of pH 9.6 (5 ml) containing 0.01 M manganese chloride, and incubated for 24 h at 37 °C. The progress of the hydrolysis of the susceptible L-antipode was followed by amino acid analysis as usual. To reach complete hydrolysis, arginase (25 mg) were added to the reaction mixture and it was incubated for a further 24 h. From the mixture deproteinized with 0.5 M perchloric acid, the products were recovered by chromatographic separation on a Dowex 50 column (2×16 cm) essentially according to the literature.[14]

erythro-*γ-Hydroxy*-L-*ornithine Hydrochloride.* *erythro-γ*-Hydroxy-DL-arginine hydrochloride (140 mg) was treated with arginase and the deproteinized solution was subjected to chromatographic separation. From the forepeak fractions, *erythro-γ*-hydroxy-L-ornithine was crystallized as its hydrochloride; yield 32 mg (56%); mp 175—176 °C (dec); $[\alpha]_D^{20}$ +10.5° (c 2, H_2O), lit,[8] $[\alpha]_D^{20}$ +10.6° (*c* 5, H_2O).

Found: C, 32.39; H, 7.06; N, 14.81%. Calcd for $C_5H_{12}O_3N_2 \cdot HCl$: C, 32.53; H, 7.10; N, 15.17%.

From the afterpeak fractions, *erythro-γ*-hydroxy-D-arginine was crystallized as its hydrochloride; yield of hygroscopic crystals, 42 mg (60%).

threo-*γ-Hydroxy*-L-*ornithine Hydrochloride*: *threo-γ*-Hydroxy-DL-arginine hydrochloride (120 mg) was treated as described for *erythro* racemate. The yield of *threo-γ*-hydroxy-L-ornithine hydrochloride was 48 mg (98%); mp 200—201 °C (dec); $[\alpha]_D^{20}$ −7.0° (*c* 2, H_2O).

Found: C, 32.53; H, 7.09; N, 14.99%. Calcd for $C_5H_{12}O_3N_2 \cdot HCl$: C, 32.53; H, 7.10; N, 15.17%.

The yield of hygroscopic crystals of *threo-γ*-hydroxy-D-arginine hydrochloride was 51 mg (85%).

Studies of Polyphenyls and Polyphenylenes. II.[1] The Synthesis and Physical Properties of Polyphenyls Containing Para Linkage

Shigeru Ozasa,* Noriko Hatada, Yasuhiro Fujioka, and Eiichi Ibuki

Department of Organic Chemistry, Kyoto College of Pharmacy, Misasagi-nakauchi-cho, Yamashina-ku, Kyoto 607

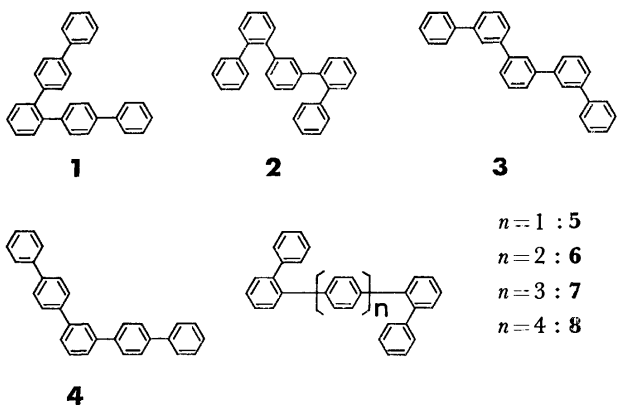
(Received January 28, 1980)

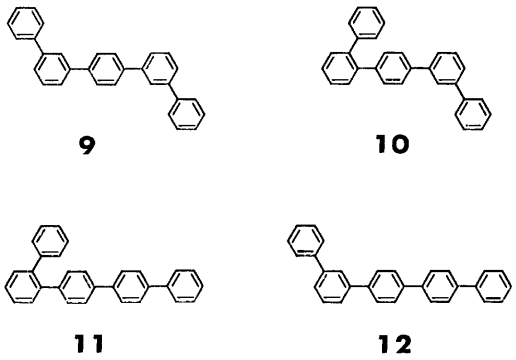
Twelve linear polyphenyls, including quinque- to octiphenyl, were synthesized by the Ullmann cross-coupling reaction of iodobiphenyl with diiodobenzene or iodoterphenyl. Ultraviolet spectral studies of the polyphenyls indicated that the positions of the K-bands above *ca.* 260 nm, regardless of the presence of *o*- or *m*-phenylene unit(s), may be considered to be an indication of the approximate number of consecutive *p*-phenylene units. Infrared studies also showed that the locations of strong or medium bands in the 815—850 cm^{-1} region may give the same information. The HMO calculations of the longest wavelength absorption bands of twenty-four polyphenyls were carried out. A comparison between the calculated and observed wavelengths gave rather good agreement, except in the cases of two compounds. The signals of the proton magnetic resonance spectra of eighteen polyphenyls were assigned tentatively. The correlations between the arrangement of the benzene rings and the spectral patterns are discussed.

In the previous paper, a series of closely related linear sexiphenyls have been synthesized to elucidate the relation between the structures and the physical properties of polyphenyls.[1] Spectral studies have proved that the sexiphenyls having one or two *p*-phenylene rings displayed marked characteristics in both their infrared (IR) and ultraviolet (UV) absorption spectra.

In the present work, in order to investigate the spectral characteristics of a wide variety of polyphenyls, we synthesized twelve symmetrical and unsymmetrical linear polyphenyls (**1**—**12**), having one to four *p*-phenylene rings and not having them for comparison. The IR, UV, and proton magnetic resonance (^{1}H-NMR) spectra of the polyphenyls have been measured, and the relationship between the number and arrangement of the benzene rings and their physical properties, especially the characteristics due to the presence of *p*-linkage, has been discussed. In addition, we performed the HMO calculations of the longest wavelength absorption bands of the polyphenyls as well as of the closely related bi-, ter-, and quaterphenyls. The calculated results have been compared with the observed values.

For the synthesis of the polyphenyls, the Ullmann cross-coupling reaction of aryl halides has been used. Among the halides used, iodobiphenyls (2- (**13**), 3- (**14**), and 4-iodobiphenyl (**15**)) and iodoterphenyls (4-iodo-*o*- (**16**) and 4-iodo-*p*-terphenyl (**17**)) were prepared from commercial aminobiphenyls, aminonitrobenzene, and terphenyls. Diiodobenzenes (*o*- (**18**), *m*- (**19**), and *p*-diiodobenzene (**20**)) were commercially available. A mixture of iodobiphenyl and diiodobenzene in the molar ratio of 2 to 1 was subjected to the reaction at 230—275 °C with copper powder for the synthesis of symmetrical polyphenyls, while a mixture of an equimolar ratio of iodobiphenyl and iodoterphenyl was used for the synthesis of unsymmetrical ones. The polyphenyls and by-products thus obtained are given in Table 1.





The quinque-, septi-, and octiphenyl, thus prepared, showed IR spectral data consistent with their structure and gave acceptable results from elemental analysis and molecular weight determination. An alternative synthesis of eight quinquephenyls has been reported earlier by other workers (**1**,[2] **2**,[2] **3**,[3] **4**,[3b,4] **5**,[3b] **9**,[3b,5] **10**,[2,6] **12**[6]). Although the melting point of **2**[7] does

not coincide with that of previous authors, those of the seven remaining quinquephenyls fall within 1—2 °C of those of the other authors.

The yields of all the pure quinquephenyls except **3** (8.1%) were 13—27%, and in all of the coupling experiments an appreciable amount of quaterphenyls formed by the homo-coupling of the corresponding iodobiphenyl were isolated as by-products. Further, in the coupling reactions using **16** or **17** as one of the iodo compounds (**13**+**16**, **14**+**16**, **15**+**16**, and **14**+**17**) a significant amount of sexiphenyls were obtained. An attempted coupling of **13**+**20** gave **6** (9.8%), **7** (7.4%), and **8** (2.4%), in which two to four *p*-phenylene rings are present respectively, together with **5** (13.9%). A similar coupling of **14**+**20**, however, failed to give the analogous sexi-, septi, and octiphenyls except for quinquephenyl, **9**. In the case of **13**+**18**, no corresponding quinquephenyl was isolated, but biphenyl (**21**, 11.1%), *o*-quaterphenyl (**22**, 30.2%), and triphenylene (**23**, 23.9%) were obtained. The formation of **23** may be comparable to that of phenyltriphenylene in the Ullmann cross-coupling reaction of 2,2'-diiodobiphenyl with **14** or **15**;[1] it shows favorable cyclization by the apparent elimination of hydrogen iodide to form a triphenylene ring.

The IR spectra of the twelve polyphenyls (**1**—**12**) were measured by the KBr-disk method. Let us now discuss the most characteristic bands due to C–H out-of-plane deformation vibrations in the 675—920 cm^{-1} region.

In the spectra of **1**, **4**, **5**, **9**, and **10**, which have one or two isolated *p*-phenylene rings, the strong or medium C–H out-of-plane bending vibration bands of two adjacent hydrogen atoms of *p*-phenylene rings were observed in the range 835—850 cm^{-1}. In the cases of **11**, **12**, and **6**—**8**, in which two to four consecutive *p*-phenylene rings are present, the analogous intense bands were observed in the region 817—832 cm^{-1} (Table 2). These spectral data show that the position of strong or medium C–H bands observed in the 817—850 cm^{-1} range is shifted toward a lower wave number in accordance with the progression of *p*-phenylene rings. The shift of C–H band was considered to be quite analogous to that reported previously in the spectra of *p*-polyphenyls by Sandroni[9] and others.[10] The results also show that the position of the C–H band is nearly independent of whether the polyphenyls have *o*- or *m*-phenylene ring(s) or not.

On the basis of these results, the positions of strong or medium bands in the 815—850 cm^{-1} region of the polyphenyls, regardless of the presence of *o*- or *m*-phenylene unit(s) in them, may be considered to be an indication of the approximate number of consecutive *p*-phenylene units.

The UV spectra of the twelve polyphenyls were measured in a cyclohexane solution. The absorption curves are shown in Figs. 1—4. The longest wavelength absorption maxima above 220 nm of the polyphenyls, except the three new compounds (**7**, **8**, and **11**), coincide within 1—3 nm with those of other workers.[2,3b,5,6,8,11]

All of the polyphenyls displayed two groups of intense bands: one in the fairly narrow region of 192—207 nm with intensities approximately proportional to the number of ring units (ε 59300—129000) and another in the broad region of 230—315 nm with a high intensity. The former, whose band position was found to be independent of the structure, is considered to be the E-band, and the latter, whose band position was substantially affected by the nature and number of phenylene rings, is regarded as the K-band, as has been discussed in regard to the spectra of sexiphenyls.[1,12]

The spectrum of **3** displayed an intense K-band at substantially the same wavelength as the biphenyl

band, but with an intensity about four times greater (Table 4). Also, the K-band (234 nm, 57700; 250 nm sh, 27000) of **2**, in which two *o*-terphenyl units hold a common *m*-phenylene ring, appeared at the similar wavelength with an intensity about two times that of *o*-terphenyl (**24**) (233 nm, 29100; 251 nm sh, 13300) (Fig. 1). In the cases of **4** and **1**, in each of which two isolated *p*-phenylene rings are present, the spectrum of the former revealed a strong K-band (280 nm, 66500) at a similar wavelength with an intensity about two times that of *p*-terphenyl (**25**) (277 nm, 31600), while the spectrum of the latter

displayed a discernible shoulder near 280 nm, together with a intense K-band at about 260 nm (264 nm, 49800; 284 nm sh, 30600). The differences of the spectra might reflect the difficult extension of the two conjugated systems of *p*-terphenyl separated by *m*-phenylene ring in the former, and the reduced π-π interaction across the pivot bonds between *o*-phenylene ring and its nearest neighbors in the latter (Fig. 2). In the cases of **10** and **9**, which each have one *p*-terphenyl unit, the spectra (250 nm, 46200; 275 nm sh, 29300) (258 nm, 50800; 280 nm sh, 38200) displayed only a discernible shoulder near 280 nm together with a prominent K-band at 250 nm or at 258 nm respectively (Fig. 3).

Then, the spectra of the series of four polyphenyls **5**—**8** (series C), in which both terminals of one or two to four consecutive *p*-phenylene units are linked by *o*-phenylene rings, showed a remarkable bathochromic shift and an increase in intensity of the characteristic K-bands with an increase in the number of consecutive *p*-phenylene rings (Fig. 4). An analogous shift and increase in intensity of the K-band were also observed in the spectra of series B, A, and D, in which one or both terminals of one or more *p*-phenylene units are linked by *m*- or *o*-phenylene ring(s), as shown in Table 3. Such a characteristic shift and increase in intensity of K-band are compatible with the observation in the spectra of four *p*-polyphenyls (series E) by Gillam and Hey.[12a]

The foregoing results in the spectra of the polyphenyls show that the K-band above *ca.* 260 nm suggest the presence of *p*-phenylene unit(s), and that the positions

a) For β, −3.70 eV was used as the mean value calculated from the absorption bands of the biphenyl and the first four *p*-polyphenyls. b) ϕ, p, m, and o refer to phenyl, *p*-, *m*-, and *o*-phenylene rings. c) And d) refer to Refs. 12a and 13.

of the bands may be an indication of the approximate number of continuous *p*-phenylene units.

A comparison between the calculated and observed longest wavelength bands of the polyphenyls and closely related compounds is given in Table 4. Here the HMO calculations were performed by assuming tentatively the dihedral angle of the pivot bond as follows: 50° for phenyl–*o*- and *o*-–*o*-phenylene linkages, 35° for *o*-–*p*- and *m*-–*p*-phenylene linkages, and 20° for the other linkages. The table shows rather good agreement between calculated and observed wavelengths except in the cases of **21** and **24**. The results may also be confirmed by the approximate linear relation of the wave numbers of the longest wavelength absorption bands to the calculated longest wavelength transition energies, as shown in Fig. 5.

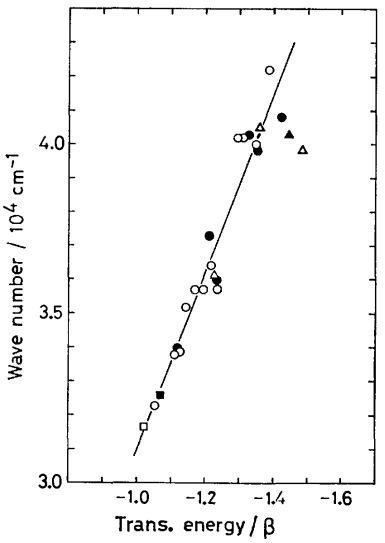

Fig. 5. Plots of wave numbers of longest wavelength absorption bands *vs.* calculated longest wavelength transition energies of the polyphenyls and related compounds.
▲: Biphenyl, △: terphenyls, ●: quaterphenyls, ○: quinquephenyls, ■: septiphenyl, □: octiphenyl.

The ^{1}H-NMR spectra of the polyphenyls and closely related compounds were measured at 80 MHz in a $CDCl_3$ solution. The chemical shifts from tetramethylsilane are summarized in Table 5.

The spectra of **1**, **5**—**8**, **10**, and **11** show one singlet peak near δ 7.44; this is assigned to the resonances of protons on one or two *o*-phenylene rings by comparison with the *o*-phenylene proton signal of **24** (δ 7.41, 4H, s, *o*-C_6H_4).

The most down field multiplet peaks (δ 7.75—7.93) found commonly in the spectra of **3**, **4**, **9**, **10**, **12**, and *m*-quaterphenyl (**26**) may be assigned to the resonances of one isolated *m*-phenylene proton by comparing with the signals of *m*-terphenyl and 1,3-di(phenyl-d_5)benzene[13] (δ 7.78—7.83, 1H, m, *m*-C_6H).

Among the spectra of the eleven polyphenyls containing *p*-linkage(s), those of **4**, **9**, **12**, and *p*-quater-

a) δ(ppm) from internal standard TMS.

phenyl (**27**) display one or two singlet peaks near δ 7.73. These are assigned to the resonances of *p*-phenylene protons by comparison with the *p*-phenylene proton signal of **25** (δ 7.68, 4H, s, *p*-C_6H_4). On the other hand, those of **1**, **6**, and **10** reveal an apparent AA'BB'-q pattern near δ 7.22 and 7.48, which may be assigned to the resonances of the *p*-phenylene protons from analogy with the spectra of *p*-phenylene protons of 2,4'-diphenylbiphenyl and 2,4'-di(phenyl-d_5)biphenyl[13] (δ 7.21 and 7.46, 4H, AA'BB'-q, J=8.6 Hz, 2'-, 6'-H and 3'-, 5'-H). Furthermore, those of **7**, **8**, and **11** show one singlet peak near δ 7.66 in addition to an apparent AA'BB'-q pattern near δ 7.22 and 7.50, and both peak and pattern are assigned to the resonances of the protons on the different types of *p*-phenylene rings. In the case of **5**, however, the resonances of the *p*-phenylene protons are observed as a singlet peak at a rather higher field (δ 6.97) as compared with those of **25**. The marked high field shift possibly reflects the ring current effect of both terminal phenyl groups. The foregoing results suggest that the two types of *p*-phenylene proton signal, a singlet peak and an AA'BB'-q pattern, are related closely with the kinds of the two groups adjacent to the *p*-phenylene ring. The correlation may be generalized as follows: 1) In the cases of polyphenyls, in which the *p*-phenylene ring is linked by two identical groups (phenyl or phenylenes) or by two different groups (phenyl or phenylenes except *o*-phenylene), the resonances of *p*-phenylene protons are generally observed as a singlet peak. 2) The resonances of *p*-phenylene protons of polyphenyls, in which the *p*-phenylene ring is linked by two different groups (phenyl or phenylenes), of which one is an *o*-phenylene ring, are generally observed as an AA'BB'-q pattern.

The spectra of **6**—**8**, **10**, and **11** reveal one singlet peak near δ 7.21. This is assigned to the resonances of protons of phenyl group(s) adjacent to *o*-phenylene ring(s), by comparison with the phenyl proton signal of **24** (δ 7.17, 10H, s, C_6H_5). However, the phenyl proton signals of **10** and **11**, each of which has a phenyl group linked by a *m*- or *p*-phenylene group, respectively, and those of **1**, **3**, **4**, **9**, **12**, and **25**—**27** are observed as multiplet peaks in the region δ 7.32—7.75. Among them, the multiplet peaks in the δ 7.32—7.75 region of **3**, **4**, **9**, **10**, **12**, and **26**, all of which have *m*-phenylene ring(s), are assigned to the resonances not only of phenyl protons but also of three adjacent *m*-phenylene protons, from analogy with the spectra of *m*-terphenyl (δ 7.78—7.83, 1H, m, *m*-C_6H; δ 7.27—7.72, 13H, m, *m*-C_6H_3 and C_6H_5) and 1,3-di(phenyl-d_5)benzene[13] (δ 7.78—7.83, 1H, m, *m*-C_6H; δ 7.51—7.61, 3H, m, *m*-C_6H_3).

The spectrum of **22** shows multiplet peaks of 10H at a rather higher field (δ 6.51—7.08). These are assigned to the resonances of protons on two terminal phenyl rings. That of **2** displays multiplet peaks (δ 6.78—7.48, 22H, m) which are quite difficult to assign.

Experimental

Low melting points were determined with a Mettler FP-51 apparatus; for those above 300 °C, a Shimadzu DSC-30M differential scanning calorimeter was employed. The UV spectra were measured on a Shimadzu QV-50 and a Hitachi EPS-2 spectrophotometer, the IR spectra on a Leitz III-G spectrophotometer, and ^{1}H-NMR spectra on a Varian CFT-20 spectrometer at 80 MHz, using TMS as an internal standard. The molecular weights were determined with a Mechrolab 301A vapor-pressure osmometer and a Hitachi RMU-6E mass spectrometer.

2- (**13**), 3- (**14**), and 4-Iodobiphenyl (**15**) were prepared as reported previously.[1]

o- (**18**), *m*- (**19**), and *p*-Diiodobenzene (**20**) were commercially available and purified before use.

4-Iodo-o-terphenyl (16). Commercially available *o*-terphenyl was subjected to nitration[14] to give 4-nitro-*o*-terphenyl (mp 117.3 °C), which was reduced with activated iron in hot benzene[15] to prepare 4-amino-*o*-terphenyl (mp 117.4 °C). Then the amine was converted to **16** in the usual manner. Colorless plates; mp 117.6 °C (lit,[16] mp 116—116.5 °C). (Found: C, 60.51; H, 3.81%).

4-Iodo-p-terphenyl (17). 4-Iodo-*p*-terphenyl was prepared by the direct iodination[17] of *p*-terphenyl. Colorless needles; mp 246.5 °C (lit,[18] mp 246—247 °C). (Found: C, 60.67; H, 3.66%).

Preparation of 4,4"-Diphenyl-o-terphenyl (1). A mixture of **15** (8.40 g, 30.0 mmol) and **18** (4.95 g, 15.0 mmol) in a reaction tube (ϕ2.5×20 cm) was heated in an oil bath at 230—240 °C, and then copper powder (19.1 g, 300 mg-atom) was added under stirring in portions over a one hour period, after which the mixture was heated at 245 °C for an additional hour. After cooling, the reaction product was extracted with hot benzene followed by hot xylene, then the solvents were distilled off. The benzene extract (5.34 g) was treated with 60 ml of a cyclohexane–benzene (5:1 v/v) mixture (C–B(5:1)) to separate the product into soluble and insoluble parts. Recrystallization of the latter together with the xylene extract (1.09 g) from benzene provided *p*-quaterphenyl (**27**) (colorless plates; mp 319 °C (lit,[19] mp 317.7—318.7 °C); yield, 1471 mg). The former was dissolved in the C–B (5:1) and then subjected to chromatography on alumina with the same solvent as the eluent, to provide biphenyl (**21**) (colorless leaves from ethanol; mp 69.4 °C; yield, 1405 mg) and **1**. The properties of the latter are as follows.

1: Colorless needles from ethanol; mp 184.5 °C (lit,[2] mp 182—184 °C); yield, 939 mg (16.4%). IR: 675 m; 700 s (γ_{C-C}); 715 w, 727 m, 737 m, 757 s (γ_{C-H}, M, *o*); 773 s (γ_{C-H}, *o*); 837 s, 842 cm^{-1} s (γ_{C-H}, *p*).[20] UV: λ_{max} (ε) 204 (85300), 264 (49800), 284 nm (sh) (30600). Found: C, 94.34; H, 5.76%; mol wt, 382. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

Preparation of 2,2"-Diphenyl-m-terphenyl (2). A mixture of **13** (8.40 g) and **19** (4.95 g) was treated with copper powder (19.1 g) at 260—270 °C for 1 h, and the mixture was heated at 275 °C for a further 1 h. The hot benzene extract of the product (6.10 g) was chromatographed on alumina with C–B (5:1) to give *o*-quaterphenyl (**22**) (colorless cubes from ethanol; mp 118.0 °C (lit,[21] mp 118 °C); 2509 mg) and **2**.

2: Colorless prisms from ethanol; mp 164.2 °C (lit,[8] mp 155.5—156.6 °C); 1362 mg (23.8%). IR: 695 s, 704 s, 711 s (γ_{C-C}); 728 w; 745 s, 749 s, 755 sh s, 764 s (γ_{C-H}, M, *o*); 779 m, 783 m (γ_{C-H}, *o*); 803 m (γ_{C-H}, *m*); 846 w, 879 w; 908 cm^{-1} m (γ_{C-H}, *m*). UV: λ_{max} (ε) 192 (73800), 204 (sh) (63400), 234 (57700), 250 nm (sh) (27000). Found: C, 94.35; H, 5.95%; mol wt, 382. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

Preparation of m-*Quinquephenyl (3).* A mixture of **14** and **19** was heated with copper powder as has been described in the preparation of **1**. The hot benzene extract of the product (5.80 g) was subjected to distillation *in vacuo*, then the distillate was chromatographed on alumina with C–B (5:2) to afford *m*-quaterphenyl (**26**) (colorless plates from ethanol; mp 87.1 °C (lit,[22] mp 85.5—86 °C); 992 mg) and **3**.

3: Colorless needles from ethanol; mp 114.0 °C (lit,[3a] mp 114—115 °C; lit,[3b] mp 115.3—115.6 °C); 462 mg (8.1%). IR: 699 s, 707 sh m (γ_{C-C}); 729 w; 750 s (γ_{C-H}, M); 779 s, 791 w, 807 w, 810 sh w (γ_{C-H}, *m*); 884 sh m, 888 m, 899 vw, 908 cm^{-1} vw (γ_{C-H}, *m*). UV: λ_{max} (ε) 196 (59300), 205 (60400), 249 nm (83200). Found: C, 93.93; H, 6.07%; mol wt, 382. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

*Preparation of 4,4″-Diphenyl-*m-*terphenyl (4).* A mixture of **15** and **19** was treated with copper powder under conditions similar to those used in the preparation of **2**. The product was extracted with hot benzene followed by hot toluene. The benzene extract (4.41 g) was treated with 50 ml of the C–B (5:2) to separate soluble [B_1] (2.50 g) and insoluble [B_2] (1.91 g) parts. The toluene extract (1.64 g) was treated as described above to separate soluble [T_1] (0.33 g) and insoluble [T_2] (1.58 g) parts. The soluble [B_1] was chromatographed on alumina with the C–B (5:2) to give **21** (378 mg). The [B_2] and [T_1] parts were combined and chromatographed with C–B (1:1) to give **4**. Crystallization of the insoluble [T_2] from benzene afforded **27** (1523 mg).

4: Colorless prisms from benzene; mp 269.7 °C (lit,[4] mp 264—266 °C; lit,[3b] mp 273.4—273.8 °C); 764 mg (13.3 %). IR: 690 s, 698 sh s (γ_{C-C}); 725 m, 732 w; 759 s (γ_{C-H}, M); 796 s (γ_{C-H}, *m*); 826 w; 845 s, 849 s (γ_{C-H}, *p*); 893 w, 910 cm^{-1} w (γ_{C-H}, *m*). UV: λ_{max} (ε) 205 (82100), 280 nm (66500). Found: C, 94.17; H, 5.76%; mol wt, 386. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

*Preparation of 2,2″-Diphenyl-*p-*terphenyl (5). Procedure A*: A mixture of **13** (8.40 g) and **20** (5.00 g) was treated with copper powder (19.1 g) at 250—260 °C for 1 h, and then at 265 °C for another hour. The hot benzene extract (6.19 g) was digested with 60 ml of the C–B (5:2) to remove insoluble material. The soluble part (6.00 g), after removal of the solvent, was subjected to chromatography on alumina with cyclohexane to afford **22** (2526 mg). Subsequent progressive elutions with C–B(5:1), then with C–B(5:2) and C–B(5:3), and finally with C–B(1:1), provided **5**, 2,2‴-diphenyl-*p*-quaterphenyl (**6**) and 2,2⁗-diphenyl-*p*-quinquephenyl (**7**), and 2,2⁗′-diphenyl-*p*-sexiphenyl (**8**) respectively.

5: Colorless needles from ethanol; mp 185.8 °C (lit,[3b] mp 185.6—185.8 °C); 798 mg (13.9%). IR: 678 w; 700 s (γ_{C-C}); 744 s, 755 s, 763 m (γ_{C-H}, M, *o*); 778 m, 781 m (γ_{C-H}, *o*); 841 s, 848 m (γ_{C-H}, *p*); 877 cm^{-1} w. UV: λ_{max} (ε) 198 (85000), 242 (43200), 280 nm (18500). Found: C, 94.36; H, 6.06%; mol wt, 382 (M^+). Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

6: Colorless leaves from benzene–ethanol; mp 236.1 °C; 670 mg (9.8%); identified by mixed-melting-point method and identical IR and UV spectra to those from the authentic sample.[1]

7: Colorless leaves from ethanol–benzene; mp 256.6 °C; 589 mg (7.4%). IR: 683 w; 706 s (γ_{C-C}); 720 m, 734 w; 747 s, 763 s (γ_{C-H}, M, *o*); 785 m (γ_{C-H}, *o*); 823 s, 830 cm^{-1} sh m (γ_{C-H}, *p*). UV: λ_{max} (ε) 206 (115800), 230 (sh) (45800), 307 nm (51000). Found: C, 94.06; H, 5.83%; mol wt, 534 (M^+). Calcd for $C_{42}H_{30}$: C, 94.34; H, 5.66%; mol wt, 534.

8: Colorless leaves from benzene; mp 309 °C; 218 mg (2.4%). IR: 684 w; 706 s (γ_{C-C}); 729 w; 743 s, 747 s, 764 s (γ_{C-H}, M, *o*); 786 m (γ_{C-H}, *o*); 817 s (γ_{C-H}, *p*); 854 cm^{-1} w. UV: λ_{max} (ε) 203 (129600), 234 (sh) (41100), 315 nm (62900). Found: C, 94.09; H, 5.55%; mol wt, 610 (M^+). Calcd for $C_{48}H_{34}$: C, 94.39; H, 5.61%; mol wt, 610.

Procedure B: A mixture of **13** (2.80 g, 10.0 mmol) and **16** (3.56 g, 10.0 mmol) was treated with copper powder (6.35 g, 100 mg·atom) at 260—265 °C for 1.5 h, and then at 270 °C for an additional hour. The hot benzene extract (3.82 g) was chromatographed as above with cyclohexane to yield **21** (40 mg) and *o*-terphenyl (**24**) (colorless needles from ethanol; mp 56.7 °C; 184 mg). Subsequent progressive elutions with C–B(9:1), then C–B(9:1) and C–B(4:1), and finally with C–B(4:1) and C–B(1:1) provided **22** (600 mg), **5** (765 mg, 20.0%), and **6** (570 mg, 12.5%) respectively.

*Preparation of 3,3″-Diphenyl-*p-*terphenyl (9).* A mixture of **14** and **20** was heated with copper powder, as has been described for the preparation of **1**. The hot benzene extract (5.50 g) was separated into soluble and insoluble parts in 150 ml of C–B(1:1). Chromatography of the former (2.90 g) with the same solvent and of the latter (2.60 g) with benzene on alumina afforded **21** (250 mg) and **26** (1600 mg), and **26** (40 mg) and **9** respectively.

9: Colorless plates from benzene; mp 235.7 °C (lit,[5] mp 235—236 °C; lit,[3b] mp 236.1—236.3 °C); 750 mg (13.1%). IR: 686 w; 699 s (γ_{C-C}); 754 s, 760 s (γ_{C-H}, M); 790 s, 798 m (γ_{C-H}, *m*); 848 m, 855 w (γ_{C-H}, *p*); 890 cm^{-1} m (γ_{C-H}, *m*). UV: λ_{max} (ε) 207 (66800), 258 (50800), 280 nm (sh) (38200). Found: C, 93.93; H, 5.94%; mol wt, 381. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

Reaction of 13 and 18. A mixture of **13** and **18** was treated under conditions similar to those used in the preparation of **2**. The hot benzene extract (6.40 g) was subjected to chromatography on alumina with cyclohexane to provide **21** (512 mg). Subsequent elution with C–B(5:1) gave **22** (1389 mg) and triphenylene (**23**).

23: Colorless needles from cyclohexane; mp 198.6 °C (lit,[23] mp 197—198 °C); 829 mg (23.9%). Found: C, 94.78; H, 5.25%; mol wt, 221. Calcd for $C_{18}H_{12}$: C, 94.70; H, 5.30%; mol wt, 228.

*Preparation of 2,3″-Diphenyl-*p-*terphenyl (10).* A mixture of **14** (2.80 g) and **16** (3.56 g) was heated as has been described in the preparation of **5** (Procedure B). The hot benzene extract (3.77 g) was chromatographed on alumina with cyclohexane to give **21** (30 mg). Subsequent elutions with C–B(9:1), then C–B(9:1) and C–B(4:1), and finally with C–B(4:1) and C–B(1:1) afforded **24** (280 mg) and **26** (270 mg), **10**, and **6** (950 mg, 20.7%) respectively.

10: Colorless plates from ethanol; mp 120.0 °C (lit,[6] mp 120.1—120.5 °C; lit,[2] mp 119.5—120.0 °C); 705 mg (18.5%). IR: 684 w, 689 w; 701 s, 704 sh s (γ_{C-C}); 736 m; 746 s, 751 sh s, 765 w (γ_{C-H}, M, *o*); 779 m (γ_{C-H}, *o*); 797 m, 812 vw (γ_{C-H}, *m*); 835 m, 841 s (γ_{C-H}, *p*); 874 w; 895 cm^{-1} m (γ_{C-H}, *m*). UV: λ_{max} (ε) 197 (81000), 250 (46200), 275 nm (sh) (29300). Found: C, 93.99; H, 5.92%; mol wt, 382 (M^+). Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

*Preparation of 2-Phenyl-*p-*quaterphenyl (11).* A mixture of **15** and **16** was treated under conditions similar to those used in the preparation of **5** (Procedure B). The product was then extracted with hot benzene, followed by hot toluene. The benzene extract (3.76 g) was subjected to chromatography on alumina with C–B(9:1) to afford **21** (58 mg). Subsequent elutions with C–B(5:1), then C–B (5:1) and C–B(5:2), and finally with benzene provided

24 (273 mg), **11** and **6** (493 mg, 10.8%), and **27** (199 mg) respectively. Crystallization of the toluene extract (0.17 g) from benzene provided more **27** (110 mg).

11: Colorless needles from benzene; mp 186.9 °C; 788 mg (24.7%). IR: 692 s, 702 s (γ_{C-C}); 720 m, 728 m; 748 s, 757 s, 763 sh s, 769 m (γ_{C-H}, M, *o*); 780 m (γ_{C-H}, *o*); 826 s (γ_{C-H}, *p*); 855 w, 876 cm^{-1} w. UV: λ_{max} (ε) 205 (79900), 237 (sh) (19400), 264 (sh) (24900), 295 nm (42100). Found: C, 93.95; H, 5.98%; mol wt, 382 (M^+). Calcd for $C_{30}H_{22}$: C. 94.20; H, 5.80%; mol wt, 382.

*Preparation of 3-Phenyl-*p*-quaterphenyl (12).* A mixture of **14** and **17** was heated as has been described in the preparation of **5** (Procedure B). The hot benzene extract (5.81 g) of the product was chromatographed on alumina with cyclohexane to afford **21** (100 mg). Subsequent elutions with C–B(9:1), then C–B(9:1) and C–B(4:1), and finally with benzene provided **26** (453 mg), *p*-terphenyl (**25**) (colorless plates from ethanol; mp 212.4 °C), and **12** respectively. The benzene-insoluble part of the product, upon repeated extraction with concentrated ammonia–water, left a solid which was sublimed at 350—400 °C/0.13 Pa to afford *p*-sexiphenyl (**28**).

12: Colorless leaves from benzene; mp 258.9 °C (lit,[6] mp 259.7—259.9 °C); 1030 mg (27.0%). IR: 698 s (γ_{C-C}); 721 w, 736 w; 755 s, 759 sh s, 768 s (γ_{C-H}, M); 798 s (γ_{C-H}, *m*); 829 s (γ_{C-H}, *p*); 855 w; 890 cm^{-1} w (γ_{C-H}, *m*). UV: λ_{max} (ε)207 (75300), 253 (sh) (23200), 296 nm (47500). Found: C, 94.38; H, 5.70%; mol wt, 382 (M^+). Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; mol wt, 382.

28: Colorless leaves; mp 441 °C (lit,[10b] mp 439—445 °C; lit,[24] mp 465 °C); 525 mg (11.5%). Found: C, 94.31; H, 5.53%; mol wt, 458 (M^+). Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

The authors would like to express their gratitude to Dr. K. Watanabe for the MO calculations, which were carried out on the FACOM 230-OS2/VS at the Inst. Chem. Res. Kyoto University. The authors are also indebted to Nippon Shinyaku Co., Ltd., for kindly performing the measurements of IR spectra. Thanks are due to Mr. Y. Fujiwara of this college for his help in ^{1}H-NMR spectral measurements.

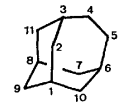
Synthesis of 2,5-Dehydrohomoadamantane (Tetracyclo[5.3.1.$0^{2,5}$.$0^{3,9}$]undecane) from 2,4-Dehydrohomoadamantane (Tetracyclo[5.3.1.$0^{3,5}$.$0^{4,9}$]undecane)[1,2]

Takeo KATSUSHIMA, Masato YOSHIKAWA, Ryohei YAMAGUCHI, and Mituyosi KAWANISI*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received January 28, 1980)

A reaction of 2,4-dehydrohomoadamantane with NBS in AcOH followed by $LiAlH_4$ reduction and subsequent CrO_3–pyridine complex oxidation gave *endo*-2-bromohomoadamantan-4-one (**9**) in good yield. A treatment of **9** with *t*-BuOK in *t*-BuOH followed by Wolff-Kishner reduction furnished 2,5-dehydrohomoadamantane.

Out of five possible "non-bridgehead" monodehydrohomoadamantanes, the strained cage compounds which incorporate a small ring in homoadamantane framework (**1**—**5**),[3-6] 2,5-dehydrohomoadamantane (**1**) is the only compound which contains a cyclobutane ring in its structure. Recently, Sasaki *et al.* reported a synthesis of **1** utilizing an intramolecular ketene cycloaddition.[3] During our search for synthesis and reactions of strained cage systems,[4b,5b,7] we have had an opportunity to investigate **1** and now wish to describe an alternative synthetic route of **1** starting from 2,4-dehydrohomoadamantane (**2**).



Homoadamantane
(Tricyclo[4.3.1.$1^{3,8}$]undecane)

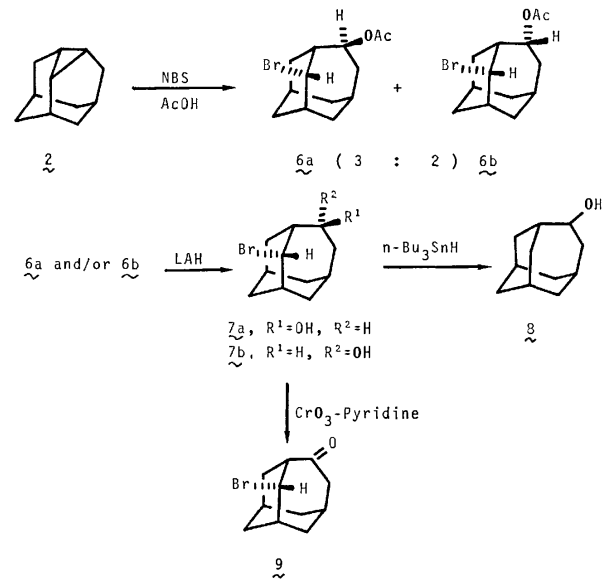
Fig. 1. "Non-bridgehead" Monodehydrohomoadamantanes.

Results and Discussion

When **2** was allowed to react with *N*-bromosuccinimide (NBS) in acetic acid, two isomeric bromo acetates, *endo*-2-bromo-*exo*-4-acetoxy- and *endo*-2-bromo-*endo*-4-acetoxyhomoadamantanes (**6a** and **6b**) were obtained in 70% combined yield in a ratio of 3:2 (GLC analysis). The structures of **6a** and **6b** were determined by the following experimental results. Reductions of **6a** and **6b** with lithium aluminum hydride gave bromo alcohols (**7a** and **8b**) in 68 and 81% yields, respectively. When a mixture of **7a** and **7b** was reduced with tributyltin hydride, only homoadamantan-4-ol (**8**)[8] was obtained in 78% yield. No other alcohol could be detected. These chemical transformations clearly indicate that the bromo acetates (**6a** and **6b**) and bromo alcohols (**7a** and **7b**) retain a homoadamantane skeleton and that the acetoxyl and hydroxyl groups are located at C_4-position in the homoadamantane system.

Each bromo alcohol (**7a** or **7b**) was further subjected to the oxidation with chromium trioxide–pyridine complex to afford the same product, *endo*-2-bromohomoadamantan-4-one (**9**) in 91 or 95% yield;



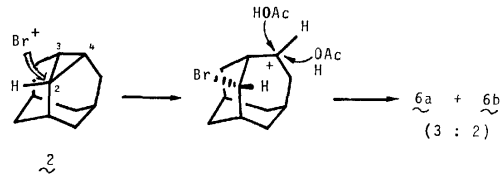
Scheme 1.

these results show that **6a** and **6b**, and **7a** and **7b** also, are isomeric in relation to C_4-position and that the bromine substituents have the same configurations. The ^{1}H-NMR (PMR) spectrum of **9** showed a singlet peak at 4.55 ppm due to the C_2 carbinyl proton. Previous studies[7a,9] showed that *exo*-C_2-proton does not couple with the adjacent protons, whereas *endo*-C_2-proton does couple, giving a triplet with a coupling constant of *ca.* 4 Hz. The configuration of the bromine substituent of **9** was thus determined to be *endo*. The configurations of substituents at C_4-positions of **6a**, **6b**, **7a**, and **7b** were deduced by comparison of their ^{13}C-NMR (CMR) and PMR spectra with each other. In a cage system such as adamantane, a γ_{syn}-carbon to a substituent has 4—7 ppm higher chemical shift than a γ_{anti}-carbon does because of a stronger interaction between the former and the substituent.[10] On the other hand, a γ_{syn}-hydrogen is reported to appear at 0.4—0.6 ppm lower field than its counterpart, a γ_{anti}-hydrogen.[11] Our results are summarized in Table 1. The chemical shifts of the carbons at the 2-positions of **6a** and **7a** are higher than those of **6b** and **7b** and the chemical shifts of the C_2-hydrogens of the former are lower than those of the latter. These facts lead to our conclusion that **6a** and **7a** are *endo*-2-bromo-*exo*-4-acetoxyhomoadamantane and *endo*-2-bromo-*exo*-homoadamantan-4-ol and that **6b** and **7b** are *endo*-2-bromo-*endo*-4-acetoxyhomoadamantane and *endo*-2-bromo-*endo*-homoadamantan-4-ol.

Table 1. Chemical shifts[a] of C_2 and C_2–H

	6a	6b	7a	7b
C-Br	56.2	59.1	56.7	60.8
CH-Br	4.75	4.40	4.87	4.38

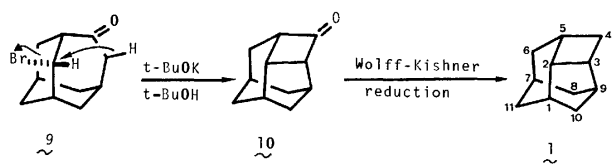
a) ppm relative to TMS.



Scheme 2.

On the basis of the structures of **6a** and **6b**, we constructed the following reaction scheme with respect to the cleavage of the cyclopropane by bromonium ion (Scheme 2). An initial attack of the strained C_2–C_4 bond by bromonium ion must occur exclusively at C_2-position with inversion of configuration giving a carbocation intermediate.[12] The subsequent nucleophilic attack by the solvent from both sides will give **6a** and **6b** almost non-selectively. The remarkable regioselectivity observed in the initial bromination stage may be attributed not only to steric but also to electronic reasons, because ^{13}C–H coupling constants of C_2 and C_4 (or C_3) ($J_{C_2\text{-}H}$=163 Hz and $J_{C_{4(3)}\text{-}H}$=158 Hz) indicate that C_2-carbon with more s-character in C_2–H bond should have more p-electron density than $C_{4(3)}$-carbon.[13]

A treatment of **9** with potassium *t*-butoxide in *t*-butyl alcohol at room temperature induced an efficient cyclization to give 2,5-dehydrohomoadamantan-4-one (**10**) in 86% yield. The ketone (**10**) showed a characteristic absorption band at 1775 cm^{-1} due to cyclobutanone in its IR spectrum; the PMR spectrum was identical with that reported.[14] The final Wolff-Kishner reduction was nicely conducted to afford 2,5-dehydrohomoadamantane (**1**) in 71% yield.



Scheme 3.

Experimental

All the temperatures were uncorrected. Melting points were measured in sealed capillaries. The IR spectra were recorded on a Shimadzu IR-27 spectrometer. The MS spectra were taken by using a Hitachi RMS-4 mass spectrometer. The PMR and CMR spectra were obtained on Varian EM-390 and CFT-20 spectrometers, tetramethylsilane being chosen as an internal standard. Micro analyses were performed in Kyoto University Elemental Analysis Center.

Reaction of Tetracyclo[5.3.1.$0^{3,5}$.$0^{4,9}$]undecane (2) with N-Bromosuccinimide (NBS). A solution of **2** (998 mg; 6.74 mmol) and NBS (1521 mg; 8.54 mmol) in AcOH (25 ml) was stirred at 60 °C under argon for 28 h. The reaction mixture was poured onto water and extracted with CH_2Cl_2. The organic solution was washed successively with brine, aqueous $NaHCO_3$, and brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue (2.16 g) was chromatographed on silica gel (100 g). Elution by hexane gave the unreacted starting material (41 mg). Subsequent elution by hexane and CH_2Cl_2 (4:1) gave **6a** (480 mg), a mixture of **6a** and **6b** (324 mg), and **6b** (250 mg). The combined yield of **6a** and **6b** (1054 mg) was 55% and the ratio of **6a** and **6b** was determined to be 3:2 by GLC analysis (PEG 20 M, 220 °C) of the crude products. Similarly, the reaction of **2** (207 mg; 1.40 mmol) and NBS (282 mg; 1.58 mmol) in AcOH (5 ml) at 45—50 °C for 6 d gave a mixture of **6a** and **6b** (282 mg, 70%). *endo*-2-Bromo-*exo*-4-acetoxytricyclo[4.3.1.$1^{3,8}$]-undecane (**6a**): bp 70 °C (bath temp)/133 Pa. MS *m/e* (rel intensity): 228, 226 (M^+—AcOH, 47, 48), 165 (17), 147 (100). IR (neat): 2825, 1740, 1445, 1365, 1240, 1015, 960, 715 cm^{-1}. PMR δ (CCl_4): 4.90 (1H, d.d.d, J=10.0, 5.4, 3.6 Hz), 4.65 (1H, s), 2.02 (3H, s), 2.75—1.20 (14H, br. complex m). CMR δ ($CDCl_3$); 169.9 (C), 76.0 (CH), 56.2 (CH), 46.9 (CH), 41.3 (CH_2), 37.7 (CH_2), 36.0 (CH, CH_2), 30.4 (CH_2), 30.2 (CH_2), 28.6 (CH), 26.7 (CH), 21.3 (CH_3). Found: C, 54.25; H, 6.58%. Calcd for $C_{13}H_{19}BrO_2$: C, 54.36; H, 6.67%. *endo*-2-Bromo-*endo*-4-acetoxytricyclo[4.3.1.$1^{3,8}$]undecane (**6b**): bp 70 °C (bath temp)/133 Pa. MS *m/e* (rel intensity): 228, 226 (M^+—AcOH, 49, 48), 165 (26), 147 (100). IR (neat): 2925, 1740, 1450, 1365, 1245, 1020, 965, 720, 710 cm^{-1}. PMR δ (CCl_4): 5.02 (1H, d.d.d, J=9.0, 6.0, 3.0 Hz), 4.40 (1H, s), 1.98 (3H, s), 2.70—1.20 (14H, br. complex m). CMR δ ($CDCl_3$): 169.9 (C), 74.8 (CH), 59.1 (CH), 46.4 (CH), 40.9 (CH_2), 40.0 (CH_2), 35.5 (CH), 34.7 (CH_2), 30.2 (CH_2), 28.7 (CH), 26.5 (CH), 25.6 (CH_2), 21.3 (CH_3). Found: C, 54.53; H, 6.76%. Calcd for $C_{13}H_{19}BrO_2$: C, 54.36; H, 6.67%.

endo-*2-Bromo*-exo-*tricyclo*[*4.3.1.*$1^{3,8}$]*undecan-4-ol* (**7a**). To a suspension of $LiAlH_4$ (60 mg) in dry Et_2O (5 ml) was added dropwise a solution of **6a** (105 mg; 0.37 mmol) in dry Et_2O (5 ml). The mixture was stirred under reflux for 10 min. Aqueous Na_2SO_4 was added to the cooled reaction mixture. The organic layer was collected and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and CH_2Cl_2 (3:2) gave **7a** (61 mg, 68%): mp 147—149 °C. MS *m/e* (rel intensity): 228, 226 (M^+-H_2O, 30, 31), 147 (100). IR (KBr): 3325, 2950, 1445, 1015, 715 cm^{-1}. PMR δ ($CDCl_3$): 4.87 (1H, s) ,4.00 (1H, d.d.d, J=10.0, 5.0, 3.0 Hz), 2.70—1.20 (15H, br. complex m). CMR δ ($CDCl_3$): 74.3 (CH), 56.7 (CH), 51.0 (CH), 43.9 (CH_2), 38.1 (CH_2), 36.2 (CH, CH_2), 30.8 (CH_2), 30.6 (CH_2), 28.7 (CH), 26.9 (CH). Found: C, 54.08; H, 7.25%. Calcd for $C_{11}H_{17}BrO$: C, 53.89; H, 6.99%.

endo-*2-Bromo*-endo-*tricyclo*[*4.3.1.*$1^{3,8}$]*undecan-4-ol* (**7b**). Reduction of **6b** (111 mg; 0.39 mmol) with $LiAlH_4$ (52 mg) in a similar manner to the above gave a crude product which was chromatographed on silica gel. Elution by hexane and CH_2Cl_2 (3:2) gave **7b** (77 mg, 81%): mp 134—136 °C. MS *m/e* (rel intensity): 246, 244 (M^+, 2, 2), 228, 226 (M^+-H_2O, 8, 8), 165 (66), 147 (100). IR (KBr): 3360, 2925, 1450, 1045, 1010, 715, 680 cm^{-1}. PMR δ ($CDCl_3$); 4.38 (1H, s), 4.08 (1H, d.d.d, J=9.0, 6.0, 3.0 Hz), 2.80—1.00 (15H, br. complex m). CMR δ ($CDCl_3$): 72.9 (CH), 60.8 (CH), 50.1 (CH), 43.5 (CH_2), 40.5 (CH_2), 35.6 (CH), 34.4 (CH_2), 30.4 (CH_2), 28.6 (CH), 26.5 (CH), 24.6 (CH_2). Found: C, 54.01; H, 7.10%. Calcd for $C_{11}H_{17}BrO$: C, 53.89; H, 6.99%.

Reduction of ***7a*** *and* ***7b*** *with* n-Bu_3SnH. A solution of a mixture of **7a** and **7b** (435 mg; 1.78 mmol) and n-Bu_3SnH (2.0 g, 6.9 mmol) in benzene (50 ml) was refluxed under nitrogen for 20 h. The solvent was evaporated and the residue was chromatographed on silica gel. Elution by hexane and CH_2Cl_2 (9:1) gave tricyclo[4.3.1.$1^{3,8}$]undecan-4-ol (**8**) (229 mg, 78%).

endo-*2-Bromotricyclo[4.3.1.*$1^{3,8}$*]undecan-4-one* (***9***). To a mixture of pyridine (1.6 ml) and CH_2Cl_2 (5 ml) was added CrO_3 (160 mg; 1.6 mmol) and then a solution of **7a** (83 mg; 0.34 mmol) in CH_2Cl_2 (5 ml). The reaction mixture was stirred at room temperature for 30 min and washed with aqueous 5% NaOH, aqueous 5% HCl, and brine, and dried (Na_2SO_4). After filtration, the solution was passed through a short silica-gel column and the solvent was evaporated to give **9** (76 mg, 91%): mp 124—126 °C. MS *m/e* (rel intensity): 244, 242 (M^+, 6, 6), 163 (100). IR (KBr): 2925, 1690, 1460, 1445, 1365, 1200, 1150, 1070, 950, 930, 800 cm^{-1}. PMR δ ($CDCl_3$): 4.55 (1H, s), 3.15 (1H, d, J=6 Hz), 2.90—1.20 (13H, br. complex m). CMR δ ($CDCl_3$): 212.5 (C), 58.8 (CH), 54.4 (CH), 49.9 (CH_2), 37.3 (CH_2), 36.8 (CH_2), 36.0 (CH), 29.3 (CH_2), 27.9 (CH_2), 26.7 (CH), 25.6 (CH). Found: C, 54.63; H, 6.19%. Calcd for $C_{11}H_{15}BrO$: C, 54.33; H, 6.22%.

The oxidation of **7b** (70 mg; 0.29 mmol) in a similar manner to the above gave **9** (67 mg, 95%) also.

Tetracyclo[5.3.1.$0^{2,5}$*.*$0^{3,9}$*]undecan-4-one* (***10***). A solution of **9** (242 mg; 1.00 mmol) and potassium *t*-butoxide (179 mg; 1.59 mmol) in *t*-butyl alcohol (15 ml) was stirred at room temperature for 1.5 h. The reaction mixture was poured onto water and extracted with hexane. The organic layer was washed with brine and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue (156 mg) was chromatographed on silica gel. Elution by hexane and CH_2Cl_2 (4:1) gave **10** (139 mg, 86%): mp 223—225 °C (lit,[3] mp 224—227 °C). MS *m/e* (rel intensity): 162(M^+, 3), 134 (97), 92 (100). IR (KBr): 2930, 1775, 1445, 1190, 1165, 1120, 1100, 1050 cm^{-1}. PMR δ (CCl_4): 3.53 (1H, q, J=6.8 Hz), 3.10 (1H, m), 2.76 (1H, q, J=7.5 Hz), 2.60—1.00 (11H, br. complex m). CMR δ ($CDCl_3$): 211.3 (C), 70.9 (CH), 54.5 (CH), 46.3 (CH_2), 35.2 (CH_2), 33.8 (CH, CH_2), 33.7 (CH), 31.9 (CH), 31.0 (CH_2), 28.1 (CH). Found: C, 81.15; H, 8.56%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

Tetracyclo[5.3.1.$0^{2,5}$*.*$0^{3,9}$*]undecane* (***1***). A mixture of **10** (206 mg: 1.21 mmol), KOH (675 mg), and 100% hydrazine hydrate (1 ml) in diethylene glycol (8 ml) was stirred at 110 °C for 30 min and then at 180 °C for 3 h under nitrogen. The sublimed product on the condenser was dissolved in pentane and washed with brine, and dried (Na_2SO_4). After filtration, the solvent was evaporated and the residue was resublimed at 110 °C/1729 Pa to give **1** (134 mg, 71%): mp 171—172 °C (lit,[3] 177—179 °C). MS *m/e* (rel intensity): 148 (M^+, 95), 106 (100). IR (KBr): 2925, 2860, 1445 cm^{-1}. PMR δ ($CDCl_3$): 2.90—1.00 (br. complex m). CMR δ ($CDCl_3$): 44.0 (CH, CH_2), 38.4 (CH), 37.9 (CH_2), 36.8 (CH), 35.6 (CH_2), 33.5 (CH), 33.2 (CH_2), 31.6 (CH), 29.6 (CH), 28.2 (CH_2). Found: C, 88.92; H, 11.02%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%.

Photo- and Thermally-induced Radical Rearrangements of Hypoiodites of 3α- and 3β-Methyl-5-cholesten-3-ols in the Presence of Mercury(II) Oxide and Iodine or Silver(II) Oxide and Iodine

Hiroshi SUGINOME*,** and Norio MAEDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

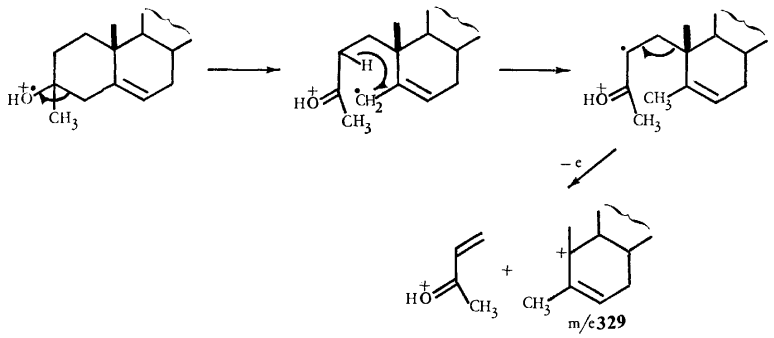
(Received February 4, 1980)

Hypoiodites of 3α- and 3β-methyl-5-cholesten-3-ols in benzene containing mercury(II) oxide and iodine gave 3α,5-epoxy-6β-iodo-3β-methyl-*A*-homo-4-oxa-5α-cholestane in 50—66% yield on irradiation or heating in the dark. Some minor products including the 6α-epimer were also found. The corresponding reaction with silver oxide and iodine reagent gave the same epoxide in 52% yield, together with a low yield of 3,4-seco-3-methyl-3-oxo-5-cholesten-4-al. Hydrogenolysis of the 6β-iodide with Pd–C as a catalyst gave 3α,5-epoxy-3β-methyl-*A*-homo-4-oxa-5α-cholestane (52% yield), together with the 6α-epimer arising from isomerization. The former, on treatment with boron trifluoride etherate and acetic anhydride in benzene, was transformed into 2-acetyl-3-methyl-5-acetoxymethyl-4-oxa-5β-cholestan-2-one. This was converted into 2β-acetyl-3α,5-epoxy-3β-methyl-4-oxa-*A*-homo-5α-cholestane by the treatment with aqueous methanolic potassium hydroxide.

In the previous paper, the photo- and thermally-induced radical rearrangements of cholesterol, epicholesterol, and 3,4,4-trimethylcholesterol hypoiodites in the presence of mercury(II) oxide and iodine were reported.[1] Cholesterol and epicholesterol hypoiodites in the presence of mercury(II) oxide and iodine were found to give 3α,5-epoxy-6β-iodo-*A*-homo-4-oxa-5α-cholestane and its 6α-isomer on irradiation and to give 3α,5-epoxy-6β-iodo-*A*-homo-4-oxa-5α-cholestane accompanied by *A*-homo-4-oxa-5-cholesten-3α-ol and 5-cholesten-3β-yl *A*-homo-4-oxa-5-cholesten-3α-yl ether on thermal reaction. The reactions of 3α,4,4-trimethyl-5-cholesten-3α-ol hypoiodite under comparable conditions gave 2α- and 2β-acetyl-4,4-dimethyl-3-oxa-5-cholestenes together with 3α,5-epoxy-*A*-homo-4-oxa-5α-steroids. Since the effects of alkyl substituents at their C-3 and C-4 positions appear to be appreciable, we investigated the photo- and thermally-induced radical rearrangements of hypoiodites of 3α- and 3β-methyl-5-cholesten-3-ols in the presence of mercury(II) oxide and iodine or silver(II) oxide and iodine. The results are reported in this paper.

Results

3α- And 3β-methyl-5-cholesten-3-ols (**1** and **2**) were prepared by previously described procedures.[2] The mass spectra of alcohols **1** and **2** were similar and exhibited a prominent peak at *m/e* 329 (69.3 and 100%). The suggested structure and genesis are shown in Scheme 1. Irradiation of 3β-alcohol **1** in benzene containing iodine and mercury(II) oxide (each 3 mol equiv.) with a 100-W high pressure mercury arc for 5 h under an argon atmosphere afforded a mixture of products (Scheme 2). In contrast to the case of cholesterol, a recrystallization of the product from methanol–diethyl ether readily gave an epoxide (**3**), mp 116.5—118.6 °C, in *ca.* 60% yield. The structure was ascertained to be 3α,5-epoxy-6β-iodo-3β-methyl-*A*-homo-4-oxa-5α-cholestane on the basis of the following spectral and chemical evidence. The mass spectrum of epoxide **3** showed a very weak molecular ion peak of *m/e* 541 and a prominent peak of *m/e* 415 (21.5%) assignable to M^+-I. Its infrared spectrum showed three 3H singlets at τ 8.60, 9.26, and 8.64 assignable to 3β-methyl, 18-H, and 19-H and an AB quartet centred at τ 6.58 and 5.77 (J=7.9 Hz) assignable to 4a-methylene protons. Besides these signals, the spectrum showed a 1-H triplet at τ 5.69 (J=3.2 Hz) assignable to a proton attached to a carbon bearing iodine (the 6α-H). Preparative TLC of the residue from the filtrate gave a further amount of epoxide **3** and a crystalline mixture. Although separation of the mixture into its components was unsuccessful, the NMR spectrum (see Experimental) indicated that it was a 1:1 mixture of 3α,5-epoxy-6α-



Scheme 1.

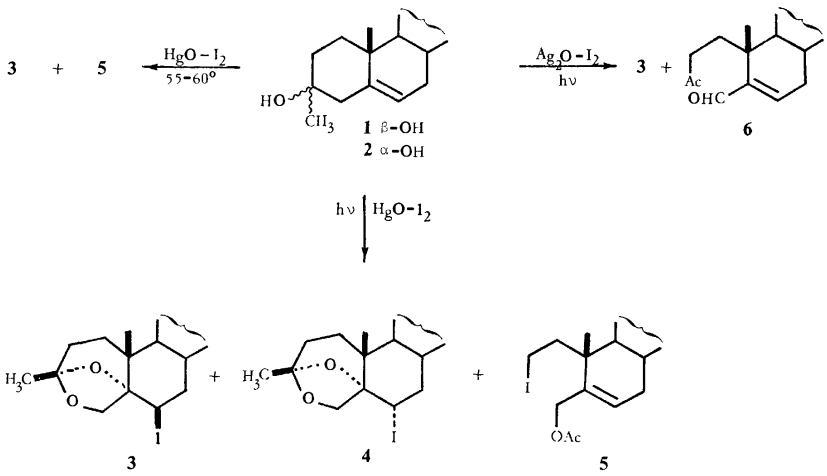


Scheme 2.

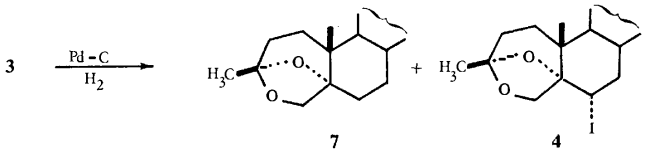
iodo-*A*-homo-4-oxa-5α-cholestane (**4**), obtained by a Pd-catalyzed isomerization of the 6β-isomer (*vide infra*), and 2-iodo-*A*-nor-2,3-seco-5-cholesten-3-ol acetate (**5**). The presence of the latter was indicated by a comparison of the signals with those of the ^{1}H NMR spectrum of 2-iodo-*A*-nor-2,3-seco-5-cholesten-3-ol formate.[1] The yields of both compounds were about 2%.

Irradiation of 3α-alcohol **2** in benzene containing iodine and mercury(II) oxide under the conditions comparable to 3β-isomer **1** gave virtually the same products (Scheme 2). The isolated yield of pure crystalline epoxide **3** was 50% and a very minor amount of seco iodide **5** was also obtained.

The photo-reaction of 3β-alcohol **1** in benzene containing iodine and silver oxide in place of mercury(II) oxide was also attempted. This reaction was found to be very slow and more silver oxide and iodine were added to the solution after 5 and 48 h in the course of the reaction; 95 h was required to complete the reaction. A recrystallization and preparative TLC of the products gave crystalline epoxide **3** (52% yield) and a new amorphous compound (**6**) (4% yield) (Scheme 2). The NMR and IR spectra indicated the new compound should be formulated as 3,4-seco-3-methyl-3-oxo-5-cholesten-4-al (**6**); the IR spectrum exhibited three bands at 1720, 1691, and 1631 cm^{-1} in the carbonyl region which can be assigned to an acetyl and an α,β-unsaturated formyl groups. The NMR spectrum showed three 3H singlets at τ 8.00, 9.40, and 8.95 (assignable to 3-methyl, 18-H, and 19-H, a 1H double doublet (J=1.8 and 6.0 Hz) at τ 3.26 assigned to 6-H, and a 1H singlet at τ 0.81 assigned to the formyl proton.

The thermal decomposition of 3α-methyl-5-cholesten-3β-ol hypoiodite in the presence of mercury(II) oxide and iodine at 55—60 °C was also studied, and a higher yield of epoxide **3** (66%) was obtained. Not even a trace of 6α-iodo isomer **4** was detected in the products (Scheme 2). The absence of 6α-isomer in the products from the thermal reaction is also found for the reaction of cholesterol and 3,4,4-trimethylcholesterol.[1]

*Some Reactions of 3α,5-Epoxy-6β-iodo-3β-methyl-*A*-homo-4-oxa-5α-cholestane (Schemes 3 and 4).* Iodo compound **3** was inert to base even under severe conditions.

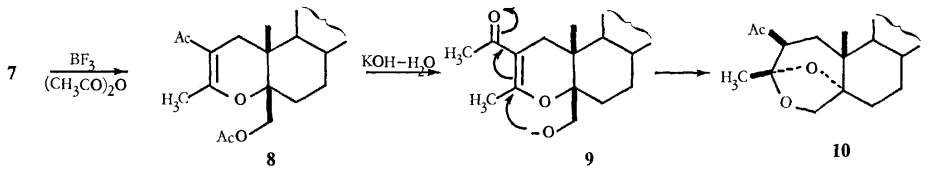


Scheme 3.

Thus, epoxide **3** in dioxan–water containing potassium hydroxide was refluxed for 25 h, but virtually no products resulting from elimination or substitution of iodine were formed and **3** was recovered unchanged.

Hydrogenolysis of iodo compound **3** with 10% Pd–C as a catalyst gave 3α,5-epoxy-3β-methyl-*A*-homo-4-oxa-5α-cholestane (**7**), mp 63.5—65.0 °C, in a 52% yield. Its NMR spectrum exhibited three 3H singlets at τ 8.57, 9.34, and 9.16 assigned to 3β-methyl, 18-H, and 19-H, and an AB quartet at τ 6.77 and 5.90 (J= 6.9 Hz). As would be expected, the signal due to the 19-H shifted upfield significantly in comparison with the corresponding signal of 6β-iodo compound **3**, proving that there is a β-oriented iodine atom in iodo compound **3**. Another amorphous product (**4**) was formed in this hydrogenolysis in a 26% yield. Iodine was still intact in product **4**; its NMR spectrum showed three 3H singlets at τ 8.52, 9.36, and 9.11 assigned to 3β-methyl, 18-H, and 19-H of 3α,5-epoxy-*A*-homo-4-oxasteroid, an AB quartet at τ 6.21 and 5.83 (J=8.3 Hz) assigned to the 4a-methylene protons, and a double doublet at τ 5.44 (J=5.3 and 12.0 Hz) assignable to a proton attached to a carbon bearing iodine. These results prove **4** to be a 6α-isomer of epoxide **3**. A homolysis of C–I bond is apparently followed by the recombination of iodine on the catalyst surface to give a more stable isomer **4**.

Treatment of iodine-free epoxide **7** with boron trifluoride etherate and acetic anhydride in benzene at room temperature for 30 min gave a crystalline product, mp 114—115 °C, in an 89% yield. All the spectral properties of the product were consistent with a dihydropyrane structure **8** (see Experimental). The mode of its formation from the epoxide has already been discussed in the previous paper.[1] Hydrolysis of product **8** with aq methanolic potassium hydroxide



Scheme 4.

TABLE. NMR PARAMETERS (100 MHz) FOR THE 3-METHYL-5-CHOLESTENES AND THE REACTION PRODUCTS IN $CDCl_3$ SOLUTION (chemical shifts τ and splittings Hz)

Compd	3-Methyl	4 or 4a-Methylene	6-H	18-H	19-H	Others
1	8.88(s)	a)	4.74(br s)	9.32(s)	8.98(s)	
2	8.99(s)	a)	4.61(br s)	9.29(s)	8.75(s)	
3	8.60(s)	6.58(d) and 5.77(d) (7.9)	5.69(br t, 3.2) b)	9.26(s)	8.64(s)

a) Unassignable. b) Superimposed with one of the 4a-methylene protons.

at room temperature for 1.5 h gave a compound (**10**), mp 131—134 °C, devoid of hydroxyl band in its IR spectrum. The mass, IR, and NMR spectra of product **10** were in full agreement with this structure: 2β-acetyl-3α,5-epoxy-3β-methyl-4-oxa-*A*-homo-5α-cholestane (**10**) formed by an intramolecular Michael addition of the first formed alcohol (**9**). Its IR spectrum showed a band at 1711 cm^{-1} due to an acetyl group and the NMR spectrum showed three 3H singlets assigned to 3β-methyl, 18-H, and 19-H, and an AB quartet assignable to 4a-methylene protons. Besides these signals, the spectrum showed a 3H singlet at τ 7.83 and a 1H double doublet at τ 7.23 (J= 5.4 and 12.0 Hz) assignable to the 2α-H. Epoxide **7** is formed in a manner entirely analogous to its 3-demethyl homologue.[1]

Discussion

The paths by which 3α,5-epoxide [*e.g.* **3** and **4**] are formed have been discussed in the previous paper.[1] Our experiments again confirmed the generality of the reaction, but the effects of a substitution by a methyl group at the C-3 of 3-hydroxy-Δ^5-steroids on the type of products and their relative yields are clear.

Thus, although thermal and photoinduced reactions of 3α- and 3β-methylcholesterol hypoiodites in the presence of mercury(II) oxide and iodine afford the products parallel to those in the corresponding reaction of cholesterol, the formation of 6β-iodo compound (*e.g.* **3**) as a single major product is noteworthy. Another feature of the present reaction is the absence of 3-oxa-5-cholesten-3β-ol under the experimental procedures comparable to the present reactions. As we suggested 4,4-dimethyl groups may be necessary in order to achieve an appropriate geometry of an intermediate to lead to 3-oxa-5-cholestenes. The absence of the 6α-isomer **4** in the products from the thermal reaction of 3α- and 3β-methylcholesterol hypoiodites[1] was again confirmed. The formation of 3α,5-epoxy-6α-iodo-*A*-homo-4-oxa-5α-steroids and 3α,5-epoxy-*A*-homo-4-oxa-5α-steroid-6-ene has been concluded to arise from an ionic reaction of intermediate carbonium ions.

No dimeric acetal, obtained from cholesterol, was formed in the thermal reaction of 3α- and 3β-methylcholesterol hypoiodites. The 3-methyl group in these hypoiodites hinders the formation of dimeric acetal in the thermal reaction and apparently facilitates the intramolecular reaction to 3α,5α-epoxy-*A*-homo-4-oxa-steroids.

Experimental

For instruments used and general procedures see Ref. 1. Mass spectra of compounds **1**, **2**, **7**, **8**, and **10** were recorded in the Faculty of Agriculture with a Hitachi JMS-D 300 spectrometer (ionizing voltage 70 eV). Mass spectra of compounds **3** and **4** were recorded in the Faculty of Pharmaceutical Sciences with a Hitachi RMU-6E spectrometer (ionizing voltage 70 eV).

*3α- And 3β-Methyl-5-cholesten-3-ols **1** and **2**.* These compounds were prepared by a described procedure.[4] 3β-Alcohol **1** mp 168.5—170.0 °C, (lit,[4] mp 167—168 °C); $[\alpha]_D^{24}$ −28.8° (*c* 1.3 in $CHCl_3$) (lit,[4] $[\alpha]_D^{25}$ −30° (*c* 1.25 $CHCl_3$); MS, *m/e* (rel intensity) 400 (M^+, 4.1%), 382 (M^+-H_2O, 100), 36.7 ($M^+-H_2O-CH_3$, 10.0), 329 (69.3), 147 (20.2), 121 (24.6), 119 (25.6), 107 (21.3) 95 (45.3), 81 (26.7), 57 (19.9), 55 (20.1), and 43 (19.9); for NMR see Table,

3α-Alcohol **2**. Mp 118.0—120.0 °C (lit,[4] mp 119—120 °C); $[\alpha]_D^{29}$ −27.2° (*c* 0.9 $CHCl_3$) (lit,[4] $[\alpha]_D^{25}$ −29° (*c* 0.94 $CHCl_3$); MS, *m/e* (rel intensity) 400 (M^+, 5.6%), 382 (M^+-H_2O, 85.9), 367 (6.8), 329 (100), 147 (19.0), 121 (25.4), 119 (34.3), 107 (22.3), 95 (39.9), 81 (25.7), 57 (20.5), 55 (23.8), and 43 (34.3); for NMR see Table.

Rearrangement of 3α-Methyl-5-cholesten-3β-ol Hypoiodite in the Presence of Mercury(II) Oxide and Iodine. By Irradiation. 3β-Alcohol **1** (1 g, 2.5 mmol), mercury(II) oxide (1.62 g, 7.5 mmol), and iodine (1.75 g, 7.5 mmol) in benzene (150 ml) were irradiated under an argon atmosphere with a 100-W high pressure mercury arc for 5 h. The solution was once filtered and the evaporation of the solvent from the filtrate at below 30 °C left a residue which was extract ed with chloroform (200 ml). The chloroform solution was washed with 5% aq sodium hydrogensulfite, water saturated with sodium chloride, and water successively, and dried (Na_2SO_4). Removal of the solvent left a residue which was recrystallized from a mixture of diethyl ether and methanol to give epoxide **3**, mp 112—114 °C, (749 mg). The specimen for analysis was obtained by recrystallizing it from methanol. Mp 116.5—118.5 °C. (Found: C, 61.82; H, 8.79; I, 23.58%. Calcd for $C_{28}H_{47}O_2I$: C, 61.98; H, 8.73; I, 23.39%); $[\alpha]_D^{34}$ −36.0° (c 1.0 $CHCl_3$); IR, 1198, 1175, 1121, 1024, and 865 cm^{-1}; MS, *m/e* (rel intensity) 541 (M^+, 0.5%), 415 (M^+-I, 21.5), 373 (100), 355 (16.7), 327 (42.9), 57 (26.2), and 43 (52.4); for NMR see Table. The filtrate from the first recrystallization was evaporated to yield a residue (570 mg). It was subjected to preparative TLC with a 2:3 mixture of hexane–benzene. The most mobile fraction (154 mg) showed two spots on TLC. This fraction was again subjected to preparative TLC to afford two fractions. The more mobile fraction was a crude acetal **3** (70 mg), which was recrystallized from methanol to yield a further amount of acetal **3** (59 mg). The less mobile fraction (47 mg) was a mixture; its NMR spectrum indicated it was almost certainly a 1:1 mixture of 3α,5-epoxy-6α-iodo-3β-methyl-*A*-homo-4-oxa-5α-cholestane and 3-acetoxy-2-iodo-*A*-nor-2,3-seco-5-cholesten-3-ol acetate. It showed three singlets at τ 9.35 (18-H), 9.09 (19-H), and 8.51 (3-methyl), an AB quartet (C-4a methylene) at τ 5.82 and 6.20 (J=8 Hz), and a double doublet at τ 5.48 (J=5 and 12 Hz) (6β-H) [a doublet at higher field was superimposed with a signal due to C-3 methylene of product **5**] of product **4**. In addition to these signals, it showed three singlets at τ 9.32, 9.01, and 7.86, a broad singlet at τ 5.48, and a diffused doublet at τ 4.11, which could be assigned to 18-H, 19-H, 3-acetoxyl, 3-H, and 6-H of seco iodide **5**. An attempted separation of these two products by means of preparative TLC was unsuccessful. More polar fractions (396 mg) were an intractable mixture.

Thermal Reaction: A reaction mixture in the same scale as that for the photo-reaction was heated at 55—60 °C under an argon atmosphere for 3 h and worked up as usual. The crude mixture (1.38 g) was recrystallized from diethyl ether–methanol to yield an acetal **3**, mp 113—115.5 °C (862 mg). Removal of the solvent left a residue (441 mg) which was subjected to preparative TLC. A fraction (52 mg) of acetal **3** was recrystallized to yield the acetal (37 mg). The less mobile fraction (22 mg) was identified to be seco ketone **6** on the basis of the NMR spectrum. In contrast to the photo-reaction results, 6α-iodo isomer **5** was absent in the product, as indicated by TLC.

Photoinduced Rearrangement of 3β-Methyl-5-cholesten-3α-ol Hypoiodite in the Presence of Mercury(II) Oxide and Iodine. 3α-Alcohol **2** (400 mg, 1 mmol), mercury(II) oxide (651 mg, 3 mmol), and iodine (762 mg, 3 mmol) in benzene (60 ml) were irradiated under an argon atmosphere for 3 h. After the usual work-up, a crude product (620 mg) was recrystallized from diethyl ether–methanol to give acetal **3** (234 mg), mp 112—115 °C. The residue from the filtrate was subjected to preparative TLC with a 2:3 mixture of hexane–benzene. The most mobile fraction (50 mg) was recrystallized to yield acetal **3** (35 mg). The next mobile fraction (10 mg) was a seco iodide, as judged by its NMR spectrum. From the less mobile fraction, the starting material (7 mg, 2%) was recovered unchanged.

*Photoinduced Rearrangement of 3β-Alcohol **1** in the Presence of Silver(II) Oxide and Iodine.* 3β-Alcohol **1** (300 mg, 0.75 mmol), silver oxide (552 mg, 2.25 mmol), and iodine (796 mg, 2.25 mmol) in benzene (40 ml) were irradiated under an atmosphere of argon for 95 h. In the course of the reaction, further amounts of silver(II) oxide and iodine were added [silver(II) oxide 340 mg and iodine 460 mg at the period of 5 h and silver(II) oxide 180 mg and iodine 400 mg at the period of 48 h]. Work-up of the reaction mixture gave a crude product (392 mg), which was recrystallized from a mixture of acetone and methanol to yield acetal **3** (203 mg), mp 116.5—118.5 °C. A residue from the filtrate was subjected to preparative TLC with a 2:3 mixture of hexane and benzene. The most mobile fraction (17 mg) was recrystallized to give acetal **3** (10 mg). The least mobile raction (50 mg) was again subjected to preparative TLC to afford an amorphous α,β-unsaturated aldehyde **6**. IR, (neat) 1720 (acetyl), 1691 and 1631 (α,β-unsaturated formyl), 1463, 1376, 1361, 1258, 1161, and 805 cm^{-1}; for NMR spectrum see Table.

*Hydrogenolysis of Epoxide **3** with 10% Palladium on Carbon Catalyst.* Epoxide **3** (543 mg) in a mixed solvent of ethanol (18 ml) and benzene (20 ml) containing potassium acetate (80 mg) and a 10% Pd–C catalyst (200 mg) was hydrogenated under an atmospheric pressure for 28 h. At the period of 24 h, a further amount of the catalyst (50 mg) was added. After removal of the catalyst and the solvent, the residue was dissolved in diethyl ether. The solution was washed with water and dried (Na_2SO_4). The residue (470 mg) was subjected to preparative TLC to give three fractions. The most mobile fraction (140 mg) was an amorphous 6α-epimer **4**. $[\alpha]_D^{20}$ −6.8° (*c* 2.0 $CHCl_3$); IR, no hydroxyl and carbonyl bands; 1276, 1234, 1134, 1039, and 734 cm^{-1}; MS *m/e* (rel intensity) 542 (M^+ +1, 0.3%), 541 (M^+, 0.1), 415 (M^+-I, 96), and 99 (100); for NMR spectrum see Table. The next mobile fraction (260 mg) was recrystallized from a mixture of diethyl ether and methanol to give 3α,5α-epoxide **7** (215 mg) in 2 crops, mp 61.5—63.0 °C. The specimen for analysis, mp 63.5—65.0 °C was obtained by further recrystallizations. (Found: C, 80.40; H, 11.70%. Calcd for $C_{28}H_{48}O_2$: C, 80.71; H, 11.61%), $[\alpha]_D^{20}$ +10.9 (*c* 1.0 $CHCl_3$); IR, 1120, 1028, and 866 cm^{-1}; MS *m/e* (rel intensity) 416 (M^+, 7.5%), 387 (55.9), 356 (28.6), 345 (100), 327 (96.7), 215 (25.1), 120 (26.2), 95 (29.2), 81 (28.1), 55 (25.3), and 43 (31.3); for NMR spectrum see Table.

*The Reaction of 3α,5α-Epoxide **7** with Boron Trifluoride Etherate and Acetic Anhydride.* 3α,5α-Epoxide (105 mg, 0.25 mmol), acetic anhydride (0.2 ml, 2 mmol), and boron trifluoride etherate, (0.05 ml, *ca.* 0.39 mmol) in benzene (10 ml) were stirred for 30 min at 22 °C. The solution was neutralized by the addition of aq sodium hydrogencarbonate and was extracted with diethyl ether. The solution was washed with aq sodium hydrogencarbonate solution and water, and dried (Na_2SO_4). Removal of the solvent gave a dihydropyrane derivative **8** (109 mg) in two crops. The specimen for analysis was obtained by further recrystalliza-

tions and melted at 114—115 °C. (Found: C, 76.53; H, 10.36%. Calcd for $C_{32}H_{52}O_4$: C, 76.75; H, 10.43%); $[\alpha]_D^{22}$ −7.7° (*c* 0.9 $CHCl_3$); UV λ_{max} (ethanol) 268 nm (ε; 11500); IR, 1754 (acetyl), 1675 and 1583 (RO-C=C-Ac), 1240, and 1043 cm^{-1}; MS *m/e* (rel intensity) 500 (M^+, 6.5%), 397 (5.2), 328 (4.9), 327 (9.6), 95 (14.2), and 43 (100); for NMR spectrum see Table.

Hydrolysis of Dihydropyrane Derivative **8**. Dihydropyrane derivative **8** (20 mg) in a mixture of diethyl ether (1 ml) and methanol (1 ml) containing water (1.1 ml) and potassium hydroxide (50 mg) was stirred for 1.5 h at room temperature. The solution was extracted with diethyl ether (20 ml). The organic layer was washed with dilute hydrochloric acid and water and dried (Na_2SO_4). The crude product (14 mg) was recrystallized from methanol to yield 3α,5α-epoxy-*A*-homo-4-oxa-steroid **10**, mp 131—134 °C. Recrystallization raised the melting point to mp 134—137 °C; IR, 1711 (acetyl), 1175 and 1026 cm^{-1}; MS *m/e* (rel intensity) 458 (10.7%), 440 (20.9), 398 (38.8), 345 (25.0), 328 (100), 327 (37.8), 247 (19.1), 215 (45.7), 121 (23.3), 120 (43.9), 119 (23.9), 95 (36.4), 81 (24.3), and 43 (55.4); for NMR spectrum see Table.

The authors are grateful to Mrs. Tomoko Okayama for the measurements of the ^1H NMR spectra.

Photo- and Thermally-induced Radical Rearrangement of 4,4-Dimethyl-5-cholesten-3β-ol Hypoiodite in the Presence of Mercury(II) Oxide and Iodine[1)]

Hiroshi SUGINOME*,** and Norio MAEDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 19, 1980)

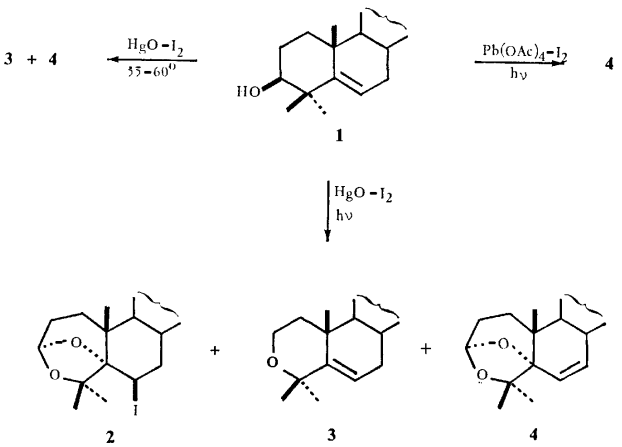
Irraidation of a benzene solution of hypoiodite of 4,4-dimethyl-5-cholesten-3β-ol (**1**) in the presence of mercury(II) oxide and iodine gave a mixture of products, from which 3α,5-epoxy-6β-iodo-*A*-homo-4-oxa-5α-cholestane (2%), 4,4-dimethyl-3-oxa-5-cholestene (**3**) (10%), and 4a,4a-dimethyl-3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-ene (**4**) (4%) were isolated. The thermally-induced reaction on **1** conducted at 55—60 °C gave **3** and **4** in lower yields. The reaction with the use of lead tetraacetate-iodine reagent also gave a complex mixture, from which only **4** was obtained in 22% yield. The formation of 4,4-dimethyl-3-oxa-5-cholestene skeleton is parallel with the case of the photo- and thermally-induced reactions of hypoiodite of 3α,4,4-trimethyl-5-cholesten-3β-ol and appears to be particular with 5-cholesten-3β-ol bearing dimethyl groups at the C-4 under similar conditions. The formation is explained in terms of radical-induced decarbonylation of initially formed 4,4-dimethyl-2-formyl-3-oxa-5-cholestene.

Previous papers[1,2)] have reported the results on the photo- and thermally-induced radical rearrangments of hypoiodite of several 5-cholesten-3-ols in the presence of mercury(II) oxide and iodine. It has been found that the reaction, regardless of whether it was induced photochemically or thermally, led generally to the formation of 3α,5-epoxy-*A*-homo-4-oxa-5α-cholestanes having α- or β-oriented iodine or 3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-enes. Methyl substituents at their C-3 or C-4, however, affected the relative yields of the products appreciably and even resulted in the formation of new products. Thus, for example, 3α,4,4-trimethylcholest-5-en-3β-ol hypoiodite gave 2-acetyl-3-oxa-5-cholestenes together with 3α,5-epoxy-*A*-homo-4-oxa-5α-cholestanes on thermal or photoindused reaction in the presence of mercury(II) oxide and iodine. These effects of the alkyl substituents were interpreted as due mainly to steric effects on the conformation of the intermediary allyl radical generated by the β-scission of oxyl radicals.[2)]

This paper reports a study of photo- and thermally-induced reactions of the hypoiodite of 4,4-dimethyl-5-cholesten-3β-ol (**1**)[3)] in the presence of mercury(II) oxide and iodine; the study was made to assess the effect of alkyl substitution at the C-4.

Results

The reactions have been conducted under the conditions reported previously.[1,2)] Thus, irradiation of 4,4-dimethyl-5-cholesten-3β-ol (**1**) in benzene containing iodine and mercury(II) oxide (each *ca.* 3 mol equiv.) with a 100-W high pressure mercury arc for about 4 h under an atmosphere of nitrogen gave a complex mixture of products, from which three products (**2**) (2%), (**3**) (10%), and (**4**) (4%) were obtained by preparative TLC and column chromatography (Scheme 1). The structures of these products were deduced by analysis of their spectra. The crystalline product **2** contained an iodine atom in the molecule; the mass spectrum showed a weak ion of *m/e* 429 attributable to M^+-I, a base peak at *m/e* 371, and a prominent peak at *m/e* 353, indicating the structure to be a 3α,5-epoxy-*A*-homo-4-oxa-5α-cholestane. The elemental analysis was in agreement with this. The genesis and the structure of the fragments of *m/e* 371 and *m/e* 353 is depicted in Scheme 2.

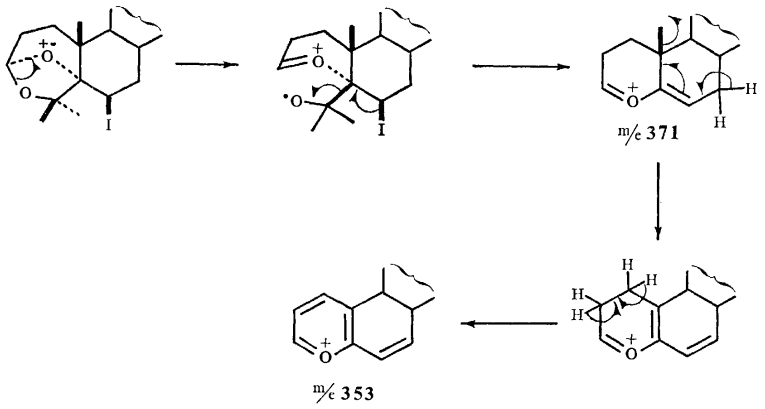


Scheme 1.

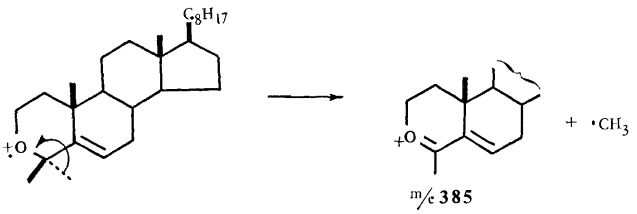
The ^{1}H NMR spectrum of **2** showed two broad singlets at τ 5.81 and 4.65. The former is ascribable to a proton attached to a carbon bearing iodine and the latter is assigned to a proton attached to a carbon bearing two oxygen atoms. Irradiation at τ 6.5 sharpened the broad singlet at τ 5.81.

A molecular formula of **3** was confirmed to be $C_{28}H_{48}O$ by high resolution mass spectrometry. The IR spectrum lacked bands arising from hydroxyl and carbonyl groups. The ^{1}H NMR spectrum of **3** indicated a 1-H double doublet centered at τ 4.65 due to an olefinic proton, a 2-H multiplet at τ 5.95—6.54 assignable to a methylene group having an ether type oxygen, and four singlets due to the four tertiary methyl groups. The fragmentation in the mass spectrum was most helpful for the assignment of the structure. The spectrum showed the base peak at *m/e* 385; no other peak whose intensity exceeded 2% was present. The fragment arises from an expulsion

** Present address: Organic Chemistry Laboratory, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060.



Scheme 2.



Scheme 3.

of a methyl group at the C-4, as confirmed by an accurate mass measurement which showed the ion of *m/e* 385 to be a species $C_{27}H_{45}O^+$ (*m/e* 385.3467). All these results can be accommodated in the structure 4,4-dimethyl-3-oxa-5-cholestene. The structure and a genesis of the base peak is depicted in Scheme 3.

The ^{13}C NMR spectrum of product **3** showed 28 signals, including those at δ 147.36, 117.98, 74.43, 57.99, 56,89, 55.92, and 49.83 ppm in the downfield region. By the aid of off-resonance decoupling, these signals could be assigned to the C-5, C-6, C-4, C-2, C-14, C-17, and the C-9 respectively.

The molecular formula of **4** was deduced to be $C_{29}H_{48}O_2$ by the mass spectrum (M^+, *m/e* 428) and the elemental analysis. The mass spectrum showed the base peak at *m/e* 370. The IR spectrum lacked any hydroxyl and carbonyl groups. The ^1H NMR spectrum showed a 1-H broad singlet at τ 4.70, assigned to a proton attached to a carbon having two oxygens. It also exhibited the signals assignable to two olefinic protons centered at τ 4.56 and 4.11. Their coupling constants (11.6 Hz) indicated that they are vicinal protons in a fused cyclohexene. The respective doublet showed further small splitting. These results of the ^1H NMR spectrum and the presence of a base peak at *m/e* 370 in the mass spectrum indicated that the structure of the product **4** was 4a,4a-dimethyl-3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-ene (**4**). The ion of *m/e* 370 may arise as depicted in Scheme 4. No other well-defined products were isolated from the product mixture.

The photoinduced reaction of the hypoiodite was also attempted by the use of lead tetraacetate–iodine reagent.[4] However, the reaction again led to a complex mixture, from which only 4a,4a-dimethyl-3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-ene (**4**) was isolated in 22% yield.

Finally, thermally-induced rearrangements were attempted. Homoallyl alcohol **1** in benzene containing mercury(II) oxide and iodine was heated at 55—60 °C for 3 h in the dark, as was previously reported for several 5-cholesten-3β-ols. Again, a mixture of products was obtained, and 4,4-dimethyl-3-oxa-5-cholestene **3** (5%) and 4a,4a-dimethyl-3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-ene **4** (2%) were isolated from the mixture by preparative TLC.

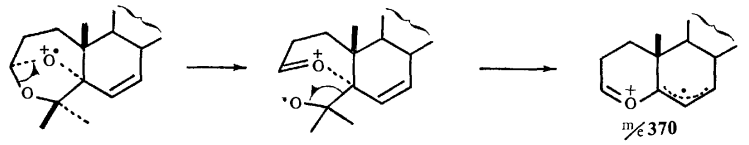
Discussion

The paths by which 3α,5-epoxy-*A*-homo-4-oxa-5α-cholestanes and 3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-enes are formed have been discussed in the previous papers.[1,2]

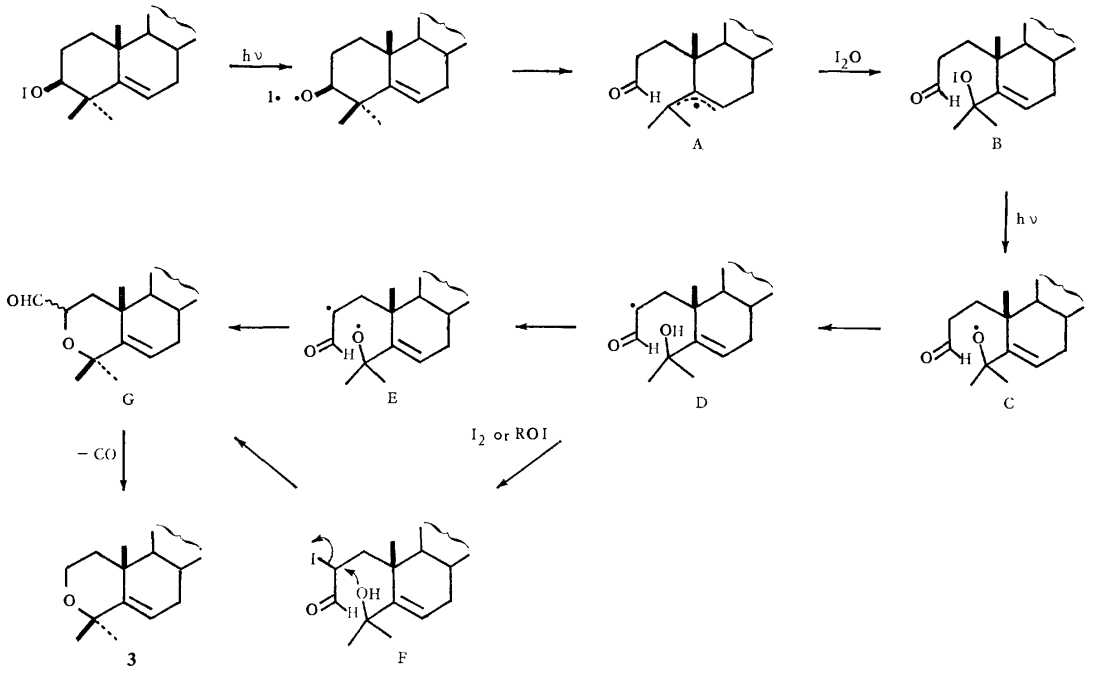
4,4-Dimethyl-3-oxa-5-cholestene (**3**) is a new type of product in this reaction, but its formation may reasonably be explained in either of the following two ways. Scheme 5 shows the first probable path. Thus, as suggested previously,[2] 3-oxa-5-cholestene skeleton (G) can be formed either *via* successive intermediates (A) to (E) or *via* (A) to (F). The second hypoiodite (B) may be formed by the reaction of iodine oxide and allyl radical intermediate (A). Radical-induced decarbonylation[5] of 4,4-dimethyl-2-formyl-3-oxa-5-cholestene (G) may take place under the experimental conditions to give the observed product **3**. The possibility of the photochemical removal of the formyl group is excluded, since **3** is also formed in the reaction under the dark.

An alternative path to 3-oxa-5-cholestene is shown in Scheme 6. In this path, 3,3-dimethyl-2-iodo-*A*-nor-2,3-seco-5-cholesten-3-ol formate (I) is formed from an intermediate (H) formed from the allyl radical (A). The transformation of the intermediate (I) into another intermediate (K) and radical or ionic cyclization of (K) may give product **3**. The formate (J) is, in fact, one of the major products in the photo-induced rearrangements of cholesterol hypoiodite in the presence of mercury(II) oxide and iodine.[2] This latter path, however, is less likely since no 3-oxa-5-cholestene is formed under the experimental conditions in the photoinduced reaction of cholesterol hypoiodite.

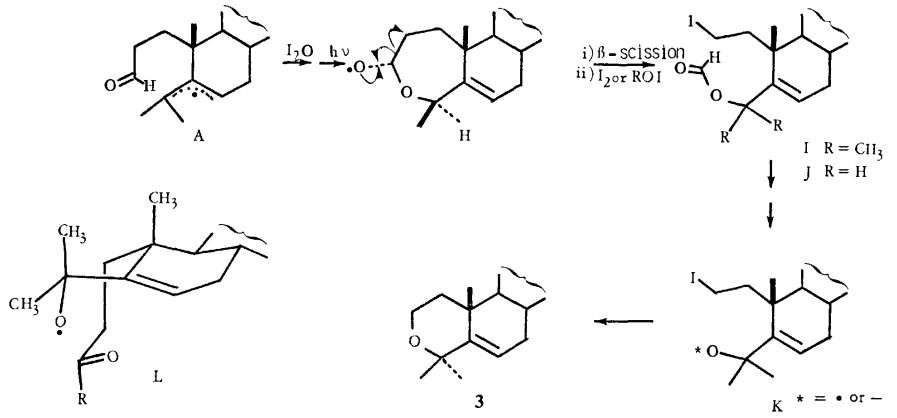
Thus, the present results are considered to be nearly parallel with those obtained in the reaction of 3α,4,4-



Scheme 4.



Scheme 5.



Scheme 6.

trimethyl-5-cholesten-3β-ol[2] although the yields of the products are lower than those in the reaction of the 3-methyl analogue.[2]

The formation of 3-oxa-5-cholestene (*e.g.* **3**) appears to be particular with 5-cholesten-3-ols having dimethyl groups at their C-4. The fact strengthens our previous hypothesis[2] that one of the methyl groups at their C-4 destabilizes a conformation (L), in which the oxyl radical attacks a carbonyl carbon to give an oxepane (H), by virtue of a quasi 1,3-diaxial relationship with its 10β-methyl group, and facilitates an intramolecular abstraction of the most weakly bound C-2–H by the oxyl radical.

Experimental

For instruments used and general procedure see Ref. 2. Low resolution mass spectra of compounds **2** and **3** and high resolution mass spectrum of **3** were recorded with a Hitachi JMS-D 300 spectrometer (ionizing voltage 70 eV) by Miss Yuko Chiba of the Faculty of Agriculture in this University. The mass spectrum of compound **4** was recorded with a Hitachi RMU-6E spectrometer (ion source temperature 80 °C, ionizing voltage 80 eV) by the staff of the Faculty of Pharmaceutical Sciences. The ^{13}C NMR spectrum was recorded with a Brucker SXD pulsed FT NMR spectrometer ($CDCl_3$, 22.63 MHz, ppm from TMS) in the Faculty of

Engineering of this University.

The Irradiation of 4,4-Dimethyl-5-cholesten-3β-ol Hypoiodite in the Presence of Mercury(II) Oxide and Iodine. 4,4-Dimethyl-5-cholesten-3β-ol (**1**) (1 g, 2.42 mmol), mercury(II) oxide (1.6 g, 7.38 mmol), and iodine (1.72 g, 6.78 mmol) in benzene (130 ml) were irradiated for 3 h 40 min. After the solution was filtered, the filtrate was evaporated to give a residue which was worked up in the usual way. The crude product (1.02 g) was subjected to preparative TLC with benzene. Seven fractions: A (214 mg), B (111 mg), C (75 mg), D (104 mg), E (60 mg), F (40 mg), and G (157 mg) were obtained in order of decreasing mobility. The ^{1}H NMR spectrum of fraction A indicated no proton signal due to aldehyde. Fractions B and C were combined and subjected to column chromatography. (Kiesel gel 60, 70—230 mesh). Elutions with a 5:1 mixture of hexane and benzene gave a 3α,5-epoxide **2** (19 mg, 2%), which was recrystallized from a mixture of diethyl ether and methanol to give a specimen for analysis, mp 131.5—133.5 °C. $[\alpha]_D^{22}$ −41.8° (*c* 0.5 $CHCl_3$); (Found: C, 62.60; H, 8.92; I, 23.02%. Calcd for $C_{29}H_{49}O_2I$: C, 62.57; H, 8.87; I, 22.80%); IR, 1171, 1148, 1119, 1104, 1025, 970 and 938 cm^{-1}; NMR, τ 9.27 (3H, s, 18-H), 8.69 and 8.57 (each 3H, s, C-5 dimethyl), 8.28 (3H, s, 19-H), 5.81 (1H, br s, $W_{1/2}$ 3.8 Hz, 3β-H); MS, *m/e* (rel intensity) 429 (0.2%, M^+-I), 372 (20.5), 371 (100), 353 (4.2), 57 (4.6), 55 (13.5), and 43 (51). Fraction D was an almost pure 3-oxa compound **3**. After recrystallization from diethyl ether–ethanol, it had mp 106.0—107.5 °C (61 mg). $[\alpha]_D^{21}$ −40.2° (*d* 1.0 $CHCl_3$); (Found: C, 83.87; H, 12.18%. Calcd for $C_{28}H_{48}O$: C, 83.93; H, 12.08%; *m/e* 400.3702. Calcd for $C_{28}H_{48}O$: M, 400.3704); IR, 917, 963, 1078, 1113, 1143, and 1177 cm^{-1}; NMR, τ 9.32 (3H, s, 18-H), 8.79, 8.67, and 8.64 (each 3H, s, C-4 dimethyl, and 19-H), 5.95—6.54 (2H, m, 2α- and 2β-H), and 4.65 (1H, dd, J=2 and 5 Hz, 6-H); MS, *m/e* (rel intensity), 400 (M^+, 0.2%) 399 (0.1), 386 (24.3), and 385 (M^+-CH_3 100). (Found; *m/e* 385.3467. Calcd for $C_{27}H_{45}O^+$: 385.3469). Fraction E was subjected to column chromatography (silica gel, 6 g). Elutions with a 1:1 mixture of hexane and benzene afforded an amorphous 3α,5α-epoxide **4** (43 mg, 4%); NMR, τ 9.40 (3H, s, 18-H), 9.06 (3H, s, 19-H), 8.78 and 8.60 (each 3H, s, C-4 dimethyl), 4.70 (1H, br s, $W_{1/2}$=3.7 Hz, 3β-H), 4.56 (1H, dd, J=11.6 and 3.1 Hz, 7H), and 4.11 (1H, dd, J=11.6 and 1.8 Hz, 6H); IR, (neat) 800, 969, 1025, 1105, and 1260 cm^{-1}; MS, *m/e* (rel intensity) 428 (M^+, 11.0%), 370 (100), 343 (12.8), 339 (14.6), 149 (47.7), 57 (60.6), and 43 (71.6). No single compound was obtained from other fractions.

The Thermal Decomposition of 4,4-Dimethyl-5-cholesten-3β-ol Hypoiodite in the Presence of Mercury(II) Oxide and Iodine. The 3β-ol (480 mg, 1.15 mmol), mercury(II) oxide (780 mg, 3.61 mmol), and iodine (860 mg, 3.39 mmol) in benzene (65 ml) were heated at 55—60 °C in the dark for 3 h. The reaction mixture was worked up as was described for the mixture from the photoinduced reaction. The amorphous residue (553 mg) was subjected to preparative TLC with benzene. Five fractions: A (34 mg), B (52 mg), C (37 mg), D (70 mg), and E (115 mg) were obtained in the order of decreasing mobility. Fraction B (52 mg) was subjected to preparative TLC with benzene to yield cyclic ether **3** (25 mg, 5%), identical with the specimen obtained from photolysis. The fractions C and D were combined and were again subjected to preparative TLC with a 4:1 mixture of hexane and diethyl ether to yield an amorphous 3α,5-epoxide **4** (11 mg, 2%).

The Reaction of 4,4-Dimethyl-5-cholesten-3β-ol with Lead Tetraacetate–Iodine Reagent. 4,4-Dimethyl-5-cholesten-3β-ol (**1**) (300 mg, 0.72 mmol), freshly prepared lead tetraacetate (962 mg, 2.17 mmol), and iodine (749 mg, 2.17 mmol) in benzene (40 ml) containing calcium carbonate (120 mg) were irradiated through Pyrex for 2.5 h with a 100-W Hg arc under an argon atmosphere. After the solution was filtered, the filtrate was washed three times with 5% aq sodium hydrogensulfite solution, washed with water, and dried (Na_2SO_4). The removal of the solvent left a residue (365 mg) which was subjected to preparative TLC with a 2:3 mixture of dichloromethane and benzene. Four fractions: A (48 mg), B (34 mg), C (60 mg), and D (69 mg) were obtained. The fraction D was 4a,4a-dimethyl-3α,5-epoxy-*A*-homo-4-oxa-5α-cholest-6-ene as indicated by the NMR spectrum.

We thank Mrs. T. Okayama and Miss H. Maki for the measurements of NMR spectra and spin decoupling experiments.

The Reaction of 3-Hydroxyflavones with Metal Salts

Mutsumi HAMADO* and Kazu KUROSAWA

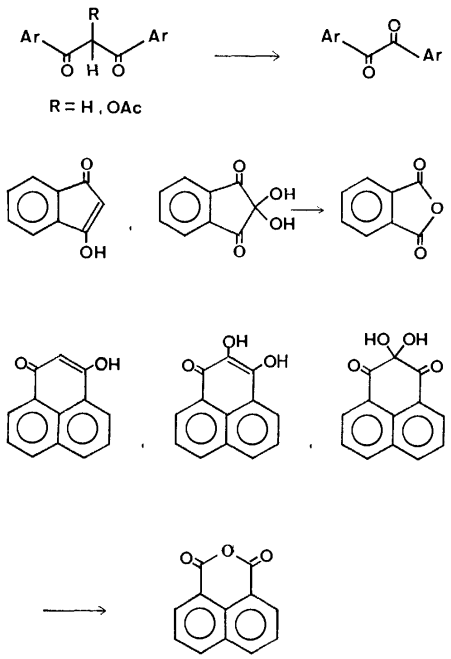
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received February 6, 1980)

The reaction of 3-hydroxyflavones (**1a—d**) with lead(IV) acetate gave 1,2-diphenylethanediones (**2a—d**), 1,2-diphenyl-2-hydroxyethanones, 2-hydroxybenzoic acids (**7** and **9**), and benzoic acids (**8** and **10**), and the reaction with manganese(III) acetate yielded **2**, **7**, **8**, **9**, and **10**. In addition to **2**, **7**, and **10**, 6-methoxy-2-(4-methoxybenzoyloxy)-3(2*H*)-benzofuranone and 2-hydroxy-4-methoxybenzaldehyde were obtained in the reaction of **1c** with manganese(III) acetate. It has been established by the studies of ^{14}C-labelled compounds that the $C_{(3)}$ in the 3-hydroxyflavone was lost during the reaction.

In previous papers,[1,2] the decarbonylation reactions of 1,3-diphenyl-1,3-propanediones and 1,3-indandiones with lead(IV) acetate have been reported. The reaction of ^{14}C-labelled compounds showed that the $C_{(2)}$ was lost completely in the case of 2-acetoxy-1,3-diphenyl-1,3-propanedione, but that 53 percent of the $C_{(\alpha)}$ was retained in the case of β-hydroxychalcone (1,3-diphenyl-1,3-propanedione), suggesting that there may be binary reaction pathways. Similar results were obtained in the reaction of ^{14}C-labelled 1,3-indandiones and 1*H*-phenalene-1,3(2*H*)-dione with lead(IV) acetate[2] (Scheme 1). In order to obtain further information about the nature of the decarbonylation reaction, we studied the reaction of 3-hydroxyflavones with lead(IV) acetate under various reaction conditions.

When 4′,7-dimethoxy-3-hydroxyflavone (**1c**) was heated in acetic acid with lead(IV) acetate, five compounds (**2c**, **3c**, **4c**, **7**, and **10**) were obtained. The NMR spectrum of **2c** indicated the presence of a para-substituted benzoyl group [δ=7.92 (2H, m) and 6.96 (2H, m)], a 2,4-disubstituted benzyol group [δ=7.4 (1H, d, J=9 Hz) and 6.25—6.5 (2H, m)],



Scheme 1. Reactions of 1,3-diaryl-1,3-propanediones, 1,3-indandiones, and 1*H*-phenalene-1,3(2*H*)-dione with lead(IV) acetate.

a hydrogen-bonded hydroxyl group [δ=11.9 (1H, s)] which disappeared on deutration, and two methoxyl groups [δ=3.82 (3H, s) and 3.85 (3H, s)]. Two carbonyl functions, one of which was hydrogen-bonded, were characterized by IR absorption at 1685 and 1630 cm^{-1}. The mass spectrum of **2c** showed four prominent ions, at *m/e* 151, 135, 123, and 107, due to the α-cleavages to the carbonyls that are shown in Fig. 1. This spectroscopic evidence clearly showed that this compound was 1-(2-hydroxy-4-methyoxyphenyl)-2-(4-methoxyphenyl)ethanedione (**2c**). The structure was confirmed by an unambiguous synthesis of **2c**: the reaction of 2′-benzyloxy-4,4′-dimethoxychalocone with thallium(III) nitrate[3] gave 1-(2-benzyloxy-4-methoxyphenyl)-2-(4-methoxyphenyl)ethanedione (**2e**), which was then debenzylated to give the identical **2c**.

The NMR spectrum of **3c** showed that presence of a para-substituted phenyl group [δ=7.28 (2H, m) and 6.85 (2H, m)], three atomatic protons [δ=7.15 (1H, d, J=8 Hz) and 6.3—6.45 (2H, m)], two methoxyl groups [δ=3.76 (3H, S) and 3.75 (3H, s)], two hydroxyl groups [δ=12.1 (1H, s) and 4.25 (1H, broad s)], and a broad singlet [5.8 (1H)]. The latter singlet became sharp and the hydroxyl groups disappeared when shaken with deuterium oxide. The IR spectrum of this compound indicated the presence of hydroxyl groups (3460 and 2500—3300 cm^{-1}) and a hydrogen-bonded carbonyl group (1640 cm^{-1}). Thus, the structure of **3c** is shown as 2-hydroxyl-1-(2-hydroxy-4-methoxyphenyl)-2-(4-meth-

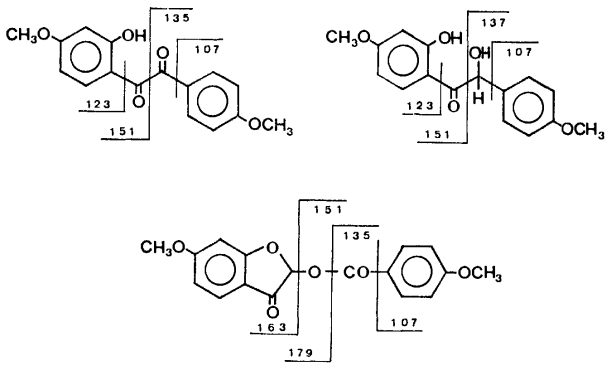


Fig. 1. The mass spectral data of 1-(2-hydroxy-4-methoxyphenyl)-2-(4-methoxyphenyl)ethanedione (**2c**), 2-hydroxy-1-(2-hydroxy-4-methoxyphenyl)-2-(4-methoxyphenyl)ethanone (**3c**), and 6-methoxy-2-(4-methoxybenzoyloxy)-3(2*H*)-benzofuranone (**5**).

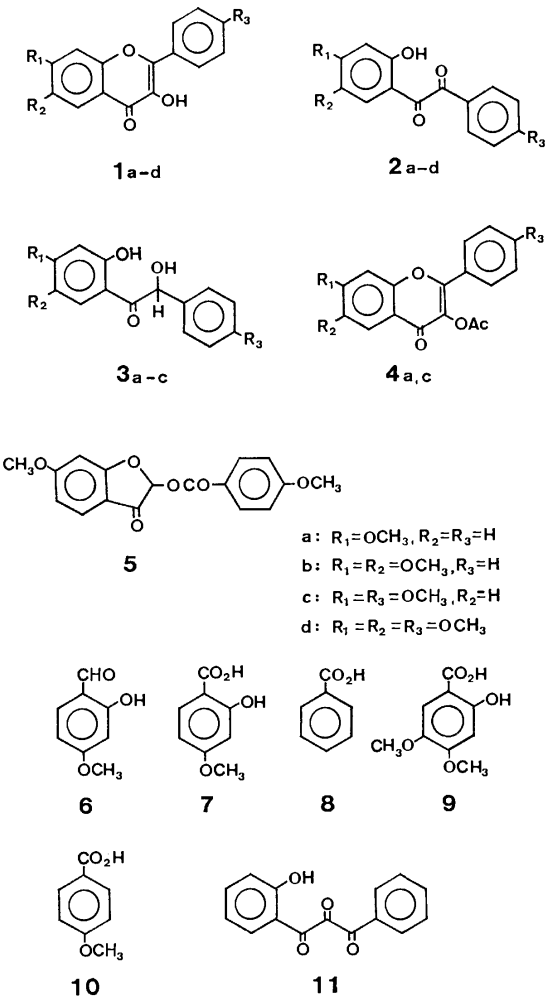
oxyphenyl)ethanone. This was further confirmed by the mass spectrum of **3c**, which showed prominent ions at *m/e* 151 and 123 due to α-cleavages to the carbonyl group, and at 137 and 107 due to α-cleavages to the alcoholic hydroxyl group (Fig. 1).

The third compound was found to be 3-acetoxy-4′,7-dimethoxyflavone (**4c**), which was identified with an authentic sample by a comparison of their IR spectra. The two carboxylic acids (**7** and **10**), as a mixture, were compared with the mixture of authentic samples on NMR, and then the methyl-esterified mixture was identified by a comparison of its GC retention time with that of the authentic specimen. When the reaction was conducted in a benzene solution, the yields of these products (**2c** and **3c**) were poor so that all the reactions hereafter were carried out in acetic acid.

When **1c** was oxidized with manganese(III) acetate, five products (**2c**, **5**, **6**, **7**, and **10**) were obtained. **6** was found to be 2-hydroxy-4-methoxybenzaldehyde. The NMR spectrum of **5** indicated the presence of a para-substituted benzoyl group [δ=8.09 (2H, m) and 6.95 (2H, m)], three aromatic protons [δ=7.69 (1H, d, J=10 Hz) and 6.53—6.84 (2H, m)], and a singlet [δ=6.50 (1H)]. The mass spectrum of **5** showed prominent ions due to all the possible cleavages shown in Fig. 1. The IR spectrum of **5** showed a carbonyl absorption at 1745 cm^{-1}. These spectral data are consistent with the structure of **5** shown in Scheme 2.

Three other 3-hydroxyflavones (**1a**, **1b**, and **1d**) were also oxidized with lead(IV) acetate to give 1-(2-hydroxyphenyl)-2-phenylethanediones (**2a**, **2b**, and **2d**), 2-hydroxy-1-(2-hydroxyphenyl)-2-phenylethanones (**3a** and **3b**), 3-acetoxy-7-methoxyflavone (**4a**), 2-hydroxybenzoic acids (**7** and **9**), and benzoic acids (**8** and **10**). The oxidations of **1a**, **1b**, and **1d** with manganese(III) acetate again gave 1-(2-hydroxyphenyl)-2-phenylethanediones (**2a**, **2b**, and **2d**).

In order to establish the nature of the decarbonylation reaction, the reaction was carried out using ^{14}C-labelled 3-hydroxyflavone. When 3-hydroxy-4′,6,7-trimethoxyflavone-3-^{14}C was oxidized with lead(IV) acetate, an inactive **2d** and an active carbon dioxide were obtained (Scheme 3), indicating that the $C_{(3)}$ was lost during the oxidation. That the 2-hydroxy-1-(2-hydroxyphenyl)-2-phenylethanones (**3a**—**c**) and the aldehyde (**6**) were isolated in the reactions seems to show the complex features of the reaction. It is well known that 1,2-diphenyl-2-hydroxyethanone is oxidized to give 1,2-diphenylethanedione, benzaldehyde, and benzoic acid by lead(IV) acetate.[4] Thus, this suggests that, *via* an unknown process, 3-hydroxyflavone



Scheme 2. 3-Hydroxyflavones and products in the oxidations of 3-hydroxyflavones with lead(IV) acetate and manganese(III) acetate.

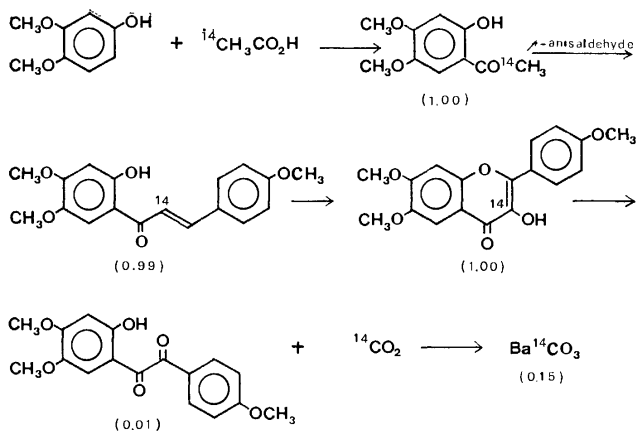
a) The reactions were carried out in acetic acid at the reflux temperature. b) Yields are based on the amount of 3-hydroxyflavone consumed. c) The yields of carboxylic acids (**7**, **8**, **9**, and **10**) are estimated from the NMR spectra.



Scheme 3. Synthesis and the oxidation of 3-hydroxy-4′,6,7-trimethoxyflavone-3-^{14}C (the figures under the formulae refer to the specific radioactivities of the compounds relative to the acetophenone).

is transformed into 1,2-diphenyl-2-hydroxyethanone, with is then oxidized to 1,2-dipehnylethanedione. However, it is still possible to assume another reaction pathway in which an open-chain triketone (**11**), formed from 3-hydroxyflavone by the oxidation, could give rise to 1,2-diphenylethanedione by decarbonylation.[5]

Experimental

All the ^1H NMR spectra were recorded for the deuteriochloroform solution with a Hitachi-Perkin-Elmer R 24 NMR spectrometer, with tetramethylsilane as the internal reference. The IR spectra were recorded for the chloroform solution with a JASCO IRA-1 grating spectrometer, while the mass spectra were measured with a Hitachi RMU-6M mass spectrometer. The melting points were determined with a Yanagimoto hot-stage apparatus and were not corrected. The radioactivities were recorded, for samples crystallized to a constant specific radioactivity, with an Aloka liquid scintillation spectrometer. The scintillator consisted of 0.4% DPO and 0.01% POPOP (Dojin Laboratories, Kumamoto) dissolved in toluene. Barium carbonate samples were suspended in a gel made up with 4% w/v CAB-O-SIL (Beckmann Instruments, Inc., U.S.A.). Sample counts were repeated twice; the maximum observed error was within 0.5%.

3-Hydroxyflavones. The 3-hydroxyflavones (**1a**—**d**) were prepared by the literature methods.[6,7]

Oxidation of 3-Hydroxyflavones with Lead(IV) Acetate. A typical procedure for the oxidation of 3-hydroxyflavones was as follows. To a 3-hydroxyflavone (500 mg) dissolved in boiling acetic acid (30 ml), lead(IV) acetate (2.0 equivalents) was added. After the removal of the acetic acid *in vacuo*, the residue was treated with 2 M hydrochloric acid (60 ml) and extracted with chloroform (100 ml). The chloroform solution was washed with an aqueous sodium hydrogencarbonate solution (100 ml) three times and then evaporated. The aqueous sodium hydrogencarbonate solution was acidified, and subsequent extraction with chloroform gave acidic products. The neutral products were separated on TLC, with chloroform as the developing solvent. The acidic products were identified by a comparison of their retention times as methyl esters and their NMR spectra with those of the authentic samples.

*p-Anisic Acid (**10**) and 2-Hydroxy-4-methoxybenzoic Acid (**7**). Oxidation Products of 3-Hydroxy-4′,6,7-trimethoxyflavone (**1d**).* *1-(4,5-Dimethoxy-2-hydroxyphenyl)-2-(4-methoxyphenyl)ethanedione (**2d**)*: Mp 129—131 °C (ethanol) (Found: C, 64.35; H, 5.15%. Calcd for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%); IR 1680 and 1630 cm^{-1}; NMR δ=11.85 (1H, s, OH), 7.96 (2H, m), 6.98 (2H, m), 6.86 (1H, s), 6.53 (1H, s), 3.92 (3H, s, OCH_3), 3.87 (3H, s, OCH_3), and 3.70 (3H, s, OCH_3).

*3,4-Dimethoxy-2-hydroxybenzoic Acid (**9**) and p-Anisic Acid (**10**)*: Mp 185 °C.

Oxidation of 3-Hydroxyflavones with Manganese(III) Acetate. A typical procedure for the oxidation of 3-hydroxyflavones with manganese(III) acetate was as follows. A mixture of a 3-hydroxyflavone (500 mg), manganese(III) acetate[8] (3.8 equivalents), and acetic acid (30 ml) was heated under reflux for several minutes. After the subsequent removal of the acetic acid *in vacuo*, the residue was extracted with chloroform and separated in the manner described previously. **1a** gave **2a**, **7**, and **8**. **1b** yielded **2b**, **8**, and **9**. **1c** gave **2c**, 6-methoxy-2-(4-methoxybenzoyloxy)-3(2*H*)-benzofuranone (**5**); mp 163—164.5 °C (ethanol) (Found: C, 64.91; H, 4.60%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%); IR 1745 cm^{-1}; NMR δ=8.09 (2H, m), 7.69 (1H, d), 6.95 (2H, m), 6.53—6.84 (2H, m), 6.50 (1H, s), 3.94 (3H, s, OCH_3), and 3.92 (3H, s, OCH_3); MS *m/e*=285, 179, 163, 151, 135, and 107, 2-hydroxy-4-methoxybenzaldehyde (**6**), mp 41 °C, **7**, and **10**. **1d** yielded **2d**, **9**, and **10**.

*1-(2-Benzyloxy-4-methoxyphenyl)-2-(4-methoxyphenyl)ethanedione (**2e**).* A mixture of 2′-benzyloxy-4,4′-dimethoxy-

chalcone[9] (1 g), thallium(III) nitrate (3.2 g), methanol (6 ml), and 35% perchloric acid (3 ml) was stirred at room temperature for 2 h. Water (150 ml) was added to the reaction mixture, and then the mixture was extracted with chloroform (30 ml). After the removal of the chloroform, the resulting substance was purified by TLC, with chloroform as the developing solvent, to give **2e**; mp 114—119 °C (ethanol) (360 mg, 36%) (Found: C, 73.14; H, 5.30%. Calcd for $C_{23}H_{20}O_5$: C, 73.39; H, 5.36%); IR 1680 cm^{-1}; NMR δ=8.02 (1H, d, J=9 Hz), 7.62 (2H, m), 6.77 (2H, m), 6.9—7.2 (5H, m), 6.4—6.73 (2H, m), 4.85 (2H, s, $-CH_2-$), and 3.80 (6H, s, $2\times OCH_3$).

Debenzylation of 2e. **2e** (50 mg) was added to a mixture of 35% perchloric acid (10 ml) and methanol (16 ml), and the mixture was heated under reflux for 2.5 h. After the removal of the methanol *in vacuo*, the residue was extracted with chloroform (60 ml) and purified on TLC to give **2c**; mp 99—101 °C (ethanol) (34 mg, 89%).

4',5'-Dimethoxy-2'-hydroxyacetophenone-2-^{14}C. A mixture of 3,4-dimethoxyphenol (10.6 g), a boron trifluoride–acetic acid complex (13 g), and sodium acetate-2-^{14}C (250 μCi, Radiochemical Center, Amersham, England) was heated at 100 °C for 25 min. The reaction mixture was then poured into 2 M hydrochloric acid (150 ml). The insoluble materials were dissolved in methanol, and the methanol solution was then added to the acid solution. After the removal of the methanol, the residue was extracted with benzene and the benzene solution was purified by means of a silica column yielding 4',5'-dimethoxy-2'-hydroxyacetophenone-2-^{14}C; mp 112—113 °C (6.85 g; 54%; specific radioactivity, 1.50 μCi/mmol).

2'-Hydroxy-4,4',5'-trimethoxychalcone-α-^{14}C. A mixture of 4',5'-dimethoxy-2'-hydroxyacetophenone-2-^{14}C (6.3 g), *p*-anisaldehyde (5.0 g), 40% aqueous potassium hydroxide (50 ml), and ethanol (50 ml) was stirred at room temperature for 2 h. The reaction mixture was then poured into cold hydrochloric acid, and the precipitates were collected. These precipitates gave 2'-hydroxy-4,4',5'-trimethoxychalcone-α-^{14}C; mp 133—135 °C (ethanol) (1.64 g; 14.3%; specific radioactivity, 1.48 μCi/mmol).

3-Hydroxy-4',6,7-trimethoxyflavone-3-^{14}C. To a mixture of 2'-hydroxy-4,4',5'-trimethoxychalcone-α-^{14}C (1.54 g), 22% aqueous potassium hydroxide (30 ml), and ethanol (90 ml), we added cold 15% hydrogen peroxide (20 ml). The reaction mixture was allowed to react for two days and then poured into 2 M hydrochloric acid. The precipitates were collected and recrystallized, giving 3-hydroxy-4',6,7-trimethoxyflavone-3-^{14}C, mp 229.5—230 °C (ethanol) (740 mg; 47%; specific radioacitivity, 1.49 μCi/mmol).

Oxidation of 3-Hydroxy-4',6,7-trimethoxyflavone-3-^{14}C *with Lead-(IV) Acetate.* To 3-hydroxy-4',6,7-trimethoxyflavone-3-^{14}C (250 mg) dissolved in boiling acetic acid (30 ml), lead(IV) acetate (676 mg) was added under a nitrogen stream, after which the reaction mixture was worked-up in a manner described previously, giving 1-(4,5-dimethoxy-2-hydroxyphenyl)-2-(4-methoxyphenyl)ethanedione (**2d**) (mp 128—130 °C (ethanol) (10 mg; 4.2%; specific radioactivity, 0.02 μCi/mmol)), carbon dioxide, which was later converted to barium carbonate (142 mg; 95%; specific radioactivity, 0.23 μCi/mmol), and *p*-anisic acid (**10**) (mp 185 °C (water) (40 mg; 28%; specific radioactivity, 0.01 μCi/mmol)).

The authors wish to thank Dr. Naotake Ogawa, Department of Pharmacology, Kumamoto University, for his kind assistance in the measurements of the radioactivities.

Conversion of Carbon–Sulfur Linkages into Carbon–Silicon Ones *via* Reductive Silylation. Preparation of Silyl Enol Ethers of Acyltrimethylsilanes[1)]

Isao KUWAJIMA,* Akio MORI, and Masahiro KATO
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received February 8, 1980)

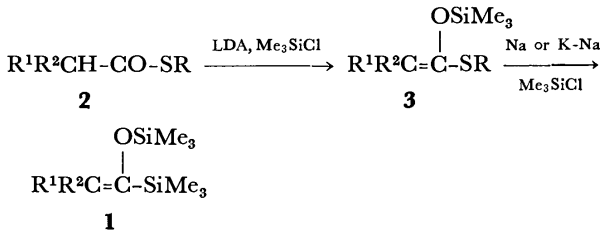
Reductive cleavage of carbon–sulfur linkages of silyl enol ethers of thiocarboxylic *S*-esters can be induced by treatment with sodium or potassium–sodium alloy in the presence of chlorotrimethylsilane, and the corresponding silyl enol ethers of acyltrimethylsilanes can be prepared in high yields.

Various organosilicon compounds have recently been employed as useful intermediates in a wide range of synthetic organic chemistry.[2)] Acyltrimethylsilanes were initially prepared from an interest of their unique spectral properties. However, it has recently been found that they have interesting properties as synthetic intermediates.[3)] Compounds of this type are usually prepared by silylation of various acyl anion equivalents,[4)] appropriate 1-trialkylsilyl-1-alkanol derivatives also being employed for their preparation.[5,6)] This paper describes a new approach to the generation of acyl anion equivalents from silyl enol ethers of thiocarboxylic *S*-esters, by which acyltrimethylsilanes can be prepared as their silylated enols.

Reductive silylation of unsaturated organic compounds[7)] with alkali metal, *e.g.* sodium or potassium–sodium alloy, has been found to be a most useful method for the synthesis of organosilicon compounds.[8)] Carbon–sulfur linkages undergo cleavage with metallic lithium in the presence of an appropriate proton source. Such a procedure has frequently been employed for removal of sulfur group from various sulfides.[9)] It was thus expected that treatment of sulfides with alkali metal and chlorotrimethylsilane would make it possible to convert the carbon–sulfur linkages into the corresponding carbon–silicon ones through silylation of the initially generated carbanionic species. Such a transformation has recently been reported by using alkyl phenyl sulfides.[10,11)]

Studies were carried out on the application of this procedure to the synthesis of silyl enol ethers of acyltrimethylsilanes **1**, used also for the preparation of parent acyltrimethylsilanes and their α-functionalized derivatives.[12)] Silyl enol ethers **3** of thiocarboxylic *S*-esters were prepared by treating the corresponding esters **2** with lithium diisopropylamide (LDA) and then with chlorosilane.[13)] Of the esters examined, succinic and glutaric esters gave no silyl enol ethers because of a facile intramolecular cyclization reaction of the ester enolate anion generated initially. Except for the above cases, various *S*-methyl and *S*-phenyl esters gave the desired silylated enols **3** in excellent yields.

A preliminary study on the effect of substituent on thiocarboxylic acid in the reductive silylation has been carried out by using the silylated enols of *S*-methyl, *S*-ethyl, and *S*-phenyl 3-phenylpropanethioates **3**. From the results, enols of *S*-methyl ester **3** ($R^1=C_6H_5CH_2$, $R^2=H$, $R=CH_3$) and of *S*-phenyl ester **3** ($R^1=C_6H_5CH_2$, $R^2=H$, $R=C_6H_5$) were found to undergo the expected reductive silylation to afford the corresponding silyl enol ether **1** ($R^1=C_6H_5CH_2$, $R^2=H$) in good yields, while that of *S*-ethyl ester **3** ($R^1=C_6H_5CH_2$, $R^2=H$, $R=C_2H_5$) was almost inert under similar reaction conditions. In the reaction with *S*-phenyl ester derivative, (phenylthio)trimethylsilane was also formed as one of the side-products, which decreased through its conversion into phenyltrimethylsilane on prolonged reaction period. On the effect of the substituent on sulfur atom in reactions of this type, the following unique features of methyl and phenyl groups have been observed. (1) In the reductive silylation of sulfides, alkyl phenyl sulfides usually undergo a facile bond cleavage between alkyl and sulfur to give alkyltrimethylsianes together with (phenylthio)trimethylsilane, but not dialkyl sulfides.[10)] (2) In the reaction with disulfides, dialkyl and diphenyl disulfides afford the corresponding thiosilanes, but dimethyl disulfide gives bis(trimethylsilyl) sulfide exclusively.[11)]



Scheme 1.

The results indicate that the phenylthio group might enhance the cleavage of another bond with sulfur of **3**, giving the corresponding carbanionic species **4** directly. On the other hand, in the reactions with the *S*-methyl ester derivative, the linkage between sulfur and methyl seems to be cleaved preferentially to the bond of sulfur with the vinyl group of **3**. 1-Trimethylsiloxy-1-trimethylsilylthio-1-alkene **5** appears to be generated as an initial intermediate and then converted into the silylated enol **1** through the bond scission between sulfur and the vinyl group. This was confirmed by the following controll experiments. Treatment of **3** ($R^1=C_6H_5CH_2$, $R^2=H$, $R=CH_3$) with 5 equiv of potassium–sodium alloy in the presence of chlorotrimethylsilane, followed by aqueous work-up of the reaction mixture gave rise to the formation of the corresponding thiocarboxylic acid **6** as a major product (66%) together with **1** ($R^1=C_6H_5CH_2$, $R^2=H$) (29%), while the reaction with 8 equiv of the same reducing agent afforded **1** ($R^1=C_6H_5CH_2$, $R^2=$

a) 1 mmHg = 133.322 Pa.

H) in 87% yield accompanied by thiocarboxylic acid **6** (9%) under similar reaction conditions.

The phenylthio and trimethylsilylthio groups seem to make the cleavage of the bond between sulfur and 1-(trimethylsiloxy)vinyl group feasible, but neither ethylthio and its homologs.

Excess amount of the reducing agent should be used in order to achieve the transformation. Otherwise, the starting material is recovered in the reaction with *S*-phenyl ester derivative **3** (R=C_6H_5), or the corresponding thiocarboxylic acid is obtained in the case with *S*-methyl ester derivative **3** (R=CH_3) in a large amount, although theoretically required amounts should be 4 equiv of the reducing agent to 1 equiv of **3** even if the reaction proceeds through an initial removal of R groups of **3**. This is a great difference from acyloin condensation, which usually proceeds with almost stoichiometric amount of the reducing agent.[7a] We have used 8—9 equiv of sodium dispersion or potassium–sodium alloy to achieve an efficient conversion into **1**.

With sodium dispersion prepared by heating in tolune or xylene, the results are sometimes irreproducible probably because of the difference in the grade of dispersion of the reducing agent. Use of commercial sodium dispersion[14] could eliminate such difficulties to give the desired silylated enol **1** over 80% yields. The usual potassium–sodium alloy can advatageously be used, especially for large scale preparation, to give slightly higher yields in comparison with the commercial sodium dispersion.

As a solvent, benzene is preferable to tetrahydrofuran or ether. Some unidentified products are formed in noticeable amount when tetrahydrofuran is used.

When start from *S*-phenyl ester derivative **3**, (phenylthio)trimethylsilane and phenyltrimethylsilane were also formed as by-products, sometimes making it difficult to separate the desired silyl enol ether **1** by distillation.

In such a case, *S*-methyl ester derivative **3** (R=CH_3) would be preferable since the side-product, bis(trimethylsilyl) sulfide, can be removed by a simple hydrolytic work-up of the reaction mixture. A small amount of 1-trimethylsiloxy-1-trimethylsilylthio-1-alkene **5** sometimes still remains in the reaction mixture, but it can be removed by treatment with aq $NaHCO_3$ solution. GLPC and NMR analyses of the resulting crude mixtures show that they are pure enough for further synthetic use without purification. For example, acidic hydrolysis[5a,e] or treatment with chlorine [12a] affords the corresponding acyltrimethylsilane or its α-chlorinated derivative almost quantitatively.

Some functional groups are compatible with the present procedure (Table 2), no difficulty being encountered in the reductive silylation of the *S*-phenyl or *S*-methyl ester derivative **3** having olefinic or acetal group.

With the α-alkoxy derivative of **3**, a side reaction such as β-elimination of the intermediate **4** into the corresponding acetylenic ether might be expected. However, from a starting material such as **3** (R^1=

OC_2H_5, R^2=H, R=CH_3), the corresponding silyl enol ether **1** (R^1=OC_2H_5, R^2=H) could be obtained satisfactorily, the yield decreasing slightly.

In contrast, with the α-alkylthio or α-phenylthio derivative **3**, β-elimination seems to take place from the intermediate **4** predominantly, no corresponding product being isolated. The solution usually turns dark purple during the course of reductive silylation, but in these cases such kind of color change has never been observed.

In contrast to the inert behavior of dialkyl sulfides to the present reducing system, various thioacetals appear to undergo a facile bond cleavage between carbon and sulfur, and the reaction with *S*-methyl ester derivative **3** having diethyl thioacetal or ethylene thioacetal group resulted in the formation of complex mixtures.

Experimental

All boiling points are uncorrected. IR spectra were recorded on a Hitachi 260-10 spectrometer, and NMR spectra on a Hitachi R-24B spectrometer using dichloromethane or benzene as an internal standard.

Materials. Tetrahydrofuran (THF) and benzene were purified shortly before use by drying and distillation over sodium-benzophenone or sodium. Chlorotrimethylsilane was purified by distillation over sodium wire. Thiocarboxylic *S*-phenyl esters were prepared by treating the corresponding acyl chlorides with benzenethiol in the presence of triethylamine in ether. *S*-Methyl esters were prepared by treating dichloromethane solution of the corresponding acyl chlorides with aqueous solution of sodium methanethiolate in the presence of tetrabutylammonium bromide.

Preparation of Trimethylsilyl Enol Ethers of Thiocarboxylic S-Esters **3**. *General Procedure*: Lithium diisopropylamide (LDA) was prepared by treating diisopropylamine (2.47 g, 24.5 mmol) and butyllithium (14.9 ml of 1.64 molar hexane solution, 24.5 mmol) in tetrahydrofuran at −78 °C under argon atmosphere. An appropriate thiocarboxylic *S*-ester (20 mmol) in tetrahydrofuran (10 ml) was added over a period of 10 min to the resulting LDA solution at −78 °C. After further addition of chlorotrimethylsilane (3.26 g, 30 mmol) for 1 min, the resulting mixture was warmed up to room temperature and stirred at that temperature for 2h. The solvent was then removed *in vacuo* and the remaining residue diluted with hexane (20 ml). The salt deposited was filtered off by means of a hyflo super cell. Removal of the solvent from the filtrate followed by fractional distillation afforded the corresponding silyl enol ether **3**. Elementary compositions of the products were determined by means of high mass spectra with use of a Hitachi RMU-7M mass spectrometer. The results are given in Table 1.

Preparation of Trimethylsilyl Enol Ethers of Acyltrimethylsilanes. **1** *(A) Reductive Silylation of* **3** *with Sodium Dispersion and Chlorotrimethylsilane*: Sodium dispersion[14] (3.68 g of 50% paraffin contained, 0.08 g atom) was washed three times with hexane (10 ml) and once with benzene (10 ml). It was then mixed with benzene (35 ml) and introduced into a flask filled with argon with a hypodermic syringe. Chlorotrimethylsilane (8.68 g, 80 mmol) was then added. To the resulting solution was added a benzene (15 ml) solution of an appropriate silyl enol ether **3** (10 mmol) during the course of 10 min. After addition was complete, the reaction mixture was heated to refluxing for 2 h. The reaction mixture was filtered through the hyflo super cell and the filtrate concentrated *in vacuo*. The residual oil was washed with 1:1 aqueous tetrahydrofuran (10 ml) solution of satd sodium hydrogencarbonate, and extracted with hexane (20 ml). After drying over anhydrous Mg_2SO_4, removal of the solvent followed by fractional distillation gave the trimethylsilyl enol ether of the corresponding acyltrimethylsilane **1**. The results are given in Table 2.

Preparation of Trimethylsilyl Enol Ethers of Acyltrimethylsilanes **1**. *(B) Reductive Silylation of* **3** *with Potassium–Sodium Alloy and Chlorotrimethylsilane*: The alloy was prepared by heating a mixture of metallic potassium (1.56 g, 0.04 g atom) and sodium (0.92 g, 0.04 g atom) in a flask filled with argon To this was added a benzene (35 ml) solution of chlorotrimethylsilane (8.68 g, 80 mmol). To the resulting solution was added an appropriate trimethylsilyl enol ether of thiocarboxylic *S*-ester **3** (10 mmol) in benzene (15 ml) at room temperature over a period of 10 min. Gentle refluxing took place immediately. After addition was complete, the reaction mixture was stirred at room temperature for 4.5 h. The reaction mixture was then treated in a similar way to that described above, the trimethylsilyl enol ether of the corresponding acyltrimethylsilane **1** being obtained (Table 2).

Controll Experiment. The reaction was carried out with the silyl enol ether of *S*-methyl 3-phenylpropanethioate **3** (R^1=$C_6H_5CH_2$, R^2=H, R=CH_3) (2.53 g, 10 mmol) by using potassium (0.975 g, 0.025 g atom) and sodium (0.575 g, 0.025 g atom) in a similar way to that described in procedure (B). The reaction mixture was filtered off and the solvent was removed *in vacuo*. The residual oil was washed with 1:1 aqueous tetrahydrofuran (10 ml) solution of satd $NaHCO_3$ and extracted with hexane. From the extracts, 1-trimethylsiloxy-1-trimethylsilyl-3-phenyl-1-propene (0.817 g, 29%) was isolated by fractional distillation. The aqueous layer was acidified with dil HCl and extracted three times with ether (10 ml). Removal of the solvent followed by bulb-to-bulb distillation afforded 3-phenylpropanethiocarboxylic acid (1.101 g, 66%). The product was identified by the following spectral data. IR (neat); 2525, 1685, and 1055 cm^{-1}. NMR (CCl_4); δ 2.78 (s, 4H, $C_6H_5C\underline{H_2}$-$C\underline{H_2}CO$–), 4.23 (s, 1H, –S<u>H</u>), and 7.02 (s, 5H, aromatic protons). MS; M^+ 166

Branched-chain Sugars. XX. Kinetic Studies on the Epimerization of 1,2 : 5,6-Di-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose[1)]

Ken-ichi SATO, Kenji KOGA,† Hironobu HASHIMOTO, and Juji YOSHIMURA*

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midoriku, Yokohama 227

(Received February 15, 1980)

A study was made on the kinetics of the epimerization of 1,2: 5,6-di-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose in nitromethane to its 3-epimer in the presence of a small amount of sodium methoxide. The activation energy was found to be 75±8 kJ/mol, the intermediate in epimerization being 1,2: 5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose with use of the labelled compound.

Cyanohydrin and nitromethane syntheses have been widely used in the reaction of carbohydrate field for lengthening the carbon chain of reducing sugars. The stereoselectivity in the formation of two isomers is explicable on the basis of conformational grounds, since in the zigzag conformation the β-hydroxyl groups come into unfavorable eclipsed proximity in the 2,4-*erythro* isomer but not in the 2,4-*threo* isomer.[2)] However, alteration of the reaction conditions such as pH can sometimes reverse the selectivity.[3)] Recently, these reactions were applied to branched-chain sugar synthesis.[4)] Data accumulated indicate that one epimer or a mixture of epimers is obtained depending on the rate of epimerization of the kinetically-controlled product to thermodynamically stabler isomer.

In a previous paper a report was given on the composition of isomers in the reaction of nitromethane with 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**) in the presence of a slight excess of sodium ethoxide over the equivalent. It was found that the reaction at −78 °C for 30 min or at 20 °C for 3 min in the usual solvent gives exclusively 1,2:5,6-di-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose (**2**), while the reaction at 25 °C for 30 min only the corresponding D-*gluco* isomer (**3**).[5)] The results indicate that the kinetically-controlled product **2** epimerizes rapidly into **3** at room temperature. This paper deals with the measurement of activation energy and deduction of the pathway of epimerization.

Experimental

Solutions were evaporated under reduced pressure at bath temperature not excceding 50 °C. NMR spectra were taken with a JEOL SP-100 spectrometer in deuteriochloroform containing tetramethylsilane as an internal reference. TLC was carried out on glass plates coated with Kieselgel 60F 254 (Merck) equilibrated in the atmosphere before use. The solvent system employed was ether–hexane (1:1 v/v). R_f values of compounds **1**, **2**, and **3** were 0.07, 0.26, and 0.30, respectively.

*1,2:5,6-Di-*O*-isopropylidene-3-*C*-(nitromethyl-^{14}C)-α-D-allofuranose.* To a suspension of excess silver nitrite in ether (20 ml) was added with stirring a solution of methyl iodide [0.3 ml (5.0 mmol) having total radioactivity of 500 μCi, the Radiochemical center, Amersham] in ether (10 ml). The reaction mixture was stirred for 20 h in the dark at room temperature, and then filtered. The filtrate was carefully concentrated to give crude nitromethane (44 mg).

To a solution of **1** (250 ml) in ethanol (1.5 ml) was added a solution of nitromethane-^{14}*C* (44 mg) and sodium ethoxide (15 mg sodium metal in 3 ml ethanol) at a temperature below −30 °C. The reaction mixture was kept at 0 °C for 48 h and then half of the reaction mixture was neutralized with 60% acetic acid and extracted with chloroform. The resulting solution was washed with water and evaporated after addition of an authentic sample of non-labelled **2** (600 mg) to give a solid, which was recrystallized twice from ethanol. Specific activity of **2** (370 mg) thus obtained was 8.62 nCi/mg.

From the remaining half of the reaction mixture was obtained in a similar manner **2** (272 mg) having specific activity of 10.18 nCi/mg. The recrystallized needles were checked on TLC to show one spot (R_f 0.26).

*Epimerization of ^{14}C-Labelled **2** to **3**.* To a solution of nitromethane (0.9 ml, 16.7 mmol) and sodium ethoxide (4.5 mg, 19.6 mmol sodium in 0.9 ml ethanol) was added a solution of ^{14}C-labelled **2** (8.62 nCi/mg, 355 mg, 1.11 mmol) in ethanol (9 ml) at room temperature. The reaction mixture heated at 65 °C for 30 min showed the presence of **3** and a trace amount of **1** on TLC, was then neutralized with 60% acetic acid and extracted with chloroform. The extract was washed with water and evaporated to give crystals which were recrystallized twice from ethanol–hexane to give pure **3** (48 mg, R_f 0.30) of 0.585 nCi/mg.

If the activity of ^{14}C-labelled **2** was completely reduced with non-radioactive nitromethane added to the isomerization mixture, the activity of **3** should be 0.537 nCi/mg. Thus, the conversion ratio of the activity corresponded to 99% of the theoretical value.

A similar epimerization of **2** (272 mg, 0.853 mmol. 10.18 nCi/mg) in the presence of non-labelled nitromethane (266.5 mg, 4.37 mmol) gave pure **3** (44.9 mg, 1.56 nCi/mg), its conversion ratio of activity being 101% of the theoretical value.

*Measurement of Epimerization Rate of **2** into **3** at various Temperatures.* A solution **2** (200 mg, 0.627 mmol) in nitromethane (2 ml, 38 mmol) was added into nitromethane (2 ml) containing sodium methoxide (0.109 mmol in 0.25 ml methanol) at various temperatures controlled by means of a thermostat. Each 0.4 ml of the reaction mixture was pipetted out at appropriate intervals, acidified promptly with 60% acetic acid to stop the epimerization, and then extracted with chloroform. The chloroform layer was washed with water, and then evaporated. The extent of the isomerization in the residual solid was estimated from the ratio of the intensities of H-1 (δ 5.91 for **2**, 5.82 for **3**) and OH (δ 3.55 for **2**, δ 3.30 for **3**) protons in the NMR spectrum. Measurements were carried out at 0, 45, 65, and 95 °C (±0.1 °C). The results are summarized in Table 1. No isomerization was observed at 0 °C for 10 h.

TABLE 1. EPIMERIZATION RATE (%)

Temp (°C)	Reaction time (min)						
	0	2	4	6	10	30	60
45	0	0	0	0	3.5	9.6	19.3
65	0	0	6.5	10.8	20.0	44.6	67.8
95	0	17.2	36.7	53.5	69.0	92.5	94.0

Discussion

Both cyanohydrin and nitromethane reactions are reversible, epimeric ratios in the asymmetric induction depending on the reaction conditions. However, except for the dependency of reaction rate on pH,[6] few kinetic studies have been carried out.

Albrecht and Moffatt[7] presumed the dehydration of the initially formed **2** to 1,2: 5,6-di-*O*-isopropylidene-3-*C*-nitromethylene-α-D-*ribo*-hexofuranose (**4**), followed by readdition of water, to be the cause of the formation of a mixture of **2** and **3** from **1** in the presence of excess butoxide. They demonstrated the conversion of **2** into **4** by treatment with dimethyl sulfoxide and acetic anhydride at 20 °C for 24 h, and that of **4** into **3** by the base-catalyzed hydration. Contrary to their presumption, our experimental results with labelled **2** showed complete reduction of the specific activity with non-labelled nitromethane, indicating that the epimerization of **2** into **3** proceeds *via* **1** (Scheme 1). Bourgeois[8] reported the epimerization of the cyanohydrin of D-*allo* configuration from **1** isomerizes into D-*gluco* isomer in aqueous potassium cyanide at room temperature. The isomerization should proceed also *via* **1**, since no equivalent intermediate to **4** can be considered in this case.

It seems likely that this type of isomerization is common in the reaction of uloses with hydrogen cyanide or nitromethane under the alkaline conditions, though the factors to control the thermodynamic stability can not be predicted correctly. The reaction of methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranoside (**5**) and hydrogen cyanide in pyridine at room temperature gave a 21:1 mixture of methyl 4,6-*O*-benzylidene-3-*C*-cyano-2-deoxy-α-D-*ribo*-hexopyranoside (**6**) and its α-D-*arabino* isomer (**7**),[9] the predominancy of **6** being attributed to the hydrogen bonding between axial hydroxyl group at C-3 and methoxyl oxygen at C-1.[10] **7** was preponderantly obtained in the same reaction in ether and aqueous sodium hydrogencarbonate.[11]

Rosenthal and Ong[12] reported that the reaction of **5** and excess nitromethane in methanol in the presence of equimolar sodium methoxide at room temperature for 16 h gives methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*-hexopyranoside (**8**) and the D-*arabino* isomer (**9**) in 63 and 22% yields, respectively. In our experiments, however, the same reaction in chloroform in the presence of three equimolar triethylamine as a basic catalyst at room temperature for 72 h gave only **8** in 82% yield. This indicates that the isomerization rate is smaller in the presence of a weaker base. In fact, treatment of **8** in nitromethane with three equimolar sodium methoxide at room temperature for 1 h gave a 1:1 mixture of **8** and **9**.[13]

For measurement of the activation energy of the isomerization of **2** into **3**, the conditions described in Experimental were chosen. The plots of $\ln a/a-x$,

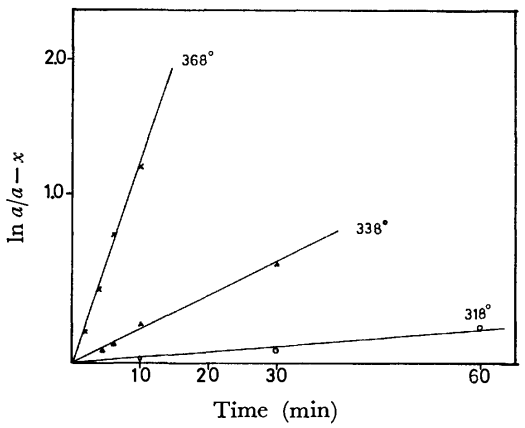

Fig. 1. Plots of a first-order rate equation for the epimerization of **2**.

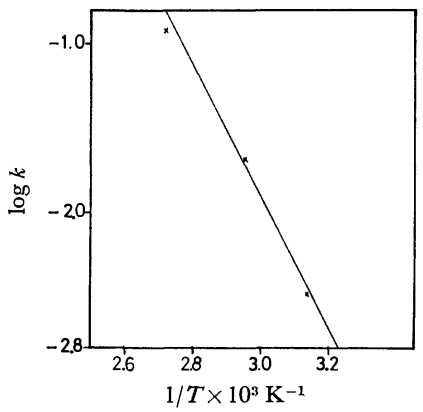

Fig. 2. Arrhenius plot.

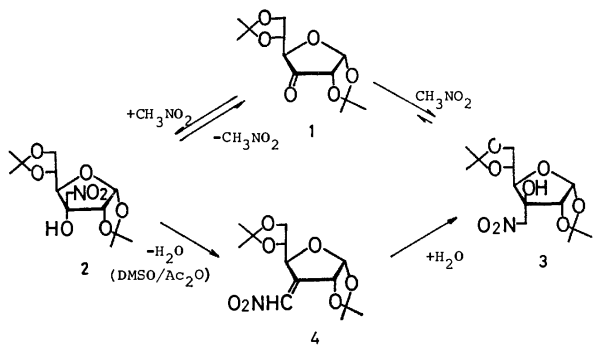
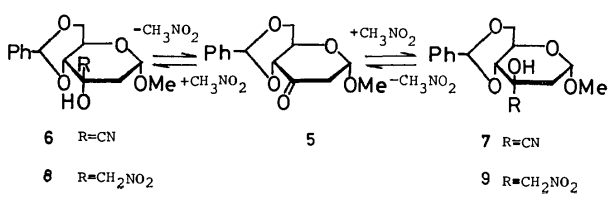


Scheme 1.



Scheme 2.

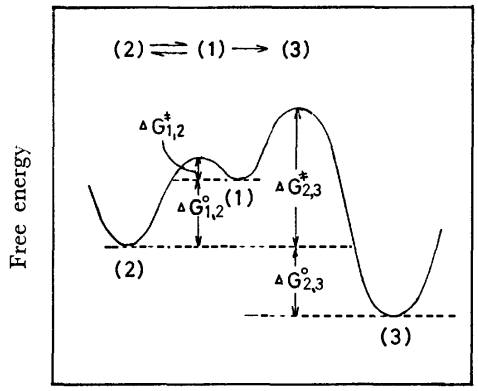


Fig. 3. Energy diagram between **1**, **2**, and **3**.

where x is the epimerization ratio, against time at three different temperatures were found to be linear at the initial stage, indicating that the reaction is of first-order (Fig. 1). The slopes of these lines give the times of half-conversion to be 5.65, 34.7, and 211 min at 95, 65, and 45 °C, respectively, and also the rate constant k. The plot of $\log k$ against the reciprocal of temperature shows a linear relationship (Fig. 2), its slope giving an activation energy of epimerization of 75±8 kJ/mol. The energy diagram of this raction system is given in Fig. 3. Since the reaction of **1** with nitromethane at −78 °C gave kinetically controlled product **2** selectively, $\Delta G^{*}_{1,2}$ value would be small as in the usual equilibration reaction. A comparison of bond energy between **1** and **2** indicates that $\Delta G^{\circ}_{1,2}$ value is *ca.* 50 kJ/mol, and the value of isomerization energy from **2** to **3**, $\Delta G^{*}_{2,3}$ we obtained is reasonable. Although $\Delta G^{\circ}_{2,3}$ value could not be measured, it would be larger than $\Delta G^{\circ}_{8,9}$ in the systems of **5**, **8** and **9**.

The present work was partially supported by a Grant-in-Aid for Encouragement of Young Scientists from the Ministry of Education, Science and Culture (No. 474244).

Functionalization of *trans*-Decalin. IV. A Stereoselective Synthesis of *dl*-β-Costol, *dl*-Arctiol, and the Related Eudesmane Type Sesquiterpenes

Sigeru Torii* and Tsutomu Inokuchi

Department of Industrial Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received February 15, 1980)

The efficient synthetic procedures to *dl*-β-costol (**1a**), *dl*-arctiol (**2**), and the related eudesmane type sesquiterpenes are described. *trans*-8,8-Ethylenedioxy-4aβ-methyldecalin-2α-ol (**6a**), prepared from *trans*-1,1-ethylenedioxy-4aβ-methyl-$\Delta^{6,7}$-octalin by epoxidation and subsequent reduction of the epoxy ring, was converted into **1a** as follows: (1) deacetalization of **6a** followed with mesylation, giving 2α-methylsulfonyloxy-4aβ-methyldecalin-8-one (**7b**), (2) condensation of **7b** with methyl sodiomalonate and subsequent Wittig reaction with methylenetriphenylphosphorane affording dimethyl (*trans*-4aβ-methyl-1-methylene-7β-decalinyl)malonate (**9**), (3) reduction of sodium salt of **9** with $NaAl(OCH_2CH_2OMe)_2H_2$. Oxidation of **1a** with PCC gave *dl*-β-costal. *dl*-Arctiol (**2**), structurally related to **1a**, was prepared from *trans*-5,5-ethylenedioxy-8aβ-methyldecalin-2-one. Introduction of two equatorial substituents, such as hydroxyl and 1-hydroxy-1-methylethyl groups at the C-2 and C-3 carbons of **2**, was carried out as follows: (1) methoxycarbonylation followed by methylation of the sodium salt of keto ester with MeLi, (2) subsequent reduction with lithium in liquid NH_3, giving *trans*-5,5-ethylenedioxy-3β-(1-hydroxy-1-methylethyl)-8aβ-methyldecalin-2α-ol (**14**), and (3) deacetalization of **14** followed by the reaction with methylenetriphenylphosphorane. *dl*-Eudesma-4(14),7(11)-dien-8-one was also prepared from **2** by oxidation with PCC followed by dehydration and subsequent isomerization of double bond.

In the course of our efforts to study the stereocontrolled synthesis of *dl*-dehydrofukinone[1] and *dl*-isopetasol,[2] we have found an efficient preparative way of *trans*-8,8-ethylenedioxy-4aβ-methyldecalin-2α-ol (**6a**)[1] and *trans*-5,5-ethylenedioxy-8aβ-methyldecalin-2-one (**11**)[2] from methyl 1-oxo-$\Delta^{6,7}$-octalin-4a-carboxylate.[3] The compounds **6a** and **11** are considered to be versatile intermediates[4] for eudesmane class sesquiterpenoid syntheses.[5] Herewith, we report the stereoselective syntheses of *dl*-β-costol (**1a**), *dl*-β-costal (**1b**), a major constituent of costus root oil[6] (*Saussurea lappa* Clark), *dl*-arctiol (**2**), found in the leaves of Gobo[7] (*Arctium lappa* L.), and *trans*-3-isopropylidene-8aβ-methyl-5-methylenedecalin-2-one (*dl*-eudesma-4(14),7(11)-dien-8-one) (**3**),[8] isolated from the essential oil of *Asarum caulescens* Maxim.

A key intermediate for the preparation of *dl*-β-costol (**1a**) must be 1,1-ethylenedioxy-4aβ-methyl-$\Delta^{6,7}$-octalin (**4**), prepared from methyl 1-oxo-$\Delta^{6,7}$-octalin-4a-carboxylate (65% overall yield).[1] Epoxidation of **4** with *m*-chloroperbenzoic acid at 0—5 °C gave the corresponding 2α,3α-epoxide **5** in 91% yield. Reductive epoxy ring opening at the C-3 position of **5** with lithium metal in liquid ammonia afforded the desired alcohol **6a** in 82% yield, in accordance with the axial ring opening rule.[9] The stereochemistry for the hydroxyl group of **6a** can be assigned by comparison of ^{13}C NMR and ^1H NMR results with those of the steroisomer **6c**, prepared from **6a** by oxidation with pyridinium chlorochromate (PCC)[10] and subsequent reduction with lithium aluminium hydride. The ^{13}C chemical shift values of the C-2 and C-8a carbons of **6a** appeared at 5.3 and 5.1 ppm higher fields than those of **6c**, due to the γ-effects,[11] are consistent with the assigned stereochemistry of the axial hydroxyl group of **6a**. In addition, the significant downfield shift of ^1H NMR signal due to the C-2 equatorial proton (δ 4.15) of **6a** as compared to the C-2 axial proton of **6c** (δ 3.58) is also consistent with the structures **6a** and **6c**.

The compound **6a** is nicely functionalized for the straightforward introduction of *exo*-methylene group as well as isopropenyl function at the C-8 and C-2 carbons. In particular, in the formation of the equatorial oriented substituent at C-7 carbon of **1**, the axial hydroxyl group of **6a** is expected to be easily replaced by a nucleophile, such as sodiomalonate. Thus, hydrolysis

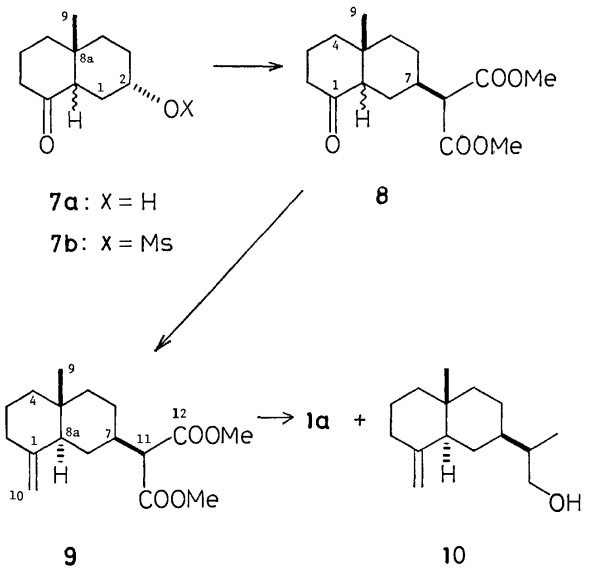
6a: X = OH, Y = H

6b: X = Y = O

6c: X = H, Y = OH

of **6a** with perchloric acid and subsequent treatment of **7a** with methanesulfonyl chloride in pyridine afforded the mesylate **7b** in 92% yield (from **6a**). The reaction of **7b** with methyl sodiomalonate in 1,2-dimethoxyethane (DME) provided the diester **8** in 82% yield. The Wittig reaction of **8** with a salt free solution of methylenetriphenylphosphorane[12] in benzene gave the *trans*-1-methylenedecalin **9** in 78% yield, accompanying with epimerization of the concomitant *cis*-fused decalin to its trans system.[13]

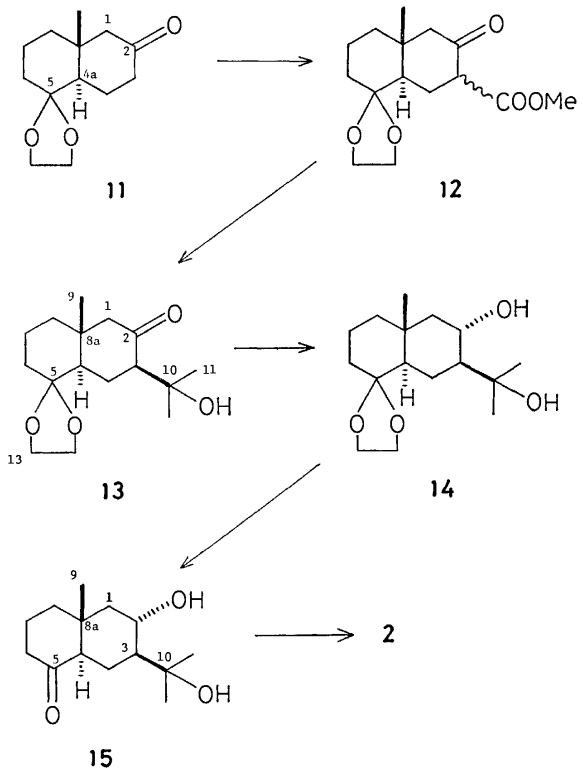
According to the slightly modified Marshall's procedure,[14] so called the malonic enolate reduction-elimination method, reduction of **9** with sodium bis(2-methoxyethoxy)aluminium hydride[15] and sodium hydride led to *dl*-β-costol (**1a**) in 74% yield along with the hydrogenated **10** (13%).[16] *dl*-β-Costal (**1b**) could be obtained in 84% yield by oxidation of *dl*-**1a** with PCC (Scheme 1).[6c,17]



Scheme 1.

We tried to prepare another eudesmane sesquiterpenes **2** and **3**, structurally related to **1**, from the masked diketone **11**.[2] One of the structural features of *dl*-arctiol (**2**) must be the C-2 and C-3 equatorial substituents. In connection with the synthesis of *dl*-isopetasol,[2] we have experienced that the reduction of the *trans*-decalin-2-one derivative with lithium metal in liquid ammonia provides the thermodynamically more stable *trans*-decalin-2α-ol, exclusively. The analogous reaction would be expected to proceed in the case of the ketone **13**, giving the 2α-alcohol **14**, a key precursor for the target **2**.

As shown in Scheme 2, the compound **11** is considered to be a suitable precursor for the preparation of the desired **13**. Methoxycarbonylation at the C-3 position of **11** with sodium hydride in dimethyl carbonate gave the keto ester **12** (84% yield) and subsequent methylation of **12** with methyllithium afforded **13**, smoothly. The stereochemistry of the C-3 substituent of **13** is considered to be a thermodynamically stable equatorial isomer.[18] The chemical shift value of the C-4a carbon (δ 50.4) of **13** is close to the C-4a

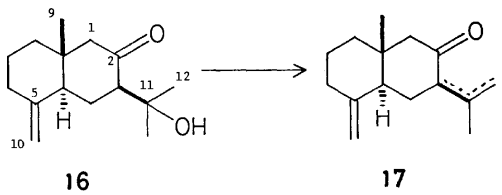


Scheme 2.

carbon (δ 50.1) of **11**, suggesting absence of the γ-effect between the C-3 substituent and the C-4a carbon of **13**.

Reduction of **13** with lithium metal in liquid ammonia provided the diol **14** in 84% yield. The tentative assignment of the equatorial hydroxyl group at C-2 of **14** is based on the comparison of ^{1}H NMR signals of the C-8a methyl group with those of **13**. In the *dl*-isopetasol synthesis,[2] we have encountered a significant 1,3-downfield shift[19] of signals due to the C-8a methyl protons of *trans*-decalin-2β-ol system in the value of 0.28 ppm compared to that of *trans*-decalin-2-one, in contrast to 0.06 ppm of the corresponding *trans*-decalin-2α-ol system. In the conversion of **13** into **14**, no remarkable shift on C-8a methyl protons was observed and the result would reveal absence of the shielding effect of C-2 axial hydroxyl group for the C-8a angular methyl protons of **14**. Hydrolysis of the ethylene acetal of **14** with perchloric acid and subsequent treatment of the ketone **15** with methylenetriphenylphosphorane afforded the desired **2** in 74% yield (from **14**), whose spectral data was identical with those of authentic specimen.[20]

dl-Eudesma-4(14),7(11)-dien-8-one (**3**), possessing a medical interest for a potential antiinflammatory activity,[21] was prepared from *dl*-arctiol (**2**) by oxi-



dation with PCC and subsequent dehydration of the ketol **16** on treatment with thionyl chloride in pyridine. Isomerization of the resulting *exo* and *endo* double bond isomers **17** by passing through an activated alumina column gave **3** in 41% yield (from **2**).[8a,17]

Experimental

Melting points and boiling points are uncorrected. IR spectra were determined with a JASCO IRA-I grating spectrometer. ^{1}H NMR (100 MHz) and ^{13}C NMR (25.05 MHz) spectra were measured with a JEOL Fourier transform spectrometer, Model FX-100. Samples were dissolved in $CDCl_3$ and signals are reported in parts per million (δ) downfield from the internal Me_4Si. Elemental analyses were performed in our laboratory.

trans-*2α,3α-Epoxy-8,8-ethylenedioxy-4aβ-methyldecalin (**5**).* To a solution of *m*-CPBA (199 mg, 1.15 mmol) in CH_2Cl_2 (5 ml) was added a solution of **4** (150 mg, 0.72 mmol) in CH_2Cl_2 (1 ml) at 0 °C. After being stirred at 0 °C for 1 h and 5 °C for 20 h, the mixture was quenched with water and taken up in CH_2Cl_2. The extract was washed with aqueous 10% $Na_2S_2O_3$ (3 ml), aqueous 5% NaOH, and brine, dried (Na_2SO_4), and concentrated. The residue was chromatographed (SiO_2, hexane–AcOEt 4:1) to give 147 mg (91%) of **5**: bp 75.0—77.0 °C/0.003 Torr (Kugelrohr); IR (neat) 1284, 1213, 1194, 1143, 1078, 1030, 901, 810, 797 cm^{-1}; ^{1}H NMR δ 0.86—2.24 (m, 11, CH_2, CH), 0.93 (s, 3, CH_3), 2.97—3.06 (m, 1, CH–O), 3.14—3.20 (m, 1, CH–O), 3.60—3.96 (m, 4, CH_2O); ^{13}C NMR δ 19.1 (t, C-6), 19.7 (q, C-9), 20.2 (t, C-1), 32.5 (s, C-4a), 35.4 (t, C-7), 40.5 (t, C-5), 41.9 (t, C-4), 42.9 (d, C-8a), 50.5 (t, C-2), 53.1 (d, C-3), 64.0 (t, C-10), 65.4 (t, C-11), 110.0 (s, C-8). Found: C, 69.72; H, 8.98%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

trans-*8,8-Ethylenedioxy-4aβ-methyldecalin-2α-ol (**6a**).* To a blue solution of lithium (35 mg, 5 mmol) in liquid NH_3 (35 ml) was added a solution of **5** (245 mg, 1.09 mmol) in DME (5 ml) at −78 °C. After being stirred for 1 h at −78 °C and for 1.5 h at −33 °C, the mixture was quenched with NH_4Cl (500 mg) at −78 °C, allowed to stand at room temperature until most of liquid NH_3 has removed. The residue was worked up in the usual manner. The crude product was chromatographed (SiO_2, hexane–AcOEt 2:1) to give 202 mg (82%) of **6a**: bp 104.0—106.5 °C/0.005 Torr (Kugelroher); IR (neat) 3400 (OH), 1095, 1063, 1030, 1000, 945, 914, 878 cm^{-1}; ^{1}H NMR δ 0.90—2.04 (m, 13, CH_2, CH), 0.98 (s, 3, CH_3), 1.90 (s, 1, OH), 3.64—4.01 (m, 4, CH_2O), 4.15 (m, 1, CH–O); ^{13}C NMR δ 17.0 (q, C-9), 19.5 (t, C-6), 27.3 (t), 28.1 (t), 35.2 (s, C-4a), 35.8 (t, C-7), 36.6 (t, C-4), 40.8 (t, C-5), 44.1 (d, C-8a), 64.0 (t, C-10), 65.3 (t, C-11), 66.5 (d, C-2), 110.3 (s, C-8). Found: C, 69.02; H, 9.97%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

trans-*8,8-Ethylenedioxy-4aβ-methyldecalin-2-one (**6b**).* To a suspension of $Py\cdot CrO_3\cdot HCl$ (449 mg, 1.68 mmol) and anhydrous AcONa (275 mg, 3.35 mmol) in CH_2Cl_2 (5 ml) was added a solution of **6a** (127 mg, 0.56 mmol) in CH_2Cl_2 (4 ml) at 0—5 °C. After being stirred for 30 min at 0—5 °C and for 3 h at room temperature, the mixture was diluted with ether (5 ml) and passed through a short silica gel column eluting with ether–AcOEt. The eluate was concentrated and the residue was chromatographed (SiO_2, hexane–AcOEt 3:1) to give 118 mg (94%) of **6b** as white solids: mp 65.5—66.6 °C: IR (Nujol) 1710 cm^{-1} (C=O); ^{1}H NMR δ 0.96—2.04 (m, 9, CH_2, CH), 1.16 (s, 3, CH_3), 2.12—2.32 (m, 4, $COCH_2$), 3.68—4.04 (m, 4, CH_2O); ^{13}C NMR δ 17.1 (q, C-9), 19.4 (t, C-6), 34.6 (s, C-4a), 35.0 (t), 36.8 (t), 37.9 (t), 39.8 (t, C-4), 41.4 (t, C-5), 49.8 (d, C-8a), 64.2 (t, C-10), 65.6 (t, C-11), 109.3 (s, C-8), 212.2 (s, C-2). Found: C, 69.74; H, 9.25%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

trans-*8,8-Ethylenedioxy-4aβ-methyldecalin-2β-ol (**6c**).* To a suspension of $LiAlH_4$ (15 mg, 0.40 mmol) in ether (0.5 ml) was added a solution of **6b** (17 mg, 0.076 mmol) in ether (0.5 ml) at 0—5 °C. After being stirred for 1 h at 5 °C and for 2 h at room temperature, the mixture was quenched with AcOEt and aqueous 5% $NaHCO_3$. The usual work-up gave 14 mg (82%) of **6c**: bp 106.0—107.5 °C/0.005 Torr (Kugelrohr); IR (neat) 3360 (OH), 1060, 1020, 958, 944, 887, 872, 852 cm^{-1}; ^{1}H NMR δ 0.99 (s, 3, CH_3), 1.08—2.02 (m, 13, CH_2, CH), 1.63 (br s, 1, OH), 3.58 (m, 1, CH–O), 3.72—4.01 (m, 4, CH_2O); ^{13}C NMR δ 17.8 (q, C-9), 19.5 (t, C-6), 29.3 (t), 31.1 (t), 34.6 (s, C-4a), 35.6 (t, C-7), 40.4 (t, C-4), 40.9 (t, C-5), 49.2 (d, C-8a), 64.2 (t, C-10), 65.4 (t, C-11), 71.8 (d, C-2), 109.8 (s, C-8). Found: C, 68.89; H, 9.77%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

*2α-Hydroxy-4aβ-methyldecalin-8-one (**7a**).* A solution of **6a** (175 mg, 0.77 mmol) and 70% $HClO_4$ (50 mg) in THF (5 ml) and H_2O (2.5 ml) was stirred for 12 h at 5 °C. The mixture was taken up in ether–benzene (1:1) and the extract was worked up in the usual manner to give 134 mg (95%) of **7a**: bp 114.5—115.5 °C/0.01 Torr (Kugelrohr); IR (neat) 3400 (OH), 1702 cm^{-1} (C=O); ^{1}H NMR δ 0.79, 0.98 (s, 3, CH_3), 1.08—2.48 (m, 13, CH_2, CH, OH), 2.72 (d, d, 1, J=11, 5 Hz, COCH), 4.15 (m, 1, CH–O). Found: C, 72.31; H, 10.09%. Calcd for $C_{11}H_{18}O_2$: 72.49; H, 9.95%.

*2α-Methylsulfonyloxy-4aβ-methyldecalin-8-one (**7b**).* To a solution of **7a** (154 mg, 0.85 mmol) in pyridine (3 ml) was added $MeSO_2Cl$ (200 mg, 1.74 mmol) at 0—5 °C. After being stirred for 20 h at 5 °C, the mixture was quenched with cold water and taken up in ether–benzene (1:1). The extract was worked up in the usual manner to give 214 mg (97%) of **7b** as white solids after chromatography (SiO_2, hexane–AcOEt 4:1): mp 91.5—93.5 °C; IR (Nujol) 1700 (C=O), 1354, 1170 cm^{-1}; ^{1}H NMR δ 0.80, 1.18 (s, 3, CH_3), 1.10—2.16 (m, 11, CH_2, CH), 2.32 (d, 2, J=7 Hz, $COCH_2$), 2.66 (d, d, 1, J=12, 2 Hz, COCH), 2.99 (s, 3, SO_2CH_3), 5.05 (br s, 1, CH–O); ^{13}C NMR (major peaks) δ 16.3 (q, C-9), 22.4 (t, C-6), 26.3 (t), 26.5 (t), 34.2 (t) 38.5 (q, SO_2CH_3), 39.0 (s, C-4a), 40.0 (t, C-4), 41.1 (t, C-5), 50.8 (d, C-8a), 79.0 (d, C-2), 211.3 (s, C-8). Found: C, 55.26; H, 7.88%. Calcd for $C_{12}H_{20}O_4S$: C, 55.37; H, 7.74%.

*Dimethyl (4aβ-Methyl-1-oxo-7β-decalinyl) malonate (**8**).* To a solution of dimethyl sodiomalonate prepared from dimethyl malonate (330 mg, 2.5 mmol) and NaH (55 mg, 2.3 mmol) in DME (3 ml) was added a solution of **7b** (105 mg, 0.40 mmol) in DME (1 ml). After being heated at reflux for 36 h, the mixture was quenched with 5% HCl at 0—5 °C and taken up in ether–benzene (1:1). The extract was washed with brine, dried (Na_2SO_4), and concentrated to give 97 mg (82%) of **8** as white solids after chromatography (SiO_2, hexane–AcOEt 3:1): mp 97.5—98.5 °C; IR (Nujol) 1750 (ester C=O), 1698 cm^{-1} (C=O); ^{1}H NMR δ 0.77, 1.13 (s, 3, CH_3), 1.10—2.40 (m, 14, CH_2 CH), 3.25 (d, 1, J=9 Hz, CHCOO), 3.72 (s, 6, OCH_3); ^{13}C NMR (major peaks) δ 16.8 (q, C-9), 22.5 (t, C-3), 24.7 (t), 25.0 (t), 37.5 (d, C-7), 39.2 (s, C-4a), 40.2 (t, C-2, C-4), 41.1 (t, C-5), 52.4 (q, OCH_3), 56.8 (d, C-8a), 57.7 (d, malonic ester CH), 168.7 (s, COO), 168.9 (s, COO), 211.7 (s, C-1). Found: C, 64.80; H, 8.29%. Calcd for $C_{16}H_{24}O_5$: C, 64.84; H, 8.16%.

*Dimethyl (*trans-*4aβ-Methyl-1-methylene-7β-decalinyl) malonate (**9**).* A salt free solution of methylenetriphenylphosphorane prepared from methyltriphenylphosphonium bromide (217 mg, 0.61 mmol) and $LiNH_2$ (95 mg, 2.43 mmol) in benzene (5 ml) was added dropwise to a solution of **8** (45 mg, 0.15 mmol) in benzene (1 ml). After being stirred for 20 h at room temperature, the mixture was quenched with aqueous 5% HCl and taken up in ether–benzene (1:1). The extracts were washed with brine, dried (Na_2SO_4), and concentrated. The residue was chromatographed (SiO_2, hexane–AcOEt 5:1) to give 38 mg (86%) of **9**: bp 101.0—102.5 °C/0.02 Torr (Kugelrohr); IR (neat) 3065, 1760 (ester C=O), 1738 (ester C=O), 1645 cm^{-1} (C=C); ^1H NMR δ 0.70 (s, 3, CH_3), 0.84—2.36 (m, 14, CH_2, CH), 3.25 (d, 1, J=9 Hz, CHCOO), 3.73 (s, 6, OCH_3), 4.35, 4.66 (br s, 2, H_2C=C); ^{13}C NMR δ 16.2 (q, C-9), 23.4 (t, C-3), 25.7 (t, C-6), 28.3 (t, C-8), 35.8 (s, C-4a), 36.7 (t, C-2), 38.4 (d, C-7), 40.5 (t, C-4), 41.7 (t, C-5), 49.3 (d, C-8a), 52.2 (q, OCH_3), 58.0 (d, C-11), 105.6 (t, C-10), 150.2 (s, C-1), 169.0 (s, C-12, C-13). Found: C, 69.35; H, 8.98%. Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%.

*dl-β-Costol (**1a**)* and trans-*7β-(2-Hydroxy-1-methylethyl)-4aβ-methyl-1-methylenedecalin (**10**).* A mixture of **9** (40 mg, 0.135 mmol) and NaH (25 mg, 1.04 mmol) in DME (3 ml) was heated at reflux for 24 h and to this solution was added a solution of 70% $NaAl(OCH_2CH_2OCH_3)_2H_2$ (540 mg, 1.87 mmol) in benzene. The mixture was heated at reflux for 1 h, quenched with MeOH at 0—5 °C, acidified with aqueous 5% HCl, and taken up in benzene–AcOEt (1:1). The extract was washed with brine, dried (Na_2SO_4), and concentrated. The residue was chromatographed (SiO_2, hexane–AcOEt 4:1) to give 22 mg (74%) of **1a** (R_f 0.82, hexane–ether 2:1) and 4 mg (13%) of **10** (R_f 0.69). **1a**: bp 79.5—81.0 °C/0.015 Torr (Kugelrohr) (lit,[6a] 150 °C/0.5 Torr, lit,[6d] 130 °C/0.3 Torr); IR (neat) 3300 (OH), 3060 (HC=C), 1645 (C=C), 1438, 1407, 1380, 1175, 1150, 1055, 1043, 1030, 1022, 885 cm^{-1}; ^1H NMR δ 0.74 (s, 3, CH_3), 0.84—2.41 (m, 15, CH_2, CH, OH), 4.13 (br s, 2, CH_2O), 4.41, 4.69 (br s, 2, H_2C=C), 4.93, 5.03 (br s, 2, H_2C=C); ^{13}C NMR δ 16.4 (q, C-9), 23.5 (t, C-3), 27.3 (t, C-6), 30.0 (t, C-8), 36.0 (s, C-4a), 36.8 (t, C-2), 41.2 (d, C-7), 41.7 (t, C-4), 41.9 (t, C-5), 50.0 (d, C-8a), 65.3 (t, C-13), 105.4 (t, C-10), 107.8 (t, C-12), 150.7 (s, C-1), 154.1 (s, C-11).

10: [6d] Bp 81.5—83.0 °C/0.01 Torr (Kugelrohr); IR (neat) 3300 (OH), 3060, 1644 (C=C), 1440, 1378, 1057, 1039, 884 cm^{-1}; ^1H NMR δ 0.71 (s, 3, CH_3), 0.85—2.40 (m, 19, CH_3, CH_2, CH, OH), 3.35—3.76 (m, 2, CH_2O), 4.39, 4.68 (br s, 2, H_2C=C).

*dl-β-Costal (**16**).* To a suspension of $Py\cdot CrO_3\cdot HCl$ (60 mg, 0.28 mmol) and AcONa (37 mg, 0.45 mmol) in CH_2Cl_2 (1 ml) was added a solution of **1a** (22 mg, 0.1 mmol) in CH_2Cl_2 (1 ml) at 0—5 °C. After being stirred for 0.5 h at 0—5 °C and for 3 h at room temperature, the mixture was diluted with ether. The usual work-up gave 16 mg (73%) of **1b** after chromatography (SiO_2, hexane–AcOEt 3:1): bp 53—57 °C/0.02 Torr (Kugelrohr) (lit,[6d] 110 °C/0.3 Torr); IR (neat) 3070, 2700, 1698 (C=O), 1646 (C=C), 1628 (C=C), 1440, 1380, 1208, 1150, 922, 918, 888 cm^{-1}; ^1H NMR δ 0.75 (s, 3, CH_3), 1.10—2.70 (m, 14, CH_2, CH), 4.36, 4.69 (br s, 2, H_2C=C), 5.98, 6.28 (s, 2, H_2C=C), 9.54 (s, 1, CHO); ^{13}C NMR δ 16.4 (q, C-9), 23.5 (t, C-3), 27.0 (t, C-6), 29.5 (t, C-8), 35.9 (s, C-4a), 36.5 (t, C-2), 36.9 (d, C-7), 41.0 (t, C-4), 41.9 (t, C-5), 49.8 (d, C-8a), 105.6 (t, C-10), 133.0 (t, C-12), 150.8 (s, C-1), 155.5 (s, C-11), 194.9 (s, C-13).

Methyl trans-*5,5-Ethylenedioxy-8aβ-methyl-2-oxodecalin-3-carboxylate (**12**).* A mixture of **11**[2] (210 mg, 0.94 mmol), dimethyl carbonate (270 mg, 3.0 mmol), and NaH (37 mg, 1.54 mmol) was heated at 60—65 °C for 3 h and quenched with aqueous 50% MeOH at 0—5 °C. The mixture was extracted with benzene–AcOEt (1:1) and the extract was washed with aqueous $NaHCO_3$, dried (Na_2SO_4), and concentrated. The residue was chromatographed (SiO_2, hexane–AcOEt 2:1) to give 223 mg (84%) of **12**: bp 137.0—139.0 °C/0.03 Torr (Kugelrohr); IR (neat) 1742 (ester C=O), 1710 (C=O), 1655, 1618 cm^{-1}; ^1H NMR δ 0.89—1.96 (m, 7, CH_2, CH), 0.99 (s, 3, CH_3), 2.04—2.50 (m, 4, CH_2), 3.76 (s, 3, OCH_3), 3.90—4.04 (m, CH_2O, COCH), 12.06 (s, OH). Found: C, 63.95; H, 8.03%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

trans-*5,5-Ethylenedioxy-3β-(1-hydroxy-1-methylethyl)-8aβ-methyldecalin-2-one (**13**).* To a suspension of NaH (50 mg, 2.1 mmol) in THF (5 ml) was added a solution of **12** (200 mg, 0.71 mmol) in THF (5 ml) at 0 °C. When H_2 evolution was complete, an ethereal solution of 1.4 M MeLi (3.1 ml, 4.3 mmol) was added at 5 °C. After being stirred at reflux for 12 h, the mixture was quenched with aqueous 10% NH_4Cl at 0—5 °C and taken up in AcOEt. The extract was washed with aqueous $NaHCO_3$, dried (Na_2SO_4), and concentrated. The residue was chromatographed (SiO_2, hexane–AcOEt 1:1) to give 27 mg of **11** and 146 mg (73%) of **13** as white solids: mp 87.0—88.5 °C; IR (Nujol) 3480 (OH), 1688 (C=O), 1290, 1228, 1172, 1098, 1074, 1051, 1032, 952, 855 cm^{-1}: ^1H NMR δ 0.93 (s, 3, CH_3), 1.10—2.48 (m, 12, CH_2, CH), 1.22, 1.26 (s, 6, CH_3), 3.68—4.02 (m, 4, CH_2O), 4.10 (br, 1, OH); ^{13}C NMR δ 18.6 (q, C-9), 19.5 (t, C-7), 23.7 (s, C-8a), 25.5 (q, C-11), 28.6 (q, C-12), 35.6 (t, C-4), 39.7 (s, C-8a), 40.4 (t, C-8), 50.4 (d, C-4a), 58.8 (t, C-1), 59.1 (d, C-3), 64.4 (t, C-13), 65.6 (t, C-14), 71.8 (s, C-10), 109.8 (s, C-5), 214.7 (s, C-2). Found: C, 68.19; H, 9.41%. Calcd for $C_{16}H_{26}O_4$: C, 68.06; H, 9.28%.

trans-*5,5-Ethylenedioxy-3β-(1-hydroxy-1-methylethyl)-8aβ-methyldecalin-2α-ol (**14**).* To a blue solution of lithium (19 mg, 2.71 mmol) in liquid NH_3 (20 ml) was added a solution of **13** (115 mg, 0.41 mmol) in ether (3 ml), EtOH (36 μl), and dioxane (0.5 ml) at −78 °C. After being stirred for 30 min at −78 °C and for 1 h at −33 °C, the mixture was quenched with NH_4Cl (200 mg) at −78 °C and allowed to stand at room temperature until the most of liquid NH_3 had evaporated. The residue was taken up in AcOEt–benzene and worked up in the usual manner to give 101 mg (87%) of **14** as while crystals after chromatography (SiO_2, hexane–AcOEt 1:1): mp 143.5—145.0 °C; IR (Nujol) 3330 (OH), 1380, 1174, 1088, 1037, 907 cm^{-1}; ^1H NMR δ 0.97 (s, 3, CH_3), 1.04—1.90 (m, 12, CH_2, CH), 1.26, 1.28 (s, 6, CH_3), 2.39 (br, 2, OH), 3.60—3.94 (m, 4, CH_2O), 4.02 (d, d, d, 1, J=10, 5, 5 Hz, CH–O); ^{13}C NMR δ 18.9 (q, C-9), 19.2 (t, C-7), 21.3 (t, C-4), 23.9 (q, C-10), 30.2 (q, C-12), 35.5 (t, C-6), 36.1 (s, C-8a), 40.4 (t, C-8), 50.8 (d, C-4a), 51.5 (t, C-1), 54.1 (d, C-3), 64.1 (t, C-13), 65.2 (t, C-14), 68.9 (d, C-2), 75.2 (s, C-10), 109.9 (s, C-5). Found: C, 67.55; H, 10.08%. Calcd for $C_{16}H_{28}O_4$: 67.57; H, 9.92%.

trans-*2α-Hydroxy-3β-(1-hydroxy-1-methylethyl)-8aβ-methyldecalin-5-one (**15**).* A mixture of **14** (53 mg, 0.19 mmol) and 70% $HClO_4$ (20 mg) in THF (3 ml) and H_2O (1.5 ml) was stirred for 12 h at 5—10 °C and taken up in CH_2Cl_2. The extract was worked up in the usual manner to give 38 mg (85%) of **15** as while crystals after chromatography (SiO_2, hexane–AcOEt 1:1): mp 164.5—165.5 °C (benzene); IR (Nujol) 3250 (OH), 1710 cm^{-1} (C=O); ^1H NMR δ 0.80 (s, 3, CH_3), 1.06—2.00 (m, 10, CH_2, CH), 1.28 (s, 6, CH_3), 2.22—2.40 (m, 3, CH_2CO, CHCO), 2.80 (br s, 2, OH), 3.97 (d, d, d, 1, J=10, 5, 5 Hz, CH–O); ^{13}C NMR δ 17.9 (q, C-9), 22.2 (t, C-4, C-7), 23.8 (q, C-11), 30.4 (q, C-12),

Production of Furan by Vapor-phase Oxidation of Crotonaldehyde Using Heteropoly Compounds as Catalysts

Mamoru Ai,* Tian-hsi Tsai, and Atsumu Ozaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received February 19, 1980)

The synthesis of furan by direct vapor-phase oxidation of crotonaldehyde has been studied. It was found that heteropoly compounds such as 12-molybdophosphoric acid are more effective than the mixed oxide (MoO_3–P_2O_5, P/Mo=1/12) as catalyst for furan formation, and that the cesium salt of 12-molybdophosphoric acid with a Cs/Mo atomic ratio of 1/12 is more effective than the 12-molybdophosphoric acid catalyst. The rate of furan formation increases with increase in steam concentration in the feed, but is nearly independent of oxygen and crotonaldehyde concentrations. The yield of furan increases by decreasing the crotonaldehyde concentration, attaining 60 mol% at a concentration of 0.17 vol% in the feed. The conversion of crotonaldehyde at maximum yield is 90—95%.

Furan is a raw material for tetrahydrofuran which is in great demand as a solvent and a starting material for polymer compounds. Tetrahydrofuran has been manufactured by three methods: the furfural process, hydrolysis of 1,4-dichloro-2-butene, and hydrogenation of maleic anhydride. Attempts were also made to obtain furan by direct oxidation of butadiene.[1] Several reports have appeared on the oxidation of crotonaldehyde, but they deal exclusively with the formation of maleic anhydride.[2–5]

One of us (M.A.) reported that furan is an intermediate in the oxidation of butene, butadiene, or crotonaldehyde to form maleic anhydride,[6] and found that the MoO_3–P_2O_5 (P/Mo atomic ratio=*ca.* 1/10) catalyst is effective for furan synthesis from butadiene or crotonaldehyde.[7,8] The effects of reaction variables on the yield of furan were studied using the MoO_3–P_2O_5 catalysts, where the best result for furan yield is 30—35 mol % in the oxidation of crotonaldehyde.[8]

Recently, heteropoly compounds were found to be effective for furan formation from butadiene,[9] suggesting that the heteropoly compounds are also effective for the oxidation of crotonaldehyde to furan.

In this study, we have directed our attention to furan formation in the oxidation of crotonaldehyde and attempted to clarify the effects of catalyst and reaction variables, since no detailed information is available on the oxidation reaction.

Experimental

Catalysts. The following three catalysts were used. (A) Heteropoly acid (HPA) catalyst: 136 g of 12-molybdophosphoric acid (Kanto Chemical Co. Inc.) was dissolved in water and 0.50 l (*ca.* 190 g) of 10—20 mesh pumice from volcanic rocks was mixed with the solution, the mixture then being evaporated with vigorous stirring below 200 °C. (B) MoO_3–P_2O_5 catalyst: 80 g of $(NH_4)_6Mo_7O_{24}\cdot 2H_2O$ and 4.6 g of 85 wt% H_3PO_4 were dissolved in hot water (P/Mo atomic ratio=1/12), and 0.30 l of the pumice was added: the mixture was then evaporated. (C) Cs–HPA catalyst: 9.75 g of Cs_2CO_3 was added to the 12-molybdophosphoric acid solution (Cs/Mo atomic ratio=1/12), the subsequent procedure being the same as that for (A). All the catalysts were calcined at 380 °C for 4—5 h in a stream of oxygen. The surface areas measured by the BET method using nitrogen at −196 °C, were (A) 2.1, (B) 9.5, and (C) 3.4 m^2/g.

Reaction Procedures. Oxidation of crotonaldehyde was carried out in the conventional continuous-flow system under atmospheric pressure. The reactor, made of a steel tube lined with aluminum, length 50 cm, i.d. 1.8 cm, was mounted vertically and immersed in a molten lead bath. The oxygen–nitrogen mixed gas was fed from the top of the reactor, liquid crotonaldehyde and water being introduced into the preheater section by means of two injection syringe pumps (micro feeders). The total flow rate was kept constant at 1.0 l/min. The amount of catalyst used was 20 g and the concentration of crotonaldehyde, oxygen, steam, and nitrogen 1.66, 6.6, 7.6, and 84.1 vol%, respectively. The effluent gas from the reactor was led successively into four chilled water-scrubbers in order to recover the water soluble compounds. The contents (*ca.* 300 ml) of the water-scrubbers were collected every 1 h. Maleic anhydride was analyzed by titration with 0.10 mol dm^{-3} NaOH, and the other compounds by gas chromatography. The inlet and exit gases were intermittently analyzed. In order to measure the catalytic activity in stationary state, the data were taken more than 7 h after the start of each run.

Results

Comparison of Performance of Catalysts. Since the Cs–HPA catalyst gives a good yield of furan in the oxidation of butadiene,[9] the actions of the HPA, MoO_3–P_2O_5, and Cs–HPA catalysts in the oxidation of crotonaldehyde were examined at different temperatures. The results are summarized in Fig. 1.

The heteropoly compound, HPA catalyst, is effective for furan formation to a greater extent than the mixed oxide, the MoO_3–P_2O_5 catalyst. Addition of a small amount of Cs^+ to the heteropoly acid promotes furan formation. The results are in line with those obtained in the oxidation of butadiene to give furan.[9]

Since a good result is obtained with the Cs–HPA catalyst, the effects of reaction variable on the reaction rates and the furan yield were studied using only the Cs–HPA catalyst.

Effect of Temperature on the Reaction Products. The main products were furan, maleic anhydride, CO, CO_2, and unidentifiable polymer compounds. The amounts of other products were negligibly small. The yields of the main products are plotted as a function

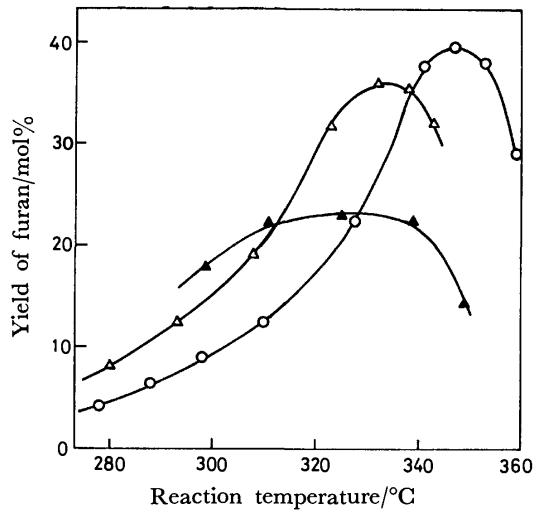

Fig. 1. Comparison of the performances of the catalysts.
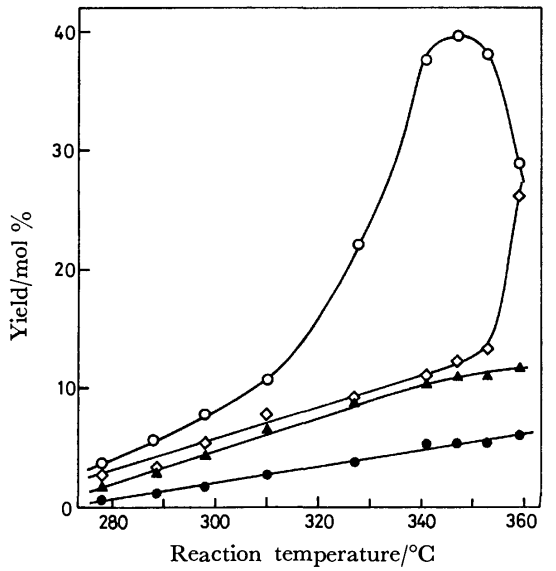
Catalyst: (△)=HPA, (▲)=MoO_3–P_2O_5, (○)=Cs–HPA.



Fif. 2. Product distribution in the oxidation of crotonaldehyde over the Cs–HPA catalyst.
(○)=furan, (◇)=maleic anhydride, (●)=1/4 CO, (▲)=1/4 CO_2.

of the raction temperature in Fig. 2.

Below 310 °C, the yield of each product increases in proportion to temperature rise, indicating that the products are formed competitively but not consecutively. However, at *ca.* 347 °C, the yield of furan attains a maximum value of 40 mol % when the conversion is estimated to be *ca.* 90—95%. The yield decreases above this temperature accompanied by a sharp increase in the yield of maleic anhydride. The results suggest that maleic anhydride is formed also by the oxidation of the produced furan. The yield of maleic anhydride attains *ca.* 55 mol% at 98—100% conversion

Effect of Contact-time on the Yields of Products. The change in the yields of products with the progress of reaction was studied at 346 °C by changing the

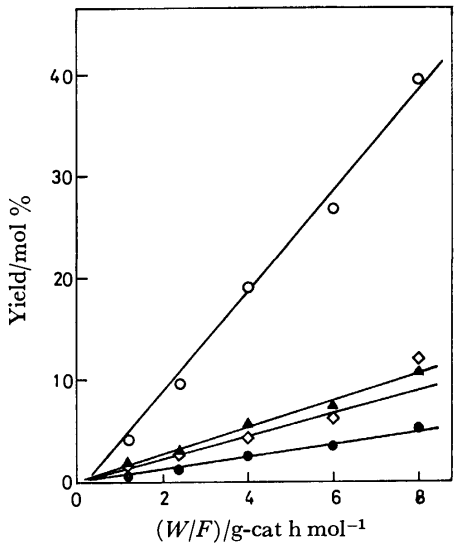


Fig. 3. Yields of products as a function of the contact time (W/F).
Temperature=346 °C, (○)=furan, (◇)=maleic anhydride, (●)=1/4 CO, (▲)=1/4 CO_2.

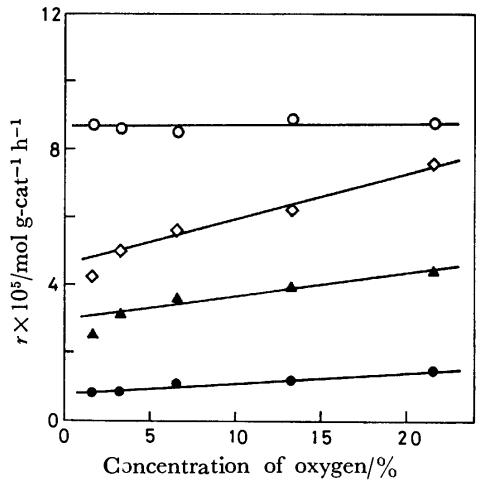

Fig. 4. Effect of oxygen concentration on the reaction rates.
Temperature=278 °C, (○)=furan, (◇)=maleic anhydride, (●)=1/4 CO, (▲)=1/4 CO_2.

amounts of catalyst from 3 to 20 g (Fig. 3). Furan, maleic anhydride, CO, and CO_2 are produced in line with the results shown in Fig. 2, suggesting zero order dependence on the crotonaldehyde concentration.

Effect of Oxygen Concentration on the Reaction Rates. The reaction was carried out by changing the oxygen concentration in the feed gas from 1.6 to 21.6 vol%. Following the principle of the differential reactor, the conversion was held at a low level. The rates of furan, maleic anhydride, CO, and CO_2 formation measured at 278 °C are plotted as a function of oxygen concentration in Fig. 4.

The rate of furan formation is independent of oxygen concentration, the rates of maleic anhydride, CO, and CO_2 formation increasing slightly with increase in the oxygen concentration.

Effect of Crotonaldehyde Concentration on the Reaction Rates. The concentration of crotonaldehyde was

varied in the range 0.34—1.66 vol%. The initial rates of formation for the main products are shown in Fig. 5. All the rates increases slightly with increase in the crotonaldehyde concentration.

Effect of Crotonaldehyde Concentration on the Furan Yield. The yield of furan was measured at five different crotonaldehyde concentrations at various temperatures. The results are shown in Fig. 6. Since the reaction order with respect to the crotonaldehyde concentration is very low (Fig. 5), it is reasonable to assume that the higher the initial crotonaldehyde concentration, the higher the temperature required to achieve sufficient conversion. The maximum yield of furan decreases with increase in the crotonaldehyde concentration. The yield of furan attains 60 mol% when the crotonaldehyde concentration is very low (0.17 vol%), becoming 40 mol% at a 1.66 vol% concentration.

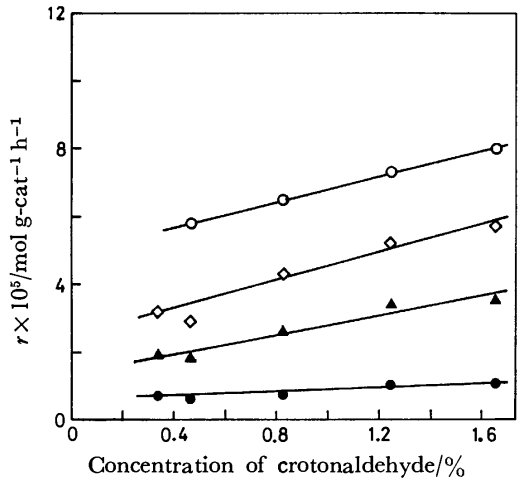

Fig. 5. Effect of crotonaldehyde concentration on the reaction rates.
Temperature=278 °C, (○)=furan, (◇)=maleic anhydride, (●)=1/4 CO, (▲)=1/4 CO_2.

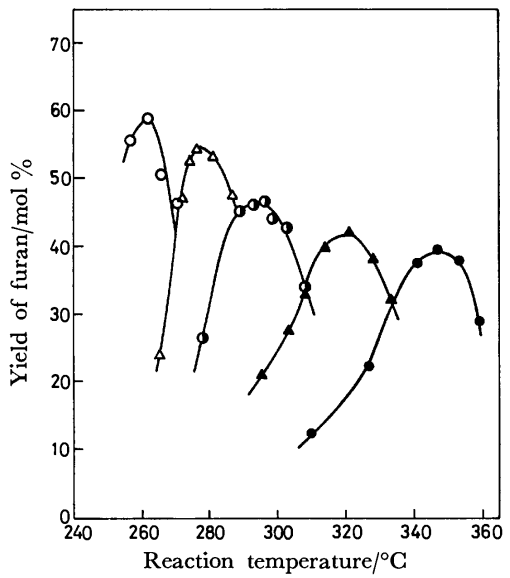

Fig. 6. Effect of crotonaldehyde concentration on the yield of furan.
Concentration of crotonaldehyde: (○)=0.17, (△)=0.25, (◑)=0.46, (▲)=0.83, (●)=1.66% in the feed.

Effect of Steam Concentration on the Reaction Rates. The effect of steam concentration on the initial rate for each product is shown in Fig. 7. The rates increase almost linearly with steam concentration, the slopes becoming more gentle at higher steam concentrations. The results are in line with those obtained in the oxidation of olefins as well as of furan over 12-molybdophosphoric acid catalyst.[10]

Effect of Steam on the Yield of Furan. The effect of steam concentration on the yield of furan was also examined. The presence of steam increases the yield of furan as well as the catalytic activity. (Fig. 8).

Discussion

The Cs–HPA catalyst as well as the HPA and MoO_3–P_2O_5 catalysts are acidic. Thus, they are active for

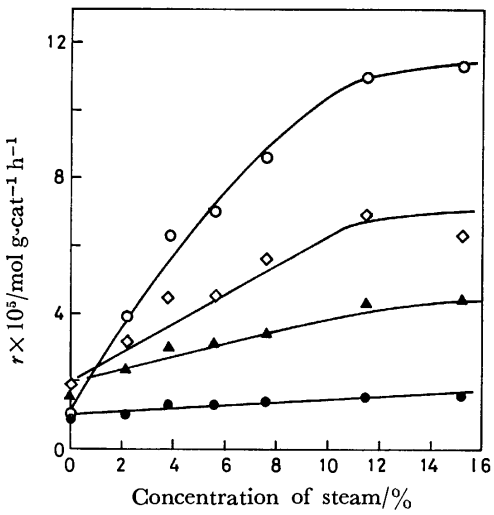

Fig. 7. Effect of steam concentration on the reaction rates.
Temperature=278 °C, (○)=furan, (◇)=maleic anhydride, (●)=1/4 CO, (▲)=1/4 CO_2.

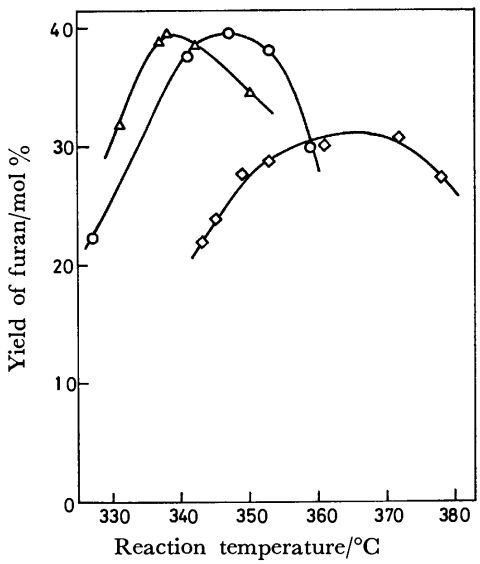

Fig. 8. Effect of steam on the yield of furan.
Concentration of steam: (◇)=3.8, (○)=7.6, (△)=15.1% in the feed.

oxidation of such basic compounds as butadiene, crotonaldehyde and furan but inactive for acidic compounds such as maleic anhydride. Their selectivity to maleic anhydride from the basic reactants at high conversion attains *ca.* 50—60 mol%.

Since furan is an intermediate product, the yield is affected by two factors:[6,11] (i) relative reactivity of furan to crotonaldehyde, and (ii) affinity of the catalyst for furan; this indicates that the stronger the furan adsorption, the larger the portion of the adsorbed furan species which goes to the next oxidation, without being desorbed to the gas phase.

The yield of furan attains a maximum at a 90—95% crotonaldehyde conversion, the catalysts being markedly more active for the oxidation of crotonaldehyde than that of furan.

On the other hand, the results indicate that the reaction rate markedly increases with increase in the steam concentration but is almost independent of the concentration of both oxygen and crotonaldehyde. This suggests that the reaction is mainly restricted by the desorption of oxidation products to gas phase, in contrast with the oxidation of butadiene which is of first order with respect to oxygen concentration.[10] The effect of steam addition on the yield of furan can be explained by assuming that the steam acts to remove the adsorbed furan.[10]

The effect of cesium addition to the heteropoly acid actalyst can also be understood on the same assumption. The addition of a basic compound such as cesium ion reduces the acidic property of catalyst and the affinity for furan, facilitating the desorption of adsorbed furan and increasing the yield of furan.

Since the character of mixed oxide has not yet been defined, it is difficult to understand the difference in catalytic behavior between the heteropoly compounds and the MoO_3–P_2O_5 mixed oxide catalyst.

Conclusion

The cesium salt of 12-molybdophosphoric acid with a Cs/Mo atomic ratio of 1/12 is an excellent catalyst for furan production by direct oxidation of crotonaldehyde as in the case of furan formation from butadiene. Reaction conditions favorable for furan formation are higher steam concentration and lower crotonaldehyde concentration. The maximum furan yield is attained at a 90—95% crotonaldehyde conversion.

Reduction by a Model of NAD(P)H. 27. Role of Bivalent Metal Ion in the Reduction of 2-Acylpyridines and 1-Acylisoquinolines

Atsuyoshi Ohno,* Shinro Yasui, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received February 22, 1980)

Reductions of 1-acetylisoquinoline (AQ), 1-benzoylisoquinoline (BQ), and isoquinoline-1-carbaldehyde have been studied kinetically and the results are compared with those of 2-acetylpyridine (AP), 2-benzoylpyridine (BP), and pyridine-2-carbaldehyde. Equilibrium constants for complexes between these substrates and zinc ion have also been studied. Kinetic deuterium isotope effects for AQ and BQ are smaller than the corresponding product isotope effects, respectively, whereas those for AP and BP are identical. The results are discussed in terms of stability and reactivity of intermediate radical-ion pair, and it is concluded that strong coordination of a metal ion onto the reaction site of a substrate facilitates the complexation but interferes the reduction.

In a previous paper of this series, it was reported that both substrate–metal ion and coenzyme model–metal ion complexes are reacting species in the zinc ion-catalyzed reductions of 2-acetylpyridine (AP) and 2-benzoylpyridine (BP) with 1-benzyl-1,4-dihydronicotinamide (BNAH).[1] Namely, computor-assisted simulation of the kinetics has revealed a key role of the metal ion-complexes on explanation of unusual behavior of metal ion in the reduction of 2-acylpyridines.[2,3]

However, relative importance between a substrate–metal ion and BNAH–metal ion complexes has not been discussed yet and the role of metal ion has still remained ambiguous. In order to obtain further insight into relative importance of complexes, we studied kinetics for the reductions of 1-acetylisoquinoline (AQ), 1-benzoylisoquinoline (BQ), and isoquinoline-1-carbaldehyde (QCA) with BNAH in acetonitrile at 50 °C in the presence of zinc perchlorate, and the results were compared with those of the corresponding pyridine derivatives; AP, BP, and pyridine-2-carbaldehyde (PCA).

PCA; R=H

It is expected that 1-acylisoquinolines and 2-acylpyridines form complexes with zinc ion in a different manner because isoquinoline system has bulky B-ring which would distort the interaction with zinc ion, whereas pyridine system does not. On elucidation of the mechanism of reductions, the difference mentioned above may give a crucial information.

Results and Discussion

Complex Formation. AQ, BQ, QCA, and PCA form complexes with zinc ion. The complexation constant, K_S, defined by Eq. 2

$$S + M \overset{K_S}{\rightleftharpoons} SM \qquad (2)$$

S; a substrate, M; zinc ion

was determined in acetonitrile at 50 °C spectrophotometrically[4] for each substrate and the results are summarized in Table 1 together with those of AP and BP.[1,5] It is known that the complexation constant for BNAH, K_B, defined by Eq. 3 is 500 M^{-1} under the same conditions.[1,5]

$$B + M \overset{K_B}{\rightleftharpoons} BM \qquad (3)$$

B; BNAH, M; zinc ion

It has been reported that the pyridine-ring nitrogen and carbonyl oxygen in 2-acylpyridines are oriented in *E* each other in liquid phase.[6] 1-Acylisoquinolines are also expected to have similar conformations. When the isoquinoline-ring nitrogen is oriented in *Z* to the carbonyl oxygen, a large steric repulsion arises between the isoquinoline-B-ring and the R group except for QCA. Examination with CPK molecular models indicates that AP and BP have small repulsion in their *Z* conformers and the magnitude of this repulsion is slightly larger in BP than in AP. It is important that increasing order of repulsion forces (PCA≃QCA≪AP<BP≪BQ<AQ) are just in agreement with decreasing order of the complexation constants. That is, the more stable the *Z*-conformer, the more stable

Table 1. Complexation constant, K_S

a) See Refs. 1 and 5 for detail.

the corresponding complex with zinc ion, which may lead to the conclusion that the complexation demands the *Z*-conformation for the carbonyl compound. The conclusion is also supported by spectroscopic investigations.[7,8] Thus, the distortion angle between the planes of carbonyl group and heterocyclic ring in the complexed substrate increases in the order; PCA≃QCA< AP≲BP<BQ≲AQ. CPK molecular models predict that the angle in PCA-complex is about 0° and that in AQ-complex is nearly 90°.

Kinetics. Pseudo-first-order kinetics at 50 °C in acetonitrile was followed spectrophotometrically by observing the decrease in the intensity of absorption from BNAH at 360 nm unless otherwise indicated in Experimental Section. Each run gave a good first-order relationship (correlation coefficient; $r>0.999$) for more than at least two half-lives. Rate constant for zinc ion-catalyzed auto-decomposition of BNAH (6.94×10^{-5} s^{-1}) was small enough to be neglected.[1] Observed first-order rate constants at appropriate concentrations of reagents are summarized in Tables 2—5.

Similarly to the previous procedure,[1] we obtain a kinetic expression shown in Eqs. 4 and 5 for the present reaction (Eq. 6).

$$k_{obsd}[B]_T = k^H[B][S][M], \quad (4)$$

$$k^H = k_1K_B + k_2K_S, \quad (5)$$

$$\left.\begin{array}{l} BM + S \xrightarrow{k_1} \\ SM + B \xrightarrow{k_2} \end{array}\right\} \text{products}, \quad (6)$$

where B, S, and M denote BNAH, a substrate, and zinc ion, respectively, and the subscript T means stoichiometric concentration. Computor-assisted analysis of kinetic data[1] gave numerical value of k^H as listed in Table 6.

Although k^H's are composite constants, there is no doubt that their relative magnitudes are in the same order as those of rate-constants for rate-determining

proton (or hydrogen atom) transfer from BNAH to the substrates. Namely, the reduction is associated by large kinetic deuterium isotope effect, whereas no deuterium isotope effect is observed on complexation constant, as will be descibed below in detail. Variation in complexation constants is much smaller than that in rate constants, which means that relative magnitude of k^H is determined mainly by kinetic term.

Isotope Effects. Kinetics were also followed with BNAH-4,4-d_2 to obtain rate constants, k^D. Thus calculated deuterium isotope effects, k^H/k^D, are listed in Table 7. Reproducibility of two or three experiments was satisfactory. Errors in rate constants for PCA and QCA were, however, too large to obtain precise kinetic isotope effects. In Table 7 product isotope effect, Y^H/Y^D, for AP and AQ are also listed. The product isotope effect is defined as the ratio of isotope content at the particular position of the product alcohol obtained by the reduction with BNAH-4-*d*. For the other substrates, Y^H/Y^D could not be obtained because of thermal unstability of the corresponding alcohols on VPC. Y^H/Y^D's in the reduction with an NAD(P)H-model compound have been reported to be larger than 3.0 for many substrates.[9-14] The results indicate clearly that a hydrogen nucleus is transferred from BNAH to a substrate in the rate-determining step of the reduction.

Table 7. Kinetic and product isotope effects

Substituent	Pyridine		Isoquinoline	
	k^H/k^D	Y^H/Y^D	k^H/k^D	Y^H/Y^D
H	—	—	—	—
Ph	3.28[a)]	—	2.79	—
Me	3.21[a)]	3.2	2.45	3—5

a) Data from Ref. 1.

It should be noted that k^H/k^D's are appreciably smaller than Y^H/Y^D's for AQ and BQ, whereas both isotope effects are identical for AP and BP. The discrepancy between k^H/k^D and Y^H/Y^D reveals the existence of at least one intermediate prior to the rate-determining step of the reduction.

Reactivity of the Substrates. For certain substrates it has been established that the reduction proceeds through transfer of an electron, a proton, and an electron (or an electron and a hydrogen atom) in this order.[9,15-17] Therefore, the present reduction can also be proposed to proceed similarly, on the basis of the results described above.[18] That is, the facility of a substrate toward the reduction can be substituted by the stability of substrate-originated anion-radical counterpart of the radical-ion pair intermediate, becasue the cation-radical counterpart originates from BNAH and is common to all reductions.

It has been established that zinc ion catalyzes the initial electron-transfer process.[10,17] Zinc ion would also contribute to stabilize the anion radical by neutralizing the negative charge. Such stabilization is expected to be the largest in the anion radicals formed from PCA and QCA, because these substrates can interact with zinc ion most effectively as indicated by large complexation constants. The effect of zinc ion on the stabilities of anion radicals from AP and BP are expected to be a little smaller but still significant. On the other hand, anion radicals from AQ and BQ are supposed to be much less stabilized by zinc ion, because the interaction of AQ or BQ with zinc ion forces to distort stable conformations of these substrates as discussed in the previous section.

However, contribution of an aryl group to the stability of anion radicals should also be taken into consideration. Since the plane of benzene ring in the BQ–Zn^{2+} complex can be coplanar with the plane of carbonyl group where negative charge of the anion radical appears mainly, the benzene ring can delocalize the negative charge and contribute to the stability of anion radical. It should be noted that the negative charge on anion radicals of AP, BP, PCA, and QCA can also delocalize into pyridyl or isoquinolyl moiety. Since the distorted AQ-complex has no moiety that can delocalize the negative charge, no factor is pointed out at all to stabilize the corresponding anion radical. Consequently, stability of the radical-ion pair intermediate will increase in the order: AQ<BQ<BP<AP<PCA$\simeq$QCA as a result of participation of substituent and zinc ion.

On the other hand, ratios of k^H's listed in Table 6 indicate that the value for AQ *vs.* AP is much larger than those for other substrates. The large ratio should be accounted for by unexpectedly high reactivity of AQ against other substrates, becasue the similarity of structures of 2-acylpyridine complexes cannot predict the low reactivity only for AP.

It has been predicted that an unstable radical-ion pair intermediate requires higher free energy of transition for the electron-transfer step than that for the proton (or hydrogen atom)transfer step resulting in large discrepancy between k^H/k^D and Y^H/Y^D.[10] The present result agrees with this prediction. That is, the most unstable AQ-complex is associated by the largest discrepancy.

Conclusion. From the above discussion, it may be concluded that factors which govern the facility for complexation and for reduction are independent. Rather, a corbonyl group which weakly coordinates onto metal ion has large reactivity toward the reduction within a limited framework of substrate structure. In other words, strong coordination of a metal ion onto the reaction site of a substrate facilitates the complexation but interferes the reduction. This is in contrast to the idea previously proposed; a substrate is activated by metal ion upon the coordination onto the reaction site.[2,3,19-21]

Experimental

Materials. Acetonitrile was distilled three times on phosphorus pentaoxide and once on potassium carbonate, then kept in a bottle filled by dry argon and capped by a silicone-rubber stopper. 2-Acetylpyridine (AP; bp 95 °C/34 mmHg), 2-benzoylpyridine (BP; mp 42—44 °C), pyridine-2-carbaldehyde (PCA; bp 75 °C/22 mmHg), and zinc perchlorate were commercially available (Nakarai Chem. Co. and Merck & Co., Inc.). These acylpyridines were purified

by recrystallization or distillation prior to the use. Zinc perchlorate was dried at 120 °C *in vacuo* for 15 h and kept in a desiccator over calcium chloride.

1-Benzyl-1,4-dihydronicotinamide (BNAH),[14] BNAH-4-*d*, BNAH-4,4-d_2,[10] 1-acetylisoquinoline (AQ; purified by column chromatography),[22] 1-benzoylisoquinoline (BQ; mp 74.5—75 °C),[22] and isoquinoline-1-carbaldehyde (QCA; mp 53—54 °C)[23] were prepared according to literature procedures. Deuterium contents in BNAH-4-*d* and BNAH-4,4-d_2 were 99.0±1.0% for both.

Product Analysis. Each 1 mmol of a substrate, BNAH, and zinc perchlorate was dissolved into 10 ml of acetonitrile, and the solution was kept at 50 °C for 1 d under nitrogen atmosphere in the dark. An aqueous EDTA was added to this mixture and the product was extracted with dichloromethane. The organic layer was concentrated *in vacuo*. After the purification on column chromatography, the product was identified to be the corresponding alcohol by NMR and IR spectra. The spectra were identical to those of authentic samples. Other products except for the pyridinium salt were not detected on TLC and NMR. The yields of the isolated products were 60—70%.

In the case of QCA, the product alcohol was not stable under the air and could not be isolated. The quantitative production of the corresponding alcohol, however, was confirmed on VPC.

Complexation Constant. A series of acetonitrile solutions containing zinc perchlorate, the concentrations of which varied from 20 to 200 times excess against appropriate concentration of the substrate, were prepared. Each solution was placed in a UV-cell (1 cm) equipped with a silicone-rubber stopper, and the cell was kept for at least 5 min in the cell-compartment of a Union Giken SM-401 Spectrophotometer which was kept at 50.0±0.1 °C. The reference cell was filled with acetonitrile. The substrate in acetonitrile was added to the sample cell, then the spectrum was recorded. Reproducibility was satisfactory for each run.

Kinetics. For AQ and BQ, an acetonitrile solution for kinetics was prepared and placed in a UV-cell (1 cm) equipped with a silicone-rubber stopper. Kinetics was followed spectrophotometrically with a Union Giken SM-401 Spectrophotometer, the cell-compartment of which was kept at 50.0±0.1 °C. The reference cell was filled with acetonitrile, then BNAH in acetonitrile was added to the sample cell. It was confirmed that the order of incubation of reagents did not affect the kinetics.

For PCA and QCA, the reaction was so rapid that stopped-flow method was employed on a Union Giken RA-401 Rapid Reaction Analyzer equipped by a Union Giken Kinetic Data Processer System 71. An acetonitrile solution of a substrate containing zinc perchlorate and that of BNAH were placed in two reservoirs separately. The reservoirs and UV-cell were kept at 50.0±0.1 °C under argon atmosphere. After a few minutes of incubation, both solutions were mixed and the reaction was followed spectrophotometrically.

Since the solution of substrate including a high concentration of zinc perchlorate had an absorption near 360 nm, the decrease in the intensity of the absorption from BNAH was monitored at longer wavelength (370—400 nm).

Product Isotope Effect. A product obtained by the reduction with BNAH-4-*d* was analyzed for deuterium contents by mass spectrometry on a Shimadzu LKB-9000S GC-MS Spectrometer equipped with a PACK 300DG-b Computing System and areas of appropriate peaks were measured.

Spectroscopy. NMR spectra were recorded on a Varian T-60 Spectrometer or a JASCO JNM-FX 100 FT NMR Spectrometer. IR spectra were obtained with a Hitachi EPI-S2 Spectrometer.

Correlation of Physical Units. Physical units used in this report are correlated with SI-units by the following relationship.

1 M = 1 mol dm^{-3}, t/°C = T/K − 273.15,

p mmHg = 13.5951 × 980.665 × 10^{-2} p Pa.

Synthetic Photochemistry. XVIII.[1] A Sensitizer Dependence in the Photooxidation of Indene and Acenaphthylene. The Occurrence of *cis*-1,2-Glycol Formation in a Rose Bengal-sensitized Reaction

Toshihide HATSUI and Hitoshi TAKESHITA*

Reaeseach Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812

(Received February 25, 1980)

Upon Rose Bengal-sensitized photooxygenation, indene and acenaphthylene afforded substantial amounts of the expected *cis*-glycols by means of the reduction of the intermediate dioxetanes. The formerly proposed structure of one of the isomeric methoxy hydroperoxides was revised on the basis of the chemical and spectral evidence.

Recently, we have found a new photochemical oxygenation process by which to form *cis*-1,2-glycols by means of the reduction of the intermediate dioxetanes.[2-4] To demonstrate the general applicability of this new process, we have carried out the experiments with indene (**1**) and acenaphthylene (**2**); the results will be described herein. Our selection of **1** as the reactant is due to the fact that, since the 1960's, the singlet oxygen oxidation of **1** has been investigated by many workers, and it is known to be the first dioxetane-forming arylolefin.[5,6] On the other hand, **2**, with no allylic hydrogen, should form only the cycloadducts.

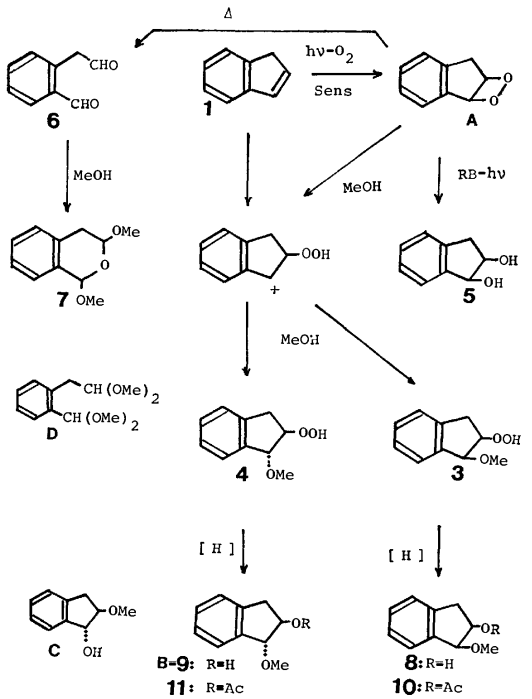
When a methanolic solution of **1** was irradiated by means of a tungsten lamp at 15—20 °C with a relatively large amount of Rose Bengal (RB) under an oxygen atmosphere, the occurrence of KI-starch positive species was indicated; in fact, the silica gel column chromatography of the mixture afforded a pair of methoxy hydroperoxides (**3**, 17%, and **4**, 34%), together with *cis*-1,2-indandiol (**5**, 21%),[7] homophthalaldehyde (**6**, a trace amount), and cylic acetal (**7**, 25%). Both **3** and **4** were hydroperoxy derivatives, for sodium borohydride reduction gave the 2-methoxy-1-indanols (**8** and **9**) the latter of which was characterized as *p*-nitrobenzoate. Although the NMR spectra of **8** and **9** were too ambiguous for us to assign the methine protons of oxygen functions, those of their acetates (**10** and **11**) provided clear information for use in determining the location and stereochemistry. The structure of **5** was evident on the basis of the NMR analysis as well as the chemical correlation with its diacetate. The occurrence of **6** was assured by the NMR analysis of its reduction product, 2-[2-(hydroxymethyl)phenyl]-ethanol (**12**).

The photooxidation of **1** with Methylene Blue (MB) in methanol disclosed similar product distributions, except for the absence of **5**.

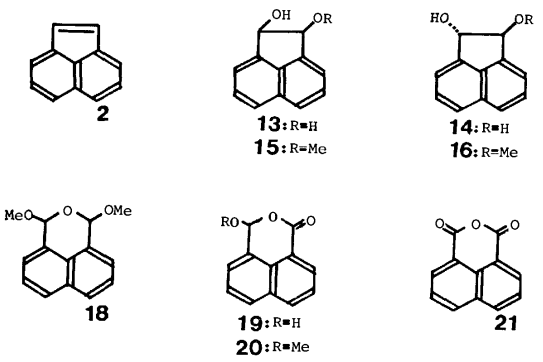
Subsequently, we have carried out the oxygenation with **2**. Thus, a methanol solution of **2** was irradiated by means of a 500-W tungsten lamp in the presence of RB under an oxygen atmosphere. The four products thus formed were identified and characterized as *cis*- (**13**, 45%) and *trans*-2-methoxy-1-acenaphthenols (**14**, 2%)[8] and *cis*- (**15**, 5%) and *trans*-2-methoxy-1-acenaphthenediols (**16**, 18%). The *cis-trans* isomerism in **15** and **16** was deduced from the different magnitudes of the spin-spin coupling constants and the indication of the internal hydrogen-bond for the methoxy-alcohol function of **15**, as well as the *m*-chloroperbenzoic acid (MCPA)-oxidation of **2**, where **16** was the major product (**16**:**15**=63:37).

However, the reaction products of **2** with MB were entirely different from those with RB; except for the *cis-cisoid-cis*-dimer (**17**, 5.3%) of **2**,[9] all the oxygenation products were related to a dioxetane, *i.e.*, 1,8-naphthalenedicarbaldehyde cyclic acetal (**18**, 22%), hydroxynaphthalide (**19**, 14%),[10,11] and methoxynaphthalide (**20**, 7%),[10,12] and 1,8-naphthalenedicarboxylic anhydride (**21**, 17%).[13] **18** was independently prepared from **13** by periodic acid-oxidation in methanol. **19** and the other carboxylic derivatives are probably secondary products produced by the autooxidation of unisolable 1,8-naphthalenedicarbaldehyde. The occurrence of *cis*-glycols from **1** and **2** was again confirmed only in the RB-sensitized photooxygenation; this sensitizer dependence for the substrates constitutes another example of the RB-sensitized photoreduction process of dioxetanes.

Previously, Kearns *et al.*[5] obtained a pair of methoxyindanols in the MB-sensitized photooxygenation of **1** and assigned them the structures of *trans*-1-methoxy-2-indanol (**B**) and *trans*-2-methoxy-1-indanol (**C**) on



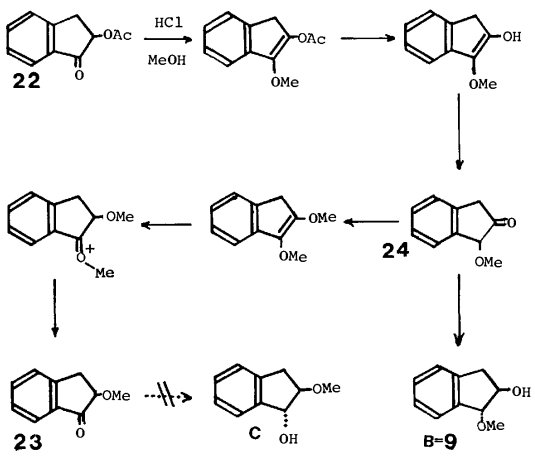
Scheme 1.



Scheme 2.

the basis of chemical correlations, following the previously known route.[14] Later, Foote *et al.*[6] suported this assignment for the structures of products derived from indene, except for that of acetal, to which Foote gave the **7** structure instead of the **D** originally given by Kearnes. The present results, however, showed some discrepancies; our **9** corresponds to **B**, but **8** does not correspond to **C**, and the structure of **7** agreed with the results of Foote. Since obtaining these indanols led Hasty and Kearns to claim a chemical trapping of the peroxirane[15] and has been cited in recent literature,[16,17] the settlement of this problem is important. The previous route of derivation involves the solvolytic substitution of 2-acetoxy-1-indanone;[18] the stable benzylic cation formed as the intermediate might therefore cause a shuffling of the substituents. Consequently, the reported formation of 2-methoxy-1-indanol based on this derivation seems to be unconvincing.

According to our reinvestigations, 2-acetoxy-1-indanone (**22**),[14,18] whose preparation from 2-bromo-1-indanone involved no rearrangement, was shown to give 2-methoxy-1-indanone (**23**, a quantitative yield) by the action of 3% hydrogen chloride in methanol under reflux for 90 min, but under less drastic conditions (40 °C for 45 min), **23** and 1-methoxy-2-indanone (**24**) were formed in a ratio of 1:1, while the additional heating of the mixture for 40 min at 40 °C caused the disappearance of **24**. In any case, we have not succeeded in finding the conditions by which to obtain



Scheme 3.

24 as a single solvolysate. Obviously, **23** is a thermodynamically stable product, while **24** is a kinetically controlled transient product, and not a simple substitution reaction, as is illustrated in Scheme 3.

The present result, the absence of an anti-Markovnikov methoxy hydroperoxide, should not only indicate the invalidity of the peroxirane hypothesis deduced on this structural basis, but should suggest also the necessity to reinvestigate the structural aspects of a related observation, *i.e.*, the formation of regioisomeric methoxy hydroperoxides from the peroxiranes of 1,3-pentadiene and 2,5-dimethyl-2,4-hexadiene.[15]

Experimental

*RB-sensitized Photooxygenation of **1** in Methanol.* A methanol solution (30 cm³) of 1 (674 mg) and RB (221 mg) was irradiated by means of a 500-W tungsten lamp at 15—20 °C for 48 h under an oxygen atmosphere. The mixture was then diluted with water and extracted with CH_2Cl_2. The extract was fractionated on a silica-gel column with hexane–ethyl acetate to give, first, a colorless oil (529 mg; 51%), which, together with a small amount of **6**, consisted mainly of **3** and **4** [δ[19]: 2.88 (1H, dd, J=17, 4 Hz), 3.32 (1H, dd, J=17, 7 Hz), 3.51 (3H, s), 4.80 (2H, m), 7.20 (4H, m), and 8.88 (1H, OH)] in a ratio of 1:2; subsequently, fractionation gave **5**, colorless crystals (mp 102.5—103 °C (lit,[7] 99—101 °C); 185 mg (21%) [δ: 2.86 (1H, dd, J=16.5, 3.5 Hz), 3.00 (1H, dd, J=16.5 6 Hz), 3.33 (2H, br. OH), 4.32 (1H, m), 4.84 (1H, d, J=5 Hz), and 7.20 (4H, m)]), together with **7**, a colorless oil (280 mg (25%) [δ: 2.92 (2H, m), 3.56 (3H, s), 3.59 (3H, s), 5.06 (1H, m), 5.64 (1H, s), and 7.2 (4H, s)]).

*Diacetate of **5**.* Prepared by acetic anhydride in pyridine as colorless needles; mp 48—48.5 °C (lit,[7] 50.8—51.6 °C) [δ: 2.06 (3H, m), 2.08 (3H, s), 3.17 (2H, m), 5.51 (1H, td, J=6.3, 5.4 Hz), 6.19 (1H, d, J=5.4 Hz), and 7.26 (4H, m)].

*Sodium Borohydride Reduction of the Mixture of RB-sensitized Photooxygenation Products of **3**.* The photooxidation mixture obtained from **1** (609 mg) with RB (164 mg) for 24 h was directly reduced with $NaBH_4$ (10 mg) at room temperature. The mixture was then evaporated *in vacuo*, and the residue was chromatographed on a silica-gel column. The products identified were **7** (123 mg; 12%), **8** (72 mg; 8.4%) [Found: M. W., 164.0820. Calcd for $C_{10}H_{12}O_2$: 164.0837. δ: 2.85 (1H, br., OH), 3.02 (2H, m), 3.52 (3H, s), 4.53 (2H, m), and 7.25 (4H, m). δ (C): 39.0, 57.0, 72.4, 84.1, 125.5, 126.5, 128.9, 139.7, and 141.0. ν: 3560. 1110, 1100, 1080 cm^{-1}]), **9** (180 mg; 21%) [Found: *m/e*, 164. δ: 2.72 (1H, dd, J=16, 5.2 Hz), 2.8 (1H, br. OH), 3.24 (1H, dd, J=16, 6.8 Hz), 3.52 (3H, s), 4.44 (1H, m), 4.58 (1H, d, J=4 Hz), and 7.20 (4H, m). ν: 3620, 3440, 1095 cm^{-1}]), and **5** (23 mg; 3%).

*Acetate (**10**) of **8**.* Prepared by the use of acetic anhydride in pyridine as a colorless oil [δ: 2.10 (3H, s), 3.12 (2H, d, J=6 Hz), 3.44 (3H, s), 4.72 (1H, d, J=5 Hz), 5.44 (1H, dt, J=6, 5 Hz), and 7.24 (4H, m). δ(C): 21.1, 35.9, 57.5, 74.3, 82.7, 125.0, 125.3, 126.9, 128.9, 139.8, and 170.9. ν: 1740, 1240 cm^{-1}].

*Acetate (**11**) of **9**.* Prepared similarly as a colorless oil [δ: 2.06 (3H, s), 2.81 (1H, dd, J=16.7, 4 Hz), 3.50 (1H, dd, J=16.7, 6.8 Hz), 3.52 (3H, s), 4.77 (1H, d, J=3.2 Hz), 5.39 (1H, ddd, J=6.8, 4, 3.2 Hz), and 7.25 (4H, m), δ(C): 21.0, 36.8, 56.9, 78.8, 87.9, 124.9, 125.3, 126.9, 129.0, 139.7, 140.3, and 170.3].

p-*Nitrobenzoate of* ***9***. Prepared by the treatment of *p*-nitrobenzoyl chloride in pyridine at room temperature as pale yellow needles; mp 84.5—85 °C [Found: C, 65.16; H, 4.68, N, 4.54%. Calcd for $C_{17}H_{15}O_5N$: C, 65.17 H, 4.82; N, 4.47%].

MB-sensitized Photooxygeanation of ***1***. A methanol solution (25 cm³) of **1** (540 mg) and MB (60 mg) was irradiated by means of 500 W tungsten lamp for 28 h under an oxygen atmosphere. The mixture was then directly reduced with $NaBH_4$ to decompose the peroxy derivatives. After the evaporation of the whole mixture, the residue was chromatographed on a silica-gel column to give **7** (59 mg; 6.5%), **12** (a colorless oil; 185 mg (27%) [δ: 2.85 (2H, t, J=6 Hz), 3.70 (2H, br. OH), 3.76 (2H, t, J=6 Hz), 4.53 (2H, s), and 7.20 (4H, m). δ(C): 35.0, 62.4, 62.8, 126.4, 128.1, 129.2, 129.9, 137.8, and 138.9]), **8** (150 mg; 20%), and **9** (153 mg; 20%).

*Bis(*p-*nitrobezoate) of* ***12***. Prepared by the usual manner as colorless prisms; mp 133.5—134 °C (lit,[20] 134—135 °C) [δ: 3.23 (2H, t, J=7 Hz), 4.51 (2H, t, J=7 Hz), 5.49 (2H, s), 7.32 (4H, m), 8.16 (4H, m), and 8.18 (4H, s)].

RB-sensitized Photooxygenation of ***2***. A mixed solution (30 cm³) of methanol and acetone (1:2) of **2** (504 mg) and RB (100 mg) was similarly irradiated by means of a tungsten lamp under an oxygen atmosphere for 90 h at 15—20 °C. The reaction mixture was then heated at 30 °C *in vacuo* to remove the solvents. The residue was chromatographed on a silica-gel column. The recovered **2** (300 mg) was obtained by elution with hexane–ethyl acetate (95:5); subsequent elution with hexane–ethyl acetate gave colorless needles of **15** (mp 91.5—92.5 °C; 14 mg (5%) [Found: C, 77.99; H, 6.11%. Calcd for $C_{13}H_{12}O_2$: C. 77.98; H, 6.04%. δ: 3.26 (1H, d, J=7 Hz, OH), 3.62 (3H, s), 5.01 (1H, d, J=6 Hz), 5.50 (1H, dd, J=7, 6 Hz), and 7.4—7.8 (6H, m). ν: 3430, 1102, 780 cm^{-1}]), a colorless oil, **16** (49 mg (18%) [Found: C, 77.77; H, 6.06%. δ: 3.15 (1H, br., OH), 3.48 (3H, s), 4.90 (1H, d, J=2 Hz), 5.31 (1H, d, J=2 Hz), and 7.2—7.7 6H, m). ν: 3620, 3430, 1110, 775 cm^{-1}]), colorless needles, **13** (mp 213—214 °C (lit,[9] 218—219 °C), 101 mg (45%) [δ: 2.76 (2H, br., OH), 5.50 2H, br. d, J=7 Hz), and 7.2—7.8 (6H, m). ν: 3330, 3200, 1110, 775 cm^{-1}]), and colorless needles, **14** (mp 158—160 °C (lit,[8] 160—163 °C), 6 mg (2%) [δ: 3.3 (2H, br., OH), 6.42 (2H, br. s), 7.4—7.6 (4H, m), and 7.7—7.9 (2H, m). ν: 3360, 985 cm^{-1}]).

Acetylation of ***13***. This yielded colorless prisms; mp 132—134 °C (lit,[8] 134.5—136.5 °C) [δ: 2.12 (6H, s), 6.60 2H, s), and 7.4—7.8 (6H, m). ν: 1775, 1240, 775 cm^{-1}]).

Acetylation of ***14***. This yielded a colorless oil (lit,[8] a colorless oil) [δ: 2.09 (6H, s), 6.54 (2H, s), and 7.4—7.9 (6H, m). ν: 1745, 1370, 1240 cm^{-1}].

MB-sensitized Photooxygenation of ***2***. A mixed solution (30 cm³) of methanol and acetone (1:2) of **2** (500 mg) and MB (60 mg) was similarly irradiated under an oxygen atmosphere for 177 h. The mixture was then heated *in vacuo* to remove the solvent, and the residue was purified through a silica-gel column; from the hexane eluent, a photodimer of **2** (**17**) as colorless needles (mp 233—235 °C (lit,[9] 232—234 °C); 13 mg) and the recovered **2** (256 mg) were thus obtained. Subsequently eluted from hexane–ethyl acetate were a dimethyl acetal of 1,8-naphthalenedicarbaldehyde, **18** (a colorless oil, 77 mg; 22%), a methoxy lactone, **20** (pale yellow prisms; mp 105—106.5 °C (lit,[10] 104 °C), 23 mg (7%) [δ: 3.66 (3H, s), 6.42 (1H, s), 7.45—7.75 (3H, m), 7.90 (1H, m), 8.08 (1H, dd, J=9, 1 Hz), and 8.40 (1H, dd, J=7, 1 Hz). ν: 1728, 1090, 1000 cm^{-1}]), a hydroxy lactone, **19** (pale yellow needles, mp 175—176 °C (lit,[12] 167 °C), 43 mg (14%) [δ: 6.86 (1H, s), 7.35—7.95 (4H, m), 8.08 (1H, dd, J=8, 1 Hz), and 8.37 (1H, dd, J=7, 1 Hz). ν: 3280, 1680, 1120, 1005, 925, 775 cm^{-1}]), and 1,8-naphthalenedicarboxylic anhydride, **21** (pale yellow needles, mp 268—270 °C (lit,[13] 271—272 °C), 55 mg; 17%).

2-Acetoxy-1-indanone (***22***) was prepared from 2-bromo-1-indanone in accordance with Ishiwara's procedure.[18] Its purity was confirmed by the NMR [δ: 2.16 (3H, s), 3.04 (1H, dd, J=17, 5 Hz), 3.60 (1H, dd, J=17, 8 Hz), 5.38 (1H, dd, J=8, 5 Hz), and 7.25—7.8 (4H, m)].

Preparation of 2-Methoxy-1-indanone (***23***). *a)*: To a methanolic 3% HCl solution (10 cm³), **22** (107 mg) was added and refluxed for 90 min. After the evaporation of the solvent, the residual mixture (95 mg) was analyzed by means of the NMR [δ: 3.00 (1H, dd, J=16, 4 Hz), 3.48 (1H, dd, J=16, 7 Hz), 3.61 (3H, s), 4.17 (1H, dd, J=7, 4 Hz), and 7.2—7.8 (4H, m)] spectrum and found to be practically pure 2-methoxy-1-indanone (**23**).

b): Similarly, **22** (80 mg) in the methanolic hydrogen chloride (8 cm³, 3%) was heated at 40 °C for 45 min. The NMR spectrometry of the mixture indicated it to be *ca.* a 1:1-mixture of **23** and 1-methoxy-2-indanone (**24**) [δ: 3.50 (2H, s), 3.57 (3H, s), 4.75 (1H, s), and 7.2—7.8 (4H, m)]. Upon prolonged heating at 40 °C with the additional introduction of a 3% methanolic HCl (5 cm³), **24** disappeared from the mixture.

MCPA-oxidation of ***2*** *in Methanol*. A methanolic solution (10 cm³) of **2** (100 mg) and MCPA (120 mg) was kept at room temperature for 24 h. Subsequently, the silica gel column chromatography of the mixture afforded **15** (31 mg; 37%), and **16** (50 mg; 60%), together with the recovered **2** (37 mg).

Cleavage of ***13*** *with Periodic Acid*. A methanol solution (5 cm³) of **13** (25 mg), containing HIO_4 (70 mg) and water (1 cm³) was kept at room temperature for 1 h. The mixture was then neutralized by $NaHCO_3$ and chromatographed on a silica-gel column to give **18** (18 mg; 49%), identical with the sample obtained by photooxygenation.

Bondings on the TeI_4 Tetramer, as Studied by Means of NQR

Tsutomu Okuda,* Koji Yamada, and Hisao Negita
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received February 29, 1980)

The ^{127}I NQR and its Zeeman effect on the TeI_4 single crystal were investigated. Ten nonequivalent iodine atoms were detected, in agreement with the X-ray analysis by Krebs and Paulat. Six of them were assigned to terminal atoms, two to bridge atoms, and the remaining two to pyramidal iodine atoms, on the basis of their quadrupole coupling constants and asymmetry parameters. One of the bridging iodine atoms takes an efg z-axis parallel to the shorter Te–I bond, but the other bridging iodine atom takes an efg z-axis perpendicular to the bridging plane. This difference can be explained by a simple model based on the Townes-Dailey treatment and is consistent with that difference to be expected from the bridging-bond length. The extremely small coupling constants for the pyramidal iodine atoms could be interpreted by covalency, assuming a hybridization of the s-orbital to the pure p-bond configuration.

According to Krebs and Paulat[1] the crystal of tellurium tetraiodide is orthorhombic (space group Pnma), with 16 TeI_4 in the unit cell. As is shown in Fig. 1, the structure is built of $(TeI_4)_4$ tetramers which are different from the $(TeCl_4)_4$ tetramer in molecular structure.[2] The $(TeI_4)_4$ tetramer has a reflection plane parallel to the ac plane. This tetramer is interesting in its structure and bonding, because it consists of three types of iodine atoms, that is, terminal, bridging, and pyramidal atoms. The last type of iodine atom was called "triply bridging iodine" by Krebs and Paulat. In the light of the NQR study, the following information has been obtained and may be discussed with the framework of the Townes-Dailey theory. (1) Angular bridging halogens are well known in dimeric compounds, M_2X_6 (M=Al, Ga, and In; X=Br and I). In these molecules, the bridging bonds are symmetrical, so that the orientations of the efg axes can be expected from the symmetry.[3,4] However, as the bridging iodine atoms in this tetramer form asymmetric bonds with two tellurium atoms, the orientations of the efg axes should depend upon the covalent character of the two Te–I bonds. In addition, it is valuable to examine the temperature dependence of the e^2Qq/h for the asymmetric bridging iodine with a definite efg axis orientation. (2) The quadrupole coupling constants for the pyramidal halogen in a normal oxidation state have been reported only for CdI_2 (X=Br and I),[5] as far as we know. The small e^2Qq/h values for the halogens in CdI_2 were interpreted in terms of covalency, assuming the hybridization of the s-orbital to the three-orthogonal-p-bonding configulation. The validity of this model was tested for the pyramidal iodine in the TeI_4 tetramer.

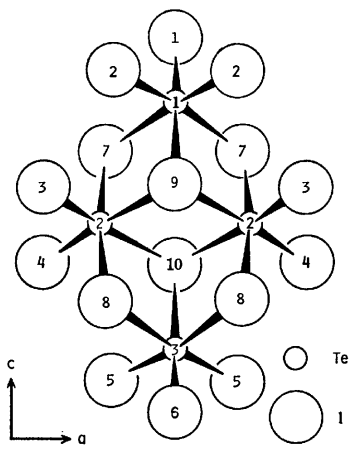

Fig. 1. Tetrameric molecular unit in the TeI_4 crystal.[1]

A part of this work has already reported elsewhere,[6] but there has been no precise discussion of the bridging iodine because of the lack of the crystal structure, which is now established.

Experimental

The TeI_4 single crystal was grown by the Bridgman-Stockbarger method in a Pyrex tube in which stoichiometric amounts of tellurium and iodine were sealed under reduced pressure. The NQR spectra and their Zeeman effect were observed according to a procedure similar to one described previously.[6,7] In the detection of the pyramidal iodine NQR signal, a Zeeman modulated Dean-type spectrometer was used. The Zeeman effect for the bridging iodine atom was observed at the temperature of liquid nitrogen in order to increase the S/N ratio of the NQR signal.

Results

The Zeeman effect on the terminal iodine was observed in order to obtaine the orientations of the crystal axes for the single crystal employed. As is to be expected from the Laue symmetry of the crystal, four zero-splitting cones were observed for the iodine in the general position. Table 1 shows the direction cosine of the efg z-axis with respect to the crystal axes, which were determined from the symmetry of the observed zero-splitting cones. As is evident from the last column of this table, the efg z-axis coincides with that of the Te–I bond within one degree.

On the other hand, in any discussion of the bridging iodine, not only the z-axis but also the x- and y-axes are necessary. In the case of an iodine atom with a pair of lines, $\nu_1(\pm 1/2 \leftrightarrow \pm 3/2)$ and $\nu_2(\pm 3/2 \leftrightarrow \pm 5/2)$, the behavior of their zero-splitting cones on η has been described elesewhere.[6] In general, efg x-, y-, and z-axes are determined only from the ν_1 cone except for $\eta \fallingdotseq 0$ and $\fallingdotseq 1$. Figure 2 shows the ν_1 patterns and the corresponding efg axes for the I(7) atom at 77 K, where the center of the pattern is pointed toward its y-axis ($\eta > 0.412$). When an η value approaches 1, such as in the case of I(8), the ν_1 and ν_2 lines both show axially symmetric cones around their y- and

z-axes respectively. Therefore, the Zeeman effect on both ν_1 and ν_2 lines must be measured in the determination of the three orthogonal efg axes. Figure 3 shows the zero-splitting patterns corresponding to ν_1 and ν_2 for the I(8) atom. Because of the small S/N ratio, two patterns out of four were observed. The other two orientations of the patterns may be expected from the crystal symmetry. The resultant orientations of the efg axes with respect to their bridging bonds are illustrated in Fig. 4, while their angles are shown in

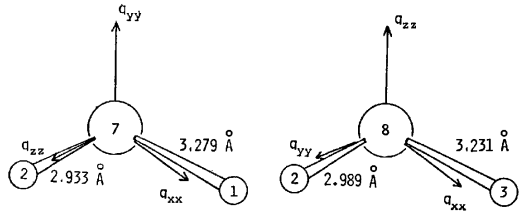

Fig. 4. Orientations of the efg axes with respect to its bridging plane.

in the Te(1)–I(7)–Te(2) are 2.933 and 3.279 Å, while those in the Te(2)–I(8)–Te(3) are 2.989 and 3.231 Å. The former bridging is more asymmetric than the latter. As is obvious from Fig. 4, the bridging atoms take their efg x-axes in the direction of their longer bonds in both cases, but the z- and y-axes change in different directions. We will explain the large asymmetry parameter and the orientations of the efg axes using a simple model. We assume that the bonding of the iodine atom is composed of pure p-orbitals, because the bridging angle is close to 90° ($\angle$Te(1)I(7)Te(2)=95.3°; $\angle$Te(2)I(8)Te(3)=95.7°). Furthermore, the p_x, p_y, and p_z orbitals of the bridging iodine atom are chosen to lie along the efg x-, y-, and z-axes of the I(7) atom. Then, Te–I–Te bonds are formed by donations from the two lone-pair electrons on the I^- ion to the orbitals of the tellurium atoms. The p_y orbital, which is normal to the bridging plane, is assumed to be occupied by a lone pair. The quadrupole coupling constants are easily obtained as follows:[10]

$$\left.\begin{aligned} e^2Qq_{xx}/e^2Qq_p &= N_x - (2+N_z)/2 \\ e^2Qq_{yy}/e^2Qq_p &= 2 - (N_x+N_z)/2 \\ e^2Qq_{zz}/e^2Qq_p &= N_z - (2+N_x)/2 \end{aligned}\right\}, \quad (1)$$

where e^2Qq_p/h is a quadrupole coupling constant for one 5p electron of iodine, and where N_x and N_z are the occupation numbers for the p_x and p_z orbitals. Then, the electrons donated to the tellurium atom from the p_x and p_z orbitals are represented by $2-N_x$ and $2-N_z$ respectively. We here introduce the parameter, k, defined by the donating-electron ratio from the I^- ion, *i.e.*:

$$k = (2-N_x)/(2-N_z), \quad (2)$$

where $0\leq k\leq 1$.

Thus Eq. 1 becomes:

$$\left.\begin{aligned} e^2Qq_{xx}/e^2Qq_p &= (2-N_z)\{(1/2)-k\} \\ e^2Qq_{yy}/e^2Qq_p &= (2-N_z)\{(1/2)+(k/2)\} \\ e^2Qq_{zz}/e^2Qq_p &= (2-N_z)\{-1+(k/2)\} \end{aligned}\right\}. \quad (3)$$

This equation holds only for the case of $0\leq k\leq 1/2$ because of the $|e^2Qq_{zz}|\geq|e^2Qq_{yy}|\geq|e^2Qq_{xx}|$ condition. In such a case, the asymmetry parameter is given by:

$$\eta = 3k/(2-k). \quad (4)$$

When $1/2\leq k\leq 1$, the absolute quadrupole coupling constant along y-axis becomes larger than that of the z-axis. Therefore, the efg z- and y-axes change their orientations in relation to each other. In this case, e^2Qq_{zz}/h is given by:

$$e^2Qq_{zz}/e^2Qq_p = (2-N_z)\{(1/2)+(k/2)\}, \quad (5)$$

with the asymmetry parameter:

$$\eta = (3-3k)/(1+k). \quad (6)$$

Using Eqs. 2—6 and the observed efg-axes orientations, we obtained k=0.395 and 0.519 for the I(7) and I(8) atoms respectively. In this calculation, the e^2Qq/h values for the I(7) and I(8) atoms were regarded as opposite in sign because of the orientation of their z-axes. These k values are consistent with the expectation from the bond length. Table 4 shows the occupation numbers of the p-orbitals.

Table 4. Bond length, p-orbital population, and net charge for the three types of iodine atoms (296 K)

Bonding type	Bond length/Å	Population	Net charge
Terminal	2.769[a]	1.30, 2.00, 2.00	−0.30
Bridge	2.933, 3.279	1.49, 1.80, 2.00	−0.29
	2.989, 3.231	1.55, 1.77, 2.00	−0.32
Pyramid[b]	3.232[a]	1.77, 1.77, 1.77	−0.30

a) Mean values. b) sp^3 hydridization assumed.

In a previous paper we reported the temperature dependence of the e^2Qq_{ii}/h values (ii=xx, yy, and zz) for the two bridging iodines, where quite different features were observed in each case. We explained it with a model in which the characteristic oscillation of the bridging atom leads to an anisotropic change in the quadrupole coupling tensor. Thus, the differnt orientations of the efg axes were predicted from the temperature dependence, although symmetrical bridging bonds were assumed at that time.

Quadrupole Coupling Constants for the Pyramidal Iodine. The mean Te–I bond length in the pyramidal iodine atoms is 3.232 Å, nearly equal to the longer bridging bond length, 3.231 Å, of Te(3)–I(8) or that of 3.279 Å of Te(1)–I(7). This fact suggests the small extent of the covalent character on the pyramidal iodine. Therefore, the extremely small e^2Qq/h value is explained by the fact that the three bonding orbitals are nearly orthogonal. We adopt an sp^3 hydridization with C_{3v} symmetry, according to Ref. 5. The quadrupole coupling constant for the pyramidal iodine is, then, given by:[11]

$$e^2Qq/e^2Qq_p = \{3\cos\theta/(\cos\theta-1)\}(N_s-N_p), \quad (7)$$

where θ is the $\angle$TeITe angle (92.08° on the average) and where N_s and N_p are the populations for the

lone pair and the Te–I bond respectively. From this equation, we get $N_p=1.766$, assuming $N_s=2.0$.

Bonding and Charge Distribution in the Tetramer. Table 4 lists the bond length, p-orbital population, and net charge on the iodine, where no s-oribtal of the terminal atom is assumed to participate in the hybridization, as was suggested by the Mössbauer parameters.[12] If we plot the p-orbital population against its bond length, a smooth line can be obtained containing all the Te–I bonds. Therefore, it seems reasonable to assume an sp^3 hybridization model on the pyramidal atom to account for its e^2Qq/h value. In addition, it is interesting that the net charges on the iodine atoms are all in the same range, in spite of their quite different bonding schemes.

The Synthesis and Decomposition of Calcium Tetraphosphate

Makoto WATANABE,* Hiroyasu SUZUMORI, Mioko MAEDA, and Tamotsu YAMADA

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai, Aichi 487

(Received January 24, 1980)

Calcium tetraphosphate was made by hydrolyzing cyclotetraphosphate in a 5-mol dm^{-3}-solution of sodium hydroxide, neutralizing the phosphate solution with 1 mol dm^{-3} hydrochloric acid, and then adding calcium chloride to the solution. The P/Ca molar ratio of the product was 1.4—1.5. The tetraphosphate was an amorphous substance containing 20—30% of water and was decomposed to phosphates with a shorter chain length with bound water at room temperature or at a higher temperature. Upon decomposition at 300 °C, the main product at the early stage was pyrophosphate. The hydrolysis of the tetraphosphate obeyed the first-order kinetics with respect to the concentration of the phosphate, and the activation energy of the hydrolysis was 105 kJ mol^{-1} at pH 3.5.

Studies of calcium orthophosphates have been made by many workers, but calcium polyphosphates have not been studied well, and even the synthetic methods for most of them have not yet been published. Among chain polyphosphates, the phosphates having shorter chain lengths than that of triphosphate have been investigated well because of the ease of the synthesis of these phosphates. Polyphosphates with longer chains than that of tetraphosphate are, however, very difficult to prepare. Tetraphosphate ions are made by the hydrolysis of cyclotetraphosphate in an aqueous sodium hydroxide solution, but they have not been isolated and have not yet been studied well. In this paper, we will discuss the synthesis of calcium tetraphosphate by means of the hydrolysis of cyclotetraphosphate and some properties of the phosphate.

Experimental

Materials and Procedure. All the materials used, other than the sodium cyclotetraphosphate, were of a commercial grade. The sodium cyclotetraphosphate tetrahydrate was made by the method described in the literature.[1] About 20 g of sodium cyclotetraphosphate tetrahydrate was added to 50 cm^3 of a 5-mol dm^{-3}-aqueous solution of sodium hydroxide, and the mixture was stirred at about 20 °C for 4 d. Most of the sodium cyclotetraphosphate tetrahydrate was not dissolved in the sodium hydroxide solution, while the tetraphosphate produced by the hydrolysis of the cyclophosphate was well dissolved in the alkaline solution. Therefore, the progress of the hydrolysis of the cyclophosphate to tetraphosphate was observed visually by the defecation of the solution. The solution was filtered and neutralized with 1-mol dm^{-3} hydrochloric acid at a temperature below 3 °C, and then an aqueous solution of calcium chloride, which has been made by dissolving 30 g of calcium chloride in 30 cm^3 of water, was added to the tetraphosphate solution. A white precipitate was filtered off, washed with cold water and ethanol, and then dried in an air bath at 50 °C.

Paper Chromatography. One-dimensional paper-chromatographic separation was carried out by using acidic (for the separation of chain phosphates) and basic (for the separation of ring phosphates) solvents.[2] About 0.5 g of the product was dissolved in 25 cm^3 of a 2—8% aqueous disodium dihydrogen ethylenediaminetetraacetate dihydrate (EDTA) solution. About 8 mm^3 of the solution was spotted on Toyo No. 51A filter paper (2 by 50 cm). The development was run at 5 °C for 2 d.

Colorimetric Measurement of Phosphates. Every individual spot on the chromatogram was cut at the demarcation line and placed in a 100-cm^3 beaker containing 10 cm^3 of a 0.1 mol dm^{-3}-ammonium hydroxide solution. After 1 h, the solution was transferred to a 25-cm^3 volumetric flask, together with 10 cm^3 of wash water, and a 1-cm^3 portion of Lucena-Conde and Prat's reagent[3] was added to the flask. The flask was heated in a boiling-water bath for 1 h, subsequently cooled by placing it in a bath of cold water, and diluted to the mark with water. The absorbance of the blue solution was measured by means of a Shimadzu Spectronic 88 spectrophotometer at 830 nm. The phosphate content (P%) was calculated by means of the absorbance data.

Determination of Phosphorus, Calcium, and Sodium in the Product. About 0.2 g of the product and 0.7445 g of EDTA were dissolved in water by using a 100-cm^3 volumetric flask. The amounts of phosphorus and calcium in the solution were determined by means of the molybdenum-blue method with Lucena-Conde and Prat's reagent and by means of the EDTA back-titration method with an NN indicator respectively. In the case of the back titration of a calcium ion in this system, the pH of the solution should be larger than 13, because the change in color of the solution is not clear in the pH regions smaller than 13. Atomic-absorption analysis was used for the determination of a sodium ion by using a Jarrell-Ash atomic-absorption spectrophotometer, AA80, while the analysis was performed by dissolving the product in a dilute hydrochloric acid solution.

X-Ray Diffractometry. The X-ray diffraction diagrams of the samples were taken with nickel-filtered Cu $K\alpha$ radiation by using a Toshiba X-ray diffractometer, ADG-102.

DTA and TG. The samples were heated at the heating rate of 5 °C min^{-1} in an ordinary atmosphere by using a Cho Balance $TRDA_1$-H-type apparatus.

Decomposition of the Tetraphosphate. The decomposition of the tetraphosphate at room temperature and at 300 °C in the atmosphere was measured by the paper-chromatographic and colorimetric methods described above.

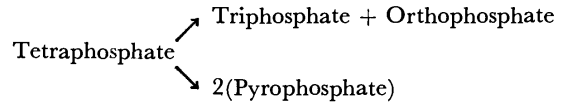
Hydrolysis of the Tetraphosphate. EDTA 4.0 g was dissolved in 100 cm^3 of water, and then 3.0 g of the tetraphosphate was dissolved in the EDTA solution. The hydrolysis of the tetraphosphate was measured by using the phosphate solution at pH 3.5 and at 50, 60, or 70±0.05 °C. The separation and the determination of the tetraphosphate and its hydrolysis products were carried out by means of the method described above.

Results and Discussion

Composition of the Product. The yield of the product depended upon the pH of the phosphate solution;

it was about 27 g for pH 10—7, about 22 g for pH 8—5, and about 16 g for pH 6—3. Paper-chromatographic identification showed that the product was tetraphosphate. As will be discussed below, the tetraphosphate was decomposed to phosphates with shorter chain lengths in the atmosphere at room temperature, so it was difficult to hold pure tetraphosphate. The product thus obtained contained 20—30% of water and was X-ray-diffractometrically amorphous. An effective amount of a sodium ion was not detected in the product. The P/Ca molar ratio of the product was 1.4—1.5. The P/Ca ratio of tricalcium tetraphosphate, $Ca_3P_4O_{13}$, is 1.33, while that of the product is a little larger. The defect of calcium may be supplemented by hydrogen.

Decomposition of the Tetraphosphate at Room Temperature. As is shown in Table 1, the tetraphosphate is gradually decomposed to phosphates with shorter chain lengths in the ordinary atmosphere at room temperature. No weight change was observed in the sample. Therefore, the decomposition may be caused by the water contained in the product. Since the content (P%) of triphosphate is about three times that of orthophosphate at each decomposition time, the decomposition of triphosphate and pyrophosphate once produced to orthophosphate may not occur, and the following decomposition process can be concluded:



DTA and TG. DTA and TG curves of the product are given in Fig. 1. A rapid weight loss of the product and a corresponding big endothermic peak are observed below 150 °C. This reaction may be caused by removing the bound water. The succeeding gradual weight loss of the product from 150—380 °C is considered to be the condensation reaction of phosphates. An exothermic and an endothermic reaction are observed at around 560 and 740 °C respectively. The sample heated at a temperature below that of the exothermic reaction was amorphous and gave no X-ray diffraction peaks, while the sample heated at a higher temperature than that of the exothermic reaction gave some X-ray diffraction peaks. As Fig. 2 shows, these peaks are assigned to those of β-type calcium pyrophosphate (ASTM card, No. 9—346). Accordingly, the exothermic reaction is caused by the crystallization of amorphous calcium pyrophosphate to the β-form. As will be discussed below, the tetraphosphate was decomposed to phosphates with shorter chain lengths by heating it at 300 °C, and the main decomposition product was pyrophosphate in the initial stage of heating. The endothermic reaction at about 740 °C may be due to the melt of a part of the phosphate species, because the sample which was taken out and cooled after the endothermic reaction was sintered. All the X-ray diffraction peaks of the sample after the endothermic reaction were assigned to those of the β-form of calcium pyrophosphate, and an increase in the intensity of the peaks was observed in comparison with that of the peaks of the sample after the exothermic reaction described above.

Decomposition of the Product at 300 °C. As Table 2 shows, the tetraphosphate thus obtained is readily decomposed to tri-, pyro-, and orthophosphates by heating at 300 °C. Among the decomposition products, the value of the pyrophosphate content is the largest at a short heating time. Therefore, the scission of the middle P–O–P linkage of the tetraphosphate may take place in preference to that of the end P–O–P linkage. This phenomenon was not observed in the decomposition of room temperature. The decomposition products, once produced, are condensed to phos-

phates with longer chain lengths.

Hydrolysis of the Product. According to the results listed in Table 3, the hydrolysis of tetraphosphate obeyed first-order kinetics with respect to the concentration of tetraphosphate at pH 3.5 and 70 °C. The increase in the pyrophosphate content with the reaction time is so much slower than that of tri- and orthophosphates that the scission of the end P–O–P group of tetraphosphate takes place faster than that of the middle P–O–P group in an aqueous solution. This tendency is the reverse of that of the decomposition of the product at 300 °C. The same results were obtained for the hydrolysis at 60 and 50 °C. The rate constants at 60 and 50 °C were 1.5×10^{-3} and 4.3×10^{-4} min^{-1} respectively. The activation energy was determined to be 105 kJ mol^{-1} by means of the least-squares method.

(Received November 13, 1979)

The absorption of 2-(substituted phenylazo)-1-naphthol-4-sulfonic acid has been studied in neutral, acidic, and alkaline aqueous solutions as well as in solid state. Assignment of band positions to azo and hydrazone tautomers has been made by calculations using the SCF-CI-MO method. Introduction of electron-donating (or electron-withdrawing) substituent in the diazo part showed bathochromic (or hypsochromic) shift of the absorption band, which was elucidated by the charge migration and the character of the substituents taking into account azo-hydrazone tautomerism. In case of compounds containing electron-donating substituents, aggregation seems to take place in the solid state.

This paper deals with a study of the physicochemical properties of azo dyes formed in 'diazo-printing' process. Substituted benzenediazonium salt and 1-naphthol-4-sulfonic acid (NW acid) are sometimes used as the photosensitive 'diazo' and 'coupler' components, respectively.[1] Coloration of the dyes formed by the reaction between the above compounds is important.

Attempts have been made to correlate the color of azo dyes with the electronic configuration. Griffiths observed a linear relationship between the absorption maxima in the visible region and the electron-withdrawing power (σ-value) of the substituents on 4-substituted phenylazo-1-naphthols in a certain range of σ value ($\sigma > -0.16$).[2,3] His explanation is not applicable to the phenylazo-1-naphthols with strongly electron-donating substituents which are widely used for imaging processes.

The electronic spectra were measured in the visible region for 2-(substituted phenylazo)-1-naphthol-4-sulfonic acids with various electron-donating or electron-withdrawing substituents, including the dye actually used for diazo-printing process. The absorption maxima of some compounds could not be explained by Griffith's relationship. The band assignment and band shift caused by the substituents are interpreted by the SCF-CI-MO method with PPP approximation.

Experimental

Materials. Substituted benzenediazonium salts were prepared from the corresponding amines (analytical grade), precipitated as tetrafluoroborates and then coupled with NW acid. The resulting dyes were purified by repeated recrystallization from water or ethanol and stores in the dark. The other materials used were of analytical grade.

Methods. Absorption spectra in aqueous solutions were measured with Shimadzu (model UV-180) and Carl-Zeiss-Jena 'Specord UV-Vis' spectrophotometers. For solid state absorption stectra the 'Opal glass method' developed by Shibata[4] was used. A small amount of solid compound was rubbed between two sheets of transparent paper (medical wrapper, Tokyo Ikarika Kikai shoji Co.) and the resulting translucent paper was used for recording the spectrum with a Shimadzu spectrophotometer, type DPS-50L. The reflection spectra were also measured with a Shimadzu Spectrophotometer QV-50, but no distinct difference was observed.

Results and Discussion

Analysis of the Absorption Spectra. In general, azo dyes exist as an azo-hydrazone tautomer (Fig. 1). The spectra of the compounds have been determined in neutral, alkaline (0.1 mol dm^{-3} NaOH), and acidic (0.1 mol dm^{-3} $HClO_4$) aqueous solutions as well as

in the solid state. As an example, Fig. 2 shows the spectra in neutral, acidic, and alkaline solutions of (*p*-dimethylamino phenylazo)-1-naphthol-4-sulfonic acid. The positions of the main absorption maxima in the visible range are summarized in Table 1.

The main visible absorption maximum lies in the range 490—520 nm in neutral aqueous medium. This can be assigned to hydrazone tautomer of the equilibrium,[5] since hydrazone tautomer usually absorbs in a visible region greater than 460 nm, and the azo tautomer in a shorter wavelength region 400—460 nm.[6-14] In our compounds no band is seen which can be ascribed to azo tautomer, except for a very weak shoulder in a few cases. This indicates the predominance of hydrazone tautomer in neutral aqueous solutions, in line with the conclusions of Gabor *et al.*[9] and Yagi[10] on 2-phenylazo-1-naphthol in non-aqueous solvents. NMR studies also support this view.[9,15] Furthermore, the band is assigned to a π-π^* transition from the bathochromic shift caused by polar solvent.[12]

In order to confirm our assignment, quantum mechanical calculations were made by the SCF-CI-MO method with PPP approximation for both azo and hydrazone forms of the parent compound, 2-phenylazo-1-naphthol. Details of the method have been reported by one of us (S.S).[16] The values of the calculated transition energies (ΔE) and oscillator strengths (f) are given in Table 2. The calculated transition energies for the hydrazone agree with experimental data.

Table 1. Visible absorption maxima of 2-(substituted phenylazo)-1-naphthol-4-sulfonic acid

Serial No.	Substituent	σ[a]	Frequency 10^{-4}/cm^{-1} (Wavelength/nm in parentheses)			
			Neutral aqueous	Acidic aqueous	Alkaline aqueous	Solid
1	*p*-NO_2	+0.78	2.02 (495)	2.05 (489)	1.88 (531)	2.02 (495)

a) Values taken from Ref. 20. b) For neutral and alkaline conditions: σ value of *p*-diethylamino substituent is not taken from the reference. Comparing *p*-ethyl substituent ($\sigma=-0.15$) with *p*-methyl one ($\sigma=-0.17$), the value of *p*-diethylamino substituent is estimated to be −0.18. c) For acidic condition: Hammett σ value is not taken from the reference. The value is estimated by comparing the Taft σ value[21] of protonated dimethylamino group with that of unprotonated one.

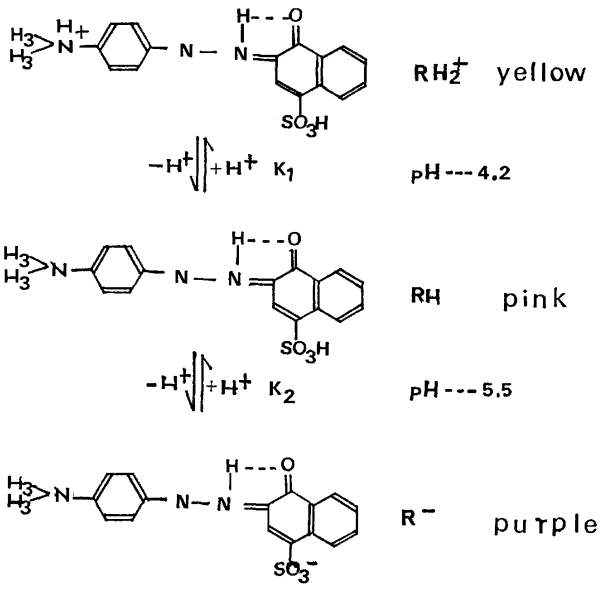
Table 2. Different parameters obtained by SCF-CI-MO calculation

Compound	Structure	ΔE(calcd)[a]/eV	f(calcd)	ΔE(expt)[a]/eV
	azo	2.90 (427) 3.93 (315) 4.13 (300)	0.65 0.14 0.63	
	hydrazone	2.60 (477) 3.75 (331) 4.48 (277)	1.11 0.31 0.37	2.52 (492) 3.54 (350) 4.25 (291)

a) Values in the parentheses give the wavelengths(nm) of the corresponding absorption bands.

In highly alkaline solutions where the phenolic group is completely dissociated, the compounds have predominantly azo character and seem to exist in anionic azo form[3] (Fig. 1).

In highly acidic medium the visible spectrum does not change markedly from that in neutral aqueous medium except in the case of (a) *p*-dimethylamino and (b) *p*-diethylamino derivatives. Figure 2 shows this for (a). When the solution of (a) is acidified from neutral condition, the color turns from purple to pink at pH 5.2, and from pink to yellow around pH 4.2. The spectrum in highly acidic medium below pH 4.2, which shows an absorption maximum at 485 nm, differs from that around pH 5.0 (maximum at 510 nm), and from that in the neutral medium (maximum at 520 nm). The results suggest the following acid-base equilibria:



Formulae dissociation equilibria of 2-(*p*-dimethylaminophenylazo)-1-naphthol-4-sulfonic acid.

The markedly different spectrum in the acidic medium in the case of dialkylamino derivatives is ascribed to the protonation of the dialkylamino group. The protonated group behaves as an electron-withdrawing one (Table 1), the absorption peak shifting to the shorter wavelength region. A slight change is also observed in the *p*-nitro derivative [λ_{max}(neutral)= 495 nm and λ_{max} (acidic)=489 nm]. This might be due to the slight dissociation of the phenolic group even in the neutral medium since some nitro phenols are reported to be strong acids.[17]

Spectra in the solid state have been taken because of their industrial importance (Fig. 6). In the solid state spectra of these compounds, there is no clear band or shoulder which can be ascribed to the azo tautomer. Thus, in the solid state also the present compounds exist predominantly as hydrazone tautomer, in agreement with the results of NMR studies.[10,15]

Dependence of Absorption Maxima on Substituent Constants. According to the theoretical calculation[6,18] on 2-phenylazo-1-naphthol during the course of the lowest π-π^* transition ($S_0 \rightarrow S_1$), there is a charge migration from the naphthalene ring towards the azo link and, to some extent, to the benzene ring in the case of azo structure. The charge migration is in the opposite direction in the hydrazone structure, from the benzene ring and N_α atom to the N_β atom and the naphthalene ring. The approximate direction of the migration moment (movement of charge) is shown in Fig. 3.

In order to elucidate the influence of the substituents on the charge migration of 2-(*p*-substituted phenylazo)-1-naphthol, Hammett's constants were employed to estimate the character of substituents. Figure 4 shows the plots of ν_{max} in the visible region *vs.* σ values of the substituents. The plots seem scattered, but two approximate straight lines are drawn with different slopes in positive and negative ranges of σ values. This is in contrast with the linear relationship between ν_{max} and σ observed on 4-phenylazo-1-naphthol derivatives by Griffiths.[3] The present set of compounds being predominantly in hydrazone structure in neutral medium, introduction of electron-donating substituents in the diazo part facilitates charge migration, resulting in bathochromic shift of the main visible band (Fig.

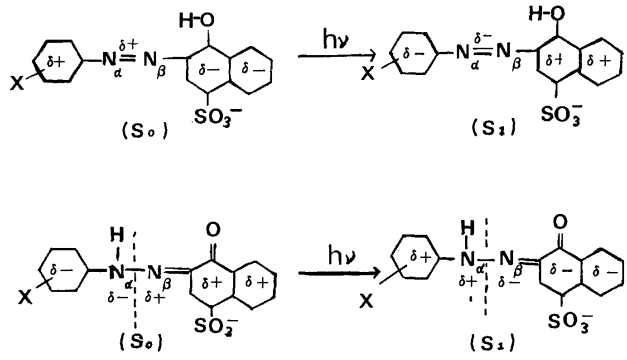


Fig. 3. Approximate scheme of charge migration during electronic transition.

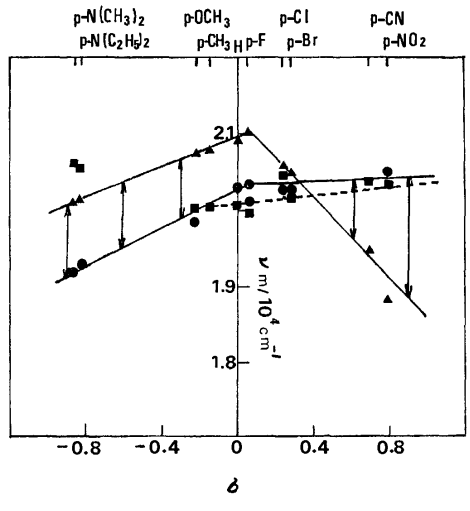

Fig. 4. Plots of ν_{max} of 2-(substituted phenylazo)-1-naphthol-4-sulfonic acid dyes agaist σ values of the substituents.
●: Neutral aqueous solution (ν_{max} of *p*-nitro derivative is in acidic solution, because the phenolic group is partly dissociated even in neutral solution), ▲: alkaline aqueous solution, ■: solid.

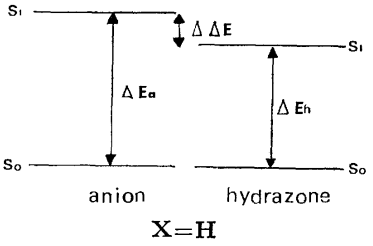

Fig. 5. Energy level diagram of the anionic azo and hydrazone forms of 2-(unsubstituted phenylazo)-1-naphthol-4-sulfonic acid.

4). The presence of electron-withdrawing substituents might cause a slight hypsochromic shift of the visible band, indicating opposition to the charge migration during the course of electronic transition. The influence of electron-withdrawing substituents in the diazo part on the visible band position is not as pronounced as that of electron-donating substituents (Fig. 4).

The dyes exist in anionic azo form in alkaline solutions (Fig. 1).[3] The unsubstituted compound (X=H) was found to show absorption at a shorter wavelength (higher ν) in alkaline solution than in neutral solution (Fig. 4 and Table 1). This is schematically explained in Fig. 5. From the foregoing discussions and Fig. 3, it is evident that electron-donating groups on hydrazone form decrease ΔE_h, while the groups on anionic azo form increase ΔE_a value. Consequently $\Delta\Delta E$ value ($\Delta E_a - \Delta E_h$) increases. Similarly ΔE_a is lowered more than ΔE_h by electron-withdrawing groups. This causes a decrease in $\Delta\Delta E$ and $\Delta\nu_{max}$ [ν_{max}(alkaline)$-\nu_{max}$(neutral)], which is proportional to $\Delta\Delta E$, with increasing σ-value (Fig. 4). The results are in line with the above discussion. Figure 4 shows that $\Delta\Delta E$ is positive for the compounds containing electron-donating and weak electron-withdrawing substituents and negative for highly electron-withdrawing substituents such as *p*-cyano and *p*-nitro groups. This is in line with the result obtained by Griffith.[2,3]

In the solid state, where the structure of the dyes is the same as in the neutral aqueous solutions as shown by the electronic spectra, the dependence of ν_{max} on σ is expected to be similar to that in neutral aqueous solution. The plot (ν_{max} *vs.* σ) in the case of compounds with electron-withdrawing substituents ($\sigma>0$) is as expected (Fig. 4). For compounds with strongly electron-donating substituents (*p*-methoxyl, *p*-dimethylamino, and *p*-diethylamino) the absorption peaks are at frequencies higher than those expected from the above consideration. The apparent anomalous behavior of these compounds is explained in the following. There is a greater scattering in the plot ν_{max} *vs.* σ in the solid state. The correlation in the solid spectra is not as good as desired. However qualitative conclusion can be drawn from it.

Aggregation in the Solid State. Distinct shoulders are present at the longer wavelength region (580—650 nm) of the main absorption bands in the solid spectra of *p*-methoxy, *p*-dimethylamino, and *p*-diethylamino derivatives. Figure 6 shows the solid absorption spectrum of *p*-dimethylamino derivative. This is not present in the other compounds. Thus the

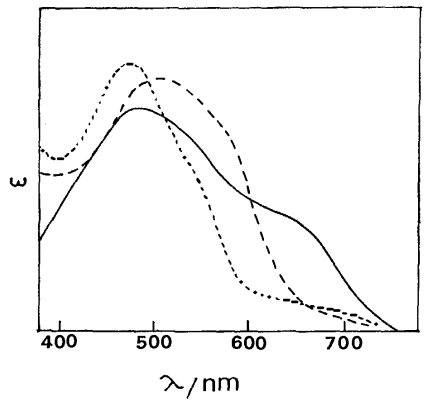

Fig. 6. Solid absorption spectra of 2-(*p*-dimethylaminophenylazo)-1-naphthol-4-sulfonic acid.
——: Untreated, ----: after treatment with alkali, ……: after treatment with acid. Molar absorptivity, arbitary.

color of the above compounds is not red as expected from the position of the main absorption bands, but purple. This shoulder does not appear in the absorption spectra in aqueous solutions.

Appearance of the additional bands might be due to the presence of aggregate species in the solid state of the compounds, as in the case of cyanine dyes used for sensitizing silver halides.[19] Only the *p*-methoxy, *p*-dimethylamino, and *p*-diethylamino derivatives of the present series of compounds form aggregate species in the solid state. The reason might be as follows. These compounds, like all other compounds, exist mainly in the hydrazone form in the solid state. There are strong donor and acceptor groups at the two ends of the molecules of these compounds. The donor groups are enhanced by the strongly electron-donating substituents. Such a situation can favor aggregation.

The aggregate band at the longer wavelength disappears in the spectrum of the *p*-dimethylamino or *p*-diethylamino derivative if a pinch of the solid compound is treated with a drop of strong acid or alkali and dried before the measurement, though no change in external appearance was observed. Figure 6 shows the solid state absorption spectra of the *p*-dimethylamino derivative before and after treatment with acid or alkali. Treatment with strong acid protonates the dialkylamino group and that with strong alkali converts the dye into anionic azo structure. In both cases, donor and acceptor groups are not simultaneously present in the molecule. The results might suport the cause of aggregation.

One of the authors (R.C. Das) is grateful to The Japan Society for Promotion of Science for the award of a Senior Co-operative Fellowship. Another author (S. Stoyanov) wishes to thank the Japanese Government for the award of UNESCO Fellowship and the Committee for Science & Technical Progress of Bulgaria for making his stay in Japan possible. Thanks are also due to Prof. H. Kobayashi, Tokyo Institute of Technology, Dr. K. Sugita and Dr. Y. Hori of Chiba University for their help and co-operation.

The Crystal Structure of the 1,3-Di-*p*-tolyl-5-phenylverdazyl Radical[1)]

Nagao AZUMA

Laboratory of Chemistry, Faculty of General Education, Ehime University, Bunkyo-cho, Matsuyama 790

(Received October 30, 1979)

Synopsis. The crystals of 1,3-di-*p*-tolyl-5-phenylverdazyl are monoclinic, with the space group $P2_1/c$ and with $a=10.66(1)$, $b=21.76(1)$, $c=8.171(6)$ Å, $\beta=98.8(1)°$, and $Z=4$. The crystal structure has been determined by means of X-ray diffraction. The molecular structure is similar to those of other verdazyls. The molecules are packed in a column along the c axis.

Following the conventional procedure, the paramagnetic susceptibility of 1,3-di-*p*-tolyl-5-phenylverdazyl (DTPV) has been discussed in this series.[2)] A linear chain of Ising spins has been proposed for DTPV crystals, with the suggestion of another possibility of an alternating linear chain of Heisenberg spins. The latter possibility correlates with the alternation in the molecular packing. In order to examine whether there is such an alternation in the DTPV crystal, crystal-structure analysis has been carried out by means of X-ray diffraction. No alternation appears in the revealed crystal structure.

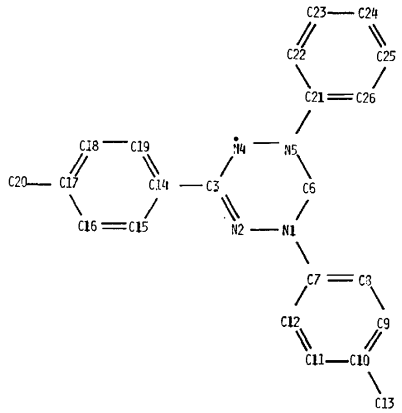

Fig. 1. The chemical structure and numbering system of 1,3-di-*p*-tolyl-5-phenylverdazyl (DTPV).

Experimental

Material and Procedure. The DTPV was prepared from *p*-tolualdehyde, *p*-toluidine, aniline, and formaldehyde, following the procedure of Kuhn and Trischmann.[3)] The crystals were purified several times through recrystallization from a methanol solution; mp=116.0—116.5 °C.

The unit-cell parameters were refined on a manually-operated four-circle diffractometer. The intensity data were collected on the same diffractometer with Zr-filtered Mo $K\alpha$-radiation up to $2\theta=45°$ through a single scan per peak for all the reflections. The background intensities around an arbitrary axis were measured as a function of the Bragg angle, and this function was assumed for all the reflections. The reflection intensities were corrected for Lorentz and polarization effects.

Crystal Data. $C_{22}H_{21}N_4$, $M=341.43$, monoclinic, space group $P2_1/c$, $a=10.66(1)$, $b=21.76(1)$, $c=8.171(6)$ Å, $\beta=98.8(1)°$, $V=1873$ Å^3, $D_m=1.2$ (by floatation), $D_x=1.210$ g/cm^3, and $Z=4$.

Structure Determination and Refinement

The structure was solved by the direct method using the *SORTE* program,[4)] with the positions of all the 26 non-hydrogen atoms located on an *E*-map. Those positions were refined by the blockdiagonal least-squares procedure. The positions of the 15 ring hydrogen atoms were deduced from a difference Fourier map. Those of the methyl hydrogen atoms were not, however, located from the difference Fourier maps and were ignored in the present refinement in view of the accuracy of the intensity data. The discrepancy index, R, for 1487 non-zero reflections was finally reduced to 0.11 by fullmatrix least-squares refinement with anisotropic thermal parameters for the non-hydrogen atoms and isotropic ones for the ring hydrogen atoms. The hydrogen isotropic thermal parameters ranged between 3.5 and 5.2 Å^2; these values were fixed in the final stage of the refinement. The atomic scattering factors were adopted from the International Tables for X-Ray Crystallography.[5)] The final positional parameters of the non-hydrogen atoms are shown in Table 1*; the numbering system refers to Fig. 1.

Discussion

Table 2 shows the bond distances and bond angles. There is no significant difference between the molecular dimensions of DTPV and those of the other verdazyls.[6)] The sums of the three bond angles around the three-coordinated nitrogen atoms, N1 and N5, are 360 and 359°. The atomic deviations of N1 and N5 from the planes defined by the N2, C6, and C7 atoms and by the N4, C6, and C21 atoms are 0.04 and 0.08 Å respectively. These two results show the sp^2 hybridization for the three-coordinated nitrogen atoms, which, accordingly, contribute two π-electrons per atom to the π-system. The conformation of the 1,2,4,5-tetrazinyl ring is an unsymmetrical boat form, with four coplanar nitrogen atoms (N-plane) and these atomic deviations from this plane: C3, −0.14; C6, −0.64; C7, 0.45; C8, 0.19; C12, 1.23; C14, −0.27; C21, 0.40; C22, 1.07; and C26, 0.14 Å. The dihedral angle between the N- and the C3-tolyl planes is 7°. Those between the N2-C6-C7 plane and the N1-tolyl plane and between the N4-C6-C21 plane and the N5-phenyl plane are 14 and 10° respectively.

* Lists of the observed and calculated structure factors (List A), of the thermal parameters (B), and of the positions of the ring hydrogen atoms (C) are kept by the office of the Chemical Society of Japan, (Document No. 8027).

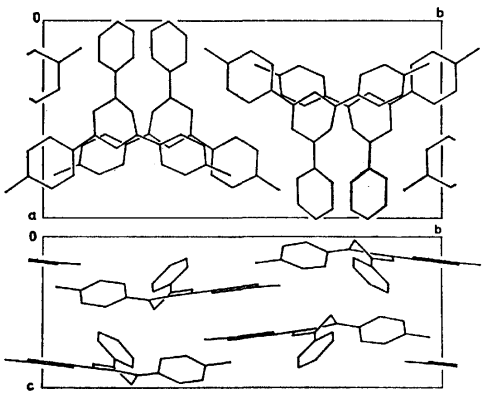

Fig. 2. The molecular packing of DTPV.

These dihedral angles can be regarded as the twist angles about the corresponding inter-ring bonds. These small twist angles and the unsymmetrical boat form of the 1,2,4,5-tetrazinyl ring have also been observed in other verdazyls.[6] Such a molecular structure of the verdazyls, containing a four-coordinated carbon atom or C6, makes the unpaired electron delocalize over the whole framework.[7]

The molecules in the crystal are packed in a column along the c axis, as is shown in Fig. 2. The shortest N...N, N...C, and C...C intermolecular atomic contacts appear in this column and are as follows: N1...N1, 4.15; N1...C12, 3.45; and C8...C3, 3.39 Å. The intermolecular contacts all seem not to be shorter than the normal van der Waals distances. There is no alternation in the molecular packing, as can be seen from Fig. 2. Therefore, the crystal structure does not support the possibility of the alternating linear chain of the spins in the DTPV crystal. For another reason, the linear chain of Ising spins is also doubtful. Based on the crvstal structure and the data from the magnetic-resonance spectroscopies, the magnetic susceptibility of the DTPV crystal will be re-

Table 2. Bond distances [l/Å] and bond angles [ϕ/°]

One-electron Reduction Potentials of Several Electron Acceptor Molecules and Cation Radicals of Donors

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 30, 1980)

Synopsis. Reversible one-electron reduction potential values of several electron acceptor molecules and cation radicals of donors were estimated by means of the equilibrium constant of electron transfer reaction between ion radicals in acetonitrile solution, and the results were compared with the observed electrochemical data.

In previous papers reports were given on a preferred electron-transfer (*i.e.*, oxidation-reduction) reaction from an anion radical to neutral electron acceptor molecule in solution.[1] The difference in reversible one-electron reduction potentials between two acceptor molecules could be estimated by measuring the equilibrium constant of the reaction spectrophotometrically. For example, the electron-transfer reaction from 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical to neutral cyano-substituted *p*-benzoquinone in acetonitrile solution is expressed by

$$TCNQ^{\cdot-} + p\text{-}X_2QCy_2 \rightleftharpoons TCNQ + p\text{-}X_2QCy_2^{\cdot-}, \quad (1)$$

where *p*-H_2QCy_2 (X=H) and *p*-Cl_2QCy_2 (X=Cl) stand for 2,3-dicyano-*p*-benzoquinone and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, respectively. By assuming that the activity coefficients of the solutes are unity and neglecting the effect of counter cations, the equilibrium constant of this reaction was determined spectrophotometrically to be $K=30$ at 20 ± 1 °C for X=H, while $K=(4.7\pm1.0)\times10^5$ at 15 °C for X=Cl, in acetonitrile solution.[1] By means of the Nernst equation and the estimated equilibrium constant, we obtain

$$E_0(p\text{-}H_2QCy_2, p\text{-}H_2QCy_2^{\cdot-}) = E_0(TCNQ, TCNQ^{\cdot-}) + 0.09\ V, \quad (2)$$

$$E_0(p\text{-}Cl_2QCy_2, p\text{-}Cl_2QCy_2^{\cdot-}) = E_0(TCNQ, TCNQ^{\cdot-}) + 0.32\ V, \quad (3)$$

where $E_0(A, A^{\cdot-})$ indicates reversible one-electron reduction potential of an acceptor, $A+e\rightleftharpoons A^{\cdot-}$, in acetonitrile solution.

On the other hand, studies were also made on the chemical equilibrium of electron transfer reaction from neutral electron donor molecule to another cation radical molecule in acetonitrile solution.[2,3] In a similar way to that for the chemical equilibria of electron acceptor molecules, the following relations of reversible one-electron reduction potentials were obtained for the cation radicals of donor molecules of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD), *N,N*-dimethyl-*p*-phenylenediamine (DMPD), *N,N,N',N'*-tetramethylbenzidine (TMB), and tetrathiafulvalene (TTF):

$$E_0(DMPD^{+\cdot}, DMPD) = E_0(TMPD^{+\cdot}, TMPD) + 0.078\ V, \quad (4)$$

$$E_0(TMB^{+\cdot}, TMB) = E_0(TMPD^{+\cdot}, TMPD) + 0.28\ V, \quad (5)$$

$$E_0(TTF^{+\cdot}, TTF) = E_0(TMPD^{+\cdot}, TMPD) + 0.086 \pm 0.008\ V, \quad (6)$$

where $E_0(D^{+\cdot}, D)$ stands for reversible one-electron reduction potential for cation radical of a donor, $D^{+\cdot}+e\rightleftharpoons D$, in acetonitrile solution.

So far, two series of reduction potentials have been independently obtained for the electron donor groups and the acceptor groups. In this paper, the two series are combined, for which purpose the following one-electron transfer reaction between donor TMPD and acceptor TCNQ in acetonitrile solution was considered:

$$TMPD + TCNQ \rightleftharpoons TMPD^{+\cdot} + TCNQ^{\cdot-}. \quad (7)$$

Yamagishi *et al.* examined the reaction and confirmed the occurrence of this chemical equilibrium.[4] They determined the equilibrium constant of Eq. 7 spectrophotometrically together with the enthalpy and entropy changes as

$$K = \frac{[TMPD^{+\cdot}][TCNQ^{\cdot-}]}{[TMPD][TCNQ]} = (7\pm2)\times10^{-2} \text{ at } 25\ °C, \quad (8)$$

$$\Delta H(\text{the enthalpy change}) = -17\pm4\ kJ\ mol^{-1}, \quad (9)$$

$$\Delta S(\text{the entropy change}) = -71\pm21\ J\ K^{-1}\ mol^{-1}. \quad (10)$$

Let us divide Eq. 7 into the following two reduction reactions,

$$TMPD^{+\cdot} + e \rightleftharpoons TMPD, \quad (11)$$

$$TCNQ + e \rightleftharpoons TCNQ^{\cdot-}. \quad (12)$$

The occurrence of the chemical equilibrium of Eq. 7 indicates that

$$E_0(TMPD^{+\cdot}, TMPD) - \frac{RT}{F}\ln\frac{[TMPD]}{[TMPD^{+\cdot}]} = E_0(TCNQ, TCNQ^{\cdot-}) - \frac{RT}{F}\ln\frac{[TCNQ^{\cdot-}]}{[TCNQ]}, \quad (13)$$

where R, T, and F are the gas constant, observed temperature, and Faraday constant, respectively. Using Eq. 8, we obtain

$$E_0(TCNQ, TCNQ^{\cdot-}) = E_0(TMPD^{+\cdot}, TMPD) + \frac{RT}{F}\ln K = E_0(TMPD^{+\cdot}, TMPD) - 0.07\ V. \quad (14)$$

The relation is important for connecting the reduction potentials of the donors with those of the acceptors. Another useful reaction is

$$TTF + TCNQ \rightleftharpoons TTF^{+\cdot} + TCNQ^{\cdot-}. \quad (15)$$

Yamagishi and Iida[3] examined the chemical equilibrium in acetonitrile solution spectrophotometrically, and determined the equilibrium constant to be $(2.8\pm0.1)\times10^{-3}$ at 11 °C. In a similar way to that for the TMPD/TCNQ system, we obtain

$$E_0(TCNQ, TCNQ^{\cdot-}) = E_0(TTF^{+\cdot}, TTF) - 0.14\ V. \quad (16)$$

With the aid of Eqs. 14 and 16, we can connect the reduction potential series of the acceptors (Eqs. 2 and 3) with those of the donors (Eqs. 4—6). If a standard value of reduction potential is given for E_0(TMPD$^{+\cdot}$, TMPD) or E_0(TTF$^{+\cdot}$, TTF), all the other reduction potential values can be determined from the above procedure. The reversible one-electron reduction potentials thus estimated for the donors and acceptors are given in Table 1, where E_0(TTF$^{+\cdot}$, TTF)=0.30 V is chosen as a standard. The E_0(TTF$^{+\cdot}$, TTF) value was determined by Wheland and Gillson polarographically *versus* saturated calomel electrode in acetonitrile solution using tetraethylammonium perchlorate as a supporting electrolyte.[5] Since our data of reduction potentials correspond to the free energy change in pure acetonitrile, our values should be compared with standard electrode potentials measured in the same solvent. However, since no such electrode potential data are available, we compare our data with polarographic reduction potentials measured by several authors.[5-7] These values are also given in Table 1. As for the E_0(TCNQ, TCNQ^{-}) value, the 0.16 V value estimated by our electron-transfer equilibrium method was in good agreement with the electrochemical value of Wheland and Gillson, 0.17 V.[5] The E_0(*p*-H_2QCy_2, *p*-$H_2QCy_2^{-}$)= 0.25 V value estimated by our method was somewhat smaller than the half-wave potential of 0.31 V in polarography measured by Scribner,[6] but our value of E_0(*p*-Cl_2QCy_2, *p*-$Cl_2QCy_2^{-}$)=0.48 V was found to agree almost with the 0.51 V value measured by Peover.[7] The one-electron reduction potential of phenothiazine (PT) cation radical is also given in Table 1. The value of E_0(PT$^{+\cdot}$, PT)=0.56 V was estimated by our electron-transfer equilibrium method in (1:3) ethanol-water solvent, using the relation of E_0(PT$^{+\cdot}$, PT)=E_0(TMPD$^{+\cdot}$, TMPD)+0.34 V,[2] the observed reduction potential of 0.58 V being the value in acetonitrile solution measured by Wheland and Gillson.[5] Although the solvents used differ from each other, a fairly good agreement was obtained between our value and that of Wheland and Gillson.

Table 1. One-electron reduction potential data for electron acceptor molecules and cation radicals of donors[a]

Reduction reaction	Calcd[b]	Obsd[c]
TCNQ + e $\rightleftharpoons$ TCNQ^{-}	0.16	0.17
p-H_2QCy_2 + e $\rightleftharpoons$ *p*-$H_2QCy_2^{-}$	0.25	0.31
p-Cl_2QCy_2 + e $\rightleftharpoons$ *p*-$Cl_2QCy_2^{-}$	0.48	0.51
TMPD$^{+\cdot}$ + e $\rightleftharpoons$ TMPD	0.22	—
TTF$^{+\cdot}$ + e $\rightleftharpoons$ TTF	0.30	0.30
DMPD$^{+\cdot}$ + e $\rightleftharpoons$ DMPD	0.30	—
TMB$^{+\cdot}$ + e $\rightleftharpoons$ TMB	0.50	—
PT$^{+\cdot}$ + e $\rightleftharpoons$ PT	0.56[d]	0.58

a) In unit of V *versus* saturated calomel electrode in acetonitrile solution. For abbreviations of compounds, see text. b) Values estimated by electron-transfer equilibrium method. E_0(TTF$^{+\cdot}$, TTF)=0.30 V is taken as a standard. c) Refs. 5—7. d) Value of phenothiazine cation radical (PT$^{+\cdot}$) estimated by electron-transfer equilibrium method in (1 : 3) ethanol-water solvent. The relation of E_0(PT$^{+\cdot}$, PT)=E_0(TMPD$^{+\cdot}$, TMPD)+0.34 V was used.[2]

For the reduction potentials of the other compounds, there are no experimental data for the purpose of comparison. However, the data obtained by our method are useful for predicting the degree of electron transfer when certain electron donor (D) and acceptor (A) molecules are mixed in acetonitrile solution. If E_0(A, A^{-})$-E_0$(D$^{+\cdot}$, D)$<-RT/F$, equilibrium constant of the reaction, D+A$\rightleftharpoons$D$^{+\cdot}$+A^{-}, is small, and most of the chemical species in solution will be neutral D and A molecules. If E_0(A, A^{-})$-E_0$(D$^{+\cdot}$, D)$>$ RT/F, the equilibrium constant becomes large, so that most of the chemical species in solution will be ionized D$^{+\cdot}$ and A^{-} radical molecules. In the case of E_0(A, A^{-})$-E_0$(D$^{+\cdot}$, D)$\approx$0, the equilibrium constant is *ca.* unity, and one can observe not only neutral D and A molecules but also ionized D$^{+\cdot}$ and A^{-} in solution. For example, if TTF is mixed with *p*-Cl_2-QCy_2 in acetonitrile solution, the following reaction will take place:

$$\text{TTF} + p\text{-}Cl_2QCy_2 \rightleftharpoons \text{TTF}^{+\cdot} + p\text{-}Cl_2QCy_2^{-}. \quad (17)$$

By means of the values of E_0(TTF$^{+\cdot}$, TTF)=0.30 V and E_0(*p*-Cl_2QCy_2, *p*-$Cl_2QCy_2^{-}$)=0.48 V (Table 1) and the Nernst equation, we can estimate the equilibrium constant, K, of Eq. 17 as

$$\ln K = \ln \frac{[\text{TTF}^{+\cdot}][p\text{-}Cl_2QCy_2^{-}]}{[\text{TTF}][p\text{-}Cl_2QCy_2]} = \frac{F}{RT}\{E_0(p\text{-}Cl_2QCy_2, p\text{-}Cl_2QCy_2^{-}) - E_0(\text{TTF}^{+\cdot}, \text{TTF})\}. \quad (18)$$

In acetonitrile solution at 25 °C, the magnitude of K was estimated to be as great as 1.1×10^3. Thus, in this system, one electron is transferred almost completely from TTF to *p*-Cl_2QCy_2, and most of the chemical species observed in acetonitrile will be ionized TTF$^{+\cdot}$ and *p*-$Cl_2QCy_2^{-}$.

MINDO/3 Prediction of the Π and Σ Electronic States of the Succinimido Radical

Osamu KIKUCHI,* Yumiko SATO, and Keizo SUZUKI
Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received March 25, 1980)

Synopsis. Restricted open-shell SCF MINDO/3 calculation gives the Σ state for the electronic ground state of the succinimido radical.

Recent works on the succinimido radical[1] has yielded a number of interesting characterizations of this radical. One of these is the recognition that two different electronic states of succinimido are being produced in the reactions of *N*-halosuccinimides, radicals with quite distinctive properties. These are considered to be the Π_N and Σ_N states.[2] Succinimido has not been detected by ESR experiment[1] and the theoretical work of this radical is worth being done.

In the simplest nitrogen radical, NH_2, the lone-pair electrons occupy the hybrid σ orbital of nitrogen and an unpaired electron occupies the nitrogen $2p_\pi$ orbital; the Π state is the ground state and the Σ state is an excited one. The *ab initio* calculation[3] gives 113 kJ mol^{-1} for the energy separation between these states; the experimental value is 130 kJ mol^{-1}.[3] The same level of the *ab initio* calculation[3] gives 46 kJ mol^{-1} for the Σ_N-Π_N energy separation of the formylaminyl (HCONH) radical. In formylaminyl, the carbonyl π^* orbital stabilizes the nitrogen $2p_\pi$ electrons, and the Σ-Π energy separation is reduced by the amount of 67 kJ mol^{-1}. In the succinimido radical, two carbonyl groups are introduced at the nitrogen atom, and its Σ-Π separation would be reduced still more; there is the possibility that the ground state of succinimido is of the Σ type.[4]

Koenig and Wielsek[5] have done the INDO calculation on the succinimido radical and concluded that the Π state is the ground state. Their results show that the energy separation between the Σ_N and Π_N states is 159 kJ mol^{-1}. This value is too large and inconsistent with the above qualitative consideration about the Σ-Π energy separation of the nitrogen radicals. We have thus examined the energy separation of succinimido using the MINDO/3 approximation.[6] The Σ and Π states of succinimido were obtained by repeated diagonalization of the correct general SCF operator which gives the optimum results for the open-shell systems.[7] The molecular structure was optimized by the use of Fletcher's variable metric method.[8] For the NH_2 radical, MINDO/3 gave the satisfactory molecular structures and the Σ-Π energy separation (Table 1). The optimized structures and the calculated heats of formation of succinimido are shown in Fig. 1. The MINDO/3 predicts the Σ ground state for the succinimido radical. This state lies 71 kJ mol^{-1} below the excited Π state.

Very recently, on the basis of the semi-empirical MNDO calculations, Clark[9] has well explained the reaction paths for the generation of the Π and Σ states of the succinimido radical from *N*-halosuccinimides. His MNDO results show that the ground state of succinimido is of Π-type, although the open-shell method employed is an approximate one. Since the present MINDO/3 calculation predicts the Σ ground state which is inconsistent with the INDO and MNDO results, another semi-empircal method, the CNDO/BW method[10] which was parametrized by Boyd and Whitehead so as to give better energetics of molecules, was also applied to succinimido. The results obtained are parallel with those of MINDO/3; the Σ state is more stable than the Π state by 41 kJ mol^{-1}.

The characterization of the ground and excited electronic states of the succinimido radical is a key factor for the analysis of the reaction mechanism in which both of the ground and excited states of succinimido are involved. The present MINDO/3 and CNDO/BW results predict the Σ state for the ground state of this radical, while the INDO[5] and MNDO[9]

TABLE 1. MINDO/3 RESULTS ON THE NH_2 RADICAL

Method	H-N-H angle/°		$E(\Sigma)-E(\Pi)$
	In Π state	In Σ state	kJ mol^{-1}
MINDO/3	102	136	100

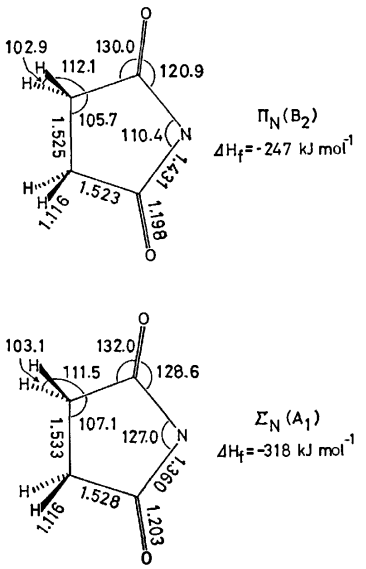

Fig. 1. The molecular structure (C_{2v}) of the Π and Σ states of the succinimido radical optimized by the restricted open-shell MINDO/3 method. These C_{2v} structures were also obtained by the geometry optimization in which the distorted (C_s) structures were used as the initial data.

calculations have predicted the Π ground state. The Σ-Π separation of succinimido is expected to be very small, and the question, whether Σ or Π is the ground state of this radical, is still open to investigation.

A Photoacoustic and Fluorescent Spectroscopic Study of Uranyl Compounds

Yoshinori SUGITANI,* Hiroshi NOMURA, and Kozo NAGASHIMA
Institute of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received October 22, 1979)

Synopsis. The fluorescent emission spectra and fluorescent lifetimes have been measured for several available uranyl salts and natural mineral zippeite. The absolute quantum efficiency data of $UO_2SO_4 \cdot 0.5H_2O$, $H_2(UO_2)_2(PO_4)_2 \cdot 8H_2O$, and $UO_2(CH_3COO)_2 \cdot 2H_2O$ have been obtained by the simultaneous measurement of the photoacoustic and excitation spectra.

The simultaneous measurement of the intensities of the photoacoustic and fluorescent excitation signals as a function of the wavelength of the exciting light enables the determination of the absolute quantum efficiencies of fluorescence without any use of reference materials.[1] The technique was successfully applied to a series of uranyl micas: uranyl phosphate of alkali, alkaline-earth, and some other bivalent metal ions. In the present work, the simultaneous measurement of some uranyl compounds have been carried out, together with the measurement of the emission spectra and the luminescence lifetimes.

Experimental

Samples. The uranyl compounds used in the present study were all prepared according to the literature[2-5] except for a natural mineral zippeite, $3UO_2 \cdot 2SO_3 \cdot 9H_2O$.

Measurement. The fluorescent emissions were measured by means of a multi-purpose spectrometer, JASCO SS-25, using an UV light of 365 nm as the excitation source. The photoacoustic spectra and fluorescent excitation spectra were measured by means of a system, which was readily arranged by the use of the spectrometer CT-25N, a lock-in amplifier, and a sample cell designed for the simultaneous detection of photoacoustic and excitation signals.[1] The intensity of the fluorescent excitation signal was monitored at the output slit of the spectrometer adjusted at 520 ± 5 nm. A 300 w xenon lamp was used as the excitation source. The fluorescent lifetimes were measured by the multi-channel photon counting method using a microcomputer-assisted apparatus made in our laboratory, the details of the procedure will be described elsewhere.[6] All of the measurements were conducted at room temperature.

Results and Discussion

Figure 1 shows the fluorescent emission(a), fluorescent excitation(b), and photoacoustic(c) spectra of the powdered sample of uranyl acetate, $UO_2(CH_3COO)_2 \cdot 2H_2O$. The three kinds of spectra for the other uranyl compounds studied are very similar to those shown in Fig. 1, except for minor differences in peak positions and/or their relative intensities. Generally, the emission and excitation spectra of uranyl compounds have six and twelve peaks respectively, which can be explained as the transitions between $^1\Sigma_g^+$ and $^3\Pi_u$ states, the both split into sublevels by the symmetric stretching of the UO_2 species.[7] It should be noted

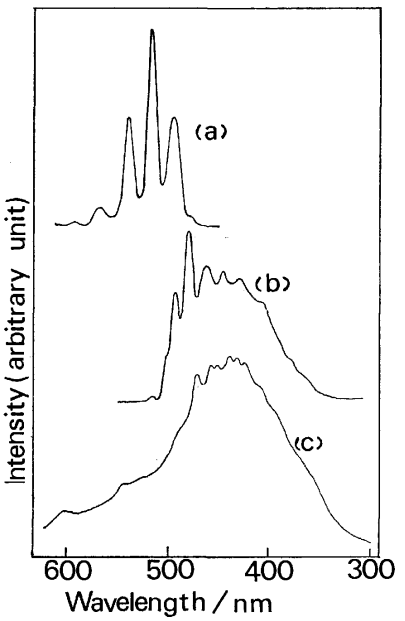

Fig. 1. Spectra of $UO_2(CH_3COO)_2 \cdot 2H_2O$.
(a) Fluorescent emission spectra, (b) fluorescent excitation spectra, (c) photoacoustic spectra (chopping frequency 80 Hz).

that the photoacoustic spectra are very similar to the excitation spectra except for a somewhat better resolution in the latter spectra, just as was the case with the uranium-mica samples. The similarity between the two spectra shows that a definite proportional amount of the energy absorbed at a certain wavelength, λ, will always be emitted as optical energy(excitation spectra), while the remaining part of the absorbed energy will be emitted as thermal energy(photoacoustic spectra). This suggests that the de-excitation processes from the twelve excited sublevels of $^3\Pi_u$ are affected by the same transition mechanism. This seems to be closely related to the fact that the six emission peaks of $Mg(UO_2)_2(PO_4)_2 \cdot nH_2O$ have the same fluorescent lifetime.[8]

The fluorescent lifetimes and quantum efficiencies of the prepared samples are given in Table 1. The lifetimes have the same order of magnitude as those of uranium-micas reported before.[8] The mineral zippeite, $3UO_2 \cdot 2SO_3 \cdot 9H_2O$, has a lifetime by an order shorter, probably because of the trace amount of impurities.

Quantum efficiency data have been obtained for the three samples through the method of the simultaneous measurement of the photoacoustic and excitation spectra, details of which have already been reported.[1] The quantum efficiency determinations for the other compounds were not successful. There is no apparent correlation between the lifetime and the

The Crystal Structure of Bis(acetylacetonato)platinum(II)

Shigeki ONUMA, Keiji HORIOKA, Hironao INOUE, and Shuzo SHIBATA*
Department of Chemistry, Shizuoka University, Oya, Shizuoka 422
(Received January 23, 1980)

Synopsis. The crystal structure of $Pt(acac)_2$ has been determined by means of X-ray diffraction. The molecule is monomeric, the coordination geometry being square-planar. The average Pt–O distance is 1.991(8) Å. The bond lengths and angles of the chelating ligands are almost the same as those for other acetylacetone complexes.

The acac ligand in $Pt(acac)_2$ is thought to be bidentate (Hacac=acetylacetone). However, some anomalous modes of ligation have been found in platinum complexes; *e.g.*, in $K[Pt(acac)_2Cl]$,[1] one of the β-diketones is unidentate and linked to the metal through the methylene carbon; in $[Me_3Pt(acac)]_2$,[2] the β-diketone is linked to one platinum atom *via* γ-carbon atom and to the other platinum *via* oxygen atoms to yield a binuclear complex. The present study has been undertaken to elucidate the crystal structure of $Pt(acac)_2$.

Experimental

The crystals were prepared by the method of Werner.[3] Crystal Data: $Pt(C_5H_7O_2)_2$, Mol. wt. 393.3, triclinic, space group $P\bar{1}$ $a=7.13(2)$, $b=5.75(2)$, $c=7.957(4)$ Å, $\alpha=70.0(1)$, $\beta=98.9(1)$, $\gamma=113.2(2)°$, $V=282(1)$ Å^3; $D_m=2.32$, $D_c=2.31$ g cm^{-3} for $Z=1$. Found: C, 30.57; H, 3.56%. Calcd for C, 30.54; H, 3.59%. Crystal dimensions: $0.08\times0.14\times0.20$ mm^3.

Intensity data were collected on a Rigaku diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Reflections were measured with the ω-scan ($2\theta\leqq30°$) and ω-2θ scan ($30°<2\theta<70°$) techniques. The scan rate was 4° min^{-1} and the scan width $(1.8+0.5\tan\theta)°$. The number of reflections with $F>3\sigma$ was 2342. The intensities were corrected for Lorentz and polarization effects, but not for absorption. The space group $P\bar{1}$ was assumed at the outset and verified by successful refinement of the crystal structure. Compliance to the centrosymmetric space group requires that the monomer possesses a crystallographic center of symmetry. The structure was solved by the heavy atom method. The positional and anisotropic thermal parameters of the eight non-hydrogen atoms were refined by the block-diagonal least-squares method. The final R value was 0.059 for 2342 reflections. The atomic scattering factors were taken from Ref. 4. Anomalous dispersion correction for platinum atom was taken into account. The resulting difference Fourier map shows no significant peaks or troughs. The final positional and thermal parameters are given in Table 1. The complete F_o-F_c data are kept at the Chemical Society of Japan (Document No. 8029).

Results and Discussion

The complex was found to be monomeric, the platinum atom having a square-planar coordination by four oxygen atoms of the acetylacetonato ligands.

OCC	127	125	126
$OCCH_3$	114	116	114
OPtO	96	95	94

The molecular structure is shown in Fig. 1, atom numbering and bond lengths and angles also being given with their esd values in parentheses. The chelate ring was found to be planar, the deviations of atoms from the least-squares plane being: Pt 0.0, O(1) 0.02, O(2) 0.02, C(1) −0.03, C(2) 0.01, C(3) 0.02, C(4) 0.00, C(5) −0.02 Å. The average values of the chemically equivalent bond lengths and angles are given in Table 2, those of other β-diketonato complexes being given for the sake of comparison. They agree with each other.

The molecules are well separated. The arrangement viewed along the a axis is shown in Fig. 2. The intermolecular distances are normal, the shortest distance between methyl carbon atoms being 4.00 Å.

Most of the calculations were carried out by using the UNICS programs[5] at the Computer Center of the University of Tokyo.

Background Atmospheric Concentrations of Halogenated Hydrocarbons in Japan

Yoshihiro MAKIDE,* Yutaka KANAI, and Takeshi TOMINAGA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received February 20, 1980)

Synopsis. The atmospheric concentrations of CCl_2F_2, CCl_3F, CCl_2FCClF_2, CH_3CCl_3, CCl_4, $CHCl{=}CCl_2$, and $CCl_2{=}CCl_2$ in remote areas in Japan and over the Japan Sea were measured in the summer of 1979. The averaged observed concentrations (in ppt: 10^{-12} v/v) for the compounds were 301 ± 12, 175 ± 7, 23 ± 2, 117 ± 11, 107 ± 6, 14 ± 10, and 19 ± 10 respectively.

Among a number of anthropogenic halogenated hydrocarbons released in large quantities into the atmosphere, greatest attention has been directed to the chlorofluoromethanes, CCl_2F_2 and CCl_3F, which have been widely used as spray propellants and refrigerants. The chlorofluoromethanes accumulated in the troposphere due to their long lifetimes rise gradually into the stratosphere, there to be decomposed by intense UV light to release atomic chlorine, which can then participate in the ClO_x-chain removal of stratospheric ozone.[1,2] While such a theoretical prediction as to stratospheric ozone depletion by chlorofluorocarbons has been essentially validated by extensive research,[3-8] precise world-wide monitoring of their background atmospheric concentrations has now become more important for the accurate estimation of possible future ozone depletion. The growing use of 1,1,1-trichloroethane (CH_3CCl_3), once classified as a 'safe' substitute for other 'labile' solvents, cannot be overlooked, since it is not decomposed completely by OH radicals in the troposphere and may similarly affect the ozone layer if the present rates of production and use continue. The development of a reliable analytical system is greatly needed in order to determine precisely its background concentration in view of the discrepancies among the reported data,[6] possibly due to contamination by the analytical systems. Measurements of unsaturated chlorocarbons, such as $CHCl{=}CCl_2$ and $CCl_2{=}CCl_2$, which are decomposed rapidly and completely in the troposphere may also be necessary for understanding their local pollution behavior, as they are extensively used as degreasing or cleaning solvents.

Since no reliable measurements of the halogenated hydrocarbons have thus far been made in Japan and Asia, we have initiated a systematic survey of the atmospheric concentrations of CCl_2F_2, CCl_3F, CCl_2FCClF_2, CH_3CCl_3, CCl_4, $CHCl{=}CCl_2$, and $CCl_2{=}CCl_2$ over Japan; we have already reported the preliminary data on more or less polluted air samples.[10] In this article we wish to describe our clean analytical system for extremely accurate measurements and our results on the averaged background atmospheric concentrations of these substances in remote areas in the summer of 1979.

Experimental

Extremely Clean Analytical System and Procedures. Stainless steel canisters were specially designed for air sampling and storage. Since Teflon stopcocks or silicone rubber plugs often cause a contamination of halogenated hydrocarbons, the sampling canister was made from a stainless steel beaker (21) by argon-arc welding and equipped with a hermetically sealed stainless steel bellows valve (Nupro SS-4H). The inside of the canister was polished electrochemically and washed ultrasonically. After the evacuation of the canister overnight to 10^{-4} Pa at 200 °C, the dead volume between the valve and a Swagelok cap was filled with ultra-high-purity nitrogen. On sampling, ambient air was introduced into the canister by simply removing the cap and opening the valve facing the wind. The composition of the atmospheric samples remain unchanged even after storage for over a year. The calibration standard was prepared by a four- or five-step static-dilution method. An extremely clean, all-stainless-steel vacuum line was built for the final stages of dilution (*e.g.*, ppb—ppt level) with ultra-high-purity nitrogen or air. Several ambient-air samples, calibrated for all components against each standard, were used as the secondary standards in routine measurements. The halogenated hydrocarbons were determined by using a constant-current-type electron capture detector (Varian 3700 EC-GC). A Silicone OV-101 column (10 wt% coated on Chromosorb W-HP, 80—100 mesh, 5 mm i.d., 3 m long) was used as the preconcentration and analytical column. The carrier-gas (nitrogen) flow rate was 80 ml/min. Methane (4 ml/min) was mixed in between the column and the detector as a make-up gas to improve the S/N ratio and to stabilize the base line without reducing the sensitivity. An aliquot of the air sample or of the standard was introduced into an evacuated sample loop until a given pressure was reached, and then it was transferred into the column cooled at −40 °C so that halogenated hydrocarbons were kept on the head of the column. The column temperature was raised linearly at a rate of 5 °C/min up to 70 °C. After the elution of the air (oxygen), ECD was connected to the analytical column by switching the four-way valve between the column and the detector, and each component was determined.

Samples. Clean-air samples were collected in the summer of 1979 at remote areas throughout Japan and over the Japan Sea. Although sampling was not always conducted under optimum meteorological conditions, we did our best to avoid local contamination within the limited sampling periods. The locations, dates, and weather conditions are listed in Table 1.

Results and Discussion

Figure 1 shows a typical EC-GC chromatogram of the atmospheric sample No. 1, collected at Nosappumisaki, together with a chromatogram of the purified nitrogen used for the dilution of the standards to ensure the absence of any halogenated hydrocarbons during the identical analytical procedure. Since impurities in the carrier gas should also have been concentrated at the head of the analytical column during preconcentration, the possible contamination from about 500 ml of purified nitrogen can not exceed the detection limit of each compound in this system: CCl_2F_2 and

$CHCl=CCl_2$ < 0.2 ppt, CCl_2FCClF_2, CH_3CCl_3, and $CCl_2=CCl_2$ < 0.05 ppt, and CCl_3F and CCl_4 < 0.01 ppt. The reproducibility of the measurement was within 2%. The absolute accuracy of the calibration under the present conditions may be less than 10 ppt. The observed concentrations (Table 1) were slightly affected by the sampling location and the meteorological conditions regarding the transport of the air mass. However, the small standard deviations in the CCl_2F_2 and CCl_3F concentrations (≈4%) demonstrate that the relatively low local emission in the rural areas may not appreciably raise their already high concentration levels. The averaged concentrations observed in Japan are close to the background concentrations reported in the northern hemisphere after the correction for the monthly increase in concentrations. The fluctuations in the $CHCl=CCl_2$ and $CCl_2=CCl_2$ concentrations may be ascribed to their short lifetimes and relatively high emissions even in remote areas in Japan. The averaged concentrations of these halogenated ethylenes have been observed to be hundreds-fold higher in Tokyo.[11)]

In conclusion, it is made clear that we can measure the background concentrations of the halogenated hydrocarbons even in Japan only if we carefully choose favorable locations and meteorological conditions. Further studies regarding the profile of local pollution in urban areas are also in progress in our laboratory.

We wish to thank Mr. Yukihiro Nojiri for the collection of the No. 5 sample. The present work was partially supported by the Toyota Foundation.

Thermal Rearrangements of 1,5-Dimethyl- and 1,3,5-Trimethyl-8-vinyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-ol and Their Alkoxides

Makoto Nitta,* Nobuo Komatsu, and Ichiro Kasahara

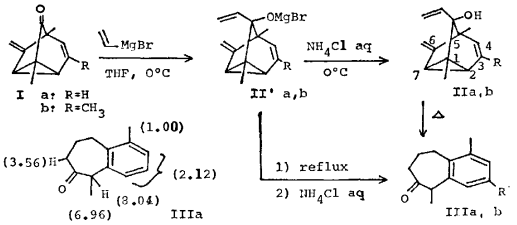
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received December 11, 1979)

Synopsis. The reactions of 1,5-dimethyl- and 1,3,5-trimethyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-one with vinylmagnesium bromide at 0 °C afforded 1,5-dimethyl- and 1,3,5-trimethyl-8-vinyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-ol, respectively. The thermal rearrangements of IIa,b and their alkoxybromomagnesium afforded 1,5-dimethyl or 1,3,5-trimethylbenzocyclohepten-6-one. It is suggested that the pathways involve an oxy-Cope rearrangement and the subsequent hydrogen migrations.

Recently, various anionic oxy-Cope rearrangements and their related sigmatropic rearrangements have been investigated, and the rate enhancements of metal alkoxides have been precisely demonstrated from the synthetic and mechanistic points of view.[1-5] In relation to the synthesis and chemistry of polycyclic compounds containing cyclopropane ring,[6,7] we ourselves tried to prepare the skeleton of bicyclo[5.4.0]undeca-1,3,5,8,10-pentaene,[8] which has a methyl group on a bridgehead. However, benzocyclohepten-6-one derivatives were obtained by the reactions of 1,5-dimethyl- and 1,3,5-trimethyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-one (Ia and Ib) with vinylmagnesium bromide and the subsequent thermal rearrangements. Therefore, we will describe here a facile synthesis of benzocyclohepten-6-one derivatives.

The reactions of Ia and Ib with vinylmagnesium bromide in anhydrous tetrahydrofuran (THF) at 0 °C afforded 1,5-dimethyl- and 1,3,5-trimethyl-8-vinyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-ol (IIa and IIb) respectively in fairly good yields. The structures of IIa, b were assigned on the basis of their spectral properties (see Experimental). The stereochemical assignment of IIa was derived from the pseudo-contact NMR spectra obtained using Eu(fod)$_3$. The chemical shifts of the hydrogens at C-3 and C-4 were much shifted downfield compared to those of the exomethylene group and hydrogen at C-7. The attacking site of vinylmagnesium bromide on Ia is similar to the case of Ia,b with lithium aluminum hydride.[9,10] Therefore, the orientation of the hydroxyl group of IIb should be the same as in the case of IIa. On the other hand, after Ia or Ib had been reacted with vinylmagnesium bromide at 0 °C, the reaction mixtures were allowed to reflux for 5 h under a nitrogen atmosphere. The benzocyclohepten-6-one derivatives, IIIa and IIIb, were thus obtained in fairly good yields. The structures of IIIa, b were determined on the basis of the spectral properties (see Experimental). The assignment of structures was also supported by the pseudo-contact NMR spectra of IIIa obtained using Eu(fod)$_3$. The relative downfield shifts (ppm/mol) of the δ's of characteristic hydrogens are given in parentheses in the structural formula IIIa in Scheme 1. When IIa or IIb was refluxed in benzene for 5 h,



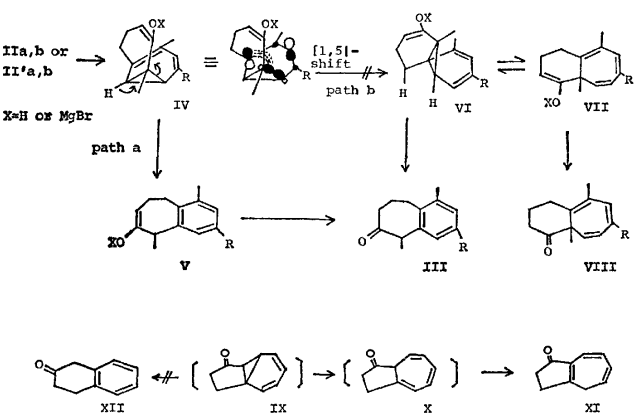
Scheme 1.

however, no thermal rearrangement into IIIa or IIIb occured, but IIa or IIb was recovered in a quantitative yield. It is known that the metal alkoxides enhance the rates of oxy-Cope rearrangements.[1-5] Therefore, IIIa, b probably originate from the anionic oxy-Cope rearrangements of the alkoxybromomagnesium derivatives, II'a and II'b.

In order to confirm this point, the thermal rearrangements of IIa and IIb were carried out at high temperatures. When IIa was heated in refluxing xylene for 30 min, a clean conversion of IIa to IIIa occured. Similarly, IIb was rearranged to IIIb in 1,2-dichlorobenzene during 15 min at the refluxing temperature.

For the facile rearrangements of IIa,b, or II'a,b, two mechanistic interpretations can be considered. In both reaction pathways, the oxy-Cope rearrangement affording IV might be the first step of the present thermal reaction, as is shown in Scheme 2. One of the possible pathways involves, perhaps, a simple stepwise aromatization of IV to III *via* V (Path a). The other possible pathway is the thermally allowed concerted [1,5]-sigmatropic rearrangement (Berson-Willcott rearrangement)[11] of IV to VI, which can give III by the cleavage of the cyclopropane ring and a concurrent hydrogen-shift.

It is known that compound IX, which has a skeleton



Scheme 2.

homologous with VI, affords bicyclo[5.3.0]decatrienone, XI, and does not afford XII.[12,13] Therefore, if the intermediate of norcaradiene, VI, is involved in the present thermal rearrangement, it should be possible for VI to equelibrate with cycloheptatriene, VII. However, VIII could not be obtained, hence, VI could not be involved in the present thermal rearrangement. Therefore, the present thermal rearrangement affording IIIa,b must proceed through Path a.

The much strained IV, which has a bridgehead double bond, could not undergo Berson-Willcott rearrangement. Since compounds Ia,b are synthesized very easily by the thermal reactions of 2,6-dimethylphenyl and 2,4,6-trimethylphenyl propargyl ether[14] respectively, the present reactions should be very useful for the preparation of benzocycloheptenone derivatives.

Experimental

Reactions of 1,5-Dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (Ia) with Vinylmagnesium Bromide. To a stirred solution of vinylmagnesium bromide, which was prepared by a usual procedure[15] using 0.730 g (30 mg-atom) of magnesium turnings, 3.50 g (32.7 mmol) of vinyl bromide, and 50 ml of anhydrous tetrahydrofuran (THF), was added 1.60 g (10 mmol) of Ia in 10 ml of THF at 0 °C. This reaction mixture was stirred another 3 h at 0 °C and then treated with aqueous ammonium chloride, followed by ether extraction. The evaporation *in vacuo* of the dried (Na_2SO_4) organic portion gave a clean oil of IIa (1.84 g, 98%): bp 66—70 °C/7 mmHg (1 mmHg=133.32 Pa); IR (neat) 3600—3400, 1600 cm^{-1}; NMR (CCl_4) δ 1.00 (s, 3H), 1.10 (s, 3H), 1.55 (s, 1H), 1.68—1.85 (m, 2H), 4.51 (s, 1H), 4.53 (s, 1H), 4.90—5.22 (m, 4H), 6.05 (m, 1H); MS *m/e* 188 (M^+). Found: C, 82.71; H, 8.64%. Calcd for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

Reaction of Ia with Vinylmagnesium Bromide and Subsequent Thermal Rearrangement. To a stirred solution of vinylmagnesium bromide, which had been prepared using 1.75 g (16.0 mmol) of vinyl bromide, 0.356 g (15.0 mg-atom) of magnesium turnings, and 25 ml of THF, was added 800 mg (5 mmol) of Ia in 5 ml of THF at an ambient temperature. This reaction mixture was allowed to reflux for another 4 h, and then it was treated with aqueous ammonium chloride, followed by ether extraction (30 ml×3). The evaporation *in vacuo* of the dried (Na_2SO_4) organic portion gave an oil of IIIa (888 mg, 95%): bp 100 °C/4 mmHg; IR (neat) 1710 cm^{-1}; NMR (CCl_4) δ 1.36 (d, J=7.0 Hz, 3H), 1.82—2.18 (m, 2H), 2.31 (s, 3H), 2.15—2.60 (m, 2H), 2.68—2.90 (m, 2H), 3.55 (q, J=7.0 Hz, 1H), 7.00 (s, 3H); MS *m/e* 188 (M^+). Found: C, 82.87; H, 8.49%. Calcd for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

Reaction of 1,3,5-Trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (Ib) with Vinylmagnesium Bromide. To a stirred solution of vinylmagnesium bromide, which had been prepared using 1.75 g (16.4 mmol) of vinyl bromide, 0.365 g (15 mg-atom) of magnesium turnings, and 25 ml of THF, was added 870 mg (5 mmol) of Ib in 10 ml of THF at 0 °C. This reaction mixture was stirred for another 4 h at 0 °C, treated with aqueous ammonium chloride, and then extracted with ether (30 ml×3). The evaporation *in vacuo* of the dried (Na_2SO_4) organic portion gave an oil of IIb (997 mg, 99%): bp 40—46 °C/4 mmHg; IR 3400, 1650 cm^{-1}; NMR (CCl_4) δ 0.95 (s, 3H), 1.22 (s, 3H), 1.95 (d, J=1.5 Hz, 3H), 1.50 (s, 1H), 1.66 (d×d, J=7.0 Hz, 3.5 Hz, 1H), 1.90 (d, J=7.0 Hz, 1H), 4.62 (s, 1H), 4.66 (s, 1H), 5.38 (m, 1H), 5.0—5.2 (m, 2H), 5.40 (m, 1H); MS *m/e* 202 (M^+). Found: C, 82.96; H, 8.67%. Calcd for $C_{14}H_{18}O$: C, 83.12, H, 8.97%.

Reaction of Ib with Vinylmagnesium Bromide and Subsequent Thermal Rearrangement. To a stirred solution of vinylmagnesium bromide, which had been prepared using 1.75 g (16.4 mmol) of vinyl bromide, 0.365 g (15.0 mg-atom) of magnesium turnings, and 25 ml of THF, was added 870 mg (5 mmol) of Ib in 10 ml of THF at an ambient temperature. After the reaction mixture had been refluxed for 4 h, it was treated with aqueous ammonium chloride and extracted with ether (30 ml×3). The evaporation *in vacuo* of the dried (Na_2SO_4) organic portion gave an oil of IIIb (950 mg, 95%); mp 60—61 °C (from hexane); IR (nujol) 1720 cm^{-1}; NMR (CCl_4) δ 1.40 (d, J=7.0 Hz, 3H), 2.30 (s, 6H), 1.75—2.10 (m, 2H), 2.10—2.60 (m, 2H), 2.80 (m, 2H), 3.55 (q, J=7.0 Hz, 1H), 6.80—7.0 (m, 2H); MS *m/e* 202 (M^+). Found: C, 83.50; H, 8.67%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

Thermal Reaction of Ia in Benzene. 30 mg of Ia in 1 ml of benzene was refluxed for 5 h. No rearrangement occured and Ia was recovered in a 95% yield.

Thermal Rearrangement of IIa to IIIa. 188 mg (1 mmol) of IIa in 1 ml of xylene were refluxed for 30 min in a nitrogen atmosphere. Subsequent VPC analysis (5% SE-30, column temp 120—160 °C) indicated a single component which was identified with the product derived *via* the Grignard-reagent procedure. This reaction mixture was chromatographed on alumina (2.5 g). Elution with hexane–benzene (4/1) gave 170 mg (90%) of IIIa.

Thermal Rearrangement of IIb to IIIb. 202 mg (1 mmol) of IIb in 1 ml of 1,2-dichlorobenzene were refluxed for 15 min in a nitrogen atmosphere. The subsequent evaporation *in vacuo* of the 1,2-dichlorobenzene gave an oil. This oil was chromatographed on alumina (10 g), using hexane as the eluent, to give 182 mg (90%) of IIIb.

The Linearity of the Substituent-induced Carbon-13 Chemical Shifts of α-Carbons with Charge Densities in Aromatic Side Chains. II. 4-Substituted Phenylacetylenes

Jun NIWA

College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 25, 1980)

Synopsis. The propriety of considering the magnetic contributions to the ^{13}C chemical shift from the neighboring carbon atoms and from the 'ring-current' has been examined for the SCS of α-carbons of 4-substituted phenylacetylenes. The SCS values corrected for the above contributions are well correlated with the 2p electron densities.

In our previous papers,[1,2] we derived expressions for estimating the contribution from the magnetic term of the neighboring carbon atom, B, which is bonded to the A atom in question (σ^{AB}_{dia}) and the long-range shielding effect of the 'ring-current' ($\sigma^{A,ring}$). It was shown that the corrected SCS values of α-carbons ($\Delta\delta^{\alpha}_{corr}$) come to be linearly correlated with the electron densities on the relevant carbon atoms, A, when the observed SCS are corrected for the above two contributions in the cases of sp^2-hybridized α-carbons of 4-substituted derivatives of styrenes, α-methylstyrenes, and biphenyls.[1]

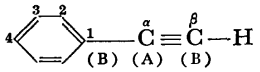
The aim of the present paper is to examine the propriety of considering the σ^{AB}_{dia} and the $\sigma^{A,ring}$ terms in interpreting the SCS of sp-hybridized α-carbons. For this purpose, we have chosen 4-substituted phenylacetylenes as a model system.

As has been shown in our previous paper,[2] the diamagnetic contribution, σ^{AB}_{dia}, from the sp-hybridized carbon atom can be expressed in the same form as the expression derived for the case of sp^2-hybridized carbon:

$$\sigma^{AB}_{dia} = (e^2/3mc^2) r_{AB}^{-1} q^B, \quad (1)$$

where r^{-1} is the inverse distance of the A atom from the point charge on the B atom and where q is the total (2s and 2p) electron density on the B atom. In the present approach, we have considered the magnetic contributions from the two neighboring carbon atoms which are directly bonded to the α-carbon of the phenylacetylene. The paramagnetic contribution, σ^{AB}_{para}, from the B atom remains almost constant so long as we assume the same average excitation-energy approximation.[3]

The carbons of the phenylacetylenes were labeled as shown below:



All the bond angles and the bond lengths of the phenylacetylenes are taken from the standard compilations.[4] When the bond lengths of the C_1–C_α and the C_α–C_β are taken to be 1.46 Å and 1.204 Å respectively:

$$\sum_B \Delta\sigma^{AB}_{dia} = 6.43\Delta q_1 + 7.80\Delta q_\beta. \quad (2)$$

The expression of the 'ring-current' effect on the SCS is the same as that in the previous papers:[1,2]

$$\Delta\sigma^{A,ring} = -0.4 f(\rho, z) |\sigma_\pi|. \quad (3)$$

The value of the $f(\rho, z)$ in the case of the α-carbon of phenylacetylene has been graphically estimated to be −1.08 ppm by utilizing the table of the Johnson-Bovey ring-current shift.[5] In evaluating the σ^{AB}_{dia} term, we have used the CNDO/2 formalism. The calculated values of the $\Delta\sigma^{AB}_{dia}$ and the $\Delta\sigma^{A,ring}$ terms are listed in Table 1.

It is expected that the $\Delta\delta^{\alpha}_{corr}$ values are linearly correlated with the electron densities on the α-carbon atoms, because $\Delta\delta^{\alpha}_{corr}$ reflects only the local magnetic term of the α-carbon atom. In Figs. 1 and 2, plots

Table 1. Observed and corrected chemical shifts of α-carbons in 4-substituted phenylacetylenes[a]

	Substituent	$\Delta\sigma^{AB}_{dia}$		$\Delta\sigma^{A,ring}$	$\Delta\delta^{\alpha}_{obsd}$[c]	$\Delta\delta^{\alpha}_{corr}$[b]
		$6.43\Delta q_1$	$7.80\Delta q_\beta$	$-0.4f(\rho, z)\|\sigma_\pi\|$		
1	NO_2	−0.145	−0.142	0.147	1.93	2.07
2	CN	−0.036	−0.048	0.108	1.69	1.67

a) All the values listed are relative to the unsubstituted compound, from the chemical shift of which the upfield shifts are represented in ppm by positive values. b) $\Delta\delta^{\alpha}_{corr} = \Delta\delta^{\alpha}_{obsd} - \sum\Delta\sigma^{AB}_{dia} - \Delta\sigma^{A,ring}$. c) Cited from Ref. 7.

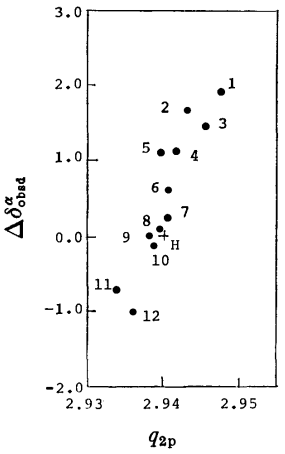

Fig. 1. Plots of $\Delta\delta^{\alpha}_{obsd}$ against the 2p electron densities on the α-carbon atoms.
Numbered points correspond to entries in Table 1.

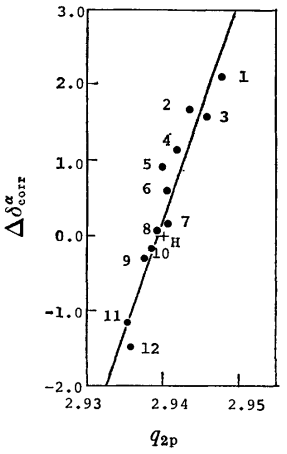

Fig. 2. Plots of $\Delta\delta^{\alpha}_{corr}$ against the 2p electron densities on the α-carbon atoms.
Numbered points correspond to entries in Table 1.

of the observed and the corrected SCS values are shown against the 2p electron densities (q_{2p})*. It may be reasonable to correlate the local magnetic terms with the 2p electron densities,[6] because the contribution of the local diamagnetic term to the SCS is very small compared with that of the local paramagnetic term. The respective correlations are expressed by least-squares fitting as:

$$\Delta\delta^{\alpha}_{obsd} = 235\Delta q_{2p} + 0.40 \quad (r=0.897,\ s=0.41) \qquad (4)$$

and:

$$\Delta\delta^{\alpha}_{corr} = 295\Delta q_{2p} + 0.23 \quad (r=0.928,\ s=0.42), \qquad (5)$$

where r is the correlation coefficient and s is the standard deviation. The values of both the intercept and the correlation coefficient in the latter case are much improved compared with those in the former case, although the values of the standard deviations are almost equal in the two cases.

This result provides further proof that it is appropriate to consider the σ^{AB}_{dia} and the $\sigma^{A,ring}$ terms in interpreting the aspect of the SCS of α-carbons in the side chains of conjugated aromatic hydrocarbons by relating the SCS to the electron densities.

The CNDO/2 calculations were carried out on a FACOM-230 75 computer at the Nagoya University Computation Center.

* The correlations between the corrected (and the observed) SCS and the total electron densities are: $\Delta\delta^{\alpha}_{corr} = 508\Delta q_{total} + 0.66$ ($r=0.868$, $s=0.5$); $\Delta\delta^{\alpha}_{obsd} = 400\Delta q_{total} + 0.72$ ($r=0.817$, $s=0.55$). In the case of the styrenes,[1] too, when the $\Delta\delta^{\alpha}_{corr}$ values are correlated with the 2p electron densities, the correlation is improved: $\Delta\delta^{\alpha}_{corr} = 135\Delta q_{total} + 0.77$ ($r=0.782$, $s=0.40$); $\Delta\delta^{\alpha}_{corr} = 122\Delta q_{2p} + 0.69$ ($r=0.844$, $s=0.34$).

Relationship between Chemical Selectivity and Melting Points of Reacting Molecules

Tadashi ENDO,* Yukiko TAKEDA, Toyohiko ORII, Akio KUWAHARA, Masahiro OHTA, Miyuki SAKAI, Reiko OKADA, and Masao HASHIMOTO

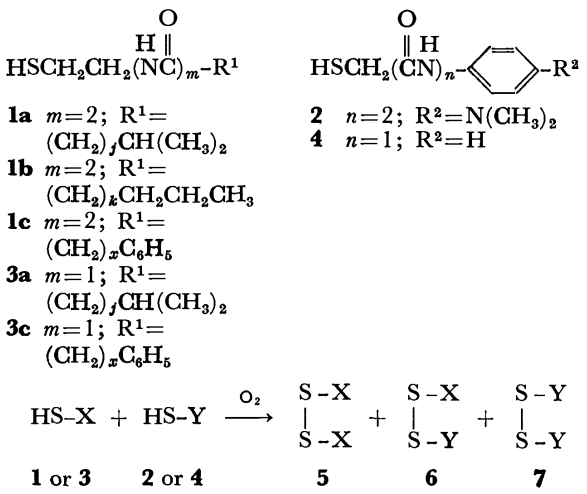
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received February 21, 1980)

Synopsis. A relationship has been found to exist between the selectivity (the ratio of an unsymmetrical disulfide to symmetrical one) in the oxidation of a pair of associating thiols, 1-acyl-3-(2-sulfhydrylethyl)urea (**1**) and 1-(*p*-*N*,*N*-dimethylaminophenyl)-3-(sulfhydrylacetyl)urea, and the melting point of **1** in cases where **1** belongs to a homologous series.

As a continuing study on a correlation of reaction behavior of molecules (*i.e.*, chemical selectivity) with their physicochemical properties,[1] this paper describes a relationship between the selectivity in the oxidation of a pair of associating thiols and the melting point of one of these two thiols.

Previously we have examined the oxidation of a pair of associating thiols (**1** and **2**) with O_2 in 80% (v/v) acetonitrile–20% water. The selectivity (R) in this oxidation was represented by the ratio of an unsymmetrical disulfide (**6**) to symmetrical one (**7**) (R=**6**/**7**).[2] The result is illustrated in Fig. 1. In the case of **1a** and **2**, maximal selectivity occurred at j=2.[2] In contrast, with **1b** and **2** alternation in the selectivity was clearly observed: R was 4.5, 0.28, 0.53, 0.29, and 0.40 for k=0, 1, 2, 3, and 4, respectively.[2] Further, with **1c** and **2**, maximal selectivity (R=16) occurred at x=2.



The data in Fig. 1 also indicate that the melting point of **1** depends sharply on the structure of R^1: **1a** or **1c** displayed maximal melting point at j=2 or x=2, respectively, while **1b** showed a striking alternation in melting points.[3] Therefore, Fig. 1 shows that the structure-selectivity profile for the oxidation of **1** and **2** is similar to the structure-melting point profile for **1**. It should be noted that this relationship between the selectivity and melting points does not hold for **1** having the para-substituted phenyl groups as R^1, which do not belong to a homologous series.

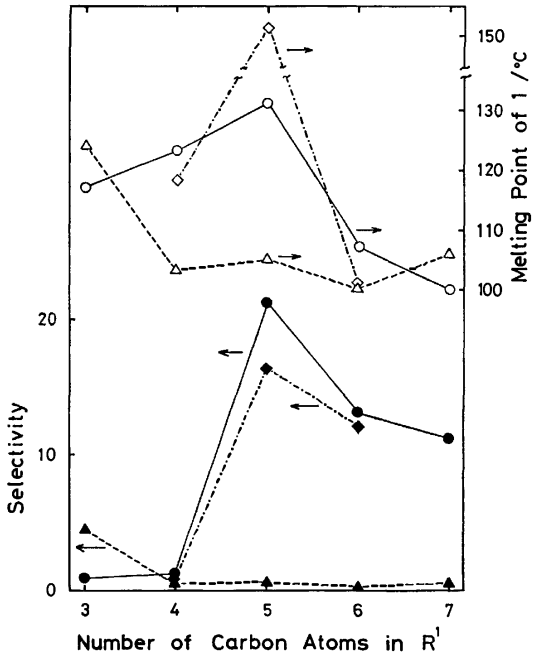


Fig. 1. Dependence of the selectivity (R=**6**/**7**), in the oxidation of a 1:1 mixture of **1** and **2** with oxygen, and of the melting point of **1** on the number of carbon atoms in R^1. With **1c** [$R^1=(CH_2)_xC_6H_5$] the number of carbon atoms in R^1 is counted as "x+3." ●, R for the oxidation of **1a** and **2**; ▲, R for the oxidation of **1b** and **2**; ◆, R for the oxidation of **1c** and **2**; ○, melting point of **1a**; △, melting point of **1b**; ◇, melting point of **1c**. Thiol **2** melted at 173 °C.

Control experiments using **1a** (or **3**) and **4** made it clear that the selectivity was insensitive to the structure of R^1 (Fig. 2): (i) in the case of **1a** and **4**, R showed a small maximum at j=1, (ii) with **3a** and **4**, R ranged only from 1.8 to 1.9, and (iii) with **3c** and **4**, R showed a small maximum at x=2. Moreover, it was found that the melting point of **3a** decreased progressively with the number of carbon atoms in R^1 and that **3c** displayed maximal melting point (66 °C) at x=2 (Fig. 2). These findings demonstrate that with **1a** (or **3**) and **4** the correlation described above does *not always* exist.[4]

^{1}H NMR results together with other experimental data revealed that **1a** (j=2) [or **1b** (k=2)] and **2** form weak complexes with each other as well as with themselves.[5] Furthermore, the degree of association (f)[6] for amide derivatives (**3** and **4**) proved to be much smaller than f for acylurea derivatives (**1** and **2**). This suggests that **1** and **2** associate strongly with themselves, while **3** and **4** associate very weakly with

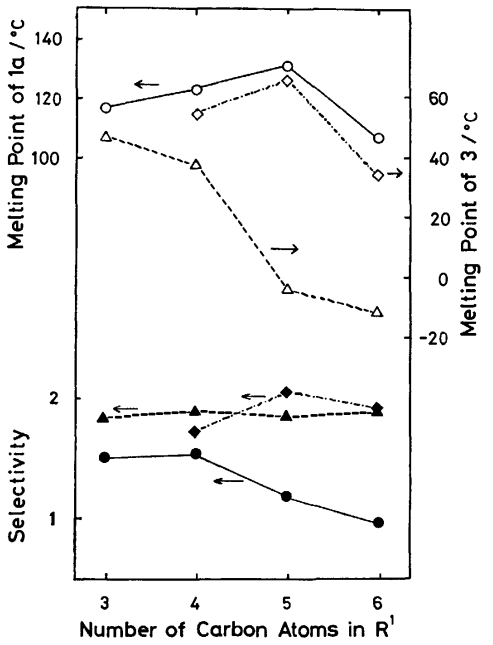

Fig. 2. Dependence of the selectivity (R=**6**/**7**), in the oxidation of a 1:1 mixture of **1a** (or **3**) and **4**, and of the melting points of **1a** and **3** on the number of carbon atoms in R^1. With **3c** [$R^1=(CH_2)_xC_6H_5$] the number of carbon atoms in R^1 is also counted as "$x+3$." ●, R for the oxidation of **1a** and **4**; ▲, R for the oxidation of **3a** and **4**; ◆, R for the oxidation of **3c** and **4**; ○, melting point of **1a**; △, melting point of **3a**; ◇, melting point of **3c**. Thiol **4** melted at 113 °C.

themselves and that **4** associates very weakly with **3**—or even with **1a** because of marked difference in f between **4** and **1a**.

All of the data presented here would suggest that chemical selectivity in the reaction of a pair of associating molecules can be correlated with the melting point of one of these two molecules in cases where one of these two molecules belongs to a homologous series.

Experimental

Materials. Thiols **1**, **2**, and **4** were prepared as described before.[5,7] Thiol **3** was synthesized according to the method previously reported.[8] Satisfactory spectroscopic data were used to support the assignment of all new compounds.

Oxidation of a Pair of Thiols. A 1:1 mixture of **1** and **2** [or of **1a** (or **3**) and **4**, 0.5 mmol each] was treated with oxygen at 35.0 °C in 12.5 ml of 80% (v/v) acetonitrile–20% water in the presence of a catalytic amount of Et_3N (0.05 mmol). When the oxidation was completed, the reaction mixture was evaporated to dryness. Yields of **6** and **7** were determined by the use of their absorption at 310 nm after separation by TLC in the oxidation of **1** and **2**,[9] and determined gravimetrically after separation by preparative TLC in the oxidation of **1a** (or **3**) and **4**.

Determination of Melting Points. Melting points of thiols (**1**—**4**) were obtained from the DTA (Differential Thermal Analysis) curves recorded with a Shimadzu DT-20B thermal analysis apparatus. The samples were finely powdered, diluted with fine-grained quartz wool in the specimen holder, and heated in a stream of nitrogen with a heating rate of 10 °C/min.

Determination of Degree of Association (f). The effective mole fraction of the solute was determined on a Hitachi Perkin-Elmer 115 molecular weight apparatus using a differential vapor pressure method at 36.0 °C and 0.01 M (1 M= 1 mol dm^{-3}) in benzene.[10]

We are grateful to Dr. Akiko Furuhashi and Miss Tomoko Nomura for helpful advice in DTA measurement and to Mr. Tomoji Murata for valuable assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Improved Resonance Energies of Nonalternant Hydrocarbons. An ω-Technique Approach

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 22, 1979)

The ω-technique of Wheland and Mann was introduced into the graph theory of aromaticity in order to improve the resonance energies of nonalternant hydrocarbons. For these compounds, the ω-technique resonance energy was more or less smaller than the resonance energy calculated on the basis of the simplest Hückel MO model. Especially, several compounds thus far considered to be aromatic were predicted to be substantially olefinic with much reduced resonance energies. They are calicene, sesquifulvalene, azulene, dibenzo[*cd*,*gh*]-pentalene, and cyclohepta[*def*]fluorene. Many aspects of their chemistry were evidently consonant with the improved resonance energies. Possible limitation of the use of electrophilic substitution as a criterion of aromaticity was discussed. Resonance energies of alternant hydrocarbons are not modified by application of the ω-technique.

The graph theory of aromaticity[1-4] has proved very successful in rationalizing aromatic character of a wide variety of cyclic conjugated compounds. A theoretical relationship between diamagnetic susceptibility exaltation and aromatic stabilization has also been verified by means of this theory.[5] The graph theory of aromaticity in its original form is based on the simplest Hückel molecular orbital (HMO) model.[1-5] In this model the assumption is tacitly made that the Coulomb integral α is a constant characteristic of an atom and independent of a conjugated system in which it appears. A standard value of α for sp^2 carbon atoms may be denoted by α_0. This assumption is indeed reasonable for alternant hydrocarbons, each with a uniform charge distribution.

However, a simple argument[6] shows that a carbon atom in a conjugated hydrocarbon on which the charge density q is not equal to unity cannot really have $\alpha=\alpha_0$. If $q<1$, the net positive charge means that the screening seen by any one electron is reduced and the Coulombic attraction to the nucleus is increased. The Coulomb integral for such a carbon atom should have a more negative value. Conversely, a carbon atom with a net negative charge should have a less negative value of α. Wheland and Mann proposed that the value of α should be linearly related to the charge on the atom concerned, namely,[7]

$$\alpha_s = \alpha_0 + (1-q_s)\omega\beta_0, \qquad (1)$$

where ω is a dimensionless parameter whose value may be so chosen as to give the best agreement with experiment, β_0 a standard value of the resonance integral between two bonded sp^2 carbon atoms, and the subscript s used to represent the s-th carbon atom.

The value appropriately selected for the ω parameter apparently allows for an average effect of other electrons. We might say that, with one empirical parameter, this ω-technique introduces some electron repulsion within the framework of the simple HMO model.[6] The use of this technique has been shown to lead to improved calculated energy values for nonalternant hydrocarbons and conjugated cations.[6-8] In this paper I would like to revise the graph theory of aromaticity[1-5] by means of the ω-technique, and present improved resonance energies of typical nonalternant hydrocarbons in conjunction with their chemistry.

Theory

One first obtains the charge distribution of a conjugated hydrocarbon according to the simplest HMO model. This charge distribution is used to calculate new α_s's according to Eq. 1, and the new charge distribution is calculated. This process is continued until the charge distribution no longer changes, that is, the system is self-consistent.[6,7] The value of ω is taken to be 1.40 as usual.[8] On the other hand, an olefinic reference structure constructed graph-theoretically for any conjugated hydrocarbon can be regarded as a kind of alternant hydrocarbon.[1] The charge density is correspondingly equal to unity on each carbon atom of the reference structure.[9] The total π-electron energy of the reference structure was termed the reference energy.[1] It can hence be calculated without regard to the charge distribution of the reference structure. In other words, the reference energy of a conjugated hydrocarbon is independent of the ω parameter. Thus the ω-technique resonance energy of any conjugated hydrocarbon can be calculated relative to the reference energy based on the simplest HMO model.

Results and Discussion

Resonance energies thus calculated for 40 nonalternant hydrocarbons are listed in Table 1. They are compared therein with the resonance energies calculated on the basis of the simplest HMO model.[1,4] First of all, it is noteworthy that the total π-electron energy of any nonalternant hydrocarbon increases by application of the ω-technique. This might imply that the effect of electron repulsion is to diminish the resonance energy of a conjugated system because the reference energy remains unchanged. Consequently, when the absolute value of the resonance energy is small, the sign of the resonance energy is often changed by application of the ω-technique. Such compounds are **1**—**5**, **17**, **19**, and **31**.

Here a new measure of aromatic stabilization is adopted, which is defined as 100 times the resonance energy, divided by the reference energy.[10] It is termed the percent resonance energy (%*RE*). This quantity nicely gives the degree of stabilization with which a conjugated system behaves aromatically as a whole.

TABLE 1. RESONANCE ENERGIES OF 40 NONBENZENOID HYDROCARBONS

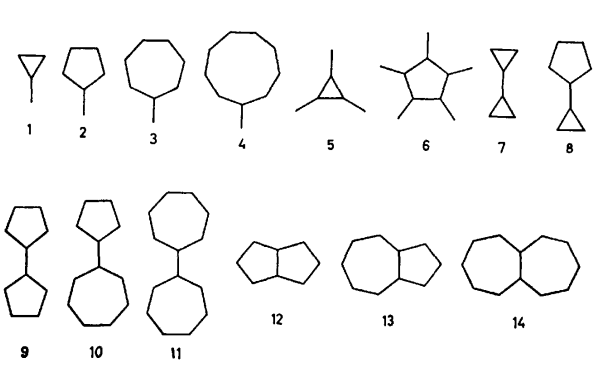
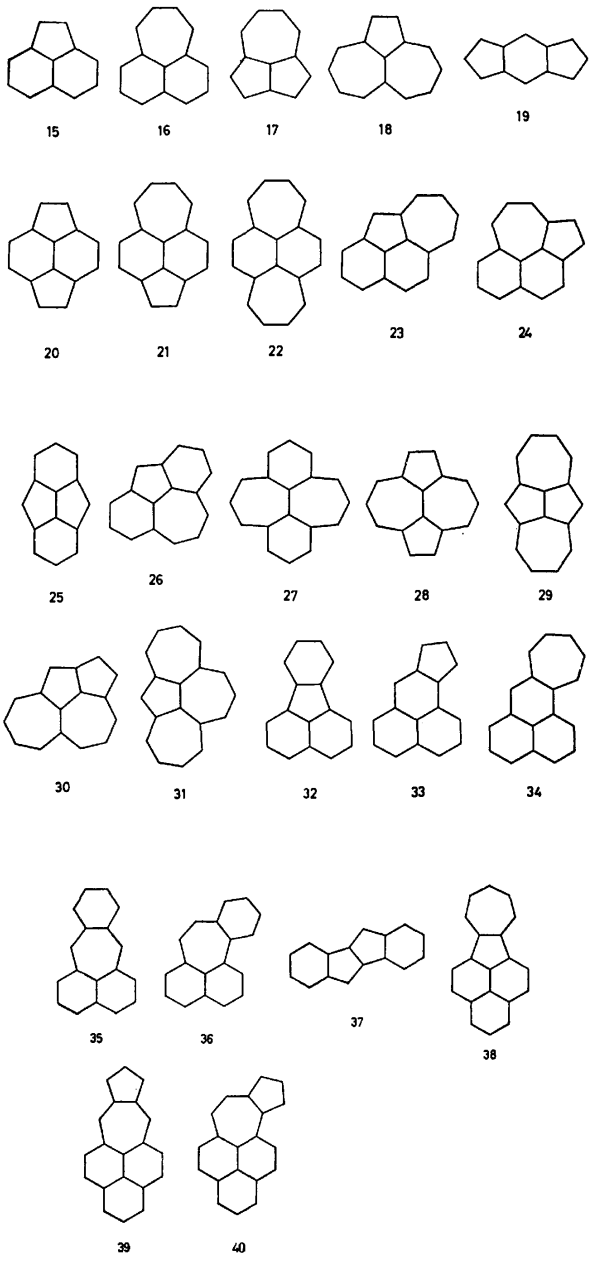
a) Resonance energy. b) References 1 and 4. c) Percent resonance energy.





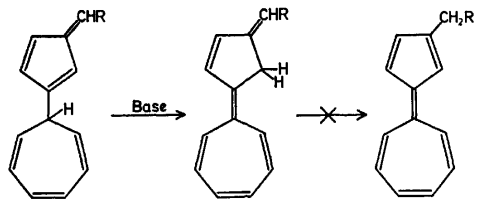
Note that the $\%RE$ neither depends upon the number of π electrons[11] nor upon the number of π bonds[12] in a conjugated system. By examining $\%RE$ values in Table 1 in detail, we can safely say that compounds with $\%RE<0.50$ might be regarded as olefinic species.

When one or more aromatic sextets[13–17] can be chosen from a nonalternant hydrocarbon, it may be called a semibenzenoid hydrocarbon.[18] Such semibenzenoid hydrocarbons are **15**, **16**, **20**—**24**, and **32**—**40**. For these compounds, a decrease in resonance energy is rather modest. Therefore, previous aromaticity considerations[1,4,11,15,17–19] are still applicable to them. They are not repeated here.

On the other hand, when a conjugated system is a combination of odd-membered π rings only, a pronounced decrease in resonance energy occurs by application of the ω-technique. Among them the following five fully nonbenzenoid hydrocarbons are

particularly noteworthy: calicene (**8**), sesquifulvalene (**10**), azulene (**13**), dibenzo[*cd,gh*]pentalene (**25**), and cyclohepta[*def*]fluorene (**26**). These compounds have been predicted to be moderately aromatic on the basis of the simplest HMO model,[1,4,11] whereas the present approach predicts them to be substantially nonaromatic with markedly reduced resonance energies. We can show below that these ω-technique resonance energies are indeed in excellent agreement with experiment.

Both calicene (**8**) and sesquifulvalene (**10**) have so far had significant $\%RE$ values.[1,11] Sesquifulvalene is known,[20] but it is not stable, polymerizing even at 30 °C. Calicene itself is not known, but a number of substituted calicene derivatives are now known.[21] Some of them, as well as sesquifulvalene, readily form adducts with tetracyanoethylene.[22] These polyene-like features of asymmetric fulvalenes are obviously consistent with the smaller $\%RE$ values. Some calicene derivatives have very large dipole moments,[23] and some have electronic spectra strongly dependent upon the solvent as might be expected for a dipolar species.[24] Such a non-uniform charge distribution in a conjugated system decreases the resonance energy when the ω-technique is applied to it.

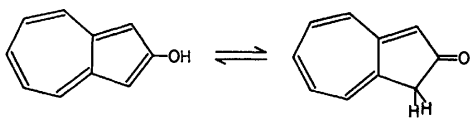


41 42 43

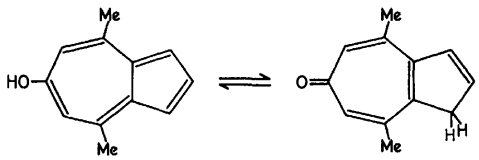
The prototropic rearrangement of 3-cycloheptatrienylfulvenes (**41**) gives the conjugated heptafulvenes (**42**) instead of the sesquifulvalene (**43**).[22,25] Here, R is an alkyl or an aryl group. An aromatic compound might be defined as a compound which tends to maintain its cyclic conjugated system since it has a larger binding energy than the olefinic reference structure. According to this definition, sesquifulvalenes can be classified as olefinic species. Compounds of the type **41** are obviously reluctant to attain a sesquifulvalene conjugated system. Neither triafulvalene (**7**) nor its derivatives have been prepared. The other symmetric fulvalenes **9** and **11** are extremely reactive.[22] Resonance energies of these fulvalenes were also decreased considerably. The same is true for triafulvene (**1**), which is not known yet.

Azulene has been a classical example of a non-benzenoid aromatic compound. Let the ratio of the resonance energy of azulene to that of the isomeric naphthalene be denoted by r. The r value based on the ω-technique resonance energies is about one-eighth, which is comparable to that of Dewar and de Llano calculated using the SCF resonance energies.[26] However, it is in poor accord with the r value of Hess and Schaad based on the simplest HMO model.[11] It must be noted here that they did not take the effect of electron repulsion into consideration,[11] but Dewar and de Llano did.[26] Azulene has a dipole moment of 1.0 D with the five-membered ring negative,[27] so the ω-technique resonance energy is aparently preferable as long as it is consistent with its chemistry. Thus azulene appears to have a small positive resonance energy, much less than that of naphthalene.

An experimental support for an olefinic nature of azulene is afforded by the occurrence of valence tautomerism of the simple derivatives in solution. 2-Hydroxyazulene (**44**) partly undergoes valence tautomerization to the nonaromatic heptafulvene derivative (**45**).[28] 4,8-Dimethyl-6-hydroxyazulene (**46**) coexists in solution with the tautomeric troponoid species (**47**),[29] in which an azulenoid bicyclic conjugated system is missing.



44 45



46 47

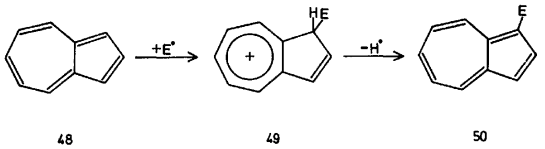
In this context, it should be remembered that 9-anthranol coexists in solution with anthrone.[30] Resonance energies of these two isomers are presumably similar to each other.[31] By analogy with this, the enol forms of hydroxyazulenes **44** and **46** must be as aromatic as the keto forms **45** and **47**, respectively. However, the latter keto forms are olefinic, so must be the former azulenoid species.

Substituted calicenes and sesquifulvalenes are protonated in acidic media to form cyclopropenium and tropylium cations, respectively.[22] Azulene itself is readily protonated, the proton adding in the 1-position of the five-membered ring to form an azulenoid cation.[32] Such a high basicity of a conjugated system is often an indication of aromaticity of the protonated species.[33] Conversely, calicene, sesquifulvalene, and azulene are not typically aromatic, in the sense that they are reluctant to maintain their original conjugated systems in acidic media.

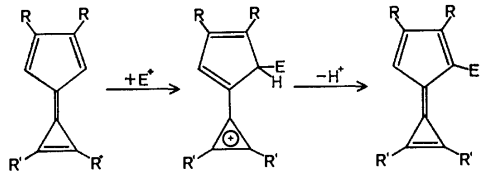
Dibenzo[*cd,gh*]pentalene (**25**) and cyclohepta[*def*]-fluorene (**26**) have not been prepared yet. Although a dianion of **25** is known,[34] attempts to prepare the neutral hydrocarbon were unsuccessful. Such synthetic inaccessibility is not congruent with large resonance energies previously reported for them.[4] The ω-technique resonance energies are both very small in good accord with their chemistry. For these compounds, only two Kekulé structures can be written with a central double bond fixed in each Kekulé structure.

The occurrence of electrophilic substitution was a long-standing criterion of aromaticity. Azulene and some calicene derivatives undergo electrophilic substitution reactions.[35,36] This chemical feature has been

used as an irrefutable evidence of aromaticities of these compounds.[11] Electrophilic substitution usually occurs *via* a Wheland-type reaction intermediate.[37] In the case of azulene and calicenes, Wheland-type reaction intermediates are shown below:



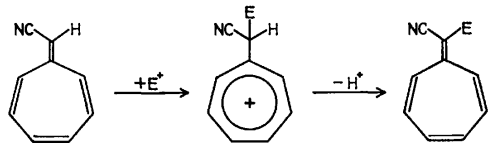
48 49 50



51 52 53

Here, E^+ is indicative of an electrophile.

However, it must be stressed that many olefinic compounds are now known to undergo electrophilic substitution reactions.[38] Such olefinic compounds are metal β-diketonates,[39] 2,3-dihydro-1,4-diazepinium salts,[38,40] 1,2-dihydropyrimidinium salts,[41] open-chain diazapolymethinium salts,[42] Nickel 1,19-dimethyltetradehydrocorrin salts,[43] 8-cyanoheptafulvene,[44] and ethylenic compounds such as vinyl ethers and vinyl sulfides.[45] For all these compounds, a Wheland-type intermediate is either a hetero-atom-stabilized carbonium ion or an aromatically-stabilized carbonium ion.[46] Therefore, specific stabilization of a reaction intermediate appears to be the most important condition for the occurrence of electrophilic substitution on polyenic compounds. For vinyl ethers and vinyl sulfides, a substitution reaction proceeds *via* a hetero-atom-stabilized carbonium ion.[45] 8-Cyanoheptafulvene (**54**) can be regarded as a trisubstituted ethylene. This compound undergoes several electrophilic substitution reactions at the *exo*-methylene group.[44] Each reaction intermediate is obviously an aromatically stabilized tropylium cation (**55**).



54 55 56

It is an interesting fact that a Wheland-type intermediate for azulene (**49**) is quite similar to that for 8-cyanoheptafulvene (**55**). Both are evidently stabilized by an aromatic tropylium structure. This analogy strongly suggests that aromaticity of azulene, if any, may not be necessary in order for substitution reactions to proceed on it. Calicenes undergo electrophilic substitution reactions *via* aromatically-stabilized cyclopropenium ion (**52**),[36] but this does not warrant aromaticities of the starting materials, either. Thus the occurrence of electrophilic substitution does not exclude the possibility that the starting material is olefinic as in the case of diazapolymethinium salts[40-42] and 8-cyanoheptafulvene.[44]

Further examination of various electrophilic substitution reactions disclosed the fact that, in general, less aromatic compounds are more favorable to such reactions. There have been several kinetic studies of electrophilic substitution reactions on monocyclic conjugated compounds.[47] For these compounds, the following order of reactivity has universally been established: benzene$<$thiophene$<$selenophene$<$tellurophene$<$furan$<$pyrrole.[47] If these compounds are arranged in an ascending order of aromaticity, this order is exactly reversed,[1,48] except for pyrrole which is much more aromatic than furan in all respects.[49]

When all or part of resonance energy is lost to form a Wheland-type reaction intermediate, the degree of destabilization of the intermediate necessarily depends upon the degree of aromaticity of the starting material. As stated above, it also depends upon the nature of the intermediate itself. One obvious conclusion which may be drawn here is that ready occurrence of electrophilic substitution is often inconsistent with high aromaticity. Benzene is then most aromatic and least reactive toward electrophiles. On the other hand, a Wheland-type intermediate for pyrrole is a highly stable azacarbonium ion,[50] *i.e.*, a kind of hetero-atom-stabilized carbonium ion,[46] so the reactivity is much greater than might be expected from its aromaticity. Thus there are not a few difficulties in using electrophilic substitution as a criterion of aromaticity.

Concluding Remarks

The graph theory of aromaticity based on the simplest HMO model[1-4] is free from any parametrization. In the present approach, only one parameter (*i.e.*, ω) had to be introduced in it to improve the resonance energies of nonalternant hydrocarbons. However, the revised theory can still retain all the simplicity and elegance as long as the accepted ω value of 1.40 is used.[6-8] The ω-technique resonance energies of nonbenzenoid hydrocarbons are more or less smaller than those calculated on the basis of the simplest HMO model.[1,11] In this paper, resonance energies of five nonbenzenoid hydrocarbons which are markedly sensitive to the ω-technique were analyzed in detail in conjunction with their chemistry. This analysis clearly indicated the inadequacy of the simplest HMO model, with all Coulomb integrals set equal, for dealing these nonalternant hydrocarbons. Conversely, it has firmly been established that the ω-technique resonance energies are in much better agreement with experiment.

The ω-technique approach can in principle be applied to all conjugated systems and to all cyclic conjugated ions alike. However, when a charge distribution in the reference structure is not uniform, the reference energy must be calculated self-consistently by iteratively evaluating all the Coulomb integrals[9] according to Eq. 1. The original reference energy cannot be used in

this case. It goes without saying that the resonance energy of any alternant hydrocarbon remains unchanged even if the ω-technique is applied to it.

It should be pointed up that the empirical theory of aromaticity, developed by Hess and Schaad,[11,48] can also be improved by application of the ω-technique. The ability to calculate in an additive manner the total π-electron energy of any acyclic polyene allowed them to calculate the reference energy of a cyclic conjugated system, and hence to obtain the resonance energy. Since acyclic polyenes are all alternant hydrocarbons, their additive π-bond energies[11] are not modified by application of the ω-technique. They can still be used to estimate reference energies. Accordingly, the Hess-Schaad resonance energy of a cyclic conjugated hydrocarbon is given as the difference between the total π-electron energy based on the ω-technique and the original reference energy.

When such a modified Hess-Schaad method is applied to nonalternant hydrocarbons, most results presented in this paper can be reproduced. Hess-Schaad resonance energy of azulene is changed from 0.23β to 0.14β, about one-fourth the resonance energy of naphthalene.[11] The r value becomes much closer to that estimated in this paper, and also to that estimated using the SCF resonance energies.[26]

Finally, another way of improving the graph theory of aromaticity[1-5] may be to include the overlap integrals S into HMO calculations.[51] Inclusion of overlap changes the spacing of energy levels. However, total π-electron energies and resonance energies do not seem to be affected significantly.[6]

The use of the facilities of the Hokkaido University Computing Center is gratefull acknowledged. A computer program for ω-technique calculations were taken from Dr. O. Kikuchi's book.[52]

ESR Studies of a New Stable π-Conjugated 4,4′-(Biphenyl-3,3′-diyl)bis(aryloxyl) Biradical

Kazuo MUKAI* and Noriko INAGAKI

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received December 7, 1979)

ENDOR observations were carried out for 2,6-di-*t*-butyl-4-phenylphenoxyl and some of its derivatives. Based on the proton hyperfine splittings, the structure of the aryloxyl monoradicals was investigated in terms of the McLachlan MO calculation. A new stable π-conjugated bis(aryloxyl) biradical, 4,4′-(biphenyl-3,3′-diyl)-bis(2,6-di-*t*-butylphenoxyl), was prepared, and the ***g***- and ***D***-tensor values of the biradical in toluene have been determined from its asymmetric frozen ESR spectrum. The ***D***-tensor values were calculated for the twisted "cis" and "trans" conformers of the biradical molecule, using the McLachlan spin densities of 2,6-di-*t*-butyl-4-phenylphenoxyl, which is a monoradical half of the biradical.

2,6-Di-*t*-butyl-4-phenylphenoxyl (aryloxyl radical (I)) (Fig. 1) is a fairly stable phenoxyl radical, which can be purely separated as a solid.[1] ESR[2] and NMR[3] studies of the aryloxyl radical (I) and some of its derivatives were already reported. In a recent paper, a report was given on the preparation of a new stable π-conjugated *m*-phenylenebis(aryloxyl) biradical, 4,4′-(*m*-phenylene)bis(2,6-di-*t*-butylphenoxyl), in which two aryloxyl monoradical parts strongly conjugated each other through the meta-position of central benzene ring.[4] Kothe *et al.*[5] prepared a stable benzene-1,3,5-tris(aryloxyl) triradical, 4,4′,4″-(1,3,5-benzenetriyl)tris-(2,6-di-*t*-butylphenoxyl), which is related to the *m*-phenylenebis(aryloxyl) biradical. The existence of triplet and quartet states in the bis and tris(aryloxyl) radicals, respectively, has been confirmed by ESR measurements in rigid media at 77 K.[4,6] However, no detailed study of the electronic and molecular structure of these bi- and tri-radicals seems to have been carried out so far.

First, ENDOR measurements were carried out in order to study the three aryloxyl monoradicals (I), (II), and (III) (Fig. 1), the detailed proton hyperfine splittings of the radicals being determined. The structure of the aryloxyl radicals was investigated by means of McLachlan MO calculation of the spin densities. The aryloxyl radical (I) is a monoradical half of the bis(aryloxyl) biradical (IV) (Fig. 1), and the aryloxyl radical (III) a monoradical precursor of the bis-(aryloxyl) biradical (IV).

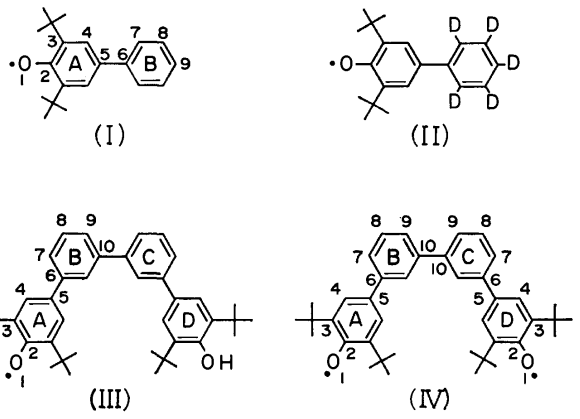

Fig. 1. Molecular structures of aryloxyl radicals (I), (II), (III), and (IV), and the atomic numbering system.

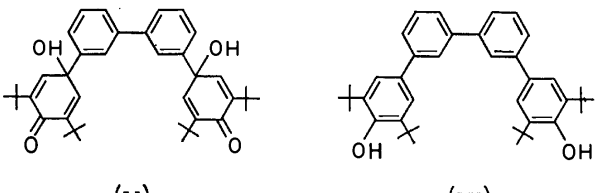
Secondly, we have prepared a new stable π-conjugated 4,4′-(biphenyl-3,3′-diyl)bis(aryloxyl) biradical (IV), and succeeded in observing the zero-field ESR spectrum in toluene rigid glass. The ESR spectrum at 77 K can be clearly analyzed as the characteristic spectrum of a non-axially symmetrical triplet, with $|D|=35.4\pm0.3$ G and $|E|=2.6\pm0.3$ G, and $g_{xx}=2.0045\pm0.0002$, $g_{yy}=2.0051\pm0.0002$ and $g_{zz}=2.0024\pm0.0002$. The D and E parameters were calculated for the assumed molecular structures, using McLachlan spin densities of the aryloxyl (I) which is a monoradical half of the biradical (IV). From the results, the conformation and electronic structure of the biradical have been discussed.

Experimental

Measurements. ESR measurements were carried out using a JES-ME-3X spectrometer equipped with a Takeda-Riken microwave frequency counter. The ENDOR spectra were recorded on a JEOL-type ES-EDX-1 spectrometer, operated with 80 Hz magnetic field modulation. About 150 W of the continuous radio wave frequency modulated at 6.5 kHz were running inside the cavity for NMR excitation. The ESR splittings were determined using $(KSO_3)_2NO$ or Mn^{+2} in MgO as a standard. The *g*-values were measuted relative to the value of Li–TCNQ powder, calibrated with $(KSO_3)_2NO$ ($g=2.0054$).[7] The aryloxyl radicals (I)—(IV) were prepared by the oxidation of the corresponding phenols with PbO_2 in toluene under a vacuum.

Preparation of Specimens. Rieker and Scheffler[2] reported the syntheses and physical properties of the phenol precursors of the aryloxyl radicals (I) and (II). Quinol (V) was synthesized by the reaction of the dimagnesium derivative of 3,3′-dibromobiphenyl with 2,6-di-*t*-butyl-*p*-benzoquinone;[8] the highly reactive magnesium investigated by Rieke and Bales[9] allows the ready preparation of many Grignard reagents which were heretofore not easily prepared or could not be prepared at all. Using their method, we have prepared the dimagnesium derivative of 3,3′-dibromobiphenyl at 20 °C.



4,4′-(biphenyl-3,3′-diyl)bis(4-hydroxy-2,6-di-*t*-butyl-2,5-cyclohexadien-1-one) (quinol (V)). Freshly cut potassium (2.81 g, 0.072 mol), $MgCl_2$ (3.81 g, 0.040 mol), KI (3.32 g, 0.020 mol), and THF (tetrahydrofuran) (90 ml) were placed in an 100 ml four-necked flask equipped with reflux condensor, dropping funnel, thermometer, heating mantle, and magnetic stirrer under nitrogen atmosphere. The mixture was refluxed for 3 h with stirring, and was then left to stand at 30 °C for 0.5 h. A THF solution of 3,3′-dibromobiphenyl (3.12 g, 0.010 mol) was added dropwise below 30 °C, and the mixture was reacted for 0.5 h at 30 °C. In the same way, a THF solution of 2,6-di-*t*-butyl-*p*-benzoquinone (4.41 g, 0.020 mol) was added slowly below 30 °C, and then the reaction mixture was refluxed for 1.5 h under stirring. The grayish black solids precipitated were quickly filtered off and hydrolyzed in saturated NH_4Cl solution (200 ml). They were then taken up in diethyl ether, washed with water, and dried over anhydrous sodium sulfate. After removal of the diethyl ether, viscous oil was remained. By adding petroleum ether (bp 50—70 °C) to the viscous oil, white solids (1.5 g, 0.0025 mol) precipitated. The solids obtained were recrystallized first from ligroin (bp 90—105 °C), and then from dioxane, and finally heated at 180 °C for 11 h under vacuum (5×10^{-3} Torr; 1 Torr=133.322 Pa) in order to completely remove the dioxane solvent included in the crystal. Mp 246—248 °C. (Found: C, 80.21; H, 8.88%. Calcd for $C_{40}H_{50}O_4$: C, 80.77; H, 8.47%). UV spectrum (λ_{max}=228 nm, log ε=4.80 in THF). NMR spectrum (δ=1.27 ppm (36H, s, *t*Bu), 2.30 (2H, s, OH), 6.58 (4H, s, *m*-ring), 7.12—7.83 (8H, multiplet, biphenylene ring); δ in $CDCl_3$ with TMS as internal standard).

3,3′-Bis(3,5-di-t-butyl-4-hydroxyphenyl) biphenyl (Bisphenol (VI)). Bisphenol (VI) was synthesized by the reduction of quinol (V) (1.0 g, 0.0017 mol) with Zn powder (1.3 g, 0.020 mol) and concd HCl (15 ml) in methyl alcohol (60 ml) at 55 °C for 2 h, by a process similar to that of Rieker and Scheffler.[2] The white solid (0.75 g, 0.0013 mol) obtained was first washed with hot methyl alcohol, and then recrystallized from dioxane, and heated at 175 °C for 7 h under vacuum (5×10^{-3} Torr) in order to completely remove the dioxane solvent included in the crystal. Mp 213—215 °C. (Found: C, 85.05; H, 9.13%. Calcd for $C_{40}H_{50}O_2$: C, 85.36; H, 8.95%). UV spectrum (λ_{max}=217 nm, log ε=4.80, λ_{max}=263 nm, log ε=4.76 in THF). NMR spectrum (δ=1.48 ppm (36H, s, *t*Bu), 5.02 (2H, s, OH), 7.28 (4H, s, *m*-ring), 7.28, 7.38, 7.58 (8H, multiplet, biphenylene ring); δ in CCl_4 with TMS as an internal standard).

Results

ENDOR Spectra of Aryloxyl Monoradicals (I), (II), and (III). The ESR spectra of the aryloxyl radicals (I) and (II) have been reported by Rieker and Scheffler.[2] The spectrum of the aryloxyl radical (III) shows a sextet-doublet hyperfine pattern. Both the ring proton hyperfine splittings and the g_{iso}-values of the radicals observed in toluene at 20 °C are given in Table 1.

The ENDOR spectrum of aryloxyl radical (I) in toluene at −85 °C (Fig. 2(a)) clearly shows five different proton hyperfine splittings (1.872, 1.752, 1.620, 0.672, and 0.064 G). On the other hand, the ENDOR spectrum of deuterated aryloxyl radical (II) in toluene at −87 °C shows only two different hyperfine splittings (Fig. 2(b)). The splitting of 1.638 G in (II) is easily assigned to the two meta protons of the phenyl ring A, and that of 0.069 G to the *t*-butyl protons. Comparing

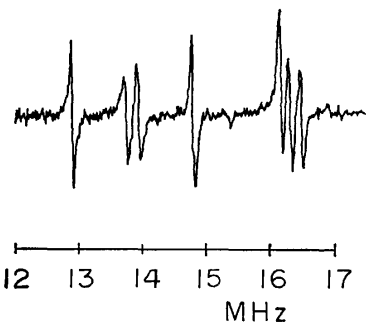

Fig. 3. ENDOR spectrum of aryloxyl radical (III) (at −65 °C) in toluene.

the ENDOR spectrum of aryloxyl radical (I) with that of aryloxyl (II), the hyperfine splittings of 1.872, 1.752, and 0.672 G of the former, which have never been observed in the latter, can clearly be identified as the proton hyperfine splittings in the substituted phenyl ring B. Of these three splittings, the smallest, 0.672 G, is also easily assigned to the two meta protons of the phenyl ring B, taking their ESR hyperfine splittings into account. In this case, we cannot distinguish the splitting due to ortho- and para-protons of the phenyl ring B. A tentative assignment was made, however, with reference to the analogous splitting of the aryloxyl radical (I) obtained by NMR measurements[3] (Table 1). The monoradical precursor (III) of the biradical (IV) shows a spectrum similar to that of aryloxyl radical (I) (Fig. 3). The value of each hyperfine splitting is very close to the corresponding value of aryloxyl radical (I). This indicates that the effects of the meta-substituion of the phenyl ring by biphenyl group are very small to induce a change in the unpaired spin distribution or molecular structure. The experimental values of the spin densities were estimated using the relation, $a_i^H = Q^H \cdot \rho_i$ and $a_{t\mathrm{Bu}}^H = Q^{t\mathrm{Bu}} \cdot \rho_i$, where Q^H and $Q^{t\mathrm{Bu}}$ were taken to be 27 and 0.28 G[10] respectively. The proton hyperfine splittings and the experimental spin densities ρ(Exp.) are summarized in Table 1.

Triplet ESR Spectrum of 4,4'-(Biphenyl-3,3'-diyl)bis-(aryloxyl) Biradical(IV). When the bisphenol precursor (VI) of bis(aryloxyl) biradical (IV) was slightly oxidized with PbO_2 in toluene under vacuum, the color of the phenol solution immediately became violet. The ESR spectrum of this solution showed a sextet-doublet hyperfine pattern (a^H=1.76±0.04 G, a^H=0.69±0.04 G, g_{iso}=2.00414±0.00003) due to the six ring protons of the monoradical precursor (III). By further oxidation, the color turned pink, a broad absorption due to the biradical being superposed on the hyperfine spectrum of the monoradical. By freezing the pink solution containing the biradical (IV) into a rigid glass (77 K), one can observe dipolar splittings as shown in Fig. 4.

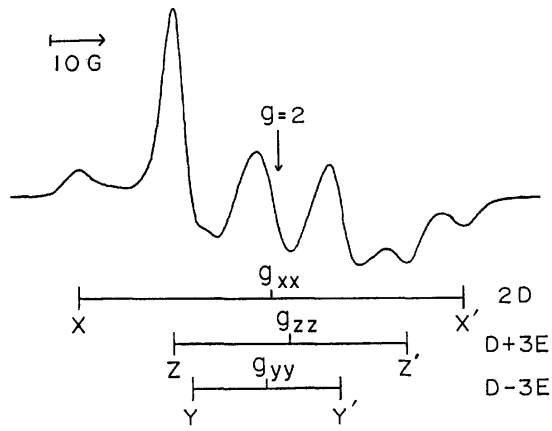

Fig. 4. ESR spectrum of 4,4'-(biphenyl-3,3'-diyl)bis-(aryloxyl) biradical (IV) in toluene at 77 K.

The biradical in a rigid glass can be treated as a two-spin system which forms a triplet and a singlet state. The usual spin Hamiltonian for the triplet state is

$$H = \beta \boldsymbol{H}\cdot\hat{\boldsymbol{g}}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\hat{\boldsymbol{D}}\cdot\boldsymbol{S} \quad (1)$$

$$= \beta \boldsymbol{H}\cdot\hat{\boldsymbol{g}}\cdot\boldsymbol{S} - XS_x^2 - YS_y^2 - ZS_z^2 \quad (S=1) \quad (2)$$

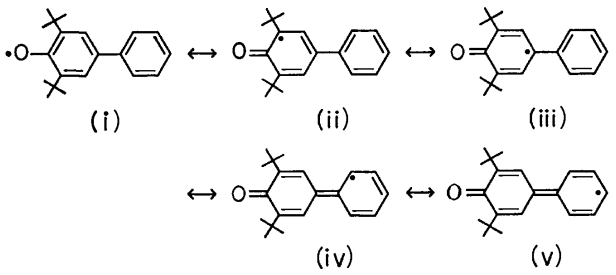
where $\boldsymbol{g}$ is the $\hat{\boldsymbol{g}}$ tensor, and $\hat{\boldsymbol{D}}$ the fine structure tensor with principal values of $-X$, $-Y$, and $-Z$, the other symbols having their usual meanings. When the radical has the property of a triplet having no axial symmetry, we usually observe three pairs of absorption lines, from whose separations the zero-field parameters (D and E) of the spin-spin dipolar interaction can be obtained.[11] In the case of biradical (IV), five out of the six lines theoretically expected for a non-axially symmetrical triplet are resolved (Fig. 4). In the spectrum, the intensity of the low-field line of the inner pair of lines is higher than the other, suggesting the overlapping of two lines. A central line at g=2 is attributable to the monoradical impurity, since the relative intensity of central line decreases when the PbO_2 oxidation proceeds from monoradical to biradical. Separation values between the three pairs of turning points (X, X'; Y, Y'; and Z, Z') in the spectrum of the biradical are 70.8±0.6, 42.6±0.6, and 27.0±0.6 G, respectively. They correspond to $2D$, $D+3E$, and $D-3E$. The D and E values were estimated to be D=35.4±0.3 G and E=2.6±0.3 G, respectively. Assuming that the principal axes of the $\boldsymbol{D}$- and $\boldsymbol{g}$-tensors are coaxial, $\boldsymbol{g}$-tensor values have been estimated from the positions of three pairs of turning points (X, X'; Y, Y'; and Z, Z').[11-13] They are g_{xx}=2.0045±0.0002 (X, X'), g_{yy}=2.0051±0.0002 (Y, Y'), and g_{zz}=2.0024±0.0002 (Z, Z'). The average g_{av} value of $1/3(g_{xx}+g_{yy}+g_{zz})$=2.0040±0.0002 agrees with the isotropic g_{iso}-value (2.00414±0.00003) measured at 20 °C, indicating that the $\boldsymbol{g}$-tensor values obtained by the above analyses are reliable.

Discussion

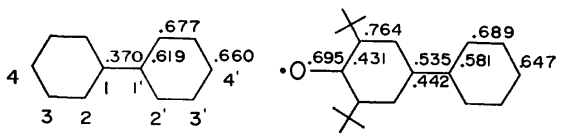
The Structure of Aryloxyl Monoradicals. McLachlan spin densities (ρ_i) of the aryloxyl radical (I) were calculated, varying the twist angle θ_{AB} between the phenyl rings A and B. The MO parameters were given the values $\alpha_O=\alpha+1.3\beta$, $\beta_{CO}=1.5\beta$, and λ=1.2.[14] The results are shown in Fig. 5. Comparing these spin densities and the experimental values calculated from the hyperfine splittings, the best accordance was found

for the twist angle $\theta_{AB}=0°$ (Table 1). Thus, spin densities (ρ_i) were calculated, in the case of the aryloxyl radical (III), holding one twist angle θ_{AB} at 0° and varying the other twist angles θ_{BC} and θ_{CD}; here we used the same MO parameters, $\alpha_O=\alpha+1.3\beta$, $\beta_{C-O}=1.5\beta$, for the oxygen atom (O_1), and the parameters $\alpha_{OH}=\alpha+0.9\beta$, $\beta_{C-OH}=0.4\beta$ for the oxygen atom of the OH group.[15] The results show that a very small unpaired spin density (lower than 1.5%) exists in the C and D rings, the spin density distribution not being sensitively affected by varying the twist angles θ_{BC} and θ_{CD}. The spin densities obtained for the structure $\theta_{AB}=\theta_{CD}=0°$, $\theta_{BC}=30°$ of the radical molecule (III) (Table 1) also show good agreement with those obtained from the hyperfine splittings of the radical (III).

The aryloxyl radical (I) may be considered to be a biphenyl derivative; the molecule of biphenyl is planar or nearly so in both the solid and triplet state, but twisted 30—40° around the central single bond in the vapor phase and in solution.[16] Thus, the degree of twisting of biphenyl molecule is clearly due to a delicate balance of non-bonded repulsion and conjugation. On the other hand, it is obvious that the inter-ring bond acquires some double-bond character in the aryloxyl radical (I) in view of a valence-bond. This is apparent in the quinoid valence structures (iv) and (v) for the aryloxyl radical (I):



We reach a similar conclusion by calculating the bond orders due to the Hückel molecular-orbital, the result for aryloxyl radical (I) indicating that the 1—1′ and 2—3 bonds are strengthened and the 1—2 and 3—4 bonds weakened as compared to biphenyl molecule.



All the results indicate that the aryloxyl radical (I) has planar character.

D*-Tensor Calculation with Spin Densities.** In order to clarify the molecular structure of the 4,4′-(biphenyl-3,3′-diyl)bis(aryloxyl) biradical (IV), and determine the directions of the principal axes, X_d, Y_d, and Z_d, of the ***D-tensor in the molecule (Figs. 6 and 8), calculations of the dipolar splitting tensors were performed for the assumed molecular structures using McLachlan spin densities of the aryloxyl radical (I).

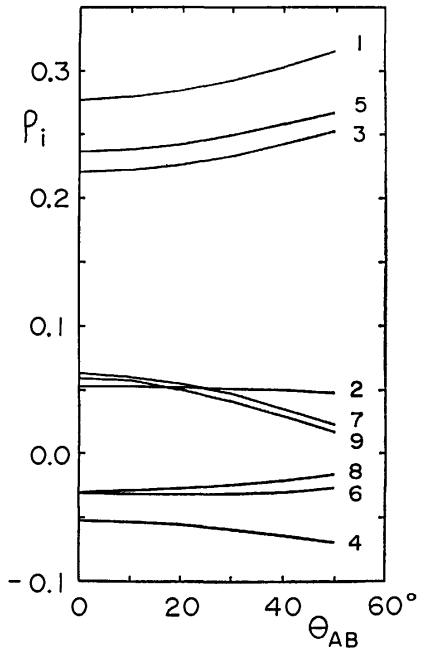


Fig. 5. Dependence of McLachlan MO spin densities (ρ_i) of carbon and oxygen atoms in aryloxyl radical (I) on twist angle θ_{AB}.

Bis(aryloxyl) (IV) is thought to be a weakly π-conjugated biradical consisting of two aryloxyl monoradical parts. The values of the hyperfine splittings of the ring protons and the isotropic g_{iso} value of the monoradical precursor (III) of the bis(aryloxyl) show an excellent agreement with the corresponding values of the aryloxyl (I), that is, a monoradical half of the biradical (Table 1). No hyperfine splitting arising from the protons in C and D rings was observed even by the ENDOR measurement with resolution higher than that of ESR measurement.[17] The results of McLachlan MO calculation of the radical (III) also supported the above anticipation, showing the existence of very small unpaired electron density (1.0—1.5%) in the C and D rings. Therefore, the dipolar magnetic system of the bis(aryloxyl) biradical may be adequately described as

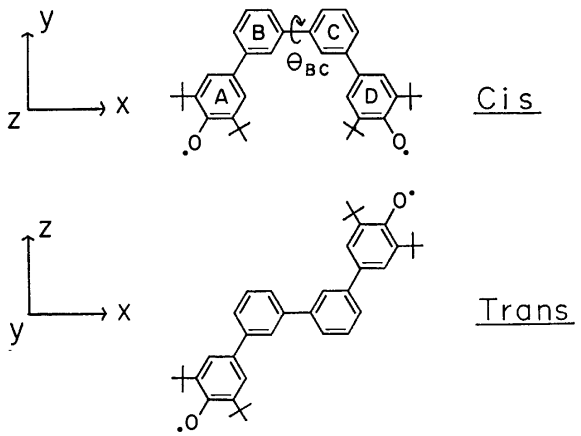

Fig. 6. Molecular structures and the coordinate systems (right-handed systems) chosen for "cis" and "trans" conformations of the 4,4′-(biphenyl-3,3′-diyl)bis(aryloxyl) biradical (IV).

an isolated two-spin system consisting of two aryloxyl groups, each containing one unpaired electron.

Aryloxyl monoradical parts of the bis(aryloxyl) (IV) seem to be planar in solution. Thus, as a most plausible case, the ***D***-tensor values have been calculated, assuming that $\theta_{AB}=\theta_{CD}=0°$ and varying θ_{BC}. Molecular structures and the coordinate systems (x, y, and z) chosen for "cis" and "trans" conformations of the bis(aryloxyl) biradical (IV) are shown in Fig. 6, where $\theta_{BC}=0°$ corresponds to a planar "cis" conformation, and $\theta_{BC}=180°$ is a planar "trans" conformer. In the planar "cis" conformation, the principal axes X_d, Y_d, and Z_d of the ***D***-tensor are parallel to the molecular axes x, y, and z, because of the symmetry of the biradical molecule[13,18] (Fig. 8). By varying the twist angle θ_{BC}, we can expect that the Y_d axis still coincides with the molecular y axis, but the X_d axis is parallel to the line inclined θ_x from the molecular x axis within xz plane.

In such a case, the ***D***-tensor components of the dipolar splitting can be calculated with the aid of the following equations.[13,19,20]

$$D_{mm} = (1/2)g^2\beta^2\sum_{i,j}\rho_i\rho_j(r_{ij}^2-3m_{ij}^2)/r_{ij}^5, \quad (m = x, y, z) \tag{3}$$

$$D_{mn} = (1/2)g^2\beta^2\sum_{i,j}\rho_i\rho_j(-3m_{ij}n_{ij})/r_{ij}^5, \quad (m, n = x, y, z; \text{ but } m \neq n) \tag{4}$$

where r_{ij} is the distance between the i and j atoms, and ρ_i and ρ_j are the McLachlan π-spin densities on the i atom in one aryloxyl group and the j atom in the other aryloxyl group, respectively, in a molecule. Here we have chosen the following parameters: the C–O bond length is 1.27 Å, and the C–C bond length is 1.40 Å on the average, as obtained by an X-ray analysis of the galvinoxyl radical.[21] The resulting tensor is then diagonalized, giving the principal values X, Y, and Z and their directions.

Several authors have carried out such calculations for the radical pairs[19,20] and the weakly π-conjugated biradicals,[13,18,22] and obtained good agreement with experiment. However, the agreement was not satisfactory[13] when the internuclear distances between two monoradical parts are small. The discrepancy between observed and calculated zero-field splitting values depends mainly on the difference between the true and the calculated zero-field splitting values for short interatomic distances. In such a case, the electron distribution within a $2p_z$ orbital has to be represented by two half-charges located above and below the plane containing the atom. This approximation has been shown to be quite good if the separation between the half-charges is 1.4 Å even when the internuclear distances are as small as 1.6 Å.[23,24]

Therefore, we calculated the ***D***-tensor values of the bis(aryloxyl) (IV), using the above approximations ((a) "point-charge" and (b) "half-charge" approximations), and compared the results obtained. How the principal values X, Y, and Z of the zero-field splitting and the value of the direction cosine ($\cos\theta_x$) of the principal axis-X_d of the zero-field splitting tensor to the molecular axis-x vary as a function of θ_{BC} is shown in Figs. 7 and 8, respectively. The results indicate that, in the above two kinds of approximations, $|X|$ is the largest

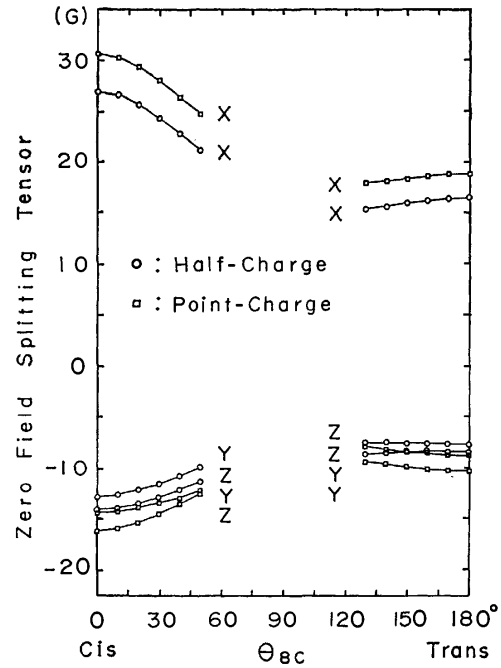

Fig. 7. The variation of the principal components of the zero-field splitting tensor as a function of the twist angle θ_{BC}.

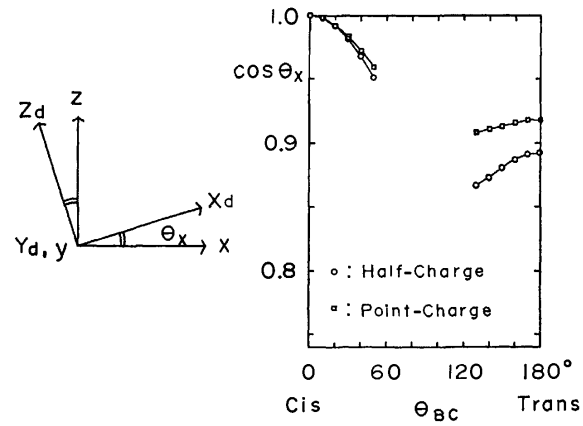

Fig. 8. The variation of the direction cosine ($\cos\theta_x$) of the pricipal axis-X_d of the zero-field splitting tensor to the molecular axis-x as a function of the twist angle θ_{BC}.

component of the zero-field splitting tensor and is consistent with our expectation. Thus, the zero-field parameters D and E are given by

$$D = -3X/2, \quad E = -(Y-Z)/2. \tag{5}$$

Figure 9 shows how the D and E parameters vary as functions of θ_{BC}. By comparing the observed D-parameter ($|D|=35.4$ G) with the calculated ones, the agreements were observed for the cases of $\theta_{BC}=35°$ in the "half-charge" approximation and $\theta_{BC}=57°$ in the "point-charge" approximation, where the θ_x values are 13° and 18°, respectively. On the other hand, in both the approximations, the absolute values of all the calculated E-parameters are smaller than the observed one ($|E|=2.6$ G). The absolute values of all the D-parameters calculated by the "point-charge" approximations are 3.6—5.4 G larger than those calculated by the "half-charge" approximation for the corresponding

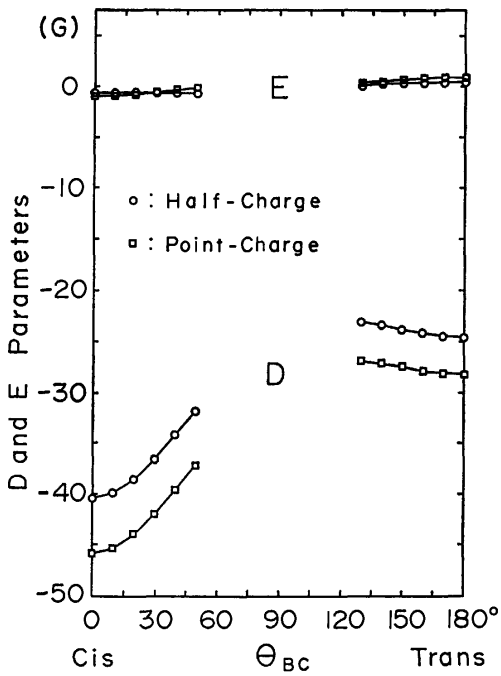

Fig. 9. The variation of the zero-field splitting parameters D and E as a function of the twist angle θ_{BC}.

twist angle θ_{BC}. For instance, in a planar "cis" conformer ($\theta_{BC}=0°$), the total D-parameters calculated are -45.8 G for the "point-charge" approximation and -40.4 G for the "half-charge" approximation, where the values of the D-parameter calculated for the nearest neighboring atoms ($C_{10B}-C_{10C}$) (Fig. 1) are -9.2 G for the former and -5.0 G for the latter. The difference (5.4 G) between the total D-parameters of the two approximations could be attributed to the difference (4.2 G) obtained for the nearest neighboring atoms ($C_{10B}-C_{10C}$). The results indicate that the "point-charge" approximation is unsatisfactory for the calculation of $\boldsymbol{D}$-tensor value of the radical molecule with short interatomic distance, such as 1.4 Å, and the "half-charge" approximation improves the calculation considerably.

Two sets of ESR spectra of the lowest excited triplet state of 2,2'-bipyridyl in poly(vinyl alcohol) (PVA) films have been observed.[25] They are interpreted to be due to its "cis" and "trans" conformations from the experimental and theoretical viewpoints, since the molecular structure in the triplet state is considered to be planar. Similar phenomena have also been observed for 3,3'-dimethylbiphenyl and 3,3'-difluorobiphenyl in rigid glass.[26,27] On the other hand, the bis(aryloxyl) biradical (IV) is considered to be a biphenyl (B and C rings) derivative. Thus, we can expect similar conformations, "cis" and "trans" forms, in the bis(aryloxyl) biradical (VI). However, the frozen-solution ESR spectrum of the bis(aryloxyl) in toluene (Fig. 4) suggests that only one conformer exists in the biradical. If two conformers exist in the aryloxyl biradical at the same time, we should, at least, observe a splitting in the X and/or X' absorption lines as the results of calculation of the D and E parameters indicate. Although the $\boldsymbol{D}$-tensor calculation presented here is of a very approximate nature for the bis(aryloxyl) biradical, the result indicates that the bis(aryloxyl) biradical has "cis" conformation rather than "trans."

We are grateful to Prof. Kazuhiko Ishizu and Dr. Fujito Nemoto for their kind advice. We also wish to thank Mr. Takayuki Yasunaga and Mr. Tsukasa Hara for their help in the preparation of aryloxyl radicals (I) and (II).

The r_s Structures of Fluoromethyl, Chloromethyl Ethers, and Methyl 2-Propynyl Ether

Michiro HAYASHI* and Hiroshi KATO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received January 21, 1980)

^{18}O enriched samples of chloromethyl methyl ether and chloromethyl ethyl ether were prepared and their microwave spectra were measured. The r_s structures of fluoromethyl methyl ether, fluoromethyl ethyl ether, chloromethyl methyl ether, chloromethyl ethyl ether, and methyl 2-propynyl ether were re-evaluated from the observed rotational constants obtained under the common constraints and assumptions on the structures of the molecules. A comparison of the r_s structures was made between the five molecules and between the molecules and their related molecules.

In previous papers, reports were given on the r_s structures of chloromethyl methyl ether,[1] chloromethyl ethyl ether,[2] and fluoromethyl ethyl ether.[3] Studies on fluoromethyl methyl ether[4] and methyl 2-propynyl ether[5] have been completed, the r_s structures of these molecules being determined.

The most populated isomer for these five molecules is the gauche isomer around the CH_2–O bond. Since several atoms in the molecules are situated close to the principal axes, solutions of the Kraitchman equation for these atoms are not reliable for coordinates having small absolute values. Moreover, a fluorine atom has no stable isotope, and thus the coordinate values of the fluorine atom should be computed from the coordinate values of the other atoms by means of the first moment equations.

The coordinate values of the oxygen atom were also obtained from those of other atoms with certain assumptions on the structure since no ^{18}O enriched samples were available.[1,2] After our results for these molecules had been reported, we succeeded in preparing ^{18}O enriched samples. Three coordinate values for the oxygen atom could then be obtained by means of the Kraitchman equation. Since we are interested in comparison of the structures of these molecules it is important to re-evaluate their structures under a common set of constraints and assumptions on the five molecules by using new additional data. This paper deals with the structures obtained under different constraints and assumptions for each molecule. They are compared in order to find the most reliable r_s structures obtained by means of the common set of constraints and assumptions on these five molecules.

Interesting features of the structural parameters for halomethyl ethers and their related molecules are given. The dipole moment, nuclear quadrupole coupling constant tensor and internal rotation are not dealt with.

For the sake of convenience, the names of the molecules referred to are abbreviated as follows: fluoromethyl methyl ether, [F, Me]; fluoromethyl ethyl ether, [F, Et]; chloromethyl methyl ether, [Cl, Me]; chloromethyl ethyl ether, [Cl, Et]; and methyl 2-propynyl ether, [Pr, Me].

The conventional terms, trans and gauche, are used instead of the IUPAC nomenclature, antiperiplanar and synclinal, respectively, since they were used in previous papers.

Experimental

^{18}O enriched samples of [Cl, Me] and [Cl, Et] were prepared by the reaction of ^{18}O enriched methanol or ethanol and paraformaldehyde with hydrochloric acid.

^{18}O enriched methanol was prepared by the method of Sawyer.[6] Tributyl orthoformate was mixed with ^{18}O enriched water (70 atom % ^{18}O, Prochem.) in the presence of hydrochloric acid in diglyme. The resulting butyl formate-carbonyl-^{18}O was reduced by lithinum aluminum hydride. The methanol obtained contains *ca.* 60 atom % ^{18}O.

^{18}O enriched ethanol was obtained by mixing acetaldehyde with ^{18}O enriched water and the resulting aldehyde was reduced with lithium aluminum hydride. The ethanol obtained was found to contain *ca.* 30 atom % ^{18}O.

The microwave spectra were measured in the range 8500—34000 MHz with a conventional Stark modulation spectrometer at dry ice temperature. Observed frequencies and rotational constants are given in Tables 1 and 2.

Determination of r_s Structures

In spite of sufficient data for determining the r_s structures of the four halomethyl ethers by the substitution method, there are several unreliable Kraitchman atom coordinate values for each molecule. The coordinate value obtained by the Kraitchman equation is hereafter referred to as the *K*-value. The identification symbols of the atoms for the XCH_2OCH_3 and $XCH_2OCH_2CH_3$ type molecules are shown in Fig. 1 where the hydrogen atoms situated on the same side as the X atom with respect to the COC plane have

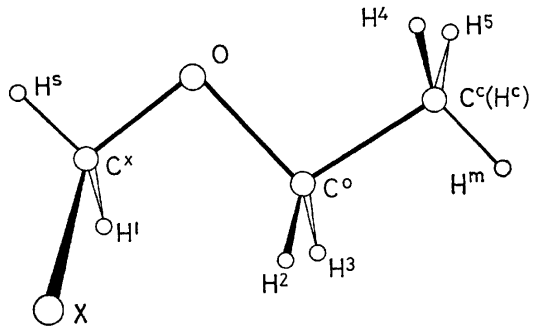

Fig. 1. Identification number of atoms in $XCH_2OCH_2CH_3$.
The symbols in parentheses indicate the atom symbols for XCH_2OCH_3.

$A=13968.12(12)$, $B=3409.25(4)$, $C=2974.86(4)$, $d_J=1.95(74)\times10^{-3}$, $d_{JK}=-1.72(43)\times10^{-2}$, $\chi_{aa}=-27.7(35)$, $\eta\chi_{aa}=-31.5(21)$

a) Since the observed components were restricted to those expected under the rule of $\Delta F=\Delta J$, the component can be designated by the F value of the lower level alone. For example, the component of the $J+1\leftarrow J$ transition labeled $F=J+3/2$ indicates the component of $F'=J+5/2\leftarrow F=J+3/2$ and so on. Dotted line indicates that the corresponding component is overlapped with the other strong line. ν_0 is the hypothetical unsplit frequency where the figures in parentheses indicate the deviations of the observed frequency from the calculated. $\Delta\nu(J+3/2)$ indicates the difference of the $F=J+3/2$ component from ν_0 where the figures in parentheses indicate the deviation of the observed frequency from the calculated one. b) Figures in parentheses indicate the uncertainties attached to the last significant figures calculated from 2.5 times the standard deviation.

a) Figures in parentheses indicate the 99% reliability intervals attached to the last significant figures. Underlined figures indicate unreliable Kraitchman values. b) Indentification symbol is shown in Fig. 1. c) Coordinate value can be determined by means of the first moment equation. d) Coordinate value can be determined by means of the first moment equation, but will be influenced by other coordinate values to be solved with other constraints. e) Kraitchman coordinate value is imaginary. f) Kraitchman coordinate value is so small that the sign of the value is also uncertain.

the moments of inertia are calculated from atom coordinate values containing the values solved by the set of the constraints and/or assumptions, a useful criterion is the root mean square deviation of the observed and calculated moments of inertia for all the species measured (referred to as RMS).

Chloromethyl Ethyl Ether (Gauche-Trans Isomer) [*Cl, Et*]. Owing to the lack of data for the ^{18}O species, three coordinate values of the oxygen atom had to be solved from the coordinate values of the other atoms as well as three unreliable *K*-values.[2] The *K*-values of the oxygen atom are regarded as reliable ones (Table 3). The coordinate values to be solved are then those of $x_b(H^3)$, $x_c(Cl)$, and $x_c(H^4)$. $x_b(H^3)$ can be solved with the aid of the first moment equation. The $x_c(H^4)$ value is obtained in two ways: 1) by assuming $\alpha(CCH^4)=\alpha(CCH^5)$, and 2) under the $I_{ac}=0$ constraint. In both cases, $x_c(Cl)$ is solved by means of the first moment equation. Since the hydrogen atom H^m corresponds to the in-plane hydrogen if the molecule has the plane of symmetry, 1) gives a symmetric methyl group (Table 4, Structure I), while 2) gives an asymmetric methyl group (Structure II).

The structure of the CCH_3 part of the molecule is obtained by the assumption that the $x_c(H^5)$ *K*-value is reliable. The reported structure[2] (Table 4) is close to Structure II for the CCH_3 part of the molecule. As regards the other part of the molecule, Structure II is better irrespective of the choice of assumptions for the CCH_3 part of the molecule, since the reported structure was obtained under several assumptions on the structure.

It is difficult to decide which of I and II is reliable. The constraint imposed on II ($I_{ac}=0$) is not applicable to the case of [F, Et]. Thus I having a symmetric methyl group is preferable to II for [Cl, Et].

Chloromethyl Methyl Ether (Gauche Isomer) [*Cl, Me*]. There are six unreliable *K*-values for [Cl, Me].[1] The *K*-values of the oxygen atom obtained from newly additional data for the ^{18}O species seem to be reliable. For the x_c coordinates, three unreliable *K*-values are situated at the same positions as those found for [F, Me] (Table 3). The constraints used for the case of [F, Me] may also be applicable to this molecule. Then three x_c coordinates, $x_c(Cl)$, $x_c(H^s)$, and $x_c(H^2)$ are solved by the first moment equation, the $I_{bc}=0$ constraint and the $\alpha(OCH^2)=\alpha(OCH^3)$ assumption, respectively. The solutions for the x_c coordinates thus obtained are independent of the uncertainties due to three unreliable x_a *K*-values since all the x_a and x_b values related to the $\alpha(OCH^2)=\alpha(OCH^3)$ assumption are reliable.

In order to obtain the three x_a coordinate values, the first moment equation for the x_a coordinates, $\sum(x_a)_i m_i=0$ and the $I_{ab}=0$ and $I_{ac}=0$ constraints might be useful besides the assumptions on the structure. However, use of the $I_{ac}=0$ constraint may produce large uncertainties since some of the x_c coordinate

a) Figures in parentheses indicate 99% reliability intervals. For bond lengths, the figures are attached to the last significant figures.

values are already solved by the other constraints and assumptions.

For this molecule, all the unreliable x_a values are the coordinates in the $ClCH_2O$ part of the molecule. Since all the K-values of the $ClCH_2O$ part are reliable for [Cl, Et] except the x_c(Cl) value, the structural parameters of this part of [Cl, Et] are considered to be reliable except those related to the chlorine atom.

Since the structure of the $ClCH_2O$ part of [Cl, Me] does not seem to be much affected by the substitution of OCH_3 with OCH_2CH_3, the structural parameters can be transferred between these two molecules.

Though four bond lengths and six angles belong to the $ClCH_2O$ part, seven parameters related to the Cl and H^s atoms cannot be used in order to evaluate the x_a values irrespective of the evaluation of the x_c values. The structural parameters of the skeleton are more important than the other parameters for our purpose so that the transfer of the $r(C^xO)$ value is not preferable. $r(CH^1)$ and $\alpha(OCH^1)$ are thus are the best parameters for the transfer.

Usually, the K-values for hydrogen atoms are regarded as unreliable for values less than 0.3 Å. However, they sometimes give reasonable structural parameters even when the values are less than 0.3 Å. Thus it is better to calculate structural parameters by using the unreliable K-values. If the structural parameters thus calculated are reasonable, the K-values used will be considered to be reliable.

Taking the above discussion into consideration, we tested ten possible sets of constraints and/or assumptions. 1) Use of the first moment equation and the $I_{ab}=0$ constraint requires one additional assumption on the coordinate value or structural parameter, there being four choices of assumption: i) the $x_a(H^s)$ K-value is reliable, ii) the $x_a(H^1)$ K-value is reliable, iii) the $r(CH^1)$ value is transferred, and iv) $\alpha(OCH^1)$ is transferred from that of [Cl, Et]. However, the results obtained from these four sets can be rejected since i) gives a too large $x_a(H^1)$ value and ii), iii), and iv) very small $\alpha(ClCH^s)$ values. Thus use of the $I_{ab}=0$ constraint is regarded to be inadequate. 2) Use of the first moment equation and two transferred structural parameter values, $r(CH^1)$ and $\alpha(OCH^1)$ also give a too large $x_a(H^s)$ value. 3) Use of the first moment equation and the $x_a(H^1)$ K-value assumed to be reliable requires one transferred parameter, either $r(CH^1)$ or $\alpha(OCH^1)$. These sets, however, give too small values of $\alpha(OCH^s)$ or $\alpha(ClCH^s)$ and can be rejected. 4) Use of the first moment equation, the $x_a(H^s)$ K-value assumed to be reliable requires one transferred parameter, either $r(CH^1)$ or $\alpha(OCH^1)$, (Table 5, Structures I and II). 5) The $x_a(H^1)$ values solved by the two sets of 4) are very close to the K-value. If we regard the K-values of $x_a(H^1)$ and $x_a(H^s)$ as reliable, the structural parameters obtained are close to those of Structures I and II. This set of structural parameters (Structure III) is obtained without transfer of the parameter values from the other molecules. Therefore, this is considered to be the most reliable set of parameters for [Cl, Me]. The structure reported[1)] is also given in Table 5 for the sake of comparison.

a) See footnote to Table 4.

Fluoromethyl Methyl Ether (Gauche Isomer) [F, Me]. Of the five molecules mentioned, [F, Me] is the most favorable for the determination of its r_s structure. There are only two unreliable K-value, $x_c(H^s)$ and $x_c(H^2)$, (Table 3). For the $x_c(H^s)$ coordinate, the K-value is so small that the sign of the coordinate value is also uncertain. Three coordinate values of the fluorine atom have to be solved by means of the first moment equations.

The $x_c(H^s)$ value is found to be very sensitive to the I_{bc} inertia product but not to the I_{ac} product. On the other hand, the effect of the $x_c(H^2)$ value on the I_{bc} and I_{ac} values is reverse to that of the $x_c(H^s)$ value. In order to find the adequacy of the use of the I_{bc} and $I_{ac}=0$ constraints, the following calculations were carried out. 1) The $x_c(H^s)$ value is evaluated by $I_{bc}=0$ on the assumption that the $x_c(H^2)$ K-value is reliable (Table 6, Structure I). 2) The $x_c(H^2)$ value is evaluated by $I_{ac}=0$ with the sign of the $x_c(H^s)$ K-value taken as a) plus, (Structure II) and b) minus. Since the latter gives a very large $\alpha(H^1CH^s)$ value, a great increase of the absolute I_{bc} value and a large RMS, the structure obtained by this assumption can be rejected.

Parameter differences between Structures I and II are found mainly in the OCH_3 group. For the former, both the $\alpha(OCH^3)$ and $\alpha(OCH^2)$ values are larger than the $\alpha(OCH^c)$ value and are close to each other, while three $\alpha(HCH)$ values are close to each other. The CH^c bond is much shorter than the other two CH bonds which can be regarded to be equal if the experimental error is taken into account. Since the H^c hydrogen atom corresponds to the hydrogen atom in the molecular plane if the molecule has the plane of symmetry, the relations on the structure indicate that the symmetric methyl group tilts towards the direction of the lone pair electrons on the oxygen atom. Thus, Structure I is essentially equal to the structure obtained on the assumption $\alpha(OCH^2)=\alpha(OCH^3)$ and the $I_{bc}=0$ constraint whose parameters are listed in Table 6 as III.

On the other hand, Structure II gives an asymmetric methyl group. It is difficult to judge which structure is more reliable. The sets of constraints applied to Structures I and II cannot be used for the case of [Cl, Me]. Structure III is thus considered to be better than the other structures when a comparison of structures is made between these molecules.

Fluoromethyl Ethyl Ether (Gauche-Trans Isomer) [F, Et]. The GT isomer of [F, Et] is the most unfavorable molecule of the four halomethyl ethers for the determination of the r_s structure. There are seven unreliable K-values and three coordinate values of the fluorine atom should be solved by means of the first moment equations.

First, the reliability of the unreliable K-values was tested in order to reduce the number of coordinate values to be evaluated. For the CCH_3 part of the molecule, the unreliable K-values are $x_b(H^5)$, $x_c(H^4)$, and $x_c(H^m)$. Since the calculations indicate that the structural parameters containing $x_b(H^5)$ and $x_c(H^m)$ give quite reasonable values as compared with the corresponding parameter values of [Cl, Et], the K-values of $x_b(H^5)$ and $x_c(H^m)$ can be regarded as reliable. On the other hand, the calculated parameter values related to $x_c(H^4)$ give a very small $r(CH^4)$ and a very large $\alpha(CCH^4)$. The $x_c(H^4)$ K-value should thus be evaluated by some other means.

A similar test indicates that the $x_a(O)$ K-value is doubtful, while the $x_c(H^s)$ K-value is quite reliable though the absolute value is small.

As regards the two K-values of $x_c(H^2)$ and $x_b(H^3)$, the test gives no conclusive result and they should be evaluated by other means.

a) See footnote to Table 4.

The original set of K-values gave the RMS value of 3.4283 amu·Å² and the large inertia products (I_{ab}, I_{ac}, I_{bc})=(−0.6012, 0.4859, −0.2993) amu·Å² (Table 7).

Since the $x_c(H^4)$ K-value was also unreliable for [Cl, Et], it was obtained on the assumption $\alpha(CCH^4)=\alpha(CCH^5)$. The same assumption is also applied to $x_c(H^4)$ of the present molecule. The RMS and I_{bc} values are reduced to 3.4056 and 0.0179 amu·Å², respectively, the structural parameters of the CCH_3 part becoming reasonably closer to those of [Cl, Et]. The $x_c(H^4)$ value thus obtained is used in all the trial calculations.

In order to evaluate the most unreliable three coordinate values, $x_a(O)$, $x_b(H^3)$, and $x_c(H^2)$, the set of the $I_{ab}=0$, $I_{ac}=0$, and $I_{bc}=0$ constraints and the three first moment equations might be applied on the assumption that the other four unreliable K-values are regarded as reliable. However, simultaneous use of the zero inertia product constraints seems dangerous for the present molecule where many unreliable K-values exist in all the x_a, x_b, and x_c coordinates.

The $x_a(O)$ value is evaluated by i) $I_{ab}=0$ or ii) $I_{ac}=0$ constraint on the assumption that the K-values of $x_b(H^s)$ and $x_c(H^2)$ and the other unreliable K-values are regarded as reliable. The $x_a(O)$ value obtained from ii) is too large, that from i) being reasonable. The RMS value for the structure from i) is 1.8570 amu·Å².

Since the $I_{bc}=0$ constraint was successfully used for the $x_c(H^s)$ value of [F, Me], it is applied to one of the $x_c(H^2)$ and $x_b(H^3)$ values. The parameters related to the oxygen atom for these two cases are essentially equal to those obtained from i) but the RMS values are reduced slightly. The parameters (Structure I, Table 7) are obtained for the case where the $x_c(H^2)$ value is obtained from the $I_{bc}=0$ constraint. For Structure I, the RMS and I_{ac} values are fairly large. We see that the RMS and I_{ac} values strongly depend on the $x_a(O)$ and $x_a(F)$ values which are related with each other by means of the first moment equation.

The $x_a(O)$ value can be solved on the assumptions that the $x_b(H^3)$ and $x_c(H^2)$ values of Structure I as reliable and one of the skeletal parameter values related to the oxygen atom for analogous molecules can be transferred to that of [F, Et]. First, the α(OCC) value of [Cl, Et] is transferred. The parameter values obtained are listed under Structure II. The RMS, I_{ab} and I_{ac} values of Structure II are fairly large. Though the structure is also obtained by use of the transferred $r(C^oO)$ value of [Cl, Et], the parameter values obtained are found to be very close to those of Structure II. The $r(C^oO)$ value of [Cl, Et] is inadequate to be transferred since the influence of the substitution of the chlorine atom with the fluorine atom seems to be too serious.

The plausible structures of [Cl, Me] and [Cl, Et] indicate that the α(COC) values of these two molecules are relatively close to each other (Table 8). On the assumption that the situation is the same for [F, Me] and [F, Et], the α(COC) value of [F,Me] is transferred (Structure III, Table 7). Though the RMS value of Structure III is satisfactorily small, the I_{ab} and I_{ac} values are fairly large. Furthermore, the skeletal parameter values of Structure III do not always seem to be reasonable, when a comparison is made between the plausible structures of fluoromethyl and chloromethyl ethers. For example, the difference between $r(C^xO)$ and $r(C^oO)$ for [Cl, Et] is larger than that for [Cl, Me], while the difference for [F, Et] is smaller than that for [F, Me].

Since the (COC) value of [Cl, Et] is slightly larger (22′) than that of [Cl, Me], the α(COC) value of [F, Et] is assumed to be larger by 22′ than that of [F, Me]. By this slight change in the α(COC) value, the RMS, I_{ab} and I_{ac} values are much reduced and the difference of two CO bond lengths becomes close to that of Structure II. From the above discussion, it is

found that assurance is necessary for the transferability of the skeletal parameter value in order to transfer the parameter values.

In spite of the large RMS and I_{ac} values, Structure I is considered to be plausible for the structure of [F, Et], since this structure is obtained with no assumption on the skeletal structure. It may be favorable for Structure I that the parameter values obtained are reasonable when a comparison of their values is made with those of the other three halomethyl ethers (Table 8).

a) See footnote to Table 4.

Structure III was proposed as the plausible structure because of the smallest RMS value.[3)] However, its parameter values cannot be regarded to be adequate from a comparison of their values with those of the other three halomethyl ethers.

The large values of RMS and I_{ac} for Structure I can be understood when the experimental errors of the x_b and x_c coordinate values of the C^c carbon atom are taken into account. Experimental errors of the x_b and x_c K-values of the C^c atom are fairly large, while its absolute x_a value is large (Table 3). The experimental errors of x_b and x_c values induce large uncertainties on the x_a values of the oxygen and fluorine atoms through the inertia product constraint ($I_{ab}=0$) and the first moment equation. Actually, when $x_b(C^c)$ and $x_c(C^c)$ values are shifted by about one-fifth of the experimental errors of the K-values (+0.005 and +0.003 Å, respectively), the RMS and I_{ac} values of the structure obtained by the same procedure as Structure I are reduced to 1.2360 and −0.1160 amu·Å², while the parameters obtained are not much shifted.

The uncertainties for the "A" rotational constants of the normal and $FCH_2OCH_2{}^{13}CH_3$ species are as small as those of the other species. However, the uncertainties on the "A" rotational constants are amplified in the uncertainties on the x_b and x_c values due to the fact that the difference of the moments of inertia ΔI_a between the normal and ^{13}C species is accidentally very small (0.0444 amu·Å²). Thus, we cannot reduce the experimental errors in the x_b and x_c

K-values though it is inevitable in order to reduce the RMS and I_{ac} values of Structure I.

Methyl 2-Propynyl Ether (Gauche Isomer) [Pr, Me]. A report has been given on the microwave spectra of the gauche isomer of [Pr, Me].[5] For this molecule, the r_s structure cannot be obtained without serious assumptions on the structure since many coordinates having small absolute values exist in the $HC{\equiv}CCH_2$– part of the molecule. However, only one unreliable *K*-value exists for OCH_3 part of the molecule. This coordinate is $x_c(H^2)$. When the assumption $\alpha(OCH^2)=\alpha(OCH^3)$ is applied to this value as in the case of the halomethyl ethers, the r_s structure of the OCH_3 part can be obtained irrespective of the uncertainties of the other part of the molecule, for which the parameters are adjusted so as to reproduce the observed moments of inertia. The results are given in Table 8.

Summary of the Applied Constraints and/or Assumptions. So far we have re-evaluated the r_s structures of halomethyl ethers and the OCH_3 part of methyl 2-propynyl ether considering several sets of constraints and/or assumptions.

The sets used for the proposed structures of these molecules are given in the following, the coordinate values obtained by each constraint being shown in square brackets:

[F, Me]

The three first moment equations, $[x_a(F), x_b(F), x_c(F)]$; $\alpha(OCH^2)=\alpha(OCH^3)$, $[x_c(H^2)]$; $I_{bc}=0$, $[x_c(H^s)]$.

[Cl, Me]

The two first moment equations, $\sum mx_a=0$ and $\sum mx_c=0$, $[x_a(C^x), x_c(Cl)]$; $\alpha(OCH^2)=\alpha(OCH^3)$, $[x_c(H^2)]$; $I_{bc}=0$, $[x_c(H^s)]$; The assumption that the $x_a(H^1)$ and $x_a(H^s)$ *K*-values are reliable.

[F, Et]

The first moment equations, $[x_a(F), x_b(F), x_c(F)]$; $\alpha(CCH^4)=\alpha(CCH^5)$, $[x_c(H^4)]$; $I_{ab}=0$, $[x_a(O)]$; $I_{bc}=0$, $[x_c(H^2)]$; The assumption that the $x_b(H^3)$, $x_c(H^5)$, $x_b(H^5)$, and $x_c(H^m)$ *K*-values are reliable.

[Cl, Et]

The two first moment equations, $\sum mx_b=0$ and $\sum mx_c=0$, $[x_b(H^3), x_c(Cl)]$; $\alpha(CCH^4)=\alpha(CCH^5)$, $[x_c(H^4)]$.

[Pr, Me], OCH_3 group

$\alpha(OCH^2)=\alpha(OCH^3)$, $[x_c(H^2)]$

The above sets indicate that the plausible r_s structures of these molecules can be obtained by use of the common constraints and/or assumptions on these five molecules. As is the case of [F, Et], even when many unreliable *K*-values are contained in the atom coordinates of a molecule to which usually no reliable r_s structure can be obtained, the proposed structure seems to be fairly reliable.

Discussion on Molecular Structures

The structures of four halomethyl ethers and [Pr, Me] have different reliabilities. However, their parameters (Table 8) exhibit interesting features when comparison is made with each other or with those of the other series of molecules.

Hereafter, for the quoted parameter values, figures in parentheses indicate the experimental uncertainties, while figures with $\pm$ such as 1.391 ± 0.002 Å indicate the dispersion of the value, *viz.*, the value between 1.393 and 1.389 Å. The value referred to as that for alkyl ethers is the value taken from those for *trans*-ethyl methyl ether,[7] dimethyl ether,[8] TT-diethyl ether,[9] and TT-methyl propyl ether,[10] where TT indicates the trans-trans isomer.

Skeleton. 1) The r(CF) value of FCH_2OR(R= CH_3, CH_2CH_3) is close to that of methyl fluoride (1.384(1) Å)[11] but smaller than that of ethyl fluoride (1.398(5) Å).[12] On the other hand, the r(CCl) value of $ClCH_2OR$ is larger than those of methyl chloride (1.781(1) Å)[13] and ethyl chloride (1.788(2) Å).[14] 2) The averages of the two r(CO) values are nearly constant for all halomethyl ethers (1.391 ± 0.002 Å) and smaller than those of alkyl ethers (1.410 ± 0.002 Å). The value for [Pr, Me] is close to those of alkyl ethers. 3) r(CO) attached to the halogen atom is much smaller than the other r(CO) which is slightly larger than that of alkyl ethers. The difference between two r(CO) values (0.073 ± 0.015 Å) is much larger than that found in alkyl ethers such as *trans*-ethyl methyl ether (0.011 Å), the difference for $XCH_2OCH_2CH_3$ being larger than that for XCH_2OCH_3. For [Pr, Me], two r(CO) values may be nearly equal to each other. 4) r(CC) of $XCH_2OCH_2CH_3$ is smaller than that of propane,[15] *trans*-ethyl methyl ether and ethyl chloride, is nearly equal to that of diethyl ether, being larger than that of ethyl fluoride though the experimental uncertainty is fairly large. 5) α(COC) of halomethyl ethers is nearly equal to each other ($114°\pm28'$) and smaller than that of alkyl ethers by about 2°. α(COC) of [Pr, Me] is smaller than that of alkyl ethers. 6) α(FCO) of FCH_2OR is smaller by *ca.* 1.5° than α(ClCO) of $ClCH_2OR$. 7) α(OCC) of $XCH_2OCH_2CH_3$ is nearly equal to that of alkyl ethers. 8) Skeletal dihedral angle τ(XCOC) increases in the order [F, Me], [F, Et], [Cl, Me], and [Cl, Et], the values being much larger (about 10°) than 60° which is presumed usual for the dihedral angle value of the gauche configuration of the molecules. For [Pr, Me], this angle is smaller by *ca.* 2° than that of halomethyl ethers. 9) Skeletal dihedral angle τ(COCC) of $XCH_2OCH_2CH_3$ is not 180° which is presumed for the value of the trans configuration, being smaller by *ca.* 4° than 180°. Since the difference from 180° is beyond the experimental error, the methyl group is situated not on the C–O–C plane but on the same side of the C–O–C plane where the halogen atom is found.

XCH_2O Group. 1) $r(CH^1)$ (1.100 ± 0.003 Å) related to the out-of-plane hydrogen H^1 might be larger than the $r(CCH^s)$ on the C–O–C plane (1.094 ± 0.003 Å). 2) The average of two α(XCH) values is much smaller than the tetrahedral angle, the average for $ClCH_2OR$ ($103°45'\pm9'$) being smaller than that of FCH_2OR ($106°33'\pm16'$). α(XCH) related to the in-plane hydrogen H^s is larger than that related to the out-of-plane hydrogen H^1. On the other hand, the α(OCH) value related to the out-of plane hydrogen H^1 is much larger than the tetrahedral angle.

OCH_2Y Group. 1) r(CH), which is nearly

parallel to the CX bond, is much larger than the usual r(CH) value except for that of [F, Me] where all the CH bonds have the usual r(CH) value. On the other hand, the other r(CH) has the usual r(CH) value within experimental error. 2) $\alpha(CCH^2)$ of $XCH_2OCH_2CH_3$ ($119°22' \pm 36'$) is much larger than the tetrahedral angle, while the corresponding angle $\alpha(H^cCH^2)$ of XCH_2OCH_3 is somewhat larger than the tetrahedral angle. 3) The dihedral angle $\tau(COCH^c)$ of XCH_2OCH_3 is smaller by about 4° than 180° as in the case of the τ(COCC) value of $XCH_2OCH_2CH_3$.

Halomethyl ethers exhibit specific chemical properties. For example, the reaction velocity of these molecules on hydrolysis strongly depends on the polarity of the solvent. They are known as material having carcinogenic activity.

Since the molecular structure attained by the isotopic substitution method sometimes shows fairly large vibrational effects, we cannot conclude that irregular or unusual structural parameter values for a molecule are directly related to its chemical properties. However, as regards halomethyl ethers, specific features of the structural parameters are found for a group of molecules considered to have different vibrational effects. These specific features seem to afford some evidence of the chemical properties of halomethyl ethers.

Selective *cis*-Isomerization of 1-Pentene Catalyzed by Ni(I)-Triphenylphosphine Complexes

Hiroyoshi KANAI,* Kenji KUSHI, Kei SAKANOUE, and Nobuji KISHIMOTO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received February 16, 1980)

Selective *cis*-isomerization of 1-pentene was carried out by $NiX(PPh_3)_3$ (X=halogen and pseudohalogen). First-order plots were obtained except for the iodo-complex. The addition of tin(II) chloride increased both activities and ratios of *cis*-2-pentene to the *trans*-isomer. Protic solvents accelerated the isomerization. Isotopic exchange between C_2D_4 and C_2H_4 or 1-pentene reveals that a metal hydride addition-elimination mechanism is operative.

We have previously reported that nickel complexes prepared *in situ* from $NiX_2(PPh_3)_2$ (X=halogen), PPh_3, and zinc catalyzed isomerization of 1-butene.[1] From the point of view that the isomerization activity and the ratio of *cis*-2-butene to the *trans*-isomer were dependent upon halides, we suggested that the catalytic species were Ni(I) complexes. A remarkable characteristic of the catalytic systems in the presence of $SnCl_2$ is the highest *c*/*t* ratio reported to date for the isomerization of terminal olefins catalyzed by transition metal complexes[2] and alkali-metal alkoxides.[3]

Halogenotris(triphenylphosphine)nickel(I) isolated from the above components has been found to be an active catalyst for isomerization of 1-pentene.[4] D'Aniello and Barefield[5] have confirmed that olefin isomerization by $NiX(PPh_3)_3$ occurred by a metal hydride pathway. The characteristics of the Ni(I) complexes in the isomerization of 1-pentene will be presented here in detail.

Experimental

Reagents. Tetrahydrofuran (THF) was refluxed over sodium, distilled, and stored in a nitrogen atmosphere. Methanol and ethanol were refluxed with sodium alkoxides and distilled. Triphenylphosphine was recrystallized from methanol. 1-Pentene was obtained from Tokyo Kasei Kogyo Co. and distilled prior to use. Other chemicals were commercial materials and used without further purification.

Nickel Complexes. Dihalogenobis(triphenylphosphine)-nickel(II) was prepared according to the method given in the literature.[6,7] A typical preparation of a Ni(I) complex was as follows. A mixture of 1.5 g (2 mmol) of $NiBr_2(PPh_3)_2$ and 0.61 g (2.3 mmol) of PPh_3 in 45 ml of benzene was treated with 0.65 g (10 mmol) of zinc dust. After a few minutes of stirring, the solution changed from green to yellow; it became red-brown and then the reaction mixture was rapidly filtered into a flask containing 0.02 g of $NiBr_2(PPh_3)_2$. When the solution turned yellow, the unreacted (undissolved) $NiBr_2(PPh_3)_2$ was removed by filtration. The filtrate was concentrated to one-third of its original volume. Thirty ml of methanol was added to the suspension to precipitate a yellow solid, which was collected and washed with five 10 ml portions of cold methanol. Drying *in vacuo* gave 1.55 g (82%) of $NiBr(PPh_3)_3$. Anal. Found: C, 70.09; H, 5.14. Calcd for $C_{54}H_{45}BrP_3Ni$: C, 70.10; H, 4.90 . $NiCl(PPh_3)_3$ and $NiI(PPh_3)_3$ were prepared in a similar manner; the yields were 61 and 46%, respectively. The elementary analyses supported the presence of Ni(I) complexes.[8]

Kinetics. The general procedure for the kinetic runs was as follows. A Ni(I) complex was weighed and added to a 100 ml flask. If an additive was used in a run, it was also weighed and added at this point. THF was vacuum distilled into the flask, which had already been evacuated and chilled in liquid nitrogen. The solvent was thawed and the mixture was stirred for 5 min to give a homogeneous yellow solution. After the mixture was again frozen in liquid nitrogen, 1-pentene was vacuum distilled into the flask. We determined the start of the isomerization to be when the mixture was thawed and stirred in a thermostated water bath at 0 °C.

Analysis. The concentrations of pentenes were followed by Shimadzu Model 2B and 4A gas chromatographs equipped with TCD and FID detectors. A 5.6 m×3 mm i.d. column packed with 60/80 mesh dimethylsulfolane (30%)/C-22 was operated at ambient temperature. Mass spectrometric analysis was made on a Hokushin time-of-flight mass spectrometer using an ionizing voltage of 12 eV.

Results and Discussion

Ligand Effects. When nickel complexes $NiX_2(PPh_3)_2$ (X=Cl, Br, I) were reduced with zinc in the presence of PPh_3 in THF or benzene, the green solution turned yellow and finally red-brown. The solutions contain a mixture of Ni(0) and Ni(I) species: the former is the red-brown species[9a] and the latter is the yellow one.[9b] The Ni(I) species was presumed to be an active catalyst for the isomerization of 1-butene.[1] This presumption has been confirmed by D'Aniello and Barefield on the basis of the isomerization of 1-butene-3,3-d_2 catalyzed by $(PPh_3)_3Ni(SnCl_3)$.[5] Since $NiX(PPh_3)_3$ was prepared by a disproportionation reaction between $Ni(PPh_3)_4$ and $NiX_2(PPh_3)_2$,[9b] it is expected that only $NiX(PPh_3)_3$ might be obtained when $NiX_2(PPh_3)_2$ is added by the amount equal to that of $Ni(PPh_3)_{3-4}$ formed in the reduction of $NiX_2(PPh_3)_2$ by zinc in the presence of PPh_3.[10] Our alternative method for the preparation of Ni(I) complexes is easy to carry out, without isolation of $Ni(PPh_3)_{3-4}$.

The first-order dependence on 1-pentene was observed without any induction periods at a 1-pentene/Ni ratio of 100, except for the iodo-complex, as shown in Fig. 1. Table 1 shows activities and *c*/*t* ratios for the isomerization of 1-pentene catalyzed by $NiX(PPh_3)_3$. Complexes with anion groups other than halogens were prepared *in situ* by replacing bromine on $NiBr(PPh_3)_3$ with KSCN, $NaOCH_3$, $AgPF_6$, and $AgClO_4$, respectively. The values in Table 1 show the results at the most favorable ratios of anions to $NiBr(PPh_3)_3$. Activities and *c*/*t* ratios are dependent upon anion ligands. Although large ions

TABLE 1. RATES AND c/t RATIOS IN THE ISOMERIZATION OF 1-PENTENE WITH $NiX(PPh_3)_3$[a]

X	k' / $10^{-3}\ s^{-1}\ M^{-1}$	c/t
Cl	1.7 (3.9)[b]	2.99
Br	2.1 (5.8)[b]	4.11
I	—[c] (4.9)[b]	5.63
SCN(5.0)[d]	1.3	1.65
OCH_3(10)[d]	1.2	3.11
PF_6(1.2)[d]	0.83	3.45
ClO_4(1.1)[d]	13.5	4.15

a) [Ni] 5×10^{-3} M, [1-pentene] 0.48—0.5 M, THF 19 ml, 0 °C. b) Conv. after 80 min. c) A first-order plot was not observed. d) Complexes were prepared *in situ* by replacing Br on $NiBr(PPh_3)_3$ with KSCN, $NaOCH_3$, $AgPF_6$, and $AgClO_4$ at given mole ratios to Ni in solution.

such as PF_6^- and ClO_4^- form counterions to $[Ni(PPh_3)_3]^+$, the high activity of the ClO_4-complex compared with that of the PF_6-complex seems to be attributed to coordinatively unsaturated nickel species, according to the abstraction of PPh_3 by $AgClO_4$.[11]

Striking increases in activities and c/t ratios were observed in the presence of $SnCl_2$ as shown in Table 2. Both activities and c/t ratios increase with the amount of $SnCl_2$ and become constant at a $SnCl_2$/Ni ratio of nearly 100 in THF. The difference of maximum c/t ratios among halogen-systems can not be regarded as significant. However, the rates increase in the following order: I<Br<Cl. Since $Ni(SnCl_3)(PPh_3)_3$ is isolated by the reaction of $NiCl(PPh_3)_3$ with $SnCl_2$ in benzene,[5] the active species responsible for high activity is $Ni(SnCl_2X)(PPh_3)_3$, shown in Eq. 1. The difference of

$$NiX(PPh_3)_3 + SnCl_2 \rightleftarrows Ni(SnCl_2X)(PPh_3)_3 \quad (1)$$

activity between halogen-systems might be attributed to that of the equilibrium constants. It is interesting to note that a first-order plot was obtained in the $NiI(PPh_3)_3$–$SnCl_2$ system, in contrast to the case of $NiI(PPh_3)_3$ alone. A small increase in rate and c/t ratio was observed at $SnBr_2/NiBr(PPh_3)_3$ ratios of 1/5—1/3, but a further addition of $SnBr_2$ retarded olefin isomerization.

TABLE 2. THE EFFECTS OF THE ADDITION OF $SnCl_2$ ON THE ISOMERIZATION OF 1-PENTENE WITH $NiBr(PPh_3)_3$[a]

X	$SnCl_2$/Ni	k' / $10^{-3}\ s^{-1}\ M^{-1}$	c/t
Cl	16	24.3	15.4
	50	44.3	22.4
	99	50.3	29.1
Br	15	11.5	16.4
	58	26.3	22.5

I	15	2.69	9.6
	49	11.5	10.1
	100	14.3	24.5

a) The reaction conditions were the same as those in Table 1.

Mixtures of $NiX_2(PPh_3)_2$ (X=Cl, Br) and $SnCl_2$ are less effective catalysts than $NiX_2(PPh_3)_2$ alone in the hydrogenation and isomerization of methyl linoleate.[7] This is because $SnCl_3$ ligand, which is a soft and π-acceptor one,[12] prefers soft metal ions such as Ni(I). Catalytic properties were greatly enhanced by replacing halogen ligands with $SnCl_3$ in the hydrogenation,[13-15] isomerization,[16-19] and hydroformylation.[20-22] The $SnCl_3$ group has a labilizing effect on other ligands, especially on a ligand *trans* to it,[23] which would facilitate the formation of a hydridonickel complex and activate Ni–H or Ni–alkyl bonds.

TABLE 3. SOLVENT EFFECTS ON THE ISOMERIZATION OF 1-PENTENE WITH $NiBr(PPh_3)_3$[a]

X	Cosolvent	vol%	k' / $10^{-3}\ s^{-1}\ M^{-1}$	c/t

	Toluene	100	1.1	4.51
	H_2O	2.6[b]	24.6	4.48
I	MeOH	50	—(20.9)[c]	8.32

a) The reaction conditions were the same as those in Table 1. b) The vol% at which max rates were obtained. c) Conv. after 80 min.

Solvent Effects. A small difference of activity appeared between different lots. When the same lot was used in a series of experiments, the results were reproducible to ±10% on repeated runs so that they were discussed as indicating certain trends. Nickel(I) complexes are soluble in THF, aromatic hydrocarbons, DMF, and MEK, but less soluble in alcohols. Table 3 indicates solvent effects in the isomerization of 1-pentene catalyzed by $NiBr(PPh_3)_3$. None of the solvents are more suitable than THF as a one-component solvent. Maximum rates were observed at the vol% given in Table 3 for CH_3CN– and DMF–THF systems. Any amount of MEK retarded the isomerization. The c/t ratios decrease with the amount of aprotic solvents, which suggests that solvent molecules coordinate appreciably to the nickel atom. The addition of a small

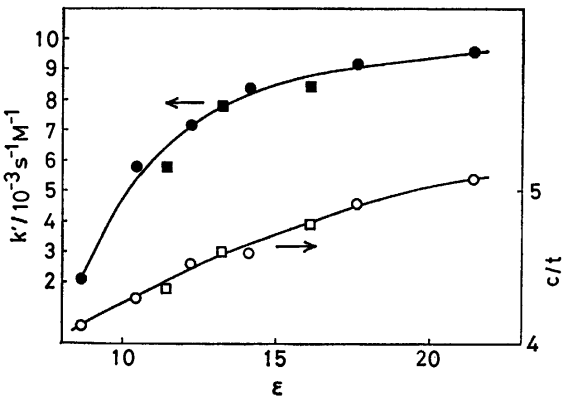

Fig. 2. Solvent effects on the rate and the *c/t* ratio in 1-pentene isomerization with $NiBr(PPh_3)_3$ in THF–alcohol system.
●, ○: MeOH, ■, □: EtOH.

amount of water led to a significant increase in activity and a slight increase in *c/t* ratio. An excess of water decreased both activity and *c/t* ratio, because the nickel(I) complex was caused to dissociate, which was followed by decomposition with butane evolution. The addition of methanol and ethanol led to the increase both in rates and *c/t* ratios, as was the case with water. Alcohols are precipitating agents for the nickel complexes, so that they are not added beyond a limited volume. Both the rate and *c/t* ratio increase with dielectric constants of THF–alcohol systems, as shown in Fig. 2. The color change was observed in protic solvent systems. The UV spectra showed λ_{max} at 343 nm ($\varepsilon=3.04\times10^3$) and 372 nm ($2.06\times10^3$) in THF, 345 nm ($4.08\times10^3$) and 370 nm ($2.79\times10^3$) in THF–MeOH, and 345 nm (4.51×10^3) and 372 nm (2.93×10^3) in THF–H_2O. Since the shifts of wavelength in λ_{max} are small, the change of the color is due to an increase of absorptivity. A similar acceleration by water or alcohols was observed in the codimerization of butadiene with ethylene catalyzed by σ-arylnickel(II) complexes–BF_3OEt_2.[24] Some complexes undergo oxidative addition of water as H and OH.[25] No results have suggested that protic solvents were used as a hydrogen source in our catalytic systems.

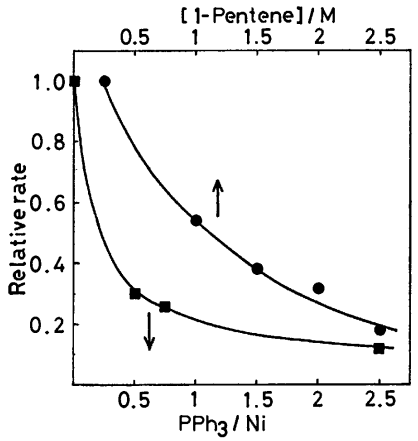

Fig. 3. Effects of excess PPh_3 and the concentration of 1-pentene on the rate of 1-pentene isomerization with $NiBr(PPh_3)_3$.

Effects of the Concentrations of Olefin and Free PPh_3. Figure 3 shows the effect of the concentlation of 1-pentene on the rate constants, where the relative rate constant is 1.0 at 0.25 M (1M=1 mol dm^{-3}) of 1-pentene. The rate constant decreases with an increase of the concentration of 1-pentene. Since no dimers of 1-pentene were observed, the retardation was due to the inhibitory impurities such as diene.[26] The presence of free PPh_3 slows activity because excess PPh_3 disturbs the coordination of olefins to the metal (Fig. 3).

Table 4. Dimerization of ethylene with $NiBr(PPh_3)_3$[a]

Solvent	Temp °C	Time h	Conv. %	Composition 1-C_4H_8 %	Composition *c/t*
THF	0	71	1.1	88	4.7
THF[b]	0	47	2.7	89	6.0
Toluene[c]	30	25	1.3	79	4.1
Toluene–MeOH (4:1)	30	25	7.7	19	3.7
THF[c]	30	25	1.4	81	4.1
THF–MeOH(4:1)[c]	30	25	11	25	3.7

a) [Ni] 2—2.5×10^{-2} M, [C_2H_4] 0.2—0.25 M, Solvent 4—5 ml. b) $NiBr(PPh_3)_2$ was prepared *in situ* from the disproportionation between $Ni(C_2H_4)(PPh_3)_2$ and $NiBr_2(PPh_3)_2$. c) A small quantity of complex was decomposed into black metal.

Dimerization of Ethylene. The dimerization of ethylene was carried out with $NiBr(PPh_3)_3$, as shown in Table 4. Though the addition of methanol accelerated dimerization and isomerization, the activity of $NiBr(PPh_3)_3$ for dimerization was on the whole low. The active species for dimerization needs one more vacant site than that for isomerization. The conversion increased at high temperatures but complexes began to decompose to give black metal. The butene composition remains over 80% unless methanol is added.

Isotopic Mixing between C_2D_4 and C_2H_4 or 1-Pentene. Two mechanisms have been proposed in the isomerization of olefins.[27] The metal hydride addition-elimination mechanism which is most common is operative in catalysis by transition metal hydrides. The second involves oxidative abstraction of C–H of olefins to form a π-allylmetal hydride, or a vinylmetal hydride intermediate.[28] Since the second mechanism involves an intramolecular 1,3-shift of hydrogen, no hydrogen scrambling occurs between olefins.

The exchange of hydrogen between C_2D_4 and C_2H_4 or 1-pentene was carried out to clarify the mechanism. Table 5 indicates: a) isotopic mixing between olefins occurs; b) the formation of metal hydride is less likely from the reaction of metal complexes and solvents; c) none of the ortho-hydrogen of PPh_3 is incorporated into olefins; d) a small amount of hydrogen from something other than olefins is incorporated into olefins. These results suggest that a metal hydride addition-elimination mechanism is operative. In this mechanism the hydride is produced from olefins *via* the reaction involving oxidative addition of an allylic

TABLE 5. ISOTOPIC MIXING BETWEEN C_2D_4 AND C_2H_4 OR 1-PENTENE CATALYZED BY Ni(I) COMPLEXES[a)]

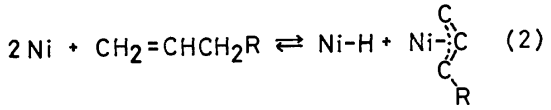
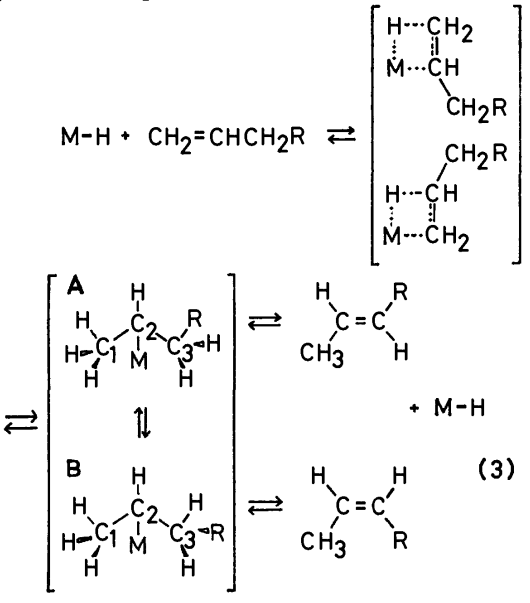
a) Deuteroethylene (C_2D_4 96.9%, C_2D_3H 3.1%) was obtained from E. Merck Co. Reactions were done in 3 ml of THF at 0 °C. b) CD_3OD (0.5 ml) was added. c) $NiBr(PPh_3)_2(P(C_6D_5)_3)$ was used. d) The isotopic distribution of ethylene. e) The isotopic distribution of pentenes (1-pentene 6.1%, *trans*-2-pentene 17.8%, *cis*-2-pentene 76.1%). d_7 0.3%, d_8 0.05%.

C–H bond of olefin to two Ni(I) centers, as D'Aniello and Barefield had confirmed.[5)] Vinylic hydrogen



would be abstracted from ethylene which has no allylic hydrogen. The low activity in the dimerization of ethylene is also attributed to the difficulty in breaking vinylic C–H bonds. The ease of hydrogen release from olefins was related to a decrease in the induction period and an increase in the rate of ethylene dimerization with $PdCl_2(PhCN)_2$.[29)] The absence of induction period in our systems indicates that a nickel hydride forms instantly. The equilibrium of Eq. 2 is responsible for the increase of nickel hydride with the amount of olefin. The opposite result (Fig. 3) suggests the inhibition is caused by the impurities.[26)]

Stereoselectivity. Selective *cis*-isomerization of terminal olefins was observed in base catalysts,[3)] $CoH(N_2)(PPh_3)_3$,[2)] and $NiX(PPh_3)_3$–$SnCl_2$ systems. The stereoselectivity in the base-catalyzed isomerization is explained by the result that the *cis*-allylic anion is thermodynamically more stable than the *trans* form.[3,30)] With a metal hydride catalyst, an olefin inserts into an M–H bond by a concerted reaction path to give σ-alkylmetal complexes:[31)]



When hydrogens bonded to C_3 approach the metal in a cyclic transition state, two structures are considered to have the C_3–R bond eclipsed and *gauche* with the C_2–H bond, as shown in **A** and **B**. The conformation of **A** is thermodynamically more stable than that of **B** for the steric repulsion between C_1 methyl and R groups, so long as the steric interaction between alkyl group and ligands is neglected. The bulkiness of ligands favors the conformation of **B** to give *cis*-2-olefins in the first-period transition metal catalyst systems: the *c*/*t* ratios decrease in the order I>Br>Cl, PPh_3>PPh_2Et>$PPhEt_2$>PEt_3 in the isomerization of 1-butene by $CoX_2(PR_3)_2$– and $NiX_2(PR_3)_2$–$NaBH_4$ systems (X= halogen, $PR_3=PPh_nEt_{3-n}$).[32)] The same trend is observed in the isomerization by $NiX(PPh_3)_3$. However, the opposite trend (Cl>Br>I) which was found in the isomerization of 1-pentene by $PdX_2(PhCN)_2$ was explained in terms of Pd–olefin stability.[33)] In the isomerization of 1-olefins catalyzed by Pt–$SnCl_3$ complexes, *trans*-2-olefins are formed preferentially.[16–19)] The high yield of *trans*-2-pentene was explained in terms of the stability of the eclipsed conformation of 2-pentyl radical coordinated to pseudo-planar platinum complex.[19)] The *cis*-selectivity in the Ni–$SnCl_3$ system is due primarily to the steric bulkiness of the $SnCl_3$ group thrusting away both C_1 methyl and R groups, as shown in **B** (Eq. 3). The bulk of the $SnCl_3$ ligand tends to favor the addition which leads to the sterically less hindered terminal-carbon–Pt complex in the hydroformylation of 1-olefins.[20)]

The π-acceptor ligands require square planar configurations rather than tetrahedral ones for four-coordinated nickel complexes. Since triphenylphosphine is bulky, $NiX(PPh_3)_3$ is forced to be tetrahedral because of steric repulsion between ligands.[9b)] If the active species are PPh_3–dissociated nickel complexes, the activated intermediates with π-acceptor ligands might be different from those with σ-donor ones such as halogen. Another effect of a π-acceptor ligand, $SnCl_3$, is to labilize the alkyl–metal bonds. Facile abstraction of β-hydrogen results in the formation of isomerized olefins before the interconversion of **A**⇌**B** in Eq. 3.

The authors wish to thank Dr. Sadayuki Mori (Institute for Chemical Research, Kyoto University) for obtaining mass spectra and for helpful discussions.

Mechanistic Interpretations of the Dye-sensitized Formation of Hydrogen Peroxide in an Aqueous Solution

Yoshiharu Usui,* Ei-jurou Kobayashi, Akira Kazami, and Shinobu Sakuma
Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo, Mito 310
(Received February 18, 1980)

Kinetic studies of the photosensitized formation of hydrogen peroxide and hyperoxide ions in a mixed aqueous solution of eosine, oxygen, and EDTA have been attempted on the basis of a switch-over of the primary processes, *i.e.*, the so-called DD, DR, and DO mechanisms. The rate constants for reactions of $E^+\cdots E^-$ and $E^+\cdots O_2^-$ intermediates with oxygen and EDTA were obtained. The yield of hydrogen peroxide *via* the DO-initiated mechanism was enhanced as much as one order of magnitude ($\approx$0.012) by the addition of 0.15 mol dm^{-3} of sodium borate or sodium carbonate. The maximum yield, 0.08, of hydrogen peroxide was obtained in an aerated aqueous solution of 1.0×10^{-4} mol dm^{-3} of eosine, 5.0×10^{-2} mol dm^{-3} of EDTA, and 8.8×10^{-2} mol dm^{-3} of sodium borate.

The investigation of the mechanism of a photosensitized oxidation is important from the point of view of photodynamic action, and several reaction mechanisms have been proposed to account for these reactions, as have been reviewed by Grossweiner,[1] Foote,[2,3] Spikes,[4] and one of the present authors.[5] As for the dye-sensitized photooxidation, the relationship between a structure and its susceptibility to photooxidation has recently been investigated by the kinetic treatment of the eosine-sensitized photooxidation of phenylalanine and tyrosine derivatives.[6]

A reaction mechanism involving the triplet state of an organic dye should be altered with the concentrations of the dye, the reductant, and the oxidant. We have previously established that a switch-over of the primary processes can occur in the photochemical reactions of dyes, *i.e.*, the so-called DD, DR, and DO mechanisms.[5,7] The classification of the primary processes for such photoredox reactions is of significance in the interpretation of the mechanism for the dye-sensitized reactions.

On the other hand, if the hyperoxide ion, O_2^-, can be efficiently produced in the course of a photosensitized oxidation in an aerated solution, it will be synthetically useful for the purpose of the specific oxidation of an organic compound by O_2^-.

This paper is an extension of our previous papers.[8,9] Its main purpose is to show we can interpret kinetic behavior in a rather complicated system by taking a switch-over of the primary processes into account. Besides, some suggestions concerning the reaction of the transient intermediates on DD and DO mechanisms will be presented.

Experimental

Materials. Eosine (Merck) (E) was recrystallized twice from ethanol. Disodium dihydrogen ethylenediaminetetraacetate (Dotite-2Na of Wako Junyaku) (EDTA) and Tetranitro Blue Tetrazolium (Sigma Chemical Co.) (TNBT) were used without further purification.

Apparatus and Procedure. To determine the yield of H_2O_2, an irradiation apparatus was set up: ten cylindrical reaction cells (1.5 cm in radius) with an optically flat bottom were placed on a filter plate in a thermostat. The filter, made of a plastic plate, cut off any absorbance below 480 nm and was turned round at 1 rpm above the light source of a daylight fluorescent circleline (10 cm in radius) outside the thermostat set up with the transparent plastic box. The depth of the sample solutions being about 2 cm in the reaction cells, the absorption of light is practically complete in the region of the visible absorption. The quantity of light absorbed by the solutions was 1.3×10^{-9} mol cm^{-3} s^{-1}, which was estimated from the values of the photobleaching rate of eosine in a plain aqueous solution and the quantum yield. The details of the method have been described in previous papers.[8,9] For the H_2O_2-accumulation experiment, air or oxygen gas was bubbled through the solution. The determination of the concentration of H_2O_2 was performed by the spectroscopic method with titanium complexing after the separation of a precipitate of eosine by the addition of sulfuric acid. The concentration of O_2^- was determined by the measurement of the absorbance of the formazan at the wavelength of 560 nm using $\varepsilon_{560}=5.0\times10^4$ mol^{-1} cm^2, when a sample containing a small amount of TNBT was irradiated.

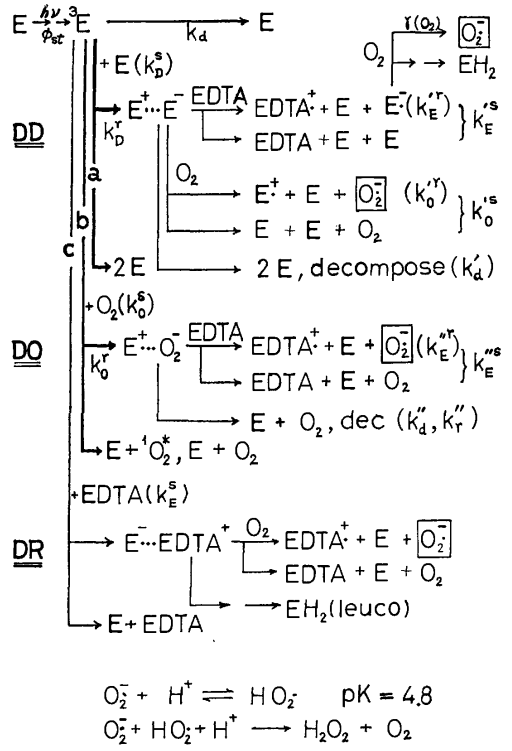
Results and Discussion

A considerable amount of H_2O_2 is really formed for eosine-sensitized photoredox reactions in aerated aqueous solutions containing EDTA. We have already studied the switch-over of the primary processes by means of oxygen-consumption experiments; *i.e.*, as is shown in Fig. 1, the processes of a, b, and c on triplet eosine, which correspond to the DD, DO, and DR mechanisms respectively, are known where the values of k_D^s (4.0×10^8 mol dm^{-3} s^{-1}), k_O^s (1.1×10^9 mol dm^{-3} s^{-1}), and k_E^s (5.0×10^5 mol dm^{-3} s^{-1}) are obtained respectively.[7,8] The consecutive processes can be assumed to be competitive reactions of EDTA and oxygen with the intermediate irrespective of the mechanisms of DD, DO, and DR.

Effect of EDTA and Oxygen Concentrations upon the Yield of H_2O_2 Formation via *the DD-initiated Mechanism* (Φ_h^{DD}). With the concentration of eosine fixed at 2.0×10^{-3} mol dm^{-3}, the effect of the EDTA concentration on the quantum yield of H_2O_2 formation was investigated over the wide range from 0 to 0.10 mol dm^{-3}. Figure 2 shows that Φ_h^{DD} tends to the constant value of the maximum yield ($\approx1.7\times10^{-2}$). See the scheme for DD mechanism shown in Fig. 1 in an air-saturated solution, assuming the relation of $k_D^s[E]\gg k_d$, $k_D^s[O_2]$, and $k_E^s[EDTA]$:

$$\Phi_h^{DD}=\frac{\phi_{st}k_D^r}{2k_D^s}\,\frac{k_O'^r[O_2]+\gamma(O_2)k_E'^r[EDTA]}{k_d'+k_O'^s[O_2]+k_E'^s[EDTA]}. \quad (1)$$

Denoting Φ_h^{DD} at [EDTA]=0 as Φ_0^{DD}, we can obtain



$$O_2^- + H^+ \rightleftharpoons HO_2 \quad pK = 4.8$$
$$O_2^- + HO_2 + H^+ \longrightarrow H_2O_2 + O_2$$

Fig. 1. The reaction scheme for eosine (E) photosensitized formation of hydrogen peroxide.

Eq. 2:

$$\frac{1}{\Phi_h^{DD}-\Phi_0^{DD}} = \frac{1}{\Phi_0^{DD}(\beta-\alpha)}\left(\alpha+\frac{1}{[EDTA]}\right) \qquad (2)$$

where $\alpha=k'^s_E/(k'_d+k'^s_0[O_2])$ and $\beta=k'^r_E\,\gamma(O_2)/k'^r_0[O_2]$. A linear relationship of $1/(\Phi_h^{DD}-\Phi_0^{DD})$ against $1/[EDTA]$ was obtained, as is shown in Fig. 2. This suggests that EDTA reacts with the intermediate, $E^+\cdots E^-$, competitively. From the values of Φ_0^{DD} (4.5×10^{-3}) and the slope and intercept of the line, the α and β values can be estimated. Using the value of $\phi_{st}k_D^r/k_D^s$ (0.112),[10,11] the values of k'^r_0/k'^s_E and $\gamma(O_2)k'^r_E/k'^s_E$ are estimated to be 0.665 and 0.22 respectively.

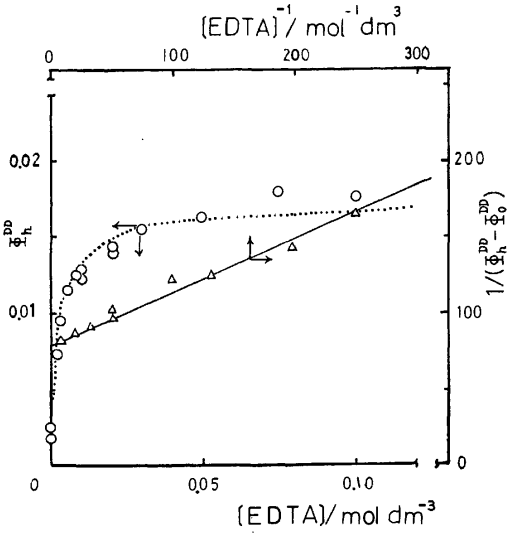


Fig. 2. Effect of EDTA concentration on Φ_h^{DD}(—○—) and the double reciprocal plots (—△—). [E]: 2×10^{-3} mol dm^{-3}, [O_2]: 2.4×10^{-4} mol dm^{-3}, pH=4.9.

At a lower concentration of EDTA (1.0×10^{-4} mol dm^{-3}) the effect of the oxygen concentration on Φ_h^{DD} was investigated under the condition of a DD-initiated mechanism. The results can be analysed by means of Eqs. 3 and 3', which are approximate to Eq. 1 as $k'^r_0[O_2]\gg k'^r_E[EDTA]\gamma(O_2)$ and $(k'_d+k'^s_0[O_2])\gg k'^s_E[EDTA]$. Equation 3 should hold without EDTA:

$$\Phi_h^{DD} \simeq \frac{\phi_{st}k_D^r}{2k_D^s}\,\frac{k'^r_0[O_2]}{k'_d+k'^s_0[O_2]} \qquad (3)$$

$$1/\Phi_h^{DD} = (2k_D^s/\phi_{st}k_D^rk'^r_0)(k'^s_0+k'_d/[O_2]) \qquad (3')$$

Judging from the data shown in Fig. 3, oxygen also reacts with the intermediate, $E^+\cdots E^-$, competitively. The slope and intercept of the linear line in Fig. 3 give the numerical values of $k'^s_0/k_d=2\times10^4$ mol dm^{-3} and $k'^r_0/k'^s_0=0.10$. Therefore, the maximum yield of Φ_h^{DD} *via* the reaction of oxygen with $E^+\cdots E^-$ should be equal to 5.5×10^{-3}, which is about one-third to that (0.017) *via* the reaction of EDTA with $E^+\cdots E^-$. Estimating the k_d value to be 1.8×10^3 s^{-1} from the data previously reported,[12,13] the rate constant for the reaction of

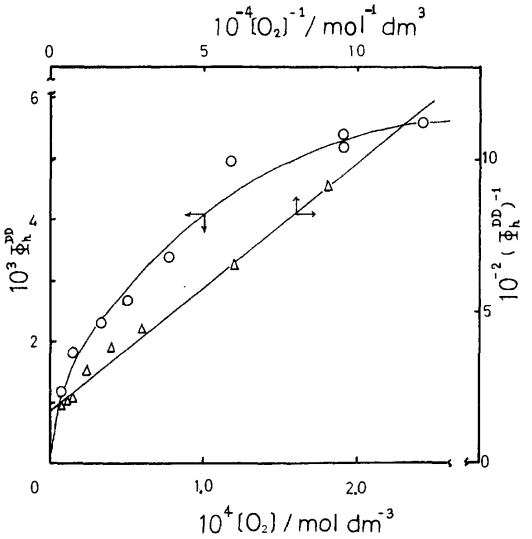

Fig. 3. Effect of oxygen concentration on Φ_h^{DD} (—○—) and the double reciprocal plots (—△—). [E]: 2×10^{-3} mol dm^{-3}, [EDTA]: 1×10^{-4} mol dm^{-3}, pH=4.9.

Table 1. Rate constants of elementary processes for the DD intermediate

Reaction	Rate constant / mol^{-1} dm^3 s^{-1}
$E^+\cdots E^-+EDTA \longrightarrow$ $E+EDTA^+\cdot+E^-$ (k'^r_E)	$\gamma(O_2)k'^r_E=$
$E^-+O_2\longrightarrow E+O_2^-$ ($\gamma(O_2)$)	8.4×10^5
$E^+\cdots E^-+EDTA \longrightarrow$ $2E+EDTA$ / $E+EDTA^+\cdot+E^-$ (k'^s_E)	2.8×10^6
$E^+\cdots E^-+O_2\longrightarrow E^++E+O_2^-$ (k'^r_0)	3.7×10^6
$E^+\cdots E^-+O_2\longrightarrow 2E+O_2$ / $E^++E+O_2^-$ (k'^s_0)	3.7×10^7

EDTA or oxygen with $E^+\cdots E^-$ listed in Table 1 are obtained.

By substituting the experimental values into Eq. 1, one can obtain the following equation:

$$\Phi_h^{DD} = (2.1\times10^5[O_2]+4.7\times10^4[EDTA])/(1.8\times10^3+3.7\times10^7[O_2]+2\ 8\times10^6[EDTA])$$

The calculated values of Φ_h^{DD} are shown with a dotted curve in Fig. 2. By comparing the k_O^s value with that of $k_E^{\prime s}$, it can be seen that oxygen can competitively attack $E^+\cdots E^-$ faster than EDTA by one order of magnitude, resulting in the production of O_2^-, as is shown in Fig. 1.

Effect of EDTA Concentration upon the Yield of H_2O_2 *Formation via DO-initiated Mechanism* (Φ_h^{DO}). When the DO-initiated mechanism is operative, Eq. 4 can be derived from the scheme in Fig. 1:

$$\Phi_h^{DO} = \phi_{st}\frac{k_O^r}{k_O^s}\frac{k_E^{\prime\prime r}[EDTA]}{k_d^{\prime\prime}+k_r^{\prime\prime}+k_E^{\prime\prime s}[EDTA]} \quad (4)$$

A linear relationship of $1/\Phi_h^{DO}$ against 1/[EDTA] was obtained by taking account of the EDTA concentration effect. The result indicates that the DO-initiated mechanism shown in Fig. 1 is operative and that the reaction of EDTA with the intermediate, $E^+\cdots O_2^-$, to produce the O_2^- ion may occur in competition with the deactivation and decomposition. Inserting the ϕ_{st} value (0.64) into the intercept of the line in Fig. 4, we obtain $k_O^r k_E^{\prime\prime r}/k_O^s k_E^{\prime\prime s}\simeq 6.2\times10^{-3}$, which leads to the inequality of $k_O^r/k_O^s \leqq 0.11$ and $0.056 \leqq k_E^{\prime\prime r}/k_E^{\prime\prime s} \leqq 1$, since the probability of singlet oxygen formation by the reaction of triplet eosine with oxygen equals 0.89.[14] The value of $(k_d^{\prime\prime}+k_r^{\prime\prime})/k_E^{\prime\prime s}$ is also obtained as 2.4 $(\pm0.3)\times10^{-3}$ mol dm^{-3} from the intercept and slope in Fig. 4. Using the numerical value of 7.0×10^5 for $k_E^{\prime\prime s}$, we obtain 1.7×10^3 s^{-1} for $(k_d^{\prime\prime}+k_r^{\prime\prime})$, which coinsides with the value of 1.2×10^3 s^{-1} for the decay constant of $E^+\cdots O_2^-$ previously reported in the experiment by means of flash photolysis.[7,9]

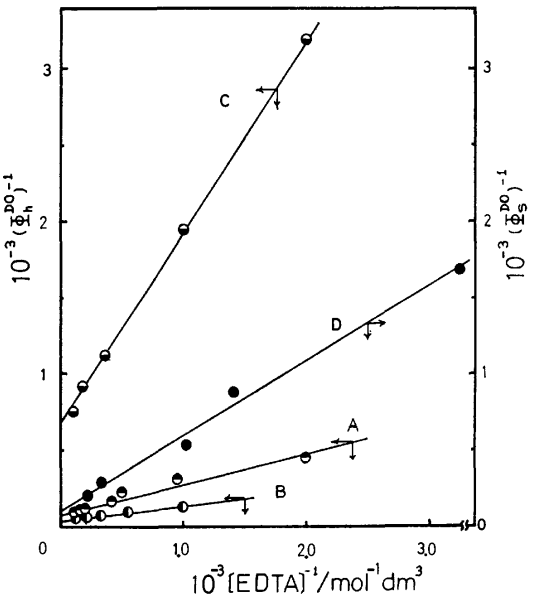

Fig. 4. Plots of $1/\Phi_h^{DO}$ (or $1/\Phi_s^{DO}$) against 1/[EDTA] for the EDTA concentration effect on Φ_h^{DO} (or Φ_s^{DO}) in 2×10^{-2} mol dm^{-3} borate buffer solution (A), 1.5×10^{-1} mol dm^{-3} borate buffer solution (B), 1×10^{-2} mol dm^{-3} acetate buffer solution (C), and 1×10^{-2} mol dm^{-3} phosphate buffer solution (D). [E]: 2×10^{-5} mol dm^{-3} and [O_2]: 2.4×10^{-4} mol dm^{-3}.

In the course of H_2O_2 production, singlet oxygen is formed simultaneously by the energy transfer between triplet eosine and oxygen. Since the yield of H_2O_2 was scarcely affected by the addition of the singlet oxygen quencher (NaN_3, 7.0×10^{-3} mol dm^{-3}), it can be said that singlet oxygen is not directly concerned in the mechanism of H_2O_2 production.

H_2O_2 Formation via the DR-initiated Mechanism. With the concentrations of eosine, oxygen, and EDTA fixed under condition when the DR mechanism is operative, the yields of H_2O_2 formation (Φ_h^{DR}) and of eosine reduction were measured. The value of Φ_h^{DR} is equal to 0.057 in the concentrations of 0.2 mol dm^{-3} of EDTA, 5.0×10^{-5} mol dm^{-3} of oxygen, and 5.0×10^{-5} mol dm^{-3} of eosine. However, the photoreduction of eosine takes place at the same time, and H_2O_2 decomposes rather rapidly after it is produced. When the deaerated solution containing 5.0×10^{-5} mol dm^{-3} of eosine, 5.0×10^{-4} mol dm^{-3} of H_2O_2, and 0.2 mol dm^{-3} of EDTA was irradiated, H_2O_2 was decomposed in the initial stage of the photoreduction of the dye. Although further investigations will be needed in order to treat Φ_h^{DR} kinetically, it may be supposed that the eosine semiquinone produced *via* the DR-initiated mechanism reacts with H_2O_2, leading to its decomposition.

Influence of Inorganic Salts on Φ_h^{DO} *via the DO-initiated Mechanism.* It was observed that the formation of H_2O_2 *via* the DO-initiated mechanism was enhanced by the addition of some inorganic salts. This effect is confirmed in the case of the DO-initiated mechanism, but not in the DD mechanism. As is shown in Table 2, the increment in the Φ_h^{DO} value was as high as one order of magnitude with 0.15 mol dm^{-3} of sodium borate or 0.16 mol dm^{-3} of sodium carbonate.

Using Eq. 4 we can analyse the effect of EDTA concentration on Φ_h^{DO} similarly and see that the DO-initiated mechanism in Fig. 1 is still operative. From the results of the kinetic analysis shown in Fig. 4, A and B, it can be seen that the value of $\phi_{st}k_O^r k_E^{\prime\prime r}/k_O^s k_E^{\prime\prime s}$ in

Table 2. Inorganic salt effect on Φ_h^{DO}

Added compound $\left(\frac{\text{concentration}}{\text{mol dm}^{-3}}\right)$	pH	Φ_h^{DO}
None	9.5	1.1×10^{-3}
$Na_2B_4O_7$ (0.15)	9.2	12×10^{-3}
Na_2CO_3 (0.16)	10.3	10×10^{-3}
Na_2SiO_3 (0.10)	11.4	5.0×10^{-3}
$Na_2P_2O_7$ (0.10)	9.9	4.5×10^{-3}
$(NH_4)_2SO_4$ (0.10)	8.5	3.4×10^{-3}
Na_2SO_4 (0.10)	8.6	2.7×10^{-3}
NaCl (0.10)	9.2	2.2×10^{-3}
CH_3COONa (0.10)	9.6	2.2×10^{-3}
Na_2HPO_4 (0.10)	7.6	2.0×10^{-3}

[E]$=5.0\times10^{-5}$ mol dm^{-3}, [EDTA]$=3.0\times10^{-3}$ mol dm^{-3}, [O_2]$=2.4\times10^{-4}$ mol dm^{-3}.

the presence of sodium borate is greater than that without the salt. For the solution to which sodium borate has been added, the yields of the triplet eosine and the semioxidized radical were checked by a flash photolysis experiment. Since no influence of the salt on these yields was observed, it may be supposed that the values of ϕ_{st} and k_0^r/k_0^s with sodium borate are equal to those without the salt. By comparing the two values of $\phi_{st}k_0^r k_E''^r/k_0^s k_E''^s$, we learn that the values of $k_E''^r/k_E''^s$ with sodium borate are seven times (at 10 °C) and twenty-five times (at 25 °C) greater than those without sodium borate. The results are shown in Table 3. The effect of the addition of sodium borate may be attributed to the enhancement of the reaction probability between $E^+\cdots O_2^-$ and EDTA.

Temperature Effect on Φ_h^{DO}. Figure 5 shows the H_2O_2 formation curves of the DO-initiated mechanism at several temperatures. The initial yield of H_2O_2 generally increases with an increase in the temperature. The Arrhenius plots for the overall rate constant, k, in the H_2O_2 formation processes, *i.e.*, $\Delta[H_2O_2]/\Delta t=kt$, give similar activation energies both in the mixed solutions of 5.0×10^{-5} mol dm^{-3} eosine, 8.0×10^{-1} mol dm^{-3} sodium borate, and 6.0×10^{-3} mol dm^{-3} EDTA ($\approx$12 kcal deg, pH=9.4), and in 5.0×10^{-5} mol dm^{-3} eosine, 1.0×10^{-2} mol dm^{-3} acetate buffer, and 6.0×10^{-3} mol dm^{-3} EDTA ($\approx$17 kcal deg, pH=5.1). With an increase in the temperature, the reaction probability, $k_0^r k_E''^r/k_0^s k_E''^s$ for $E^+\cdots O_2^-$, increases as is listed in Table 3. However, at higher temperatures ($T\gtrsim30$ °C), H_2O_2 formation curves give maximum values during irradiation and then fall, as is shown in Fig. 5. By a vacuum distillation of the irradiated solution containing the borate ion (pH=8.0), H_2O_2 was not distilled out completely; however, the residual H_2O_2 was quantitatively distilled as a result of the neutralization by the addition of hydrochloric acid. This suggests that a nonvolatile compound such as a peroxo salt of $[B_2(O_2)_2(OH)_4]^{2-}$ might be formed during the irradiation and partially dissociated.[15] It was confirmed that the peroxo compound is unstable in an aqueous solution and rapidly decomposes at temperatures higher than 20 °C. There is no maximum value in the formation curves without the borate ion even at 40 °C within the present observation time; rather, the curves rise straight. Therefore, the decomposition of H_2O_2 is negligible in this system. It may be suggested that O_2^- (or H_2O_2) makes the peroxo compound with borate ions and then decomposes at higher temperatures ($T\gtrsim20$ °C).

Supplementally, we checked the pH dependency on Φ_h. The values of Φ_h^{DO} were not practically affected by the pH in the region of pH=5—10, but those of Φ_h^{DP} became relatively small at pH$\lesssim$7.

EDTA Concentration Effect on the Yield of O_2^- *Ion Formation* (Φ_s^{DO}). Using TNBT (16 μmol dm^{-3}) as the radical trap for O_2^-, the values of Φ_s^{DO} were determined by measuring the optical absorption of the formazan at the wavelength of 560 nm.[16] Since the relationship of the $\Phi_s^{DO}/2=\Phi_h^{DO}$ is always obtained in the systems without sodium borate, it may be supposed that the disproportionation reaction between O_2^- ions occurs quantitatively in an alkaline solution. From the results of the EDTA-concentration effect on Φ_s^{DO}, a linear relationship of $1/\Phi_s^{DO}$ against 1/[EDTA] was obtained; the values of $k_0^r k_E''^r/k_0^s k_E''^s$ and $k_E''^r/(k_d''+k_r'')$ agree with those obtained from the same analytical treatment

Table 3. Rate constants of elementary processes for the DO intermediate

Conditions (pH)	T/°C	$k_0^r k_E''^r/k_0^s k_E^s$	$k_E''^s/(k_r''+k_d'')$
A) 2×10^{-2} mol dm^{-3} Borate buffer (9.2)	10	4.4×10^{-2}	3.0×10^{-2}
B) 1.5×10^{-1} mol dm^{-3} Borate buffer (9.2)	25	1.56×10^{-1}	9.0×10^{-3}
C) 1.0×10^{-2} mol dm^{-3} Acetate buffer (4.9)	25	6.2×10^{-3}	4.1×10^{-2}
D) 1.0×10^{-2} mol dm^{-3} Phosphate buffer (8.9)	25	6.0×10^{-3}	4.2×10^{-2}

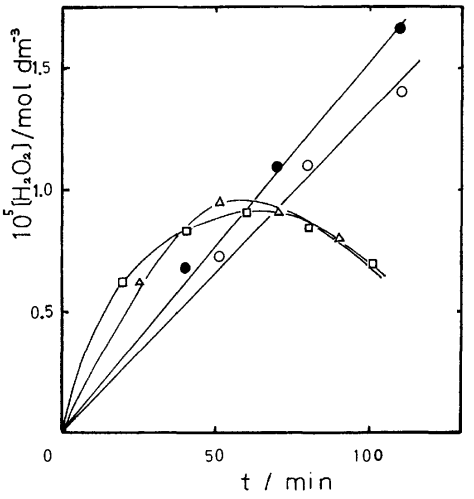

Fig. 5. H_2O_2 formation curves at several temperatures on DO started mechanism. [E]: 5×10^{-5} mol dm^{-3}, [EDTA]: 6×10^{-3} mol dm^{-3}, [O_2]: 2.4×10^{-4} mol dm^{-3}, and [$Na_2B_4O_7$]: 8×10^{-2} mol dm^{-3}. T=10 °C (—○—), 30 °C (—△—), 40 °C (—□— and —●— without $Na_2B_4O_7$).

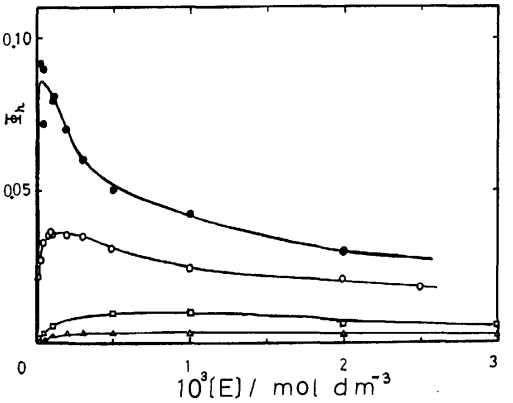

Fig. 6. Effect of eosine concentration on Φ_h in aerated aqueous solution. [EDTA]: 1×10^{-1} mol dm^{-3} (—○—), 3×10^{-3} mol dm^{-3} (—□—), and 0 mol dm^{-3} (—△—) without $Na_2B_4O_7$ (pH=4.9). [EDTA]: 5×10^{-2} mol dm^{-3} (—●—) with 8.8×10^{-2} mol dm^{-3} $Na_2B_4O_7$ (pH=7.8).

as that used for Φ_h^{po} (*cf.* Fig. 4. and Table 3, D and C). These results support the idea that the H_2O_2 formation from the O_2^- ion is exclusively due to the disproportionation between O_2^- ions in this system and that the contribution of the reaction of TNBT with the triplet eosine to make the formazan is negligible at low concentrations of 16 μmol dm^{-3}.

However, as for the addition effect of the borate ion on Φ_s^{po}, no significant increasing effect on Φ_s^{po} was observed in the system with EDTA. Under the DO mechanism in the solution without EDTA, no free O_2^- is liberated from $E^+\cdots O_2^-$; absolutely no H_2O_2 was detected.[17] In spite of such results, the formazan was still formed upon the irradiation of a sample without EDTA. It is considered that TNBT might react with $E^+\cdots O_2^-$. Furthermore, the yield of the formazan was increased by the addition of the borate ion. In the case of EDTA addition, if the borate ion could stabilize the free O_2^- liberated by the following reaction:

$$EDTA + E^+ \cdots O_2^- \longrightarrow EDTA + E + O_2^-$$

the enhancement of Φ_s^{po} by the borate ion would also be observed. Assuming that the borate ion stabilizes the O_2^- radical, which exists in an intermediate including EDTA in the above reaction, and that, in preference to the stabilization by the borate ion, TNBT reacts with O_2^- in the intermediate, no enhancement effect by the borate ion may appear. Further investigations of the reasons will be needed in the future.

Eosine Concentration Effect on Φ_h and the Accumulation Experiment of H_2O_2. In order to ascertain the conditions for the highest yield of H_2O_2 formation, Φ_h was measured at various concentrations of eosine and EDTA with or without the borate ion. As is shown in Fig. 6, the maximum yield of 0.04 (Φ_h^{max}) is obtained under the conditions of [E]: $1—2\times10^{-4}$ mol dm^{-3}, $[O_2]$: 2.4×10^{-4} mol dm^{-3}, and [EDTA]: 0.1 mol dm^{-3} without the borate ion. Further, the value of Φ_h^{max} is close to 0.08—0.10 under the conditions of [E]: 1.0×10^{-4} mol dm^{-3}, $[O_2]$: 2.4×10^{-3} mol dm^{-3}, and [EDTA]: 0.05 mol dm^{-4} with 0.088 mol dm^{-3} of the borate ion, where the maximum concentration of H_2O_2 is $\approx6\times10^{-3}$ mol dm^{-3}. Since is H_2O_2 decomposed by a catalytic reaction, the reversible fixation of gaseous oxygen was performed photochemically in the presence of EDTA, *i.e.*,

$$O_2 + 2\,EDTA + 2H^+ \xrightarrow{h\nu/\text{sensitizer}} H_2O_2 + 2\,EDTA^+$$
$$\xrightarrow{\text{catalysis}} (1/2)H_2O + (1/2)O_2.$$

This reaction leads to the consumption of EDTA.

The authors would like to express their thanks to Professor Hiroshi Kokubun of the Department of Chemistry in Tohoku University for his kind permission to use the flash photolysis apparatus. We also wish to thank to Miss Setsuko Kodera for her assistance.

Nuclear Quadrupole Resonance of $AlBr_3$ Molecular Complexes

Tsutomu Okuda,* Hiroshi Ohta, Hideta Ishihara, Koji Yamada, and Hisao Negita

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received February 18, 1980)

We observed the ^{81}Br NQR of several molecular complexes of $AlBr_3$ with amines such as $(CH_3)_3N$, C_5H_5N, $C_6H_5NH_2$, and $(C_6H_5)_2NH$. All the ^{81}Br resonance lines were found in the frequency range of 78—86 MHz at room temperature except for $AlBr_3 \cdot 2C_5H_5N$. From the Zeeman analysis, it was proved that $AlBr_3 \cdot 2C_5H_5N$ should be expressed with the molecular formula $2AlBr_3 \cdot 4C_5H_5N$ and contains cation species $AlBr_2(C_5H_5N)_4^+$ with two ^{81}Br resonance lines near 70 MHz and anion species $AlBr_4^-$ with four ^{81}Br resonance lines near 80 MHz. The two ^{81}Br resonance lines of $AlBr_3 \cdot (CH_3)_3N$ disappeared at about 40 °C due to hindered rotation of the whole molecule. The lower two ^{81}Br resonance lines of $AlBr_2(C_5H_5N)_4^+$ have positive temperature coefficients.

Aluminum tribromide is a Lewis acid and forms a number of molecular complexes with organic bases. The mechanism of complex formation is assumed to be mainly due to the interaction between the lone pair of the donor atom and the vacant sp^3 hybrid orbital of the Al atom.

NQR has been widely used for the study of these complexes of the $n\sigma$ type. Some NQR frequencies have been reported for molecular complexes of the type $AlBr_3 \cdot L$ (L=ethers, ketones, and pyridine).[1,2] However, no NQR result has been reported for the molecular complexes of the type $AlBr_3 \cdot 2L$.

In this investigation, we prepared several molecular complexes of $AlBr_3$ with amines and observed the ^{81}Br NQR spectra in order to examine the character of Al–Br bonds and the molecular structure.

Experimental

The complexes of $AlBr_3 \cdot (CH_3)_3N$ and $AlBr_3 \cdot 2(CH_3)_3N$ were prepared by the procedure described in the literature.[3,4] The others were obtained by melting the stoichiometric amounts of $AlBr_3$ and L (L=C_5H_5N, $C_6H_5NH_2$, and $(C_6H_5)_2$-NH) in closed glass ampoules. The single crystals of $AlBr_3 \cdot C_6H_5NH_2$ and $AlBr_3 \cdot 2C_5H_5N$ were grown by the method described previously.[5] The spectrometer used in the present experiment was a super-regenerative oscillator, and the absorption lines were observed on an oscilloscope. The Zeeman effect was examined by means of the zero-splitting cone method in a weak magnetic field of about 250 G provided by a Helmholtz coil. The temperature dependences of NQR frequencies were measured in the temperature range from liquid nitrogen temperature to the melting point. The temperature of the sample was determined using a copper-constantan thermocouple.

Results and Discussion

Table 1 shows ^{81}Br NQR frequencies and the signal-to-noise ratios in several molecular complexes of $AlBr_3$ with amines, determined at room temperature.

$AlBr_3 \cdot (CH_3)_3N$ and $AlBr_3 \cdot 2(CH_3)_3N$. $AlBr_3 \cdot (CH_3)_3N$ shows two ^{81}Br resonance lines with the intensity ratio of about 1:2. Though the crystal structure of this complex has not been determined as yet, $AlCl_3 \cdot (CH_3)_3N$ has been shown to have an ethane-like structure containing an Al–N bond, by means of X-ray diffraction.[6] The molecular structure of the bromide seems to be similar to that of the chloride in the light of the NQR results.

Table 1. ^{81}Br NQR frequencies in $AlBr_3$ molecular complexes at room temperature

Compounds		ν (MHz)	S/N
$AlBr_3 \cdot (CH_3)_3N$		79.108	4
		80.471	9
$AlBr_3 \cdot 2(CH_3)_3N$		83.168	4.5
		84.290	2.5
$AlBr_3 \cdot C_5H_5N$		79.575	7
		80.565	5
		81.424	7
$AlBr_3 \cdot 2C_5H_5N$	A	69.875	5.5
	B	69.955	5
	C	79.589	5
	D	79.667	5
	E	81.328	4.5
	F	81.331	4.5
$AlBr_3 \cdot C_6H_5NH_2$	A	79.194	3
	B	79.899	3.5
	C	84.853	4
$AlBr_3 \cdot (C_6H_5)_2NH$		78.497	4
		85.380	4.5
		85.511	4.5
Al_2Br_6[a]		79.84	(bridge)
		92.45	(terminal)
		93.61	(terminal)

a) T. Okuda *et al.*, *J. Chem. Phys.*, **52**, 5489 (1970).

The temperature dependences of ^{81}Br NQR frequencies were observed. Each resonance line began to broaden at about 30 °C and was no longer observable at about 40 °C, which is much below its melting point 156.9 °C. This disappearance is probably due to the hindered rotation of the whole molecule in the same manner as $BCl_3 \cdot (CH_3)_3N$ and $BBr_3 \cdot (CH_3)_3N$.[7,8] In the slope of the resonance frequency *versus* temperature curve we could not observe any abnormality which would be due to the reorientation of a methyl group or the rotation of a trimethylammonio group.[7]

Two ^{81}Br resonance lines were observed for $AlBr_3 \cdot 2(CH_3)_3N$. Their resonance frequencies are considerably higher than those of $AlBr_3 \cdot (CH_3)_3N$. Beattie *et al.* suggested from the study of the Raman spectra that the central Al atom in $AlBr_3 \cdot 2(CH_3)_3N$ is coordinated trigonal-bipyramidally, having two N atoms at axial sites and three Br atoms at equatorial sites.[4] This configuration about the Al atom is supported from the

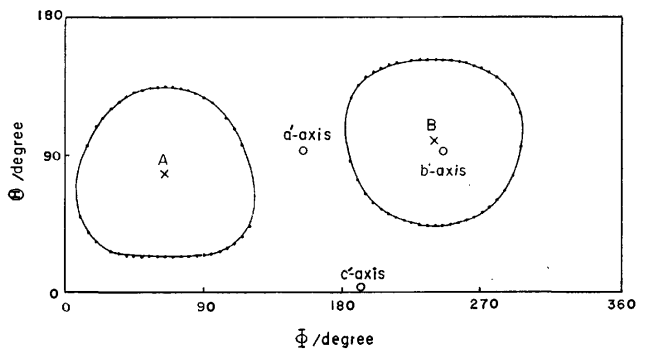

Fig. 1a. Zero-splitting patterns of ^{81}Br Zeeman lines of $AlBr_2(C_5H_5N)_4^+$ ion in $AlBr_3 \cdot 2C_5H_5N$.

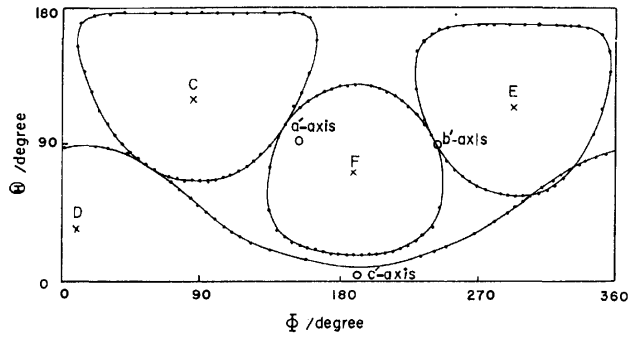

Fig. 1b. Zero-splitting patterns of ^{81}Br Zeeman lines of $AlBr_4^-$ ion in $AlBr_3 \cdot 2C_5H_5N$.

present results, because the difference in resonance frequencies is small.

$AlBr_3 \cdot C_5H_5N$ and $AlBr_3 \cdot 2C_5H_5N$. As listed in Table 1, three and six ^{81}Br resonance lines were observed in $AlBr_3 \cdot C_5H_5N$ and $AlBr_3 \cdot 2C_5H_5N$, respectively. Let us label the six resonance lines A, B, ···, F, from the lower to the higher, and label the Br atoms contributing to A, B, ···, F, Br(A), Br(B), ···, Br(F). It is found that two resonance lines, A and B, are remarkably lower than the rest. The Zeeman effect on ^{81}Br resonance lines in $AlBr_3 \cdot 2C_5H_5N$ was measured using a single crystal. Zero-splitting patterns are shown in Figs. 1a and 1b. Although four zero-splitting patterns were obtained for each resonance line, these figures show only one set of them which corresponds to a molecule in order to avoid unnecessary complexity. As all the asymmetry parameters are within ten percent, as listed in Table 2, no bridging Br atom is commonly assumed

TABLE 2. ^{81}Br NQR PARAMETERS IN $AlBr_3$ MOLECULAR COMPLEXES AT ROOM TEMPERATURE

Compounds	η (%)	e^2Qq/h(MHz)

∠Br(D)–Al–Br(F)	113.6
∠Br(E)–Al–Br(F)	108.0

to exist in this complex, and the center of the zero-splitting pattern, *i.e.*, the direction of the z-principal axis of the electric field gradient, is regarded as the direction of Al–Br bond. Angles between Al–Br bonds were thus obtained from these patterns. The crystallographic axes were not determined from the Zeeman effect alone because of the higher class of crystal symmetry, though the axes corresponding to them were obtained from the symmetry of the zero-splitting pattern. For convenience, the axes obtained from NQR are arbitrarily termed the a'-, b'-, and c'-axis; these are perpendicular to each other. Angles between these axes and Al–Br bonds are tabulated in Table 3. The Al–Br(A) bond is perpendicular to the a'-axis and exists in the b'c' plane. Bond angles, ∠Br–Al–Br, are liested in Table 4. On the basis of the results obtained, the directions of Al–Br bonds in $AlBr_3 \cdot 2C_5H_5N$ are shown in Fig. 2. Br(A) and Br(B), whose ^{81}Br NQR

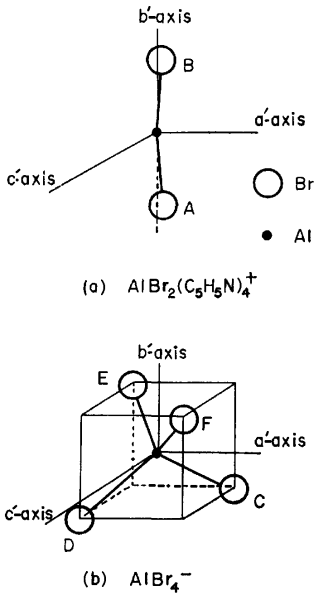

Fig. 2. Directions of Al–Br bonds with respect to the a'-, b'-, and c'-axis in $AlBr_3 \cdot 2C_5H_5N$.

frequencies are much lower than the rest, are at the axial sites and four pyridines are at the equatorial sites, near the a'c' plane, because of the well-known stableness of a six-coordinated Al atom. Br(C), Br(D), Br(E), and Br(F) are considered to belong to $AlBr_4^-$. Therefore, $AlBr_3 \cdot 2C_5H_5N$ is expressed with the molecular formula $2AlBr_3 \cdot 4C_5H_5N$ and contains cation species $AlBr_2(C_5H_5N)_4^+$ and anion species $AlBr_4^-$.

Recently, an X-ray study by Howard *et al.* revealed that the crystal of $AlCl_3 \cdot 2CH_3CN$ contains discrete $AlCl(CH_3CN)_5^{2+}$ and $AlCl_4^-$ ions together with one uncoordinated CH_3CN molecule per asymmetry unit.[9] Schmulbach reported from the phase study of $AlCl_3$–CH_3CN system that $AlCl_3 \cdot CH_3CN$ melts at 183.4 °C but $AlCl_3 \cdot 2CH_3CN$ melts incongruently at 74.2 °C.[10] The extraordinarily low melting point of the latter may be due to the solvation. On the other hand, the phase study of $AlBr_3$–C_5H_5N system showed that $AlBr_3 \cdot C_5H_5N$ and $AlBr_3 \cdot 2C_5H_5N$ melt congruently at 116.0 °C and 183.4—185.1 °C, respectively.[11] The tendency to melt in the 1 : 1 and 1 : 2 complexes is different between $AlCl_3$–CH_3CN and $AlBr_3$–C_5H_5N systems. This seems to arise from the difference in ionic structure of the 1 : 2 complex between the two systems.

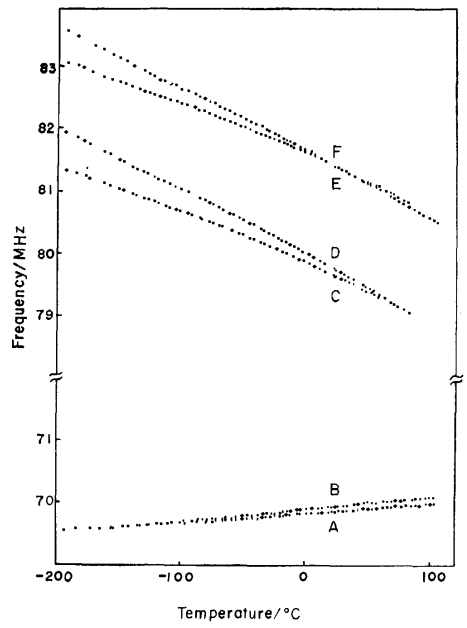

Fig. 3. Temperature dependences of ^{81}Br NQR frequencies in $AlBr_3 \cdot 2C_5H_5N$.

The temperature dependence of ^{81}Br NQR frequencies in $AlBr_3 \cdot 2C_5H_5N$ is shown in Fig. 3. In general, NQR frequencies decrease with increasing temperature as the electric field gradient of the resonant nuclei is averaged by the exciting of molecular motions. In this case, resonance frequencies corresponding to Br(A) and Br(B) increase with increasing temperature, while those of the rest decrease. Various compounds showing a positive temperature dependence have been found and the abnormality has been explained in terms of π-bonding or hydrogen bonding.[12,13] In the present case, a hydrogen bond does not occur because pyridine is not a proton donor but a proton acceptor.[14] We attributed the present positive temperature coefficient to a weak $p\pi$–$d\pi$ bond between aluminum and bromine atoms. This is probably due to π-back donation from the $4p_x$ and $4p_y$ orbitals of the bromine atom to the vacant 3d orbital of six-coordinated aluminum atom; the resonance frequency of the bromine atom thus decreases. However, this effect is cancelled with increasing temperature because the thermal vibration breakes the π-bond. Accordingly, the frequency increases with temperature will result from the stronger effect of the latter.

$AlBr_3 \cdot C_6H_5NH_2$ and $AlBr_3 \cdot (C_6H_5)_2NH$. Three resonance lines (designated as A, B, and C) were observed in $AlBr_3 \cdot C_6H_5NH_2$. There is a large difference in the frequency between the higher and the lower resonance lines. Since resonance lines were weak, we observed only a few zero-splitting patterns whose z-principal axes formed large angles to the rf coil axis. Asymmetry parameters and quadrupole coupling constants obtained are listed in Table 2. The asymmetry parameters of Br(A) and Br(B) are rather large, whereas that of Br(C) is small. This seems to be due to the difference in intermolecular interaction.

In contrast to $AlBr_3 \cdot C_6H_5NH_2$, two ^{81}Br resonance lines were observed in the high region and one line in the low region for $AlBr_3 \cdot (C_6H_5)_2NH$. This discrepancy between the two complexes may arise from a difference in intermolecular interaction or from a dimer formation like $2AlBr_3 \cdot C_6H_6$ because of a large steric effect of the ligand. The crystal structure determination is very desirable in order to discuss this problem in more detail.

Complexes between Nucleotide Base and Amino Acid. IV. Crystal and Molecular Structure of Cytosine : *N,N*-Phthaloyl-DL-glutamic Acid Complex Dihydrate

Akio TAKENAKA,* Minoru OHKI, and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received February 19, 1980)

Crystals of cytosine: *N,N*-phthaloyl-DL-glutamic acid complex dihydrate were obtained from an aqueous solution of the two components. The space group is $P2_1/c$ with unit-cell dimensions of $a=5.243(1)$, $b=39.133(6)$, $c=9.192(1)$ Å, $\beta=93.66(1)°$, and $Z=4$. The structure was solved by the direct method and its parameters were refined by a block-diagonal least-squares method. The complex is formed by the two hydrogen bonds between the oxygen atoms of the ionized α-carboxyl group of glutamic acid and the nitrogen atoms, N(4) and protonated N(3), of cytosine. This binding mode is the same as that found in cytidine: *N*-benzyloxycarbonyl-L-glutamic acid complex, but quite different from that of 5-bromocytosine: *N*-acylglutamic acid complexes. The substituted bromine atom at C(5) of cytosine is thought to prescribe the binding mode in complex formation. The binding mode between cytosine and glutamic acid, which might be a possible elementary pattern of protein: nucleic acid interactions, is discussed in terms of dissociation constant.

In the studies of the elementary interaction patterns between amino acid and purine-pyrimidine base, we have found that *N*-tosyl-L-glutamic acid and *N,N*-phthaloyl-DL-glutamic acid are hydrogen-bonded to 5-bromocytosine with their γ-carboxyl group,[1,2] while Hata, Yoshikawa, Sato, and Tamura reported that in cytidine: *N*-benzyloxycarbonyl-L-glutamic acid complex dihydrate, cytosine base binds to α-carboxyl group of the amino acid.[3] It is interesting to examine what causes such different mode of cytosine: glutamic acid interactions. An X-ray analysis of the crystal structure of cytosine: *N,N*-phthaloyl-DL-glutamic acid complex has been performed, whose structure has revealed the effect of bromine atom on the complex formation.

Experimental and Structure Determination

Single crystals suitable for X-ray studies were obtained by slow evaporation of an aqueous solution containing equimolar amounts (0.2 mmol) of cytosine and *N,N*-phthaloyl-DL-glutamic acid, both of which were purchased from Tokyo Kasei Kogyo Co. The complex formation was confirmed by a preliminary X-ray experiment, an elemental analysis and IR spectrum of these crystals. Found: C, 48.0; H, 4.62; N, 13.2%. Calcd for $C_4H_5N_3O \cdot C_{13}H_{11}NO_6 \cdot 2H_2O$: C, 48.1; H, 4.75; N, 13.2%. Density was measured by the flotation method. Weissenberg photographs showed the systematic absences, $h0l$ for $l=2n+1$ and $0k0$ for $k=2n+1$, indicating the space group to be $P2_1/c$. A crystal $0.8\times0.8\times0.9$ mm was used for data collection on a Rigaku four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). The unit-cell dimensions were calculated with 41 high-angle reflexions. The crystal data are given in Table 1.

TABLE 1. CRYSTAL DATA

Cytosine: *N,N*-Phthaloyl-DL-glutamic Acid Dihydrate	
$C_4H_5N_3O: C_{13}H_{11}NO_6: 2H_2O$	
Space group : $P2_1/c$	
$a=5.243(1)$ Å	$U=1882.2(4)$ Å^3
$b=39.133(6)$	$Z=4$
$c=9.192(1)$	$D_x=1.497$ g cm^{-3}
$\beta=93.66(1)°$	$D_m=1.49_7$

Intensities were measured in the ω scan mode with a scan width of 1° (in ω) plus α_1-α_2 divergence and a scan speed of 4° (in 2θ) min^{-1}. Five reference reflexions showed no significant intensity deterioration throughout the data collection. The intensities were corrected for Lorentz and polarization factors but not for absorption effects. Of 4306 independent reflexions in the range $2<2\theta<55°$, 1090 weak reflexions below background were considered as zero-reflexions; the observed threshold value, F_{11m}, was 2.55. The standard deviations were estimated by the equation of $\sigma^2(F_o)=\sigma_P^2(F_o)+qF_o^2$, where $\sigma_P(F_o)$ is evaluated by counting statistics and q (3.39×10^{-5}) was derived from the variations of the monitored reflexions.[4]

The structure was solved by the direct method and its parameters were refined by block-diagonal least-squares techniques. All the hydrogen atoms, found on a difference map, were included. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, with $w=1/\sigma^2(F_o)$. The zero-reflexions, for which $|F_c|>F_{11m}$, were included in the least-squares calculation by assuming $F_o=F_{11m}$ and $w=w(F_{11m})$. The final R was 0.55 for 2949 reflexions with $F_o>3\sigma(F_o)$; the maximum shift of parameters in the last cycle was 0.03σ for C, 0.45σ for H, 0.07σ for N, and 0.17σ for O atoms. Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[5]

Atomic parameters are listed in Table 2, observed and calculated structure factors in Table 3.[6] Figure 1 shows a stereoscopic view of the cytosine: *N,N*-phthaloyl-DL-glutamic acid complex dihydrate. Bond distances and angles are shown in Fig. 2 together with the atomic numbering system. Bond angles involving hydrogen atoms are given in Table 4, least-squares planes together with deviations of atoms in Table 5, and hydrogen bond distances and angles in Table 6.

Results and Discussion

Molecular Structure. *N,N*-Phthaloyl-DL-glutamic acid is dissociated at the α-carboxyl group but not at the γ-carboxyl group, as confirmed by a difference synthesis. The bond distances and angles of the α- and γ-carboxyl groups are typical as those of the ionized and neutral carboxyl groups, respectively. The two identical C–O lengths of the α-carboxyl group suggest that the negative charges are equally localized on the two oxygen atoms.

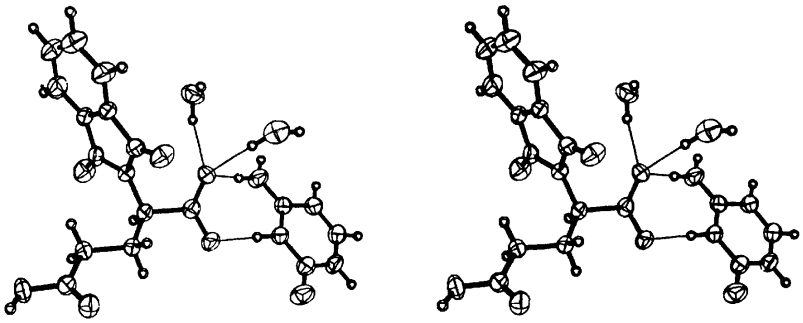

Fig. 1. Stereoview of the cytosine: *N,N*-phthaloyl-DL-glutamic acid complex dihydrate with 50% probability ellipsoids for the non-hydrogen atoms.

TABLE 2. FINAL POSITIONAL AND THERMAL PARAMETERS OF CYTOSINE: *N,N*-PHTHALOYL-DL-GLUTAMIC ACID COMPLEX DIHYDRATE

Standard deviations are given in parentheses. The anisotropic thermal factors has the form $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$.

The phthalimido group is almost planar, though the deviations of atoms from the mean plane indicate the slight bending of the group along its long axis (see Table 3). The N(5) and C(8) atoms also lie on this plane, suggesting an sp^2 hybridization of N(5). The bond distances and angles of the phthaloyl group are in good agreement with those in 5-bromocytosine: *N,N*-phthaloyl-DL-glutamic acid complex[2] and in the other related compounds.[7]

The torsion angles of the glutamic acid are shown in Fig. 3. The γ-carboxyl group has a synplanar C–C–C=O conformation as a common feature of carboxylic acids.[8] The extended conformation of the C–C chain is different from the folded form found in 5-bromocytosine: *N,N*-phthaloyl-DL-glutamic acid complex, where the C(9)–C(10) bond is in gauche conformation.[2] The conformation of the phthaloyl group is similar to that in 5-bromocytosine: *N,N*-phthaloyl-DL-glutamic acid.[2]

The hydrogen atom released from the α-carboxyl group is transferred to N(3) of cytosine molecule. As compared with the neutral cytosines, the protonation gives rise to a change of cytosine geometry similar to that discussed in cytosine: *N*-formylglycine complex.[9] Figure 4 compares the bond distances of cytosinium cations found in different environments. In cytosine: *N*-formylglycine complex (a), the positive and negative charges are mainly localized on the N(3) atom of

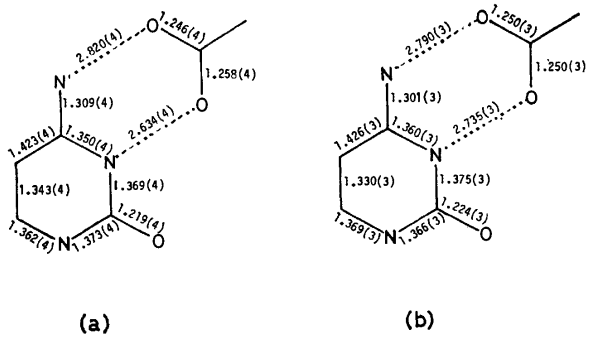

Fig. 4. A comparison of bond distances between (a) cytosine: *N*-formylglycine complex and (b) the present complex, cytosine: *N,N*-phthaloyl-DL-glutamic acid.

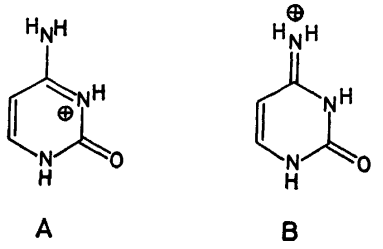
cytosine and its hydrogen-bonded oxygen atom of carboxyl group, respectively, and in consequence their distance becomes considerably shorter than that of N(4)···O. In the present complex (b), however, the two C–O distances of α-carboxyl group are identical and in addition these two oxygen atoms are hydrogen-bonded to N(3) and N(4) of cytosine at almost the same distances. In such a situation, the cytosinium cation is perturbed, so that the contribution from the canonical formula B increases, as compared with (a) in which the canonical formula A is predominant.



Slight differences in bond lengths seem to be consistent with this interpretation. Similar trend is also observed in cytidine: salicylic acid complex.[10]

The planarity of the present cytosine is excellent; only the N(4) atom deviates slightly from the mean plane (Table 5).

Crystal Structure. As shown in Figs. 1 and 5, the complex is formed by the two hydrogen bonds between the oxygen atoms of the dissociated α-carboxyl group of glutamic acid and the nitrogen atoms, N(4) and protonated N(3), of cytosine. This double hydrogen-bonded system is the same as that found in cytidine: *N*-benzyloxycarbonyl-L-glutamic acid complex.[3] The two N···O distances, N(3)···O(3) and N(4)···O(4), are nearly equal to each other, although the planar α-carboxyl group makes an angle of 35.3(7)° with the cytosine plane. This feature of the system is contrary to that of the above complex.[3]

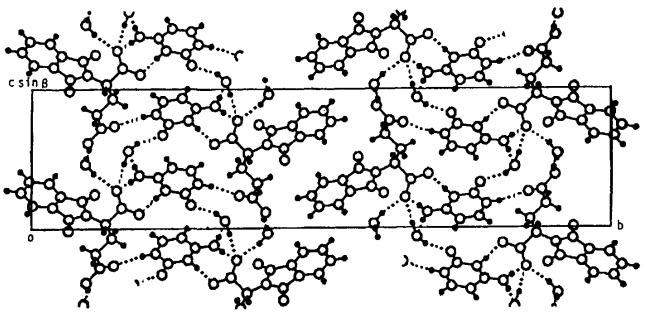


Fig. 5. Crystal structure of the cytosine: *N,N*-phthaloyl-DL-glutamic acid dihydrate, projected along the c axis.

The O(3) atom is also an acceptor of hydrogen bonds with the two water molecules. The O(W2) atom donates its hydrogen atom to O(2) of neighbouring cytosine and at the same time, accepts from N(4) of another cytosine. The γ-carboxyl group forms two hydrogen bonds; O(5) is a donor for O(W1) and O(6) is an acceptor from N(1) of adjacent cytosine. One of the two hydrogen atoms of water O(W1) is free from hydrogen bonding but directed to O(5) at $x,y,1+z$ with the O(W1)–H(W1B)···O(5) angle of 175(3)° and the distances, 3.306(2) Å for O(W1)···O(5) and 2.53(3) Å for H(W1B)···O(5).

The cytosine molecules are arranged parallel to one another on the c-glide plane. On the other hand, the phthaloyl groups come together around the inversion centres and packed parallel to form a sheet.

Complex Formation. In the present cytosine: *N,N*-phthaloyl-DL-glutamic acid complex and cytidine: *N*-benzyloxycarbonyl-L-glutamic acid complex,[3] the

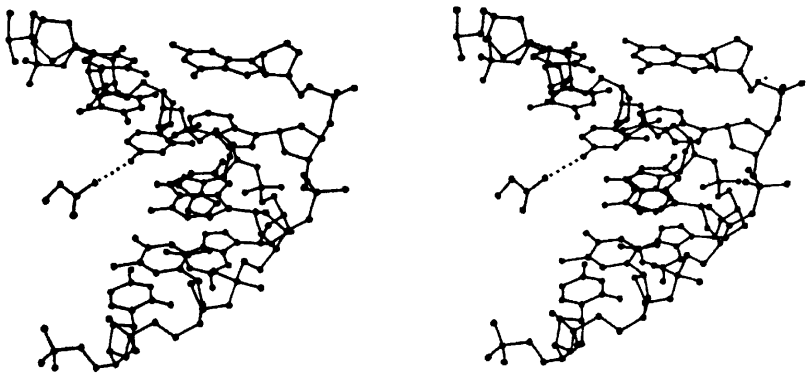

Fig. 7. A fitting feature between acidic side group of protein and cytosine moiety paired with guanine residue in the major groove of a double helical DNA (conformation B), in Type II mode.

binding modes are the same one (hereafter we designate Type I, see Fig. 6(a)) inspite of the different substitutions of glutamic acid and of cytosine, and the different crystal packings. On the other hand, the complexes with 5-bromocytosine are formed in the different mode (hereafter Type II, see Fig. 6(b)) for the two different acyl groups of the amino acids.[1,2] Consequently, it seems that the bromine atom at C(5) of cytosine determines the binding mode. The geometrical change of cytosine skeleton, which is caused by the steric and electronic effects of bromination at C(5), can be related to their dissociation constants in solution.[11] Accordingly, the complex formation modes may be interpreted in terms of pK_a values.

Table 7 lists the dissociation constants of cytosine, its derivatives and some *N*-acylamino acids. The pK_a values of *N*-acylglycines are almost invariant for different acyl groups. So, it is reasonable to assume pK_a^I and pK_a^{II} values of *N*-acylglutamic acids to be close to those of *N*-benzoylglutamic acid. Accordingly, the pK_a value of the α-carboxyl group of *N*-acylglutamic acids may be lower than that of cytosine or cytidine. In a solution containing *N*-acylglutamic acid and cytosine or cytidine, the latter molecule is easily protonated by the amino acid and both interact with each other in the Type I binding mode. On the other hand, the pK_a value of 5-bromocytosine is even less than that of the α-carboxyl group of *N*-acylglutamic acid. Therefore, 5-bromocytosine molecule could scarcely take a proton from *N*-acylglutamic acid. Consequently, the α-carboxyl groups are associated to form a dimer or tetramer[2] in the crystal, whereas 5-bromocytosine molecules are coupled with each other by the two N(4)–H···N(3) hydrogen bonds, the amino group of which are hydrogen-bonded to the γ-carboxyl group.[1,2]

Protein: Nucleic Acid Interaction. In the previous paper, we have proposed that the two binding modes, Type I and Type II, are elementary patterns of protein: nucleic acid interactions.[1,2] The pK_a values of proteins at the C terminal and at the acidic side groups respectively might be near pK_a^I of glycylglycine or glycylalanine and pK_a^{II} of *N*-acylglutamic acid. On the other hand, in nucleic acid cytosine bases would have a pK_a close to that of cytidine 5′-phosphate (CMP),

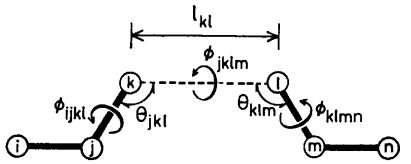

Fig. 8. Definition of the binding parameters in Table 8.

which is a value between those of carboxyl groups in proteins mentioned above. Therefore, the above discussion in terms of pK_a is also applicable and supports our previous proposal that the Type I is a binding pattern, *e.g.* between the unpaired cytosine in CCA terminus of tRNA and the C-terminal carboxyl group in enzyme, and the Type II is an elementary pattern of interaction between paired cytosine and acidic side group of amino acid residue.

To examine the above-mentioned argument, we have attempted to fit the binding geometry of Type II into a major groove of a double helical DNA (conformation B) using an interactive modelling programme[15] with computer graphics; atomic coordinates were taken from the works of Arnott and Hukins.[16] Trials show that the major groove† of B-DNA is not so wide for binding

† The major groove of B-DNA has been suggested to be a binding site from its surface accessibility[17] and from its methylation reactions.[18]

of carboxyl group to cytosine residue, due to their directional properties of hydrogen bondings. Base sequences also restrict the region. Interacting feature free from any steric hindrance, shown in Fig. 7, was constructed with small adjustment of torsional angles or bond angles. The binding data used are given in Table 8, parameters of which are defined in Fig. 8. The hydrogen bonding patterns described in the present series, together with those in adenine: indole,[19] adenine: carboxyl group,[20] and adenine: amide group[21] systems, will be useful for understanding the protein: nucleic acid interactions.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education and by the Kawakami Foundation, to which the authors' thanks are due.

Thermal Decomposition of Graphite Fluoride. I. Decomposition Products of Graphite Fluoride, $(CF)_n$ in a Vacuum

Nobuatsu WATANABE,* Satoshi KOYAMA, and Hiroki IMOTO**

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received February 22, 1980)

The mechanism of thermal decomposition of graphite fluoride, $(CF)_n$ in a vacuum was studied by means of chemical and gas analyses, and the measurement of crystallinity. The crystallinity of $(CF)_n$ was slightly improved in the step of initial decomposition. The fluorine/carbon atomic ratio of initial gaseous product evolved by decomposition was about 2. The product is CF_2 or C_2F_4, and then it gives several compounds by secondary reaction. Every second layers of $(CF)_n$ are decomposed, and the evolved molecules or radicals abstract fluorine atoms which are bonded to the neighboring two layers.

Graphite fluoride $(CF)_n$ is obtained by the direct reaction of elemental fluorine with graphite or other carbon materials, and its atomic ratio F/C is unity.[1] Its crystal structure is shown in Fig. 1. Graphite fluoride retains the layer structure of graphite, but the layer has a zig-zag form because of the formation of C–F bond. The network of carbon atoms is therefore covered with fluorine atoms. Furthermore, the spacing between neighboring two layers is expanded from that of graphite, 3.35 Å to a larger value between 5.8 and 8.9 Å. Carbon atoms which are placed at the edge site of the layer are connected with two or three fluorine atoms.[2] However, the product actually formed is considerably strained,[3] and has a turbostratic structure.[4]

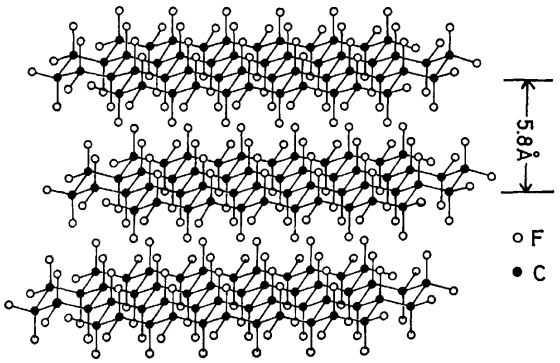

Fig. 1. Crystal structure of $(CF)_n$.
○: Fluorine atom, ●: carbon atom.

Thermal decomposition of graphite fluoride in a vacuum can be represented by:[5]

$$(CF)_n \longrightarrow \text{amorphous carbon} + C_2F_6 + CF_4 + C_3F_8 + C_2F_4 + \text{other perfluorocarbons.} \quad (1)$$

The rate of thermal decomposition is expressed by Avrami-Erofeyev's equation:

$$-\ln(1-\alpha) = (kt)^n, \quad (2)$$

where α is the fraction decomposed, k is the rate constant and n is the dimension of the nucleus growth. Kamarchik and Margrave[6] reported that n was 2 in Eq. 2. This result suggests that the decomposition proceeds two-dimensionally around an active site or a nucleus, and the reaction is auto-catalytic. However, they have not postulated a detailed mechanism for the decomposition.

In this work, the elemental and gas analyses were made in order to reveal the mechanism of the decomposition of $(CF)_n$ in a vacuum. The crystallinity of partially decomposed $(CF)_n$ was also measured.

Experimental

Powdery natural graphite whose grain size was 46—62 μm and flaky natural graphite whose grain size was 279—840 μm were fluorinated with elemental fluorine at 600 °C for 11 h for the former (sample I) and 24 h for the latter (sample II). Samles I and II thus obtained were used as the starting material for decomposition study. Interlayer spacings of samples I and II were 6.00 Å and 5.84 Å, and the F/C ratios were 0.94 and 0.93, respectively. The grain size of $(CF)_n$ is almost the same as that before fluorination.

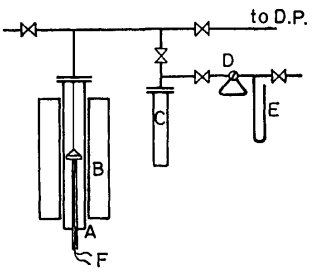

Fig. 2. Schematic diagram of apparatus for thermal decomposition.
A: Reaction tube, B: furnace, C: cold trap, D: gas sampler for gas chromatography, E: Hg manometer, F: thermocouple.

An apparatus made of Monel metal as shown in Fig. 2 was used for gas analysis. The gaseous products evolved by the decomposition were collected in a cold trap kept in liquid N_2. After the decomposition, the trapped gases were evaporated, and the total gas pressure was measured by Hg manometer. The gases were then introduced into a gas sampler, sepa rated and determined by means of gas chromatography. The identification was made by IR spectroscopy.

In another experiment, the sample was partially decomposed at 586 °C, and the residual substances were examined by X-ray diffraction and elemental analysis. The fluorine content was determined by a fluoride ion electrode after all fluorine atoms in $(CF)_n$ were allowed to form hydrogen fluoride by the oxygen flask combustion method.

** Present address: Research Laboratories of Osaka Soda Co., Ltd., Ohtakasu-cho, Amagasaki 660.

Results and Discussion

Change in Crystallinity of Graphite Fluoride and Carbon during Decomposition Process. The sample I was partially decomposed at 586 °C in a vacuum. The X-ray diffraction patterns were taken for residual substances.

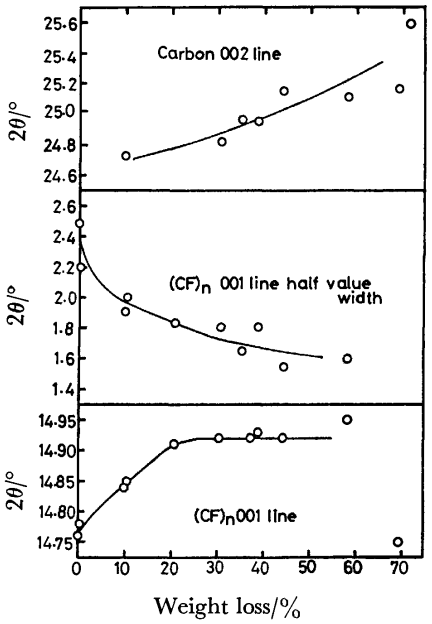

Fig. 3. Change in the crystallinity of graphite fluoride $(CF)_n$ and carbon formed during decomposition. Sample I was used.

Figure 3 shows the change in the position of the 002 line of carbon formed by decomposition, and the position and the half width of the 001 line of $(CF)_n$ during decomposition. The 002 line of carbon shifts to higher angle as the decomposition proceeds. The crystallinity of carbon is improved as the decomposition proceeds. The half width of 001 line of $(CF)_n$ becomes narrower and the position of the line profile shifts to higher angle, namely, the crystallinity of $(CF)_n$ is improved by decomposition, and the shift continues until the weight loss reaches to 20%. From the results, the decomposition is initiated at a strained region distributed in $(CF)_n$ crystal. In this region, a high stress is applied and the interlayer spacing of $(CF)_n$ tends to expand.[3] The strained region is perfectly decomposed within 20% weight loss.

The Composition Change of Graphite Fluoride. Figure 4 shows the composition change of $(CF)_n$ during decomposition at 586 °C. The plot from experiment shows a good agreement with the curve calculated under the assumption that the F/C ratio of gaseous products is 2. Therefore, the initial gaseous product is supposed to be C_2F_4 or CF_2. To confirm this, the decomposition of sample I was carried out in two different apparatus made of either pyrex glass or Monel metal shown in Fig. 2. Figure 5 shows the IR spectra of all gaseous compound by the decomposition. In the former apparatus, the absorption band of SiF_4 was more intense than that of other fluorocarbons (for example, 1250

cm^{-1} for C_2F_6), and the absorption band of CO_2 was observed at 2300 cm^{-1}. They are the reaction products with glass at high temperature. However, Atkinson and Atkinson reported that C_2F_4 did not react with glass below 700 °C.[7] Therefore, the main gaseous product should be an active substance such as CF_2, beside C_2F_4.

Analysis of Gaseous Products. Reaction conditions and the amounts of each gas evolved by decomposition of 100 mg of $(CF)_n$ are shown in Table 1. C_2F_6, C_3F_8, and other saturated fluorocarbons were observed in addition to C_2F_4. They would be produced by the secondary reaction of C_2F_4 or CF_2. It is noteworthy that the amounts of unsaturated fluorocarbons, C_2F_4 and C_3F_6, formed in the experiment without trapping the gas during the reaction (run 6) are small compared with those formed in the experiment with trapping them (run 4). Moreover, the amounts of CF_4 and C_2F_6 are

a) Without trapping the gases during the decomposition.

almost the same in both runs 4 and 6. From the result, it is clear that C_2F_4 and C_3F_6 do not form CF_4 or C_2F_6 but such compounds which have higher molecular weight. In fact, Atkinson and Atkinson[7] have reported that C_2F_4 cannot be decomposed into CF_4 at temperatures below 700 °C. Therefore, thermal decomposition of $(CF)_n$ should be expressed by the following equation,

$$2(CF)_n \longrightarrow nC^* + XCF_2 + YC_2F_4, \quad (X+2Y=n) \quad (3)$$

where C* is amorphous carbon. Kamarchik and Margrave[6] have concluded that the initial gaseous product in the decomposition of $(CF)_n$ is only C_2F_4, and that it changes to various gaseous products by secondary reactions. Their conclusion is inconsistent with the present results and those obtained by Atkinson and Atkinson.[7]

Other Products. In the decomposition of $(CF)_n$, a tarry product[8] and carbon have been found on the wall of the reaction tube in addition to the gaseous compounds. C_2F_4 or CF_2[9] formed by the initial reaction reacts with each other on the wall of apparatus or in the gas phase to form the tarry product, carbon deposit and perfluorocarbons of low molecular weight.

Process of Thermal Decomposition of Graphite Fluoride. Since the F/C ratio of gaseous compounds formed by thermal decomposition of $(CF)_n$ is 2, the remaining carbon atoms in $(CF)_n$ must be formed as perfectly amorphous carbon, and its crystallinity will never be improved even if the decomposition proceeds. However, the X-ray diffraction pattern of the residual carbon shows the improvement of the crystallinity, and moreover, the residual carbon obtained by complete decomposition has almost the same shape as that before decomposition. From these facts, every layer of $(CF)_n$ does not necessarily decompose, namely, C–C bonds in every second layer of $(CF)_n$ are ruptured by decomposition to form radicals, which abstract fluorine atoms bonded to the neighboring two layers to form CF_2 or C_2F_4 as shown in Fig. 6A.

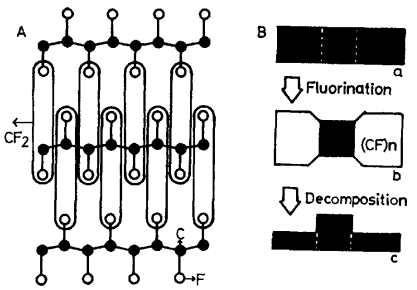

Fig. 6. Schematic illustration of thermal decomposition of graphite fluoride $(CF)_n$ (A) and thermal decomposition of partially fluorinated graphite (B).
a: Original graphite, b: partially fluorinated graphite, c: residual carbon after perfect decomposition.

Kamarchik and Margrave proposed the following mechanism as the thermal decomposition of $(CF)_n$. Fluorine atoms migrate from the interior of the particle to the edge, from which C_2F_4 is released.[6] According to their suggestion, the area of layer plane of residual carbon should become a half that of undecomposed one, and the thickness in the direction of c-axis should be the same as that of original graphite.

To confirm this, the change of the shape in the decomposition of flaky $(CF)_n$ having unreacted graphite in the sample[10] was observed by a microscope. The shape of the sample (Fig. 7) after decomposition was almost the same as that of the original one. The decomposed $(CF)_n$ region becomes thinner than the unreacted graphite. This process is shown by Fig. 6B. The mechanism of thermal decomposition of $(CF)_n$ postu-

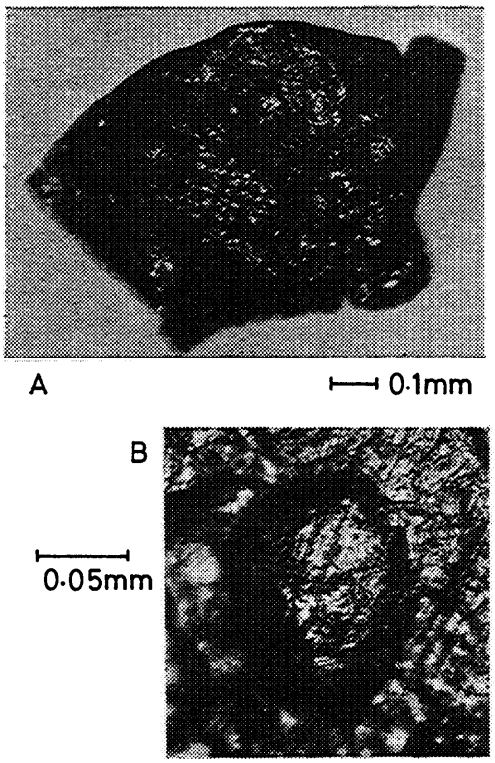

Fig. 7. Residual carbon formed from graphite fluoride having unreacted graphite.
A part of A is enlarged and shown in B.

lated by Kamarchik and Margrave cannot explain this phenomenon.

This reaction is similar to the mechanism of the decomposition of other graphite intercalation compounds.[11] In the case of thermal decomposition of $(CF)_n$, every second layers can be regarded as intercalants and the other layers as graphite layers. After releasing the intercalants, the interlayer spacing of the residual graphite decreases to that of original graphite. Owing to the decomposition of $(CF)_n$, the thickness of the particle in the direction of c-axis decreases to a half that of the original graphite. On the other hand, since the layer of unbonded carbon atoms with fluorine in $(CF)_n$ does not take part in decomposition, it maintains the original thickness.

The authors wish to express their thanks to Dr. Matae Iwasaki and Dr. Haruka Shinohara, Japan Atomic Energy Research Institute, for helpful advice.

Intrinsic Quantum Efficiencies of Semiconductor Photoelectrodes Obtained by Temperature Measurement

Akira FUJISHIMA,* Yasuhisa MAEDA, and Kenichi HONDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 20, 1980)

Quantum efficiencies of photoelectrochemical reactions on n-type and p-type semiconductor electrodes can easily be determined by the measurement of temperature changes of the surface of semiconductor electrodes by use of thermistors. The quantum efficiencies are intrinsic, since only the absorbed light quanta contribute to temperature change. The merits of the method, simplicity and applicability to the semiconductor of large surface reflectance, are discussed. The intrinsic quantum efficiencies were compared with those obtained by the usual chemical actinometric method.

Photothermal spectroscopy (PTS), a new spectroscopic method, has recently been developed.[1] A thermistor is placed on or close to a sample, and the temperature changes *i.e.*, thermistor resistance changes are measured during the course of irradiation of the sample with monochromatic light. It was found that the temperature change caused by light absorption is in line with the results of optical absorption spectroscopy. The method is applicable to cases in which samples are metal and semiconductor electrodes.[2-4]

A number of photoelectrochemical cells with use of semiconductor electrodes have been reported for the photodecomposition of water and the conversion of solar energy into electricity.[5-10] The energy conversion efficiencies and quantum efficiencies of electrochemical photocells are important for effective utilization of solar energy. Thermal measurements of semiconductor electrodes during the course of electrolysis facilitate the determination of the efficiencies.[4]

During the course of photoelectrochemical reaction only a portion of the light energy absorbed by the semiconductor can be utilized in the electrode reaction.[11] The remaining portion of energy is exhausted as heat. Thus, the efficiency of the process can be studied by monitoring temperature changes at the photoelectrodes as a function of electrode potential. In a previous paper, experimental results obtained by using CdS and TiO_2 single crystal photoanodes were presented, interpretation being given by means of a model for the energy balance within the system. The quantum efficiency and power efficiency could be determined without calibration of the irradiation source. The equation was derived by considering the energy balance within a semiconductor photoelectrode.[4] Let us consider the case in which the semiconductor electrode is illuminated with a monochromatic light pulse having an energy E (eV/photon), with an average absorbed intensity I (photon/s) for time t (s). The incoming energy (EIt) can then either be consumed by the semiconductor to promote the electrode reaction with the production of electric work (Vit) or evolved as heat in the semiconductor ($Q_{s.c.}$) *via* recombination and radiationless processes.

Thus the final equation for the overall photoelectrochemical reaction in the limiting photocurrent region is

$$E\frac{\Delta T}{\Delta T^\circ} = \frac{Q_{s.c.}+T\Delta S}{It} + e\eta_q(V-V_{fb}), \qquad (1)$$

where

ΔT: temperature change of the semiconductor surface
ΔT°: temperature change of the semiconductor surface in the open circuit
ΔS: entropy change for the semiconductor electrode reaction
$Q_{s.c.}$: heat evolved in the semiconductor *via* recombination and radiationless processes
$\eta_q\left(=\frac{i}{I}\right)$: quantum efficiency of photo-electrode reaction
V: applied potential (V *vs.* reference electrode)
V_{fb}: flatband potential (V *vs.* reference electrode).

Thus under constant illumination conditions (constant EIt) the plot $E\frac{\Delta T}{\Delta T^\circ}$ *vs.* $(V-V_{fb})$ gives the quantum efficiency, η_q, from the slope of the straight line and the loss term, $\frac{Q_{s.c.}+T\Delta S}{It}$, is obtained from the intercept of the $E\frac{\Delta T}{\Delta T^\circ}$ axis at $V=V_{fb}$ as shown in Fig. 1.

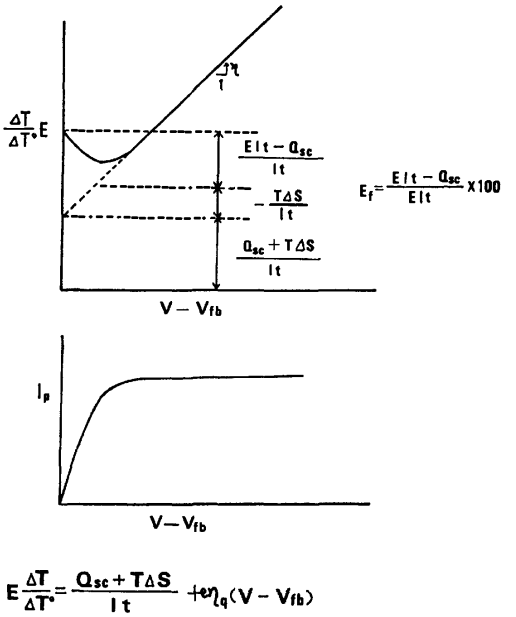

Fig. 1. Theoretical behavior of the temperature change *versus* potential.

From the loss term $\frac{Q_{s.c.}+T\Delta S}{It}$ the energy conversion efficiency

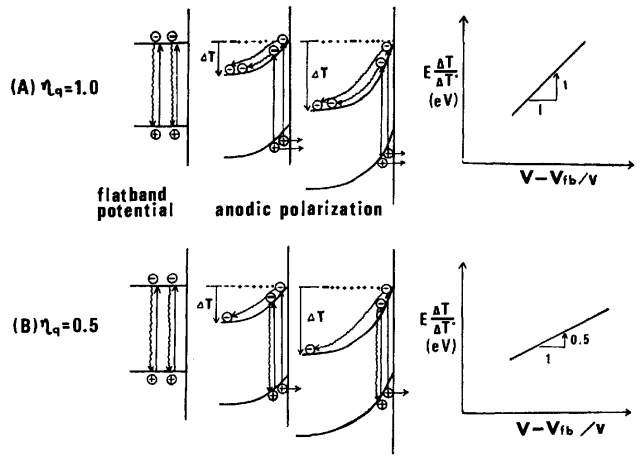

Fig. 2. Relationship between the temperature change and the applied potential in two model cases ((A), (B)). (A): Quantum efficiency is 1.0, (B): quantum efficiency is 0.5.

$$\eta_e = \frac{EIt - Q_{s.c.}}{EIt} \qquad (2)$$

can be easily obtained by making appropriate correction for the entropy change $T\Delta S$ associated with the electrode reaction.

In order to illustrate the use of Eq. 1 for obtaining quantum efficiency, two model cases are given (Fig. 2). When $\eta_q=1.0$, the slope of $E\frac{\Delta T}{\Delta T^\circ}$ against V should be 1.0, since all the electrons excited into the conduction band by light irradiation move from the surface into the bulk of the semiconductor through the space charge layer giving rise to heat generation. When $\eta_q=0.5$, the slope should be 0.5, since half of the excited electrons are recombined with the holes in the surface region.

Determination of the quantum efficiencies of various photoelectrodes [semiconductors of n-type (CdS, CdSe, GaP, GaAs, ZnO, TiO_2, and MoS_2), and p-type (GaP and GaAs)] can easily be carried out by direct measurement of temperature changes in the semiconductor electrodes.

Experimental

Procedure. The photothermal experiment on the photoelectrodes made of single crystals or polycrystals of n-CdS, n-CdSe, n-GaP, n-GaAs, n-TiO_2, n-ZnO, n-MoS_2, p-GaP, and p-GaAs (Table 1) was carried out according to the method reported.[4] Results are given for monochromatic irradiation at wavelengths shorter than that corresponding to the band gap energy (*e.g.* 340 nm for CdS). Photothermal responses were obtained for the photoelectrodes during anodic (n-type semiconductor) or cathodic (p-type) polarization, and under open circuit conditions in the electrolyte solutions. The corresponding current and temperature changes were then plotted as a function of potential *vs.* flatband potential or applied potential.

Apparatus. A block diagram of the apparatus is shown in Fig. 3. The light source employed was a 500 W high pressure mercury lamp (Ushio Electric) in an Ushio Model UI-501C lamp house. A lens to focus the light beam, interference filters (Koshin Kogaku) to select the wavelength of the exciting light, and a shutter with two timers (Ishikawa Seisakusho) to fix the irradiation period precisely were used.

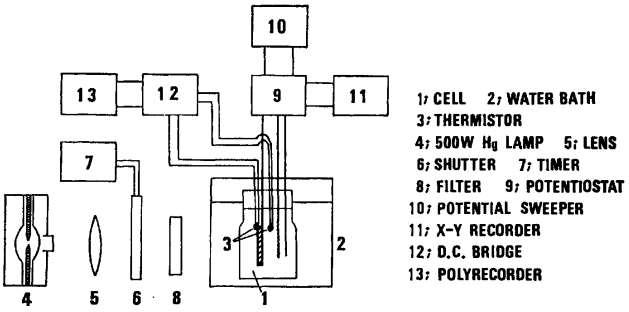

Fig 3. Measurement assembly.

The current-potential and current-time curves were measured under potentiostatic conditions with a potentiostat and a potential programmer (Nikko Keisoku, Models NPGS-301 and NPS-2). Cyclic voltammograms and current-time curves were displayed on an X-Y recorder (Yokokawa, Type 3078).

Characteristics of the semiconductor electrodes are given in Table 1. After ohmic contact, a copper wire was attached to the contact with conducting silver epoxy (Seisin Shoji, No. 4922). The back and sides of the crystal were insulated and mounted on a flat piece of glass attached to a glass rod with epoxy resin (Cemedain).

In order to measure the temperature changes, we used matched pairs of thermistors (Shibaura Electronics, Model BSB4-41A; nominal resistance 4 K Ω, sensitivity 0.052 °C/Ω). The thermistors having a time constant 0.4 s when immersed in still water were used in a differential arrangement with one held against the front surface of the semiconductor electrode and the other placed behind the electrode but not touching it. The cell was placed so that the monochromatic light beam struck only the electrode and none of the thermistors. Thus a change in temperature of the electrode caused a resistive change in the thermistor, producing a voltage imbalance in the DC bridge. The small voltage was amplified and then displayed on a strip chart recorder (Toa Electronics, Model EPR-2T).

The monochromatic light intensity was measured accurately in order to know the usual quantum efficiencies of the photoelectrodes using a chemical actinometric method (potassium ferrioxalate).[12]

All chemicals were of reagent grade and used without further purification. Where necessary, prepurified nitrogen gas was bubbled through the solution in order to remove dissolved oxygen.

Results and Discussion

CdS-Na_2SO_3 System. $E\frac{\Delta T}{\Delta T^\circ}$ was plotted against $(V-V_{fb})$ for an illuminated CdS single crystal electrode in a sodium sulfite aqueous solution in accordance with Eq. 1, where illumination conditions are constant [I: constant, E: 340 nm (3.6 eV), t: 20 s] (Fig. 4).

From the intercept of the y axis obtained by extrapolating the linear portion of the curve to the flatband potential, the energy conversion efficiency of the photoelectrode can be calculated if the heat evolved in terms of an entropy change ($T\Delta S$) attributable to the electrode reaction is obtained.[13] Though the heat

($T\Delta S$) accompanied by oxidation of sulfite ions is exothermic, the correction value for the heat ($T\Delta S$) has the opposite sign as compared with the case of oxidation of $K_4Fe(CN)_6$.[4] Energy conversion efficiencies of various kinds of semiconductor photoelectrodes obtained by the photothermal measurement were reported.[14]

A straight line with a slope equal to 1.0 can be observed in the limiting photocurrent region (Fig. 4), indicating that the quantum efficiency of the oxidation of sulfite ions on the illuminated CdS single crystal electrode is unity as shown in Fig. 2.[4]

The results were obtained under the conditions where each parameter, E, I, t, is constant. The effects of various parameters on the quantum efficiencies (slopes) were checked at first, using the CdS–Na_2SO_3 and ZnO–Na_2SO_4 system.

Effect of Exciting Wavelengths. On usual semiconductor photoelectrodes, the quantum efficiencies are almost the same in the wavelength region shorter than that corresponding to the band gap energy.

Figure 5 shows the results of the effect of exciting wavelengths on the slope using the CdS–Na_2SO_3, where t and I are constant. The wavelengths of monochromatic light irradiated were 340, 400, and 490 nm. When 340 nm was used to excite the CdS electrode, the temperature increase measured at open circuit corresponded to $E=3.6$ eV. Three parallel straight lines were observed. Use of the shortest wavelength light gave a line located in the highest position, indicating that electrons excited into the conduction band move through radiationless processes to the bottom of the conduction band, giving rise to an increase in $Q_{s.c.}$. The fact that the slope was 1.0 in all cases indicates that quantum efficiency was 1.0 at all three wavelengths. Thus we could use light of any wavelength

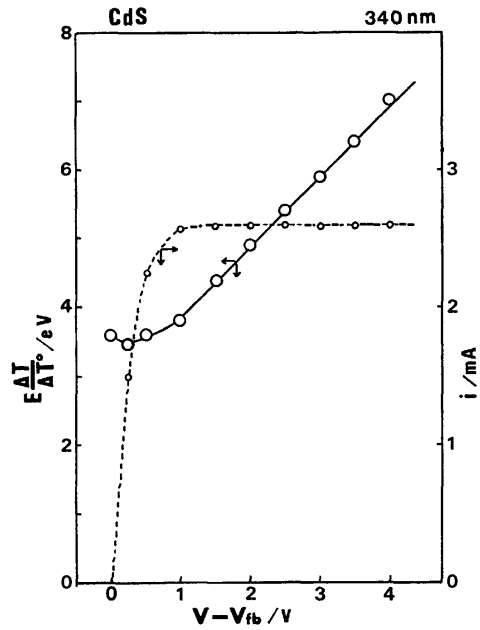

Fig. 4. Standardized temperature change *versus* potential from the flatband potential of the CdS single crystal electrode in 0.1 M Na_2SO_3 and 0.2 M Na_2SO_4.

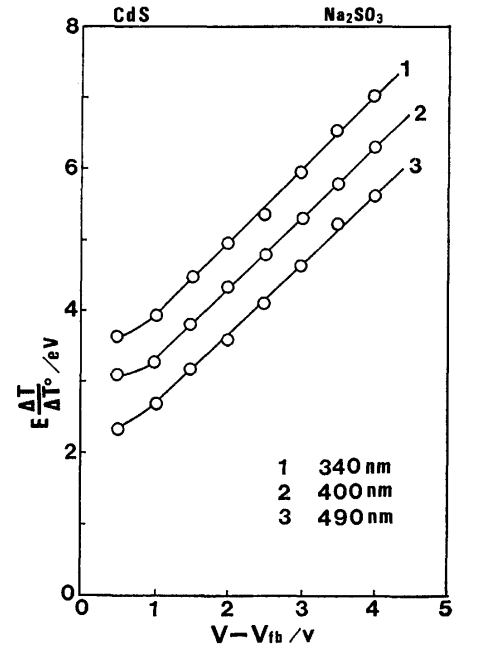

Fig. 5. The effect of exciting wavelengths on slope for the CdS single crystal electrode in 0.1 M Na_2SO_3 and 0.2 M Na_2SO_4.

shorter than that corresponding to the band gap energy to determine the quantum efficiency of a semiconductor reaction. If quantum efficiency changes with wavelengths, the slopes would also change.

Effect of Irradiation Time. The potential-ΔT relationship for the CdS–Na_2SO_3 system was measured at different irradiation times with light of constant intensity (photon numbers 5×10^{15} cm^{-2} s^{-1}), the slope being 1.0 in the irradiation time range 5—60 s (Fig. 6). A slope of 1.0 might be obtained even when irradiation

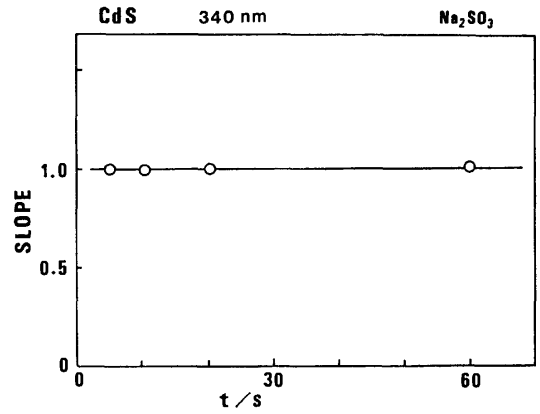

Fig. 6. The effect of irradiation time on slope for the CdS single crystal electrode in 0.1 M Na_2SO_3 and 0.2 M Na_2SO_4.

time is below 5 s. This was the case for 1.0 s irradiation time. However, in this case light of stronger intensity (1.8×10^{16} cm^{-2} s^{-1}) was introduced to the semiconductor surface to obtain a distinct rise in temperature. A slope can also be measured precisely by using a chopping system of light irradiation and a lock-in amplifier technique. When the semiconductor surface is excited for longer than 1 min (*e.g.* 2—5 min), the slope is expected to also be 1.0. However, in the irradiation time range 5—60 s, which we usually use, measurement is very easy.

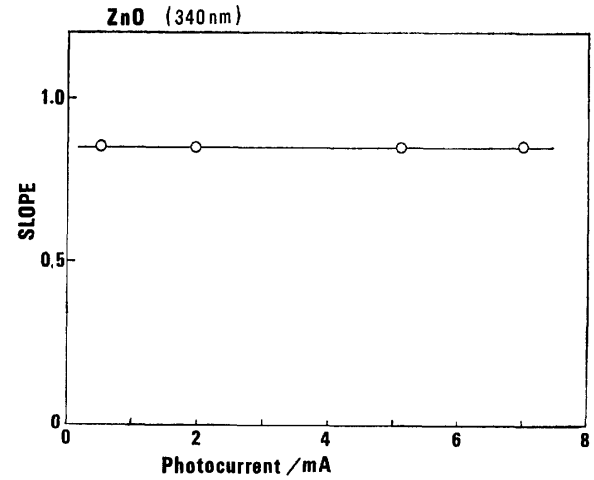

Fig. 7. The effect of light intensity on slope for the ZnO polycrystal electrode in 0.2 M Na_2SO_4.

Effect of Light Intensity. The effect of light intensity on the slope was studied using a polycrystal ZnO electrode in 0.2 M Na_2SO_4 (1 M=1 mol dm^{-3}) electrolyte solution. The results are shown in Fig. 7, where the abscissa represents the saturated photocurrent, which is proportional to the light intensity controlled by use of neutral density filters. The slope, *i.e.*, the quantum efficiency of the anodic reaction of the ZnO, was constant (0.85) at photocurrents of 500 μA cm^{-2}—7 mA cm^{-2} under the conditions of 340 nm wavelength and 20 s irradiation time (Fig. 7). The number of photons irradiated, as counted by chemical actinometry,

was between 4×10^{15}—6×10^{16} cm^{-2} s^{-1}. The magnitude of the photocurrent and the number of photons observed are of almost the same order as when measured in typical semiconductor electrode reactions.

The fact that these three parameters, *i.e.* wavelength, irradiation time, and intensity of light, can be appropriately selected depending on the characteristics of semiconductor electrodes indicates that this method is useful for obtaining quantum efficiencies.

n-Type Semiconductor Electrodes. *CdS Single Crystal*: As seen in the result for the CdS single crystal electrode, *i.e.* a slope of 1.0 (Fig. 4), oxidation of the sulfite ions occurs instead of dissolution of the CdS in a sodium sulfite solution.[15] On the other hand, quantum efficiency obtained by a comparison of the number of electrons calculated from the magnitude of photocurrent with the number of photons counted by chemical actinometry is 0.90—1.00, depending on the surface treatment.

CdS Polycrystal: The same reducing agent, SO_3^{2-}, was also used to suppress the dissolution of the polycrystal CdS electrode. The slope was 0.67, smaller than that of the single crystal CdS, probably due to the increase in surface recombination.

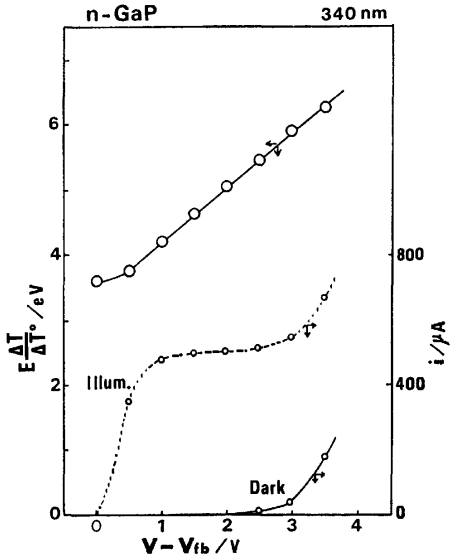

Fig. 8. Standardized temperature change *versus* potential and photocurrent *versus* potential of the n-GaP single crystal in 0.1 M Na_2S and 1 M NaOH.

n-CdSe, n-GaP, and n-GaAs Single Crystals: These semiconductor electrodes are also unstable in the usual electrolyte solution. For example, in 1 M NaOH, n-GaP dissolves under irradiation as follows:[16]

$$GaP + 11OH^- + 6p^+ \longrightarrow GaO_3^{3-} + HPO_3^{2-} + 5H_2O.$$

However, by using a strong reducing agent such as Na_2Se, the dissolution reactions can be suppressed.[17] Photothermal data and photocurrent-potential curves for the n-GaP electrode in a Na_2S aqueous electrolyte solution are shown in Fig. 8. Ellis *et al.*[17] reported that n-GaP was not stabilized perfectly in the Na_2S aqueous solution. However, we observed a constant photocurrent flow, indicating that the surface of the GaP electrode does not change during such a short irradiation period and weak intensity of light. The slope of $E\frac{\Delta T}{\Delta T^\circ}$ against potential was 0.85, which was larger than the quantum efficiency 0.62 obtained by chemical actinometry. In aqueous electrolyte solutions of the same reducing agent (Na_2S) the slope obtained for n-CdSe was 0.42 and that for n-GaAs 0.80. The value obtained for GaAs by chemical actinometry was considerably smaller (0.47). The large difference between the quantum efficiency from the slope and that from the chemical actinometry is not easy to interpret, since the surface of GaAs was not highly reflective as in the case of MoS_2.

TiO_2 Single Crystal: The slope, *i.e.* the quantum efficiency from temperature measurement, for TiO_2 changes with reduction treatment. By using TiO_2 single crystal reduced in a hydrogen atmosphere at 600 °C for 20 min, we obtained a slope of 0.7 in an aqueous solution of sulfuric acid.

ZnO Polycrystal: The results are shown in Fig. 7. The quantum efficiency from the slope is 0.85.

n-MoS_2 Single Crystal: For lustrous semiconductors, it is difficult to estimate the quantum efficiency of the photoelectrode reaction by the usual method of counting the number of photons by chemical actinometry. By the temperature method, we count only the photons absorbed in the surface of the semiconductor, with the result that value thus obtained for quantum efficiency can be taken as an intrinsic quantum efficiency. One of the most lustrous semiconductors is MoS_2, known as a layer compound semiconductor. Tributsch[18,19] reported that n-MoS_2 is a most promising photoelectrode for the electrochemical photocell because of its wide wavelength spectrum for photoactive reactions. Figure 9 shows the results with an n-type MoS_2 electrode. Under irradia-

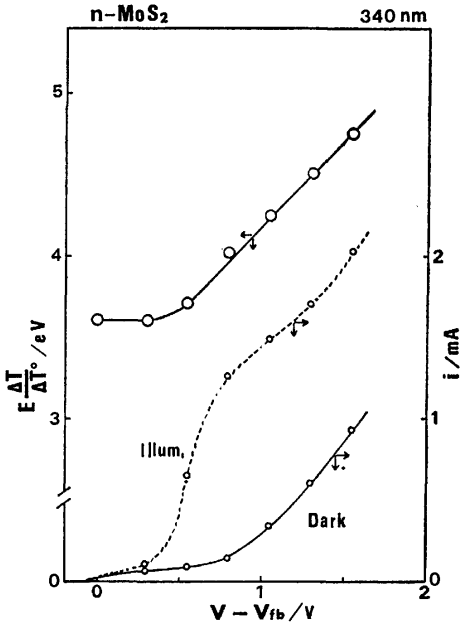

Fig. 9. Standardized temperature change *versus* potential and photocurrent *versus* potential of the n-MoS_2 single crystal in 0.2 M Na_2SO_4.

tion the limiting anodic photocurrent was obtained by substracting the anodic dark current. The slope of $E\frac{\Delta T}{\Delta T^{\circ}}$ due to a saturated photocurrent against the applied potential was 1.0. On the other hand, the quantum efficiency from the usual actinometric method was 0.54, suggesting that the temperature method is useful to determine the intrinsic quantum efficiency of a semiconductor electrode with a brilliant surface.

p-Type Semiconductor Electrodes. p-GaP and p-GaAs Single Crystal: In p-type semiconductor electrodes, the cathodic current increases by light irradiation. In the cathodic limiting photocurrent region, the relationship between temperature change and the applied potential can also give information on the intrinsic quantum efficiency. Figure 10 shows the results for a p-GaP single crystal electrode. From the linear slope, it was possible to obtain the intrinsic quantum efficiency of 0.80 for the hydrogen evolution reaction.

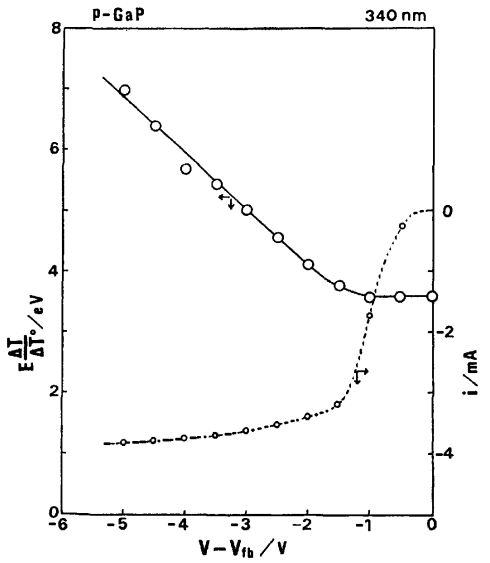

Fig. 10. Standardized temperature change *versus* potential and photocurrent *versus* potential of the p-GaP single crystal in 0.5 M H_2SO_4.

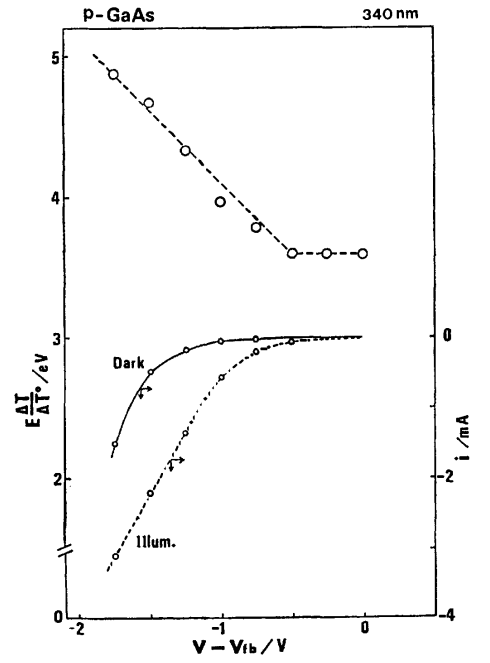

Fig. 11. Standardized temperature change *versus* potential and photocurrent *versus* potential of the p-GaAs single crystal in 0.5 M H_2SO_4.

Figure 11 shows the results for a p-GaAs single crystal electrode. Even in the limiting photocurrent region, the cathodic photocurrent increases gradually with cathodic polarization, the $E\frac{\Delta T}{\Delta T^{\circ}}$ *vs.* V curve showing no straight line. In this case, the slope of the tangent of the curve might indicate the quantum efficiency. Even in actinometric method, the quantum efficiencies showed different values depending on the applied potential, since the photocurrent is dependent on the applied potential in spite of the constant number of photons irradiated.

Summary

A comparison is made of the intrinsic quantum efficiencies obtained from the temperature measurement of the semiconductor surfaces (Table 2).

TABLE 2. COMPARISON OF QUANTUM EFFICIENCIES

340 nm

Electrode	η_t	η_a	Electrolyte
n-CdS s	1.00	1.00	Na_2SO_3
n-CdS p	0.67	0.67—0.70	Na_2SO_3
n-CdSe s	0.42	0.40—0.42	Na_2S
n-GaP s	0.85	0.62	Na_2S
n-GaAs s	0.80	0.47—0.49	Na_2S
n-TiO_2 s	0.70	0.70	H_2SO_4
n-ZnO p	0.85	0.76—0.78	Na_2SO_4
n-MoS_2 s	1.00	0.54	Na_2SO_4
p-GaP s	0.80	0.60—0.66	H_2SO_4
p-GaAs s	0.80—1.00	0.56—0.59	H_2SO_4

η_t:Quantum efficiency by temperature measurement. η_a:Quantum efficiency by actinometry. s: Single crystal. p: Polycrystal.

This temperature method has advantages over the usual actinometric method; i) simplicity, ii) no necessity of counting the number of photons irradiated and/or absorbed, iii) the possibility of obtaining intrinsic quantum efficiencies even for semiconductors which have large surface reflectance and/or scattering.

Effect of Cl^- and Br^- Ions and pH on the Flatband Potentials of Silver Halide Sheet Crystal Electrodes

Seiichi SUMI, Tadashi WATANABE, Akira FUJISHIMA,* and Kenichi HONDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 23, 1980)

Flatband potential (E_{fb}), which coincides with the Fermi level in energy, was determined for AgCl and AgBr electrodes by electrochemical measurement of the capacitance of the space charge layer of a semiconductor in contact with a solution. The values of E_{fb} for both AgCl and AgBr electrodes in an electrolyte solution were −4.8 V *vs.* vacuum. The energy levels of the electrodes could be determined from this value. The behavior of the AgCl electrode is somewhat like an n-type semiconductor, and that of the AgBr electrode very much like an intrinsic semiconductor. The E_{fb} values for the AgCl and AgBr electrodes change cathodically in electrolyte solutions with Cl^- and Br^- ions, respectively, but not with H^+ or OH^- ions. This seems to be associated with the Ag^+ ion effect in spectral sensitization. It is concluded that the Ag^+ ion effect arises from a downward shift of the band edge of silver halides.

Studies are in progress on silver halides (AgX), major constituents of photographic emulsions, with respect to such problems as the number of silver atoms needed to form the minimum latent image,[1] and whether the ionic[2] or the electronic process[3] comes first in latent image formation. Positions of the conduction and valence bands are important for semiconductors, but, the data given by investigators for AgX differ as much as 0.1 V.[4–7]

Only a few papers have appeared on the Fermi energy level of AgX. Williams *et al.*[8] analyzed ultraviolet photoemission and reported energy differences between the Fermi energy level and the top of the valence band, 1.7 eV for AgCl, 1.2 eV for AgBr, and 1.1 eV for AgI. They determined the energy differences but not the positions of the Fermi energy levels of AgX *vs.* a reference electrode. In this study, the positions of the Fermi energy level for Ag/AgX/solution electrodes (X=Cl and Br) were determined *vs.* a saturated caromel electrode (SCE) as the flatband potential (E_{fb}) by electrochemical measurement of the capacitance of the space charge layer of a semiconductor in contact with a solution. The positions thus obtained seem to be useful for the electrochemical study of AgX.

Wagner[9] and Matejec[10] investigated the conductance of AgX (X=Cl, Br, and I) under various halogen pressures and found that there are many more electrons than holes for AgCl and somewhat more for AgBr in contact with silver at room temperature. Other investigators[11–13] reported that silver halides are n-type or p-type semiconductors. However, from the results of E_{fb} measurements, we have found the properties of AgCl and AgBr electrodes to be n-type and intrinsic semiconductors, respectively.

The spectral sensitivity of a photographic emulsion increases as the pAg (pAg=−log [Ag^+]) decreases. The Ag^+ ion effect was explained by Gilman,[5] and Collier and Gilman[14] in terms of subconduction band event, Ag^+ ions on the AgX surface acting as an electron trap. Iwasaki *et al.*[15] found that the sensitized photocurrent due to the electron injection from a photoexcited sensitizing dye increases with lowering of the pAg of the electrolyte solution. They concluded that the Ag^+ ion effect results from the anodic band edge shift of the AgCl electrode. Thus, the band edge shift due to Ag^+ ions seems to be important for clarifying the mechanism of the Ag^+ ion effect. The band edge shift of AgX could be determined by measuring E_{fb}. The Ag^+ ion effect was also investigated from the result of E_{fb} measurement.

Basic Principle

In the electrochemistry of semiconductors, the E_{fb} value is important for determining their energy levels and studying their electrode reactions. The relation between the capacitance of the space charge layer (C_s) and the surface potential ($\Delta\Phi_s$) is as follows.[16,17]

$$C_s = \frac{\varepsilon\cdot\varepsilon_0}{L}\frac{|y(e^{-V_s}-1)-y^{-1}(e^{+V_s}-1)|}{[y(e^{-V_s}-1)+y^{-1}(e^{+V_s}-1)+(y-y^{-1})V_s]^{1/2}} \quad (1)$$

where

$$y=\left(\frac{P_0}{N_0}\right)^{1/2},\ V_s=\frac{e_0\cdot\Delta\Phi_s}{k\cdot T},\ L=\left(\frac{\varepsilon\cdot\varepsilon_0\cdot k\cdot T}{2\cdot N_i\cdot e_0^2}\right)^{1/2},$$
$$\Delta\Phi_s=\Phi_s-\Phi_i,$$

and ε=dimensionless dielectric constant of semiconductor, ε_0=dielectric constant of the vacuum, P_0,N_0= equilibrium concentration of holes and electrons in bulk of semiconductor, k=Boltzmann constant, T=absolute temperature, e_0=elementary charge, $N_i=\sqrt{P_0\cdot N_0}$, Φ_s=potential of semiconductor surface, and Φ_i= potential of semiconductor bulk. When $\Delta\Phi_s$ and $1/C_s^2$ are represented by abscissa and ordinate, respectively, curves can be obtained depending on the values of y, ε, and N_i. The potential at which $\Delta\Phi_s$ becomes zero is E_{fb}. The value of $\Delta\Phi_s$ shows the potential difference between the bulk and the surface of a semiconductor, not directly showing the potential *vs.* reference electrode. This can be altered by changing the potential of a semiconductor bulk which can be changed by the electrode potentials (E) *vs.* reference electrode. The value of E_{fb} can be determined from the shape of the $1/C_s^2-E$ curve with respect to a reference electrode.

Equation 1 can be applied to n-type, intrinsic, and p-type semiconductors. However, it is so complicated that it is not generally used for n- or p-types. In the case of a highly doped n-type (or p-type) semiconductor, Eq. 1 can be simplified to the Mott-Schottky relation-

ship:

$$\frac{1}{C_s^2} = \frac{2}{\varepsilon \cdot \varepsilon_0 \cdot e_0 \cdot C_D}\left(\Delta\phi_s - \frac{k \cdot T}{e_0}\right), \quad (2)$$

where C_D=the donor concentration of an n-type semiconductor or the acceptor concentration of a p-type. It is significant that the plots of $1/C_s^2$ *vs.* $\Delta\phi_s$ or (E) derived from Eq. 2 are linear. The donor (acceptor) concentration can be calculated from the slope, giving the concentration of impurity added to the semiconductor. The potential where $1/C_s^2$ nearly approaches zero is E_{fb} in Eq. 2, the slope of the $1/C_s^2$—E curve being upward for an n-type semiconductor and downward to the right for a p-type.

Experimental

The methods of crystal preparation were the same as before,[18] except that the melting temperature was 455 °C for the AgBr crystal.

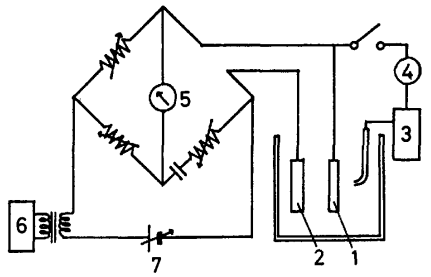

Fig. 1. Capacitance bridge circuit.
1: AgX electrode, 2: Pt counter-electrode, 3: SCE, 4: Voltmeter, 5: Null detector, 6: Oscillator (1 kHz), 7: Dry cells.

One side of the sheet crystals (diameter: 10 mm) was fastened to a lead wire with silver paste and to a glass spatula with epoxy resin, the electrodes prepared being left to stand overnight. The other surface was then etched with 1 M (1 M= 1 mol dm^{-3}) KCN for 5 min and washed thoroughly with distilled water. The AgX electrodes were immersed in electrolyte solutions of various compositions, C_S being measured by means of the capacitance bridge circuit shown in Fig. 1. The electrode potential *vs.* SCE was controlled by dry cells. During the course of measurements, contact to the voltmeter was cut to exclude extraneous capacitances. All experiments were carried out in a darkroom at room temperature. The electrolyte solutions were not deoxygenated. In addition to C_S, electrochemical cells also have counter electrode capacitance and Helmholtz layer capacitance, but they can be disregarded.

Results and Discussion

AgCl Electrode. $1/C_s^2$ is plotted against the electrode potential *vs.* SCE for the AgCl electrode in 0.1 M KCl aqueous solution (Fig. 2). The linearity of the plots shows that the Mott-Schottky relationship (Eq. 2) holds for AgCl. The E_{fb}, the potential where $1/C_s^2$ is close to zero, was 0.0 V *vs.* SCE, the value showing the position of the Fermi energy level of the AgCl electrode in 0.1 M KCl aqueous solution. The value of kT/e_0 in Eq. 2 is about 26 mV at room temperature, not being considered significant in comparison with the data of other investigators. Since the $1/C_s^2$

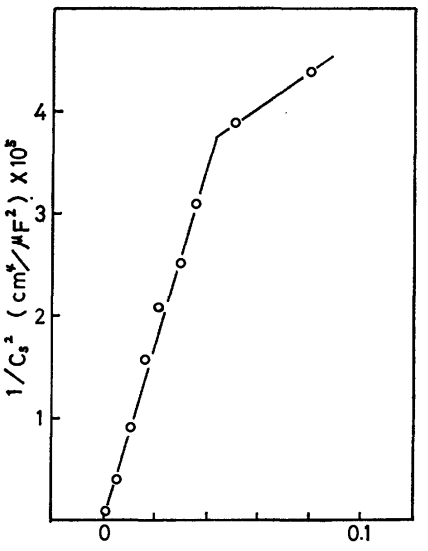

Fig. 2. Mott-Schottky plot for the AgCl electrode in 0.1 M KCl aqueous solution.

value increases with anodic polarization, the AgCl electrode can be considered as an n-type semiconductor. Assuming that ε of AgCl is 11.2[19] and the roughness factor of the electrode surface is 1, the donor concentration (C_D in Eq. 2) can be calculated from the slope to be 1.7×10^{13}, much smaller than the values for other perfectly n-type semiconductors (*e.g.*, 10^{16}—10^{17} for ZnO[20]). Though reproducibility was poor for the slope, it was good for E_{fb}. It seems that the C_D of the AgCl electrode shows either the concentration of interstitial silver ions or of divalent cation impurities.

The energy level of AgCl obtained from E_{fb} is shown in Fig. 3. The Fermi energy level *vs.* vacuum was determined in this work to be −4.8 eV. It should be noted that an energy of −4.5 eV vacuum is found to be equivalent to 0.0 eV *vs.* a standard hydrogen electrode.[21] The energy difference of 1.7 eV between the valence band and the Fermi energy level reported by Williams *et al.*[8] gives the position of the valence band. The band gap of 3.1 eV was determined from the average values of other investigators,[4-7] giving the position of the conduction band. Despite the simplicity of the method the energy levels we obtained coincide approximately with those of the other investigators.

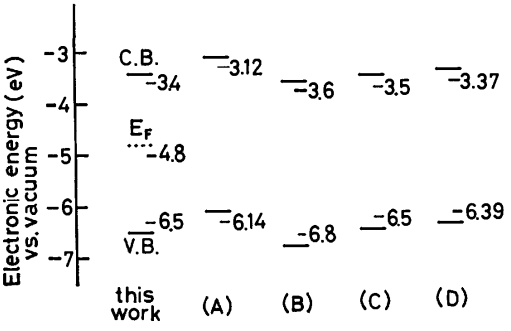

Fig. 3. Energy level of the AgCl electrode obtained from the flatband potential, C.B.: conduction band, V.B.: valence band, E_F: Fermi energy level, (A): Berry,[7] (B): Brown,[4] (C): Peterson,[6] (D): Gilman.[5]

The position of the Fermi energy level is slightly higher than the mid-point between the conduction and the valence bands (Fig. 3). In the case of a highly doped n-type semiconductor, the position of the Fermi energy level is almost identical to that of conduction band. We see that the AgCl electrode behaves like an n-type semiconductor. This coincides qualitatively with Wagner's findings that electrons are majority carriers for AgCl in contact with silver at room temperature.[9,10] Thus the conclusion that AgCl behaves like an n-type semiconductor was derived by studies of an Ag/AgCl/ solution electrode, the AgCl crystals contained in photographic emulsions not being an n-type but an intrinsic semiconductor.

The position of the conduction band obtained (Fig. 3) seems to be of great importance for studies of the spectral sensitization by electrochemical methods. The relation between sensitized photocurrents and the lowest vacant levels of sensitizing dyes was also investigated electrochemically.[18] The position of the AgCl conduction band at −3.4 eV *vs.* vacuum is also supported by the result that the sensitization of AgCl was initiated by the sensitizing dye having the lowest vacant level from −3.52 to −3.61 eV *vs.* vacuum.

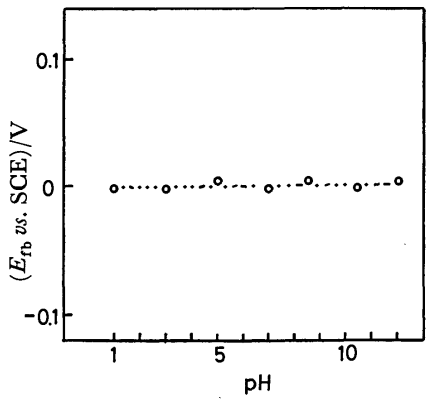

Fig. 4. pH dependence of the flatband potential (E_{fb}) of AgCl in 0.1 M KCl aqueous solution, pH control using HCl or KOH.

The E_{fb} of AgCl was measured in 0.1 M KCl aqueous solutions having different pH adjusted by the addition of HCl or KOH. As shown in Fig. 4, neither H^+ nor OH^- ions affect the E_{fb}, indicating that the band edeg of AgCl does not change with H^+ or OH^- ions, and that the photocurrent sensitized by a sensitizing dye is not dependent on the pH of electrolyte solution.[15]

E_{fb} was also measured with various concentrations of Cl^- ion (Fig. 5), and was found to shift cathodically with an increase in Cl^- ions. In order to make a comparison with the Cl^- ion effect on E_{fb}, current-potential curves were measured at various concentrations of Cl^- ion, and the relation between zero-current potential (E_z) and the concentration of Cl^- ion was plotted (Fig. 6). Measurements of photocurrent were carried out under illumination from a 500 W Xe lamp without filter. The photocurrent was measured while increase in current occurring when the AgCl electrode was exposed to the light. The photocurrent was about one-tenth of the dark current. The E_z value coincided well

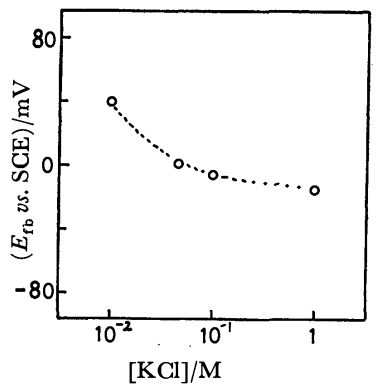

Fig. 5. Cl^- ion dependence of the flatband potential (E_{fb}) of AgCl.

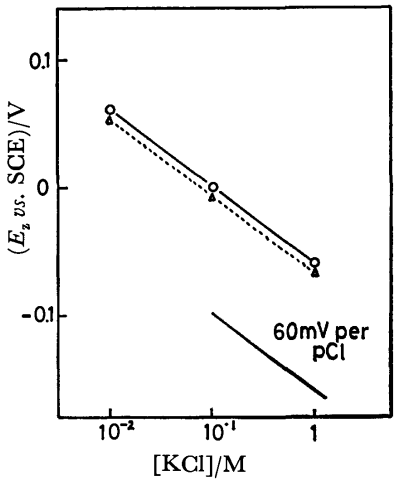

Fig. 6. Cl^- ion dependence of the zero-current potential (E_z) of AgCl, —○—: dark current, ···▲···: photocurrent.

with the E_{fb} measured in 0.1 M KCl.

Thus taking into consideration the following electrochemical reactions of Ag/AgCl/Cl^-

$$AgCl(s) \rightleftarrows Ag^+ + Cl^- \quad (3)$$

$$Ag^+ + e \rightleftarrows Ag(s) + Cl^- \quad (4)$$

$$AgCl(s) + e \rightleftarrows Ag(s) + Cl^- \quad (5)$$

and making use of the Nernst equation, we have for the shift of electrode potential ΔE,

$$\Delta E = \text{const} + \frac{RT}{F} \ln \frac{a(Ag(s))}{a(AgCl(s))} + \frac{2.3RT}{F} pCl \quad (6)$$

where AgCl(s)=solid AgCl, Ag(s)=solid Ag, e=electron, R=gas constant, F=Faraday constant, a ( )=activity, and pCl=−log [Cl^-]. Equation 6 suggests that an electrode potential shift of *ca.* 60 mV (2.3 RT/F) per unit on the pCl scale should be detected. Though the shift per pCl is *ca.* 60 mV for E_z (Fig. 6), it is about 30 mV for E_{fb} (Fig. 5). Mobile interstitial Ag^+ ions seem to be associated with the difference in the shifts in E_{fb} and E_z. The band edge of AgCl shifts cathodically with an increase in the concentration of Cl^- ion.

The Cl^- ion effect on the band edge of AgCl can be considered as a reverse effect of the Ag^+ ion effect on the

band edge of AgCl. However, the effect could not be measured directly since the Ag^+ ions in the electrolyte solution were deposited as silver on the surface of the AgCl electrode when concentrated $AgNO_3$ solution was added to the solution. Iwasaki *et al.*[15] reported that with increase in Ag^+ and Cl^- ions, the equilibrium potential of the AgCl electrode shifts anodically and cathodically, respectively. Minoura *et al.*[22] reported that with an increase in S^{2-} and Cd^{2+} ions, the E_{fb} of CdS shifts cathodically and anodically, respectively. Since the constituent ions of AgCl are Ag^+ and Cl^-, we might presume that E_{fb} of the AgCl electrode also shifts cathodically and anodically with the addition of Cl^- and Ag^+ ions, respectively. The anodic shift of the band edge gives rise to an increase in electron injection from excited sensitizing dyes,[15,18] the cathodic shift decreasing. The Ag^+ ion effect on spectral sensitization (Fig. 7) can be explained in terms of a band edge shift of the AgCl electrode.[15,18]

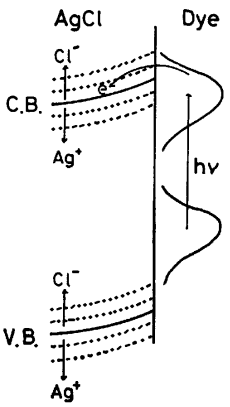

Fig. 7. Scheme of the Ag^+ and Cl^- ion effect in spectral sensitization, C.B.: conduction band, V.B.: valence band, e: electron.

Watanabe *et al.*[23] found a phenomenon similar to the Ag^+ ion effect, using TiO_2 electrode and electrochemical techniques. The sensitized photocurrent increased with decrease in the pH of the electrolyte solution. This was attributed to the shift in the E_{fb} of TiO_2 due to H^+ ions in the electrolyte solution.

AgBr Electrode. The capacitance of the space charge layer of AgBr electrodes was measured by the same procedure as for the AgCl electrode. Since the $1/C_s^2$—E plots for AgBr were not linear, Eq. 1, which can be adapted to intrinsic semiconductors, was used instead of Eq. 2. The value of y in Eq. 1 was varied from 10^{-10} to 10^{10} and the theoretical $1/C_s^2$—E curves were calculated. The capacitances were calculated on the assumption that $\varepsilon\cdot\varepsilon_0/L$ equals 1, because the N_i of the AgBr used was unknown and the value of $\varepsilon\cdot\varepsilon_0/L$ does not change the shape of $1/C_s^2$—E curve. Equation 1 can be considered to be adapted to AgBr, if the shape of the theoretical curve resembles that of the experimental one.

Figure 8 shows the theoretical $1/C_s^2$—E curves ($y=10^{-10}$—10^{10}) and the experimental values measured in 0.1 M KBr aqueous solution. Since the potential at

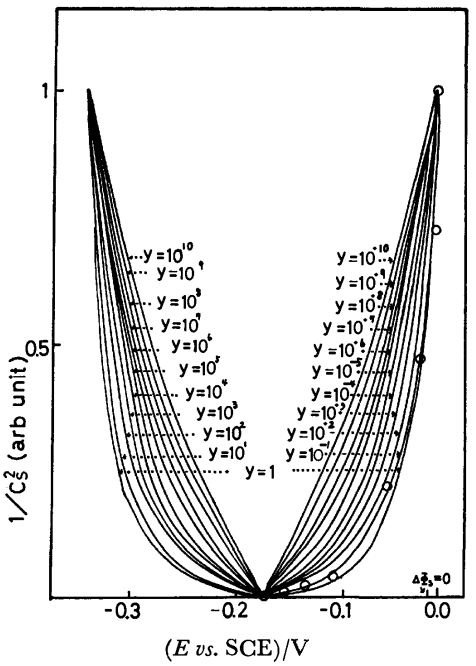

Fig. 8. $1/C_S^2$-E plot for the AgBr electrode in 0.1 M KBr aqueous solution, ——: theoretical curve, ○: measured values.

which $1/C_s^2$ is closest to zero is -0.17 V *vs.* SCE by measurement, the theoretical curve at which $1/C_s^2$ is closest to zero was based at -0.17 V. The $1/C_s^2$ of both theoretical and measured values were normalized to 1 at 0.00 V *vs.* SCE when $y<1$, and at -0.34 V when $y>1$, since the change in C_s was found only at potential more negative than 0.00 V *vs.* SCE. The experimental values coincide with the curve of $y=10^{-1}$ (Fig. 8). Not all AgBr electrodes, however, agree with the theoretical curve. More precise value than $y=10^{-1}$ could not be determined. The E_{fb} value of the $y=10^{-1}$ curve, $\Delta\phi_s=0$, was -0.01 V *vs.* SCE, and not -0.17 V. The E_{fb} of the AgBr electrode was concluded to be 0.0 V *vs.* SCE. The value for $y=10^{-1}$ coincides with that reported by Wagner[9] and others,[10] who suggested that the number of electrons is 10^1—10^2 times the number of holes when AgBr is brought into contact with silver at room temperature.

Figure 9 shows the energy level of the AgBr electrode

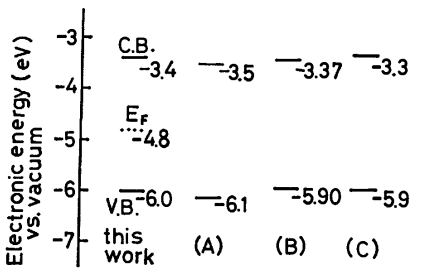

Fig. 9. Energy level of the AgBr electrode obtained from the flatband potential, C.B.: conduction band, V.B.: valence band, E_F: Fermi energy level, (A): Brown,[4] (B): Gilman,[5] (C): Berry.[7]

obtained from E_{fb}. The potential *vs.* vacuum was determined by Lohmann's value[21] as AgCl electrode. An energy difference 1.2 eV between the Fermi energy level and the valence band of AgBr was reported by Williams *et al.*,[8] giving the position of the valence band. The band gap, 2.6 eV, was determined by averaging the values of the other investigators,[4,5,7] giving the position of the conduction band. The positions of the conduction and valence bands we obtained coincide with those of other investigators.

AgBr electrode behaves almost like an intrinsic semiconductor, since the Mott-Schottky relationship could not be used for AgBr, the Fermi energy level being almost midpoint between the conduction and valence bands.

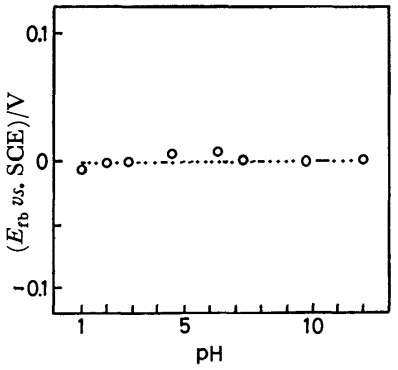

Fig. 10. pH dependence of the flatband potential (E_{fb}) of AgBr in 0.1 M KBr aqueous solution, pH control using HBr or KOH.

The E_{fb} value of the AgBr electrode, like that of the AgCl electrode, was not affected by H^+ or OH^- ions (Fig. 10). The sensitized photocurrent is expected to remain unchanged by H^+ or OH^- ions in electrolyte solution.

Figure 11 shows the Br^- ion dependence of E_{fb}. The E_{fb} shifts cathodically with an increase in Br^- ions, the slope being *ca.* 20 mV per pBr. The relation of E_z to Br^- ion concentration is shown in Fig. 12. The potentials of both photocurrents and dark currents shift cathodically with falling pAg. The photocurrents were measured as the increase in current during the course of illumination. The potential difference between dark and

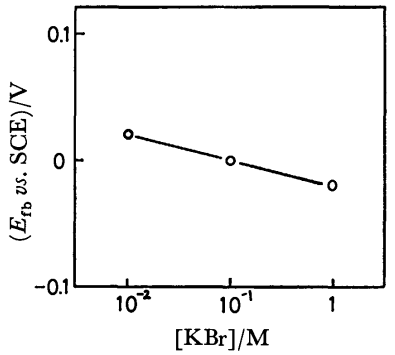

Fig. 11. Br^- ion dependence of the flatband potential (E_{fb}) of AgBr.

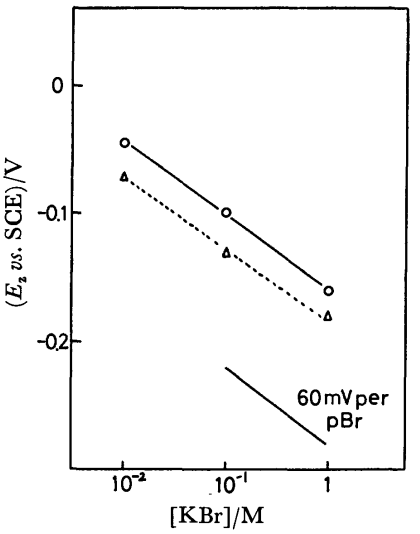

Fig. 12. Br^- ion dependence of the zero-current potential (E_z) of AgBr, —○—: dark current, ···△···: photocurrent.

photocurrents at a given concentration of Cl^- ion was based on the Dember effect, both slopes being *ca.* 60 mV per pBr. These phenomena can be explained by means of an equation similar to (6). The Br^- ion effect on the potentials suggest that sensitized photocurrent would decrease with falling pBr.

The Ag^+ ion effect in spectral sensitization is due to the anodic shift of the AgBr band edge as in the case of AgCl, since the sensitized photocurrent increases with decreasing pAg and decreases with decreasing pBr.

Conclusion

1. The flatband potentials of both AgCl (in 0.1 M KCl) and AgBr (in 0.1 M KBr) are 0.0 V *vs.* SCE, and the AgCl electrode behaves somewhat like an n-type semiconductor, while the AgBr electrode behaves almost like an intrinsic semiconductor.
2. The flatband potentials of AgCl and AgBr are affected by Cl^- and Br^- ions, respectively, in electrolyte solution. In both cases, the flatband potentials shift cathodically with an increase in halide ion concentration.
3. The effects of Cl^- ion and Br^- ion can be considered as a reverse effect of the Ag^+ ion. The Ag^+ ion effect in spectral sensitization is due to the anodic shift of the AgX band edge.

We wish to thank Dr. Kiminori Itoh for his advice and comments on the interpretation of the results, and Mr. Hiroyuki Taiko for assistance in carrying out the experiments.

An On-line Automated Adiabatic Calorimeter in the 13—300 K. Heat Capacity of Cyclohexanol†

Kōji Kishimoto, Hiroshi Suga,* and Syûzô Seki**
Department of Chemistry, Faculty of Science Osaka University, Toyonaka, Osaka 560
(Received February 22, 1980)

A computerized adiabatic calorimeter system operating in the temperature range 13—300 K is described. A digital voltmeter is used for energy measurement and the duration of energy input is determined by a program unit operated by 1 Hz pulse. Temperatures of the calorimeter are measured by a 25 Ω platinum resistance thermometer and an automated ac double bridge. The measured resistance is converted into temperature (IPTS-68) by a calibration table stored in a mini-computer. Criterion for the realization of thermal equilibration is that a temperature drift calculated from the latest six data becomes smaller than a preset value, usually 7×10^{-8} Ω s^{-1}. The system is able to measure the heat capacity of solid and liquid in an intermittent heating mode and gives the computed results during measurement. Some examples of the test runs on cyclohexanol crystal are shown and the results are compared with those obtained by manual measurements by use of dc Müller bridge. A relaxational heat capacity anomaly observed in glassy crystalline state of cyclohexanol is discussed in correlation with a secondary relaxation observed by previous dielectric measurement.

Adiabatic calorimeter with intermittent heating mode is believed to give the most accurate and precise heat capacity data at low temperatures.[1] Numerical values of the static equilibrium properties such as enthalpy, entropy and Gibbs energy function can be derived from the data. While, a series of systematic studies on glassy states of materials[2] have proved that the calorimetric technique under a good adiabatic condition provided valuable information on dynamical nature of molecular motion through the observation of relaxational behavior of enthalpy of the specimen. Thus, temperature changes due to enthalpy relaxation in cyclohexanol crystal[3] at around 150 K were followed to give calorimetric relaxation time, which was correlated with dielectric relaxation time.[4] Kinetic parameters derived from calorimetric measurement of 1,2-difluoro-1,1,2,2-tetrachloroethane crystal[5] were correlated with those obtained by NMR techniques. A relaxational process due to possible rearrangement of proton configuration in hexagonal ice[6] was persued for about a month.

The relaxation time obtained by this method ranges 5 minutes to one week (or of the order of 10^{-3} to 10^{-7} Hz in terms of frequency). Since it is almost impossible at the present stage to get such a long relaxation time by other techniques, the calorimetric method provides complementary knowledge on the dynamics of slow molecular motion in the condensed state. The prolonged observation of temperature of a system with extremely long relaxation time necessitates to build an automatic data acquisition system for calorimetry.

The development of modern electronic techniques makes possible to replace the laborious manual operations by an automatic measurement and control without loss of accuracy. There are many approaches[7-10] to the problem of automatic data acquisition in calorimetry according to the heating mode and to the method of temperature measurement. Here, a new approach of data acquisition system suitable for our purpose is reported. The system is able to give quick information of any thermal anomaly that may be encountered during measurement. The electronic system, the soft ware logic, and the method of processing the data are described. The operation of the system is illustrated by results on cyclohexanol crystal.

Automatic Heat Capacity Measurement System

An adiabatic calorimeter[11] with an immersion-type cryostat was used for the present purpose. A sample cell loaded with platinum resistance thermometer and heater is surrounded by two (inner and outer) adiabatic shields and by massive thermal station. Heat capacity of the cell is measured as a function of temperature by the standard discrete heating method. In this intermittent mode, the sequence of heat capacity measurement is composed of two successively alternating periods. One is called a drift period during which the temperature of the calorimeter cell is measured as a function of time. The other is the energy input period during which a definite amount of electrical energy is supplied to the calorimeter cell. The supplied energy is assessed on the basis of measurements of voltage and current across and through the cell heater as well as of time interval of the energy input.

Adiabatic condition of the calorimeter cell is realized by use of high vacuum and four-channels temperature controller. Each channel consists of a multi-junction thermocouple, dc amplifier and power amplifier. Controllers with proportional-integral-differential control mode are indispensable for the automatic control of the shield temperature in the discrete heating method. Small temperature difference was set between the inner and the outer shields, and the inner shield and the station, so as to produce the least temperature drift rate of the cell.

Figure 1 is a block diagram illustrating the system for automatic heat capacity measurement. This system may be divided into four major parts: (1) measuring circuits, (2) control system, (3) interface system, and (4) mini-computer.

† Contribution No. 4 from Chemical Thermodynamics Laboratory.

** Present address: Department of Chemistry, School of Science, Kwansei Gakuin University, Nishinomiya 662.

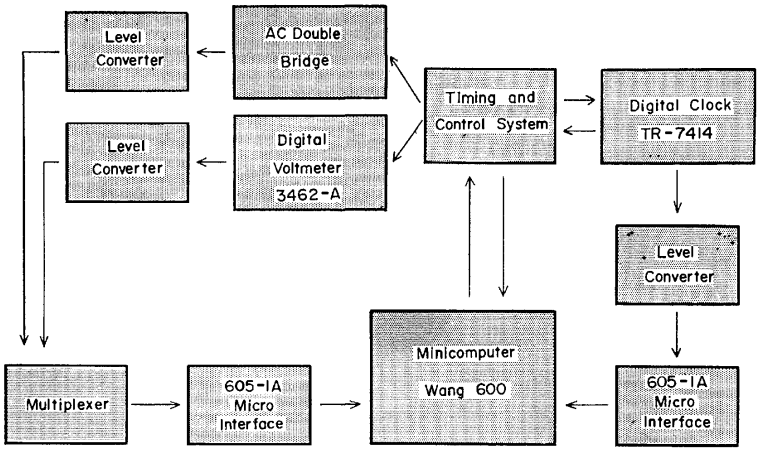

Fig. 1. Block diagram of the system for the automatic heat capacity measurement.

(1) Measuring Circuits. Resistance of the working platinum thermometer was measured by the Automatic System Laboratory A-7 precision ac double bridge. The bridge utilizes inductive voltage divider arranged as a Kelvin double bridge and is energized at 390 Hz. The bridge measures the ratio between two resistances R_t and R_s. Changes in resistance are automatically balanced and the ratio $R_t/(R_t+R_s)$ is displayed in seven digits. A capsule type platinum thermometer (Leeds and Northrup, 8164) was used in conjunction with one of four standard resistors (General Radio card-type 1440, 0.01, 0.1, 1, and 10 Ω). The four standard resistors were mounted inside a double-walled air thermostat.

The maximum temperature coefficient of the standard resistor was stated by manufacturer to be ±20 ppm/K,

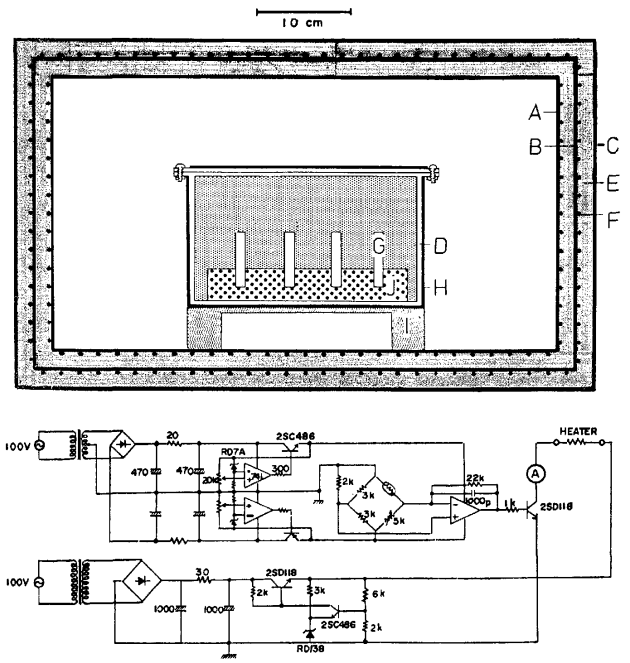

Fig. 2. Schematic drawing of an air thermostat for standard resistors and its regulator circuits.
A—C, Aluminum plates; D, copper box; E, styroform insulation; F, regulator heater; G, card-type standard resistor; H, polyurethane insulation; I, wooden pedestral; J, polyvinylchloride supporter.

while the bridge has $\pm 4\times10^{-7}$ inaccuracy. Thus, for the measurement of temperature with the accuracy better than 4×10^{-7}, the thermostat must be controlled within ±5 mK. The assembly shown in Fig. 2 consists of two parts; the boxes made of aluminum plate, A—C, and copper box, D. The spaces between A and B, and between B and C are packed with styrofoam insulation E and heater F. A and B are thermostatted independently at 36 °C and 33 °C, respectively, by use of the regulator circuit with thermistors as temperature sensors. The copper box housing the standard resistors G is wrapped by polyurethane H, and is positioned on wooden pedestral I. The thick copper wall plays a role as a buffer against fluctuation of temperature inside the aluminum box A.

The condition of the bridge balance has been given by Harris[12] in detail. Noise induced in the leads of the thermometer was liable to induce hunting in the bridge balance at the band width of 100 Hz. Since the bridge had the band widths of 100, 25, and 6.2 Hz as received from the manufacturer, it was modified so that any of setting with 30, 7.5, and 0.94 Hz could be adopted for avoiding the situation. For further improvement of the bridge balance, a normal counting logic system must be applied beside a short-cut logic system as pointed out by Martin *et al.*[8]

The electrical power supplied to the calorimeter cell was determined as follows. Values for the heater current are obtained by measuring the voltage across a 100 Ω standard resistor placed in series with the calorimeter heater. The voltages across the heater and the standard resistor are measured by means of a digital voltmeter (DVM, Hewlett-Packard 3462 A). The two DVM inputs are selected by a magnecraft mercury relay at an interval of 30 seconds during a heating period. The electrical energy dissipated in the calorimeter heater can be assessed by the equation, $E=60\sum_{i=1}^{N} V_i I_i$, where N is the total count during the heating or the heating time in unit of minute because the heating time is chosen to be multiple of one minute as will be described later.

In the drift period, the current from the power supply is circulated through a dummy resistance in

place of the calorimeter heater in order to maintain a constant drain on the power supply. The resistance used as a calorimeter heater (*ca.* 100 Ω) and the dummy resistance are switched by use of a magnecraft type MCN-IN high-speed mercury-relay, which has exceedingly low stray emf and contact resistance. All timing operations are based on a digital clock (Takeda Riken TR 7414B). As received from the manufacturer the clock had no output of one-second clock pulse which is required for the system control. One-second clock pulse fed into the Timing and Control described below are therefore taken out from the digital IC mounted in the clock.

The instrument has a claimed accuracy of 0.01% which comes from the stability of quartz crystal oscillators in it.

(2) Timing and Control System. The Timing and Control System (TCS) controls all timing operations on the basis of 1 Hz pulse generated by the digital clock. This system serves as an assistant of the mini-computer which is a data-entry-only device (or, has no interrupt system). When an energy-input command is issued from the program of the mini-computer, TCS transforms it into the electrical command signal. At the instant the energy input command signal coincides with the one-second-clock pulse, TCS makes the timer start and allows the magnecraft mercury-relay for energy input to be turned on. From this instant the energy input period starts. In the present work, the heating time interval is selected to be multiple of 1 min or 1 h. In this period, select signals are generated every 30 s from the clock and serves to select either voltage or current reading by operating a magnecraft mercury-relay.

Since the DVM can not measure voltage within a claimed accuracy (0.0004%) immediately after a sudden change in an input voltage, trigger pulses for the DVM readings are generated twice by TCS in each V and I reading period, and the second reading at the mid-time of each period is adopted. In the drift period, TCS supplies trigger pulses for DVM readings every 10 s, which are available for adjustment of the variable dummy resistance. In a normal use, an energy input is performed automatically under a program control and the heating period is fixed to the preset time interval. However, if desired, the heater on-off operation can be made manually, which is helpful in such a case as enthalpy determination of phase transition.

(3) Interface System. The interface system consists of level converter, multiplexer and micro-interface Wang 605, which interfaces the peripheral devices to a mini-computer Wang 600. The digital output levels of these measuring instruments are not directly compatible with TTL/DTL levels of Wang 600. Therefore, a level converter assembly is required between the computer and the peripheral devices. There exists no necessity of sampling of data from the ac double bridge and from the DVM in the same period. A multiplexer selects the data from the bridge in the drift period and the data from DVM in the heating period.

(4) Mini-computer and Program. The mini-computer Wang 600 takes advantages of facilities of a cassette system offering a low-cost alternative to disk and card systems. The resistance values of a working thermometer are stored on a cassette tape at an interval of 0.1 K over the temperature range from 10 to 380 K.

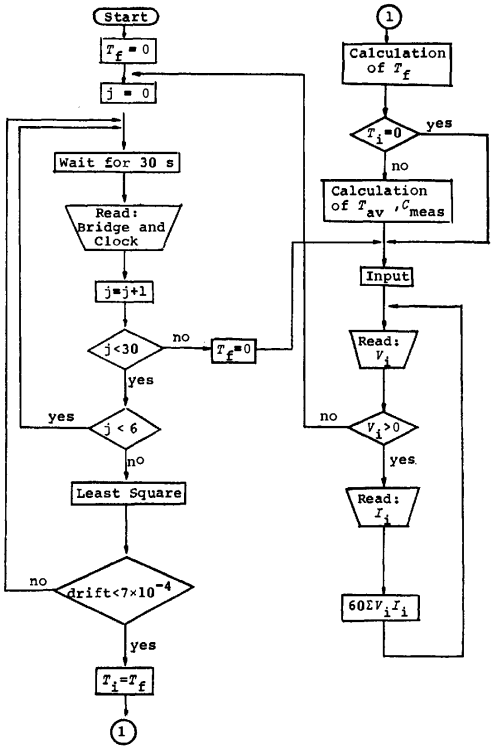

Fig. 3. Flow chart for the procedure of automatic operation of heat capacity measurement.

A flow chart for the procedure of automatic operation is drawn in Fig. 3. A typical sequence of program is as follows.

Step (1): In a drift period, the computer commands every 30 s the ac double bridge to transfer the measured resistance of a thermometer, data transfer being performed at the time when the bridge becomes at balance.

Step (2): Next the computer asks the clock to tell the time at which the measurement was made. The time is stored into a register and printed out along with the values of the measured resistance.

Step (3): The program examines whether the number of data points is smaller than six. If the answer is "yes," the program returns to step (1), after waiting for 30 s. If the answer is "no," the program proceeds to step (4).

Step (4): If the number of data points is smaller than 30, a temperature drift rate is determined from last six pairs of data by the least squares method. When a specimen accompanies with an enthalpy relaxation phenomenon, spontaneous temperature increase or decrease should be observed. In that case, 30 data points are accumulated and are used to analyse a kinetic characteristics of the relaxational process. Then, the program branches to step (7).

Step (5): A decision is made whether the drift rate is smaller than a preset value, usually 0.7 mK/ks. If

not, the program judges that the thermal equilibrium in the calorimeter cell is not established yet, and the program returns to Step (1). If so, the last six values of resistance are averaged to give an equilibrium resistance. Then, the computer converts this resistance value to temperature on the basis of T *vs.* R conversion table stored in a data bank. The corresponding value is designated as a final temperature, T_f.

Step (6): The computer calculates T_{av} which is equal to the averaged value of initial, T_i, and final, T_f, temperatures, and C_{meas} ($=60\ \Omega\ V_iI_i/(T_f-T_i)$). When the heat capacity of the empty sample cell and the weight of a sample are already known, the molar heat capacity of the sample can be calculated.

Step (7): The energy input command is issued from the program to TCS.

Step (8): Reading commands for DVM readings are generated by TCS. The computer receives these values from DVM and calculates the energy dissipated in the cell per 1 min. As Wang 600 is a data-entry-only device, a check is made whether the sign of entered data is positive or not. TCS assigns positive sign to the data from DVM and negative sign to the data from the ac double bridge. The positive sign means that the calorimeter heater is in on-state, and the input energy per 1 min must be added to give a total input energy and step (8) is repeated. In a case of negative sign the program will return to step (1) and the next cycle commences.

Calibration of the Thermometer

A platinum thermometer of 25 Ω ice-point resistance employed as working thermometer was calibrated against the laboratory standard thermometer certified at the US National Bureau of Standards according to the IPTS-68. The two thermometers were mounted in a massive copper block and the respective resistances were measured simultaneously at any fixed temperature. Since the standard thermometer is calibrated by d.c. method and since the value of resistance read with a.c. method is slightly different from that with d.c. method, the resistance of the standard thermometer was measured by Müller bridge (Leeds and Northrup, G-3), while that of the working thermometer with a.c. double bridge at fixed frequency of 390 Hz. An apparent resistance value including effects of lead impedance, self-heating and thermometer inductance *etc.* was related with IPTS-68 scale realized by the standard thermometer.

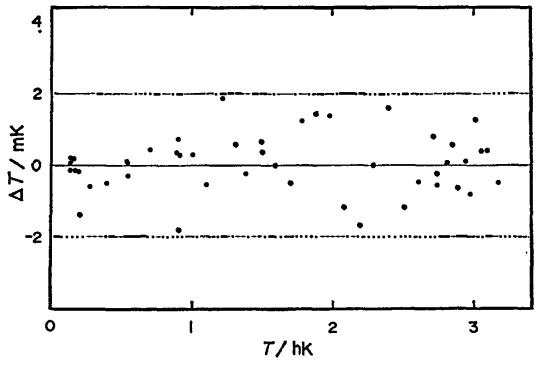

Fig. 4. Deviation plot of a working platinum resistance thermometer.

The resistance-temperature relation was established by measurements at eight fixed temperatures and by use of the interpolation formula according to the IPTS-68 in the temperature range from 13.81 to 320 K. The calibration table was given at an interval of 0.1 K and was stored in the casette tape. Figure 4 shows the deviations of the measured temperatures with use of the working thermometer from the IPTS-68 temperature scale.

Test Run for Cyclohexanol

The performance of the present automatic system was determined by measuring the heat capacity of cyclohexanol crystal. Table 1 reproduces a part of the experimental results taken with unattended operation for the low-temperature modification of cyclohexanol crystal. The bridge balance was taken at 0.94 Hz band width and the first data in an equilibration time was obtained usually about 4 min after an energy input. The notations A, B, E, C, D, G, H, and Y stand for resistance (in Ω), real time (in s), initial temperature (in K), heat capacity (in J K^{-1}), average temperature (in K), real time when an energy input was over, amount of input energy (in J) and the time duration of energy input (in s). A slight irregular variation of the bridge readings with time is not due to actual change of temperature but due to noise appearing in the thermometry circuits. This was confirmed by measuring the resistance of the thermometer with d.c. bridge. Difficulties of complete elimination of noise in the bridge circuitry lead us to take the method of averaging the latest six data points in determining an equilibrium temperature.

Figure 5 gives a graphical plot of the heat capacity data obtained for cyclohexanol crystal around liquid nitrogen temperature. In the figure, the filled circles represent the data obtained by the present automatic system with a.c. thermometry, while the open circles by the manual method with d.c. thermometry. Both of them coincide each other within 0.1% error. The accuracy of the calorimeter with d.c. thermometric technique has already been determined[11] by the use of standard benzoic acid crystal recommended by the US Calorimetry Conference.[13]

β-Relaxation Phenomenon of Cyclohexanol

A secondary (β) relaxation was observed[4] in the glassy crystalline state of cyclohexanol by dielectric measurement. The dielectric loss peak associated with the β relaxation was much smaller than that of primary (α-relaxation responsible for glass transition around 150 K. A plot of logarithm of the frequency of maximum dielectric loss against reciprocal temperature gave a linear line for the β relaxation, in contrast to the non-linear behavior for the α relaxation. Since the glass

transition temperature of cyclohexanol observed calorimetrically corresponded to the temperature at which the dielectric relaxation time of α relaxation becomes of the order of 10^3 s, we extrapolated simply the Arrhenius plot to the same time scale. The temperature at which the mode for the β relaxation is expected to be frozen in was about 75 K.

We have pointed out[4] already that the heat capacity of the glassy crystalline cyclohexanol started to deviate from that of low-temperature modification at around 70 K and the anomalous increase may be associated with the onset of motion responsible for the β relaxation. A close examination of the previous heat capacity data of cyclohexanol in that temperature region does not disclose any anomalous behavior in temperature drift. This may be due to rather large heat leakage arizing from incomplete adiabatic condition at that time. Since the techniques in realizing adiabatic condition have been much improved, we attempted to reinvestigate the thermal behavior of glassy crystalline cyclohexanol.

The glassy crystalline cyclohexanol was prepared by cooling the high-temperature modification with an average rate of -3 K min^{-1} in the temperature interval between 270 K and 90 K and the heat capacity measurements were initiated. Table 2 lists the heat capacity data relevant to the temperatures in problem. Series I is for the specimen cooled rapidly from 90 K to 20 K with the rate of -1 K min^{-1}, while series II is for annealed specimen at 64 K for about 40 h. These data are plotted in Fig. 6 in the form of excess heat capacities over that of low-temperature modification so as to exaggerate an anomalous behavior that may be encountered. Also shown below in the figure is the rate of temperature drift. Thermal equilibrium was attained usually during 4 or 5 min after turning off the calorimeter heating. At temperature around 60 K, a marked exothermic temperature drift was observed for quenched specimen. The drift changed into an endo-

thermic one around 70 K on further heating and returned to normal behavior around 80 K. In this temperature interval, no energy-input command signal was issued during equilibration period and 30 data points were accumulated for each drift period. In the calculation of heat capacity, effect of the temperature drifts was treated as if they were arizen from thermal leakage.

While for the annealed specimen, a humped heat-capacity anomaly was observed and the corresponding temperature drift was endothermic in the relevant temperature interval. These thermal behavior are characteristic of a freezing phenomenon and it seems to be natural to ascribe these anomalies to the β relaxation.

Many explanations can be offered to account for the presence of secondary relaxation. We have discussed previously[4] the origin of the β relaxation of cyclohexanol crystal in terms of intramolecular motion of OH groups between two hydrogen-bonded states, in an analogous way with those traditionally invoked for polymer and molecular glasses.[14] Systematic studies[15] of a number of molecular glasses which lack either a side chain or any other internal degree of freedom have revealed a remarkable similarity in the dielectric relaxation of these glasses to those of polymers, and a surprizing uniform pattern of behavior. The conclusion drawn from the study was that the molecular mobility seen as β relaxation is intrinsic nature of the glassy state. Although a few models were proposed for the structure of amorphous solid that is consistent with the general occurrence of β relaxation phenomenon, there seems no experimental method that favors one of them. An accurate statistical mechanical approach to the description of thermodynamic and kinetic features of the frozen-in disordered system is highly desirable.

The present studies were supported in part by the Grant-in-Aid for Scientific Research from the Ministry of Education. We wish to thank Mr. N. Nakamura for helping us in a part of the experimental work.

Calorimetric Study on Orientationally Disordered Crystals. Cyclohexene Oxide and Cyclohexanone†

Nobuo NAKAMURA, Hiroshi SUGA,* and Syûzô SEKI**

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 22, 1980)

Low-temperature calorimetric quantities were determined for cyclohexene oxide and cyclohexanone in the temperature range between 13 and 300 K. Molar heat capacity at saturation pressure of the condensed phases, transition and melting temperatures, and enthalpies of transition and melting were measured by an on-line automated adiabatic calorimeter with intermittent heating mode. Purities of both calorimetric specimens were determined from their melting behavior. The following thermodynamic quantities, C_S°, S_S°, $[H_S^\circ(T)-H_S^\circ(0)]/T$, and $-[G_S^\circ(T)-H_S^\circ(0)]/T$ were tabulated at selected temperatures. The entropies of melting of both compounds were compared with those of cyclohexanol and cyclohexane. A factor affecting the entropy of melting was discussed from the viewpoint of non-globularity of the constituting molecules. The discussion was extended to the thermal stability of a number of orientationally disordered crystals so far studied.

Abrupt changes in the freedom of molecular motion within the crystalline solid are still among the most fascinating and least understood of physical properties. A class of crystals in which the orientational degrees of freedom of the constituent molecules are highly disordered was defined by Timmermans[1] as plastic crystals because of their high plasticity. In such a phase, the constituent molecules are located on a regular lattice with high crystallographic symmetry and reorient rapidly among several orientations. The other characteristic features of the phase are higher triple point and lower entropy of fusion in comparison with the crystal composed of less symmetric molecules. Actually it was the low entropy of fusion which led Timmermans to the recognition of plastic crystals as a unique intermediate state of matter. He set rather arbitrarily an upper limit of 5 cal K^{-1} mol^{-1} ($\simeq$21 J K^{-1} mol^{-1}) to the entropy of fusion for the criterion of plastic crystals. He recognized that such crystals are typically made up of "globular" molecules. Here, the term "globular" means either spherical or pseudo-spherical by rotation around an axis. Thus, attention of various workers in this field has been paid mainly to the crystals composed of such symmetrical tetrahedral molecules as CX_4 type, octahedral molecules as MX_6 or C_2X_6 type, cyclic molecules as cyclohexane, and caged molecules as camphor.

When we had measured the thermodynamic properties of cyclohexanol,[2] we noticed that the entropy of fusion of less symmetric and less globular cyclohexanol was smaller than that of cyclohexane. At that time, we considered that the smaller entropy of fusion originated from association effect due to intermolecular hydrogen bonding in the liquid state of cyclohexanol. This effect was found really to exist in 2-methyl-2-propanol[3] and methanol. NMR observation[4] of the cyclohexanol, however, revealed highly disordered nature of orientational and positional degrees of freedom of the molecules in the crystal. Intra- and intermolecular dipolar broadening of protons are averaged out so extensively that chemical shifts of proton—OH, CH(α), CH(β), and CH(γ)—are able to observe even in the crystalline state. There might be a possibility that less globular shape of the molecule caused to reduce the entropy of melting. In order to consider factors of the constituent molecules that diminish the entropy of melting and hence enhance their characteristics as the plastic crystals, thermal properties of cyclohexene oxide and cyclohexanone were measured with an adiabatic calorimeter in the temperature range between 13 and 300 K. Both compounds are non-globular and lack their ability of hydrogen bonding formation. Previous DTA experiments[5,6] for both compounds revealed their ability to form plastic crystalline phases. Heat capacity data of cyclohexanone are available literally[7] only for a limited temperature range.

Experimental

Materials. Cyclohexene oxide (Tokyo Kasei Co. Ltd., G. R. grade) was fractionally distilled in a double-wall glass column operated at a high reflux ratio. Temperature of the still was monitored by a thermocouple. Fractions were compared by differential thermal analysis (DTA) to monitor the purity of that part. The best fraction of the distillate was further purified by vacuum distillation and finally distilled into calorimeter cell *in vacuo*. A part of the purified specimen was transferred into a DTA tube and was used for characterization of thermal behavior. Since the material is easily polymerizable at high temperature, the sample was kept below 5 °C. The purity of the calorimetric sample was determined to be 99.97_3% from the analysis of equilibrium melting curve described later.

Cyclohexanone (Tokyo Kasei Co. Ltd., G. R. grade) was subjected to essentially the same purification process as that of cyclohexene oxide. The final purity was determined to be 99.91_9%.

Apparatus. Heat capacity measurements were made by the on-line automated calorimeter[8] built recently in our laboratory. The temperatures of the inner and the outer shields, and the tempering ring were controlled with separate temperature controllers. The electrical power supplied to the calorimeter heater was measured with a digital voltmeter operated by a program unit. Resistances of a working platinum thermometer were measured by a.c. double bridge and stored in a mini-computer. After reaching an equilibrium state, the equilibrium resistance value was converted into the

† Contribution No. 5 from Chemical Thermodynamics Laboratory.

IPTS-68 temperature scale and the heat capacity was calculated during the measurement. The sample cell equipped with horizontal perforated heat-distributing disks of platinum contained 29.901 g (0.30467 mol) of cyclohexene oxide and 26.081 g (0.26473 mol) of cyclohexanone, respectively.

Results

DTA. Thermal behavior of cyclohexene oxide at low temperatures was examined by use of DTA, the result being given in Fig. 1. Run 1 shows the cooling curve with a rate of -1.5 K min^{-1}. Run 2 and Run 3 are the subsequent heating curves, respectively. The heating curve Run 3 is in good agreement with that previously reported.[5] All the phase changes undercooled easily. A new intermediate phase was observed to appear always on cooling the liquid. From a comparison of respective peak areas, the intermediate phase as well as the high temperature phase are considered to be highly disordered state. Considering the manner by which the respective phase changes take place, the intermediate phase is expected to be a metastable phase.

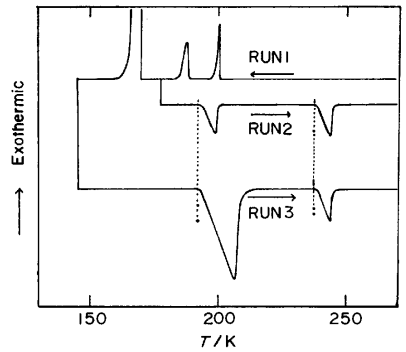

Fig. 1. DTA curves of cyclohexene oxide.

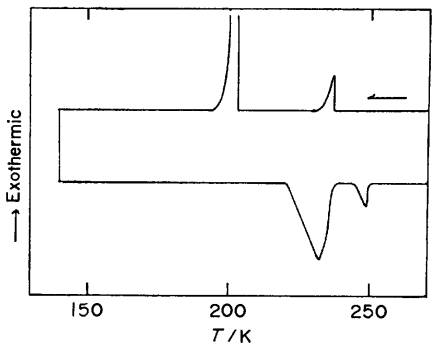

Fig. 2. DTA curves of cyclohexanone.

Figure 2 gives DTA curves of cyclohexanone for cooling and heating. Both of the solidification and solid-solid phase transition were found to undercool considerably. The peak due to the phase transition observed for heating is a little anomalous in shape and suggests a possibility that the transition proceeds in two or more steps. This possibility was examined carefully in later heat capacity measurement.

Heat Capacity. The experimental heat capacity determinations are presented in Table 1 for cyclohexene

oxide and in Table 2 for cyclohexanone, along with the approximate temperature increments. In most cases, the temperature increments were small enough to eliminate the need of curvature correction. Correction of the vaporization was found to be negligible in both cases. The imprecision of the experimental heat capacity was usually less than 0.1%, except in the transition and melting regions. The loss of precision in these ranges was caused by slow thermal and compositional equilibration. Accuracy uncertainty in heat capacity is about 1% below 20 K and 0.2% above 50 K. The heat capacity data are reproduced graphically in Figs. 3 and 4, respectively.

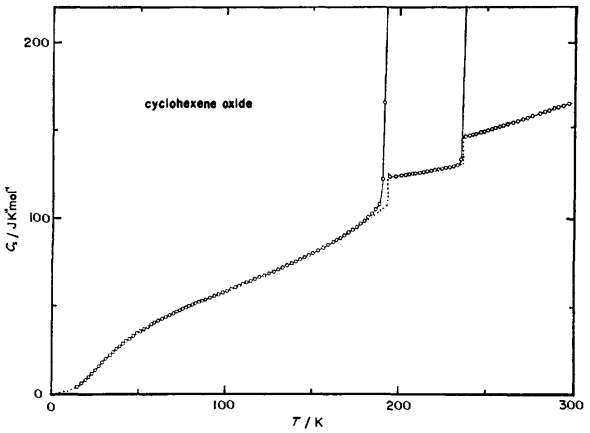

Fig. 3. Molar heat capacity of cyclohexene oxide.

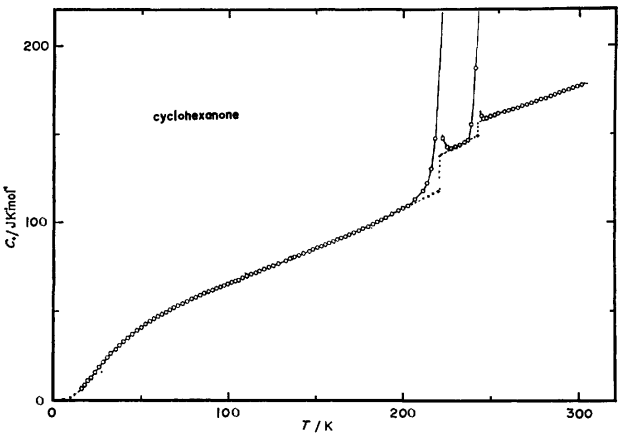

Fig. 4. Molar heat capacity of cyclohexanone.

Phase Transition. Cyclohexene oxide showed a sharp transition at 193.10 K. The thermal equilibrium was extremely difficult to attain during the transition. Hence, a temperature about 100 min after an energy input was regarded conveniently as an equilibrium temperature and was used for the calculation of apparent heat capacity. Figure 5 gives a plot of enthalpy increment against temperature during the course of phase transition of cyclohexene oxide. The transition proceeded in a single step and the temperature of transition was determined as the one at which the heat capacity reached its maximum value. The enthalpy of transition was determined from the total enthalpy

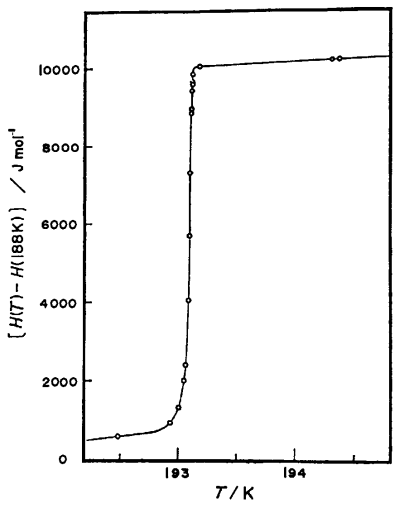

Fig. 5. Enthalpy change of cyclohexene oxide around the transition temperature.

change between equilibrium temperatures below and above the transition temperature. The isothermal increment was calculated by subtracting from the total enthalpy those part associated with the "normal" heat capacity given by dotted lines in Figs. 3 and 4, respectively. The results of replicate determinations of the enthalpies of transition for both compounds are summarized in Table 3.

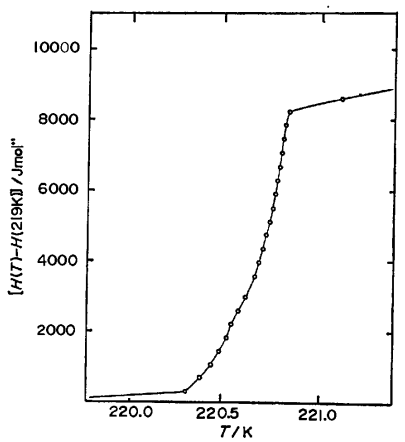

Fig. 6. Enthalpy change of cyclohexanone around the transition temperature.

Enthalpy increment during the course of the phase transition of cyclohexanone is plotted in Fig. 6 as a function of temperature. Here, the phase transition takes place over a temperature range and does not proceed uniformly. In order to make clear this situation, apparent heat capacities were calculated over the transition range and they are given in Fig. 7. Evidently, the transition proceeds in two steps. This observation accords well with suggestion by Crowe and Smyth[9] from their dielectric study and with phase diagram study of cyclohexanone–CCl_4 system by Miltenburg.[7] Würflinger and Kreutzenbeck have found a third modification of cyclohexanone by DTA under high pressures. They reported that the triple point among the three crystalline phases coincided with atmospheric pressure within the limits of experimental error. They could not reveal a superposed second solid-solid transition at atmospheric pressure by their DTA experiment, possibly because of their high heating rate.

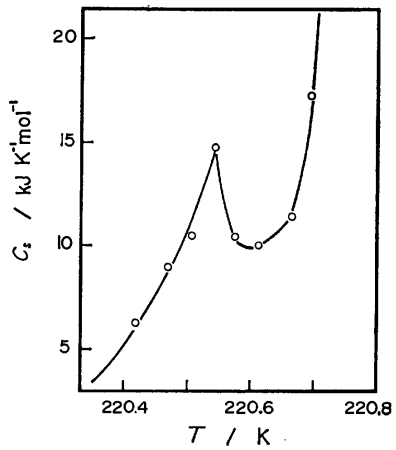

Fig. 7. Apparent heat capacity of cyclohexanone around the transition temperature.

Cataliotti and Paliani[10] reported the existence of an additional phase transition in cyclohexanone at 168 K. However, this or any other phase transition was not observed by the present calorimetric work.

Enthalpy of Melting and Sample Purity. The enthalpy of melting was determined as the isothermal

segment of the enthalpy required to heat from an initial equilibrium temperature of the crystal to a final temperature of the liquid. Here, a normal heat capacity was assumed, being represented as the dotted lines in Figs. 3 and 4.

For the determination of the melting point and the purity of the sample, a fractional melting experiment was carried out. The equilibrium temperatures $T(f)$ were observed at several fractions f of the sample melted. The melting temperature plotted against the reciprocal fraction did not give a straight line, indicating a possibility of solid-soluble impurity scheme. Following the theoretical treatment by Mastrangelo-Dornte,[11] we have estimated the total amount of impurities x and the triple point of pure compound $T°_m$. These melting data are summarized in Tables 4 and 5.

Thermodynamic Functions. The experimental heat capacities were smoothed by a spline fit and then numerically integrated to obtain the final tabular values of the standard thermodynamic functions. They are listed in Tables 6 and 7 at selected round temperatures. Below the lowest temperature attained, the heat capacity data were extrapolated by means of the Debye law. The parameters of the Debye functions were assigned as θ=140 and 132 K for six degrees of freedom for cyclohexene oxide and cyclohexanone, respectively.

Discussion

Characterization of the plastically crystalline state is a topic of current solid-state chemical and physical interest.[12] The appearance of the plastic crystal state has been attributed to the onset of molecular reorientational motion in the solid and can be expected for globular molecules, *i.e.*, molecules of high symmetry and nearly spherical shape. The distinct difference between the phase behavior of pentane and of neopentane is cited in many textbook[13] as showing the importance of globularity of the constituent molecules in the formation of plastic crystals. A suggestion[14] that plastic crystals might better be called "crystals with globular molecules" reflects this widespread recognition.

The values of ΔS_m for cyclohexene oxide and cyclohexanone are comparable in magnitude to that of cyclohexanol,[2] 5.68 J K^{-1} mol^{-1} and less than that of cyclohexane,[15] 9.56 J K^{-1} mol.$^{-1}$ The relevant thermodynamic data are summarized in Table 8. This fact means that the calorimetric feature as the plastic crystalline behavior is enhanced by reduction of globularity of the constituent molecules. As pointed out already, the subject of plastic crystals began from the recognition by Timmermans that the crystal has considerably small entropy of melting and that the

crystal is of high crystallographic symmetry.

The f.c.c. lattice is the one most frequently encountered for the plastic crystalline phase in which the constituent molecules have intense orientational disorder. Actually, cyclohexane, cyclohexanone and cyclohexanol are known to crystallize in f.c.c. lattice.[16] That of cyclohexene oxide has not yet been determined. However, X-ray powder diffraction experiment[5] gave a characteristic photograph of the plastic crystals; relatively intense background and a few diffuse Bragg scattering associated with large Debye-Waller factor. While the parent molecule, cyclohexane, has D_{3d} symmetry, the three oxy-derivatives can not be expected to have any symmetry element other than mirror. Microwave experiment[17] of cyclohexene oxide shows that the molecule has no symmetry.

In order to fulfil a high crystallographic site symmetry at the lattice point, molecules must reorient among several orientations. The time-averaged distribution of a molecule tends towards spherical symmetry, hence the closest packed structure is realized. A less symmetric molecule has to compensate by taking a greater number of molecular orientations than a symmetric molecule. Short-range repulsive interactions between neighboring molecules cause the reorientational motion of an asymmetric molecule to couple more closely with lattice vibrational motion, because the asymmetric molecule must reorient itself by displacing its center of mass from the lattice point. Observation of anomalously large Debye-Waller factors for these crystals reflects this coupling effect. The stronger the coupling, the smaller will be the entropy of melting, since partial positional disordering occurs concomitantly with orientational disordering at the phase transition. The stronger the coupling, the narrower will be the temperature range of plastic crystalline phase, since vibrational motion is highly excited at the phase transition. According to the simple picture by Lindemann,[18] melting might be expected when the mean amplitude of lattice vibration becomes some fraction of the lattice distance.

In order to test this intuitive idea, the relation between the entropy of melting and the temperature range of the plastic crystalline phase is examined for some plastic crystals composed of molecules with various symmetries. A list of some plastic crystals is given in Table 9, along with data for ΔS_m in units of J K^{-1} mol^{-1}. For the range of entropies of melting suggested by Timmermans for plastic crystals (<21 J K^{-1} mol^{-1}) we consider three groups: category A (ΔS_m/J K^{-1} mol^{-1} >14); category B ($14>\Delta S_m$/J K^{-1} mol^{-1} >7); category C ($7>\Delta S_m$/J K^{-1} mol^{-1}). We note that category A contains octahedral molecules or almost spherical molecules while many diatomic or tetrahedral molecules and some cyclic or caged molecules are to be found in category B. Category C contains the least globular molecules. Inert gas molecules like argon and krypton have entropies of melting between categories A and B (≈ 14 J K^{-1} mol^{-1}). They show rather high plasticity and the vapor snake phenomenon[19] near their mp. Although these crystals exhibit no phase transition, they can be legitimately considered as plastic crystals. The fact that ΔS_m values for non-globular molecules are less than those for spherical molecules (Ar, Kr) suggests strongly the importance of the orientation-position coupling effect. This coupling will also affect the temperature range in which stable plastic crystals can exist. The plastic crystals belonging to category A have a wide temperature range of existence. This is

Table 9. Entropies of fusion of some plastic crystals

		$C_6H_{10}O$ cyclohexene oxide (4.48)	

exemplified typically by 220 K for hexamethylethane, and 335 K for adamantane. On the other hand, the compounds belonging to category C are characterized by quite narrow plastic crystal ranges: 45 K for cyclohexene oxide; 34 K for cyclohexanol; 25 K for cyclohexanone.

The present conclusion that non-globularity of the constituent molecules operates to diminish the value of ΔS_m and to narrow the plastic crystal range has some limitations. If the non-globularity of molecule exceeds some critical value, the hindering potential opposing randomization of orientation of the molecule increases too much for the orientationally disordered state to be realized before the melting point is reached. In this sense, cyclohexanone may be considered as an extreme case of a cyclohexane derivative that can exist as a plastic crystal. Pople and Karasz[20] were the first to take account of the fact in a rather qualitative way. In view of the complex nature of the intermolecular forces in this particular crystal, it is still not possible to define a critical parameter in a quantitative way.

Although the physical significance of the smallness of ΔS_m of plastic crystals has still to be clarified satisfactorily, this calorimetric feature should be correlated with the mechanical feature of the crystals. Dunning[16] suggested that the high plasticity may be analogous to the high-temperature creep of metals, which has been ascribed to the diffusional motion of vacancies through the crystalline lattice. It is this motion that also accounts for the easiness of self-diffusion observed in a number of plastic crystals and may have some correlation with the unusual freezing behavior called "vapor snake phenomenon."[19] Organic crystals in which the self-diffusion has been observed by NMR study were all characterized by their low values of ΔS_m. A kinetic parameter governing the self-diffusion in the highly disordered crystal was correlated well with the melting parameter[21] of the crystal. Valuable advances will be made by such correlation between more than one property of the plastic crystals.

Thermochemical Estimation of Destabilization Energies of 1,2-, 1,3-, and 1,4-Dicyanobenzenes Due to Interactions between Substituents. Appendix: Dipole Moments in Solution of the Dicyanobenzenes†

Tomoko SATO-TOSHIMA,** Minoru SAKIYAMA,* and Syûzô SEKI***
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received March 7, 1980)

Enthalpies of combustion of 1,2-, 1,3-, and 1,4-dicyanobenzenes were determined by precision oxygen-bomb calorimetry. Enthalpies of sublimation of these compounds were obtained by the measurement of temperature dependence of vapor pressure. The standard enthalpies of combustion ΔH_c°(298.15 K)/kJ mol^{-1} and the standard enthalpies of sublimation ΔH_s°(298.15 K)/kJ mol^{-1} are as follows: -4000.36 ± 0.67 and 86.9 ± 1.5 for 1,2-dicyanobenzene; -3992.29 ± 0.75 and 90.1 ± 1.5 for 1,3-dicyanobenzene; -3988.04 ± 0.59 and 88.8 ± 1.5 for 1,4-dicyanobenzene, respectively. Thermochemical destabilization energies were estimated by comparing the derived standard enthalpies of formation in gaseous state with those estimated for hypothetical non-destabilized molecules. They were discussed in terms of electrostatic interactions between highly electronegative and dipolar cyano substituents on one and the same benzene ring. Dipole moments of the dicyanobenzenes in benzene and dioxane solutions are reported in Appendix.

Determination of standard enthalpy of formation in gaseous state of a compound is the essentially sole experimental method to evaluate intramolecular energy of molecules. The method has been applied for polyhalobenzenoid compounds to study the interaction energies between substituents by Cox *et al.*,[1,2] who have shown the need to take account of electrostatic interactions between the substituents in the interpretation of standard enthalpies of formation in gaseous state.

As is well-known, a cyano group as well as halogen atoms is highly electronegative substituent. In addition, a cyano group is considered to be dipolar by itself. Thus, a cyano group has been situated at the most electronegative end of general electronegativity sequence of substituents.[3] Cyanohydrocarbons exhibit dipole moments higher than 3 Debye†† as a rule.

This study has been carried out to elucidate the interaction between cyano substituents on one and the same benzene ring. For this purpose, the standard enthalpies of combustion of 1,2-, 1,3-, and 1,4-dicyanobenzenes each in the crystalline state were measured by oxygen bomb calorimetry. Enthalpies of sublimation of the compounds were determined from the measurement of temperature dependence of vapor pressure. In this paper, results of the calorimetric and vapor pressure measurements are reported. From standard enthalpies of formation in gaseous state thus derived, destabilization energies were estimated and discussed in terms of electrostatic interactions between cyano substituents on the same benzene ring.

Experimental

Materials. Commerical 1,2-dicyanobenzene (Tokyo Kasei, G. R.) was purified by recrystallization from benzene and acetone solutions, and then by fractional sublimation *in vacuo* (0.1 Pa). Orthorhombic and monoclinic crystals are known for this compound,[4,5] though it is not clear which form is more stable. The purified sample showed neither exothermic nor endothermic anomalies between ambient and melting temperatures on DSC curves. In this respect the sample obtained is supposed to be in the stable form. 1,3-Dicyanobenzene supplied from Nihon Shokubai Kagaku Co., Ltd., and commerical 1,4-dicyanobenzene (Nakarai, G. R.) were purified by recrystallization from benzene solution, and subjected to fractional sublimation *in vacuo* (0.1 Pa), and again recrystallization from acetone solution. After brief drying *in vacuo*, a pellet drying procedure[31,32] was applied for the samples. A small endothermic peak with complicated shape was observed at *ca.* 430 K in every DSC heating curve of the latter compound, but the anomaly was not studied in further detail. Purity assessment for the three samples by DSC continuous method gave values higher than 99.9%.

Combustion Calorimetry. A rotating bomb calorimeter of isoperibol type with a platinum-lined bomb, described elsewhere,[6] was used in this study without rotating the bomb. The calorimeter was calibrated with the United States National Bureau of Standards S. R. M. 39i benzoic acid . The mean and standard deviation of mean for energy equivalents of the standard calorimetric system from six calibration experiments were (15164.84 ± 0.53) J K^{-1}.

The dicyanobenzenes are as volatile as may be purified by vacuum sublimation. However, no significant loss in mass was observed for pellets of the compounds each weighing about 1 g, when placed in air at ambient temperatures for several hours. All the combustion experiments were, therefore, carried out without enclosing the samples. An ordinary platinum crucible weighing 11.1 g was used to burn pellets of the compounds. In some of the experiments on 1,4-dicyanobenzene a deep platinum crucible with a baffle (total mass: 29.5 g) described previously[7] was employed, since the pellets showed some tendency of explosion to get out of the open crucible when partially burnt.

In order to determine a small amount of nitric acid produced as a by-product of combustion, the internal space of the bomb was washed with distilled water and the washings were adjusted to 100 cm^3. The nitric acid in the washings was titrated potentiometrically with sodium hydroxide solution, which in turn was standardized with potassium dihydrogenphosphate. Nitric acid formed in the calibration experiments was determined spectrophotometrically by using a UV absorption band

Measurement of Temperature Dependence of Vapor Pressure. The vapor pressures of the samples were measured relatively with a DuPont Model 916 Thermal Evolution Analyzer, which was used in conjunction with a DuPont 990 Thermal Analysis System. It is based on the gas-saturation method and a flame ionization detector (F. I. D.) is used for quantitative determination of a small amount of organic species effused from the Knudsen type cell to carrier gas.[8] Increase h in the F. I. D. current caused by saturation of the carrier gas with the effused organic vapor was measured as a function of temperature. The quantity h is taken to be proportional with the saturation vapor pressure of the compound. Details of the experimental procedures were described elsewhere.[9]

Auxiliary Quantities. The experimental results were based on relative atomic weights recommended by IUPAC Commission on Atomic Weights (1970). The data of density ρ, specific heat capacity c_p, and compression energy $(\partial E/\partial p)_T$ at 298.15 K used for reduction to the standard state and for correction of weights in air to masses are shown in Table 1. The densities of the dicyanobenzenes given in Table 1 were determined by measuring the mass of a pellet of measured size as was reported by Good *et al.*[10] The procedure was examined for benzoic acid. The derived density (1.32 g cm^{-3}) agreed well with a literature value.[30] The densities thus determined were in fair agreement with the values obtained by X-ray method: 1.25 and 1.21 g cm^{-3} for orthorhomboic[4] and monoclinic[5] forms of the 1,2-isomer, respectively, and 1.283 g cm^{-3} for the 1,4-isomer.[20]

The specific heat capacities and compression energies for the dicyanobenzenes given in Table 1 are estimated values. Other auxiliary quantities used in the calculation are also collected in the table. Uncertainties given in this paper are uncertainty intervals defined by Rossini,[33] *i. e.* twice the final overall standard deviation of mean, unless otherwise stated.

Results

Standard Energies of Combustion. Six combustion experiments were carried out for 1,2- and 1,3-dicyanobenzenes, respectively. Eight combustion experiments were carried out for 1,4-dicyanobenzene, among which the deep crucible with a baffle was employed for six samples. The idealized combustion reaction at 298.15 K, to which standard energies and enthalpies of combustion refer, is expressed by the following equation:

$$C_8H_4N_2(c) + 9O_2(g) = 8CO_2(g) + 2H_2O(l) + N_2(g).$$

Results of typical combustion experiments are shown in Table 2. Symbols used in the table are similar to those used by Hubbard *et al.*[12] except for ΔE (std. state), which is the sum of items 81—85 and 87—94 as defined by Hubbard *et al.*[12] Six derived standard energies of combustion ΔE_c°/kJ mol^{-1} for 1,2-dicyanobenzene were −4000.12, −4000.36, −3999.52, −4000.08, −4001.44, and −4000.65, respectively, and mean and standard deviation of mean was −(4000.36±0.26). For 1,3-dicyanobenzene, they were −3991.43, −3991.88, −3991.60, −3992.73, −3992.66, and −3993.41, and mean and standard deviation of mean was found to be −(3992.28±0.31). For 1,4-dicyanobenzene, they were −3988.61, −3988.23, −3987.35, −3988.59, −3988.73, −3987.88, −3987.72, and −3987.23, of which the latter six were obtained by using the deep crucible with a baffle. Mean and standard deviation of mean were −(3988.42±0.19) for

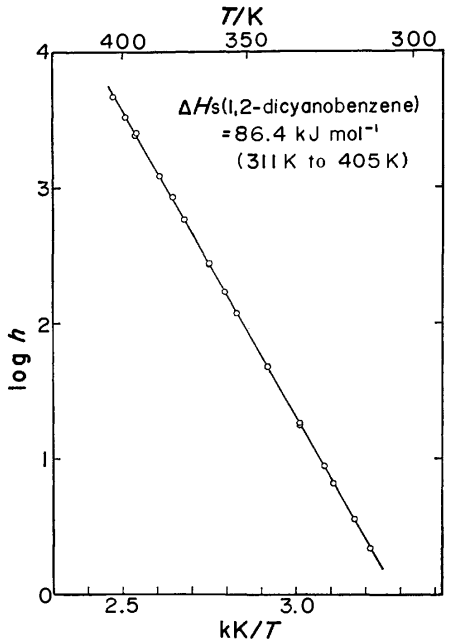

Fig. 1. Temperature dependence of vapor pressure of 1,2-dicyanobenzene. The quantity h is proportional to saturation vapor pressure of the compound and is given in arbitrary unit.

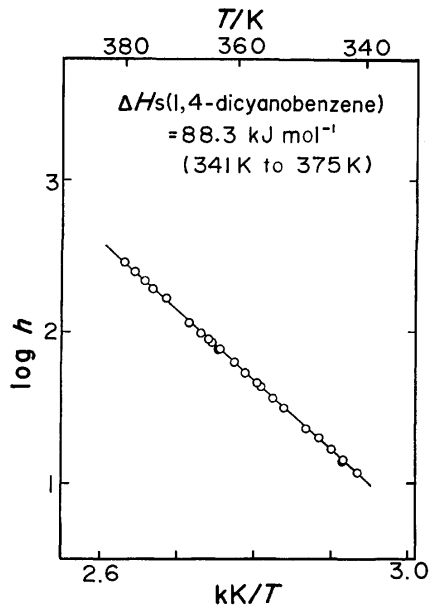

Fig. 3. Temperature dependence of vapor pressure of 1,4-dicyanobenzene. The quanitty h is proportional to saturation vapor pressure of the compound and is given in arbitrary unit.

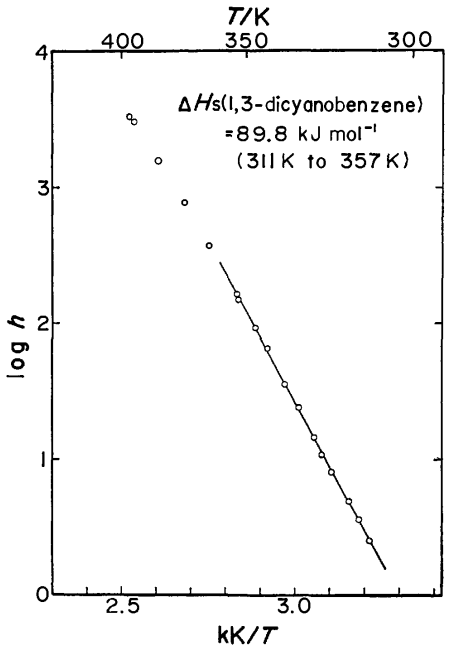

Fig. 2. Temperature dependence of vapor pressure of 1,3-dicyanobenzene. The quantity h is proportional to saturation vapor pressure of the compound and is given in arbitrary unit.

the former two and $-(3987.92\pm0.58)$ kJ mol^{-1} for the latter six experiments, respectively. In spite of difference in the mass of crucible and the amount of nitric acid formed between these kinds of experiments, the discrepancy of the derived enthalpies of combustion was not significant. Hence, the final mean and standard deviation of mean for 1,4-dicyanobenzene were calculated for all of the combustion experiments as follows: ΔE_c°/kJ mol^{-1} $=-(3988.04\pm0.21)$.

Enthalpies of Sublimation. Plots of log h against T^{-1} are given in Figs. 1, 2, and 3 for 1,2-, 1,3-, and 1,4-dicyanobenzenes, respectively. With a least squares method, the plots were fitted to straight lines and enthalpies of sublimation at mean temperatures were calculated from the slope of the straight lines on the basis of Clausius-Clapeyron equation. Vapor pressures are so low in the experimental temperature ranges that the enthalpies of sublimation were taken to be standard enthalpies of sublimation. The derived standard enthalpies of sublimation ΔH_s°/kJ mol^{-1} and mean temperatures T_m/K are as follows: 86.4 ± 1.5, 358 for 1,2-dicyanobenzene; 89.8 ± 1.5, 334 for 1,3-dicyanobenzene; 88.3 ± 1.5, 358 for 1,4-dicyanobenzene, respectively, where uncertainties are estimated values. Reduction of the standard enthalpies of sublimation at the mean temperatures to those at 298.15 K were performed by estimating molar heat capacities common to three

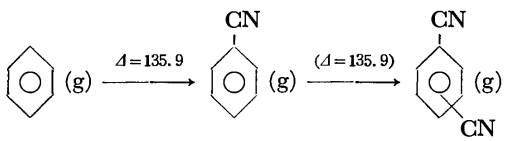
dicyanobenzenes in gaseous and crystalline states. For gaseous state group contributions given by Benson *et al.*[13] were used and for crystalline state specific heat capacities were assumed to be given by the following expression: c_p/J K^{-1} g^{-1}=1.10+0.0035 (T−298.15). The corrections amounted to +0.5, +0.3 and +0.5 kJ mol^{-1} for 1,2-, 1,3-, and 1,4-dicyanobenzenes, respectively.

Derived Thermodynamic Quantities. In Table 3 are given the standard energies of combustion ΔE_c°(c) and standard enthalpies of combustion ΔH_c°(c) determined for three dicyanobenzenes together with standard enthalpies of sublimation ΔH_s° and derived standard enthalpies of formation of crystalline state ΔH_f°(c) and of gaseous state ΔH_f°(g) at 298.15 K. ICSU-CODATA key values[14] for standard enthalpies of formation of CO_2(g) and H_2O(l) were employed to calculate the standard enthalpies of formation in crystalline state.

Discussion

Comparison with Literature Values. No thermochemical determinations have been reported so far for 1,2-, 1,3-, and 1,4-dicyanobenzenes, except for the combustion calorimetric result of Salley and Gray[15] for the 1,2-isomer. The reported standard enthalpy of combustion, corrected for molar atomic masses and density, is −3995.49±1.00 kJ mol^{-1}, which is well outside the uncertainty interval of the present result, the difference being *ca.* 0.125% of the total. The calorimetric sample of Salley and Gray had been purified by recrystallization of a commercial sample from ethanol solution and had a melting point of 411.7—413.2 K. The observed nitrogen content was 99.0% of the theoretical. They stated that the accuracy of their value was almost certainly poorer than the precision (*e.g.*, 0.025% for 1,2-dicyanobenzene) of determinations, since the purity of the sample was the limiting factor.[15] In addition, 1,2-dicyanobenzene was not included in their list of compounds which was considered to be relatively pure.

Estimation of Destabilization Energies. The increment of intramolecular energy which is accompanied by the substitution of one cyano group to a benzene ring was evaluated as the difference (Δ=+135.9 kJ mol^{-1}) between the enthalpy of formation in gaseous state ΔH_f°(g) of cyanobenzene[16] and that of benzene,[17] as illustrated below:

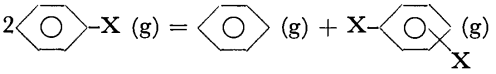


$\frac{\Delta H_f^\circ(g)}{\text{kJ mol}^{-1}}$: 82.9 218.8 (354.7)

If the increment, 135.9 kJ mol^{-1}, were assumed to be transferable to the substitution of the second cyano group, the standard enthalpy of formation in gaseous state of dicyanobenzene would be 354.7 kJ mol^{-1} as shown above. This value may be taken to be the standard enthalpy of formation in gaseous state of hypothetical "non-destabilized" dicyanobenzene. Comparison of the experimental values with this value gave destabilization energies of 12.8±1.9, 8.0±2.0, and 2.4±1.9 kJ mol^{-1} for 1,2-, 1,3- and 1,4-dicyanobenzenes, respectively.††† Among them, the 1,4-isomer is most stable and barely destabilized, the 1,3-isomer is intermediate and the 1,2-isomer is least stable. In this scheme, contributions from interactions between a benzene ring and a cyano group is eliminated automatically. Hence, the destabilization energies thus calculated are related only with interactions between the cyano-substituents.

Table 4. Destabilization energies E_{destab} of di-substituted benzenes

The energies were calculated as enthalpy changes for the following hypothetical reactions:



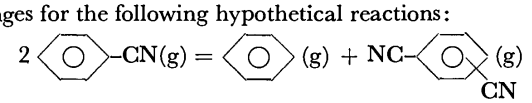
Isomer	E_{destab}/kJ mol^{-1}		
X=	F	Cl	CN
1,2-	21.2	10.4	12.8
1,3-	5.7	6.2	8.0
1,4-	8.4	2.9	2.4

Destabilization energies calculated similarly for difluoro- and dichlorobenzenes[17] were compared with those of dicyanobenzenes in Table 4. Destabilization energy of dicyanobenzene are of similar magnitude to that of the corresponding dichlorobenzene and lower than that of the corresponding difluorobenzene. It is worth noting that for difluorobenzene the 1,3-isomer is more stable than the 1,4-isomer in contrast to the trend found in dichloro- and dicyanobenzenes. Niessen[18] made *ab initio* MO calculations to obtain total energies of disubstituted benzenes including difluoro- and dicyanobenzenes. In all cases, the total energies were found to increase in the sequence of 1,3-, 1,4-, and 1,2-isomers in accordance with the trend experimentally found for difluorobenzenes. However, the differences in the total energies between 1,4- and 1,3-isomers and between 1,2- and 1,3-isomers obtained by Niessen were 0.67 and 2.72 kJ mol^{-1} for dicyanobenzenes, respectively, and 62.9 and 95.4 kJ mol^{-1} for difluorobenzenes, respectively. The latter differences are too large as compared with thermochemical values.

Interpretation of Destabilization Energies. The molecular structure of cyanobenzene was determined by Bak *et al.* from microwave spectroscopy.[19] The C–C distance of benzene is practically conserved in the structure. Changes of valence angles are definitely present, but are small (0—2.5°). The C–CN and C–N distances are 0.1455(7) and 0.1159(2) nm, respectively, where numbers in parentheses are estimated uncertainties for the final significant figures. The cyano group is coplanar with the benzene ring.

The molecular and crystal structures of 1,4-dicyano-

††† The destabilization energies are equivalent to enthalpy changes for the following hypothetical reactions:



benzene were determined by van Rij and Britton[20] from X-ray diffraction method. The C–C distances in the benzene ring are all normal. The C–CN and C–N distances are 0.1438(3) and 0.1147(4) nm, respectively, where numbers in parentheses are estimated standard deviations expressed in the same way as above. The cyano groups deviated from coplanarity significantly, but slightly. 1,2-Dicyanobenzene crystallizes in two forms: orthorhombic[4] and monoclinic.[5] X-ray diffraction studies on these crystals indicated that the bond distances in the molecule are almost equal to the corresponding ones in a 1,4-dicyanobenzene molecule and the cyano groups are almost coplanar with the benzene ring.[4,5] No structural determinations have been reported for 1,3-dicyanobenzene.

These facts show that no remarkable difference in corresponding molecular parameters are observed among cyanobenzene and 1,2- and 1,4-dicyanobenzenes. It seems likely that the same would hold for 1,3-dicyanobenzene. These statements may be part of the reasonings which support the estimation of distabilization energies between substituents based on the scheme described above.

The dipole moment of a free cyanobenzene molecule is 4.14 Debye, which has been determined by Lide from microwave spectroscopy.[21] Charge distribution and dipole moment of a cyanobenzene molecule in the ground state have been studied by using molecular orbital methods of various levels. At the level of semi-empirical all valence electron MO methods, King and van Putten[22] calculated charge densities on all the atoms of the molecule (CNDO/CI method) and Klasing *et al.*[23] calculated charge densities on carbon and nitrogen atoms (CNDO/2 method). Charge densities on cyano carbon and nitrogen atoms and negative charge donated from the benzene ring to the substituent were calculated to be $+0.090e$, $-0.212e$, and $-0.122e$ by King and van Putten[22] and $+0.089e$, $-0.166e$, and $-0.077e$ by Klasing *et al.*,[23] respectively. Bloor and Breen[24] used a CNDO/2 method to calculate contributions to total dipole moment from atomic charge densities (p^σ and p^π, where σ and π denote σ and π electrons, respectively) and from the atomic dipole moment(p_{sp}) arising from the mixing of the s and p orbitals on the same atom and including lone-pair moment of the hetero-atom. The derived results were as follows: $p^\sigma=0.25$, $p^\pi=1.52$ and $p_{sp}=1.45$ Debye and total dipole moment was 3.23 Debye. At the level of *ab initio* MO method, Hehre *et al.*[25] made a calculation with the minimal STO-3G basis set to determine the total dipole moment p and total σ and π charges, q^σ and q^π, donated from the benzene ring to the substituent. Derived results were as follows: $p=3.65$ Debye, $q^\sigma=-0.104e$, and $q^\pi=-0.022e$.

As described in Appendix, the dipole moments of 1,2- and 1,3-dicyanobenzenes in benzene solution amount to *ca.* 95% of the values calculated as vector sum of the dipole moment of cyanobenzene in benzene solution and that of the 1,4-isomer is, at least, nearly equal to zero. The dipole moments in dioxane solution showed similar tendency. The charge distribution in the cyano groups of dicyanobenzene molecules is considered to be similar to that in the molecules of cyanobenzene. This is another reasoning to support the use of the scheme described above to obtain destabilization energies.

Although the destabilization of 1,2-dialkylbenzene may be ascribed to repulsive interaction between buttressed alkyl groups, that of 1,2-dicyanobenzene may hardly be due to the same cause. The molecular orbital calculations did not reproduce exactly the experimental total permanent dipole moment of 4.14 Debye, but indicated that the dipole moment of cyanobenzene comes from (1) net charge donated from the benzene ring to the substituent, (2) polarization of the C–N bond and (3) lone pair electrons on the nitrogen atom. Hence, the destabilization in the dicyanobenzenes is most likely to be due to electrostatic interactions between the substituents.

The validity of the inference may be shown by the calculation described below. For simplicity, the electrostatic interaction is assumed to be represented by dipole-dipole interaction between electric dipoles located at the positions of nitrogen atoms. Interaction energy E_{el} between two electric dipoles with moments μ_1 and μ_2, respectively, is expressed by the following equation:

$$E_{el}=\frac{\mu_1\mu_2}{r_{12}^3}(3\cos\theta_1\cos\theta_2-\cos^2\theta_{12}), \qquad (1)$$

where, r_{12} is the distance between the dipoles, θ_1 and θ_2 are the inclination angles of them to the line of centers, and θ_{12} is the angle between them.

If the dipole-dipole interaction energy and the thermochemical destabilization energy for 1,2-dicyanobenzene (12.8 kJ mol^{-1}) are equated, the dipole moment of 3.27 Debye is derived. Use of this value together with equation (1) leads in turn to dipole-dipole interaction energies of 4.3 and 2.6 kJ mol^{-1} for 1,3- and 1,4-dicyanobenzenes, respectively. In this calculation the following assumptions were made of the molecular structure of the dicyanobenzenes: (i) C–C–N moiety is linear, (ii) the molecules are planar including the substituents, (iii) C–CN and C–N distances are transferable between 1,4-dicyanobenzene and both of the 1,2- and 1,3-isomer; the reported values for the 1,4-isomer[20] were used in common, and (iv) benzene rings are regular hexagons with C–C distances of 0.1393 nm.

The derived dipole moment, 3.27 Debye, is considered to be of reasonable magnitude in view of the observed dipole moments of the dicyanobenzenes in benzene and dioxane solutions and also the result of the MO calculations on cyanobenzene. The magnitude of the calculated dipole-dipole interaction energies for 1,3- and 1,4-dicyanobenzenes are comparable with the thermochemical destabilization energies. Thus, experimental results from thermochemical and dielectric measurements have been interpreted consistently on the basis of the single model. Accordingly, it may be concluded that electrostatic interactions between the cyano substituents on one and the same benzene ring are responsible for the destabilization observed for the molecules of 1,2-, 1,3-, and 1,4-dicyanobenzenes.

The authors are indebted to Mr. Keiichi Nishiyama and Mr. Junichi Furukawa, who assisted the determinations of enthalpies of sublimation and of dipole moments, respectively. They also thank Professor Doyle Britton of University of Minnesota, Professor Kenji Osaki and Dr. Tsuneyuki Higashi of Kyoto University, and Dr. Noritake Yasuoka and Mr. Atsushi Kume of Osaka University for communicating the results of X-ray diffraction studies prior to publication and Nihon Shokubai Kagaku Co., Ltd. for their kind supply of dicyanobenzenes.

Appendix

Dipole Moments in Solution of 1,2-, 1,3-, and 1,4-Dicyanobenzenes. Dielectric constant and refractive index were measured at 298.15 K for the benzene and dioxane solutions of the dicyanobenzenes in the range up to 0.15 mol dm^{-3}. The cell used for the dielectric measurement was similar to that described by Hassion and Cole.[26] Dielectric constant was measured at 1 kHz with a General Radio Type 1615 Capacitance Bridge.

Dipole moment, p, was calculated on the basis of the Guggenheim's equation:[27]

$$\left(\frac{p}{\text{Debye}}\right)^2 = \frac{9\times10^{36}kT}{4\pi N_A}\frac{3}{(\varepsilon_1+2)(n_1^2+2)} \times\left[\frac{(\varepsilon_{12}-n_{12}^2)-(\varepsilon_1-n_1^2)}{(c/\text{mol dm}^{-3})}\right]_{c\to0},$$

where ε_1 and ε_{12} are the dielectric constants of the solvent and solution, respectively, and n_1 and n_{12} are the refractive indices of the solvent and solution, respectively; c is the concentration, k the Boltzmann constant, and N_A the Avogadro constant. In Table 5, the derived dipole moments are presented and compared with the calculated values for benzene solutions, which were obtained as the vector sums of the dipole moment of cyanobenzene in benzene solution.[28,29]

Table 5. Dipole moment p in benzene and dioxane solutions of 1,2-, 1,3-, and 1,4-dicyanobenzenes

Compound	p/Debye[a]		
	In benzene		In dioxane
	Exptl	Calcd	Exptl
Cyanobenzene	4.05[c]	4.05	
1,2-Dicyanobenzene	6.57	7.00	6.82
1,3-Dicyanobenzene	3.86	4.05	3.99
1,4-Dicyanobenzene	——[b]	0	——[b]

a) Debye/C m$=3.333\times10^{-30}$. b) The value is small and not significant. c) Refs. 28 and 29.

Liposomal Membranes. III. Permeation of Pyrene-labeled Lecithin into Matrix of Liposomal Bilayers

Junzo SUNAMOTO,* Tadashi NOMURA, and Hiroshi OKAMOTO

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received February 27, 1980)

The permeation of a novel pyrene-labeled phosphatidylcholine, DPDL (1,2-bis[10-(1-pyrenyl)decanoyl]-*sn*-glycero-3-phosphatidylcholine), into the dipalmitoyl and egg phosphatidylcholine liposomes was studied. DPDL can adopt a sandwich conformation at the ground state, which comes in the fluorescence excimer emission. The fluorescent probe undergoes the initial rapid adsorption onto the liposome surfaces along with the instantaneous fluorescence enhancement followed by the relatively slow permeation into and diffusion in the liposomal bilayers. Through monitoring the relative quantum efficiency, I_e/I_m (see text), during the permeation, suggestive information about the bilayer structure is obtained at least around the probe. The initial binding to and the subsequent diffusion in the membrane occur mostly as the monomeric form of the probe. At lower temperature without cholesterol the bilayer structure seems to be a *lipid-separated* conformation (Fig. 1 (c)) and above the chain-melting transition the bilayer seems to exist as a *lipid-intimate* conformation (Fig. 1 (b)). These results completely coincide with those obtained in our previous study on the codispersion of the probe with phospholipids (J. Sunamoto, *et al.*, *J. Am. Chem. Soc.*, **102**, 1146 (1980)).

In a preceding paper we described syntheses of fluorescent probes, DPDL (1,2-bis[10-(1-pyrenyl)-decanoyl]-*sn*-glycero-3-phosphatidylcholine) and EP (ethyl 10-(1-pyrenyl)decanoate), and their fluorescence characteristics in the liposomal bilayers.[1] DPDL carries a pyrene moiety at the end of each fatty acyl chain of the lipid and can adopt a sandwich configuration of the pyrene moieties in the ground state, which fluorescence the excimer emission from the intramolecular ground state dimer.[1,2] When DPDL was codispersed with phosphatidylcholines, it could be intercalated in good order in the liposomal bilayers and gave meaningful informations about the structure of liposomal bilayers. (1) The relative quantum efficiency (the intensity ratio of the excimer emission at 480 nm to the monomer emission at 378 nm from DPDL, I_e/I_m) was significantly affected by the bilayer structure. (2) The addition of cholesterol into liposomes made the relative quantum efficiency larger. (3) Increasing temperature also caused an increase in the I_e/I_m ratio of DPDL in the egg phosphatidylcholine (softer) bilayers. The value always exceeded that in the dipalmitoyl phosphatidylcholine (more rigid) bilayers. (4) The observed I_e/I_m-temperature profile was thermotropically reversible. From these previous results, we proposed a conformational equilibrium of the liposomal bilayer structure as a function of temperature and as affected by cholesterol (Fig. 1). In order for the liposomal membranes to hold the observed bilayer thickness (46.5—46.8 Å)[3] with fully extended hydrocarbon chains (28.3 Å), the lipid molecule must be either the tilted conformation by about 30—35 degrees with respect to the bilayer plane (structure (a) in Fig. 1) or a shrunk one with hydrocarbon chains perpendicular to the bilayer plane ((b) or (c) in Fig. 1) at least below the chain melting transition. The codispersion studies using the probe DPDL suggested that below the chain melting transition without cholesterol the lipid bilayer structure is very probably the *lipid-separated* conformation (c), which comes in the predominant monomer emission. Above the chain melting transition or in the presence of cholesterol, on the other hand, the probability for the liposomal bilayers to be the *lipid-intimate* conformation (b) increases, which produces more excimer and results in the larger I_e/I_m ratio.

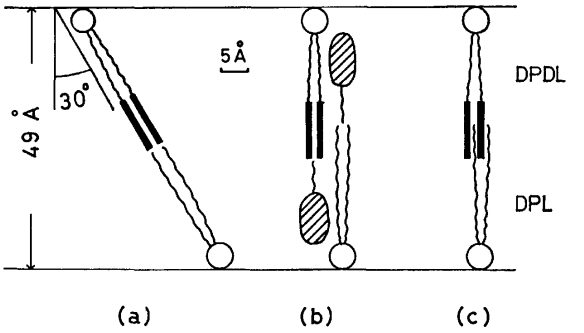

Fig. 1. Schematic representation of the structure of liposomal bilayers. The blocked group represents the pyrene moiety of DPDL. The hatched group represents the steroid nucleus of cholesterol. (a) Fully extended and tilted conformation. (b) The shrunk structure with the lipid-intimate conformation. (c) The shrunk structure with the lipid-separated conformation.

The interaction of the hydrophobic probes with liposomal membranes occurs in two successive kinetic phases; the initial rapid adsorption of probes onto the liposome surface and the second slow diffusion in the liposomal bilayer or transport across the bilayers.[4,5] In this work, we studied the permeation of DPDL or EP into the liposomal membranes and the diffusion of the probes in the bilayers in slow kinetic phase. Through the dynamic studies on the permeation and diffusion of the probes in the liposomal bilayers, the lipid conformation around the probe molecule will be discussed.

Experimental

Materials. Synthetic dipalmitoyl-DL-α-phosphatidylcholine was purchased from Sigma Chemical Company, St. Louis, Mo. and purified prior to use. Egg yolk lecithin was isolated and purified from egg yolk.[1,6,7] 1,2-Bis[10-(1-pyrenyl)decanoyl]-*sn*-glycero-3-phosphatidylcholine (DPDL) and ethyl 10-(1-pyrenyl) decanoate (EP) were the same as those used in the previous investigation.[1] Prior to use, the

purity of all the lecithins employed was inspected by TLC on silica-gel plate (Tokyo Kasei Spot Film S-160) with the solvent chloroform–methanol–water (65 : 25 : 4 by vol.).[8] All the detections by iodine staining, UV light irradiation, and Dragendorff's reagent showed only one spot of the corresponding lecithin.

Preparation of Liposomes. Multicompartment liposomes were prepared by the injection technique according to the method previously described.[1] Single compartment liposomes were formed by sonication technique and isolated by the gel-filtration using Sepharose 4B column.[7] Formations of single and multicompartment liposomes were respectively visualized by negatively staining with 2% aqueous potassium tungstophosphate on a JEOL JEM-100 V electron microscope. Phospholipid concentrations were determined as inorganic phosphate by the Allen's methods.[9]

Fluorescence Measurements. All the fluorescence measurements were made under atmospheric conditions on a Hitachi 650-10S fluorospectrometer exciting at 342 nm with the use of slits of 2 nm for excitation side and 10 nm for emission side, respectively. Under the conditions, good reproducibilities were ensured. Since the fluorescence intensity is proportional to the quantum yield when the exciting light intensity and concentration of absorbing molecule are kept constant, the fluorescence intensities for the monomer (378 nm) and the excimer (480 nm) from the pyrene moiety were determined.

For the permeation of fluorescent probes into bilayers of single-walled liposomes, an appropriate amount of ethanolic solution of the probes was injected using a microsyringe into the liposome solutions preincubated for 10 min at a given temperature. The content of ethanol in liposome solutions was depressed less than 8% (v/v). All the runs were duplicated.

Results and Discussion

Permeations of EP and DPDL. When EP was dispersed into the aqueous buffered solution, it showed the strongly quenched emission of fluorescence excimer but no monomer emission, and formation of small micelles or aggregates was electronmicrographically visualized. On the other hand, when EP was added into the liposome solutions, significant emissions of both fluorescence monomer and excimer were observed. The monomer emission as a function of time, then, gradually increased with a concomitant decrease of the excimer emission with an isolampsic (isoemissive) point at 442 nm (Fig. 2). When the fluorescent probe interacts with the liposomal bilayers, two distinct kinetic phases are observable.[4,5] They are a rapid initial adsorption of the probe onto the outer surface of liposomes and a much slower lateral diffusion in the outer half of bilayers[10] or transport across the inner layer of liposomal membranes.[4a] The instantaneous increase of fluorescence emission and the subsequent slow enhancement of the monomer emission suggest that aggregates or micelles of EP bind onto the liposome surface and subsequently the probe is intercalated in bilayers. Several typical examples of the change in individual values of I_e and I_m as a function of time are illustrated in Fig. 3. During 10 or 20 min after injection of the probe, both values usually level off and the system attains equilibrium. When EP was codispersed with phospholipids, no excimer emission was observed at

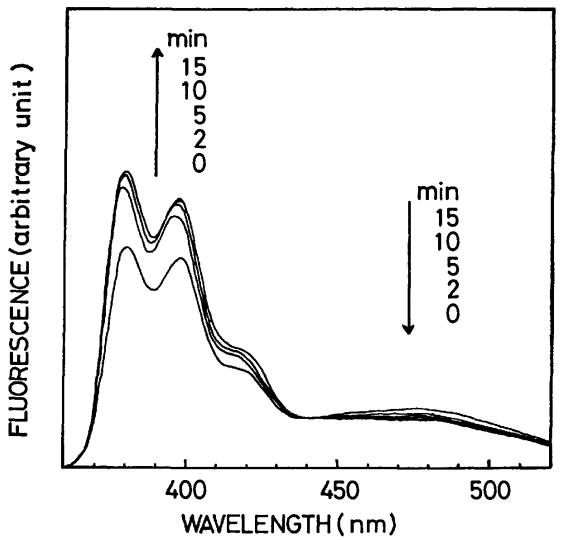

Fig. 2. Fluorescence spectra of EP as a function of time when EP was added into the multicompartment liposome solutions containing 7.84×10^{-6} M of dipalmitoyl lecithin in 0.028 M acetate buffer with 0.10 M NaCl at 25.0 °C. The final concentration of EP was 7.75×10^{-8} M in cuvette.

all.[1)] In the present case, however, as reflected on the relative quantum efficiency, I_e/I_m (Fig. 4), a small extent of the excimer emission still remained even in the slow second kinetic phase. This means that a portion of EP molecules may permeate into bilayers as the small aggregates. The concentration of EP injected, temperature, existence of cholesterol, sort of employed lecithin, and state of liposomes, that is, multi or single compartment liposomes all the factors have an influence on the I_e/I_m ratio (Fig. 4 and Table 1). With an increase in the initial concentration of EP added, the I_e/I_m ratio increased. Mostly in the multilamellar liposomes than in the single-walled liposomes, in single-walled liposomes of dipalmitoyl lecithin than in that of egg lecithin, and at higher incubation temperatures than the chain melting transition temperature of the adopted lecithin, the larger I_e/I_m values are obtained (though with several exceptions).

Differently from the case of EP, when DPDL was dispersed into an aqueous buffered solution containing no liposomes, the bilayer structure was obviously visualized by electronmicrography. And the fluorescence emission from DPDL was completely quenched. On the other hand, when DPDL was injected from the exterior of liposomes, the fluorescence quantum yield of the probe significantly increased. The initial and

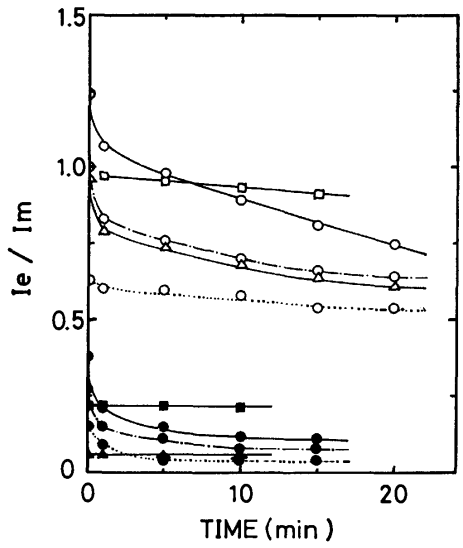

Fig. 4. The relative quantum efficiencies I_e/I_m of DPDL and EP in the single-walled liposomes of dipalmitoyl lecithin as a function of time. Open symbols are for DPDL, while closed symbols for EP: —●—, run 1; -·-●-·-, run 2; ···●···, run 3; —■—, run 4; —▲—, run 6; —○—, run 27; -·-○-·-, run 28; ···○···, run 29; —□—, run 30; and —△—, run 33, respectively. Run numbers should be referred to Table 1.

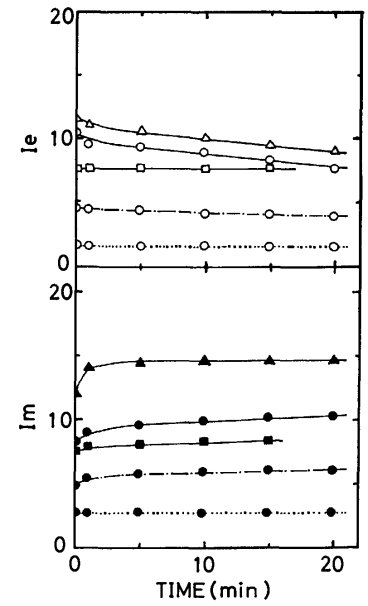

Fig. 6. Fluorescence intensities of excimer emission (I_e, open symbols) and monomer emission (I_m, closed symbols) from DPDL as a function of time in the single-walled liposome of dipalmitoyl lecithin: —●— and —○— are run 27; -·-●-·- and -·-○-·-, run 28; ···●··· and ···○···, run 29; —■— and —□—, run 30; and —▲— and —△—, run 33, respectively. Run numbers should be referred to Table 1.

instantaneous enhancement of fluorescence from DPDL is interpreted in terms of the rapid uptake of the disorganized probe by liposomes and the consequent change in polarity of the microenvironment around the probe.[4a] Similarly to the case of EP, after the instantaneous enhancement of fluorescence emission, the monomer emission gradually increased with a concomitant decrease of the excimer emission (Fig. 5). The I_e/I_m values for DPDL as a function of time are

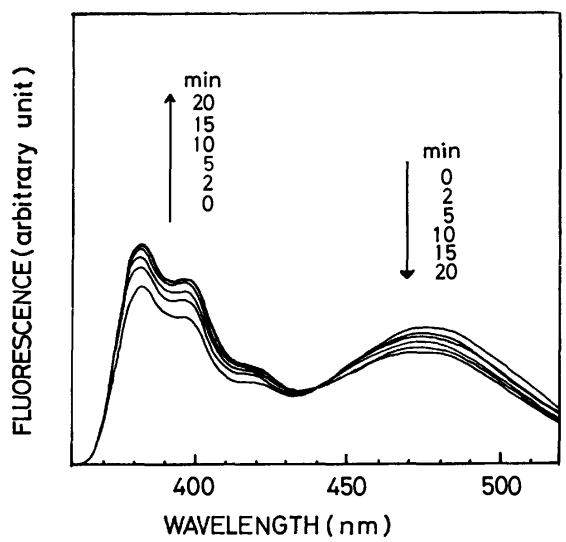

Fig. 5. Fluorescence spectra of DPDL as a function of time in the single-walled liposome of dipalmitoyl lecithin at 25 °C. DPDL (7.65×10^{-8} M) was added from exterior of the liposomes (7.80×10^{-6} M) in 0.028 M aqueous actate buffered solution containing 0.10 M NaCl.

seen in Fig. 4 along with those for EP. The I_e/I_m ratios for DPDL are always larger than those for EP (Fig. 4 and Table 1). Comparing with the case of codispersion of DPDL with lecithins, more DPDL seem to be intramolecular excimer or the ground-state dimer during the permeation. It is true also for EP. Differently from the case of codispersion experiments, in the present study even EP shows the excimer formation. The lecithin analogue probe, DPDL, seems to diffuse more slowly in liposomal bilayers comparing with the smaller and neutral probe, EP. Fluorescence intensities of excimer and monomer emissions from DPDL as a function of time are plotted, respectively, in Fig. 6. With the increase in the initial concentration of DPDL injected and with raising temperature, the I_e/I_m ratio for DPDL increased (Table 1). However, effects of state of liposomes on the I_e/I_m ratio of DPDL are rather complicated. Contrary to what would be expected, the I_e/I_m ratios for DPDL in dipalmitoyl lecithin liposomes were always higher in single compartment liposomes than in multicompartment liposomes irrespective of the incubation temperature and the presence of cholesterol. However, for egg lecithin liposomes the values were larger in multilamellar liposomes than in single-walled liposomes, which is similarly seen in the case of EP. Since the apparent surface area of single compartment liposomes is larger than that of multicompartment liposomes if the lecithin concentration in solutions were the same, the apparent concentration of the probe bound to the liposome surface should be higher in the latter liposomes than in the former ones.[11] This will lead to the higher I_e/I_m ratio. However, this is not the

case for DPDL in the dipalmitoyl lecithin liposomes.

Lenz and his coworkers previously stated that the uptake of DPH (1,6-diphenyl-1,3,5-hexatriene) by multicompartment liposomes is a more complex process than that by single-walled liposomes; the fluorescence intensity of DPH increases in stepwise fashion in multilamellar liposomes.[5] Differently from the case of DPH, permeations of DPDL and EP both were relatively simple even into multilamellar liposomes. The rate of fluorescence enhancement in the slower kinetic phase must concern with the diffusion velocity or mobility of the probes in bilayers.[4,5,10] It is, therefore, reasonable that the I_e/I_m values of the probes attain equilibrium rather rapidly in fluid liposomal bilayers containing cholesterol or being incubated at higher temperatures. From facts that trans-membrane movements of phosphatidylcholine,[12] cholesterol,[13] and lysophosphatidylcholine[14] are extremely slow, the probes (DPDL and EP) are expected to be locating mostly in the outer half of bilayers,[4] especially when they are penetrated from the exterior of liposomes at low temperature.

Conformation of DPDL in Matrix of Liposomal Bilayers. Clearly from our previous study,[1] the I_e/I_m ratio for DPDL intercalated in liposomal bilayers will give a noteworthy information about the structure of bilayers at least around the probe. The high I_e/I_m ratio suggests a conformation by which the probability to take ground-state dimer increases (structure (b) in Fig. 1). Alternately, if the low I_e/I_m ratio were obtained, it suggests that DPDL should take the lipid-separated conformation in bilayers (structure (c) in Fig. 1). The relative quantum efficiencies obtained by the present permeation technique show substantially similar tendency to those obtained by the codispersion experiment.[1] That is, in more fluid liposomes such as egg lecithin liposomes than dipalmitoyl lecithin liposomes or liposomes incubated at higher temperatures than the phase transition temperature, DPDL shows larger values of I_e/I_m in equilibrium. For DPDL, there is no large difference also in the actual value of I_e/I_m ratio between the two distinct experiments. The I_e/I_m values from DPDL lie in a range of 0.5—1.0 and never exceed the value of 1.7 obtained for DPDL in ethanol.[1] Hence, it is reasonable to consider that DPDL permeates into and laterally diffuses in liposomal bilayers mostly with a lipid-separated conformation especially at low incubation temperature in the dipalmitoyl lecithin bilayers. Increasing the mobility of lipid and probe molecules in the hydrophobic domain of bilayers enhances the probability to take more lipid-intimate conformation.

Effect of cholesterol is completely different between the codispersion[1] and permeation studies. In our previous codispersion experiments,[1] addition of cholesterol abolished the phase transition of dipalmitoyl lecithin liposomes and increased the fluidity of membranes. In the present studies, for both probes (EP and DPDL) and for both lecithin liposomes (egg lecithin and dipalmitoyl lecithin), except the permeation of DPDL into multilamellar liposomes of dipalmitoyl lecithin, the addition of cholesterol diminished the I_e/I_m value during the permeation of the probes. This means that effect of cholesterol on the diffusion of the probe is different between the two cases, the codispersion and the permeation.

Liposomal Membranes. IV. Fusion of Liposomal Membranes Induced by Several Lipophilic Agents

Junzo SUNAMOTO,* Tomiko HAMADA, and Hiroki MURASE

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received February 27, 1980)

It was found that several lipophilic agents, such as *cis*-, *trans*-ethyl decaprenoate and their structural analogues, significantly induce the liposome-liposome fusion when incubated together a set of two different liposomes, the *A*-liposome containing a marker and the *B*-liposome involving a lipophilic agent. The rate and extent of fusion were followed spectrophotometrically by monitoring the leakage of an amphiphilic marker, Bromothymol Blue, from the fused liposomes. Fusion was also visualized directly by electronmicrographic technique. When only *A*-liposome was incubated or when a blank liposome containing no lipophilic agents was added to the *A*-liposome after the preincubation, neither the fusion nor the marker release was observed at least in periods of several hours. Also, neither fusion nor the marker release was observed when either *A*- or *B*-liposome or both were multicompartment liposome. Removing cholesterol from liposome significantly depressed the fusion. The effect of cholesterol was more prominent on the *A*-liposome side. *trans*-Ethyl decaprenoate was more effective about three-fold to induce the fusion than the *cis*-isomer. Interestingly, the effect was parallel to the antihypertensive activity of the agent.

The transformation of liposomal membranes has generated much interest because of its possible analogy to biomembrane fusion and phagocytosis of importance in both membrane biology[1] and drug delivery system.[2] Taupin and McConnell were the first to suggest that small single compartment liposomes transform to larger multicompartment liposomes involving liposome-liposome fusion process in periods of several hours when incubated at appropriate temperatures.[3] Thereafter, the Ca(II) ion,[4-6] fatty acids,[7-9] and surface-active drugs[10,11] have been found to accelerate the fusion process of liposomes. In the case of Ca(II)-induced fusion, the key event leading to membrane fusion is the isothermal phase separation induced by Ca(II) ion.[5] The fatty acid-induced fusion also required lateral separation of a fatty acid rich phase.[7] Alamethicin, which is an extracellular cyclic-polypeptide antibiotic and a kind of surface active agents, stimulated fusion of liposomes followed by the preliminary interaction with the polar choline headgroup of the lecithins.[10] These earlier investigations suggest to us that perturbation of the membrane surface by the electrostatic interaction with ionic inducers[4-6,10] or by dispersing hydrophobic components in the bulk bilayer phase and resultant phase separation[7-9] are responsible for the liposome fusion. In earlier studies, meanwhile, homogeneous fusion of liposomes has been characterized by the growth of small vesicles to larger multicompartment liposomes, which is monitored indirectly by physical changes of membrane properties using various techniques such as NMR,[7,9] DSC,[5,6,8] turbidity,[12,13] luminescence assay,[14-16] or osmotic gradient measurements[4] and also visualized directly by electronmicrographic technique.[4,6,8,10]

In certain cases the liposome fusion also is accompanied by the leakage of contents in the interior core of vesicles.[4,9] It is, therefore, possible that appropriately prepared liposomes may be used to penetrate drugs into specific cell membranes through the liposome-cell membrane fusion. However, the details of the membrane fusion process are not yet well established. If it were clarified, therefore, one may conveniently control both the release of the liposome-encapsulated drugs and the delivery of drugs to the target organ.

In a recent paper we indicated that a functional surfactant bearing an imidazole moiety at the head group plays a role as a simple lipase model to cause chemical lysis of lecithin liposomes.[17] The chemical lysis could be monitored by following a leakage of amphiphilic marker dye, Bromothymol Blue (BTB), from the bulk bilayer phase to the exterior aqueous media.[17] Not only by the lysis of liposomal membranes but also even by physico-chemically perturbing the bilayer structure, BTB being entrapped closely to the membrane surface is released from the bilayer to the exterior. In this work we would like to describe the liposome-liposome fusion induced by several lipophilic

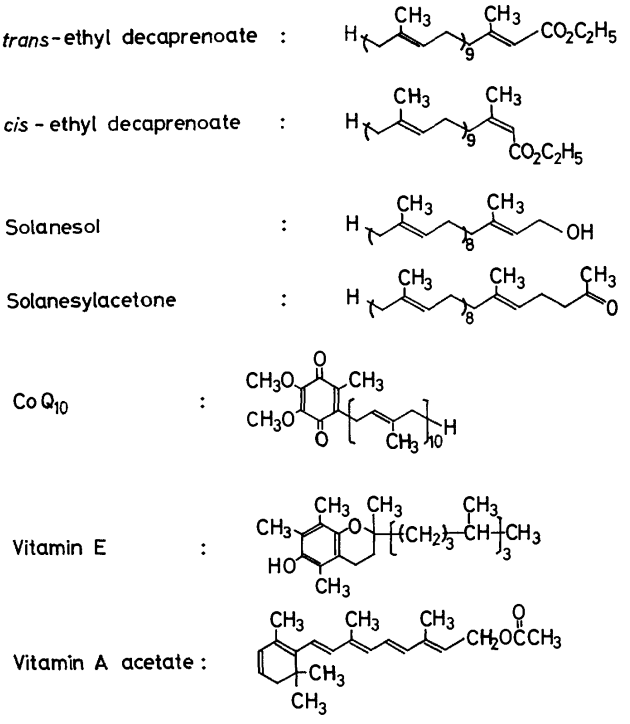

Fig. 1. Chemical structures of lipophilic agents employed in this work.

agents, where we adopted again the same marker-release technique to observe the fusion caused by the fluctuation of bilayer structure. A set of two different single compartment liposomes, the *A*-liposome encapsulating BTB and the *B*-liposome containing the neutral and lipophilic agents, respectively, was prepared. The liposome-liposome fusion can also be visualized directly by electron micrography. As the hydrophobic and neutral agents which are expected to accelerate the fusion, several kinds of polyisoprenoid pharmacological agents, *cis*- and *trans*-ethyl decaprenoate, solanesol, solanesylacetone, coenzyme Q_{10} (CoQ_{10}), vitamin E, and vitamin A acetate were employed (Fig. 1).

Experimental

Materials. All the lipophilic agents employed here were a gift from Eisai Co. Ltd., Tokyo. Egg yolk phosphatidylcholine (EL) was isolated and purified from egg yolk as described in Refs. 18 and 19. Purity of the lecithin was ascertained by TLC on silica-gel plates (Tokyo Kasei, S-160).[18,19] Bromothymol Blue was the same as that used in previous work.[17]

Preparation of Liposomes. Single and multicompartment liposomes containing BTB (*A*-liposome) or a lipophilic agent (*B*-liposome) were prepared independently according to the essentially same procedures as described in a previous paper.[17] A mixed thin film of egg phosphatidylcholine with or without cholesterol, the marker, or lipophilic agents was dispersed and swollen in 0.1 M aqueous citrate buffer solution (pH 5.0) containing 0.1 M NaCl to form multicompartment liposome, and then sonicated under nitrogen atmosphere to obtain single compartment liposomes. Single compartment liposomes were isolated by passing through a Sepharose 4B column[20] using 0.1 M NaCl as an eluant. Optically transparent liposome solutions were obtained by ultrafiltration using a Sartrius Membrane Filter SM 16315 equipped with a filter SM 11310 (0.05 μ), if necessary. By this technique, BTB was incorpotated in the bulk bilayers, not in the interior aqueous core.[17] Liposome-encapsulated BTB was determined spectrophotometrically ($\varepsilon_{617}=7.3\times10\ M^{-1}\cdot cm^{-1}$ at pH 7) after the gel-filtration, when liposomes were completely destructed by hydrolysis in strongly alkaline media at elevated temperature.[17] All the lipophilic agents employed are insoluble in water. They also were, therefore, almost quantitatively intercalated in the bulk phase of liposomal bilayers. Liposome concentrations were determined as inorganic phosphates by the modified Allen's method.[21] To obtain reliable data, for a series of experiments to compare each other, we prepared a large amount of concentrated stock solutions of liposomes as possible and diluted or devided them into several portion.

Typical Procedures to Monitor Bromothymol Blue Release upon Fusion. A 0.5 ml solution of the *A*-liposome, 1.5 ml of ethanol,[22] and 1.0 ml of aqueous buffered solution (phosphate, pH 7.0[23]) were placed in a thermoregulated cuvette cell and preincubated for 10 min at 25.0 °C unless otherwise stated. The BTB release induced by the addition of an appropriate amount of *B*-liposome solution was followed by monitoring the increase of intensity at 617 nm on a Hitachi 124 recording spectrophotometer.

During the preincubation, we could not find any spontaneous release of the marker. The percentage of BTB release was obtained by Eq. 1; where *A* is the absorbance at 617 nm, the subscripts *t* and 0 refer to the times of samples and to the instant when the *B*-liposome solution was added to the *A*-liposome solution, respectively. A_∞ stands for the absorbance of total amount of the liposome-encapsulated marker in *A*-liposome.

$$\%\ \text{BTB-release} = \frac{A_t - A_0}{A_\infty - A_0} \times 100 \qquad (1)$$

Maximum % release of BTB was the value over the plateau region after leveled off, usually after 60 min. All the runs were duplicated.

Results and Discussion

Fusion process of membranes, where the membrane of small vesicles is incorporated into larger membrane arrays, is one of the important problems to understand biological membranes.

Either when only *A*-liposome solution was incubated by itself or when a blank *B*-liposome containing no lipophilic agents was added to the preincubated *A*-liposome, no BTB release was observed at least in periods of several hours. This means that no fusion occurs. On the other hand, when an appropriate amount of liposome-encapsulated ethyl decaprenoate (a mixture of 15% *cis* and 85% *trans* isomers) was added into the *A*-liposome solution, enhanced BTB release upon the liposome-liposome fusion was observed. If we accept the mechanism of the liposomal fusion proposed by Papahadjopoulos and his co-workers,[5] it is reasonable to observe the marker release upon fusion. The liposome-liposome fusion accompanied by the BTB release was directly visualized by electron micrography,

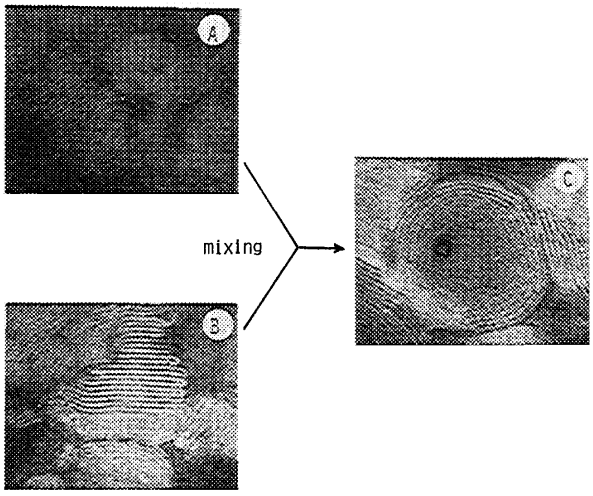

Fig. 2. Electron micrographic observation of the liposome-liposome fusion induced by a lipophilic agent, ethyl decaprenoate. Single compartment liposomes were prepared from egg phosphatidylcholine. A: The single compartment *A*-liposome containing BTB (0.82 mol %) and cholesterol (41.4 mol %). B: The single compartment *B*-liposome containing ethyl decaprenoate (28.2 mol%) and cholesterol (30.3 mol%). C: Multicompartment liposomes obtained by mixing *A*- and *B*-liposome solutions at 25 °C. All the liposome solutions were negatively stained with 2% (by wt.) aqueous sodium tungstophosphate solution. Measurements were run on a JEOL JEM 100 V electron microscope. Magnification ×250000.

which showed the evident growth of small single compartment liposomes to larger multilamellar liposomes (Fig. 2). The extent and the rate of fusion was comparable with those of the BTB release from the *A*-liposomes. The unstable state of membranes susceptible to fusion should makes the liposomal membranes highly permeable.[5] Several studies have shown that small, physiologically active, and lipophilic agents fluidize membranes.[24,25] Contrary to this, a few studies showed that lipophilic molecules may also exert a condensing effect on the liposomal bilayers.[26,27] The condensation in the bilayers may well create structural defects with resulting in fusion.[5,10] Increasing the content of the intercalated marker in the liposomal bilayer also will give rise to the instability of the membranes.[24,25] Therefore, the content of BTB in the *A*-liposomes was usually depressed less than 10 mol %. In any event, factors affecting the initial rate and the extent of the induced fusion by lipophilic agents are very complicated.

For investigating the lipophilic agent-induced fusion, all the following parameters must be perfectly controlled and kept satisfactorily constant; (i) the content of the marker in the *A*-liposome, (ii) the amount of lipophilic agents intercalated in the *B*-liposome, (iii) actual concentrations of *A*- and *B*-liposome, that is, the concentration ratio of *A*-liposome to *B*-liposome, and (iv) amount of multicompartment liposomes contaminated. Unfortunately, it was very difficult to establish

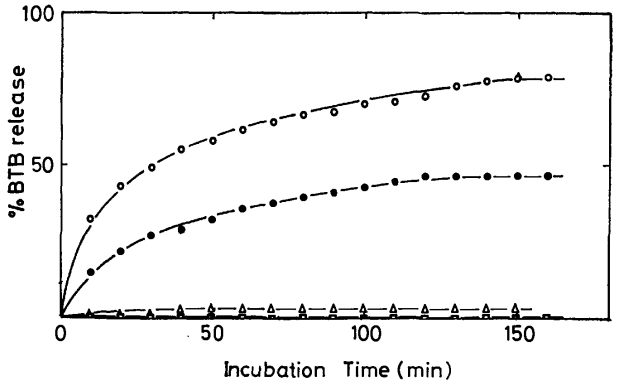

Fig. 3. Effect of cholesterol on the ethyl decaprenoate-induced fusion of egg lecithin single compartment liposomes at 25 °C and pH 7.0 (phosphate buffer). ○: *A*-Liposome consisting of 13.8 mM egg lecithin, 10.2 mM cholesterol, and 4.82 mM BTB was stimulated with *B*-liposome consisting of 1.15 mM egg lecithin, 0.83 mM cholesterol, and 0.78 mM ethyl decaprenoate. ●: *A*-Liposome consisting of 13.8 mM egg lecithin, 10.2 mM cholesterol, and 4.82 mM BTB was stimulated with *B*-liposome consisting of 1.15 mM egg lecithin and 0.78 mM ethyl decaprenoate *without* cholesterol. △: *A*-Liposome consisting of 13.8 mM egg lecithin and 4.82 mM BTB *without* cholesterol was incubated with *B*-liposome consisting of 1.15 mM egg lecithin, 0.83 mM cholesterol, and 0.78 mM ethyl decaprenoate. □: *A*-Liposome consisting of 13.8 mM egg lecithin, 10.2 mM cholesterol, and 4.82 mM BTB was incubated with a blank liposome consisting of 15.0 mM egg lecithin and 10.9 mM cholesterol without any lipophilic agent.

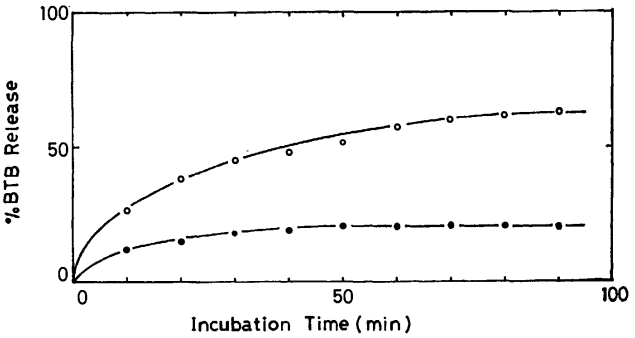

Fig. 4. Difference in efficiency of *cis*- and *trans*-ethyl decaprenoate on the liposome-liposome fusion as induced by lipophilic agents. *A*-Liposome consisting of 9.5 μM egg lecithin, 7.0 μM cholesterol, and 1.52 μM BTB was stimulated with *B*-liposomes consisting of 5.08 μM egg lecithin, 3.71 μM cholesterol, and 3.45 μM ethyl decaprenoate (*trans* (○) and *cis* (●) isomers) at 25.0 °C and pH 7.0.

the completely controlled conditions to satisfy all the above requirements. Therefore, we could discuss only the results obtained from a series of experiments employing the same liposome stock solution.

After the relatively rapid release of the marker at the initial stage, the marker release leveled off (Figs. 3 and 4). Since an excess surface free energy is the main thermodynamic driving force for fusion, the initial growth from small vesicles to diameters of negligible curvature results in the reduced surface free energy and the fusion will cease.[28,29] It is evident from the fact that we could not observe any fusion and BTB release when multicompartment liposomes were used. The rate-determining step of the fusion process is to be seen in the reaction which leads from the short-lived encounter complex of two colliding vesicles to the finally fused vesicle. According to Lawaczeck's theory[30] and if it were the liposome-liposome direct fusion in a spontaneous manner, therefore, one can establish a linear relationship between the initial rate of fusion and the square of the lecithin or liposome concentration. That is, under the assumption of a critical bilayer concentration,[30] the direct liposome fusion is considered as a reaction of second order in the lecithin or liposome concentration. If fusion is considered as one liposome is absorbed by another one,[31] however, the state of affairs may be different. In our present case, in addition, fusion is not spontaneous but induced by the lipophilic agent-encapsulated liposome and experiments were always carried out under conditions where the concentration of *A*-liposomes was higher than that of *B*-liposomes. Hence, we could not attain any linear relationship between the BTB release at a given interval and the product of concentrations of *A*- and *B*-liposomes.

At a given concentration of *A*-liposomes the maximum of % BTB release was directly affected by the concentration of *B*-liposomes (Table 1). Removing cholesterol from either side of liposomes significantly depress the fusion (Fig. 3). Its effect was more prominent on the *A*-liposome side, in which removal of cholesterol gave rise to the complete depression of the induced fusion. One role of cholesterol in membranes is to regulate the

degree of order and mobility of the acyl chains of lecithins as a modulator of the packing.[32-34] But, the orientation of the headgroup is not changed by the addition of cholesterol.[35] Above the phase transition temperature of lipids, addition of cholesterol to liposomes induces a higher molecular order in the bilayers[36] and reduces the mobility of the acyl chain.[32] In the bilayer phase, however, lipids and cholesterol are considered as totally and uniformly miscible.[37] It is certain, in any event, that the incorporation of cholesterol is considered as an important factor for fusion to initiate. Above phase transition temperature, changing the incubation temperature from 15 °C to 26 °C did not necessarily affect the extent of fusion. The concentration of *B*-liposomes rather than the incubation temperature largely affect the induced fusion.

Figure 4 indicates the difference in the efficiency on the induced fusion between *cis* and *trans* isomers of ethyl decaprenoate which were carefully isolated from the mixture by column chromatography. Very recently, Seelig and Seelig indicated that the incorporation of a *cis* double bond into a bilayer membrane leads to a general decrease in the hydrocarbon chain ordering in all parts of the bilayer and it seems to be accompanied by some increase in the rate of motion.[38] Another group found that most phospholipids derived from *cis*-parinaric acid shows the melting transition at about 1 °C lower than those from the *trans*-isomer.[39] *trans*-Parinaric acid preferentially associates with solid-phase lipid, while the *cis*-isomer shows a more equal distribution between solid and fluid lipids.[39] Judging from these previous findings,[39,40] the encapsulation of *cis*-ethyl decaprenoate is expected as more effective as to induce fusion. Contrary to what would be expected, however, *trans*-ethyl decaprenoate was more effective about three-fold than the *cis*-isomer. Though unfortunately we can not explain the reason at the present time, an interesting finding is that the antihypertensive activity of the *trans*-isomer, which was investigated *in vivo* using hypertensive rats, is higher than the *cis*-isomer.[40]

Table 1 reveals the BTB release induced by different lipophilic agent encapsulated liposomes. Spisni *et al.* recently investigated the interaction between ubiquinones and egg lecithin liposomes.[41] They found from ESR studies that the presence of ubiquinones induces the fluidity of membranes, as shown by the decrease of the $2T_{\parallel}$ parameter and the shorter correlation time of the spin-probe.[41] This means the disordering effect of the side chain of ubiquinones intercalating in the hydrocarbon region of the liposomal bilayer. As expected from the previous investigation,[41] CoQ_{10}, vitamin E, and vitamin A acetate significantly induced the liposome fusion (Table 1). Their effects were relatively large comparing with those of simple polyisoprenoids. Increasing the drug content in the *B*-liposome generally gave rise to the decrease of the apparent BTB release. When the content ratio of CoQ_{10} to egg lecithin in the *B*-liposome exceeded about 10 mol% (more than about 40 mol% for vitamines), some aggregates just like oil drops along with regular liposomes were visualized on their electron micrographies. This means that introducing a large amount of these agents causes the destruction of liposome structure itself. Relative efficiency of the BTB release upon the fusion as induced by lipophilic drugs was as follows: *cis*-ethyl decaprenoate<*trans*-ethyl decaprenoate<solanesyl-

Table 1. Maximum bromothymol blue (BTB) release upon fusion induced by lipophilic agent encapsulated liposomes under various conditions at pH 7.0

a) Numbers in parentheses are the mole ratio of the marker, lipophilic agent, or cholesterol to egg lecithins isolated as single compartment liposomes. All the concentrations are those in cuvette cell. b) The maximum BTB release was obtained at 60 min later after injection of the *B*-liposomes (see text). The marker releases were calculated by Eq. 1. Details are described under Experimental. c) Unless stated otherwise, ethyl decaprenoate was a mixture of 15% *cis* and 85% *trans* isomers.

acetone < solanesol ≪ CoQ_{10} < vitamin E ≃ vitamin A acetate. Difference of these agents in the induced liposome fusion is difficult to argue at the present time. But, one possibility is that the structure of head group of polyisoprenoids and their analogues seems to act delicately on the local property of membrane surface. Liposomal bilayers are capable of a high degree of structural discrimination, and lends support to the hypothesis that the lipid phase of cell membranes may be the site of action of these lipophilic agents.

Our thanks are due to Mr. Kazuo Egashira for the partial assistance in experiments and to Mr. Yoshio Hara for his skilled technical assistance on the electron micrographic studies. Authors also acknowledge helpful discussions of Professor Hiroshi Kaneto, Department of Pharmacology, Faculty of Pharmaceutical Sciences, Nagasaki University, and Dr. Toji Konishi, Eisai Co. Ltd., Tokyo.

Liposomal Membranes. V. Interaction of Zinc(II) Ion with Egg Phosphatidylcholine Liposomes

Junzo SUNAMOTO,* Masaharu SHIRONITA, and Noriaki KAWAUCHI

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received February 27, 1980)

The efficiency of encapsulation of several divalent metal ions, mainly Zn(II) ion, into egg lecithin liposomes has been investigated with particular attention to the stability of liposomal membranes against the transition metal(II) ions. The stronger interaction of metal ions to lecithins led to the less formation of liposomes. The addition of a suitable amount of nonionic detergent, 2-[ω-hydroxypentadeca(oxyethylene)-α-yl]-1,3-bis(dodecyloxy)propane ($2C_{12}15G$, see text), enhanced the encapsulation of Zn(II) and Cu(II) ions in liposomes. The stoichiometric measurement for the binding of Zn(II) ion to single compartment liposomes of egg lecithin suggested that a Zn(II) ion is interacting with three or four lecithin molecules on the average in both halves of liposomal bilayers. Even under the circumstances, the bilayer structure of liposomes was certainly kept stable, which was electron micrographically visualized.

Since Bangham and his coworkers reported on the bilayer structure of liposome and its resemblance to biological membranes, liposomes have attracted much attention as a suitable model of biomembranes.[1] The interaction of various metal ions with liposomal membranes has been also extensively investigated from this standpoint. The spontaneous permeability and the transmembrane movement[2-4] of metal ions, such as K^+, Na^+,[5,6] Ca^{2+}, or Mg^{2+} ion,[7] as affected by the hydrogen ion concentration,[8] the ionic strength,[9] several antibiotics providing ionophore activity,[8,10,11] and detergents[12] have been studied. Transition metals, Cr, Mn, Fe, Co, Cu, Zn, and Mo, are biologically called the "essential trace metals" since they are essentially required for enzymes or coenzymes to hold the activity.[13] The lack of these metal ions, in fact, induces specific diseases, and that the administration of the metal ions can therapeut these diseases is well known.[14,15] More recently, Gregoriadis and his coworkers have proposed that liposomes are able to be utilized as a drug carrier for therapeutic purposes.[16] Since the liposomes can encapsulate drugs,[17-19] proteins,[20] or enzymes,[21] it can be administered intravenously or orally to patients of various kinds of disease.[22] The most expedient point of liposomes as a drug-carrier is based on the following two unique features: (1) Since liposomes are constructed of amphiphilic lecithins, liposomes can also encapsulate both hydrophilic and lipophilic drugs.[19] Encapsulating water soluble drugs into the interior core of vesicles eases the permeability of these drugs across the hydrophobic cell membranes, while encapsulation of lipophilic drugs in the bulk liposomal bilayers makes the drugs easy to move in aqueous blood stream.[22] (2) If liposomes were constructed of natural phospholipids, they are biodegradable and easily metabolized. And this will promise that toxicological and immunological effects of liposomes are minimized *in vivo*.

From these aspects, we have investigated on the interaction with and the encapsulation in liposomes for several divalent metal ions which are, in a sense, thought to be a kind of hydrophilic and therapeutic drugs. This work will afford a basic knowledge on the stability of biomembranes against several divalent metal ions in one hand and on the efficiency of encapsulation of the metal ions into liposomes in other hand.

Experimental

Egg phosphatidylcholine (egg PC) was isolated and purified from fresh egg yolk according to the method in literature[23] with minor modification. Divalent metal nitrates were commercially available as analytical grade. Water used in this work was very carefully purified by deionization and redistillation using glass apparatus.

Formation of Liposomes Encapsulating Divalent Metal Ions. Liposomes were usually prepared from a mixture of egg PC and 40 mol % of chloesterol. Thirty mg of egg PC and 10 mg of cholesterol were dissolved in 1—2 ml of dry chloroform and placed in a 50 ml vol round bottom flask. Chloroform was removed off using a rotary vacuum evaporator under nitrogen atmosphere to form a thin film. The film was disperesd with 4 ml of aqueous 20 mM acetate buffer solution (pH 5.1) containing 0.1 M NaCl and 250 mM of aqueous metal ion solution by shaking on a Vortex mixer at 20 °C for 15 min. The resulting milky suspension is mostly consisted of multicompartment liposomes,[24] which was submitted to a Sephadex G-50 column (1.8×30 cm) to remove off free metal ions[10,25] and decomposed lecithins. To obtain single compartment liposomes the above milky suspension was sonified under stream of nitrogen at 2—5 °C for 15 min at 30 s intervals using a Tomy UR-200P probe-type sonifier. The sonified liposome solution (about 1.0—2.0 ml) was passed through a Sepharose 4B column (1.8×30 cm) to remove both free metal ions[10,25] and multicompartment liposomes. The amount of metal ions entrapped in liposomes was determined by atomic absorption analysis, fluorometric analysis,[26] or other spectrophotometric techniques.[27] Determination of lipid concentration was accomplished by the modified Allen's method.[28] Reproducibility of liposome formation which was ascertained by lecithin assay was rather good within about ±6% in error.

Electron Micrography of Liposomal Membranes. Liposome solution for electron micrographic measurement were negatively stained with 2% (by wt.) aqueous sodium tungstophosphate solution. A drop of the stained liposome solution was carefully put on a copper sheet-mesh using 1 μl-microsyringe, and excess sample solution was taken off with a scrap of filter paper. The sheet-mesh bearing samples was kept overnight in a vacuum desiccator and run on a JEOL JEM 100 V electron microscope.

Assay of Divalent Metal Ions; Zn(II), Cu(II), Mn(II), and Ca(II) Ions. To 0.5—1 ml of sample solution in a 3 ml-vol. Kjeldahl flask containing 0.01—250 mM metal(II) ions

was added 1 ml of 60% (v/v) perchloric acid, and heated to dryness, which was repeated thrice. After final evaporation of perchloric acid, it was diluted with 10 mM perchloric acid up to the concentration corresponding to about 10 μM of the metal(II) ions and measured on a Simadzu AA-620 atomic absorption flame spectrophotometer by regular procedures using the specific standard solution for respective metal ions.

Results and Discussion

Interaction of Liposomal Membranes with Divalent Metal Ions. The interaction of divalent metal ions and SeO_3^{2-} ion[29] with liposomal membranes of egg PC containing cholesterol was investigated focusing on the two points; (1) the amount of metal ions interacting with lecithin molecules in liposomes, $(M)_{lip}/(lecithin)_{lip}$, and (2) the % yield of lecithin molecules as recovered as liposomes after sonication and gel-filtration in the presence of metal ions. Table 1 shows the encapsulation efficiency of metal ions into liposomes. The efficiency was scarcely altered by the metal(II) ions except SeO_3^{2-} (Table 1). The stronger interaction of metal ions to liposomal membranes leads to the more destruction of liposomes, that is, the less recovery of lecithins as liposomes. Similarly, harder ultrasonication in the presence of metal ions increases the chance for metal(II) ions to interact with lecithins, but resulting in the lower lecithin recovery. The positively charged surface of egg PC liposomal membranes drastically depresses the $(Zn^{2+})_{lip}/(lecithin)_{lip}$-value comparing with the neutral surface. Contrary to what would be expected, on the other hand, the negatively charged surface hardly affect the interaction of the metal ion with membranes. The anionic phosphate moiety of phosphatidylcholines itself may present an effective binding site for metal ions. Table 1 also reveals the effect of chelating agents, EDTA and perhydrodibenzo-18-crown-6, on the encapsulation of zinc(II) ion into liposomes. EDTA was added as an aqueous solution along with zinc(II) ions during the dispersion of lipid, while dicyclohexyl-18-crown-6 was employed as a chloroform solution together with lipids during the thin lipid-film formation. The result shows that the adoption of EDTA or perhydrodibenzo-18-crown-6 rather decreases the encapsulation of zinc(II) ions. In the presence of EDTA or the crown compound, however, the lecithin recovery increased comparing with that in the absence of these chelating agents. Clearly from the fact that most of these agents adopted first are recovered during the gel-filtration, both chelating agents seem to be hardly encapsulated in liposomes. Therefore, metal ions bind predominantly to these agents in bulk aqueous solutions rather than to lecithins, which leads to saving liposomes from the destruction.

Table 1. Encapsulation of different divalent metal ions into multicompartment liposomes of egg lecithin at 25.0 °C[a]

Metal(II) ion	$\frac{(M)_{lip}}{(Lecithin)_{lip}}$[b]	Encapsulation[c] %	Lecithin[d] recovery %
None	—	—	85
Cu(II)	0.57	0.59	56
Mn(II)	0.23	0.23	81
Ca(II)	0.52	0.65	77
SeO_3^{2-}	0.03	0.03	78
Zn(II)	0.38	0.63	73
Zn(II)[e]	0.32	0.48	83
Zn(II)[f]	0.15	0.15	59
Zn(II)[g]	0.48	0.99	56
Zn(II)[g,h]	0.32	1.02	59
Zn(II)[g,i]	0.38	1.22	62
Zn(II)[g,j]	0.35	1.33	72

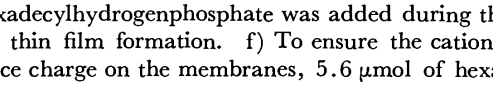
a) 40 μmol of egg lecithin with 26 μmol of cholesterol was dispersed in 4.0 ml of 20 mM acetate buffer containing 0.1 M NaCl and 250 mM of metal(II) nitrates at 25.0 °C. After sonication (25 W for 15 min) and gel-filtration (Sephadex G-50), concentrations of metal(II) ions and lecithin were independently determined as described under Experimental. All the values are average of duplicated or triplicated runs. b) Error which stems from assay of metal ions was as follows: ± 6.0% for Zn(II), ±0.5% for Mn(II), ±2.5% for Cu(II), and ±9.0% for Ca(II). c) Encapsulation $\% = 100 \times (M)_{lip}/(M)_{total}$. d) Lecithin recovery $\% = 100 \times (lecithin)_{lip}/(lecithin)_t$. Experimental error was within ±6.0%. e) To ensure the anionic surface charge on the liposomal membranes, 5.6 μmol of dihexadecylhydrogenphosphate was added during the lipid thin film formation. f) To ensure the cationic surface charge on the membranes, 5.6 μmol of hexadecylamine was employed during the course of thin-film formation. g) Sonicated at 60 W for 15 min. h) 10 μmol of EDTA was added. i) 25 μmol of EDTA was added. j) 10 μmol of crown ether was added.

Table 2. Effect of nonionic detergent, $2C_{12}15G$, on the encapsulation of Zn(II) ions in egg lecithin liposomes[a]

Liposomes Lecithin μmol	$2C_{12}15G$ μmol	$\frac{(Zn(II))_{lip}}{(Lecithin)_{lip}}$	Encapsulation %
40	0	0.38	0.63[b]
38	2	0.37	0.93
36	4	0.39	1.26
32	8	0.35	0.72
28	12	0.27	0.83
20	20	0.03	0.13

a) The nonionic detergent was mixed with egg lecithin in the absence of cholesterol during the course of thin film formation. Liposome solutions were sonicated at 25 W for 15 min. b) The same data as that listed in Table 1.

The effect of nonionic detergent, $2C_{12}15G$,[30] on the encapsulation of Zn(II) ion is listed in Table 2. The detergent



2-[ω-hydroxypentadeca(oxyethylene)-α-yl]-1,3-bis(dodecyloxy)propane ($2C_{12}15G$)

is bearing long ethylene oxide moiety as the hydrophilic part, which is expected to behave just like as an acyclic

antibiotic ionophore.[11] Intercalating up to about 10 mol% of $2C_{12}15G$ in liposomes without cholesterol enhanced the encapsulation of the metal(II) ion different from cases of the former two chelating agents. Leakage of the nonionic detergent from the liposomal bilayers to the exterior aqueous phase can be neglected under the present conditions. The totally similar effect was observed also for the encapsulation of Cu(II) ion (not shown). Addition of more detergent, however, rather decreased the efficiency of encapsulation of metal ions. Electron micrographic studies indicated that adopting the detergent up to 10 mol% against lecithins still holds reliable bilayer structure of multicompartment liposomes, but the presence of more detergent than 20 mol% gradually causes the physico-chemical damage on the bilayer structure (Fig. 1). This is very comparable to the efficiency on the metal ion encapsulation. Interestingly, in addition, as increasing the content of the detergent, the bilayer thickness determined on the electron micrograph pictures also increased: 30 Å for 100% lecithin liposomes, 34 Å for liposomes containing 10 mol% of $2C_{12}15G$, 37 Å for 20 mol%, 39 Å for 30 mol%, and 45 Å for more than 50 mol%.

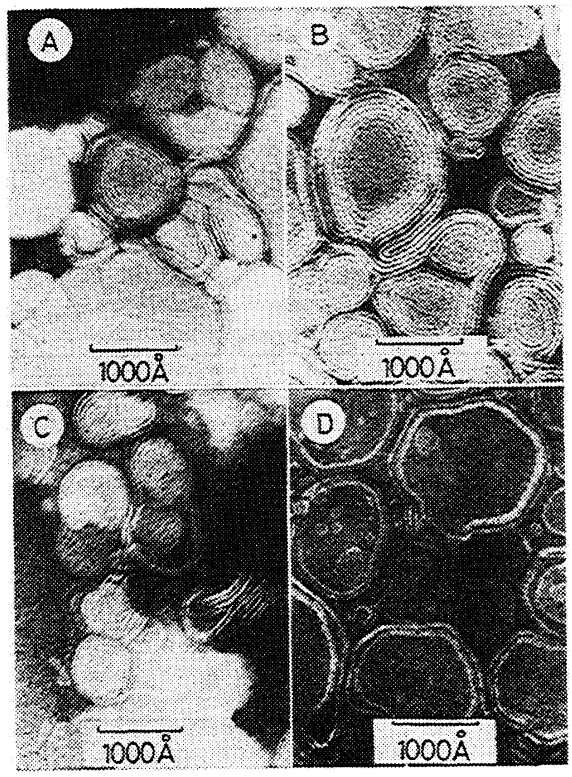


Fig. 1. Electron micrographs of egg lecithin multicompartment liposomes containing nonionic detergent, $2C_{12}15G$, at different concentrations (A, 0 mol%; B, 10 mol%; C, 30 mol%; and D, 50 mol%) in the presence of Zn (II) ion.

Adsorption of Zinc(II) Ion on the Liposomal Bilayers. Electrophoretic mobility and ^{31}P-NMR measurements were combined by McLaughlin and his coworkers[31] to test whether the combination of Henry, Boltzmann, and Grahame equations is capable of describing the adsorption of the divalent metal ions to phosphatidylcholine membrane, where they assumed a 1:1 stoichiometry for the binding of the divalent ions to phosphatidylcholine. In this work, amounts of each Zn(II) ion being in the interior of vesicles and adsorbing onto the outer surface of vesicles were independently determined by following procedures. After the gel-filtration of the single compartment liposome solutions containing Zn(II) ions, which were prepared according to the regular technique as described under Experimental, the total amount of metal ions interacting with lecithins ($(Zn(II))_{lip}$) was determined: it was 6.27 μmol. Then, the liposomes were washed by adding about 0.02 M EDTA aqueous solution[10] (about 100 times excess to total metal ions entrapped in liposomes) and contributed again to the gel-filtration in order to remove off Zn(II) ions adsorbed only on the outer surface of membranes.[10] At this stage both amounts of metal ions adsorbing on the outer surface ($(Zn(II))_{lip\cdot out}$) and locating in the interior core of vesicles ($(Zn(II))_{lip\cdot in}$) could be determined: they were 3.78 and 1.79 μmol, respectively. Hence, the yield of Zn(II) ions recovered during the above procedures was about 90%. Same experiment was repeated twice. The result also indicates that about 70% of Zn(II) ions in liposomes are binding onto the outer half of liposomal bilayers. To ascertain the result, on the other hand, the blank single compartment liposomes containing no metal ions were independently prepared. And Zn(II) ion was then added from the exterior of liposomes. After the gel-filtration to remove free metal ions off, the amount of Zn(II) ions, which corresponds to those bound only to the outer surface of liposomes ($(Zn(II))_{lip\cdot out}$), was determined: it was 4.13 μmol. This value is in good agreement with the preceding one (3.78 μmol) within experimental error (±10%). Finally, the resulting liposome solutions were washed by 0.02 M EDTA and gel-filtered again. Hence, the amount of Zn(II) ions remained in liposomes was determined: it was 0.36 μmol. This may mean that only 8.7% of Zn(II) ions permeates into the liposomes as a complex with EDTA and/or lecithins during the course of washing the outer surface of liposomes by EDTA.

Table 3. Number of Zn(II) ion binding onto respective halves of bilayers of egg lecithin single compartment liposomes

$(Zn(II))_{lip.out}$ μmol	$\frac{(Zn(II))_{lip.out}}{(lecithin)_{lip.out}}$	$(Zn(II))_{lip.in}$ μmol	$\frac{(Zn(II))_{lip.in}}{(lecithin)_{lip.in}}$
4.13(3.78)[a]	0.30—0.34	1.79	0.30—0.41

a) The parenthesized value was obtained from the codispersion experiment.

The area ratio of the outer surface to the inner surface of the single compartment liposomes is in proportion to the ratio of the number of lecithin molecules involving in respective two halves of bilayers. Assuming that the average size of single compartment liposomes is 250—300 Å[22,24] in diameter, the thickness of bilayers is 40—50 Å, and a vesicle is consisted of 3000—4000 molecules of phosphatidylcholines,[22] thus, one can estimate the

number of Zn(II) ions interacting with lecithins of both halves of bilayers (Table 3). The estimation suggests 1 to 3—4 stoichiometry for the zinc(II) ion interacting with phosphatidylcholine in both halves of liposomal bilayers. Alternatively, if assumed that all the Zn(II) ions locating in the interior water pool of liposomes are free, the estimation suggests that the initial aqueous solutions of metal ion added when forming liposomes is diluted about two-fold. But, this seems unlikely. Surprisingly, even under the circumstances, the bilayer structure of vesicles was certainly kept stable as visualized by electron micrography.

The authors are indebted to Professor Toyoki Kunitake, Kyushu University, for a gift of nonionic detergent. Thanks are also due to Analysis Center for Laboratory Waste and Noise, Nagasaki University, for measurements using atomic absorption flame spectrophotometer.

The Structure of the Cyclodextrin Complex. IX. The Crystal Structure of α-Cyclodextrin-*m*-Nitroaniline (1:1) Hexahydrate Complex

Kazuaki HARATA

Research Institute for Polymers and Textiles, 1-1-4, Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received March 12, 1980)

The crystal structure of α-cyclodextrin–*m*-nitroaniline hexahydrate complex was determined by X-ray analysis. The crystal is monoclinic and the space group is $P2_1$ with $Z=2$. The cell dimensions are: $a=8.054(1)$, $b=13.508(1)$, $c=25.331(2)$ Å, and $\beta=103.90(1)°$. The structure was solved by an inspection of a Patterson map and by a trial-and-error method. The refinement was done by the block-diagonal least-squares method to the final *R*-value of 0.11 for 2351 reflections ($\sin\theta/\lambda<0.49$). α-Cyclodextrin molecules are stacked along the a axis in the head-to-tail fashion to form a channel-type structure. Most of the primary hydroxyl groups of α-cyclodextrin are in a *gauche-gauche* conformation and linked by hydrogen bonds directly or through water molecules to the secondary hydroxyl groups of the next α-cyclodextrin molecule along the channel. The guest *m*-nitroaniline molecules are linearly arranged in the channel. The α-cyclodextrin ring includes the nitrophenyl group, while the amino group protrudes outside from the secondary hydroxyl side of α-cyclodextrin and is hydrogen-bonded to a primary hydroxyl group of the next α-cyclodextrin molecule. Along the channel, *m*-nitroaniline molecules are linked to each other by a weak N–H···O hydrogen bond between the amino group and the nitro group. Columns formed by the stack of α-cyclodextrin are closely packed in the crystal, and intermolecular spaces are filled with water molecules which form many hydrogen bonds with each other and with α-cyclodextrin.

Cyclodextrins form a number of inclusion complexes with a variety of guest molecules. Cyclodextrin complexes with aromatic guests have been intensively studied, mainly in relation to an enzyme model.[1] Crystal structures of α-cyclodextrin complexes with *m*- and *p*-nitrophenols[2,3] have well interpreted the stereospecific acceleration of the hydrolysis rate of nitrophenyl acetates. α-Cyclodextrin also catalyzes hydrolysis of nitroacetanilides, and it has shown to act as a true catalyst in that case.[4]

Several α-cyclodextrin complexes with para-disubstituted benzenes have been investigated by the X-ray method.[2,3,5-7] The benzene ring has been found at the same position in those complexes in spite of various substituents. On the other hand, among the α-cyclodextrin complexes with meta-isomers, only the structure of a 1:2 complex with *m*-nitrophenol has been determined.[2] In the present work, we investigated the crystal structure of the α-cyclodextrin–*m*-nitroaniline complex. Unlike the *m*-nitrophenol complex, the *m*-nitroaniline complex gives a 1:1 host-guest stoichiometry; therefore, the inclusion geometry of the complex is of particular interest, for comparison with the *m*-nitrophenol complex as well as in relation to the catalytic reaction.

Experimental

Crystals of α-cyclodextrin–*m*-nitroaniline (1:1) hexahydrate complex were prepared by slowly cooling a hot aqueous solution of α-cyclodextrin saturated with *m*-nitroaniline. They are orange prisms elongated along the a axis. The determination of the lattice parameters and the intensity measurement were carried out on a Rigaku automatic four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The crystal was sealed in a quartz capillary with a drop of mother liquor since the crystal breaks up in air. 2677 independent reflections were obtained up to 40° in 2θ by using an ω-scan technique. But 324 reflections with $|F_o|<3\sigma(F)$ were treated as unobserved. No corrections were made for absorption and extinction.

Crystal Data: $C_{36}H_{60}O_{30}\cdot C_6H_7N_2O_2\cdot 6H_2O$, *F. W.* = 1220.1, monoclinic, space group $P2_1$, $Z=2$, $a=8.054(1)$, $b=13.508(1)$, $c=25.331(2)$Å, $\beta=103.90(1)°$, $V=2675.1$ Å^3, $D_x=1.515$, $D_o=1.50$ g·cm^{-3}.

Determination and Refinement of the Structure

A Patterson map showed that the α-cyclodextrin ring is located nearly perpendicular to the a axis. The position and orientation of the molecule were determined by the trial-and-error method. At this stage, the position and orientation of each glucose residue were refined by the rigid-body least-squares method. *m*-Nitroaniline and water molecules were found on Fourier and difference-Fourier maps. Two primary hydroxyl groups (O(6,G2) and O(6,G3)) of α-cyclodextrin were found to be disordered. Their occupancies were estimated from an electron-density map, but they were not refined. The refinement of atomic parameters was carried out by the block-diagonal least-squares method by using isotropic temperature factors. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, with $w=1.0$ for all the reflections used. The final *R*-value was 0.11. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[8] The atomic parameters are listed in Table 1. A table of observed and calculated structure factors and a table of bond distances, angles, and conformation angles in α-cyclodextrin are kept at the office of The Chemical Society of Japan (Document No. 8028).

Description and Discussion of the Structure

Structure of α-Cyclodextrin. The structure and the numbering scheme of the α-cyclodextrin–*m*-nitroaniline hexahydrate complex are shown in Fig. 1. The average bond distances and angles over six glucose residues are given in Fig. 2. These values are in good agreement

Table 1. Final positional ($\times 10^4$) and thermal parameters
Estimated standard deviations are given in parentheses. OC indicates an occupancy factor for disordered atom.

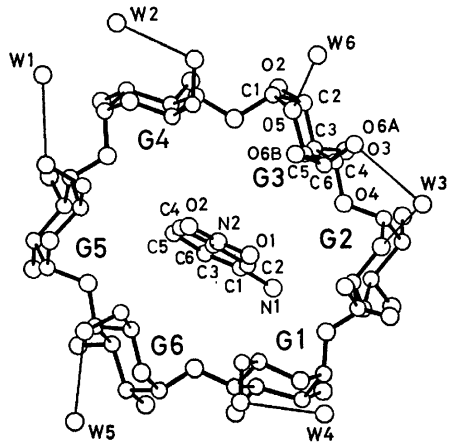

Fig. 1. Structure and numbering scheme of α-cyclodextrin–*m*-nitroaniline hexahydrate complex. O6A and O6B indicate disordered primary hydroxyl groups with *gauche-gauche* and *gauche-trans* conformations respectively. Water molecules are denoted by W1, W2, W3, W4, W5, and W6. Thin lines indicate intermolecular contacts less than 3.0 Å.

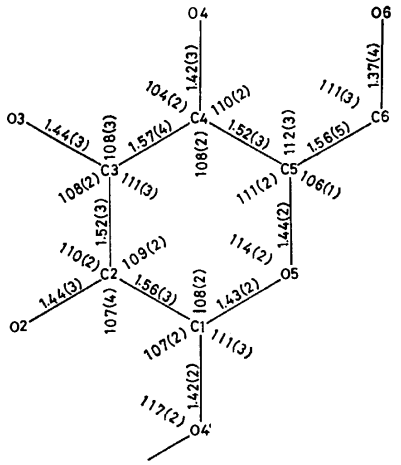

Fig. 2. Average bond distances (l/Å) and angles (ϕ/°) over six glucose residues. Standard deviations in parentheses were estimated according to the equation $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x})^2/5]^{1/2}$, where x_i referes to the bond distance or angle in the i-th residue and $\bar{x}$ is the average value.

with those of other α-cyclodextrin complexes.[2,3,5-7] The primary hydroxyl groups in G2 and G3 residues are statistically disordered, and show *gauche-gauche* (O(6A)) and *gauche-trans* (O(6B)) conformations, while the others are in the *gauche-gauche* conformation. The geometrical data for the α-cyclodextrin ring are given in Tables 2 and 3. The α-cyclodextrin ring is elliptically distorted owing to the inclusion of the planar molecule, and elongated along the guest plane. The difference in the longest and shortest diagonal distances, which are measured between glycosidic oxygen atoms, is 0.99 Å. This value is nearly the same as the corresponding values found in the α-cyclodextrin complexes with para-disubstituted benzenes,[3] but is larger than the value found in the *m*-nitrophenol complex (0.40 Å).[2] The O(4)···O(4) distances between adjacent glucose residues and the torsion-angle indices indicate that the distortion of the pyranose ring is smaller than that

TABLE 2. GEOMETRICAL DATA FOR α-CYCLODEXTRIN RING

I. O(4)···O(4) distances.[a]

Distance(l/Å)		Distance(l/Å)	
O(4,G1)···O(4,G2)	4.38	O(4,G5)···O(4,G6)	4.10
O(4,G1)···O(4,G6)	4.36	O(4,G1)···O(4,G4)	8.03
O(4,G2)···O(4,G3)	4.14	O(4,G2)···O(4,G5)	8.99
O(4,G3)···O(4,G4)	4.43	O(4,G3)···O(4,G6)	8.55
O(4,G4)···O(4,G5)	4.21		

a) Estimated standard deviations are between 0.03 and 0.04 Å.

II. O(2)···O(3) distances between adjacent glucose residues.[b]

Distance(l/Å)		Distance(l/Å)	
O(2,G1)···O(3,G2)	3.45	O(2,G3)···O(3,G4)	2.81
O(3,G1)···O(2,G6)	2.74	O(2,G4)···O(3,G5)	2.91
O(2,G2)···O(3,G3)	2.80	O(2,G5)···O(3,G6)	2.84

b) Estimated standard deviations are between 0.03 and 0.04 Å.

III. Torsion-angle indices and tilt-angles for glucose residue.

Residue	Torsion-angle index (ϕ/°)	Tilt-angle (ϕ/°)
G1	132	17.6
G2	140	19.7
G3	120	10.1
G4	124	9.9
G5	126	11.2
G6	121	18.5

observed in the complexes with para-disubstituted benzenes.[3] Five O(2)···O(3) distances between adjacent glucose residues are in the range capable of hydrogen-bond formation (from 2.74 to 2.91 Å), while the O(2,G1)···O(3,G2) distance of 3.45 Å indicates no hydrogen bond. The six glycosidic oxygen atoms (O(4)) are in the same plane within the deviation of 0.16 Å. The tilt-angle of the glucose residue, which is measured between the plane through the six O(4) atoms and the plane through the O(4*), C(1), C(4), and O(4) atoms, is in the range from 9.9 to 19.7°. These values

TABLE 3. LEAST-SQUARES PLANES AND DEVIATIONS OF ATOMS FROM THE PLANE

The plane equation is of the $AX+BY+CZ=D$ form, where X, Y, and Z are the coordinates in Å units along the a, b, and c* axes, respectively.

I. The plane through the six O(4) atoms

$0.982X-0.187Y-0.038Z=-0.730$

O(4,G1)	0.07	O(4,G4)	−0.02
O(4,G2)	−0.16	O(4,G5)	−0.08
O(4,G3)	0.13	O(4,G6)	0.05

II. *m*-Nitroaniline

$0.036X+0.888Y-0.459Z=6.565$

C(1,NP)	0.00	C(6,NP)	−0.04
C(2,NP)	0.02	N(1,NP)	−0.01
C(3,NP)	0.01	N(2,NP)	0.01
C(4,NP)	0.08	O(1,NP)	0.01
C(5,NP)	−0.01	O(2,NP)	−0.07

are relatively larger than those found in the α-cyclodextrin complexes with para-disubstituted benzenes (average value of 11.3°)[9] and *m*-nitrophenol (average value of 10.7°).[2]

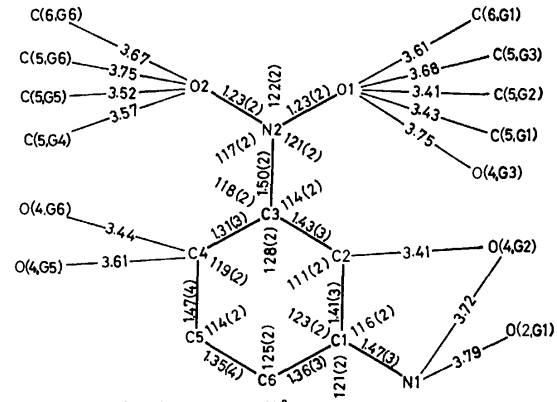

Fig. 3. Bond distances (l/Å) and angles (ϕ/°) in *m*-nitroaniline and selected intermolecular distances (l/Å) between *m*-nitroaniline and α-cyclodextrin. Estimated standard deviations in *m*-nitroaniline are given in parentheses, and those for intermolecular distances are in the range from 0.03 to 0.04 Å.

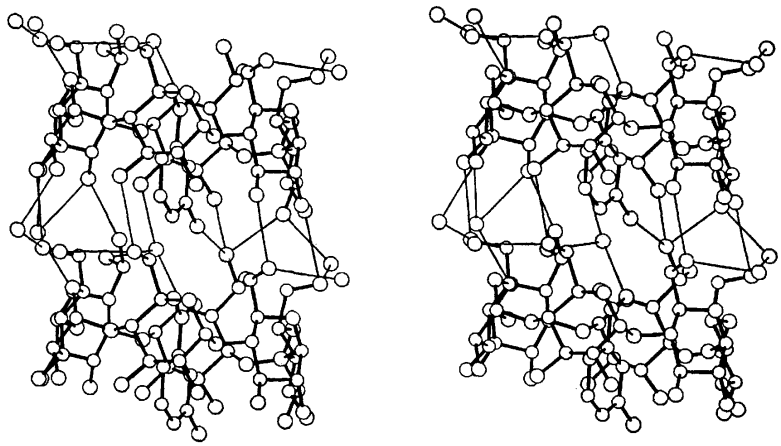

Fig. 4. A stereo-drawing of the packing feature of the complex with associated water molecules. Thin lines denote intermolecular contacts less than 3.0 Å.

Geometry of Inclusion. Figure 3 shows bond distances and angles in *m*-nitroaniline, and selected intermolecular distances between *m*-nitroaniline and α-cyclodextrin. α-Cyclodextrin molecules are stacked in head-to-tail fashion to form an endless channel, in which *m*-nitroaniline molecules are arranged as shown in Fig. 4. The nitrophenyl group is inserted into the α-cyclodextrin ring, while the amino group protrudes outside from the secondary hydroxyl side of α-cyclodextrin and forms a hydrogen bond with the primary hydroxyl group (O(6B,G2)) of the next α-cyclodextrin molecule. The nitrophenyl plane faces the G3 and G6 residues, and makes an angle of 83.5° with the plane through the six O(4) atoms. The shortest intermolecular distance is 3.41 Å, found in O(4,G2)···C(2,NP), and C(5,G2)···O(1,NP) contacts. The nitro group is surrounded by hydrogen atoms of C(5) methine groups and C(6) methylene groups. This inclusion geometry of the nitrophenyl group is quite similar to that found in the α-cyclodextrin–*p*-nitrophenol complex,[3] although the orientation of the nitrophenyl plane is slightly changed. In the *m*-nitroaniline complex, the nitrophenyl plane is parallel to the C(4)···C(4) diagonal of α-cyclodextrin, while the nitrophenyl group in the *p*-nitrophenol complex is parallel to the C(2)···C(2) diagonal. α-Cyclodextrin forms a 1:2 crystalline complex with *m*-nitrophenol[2] and also has a head-to-tail channel-type structure. Although one *m*-nitrophenol is located outside the α-cyclodextrin column, the other one is arranged in the channel. In that case, only the nitro group is inserted into the α-cyclodextrin ring, and therefore, the *m*-nitrophenol molecule is more loosely bound than the *m*-nitroaniline molecule.

In the *m*-nitroaniline complex, guest molecules are linearly arranged in the channel (Fig. 4). Some short contacts are observed between neighboring *m*-nitroaniline molecules: N(1,NP)···O(1,NP) distance of 3.14 Å and C(6,NP)···O(2,NP) distance of 3.24 Å. The O···N distance suggests a weak N–H···O hydrogen bond. The short C···O distance also shows that the *m*-nitroaniline molecules are very closely packed in the channel. Such short contacts were not observed in the *m*-nitrophenol complex.[2] The *m*-nitrophenol molecule is more tilted with respect to the channel axis, and the repetition unit along the channel (8.15 Å) is longer than that found in the *m*-nitroaniline complex (8.05 Å). As the result, the adjacent *m*-nitrophenol molecules are apart by 3.40 Å which is found between the phenolic hydroxyl group and the nitro group.

The tight packing of the guest *m*-nitroaniline molecule seems to affect its electronic state. Crystals of *m*-nitroaniline are dark yellow. When it forms the crystalline complex with α-cyclodextrin, the color changes to bright orange. This typical color change associated with the complex formation has been observed in the α-cyclodex-

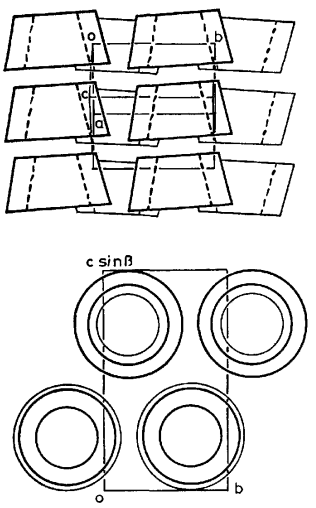

Fig. 5. Schematic drawings of the packing feature of α-cyclodextrin in the crystal.

trin–polyiodide complexes,[10] where the extensive delocalization of electrons has been suggested as an explanation. In the *m*-nitroaniline complex, the charge-transfer may also occur through the hydrogen bond between the amino group and the nitro group.

Crystal Structure. Schematic drawings of the packing features of α-cyclodextrin molecules in the crystal are shown in Fig. 5. Projections of the crystal structure are given in Figs. 6 and 7. Intermolecular distances less than 3.0 Å are given in Table 4. Most of these contacts are considered to be hydrogen bonds. α-Cyclodextrin molecules are stacked along the a axis in head-to-tail fashion, thus forming an endless column. The packing of α-cyclodextrin molecules differes from other head-to-tail channel-type structures with the space group of $P2_12_12$,[2,11] in which the α-cyclodextrin molecule is located on the two-fold axis. On the other hand, the α-cyclodextrin ring in the *m*-nitroaniline complex is not perpendicular to the channel axis, but makes an angle of 79.0°. Owing to such a tilt of the α-cyclodextrin ring and the *gauche-gauche* conformation of the primary hydroxyl groups, intermolecular contacts between α-cyclodextrin molecules are quite different from those found in the $P2_12_12$ crystals. The adjacent α-cyclodextrin molecules along the channel are linked by O(2)···water···O(6) hydrogen bonds for G1, G4, and G6 residues and O(2)···water···O(5) hydrogen bonds for G2 and G3 residues, as well as by O(3)···O(6) hydrogen bonds for each glucose residue (Fig. 4). The O(2)···water···O(5) hydrogen bond is observed when the primary hydroxyl group is in the *gauche-trans* conformation. Neighboring α-cyclodextrin columns are closely packed in the crystal (Fig. 6) and are linked by hydrogen bonds directly or through water molecules. On the other hand, such close packing is not found in the $P2_12_12$ crystals, in which there is a sufficient intermolecular space to accommodate a part of the guest molecules. Water molecules fill intermolecular spaces. They are separated into two groups. W1, W2, and W5 are located in the space encircled by G4, G5, and G6 residues. They are connected to each other by a W1···W2···W5 hydrogen-bonding linkage. On the other hand, W3, W4, and W6, which are also linked by hydrogen bonds, are surrounded by G1, G2, and G3 residues.

The author wishes to thank Dr. Hisashi Uedaira for supporting this study. The computation was done on a HITAC M-160II computer in our laboratory.

Raman Spectra of Cobalt(III) Complexes. II. Nitroammine Series of Cobalt(III) Complexes

Kan KANAMORI,* Tsutomu MORIKAWA, and Kiyoyasu KAWAI
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received March 22, 1980)

Solid and aqueous Raman spectra of the nitroammine series of cobalt(III) complexes, $[Co(NO_2)_n(NH_3)_{6-n}]^{(3-n)+}$ (n=1—6), have been measured for the region of 1500—100 cm^{-1}. The assignments of the Raman bands due to the skeletal vibrations of the complexes have been made on an empirical basis and compared with those of the infrared bands in the literature.

Infrared investigations[1-3] of the nitroammine series and the halogenoammine series of cobalt(III) complexes, including normal coordinate treatments by Nakagawa and Shimanouchi,[2,3] have offered interesting problems in the study of coordination bonds as well as in the stereoisomerism. The facial isomer of trinitrotriamminecobalt(III) was synthesized very recently,[4] though *cis*-tetranitrodiamminecobaltate(III) has not yet obtained.

Recently, the Raman spectra of the halogenoammine series have been measured by Swaddle *et al.*[5] and Loehr *et al.*[6] and the assignments of the infrared bands have been reexamined. Therefore, a detailed Raman study of the nitroammine series seems to be required for the full assignments of the skeletal vibrations of the complexes; brief communications for *trans*-$[Co(NO_2)_4(NH_3)_2]^-$ [7] and $[Co(NO_2)_6]^{3-}$ [8,9] have already appeared.

In the present work, we have measured the solid and the aqueous Raman spectra of the nitroammine series of cobalt(III) complexes and reinvestigated the assignments of the skeletal vibrations. We have also studied the intra-ligand vibrations of the *N*-deuterated complexes in D_2O, for which the overlapping of the bands due to the ammine and the nitro groups are eliminated.

Experimental

fac-Trinitrotriamminecobalt (III) was prepared by the method of Siebert.[4] Potassium pentanitroamminecobaltate (III) was prepared by the method of Shibata *et al.*[10] All other complexes were prepared by standard means. All the complexes were identified by the visible and ultraviolet spectra and by elemental analysis. *mer*- and *fac*-trinitrotriamminecobalt (III) complexes were also identified by the ^1H-NMR spectra.

The Raman spectra were recorded for the region lower than 1500 cm^{-1} on a JASCO R-800 Raman spectrometer with a data processor, using a He–Ne (632.8 nm) laser as an excitation source. The spectra observed in the low frequency region are shown in Fig. 1. The infrared spectra were recorded on a JASCO A-3 and Hitachi FIS infrared spectrometer. The observed frequencies were calibrated by those of indene for the Raman spectra and those of polystylene film for the infrared spectra. The observed frequencies are accurate within ± 2 cm^{-1}.

Results and Discussion

Intra-ligand Vibrations. The assignment of the vibrations due to ammine or nitro groups of coordination compounds has already established by many authors.[11] Table 1 summarizes the observed frequencies for the *N*-deuterated nitroammine cobalt(III) complexes in D_2O and their approximate modes.

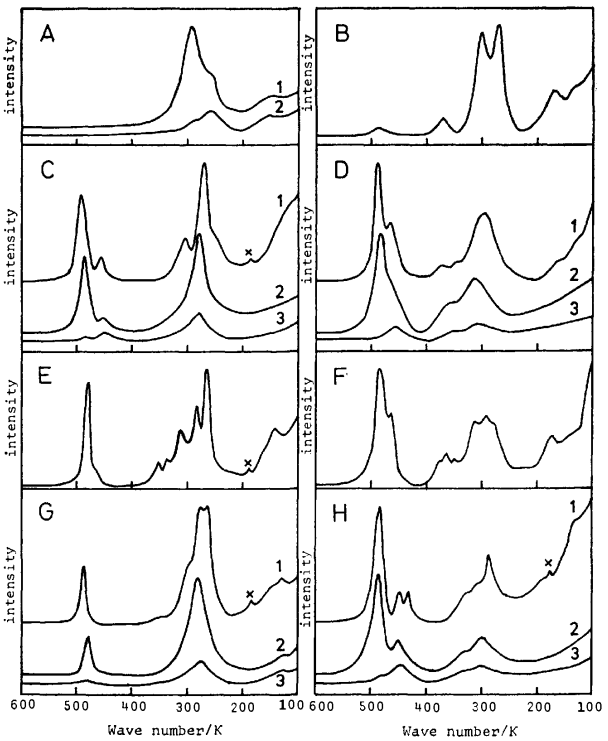

Fig. 1. Raman spectra of nitroammine cobalt (III) complexes. A: $Na_3[Co(NO_2)_6]$ in aqueous solution, //1, ⊥2. B: $K_2[Co(NO_2)_5(NH_3)]$ in solid state. C: *trans*-$[Co(NO_2)_2(NH_3)_4]NO_3$ in solid state, 1 and the fluoride in aqueous solution, //2, ⊥3. D: *cis*-$[Co(NO_2)_2(NH_3)_4]NO_3$ in solid state, 1 and the fluoride in aqueous solution, //2, ⊥3. E: *mer*-$[Co(NO_2)_3(NH_3)_3]$ in solid state. F: *fac*-$[Co(NO_2)_3(NH_3)_3]$ in solid state. G: *trans*-$NH_4[Co(NO_2)_4(NH_3)_2]$ in solid state, 1 and in aqueous solution, //2, ⊥3. H: $[Co(NO_2)(NH_3)_5]Br_2$ in solid state, 1 and the fluoride in aqueous solution, //2, ⊥3. x; no lasing line.

It is very interesting to compare the spectra of *trans* and *cis* isomers of $[Co(NO_2)_2(NH_3)_4]^+$ with a view toward differentiating between the geometric isomers. Faust and Quagliano[12] compared the solid infrared spectra of the isomeric pair. However, no essential difference was found between the spectra of the isomers, though the spectrum of the *cis* isomer is slightly more complicated than that of the *trans* isomer. The *cis* isomer of $[Co(NO_2)_2(NH_3)_4]^+$ shows two Raman bands

TABLE 1. OBSERVED FREQUENCIES (cm^{-1}) AND APPROXIMATE MODES OF THE INTRA-LIGAND VIBRATIONS OF *N*-DEUTERATED NITROAMMINE COBALT(III) COMPLEXES IN D_2O

(one polarized and another depolarized) in both the NO_2 symmetric stretching and the NO_2 bending vibration regions; three of the four bands have counterparts in the infrared spectrum. On the other hand, the *trans* isomer shows only one band in each region of the Raman and infrared spectra; here the mutual exclusion is found.

The mutual exclusion is also found for *trans*-$[Co(NO_2)_4(NH_3)_2]^-$. If it is assumed that this complex has a D_{4h} molecular symmetry, the NO_2 symmetric stretching and the NO_2 bending vibrations transform as $(A_{1g}+B_{1g}+E_u)$. This complex shows two Raman bands but only one infrared band in the NO_2 symmetric stretching and in the NO_2 bending vibration regions. The infrared frequency in each region does not coincide with either of the two Raman frequencies; this is consistent with the molecular symmetry assumed for the complex. In conclusion, it seems to be useful for differentiation of stereoisomers of nitrocomplexes to study the aqueous Raman and infrared spectra in the NO_2 symmetric stretching and the NO_2 bending vibration regions.

No useful aqueous Raman and infrared spectra have been observed for *mer*- and *fac*-$[Co(NO_2)_3(NH_3)_3]$ because of the low solubilities of the complexes in H_2O nor for $K_2[Co(NO_2)_5(NH_3)]$ because of the instability in water. No essential difference was found between the solid Raman spectra of the isomeric pair of $[Co(NO_2)_3(NH_3)_3]$. (see Table 2)

Skeletal Vibrations. Nakagawa and Shimanouchi[2] have studied the solid infrared spectra of the nitroammine series of cobalt(III) complexes and have performed a normal coordinate analysis for $[Co(NO_2)_6]^{3-}$, $[Co(NO_2)(NH_3)_5]^{2+}$, and *trans*- and *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ complexes.

In order to assign the observed Raman bands in this region, we will use two qualitative band intensity criteria. One is concerned with deformation vibrations. The skeletal bending vibrations of $[Co(NH_3)_6]^{3+}$ and $[Co(NO_2)_6]^{3-}$ appear as very weak and diffused bands in the aqueous Raman spectra.[5,13] Rocking vibrations of nitro groups of $[Co(NO_2)_6]^{3-}$ were not observed in the Raman spectrum.[9] So we can expect similar band profiles and intensities for the skeletal bending and nitro rocking vibrations of the nitroammine complexes. Therefore, the strong bands near 300 cm^{-1} in the aqueous Raman spectra of the nitroammine complexes will be confidently assigned to cobalt-nitro stretching vibrations, though skeletal bending and nitro rocking vibrations are expected to be in the same region.

Another criteria is concerned with stretching vibrations. Table 3 shows symmetry correlations related to metal-ligand stretching vibrational modes among $[Co(NH_3)_6]^{3+}$ (O_h), *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ (D_{2h}), and $[Co(NO_2)(NH_3)_5]^{2+}$ (C_{2v}). For instance, the B_1 and B_2 modes due to the four equatorial Co–NH_3 bonds in C_{2v} symmetry, though formally Raman-allowed, correlate with the B_{2u} and B_{3u} modes in D_{2h} symmetry, respectively, so we expect that they will be hardly

detectable in the Raman spectrum of $[Co(NO_2)(NH_3)_5]^{2+}$.

$[Co(NO_2)_6]^{3-}$: The Raman spectra of $[Co(NO_2)_6]^{3-}$ have been studied for the potassium salt by Nakagawa[9] and for the sodium salt and the aqueous solution by Krasser.[8] Krasser[8] has reported the Raman bands at 410, 300, 245, 175, and 150 cm^{-1} for the complex in aqueous solution. We have observed only three bands in this region of the aqueous spectrum (see Fig. 1A). The most intense and polarized band at 292 cm^{-1}, the somewhat intense and depolarized band at 262 cm^{-1}, and the weak and depolarized band at 158 cm^{-1} are assigned, respectively, to the $\nu(Co–NO_2)$ A_g, the $\nu(Co–NO_2)$ E_g, and the $\delta(NO_2–Co–NO_2)$ F_g modes; this assignment is consistent with the assignment of the solid spectrum by Nakagawa.[9] The weak shoulder near 230 cm^{-1} is attributed to a degradation product, since the relative intensity of the shoulder increased with time.

trans- *and* cis-*$[Co(NO_2)_2(NH_3)_4]^+$* *and* trans-*$[Co(NO_2)_4(NH_3)_2]^-$*: The observed frequencies and assignments of the skeletal vibrations for *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ and *trans*-$[Co(NO_2)_4(NH_3)_2]^-$ are summarized in Table 4 and those for *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ in Table 5.

The X-ray study[14] for *trans*-$[Co(NO_2)_2(NH_3)_4]NO_3 \cdot H_2O$ shows that this complex has approximately D_{2h} symmetry, with the first mirror containing the two nitro groups, the second containing the four nitrogens of the ammine groups and the last perpendicular to the other mirrors.

There appears to be no previous Raman study of this complex. If it is assumed that this complex possesses an idealized D_{2h} molecular symmetry, the metal-ligand stretching vibrations transform as shown in Table 3, with the g modes being Raman active and the u modes being infrared active. The aqueous Raman spectrum has a very simple shape (see Fig. 1C) and can be easily assigned on the basis of polarization measurements and comparison with the assignments of $[Co(NH_3)_6]^{3+}$ and $[Co(NO_2)_6]^{3-}$.

The X-ray study[15] for *cis*-$[Co(NO_2)_2(NH_3)_4]NO_3$ shows that this complex actually has a lower symmetry than C_{2v}. However, if it is assumed that this complex possesses an idealized C_{2v} symmetry, the cobalt-ligand stretching vibrations transform as $(2A_1+B_1+B_2$ for $\nu(Co–NH_3))$, and $(A_1+B_1$ for $\nu(Co–NO_2))$, all of which are Raman and infrared active. According to the normal coordinate analysis[2] based on the C_{2v} symmetry of this complex, the frequency order of the four $\nu(Co–NH_3)$ is $B_2>A_1>B_1>A_1$. The most strong and polarized band at 483 cm^{-1} is assigned to the A_1 mode

of higher frequency. Nakagawa and Shimanouchi[2] have assigned the infrared band at 385 cm^{-1} to another A_1 mode. This frequency seems to be rather low for $\nu(Co-NH_3)$ and we have observed no distinct Raman band near 385 cm^{-1}. This A_1 mode may be assigned to the shoulder near 445 cm^{-1} observed in the solid Raman spectrum of *cis*-$[Co(NO_2)_2(NH_3)_4]Cl$; this would be consistent with the assignment for the Raman spectrum of *cis*-$[CoCl_2(NH_3)_4]Cl$,[5] where the band at 435 cm^{-1} has been assigned to the corresponding mode. The B_2 mode has been assigned to the infrared band at 518 cm^{-1},[2] but no distinct Raman band has been observed at the frequency. The Raman intensity of this mode is expected to be rather weak, because this mode corresponds to an antisymmetric cobalt-ammine stretching vibration of the linear NH_3–Co–NH_3 moiety.

The peak frequency of the band near 310 cm^{-1} in the isotropic spectrum of *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ is 7 cm^{-1} higher than that in the anisotropic one. This discrepancy of the band maxima suggests that the band near 310 cm^{-1} consists of two components. The polarized component at 310 cm^{-1} and the depolarized component at 303 cm^{-1} are assigned to the $\nu(Co-NO_2)$ A_1 and B_1 modes, respectively.

It is interesting to compare the Raman and infrared spectra of *trans*- and *cis*-$[Co(NO_2)_2(NH_3)_4]^+$. The coincidence of the Raman frequencies with the infrared ones has not been found in the *trans* isomer, but in the *cis* isomer (see Table 5). The relative intensity of the Raman band due to $\nu(Co-NO_2)$ is stronger in the *trans* isomer than in the *cis* isomer (see Figs. 1C and D). A similar intensity difference of $\nu(Co-NO_2)$ between isomeric pairs is also found in *mer*- and *fac*-$[Co(NO_2)_3(NH_3)_3]$.

The X-ray study[16] for *trans*-$NH_4[Co(NO_2)_4(NH_3)_2]$ shows that the four nitro groups are tilted 56°, 42°, 48°, and 86° to the square plane and actually this complex has no center of symmetry. This lowering of the molecular symmetry in solid state is reflected in the complexity of the spectral features. The observed data are listed in an Appendix. On the other hand, in aqueous solution this complex can be assumed to possess a D_{4h} symmetry as stated above, and so one can expect that there will appear two bands (one polarized and another depolarized) due to the $\nu(Co-NO_2)$ and one polarized band due to the $\nu(Co-NH_3)$ in the Raman spectrum. The aqueous Raman spectrum exhibits two bands which can be attributed to the $\nu(Co-NO_2)$ and the $\nu(Co-NH_3)$, respectively. However, the discrepancy between the peak frequencies of the $\nu(Co-NO_2)$ of the isotropic and the anisotropic spectra suggests that two Raman bands are overlapped. The polarized component at 282 cm^{-1} and the depolarized component at 276 cm^{-1} are assigned to the $\nu(Co-NO_2)$ A_g and B_{1g} modes, respectively. The polarized band at 479 cm^{-1} is unambiguously assigned to the $\nu(Co-NH_3)$ A_g mode. Accordingly, the aqueous Raman spectrum of *trans*-$[Co(NO_2)_4(NH_3)_2]^-$ is explained reasonably in terms of D_{4h} symmetry in the skeletal vibration as well as in the intra-ligand vibration regions.

$[Co(NO_2)(NH_3)_5]^{2+}$ and $[Co(NO_2)_5(NH_3)]^{2-}$: The X-ray study[17] for $[Co(NO_2)(NH_3)_5]Br_2$ shows that the virtual symmetry of this complex is very close to C_{2v}, with one of the mirrors containing the NO_2 group and bisecting the NH_3–Co–NH_3 angle. On the basis of C_{2v} symmetry for this complex, the metal-ligand stretching vibrations transform as shown in Table 3, with all modes being Raman active and all but the A_2 mode being infrared active. However, we can hardly expect the Raman bands corresponding to the B_1 and B_2 modes due to the stretching vibrations of the equatorial ammine groups, according to the qualitative band intensity criteria discussed above.

The observed frequencies and the assignment of $[Co(NO_2)(NH_3)_5]^{2+}$ are summarized in Table 6 along with the infrared data. The somewhat intense band near 450 cm^{-1} is unambiguously assigned to the $\nu(Co-NH_3)_{eq}$ A_2 mode since this band is depolarized and has no counterpart in the infrared spectrum. The most intense band near 490 cm^{-1} is assigned to the $\nu(Co-NH_3)_{eq}$ A_1 mode on the basis of the correlation with the $\nu(Co-NH_3)$ A_{1g} mode of *trans*-$[Co(NO_2)_2(NH_3)_4]^+$, though the corresponding infrared band has been assigned to the $\nu(Co-NH_3)_{ax}$.[2] Our assignment is consistent with that for the $\nu(Co-NH_3)_{eq}$ of $[CoCl(NH_3)_5]^{2+}$ proposed by Swaddle *et al.*[5] and Loehr *et al.*[6] These authors have assigned the $\nu(Co-NH_3)_{ax}$ A_1 mode of $[CoCl(NH_3)_5]^{2+}$ to the medium band at 463 cm^{-1}. By the comparison

TABLE 6. OBSERVED FREQUENCIES (cm^{-1}) AND ASSIGNMENT OF $[Co(NO_2)(NH_3)_5]^{2+}$

with the assignment, the shoulder near 460 cm^{-1}, which is observed in the solid Raman spectrum of $[Co(NO_2)(NH_3)_5](NO_3)_2$, may be assigned to the $\nu(Co-NH_3)_{ax}$ A_1 mode. The band at 429 cm^{-1} of the solid Raman spectrum of nitropentaamminecobalt(III) bromide or chloride has not been observed for the aqueous solution nor for the nitrate, though the corresponding band has been observed for the infrared spectrum.[2] This band is rather low in the frequency for $\nu(Co-NH_3)$ and may not be a fundamental vibration.

No X-ray study has been done for $K_2[Co(NO_2)_5(NH_3)]$. The observed frequencies of the solid Raman spectrum are listed in the Appendix. The band at 488 cm^{-1} is confidently assigned to the $\nu(Co-NH_3)$. However, a detailed assignment of other bands is difficult, since a useful aqueous Raman spectrum could not be obtained because of the fast decomposition in water. In the aqueous Raman spectrum, the band at 488 cm^{-1} disappears and a new band appers at 467 cm^{-1}.

Table 7. Observed frequencies (cm^{-1}) and approximate mode of *mer* and *fac* isomers of $[Co(NO_2)_3(NH_3)_3]$

a) For DMSO solution. b) N and N′ stand for NH_3 and NO_2 groups, respectively.

mer- *and* fac-$[Co(NO_2)_3(NH_3)_3]$: The X-ray study[18] for the *mer* isomer shows that this complex has a lower symmetry than C_{2v}. No X-ray study has been reported for the *fac* isomer. We have observed the Raman spectrum of dimethylsulfoxide solution of each isomer because of the low solubility of these complexes in water. The observed frequencies and the tentative assignments are summarized in Table 7. As explained for the relative intensities of $\nu(Co-NO_2)$ of *trans*- and *cis*-$[Co(NO_2)_2(NH_3)_4]^+$, the *mer* isomer, which contains *trans* nitro groups, exhibits a very strong band due to $\nu(Co-NO_2)$, while the *fac* isomer, which contains *cis* nitro groups only, exhibit medium or weak bands (see Figs. 1E and F).

The authors are indebted to professor Yoichi Shimura of Osaka University and Dr. Isao Kanesaka of our university for their valuable discussions.

Solvent Induced Structural Change of 18-Crown-6 Complexed Ion Pair with 9-Fluorenone Anion Radical as Studied by ESR Spectroscopy

Kazuo NAKAMURA

Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received March 24, 1980)

ESR spectra of the ion pairs of the 9-fluorenone anion radical with 18-crown-6 complexed sodium and potassium ions were examined. From the dependence of the carbonyl ^{13}C hyperfine splitting of the fluorenone anion on temperature and solvent, it was conclude that an ethereal solvent molecule can solvate the crown complexed cation on the opposite side of the anion with respect to the plane of the crown ether ring, equilibrium taking place between the solvated and unsolvated ion pairs in ethereal solution. The unsolvated species of both the potassium and the sodium ion pairs and the solvated species of the sodium ion pair are classified as contact ion pairs, the solvated species of the potassium ion pair a crown separated one. The equilibrium constant between the solvated and unsolvated ion pairs changes with temperature and solvent. From this change the enthalpy changes of solvation process were estimated for several solvents.

Recently interest has been focused on the high complexing ability of macrocyclic polyethers (crown ethers) with respect to the alkali metal ions. Since crown ethers form two dimensional complexes with cations in most cases, a counteranion and other donor molecules are capable of interacting with the cation on either or both sides of the plane of the crown ether ring, as demonstrated by X-ray crystallographic studies of a number of crown complexed inorganic salts.[1,2] This behavior of the complexes will be observed in solution.

Crown complexes alkali metal ions exist as ion pairs in ethereal solvents.[3-6] In these ion pairs it is possible that ethereal molecules can participate in coordination of the cation, since ethereal molecules are very strong cation-complexing agents[7] and one side of the two dimensional crown complex is occupied by a counteranion but the other is vacant. If this is the case, the structure of the ion pair in ethereal solvents would differ to some extent from those in solvents incapable of participating in coordination.

This paper deals with the solvation phenomena of the crown complexed ion pairs, on the basis of ESR studies of the 9-fluorenone anion radical forming an ion pair with 18-crown-6 complexed sodium and potassium ions. The carbonyl ^{13}C hyperfine splitting of the fluorenone anion is sensitive to environmental conditions, reflecting the structural changes of the ion pairs caused by cation solvation.

Experimental

Solvents. Ethereal solvents and toluene were used after being dried with sodium hydride or Na–K alloy.

Material. 15-Crown-5 and 18-crown-6 ethers (M. E. Merck) were used without further purification.

Preparation of the Anion Radical. The anion was prepared by reduction of 9-fluorenone with sodium or potassium mirror in a solution containing excess crown ether. All the operations were carried out in a high vacuum.

Measurements of ESR Spectra. A JES-PE ESR spectrometer, equipped with a magnet of a 10 in diameter pole piece and with a JES-VT-3A2 variable temperature controller was used.

Results and Discussion

Solvent Effect on the 18-Crown-6 Complexed Ion Pair. The carbonyl ^{13}C hyperfine splitting (a_C) of the fluorenone anion radical forming the ion pair with 18-crown-6 (C-6) complexed sodium ion shows an appreciable solvent dependence, ranging from 4.21 G in tetrahydrofuran (THF) to 5.00 G in toluene, diethyl ether and diisopropyl ether (Table 1). Since ethereal solvents solvate anions weakly and cations strongly, it is reasonable to assume that the solvent effect can be attributed to the difference of solvent in cation solvating power. It has been found that a_C increase with increasing cationic field acting on the carbonyl group,[8-10] the cationic field decreasing with increase in the separation between the cation and the anion. The observed decrease of a_C from toluene to THF certainly arises from the increase in the cation-anion separation caused by enhancement of cation solvation. Thus, the solvent order of decreasing a_C corresponds to that of increasing cation solvation. The solvent order of cation solvation (Table 1) differs somewhat from that observed in most cases. Polydentate solvents such as 1,2-dimethoxyethane and diglyme usually show stronger cation solvation than monodentate solvents such as THF and tetrahydropyran.[11,12] In the present system, however, the order is reversed. This suggests that the polydentate

Table 1. Solvent data on ^{13}C hfs (a_c) and ratio of solvated to unsolvated species (K) for sodium ion pair at 20 °C

Solvent	a_c(G)	K
Tetrahydrofuran	4.21	2.93
Tetrahydropyran	4.48	0.96
2-Methyltetrahydrofuran	4.51	0.86
Dioxane	4.58	0.66
1,2-Dimethoxyethane	4.58	0.66
Diglyme	4.59	0.63
1,2-Diethoxyethane	4.78	0.26
2,5-Dimethyltetrahydrofuran	4.85	0.16
Diisopropyl ether	5.00	0
Diethyl ether	5.00	0
Toluene	5.00	0

character of solvent does not work effectively, probably because most part of the coordination sphere around the cation is already occupied by the carbonyl and 18-crown-6 oxygen atoms, and the residual part can not allow more than one oxygen atom of solvent to coordinate the cation. This also indicates that only one solvent molecule can solvate the crown complexed cation forming the ion pair.

Since it is unreasonable to assume any specific interaction between an alkali metal ion and a toluene molecule, the crown complexed ion pair in toluene would exist in unsolvated state. The fact that a_C in diethyl ether and diisopropyl ether is identical with a_C in toluene indicate that these solvents can not solvate the crown complexed cation in the present system.

Hyperfine splittings due to sodium were observed, irrespective of solvent. Addition of C-6 led to the increase of the sodium hyperfine splitting (a_{Na}) in a solvent, in contrast to the decrease of a_C (for example, in the THF solution, $a_{Na}=0.49$ G in the presence of C-6, while $a_{Na}=0.41$ G in the absence of C-6 at 20 °C).[13] Since the complex formation of a crown ether with a cation causes increase in the separation of the cation and the counteranion, the increase of a_{Na} observed suggests that factors other than the cation-anion separation play an important role for deciding the magnitude of a_{Na}.[10,13]

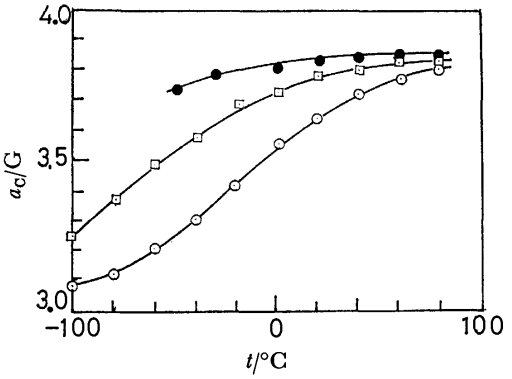

Fig. 1. Temperature dependence of the ^{13}C hfs in the fluorenone anion radical for potassium ion pair.
○: THF, □: MTHF, ●: DMTHF.

Temperature Dependence of a_C. The a_C values of both the potassium and the sodium ion pairs decrease with lowering in temperature, the magnitude of decrease varying with solvent. In a solvent with stronger cation solvation power a_C shows a larger temperature dependence. The change of a_C with temperature is significant in THF, but almost independent of temperature in diethyl ether. Figure 1 shows temperature *vs.* a_C curves of the C-6 complexed potassium ion pair in THF, 2-methyltetrahydrofuran (MTHF), and 2,5-dimethyltetrahydrofuran (DMTHF) in the temperature range −100 °C—+80 °C. At high temperature a_C of these three solutions approach each other, converging to the value nearly equal to a_C in diethyl ether ($a_C=3.90$ G); at low temperatures a_C in THF shows a value of lower limit ($a_C=3.05$ G). Similar features can be observed in the temperature *vs.* a_C curves of the C-6 complexed

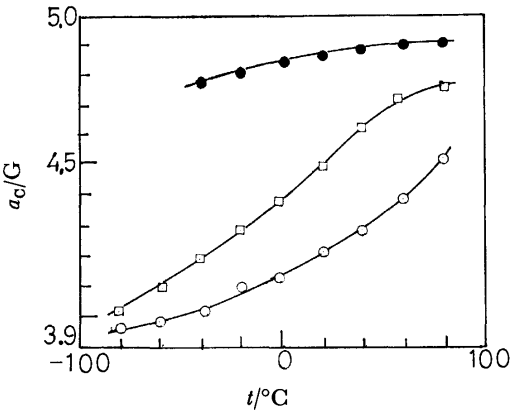

Fig. 2. Temperature dependence of the ^{13}C hfs in the fluorenone anion radical for sodium ion pair.
○: THF, □: MTHF, ●: DMTHF.

sodium ion pair (Fig. 2).

The temperature and solvent dependence of a_C could be explained in terms of the equilibrium between the solvent and unsolvated species of the C-6 complexed ion pair:

$$A^-M^+C + S \rightleftharpoons \underset{C}{A^-M^+S}, \quad (1)$$

where A^- is the fluorenone anion, M^+ an alkali metal ion, C a crown ether molecule, and S a solvent molecule. We always observe the average a_C of the solvated and unsolvated species, since the exchange rate between the both species is high in the ESR time scale. Since the solvation process is exothermic, the observed a_C approaches a_C of the unsolvated species at high temperature and a_C of the solvated species at low temperature. The equilibrium constant of Eq. 1 can be expressed by

$$K = (a_u - a_m)/(a_m - a_s), \quad (2)$$

where a_u and a_s are a_C of the unsolvated and solvated species respectively, and a_m is the observed splitting. a_u would be equal to a_C in toluene or diethyl ether, and a_s to or slightly smaller than the limiting value of a_C in THF at low temperatures. Therefore, substituting 5.00 G for a_u and 3.94 G for a_s in the sodium ion pair, and 3.90 G for a_u and 3.05 G for a_s in the potassium ion pair, we are able to calculate the equilibrium constant K of Eq. 1 by means of Eq. 2. The values of K at 20 °C for each solvent used are given in Table 1. The enthalpy change of the solvation process expressed by Eq. 1 can be estimated from the plots of ln K *vs.* $1/T$ for THF, MTHF, and DMTHF solutions of the sodium and potassium ion pairs (Table 2). The plots show that linearity holds between ln K and $1/T$ (Figs. 3 and 4).

A Possible Model. Possible models for solvation

process of the crown complexed cation are schematically shown in Fig. 5. In the unsolvated ion pairs the cation is pulled out of the plane of the crown oxygen atoms toward the fluorenone anion (Fig. 5 (a)). When a solvent molecule solvates the cation on the opposite side of the anion with respect to the plane of the crown ether ring, the location of the cation shifts toward the center of the ring plane (Fig. 5 (b)), the cation being located on the other side of the anion with respect to the crown ether (Fig. 5 (c)). For both cases of solvation, a conformational change of the crown ether molecule would take place and the separation between the anion and the cation would increase due to steric hinderance of the crown ether. When the ion pairs are classified in terms of a contact and crown-separated ion pair, the species for Fig. 5 (a) and (b) should be referred to a contact ion pair, and the species for Fig. 5 (c) to a crown-separated one. Since the lower limit of a_C for the crown complexed sodium ion in THF (a_C=3.94 G) is close to the uncomplexed caesium ion pair in THF at 20 °C (a_C=3.90 G),[13] the solvated sodium ion pair can be classified as a contact ion pair and would have the structure of Fig. 5 (b). On the

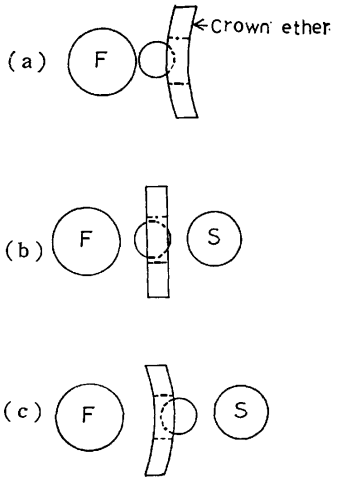

Fig. 5. Schematic representation for solvation process. Ⓕ: Fluorenone anion. Ⓢ: Solvent molecule. ○: Alkali metal cation.

other hand, the lower limit of a_C for the crown complexed potassium ion pair in THF (a_C=3.05 G) is considerably small as compared with a_C of any uncomplexed contact ion pair observed so far, and even smaller than a_C of the free anion in dimethyl sulfoxide (a_C= 3.20 G). The a_C value of the free anion is dependent on the anion solvation power of solvent. a_C of the free anion in THF is estimated to be 1.34 G, using the relation between Gutmann's acceptor number and a_C obtained previously.[14] The potassium ion pair complexed by both a crown ether and solvent molecule would have a structure such as Fig. 5 (c) classified as a crown-separated ion pair. The model, in which the anion and a solvent molecule are located on each side of the plane of the crown ether ring, is supported by the result of ESR studies on the 15-crown-5 complexed potassium ion pair, a_C of the 15-crown-5 complexed ion pair (a_C=3.92 G) being almost independent of solvent and temperature. This is probably due to the fact that, since the size of a potassium ion is too large to fit the cavity of 15-crown-5 ether, the solvent molecule can not solvate the crown complexed cation in such a manner as shown in Figs. 5 (b) and (c).[15]

The present conclusion is also supported by X-ray structures for dibenzo-18-crown-6 complexed NaNCS and $NaBr2H_2O$.[1,2] In the former the sodium ion is pulled out of the plane of the crown ether oxygen atoms toward the anion by 0.05 nm, while in the latter the sodium ion is sandwiched by a bromide ion and a water molecule and pulled out of the plane toward the bromide ion only by 0.027 nm.

The difference in a_C between the unsolvated and solvated species of the sodium ion pair is greater than that in a_C between the sodium ion pair (a_C=4.85 G) and caesium ion pair (a_C=3.90 G) in THF in the absence of C-6. This indicates that the increase of the cation-anion separation caused by the solvation of one ethereal molecule is of the same order of magnitude as the difference in ionic radius between a caesium ion and a sodium ion amounting to 0.07 nm. The reason why the interaction of one ethereal molecule with the

sodium ion can induce such a large change in the separation might be considered as follows. On the basis of measurement of the electric dipole moment of the ion pair of *p*-toluenesulfonate with a dibenzo-18-crown-6 complexed potassium ion in octanoic acid, Ting-Po I and Grunwald[16] estimated the relative stabilities of several models for the ion pairs, ignoring the solvation energy of the cation, and shown that although the contact ion pair such as shown in Fig. 5 (a) is the most stable, the energy difference between models including crown-separated ion pairs are only few kilocalories per mole. The difference in energy is comparable to the solvation energy of a cation by one ethereal molecule. If the situation is similar to the present system, the solvation of the cation by one solvent molecule would be capable of inducing the observed structural changes of the ion pairs.

Electrical and Optical Properties of the 5,6:11,12-Bis(epidithio)-naphthacene-Bromine System (TTT-Br_n). Formation of Organic Mixed-valence Compounds (TTT)-$(TTT^+)Br^-$ and $(TTT^+)(TTT^{2+})(Br^-)_3$

Yoshio MATSUNAGA* and Kazuhiro TAKAYANAGI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 10, 1980)

The electrical resistivity of the 5,6: 11,12-bis(epidithio)naphthacene–bromine system (TTT–Br_n) was examined over the composition range from $n=0.3$ to 2.0 using polycrystalline compactions. The room-temperature resistivity shows a minimum of about 7 Ω cm near $n=0.5$, suggesting the formation of a mixed-valence compound, (TTT)-$(TTT^+)Br^-$. The resistivity increases monotonously with n. No anomaly was found at the composition of (TTT^+)-Br^-. The formation of another mixed-valence compound, the ideal composition of which may be expressed by the formula $(TTT^+)(TTT^{2+})(Br^-)_3$, is indicated by an abrupt change of the resistivity from 100 to 4000 Ω cm around $n=1.5$. This change is accompanied by an increase of the activation energy for semiconduction by a factor of almost two and also by the change of sign in the variation of the Seebeck coefficient with the temperature from positive to negative. A further increase of the resistivity by a factor of ten was observed between $n=1.5$ and 2.0. The electronic and vibrational spectra support the coexistence of the TTT molecule and the TTT^+ ion near $n=0.5$ and that of the TTT^+ and TTT^{2+} ions near $n=1.5$.

The term "mixed-valence" has been adopted for the description of the inorganic systems containing an element in two different states of oxidation. Such systems are of great interest as their properties are frequently far from the sum of the properties of the two metal ions taken separately. The appearance of electronic conduction much higher than those in the compounds containing either valence state alone, as is exemplified by magnetite, $Fe^{II}Fe^{III}{}_2O_4$, is one of the striking features of many mixed-valence compounds. A large number of organic compounds, which contain both the molecules and the radical ions, have been prepared in the last two decades. Some of them are highly conducting. Tetrathiafulvalene–tetracyano-*p*-quinodimethane (TTF–TCNQ), complex TCNQ salts, and so-called iodine complexes are notable examples. In contrast to a great variety of valence in inorganic compounds, all the organic compounds so far studied consist of the formally neutral molecules and the monopositive or mononegative radical ions. In this work, we searched for the first example of the organic mixed-valence compounds where the mean valence would be higher than one. 5,6 : 11,12-Bis(epidithio)-naphthacene (TTT) seemed to be the best molecular species for our purpose as a number of the stable TTT^+ salts and also fairly stable TTT^{2+} salts are known from the work of Marschalk and Niederhauser.[1] The counter ions which they used to prepare both TTT^+ and TTT^{2+} salts are Cl^-, Br^-, NO_3^-, and SO_4^{2-}. We selected the bromides as the most promising component compounds.

The mixed-valence compounds of TTT with the mean valence of less than one have been studied by several workers. One of the present authors reported the preparation of the *o*-chloranil and *o*-bromanil complexes of a 3 : 1 mole ratio.[2,3] In their electronic spectra, there are strong absorption bands assignable to the TTT^+ ion. In addition, a broad electronic absorption band having a maximum around 2500 cm^{-1} is indicative of an interaction between the TTT molecule and the TTT^+ ion. The compactions exhibit resistivities of the order of one Ω cm at room temperature. The bis(1,2-ethylenedithiolato)nickel(II) complex prepared by Interrante *et al.* is another example.[4] As the complex has the empirical formula $TTT_{1.2}(NiS_4C_4H_4)$ and there is complete charge transfer from TTT to $NiS_4C_4H_4$, on the average each of the TTT molecules bears a formal charge of +5/6. The dc resistivity along the c-axis direction of the single crystal has been reported to be about 0.03 Ω cm at 25 °C. The extensively-studied iodine complex TTT–$I_{1.5}$ is also a kind of mixed-valence compound.[5-7] Because of the formation of polyiodide ions, the mean valence is less than one even if more iodine is added.[8] The single crystal resistivities measured along the needle axes in both the TTT–$I_{1.5}$ and TTT–$I_{2.7}$ phases are known to be metallic in the temperature range from 200 to 300 K. Therefore, it seemed very likely that low-resistivity mixed-valence compounds can be found with the TTT–Br_n system.

Experimental

Materials. TTT was synthesized following the method reported by Marschalk and Stumm and recrystallized three times from trichlorobenzene.[9] The dibromide was prepared by the oxidation of powdered TTT suspended in trichlorobenzene with bromine.[1] The samples with n values less than two were prepared by grinding the weighed $TTT^{2+}(Br^-)_2$ and TTT in an agate mortar in the presence of a small amount of benzene; the powders were then dried at 100 °C. The compositions were determined by microanalysis.

Measurements. The electrical resistivities and Seebeck coefficients of polycrystalline compactions were recorded as functions of the temperature from −100 to 100 °C by the procedures employed in our previous work.[8] The electronic and vibrational spectra were measured both as potassium bromide disks by means of a Beckman DK 2A spectrophotometer and a JASCO IR-G spectrophotometer respectively.

Results and Discussion

Electrical Properties. The temperature depend-

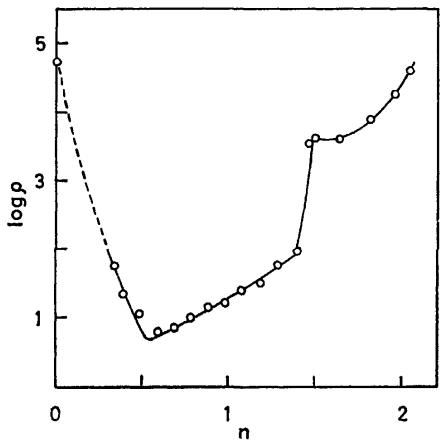

Fig. 1. Electrical resistivity at 25 °C plotted against the bromine content (n Br atoms/TTT molecule).

ence of the resistivity, ρ, of the polycrystalline compactions follows the typical semiconductor behavior: $\rho=\rho_0\exp(E_a/kT)$. In Fig. 1, the logarithm of resistivity at 25 °C is plotted against n. The drastic decrease of the resistivity compared to those at $n=0$ and 2 is clearly due to the oxidation-reduction between the TTT molecule and the TTT^{2+} ion. The solid-state and solution spectra of the mono- and dibromides are distinctly different from each other,[10] so there is no doubt about the existence of TTT^+Br^- and $TTT^{2+}(Br^-)_2$. The specimens with n values between one and two must formally consist of the TTT^+ and TTT^{2+} ions and bromide ions; those with n values less than one must consist of the TTT molecules, the TTT^+ ions, and bromide ions. As the resistivity is sensitive to the composition change, its measurement provides a simple means of detecting the possible mixed-valence compounds. An anomaly appearing in these two composition ranges can be assigned to such a compound. A minimum resistivity of about 7 Ω cm found near $n=$ 0.5 is indicative of the formation of the compound $(TTT)_2Br$. The formation of this mixed-valence compound is not unexpected. Very recently, Ritvay-Emandity *et al.* have concluded that the chloride precipitated upon mixing the methanol solutions of TTT^+ acetate and potassium chloride has the composition of $(TTT)_2Cl$.[11] In addition, a closely-related 5,6:11,12-(epidiseleno)naphthacene (TSeT) has been known to form the chloride of the same ratio, $(TSeT)_2Cl$.[12]

The electrical resistivity increases monotonously up to 100 Ω cm by $n=1.4$. No indication of a well-established compound TTT^+Br^- is found in the resistivity-composition isotherm. For this compound, Perez-Albuerne *et al.* have reported a resistivity of 50 Ω cm at 25 °C.[13] Our value at this composition is 18 Ω cm. Between $n=1.4$ and 1.5, the resistivity increases by a factor of forty. Such a behavior may arise from the formation of a nonstoichiometric compound, the lower limit of the existence region being located at $n=1.4$. The sharp edge appearing in this figure suggests that the ideal composition of this phase is $(TTT)_2Br_3$. This is the kind of compound we looked for in this system. The additional carriers introduced by the incorporation of extra TTT^+ ions into this ideal compound account for the marked decrease of the resistivity in this narrow composition range. Above $n=1.5$, the resistivity increases again and reaches about 4×10^4 Ω cm at $n=2$.

The formation of the latter mixed-valence compound is strongly supported by the variation in the activation energy for semiconduction in its existence region. The activation energy is approximately constant below $n=1$, the value being 0.115 eV. This value is in good agreement with 0.11 eV reported by Perez-Albuerne *et al.* for TTT^+Br^-. The energy increases gradually to 0.13 eV by $n=1.4$ and then abruptly to 0.21 eV by $n=1.5$. Above this composition, it remains at this value.

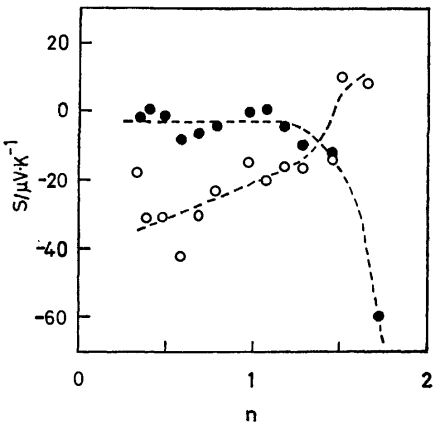

Fig. 2. Seebeck coefficients at −90 °C (○) and at 60 °C (●) plotted against the bromine content.

The whole composition range is also divided into two by the sign and temperature dependence of the Seebeck coefficient. When n is less than one, the coefficient is −20 to −30 μV K^{-1} at low temperatures and increases monotonously to about 0 μV K^{-1} at high temperatures. The direction of the temperature variation is reversed above $n=1.5$. A small positive value found below 0 °C is nearly independent of the temperature. The coefficient becomes negative above 0 °C and shows a large decrease by the further raising of the temperature. In Fig. 2, the behavior is exemplified by the values at −90 °C shown by open circles and by those at 60 °C shown by shaded circles. Thus, the existence of the mixed-valence compound, $(TTT)_2Br_3$, is manifested by the anomalous changes observed with all the electrical quantities examined.

Optical Properties. The electronic spectra of the TTT^+ and TTT^{2+} salts in both the solid and dissolved states have been examined by one of the present authors.[10] The monomeric TTT^+ ion in alcohol exhibits three weak bands at 8.0, 9.5, and 10.7×10^3 cm^{-1}, and a strong band at 17.3×10^3 cm^{-1}, followed by weaker ones at 18.7 and 21.5×10^3 cm^{-1}. The three in the near-infrared region may be ascribed to the vibrational structure of the first electronic transition.[14] The solid-state spectrum resembles the solution spectrum. By means of the transmission measurements through potassium bromide disks, we observed absorption maxima at 7.5, 9.2, 18.0, and 21.2×10^3 cm^{-1}. Except for the lowest-energy transition, these wave-

numbers are in good agreement with those obtained earlier by the diffuse reflectance method; namely, 6.3, 9.5, and 18.0×10^3 cm^{-1} and a shoulder located at 21×10^3 cm^{-1}.[10] The bands appearing in the near-infrared region are very much widened and intensified in the solid state, compared to the bands in the dissolved state. This is the region where we expect the absorption associated with the interaction between the TTT^+ ions. This expectation is consistent with the fact that the intensity ratio between the band in this region and that in the visible region depends markedly on the kind of the counter ion.[10] Furthermore, Kamaras and Grüner have recently demonstrated that an intense absorption emerges at 5.6×10^3 cm^{-1} upon cooling the methanol solution of TTT^+ acetate.[15] They attributed the new absorption to the dimer ion, $(TTT^+)_2$.

The spectrum of the brown-colored $TTT^{2+}(Br^-)_2$ is rather similar to the above-mentioned in the visible region; that is, the maxima are located at about 18 and 21×10^3 cm^{-1}. No absorption appears in the infrared region. When the salt is dissolved in dilute acid, the bands become sharper and are shifted to 20.7 and 23.6×10^3 cm^{-1} respectively. In addition, a shoulder is found at 22.7×10^3 cm^{-1}.

The mixed-valence compound, $(TTT)_2Br$, exhibits a spectrum close to that of TTT^+Br^-. However, the bands at 7.5 and 9.2×10^3 cm^{-1} are weakened compared to those in the visible region and an extra band seems to exist below 5×10^3 cm^{-1}. This new transition may be indicative of an interaction between the TTT molecule and the TTT^+ ion. The spectrum at the composition of $(TTT)_2Br_3$ looks like a superposition of those of TTT^+Br^- and $TTT^{2+}(Br^-)_2$. No sign of the interaction between the TTT^+ and TTT^{2+} ions could be seen in the electronic spectrum.

Perez-Albuerne *et al.* have noted that the vibrational spectra clearly show the difference between neutral TTT and the TTT^+ salts.[13] More recently, Ritvay-Emandity *et al.* have observed that the spectrum of $(TTT)_2Cl$ consists of bands corresponding to both the TTT molecule and TTT^+ ion.[11] Our mixed-valence compound, $(TTT)_2Br$, shows a spectrum which is also a superposition of those of TTT and TTT^+Br^-. As the former spectrum is much simpler than the latter, the spectrum of $(TTT)_2Br$ is dominated by the contribution from the cation. Nevertheless, the presence of both TTT and TTT^+ ion is apparent from the relative intensities, which are markedly different from those in the spectrum of TTT^+Br^-. In Table 1, the bands found in the second mixed-valence compound, $(TTT)_2Br_3$, are listed together with those found in TTT^+Br^- and $TTT^{2+}(Br^-)_2$. Our wavenumbers for TTT^+Br^- are mostly in good agreement with those reported by Ritvay-Emandity *et al.*[11] The existence of the TTT^+ ion in this compound can be confirmed by the bands appearing at 1290, 1280, 1131, 1000, and 750 cm^{-1}. The bands assignable to the TTT^{2+} ion are also abundantly observed in this mixed-valence compound. Apparently, the bands located at 1473, 1452, 1390, 1325, and 780 cm^{-1} arise from the TTT^{2+} ion. These observations indicate that the lifetime of a definite valence state on the TTT molecule is longer than the vibrational period. An entirely different situation has been reported for some other organic mixed-valence compounds prepared by us. For example, in the spectrum of cobalticinium(3,3′,5,5′-tetrachloro-*p*-diphenoquinone)$_2$ neither the vibrational pattern due to the quinone molecule nor that due to the semiquinone anion has been found.[16] A single broad carbonyl stretching band is located at 1610 cm^{-1}; this is intermediate between that in the quinone, 1640 cm^{-1}, and that in the semiquinone salt, 1530 cm^{-1}. Similarly, the vibrational spectrum of (phenothiazine)$_2$Br is different from either that of the neutral molecule or that of its cation.[17] There is a pattern characteristic of the phenothiazine molecule bearing the charge of $+1/2$. In other words, the constituent molecules in these examples are equivalent to each other on the time scale of infrared spectroscopy. It may be added that the electrical resistivities of these two compounds are of the order of 10 or 100 Ω cm and are intermediate between the resistivity of $(TTT)_2Br$ and that of $(TTT)_2Br_3$.

The authors wish to express their thanks to Dr. Kohji Fukushi for the recording of the laser Raman spectra of some specimens in order to check for polybromide bands. This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 234028).

Direct Measurement of Interaction Energy between Solids and Gases. VII. Heats of Adsorption of Carbon Monoxide on Cu(II)-exchanged Zeolites Y

Yoji MIWA,* Kazuo TSUTSUMI, and Hiroshi TAKAHASHI
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received April 24, 1979; revised December 22, 1979)

Differential heats of the adsorption of carbon monoxide on Cu(II)Y zeolites were calorimetrically determined. The heat of adsorption was larger on Cu(II)Y zeolites than on the NaY zeolite, and increased with the degree of Cu(II) ion-exchange. Repeated adsorption-desorption measurements revealed an increase in the heat of adsorption, which is considered to be due mainly to the migration of copper(II) ions from inaccessible sites for carbon monoxide to accessible ones in the process of adsorption-desorption.

The adsorption properties and catalytic activities of zeolites are markedly affected by the nature and the distribution of cations in the zeolites. Investigations of the interaction between simple gas molecules and the zeolite surface have often provided important information on the nature and the distribution of these cations. Carbon monoxide is an attractive choice for such investigations.[1)]

There have been a number of investigations of the adsorption of carbon monoxide on zeolites, but, as far as we know, there is only a little information about the cation migration by carbon monoxide.[1)] In this study, we have determined the heats of the adsorption of carbon monoxide on Cu(II)Y zeolites to provide calorimetric evidence for the migration of copper(II) ions under the conditions of the adsorption-desorption of carbon monoxide.

Experimental

Materials and Gas. The copper(II)-exchanged zeolites were prepared by the ion-exchange of NaY zeolite (Linde SK-40), in an excess of a 5 mM (1M= 1 mol dm^{-3}) copper-(II) nitrate solution at room temperature for 14.3 and 50.3% exchange, and at *ca.* 80 °C for 80.7%.

The Cu(II)-exchanged samples were then thoroughly washed with distilled water and dried for 6 h at 110 °C, and finally stored over a saturated ammonium chloride solution at *ca.* 25 °C for at least one week before use. The samples were sieved to 28—60 mesh for use.

The degree of exchange was determined from the chemical analysis of the sodium and the atomic absorption analysis for copper(II).

The carbon monoxide (Takachiho Chem. Co., Ltd.), which was stated to have a purity greater than 99.5% (the main impurities were air, H_2, and CO_2), was purified by passing it through a liquid nitrogen cold trap before storage.

Apparatus. The heats of adsorption were measured with a twin conduction calorimeter (Tokyo Riko Co., Ltd., MPC-10 type), which was connected to a volumetric adsorption system, with an error of *ca.* 5%. The ESR measurements were carried out at room temperature with an X-band 9.38 GHz spectrometer (Japan Electron Optics Laboratory Co., Ltd., JES-ME-3X). The phosphorescence spectra of CuY were taken with a Toshiba UV-D33S spectrophotometer at room temperature. The measurement of the electronic spectra was carried out with a spectrophotometer Shimazu MPS-5000 using the reflectance method.

Procedure. Each 0.5-g zeolite sample (including *ca.* 25% H_2O) in a sample cell was evacuated under a pressure of 10^{-1} Pa, heated up at a rate of 8 °C/min to 400 °C(or 100, 250 °C), and then held at that temperature for 5 h under a vacuum of 10^{-3} Pa. The sample cell was then cooled down *in vacuo* and set in a calorimeter thermostated at the desired temperature (25±0.01 °C) for measurements.

Results

Heats of Adsorption. The heats of the adsorption of carbon monoxide on NaY and three fresh Cu(II)Y (14.3, 50.3, and 80.7% exchanged) zeolites are plotted against the amounts adsorbed in Fig. 1. In the initial portion, the differential heats of the adsorption of carbon monoxide on Cu(II)Y were larger than on NaY, and they increased with the degree of copper(II) ion-exchange.

Figure 2 shows the adsorption isotherms of carbon monoxide on Cu(II)Y-80.7 pretreated at 400 °C under a pressure of 10^{-3} Pa for 5 h. The adsorption measurements for the second isotherm were carried out after desorbing the adsorbed CO under a vacumm of 10^{-3} Pa for *ca.* 3 d. The third was made after the desorption of the second, and so forth. The adsorption-desorption cycle increased the amount of adsorption. However, the degree of increase in the adsorbed amount became smaller with the number of cycles, and finally no such an increase was detected between the tenth and the

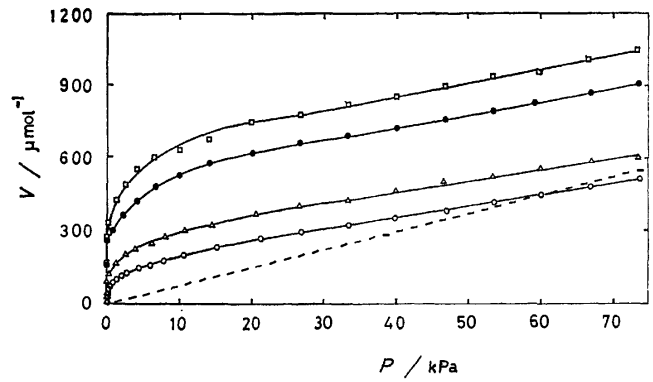

Fig. 2. Adsorption isotherms of CO on Cu(II)Y-80.7. After adsorption measurement up to *ca.* 73 kPa equilibrium pressure zeolite was evacuated at 10^{-3} Pa for *ca.* 3 d then the next run of adsorption was carried out. This procedure repeated until the isotherm practically agreed with the preceding one.

eleventh isotherms.

The heat curves corresponding to the above-mentioned isotherms are shown in Fig. 3. Apart from the initial portion, the heat curves were also shifted to the higher side. The initial heats of adsorption, on the contrary, gradually decreased with the number of the run. The tenth and eleventh curves agreed with each other within experimental uncertainty.

Changes in the Heats of Adsorption in the Process of Repeated Adsorption-desorption on Cu(II)Y. Thermograms of the repeated adsorption and desorption of carbon monoxide on NaY, Cu(II)Y-14.3, and Cu(II)Y-80.7 are shown in Fig. 4. After pretreatment at 400 °C, the heats of adsorption and desorption were measured by admitting measured amounts of CO: 80 μmol g^{-1} for NaY and Cu(II)Y-14.3; 20 μmol g^{-1} for Cu(II)Y-80.7. After the first thermogram had been drawn, the first heat of desorption (Q_{d1}) was measured under evacuation up to 10^{-3} Pa; then the same procedure of adsorption and desorption was repeated several times.

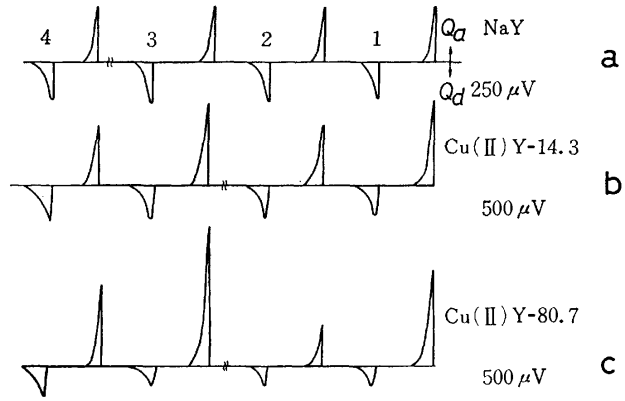

Fig. 4. Thermograms of repeated CO adsorption-desorption on NaY and Cu(II)Y, pretreated at 400 °C under a pressure of 10^{-3} Pa for 5 h. Q_a: Heat of adsorption, Q_d: heat of desorption. Admitted amount of CO: 80 μmol g^{-1} for NaY and Cu(II)Y-14.3; 20 μmol g^{-1} for Cu(II)Y-80.7. For NaY after 3 rd run and Cu(II)Y after 2 nd run the samples were evacuated overnight. 250 or 500 μV represents the full scale of the recorder response.

In the case of NaY, the heats of adsorption, Q_a, and desorption, Q_d, were practically identical at all times, not only from Q_{a1} to Q_{d3}, which were measured successively, but also at Q_{a4} and Q_{d4} which were measured after evacuation overnight under 10^{-3} Pa. In the case of Cu(II)Y-14.3, the second heat of adsorption, Q_{a2}, was smaller than the first, Q_{a1}, by 42%. This decrease occurred because of an incomplete desorption of strongly adsorbed carbon monoxide on Cu(II)Y-14.3 (Q_{d1} was smaller than Q_{a1} by 53%). However, Q_{a3}, which was measured after degassing overnight under 10^{-3} Pa, was much the same as Q_{a1}. These results showed that the carbon monoxide on Cu(II)Y-14.3 is desorbed when the sample is evacuated over a period of *ca.* 10 h (several times as long as for NaY). This was also supported by IR observation. However, when Q_{a5} (which is not shown in Fig. 4) was measured after degassing overnight under 10^{-3} Pa, an interesting phenomenon was observed: $Q_{a5}>Q_{a1}$. This phenomenon of the increase in the heat of adsorption was also, remarkably observed in the sample of higher exchanged Cu(II)Y-80.7: Q_{a2} was very much smaller than Q_{a1}, while Q_{a3}, measured after degassing overnight under 10^{-3} Pa, was *ca.* 1.5 times as large as Q_{a1}.

Figure 5 shows the changes in the thermograms with the pretreatment temperatures. The changes in the heats of adsorption markedly depended upon the pretreatment temperatures (*cf.* Fig. 4,c). In the case of the 100 °C-pretreatment in spite of the incomplete first desorption ($Q_{d1}<Q_{a1}$), the second heat of adsorption, Q_{a2}, was larger than Q_{a1}, and Q_{a3} was also larger than Q_{a2}. Furthermore, Q_{a4}, measured after evacuation overnight, was *ca.* 7.5 times as large as Q_{a1}. Intermediate behavior was observed in the case of the 250 °C-pretreatment.

The changes in the heat of adsorption, q/kJ mol^{-1}, corresponding to Figs. 4 and 5 are summarized in Table 1.

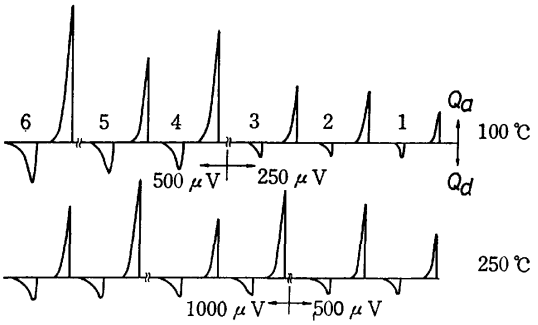

Fig. 5. Changes of thermograms of adsorption and desorption of CO on Cu(II)Y-80.7 with pretreatment temperatures 100 and 250 °C. Q_a: heat of adsorption, Q_d: heat of desorption. Admitted amount of CO: 20 μmol g^{-1}. 250, 500, or 1000 μV represents the full scale of the recorder response.

ESR and Phosphorescence Measurements. From the phosphorescence spectra (Fig. 6), the formation of Cu(I) was observed[2] when dehydrated Cu(II)Y-80.7 was treated with 20 kPa of CO at 400 °C for 36 h. In this case, contrary to Huang,[3] the reduction of Cu(II)Y by CO was not complete. A complete reduction was, however, achieved, as Huang[3] had reported, when NH_3 was preadsorbed in dehydrated Cu(II)Y-80.7 at a pressure of *ca.* 1.33 kPa; then the sample was treated with 20 kPa of CO at 400 °C for 1 h. However, no indication of Cu(I) formation was observed in either the sample of Cu(II)Y-80.7 evacuated at 400 °C under a pressure of 10^{-3} Pa for 5 h or, the Cu(II)Y-80.7 evacuated, followed by the adsorption of CO at room temperature. These results were in agreement with those of the ESR (Fig. 7).

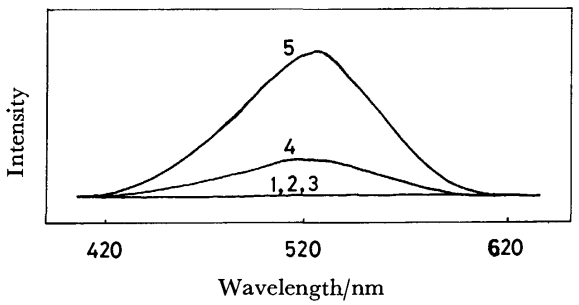

Fig. 6. Phosphorescence spectra of CuY-80.7 recorded at room temperature under the same optical conditions and nearly identical sample geometries.
(1): Cu(II)Y-80.7 untreated, (2): after evacuation of Cu(II)Y-80.7 at 400 °C under a pressure of 10^{-3} Pa for 5 h, (3): after (2) adsorption of 13.3 kPa CO at room temperature for 1 h, (4): after (2) adsorption of 20 kPa CO at 400 °C for 36 h, (5): after (2) adsorption of 1.33 kPa NH_3 at room temperature for 1 h then adsorption of 20 kPa CO at 400 °C for 1 h.

Measurement of Electronic Spectra. In the near-infrared region, the Cu(II)Y-80.7 zeolites hydrated or pretreated at 100 °C showed the absorption maxima at *ca.* 1450 and 1950 nm. However, in the case of 250 or 400 °C-pretreatment these peaks were not observed. These two bands are assigned to the overtone band ($2\nu_3$) and the combination band ($\nu_2+\nu_3$) of the adsorbed water respectively.[14]

Discussion

The synthetic Y zeolites have two sets of cavities. The larger cavities, called supercages, have a diameter of *ca.* 13 Å. The entrances to the supercages have a free diameter of approximately 9 Å. The smaller cavities, called sodalite cages, have a free diameter of 7 Å and are connected to the supercages by openings with a free diameter of 2.5 Å. The sodalite cages are joined to each other by 2.4 Å free-diameter hexagonal prisms.[4,5] The kinetic diameter of the carbon monoxide molecule is *ca.* 3.8 Å,[6] and so it must be unable to pass through these small openings. According to Smith[7] and Mortier,[8] there are five kinds of cation sites in Y zeolite; *i.e.*, SI, at the center of a hexagonal prism; SI′, displaced from a shared hexagonal face into the sodalite cage; SII′, displaced from an unshared hexagonal face into the sodalite cage; SII, slightly displaced into the supercage, and SIII′, in the supercage, formed by two O_1 and O_4 oxygens. Thus, carbon monoxide would possibly be chemisorbed, with a relatively strong interaction, on Cu(II) at the SII or SIII′ sites. The Cu(II) ions at the SI, SI′, or SII′ sites may not be accessible to carbon monoxide, as is supported by the work of Egerton and Ston.[1] They showed by experiments on a sample of synthetic sodalite that CO was not

adsorbed at temperatures below 200 °C. Also, they pointed out that a slow adsorption of CO occurring on Cu(II)Y and Ni(II)Y zeolites was to be ascribed to a gradual increase in the number of adsorption sites caused by the adsorption-induced migration of the divalent cations.

The present results and those formerly reported by other workers can well be interpreted in terms of the model to be discussed below. The difference between the adsorption properties of NaY and Cu(II)Y is primarily to be ascribed to the existence of the accessibility of Cu(II) to the visiting CO. The higher values of q in the initial portion of q *vs.* V curves are attributable to the adsorption on exchangeable cations. The curves in Fig. 1 show that Cu(II) adsorbs CO with a stronger interaction than does Na, and that the quantity of Cu(II) accessible to CO increases with the increase in the content of Cu(II). When the adsorbed amount increases, the q-value converges to 20 kJ mol^{-1} for all the samples studied. It is known that, in such a region, CO is adsorbed on the framework oxygen. Thus, the amount of the accessible Cu(II) can easily be estimated from Fig. 1; it is found to increase with the number of the adsorption-desorption cycles, as is shown in Fig. 3 and Table 2. This can be explained as follows. The Cu(II) ions at the SI, SI′, and/or SII′ sites migrate, in the course of the cycle, to the SII and/or SIII′ sites, which are accessible to the visiting CO. Though there are many possibilities, the most plausible one is that a predominant part of the Cu(II) migration occurs from the SII′ to the SII site. This change corresponds to a small displacement from one side of the 6-membered oxygen ring to the other side, and may take place with a small activation energy.

Table 2. Increase in the number of accessible Cu(II) ions with the adsorption-desorption run

Number of run	$V_{sp.ad}$ / μmol g^{-1}		Ratio of accessible Cu(II) ions compared with 1st run	
	a	b	a	b
I	270	170	1	1
III	500	280	1.9	1.6
VII	700	510	2.6	3.0
XI	800	620	3.0	3.6

a) The amount of specific adsorption was determined from the amount adsorbed where the heat curves of Cu(II)Y intersect with that of NaY. b) The amount of specific adsorption was determined by the extrapolation of the lines in the high-pressure region of the isotherms in Fig. 2 to 0 pressure.

The above discussions are based on the assumption that no reduction of Cu(II) to Cu(I) occurred; this assumption was supported by the ESR and phosphorescence studies. The ESR signal ascribed to the Cu(II) ion did not change in repeated adsorption-desorption cycles. It should have decreased if any reduction of Cu(II) had occurred. The phosphorescence spectrum in Fig. 6 shows that Cu(I) was not produced in the present treatments.

The extent of cation migration depends upon also the quantity of residual water molecules.[9-13] The present electronic spectral data show that the samples pretreated at 250 or 400 °C are considered to be dehydrated ones, and that at 100 °C, partially hydrated. This is compatible with the electronic spectral data reported by De Wilde *et al.*[15] The increase in the heat of adsorption (q) shown in Table 1 may be ascribed to another reason besides the above-mentioned migration of Cu(II): that is, the release of coordinated H_2O (or OH group). Since the samples pretreated at 250 or 400 °C are considered to be dehydrated, the phenomenon is ascribed to the Cu(II) migration, whereas in the sample pretreated at 100 °C the second reason cannot be neglected.

In conclusion, the observed results can consistently be explained by the proposed model that Cu(II) at the SII and/or SIII′ sites strongly adsorb CO, and that the number of such Cu(II) cations increases with the adsorption-desorption cycles as a result of the Cu(II) migration from the inaccessible sites to the accessible ones. In the case of partially hydrated Cu(II)Y, the replacement of coordinated H_2O (or OH group) by CO may also occur.

The authors wish to express their thanks to Professor Minoru Kinoshita and Miss Noriko Iwasaki of The Institute for Solid State Physics, The University of Tokyo, for the measurements of the phosphorescence spectra and for their helpful discussions, and to Mr. Minoru Suzuki for ESR measurements.

X-Ray Diffraction Study of Liquid Water

Keiko NISHIKAWA* and Nobuko KITAGAWA

Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received September 22, 1979)

The energy-dispersive X-ray diffractometer has been applied to the structural study of liquid water. The intensity data are in good agreement with those obtained by the use of an angle-dispersive method. Water has a structural correlation up to only 8 Å at 25 °C.

By using an energy-dispersive X-ray diffractometer for the determination of the liquid structure, new information was obtained about CCl_4; that is, the existence of fine structures in the diffraction pattern was obtained in the liquid for the first time.[1-3] The fine structures in the diffraction pattern reflect the long-range correlation in the liquid structure. In fact, liquid CCl_4 has a structural correlation up to 28 Å at a low temperature (−20 °C)[3] and even at room temperature.[2] The long-range correlation can be expected to exist also in liquid water, since the molecular interaction of water is a strong hydrogen bond. Therefore, it seems that it is interesting to study the diffraction pattern of water by the energy-distersive method.

At the same time, it is necessary to examine the analytical procedures of the energy-dispersive method. Some difficulties arise for the analysis of the data obtained by this method. One is the consistency of the data which were observed at different scattering angles in the overlapping region, and the other is the absorption correction. The errors caused by the difficulties mentioned above influence the intensity curve in the form of the spurious background and the discontinuity of the curve at the connected points. In this case, the radial distribution curve has ghost peaks. Therefore, it is important to compare our data obtained by the energy-dispersive method with good data obtained by the angle-dispersive method. In 1967, Narten, Danford, and Levy published their results obtained by the X-ray diffraction study of liquid water in the temperature range 4—200 °C.[4] Thereafter they published other related results.[5-7] Though the radial distribution function was also confirmed by other groups,[8-12] the work of Narten *et al.* is regarded as most precise results. It seems, therefore, that it is suitable to compare our data and the results of Narten *et al.*

Another judgement of the correctness of the data analysis can be made by a comparison of the absolute total coherent intensity at $s=0$ with the value calculated from the isothermal compressibility. Moreover, Chonacky and Beeman measured the absolute scattering intensity for water at small scattering angles.[13] This value can also be compared with our data.

Experimental

The scattering intensity of X-rays from liquid water was measured at 25 °C. An energy-dispersive diffractometer[1] with a vertical goniometer (θ—2θ scanning system) was used. A fine-focus X-ray tube with a tungsten target was used at 45 kV, 20 mA. The scattering intensity was recorded by a Si(Li) detector connected with a multi-channel pulse-height analyzer.

The scattering intensity was measured by the transmission method at the scattering angles(2θ) of 2, 4, 8, 12, 17, and 27°. The reflection method was applied at $2\theta=35$ and 70°. By using white X-rays with wavelengths ranging from 0.46 to 1 Å, these measurements cover the ranges of s ($4\pi \sin\theta/\lambda$, λ: wavelength) $=0.22$—0.48, 0.44—0.96, 0.88—1.92, 1.31—2.88, 1.85—4.07, 2.93—6.43, 3.78—8.29, and 7.20—16.00 Å^{-1} respectively. In order to avoid mistakes in the data analysis for the energy-dispersive method, the scattering angles were set so closely that the two ends of the intensity curves obtained at adjacent angles could overlap widely with each other.

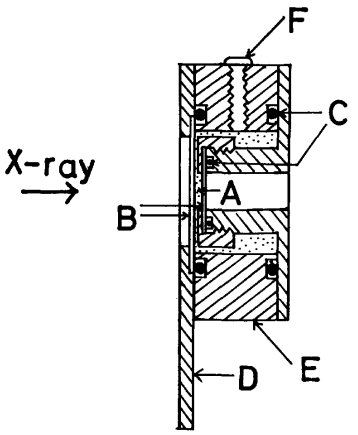

Fig. 1. A modified sample holder for the transmission method. (A): Sample, (B): Be or Myler window, (C): O-ring, (D): stainless steel plate to set the holder to the goniometer, (E): ring (The thickness of the sample can be changed by the exchange of this ring.), (F): the hole from which the sample is injected.

The sample holder used for the reflection method was the same as that used previously.[1] For the transmission method, the sample holder used in our earlier experiment was modified as shown in Fig. 1 in order to set the Be or Myler windows (B) tight and parallel to a narrow spacing. In the present study, Myler film (20 μm thick) was used; the thickness of the sample was 0.194 cm. The scattering intensity was measured for 3×10^4—10^5 s at each scattering angle, and more than 1×10^4 counts per channel were collected.

The scattering intensities from the Myler film of the sample holder and that from air, I_w, were measured, the magnitude of I_w being about 5—8% of the total scattering intensity.

Data Analysis

After smoothing, each scattering intensity curve from which the intensity, I_w, was subtracted was divided by the energy distribution curve of the incident beam (normalization).

As the linear absorption coefficient, μ, changes with the energy of the X-rays, the μ values were calculated in a way similar to that described in a previous paper,[1] in which the C parameters for oxygen and hydrogen atoms were 3.18 and 0.0127 respectively, and in which the D's were 0.0654 and 0.466×10^{-5}.[14] The values of μ, determined from the transmittance of the sample at $\theta=0°$, agree well with the calculated values in the range of wavelengths of 0.46—1 Å within the experimental error. By using the calculated values of the absorption coefficient, the normalized scattering intensity curve were corrected over the wavelength range from 0.46 to 1 Å.

The corrected intensity curve were then converted into the absolute scale (in electron units) by fitting the experimental intensity to the theoretical intensity at large s-values. In the calculation of the theoretical intensity, the internuclear distances and the mean-square amplitudes of the vibration in a water molecule obtained by gas-electron diffraction[15] were used, and the Compton scattering intensity calculated by Cromer[16] was employed. The conversion factor from the experimental to the absolute intensity, K, was easily obtained from $2\theta=2$, 4, 8, 12, and 17°; each intensity curve was successively connected with that at $2\theta=27°$ after the absorption correction. Then, K was obtained for each intensity curve. The observed total coherent intensity;

$$I_{co}(s) = \sum_n f_n(s)^2 + i_1(s) + i_2(s) \qquad (1)$$

is shown in Fig. 2, where $f_n(s)$ is the atomic scattering factor and where $i_1(s)$ and $i_2(s)$ represent the coherent intensities from atom pairs within a molecule and between different molecules respectively. The weighted structure function, $si(s)=s(i_1(s)+i_2(s))$, shown in Fig. 3, was then calculated.

The electronic radial distribution function from which the bulk density was subtracted, $4\pi r^2(\rho-\rho_0)$, was obtained by the Fourier transformation of $si(s)$:

$$4\pi r^2(\rho-\rho_0) = \frac{2r}{\pi\sum_n Z_n^2}\sum_{s=0}^{s_{max}} si(s)\cdot\sin sr\cdot\Delta s, \qquad (2)$$

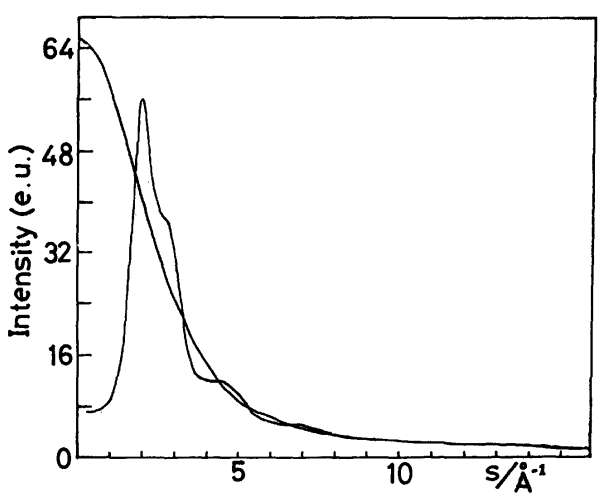

Fig. 2. Observed total coherent intensity I_{co} for liquid water at 25 °C and independent atomic scattering intensity.

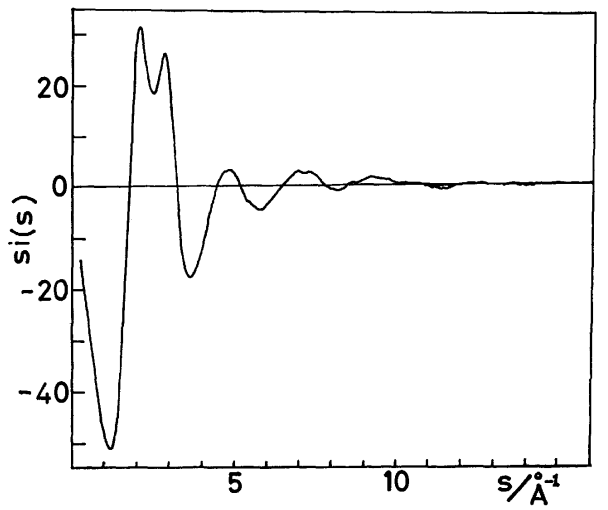

Fig. 3. Weighted structure function $si(s)$ for liquid water at 25 °C.

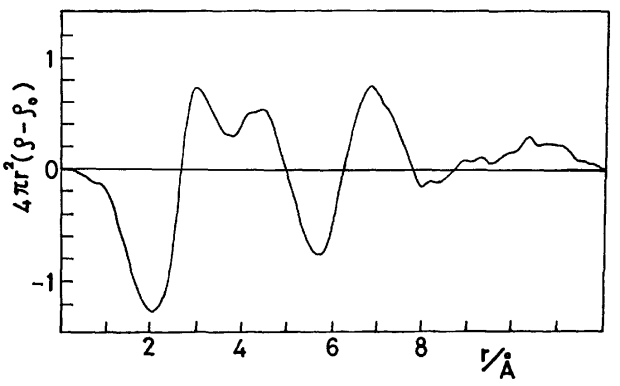

Fig. 4. Electronic radial distribution function from which the bulk density was subtracted, $4\pi r^2(\rho-\rho_0)$.

where ρ_0 is the bulk liquid density and where Z_n is the atomic number of the n-th atom. The electronic radial distribution function is shown in Fig. 4.

Results and Discussion

First, we examined to see whether or not the processing of the data obtained by the energy-dispersive method is adequate. In order to show the connection between several intensity data measured at different angles, the raw-intensity-data sets corrected for absorption are plotted in Fig. 5. The data in the $s>6$ Å^{-1} region are not shown in this figure because, in this region, the intensities are almost equal to the self-scattering ones from the corresponding atoms. In each set, the intensity at the extreme of the higher-energy region falls down slightly. In this region, the calculated values of the linear absorption coefficient, μ, are slightly smaller than the observed ones. Except for this, the intensities of the overlapped regions observed at different angles are in good agreement.

It was also confirmed that there was no spurious background which might be caused by inadequate data processing or apparatus functions. Figure 6 shows the weighted structure function, $si(s)$, which was observed

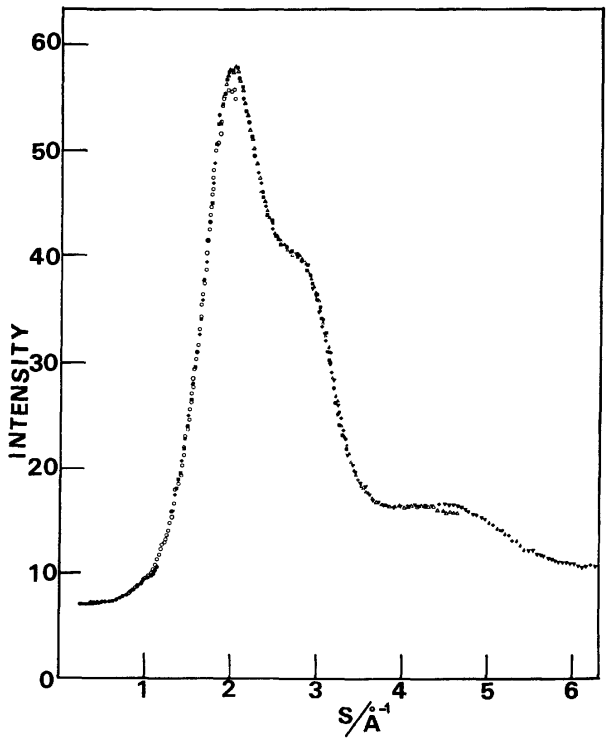

Fig. 5. The raw intensity data of liquid water after absorption correction. Each sign such as ——, ●, ○, ■, △, and ▼ shows the data obtained by angle-setting at $2\theta=2$, 4, 8, 12, 17, and 27° respectively.

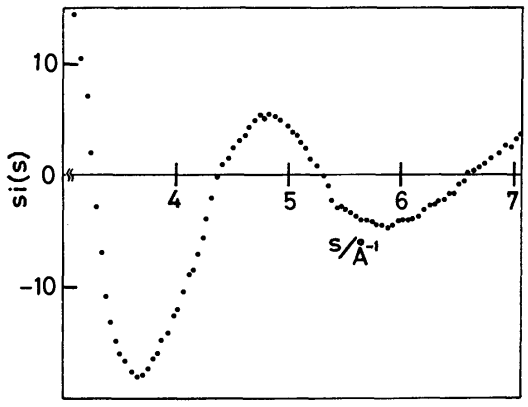

Fig. 6. The weighted structure function $si(s)$, obtained by angle setting at $2\theta=27°$. This result shows that the data do not contain apparatus functions.

at the scattering angle $2\theta=27°$. This curve was obtained as follows. In the case of water, the $i_2=0$ approximation is valid in the $s>6$ Å^{-1} region. Therefore, the data at $2\theta=27°$ could be converted into the absolute scale by adjusting the experimental intensity to the calculated intensity. If the data analysis were not correct, or if the apparatus function were contained in the data, the $si(s)$ curve would ride on a background curve and would never oscillate around the zero line as is shown in Fig. 6.

Second, the above-mentioned data obtained by the energy-dispersive method were compared with those of Narten and Levy[7] measured by the angle-dispersive method. The intensity data of the present work were, therefore, expressed in the form of $H_M(s)$. $H_M(s)$, the structure function whose Fourier transformation gives molecular-pair correlation, is difined as follows:

$$H_M(s) = [I(s)-\langle F^2\rangle]/\langle F\rangle^2. \quad (3)$$

$I(s)$ is the total coherent intensity from the liquid and $\langle F^2\rangle$ is scattered intensity from one molecule and is given by:

$$\langle F^2\rangle = \sum_i\sum_j f_i(s)f_j(s)\frac{\sin sr_{ij}}{sr_{ij}}\exp\left(-\frac{l_{ij}^2}{2}s^2\right), \quad (4)$$

where l_{ij} denotes the root mean-square amplitude of the vibration around the mean internuclear distance, r_{ij}, $\langle F\rangle$ is defined by:

$$\langle F\rangle = \sum_i f_i(s)\frac{\sin sr_i}{sr_i}\exp\left(-\frac{l_i^2}{2}s^2\right), \quad (5)$$

where r_j is the distance from the scattering center to the i-th atom. The results are listed in Table 1, with the values obtained by Narten and Levy at 25 °C. The two set of data are in good agreement with each other within 5—6% differences in the range where the intensity curve is gentle. However, a large derivation in the value of $H_M(s)$ is observed at a peak or valley in the intensity curve, for example, at the first peak at nearly $s=2.0$ Å^{-1}. It seems that this deviation is caused by an experimental error in the determination of the s-value. This determination error is within 0.02 Å^{-1} in the s-value, which corresponds to 0.05° angle-setting error for the peak at $s=2.0$ Å^{-1}. From these considerations, it may be concluded that the energy-dispersive data are in good agreement with Narten's data, within the limits of experimental error.

Finally, we have used the absolute total coherent intensity at $s=0$, $I(0)$, for judging the correctness of the data processing. $I(0)$ is related to the isothermal compressibility, κ, as follows:[17]

$$I(0)/(\sum_n Z_n)^2 = \kappa\rho_0 kT \quad (6)$$

where k is the Boltzmann constant and T the absolute temperature. The observed $I(0)$ (7.0 e.u.) does not differ significantly from the value (6.3 e.u.) calculated from Eq. 6 by the use of the reported κ-value (45.7×10^{-12} cm^2 dyn^{-1}, at 25 °C),[18] and it is also almost the same as that obtained by Chonacky and Beeman.[13]

Reproducible fine structures could not be found in the diffraction pattern of liquid water (Fig. 3). As a result of the Fourier transformation of the weighted structure function, the correlation was observed only up to 8 Å. This distance is very short compared with that in CCl_4 (28 Å).[2,3] The finding that the long-range correlation does not exist in liquid water can be interpreted as follows. A water molecule is well arranged among its neighbors according to the strong hydrogen bond, so the structure of liquid water is very bulky. This bulkiness helps to enhance the disorder of the liquid structure. This fact is supported by the density fluctuation obtained by the scattering intensity at small s-values. The observed $I_{CO}(0)$ was obtained by extrapolating the absolute total coherent intensity at small s-values and became 7.0 e.u. (electron units). This value shows that one water molecule fluctuates in a

volume of 467 Å^3. In other word, since 15.6 water molecules are contained in this volume, there are 15.6 ± 1 molecules in 467 Å^3 for water at room temperature. On the other hand, there are 63 ± 1 molecules in 1.00×10^4 Å^3 for liquid CCl_4.[1)]

There are many models for the structure of liquid water,[19)] and an effort to obtain the atom-atom pair correlation functions, that is $g_{OO}(r)$, $g_{OH}(r)$, and $g_{HH}(r)$ has been made experimentally.[20,21)] However, our search for a satisfactory model of liquid water must

be left for future study.

In conclusion, it was ascertained that the analysis for the energy-dispersive method was appropriate, and that data obtained by the use of energy-dispersive method were in good agreement with Narten's results within the limits of experimental error. It seems that in the present experiment the energy-dispersive method was given a sound basis for further application to more different systems.

The authors would like to express their thanks to Professor Yoshitada Murata, The Institute for Solid State Physics, The University of Tokyo and Professor Takao Iijima, Gakushuin University for their helpful discussions.

(Received January 12, 1980)

The proton spin-lattice relaxation times T_1 and T_{1D} along the static and dipolar magnetic fields have been measured at 18 MHz for the water molecule in powdered hemihydrate gypsum $CaSO_4 \cdot (1/2)H_2O$. The minima of T_1 and T_{1D} were observed at $10^3/T=4.3$(233 K) and 7.0(143 K) respectively. These are ascribed to the 180° flip motion of water molecules, with an activation energy of 15.1 kJ/mol. At higher temperatures, the translational diffusion of water molecules becomes dominant; this is not observed in gypsum $CaSO_4 \cdot 2H_2O$. The activation energy of this motion is estimated to be 32.2 kJ/mol. In hemihydrate gypsum, though the diffusion is supposed to be anisotropic, the jumping distance of the water molecule is tentatively examined by Torrey's lattice diffusion theory.

In the series of crystal forms of gypsum $CaSO_4 \cdot nH_2O$, two kinds of hemihydrate gypsum, $CaSO_4 \cdot (1/2)H_2O$, are known. These are called α- and β-hemihydrate gypsum, and are obtained with different methods of preparation. The NMR method has been applied by several workers to investigate the internal motions of water molecules in gypsum. Holcomb and Pedersen[1] measured the spin-lattice relaxation time T_1 in gypsum over a wide temperature range, and showed that the relaxation is dominated by the 180° flip motion which modulates the interactions with protons on neighboring water molecules. Look and Lowe[2] examined the rotating frame spin-lattice relaxation time $T_{1\rho}$. Jeener *et al.*[3,4] evaluated the 180° flips of water molecules in gypsum and pointed out the additional relaxation due to infrequent, thermally activated jumps of water molecules at high temperatures.

It is interesting to consider the difference between the crystal structures of gypsum and hemihydrate gypsum, in which the nuclear motion affects the magnetic resonance linewidth and relaxation times. The crystal structure of gypsum consists of layers parallel to the (010) plane. The layers are bound together by bonds from water molecules, which link the Ca^{2+} ion and O atom of a SO_4^{2-} ion in one layer with an O atom of SO_4^{2-} in the adjacent layer.[5,6] A number of studies have been done on the crystal structure of hemihydrate gypsum.[7-11] The space group of the trigonal unit cell is $P3_221$ and the cell dimensions are $a=b=6.83$ Å, $c=12.70$ Å, $\gamma=120°$, and $Z=6$. These results indicate that the characteristic features of hemihydrate gypsum are due to the existence of tunnels (or systems of interconnected cavities) which serves as the passage of the water molecules through the c-axis; water molecules are held together in these tunnels, with the closest neighboring O–O distance of water molecules being 4.23 Å. Accordingly, the motion of the water molecule in hemihydrate gypsum seems to have more degrees of freedom than that in gypsum. In hemihydrate gypsum, no fundamental difference of the crystal structure has been found between α- and β-hemihydrate gypsum.[12,13] But Lasis suggests that β-hemihydrate gypsum contains more lattice defects than α-hemihydrate gypsum.[14]

Differential thermal analysis was performed in order to distinguish the α- and β-hemihydrate gypsum; this proved to be superior to the X-ray powder diffraction method. These two methods, however, gave little information on the internal motions of water molecules. Therefore, the NMR experiment was performed in order to obtain a valuable check on the motions of the water molecules. Both pulse and cw methods were employed on the powdered α- and β-hemihydrate gypsum, and the spin-lattice relaxation times T_1 along the static, T_{1D} along the dipolar magnetic fields, and the second moments were measured to examine the motion of water molecules in hemihydrate gypsum.

Experimental

The proton relaxation time T_1 was measured at 18 MHz by the solid echo method, because the free-induction decay signals were so weak in hemihydrate gypsum. T_{1D} was obtained by the 90°-45°-45° pulse method. In order to do the on-line measurement, the free decay on an oscilloscope was amplitude-to-time converted (ATC) and measured by a digital counter, while the pulse interval was measured by

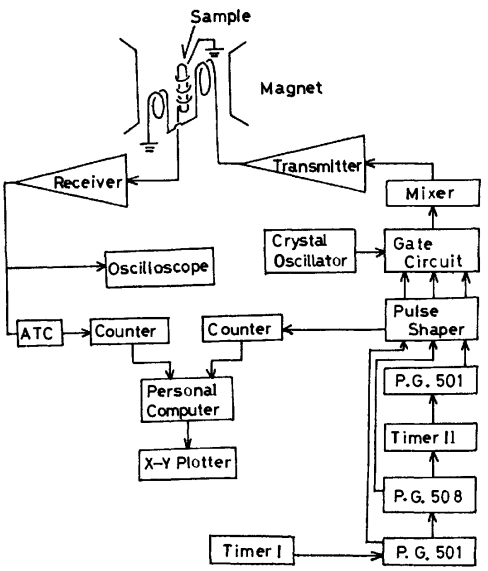

Fig. 1. Block diagram of the pulse NMR spectrometer.

another counter. These results were displayed on an X-Y plotter through a PC-7200 computer. A block diagram of the pulse NMR spectrometer is shown Fig. 1. The resonance-line-shape curve was measured at 40 MHz using a JEOL model JES-BE-1. The samples are powdered gypsum and hemihydrate gypsum from commercial sources. Three kinds of samples, K-α, P-α, and O-β, named after the makers and types of hemihydrate gypsum, were used for the experiment. A sample of hemihydrate gypsum which had been kept for about 47 h at 10^{-2}—10^{-3} Torr** was also examined. In this case, preparation was performed at about 0 °C, with care to avoid the evacuation of the water of crystallization.[15]

Results and Discussion

Second Moment. Figure 2 shows the temperature dependence of the second moments in hemihydrate gypsum. The second moments in K-α, P-α, and O-β are 24 G^2,** 25 G^2, and 23 G^2 at 123 K respectively, and the gypsum value is 30 G^2 at 173 K. This fact shows the distance between the protons in the hemihydrate gypsum is larger than that in the gypsum. But, as shown in Fig. 2, the second moments at 123 K have not reached their rigid lattice values, so we will not discuss further these values of the second moments. It is seen in Fig. 2 that the second moments of raw hemihydrate gypsum decrease suddenly above room temperature and have a minimum value (*ca.* 13 G^2) at 330 K. This remarkable anomaly is pronounced in K-α, whereas the same decrease is not observed in the evacuated hemihydrate gypsum. Recovery of the second moment occurs gradually above 330 K in the raw samples, and the curve becomes similar to that of the evacuated samples. Above 383 K the second moments decrease in the same way for both raw and evacuated hemihydrate gypsum.

** Throughout this paper 1 Torr = 133.322 Pa and 1 G = 10^{-4} T.

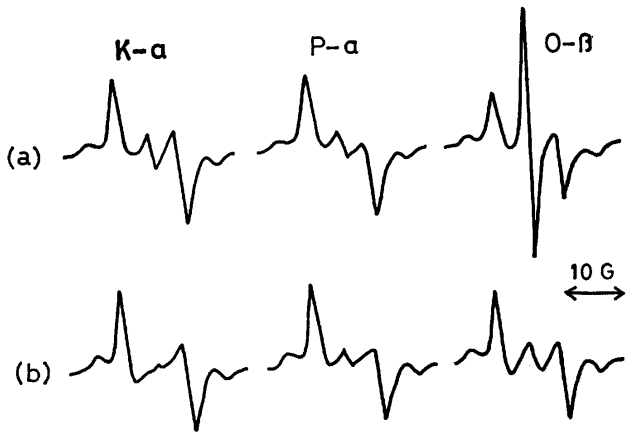

Fig. 3. Absorption derivative curves in the raw and evacuated hemihydrate gypsum at room temperature. (a) Raw samples, (b) evacuated for about 47 h at 10^{-2}—10^{-3} Torr.

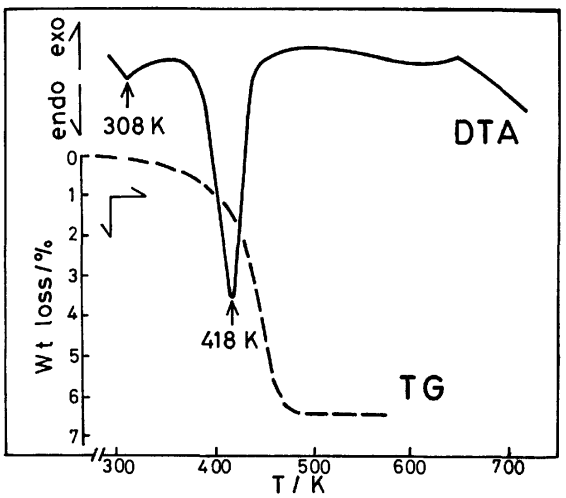

Fig. 4. DTA and TG curves in raw O-β.
Solid line indicates the DTA curve and dashed line TG curve.

Figure 3 shows the derivative curves of absorption spectra in raw and evacuated hemihydrate gypsum at room temperature; the difference in the central parts is important. It is obvious that the central part of the spectra, which is characterized by the diffusing adsorption waters, is remarkable in raw O-β, compared with both raw K-α and P-α. In an effort to explain the anomaly in the second moment at around 330 K, the thermal properties of hemihydrate gypsum were examined. Figure 4 shows the DTA and TG curves of O-β. The endothermic peaks at 308 K and 418 K correspond to dehydration of adsorption water and water of crystallization respectively. In hemihydrate

gypsum, adsorption water seems to be held on the surface as well as in the crystal lattice. When the temperature is higher than 290 K, the adsorption water molecules in the raw sample diffuse in the crystal lattice and leave from its surface, so that the motional-narrowing of the resonance line due to diffusion appears and contributes to the central part of the resonance line, resulting in the decrease of the second moment. The recovery of the second moment above 330 K in the raw sample can be ascribed to the exhaustion of the diffusing adsorption water molecules in the crystal, which restores the second moment back to that of the evacuated sample which has less mobile water molecules. The decrease of the second moment above 383 K seems to be ascribed to the diffusion of the water molecule due to the dehydration of rigidly bound water, which agrees well with the results of the DTA and TG curves.

Spin-lattice Relaxation Time. The spin-lattice relaxation times T_1 and T_{1D} *vs.* inverse temperature in gypsum are shown in Fig. 5, in which $(T_1)_{min}$($\approx$90 ms) appears at $10^3/T$=4.0(250 K) and $(T_{1D})_{min}$($\approx$1 ms) is expected to be present at $10^3/T$=7.0—8.0(143—125 K). The observed T_1 curve below 250 K gives the activation energy of 24.7 kJ/mol; we found $T_1 \approx 3T_{1D}$ on the higher temperature side of $(T_1)_{min}$. The relaxation times as a function of temperature are also shown for the three kinds of hemihydrate gypsum in Fig. 6. In hemihydrate gypsum, $(T_1)_{min}$ appears at $10^3/T$=4.3(233 K) and $(T_{1D})_{min}$ at $10^3/T$=7(143 K). These two minima are ascribed to the same mechanism. $(T_1)_{min}$ at $10^3/T$=4.3 are 0.8, 1, and 1.4 s in O-β, K-α, and P-α respectively. On the higher temperature side of $(T_1)_{min}$, T_1 decreases rapidly; this is not observed in gypsum. This tendency is seen also in T_{1D} curves. It may be concluded that $(T_1)_{min}$ may exist at $10^3/T$=2.5—2.6(*ca.* 390 K) with the value of 0.1—0.2 s, if we take the value of $(T_{1D})_{min}$ at $10^3/T$ to be 3.5(286 K). The temperature dependence

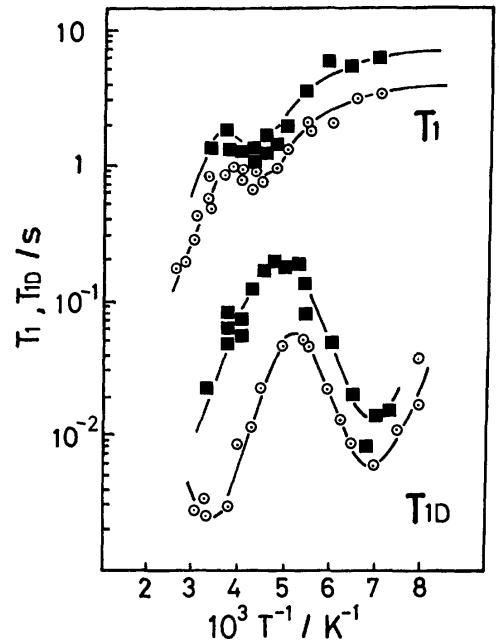

Fig. 7. Temperature dependence of the proton T_1 and T_{1D} in the evacuated O-β. Relaxation times in raw O-β are also shown.
⊙: Raw sample, ■: evacuated sample.

of T_1 and T_{1D} in evacuated O-β is shown in Fig. 7. It is obvious from Fig. 7 that T_1 and T_{1D} of the evacuated sample are longer than those of the raw sample.

At temperatures lower than 182 K, the T_1 *vs.* $1/T$ curve has a small gradient. This shows that the relaxa-

tion rate due to paramagnetic impurities predominates in this temperature region, which is important in O-β and K-α but not in P-α. Therefore, the observed relaxation time $(T_1)_{obsd}$ can be expressed as:

$$\frac{1}{(T_1)_{obsd}} = \frac{1}{(T_1)_e} + \frac{1}{(T_1)_n}, \tag{1}$$

where $1/(T_1)_e$ is the relaxation rate due to paramagnetic impurities and $(T_1)_n$ is the relaxation time due to other sources. In Fig. 8 $(T_1)_n$ were plotted after the contribution of the paramagnetic impurities was removed. In Fig. 8 we obtain $(T_1)_{min}=1$, 1.4, and 1.6 s for O-β, K-α, and P-α respectively, and 1.5 s for evacuated O-β.

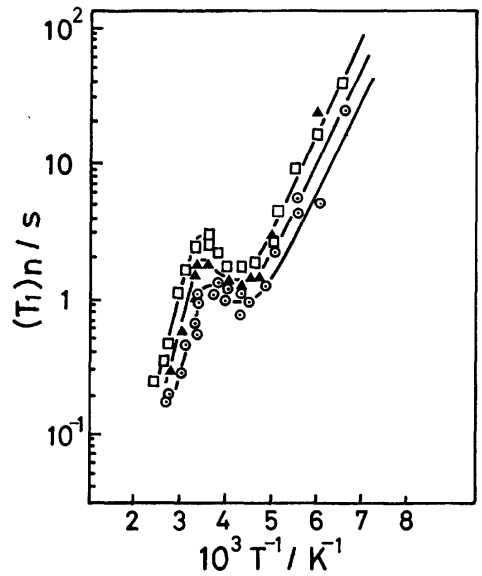

Fig. 8. Temperature dependence of the T_1 in hemihydrate gypsum. Contribution due to paramagnetic impurity is subtracted from the observed T_1 values.
⊙: O-β, ▲: K-α, □: P-α.

The proton relaxation time may be associated with two types of molecular motions: (1) the 180° flip of a water molecule about the bisector of the H-O-H angle, and (2) the translational diffusion of the water molecules. Since the intramolecular dipole-dipole interaction Hamiltonian is invariant to 180° flip motion, the intramolecular interaction makes no contribution to T_1, for which only the intermolecular interactions are responsible. The value of the second moment, which mainly comprises the intramolecular interaction, is not affected by the flip motion. Thus, as shown in Fig. 2, the observed second moment of the evacuated sample does not change appreciably up to the temperature of dehydration. Accordingly, we assign the 180° flip process to the low temperature $(T_1)_{min}$. The spin-lattice relaxation time T_1 due to this flipping is given by[2,16]

$$\frac{1}{T_1} = \gamma^4\hbar^2\frac{3I(I+1)}{16N}\sum_{i\neq j}\left[B_{ij}^{(1)}\frac{\tau_c}{1+(1/4)\omega_0^2\tau_c^2} + (2A_{ij}^{(1)}+B_{ij}^{(2)})\frac{\tau_c}{1+\omega_0^2\tau_c^2} + 2A_{ij}^{(2)}\frac{\tau_c}{1+4\omega_0^2\tau_c^2}\right], \tag{2}$$

where the notation is that of Ref. 16. Equation 2 at $\omega_0\tau_c \gg 1$ gives

$$\frac{1}{T_1} = \frac{C}{\omega_0 N\tau_c}, \tag{3}$$

where the constant C includes the proton-proton distances between water molecules. We obtained 15.1 kJ/mol for the activation energy E_a from $(T_1)_n$ data in Fig. 8 by assuming the relation $\tau_c=\tau_c^0\exp(E_a/RT)$. This value is identical to that obtained from the observed T_{1D}. The slight difference of T_1 values between α- and β-hemihydrate gypsum may be due to the amount of water molecules in the crystal lattice.

We next turn to the effect of translational diffusion on T_1 in the hemihydrate gypsum. No theoretical treatment of the diffusion has been done on a non-cubic crystal. Assuming a homogeneous distribution of nuclear dipoles, Bloom[17] obtained T_1 for the case of self-diffusion as follows:

$$\frac{1}{T_1} = \frac{8\pi}{5}\gamma^4\hbar^2 I(I+1)N \times\int_a^\infty r^{-4}\left\{\frac{\tau_c}{1+\omega_0^2\tau_c^2}+\frac{4\tau_c}{1+4\omega_0^2\tau_c^2}\right\}dr, \tag{4}$$

where N is the number of diffusing spins per unit volume and a is the distance of the closest approach of pairs of nuclei. It follows from the crystal data of hemihydrate gypsum that $N=1.17\times10^{22}/cm^3$. At the $(T_1)_{min}$ where $\omega_0\tau_c=0.62$, the following Eq. 5 is obtained from Eq. 4[18]

$$\frac{1}{(T_1)_{min}} = \frac{6\pi}{5}\gamma^4\hbar^2 N\frac{0.475}{\omega_0 a^3}. \tag{5}$$

Substituting $\tau_c=r^2/12D$[19] on the lower temperature side where $\omega_0^2\tau_c^2\gg1$, an asymptotic form is obtained from Eq. 4 as follows:

$$\frac{1}{T_1} = \frac{144\pi}{25}\gamma^4\hbar^2 ND\frac{1}{\omega_0^2 a^5}, \tag{6}$$

where D is the diffusion coefficient and can be expressed as $D_0\exp(-E_a/RT)$. On the higher temperature side where $\omega_0^2\tau_c^2\ll1$, we also obtain

$$\frac{1}{T_1} = \gamma^4\hbar^2 N\frac{\pi}{2Da}. \tag{7}$$

In order to examine the common features for both BPP (Bloembergen, Purcell, and Pound) and Torrey's theories, we consider the case where three-dimensional isotropic diffusion occurs in a space lattice. T_1 due to this motion is given for $I=1/2$ as follows:[20]

$$\frac{1}{T_1} = \frac{9}{8}\gamma^4\hbar^2\{S_1(\omega)+4S_1(2\omega)\}, \tag{8}$$

where S_1 is the spectral density of the random time function. In the limiting case $\langle r^2\rangle \gg a^2$, for which the mean flight distance is long, we obtain

$$S_1(\omega) = \frac{8\pi N}{45a^3}\left\{\frac{\tau}{1+(\omega\tau/2)^2}\right\}. \tag{9}$$

Then T_1 is given by

$$\frac{1}{T_1} = \frac{2\pi N}{5a^3}\gamma^4\hbar^2\left\{\frac{\tau/2}{1+(\omega\tau/2)^2}+\frac{2\tau}{1+(\omega\tau)^2}\right\}, \tag{10}$$

where the correlation time τ_c is equal to $\tau/2$.

At a temperature which satisfies the relation $\omega\tau=1.23$, Eq. 10 gives a $(T_1)_{min}$

$$\frac{1}{(T_1)_{min}} = \frac{2\pi N}{5a^3}\gamma^4\hbar^2\frac{1.425}{\omega} = \frac{6\pi N}{5}\gamma^4\hbar^2\frac{0.475}{\omega a^3}, \quad (11)$$

which agrees well with Eq. 5. In general, when the correlation time is short ($\omega_0^2\tau_c^2 \ll 1$), Torrey's theory agrees well with the BPP theory.[20] On the other hand, where $\omega_0^2\tau_c^2 \gg 1$, the former theory provides a much better fit than the latter. But, as shown in Eqs. 5 and 11, both theories give the same $(T_1)_{min}$ so that we can estimate the parameters a and D from this region.

In O-β, $(T_1)_{min}$ is estimated to be about 0.16 s at $10^3/T=2.25$; we obtain $a=2.56$ Å from Eq. 5 or 11. Distance a changes from 2.45 Å to 2.67 Å, if $(T_1)_{min}$ is taken from 0.14 to 0.18 s. If we put Eq. 6 equal to Eq. 7, we have an approximate condition at the $(T_1)_{min}$[18] and we obtain

$$D = \sqrt{\frac{25}{288}}\omega_0 a^2. \quad (12)$$

From this equation $a=2.56$ Å yields $D=2.1\times10^{-8}$ cm^2/s. On the other hand, we found the activation energy $E_a=32.2$ kJ/mol for diffusion from T_1 in Fig. 6 and the constant D_0 was then obtained to be 4.28×10^{-4} cm^2/s. In Fig. 9, the straight line indicates the calculated relaxation time T_1 which is followed by Eq. 6.

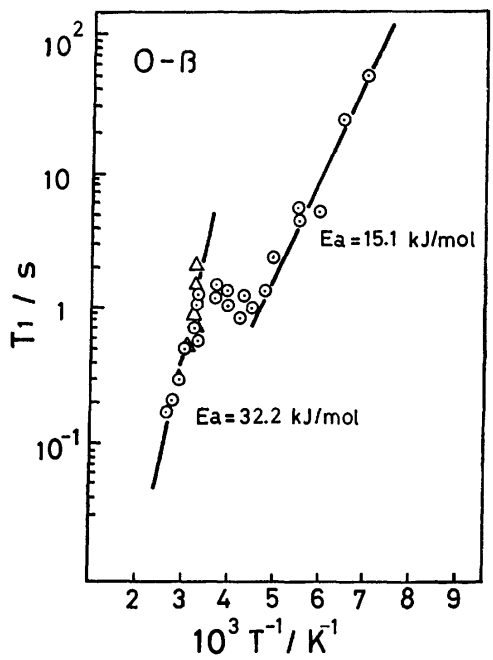

Fig. 9. Calculated T_1 values in O-β.
The straight line at the left is obtained from Eq. 6, and the right is a best fit of Eq. 3 to the data. Diffusion controlled contribution to T_1 is indicated by △.

Now we consider the case of lattice diffusion in which a spin-bearing nucleus jumps between nearest-neighbor lattice sites. We will be able to estimate the jumping distance of nucleus in the crystal lattice. The spectral density $S_1(\omega)$ is given by[21]

$$S_1(\omega) = \frac{8c}{15\omega^2\tau}\sum_i\frac{1}{r_i^6}\left\{1-\frac{1}{z}\sum_j\left(\frac{r_i}{r_j}\right)^3\left(1-\frac{3l^2}{2r_j^2}\sin^2\Theta_j\right)\right\}, \quad (13)$$

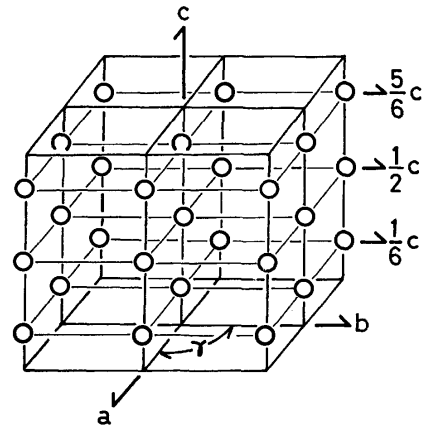

Fig. 10. The crystal structure of hemihydrate gypsum.
Positions of water molecules are shown by large circles. Cell dimensions of the trigonal unit cell are $a=b=$ 6.83 Å, $c=12.70$ Å, $\gamma=120°$, and $Z=6$.

where Θ_j is the angle between proton-proton vectors $\boldsymbol{r}_j$ and $\boldsymbol{r}_i$, z is the number of the nearest neighbors of a lattice site, and c is the ratio of the number of nuclei to the number of lattice sites. In a water molecule, we let $c=2$ as a rough estimation.[22] Figure 10 shows the positions of water molecules in hemihydrate gypsum. In order to estimate the jumping distance l, we substitute the distance r for l. Then Eq. 13 becomes

$$S_1(\omega) = \frac{124}{15\omega^2\tau}l^{-6}. \quad (14)$$

Next we evaluate the value of T_1 for two cases, that is, $l=4.23$ Å (closest O–O bond distance between the water molecules along the c-axis) and 6.83 Å (the corresponding distance on a horizontal plane). In the former case

$$S_1(\omega) = 1.437\times10^{45}\frac{1}{\omega^2\tau} \quad (15)$$

and

$$\frac{1}{T_1} = 3.234\times10^{45}\frac{\gamma^4\hbar^2}{\omega^2\tau} = 4.81\times10^8 D, \quad (16)$$

whereas for the latter case

$$S_1(\omega) = 8.144\times10^{43}\frac{1}{\omega^2\tau} \quad (17)$$

and

$$\frac{1}{T_1} = 1.832\times10^{44}\frac{\gamma^4\hbar^2}{\omega^2\tau} = 1.05\times10^7 D, \quad (18)$$

in which $\tau=l^2/6D$ is applied. For example, at $10^3/T=$ 3.0 and $D=3.82\times10^{-9}$ cm^2/s, we obtain $T_1=0.5$ s for $l=4.23$ Å and 25 s for $l=6.83$ Å. The observed value is about 0.3 s. Moreover, since $D=9.85\times10^{-10}$ cm^2/s at $10^3/T=3.35$, we obtain $T_1=2.1$ s for $l=4.23$ Å and $T_1=96$ s for $l=6.83$ Å. The observed T_1 is about 2 s. It is obvious from these results that the lattice diffusion model for $l=4.23$ Å agrees better with the experimental value.

Conclusion

The investigation of the proton magnetic resonance spectra and its relaxation times of hemihydrate gypsum

has lead to the following conclusions:

1) β-Hemihydrate gypsum contains more adsorption water in the crystal lattice than α-hemihydrate gypsum.

2) It is found that the 180° flip of the water molecule (E_a=15.1 kJ/mol) already begins at the temperature below 125 K which is the lower temperature limit of the T_{1D} measurement. In raw samples, the adsorption water which combines loosely with the crystal lattice is released at about room temperature. The translational diffusion of the water molecule (E_a=32.2 kJ/mol) begins in the crystal lattice above the temperature of 200 K, and results in the dehydration of the water of crystallization at about 380 K.

3) In O-β, we obtain $D_0 \approx 4 \times 10^{-4}$ cm^2/s and the distance of closest approach of the water molecules $a \approx 2.6$ Å. Applying 4.23 Å as the jumping distance of the water molecule between the lattice points in Torrey's theory, we can explain the observed T_1 values above 286 K successfully.

Outer-sphere Assocation of Some Achiral Cobalt(III)-Amine Complexes as Measured by Their Induced Circular Dichroism Spectra in Aqueous (*R,R*)-Tartrate Solutions

Katsuhiko MIYOSHI, Chang Eon OH, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received October 11, 1979)

Outer-sphere association constants K_A of inherently achiral cobalt(III)–amine complexes, $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_4(en)]^{3+}$, and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ with (*R,R*)-tartrate anion (*d*-tart^{2-}) were determined by measuring their weak CD spectra induced when they were dissolved in aqueous *d*-tart^{2-} solutions at 25 °C. It was found that the K_A values are not so different among these three complexes, whereas their molar CD intensity $\Delta\varepsilon_{MX}$ gained by the association with *d*-tart^{2-} increases with increasing number of their chelate rings. This was tentatively interpreted to mean that the distortion of the Co(III)–N bonds brought about by outer-sphere association with chiral *d*-tart^{2-} is greater when bidentate ligands (en) are coordinated than when unidentate ones (NH_3) are, *i.e.*, when the complex has more chelate rings. Also it was found that the K_A value thus obtained for $[Co(NH_3)_6]^{3+}$ is much smaller than that determined by measuring the magnitude of its charge-transfer band which newly appears upon the addition of *d*-tart^{2-}. From the above finding and other experimental results, it was suggested that induced CD is well developed in these achiral amine complexes when the two hydroxyl oxygen atoms of *d*-tart^{2-} simultaneously form hydrogen-bonds with amine protons of the ligands.

It is well known that UV and CD spectra of metal complexes are subjected to a considerable change in shape and/or magnitude upon the addition of highly charged counterions in solution. The change is attributed to their outer-sphere association with added counterions, and has been utilized to investigate their outer-sphere interactions.[1] In particular, tris(diamine)-cobalt(III) complexes have been widely studied by many workers.[1-5] Among them, Ogino and Saito[6] were the first to find that the association constant of $[Co(en)_3]^{3+}$ with (*R,R*)-tartrate anion (*d*-tart^{2-}) is different between its two enantiomers in aqueous solution, and their pioneering work initiated extensive studies[7-11] on the discriminating interaction of chiral metal complexes with *d*-tart^{2-} in solution.

On the other hand, Mason and Norman[12] found in 1965 that weak CD is induced for inherently achiral metal complexes like $[Co(NH_3)_6]^{3+}$ when they are dissolved in aqueous (*R,R*)-tartaric acid, sodium (*R,R*)-tartrate, or diethyl (*R,R*)-tartrate solution. Since then, several attempts[13-17] have been made to elucidate the mechanisms leading to this phenomenon called induced CD (ICD) hereafter. Among several proposals made so far, outer-sphere association with the above chiral substances through hydrogen-bonding is the most plausible interpretation for the ICD of metal–amine complexes.[12-14,17,18] If this interpretation is valid, the ICD is also applied to study the outer-sphere interaction of achiral metal–amine complexes with (*R,R*)-tartrate ion (*d*-tart^{2-}) in solution.

Recently, Jonas and Norden[14a] estimated the molar ICD intensity of $[Co(NH_3)_6]^{3+}$ gained through the 1:1 association with *d*-tart^{2-} to be -1.57×10^{-2} in water at the wavelength of its maximum intensity (480 nm) by using its association constant determined by UV measurements.[10] However, the steric requisite in the association with *d*-tart^{2-} is supposed to be severer for the induction of CD than for the development of a new charge-transfer band in achiral complexes like $[Co(NH_3)_6]^{3+}$, as already pointed out by Mason and Norman.[12] In fact, it has been reported[10,19] that CD measurements are apt to give somewhat smaller association constants than UV measurements, at least for the $[Co(en)_3]^{3+}$–*d*-tart^{2-} system.[20] In the present study, the magnitude of the ICD for three achiral complexes, $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_4(en)]^{3+}$, and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ was measured in aqueous solutions as a function of *d*-tart^{2-} concentration, and their association constant K_A with *d*-tart^{2-} and accompanying molar ICD intensity $\Delta\varepsilon_{MX}$ were directly derived and compared with each other.

Experimental

Materials. All the complexes except $[Co(NH_3)_4(R\text{-pn})]Cl_3$ and $[Co(NH_3)_4(tn)]Cl_3\cdot H_2O$ were prepared in the same manner as before[21] and when necessary, they were converted to appropriate salts by ion-exchange techniques. The two tetraammine-complexes were prepared after the methods[22,23] described in the literature. They were identified by their UV and/or CD spectra. Other chemicals used were of reagent grade.

Measurements. Induced CD spectra were recorded on a JASCO J-40CS spectropolarimeter for aqueous solutions of each complex (8.0×10^{-3} mol dm^{-3}) containing varying amounts of sodium (*R,R*)-tartrate (*d*-tart^{2-}), diethyl (*R,R*)-tartrate, or (*R,R*)-tartaric acid up to 3.0 mol dm^{-3}.

To obtain the association constant from the ICD spectra, the ICD magnitudes were measured at 25 °C for aqueous solutions containing sodium (*R,R*)-tartrate or sodium (*R,R*)-tartratoantimonate(III) (Sb_2d-tart$_2^{2-}$) ranging in concentration from 0.08 to 0.15 mol dm^{-3} or from 0.05 to 0.1 mol dm^{-3}, respectively. The concentration of each complex (chloride salt) was kept constant: 8.0×10^{-3} mol dm^{-3} in *d*-tart^{2-} and 7.0×10^{-3} mol dm^{-3} in Sb_2d-tart$_2^{2-}$ solutions. The ionic strength μ was adjusted with NaCl. The pH value of sample solutions thus prepared was around 7 for *d*-tart^{2-} and 4 to 5 for Sb_2d-tart$_2^{2-}$. For the determination of the association constant by UV measurements,[6,10,19] the same experimental conditions as above were adopted except that $NaClO_4$ was added to adjust the ionic strength and perchlorate salts of respective complexes were used in place of the chloride salts.

Results and Discussion

Comparison of ICD Magnitudes. In Fig. 1 are shown the induced CD (ICD) spectra reported previously[21] in the first d-d transition region for $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_4(en)]^{3+}$, and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (0.01 mol dm^{-3} for each) in aqueous Na_2d-tart and Na_2Sb_2d-$tart_2$ solutions (0.1 mol dm^{-3}) together with that for $[Co(NH_3)_4(tn)]^{3+}$ in d-$tart^{2-}$ solution. It is evident that the ICD magnitude increases in the following order in d-$tart^{2-}$ solutions; $[Co(NH_3)_6]^{3+} \ll [Co(NH_3)_4(en)]^{3+} < trans$-$[Co(NH_3)_2(en)_2]^{3+}$. In contrast, Taniguchi *et al.*[18] found the reversed order in acetone containing diethyl (*R,R*)-tartrate (*ca.* 5 mol dm^{-3}). However, direct comparison between their results and ours is meaningless, since the concentration of d-$tart^{2-}$ employed in our experiments is much lower. Then, the ICD magnitude was measured as a function of the concentration of the two chiral substances, Na_2d-tart and diethyl (*R,R*)-tartrate up to 3 mol dm^{-3} in aqueous solutions. For comparison, the ICD magnitude was also measured in aqueous (*R,R*)-tartaric acid solutions.

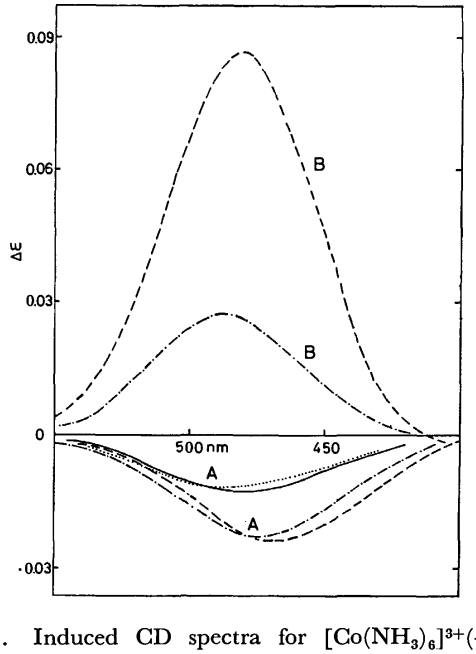

Fig. 1. Induced CD spectra for $[Co(NH_3)_6]^{3+}$(——), $[Co(NH_3)_4(en)]^{3+}$ (-•-·-), *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (——), and $[Co(NH_3)_4(tn)]^{3+}$ (·····) in aqueous d-$tart^{2-}$ (A) and Sb_2d-$tart_2^{2-}$ (B) solutions.

In Fig. 2 are plotted the ICD magnitudes obtained for $[Co(NH_3)_6]^{3+}$ (A), $[Co(NH_3)_4(en)]^{3+}$ (B), and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (C) (8×10^{-3} mol dm^{-3} for each) at the wavelength of their maximum intensity (478, 474, and 466 nm, respectively) against the concentration of Na_2d-tart, diethyl (*R,R*)-tartrate, and (*R,R*)-tartaric acid. When their concentration is low (below *ca.* 0.3 mol dm^{-3}), the ICD magnitude is greatest in d-$tart^{2-}$ solutions for all the complexes and it increases in the following order $[Co(NH_3)_6]^{3+} < [Co(NH_3)_4(en)]^{3+} <$ *trans*-$[Co(NH_3)_2(en)_2]^{3+}$, irrespective of the kind of the

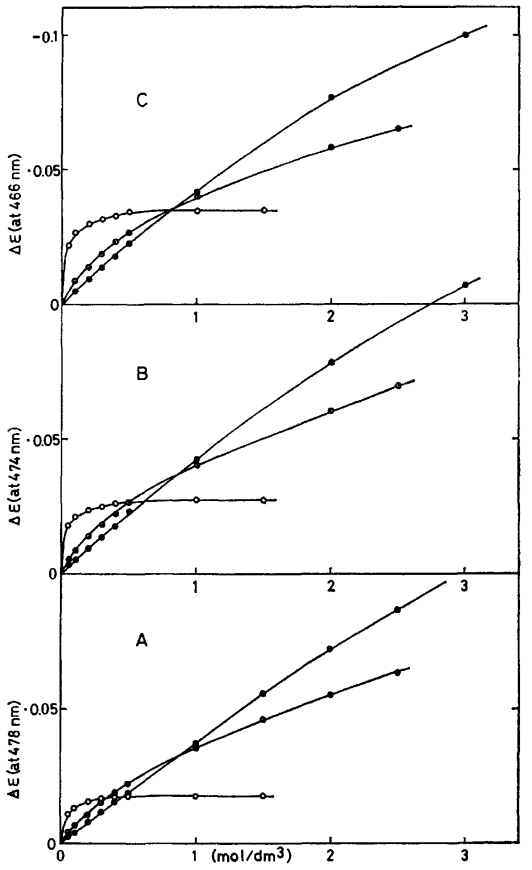

Fig. 2. Plots of the ICD magnitude for $[Co(NH_3)_6]^{3+}$ (A), $[Co(NH_3)_4(en)]^{3+}$(B), and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (C) at the wavelength of the maximum intensity against the concentration of sodium (*R,R*)-tartrate (○), diethyl (*R,R*)-tartrate (●), and (*R,R*)-tartaric acid (⊙) in aqueous solutions.

chiral substances added. This order is in agreement with the increasing order of en chelate rings in the complexes. However, the ICD magnitude in d-$tart^{2-}$ solutions gradually ceases to increase with d-$tart^{2-}$ concentration and it finally becomes constant above *ca.* 0.5 mol dm^{-3}, the limiting ICD magnitude being -1.8×10^{-2}, -2.7×10^{-2}, and -3.5×10^{-2} for $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_4(en)]^{3+}$, and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$, respectively. This indicates that no free complex (not associated with d-$tart^{2-}$) exists in such high d-$tart^{2-}$ concentration ranges. On the contrary, the ICD magnitude gained in diethyl (*R,R*)-tartrate and (*R,R*)-tartaric acid solutions keeps increasing even at 3 mol dm^{-3}. These facts imply that the interaction of these cationic complexes with d-$tart^{2-}$ anion is comparatively strong, probably due to the electrostatic attraction, while the interaction with diethyl (*R,R*)-tartrate or (*R,R*)-tartaric acid is very weak.[12] Furthermore, a close inspection of Fig. 2 reveals that the ICD magnitude gained in diethyl (*R,R*)-tartrate solution gradually becomes greater for $[Co(NH_3)_4(en)]^{3+}$ than for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ as the diethyl (*R,R*)-tartrate concentration is increased. Therefore, we suppose that the increasing order of the ICD magnitude obtained at low concentration of diethyl (*R,R*)-tartrate

will be eventually reversed and agree with the order found by Taniguchi *et al.* in more concentrated solutions.

Similar concentration dependence of the ICD magnitude could not be examined in Sb_2-*d*-$tart_2^{2-}$ solutions owing to the solubility limitation. However, it is worthy of noting that the ICD for a particular complex is certainly greater in magnitude in Sb_2-*d*-$tart_2^{2-}$ solutions than in *d*-$tart_2^{2-}$ solutions (Fig. 1). This will be discussed later.

Determination of Association Constants. If it is assumed that 1:1 association between the achiral complexes and *d*-$tart^{2-}$ is completely attained in the concentration ranges where the curves for the ICD magnitude level off in Fig. 2 (*i.e.*, above *ca.* 0.5 mol dm^{-3}), the limiting ICD magnitude in *d*-$tart^{2-}$ solutions should correspond to the molar ICD intensity of the achiral complexes gained by the association with one *d*-$tart^{2-}$ ion. In fact, the limiting ICD magnitude of $[Co(NH_3)_6]^{3+}$ (-1.8×10^{-2}) is close to its molar ICD intensity estimated by Jonas and Norden (-1.57×10^{-2}).[14a] However, this is quite an accidental coincidence, since the 1:2 association with *d*-$tart^{2-}$ is expected to take place in such high concentration ranges, as shown later. Then, we attempted to determine directly

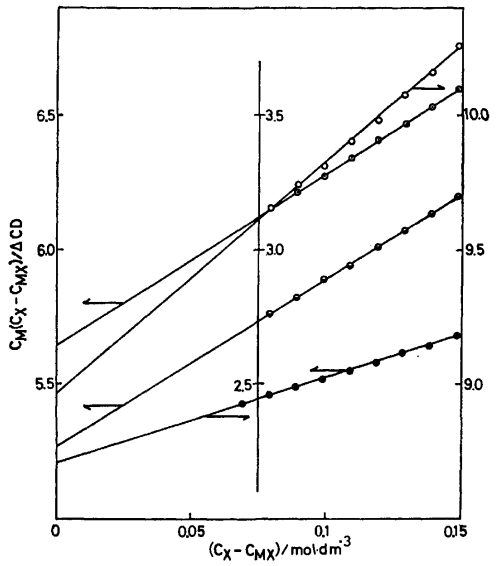

Fig. 3. Plots of Eq. 1 for $[Co(NH_3)_6]^{3+}$ (○), $[Co(NH_3)_4(en)]^{3+}$ (◎), *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (◒), and *rac*-$[Co(en)_3]^{3+}$ (●) in aqueous *d*-$tart^{2-}$ solutions.

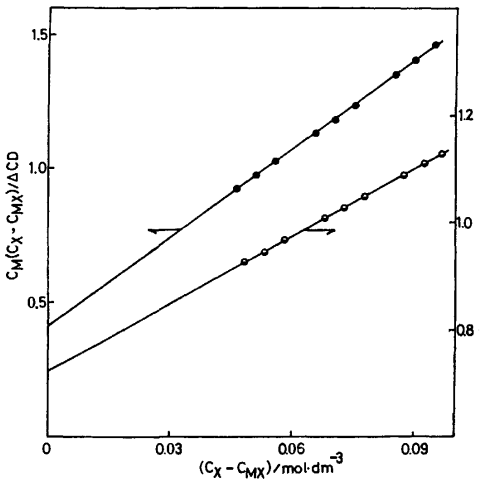

Fig. 4. Plots of Eq. 1 for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (◒) and *rac*-$[Co(en)_3]^{3+}$ (●) in aqueous Sb_2-*d*-$tart_2^{2-}$ solutions.

the association constants K_A and accompanying ICD intensity $\Delta\varepsilon_{MX}$ by measuring the ICD spectra of the three achiral complexes in aqueous solutions containing varying amounts of *d*-$tart^{2-}$ at 25 °C. When possible, the K_A and $\Delta\varepsilon_{MX}$ values were also determined in Sb_2-*d*-$tart_2^{2-}$ solutions.

All the data obtained were analyzed by using the following general equation[11,19]

$$C_M(C_X-C_{MX})/\Delta CD = (C_X-C_{MX})/\Delta\varepsilon_{MX} + 1/K_A\Delta\varepsilon_{MX} \quad (1)$$

where C_M, C_X, and C_{MX} refer to the concentration of the complex (M), *d*-$tart^{2-}$ or Sb_2-*d*-$tart_2^{2-}$ (X), and their associated species (MX), and ΔCD and $\Delta\varepsilon_{MX}$ to the observed CD intensity and the molar ICD intensity of MX, respectively. The plots of the quantity on the left-hand side of Eq. 1 *vs.* (C_X-C_{MX}) gave fairly good straight lines (Figs. 3 and 4), indicating that only 1:1 association takes place for all the complexes under our present experimental conditions. The K_A and $\Delta\varepsilon_{MX}$ values obtained from these plots are listed in Table 1. For comparison, similar experiments were made on racemic $[Co(en)_3]^{3+}$ by using its ICD spectra arising from the differential CD change between its two enantiomers upon the addition of *d*-$tart^{2-}$ or Sb_2-*d*-$tart_2^{2-}$.[21]

Two important facts should be noted in Table 1.

Table 1. Association constant K_A and molar ICD intensity $\Delta\varepsilon_{MX}$ determined by ICD measurements

	λ/nm[a]	K_A	$\Delta\varepsilon_{MX}$	μ(NaCl)
(*R*,*R*)-$tart^{2-}$				
$[Co(NH_3)_6]^{3+}$	478	0.97±0.05	−0.116±0.005	0.49
$[Co(NH_3)_4(en)]^{3+}$	474	1.14±0.02	−0.156±0.003	0.49
trans-$[Co(NH_3)_2(en)_2]^{3+}$	466	1.19±0.02	−0.159±0.003	0.49

Sb_2(*R*,*R*)-$tart_2^{2-}$				
trans-$[Co(NH_3)_2(en)_2]^{3+}$	484	5.8±1.0	0.239±0.003	0.33
rac-$[Co(en)_3]^{3+}$	461[b]	26.6±1.2	−0.091±0.002	0.32

a) Wavelength at which the ICD is measured and has its maximum intensity. b) *rac*-$[Co(en)_3]^{3+}$ has a maximum ICD intensity at 469 nm in Sb_2-*d*-$tart_2^{2-}$ solution.

The first is that the K_A values with d-tart^{2-} are not appreciably different among three achiral complexes, while the $\Delta\varepsilon_{MX}$ value of $[Co(NH_3)_6]^{3+}$ is much smaller than those of the other two complexes. Therefore, a smaller $\Delta\varepsilon_{MX}$ value of $[Co(NH_3)_6]^{3+}$ is responsible for its weaker ICD developed in d-tart^{2-} solution (Fig. 1). On the other hand, both the K_A and $\Delta\varepsilon_{MX}$ values for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ are slightly greater than the corresponding values for $[Co(NH_3)_4(en)]^{3+}$ in d-tart^{2-} solutions. Then, it is natural that the ICD similar in magnitude is developed for the two complexes as shown in Fig. 1.

Another noteworthy fact is that both the K_A and $\Delta\varepsilon_{MX}$ values for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ are much greater in Sb_2d-tart$_2^{2-}$ solution than in d-tart^{2-} solution, though the ionic strength is somewhat lower in the former solution. As a result, it is this fact that is responsible for much stronger ICD developed for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ in Sb_2d-tart$_2^{2-}$ than in d-tart^{2-} solutions. The same will probably hold for $[Co(NH_3)_4(en)]^{3+}$ whose association constant with Sb_2d-tart$_2^{2-}$ cannot be determined owing to the formation of a precipitate. Similarly, the K_A value obtained for *rac*-$[Co(en)_3]^{3+}$ is surprisingly greater with Sb_2d-tart$_2^{2-}$ than with d-tart^{2-}.[24] Therefore, we suppose that Sb_2d-tart$_2^{2-}$ interacts with these amine-complexes in quite a different fashion from d-tart^{2-}.[25] In fact, $[Co(NH_3)_4(en)]^{3+}$ and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ show a positive ICD band in Sb_2d-tart$_2^{2-}$ solution, while the two complexes and $[Co(NH_3)_6]^{3+}$ show a negative ICD band in d-tart^{2-} solution. Furthermore, the wavelength at which the ICD of these complexes has a maximum intensity is considerably different between d-tart^{2-} and Sb_2d-tart$_2^{2-}$ solutions (Fig. 1 and Table 1).

For *rac*-$[Co(en)_3]^{3+}$, however, its apparent $\Delta\varepsilon_{MX}$ value is not directly compared with those of the achiral complexes, since the mechanism leading to the ICD in racemic complexes is essentially different from that in achiral complexes.[21]

In Table 2 are given the association constants K_A of $[Co(NH_3)_6]^{3+}$ and *rac*-$[Co(en)_3]^{3+}$ with d-tart^{2-} determined in the present study by UV measurements. Also given are the K_A values reported by other workers. Here the ionic strength μ is adjusted with $NaClO_4$. Again, two noticeable facts are found in Table 2. First, the K_A value obtained for $[Co(NH_3)_6]^{3+}$ is greater than that for $[Co(en)_3]^{3+}$. Nevertheless, when the ICD measurements are applied, the resulting K_A value is greater for *rac*-$[Co(en)_3]^{3+}$ than for $[Co(NH_3)_6]^{3+}$. Another fact to be noted is that the K_A value derived from ICD measurements is much smaller than that obtained by UV measurements both for $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, as seen in Tables 1 and 2. These facts strongly suggest that the steric requisite in the association with d-tart^{2-} is much severer for the induction of CD in the first d-d transition region than for the development of a new charge transfer band in the UV region for achiral complexes.[12]

Mason and Norman[12] have already found that no detectable CD is induced[26] for $[Co(NH_3)_6]^{3+}$ when mixed with (*S*)-malic acid or sodium (*S*)-malate having only one OH group on the asymmetric carbon atom. However, the addition of (*S*)-malate^{2-} as well as d-tart^{2-} gives an appreciable change in the UV spectrum of the complex, suggesting that the interaction with the two $-COO^-$ groups gives rise to the change in the UV spectrum of the complex.[6] Therefore, we suppose that the ICD is well developed only when the two OH groups on the asymmetric carbon atoms simultaneously participate in the interaction with these achiral amine complexes. The most probable interaction imagined here is the hydrogen-bonding of the hydroxyl oxygen atoms with the amine protons of the ligands.[17] In fact, ICD is well developed for $[Co(NH_3)_6]^{3+}$ and other two achiral complexes when mixed with diethyl (*R,R*)-tartrate or (*R,R*)-tartaric acid having no $-COO^-$ group.[27]

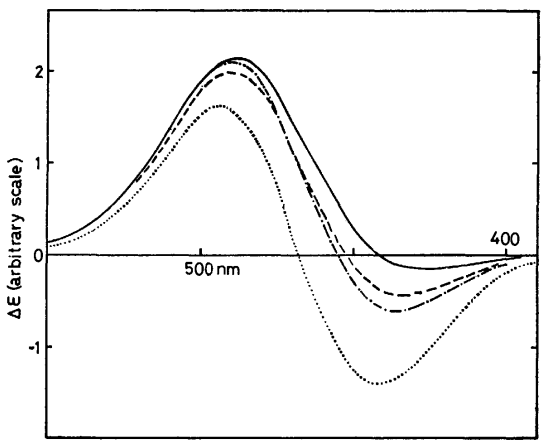

Fig. 5. CD spectra of *Λ*-$[Co(en)_3]^{3+}$ (2×10^{-3} mol dm^{-3}) in the absence (——) and presence of d-tart^{2-}; 0.0275 mol dm^{-3} (——) and 1.0 mol dm^{-3} (-·-·-), and calculated CD spectrum of *Λ*-$[Co(en)_3]^{3+}$ associated with d-tart^{2-} (……) in aqueous solutions.

Comparison of $\Delta\varepsilon_{MX}$ Values with Limiting ICD Magnitudes. Before the limiting ICD magnitudes attained in Fig. 2 are discussed and compared with the $\Delta\varepsilon_{MX}$ values listed in Table 1, the influence of added d-tart^{2-} on the natural CD spectrum of *Λ*-$[Co(en)_3]^{3+}$ is examined here. In Fig. 5 are shown the CD spectra of *Λ*-$[Co(en)_3]^{3+}$ (2×10^{-3} mol dm^{-3}) in water in the absence and presence of d-tart^{2-} (2.75×10^{-2} and 1.0 mol dm^{-3}).

The association constant of the complex with *d*-tart^{2-} has been estimated by CD measurements to be 13.0± 1.0[11] at μ=0.1 ($NaClO_4$). By using this value, the hypothetical CD spectrum of *Λ*-$[Co(en)_3]^{3+}$ associated with *d*-tart^{2-} was calculated and is shown as a dotted line in Fig. 5. It is evident that the CD spectrum in the presence of a large amount of *d*-tart^{2-} (*e.g.*, 1.0 mol dm^{-3}) is entirely different from the calculated spectrum. This unambiguously means that successive association[4a] of the complex with *d*-tart^{2-} must be taken into account at such high *d*-tart^{2-} concentrations. The same is naturally expected for the three achiral complexes in question, since all of them bear 3+ charges like $[Co(en)_3]^{3+}$. However, the association higher than 1 : 2 is improbable under our experimental conditions, as pointed out by Olsen and Bjerrum for the $[Co(en)_3]^{3+}$–$S_2O_3^{2-}$ system.[28] As a result, it follows that the 1 : 2 association with *d*-tart^{2-} is completely attained in extremely high *d*-tart^{2-} concentration ranges (Fig. 2) and that the limiting ICD magnitudes thus correspond to the molar ICD intensities of the respective achiral complexes gained by interacting with two *d*-tart^{2-} ions at a time. On the other hand, the $\Delta\varepsilon_{MX}$ values correspond to the molar ICD intensities gained by the association with only one *d*-tart^{2-} ion.

Now we are ready to compare the limiting ICD magnitudes with the $\Delta\varepsilon_{MX}$ values. First of all, it should be noted that the limiting ICD magnitude is much smaller than the $\Delta\varepsilon_{MX}$ value for all the complexes examined. If the former indeed reflects the molar ICD intensity of the achiral complex associated with two *d*-tart^{2-} ions, we are obliged to conclude that the ICD magnitude gained in the 1 : 1 association with *d*-tart^{2-} is greatly diminished (almost to one-fifth) in the 1 : 2 association, probably due to restored high symmetry[4a] of the resulting outer-sphere complex with two *d*-tart^{2-} ions. It is also highly plausible that the strain imposed on the achiral complex in the 1 : 1 association is relaxed in the 1 : 2 association owing to the electrostatic repulsion between the two *d*-tart^{2-} anions, the overall ICD magnitude being thereby diminished greatly.

Finally, the most important problem remains unanswered why the $\Delta\varepsilon_{MX}$ value for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (−0.159) is only slightly greater than that for $[Co(NH_3)_4(en)]^{4+}$ (−0.156), while the limiting ICD magnitude is appreciably greater for the former complex (-3.5×10^{-2}) than for the latter (-2.7×10^{-2}). Though detailed mechanisms of the ICD developed in these achiral complexes are not known, some authors[13,18,29] favor the view that the ICD owes its origin to a fixed conformation (δ or λ) of the chelate rings of the complex in the presence of chiral substances. However, we are not inclined to adopt this view in the present system, since the ICD spectra obtained for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ and $[Co(NH_3)_4(en)]^{3+}$ (Fig. 1) do not resemble the natural CD spectra of *trans*-$[Co(NH_3)_2$(*R*- or *S*-pn)$_2]^{3+}$ and $[Co(NH_3)_4$(*R*- or *S*-pn)$]^{3+}$,[22] respectively, and similar CD is induced also for $[Co(NH_3)_6]^{3+}$ having no chelate. In addition, $[Co(NH_3)_4$(*R*-pn)$]^{3+}$ in which a pn chelate ring is thought to be fixed to a λ-conformation suffers a considerable change in its CD spectrum when mixed with *d*-tart^{2-} or Sb_2*d*-tart$_2^{2-}$, as shown in Fig. 6.

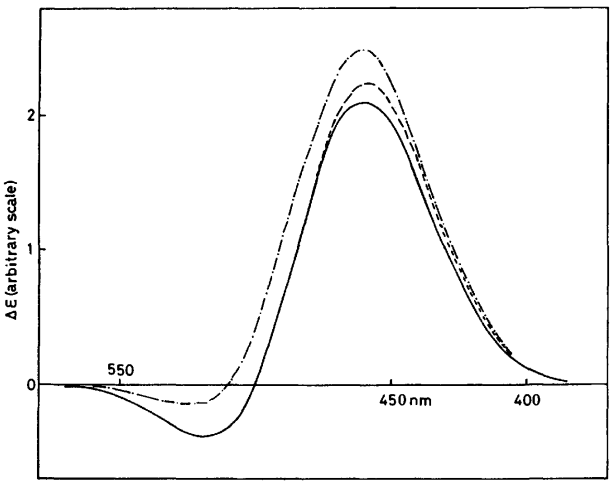

Fig. 6. CD spectra of $[Co(NH_3)_4$(*R*-pn)$]^{3+}$ in the absence (——) and presence of *d*-tart^{2-} (– – –) and of Sb_2*d*-tart$_2^{2-}$ (–·–·–) in aqueous solutions.

It is certain, however, that the ICD developed in *d*-tart^{2-} solution increases in magnitude with increasing number of en chelate rings in the complexes. This leads us to propose that the ICD magnitude depends on the degree of the distortion[13] of the Co(III)–N bonds brought about by the outer-sphere association with *d*-tart^{2-}, since a greater distortion is expected when the coordinated ligands are bidentate (en) than when they are unidentate (NH_3), *i.e.*, when the complex has more chelate rings. In accordance with this proposal, the ICD magnitude of $[Co(NH_3)_4(en)]^{3+}$ is greater than that of $[Co(NH_3)_4(tn)]^{3+}$, the strain exerted upon which is not effectively propagated to the central Co(III) ion owing to the flexibility of a tn chelate ring.

If our proposal that the strain exerted upon chelate rings is effective in inducing CD in achiral complexes is valid, a tentative answer can now be put forward to the problem mentioned above. In the 1 : 1 association with *d*-tart^{2-}, both *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ and $[Co(NH_3)_4$-$(en)]^{3+}$ having at least one en chelate ring are expected to suffer a similar distortion, since *d*-tart^{2-} cannot interact with *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ so as to exert a strain on the two en rings simultaneously. As a result, it is natural that CD similar in magnitude is induced for the two complexes. On the other hand, when the 1 : 2 association takes place, *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ is differentiated from $[Co(NH_3)_4(en)]^{3+}$, since the former complex has another en chelate ring available for the further interaction with *d*-tart^{2-}, while the latter not. Therefore, relatively stronger CD is expected to be induced for the former complex in concentrated solution of *d*-tart^{2-}, though the overall ICD magnitude gained in the 1 : 2 association is by far smaller than that in the 1 : 1 association. In this way, an appreciably great difference in the limiting ICD magnitude between $[Co(NH_3)_4(en)]^{3+}$ and *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ is reasonably interpreted.

Though the solubility limitation does not allow us to obtain the limiting ICD magnitudes in Sb_2*d*-tart$_2^{2-}$ solution, the ICD magnitude for *trans*-$[Co(NH_3)_2(en)_2]^{3+}$

is considerably greater than that for $[Co(NH_3)_4(en)]^{3+}$ even when the concentration of $Sb_2d\text{-}tart_2^{2-}$ is relatively low (Fig. 1). This tacitly means that the arguments presented above are not applied to the interpretation of the ICD developed in $Sb_2d\text{-}tart_2^{2-}$ solutions.

Kinetics of the Stereoselective Deuteration of Malonate Hydrogens in Some Bis(malonato)cobalt(III) Compounds and the Reversal of Stereoselectivity Induced by the Solution pH[1]

Ushio SAKAGUCHI, Kaiji MORITO, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received February 26, 1980)

The deuteration rates at malonate methylene groups have been measured for several $[Co(mal)_2(N)_2]^-$ ions over the pD range of 2 to 9 at 36.4 °C, where mal = malonate ion, $(N)_2$ = ethylenediamine, *cis*-$(NH_3)_2$, 1,3-propanediamine, *N,N'*-dimethylethylenediamine, *cis*-(pyridine)$_2$, and 1,10-phenanthroline. The malonate deuteration is acid-catalysed at pD less than about 4 and base-catalysed at higher pD in all the compounds. In the amino-containing compounds (the first four compounds), the reaction proceeds stereoselectively in both high and low pD regions. Though the degree of the stereoselectivity depends upon the compound, the fast-exchanging hydrogen is, for all the amino-containing compounds, the one which is adjacent to the coordinating nitrogen atom. The mechanisms of acid- and base-catalysed deuteration, as well as the origin of the stereoselectivity, are discussed. For the ethylenediamine and *cis*-$(NH_3)_2$ compounds, reversal of the stereoselectivity takes place at around pD = 8 and 9, respectively, and the fast-exchanging hydrogen becomes the one farthest apart from the coordinating nitrogen. Concomitant with this reversal, both malonate and amine exchange rates fall together. Thus, the rate of hydrogen-deuterium exchange at the NH_3 groups does not show the usual first-order dependence upon the OD^- concentration. These observations are explained by a mechanism in which equally reactive malonate and amine hydrogens compete for OD^- catalyst.

In the preceding paper,[2] we investigated the deuteration kinetics of malonate methylenes in monomalonatocobalt(III) compounds. The chelated and the non-chelated malonate ligands behaved quite differently and the deuteration mechanisms are discussed. The acidity of the malonate hydrogens coordinated to Co(III) has been studied by several workers. Yoneda and Morimoto[3] observed that the malonate deuteration proceeds quite easily simply by dissolving malonatocobalt(III) compounds in deuterium oxide. Buckingham *et al.*[4] noted that the malonate methylenes of $[Co(mal)_2(en)]^-$ and $[Co(mal)(en)_2]^+$ ions[5] undergo acid-catalysed and probably base-catalysed deuteration. They also found that the two types of hydrogens of coordinated malonate in $[Co(mal)_2(en)]^-$ exchange with deuterium at unequal rates. Recently, Farago and coworkers[6] made temperature dependence studies on the malonate deuteration of $[Co(mal)_2(en)]^-$, $[Co(mal)(en)_2]^+$, and $[Co(mal)(bpy)_2]^+$ in the pD region of 2 to 3. The last result confirmed that the deuteration is acid-catalysed. Here we have examined the deuteration rates of malonate ligands in $[Co(mal)_2(N)_2]^-$ type of compounds over the pD range of 2 to 9 and at 36.4 °C.

Experimental

Materials. Deuterium oxide (99.8 atom%D minimum) was obtained from E. Merck(Darmsdadt). *cis*-$K[Co(mal)_2(NH_3)_2]$[7] $2.5H_2O$, and *cis*-$K[Co(mal)_2(py)_2]3.5H_2O$[8] were prepared after Shibata *et al.* $K[Co(mal)_2(en)]H_2O$ was prepared and resolved by *levo*-$[Co(NO_2)_2(en)_2]^+$ after Dwyer and coworkers.[9] The tn complex was made after Brennan *et al.*[10] and the number of water molecules of crystallization was 2.5 instead of 2. Found: N, 6.69; C, 25.81; H, 4.38%. Calcd for $K[Co(mal)_2(tn)]\cdot 2.5H_2O$: N, 6.65; C, 25.66; H, 4.55%.

The phen compound was prepared as follows. The tris(malonato)cobalt(III) solution was prepared after Kneten and Spees[11] from 24 g(0.08M) of $Co(NO_3)_2\cdot 6H_2O$. To the filtered $[Co(mal)_3]^{3-}$ solution, 15.9 g(0.08M) of 1,10-phenanthroline monohydrate was added. After stirring at 45 °C for 1 h the solution was left standing at room temperature overnight. The precipitate, $[Co(mal)(phen)_2]$ $[Co(mal)_2(phen)]$, was filtered and redissolved in water. The double complex salt was loaded on an SP-Sephadex C-25 cation-exchange column, and eluted with water. The anionic eluent containing $[Co(mal)_2(phen)]^-$ was reloaded on a QAE-Sephadex A-25 anion-exchange column and eluted with a concentrated solution of potassium chloride. The concentrated eluent was kept in a refrigerator overnight to give needle-like crystals. Yield was about 2.0 g. Found: N, 4.84; C, 37.07; H, 2.91%. Calcd for $K[Co(mal)_2(phen)]\cdot KCl\cdot 5H_2O$: N, 4.80; C, 37.03; H, 2.59%.

Measurements. All the compounds were dissolved in deuterium oxide to about 0.20 to 0.30 mol dm^{-3}. Ionic strength was not controlled. The solution pD was adjusted by appropriate amount of HCl or K_2CO_3 and measured by a Hitachi-Horiba Model F-7 pH meter with a microelectrode accessory, immediately after kinetic measurements. The apparent pH meter readings were converted to the pD values by the empirical formula developed by Fife and Bruice,[12] pD = pH(meter readings) + 0.35(at 36.4 °C). Nuclear magnetic resonance spectra were run at 36.4 °C on a Varian T-60 spectrometer operating at 60 MHz. Chemical shifts were referred to internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate(DSS).

Absorption spectra were obtained on a Shimadzu UV-200 double beam spectrophotometer and circular dichroism spectra on a JASCO J-40CS spectropolarimeter.

Deuteration Rates. The hydrogen-deuterium exchange rates at amine groups were obtained from the slope of the plots of ln(intensity) *vs.* time, as in the previous studies.[13]

For malonate exchange, we first note that $[Co(mal)_2(N)_2]^-$ contains two types of malonate hydrogens, see Fig. 1. In the figure, H_N is adjacent to the coordinated nitrogen atom and H_O is close to the malonate oxygen atom. These two types of hydrogens give rise to an AB quartet immediately after dissolution of the compounds, see Fig. 2. If only H_N is deuterated, we have the species D–C–H_O, which should yield the H_O singlet. In Fig. 2, the H_O hydrogen is assumed to resonate at a higher magnetic field, in accordance with our assignment (*vide infra*). The rate constant for this process is

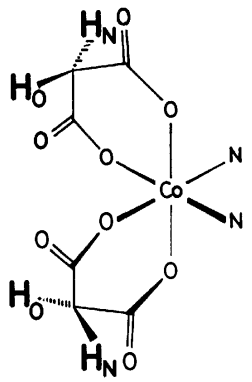

Fig. 1. A schematic presentation of the $[Co(mal)_2(N)_2]^-$ ion, showing that there are two types of malonate hydrogenes, H_N and H_O.

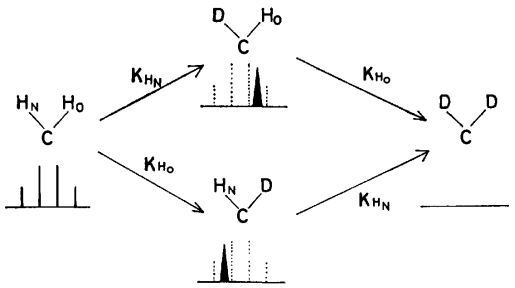

Fig. 2. The scheme for hydrogen-deuterium exchange kinetics of the H_N–C–H_O fragment. Kinetic isotope effect is not taken into account.

denoted as k_{HN}. Similarly, the species H_N–C–D produced by deuteration of only H_O would give rise to the H_N singlet. As the deuteration of H_N–C–H_O proceeds, the intensity of the initial quartet will decrease and that of the H_O and/or H_N singlet(s) will grow. This is the first stage of deuteration. Since both H_O and H_N are exchanged with deuterium in due course, these singlets diminish in intensity with time and eventually vanish. If we neglect the kinetic isotope effect[14] expected for the disappearance of H_N and H_O singlets, the rate constants for the decrease of these singlets are k_{HN} and k_{HO}, respectively. The situation is illustrated schematically in Fig. 2. We may set up simultaneous kinetic equations for the scheme of Fig. 2.

$$-\frac{d}{dt}[H_N\text{-}C\text{-}H_O] = (k_{HO}+k_{HN})[H_N\text{-}C\text{-}H_O] \quad (1)$$

$$-\frac{d}{dt}[D\text{-}C\text{-}H_O] = k_{HO}[D\text{-}C\text{-}H_O] - k_{HN}[H_N\text{-}C\text{-}H_O] \quad (2)$$

$$-\frac{d}{dt}[H_N\text{-}C\text{-}D] = k_{HN}[H_N\text{-}C\text{-}D] - k_{HO}[H_N\text{-}C\text{-}H_O], \quad (3)$$

where $[D\text{-}C\text{-}H_O]$, for example, is the concentration at time t of the species D–C–H_O and the other notations have similar meanings. Equation 1 is equivalent to

$$[H_N\text{-}C\text{-}H_O] = [H_N\text{-}C\text{-}H_O]_{t=0} \exp[-(k_{HN}+k_{HO})t]. \quad (4)$$

Namely, since H_N–C–H_O is to give either D–C–H_O or H_N–C–D or both, the rate constant for the decrease of the AB quartet, k_Q, is the sum of two rate constants k_{HN} and k_{HO},

$$k_Q = k_{HN} + k_{HO}. \quad (5)$$

Experimentally, k_Q was obtained as follows. The natural logarithms of the averaged intensity of the inner pair of the AB quartet and that of the outer pair of the quartet were plotted separately against time. These two plots gave straight lines and the slopes of these lines were the same within experimental error. The avarage of the two slopes was taken as the rate constant k_Q.

Equations 2 and 3 can be solved to give

$$[D\text{-}C\text{-}H_O] = [H_N\text{-}C\text{-}H_O]_{t=0}\{\exp(-k_{HO}t) - \exp[-(k_{HO}+k_{HN})t]\} \quad (6)$$

$$[H_N\text{-}C\text{-}D] = [H_N\text{-}C\text{-}H_O]_{t=0}\{\exp(-k_{HN}t) - \exp[-(k_{HO}+k_{HN})t]\}. \quad (7)$$

Equations 6 and 7 tell us that in the initial stage of deuteration the H_O and/or H_N singlet(s) will grow in intensity with rate constant k_{HN} and/or k_{HO}, respectively, owing to the process H_N–C–$H_O \rightarrow$D–C–H_O and/or H_N–C–D. Experimentally, it was difficult, however, to follow these initial processes over the whole pD range simply because the rates were too large in some pD region. We are forced, therefore, to estimate the separate rate constant by following the decrease in singlet intensity, which was found to be almost exponential. This corresponds to the second stage of deuteration.

Results and Discussion

Figure 3 gives the tracings of the NMR spectra in pure deuterium oxide for all the complexes investigated here. Chemical shift data are summarized in Table 1. In Fig. 3, the strong peak at δ 4.62 is due to solvent HDO. The *cis*-$(NH_3)_2$ compound, Fig. 3(a), gives the AB quartet centered at δ 3.43 and a broad resonance at δ 3.80 due to the coordinated ammonia groups. The tn compound, Fig. 3(b), shows the complex multiplets of methylene groups at δ 2.28 (C_1 and C_3 methylenes) and δ 1.95 (C_2 methylene), and a broad absorption at δ 4.62 due to the coordinated amine group (overlapped with the HDO resonance), in addition to the malonate quartet. The spectrum of the en compound, Fig. 3(c),

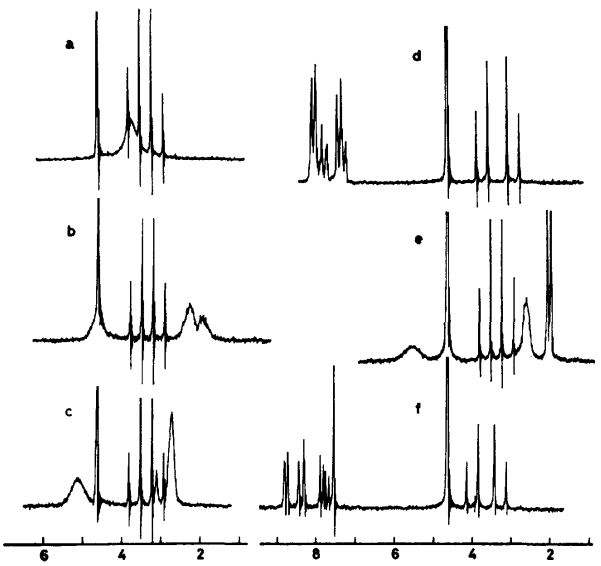

Fig. 3. The 60 MHz spectra of $[Co(mal)_2(N)_2]^-$ compounds, where $(N)_2$ stands for (a) *cis*-$(NH_3)_2$, (b) tn, (c) en, (d) *cis*-py_2, (e) dmen, and (f) phen. These spectra were taken immediately after dissolution in pure D_2O.

Table 1. Summary of the chemical shifts and the coupling constants, both values being expressed in Hz

The isotope shifts(Hz) are taken to be plus for upfield shifts in the resonance of CHD group compared with the resonance of CH_2 group, in accordance with the usual convention.

Ligand	CH_2 species		CHD species		Isotope shift		J	pD	Concn (mol dm^{-3})
	$\nu(H_N)$	$\nu(H_O)$	$\nu(H_N)$	$\nu(H_O)$	$\delta\nu(H_N)$	$\delta\nu(H_O)$			
en	218.62	187.38	—	186.98	—	+0.40	18.0	6.50	0.19
tn	216.12	184.88	215.72	184.37	+0.40	+0.51	18.3	6.83	0.12
dmen	220.44	188.31	—	187.80	—	+0.51	18.7	4.67	0.27
cis-$(NH_3)_2$	220.98	190.02	220.37	189.21	+0.61	+0.81	18.5	8.35	0.28
cis-py_2	234.04	187.96	234.65	186.38	−0.61	+1.58	18.8	6.20	0.24
phen	243.66	203.54	242.99	202.70	+0.67	+0.84	18.3	5.67	0.13

is reported[3,4,6] and consists of the malonate quartet at δ 3.38, a broad singlet at δ 2.75 due to methylene hydrogens of the coordinated ethylenediamine, and a broad peak at δ 5.12 due to the NH_2 group. The pyridine resonance of the *cis*-py_2 compound appears between δ 7.35 and 8.30, as reported previously (Fig. 3(d)).[8] The spectrum of the dmen compound consitsts of the methyl doublet (δ 2.07, $J\approx5$ Hz), a broad peak (δ 2.63) due to the methylene group, and a broad singlet (δ 5.53) due to the coordinated amine group, see Fig. 3(e). The methyl doublet collapsed into a singlet upon deuteration of the amine group. Figure 3(f) shows the spectrum of the phen compound and contains the phen multiplets between δ 7.50 and 8.90. In all the compounds, the malonate hydrogens appear as an AB quartet at around δ=3.1—4.1 and the J values assume almost constant values of about 18 Hz. The spectral parameters of these quartets (chemical shifts and J values) did not change with the solution pD. The AB quartet results from different magnetic environments seen by H_N and H_O.[3,4] The origin of this difference was discussed by Buckingham *et al.*[4] in connection with the conformation of malonate chelates. As shown in Table 1, the chemical shift differences between the H_N and H_O hydrogens are rather large, ranging from 30.96 Hz of the *cis*-$(NH_3)_2$ compound to 46.08 Hz of the *cis*-py_2 compound. Therefore, it is expected for all the compounds that the H_N hydrogen, for example, must be assigned either to the high-field pair of the quartet or the low-field counterpart. Several factors might be conceivable as the origin of the shift difference between H_N and H_O. They are the magnetic anisotropy of the central cobalt(III) ion and the anisotropic magnetic shielding of the C=O and C–O groups. The r^{-3} dependence of the former effect predicts[15] that the two hydrogens, H_N and H_O, more than 3.5 Å apart from the Co(III) ion of the *cis*-CoN_2O_4 chromophore do not exhibit the shift difference as large as 30 Hz (0.5 ppm), the value observed. The anisotropic shielding effect of the C=O and C–O groups of one malonate upon the chemical shift of the other malonate appears also unlikely, because the maximum shift difference observed for the Δ- and Λ-$[Co(ox)_2(R\text{-}pn)]^-$ pair is 0.16 ppm of the alpha hydrogen and the corresponding quantity in Δ- and Λ-$[Co(acac)_2(S\text{-}ala)]$ is 0.20 ppm.[16] The combined effect of the two COO groups within one malonate moiety would, however, amount to more than 0.6 ppm in some cases.[16d] It is rather difficult to assess quantitatively the shift difference since the shift difference of H_N and H_O depends critically on the conformation of the malonate chelate. The six-membered cobalt-malonate ring can adopt several conformation; the chair, boat, skew-boat, and intermediate stage conformations of these. The interconversion among these conformations will certainly be rapid, as discussed by Yoneda and Morimoto[3] and Buckingham *et al.*[4] In the absence of any other evidence, we can not decide the most stable conformation at present. Thus, it does not seem pertinent to discuss the chemical shift difference of H_N and H_O further.

The assignment of H_N, for example, to either the high-field or the low-field pair of the quartet will be made by comparing the chemical shift changes caused by changing nitrogen ligands. Among the en, tn, dmen, and *cis*-$(NH_3)_2$ complexes, the shift variations are relatively small and within 4.86 Hz for the low-field hydrogen and 5.14 Hz for the high-field one. For the compounds with aromatic ligands, we observed large shift variations, especially in the low-field pair. Thus, on going from the en compound to the *cis*-py_2 compound, we note that the chemical shift change of the low-field pair is 15.42 Hz while that of the high-field pair is 0.58 Hz. Likewise, the chemical shift differences between the en and phen complexes are 25.04 Hz and 16.16 Hz for the low- and the high-field pairs, respectively. The larger downfield shift of the low-field pair observed for aromatic ligands is probably due to the ring current effect[16d] of py and phen ligands and suggests that the hydrogen giving rise to the low-field pair is adjacent to the coordinating nitrogen. Therefore we propose that the hydrogen H_N undergoes a greater chemical shift change owing to its closeness to nitrogen ligands and is assigned to the low-field pair of the AB quartet.

To confirm the assignment, we have compared the chemical shift of $[Co(mal)_2(en)]^-$ and $[Co(mal)_2(meen)]^-$ ions, and of $[Co(mal)_2(gly)]^{2-}$ and $[Co(mal)_2(sar)]^{2-}$ ions.[17] In both pairs, the effect of *N*-methylation was greater for the low-field hydrogens than for the high-field ones. For example, the Meen compound exhibits two AB quartets due to malonate and the shift values of the high- and low-field hydrogens of one quartet are δ 3.11 and 3.62, respectively, and the corresponding values of the other quartet are δ 3.15 and 3.67. The latter values correspond nicely to the values

of the dmen compound (δ 3.14 and 3.67) so that this quartet is most probably due to the malonate CH_2 group adjacent to the *N*-methyl group of Meen. Thus the *N*-methylation of en caused a down-field shift of the low-field hydrogen by 0.03 ppm in both Meen and dmen compounds.

It should be pointed out that the present assignment of the AB quartet is opposite to the assignment of Farago and Smith.[6] Their assignment is based on the assumption that in the time averaged conformation of malonate-cobalt rings the H_N hydrogen is displaced, owing to the malonate-malonate repulsion, toward the NH_2 groups and is surrounded by more valence electrons than H_O. The high-field hydrogen is thus assigned to H_N. For reasons mentioned above, we do not favor their assignment.

In Table 1, the values of isotope shift[18] are also given. These values range from -0.61 to $+1.58$ Hz and they are of the magnitude usually observed.[18] In the *cis*-py_2 compound, a down-field isotope shift is found for the H_N hydrogen (-0.61 Hz). The H_O hydrogen of the same compound shows the usual upfield shift ($+1.58$ Hz). It will be interesting to note that stereochemically different hydrogens can show isotope shifts of opposite signs even if they are bonded to the same carbon atom. Generally, deuterium substitution

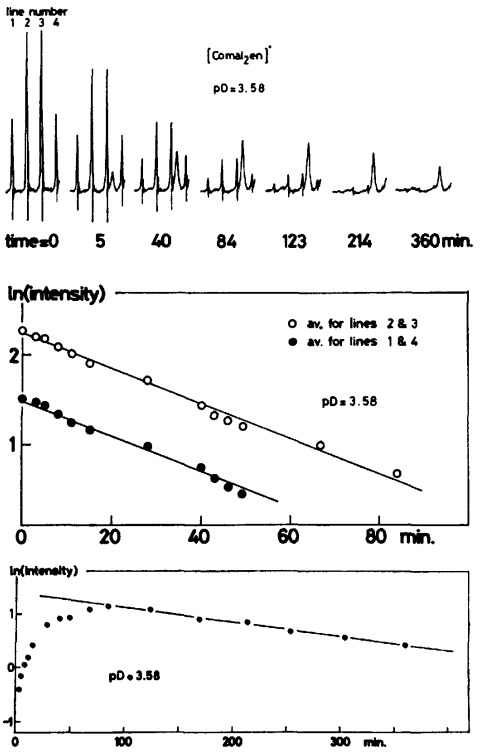

Fig. 4. An example of the kinetic analysis. The sample is $[Co(mal)_2(en)]^-$ at pD=3.58 and at 36.4 °C. (Top) The variation of the malonate portion of the spectrum with time, the H_O singlet being not numbered. (Mid-) dle) The ln (intensity) *vs.* time plots for the inner pair (lines 2 and 3, open circles) and the outer pair (lines 1 and 4, closed circles) of the quartet. (Bottom) The ln (intensity) *vs.* time plots of the H_O singlet. The solid line is the asymptote for the second stage of deuteration.

gem to a proton is reported to cause the proton resonance to be shifted upfield.[18] Only one exception is known to date; the NH_4^+ ion exhibited a downfield isotope shift.[19] This unusual isotope shift has been explained by electrostatic effects arising from hydrogen bonding with the polar deuterium oxide solvent. It appears that the isotope shifts of opposite sign exhibited by H_N and H_O of the *cis*-py_2 compound are reflecting different degrees of solvation around these hydrogens.

Stereoselectivity. The kinetic behavior expected from Eq. 4 to 7 is illustrated in Fig. 4 for the data of the en compound at pD=3.58. The top figure shows the time variation of the malonate portion of the spectrum. Immediately after dissolution we observed only the AB quartet, as expected for the presence of only H_N–C–H_O species. As time passes, the quartet decreases in intensity and at the same time a singlet appears exactly at the chemical shift of the high-field H_O hydrogen and grows in intensity with time. Then, the singlet begins to decrease in intensity and disappears eventually. The middle figure gives the time variation of the quartet intensity. In the figure, the natural logarithms of an average of the intensities of the inner and outer pair of the quartet are plotted against time by the open and closed circles, respectively. Both plots give straight lines and the slopes of both plots are the same within experimental uncertainties. Thus, the quartet intensity decreased exponentially with time over at least 2—3 half lives. As indicated by Eq. 4, these slopes correspond to k_Q or equally $k_{HN}+k_{HO}$. The bottom figure illustrates the time variation of the H_O singlet intensity. From this figure it appears rather difficult to obtain the initial rate constant, k_{HN} in this case. However, the second stage of deuteration follows the exponential law rather well, as indicated by the solid line in the figure. The slope of this asymptote corresponds to k_{HO}, as dictated by Eq. 6. The rate constant k_{HN} was obtained by $k_{HN}=k_Q-k_{HO}$, Eq. 5.

In the top figure we do not observe the H_N singlet due to the species H_N–C–H_O throughout the deuteration process. This means that the whole spectral change with time should be explained by the process

$$H_N\text{–C–}H_O \longrightarrow D\text{–C–}H_O \longrightarrow D\text{–C–}D,$$

where the species H_N–C–D was not produced during this deuteration process. Therefore, the deuteration takes place stereoselectively; the rate of deuteration of H_N is much larger than that of H_O.

The degree of the stereoselectivity can be defined by the ratio k_{HN}/k_{HO}. Qualitatively, the intensity ratio of the high- to low-field singlets can be taken as a rough measure of the degree of stereoselectivity. Figure 5 shows collectively the malonate portion of the NMR spectra of dmen, tn, *cis*-py_2, and phen compounds, taken some time after dissolution. The dmen and tn compounds exhibit marginally observable H_N singlet, in addition to the H_O singlet. This result indicates that the rate of deuteration of H_N is much faster than that of H_O in the dmen and tn compounds. The *cis*-py_2 and phen compounds show both H_N and H_O singlets in almost equal intensities, implying that the deuteration in these compounds proceeds with little or no stereoselectivity.

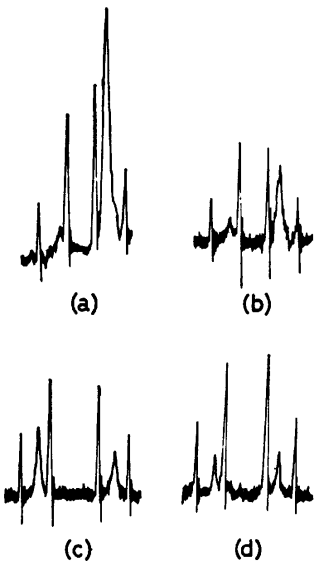

Fig. 5. The malonate portion of the NMR spectra of (a) dmen (pD=5.02), (b) tn (pD=7.18), (c) *cis*-py_2 (pD=6.55), and (d) phen (pD=6.02) complexes, taken some time after dissolution.

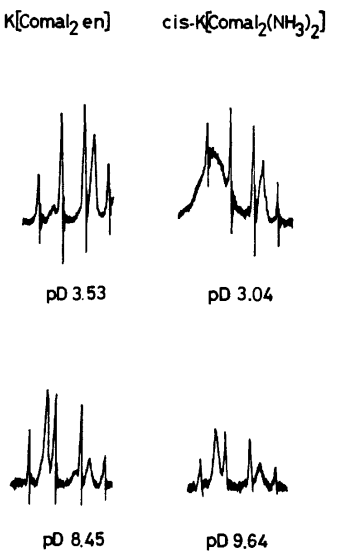

Fig. 6. The malonate portion of the NMR spectra of the en and *cis*-$(NH_3)_2$ compounds in acidified and basic deuterium oxide, taken some time after dissolution. The broad lump of the *cis*-$(NH_3)_2$ compound at pD= 3.04 is due to coordinated ammonia groups. This lump disappears in basic solution owing to the hydrogen-deuterium exchange at the ammonia groups.

Figure 6 illustrates the malonate portion of the NMR spectra of the en and *cis*-$(NH_3)_2$ compounds, taken some time after dissolution in acidified and basic deuterium oxide. At low pD, only the high-field H_O singlet can be observed for both compounds. At high pD, both the low-field H_N and the high-field H_O singlets are observed and the former is greater in intensity. These spectra are evidence that at low pD it is H_N that exchanges with deuterium first and at high pD it is H_O. Apparently the stereoselectivity in these two compounds is reversed on going from low to high pD region.

In Table 2, the second-order rate constants are given; the definition of these quantities is presented later. In terms of the second-order rate constants, the degree of the stereoselectivity is k'_{HN}/k'_{HO} or k''_{HN}/k''_{HO}. From Table 2, we see that while the degree of the stereoselectivity does not differ greatly for all the compounds in acid-catalysed reaction, it depends strongly upon the nitrogen ligand at high pD and is in the order (pD>8),

dmen > en, tn > *cis*-$(NH_3)_2$ > *cis*-py_2≈phen≈0

It is interesting to note that in *trans*-[Co(edda)(en)]$^+$ base-catalysed deuteration at glycine residues is more stereoselective than in acid-catalysed one.[20] It is reported that the degree of stereoselectivity is high and amounts to about 100 in the base-catalysis while it is about 10 in acid-catalysis.

Deuteration Mechanisms. The log(k) *vs.* pD plots for all the compounds are shown in Figs. 7 and 8, in which the deuteration rates of amine groups are also provided. The deuteration of amine groups is base-catalysed, as reported previously,[13] except for the *cis*-$(NH_3)_2$ compound at pD≈8. In other metal amine compounds, the hydrogen deuterium exchange reaction showed the first-order dependence on OD^- concentration in all instances.[13] This first-order dependence obtains even for systems where strong ion-pairing or stereoselective ion-association occurs between the amine group(s) and counter anions.[21] In the present systems,

Table 2. The second-order rate constants (s^{-1} mol^{-1} dm^3, 36.4 °C) for the deuteration of malonate hydrogens in bis(malonato)cobalt(III) complexes[a]

Ligand	Acid-catalysis			Base-catalysis			
	k'_Q	k'_{HN}	k'_{HO}	$k''_Q\times10^{-3}$	$k''_{HN}\times10^{-3}$	$k''_{HO}\times10^{-3}$	
en	1.4±0.8	(1.2)	0.2±0.1	38±20	(37)	1±0.6	pD<7
				1.3±0.7	0.25±0.14	(1.1)	pD>8
dmen	0.79±0.05	(0.7)	0.08±0.05	310±180	(300)	15±11	
tn	1.8±1.0	(1.6)	0.2±0.1	1±0.6	(0.8)	0.2±0.2	
cis-py_2	2.1±1.3	(1)[b]	(1)[b]	30±17	(15)[b]	(15)[b]	
phen	0.83±0.50	(0.4)[b]	(0.4)[b]	19±28	(10)[b]	(10)[b]	
cis-$(NH_3)_2$	3.2±3.0	(2.8)	0.4±0.3	0.55±0.32	0.32±0.14	(0.32)	pD>9

a) The values in parentheses are obtained by the relation; $k'_Q=k'_{HN}+k'_{HO}$ or $k''_Q=k''_{HN}+k''_{HO}$.b) Intensities of the H_N and H_O singlets are too small to allow rate measurements, but Fig. 5 indicates that k_{HN} is approximately equal to k_{HO}. Therefore these values are obtained on the assumption that $k_{HN}=k_{HO}$.

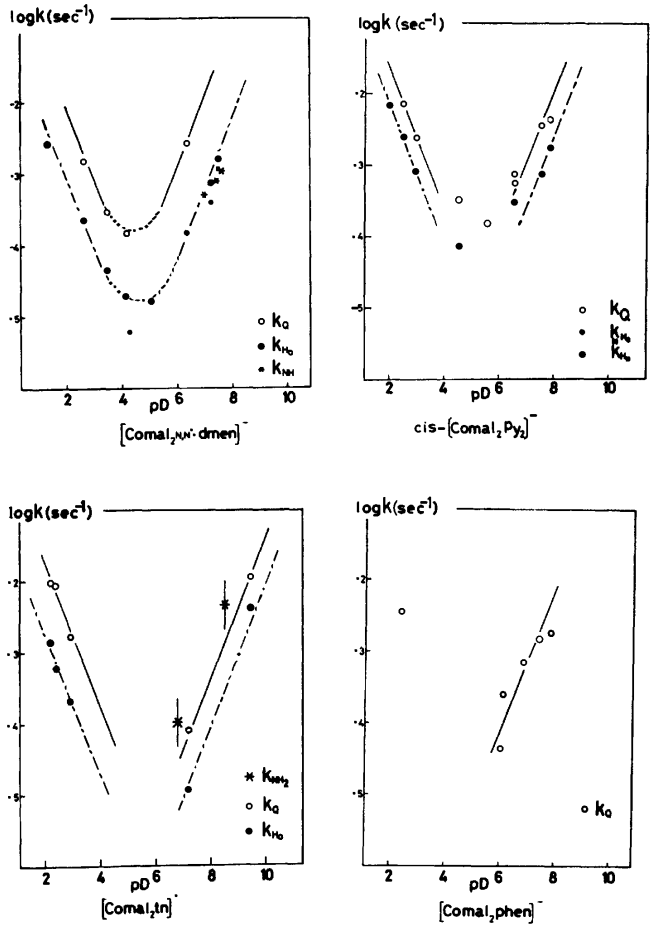

Fig. 7. The log(k) *vs.* pD plots for dmen, *cis*-py_2, tn, and phen complexes. The solid lines have a slope of $+1$ or -1.

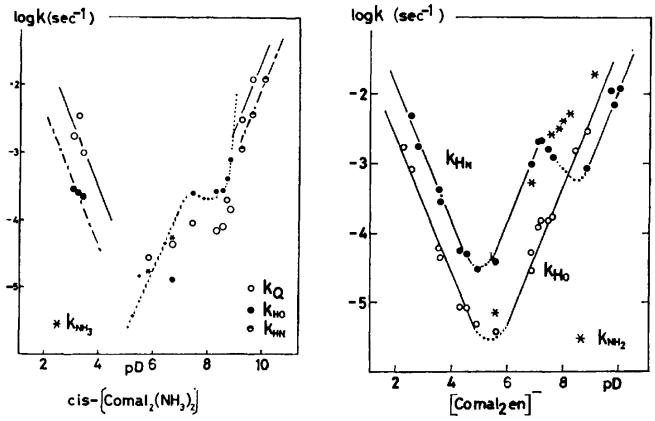

Fig. 8. The log(k) *vs.* pD plots for *cis*-$(NH_3)_2$ and en compounds. The solid lines have a slope of $+1$ or -1.

the compounds are singly-charged and it is safely assumed that the effect of ion-association upon amine exchange is minimal. The disparity found for the *cis*-$(NH_3)_2$ compound at pD$\approx$8 will be discussed later in connection with the reversal of the stereoselectivity.

It is seen that the deuteration of malonate groups is acid-catalysed at pD$<$4 and base-catalysed at pD$>$6. Thus, we have

$$k_1 = k_1'[D_3O^+] + k_1''[OD^-] \quad (i=Q,\ H_N,\ \text{or}\ H_O)$$

where k_1' and k_1'' are the second-order rate constants for the acid- and base-catalysed reactions, respectively. Apparently, this first-order dependence on catalyst concentration is not obeyed again by the en and *cis*-$(NH_3)_2$ compounds in the region of pD 7 to 8 and this point will be discussed later. The D_3O^+ and OD^- concentrations are estimated by pD and $pK_{w(D,O)}=14.37$[12c] and the second-order rate constants are obtained. In Table 2, the second-order rate constants are summarized. They do not vary greatly from compound to compound at low pD, but in base-catalysed deuteration they differ significantly. At high pD, the value of k'' decreases in the order

$$\text{dmen} > \textit{cis}\text{-py}_2,\ \text{phen} > \text{en},\ \text{tn} > \textit{cis}\text{-}(NH_3)_2$$

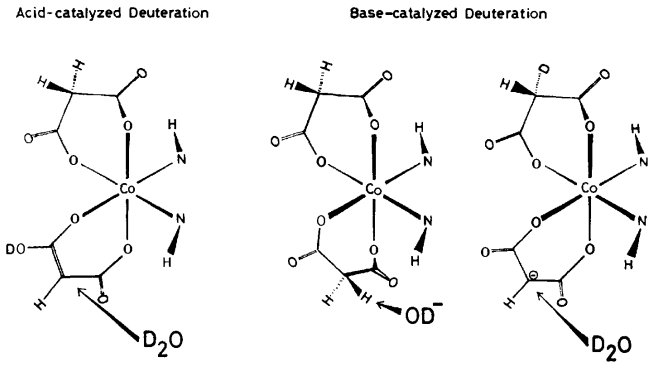

Fig. 9. A possible mechanism of acid- and base-catalysed deuteration that brings about stereoselectivity.

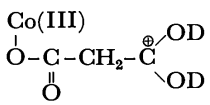
Mechanistically, acid-catalysed deuteration is effected by D_2O donating D^+ to the enol form, as depicted in Fig. 9. The enol results from the tautomerization of the protonated carbonyl form and is planar.[2,6] Therefore, if deuteration is to be stereoselective, it should take place preferentially either from the side adjacent to the coordinating amine group or from the side inbetween the two malonate groups. In the former case, H_N is deuterated first and we will observe the high-field H_O singlet. This is what we have found experimentally (*vide supra*).

In the acid-catalysed reaction, another mechanism will be considered. This mechanism is similar to the one proposed by Terrill and Reilley[22] for the deuteration of glycine residues in [Co(edta)]$^-$ ion. This involves the carbonyl protonation and subsequent rupture of the carboxylatocobalt bond. Since it assumes the unidentate carbonium ligand, such as



we may reasonably expect concomitant racemization at the metal center. For [Co(edta)]$^-$ ion, Terrill and Reilley in fact confirmed that deuteration is accompanied by racemization. To check the possibility of this mechanism, we resolved the en compound into optical isomers and measured the circular dichroism spectrum over the pH region of 2 to 12. Experimentally, however, we did not observe any measurable change in

the spectrum over the whole pH range and over several half lives of deuteration. This optical stability of the en compound corresponds well to the result of Dwyer *et al.*[9] It appears, therefore, that this mechanism is not appropriate at least to the en compound.

A probable mechanism of the base-catalysed deuteration is proposed previously.[2] It will suffice here to recall that the postulated mechanism involves the carbanion intermediate produced by hydrogen abstraction by OD^-. In the base-catalysed reaction, setereoselective deuteration may be effected in two ways; (a) hydrogen abstraction by OD^- is stereoselective, (b) deuteration by D_2O upon the carbanion intermediate is stereoselective. These two pathways are illustrated schematically in Fig. 9. Both processes may contribute to enhance the stereoselectivity if they occur from the N–H side(Note that the stereoselectivity is observed only for the amino-containing compounds.). It should be noted, however, that even if the hydrogen abstraction by OD^- had occurred stereoselectively, the resulting carbanion becomes most probably planar and loses its memory. The carbonion can be resonance stabilised with the adjacent carbonyl groups, which favors the planar structure. Further it is reported that retention of configuration has never been observed with simple carbanions.[23] Thus, (b) is considered the only likely process.

From the above, it is clear that the stereoselective deuteration in both acid- and base-catalysis is effected by D_2O donating D^+ to the enol and the carbanion intermediates, respectively. The present results indicate that at any pD the D_2O molecule prefers the access from the N–H side to that from the malonate side, except the high pD case of the en and *cis*-$(NH_3)_2$ compounds. The explanation of the stereoselectivity might be found in the conformation of the enol and carbanion intermediates. If the planar malonate moiety of these intermediates bends toward the coordinated nitrogen, steric repulsion is clearly expected between the amine group and the π-electron cloud of the enol or the unshared pair electron density of the carbanion. The planarity of these intermediates enforces the six-membered chelate ring to bend away from the coordinated nitrogen toward the other malonate-cobalt chelate. In this stable conformation of the intermediates, the access of D_2O molecule is likely to occur from the less-hindered side of coordinated nitrogen rather than from the more crowded malonate side.

Terrill and Reilley[22] made the variable temperature NMR studies on the stereoselective deuteration of $[Co(edta)]^-$. Sudmeier and Occupati[20] made a similar experiments on *trans*-$[Co(edda)(en)]^+$. For *trans*-$[Co(edda)(en)]^+$, $[Co(edta)]^-$, and their analogues,[24] the stereoselectivity was explained as the protection of a particular hydrogen from solvent molecules by the ethylenediamine backbone in the chelates. Farago and Smith[6] obtained the kinetic parameters for the deuteration of $[Co(mal)_2(en)]^-$ at about pD=3. This result is in good agreement with our data and indicated the stereoselectivity being entropy controlled. Further the data for the $[Co(mal)(en)_2]^+$ and $[Co(mal)(bpy)_2]^+$ ions pointed to the importance of the affinity of D_3O^+ or OD^- catalyst toward the ligands.

Origin of the Reversal of the Stereoselectivity. The reversal of the stereoselectivity as found for the en and *cis*-$(NH_3)_2$ compounds may be the most intersting aspect of the malonate exchange. In the $\log(k)$ *vs.* pD plots of Fig. 8, we note that the reversal takes place at about pD=7.5 and that the deuteration rates are retarded at around this pD. Concomitant with this anomalous pD dependence is the anomaly in the deuteration rate of coordinated amine groups. In the figure amine exchange rate is denoted by an asterisk. Above pD=8.5, a nomal first-order dependence of malonate exchange rates upon $[OD^-]$ obtains again. In the plots of the en compound, it is noteworthy that the rate of H_N is suppressed in the pD range of 7 to 8 and at pD=8, k_{HN} reverts to a $\log(k_{HN}) \propto +$pD line whereas k_{HO} appears unaffected. If we note that the reversal is accompanied by anomalous decreases in both malonate and amine exchange rates, the amine exchange may be considered to play an important role in this phenomenon. The *cis*-py_2 and phen compounds lack exchangeable N–H groups. Though the dmen and tn compounds do have these groups, their exchange rates are slower than or at most similar to those of the malonate exchange in each complex. The NH_2 resonance of the tn compound overlapped with a strong solvent HDO signal as seen in Fig. 3(b), which precluded accurate rate measurements. For *cis*-$(NH_3)_2$ compounds, it appears that the reversal of stereoselectivity takes place at such a pD value that the rate of amine exchange exceeds significantly that of malonate exchange. At this pD value, both amine and malonate hydrogens may be considered to have become equally reactive so that they might well compete for the OD^- catalyst. As a result, it is probable that both rates tend to fall together.

In the plots of the en compound, the anomaly of the amine exchange rate is less prominent than that of the malonate exchange rate. The point to be noted here is that the amine exchange rate is close to but slower than the malonate exchange even at the pD value where the k_{HN} begins to be suppressed. This observation suggests that though amine exchange does pertain in some way to the reversal, but it is not the only cause for the reversal. Some probable factors other than competition for the OD^- catalyst might be invoked. For example, one may consider the possibility that the amine and malonate hydrogens are exchanging between themselves in the pD region of 7 to 9. Under such conditions, both amine and malonate exchange rates might well be suppressed since these hydrogens are not exchanging with solvent deuterium but among themselves. By dissolving the en compound in acidified D_2O and precipitating with dry dioxane after suitable time intervals, we obtained the partially deuterated compound $K[Co(mal\text{-}d_2)_2(en)]$, for which only the malonate is deuterated completely leaving the amine group undeuterated. If the abovementioned intramolecular exchange is present, we may observe the malonate resonance to grow with time by dissolving this partially deuterated compound in D_2O at pD$\geqq$7.5. This is because the amine hydrogens that survived the partial deuteration are going to be transferred to the malonate.

We have not, however, succeeded in detecting the expected malonate resonance despite our repeated trials. We are therefore inclined to regard this intramolecular hydrogen exchange less probable. One may consider, further, that the conformation of the malonate ring changes at around pD=7 specifically in the en and *cis*-$(NH_3)_2$ compounds. It is well known[25] that conformational changes of chelate rings often show up as a change of circular dichroism spectrum. To check this possibility we have resolved the en compound into optical isomers and measured the circular dichroism spectrum over the pD range of 2 to 11. However, the circular dichroism spectrum of the optically resolved en compound exhibited no change against pD, rendering the conformational change also unlikely.

After all, our explanation at this stage is that at this pD region amine and malonate hydrogens compete for the OD^- catalyst for some reasons. In order for this process to occur, some stereochemical condition should be fulfilled. In the plots of the en compound of Fig. 8, only the rate of H_N hydrogen, which is adjacent to the amine group, is retarded while that of the H_O hydrogen, which is situated farthest apart from the amine group, remains unaffected. This will be taken to suggest that stereochemically close and, in addition, equally reactive groups are allowed to interfere with each other's exchange.

Studies on Characteristics of Electron Capture Responses. IV. Carrier Gas Flow-rate Dependence of Electron Capture Coefficients

Masahiro TAKEUCHI

Tokyo Metropolitan Research Laboratory of Public Health, Hyakunincho, Shinjuku-ku, Tokyo 160

(Received October 22, 1979)

The electron capture coefficients, K, defined by Wentworth *et al.* were measured on several samples in various carrier gas flow-rates at the detector temperatures of 200—320 °C. The effect of the flow-rate on the value of K was considered. The results revealed that the flow-rate dependence of K for each sample was closely related to one of the three electron capture reaction processes. In a sample undergoing the non-dissociative electron capture reaction, the values of K were generally not affected by the flow-rate; they decreased slightly with increasing the flow-rate at higher temperatures. In a sample undergoing the dissociative electron capture reaction, the values of K increased significantly with increasing the flow-rate at all temperatures. In a sample undergoing the dissociative electron capture reaction through an anion radical intermediate, the values of K were slightly or not at all affected by the flow-rate at lower temperatures, but increased gradually with increasing the flow-rate at higher temperatures.

Its high sensitivity and selectivity to halogen-containing compounds have caused the electron capture detector (ECD) to be widely used in the trace analysis of organochloro pesticides, polychlorinated biphenyls, *etc.*, remaining in various environmental samples. Though the practical applications are familiar, the theoretical details of the ECD have not received much study. The author has thus studied the responses of the ECD in order to understand the events occurring within it.

The ECD is a concentration-sensitive detector.[1-3] Its response function, studied by Wentworth *et al.*,[4-6] is given by

$$\frac{I_b - I_e}{I_e} = KC, \quad (1)$$

where I_b is the base current due to pure carrier gas, I_e is the current in the presence of a concentration C of electron capturing vapor, and K is the electron capture coefficient, which expresses the sensitivity of the detector to the vapor. In the practical gas chromatography, K is given by

$$K = \frac{1}{n}\frac{F}{S}\int \frac{I_b - I_e}{I_e} dX, \quad (2)$$

where n is the number of moles injected, F is the carrier gas flow-rate in l/min, S is the chart speed in cm/min, and X is the chart distance in cm.

Equation 2 shows that the peak areas, $\int(I_b - I_e)/I_e dX$, are inversely proportional to F under the constant conditions of S and n: If F increases to 2, 3, 4··· times as much as the initial run, the peak area will decrease to 1/2, 1/3, 1/4···, respectively. Consequently, as long as the response function of Wentworth *et al.* is correct, the value of K for a sample obtained from Eq. 2 is constant at any flow-rate. However, it was reported in the previous paper[7] that there were some samples whose values of K varied with the flow-rate. A similar result has been obtained by Devaux and Guiochon.[2] Therefore, in the present paper, the relation between the electron capture coefficient and the carrier gas flow-rate has been studied. The results have revealed that the carrier gas flow-rate dependence of K is closely related to one of the three electron capture reaction processes.

Experimental

Apparatus and Samples. A Shimadzu GC-5A gaś chromatograph equipped with an ECD was used. The ECD was of co-axial geometry and contained a 10 mCi ^{63}Ni radioactive source. Pulses were supplied by a DuMont 404 pulse generator. The pulse conditions were set up as follows in order to collect all of the electrons and to assure a steady state[4,6,8] under which Eq. 1 can be derived: the pulse period, 2000 μs; the pulse width, 2.0 μs; and the pulse amplitude, 30 V. An analog device was used for the conversion of the normal response, $I_b - I_e$, into the Wentworth response, $(I_b - I_e)/I_e$.[9] The carrier gas was pure nitrogen. Before being introduced into the system, the gas was passed through a 40 cm × 5 mm i.d. stainless steel column packed with Molecular Sieve 13 X. The flow-rate was measured at the exit end of the system with a bubble flow meter and a stopwatch. Peak areas were obtained with a Spectra-Physics Autolab System IV integrator. Two different kinds of chromatographic columns were used. One of these was a 1 m × 3 mm i.d. glass column packed with 2% Silicon OV-17 on Chromosorb W, 80—100 mesh (Column I); the other was a 1 m × 3 mm i.d. glass column packed with 2% Silicon OV-275 on Chromosorb W, 60—80 mesh (Column II). The column oven was maintained at temperatures in the range of 140—180 °C on Column I and 100—140 °C on Column II. The ECD temperature was measured with a thermometer inserted into the detector oven rather than with the thermocouple provided.

The samples used in the present study were commercially available reagents. Aldrin, γ-BHC, *p, p'*-DDE, and 2,4,6-trichlorobiphenyl were chromatographed by Column I, and nitrobenzene, azulene, iodobenzene, and 1,2,4-trichlorobenzene were chromatographed by Column II. Solutions of the samples were prepared to give suitable peak sizes, *i.e.*, $(I_b - I_e)/I_e = 1$—4.[9]

Results

Figure 1 shows the variation of I_b with the carrier gas flow-rate. Since I_b is the base current due to pure carrier gas, it ought to be kept constant. In practice, however, I_b decreased with decreasing the flow-rate, owing mainly to column bleed.[4-7] Therefore, a correction factor of I_0/I_b, where I_0 is the base current when no column bleed is observed, was utilized to adjust the value of K: the left side of Eq. 2 was multiplied by this

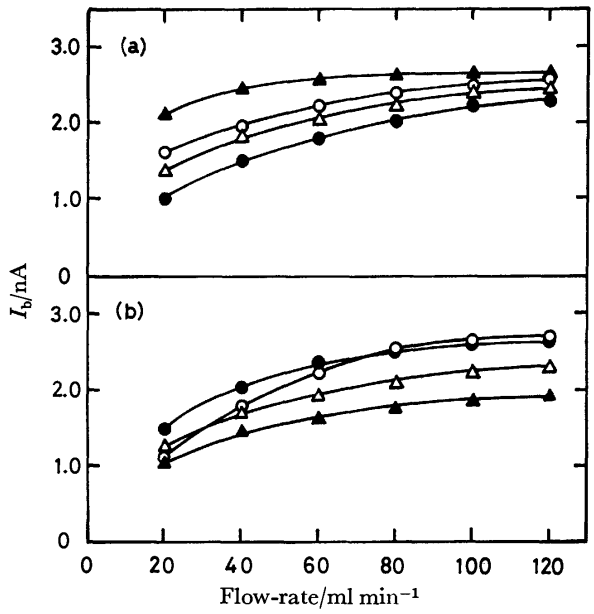

Fig. 1. Variation of base current with carrier gas flow-rate for Column I at 180 °C (a), Column II at 140 °C (b).

factor.[4-6] In this paper, I_0 was regarded as I_b when the column oven was cooled to room temperature.

Figure 2 shows the values of K for nitrobenzene. No variations of K with the carrier gas flow-rate were observed at any temperature. Figure 3 shows the values of K for azulene. At lower temperatures, the values of K were not affected by the flow-rate at all. At higher temperatures, however, the values of K decreased slightly with increasing the flow-rate. Figures 4—6 show the values of K for Aldrin, γ-BHC, and p,p'-DDE, respectively. In these samples, the values of K increased significantly with increasing the flow-rate at all temperatures. Figures 7—9 show the values of K for 1,2,4-trichlorobenzene, 2,4,6-trichlorobiphenyl, and iodobenzene, respectively. In these samples, the values of K were slightly or not at all affected by the flow-rate at lower temperatures, but increased gradually with increasing the flow-rate at higher temperatures.

Discussion

The response of the ECD results from the electron capture reaction, which usually occurs through one of the three following processes:[4-6]

$$AB + e^- \rightleftarrows AB^- \quad (3)$$

$$AB + e^- \longrightarrow A\cdot + B^- \quad (4)$$

$$AB + e^- \rightleftarrows [A\cdot - B]^- \longrightarrow A\cdot + B^-. \quad (5)$$

Equation 3, called the non-dissociative electron capture process, represents a reaction in which an electron capturing molecule, AB, reacts with an electron to form a stable molecular anion, AB^-. Equation 4, called the dissociative electron capture process, represents a reaction in which an electron capturing molecule dissociates into a radical, A·, and an anion, B^-. Equation 5, called the intermediate-dissociative electron capture process,[10] represents a reaction in which an electron capturing molecule dissociates slowly through an anion radical intermediate, [A·—B]$^-$.

These electron capture processes are closely related to the temperature dependence of K.[4-6] In the case of the non-dissociative process, the plot of ln $KT^{3/2}$ *vs.* $1/T$ has a slope of nearly zero at lower temperatures, and/or a positive slope at higher temperatures. In the case of the dissociative process, the plot has a negative slope at higher temperatures. In the case of the intermediate-dissociative process, the slope of the plot changes from zero to either negative through positive or negative directly with the rise of temperature, *i.e.*, the decrease of $1/T$. If we examine Fig. 10 from these points of

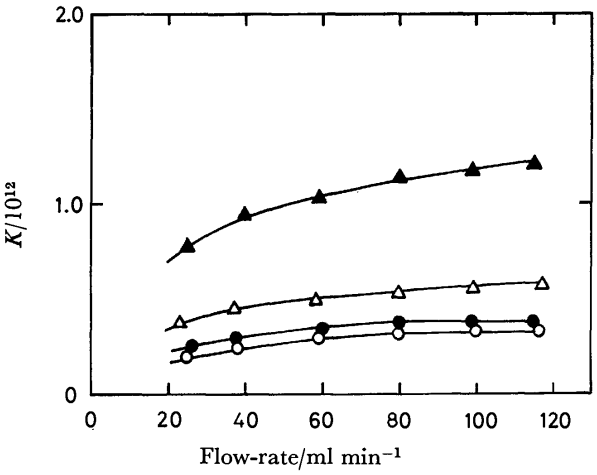

Fig. 9. Values of K for 2,4,6-trichlorobiphenyl *vs.* carrier gas flow-rate.
ECD temperatures: 200 °C (○), 240 °C (●), 280 °C (△), and 320 °C (▲).

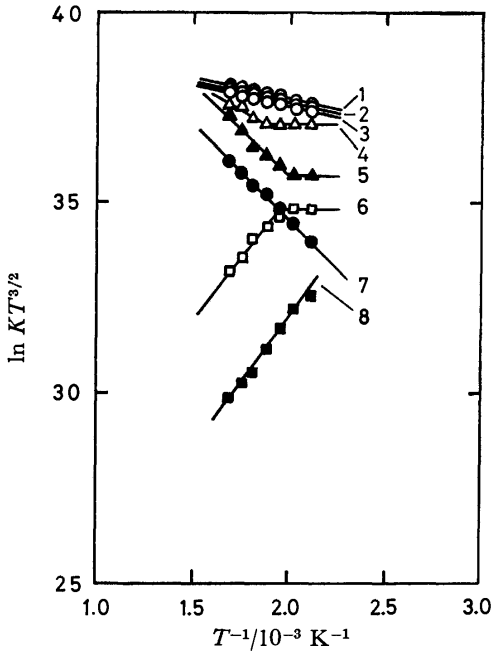

Fig. 10. Plots of ln $KT^{3/2}$ *vs.* $1/T$ for Aldrin (1), *p,p'*-DDE (2), γ-BHC (3), iodobenzene (4), 2,4,6-trichlorobiphenyl (5), nitrobenzene (6), 1,2,4-trichlorobenzene (7), and azulene (8).

view, we recognize that nitrobenzene and azulene are non-dissociative, Aldrin, γ-BHC, *p,p'*-DDE, and 1,2,4-trichlorobenzene are dissociative, and 2,4,6-trichlorobiphenyl and iodobenzene are intermediate-dissociative.

The carrier gas flow-rate dependence of K can also be related to the electron capture processes: The values of K for the samples undergoing the non-dissociative electron capture reaction are either not affected at all by the carrier gas flow-rate at any temperature, or decrease slightly with increasing the flow-rate at higher temperatures. The molecular anion formed within an ECD returns to the original molecule by recombination with a cation and/or progress of the reverse reaction before passing through the exit of the ECD. Therefore, no chemical reaction occurs, that is, the sample is unchanged by the act of detection. In such a case, the ECD acts as a concentration-sensitive detector, and consequently the values of K are either not effected by the carrier gas flow-rate, or decrease with increasing the flow-rate.[11]

The carrier gas flow-rate dependence of K for the samples undergoing the dissociative electron capture reaction are divided into two groups: One is the group whose values of K increase significantly with increasing the flow-rate (Aldrin, γ-BHC, and *p,p'*-DDE), and the other is the group whose values of K are little or not at all affected by the flow-rate at lower temperatures, but increase gradually with increasing the flow-rate at higher temperatures (1,2,4-trichlorobenzene). Each plot of ln $KT^{3/2}$ *vs.* $1/T$ for the samples belonging to the first group has a negative slope of nearly zero. Consequently the activation energy, E^*, which can be calculated from $E^* = -\text{slope} \times R$, where R is the gas constant, is very small. Therefore, it is considered that the samples in this group dissociate perfectly within the ECD. Under these circumstance, the ECD is close to coulometric in response,[12] and acts as a mass-sensitive detector rather than a concentration-sensitive detector.[13] Hence, the values of K calculated from Eq. 2, which represents the response function as the concentration-sensitive detector, increase with increasing the flow-rate. The sample belonging to the second group, *i.e.*, 1,2,4-trichlorobenzene is seemingly dissociative from Fig. 10, because it has a negative slope of the ln $KT^{3/2}$ *vs.* $1/T$ plot at higher temperatures. However, the carrier gas flow-rate dependence of K reveals that the sample is not necessarily dissociative. The values of K are not effected at all by the flow-rate at lower temperatures, although they increase gradually with increasing the flow-rate at higher temperatures. Therefore, it is considered that the reaction occurs non-dissociatively at lower temperatures and dissociatively at higher temperatures, that is, an intermediate-dissociative electron capture reaction occurs. Satouchi and Kojima[14] have pointed out from the values of E^* that the dissociative electron capture reaction for a halobenzene probably proceeds through an anion radical intermediate and that this reaction mechanism is similar to the S_N2 displacement for aromatic compounds. Furthermore, Dzidic *et al.*[15] have actually observed the anion radicals of some polychlorinated benzenes containing 1,2,4-trichlorobenzene by atmospheric pressure ionization mass spectrometry. Recently, Grimsrud and Kim[16] have suggested that the molecular anion resulting from the electron capture reaction of *p*-bromochlorobenzene survives long enough to be stabilized. These descriptions are quite in agreement with the conclusion obtained from the carrier gas flow-rate dependence of K that 1,2,4-trichlorobenzene is practically intermediate-dissociative, although it seems to be dissociative from the temperature dependence of K.

From the temperature dependence of K, iodobenzene and 2,4,6-trichlorobiphenyl should be regarded as intermediate-dissociative. Also, from the carrier gas flow-rate dependence of K, both samples seem to be intermediate-dissociative, since the values of K are not

appreciably affected by the flow-rate at lower temperatures, and increase with increasing the flow-rate at higher temperatures.

The author wishes to express his thanks to Emeritus Professor Shun Araki and Professor Shigetaka Suzuki, Tokyo Metropolitan University, for their encouragement and advice.

(Received November 10, 1979)

The aquation rate of *trans*(NO_2,O_2)-$[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)]^{2+}$ has been measured in acidic aqueous solution at $[H^+]=0.003$—0.25 M and $I=0.50$ M ($LiClO_4$), the final products being *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ and H_2O_2 in marked contrast to the acid decomposition of $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ where the final products are Co(II) and O_2. The reaction consists of two stages, each of which has preequilibrium of protonation. The observed rate constants for the first and second stages are consistent with the formula, $k_i^{obsd}=k_iK_i[H^+]/(1+K_i[H^+])$ (i=1, 2), indicating the existence of protonated reactive forms in both stages. The rate constants, activation parameters and equilibrium constants are $k_1=7.46\ s^{-1}$ (25 °C), $\Delta H_1^{\ddagger}=66.9\pm1.3$ kJ mol^{-1}, $\Delta S_1^{\ddagger}=-2.9\pm4.2$ J K^{-1} mol^{-1}, and $K_1=3.44\ M^{-1}$ (25 °C) for the first stage and $k_2=0.400\ s^{-1}$ (25 °C), $\Delta H_2^{\ddagger}=85.4\pm2.1$ kJ mol^{-1}, $\Delta S_2^{\ddagger}=33.5\pm7.1$ J K^{-1} mol^{-1}, and $K_2=2.98\ M^{-1}$ (25 °C) for the second stage. The solution of the reaction intermediate $[Co(NO_2)(O_2H)(en)_2]^+$ has been obtained by ion exchange technique and characterized by the UV and visible spectra. The factors which decide the reaction path are discussed.

While μ-hyperoxo dicobalt(III) complexes are usually resistant to acids, the μ-peroxo dicobalt(III) complexes are more or less susceptible to them. Thus $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ is decomposed almost instantaneously in acidic solution to give Co^{2+}, NH_4^+, and O_2, the reaction rate, however, being inverse in $[H^+]$.[1,2] On the other hand, double-bridged μ-amido-μ-peroxo dicobalt(III) complexes do not evolve oxygen but undergo isomerization.[3] A third case would be formation of hydrogen peroxide and mononuclear cobalt(III) complexes, as exemplified by μ-peroxo cyano cobalt(III) complex.[4] The kinetic study of the third case has not yet been reported.

We are now going to report a new example of this third case, *i.e.*, the reaction of *trans*(NO_2,O_2)-[μ-peroxo-bis{nitrobis(ethylenediamine)cobalt(III)}] complex with acid. The reaction gives 2 mol of mononuclear cobalt(III) complex and 1 mol of hydrogen peroxide from 1 mol of the μ-peroxo dicobalt(III) complex. This very clear-cut stoichiometry enabled us to obtain the reaction rate and the acid association equilibrium constants on a quantitative basis.

Experimental

Preparation. trans-(NO_2,O_2)-[μ-*Peroxo-bis{nitrobis(ethylenediamine)cobalt(III)}*] *Perchlorate Dihydrate*: The perchlorate salt was prepared by the addition of sodium perchlorate to an aqueous solution of the corresponding nitrate.[5] Found: C, 13.21; H, 4.86; N, 19.35%. Calcd for $[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)](ClO_4)_2\cdot 2H_2O$: C, 13.40; H, 5.06; N, 19.53%.

trans-[*Aquanitrobis(ethylenediamine)cobalt(III)*] *Perchlorate Hydrate*: Sixty percent $HClO_4$ (10 ml) was added to the μ-peroxo complex (1 g, see above) and filtered. Ethanol (20 ml) was added slowly to the solution, which was then cooled for several hours. Orange crystals deposited were filtered and washed successively with ethanol and diethyl ether. Yield 0.9 g. Found: C, 10.45; H, 4.35; N, 15.42%. Calcd for $[Co(NO_2)(OH_2)(en)_2](ClO_4)_2\cdot H_2O$: C, 10.44; H, 4.38; N, 15.22%. The identification of the compound as the *trans* isomer has been made spectrophotometrically.[6] The *trans* configuration has also been confirmed by ir spectroscopy: one band (888 cm^{-1}) between 870 and 900 cm^{-1} [7] and three bands (600, 565, and 520 cm^{-1}) between 500 and 610 cm^{-1}.[8]

Analysis of the Reaction Products. *Hydrogen Peroxide*: The μ-peroxo complex $[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)](ClO_4)_2\cdot 2H_2O$ was dissolved in 1 M H_2SO_4 and the hydrogen peroxide formed was titrated with permanganate, using *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ solution as a reference. As expected from Eq. 1 in the following section, 0.99 ± 0.01 mol of H_2O_2 was formed for each mole of the μ-peroxo complex.

trans-[*Aquanitrobis(ethylenediamine)cobalt(III)*]$^{2+}$ *ion*: The μ-peroxo complex was dissolved in 0.1 M $HClO_4$ and the spectrum of *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ formed was taken. The ε-value (at $\lambda_{max}=335$ nm 1015 cm^{-1} M^{-1}) was in good agreement with the literature value.[6]

Measurement of Reaction Kinetics. A large excess of perchloric acid over the μ-peroxo complex was used in each run ($I=0.5$ M, $LiClO_4$). The reaction was pursued by the observation of absorption changes at 305 nm at which large differences can be found between absorptivities of the complexes present. As will be described in the following section, the reaction consists of two distinct stages, each stage showing strong acid dependence. In the region of lower acid concentration ($[H^+]$[9] ≈0.003—0.01 M, and [complex] ≈0.0001 M) at 15.4 °C, both stages were followed by the conventional spectrophotometric method using a Hitachi 200-10 Spectrophotometer. In the region of higher acid concentration ($[H^+]\approx0.01$—0.25 M, and [complex] ≈0.001 M), the first stage of the reaction was followed by the stopped flow technique using Union RA 401 Instrument, while the second stage was monitored by the conventional technique.

Separation of the Intermediate. An attempt was made by use of ion exchange technique to isolate the intermediate produced at the first stage of the reaction. Thirty-six milligram (5×10^{-5} mol) of μ-peroxo complex perchlorate was dissolved in 20 ml of water, 1 ml of 0.1 M $HClO_4$ (10^{-4} mol) was added to it and the mixture was poured onto the top of a coloumn of 5 cm in length and 0.8 cm in diameter containing Dowex 50W-X2 cation exchange resin in Na-form. Elution with 0.5 M $NaClO_4$ gave a fraction of orange color, and successive elution with 1.0 M $NaClO_4$ containing 0.01 M $HClO_4$ gave another orange fraction which was spectrophotometrically identified[6] with *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$. The first

eluate is considered to contain the desired intermediate having charge +1 as judged from its easier elution than in the case of *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$.

Results

Reaction Stoichiometry and Spectra of Related Complexes. Spectrophotometry as well as permanganate titration of the final reaction products proved formation of 2 mol of *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ and 1 mol of H_2O_2 from 1 mol of the dicobalt(III) complex, thus pointing to the following stoichiometry:

$$[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)]^{2+} + 2H^+ + 2H_2O \longrightarrow 2\ trans\text{-}[Co(NO_2)(OH_2)(en)_2]^{2+} + H_2O_2. \quad (1)$$

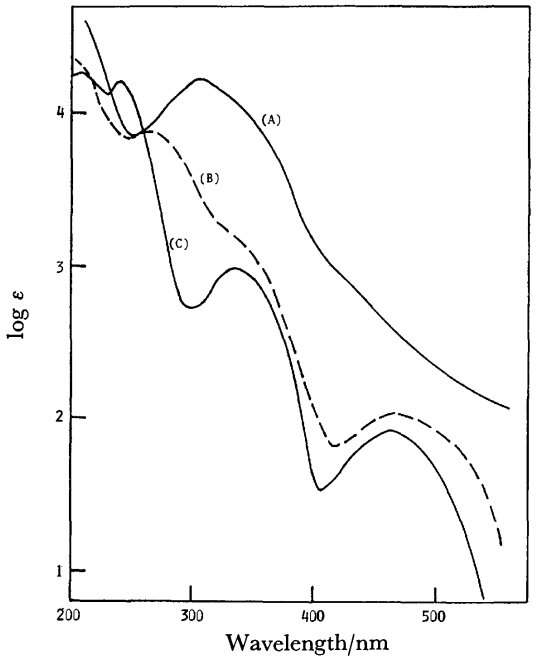

Fig. 1. UV and visible spectra.
(A): *trans*(NO_2,O_2)-$[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)]^{2+}$,
(B): *trans*-$[Co(NO_2)(O_2H)(en)_2]^{+}$,
(C): *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$.

Spectra of the starting material and the final product are given by curves A and C in Fig. 1, respectively. Peak positions and ε-values (in parentheses) are as follows: $[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)](ClO_4)_2 \cdot 2H_2O$, 307 nm (16000); *trans*-$[Co(NO_2)(OH_2)(en)_2](ClO_4)_2 \cdot H_2O$, 205 (17700), 238 (15200), 335 (975), and 463 nm (86). The ε-value (975) of the latter at 335 nm is slightly (*ca.* 4%) different from that (1015) obtained directly from the acid hydrolysis of μ-peroxo dicobalt(III) complex. This could be explained by assuming *trans* to *cis* isomerization (*ca.* 3%) during the course of the formation reaction.[10] Although the isolation of the intermediate as crystals has not yet been succesful, its absorption spectrum (Fig. 1, curve B) has been obtained.[11] The absolute ε-values of the spectrum were calculated in reference to the ε-values of *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ produced therefrom by further action of perchloric acid.

Kinetic Data. As is seen in Fig. 2(A), the reaction

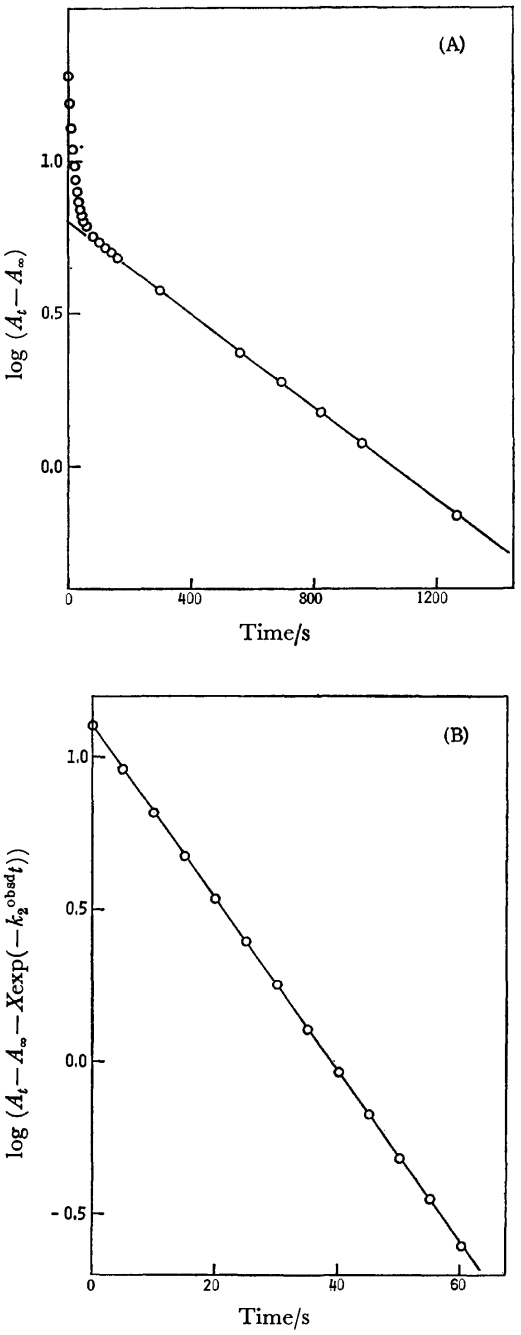

Fig. 2. Analysis of the consecutive reactions at 15.4 °C, I=0.5 M ($LiClO_4$), $[H^+]=5.69\times10^{-3}$ M, [complex]≈ 1×10^{-4} M.
(A) Plot of log (A_t-A_∞) *vs.* time for the second stage.
(B) Plot of log $(A_t-A_\infty-X\exp(-k_2^{obsd}t))$ *vs.* time for the first stage, where X=6.52 and $k_2^{bosd}=1.75\times10^{-3}$ s^{-1} obtained from (A) were used.

consists of two stages having considerably different rate, both of which are strongly acid dependent. Since the first stage dies down very quickly, the plot $\log(A_t-A_\infty)$ *vs.* t except at the initial stage forms a good straight line, from which the pseudo-first order rate constant of the second stage k_2^{obsd} can be obtained. The pseudo-first order rate constant of the first stage can then be obtained by re-plotting $\log(A_t-A_\infty-X\exp(-k_2^{obsd}t))$ *vs.* t (Fig. 2(B)), where $\log(X)$ is the intercept of the first plot

(Fig. 2(A)).[12] In the actual case, k_2^{obsd} is small enough as compared with k_1^{obsd} and the term $X\exp(-k_2^{obsd}t)$ may be regarded as nearly constant in the time scale used in the estimation of k_1^{obsd}. This approximation was used in most of the present treatment since such a treatment proved to give the same result as when the exact consecutive treatment was applied.

TABLE 1. FIRST ORDER RATE CONSTANTS, k_1^{obsd}/s^{-1} FOR THE ACID HYDROLYSIS OF *trans*(NO_2,O_2)-[μ-PEROXO-BIS{NITROBIS(ETHYLENEDIAMINE)COBALT(III)}] TO THE INTERMEDIATE, AND k_2^{obsd}/s^{-1} FOR THE ACID HYDROLYSIS OF THE INTERMEDIATE TO THE FINAL PRODUCTS; I=0.5 M ($LiClO_4$), λ=305 nm[a]

0.247	1.32	2.49	4.45	8.49	14.5

a) Experiments at lower [H+] were made only at 15.4 °C:

$[H^+]\times10^3$/M	$k_1^{obsd}\times10^2/s^{-1}$	$k_2^{obsd}\times10^4/s^{-1}$
2.72	2.94	8.25
5.69	6.40	17.5
8.65	9.77	27.2
11.6	13.1	37.2

These data were not used in the estimation of k_1 and k_2 in Table 2.

Both rate constants k_i^{obsd} (i=1, 2) obtained in this way increased with the increase in acidity with a certain tendency of saturation (Table 1), implying the existence of preequilibrium of protonation in both stages. Linear dependence of $1/k_i^{obsd}$ (i=1, 2) against $1/[H^+]$ was observed at each temperature as consistent with (2) for both stages as can be seen in Figs. 3(A) and 3(B), and from these we could calculate the values of k_1, K_1, k_2, and K_2, *i.e.*, the rate and preequilibrium constants for the first and second stages, respectively (Table 2).

$$k_i^{obsd} = k_iK_i[H^+]/(1+K_i[H^+]). \quad (2)$$

The relevant activation and thermodynamic parameters are given in Table 3.

The Nature of the Reaction Intermediate and the Constituion of the Reaction. On addition of perchloric acid to the solution of the intermediate as described in Experimental, spectral change was observed with isosbestic points as shown in Fig. 4, and the final solution was found to contain *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ and H_2O_2 as evidenced by spectrophotometry and permanganate titration. These findings and estimated charge +1 suggest that the intermediate would be *trans*-$[Co(NO_2)(O_2H)(en)_2]^+$ produced from the pro-

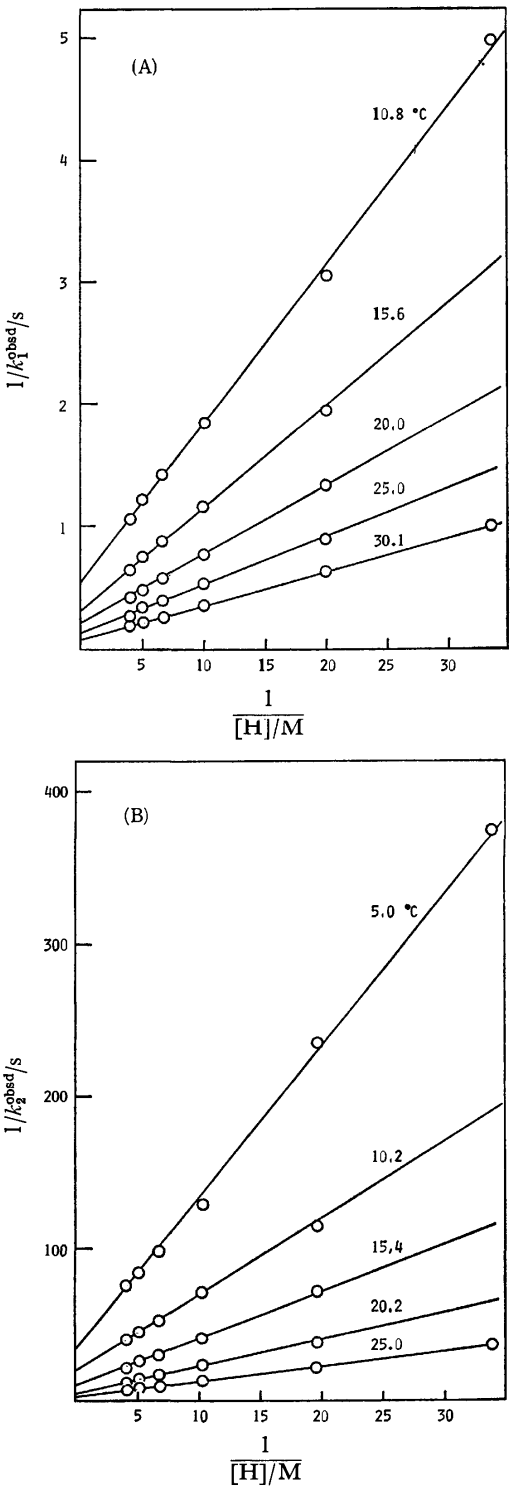

Fig. 3. Plot of $1/k_i^{obsd}$ *vs.* $1/[H^+]$ for the acid hydrolysis of the μ-peroxo complex $[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)]^{2+}$, at I=0.5 M ($LiClO_4$).

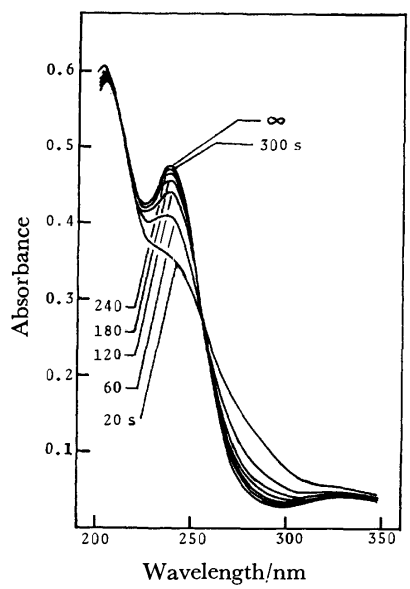

Fig. 4. Absorption changes for the acid hydrolysis of the intermediate *trans*-$[Co(NO_2)(O_2H)(en)_2]^+$ at 15 °C, I=0.5 M ($LiClO_4$), $[H^+]$=0.0294 M, and [complex]=3.0×10^{-5} M.

tonated form of the starting complex *via* protonation preequilibrium,

$$[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)]^{2+} + H^+ \overset{K_1}{\rightleftharpoons} [(NO_2)(en)_2Co(O_2H)Co(en)_2(NO_2)]^{3+} \quad (3\text{-a})$$

$$[(NO_2)(en)_2Co(O_2H)Co(en)_2(NO_2)]^{3+} + H_2O \xrightarrow{k_1} trans\text{-}[Co(NO_2)(O_2H)(en)_2]^+ + trans\text{-}[Co(NO_2)(OH_2)(en)_2]^{2+} \quad (3\text{-b})$$

in conformity with the form of the rate equation. The second stage would then be the acid hydrolysis of the hydroperoxo intermediate into *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ and H_2O_2, being, again, initiated by protonation:

$$trans\text{-}[Co(NO_2)(O_2H)(en)_2]^+ + H^+ \overset{K_2}{\rightleftharpoons} trans\text{-}[Co(NO_2)(O_2H_2)(en)_2]^{2+} \quad (3\text{-c})$$

$$trans\text{-}[Co(NO_2)(O_2H_2)(en)_2]^{2+} + H_2O \xrightarrow{k_2} trans\text{-}[Co(NO_2)(OH_2)(en)_2]^{2+} + H_2O_2. \quad (3\text{-d})$$

The rate of acid hydrolysis of the intermediate in the solution separated by ion exchange technique ($k^{obsd}=2.38\times10^{-2}$ s^{-1}, $[H^+]$=0.0985 M, 15.4 °C) was in good agreement with the acid hydrolysis rate of the second stage ($k_2^{obsd}=2.41\times10^{-2}$ s^{-1}, $[H^+]$=0.0985 M, 15.4 °C).

The *trans* structure of the starting μ-peroxo complex has already been established,[13] and *cis-trans* isomerization of $[Co(NO_2)(OH_2)(en)_2]^{2+}$ need not be considered here because of its slow isomerization rate.[6]

If the acid hydrolysis of the μ-peroxo compound is carried out under the exposure to sunlight, the absorbance at 335 nm of the final products decreases to *ca.* two thirds compared to the case without the sunlight exposure, indicating the appearance of an additional reaction path leading to Co(II) species. An attempt was made to find the wavelength most effective to bring about the side reaction using monochromated light from as apectrophotometer, but the intensity of the light from the spectrophotometer was found too weak to induce the side reaction.

If small amounts of acid were used for the separation of the intermediate, a different intermediate showed up, which had peaks at 337 and 462 nm and which did not give the *trans*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$ even by the addition of excess amount of acids. The final products, in this case, have not yet been fully characterized.

Discussion

As stated in the introduction, the action of acid upon the μ-peroxo dicobalt(III) complexes causes in some cases the decomposition to Co(II) and O_2 (route A), and in other cases the hydrolysis to Co(III) complex and H_2O_2 (route B).

$$\left[Co^{III}\diagup O\diagdown O\diagup Co^{III}\right] + H^+ \rightleftharpoons \left[Co^{III}\diagup \overset{H}{O}\diagdown O\diagup Co^{III}\right]$$

route A: $\rightarrow Co(II)+O_2$

$+H^+$, route B: $\rightarrow Co(III)+H_2O_2$

The main factors to decide the choice among these rather different modes, *i.e.*, route A and route B, appear to be the relative stability of Co(II) and Co(III) species and the ease with which the peroxo bridge is replaced.

The first group usually contains μ-peroxo single-bridged complexes only with amine ligands. The easiness in the decomposition of these complexes, as contrasted to the stability generally seen in mononuclear Co(III) complexes towards acids, probably owes its origin to the reducing power of O_2^{2-} which itself is liable to change to O_2 by the loss of electrons, and to the more labile nature of the μ-peroxo dicobalt(III) complexes[14] as compared with other cobalt(III) complexes, because of the presence of excess electrons in the antibonding π-orbitals of O_2. The addition of acid would reduce the concentration of NH_3 in solution by the formation of NH_4^+ and promotes replacement of NH_3 by H_2O in the coordination sphere of these rather labile complexes. This makes Co(III) unstable enough to be reduced by the binding O_2^{2-} group, resulting in the formation of Co(II) and O_2. In this case, protonation to O_2 bridge itself would be rather to pull electron pair from cobalt to O_2 bridge and hinder the liberation of O_2 as proved by the experiment by Ferrer *et al.*[2] who showed that in the acid decomposition of $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$, the protonated species is non-reactive.

In the acid hydrolysis of $[(NO_2)(en)_2CoO_2Co(en)_2(NO_2)]^{2+}$, and possibly of $[Co_2O_2(CN)_{10}]^{6-}$ and $Co_2O_2(CN)_6(en)_2]^{2-}$, on the other hand, the protonated species is reactive and the final products are Co(III) and H_2O_2 (route B). The presence of electron-withdrawing CN^- or NO_2^- group in the coordination sphere would partly cancel the above-mentioned labilizing effect of O_2^{2-} in the μ-peroxo dicobalt(III) complexes which would otherwise cause the complex to choose the route A. The stronger ligand field of these ligands at the same time is considered to stabilize Co(III) which is the product of route B.

Relatively fast acid hydrolysis of *trans*-$[Co^{III}LCl(en)_2]^{n+}$ was reported in the case of $L=NO_2^-$ or CN^- as compared to the case of $L=NH_3$, and was explained in terms of the role of π-bonding: the electron-accepting group such as nitro and cyano reduce the electron density around the group trans to the nitro or cyano group and make it easier for a solvent molecule to attach itself to cobalt and to initiate the substitution.[15]

The NO_2^- coordinated in the *trans*-position to μ-peroxo bridge in the dicobalt(III) complexes thus seems to prepare an ideal situation for the complex to be hydrolyzed to form mononuclear Co(III) complex and H_2O_2 through route B.

The acid association constants K_1 (3.44 M^{-1}, 25 °C) and K_2 (2.98 M^{-1}, 25 °C) are similar to each other and also to the acid association constants of $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ (11.9 M^{-1}, 25 °C, $I=0.1$ M, as calculated from acid dissociation constant),[2] and $[(en)_2Co(\mu\text{-}NH_2)(\mu\text{-}O_2)Co(en)_2]^{3+}$ (5.1 M^{-1}, 25 °C, $I=0.1$ M).[3] μ-Peroxo dicobalt complexes thus have considerably greater tendency to be protonated than hydrogen peroxide which is reported to have the acid association constant of $K\approx10^{-3}$.[16]

Ferrer *et al.*[2] reported a relatively large entropy of activation (36.4 J K^{-1} mol^{-1}) in the acid decomposition of $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ through route A, and attributed it to the charge neutralization within the complex. Smaller value of entropy of activation ($\Delta S_1^* = -2.9$ J K^{-1} mol^{-1}) may be due to the difference in the reaction route. Entropy of activation of the second stage ($\Delta S_2^* = 33.5$ J K^{-1} mol^{-1}), however, is not small and the situation seems to be too complicated to allow detailed discussions.

The authers are grateful to Dr. K. Takeda for the use of the stopped flow apparatus and to Prof. A. G. Sykes of the University of Newcastle upon Tyne, England, for helpful discussions.

Precise Determination of Dissolved Gases in Sea Water by Shipboard Gas Chromatography

Toshitaka GAMO* and Yoshio HORIBE

Ocean Research Institute, The University of Tokyo, Minamidai, Nakano-ku, Tokyo 164

(Received February 12, 1980)

A gas chromatographic system is applied to shipboard measurement of dissolved argon, oxygen, nitrogen, and total inorganic carbon dioxide in sea water. Gases are stripped from acidified sea water with helium carrier gas, separated by passing through silica-gel and molecular sieve 5A columns, and subsequently analyzed with a thermal conductivity detector and an ultrasonic detector. *Ca.* 15 min is required to analyze a 3 cm^3 sea water sample. Intercalibration by other analytical techniques for oxygen and total carbon dioxide confirmed the accuracy of this method. Vertical profiles of the gases in the Pacific Ocean demonstrate the merit of the method.

Oxygen, nitrogen, argon, and total inorganic carbon dioxide ($\sum CO_2$), which are the major dissolved gases in sea water, afford valuable information on chemical and physical processes in the ocean. O_2 and $\sum CO_2$ are involved in life processes in sea water. Near the ocean surface, photosynthesis causes enrichment of O_2 and depletion of $\sum CO_2$, while in the deep layer O_2 is consumed, changing into $\sum CO_2$ by oxidative decomposition of organic material falling from the surface. N_2 and Ar, on the other hand, are little affected by biochemical reactions because of their inertness, and can thus be used as conservative tracers. Except for O_2, however, little data on the oceanic distributions of these gases are available due to the lack of an adequate analytical method for accurate shipboard measurement.

Since Swinnerton *et al.*[1,2] developed a simple on-line gas stripping technique combined with gas chromatography, it has subsequently been adopted by a number of workers for the determination of dissolved gases in aqueous solutions.[3-7] Weiss and Craig[5] developed a set of gas chromatographs for shipboard measurement of dissolved N_2, O_2, Ar, and $\sum CO_2$. In their systems, it is necessary to inject two aliquots of a sample separately, one for the measurement of N_2, O_2, and Ar, and the other for $\sum CO_2$. It would be desirable to measure all the gases simultaneously using the same aliquot.

In this paper, a report is given on a gas chromatograph as a simpler and more convenient system for routine shipboard operations for simultaneous analysis of the four dissolved gases. Swinnerton's technique was applied to gas extraction from sea water, two detectors being employed in series: a thermal conductivity detector for the analysis of $\sum CO_2$, and an ultrasonic detector for that of Ar, O_2, and N_2. The high sensitivity of the ultrasonic detector caused significant reduction in sample volume. The dual detector system made it possible to analyze the four gases simultaneously with a single aliquot of a sample.

Experimental

Sampling and Gas Extraction. Sea water samples were taken in 60 cm^3 glass bottles with rubber stoppers from Niskin-type samplers immediately after each sampler had been brought aboard. The sample was allowed to overflow more than four times the volume of the bottle in order to avoid air contamination during the course of transfer.[8] Samples were kept in the dark before analysis for less than 10 h in order to prevent biological alteration of the dissolved gases.[9]

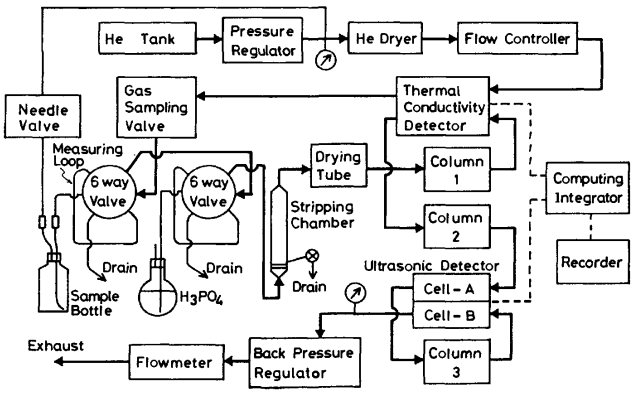

Fig. 1. Schematic diagram of the shipboard gas chromatograph. The thick arrows are the path of the carrier gas in the analysis procedure, and the broken lines are electric connections.

The gas chromatographic system is shown schematically in Fig. 1. Helium was used as a carrier gas. The head and back pressures were regulated at 3.2 and 1.5 kg cm^{-2}, respectively. A constant flow rate of 75 cm^3 min^{-1} supplied by a flow controller (Matheson, series 8287) was occasionally monitored by a soap bubble flowmeter at the end of the flow system, the average HETP of columns being the smallest at this flow rate. Helium (purity>99.995%) was dried and purified by passing through a large trap of molecular sieve 5A (10/20 mesh) at ambient temperature before it entered the flow system.

A sample bottle was connected to a six-way rotary valve. By application of helium pressure, the sample sea water was continuously made to flow out of the bottle through a measuring loop made of nylon tubing (i. d. 2 mm), its volume being calibrated accurately to 2.865 ± 0.002 cm^3. The volume was selected to maximize the Ar output of the ultrasonic detector without permitting ultrasonic phase foldover due to N_2 peak.

By turning the six-way valve, the sample was transferred to the stripping chamber, a glass cylinder (length 70 mm, i. d. 10 mm) with a coarse glass frit at the bottom. The carrier gas immediately began to strip the sample of the dissolved gases, carrying them into subsequent columns.

Carbonate and bicarbonate extractions as CO_2 were facilitated by mixing the sample with *ca.* 0.8 cm^3 of H_3PO_4 solution (1 : 10) which had been introduced into the chamber through another six-way valve (Fig. 1) and degassed similarly by carrier gas bubbling prior to the sample injection.

Separation and Detection. The gases evolved were dried by passing through a glass U-tube packed with 16/32

mesh $Mg(ClO_4)_2$. Three separation columns (stainless steel, i. d. 3 mm) were employed in series for isolating the four gas components. Column 1 (length 35 cm, packed with 40/60 mesh silica gel) separated CO_2 from the gas component (Ar, O_2, and N_2), column 2 (length 105 cm, packed with 30/60 mesh molecular sieve 5A) separated N_2 from Ar and O_2, and column 3 (length 80 cm, packed with 80/100 mesh molecular sieve 5A) separated Ar from O_2. Columns 1 and 2 were used at ambient temperature (24±1 °C), and column 3 was cooled at Dry Ice temperature.[10] It was necessary to raise the temperature of column 3 to ambient temperature for every 10 samples in order to regenerate its activity by releasing trapped N_2 out of it, while the other columns were kept activated after more than 200 analyses.

Analysis of CO_2 was carried out with a thermal conductivity cell (Gasukuro Kogyo Co., Ltd., E-121), and that of Ar, O_2, and N_2 with an ultrasonic detector (Tracor Inc., U-90) because of its high sensitivity.[11] Although the ultrasonic detector has two independent cells A and B, it is impossible to detect signals of both cells at the same time. Thus, the lengths of columns 2 and 3 were adjusted in such a way that Ar enters cell B after N_2 has finished passing through cell A.

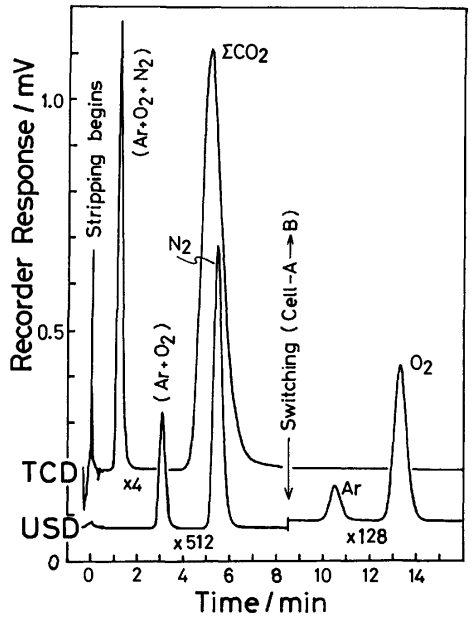

Fig. 2. Typical chromatograms of the thermal conductivity detector (TCD) and the ultrasonic detector (USD).

Typical chromatograms of both detectors are shown in Fig. 2. Retension times were 5.0, 5.4, 10.5, and 13.3 min for CO_2, N_2, Ar, and O_2, respectively. In order to calculate each peak area immediately and automatically, outputs of the detectors were connected to a computing integrator (Spectra-Physics, Autolab System IV). The relative precision of the measured values was estimated from the dispersion of shipboard analyses of a sea water sample. The standard deviations were as follows: ±0.3% for Ar and O_2, ±0.2% for N_2, and ±0.5% for CO_2.

Calibration. A calibration curve of each gas component was prepared over the proper concentration range prior to a cruise, by using a mixture of tank CO_2 and fresh air. Both gases were dried by passing through a dry ice trap before mixing. When the stripping chamber was filled with degassed sea water, a known amount of the calibration gas was injected through a gas sampling valve, and subsequently analyzed by the same procedure as used for analysis of unknown samples. Since the sensitivity of the ultrasonic detector was found not to be proportional to the amount of gas,[12] Ar, O_2, and N_2 calibrations were performed particularly in detail.

Shipboard calibration was performed every 4-5 h of operation by analyzing dried tank CO_2 or fresh air at one or two representative concentration points for each gas, in order to correct systematic shifting of the original calibration curve because of slight change in experimental conditions.

Results and Discussion

Intercalibrations with other conventional analytical methods were carried out in order to confirm the absolute accuracy of gas chromatography (GC) during routine shipboard operations. Dissolved oxygen values determined by GC were compared with those by the Carpenter-modified Winkler titration,[13] and the $\sum CO_2$ values by GC were compared with those calculated from pH and titration alkalinity.[14]

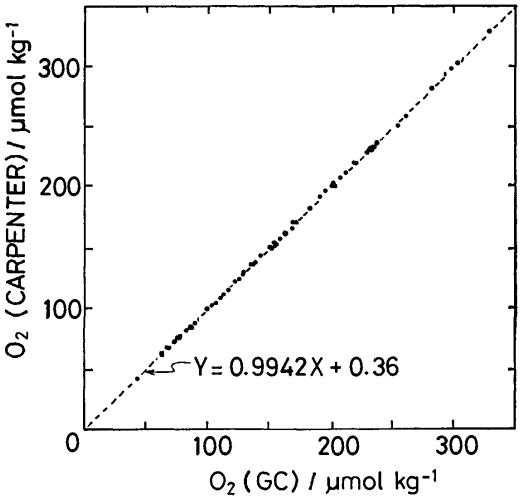

Fig. 3. Intercomparison of dissolved oxygen concentrations by the gas chromatography (GC) and the Carpenter-modified Winkler titration.
The broken line is the best fitted line by the method of least squares.

Figure 3 shows the relationship between the two sets of O_2 data obtained during the Pegasus Expedition in the Japan Sea,[15] and Vega Expedition in the Philippine Sea.[16] The estimated standard deviation of the titration method was ±1 μmol kg^{-1}. Each set of data by GC and titration was in good agreement within analytical errors of both methods. By using the method of least squares with statistical weighting,[17] a straight line of $Y=AX+B$ was fitted to the data (74 pairs), where X and Y are the GC value and the titration value, respectively. The calculated parameters with standard deviation ($\pm\sigma$) are as follows:

$$A = 0.9942 \pm 0.0017,$$
$$B = 0.36 \pm 0.28 \ (\mu\text{mol kg}^{-1}).$$

T-tests for A and B indicate that B is not significantly different from zero, while A is slightly different from unity, when α (level of significance) is 0.05. The

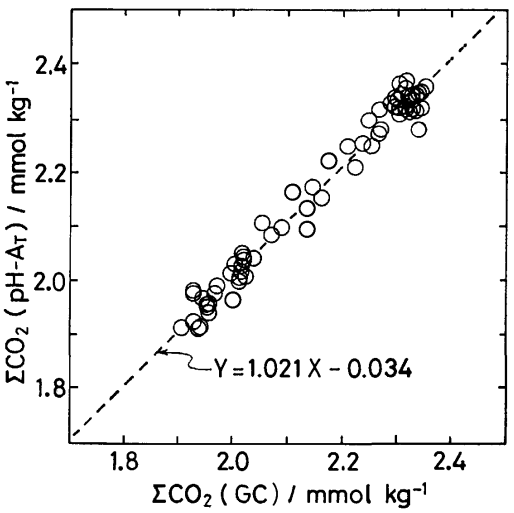

Fig. 4. Intercomparison of $\sum CO_2$ data measured by the gas chromatography (GC) and calculated from pH and titration alkalinity.
The broken line is the best fitted line by the method of least squares.

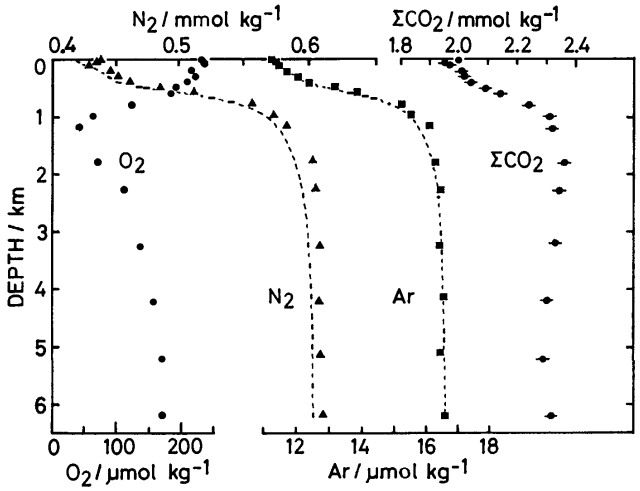

Fig. 5. Vertical profiles of O_2, N_2, Ar, and $\sum CO_2$ at Vega station 11 (29°39'N, 146°15'E).
Broken lines indicate the solubility values calculated from potential temperature and salinity at each depth.

tendency that the titration value is systematically lower than the GC value can be attributed to the loss of iodine by vaporization during the course of titration.

Figure 4 shows a comparison of $\sum CO_2$ data obtained during the Vega Expedition. The abscissa (X-axis) represents the GC value, and the ordinate (Y-axis) the value calculated by Tsubota (unpublished data) from pH and titration alkalinity measurements. The estimated standard deviation of the calculated value is $\pm 0.5\%$. The method of least squares was also applied to the sets of data (80 pairs) to give the following parameters:

$$A = 1.021 \pm 0.016,$$

$$B = -0.034 \pm 0.036 \text{ (mmol kg}^{-1}\text{)}.$$

There is a tendency that the calculated value is somewhat greater than the GC value. T-tests show, however, that A and B do not differ from unity and zero, respectively, at the level of $\alpha = 0.05$. The GC values are in good agreement with the calculated values in view of statistics.

The results of intercalibrations confirmed that the present gas chromatographic system is correctly calibrated, giving accurate and reliable O_2 and $\sum CO_2$ data on board. The accuracy of the determination of Ar and N_2 should not differ a great deal from that for O_2 and $\sum CO_2$, since all the gases were analyzed simultaneously under the same conditions.

As an example of simultaneous shipboard measurement, Fig. 5 shows vertical profiles of Ar, O_2, N_2, and $\sum CO_2$ at Vega station 11 (29°39'N, 146°15'E). The broken lines for Ar and N_2 are the saturation values calculated from the potential temperature and salinity at each depth by using the solubility equation of Weiss.[18] From surface to bottom, N_2 values are supersaturated by an average of 1.8%, Ar values being less supersaturated by an average of 0.7%. This saturation anomaly of both inert gases might reflect the effect of air injection at the ocean surface under turbulent conditions, since the N_2/Ar ratio in air bubbles is approximately twice that in sea water in equilibrium with the atmosphere.[18]

Except for the euphotic zone of the ocean surface, O_2 is only consumed by the decomposition of organic matters to produce CO_2 and nutrients. This is the reason why vertical profiles of O_2 and $\sum CO_2$ are inversely correlated with each other. By applying a vertical diffusion-advection model[19] to the deep layer (depth, 1—3 km) of station 11, the average O_2 consumption and CO_2 production rates were estimated to be 0.45 and 0.34 μmol kg^{-1} per year, respectively, when upward advection velocity of sea water was assumed to be 5 m per year. Oceanographical considerations of the results are given elsewhere in detail.[20]

The present gas chromatographic system was used for the analysis of volcanic CO_2 gas dissolved in northern Kagoshima Bay in order to calculate the CO_2 flux from bottom fumaroles.[21] With some modifications, the system will also be applicable to analysis of dissolved gases in fresh water or polluted water samples as well as sea water.

The authors wish to thank Prof. Hiroyuki Tsubota, Hiroshima University, for kindly making his unpublished $\sum CO_2$ data available. They are grateful to the officers and crew of *R. V. Hakuho Maru* for their assistances in getting sea water samples.

The Preparation of Vanadium Tetrachloride from Vanadium Dichloride Oxide and Vanadium Trichloride and the Hydrogen Reduction Process of Vanadium Tetrachloride

Akimasa YAJIMA, Ryoko MATSUZAKI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received February 14, 1980)

The reactions of VCl_2O and VCl_3 with chlorine, and the reaction of VCl_3O, formed by the chlorination of VCl_2O, with chlorine in the presence of carbon were examined. The products formed by the reaction between gaseous VCl_4 and hydrogen at various temperatures, and the behavior of VCl_3 and VCl_2 on heating in a hydrogen stream were examined. The reaction between VCl_2O and chlorine occurs above *ca.* 120 °C and proceeds markedly above *ca.* 170 °C to form VCl_3O. VCl_4 can be obtained by passing the gaseous VCl_3O together with chlorine through a carbon bed held at *ca.* 700 °C. The reaction between VCl_3 and chlorine occurs above *ca.* 80 °C and proceeds markedly above *ca.* 170 °C to form VCl_4. The hydrogen reduction process of VCl_4 in the vapor phase may be represented as follows: The reaction between VCl_4 and hydrogen, $2VCl_4(g)+H_2(g)\rightarrow 2VCl_3(s)+2HCl(g)$, proceeds above *ca.* 500 °C to form VCl_3. Subsequently, the hydrogen reduction of the VCl_3, $2VCl_3(s)+H_2(g)\rightarrow 2VCl_2(s)+2HCl(g)$, and the disproportionation of the VCl_3, $2VCl_3(s)\rightarrow VCl_2(s)+VCl_4(g)$, proceed to form VCl_2. Above *ca.* 620 °C, the reaction between the VCl_2 and hydrogen, $VCl_2(s)+H_2(g)\rightarrow V(s)+2HCl(g)$, proceeds to form vanadium.

The vanadium trichloride oxide (VCl_3O) which is dissolved in the titanium tetrachloride ($TiCl_4$) prepared by the chlorination of titanium ores is commercially removed as a non-volatile vanadium-containing precipitate by bubbling hydrogen sulfide through the $TiCl_4$. The present authors[1] have previously reported that the precipitate formed by the reaction between VCl_3O and hydrogen sulfide is a mixture of vanadium dichloride oxide (VCl_2O), vanadium trichloride (VCl_3), and sulfur. The sulfur can be selectively separated by heating the mixture at *ca.* 250 °C in an argon stream.[2,3]

From the view point of resources utilization, it is important to obtain fundamental information on the preparation of vanadium tetrachloride (VCl_4) from the mixture of VCl_2O and VCl_3 and on the preparation of vanadium by the hydrogen reduction of the VCl_4.

There has been no report on the reaction between VCl_2O and chlorine. It has been reported that VCl_3 reacts with chlorine at 600 °C to form VCl_4.[4] Regarding the hydrogen reduction of VCl_4 in the vapor phase, Jantsch and Zemek[5] have reported that vanadium is obtained by the hydrogen reduction of VCl_4 at 680—700 °C. On the other hand, it has been reported that vanadium dichloride (VCl_2) is obtained by the reaction between VCl_4 and hydrogen above 650 °C,[6] or at 750—800 °C.[7]

In this paper, the reactions of VCl_2O and VCl_3 with chlorine, and the reaction of VCl_3O, formed by the chlorination of VCl_2O, with chlorine in the presence of carbon were examined. The hydrogen reduction process of VCl_4 in the vapor phase was also examined.

Experimental

Materials. The VCl_2O used was prepared from VCl_3, divanadium trioxide(V_2O_3), and VCl_3O,[8] and confirmed to be VCl_2O[9] by X-ray analysis. The chemical analysis gave V, 37.0; Cl, 51.4% (Calcd for VCl_2O: V, 36.96; Cl, 51.44%). VCl_3 was obtained by the thermal decomposition of VCl_4 at 180 °C in an argon atmosphere,[3] and confirmed to be VCl_3[10] by X-ray analysis. The chemical analysis gave V, 32.4; Cl, 67.6% (Calcd for VCl_3: V, 32.38; Cl, 67.62%). VCl_3O was prepared by the reaction between V_2O_5, which had been obtained by the thermal decomposition of guaranteed reagent ammonium metavanadate, and chlorine in the presence of carbon at 300 °C.[11] The chemical annlysis gave V, 29.4; Cl, 61.3% (Calcd for VCl_3O: V, 29.40; Cl, 61.37%). Carbon was obtained by the thermal decomposition of guaranteed reagent glucose. VCl_4 was prepared by the reaction between vanadium (V, 99.8% up) and chlorine at 500 °C.[3] The chemical analysis gave V, 26.4; Cl, 73.5% (Calcd for VCl_4: V, 26.43; Cl, 73.57%). VCl_2 was obtained by the disproportionation of VCl_3 in an argon stream at 650 °C,[3] and confirmed to be VCl_2[12] by X-ray analysis. The chemical analysis gave V, 41.8; Cl, 58.1% (Calcd for VCl_2: V, 41.81; Cl, 58.19%).

Experimental Procedures. The percentages of reacted VCl_2O or VCl_3 on heating in a chlorine stream at various temperatures for a specified period were examined as follows: The sample (1.0 g) in a quartz boat (60 mm length, 13 mm width, 7 mm depth) was placed in a straight reaction tube (17 mm i. d.) with a condenser. Chlorine was introduced into the reaction tube at a flow-rate of 50 cm^3/min. The sample part was then placed in the center of an electric furnace (300 mm in heating length) maintained at a specified temperature. The weight loss of the sample on heating in a chlorine stream for a specified period was measured. The temperature of the sample part was controlled to within ± 2 °C.

The reaction between VCl_3O and chlorine in the presence of carbon was examined as follows: Gaseous VCl_3O was formed by heating VCl_3O (27 g) at 120 °C and carried by a stream of argon (40 cm^3/min) to a carbon bed (30 mm diameter, 150 mm length) held at a specified temperature. Chlorine was simultaneously introduced at a flow-rate of 100 cm^3/min through a separate tube into the carbon bed. The mean flow-rate of gaseous VCl_3O was 10.7 cm^3/min. The reaction was allowed to proceed for 1 h.

The products obtained by the hydrogen reduction of VCl_4 in the vapor phase at various temperatures were examined as follows: Gaseous VCl_4 was formed by heating VCl_4 (28 g) at 130 °C and carried by a stream of argon (50 cm^3/min) to the reaction zone (28 mm i. d., 250 mm length) held at a specified temperature. Hydrogen was simultaneously introduced at a flow-rate of 150 cm^3/min through a separate tube into the reaction zone. The mean flow-rate of gaseous VCl_4 was 7.4

cm^3/min. A quartz or high purity alumina tube was inserted inside the reaction tube. The reaction was allowed to proceed for 2 h.

Throughout this work, the chlorides and chloride oxides of vanadium were handled in an argon atmosphere or *in vacuo* to prevent any contamination from moisture in the air.

Thermogravimetry(TG). The sensitivity of the quartz helix used for TG was approximately 67 mm/g. The sample (0.15 g) was heated at a rate of 2.5 °C/min and the flow-rate of chlorine or hydrogen was maintained at 50 cm^3/min.

Analytical. X-Ray analysis of the solid sample was performed using Ni filtered Cu radiation. The sample chamber of the diffractometer was maintained under dry nitrogen atmosphere to prevent the contamination of the sample from moisture in the air during the irradiation.

The vanadium content in the sample was determined by chelatometric titration;[13] the chlorine content was gravimetrically determined as AgCl, after dissolving the sample in dilute nitric acid.

Results and Discussion

Preparation of Vanadium Tetrachloride from Vanadium Dichloride Oxide and Vanadium Trichloride. Reaction between VCl_2O and Chlorine: On heating VCl_2O in an argon stream, the VCl_2O disproportionates above *ca.* 295 °C according to the reaction, $2VCl_2O(s) \rightarrow VClO(s) + VCl_3O(g)$, as previously reported by the present authors.[2] The TG curve of VCl_2O in a chlorine stream showed that VCl_2O began to react with chlorine before disproportionating and that the weight loss reached 100%. The percentages of reacted VCl_2O on heating VCl_2O in a chlorine stream at various temperatures for 0.25—3 h were examined. At 110 °C, no reaction product was observed. The results obtained at various temperatures above 120 °C are shown in Fig. 1.

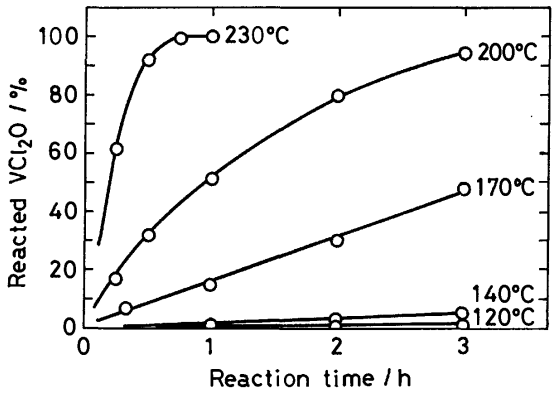

Fig. 1. Effect of temperature on the reaction between VCl_2O and chlorine.

The chemical analysis of the reaction product obtained by heating VCl_2O at 200 °C in a chlorine stream gave V, 29.4; Cl, 61.3%. From this result, the reaction product between VCl_2O and chlorine was found to be VCl_3O (Calcd: V, 29.40; Cl, 61.37%).

The above-mentioned results reveal that VCl_2O reacts with chlorine above *ca.* 120 °C according to the reaction,

$$2VCl_2O(s) + Cl_2(g) \longrightarrow 2VCl_3O(g), \quad (1)$$

and the reaction proceeds markedly above *ca.* 170 °C.

Since the vapor pressure of VCl_3O is 12.3 mmHg[8] even at room temperature (20 °C), the VCl_3O formed by heating VCl_2O (5.0 g) in a chlorine stream (100 cm^3/min) at 200 °C for 2 h was condensed in a trap held at 20 °C, 0 °C (P_{VCl_3O}=4.0 mmHg),[8] or −18 °C (P_{VCl_3O}=1.2 mmHg).[8] The percentage of the amount of VCl_3O condensed in the trap held at 20 or 0 °C to the calculated value based on the amount of reacted VCl_2O was 82 or 94%, respectively. When the temperature of the cooling trap was −18 °C, it was observed that a small amount of chlorine was dissolved in the condensed VCl_3O.[14] The amount of chlorine dissolved in the VCl_3O was determined as follows: after the chlorination was over, the VCl_3O was allowed to warm up to 0 °C in an argon atmosphere in order to liberate the chlorine from the VCl_3O. The liberated chlorine was absorbed in sodium hydroxide (NaOH) solution. A small amount of VCl_3O which vaporized during the above procedure was also absorbed in the NaOH solution. The total amount of chlorine in the NaOH solution was gravimetrically determined as AgCl, while the vanadium content in the NaOH solution was also determined by chelatometric titration. From the vanadium content, the amount of the VCl_3O absorbed in the NaOH solution was calculated. The amount of chlorine dissolved in the VCl_3O was calculated by subtracting the amount of chlorine corresponding to the VCl_3O absorbed in the NaOH solution from the total amount of chlorine in the NaOH solution. The result showed that the VCl_3O condensed in the trap held at −18 °C contained 2.0% of chlorine. The percentage of the amount of VCl_3O obtained after liberating the chlorine to the calculated value based on the amount of reacted VCl_2O was 97%.

Reaction between VCl_3 and Chlorine: On heating VCl_3 in an argon stream, the VCl_3 disproportionates above *ca.* 350 °C according to the reaction, $2VCl_3(s) \rightarrow VCl_2(s) + VCl_4(g)$, as previously reported by the present authors.[3] The TG curve of VCl_3 in a chlorine stream showed that VCl_3 began to react with chlorine before disproportionating and that the weight loss reached 100%. The percentages of reacted VCl_3 on heating VCl_3 in a chlorine stream at various temperatures for

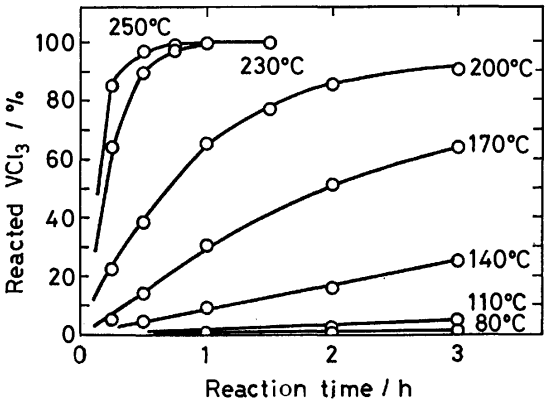

Fig. 2. Effect of temperature on the reaction between VCl_3 and chlorine.

0.25—3 h were examined. At 70 °C, no reaction product was observed. The results obtained at various temperatures above 80 °C are shown in Fig. 2.

The chemical analysis of the reaction product obtained by heating VCl_3 in a chlorine stream at 200 °C gave V, 26.4; Cl, 73.5%. From the result, the reaction product between VCl_3 and chlorine was found to be VCl_4 (Calcd: V, 26.43; Cl, 73.57%).

The above-mentioned results reveal that VCl_3 reacts with chlorine above *ca.* 80 °C according to the reaction,

$$2VCl_3(s) + Cl_2(g) \longrightarrow 2VCl_4(g), \quad (2)$$

and that the reaction proceeds markedly above *ca.* 170 °C.

Since the vapor pressure of VCl_4 is 5.4 mmHg[15] even at room temperature (20 °C), the VCl_4 formed by heating VCl_3 (5.0 g) in a chlorine stream (100 cm^3/min) at 200 °C for 2 h was condensed in a trap held at 20 °C, 0 °C ($P_{VCl_4} = 1.7$ mmHg),[15] or −18 °C ($P_{VCl_4} = 0.5$ mmHg).[15] The percentage of the amount of VCl_4 condensed in the trap held at 20 °C to the calculated value based on the amount of reacted VCl_3 was 92%. When the temperature of the cooling trap was 0 or −18 °C, it was observed that a small amount of chlorine was dissolved in the condensed VCl_4.[16] The VCl_4 formed is allowed to warm up to 20 °C in an argon atmosphere in order to liberate the chlorine. The amount of chlorine dissolved in the VCl_4 was determined in the same manner as described in the experiment on VCl_2O. From the results, the amounts of chlorine dissolved in the VCl_4 condensed at −18 and 0 °C were 0.7 and 4.0%, respectively. The percentage of the amount of VCl_4 obtained after liberating the chlorine to the calculated value based on the amount of reacted VCl_3 was 96% at 0 °C and 97% at −18 °C.

Reaction between VCl_3O and Chlorine in the Presence of Carbon: As mentioned above, VCl_3O is formed by the reaction between VCl_2O and chlorine. To obtain knowledge of formation of VCl_4 from the VCl_3O, the products obtained by passing gaseous VCl_3O together with chlorine through a carbon bed held at various temperatures were examined. The results are shown in Table 1.

Table 1. Reaction product between gaseous VCl_3O and chlorine in the presence of carbon

Temp °C	Chemical analysis/%		Product/%	
	V	Cl	VCl_4	VCl_3O
400	29.4	61.3	—	100
500	28.7	64.3	24	76
600	27.3	70.0	71	29
650	26.7	72.5	91	9
700	26.4	73.5	100	—

The chloride and chloride oxide of vanadium in the liquid state at room temperature are VCl_4 (Calcd: V, 26.43; Cl, 73.57%) and VCl_3O (Calcd: V, 29.40; Cl, 61.37%). This fact and the chemical analysis shown in Table 1 showed that VCl_4 was formed above 500 °C, and that the weight percentage of VCl_4 increased with increasing temperature. At 700 °C, VCl_4 alone was obtained. When VCl_4 formed by the chlorination of VCl_3O at 700 °C in the above manner was condensed in a trap cooled at −18 °C, VCl_4 was obtained in a 97% yield.

The above-mentioned results suggest that the following method is preferable for preparing VCl_4 from a mixture of VCl_2O and VCl_3: By heating a mixture of VCl_2O and VCl_3 at *ca.* 200 °C in a chlorine stream, VCl_4 and VCl_3O are formed. Subsequently, VCl_4 is prepared by passing the gaseous mixture of VCl_4 and VCl_3O together with chlorine through a carbon bed held at *ca.* 700 °C. The resulting VCl_4 is condensed in a trap cooled at −18 °C.

Hydrogen Reduction Process of Vanadium Tetrachloride. Reduction Products of Gaseous VCl_4 with Hydrogen: Prior to the examination of the hydrogen reduction of VCl_4 in the vapor phase, the thermal decomposition of gaseous VCl_4 was examined to know whether the thermal decomposition of gaseous VCl_4 occurs under the experimental conditions of this work. The experimental procedure was the same as that for the hydrogen reduction described in the previous paragraph, except that argon was introduced into the reaction zone instead of hydrogen at the same flow-rate as that of hydrogen.

The experimental results showed that 0.009 g of VCl_3 and 0.002 g of chlorine were formed by the thermal decomposition of gaseous VCl_4 at 200, 600, and 1000 °C, regardless of the heating temperature. The result indicated that *ca.* 0.1% of gaseous VCl_4 introduced into the reaction zone thermally decomposed. From the result, it was considered that the decomposition of gaseous VCl_4 could be neglected in the discussion about the experimental results for the hydrogen reduction of gaseous VCl_4, to be described later.

The products formed by heating gaseous VCl_4 in a hydrogen stream at various temperatures were examined by X-ray analysis and chemical analysis. At 400 °C, it was observed that the reaction between gaseous VCl_4 and hydrogen did not proceed. The results obtained above 500 °C are shown in Table 2.

Table 2. Reduction products of gaseous VCl_4 with hydrogen at various temperatures

Temp °C	Products and their yields/mol%						Unreacted VCl_4/mol%
	In the reaction zone			Outside the reaction zone			
	V	VCl_2	VCl_3	V	VCl_2	VCl_3	
500	—	<1	2	—	—	1	96
600	—	23	—	—	19	<1	56
700	2	63	—	—	34	—	—
800	4	64	—	<1	31	—	—
900	34	29	—	6	30	—	—
1000	76	—	—	23	—	—	—

The results indicate that the reaction between gaseous VCl_4 and hydrogen proceeds above *ca.* 500 °C, giving VCl_3 and VCl_2 at 500—600 °C, VCl_2 and vanadium at 700—900 °C, and vanadium alone at 1000 °C.

Behavior of VCl_3 and VCl_2 on Heating in a Hydrogen Stream: In order to reveal the hydrogen reduction process of gaseous VCl_4, the behavior of VCl_3 and VCl_2, formed during the reduction process, on heating in a hydrogen stream was examined.

The TG curve of VCl_3 in a hydrogen stream is shown in Fig. 3(a). The result showed that VCl_3 began to react with hydrogen at *ca.* 270 °C before the disproportionation described in the previous paragraph occurred. The sample heated up to 600 °C was found to be VCl_2 by X-ray analysis. The formations of hydrogen chloride and VCl_4 were observed during the weight loss. The final weight loss was 47.7%. This value was larger than the calculated value, 22.54%, based on the hydrogen reduction of VCl_3 to form VCl_2,

$$2VCl_3(s) + H_2(g) \longrightarrow 2VCl_2(s) + 2HCl(g), \quad (3)$$

and was smaller than the calculated value, 61.27%, based on the disproportionation of VCl_3 to form VCl_2,

$$2VCl_3(s) \longrightarrow VCl_2(s) + VCl_4(g). \quad (4)$$

These facts were considered to indicate that, on heating VCl_3 in a hydrogen stream, both the hydrogen reduction and the disproportionation of VCl_3 occurred. The experimental value of the weight loss showed that 35% of VCl_3 was reduced with hydrogen and 65% of VCl_3 disproportionated.

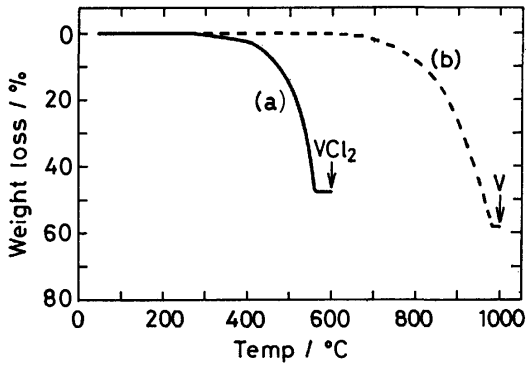

Fig. 3. TG curves of VCl_3 and VCl_2 in a hydrogen stream.
(a): VCl_3, (b): VCl_2.

From the results, on heating VCl_3 in a hydrogen stream, the hydrogen reduction of VCl_3 (Reaction 3) occurs above *ca.* 270 °C, and the disproportionation of VCl_3 (Reaction 4) occurs above *ca.* 350 °C in addition to Reaction 3. This result is contrary to the result by Pechkovskii and Vorob'ev,[17] who reported that on heating VCl_3 in a hydrogen stream above *ca.* 480 °C, VCl_2 was formed by the hydrogen reduction of VCl_3.

The TG curve of VCl_2 in a hydrogen stream is shown in Fig. 3(b). In this case, a platinum basket was used for TG, because it had been reported that vanadium reacted with quartz above *ca.* 1000 °C.[18] The sample heated up to 1000 °C was found to be vanadium[19] by X-ray analysis.

These results reveal that on heating VCl_2 in a hydrogen stream, VCl_2 reacts with hydrogen to form vanadium above *ca.* 620 °C according to the reaction,

$$VCl_2(s) + H_2(g) \longrightarrow V(s) + 2HCl(g). \quad (5)$$

Consideration on Hydrogen Reduction Process of VCl_4: From the above-mentioned results, the hydrogen reduction process of VCl_4 in the vapor phase was discussed.

As shown in Table 2, on heating VCl_4 in a hydrogen stream, VCl_3 and VCl_2 were formed at 500—600 °C. The only reaction which gave VCl_3 was thought to be

$$2VCl_4(g) + H_2(g) \longrightarrow 2VCl_3(s) + 2HCl(g), \quad (6)$$

since the thermal decomposition of gaseous VCl_4 scarcely proceeded as described before. The reactions which gave VCl_2 were considered to be the hydrogen reduction and the disproportionation of the VCl_3, since the hydrogen reduction of VCl_3 (Reaction 3) occurs above *ca.* 270 °C and the reduction is accompanied by the disproportionation (Reaction 4) above *ca.* 350 °C, as described before. As shown in Table 2, above 700 °C, vanadium was formed in addition to VCl_2, and vanadium alone was obtained at 1000 °C. Since VCl_2 is reduced with hydrogen to vanadium (Reaction 5) above *ca.* 620 °C, it was considered that the vanadium obtained was formed by the hydrogen reduction of the VCl_2 formed by Reactions 3 and 4.

These results allow us to represent the hydrogen reduction process of VCl_4 in the vapor phase as follows: the reaction between gaseous VCl_4 and hydrogen proceeds above *ca.* 500 °C to form VCl_3 (Reaction 6). Subsequently, the hydrogen reduction of the VCl_3 (Reaction 3) and the disproportionation of the VCl_3 (Reaction 4) proceed to form VCl_2. Above *ca.* 620 °C, the reaction between the VCl_2 and hydrogen proceeds to form vanadium (Reaction 5).

The present work was partially supported by the Asahi Glass Foundation for Industrial Technology.

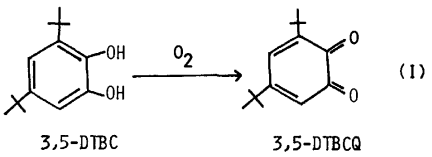
Reaction between Various Copper(II) Complexes and Ascorbic Acid or 3,5-Di-*t*-butylcatechol

Naoyasu Oishi, Yuzo Nishida,* Kazuhiko Ida, and Sigeo Kida
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received February 27, 1980)

The electron transfer reactions between various copper(II) complexes and two-electron donors, such as ascorbic acid and 3,5-di-*t*-butylcatechol, were investigated. Mononuclear copper(II) complexes with a distorted tetrahedral and a trigonal bipyramidal structure, and some binuclear complexes were readily reduced to copper(I) complexes by the two-electron donors, but not mononuclear planar copper(II) complexes. The catalytic activities of these copper(II) complexes for the oxidation of 3,5-di-*t*-butylcatechol by O_2 were studied in relation to the above reactions.

Copper(II) ion in proteins are classified into three types, Type I, Type II, and Type III, Type I and Type II copper ions being isolated from other copper ions and functioning as mononuclear complexes, while a binuclear structure has been proposed for Type III because of its ESR-nondetectable nature.[1,2] The structures of two proteins containing a copper(II) ion in Type I form (plastocyanin and azurin)[3] have been determined by X-ray analysis, but the geometries around copper(II) ions are still unclarified for other copper proteins.

All the copper(II) ions have relatively high redox potentials, being readily reduced to copper(I) by ascorbic acid, hydroquinones and catechols.[1,2] We have investigated the reaction of various copper(II) complexes with two-electron donors, such as ascorbic acid and 3,5-di-*t*-butylcatechol (hereafter abbreviated as 3,5-DTBC) in order to elucidate the relationship between 1) the structure and reactivity of copper(II) complexes in the reduction to copper(I) complexes by two-electron donors, and 2) the catalytic activity for the oxidation of 3,5-DTBC by O_2 (corresponding quinone formed according to reaction (I)) and the structure of copper(II) complexes.



(I)

3,5-DTBC 3,5-DTBCQ

Experimental

Copper(II) Complexes. The copper(II) complexes we used are shown in Fig. 1, **5** being a new complex.

Preparation of **5**, $[Cu_2(me\text{-}ox)]X_2(X=ClO_4, PF_6)$. An ethanol solution of *N*-[2-(dimethylamino)ethyl]-1,3-propanediamine(0.01 mol) and diethyloxalate(0.005 mol) was refluxed for 1 h, and resulting solution was mixed with an aqueous solution of $Cu(H_2O)_6(ClO_4)_2$(0.01 mol). Violet prisms separated immediately were recrystallized from hot water. Found: C, 28.96; H, 5.23; N, 12.70%. Calcd for $[Cu_2(me\text{-}ox)](ClO_4)_2$: C, 28.74; H, 5.12; N, 12.56%. The magnetic moment of the perchlorate complex is 1.16 BM at 295 K. Its magnetic property can be explained in terms of the Bleaney-Bowers equation[4] (temperature range, 80—295 K, $2J=-440$ cm^{-1}, and $N\alpha=60\times10^{-6}$ cgs). By adding NH_4PF_6 to a hot water solution of the perchlorate, $[Cu_2(me\text{-}ox)](PF_6)_2$ was obtained as red needles.

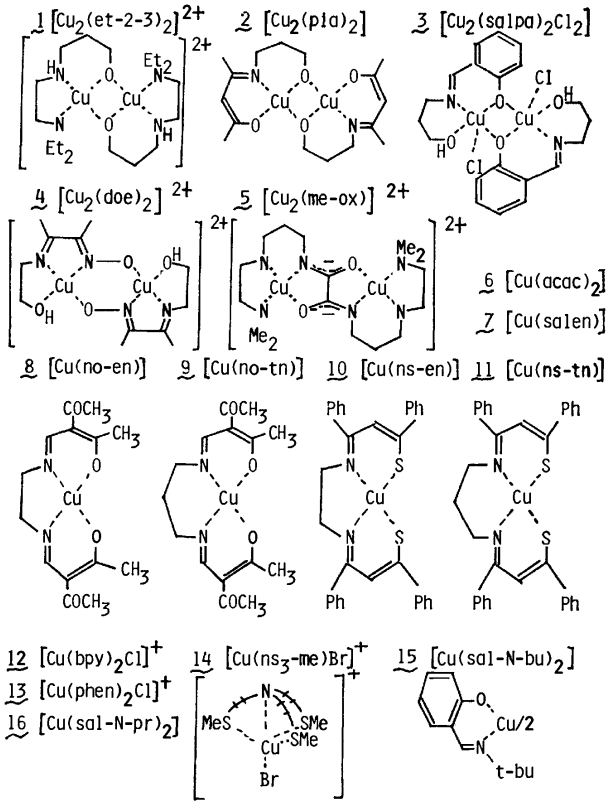


Fig. 1. Copper(II) complexes used in this study.
The abbreviations of ligands are: **6**; H(acac), acetylacetone, **7**; H_2(salen), *N*,*N*′-disalicylideneethylenediamine, **12**; bpy, 2,2′-bipyridine, **13**; phen, 1,10-phenanthroline, **16**; H(sal-N-pr), *N*-salicylideneisopropylamine.

Complexes **1**—**5** are binuclear, the structural and magnetic properties of **1**—**4** being reported (**1**,[5,6] **2**,[7] **3**,[8] and **4**[9]). In these binuclear copper(II) complexes, the strong antiferromagnetic interaction was found to be operative between two copper atoms. Complexes **6**—**11** are of four-coordinated planar structure, **6**, **7**—**9**[10], and **10**—**11**[11] having $[CuO_4]$-, $[CuN_2O_2]$- and $[CuN_2S_2]$-type coordinations, respectively. Complexes **12**—**14**[12] and **15**—**16** are of trigonal bipyramidal and distorted tetrahedral structures, respectively.

Reaction with Ascorbic Acid or Catechol. A methanol solution containing stoichiometric amount of ascorbic acid was added to a methanol solution of copper(II) complexes at 20 °C under nitrogen atmosphere and the absorption spectra of the resulting solutions were measured in the visible

region. When 3,5-DTBC was used instead of ascorbic acid, the same procedure was applied except for the addition of triethylamine[13] (3,5-DTBC: base=2: 1).

Catalytic Activity for the Oxidation of 3,5-DTBC by O_2. Oxidation was carried out according to the method of Tsuruya and Linvedt.[13] A methanol solution(20 cm^3) of 3,5-DTBC(0.1 mol/dm^3), triethylamine(0.015 mol/dm^3) and copper(II) complex (0.002 and 0.001 mol/dm^3 for mononuclear and binuclear complexes, respectively) was kept at 15 °C (in a thermostat) in a 12 mm diam. necked flask for 6—7 h. The yield of quinone(3,5-DTBCQ) formed was determined by the measurements of absorption spectra of the resulting solutions. 3,5-DTBCQ shows a characteristic absorption band at 400 nm (ε/mol^{-1} dm^3 cm^{-1}=1900 in methanol[14]).

Measurements. Absorption spectra were obtained with a Shimadzu Multipurpose spectrometer model MPS-5000.

Results and Discussion

Electron-transfer Reaction between Two-electron Donors and Various Copper(II) Complexes. Compounds **12**, $[Cu(bpy)_2Cl]Cl$ and **13**, $[Cu(phen)_2Cl]Cl$ are easily reduced to copper(I) complexes by ascorbic acid, where bpy and phen denote 2,2'-bipyridine and 1,10-phenanthroline, respectively. The green color of **14**, $[Cu(ns_3\text{-}me)Br]^+$ disappeared immediately upon addition of ascorbic acid (or 3,5-DTBC), indicating that the complex is reduced to copper(I) complex by two-electron donors.

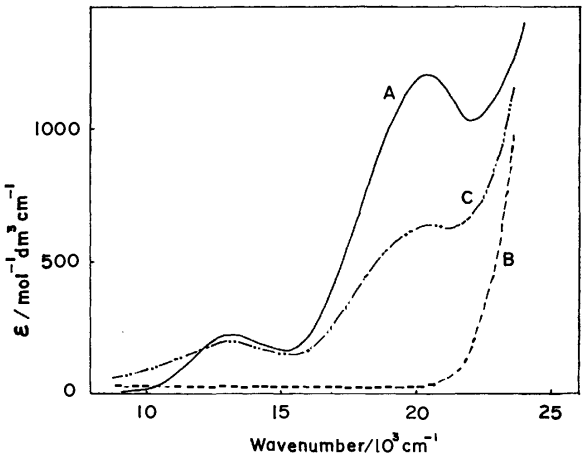

Fig. 2. Absorption spectra of **15** [Cu(sal-N-bu)$_2$] (in methanol, 15 °C).
A: [Cu(sal-N-bu)$_2$], B: [Cu(sal-N-bu)$_2$]+ascorbic acid (in N_2), C: solution (B) +O_2(in air).

Figure 2 shows that the spectral change of **15**, [Cu(sal-N-bu)$_2$], caused by the addition of ascorbic acid. The d-d band (*ca.* 13000 cm^{-1}) due to copper(II) ion disappears immediately upon the addition of ascorbic acid under nitrogen atmosphere, reappearing when the solution was exposed to the air. This indicates that the copper(II) complexes with a distorted tetrahedral structure are reduced to copper(I) by ascorbic acid (or 3,5-DTBC). On the other hand, planar mononuclear copper(II) complexes such as **6**, $[Cu(acac)_2]$ and **7**, [Cu(salen)] are not reduced by these two-electron donors at room temperature.

Patterson and Holm[15] measured the reduction potentials of various copper(II) complexes by polarography, and concluded that mononuclear copper(II) complexes with nonplanar structure (*e.g.*, distorted tetrahedron and trigonal bipyramid) are readily reduced as compared with their planar analogs. Our results seem to be in line with their conclusion. This indicates that nonplanar mononuclear copper(II) complexes can be a good model for Types I and II in biological systems.

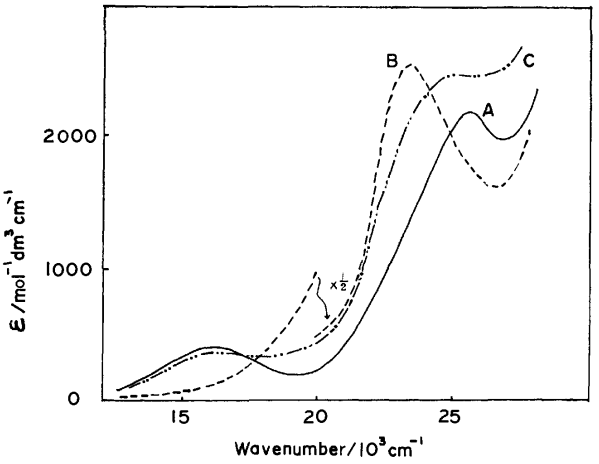

Fig. 3. Absorption spectra of **4** $[Cu_2(doe)_2](NO_3)_2$(in methanol, 15 °C).
A: $[Cu_2(doe)_2](NO_3)_2$, B: $[Cu_2(doe)_2](NO_3)_2$+ascorbic acid(in N_2), C: solution (B)+O_2(in air).

Binuclear copper(II) complexes (Fig. 1) except for **5** were also found to be readily reduced to copper(I) complexes by ascorbic acid and/or 3,5-DTBC. The spectral change of **4**, $[Cu_2(doe)_2]^{2+}$ in the reaction with ascorbic acid is shown as an example in Fig. 3. The d-d band at 16000 cm^{-1} disappears upon addition of ascorbic acid under nitrogen atmosphere, appearing again when the solution is exposed to air. It is noteworthy that planar mononuclear copper(II) complexes such as **6** and **7** are not reduced by ascorbic acid, while binuclear copper(II) complexes with planar structure such as **2**, **3**, and **4**, are readily reduced to copper(I) by ascorbic acid.

Catalytic Activity for the Oxidation of 3,5-DTBC. Since 3,5-DTBCQ shows a characteristic absorption band at 400 nm and the content of copper(II) complex is very small, the absorbance at 400 nm can be a good measure for the catalytic activity of copper(II) complexes to the oxidation of 3,5-DTBC. Examples are given in Figs. 4 and 5. Square planar mononuclear complexes (**6** and **7**) have little catalytic activity, while nonplanar copper(II) complexes (such as **12**, **14**, and **15**) and binuclear complexes (except for **5**) act as a good catalyzer for the oxidation of 3,5-DTBC. In the cases of **14** and **4**, 100% formation of 3,5-DTBCQ was observed within 6 hours. The results obtained for binuclear complexes (**1**—**4**) are in line with that of Tsuruya and Lintvedt,[13] who first pointed out the high catalytic activity of a binuclear complex, **17**, relative

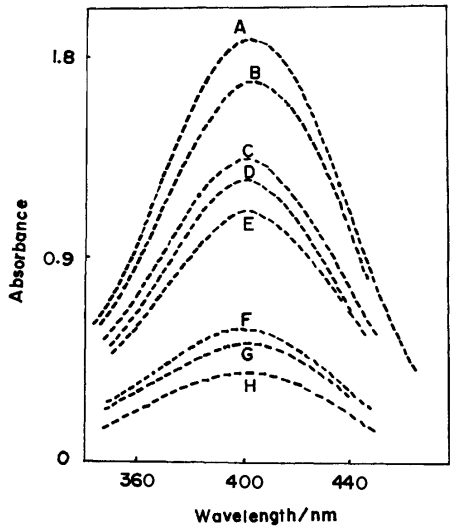

Fig. 4. Absorbance at 400 nm of the solution containing a copper (II) complex and 3,5-DTBC(in methanol, 15 °C, after 6 h).
A: **12** $[Cu(bpy)_2Cl]Cl$, B: **4** $[Cu_2(doe)_2](NO_3)_2$, C: **15** $[Cu(sal\text{-}N\text{-}bu)_2]$, D: **14** $[Cu(ns_3\text{-}me)Br]ClO_4$, E: **2** $[Cu_2(pia)_2]$, F: **6** $[Cu(acac)_2]$, G: **8** [Cu(no-en), H: no copper(II) complex.

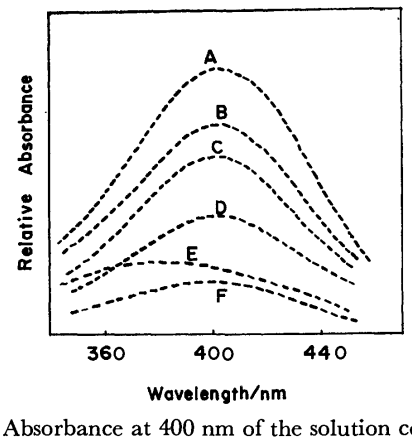

Fig. 5. Absorbance at 400 nm of the solution containing a copper (II) complex and 3,5-DTBC(in $CHCl_3$, 15 °C, after 10 h).
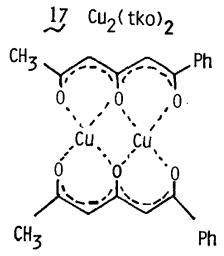
A: **11** [Cu(ns-tn)], B: **10** [Cu(ns-en)], C: **9** [Cu(no-tn)], D: **8** [Cu(no-en)], E: **7** [Cu(salen)], F: no copper(II) complex.

to that of a mononuclear complex, **6**, for the oxidation of 3,5-DTBC by O_2.



Since **10** and **11** are insoluble in methanol, the result in Fig. 5 was obtained in a $CHCl_3$ solution. Thus the catalytic activity of **11** and **10** cannot be compared directly with that of **14** and **15**. The order of catalytic activity is as follows: **12**~**13**>**14**; **15**>**16**; **11**>**10**>**9**>**8**>**7**~**6** and **4**>**1**~**2**~**3**≫**5**. Although **8** has a $[CuN_2O_2]$-type coordination similar to that of **7**, **8** is more reducible than **7** because of the presence of electron-withdrawing group in the chelate ring.[16,17] Copper(II) complexes with a $[CuN_2S_2]$-type coordination are more reducible than those with a $[CuN_2O_2]$-type coordination.[15] Complexes with 6-membered chelate ring (such as **11** and **9**) are more reducible than the corresponding complexes with 5-membered chelate ring (such as **10** and **8**).[15,16] Thus, the results indicate that more reducible mononuclear copper(II) complexes can be a better catalyzer for the oxidation of 3,5-DTBC by O_2, suggesting that the reversible change of oxidation state, *i.e.*, Cu(II)⇄Cu(I), plays an important role in the catalytic function of mononuclear copper(II) complexes. Since binuclear complexes, **1**—**4**, are reduced by 3,5-DTBC and readily oxidized by O_2 again, these binuclear copper(II) complexes act as a good catalyzer for the oxidation of 3,5-DTBC by O_2.

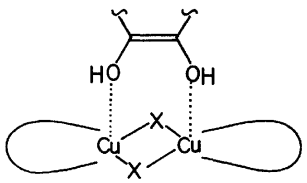


Fig. 6. "Steric match" proposed for electron transfer reaction between ascorbic acid and a binuclear copper (II) complex. This situation is impossible for ascorbic acid and a mononuclear planar copper(II) complex.

The reduction potentials of the two copper(II) complexes, **6** and **17**, are almost the same (**6**; −0.50 V, **17**; −0.48 V), **6** and **17** undergoing two-electron reduction to Cu^0 and Cu^I–Cu^I, respectively at the electrode.[18] However, the difference of reactivity between the two complexes in the electron transfer reaction with 3,5-DTBC (and/or ascorbic acid) cannot be explained by the electrochemical data. Accordingly we propose that a "steric match" between a donor and an acceptor (Fig. 6) is important in the electron transfer reaction between planar copper(II) complexes and two-electron donors, such as ascorbic acid and 3,5-DTBC. Thus on this basis the very low catalytic activity of **5** can be explained; *i.e.*, the distance between two copper atoms is estimated to be larger than 5 Å from the X-ray analysis of anologous complexes,[19] so that the "steric match" is impossible between **5** and two-electron donors.

Electrochemical Reduction of Elemental Sulfur in Acetonitrile

Taitiro FUJINAGA, Tooru KUWAMOTO, Satoshi OKAZAKI, and Masashi HOJO*,†

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received February 28, 1980)

Electrochemical reduction of elemental sulfur (S_8) has been carried out in acetonitrile using a platinum electrode. The products were identified by means of spectrophotometry and ESR. Sulfur is reduced voltammetrically in two steps:

$$S_8 + 2e \longrightarrow S_8^{2-}, \qquad S_8^{2-} + 2e \longrightarrow 2S_4^{2-}$$

These products turns into more stable species by the succeeding chemical reactions in a bulk solution as follows:

$$S_8^{2-} \overset{K}{\rightleftharpoons} S_6^{2-} + 1/4S_8 \qquad (K = 1.6\times10^{-2})$$

$$S_6^{2-} \overset{K_d}{\rightleftharpoons} 2S_3^{\cdot-} \qquad (K_d = 1.2\times10^{-3})$$

The S_4^{2-} species was enough active to react with S_8 into S_8^{2-}, which was regarded as the cause of a current maximum on the current-time curve in a controlled potential coulometry of S_8 at a potential of the second reduction step.

The authors have reported in the previous paper[1] that sulfur monochloride (S_2Cl_2) is reduced electrochemically into chloride ion and elemental sulfur (S_8 form) in an aprotic solvent, acetonitrile (AN), and that the produced sulfur can be further reduced at the more negative potential. Elemental sulfur has been reduced[2-5] in dimethyl sulfoxide and *N,N*-dimethylformamide to produce blue colored species, which is attributed to $S_3^{\cdot-}$ (trisulfur anion radical). However, as the system is very complicated, the different values of the equilibrium constants for the present species in a solvent are reported between two groups[3,5] of investigators.

Moreover, the authors have showed that S_8 molecule exists stably in less basic solvents, such as acetonitrile or propylene carbonate (PC), but S_8 is activated by the basicity of the solvent, not only in *N,N*-dimethylformamide but also dimethyl sulfoxide according to the conductivity data.[1] In the present work, the electrochemical reduction of S_8 in acetonitrile has been studied, and the reaction mechanism in the solution is discussed.

Experimental

Commercial acetonitrile was purified, and Et_4NClO_4 used as the supporting electrolyte was prepared by the method described previously.[1] The electrode potential was measured against a silver electrode (Ag/0.1 M $AgClO_4$–AN). A rotating platinum electrode (geometric surface area of 0.13 cm^2) and a platinum-gauze electrode were used as the working electrode. The controlled potential coulometry was carried out using a Prinston Applied Research (PAR) Model 173 Potentiostat and Model 179 Didital Coulometer. Other apparatus and equipments were the same as those in the previous report.[1]

Elemental sulfur (S_8) was dissolved in acetonitrile, heating on a hot-plate. Absorption spectra of electrolyzed sulfur solution were measured in an optical flow-cell with 1 cm path length. As the electrolytic products were affected strikingly by oxygen gas, high-purity nitrogen gas was bubbled vigorously through the solution. ESR measurements were performed with a JEOL PE-3X following the method of Umemoto.[6]

† Present address: Department of Chemistry, Faculty of Science, Kochi University, Kochi 780.

Results and Discussion

Figure 1 shows the voltammograms of S_8 in acetonitrile solution with a rotating platinum electrode. S_8 was reduced through two steps. The half-wave potential ($E_{1/2}$) of the first and second wave was -1.20—-1.16 V and -1.60 V, respectively. The first wave was irreversible (log-plot slope of 100—200 mV), whereas the second seemed to be less irreversible (the slope of *ca.* 60 mV). The wave height of both the first and second wave were proportional to the concentration of S_8. The number of electrons involved in each step was found to be both about 2 electrons by controlled potential coulometry measurements at -1.4 V and -1.8 V. Therefore, S_8 may be reduced voltammetrically through the following process;

$$\text{at the first wave,} \quad S_8 + 2e \longrightarrow S_8^{2-} \qquad (1)$$

$$\text{at the second wave,} \quad S_8^{2-} + 2e \longrightarrow 2S_4^{2-} \qquad (2)$$

Figure 2 shows the current-time curves during coulometry. The current decreases exponentially when the potential is setted at -1.4 V, which corresponds to the first wave in voltammetry. The current reached to almost zero when about 2 electrons was consumed, but it still continued to flow very slowly until about 2.7 electrons. The solution turned purple in color gradually during the electrolysis and it changed into blue after Z^{**}=*ca.* 2.0. At -1.8 V (at the second wave), a

** Z indicates the number of electrons added to for S_8.

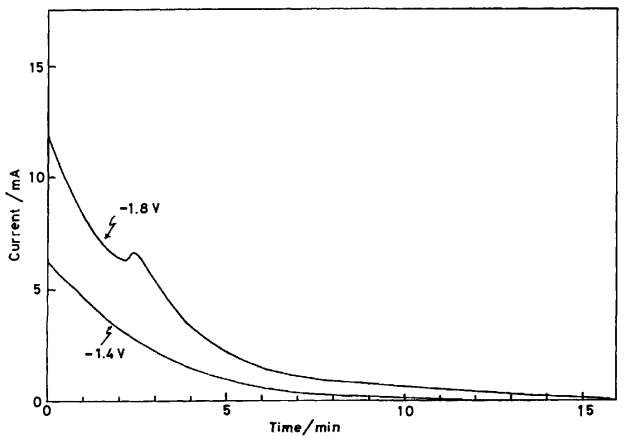

Fig. 2. Current-time relationship for the controlled potential coulometry of sulfur on Pt-gauze, $[S_8]=0.50\times10^{-4}$ M.

maximum of current was observed after a few minutes from the beginning of the electrolysis. The maximum and the minimum appeared each time at the constant number of electrons of 2.4—2.6 and 2.2—2.3, respectively, even if the position where they appear were shifted, changing the area of electrode or the concentration of the depolarizer ($[S_8]=0.1$—4.0×10^{-4} M***).

The relation between log i and t was linear for the both regions from the beginning of the electrolysis to the minimum and after the maximum. The slope of log i—t for the region after the maximum was larger than that to the minimum by the factor of 1.3—1.5. The color of the solution changed suddenly from purple to blue in the region where the current increased. These results may suggest that the electrode reaction in the region from the beginning of the electrolysis to the minimum is different from that after the maximum. The number of electrons reached 4 for S_8 after about ten minutes from the beginning of the electrolysis, but small current still continued to flow, the relation of log i—t deviating from the linearity.

The absorption spectra of the sulfur solution electrolyzed at −1.4 V are shown in Fig. 3. The spectrum had peaks of 613, 480, and 350 nm at $Z=2.0$. At about $Z=2.7$, the spectrum had peaks of 613, 450, and 270 nm and a shoulder of 340 nm. When the solution was electrolyzed at −1.8 V, it gave a spectrum similar to that of −1.4 V up to $Z=ca.$ 2.7. When the solution is completely electrolyzed at −1.8 V, however, the peak of 613 nm almost disappeared, and a peak of 330 nm and a shoulder of 400 nm appeared instead.

The change of absorbance at 613 and 480 nm during the electrolysis at −1.4 V is shown in Fig. 4. The absorbance at 613 nm increased with the increase of the number of electrons, and the increase of the absorbance was accelerated after $Z=2.0$. On the other hand, the absorbance at 480 nm reached the maximum at $Z=2$ and disappeared when the electrolysis was completed. The change of absorbance for the electrolysis at −1.8 V is also shown in Fig, 4. The same results were obtained as the case of the electrolyses at −1.4 V up to $Z=8/3$,

*** Throughout this paper 1 M = 1 mol dm^{-3}.

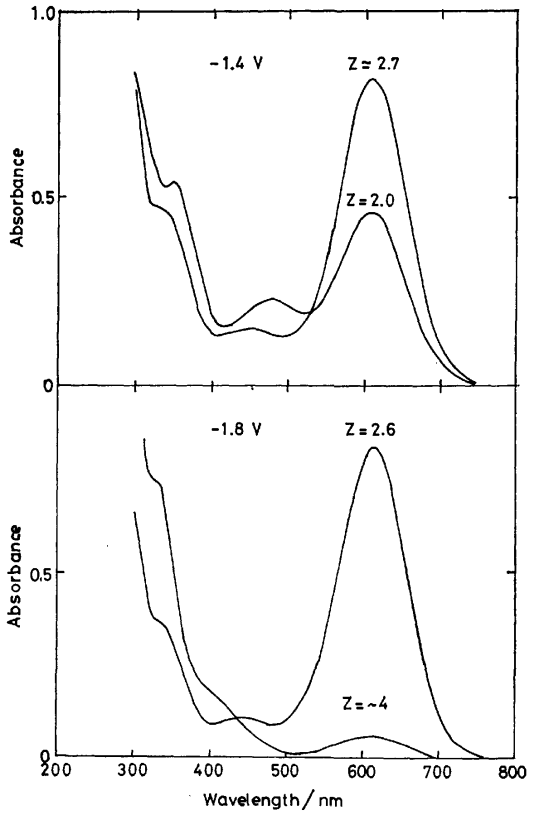

Fig. 3. Absorption spectra of sulfur solution after electrolysis at −1.4 and −1.8 V, $[S_8]=1.0\times10^{-4}$ M.

although the speed of electrolysis at −1.4 V was much slower than that at −1.8 V, especially after $Z=2.0$. The peak intensity at 613 nm began to decrease after $Z=8/3$ and almost disappeared when the electrolysis was completed. The peak at 330 nm appeared instead of the peak of 340 nm after $Z=8/3$.

These results show that the same products are obtained regardless of the potential of electrolysis so long as the same number of electrons. Considering the number of electrons, the peak at 480 nm is due to S_8^{2-}, that at 613 nm to S_6^{2-} (or a species derived from S_6^{2-}), and that at 330 nm may be to S_4^{2-}.

The color of the solution turned blue when unelectrolyzed S_8 solution was added to the solution completely electrolyzed at −1.8 V which looks yellow. Figure 5 (upper) shows the absorbance of the solution of various mixing ratio. The change of absorbance at 613, 480, and 330 nm of the mixed solution is similar to that of the solution electrolyzed at −1.8 V (see Fig. 4). This experiment shows that the following reaction occurs easily.

$$S_8 + 2S_4^{2-} \longrightarrow 2S_8^{2-} \quad (3)$$

Similary, the solution electrolyzed up to $Z=8/3$ at −1.8 V was mixed with unelectrolyzed S_8 solution (see the lower in Fig. 5). (At $Z=8/3$, all sulfur is formally S_6^{2-} state, as described in next paragraph). In this case, the resulting change of absorbance was the same as the case of the solution electrolyzed at −1.4 V. The appearence of the peak at 480 nm shows the formation of S_8^{2-} species.

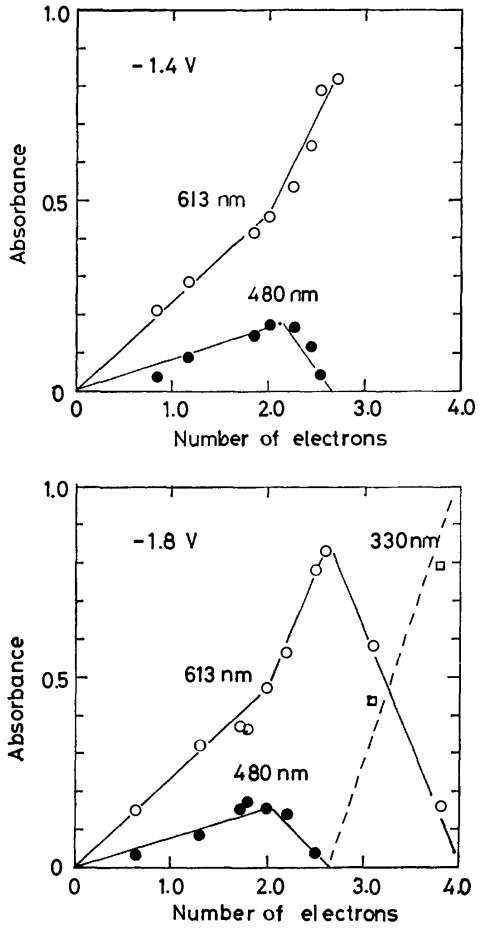

Fig. 4. Variation of absorbance during the electrolysis at -1.4 and -1.8 V.
(Absorbance at 480 and 330 nm is shown as the corrected value.)

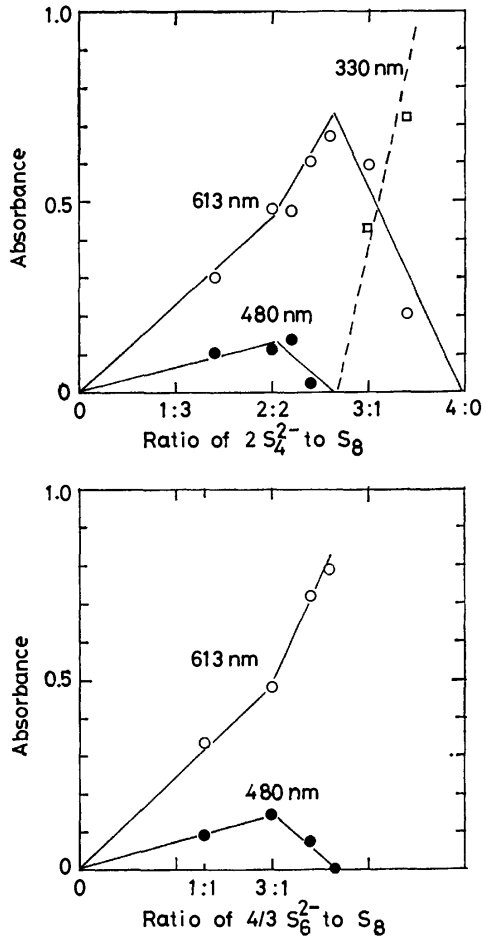

Fig. 5. Absorbance for the mixture of S_4^{2-} and S_8, and that of S_6^{2-} and S_8.
(See Fig. 4 for the absorbance at 480 and 330 nm.)

$$S_8^{2-} \overset{K}{\rightleftharpoons} S_6^{2-} + 1/4S_8 \quad (4)$$

The absorbance at $Z=8/3$ is plotted against the S_8 concentration without electrolysis in Fig. 6. At this point of the number of the electrons, all sulfur species must be formally "S_6^{2-}" state. The peak at 613 nm showed negative deviation (absorptivity falls off with increasing concentration). On the other hand, the peaks at 450 and 340 nm showed positive deviation. The spectra at $Z=8/3$ of various concentrations of S_8 showed an isosbestic point at 510 nm as shown in Fig. 7. These results suggest that S_6^{2-} dissociates into $S_3^{\cdot-}$, and the peak at 613 nm can be assigned to $S_3^{\cdot-}$ and those at 450 and 340 nm to S_6^{2-}. The presence of a radical with the g-value of *ca.* 2.03 was proved by the ESR measurement for the sulfur solution of 4×10^{-4} M at $Z=ca.$ 8/3. This g-value agrees well with that of $S_3^{\cdot-}$ species reported in the litareture.[7] Consequently, the blue species which shows the peak at 613 nm in acetonitrile is concluded to be $S_3^{\cdot-}$.

$$S_6^{2-} \overset{K_d}{\rightleftharpoons} 2S_3^{\cdot-} \quad (5)$$

The molar absorptivity of $S_3^{\cdot-}$ at 613 nm was obtained as $\varepsilon=3.9\times10^3$ and the dissociation constant for Eq. 5 as $K_d=1.2\times10^{-3}$ by the method of trial and error. The

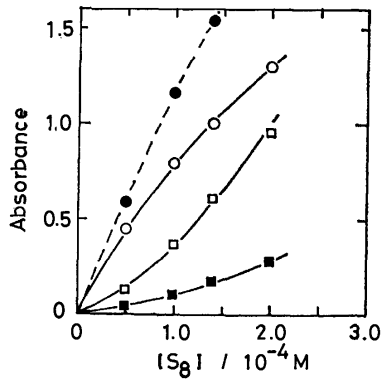

Fig. 6. Calibration curves of S_8 electrolyzed to $Z=8/3$ at -1.8 V.
●: 270, ○: 613, □: 340, ■: 450 nm.

molar absorptivity of S_6^{2-} is 3.1×10^3 at 450 nm, 1.1×10^4 at 340 nm. The peak of 270 nm may be due to $S_3^{\cdot-}$ judging from the behavior of the calibration curve.

In Fig. 8, the absorbance of electrolyzed solution at $Z=2.0$ is plotted against the initial S_8 concentration. At this point, sulfur must be electrolyzed to S_8^{2-} state.

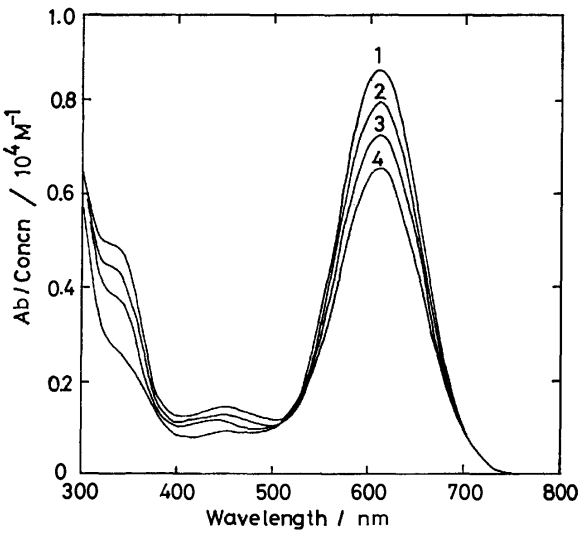

Fig. 7. Absorption spectra of S_8 electrolyzed to $Z=8/3$ at -1.8 V. Initial concn of S_8; 1: 0.5, 2: 1.0, 3: 1.4, 4: 2.0×10^{-4} M.

However, the S_8^{2-} produces more stable species, S_6^{2-} following the equilibrium of Eq. 4, so S_8^{2-}, S_6^{2-}, $S_3^{\cdot-}$, and S_8 exist together in the solution. The absorbance of $S_3^{\cdot-}$ at 613 nm deviated much more downwards from the linearity than the case of $Z=8/3$. The absorbance of 613 nm at $Z=2.0$, the molar absorptivity of $S_3^{\cdot-}$ ($\varepsilon=3.9\times10^3$) and the dissociation constant ($K_d=1.2\times10^{-3}$) enable the authors to calculate the equilibrium constant, K for Eq. 4 to be 1.6×10^{-2}. The peaks at 350 and 480 nm, due to S_8^{2-} showed positive deviation. The absorbances at 350 and 480 nm are enhanced by the additional absorption of the close peaks at 340 and 450 nm (both due to S_6^{2-}), respectively. From the corrected values of absorbance and the evaluated concentration of S_8^{2-}, the molar absorptivity of S_8^{2-} at 350 and 480 nm was obtained as 1.0×10^4 and 4.4×10^3, respectively.

As for the solution electrolyzed completely at the second wave, the absorbances at 330 and 400 nm,

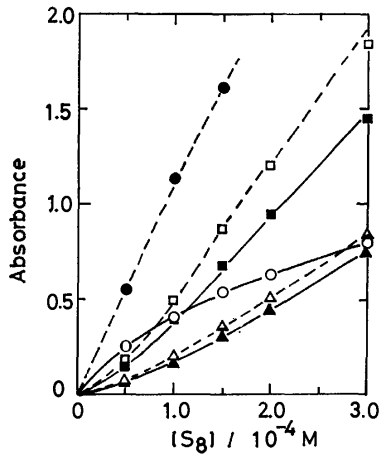

Fig. 8. Calibration curves of S_8 electrolyzed to $Z=2.0$ at -1.8 V.
●: 270, □: 350, ■: 350 corrected, ○: 613, △: 480, ▲: 480 nm corrected.

which may be due to S_4^{2-}, showed the linear dependence on the initial concentration of S_8. The molar absorptivity of S_4^{2-} at 330 and 400 is *ca.* 4.2×10^3 and 1.0×10^3, respectively. Sawyer *et al.*[3] reported the dissociation constant K_d to be 9×10^{-3}, and K in Eq. 4 to be 1.68×10^{-2} ($K^4=8\times10^{-8}$) in DMSO. However, the values obtained be Bonnaterre *at al.*[5] are much different from those by the present authors or Sawyer *et al.*[3]

The detail conditions were examined about the maximum of current in course of the coulometry at the potential of the second wave. First, the sulfur solution was electrolyzed to a certain number of electrons at -1.4 V. Then the potential was stepped to -1.8 V quickly, and the electrolysis current was recorded as shown in Fig. 9. The solution which was electrolyzed up to $Z=2.0$ at -1.4 V showed the maximum after the current decreased once. The solution electrolyzed to $Z=2.2$ showed a maximum just after the potential was stepped at -1.8 V. While, for the solution of $Z=2.5$ or more, the current decreased without the maximum.

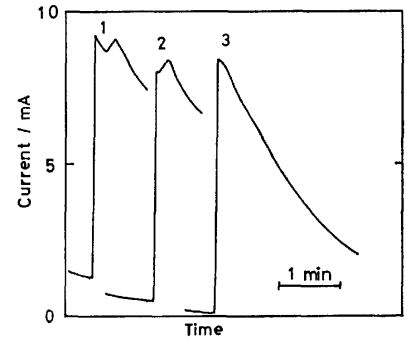

Fig. 9. Current after potential is stepped to -1.8 V from -1.4 V on various number of electrons.
$[S_8]=0.50\times10^{-4}$ M, 1: $Z=2.0$, 2: 2.2, 3: 2.5.

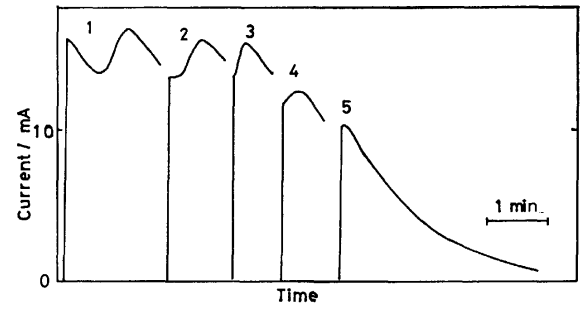

Fig. 10. Current change after addition of S_8 solutions into S_4^{2-} solutions.
Potential -1.8 V, ratio of $S_8/(2\,S_4^{2-})$; 1. 13: 7, 2. 11: 9, 3. 10: 10, 4. 8: 12, 5. 5: 15, total sulfur concn; 1.0×10^{-4} M in each case.

Similar results were obtained for the mixture of S_4^{2-} and unelectrolyzed S_8 solution as shown in Fig. 10. The solution with the mixing ratio $S_8/2S_4^{2-}$ of 10: 10, in which solution, sulfur is calculated to be $Z=2.0$ state, showed the maximum when electrolyzed at -1.8 V. The solution of the ratio of 5: 15 ($Z=3.0$ state), however, did not show the maximum any more. These

results clarify again that the appearence of the maximum in the coulometry is related to only the number of electrons up to which the sulfur is electrolyzed. As shown above, the products are same, that is, S_8, S_8^{2-}, S_6^{2-}, and $S_3^{\cdot-}$ are present each other at the same ratio of concentration when electrolyzed at -1.4 V or -1.8 V, only if the solution is in a same "electron state." The difference between the solutions electrolyzed at -1.4 and -1.8 V is whether the species of S_4^{2-} exists or not, which is observed apparently only after $Z=8/3$ at -1.8 V. It seems that the maximum current in coulometry at the second wave potential is caused by attacking of S_4^{2-} to S_8.

Lingane and Niedrach[8] observed similar i—t behavior during the electrochemical reduction of selenium (IV) in an aqueous buffer. They attributed the cause of the maximum of current to the formation of easily reduced polyselenide Se_x^{2-} by attacking of the final product Se^{2-} to elemental selenium.

The authors wish to express their thanks to Mr. Tsutomu Nagaoka for his kind assistance in the measurements of ESR spectra.

The Electrochemical Studies of Tetrasulfur Tetranitride in Acetonitrile

Masashi Hojo*

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received March 1, 1980)

$S_4(NH)_4$ has been prepared in a good yield (80% or more) by the electrolytic reduction (4-electrons) of S_4N_4 in the presence of a proton donor in acetonitrile. In the proton donor, a fairly high acidity (acetic acid or a stronger acid) and a much higher concentration than would be expected from the stoichiometry was needed. With a low acidity (*e.g.*, phenol) or a low concentration of the proton donor, a side reaction occurred with the formation of H_2S and NH_3. Under these conditions, a blue species was produced in the course of the electrolysis; this species was confirmed to be S_3^-. The re-oxidation of $S_4(NH)_4$, the oxidation of S_4N_4, and the reduction of $S_4(NH)_4$ were also examined in this connection.

The present author and his co-workers have investigated the electrode reaction with disulfur dichloride (S_2Cl_2),[1] which has a bond of sulfur-chlorine, and elemental sulfur (S_8),[2] which has only a bond of sulfur-sulfur. Tetrasulfur tetranitride (S_4N_4) is the best-known nitride of sulfur, and it has formed the starting point of most previous investigations in sulfur-nitrogen chemistry.

The reduction of S_4N_4 with potassium metal in 1,2-dimethoxyethane has been reported by Chapman and Massey[3] to produce a species of color changes attributed to ions of the $S_4N_4^{n-}$ type (n=1—4). Meinzer *et al.*[4] assigned the ESR spectrum produced by the electrochemical reduction of S_4N_4 in acetonitrile to $S_4N_4^-$, which has a structure similar to S_4N_4. It was further demonstrated that this radical anion is only stable at temperatures below *ca.* −25 °C, while above 0 °C rapid decomposition occurs. Prater *et al.*[5] conclusively identified the $S_4N_4^-$ radical and showed that it decayed according to a first-order rate law. However, it was unknown what species was produced by the decomposition of the $S_4N_4^-$ radical. Very recently, Bojes *et al.*[6,7] confirmed the formation of the $S_3N_3^-$ ion as the final product of the electrochemical reduction of S_4N_4 in ethanol at room temperature.

$$S_4N_4 + 4/3e \longrightarrow 4/3\ S_3N_3^-$$

In the present paper, the mechanism of the electrochemical reaction for S_4N_4 and the related compounds in acetonitrile will be reported. The effect of proton donors on the electrode reaction will also be examined in detail.

Experimental

Reagents. S_4N_4 was prepared from S_2Cl_2 and ammonia.[8] IR absorptions (CS_2 solvent) occurred at 940 m and 700 s cm^{-1}. Found: S, 68.83, N, 30.50%. Calcd for S_4N_4: S, 69.59, N, 30.41%. $S_4(NH)_4$ was prepared by the reaction of S_4N_4 with methanolic tin(II) chloride.[9] Its IR spectrum (KBr) was coincident with in the literature.[10] Found: S, 67.88, N, 30.09, H, 2.3% . Calcd for S_4N_4: S, 68.1, N, 29.8, H, 2.1%.

The method of purifying acetonitrile and the method of preparing the Et_4NClO_4 used as a supporting electrolyte has been described elsewhere.[1] The other chemicals were of G. R. grade and were used without further purification.

* Present address: Department of Chemistry, Faculty of Science, Kochi University, Kochi 780.

Apparatus and Procedure. The apparatus and equipment used in the voltammetry, controlled potential coulometry, spectrophotometry, and ESR measurements were the same as those used before.[1,2] IR spectra were measured by a Japan Spectroscopic Co., Ltd., Diffraction Grating Infrared Spectrometer, Model IRA-1. The dropping mercury electrode had the following characteristics: m=0.70 mg/s at 60 cm in the open circuit, τ=4.3 s at −1.1 V *vs.* a Ag/0.1 M** $AgClO_4$–AN electrode in 0.1 M Et_4NClO_4–AN solution. The rotating platinum electrode had a geometric surface area of 0.10 cm^2.

The concentration of the hydrogen ion in an acetonitrile solution was determined, after a good amount of water had been added to the solution, by titration with Et_4NOH (6.75 mM aqueous solution) using a Horiba glass electrode. Ammonia and hydrogen sulfide were trapped successively in 0.005 M H_2SO_4 and 0.1 M KOH aqueous solutions respectively. The ammonia was analyzed by the Nessler method, while the hydrogen sulfide was detected by the use of sodium nitroprusside and determined by polarography.

Results and Discussion

Reduction of S_4N_4. A polarogram of S_4N_4 in acetonitrile is shown in Fig. 1; it gives main two reduction waves. The half-wave potentials of the two waves were −0.93 and −2.58 V respectively. The limiting currents for both waves were proportional to the concentration in the range from 0.5 to 5×10^{-4} M. In

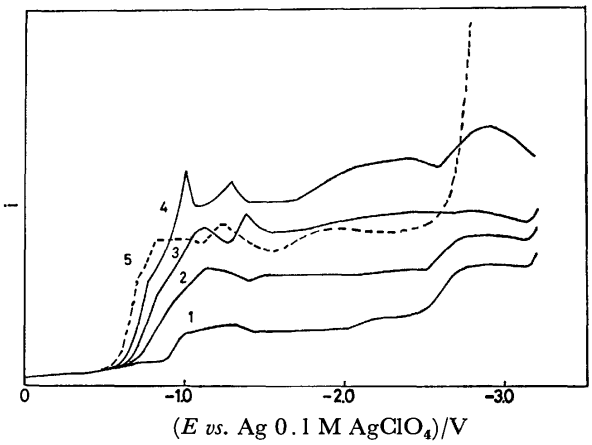

Fig. 1. Polarograms of 0.1 mM S_4N_4 with acetic acid in acetonitrile containing 0.1 M Et_4NClO_4.
(1) 0, (2) 0.2, (3) 0.5, (4) 1.0, (5) 5.0 mM of the acid.

** Throughout this paper 1 M=1 mol dm^{-3}.

order to determine the number of electrons involved in the reduction, a S_4N_4 solution was electrolyzed at the controlled potential of -1.2 V on a Hg-pool electrode; this gave a *n*-value of 1.3 for the first wave. The electrolyzed solution was pumped into an optical flow-cell, and the absorption spectrum was measured to give a peak at 360 nm. The product can be identified as $S_3N_3^-$ according to the *n*-value and the peak wavelength, with reference to the results in ethanol.[6] The absence of the $S_4N_4^{\cdot-}$ radical in the solution (the initial concn of S_4N_4 was $1—5\times10^{-4}$) at room temperature was proved by ESR measurements, as predicated by Meinzer *et al.*[4] The further reduction at the second wave caused the solution to turn colorless from yellow, with an *n*-value of 5—6 electrons.

Table 1. Voltammetric and coulometric data for S_4N_4 and $S_4(NH)_4$

Electrode	Reduction		Oxidation
	Hg	Pt	Pt
S_4N_4			
$E_{1/2}$/V	-0.93, -2.58	-0.95, (-1.48)[a]	$+1.64$
Slope[b]/mV	57.2, 120	61	170
n-Value[c]	1.3 (5—6)	1.3	*ca.* 4.0
$S_4(NH)_4$			
$E_{1/2}$/V	-2.80[d]	—[e]	$+0.95$, $+1.62$
Slope[b]/mV	127[d]		180, 140
n-Value[c]	($\approx$6)		4.0

a) A small wave appeared. b) Slope of the $-E$ *vs.* log-$[(i/(i_d-i)]$ plot. c) The number of electrons obtained by coulometry. d) Estimated value attributable to a polarographic maximum. e) With a Pt electrode, the potential can be measured to -2.0 V *vs.* Ag/0.1 M $AgClO_4$–AN at most.

The results of the voltammetry and coulometry with a platinum electrode were similar to those with mercury electrode for the first wave, as shown in Table 1, except that the absorbance at 360 nm due to $S_3N_3^-$ by the electrolysis on Hg-pool was a little smaller than that on Pt-electrode. This difference may be caused by the interaction between $S_3N_3^-$ and mercury. The molar absorptivity of $S_3N_3^-$ at 360 nm was estimated to be *ca.* 8.2×10^3 in acetonitrile, based on the experiments with Pt-gauze.

By the addition of acetic acid as a proton donor to a S_4N_4 solution, the wave height of the first wave increased and the half-wave potential shifted positively (see Fig. 1). Similar results were also obtained with benzoic acid of a degree of acidity similar to that of acetic acid.

Figure 2 shows the dependence of the wave height of the first wave on the concentration of the proton donor. With the addition of acetic acid or chloroacetic acid, the wave height increased by a factor 5—6, compared to that without a proton donor. The wave height decreased upon the further addition of the acids and then attained a constant value (*ca.* 3.5—4 times). With phenol, which is a much weaker acid, the wave

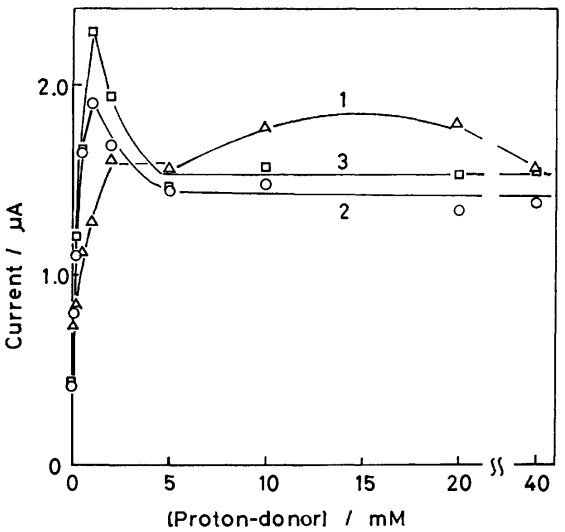

Fig. 2. Effect of proton-donor on the first wave height of S_4N_4. $[S_4N_4]=0.1$ mM, (1) phenol, (2) acetic acid, (3) monochloroacetic acid.

height increased by a factor of 4—5. The effect of water on the polarogram of S_4N_4 was very small. The presence of 5% water in acetonitrile made the first wave height increase by only a foctor of 1.6, while the second wave was not changed.

The increase in the wave height in the presence of proton donors suggested an increase in the *n*-value in the electrode precess. Figure 3 shows the *n*-values in the controlled potential coulometry with the Hg-pool electrode in the presence of proton donors. Without a proton donor, the *n*-value is 1.3, as mentioned above. However, the *n*-value increased to 8.2 with the addition of 5 mM of acetic acid to 0.1 mM of S_4N_4, and attained a constant value of 4.0 with 400 times acid, as much, when electrolyzed at -1.2 V. At -1.8 V, the *n*-value exceeded 10 with 2 mM of the acid and then decreased with more acid, but it never reached as law as 4.0.

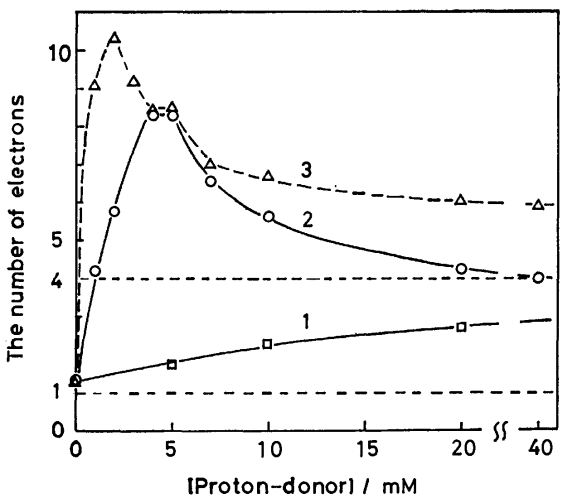

Fig. 3. The number of electrons in controlled potential coulometry. $[S_4N_4]=0.1$ mM, on Hg-pool electrode, (1) with phenol, potential at -1.2 V, (2) acetic acid, at -1.2 V, (3) acetic acid, at -1.8 V.

With phenol at −1.2 V, although the *n*-value increased from 1.3 toward a large value, a black solid was formed over the mercury electrode surface. The same black solid was also observed in the case of the presence of less than 2 mM of acetic acid.

The formation of $S_4(NH)_4$ was suggested by the *n*-value of 4 in the presence of acetic acid. The absorption spectrum of the solution electrolyzed at −1.2 V with 40 mM of acetic acid to 0.1 mM of S_4N_4 is shown in Fig. 4. $S_4(NH)_4$ gave a shoulder near 235 nm with a molar absorptivity of *ca.* 1.9×10^3 in acetonitrile, and the electrolyzed S_4N_4 solution showed the same spectrum as $S_4(NH)_4$. The yield was directly estimated to be about 90%, but the intensity of the shoulder was so small that an error may have occurred. Accordingly, the tetraimide produced was re-oxidized back to S_4N_4 at +1.2 V on the Pt electrode, and the absorbance at 250 nm was compared with that of the initial S_4N_4. The molar absorptivity of S_4N_4 at 250 nm was *ca.* 1.6×10^4. The yield in an experiment was 81%. As will be described in detail in the following section, the re-oxidation, that is, the oxidation of $S_4(NH)_4$ to S_4N_4 was established to proceed almost quantitatively. The formation of $S_4(NH)_4$ was confirmed also by voltammetry with a platinum electrode.

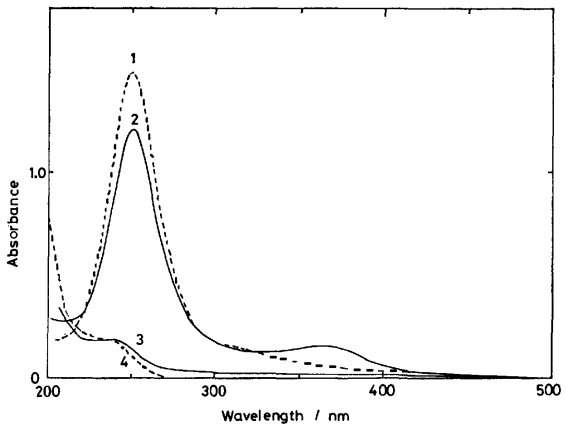

Fig. 4. Absorption spectra of the product from S_4N_4. (1) original 0.1 mM S_4N_4 solution. (2) oxidation (+1.2 V) product from (3), (3) reduction (−1.2 V) product from S_4N_4 with 40 mM acetic acid, (4) 0.1 mM $S_4(NH)_4$ solution. The absorption of the acid is corrected for (2) and (3).

For a higher concentration of S_4N_4 (*e.g.*, 0.2 or 0.5 mM), the tetraimide was obtained with about 400 times as much acid as S_4N_4. The product was isolated by being evaporated to dryness at room temperature; it was then washed with distilled water to remove the supporting electrolyte and the residues of the solvent and the acid. The IR spectrum of the product coincided with that of $S_4(NH)_4$ prepared chemically.

The above result can be summarized as follows: in the presence of a proper proton donor, S_4N_4 is reduced, and then the proton addition occurs, forming tetrasulfur tetraimide:

$$S_4N_4 + 4HA + 4e \longrightarrow S_4(NH)_4 + 4A^- \quad (1)$$

Acetic acid is such a weak acid in acetonitrile (pK_d= 22.3 by Kolthoff and Chantooni[11]) that it does not dissociate by itself to proton and acetate ions. The polarograms of the electrolyzed solution which formed $S_4(NH)_4$ showed a complicated anodic wave of mercury dissolution. This wave is thought to be caused by the acetate ion (A^-) or HA_2^-. The acetate ion is very active in an aprotic solvent. Kolthoff and Chantooni[11] have represented the constant of $K_{homo}=4.7\times10^3$ for the following homoconjugation reaction for acetic acid in acetonitrile: $A^- + HA \rightleftarrows AHA^-$

The fact that the yield of the tetraimide formation decreases, and the *n*-value far exceeds 4, with low concentrations of acetic acid suggests that the decomposition of S_4N_4 occurs as one of the side reactions. In the presence of about 40 times as much acetic acid as S_4N_4, the following reaction was confirmed to occur about 30% from the analysis of H_2S and NH_3:

$$S_4N_4 + 20HA + 20e \longrightarrow 4H_2S + 4NH_3 + 20A^- \quad (2)$$

The anodic wave in the polarogram of the solution after the electrolysis which formed H_2S and NH_3 was much higher than that in the case of Eq. 1. The acetate ion thus produced was determined by means of amperometric titration with 0.1 M $HClO_4$–AN solution. Under the conditions in which the reaction of Eq. 1 proceeds fully, the electrolyzed solution consumed 4 equivalents of the perchloric acid. On the other hand, with 40 times as much acetic acid as S_4N_4, the electrolyzed solution consumed 8 equivalents, which corresponds to the *n*-value in coulometry.

Another evidence of the decomposition reaction is the fact that the solution turned blue in the course of the electrolysis when 2—5 mM of acetic acid or 5—20 mM of phenol was added to 0.1 mM of S_4N_4. The absorption spectra gave a peak at 613 nm, as is shown in Fig. 5, with acetic acid. (The spectra with 2 mM

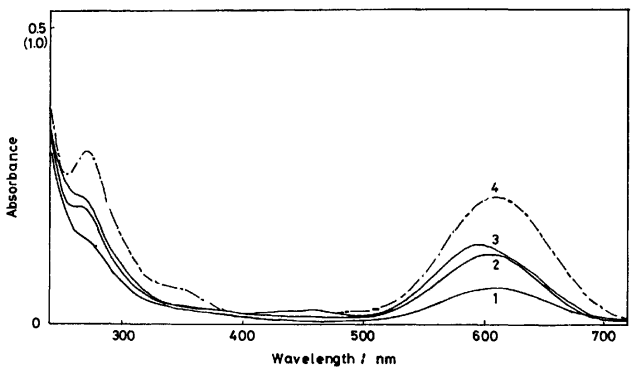

Fig. 5. Absorption spectra of S_4N_4 and S_8 solution in the course of electrolysis at −1.8 V†. (1) $[S_4N_4]$= 0.1 mM, with acetic acid 5 mM, Z=*ca.* 6.9, (2) with acetic acid 3 mM, Z=*ca.* 7.7 (3) with acetic acid 2 mM, Z=*ca.* 7.8, (4) $[S_8]$=0.05 mM, Z=2.66.†† The enlarged scale of absorbance should be used only for (4).

† As the decomposition reaction seemed to proceed more greatly at −1.8 V than −1.2 V according to Fig. 3, the results for −1.8 V are shown here. At −1.2 V, of course, the S_4N_4 solution gives same blue Species as −1.8 V.

†† S_8 is reduced to $S_3^{\cdot-}$ at Z=2.66, see Ref. 2) in detail.

of the acid gave a peak at 590 nm at $Z^{***}=7.8$, but the peak shifted to 613 nm at $Z=8.2$). Here, the blue species was confirmed to be S_3^-, for the author and co-workers have previously established[2] that the blue species is S_3^-, which gives a peak at 613 nm in the electrolytic reduction of elemental sulfur in acetonitrile. The sulfur produced by the decomposition of S_4N_4 passes through the stable species, S_3^-, before being utterly reduced to H_2S.

Proposed reduction mechanism

$$S_4N_4 \xrightarrow{e} S_4N_4^- \xrightarrow{H^+,\,e} S_4(NH)_4$$

$$\downarrow$$

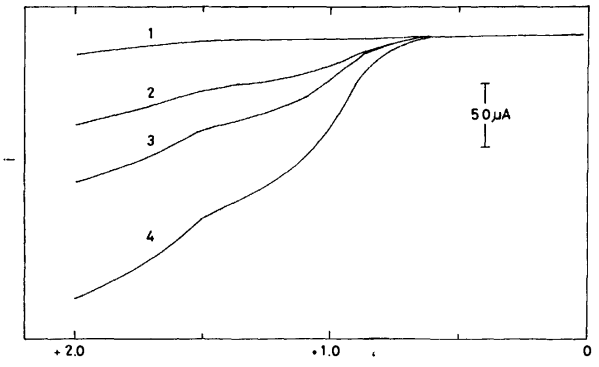
$$S_3N_3^- \xrightarrow{H^+,\,e} S_3^-,\ NH_3,\ \text{and other products}$$

$$\downarrow H^+,\,e$$

$$H_2S$$

Scheme 1.

All the experiments suggest the reduction mechanism shown in Scheme 1. $S_4(NH)_4$ would be formed through the $S_4N_4^-$ radical if the radical is surrounded by a large amount of proton donors, so the protonation to $S_4N_4^-$ occurs easily. The protonated species may be reduced further at the same potential, and the protonation and the reduction will continue until $S_4(NH)_4$ is formed. Without a proton donor, $S_4N_4^-$ decomposes to $S_3N_3^-$ very rapidly at room temperature. When the $S_4N_4^-$ is not protonated enough with a small amount of the proton donor, almost all the radicals may decompose to $S_3N_3^-$. The formation of NH_3 or H_2S may occur through the species of $S_3N_3^-$. It seems reasonable to regard the species of $S_3N_3^-$ as the intermediate of the decomposition reaction, because the electrolysis of $S_3N_3^-$ in the presence of a sufficient amount of the acid did not produce the tetraimide any more, but NH_3, H_2S, and others.



(E *vs.* Ag/0.1 M $AgClO_4$)/V

Fig. 6. Anodic waves of $S_4(NH)_4$ in acetonitile containing 0.1 M Et_4NClO_4 on the rotating platinum electrode. (1) 0, (2) 0.1, (3) 0.2, (4) 0.4 mM of $S_4(NH)_4$.

*** Z indicates the number of electrons added for S_4N_4.

The Oxidation of $S_4(NH)_4$ and S_4N_4, and the Reduction of $S_4(NH)_4$. $S_4(NH)_4$ was oxidized in two steps on the rotating platinum electrode, as is shown in Fig. 6 (see also Table 1). The limiting current of the first wave was proportional to the concentration of the depolarizer in the range of 0.1—0.7 mM. The second wave was much smaller than the first wave. The controlled potential coulometry at +1.2 V on the Pt-gauze electrode gave the n-value of 4.0 ± 0.15 for the first wave. The absorption spectrum of the solution just after the electrolysis had a peak at 250 nm, which showed the formation of S_4N_4 in a 96% yield. About 4 equivalents of the hydrogen ion were detected in the solution by acid-base titration. Therefore, the following electrode reaction is proved to occur almost quantitatively at +1.2 V:

$$S_4(NH)_4 \longrightarrow S_4N_4 + 4H^+ + 4e \qquad (3)$$

The yield for this electrode reaction was largely dependent on the potential at which the tetraimide was oxidized. For example, the yield of S_4N_4 fell to 68% at +1.3 V, and S_4N_4 was little detected by means of the UV spectrum at +1.4 V. The absorbance at 250 nm decreased with the passage of time because the proton produced behaved as a strong acid in acetonitrile and reacted with S_4N_4 to decompose. The reaction of the proton may also be related to the fact that the analyzed concentration of the proton was smaller than the calculated value by a factor of more than 10% several hours after the experiment of the electrolysis. When perchloric acid of 5 mM was present in the S_4N_4–AN solution of 0.1 mM, the absorbance at 250 nm decreased by factors of 2.7 and 4.1% after 15 min and 1 h respectively. On the other hand, hydrochloric acid of 1 mM caused the absorbance of S_4N_4 to decrease to half after 5 h. Nair and Murthy[12] reported that, when the sulfur nitride allowed to react with anhydrous hydrogen iodide in nonaqueous solvent like carbon tetrachloride, all the sulfur was reduced to hydrogen sulfide and that all the nitrogen was converted into ammonia as per the equation:

$$S_4N_4 + 20HI \longrightarrow 4H_2S + 4NH_3 + 10I_2$$

As the half-wave potential of the second wave of the imide is close to that of the anodic wave of S_4N_4, as is shown in Table 1, the S_4N_4 derived from $S_4(NH)_4$ may be thought to be further oxidized at the second wave. However, the second wave height of $S_4(NH)_4$ is much smaller than the wave height of S_4N_4, which is probably due to the proton produced at once according to Eq. 3. S_4N_4 was, furthermore, oxidized with a n-value of *ca.* 4.0 by controlled-potential coulometry at +2.0 V on the Pt-gauze electrode. The absorption spectrum of the product gave a peak at 280 nm, which might be due to the SN^+ ion, judging from the n-value of 4. The species of SN^+ has already been isolated in the $SN^+\cdot AsF_6^-$ form.[13] S_4N_4 may be oxidized as follows:

$$S_4N_4 \longrightarrow 4SN^+(?) + 4e \qquad (4)$$

$S_4(NH)_4$ gave a reduction wave accompanied by a polarographic maximum on a dropping mercury electrode before the cation of the supporting electrolyte (Et_4N^+) was reduced. The wave height was proportional

to the concentration of the depolarizer of 0.1—0.5 mM, and the number of electrons involved in the reduction step was estimated to be unity from the wave height. However, the current showed unusual behavior in coulometry at −3.0 V with a Hg-pool electrode: The current initially decreased in the usual manner, the solution turning pale red-purple. Then the current increased again with the color disappearance just after the 1-electron was consumed, and subsequently went through a maximum. Finally, an *n*-value of near 6 was obtained. This result might suggest that $S_4(NH)_4^-$ is produced by the one-electron reduction of $S_4(NH)_4$ and decomposed by the further addition of electrons. A similar current maximum in coulometry has previously reported for elemental sulfur in acetonitrile.[2)]

Conclusion

In a chemical preparation of the tetraimide, water or alcohol gives hydrogen to S_4N_4 to produce $S_4(NH)_4$. However, not even phenol can contribute to the formation of $S_4(NH)_4$; only acetic acid or a stronger acid can do so in an electrochemical reduction.

The author is indebted to Professor Taitiro Fujinaga for his invaluable advice and encouragement. Thanks are also due to Dr. Satoshi Okazaki for some valuable suggestions. The elemental analyses were made in the Laboratory for Organic Elemental Microanalysis Faculty of Pharmaceutical Science, Kyoto University. The author wishes to express his thanks to the Laboratory.

The Determination of the Oxidation States of Neptunium in Sodium Hydroxide Solutions by Adsorption on Zirconium(IV) Hydroxide

Yoshinobu SHIOKAWA,* Akiko SATŌ, and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira, Sendai 980

(Received March 4, 1980)

An adsorption method for determining the distribution of the oxidation states of neptunium in sodium hydroxide solutions is proposed. In the range of sodium hydroxide concentrations of 1—2 M (1 M=1 mol dm^{-3}), the Np(V) was almost entirely adsorbed on zirconium(IV) hydroxide, while both Np(VI) and Np(VII) remained in the supernatant. By means of this adsorption method, it was found that Np(V) in tracer quantities, though it was most stable in acidic or neutral solutions, was not the most stable state in sodium hydroxide solutions. Also, the oxidation and reduction of Np in sodium hydroxide solutions were investigated.

Since the discovery of heptavalent neptunium in sodium hydroxide solutions,[1] the chemical behavior of neptunium in those solutions has been investigated with interest. From the polarographic study, the oxidation states found in sodium hydroxide solutions were the penta-, hexa-, and heptavalent states.[2] In order to investigate this chemical behavior it is important to find a method both for preparing the oxidation state of interest and for determining the distribution of the oxidation states in sodium hydroxide solutions. Certainly there are some oxidants suitable for the preparation of heptavalent neptunium; also, we can satisfactorily confirm its existence by means of spectrophotometry.[1]

However, no reductant or oxidant suitable for preparing penta- and hexavalent neptunium in sodium hydroxide solutions has been found, though they have been prepared by electrolysis.[3,4] Unfortunately, spectrophotometry is quite insensitive for identifying these two oxidation states because of the low solubility and low molar-extinction coefficients.[5] The absorption spectra of neither penta- and hexavalent neptunium in sodium hydroxide solutions has yet been published. Thus, in order to determine the distribution of the oxidation states of neptunium in sodium hydroxide solutions, a method different from spectrophotometry and applicable to low concentrations of neptunium is required. For this purpose it is necessary to prepare the oxidation state of interest. However, neither the determination method nor the preparation method for the oxidation states of neptunium in sodium hydroxide solutions has been established except for heptavalent neptunium of an ordinary concentration.[1]

In the first step of the present work, the oxidation states of neptunium in sodium hydroxide solutions were tentatively divided into the "reduced state" and the "oxidized state." The "reduced state" was prepared by the addition of hydrazine, and the "oxidized state," by the addition of bromine. As a result of our examination, the difference in chemical behavior necessary for discriminating these two states was found in the adsorption on zirconium(IV) hydroxide. Second, the oxidation state of the reduced and oxidized neptunium was determined by the titration of heptavalent neptunium. Third, the oxidation and reduction of neptunium in sodium hydroxide solutions were examined by utilizing the adsorption on zirconium(IV) hydroxide.

Experimental

The stock solution of sodium hydroxide was prepared by filtrating its saturated solution through a Millipore Mitex filter with a pore size of 10 μm. In order to prevent the sodium hydroxide solutions from being contaminated by carbon dioxide or neptunium from being oxidized by air, the necessary experimental procedures were carried out in an atmosphere of nitrogen or argon gas.

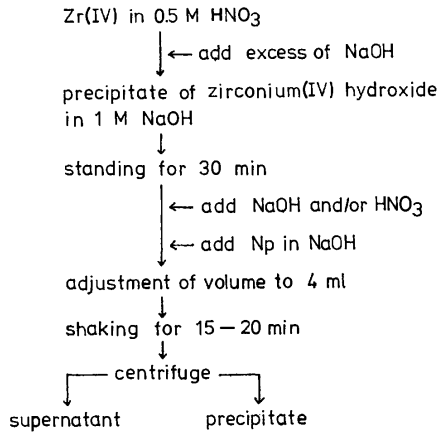

Fig. 1. Experimental procedures of the adsorption on zirconium (IV) hydroxide.

The reduced and oxidized neptunium in sodium hydroxide solutions were prepared by alkalizing a 0.5 M nitric acid solution of neptunium and by then adding hydrazine or bromine respectively. The ^{237}Np was obtained from The Radiochemical Centre, Amersham, while the ^{239}Np tracer was prepared by milking from ^{243}Am by the method of Espinosa.[6] In the preliminary experiments it was confirmed that the reduced and oxidized neptunium in sodium hydroxide solution were neither centrifuged nor adsorbed on glass.

The procedures for the adsorption on zirconium(IV) hydroxide are shown in Fig. 1. A suitable aliquot of a 0.5 M nitric acid solution of zirconium(IV) was transferred into a glass test tube equipped with a plug. In order to obtain zirconium(IV) hydroxide, a sodium hydroxide solution was added to an excess concentration of 1 M, and then, after 30 min, we added a sodium hydroxide solution and/or nitric acid solution in order to adjust the hydroxide ion-concentration. Then the sodium hydroxide solution of neptunium in the desired state was added, and the volume of the mixture was adjusted to 4 ml. The mixture was shaken for time enough to obtain an apparently constant adsorption. The recommended shaking

time was 15—20 min. By measuring the ^{239}Np activity by means of a NaI scintillation or Ge detector in both the mixture and the supernatant obtained by centrifuging, the percentage of neptunium adsorbed was determined.

The procedures for the titration of heptavalent neptunium were as follows. Heptavalent neptunium of about 5×10^{-4} M was prepared by the passage of ozone into $^{237+239}Np$ hydroxide in a 1 M sodium hydroxide solution, after which the excess ozone was swept out by argon-gas bubbling. The heptavalent solution (2—2.5 ml) was then transferred into a glass test tube equipped with a plug, and then 1×10^{-2} M hydrazine solution of 5—100 μl was added. After it was stood for 20—60 min at room temperature or 40 °C, this mixture was centrifuged, taking account of the low solubility of all the oxidation states except the heptavalent state. The supernatant was transferred into another test tube, and the adsorption on zirconium(IV) hydroxide was examined. In this experiment, the dissolved oxygen in the solution was swept out by the particularly careful passage of argon through just before use. The neptunium was determined by α- and γ-spectrometry, and the hydrazine, by iodometry.

Results and Discussion

Adsorption of the Reduced and Oxidized Neptunium on Zirconium(IV) Hydroxide. At first, the adsorption behavior on zirconium(IV) hydroxide under the various conditions was investigated for both the reduced and the oxidized neptunium in tracer quantities. Figure 2 shows the dependence of the adsorption on the amount of zirconium(IV) in a 0.96 M sodium hydroxide solution. In the range of 0.5—5 mg zirconium(IV), more than 95% of the reduced neptunium was adsorbed; on the other hand, the adsorbed fraction of the oxidized neptunium was less than 5%.

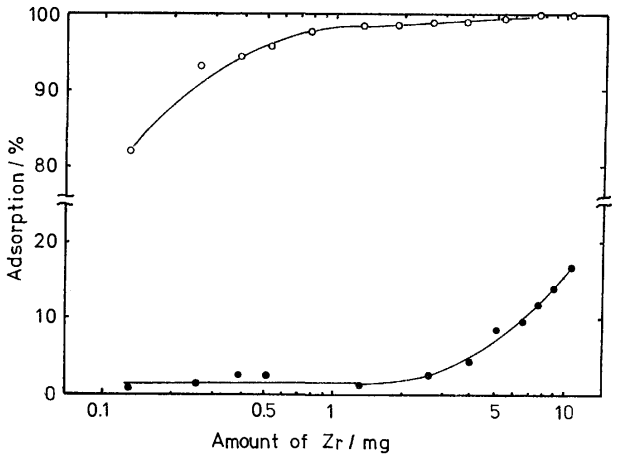

Fig. 2. Dependence of the adsorption on the amount of Zr(IV) at 0.96 M NaOH.
○: $Np+N_2H_4\cdot2HCl(1\times10^{-3}$ M),
●: $Np+Br_2(2\times10^{-2}$ M).

Figure 3 shows the dependence of the adsorption on the concentration of sodium hydroxide at a constant amount of zirconium(IV). For the reduced neptunium, the fraction adsorbed was about 99% in the range of the concentration of sodium hydroxide from 0.2 to 1 M; it decreased with the increase in the concentration,

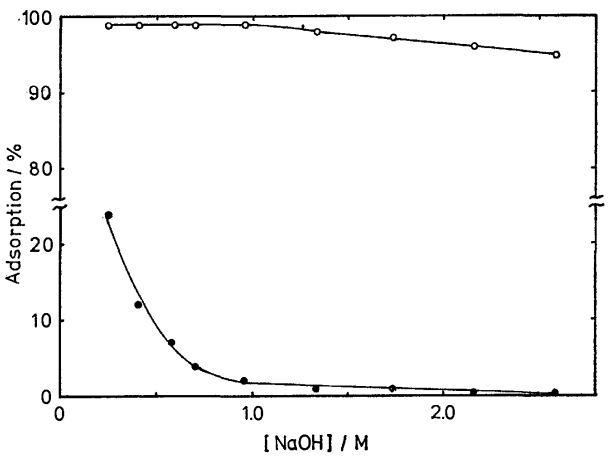

Fig. 3. Dependence of the adsorption on the concentration of NaOH using 2.9 mg Zr(IV).
○: $Np+N_2H_4\cdot2HCl(1\times10^{-3}$ M),
●: $Np+Br_2(1\times10^{-2}$ M).

reaching about 95% at 2.5 M. For the oxidized state, the fraction adsorbed was less than 2% above the concentration of 1 M, but it increased below 1 M.

Considering the dependency of the adsorption on both the amount of zirconium(IV) and the concentration of sodium hydroxide, as is shown in Figs. 2 and 3, it is possible to discriminate between the reduced and oxidized neptunium, if the adsorption is carried out with from 0.5 to 5 mg of zirconium(IV) per 4 ml of the mixture and at a sodium-hydroxide concentration from 1 to 2 M.

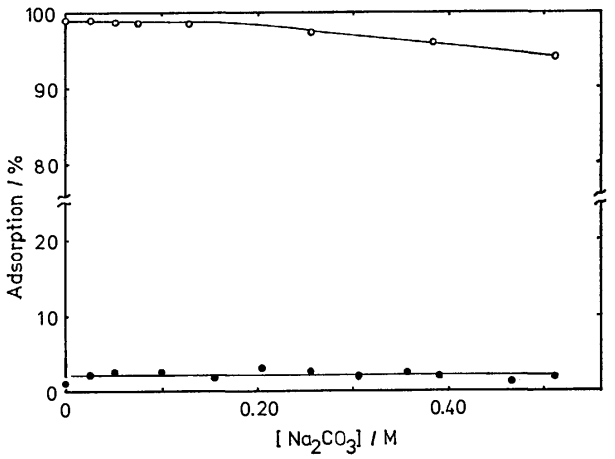

Fig. 4. Dependence of the adsorption on the concentration of Na_2CO_3 at 1.16 M NaOH using 2.6 mg Zr(IV).
○: $Np+N_2H_4\cdot2HCl(1\times10^{-3}$ M),
●: $Np+Br_2(2\times10^{-2}$ M).

The dependence of the adsorption on the concentration of the carbonate at a constant amount of zirconium(IV) and a constant concentration of sodium hydroxide is shown in Fig. 4. In the range of the carbonate concentrations examined, the fraction of the oxidized neptunium adsorbed remained constant, whereas that of the reduced neptunium was somewhat decreased

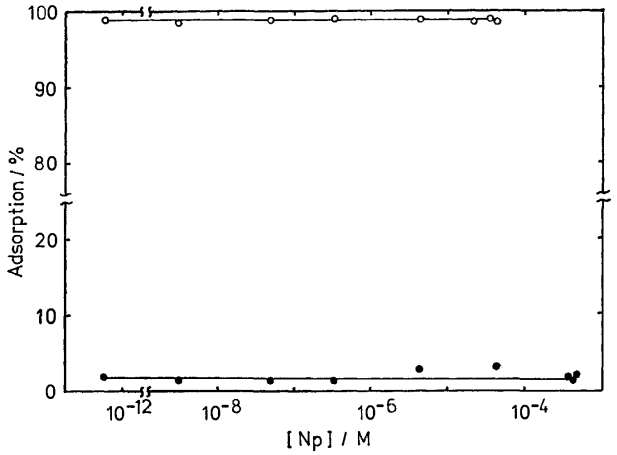

Fig. 5. Dependence of the adsorption on the concentration of Np at 1.25 M NaOH using 2.7 mg Zr(IV).
○: $Np+N_2H_4 \cdot 2HCl(1\times10^{-3}$ M),
●: $Np+Br_2(2.5\times10^{-2}$ M).

above the concentration of 0.15 M. As is shown in Fig. 4, the adsorption is little affected by the existence of the carbonate, and so this adsorption procedure may be applicable in the atmosphere of air. In the present work, however, in order to prevent the results from being disturbed, all the procedures were carried out in an atmosphere of nitrogen or argon gas.

Though the results of Figs. 2, 3, and 4 are for the reduced and oxidized neptunium in tracer quantities, the dependence of the adsorption on the concentration of neptunium is shown in Fig. 5. As is shown in Fig. 5, the fraction adsorbed was almost constant for both the reduced and oxidized neptunium over a wide range of the neptunium concentrations. Because of the low solubility of neptunium in sodium hydroxide solutions, the concentrations of neptunium examined ranged up to about 5×10^{-4} M for the oxidized neptunium and up to about 5×10^{-5} M for the reduced neptunium.

Titration of Heptavalent Neptunium by Hydrazine. As has been mentioned above, it is the only heptavalent state to be identified among some kinds of oxidation states of neptunium which occur in sodium hydroxide solutions. Therefore, if the reduced and oxidized neptunium can be prepared by adding an adequate reductant to heptavalent neptunium, it is possible to determine their oxidation states by considering the relationship between the amount of heptavalent neptunium and that of the reductant. We preferred hydrazine, which was able to reduce heptavalent neptunium quantitatively into hexavalent in sodium hydroxide solutions.[7]

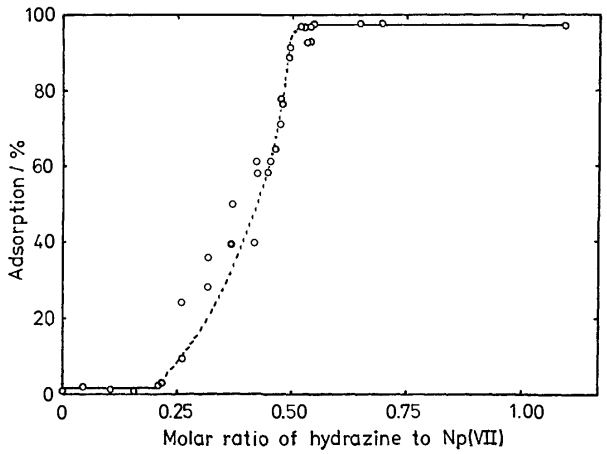

Fig. 6. Titration curve of Np(VII) by hydrazine at 1.0 M NaOH using 2.6 mg Zr(IV).

The results of the titration of heptavalent neptunium by hydrazine are shown in Fig. 6. As the equivalence point is the molar ratio of 0.25 for the reduction of heptavalent neptunium into hexavalent,[7] the adsorption at the molar ratio of 0 corresponds for heptavalent neptunium, and that at the molar ratio of 0.25, for hexavalent neptunium. Moreover, in the region of the molar ratios from 0 to 0.25, the adsorption corresponds for the mixture of hepta- and hexavalent neptunium. As is shown in Fig. 6, the fraction adsorbed in this region is very small. Consequently, both hepta- and hexavalent neptunium are hardly adsorbed at all on zirconium(IV) hydroxide.

On the other hand, the fraction adsorbed gradually increases in the region of the molar ratios between 0.25 and 0.50, and the neptunium is almost entirely adsorbed in the region of molar ratios more than 0.50. From this adsorption behavior, it is concluded that the neptunium in the oxidation state below the pentavalent state is almost entirely adsorbed on zirconium(IV) hydroxide. Moreover, if it is considered that the reduced rate of neptunium into the tetravalent state by hydrazine is negligibly small in the range of pH from weak acid to neutral solutions, and that the rate is rapid only in the strongly acid solutions,[8,9] the oxidation state of neptunium must be the pentavalent state in the region of molar ratios more than 0.5; therefore, the neptunium adsorbed on zirconium(IV) hydroxide must be in the pentavalent state.

In the region of the molar ratios between 0.25 and 0.50, the adsorption shows some scatter. This may be ascribed to the difference in the standing time and temperature on the reduction of heptavalent neptunium by hydrazine, because the solubility of hexavalent neptunium is about ten times as large as that of pentavalent neptunium in 1 M sodium hydroxide solutions, as is mentioned in the explanation of Fig. 5.

From the above discussion, it is apparent that the reduced neptunium prepared by hydrazine is in the pentavalent state, but the oxidized state cannot be assigned whether the hexavalent state, the heptavalent state, or a mixture.

Determination of the Oxidation State of Neptunium of Tracer Quantities. In the solution of neptunium without any foreign oxidants or reductants, the change of the oxidation state is as is shown in Table 1. Here, in addition to the adsorption on zirconium(IV) hydroxide, the oxidation state was determined by the adsorption on silica gel, in which hexavalent neptunium was quantitatively adsorbed, while pentavalent neptunium remained in the supernatant solution in the pH range of 6—7.[9]

At first, a solution of ^{239}Np in a 0.5 M nitric acid solution was prepared in the absence of foreign oxidants

TABLE 1. THE VARIATION IN THE OXIDATION STATE OF NEPTUNIUM IN TRACER QUANTITIES IN RELATION TO THE pH

	Adsorption[a]/%		Oxidation state
	Silica gel pH 6—7	$Zr(OH)_4$ 1 M NaOH	
Np in 0.5 M HNO_3	2		V
Np in 1 M NaOH		18	VI+(V)
Np in acetate buffer (pH 6.35)	1		V

a) The amounts of silica gel and Zr(IV) were 100 mg and 2.7 mg respectively.

or reductants; its oxidation state was acertained to be the pentavalent from the results of the adsorption on silica gel. Second, a 1 M sodium hydroxide solution of neptunium was prepared by alkalizing a 0.5 M nitric acid solution; the oxidation state was then examined by means of the adsorption on zirconium(IV) hydroxide. Because neptunium is never oxidized by oxygen into the heptavalent state,[1] the results shown in Table 1 indicate that a large portion of the neptunium in the 1 M sodium hydroxide solution exists in the hexavalent state, and a small portion, in the pentavalent state. Third, the neutral solution of neptunium was prepared by adding an acetate buffer solution to a 1 M sodium hydroxide solution; its oxidation state was found to be pentavalent.

It is well known that the most stable oxidation state of neptunium is the pentavalent state, and it has been confirmed, not only by the present work, but also by Inoue *et al.*,[9] that the oxidation state of neptunium in tracer quantities is pentavalent in the region from an acidic to a neutral solution in the absence of foreign oxidants or reductants. However, in a 1 M sodium hydroxide solution of neptunium in tracer quantities, the most stable oxidation state is not the pentavalent state, but a mixture of the pentavalent and hexavalent states, because pentavalent neptunium must be oxidized by the oxygen dissolved in the solution.

Espinosa investigated the preparation and identification of penta-, hexa-, and heptavalent neptunium in tracer quantities in alkaline solutions by means of glass fiber-electrophoresis and solvent extraction.[6] He concluded that neptunium in a sodium hydroxide solution, in the absence of foreign oxidants or reductants, was pentavalent. However, as is shown in Table 1, his method of preparation and his identification of pentavalent neptunium is questionable.

The adsorption of neptunium in tracer quantities on zirconium(IV) hydroxide in the presence of some oxidants or reductants is shown in Table 2. The pentavalent neptunium in a 1 M sodium hydroxide solution can be prepared by adding hydroxylamine and tin(II) besides hydrazine. However, it is difficult to prepare pentavalent neptunium by the use of hexacyanoferrate(II), ascorbic acid, and hydrogen peroxide, which are known as reductants capable of reducing heptavalent neptunium quantitatively into hexavalent.[1,7] The adsorption of neptunium in the presence of bromate, chlorite, and peroxosulfate is nearly equal to that in the absence of any oxidants or reductants. Therefore, these three reagents are not effective oxidants in 1 M sodium hydroxide solutions. Neptunium in tracer quantities is oxidized only to some extent by peroxosulfate at 50 °C, and in the presence of ozone, though under the same conditions neptunium of an ordinary concentration is oxidized into the heptavalent state.[1] By the use of hexacyanoferrate(III), permanganate, and bromine, neptunium is oxidized into a hexavalent or heptavalent state, as is shown in Table 2.

TABLE 2. THE REDUCTION AND OXIDATION OF NEPTUNIUM IN TRACER QUANTITIES IN 1 M NaOH

Reductant and oxidant		Adsorption[b]/% Standing time	
		15—20 min	3 h

$NaClO_2$	1×10^{-2} M	16	13
$K_2S_2O_8$	1×10^{-2} M	15	14
$K_2S_2O_8$(50 °C)	1×10^{-2} M		9
O_3	1.5 g/h		6
$K_3Fe(CN)_6$	1×10^{-2} M	5	2
$KMnO_4$	1×10^{-2} M	3	1
Br_2	4×10^{-2} M	2	2

a) The concentrations were at the stage of reduction and oxidation, and were reduced to 1/4 of the value given at the stage of adsorption. b) The amount of Zr(IV) was 2.7 mg.

As has been mentioned above, pentavalent neptunium is found to be selectively absorbed on zirconium(IV) hydroxide, and the method proposed is effective for determining the distribution of the oxidation state of neptunium in a sodium hydroxide solution.

A Potentiometric Study on Complex Formation of Silver(I) Ion with Glycine and β-Alanine in Aqueous Solution

Hitoshi OHTAKI,* Masayuki ZAMA, Hidemi KOYAMA, and Shin-ichi ISHIGURO

Department of Electronic Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received March 17, 1980)

The complex formation of silver(I) ion with glycine and β-alanine was studied at 25 °C in an aqueous solution containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium by means of potentiometric titrations. At a relatively low pH region, the $AgHL^+$ complex (L^- represents glycinate and β-alaninate ions) was formed, in which the silver ion was coordinated with the carboxyl group of the ligands. At a medium pH range, the AgL and AgL_2^- complexes were formed. From the formation constants of the complexes, it is suggested that the silver ion within the complexes may be coordinated with the amino group of the ligands and the interaction between the metal ion and the carboxyl group within the complexes is so weak that the interaction does not appreciably stabilize the complexes. At the highest pH region, the hydrolyzed species $Ag(OH)L^-$ was formed.

In previous papers,[1,2] we have reported the complex formation reactions of silver(I) ion with some aliphatic diamines. In these cases, not only mononuclear complexes but also polynuclear, protonated, and hydrolyzed complexes were formed, and their formation constants were discussed in connection with the length of the methylene chain within the aliphatic diamines.

Although several investigations of complex formation reactions between silver(I) ion and amino acids have so far been made,[3] the pH ranges covered in most studies were rather limited, so that the formation of only AgL and AgL_2^- complexes have been reported,[4-6] and no further attention has been paid for the formation of protonated and hydrolyzed complexes.

In the present study, we examined the complex formation reactions of silver(I) ion with glycine and β-alanine in aqueous solution where the concentration of hydrogen ions was widely changed ($2 < -\log[H^+] < 11$). The $AgHL^+$ and $Ag(OH)L^-$ complexes were found together with the AgL and AgL_2^- complexes and their formation constants were obtained.

Experimental

Reagents. *Glycine and β-alanine* were recrystallized three times from an ethanol–water mixture and were dried at 80—110 °C in an electric oven. Crystals thus prepared were stored in vacuum.

Other chemicals were the same as those used previously.[1,2]

Measurements. Beckman (Nos. 40495 and 40498) glass electrodes were used in combination with an Orion Digital pH Meter Model 801. The concentration of free silver(I) ion was determined by using an Ag–AgCl electrodes in combination with Takeda Riken Digital Voltmeter (TR-6515). The Kawai-type reference half cell was used,[7] in which an Ag–AgCl electrode was set. The Ag–AgCl electrodes used were prepared according to Brown.[8]

During the potentiometric titrations the total concentration of perchlorate ion was kept constant at 3 mol dm^{-3} by using lithium perchlorate. The concentrations of silver and amino acids were changed over the range of 2.5—10 mmol dm^{-3} and 10—80 mmol dm^{-3}, respectively. The ratio of the total concentration of an amino acid to that of silver ion (C_L/C_{Ag}) ranged from 2 to 32. Measurements were performed at 25.00±0.01 °C in a paraffin oil bath set in a room thermostatted at 25.0±0.5 °C.

Details of the method of measurements were described elsewhere.[1,2]

Results

Titration curves of silver–glycine and silver–β-alanine systems are represented in Figs. 1 and 2, respectively. The value $-\log[H^+]$ was plotted against X ($=-H/C_L$; H stands for the analytical excess concentration of hydrogen ion). Titration data were first analyzed by graphical methods and the composition of the complexes

and their approximate formation constants were determined. The formation constants thus obtained were finally optimized by the least-squares method using an electronic computer (FACOM M-160). The least-squares method used was based on a modified MINIQUAD program[9] which minimizes the sum of squared residuals for all mass-balance equations.

In a lower pH range where most acids are present as HL the following equilibrium between silver ion and an amino acid may be assumed:

$$pAg^+ + rHL = Ag_pH_qL_r^{(p+q-r)+} + (r-q)H^+. \quad (1)$$

The equilibrium constant of Eq. 1 is defined as follows:

$$\kappa_{pqr} = \frac{[Ag_pH_qL_r^{(p+q-r)+}][H^+]^{r-q}}{[Ag^+]^p[HL]^r} = \beta_{pqr}/\beta^r_{011}, \quad (2)$$

where β_{pqr} denotes the overall formation constant of the $Ag_pH_qL_r^{(p+q-r)+}$ complex:

$$\beta_{pqr} = [Ag_pH_qL_r^{(p+q-r)+}]/[Ag^+]^p[H^+]^q[L^-]^r. \quad (3)$$

The material balance of the metal ion gives the following equation:

$$\frac{C_{Ag}-[Ag^+]}{[Ag^+]} = \phi - 1 = \sum_p\sum_q\sum_r p\kappa_{pqr}[Ag^+]^{p-1}[H^+]^{-(r-q)}[HL]^r. \quad (4)$$

If we assume as a first approximation that only one complex is formed in the pH range, the following equation can be readily derived:

$$\log(\phi-1) - \log[HL] = \log p\kappa_{pqr} + (p-1)\log[Ag^+] - (r-q)\log[H^+] + (r-1)\log[HL]. \quad (5)$$

Since the amount of the $Ag_pH_qL_r^{(p+q-r)+}$ complex formed was small, the concentration of the free ligand, HL, was approximated to the total concentration of the ligand, *i.e.*, $[HL]\approx C_L$. The plots of $\log(\phi-1)-\log C_L$ against $-\log[H^+]$ for the silver(I)-β-alanine system are shown in Fig. 3 as an example. The plots were practically independent of the total concentrations of both silver ion and the ligand and fell on an almost single straight line with the slope zero. Therefore, $p-1=0$, $r-1=0$ and $r-q=0$ were obtained, and thus, the complex formed was identified to be the $AgHL^+$ complex.

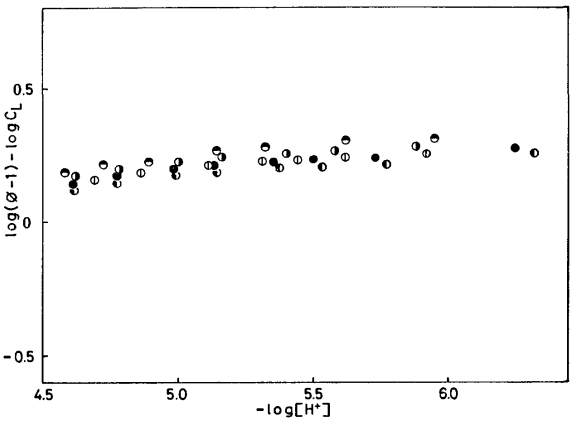

Fig. 3. Plots of $\log(\phi-1)-\log C_L$ *vs.* $-\log[H^+]$ in the silver-β-alanine system. Symbols are the same as those used in Fig. 2.

Graphical procedures were applied to the estimation of the composition and approximate formation constants of other complexes over the whole pH region. Formation of the complexes, AgL, AgL_2^- and $Ag(OH)L^-$ were estimated. The formation constants of the complexes thus evaluated by the graphical procedures were further refined by the least-squares method. The assumptions

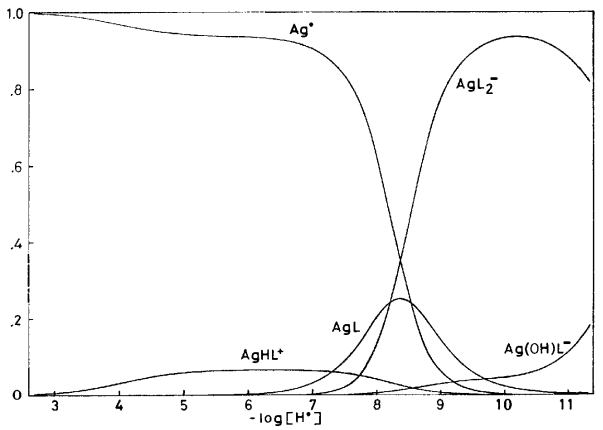

Fig. 4. Distribution of silver-β-alanine complexes.
C_{Ag}=5 mmol dm^{-3}, C_L=40 mmol dm^{-3}.

of the formation of the $AgHL_2$, $AgH_2L_2^+$, and AgOH complexes beside the complexes graphically obtained were all rejected in the course of the least-squares procedures. The final results are summerized in Table 1, together with the formation constants of ethylendiamine and 1,3-propanediamine complexes.[1,2] The solid lines in Figs. 1 and 2 were calculated by Eq. 6:

$$X_{calc}=\frac{C_L+K_1[H^+]^{-1}-[H^+]-\sum_p\sum_q\sum_r q\beta_{pqr}[Ag^+]^p[H^+]^q[L^-]^r}{C_L}, \quad (6)$$

where K_1 denotes the autoprotolysis constant of water in 3 mol dm^{-3} $LiClO_4$ aqueous solution and is $10^{-13.87\pm0.01}$ mol^{-2} dm^6,[10] and the formation constant β_{pqr} used are those in Table 1. A typical set of distribution curves of the silver–β-alanine complexes is depicted in Fig. 4.

Discussion

The equilibrium constant K(AgHL/HL) for the reaction

$$Ag^+ + HL = AgHL^+ \quad (7)$$

$$K(AgHL/HL) = [AgHL^+]/[Ag^+][HL] \quad (8)$$

can be calculated from the formation constants listed in Table 1. The values log K(AgHL/HL) for glycine and β-alanine are 0.07 and 0.23, respectively. The values are much smaller than those for diamines (*e.g.*, 2.79 for ethylenediamine), whilst they are very similar to the value for acetic acid (0.36).[11] Thus, the metal ion within the AgHL complex may be coordinated with the carboxyl group of the ligands. The value of log K(AgHL/HL) for glycine is smaller than that for β-alanine. A stronger electrostatic repulsion between silver ion and the terminal hydrogen ion at the amino group within the silver–glycine complex than that within the silver–β-alanine complex may reduce the stability of the former complex compared with the latter.

Stepwise formation constants log K(AgL/L) and log $K(AgL_2/L)$ for the reactions, $Ag^+ + L^- = AgL$ and $AgL + L^- = AgL_2^-$, respectively, are readily calculated from the data in Table 1, that is, log K(AgL/L) = 3.28 and log $K(AgL_2/L)$ = 3.68 for the silver–glycine complexes and log K(AgL/L) = 3.58 and log $K(AgL_2/L)$ = 3.88 for the silver–β-alanine complexes. The trend that the $K(AgL_2/L)$ value is larger than the K(AgL/L) value is the same as that found for silver–ammine and silver–monoamine complexes having a linear structure, and is opposite to that observed for silver–diamine complexes in the previous work[2] in which we reported that they have a distorted tetrahedral structure. These results suggest, therefore, that glycine and β-alanine essentially act as monodentate ligands to the central silver ion and the interaction between the positively charged silver ion and the negatively charged carboxyl group of the ligands may be so weak that it does not appreciably contribute to stabilization of the nitrogen-coordinated complexes.

The equilibrium constants of the hydrolytic reaction of the amino acid silver complexes, $AgL + H_2O = Ag(OH)L^- + H^+$ are given as log $^*K$(Ag(OH)L/AgL) = −9.76 and −9.70 for the glycinato and β-alaninato complexes of silver ion, respectively. These values are slightly larger than those of silver–ethylenediamine (−10.08) and 1,3-propanediamine (−10.16) complexes in the same medium.[2]

Table 1. Formation constants of the $Ag_pH_qL_r$ complexes, log β_{pqr}, in 3 mol dm^{-3} $LiClO_4$ at 25 °C[a]

$\beta_{pqr}=[Ag_pH_qL_r]/[Ag]^p[H]^q[L]^r$

Complex	gly⁻	β-ala⁻	en[2]	pn[2]

Indirect Spectrophotometric Determination of Phosphate Employing the Solubilization of Methylene Blue Molybdophosphate with Zephiramine

Junichi SHIDA* and Tsutomu MATSUO

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Jonan-4, Yonezawa, Yamagata 992

(Received April 4, 1980)

A highly sensitive indirect spectrophotometric method for phosphate was developed. The ion-association complex of molybdophosphate with Methylene Blue was precipitated in a nitric-acid medium. The complex was adsorbed on (1+4 v/v) cyclohexane–MIBK. The excess of Methylene Blue was removed by washing the organic phase with water. The complex was solubilized with a Zephiramine acidic aqueous solution. By measuring the absorbance of Methylene Blue in the aqueous solution at 660 nm, the phosphate was determined. The calibration curve was linear in the 0.31—3.1 μg range of phosphate, and the molar absorptivity was 2.5×10^5 l·mol^{-1}·cm^{-1}. The absorbance of the reagent blank was 0.019±0.001, and the recommended procedure was applied to the repetitive determination of 1.55 μg of phosphorus. The ten determinations produced a coefficient of variation of 1.6%. Arsenic, germanium and silicon, which form heteropolyacids like phosphorus, interfered seriously.

The studies of the solvent extraction of the ion pairs formed between complex anions and large cations are very important in analytical chemistry. Of these extractions, the one with a basic dye possessing a large molar absorptivity can be applied to the spectrophotometric determination of metals. Kirkbright *et al.*[1] have reported a method based on the formation of a complex between Rhodamine B and molybdophosphoric acid. Golkowska and Pszonicki[2] have studied the composition and properties of the ion-association complex of Rhodamine B with molybdosilicic acid, and have then used this method for the determination of silicon. Recently, Fogg *et al.*[3] have reported the spectrophotometric determination of inorganic phosphate in biological systems with Crystal Violet. The absorbance characteristics of the ion-association complex formed between molybdophosphate (MoP) and Methylene Blue (MB) are similar to those of MB itself. In a previous paper,[4] the large excess of MB co-extracted into MIBK was removed by washing it with a 2 M nitric acid solution, but the sensitivity and reproducibility were not satisfactory. This paper will report on a method for the indirect determination of phosphate by spectrophotometry. As the Methylene Blue molybdophosphate (MB·MoP) complex is only slightly soluble in the aqueous phase, it can be separated from the large excess of MB by filtration or floatation.[2] We adopted the adsorption[5] of the ion-association complex on the organic solvent; the MB·MoP complex precipitated as a thin layer on the phase boundary to separate from the large excess of MB. The MB^+ of the MB·MoP complex on the organic phase was replaced with the benzyldimethyltetradecylammonium ion (Zephiramine ion), and the free MB ion was transferred into the aqueous phase. By measuring the absorbance of the free MB ion in the aqueous phase, the amount of phosphate was determined.

Experimental

Apparatus and Reagents. A Hirama model 6B spectrophotometer with 10-mm glass cells was used. An Iwaki, model S-L type KM, shaker was used to shake the separatory funnel. All the chemicals were of analytical-reagent grades and were stored in polyethylene bottles. The nitric acid was distilled and diluted with water. The water was deionized and distilled.

Standard Phosphate Solution, 31 μg P ml^{-1}: Dissolve 0.1361 g of potassium dihydrogenphosphate in water and dilute to 1 l. This solution is then diluted as required to 0.31 μg P ml^{-1} with water.

Ammonium Molybdate Solution, 0.1 M: Dissolve 17.7 g of hexaammonium heptamolybdate tetrahydrate, $(NH_4)_6Mo_7O_{24}\cdot4H_2O$ in water and dilute to 1 l.

Methylene Blue Solution, 2×10^{-3} M: Dissolve 0.747 g of Methylene Blue (Wako Pure Chemical Industries, Ltd.; 98.5% content) in water and dilute to 1 l.

Organic Solvent: A (1+4 v/v) mixture of cyclohexane and isobutyl methyl ketone(MIBK) was used.

Zephiramine Solution, 5.0×10^{-3} M: Dissolve 1.84 g of Dotite Zephiramine (Dojindo Laboratories) in water and dilute to 1 l.

Recommended Procedure. Transfer a 20-ml portion of the sample solution(previously neutralized) containing less than 3 μg P into a 100-ml separatory funnel. Add 10 ml of 4 M nitric acid, 10 ml of a 0.1 M molybdate solution, and 5 ml of a 1 M potassium nitrate solution. Allow to stand for 10 min. Then, add 1 ml of a 2×10^{-3} M Methylene Blue solution and dilute with water to 50 ml. Mix well and add about 10 ml of the organic solvent. Shake vigorously for 10 min, allow the phases to separate, and discard the aqueous phase carefully. Then, add 25 ml of water and shake for 1 min. Allow the phases to separate and discard the aqueous phase. Repeat the washing with 25 ml of water once more. Add 5 ml of a 5.0×10^{-3} M Zephiramine solution and 5 ml of 0.5 M nitric acid, and shake vigorously for 5 min. After phase separation, transfer the aqueous phase and washings into a 25-ml volumetric flask. Dilute to the mark with water. Mix well and measure the absorbance at 660 nm against a reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of MB in the Zephiramine acidic solution obtained by the recommended procedure are shown in Fig. 1. There are shoulders at 600—620 nm and an absorption maximum at 660 nm, where the absorbance of the reagent blank is very small; that is, the absorbance is 0.019±0.001 (ten determinations).

Effects of Reaction Variables. Concentration of Nitric Acid: The optimum acidity of the aqueous phase for

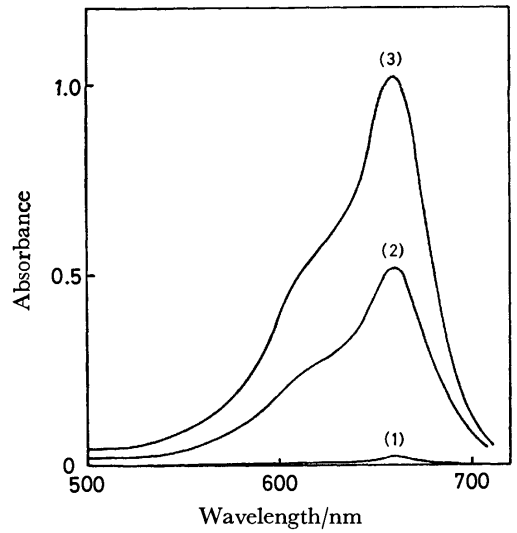

Fig. 1. Absorption spectra of Methylene Blue in Zephiramine acidic solution.
(1) Reagent blank, (2) P: 1.55 μg, (3) P: 3.10 μg. Reference: water.

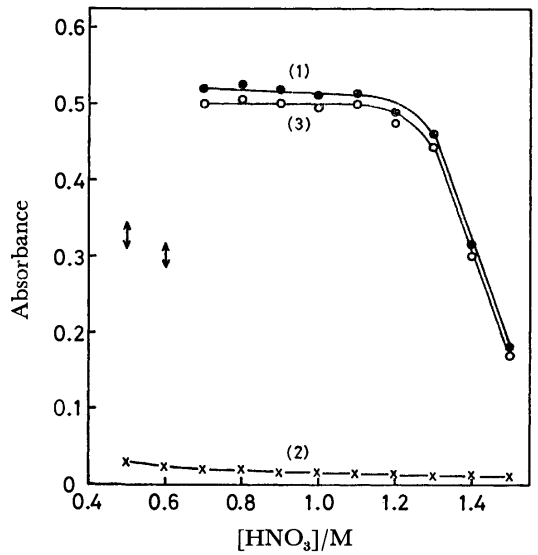

Fig. 2. Effect of nitric acid concentration on absorbance.
(1) P: 1.55 μg, (2) reagent blank, (3) net. Reference: water.

the formation of the MB·MoP complex was found to be 0.7—1.1 M nitric acid, as is shown in Fig. 2. The absorbance decreased gradually over the 1.2—1.5 M range of nitric acid. The reproducibility was poor below 0.6 M of nitric acid, because the excess of molybdate formed a precipitate with MB. A concentration of 0.8 M nitric acid in the initial solution was, therefore, chosen as the optimum.

The Amounts of Ammonium Molybdate Solution: For 1.55 μg P the absorbance increased upon the addition of 0.1 M ammonium molybdate up to 7 ml, and then remained constant for up to 20 ml of the reagent; 10 ml of the molybdate solution was used in further work.

The Amounts of Methylene Blue Solutions: As is shown in Fig. 3, a constant and maximum absorbance was

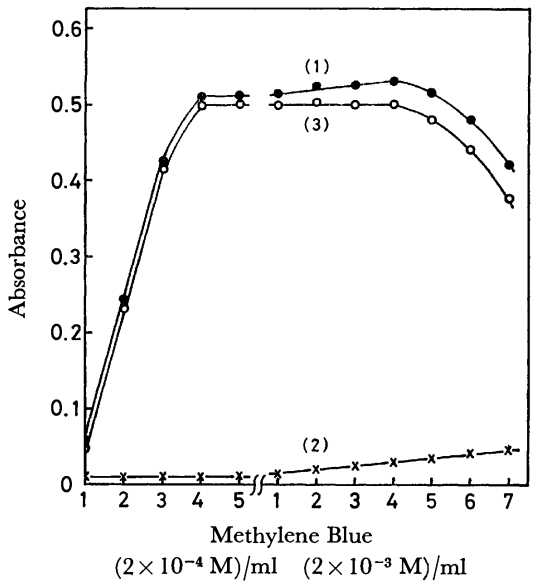

Fig. 3. Effect of the amounts of Methylene Blue solution.
(1) P: 1.55 μg, (2) reagent blank, (3) net. Reference: water.

obtained when from 4 ml of a 2×10^{-4} M solution to 3 ml of a 2×10^{-3} M MB solution were added. When a MB solution below 4 ml of 2×10^{-4} M or over 3 ml of 2×10^{-3} M was added, the absorbances decreased gradually.

Concentration of Zephiramine Solution: The effect of the Zephiramine concentration in the acidic aqueous phase on the solubilization of the MB·MoP complex was also studied. The absorbance increased up to 2.5×10^{-4} M Zephiramine, this remained constant when the reagent concentration was increased further. Therefore, 2.5×10^{-3} M Zephiramine in 0.25 M nitric acid was used. Unless the acid is added in the Zephiramine solution, it is difficult to separate the phases.

Adsorption and Separation of the MB·MoP Complex.

The Choice of Organic Solvents: The considerations for the choice of the organic solvents to adsorb the MB·MoP complex are as follows: (1) the solvent should have a smaller specific gravity of the organic solvents than that of water, such a smaller specific gravity being advantageous for washing the excess of MB, (2) there should be little extractability of the MB·MoP complex, and (3) it should be possible to separate the phases rapidly after shaking. Though there are several solvents which satisfy these conditions, the mixture of MIBK and cyclohexane was most recommended.

Effect of the Addition of Cyclohexane to MIBK: As is shown in Fig. 4, the optimum range was 20—30% (v/v) cyclohexane in MIBK, at which the absorbance of the reagent blank was very small. The emulsion forms in a yield of more than 40% upon shaking with the Zephiramine solution. Therefore, the shaking was carried out at 20%; that is, a (1+4) cyclohexane–MIBK mixture was used in further work.

Volume of (1+4)Cyclohexane-MIBK: The effect of (1+4) cyclohexane-MIBK was examined by varying the volume from 5 to 20 ml according to the recom-

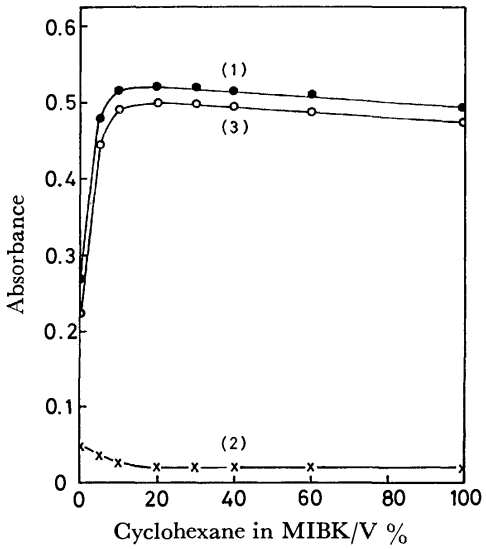

Fig. 4. Effect of the addition of cyclohexane.
(1) P: 1.55 μg, (2) reagent blank, (3) net. Reference: water.

mended procedure. However, no effect of the volume was observed. Therefore, about 10 ml of the solvent was used in further work.

Washing the Organic Phase: To remove the large excess of MB after the adsorption of the MB·MoP complex, we washed the organic phase with water. Washing twice with 25-ml portions of water was sufficient to remove the excess reagent. The shaking time for washing was 1 min.

Calibration Curve, Sensitivity, and Precision. The calibration curve obtained by the recommended procedure was linear in the range from 0.31 to 3.1 μg of phosphorus, and the molar absorptivity, as calculated from the slope of the curve, was 2.5×10^5 l·mol^{-1}·cm^{-1}. The recommended procedure was applied to the repetitive determination of 1.55 μg of phosphorus. The ten determinations produced a coefficient of variation of 1.6%.

Composition of the MB·MoP Complex. When the MB·MoP complex was dissolved with the Zephiramine solution, it was found that MB was transferred into the aqueous phase and that MoP was extracted into the organic phase. The absorbance of free MB in the aqueous phase was measured, and the concentration of MB was determined using the calibration curve of free MB. The P: MB ratio was 1: 3. After removing the organic solvent by volatilization, the analysis of MoP for molybdenum by atomic-absorption spectrophotometry, and that for phosphorus by the molybdenum blue method,[6] gave these results, P : Mo=1 : 12. The composition of the MB·MoP complex was estimated as $(MB)_3PMo_{12}O_{40}$.

Table 1. Effect of diverse ions on the recovery of phosphorus

Ion	Added as	Amount (μg)	Recovery (%)
As(V)	$Na_2HAsO_4\cdot7H_2O$	0.15	103
		1.0	119
As(III)	As_2O_3[a)]	5.0	103
		20	112
Ge(IV)	GeO_2[a)]	0.50	102
		5.0	122
Si(IV)	SiO_2[a)]	20	102
		200	122
V(V)	NH_4VO_3	2.0	104
		40	110
Cr(VI)	$K_2Cr_2O_7$	15	98
		200	87

a) Treated with NaOH. P: 1.55 μg.

Effect of Diverse Ions. The effect of diverse ions on the recovery produced from 1.55 μg of phosphorus by the recommended procedure was investigated. An ion was considered not to interfere when the error in the recovery was less than ±4% for the test solutions compared with the standards. As is shown in Table 1, arsenic, germanium and silicon, which form heteropolyacids like phosphorus, interfered seriously. These results are in agreement with those of a previous paper.[4]

Application. The method described may be used for the microanalysis of phosphate, for example, sea water and river water. Because the MB·MoP complex dissolves in alcohols (methanol, ethanol, *etc.*) or amides (*N,N*-dimethylformamide, *etc.*), phosphorus can be determined directly by measuring the absorbance of the complex in an organic solvent. Therefore, this makes possible a considerable reduction in time.

Binuclear Metal Complexes. XXXIII.[1] Synthesis, Structure, Spectra, and Magnetism of Binuclear Copper(II) Complexes with 2-[2-(Dialkylamino)ethylthio]ethanol

Masahiro MIKURIYA, Hisashi OKAWA, and Sigeo KIDA*

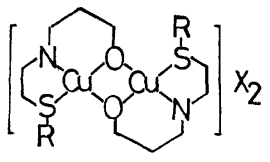
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 10, 1980)

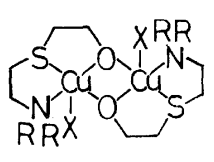
Binuclear copper(II) complexes with 2-[2-(dialkylamino)ethylthio]ethanol, Cu{$R_2N(CH_2)_2S(CH_2)_2O$}X (abbreviated as Cu(R-nso)X, where R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9; X=Br, Cl, NO_3), were prepared and characterized by elemental analyses, infrared and electronic spectra and magnetic susceptibilities (80—300 K). They exhibit a band at 22—26$\times 10^3$ cm^{-1} characteristic of alkoxo-bridged structure. The magnetic data of Cu(n-C_4H_9-nso)Cl indicate that a strong antiferromagnetic interaction is operating between the copper ions. However, temperature dependence of magnetic susceptibilities of the other complexes do not obey the equation based on a binuclear structure. The crystal structure of Cu(CH_3-nso)Br was determined by the single-crystal X-ray diffraction method. The crystals are monoclinic, space group $P2_1/c$, a=10.133(2), b=7.858(2), c=14.893(3) Å, β=118.8(1)°, and Z=2. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method to an R factor of 0.042. The structure consists of alkoxo-bridged binuclear units, Cu_2-(CH_3-nso)$_2Br_2$. The coordination geometry of the copper ion is distorted square pyramid. Since the distances between the binuclear clusters are too long to give rise to an intercluster magnetic interaction, it is suggested that some structural change takes place at low temperature.

In blue copper oxidases (*e.g.*, laccase, ceruloplasmin, and ascorbate oxidase), type III copper is believed to be present as an antiferromagnetically coupled copper(II) dimer.[2] Although no exact information is available yet on the coordination geometry or the nature of the donor atoms for type III copper, models incorporating sulfur donor ligands have attracted a remarkable attention. However, few spectral and magnetic data and almost no structural data are available on binuclear copper(II) complexes with sulfur donor ligands.[3-6]

As a part of the continuing project dealing with binuclear copper(II) complexes of sulfur-containing ligands, we recently reported the synthesis and spectral and magnetic properties of the binuclear copper(II) complexes with *N*-[2-(alkylthio)ethyl]-3-amino-1-propanol, Cu{$RS(CH_2)_2NH(CH_2)_3O$}X (abbreviated as Cu(R-sno)X, where R=alkyl, X=anion).[1,7] In this study, we have prepared binuclear copper(II) complexes with 2-[2-(dialkylamino)ethylthio]ethanol, Cu{$R_2N(CH_2)_2S(CH_2)_2O$}X (abbreviated as Cu(R-nso)X, where R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9; X=Br, Cl, NO_3) and investigated their spectral and magnetic properties. In these complexes, the sulfur atom was considered to link two five-membered chelate rings upon complexation. Such a condensed-ring system should bring about a considerable strain, if all donating atoms and copper(II) ions are placed on a plane. Thus, the ligands have the potential to adopt a nonplanar arrangement about the copper ion, promoting stabilization of the copper(I) oxidation state.[8] In order to clarify the detailed molecular structure, the crystal structure of bromo{2-[2-(dimethylamino)ethylthio]ethanolato}copper(II), Cu(CH_3-nso)Br, was determined by the single-crystal X-ray diffraction method.



Cu(R-sno)X



Cu(R-nso)X

Experimental

Preparation of the Ligands. *N,N*-Dialkyl-2-chloroethylamine hydrochlorides were prepared from 2-(dialkylamino)-ethanols and thionyl chloride by the method described in the literature.[9] The ligands, $R_2N(CH_2)_2S(CH_2)_2OH$ (R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9), were prepared by the reaction of *N,N*-dialkyl-2-chloroethylamine hydrochlorides and 2-mercaptoethanol by the method of Clinton *et al.*[10]

Preparation of the Complexes. The synthetic methods of the chlorides, Cu(R-nso)Cl (R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9), are nearly the same and exemplified by Cu(CH_3nso)Cl. To a solution of CH_3-nsoH (149 mg) in absolute ethanol (5 ml) was added a solution of copper(II) chloride dihydrate (85 mg) in absolute ethanol (5 ml). From the mixture, green crystals were immediately formed. They were collected by filtration and dried *in vacuo* over P_2O_5.

The nitrates and bromides, Cu(R-nso)X (X=NO_3,Br), were prepared by a method similar to that for the chlorides

except for using copper(II) nitrate trihydrate and copper(II) bromide, respectively, instead of copper(II) chloride dihydrate.

Carbon, hydrogen, and nitrogen analyses were carried out at the Service Center of Elemental Analysis, Kyushu University. The results of elemental analyses for these complexes are listed in Table 1.

Measurements. Infrared spectra were measured with a Hitachi Grating Infrared Spectrophotometer Model 215 in the region 4000—650 cm^{-1} on a KBr disk. Electronic spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000 at room temperature. Magnetic susceptibilities were measured by the Faraday method in the temperature range from liquid nitrogen temperature to room temperature. The apparatus was calibrated by the use of $[Ni(en)_3]S_2O_3$.[11] All the susceptibilities were corrected for the diamagnetism of the constituting atoms by the use of Pascal's constants.[12] Effective magnetic moments were calculated from the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the atomic magnetic susceptibility and $N\alpha$ is the temperature-independent paramagnetism. For the present complexes, $N\alpha$ was assumed to be 60×10^{-6} cgs emu.[13]

X-Ray Crystal Structure Analysis of Cu(CH$_3$-nso)Br. A photographic study using Weissenberg camera indicated monoclinic symmetry. Preliminary cell constants were obtained. The systematic absences observed, l odd for $h0l$ and k odd for $0k0$, uniquely define the space group as $P2_1/c$. The unit cell parameters and intensities were measured on a Syntex $P\bar{1}$ automated four-circle diffractometer with Mo $K\alpha$ radiation monochromated by a graphite plate ($\lambda=0.71073$ Å). The crystal was ground to a sphere (radius 0.148 mm). The unit cell parameters were determined by the least-squares refinement based on the 15 reflections in the range of $21°<2\theta<31°$. The values are $a=10.133(2)$, $b=7.858(2)$, $c=14.893(3)$ Å, $\beta=118.8(1)°$ and $V=1039.3(4)$ Å^3. The density $D_m=1.85$ g/cm^3 obtained by floatation in hexane–1,2-dibromoethane solutions agrees well with the density $D_C=1.864$ g/cm^3 calculated for two dimer units per unit cell.

Intensity data were collected by the θ-2θ scan technique with a variable scan rate of 4.0 to 24.0 °/min. Three standard reflections were monitored every 50 reflections, and their intensities showed a good stability. A total of 1943 independent reflections with $2\theta\leq50°$ were collected. The intensities were corrected for the Lorentz and the polarization effects. Absorption correction was applied with the values of the absorption-correction factors, A^*, tabulated in International Tables for X-Ray Crystallography.[14] 1595 independent reflections with $|F|>3\sigma(|F|)$ were considered as "observed" and were used for the structure analysis, where $\sigma(|F|)$ is the standard deviation of the observed structure amplitude due to counting statistics. An initial scale factor and over-all temperature factor were obtained by the Wilson statistics.

The structure was solved by the heavy atom method. The positions of the bromine and the copper atoms were obtained from a three-dimensional Patterson synthesis. The successive Fourier synthesis revealed all the nonhydrogen atoms. Refinement was carried out by the block-diagonal least-squares method. Anisotropic thermal parameters being introduced, the block-diagonal least-squares refinement yielded discrepancy factors $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.049$ and $R_2=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.082$. Hydrogen atoms were inserted in their calculated positions and included in the refinement. Further refinement with anisotropic thermal parameters for nonhydrogen atoms and isotropic temperature factors for hydrogen atoms gave final values of 0.042 and 0.072 for R_1 and R_2, respectively. In the least-squares refinement the function minimized was $\sum w(|F_o|-k|F_c|)^2$, and the weighting scheme was $w=(6.76+|F_o|+0.086|F_o|^2)^{-1}$.[15] The final shift in the atomic parameters of the nonhydrogen atoms averaged 0.024σ with the maximum of 0.127σ. The final difference Fourier synthesis showed no significant features except two peaks of 0.8 e/Å^3 in the vicinity of the bromine atom. The atomic scattering factors for Br, Cu, S, O, N, and C_{val} and the anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$ for Br, Cu, and S, were taken from the International Tables for X-Ray Crystallography.[16] For the hydrogen atom, the scattering factors were adopted from the tables of Stewart *et al.*[17] All the calculations were carried out by the FACOM M-190 computer in the Computer Center of Kyushu University using the UNICS-II program system.[18] The drawings were made by the use of ORTEP program.[19] Lists of the observed and calculated structure factors are kept as Document No. 8032 at the Chemical Society of Japan. The final positional and thermal parameters with their estimated standard deviations are given in Table 2.

Results and Discussion

Description of the Structure of Cu(CH$_3$-nso)Br. A perspective drawing of the complex and the numbering system are illustrated in Fig. 1. Bond lengths and angles are listed in Table 3.

The crystal structure essentially consists of the alkoxo-bridged binuclear units, $Cu_2(CH_3\text{-nso})_2Br_2$. The $Cu_2(CH_3\text{-nso})_2Br_2$ unit is located at the crystallographic

inversion center. The Cu–S bond length (2.316(2) Å) is almost equal to the sum of the covalent-bond radii (2.32 Å) given by Pauling.[20] This distance is rather short for the copper(II)-thioether sulfur bond length.[21–27] In the present complex the thioether donor atom is placed at the inner coordination position of the tridentate ligand, so that, upon complexation, the coordination of sulfur atom is facilitated by the chelate effect. The Cu–Br bond length (2.385(1) Å) is slightly shorter than the sum of the covalent-bond radii (2.42 Å),[20] but is comparable to those found in bromo [2-(dialkylamino)ethanolato]copper(II) (2.239—2.395 Å).[28–32]

The coordination geometry around the copper ion is intermediate between a trigonal bipyramid and a square pyramid. Viewing the structure as a square pyramid, nitrogen atom occupies the apical position, and Br, S, O, and O^{i} atoms form a basal plane. On the stand point of regarding the coordination geometry as a trigonal bipyramid, Br, O, and N define the equatorial plane of the molecule. Least-squares planes with the deviations of the atoms from the planes are given in Table 4. The degree of distortion of coordination geometry from either of the limiting structures can be estimated by the bond angle Br–Cu–O. For a regular trigonal bipyramid this angle should be 120°, whereas for a square pyramid the angle should be 180°. In this complex this angle is 156.0(1)°, showing that the coordination geometry is slightly close to the latter rather than the former. In square pyramid copper(II)

Dihedral angles between the planes (φ/°)

(I) and (II)	1.8	(II) and (III)	100.1
(I) and (III)	100.2	(II) and (IV)	95.2
(I) and (IV)	96.9	(III) and (IV)	84.3

a) The equation of the plane is expressed as $LX+MY+NZ=D$, where X, Y, and Z are in Å units referred to the crystallographic axes. b) Deviations (l/Å) of atoms from the planes are listed in square brackets. Superscripts are defined as in Table 3.

complexes, the apical bonds are generally longer than basal ones.[33] The Cu–Br, Cu–S, Cu–O, and Cu–O^{i} bond legnths are in the range of those of the normal in-plane coordination, while the Cu–N bond length (2.334(6) Å) is significantly longer than values of a normal in-plane coordination. From these facts the geometry around the copper ion is best described as a distorted square pyramid.

Bond lengths of the ligand have normal values except for the O–C(1) and C(1)–C(2) distances. The O–C(1) (1.382(13) Å) and C(1)–C(2) (1.418(23) Å) bond lengths are shorter than the corresponding O–C and C–C distances observed in other alkoxo-bridged copper(II) complexes, respectively.[28–32,34–37] This is attributable to the large values of anisotropic thermal parameters for C(1). The thermal ellipsoid for C(1) (Fig. 1) gives strong indication of either disorder or large vibration approximately normal to the coordination plane. This is probably due to the strain of two adjacent five-membered chelate rings. The carbon atoms of the ethylene group, C(1) and C(2), are located above the plane through Cu, S, and O by 0.239 and 0.135 Å, respectively. Another five-membered chelate ring, Cu–S–C(3)–C(4)–N, assumes the usual gauche conformation, and C(3) and C(4) deviate from the plane through Cu, S, and N by 0.294 and −0.335 Å, respectively.

The bond angles around the nitrogen atom (Cu–N–C(4) 108.8(4), Cu–N–C(5) 107.7(5), Cu–N–C(6) 111.2(5), C(4)–N–C(5) 108.9(7), C(4)–N–C(6) 109.0(7), C(5)–N–C(6) 111.2(7)°) are close to that for a regular tetrahedron, whereas the bond angles around the sulfur atom (Cu–S–C(2) 97.7(4), Cu–S–C(3) 98.8(3), C(2)–S–C(3) 103.7(4)°) are considerably less than those around the nitrogen atom.

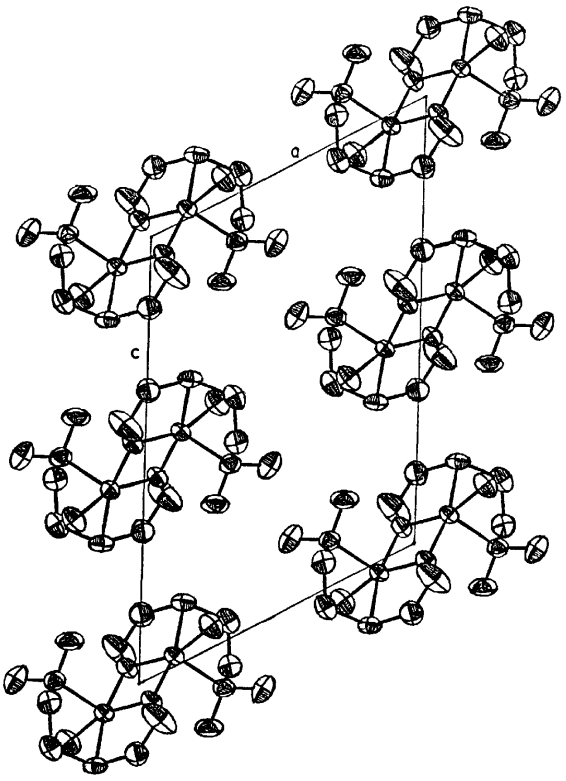

Fig. 2. A view of the packing along the b axis.

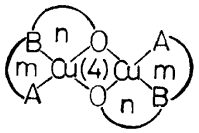
The molecular packing in the unit cell is shown in Fig. 2. As is evident from the packing diagram and the distances between the binuclear clusters (Table 3), the complex consists of discrete dimeric units.



6-6-(4)-6-6

5-6-(4)-6-5 ≫ 5-5-(4)-5-5

6-5-(4)-5-6

Fig. 3. The fused chelate ring system of alkoxo-bridged copper(II) complexes.

As shown in Fig. 3, the fused chelate ring system of a binuclear copper(II) complex with amino alcohol is expressed with m–n–(4)–n–m. It is known that for the formation of the binuclear copper(II) complexes the favorable chelate ring system is 6–6–(4)–6–6 and 5–6–(4)–6–5 fused chelate ring systems.[38] The binuclear cluster consisting of 6–5–(4)–5–6 fused chelate ring system may be stable in some cases,[37,39] but it often forms a stable tetranuclear cubane structure.[34,40–44] On the other hand, it has been believed that the 5–5–(4)–5–5 fused chelate ring system is unfavorable in forming a binuclear structure, since no stable binuclear copper(II) complex containing such a fused chelate ring system has been isolated so far.[38,45–49] However, the present X-ray crystal structure analysis showed that the binuclear units containing a 5–5–(4)–5–5 fused chelate ring system exist in the crystal. This complex is the first example of such a binuclear copper(II) complex. The moderate stability of the binuclear structure can be ascribed to the "small bond angle" and the "large radius" of the sulfur atom.

Infrared Spectra. The OH stretching vibration band at ≈3350 cm^{-1} observed for the free ligands is absent in the spectra of the copper(II) complexes. This indicates that the alcoholic proton is lost upon complexation. In the case of the nitrates, Cu(R-nso)NO_3, strong bands appear at 1280—1295, 1375—1410, and 1455—1480 cm^{-1} and a sharp band at 810 cm^{-1}, which are indicative of monodentate nitrate coordination.[50]

Electronic Spectra. The band maxima of the diffuse reflectance spectra and the electronic absorption spectra in 1,2-dichloroethane solutions are given in Table 5. The band around 12.5×10^3 cm^{-1} is undoubtedly assigned to a d-d transition. Judging from the band shape and position, five-coordinate copper environment is assumed.[51] The infrared spectra of Cu(R-nso)NO_3 are consistent with this view. Moreover, the X-ray crystal structure analysis of Cu(CH_3-nso)Br confirms the five-coordinate copper(II) dimer. The position of the d-d band does not vary significantly with changing the anion X. The band at 22.3—26.2×

10^3 cm^{-1} should correspond to the band observed at 24—25$\times10^3$ cm^{-1} for Cu(R-sno)X,[1,7] and is assigned to the p_π(O)→d(Cu) charge transfer transition. This charge transfer band of Cu(R-nso)X shifts to a lower frequency with the change of X in the order NO_3>Cl>Br. Assuming that the nonbonding p_π electron on alkoxide oxygen varies little in energy, the charge transfer band reflects the optical electronegativity of the copper ion. Since optical electronegativity of a metal increases when a donor atom is replaced with a more softer one, the optical electronegativity of the copper ion for Cu(R-nso)X should increase in the order of X=NO_3<Cl<Br. The p_π(O)→d(Cu) transition observed for Cu(R-nso)X is compatible with this expectation. The absorption around 30×10^3 cm^{-1} may be assigned to the σ(S)→d(Cu) charge transfer transition.[52-54] The ultraviolet absorptions ($\approx34\times10^3$ cm^{-1}) of Cu(R-nso)Br fall in the range for either the Br→d(Cu) or the σ(N)→d(Cu) transition. The absorption at 38×10^3 cm^{-1} of Cu(R-nso)Cl may be assigned to a superposition of the Cl→d(Cu) and the σ(N)→d(Cu) transitions.[52-56]

Magnetic Susceptibilities. The magnetic susceptibilities were measured over the temperature range 80—300 K. The magnetic moments per copper atom are subnormal at room temperature and decrease with lowering of temperature, indicating the existence of an antiferromagnetic spin-exchange interaction (Table 6). The temperature dependence of magnetic susceptibility for Cu(n-C_4H_9-nso)Cl is shown in Fig. 4. The small increase in the magnetic susceptibility at low temperature is most likely due to a small amount of mononuclear paramagnetic impurity. Accordingly, the impurity term was added to the Bleaney-Bowers equation[57] giving,

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-p) + \frac{0.45p}{T} + N\alpha, \quad (1)$$

where χ_A is susceptibility per copper atom, p is the

ratio of mononuclear copper(II) ions to total copper(II) ions, and N, g, J, β, and $N\alpha$ have the usual meanings.[58] The $-2J$, g, $N\alpha$, and p values obtained by the best fit of the susceptibility data to Eq. 1 are 735 cm^{-1}, 2.10, 60×10^{-6} cgs emu/mol, and 0.015, respectively. The $-2J$ value, the energy separation between the spin-singlet ground state and the lowest spin-triplet state, is comparable to those of Cu(R-sno)X,[1,7] indicating that a strong antiferromagnetic interaction is operating between the copper(II) ions. However, the temperature dependence of magnetic susceptibilities of Cu(R-nso)X (R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9; X=Br, Cl, NO_3) except for Cu(n-C_4H_3-nso)Cl can not be interpreted by the equation based on a binuclear structure, in spite of the present X-ray result that Cu(CH_3-nso)Br consists of discrete binuclear clusters. Some of the examples are shown in Fig. 4. Therefore, it seems to be difficult to explain the magnetic behavior only in terms of the crystal structure obtained here. For the reasonable explanation, one should notice the crystal structure is not always independent of temperature. A remarkable variation in the coordination sphere around the copper atom may take place at low temperature, and this may cause the deviation of the χ_A-T curve from the theoretical one.

The authors wish to express sincere thanks to Prof's. Ikuhiko Ueda and Shigeaki Kawano of Kyushu University for their helpful advices and discussions. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 454199 from the Ministry of Education, Science and Culture.

Enrichment and Spectrophotometric Determination of a Trace Amount of Chromium(VI) as the Diphenylcarbazide Complex on a Mixed Resin Prepared from Finely Divided Anion and Cation Exchangers

Kunio Ohzeki, Toshiaki Sakuma, and Tomihito Kambara*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 15, 1980)

A rapid and sensitive method has been developed for the determination of a trace amount of chromium(VI). It is based on the pre-concentration of chromium(VI) as the diphenylcarbazide (DPC) complex on a mixed resin prepared from finely divided anion and cation exchangers and the subsequent measurement of absorbance of the resin phase after collection on a filter paper as a uniform thin layer. The sensitivity of the method is approximately 100 times higher than the ordinary solution method using 1-cm cell. The extraction of chromium(VI) with tributyl phosphate followed by back extraction into water is effective for reducing the influence of interfering ions.

Analytical utilization of a resin mixture of finely divided anion and cation exchangers, the diameter being smaller than 30 μm, has been reported. Rapid and selective enrichment of trace amounts of copper(II)[1] and manganese(II)[2] on the mixed resin were carried out by batch method in the presence of 8-hydroxy-5-quinolinesulfonate and 4-(2-pyridylazo)resorcinol, respectively. The ions on the resin were then eluted and determined by atomic absorption spectrometry.

Yoshimura *et al.* reported ion-exchanger colorimetry[3,4] based on the pre-concentration of metal complex with negative or positive charge on respective ion exchanger ranging 200—400 mesh, and the subsequent measurement of the absorbance of the complex in the resin phase after transferring a part of the resin into a cell of 0.1 cm in thickness. The method has been successfully applied to the determination of chromium[5] and zinc[6] in water.

This article deals with a new method of ion-exchanger colorimetry[7] for chromium(VI) by means of the combined use of DPC and a mixture of finely divided anion and cation exchangers. Finely divided cation exchanger collects chromium(VI)–DPC complex rapidly by the batch method in combination with anion exchanger to form a bulky material. The coagulated resin is then separated by filtration and the resulting thin layer of the colored resin on a filter paper is directly subjected to spectrophotometric measurement.

Experimental

Reagents. A stock solution of chromium(VI) (0.5 mg/ml) was prepared by dissolving 1.415 g of analytical grade potassium dichromate in one liter of water. The solution was diluted to give 0.1 μg per ml of chromium(VI) immediately before use.

Diphenylcarbazide was used in a 0.4 (w/v)% acetone–water (1 : 1) solution, a fresh solution being made each day.

Synthetic sea water was prepared according to JIS K 2510-1971.[8]

Tributyl phosphate (TBP) saturated with 0.1 M (1 M=1 mol dm^{-3}) hydrochloric acid was used. A 150-ml portion of the ester was shaken with 50 ml of the synthetic sea water containing 0.1 M hydrochloric acid.

Ion Exchange Resin. Macroreticular type Amberlyst 15 and A-26 (both Rohm and Haas Co.) in RSO_3H and $RN(CH_3)_3Cl$ forms, respectively, were used. Suspension of the resins was prepared according to the method reported.[1] The stock suspension was stirred immediately before being pipetted off.

General Procedure. A 100-ml aliquot of the solution containing less than 1.0 μg of chromium(VI) was taken into a separatory funnel, and then 10 ml of 0.1 M sulfuric acid, 3.0 ml of anionic resin suspension (ARS), 1.0 ml of cationic resin suspension (CRS) and finally 1.0 ml of 0.4% DPC solution were added. The mixture was then shaken for 12 min and the resulting coagulated material was collected onto a filter paper (Toyo Roshi No. 5A) placed on a holder. A disk of colored resin of 17 mm diameter and about 0.3 mm in thickness was obtained. The filter strip was dipped into a dilute acetate buffer solution of pH 4.8 for 10 s in order to stabilize the coloration. Another disk of resin was prepared without addition of chromium(VI) and used as a reference. The filter strips were fixed on the glass plate and the absorbances were measured at 550 and 700 nm, the absorption maximum lying at the former wavelength and the complex having no absorption at the latter. The net absorbance was obtained by the difference.

Results and Discussion

Determination of Exchange Capacity. The ion exchange capacity of the resin in the suspension was determined by conductometric titration. A known amount of CRS and ARS was titrated with the standard solution of sodium hydroxide and silver nitrate, respectively. In both cases inverse L-shaped titration curves were obtained. The exchange capacities were 13.3×10^{-3} meq ml^{-1} for CRS and 7.22×10^{-3} meq ml^{-1} for ARS.

Coagulation. The mutual coagulation of the finely divided anion and cation exchangers was examined according to the method reported.[1] The 1.0-ml portion of CRS was most satisfactorily deposited from the solution with addition of 3.0 ml of ARS.

Exchange Capacity of the Coagulated Resin. The number of ion exchange sites consumed for the association of 3.0 ml of CRS with 9.0 ml of ARS was estimated by determining the hydrogen ion expelled from the cationic exchanger as a result of mutual coagulation. The proportions of the ion exchange sites taking part in coagulation to the total ion exchange sites in CRS and ARS were found to be 11.8% and 14.1%, respectively. The remaining sites are effective to fix cation

or anion in the solution.

Shaking Time. During the course of shaking, the cationic chromium(VI)–DPC complex is fixed on the cationic exchanger, the latter combining with anionic exchanger to form coagulated material. A constant and maximum recovery was achieved in the shaking period of 12—16 min. With prolonged shaking, the absorbance decreased slightly.

Preparation of Thin Layer. The colored coagulated material was collected onto a filter paper placed on a holder and washed with a small amount of water. The rate of filtration was about 40 ml min^{-1} with suction. At the end of washing, the suction should be stopped in order to avoid the formation of cracks in the resin phase.

Stability of the Coloration. The resin was stored wet by dipping the end of filter paper in water. The absorbance of the complex was reduced by *ca.* 4% after 30 min. When the resin was soaked for 10 s in a dilute acetate buffer solution immediately after filtration, the coloration being stable at least for 30 min. However, in the presence of a large amount of magnesium the color based on magnesium–DPC complex developed after long immersion in the acetate buffer solution. The absorbance should be measured as soon as possible.

Absorption Measurement. The thin layers of sample and reference together with filter paper were fixed with water on a glass plate fitted directly to the window of detector. The absorbance was measured with the slit width of 2.5 mm. The chromium(VI)–DPC complex in the resin phase has the absorption maximum at 550 nm. The absorbance is given by

$$A = A_{RC} + (A_{B,s} - A_{B,r}),$$

where A_{RC} denotes the absorbance of the complex in the resin phase and $A_{B,s}$ and $A_{B,r}$ denote the background absorption of the sample and reference, respectively, which are caused by the resin phase, the filter paper and the glass plate. The difference in the background absorption is estimated from the absorbance at 700 nm where the complex has no absorption. Consequently, the net absorbance of chromium(VI)–DPC complex is given by the difference in measurement at 500 nm and 700 nm.

Calibration Curve. The calibration curve deviates slightly from proportionality (Fig. 1). The relative standard deviation was 2.1% (n=6) for 1 μg of chromium(VI) and 3.3% (n=5) for 0.4 μg. The absorbance of thin layer prepared from the 100 ml of solution containing 1 μg chromium(VI) is almost the same as that for 1 ppm chromium(VI)–DPC solution in 1-cm cell. The sensitivity of the present method is approximately 100 times higher than the ordinary solution method.[9]

Sample Volume. A 1-μg portion of chromium(VI) was recovered effectively from 100—400 ml of sample solution (Fig. 2). The lower absorbance was measured with a disk prepared from 50 ml of sample solution, the reason for which is not yet clear but the result was reproducible.

Divers Ions. Effects of sodium chloride and calcium chloride examined are shown in Fig. 3. The recovery of chromium(VI)–DPC complex decreased considerably with the addition of calcium chloride, which is attributable to the competition between cations of chromium(VI)–DPC complex and calcium ion for cation exchange sites in the mixed resin. The effects of other cations are given in Table 1. Chromium-

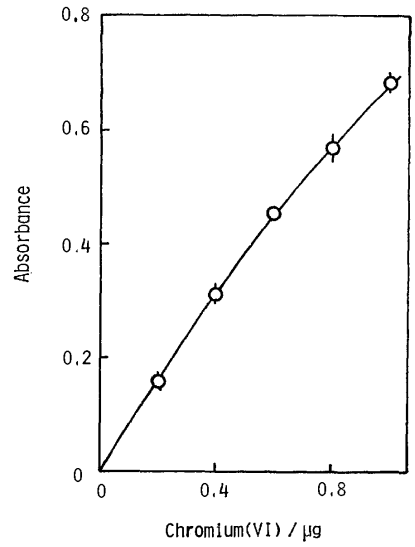

Fig. 1. Calibration curve of chromium(VI) as the complex with diphenylcarbazide. Sample volume: 100 ml. The vertical line on each plot denotes 95% confidence interval.

G: F+Fe(III) 50 μg+ Cu(II) 20 μg	0.348	3.7(5)	91.5

a) Calculated from the calibration curve in Fig. 1.
b) The sample was prepared according to JIS K 2510-1971. The components (g/l) were: NaCl 24.54, $MgCl_2 \cdot 6H_2O$ 11.10, Na_2SO_4 4.09, $CaCl_2$ 1.16, KCl 0.69, $NaHCO_3$ 0.20, KBr 0.10, H_3BO_3 0.03, $SrCl_2 \cdot 6H_2O$ 0.04, NaF 0.003.

(III), cadmium(II), lead(II), and zinc(II) have a tendency to give a positive error, iron(III), copper(II), and aluminum(III) a negative error.

Extraction of Chromium(VI) with TBP. The extraction of chromium(VI) with tributyl phosphate[10,11] was examined with synthetic sea water. General procedure is as follows: A 100-ml portion of the synthetic sea water containing less than 1 μg of chromium(VI) was mixed with 5 ml of 2 M hydrochloric acid. The solution was then shaken with 20 ml of TBP for about 3 min. Chromium(VI) in the organic phase was stripped first with 30 ml of water for 3 min and subsequently 10 ml of water for 3 min. The two aqueous phases were combined. The final sample volume was adjusted to 100 ml by addition of water, chromium(VI) being determined by the method stated above.

Chromium(VI) was most effectively extracted from 0.06—0.14 M hydrochloric acid into TBP by shaking for 2—5 min. Rapid phase separation was attained with use of 30 ml of water for the first stripping and 10 ml of water for the second stripping. Greater amount of water has no advantage.

The TBP extraction was effective to eliminate the influence of divers ions (Table 2). About 95% of chromium(VI) is recovered by the extraction-stripping procedure.

Preparation and Stereochemistry of Bis(1,10-phenanthroline)- and Bis-(2,2′-bipyridine)chromium(III) Complexes Containing 2,2′-Bipyridine *N,N′*-Dioxide or Its 3,3′-Dimethyl Derivative

Hideaki KANNO,† Kazuo KASHIWABARA, and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received April 16, 1980)

Bis(1,10-phenanthroline)- and bis(2,2′-bipyridine)chromium(III) complexes containing a seven-membered chelate ligand, 2,2′-bipyridine *N,N′*-dioxide(bpdo) or 3,3′-dimethyl-2,2′-bipyridine *N,N′*-dioxide(mbdo) were prepared. Each complex gave only one of two possible pairs of enantiomers resolved by SP-Sephadex column chromatography. On the basis of the circular dichroism spectra, molecular models, and recovery of the optically active free mbdo ligand from the resolved mbdo complexes, it was found that all the enantiomeric pairs consist of $\Delta(\delta)$ and $\Lambda(\lambda)$ isomers involving the skew dioxide chelate ligands in the *ob* configuration.

A seven-membered, skew chelate conformation of 2,2′-bipyridine *N,N′*-dioxide (bpdo) in metal complexes has been confirmed by X-ray analysis of $[La(bpdo)_4](ClO_4)_3$.[1] The skew conformation can exist in a pair of enantiomers, δ and λ (Fig. 1). We found that tris-type chromium(III) complexes with bpdo[2] and its derivative, 3,3′-dimethyl-2,2′-bipyridine *N,N′*-dioxide (mbdo)[3] give one and three diastereomers, respectively, of four possible ones, $lel_3(\Delta(\lambda\lambda\lambda), \Lambda(\delta\delta\delta))$, $lel_2ob(\Delta(\lambda\lambda\delta), \Lambda(\delta\delta\lambda))$, $lelob_2(\Delta(\lambda\delta\delta), \Lambda(\delta\lambda\lambda))$, and $ob_3(\Delta(\delta\delta\delta), \Lambda(\lambda\lambda\lambda))$. Δ and Λ denote the absolute configuration of a chromium(III) ion and *lel* and *ob* the diastereoisomerism of a complex with skew chelate rings analogous to that in $[M(en)_3]^{n+}$ (en=ethylenediamine).[4] The number of diastereomers formed in the dioxide complexes is related to whether a dioxide chelate ring can change the skew conformation between δ and λ.

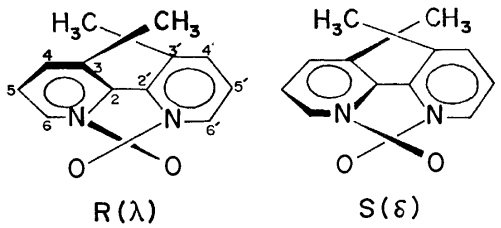

Fig. 1. A pair of enantiomers of mbdo.

This paper describes the preparation and stereochemistry of bis-phen and bis-bpy chromium(III) complexes containing bpdo or mbdo, where phen and bpy denote 1,10-phenanthroline and 2,2′-bipyridine, respectively. Since both phen and bpy ligands form planar chelate rings upon coordination to a metal ion, each of the complexes can have two diastereomers, $lel(\Delta(\lambda), \Lambda(\delta))$ and $ob(\Delta(\delta), \Lambda(\lambda))$. Bis(α-diimine) metal complexes containing a seven-membered chelate ligand do not seem to have been reported except for $[Co(bpy)_2(2,2'\text{-diaminobiphenyl})]^{3+}$ whose stereochemistry was not fully characterized because of instability.[5]

Experimental

The new complexes are photosensitive causing hydrolysis and the following procedures should be carried out in the dark.

† Present address: Department of Chemistry, Faculty of Science, Shizuoka University, Shizuoka 422.

[Cr(phen)$_2$(bpdo)]$^{3+}$ and [Cr(phen)$_2$(mbdo)]$^{3+}$. $[CrCl_2(phen)_2]Cl\cdot 2H_2O$[6] (2.0 g, 3.6 mmol) was added to an aqueous solution (50 cm^3) containing bpdo·H_2O[7] (0.75 g, 3.6 mmol) or racemic mbdo[3] (0.9 g, 4.2 mmol). The solution was adjusted to pH *ca.* 2 with hydrochloric acid in order to avoid the formation of hydroxo complexes, kept at 85 °C with stirring for 6 h, and cooled to room temperature. The resulting solution was diluted with water (0.5 dm^3) and passed through a short column (ϕ 2.7×5 cm) of SP-Sephadex C-25. The resin which adsorbed the red orange product was loaded on a column (ϕ 2.7×80 cm) of SP-Sephadex C-25 and the complexes were eluted with an aqueous 0.2 mol/dm^3 Na_2SO_4 solution adjusted to pH 2 with hydrochloric acid. The column showed two bands, red and orange, the red band being eluted faster than the orange one. The red eluate was found to involve $[Cr(H_2O)_2(phen)_2]^{3+}$ from the absorption spectrum.[8] The orange eluate was diluted with water and poured again on a small column (ϕ 2.7×3 cm) of SP-Sephadex C-25, and the complex adsorbed was eluted with an aqueous 0.5 mol/dm^3 $NaClO_4$ solution. The eluate gave an orange precipitate on standing at room temperature, which was collected and washed with a small amount of water. Recrystallization from hot water gave orange needle crystals. Yield: bpdo-complex, 0.7 g (22%); mbdo-complex, 0.6 g (17%).

[Cr(bpy)$_2$(bpdo)]$^{3+}$ and [Cr(bpy)$_2$(mbdo)]$^{3+}$. Orange needle crystals of the complexes were obtained by the same method as that for the corresponding phen complexes using $[CrCl_2(bpy)_2]Cl\cdot 2H_2O$[9] (2.7 g, 5.3 mmol) and bpdo·H_2O (1.2 g, 5.8 mmol) or racemic mbdo (1.3 g, 6.0 mmol). Yield: bpdo-complex, 1.9 g (41%); mbdo-complex, 0.9 g (18%).

Each of the phen and bpy complexes gave only one diastereomer, no indication for the formation of another isomer being detected on column chromatography.

Resolution of the Complexes. All the complexes were completely resolved by SP-Sephadex column chromatography. Each complex was loaded on a column (ϕ 2.7×130 cm) of SP-Sephadex C-25. By elution with a 0.15 mol/dm^3 sodium $(+)_{589}$-tartratoantimonate(III) solution, the column gave two separate bands of $(+)_{589}$- and $(-)_{589}$-isomers, the former being eluted faster. Each isomer was isolated as perchlorate and recrystallized from hot water by the same method as that for the racemate. Analytical data of the racemic and optically active complexes are given in Table 1.

Recovery of mbdo from the Complexes. The optically active free mbdo ligand was recovered from $(-)_{589}$-$[Cr(phen)_2(mbdo)]^{3+}$ and $(-)_{589}$-$[Cr(bpy)_2(mbdo)]^{3+}$ by the same method as that for $[Cr(mbdo)_3]^{3+}$.[3] Both mbdo recovered gave positive rotation at 589 nm.

Measurements. Absorption and circular dichroism (CD) spectra of the complexes in aqueous solutions were obtained

with a Hitachi 323 spectrophotometer and a Jasco J-40 spectropolarimeter, respectively. Optical rotations were measured with a Jasco DIP-4 polarimeter.

Results and Discussion

Each of the four new complexes, $[Cr(L)_2(bpdo)]^{3+}$ and $[Cr(L)_2(mbdo)]^{3+}$ (L=phen, bpy) gives only one pair of enantiomers stereoselectively by the reaction of the corresponding dichloro complex with the dioxide ligand in water, although there are two possible pairs of enantiomers, *lel*($\Lambda(\lambda)$, $\Lambda(\delta)$) and *ob*($\Lambda(\delta)$, $\Lambda(\lambda)$) (Fig. 1). The enantiomers are completely resolved by SP-Sephadex column chromatography using sodium $(+)_{589}$-tartratoantimonate(III) as an eluent. The complexes in aqueous solutions are stable in the dark, undergoing gradual hydrolysis in the light.

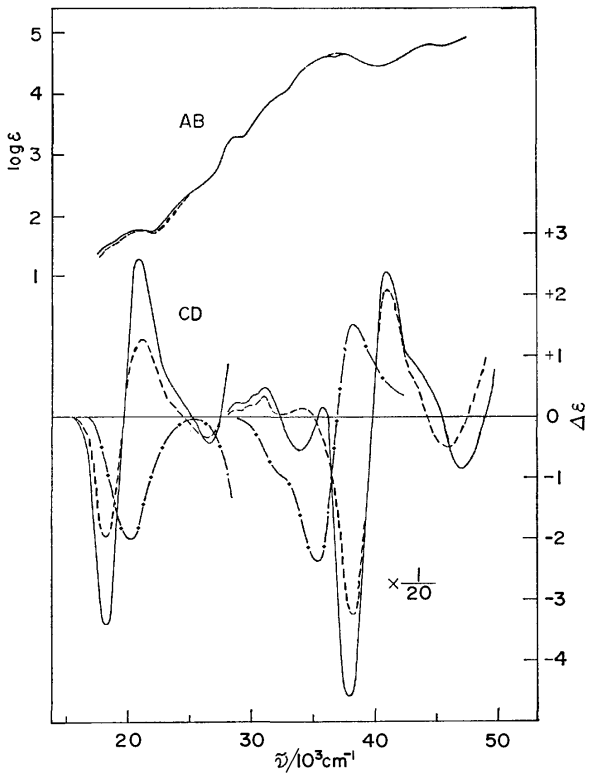

Fig. 2. Absorption and CD spectra of $(-)_{589}$-$[Cr(phen)_2(mbdo)]^{3+}$ (——) and $(-)_{589}$-$[Cr(phen)_2(bpdo)]^{3+}$ (----), and CD spectrum of Λ-$[Cr(ox)(phen)_2]^+$ (-·-·-).[12]

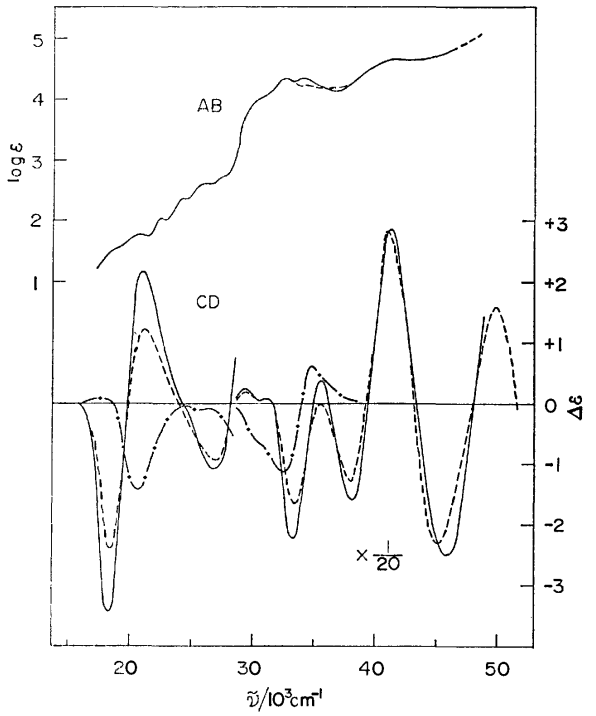

Fig. 3. Absorption and CD spectra of $(-)_{589}$-$[Cr(bpy)_2(mbdo)]^{3+}$ (——) and $(-)_{589}$-$[Cr(bpy)_2(bpdo)]^{3+}$ (----), and CD spectrum of Λ-$[Cr(ox)(bpy)_2]^+$ (-·-·-).[12]

Absorption and CD spectra of $(-)_{589}$-$[Cr(phen)_2(L)]^{3+}$ are shown in Fig. 2 and those of $(-)_{589}$-$[Cr(bpy)_2(L)]^{3+}$ in Fig. 3 (L=bpdo, mbdo). The spectral data are given in Table 2. The absorption spectra of the bpdo and mbdo complexes are nearly the same over the whole region. The bands at 20750 cm^{-1} with a shoulder (18500 cm^{-1}) and *ca.* 20850 cm^{-1} with a shoulder (18900 cm^{-1}) for the phen and bpy complexes, respectively, can be assigned to the first absorption band ($^4T_{2g} \leftarrow {}^4A_{2g}$), although the assignments are somewhat ambiguous because of adjacent strong charge-transfer bands. These first absorption bands are shifted to small wavenumbers by 450—500 cm^{-1} from those of the corresponding oxalato complexes.[10] In the ultraviolet region, all the complexes show complicated spectra due to absorptions arising from intramolecular transitions of the ligands and charge-transfer transitions from the ligands to a Cr(III) ion.

The CD spectra of all the $(-)_{589}$-isomers show a very similar pattern in the region of the first absorption band. The bpdo and mbdo complexes give similar CD spectra over the whole region. This suggests that all the $(-)_{589}$-isomers have the same absolute configuration including chirality of a skew dioxide chelate ring. The CD spectra of the dioxide complexes are compared with those of Λ-$[Cr(ox)(phen)_2]^+$ and Λ-$[Cr(ox)(bpy)_2]^+$ in Figs. 2 and 3, respectively. The absolute configurations

of the oxalato complexes were assigned on the basis of the CD pattern in the regions of the first spin-allowed d-d,[11-13] the spin-forbidden d-d,[13] and the $\pi^*\leftarrow\pi$ transitions.[11,12] There seems to be little similarity in CD spectra between the dioxide and the oxalato complexes. The dioxide complexes show two CD components of similar strength with opposite signs in the region of the first absorption band; it is not clear which component is dominant. In addition the complexes do not exhibit typical exciton CD bands in the region of the $\pi^*\leftarrow\pi$ transitions of the phen (*ca.* 37000 cm^{-1}) or bpy (*ca.* 33000 cm^{-1}) ligand, although the spectra of the bpy complexes in this region somewhat resemble the spectrum of Δ-[Cr(ox)(bpy)$_2$]$^+$. Thus the absolute configuration of the dioxide complexes can not be assigned without ambiguity from the CD spectra in the region given. However, CD signs in the region of the spin-forbidden d-d transitions can be utilized for assigning the absolute configuration of chromium(III) complexes.

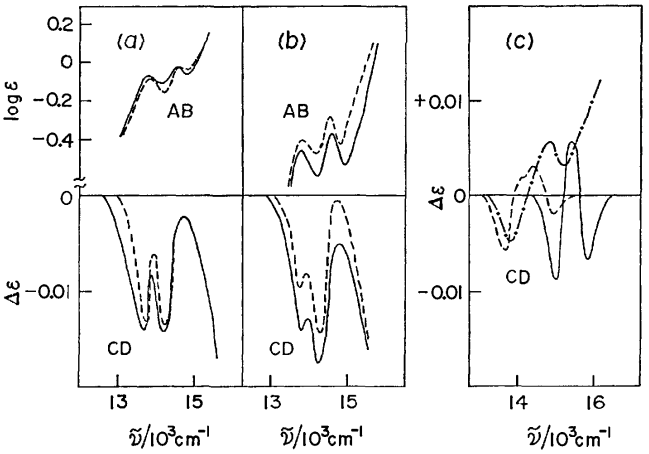

Fig. 4. Absorption and CD spectra in the region of the spin-forbidden d-d transitions. (a) $(-)_{589}$-[Cr(phen)$_2$-(mbdo)]$^{3+}$ (——) and $(-)_{589}$-[Cr(phen)$_2$(bpdo)]$^{3+}$ (----). (b) $(-)_{589}$-[Cr(bpy)$_2$(mbdo)]$^{3+}$ (——) and $(-)_{589}$-[Cr(bpy)$_2$(bpdo)]$^{3+}$ (----). (c) Δ-[Cr(en)$_3$]$^{3+}$ (——),[13] Δ-[Cr(ox)(phen)$_2$]$^+$ in 70% HClO$_4$ (-·-·-),[13] and Δ-[Cr(ox)(bpy)$_2$]$^+$ (----).[13]

Kaizaki *et al.*[14] found that in tris-chelate chromium(III) complexes except for a few complexes such as those with biguanide or acetylacetonate, the smallest wavenumber CD band in the region of the spin-forbidden d-d transitions shows the same sign as that of a dominant CD band in the region of the first spin-allowed d-d transitions. The smallest wavenumber CD bands of all the $(-)_{589}$-dioxide complexes give a negative sign in the region of the spin-forbidden bands (Fig. 4). Thus dominant CD bands of the isomers in the region of the first spin-allowed band should be negative, and the isomers can be assigned to the Δ-configuration.[15] The Δ-isomers of [Cr(ox)(L)$_2$]$^+$ (L=phen, bpy) and a typical tris-chelate complex, [Cr(en)$_3$]$^{3+}$ (en=ethylenediamine) also give negative CD bands at the smallest wavenumber in the region of the spin-forbidden d-d transitions.

The $(-)_{589}$-dioxide complexes can have two diastereomers, $\Delta(\delta)(ob)$ and $\Delta(\lambda)(lel)$. Since the free mbdo ligand is optically stable,[3] it was recovered from $(-)_{589}$-Δ-isomers of the phen and bpy complexes in order to know the absolute configuration. Both mbdo recovered show positive rotation at 589 nm. The $(+)_{589}$-mbdo

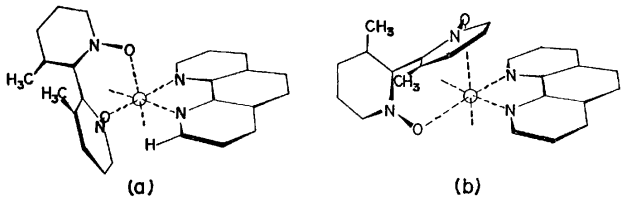

Fig. 5. Schematic drawing of the two diastereomers of Δ-[Cr(phen)$_2$(mbdo)]$^{3+}$; (a) $\Delta(\lambda)(lel)$, (b) $\Delta(\delta)(ob)$.

ligand is the same as that recovered from $(+)_{589}$-[Cr(mbdo)$_3$]$^{3+}$ which was assigned to the $\Delta(\delta\delta\delta)(lel_3)$-configuration.[3] Thus the $(-)_{589}$-Δ-isomers involve mbdo of the $\delta(S)$ chirality to form a $\Delta(\delta)(ob)$ diastereomer. Since the bpdo complexes give CD spectra similar to those of the mbdo complexes over the whole region, it is concluded that the bis-phen and bis-bpy chromium(III) complexes of these dioxides form only an *ob* isomer stereoselectively. Such stereoselectivity is in contrast with the fact that the stability of complexes with skew chelate rings decreases with an increase in the number of *ob* ligands.[4] The [Co(en)$_2$(L)]$^{3+}$ (L= 2,2′-diaminobiphenyl,[5,16] and its 6,6′-dimethyl derivative[16]) complexes, the ligands in which form skew seven-membered chelate rings similar to the dioxides, give only a *lel* isomer. The formation of only *ob* isomers for the dioxide complexes seems to be caused by steric interactions between the dioxide and the α-diimine ligands in the *lel* form. Figure 5 shows a schematic drawing of the two isomers of Δ-[Cr(phen)$_2$($(+)_{589}$-mbdo)]$^{3+}$ by Dreiding molecular models. In the $\Delta(\lambda)(lel)$ form, each 2- (or 9-) hydrogen atom of the phen ligands comes very close to the 6- and 6′-carbon (and hydrogen) atoms of mbdo. On the other hand, there is no such extreme proximity among atoms of the ligands in the $\Delta(\delta)(ob)$ form, each pyridine ring of mbdo becoming nearly parallel to each of the phen ligands to form a stable structure. Thus the bis-phen and bis-bpy complexes of bpdo and mbdo would give only one pair of *ob* enantiomers, $\Delta(\delta)$ and $\Lambda(\lambda)$, stereoselectively.

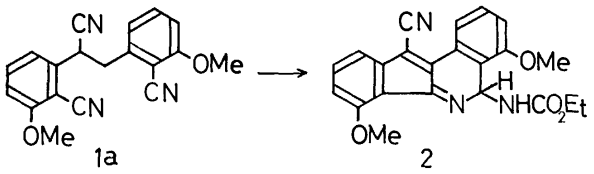
Cyclization Reactions of 2,3-Bis(2-cyanophenyl)propionitriles. III.[1] Substituent Effect on the Carbanion Reactivies of the Propionitriles and Tautomerism of 5-Acetamido-11-cyanoindeno[1,2-*c*]isoquinolines

Kazuo ANDO,*,† Takashi TOKOROYAMA, and Takashi KUBOTA††
Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558
(Received June 27, 1979)

The substituent effect in the base-catalyzed cyclization reaction of 2,3-bis(2-cyanophenyl)propionitriles (**1**) to 5-amino-11-cyano-11*H*-indeno[1,2-*c*]isoquinolines has been studied and the result is discussed in terms of the dichotomic carbanion reactivities of **1**. Preparation of **1** and the tautomerism of 5-acetamido-11-cyanoindeno-[1,2-*c*]isoquinolines between 5*H* and 11*H* structures are described.

When 2,3-bis(2-cyano-3-methoxyphenyl)propionitrile (**1a**) was allowed to react with sodium ethoxide and diethyl carbonate in ethanol, a red pigment was obtained in 79.3% yield, to which we assigned the structure **2** (Scheme 1).[2]



Scheme 1.

The formation of **2** from **1a** involves the preferential attack of C-3 carbanion to the cyano group on aromatic ring.

The cause for the less stable C-3 carbanion participating exclusively in the cyclization deserves further study. We have confirmed that the cyclization product derived from the more stable C-2 carbanion is also obtained and examined the relative reactivity of the dichotomic carbanions in terms of the substituent effect. We have found an interesting tautomerism between 11*H*- and 5*H*-indeno[1,2-*c*]isoquinoline systems, which is markedly influenced by the substitution patterns of the aryl rings.

Results and Discussion

Preparation of 2,3-Bis(2-cyanophenyl)propionitriles (1). The reaction of 2-cyano-3-methoxybenzyl bromide (**3a**) with sodium cyanide afforded 2,3-bis(2-cyano-3-methoxyphenyl)propionitrile (**1a**) in variable ratios to the normal product, 2-cyano-3-methoxybenzyl cyanide (**5a**), depending on the conditions.[3] Formation of the former compound is accelerated in the case of low cyanide concentration and in a polar aprotic medium such as DMSO. Since the reactivity of the benzyl cyanides (**4**) initially produced is affected to a large extent by the substituents in aryl rings, a proper modification of the reaction procedure was necessary in order to prepare propionitriles (**1**) in acceptable yields. The following methods were investigated.

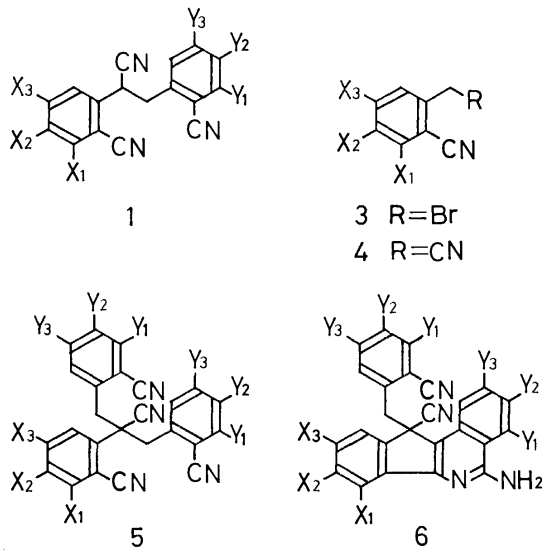
A. A solution of a bromide and NaCN in ethanol–water (2: 1) was allowed to stand at −20 °C for 48 h.

B. A solution of a bromide and NaCN in ethanol–water (4: 1) was refluxed for 6 h.

C. A mixture of a bromide, NaCN, a trace of NaI, and acetone was stirred at room temperature for 48 h.

D. A mixture of a bromide, NaCN, a trace of NaI, and acetone was stirred and refluxed for 24 h.

The results obtained in the reactions of the substrates **3a**—**3f** are summarized in Table 1. Method D was generally applicable (**3a**, **3b**, **3c**, and **3f**) except when



a $X_1=Y_1=OMe$, $X_2=X_3=Y_2=Y_3=H$
b $X_1=X_3=Y_1=Y_3=H$, $X_2=Y_2=OMe$
c $X_1=X_2=Y_1=Y_2=H$, $X_3=Y_3=OMe$
d $X_1=X_3=Y_1=Y_3=H$, $X_2=Y_2=Cl$
e $X_1=X_2=Y_1=Y_2=H$, $X_3=Y_3=Cl$
f $X_1=X_2=X_3=Y_1=Y_2=Y_3=H$
g $X_1=OMe$, $X_2=X_3=Y_1=Y_2=Y_3=H$
h $X_1=X_2=X_3=Y_2=Y_3=H$, $Y_1=OMe$

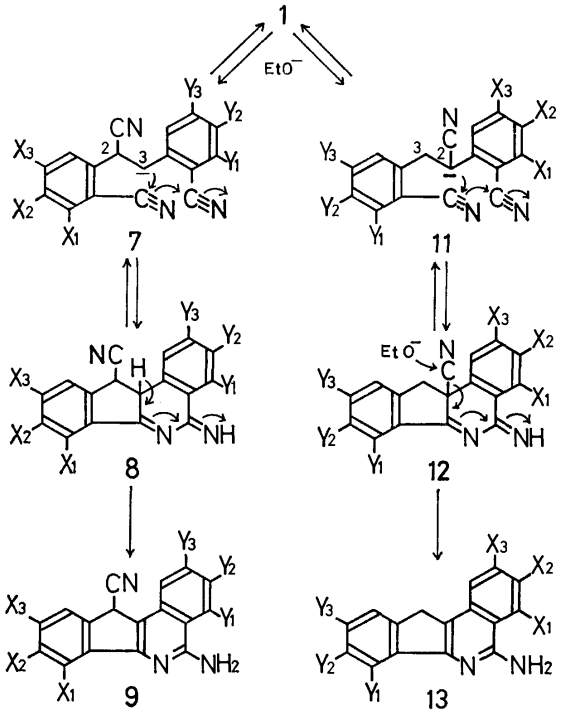
8	**3f**	D	3.0	77.0	0	0	0

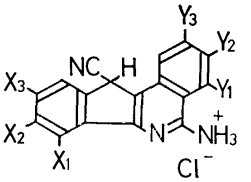
the intermediary benzyl cyanides (**4**) were unusually reactive as in the case of compounds **3d** and **3e** with chlorosubstituents. For example, the reaction of **3d** by method C (entry 6) gave only the disubstituted compound **5d** and **6d**, which would be formed by cyclization of **5d**. Method A was introduced in such cases. Use of protic solvents and a large excess of sodium cyanide suppressed the disubstitution.

Cyclization Reactions of 2,3-Bis(2-cyanophenyl)propionitriles (1). Of the reactants used in the original red pigment formation,[2] diethyl carbonate does not seem to be essential for the cyclization reaction.

Thus, when a solution of the propionitrile (**1a**) in ethanol was refluxed in the presence of two molar equivalents of sodium ethoxide under nitrogen atmosphere for 2 h, a dark brown reaction mixture was obtained. This mixture was warmed with 1% sodium hydroxide solution for a short time in order to confirm the dissolution of the acidic product. It was then filtered. After acidification of the filtrate with dil. hydrochloric

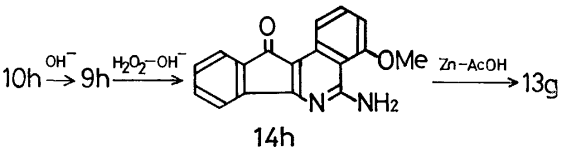


Scheme 2.



10

Fig. 2.



Scheme 3.

acid solution, the cyclized product **9a** was isolated as a colorless hydrochloride (**10a**) in 55% yield.[4] The undissolved material was separated by silica gel chromatography to afford a product in 3% yield, identified as **13a**. **13a** was obtained from **2** by treatment with alkaline hydrogen peroxide and the subsequent reduction with zinc-acetic acid.[2a] The formation of **13** is best interpreted by the cyclization of **1** *via* C-2 anion **11** followed by aromatization of the resulting heterocyclic ring with loss of the cyano group (Scheme 2). The possibility of the formation of **13** *via* **9** was excluded by the fact that cyclization of the propionitrile (**1g**) afforded **13g** and not **13h**. The substitution pattern was confirmed by the derivation of **13g** from **9h** through the reaction sequence used for the conversion of **2** into **13a** (Scheme 3). Thus the cyclization reaction of the 2,3-bis(2-cyanophenyl)propionitriles (**1**) with a base is dichotomic.

Cyclization experiments carried out in the same way as above for variously substituted 2,3-bis(2-cyanophenyl)propionitriles (**1**) have confirmed this to be the case.

Table 2. Cyclization reactions of 2,3-bis(2-cyanophenyl)propionitriles (**1**)

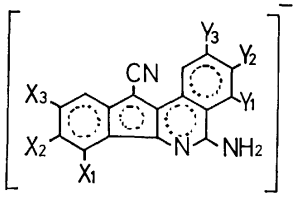
Substrate	Reaction conditions: NaOEt (mol eq.)	Reaction conditions: Time (h)	Yield (%): **9**	Yield (%): **13**	Ratio **9**/**13**
1a	2	2	55	3	18.3
1b	14	2	0	81	0
1c	2	2	66	7	9.4
1d	2	2	34	40	0.85
1e	2	2	61	6	10.2
1f	2	2	32	45	0.71
1g	4	4	23	46	0.50
1h	2	2	27	50	0.54

The results are summarized in Table 2. Formation of the dual products **9** and **13** takes place, with the exception of **1b**, which is extremely nonreactive, giving only **13b** upon reaction with use of excess base (14 molar equiv.). In the case of the propionitrile with unsubstituted aryl rings (**1f**) and the *p*-substituted analog (**1d**), the molar ratios of **9** to **13** are smaller than 1.

On the other hand, the molar ratios of *m*-substituted compounds (**1a**, **1c**, and **1e**) are larger than 1. Thus the formation ratios of **9** to **13** are considerably affected by the substitution patterns of the aryl rings, especially by the position of the substituents.

This should be interpreted in terms of the substituent effect on the relative reactivity of the intermediate anions **7** and **11**. The C-3 carbanion **7** would be formed in much smaller amount as compared to the C-2 carbanion **11**.

However, the cyclization of **7** gives the product **9**, which is in turn converted into a stabilized anion **15**.



15

Fig. 3.

In contrast, the reaction of **11** leads to the formation of unstable cyclization product **12**, which could be aromatized only by the loss of the angular cyano group; **12** would be mostly reverted to **11**. The results obtained for the compounds **1g** and **1h**, in which the two aromatic rings are substituted in different ways, indicate that the formation ratios of **9** to **13** can not be explained by the substituent effect on the relative stability of the intermediate anions **7** and **11**. Unless the C-3 carbanion formation is extremely depressed by the presence of an electron-releasing group in para position as in the case of **7b**, the formation of **9** is considered to become comparable to that of **13** (**1d** and **1f**). The promoting effect of *m*-substituents, especially *m*-methoxyl group for the cyclization to **9** is remarkable (**1a**, **1c**, and **1e**) but it is difficult to give an explanation entirely in terms of inductive effect.

Tautomerism of the Acetamides 18 and 19 Derived from 9. For the purpose of identification, analogs **9** substituted in various ways were converted into acetamides by treatment with acetic anhydride and a catalytic amount of concd. sulfuric acid. The resulting solution of isoquinolinium salt (**16**) was poured into ice-water, yielding the colored acetamides (**18**). The 5*H*-indeno-[1,2-*c*]isoquinoline structures (**18**) were characterized by coloration and strong absorption near 2160 cm^{-1}. The specific formation of **18** from **16** can be accounted for by the mechanism shown in Scheme 4. The hydrolysis of **16** is initiated by the release of the proton at position 11 rather than that on ring nitrogen atom, which is trapped by strong hydrogen bonding.

When compounds **18** were dissolved in chloroform, one of them gave a colorless solution, while the others gave solutions with the same color as the original compound or a different one. Crystallization from the solutions gave either the original 5*H*-indeno[1,2-*c*]-isoquinolines (**18**), or a colorless compound. The IR spectrum of the latter compound exhibits a weak absorption band due to the nitrile group at 2250 cm^{-1},

a) (s): strong, (w): weak.

indicating that it represents the 11*H*-indeno[1,2-*c*]-isoquinoline structure (**19**), tautomeric with **18**. The behavior of **9** by the above treatment in relation to the substitution patterns of the aryl rings can be classified into three groups (Table 3).

(i) No color change on dissolution in chloroform and recovery of the 5*H*-isomer on crystallization.

(ii) Color change to pale yellow and recovery of the 5*H*-isomer.

(iii) Change to colorless and conversion into 11*H*-isomer.

The correlation between the relative stability of 5*H*- and 11*H*-isomers, and the substitution patterns of the aryl rings is not clear from the data available.

Experimental

Melting points were uncorrected. IR spectra were measured in Nujol mull. NMR spectra were determined at 60 MHz unlesso therwise stated. Chemical shifts are given in δ-values, using TMS as an internal standard. The instruments used are the same as those reported.[2a)]

water (4 : 1, 250 ml) was refluxed for 6 h. After extraction with chloroform and evaporation of the solvent. the residue was chromatographed on silica gel. Elution with benzene–chloroform (1 : 1) afforded **4a** (4.02 g). Further elution with the same eluent gave **1a** (1.08 g). The physical data of **1a**—**1h**, **4a**, **4b**, **4d**, and **4e** are summarized in Table 4.

Method D: A mixture of **3a** (1 g), NaCN (434 mg), NaI (45 mg), and dry acetone (12 ml) was stirred and refluxed for 24 h. After addition of water, extraction with chloroform and evaporation of the solvent, the residue on crystallization from methanol gave **1a** (547 mg).

*2,3-Bis(2-cyano-4-methoxyphenyl)propionitrile (**1b**).* *Method D*: A mixture of **3b** (7.0 g), NaCN (5.25 g), NaI (420 mg), and dry acetone (60 ml) was treated in the same way as described for **1a**. After evaporation of the solvent, the residue was chromatographed on silica gel.

Elution with benzene afforded **4b** (1.06 g). Elution of the column with benzene–chloroform (1: 1) gave **1b** (2.89 g).

*2,3-Bis(2-cyano-5-methoxyphenyl)propionitrile (**1c**).* *Method D*: **3c** (6.76 g) was cyanated as above. After evaporation of the solvent, the residue was crystallized from methanol–benzene to give 2-cyano-1,2,3-tris(2-cyano-5-methoxyphenyl)-propane (**5c**) (307 mg), mp 211—212 °C; ν_{max} 2220 cm⁻¹ (–CN); δ(CF_3CO_2H) 4.12 (4H, s, 2×$ArCH_2$–), 3.89 (3H, s, $ArOCH_3$), and 3.85 (6H, s, 2×$ArOCH_3$). Found: C, 72.80; H, 4.87; N, 12.00%. Calcd for $C_{28}H_{22}N_4O_3$: C, 72.71; H, 4.79; N, 12.12%. The filtrate was chromatographed on silica gel.

Elution with benzene–chloroform (1: 1) gave **1c** (4.0 g).

*2,3-Bis(2-cyano-4-chlorophenyl)propionitrile (**1d**).* *Method A*: A solution of **3d** (5.74 g) in ethanol (92 ml) was added to a solution of NaCN (15.5 g) in water–ethanol (1 : 1, 186 ml) and mixed. The resulting solution was allowed to stand at −20 °C for 48 h. After addition of water (300 ml), extraction with chloroform and evaporation of the solvent, the residue was chromatographed on silica gel. Elution with benzene–petroleum ether (1: 1) gave **4d** (1.1 g). Further elution with the same eluent gave **1d** (2.19 g).

Method C: A mixture of **3d** (1 g), NaCN (1 g), NaI (20 mg), and dry acetone (10 ml) was stirred at room temperature for 48 h. After addition of water, extraction with chloroform and evaporation of the solvent, the residue was chromatographed on silica gel. Elution with benzene gave 2-cyano-1,2,3-tris(2-cyano-4-chlorophenyl)propane (**5d**) (186 mg), mp 210—211 °C (from benzene–petroleum ether); ν_{max} 2230 cm⁻¹ (–CN); δ($CDCl_3$) 4.22, 3.80 (4H, ABq, J=14.0 Hz, 2×$>CH_2$). Found: C, 63.41; H, 2.90; N, 11.59%. Calcd for $C_{25}H_{13}N_4Cl_3$: C, 63.11; H, 2.75; N, 11.78%. Elution of the column with chloroform gave 5-amino-11-cyano-3,8-dichloro-11-(2-cyano-4-chlorobenzyl)-11*H*-indeno[1,2-*c*]isoquinoline (**6d**) (157 mg), mp 209—210 °C (from methanol); $\lambda_{max}^{H_2SO_4\text{-EtOH}}$ 208 (ε×10⁻³, 61.4), 225 (55.9), 233 sh (49.6), 341 (18.2) 372 (13.2), and 390 nm (10.0); ν_{max} 3490 and 3380 (–NH_2) and 2230 cm⁻¹ (–CN); δ($CDCl_3$) 8.10—6.77 (9H, m, ArH), 5.57 (2H, s, –NH_2, dissappears on D_2O exchange), 4.00 (1H, d, J=14.0 Hz, $>CH_AH_B$) and 3.45 (1H, d, J=14.0 Hz, $>CH_AH_B$). Found: C, 62.66; H, 2.76; N, 11.63%.

Calcd for $C_{25}H_{13}N_4Cl_3$: C, 63.11; H, 2.75; N, 11.78%.

*2,3-Bis(2-cyano-5-chlorophenyl)propionitrile (**1e**).* *Method A*: **3e** (1.58 g) was treated in the same way as described for **1d**. Elution of the silica gel column with benzene–petroleum ether (1 : 1) gave **4e** (245 mg). Elution of the column with benzene–chloroform (1: 1) gave **1e** (800 mg).

*2,3-Bis(2-cyanophenyl)propionitrile (**1f**).* *Method D*: **3f**

(10.5 g) was treated in the same way as described for **1a** to give **1f** (5.54 g).

2-(2-Cyano-3-methoxyphenyl)-3-(2-cyanophenyl)propionitrile (1g) and 2-(2-Cyanophenyl)-3-(2-cyano-3-methoxyphenyl)propionitrile (1h). A mixture of **4a** (2.0 g), **3f** (2.27 g), K_2CO_3 (1.6 g), NaI (150 mg, and dry acetone (30 ml) was refluxed for 24 h. After filtration and evaporation, the residue was crystallzed to give **1g** (2.76 g, 82.6%). **1h** was similarly prepared in 72% yield from **4f**[6] and **3a**.

Cyclization Reactions of the Propionitriles (1). General Procedure: A solution of sodium ethoxide (2 mmol; 14 and 4 mmol for **1b** and **1g** respectively) in ethanol (5 ml) was added to a mixture of **1** (1 mmol) and ethanol (10 ml). The mixture was stirred and refluxed for 2 h (4 h for **1g**). When the reaction was completed,[7] 1% NaOH aqueous solution (30 ml) was added and warmed for 30 min. The solution was then cooled and allowed to stand in a refrigerator overnight. The precipitates were collected by filtration and chromatographed on silica gel. Elution with chloroform gave **13**. By acidification of the filtrate with an excess of dilute hydrochloric

acid, **10**, a hydrochloride of **9**, was obtained as a colorless precipitate. The physical data of **10** and **13** are given in Tables 5 and 7.

*Oxidative Degradation of **10h** with Alkaline Hydrogen Peroxide.* To a solution of **10h** (600 mg) in a mixture of 10% NaOH–EtOH (1: 4, 50 ml) was added 3% H_2O_2 (40 ml) and the mixture was stirred at 0 °C for 30 min. After dilution with water (400 ml) the resulting red precipitate was collected by filtration and recrystallized from chloroform to afford 5-amino-4-methoxy-11*H*-indeno[1,2-*c*]isoquinolin-11-one (**14h**) (396 mg, 77.5%), mp 247.5—248 °C; ν_{max} 3500, 3290, and 3130 ($-NH_2$) and 1685 cm^{-1} (>CO); δ(CF_3CO_2H) 8.47—7.17 (7H, m, ArH) and 4.22 (3H, s, $ArOCH_3$). Found: C, 73.74; H, 4.46; N, 10.19%. Calcd for $C_{17}H_{12}N_2O_2$: C, 73.90; H, 4.38; N, 10.14%.

*Zinc Dust Reduction of **14h**.* **14h** (440 mg), zinc dust (2.2 g), and glacial acetic acid (20 ml) were mixed and refluxed for 2 h. The insoluble material was removed by filtration. The filtrate was made basic by the addition of ammonia solution under ice-cooling. The resulting precipitate was collected by filtration and recrystallized from methanol to give pure 5-amino-4-methoxy-11*H*-indeno[1,2-*c*]isoquinoline (375 mg, 90%), mp 193.5—194.5 °C, which was identical with **13g** produced by the cyclization of **1g** in comparison of their TLCs, mps, and IR spectra.

*Acetylation of **9**. General Procedure*: To a mixture of **10** (100 mg) and Ac_2O (10 ml) was added a few drops of concd. H_2SO_4 at room temperature. After being left to stand for a certain time (1 h for **10a**, **10d**, and **10f**; a few min for **10e**), the mixture was poured into ice–water. The precipitated pigment was collected by filtration and crystallized from chloroform. The physical data of the acetamides **18** and **19** are summarized in Tables 6 and 7.

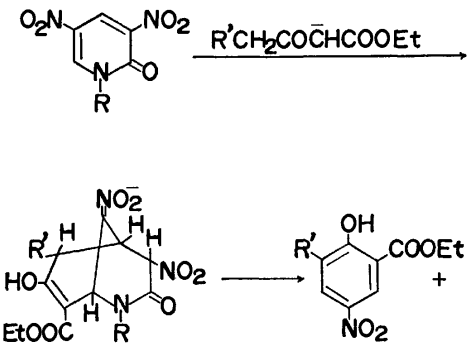
Nucleophilic Reaction of Electron-deficient Pyridone Derivatives. II. Ring Transformation of 1-Substituted 3,5-Dinitro-4-pyridones with Sodio β-Keto Esters

Eizo MATSUMURA, Masahiro ARIGA,* and Yasuo TOHDA
Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka 543
(Received October 16, 1979)

The reactions of 1-substituted 3,5-dinitro-4-pyridones [1-substituents: methyl (**1a**), 2-pyridyl (**1b**), 6-methyl-2-pyridyl (**1c**), and 4-pyridyl (**1d**)] with diethyl sodio-3-oxopentanedioate give 1-substituted 3,5-bis(ethoxycarbonyl)-4-pyridones and sodio-1,3-dinitro-2-propane. On the other hand, the reactions of the 4-pyridones (**1b**, **1c**, and **1d**) with ethyl sodioacetoacetate give ethyl 4-hydroxy-3,5-dinitrobenzoate together with aminopyridine homologues, and that of **1a** gives furo[3,2-*b*]pyridine derivative. On the basis of the concept of soft and hard acids and bases, a stepwise nucleophilic attack of the anion of β-keto esters at the electrophilic center of the 2 and 6-positions or 2 and 3-positions of the 4-pyridones is proposed to interpret the variations of the reaction courses.

We have previously shown that 1-substituted 3,5-dinitro-2-pyridones give nitrophenol derivatives and *N*-substituted α-nitroacetamides. A reaction course of the reaction has been elucidated by the isolation of intermediately produced meta-bridging bicyclic addition compounds.[1)]



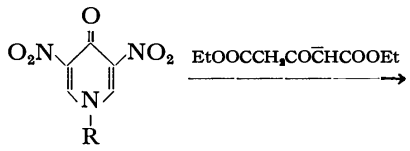
In this paper, we describe the reaction of 1-substituted 3,5-dinitro-4-pyridones with β-keto esters.

Results and Discussion

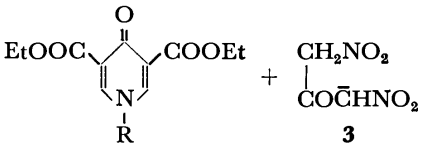
The reactions of 3,5-dinitro-1-methyl- (**1a**), 3,5-dinitro-1-(2-pyridyl)- (**1b**), 3,5-dinitro-1-(6-methyl-2-pyridyl)- (**1c**), and 3,5-dinitro-1-(4-pyridyl)-4-pyridone (**1d**) with the monosodium salts of β-keto esters were studied.

Treatment of **1a** with 1.5 equivalent amounts of diethyl sodio-3-oxopentanedioate (Na·DOPD) in pyridine gave 3,5-bis(ethoxycarbonyl)-1-methyl-4-pyridone (**2a**). The product **2a** showed strong absorption in the IR at 1735 and 1655 cm^{-1}, indicating the presence of ester carbonyl and pyridone carbonyl groups, respectively. The NMR spectrum of **2a** showed the presence of two ethyl groups. The other signals were very similar to that of the substrate **1a** except for the paramagnetic shift of the ring protons of about 1 ppm. The empirical formula of **2a**, $C_{12}H_{15}NO_5$, supports the structure indicated.

A yellow reisdue obtained after extraction of **2a** with chloroform was confirmed to be a monosodium salt of 1,3-dinitro-2-propanone (**3**), as follows. By coupling[2)] with 1 mol of benzenediazonium chloride at 0 °C, **3**



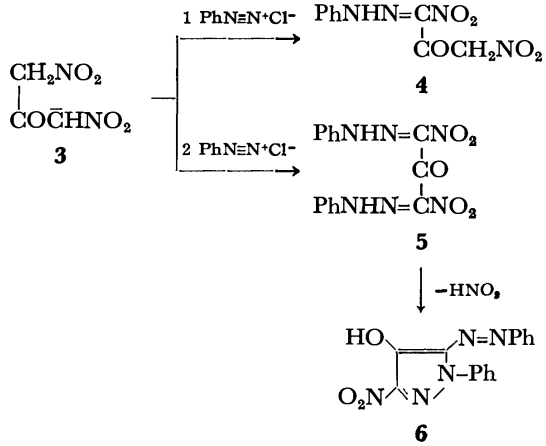
1 (a, b, c, d)



2a: Y. 84.9%
2b: Y. 66.35%
2c: Y. 58.5%
2d: Y. 61.5%

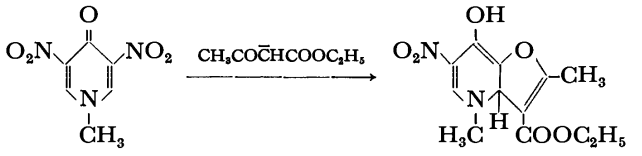
a: R=methyl
b: R=2-pyridyl
c: R=6-methyl-2-pyridyl
d: R=4-pyridyl

yielded yellow powder (**4**) of mp 167.0—168.0 °C, and with two moles of the chloride at 0 °C, another yellow powder (**5**) which decomposed at 138 °C. On the basis of their empirical formulae and their spectral properties, these products were identified as 1,3-dinitro-1-phenylhydrazono-2-propanone (**4**) and 1,3-dinitro-1,3-bis(phenylhydrazono)-2-propanone (**5**), respectively. The latter compound **5** was easily converted to 4-hydroxy-3-nitro-1-phenyl-5-(phenylazo)pyrazole (**6**) with loss of nitrous acid by heating in methanol



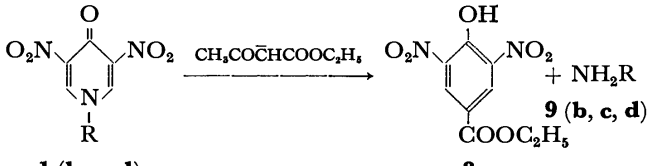
Similarly, treatment of **1b**, **1c**, and **1d** with Na·DOPD gave 3,5-bis(ethoxycarbonyl)-1-(2-pyridyl)- (**2b**), 3,5-bis(ethoxycarbonyl)-1-(6-methyl-2-pyridyl)- (**2c**), and 3,5-bis(ethoxycarbonyl)-1-(4-pyridyl)-4-pyridone (**2d**), respectively. **3** was also isolated from these reactions.

On the other hand, the reaction of **1a** with ethyl sodioacetoacetate (Na·EAA) offered different types of reaction products. First, by treatment of **1a** with Na·EAA in pyridine, colorless needles (**7a**) of mp 127.0—128.0 °C were obtained. The IR spectrum of the product showed the presence of an ester carbonyl group (1765 cm^{-1}) and a nitro group (1515, 1340 cm^{-1}). The NMR spectrum of **7a** indicated the presence of an ethoxyl group, 1.24 ppm (3H, t), 4.26 ppm (2H, q), a bridgehead proton, 6.51 ppm (1H, s), a highly deshielded proton, 8.69 ppm (1H, s), and a hydroxyl proton, 13.12 ppm (1H, s). The empirical formula of **7a** was consistent with $C_{12}H_{14}N_2O_6$. From the above data, 3-ethoxycarbonyl-7-hydroxy-2,4-dimethyl-6-nitro-3a,4-dihydrofuro[3,2-*b*]pyridine was assigned to **7a**.



1a **7a**

The reaction of **1b** with Na·EAA was carried out at 65—70 °C in pyridine. On work-up, ethyl 4-hydroxy-3,5-dinitrobenzoate (**8**)[3] and 2-aminopyridine (**9b**) were obtained. Similar results were observed in the reaction of **1c** and **1d** with Na·EAA; the products were **8** and either 2-amino-6-methylpyridine (**9c**) or 4-aminopyridine (**9d**).

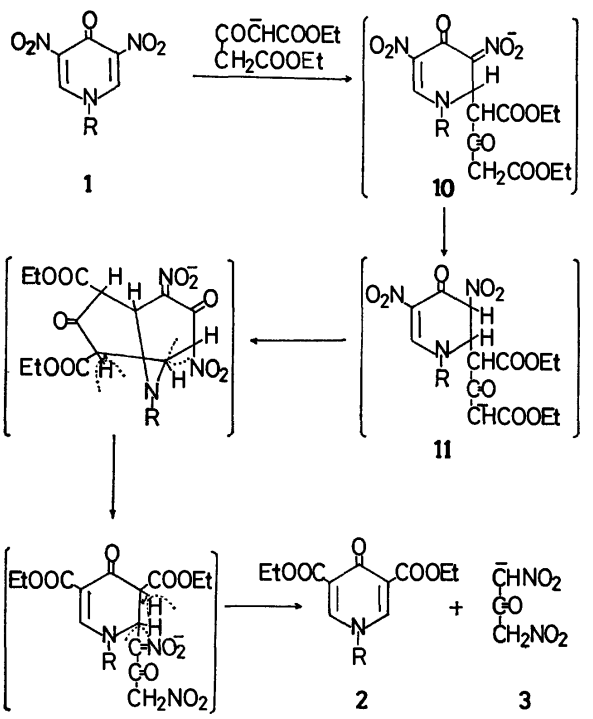


1 (b, c, d) **8** **9 (b, c, d)**

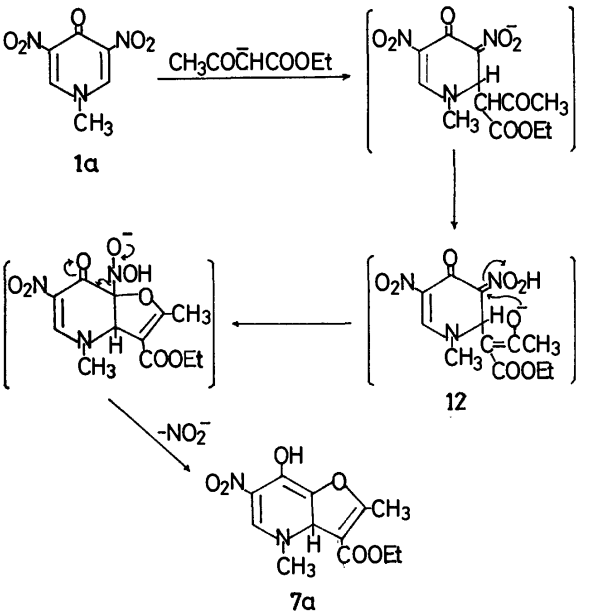
b: R=2-pyridyl
c: R=6-methyl-2-pyridyl
d: R=4-pyridyl

The formation of **2a**, **2b**, **2c**, and **2d** may proceed through a favorable nucleophilic attack of the nucleophile at the 2-position of the 4-pyridone to give the anion **10**, from which anion **11** can be derived by the prototropy. The successive steps to **2** and **3** may involve an intramolecular nucleophilic attack of an anion at the 6-position of the parent 4-pyridone. Scheme 1 may be proposed as one of the most likely reaction courses. The leaving carbanions may be considered to be soft leaving groups.

On the other hand, the formation of **7a** may proceed through the initial attack of a soft nucleophile of the enolate anion of ethyl acetoacetate ($CH_3COCHCOOEt$) at the softer 2-position of the 4-pyridone nucleus. The subsequent intramolecular nucleophilic attack of a harder *O*-anion of **12** at the 3-position of the parent



Scheme 1.

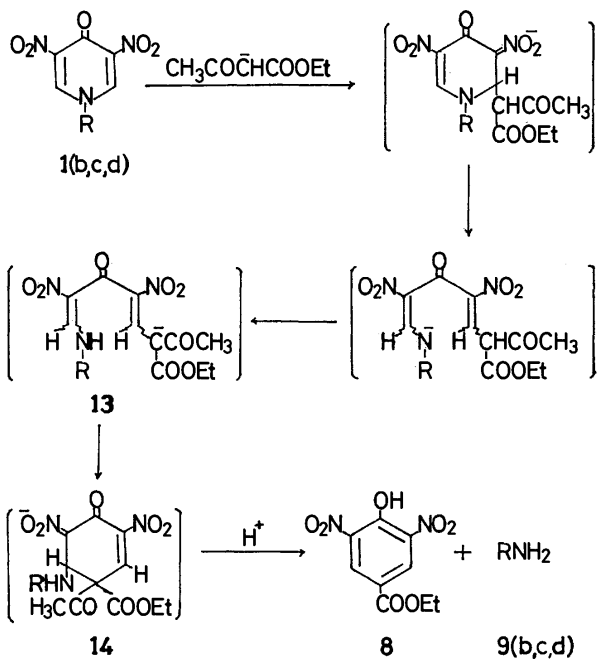


Scheme 2.

4-pyridone nucleus may lead to **7a** by loss of the harder nitrite anion (Scheme 2).

The course of the reaction of **1a** and Na·EAA is very similar to that of 3-bromo-4-nitropyridine *N*-oxide with Na·EAA.[4]

The probable course of the reaction of **1b**—**1d** with Na·EAA is shown in Scheme 3; the electron withdrawing interaction of the 5-nitro group of the parent 4-pyridone would allow the intramolecular nucleophilic attack of the carbanion **13** to lead to a cyclic intermediate **14**. Aromatization of **14** may give **8**



Scheme 3.

and **9**.

In the case of the reaction of **1a** with Na·EAA, the reason why the predominant attack of *O*-anion proceeds at the β-position which is substituted by the nitro group can be explained by the observation that the nature of the leaving group on the alkyl halides affects the proportion of *C* to *O* alkylation of the enolate ion. Sarthou *et al.*[5] concluded that the harder the leaving group, the lower the proportion of *C*-alkylation. A harder nitrite anion, however, classified as a border-line base, may be a favorable leaving group in the intramolecular nucleophilic substitution.

The difference between the reaction paths of **1a** with Na·EAA and those of **1b**—**1d** evidently depend upon the electronic behavior of the *N*-substituents of the 4-pyridone nucleus. The interaction of the electron donating 1-methyl group with the electron attracting β-nitro group may favor an initial attack of the soft end of the nucleophile at the 2-position of 4-pyridone nucleus without ring fission. The subsequent attack of the *O*-anion is promoted by the resonance interaction of the β-nitro group. On the other hand, the electron withdrawing 1-substituents such as 2-pyridyl and 4-pyridyl groups may reduce the resonance interaction of the 1-nitrogen atom with the β- or β′-nitro group; then the initial attack of the soft nucleophile at the somewhat harder 2-position of the 4-pyridone can not be allowed without the subsequent fission of the C_2–N bond.

In spite of the similar conditions, we find a remarkable difference of the reaction paths between the reaction of 1-substituted 3,5-dinitro-4-pyridones with Na·DOPD and those with Na·EAA. With 1-substituted 3,5-dinitro-4-pyridones and Na·DOPD, **2** were always obtained by the C_5 and C_3-anion heterolysis of the C_5–C_6 and C_2–C_3 bonds of the 4-pyridone nucleus. On the other hand, similar reactions with Na·EAA were affected not only by the nucleophile but also by the 1-substituted group.

Experimental

All the melting points are uncorrected. The IR spectra were obtained on a Hitachi EPI-S2 as Nujol muls. The NMR spectra were recorded on a Hitachi R 20-B with TMS as the internal standard.

3,5-Dinitro-1-methyl-4-pyridone (1a). Five grams of 1-methyl-4-pyridone[6] was dissolved in 50 ml of fuming sulfuric acid (30% SO_3), then 25 g of potassium nitrate was added in portions with cooling. The mixture was heated at 110 °C for 5 h and then poured onto crushed ice. Crystalline precipitates were recrystallized from water to give 4.8 g (52.1%) of **1a**, mp 214.0—215.0 °C. IR: 1680 cm^{-1} (C=O), 1550, 1360 (NO_2). NMR (DMSO-d_6): δ 3.90 (3H, s), 8.95 (2H, s). Found: C, 36.11; H, 2.63; N, 20.89%. Calcd for $C_6H_5N_3O_5$: C, 36.19; H, 2.53; N, 21.10%.

3,5-Dinitro-1-(2-pyridyl)-4-pyridone (1b). A mixture of 2-bromopyridine and sodium salt of 4-hydroxypyridine in DMSO was heated at 150 °C for 8 h to give 1-(2-pyridyl)-4-pyridone in 76.9% yield. This pyridone was treated with 10 equimolar amounts of potassium nitrate in fuming sulfuric acid (30% SO_3) at 130 °C for 10 h to give **1b** in 31.4% yield; mp 219.5—220.0 °C (water). IR: 1675 cm^{-1} (C=O), 1520, 1360 (NO_2). NMR (DMSO-d_6): δ 7.60 (1H, m), 8.12 (2H, m), 8.62 (1H, dd), 9.59 (2H, s). Found: C, 45.65; H, 2.20; N, 21.47%. Calcd for $C_{10}H_6N_4O_5$: C, 45.81; H, 2.31; N, 21.37%.

3,5-Dinitro-1-(6-methyl-2-pyridyl)-4-pyridone (1c). 1-(6-Methyl-2-pyridyl)-4-pyridone, prepared from sodium salt of 4-hydroxypyridine and 2-bromo-6-methylpyridine, was worked up according to the preceding method to give **1c** in 24.0% yield; mp 245.0—246.0 °C (aqueous acetic acid). IR: 1675 cm^{-1} (C=O), 1520, 1360 (NO_2). NMR (DMSO-d_6): δ 3.31 (3H, s), 7.4 (1H, m), 7.8 (2H, m), 9.61 (2H, s). Found: C, 47.99; H, 2.88; N, 19.90%. Calcd for $C_{11}H_8N_4O_5$: C, 47.83; H, 2.92; N, 20.24%.

3,5-Dinitro-(4-pyridyl)-4-pyridone (1d). 1-(4-Pyridyl)-4-pyridone[7] was treated as above to give **1d** in 36.2% yield; mp 242.0—243.0 °C (water). IR: 1680 cm^{-1} (C=O), 1520, 1315 (NO_2). NMR (DMSO-d_6): δ 7.81 (2H, dd), 8.82 (2H, dd), 9.31 (2H, s). Found: C, 45.49; H, 2.23; N, 21.37%. Calcd for $C_{10}H_6N_4O_5$: C, 45.81; H, 2.31; N, 21.37%.

Reaction of 3,5-Dinitro-1-methyl-4-pyridone (1a) with Na·DOPD. To a solution of 1.0 g of **1a** in 100 ml of pyridine was added a pyridine solution (20 ml) of Na·DOPD, prepared from 0.17 g of sodium and 1.7 g of diethyl 3-oxopentanedioate, with cooling. The mixture was heated at 50 °C for 5 h. The solvent was evaporated under reduced pressure, and the residue was extracted with $CHCl_3$. After the solvent was distilled off, the residual cake was rinsed with a small amount of diethyl ether, and recrystallized from benzene to give 1.08 g (84.9%) of 3,5-bis(ethoxycarbonyl)-1-methyl-4-pyridone (**2a**); colorless plates, mp 138.0—139.0 °C. IR: 1735 cm^{-1} (C=O), 1655 (C=O). NMR ($CDCl_3$): δ 1.31 (6H, t), 3.73 (3H, s), 4.28 (4H, q), 7.92 (2H, s). Found: C, 56.70; H, 5.95; N, 5.26%. Calcd for $C_{12}H_{15}NO_5$: C, 56.92; H, 5.93; N, 5.53%.

The residual powder which did not dissolve in $CHCl_3$ was washed with ethanol, and was dissolved in 50 ml of cold water. To this solution 10 g of sodium acetate was added, then aqueous benzenediazonium chloride solution formed from 0.5 g of aniline and 0.4 g of sodium nitrite was added dropwise at 0 °C. The precipitates were collected by filtration and were rinsed with methanol to give 0.40 g (31.7%) of 1,3-dinitro-1-phenylhydrazono-2-propanone (**4**); mp 167.0—

168.0 °C. IR: 3200 cm^{-1} (N–H), 1720 (C=O), 1530, 1330 (NO_2). NMR (acetone-d_6): δ 6.10 (2H, s), 7.25—7.80 (5H, m), 12.40 (1H, b, s). Found: C, 43.43; H, 3.14; N, 23.54%. Calcd for $C_9H_8N_4O_5$: C, 42.86; H, 3.20; N, 22.22%.

When three equimolar amounts of benzenediazonium chloride were used, 1,3-dinitro-1,3-bis(phenylhydrazono)-2-propanone (**5**) was obtained in 35.7% yield; dec. 138 °C. IR: 3230 cm^{-1} (N–H), 1700 (C=O), 1530, 1350 (NO_2). NMR (acetone-d_6): δ 7.1—7.7 (10H, m), 12.48 (2H, b. s). Found: C, 50.68; H, 3.10; N, 23.64%. Calcd for $C_{15}H_{12}N_6O_5$: C, 50.56; H, 3.39; N, 23.59%.

*3,5-Bis(ethoxycarbonyl)-1-(2-pyridyl)-4-pyridone (**2b**).* One gram of **1b** was treated according to the manner described above to give 0.8 g (66.3%) of **2b**; colorless prisms (benzene), mp 150.0—151.0 °C. IR: 1715 cm^{-1} (C=O), 1665 (C=O). NMR ($CDCl_3$): δ 1.32 (6H, t), 4.31 (4H, q), 7.4 (2H, m), 7.9 (1H, m), 8.53 (1H, dd), 8.93 (2H, s). Found: C, 61.03; H, 4.96; N, 8.98%. Calcd for $C_{16}H_{16}N_2O_5$: C, 60.75; H, 5.10; N, 8.86%.

*3,5-Bis(ethoxycarbonyl)-1-(6-methyl-2-pyridyl)-4-pyridone (**2c**).* From 1.0 g of **1c**, 0.75 g (58.5%) of **2c** was obtained; colorless prisms (benzene), mp 168.5—169.5 °C. IR: 1750 cm^{-1} (C=O), 1675 (C=O). NMR ($CDCl_3$): δ 1.42 (6H, t,) 2.62 (3H, s), 4.33 (4H, q), 7.2 (2H, m), 7.82 (1H, t), 8.81 (2H, s). Found: C, 62.02, H, 5.56; N, 8.54%. Calcd for $C_{17}H_{18}N_2O_5$: C, 61.81; H, 5.49; N, 8.48%.

*3,5-Bis(ethoxycarbonyl)-1-(4-pyridyl)-4-pyridone (**2d**).* From 1.0 g of **1d**, 0.75 g (61.9%) of **2d** was yielded; colorless plates (benzene), mp 201.0—202.0 °C. IR: 1755 cm^{-1} (C=O), 1650 (C=O). NMR ($CDCl_3$): δ 1.32 (6H, t), 4.33 (4H, q), 7.39 (2H, dd), 8.34 (2H, s), 8.82 (2H, dd). Found: C, 60.98; H, 5.11; N, 8.67%. Calcd for $C_{16}H_{16}N_2O_5$: C, 60.75; H, 5.10; N, 8.86%.

*4-Hydroxy-3-nitro-1-phenyl-5-(phenylazo)pyrazole (**6**).* A mixture of 0.1 g of **5** and 100 ml of methanol was refluxed for 2h, and the solvent was evaporated to half volume. 0.08 g (93.2%) of **6** was precipitated; red needles (methanol), mp 218.0—219.0 °C. IR: 3400 cm^{-1} (O–H), 1590 (C=N), 1520, 1345 (NO_2). Found: C, 58.32; H, 3.43; N, 22.63%. Calcd for $C_{15}H_{11}N_5O_3$: C, 58.25; H, 3.59; N, 22.65%.

*Reaction of **1a** with Na·EAA.* To a solution of 0.5 g of **1a** in 25 ml of pyridine was added a solution of Na·EAA, prepared from 0.17 g of sodium and 1.10 g of ethyl acetoacetate, in 25 ml of pyridine with cooling. The mixture was heated at 65—70 °C for 5 h. Pyridine was evaporated under reduced pressure, the residue was acidified to pH 3 with dil. HCl, extracted with $CHCl_3$. After the extract was dried over anhydrous sodium sulfate, the solvent was distilled off, and the residual syrup was chromatographed on a silica gel column. From the chloroform elute, 0.17 g (16.2%) of 3-ethoxycarbonyl-7-hydroxy-2,4-dimethyl-6-nitro-3a,4-dihydrofuro[3,2-*b*]pyridine (**7a**) was obtained; colorless needles (ethanol–diisopropyl ether), mp 127.0—128.0 °C. Found: C, 51.12; H, 4.90; N, 9.69%. Calcd for $C_{12}H_{14}N_2O_6$: C, 51.06; H, 5.00; N, 9.93%.

*Reaction of **1b** with Na·EAA.* A mixture of 0.5 g of **1b** and Na·EAA, prepared from 0.13 g of sodium and 0.8 g of ethyl acetoacetate, in 50 ml of pyridine was heated at 65—70 °C for 5 h. Pyridine was evaporated under reduced pressure. To the residue ethanol was added and evaporated to dryness. The residue was extracted with $CHCl_3$. Evaporation of $CHCl_3$ gave crude 2-aminopyridine (**9b**), which was purified by column chromatography on silica gel, using diethyl ether for eluent, to give 0.11 g (61.5%) of pure sample. The chloroform insoluble layer was acidified with dil. HCl to pH **3**, extracted with $CHCl_3$, and dried over anhydrous sodium sulfate. The solvent was distilled off and the residue was chromatographed on a silica gel column. From the benzene elute, 0.33 g (65.0%) of ethyl 4-hydroxy-3,5-dinitrobenzoate (**8**) was obtained; pale yellow needles (petroleum benzine), mp 88.0—89.0 °C (lit. mp 87 °C).[3] IR: 3300 cm^{-1} (O–H), 1730 (C=O), 1540, 1340 (NO_2). NMR ($CDCl_3$): δ 1.40 (3H, t), 4.41 (2H, q), 8.94 (2H, s), 11.0 (1H, b. s). Found: C, 42.37; H, 3.43; N, 10.79%. Calcd for $C_9H_8N_2O_7$: C, 42.19; H, 3.15; N, 10.94%.

When the reaction mixtrue was worked up without preceeding extraction with $CHCl_3$, 0.53 g (85.3%) of salt of 2-aminopyridine with **8** was obtained; yellow needles (ethanol), mp 217.0—218.0 °C. IR: 3400, 3250, 3200 cm^{-1} (N–H), 1720 (C=O), 1560, 1340 (NO_2). NMR (DMSO-d_6): δ 1.28 (3H, t), 4.21 (2H, q), 7.7—8.1 (2H, m), 8.7—9.2 (2H, m) 8.5—10.0 (3H, br), 9.20 (2H, s). Found: C, 48.32; H, 3.67; N, 16.29%. Calcd for $C_{14}H_{14}N_4O_7$: C, 48.00; H, 4.03; N, 16.00%.

*Reaction of **1c** with Na·EAA.* A similar treatment of 0.5 g of **1c** with Na·EAA gave 0.12 g (66.9%) of 2-amino-6-methylpyridine (**9c**) and 0.35 g (72.9%) of **8**.

*Reaction of **1d** with Na·EAA.* From 0.3 g of **1d**, 0.1 g (55.95%) of 4-aminopyridine (**9c**) and 0.26 g (51.0%) of **8** were obtained.

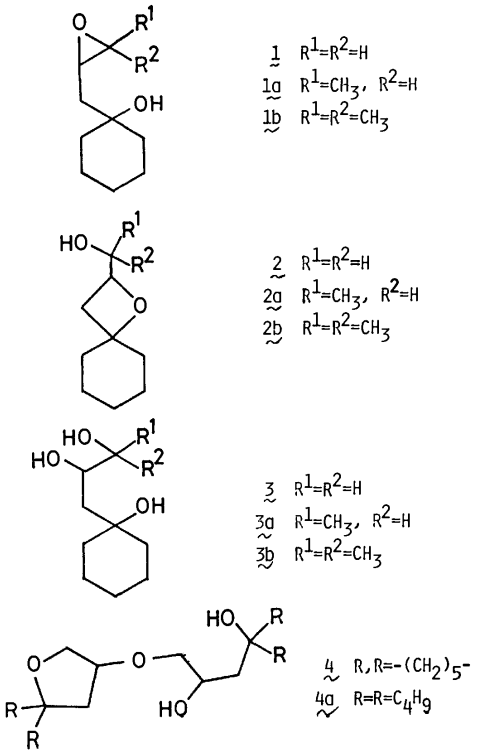
Steric Effect in Regioselective Cyclization of 3,4-Epoxy Alcohols to Oxetanes[1)]

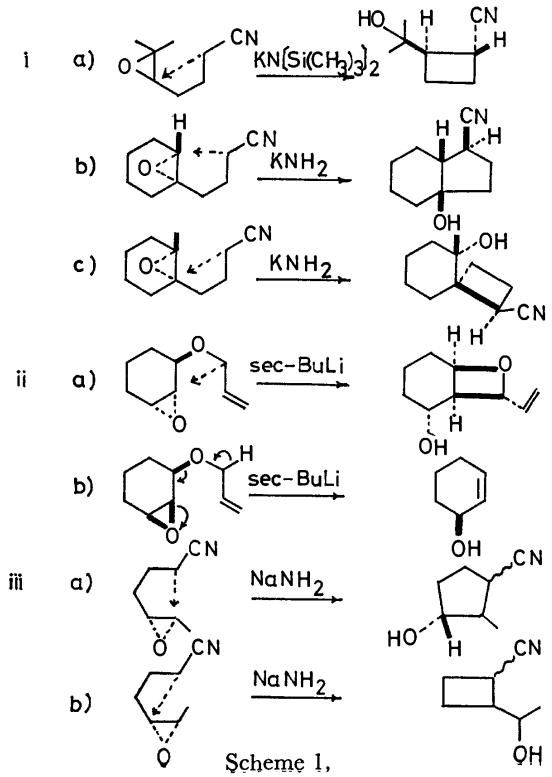
Tadashi MASAMUNE,* Shingo SATO, Atsushi ABIKO, Mitsunori ONO, and Akio MURAI
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 3, 1979)

A number of 3,4-epoxy alcohols, involving critical structural factors for oxetane formation by intramolecular cyclization, were prepared and treated with base under aqueous (KOH in 75% aq DMSO) and anhydrous conditions (NaH in THF). The result of the reactions of *cis*- and *trans*-4,5-epoxy-2-methyl-2-undecanols, coupled with that of 1-(2,3-epoxybutyl)- and 1-(2,3-epoxy-3-methylbutyl)-1-cyclohexanols (**1a** and **1b**), indicated that the regioselective oxetane formations of 3,4-epoxy alcohols with alkoxide anions are much insensitive to steric hindrance at the attacked oxirane rings, compared with the corresponding reactions with carbanions, while that of 1-(2,3-epoxypropyl)-1-cycloalkanols revealed that the relevant reactions depend on bulkiness of attacking alkoxide anions. Moreover, the result of the reactions of 1-(1,2-epoxycycloalkyl)-2-methyl-2-propanols under the aqueous conditions demonstrated that the oxetane formations are affected seriously by steric hindrance at the attacked oxirane rings, although the result was in striking contrast with the corresponding result with carbanions. On the other hand, the reactions of 3,4-epoxy alcohols under the anhydrous conditions proceeded in different manner, depending on the structures of the epoxides; namely, fragmentation took place as major reactions with some epoxides, while intramolecular cyclization occurred predominantly with other epoxides.

In previous papers[2a)] we reported that treatment of 1-(2,3-epoxypropyl)-1-cyclohexanol (**1**) and its methyl analogues with base in 75% aqueous dimethyl sulfoxide (DMSO) produced the corresponding four-membered ether (oxetane) (**2**) and its methyl analogues as the sole cyclized products other than hydrolysis products (**3**), while the treatment under anhydrous conditions in aprotic solvents led to formation of a dimeric five-membered ether (oxolane) (**4**) or of a simple alcoholysis product.[2b)] The regioselective formation of oxetanes was rationalized[2b)] mainly in terms of "collinearity requirement," which was proposed first by Stork and coworkers[3)] on the basis of the regioselective cyclization of 4,5-epoxy nitriles to cyclobutanes (Scheme 1, i-a), and accentuated later by Still[4)] from intramolecular cyclization of allyl 2,3-epoxyalkyl ether to a four-membered ring (oxetane) (Scheme 1, ii-a). However, Lallemand and Onanga[5)] criticized their explanation from the result of preferential cyclizations of "non-rigid" *trans*- and *cis*-3,4-epoxy nitriles to cyclopentanes and cyclobutanes, respectively, (Scheme 1, iii, *cf.*, i-b and i-c) and emphasized the importance of "steric hindrance" at the oxirane rings towards the attack of carbanions rather than the "requirement." Moreover, Stork and coworkers[3)] pointed out the effect of "bond distortion" as one of the factors which control the "requirement" on the basis of the result of the cyclizations of 4,5-epoxy nitriles. These apparently inconsistent facts on steric factors concerning the oxirane



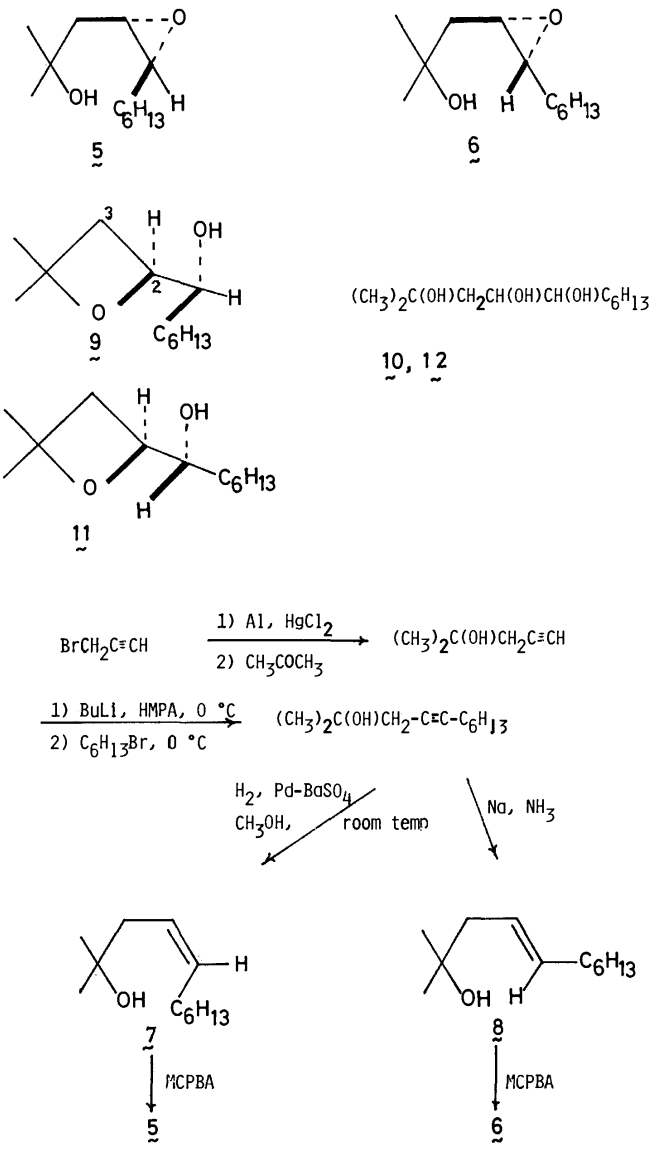


Scheme 1.

ring cleavage[6] prompted us to investigate the reactions of 3,4-epoxy alcohols, whose structures are closely related to the geometrical features of the above reactions, with base under the aqueous conditions. The results corroborating the relevant regioselectivity have recently been reported in preliminary form,[7] and the details are described in the present paper with additional results on the reactions carried out under anhydrous conditions.

Aqueous Conditions. I. Non-fused System.[8] *cis*- and *trans*-4,5-Epoxy-2-methyl-2-undecanols (**5** and **6**) were prepared by epoxidation[9] of the corresponding alkenols, *cis*- and *trans*-2-methyl-4-undecen-2-ols (**7** and **8**), as depicted in Scheme 2. These epoxy alcohols (**5** and **6**), corresponding to Lallemand's *cis*- and *trans*-4,5-epoxy nitriles (Scheme 1, iii), were submitted to base treatment under the controlled conditions [10 equiv KOH in 75% aq DMSO, 105—110 °C (bath temp), 2 h].[10] The reaction of *cis*-epoxide (**5**) proceeded as expected to give the corresponding oxetane (**9**) and hydrolysis product (triol) (**10**) in 40 and 30% yields with the recovered epoxide (**5**, 15%). In accordance with the assigned oxetane structure, compound **9** exhibited a strong absorption at 964 cm^{-1} in the IR spectrum and displayed signals due to protons at C-3 and C-2 on the oxetane (not oxolane) ring at δ 2.18 (2H, d, J=8 Hz) and 4.40 (1H, dt, J=5 and 8 Hz) in the NMR spectrum. These spectral patterns were characteristic of oxetanes, as had been demonstrated previously.[2] The same reaction of *trans*-epoxide **6** gave almost the same result; namely, the corresponding oxetane (**11**) and triol (**12**) were isolated in 50 and 19% yields, respectively, with the recovered epoxide (**6**, 8%). The structure of oxetane **11** was also clarified by the spectral data: IR, 984 and 960 cm^{-1}; NMR, δ 2.10 and 2.30 (each 1H, dAB_q, J=12 and 8 Hz, 3-H) and 4.53 (1H, dt, J=4 and 8 Hz, 2-H). The reaction result, in contrast with the Lallemand result (preferential cyclopentane formation from the *trans*-epoxy nitriles),[5] indicates that the intramolecular reactions of non-rigid 3,4-epoxy alcohols with alkoxide anions in 75% aqueous DMSO are much insensitive to steric hindrance at the attacked oxirane, compared with those with carbanions.

In connection with this, we treated 1-(2,3-epoxybutyl)-1-cyclohexanol[2] (**1a**) and its 3-methyl analogue (**1b**) with base under almost the same aqueous conditions. The latter epoxide (**1b**) could be prepared by epoxidation of the corresponding olefin[2a] with *m*-chloroperbenzoic acid (MCPBA) in an alkaline "biphasic" solvent system[11] in a 91% yield, although the compound (**1b**) was very sensitive to acid and converted readily into the corresponding oxolane, as had been described previously.[2a] Interestingly, both the epoxy alcohols (**1a** and **1b**) gave the corresponding oxetanes (**2a** and **2b**) in practically the same yields (73 and 72%) along with the simple hydrolysis products (**3a** and **3b**) (9 and 8%). This result indicates that yields of the oxetanes formed do not always increase with the number of substituents on the oxirane ring, supporting the aforementioned insensitivity to steric hindrance at the attacked oxirane rings in the oxetane formation.



Scheme 2.

Moreover, the fact that these oxetanes (**2a** and **2b**) were formed in better yields (73%) than oxetanes **9** and **11** (40 and 50%) led us to have interest in examining the effect of the bulkiness of the attacking alkoxide anions in the relevant cyclization.

Four 1-(2,3-epoxypropyl)-1-cycloalkanols (**1**, **13**—**15**), differing only in bulkiness of the attacking anions, were used for the examination; namely, the cyclohexanol[2] (**1**), cycloheptanol (**13**), cyclooctanol (**14**), and 4-butyl-1,2-epoxy-4-octanol (**15**) were prepared from the corresponding olefins as described in Scheme 3 and treated with base under the relevant aqueous conditions. The result is summarized in Table 1. The structures of these products were deduced mainly from the spectral data, as exemplified by those of oxetane **18**, which showed a strong absorption at 965 cm^{-1} in the IR spectrum and exhibited a two-proton doublet (J=8 Hz) at δ 2.21 and one proton multiplet at δ 4.60 due to protons at C-3 and C-2 on the oxetane ring, respectively, and also two double doublets (each 1H, dAB_q, J=12, 5 and 12, 3.5 Hz) due to two hydroxymethyl

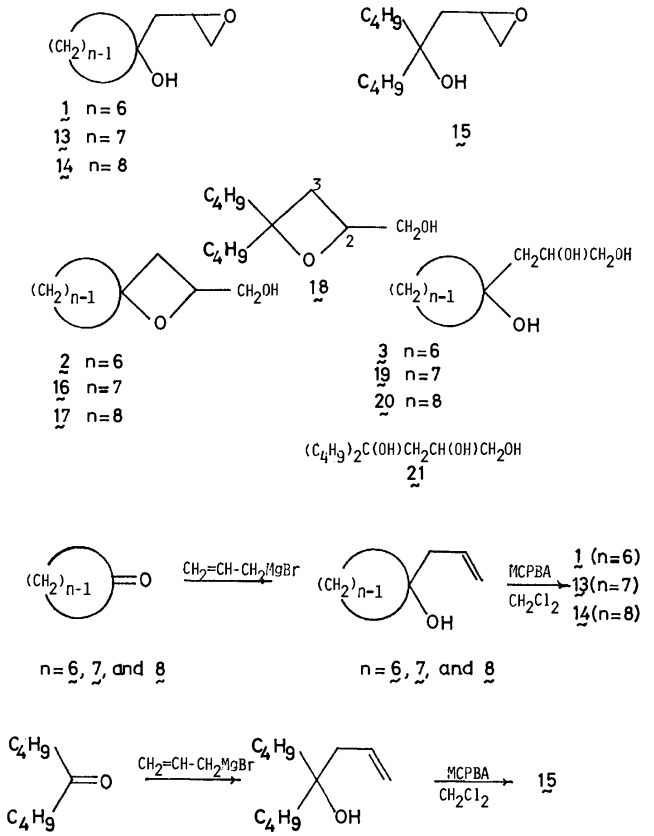
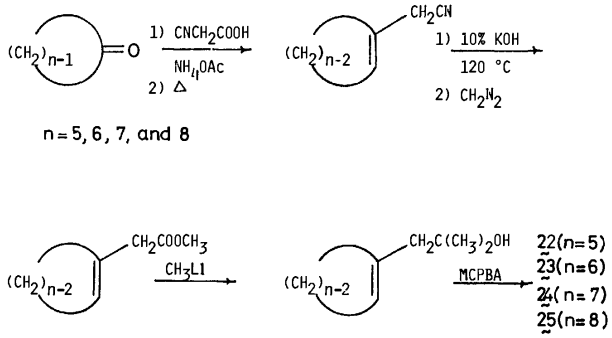
protons at δ 3.54 and 3.68, respectively. As shown in Table 1, only the corresponding oxetanes and triols were isolated in all the cases. However, the yield of oxetanes decreased in the order of increasing ring size. The result, coupled with the aforementioned one (**1a** and **2a**), implies that the increasing bulkiness of attacking alkoxide anions considerably suppresses the intramolecular reaction (oxetane formation) rather than the intermolecular (hydrolysis).



Scheme 3.

Aqueous Conditions. II. Fused System.[8)] Four 1-(1,2-epoxycycloalkyl)-2-methyl-2-propanols (**22**—**25**), were prepared from cycloalkanones *via* six-step processes as described in Scheme 4. These 3,4-epoxy alcohols, in each of which an oxirane ring is fused with a cycloalkane ring, correspond to Stork's fused 4,5-epoxy nitriles[3)] (Scheme 1, i-b). Treatment of the compounds with base under almost the same aqueous conditions produced multi-component mixtures, which were separated by preparative TLC, respectively. The structure and yield of identified products are summarized in Table 2. A typical example of the structure elucidation is illustrated by the oxolane (**29**) in the Table. The MS [*m/e* 170 (M^+), 155, and 137], IR [3600, 3420, 1150, and 1035 cm^{-1}], and NMR spectra [δ 1.35 (6H, s, $2CH_3$), 1.84 and 1.94 (each 1H, d, J=13 Hz, 3-H)] were consistent with the assigned structure. The relevant bridge-head proton on the carbon (C-7a) adjacent to the oxolane oxygen atom was observed at δ 3.79 as a triplet with J=4 Hz. The coupling constant indicates that the oxolane C-7a–O bond is oriented axial and



Scheme 4.

Table 2. Reactions of 1-(1,2-epoxycycloalkyl)-2-methyl-2-propanols (**22**—**25**) with base under aqueous conditions[a)]

Compound	Temp/°C	Time/min	Products[b)]

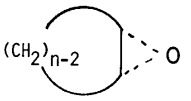
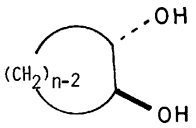
hence the oxolane C-3a–C-3 bond must be equatorial in respect to the cyclohexane ring. This assignment demonstrates that the oxolane (**29**) was formed by attack of the alkoxide anion to the oxirane ring from the back side.[6c,12] The configurations of all products in Table 2 were assigned on the basis of the spectral data and the back-side attack.

As shown in Table 2, the cyclopentene and cyclohexene oxides (**22** and **23**) afforded the corresponding oxetanes (**26** and **27**) as the sole and major cyclized products, respectively. However, the cycloheptene oxide (**24**) gave both the corresponding oxetane and oxolane (**28** and **30**) in almost the same yields, while the cyclooctene oxide (**25**) underwent no oxirane ring cleavage. In connection with this, simple (unsubstituted) cycloalkene oxides (**33**—**36**) were treated under almost the same conditions [10 equiv KOH in 75% aq DMSO, 100—110 °C (bath temp)]. While cyclohexene oxide



33 n = 6
34 n = 7
35 n = 8
36 n = 12

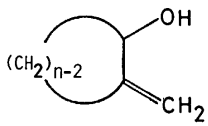


37 n = 6
38 n = 7

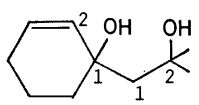
(**33**) was hydrolyzed rapidly to yield cyclohexane-1,2-diol (**37**) (100% within 0.5 h), cycloheptene oxide (**34**) reacted relatively slowly giving the corresponding diol (**38**) in 70 and 80% yields after 0.5 and 3 h, respectively. On the other hand, cyclooctene and cyclododecene oxides (**35** and **36**) were recovered unchanged almost quantitatively after 3 h treatment. The reactivity in the hydrolysis of these simple cycloalkene oxides clearly reflects steric hindrance against the back-side attack of hydroxide anions to the oxirane carbon atoms. Examination of the Dreiding model reveals that the hindrance also make it difficult to achieve the "collinear arrangement" for the intramolecular cyclization leading to formation of oxetane rather than that of oxolane. The result of the reactions of compounds **24** and **25** with fused medium-sized cycloalkane rings illustrates oxetane formation which is affected seriously by the "steric hindrance" under the relevant aqueous conditions. Nevertheless, the result shown in Table 2 is in striking contrast with the Stork's result. In summary, the oxetane formation from 3,4-epoxy alcohols, apart from the compounds with the afore-mentioned exceptional structural features (*e.g.*, compounds **24** and **25**), under the aqueous conditions proceeds regioselectively and would be rationalized mostly in terms of the "collinearity requirement" in the transition state, though it obviously depends on "steric effect" to some extent.

Anhydrous Conditions. Two non-fused compounds **1b** and **15** and three fused compounds **23**, **24**, and **25** were examined under anhydrous conditions. Compound **15**, when treated with sodium hydride (NaH) in tetrahydrofuran (THF) under reflux, gave the corresponding dimeric oxolane (**4a**) in a 60% yield as expected from the result of the reactions of related compounds.[2a] However, the same treatment of **1b** produced the corresponding oxetane (**2b**) in a 30% yield as a sole cyclized product, leaving a considerable amount (57%) of the starting epoxide (**1b**) unchanged. The fact offers the first example indicating importance of the steric hindrance in oxirane ring opening in anhydrous aprotic solvents. This apparently unexpected result, which is also inconsistent with "Thorpe-Ingold effect,"[13] seems to be in line with our previous rationalization proposed for the solvent dependency in ring closure;[2a] namely, "the cyclization in question in anhydrous aprotic solvents would proceed with displacement at the less-substituted carbon of the oxirane ring, leading to formation of oxygen heterocycles with less steric constraint." However, for want of other examples, we do not prefer to make further mechanistic discussion.

Treatment of the fused compounds (**23**—**25**) with base under almost the same anhydrous conditions resulted in fragmentation as the respective main reactions. The cyclohexene oxide (**23**), when treated with NaH in refluxing THF, gave a complex mixture, from which 2-methylenecyclohexanol (**39**) was isolated as a major product (38%) along with the corresponding oxetane (**27**) (27%) and 1-(2-hydroxy-2-methylpropyl)-2-cyclohexene-1-ol (**40**) (9%) by preparative TLC. The same treatment of the cycloheptene and cyclooctene oxides (**24** and **25**) afforded the corresponding 2-methylenecycloalkanols (**41** and **42**) in 55 and 18% yields, respectively, with recovery of the starting epoxides (**24** and **25**, 9 and 52%), no other compounds being detected. Formation of these 2-methylenecycloalkanols (**39**, **41**, and **42**) and cyclohexenol (**40**) might

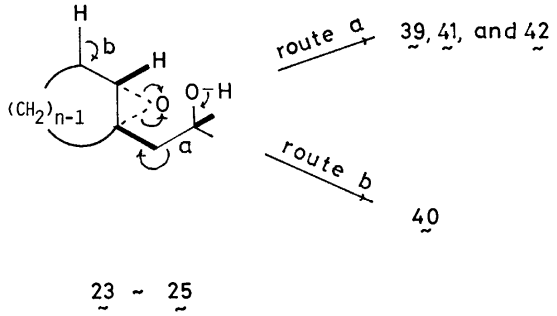


39 n = 6
41 n = 7
42 n = 8



40

be understood as results of usual fragmentation reactions, route a (*cf.*, Scheme 1, ii-b) and route b, as shown in Scheme 5, indicating the special character of 75% aqueous DMSO as a solvent system. However, the



Scheme 5.

reason why the fragmentation occurred predominantly with the fused epoxy alcohols and that why the oxetane (**27**) was formed in preference to the corresponding oxolane (**29**), were explained only with difficulty. In view of the remarkable contrast of the results between the aqueous and anhydrous conditions as well as between the non-fused and fused compounds, we only emphasize that the present results provide intrinsic problems for the mechanistic studies involving steric factors, solvent effects, and others.

Experimental

All the melting and boiling points were uncorrected. The homogeneity of each compound was always checked by TLC over silica gel (Wakogel B-5F) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid. The IR and NMR (100 MHz) spectra were measured in liquid state and in chloroform-*d*, respectively, unless otherwise stated. The abbreviations "s, d, t, m, and br" in the NMR spectra denote "singlet, doublet, triplet, multiplet, and broad," respectively. The preparative TLC and column chromatography were carried out over silica gel (Wakogel B-5F) and silicic acid (Merck, Kieselgel 60, 70—230 mesh), respectively. The following solvents were distilled before use after being dried; ether and THF from lithium aluminium hydride (LAH); dichloromethane from phosphorus pentaoxide; DMSO and hexamethylphosphoramide (HMPA) from calcium hydride. The latter two solvents were stored over Molecular Sieve.

*Preparation of 1-(2,3-Epoxy-3-methylbutyl)-1-cyclohexanol (**1b**).* A mixture of 1-(3-methyl-2-butenyl)-1-cyclohexanol[28a] (116 mg) in dichloromethane (5 ml) and 0.5 M aq sodium hydrogencarbonate ($NaHCO_3$, 4 ml) (pH 8.3) was stirred with MCPBA (173 mg, purity 90%) at 0 °C for 30 min.[9] The mixture was washed with 5% aq sodium thiosulfate ($Na_2S_2O_3$), 5% aq $NaHCO_3$ and water, dried and evaporated to leave **1b** (119 mg), oily; MS, *m/e* 184 (M^+) and 166; IR ($CHCl_3$), 3620, 3460, 1110, 1035, 1010, and 910 cm^{-1}; NMR, δ 1.29 and 1.35 (each 3H, s, CH_3 at C-3), and 3.04 (1H, dd, J=5 and 8 Hz, 2-H). The oil was used for the next reaction without further purification.

Preparation of cis- *and* trans-*4,5-Epoxy-2-methyl-2-undecanols (**5** and **6**). i)*: To a solution of 2-methyl-4-pentyn-2-ol[14] (3.0 g, 0.03 mol) in dry HMPA (80 ml) cooled with an ice–water bath was added 15% butyllithium in hexane (40 ml) under stirring. The mixture was stirred at 0 °C for 40 min and then warmed at *ca.* 25 °C under reduced pressure, when the hexane had been removed. To the residue was added freshly distilled hexyl bromide (8 g, 0.048 mol) dropwise at 0 °C, and the mixture was stirred at 0—15 °C for 18 h and at 40—50 °C for 1 h, and cooled.[15] The reaction mixture was mixed with water (50 ml) and extracted with ether (4×50 ml). The ether solution was washed with water and with saturated brine, dried and evaporated to leave an oily substance (4.0 g), which was purified by passing through a silica gel column to yield 2-methyl-4-undecyn-2-ol; bp 113—117 °C (bath temp) (17 Torr); MS, *m/e* 182 (M^+) and 167; IR, 3380, 1148, 1125, and 980 cm^{-1}; NMR, δ 0.90 (3H, br t, J=6 Hz, 11-H), 1.28 (6H, s, CH_3 at C-2 and 1-H), 2.04 (1H, s, OH), 2.20 (2H, m, 6-H), and 2.35 (2H, t, J=2 Hz, 3-H).

The alkynic alcohol (300 mg) was hydrogenated over Lindlar catalyst (500 mg) in methanol at room temperature for 1 h under stirring. After removal of the catalyst, the mixture was evaporated to give *cis*-2-methyl-4-undecen-2-ol (**7**, 290 mg), showing a single spot on TLC, bp 83—86 °C (bath temp) (17 Torr); MS, *m/e* 169 (M^+-CH_3) and 166 (M^+-H_2O); IR, 3380, 905, and 790 cm^{-1}; NMR, δ 1.89 (3H, br t, J=6 Hz, 11-H), 1.24 (6H, s, CH_3 at C-2 and 1-H), 2.10 (2H, m, 6-H), 2.29 (2H, d, J=6 Hz, 3-H), 5.51 and 5.63 (each 1H, dt, J=11 and 6 Hz, 5- and 4-H).

To a solution of **7** (240 mg, 1.3 mmol) in dry dichloromethane (10 ml) cooled with an ice–water bath was added MCPBA (0.51 g, 1.9 mmol), and the mixture was stirred at 0 °C for 15 min and then allowed to stand in a refrigerator for 15 h. The reaction mixture was washed with 5% aq $Na_2S_2O_3$ and then with 5% aq sodium carbonate (Na_2CO_3), and extracted with dichloromethane (3×20 ml). The dichloromethane solution was worked up as usual to leave oily residue, which was purified by chromatography over silica gel to give **5** (204 mg), bp 108—110 °C (14 Torr); MS, *m/e* 200 (M^+), 185, 167, 127, and 86 (base); IR, 3420 and 1240 cm^{-1}; NMR, δ 0.90 (3H, br t, J=6 Hz, 11-H), 1.33 and 1.36 (each 3H, s, CH_3 at C-2 and 1-H), 2.96 (1H, m, 5-H), and 3.20 (1H, dt, J=4 and 9 Hz, 4-H). Found: C, 71.55; H, 11.96%. Calcd for $C_{12}H_{14}O_2$: C, 71.95; H, 12.08%.

ii): To liquid ammonia (6 ml), distilled from sodium, containing sodium (207 mg, 9 mmol) was added the aforementioned alkynic alcohol (360 mg, 2 mmol) in dry ether, and the mixture was stirred under reflux for 2 h. After additions of ammonium chloride (2 g) and then of aq ammonia (5 ml), the reaction mixture was evaporated and extracted with ether (3×30 ml). The ether solution was washed with dil hydrochloric acid (HCl) and water, dried and evaporated to give *trans*-2-methyl-4-undence-2-ol (**8**, 230 mg), showing a single spot on TLC, bp 102—105 °C (bath temp) (17 Torr); MS, *m/e* 169 (M^+-CH_3) and 166 (M^+-H_2O); IR, 3380 and 968 cm^{-1}; NMR, δ 0.85 (3H, br t, J=6 Hz, 11-H), 1.16 (6H, s, CH_3 at C-2 and 1-H), 2.16 (4H, br m, 3- and 6-H), and 5.48 (2H, m, 4- and 5-H).

Compound **8** (150 mg) was epoxidized with MCPBA (0.40 g) in dichloromethane (10 ml) in the same manner as described above to yield **6** (110 mg), bp 126—130 °C (bath temp) (17 Torr); MS, *m/e* 200 (M^+), 185, 127, and 86 (base); IR, 3420 and 1240 cm^{-1}; NMR, δ 0.86 (3H, br t, J=6 Hz, 11-H), 1.28 and 1.31 (each 3H, s, CH_3 at C-2 and 1-H), 2.70 and 2.90 (each 1H, m, 5- and 4-H). Found: C, 71.57; H, 11.97%. Calcd for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%.

*Reaction of **5** and **6** under Aqueous Conditions. i)*: A solution of **5** (150 mg, 0.75 mmol) in DMSO (22.5 ml) and water (7.5 ml) was heated gradually from 50 °C to 115 °C (bath temp) for 2 h (at 50 °C for 0.5 h, at 80 °C for 0.5 h, at 95 °C for 0.5 h and then at 115 °C for 0.5 h), with potassium hydroxide (KOH, 520 mg, 9.3 mmol) under nitrogen with stirring, when the spot of **5** had disappeared on TLC. The reaction mixture was cooled, poured into saturated brine, and extracted with ethyl acetate (5×30 ml). The organic solution was washed with saturated brine, dried and evaporated to leave an oily residue, which was separated by chromatography over silica gel (10 g), benzene–ethyl ether mixtures being used as solvents. Fractions eluted with benzene–ether (10 : 1) gave *threo*-2-(1-hydroxyheptyl)-4,4-dimethyloxetane (**9**, 58 mg), bp 85—87 °C (bath temp) (15 Torr); MS, *m/e* 185 (M^+-CH_3) and 115; IR, 3440, 964, 940, and 910 cm^{-1}; NMR, δ 0.85 [3H, br t, J=5 Hz, $(CH_2)_5CH_3$], 1.35 and 1.47 (each 3H, s, CH_3 at C-4), 2.18 (2H, d, J=8 Hz, 3-H), 3.54 [1H, t, J=5 Hz, CH(OH)], and 4.40 (1H, dt, 5 and 8 Hz, 2-H). Found: C, 71.99; H, 12.11%. Calcd for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%. Later fractions eluted with benzene–ether (1: 1) afforded 2-methylundecane-2,4,5-triol (**10**, 64 mg), amorphous; MS, *m/e* 203 (M^+-CH_3) and 200; IR, 3380 cm^{-1}; NMR, δ 0.89 (3H, br t, J=6 Hz, 11-H), 1.28 and 1.33 (each 3H, s, CH_3 at C-2 and 1-H), 1.49 and 1.80 (each 1H, dd, J=

14, 2.5 and 14, 10 Hz, 3-H), 3.39 and 3.84 (each 1H, m, 5- and 4-H). Found: C, 65.88; H, 12.01%. Calcd for $C_{13}H_{26}O_3$: C, 66.01; H, 12.00%.

ii): Compound **6** (100 mg, 0.5 mmol) was treated with KOH (360 mg, 6 mmol) in DMSO (15 ml) and water (5 ml) in the same manner as **5**. The reaction mixture was worked up and purified as mentioned above to give *erythro*-oxetane (**11**, 50 mg), a diastereoisomer of **9**, and triol (**12**, 21 mg), which showed the following spectra. **11**, bp 106—108 °C (bath temp) (15 Torr); Ms, *m/e* 200 (M^+) and 185; IR, 3430, 984, and 960 cm^{-1}; NMR, 0.86 [3H, br t, J=6 Hz, $(CH_2)_5$-CH_3], 1.35 and 1.49 (each 3H, s, CH_3 at C-4), 2.10 and 2.30 (each 1H, dAB_q, J=12 and 8 Hz, 3-H), 3.69 [1H, m, CH(OH)] and 4.53 (1H, dt, J=4 and 8 Hz, 2-H). Found: C, 71.96; H, 12.09%. Calcd for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%. **12**, mp 50—53 °C (from ether–hexane); MS, 203 ($M^+ - CH_3$) and 200 ($M^+ - H_2O$); IR (Nujol), 3260 cm^{-1}; NMR, δ 0.88 (3H, br t, J=6 Hz, 11-H), 1.29 (6H, s, CH_3 at C-2 and 1-H), 1.76 (1H, dAB_q, J=10 and 14 Hz, one of 3-H), 3.61 (1H, m, 5-H), and 3.93 (1H, ddd, J=14, 6, and 2 Hz, 4-H). Found: C, 66.42; H, 11.82%. Calcd for $C_{12}H_{26}O_3$: C, 66.01; H, 12.00%.

Preparation of 1-(2,3-Epoxypropyl)-1-cycloheptanol (13), 1-(2,3-Epoxypropyl)-1-cyclooctanol (14), and 1,2-Epoxy-4-butyl-4-octanol (15). *i)*: A solution of freshly distilled cycloheptanone (1.12 g, 0.01 mol) in ether (10 ml) was added dropwise to a cold suspension of allylmagnesium bromide, prepared from allyl bromide (2.44 g) and magnesium (0.5 g), activated by heating, in ether (16 ml), and the whole mixture was stirred at room temperature for 13.5 h.[16] After dropwise addition of dil aq ammonia (7 ml), the reaction mixture was extracted with ether (4×10 ml). The ether solution was worked up as usal to leave an oily residue, which was distilled fractionally under reduced pressure to give 1-allyl-1-cycloheptanol (1.12 g), bp 85—88 °C (11 Torr); MS, *m/e* 154 (M^+) and 136; IR, 3380, 3060, 1640, and 905 cm^{-1}; NMR, δ 2.22 (2H, d, J= 8 Hz, CH_2=CHCH_2), 5.04 and 5.12 (each 1H, dd, J=4, 17 and 4, 10 Hz, CH_2=CHCH_2), and 5.80 (1H, ddt, J=17, 10, and 8 Hz, CH_2=CHCH_2). Found: C, 77.66; H, 11.75%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%.

The allyl cycloheptanol (1.01 g, 6.60 mmol) in dichloromethane (35 ml) was epoxidized with MCPBA (2.26 g) at room temperature under stirring in a usual manner. The reaction mixture was worked up as usual and purified by chromatography over silica gel (35 g) to give **13** (985 mg), bp 83—85 °C (15 Torr); MS, *m/e* 170 (M^+) and 152; IR, 3440 and 1250 cm^{-1}; NMR, δ 1.89 [2H, d, J=7 Hz, CH_2CH-(–O–)CH_2], 2.05 and 2.77 [each 1H, dd, J=5, 2 and 5, 5 Hz, CH_2CH(–O–)CH_2], and 3.13 [1H, m, CH_2CH(–O–)CH_2]. Found: C, 70.32; H, 10.54%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

ii): 1-Allyl-1-cyclooctanol (2.35 g) was prepared by treatment (room temp, 17 h) of cyclooctanone (2.27 g, 0.018 mol) with allylmagnesium bromide, prepared from allyl bromide (4.36 g, 0.036 mol) and magnesium turnings (0.9 g, 0.036 mol) in ether (50 ml), followed by fractional distillation, and had the following properties: bp, 99—101 °C (12 Torr); MS, *m/e* 168 (M^+) and 150; IR, 3400, 3070, 1640, and 910 cm^{-1}; NMR, δ 2.20 (2H, d, J=8 Hz, CH_2CH=CH_2), 5.07 and 5.11 (each 1H, dd, J=17, 1 and 10, 1 Hz, CH_2CH=CH_2), and 5.88 (1H, m, CH_2CH=CH_2). Found: C, 78.56; H, 11.91%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

The olefin (612 mg, 3.3 mmol) was oxidized with MCPBA (1.13 g, 5.0 mmol) in dichloromethane (20 ml) at room temperature for 17 h. The reaction mixture was worked up as usual and purified by chromatography to yield **14** (656 mg), bp 117—119 °C (14 Torr); MS, *m/e* 184 (M^+) and 166; IR, 3440, 1255, and 1015 cm^{-1}; NMR, δ 1.91 [2H, d, J=8 Hz, CH_2CH(–O–)CH_2], 2.49 and 2.81 [each 1H, dd, J=5, 2 and 5, 2 Hz, CH_2CH(–O–)CH_2], and 3.19 [1H, m, CH_2-CH(–O–)CH_2]. Found: C, 71.77; H, 10.89%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%.

iii): 5-Nonanone (1.1 g) was reacted with allylmagnesium bromide, prepared from allyl bromide (2 g) and magnesuim (0.4 g) in ether, in the same manner as mentioned above to give 4-butyl-1-octen-4-ol (1.2 g), which was used for the next epoxidation without further purification. The alkenyl alcohol (1.2 g) was treated with MCPBA (2.4 g) in dichloromethane (60 ml) at room temperature for 15 h. The reaction mixture was worked up as usual and purified by chromatography to give **15** (637 mg), bp 128—131 °C (bath temp) (18 Torr); MS, *m/e* 182 ($M^+ - H_2O$); IR, 3445 and 1250 cm^{-1}; NMR, δ 0.88 [6H, br t, J=7 Hz, $(CH_2)_3CH_3$ and 8-H], 2.45 and 2.77 [each 1H, dd, J=6, 3 and 6, 6 Hz, CH_2CH(–O–)CH_2], 3.09 [1H, m, CH_2CH(–O–)CH_2]. Found: C, 71.80, 12.06%. Calcd for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%.

Reactions of 1b, 13, 14, and 15 under Aqueous Conditions.

i): A solution of **1b** (104 mg, 0.56 mmol) in DMSO (17.25 ml) and water (5.75 ml) was stirred with KOH (370 mg, 5.6 mmol) at room temperature for 10 min and then at 108 °C (bath temp) for 1.4 h under nitrogen, when the spot of **1b** had disappeared on TLC. The mixture was cooled, poured into ice–water, and extracted with ethyl acetate. The acetate solution was washed with water, dried and evaporated to leave an oily residue (114 mg), showing two spots on TLC, which was separated into two fractions by preparative TLC over silica gel (20×20 cm^2, 5 plates), a 1:1 mixture of benzene and ether being used as a solvent. A more mobile fraction gave 2-(1-hydroxy-1-methylethyl)-4,4-pentamethyleneoxetane (**2b**, 74 mg), bp 98—102 °C (10 Torr); MS, *m/e* 184 (M^+), 166, 99, and 98; IR ($CHCl_3$), 3580, 3460, 1020, and 990 cm^{-1}; NMR, δ 1.02 and 1.16 (each 3H, s, CH_3), 2.06 and 2.32 (each 1H, dd, J=10.5 and 8 Hz, 3-H). Found: C, 71.44; H, 10.82%. Calcd for $C_{11}H_{20}O_2$: C, 71.74; H, 10.87%. A less mobile fraction afforded 1-(1-hydroxycyclohexyl)-3-methyl-2,3-butanediol (**3b**, 10 mg), amorphous; MS, *m/e* 202 (M^+) and 184; IR ($CHCl_3$), 3440 cm^{-1}; NMR, δ 1.14 and 1.18 (each 3H, s, CH_3 at C-3 and 4-H), and 3.73 (1H, dd, J=10 and 4 Hz, 2-H),

ii): A solution of **13** (172 mg, 1 mmol) in DMSO (30 ml) and water (10 ml) was heated up to 140 °C for 75 min with KOH (690 mg, 10 mmol) under nitrogen with stirring. The reaction mixture was worked up as described before and purified by chromatography over silica gel (7 g) with benzene–ether. More mobile fractions eluted with benzene–ether (5:1) gave 2-hydroxymethyl-4,4-hexamethyleneoxetane (**16**, 43 mg), bp 131—135 °C (bath temp) (17 Torr); MS, *m/e* 170 (M^+) and 152; IR, 3400, 1044, 965, and 876 cm^{-1}; NMR, δ 2.19 and 2.36 (each 1H, d, J=12 Hz, 3-H), 3.52 and 3.72 (each 1H, dd, J=12 and 4 Hz, CH_2OH), and 4.60 (1H, m, 2-H:). Found: C, 70.39; H, 10.71%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%. Less mobile fractions eluted with benzene–ether (1 : 1) afforded 4,4-hexamethylene-1,2,4-butanetriol (**19**, 103 mg), mp 69—72 °C (from hexane); MS, *m/e* 188 (M^+), 170, and 157; IR (Nujol), 3280 cm^{-1}; NMR δ 3.40 and 3.58 (each 1H, dd, J=11, 6 and 11, 4 Hz, 1-H), 3.52 and 4.49 (2H and 1H, each br s, OH), and 4.04 (1H, m, 2-H). Found: C, 63.56; H, 10.76%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%.

iii): Compound **14** (190 mg) in DMSO (30 ml) and water (10 ml) was heated up to 85 °C (bath temp) (at 50 °C for 0.5 h, at 80 °C for 0.5 h, and 85 °C for 0.5 h) with KOH (690 mg) in the same manner as mentioned above. The reaction mixture was worked up and purified as usual to give

2-hydroxymethyl-4,4-heptamethyleneoxetane (**17**, 38 mg), bp 142—144 °C (bath temp) (17 Torr), and 4,4-heptamethylene-1,2,4-butanetriol (**20**, 122 mg), mp 86—88 °C (from hexane). **17**, MS, *m/e* 184 (M^+) and 166; IR, 3390, 957, and 910 cm^{-1}; NMR, δ 2.22 (2H, d, J=8 Hz, 3-H), 3.64 (2H, dd, J=7 and 3 Hz, CH_2OH), and 4.66 (1H, m, 2-H). Found: C, 71.30; H, 11.04%. Calcd for $C_{11}H_{30}O_2$: C, 71.69; H, 10.94%. **20**, MS, *m/e* 202 (M^+) and 171; IR (Nujol), 3260 cm^{-1}; NMR, δ 3.44 and 3.57 (each 1H, dd, J=11, 6 and 11, 4 Hz, 1-H), and 4.06 (1H, m, 2-H). Found: C, 65.33; H, 11.00%. Calcd for $C_{11}H_{22}O_3$: C, 65.31; H, 10.96%.

iv): Compound **15** (202 mg) in DMSO (30 ml) and water (10 ml) was heated with KOH (690 mg) almost in the same manner (at 40 °C for 0.5 h, at 60 °C for 0.5 h, and at 80 °C for 0.25 h) as mentioned above, and the reaction mixture was worked up and purified as described before to give 4,4-dibutyl-2-hydroxymethyloxetane (**18**, 43 mg), bp 113—116 °C (bath temp) (17 Torr), and 4-butyl-1,2,4-octanetriol (**21**, 154 mg), amorphous. **18**, MS, *m/e* 200 (M^+), 182, and 143; IR, 3410, 965, and 928 cm^{-1}; NMR, δ 2.21 (2H, d, J=8 Hz, 3-H), 3.54 and 3.68 (each 1H, dd, J=12, 5 and 12, 3.5 Hz, CH_2OH), and 4.60 (1H, m, 2-H). Found: C, 71.58; H, 12.10%. Calcd for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%. **21** MS, *m/e* 218 (M^+) and 187; IR, 3360 cm^{-1}; NMR, δ 0.87 (6H, br t, J=7 Hz, CH_3), 2.95 and 4.25 (2H and 1H, each br s, OH), 3.40 and 3.56 (each 1H, dd, J=11.5, 7 and 11.5, 3.5 Hz, 1-H), and 4.03 (1H, m, 2-H). Found: C, 65.88; H, 12.30%. Calcd for $C_{12}H_{26}O_3$: C, 66.01; H, 12.00%.

Preparation of 1-(1,2-Epoxycyclopentyl)-, 1-(1,2-Epoxycyclohexyl)-, 1-(1,2-Epoxycycloheptyl)-, and 1-(1,2-Epoxycyclooctyl)-2-methyl-2-propanols (22—25). *i)*: A suspended mixture of cyclopentanone (8.4 g, 0.1 mol), cyanoacetic acid (8.5 g, 0.1 mol), and ammonium acetate (1.5 g, purity 95%) was refluxed in dry benzene (12 ml) on an oil-bath (145—155 °C) for 2 h under stirring, water being removed by a Dean-Stark apparatus.[7] The reaction mixture was evaporated to remove benzene, leaving yellow solid residue, which was submitted to distillation with concomitant decarboxylation at 155—165 °C (bath temp) under reduced pressure (40—55 Torr). Fractions distilled at 60—80 °C (40—55 Torr) were collected and dissolved in ether (25 ml), washed with 10% aq Na_2CO_3 and water, dried, evaporated and again distilled to give 2-(1-cyclopentenyl)acetonitrile (5.85 g), bp 68—71 °C (12 Torr); MS, *m/e* 107 (M^+); IR, 2240 and 1638 cm^{-1}; NMR, δ 3.14 (2H, s, 2-H) and 5.76 (1H, m, C=CH).

The nitrile (5.5 g) was stirred with 10% aq KOH (160 ml) on an oil bath (120—130 °C) for 4.5 h under nitrogen. The reaction mixture was cooled, washed with ether (50 ml), made acidic to pH ≈2 with 2M aq HCl, and extracted with chloroform (5×30 ml). The chloroform solution was dried and evaporated to give crude 2-(1-cyclopentenyl)acetic acid (5.79 g); IR (Nujol), 3040, 2640, and 1710 cm^{-1}; NMR, δ 3.18 (2H, s) and 5.60 (1H, br s). The crude acid was converted into the methyl ester as follows. To a solution of water (5 ml), ether (5 ml), and ethanol (35 ml) containing KOH (purity 85%) heated at 60—65 °C was added dropwise *p*-tolylsulfonylmethylnitrosamide (10.8 g) in ether (82 ml) under stirring, and the distilled diazomethane was dissolved in cold ether.[18] To the diazomethane solution cooled with an ice–salt bath was added dropwise the crude acid (2.0 g) in ether (14 ml), and the ether solution was evaporated to give crude methyl 2-(1-cyclopentenyl)acetate (2.3 g), which was used for the next reaction without further purification; IR, 1745 and 1655 cm^{-1}; NMR, δ 3.17 (2H, s), 3.72 (3H, s), and 5.62 (1H, m).

To lithium (6.6 g) in dry ether (252 ml) was added dropwise methyl iodide (29 ml, 64.9 g) in ether (50 ml) under gentle reflux with stirring, and the mixture was then refluxed for 2 h. The methyllithium solution (170 ml) was added to a cold solution of the crude acetate (2.0 g) in ether (80 ml), and the whole solution was stirred at 0 °C for 1 h. After addition of water (50 ml), the reaction mixture was separated into two layers, and the aqueous layer was extracted with ether (3× 50 ml). All the ether solutions were combined, washed with water, dried and evaporated to leave an oily residue, which was purified by chromatography over silica gel (70 g) to give 1-(1-cyclopentenyl)-2-methyl-2-propanol (1.22 g), bp 74—76 °C (bath temp) (12 Torr); MS, *m/e* 140 (M^+), 125, and 122; IR, 3380, 1645, and 1370 cm^{-1}; NMR, δ 1.22 (6H, s, CH_3 at C-2 and 3-H), 1.70 (1H, s, OH), 2.36 [6H, br, m, $(CH_2)_3$], and 5.50 (1H, t, J=5 Hz, CH=C). Found: C, 77.12; H, 11.61%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

The unsaturated alcohol (570 mg) was epoxidized with MCPBA (1.7 g) in dichloromethane (30 ml) at 0 °C for 3 h in the same manner as described before. The reaction mixture was worked up and purified as usual to give **22** (578 mg), bp 90—92 °C (12 Torr) (bath temp); IR, 3440, 1210, and 1115 cm^{-1}; NMR, δ 1.28 and 1.35 (each 3H, s, CH_3 at C-2 and 3-H), 1.97 (2H, s, 1-H), and 3.31 (1H, s, CH(–O–)C). Found: C, 69.27; H, 10.33%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

ii): 2-(1-Cyclohexenyl)acetonitrile, bp 96—98 °C (bath temp) (15 Torr), was prepared according to the reported procedure.[18] The nitrile (8.6 g) was refluxed (bath temp, 120—130 °C) with 10% aq KOH for 4.5 h under nitrogen with stirring. The reaction mixture was cooled and washed with ether (50 ml). The aqueous solution was acidified with 2 M aq HCl to pH ≈2, and extracted with chloroform (4×50 ml). The chloroform extracts were worked up as usual to give crude 2-(1-cyclohexenyl)acetic acid (10.3 g); IR, 3000 and 1713 cm^{-1}; NMR δ 1.65 and 2.07 (each 4H, m), 3.02 (2H, s), 5.64 (1H, m), and 10.70 (1H, br, W_H=30 Hz). The crude acid (2.0 g) was then converted with diazomethane in ether[18] into the corresponding crude methyl ester (2.3 g), which was used for the next reaction without further purification; IR, 1745 and 1645 cm^{-1}; NMR, δ 1.61 and 2.02 (each 4H, m), 2.97 (2H, s), 3.67 (3H, s), and 5.56 (1H, m).

To a solution of the crude ester (2.3 g) in dry ether (100 ml) cooled with an ice-bath was added a methyllithium solution in ether (100 ml) (1.5 M CH_3Li in ether) under stirring, and the mixture was stirred at room temperature for 1 h. After dropwise addition of water (50 ml), the mixture was separated into two layers, and the aqueous solution was extracted with ether (3×50 ml). All the ether solutions were combined, washed with water (2×50 ml), dried and evaporated to leave an amorphous residue, which was purified by chromatography to give 1-(1-cyclohexenyl)-2-methyl-2-propanol (1.16 g), bp 46—48 °C (bath temp) (0.15 Torr); MS, *m/e* 154 (M^+), 139, and 136; IR, 3400, 1660, and 1150 cm^{-1}; NMR, δ 1.01 (6H, s, CH_3 at C-2 and C-1), 1.62 [4H, CH_2-$(CH_2)_2CH_2$], 2.08 [4H, m, $CH_2(CH_2)_2CH_2$], 2.13 (2H, s, 3-H), and 5.52 (1H, br s, W_H=8 Hz, C=CH). Found: C, 77.49; H, 11.72%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%.

The unsaturated alcohol (505 mg) was oxidized with MCPBA (1.4 g) in chloroform (30 ml) at 0 °C for 5 h under stirring. The reaction mixture was worked up and purified as described above to give **23** (506 mg), bp 95—97 °C (bath temp) (15 Torr); MS, *m/e* 170 (M^+), 155, and 152; IR, 3440, 1380, 1370, and 1250 cm^{-1}; NMR, δ 1.27 and 1.37 (each 3H, s, CH_3 at C-2 and 3-H), 1.72 and 1.86 (each 1H, d, J=15 Hz, 1-H), and 3.06 [1H, t, J=2 Hz, $CH_2CH(–O–)$]. Found: C, 70.43; H, 10.58%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

iii): Cycloheptenylacetonitrile (4.3 g), bp 98—100 °C (12

Torr), was prepared by treatment of cycloheptanone (5.6 g) with cyanoacetic acid (4.3 g) and ammonium acetate (1.0 g) in benzene (10 ml) at 165—175 °C (bath temp) for 2 h in almost the same manner as cyclopentylacetonitrile; IR, 2440 and 1615 cm^{-1}; NMR, δ 3.05 (2H, s) and 5.92 (1H, t, J=6 Hz). The acetonitrile (4.2 g) was then hydrolyzed by heating (120—130 °C) (bath temp) in 15% aq KOH (80 ml) for 16 h to yield the corresponding crude acid (3.54 g); IR, 3000, 2660, 1715, and 1630 cm^{-1}; NMR, δ 3.05 (2H, s) and 5.74 (1H, t, J=6 Hz). The crude acid (0.6 g) was converted into the methyl ester (0.64 g); IR, 1745 cm^{-1}; NMR, δ 3.02 (2H, s), 3.68 (3H, s), and 5.69 (1H, t, J=7 Hz). The crude methyl ester (0.62 g) was transformed by treatment with methyllithium, prepared from methyl iodide (15 g) and lithium (1.63 g) in ether (80 ml), at room temperature for 15 h into 1-(1-cycloheptenyl)-2-methyl-2-propanol (0.49 g), bp 88—91 °C (bath temp) (12 Torr); MS, *m/e* 168 (M^+), 153, and 150; IR, 3380 and 1370 cm^{-1}; NMR, δ 1.22 (6H, s), 2.20 (2H, s), and 5.68 (1H, t, J=8 Hz). Found: C, 78.33; H, 12.01%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%. The unsaturated alcohol (0.44 g) was oxidized with MCPBA (1.3 g) in chloroform (15 ml) at 0 °C for 4 h under stirring. The reaction mixture was worked up and purified as usual to give **24** (0.38 g), bp 105—107 °C (bath temp) (12 Torr); MS, *m/e* 169 ($M^+ - CH_3$) and 166 ($M^+ - H_2O$); IR, 3440, 1240, and 1150 cm^{-1}; NMR, δ 1.21 and 1.38 (each 3H, s), 1.79 (2H, s), and 2.99 (1H, dd, J=4 and 6 Hz). Found: C, 71.39; H, 10.87%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%.

iv): Cyclooctanone (2.5 g) was refluxed with cyanoacetic acid (1.7 g) and ammonium acetate (0.3 g) in benzene (10 ml) at 170—180 °C (bath temp) for 2 h and then at 100 °C (bath temp) for 1 h under stirring. After removal of benzene, the mixture was gently heated to *ca.* 190 °C (bath temp) under reduced pressure (20—40 Torr) until evolution of carbon dioxide gas ceased, and was then distilled. Fractions boiling at 90—105 °C (15 Torr) were collected and dissolved in ethyl acetate (50 ml). The acetate solution was washed with 10% aq Na_2CO_3 (2×10 ml) and with water (10 ml), dried and evaporated to leave an oily residue, which was distilled fractionally to give 1-cyclooctenylacetonitrile (1.89 g), bp 103—105 °C (13 Torr); IR, 2240 cm^{-1}; NMR, δ 1.51 (8H, br s), 3.06 (2H, s), and 5.74 (1H, t, J=8 Hz).

The nitrile (2.1 g) was heated with 15% aq KOH (70 ml) at 120—130 °C (bath temp) for 11 h under nitrogen with stirring. After being shaken with ether (100 ml), the mixture was made acidic (pH ≈2) with 2 M aq HCl and extracted with dichloromethane (100 ml). The dichloromethane solution, after usual work-up, left crude cyclooctenylacetic acid (1.81 g); IR, 3000 and 1713 cm^{-1}; NMR, δ 1.50 (8H, s), 3.05 (2H, s), and 5.58 (1H, t, J=8 Hz). The crude acid (1.9 g) in ether (10 ml) was converted into the methyl ester (1.97 g), oily, by treatment with diazomethane, prepared from *p*-tolylsulfonylmethylnitrosamide (11 g), ethanol (15 ml), KOH (4 g), water (6 ml), and ether (6 ml);[18] IR, 1745 cm^{-1}; NMR, δ 1.49 (8H, s), 3.04 (2H, s), 3.70 (3H, s), and 5.56 (1H, t, J=8 Hz). To the crude methyl ester (1.0 g) in ether (20 ml) was added dropwise a methyllithium solution in ether (1.5 M, 110 ml) at ice–water bath temperature under stirring during 0.5 h. The mixture was stirred at the temperature and mixed with ice–water (30 ml). The whole reaction mixture was poured into saturated brine and extracted with ether (3×50 ml). The ether solution was worked up and purified by chromatography over silica gel (30 g) as mentioned above to give 1-(1-cyclooctenyl)-2-methyl-2-propanol (0.78 g), bp 113—115 °C (bath temp) (12 Torr); MS, *m/e* 182 (M^+), 167, and 164; IR, 3420 cm^{-1}; NMR, δ 1.13 (6H, s), 1.45 (8H, s) and 5.40 (1H, t, J=8 Hz). Found: C, 79.14; H, 12.08%. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

The unsaturated alcohol (620 mg) in dichloromethane (22 ml) was oxidized with MCPBA (1.73 g) at 0 °C under stirring for 2.5 h. The reaction was ceased by addition of 5% aq $Na_2S_2O_3$ (5 ml) and the mixture was worked up as usual and purified by chromatography over silica gel (20 g). Fractions eluted with benzene and benzene–ether (10 : 1) gave **25** (411 mg), bp 125—127 °C (bath temp) (12 Torr), showing a single spot on TLC; MS, *m/e* 198 (M^+), 183, and 180; IR, 3460 and 1260 cm^{-1}; NMR, δ 1.24 and 1.39 (each 3H, s) and 2.80 (1H, dd, J=4 and 8 Hz). Found: C, 72.40; H, 11.05%. Calcd for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

*Reactions of **22**, **23**, **24**, and **25** under Aqueous Conditions.*

i): A solution of **22** (156 mg) in DMSO (30 ml) was heated with KOH (680 mg, 85% purity) in water (10 ml) at 130 °C (bath temp) for 0.5 h and then at 135 °C (bath temp) for 1 h under nitrogen with stirring. The reaction mixture was cooled, poured into brine, and extracted with ethyl acetate (6×50 ml). The acetate solution was washed with saturated brine (2×50 ml), dried and evaporated to leave an oily residue (320 mg), which was separated by chromatography over silica gel (8 g) with benzene–ether (5: 1). Most mobile fractions gave 2,2-(2-hydroxytetramethylene)-4,4-dimethyloxetane (**26**, 55 mg), bp 85—87 °C (bath temp) (12 Torr); MS, *m/e* 156 (M^+), 141, and 138; IR, 3420, 970, 950, and 930 cm^{-1}; NMR, δ 1.42 and 1.46 (each 3H, s, C<u>H</u>$_3$ at C-4), 2.13 and 2.67 (each 1H, ABq, J=11 Hz, 3-<u>H</u>), and 4.02 [1H, t, J=4 Hz, C<u>H</u>(OH)]. Found: C, 68.92; H, 10.35%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%. Compound **26** (16 mg) was converted by treatment with acetic anhydride (0.3 ml) and pyridine (0.6 ml) at 20 °C for 16 h into the monoacetate (**26a**), oily; MS, *m/e* 198 (M^+), 183, and 138; IR, 1745 and 850 cm^{-1}; NMR, δ 1.42 (6H, s), 2.07 (3H, s), 2.20 and 2.54 (each 1H, ABq, J=12 Hz), and 5.16 (1H, m).

Middle fractions afforded 2-(2-hydroxy-2-methylpropyl)-2-cyclopenten-1-ol (**31**, 13 mg), bp 81—83 °C (bath temp) (15 Torr); MS, *m/e* 141 ($M^+ - CH_3$) and 138 ($M^+ - H_2O$); IR, 3280, 1115, and 840 cm^{-1}; NMR, δ 1.22 and 1.30 (each 3H, s, C<u>H</u>$_3$ at C-2 and 3-<u>H</u>), 3.73 (2H, br, W_H=16 Hz, O<u>H</u>), 4.68 (1H, m, 1-<u>H</u>), and 5.83 (1H, br s, 3-<u>H</u>). Found: C, 68.83; H, 10.46%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%. The glycol (**31**, 10 mg) was converted into the monoacetate (**31a**, 10 mg), oily; MS, *m/e* 183 ($M^+ - CH_3$), 180, and 138; IR, 3440, 1735, 1120, and 855 cm^{-1}; NMR, δ 1.20 and 1.24 (each 3H, s), 2.05 (3H, s), 5.74 (1H, m), and 5.84 (1H, br s).

Least mobile fractions gave 1-(2-hydroxy-2-methylpropyl)-cyclopentane-1,2-diol (30 mg), mp 71—73 °C (from hexane); MS, *m/e* 174 (M^+), 159, and 156; IR ($CHCl_3$), 3620 and 3400 cm^{-1}; NMR, δ 1.35 and 1.43 (each 3H, s, C<u>H</u>$_3$ at C-2 and 3-<u>H</u>), 2.91 (3H, br, W_H=8 Hz, O<u>H</u>), and 4.03 (1H, m, 2-<u>H</u>). Found: C, 62.41; H, 10.44%. Calcd for $C_9H_{16}O_3$: C, 62.04; H, 10.41%. The triol (16 mg) gave the monoacetate (18 mg), amorphous; MS, *m/e* 190 (M^+), 175, 172, and 130; IR (Nujol), 3280 and 1735 cm^{-1}; NMR, δ 1.24 and 1.36 (each 3H, s), 1.86 (2H, s), 2.06 (3H, s), and 5.00 (1H, dd, J=5 and 1 Hz).

ii): Compound **23** (170 mg) in DMSO (30 ml) was heated with KOH (685 mg, purity 85%) in water (10 ml) at *ca.* 140 °C for 1.5 h under nitrogen with stirring. The reaction mixture was worked up as described above and separated into three fractions by chromatography over silica gel (7 g), a 5 : 1 mixture of benzene and ether being used as solvent. The most mobile fraction gave 2,2-(2-hydroxypentamethylene)-4,4-dimethyloxetane (**27**, 78 mg), bp 83—85 °C (bath temp) (12 Torr); MS, *m/e* 170 (M^+), 155, and 152; IR, 3420, 967, and 880 cm^{-1}; NMR, δ 1.40 and 1.47 (each 3H, s, C<u>H</u>$_3$

at C-4), 1.88 and 2.40 (each 1H, d, J=11 Hz, 3-H), and 3.36 [1H, dd, J=11 and 4 Hz, CH(OH)]. Found: C, 70.63; H, 10.71%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%. Compound **27** (15.5 mg) was converted into the monoacetate (**27a**, 15 mg), oily; MS, 212 (M^+); IR, 1745, 970, and 880 cm^{-1}; NMR, δ 1.40 and 1.44 (each 3H, s), 2.13 (3H, s), 1.99 and 2.30 (each 1H, d, J=10 Hz), and 4.72 (1H, dd, J=10 and 4 Hz).

The middle fraction afforded 2,2-dimethyl-1-oxaperhydroinden-3a-ol (**29**, 12 mg), mp 69—71 °C (from hexane); MS, *m/e* 170 (M^+), 155, and 137; IR ($CHCl_3$), 3600, 3420, 1150, and 1105 cm^{-1}; NMR, δ 1.35 (6H, s, CH_3 at C-2), 1.84 and 1.94 (each 1H, ABq, J=13 Hz, 3-H), and 3.79 (1H, t, J=4 Hz, 7a-H). Found: C, 70.22; H, 10.69%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%. The least mobile fraction gave 1-(2-hydroxy-2-methylpropyl)cyclohexane-1,2-diol (22 mg), amorphous; MS, *m/e* 188 (M^+), 173, and 170; IR (Nujol), 3360 cm^{-1}; NMR, δ 1.28 and 1.38 (each 3H, s, CH_3 at C-2 and 3-H), 3.20 (3H, br, OH), and 3.46 (1H, dd, J=8 and 4 Hz, 2-H). Found: C, 63.51; H, 10.75%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%. The triol (15 mg) afforded the monoacetate (16 mg), amorphous; MS, *m/e* 215 ($M^+ - CH_3$) and 212 ($M^+ - H_2O$); IR, 3410 and 1737 cm^{-1}; NMR, δ 1.28 and 1.34 (each 3H, s), 2.07 (3H, s), and 4.75 (1H, dd, J=8 and 4 Hz).

iii): Compound **24** (186 mg) was heated at *ca.* 115 °C (bath temp) for 2 h with KOH (685 mg, purity 85%) in DMSO (30 ml) and water (10 ml) under nitrogen with stirring. The reaction mixture was worked up as usual and separated by chromatography over silica gel (6 g) with benzene–ether (10: 1) to yield the unchanged starting material (**24**, 25 mg) and the following three products: 4,4-(2-hydroxyhexamethylene)-2,2-dimethyloxetane (**28**, 39 mg), 2,2-dimethyl-1-oxaperhydroazulen-3a-ol (**30**, 36 mg), and 2-(2-hydroxy-2-methylpropyl)-2-cyclohepten-1-ol (**32**, 15 mg), **28**, bp 109—112 °C (bath temp) (12 Torr); MS, 184 (M^+), 169, and 151; IR ($CHCl_3$), 3600, 3440, 988, and 955 cm^{-1}; NMR, δ 1.36 and 1.47 (each 3H, s, CH_3 at C-2), 1.96 and 2.52 (each 1H, d, J=12 Hz, 3-H), and 3.41 [1H, J=10 and 4 Hz, CH(OH)]. Found: C, 71.37; H, 11.00%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%. Monoacetate (**28a**) of **28**, oily, MS, *m/e* 226 (M^+), 211, 208, and 166; IR, 1740, 1040, and 850 cm^{-1}; NMR, δ 1.24 and 1.42 (each 3H, s), 2.10 (3H, s), 2.29 (1H, d, J=12 Hz), and 4.19 (1H, dd, J=10 and 4 Hz). **30**, mp 60—62 °C (from hexane); MS, *m/e* 184 (M^+), 169, and 166; IR ($CHCl_3$), 3600, 3440, 1105, and 1070 cm^{-1}; NMR, δ 1.28 and 1.39 (each 3H, s, CH_3 at C-2), 1.82 and 1.91 (each 1H, d, J=12 Hz, 3-H), and 3.96 (1H, dd, J=9 and 3 Hz). Found: C, 71.46; H, 10.98%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%. **32**, mp 76—78 °C (from hexane); MS, 169 ($M^+ - CH_3$) and 166 ($M^+ - H_2O$); IR ($CHCl_3$), 3620 and 3400 cm^{-1}; NMR, δ 1.20 and 1.22 (each 3H, s, CH_3 at C-2 and 3-H), 2.24 and 2.36 (each 1H, ABq, J=14 Hz, 1-H), 4.40 [1H, dd, J=6 and 2 Hz, CH(OH)], and 5.56 (1H, t, J=7 Hz, 3-H). Found: C, 71.32; H, 10.69%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%.

iv): Compound **25** (198 mg) was heated at *ca.* 140 °C (bath temp) for 2.5 h with KOH (685 mg, purity 85%) in DMSO (30 ml) and water (10 ml) under nitrogen with stirring. The reaction mixture was worked up as mentioned above and purified by chromatography as usual to give the starting material (**25**, 170 mg) unchanged.

Hydrolysis of Cycloalkene Oxides (33—36). Each (112—182 mg) of compounds **33**,[19] **34**,[20] **35**,[21] and **36**[22] in DMSO (15 ml) was added rapidly to an aqueous KOH (10 mol equiv) solution (5 ml) heated at 100—110 °C (bath temp), and the whole solution was stirred at the temperature for 0.5 h or for 3 h. After being cooled, the mixture was worked up as usual to give the hydrolysis product (**37**[23] or **38**[24]) and/or the starting epoxides. The result is summarized in the text.

*Reactions of **1b** and **15** under Anhydrous Conditions. i)*: A suspension of **1b** (186 mg, 1 mmol) and sodium hydride (NaH, 120 mg, purity 50%, 2.5 mmol) in dry THF (30 ml) was heated gently under reflux for 11 h. The reaction mixture was cooled, poured into ice–water, and extracted with ethyl acetate. The acetate solution was worked up as usual to leave an oily residue (170 mg), showing two spots, which was separated into two fractions by preparative TLC (5 plates) over silica gel. The less mobile fraction gave **2b** (53 mg) and and the more mobile the starting epoxide (**1b**, 102 mg).

ii): A suspended mixture of **15** (100 mg, 0.5 mmol) and NaH (60 mg, purity 50%, 1.25 mmol) in THF (10 ml) was refluxed for 13 h under nitrogen. The reaction mixture was worked up as mentioned above and purified by chromatography over silica gel (6 g) with benzene–ether (2: 1) to yield the starting epoxide (**15**, 17 mg) and 4,4-dibutyl-2-(4-butyl-2,4-dihydroxyoctyloxy)oxolane (**4a**, 64 mg), amorphous; MS, *m/e* 400 (M^+), 382, and 364; IR (Nujol), 3460, 1135, and 1070 cm^{-1}; NMR, δ 0.90 (12H, br t, J=7 Hz, CH_3), 3.48 [4H, m, CH_2(–O–)], 3.64 [1H, m, CH(OH)], and 4.21 [1H, m, CH(–O–)]. Found: C, 71.63; H, 12.10%. Calcd for $C_{24}H_{48}O_4$: C, 71.95; H, 12.10%.

*Reactions of **23**, **24**, and **25** under Anhydrous Conditions. i)*: A solution of **23** (120 mg) in THF (10 ml) was added to a stirred suspension of mineral-oil free NaH (85 mg) in THF (10 ml). The mixture was refluxed gently for 15 h, cooled and mixed with water (2 ml). After removal of THF by evaporation, the mixture was poured into brine and extracted with ethyl acetate, dried and evaporated to leave oily residue (125 mg), which was separated by column chromatography over silica gel (4 g) with benzene–ether (2: 1) and subsequent preparative TLC to yield three products, 2-methylenecyclohexanol (**39**, 38 mg), oxetane **27** (33 mg), and 2-(2-hydroxy-2-methylpropyl)-2-cyclohexen-1-ol (**40**, 12 mg). **29**, bp 65—67 °C (bath temp) (12 Torr); MS, *m/e* 112 (M^+) and 94; IR, 3340, 3080, 1640, and 897 cm^{-1}; NMR, δ 4.07 (1H, m, 1-H), 4.73 and 4.86 (each 1H, s, $=CH_2$). Found: C, 74.61; H, 10.83%. Calcd for $C_7H_{12}O$: C, 74.95; H, 10.78%. **40**, bp 97—98 °C (bath temp) (12 Torr); MS, *m/e* 170 (M^+), 155, and 152; IR, 3300 cm^{-1}; NMR, δ 1.21 and 1.28 (each 3H, CH_3 at C-2 and 3-H), 3.72 (2H, br, OH), 4.10 and 5.56 (each 1H, t, J=4 Hz, 1- and 3-H). Found: C, 70.18; H, 10.71%. $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

ii): A suspension of **24** (170 mg) in dry THF (20 ml) containing NaH (110 mg) was heated under reflux for 15 h. The mixture was worked up as mentioned above and separated by column chromatography over silica gel (6 g) with benzene–ether (10: 1) to yield the unchanged epoxide (**24**, 17 mg) and 2-methylenecycloheptanol (**41**, 69 mg), bp 73—76 °C (bath temp) (12 Torr); MS, *m/e* 126 (M^+) and 108; IR, 3360, 3060, 1645, and 895 cm^{-1}; NMR, δ 4.28 (1H, t, J=6 Hz, 1-H), 4.88 (1H, s, $C=CH_2$), and 5.00 (1H, t, J=1.5 Hz, $C=CH_2$). Found: C, 75.83; H, 11.30%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

iii): Compound **25** (199 mg) was treated with NaH (130 mg) in THF (20 ml) in the same manner as **24**. The reaction mixture was worked up as mentioned above and separated by chromatography over silica gel (5.5 g) with benzene–ether (10 : 1), giving the starting epoxide (**25**, 103 mg) and 2-methylenecyclooctanol (**42**, 26 mg): **42**, bp 92—95 °C (12 Torr); MS, *m/e* 140 (M^+) and 122; IR, 3400, 3060, 1630, and 895 cm^{-1}; NMR, δ 4.19 (1H, dd, J=8 and 6 Hz, 1-H), 4.96 and 5.12 (each 1H, s, $C=CH_2$). Found: C, 76.87; H, 11.56%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

Dehydrooligopeptides. I. The Facile Coupling of α-Amino Acids with α-Dehydroamino Acids to Dehydrodipeptides

Yasuchika YONEZAWA, Chung-gi SHIN,* Yuji ONO, and Juji YOSHIMURA†

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

†*Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received December 14, 1979)

N-Cbz- or *N*-Tos-α-dehydroamino acid (DHA) and its ester were prepared by the condensation of 2-oxo carboxylic acid or ester with benzyl carbamate or *p*-toluenesulfonamide. Subsequently, the N-protected DHA and its N-free ester thus obtained were coupled with several L-α-amino acid esters and N-protected (Boc or Cbz)-L-α-amino acid respectively by the usual peptide synthetic methods to give a number of different types of dehydrodipeptide. The configurations of all the new DHA and dehydrodipeptides obtained were shown to have (*Z*)-geometry.

Recently, much interest has been directed to the synthesis and bioactivity of dehydropeptide (DHP), containing α-dehydroamino acid (DHA) residues, which are very important constituents in an increasing number of antibiotic and phytotoxic peptides.[1-3] The previous methods of synthesizing the simple DHP has been almost exclusively indirect, *i.e.*, methods using the reaction of unsaturated azlactone with α-amino acid[4,5] and the β-elimination of peptide, which has a leaving group.[6-8] Concerning the direct condensation, no report has been published on the coupling of DHA with α-amino acid, except for two examples[9,10] involving earlier work by one of the present authors (C. S.).

In a previous paper, we briefly reported the direct coupling of (*Z*)-2-(benzyloxycarbonylamino)-2-alkenoic acid (**4**) as a carbonyl component with the L-leucine ethyl ester by the usual synthetic method.[11]

In the present paper, we wish to report in detail on the general preparation of the DHA N-protected with the benzyloxycarbonyl (Cbz) group (**2** and **4**) or the *p*-tolylsulfonyl (Tos) group (**3** and **5**), and on the facile synthesis of the two kinds of N-protected DHP from the N-protected DHA (ΔAA)[12] and several L-α-amino acid (AA) esters, and from N-protected AA and ethyl (*Z*)-2-amino-2-alkenoate (**1**)[13,14] by the mixed anhydride, DCC, or azide method.

Results and Discussion

N-Protected (Z)-α-Dehydroamino Acids. In order to prepare the DHA with a useful protecting group as a carboxyl component, according to the method reported previously by us,[15] the condensation reaction of α-oxoalkanoic acids with amides under various acidic conditions have been extensively reinvestigated. As a result, the optimum experimental conditions for the preparation of 2-Cbz- or 2-Tos-amino-2-alkenoic acids (**4** and **5**) and ethyl 2-Cbz- or 2-Tos-amino-2-alkenoates (**2** and **3**) were established as follows. The condensation reaction of equimolar 2-oxoalkanoic acid with benzyl carbamate or *p*-toluenesulfonamide in benzene in the presence of *p*-toluenesulfonic acid (PTS) as the catalyst under reflux for *ca.* 4 h gives **4** and **5** in yields *ca.* 75 and *ca.* 51% respectively. On the other hand, in the case of the reaction of ethyl 2-oxoalkanoate with benzyl carbamate or *p*-toluenesulfonamide, it was found that a similar condensation readily occurred in the presence of phosphoryl chloride rather than PTS to give **2** and **3** in *ca.* 69 and 72% yields respectively. However, the attempt to effect a similar direct condensation of 2-oxoalkanoic acid or its ester with *t*-butyl carbamate failed because of the unstability of the *t*-butoxycarbonyl (Boc) group under acidic conditions.

The α-dehydroamino acid structure of **2**—**5** was supported by the characteristic signals of olefinic (δ 5.63—6.94), vinyl (δ 5.68—6.22), and γ-protons (δ 1.68—3.19) in the NMR spectra and the characteristic absorption bands of NH (3220—3310 cm^{-1}), ester (1720—1740 cm^{-1}), carbonyl (1705—1710 cm^{-1}), and carbon-carbon double bond (1640—1665 cm^{-1}) functions in the IR spectra. Although the configuration of **2**—**5** could not be determined from the above spectroscopic data, the geometric structures of the esters were unambiguously determined to have (*Z*)-geometry by comparison with **2** and **3** prepared independently by the acylation of (*Z*)-**1**[14] with benzyloxycarbonyl chloride (Cbz-Cl) or tosyl chloride (Tos-Cl) respectively in the usual way. Moreover, the configurational structures of the free acid prepared by the hydrolysis

a) Yield from 2-oxoalkanoic acid and benzyl carbamate or *p*-toluenesulfonamide. b) Yield from the hydrolysis of **2** or **3**. c) Colorless needles from chlorobenzene. d) Colorless needles from cyclohexane–benzene. e) Colorless prisms from chloroform. f) Colorless prisms from benzene. g) Colorless prisms from 50% ethanol. h) Overlapped with phenyl protons.

of (*Z*)-**2** and **3** were identical with those of **4** and **5** respectively.

The yields, physical constants, and NMR spectral data of **2**—**4** and **5** are listed in Tables 1 and 2.

Coupling of (Z)-DHA with L-α-*Amino Acid.* As has been reported in the preceding communication,[11] Compound **4** as a carboxyl component was subjected to a reaction with the appropriate L-α-amino acid (Gly, Ala, Ser, Leu, Met, Cys(benzyl), Phe, Trp, and Tyr) esters (methyl and ethyl). As expected, the equimolar coupling of N-protected DHA with the amino acid ester by either the mixed anhydride (MA) method (in the presence of triethylamine and ethyl chloroformate in THF–chloroform at 0 °C for 1 h), the DCC method (in the presence of dicyclohexylcarbodiimide and triethylamine in chloroform at 0 °C for 3 h), or the usual azide method occurred to give Cbz-(*Z*)-dehydroaminoacylamino acid esters (**6**) as colorless syrup or crystals in *ca.* 70% yields.

On the other hand, N-protected L-α-amino acid (Leu, Cys(benzyl), and Phe) was first coupled with (*Z*)-**1** as an amine component by the similar DCC method to

Table 3. Cbz–(*Z*)-ΔAA–L-AA–OR (**6**)

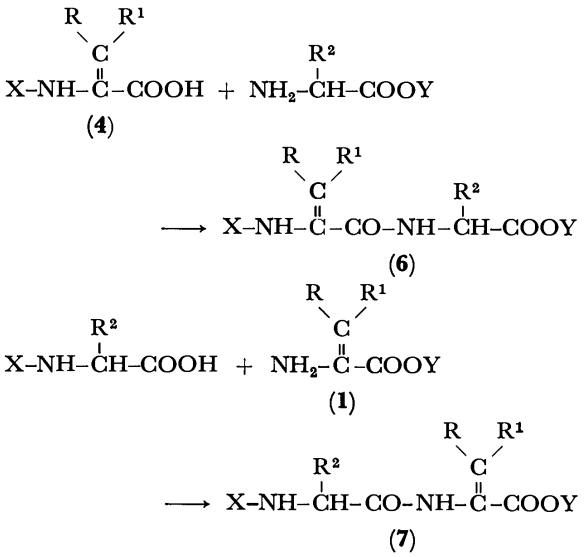
give N-protected L-leucyl-, benzylcysteinyl-, or phenylalanyl-(*Z*)-dehydroamino acid esters (**7**) as colorless crystals in *ca.* 56% yields. However, the coupling of the α-dehydrophenylalanine ester with N-protected amino acid scarcely proceeded at all because of the weak basicity of the amino group in the amine component.

In the IR spectral data, the characteristic differences between **6** and **7** could not be recognized. The presence of secondary amide absorption bands in the 1620—1670 and 1520—1560 cm^{-1} regions indicated the formation of the peptide bond. Moreover, the absorption bands of NH (3200—3400 cm^{-1}), ester carbonyl (1735—1750 cm^{-1}), and carbon-carbon double bond (1640—1685 cm^{-1}) functions are constituent with the assignment of the dehydrodipeptide structure.

The chemical shifts and the coupling constants of **6** and **7** were assigned as is shown in Tables 3 and 4. In the NMR spectrum of **6**, the signals in the δ 4.07—4.95 region as multiplets and in the δ 6.72—7.21 region as doublets are attributable to methine and NH protons of the α-AA residue, while the signals at δ 5.34 and in the 6.08—7.35 and 6.55—6.99 regions are attributable as singlets to vinyl, olefinic, and NH protons of the ⊿AA residue respectively. On the other hand, in the case of **7**, the corresponding signals of the α-AA residue appeared in the δ 4.36—4.60 as double triplets and in the δ 5.24—5.80 region as doublets, while those of the ⊿AA residue appeared in the δ 6.48—6.86 and 7.58—7.90 regions as singlets.

The configurations of **6** and **7** were readily determined to have (*Z*)-geometry, since the chemical shifts and the spectral patterns of the DHA residue in **6** and **7** were quite similar to the those of the corresponding (*Z*)-configurational **2**—**5**. Accordingly, it was found that the (*Z*)-configuration of DHA residue has been maintained during the peptide formation reaction.

The yields, physical constants, and NMR spectral data of **6** and **7** are listed in Tables 3 and 4.



α-Amino acid residues=Gly, Ala, Ser, Leu, Met, Cys-(benzyl), Phe, Tyr, and Trp. α-Dehydroamino acid residues=⊿Ala, ⊿But, ⊿Val, ⊿norVal, ⊿norLeu, ⊿Leu, and ⊿Phe. X=Cbz and Boc groups. Y=Me and Et.

Scheme 2.

Experimental

All the melting points are uncorrected. The IR spectra were recored with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Laboratory Co. Ltd.), using tetramethylsilane as the internal standard. The specific rotations were measured in a 0.5 dm using a JASCO DIP-4 Polarimeter (Japan Spectroscopic Co., Ltd.).

Preparation of **2**. *Procedure A*: A solution of ethyl 2-oxoalkanoate (50 mmol), benzyl carbamate (60 mmol), and $POCl_3$ (3 ml) in dry benzene (70 ml) was refluxed for 4 h. To the reaction solution we then added benzene at room temperature, after which the resultant solution was washed with saturated aqueous $NaHCO_3$ and three times with water. The benzene layer was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to give a syrupy residue, which was purified on a silica gel column, using benzene as the eluent, to give **2** as a colorless viscous oil or colorless crystals.

Procedure B: Into a solution of (*Z*)-**1** (20 mmol) and pyridine (30 mmol) in dry diethyl ether (14 ml), we stirred Cbz-Cl (20 mmol), drop by drop, under cooling. After stirring at room temperature for 6 h, more diethyl ether (40 ml) was added to the reaction solution. The pyridinium salt thus deposited was filtered off, and the filtrate was successively washed with chilled 3 M HCl, saturated aqueous $NaHCO_3$, and water, and finally dried over anhydrous Na_2SO_4. The syrupy residue thus obtained was similarly worked up to give **2**.

Preparation of **3**. *Procedure A*: In a manner analogous Procedure A described for **2**, the solution of ethyl 2-oxoalkanoate (50 ml), *p*-toluenesulfonamide (60 mmol), and $POCl_3$ (3 ml) in dry benzene (60 ml) was worked up for 9 h to give **3** as colorless crystals.

Procedure B: Into a solution of (*Z*)-**1** (20 mmol) in dry pyridine (14 ml) we stirred Tos-Cl (20 mmol) under cooling. After stirring at room temperature for 12 h, the excess pyridine was evaporated under reduced pressure. The syrupy residue thus obtained was dissolved in ethyl acetate (40 ml), and then the resultant solution was similarly worked up to give **3**.

Preparation of **4**. *Procedure A*: A solution of 2-oxoalkanoic acid (50 mmol), benzyl carbamate (50 mmol), and PTS (2 g) in dry benzene (70 ml) was refluxed for *ca.* 4 h, by which time the theoretical amount of water has separated out. After the solution had then been allowed to stand at room temperature, the crystals deposited were filtered. The filtrate was further extracted twice with saturated aqueous $NaHCO_3$ and the aqueous layer was washed once with ethyl acetate. The resultant aqueous layer was acidified to pH 2 with 6 M HCl and extracted well with ethyl acetate. The organic layer was washed with 20% aqueous NaCl and then dried over anhydrous Na_2SO_4. After the removal of the ethyl acetate, more crystals were obtained. The recrystallization of the combined crystals from chlorobenzene or cyclohexane–benzene gave **4** as colorless needles.

In an analogous manner, pyruvic acid (250 mmol) was treated with benzyl carbamate (100 mmol) in the absence of PTS to give **4a**.

Procedure B: A solution of **2** (10 mmol) in dioxane (20 ml) was treated with 1 M NaOH (30 ml) with stirring at *ca.* 35 °C for 2 h. After cooling with ice water, the reaction solution was acidified to pH 2 with 3 M HCl, and the resultant solution was extracted three times with ethyl acetate (30 ml). The extracts were washed with saturated aqueous NaCl, dried over anhydrous Na_2SO_4, and then concentrated under reduced

pressure to give **4**.

Preparation of **5**. *Procedure A*: A solution of 2-oxoalkanoic acid (50 mmol), *p*-toluenesulfonamide (50 mmol), and PTS (2.4 g) was worked up exactly according to Procedure A above to give **5** as colorless prisms.

Procedure B: The hydrolysis of **3** (10 mmol) with 1 M NaOH (30 ml) in dioxane (20 ml) was done exactly according to Procedure B above to give **5**.

Preparation of **6**. *Procedure A*: Into a solution of **4** (20 mmol) and triethylamine (20 mmol) in dry THF (60 ml) we vigorously stirred ethyl chloroformate (20 mmol), below −15 °C. After stirring had been continued for 15 min, a solution of an appropriate α-amino acid ester (20 mmol) in dry $CHCl_3$ (60 ml) was stirred into the resultant solution at 0 °C. After stirring at 0 °C for 1.5 h and then at room temperature for a further 12 h, the reaction solution was concentrated under reduced pressure to give a residual syrup, which was subsequently dissolved in a mixture of ethyl acetate (300 ml) and water (150 ml). The resulting organic layer was successively washed with 4% aqueous $NaHCO_3$, water, 10% aqueous citric acid, and water, and finally dried over anhydrous Na_2SO_4. The evaporation of the ethyl acetate under reduced pressure gave crude crystals or a syrup, subsequently purified on a silica gel column, using benzene as the eluent, to give **6**. Cbz–⊿Leu–Leu–OEt; yield, 52%. Cbz–⊿phe–Gly–OEt; yield, 56%. Cbz–⊿But–Ala–OEt; yield, 50%.

Procedure B: Into a solution of **4** (10 mmol) and an appropriate α-amino acid ester (10 mmol) in DMF (10 ml) we stirred DCC (11 mmol), portion by portion, under cooling. After the mixture had been stirred at room temperature for 12 h, the urea deposited was filtered off and washed well with ethyl acetate. The filtrate was poured into water (70 ml), and the aqueous solution was extracted twice with ethyl acetate (60 ml). The combined extracts were successively washed with 2% aqueous HCl, water, saturated aqueous $NaHCO_3$ and water, and finally dried over anhydrous Na_2CO_3. The evaporation of the ethyl acetate under reduced pressure gave crystals or a syrup, subsequently purified on a silica gel column, using benzene–ethyl acetate (4 : 1 v/v), to give **6**. See Table 3.

Procedure C: Into a solution of ethyl α-(Cbz-amino)cinnamate (**2f**; 5 mmol) in ethanol (20 ml) we stirred hydrazine hydrate (5.5 mmol) at room temperature. After the mixture had been stirred for 5 h, the ethanol was evaporated to give a residual syrup. To a solution of the syrup obtained in 1 M HCl (15 ml) and ethyl acetate (20 ml) we added a solution of $NaNO_2$ (5.5 mmol) in water (12 ml) by stirring below 0 °C. After stirring had been continued for 30 min, chilled ethyl acetate (15 ml) was added to the reaction solution and the resulting organic layer was dried over anhydrous Na_2SO_4 at 0 °C. Finally, to the resultant chilled solution we added a solution of Gly–OEt (6 mmol) in dry diethyl ether (16 ml), and then the solution was stirred at 0 °C for 12 h and then at room temperature for 12 more h. The reaction solution was washed successively with 2 M HCl, 3% aqueous $NaHCO_3$, and water, and then dried over anhydrous Na_2SO_4. The subsequent evaporation of the solvent gave Cbz–⊿Phe–Gly–OEt in a 61% yield.

Preparation of **7**. *Procedure A*: Into a solution of Boc–L-AA (20 mmol) in dry THF (60 ml) and triethylamine (20 mmol) we vigorously stirred ethyl chloroformate (20 mmol) at −15 °C. After stirring had been continued for 5 min, a solution of (*Z*)-**1** (20 mmol) in dry $CHCl_3$ (50 ml) was stirred into the resultant solution. The reaction solution was then worked-up exactly according to Procedure A above to give **7**. Boc–Phe–⊿But–OEt; yield, 33%. Boc–Phe–⊿Leu–OEt; yield, 34%.

Procedure B: Into a solution of (*Z*)-**1** (10 mmol) and an appropriate N-protected L-AA (10 mol) in CH_2Cl_2 (10 ml) we vigorously stirred DCC (11 mmol), portion by portion, below 0 °C. After stirring had been continued at room temperature for 20 h, the reaction solution was worked-up exactly according to Procedure B above to give **7**. See Table 4.

New Methods for Stereoselective Synthesis of α-Alkylidene-γ-butyrolactones Using Monoanion of *O*-Ethyl *S*-(Tetrahydro-2-oxo-3-furanyl) Thiocarbonate and Dianion of α-Mercapto-γ-butyrolactone

Kazuhiko TANAKA,* Hideki UNEME, Nobuyuki YAMAGISHI, Rikuhei TANIKAGA, and Aritsune KAJI

(Received January 12, 1980)

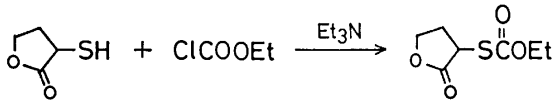
The lithium enolates of *O*-ethyl *S*-(tetrahydro-2-oxo-3-furanyl) dithiocarbonate and thiocarbonate were found to be efficient reagents for the stereoselective synthesis of α-alkylidene-γ-butyrolactones from carbonyl compounds. The dianion of α-mercapto-γ-butyrolactone was successfully generated by treatment of α-mercapto-γ-butyrolactone with 2.2 equivalents of lithium diisopropylamide in the presence of *N,N,N',N'*-tetramethylethylenediamine at −78°C in THF. The dianion thus formed has been utilized for the efficient and stereoselective synthesis of α-alkylidene-γ-butyrolactones from carbonyl compounds.

Much attention has been focused on the synthesis of α-methylene-γ-butyrolactone (dihydro-3-methylene-2(3*H*)-furanone) and α-alkylidene-γ-butyrolactones (3-alkylidenedihydro-2(3*H*)-furanone) since these compounds serve as useful intermediates in organic synthesis[1] and constitute the biologically active natural products.[2] Since carbonyl compounds such as aldehydes and ketones are readily available in organic synthesis, the direct procedure for the preparation of these unsaturated lactones from carbonyl compounds is very attractive. Several methods have been reported for the direct introduction of an alkylidene group α to a γ-butyrolactone. These have included (1) the base-catalyzed condensation of γ-butyrolactone with aldehydes[3] and (2) the reaction of aldehydes with the anion of α-triphenylphosphoranylidene-γ-butyrolactone,[4] the anion of diethyl (tetrahydro-2-oxo-3-furanyl)phosphonate,[5] or the anion of α-trimethylsilyl-γ-butyrolactone.[6] However, there has been no general method for the stereoselective introduction of an alkylidene moiety onto the α-position of γ-butyrolactone.

We have reported in the preliminary communications[7,8] that lithium enolates of *O*-ethyl *S*-(tetrahydro-2-oxo-3-furanyl) dithiocarbonate and the corresponding thiocarbonate as well as the dianion of α-mercapto-γ-butyrolactone are useful and convenient reagents for the direct synthesis of α-alkylidene-γ-butyrolactones with high stereoselectivity. This report will provide, in greater detail, the scope and limitations of these useful and stereoselective α-ylidenation of γ-butyrolactone.

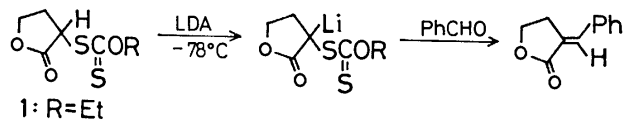
Results and Discussion

Lithium Enolates of O-*Ethyl* S-*(Tetrahydro-2-oxo-3-furanyl) Dithiocarbonate and Thiocarbonate.* Treatment of *O*-ethyl *S*-(tetrahydro-2-oxo-3-furanyl) dithiocarbonate (**1**)[9] with lithium diisopropylamide (LDA) at −78 °C in THF produced the yellow solution of lithium enolate **4**, which reacted with benzaldehyde to afford exclusively (*E*)-α-benzylidene-γ-butyrolactone (**5a**)[5] in 60% isolated yield. The starting material **1** can easily be prepared by the addition of α-bromo-γ-butyrolactone to potassium *O*-ethyl dithiocarbonate in ethanol. Attempts to purify the dithiocarbonate **1** by distillation, however, failed due to decomposition. This material can be purified by column chromatography on silica gel using benzene as eluent, but the procedure is unsuitable for the large scale preparation of **1**. Attempts to transform the dithiocarbonate **1** into the volatile liquid or the readily crystallizable material by preparing *O*-methyl *S*-(tetrahydro-2-oxo-3-furanyl) dithiocarbonate (**2**) or *O*-isopropyl analogue **3** were also fruitless. We have found that a monothiocarbonate (**7**), readily prepared from α-mercapto-γ-butyrolactone (**6**)[10] and ethyl chloroformate in high yield, can be easily purified



6 7 (91%)

by distillation. Reaction of **7** with lithium amide afforded the enolate **8** which smoothly reacted with benzaldehyde to give exclusively (*E*)-**5a**. Among the various lithium amides examined, lithium diethylamide is the most efficient base for converting thiocarbonate **7** into the enolate **8** as shown in Table 1. To show the generality of this method, a series of carbonyl compounds was utilized for α-ylidenation of γ-butyrolactone. In all cases examined, (*E*)-isomers were obtained predominantly. The *E*/*Z* ratio of a product **5** was determined by NMR and GLC analysis. For example, the ^{1}H-NMR spectrum of **5b** shows the vinyl proton β to the carbonyl



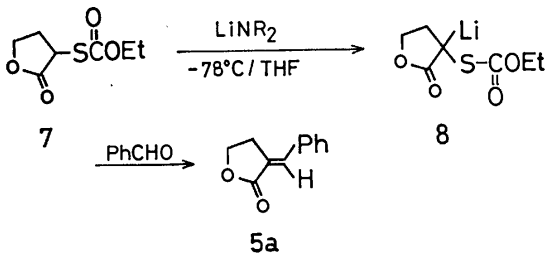


Table 1. Effect of lithium amide in the reaction of **7** with benzaldehyde

Lithium amide	% Yield of **5a**
$(i\text{-Pr})_2NLi$	53
$(i\text{-Pr})_2NLi$–TMEDA	54
$(Me_3Si)_2NLi$	39
Et_2NLi	84

at δ 6.48 for *E*-isomer and at δ 6.00 for *Z*-isomer, respectively. Integration of the vinyl proton gave a 93: 7 mixture of *E*-**5b** and *Z*-**5b**, being identical with the ratio obtained by GLC analysis (*E*/*Z*=94/6). The reaction appears to follow the pathway outlined in Scheme 1. The lithium reagent **8** attacks at the carbonyl carbon leading to **10** with transfer of the ethoxycarbonyl group from sulfur to oxygen. The intramolecular displacement affords a thiirane **11** which loses sulfur to give α-alkylidene-γ-butyrolactone (**5**). The extrusion of sulfur from thiiranes having electron-attracting substituents such as alkoxycarbonyl or cyano groups is a well-recognized process.[11,12]

Table 2. Synthesis of α-alkylidene-γ-butyrolactones from *O*-ethyl *S*-(tetrahydro-2-oxo-3-furanyl) thiocarbonate (**7**) and carbonyl compounds

Carbonyl compound	(mmol)	Product (5)		Yield %	E/Z ratio

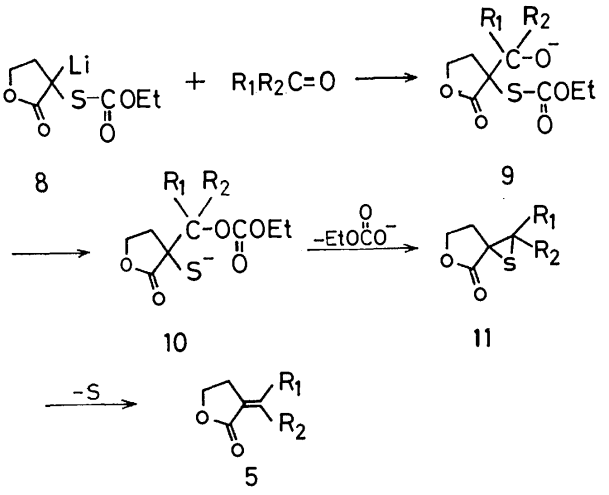
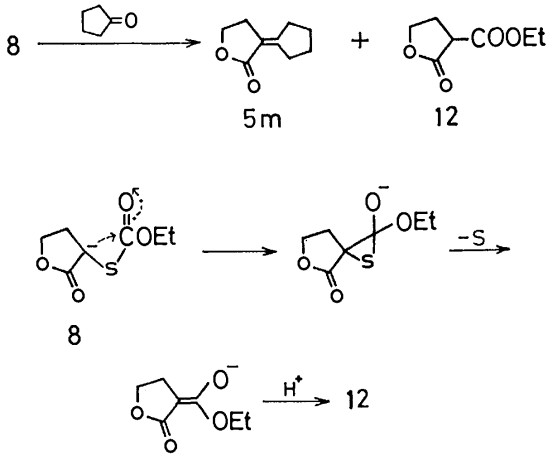
Stability of Lithium Enolate 8. In the case of cyclopentanone, we obtained 39% of α-ethoxycarbonyl-γ-butyrolactone (**12**)[13] in addition to 16% of α-cyclopentylidene-γ-butyrolactone (**5m**). This result suggests that the self-rearrangement of lithium enolate **8** takes place competitively. In order to examine the stability of lithium reagent **8**, the thiocarbonate **7** was treated with 1.1 equiv of lithium diethylamide in THF at

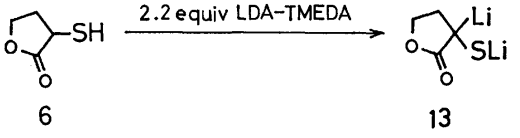


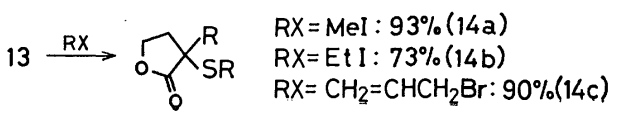
Scheme 1.

−78 °C, allowed to reach room temperature, and then quenched with saturated aqueous ammonium chloride solution. Upon workup, the lactone **12** was isolated in 45% yield. This transformation appears to involve the formation of a thiirane by intramolecular cyclization, followed by expulsion of sulfur.

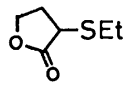


Dianion of α-Mercapto-γ-butyrolactone. The dianion of α-mercapto-γ-butyrolactone (**6**) is readily produced under mild conditions. Thus, treatment of **6** with 2.2 equiv of LDA in the presence of 2.2 equiv of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) in THF at −78 °C generated the dianion **13**, which afforded the dialkylated products (**14**) in high yields upon quenching





with excess of alkyl halides. The yield of the dialkylated compound (**14b**), however, decreased to 73% when ethyl iodide was used, providing a significant amount of the mono-alkylated derivatives, α-ethylthio-γ-butyrolactone (**15**) (22%). The dimethylated product **14a**



15

can be converted into α-methylene-γ-butyrolactone (Tulipalin A, **17**) by the reported procedure.[14] Thus, oxidation of **15a** and dehydrosulfenylation of **16** afforded Tulipalin A (**17**) and **18** in a ratio of 15:85. The dianion **13** is highly reactive toward carbonyl compounds. Thus, treatment of **13** with carbonyl compounds

TABLE 3. SYNTHESIS OF α-ALKYLIDENE-γ-BUTYROLACTONES FROM DIANION (**13**) AND CARBONYL COMPOUNDS

Carbonyl compound	(mmol)	Product (5)		Yield %	E/Z ratio
Benzaldehyde	40		(5a)	54	100/0
Propanal	22		(5b)	36	92/8
Butanal	25		(5c)	61	97/3

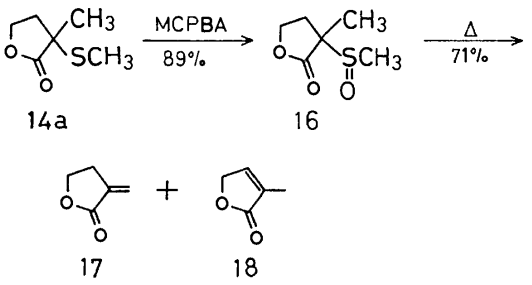
a) Lithium diethylamide was used as a base. b) Not determined.

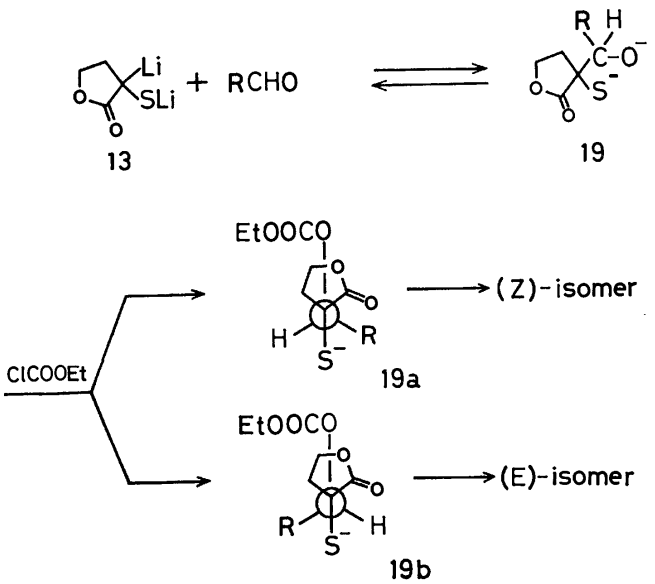


14a 16

17 18

at −78 °C and subsequent treatment of the reaction mixture with ethyl chloroformate gave predominantly (*E*)-α-alkylidene-γ-butyrolactones (**5**) in good yields. The scope of this experimentally simple synthesis of **5** is illustrated in Table 3. This reaction can be applied to a variety of aliphatic, aromatic, and heteroaromatic aldehydes, as well as α,β-unsaturated aldehydes, and afforded the desired products in moderate to good yields. However, the reaction of the dianion **13** with gaseous formaldehyde gave a disappointing yield of 7% for α-methylene-γ-butyrolactone (**5n**), probably due to polymerization of formaldehyde.

As can be seen from the data listed in Tables 2 and 3, the predominant geometry of the α-alkylidene unsaturation in **5** is *E* configuration. Such a result can be rationalized by considering the conformations of two possible stereoisomeric precursors (**19a** and **19b**) leading to **5** as shown in Scheme 2. In both cases, if the conformation, in which the OCO_2Et and S^- groups are anti-periplanar, is favorable one for the subsequent intramolecular attack of S^- group and elimination of the $^-OCO_2Et$ species, the orientation of R group is represented as **19a** and **19b**, respectively. The equilibrium between the stereoisomers **19a** and **19b**, if present with or without the participation of the *S*-ethoxycarbonylated derivative such as **9**, would surely favor **19b**, since the steric interaction between a bulky R group and a lactone carbonyl is minimized in **19b**. On the other hand, the stereoisomer **19a**, in which the alkyl and carbonyl group are *gauche*, would exhibit severe



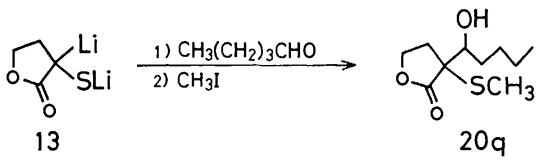
13 19 19a 19b

Scheme 2.

interactions. Thus, the *E*-isomer of α-alkylidene-γ-butyrolactone predominates.

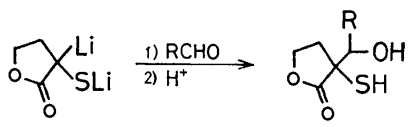
In the case of the reaction of the carbanion **8** with carbonyl compounds, the predominant formation of the *E*-isomer is also explained by the same argument.

Evidence for the adduct **19** rests on quenching the reaction mixture of **13** and pentanal at −78 °C with methyl iodide and isolating the lactone **20q** in 84% yield. The ^{1}H-NMR spectrum of **20q** shows a doublet at δ 2.10 which indicates a mixture of diastereoisomers. An attempt to determine the ratio of this mixture by gas chromatography, however, failed due to decomposition.



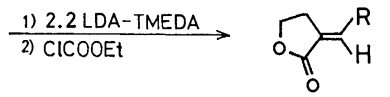
13 20q

When the reaction mixture of **13** and an aldehyde was quenched with saturated aqueous ammonium chloride solution at −78 °C, the adduct **21** was obtained in good yield as shown below. Reaction of adduct **21a**



13

21a : R = C_6H_5 (76%)
21c : R = $CH_3CH_2CH_2$ (87%)



5a: R = C_6H_5 (35%; E/Z=100/0)
5c: R = $CH_3CH_2CH_2$ (42%; E/Z=96/4)

and **21c** with 2.2 equiv of LDA in the presence of TMEDA at −78 °C followed by the addition of ethyl chloroformate afforded the corresponding α-alkylidene-γ-butyrolactone **5a** and **5c**.

Experimental

General. Melting points were determined with a Yanagimoto melting point apparatus and are uncorrected. Boiling points were determined during distillation and are uncorrected. Nuclear magnetic resonance spectra were determined on a JEOL Model PS-100 spectrometer. Chemical shifts are given in δ units, part per million relative to tetramethylsilane as internal standard. Infrared spectra were determined on a Hitachi Model 215 spectrophotometer. Gas chromatograms were obtained using a Varian Aerograph Model 920 instrument with a 0.15 cm × 120 cm glass column (20% Silicone DC-550 on Celite 545). Mass spectra were determined on a Hitachi Model M-52 mass spectrometer. Tetrahydrofuran (THF) was dried by distillation from calcium hydride and by subsequent distillation from lithium aluminum hydride under a nitrogen atmosphere. Diisopropylamine, diethylamine, and *N,N,N',N'*-tetramethylethylenediamine were distilled from calcium hydride and stored over molecular sieves. All reactions were performed under a nitrogen atmosphere. The glassware was dried by flaming in a nitrogen stream.

Preparation of O-*Ethyl* S-*(Tetrahydro-2-oxo-3-furanyl) Dithiocarbonate (1).* To an ethanol solution of freshly prepared potassium *O*-ethyl dithiocarbonate (0.167 mol) was added a solution of 25 g (0.152 mol) of α-bromo-γ-butyrolactone in 100 ml of ethanol at 0 °C. After the reaction mixture was stirred for 7 h at room temperature, the ethanol was removed under reduced pressure, the residue was extracted with ether three times, washed, and dried (anhydrous Na_2SO_4), and evapoarated to give **1** as a viscous yellow oil which was unstable toward distillation. The crude product was chromatographed twice on silica gel using benzene as eluent to give an analytical sample of dithiocarbonate **1**: ^{1}H-NMR(CCl_4) δ 4.60 (q, J=7 Hz, 2H, CH_2O), 4.30 (m, 3H, CH_2 and CH), 2.00—3.00 (m, 2H, CH_2), 1.40 (t, J=7 Hz, 3H, CH_3). IR (neat); 2990, 1775, 1220, 1040 cm^{-1}. Found: C, 40.63; H, 5.03%. Calcd for $C_7H_{10}O_3S_2$: C, 40.76; H, 4.89%.

Synthesis of α-Benzylidene-γ-butyrolactone Using Lithium Enolate 4. To a solution of diisopropylamine (3.4 ml, 20 mmol) in 40 ml of THF at −78 °C was added butyllithium (20 mmol, 14 ml, 1.43 mol dm^{-3} in hexane) over 5 min. After the resulting pale yellow solution was stirred at −78 °C for 20 min, a solution of 4.13 g (20 mmol) of *O*-ethyl *S*-(tetrahydro-2-oxo-3-furanyl) dithiocarbonate (**1**) in 5 ml of THF was added over 6 min. After 30 min, a solution of 2.33 g (20 mmol) of benzaldehyde in 3 ml of THF was added over 2 min. The reaction mixture was stirred at −78 °C for 2 h and at room temperature for 1 h before quenching with saturated aqueous ammonium chloride solution (10 ml) and 0.6 mol dm^{-3} hydrochloric acid (100 ml). The resulting mixture was extracted four times with 50 ml portions of ether. The combined organic extracts were washed three times with saturated aqueous sodium chloride solution, dried (Na_2SO_4), and concentrated. Silica gel chromatography (benzene) gave 2.10 g (60%) of α-benzylidene-γ-butyrolactone, mp 117.5—118.5 °C. The product was identified by comparison of ^{1}H-NMR spectrum with the corresponding data from independently synthesized material.[8]

Preparation of O-*Ethyl* S-*(Tetrahydro-2-oxo-3-furanyl) Thiocarbonate (7).* To a mixture of 13 g (0.11 mol) of α-mercapto-γ-butyrolactone[10] (**6**) and 11.9 g (0.11 mol) of ethyl chloroformate in 80 ml of dry benzene at 0 °C was added a solution of 11.1 g (0.11 mol) of dry triethylamine in 20 ml of dry benzene. When addition was complete, the ice-bath was removed, and reaction mixture was stirred at room temperature for 2 h. Product isolation gave an oil that was distilled twice (bp 122 °C/0.6 Torr) (1 Torr=133.322 Pa), afforded 19 g (91%) of **7**: ^{1}H-NMR(CCl_4) δ 4.30 (q, J=7 Hz, 2H, CH_2), 4.20 (m, 2H, CH_2O), 4.00 (t, J=9 Hz, 1H, CH), 2.80 (m, 1H), 2.42 (m, 1H), 1.36 (t, J=7 Hz, 3H, CH_3). IR (neat); 2990, 1790, 1727, 1160, 1010 cm^{-1}. Found: C, 44.07; H, 5.45%. Calcd for $C_7H_{10}O_4S$: C, 44.20; H, 5.30%.

Reaction of Lithium Enolate of 7 with Carbonyl Compounds. *General Procedure*: Lithium diethylamide (22 mmol) was prepared as usual in 40 ml of THF at −78 °C. After 20 min, a solution of 3.80 g (20 mmol) of *O*-ethyl *S*-(tetrahydro-2-oxo-3-furanyl) thiocarbonate (**7**) in 5 ml of THF was added over a period of 3 min. After stirring at −78 °C for 1 h, a solution of a carbonyl compound (25 mmol) in 3 ml of THF was added. The reaction mixture was stirred at −78 °C for 2 h and then at room temperature for 1 h. The reaction mixture was poured into a separatory funnel containing 100 ml of 0.6 mol dm^{-3} hydrochloric acid and extracted four times with 50 ml portions of ether. The extracts were washed

with saturated sodium chloride solution, dried (Na_2SO_4), and evaporated. The crude product was purified by distillation and/or column chromatography over silica gel.

Decomposition of Lithium Enolate 8. The lithium enolate **8** was generated as usual from 3.80 g (20 mmol) of **7** and 22 mmol of lithium diethylamide in 40 ml of THF. After stirring at −78 °C for 1 h, the cooling bath was removed, and the reaction mixture was stirred at room temperature for 1 h. The reaction was quenched by adding 10 ml of saturated aqueous ammonium chloride solution. Product isolation gave 1.42 g (45%) of α-ethoxycarbonyl-γ-butyrolactone (**12**): bp 105—110 °C/1.5 Torr (lit,[13] bp 175 °C/25 Torr); ^{1}H-NMR(CCl_4) δ 4.0—4.5 (m, 4H, CH_2 and CH_2O), 3.47 (t, J=9 Hz, 1H, CH), 2.4—2.7 (m, 2H, CH_2), 1.32 (t, J=7 Hz, 3H, CH_3); IR(neat); 1770(COO), 1730(COO) cm^{-1}; MS(20 eV) *m/e* (relative intensity) 158 (M^+, 2), 86 (100). Found: C, 52.97; H, 6.54%. Calcd for $C_7H_{10}O_4$: C, 53.16; H, 6.37%.

Generation of Dianion of α-Mercapto-γ-butyrolactone (6) and Dialkylation. In a nitrogen atmosphere, 44 mmol of butyllithium was added to a solution of 4.5 g (44 mmol) of diisopropylamine and 5.1 g (44 mmol) of TMEDA in 40 ml of THF at −78°C. After stirring at −78 °C for 20 min, a solution of 2.4 g (20 mmol) of α-mercapto-γ-butyrolactone (**6**) in 7 ml of THF was added slowly with a syringe. After stirring for 1 h at −78 °C, 11.4 g (80 mmol) of methyl iodide was added. The reaction mixture was stirred for 30 min and then at room temperature for 1 h. To this was added 10 ml of saturated aqueous ammonium chloride solution, and the mixture was poured into 0.6 mol dm^{-3} hydrochloric acid (100 ml) and extracted four times with ether. The ether extracts were washed twice with saturated aqueous sodium chloride solution, dried (Na_2SO_4), and concentrated. The residue was distilled to give 2.7 g (93%) of α-methyl-α-methylthio-γ-butyrolactone (**14a**)[14]: bp 80—81 °C/2.5 Torr; ^{1}H-NMR (CCl_4) δ 4.24 (m, 2H, CH_2O), 2.0—2.5 (m, 2H, CH_2), 2.13 (s, 3H, SCH_3), 1.51 (s, 3H, CH_3). IR (neat); 1760 (COO) cm^{-1}. Similar procedures to the above were used for diethylation and diallylation.

α-Ethyl-α-ethylthio-γ-butyrolactone (14b): Bp 77—80 °C/0.75 Torr; ^{1}H-NMR(CCl_4) δ 4.2—4.5 (m, 2H, CH_2O), 1.5—2.8 (m, 6H, $3CH_2$), 1.23 (t, J=7 Hz, 3H, CH_3), 1.02 (t, J=7 Hz, 3H, CH_3); MS(20 eV) *m/e* (relative intensity) 174 (M^+, 6), 114 (100). IR (neat); 1760 (COO) cm^{-1}. Found: C, 55.43; H, 8.45%. Calcd for $C_8H_{14}O_2S$: C, 55.14; H, 8.10%.

α-Ethylthio-γ-butyrolactone (15): ^{1}H-NMR (CCl_4) δ 4.2—4.5 (m, 2H, CH_2O), 3.3—3.5 (m, 1H, CH), 1.9—3.0 (m, 4H, $2CH_2$), 1.30 (t, J=7 Hz, 3H, CH_3). IR (neat); 1765 (COO) cm^{-1}. MS (20 eV) *m/e* (relative intensity) 146 (M^+, 26), 86 (100).

α-(2-Propenyl)-α-(2-propenylthio)-γ-butyrolactone (14c): Bp 93—95 °C/0.75 Torr; ^{1}H-NMR (CCl_4) δ 5.5—6.0 (m, 2H, 2CH=C), 4.9—5.4 (m, 4H, $2CH_2$=C), 4.0—4.5 (m, 2H, CH_2O), 3.1—3.5 (m, 2H, SCH_2), 2.55 (d, J=7 Hz, 2H, CH_2), 1.9—2.5 (m, 2H, β-CH_2). MS (20 eV) *m/e* (relative intensity) 198 (M^+, 2), 126 (100). IR (neat); 1760 (COO), 1640 (C=C) cm^{-1}. Found: C, 60.46; H, 7.32%. Calcd for $C_{10}H_{14}O_2S$: C, 60.58; H, 7.12%.

Preparation of α-Alkylidene-γ-butyrolactones from Dianion 13 and Carbonyl Compounds. The example of benzaldehyde is given here as a typical experiment. To a magnetically stirred solution of the dianion **13** prepared from 44 mmol of LDA and 44 mmol of TMEDA in 40 ml of THF at −78 °C was added a solution of benzaldehyde (40 mmol) in 3 ml of THF. Stirring was continued at −78 °C for 2 h and then a solution of ethyl chloroformate (2.2 g, 20 mmol) in dry THF (5 ml) was added dropwise at −78 °C. The reaction mixture was stirred at −78°C for 30 min and the cooling bath was removed. After 1 h the reaction mixture was quenched with saturated aqueous ammonium chloride solution (10 ml) and extracted with ether (4×50 ml). The combined ether extracts were washed with brine, saturated $NaHCO_3$ solution, and brine. The dried (Na_2SO_4) solvent were removed and the residue was purified by column chromatography (silica gel, chloroform) to afford pure **5a** (1.89 g, 54%) as colorless crystals.

Physical Properties of α-Alkylidene-γ-butyrolactones. The analytical samples were obtained by silica gel chromatography and/or distillation.

(E)-α-Benzylidene-γ-butyrolactone (5a): Recrystallization from ethanol–acetone afforded an analytical sample of **5a**. Mp 117.5—118.5 °C (lit,[5] mp 118.5°C). ^{1}H-NMR ($CDCl_3$) δ 7.2—7.6 (m, 6H, aromatic and CH=C), 4.46 (t, J=6.8 Hz, 2H, CH_2O), 3.25 (dt, J=6.8, 3 Hz, 2H, CH_2); ^{1}H-NMR (C_6D_6) δ 7.59 (t, J=3 Hz, 1H, CH=C), 7.12 (s, 5H, aromatic), 3.65 (t, J=6.5 Hz, 2H, CH_2O), 2.28 (dt, J=6.5, 3 Hz, 2H, CH_2). IR (KBr pellet); 1740 (COO), 1650 (C=C) cm^{-1}. MS (20 eV) *m/e* 174 (M^+). Found: C, 75.55; H, 5.78%. Calcd for $C_{11}H_{10}O_2$: C, 75.84; H, 5.79%.

α-Propylidene-γ-butyrolactone (5b): Bp 70—75 °C/0.6 Torr. (lit,[5] bp 60 °C/0.5 Torr). The *E*- and *Z*-isomers of **5b** were separated by gas chromatography. *E*-Isomer: ^{1}H-NMR (CCl_4) δ 6.48 (m, 1H, CH=C), 4.22 (t, J=7 Hz, 2H, CH_2O), 2.80 (m, 2H, CH_2), 2.20 (m, 2H, CH_2), 1.10 (t, J=7 Hz, 3H, CH_3). MS (20 eV) *m/e* 126 (M^+). IR (neat); 1750 (COO), 1680 (C=C) cm^{-1}. *Z*-Isomer: ^{1}H-NMR (CCl_4) δ 6.0 (m, 1H, CH=C), 4.2 (t, J=7 Hz, 2H, CH_2O), 2.8 (m, 4H, $2CH_2$), 1.0 (t, J=7 Hz, 3H, CH_3). MS (20 eV) *m/e* 126 (M^+). IR (neat); 1750 (COO), 1670 (C=C) cm^{-1}.

α-Butylidene-γ-butyrolactone (5c):[15] Bp 88—94 °C/0.8 Torr. ^{1}H-NMR (CCl_4) δ 6.12 (m, 0.05H, CH=C for *Z*-isomer), 6.53 (m, 0.95H, CH=C for *E*-isomer), 4.27 (t, J=7 Hz, 2H, CH_2O), 2.84 (m, 2H, CH_2), 2.18 (m, 2H, CH_2), 1.2—1.7 (m, 2H, CH_2), 0.98 (t, J=7 Hz, 3H, CH_3). MS (20 eV) *m/e* 140 (M^+). IR (neat); 1755 (COO), 1680 (C=C) cm^{-1}. Found: C, 68.18; H, 8.57%. Calcd for $C_8H_{12}O_2$: C, 68.53; H, 8.63%.

α-(2-Furylmethylene)-γ-butyrolactone (5d): Mp 94—95 °C (lit,[4a] mp 91—92 °C). ^{1}H-NMR ($CDCl_3$) δ 7.54 (m, 1H, furan), 7.30 (m, 1H, CH=C), 6.6 (m, 2H, furan), 4.42 (t, J=7 Hz, 2H, CH_2O), 3.26 (m, 2H, CH_2). MS (20 eV) *m/e* 164 (M^+). IR (KBr pellet); 1730 (COO), 1645 (C=C) cm^{-1}. Found: C, 66.07; H, 5.10%. Calcd for $C_9H_8O_3$: C, 65.85; H, 4.91%.

α-Heptylidene-γ-butyrolactone (5e): Bp 108—112 °C/0.4 Torr. ^{1}H-NMR (CCl_4) δ 6.52 (m, 1H, CH=C), 4.26 (t, J=7 Hz, 2H, CH_2O), 2.83 (m, 2H, CH_2), 2.18 (m, 2H, CH_2), 1.2—1.6 (m, 8H, $4CH_2$), 0.09 (m, 3H, CH_3). MS (20 eV) *m/e* 182 (M^+). IR (neat); 1760 (COO), 1680 (C=C) cm^{-1}. Found: C, 72.31; H, 9.65%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

α-(2-Methylbutylidene)-γ-butyrolactone (5f): Bp 80—85 °C/0.6 Torr. ^{1}H-NMR (CCl_4) δ 6.25 (m, 1H, CH=C for *E*-isomer), 5.8 (m, CH=C for *Z*-isomer), 4.2 (t, J=7 Hz, 2H, CH_2O), 2.80 (m, 2H, CH_2), 2.2 (m, 1H, CH), 1.1—1.6 (m, 2H, CH_2), 0.7—1.1 (m, 6H, $2CH_3$). IR (neat); 1760 (COO), 1680 (C=C) cm^{-1}. Found: C, 70.18; H, 9.25%. Calcd for $C_9H_{14}O_2$: C, 70.10; H, 9.15%.

α-(Cyclohexylmethylene)-γ-butyrolactone (5g): Bp 110—111 °C/0.5 Torr. ^{1}H-NMR (CCl_4) δ 6.33 (dt, J=9.5, 2.7 Hz, 1H, CH=C), 4.25 (t, J=7 Hz, 2H, CH_2), 2.86 (dt, J=7, 2.7 Hz, 2H, CH_2), 2.20 (m, 1H), 0.7—1.9 (m, 10H). MS (20 eV) *m/e* 180 (M^+). IR (neat); 1760 (COO), 1680 (C=C) cm^{-1}.

α-[(E)-2-Hexenylidene]-γ-butyrolactone (5h): Bp 113—115 °C/0.8 Torr. The *E*- and *Z*-isomers of **5h** were separated by

silica gel chromatography using benzene as eluent. *E*-Isomer: ^{1}H-NMR (CCl_4) δ 6.9 (m, 1H, CH=C), 5.9—6.3 (m, 2H, CH=C), 4.03 (t, J=7 Hz, 2H, CH_2O), 2.93 (m, 2H, CH_2), 2.20 (m, 2H, CH_2), 1.48 (m, 2H, CH_2), 0.96 (t, J=7 Hz, 3H, CH_3). MS (20 eV) *m/e* 166 (M^+). IR (neat); 1750 (COO), 1650 (C=C) cm^{-1}. *Z*-Isomer: ^{1}H-NMR (CCl_4) δ 7.2—7.6 (m, 1H, CH=C), 6.45 (m, 1H, CH=C), 5.78 (m, 1H, CH=C), 4.24 (t, J=7 Hz, 2H, CH_2O), 2.92 (m, 2H, CH_2), 2.19 (m, 2H, CH_2), 1.48 (m, 2H, CH_2), 0.94 (t, J=7 Hz, 3H, CH_3). MS (20 eV) *m/e* 166 (M^+). IR (neat); 1740 (COO), 1650 (C=C) cm^{-1}.

α-(1-Methylethylidene)-γ-butyrolactone (**5i**): Bp 70—73 °C/0.7 Torr. ^{1}H-NMR (CCl_4) δ 4.06 (t, J=7 Hz, 2H, CH_2), 2.78 (m, 2H, CH_2), 2.06 (t, J=2 Hz, 3H, CH_3), 1.80 (t, J=1.5 Hz, 3H, CH_3). MS (20 eV) *m/e* 126 (M^+). IR (neat); 1740 (COO), 1660 (C=C) cm^{-1}. Found: C, 66.57; H, 8.21%. Calcd for $C_7H_{10}O_2$: C, 66.65; H, 7.99%.

α-Cyclohexylidene-γ-butyrolactone (**5j**): Bp 115—120 °C/2.5 Torr (lit,[5] bp 106 °C/0.5 Torr). ^{1}H-NMR (CCl_4) δ 4.18 (t, J=7 Hz, 2H, CH_2O), 2.86 (m, 4H, $2CH_2$), 2.22 (m, 2H, CH_2), 1.64 (m, 6H, $3CH_2$). MS (20 eV) *m/e* 166 (M^+). IR (neat); 1745 (COO), 1660 (C=O) cm^{-1}.

α-Hexylidene-γ-butyrolactone (**5s**): Bp 115—117 °C/1.1 Torr. ^{1}H-NMR (CCl_4) δ 6.46 (m, 0.96H, CH=C for *E*-isomer), 6.10 (m, 0.04H, CH=C for *Z*-isomer), 4.23 (t, J=7 Hz, 2H, CH_2O), 2.83 (m, 2H, CH_2), 1.9—2.3 (m, 2H, CH_2), 1.1—1.7 (m, 6H, $3CH_2$), 0.90 (m, 3H, CH_3). MS (20 eV) *m/e* 168 (M^+). IR (neat); 1750 (COO), 1680 (C=C) cm^{-1}. Found: C, 71.44; H, 9.55%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

α-Nonylidene-γ-butyrolactone (**5t**): Bp 140—149 °C/1.5 Torr. ^{1}H-NMR (CCl_4) δ 6.46 (m, 0.95H, CH=C for *E*-isomer,) 6.08 (m, 0.05H, CH=C for *Z*-isomer), 4.22 (t, J=7 Hz, 2H, CH_2O), 2.91 (m, 2H, CH_2), 1.9—2.3 (m, 2H, CH_2), 1.1—1.7 (m, 12H, $6CH_2$), 0.87 (m, 3H, CH_3). MS (20 eV) *m/e* 210 (M^+). IR (neat); 1760 (COO), 1685 (C=C) cm^{-1}. Found: C, 74.06; H, 10.65%. Calcd for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54%.

α-[(E)-2-Butenylidene]-γ-butyrolactone (**5u**): Bp 100—106 °C/1.2—1.3 Torr. ^{1}H-NMR (CCl_4) δ 6.7—7.3 (m, 1H, CH=C), 5.7—6.2 (m, 2H, CH=C), 4.27 (m, 2H, CH_2O), 2.91 (m, 2H, CH_2), 1.90 (m, 3H, CH_3). MS (20 eV) *m/e* 138 (M^+). IR (neat); 1740 (COO), 1650 (C=C) cm^{-1}.

α-(3-Phenyl-2-propenylidene)-γ-butyrolactone (**5v**): Mp 135—136 °C (lit,[5] mp 135—136 °C). ^{1}H-NMR ($CDCl_3$) δ 7.1—7.7 (m, 6H, aromatic and CH=C), 6.6—7.0 (m, 2H, CH=C), 4.43 (t, J=7 Hz, 2H, CH_2O), 3.08 (dt, J=7, 2 Hz, 2H, CH_2). MS (20 eV) *m/e* 200 (M^+). IR (neat); 1740 (COO), 1640 (C=C) cm^{-1}. Found: C, 77.81; H, 5.97%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%.

Preparation of α-(1-Hydroxypentyl)-α-methylthio-γ-butyrolactone (**20q**): Into a solution of 22 mmol of the dianion **13** of α-mercapto-γ-butyrolactone (generated from 44 mmol of LDA and 44 mmol of TMEDA) in 40 ml of THF, was added at −78 °C 2.1 g (25 mmol) of pentanal. After 1 h at −78 °C, a solution of 3.1 g (22 mmol) of methyl iodide in 3 ml of THF was added with a syringe over a 3-min period. The resulting solution was stirred at −78 °C for 30 min and at room temperature for 1 h. The usual workup and distillation gave 3.65 g (84%) of **20q**: bp 125—132 °C/1.0—1.1 Torr. ^{1}H-NMR (CCl_4) δ 4.22 (m, 2H, CH_2O), 3.78 (m, 1H, CH), 3.45 (brs, 1H, OH), 2.2—2.9 (m, 2H, CH_2), 2.06 and 2.14 (s, 3H, SCH_3), 1.0—2.0 (m, 6H, $3CH_2$), 0.9 (m, 3H, CH_3). IR (neat); 3520 (OH), 1750 (COO) cm^{-1}.

α-(α-Hydroxybenzyl)-α-mercapto-γ-butyrolactone (**21a**): The dianion of 4.2 g (44 mmol) of **6** was generated with 88 mmol of LDA and 88 mmol of TMEDA in 80 ml of THF at −78 °C. A solution of benzaldehyde (4.2 g, 40 mmol)in dry THF (40 ml) was added dropwise and the reaction mixture was stirred at −78 °C for 2 h. The cooling bath was removed and the reaction mixture was quenched with 20 min of saturated aqueous ammonium chloride solution, diluted with chloroform (40 ml). The product was extracted with chloroform (4×50 ml), and the combined chloroform solution was washed with brine and dried (Na_2SO_4). The residue obtained after evaporation was chromagraphed on a silica gel column using benzene as eluent to afford pure **21a** (3.14 g, 76%): mp 125—125.5 °C. ^{1}H-NMR ($CDCl_3$) δ 7.34 (m, 5H, aromatic), 4.97 (s, 1H, CH), 3.98—4.5 (m, 3H, CH_2 and OH), 1.6—2.8 (m, 3H, CH_2 and SH). IR (KBr pellet) 3535 (OH), 2550 (SH), 1740 (C=O) cm^{-1}. Found: C, 58.93; H, 5.32%. Calcd for $C_{11}H_{12}O_3S$: C, 58.91; H, 5.40%.

α-(1-Hydroxybutyl)-α-mercapto-γ-butyrolactone (**21c**): A similar reaction utilizing 44 mmol of the dianion **13** and 3.60 g (50 mmol) of butanal gave 6.63 g (87%) of **21c**: bp 128—131 °C/

2.0 Torr. ^{1}H-NMR (CCl_4) δ 4.1—4.6 (m, 2H, CH_2O), 3.4—4.0 (m, 1H, OH), 1.1—3.0 (m, 8H), 0.97 (m, 3H, CH_3). IR (neat) 3520 (OH), 2555 (SH), 1755 (COO) cm^{-1}.

Preparation of (E)-α-Benzylidene-γ-butyrolactone (5a) from α-(α-Hydroxybenzyl)-α-mercapto-γ-butyrolactone (21a): Into a solution of 20.5 mmol of LDA in 19 ml of THF and 2.8 ml (20.5 mmol) of TMEDA, 2.09 g (9.30 mmol) of **21a** in 6 ml of THF was added at −78 °C. After stirring at −78 °C for 30 min, ethyl chloroformate (9.3 mmol) in 3 ml of THF was added. After stirring at −78 °C for 30 min and then at room temperature for 1 h, the usual workup and chromatographic isolation yielded 0.57 g (35%) of **5a**, which was identical by spectroscopic comparison with an authentic sample.

α-Butylidene-γ-butyrolactone (5c): A similar reaction utilizing 21.1 mmol of LDA, 2.9 ml of TMEDA, 1.82 g (9.57 mmol) of **21c**, and 9.6 ml of ethyl chloroformate gave 0.56 g (42%) of **5c**.

(Received January 21, 1980)

Incorporation of an amino acid into the 6 position of the muramic acid moiety of muramyl dipeptide has been achieved, providing an effective means for the synthesis of various new derivatives. Six new muramyl dipeptide derivatives with an *N*-acylated amino acid were synthesized using these intermediates and their immunological activity was examined. All the derivatives exhibited adjuvant activity on the induction of delayed-type hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine.

N-Acetylmuramyl-L-alanyl-D-isoglutamine (muramyl dipeptide or MDP) was found to be of the adjuvant-active minimal structure of bacterial cell wall peptidoglycans.[2)] Efforts to develop a new antitumor agent by modifying the MDP molecule led to the discovery of mycoloyl derivatives[3)] and synthetic mycoloyl-mimic long-chain fatty acid derivatives.[4)] Recently it was found that quinonyl derivatives of MDP display potent antitumor activity on the suppression of tumor growth (Meth-A fibrosarcoma) in syngeneic BALB/c female mice.[5)]

In these compounds, the 6 position of the muramyl moiety of MDP was acylated to render a lipophilic nature to the molecule. Acylation with mycolic acids, however, involves several steps and the use of 18-crown-6,[3)] the type of acid that can be introduced being restricted by the final deprotection by catalytic hydrogenolysis. The synthesis of quinonyl MDP derivatives also requires catalytic hydrogenolysis in the final stage.[5)] Thus, we tried to incorporate benzyloxycarbonylamino acids into the 6 position of the muramic acid moiety as a linking unit to introduce a lipophilic acyl group (Scheme 1). After the hydrogenolytic deprotection of all protecting groups, *O*-aminoacyl derivatives of MDP (**4**) can be coupled with various carboxylic acids as well as sulfonic and phosphoric acids, providing a valuable means for the synthesis of new derivatives of MDP. The insertion of various amino acids would affect the immunological activity.

In this paper, we describe the synthesis of six new MDP derivatives *via* *O*-aminoacyl intermediates (**4**) and their immunological activities.

The starting protected MDP derivatives (**1**) were synthesized according to the method described in a previous paper.[6)] Heating of **1** in aqueous acetic acid removed the benzylidene moiety to give partially protected MDP derivatives[7)] (**2**), which were then coupled with benzyloxycarbonylamino acid *p*-nitrophenyl ester in the presence of 1-hydroxybenzotriazole (HOBt) and *N*-ethylmorpholine (NEM) in *N*,*N*-

dimethylformamide (DMF) in 50—70% yields. α, β, or ω-Amino acid was coupled as a linking unit (Table 1). This procedure was originally adopted by Klausner and Chorev for the preparation of depsipeptides.[8] Efficient acylation of MDP components was accomplished with a twofold excess of protected amino acid active esters in a minimum amount of DMF. HOBt and NEM were added in a fourfold excess over the amount of MDP components. The resulting protected *O*-aminoacyl derivatives (**3**) were subjected to catalytic hydrogenolysis in acetic acid or methanol with palladium black as a catalyst in order to remove all the protecting groups. The physicochemical properties of the *O*-aminoacyl derivatives (**4**) thus obtained are given in Table 1 together with those of partially protected MDP derivatives (**2**) and protected *O*-aminoacyl derivatives (**3**).

The *O*-aminoacyl derivatives have been coupled with various carboxylic acids such as 10-(2,3-dimethoxy-5-methyl-1,4-benzoquinon-6-yl)decanoic acid[9] (**5a** and **5c**), 9-(2-methyl-1,4-naphthoquinon-3-yl)nonanoic acid[9] (**5b**), 3-(2,3-dimethoxy-5-methyl-1,4-benzoquinon-6-yl)propionic acid[9] (**5d**), all-*trans*-5,9,13,17-tetramethyl-4,8,12,16-octadecatetraenoic acid[10] (geranylgeranylacetic acid, **5e**), and retionic acid[11] (**5f**), by means of the active ester method in an attempt to obtain a variety of immunologically active compounds, especially with autitumor activity. Structures of carboxylic residues of **5a**—**f** are given in Table 2. Purification of the final products was carried out by column chromatography over silica gel and Sephadex LH-20. The structures of the compounds are given in Table 2 together with their physicochemical properties.

Their adjuvant activity on the induction of delayed-type hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine (ABA–Tyr) in guinea pigs was assayed according to a method described earlier.[6] All the compounds tested were found to be immunoadjuvant active, compounds **5a**, **5b**, and **5d** being more active than MDP (Table 3). Attachment of the lipophilic quinonyl moiety to the MDP molecule with 11-aminoundecanoic acid as a linking unit (**5d**) was found to be most favorable. Replacement of L-alanine of MDP by α-aminoisobutyric acid combined with the incorporation of quinonyl acids (**5a** and **5b**) also had a favorable effect on the biological potency.

The results show that the approach should provide a practical means for obtaining various MDP derivatives with immunological activities.

Experimental

Melting points were taken in open capillaries and are uncorrected. Optical rotations were determined with a Perkin-Elmer Model 141 polarimeter. All chemicals and solvents were of reagent grade and used without further purification. The reactions were monitored on TLC with Merck F_{254} silica gel plates, which were developed with

$CHCl_3$–acetone–MeOH (10 : 3 : 2, v/v) for compounds **2**, $CHCl_3$–MeOH–AcOH (18: 2: 1, v/v) for **3**, *n*-BuOH–AcOH–EtOAc–H_2O (1:1:1:1, v/v) for **4** and **5**, and EtOAc–pyridine–H_2O–AcOH (30 : 10 : 5 : 3, v/v) for **5**. Evaporation was carried out in a rotary vacuum evaporator under reduced pressure below 45 °C.

N-Acetyl-1-O-benzyl-α-muramyl-α-aminoisobutyryl-D-isoglutamine Benzyl Ester (2a). *N*-Acetyl-1-*O*-benzyl-4,6-*O*-benzylidene-α-muramyl-α-aminoisobutyryl-D-isoglutamine benzyl ester[5] (8.60 g, 11.1 mmol) was suspended in 75% AcOH (200 ml). The suspension was heated on a boiling water bath for 30 min, during which it gradually became clear. After evaporation of the solvent, the residue was flushed with H_2O and dissolved in a mixture of EtOAc (150 ml) and *n*-BuOH (50 ml). The solution was then washed successively with satd NaCl, 5% $NaHCO_3$–satd NaCl (1 : 1, v/v) and satd NaCl, and then dried over anhyd Na_2SO_4. Concentration followed by addition of Et_2O gave a white precipitate of **2a**: 6.90 g, 90.5% (Table 1).

Other partially protected MDP derivatives (2b and 2c) were prepared from appropriate protected MDP derivatives in a similar manner.

N-Acetyl-1-O-benzyl-6-O-benzyloxycarbonylglycyl-α-muramyl-α-aminoisobutyryl-D-isoglutamine Benzyl Ester (3a). A mixture of **2a** (412 mg, 0.6 mmol), benzyloxycarbonylglycine *p*-nitrophenyl ester (396 mg, 1.2 mmol), HOBt (324 mg, 2.4 mmol) and NEM (0.31 ml, 2.4 mmol) in DMF (3 ml) was stirred at room temperature for 40 h. After evaporation of the solvent, the residue was dissolved in EtOAc (15 ml) and the solution was washed with 5% $NaHCO_3$ (1×10 ml) then satd NaCl (1×10 ml), and dried over anhyd Na_2SO_4. The residue was purified by column chromatography of silica gel (30 g) with $CHCl_3$–acetone–MeOH (10 : 3 : 2, v/v) as an eluent, giving **3a**, 356 mg, 67.6% (Table 1).

Other protected MDP derivatives (3b—3e) were prepared from appropriate *N*-protected amino acid *p*-nitrophenyl ester and the partially protected MDP derivatives in a similar manner.

N-Acetyl-6-O-glycylmuramyl-α-aminoisobutyryl-D-isoglutamine (4a). Compound **3a** (307 mg, 0.55 mmol) was hydrogenated in acetic acid (10 ml) with palladium black as a

catalyst at room temperature for 3 h. After filtration and evaporation, the residue was purified by column chromatography of Sephadex LH-20 (1.8 cm×45 cm) with EtOH–0.1 M AcOH (3 : 2, v/v) as an eluent, giving **4a**, 184 mg, 69.3% (Table 1).

*Other MDP derivatives with an amino acid (**4b**—**4e**)* were prepared from appropriate protected MDP derivatives with an *N*-protected amino acid in a similar manner.

N-*Acetyl-6*-O-[*10-(2,3-dimethoxy-5-methyl-1,4-benzoquinon-6-yl) decanoylglycyl*]*muramyl-α-aminoisobutyryl-*D-*isoglutamine (**5a**).* 10-(2,3-Dimethoxy-5-methyl-1,4-benzoquinon-6-yl)decanoic acid *p*-nitrophenyl ester (47.4 mg, 0.1 mmol) was added to a solution of **4a** (56.4 mg, 0.1 mmol) and NEM (12.8 μl, 0.1 mmol) in DMF (1 ml). The mixture was stirred at room temperature for 16 h and evaporated. The residue was applied onto silica-gel column, the column being developed with EtOAc–pyridine–H_2O–AcOH (30 : 20 : 5 : 3, v/v) as an eluent. The fractions containing the product were collected and evaporated. The residue was rechromatographed over Sephadex LH-20 with EtOH–0.1 M AcOH (3: 2, v/v) as an eluent, giving **5a**, 50.5 mg, 55.4% (Table 2).

Other MDP derivatives with an N-*acylated amino acid (**5b**—**5f**)* were prepared from appropriate carboxylic acid active esters and MDP derivatives with an amino acid in a similar manner.

Biological Assays. Determination of the adjuvant activity on the induction of delayed-type hepersentivity was carried out according to the reported method.[6]

Aromatic Nucleophilic Substitution. XIII.[1] Confirmation of the Anionic σ Complexes in the Reactions of 2,4-Dinitro- and 2,4,5-Trinitro-1-(1-piperidyl)naphthalenes with Piperidine in Dimethyl Sulfoxide

Shizen SEKIGUCHI,* Reiko HIKAGE, Kenmi OBANA, Kohji MATSUI, Yumiko ANDO, and Noboru TOMOTO**

Department of Synthetic Chemistry, Gunma University, Tenjin-cho Kiryu, Gunma 376

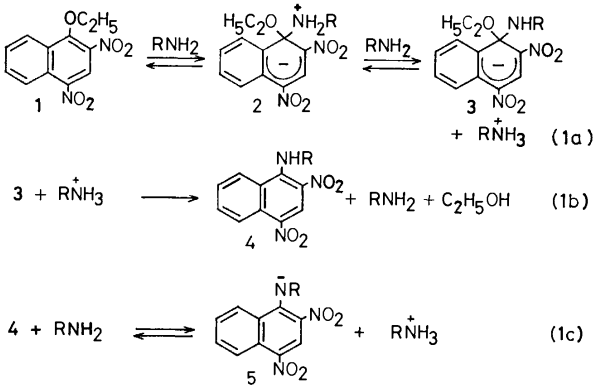
(Received January 25, 1980)

In the reactions of 2,4-dinitro- and 2,4,5-trinitro-1-(1-piperidyl)naphthalenes with piperidine in dimethyl sulfoxide, the 1,1-disubstituted anionic σ complex was confirmed to exist with visible absorption and NMR spectra. Especially in the latter case the 1,3-disubstituted anionic σ complex was formed, the cause of formation of which was ascribed to the deactivating effect of 1-piperidyl group on C_1-position of a napthtalene ring and the steric effect of 1-piperidyl group on the nucleophilic attack of piperidine on C_1-position. These factors make the 1,1-disubstituted anionic σ complex unstable.

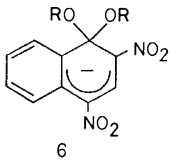
Many Jackson-Meisenheimer complexes have been prepared by nucleophilic attack on aromatic polynitro compounds.[2] In 1970 Orvik and Bunnett[3] carried out the detailed kinetics of the reactions of 1-ethoxy-2,4-dinitronaphthalene (**1**) with primary amines in dimethyl sulfoxide (DMSO), and confirmed the presence of relatively stable Meisenheimer complex (**3**, hereafter referred to as anionic σ complex) during the course of reaction (Eq. 1).



Before and since then much attention of many chemists has been concentrated on the properties and reactions of anionic σ complexes. As for anionic σ complexes found before 1970, Strauss' excellent review already appeared.[4] The later development in the chemistry of anionic σ complexes have been recently summarized by Sekiguchi.[5]

However, almost all the familar aromatic nucleophilic reactions studied so far have been limited to those of activated alkoxyarenes with primary and secondary amines or metal alkoxides[6] or to those of activated dialkylaminoarenes with metal alkoxides.[7-10] Therefore, anionic σ complexes obtained are such as **3** and **6** (hereafter referred to as 1,1-disubstituted anionic σ complex).

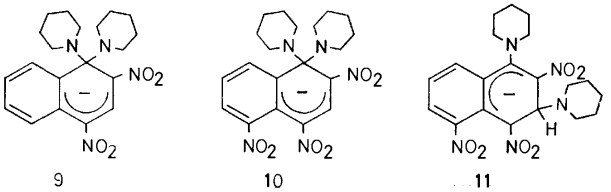
Although it was confirmed spectrophotometrically that in the reaction (Eq. 1) the final species is **5**,[3] what would become the final species, when a secondary amine is used in place of a primary one? In such a case, an



amine could not abstract a proton from **4** (Eq. 1c). Furthermore, how would 1-secondary amino group affect the rate of nucleophilic attack of corresponding amine compared with 1-alkoxyl group?

Prior to carrying out the kinetics of the reactions of 2,4-dinitro- (**7**) and 2,4,5-trinitro-1-(1-piperidyl)naphthalenes (**8**) with piperidine in DMSO, respectively, we have examined their reaction courses using NMR and visible absorption spectra.

This paper reports the presence of stable 1,1-disubstituted anionic σ complexes (**9** and **10**) in both reactions, and the presence of 1,3-disubstituted anionic σ complex (**11**) in the reaction of **8** with piperidine in addition to **10**.



Results and Discussion

Visible Absorption Spectra Relevant to the Reactions of 2,4-Dinitro- (7) and 2,4,5-Trinitro-1-(1-piperidyl)naphthalenes (8) with Piperidine in DMSO. Figure 1 shows the time-dependent spectral change of the reaction of **7** (6.63×10^{-5} M; hereafter M means mol dm^{-3}) with piperidine (1.01 M) in DMSO at room temperature. In our previous work,[11] the electronic structure of 1,1-disubstituted 2,4-dinitronaphthalene anionic σ complexes such as **3** and **6** was determined and the electronic transitions in them were assigned. From this MO calculation and the NMR spectral evidence as will be shown later, the spectrum (d)

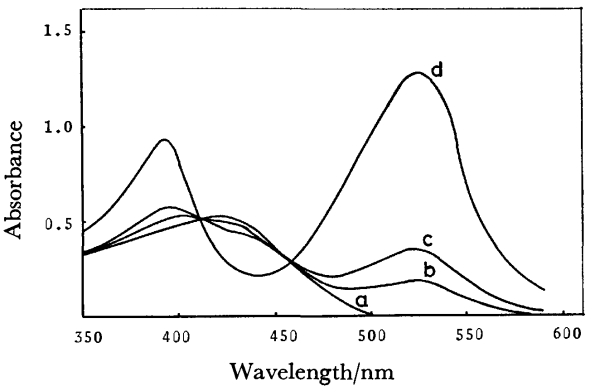


Fig. 1. Absorption spectra of 2,4-dinitro-1-(1-piperidyl)-naphthalene (**7**) with piperidine in DMSO.
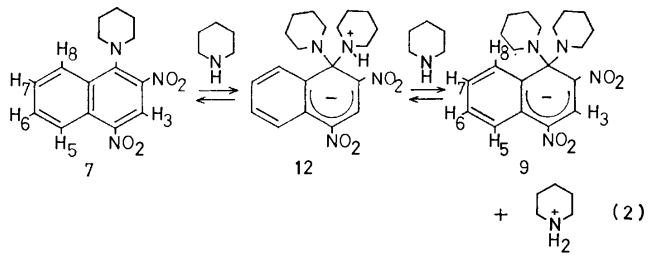
a **7**; b, c, and d 10, 24, and 480 h after addition of piperidine.

obtained in 480 h after mixing of **7**, piperidine and piperidinium chloride can be clearly attributed to **9**. As a result, the reaction is considered to proceed as follows: piperidine slowly attacks C_1-position of **7** (rate-determining), followed by the fast abstraction of ammonium hydrogen by piperidine.[3]



For comparison, we tried to carry out the reaction of 1-ethoxy-2,4-dinitronaphthalene [**1**, 2.87×10^{-5} M, λ_{max} 358 nm (ε 8.9×10^{-3})] with piperidine (1.01 M) in the presence of piperidinium chloride (8.08×10^{-2} M), in which immediately after mixing, the similar spectrum was obtained [λ_{max} 524 (ε 2.50×10^{4}), 365 (ε 1.55×10^{4}), and 357 nm (sh)]. Accordingly it is found that 1-piperidyl group deactivates C_1-position of a naphthalene ring considerably, compared with 1-ethoxyl one.

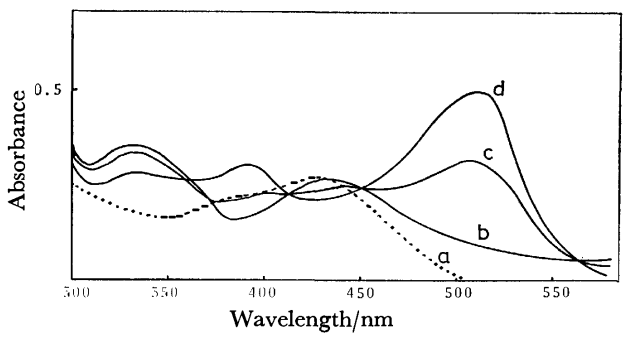


Fig. 2. Absorption spectra of 2,4,5-trinitro-1-(1-piperidyl)naphthalene (**8**) with piperidine in DMSO.
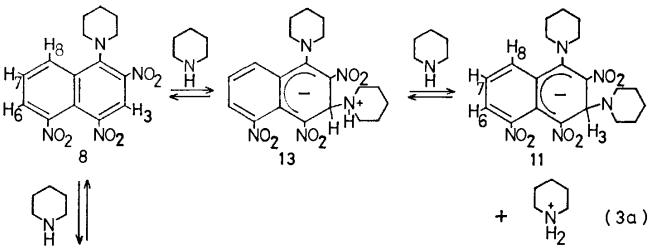
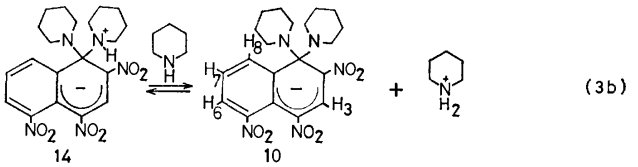
a **8**; b, c, and d immediately, 46, and 260 h after addition of piperidine.

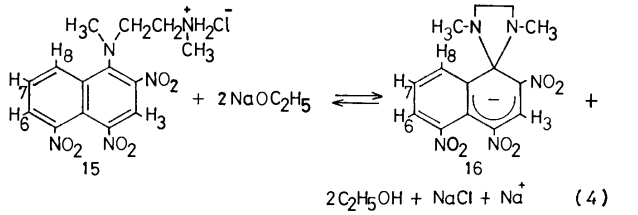
Figure 2 shows the time-dependent spectral change of the reaction of **8** (3.11×10^{-5} M) with piperidine (0.37 M) in the presence of piperidinium chloride (0.01 M) in DMSO at room temperature. Immediately after piperidine and piperidinium chloride has been added to the DMSO solution of **8**, it turned out red at once and the spectrum with double maxima [λ_{max} 434 (ε 1.00×10^{4}) and 330 nm (ε 1.29×10^{4})] was obtained. As will be shown later by NMR spectral evidence, the spectrum (b) can be attributed to **11** (Eq. 3a). There is no isosbestic point among curves a, b, c and d. That is to say, after excess piperidine is added to the DMSO solution of **8**, the equilibrium (**8**⇄**11**) is rapidly established. Just after then, **11** slowly changes into **10** *via* **8** (**11**⇄**8**⇄**14**⇄**10**). Therefore, the isosbestic points are seen among curves b, c, and d.





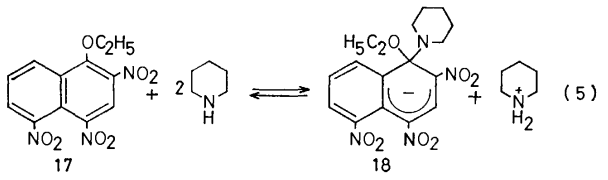
This is the first case in which a 1,3-disubstituted naphthalene anionic σ complex is found on the nucleophilic attack of an amine.

The spectrum (d) obtained in 260 h after mixing is attributed to **10** by considering the NMR spectral evidence in the next paragraph. In order to get the detailed information, we tried to carry out the following reaction in DMSO[12,13] (Eq. 4). In the case of the reaction of **15** with $NaOC_2H_5$ such an anionic σ complex

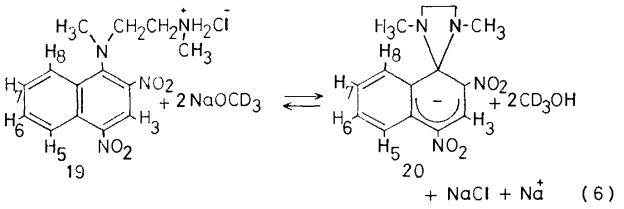


as **11** could not be formed but such one as **10** should be always formed. In 20 min after 20 equivalents of ethanolic $NaOC_2H_5$ had been added to the DMSO solution of **15** (2.57×10^{-5} M) at room temperature, the solution turned out red at once, indicating the absorption with double maxima [λ_{max} 511 (ε 2.34×10^{4}) and 352 nm (ε 9.6×10^{3})]. This result strongly supports that the spectrum (d) in Fig. 2 is due to **10** and the spectrum (b) due to **11**.

Furthermore, in the reaction of 1-ethoxy-2,4,5-trinitronaphthalene (**17**, 3.12×10^{-5} M) with piperidine



(0.377 M) and piperidinium chloride (0.020 M) in DMSO at room temperature the solution instantly turned out red after mixing, indicating the absorption with double maxima [λ_{max} 506 (ε 2.35×10^4) and 354 nm (ε 1.00×10^4)], which is attributed to **18** by the NMR spectral evidence in the next paragraph. As with **1**, 1-ethoxyl group activates C_1-position of a naphthalene ring of **17** considerably, compared with 1-piperidyl group (Eq. 3). Together with the less steric hindrance exerted by 1-ethoxyl group compared with 1-piperidyl one, this effect makes the formation of 1,1-disubstituted anionic σ complex much easier than that of 1,3-disubstituted one.



NMR Spectra Relevant to the Reaction of 7 and 8 with Piperidine in DMSO. For comparison, the time-dependent NMR spectra of the reactions of **19** and **15** with $NaOCD_3$ in DMSO-d_6 are shown in Figs. 3A—B and 3C—D, respectively. In these cases, on addition of methanolic $NaOCD_3$ (2 equivalents) to the DMSO-d_6 solution of **19** or **15** the solution turned out red at once, indicating the formation of σ complex. In the reaction course (Eq. 6) each singlet of the two CH_3 groups of **19** [not shown in Fig. 3A, δ 3.17 (N–CH_3) and 3.42 ($\overset{+}{N}$–CH_3, overlapped with the signal of $-CH_2-CH_2-$ group)] coalesced to one sharp singlet [δ 1.98 (6H)], indicating the change in hybrid orbital of C_1 ($sp^2\rightarrow sp^3$). The broad singlet of ammonium hydrogen (δ 9.30) of **19** disappeared in the spectrum of **20** (Fig. 3B). In the transformation of **19** to **20**, the H_3 singlet and H_8 doublet [δ *ca.* 8.81, $J_{8,7}$=8 Hz, the signal is finely splitted by the long-range coupling between the H_8 and H_6 protons] shifted downfield (δ 8.74→9.23 and 8.81→8.83), and the H_5 doublet (δ 8.56, $J_{5,6}$=8 Hz, $J_{5,7}$=2 Hz) and $H_{6,7}$ multiplet shifted upfield (δ 8.56→7.68 and 7.96→7.17) (Fig. 3B), respectively. With **15**, too, the similar change was found [δ 3.23 (N–CH_3) and 3.45 ($\overset{+}{N}$–CH_3, overlapped with the signal of $-CH_2-CH_2-$ group)→2.02 (6H, sharp singlet for N–CH_3 in **16**)]. The broad singlet of ammonium hydrogen of **15** [δ 9.30, overlapped with the H_6 doublet ($J_{6,7}$=8 Hz)] disappeared in the spectrum of **16** (Figs. 3C and D)]. In the transformation of **15** to **16**, the H_3 singlet shifted downfield (δ 8.83→9.03), and the H_6 ($J_{6,7}$=8 Hz) and H_8 ($J_{7,8}$=8 Hz) doublets and H_7 triplet ($J_{6,7}=J_{7,8}$=8 Hz) shifted upfield (δ 9.30→7.92, 8.65→7.68, and 8.01→7.21), respectively.

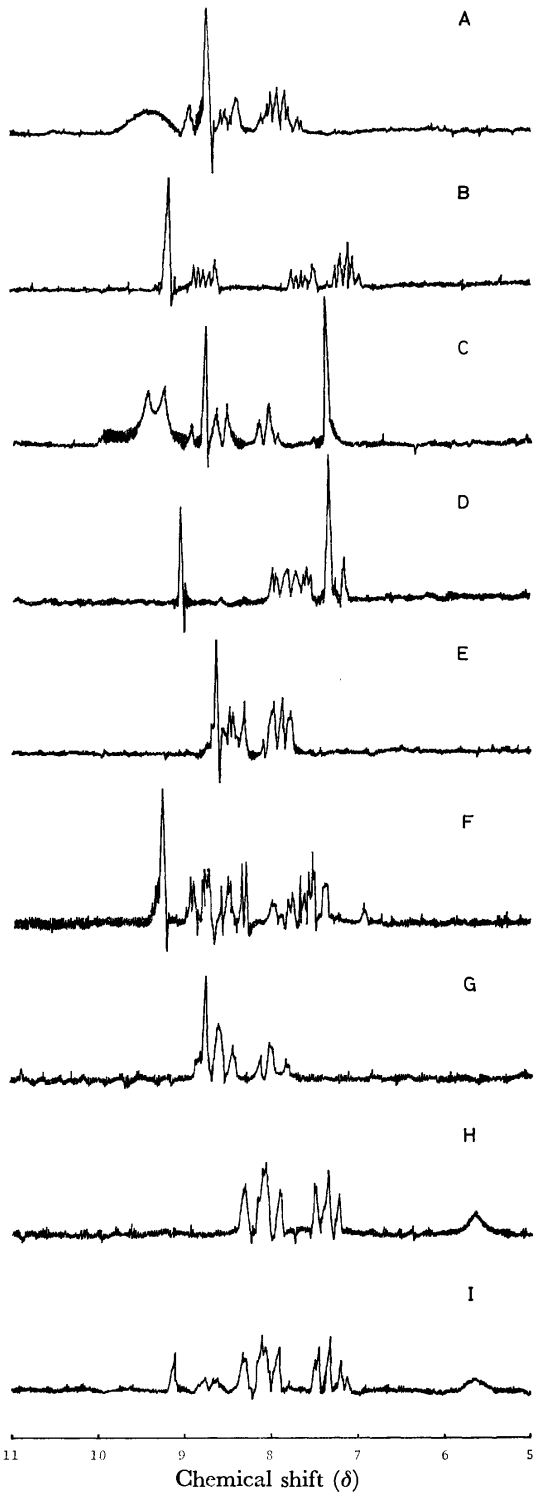


Fig. 3. NMR spectra of the reactions of *N*-methyl-2-[*N*-methyl-*N*-(2,4-dinitro-1-naphthyl)amino]ethyl-(**19**) and *N*-methyl-2-[*N*-methyl-*N*-methyl-*N*-(2,4,5-trinitro-1-naphthyl)amino]ethylammonium chlorides (**15**), and of the reactions of 2,4-dinitro- (**7**) and 2,4,5-trinitro-1-(1-piperidyl)naphthalenes (**8**) with piperidine in DMSO-d_6. A **19**; B immediately after addition of $NaOCD_3$ to the DMSO solution of **19**; C **15**; D immediately after addition of $NaOCD_3$ to the DMSO solution of **15**; E **7**; F 64 d after addition of piperdine to the DMSO solution of **7**; G **8**; H and I 8 and 14 d after addition of piperidine.

The difference between the chemical shifts of the H_8 doublets in **15** and **16** is much larger, compared with that in **19** and **20**. In **15**, 4- and 5-nitro groups deviate from coplanarity with a naphthalene ring by steric hindrance. However, when one negative charge is donated by an amino group (**15**⇄**16**), it is delocalized over three nitro groups, especially over 4-nitro one.[4] As a result, the coplanarity of 4-nitro group with a naphthalene ring increases. Accordingly 5-nitro group in **16** deviates from coplanarity to a larger extent and then comes to exert a less electron-attracting effect to H_8, which may bring about the larger upfield shift. The sharp singlet (δ 7.39) in Figs. 3C and D is due to the protons of benzene, which remained in the preparation of **15** (see Experimental).

The change in chemical shifts in both transformation is characteristic of the formation of 1,1-disubstituted anionic σ complexes.[4,5,14]

With **7**, the H_3 singlet and $H_{6,7}$ multiplet appeared at δ 8.60 and 7.90, respectively, and the $H_{5,8}$ multiplet at δ 8.47 (Fig. 3E). Sixty four days after 20 equivalents of piperidine had been added to the DMSO-d_6 solution of **7**, the H_3 singlet and H_8 doublet shifted downfield, respectively [δ 8.60→9.26 and 8.47→8.82 (d-d, $J_{7,8}$= 8 Hz, $J_{6,8}$=2 Hz)], the H_5 doublet (d-d, $J_{5,6}$=8 Hz, $J_{5,7}$=2 Hz) appeared at δ 8.49, and the $H_{6,7}$ multiplet shifted upfield (δ 7.90→7.56) (Fig. 3F). Even after a long time (64 d) the $H_{6,7}$ signals of **7** still remained (δ *ca.* 7.96), indicating the very slow nucleophilic attack of piperidine (Fig. 3F).

On the other hand, with **8** the conspicuously different signal pattern was obtained. Figures 3G, H, and I show the time-dependent NMR spectra of the reaction of **8** (6.6×10^{-5} M) with piperidine (18 equivalents) in DMSO-d_6 at room temperature. Five days after piperidine had been added to the DMSO solution of **8**, the H_3 singlet (δ 8.77), H_6 (δ 8.71) and H_8 (δ 8.58) doublets (d-d, $J_{6,7}=J_{7,8}$=8 Hz, $J_{6,8}$=2 Hz), and H_7 triplet (δ 8.05, $J_{7,8}=J_{6,7}$=8 Hz) shifted upfield (δ 5.70 singlet for H_3, δ 8.00, multiplet for $H_{6,8}$, and δ 7.43, triplet for H_7 (Figs. 3G—H)).

The extraordinary upfield shift of the H_3 singlet indicates the formation of **11**.[4,5,8,9,16-19] The intensity of the H_3 singlet corresponds to one proton. As was already mentioned, **11** slowly rearranges to **10** just after the equilibrium (**8**⇄**11**) is established. Therefore, the sharpness of the H_3 signal of **11** may depends upon the life time of **11** and the NMR resolving power. Formation of 1,3-disubstituted anionic σ complexes such as **11** is usually kinetically controlled,[15] and such complexes, therefore, are so unstable as to rearrange to 1,1-disubstituted ones, which are equilibrium-controlled.[5,8] However, even after 8 days had passed after mixing, a considerable amount of the 1,3-disubstituted anionic σ complex (**11**) still remained (Fig. 3H). Figure 3I shows that 14 d after mixing a small part of **11** rearranged to **10**, the H_3 singlet of which appeared at δ 9.13. Here, the summation of the intensities of the H_3 signals at δ 5.79 and 9.13 nearly corresponds to one proton. Fifty days after mixing, the same pattern as that in Fig. 3D was obtained. It is, therefore, considered that 1-piperidyl group considerably deactivates C_1-position of a naphthalene ring and furthermore **10** becomes more unstable owing to steric crowding of two piperidyl groups, compared with **18**. As a result, such factors would make the rearrangement of 1,3- to 1,1-disubstituted anionic σ complex slower.

In conclusion, the 1,1-disubstituted anionic σ complex is confirmed to exist in the reaction course of **7** or **8** with piperidine in DMSO and, in the latter case, the 1,3-disubstituted one confirmed additionally to be formed.

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer. Visible absorption spectra were measured on a Hitachi Model 200-10 spectrophotometer. Capillary Mps were uncorrected. Elemental analyses were conducted at the Microanalytical Center of Gunma University.

*Materials. 2,4-Dinitro- (**7**) and 2,4,5-Trinitro-1-(1-piperidyl)naphthalenes (**8**)*: To a stirred 50 ml DMSO solution of 2.52 g (0.01 mol) of 1-chloro-2,4-dinitronaphthalene (CDNN, Eastman Kodak) was dropwise added 2 equivalents of piperidine (*ca.* 2 ml) at room temperature. Furthermore, the mixture was poured into *ca.* 500 ml of ice water to form the yellow precipitate. It was filtered, dried, and recrystallized from ethanol to give 2.4 g of **7** (80%); MP 136—136.5 °C, λ_{max} 422 nm (ε 7.88×10^3, DMSO). Found: C, 60.05; H, 5.35; N, 14.13%. Calcd for $C_{15}H_{15}N_3O_4$: C, 59.80; H, 5.02; N, 13.95%.

Compound **8** was prepared by the similar method to the above-described one; yield 75%, mp 194—195 °C, λ_{max} 430 nm (ε 8.4×10^3, DMSO). Found: C, 52.21; H, 4.25; N, 16.33%. Calcd for $C_{15}H_{14}N_4O_6$: C, 52.02; H, 4.08; N, 16.18%.

*1-Ethoxyl-2,4-dinitronaphthalene (**1**)*: Compound **1** was prepared by the action of C_2H_5ONa on an ethanolic solution of CDNN;[20] yield 76%, mp 91—92 °C (92 °C[20]).

*N-Methyl-2-[N-methyl-N-(2,4-dinitro-1-naphthyl)amino]-ethylammonium Chloride (**19**)*: To a stirred 400 ml ethanol solution of 2.5 g (0.0147 mol) of CDNN was dropwise added 1.3 g (0.0099 mol) of commercial *N,N'*-dimethylethylenediamine (DMED) at room temperature. The mixture was further stirred for 3 h at room temperature to form the precipitate. The filtrate was acidified with HCl and the alcohol was evaporated to *ca.* 30 ml. Then, the solution was allowed to stand 1 d. Of two kinds of crystals formed (orange and yellow) the orange ones were seperated with tweezers. If the yellow crystals were precipitated at frist, they were filtered off and the filtrate was concentrated and allowed to stand. The orange cubic crystals were obtained and recrystallized from HCl-acidified ethanol, yielding an analytical sample (1.3 g, 39%); mp 199.5—201 °C. Found: C, 49.51; H, 5.25; N, 16.60%. Calcd for $C_{14}H_{17}ClN_4O_4$: C, 49.34; H, 5.03; N, 16.44%.

*N-Methyl-2-[N-methyl-N-(2,4,5-trinitro-1-naphthyl)amino]-ethylammonium Chloride (**15**)*: 1-Chloro-2,4,5-trinitronaphthalene (CTNN) was prepared by Rindl's method;[21] yield 60%, mp 143.5—144.5 °C (143—144 °C[20]). The compound (**15**) was prepared from CTNN and *N,N'*-dimethylethylenediamine according to the method for **19** except for the following procedure: at the later stage the concentrated filtrate was allowed to stand overnight. The orange crystals were formed and filtered, and the residue was dissolved in the solution of benzene (30 ml), ethanol (10 ml) and a small amount of aqueous HCl. Then, the mixture was refluxed for 1.5 h. After the evaporation of the solvent the oily product (**15**) was

obtained, the crystallization of which was unsuccessful. Then, the product was dried over P_2O_5 in an evacuated desiccator for 7 d. The NMR spectrum shows that **15** has a certain amount of benzene. Found: C, 45.06; H, 4.64; N, 17.75%. Calcd for $C_{14}H_{16}ClN_5O_6 \cdot 1/6C_6H_6$: C, 44.61; H, 4.72; N, 17.34%.

Piperidinium Chloride. To a stirred 20 ml solution of piperidine (0.201 mol) was added dropwise 17 ml (0.205 mol) of concd HCl at room temperature and then the mixture was cooled in an ice-water bath. After 10 min's stirring the precipitate formed was filtered and washed with cooled ethanol. Recrystallization from ethanol gave 5.43 g (22%) of an analytical sample: Mp 246—247 °C. Found: C, 49.59; H, 10.10; N, 11.77%. Calcd for $C_5H_{12}ClN$: C, 49.38; H, 9.95; N, 11.52%.

NMR Measurement. A certain amount of a sample (*ca.* 35 mg) was dissolved in a small amount of DMSO-d_6 (*ca.* 0.25 ml) in a NMR tube. After excess amine (*ca.* 200 μl) had been added into the solution through a microsyringe and shaken vigorously, the mixture was measured.

Absorption Spectra Measurement. With **7**, just after *ca.* 28 μl of piperidine had been added to *ca.* 3 ml of the DMSO solution of **7** (nearly equal to 6.63×10^{-5} M) throughout a microsyringe and the mixture stirred rapidly, the spectra were taken. With **8**, the DMSO solution of **8** (6.22×10^{-5} M) and the other solution of piperidine (0.74 M) and piperidinium chloride (0.02 M) were prepared. Just after 1.5 ml of the latter solution had been added to 1.5 ml of the former one and the mixture stirred rapidly, the spectra were taken. With **1**, the spectra were measured by the similar procedure to that with **8**.

This research was supported in part by Grant-in-Aid for Scientific Research (No. 455330) from the Ministry of Education, Japan, to which the author (S.S.) is so grateful.

Synthetic Identification of Bitter Heptapeptide in Tryptic Hydrolysate of Casein

Akio HASHIMOTO,† Haruhiko AOYAGI,* and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received January 26, 1980)

A heptapeptide, H-Gly-Pro-Phe-Pro-Ile-Ile-Val-OH (**1**), was synthesized and found to be indistinguishable from the natural peptide (**2**), isolated from a tryptic hydrolysate of Hammersten casein by means of chromatography, amino acid analyses, and mass spectrometric measurements. Both peptides (**1** and **2**) have a strong bitter taste.

Bitter peptides have been found widely in proteolytic hydrolysates of proteins. Two bitter peptides were isolated from the proteolytic hydrolysates of casein and their structures determined to be H-Gly-Pro-Phe-Pro-Val-Ile-OH (**3**)[1] and H-Arg-Gly-Pro-Pro-Phe-Ile-Val-OH (**4**).[2] Ribadeau Dumas *et al.* determined the whole primary structure of bovine β-casein[3] which contains the partial sequence of Arg(202)-Gly(203)-Pro-Phe-Pro-Ile(207)-Ile-Val(209)-OH in the *C*-terminal portion. No amino acid sequence of **3** or **4** can be found in the structure of the casein, but **3** and **4** are very similar to the *C*-terminal portion of the casein. Reports have been given on the synthesis of a natural hexapeptide (H-Arg-Gly-Pro-Phe-Pro-Ile-OH) as a sex factor in yeast, its sequence being identical with the 202—207 portion of casein.[4,5] Natural hexapeptide also has a strong bitter taste. Thus, we assumed that a heptapeptide, H-Gly-Pro-Phe-Pro-Ile-Ile-Val-OH (**1**), corresponding to the *C*-terminal portion (203—209) of casein and isolated from tryptic hydrolysate of casein, might show bitterness.

This paper deals with the synthesis of **1** by the conventional method and a comparison of the synthetic peptide with the natural peptide (**2**), isolated from tryptic hydrolysate of casein, by means of chromatography, amino acid analyses, mass spectrometric (MS) measurements and biological assays.

The synthetic route of **1** is shown in Fig. 1.[6] MA and EDC methods were used for the coupling reaction, Boc groups of the intermediates being removed by the action of HCl in EtOAc. Hydrogenation of **11** afforded **1** as dihydrate. The homogeneity of **1**·$2H_2O$ was confirmed by thin-layer chromatography (TLC) and paper chromatography (PPC). For tryptic digestion of casein and the subsequent isolation of the natural bitter peptide (**2**), the methods reported by Ribadeau Dumas *et al.*[3] and Matoba *et al.*[1] were used with slight modifications.

A comparison of **2** with **1** was carried out by TLC, PPC, and amino acid analysis. Compounds **1** and **2** are essentially the same, although **2** contains minor constituents as observed in TLC and amino acid analysis, and both have a strong bitter taste in almost the same threshold value. Field desorption mass spectra (FDMS) of **1** and **2** were measured at two different anode heating currents at 20 and 23 mA, respectively. Patterns of FDMS at 20 mA are shown in Fig. 2. Some peaks assigned to **1** and **2** at 20 mA are as follows: *m/e* 742 ([(M+H)$^+$] of the heptapeptide), 724 (loss of H_2O from [(M+H)$^+$]), and 697 (loss of CO_2 from [M$^+$]). A peak

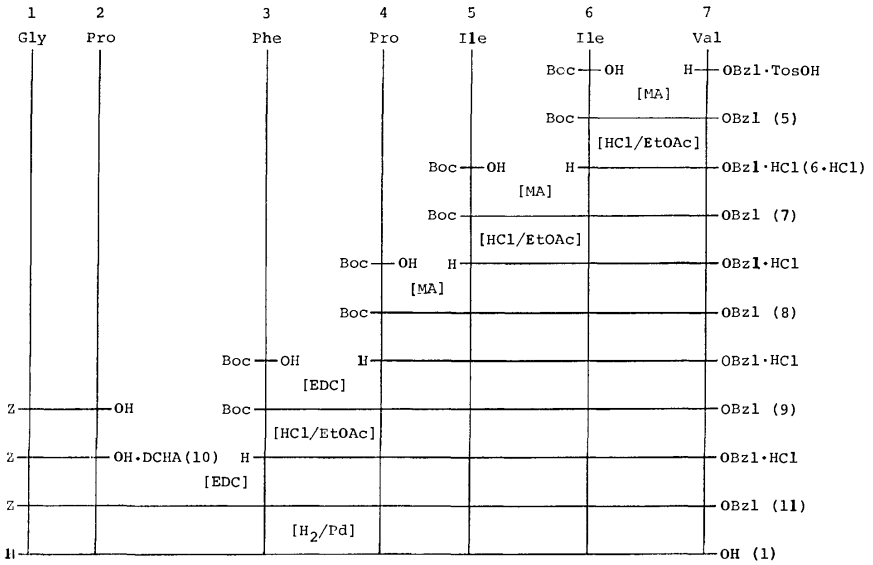

Fig. 1. Synthesis of a heptapetide, **1**.

† Present address: The Kitakyushu Municipal Institute of Environmental Health Sciences, Shin-ike, Tobata-ku, Kitakyushu 804.

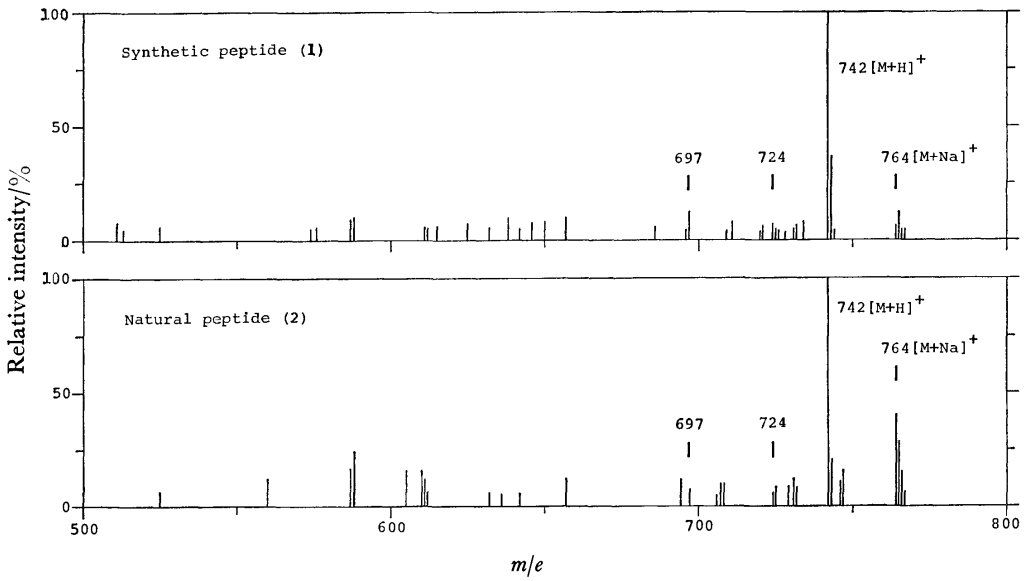

Fig. 2. FDMS of synthetic peptide (**1**) and natural peptide (**2**) measured at anode heating current of 20 mA.

at 23 mA is as follows: *m/e* 640 (loss of CO_2 from H–Pro–Phe–Pro–Ile–Ile–Val–OH which revealed *N*-terminal amino acid as Gly).

The results indicate that **2** is a new bitter peptide having the structure of H–Gly–Pro–Phe–Pro–Ile–Ile–Val–OH, the presence of several hydrophobic amino acids being important for showing bitterness as pointed out by Clegg *et al.*[7,8]

Experimental

TLC was carried out on Merck silica gel G with the systems, R_f^1, $CHCl_3$–MeOH (5 : 1); R_f^2, $CHCl_3$–MeOH (9 : 1); R_f^3, *n*-BuOH–AcOH–pyridine–H_2O (15 : 3 : 10 : 12), and on micro crystalline cellulose (AVICEL) (Funakoshi Yakuhin Co. Ltd., Tokyo) with the system R_f^4, *t*-pentyl alcohol–pyridine–H_2O (10: 4: 5). PPC was performed on Toyo Roshi No. 52 paper with the system R_f^5, the same solvent as used for R_f^4. Optical rotations were measured on a Union high sensitivity polarimeter, PM-71. Amino acid analyses were performed with a Hitachi amino acid analyzer, KLA-5. Crystalline trypsin (Sigma Chemical Co., U. S. A.) and Hammersten casein (E. Merck AG, Darmstadt, Germany) were used.

Boc–Ile–Val–OBzl (5). **5** was prepared from Boc–Ile–OH and H–Val–OBzl·TosOH by the usual MA method;[9] yield, 75%; R_f^1 0.95. Physical constants and elemental analyses of crystalline compounds are given in Table 1.

Boc–Ile–Ile–Val–OBzl (7). Compound **5** (5.0 mmol) was dissolved in 2 M HCl in EtOAc (25 ml). The solution was left to stand at room temperature for 1 h, and evaporated; yield of a solid H–Ile–Val–OBzl·HCl (**6**·HCl), 98%. **7** was then prepared from Boc–Ile–OH and **6**·HCl by the MA method; yield, 75%; R_f^1 0.75.

Boc–Pro–Ile–Ile–Val–OBzl (8). **8** was prepared from Boc–Pro–OH and H–Ile–Ile–Val–OBzl·HCl derived from **7** by the MA method; yield, 84%; R_f^2 0.75.

Boc–Phe–Pro–Ile–Ile–Val–OBzl (9). **9** was prepared from Boc–Phe–OH and H–Pro–Ile–Ile–Val–OBzl·HCl derived from **8** by the usual EDC method;[10] yield, 93%; R_f^2 0.67.

Z–Gly–Pro–OH·DCHA (10). **10** was prepared from Z–Gly–Pro–OH[11] and DCHA by the usual procedure;[12] yield, 66%.

Z–Gly–Pro–Phe–Pro–Ile–Ile–Val–OBzl (11). **11** was prepared from **10** and H–Phe–Pro–Ile–Ile–Val–OBzl·HCl derived from **9** by the EDC method; yield, 88%; R_f^2 0.52.

H–Gly–Pro–Phe–Pro–Ile–Ile–Val–OH (1). Compound **11** (0.31 g, 0.31 mmol) dissolved in a mixture of MeOH (8 ml), AcOH (4 ml), and H_2O (1 ml) was hydrogenated in the presence of Pd black. The filtrate from the catalyst was evaporated to leave a solid. Recrystallization from EtOH–EtOAc gave 0.22 g (91%); R_f^3 0.75, R_f^4 0.81, R_f^5 0.71; mass spectrum, *m/e* 741 (calcd, 741.4). Amino acid ratios in an acid hydrolysate: Pro (2.08), Gly (1.00), Val (1.03), Ile (2.09), Phe (0.99).

Isolation of Bitter Peptide from Tryptic Hydrolysate of Casein. A mixture of casein (10 g) and trypsin (150 mg) in H_2O (1000 ml) was incubated at pH 8.5 and 37 °C for 2 d. After the

Table 1. Analytical data of synthetic peptides

Compound	Mp/°C	$[\alpha]_D^{20}$ in EtOH	Formula	Found (%)			Calcd (%)		
				C	H	N	C	H	N
5	89—91	−48° (*c* 1.9)	$C_{23}H_{36}O_5N_2$	65.55	8.58	6.54	65.69	8.63	6.66
7	173—174	−77° (*c* 2.2)	$C_{29}H_{47}O_6N_3$	64.83	8.84	7.75	65.26	8.88	7.87
8	191—193	−82° (*c* 1.1)	$C_{34}H_{54}O_7N_4$	64.58	8.59	8.78	64.73	8.63	8.88
9	165—166	−81° (*c* 2.0)	$C_{43}H_{63}O_8N_5 \cdot 1/2H_2O$	65.94	8.11	8.79	65.62	8.20	8.90

11	133—134	−106° (*c* 1.0)	$C_{53}H_{71}O_{10}N_7 \cdot H_2O$	64.75	7.42	9.86	64.68	7.48	9.96
1	160—163	−116° (*c* 0.5)	$C_{38}H_{59}O_8N_7 \cdot 2H_2O$	58.58	7.99	12.30	58.67	8.16	12.60

solution had been adjusted to pH 7.0, it was extracted with 1-butanol (1000 ml × 3). The butanol phase was concentrated *in vacuo* and lyophilized. A solution of the residue in H_2O (100 ml) was adjusted to pH 10, and then acidified slowly to pH 5.4. The precipitates were removed by filtration, and the filtrate was concentrated and lyophilized. The residue obtained was purified by a series of column chromatography as follows: Sephadex G-25 (2 × 35 cm) with 0.01 M phosphate buffer (pH 7.5), Dowex 50X8 (1 × 45 cm) with 1 M pyridine–AcOH (pH 4.1), Dowex 50X8 (1 × 45 cm) with 0.4 M pyridine–AcOH (pH 3.5), Sephadex G-10 (1.6 × 12 cm) with H_2O, AVICEL (1.6 × 17 cm) with *t*-pentyl alcohol–pyridine–H_2O (10 : 4 : 5), Dowex 1X2 (1.6 × 17 cm) with 0.1 M AcOH and finally Sephadex G-10 (2.0 × 10 cm) with H_2O. In each case, the eluate fractions showing the same R_f values as that of **1** by TLC were collected, concentrated and lyophilized. The residue was dissolved in a small amount of EtOH. EtOAc was added to the solution until precipitates appeared. The precipitates were collected by filtration; yield, 8 mg; R_f[3] 0.73, R_f[4] 0.81, R_f[5] 0.71; mass spectrum, *m/e* 741 (calcd, 741.4). Amino acid ratios in an acid hydrolysate: Pro (2.27), Gly (1.00), Val (1.35), Ile (2.15), Phe (1.27). Minor amounts of Asp, Thr, Ser, Glu, and Ala were also found in the hydrolysate.

FDMS Measurements. Measurements were carried out on a Nihondenshi mass spectrometer Model JMS-01SG-2 equipped with a combined EI/FI/FD source. The mass spectra of **1**·2H_2O and **2** in MeOH (5 mg/ml) were measured at anode heating currents at 20 and 23 mA, respectively.

Bitterness Evaluation. The degree of bitterness was determined according to the method reported by Matoba *et al.*[1] Compounds **1**·2H_2O and **2** have the same degree of bitterness at 0.17—0.34 mM (0.13—0.25 mg/ml).

We wish to thank Mr. M. Koga, The Kitakyushu Municipal Environmental Health Sciences, for the FDMS measurements.

Highly Strained Ring Systems. Hydrolysis of *endo*-Tetracyclo-[5.2.0.0^{2,4}.0^{3,5}]non-8-en-6-yl *p*-Nitrobenzoate. Importance of Anchimeric Assistance by Bicyclobutane Ring. II[1]

Masayoshi Isobe and Kazuyuki Yano*

Department of Chemistry, Saitama Medical School, 981 Kawakado, Moroyama, Iruma-gun, Saitama 350-04

(Received January 26, 1980)

Solvolytic reactivity of *endo*-tetracyclo[5.2.0.0^{2,4}.0^{3,5}]non-8-en-6-yl *p*-nitrobenzoate(**1**-OPNB), *endo*-bicyclo-[4.1.0]hept-2-yl *p*-nitrobenzoate(**2**-OPNB), and *endo*-bicyclo[4.2.0]oct-7-en-2-yl *p*-nitrobenzoate(**4**-OPNB) was investigated in 50% aqueous acetone. **1**-OPNB was less reactive than **2**-OPNB that has no cyclobutene ring and more reactive than **4**-OPNB that has no bicyclobutane ring. Product study in solvolysis of **1**-OPNB was undertaken leading to the rearranged tricyclic alcohol as a major product. The importance of conformational factor for anchimeric assistance by bicyclobutane ring is discussed.

In spite of many studies of solvolytic reactions of cyclopropyl systems,[2] only a few investigations with bicyclo[1.1.0]butane derivatives, which involve the highest strain energy in bicyclic ring systems, have been reported.[3]

Masamune *et al.*[3a] reported that in ethanolysis of 5,6-diphenyltricyclo[2.1.1.0^{5,6}]hexan-2-yl *p*-toluenesulfonate a portion of the driving force for the reaction could arise from relief of angle strain on ring opening of the bicyclobutane ring. In contrast, Breslow *et al.*[3b] reported that none of the overall strain relief was found at the transition state for solvolyses of bicyclo[1.1.0]but-2-ylcarbinyl derivatives in spite of the fact that all products were derived from ring expanded cations. These studies have been made with the bicyclobutane derivatives substituted with phenyl groups or alkyl groups on the bridge heads of the bicyclobutane ring. Thus, there may be some influence on the reactivity due to π-electron systems or alkyl groups, and the effect of the bicyclobutane itself to the reaction center has some ambiguous factors.

On the other hand, we previously demonstrated importance of anchimeric assistance by bicyclobutane ring in solvolysis of a tricyclic system.[1] Taking these results into consideration, we have synthesized *endo*-tetracyclo[5.2.0.0^{2,4}.0^{3,5}]non-8-en-6-yl *p*-nitrobenzoate (**1**-OPNB),[4] *endo*-bicyclo[4.1.0]hept-2-yl *p*-nitrobenzoate(**2**-OPNB),[5] and *endo*-bicyclo[4.2.0]oct-7-en-2-yl *p*-nitrobenzoate(**4**-OPNB),[6] which have a partial structure of **1**-OPNB, and investigated their solvolytic reactivity to assess the effect of bicyclobutane and cyclobutene[7] in a polycyclic ring system.

1-OPNB PNB **2**-OPNB **3**-OPNB **4**-OPNB

Results and Discussion

The synthesis of tetracyclo[5.2.0.0^{2,4}.0^{3,5}]non-8-en-6-one (**5**) has been previously described.[4] Sodium borohydride reduction of **5** afforded exclusively the *endo* alcohol (**1**-OH). The stereochemical assignment of the *endo* isomer (geometry of the hydroxyl group relative to the cyclobutenyl group of **1**-OH) was based upon lanthanoid-induced chemical shift studies of ^{1}H NMR (Table 1). From the values of increment in chemical shift, it was predicted that the distances of the hydrogens (H_7, H_8) from the oxygen are shorter than that of H_4($\overline{OH}_7$, $\overline{OH}_8$<$\overline{OH}_4$).[8] This prediction was supported by an examination of the oxygen-hydrogen distances from the molecular model of the *endo* alcohol (**1**-OH) using Frame work Molecular Models. The stereospecific reduction of **5** from the less hindered side of the carbonyl group by sodium borohydride also suggested the *endo* isomer.[9] Additional information about the *endo* structure was gained from the coupling constants ($J_{6,5}$ and $J_{6,7}$) of the C_6 proton signal on the NMR spectrum of **1**-OPNB. From the corresponding dihedral angles (θ) obtained from the molecular model (FMM) of **1**-OPNB, the vicinal coupling constants were calculated as $J_{6.5}^{endo}$=2.50 Hz (θ=55°) and $J_{6.7}^{endo}$=7.21 Hz (θ=20°), and $J_{6.5}^{exo}$=1.83 Hz (θ=60°) and $J_{6.7}^{exo}$=0 Hz (θ=100°) using the Karplus equation.[10] The NMR data of **1**-OPNB showed $J_{6,5}$=2.0 Hz and $J_{6,7}$=9.4 Hz supporting the *endo* structure. Contrary to our all effort, attempts to prepare the *exo* epimer of **1**-OPNB encountered with failure.

The hydrolysis of **1**-OPNB, **2**-OPNB, and **4**-OPNB were measured in 50% aqueous acetone by titrating released *p*-nitrobenzoic acid using Bromothymol Blue as an indicator. All runs showed nice first-order plots. The kinetic data were summarized in Table 2 with literature values for a related compound. From Table 2, **1**-OPNB is 38 times more reactive than **4**-OPNB suggesting that this bicyclobutane ring stabilizes the transition state of the solvolysis of **1**-OPNB by *ca.* 2.7 kcal/mol (100 °C). On the other hand, the rate of **1**-OPNB decreases to one sixth comparing with that of **3**-OPNB in spite of the fact that **4**-OPNB is more reactive than cyclohexyl *p*-nitrobenzoate.[11] The difference in the reactivity of **1**-OPNB and **3**-OPNB is rationalized by considering the following two factors. First, when compared to **3**-OPNB, **1**-OPNB has a more rigid six-membered ring caused by the cyclobutene ring, and, as a result, it has a less favorable geometry for the "bisected" ion type interaction (**10**) that is the most stable structure of its transition state.[12] Second, the reactivity of **1**-OPNB probably decreases due to an inductive effect by the double bond (*ca.* by a factor

Table 1. Lanthanoid-induced chemical shifts in 1-OH[a)]

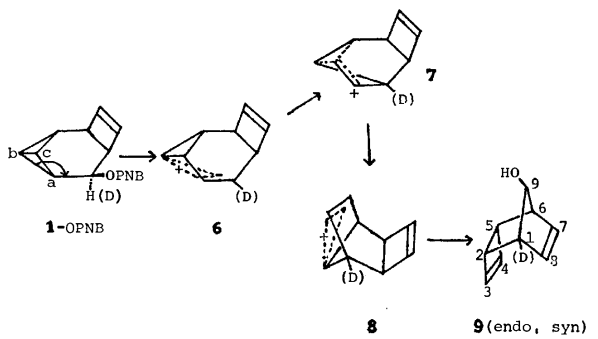
2—3).[7d,7e,13)] The rate acceleration of **4**-OPNB compared to the cyclohexyl *p*-nitrobenzoate by a factor of 7×10^4 might be mainly related to a relief of back side strain[14)] and rate retarding effect by the double bond (by a factor 2—3) would be small enough compared with the back side strain. In the case of **1**-OPNB, however, the ground-state strain resulting from nonbonded interaction between the cyclobutene ring and the leaving group would bend the leaving group to the conformationally undesirable direction for the interaction between the bicyclobutane ring and p orbital at C_6 in the transition state. In consequence, the anchimeric assistance by the bicyclobutane ring in **1**-OPNB was so important that the cyclobutene ring would influence the ionization rate of **1**-OPNB negatively. Similar relation exists in the rigid molecules such as *endo*-bicyclo[3.1.0]hex-2-yl *p*-nitrobenzoate and *endo*-tricyclo[4.2.0.$0^{2,4}$]octan-5-yl *p*-nitrobenzoate.[2f)] In them the ionization rate of the latter involving the cyclobutane ring appears comparable with the former under allowance for solvent differences.

The cyclopropylcarbinyl derivative (**2**-OPNB) which is a partial structure of **1**-OPNB underwent solvolysis at a rate *ca.* 60 times as fast as **1**-OPNB (100 °C), and its reactivity was even greater than that of **3**-OPNB by a factor of 10. In the other words, **1**-OPNB and **3**-OPNB which involve the bicyclobutane ring that has greater strain energy than the cyclopropane ring were less reactive than **2**-OPNB involving the cyclopropane ring. This result indicates that the most important factor ruling the solvolytic reactivity of **1**-OPNB is the conformational factor for stabilization of its transition state by the anchimeric assistance of the cyclopropyl ring in the bicyclobutane rather than the relief of its ring strain.[1,3b)]

Hydrolysis of **1**-OPNB produced predominantly *endo, syn*-tricyclo[4.2.1.$0^{2,5}$]nona-3,7-dien-9-ol (**9**) (91%, GLC analysis) and two unidentified minor products (<5%). Although **1**-OH was found to be unstable under the solvolysis conditions, it did not produce **9** (from GLC and TLC) suggesting that **9** is a solvolysis product of the C–O bond cleavage rather than that of alkaline hydrolysis of the ester. The structural assignment of **9** was based upon its NMR spectrum and physical property. The *endo* fusion of the cyclobutene ring to the norbornene moiety in **9** was supported by its NMR data of vinyl protons (δ 5.76, s, 4H) shifting toward up-field from that of *exo*-fused alcohol (δ 6.66 or 6.24)[7a)] due to the long range shielding effects by the other double bond.[15)] The disposition of the hydroxyl group *syn* to the cyclobutene ring was determined by its physical property (mp 87.5—88.5 °C) since the *anti* epimeric alcohol has a different melting point (41.5—42.5 °C).[16)] This assignment was also in agreement with the following mechanism: the backside participation of a–b bond of **1**-OPNB affords the "bicyclobutonium" ion **6**,[1,12)] which rearranges to **7**, and further the ion **7** gives predominantly **9** through stable bishomocyclopropenyl ion **8**.[17)] In this process, the fused cyclobutene ring is thought to act only as a stereochemical marker. The deuterated **1**-OPNB (C_6-*d*) was hydrolyzed to the C-1 (C-6) labeled alcohol **9** (C_1-*d*).



In summary, the difference in the solvolytic reactivity of **1**-OPNB, **2**-OPNB, and **3**-OPNB may depend on their effective conformations, which are related to the deviation from the most stable "bisected" structure (**10**) toward the less stable "bicyclobutonium" structure (**11**) in the transition state, for anchimeric assistance. The hydrolysis product study of **1**-OPNB also suggests the importance of anchimeric assistance by the bicyclobutane ring.

Experimental

Melting points were taken on a Yamato MP-21 melting point apparatus and are uncorrected. Infrared spectra were recorded on a Shimadzu IR-400 spectrophotometer and nuclear magnetic resonance spectra were recorded using a Hitachi R-24 instrument with chemical shift (δ) given in parts per million downfield from Me_4Si. Gas-liquid chromatography was performed on a Shimadzu GC-4B instrument. Microanalyses were determined in the microanalytical laboratory of the Institute of Physical and Chemical Research, Wako-shi, Saitama.

endo-*Tetracyclo*[*5.2.0.0*^{2,4}*.0*^{3,5}]*non-8-en-6-yl* p-*Nitrobenzoate (1-OPNB).* To a solution of *endo*-tetracyclo[5.2.0.0^{2,4}.0^{3,5}]-non-8-en-6-one[4] (639 mg, 4.84 mmol) in 15 ml of methanol was added sodium borohydride (114 mg, 3.02 mmol) at 0 °C. The resulting solution was allowed to stir at room temperature for 15 h. After addition of 15 ml of saturated sodium chloride solution, the resulting solution was extracted with ether three times. The ethereal solution was washed with saturated sodium chloride solution, dried ($MgSO_4$), and concentrated under vaccum to give 554 mg (85%) of the crude alcohol (**1**-OH) as a colorless liquid. Owing to unstability of **1**-OH, the NMR spectrum of **1**-OH was examined without purification. **1**-OH: IR (neat) 3370 (OH), 2990, 2920, 1275, 1140, and 1040 cm^{-1}; NMR (CCl_4) δ 6.19 and 6.07 (2d, 2H, vinyl, J=3.0, 7.0 Hz), 3.95—3.35 (m, 1H), 3.30—2.25 (m, 5H), and 1.63 (t, 2H, J=2.8 Hz).

To a solution of **1**-OH (554 mg, 4.13 mmol) in 15 ml of dry pyridine was added *p*-nitrobenzoyl chloride (1060 mg, 5.71 mmol) in small portions at 0 °C. The resulting solution was allowed to stand in a refrigerator for 3 d, and then poured onto 60 g of ice with 2 ml of concentrated hydrochloric acid. The product was extracted with chloroform (60 ml×3), washed with 5% HCl solution (twice), water, 5% $NaHCO_3$ solution (twice), water (twice), dried ($MgSO_4$), and concentrated give 831 mg (71%) of **1**-OPNB: mp 90.0—91.0 °C; IR (KBr) 1710 (C=O), 1515, 1340, 1285, 1260, 1100, and 715 cm^{-1}; NMR ($CDCl_3$) δ 8.28 (s, 4H, aromatic), 6.18 and 6.05 (2d, 2H, vinyl, J=3.0, 7.4 Hz), 5.22 and 5.07 (2d,1H, J=2.0, 9.4 Hz), 3.31 and 3.16 (2d, 1H, J=4.0, 9.4 Hz), 3.04—2.54 (m, 3H), 1.94—1.74 (m, 2H). Found: C, 67.58; H, 4.74%. Calcd for $C_{16}H_{13}O_4N$: C, 67.84; H, 4.63%.

endo-*Bicyclo*[*4.2.0*]*oct-7-en-2-yl* p-*Nitrobenzoate(4-OPNB).* To a solution of *endo*-bicyclo[4.2.0]oct-7-en-2-one[6] (1.23 g, 10 mmol) in 15 ml of methanol was added sodium borohydride (266 mg, 7 mmol) at 0 °C. The resulting solution was stirred at room temperature for 15 h. After the addition of the saturated sodium chloride solution, ether extraction gave 1.17 g (94%) of the crude alcohol as a colorless liquid. This alcohol was purified by chromatography on a silica gel column to yield the *endo*-alcohol (61%): IR (neat) 3350 (OH), 3040, 2920, 2870, 1445, 1325, 1040, 785, and 725 cm^{-1}; NMR (CCl_4) δ 6.22 (s, 2H, vinyl), 3.97 (m, 1H), 2.87—3.25 (m, 2H), 2.56 (s, OH), 1.62 (bs, 6H). The *endo* alcohol (410 mg, 3.3 mmol) was converted to its corresponding *p*-nitrobenzoate (**4**-OPNB) as described above for **1**-OPNB to yield 512 mg (57%): mp 52.0—54.0 °C; IR (KBr) 1725 (C=O), 1525, 1355, 1280, 1120, 1110, and 730 cm^{-1}; NMR (CCl_4) δ 8.29 (s, 4H, aromatic), 6.43—6.17 (m, 2H, vinyl), 5.45 (br d, 1H, J=4.6 Hz), 3.56—3.07 (m, 2H), 2.17—1.57 (m, 6H). Found: C, 65.63; H, 5.52%. Calcd for $C_{15}H_{15}O_4N$: C, 65.92; H, 5.53%.

Kinetic Measurements. The *p*-nitrobenzoates were hydrolyzed in aqueous acetone, and the rates were measured as previously described.[7b] The kinetic data are shown in Table 2.

Solvolysis Product Study. *p*-Nitrobenzoate (**1**-OPNB) (300 mg, 1.06 mmol) in 150 ml of 50% aqueous acetone containing 267 mg of sodium hydrogencarbonate was divided and sealed into nine test tubes under nitrogen and the tubes were heated for 30 h at 100 °C. After cooling, the contents were evaporated for removal of acetone and added saturated sodium chloride solution. The resulting slurry was extracted with three portions of chloroform (40 ml). The combined extracts were washed with saturated sodium chloride solution, dried ($MgSO_4$), and evaporated. The product was purified by chromatography on a silica gel column eluting with 30% ether in hexane to give 58 mg (41%) of **9** as white crystals (mp 87.5—88.5 °C). The low isolated yield were attributed to sublimation during drying and an unidentified hydrocarbon which had a very short retention time in GLC. **9**: IR (KBr) 3280 (OH, br), 2975, 2950, 1286, 1225, 1065, 1055, 782, and 740 cm^{-1}; NMR (CCl_4) δ 5.76 (s, 4H, vinyl), 3.98 (br s, 1H), 3.21 (d, 2H, J=4.0 Hz), 2.55—2.30 (m, 2H), 1.99 (br s, 1H, OH).

The NMR spectrum of **9** from hydrolysis of the deuterium labeled **1**-OPNB (C_6-*d*) showed that the proton intensity at δ 2.55—2.30 (2H) was reduced to 1H indicating the deuterium staying on C_1 (or C_6).

Stability of 1-OH under the Solvolysis Conditions. Alcohol (**1**-OH) (44 mg) in 16 ml of 50% aqueous acetone containing 82.7 mg of sodium hydrogencarbonate was sealed in a test tube under nitrogen and the tube was heated at 100 °C for 30 h. After work up, the crude product was examined by GLC and TLC analyses to indicate no existance of **9** and **1**-OH.

Low-temperature Photolysis of *ortho*-Substituted Azidobiphenyls. Formation of Phenazines from 2,2′-Diazidobiphenyls[1]

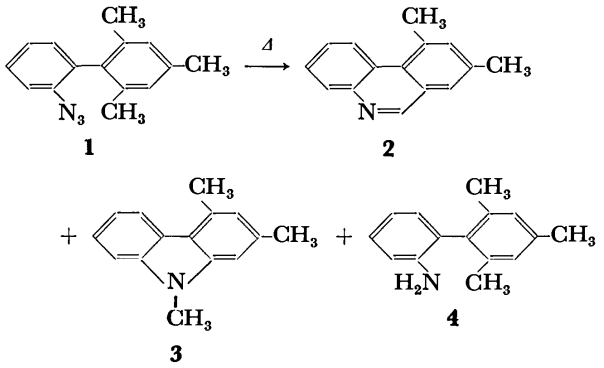
Akira YABE

National Chemical Laboratory for Industry, 1-1 Yatabe-Higashi, Tsukuba, Ibaraki 305

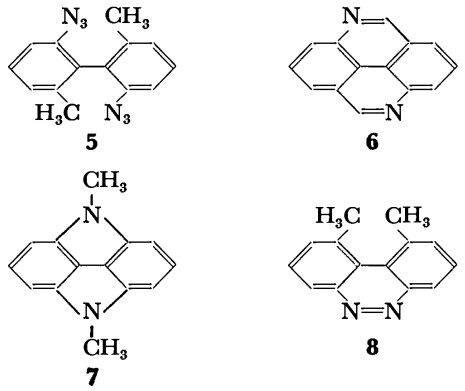
(Received January 30, 1980)

It was found that the unexpected phenazines were formed as minor products by the low-temperature photolysis of 2,2′-diazidobiphenyls in a rigid matrix. The phenazine formation results from the 1,1′-C–C bond fission of the biphenyl nucleus and suggests the aziridine intermediates. The low-temperature photolysis of 2-azido-2′-methylbiphenyl and 2-azido-2′,4′,6′-trimethylbiphenyl leads to the triplet-derived phenanthridine derivatives as major products.

It has been reported that 2-azido-2′,4′,6′-trimethylbiphenyl (**1**) gives the phenanthridine **2** (48%), as well as the carbazole **3** (5%) and the hydrogen abstraction product **4** (29%), on thermolysis.[2] When, on the other



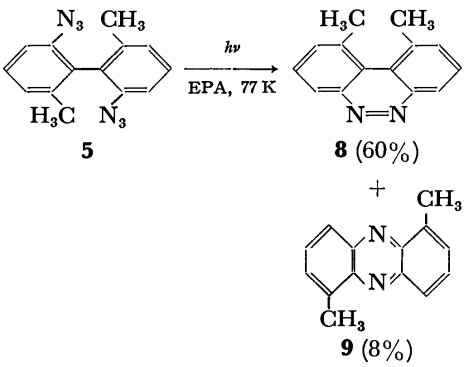
hand, the related 2,2′-diazido-6,6′-dimethylbiphenyl (**5**) was heated alone or in a number of solvents, tar rather than expected 4,9-diazapyrene (**6**) or *N*,*N*′-dimethylpyrrolo[2,3,4,5-*def*]carbazole (**7**) was obtained.[3] However, it was found, in the course of work on the low-temperature photochemistry of 2,2′-diazidobiphenyl,[4] that the photolysis of **5** in EPA at 77 K gave 1,10-dimethylbenzo[*c*]cinnoline (**8**) in a 60% yield. The



present author has now reinvestigated the possibility of forming the compound **6** or **7** as a minor product. The present paper reports that the unexpected 1,6-dimethylphenazine instead of the expected **6** and **7** was formed, together with the major product, **8**, by the low-temperature photolysis of **5** in glassy matrices. The phenazine formation involving the unusual 1,1′-C–C bond fission of the biphenyl nucleus will be discussed in terms of the interesting intermediate aziridine in nitrene chemistry. Moreover, the low-temperature photolysis of 2-azido-2′,4′,6′-trimethylbiphenyl will briefly be reported.

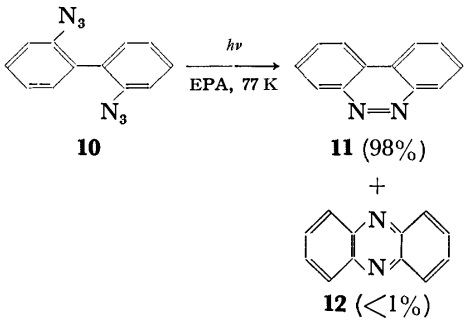
Results and Discussion

The previous paper reported that 2,2′-diazidobiphenyl afforded benzo[*c*]cinnoline (98%) almost quantitatively upon irradiation in glassy matrices at 77 K, and that, in the case of **5**, the yield of **8** was decreased to 60% by the steric effects.[4] The 3.18×10^{-4} mol dm^{-3} EPA (5: 5: 2) solution of **5** was irradiated at 77 K with a low-pressure mercury lamp. The residue remaining after the removal of solvents from the irradiated solution was examined by thin-layer chromatography. Initial TLC (silica gel) results using ether–hexane eluants indicated the unchanged starting material, **5**, as the first elute, and **8** as the second elute, plus a chromatographically nonmobile material, as described in the previous paper. However, the TLC results using the eluent benzene indicated a new fraction as the second elute, and bright yellow crystals were isolated in an 8% yield. It was identified as 1,6-dimethylphenazine (**9**) on the basis of the microanalysis and spectral properties. The chromatographically nonmobile material is, from the intermediate, presumed to be a polymeric product, because the existence of another remaining azido group was ascertained from the IR absorption spectrum (2120 cm^{-1}).



Similarly, the irradiation of 2,2′-diazidobiphenyl (**10**) in EPA at 77 K and the separation by TLC were reexamined in order to confirm that the phenazine formation was a general reaction of 2,2′-diazidobiphenyls. The parent phenazine (**12**) was detected in the second fraction, along with the major product, benzo-

[*c*]cinnoline (**11**), in the third fraction. The yield, which was determined by absorption spectroscopy, consisted of trace amounts (less than 1%).



10 **11** (98%) + **12** (<1%)

The photochemical reaction with the increase in the irradiation time was followed by absorption spectroscopy. From the spectra shown in Fig. 1, it becomes apparent that 1,6-dimethylphenazine (**9**) is formed not by the thermal reaction of some photoproducts from **5**, but by the irradiation of **5** in a rigid matrix. The absorption maximum at 308 nm that is observed in the early stages is a transient absorption which disappears on warming to room temperature. It is tentatively identified as the nitrene, **13**, based on its similarity to other nitrenobiphenyls.[5] With the increase in the irradiation time the absorption maximum of the transient is obscured by the appearance of the absorption in the 320—330 nm range; this shows the formation of the major photoproduct, **8**. In addition, a small absorption at 362 nm is also observed on the tail of the large absorption of **8**. That is, the absorption (λ_{max} 362 nm) which is attributed to phenazine appears, together with that of **8**, as a secondary product from the nitrene, **13**.

The irradiations of **5** in different solvents, at different temperatures, and more different light intensities were carried out in order to find the factors governing the phenazine formation. The results in Table 1 seem to show that the nature of the solvent plays no substantial role. The difference in the room-temperature *vs.* low-temperature photolysis is represented by the rigidity of the reaction medium together with the reaction

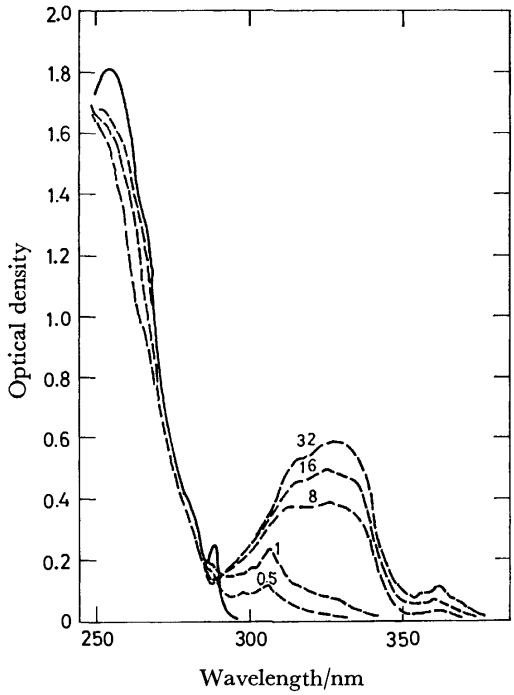


Fig. 1. Absorption spectra of 2,2′-diazido-6,6′-dimethylbiphenyl prior to (——) and after (——) photolysis in EPA at 77 K. Numbers refer to irradiation time in minute.

temperature. In a series of photolyses in IP-3MP matrices whose viscosities are varied in the range of five orders, the ratios of the yields of **8** and **9** are very similar, within the range of experimental error. However, the formations of both **8** and **9** are subject to suppression in more viscous media. The rise in the temperature, although the reaction medium is still highly rigid, changed the photolytic reaction, which could not be characterized. The formation of **8** and **9** was no longer detectable. In conclusion, the reaction is found to be highly sensitive to the reaction temperature rather than the rigidity. Table 2 shows the dependency of the product yields on the light intensity in the photolysis at 77 K in EPA. It is of interest that the yield of

a) EPA (diethyl ether, isopentane, ethanol), MCH (methylcyclohexane), IP (isopentane), 3MP (3-methylpentane). b) Cited from Ref. 6. The values in parentheses are estimated from the figures cited in the literature. c) Not detectable, or negligible even if formed.

Table 2. Dependence of product distributions on the light intensity
(Irradiations of **5** at 77 K in EPA)

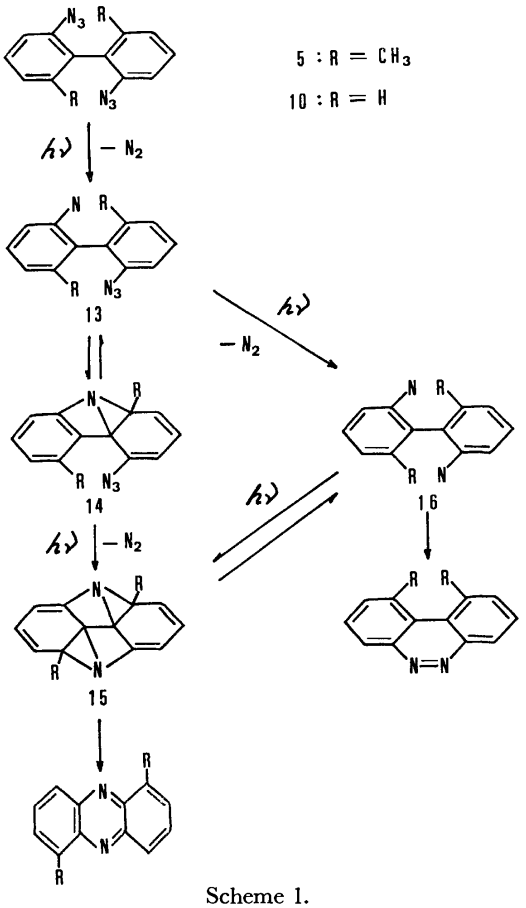
Run	Light[a)]	Yield/% Cinnoline **8** : Phenazine **9**
1	L-P(100%)	60 : 8
2	L-P(50%)	62 : 3
3	L-P(12.5%)	58 : *ca.* 1
4	L-P(100%) H-P	55 : 14

a) L-P (a 15 W low-pressure mercury lamp); H-P (a 500-W high-pressure mercury lamp through a UV-31 filter). The light intensity of the low-pressure mercury lamp was regulated with slits (transmittances of 50 and 12.5%).

phenazine **9** rises to 14% when the sample is simultaneously irradiated with strong long-wavelength light (λ>310 nm) in addition to the usual source of 254 nm light.

The phenazine formation by the decomposition of 2,2′-diazidobiphenyls is quite unexpected and unusual, involving the 1,1′-C–C bond fission of the biphenyl structure. A plausible mechanism to account for the phenazine formation is depicted in Scheme 1.

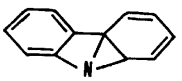
As the intermediate, **13**, is stable indefinitely at 77 K in rigid medium, the **13**→**14** conversion is a photochemical process. It is well-known that the ground states of arylnitrenes are triplet.[7)] Although **13** is once



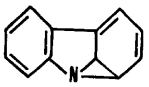
Scheme 1.

populated from the ground state to the excited triplet state (T*) by light absorption, the excited singlet state may also be efficiently populated *via* T*. Therefore, the multiplicity of the nitrene leading to the aziridine intermediate can not be concluded easily without the direct observation of the excited state. In rigid matrices at 77 K the **13**→**14** process must be less effective, much like the carbazole formation from 2-nitrenobiphenyl,[5)] than the process to benzo[*c*]cinnoline *via* **16**. The dependence on the light intensity obtained from Table 2 is revealed in the two competitive processes: the **13**→**14** conversion and the decomposition of the second azido group. The strong long-wavelength light appreciably facilitates the less effective process, **13**→**14**. Moreover, the light-intensity dependency may mean that the **16**→**15** conversion occurs by light absorption, while the reverse conversions, **14**→**13** and **15**→**16**, occur spontaneously as nonphotonic processes. In the competitive processes from **13**, the steric effects by the 6,6′-dimethyl substitution, which suppresses the coupling of nitrenes to lead to the cinnoline, contribute to the difference in the yields between **8** and **12**. As the **14** structure is highly strained, the 1,1′-C–C bond must be bent. Therefore, the **14**→**15** process may be relatively facile compared with the **13**→**14** process, although the **15** structure must be much more strained than **14**. Once the intermediate, **15**, is formed, the phenazine formation will follow to stabilize it by aromatization. The finding that **8** and **9** are formed only at a restricted low temperature is ascribable to facile side reactions from the reactive intermediates, **13**—**16**, although the details of the mechanism remain unknown.

The mechanism of the phenazine formation contains two aziridine intermediates, **14** and **15**. The structure of **14** is similar to that (**17**) proposed in the carbazole formation from 2-azidobiphenyl.[8b)] However, Sundberg and his co-workers[8)] proposed another aziridine, **18**, rather than **17**, as a result of their estimation that **17**



17



18

is about 10 kcal/mol less stable than **18**. The aziridine intermediate **17** has not been well-confirmed in the carbazole formation from azidobiphenyls. The phenazine formation, however, results from the attack of the nitrene on 1′-C and the 1,1′-C–C bond fission of the biphenyl nucleus; consequently, the **14** and **15** structures may be suggested as appropriate intermediates. These intermediates are of great interest in nitrene chemistry, although the direct evidence for them and further mechanistic aspects remain to be elucidated.

In the low-temperature photolysis of *ortho*-substituted azidobiphenyls, there has been considerable interest in the possibility of intramolecular arylnitrene insertion into a suitably located methyl group. The intramolecular reaction between the arylnitrene and the methyl group could not occur in the case of **5**, so that neither 4,9-diazapyrene nor phenanthridine derivatives were

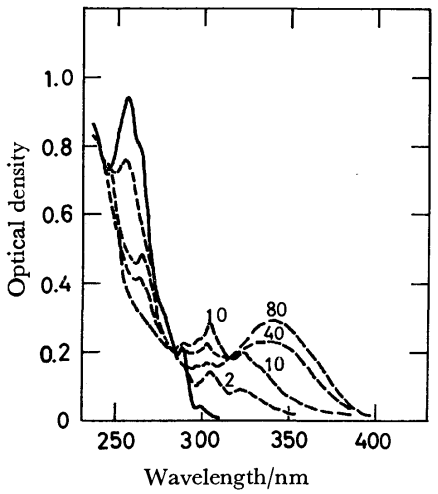


Fig. 2. Absorption spectra of 2-azido-2′-methylbiphenyl prior to (——) and after (----) photolysis in EPA at 77 K. Numbers refer to irradiation time in minute.

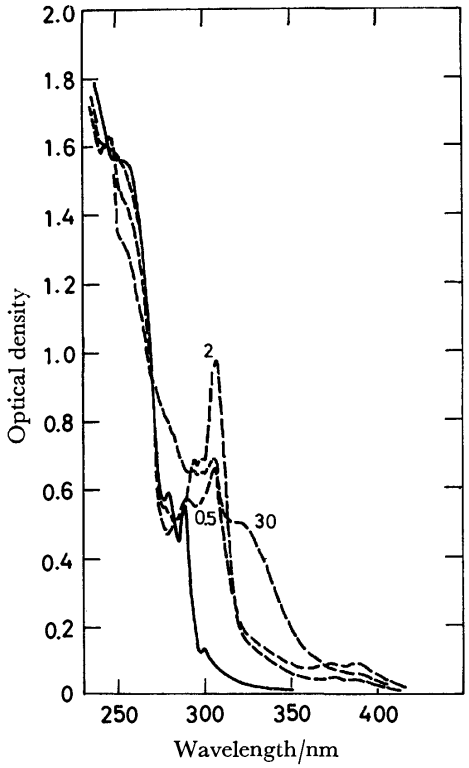

Fig. 3. Absorption spectra of 2-azdio-2′,4′,6′-trimethylbiphenyl prior to (——) and after (----) photolysis in EPA at 77 K. Numbers refer to irradiation time in minute.

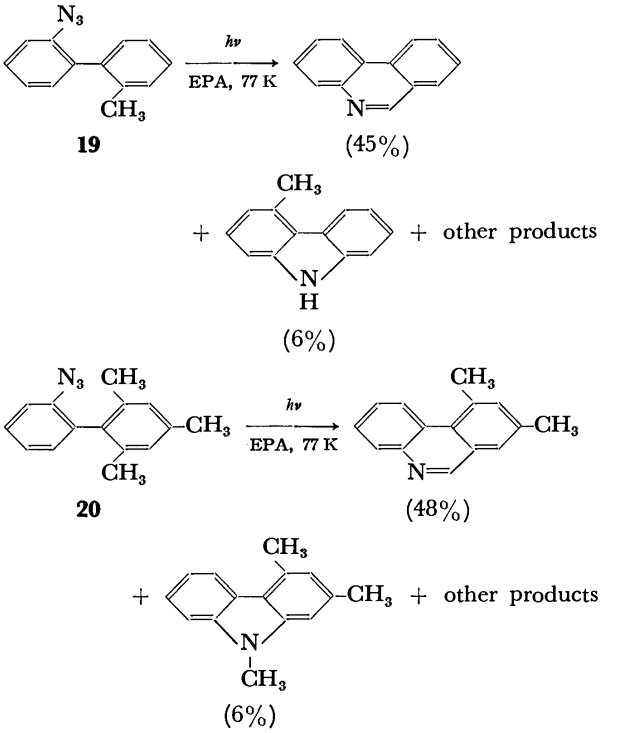
detected. In this connection, the low-temperature photolysis of 2-azido-2′-methylbiphenyl (**19**) and 2-azido-2′,4′,6′-trimethylbiphenyl (**20**) was briefly studied. Figures 2 and 3 show the spectral changes in **19** and **20** respectively in EPA at 77 K with the increase in the irradiation time. In both cases, the formation of intermediate nitrenes with transient absorptions is observed in the early stages; they become photoproducts with absorption at the longer wavelengths after long irradiation times. By separate experiments with a preparative scale, the photoproducts were isolated as follows.



It should be noted that these products contain thermally reacted products in addition to the photoproducts formed in a rigid matrix, because an appreciable amount of the intermediate nirenes remains when the irradiation is stopped. Although the details of these photolyses can not be discussed in this report, it has become apparent that the phenanthridine formation occurs with a higher selectivity than the thermolysis[2,3] or triplet-sensitized photolyses at room or high temperatures.[9] Consequently, the intramolecular arylnitrene insertion into a methyl group occurs effectively in these compounds in a rigid matrix at a low temperature. It is of interest, therefore, that, in the case of **5**, the phenazine formation occurs instead of the insertion into methyl groups.

Experimental

Measurements. The IR and UV spectra were recorded on Hitachi Model 260—30 and Shimadzu Model UV-300 spectrophotometers respectively. The ^{1}H-NMR and ^{13}C-NMR spectra were recorded on Varian Model XL-100-12 (100 MHz) and JEOL Model FX-100 (25 MHZ) spectrometers, respectively, using TMS as the internal standard. The mass spectrum was recorded on a Hitachi Model RMU-6M spectrometer. The microanalysis was performed at the Institute of Physical and Chemical Research.

Materials. 2,2′-Diazido-6,6′-dimethylbiphenyl (**5**),[3] 2-azido-2′-methylbiphenyl (**19**),[3] and 2-azido-2′,4′,6′-trimethylbiphenyl (**20**)[2] were prepared according to the literature. The crude materials were purified by column chromatography on silica gel.

Irradiation of Azides. Low-temperature irradiations on a preparative scale were carried out in a doughnut-shaped quartz vessel (volume: about 160 ml; thickness: 7 mm) which was immersed in liquid nitrogen with a 30-W low-pressure

mercury lamp (Riko UVL-30LA) protected with a transparent quartz Dewar vessel. Irradiations at 77 K for spectroscopy were carried out with a cell (path length: 10 mm) which had been immersed in liquid nitrogen in a quartz Dewar vessel equipped with optical windows on opposite sides. An Oxford Instruments DN-704 liquid nitrogen cryostat was used for the spectroscopic measurements by the irradiation at low-temperatures over 77 K.

Products Analysis. The separation and the yield determination of the photoproducts were carried out with a preparative thin-layer chromatograph (Merck Silicagel 60 F_{254}), and were followed by UV analysis. The identification of the known compounds were confirmed by comparison with authentic samples. *1,6-Dimethylphenazine (9)* was determined on the basis of the following microanalysis and spectral properties.[10] Found: C, 79.23; H, 5.85; N, 12.74%. Calcd for $C_{14}H_{12}N_2$: C, 80.74; H, 5.81; N, 13.45%. MS, *m/e* 208 (M^+). IR (KBr) 2955, 2880, 1730, 1624, 1538, 1480, 1450, 1375, 1348 cm^{-1}. UV (MeOH) 362 (ε 11700), 254 nm (108000). ^{1}H-NMR ($CDCl_3$) δ 2.93 (s, 6H), 7.6—7.8 (m, 4H), 8.0—8.2 (m, 2H) ppm. ^{13}C-NMR ($CDCl_3$) δ 17.6 (q), 128.0 (d), 129.2 (d), 129.7 (d), 137.7 (s), 142.8 (s), 142.9 (s) ppm.

The author wishes to thank Dr. Ikuo Sakai (Toray Research Center) for his measurements and assignment of the NMR spectra.

Photoreactions of Flavanones

Ryoka MATSUSHIMA,* Tsuneo KISHIMOTO, Morio SUZUKI, Motonobu MORIOKA, and Hideo MIZUNO

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received February 27, 1980)

Parent and substituted flavanones undergo photochemical opening of the pyrone ring to give corresponding 2'-hydroxychalcones in benzene, pyridine, acetonitrile *etc.*, the yields varying from 0 to 70% with substituents. The reaction is depressed by the addition of 1,3-pentadiene, nitrosobenzene, or acrylonitrile. On the other hand, flavanone and 4-chromanone undergo photoreduction in 2-propanol to give reductive coupling products and solvent adducts as isomeric mixtures. 7,8-Benzoflavanone does not undergo photoreduction in 2-propanol but the ring opening reaction instead. Mechanisms have been discussed in terms of the relative contribution of n,π^* and π,π^* character in the lowest triplet states.

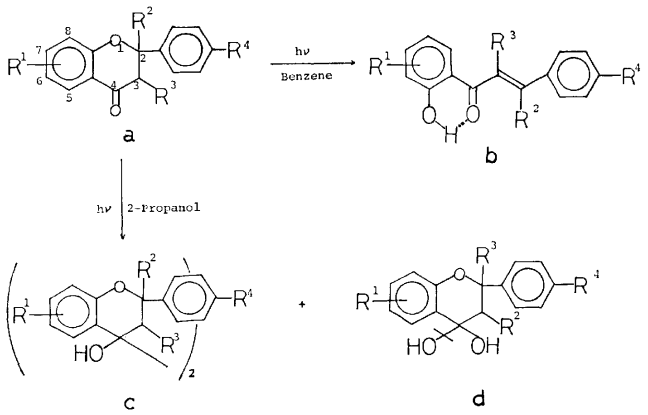
Flavanones have been shown to undergo photochemical ring opening reaction to give 2'-hydroxychalcones in inert solvents such as benzene[1-4] and photoreduction to give reductive coupling products in hydrogen-donating solvents.[2,3] Both biradical[1,2] and concerted[3] mechanisms have been suggested for the photochemical ring opening reaction, though not proved.

On the other hand, photoisomerization of substituted 3-chromanones have extensively been studied and the mechanism has been shown to involve prior photochemical enolization.[5] In this view, interesting mechanisms involving enolization followed by 6π-electrocyclic reactions have been postulated for the photochemical ring opening reaction of flavanones[3] and for the photochemical cyclization of 2'-hydroxychalcones to flavanones.[6]

The present work reports on the photochemistry of parent and substituted flavanones, with discussion on the mechanisms in terms of n,π^* and π,π^* character in the lowest triplet states.

Results

Photochemical Ring Opening Reaction. Dilute solutions of parent or substituted flavanones in benzene



Scheme 1.

underwent photochemical ring opening reaction to give corresponding 2'-hydroxychalcones, on irradiation under a nitrogen atmosphere at room temperature with a high pressure mercury lamp (Scheme 1). The products proved identical with independently prepared authentic samples of 2'-hydroxychalcones. Irradiation of **5a**, **7a**, **8a**, **11a**, **12a**, and 4-chromanone **14a** resulted in the recovery of the starting materials: their NMR spectra remained unchanged. The yields for the reaction depended on the substituents (Table 1). Thus, electron-

Table 1. Substituent effects on the photochemical ring opening of flavanones in benzene[a]

Flavanone	Substituent				2'-Hydroxychalcone	Yield[b] %
	R^1	R^2	R^3	R^4		
1a	H	H	H	H	**1b**	14
2a	H	H	H	OMe	**2b**	40
3a	H	H	H	OCOMe	**3b**	70
4a	6-OMe	H	H	H	**4b**	15
5a	6-OCOMe	H	H	H	**5b**	0
6a	7-OMe	H	H	H	**6b**	11
7a	5-OH, 7-OMe	H	H	H	**7b**	0
8a	5,6-Benzo	H	H	H	**8b**	0
9a	7,8-Benzo	H	H	H	**9b**	5

13a	7-Cl	H	H	H	**13b**	2

a) Each flavanone solution (8.8×10^{-3} mol/dm^3) was irradiated under a nitrogen atmosphere for 16.5 h at room temperature with a 100-W high pressure mercury lamp. b) Estimated from the NMR signal intensities of the phenolic protons at δ 12—15 ppm.

withdrawing groups in R^1 seem to depress the reaction (**5a**, **13a**), while electron donating groups do not (**4a**, **6a**, **10a**).

Substitution of methyl group at the C_3-position retards the reaction (**11a**, **12a**), whereas methyl substitution at the C_2-position permits the reaction (**10a**). The photochemical intertness of **11a**, **12a**, and **7a** is ascribable to a reversible intramolecular hydrogen transfer *via* a five-membered (**11a**, **12a**) or six-membered (**7a**) cyclic configuration. The low or nil reactivity of **8a** and **9a** may, at least partly, be relevant to their low-lying or less reactive π,π^* triplet states.

Table 2. Photochemical ring opening of **2a** in different solvents[a)]

Solvent	Yield of **2b**/%
Carbon tetrachloride	31
Benzene	69
Benzene (air)[b)]	49
Pyridine	66
Acetonitrile	48

a) Irradiated in ampule with a 400 W high pressure mercury lamp for 3 h at 15 °C; [**2a**] = 10^{-3} mol/dm^3. b) Without deoxygenation.

Table 2 lists the solvent effects on the photochemical ring opening reaction of **2a**. No simple correlation with solvent polarity or basicity is found. Dissolved oxygen seems to depress the reaction to some extent.

Addition of 1,3-pentadiene (1.5×10^{-3} mol/dm^3) to a benzene solution of **2a** (10^{-3} mol/dm^3) resulted in significant depression of the photoreaction (Table 3). Both acrylonitrile and nitrosobenzene, which are known to inhibit a free radical reaction, significantly depress the photoreaction.

Table 3. Effects of additives on the photochemical ring opening of **2a**

Additive	Concn of additive / 10^{-3} mol dm^{-3}	Yield of **2b** / %
1,3-Pentadiene	0.0	64[a)]
	1.5	35[a)]
Acrylonitrile	0.0	40[b)]
	4.5	5[b)]
Nitrosobenzene	0.0	46[c)]
	6.4	5[c)]

a) Benzene solution of **2a** (10^{-3} mol/dm^3) was irradiated in ampule with a 400-W high pressure mercury lamp for 70 min. b) A 50 ml benzene solution of **2a** (3×10^{-4} mol/dm^3) was irradiated with a 100-W high pressure mercury lamp for 16 h. c) A 6 ml benzene solution of **2a** (10^{-3} mol/dm^3) was irradiated in ampule with a 400-W high pressure mercury lamp for 40 min.

Photolysis of Flavanones and 4-Chromanone in 2-Propanol. A deoxygenated solution of flavanone **1a** (4.5×10^{-3} mol/dm^3) in 2-propanol gave reductive coupling product **1c** (as isomeric mixture) and solvent adduct **1d** (as 1 : 1 isomeric mixture) besides unidentified products, on irradiation with a 100 W high pressure mercury lamp at room temperature (Scheme 1 and Table 4).

Table 4. Photolyses of flavanones and 4-chromanone in 2-propanol

Starting material	Concentration / 10^{-3} mol/dm^3	Irrad. time / h	Products	ϕ_{dis}[a)]
1a	4.5	5	**1c**(39%)[b)] **1d**(8%)[c)] Unknown (20%)	0.43
7a	7.4	5	None[d)]	0.00
8a	10	12	None[d)]	0.00
9a	9.4	16	**9b** (33%)	0.02
14a	4.8	5.5	**14c** (89%)[e)]	0.24

a) Quantum yield for the disappearance of each starting material during 10 min irradiation. b) Sum of the meso and the racemic mixtures of 4,4′-biflavanol isomers. c) Sum of 1 : 1 *cis*- and *trans*-4-hydroxy-4-(1-methyl-1-hydroxyethyl)flavanes. d) The NMR spectra remained unchanged and no TLC spot was detected other than that of the starting material. e) The sum of the meso (53%) and the racemic (36%) forms of 4,4′-bichromanol isomers.

Similar photolysis of 4-chromanone **14a** gave corresponding coupling product **14c** in a high yield. Photolysis of **6a**, **13a**, and 5,7-dimethylflavanone **15a** gave too complex mixtures to permit their analyses, while **7a** and **8a** did not react. The results are summarized in Table 4, together with the quantum yield for the disappearance of each starting material at an initial stage of the reaction. Interestingly, 7,8-benzoflavanone **9a** underwent ring opening reaction to give **9b** in 2-propanol, instead of the photoreductive coupling reaction. In addition, the yield for the ring opening reaction of **9a** is higher in 2-propanol than in benzene by a factor of 6.

Discussion

Owing to the rapid and efficient intersystem crossing, the singlet lifetimes of aromatic carbonyl compounds are usually too short ($\leqq10^{-8}$ s)[7] to permit bimolecular singlet quenching in low concentrations of donor and quencher. The significant quenching effect of 1,3-pentadiene (1.5 mmol/dm^3) supports for a triplet mechanism.[2] The depression effects of acrylonitrile and nitrosobenzene favors for radical processes,[1] in accord with the triplet mechanism.

The variation in the relative reactivities in Table 1 may simply be interpreted as due to the inductive and electromeric effects of substituents in some cases (**4a**—**6a**, **10a**, **13a**); such simple interpretation, however, does not hold for some others (**1a**—**3a**).

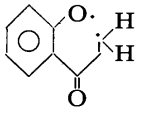
It seems more reasonable to interpret as due to the relative contribution (importance) of n,π^* and π,π^* character: the ring opening reaction takes place from π,π^* triplet states while reductive coupling reaction from n,π^* triplet states. Benzoflavanones **8a** and **9a**, for example, are expected to have a dominant π,π^* character in the lowest triplet states in any solvents, because of the extended π-conjugation in the molecules. Thus, the lack of the photoreduction of **8a** and **9a** in 2-propanol is ascribable to nil or insufficient contribution of n,π^* character in the lowest triplet states.

Instead, **9a** undergoes photochemical ring opening reaction in 2-propanol, reflecting a dominant contribution of π,π^* character.

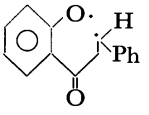
The higher efficiency for the ring opening reaction of **9a** in 2-propanol than in benzene may be attributable at least partly, to the more stabilization and contribution of the π,π^* state.

All other flavanones in Table 1 are also assumed to have considerable π,π^* character in their lowest triplet states, since the lowest triplet states of methoxy-substituted acetophenones are mostly of π,π^* in nature.[8] Relative importance of n,π^* and π,π^* character depends on solvent and substituents. Thus, reductive coupling reaction, as a reflection of n,π^* character, dominates in a hydrogen-donating solvent such as 2-propanol. In benzene, the n,π^* character in the lowest triplet states would increase (the π,π^* would decrease) in favor of hydrogen atom abstraction. However, the C–H bond of benzene is much stronger (*e.g.*, by 22 kcal/mol or more in the gas phase) than the C_2–H bond of 2-propanol, and hydrogen atom abstraction from benzene is unfavorable even though the n,π^* character is somewhat increased. Thus, the alternative pathway which does not involve hydrogen atom abstraction, *i.e.*, the ring opening reaction, would become dominant in benzene even though the π,π^* character is somewhat decreased.

The lack of the photochemical ring opening reaction of **14a** is ascribable to the less stability of the intermediate species, *e.g.*, biradical **16** as compared with **17** having benzyl radical stability.



16



17

On the other hand, the high efficiency for the reductive coupling reaction of **14a** in 2-propanol is due partly to a small steric hindrance of the chromanone ketyl radicals compared to that of the flavanone ketyl radicals in bimolecular coupling processes, and partly to the essential n,π^* character in its lowest triplet state.

As an alternative to the unimolecular mechanism above discussed it might be thought that the photochemical ring opening reaction proceeds *via* bimolecular hydrogen atom abstraction. Hydrogen atoms at the C_3-position of ground state flavanones could be abstracted by n,π^* triplets of another flavanone molecules, followed by β-cleavage or hydrogen atom transfer of radical intermediates giving eventually 2′-hydroxychalcones. However, such mechanism seems less likely.

The recovery of each starting isomer **11a** or **12a** without *cis-trans* isomerization, or the lack of inversion at the C_3-center, suggests that hydrogen atom abstraction from the C_3-position is less important.

Bimolecular hydrogen atom abstraction from the C_2-position (the weakest C–H bond) might be thought to occur and affect the ring opening reaction. However, substitution of the hydrogen atom at the C_2-position by methyl group did not affect the efficiency (compare **10a** with **6a**), thus bimolecular C_2–H abstraction seems irrelevant to the ring opening reaction.

Experimental

Chemicals. Flavanones and 4-chromanone were prepared according to the reported methods as summarized in Table 5 together with the UV absorption maxima. Typical methods for the preparation of 2′-hydroxychalcones are shown in Table 6 together with their melting points and spectral data. Solvents and other chemicals were of guaranteed grade without further purification, except that acrylonitrile was purified just before use to eliminate polymerization inhibitors.[28]

a) The NMR signals of the phenolic protons disappeared on addition of D_2O. b) Indicated are the Reference numbers.

Apparatus and Procedures. The IR, UV, and NMR spectra were measured by means of a JASCO IRA-I spectrometer, a Hitachi 124 spectrometer, and a Hitachi R-24 NMR spectrometer, respectivery. The light source was a 100 W high pressure mercury lamp (Riko) immersed in the reaction vessel, for preparative photoreactions; or a 400 W high pressure mercury lamp with a merry-go-round irradiation apparatus thermostated at 20 °C, for small scale experiments. Quantum yields were measured by the usual method[29] using aqueous tris(oxalato)ferrate(III) solution and with the light beams of 313 and 334 nm paralleled and through a glass filter (Toshiba UV-D2).

Photochemical Ring Opening Reaction. Typical procedures are as follows. A 100 ml benzene solution of **1a** (197 mg, 0.88 mmol) was irradiated with a 100 W high pressure mercury

a) Uncorrected. b) DMSO-d_6 was used for **1c** ((racemic) and **14c** (racemic). c) Treatment with lead tetraacetate in acetic acid gave starting material at room temperature. d) Disappeared on addition of D_2O.

lamp for 16.5 h. Oxygen-free nitrogen current was passed through the solution before and during the photolysis.

The products were separated on silica gel–benzene. Similarly the photochemical ring opening products of other flavanones were isolated. They were identified by comparing their mp, IR, and NMR spectra (Table 6) with those of authentic samples independently prepared. The amounts of the products were determined by measurement of either the UV absorption at near 360 nm after separation on silica gel or the NMR signal intensities of the phenolic protons at near 13 ppm as mixture solutions.

*Photoreduction of **1a** and **14a** in 2-Propanol.* A 100 ml solution of **14a** (1 g, 4.8 mmol) in 2-propanol was irradiated with a 100 W high-pressure mercury lamp for 5.5 h. Separation of the products on silica gel–benzene and crystalization from methanol yielded colorless crystals A (53%) and B (36%).

The spectral and CH analysis data in Table 7 show that A and B are 4,4′-bichromanol isomers. Relative rates of oxidative decomposition with lead tetraacetate can serve as a method of identification of a series of isomeric 1,2-diols: the rate is rapid for gauche structure (with respect to the two hydroxyl groups) and slow for anti one.[27] Both A and B gave **14a** on treatment with lead tetraacetate with relative rates A : B = 1 : 4 in acetic acid at room temperature. Thus, A and B are ascribable to anti (meso) and gauche (racemic) forms, respectively.

Molecular models implied that the racemic form favors for intramolecular hydrogen bonding while the meso form is sterically unfavorable. Thus, the O–H streching absorption appearing in two bands (3500 and 3450 cm^{-1}) and the low-field shift of the hydroxyl protons (5.24 ppm as compared to 2.3—3.3 ppm for A) of B are ascribable to intramolecular hydrogen bonding of the racemic isomer.[30,31]

Similar photolysis of **1a** (1 g, 4.5 mmol) in 2-propanol for 5 h gave a mixture of 4,4′-biflavanols **1c** and 4-hydroxy-4-(1-hydroxy-1-methylethyl)flavanones **1d**. By separation on silica gel and crystallization, **1c** gave colorless crystals E (from benzene), F (from acetone), and G (from ligroin), while **1d** gave K and L (both from petroleum benzine).

The product E is assumed to have racemic form since the low-field shift of the hydroxyl protons (5.24 ppm) and the O–H streching appearing in two bands (3590 and 3445 cm^{-1}) are comparable with those of the racemic isomer of **14c**. On the other hand, F and G are assumed to have meso forms since their IR and NMR spectra are comparable to those of the meso isomer of **14c**.

According to Bolger *et al.*,[32] the coupling constants of the C_3-methylene protons of 4-flavanols are generally large for isomers with equatrial 4-hydroxyl group but small for isomers with axial 4-hydroxyl group: J_{eq}=15—17, J_{ax}=5—6 Hz.

Thus, relatively large coupling constant of K (12.3 Hz) is ascribable to the *cis* isomer (in which 4-hydroxyl group is equatrial) of **1d**. Molecular models of the isomers of **1d** implied that the *cis* form is favorable but the *trans* form is sterically unfavorable for intramolecular hydrogen bonding between two hydroxyl groups. Thus, the O–H stretching absorption (3520 and 3450 cm^{-1}) is ascribable to the *cis* isomer.

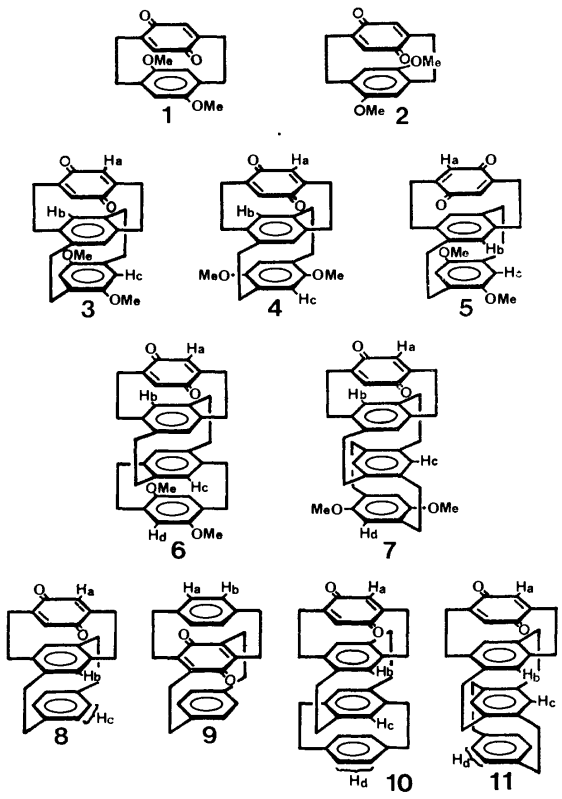
Layered Compounds. LXIV.[1] Syntheses and Charge Transfer Spectra of Multilayered Paracyclophanequinones[2]

Hideki MACHIDA, Hitoshi TATEMITSU, Tetsuo OTSUBO,†
Yoshiteru SAKATA, and Soichi MISUMI*
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received March 4, 1980)

Three isomeric triple-layered and two isomeric quadruple-layered charge transfer cyclophanes containing benzoquinone and dimethoxybenzene moieties have been synthesized together with two triple-layered and two quadruple-layered paracyclophanequinones. The structures of the isomers were determined by ^{1}H- and ^{13}C-NMR spectra and/or alternative syntheses. By comparing the CT bands of a series of dimethoxycyclophanequinones with those of the corresponding cyclophanequinones, it is concluded that the CT stabilization of multilayered dimethoxyquinones should be attributed mainly to the π-basicity of the durene ring which faces the acceptor quinone ring and partly to the decreasing π-basicity of dimethoxybenzene ring as the layer number increases. No orientational dependence of quinone and dimethoxybenzene moieties on CT transition was observed in the multilayered series.

A wide variety of charge transfer (CT) cyclophanes with both donor and acceptor moieties have been synthesized for studying the relationship between the structure and the CT interaction on intermolecular CT complexes.[3] A marked difference, dependent upon the donor-acceptor orientation, was observed in the electronic spectra of double-layered CT cyclophanes, *e.g.*, **1** and **2**.[4] In the previous paper of this series, we reported that a series of multilayered [2.2]paracyclophanes showed the increase of the transannular interaction with an increase of layer number.[5] This change in their electronic spectra was interpreted as due to the configurational interactions of charge transfer and neutral excitation states.[6] The CT cyclophanes, in which the two outer benzene rings of the multilayered paracyclophanes are replaced by a donor and an acceptor moiety, are particularly interesting in connection with both the CT and the transannular interactions. We now report the syntheses and properties of three isomeric triple-layered (**3**—**5**) and two isomeric quadruple-layered CT cyclophanes (**6** and **7**) having parabenzoquinone moiety as an acceptor as well as two isomers of triple-layered (**8** and **9**) and two isomers of quadruple-layered quinones (**10** and **11**) as spectral references.



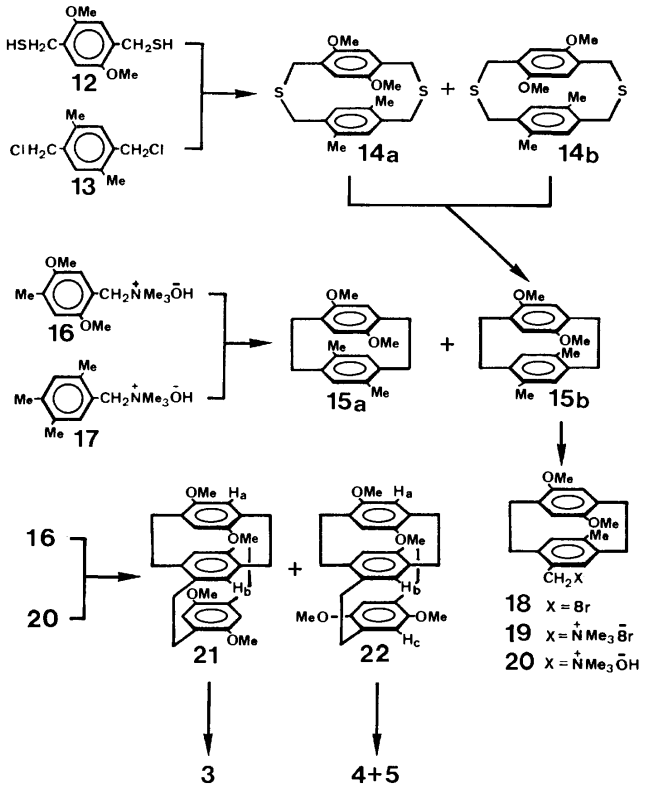
For the same purpose, we previously reported other examples of triple-layered CT cyclophanes which have tetracyanoquinodimethane moiety as an acceptor.[7] During the course of the present study, Staab and his coworkers independently reported the syntheses of **3**,[8] **4**,[8] **6**,[9] and **7**.[9]

Results and Discussion

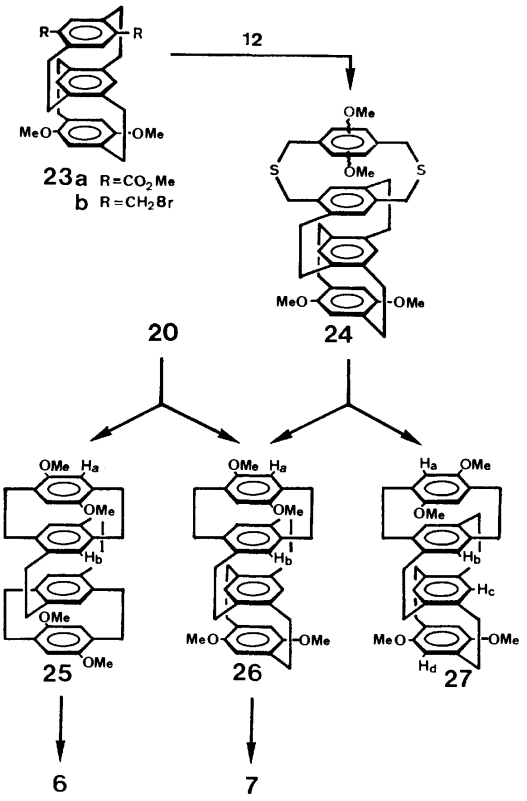
Syntheses. The synthetic routes of dimethoxyquinones (**3**—**7**) and quinones (**8**—**11**) are shown in Schemes 1—3. A key intermediate of the routes, dimethoxy double-layered cyclophane **15b**, was prepared by two general methods, *i.e.*, the Hofmann elimination and the photodesulfurization.[10] Thus, the pyrolytic cross-breeding reaction of two quarternary ammonium hydroxides, **16** and **17**,[11] gave **15b** in 11.7% yield, whereas sulfur photo-extrusion from a mixture of isomeric disulfides, **14a** and **14b**, prepared by coupling of dithiol **12**[12] and dichloride **13**, gave the identical compound **15b** in 63% yield. The product by the latter method consisted of only the staggered isomer **15b**, indicating the intramolecular overcrowding of methyl and methoxyl groups in the eclipsed isomer **15a**.

Pyrolysis of **16** with ammonium hydroxide **20**, derived from **15b**, afforded a mixture of tetramethoxy triple-layered paracyclophane, **21** of D_2 symmetry and **22** of C_2 symmetry, in 6.1% yield, together with 7.7% of tetramethoxy double-layered and 2.5% of tetramethoxy quadruple-layered paracyclophanes. The separation of **21** and **22** was accomplished by repeated

† Present address: Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Hiroshima 730.



Scheme 1.

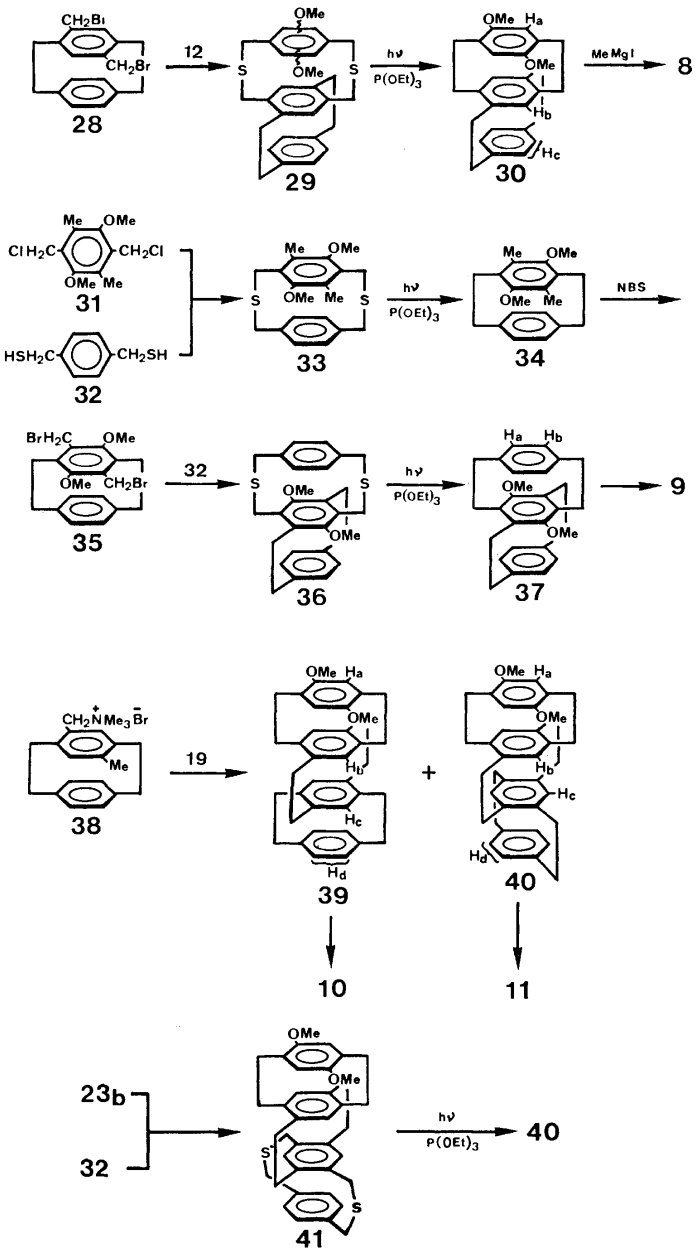


Scheme 2.

recrystallization from ethanol. Their structures were easily assigned by ^{1}H-NMR spectra, as described later. Treatment of **21** with boron tribromide followed by oxidation with silver oxide gave triple-layered dimethoxyquinone **3** in 33% yield. According to the same procedure, on the other hand, **22** gave two isomeric triple-layered dimethoxyquinones, **4** and **5**, in 41.7% total yield. The preparation of dimethoxyquinones **3** and **4** was also reported by Staab *et al.*[8] but with no isolation of the third isomer **5**. The formations of a single dimethoxyquinone from **21** and of two isomeric dimethoxyquinones from **22** provide chemical evidence to support the NMR assignment of **21** and **22**.

Pyrolysis of quarternary ammonium hydroxide **20** in boiling xylene gave a mixture of two isomeric tetramethoxy quadruple-layered paracyclophanes, **25** of C_{2h} symmetry and **26** of D_2 symmetry, in 21.8% total yield. The separation of these isomers was barely accomplished by fractional recrystallization from toluene, after many unfruitful attempts using column and liquid chromatographies. The structures of the isomers could not be unequivocally determined by ^{1}H- and ^{13}C-NMR spectra, although they were tentatively assigned by the chemical shifts of methylene carbons as described later. To confirm this ^{13}C-NMR assignment, an alternative synthesis of **26** was carried out. Here a photodesulfurization of a mixture of two isomeric disulfides **24**, prepared by coupling of dithiol **12** and triple-layered dibromide **23b**, which has a well-determined structure,[7] gave a mixture of two isomeric tetramethoxy quadruple-layered paracyclophanes (1 : 1 ratio) in 47% yield. The less soluble isomer, separated by repeated recrystallization of the mixture from hexane, was identical with **26** on the basis of various spectral data; thus **26** undoubtedly has the D_2 symmetric structure. The other two isomers, **25** and **27**, are, consequently, assigned to C_{2h} and C_2 symmetric structures, respectively. Demethylation and oxidation of **25** and **26** in a similar manner as done for the triple-layered analogues gave dimethoxy quadruple-layered paracyclophanequinones, **6** and **7**, in 10 and 9% yields, respectively. Staab and Zapf[9] also reported the preparation of **6** and **7** from **25** and **26** in the same way, after an X-ray crystallographic determination that the precursor **25** had a centrosymmetric structure.

Triple-layered paracyclophane derivatives, **30** and **8**, were prepared for spectral reference, as shown in Scheme 3. A mixture of two isomeric disulfides **29**, prepared by coupling of dibromide **28**[13] with dithiol **12**, was irradiated with a high pressure mercury lamp to give one of two possible isomers of dimethoxy compound, **30**, in 75% yield. Treatment of **30** with methylmagnesium iodide afforded, without oxidation with silver oxide, reddish orange quinone **8** in 72% yield. Dichloride **31** obtained by chloromethylation of 2,5-dimethoxy-*p*-xylene[14] was coupled with dithiol **32** to afford disulfide **33** in 65% yield. Sulfur photo-extrusion of **33** gave 60% yield of dimethoxydimethyl[2.2]-paracyclophane **34**. Disulfide **36** was obtained by bromination (86%) of **34** with NBS, followed by coupling (49%) with **32**. Photodesulfurization of **36** was performed in a similar manner to give dimethoxy triple-layered paracyclophane **37** in 69% yield. Demethylation of **37** with methylmagnesium iodide at 160 °C, followed by treatment with silver oxide, afforded yellow



Scheme 3.

inner-quinone **9** in 12.3% yield.

Dimethoxy quadruple-layered cyclophanes, **39** and **40**, were prepared by cross-breeding pyrolysis of a mixture of two quarternary ammonium hydroxides prepared from ammonium bromides, **19** and **38**.[5] After removal of non-substituted and tetramethoxy quadruple-layered cyclophanes from the reaction mixture by column chromatography, a mixture of the desired dimethoxy compounds, **39** and **40**, was separated by fractional crystallization from hexane. The structures of both isomers were assigned by ^{13}C-NMR spectra. In order to confirm this assignment, isomer **40** was prepared by an alternative route, as shown in Scheme 3. Photodesulfurization of disulfide **41**, prepared by coupling of dibromide **23b** and dithiol **32**, gave dimethoxy quadruple-layered paracyclophane in 25% yield. This product was identical, in all respects, with a more soluble isomer **40** obtained by the cross-breeding pyrolytic method. Quadruple-layered paracyclophanequinones **10** and **11** were obtained as red needles in 28 and 29% yields, respectively, by successive demethylation and oxidation from **39** and **40** in a similar manner as done for dimethoxy triple-layered one **6**.

NMR Spectra. *^{1}H-NMR*: The chemical shifts of multilayered quinones **3**—**11** and related compounds are summarized in Table 1. We previously reported that there is an additivity among the chemical shifts of aromatic protons in a series of multilayered [2.2]-paracyclophanes and that the additivity is based on the anisotropic effect of facing benzene rings as well as the steric compression and magnetic anisotropic effects of pseudo-gem and pseudo-ortho substituents.[8] Reich and Cram also described such effects of various substituents on the chemical shifts of aromatic protons in a

series of substituted [2.2]paracyclophanes.[9]

As seen in Table 1, the inner aromatic protons of three triple-layered dimethoxyquinones, **3**—**5**, and their precursors, two tetramethoxy compounds, **21** and **22**, show relatively large differences in chemical shift compared to the outer ring protons. In order to determine their structures, the magnetic effects ($\Delta\delta$) of dimethoxy and quinone groups on pseudo-ortho protons of facing benzene rings were evaluated from the observed chemical shifts of reference compounds, as shown in Fig. 1. Using these values, we calculated the chemical shifts of the inner aromatic protons of the above-mentioned triple-layered paracyclophane derivatives. For example, the calculated value of Hb in **4** is given from the chemical shift (δ 5.40) of the inner proton of **42** as follows;

$$\delta(\text{Hb of } \mathbf{4}) = \delta(\text{Hb of } \mathbf{42}) + \Delta\delta_{\text{H}\rightarrow\text{OMe}}(\text{pseudo-ortho effect}) + \Delta\delta_{\text{H}\rightarrow=\text{O}}(\text{pseudo-gem effect}) = 5.40+0.30+0.48 = 5.91 \text{ ppm}$$

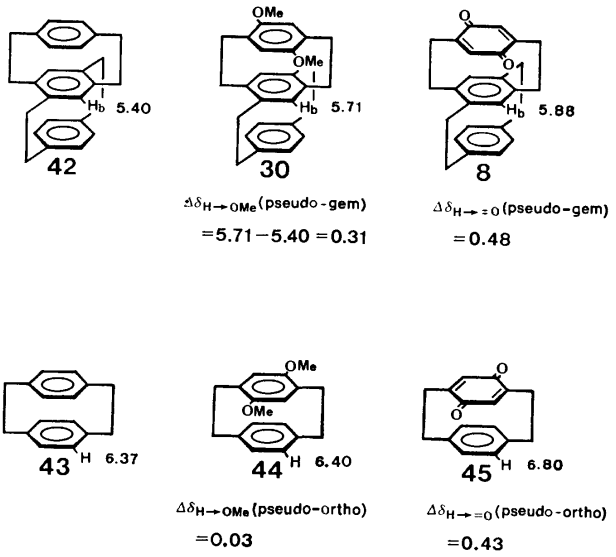

Fig. 1. ^{1}H-NMR chemical shifts of aromatic protons of five reference compounds in deuteriochloroform.

The calculated values in Table 1 are in good agreement with the observed values. The assignment of isomeric structures is consequently achieved.

On the other hand, the structures of four pairs of isomeric quadruple-layered cyclophanes, **6** and **7**, **10** and **11**, **25** and **26**, and **39** and **40**, could not be assigned only by ^{1}H-NMR spectra, because the chemical shifts of all corresponding protons are almost equal to each other in each pair. But the inner and outer aromatic protons of tetramethoxy compounds, **25**—**27**, were easily assigned on the basis of the solvent effect as described for non-substituted multilayered paracyclophanes.[8] As shown in Table 2, aromatic protons displaying larger chemical shift differences in two solvents, carbon tetrachloride and deuteriochloroform, were assigned to the outer benzene protons, while those displaying smaller differences (*ca.* 0.06 ppm) were assigned to inner benzene protons.

Table 2. Solvent effect of aromatic protons of tetramethoxy quadruple-layered paracyclophanes (δ value)

Compd		Solvent		$\Delta\delta$
		$CDCl_3$	CCl_4	($\delta_{CDCl_3} - \delta_{CCl_4}$)
25	outerH	5.39	5.23	0.16
	innerH	5.48	5.43	0.05
26	outerH	5.39	5.24	0.15
	innerH	5.47	5.41	0.06
27	innerH	5.15	5.08	0.07
	outerH	5.39	5.23	0.16
	innerH	5.46	5.40	0.06

^{13}C-NMR: To determine the structures of isomeric quadruple-layered cyclophanes, **25** and **26**, and **39** and **40**, ^{13}C-NMR spectra were examined. The data are shown in Fig. 2 together with those of reference compounds. The assignment was performed by an off-resonance technique and by comparing with the

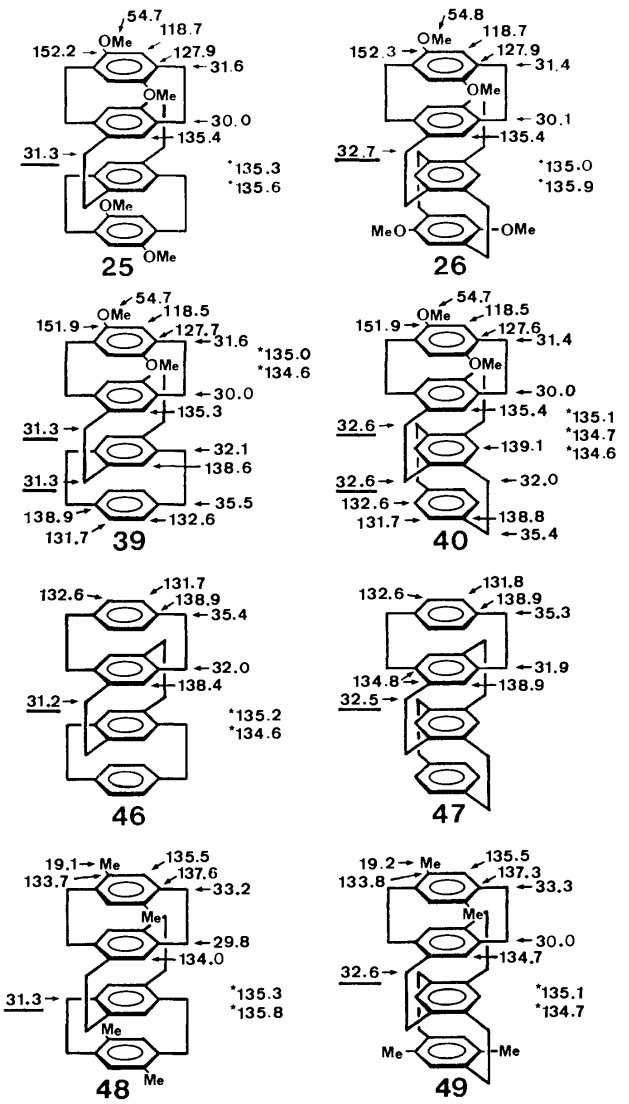

Fig. 2. ^{13}C-NMR data of quadruple-layered cyclophanes in deuteriochloroform. Values marked with star are difficult to assign.

chemical shifts which were calculated by adding the substituent effect to the chemical shifts of the parent hydrocarbons, **46** and **47**.[15] Each isomeric pair showed chemical shifts very close to each other, except for the underlined signals of the methylenes bridging two inner benzene rings.

The difference in carbon chemical shifts of the inner bridging methylenes, though slight, can be used to assign isomeric structures of reference compound pairs, **46** *vs.* **47** and **48** *vs.* **49**; these structures were clearly determined by X-ray analysis[16] or by an alternative stepwise synthesis.[5] Thus, the chemical shifts of the inner methylenes under consideration are 31.2 ppm for C_{2h} symmetric cyclophanes (**46** and **48**) and about 32.5 ppm for D_2 symmetric ones (**47** and **49**), though the relationship between structure and chemical shift is not clear. On the basis of this result, we assigned the cyclophanes displaying an inner methylene signal at 31.3 ppm to C_{2h} symmetric parent structure (**25** and **39**) and those having a signal around 32.6 ppm to D_2 symmetric parent structure (**26** and **40**). These assignments were satisfactorily supported by the alternative syntheses of **26** and **40** described before.

Electronic Spectra. The electronic spectra of **3**—**11** are shown in Figs. 3—5. All the broad and structureless bands in the longer wavelength region are associated with intramolecular charge transfer interactions, because neither the component chromophore nor the parent multilayered paracyclophane shows such an intensive band in the longer wavelength region.

It was reported that CT transitions of various double-layered CT cyclophanes such as **1** and **2** are markedly affected by the orientation of the donor and the acceptor moieties. However, the isomeric pairs (**3** *vs.* **5** and **6** *vs.* **7**) of the present triple- and quadruple-layered CT cyclophanes do not follow such a case. Thus, these isomeric pairs show nearly superimposable absorption curves, indicating no orientational dependence of the presumed main donor (dimethoxybenzene) and acceptor

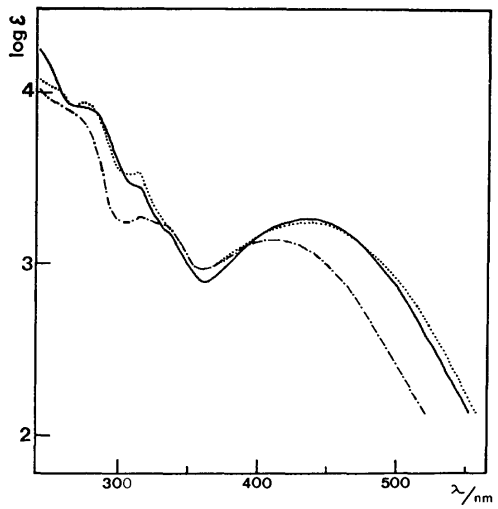

Fig. 3. Electronic spectra of three isomers of dimethoxy triple-layered [2.2]paracyclophanequinone in dichloromethane (**3**, ·····; **4**, -·-·-, **5**, ——).

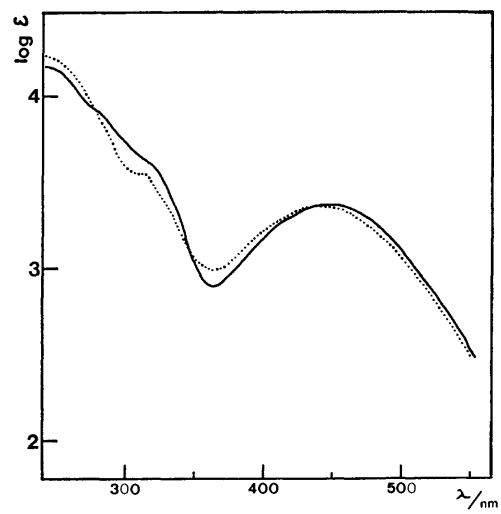

Fig. 4. Electronic spectra of two isomers of dimethoxy quadruple-layered [2.2]paracyclophanequinone in dichloromethane (**6**, ·····, **7**, ——).

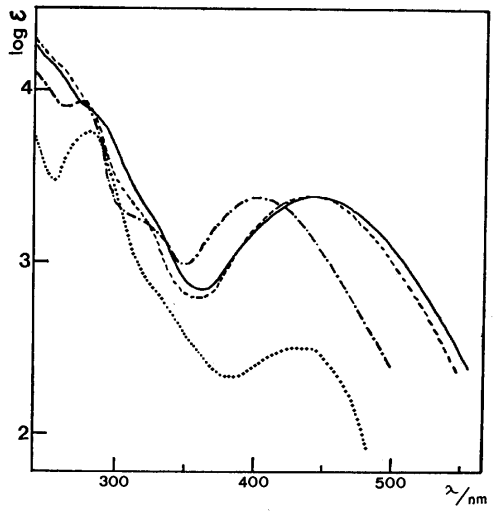

Fig. 5. Electronic spectra of two triple-layered (**8**, -·-·-; **9**, ·····) and two quadruple-layered [2.2]paracyclophanequinones (**10**, ——; **11**, ——) in dichloromethane.

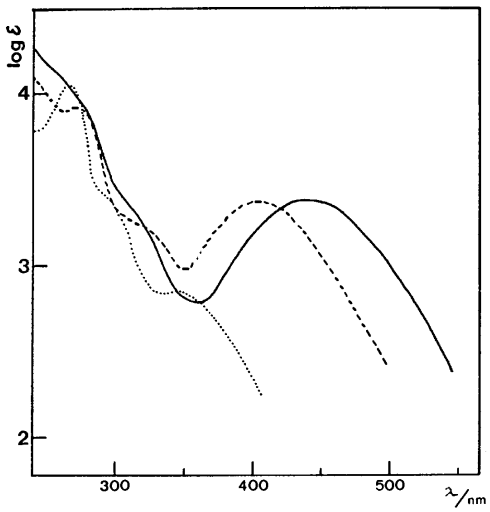

Fig. 6. Electronic spectra of double- to quadruple-layered [2.2]paracyclophanequinones in dichloromethane (**45**, ·····; **8**, ——; **10**, ——).

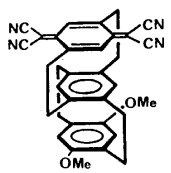
(benzoquinone). The only exception is the blue shifted CT band of dimethoxyquinone **4**, where the two methoxyl groups are substituted at the positions pseudogem to the bridged methylenes. The reason of the blue shift is probably the decrease of the π-basicity of dimethoxybenzene ring which results from the overcrowding interaction between the methoxyl and the methylene groups. A similar blue shift was also observed in the spectrum of TCNQ cyclophane **50**, which has the same steric relationship between dimethoxyl and bridged methylene groups.[7]



50

The electronic spectra of CT cyclophane analogues with different numbers of layers are shown in Figs. 6 and 7. In a series of paracyclophanequinones (Fig. 6), the CT bands shifted to longer wavelengths as the number of layers increased. This indicates that the π-basicity of the benzene ring facing the acceptor quinone ring becomes larger with the increase of layer number. A similar result was observed in the spectra of intermolecular CT complexes between a series of multilayered [2.2]paracyclophanes and π-acceptors.[5]

For a series of dimethoxyquinones (Fig. 7), on the other hand, the order of CT band maxima does not correspond to that of layer number, that is, **1**>**6**>**3**. In compound **1**, the dimethoxydimethylbenzene moiety having a relatively lower ionization potential is so closely fixed to the acceptor quinone that the CT band of **1** shifts to a longer wavelength compared to those of the others, **3** and **6**. In contrast to **1**, multilayered dimethoxyquinones (**3** and **6**) have two types of donors: durene moiety (the inner benzene ring faced to quinone

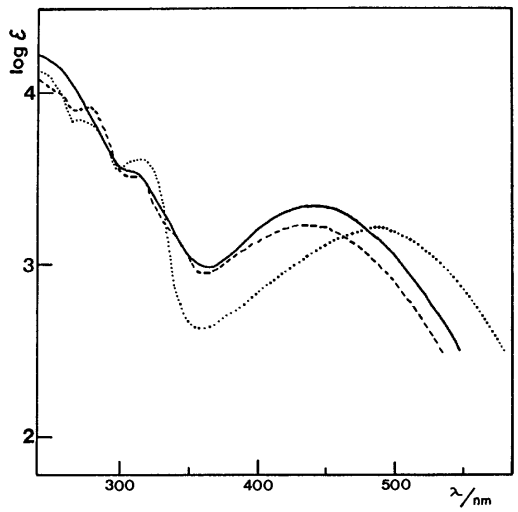


Fig. 7. Electronic spectra of double- to quadruple-layered dimethoxy[2.2]paracyclophanequinones in dichloromethane (**1**, ·····; **3**, ——; **6**, ——).

ring) and dimethoxydimethylbenzene moiety. In the case of the quadruple-layered compound **6**, the durene moiety is concluded to be the main donor, from the fact that the absorption curves of two quadruple-layered quinones, **6** and **10**, are roughly superimposable over each other. In other words, the two methoxyl groups show no contribution to the CT transition. The same conclusion for triple-layered compound **3** is obtained by comparing the spectra of **3** and **8**, but in this series, the dimethoxydimethylbenzene ring increases the π-basicity of the durene moiety by the transannular electron release. In conclusion, the blue shifts of CT bands of **3** and **6** are attributed to the durene moiety acting as the main donor in place of the dimethoxydimethylbenzene ring which has a lower ionization potential but is more remote from the acceptor. Undoubtedly, this is why there is no orientational dependence of the quinone and the dimethoxybenzene moieties on the CT transitions of **3**—**7** mentioned before.

Experimental

All melting points are uncorrected. The IR, NMR, mass and electronic spectra were recorded with a Hitachi EPI-G2, a JEOL JNM-FX-100 (100 MHz for ^1H; 25 MHz for ^{13}C) and a Hitachi R-20, a Hitachi RMU-7 or JEOL JMS-01SG-2 and a Hitachi EPS-3T spectrometer, respectively. Liquid chromatography was performed with a Nihonbunsekikogyo LC-08 of GPC type and a Waters Prep 500.

Staggered and Eclipsed 5,8-Dimethoxy-14,17-dimethyl-2,11-dithia-[3.3]paracyclophanes (14a and 14b). All the solvents were bubbled with nitrogen before use. A solution of 2,5-bis-(chloromethyl)-*p*-xylene **13** (8.13 g, 40 mmol) and 2,5-bis-(mercaptomethyl)-1,4-dimethoxybenzene **12** (9.22 g, 40 mmol) in benzene (800 ml) was added to a stirred solution of sodium hydroxide (3.92 g, 44 mmol) in water (50 ml) and ethanol (2 l) with reflux under nitrogen for 28 h. Reflux was continued for an additional 18 h. After removal of the solvents, the residue was taken up with benzene and chromatographed on silica gel with benzene–hexane (1 : 1). The crude product was recrystallized from benzene–hexane to give 9.82 g (68.1%) of **14a** and **14b**. The mixture was separated into the two isomers by repeated chromatography on silica gel.

14a: Colorless prisms, mp 188.0—189.0 °C. NMR ($CDCl_3$, δ): 6.71 (s, 4H, ArH), 3.79 (s, 6H, OCH_3), 2.33 (s, 6H, CH_3). Found: C, 66.38; H, 6.71; S, 17.50%. Calcd for $C_{20}H_{24}S_2O_2$: C, 66.63; H, 6.71; S, 17.79%.

14b: Colorless prisms, mp 202.0—202.5 °C. NMR ($CDCl_3$, δ): 6.86 (s, 2H, dimethylArH), 6.59 (s, 2H, dimethoxyArH), 3.71 (s, 6H, OCH_3), 2.20 (s, 6H, CH_3). Found: C, 66.48; H, 6.72; S, 17.79%. Calcd for $C_{20}H_{24}S_2O_2$: C, 66.63; H, 6.71; S, 17.79%.

4,7-Dimethoxy-12,15-dimethyl[2.2]paracyclophane (15a and 15b). *By Photodesulfurization*: A mixture of **14a** and **14b** (2.21 g, 5.8 mmol) in benzene–triethyl phosphite (300 ml, 1 : 1 vol ratio) was irradiated with a high pressure mercury lamp for 2 h while nitrogen was bubbled through the solution. After removal of the solvents, the residue oil was chromatographed on silica gel with benzene and recrystallized from methanol to give 1.15 g (63.3%) of **15b**.

15b: Colorless needles, mp 123.5—124.0 °C. NMR ($CDCl_3$, δ): 6.32 (s, 2H, dimethylArH), 6.08 (s, 2H, dimethoxyArH), 3.68 (s, 6H, OCH_3), 2.08 (s, 6H, CH_3). Found: C, 80.78; H, 8.03%. Calcd for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16%.

By Hofmann Elimination: An aq solution of (2,4,5-trimethylbenzyl)trimethylammonium chloride[11] (364 g, 1.6 mol) and (2,5-dimethoxy-4-methylbenzyl)trimethylammonium bromide (242 g, 0.8 mol) was passed through a column of anion exchange resin (Dowex 1-X8) to give an aq solution of quarternary ammonium hydroxides **16** and **17**. This solution was dropwise added to a boiling solution of phenothiazine (5 g) in xylene, (2.8 l) which was placed in a three-necked flask equipped with a condenser, a mechanical stirrer, and a water separater. During the reaction, the bath temperature was kept at 140 °C. After water removal was over, heating was continued for 3 h. To the mixture was added benzene (1 l) and the solution was filtered off to remove insoluble solid. The filtrate was concentrated to dryness and the residue was treated with boiling hexane (2 l) and filtered. After removal of the solvent, the residue was passed through a short column of silica gel with benzene. Evaporation of the solvent gave an oil, to which hexane (50 ml) was added, the mixture was left overnight. The resulting precipitate was recrystallized from benzene to give 5 g (2.3%) of the less soluble isomer **15a**.

15a: Colorless prisms from benzene, mp 205.0—206.0 °C. NMR ($CDCl_3$, δ): 6.15 (s, 2H, dimethylArH), 5.87 (s, 2H, dimethoxyArH), 3.64 (s, 6H, OCH_3), 2.23 (s, 6H, CH_3). Found: C, 80.80; H, 8.04%. Calcd for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16%.

The more soluble isomer **15b** was obtained by addition of hexane to the filtrate of **15a** and by liquid chromatography of the second mother liquor: yield, 27 g (11.7%).

Quarternary Ammonium Bromide 19. A mixture of **15b** (3 g, 10 mmol) and NBS (1.44 g, 8.1 mmol) in carbon tetrachloride (40 ml) was refluxed for 2.5 h under irradiation with a tungsten lamp. The resulting imide was filtered off and the filtrate was cooled on ice. A cold ethereal solution (14 ml) of trimethylamine (4 ml, 45.5 mmol) was added to the above solution. After the mixture was allowed to stand overnight, the precipitate was collected and dried in vacuum to yield 3.2 g (73.7%) of **19**.

Tetramethoxy Triple-layered [2.2]Paracyclophanes (21 and 22). To a refluxing solution of phenothiazine (350 mg) in xylene (240 ml) was added dropwise an aq solution of two quarternary ammonium hydroxides, **16** and **20**, which was produced by passing an aq solution of ammonium bromides, **19** (28.5 g, 65.6 mmol) and (2,5-dimethoxy-4-methylbenzyl)trimethylammonium bromide (40.2 g, 132.1 mmol) through a column of anion exchange resin (Dowex 1-X8). After water was removed by azeotropic distillation, heating was continued for an additional 2 h. Benzene (500 ml) was added to the cooled reaction mixture and the polymer was filtered off. The solvent was evaporated and the residue was chromatographed on silica gel with benzene–hexane. The crude product was separated into two tetramethoxy double-layered (1.67 g, 7.7%), triple-layered (1.84 g, 6.1%), and quadruple-layered paracyclophanes (0.49 g, 2.5%) by liquid chromatography. Separation of two isomeric triple-layered cyclophanes was carried out by fractional crystallization from ethanol to give the sparingly soluble isomer **22** and the more soluble isomer **21**.

21: Colorless needles, mp 204.0—204.5 °C. Found: C, 78.80; H, 7.70%. Calcd for $C_{30}H_{34}O_4$: C, 78.57; H, 7.47%.

22: Colorless needles, mp 226.5—226.7 °C. Found: C, 78.36; H, 7.43%. Calcd for $C_{30}H_{34}O_4$: C, 78.57; H, 7.47%

Dimethoxy Triple-layered [2.2]Paracyclophanequinone (3). A solution of **21** (49.3 mg, 0.11 mmol) in dry dichloromethane (4 ml) was added dropwise for 10 min to a stirred solution of boron tribromide (120 mg, 0.48 mmol) in dry dichloromethane (0.5 ml) under ice-salt cooling. After the addition was over, the stirring was continued for 1.5 h; then the mixture was treated with water and extracted with diethyl ether. The extract was washed with water and dried on $MgSO_4$. After removal of the solvents, acetone (5 ml) and silver oxide (126 mg) were added to the residue and the mixture was stirred for 30 min at room temperature and then for 30 min at 50 °C. Insoluble material was filtered off and the filtrate was concentrated to dryness. The crude product was chromatographed on silica gel with benzene to give 15.2 mg (33.0%) of **3**.

3: Red needles from ethanol, dec>220 °C. Found: M^+, 428.19880. Calcd for $C_{28}H_{28}O_4$: 428.19874.

Dimethoxy Triple-layered [2.2]Paracyclophanequinones (4 and 5). A solution of **22** (48.7 mg, 0.106 mmol) in dry dichloromethane was added to a stirred solution of boron tribromide (100 mg, 0.4 mmol) in dry dichloromethane (0.5 ml) at −20 °C for 5 min. The stirring was continued at that temperature for 2.5 h and then at 0 °C for 50 min. The reaction mixture was worked up as described for **3**. Silica gel chromatography of the oxidation product with benzene gave **4** from the initial eluate and **5** from the following eluate in a total yield of 19.0

mg (41.7%).

4: Red needles from ethanol, dec>225 °C. Found: M+, 428.19933. Calcd for $C_{28}H_{28}O_4$: 428.19874.

5: Red needles from ethanol, dec>210 °C. Found: C, 78.24; H, 6.35%; M+, 428.19971. Calcd for $C_{28}H_{28}O_4$: C, 78.48; H, 6.59%; M+, 428.19874.

Tetramethoxy Quadruple-layered [2.2]Paracyclophanes (25 and 26). Pyrolysis of quarternary ammonium hydroxide **20** was carried out as described for **15**. The crude product was chromatographed on silica gel with benzene–hexane to give a mixture of **25** and **26** in a total yield of 5.3 g (21.8%). Recrystallization of the mixture from toluene gave colorless plates of **25** and colorless needles of **26**, which were separated with a pincette and purified by recrystallization from ethyl acetate.

25: Colorless prisms, dec>260 °C. Found: C, 81.76; H, 7.58%. Calcd for $C_{40}H_{44}O_4$: C, 81.60; H, 7.53%.

26: Colorless needles, dec>260 °C. Found: C, 81.56; H, 7.36%. Calcd for $C_{40}H_{44}O_4$: C, 81.60; H, 7.53%.

4,7-Bis(bromomethyl)-20,23-dimethoxy Triple-layered[2.2]-Paracyclophane (23b). A solution of dimethoxy bis(methyl ester) **23a**[7] (316.1 mg, 0.6 mmol) in dry THF (20 ml) was dropwise added to a suspension of $LiAlH_4$ (1 g) in dry THF (10 ml) under reflux and stirring. After cooling, the mixture was worked up in the usual manner and extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated to dryness. To the solution of the residue in benzene (30 ml) was dropwise added a solution of PBr_3 (700 mg) in benzene (10 ml). The mixture was stirred at 45 °C overnight and worked up in the usual manner to give dibromide **23b** (298.4 mg, 83.2%).

23b: Colorless fine crystals from benzene–hexane, dec >280 °C. NMR ($CDCl_3$, δ): 6.14 (s, 2H, ArH), 5.86 (s, 2H, ArH), 5.48 (s, 2H, ArH), 4.35, 4.07 (AB, $J=10$ Hz, 4H, CH_2Br), 3.54 (s, 6H, OCH_3).

Tetramethoxy Quadruple-layered [2.2]Paracyclophanes (26 and 27). A solution of dibromide **23b** (407.6 mg, 0.7 mmol) and dithiol **12** (160.6 mg, 0.7 mmol) in benzene (40 ml) was added to a stirred solution of potassium hydroxide (142.6 mg) in methanol (100 ml) for 5 h under reflux and nitrogen atmosphere. After an additional reflux for 2 h, the mixture was worked up in the usual manner. The crude product was chromatographed on silica gel with benzene to give colorless disulfide **24** (86.1 mg, 18.8%) as a mixture of two isomers.

A solution of **24** (86.1 mg, 0.13 mmol) in benzene (12 ml) and triethyl phosphite (40 ml) was irradiated with a high pressure mercury lamp under bubbling of nitrogen for 75 min. After removal of the solvents, the residue was chromatographed on silica gel to give a mixture of **26** and **27** (1: 1 ratio) in 47.0% yield (36.5 mg). The mixture was separated into the two isomers by fractional crystallization from hexane.

The less soluble isomer was in all respects identical with **26** obtained by pyrolysis of **20**. The more soluble isomer **27** was recrystallized from ethyl acetate.

27: Colorless columns, dec>260 °C. Found: M+ 588.32559. Calcd for $C_{40}H_{44}O_4$: 588.32394.

Dimethoxy Quadruple-layered [2.2]Paracyclophanequinone (6). A solution of boron tribromide (180 mg, 0.72 mmol) in dry dichloromethane (12 ml) was dropwise added to a stirred solution of **25** (104.5 mg, 0.18 mmol) in dry dichloromethane (3 ml) at 0 °C for 5 min and the stirring was continued at that temperature for 20 min. The reaction mixture was treated with water and extracted with diethyl ether. After drying ($MgSO_4$) and removal of the solvent, acetone (30 ml) and silver oxide (500 mg) were added to the residue, then the mixture was stirred at room temperature for 30 min and at 50 °C for 30 min. Insoluble material was filtered off and the filtrate was concentrated to dryness. The crude product was purified by column chromatography on silica gel with benzene–hexane to give 10.3 mg (10.4%) of **6**.

6: Red needles from ethanol, dec>220 °C. Found: M+, 558.2770. Calcd for $C_{38}H_{38}O_4$: 558.2771.

Dimethoxy Quadruple-layered [2.2]Paracyclophanequinone (7). Demethylation and oxidation of **26** were carried out as described for **6**. The crude product was chromatographed on silica gel with benzene to give **7** in 8.7% yield.

7: Red needles from ethanol, dec>230 °C. Found: M+, 558.2770. Calcd for $C_{38}H_{38}O_4$: 558.2771.

Triple-layered Dimethoxy Disulfide 29. A solution of 4,7-bis(bromomethyl)[2.2]paracyclophane **28**[13] (1.60 g, 4.06 mmol) in benzene (50 ml) and a solution of dithiol **12** (0.85 g 3.70 mmol) and potassium hydroxide (0.46 g) in aq ethanol (50 ml) were dropwise and simultaneously added to ethanol (150 ml) for 2.5 h under reflux and nitrogen atmosphere. After further reflux for 10 h, the solvents were evaporated and the residue was chromatographed on silica gel with benzene–hexane (1 : 1) to give a mixture of isomeric disulfide **29**.

29: Colorless prisms from benzene–hexane (1 : 1), mp 216—221 °C (dec). NMR ($CDCl_3$, δ): 6.6—6.1 (A_2B_2, 4H, ArH), 6.29 (s, 2H, ArH), 5.93 (d, 2H, ArH), 4.3—2.2 (m, 16H, CH_2), 3.64 (s, 6H, OCH_3); MS *m/e* 462 (M+), 263. Found: C, 72.98; H, 6.54; S, 14.00%. Calcd for $C_{28}H_{30}O_2S_2$: C, 72.69; H, 6.54; S, 13.86%.

4,7-Dimethoxy Triple-layered [2.2]Paracyclophane (30). A solution of disulfide **29** (56 mg, 0.12 mmol) in triethyl phosphite (15 ml) was irradiated with a high pressure mercury lamp for 2 h under nitrogen bubbling. After removal of the solvent, the residue was chromatographed on silica gel with benzene–hexane (1: 2) to give **30**, 36 mg (75%).

30: Colorless prisms from benzene–hexane (1: 1), mp 250 °C (dec). NMR ($CDCl_3$, δ): 6.24 (s, 4H, ArH), 5.71 (s, 2H, ArH), 5.47 (s, 2H, ArH), 3.54 (s, 6H, OCH_3), 3.4—2.1 (m, 16H, CH_2); MS *m/e* 398 (M+), 294, 234. Found: C, 84.13; H, 7.36%. Calcd for $C_{28}H_{30}O_2$: C, 84.38; H, 7.59%.

Outer Triple-layered [2.2]Paracyclophanequinone (8). A solution of dimethoxy compound **30** (21 mg, 0.06 mmol) and methylmagnesium iodide (from methyl iodide 410 mg and magnesium 100 mg) in dry diethyl ether (10 ml) was refluxed for 30 min. After removal of the solvent, the residue was heated at 160 °C for 1.5 h. To the cooled product were added diethyl ether (10 ml), water (10 ml), and dil HCl, successively. The ether layer was separated and the aqueous layer was extracted with ether several times. The combined ether solution was washed with water and dried over anhyd Na_2SO_4. After solvent removal the residue was chromatographed on silica gel to give **8**, 14 mg (72%).

8: Reddish orange crystals from benzene, mp *ca.* 225 °C (dec), MS *m/e* 368 (M+). NMR ($CDCl_3$, δ): 6.37 (s, 4H, ArH), 5.88 (s, 2H, ArH), 5.53 (s, 2H, quinone), 3.4—2.3 (m, 16H, CH_2). Found: C, 84.75; H, 6.51%. Calcd for $C_{26}H_{24}O_2$: C, 84.75; H, 6.57%.

2,5-Bis(chloromethyl)-3,6-dimethoxy-p-xylene (31). Into a solution of 2,5-dimethoxy-*p*-xylene[14] (119.4 mg, 0.72 mmol) and paraformaldehyde (222.1 mg, 3.6 mmol) in dioxane (12 ml) and concd HCl (6 ml) was bubbled hydrogen chloride gas at room temperature and then at 70 °C under stirring for 5 h. In the course of this process, an additional amount (222 mg, 3.6 mmol) of paraformaldehyde was added to the mixture. After adding ice, the mixture was extracted with diethyl ether and the extract was washed with sodium hydrogencarbonate and sat NaCl aq solution and dried (Na_2SO_4). After removal of the solvent, the residue was chromatographed on silica gel to give a colorless solid of **31**

(151.1 mg, 80.0%).

31: Colorless needles from benzene–hexane (1 : 2), mp 168.0—168.5 °C, MS *m/e* 262 (M^+), 264. NMR ($CDCl_3$, δ): 4.71 (s, 4H, CH_2), 3.83 (s, 6H, OCH_3), 2.36 (s, 6H, CH_3). Found: C, 54.48; H, 5.91%. Calcd for $C_{12}H_{16}O_2Cl_2$: C, 54.76; H, 6.13%.

5,8-Dimethoxy-6,9-dimethyl-2,11-dithia[3.3]paracyclophane ***33***. A solution of dichloride **31** (1.048 g, 3.98 mmol) in benzene (100 ml) and a solution of dithiol **32** (681 mg, 4.00 mmol) and sodium hydroxide (399 mg, 9.97 mmol) in aq ethanol (104 ml) were simultaneously and dropwise added to a boiling ethanol (100 ml) for 1 h under nitrogen; the mixture was refluxed under stirring for 6 h. After removal of the solvent, the residue was chromatographed on silica gel (40 g) with benzene. Disulfide **33** was obtained as a colorless oil (941 mg, 65.5%) which crystallized on standing or by adding a small amount of hexane.

33: Colorless prisms from methanol, mp 137—138 °C, MS *m/e* 360 (M^+); UV (THF, λ_{max} nm): 303 (ε 1010), 279 sh (1390), 260.5 (4000), 223.5 (16900). NMR ($CDCl_3$, δ): 7.04 (A_2B_2, 4H, ArH), 4.13 (d, J=13.8 Hz, 2H, CH_2), 3.79 (s, 4H, CH_2), 3.56 (s, 6H, OCH_3), 3.51 (d, J=13.8 Hz, 2H, CH_2), 2.19 (s, 6H, CH_3). Found: C, 66.43; H, 6.55; S, 17.75%. Calcd for $C_{20}H_{24}O_2S_2$: C, 66.63; H, 6.71; S, 17.79%.

4,7-Dimethoxy-5,8-dimethyl[2.2]paracyclophane ***(34)***. Disulfide **33** (102 mg, 0.29 mmol) in triethyl phosphite (10 ml) was irradiated with a high pressure mercury lamp under nitrogen bubbling for 2.5 h. The residue obtained by solvent removal was chromatographed on silica gel (15 g) with benzene–hexane (1 : 1) and then benzene. The benzene eluate was condensed and recrystallized from methanol to give **34** (50.1 mg, 59.8%).

34: Colorless prisms, mp 126—127 °C, MS *m/e* 296 (M^+); UV (THF, λ_{max} nm): 313 (ε 660), 291 (420), 254 sh (4260), 229 (17600). NMR ($CDCl_3$, δ): 6.64 (s, 4H, ArH), 3.52 (s, 6H, OCH_3), 2.93 (m, 8H, CH_2), 1.92 (s, 6H, CH_3). Found: C, 80.83; H, 8.04%. Calcd for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16%.

4,7-Dimethoxy-5,8-bis(bromomethyl)[2.2]paracyclophane ***(35)***. A mixture of **34** (309.8 mg, 1.05 mmol), NBS (413.3 mg, 2.32 mmol), and a catalytic amount of benzoyl peroxide in carbon tetrachloride (60 ml) was refluxed for 3 h. The mixture was worked up in the usual manner. The solid thus obtained was recrystallized from hexane to give dibromide **35** (407.2 mg, 85.8%).

35: Colorless cubic crystals from hexane, mp 176—177 °C, MS *m/e* 452 (M^+), 454, 456. NMR ($CDCl_3$, δ): 6.68, 6.36 (A_2B_2, J=8, 2 Hz, 4H, ArH), 4.59, 4.02 (AB, J=9.6 Hz, 4H, CH_2Br), 3.71 (s, 6H, OCH_3), 2.6—3.4 (m, 8H, CH_2). Found: C, 52.69; H, 4.69; Br, 35.29%. Calcd for $C_{20}H_{22}O_2Br_2$: C, 52.88; H, 4.88; Br, 35.19%.

Triple-layered Dimethoxy Disulfide ***(36)***. A solution of dibromide **35** (212.2 mg, 0.47 mmol) in benzene (25 ml) and a solution of dithiol **32** (81.4 mg, 0.48 mmol) and NaOH (56.8 mg, 1.42 mmol) in aq ethanol (24 ml) were added simultaneously and dropwise to a boiling ethanol (20 ml) for 67 min under nitrogen. The mixture was refluxed for 6.5 h and worked up as described for **33** to give disulfide **36**, 106.5 mg (49.3%).

36: Colorless fine crystals from benzene–methanol (1 : 3), mp 211—213 °C, MS *m/e* 462 (M^+); UV (THF, λ_{max} nm): 351 (ε 1140), 311 sh (950), 290 sh (2020), 225 (20300). NMR ($CDCl_3$, δ): 6.83 (s, 4H, ArH), 6.54, 6.26 (A_2B_2, J=8, 2 Hz, 4H, ArH), 3.96 (s, 6H, OCH_3), 3.72, 3.30 (AB, J=14 Hz, 4H, CH_2), 3.70 (s, 4H, CH_2), 2.82 (m, 8H, CH_2). Found: C, 72.43; H, 6.29; S, 13.87%. Calcd for $C_{28}H_{30}O_2S_2$: C, 72.69; H, 6.54; S, 13.86%.

12,15-Dimethoxy Triple-layered [2.2]Paracyclophane ***(37)***. Dimethoxy disulfide **36** (31.7 mg, 6.5 mmol) in triethyl phosphite (10 ml) was irradiated with a high pressure mercury lamp for 2 h. The mixture was worked up as described for **34**.

37: Colorless fine crystals from hexane, mp 230 °C (dec), MS *m/e* 398 (M^+); UV (THF, λ_{max} nm): 385 sh (ε 800), 375 (970), 315 sh (1280), 294 (1680), 226 (17500). NMR ($CDCl_3$, δ): 6.61 6.19 (A_2B_2, J=8, 2 Hz, 8H, ArH), 3.99 (s, 6H, OCH_3), 2.3—3.1 (m, 16H, CH_2). Found: C, 84.12; H, 7.57%. Calcd for $C_{28}H_{30}O_2$: C, 84.38; H, 7.59%.

Inner Triple-layered [2.2]Paracyclophanequinone ***(9)***. A solution of dimethoxy compound **37** (52.6 mg, 0.13 mmol) in diethyl ether (30 ml) was worked up as described for **8**. The resulting brown oil in acetone (10 ml) was refluxed with silver oxide (0.5 g) and magnesium sulfate (1 g) for 1 h. After removal of insoluble material by filtration and washing with benzene, the combined solution was chromatographed on silica gel (5 g) with benzene to give yellow quinone **9**, 6.0 mg (12.3%) from benzene–hexane (1: 2).

9: Yellow prisms, dec>250 °C with sublimation, MS *m/e* 368 (M^+). NMR ($CDCl_3$, δ): 6.56, 6.33 (A_2B_2, J=8.0, 1.4 Hz, 8H, ArH), 3.3—2.2 (m, 16H, CH_2). Found: C, 84.54; H, 6.53%. Calcd for $C_{26}H_{24}O_2$: C, 84.75; H, 6.57%.

Dimethoxy Quadruple-layered [2.2]Paracyclophanequinones ***(39 and 40)***. Cross-breeding reactions of quarternary ammonium bromides, **19** and **38**,[5] were done as described for **15**. After the reaction was over, benzene was added to the reaction mixture and the insoluble polymer was filtered off. The filtrate was condensed and passed through a short column of silica gel to remove the polymer. The crude product was chromatographed on silica gel with benzene–hexane to separate non-substituted and tetramethoxy quadruple-layered paracyclophanes from the desired dimethoxy compound. The dimethoxy compound was separated by recrystallization from hexane into two isomers, the less soluble isomer **39** and the more soluble one **40**.

39: Colorless prisms, mp 205.5—206.5 °C with decomp. Found: C, 86.14; H, 7.54%. Calcd for $C_{38}H_{40}O_2$: C, 86.32; H, 7.63%.

40: Colorless columns, mp 205.0—205.5 °C. Found: C, 86.10; H, 7.44%. Calcd for $C_{38}H_{40}O_2$: C, 86.32; H, 7.63%.

Alternative Synthesis of ***40***. Coupling of dibromide **23b** and dithiol **32** was carried out as described for **14**. The crude product was chromatographed on silica gel with benzene to give quadruple-layered disulfide **41** in 33.1% yield. Without further purification, **41** was used for the following reaction. A solution of **41** (117.1 mg) in benzene (30 ml) and triethyl phosphite (70 ml) was irradiated with a high pressure mercury lamp under bubbling of nitrogen for 1.3 h. The solvent was removed under vacuum and the crude product was purified by column chromatography on silica gel to give a 25.2% yield of **40** which was in all respects identical with the more soluble isomer described above.

Quadruple-layered [2.2]Paracyclophanequinone ***(10)***. To a methylmagnesium iodide solution (from 101.3 mg, 4.2 mmol of magnesium and excess of methyl iodide in dry diethyl ether, 50 ml) was added crystals of **39** (109.1 mg, 0.21 mmol) in a portion. After stirring for 40 min and removal of the solvent, the residue was heated at 160—170 °C for 50 min. The mixture was worked up as described for **6**. The crude product was chromatographed on silica gel with benzene to give 29.1 mg (28.3%) of **10**.

10: Red needles from ethanl, odec>235 °C. Found: M^+, 498.2570. Calcd for $C_{36}H_{34}O_2$: 498.2558.

Quadruple-layered [2.2]Paracyclophanequinone ***(11)***. Demethylation and oxidation of **40** were carried out as described

for **6**. The crude product was chromatographed on silica gel with benzene to give **11** in 29.0% yield.

11: Red needles from ethanol, dec>230 °C. Found: M^+, 498.2558. Calcd for $C_{36}H_{34}O_2$: 498.2558.

(Received March 8, 1980)

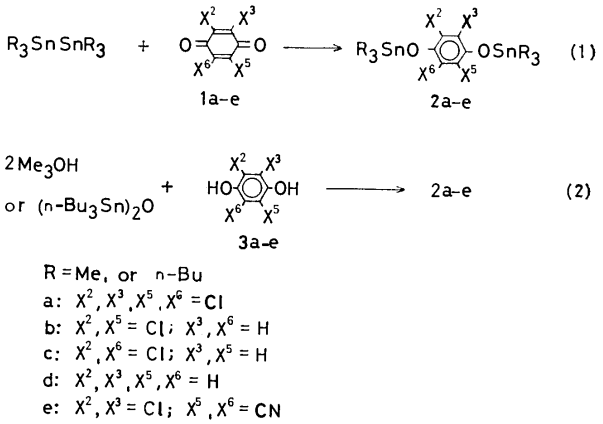
The mechanism of the oxidative cleavage of tin-tin bonds in hexamethyldistannane ($Me_3SnSnMe_3$) and hexabutyldistannane ($Bu_3SnSnBu_3$) with several 1,4-benzoquinones was investigated. Chlorine-substituted 1,4-benzoquinones exerted higher reactivity, implying that the electron-acceptability of quinone is a factor governing the reaction. Stoichiometric treatments of chloranil with the distannanes ruled out the alleged isolation of the free radical, 4-(trimethylstannoxy)phenoxyl radical, reported by Cornwell *et al.* The final products were not the free radical entity but normal compounds, 1,4-bis(trimethylstannoxy)benzenes. Measurements of ESR spectra revealed the formation of the semiquinone radical anions and the subsequent formation of 4-(tributylstannoxy)phenoxyl radicals as reactive intermediates in the reaction pathway.

Oxidative cleavage of the Sn–Sn bonds in hexaorganodistannanes ($R_3Sn–SnR_3$) with halogens, oxygen, and other oxidative materials has been widely investigated.[1–7] Recently, the ability of the σ(Sn–Sn) bond as an electron donor has been obviously demonstrated by the reaction of $R_3Sn–SnR_3$ with powerful π-electron acceptors such as tetracyanoethylene (TCNE),[8] and tetracyanoquinodimethane (TCNQ).[9] In these papers, formations of charge transfer complexes, $(R_3Sn–SnR_3)^+(TCNE)^-$[8] and $(Ph_3Sn–SnPh_3)^+(TCNQ)^-$,[9] were reported, referring also to the formations of free radicals, $R_3Sn–TCNE\cdot$[8] and $R_3Sn–TCNQ\cdot$.[9]

Concerning the reaction with less powerful π-electron acceptors, *viz.* 1,4-benzoquinones and its chlorinated compounds, quite limited information has ever been available. The anion radical of 1,4-benzoquinone was detected by an ESR spectroscopy in the photolytic reaction of $Bu_3Sn–SnBu_3$ in the presence of di-*t*-butyl peroxide and 1,4-benzoquinone.[10,11] A stable free radical, Me_3Sn–chloranil·, was reported to be isolated by simple mixing of $Me_3Sn–SnMe_3$ with chloranil in molar ratio of 1 : 2, however, no structural information except elemental analysis was presented.[9] Recent report on the ESR spectrum of Me_3Sn–9,10-phenanthrenequinone radical[12] prompted us to disclose our results of the oxidative cleavage of σ(Sn–Sn) bond of R_3SnSnR_3 with several 1,4-benzoquinones. We would like to show that the free radicals, R_3Sn–1,4-benzoquinone·, could be successfully detected by ESR spectroscopy in tetrahydrofuran at low temperature, but was too unstable to be isolated at room temperature. The reaction scheme is discussed on the basis of ESR and ^{1}H-NMR spectra.

Results and Discussion

An equimolar solution of $Me_3SnSnMe_3$ and 2,3,5,6-tetrachloro-1,4-benzoquinone (chloranil, **1a**) in benzene was stirred at room temperature under ambient daylight in a nitrogen atmosphere. Gradual color change from the pale greenish yellow of **1a** into brown was observed.



Scheme 1.

Grayish white solid began to appear in about 2 h, and precipitation almost completed within 30 h. The precipitates were identified as 1,4-bis(trimethylstannoxy)-2,3,5,6-tetrachlorobenzene (**2a**) by elemental analysis and by comparing the IR and ^{1}H-NMR spectra with those of the sample prepared by the dehydration method (Eq. 2 in Scheme 1).[13]

Cornwell, Harrison, and Richards reported the isolation of pale creamy solid which they referred to a free radical, Me_3Sn–chloranil·, by the reaction of 1 mol of $Me_3SnSnMe_3$ with 2 mol of **1a** in benzene. Repetition of this reaction allowed us to obtain similar colorless crystals. This crystalline product, however, has now been identified as the normal compound **2a**. One mol of excess **1a** was recovered unchanged from the supernatant solution of the reaction mixture. The analogous reaction of 1 mol of $Me_3SnSnMe_3$ with each 2 mol of 2,5-dichloro-1,4-benzoquinone (**1b**), 2,6-dichloro-1,4-benzoquinone (**1c**), 1,4-benzoquinone (**1d**), and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (**1e**) were carried out to give the regular products **2b**—**e**, and 1 mol of each **1b**—**e** was recovered unchanged.

^{1}H-NMR studies on the reaction of 1 mol of Me_3Sn-$SnMe_3$ with 2 mol of these 1,4-benzoquinones (**1b**—**d**)

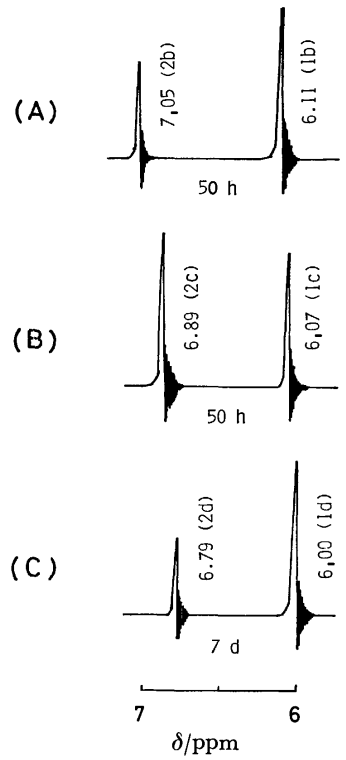


Fig. 1. ^{1}H-NMR spectra of the reaction mixtures of $Me_3SnSnMe_3$ (1 mol) with 1,4-benzoquinones (**1b—d**) (2 mol) in C_6D_6. (A): 2,5-Dichloro-1,4-benzoquinone, (B): 2,6-dichloro-1,4-benzoquinone, (C): 1,4-benzoquinone.

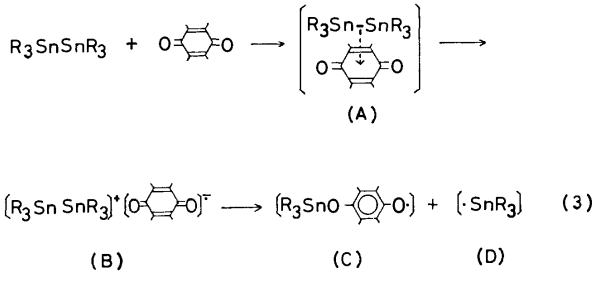
in C_6D_6 solution clearly showed that final products were not the free phenoxyl radicals but **2b—d**, and hence that 1 mol of the excess free 1,4-benzoquinones (**1b—d**) was always present in the solution (Fig. 1).

The electron affinity of the 1,4-benzoquinones is nicely correlated to the reaction times necessary for completing quantitative conversion in the reaction with **2e** (20 h), **2a** (1 d), **2b** (3 d), **2c** (3 d), and **2d** (a week). Particularly in the case of **2d**, the reaction was not induced in the dark even after 5 d at room temperature. These reactions were accelerated by heating and, more effectively, by UV irradiation. When the benzene solution was irradiated with a high pressure mercury lamp, the reaction was completed in less than 60 min.

Similar treatment of an equimolar solution of $Bu_3SnSnBu_3$ with 1,4-benzoquinones in benzene gave brownish (**2a—d**) and reddish oily products (**2e**).

The following scheme (Scheme 2) delineates a possible pathway. This is analogous to the proposed



Scheme 2.

mechanism for the similar reaction of $Me_3SnSnMe_3$ with 9,10-phenanthrenequinone:[10] The electron-donating σ(Sn–Sn) bond of R_3SnSnR_3 might interact with the electron defficient 1,4-benzoquinones (acceptor) to form (σ-π) charge transfer complexes (**A**) at the initial step. The transient appearance of the dark brown color in the reaction mixture could be attributed to the formation of **A**. Then, one electron transfer from the Sn–Sn bond into the 1,4-benzoquinone to produce the semiquinone radical anion along with the radical cation of the distannane (**B**). The succeeding cleavage of the Sn–Sn bond of the cation radical in **B** affords both 4-(trialkylstannoxy)phenoxyl radical (**C**) and trialkylstannyl radical (**D**).

ESR measurements have supported the above reaction scheme. The intermediary formation of the semiquinone radical anions (**B**) and the subsequent phenoxyl radicals (**C**) has been clearly demonstrated.

The ESR spectrum of a solution of $Me_3SnSnMe_3$ and **1b** in benzene measured at room temperature displayed a triplet signal (1 : 2 : 1, a_H=1.98 G) assignable to the radical anion of **1b**.[14] The intensity of the signals gradually increased to reach a maximum in 24 h, and then began to decrease, and became finally undetectable after 3 d. Analogous semiquinone radical anion of **1c** has been observed (Table 1). In the case of **1d**, feeble signal of the semiquinone radical was detected with difficulty.

TABLE 1. ESR DATA OF THE SEMIQUINONE RADICALS OBSERVED IN THE REACTION OF $Me_3SnSnMe_3$ OR $Bu_3SnSnBu_3$ WITH 1,4-BENZOQUINONES

Radicals	$(Me_3Sn)_2$	$(Bu_3Sn)_2$
		g=2.0061 singlet
	g=2.0055 triplet (1 : 2 : 1) a_H=1.98 G	g=2.0055 weak and complicated
	g=2.0053 triplet (1 : 2 : 1) a_H=2.38 G	g=2.0053 weak and complicated
	very weak	g=2.0050 quintet (1 : 4 : 6 : 4 : 1) a_H=2.32 G
		g=2.0052 quintet (1 : 2 : 3 : 2 : 1) a_N=0.61 G

By contrast, in the ESR spectra of $Bu_3SnSnBu_3$–1,4-benzoquinones systems, stronger and more clearly detectable quintet signal of the semiquinone radical of **1d** (Table 1) was observed, when a benzene solution of **1d** and $Bu_3SnSnBu_3$ was warmed up from a liquid nitrogen temperature and was kept at room temperature for 1 h. The ESR spectra of the benzene solution of $Bu_3SnSnBu_3$ with **1b** or **1c** displayed broad and weak signals. The concentration of **B** from **1b** or **1c** was too

low to be detected by ESR spectra, since **B**, if formed, could be comparatively labile and readily converted into the corresponding **C**. These different results of $Bu_3SnSnBu_3$ from those of $Me_3SnSnMe_3$ could be interpreted by taking account of the more electron donating ability of $Bu_3SnSnBu_3$ than that of $Me_3SnSnMe_3$.[7]

When the ESR spectroscopy was carried out in toluene at lower temperature, mixtures of **1b** or **1c** with $Bu_3SnSnBu_3$ afforded complicated spectra consisting of the mixed signals of **B** and **C**. The ESR spectra of the $Bu_3SnSnBu_3$–**1d** and –**1e** systems in toluene displayed strong quintet signals of the corresponding semiquinone radical anions.

In order to obtain the more detectable ESR spectra of less stable phenoxyl radical (**C**) at low temperature, tetrahydrofuran (THF) was used as a solvent. It could be expected that THF could accelerate both the electron transfer from the Sn–Sn bond and the heterolytic cleavage of Sn–Sn bond to readily convert **B** into **C**, then the concentration of **C** increased in the sample. The ESR signals of the unstable phenoxyl radicals (**C**) have now been observed at low temperature, as described below.

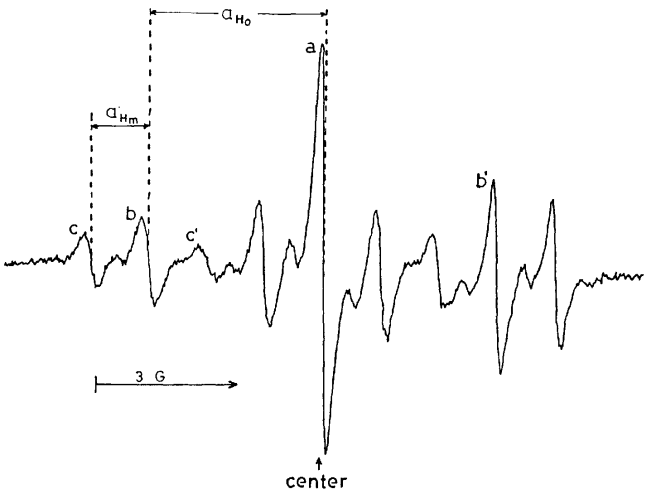


Fig. 2. The ESR spectrum of a THF solution of $Bu_3SnSnBu_3$ and 1,4-benzoquinone at −80 °C.

When a freshly prepared THF solution of $Bu_3SnSnBu_3$ and **1d** was warmed from liquid nitrogen temperature up to about 50 °C for 1 min, and was subjected to the ESR measurement at −80 °C, there were obtained ESR signals (Fig. 2). The triplet (1:2:1) of triplet (1:2:1) pattern of the signal is clearly different from that of **B** which displays the quintet, but is consistent with that of the 4-(tributylstannoxy)phenoxyl radical (**C**) (Table 2), as compared with those of the other phenoxyl radicals.[15] As the temperature of the cavity was raised from −80 °C, the ESR signals collapsed to become broad, and completely disappeared at about −20 °C. This could be due to the unstability of **C** above −20 °C. When the cavity was cooled back to −80 °C, the same spectral pattern reappeared. A short time irradiation by UV light of the solution kept in the cavity at −80 °C resulted in the increase of these ESR signals. When the reaction had been completed by 20 min irradiation with UV light in the cavity, ESR signal was no longer observed.

Table 2. Hyperfine splitting constants in 4-(tributylstannoxy)phenoxyl radicals

Radicals	g	a_{H_o}/G	a_{H_m}/G	a^{119}_{Sn}/G, a^{117}_{Sn}/G	Pattern
	2.0050	—	—	2.21 2.11	singlet
	2.0054	3.12	1.04	1.94 1.85	doublet of doublet
	2.0053	—	1.28	1.35 1.29	triplet
	2.0047	3.67	1.22	1.36 1.30	triplet of triplet
	not detected				

When the reaction of $Bu_3SnSnBu_3$ with **1e** was carried out in THF, the ESR spectrum exhibited a clearly detectable quintet of **B** at −30 °C——80 °C, but no signal of **C** even at −80 °C. Warming up the solution at 50 °C for 2 min resulted in collapse of the quintet signals. This result might be attributed to the rapid conversion of the phenoxyl radical into the final product (**2e**).

The transient free phenoxyl radical (**C**), assigned by ESR spectroscopy in THF, could be converted into the product (**2**) either by the coupling with the radical (**D**), or by the reaction of **C** with R_3SnSnR_3 (Eqs. 4 and 5 in Scheme 3).

Scheme 3.

In all cases of $Me_3SnSnMe_3$ with **1b**—**e**, no definite ESR spectrum for the free phenoxyl radical was obtained even in THF solution at low temperature. This could be attributed to the more rapid consumption of **C** (R=Me) with $Me_3Sn\cdot$ or $Me_3SnSnMe_3$ than that of **C** (R=Bu) with $Bu_3Sn\cdot$ or $Bu_3SnSnBu_3$, probably because $Me_3Sn\cdot$ group or $Me_3SnSnMe_3$ has much less steric hindrance than $Bu_3Sn\cdot$ or $Bu_3SnSnBu_3$.

Experimental

All reactions were carried out in a nitrogen atmosphere. 1,4-Benzoquinones (**1a**—**e**) were purified either by vacuum sublimation or recrystallization immediately before use. The ^{1}H-NMR spectra were measured with JEOL-C60HL spectrometer operating at a resonance frequency of 60 MHz. The ^{13}C-NMR spectra were recorded in the pulse Fourier transform mode using a JEOL-FX60 spectrometer operating at a resonance frequency of 15.03 MHz. Chemical shifts were referred to tetramethylsilane.

The ESR measurements were made using a JEOL X-band spectrometer (Model ME-3) equipped with 100 kHz field modulation. The magnetic field was calibrated by the hyperfine splittings of Mn^{2+} doped in MgO and of ^{14}N of the peroxylaminedisulfonate ion.

The samples for the ESR measurements were prepared as follows. To a mixture of R_3SnSnR_3 and 1,4-benzoquinones in a quartz tube attached to a high vacuum line, anhydrous benzene, toluene, or THF was transferred. The solution was degassed at least four times. The sealed benzene solution was kept at room temperature under ambient diffused light. The ESR spectra of the benzene solution were measured at room temperature. The sealed THF solution was kept in a liquid nitrogen bath. Just before the measurement, the solution was taken out from the cold bath and warmed up at 50°C. After the solution was kept at 50 °C for several minutes in a water bath, it was cooled to −80 °C in a cavity.

*Reaction of **1a** with $Me_3SnSnMe_3$.* An equimolar mixture of $Me_3SnSnMe_3$ (0.800 g, 0.24 mmol) and **1a** (0.053 g, 0.22 mmol) in benzene (10 ml) was kept at room temperature under ambient daylight. The color of the solution gradually darkened and became dark brown in 2 h. Colorless crystals began to appear in 3 h, and were completely precipitated in 1 d. After 2 d, the crystals were collected and washed twice with benzene, and dried *in vacuo* to give colorless hexagonal plates (0.111 g), which was identified as 1,4-bis(trimethylstannoxy)-2,3,5,6-tetrachlorobenzene (**2a**). This compound (**2a**) was also prepared by the dehydration method[13] from trimethyltin hydroxide and 2,3,5,6-tetrachloro-1,4-benzenediol (**3a**) (Eq. 2 in Scheme 1). Both samples displayed the same IR and ^{1}H-NMR spectra (Table 3). Benzene of the supernatant solution was evaporated off to give brown solid (0.034 g), which was rinsed with benzene to afford **2a** (0.021 g). Total yield of **2a** was 0.132 g (94%).

A solution of $Me_3SnSnMe_3$ (0.073 g, 0.22 mmol) and **1a** (0.096 g, 0.39 mmol) in benzene (30 ml) was kept at room temperature. The reaction proceeded in the same process as the equimolar reaction. After 2 d, the crystals (**2a**, 0.109 g) were collected by decantation. Benzene of the yellowish brown supernatant solution was evaporated off *in vacuo* to give yellow crystals (0.078 g), which was dissolved in benzene (5 ml). The insoluble **2a** (0.004 g) was separated [total yield of **2a** was 0.113 g (85%)]. The benzene solution was subjected to column chromatography (silica gel, benzene) to recover the excess amount of analytically pure **1a** (0.048 g).

*Reaction of **1b** with $Me_3SnSnMe_3$.* An equimolar mixture of $Me_3SnSnMe_3$ (0.072 g, 0.22 mmol) and **1b** (0.035 g, 0.20 mmol) in benzene (10 ml) was kept at room temperature. The color of the solution darkened gradually from yellow to brown, and finally reddish brown. After 4 d, the solvent was evaporated off *in vacuo* to give pale brown solid (0.110 g) of **2b** identified by IR and ^{1}H-NMR spectra (Table 3).

A solution of $Me_3SnSnMe_3$ (0.061 g, 0.19 mmol) and **1b** (0.058 g, 0.31 mmol) in benzene (10 ml) was kept at room temperature. After 4 d, the solvent was evaporated off *in vacuo* to give pale brown solid (0.122 g). This solid was rinsed with a mixed solvent of cyclohexane (4 ml) and benzene (2 ml), and was recrystallized from benzene to give pale brown crystals (**2b**, 0.063 g). The solvent of the supernatant solution was evaporated off and the residue was redissolved in the mixed solvent to give the insoluble solid (**2b**, 0.010 g). The solvent of the rinsed solution was evaporated off to give brown solid (0.040 g), whose ^{1}H-NMR spectrum ($CDCl_3$) had two singlets; the one (+6.00 ppm) was assigned to **1b**, the other (+0.63 ppm) was assigned to Me_3SnOH.

*Reaction of **1c** with $Me_3SnSnMe_3$.* An equimolar solution of $Me_3SnSnMe_3$ (0.154 g, 0.47 mmol) and **1c** (0.083 g, 0.47 mmol) in benzene (15 ml) was kept at room temperature. The color of the solution darkened gradually from yellow to brown, and finally dark brown. After 4 d, the solvent was evaporated off *in vacuo* to give dark violet solid (0.230 g) identified as **2c** by IR and ^{1}H-NMR (Table 3 . ^{13}C-NMR ($CDCl_3$): δ −2.3 (methyl carbons), +119.5 (3,5-carbons), +126.3 (2,6-carbons).

A solution of $Me_3SnSnMe_3$ (0.097 g, 0.30 mmol) and **1c** (0.092 g, 0.52 mmol) in benzene (10 ml) was kept at room temperature. After 4 d, the solvent was evaporated off *in vacuo* to give brown solid (0.187 g). Mixed solvent of cyclohexane (2.5 ml) and benzene (1.5 ml) was added to the brown solid and insoluble solid was collected, rinsed with benzene to give pale brown solid (**2c**, 0.077 g). The solvent of the supernatant solution was evaporated off to give brown solid, which was rinsed with the mixed solvent, and further with benzene to afford **2c** (0.013 g) [total yield of **2c** was 0.090 g (63%)]. The solvent was evaporated off from the rinsed solution to give brown solid (0.091 g), whose ^{1}H-NMR ($CDCl_3$) showed two singlets; the one (+6.05 ppm) was assigned to **1c**, the other (+0.58 ppm) was assigned to Me_3SnOH.

*Reaction of **1d** with $Me_3SnSnMe_3$.* An equimolar solution of $Me_3SnSnMe_3$ (0.165 g, 0.50 mmol) and **1d** (0.055 g, 0.51

Table 3. Melting points, analytical and ^{1}H-NMR (THF) data of **2a**—**e** (R=Me)

a) Elemental analyses did not give satisfactory results in spite of efforts of repeated preparations and analysis. The deviation found in the elemental analyses might be due to the partial hydrolysis of the sample during recrystallization procedures.[16] b) **2d** was partially hydrolyzed during repeated recrystallizations to give analytically pure 4-(trimethylstannoxy)phenol, dp 200 °C—215 °C.[18] c) Lit, 187 °C.[17] d) Dp.

mmol) in benzene (10 ml) was kept at room temperature. The solution darkened slightly in a week. After 2 weeks the solvent was evaporated off to give pale brown solid (0.210 g). This was rinsed with cyclohexane to give pale brown solid (0.168 g, 77%) identified as **2d** by ^{1}H-NMR (Table 3) and IR spectra.[17]

Reaction of ***1e*** *with* $Me_3SnSnMe_3$. An equimolar solution of $Me_3SnSnMe_3$ (0.070 g, 0.21 mmol) and **1e** (0.046 g, 0.20 mmol) in benzene (10 ml) was kept at room temperature. The solution gradually turned brown in 15 min and reddish yellow crystals began to precipitate. The solution turned yellow in 3 h. When the mixture was kept for 20 h, the reaction was completed. The crystals were separated and recrystallized with benzene to give orange yellow needles (0.109 g, 98%) identified as **2e** (Table 3).

A solution of $Me_3SnSnMe_3$ (0.067 g, 0.20 mmol) and **1e** (0.092 g, 0.40 mmol) in benzene (10 ml) was kept at room temperature. After 2 d, crystalline **2e** (0.100 g, 90%) was collected. Benzene of the reddish brown supernatant solution was evaporated off *in vacuo* to recover the excess amount of **1e** (0.052 g).

Reaction of ***1a—d*** *with* $Me_3SnSnMe_3$ *under Irradiation.* An equimolar solution of **1a** (0.049 g, 0.20 mmol) and $Me_3SnSnMe_3$ (0.075 g, 0.23 mmol) in benzene (10 ml) in a sealed Pyrex glass tube was irradiated externally with a high pressure mercury lamp (450 W) at 20 °C. After 10 min irradiation, colorless solid precipitated and the solution turned almost colorless. After 20 min, the precipitates were collected by decantation, rinsed with benzene and dried *in vacuo* to give pure **2a** (0.083 g, 73%). The solvent of the supernatant solution was evaporated off and washed with benzene to give **2a** (0.030 g, 26%).

The reactions of **1b—d** with $Me_3SnSnMe_3$ were carried out analogously as described above: The reactions were completed within 1 h to obtain **2b**, **2c**, and **2d** in the yields of 86%, 82%, 74%, respectively.

Reaction of $Bu_3SnSnBu_3$ *with* ***1a—e***. A solution of $Bu_3SnSnBu_3$ (0.18 mmol) and **1a** (0.17 mmol) in benzene (10 ml) was stirred at room temperature being exposed to ambient diffused light. Almost quantitative yield of a brown viscous liquid, **2a** also was obtained in 25 h.

The reactions of $Bu_3SnSnBu_3$ with **1b—e** were carried out in the same manners as mentioned above. The reactions were completed in 66, 63, 140, and 24 h, respectively. Brown oily products were identified as **2b—e**, by comparing the IR and ^{13}C-NMR spectra with those of the samples prepared by Eq. 2 in Scheme 1.[13]

Reaction of $Bu_3SnSnBu_3$ *with* ***1a*** *under Irradiation.* A solution of $Bu_3SnSnBu_3$ (0.37 mmol) and **1a** (0.37 mmol) in benzene (15 ml) was irradiated. After 10 min irradiation, the color of the solution changed from pale greenish yellow to brown, and $\nu_{C=O}$ absorption of **1a** (1690 cm^{-1}) in the IR spectrum disappeard completely. Removal of the solvent *in vacuo* gave almost quantitative yield of **2a**.

Thermal Reaction of $Bu_3SnSnBu_3$ *with* ***1a***. An equimolar mixture of $Bu_3SnSnBu_3$ (0.31 mmol) and **1a** (0.27 mmol) in benzene was heated under reflux for 1.5 h. The $\nu_{C=O}$ absorption in the IR spectrum was absent, and the solvent was evaporated off to give **2a** quantitatively.

A Facile Synthesis of 1,2-Divinylcycloalkanols and Their Behavior in the Oxy-Cope Rearrangement[1]

Tetsuya KATO,* Hisao KONDO, Masaki NISHINO, Minoru TANAKA, Go HATA, and Akihisa MIYAKE

Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura 248

(Received March 12, 1980)

The reaction of 2-chlorocycloalkanones with vinylmagnesium chloride gives 1,2-divinylcycloalkanols. Divinylation proceeds *via* a rearrangement of initially formed 2-chloro-1-vinylcycloalkanols to 2-vinylcycloalkanones followed by further vinylation of 2-vinylcycloalkanones. Thermal sigmatropic rearrangement of 1,2-divinylcycloalkanols gives 5-cycloalken-1-ones in good yields. The influence of the size of rings on the reaction pathways is discussed.

The oxy-Cope rearrangements are powerful reactions for the preparation of α,ε-unsaturated carbonyl compounds and α,δ-dicarbonyl derivatives.[2] Marvell and Whally extended this utility to the formation of ten-menbered rings from *trans*- and *cis*-1,2-divinylcyclohexanols.[3] Although good yields can be obtained in these reactions, the preparation of 1,2-divinylcyclohexanols requires multistep reactions, *i.e.*, vinylation of cyclohexene oxide with vinyllithium and oxidation of the resulting 2-vinylcyclohexanol with chromium trioxide followed by vinylation of 2-vinylcyclohexanone with vinylmagnesium bromide. We wish to report on the one-step synthesis of 1,2-divinylcycloalkanols and their behavior in the oxy-Cope rearrangement. The influence of the size of rings on the reaction pathways is also discussed.

Results and Discussion

Divinylation of 2-Chlorocycloalkanones. The reaction of 2-chlorocycloalkanones **1** with vinylmagnesium chloride in tetrahydrofuran (THF)[4] gives 1,2-divinylcycloalkanols **5**. Divinylation was carried out in the presence of more than 2 molar equiv of vinylmagnesium chloride at temperatures above 50 °C. The results are summarized in Table 1.

The results suggest that the yields of 1,2-divinylcycloalkanols **5** are markedly influenced by the size of rings, decreasing in the order: n=4>5>10>3>9>2. The reaction of 2-chlorocyclobutanone **1a** showed an exceptional trend, affording no detectable amount of 1,2-divinylcyclobutanol **5a**.

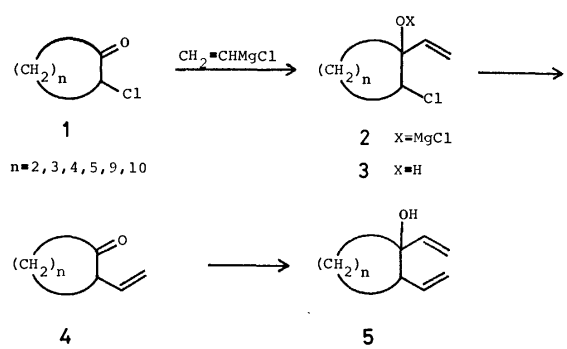
Divinylation of 2-chlorocycloalkanones **1**, except for the case of 2-chlorocyclobutanone **1a**, was found to proceed *via* the vinyl group rearrangement of the initially formed chlorohydrin derivatives **2**, followed by further vinylation of the resulting 2-vinylcycloalkanones **4**. The reaction pathways can be reasonably accounted for by the following observations. Treatment of 2-chlorocycloalkanones **1** with vinylmagnesium chloride in THF below room temperature predominantly affords chlorohydrins **3**.[5,6] The direct attack of vinylmagnesium chloride on chlorine atom is a minor reaction pathway.[7] For example, when 2-chlorocyclododecanone **1f** was treated with 1.15 molar equiv of vinylmagnesium chloride in THF at 0 °C, 2-vinylcyclododecanone **4f** was obtained in less than 1.6% yield, whereas 2-chloro-1-vinylcyclododecanol **3f** was obtained in 87—94% yield.

1,2-Migration of the vinyl group in chlorohydrins **3** takes place smoothly to afford 2-vinylcycloalkanones **4** when the magnesium salts of the chlorohydrins **3** (n= 3, 4, 5, 9, 10) are heated[5-9] in a solution above 50 °C. On the other hand, the reaction of 2-chlorocyclobutanone **1a** with vinylmagnesium chloride predominantly affords 1-cyclopropyl-4-penten-1-one **7**. Formation of **7** can be rationalized by assuming that the reaction proceeds *via* the ring contraction of the chlorohydrin derivative **2** (n=2) in place of the vinyl group rearrangement, followed by the conjugate addition of vinylmagnesium chloride to the resulting 1-cyclopropyl-2-propen-1-one **6**.[10] In the reaction of 2-chlorocycloalkanones **1** (n=3, 4, 5, 9,10) the ring contraction is a minor pathway. For example, 2-chlorocyclododecanone **1f** upon treatment with vinylmagnesium chloride at 55 °C gave 1-cycloundecyl-4-penten-1-one **8** only in 2% yield.

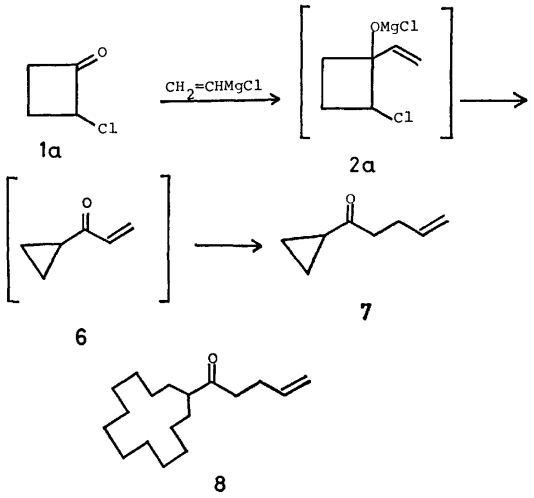
2-Vinylcycloalkanones **4** were easily converted into 1,2-divinylcycloalkanols **5** with vinylmagnesium chloride

Table 1. Divinylation of 2-chlorocycloalkanones with vinylmagnesium chloride

	n	Molar ratio CH_2=CHMgCl/**1**	Temp/°C	Yield **5** (%)
1a	2	2.60	55	0
1b	3	2.32	55	31
1c	4	2.50	55	90
1d	5	2.52	55	75
1e	9	2.20	55	7
1f	10	2.20	55	53

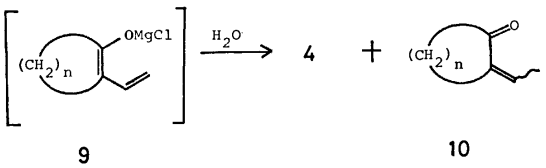


Scheme 1.



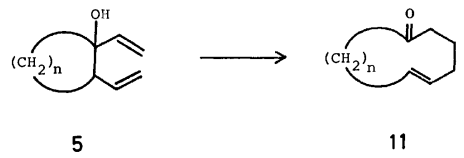
Scheme 2.

in THF at 0 °C. The major side reaction in the vinylation of **4** is the formation of enolates **9**[11] which upon hydrolysis lead to the recovery of **4** as well as the formation of 2-ethylidenecycloalkanones **10.**



Scheme 3.

The Oxy-Cope Rearrangement of 1,2-Divinylcycloalkanols. Thermal [3,3] sigmatropic rearrangement of 1,2-divinylcycloalkanols **5** at 165—220 °C gave 5-cycloalken-1-ones **11.** The rearrangement was carried out by using a mixture of *trans-* and *cis*-1,2-divinylcycloalkanols prepared by the direct divinylation of 2-chlorocycloalkanones **1.** The results are summarized in Table 2. When 1,2-divinylcyclohexanol **5c** was used, the highest yield (82%) was obtained. The yields of **11** decreased



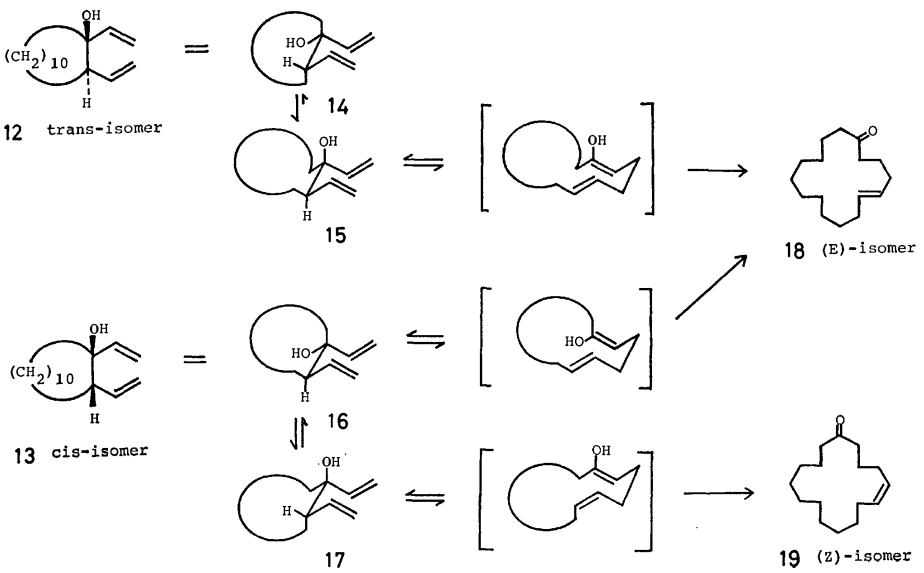
Scheme 4.

Table 2. Thermal [3,3] sigmatropic rearrangement of 1,2-divinylcycloalkanols

	n	Temp/°C	Time/h	Yield **11** (%)
5b	3	200	4	60
5c	4	220	2	82
5d	5	220	2	80
5e	9	180	2	74
5f	10	165	6	77

in the order: n=4>5>10>9>3.

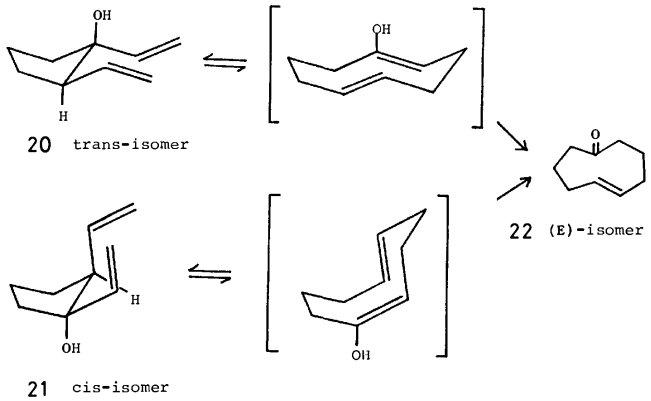
Marvell and Whally examined the thermal rearrangement of *trans-* and *cis*-1,2-divinylcyclohexanols to 5-cyclodecen-1-one **11c** in detail.[3] We have examined the thermal rearrangement of *trans*-**12** and *cis*-1,2-divinylcyclododecanols **13**, and *trans*-**20** and *cis*-1,2-divinylcyclopentanols **21** in order to clarify the influence of the size of rings on the oxy-Cope rearrangement. Divinylation of 2-chlorocyclododecanone **1f** afforded a 40 : 60 ratio of *trans*-**12** and *cis*-1,2-divinylcyclododecanols **13.** When the minor isomer was heated at 180 °C for 3 h, the single product, (*E*)-5-cyclohexadecen-1-one **18** was obtained in 92% yield. The major isomer, under the same conditions, provided a mixture containing (*E*)-**18** and (*Z*)-5-cyclohexadecen-1-ones **19** in 24: 76 ratio in 67% yield. Infrared spectroscopy was used to distinguish (*E*)- (970 cm^{-1}) **18** from (*Z*)-5-cyclohexadecen-1-ones (720 cm^{-1}) **19.** Assuming that the rearrangement involves a concerted stereospecific Cope reaction *via* a chair-like transition state (**15, 16,** and **17**),[12] which minimizes 1,3-pseudo-diaxial interactions, the major isomer can be assigned to *cis*-1,2-



Scheme 5.

divinylcyclododecanol **13**. The stereochemical results are similar to those of 1,2-divinylcyclohexanols.[3]

Divinylation of 2-chlorocyclopentanone **1b** afforded an 81: 19 ratio of *trans*- **20** and *cis*-1,2-divinylcyclopentanols **21**. The major isomer was assigned to *trans*-1,2-divinylcyclopentanol **20** on the basis of the predominance of *trans* products in the addition of the Grignard reagents to 2-alkylcyclopentanones.[13] The thermal rearrangement of both *trans*- **20** and *cis*-1,2-divinylcyclopentanols **21** provided the single product (*E*)-5-cyclononen-1-one **22**,[14] in 46 and 72% yields, respectively, no detectable amount of (*Z*)-5-cyclononen-1-one being obtained. The stereochemistry of the product can be rationalized by assuming that chair-like transition geometries (**20** and **21**) are involved in the rearrangement of *trans*- and *cis*-1,2-divinylcyclopentanols.[15]



Scheme 6.

Experimental

Melting and boiling points are uncorrected. Gas-liquid chromatography (GLPC) analyses were performed on a Shimadzu 3BT instrument using 10% Silicone OV-17 or 5% PEG-20M coated on Chromosorb WHP (80—100 mesh) packed in glass columns (1.2 m). The following spectrometers were used: IR, Hitachi 215; NMR, Varian XL-100 or JEOL FX-100 (TMS as an internal standard); mass spectra, Hitachi RMU-7M or RMS-4. Silica gel (Merck, 70—230 mesh) was used for column chromatography. Unless otherwise stated, 2-chloro-1-vinylcycloalkanols **3**, 1,2-divinylcycloalkanols **5**, and 5-cycloalken-1-ones **11** consist of *trans*- and *cis*-isomers, or (*E*)- and (*Z*)-isomers.

2-Chlorocycloalkanones (1). 2-Chlorocycloalkanones **1** were prepared by the chlorination of cycloalkanones.[16-18]

Chlorohydrins (3). Typical Procedure: A solution of 2-chlorocycloundecanone **1e** (16.0 g, 79.0 mmol) in THF (20 ml) and a solution of vinylmagnesium chloride in THF (1.73 mol/l, 54.8 ml, 94.8 mmol) were added dropwise to THF (183 ml) at 0 °C during a period of 1 h. The mixture was stirred at 0 °C for 1.5 h, poured into an aqueous ammonium chloride solution and extracted with hexane. The hexane extracts were washed with water, dried over anhydrous sodium sulfate and concentrated to give 16.95 g of oil. GLPC analysis showed two major peaks due to 2-chloro-1-vinylcycloundecanol **3e** (69.3%). The oil was chromatographed on silica gel (benzene) to give a mixture of *trans*- and *cis*-2-chloro-1-vinylcycloundecanols (7.18 g, 39%). **3e**: bp 112—113 °C/0.6 Torr, mp 37—40 °C; IR (neat) 3570, 3080, 1643, 1140, 988, 922 cm^{-1}; NMR (CCl_4) δ 1.1—2.4 (m, 18H), 2.02 (s, 1H), 4.18 (dd, J=3 and 8 Hz, 1H), 5.10 (dd, J=2 and 11 Hz, 1H), 5.30 (dd, J=2 and 17 Hz, 1H), 5.96 (dd, J=11 and 17 Hz, 1H); MS *m/e* 232, 230 (M^+). Found: C, 67.92; H, 10.06; Cl, 15.34%. Calcd for $C_{13}H_{23}OCl$: C, 67.66; H, 10.05; Cl, 15.36%.

2-Chloro-1-vinylcyclobutanol (3a): Bp 65—75 °C/21 Torr; IR (neat) 3445, 1638, 985, 925, 855 cm^{-1}; NMR (CCl_4) δ 1.7—2.7 (m, 5H), 4.16—4.38 (m, 1H), 4.98—5.46 (m, 2H), 5.85 (dd, J=10 and 16 Hz, 1H). MS *m/e* 134, 132 (M^+). Found: C, 54.49; H, 6.91; Cl, 26.64%. Calcd for C_6H_9OCl: C, 54.34; H, 6.79; Cl, 26.79%.

2-Chloro-1-vinylcyclododecanol (3f, trans-*Isomer)*: Mp 55—55.5 °C; IR (KBr) 3550, 1640, 1118, 988, 919, 758 cm^{-1}; NMR (CCl_4) δ 1.1—2.3 (m, 21H), 4.03 (d, J=8 Hz, 1H), 5.10 (dd, J=2 and 11 Hz, 1H), 5.29 (dd, J=2 and 17 Hz, 1H), 5.92 (dd, J=11 and 17 Hz, 1H); MS *m/e* 246, 244 (M^+). Found: C, 68.47; H, 10.07; Cl, 14.63%. Calcd for $C_{14}H_{25}OCl$: C, 68.69; H, 10.29; Cl, 14.48%. (*3e*, cis-*isomer*): mp 63—65 °C; IR (KBr) 3550, 1638, 994, 908, 768 cm^{-1}; NMR (CCl_4) δ 1.0—2.3 (m, 21H), 4.03 (d, J=8 Hz, 1H), 5.05 (dd, J=2 and 11 Hz, 1H), 5.27 (dd, J=2 and 17 Hz, 1H), 5.90 (dd, J=11 and 17 Hz, 1H); MS *m/e* 246, 244 (M^+). Found: C, 68.51; H, 10.08; Cl, 14.52%. Calcd for $C_{14}H_{25}OCl$: C, 68.69; H, 10.29; Cl, 14.48%.

2-Vinylcycloalkanones (4). Typical Procedure: A solution of 2-chloro-1-vinylcycloundecanol **3e** (6.99 g, 30.3 mmol) in benzene (98 ml) was added to a stirred solution of ethylmagnesium bromide in ether (1.87 mol/l, 15.1 ml, 28.3 mmol) at 0 °C during a period of 1 h. After being stirred at 0 °C for 10 min, the reaction mixture was heated at 70 °C for 30 min, cooled, poured into an aqueous ammonium chloride solution and extracted with benzene. The benxene extracts were washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled (bp 91—93 °C/0.5—0.6 Torr) to give 5.16 g of oil. GLPC analysis showed one major peak due to 2-vinylcycloundecanone **4e** (82.7%). The yield of **4e** was 74%. The oil was chromatographed on silica gel (benzene) to give pure **4e** (2.60 g). **4e**: bp 88—89 °C/0.5 Torr; mp 35—37 °C; IR (neat) 3080, 1720, 1635, 995, 915 cm^{-1}; NMR (CCl_4) δ 1.1—2.3 (m, 16H), 2.3—2.7 (m, 2H), 3.29 (t, J=9 Hz, 1H), 4.91—5.18 (m, 2H), 5.50—5.90 (m, 1H); MS *m/e* 194 (M^+). Found: C, 80.51; H, 11.56%. Calcd for $C_{13}H_{22}O$: C, 80.36; H, 11.41%.

2-Vinylcyclododecanone (4f): Bp 80—84 °C/0.2 Torr; n_D^{20}= 1.4943; IR (neat) 3080, 1712, 1638, 995, 915 cm^{-1}; NMR (CCl_4) δ 1.0—2.1 (m, 18H), 2.25—2.60 (m, 2H), 3.10—3.40 (m, 1H), 4.90—5.20 (m, 2H), 5.53—5.94 (m, 1H); MS *m/e* 208 (M^+). Found: C, 67.84; H, 10.20; N, 15.88%. Calcd for $C_{15}H_{27}ON_3$ (semicarbazone, mp 182—184 °C): C, 67.84; H, 10.27; N, 15.84%.

1,2-Divinylcycloalkanols (5). Typical Procedure: A solution of 2-vinylcycloundecanone **4e** (2.40 g, 12.4 mmol) in THF (10 ml) was added dropwise to a stirred solution of vinylmagnesium chloride in THF (1.00 mol/l, 23.2 ml, 23.2 mmol) at 0 °C during a period of 1 h. After being stirred at 0 °C for 1.5 h, the reaction mixture was poured into an aqueous ammonium chloride solution and extracted with hexane. The hexane extracts were washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled (oil bath 140 °C/0.5 Torr) to give 1.71 g of oil. GLPC analysis showed a peak due to 1,2-divinylcycloundecanol **5e** (23.5%). The yield of **5e** from **4e** was 14.6%. The oil was chromatographed on silica gel (benzene) to give pure **5e**. **5e**: IR (neat) 3470, 3070, 1638, 1175, 1125, 995, 915 cm^{-1}; NMR (CCl_4) δ 1.0—2.0 (m, 19H), 2.0—2.3 (t, J=4 Hz, 1H), 4.65—5.10 (m, 4H),

5.30—5.85 (m, 2H); Found: C, 80.99; H, 11.65%. Calcd for $C_{15}H_{26}O$: C, 81.02; H, 11.78%.

*1,2-Divinylcyclopentanol (**5b**, trans-Isomer)*: $n_D^{23}=1.4810$; IR (neat) 3500, 3080, 1648, 1000, 920 cm^{-1}; NMR (CCl_4) δ 1.5—2.0 (m, 7H), 2.10—2.45 (m, 1H), 4.80—5.24 (m, 4H), 5.42—5.90 (m, 2H). Found: C, 78.42; H, 10.19%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

*(**5b**, cis-Isomer)*: $n_D^{23}=1.4859$; IR (neat) 3430, 3080, 1645, 995, 918 cm^{-1}; NMR (CCl_4) δ 1.3—2.6 (m, 8H), 4.70—5.18 (m, 4H), 5.30—5.90 (m, 2H). Found: C, 77.71; H, 10.23%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.20%.

*1,2-Divinylcyclohexanols (**5c**, trans- and cis-Isomers)*: The IR and NMR spectra of **5c** were identical with those of authentic samples.[3]

*1,2-Divinylcyclododecanol (**5f**, trans-Isomer)*: Mp 51—52 °C; IR (KBr) 3400, 3060, 1638, 997, 980, 918, 906 cm^{-1}; NMR (CCl_4) δ 1.0—2.0 (m, 21H), 2.15 (t, $J=10$ Hz, 1H), 4.70—6.02 (m, 6H). Found: C, 81.59; H, 11.99%. Calcd for $C_{16}H_{28}O$: C, 81.29; H, 11.94%.

*(**5f**, cis-Isomer)*: Bp 122—123 °C/0.7 Torr; mp 15—16 °C; $n_D^{20}=1.5023$; IR (neat) 3540, 3060, 1638, 998, 920 cm^{-1}; NMR (CCl_4) δ 0.95—1.9 (m, 21H), 2.30 (t, $J=10$ Hz, 1H), 4.88—6.02 (m, 6H). Found: C, 81.51; H, 11.91%. Calcd for $C_{16}H_{28}O$: C, 81.29; H, 11.94%.

*Direct Divinylation of 2-Chlorocycloalkanones (**1**) with Vinylmagnesium chloride. Typical Procedure*: A solution of 2-chlorocycloundecanone **1e** (10.1 g, 50.0 mmol) in THF (12 ml) and a solution of vinylmagnesium chloride in THF (1.73 mol/l, 34.7 ml, 60.0 mmol) were added dropwise to THF (60 ml) at 0 °C during a period of 1 h. Stirring was continued at 0 °C for 1.5 h. After a solution of vinylmagnesium chloride in THF (1.73 mol/l, 28.9 ml, 50.0 mmol) had been added during a period of 10 min, the reaction mixture was heated at 55 °C for 15 h, poured into an aqueous ammonium chloride solution and extracted with benzene. The benzene extracts were washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled (bp 100—106 °C/0.5 Torr) to give 6.28 g of oil. GLPC analysis showed a peak due to 1,2-divinylcycloundecanol **5e** (12.9%). The yield of **5e** from **1e** was 7.3%.

*Thermal Rearrangement of 1,2-Divinylcycloalkanols (**5**).*

Typical Procedure: *trans*-1,2-Divinylcyclopentanol **20** (3.00 g, 16.7 mmol) was heated at 200 °C for 3 h. The reaction mixture was distilled (bp 61 °C/3 Torr) to give 1.47 g of oil. GLPC analysis showed one major peak (94.5%) due to (*E*)-5-cyclononen-1-one **22**. The yield was 46%. *cis*-1,2-Divinylcyclopentanol **21** (1.00 g, 5.55 mmol), under the same conditions, gave an oil (0.68 g) containing (*E*)-5-cyclononen-1-one **22** (94.6%) as a major product, the yield being 72%. The IR and NMR spectra of (*E*)-5-cyclononen-1-one **22** were identical with those of an authentic sample.[14]

*5-Cyclodecen-1-one [**11c**, (E)- and (Z)-Isomers]*: The IR and NMR spectra of **11c** were identical with those of authentic samples.[3]

*5-Cycloundecen-1-one (**11d**)*: Bp 74 °C/1 Torr; $n_D^{25}=1.4904$; IR (neat) 3025, 1718, 1625, 980, 762 cm^{-1}; NMR (CCl_4) δ 1.1—2.6 (m, 16H), 4.88—5.48 (m, 2H); MS *m/e* 166 (M^+). Found: C, 79.93; H, 10.93%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

*5-Cyclopentadecen-1-one (**11e**)*: Mp 28—29 °C; IR (Nujol) 3025, 1720, 970, 739 cm^{-1}; NMR (CCl_4) δ 1.1—2.5 (m, 24H), 5.18—5.34 (m, 2H); MS *m/e* 194 (M^+). Found: C, 81.35; H, 11.76%. Calcd for $C_{15}H_{26}O$: C, 81.01; H, 11.78%.

*5-Cyclohexadecen-1-one [**11f**, (E)-Isomer]*: BP 114 °C/0.1 Torr; mp 11—12.5 °C; $n_D^{20}=1.4883$; IR (neat) 3040, 2940, 2880, 1710, 970 cm^{-1}; NMR (CCl_4) δ 1.1—1.8 (m, 18H), 1.8—2.1 (m, 4H), 2.1—2.4 (m, 4H), 5.18—5.34 (m, 2H). Found: C, 81.27; H, 11.64%. Calcd for $C_{16}H_{28}O$: C, 81.29; H, 11.94%.

*5-Cyclohexadecen-1-one [**11f**, (Z)-Isomer]*: Bp 137 °C/0.5 Torr; mp 36—37 °C, IR (neat) 3040, 2940, 1710, 1460, 720 cm^{-1}; NMR (CCl_4) δ 1.1—1.8 (m, 18H), 1.8—2.1 (m, 4H), 2.2—2.4 (m, 4H), 5.18—5.36 (m, 2H). Found: C, 81.35; H, 11.75%. Calcd for $C_{16}H_{28}O$: C, 81.29; H, 11.94%.

*1-Cyclopropyl-4-penten-1-one (**7**)*. A solution of vinylmagnesium chloride in THF (1.73 mol/l, 120 ml, 208 mmol) was added to a stirred solution of 2-chlorocyclobutanone **1a** (8.34 g, 79.9 mmol) in THF (70 ml) at 0 °C during a period of 2 h. The mixture was heated at 55 °C for 20 h, poured into an aqueous ammonium chloride solution and extracted with ether. The ether extracts were washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled (bp 60—90 °C/20 Torr) to give 5.60 g of oil. The oil was chromatographed on silica gel to give pure **7**. **7**: IR (neat) 3075, 1705, 1642, 1085, 1000, 915 cm^{-1}; NMR (CCl_4) δ 0.5—1.1 (m, 4H), 1.7—2.0 (m, 1H), 2.14—2.44 (m, 2H), 2.44—2.70 (m, 2H), 4.82—5.16 (m, 1H); MS *m/e* 124 (M^+). Found: C, 77.02; H, 9.61%. Calcd for $C_8H_{11}O$: C, 77.37; H, 9.74%.

*1-Cycloundecyl-4-penten-1-one (**8**)*: Bp 116—118 °C/0.3 Torr; $n_D^{25}=1.4873$; IR (neat) 3070, 1710, 1640, 995, 910 cm^{-1}; NMR (CCl_4) δ 1.1—1.8 (m, 20H), 2.2—2.5 (m, 5H), 4.82—5.12 (m, 2H), 5.55—5.96 (m, 1H); MS *m/e* 236 (M^+). Found: C, 81.29; H, 11.93%. Calcd for $C_{16}H_{28}O$: C, 81.27; H, 11.82%.

The Chemical Conversion of the Photo-dimer of 2-Acetyl-5-methyl-1,4-benzoquinone. The Determination of the Regiochemistry of the Dimer

Yo Miyagi,* Kazuhiro Maruyama,† and Sachiko Yoshimoto
Faculty of Education, Kanazawa University, Kanazawa 920

(Received March 21, 1980)

From the photo-dimer (**2a**) of 2-acetyl-5-methyl-1,4-benzoquinone, mono- and diacetyl derivatives and 2,6-dimethyl-1,4,5,8,9-pentaacetoxyphenanthrene (**3**) were prepared. **3** was oxidized to 2,6-dimethyl-1,4,5,8-tetraacetoxy-9,10-phenanthrenequinone (**4**). The acetoxyl groups of **4** were partly deuterated to assign their ^{1}H NMR signals. A series of chemical conversions of **2a** to **4** *via* **3** unambiguously clarified the regiochemistry of **2a**.

Previously we reported[1] that 2-acyl-1,4-benzoquinones (**1**) underwent a regioselective and stereoselective photo-dimerization to give 4aα-acyl-10β-alkyl-5,8-dihydroxy-4aα,10aα-dihydro-1,4,9(10*H*)-phenanthrenetriones (**2**). Although the structure of **2** was finally established by X-ray structure analysis, its regiochemistry had been determined by a certain sequence of reactions, which converted the dimer of **1a**, (**2a**), to a 9,10-phenanthrenequinone (**4**) through a phenanthrene (**3**).[2] This conversion excluded another possible alternative (**2'**), because **2'a** should give **4'** through **3'**. The series of reactions used in this chemical conversion are unusual and worth to describe. In this paper, the details of these unique and interesting reactions will be given.

On treatment with acetic anhydride containing a crop of *p*-toluenesulfonic acid at room temperature for 24 h, **2a** gave a monoacetyl derivative (**5**).[3] When the solution was further left to stand for 24 h after the addition of a small amount of pyridine, a diacetyl derivative (**6**) was obtained. Their structures were straightforward, judging from their ^{1}H NMR spectra: they were similar to that of **2a** except for the presence of a chelated hydroxyl signal of **5** as well as the lack of hydroxyl signals of **6**.

When a solution of **2a** in Ac_2O–pyridine was left standing over 10 d, 2,6-dimethyl-1,4,5,8,9-pentaacetoxyphenanthrene (**3**) was obtained.[4] Some plausible paths of the reactions are shown in Scheme 1. The structure

of **3** was clarified by its elemental analysis and spectroscopic data. The mass spectrum indicated the presence of five acetoxyl groups. The ^{13}C NMR spectrum was compatible with **3**, showing three doublets and eleven singlets of aromatic carbons (Table 1). The ^{1}H NMR spectrum showed complex signals due to methyl and acetoxyl groups between 2.1 and 2.5, though three singlets due to aromatic protons were observed at 7.12,

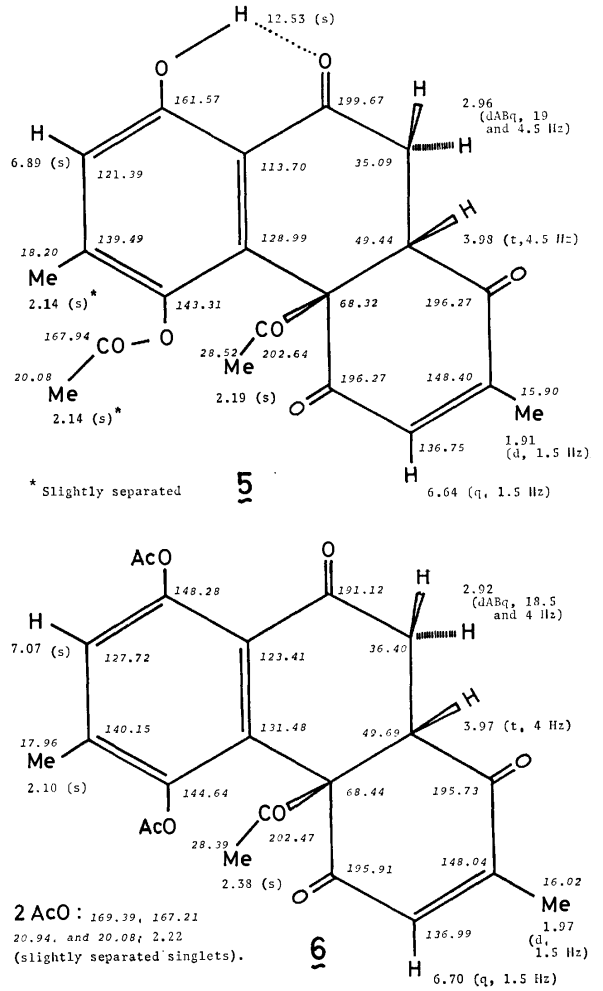

Fig. 1. The ^1H and ^{13}C NMR signals of **5** and **6** in $CDCl_3$ (δ); the ^1H NMR signals of **2a** were shown in Ref. 1; **2a** is not soluble in $CDCl_3$ enough for a ^{13}C NMR measurement and decomposes slowly in acetone.

7.28, and 7.31 in chloroform-*d*. A partially deuterated homologue of **3**, (**3**-d_{15}), was similarly prepared from **2a** with the aid of Ac_2O-d_6. The methyl groups of **3**-d_{15} showed two singlets, at 2.24 and 2.27, in pyridine-d_5; by chance, these singlets arose at the same position (2.30) in chloroform-*d*.

When **3** was oxidized by chromium trioxide, 2,6-dimethyl-1,4,5,8-tetraacetoxy-9,10-phenanthrenequinon (**4**) was obtained. Its ^{13}C NMR spectrum showed two

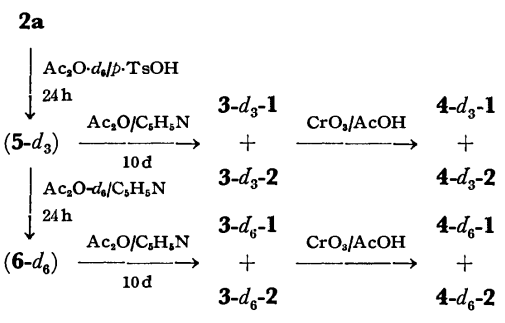
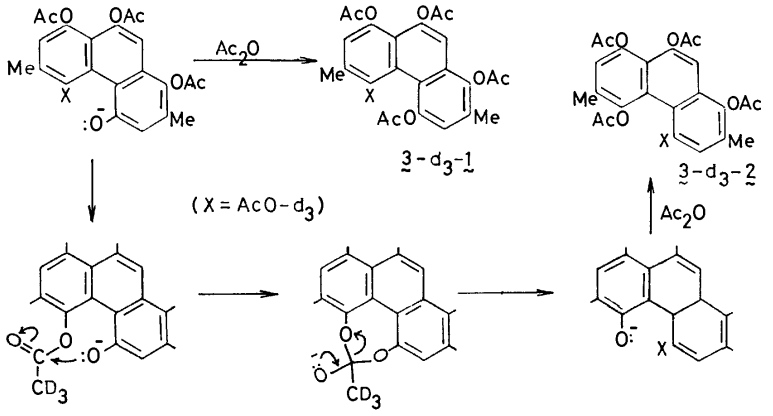
doublets and ten singlets of aromatic carbons and two singlets of quinonoid carbonyl carbons (Table 1).

The ^1H NMR spectrum of **4** in chloroform-*d* showed two singlets[5] due to the aromatic protons at 7.08 and 7.48. In addition, it showed three singlets due to four acetoxyl groups at 2.16, 2.30, and 2.42, and two slightly split singlets due to two methyl groups at 2.27, with the relative-intensity ratio of 1 : 1 : 2 : 2. This assignment was made by a comparison of the spectrum with that of a partially deuterated homologue of **4**, (**4**-d_{12}), which was similarly prepared from **3**-d_{15}; the methyl signals of **4**-d_{12} arose clearly separated at 2.15 and 2.22 in pyridine-d_5. To assign the three singlets at 2.16, 2.30, and 2.42 to the individual acetoxyl groups, partial deuterium labellings of the acetoxyl groups of **4** were undertaken (Scheme 2).



Scheme 2.



Scheme 3.

At first, after letting a solution of **2a** in Ac_2O-d_6–*p*-TsOH stand for 24 h, the concentrated residue[6] (the main component, **5**-d_3) was further treated with Ac_2O–pyridine for 10 d. At this stage, the scrambling of the CD_3CO group between the C-4 and C-5 positions was expected to give a mixture of **3**-d_3-**1** and **3**-d_3-**2**, as is shown in Scheme 3. The mixture thus obtained was oxidized by chromium trioxide to give a mixture of **4**-d_3-**1** and **4**-d_3-**2**, which showed a ^{1}H NMR spectrum in chloroform-*d* identical with that of **4**, with the exception of the decreased intensities of the signals at 2.16 and 2.30. Consequently, these two signals were ascribed to the acetoxyl groups at the C-4 and C-5 positions of **4**.

Secondly, after letting a solution of **2a** in Ac_2O-d_6–*p*-TsOH stand for 48 h, while meanwhile adding a small amount of pyridine, the concentrated residue[6] of the solution (the main component, **6**-d_6) was treated again with Ac_2O–pyridine for 10 d. A scrambling of the CD_3CO group similar to that described above was expected to give a mixture[7] of **3**-d_6-**1** and **3**-d_6-**2**, which was also oxidized to a mixture of **4**-d_6-**1** and **4**-d_6-**2**. The ^{1}H NMR spectrum of the mixture in chloroform-*d* showed the signals at 2.16, 2.30, and 2.42 with decreased intensities. Accordingly, the signal at 2.42 was assignable to two acetoxyl groups at the C-1 and C-8 positions of **4**.

The above spectroscopic studies excluded the reaction sequence of **2'a**→**3'**→**4'**, for the ^{13}C and ^{1}H NMR spectra obtained for **4** were inconsistent with **4'**; **4'** should show a doublet and five singlets of the aromatic carbons and a singlet of the quinonoid carbonyl carbons because of its molecular symmetry, while the ^{1}H NMR spectrum should give a singlet due to the methyl groups, two due to the acetoxyl groups, and one due to the aromatic protons.

Experimental

The Monoacetyl Derivative of ***2a****, 5-Acetoxy-4aα-acetyl-2,6-dimethyl-8-hydroxy-4aα,10aα-dihydro-1,4,9(10H)-phenanthrenetrione (5).* A homogeneous solution was made by occasionally swirling a suspension of **2a** (0.5 g) in acetic anhydride (30 ml) containing a crop of *p*-toluenesulfonic acid. After the solution had stood for 24 h, the solvent was evaporated by bulb-to-bulb distillation through a vacuum-line. The syrupy residue became a semi-solid on standing overnight. After rinsing with benzene, the solid was dissolved in a minimum amount of chloroform. After the addition of petroleum ether, the solution was stored in a refrigerator. Colorless crystals obtained in 10—30% yields gradually melted at 110—130 °C in a vacuum-sealed capillary. Found: C, 64.57; H, 4.66%. Calcd for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%. MS: *m/e* 370 (M^+), 328, 286.

The Diacetyl Derivative of ***2a****, 4aα-Acetyl-5,8-diacetoxy-2,6-dimethyl-4aα,10aα-dihydro-1,4,9(10H)-phenanthrenetrione (6).* After the above solution of **2a** in Ac_2O–*p*-TsOH had stood for 24 h, the solution was left further to stand for 24 h with the addition of pyridine (0.5 ml). Colorless crystals were thereafter obtained in 10—30% yields by the same procedure as above. They melted at 110—130 °C in a vacuum-sealed capillary. Found: C, 63.84; H, 4.76%. Calcd for $C_{22}H_{20}O_8$: C, 64.07; H, 4.89%. MS: *m/e* 412 (M^+), 370, 328, 286.

2,6-Dimethyl-1,4,5,8,9-pentaacetoxyphenanthrene (3). The above solution of **2a** in Ac_2O–pyridine was left standing for 10 d. The solvent was then evaporated by bulb-to-bulb distillation through a vacuum-line. The black semi-solid residue was rinsed with benzene and purified by column chromatography on silica gel (10ϕ × 100 mm; petroleum ether–diethyl ether (1 : 1)). Colorless crystals obtained in 20—40% yields were rectystallized from acetone. Mp 233—234 °C. Found: C, 62.78; H, 4.86%. Calcd for $C_{26}H_{24}O_{10}$: C, 62.90; H, 4.87%. MS: *m/e* 496 (M^+), 454, 412, 370, 328, 286. ^{1}H NMR: δ ($CDCl_3$) 2.18 (3H, s, AcO), 2.32 (6H, two slightly split s, 2 Me), 2.37 (9H, m, 3 AcO), 2.44 (3H, s, AcO), 7.12 (1H, s, ArH), 7.18 (1H, s, ArH), 7.32 (1H, s, ArH).

2,6-Dimethyl-1,4,5,8-tetraacetoxy-9,10-phenanthrenequinone (4). **3** (0.3 g) was dissolved in acetic acid (10 ml) by slight warming. CrO_3 (0.5 g) was dissolved in a minimum amount of water and diluted with acetic acid (5 ml). The CrO_3 solution was added dropwise to the solution of **3** over 1 h at 15 °C. After stirring for an additional hour, the solution was poured into water. The product was immediately extracted with choroform, washed, dried, and concentrated. The solid residue was dissolved in benzene (30 ml), while an amorphous solid remained undissolved. The yellow supernatant was concentrated to a solid, which was dissolved again in benzene. The yellow crystals obtained by repeating this procedure were rinsed with dry acetone and then washed with hot ligroine. Yield, 20—30%; mp 259—264 °C (in a vacuum-sealed capillary; softening, 240 °C). Recrystallization from hot solvents was unsuccessful because of decomposition. Found: C, 61.29; H, 4.15%. Calcd for $C_{24}H_{20}O_{10}$: C, 61.54; H, 4.30%. MS: *m/e* 468 (M^+), 426, 384, 342, 300. ^{1}H NMR:

δ ($CDCl_3$) 2.16 (3H, s, AcO), 2.27 (6H, slightly separated s, 2 Me), 2.30 (3H, s, AcO), 2.42 (6H, s, 2 AcO), 7.08 (1H, s,[5] ArH), 7.48 (1H, s,[5] ArH); δ (pyridine-d_5) 2.15 (6H, s, AcO and Me), 2.22 (3H, d, J=0.7 Hz, Me), 2.32 (3H, s, AcO), 2.38 (6H, s, 2 AcO), 7.68 (1H, s,[5] ArH[8]).

2,6-Dimethyl-1,4,5,8,9-penta(acetoxy-d_3)phenantherene (3-d_{15}). It was prepared from **2a** using Ac_2O-d_6 by the same method as that used for **3**, and it gave satisfactory results in mass analysis; ^{1}H NMR: δ ($CDCl_3$) 2.30 (6H, s, 2 Me), 7.09 (1H, s, ArH), 7.15 (1H, s, ArH), 7.30 (1H, s, ArH); δ (pyridine-d_5) 2.24 (3H, s, Me), 2.27 (3H, s, Me), 7.36 (1H, s, ArH), 7.52 (1H, s, ArH[8]).

2,6-Dimethyl-1,4,5,8-tetra(acetoxy-d_3)-9,10-phenanthrenequinone (4-d_{12}). It was prepared from **3**-d_{15} by the same method as that used for **4**, and it gave satisfactory results in mass analysis; ^{1}H NMR: δ ($CDCl_3$) 2.27 (6H, s, 2 Me), 7.04 (1H, s,[5] ArH), 7.48 (1H, s,[5] ArH); δ (pyridine-d_5) 2.15 (3H, s, Me), 2.22 (1H, s, Me), 7.70 (1H, s, ArH[8]).

The Partially Deuterated Homologues of 3 and 4, (3-d_3-1+3-d_3-2), (3-d_6-1+3-d_6-2), (4-d_3-1+4-d_3-2), and (4-d_6-1+4-d_6-2). These were prepared by the method described in the preceding section.

NMR measurements were made with a JEOL JNM-PS 100 spectrometer. We wish to thank Dr. Y. Itatani, Faculty of Pharmaceutical Sciences, Kanazawa University, for the NMR measurements and for his valuable discussions.

1) Y. Miyagi, K. Maruyama, H. Ishii, S. Mizuno, M. Kakudo, N. Tanaka, Y. Matsuura, and S. Harada, *Bull. Chem. Soc. Jpn.*, **52**, 3019 (1979).

2) Y. Miyagi, K. Kitamura, K. Maruyama, and Y. L. Chow, *Chem. Lett.*, **1978**, 33.

3) By the same procedure, **2** (R=Me, Y=Cl) gave the monoacetyl derivative corresponding to **5**.[1]

4) Similarly, 1,4,5,8,9-pentaacetoxyphenanthrene (mp 192—194.5 °C) and 10-methyl-1,4,5,8,9-pentaacetoxyphenanthrene (mp 190—193 °C) were obtained from **2** (R=Y=H) and **2** (R=Me, Y=H) respectively. The mass spectroscopic analysis of the latter phenenthrene indicated the contamination with methyl(propanoyloxy)tetraacetoxyphenanthrene, which supports the reaction mechanism of Scheme 1: acetic propionic anhydride and a phenanthrolate are formed by the Retro-Cleisen condensation, and the reaction between them gives the third phenanthrene and an acetate anion.

5) They seemed to be quartets in expanded measurements.

6) Because the isolation of the partially deuterated products (**3**-d_3 and **4**-d_6) in each step did not produce yields good enough to obtain the final products, the concentrated residue was submitted to further reactions. The evaporation of the solvent was effected by bulb-to-bulb distillation through a vacuum-line.

7) The complex signals of **3** at 2.37 did not become enough simpler to assign them to the individual acetoxyl groups by deuteration.

8) The signal of another aromatic proton might be behind the signals of the residual protons of pyridine.

Total Synthesis of Furanoeremophilane and 14-Norfuranoeudesmane Derivatives by a Route Involving Alkylation of 2,4-Dimethyl-3-furoic Acid[1]

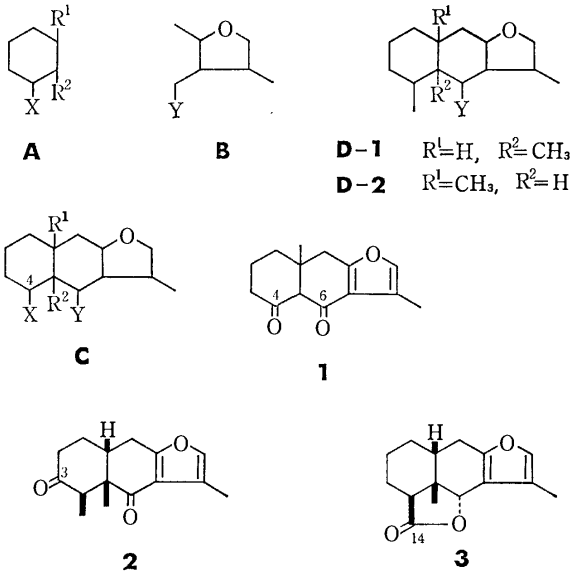
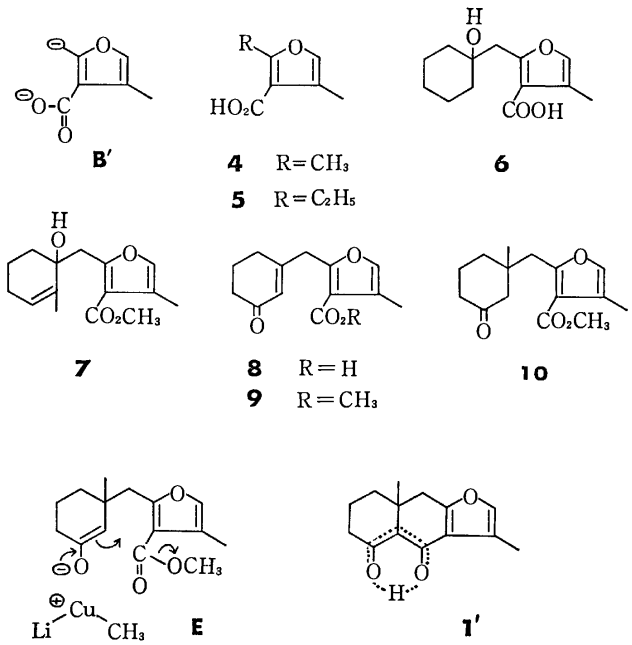
(Received March 26, 1980)

(±)-14-Norfuranoeudesmane-4,6-dione, (±)-furanoeremophilane-3,6-dione, and (±)-furanoeremophilan-14, 6α-olide were synthesized by a route involving alkylation of a dianion obtained from 2,4-dimethyl-3-furoic acid.

Various types of sesquiterpenes possessing a furan or γ-lactone moiety have been isolated from many species of higher and lower plants.[2] Although the true mechanism of biogenetical formation of a γ-lactone ring of sesquiterpenes is not clarified, furan ring is considered to be a possible precursor of the γ-lactone ring.[3] In fact oxidation of the furan ring with peracid[4] or oxygen[5] gives a γ-lactone ring. A number of syntheses of sesquiterpene lactones have been reported, but only a few of furanosesquiterpenes have been described.[6] We have undertaken the construction of furanoeremophilane- and furanoeudesmane-frameworks by combination of two moieties, **A** and **B**, to give **C**, successive transform ation of the substituent (X) into methyl group leading to furanoeremophilane- (**D-1**) and furanoeudesmane-skeletons (**D-2**), and the corresponding γ-lactones being derived from these furans. This paper deals with the synthesis of (±)-14-norfuranoeudesmane-4,6-dione (**1**), (±)-furanoeremophilane-3,6-dione (**2**),[7a] and (±)-furanoeremophilan-14,6α-olide (**3**).[8]



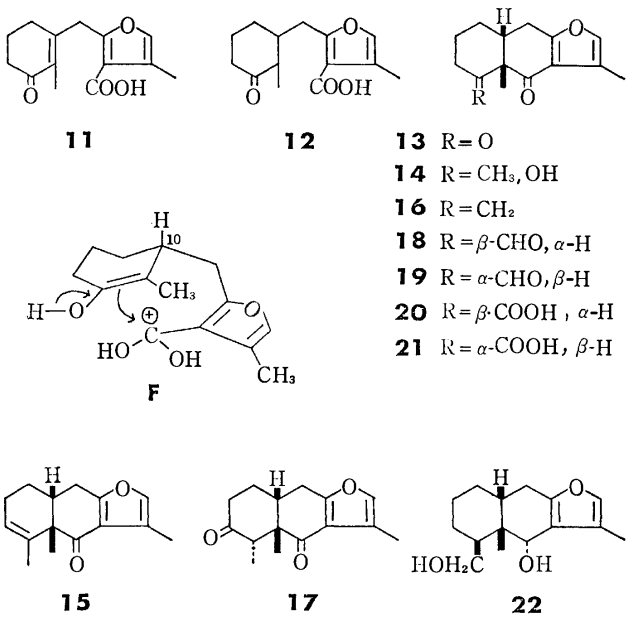
A dianion (**B'**) generated from 2,4-dimethyl-3-furoic acid (**4**) was used as a synthon corresponding to **B**. Treatment of 2,4-dimethyl-3-furoic acid (**4**)[9] with two equivalent mole of lithium diisopropylamide in a mixture of tetrahydrofuran and hexane (9: 2) at −78 °C gave an orange homogeneous solution. Alkylation of the dianion (**B'**) was then studied. The orange solution was quenched with one equivalent mole of methyl iodide at 0 °C and acidified with hydrochloric acid to give 2-ethyl-4-methyl-3-furoic acid (**5**) in 96% yield, suggesting a dianion nature for **B'**. Similar alkylation of **B'** with cyclohexanone gave a hydroxy acid (**6**) in 80% yield. Treatment of **B'** with 2-methyl-2-cyclohexen-1-one gave a 1,2-addition product in 70% yield, identified as its methyl ester (**7**). Although 1.1 or 2.5 equivalent moles of copper(I) iodide was added to **B'** before alkylation, the same 1,2-addition product was obtained as the main product.



(±)-14-Norfuranoeudesmane-4,6-dione. The dianion **B'** was treated with 3-methoxy-2-cyclohexen-1-one and then acidified with hydrochloric acid to give an acid (**8**) in 78% yield. The acid (**8**) should be formed by concomitant dehydration of the addition product. Treatment of an ester (**9**) derived from **8** with lithium dimethylcuprate(I) at 0 °C for 45 h gave (±)-14-norfuranoeudesmane-4,6-dione (**1**) in 73% yield, *via* an intermediate anion (**E**) which underwent cyclization. When the reaction was carried out for 3 h, a keto ester (**10**) and **1** were obtained in 71 and 26% yields, respectively. The ^{1}H-NMR spectrum of the diketone (**1**) shows that **1** in deuteriochloroform exists in equilibrium between **1** and an enol ketone (**1'**) in the ratio 3: 7.

(±)-Furanoeremophilane-3,6-dione. (±)-Furanoeremophilane-3,6,9-trione and (±)-furanoeremophilane-3,6-dione[7a] (**2**) have been synthesized from resorcinol by Yamakawa and Satoh,[6a] *via* a diene adduct of 3,5-dimethylbenzofuran-4,7-dione and 3-ethoxy-1,3-pentadiene in overall yields of *ca.* 5 and *ca.* 4%, respectively. Synthesis of **2** starting from **4** was carried out as follows.

Alkylation of the dianion (**B'**) with 3-methoxy-2-methyl-2-cyclohexen-1-one gave an acid (**11**) in 74% yield, which was hydrogenated over 5% palladium–charcoal in ethanol to afford its dihydro derivative (**12**) quantitatively. The acid (**12**) was cyclized by treatment with *p*-toluenesulfonic acid in diphenyl ether under reflux to give 14-norfuranoeremophilane-4,6-dione (**13**) in 44% yield as the sole product. A *cis* A/B ring juncture was observed for **13** by its conversion into **2**. Preferential attack of the intermediate cation produced from **12** should be accomplished from the side opposite to the hydrogen atom at C-10 to give **13** as depicted in **F**.



The diketone (**13**) was methylated regioselectively with 1.2 equivalent moles of methyllithium in ether at −78 °C for 1 h, giving 4-hydroxy 4-methyl ketone (**14**) in 99% yield. Dehydration of **14** with phosphoryl chloride in pyridine under reflux gave a mixture of olefins, which was separated by preparative thin-layer chromatography to afford an *endo*-olefin (**15**) in 69% yield and an *exo*-olefin (**16**) in 12% yield. The *endo*-olefin (**15**) was subjected to hydroboration with diborane in tetrahydrofuran at 0 °C and then alkaline hydrogen peroxide oxidation to give a mixture of alcohols. This mixture was oxidized, without further purification, with pyridinium chlorochromate[10] in dichloromethane to give (±)-furanoeremophilane-3,6-dione (**2**)[6a,7a] in 4% yield and (±)-4β*H*-furanoeremophilane-3,6-dione (**17**)[6a] in 78% yield. Isomerization of **17** into **2** was effected in refluxing benzene containing a catalytic amount of *p*-toluenesulfonic acid in 94% yield.[6a] (±)-Furanoeremophilane-3,6-dione (**2**) was synthesized from **4** in 7 steps in an overall yield of 17%.

Since the dione (**2**) has been converted into (±)-ligularone[11] (furanoeremophilan-6-one), (±)-ligularol[11] (petasablin; furanoeremophilan-6β-ol), and (±)-furanofukinol[7] (furanoeremophilane-3β,6β-diol) by Yamakawa and Satoh,[6] the synthesis of **2** indicates the formal total synthesis of these furanoeremophilane derivatives.

(±)-Furanoeremophilan-14,6α-olide. Furanoeremophilan-14,6α-olide (**3**) has been isolated from *Ligularia Hodgsoni* Hook, f.[8] Synthesis of the furanoeremophilane with an extra γ-lactone ring was studied.

The Wittig reaction of (±)-14-norfuranoeremophilane-4,6-dione (**13**) with methylenetriphenylphosphorane in tetrahydrofuran at room temperature proceeded regioselectively to give the *exo*-olefin (**16**) in 45% yield besides unchanged **13**. The olefin (**16**) was subjected to hydroboration with diborane in tetrahydrofuran and then alkaline hydrogen peroxide oxidation. The product, without further purification, was oxidized with pyridinium dichromate (PDC)[12] in *N,N*-dimethylformamide at room temperature to give a mixture of aldehydes and carboxylic acids, which was separated by preparative thin-layer chromatography, giving 6-oxofuranoeremophilan-14-al (**18**) in 3% yield, 6-oxo-4β*H*-furanoeremophilan-14-al (**19**) in 46% yield, 6-oxofuranoeremophilan-14-oic acid (**20**) in 10% yield, and 6-oxo-4β*H*-furanoeremophilan-14-oic acid (**21**) in 7% yield.

The stereochemistry at C-4 of **18** and **20** was determined to be 4α*H* based on the formation of **18** and **20** on oxidation of known furanoeremophilane-14,6α-diol (**22**)[8] with PDC in *N,N*-dimethylformamide. This led to 4β*H*-configuration for **19** and **21**. A preferential attack of borane to the olefin (**16**) occurred from the less hindered β-side to give **19** and **21**. Both **19** and **21** were found to be stable on acid (*p*-TsOH–PhH, under reflux) and alkaline (KOH–MeOH, under reflux) treatment. On treatment with potassium hydroxide in methanol at room temperature, **18** isomerized into **19**. Thus the conversion of **19** (or **21**) into **18** (or **20**) with desired 4α*H*-configuration was unsuccessful. Finally, reduction of **20** with lithium borohydride in tetrahydrofuran followed by acidification with acetic acid afforded (±)-furanoeremophilan-14,6α-olide (**3**)[8] in 71% yield. The overall yield of **3** from **13** was 3%. This constitutes the first total synthesis of **3**.

In conclusion, two key intermediates, 14-norfuranoeudesmane-4,6-dione (**1**) and 14-norfuranoeremophilane-4,6-dione (**13**), were obtained from **4** in 56 and 32.5% yields, respectively; **2**, **15**, and **16** were derived from **13** in reasonable yields. This presents a useful route for the synthesis of sesquiterpene lactones and furans of an eudesmane- and an eremophilane-type with oxygenated functional groups on C-3, C-4, C-6, C-14, *etc.*

Experimental

Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncor-

rected. IR spectra were measured with a Hitachi EPI-G2 or a Hitachi 260-30 spectrometer, ^{1}H-NMR spectra with a Hitachi R-20B (60 MHz) or a Varian EM-390 (90 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, low resolution mass spectra with a Hitachi RMU-6-Tokugata mass spectrometer at 70 eV with a direct inlet system and high resolution mass spectra with a JEOL JMS-D300 mass spectrometer; the relative peak intensities in the mass spectra are given in parentheses. Thin-layer chromatography was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness for analytical use and 0.5 mm thickness for preparative use. Wakogel C-200 and Florisil "mesh 100—200" (Wako Pure Chemical Industries) were used for column chromatography. All experiments were carried out under nitrogen atmosphere.

Alkylation of 2,4-Dimethyl-3-furoic Acid (4) with Methyl Iodide, Cyclohexanone, and 2-Methyl-2-cyclohexen-1-one. Butyllthium (4.2 mmol) in hexane (2.8 ml) was added to a solution of diisopropylamine (0.6 ml; 4.2 mmol) in dry tetrahydrofuran (15 ml) with cooling in an ice-bath. After being stirred at room temperature for 20 min, the solution was cooled to −78 °C and then treated with 2,4-dimethyl-3-furoic acid (**4**; 280 mg, 2 mmol) in tetrahydrofuran for 30 min, the color of the solution turning to orange due to formation of the dianion (**B′**).

Methyl iodide (0.14 ml; 2.2 mmol) was added to the dianion solution, and the solution was stirred at 0 °C for 1 h. The orange color of the dianion solution disappeared almost immediately. After addition of water, the mixture was acidified with hydrochloric acid and extracted with ether. The ethereal solution was washed with brine, dried ($MgSO_4$) and evaporated. The residue was purified by sublimation (100 °C, 3 mmHg) to give **5** (296 mg) in 96% yield. 2-Ethyl-4-methyl-3-furoic acid (**5**): mp 69.5—70.5 °C; IR (Nujol) *ca.* 3000 (broad) and 1680 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.25 (3H, t, J=7 Hz), 2.15 (3H, d, J=1.5 Hz), 3.00 (2H, q, J=7 Hz), and 7.03 (1H, m). Found: *m/e* 154.0640. Calcd for $C_8H_{10}O_3$: M, 154.0630.

Cyclohexanone (0.23 ml) was added to a solution of dianion **B′** (2 mmol) (*vide supra*) at 0 °C. After being stirred for 30 min at 0 °C, a 10% sodium hydrogencarbonate solution was added to the reaction mixture and the mixture was extracted with ether. The ethereal solution was further treated with a 10% sodium hydrogencarbonate solution. The combined aqueous solution was acidified with hydrochloric acid and extracted with ether. The ethereal solution was treated in the usual way to give a residue which was chromatographed on a column of silica gel (20 g). Elution with hexane–ether gave **6** (380 mg) in 80% yield. 4-Methyl-2-(1-hydroxycyclohexylmethyl)-3-furoic acid (**6**): an oil; IR (neat) *ca.* 3500 (broad), *ca.* 3000 (broad), and 1680 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 2.12 (3H, d, J=1.2 Hz), 3.16 (2H, s), 7.14 (1H, m), and *ca.* 7.5 (2H, broad signal). Found: *m/e* 238.1224. Calcd for $C_{13}H_{18}O_4$: M, 238.1206.

The solution of dianion **B′** (2 mmol) (*vide supra*) was treated with 2-methyl-2-cyclohexen-1-one (2.1 mmol) at 0 °C for 20 min. The reaction mixture was treated as in the preparation of **6**, giving a carboxylic acid, which was methylated with diazomethane. The product was purified by column chromatography (silica gel) to give **7** (365 mg) in 70% yield. Methyl 4-methyl-2-(1-hydroxy-2-methyl-2-cyclohexenylmethyl)furan-3-carboxylate (**7**): an oil; IR (neat) *ca.* 3450 (broad) and 1710 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.83 (3H, broad signal), 2.13 (3H, d, J=1.2 Hz), 3.03 (1H, d, J=14.5 Hz), 3.53 (1H, d, J=14.5 Hz), 3.84 (3H, s), 5.50 (1H, m), and 7.11 (1H, m). Found: *m/e* 264.1350. Calcd for $C_{15}H_{20}O_4$: M, 264.1360.

When 1.1 equivalent mole (420 mg) or 2.5 equivalent mole (1 g) of copper(I) iodide was added to the solution of **B′** before the treatment with 2-methyl-2-cyclohexen-1-one, the same 1,2-addition product was obtained as the main product identified as its methyl ester (**7**).

Methyl 4-Methyl-2-(3-oxo-1-cyclohexenylmethyl)furan-3-carboxylate (9). 3-Methoxy-2-cyclohexen-1-one (1.8 g; 14 mmol) in tetrahydrofuran (5 ml) was added at 0 °C to a solution of dianion **B′**, prepared by treatment of **4** (1.96 g, 14 mmol) in tetrahydrofuran (15 ml) with lithium diisopropylamide (33 mmol) in tetrahydrofuran (90 ml)–hexane (22 ml) (*vide supra*). After being stirred at 0 °C for 1 h, water was added to the reaction mixture and the mixture was acidified with hydrochloric acid and extracted with ether. The ethereal solution was washed with brine, dried, and evaporated. The residue was chromatographed on a column of silica gel (100 g, elution with hexane–ether) to give **8** as yellow crystals (2.55 g) in 78% yield. Crystallization from hexane–ether gave pure **8**. 4-Methyl-2-(3-oxo-1-cyclohexenylmethyl)-3-furoic acid (**8**): mp 89—91 °C; IR ($CDCl_3$) *ca.* 3100 (broad), 1710, 1670, and 1615 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 2.18 (3H, d, J=1.2 Hz), 3.94 (2H, broad singlet), 5.85 (1H, m), 7.15 (1H, m), and *ca.* 10.2 (1H, broad signal). Found: *m/e* 234.0888. Calcd for $C_{13}H_{14}O_4$: M, 234.0891.

The carboxylic acid (**8**) was treated with diazomethane in ether to give a methyl ester (**9**). Methyl 4-methyl-2-(3-oxo-1-cyclohexenylmethyl)furan-3-carboxylate (**9**): an oil: IR (neat) 1725, 1670, 1625, and 1610 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 2.15 (3H, d, J=1.5 Hz), 3.82 (3H, s), 3.88 (2H, s), 5.78 (1H, m), and 7.12 (1H, m). Found: *m/e* 248.1057. Calcd for $C_{14}H_{16}O_4$: M, 248.1049.

14-Norfuranoeudesmane-4,6-dione (1). The ester (**9**) (310 mg; 1.25 mmol) in ether was added to a solution of lithium dimethycuprate (I) (3.8 mmol) in ether at 0 °C to form a yellow suspension. This was stirred at 0 °C for 45 h. The mixture was acidified with 2 M hydrochloric acid, stirred at room temperature for 1 h, and then extracted 6 times with ether. The combined ethereal solution was washed with a 5% sodium sulfite solution and brine, dried, and evaporated. The residue was purified by chromatography on a column of silica gel (20 g, elution with hexane–ether) to give **1** (213 mg) in 73% yield. Crystallization from hexane–ether gave pure **1**. (±)-14-Norfuranoeudesmane-4,6-dione (**1**): mp 91.5—93 °C; IR (KBr) *ca.* 2960 and 1612 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.18 (3H, s), 2.23 (3H, d, J=1.8 Hz), 2.69 (2H, s), 3.82 (0.3H, s), 7.07 (1H, m), and 15.26 (0.7H, s). Found *m/e* 232.1108. Calcd for $C_{14}H_{16}O_3$: M, 232.1100.

When the reaction was carried out for 3 h and interrupted by addition of hydrochloric acid, the reaction product from **9** (290 mg) gave, after separation by column chromatography, a keto ester (**10**, 220 mg) and **1** (70 mg) in 71 and 26% yields, respectively. Methyl 4-methyl-2-(1-methyl-3-oxocyclohexylmethyl)furan-3-carboxylate (**10**): an oil; IR (neat) 1720 (broad) cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.97 (3H, s), 2.15 (3H, d, J=1.2 Hz), 3.51 (2H, broad singlet), 3.83 (3H, s), and 7.16 (1H, m). Found: *m/e* 264.1348. Calcd for $C_{15}H_{20}O_4$: M, 264.1360.

4-Methyl-2-(2-methyl-3-oxo-1-cyclohexenylmethyl)-3-furoic Acid (11). 3-Methoxy-2-methyl-2-cyclohexen-1-one (1.80 g, 12.3 mmol) was added to the solution of dianion **B′** (14 mmol) (*vide supra*) at 0 °C and the mixture was stirred for 1 h. The reaction mixture was poured into water, acidified with hydrochloric acid and extracted with ether. The ethereal solution was treated in the usual way to give a residue, which was chromatographed on a column of silica gel (150 g). Elution with hexane–ether (1 : 1) afforded a carboxylic acid (**11**; 2.55 g) in 74% yield. 4-Methyl-2-(2-methyl-3-oxo-1-cyclohexenyl-

methyl)-3-furoic acid (**11**): mp 115—116 °C (crystallized from hexane–ether); IR (Nujol) 1670, 1602, and 1557 cm^{-1}; IR ($CHCl_3$) 1680 and 1660 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.90 (3H, s), 2.00 (3H, d, J=2 Hz), 4.03 (2H, s), 6.85 (1H, broad signal), and 7.10 (1H, m); MS *m/e* 248 (M^+; 100), 175 (43), 149 (34), 109 (85), and 53 (60). Found: C, 67.47; H, 6.64%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

Hydrogenation of the Carboxylic Acid (11). The carboxylic acid (**11**; 1 g) in ethanol (50 ml) was hydrogenated in the presence of 5% palladium–charcoal (*ca.* 150 mg) at room temperature for 4 h. After filtration of the catalyst, the solvent was removed to give a dihydro derivative (**12**; 1 g) in quantitative yield. 4-Methyl-2-(2-methyl-3-oxocyclohexylmethyl)-3-furoic acid (**12**): mp 123—127 °C (crystallized from hexane–ether); IR (Nujol) 1700, 1678, 1598, and 1550 cm^{-1}; IR ($CHCl_3$) 1710 and 1680 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.16 (3H, d, J=6 Hz), 2.17 (3H, d, J=2 Hz), 2.94 (1H, dd, J=18 and J=8 Hz), 3.31 (1H, dd, J=18 and J=5 Hz), 7.07 (1H, m), and 7.36 (1H, broad signal; disappeared on addition of D_2O); MS *m/e* 250 (M^+; 26), 178 (57), 122 (74), and 111 (100). Found: C, 67.11; H, 7.51%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

Cyclization of the Dihydro Carboxylic Acid (12). The dihydro carboxylic acid (**12**; 270 mg) was dissolved in diphenyl ether (20 ml) containing *p*-toluenesulfonic acid (*ca.* 50 mg), and the mixture was refluxed under a Dean-Stark water separator for 3.5 h. The reaction mixture was extracted with ether. The etheral solution was washed with a 5% aqueous sodium hydroxide solution and brine, dried, and evaporated to give an oil, which was chromatographed on a column of silica gel (20 g). Fractions eluted with hexane–ether (1 : 1) were combined and subjected to purification by chromatography under the same conditions as mentioned above to give **13** (111 mg) in 44% yield. (±)-14-Norfuranoeremophilane-4,6-dione (**13**): mp 105.5—106 °C (crystallized from ether); IR (Nujol) 1715, 1665, 1608, and 1565 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.37 (3H, s), 2.19 (3H, d, J=2 Hz), 2.70 (1H, dd, J=18 and J=2 Hz), 3.22 (1H, dd, J=18 and J=6 Hz), and 7.18 (1H, m); MS *m/e* 232 (M^+; 16), 122 (100), and 94 (30). Found: C, 72.22; H, 7.04%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%.

Methylation of 14-Norfuranoeremophilane-4,6-dione (13). 14-Norfuranoeremophilane-4,6-dione (**13**; 127 mg) in ether (20 ml) was treated with methyllithium (0.6 mmol) in ether (1.2 ml) at −78 °C for 1 h. The reaction mixture was poured into water and extracted with ether. The ethereal solution was treated in the usual way to give a hydroxy ketone (**14**; 134 mg) in 99% yield. The product showed one spot on thin-layer chromatogram and ^{1}H-NMR methyl signals corresponding to one configurational isomer. However, the configuration at C-4 remained undetermined. 4ξ-Hydroxyfuranoeremophilan-6-one (**14**): mp 115—116.5 °C (crystallized from hexane); IR (Nujol) 3450, 1648, 1608, and 1565 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.21 and 1.37 (each 3H, s), 2.18 (3H, d, J=2 Hz), 2.53 (1H, dd, J=18 and J=2 Hz), 3.16 (1H, dd, J=18 and J=6 Hz), 5.74 (1H, s-like; disappered on addition of D_2O), and 7.13 (1H, m); MS *m/e* 248 (M^+; 27), 205 (16), 163 (100), and 135 (30). Found: C, 72.35; H, 8.35%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Dehydration of the Hydroxy Ketone (14). Phosphoryl chloride (0.3 ml) was added dropwise to a solution of the hydroxy ketone (**14**; 113 mg) in pyridine (5 ml) and the mixture was heated under reflux for 2 h. The reaction mixture was poured into ice water, and the product was extracted with ether. The ethereal solution was treated in the usual way to give a residue, which was subjected to separation by preparative thin-layer chromatography [developed with hexane–ether (4 : 1)] to give an *endo*-olefin (**15**; 73 mg; R_f 0.53) in 69% yield and an *exo*-olefin (**16**; 13 mg; R_f 0.47) in 12% yield. Furanoeremophil-3-en-6-one (**15**): mp 69—69.5 °C (crystallized from hexane); IR (Nujol) 1675, 1610, and 1565 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.39 (3H, s), 1.73 (3H, d, J=2 Hz), 2.17 (3H, d, J=2 Hz), 2.74 and 2.98 (each 1H, dd, J=18 and J=6 Hz), 5.49 (1H, m), and 7.10 (1H, m); MS *m/e* 230 (M^+; 23), 122 (100), and 94 (31). Found: C, 78.14; H, 7.93%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%. Furanoeremophil-4(14)-en-6-one (**16**): an oil; IR (neat) 1675, 1615, 1568, and 902 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.39 (3H, s), 2.20 (3H, d, J=2 Hz), 2.61 (1H, dd, J=18 and J=3 Hz), 3.14 (1H, dd, J=18 and J=6 Hz), 4.79 and 5.00 (each 1H, s), and 7.13 (1H, m); MS *m/e* 230 (M^+; 25), 122 (100), and 94 (41). Found: C, 78.50; H, 8.14%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

(±)-Furanoeremophilane-3,6-dione (2). A solution of diborane (0.8 mmol) in tetrahydrofuran (0.4 ml) was added to a solution of the *endo*-olefin (**15**; 67 mg) in tetrahydrofuran (10 ml) at 0 °C. The mixture was stirred at 0 °C for 1.5 h and then at room temperature for 30 min to complete the reaction. Excess of the reagent was destroyed by careful addition of water (0.5 ml). After addition of a 3 M aqueous sodium hydroxide solution (0.2 ml), hydrogen peroxide (30%, 0.2 ml) was added dropwise to the mixture with stirring at a rate such that the temperature of the reaction mixture did not exceed *ca.* 40 °C. The reaction mixture was then heated at 40—50 °C and maintained in this temperature range for 30 min to complete the oxidation reaction. The reaction mixture was treated in the usual way to give an oil, which, without further purification, was oxidized with pyridinuim chlorochromate (PCC,[10] 356 mg) in dichloromethane (1.5 ml) at room temperature for 5 h. After addition of 2-propanol (1 ml) in order to destroy excess of the oxidant, the reaction mixture was passed through a column of Florisil, the solvent being removed by evaporation. The residue was subjected to separation by preparative thin-layer chromatography [developed with hexane–ether (1: 9)] to give **2** (3.1 mg; R_f 0.54) in 4% yield and **17** (56.2 mg; R_f 0.45) in 78% yield. (±)-Furanoeremophilane-3,6-dione (**2**):[6a] mp 176—177 °C (crystallized from hexane–ether): IR (Nujol) 1710, 1660, 1605, and 1565 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 0.92 (3H, d, J=7 Hz), 1.12 (3H, s), 2.18 (3H, d, J=2 Hz), 2.91 (1H, dd, J=18 and J=6 Hz), 3.27 (1H, dd, J=18 and J=10 Hz), and 7.11 (1H, m); MS *m/e* 246 (M^+; 31), 122 (100), and 94 (17). Found: C, 73.02; H, 7.52%. Calcd for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%. The compound was found to be identical with (±)-furanoeremophilane-3,6-dione (**2**) prepared by Yamakawa and Satoh.[6a] (±)-4βH-Furanoeremophilane-3,6-dione (**17**):[6a] mp 119.5—120 °C (crystallized from hexane–ether); IR (Nujol) 1705, 1665, 1604, and 1560 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.37 (3H, d, J=7 Hz), 1.14 (3H, s), 2.12 (3H, d, J=2 Hz), 2.71 (1H, dd, J=18 and J=6 Hz), 3.30 (1H, dd, J=18 and J=5 Hz), and 7.07 (1H, m); *m/e* 246 (M^+; 22), 122 (100), and 94 (25). Found: C, 72.87; H, 7.55%. Calcd for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%.

Isomerization of 4βH-Furanoeremophilane-3,6-dione (17). According to the procedure of Yamakawa and Satoh,[6a] the diketone (**17**; 43.3 mg) dissolved in benzene (6 ml) containing *p*-toluenesulfonic acid (8 mg) was treated under reflux for 1 h. The crude product mixture was subjected to separation by preparative thin-layer chromatography [developed with hexane–ether (1 : 9)] to give **2** (40.5 mg) in 94% yield and unchanged **17** (2.2 mg).

Wittig Reaction of 14-Norfuranoeremophilane-4,6-dione (1). Butyllithium (7.3 mmol) in hexane (4.7 ml) was added to a solution of methyltriphenylphosphonium iodide (3.02 g; 7.5

mmol) in dry tetrahydrofuran (120 ml) at room temperature, and the mixture was stirred for 6.5 h. The diketone (**1**; 324 mg) in tetrahydrofuran (10 ml) was then added to this solution, the mixture being stirred for 11 h. The reaction mixture was treated in the usual way to give a residue, which was chromatographed on a column of silica gel (60 g). Elution with hexane–ether (4 : 1) gave furanoeremophil-4(14)-en-6-one (**16**; 146 mg) in 45% yield and the unchanged diketone (**1**; 56 mg).

Hydroboration and Successive Oxidation of Furanoeremophil-4(14)-en-6-one (16). The *exo*-olefin (**16**; 85 mg) in tetrahydrofuran (10 ml) was subjected to hydroboration with diborane (3.6 mmol) in tetrahydrofuran (3.6 ml) at room temperature for 1 h. Excess of the reagent was destroyed by addition of water (1 ml). After addition of a 3 M aqueous sodium hydroxide solution (0.4 ml) and hydrogen peroxide (30%, 0.4 ml), the mixture was heated at 40—50 °C for 30 min. The reactions mixture was treated in the usual way to give a residue, which was oxidized with pyridinium dichromate (PDC,[12] 1.0 g) in *N,N*-dimethylformamide at room temperature for 2 d. The reaction mixture was poured into water and extracted with ether. The ethereal solution was treated in the usual way to give a residue, which was subjected to separation by preparative thin-layer chromatography (developed with ether) to afford **18** (2.7 mg, R_f 0.89) in 3% yield, **19** (41.6 mg; R_f 0.79) in 46% yield, **20** (9.3 mg, R_f 0.71) in 10% yield, and **21** (7 mg; R_f 0.57) in 7% yield. 6-Oxofuranoeremophilan-14-al (**18**): an oil; IR (neat) 1720, 1670, and 1563 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.38 (3H, s), 2.18 (3H, d, J=2 Hz), 2.57 (1H, dd, J=18 and J=3 Hz), 3.15 (1H, dd, J=18 and J=6 Hz), 3.23 (1H, t, J=4 Hz), 7.08 (1H, m), and 9.84 (1H, d, J=2 Hz); MS *m/e* 246 (M^+; 0.1), 122 (100), and 94 (42). Found: *m/e* 246.1257. Calcd for $C_{15}H_{18}O_3$: M, 246.1254. 6-Oxo-4βH-furanoeremophilan-14-al (**19**): an oil; IR (neat) 1715, 1662, 1608, and 1562 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.50 (3H, s), 2.15 (3H, d, J=2 Hz), 2.54 (1H, dd, J=18 and J=1.5 Hz), 3.32 (1H, dd, J=18 and J=6 Hz), 3.44 (1H, t, J=7 Hz), 7.03 (1H, m), and 10.04 (1H, s); MS *m/e* 246 (M^+; 1), 232 (35), 218 (13), 122 (100), and 94 (16). Found: *m/e* 246.1249. Calcd for $C_{15}H_{18}O_3$: M, 246.1254. 6-Oxofuranoeremophilan-14-oic acid (**20**): an oil; IR (neat) 1705, 1670, 1610, and 1568 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.30 (3H, s), 2.18 (3H, d, J=2 Hz), 2.52 (1H, dd, J=18 and J=2 Hz), 3.16 (1H, dd, J=18 and J=5 Hz), 3.46 (1H, t, J=4 Hz), 7.04 (1H, m), and 7.23 (1H, broad signal); MS *m/e* 262 (M^+; 22), 244 (11), 122 (100), and 94 (35). Found: *m/e* 262.1211. Calcd for $C_{15}H_{18}O_4$: M, 262.1205. 6-Oxo-4βH-furanoeremophilan-14-oic acid (**21**): an oil; IR (neat) 1712, 1663, 1615, and 1565 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.43 (3H, s), 2.17 (3H, d, J=2 Hz), 2.54 (1H, dd, J=18 and J=1.5 Hz), 3.30 (1H, dd, J=18 and J=5 Hz), 3.38 (1H, t, J=4 Hz), 7.07 (1H, m), and 7.40 (1H, broad signal); MS *m/e* 262 (M^+; 0.3), 218 (37), 203 (27), and 122 (100). Found: *m/e* 262.1211. Calcd for $C_{15}H_{18}O_4$: M, 262.1205.

Oxidation of Furanoeremophilane-14,6α-diol (22). Furanoeremophilane-14,6α-diol[8] (**22**; 19.5 mg) was oxidized with PDC[12] (1 g) in *N,N*-dimethylformamide (1 ml) at room temperature for 8 h. After treatment in the usual way, the product mixture was separated by preparative tihn-layer chromatography [developed with hexane–ether (2: 3)] to afford 6-oxofuranoeremophilan-14-al (**18**; 8.3 mg) as a main product in 44% yield and 6-oxofuranoeremophilan-14-oic acid (**20**; 2.2 mg) in 11% yield.

(±)-Furanoeremophilan-14,6α-olide (3). Lithium borohydride (*ca.* 10 mg) was added to a solution of 6-oxofuranoeremophilan-14-oic acid (**20**; 6.4 mg) in tetrahydrofuran (10 ml) at room temperature, and the mixture was stirred for 45 min. After addition of acetic acid (8 ml), the mixture was stirred for 12 h at room temperature, and extracted with ether. The ethereal solution was treated in the usual way to give an oil, which was subjected to separation by preparative thin-layer chromatography [developed with hexane–ether (1: 1)] to give **3** (4.3 mg; R_f 0.47) in 71% yield and unchanged **20** (0.8 mg). (±)-Furanoeremophilan-14,6α-olide (**3**): mp 125—127 °C (crystallized from hexane–ether); IR (CCl_4) 1768, 1638, and 1562 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ 1.27 (3H, s), 2.02 (3H, d, J=2 Hz), 2.66 (2H, dd, J=18 and J=2 Hz), 5.07 (1H, m), and 7.06 (1H, m); MS *m/e* 246 (M^+; 100) 202 (28), and 95 (31). Found: *m/e* 246.1262. Calcd for $C_{15}H_{18}O_3$: M, 246.1257. The spectral data of (±)-**3** were found to be identical with those of natural (−)-**3**.[8]

The authors wish to thank Prof. Koji Yamakawa and Dr. Tsuyoshi Satoh, Science University of Tokyo, for the supply of spectral data of **2** and **17** together with an authentic specimen of **2**. The authors are also indebted to Dr. Hiroshi Hirota, the University of Tokyo, for measurements of high-resolution mass spectra.

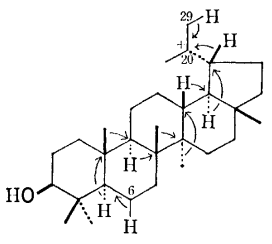
(Received March 28, 1980)

D:*A*-Friedo-18β-lup-19-en-3-one was transformed into *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol by two routes, 1) bromination-dehydrobromination of an enol benzoate of *D*:*A*-friedo-18β,19α*H*-lupan-3-one and 2) $BF_3 \cdot Et_2O$-catalyzed backbone rearrangement of 3β,4β-epoxy-*D*:*A*-friedo-18β,19α*H*-lupane. The 18β*H*,19α*H*-configuration in these *D*:*A*- and *D*:*B*-friedo-type lupane derivatives was determined by means of X-ray diffraction for a 3α,4α-epoxide derived from *D*:*A*-friedo-18β,19α*H*-lupan-3β-ol. The synthetic *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol was found to be not identical with guimarenol isolated from *Ceropegia dichotoma*.

From the viewpoint of acid-catalyzed backbone rearrangement of triterpenes, we are interested in the structure of guimarenol (**1**), a triterpene alcohol obtained from *Ceropegia dichotoma* by González *et al.*[2)] They proposed a novel *D*: *B*-friedolupane framework with a double bond between $C_{(5)}$ and $C_{(6)}$ and a 3β-hydroxyl group for guimarenol (**1**), though the stereochemistry at $C_{(13)}$, $C_{(14)}$, $C_{(17)}$, $C_{(18)}$, and $C_{(19)}$ remained undetermined.

Only a few reports have been given on investigations on the migrated lupane derivatives, such as isolation of guimarenol (**1**) and lup-18-en-3β-ol (**2**)[2)] and preparation of 3β-acetoxy-19α*H*-lup-13(18)-ene (**3**) from lupenyl acetate (**4**).[3)] The synthesis of *D*: *A*-friedo-18β-lup-19-ene (**5**) and its 3-oxo derivative (**6**) from friedelin (**7**) and also the conversion of **5** into a migrated baccharane derivative, methyl trinorshionanoate (**8**) were recently reported.[4)]

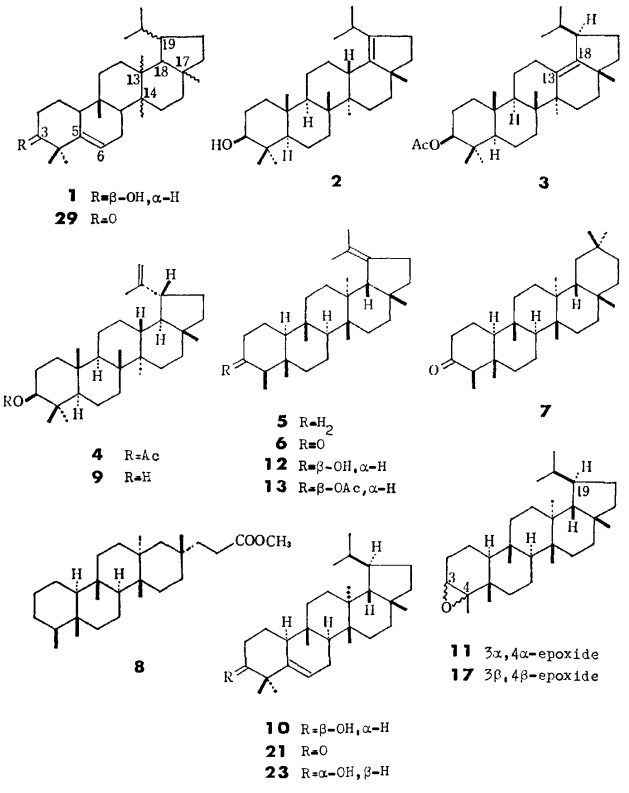
Biosynthesis of lupeol (**9**) is presumed to proceed *via* a pentacyclic intermediate (**A**) carrying a positive charge on $C_{(20)}$ or its equivalent species.[5)] Deprotonation of a proton on $C_{(29)}$ would afford lupeol (**9**), while a sequential shift of methyl groups and hydrides followed by removal of a proton on $C_{(6)}$ would give *D*: *B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**10**) as shown in Fig. 1. Thus, the 18β*H*- and 19α*H*-configuration could be biogenetically assumed for migrated lupane derivatives including guimarenol (**1**). This paper describes the synthesis of *D* : *B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**10**) from *D* : *A*-friedo-18β-lup-19-en-3-one (**6**)[4b)] and determination of the configuration at $C_{(18)}$ and $C_{(19)}$ of 3α,4α-epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**11**) derived from a synthetic intermediate by means of X-ray crystallography. Discrepancy of physical constants and spectral data between the synthetic triterpene (**10**) and guimarenol (**1**) is also described.

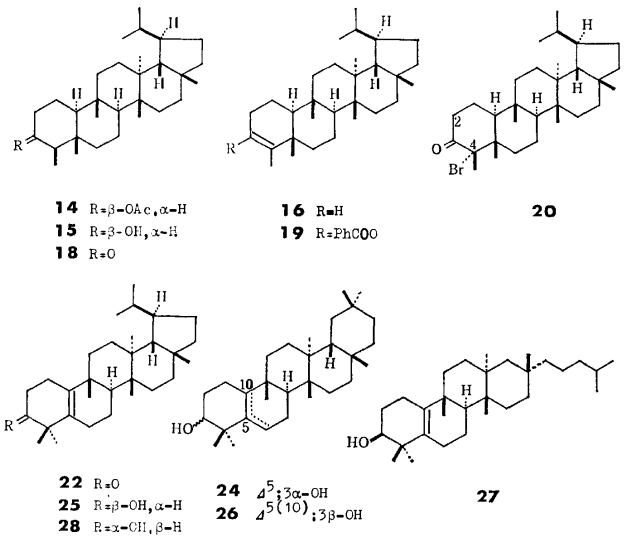


A

Fig. 1

The synthesis starts from the conversion of *D* : *A*-friedo-18β-lup-19-en-3-one (**6**) into an acetate (**13**) *via* an alcohol (**12**). The next step, hydrogenation of the acetate (**13**) seems crucial, since the hydrogenation is likely to occur from both α- and β-sides. However, it was inferred by use of a Dreiding model that hydrogenation from the α-side to generate a 19β-isopropyl group would take place more easily than that from the β-side. The acetate (**13**) in acetic acid was hydrogenated under atmospheric pressure over platinum catalyst at 40 °C. Although the product (**14**), $C_{32}H_{54}O_2$ (determined by elemental analysis and mass spectrometry), was found





to be single by GLC and ^{1}H NMR measurement, the configuration of the 19β-isopropyl group could not be fully established until X-ray analysis clarified that 3α,4α-epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**11**) derived from the hydrogenation product possesses the desired 19α*H*-configuration (*vide infra*).

Saturated acetate (**14**) was treated with lithium aluminium hydride to give *D* : *A*-friedo-18β,19α*H*-lupan-3β-ol (**15**), which on treatment with phosphoryl chloride in pyridine under reflux, gave *D* : *A*-friedo-18β,19α*H*-lup-3-ene (**16**), $C_{30}H_{50}$, showing ^{1}H NMR signals at δ 5.18 (1H, m, $W_{1/2}$=9 Hz). The dehydration product (**16**) was treated with *m*-chloroperbenzoic acid in chloroform to afford a mixture of two epoxides in a 9: 5 ratio, their configurations being easily assigned by ^{1}H NMR measurement.[6] The major epoxide with a signal at δ 2.85 (t, J=2.5 Hz) was 3α,4α-epoxide (**11**) and the minor one with a signal at δ 2.90 (t, J=1 Hz) 3β,4β-epoxide (**17**).

The stereochemistry of the isopropyl group of **14** was unambiguously determined by X-ray diffraction analysis of 3α,4α-epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**11**). A single crystal of **11** belongs to the monoclinic space group $P2_1$ with cell parameters a=13.996(6), b=11.461(5), c=8.199(4) Å, β=106.34(6)° the two molecules being contained in the cell. The intensity data were collected on a Phlips PW1100 automatic diffractometer using graphite-monochromated Cu $K\alpha$ radiation. A total of 2494, non-zero, independent reflections with $2\theta \leq 156°$ were measured by means of θ-2θ scanning.

a) The form of the anisotropic temperature factor is: $T=\exp(-B_{11}h^2-B_{22}k^2-B_{33}l^2-2B_{12}hk-2B_{13}hl-2B_{23}kl)$.

The intensities were corrected for Lorentz and polarization factors, but not for absorptions. The structure was solved by the direct method using program MULTAN.[7] An *E*-map calculated from 323 reflections with $|E| \leq 1.5$ revealed the locations of 25 nonhydrogen atoms out of 31, and all the other nonhydrogen atoms emerged in successive Fourier maps. The structural parameters were refined by the block-diagonal least-squares calculations assuming anisotropic thermal vibrations. The final *R*-factor was 9.9% excluding hydrogen atoms.[8] The weighting scheme $\sqrt{w}=20.0/|F_0|$ when $|F_0| \geq 20.0$, $\sqrt{w}=1.0$ when $20.0>|F_0| \geq 3.0$, and $\sqrt{w}=0.8$ when $|F_0|<3.0$ was applied. The atomic scattering factors were taken from International Tables for X-ray Crystallography.[9] The atomic positional and thermal parameters are given in Table 1. There are no abnormal bond lengths and angles as compared with those found in this type of compound except for the bond lengths $C_{(17)}$–$C_{(18)}$ and $C_{(13)}$–$C_{(14)}$ of 1.592 and 1.589 Å, respectively (Figs. 2a and 2b). The lengthening of the C–C bond at the fully substituted ring juncture is commonly observed in triterpenes, and for the above mentioned two bonds; the effect of repulsions between the 1,3-diaxial substituted groups may be responsible for the lengthening. Figure 3 shows a computer-generated perspective drawing of the molecule of the epoxide (**11**), with the 19α*H*-configuration as well as the 18β*H*-configuration.

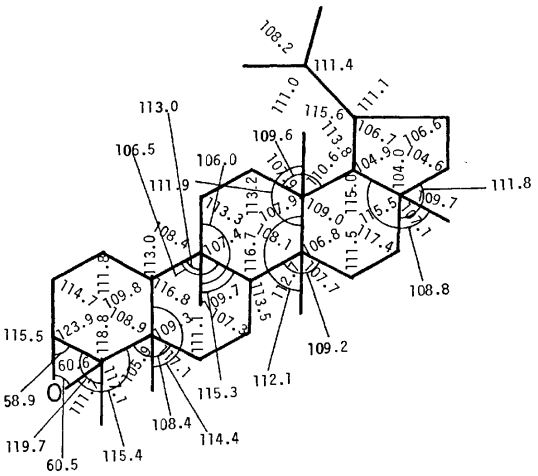

Fig. 2b. Bond angles (Φ/°) of **11**.

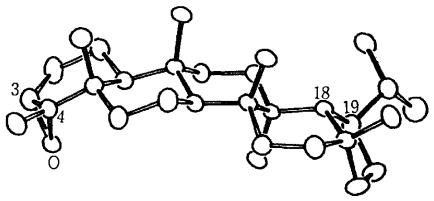

Fig. 3. Perspective view of **11**.

The saturated alcohol (**15**) was subjected to oxidation with the Jones reagent to give a ketone (**18**). The ketone is formulated *D* : as *A*-friedo-18β,19α*H*-lupan-3-one, corresponding biogenetically to the ultimate rearranged product in the migrated lupane series.

The conversion of a *D*: *A*-friedo type 3-keto triterpene into a *D* : *B*-friedo type ketone was carried out by the bromination-dehydrobromination reaction.[10,11] On treatment with benzoyl chloride under reflux, *D* : *A*-friedo-18β,19α*H*-lupan-3-one (**18**) gave 3-benzoyloxy-*D* : *A*-friedo-18β,19α*H*-lup-3-ene (**19**) selectively in a good yield. The absence of Δ^2-isomer was indicated by ^{1}H NMR measurement. The reaction product, after recrystallization from methanol, was brominated with bromine in pyridine at room temperature[10] to afford a monobromide (**20**), $C_{30}H_{49}OBr$ (M^+ 506.2946 and 504.2992), ^{1}H NMR δ 1.71 (3H, s) and δ 3.38 (1H, ddd; J=20, 13, and 8 Hz). The 4α-orientation of the bromine atom was deduced by the ^{1}H NMR spectrum: the signals at δ 3.38 were assignable to a $C_{(2\alpha)}$–H and the down-field shift was ascribed to a 1,3-diaxial relationship between the $C_{(4\alpha)}$–Br and the $C_{(2\alpha)}$–H.

The 4α-bromo derivative (**20**) was subjected to reaction with silver acetate in a mixture of diethyl ether and acetic acid.[11] The reaction product was purified by preparative TLC to afford a mixture of *D* : *B*-friedo-18β,19α*H*-lup-5-en-3-one (**21**) and -5(10)-en-3-one (**22**). The relative amount of two isomeric ketones (**21** and **22**) was estimated to be about 1 : 2 by GLC examination and ^{1}H NMR measurement. Since the mixture gave only one spot on TLC and only one peak on HPLC examination, separation of the mixture was abandoned.

The mixture was therefore reduced with sodium borohydride to afford a mixture of two pairs of epimeric alcohols. Although the alcohol mixture could not be separated into four components by a single procedure, it could be separated into two fractions by TLC, each fraction being further separated into two components by HPLC. Thus, the mixture was subjected to separation by preparative TLC into two fractions, a major fraction (R_f 0.3) and a minor one (R_f 0.4). The major fraction with a smaller R_f value on TLC was further separated by preparative HPLC into two alcohols, **23** and **25**. **23** seems to be *D*: *B*-friedo-18β,19α*H*-lup-5-en-3α-ol from the ^{1}H NMR spectrum: an olefinic proton at $C_{(6)}$ (δ 5.61, 1H, m, $W_{1/2}$=9 Hz) and $C_{(3\beta)}$-proton (δ 3.20, 1H, dd, J=10 and 4 Hz) attached to a hydroxyl-bearing carbon atom resembled those of *D*: *B*-friedo-olean-5-en-3α-ol (**24**)[12] (δ 5.63, 1H, m, $W_{1/2}$=9 Hz; δ 3.21, 1H, dd; J=10 and 5 Hz). **25** seems to be *D* : *B*-friedo-18β,19α*H*-lup-5(10)-en-3β-ol from a comparison of the ^{1}H NMR spectral data (δ 3.48, 1H, dd, J=10 and

4 Hz) with those of *D* : *B*-friedoolean-5(10)-en-3β-ol (**26**)[6b] (δ 3.45, 1H, dd; J=9.5 and 4.5 Hz) and *D* : *B*-friedobacchar-5(10)-en-3β-ol (**27**)[6a] (δ 3.48, 1H, dd; J=10 and 4 Hz).

The other fraction with a larger R_f value on TLC separation was found to be a 2:1 mixture of two alcohols by HPLC examination and was separated by preparative HPLC into two alcohols **28** (R_t=22.8 min) and **10** (R_t=20.3 min). The major alcohol (**28**) was found to be *D* : *B*-friedo-18β,19α*H*-lup-5(10)-en-3α-ol from the ^{1}H NMR spectrum and chemical conversion. The two alcohols **25** and **28** gave the same original ketone (**22**) on oxidation with chromium trioxide–pyridine complex. The fourth alcohol (**10**) should be the desired *D* : *B*-friedo-18β,19α*H*-lup-5-en-3β-ol. However, yield was less than 3% from the bromide (**20**). No satisfactory characterization could be achieved.

Treatment of 3β,4β-epoxides of *D* : *A*-friedo-type triterpenes with boron trifluoride etherate gives a mixture of backbone-rearranged products, from which *D* : *B*-friedo-Δ^5- and -$\Delta^{5(10)}$-triterpene 3β-alcohols are obtained. For example, *D* : *B*-friedobacchar-5-en-3β-ol was obtained from 3β,4β-epoxyshionane[13] and *D*: *B*-friedoolean-5-en-3β-ol from 3β,4β-epoxyfriedelane[6b] together with their 5(10)-ene isomers, respectively. 3β,4β-Epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**17**) was treated with boron trifluoride etherate in benzene to give a complex mixture, from which an alcohol was obtained. The ^{1}H NMR spectrum of the alcohol showed the presence of an olefinic proton [at δ 5.65 (1H, m, $W_{1/2}$=7 Hz)] and a proton attached to a hydroxyl-bearing carbon atom [at δ 3.45 (1H, m, $W_{1/2}$= 7 Hz)].[6b] The structure, *D*: *B*-friedo-18β,19α*H*-lup-5-en-3β-ol was established for this alcohol (**10**) by the following evidence. **10** was oxidized with chromium trioxide–pyridine complex to give a ketone, *D*: *B*-friedo-18β,19α*H*-lup-5-en-3-one (**21**), identical with that obtained by the oxidation of *D*: *B*-friedo-18β,19α*H*-lup-5-en-3α-ol (**23**). Retention times on GLC and HPLC examinations and R_f value on TLC of **10** were identical with those of the fourth alcohol obtained by the bromination-dehydrobromination reaction of the ketone (**18**) (*vide supra*).

The ^{1}H NMR, mass spectral data, and melting points of the four alcohols (**10**, **23**, **25**, and **28**) and the ketones (**21** and **22**) together with those of guimarenol (**1**) and guimarenone (**29**) are given in Table 2. The physical and spectral data of guimarenol (**1**) and the corresponding ketone, guimarenone (**29**), differ distinctly from those of the synthetic *D*: *B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**10**) and the corresponding 3-one (**21**), respectively. The structure of guimarenol (**1**)[2] should be reinvestigated.

Experimental

General Procedure. Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncorrected. IR spectra were measured in Nujol mull with a Hitachi-EPI-G2 spectrometer or a Hitachi 260-30 spectrometer, mass spectra on a Hitachi RMU-6-Tokugata mass spectrometer at 70 eV with a direct inlet system, and high resolution mass spectra on a JMS-D300 (JEOL) mass spectrometer. Relative intensities are given in parentheses. ^{1}H NMR spectra were measured with a Hitachi R-20B (60 MHz) spectrometer, a Varian EM-390 (90 MHz) spectrometer or a JNM-FX60 FT-NMR (60 MHz) spectrometer (JEOL). Chemical shifts are given in δ downfield from TMS as an internal standard and coupling constants in Hz. GLC analyses were carried out with a Shimadzu Gas Chromatograph GC-6A equipped with a hydrogen flame ionization detector (column: Dexsil 300GC, temperature 270—290 °C). HPLC analysis and preparation were carried out on a Waters Liquid Chromatograph ALC/GPS 202/401 at room temperature with an RI detector (column: μ-Porasil 1/4 (inch)×1 (foot); solvent system: 1.5% diethyl ether–hexane (unless otherwise described); flow rate: 3 ml/min (unless otherwise described); pressure: *ca.* 700 psi). TLC was carried out on Kieselgel 60 GF_{254} (E. Merck) coated in 0.25 mm thickness (for analytical) and in 0.5 mm thickness (for preparative). Wakogel C-200 (Wako) was used for column chromatography.

D: A-*Friedo-18β-lup-19-en-3β-yl Acetate (13).* Excess of sodium borohydride (*ca.* 10 mg) was added to a solution of *D*: *A*-friedo-18β-lup-19-en-3-one (**6**; 7.5 mg) in methanol (30 ml) at room temperature, the mixture being stirred

Table 2.

overnight. The usual work-up and purification by preparative TLC (benzene: diethyl ether=9 : 1) gave *D* : *A*-friedo-18β-lup-19-en-3β-ol (**12**; 7.2 mg) in 95% yield: mp 173—175 °C (crystallized from acetone); IR 3460 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.8—1.0 (18H, 6×CH_3), 1.65 (6H, br s; >C=C(CH_3)$_2$), and 3.75 (1H, m, $W_{1/2}$=6 Hz); MS *m/e* 426 (M^+; 17) and 275 (100).

19-En-3β-ol (**12**; 7.2 mg) dissolved in pyridine (1 ml) was treated with acetic anhydride (1 ml) at room temperature and the mixture was left overnight. The usual work-up and purification by preparative TLC (benzene) gave *D* : *A*-friedo-18β-lup-19-en-3β-yl acetate (**13**; 6.8 mg) in 86% yield; mp 240—242.5 °C (crystallized from acetone); IR 1738 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.75—0.95 (18H, 6×CH_3), 1.63, 1.67 (each 3H, br s; >C=C(CH_3)$_2$), 2.04 (3H, s), and 4.92 (1H, m, $W_{1/2}$=7 Hz); MS *m/e* 468 (M^+; 60) and 317 (100); Found: C, 81.74; H, 11.09%. Calcd for $C_{32}H_{52}O_2$: C, 81.99; H, 11.18%.

D : A-*Friedo-18β,19α*H-*lupan-3β-yl Acetate* (**14**). The acetate (**13**; 632.2 mg) in acetic acid (350 ml) was hydrogenated in the presence of catalyst [prepared from platinum dioxide (851 mg)] under atmospheric pressure at 40 °C for 3.5 d. The catalyst was filtered off, and the solvent distilled off. The residue was purified by silica gel (35 g) column chromatography to give quantitatively a dihydro derivative, *D* : *A*-friedo-18β,19α*H*-lupan-3β-yl acetate (**14**; 637 mg); mp 251—253 °C (crystallized from acetone); IR 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.8—1.0 (18H, 6×CH_3), 2.03 (6H, s), and 4.94 (1H, m, $W_{1/2}$=6 Hz); MS *m/e* 470(M^+; 58) and 410 (100); Found: C, 81.70; H, 11.81%. Calcd for $C_{32}H_{54}O_2$: C, 81.64; H, 11.56%.

D : *A-Friedo-18β,19α*H-*lupan-3β-ol* (**15**). The saturated acetate (**14**; 370 mg) dissolved in tetrahydrofuran (200 ml), was treated with lithium aluminium hydride (616 mg) under reflux for 1 h. The usual work-up gave *D* : *A*-friedo-18β,19α*H*-lupan-3β-ol (**15**; 327 mg) in 97% yield; mp 225—227 °C (crystallized from acetone); IR 3440 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.8—1.1 (24H, 8×CH_3) and 3.75 (1H, m, $W_{1/2}$= 7 Hz); MS *m/e* 428 (M^+; 100).

D : A-*Friedo-18β,19α*H-*lup-3-ene* (**16**). Freshly distilled phosphoryl chloride (1.8 ml) was added to a solution of 3β-ol (**15**; 317.3 mg) in dry pyridine (60 ml), the mixture being refluxed for 40 min. The residue obtained by the usual work-up was chromatographed on silica gel (60 g) impregnated with 25% silver nitrate to give *D* : *A*-friedo-18β,19α*H*-lup-3-ene (**16**; 254 mg) in 84% yield; mp 169—170 °C (crystallized from acetone); IR 795 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.95—1.15 (21H, 7×CH_3), 1.56 (3H, d; *J*=1.5 Hz), and 5.18 (1H, m, $W_{1/2}$=9 Hz); MS *m/e* 410 (M^+; 65) and 318 (100); Found: C, 87.78; H, 12.34%. Calcd for $C_{30}H_{50}$: C, 87.73; H. 12.27%.

Epoxidation of D : A-*Friedo-18β,19α*H-*lup-3-ene* (**16**). *m*-Chloroperbenzoic acid (578 mg) was added to a solution of the 3-ene (**16**; 254 mg) in chloroform (150 ml) at 0 °C, the solution being stirred at the same temperature for 1.5 h. A saturated aqueous sodium thiosulfate (50 ml) and a saturated aqueous sodium hydrogencarbonate (30 ml) were added to the solution, the mixture being stirred for 30 min at room temperature. Extraction with chloroform and the usual work-up gave a residue which was purified by preparative TLC [Kieselgel G (E. Merck); hexane: chloroform=3 : 2] to give 3α,4α-epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**11**; 157.5 mg) and 3β,4β-epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**17**; 87.5 mg) in 60 and 33% yields, respectively. 3α,4α-Epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**11**): mp 200—202 °C (crystallized from acetone); ^1H NMR ($CDCl_3$) δ 0.85 (15H, 5×CH_3), 0.96, 1.07, 1.19 (each 3H, s) and 2.85 (1H, t; *J*=2.5 Hz); MS *m/e* 426 (M^+; 77) and 411 (100); Found: C, 84.72; H, 11.95%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%. 3β,4β-Epoxy-*D* : *A*-friedo-18β,19α*H*-lupane (**17**): mp 215—216 °C crystallized from acetone); ^1H NMR ($CDCl_3$) δ 0.88 (15H, 5×CH_3), 0.96, 1.05, 1.17 (each 3H, s) and 2.90 (1H, t; *J*=1 Hz); MS *m/e* 426 (M^+; 100); Found: C, 84.67; H, 11.94%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

D : A-*Friedo-18β,19α*H-*lupan-3-one* (**18**). The 3β-ol (**15**; 246 mg) dissolved in acetone (150 ml) was treated with the Jones reagent at 0 °C for 1 h. The usual work-up gave *D*:*A*-friedo-18β,19α*H*-lupan-3-one (**18**; 236 mg) in 96% yield; mp 260—262 °C (crystallized from acetone); IR 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.72 (3H, s) and 0.8—1.0 (21H, 7×CH_3); ^1H NMR ($CDCl_3$) using Eu(fod)$_3$-d_{27}/**18**=0.2 (M/M) δ 1.72 (3H, d; *J*=7 Hz; 4β-CH_3); MS *m/e* 426 (M^+; 100); Found: C, 84.66; H, 11.79%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

3-Benzoyloxy-D : A-*friedo-18β,19α*H-*lup-3-ene* (**19**). *D*:*A*-friedo-18β,19α*H*-lupan-3-one (**18**; 144 mg) was treated with benzoyl chloride (2 ml) under reflux for 2 h. The solution was cooled to 0 °C, methanol (*ca.* 5 ml) being added in order to destroy excess benzoyl chloride. When the mixture was allowed to stand for 30 min, crystals began to precipitate. The precipitate was collected on a filter paper and washed with methanol. 3-Benzoyloxy-*D*:*A*-friedo-18β,19α*H*-lup-3-ene (**19**; 168 mg) was obtained in 94% yield; mp 255—256 °C (crystallized from acetone); IR 1732 cm^{-1}: ^1H NMR ($CDCl_3$) δ 0.9—1.0 (18H, 6×CH_3), 1.09, 1.49 (each 3H, s), 7.4—7.7 (3H, m), and 8.0—8.3 (2H, m); MS *m/e* 530 (M^+; 5) and 105 (100); Found: C, 83.75; H, 10.13%. Calcd for $C_{37}H_{54}O_2$: C, 83.72; H, 10.25%.

4α-Bromo-D : A-*friedo-18β,19α*H-*lupan-3-one* (**20**). A mixture of bromine (0.1 ml) and pyridine (0.5 ml) was added to a chloroform solution (5 ml) of the enol benzoate (**19**; 50.3 mg) at room temperature. After being stirred for 3 h, a small amount of aqueous sodium thiosulfate was added and the mixture was stirred for several hours. The usual work-up and purification by preparative TLC (hexane: benzene=1:1) gave 4α-bromo-*D* : *A*-friedo-18β,19α*H*-lupan-3-one (**20**; 31.6 mg) in 66% yield; mp 192.5—194.5 °C (crystallized from methanol); IR 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.8—1.0 (21H, 7×CH_3), 1.71 (3H, s), and 3.38 (1H, ddd; *J*=20, 13, and 8 Hz); MS *m/e* 506 (M^+; 12), 504 (M^+; 12), and 123 (100); Found: *m/e* 506.2946. Calcd for $C_{30}H_{49}O^{81}Br$: M, 506.2903. Found: *m/e* 504.2992. Calcd for $C_{30}H_{49}O^{79}Br$: M, 504.2967.

Dehydrobromination of 4α-Bromo-D : A-*friedo-18β,19α*H-*lupan-3-one* (**20**). A mixture of silver acetate (34 mg), water (0.3 ml), and acetic acid (16 ml) was added to an ethereal solution (12 ml) of the 4α-bromo ketone (**20**; 31.6 mg). The solvent was distilled off until the vapor temperature reached *ca.* 100 °C, the solution then being refluxed for 1 h. The usual work-up gave a residue (24.6 mg) which was purified by preparative TLC (benzene) to give a *ca.* 1: 2 mixture (19.6 mg) of *D*:*B*-friedo-18β,19α*H*-lup-5-en-3-one (**21**) and *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3-one (**22**) in 74% yield. The relative ratio of the product was estimated from the peak area of GLC and the integrated area of olefinic proton signal in the ^1H NMR spectrum. These two olefinic isomers, however, could not be separated from each other by TLC or HPLC.

Readuction of the Mixture of Keto Olefins (**21** *and* **22**). A mixture (19.6 mg) of two olefinic isomers (**21** and **22**) was dissolved in methanol (5 ml) and kept at 0 °C. Excess sodium borhydride (*ca.* 30 mg) was added and the solution was stirred for 1 h. The usual work-up and purification by preparative TLC (benzene) gave a pair of mixtures. GLC examination showed that a mixture (16.6 mg) with a smaller R_f value on TLC consists of *D*: *B*-friedo-18β,19α*H*-lup-5-en-3α-ol (**23**) and *D*: *B*-friedo-18β,19α*H*-lup-5(10)-en-3β-ol (**25**), and the other

mixture (2.1 mg) with a larger R_f value consists of *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**10**) and *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3α-ol (**28**). The former mixture was separated by preparative HPLC into *D*:*B*-friedo-18β,19α*H*-lup-5-en-3α-ol (**23**; 5.2 mg) and *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3β-ol (**25**; 9.8 mg). *D*:*B*-Friedo-18β,19α*H*-lup-5-en-3α-ol (**23**): mp 181—182 °C (crystallized from acetone); IR 3320 and 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.8—1.0 (24H, 8$\times CH_3$), 3.20 (1H, dd; J=10 and 4 Hz), and 5.61 (1H, m, $W_{1/2}$=9 Hz); MS *m/e* 426 (M^+; 10) and 274 (100); HPLC (solvent system: 10% diethyl ether–hexane; flow rate: 2 ml/min) R_t=38.9 min; Found: *m/e* 426.3808. Calcd for $C_{30}H_{50}O$: M, 426.3860. *D*:*B*-Friedo-18β,19α*H*-lup-5(10)-en-3β-ol (**25**); mp 191—193 °C (crystallized from acetone); IR 3350 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.8—1.05 (24H, 8$\times CH_3$) and 3.48 (1H, dd, J=10 and 4 Hz); MS *m/e* 426 (M^+; 13), 408 (100), and 205 (72); HPLC (solvent system: 10% diethyl ether–hexane; flow rate: 2 ml/min) R_t=41.3 min; Found: *m/e* 426.3846. Calcd for $C_{30}H_{50}O$: M, 426.3860.

The latter mixture of **10** and **28** was separated by preparative HPLC into *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**10**; less than 0.5 mg) and -5(10)-en-3α-ol (**28**; 1.1 mg). *D*:*B*-Friedo-18β,19α*H*-lup-5(10)-en-3α-ol (**28**): mp 195.5—196 °C (crystallized from acetone); IR 3620 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.90 (6H, d; J=7 Hz, ($C\underline{H}_3$)$_2$CH–), 0.97, 1.03 (each 3H, s), 0.89, 1.00 (each 6H, s, 2$\times CH_3$), and 3.48 (1H, dd; J=10 and 4 Hz); MS *m/e* 426 (M^+; 10) and 205 (100); HPLC (solvent system: 10% diethyl ether–hexane; flow rate: 2 ml/min) R_t= 22.8 min; Found *m/e* 426.3880. Calcd for $C_{30}H_{50}O$: M, 426.3860.

Boron Trifluoride Etherate-catalyzed Backbone Rearrangement of 3β,4β-Epoxy-D:A-*friedo-18β,19α*H*-lupane (**17**) in Benzene.* A solution of 3β,4β-epoxy-*D*:*A*-friedo-18β,19α*H*-lupane (**17**; 47 mg) in benzene (25 ml) was treated with boron trifluoride etherate (0.3 ml) at room temperature for 1 h. The usual work-up gave a mixture, which was separated by preparative TLC (benzene) into *D*:*A*-friedo-18β,19α*H*-lupan-3-one (**18** 0.5 mg), *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**10**; 4.4 mg), and a complex mixture of alcohols (37.2 mg). *D*:*B*-Friedo-18β,19α*H*-lup-5-en-3β-ol (**10**): mp 166—167 °C (crystallized from acetone); IR 3400 (br), 1195, 1045, 973, and 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.88, 1.03, 1.13, 1.24 (each 3H, s; *t*-CH_3), 0.90 (6H, d; J=6 Hz; ($C\underline{H}_3$)$_2$CH–), 0.97 (6H, s, 2$\times$*t*-CH_3), 3.45 (1H, m, $W_{1/2}$=7 Hz), and 5.65 (1H, m, $W_{1/2}$=7 Hz); MS *m/e* 426 (M^+; 7) and 274 (100); HPLC (solvent system: 10% diethyl ether–hexane; flow rate: 2 ml/min) R_t=20.3 min; Found: *m/e* 426.3852. Calcd for $C_{30}H_{50}O$: M, 426.3860.

D: B-*Friedo-18β,19α*H*-lup-5-en-3-one* (**21**). *a)*: A large excess of chromium trioxide–pyridine complex in pyridine (0.5 ml) was added to a solution of *D*:*B*-friedo-18β,19α*H*-lup-5-en-3α-ol (**23**; 4.3 mg) in dichloromethane (3 ml), the solution being stirred at room temperature for 6 h. The usual work-up and preparative TLC (benzene) gave *D*:*B*-friedo-18β,19α*H*-lup-5-en-3-one (**21**; 1.6 mg).

b): The same oxidation of *D*:*B*-friedo-18β,19α*H*-lup-5-en-3β-ol (**10**; 4.4 mg) in dichloromethane (3 ml) with a large excess of chromium trioxide–pyridine complex in pyridine (0.5 ml) gave **21** (1.6 mg); mp 149—153 °C (crystallized from acetone); IR 1718 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.82. 0.90 (each 3H, s), 0.83 (6H, d; J=7 Hz; ($C\underline{H}_3$)$_2$CH–), 1.21 (12H, s, 4$\times CH_3$), and 5.63 (1H, m, $W_{1/2}$=11 Hz); MS *m/e* 424 (M^+; 11), 274 (100), and 123 (93); Found: *m/e* 424.3731. Calcd for $C_{30}H_{48}O$: M, 424.3705.

D: B-*Friedo-18β,19α*H*-lup-5(10)-en-3-one* (**22**). *a)*: Pyridinium chlorochormate[14] (16 mg) was added to a solution of *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3α-ol (**28**; 12.5 mg) in dichloromethane (3 ml), the solution being stirred at room temperature for 5 h. The usual work-up and silica gel chromatography gave *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3-one (**22**; 10.1 mg).

b): A solution of *D*:*B*-friedo-18β,19α*H*-lup-5(10)-en-3β-ol (**25**; 5.2 mg) in dichloromethane (3 ml) was oxidized with pyridinium chlorochromate (41 mg) in the same way as above to give **22** (5 mg); mp 180—182 °C (crystallized from acetone); IR 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.8—0.95 (12H, 4$\times CH_3$), 0.97, 1.03, 1.13, and 1.16 (each 3H, s); MS *m/e* 424 (M^+; 68) and 205 (100); Found: *m/e* 424.3705. Calcd for $C_{30}H_{48}O$: M, 424.3705.

Restricted Rotation Involving the Tetrahedral Carbon. XXXIII.[1] Restricted Rotation about a C_{sp^3}–C_{sp^2} Bond in 10,10-Disubstituted 9-(2,6-Xylyl)-9,10-dihydroanthracene Derivatives[2]

Mikio NAKAMURA and Michinori ŌKI*,†

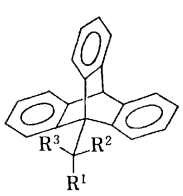
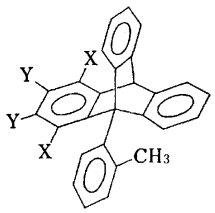
(Received April 12, 1980)

A series of 10,10-disubstituted 9-(2,6-xylyl)-9,10-dihydroanthracene derivatives have been prepared and their conformations and barriers to internal rotation about the C_{xylyl}–C_9 bond have been examined. These compounds exist predominantly as a pseudo-equatorial form in the ground state for rotation. A large effect is inserted by the substituents in 10 position on barriers to rotation and is interpreted in terms of a rotation-inversion mechanism rather than a simple rotation mechanism for the methyl-exchange process which is observed by ^1H NMR spectra. The highest barrier to rotation has been found in the compound having two peri-chloro groups and a hydroxyl group in 9-position. The high barrier is ascribed to destabilization of the transition state, where 9-aryl group takes axial conformation, due to the three electronegative groups which are forced to be arranged parallelly in quite a near region. The change of 9-OH to 9-H thus decreases the barrier to rotation when peri-chlorines are present, while the increase in barrier is observed as in the case of 9-arylfluorenes and 9-arylxanthenes when they are absent.

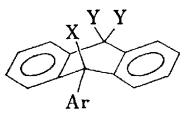
It is well known that the barrier to rotation of 9-alkyltriptycenes (**1**) are extraordinarily high and in some cases rotational isomers have been isolated as stable entities at room temperature.[3] Barriers to rotation of aryl groups in 9-aryltriptycenes are, on the other hand, lower than those expected.[4] Although the molecular model of 9-(*o*-tolyl)triptycenes (**2**) indicated the existence of extremely high repulsion between the methyl and a peri hydrogen in the transition state for rotation, the barriers were in the range of 54—63 kJ mol^{-1} depending on the substituents in the peri position. These facts were interpreted in terms of destabilization of the ground state due to repulsive interaction between



1



2



3

6′ and peri hydrogens. This means that the removal of a benzo group from 9-aryltriptycene, which leads to 9-aryl-9,10-dihydroanthracene skeleton (**3**), eliminates the repulsion mainly in the ground state and should lead to an increase in barriers to rotation. But a previous paper which dealt with restricted rotation of the aryl group in 9-(2,6-xylyl)xanthenes (**4**), 10-oxa analogs of **3**, showed relatively low barriers to rotation.[5] McKinley *et al.* explained the low barriers in this system, comparing with those of the structurally similar 9-mesitylfluorene derivatives (**5**),[6] on the basis of the difference in the direction of the substituents: the aryl group in the xanthene system takes an axial conformation both in the ground state and in the transition state for rotation. If the aryl group is axial in the boat form of the 9,10-dihydroanthracene type molecules,[7] the steric repulsion between 1,8-substituents of the xanthene ring and 2′,6′-substituents of the aryl ring will not

increase in the transition state for rotation in contrast to the case of the 9-arylfluorene system.

The consideration described above leads to the idea that the barrier to rotation of the 9-aryl group in a 9,10-dihydroanthracene type molecule may be increased if the 9-aryl group is forced to take an equatorial conformation. It seems possible to realize such a situation by the introduction of two substituents in the 10 position. If a bulky group in the 9-position takes an axial conformation, it opposes a substituent in the 10 position which is also axial. Therefore, introduction of two bulky substituents in the 10 position, which assures that one of the two groups is always axial irrespective of the ring inversion, a bulky substituent in the 9 position will inevitably take the equatorial conformation. Under such expectation, we synthesized several 10,10-disubstituted 9-aryl-9,10-dihydroanthracenes (**6**—**11**) and measured the barriers to rotation about the C_9–C_{ar} bond by dynamic NMR method. This paper reports the results of the investigation and discusses the mechanism for rotation.

Experimental

General. Melting points are uncorrected. ^{1}H NMR spectra were recorded either on a Hitachi R-20B spectrometer operating at 60 MHz or on a Varian EM 390 spectrometer at 90 MHz. IR spectra were measured on a Hitachi EPI-G3 grating infrared spectrophotometer. High and low temperature ^{1}H NMR spectra were measured in hexachlorobutadiene and chloroform-*d* solutions, respectively. The probe temperature was measured by the peak separation of methanol or ethylene glycol or by a thermocouple.

Syntheses. 9-(2,6-Xylyl)-10,10-dimethyl-9,10-dihydroanthracen-9-ol (6): To a vigorously stirred tetrahydrofuran solution of 2,6-xylylmagnesium bromide, prepared from 1.0 g (0.0054 mol) of 2-bromo-*m*-xylene and 0.144 g (0.0060 mol) of magnesium, was added 0.299 g (0.00135 mol) of 10,10-dimethylanthrone[8] at 0 °C. The reaction mixture was stirred for 3 h at room temperature, heated with stirring at 80 °C for 1 h, cooled, and treated with aqueous ammonium chloride. The organic layer was separated and the water layer was extracted with ether. The combined ether solution, after dried over sodium sulfate, was evaporated and the resulting oil was separated by chromatography on silica gel. Elution with hexane and benzene (10 : 1) gave white crystals which were recrystallized from hexane. The yield was 78% based on anthrone. The melting point was 153—154 °C. Found: C, 87.76; H, 7.48%. Calcd for $C_{24}H_{24}O$: C, 87.76; H, 7.37%. NMR($CDCl_3$, δ at 0 °C): 1.35 (3H, s), 1.70 (3H, s), 1.83 (3H, s), 1.9 (1H, s), 2.92 (3H, s), 7.0—7.8 (11H, m).

9-(2,6-Xylyl)-10,10-dimethyl-9,10-dihydroanthracene (7). To a solution of 102 mg (0.31 mmol) of **6** in 10 ml of acetic acid was added 2.0 ml of 57% hydriodic acid. The solution was stirred for 5 h at room temperature. The reaction mixture was poured into water and extracted with ether. The ether layer was washed with aqueous sodium hydrogencarbonate and then with aqueous sodium hydrogensulfite, and dried over sodium sulfate. After evaporation of the solvent, the products were separated by chromatography on silica gel. Elution with hexane followed by recrystallization from ethanol afforded 79 mg (81%) of white fluorescent crystals, mp 133—134 °C. Found: C, 92.18; H, 7.78%. Calcd for $C_{24}H_{24}$: C, 92.26; H, 7.74%. NMR ($CDCl_3$, δ): 1.40 (3H, s), 1.54 (3H, s), 1.90 (3H, s), 2.57 (3H, s), 5.80 (1H, s), 6.6—7.8 (11H,m).

1,8-Dichloro-9-(2,6-xylyl)-10,10-dimethyl-9,10-dihydroanthracen-9-ol (8), mp 199—200 °C, was prepared by treating 2,6-xylyllithium, prepared from 1.0 g (0.0054 mol) of 2-bromo-*m*-xylene and 0.081 g (0.012 mol) of lithium, with 0.103 g (0.00035 mol) of 1,8-dichloro-10,10-dimethylanthrone[9,10] in 30 ml of ether. The reaction mixture was separated by chromatography on silica gel. The white crystals thus obtained were recrystallized from ethanol. The yield was 63% based on anthrone. Found: C, 72.85; H, 5.44; Cl, 17.38%. Calcd for $C_{24}H_{22}Cl_2O$: C, 72.55; H, 5.58; Cl, 17.85%. This compound could not be obtained from the Grignard reaction as in the case of compound **6**. NMR ($CDCl_3$, δ): 1.40 (3H, s), 1.62 (3H, s), 1.93 (3H, s), 2.9 (1H, s), 3.10 (3H, s), 6.5—7.6 (9H, m).

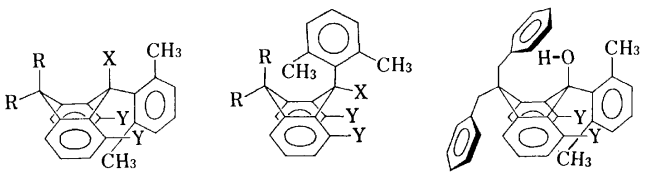
1,8-Dichloro-9-(2,6-xylyl)-10,10-dimethyl-9,10-dihydroanthracene (9), mp 206—207 °C, was similarly prepared by the reaction of **8** with 57% hydriodic acid in acetic acid followed by similar treatment as **7**. Recrystallization from hexane gave white crystals in 78% yield. Found: C, 75.77; H, 5.86; Cl, 18.63%. Calcd for $C_{24}H_{22}Cl_2$: C, 75.59; H, 5.82; Cl 18.60%. NMR-($CDCl_3$, δ): 1.51 (3H, s), 1.63 (3H, s), 2.00 (3H, s), 2.87 (3H, s), 5.90 (1H, s), 6.6—7.6 (9H, m).

9-(2,6-Xylyl)-10,10-dibenzyl-9,10-dihydroanthracen-9-ol (10), mp 216—217 °C, was prepared by treating 2,6-xylylmagnesium bromide, prepared from 3.2 g (0.0173 mol) of 2-bromo-*m*-xylene and 0.411 g (0.0173 mol) of magnesium, with 2.0 g (0.0057 mol) of 10,10-dibenzylanthrone[8] in 50 ml of THF. The reaction mixture was separated by chromatography on silica gel. Elution with hexane and benzene (10 : 1) gave white crystals which were recrystallized from ethanol. The yield was 55% based on anthrone. Found: C, 89.76; H, 6.46%. Calcd for $C_{36}H_{32}O$: C, 89.96; H, 6.71%. NMR ($CDCl_3$, δ): −0.2 (1H, s), 0.26 (3H, s), 2.55 (3H, s), 3.45 (2H, s), 3.86 (2H, s), 6.1—7.6 (19H, m), 8.1 (2H, dd).

1,8-Dichloro-9-(2,6-xylyl)-10,10-dibenzyl-9,10-dihydroanthracen-9-ol (11), mp 283—285 °C, was synthesized by treating 2,6-xylyllithium, prepared from 2.20 g (0.012 mol) of 2-bromo-*m*-xylene and 173 mg (0.025 mol) of lithium, with 1.22 g (0.0028 mol) of 1,8-dichloro-10,10-dibenzylanthrone in 30 ml of ether. The product was recrystallized from benzene–hexane. The yield was 60% based on anthrone. Found: C, 78.92; H, 5.26; Cl, 12.76%. Calcd for $C_{36}H_{30}Cl_2O$: C, 78.68; H, 5.50; Cl, 12.90%. NMR ($CDCl_3$, δ): −0.2 (1H, s), 0.35 (3H, s), 2.78 (3H, s), 3.30 (2H, s), 5.00 (2H, s), 6.1 (2H, m), 6.3 (1H, dd), 6.7—7.6 (14H, m), 8.1 (2H, dd).

Results and Discussion

Ground State Conformation. Before discussing the barriers to rotation of these compounds, it is necessary to consider the ground state conformation. These compounds could exist as two conformers, pseudo-equatorial (**12**) and pseudo-axial (**13**), with respect to 9-aryl orientation. The molecular model indicates that, while extremely large repulsion exists in **13**, such large repulsive interaction can not be expected in **12** and suggests that the 9-aryl group takes the conformation which bisects the 9,10-dihydroanthracene ring. That the preferred conformation of these compounds is pseudo-equatorial is clearly demonstrated by the ^{1}H NMR spectra, especially in the case of **10** and **11**. In



12 13 14

both compounds one of the methyl signals appeared at an abnormally high magnetic field. In addition, the hydroxyl signals of these compounds also appeared at quite a high field ($\delta = -0.2$). The high chemical shifts of these protons can be explained by the 9-aryl equatorial form with the conformation of benzyl groups which is discussed below. Two benzyl groups are arranged in such a manner that the two bulky benzene rings take the conformation anti to each other to avoid severe steric interaction. As a result one benzene ring of the benzyl group faces the methyl in the 2′ position and another the OH group, making these protons shift to quite a high field. In fact there are no such signals in 10,10-dimethyl derivatives **6** and **8**. Thus the most plausible conformation of **10** and **11** are considered to be **14**. Another piece of evidence for the conformation can be supplemented by the IR spectra. As are shown

Table 1. ν_{OH} Absorption[a)]

Compound	6	8	10	11
ν_{OH}/cm^{-1}	3596	3586	3547	3542

a) Carbon tetrachloride solutions of which concentrations were *ca.* 10 mmol l^{-1}

in Table 1, those compounds which carry benzyl groups exhibit ν_{OH} absorptions at around 3545 cm^{-1}, whereas those carrying methyl groups in the 10 position at around 3590 cm^{-1}. The latter absorption is characteristic of tertiary benzylic alcohols[11] but the former is too low to assign to the normal tertiary benzylic alcohols. Instead, the existence of the OH···π interaction[12] is suggested. Then the benzylic phenyl and the hydroxyl groups must be located in proximity. The existence of two aromatic protons which appeared at a field lower than δ 8.0 as a double doublet can also be explained by this conformation. These signals are assigned to the protons in 4 and 5 positions, because in **14** they reside in the deshielding zone of the benzene ring of the benzyl group.

In the case of the 10,10-dimethyl derivatives (**6**—**9**), it is very difficult to decide whether or not the 9-aryl groups of these compounds take the equatorial conformation on the basis of their ^1H NMR spectra, because there are no so characteristic signals as to suggest a conformation. But comparison of barriers to rotation of **6** and **7** with those of the corresponding xanthene derivatives **4a** and **4b** clearly indicates that the 9-aryl groups also take the equatorial conformation, the reason of which will be mentioned in the later part of this paper.

Barriers to Rotation. In every compound examined, two methyl signals in 2′ and 6′ positions broadened when the temperature was raised. However, no change in chemical shifts and spectral widths was observed in the signals in 10 position. This clearly shows that the coalescent phenomenon of this system is not due to the slow inversion of 9,10-dihydroanthracene ring but due to the restricted rotation of the 9-aryl ring.

In Table 2, activation free energies of these compounds including structurally similar **4** and **5** are listed together with the coalescence temperatures and the chemical shift differences between two methyl signals in 2′ and 6′ positions. Inspection of Table 2 reveals that the replacement of two methyl groups in 10 positions by benzyl groups causes the increase in energy barrier by 17.6 kJ mol^{-1} (**6**→**10**) and by more than 4.6 kJ mol^{-1} (**8**→**11**). Since the substituents in 10 positions are located far away from the two methyls in the pseudo-equatorial 9-aryl group, the increase in energy observed here seems to be too large as the substituent effect on barriers to rotation.

Table 2. Chemical shifts and barriers to rotation

a) Data from McKinley *et al.*[5)] b) Data from Rieker and Kessler.[6c)]

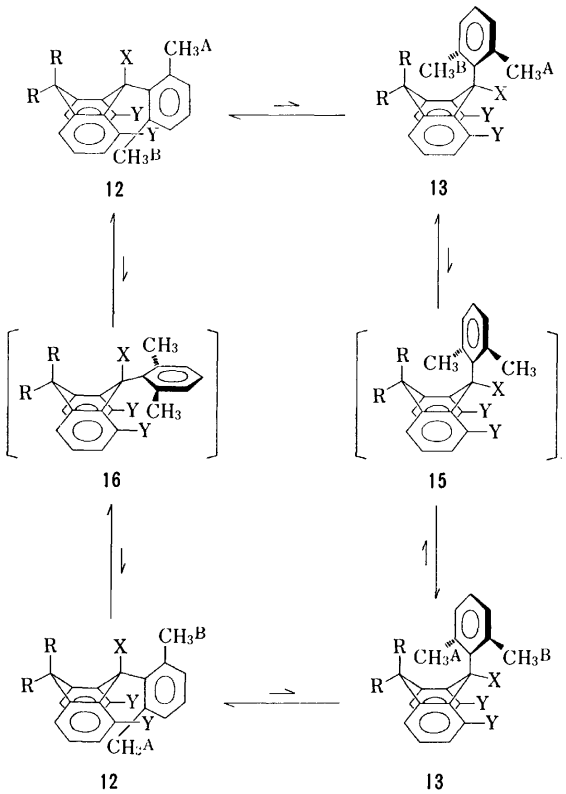

Fig. 1. Mechanism for the exchange of two methyls in the 2,6-xylyl group.

Two paths may be possible as the methyl-exchange mechanism as shown in Fig. 1. One is a simple rotation process during which the 9-aryl group is fixed in the equatorial form. The conformation of the transition state of this process is shown as **16**. The other is an inversion-rotation process which indicates that the methyl-exchange occurs through inversion of the 9,10-dihydroanthracene ring followed by rotation in the pseudo-axial conformation and then inversion to the methyl-exchanged ground state. The conformation of the transition state in this process is **15**. If the former is the case, the substituent effect in 10 position is, as mentioned, too large. In fact extremely large repulsion is expected between the xylyl group and 1,8-substituents in the conformation **16**. The barrier would have been very high in this case. If, on the other hand, the latter is occuring, the large substituent effect can be explained on the basis of the bulkiness of the benzyl groups in 10 position. In the transition state for the

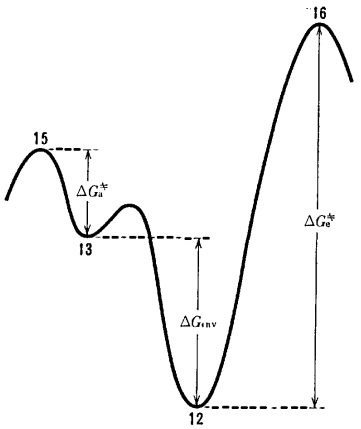

Fig. 2. Free energy profile for the rotation in 10,10-disubstituted 9-(2,6-xylyl)-9,10-dihydroanthracenes.

exchange, the two methyl groups in the pseudo-axial 9-aryl ring interact with the atoms in 1,8-positions as shown in **15**. In such a conformation two benzyl groups in **10** and **11** can not be arranged as in the ground state **14**; inside benzyl group takes the conformation in which the bulky benzene ring rotates away from the 9-aryl ring to avoid steric interaction and the rotation causes, in turn, repulsion between the two benzyl groups to result in an increase in energy of this state. In compounds **6** and **8**, on the other hand, such an additional increase in energy caused by the interaction between the two methyl groups in 10 position does not occur in the transition state for rotation. This may be the reason why **10** and **11** have higher barriers to rotation than those of the corresponding **6** and **8**. The energy profile in this system thus becomes the one described in Fig. 2, where ΔG_{inv}, ΔG_a^*, and ΔG_e^* stand for the difference in free energy between **12** and **13**, the barrier to rotation in the pseudo-axial state, and that in the pseudo-equatorial state, respectively.

The reason why we take ΔG_a^* smaller than ΔG_{inv} is as follows. If we assume that two methyls exchange only through the inversion of dihydroanthracene ring as described above, the free energy of activation (ΔG^*) in Table 2 are given by

$$\Delta G^* = \Delta G_{inv} + \Delta G_a^*.$$

Since the barrier to rotation of the xylyl group in structurally similar **4a**, where the 9-aryl group is axial both in the ground and in the transition state for rotation, was reported to be 45.6 kJ mol^{-1}, ΔG_a^* in this system is expected to be far lower than this value because of the existence of two substituents in 10 position which destabilize the aryl-axial form **13**. Therefore, the main portion of ΔG^* is occupied by ΔG_{inv}. A similar discussion has been made recently by Miller for the restricted rotation in 3-mesityl-1*H*,3*H*-naphtho-[1,8-*de*]pyrans.[13] The above discussion clearly indicates that the ground state conformation of 10,10-dimethyl derivatives (**6**—**9**) is also equatorial. If the 9-aryl groups of these compounds were axial, the ΔG^* should have been equal to ΔG_a^* which must be lower than that of **4a**. Actually, however, the reverse is true in this system.

Introduction of two chloro groups in 1 and 8 positions causes a strange effect on barriers to rotation: the increase in energy by more than 13.0 kJ mol^{-1} (**10**→**11**) and by 26.0 kJ mol^{-1} (**6**→**8**) was observed in the 9-OH derivatives, while the decrease in energy by as much as 19.2 kJ mol^{-1} was found in the 9-H derivatives (**7**→**9**). These results may be explained as follows. Introduction of two chloro groups raises the energy state of both the ground state **12** and the transition state **15** for rotation. But the degree of the increase is much greater in the latter than in the former when X is OH, because in **15** three bond dipoles are forced to be arranged parallelly in quite a narrow region. Since such a repulsion in **15** is not expected in the 9-H compound (**9**), the increase in energy of the ground state is large relative to the transition state, resulting in a low barrier to rotation.

The change in barriers, observed on the change in the 9-substituent from OH to H, is also interesting. In the case of a pair of **6** and **7**, the increase in energy of *ca.* 17.6 kJ mol^{-1} is ascribed mainly to the stabilization of the ground state. Such a stabilization of the ground state due to loss of repulsion between 9-OH and 2'-methyl is well known in **4** and **5**. On the contrary, relatively large decrease in rotational barrier (27.6 kJ mol^{-1}) was found when **8** was changed to **9**. Probably, the role of parallel arrangement of the three dipoles in the transition state of **8** exceeds that of the increase in the steric interaction in the ground state of **8** in contribution to the barrier to rotation.

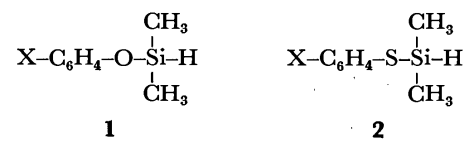
Nuclear Magnetic Resonance Studies of Hydrosilanes. III.[1] A Correlation of Hammett σ Constants with ^{29}Si–H Coupling Constants for Substituted Phenoxy- and (Phenylthio)dimethylsilanes

Hamao WATANABE,* Ryoichi AKABA, Takao IEZUMI, and Yoichiro NAGAI*
Department of Applied Chemistry, Faculty of Engineering, Gunma University, Kiryu 376
(Received April 19, 1980)

The ^{29}Si–H coupling constants and Si–H chemical shifts have been determined for a series of substituted phenoxy- and (phenylthio)dimethylsilanes. The $J(^{29}Si–H)$ values are shown to be correlated well with the Hammett σ constants for the substituent on benzene ring in compounds Ar–Y–$SiMe_2H$, where Y=O and S. In comparison with the data for the analogs of the other types of organodimethylsilanes, such as aryldimethylsilanes, substituted benzyldimethylsilanes, and aryltetramethyldisilanes, the present results are discussed on the basis of the substituent effects through the intervening oxygen and sulfur. The transmission efficiency of Y was in the order, $S > CH_2 \approx SiMe_2 > O$. For the series of (phenylthio)dimethylsilanes, the $J(^{29}Si–H)$ values observed were larger than those for the predicted ones. This deviation was interpreted in terms of the sulfur d-orbital participation *via* the electron-acceptor, "σ-π" conjugation.

There have been many reports on Hammett treatment NMR data, proton chemical shifts and ^{13}C–H coupling constants, for a variety of substituted aromatics, such as toluenes, *t*-butylbenzene, *N,N*-dimethylanilines, anisoles, methylthiobenzenes, phenyltrimethylsilanes, *etc.*[2–10] We have recently determined the ^{29}Si–H and ^{13}C–H coupling constants and SiH chemical shifts for a series of substituted phenylsilanes, phenylmethylsilanes and phenyldimethylsilanes and found that there exist excellent correlations between the coupling constants and the Hammett σ constants of the ring substituents for these series.[11,12] Cartledge and Riedel have also shown that the ^{29}Si–H and ^{13}C–H coupling constants for a series of substituted benzyldimethylsilanes and phenyltetramethyldisilanes are directly proportional to the Hammett σ constant for the *meta* and *para* substituents and that the ρ values for the relationships can be interpreted in terms of transmission of electronic substituent effects through C–Si and Si–Si bonds.[13]

The transmission of substituent effects is quite an interesting subject in silicon chemistry and one of the problems in this fields concerns the role of d-orbitals in transmitting the electronic effects of substituents. In view of our continuing interest in the chemistry of organosilicon hydrides[11,14] we have prepared two series of compounds, phenoxy- (**1**) and (phenylthio)dimethylsilanes (**2**) and have determined the ^{29}Si–H coupling constants and Si–H chemical shifts. In the present paper, we will describe the Hammett dependence of the ^{29}Si–H coupling constants for the two series of compounds. The transmission efficiency of substituent effects of oxygen and sulfur was compared with those for the structurally related compounds in which $Y=CH_2$ and $SiMe_2$, and the electronic structure of Y which affects the magnitude of the $J(^{29}Si–H)$ values is also discussed.



1 **2**

Results and Discussion

Transmission Efficiency of Y. Table 1 summarized all the NMR parameters determined for the two series, phenoxy- and (phenylthio)dimethylsilanes, and lists the Hammett σ constants for the substituent on benzene ring of these compounds. The Si–H coupling constants (J) for the two series of compounds are plotted against the Hammett σ constants in Fig. 1, giving the respective straight-line relationships. The slope (ρ), intercept (C) and correlation coefficient (γ) were determined by the method of least-squares and are given in Table 2, in

which the data for aryldimethylsilanes obtained by our previous work[11] and those for substituted benzyldimethylsilanes and aryltetramethyldisilanes by Cartledge and co-worker[13] were listed together.

The Si–H coupling constants presented in the Table 1 exhibited the expected trend in the two series. The presence of an electron-donating substituent (X) leads to a decrease in absolute magnitude of the coupling constant, whereas the presence of an electron-attracting substituent increases it. For example, the ^{29}Si–H coupling constants for *p*-methoxyphenoxy-, phenoxy-, and *m*-chlorophenoxysilane are −207.6, −208.0, and −209.6 Hz, respectively.

a) Correlation coefficient.

As seen from Fig. 1, the $J(^{29}Si–H)$ values of phenoxy- and phenylthiosilanes correlate well with Hammett σ constant. The ρ values obtained from phenoxy- and phenylthiosilanes were −3.3 and −4.9 Hz/σ with γ= 0.989 and 0.956, respectively, and can be compared with those of the other related silanes listed in Table 2. It is seen from the ρ values that the transmitting efficiency of the intervening Y (atom or group) in Ar–Y–$SiMe_2H$ decreases in the order:

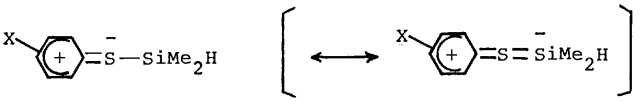
$$S > CH_2 \approx SiMe_2 > O.$$

With respect to the transmission of substituent effect through Y in the type of compounds, XC_6H_4–Y–H, Marcus *et al.* have paid particular attention to oxygen and sulfur when they form part of Y.[2] Thus, by comparing the ρ values for anisoles (Y=OCH_2) with that for methylthiobenzene (Y=SCH_2) in the Hammett dependence of the methyl proton chemical shifts, they found that the efficiency of oxygen in transmitting the substituent effects is greater than that of sulfur. This observation was explained in terms of the balance of various factors, such as nonconjugative and conjugative effects of Y, medium effect, *etc.* They also discussed the transmission efficiency of these atoms by citing several experimental results other than chemical shifts and commented that the sulfur atom must show greater efficiency when it acts as an electron acceptor in conjugated systems ("conjugative-acceptor case").

Fueno *et al.* have also determined the proton chemical shifts for a series of aryl vinyl ethers and aryl vinyl sulfides and found a good carrelation between the chemical shifts for β-proton and Hammett σ constants.[9] It has been shown that the ρ-value of the sulfide series is greater than that of the ethers, and that the result supports the above Marcus' conjecture regarding an enhanced transmission efficiency of sulfur relative to oxygen. In the sulfur compounds, various electronic contributions, such as electron-donating, electron-accepting Pπ-dπ, and through-conjugative interaction[15,16] were taken into consideration to explain the transmission efficiency. They have concluded that the transmission through sulfur is enhanced by the contribution of the canonical structure involving "through-conjugative" interaction which was defined as Pπ-dπ-Pπ conjugation:

Subsequently, by comparing the Hammett dependence of the ^{13}C chemical shifts in the two series of compounds, they have obtained a similar results which supports the "through-conjugative" participation of sulfur d-orbitals in π-conjugation.[17]

In our system, the transmission efficiency of subsituent effect of sulfur was shown to be greater than that of oxygen. This fact would be attributed to the presence of sulfur atom attached to the silicon. Considering that sulfur has electron-accepting d-orbitals and lone-pair electrons available for electron donation and that silicon also electron-accepting d-orbitals,[18] the contribution of a canonical structure containing the electron-accepting conjugation is possible. This is the structure A. In addition, this conjugation could be reached to the silicon, forming a new type of "through-conjugative" interaction, or Pπ-dπ-dπ conjugation (B), as the resonance structure of A, which is similar to that of aryl vinyl sulfides as shown by Fueno and coworkers.[9,17] However, it is not clear at the present time whether the contribution of such conjugation (B) is necessary or not to explain the enhanced transmission of substituent effect.



Pπ-dπ conjugation (A)

Pπ-dπ-dπ conjugation (B) (or "through-conjugative" interaction)

Similarly, oxygen in the phenoxide series serves as an electron donor to form Pπ-Pπ (C) and Pπ-dπ (D) conjugations. However, there can be no contribution by such a "through-conjugative" interaction as above mentioned.

Pπ-Pπ conjugation (C)

Pπ-dπ conjugation (D)

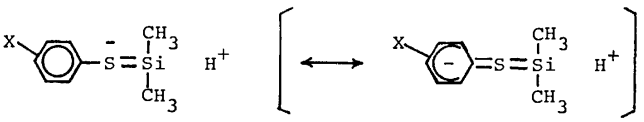
The ρ values of −4.4 and −4.0 Hz/σ for the two series of Y=CH_2 and $SiMe_2$, respectively, suggest roughly equal transmitting abilities for carbon and silicon.[13] This result is consistent with that obtained from the ^{13}C chemical shifts for the type of compounds, XC_6H_4–Y–$(CH_3)_3$ where Y=C and Si.[19] It is interesting, however, that the transmission efficiency of the two systems falls between those for the systems of Y=S and O.

It is worthwhile to note that the ρ value (-6.7 Hz/σ) for phenyldimethylsilanes is to be the greatest one (Table 2). The transmitting ability of the system is easily rationalized by the structure and the SiH group is one atom closer to the benzene ring than it is in the other series.

In contrast, the plots of the Si–H chemical shifts, listed in Table 1, *vs.* Hammett σ constants in the two series of oxygen and sulfur exhibited essentially no good correlation. In these cases, the correlations of the δ(SiH) with Hammett σ constants were too poor.

Electronic Behavior of Y. Although factors governing the magnitude of Si–H coupling constants cannot be said to be fully understood, the effective electronegativity of the substituent attached to silicon affects it,[11,14,20,21] as has been shown by Jensen's equation.[22] In the present system, Ar–Y–$SiMe_2H$, the magnitude of the Si–H coupling constants can be definitely related to the effective electronegativity of Y because of only change of Y. Thus, the greater this electronegativity, the greater the coupling constant. This is readily seen from an examination of the Si–H coupling constants in Table 3. The J values for (phenylthio)dimethylsilane, phenoxydimethylsilane, phenyldimethylsilane, benzyldimethylsilane, and phenyltetramethyldisilane are -209.7, -208.0, -188.3, -186.9, and -175.0 (Hz), respectively.

The decreasing trend in the absolute magnitude follows the order of decreasing electrogegativity of Y, except the case of Y=S. The ^{29}Si–H coupling constant of phenylthiosilane is greater than what would be predicted on the basis of the electronegativity of Y. Table 3 shows the correlation of the J values for the five hydrosilanes with the electronegativity of respective Y's on the Pauling scale. The plots of $J(^{29}\text{Si–H})$ for the compounds of Y=$SiMe_2$, none, CH_2, and O *vs.* the electronegativity (En) of the respective key atoms in Y show approximately a linear relationship, while the plot for the sulfur compound anormally deviates from the relationship. This deviation is attributable to sulfur attached to silicon. Within the framework of the "through-conjugation," it is possible to assume that the contribution of the structure *via* the interaction between d-orbital of sulfur and Si–H bond electrons, "σ-π" interaction, appears to play an important role affecting the silicon hybrid orbitals bonded to the hydrogen. The direction of the electron shifts *via* the conjugation is opposite to those of the conjugation A and B, and the following canonical structures can be illustrated as E and F. Thus, the charge-separated contributors would tend to increase the s character of the Si–H bond due to the structure change around the silicon ($sp^3 \rightarrow sp^2$), producing the enhancement of the absolute magnitude of the Si–H coupling constant.



"σ-π" conjugation (E) "through-conjugative" interaction (F)

Table 3. Comparisons of the $J(^{29}\text{Si–H})$ for the related compounds

Compound	$J(^{29}\text{Si–H})$ (Hz)	En[a]	Ref.

Ph–$SiMe_2H$	-188.3	2.5	11

a) Electronegativity (Pauling scale) of the key atom in the intervening Y atom or group.

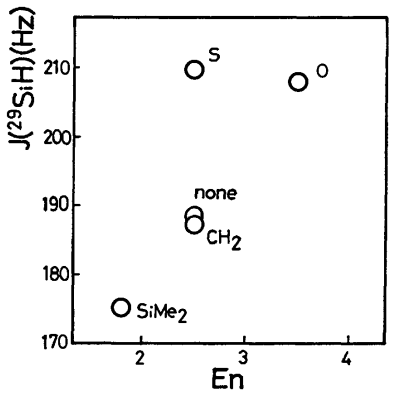

Fig. 2. Plot of the $J(^{29}\text{Si–H})$ *vs.* the electronegativity (En) of the key atom in Y.

Recently, Ojima, Nihonyanagi, and Nagai have determined the $J(^{29}\text{Si–H})$ for two series of sulfur compounds, RR'(PhS)SiH and RR'(EtS)SiH, and showed that these compounds have considerably large J values compared to that for triethylsilane.[23,24] They have stated that the large absolute values may reflect the large fraction of s character employed by silicon in the Si–H bond. This explanation is consistent with the idea of the "σ-π" interaction and provides supporting evidence for our present results.

On the other hand, the electron-accepting "σ-π" conjugation cannot occur in the series of phenoxysilanes, but oxygen serves as an electron donor, forming the Pπ-Pπ (C) and Pπ-dπ (D) conjugations. Although the two conjugations actually seem possible as has been shown by many workers in a variety of oxygen-bonded silicon compounds, the Pπ-dπ conjugation (D) in the present system should contribute to decrease the magnitude of the Si–H coupling constant. However, as the plot of the $J(^{29}\text{Si–H})$ for phenoxydimethylsilane *vs.* the electronegativity of oxygen appears to be in line of the correlation as shown in Fig. 2, the contribution of the conjugative interaction (D) might not be so important.

Experimental

All boilling points are uncorrected. IR spectra were recorded using neat liquid films with a Hitachi EPI-G3 spectrometer. Mass spectra were obtained with a Hitachi RMU-6L spectrometer. GLC analyses were conducted using Ohkura Model 807 and 1700 gas chromatographs.

Materials. *sym*-Tetramethyldisilane was prepared *via* $LiAlH_4$-reduction of the corresponding dichlorosilane obtained by chlorination of hexamethyldisilane.[25] Hexamethyldisilane was obtained by MeMgBr-methylation of chlorodisilane fraction (bp 148—160 °C) in the "Direct Synthesis."[26] *p*-Methoxybenzenethiol (bp 85—88 °C/3 mmHg; lit,[27] bp 89 °C/5 mmHg) was prepared by the literature method from anisole *via* chlorosulfonation with chlorosulfuric acid and then Zn–H_2SO_4 reduction of the resulting *p*-methoxybenzenesulfonyl chloride.[28] *m*-Methylbenzenethiol (bp 80—84 °C/24 mmHg; n_D^{25} 1.5715; lit,[29] bp 90—93 °C/25 mmHg; n_D^{25} 1.568—1.571) was also prepared from toluidine *via* diazotization

followed by treatment with potassium *O*-ethyl dithiocarbonate. All the other materials were commerically available.

Preparation of Substituted Phenoxydimethylsilanes. The method used for the reaction to give phenoxydimethyldisilane is representative.[30] Under argon, a mixture of phenol (10 mmol) and *sym*-tetramethyldisilane (10 mmol) was added with chlorotris(triphenylphosphine)rhodium, RhCl $(PPh_3)_3$, 0.5 mol% relative to the substrate used) and magnetically stirred at room temperature for 30 min at the stage of which gas evolution of dimethylsilane (Me_2SiH_2) ceased. GLC analysis for the resulting mixture thus obtained showed that almost of it was the reaction product, phenoxydimethylsilane, in a quantitative yield. The pure sample was obtained by distillation. Pertinent physical, spectral, and analytical data for all the compounds thus prepared are give in Tables 4 and 5.

Preparation of Substituted (Phenylthio)dimethylsilanes. Similarly, (phenylthio)dimethylsilanes were prepared by reacting substituted benzenethiols (4—15 mmol) with tetramethyldisilane (10—20 mmol) in the presence of RhCl-$(PPh_3)_3$ catalyst (0.2—0.5 mol% relative) to the benzenethiols (r. t.; 10—60 min).[23,30] The yield of the products by GLC analyses were fairly high (40—70%), but the products, except *m*-methyl derivative which could be isolated by distillation (bp 85—86 °C/13 mmHg), were only isolable by preparative GLC in 90—98% purity and further purification could not be achieved because of their instabilities under the GLC conditions. Therefore, the pure samples for elemental analyses could not be obtained, but they are enough in purity for spectral determinations. Table 6 lists the physical and spectral data which were carefully determined.

NMR Measurements. NMR constants were determined from spectra obtained on a Varian A-60D spectrometer. Measurements of the coupling constants $J(^{29}Si-H)$ and Si–H chemical shifts were made in CCl_4 solution by the method described previously.[11]

Removal and Recovery of Organic Pollutants from Aquatic Environment. V. Crosslinked Poly(hydroxystyrene) as a Polymeric Adsorbent for Removal and Recovery of ε-Caprolactam from Aqueous Solution

Nariyoshi KAWABATA* and Yukihiko TAKETANI

Laboratory of Environmental Chemistry, Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received April 10, 1980)

Crosslinked poly(hydroxystyrene) (PHS resin) was found to be useful as a polymeric adsorbent for removal and recovery of ε-caprolactam from aqueous solution. The breakthrough capacity of PHS resins with <1-mg/l leakage in the effluent was 50—90 mg/dry g, which was scarcely affected by the presence of hydrochloric acid, sodium hydroxide, and inorganic salts such as sodium chloride, potassium chloride, calcium chloride, and magnesium chloride. Elution of the adsorbed ε-caprolactam from PHS resin was easily accomplished by a simple treatment with methanol, and PHS resin was efficiently regenerated. ε-Caprolactam was concentrated into 10—30 g/l solution.

In this series of investigations, attempts have been made to find new polymeric adsorbents which are useful for removal and recovery of organic pollutants from aquatic environment. This methodology is important not only in the protection of the environment from pollution, but also in the effective use of raw materials, because the organic pollutants can be recovered without chemical change. This paper deals with the removal and recovery of ε-caprolactam from aqueous solution by polymeric adsorbents.

ε-Caprolactam is the most important lactam in use by chemical industry. The wastewater from the manufacturing process contains some amount of the lactam, which is usually treated with activated sludge. However, the biological treatment needs a long time and a wide space. The adsorption process using a suitable polymeric adsorbent may be more convenient because the process saves time and space of the treatment, and makes it possible to reuse the recovered ε-caprolactam. We have tried to use various polymeric adsorbents for this purpose, and found that the crosslinked poly(hydroxystyrene) (PHS resin) was most useful.

Experimental

Materials. *p*-Acetoxystyrene provided by Maruzen Oil Co., Tokyo, was purified by distillation before use. Commercial products of divinylbenzene and toluene were purified by distillation before polymerization. Methanol, petroleum ether, ε-caprolactam, 2,2′-azobisisobutyronitrile, sodium hydroxide, hydrochloric acid, calcium hydride, and other chemicals were used without further purification.

Crosslinked Poly(hydroxystyrene) (PHS Resin). PHS resin was prepared by hydrolysis of the copolymer of *p*-acetoxystyrene with divinylbenzene according to the procedure of Packham[1] with minor modification. Dried copolymer of *p*-acetoxystyrene with divinylbenzene was ground using an ishiusu (a Japanese classical hand mill made of stone) and sifted out to 60—80 mesh. The sifted copolymer was hydrolyzed to give PHS resin. One sample of PHS resin (PHS-9) was prepared by a direct radical copolymerization of *p*-vinylphenol with divinylbenzene in benzene, which was ground and sifted out to 20—30 mesh. These PHS resins were rinsed with 10 Bed Volume (BV) of methanol by a batch method followed by washing with 30—40 BV of water by the continuous flow column method. Mole fraction of *p*-acetoxystyrene in the copolymer of *p*-acetoxystyrene with divinylbenzene before hydrolysis, and that of *p*-vinylphenol in PHS-9 were determined by elemental analysis. Content of water in the swollen state and the mean particle diameter of these PHS resins were determined, and results are given in Table 1.

Commercial Polymeric Adsorbents. For comparison with PHS resin, four commercial resins provided by Rohm and Haas Co., Philadelphia, Pa. were used. Amberlite IR-120B was used as a strong acid cation exchange resin which had a styrene–divinylbenzene matrix with sulfonate group. This

Table 1. Characteristics of crosslinked poly(hydroxystyrene) (PHS resin)

Crosslinked polyhydroxystrene	PHS-1	PHS-2	PHS-3	PHS-4	PHS-5	PHS-6	PHS-7	PHS-8	PHS-9[a)]

a) Prepared by a direct copolymerization of *p*-vinylphenol with divinylbenzene. b) Mole fraction of *p*-vinylphenol.

resin was used in the hydrogen ion form. Amberlite IRC-50 was used as a weak acid cation exchange resin which had a styrene–divinylbenzene matrix with carboxyl group. This resin was also used in the hydrogen ion form. Amberlite XAD-2 and XAD-4 were used as porous styrene–divinylbenzene resins with no ion exchange functional group. The surface area of XAD-2 and XAD-4 were claimed by the supplier to be 300 and 784 m^2/g, respectively.

Amberlite IR-120B was preconditioned and transferred to the hydrogen ion form as follows: (1) placing it in a column of 2.5-cm diameter with a fritted glass filter; (2) washing with 10 BV of methanol; (3) washing with 10 BV of deionized water; (4) slowly contacting with 10 BV of 2 mol/l hydrochloric acid; (5) washing with 10 BV of deionized water; (6) slowly contacting it with 10 BV of 2 mol/l sodium hydroxide; (7) washing with 10 BV of deionized water; (8) repeating steps 4 through 7 several times; (9) slowly contacting it with 20—30 BV of 2 mol/l hydrochloric acid; (10) extensive washing with deionized water until the effluent pH was close to the influent pH. The ion exchange capacity of the resin was 4.4 meq/dry g, which was determined by back titration with 0.1 mol/l hydrochloric acid using phenolphthalein as indicator in 1 mol/l sodium hydroxide after the addition of standard sodium hydroxide solution. Percentage moisture of the resin was determined after drying *in vacuo* to constant weight. Amberlite XAD-2 and XAD-4, and Amberilte IRC-50 in the hydrogen ion form were preconditioned by washing with 10 BV of methanol followed by washing with 30 BV of deionized water.

For comparison with the non-ionic XAD resins, we also used pulverized copolymer of styrene with divinylbenzene containing 57 mol% styrene, which was prepared as was described in a previous paper of this series.[2)]

Adsorption Tests. Column studies were conducted using a 1.0-cm diameter glass column with a fritted glass filter connected with a 200-ml dropping funnel in a down-flow fashion at room temperature. The preconditioned polymeric adsorbent was placed in the column. The bed was carefully backwashed to eliminate entrained air and then tapped to ensure packing of the bed. The dropping funnel was used to contain influent solution. Samples were taken manually and were checked for the concentration of ε-caprolactam. The flow rate was 3 BV/h throughout this work. The influent concentration of ε-caprolactam was controlled to be about 2000 mg/l.

The capacity of polymeric adsorbents for the adsorption of ε-caprolactam was determined by continuous flow column method in two ways: (i) the breakthrough capacity, which was based upon the total amount of adsorbed ε-caprolactam before the effluent concentration reached 1 mg/l; (ii) the total capacity, which was determined based upon the total amount of adsorbed ε-caprolactam until the effluent concentration became close to the influent concentration.

The breakthrough capacity and the total capacity of the PHS resin for sodium hydroxide adsorption were determined using aqueous 0.02 mol/l sodium hydroxide solution by the continuous flow column method. Results are given in Table 1.

Equilibrium adsorption tests were conducted by placing weighed quantities of polymeric adsorbent and samples of aqueous solution of ε-caprolactam in a 300-ml Erlenmeyer flask sealed by rubber stopper in a water bath maintained at 30 ± 1 °C with magnetic stirring. After the mixture reached equilibrium, the concentration of ε-caprolactam was determined.

Recovery of Adsorbed ε-Caprolactam from Polymeric Adsorbents. Polymeric adsorbents were saturated with ε-caprolactam by the continuous flow column method carried out until the effluent concentration became 1 mg/l using about 2000 mg/l of aqueous ε-caprolactam solution. Elution of the adsorbed ε-caprolactam from the polymeric adsorbents was conducted by the continuous flow column method using methanol as the eluant with flow rate of 3 BV/h in a down-flow fashion.

Analyses. Elemental analyses were performed at the Elementary Analyses Center of Kyoto University. Quantitative analysis of ε-caprolactam in aqueous and/or methanolic solution was performed with Shimadzu Model UV-200S spectrophotometer based upon the absorptivities at 203 nm. The pH value of solutions was determined with a Horiba Model F-7AD pH meter.

Results and Discussion

Adsorption of ε-Caprolactam on Various Polymeric Adsorbents Studied by the Continuous Flow Column Method. The breakthrough curves are illustrated in Fig. 1. PHS resin and XAD-4 showed the ability to adsorb ε-caprolactam in aqueous solution, but the cation exchange resins IR-120B and IRC-50 did not adsorb ε-caprolactam under our experimental conditions. We calculated the breakthrough capacity and the total capacity for the adsorption of ε-caprolactam. Results are summarized in Table 2. The adsorption capacity of the PHS resin was not very sensitive to the content of *p*-acetoxystyrene before hydrolysis, but showed a maximum at the content of about 40 mol%.

Conditions: influent concentration of ε-caprolactam, 2000 mg/*l*; flow rate, 3 BV/h; (▲) PHS-1; (○) PHS-4; (●) PHS-5; (×) XAD-4.

Among the styrene–divinylbenzene resins with no ion exchange functional group, XAD-4 (claimed by the supplier to have the surface area of 784 m^2/g) showed a breakthrough capacity of 55 mg/dry g, but XAD-2 (claimed by the supplier to have a surface area of 300 m^2/g) showed a much lower capacity to adsorb ε-caprolactam. This result indicates the importance of the surface area of the polymeric adsorbents. In this work, we used the PHS resins in the pulverized form, but they showed breakthrough capacities of 50—90 mg/dry g as can be seen in Table 2. If we supposed a

TABLE 2. CAPACITIES OF POLYMERIC ADSORBENTS FOR ε-CAPROLACTAM ADSORPTION[a]

a) Determined by the continuous flow column method using about 2000 mg/l of aqueous ε-caprolactam solution. The flow rate was 3 BV/h. b) Claimed to have the surface area of 300 m^2/g. c) Claimed to have the surface area of 784 m^2/g.

spherical form for PHS resins, the surface area of PHS-1—PHS-8 were assumed to be about 30 cm^2/g. Thus the actual surface area of the PHS resins would be less than 0.1 m^2/g. If porous PHS resins with large surface area were used, the adsorption capacity could be further improved. PHS-9 showed a lower capacity than the other PHS resins for the adsorption of ε-caprolactam. The result can be ascribable, at least partly, to the smaller surface area, because the particle size of PHS-9 was much larger than those of the other PHS resins as can be seen in Table 1.

Effect of Some Inorganic Salts in Aqueous Solution on the Breakthrough Capacity of Polymeric Adsorbents for ε-Caprolactam Adsorption. In the practical use of polymeric adsorbents for removal and recovery of ε-caprolactam from wastewater, it is difficult to avoid the presence of some inorganic salts. Inorganic cations in wastewater might reduce the capacity of PHS resin for the adsorption of ε-caprolactam if it adsorbed through an ion exchange mechanism. In order to obtain some information on this subject, we have investigated the effect of the presence of some inorganic salts in aqueous solution on the breakthrough capacity of PHS resin for ε-caprolactam adsorption.

TABLE 3. CAPACITIES OF POLYMERIC ADSORBENTS FOR ε-CAPROLACTAM ADSORPTION IN THE PRESENCE OF INORGANIC SALTS[a]

Polymeric adsorbent	Inorganic salt	Breakthrough capacity (mg/dry g)	Total adsorption capacity (mg/dry g)
PHS-5	none	87	96
PHS-5	NaCl	85	101
PHS-5	KCl	87	103
PHS-5	$MgCl_2$	89	103
PHS-5	$CaCl_2$	89	103
XAD-4	none	55	91
XAD-4	NaCl	57	96

a) Determined by the continuous flow column method using about 2000 mg/l of aqueous ε-caprolactam solution containing 0.1 mol/l of inorganic salts. The flow rate was 3 BV/h.

Since major inorganic cations commonly appearing in natural water are sodium, potassium, calcium, and magnesium cations, we first determined the breakthrough capacities of PHS resins, and XAD-4 for comparison, for the adsorption of ε-caprolactam in the presence of sodium chloride, potassium chloride, calcium chloride, and magnesium chloride. Results are given in Table 3. The capacity did not decrease in the presence of these inorganic salts.

Effect of Acid and Alkaline Materials in Aqueous Solution on the Breakthrough Capacity of Polymeric Adsorbents for the Adsorption of ε-Caprolactam. In the practical use of polymeric adsorbents for wastewater treatment, it is also difficult to avoid the presence of acid and alkaline materials. In order to obtain some information on this subject, we have investigated the effect of hydrochloric acid and sodium hydroxide in aqueous solution on the capacity of PHS resin, and XAD-4 for comparison, for the adsorption of ε-caprolactam. Results are summarized in Table 4. The breakthrough capacity was scarcely affected by the presence of these acid and alkaline materials.

Adsorption Equilibrium for ε-Caprolactam and Polymeric Adsorbents. The experimental isotherms of ε-caprolactam adsorption on PHS resin are shown in Fig. 2. Similar results were obtained with PHS resins and XAD-4.

Recovery of ε-Caprolactam from Polymeric Adsorbents. In addition to the removal of ε-caprolactam from aqueous solution, the major objective of this work is to recover as much ε-caprolactam as possible from the polymeric adsorbents. This is necessary not only in the effective regeneration of the polymeric adsorbents, but also in the reuse of the recovered ε-caprolactam. We examined the elution of ε-caprolactam from PHS resin and XAD-4 by the continuous flow column method using methanol as the eluant. Results are shown in Fig. 3. The adsorbed ε-caprolactam was quantitatively recovered using 2—3 BV of methanol as the eluant, and PHS resin and XAD-4 were efficiently regenerated. ε-Caprolactam was concentrated into 10—30 g/l solution.

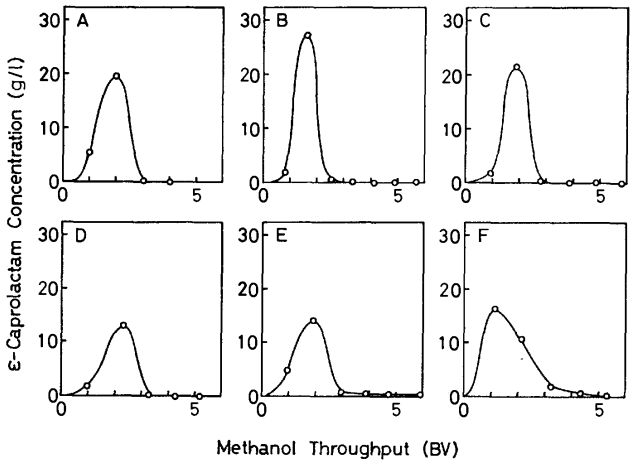

Fig. 3. Elution of adsorbed ε-caprolactam from polymeric adsorbents using methanol as the eluant by the continuous flow column method.
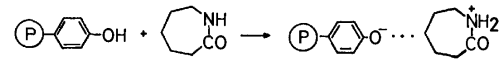
Flow rate was 3 BV/h; (A) PHS-5; (B) PHS-6; (C) PHS-7; (D) PHS-8; (E) PHS-9; (F) XAD-4.

Mechanism of the Adsorption of ε-Caprolactam on PHS Resin. Although mechanism of the adsorption of ε-caprolactam on PHS resin has not been elucidated as yet, experimental results gave some suggestions on this problem. It is reasonable to speculate that the adsorption of ε-caprolactam by PHS resin was derived from an intermolecular interaction between ε-caprolactam and phenolic hydroxyl group of PHS resin, because PHS resin showed a comparable or a rather higher capacity than the porous styrene–divinylbenzene resin with no ion exchange functional group, in spite of the fact that we used PHS resin in a pulverized form.

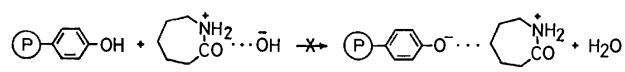
Although we used PHS resin in a pulverized form, it showed a high hydrophilicity and considerably swelled in water as can be seen in Table 1. Thus the effective surface area in water might be unexpectedly large. However, this high hydrophilicity would not wholly explain the adsorption capacity of PHS resin for ε-caprolactam, because a vinylpyridine–divinylbenzene copolymer in a pulverized form[2] did not adsorb ε-caprolactam under similar conditions, in spite of the fact that the copolymer also showed a high hydrophilicity. Therefore, the high hydrophilicity of PHS resin can not wholly explain its capacity for ε-caprolactam adsorption. The intermolecular interaction between ε-caprolactam and phenolic hydroxyl group of PHS resin appears to be an important factor for the adsorption.

Since phenol is a weak acid, and ε-caprolactam is a very weak base, the following interaction was hypothesized between PHS resin and ε-caprolactam:



Here, ε-caprolactam uptakes a proton from phenolic hydroxyl group of PHS resin and forms a complex with phenoxide anion as the associated counterion.

On the other hand, since weak acid and strong acid cation exchange resins did not adsorb ε-caprolactam under our experimental conditions, the following ion exchange mechanism would not be suitable for the adsorption of ε-caprolactam by PHS resin.



Further research is required to determine the mechanism of the interaction between ε-caprolactam and PHS resin.

Assignment of Fundamental Vibrations of *N,N'*-Dimethylthiourea

Kolar Ramakrishnaiaa Gayathri Devi and Dixit Narayanarao Sathyanarayana*
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India
(Received December 10, 1979)

The infrared spectra of symmetric *N,N'*-dimethylthiourea (s-DMTU) and its *N*-deuterated (s-DMTU-d_2) species have been measured. The fundamental frequencies have been assigned by comparison with the assignments in structurally related molecules and the infrared band shifts on *N*-deuteration, *S*-methylation, available Raman data and with the aid of theoretical band assignments from normal coordinate treatments for s-DMTU-d_0 and -d_2. A force field is derived for s-DMTU by transferring the force constants chiefly from *N*-methylthiourea and the subsequent refinement of the force constants by a least squares procedure.

There is continued interest in the vibrational spectra of thiourea derivatives. The infrared and Raman spectra and normal coordinates of thiourea (TU)[1-3] and its *N*-methyl compounds namely, *N*-methylthiourea (NMTU),[4] unsymmetric *N,N*-dimethylthiourea (u-DMTU),[5] and *N,N,N',N'*-tetramethylthiourea (TMTU)[6,7] have been published. In this context, it was felt desirable to obtain a more complete assignment for symmetric *N,N'*-dimethylthiourea (s-DMTU), and compare the results with its oxygen analogue, symmetric *N,N'*-dimethylurea (DMU),[8] and with thiocarbohydrazide (TCH, $H_2NNHCSNHNH_2$),[9] with which it is isoelectronic.

The infrared spectrum of s-DMTU was previously reported by Rao *et al.*[7] These authors have also carried out a normal coordinate treatment for only the in-plane vibrations employing a point mass approximation for the methyl group on a molecular model with a point group symmetry C_{2v}. Afterwards, Ritchie *et al.*[10] reinvestigated the vibrational spectra of s-DMTU-d_0 and -d_2 and performed a vibrational analysis for mainly the in-plane vibrations also assuming a molecular symmetry C_{2v}. However, they point out that the available Raman depolarization data suggests that the molecule is likely to have a lower molecular symmetry (C_s). There are some significant differences between the assignments of Rao *et al.* and Ritchie *et al.* And further, a complete interpretation of the vibrational spectra of this interesting molecule is lacking.

The results of the force field calculations for all the fundamentals of s-DMTU-d_0 and -d_2 are presented for the more stable *cis-trans* conformation in this paper. The present assignments for s-DMTU are compared with the earlier ones and are discussed in relation to the assignments available for other thioureas and related compounds. In order to obtain some support for the C=S and C–N stretching bands from the band shifts, the infrared spectrum of the *S*-methyl derivative of s-DMTU is also studied.

Experimental

s-DMTU was synthesized starting from methyl isothiocyanate and methylamine.[11] It was recrystallized from dry ethanol mp 62°.

s-DMTU was *N*-deuterated by dissolving it in D_2O and evaporating the solution *in vacuo*. The process was repeated several times till the infrared spectrum showed practically no bands due to NH vibrations. The *S*-methyl derivative of s-DMTU was prepared according to the method of Brand and Brand.[12] It was dried under vacuo over phosphorus pentaoxide.

Spectra: The infrared spectra were measured on a Carl-Zeiss UR 10 spectrophotometer in the range 4000 to 400 cm^{-1} by Nujol mull and KBr pellet techniques. The bands in the far infrared region and also the Raman frequencies were taken from the recently published spectra.[13] The solution infrared spectra in $CHCl_3$ were recorded for different concentrations between 4000—500 cm^{-1} using NaCl windows of path length 0.4 mm.

Normal Coordinate Analysis

Wilson's GF matrix method was employed.[14] A stable *cis-trans* conformation may be expected for s-DMTU.[10,15-19] The molecular geometry for s-DMTU was constructed on the basis of the results of the X-ray diffraction structural information on the metal complexes[18,19] of s-DMTU and free TMTU.[20] The molcular parameters employed are, C=S 0.171, C–N 0.133, N–CH_3 0.147, C–H 0.109, N–H 0.101 nm, HCH, HCN 109°28′, and all interbond angles of 120° for the planar skeleton.

The 36 normal modes of s-DMTU are classified in the point group C_s into 23 of species a′ (in-plane) and 13 of species a″ (out-of-plane) vibrations. All the normal modes are infrared and Raman allowed. The internal displacement coordinates are shown in Fig. 1, and the symmetry coordinates employed are not listed here for the sake of brevity. A simple Urey-Bradley force field (UBFF) was employed. For the out of plane vibrations of the planar skeleton, valence force constants were used. Pilot calculations were made for the in-plane vibrations of s-DMTU by transferring the force constants from NMTU[4] (set 1) and *N*-(methyl)thioacetamide[21,22] (NMTA) (set 2). It was pleasing to note that the agreement between the observed and calculated frequencies for the zero order sets was good indicating the transferability property of the force constants.

The initial values of the valence force constants for a″ modes were obtained from NMTU.[4] The transferred values of the force constants (set 1) were refined for the in-plane vibrations by a least squares procedure[23,24] by keeping some of the force constants such as stretching (CS, CN, NH, and CH), bending (HCH) and repulsion (SCN, NCN) force constants fixed. For the out-of-plane vibrations the force constants were refined by progressive adjustments to obtain a desired agreement between the observed and calculated frequencies. For simplicity, the same force constants

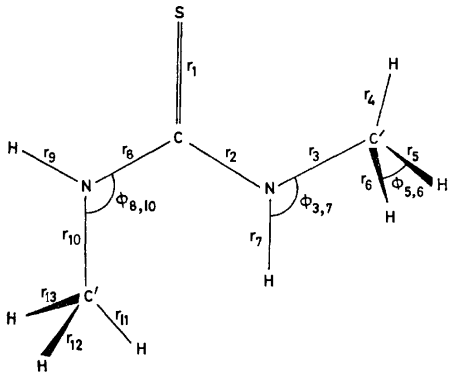

Fig. 1. Molecular structure and internal coordinates of s-DMTU.

were employed for both the *cis* and the *trans*-NH and -CH_3 moieties. For this reason the deviation between the observed and calculated frequencies is larger, particulary for the 1188, 1020, and 237 cm^{-1} bands. During the refinement process, it was noted that the potential energy distributions largely remain unaffected.

The computations were performed on an IBM 360/44 digital computer using Fortran programs similar to those of Shimanouchi.[25]

Results and Discussion

Force Field. The previous applications of the normal coordinate procedures for *N*-alkylated thioureas and thioamides have successfully employed the Urey-Bradley force.[1,3-5,7,21,22,26,27] The same has been utilized in the present study. The final values of the force constants are listed in Table 1. The values of the force constants seem reasonable.

The characteristic C=S and C–N stretching constants may now be compared. The C=S stretching constant of s-DMTU (2.65 mdyn/Å) is somewhat lower compared to that of thioacetamide (TA)[26,27] and TCH[9] (3.45 mdyn/Å). The C–N stretching constant of s-DMTU (5.45 mdyn/Å) is closer to that of TCH[9] and NMTU[4] (5.35 mdyn/Å) and *N*-(alkyl)thioamides[21,27] (5.50—5.75 mdyn/Å). The lower C=S and C–N stretching constants of s-DMTU compared to those of TA seem reasonable in relation to their π bond orders. The π bond orders of the C=S group in TA and s-DMTU are 0.637 and 0.514, respectively, while that of C–N bond is 0.585 and 0.550, respectively, as obtained by the CNDO/2 method.[28]

Vibrational Assignments. In Table 3, the results of the present investigation given in Table 2 are compared with the earlier assignments for s-DMTU and also for s-DMU. A satisfactory interpretation of all the frequencies is made by referring to the band shifts on *N*-deuteration and *S*-methylation and the characteristic group frequencies of related thioamides and thioureas.

In-plane Thioureide Group Vibrations. NH and CN Vibrations: The infrared spectrum of s-DMTU in the solid phase exhibits a broad band centred at 3005 cm^{-1}, which could easily be assigned to in- and out-of-phase vibrations of the NH group. The spectrum in $CHCl_3$ at different concentrations gives a strong sharp peak at 3450 cm^{-1} and a broad medium band centered at 3335 cm^{-1}. The intensity of the sharp peak increases and that of the broad band decreases with dilution, indicating the existence of strong hydrogen bonding in the solid state. On *N*-deuteration this broad band is replaced by the new absorptions at 2440 and 2420 cm^{-1}.

According to the normal coordinate calculations, the band at 1560 cm^{-1} is attributable to thioamide III band (B band of Jensen and Nielsen)[29] of the secondary thioamide group. It is slightly coupled with NH bending mode. The analogous band in NMTU[4] (1567 cm^{-1}) and TCH[9] (1547 cm^{-1}) is found in the same region. The potential energy distribution reveals that the 1506 cm^{-1} band could be attributed to a mixed mode of NH bending and C–N stretching. The assignment for the C–N stretching bands may be substantiated by the spectrum of the *S*-methyl derivative. On *S*-methylation, the 1560 cm^{-1} band of s-DMTU shows a larger shift and is found at 1610 cm^{-1} while 1506 cm^{-1} band is found around 1520 cm^{-1}.

The assignment of NH bending vibrations differs from the previous ones.[7,10] Alternate assignments for the NH bending mode were probed through the force field calculations. The assignments described below seemed acceptable.

The potential energy distributions (PEDs) reveal that the *trans*-NH bending mode contributes predominantly (51%) to the 1355 cm^{-1} band which disappears on *N*-deuteration. A new strong band is noted at 936 cm^{-1} in the spectrum of s-DMTU-d_2 as is to be expected consequent to the mass change on replacement of H by D. This assignment of NH bending is in good agreement with that of s-DMU[8] (1328 cm^{-1}), TCH[9] (1333 cm^{-1}) and somewhat higher than in NMTU[4] (1302 cm^{-1}). The other NH bending vibration *cis* to the thiocarbonyl group is coupled mainly with C–N stretching and contributes nearly equally ($\approx$36%) to the bands at 1506 cm^{-1} and a doublet at 1287 and 1260 cm^{-1}.

C=S Stretching: Of particular interest in the spectrum of s-DMTU is the assignment of the C=S stretching (Thioamide I band). Jensen and Nielsen[29] have qualitatively assigned for s-DMTU by comparison with its selenium analogue (s-DMSU), a band at 637 cm^{-1} to C=S stretching. However, the difference in frequency between s-DMTU and s-DMSU (605 cm^{-1}) is rather small (32 cm^{-1}).

According to the potential energy distribution the C=S stretching coordinate contributes substantially ($\approx$40%) to the 725 cm^{-1} absorption. The C=S stretching also contributes significantly ($\approx$20%) to the low frequency bands at 550 and 445 cm^{-1} and to a lesser extent to the high frequency bands at 1020 and 1274 cm^{-1}. Hence the 725 cm^{-1} band may qualitatively be assigned to the C=S stretching vibration. This assignment is in agreement with Ritchie *et al.*[10] and is concordant with the Raman data.[10,13] Further evidence for the assignment of C=S mode comes from the infrared spectrum of the *S*-methyl derivative. The 725 cm^{-1} band shifts to 708 cm^{-1} with the decreasing C=S bond

a) Ref. [8]. b) Ref. [7]. c) Ref. [10].

order upon *S*-methylation. The C=S stretching frequency of s-DMTU is thus in the same region as in TA[26] (719 cm^{-1}), TU[1] (736 cm^{-1}), and NMTA[21] (699 cm^{-1}).

Skeletal Bending: The skeletal bending modes occur as highly coupled vibrations. Calculations indicate that NCN bending is highly delocalized and contributes to the frequencies at 193, 445, 550, 725, and 1274 cm^{-1}. In contrast, in s-DMU, NCN bending contributes mainly (46%) to 504 cm^{-1} band and to some extent (22%) to the 202 cm^{-1} frequency.[8] The characteristic NCS bending is also a highly mixed mode and contributes to the bands at 550, 445, and 211 cm^{-1}. The 445 cm^{-1} band could qualitatively be assigned to NCS bending in comparison with the 460 cm^{-1} of TA.[26] The contribution of NCS bending vibration to 550 and 445 cm^{-1} bands is evidenced by the shifting of these bands to slightly higher wave numbers (567 and 452 cm^{-1}) in the infrared spectrum of the *S*-methyl derivative.

According to the coordinate treatment, the 211 and 193 cm^{-1} bands correspond to CNC bending vibrations. This assignment compares reasonably with that of s-DMU[8] assigned at 282 and 202 cm^{-1}.

Out-of-plane Vibrations. There are five a'' modes for the planar skeleton. The present study indicates that the 662 and 642 cm^{-1} bands have their origin in the N–H vibrations as inferred by deuteration studies and normal coordinate analysis. On deuteration these bands disappear and the intensity of the 445 cm^{-1} band of s-DMTU increase in the spectrum of s-DMTU-d_2 indicating overlapping of ND out-of-plane bending with the 445 cm^{-1} fundamental. The present assignment for NH bending is at a lower frequency than the analogous band of TCH (768, 579 cm^{-1}).

The out-of-plane C=S bending is assigned to the 445 cm^{-1} band in the infrared (at 450 cm^{-1} in the Raman) in comparison with that in NMTU (400 cm^{-1}). The two CN torsional vibrations are strongly coupled with out-of-plane NH bending modes and contribute to low frequencies at 193, 150, and 142 cm^{-1}. These assignments are comparable with those in TMTU[6] at 144 and 127 cm^{-1} and in TCH[9] at 194 and 140 cm^{-1}.

Methyl Group Vibrations. The stretching and bending vibrations of the CH_3 group are easily assigned as shown in Table 2. The CH_3 rocking vibrations occur as coupled vibrations. They contribute principally to the bands at 1035 and 1020 cm^{-1} coupled with C'N stretching vibrations. The frequencies of the rocking vibrations are in the same region as observed for

NMTU[4] at 980 cm^{-1}, NMTA[21] at 1023 cm^{-1} and TMTU[6] at 1061 and 1035 cm^{-1}. The band at 1035 cm^{-1} may be attributed to both the out-of-plane CH_3 rocking (wagging) vibrations overlapping with an in-plane fundamental. The analogous rocking vibrations are observed for u-DMTU at 1068 and 1035 cm^{-1}, and in NMTU and TMTU near 1040 cm^{-1}.

The calculations suggest that the CH_3 torsional vibrations could be assigned to the bands near 140 and 130 cm^{-1}. The 144 and 127 cm^{-1} bands of TMTU are the corresponding ones. The CH_3 torsion is found near 130 cm^{-1} in NMTU[4] and *N,N*-dimethylselenoformamide.[30]

Differential Refractometric Studies on Some Strong and Weak Molecular Complexes

Ram Sahai,* Vinod Singh, and Rekha Verma
Department of Chemistry, V.S.S.D. College, Kanpur University, Kanpur-208002, India
(Received January 18, 1980)

A more adequate model has been developed to determine the equilibrium constant (K_1) and stoichiometry of molecular complexes. This model involves the assumption:

$$\Delta\phi_a/C_D^\circ = \{K_1C_A^\circ/\alpha(1+K_1C_A^\circ)\} - \{K_1\Delta\phi_a/(1+K_1C_A^\circ)^2\}$$
$$\Delta\phi_d/C_D^\circ = \{K_1C_A^\circ/\alpha(1+K_1C_A^\circ)\} - \{K_1\Delta\phi_d/(1+K_1C_A^\circ)^2\}$$

where $\Delta\phi_a$ is the difference in the refraction per cm^3 of solution and acceptor; $\Delta\phi_d$ is the difference in the refraction per cm^3 of solution and donor; α is the extent of electronic polarization. C_A° and C_D° are the initial concentrations of acceptor and donor respectively. This model has been verified on some strong and weak complexes and was found better than that of earlier methods. $\Delta\phi_a$, $\Delta\phi_d$, and $\Delta\Omega C_{DA}$ (refraction per cm^3 due to charge-transfer complex) have also been used to Yoshida and Ōsawa's method. The K_1 obtained from the plot of $\Delta\phi_a$ or $\Delta\phi_d$ *versus* molar ratio of solutes were found more reliable for weak complexes than K_1 calculated from Yoshida and Ōsawa's plot. From these plots the percentage of contribution of donor or acceptor in total 30% solute aggregation as proposed by Yoshida and Ōsawa has been calculated. It is also noted that Yoshida and Ōsawa's method may give the reliable value for strong complexes but for weak complexes only differential refractometric method can provide the best values.

In our previous investigations,[1-4] refractometric[1,4] and differential refractometric[2-4] methods have been used to determine the stoichiometry and formation constant of molecular complexes. In our first paper on refractometric technique,[1] the refraction per cm^3 due to donor (D), acceptor (A) and donor–acceptor (DA) complex, $\delta\phi$, has been collectively considered, but in second paper,[3] a differential refractometric method has been developed to get the refraction per cm^3 due to donor–acceptor complex, $\Delta\Omega C_{DA}$. In these papers the refractions per cm^3 due to D and DA ($\Delta\phi_d$) and A and DA ($\Delta\phi_a$) have not been considered. The purpose of this paper is to consider these refractions, to determine equilibrium and the results are compared with those of previous techniques.

Recently we have applied $\Delta\Omega C_{DA}$ to Yoshida and Ōsawa's method to calculate the K_1 of weak molecular complexes (phenol–naphthalene) and better results were noted.[2] The purpose of the present paper is also to use $\Delta\Omega C_{DA}$, $\Delta\phi_a$, and $\Delta\phi_d$ to Yoshida and Ōsawa's method[5] and to observe the effect on the equilibrium constant. An attempt has also been made to calculate the contribution of donor and acceptor separately in the total 30% solute (donor+acceptor) aggregation as proposed by Yoshida and Ōsawa[5] for weak complexes.

Theoretical

Consider the condition of equilibrium for 1:1 complex DA, for the interaction of a donor (D) and an acceptor (A), $D+A \overset{K}{\rightleftharpoons} DA$; K is given by Eq. 1:

$$K = K_1K_\gamma; K_\gamma = \frac{\gamma_{DA}}{\gamma_D\gamma_A}. \quad (1)$$

In Eq. 1 γ is the Raoult's activity coefficient of species, i. In general, K_1 and $K\gamma$ are not constant but are functions of concentrations of reactants and products. Until recently complexes had been studied almost entirely in solution. It generally has been assumed that $K\gamma$ is unity; so that the calculations of equilibrium constants were based on the Eq. 2.

$$K_1 = C_{DA}/[(C_A^\circ - C_{DA})(C_D^\circ - C_{DA})] \quad (2)$$

where C_A° and C_D° represent the initial concentrations of acceptor and donor respectively and C_{DA} is the equilibrium concentrations of the complex.

In refractometric investigation, the refraction per cm^3 due to solution (donor+acceptor), ϕ; donor, ϕ_D; acceptor, ϕ_A, have been calculated as reported earlier.[1-4] The difference in the refraction per cm^3 of solution and acceptor, $\Delta\phi_a$, may be calculated using the method of Colter and Grunwald.[6]

$$10^3(\phi-\phi_A) = 6000(n-n_A)n_A/(n_A^2+2)^2 = \Delta\phi_a \quad (3)$$

Similarly $\Delta\phi_d$, the difference in the refraction per cm^3 of solution and donor may be calculated as:

$$10^3(\phi-\phi_D) = 6000(n-n_D)n_D/(n_D^2+2)^2 = \Delta\phi_d. \quad (4)$$

Now it can be assumed that the extent of charge-transfer from donor will measure the concentration of the complex and hence it will be proportional to the difference in the refraction per cm^3 of solution and acceptor, $\Delta\phi_a$, or donor, $\Delta\phi_d$. Now taking the case of $\Delta\phi_a$ we have,

$$C_{DA} = \alpha\Delta\phi_a, \quad (5)$$

where α is a constant determined by the extent of electronic polarization due to incidence of light. Hence Eq. 2 becomes,

$$K_1 = \alpha\Delta\phi_a/(C_A^\circ - \alpha\Delta\phi_a)(C_D^\circ - \alpha\Delta\phi_a). \quad (6)$$

On solving Eq. 6 as it was done in NMR,[7] spectrophotometric,[8] refractometric[1] and differential refractometric[3] techniques, Eq. 7 is obtained:

$$\Delta\phi_a/C_D^\circ = \{K_1C_A^\circ/\alpha(1+K_1C_A^\circ)\} - \{K_1\Delta\phi_a/(1+K_1C_A^\circ)^2\}. \quad (7)$$

Similarly, Eq. 8 can be obtained when $\Delta\phi_d$ was considered:

$$\Delta\phi_d/C_D^\circ = \{K_1C_A^\circ/\alpha(1+K_1C_A^\circ)\} - \{K_1\Delta\phi_d/(1+K_1C_A^\circ)^2\}. \quad (8)$$

Equations 9 and 10 as derived earlier[1,3] have also

been used to calculate K_1 for strong and weak molecular complexes.

$$\delta\phi/C_D^\circ = \{K_1C_A^\circ/\alpha(1+K_1C_A^\circ)\} - \{K_1\delta\phi/(1+K_1C_A^\circ)^2\} \quad (9)$$

$$\Delta\Omega C_{DA}/C_D^\circ = \{K_1C_A^\circ/\alpha(1+K_1C_A^\circ)\} - \{K_1\Delta\Omega C_{DA}/(1+K_1C_A^\circ)^2\} \quad (10)$$

As expected a plot of $\Delta\phi_a$ *versus* $\Delta\phi_a/C_D^\circ$, $\Delta\phi_d$ *versus* $\Delta\phi_d/C_D^\circ$, $\delta\phi$ *versus* $\delta\phi/C_D^\circ$ and $\Delta\Omega C_{DA}$ *versus* $\Delta\Omega C_{DA}/C_D^\circ$ gave a straight line with a slope $-\{K_1/(1+K_1C_A^\circ)^2\}$ and intercept, $K_1C_A^\circ/\alpha(1+K_1C_A^\circ)$ (Fig. 1).

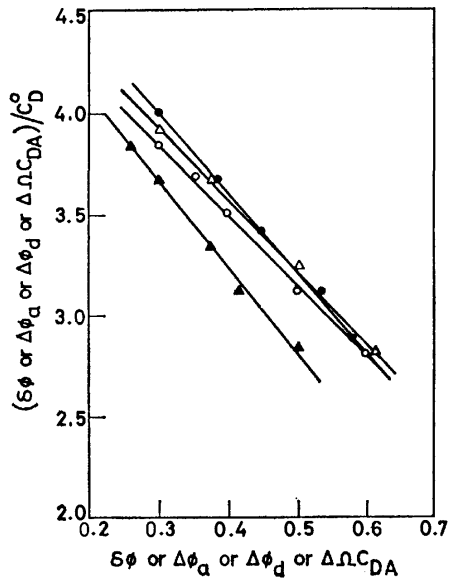

Fig. 1. Plots of $\delta\phi$ *versus* $\delta\phi/C_D^\circ$ (▲-▲-▲), $\Delta\phi_a$ *versus* $\Delta\phi_a/C_D^\circ$ (△-△-△), $\Delta\phi_d$ *versus* $\Delta\phi_d/C_D^\circ$ (●-●-●), and $\Delta\Omega C_{DA}$ *versus* $\Delta\Omega C_{DA}/C_D^\circ$ (O-O-O) for phenol-naphthalene complex in cyclohexane at 35 °C.

The equilibrium constant have also been calculated by Yoshida and Ōsawa's[5] method using Eq. 11.

$$K_1 = 2\sqrt{k}\{\sqrt{k}(C+C') - (C+kC')\}/(C-kC')^2 \quad (11)$$

where C and C' are the maximum concentrations of both the systems and k is the maximum deviation from additive or base line when molar ratio of solutes is plotted against n^2 or $\Delta\phi_a$ or $\Delta\phi_d$ or $\Delta\Omega C_{DA}$. Equation 11 has also been used to calculate K_1 after getting more reliable value of k through the plots of $\Delta\phi_a$ or $\Delta\phi_d$ *versus* molar ratio of solutes. Differential refractometric[2] method has also been used to calculate K_1. In this method, the refraction per cm³ due to charge-transfer, $\Delta\Omega C_{DA}$ has been plotted against molar ratio of solutes.

Experimental

The method of experimentation was essentially the same as it was reported earlier.[1-4]

Results and Discussion

Strong Interaction. The equilibrium constant (K_1) calculated for some strong complexes from Eqs. 7, 8, 9, and 10 are listed in Table 1. From this table it is clear that K_1 calculated from these equations are almost the same. Their percentage deviation from the spectrophotometric value comes under the experimental error (10—15%). For strong complexes, the concentration of solutes was kept low (10^{-3} mol dm^{-3}). Therefore the possibility of solute aggregation becomes quite low. The difference noted in K_1's values, obtained from these equations may be due to the bet-

Table 1. Equilibrium constant (K_1) and solute aggregation data for 1:1 molecular complexes in different solvents at 35 °C

Number in parenthesis indicates the reference number.

terment of respective equations. The K_1 calculated from Eq. 9, in which refraction per cm^3 due to solvent was considered, show maximum percentage of error. But for the same complex if Eq. 7, in which the refraction per cm^3 of solution and acceptor was considered, the percentage error is less. The value of K_1 calculated from Eq. 8 were noted to be the same as calculated from Eq. 7. This indicates that the contribution of donor or acceptor in the solute aggregation is almost negligible. The best values have been obtained when Eq. 10 has been used in which differential refractometric method has been applied to evaluate $\Delta\Omega C_{DA}$.

The equilibrium constant calculated from Yoshida and Ōsawa's plot[5] and from the plot of $\Delta\phi_a$ or $\Delta\phi_d$ or $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes are listed in Table 2. The K_1 calculated from the plot of n^2 *versus* molar ratio of solutes and from the plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes, show slight difference. This difference may again be interpreted due to the betterment of the differential refractometric method. Consequently for strong complexes Yoshida and Ōsawa's method can give the reliable value of K_1, but to get accurate results, the differential refractometric method should be used. We could not get different values for the maximum deviation from the base line (k), when plotted $\Delta\phi_a$ or $\Delta\phi_d$ *versus* molar ratio of solutes. Thus, it was not possible to calculate the different K_1 values through these plots. This was due to the limited accuracy of the instrument.

In strong complexes, a positive deviation was observed at 1:1 molar ratio of solutes indicating 1:1 stoichiometry of these complexes (Fig. 2). But in case of Et_3N–I_2 system a negative deviation was observed (Fig. 3). A similar observation was also made by Singh and Bhat.[9] After applying the differential refractometric method, negative $\Delta\Omega C_{DA}$ values were calculated and have been plotted against molar ratio of solutes (Fig. 4). From this figure it is clear that the deviation is large which indicates strong interaction between Et_3N and I_2. The molar refraction is a measure of deformability of the electronic seath. The

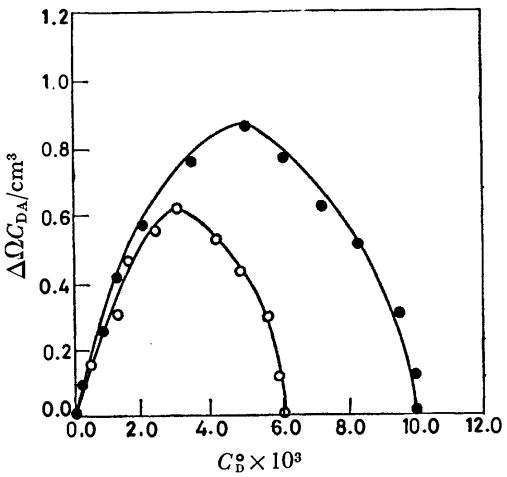

Fig. 2. Plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes indicating 1:1 stoichiometry of Ph_3Sb–I_2 complex in $CHCl_3$ at 35 °C.

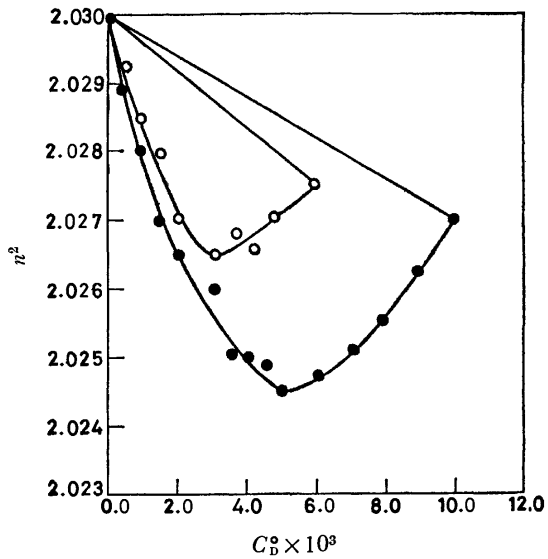

Fig. 3. Plot of n^2 *versus* molar ratio of solutes indicating 1:1 stoichiometry through negative deviation of Et_3N–I_2 in cyclohexane at 35 °C.

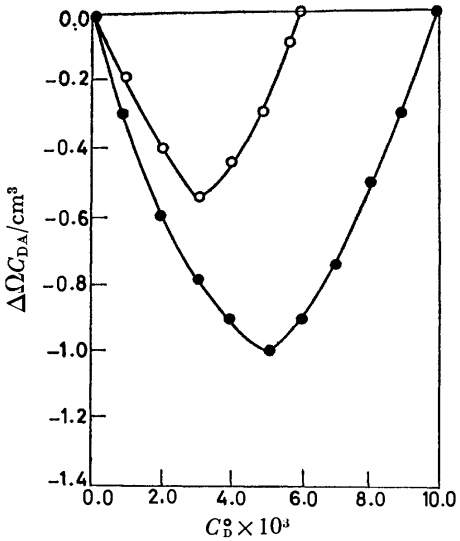

Fig. 4. Plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes indicating 1:1 stoichiometry through negative deviation of Et_3N–I_2 complex in cyclohexane at 35 °C.

decrease in refractive index of Et_3N–I_2 complex shows the increase of molar refractivity. Thus the complex is more polar. Similar results was obtained earlier through dipole moment studies on this system.[10]

Weak Interaction. From Table 1 it is evident that K_1 calculated for weak complexes from Eqs. 7, 8, 9, and 10 show greater difference. In order to get appropriate variation in scale due to limited accuracy of the instrument and low K_1 values, the solute concentration was raised (10^{-1} mol dm^{-3}).[2,5,11] As pointed out by Yoshida and Ōsawa[5] that at such a higher concentration, the solute aggregation occurs (about 30%) which prevents to give the reliable value of K_1. Therefore K_1 calculated from Eq. 9 shows maximum percentage of error. This error becomes less when Eq. 7 or 8 has been used but the best values were noted when Eq. 10 was used.

Table 2. Equilibrium constant (K_1) and solute aggregation data for 1:1 molecular complexes obtained on the basis of Yoshida and Ōsawa's equation in different solvents at 35 °C

Complex	Solvent	K_1/dm³ mol⁻¹ Refractometric methods 1[a]	2[b]	3[c]	4[d]	SA_d	SA_a
Phenol-naphthalene	Cyclohexane	6.2	5.6	5.2	4.9(2)	6.93	23.07
Ethanol-naphthalene	Cyclohexane	5.2	4.6	4.1	3.2	13.50	16.50
Indole-chloranil	CCl_4	3.6	3.1	2.8	2.3	11.53	18.47
Ph_3As-I_2	CCl_4	842	—	—	746.00		
Ph_3As-I_2	$CHCl_3$	8730	—	—	8710.00		
Ph_3Sb-I_2	$CHCl_3$	2127	—	—	1830.00		
Et_3N-I_2	Heptane	2550	—	—	2000.00		
Et_3N-I_2	Cyclohexane	2917	—	—	2552.00		
Tryptophan-chloranil	50% (aq) Ethanol	208(4)	—	—	157.54(4)		
Tyrosine chloranil	50% (aq) Ethanol	191.30(4)	—	—	140.72(4)		
Phenylalanine-chloranil	50% (aq) Ethanol	157.54(4)	—	—	127.16(4)		

Number in parenthesis indicates the reference number. a) Calculated from the plot of n^2 *versus* molar ratio of solutes. b) Calculated from the plot of $\Delta\phi_a$ *versus* molar ratio of solutes. c) Calculated from the plot of $\Delta\phi_d$ *versus* molar ratio of solutes. d) Calculated from the plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes.

The K_1 calculated for weak complexes from the plots of n^2 or $\Delta\phi_a$ or $\Delta\phi_d$ or $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes are listed in Table 2. For weak complexes we could get different K values for the same system when plotted $\Delta\phi_a$ or $\Delta\phi_d$ *versus* molar ratio of solutes. Thus for the same system, different K_1 values calculated from these plots are noted in Table 2. It was not observed for strong complexes. For weak complexes, the best K_1 values have been observed when differential refractometric method was used in which the refraction per cm³ due to charge-transfer complex ($\Delta\Omega C_{DA}$) is plotted against molar ratio of solutes. The present study indicates that the contribution of refraction per cm³ of donor, acceptor and solvent is more important for moderate and weak complexes than that for strong complexes. Now, we can conclude that Yoshida and Ōsawa's method[5] can give satisfactory results for strong complexes only and not for weak complexes. But more accurate values for strong complexes can be obtained by using differential refractometric method.[2] For weak complexes only the differential refractometric method[2] can provide the best values.

Assuming that K_1 calculated from the plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes are absolute, and that the K_1 calculated from the plot of n^2 *versus* molar ratio of solutes incorporates 30% solute aggregation, then the contribution of donor or acceptor in the total 30% solute aggregation may be calculated as:

$K_n2=K_1$ calculated from the plot of n^2 *versus* molar ratio of solutes or from Eq. 8.

$K_{\Delta\phi_a}=K_1$ calculated from the plot of $\Delta\phi_a$ *versus* molar ratio of solutes or from Eq. 7.

$K_{\Delta\phi_d}=K_1$ calculated from the plot of $\Delta\phi_d$ *versus* molar ratio of solutes or from Eq. 9.

$K_{\Delta\Omega C_{DA}}=K_1$ calculated from the plot of $\Delta\Omega C_{DA}$ *versus* molar ratio of solutes or from Eq. 10.

Thus,

$\Delta K_{da}=K_n2-K_{\Delta\Omega C_{DA}}$=Total 30% solute aggregation.

$\Delta K_a=K_n2-K_{\Delta\phi_d}$=Solute aggregation due to acceptor.

$\Delta K_d=(\Delta K_{da}-\Delta K_a)$=Solute aggregation due to donor.

Thus the contribution of acceptor (SA_a) and donor (SA_d) in total 30% solute aggregation may be expressed by Eqs. 12 and 13 respectively.

$$SA_a = 30\times\Delta K_d/\Delta K_{da} \quad (12)$$

$$SA_d = 30\times\Delta K_a/\Delta K_{da} \quad (13)$$

The values of SA_d and SA_a calculated from Eqs. 12 and 13 are listed in Tables 1 and 2. From these tables it is evident that in case of weak complexes the contribution of donor in total 30% solute aggregation is less than that of acceptor.

The authors are grateful to Kanpur University, Kanpur for the award of UGC-JRF to VS and CSIR-JRF to RV. They also wish to thank Prof. P. C. Nigam (I.I.T., Kanpur) for providing some experimental facilities.

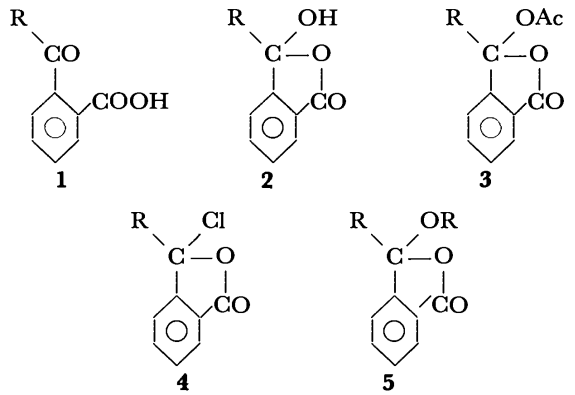
Synthesis and Studies of Some Novel Analogues of Phthalein Dyes

R. P. Chamoli,*,† S. J. Rai, and P. C. Gupta
Department of Chemistry, University of Allahabad, Allahabad, India

(Received October 11, 1979)

Some novel analogues of phthalein dyes have been synthesized by condensing a γ-keto acid, 2-(2-thenoyl) benzoic acid with various phenols. The dyes so obtained are unsymmetrically substituted phthalides where the central carbon atom is attached with two different rings and these dyes have been named as phthal-as-eins; -'as' representing unsymmetry, and-'ein' class of the compound (phthal-ein). The structures of these products have been established on the basis of their elemental analysis and chemical reactions. Absorption maxima of these new dyes have been determined and compared with those of true phthaleins.

The γ-keto acids have been found to exist in open **1** and cyclic **2** form due to keto-lactol tautomerism.[1] Generally it has been observed that γ-keto acids exist chiefly as lactol or equilibrium mixture of keto and ctol forms.a[2,3] These lactols give crystalline acetyl derivatives **3**[4,5] retaining their cyclic structure. Hence it has been concluded that the lactol form of the γ-keto acids is more stable than their open form.[5] The cyclic derivatives, pseudo chlorides (**4**)[6] and pseudo esters (**5**)[7-9] are obtained through the lactol form.



1 **2** **3** **4** **5**

Many chemical reactions[10,11] of γ-keto acids have been explained on the basis of their cyclization to lactol. IR,[8,12] Raman,[9] and NMR[13] spectra have further confirmed the formation of cyclic isomers.

It has been observed that ring tautomerism of γ-keto acids is further exalted by changing R to larger alkyl or aryl groups.[14] It increases further when hydrogen atoms on carbon atoms α to carboxyl group (in γ-keto acids of the type, R–CO–CH_2–CH_2–COOH), are also changed to larger alkyl groups or α,β-ethylenic bond.[15] In continuation of previous work[16-23] on synthesis of mixed phthaleins and succineins, we report in this paper synthesis of a new series of phthal-as-eins from a γ-keto acid, 2-(2-thenoyl)benzoic acid.

Results and Discussion

2-(2-Thenoyl)benzoic acid has also been found spectroscopically to exist as a mixture of keto **6** and lactol form **7**. IR spectrum of the acid shows notable absorption band at 1695, 1680, and 1740 (weak) cm^{-1} indicating the presence of carboxyl >C=O, diaryl ketonic >C=O, and lactonic >C=O respectively. Absorption peaks due to -OH of carboxyl group and -OH

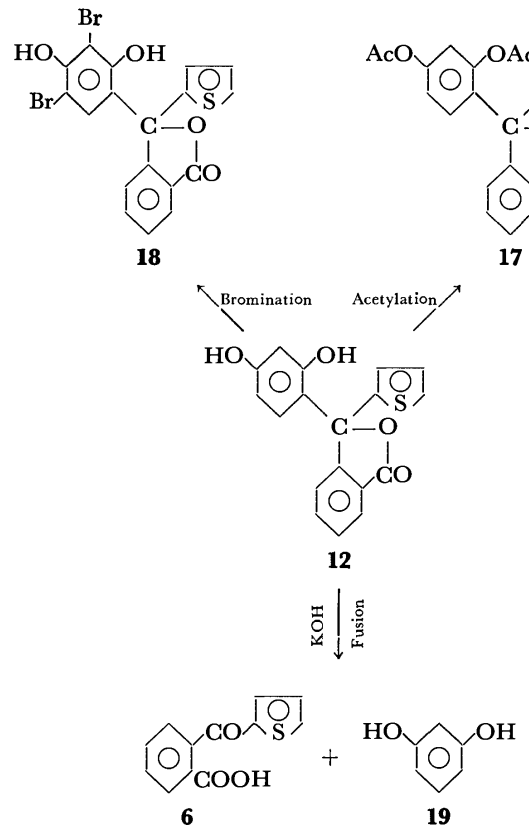
of lactol appear at 2640 (weak) and 3090 (broad) cm^{-1} respectively. In the NMR spectrum of the acid besides other peaks, there is a broad singlet of low intensity at τ 5.5 (1H) which may be assigned to hydroxyl proton of lactol form present in the acid.

IR spectrum of the acetyl derivative of the acid shows a very sharp peak at 1760 cm^{-1} which has been assigned to lactonic >C=O. Peaks at 1750, 1235, 1205, and 1010 cm^{-1} are due to presence of acetate group. Peaks present in the IR spectrum of the acid at 3090, 2640, 1695, and 1680 cm^{-1} are found to be absent in the IR spectrum of the acetyl derivative of the acid. In the NMR spectrum of the acetyl derivative there is no signal at τ 5.5 (present in the NMR spectrum of the acid) but there is new signal as a singlet at τ 7.5 (3H) due to acetate group.

On the basis of above spectral studies it has been concluded that acetyl derivative of the acid possesses a cyclic structure and its formation takes place through the lactol form **7** of the acid **6** (Scheme 1).

The phthal-as-eins have been prepared by condensing the acid with phenols (**9**). The condensation follows through the equilibrium process of lactol form **7** of acid (**6**) and with excess of phenols, the entire acid taken reacts as lactol. The purity of the dyes has been confirmed by TLC and paper chromatography. Their structures have been confirmed on the basis of elemental analysis, bromination, acetylation and KOH degradation studies. Formation of diacetyl derivative (**17**) and dibromo derivative (**18**) support the presence of only one resorcinol molecule in the dye molecule (**12**). KOH fusion of dye (**12**) gave acid (**6**) and resorcinol (**19**).

The absorption maxima (λ_{max}) of the phthal-as-eins are given in Table 2. Table 3 shows λ_{max} of true phthaleins prepared in similar manner. Absorption maxima of phthal-as-eins **11**, **12**, and **18** have been compared with those of phenolphthalein, fluorescein, and eosin respectively and a closeness has been observed.



Scheme 2.

Experimental

All melting points are uncorrected. The absorption maxima (visible) have been measured with the help of model DU Beckman spectrophotometer in absolute ethanol (neutral and alkaline media). IR spectra were recorded in KBr on a Perkin Elmer infracord. NMR spectra were run in DMSO-d_6 on Varian A-60 spectrophotometer using TMS as internal standard. For TLC, plates coated with Alumina G-Silica gel G (1:1) layers were run in ethyl acetate–meth-

anol–5 mol dm^{-3} aqueous ammonia solution (60:30:10) and spots were developed with 5% aqueous NaOH.

2-(2-Thenoyl)benzoic acid was prepared according to reported procedure.[24] Its acetyl derivative prepared by refluxing it with acetic anhydride in presence of fused sodium acetate. The phenols (phenol, resorcinol, catechol, hydroquinone, phloroglucinol, and pyrogallol) have been taken in slight excess of molecular proportion than the acid (**6**) and concentrated sulfuric acid (4—5 drops) has been used as condensing agent throughout. Analogous to phthaleins, the condensation is supposed to have taken place as shown in Scheme 1.

*Synthesis of 3-(2,4-Dihydroxyphenyl)-3-(2-thienyl) phthalide (**12**).* An intimate mixture of 2-(2-thenoyl)benzoic acid (4.6 g) and resorcinol (3.0 g) was taken in a hard glass boiling tube and heated to 240 °C. Concentrated sulfuric acid (4—5 drops) was added and heating was continued between 240—250 °C for about 2 h till the contents became hard and brittle on cooling. The condensed mass was crushed, and washed thoroughly with water to remove excess of resorcinol. Then it was extracted with 2% aqueous sodium hydroxide and filtered. The dye was precipitated from red-brown (green fluorescent) filtrate by acidification with dilute hydrochloric acid. It was filtered, washed with water and purified by repeated crystallization from rectified ethanol, dried in an oven at 120 °C and then in a vacuum desiccator (3.6 g, 56% of the theoretical yield).

The yellow-brown dye, mp >300 °C is microcrystalline. The ethanolic solution is yellowish brown with light green fluorescence which on addition of alkali gives red-brown color with intensified green fluorescence. Found: C, 66.92; H, 3.50; S, 9.52%; mol wt, 315.00 (Rast). Calcd for $C_{18}H_{12}O_4S$: C, 66.66; H, 3.70; S, 9.87%; mol wt, 324.

The preparation of rest of the dyes, given in Table 1 has been done in the identical manner as already described.

*Paper Chromatography of Dye (**11**).* On test paper Whatman No. 1, 1-butanol–ammonia was allowed to run for 13 h (descending) to give two corresponding red-pink spots of the dye (**11**) and reference dye phenolphthallein, R_f: (**11**), 0.89, phenolphthalein, 0.91 (lit,[26] R_f, 0.92).

*Acetylation of Dye (**12**).* The dye (XII) (1.0 g) was refluxed with acetic anhydride (15 ml) and fused sodium acetate (3.0 g) at 130—140 °C for 4 h to give yellowish white microcrystalline diacetyl compound (0.6 g), mp, 175—176 °C (from rectified ethanol). It is soluble in ethanol, acetone, and acetic acid. Found: C, 64.92; H, 3.65; S, 7.60; acetyl, 20.70%. Calcd for $C_{22}H_{16}O_6S$ or $C_{18}H_{10}O_4S$ $(COCH_3)_2$: C, 64.70; H, 3.92; S, 7.84; Acetyl, 20.58%.

*Bromination of Dye (**12**).* The dye (XII) (1.0 g) and 10% solution of bromine in acetic acid (10 ml) were refluxed at 130—140° for 1 h. The reaction mixture on cooling and dilution with water gave brick red dibromo compound (1.0 g), mp 235 °C (from rectified ethanol). The ethanolic solution of the dibromo compound is red with light green fluorescence which is intensified on addition of alkali. Found: Br, 33.32%. Calcd for $C_{18}H_{10}O_4SBr_2$: Br, 33.15%.

*Caustic potash treatment of Dye (**12**).* The dye (XII) (1.5 g) was taken in a platinum cruciblle and mixed with a paste of caustic potash pellets (10.0 g). The contents were heated at aobut 250 °C for 3 h until the red color of the dye disappeared completely. The residue was cooled and dissolved in water (50 ml) and filtered. The excess of alkali was just neutralized by dilute hydrochloric acid when a yellowish brown residue (A) settled down which was filtered and washed with water. The filtrate was further acidified by adding an excess of hydrochloric acid giving a white residue (B); it was also filtered and washed with water. The filtrate was shaken with ether and on evaporation of excess of solvent a brownish red residue (C) was obtained. Residues A, B, and C were identified as unreacted residual dye (**12**), acid (**6**), and resorcinol (**19**) respectively by direct comparison (m. m. p, co-TLC, co-IR) with their authentic samples.

Ortho Effects in Organic Molecules on Electron Impact. VIII. Intramolecular Aromatic Substitution in (Arylmethylene)barbituric Acids

Devalla Venkata RAMANA* and Somayajula KASI VISWANADHAM
Department of Chemistry, Indian Institute of Technology, Madras-600 036, India

(Received January 14, 1980)

Mass spectral decomposition process involving intramolecular aromatic substitution with the ejection of either the hydrogen or the substituent in the ortho position from the $M^{+\cdot}$ ion is noticed in the eleven 5-(arylmethylene)barbituric acids studied. It has been generally noticed that for such a cyclization to occur, the presence of an α,β-unsaturated carbonyl function, in conjugation with the ring, is essential in aromatic systems.

The mass spectral behaviour[1-5] of cinnamic acid, methyl cinnamate, benzylideneacetophenone, and benzylideneacetone is characterized by the formation of intense $M-H^{\urcorner+}$ ion. An intramolecular cyclization mechanism has been proposed for the above mentioned decomposition process leading to a benzopyrylium ion. Similar observation has also been made in the case of *o*-methoxycinnamic acid[6] and alkyl *o*-chlorostyryl ketones.[7] In order to understand this process more clearly and to establish the generality of this process, the mass spectral study of 5-(arylmethylene)barbituric acids has been chosen in the present work, where the carbonyl function is a part of the ring system.

Results and Discussion

The mass spectra of all the substituted (arylmethylene)barbituric acids (I—XI) (Scheme 1) present intense molecular ions except in the case of the ortho-isomers. The expected intense $M-H^{\urcorner+}$ or $M-R^{\urcorner+}$ (in the case of the ortho substituent) ions are noticed in all the spectra. In fact, in the case of *o*-chloro(III) and *o*-nitro(V) compounds, the molecular ion is non-existent and the $M-R^{\urcorner+}$ ions happen to be the base peaks. A cyclization mechanism involving an intramolecular aromatic substitution is being proposed for the formation of the above mentioned ions. It is envisaged that the oxygen of the heterocyclic ring attacks the ortho-carbon atom of the phenyl ring giving rise to a cyclized molecular ion, which then expels either the ortho hydrogen or the substituent affording the intense ion 'a' (Scheme 2). That the hydrogen, which is expelled for the formation of 'a' comes from the phenyl ring is substantiated by the fact that the compound(XI) gives exclusively $M-D^{\urcorner+}$ on electron impact and the $M-H^{\urcorner+}$ ion in this compound is totally absent. Furthermore, that the cyclization takes place with the ortho-carbon is supported by the observation that only the ortho substituents are lost during this mode of fragmentation, while in the case of meta- and para- isomers $M-H^{\urcorner+}$ ion only is noticed. These observations provide indirect proof for the mechanism suggested for the formation of the ion 'a'. The driving force for the cyclization appears to be the formation of the stable ion 'a', which is fully conjugated.

The other general mass spectral fragmentation processes noticed in these compounds are the formation of the ion 'b', by the ejection of a NHCO moiety from 'a', and the fragments 'c' and 'd' from the molecular ion (Scheme 3). Although no metastable evidence is seen for the formation of 'c' and 'd' directly from the $M^{+\cdot}$ ion, these ions are shifted to *m/z* 134 and *m/z* 107 (Table 1) respectively in the d_5-compound(XI), while the ion 'b' is shifted only the *m/z* 176. That the NHCO, that is expelled from 'a' for the formation

of the fragment 'b', is from the 1 and 2 positions of the hetero ring is adduced from the fact that compound II loses exclusively NHCS from 'a' but not the NHCO moiety.

In order to examine the general nature of the electron impact cyclization process, the mass spectra of compounds XII—XIX (Scheme 4) were studied. The mass spectra of cinnamyl alcohol[8,9] and cinnamyl phenyl ether(XII) do not show any prominent M–H^{+} ion indicating that the alcohol and ether oxygens do not readily take part in the cyclization reaction. The base peak in the mass spectrum of 2-benzylidene-1,3-indandione(XVIII) is the M–H^{+} ion, suggesting that the cyclization process is very facile in this compound. Furthermore, 5,5,5′,5′-tetramethyl-2,2′-benzylidenedi(1,3-cyclohexanedione) eliminates a molecule of dimedone during the electron impact[10] giving rise to an intense fragment at m/z 228 (72%) which corresponds to the molecular ion of 2-benzylidene-5,5-dimethyl-1,3-cyclohexanedione. This ion loses a hydrogen radical to give the base peak for which a cyclized structure has been proposed. Cinnamamide(XIII), whose mass spectrum was not studied hitherto, showed M–H^{+} ion as the base peak. This observa-

tion, together with the earlier ones reveal that any carbonyl oxygen (aldehyde, ketone, acid, ester, and amide) takes part readily in the cyclization in the absence of any other facile fragmentation process. However, the loss of $H\cdot$ from the $M^{+\cdot}$ of cinnamanilide-(XIV) is not a facile process, perhaps, due to a more favourable α-cleavage with respect to the carbonyl function, which leads to stable species. On the contrary the thioanalogues XV and XVI of XIII and XIV respectively exhibit more intense $M-H^{\urcorner+}$ ions in their mass spectra (Table 1). In fact the ratio of the intensity of the $M-H^{\urcorner+}$ ion with that of the $M^{+\cdot}$ ion $[(M-H^{\urcorner+})/(M^{+\cdot})]$ is 1.28 for XV and 1.563 for XVI. This may, most probably, be due to the greater size and the lower electronegativity of the sulfur atom.

The formation of six-membered ring during the cyclization reaction is energetically more favourable than the formation of an eight-membered ring and hence the mass spectrum of XVII does not contain any $M-H^{\urcorner+}$ ion. It is also noticed that 5-furfurylidenebarbituric acid(XIX) does not eject a hydrogen radical from the molecular ion implying that an aromatic hydrogen is required for the cyclization process. 3-Phenylpropionic acids and their corresponding methyl esters, where the double bond in the side chain is reduced, do not lose[11] any hydrogen radical from the $M^{+\cdot}$ on electron impact suggesting that the α,β-unsaturation is necessary for the cyclization process to occur.

From these observations, it can be generalized that the cyclization of the type discussed above becomes facile in the presence of an α,β-unsaturated carbonyl function in conjugation with the aromatic ring and in the absence of other favourable competing fragmentation processes.

Experimental

All the compounds discussed in this work are known in literature and were prepared by the methods already reported.[12,13] The purity of all the compounds was confirmed by TLC. The mass spectra were taken on a VARIAN MAT CH-7 mass spectrometer. The spectra were run at 70 eV with the emission current of 100 μA. The temperature of the ion source was 125 °C. The samples were introduced into the mass spectrometer through direct probe insertion at temparatures between 100 °C—170 °C.

One of us (S. K. V.) thanks the C. S. I. R., New Delhi (India), for a fellowship.

(Received October 22, 1979)

1-Hydroxy- and/or 1-aminoanthraquinones was allowed to react with formaldehyde in an alkaline medium to give 1-hydroxy- or 1-amino-2-hydroxymethyl-9,10-anthracenediols, which gave by air oxidation, (hydroxymethyl) anthraquinone derivatives. Interaction of 1-amino-2-(hydroxymethyl)anthraquinone or its 4-bromo derivative with carbonyl compounds in the presence of an acid catalyst gave 1,3-oxazine derivatives (**2**). The methylene group in position-2 of the 1,3-oxazine ring was found to be highly reactive and reacted with carbonyl compounds to form the corresponding 2-arylmethylene derivatives. Selective oxidation of dimethyloxazine derivatives with SeO_2 gave the corresponding dialdehyde, which interacted with aromatic amines to give the corresponding Schiff's bases. The bromine atom in the 6-position of **2** was easily replaced by aromatic amines to give blue disperse dyes.

Originally introduced as dyes for acetate fibers, disperse anthraquinone dyes are now used for a wide range of fiber types, such as polyamide, polyester, triacetate, and acrylics. The lightfastness of this class of disperse dyes is dependent on the substrate. Dyeings on acetate exhibit marginally higher lightfastness than those on nylon 66, while those on polyester are highest. Giles and Rahman[1] suggest that one parameter controlling the lightfastness of a disperse-dyed fiber is the regain of the substrate. Hence the rate of photofading on polyester may be retarded because access of water vapour to the dye particle is restricted.

Most anthraquinone disperse dyes contain either one or two amino groups (free or substituted), usually in the 1- and 4-positions. The substitution pattern can have a marked effect on the lightfastness of such dyes as shown by nature and position of both *N*- and nuclear substituents.[2] The aim of this work is to prepare some new disperse anthraquinone dyes provided by annellation of heterocyclic moiety namely the oxazine ring to the anthraquinone nucleus. The selection of oxazine ring is based on the fact that little is known in the literature concerning the structural factors that influence their application as disperse dyes for synthetic fibers. This paper is devoted for the chemistry of these dyes, while application and factors affecting fastness properties on synthetic fibers will be delt later. An extension of this area of investigation will be a comparison of the electron impact-induced fragmentation patterns of these dyes with their lightfastness on polyester.

1-Hydroxy- and 1-aminoanthraquinones react in an alkaline medium with formaldehyde or formaldehyde/aliphatic amines to give 2-(hydroxymethyl)- or 2-(aminomethyl)-substituted 9,10-anthracenediols which undergo an intramolecular redox reaction to yield the corresponding methyl-substituted anthraquinones.[3] If the reaction is interrupted by oxidation, (hydroxymethyl)- or (aminomethyl)anthraquinones can be isolated[4] (*cf.* Table 1). Interaction of carbonyl compounds with 1-amino-2-(hydroxymethyl)anthraquinone or its 4-bromo derivative in the presence of dilute hydrochloric acid as a catalyst gave 1,3-oxazine derivatives (**2**).[5] The reaction mechanism probably involves an amino aldehyde addition reaction to give intermediate (a) which under acidic conditions loses water to form the carbonium ion (b). Deprotonation of this ion leads to the 1,3-oxazine derivatives (**2**). The reaction course can be represented as follows:
