Alternative Routes. Besides the combination of the routes mentioned above, other sets of routes for the k_a and k_b paths can satisfy Eq. 6; a) the P Route for the k_a path and a water-assisted route, in which a water molecule assists the proton transfer in the P Route (II*→II in Scheme 1), for the k_b path, and b) catalytic action of Hacac or H_2O as a proton donor to the original complex or to some of the intermediates, *e.g.*, the formation of II* in the P Route without and with the aid of a proton of H_2O for the k_a and k_b paths, respectively. However, if these routes operated in the exchange, the deuterium isotope effect on k_a and k_b might be observed. In the exchange of $Cr(acac)_3$[5] and $Co(acac)_3$[7] in acetonitrile, the effect was significant in a water-assisted ($k_H/k_D=1.5$) and an acid-catalyzed ($k_H/k_D=0.4$) processes, respectively. Hence the routes shown in a) and b) are considered to be unlikely on the basis of the absence of the isotope effect in both k_a and k_b.

Therefore, the P and P' Routes are concluded to be the most plausible mechanisms and illustrated again in Fig. 4.

Substitution Mechanism in the Rate-determining Steps. An S_N2 mechanism can be assigned to the rate-determining k_1 step on the basis of the negative value of $\Delta S^{\ddagger}$ (Table 2) and the first-order dependency of k_a on [Hacac] (Fig. 3). In the exchange of $Co(acac)_3$ in acetonitrile[7] and in Hacac,[3] $\Delta S^{\ddagger}$ has large positive values and the rate is independent of [Hacac]. An S_N1 mechanism has been clearly assigned to the exchange of the Co^{III} complex on the basis of these features and the almost identical rate of the exchange with that of the racemization.[8]

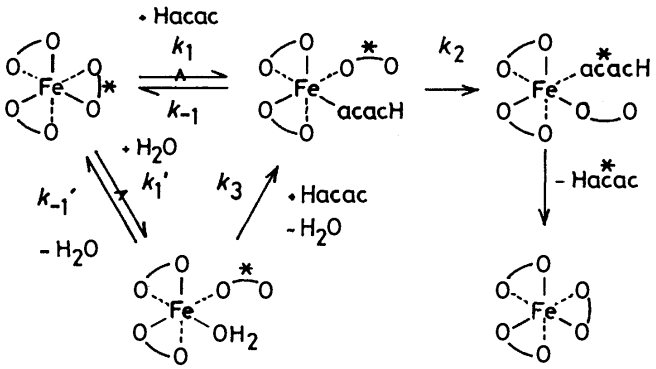

Fig. 4. Plausible mechanism of the ligand exchange of $Fe(acac)_3$ in acetylacetone.

The negative value of $\Delta S^{\ddagger}$ for k_b also suggests an S_N2 attack of H_2O in the k_1' step.

The $\Delta S^{\ddagger}$ value for k_b is less negative than that for k_a by *ca.* 16 cal K^{-1} mol^{-1}, while the $\Delta H^{\ddagger}$ value for k_b is slightly larger than that for k_b. On the other hand, the contributions of the k_a and the k_b term for the rate are comparable, while the concentration of H_2O (0.02—0.1 M) is much less than that of Hacac (9.7 M). The result suggests the prevailing nucleophilicity of H_2O over that of Hacac. Such a difference may be attributable to the steric factor of the nucleophiles.

Comparison with Related Reactions. Kinetic parameters of the present exchange and the solvent exchange reactions of $Fe^{III}O_6$ type complexes are collected in Table 3. The present k_o is different from that of the other reactions involving unidentate ligands, the ratio amounting to 10^4. Such a marked inertness in substitution of bidentate ligands in iron(III) complexes has been also found in the aquation of $[Fe(C_2O_4)(H_2O)_4]^+$ ($k=3\times10^{-3}$ s^{-1} at 25 °C)[1d] and in the replacement of $acac^-$ in $Fe(acac)_3$ by 2-thenoyltrifluoroacetonate in CCl_4 ($k=6\times10^{-3}$ s^{-1} at 25 °C).[2]

On the other hand, the reactions in Table 3 exhibit a common tendency in the values of the activation parameters. There seems to be a common trend that these exchange reactions proceed *via* an S_N2 mechanism, regardless of the dentate number of the ligands. The assignment is consistent with the recent assignment

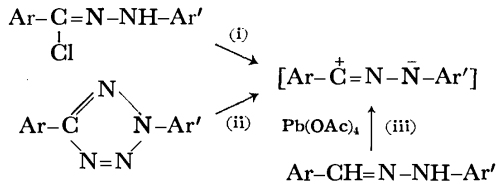
(Received February 15, 1979)

The reaction of the *p*-tolyl(or phenyl)sulfonylhydrazones of some 2-(alkenyloxy)benzaldehydes with lead tetraacetate leads, *via* the nitrile imide intermediates, Ar–C(+)=N–N(−)–SO_2–C_6H_4–X-*p*, to intramolecular 1,3-dipolar cycloadducts and 1-acetyl-2-aroyl-1-[*p*-tolyl(or phenyl)sulfonyl]hydrazines in 20—65% and 7—70% yields respectively, while the intermolecular reactions of the benzaldehyde *p*-tolylsulfonylhydrazone with a dipolarophile such as acrylonitrile or styrene in the presence of lead tetraacetate gives only 1-acetyl-2-benzoyl-1-(*p*-tolylsulfonyl)-hydrazine. The treatment of the *N*-(*p*-tolylsulfonyl)-*o*-(allyloxy)benzohydrazonoyl chloride (**10**) with triethylamine or by refluxing a benzene solution of **10** also gives an intramolecular 1,3-dipolar cycloadduct in a good yield.

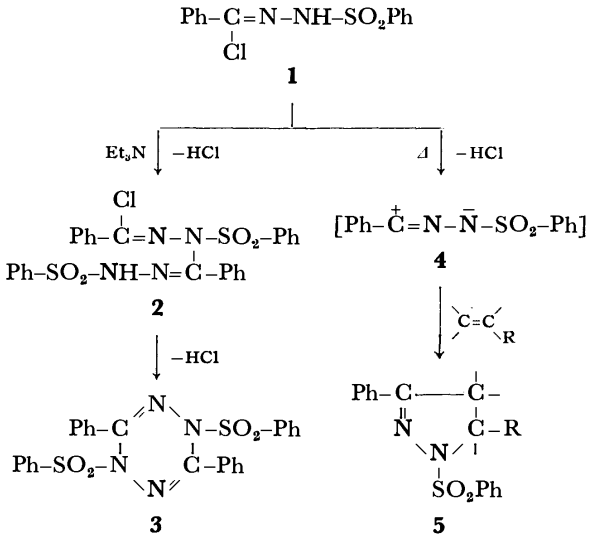
1,3-Dipolar cycloaddition reactions are one of the most useful methods for the preparation of five-membered heterocyclic rings.[1] These reactions are usually regarded as concerted reactions,[2] but sometimes a diradical intermediate has been postulated.[3] The stereochemistry of the dipolarophiles is usually maintained, and the orientation phenomena can be ascribed to frontier orbital interactions.[4]

In this decade, many studies of intramolecular 1,3-dipolar cycloaddition reactions have been reported.[5-10] The most interesting aspects of these reactions are as follows: first, the reaction products are complex polycyclic, annelated, and fused ring molecules which are difficult to prepare by any other methods. Second, a comparison of the results of an intermolecular reaction with that of an intramolecular reaction suggests several things. For example, much information has been obtained from the various intramolecular cycloadditions of nitrile oxides,[5] nitrile imines,[6] nitrones,[7] nitrile ylides,[8] azides,[9] diazoalkanes,[10] and azomethine imines[6b,7b] as dipoles.

Except for a few instances, most dipoles are prepared by multistep reactions and, consequently, in low yields. For example, nitrile imines are generally generated (i) from hydrazonyl halides by treatment with a base[11] or (ii) from the thermal decomposition of 2,5-disubstituted tetrazoles.[12] These methods, while moderately satisfactory, are rather combersome. However, a new method (iii) reported by Gladstone[13] has been shown to be a simpler preparative method for nitrile imines.



Several attempts to prepare the *N*-sulfonyl nitrile imide (**4**) have been made.[14,15] It has been reported that the reaction of *N*-sulfonyl hydrazonoyl chloride (**1**) with triethylamine gave only a dimer (**3**) *via* the intermediate (**2**).[14] On the other hand, when a toluene solution of **1** and a dipolarophile was refluxed, the 1,3-dipolar cycloadduct (**5**) was obtained.[15] We found



that the new method reported by Gladstone was equally useful for the preparation of *N*-sulfonyl nitrile imide from *p*-tolylsulfonylhydrazone of aromatic aldehyde.

$$\text{Ar–CH=N–NH–SO}_2\text{–Tol-}p \xrightarrow{\text{Pb(OAc)}_4} \mathbf{4'}$$

This paper will describe some smooth intramolecular cycloaddition reactions using these sulfonylhydrazones.

Results and Discussion

An expected intramolecular cycloadduct, 2,3,3a,4-tetrahydro-2-*p*-tolylsulfonyl[1]benzopyrano[4,3-*c*]-pyrazole (**7a**), and the unexpected 1-acetyl-2-(*o*-allyloxy)benzoyl-1-*p*-tolylsulfonylhydrazine (**8a**) were isolated from a reaction mixture of *p*-tolylsulfonylhydrazone of 2-(*o*-allyloxy)benzaldehyde (**6a**) and lead tetraacetate by fractional recrystallization and/or column chromatography. Some of the hydrazones (**6**), shown in Table 1, also gave the intramolecular cycloadducts (**7**) and *N*-acetylated hydrazines (**8**). These results are shown in Tables 2 and 3 respectively.

The structure of **7a** was established on the basis of elemental analysis and the spectral data, IR (cm^{-1}): 1180 (N–SO_2); NMR ($CDCl_3$) δ: 2.40 (3H, s, CH_3), 2.60—4.70 (4H, m), 6.7—7.5 (5H, m), and 7.7—7.95 (3H, m). The assignment of the structure **7a** was further

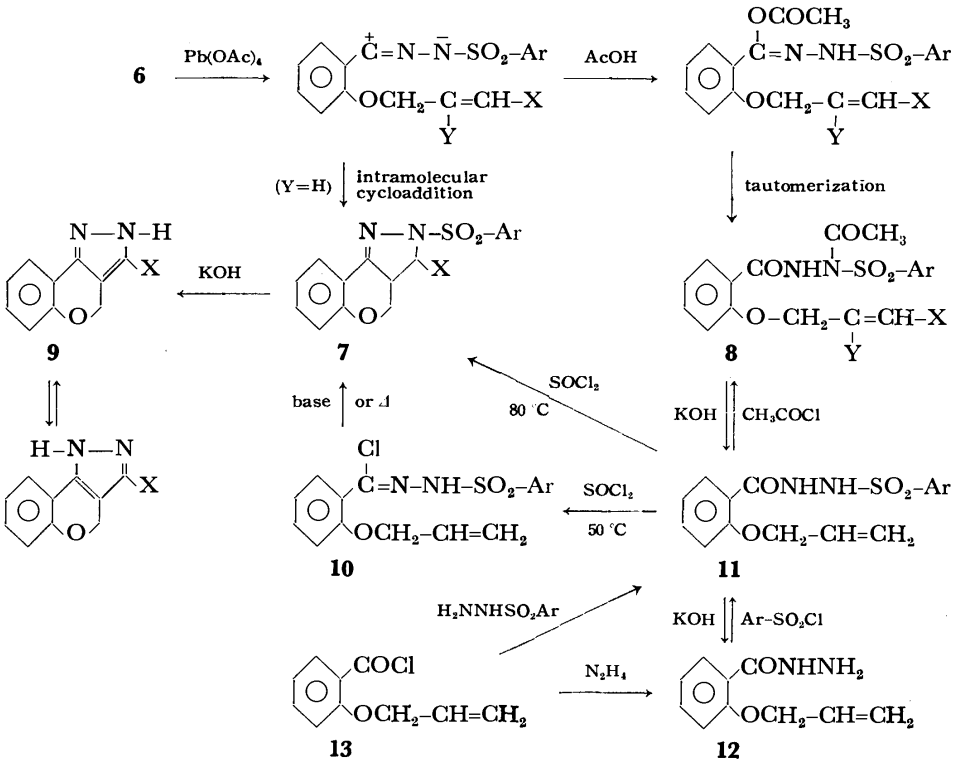
gave only *N*-acetylated compounds (**8e** and **8f**); no 1,3-dipolar cycloadducts could be detected. Our method described above gave **7a** in 40% total yield *via* only two reaction steps from salicylaldehyde. Though Compound **7a** was also prepared in a 26% overall yield *via* hydrazonoyl chloride (**10**) from methyl salicylate (see Scheme 1), this method is rather combersome because it involves six reaction steps. It is interesting that *N*-sulfonyl hydrazonoyl chloride (**10**), another precursor of the nitrile imide for the cycloadduct, also gave the cycloadduct (**7a**) when treated with triethylamine. Even in the absence of triethylamine, the precursor (**10**) yielded **7a** with liberating hydrogen chloride when subjected to reflux in a benzene solution. In these reactions, no dimer like **3** was detected; this indicates a favorable intramolecular cycloaddition reaction.

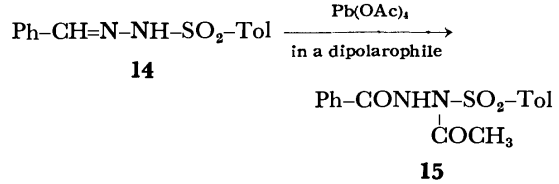
The structure of the *N*-acetylated compound (**8a**) was assigned on the basis of a comparison of the spectra with those of analogous compounds reported by Scott *et al.*[16] The following results also support the structure



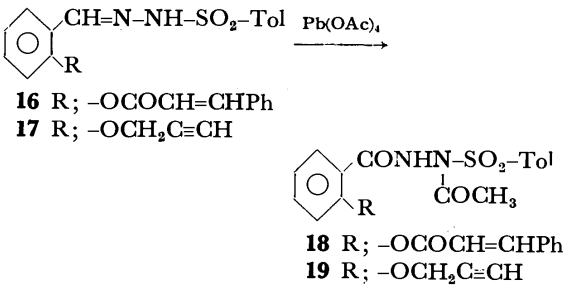
Scheme 1.

(**8a**): the deacetylation of **8a** with aqueous potassium hydroxide under mild conditions gave 2-[*o*-(allyloxy)-benzoyl]-1-(*p*-tolylsulfonyl)hydrazine (**11a**), which was then further hydrolyzed to [*o*-(allyloxy)benzoyl]-hydrazine (**12a**) under more severe conditions. These compounds, **11a** and **12a**, have properties identical with those of authentic specimens prepared by the reaction of *o*-(allyloxy)benzoyl chloride (**13**) with *p*-tolylsulfonylhydrazine or hydrazine hydrate respectively. **8a** can be prepared by the reaction of **11a** with acetyl chloride.

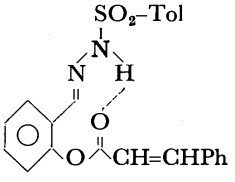
Since the intramolecular 1,3-dipolar cycloadducts (**7**) were obtained from the reaction of sulfonylhydrazones (**6**) with lead tetraacetate, the possibility of the intermolecular cycloaddition reactions was examined under the same conditions. When benzaldehyde *p*-tolylsulfonylhydrazone (**14**) was treated with lead tetraacetate in a dipolarophile such as styrene, acrylonitrile, diethyl maleate, diethyl fumarate or allyl phenyl ether, no cycloadducts were obtained; the only isolated compound was the *N*-acetylated compound (**15**) in any case. These results suggest that *N*-sulfonyl nitrile



imide is less reactive for 1,3-dipolar cycloaddition reactions and, consequently, undergoes an entropically favored reaction as intramolecular cycloaddition[7b] or the reaction with the acetic acid which exists near the nitrile imide when it is generated. A similar reaction was carried out using the compound bearing a cinnamoyl (**16**) or propargyl group (**17**), which groups are usually more reactive dipolarophiles toward nitrile imine, but *N*-acetylated compounds (**18** and **19**) were the only products isolated from the reaction mixture in each case. There may be many explanations for this result, but



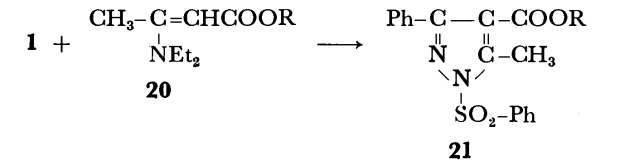
we have no definitive information in this connection. While the carbonyl absorption of phenyl cinnamate appears at 1730 cm^{-1}, that of **16** does so at 1695 cm^{-1}. The broad NH absorption of the hydrazone (**16**) at 3130 cm^{-1} is in sharp contrast with that of the compounds (**6**) which show a sharp absorption at 3200 cm^{-1}. This is presumably a result of an intramolecular hydrogen bonding such as **16'**, in which case the double bond of **16** is relatively remote from the hydrazone group.



It is thought that compound (**17**) can not attain the optimum overlap needed for cycloaddition reaction because the propargyl group has a linear configuration. While the diaryl nitrile imine, which has a propargyl group, really gave the intramolecular cycloadduct,[6c] no cycloadducts were isolated from the reaction of *N*-sulfonyl hydrazonoyl chloride (**1**) with phenylacetylene or ethyl propiolate.[15]

These results may be explained on the basis of the strong electron-withdrawing property of the sulfonyl group. Thus, the *N*-sulfonyl nitrile imide should function as an electron-accepting one and should react with electron-rich olefins in the dipole-LUMO controlled manner,[20] not with an electron-poor one such as cinnamate.

Though the successful intramolecular cycloadditions may be interpreted in terms of a dipole-LUMO controlled 1,3-dipolar cycloaddition reaction with an allyloxy group which is moderately electron-rich, a step-by-step mechanism can also be considered. An interesting reaction of **1** with enamines (**20**) has been reported.[14] Though the cycloadducts **21** are obtained from the reaction mixture in good yields, this pyrazole



20 **21**

formation is interpreted in terms of a step-by-step process involving the nucleophilic attack of the enamines on the hydrazonoyl chloride.

Finally, we may resonably suppose that the intermediate in the reaction of **6** to **7** and **8** is the 1,3-dipole shown in Scheme 1 and that the *N*-sulfonyl nitrile imides which are prepared by the reaction of **6** with lead tetraacetate usually do not undergo 1,3-dipolar cycloadditions except for the case of an intramolecular reaction which is entropically favored.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were determined on a Hitachi 215 Infrared Spectrophotometer. The PMR spectra were measured on a Varian T-60A instrument with TMS as an internal standard.

Materials. The lead tetraacetate (90.6%) was commercially obtained (Nakarai Chem. Co.) and was used without further purification. The (*o*-alkenyloxy)benzaldehydes were prepared from salicylaldehyde and 1-substituted 3-bromopropenes according to the method in the literature.[5,18] The *N*-(phenylsulfonyl)benzohydrazonoyl chloride (**1**) was prepared by the method of Ito *et al.*[14]

Preparation of the Sulfonylhydrazone. The sulfonylhydrazones (**6**) were prepared by the method of Kirmse *et al.*[10c] The structure of **8b—j** was confirmed on the basis of IR and NMR; IR (Nujol): 3175—3200 (NH), 1160—1172 ($N-SO_2$) and 2240 cm^{-1} (CN); NMR ($CDCl_3$) δ: 8.2—8.3 (s, NH), 4.4—4.8 ($O-CH_2-$), 2.3—2.4 [s, $-CH_3(Z)$] and 1.70 [d, J=4 Hz, $-CH_3(X)$].

*Reaction of Sulfonylhydrazones (**6**) with Lead Tetraacetate. General Procedure*: To a stirred solution of lead tetraacetate (15 mmol) in chloroform (300 ml), we added, drop by drop, a solution of sulfonylhydrazone (**6**) (10 mmol) in chloroform (100 ml) at 0 °C over a period of 30 min. The mixture was stirred at the same temperature for 1 h and then at room temperature overnight. The insoluble material thus precipitated was filtered off using a Celite bed. The filtrate was washed with water (500 ml), and the mixture was filtered using the Celite bed. The organic layer was washed with additional water several times and dried over magnesium sulfate. The subsequent evaporation of the organic layer yielded a viscous oil which solidified upon scraching with a glass rod. Recrystallization from ethanol gave colorless needles of the cycloadduct (**7**) and then an *N*-acetylated compound (**8**). The residue of the concentration of the filtrate from the recrystallization was chromatographed (silica gel) with chloroform to give additional needles, **7** and **8**. For **7a**, the spectral data are shown in the text; the other compounds (**7b—j**) show similar spectral data with an absence of NH absorption in the IR spectrum and an absence of olefinic protons in the NMR spectrum. The spectral data for **8** were as follows: IR (Nujol): 3350—3395 (NH), 1720—1725 (-CONH-), 1675—1690 (CON), 1165—1170 ($N-SO_2$) and 2240 cm^{-1} (CN), and NMR (DMSO-d_6) δ: 10.2 (s, NH), 2.10 (s, $-COCH_3$), 2.40 [s, $-CH_3(Z)$] and 1.80 [d, J=4 Hz, $-CH_3(X)$].

*Reaction of **16** with Lead Tetraacetate.* The reaction was carried out by the General Procedure. 4.4 g (10 mmol) of **16** were treated with lead tetraacetate (10 g, 20 mmol) to give white crystals (**18**) in a 62% yield; mp 185 °C (from ethanol). IR (Nujol): 3375 (NH), 1730 and 1685 (three carbonyl groups), and 1160 cm^{-1} ($N-SO_2$); NMR ($CDCl_3$) δ: 2.10 (s, 3H, $-COCH_3$), 2.37 (s, 3H, $-CH_3$), 6.68 (d, 1H, J=16 Hz, =CH-Ph), 7.1—8.1 (m, 14H, aromatic protons and -CO-CH=) and 9.06 (s, 1H, NH). Found: C, 63.24; H, 4.75; N, 5.78%. Calcd for $C_{25}H_{22}O_6N_2S$; C, 62.75; H, 4.63; N, 5.85%.

*Reaction of **17** with Lead Tetraacetate.* The reaction was carried out by the General Procedure. 3.3 g (10 mmol) of **17** were treated with lead tetraacetate (9 g, 18 mmol) to give white crystals (**19**) in a 30% yield; mp 166—168 °C (from ethanol). IR (Nujol): 3400 (NH), 3300 (≡CH), 2130 (C≡C), 1730 and 1690(two carbonyl groups) and 1170 cm^{-1}($N-SO_2$); NMR ($CDCl_3$) δ: 2.13 (s, 3H, $-COCH_3$), 2.43 (s, 3H, CH_3), 2.63 (t, J=2.6 Hz, 1H, ≡CH), 4.93 (d, J=2.6 Hz, 2H, $-CH_2-$), 7.0—7.73 (m, 5H, aromatic protons), 7.90—8.27 (m, 3H, aromatic protons) and 9.97 (s, 1H, NH). Found: C, 59.61; H, 4.92%. Calcd for $C_{19}H_{18}O_5N_2S$; C, 59.06; H, 4.70%.

*Treatment of **14** with Lead Tetraacetate in Dipolarophiles.* To a stirred solution of lead tetraacetate in 100 ml of dipolarophile and benzene (1: 1) we added, drop by drop, a solution of hydrazone (**14**) (10 mmol) in benzene (50 ml) at room temperature. The mixture was then stirred at room temperature overnight. After the usual work-up, shown in the General Procedure, a 70% yield of 1-acetyl-2-benzoyl-1-(*p*-tolylsulfonyl)hydrazine (**15**) was obtained; mp 204—205 °C (from ethanol) [lit,[16] mp 197—198 °C]; IR (Nujol): 3310 (NH), 1723 and 1675 (two carbonyl groups) and 1160 cm^{-1} ($N-SO_2$); NMR (DMSO-d_6) δ: 2.10 (s, 3H, $-COCH_3$), 2.40 (s, 3H, $-CH_3$), 7.26—8.21 (m, 9H, aromatic protons) and 11.6 (s, 1H, NH).

*Hydrolysis of the Cycloadducts (**7**) with Potassium Hydroxide.* To a solution of potassium hydroxide (2 g, 36 mmol) in 95% aqueous ethanol (60 ml) we added 300 mg of **7**, after which the mixture was stirred for 1 h under refluxing. After the evaporation of the solvent of the reaction mixture, the residue was treated with water (60 ml) and extracted with benzene (50 ml). The organic layer was dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent yielded the pyrazoles (**9**) in 90—95% yields; they were recrystallized from ethanol to give colorless substances. The spectral data for these pyrazoles were as follows: IR (Nujol): 3100—3120

(NH), 3230 [NH_2(**9g, h**)] and 1705 cm^{-1} [CON(**9g, h**)], and NMR ($CDCl_3$) δ: 5.24—5.5 (s, 2H, $-CH_2O-$) and 9.33—11.4 (br NH).

Hydrolysis of the N-*Acetylated Compound (8a) with Potassium Hydroxide.* To a solution of potassium hydroxide (600 mg, 11 mmol) in 95% aqueous ethanol (50 ml) we added **8a** (300 mg, 0.77 mmol), after which the mixture was stirred for 1 h under refluxing. After the subsequent removal of the solvent from the reaction mixture, the residue was treated with water (50 ml) and extracted with ether (50 ml). The ethereal layer was then dried over anhydrous sodium sulfate. The evaporation of the solvent yielded 150 mg (56%) of **11a**; mp 127—128 °C (from ethanol). IR (Nujol): 3370, 3140 (NH) and 1160 cm^{-1} ($N-SO_2$); NMR ($CDCl_3$) δ: 2.34 (s, 3H, $-CH_3$), 4.72 (d, J=6 Hz, $-OCH_2-$), 5.13—5.66 (m, 2H, $=CH_2$), 5.8—6.5 (m, 1H, $-CH=$), 5.8—6.5 (m, 1H, $-CH=$), 6.80—8.00 (m, 9H, aromatic protons and NH) and 9.66 (d, J=6 Hz, NH).

Hydrolysis of 11a with Potassium Hydroxide. To a solution of potassium hydroxide (2 g, 36 mmol) in 95% aqueous ethanol (50 ml) we added **11a** (150 mg, 0.43 mmol), after which the mixture was refluxed for 1 h with stirring. After the subsequent removal of the solvent from the mixture, the residue was treated with water (50 ml) and extracted with ether (50 ml). The evaporation of the solvent yielded 50 mg (60%) of **12a**; mp 51—54 °C. IR (Nujol): 3250 (NH) and 1615 cm^{-1} (C=O); NMR ($CDCl_3$) δ: 4.17 (s, 2H, NH_2), 4.57 (d, J=5 Hz, 2H, $-CH_2-$), 5.07—5.55 (m, 2H, $=CH_2$), 5.67—6.33 (m, 1H, $-CH=$), 6.67—7.50 (m, 3H, aromatic protons), 7.90—8.23 (m, 1H, aromatic proton) and 8.87 (s, 1H, NH).

Methyl o-*(Allyloxy)benzoate.* To a mixture of methyl salicylate (76 g, 0.5 mol), allyl bromide (70 g, 0.58 mol) and acetone (250 ml) we added potassium carbonate (100 g, 0.72 mol), after which the mixture was refluxed overnight with stirring. After the filtration of the inorganic salts and the evaporation of the acetone, the residue was distilled *in vacuo* to give the ester; bp 147—151 °C/19 mmHg; 96 g (quantitative).

o-*(Allyloxy)benzoic Acid.* To a solution of sodium hydroxide (50 g, 1.25 mol) in 90% aqueous ethanol (300 ml) we added methyl *o*-(allyloxy)benzoate (80 g, 0.42 mol), after which the mixture was refluxed overnight with stirring. The reaction mixture was acidified with hydrochloric acid and extracted with benzene (200 ml). The subsequent evaporation of the solvent yielded 69 g (95%) of *o*-(allyloxy)benzoic acid; mp 85 °C (lit,[8a] 64—65 °C). The NMR spectra of this compound agreed with the previously reported one.[8a]

o-*(Allyloxy)benzoyl Chloride (13).* This compound was prepared by the reaction of the corresponding carboxylic acid and thionyl chloride by the method of Padwa *et al.*[8a]

Reaction of 13 with p-*Tolylsulfonylhydrazine.* To a mixture of *p*-tolylsulfonylhydrazine (19 g, 0.1 mol) and triethylamine (20 g, 0.2 mol) in benzene (150 ml) we added, drop by drop, a solution of **13** (15 g, 76 mmol) in benzene over a period of 30 min at room temperature. The mixture was then refluxed for 3 h with stirring. After the filtration of the triethylamine hydrochloride, the filtrate was washed with water and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave **11a** in a 57% (15 g) yield; it was recrystallized from ethanol to give a colorless substance; mp 127—128 °C. IR (Nujol): 3380, 3150 (NH), 1650 (C=O) and 1163 cm^{-1} ($N-SO_2$); NMR ($CDCl_3$) δ: 2.34 (s, 3H, $-CH_3$), 4.72 (d, J=6 Hz, 2H, $-CH_2-$), 5.23—5.66 (m, 2H, $=CH_2$), 5.83—6.53 (m, 1H, $-CH=$), 6.83—7.63 (m, 5H, aromatic protons), 7.63—8.00 (m, 4H, aromatic protons and NH) and 9.71 (d, J=6 Hz, 1H, NH).

Reaction of 11a with Acetyl Chloride. A solution of **11a** (2 g, 5.78 mmol) in acetic acid–acetyl chloride (1: 1) (100 ml) was refluxed for 1 h. The reaction mixture was poured into the water (200 ml) and extracted with ether (150 ml). The ethereal layer was dried over anhydrous sodium sulfate and evaporated to give **8a** in a 54% (1.2 g) yield; mp 122—123 °C (from ethanol).

Reaction of 11a with Thionyl Chloride. (A) A mixture of **11a** (3 g, 8.67 mmol) and thionyl chloride (5 g, 42 mmol) was refluxed for 4 h. After cooling, ethanol (20 ml) and then water (100 ml) were added to the reaction mixture, and it was extracted with ether (70 ml). The subsequent evaporation of the solvent gave **7a** in a 21% (0.7 g) yield; mp 199—200 °C (from ethanol). (B) A mixture of **11a** (2.3 g, 6.65 mmol) and thionyl chloride (5 g, 42 mmol) was stirred at 50—60 °C for 3 h. After cooling, the reaction mixture was added, drop by drop, to ice water and then extracted with chloroform (50 ml). The subsequent evaporation of the solvent gave **10** in a 78% (1.9 g) yield; mp 199—201 °C.

Reaction of Methyl o-*(Allyloxy)benzoate with Hydrazine Hydrate.* A mixture of methyl *o*-(allyloxy)benzoate (15.2 g, 0.1 mol), hydrazine hydrate (50 g, 1 mol), and methanol (50 ml) was refluxed for 6 h. After the distillation of the methanol and the hydrazine hydrate, the residue was solidified to give [*o*-(allyloxy)benzoyl]hydrazine (**12**) in a 75% (11.4 g) yield.

Syntheses and Reactions of Optically Active Alkoxyaminosulfonium Salts

Kentaro Okuma, the late Hiroshi Minato, and Michio Kobayashi*

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received March 28, 1979)

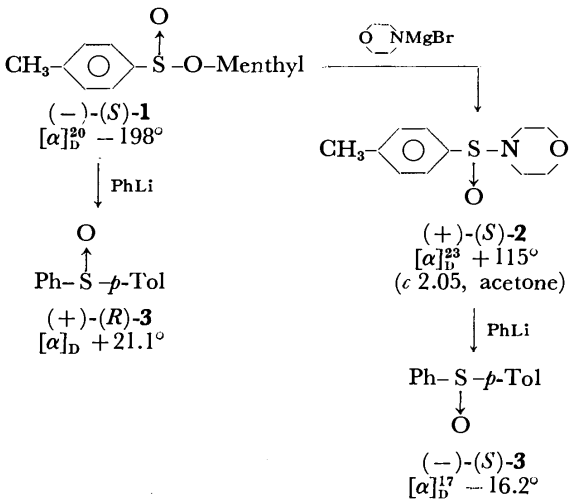
The optically active methoxymorpholino-*p*-tolylsulfonium salt has been synthesized by the reaction of optically active *N*-*p*-toluenesulfinylmorpholine with methyl trifluoromethanesulfonate. The sulfonium ion methylated benzylethylphenylamine and benzyl ethyl sulfide with asymmetric induction to give the optically active benzylethylmethylphenylammonium ion and benzylethylmethylsulfonium ion respectively. The optically active methoxymorpholino-*p*-tolylsulfonium salt and diaminosulfonium salts have been prepared in a one pot reaction between *N*-*p*-toluenesulfenylmorpholine and 1-chlorobenzotriazole with methanol in the presence of 1-menthol at −80 °C.

Stereochemically, the sulfonium ions are of great interest. The absolute configuration of the ethylmethylphenylsulfonium ion has been reported,[1] and the syntheses and absolute configuration of the oxosulfonium ions have been reported.[2-4] Johnson and Schroeck have studied the syntheses of optically active sulfoximines and the reactions of aminooxosulfonium methylide with carbonyl compounds.[5]

Several kinds of alkoxyaminosulfonium salts have been reported and it has been found that the sulfonium ions alkylate amines and sulfides to give the corresponding ammonium and sulfonium salts in high yields.[6] It is expected that the optically active alkoxyaminosulfonium ions alkylate amines and sulfides with asymmetric induction. In this paper, the syntheses of optically active alkoxyamino- and diaminosulfonium salts and their optical resolution will be described.

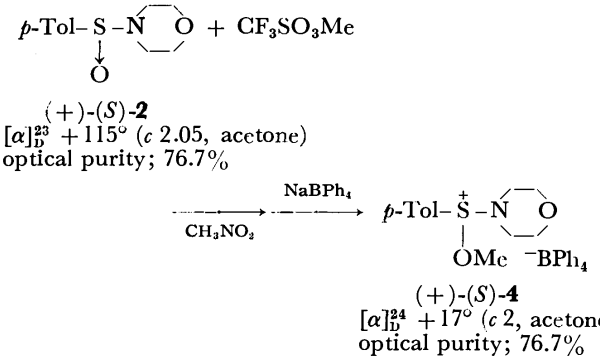
Results and Discussion

(−)-(*S*)-Menthyl *p*-toluenesulfinate ($[\alpha]_D^{20}$ −198°)(**1**) was treated with morpholinomagnesium bromide according to the literature[7] to give the optically active *N*-*p*-toluenesulfinylmorpholine (**2**); $[\alpha]_D^{23}$ +115°. In the handling of **2**, it was necessary to work below room temperature in the absence of light and oxygen in order to prevent optical deterioration. The treatment of **2** with phenyllithium gave phenyl *p*-tolyl sulfoxide in good yields; $[\alpha]_D^{23}$ −16.2°. Mislow prepared phenyl *p*-tolyl sulfoxide ($[\alpha]_D$ +21.1°) by the reaction of **1** with phenyllithium, and determined its absolute configuration to be (+)-(*R*).[8] Therefore, the absolute configuration of phenyl *p*-tolyl sulfoxide ($[\alpha]_D^{23}$ −16.2°) obtained in this reaction should be (−)-(*S*), and the optical purity was calculated as 76%. The reaction of sulfinamide with organolithium compounds is known to proceed with 100% inversion of configuration around the sulfur atom,[9] and consequently the absolute configuration of **2** obtained in the reaction of **1** with morpholinomagnesium bromide should be (+)-(*S*), with an assumed optical purity of 76%. The configurational relationships between the sulfinic ester, the sulfinamide and the sulfoxide are illustrated in the following scheme.



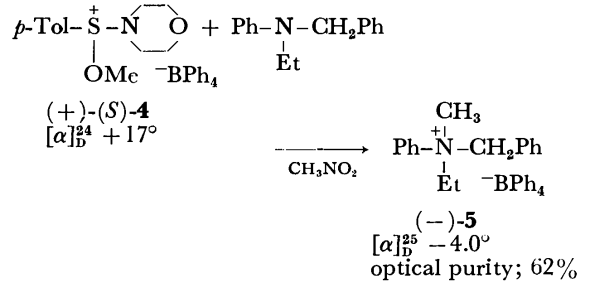
It has been reported that alkoxyaminosulfonium ions alkylate amines and sulfides quantitatively.[6] With optically active sulfonium ions, asymmetric induction is to be expected and this has been investigated by the reactions of optically active methoxymorpholino-*p*-tolylsulfonium tetraphenylborate (**4**) with benzylethylphenylamine and benzyl ethyl sulfide.

Optically active **4** ($[\alpha]_D^{24}$ +17°) was prepared by the methylation of optically active (+)-(*S*)-**2** with methyl trifluoromethanesulfonate in nitromethane at 0 °C for 5 h followed by the anion exchange reaction with sodium tetraphenylborate. Assuming the optical purity of the sample is the same as the starting sulfinamide, the optical activity of pure (+)-(*S*)-**4** is estimated to be $[\alpha]_D^{24}$ +22.2°.

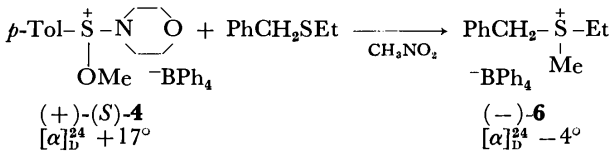


Optically active **4** ($[\alpha]_D^{24}$ +17°) was treated with benzylethylphenylamine in nitromethane at room temperature for 7 d and a salt-like product was obtained. This was shown to be benzylethylmethylphenylammonium tetraphenylborate (**5**), the optical activity of which was found to be $[\alpha]_D^{23}$ −4.0°. Optically pure (+)-**5** was prepared separately by the anion exchange

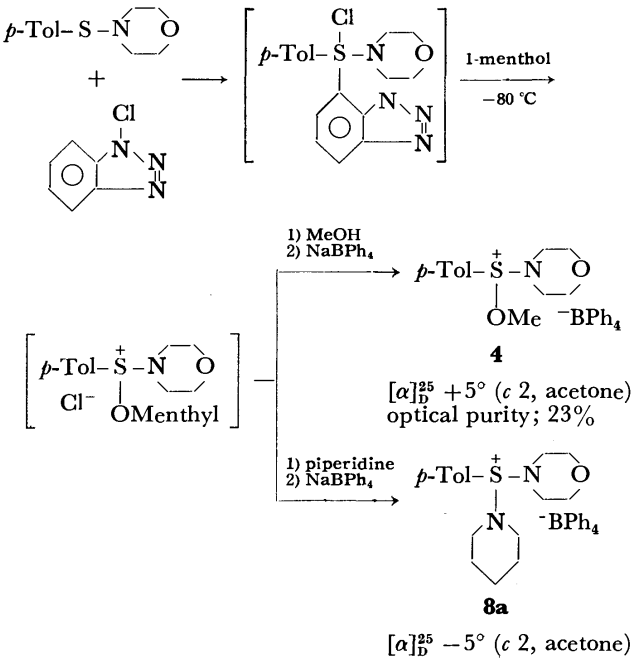
reaction of optically pure benzylethylmethylphenylammonium *d*-camphorsulfonate with sodium tetraphenylborate,[9] $[\alpha]_D^{20}$ +6.5°. Assuming $[\alpha]_D^{20}$ −6.5° for the optically pure (−)-**5**, the optical purity of the methylated amine by the reaction of **4** with benzylethylphenylamine was estimated as 62%.



Opically active **4** ($[\alpha]_D^{24}$ +17°) was allowed to react with benzyl ethyl sulfide in nitromethane at room temperature for 5 h and asymmetric benzylethylsulfonium tetraphenylborate (**6**) was formed. The optical activity of the salt (**6**) was determined; $[\alpha]_D^{23}$ −4°.



Oae and coworkers reported the syntheses of optically active diarylsulfilimines by the reaction of diarylsulfides and *t*-butyl hypochlorite in the presence of l-menthol, followed by treatment with sodium *N*-tosylamide.[10] The asymmetric syntheses of **4** were investigated by applying the method of Oae. *N-p*-toluenesulfenylmorpholine was treated with 1-chlorobenzotriazole in dichloromethane at −80 °C for 10 min and l-menthol was added to this solution. The subsequent addition of methanol and sodium tetraphenylborate gave **4**, exhibited optical activity; $[\alpha]_D^{25}$ +5° (*c* 2, acetone).



The optical purity of **4** thus obtained was only 23%. This synthetic method for optically active sulfonium salts has an advantage however in that the reaction can be conducted in one pot. **8a** was prepared in a similar method by the addition of piperidine replacing methanol; $[\alpha]_D^{25}$ −5° (*c* 2, acetone). This is the first example of the optically active diaminosulfonium ion (**8**).

On the basis of these findings, the optically active alkoxyaminosulfonium ion appears to be more useful for asymmetric inducing alkylation for amines and sulfides than the optically active alkoxysulfonium ion.[11]

Experimental

General. Optical rotation was measured on a Applied Electric Lab. MP-1T polarimeter using a 0.5-dm cell. Infrared spectra were obtained on a Hitachi EPI-G_2 spectrometer. NMR spectra were recorded on a Hitachi R-20B spectrometer. Melting points are uncorrected.

Materials. (−)-(*S*)-Menthyl *p*-toluenesulfinate was prepared according to the usual manner; $[\alpha]_D^{20}$ −198° (*c* 2, acetone); lit,[8] $[\alpha]_D^{25}$ −202° (*c* 2, acetone). 1-Chlorobenzotriazole was prepared from benzotriazole and 10% aq NaOCl solution according to the method in the literature.[12] *N-p*-toluenesulfenylmorpholine was prepared by the method reported previously; bp 80 °C/4.5 mmHg, mp 39—42 °C.[13]

Preparation of Optically Active N-p-*Toluenesulfinylmorpholine* (*2*). An anhydrous THF solution (30 ml) of morpholinomagnesium bromide (20 mmol), which was prepared by the reaction of phenylmagnesium bromide (3.73 g; 20 mmol) with morpholine (1.74 g; 20 mmol) was added dropwise to a stirred ether solution (80 ml) of **1** (5.88 g; 20 mmol) for 1 h at 0 °C. The reaction mixture was stirred at 0 °C for an additional 3 h. A saturated ammonium chloride solution (100 ml) was added to the above solution and the ether–THF layer separated. The aqueous layer was extracted three times, with dichloromethane (20 ml), and the combined extracts were concentrated under reduced pressure below 30 °C to give a pale yellow oil. The residue subjected to elution chromatography on silica gel (hexane–ether eluent) afforded 1.24 g of (+)-**2** (5.54 mmol; 28%); $[\alpha]_D^{23}$ +115° (*c* 2.05, acetone).

To ascertain the optical purity, the reaction of **2** with phenyllithium was conducted. An anhydrous ether solution (30 ml) of phenyllithium (10 mmol) was added dropwise to a stirred ether solution (20 ml) of **2** (500 mg; 2.4 mmol) for 30 min at 0 °C. The mixture was stirred at 0 °C for an additional 1 h. A saturated sodium chloride solution (40 ml) was added to the reaction mixture, and the ether layer separated. The aqueous layer was extracted three times with ether. The combined extracts were dried over anhydrous magnesium sulfate, and the solvent evaporated to give oil. The residual oil was separated by column chromatography on silica gel (hexane–ether eluent) to afford (−)-(*S*)-**3**; 150 mg (29%), $[\alpha]_D^{17}$ +21.1° (*c* 1.64, acetone).[8] These rsults indicate that (−)-**2**, which was obtained by the reaction of (−)-(*S*)-**1** with morpholinomagnesium bromide, has 76% optical purity.

*Preparation of Optically Active Methoxymorpholino-*p-*tolylsulfonium Tetraphenylborate (4).* A nitromethane solution (10 ml) of (+)-(*S*)-**2** (620 mg; 2.76 mmol) and methyl trifluoromethanesulfonate was stirred for 5 h at 0 °C. To this orange solution a nitromethane solution (10 ml) of sodium tetraphenylborate (950 mg; 2.8 mmol) was added. The addition of ether (30 ml) to the reaction mixture formed a precipiatate of sodium trifluoromethanesulfonate, which was removed by

filtration. The further addition of ether (60 ml) to the filtrate resulted in the precipitation of **4**; 650 mg, 1.16 mmol (42%). Found: C, 77.37; H, 7.06; N, 2.74%. Calcd for $C_{36}H_{38}NO_2SB$: C, 77.27; H, 6.84; N, 2.56%. $[\alpha]_D^{24}$ +17° (*c* 2, acetone).

Preparation of Optically Active 4. A dichloromethane solution (10 ml) of *N-p*-toluenesulfenylmorpholine (3 mmol) and a dichloromethane solution (10 ml) of 1-chlorobenzotriazole (3 mmol) were mixed at −80 °C to give yellow solution. A dichloromethane solution (10 ml) of l-menthol (3 mmol) and methanol (10 ml) was added to this solution at −80 °C. A cooled acetonitrile solution (10 ml) of sodium tetraphenylborate (3 mmol) was added to this solution at −80 °C, and the addition of ether caused the precipitation of a mixture of **4** and sodium chloride which was removed by filtration. Ether was added to the acetone solution to give **4** as colorless needles; 1.05 mmol, yield, 35%, $[\alpha]_D^{25}$ −5° (*c* 2, acetone), mp 149—150 °C.

Preparation of Optically Active 8. A dichloromethane solution (10 ml) of *N-p*-toluenesulfenylmorpholine (3 mmol) and a dichloromethane solution (10 ml) of 1-chlorobenzotriazole (3 mmol) were mixed at −80 °C. The addition of a dichloromethane solution (5 ml) of l-menthol (3 mmol) to this yellow solution at −80 °C caused the solution to lose color. A dichloromethane solution (10 ml) of piperidine (3 mmol) was added immediately to this solution, and the solution warmed to room temperature. A nitromethane solution (15 ml) of sodium tetraphenylborate (3 mmol) was added to this pale yellow solution. After 3 h, the addition of ether precipitated a mixture of sodium chloride and morpholino-piperidino-*p*-tolylsulfonium tetraphenylborate (**8a**), which dissolved in acetone–ether to give colorless crystals of **8a**; 200 mg (0.32 mmol; 11.1%), mp 220.5—222 °C, $[\alpha]_D^{25}$ −5° (*c* 2, acetone). Found: C, 78.88; H, 7.04; N, 4.07%. Calcd for $C_{40}H_{45}N_2OSB$: C, 78.41; H, 7.40: N, 4.57%. Optically active *N*-methylphenylaminomorpholino-*p*-tolylsulfonium tetraphenylborate (**8b**), (0.79 mmol, 26%) was prepared in a similar manner from *N-p*-toluenesulfenylmorpholine (3 mmol) and *N*-methylaniline (3 mmol), mp 155—156 °C, $[\alpha]_D^{25}$ −4.8° (*c* 2.4, acetone). Found: C, 79.26; H, 6.70, N, 4.41%. Calcd for $C_{42}H_{43}N_2OSB$: C, 79.48; H, 6.83; N, 4.42%.

Mechanisms of Stannyl-Carbon Bond Cleavages by Reactions with Benzoyl Peroxide

Seizi KOZUKA,* Ikuya NARIBAYASHI, Jun-ichi NAKAGAMI, and Kenji OGINO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi, Osaka 558

(Received April 23, 1979)

The mechanism for the process giving trimethyl(benzoyloxy)stannane by the reaction of benzoyl peroxide with trimethylphenylstannane or tetramethylstannane has been investigated. The kinetic results exclude the possibility that the decomposition of the peroxide is induced by the stannanes. The addition of dicyclohexylcarbodiimide as a trapping agent for benzoic acid markedly depressed the yield of the benzoyloxystannane by the reaction of trimethylphenylstannane, suggesting that the benzoyloxystannane is mainly or exclusively produced by the protodestannylation reaction of trimethylphenylstannane with benzoic acid. In the reaction of tetramethylstannane with benzoyl peroxide, trimethyl(benzoyloxy)stannane was formed only when a large excess of the stannane was used, and dicyclohexylcarbodiimide showed no significant effect upon the formation of the benzoyloxystannane. A homolytic process has been suggested for the reaction giving the benzoyloxystannane from tetramethylstannane.

There are many reactions which have been established to involve homolytic cleavages of the stannyl–carbon bond caused by free-radical attack.[1] An example is the reaction of diacyl peroxide with tetraalkylstannane or trialkylarylstannane.[2] The thermal decomposition of benzoyl peroxide in trimethylphenylstannane was examined by Razuvaev *et al.*; they found carbon dioxide, benzene, biphenyl, and trimethyl(benzoyloxy)stannane as the products. Since the formation of carbon dioxide and the hydrocarbons was thought to strongly suggest the generation of the benzoyloxyl radical through the thermolysis of the benzoyl peroxide, the formation of trimethyl(benzoyloxy)stannane was explained in terms of the attack of the benzoyloxyl radical on the stannane.[2a,b] However, there was no definite evidence

$$(PhC(=O)-O-)_2 \longrightarrow PhC(=O)-O\cdot \xrightarrow{Me_3SnPh} PhC(=O)-O-SnMe_3 + Ph\cdot$$

in support of their mechanism for the process giving trimethyl(benzoyloxy)stannane from trimethylphenylstannane. Some other mechanisms are possible; for example, the reaction of diacyl peroxide with the stannane by way of the coordination of the tin atom to the carbonyl oxygen of the peroxide, analogous to the Lewis acid-catalyzed decomposition,[3] may produce the benzoyloxystannane. A somewhat modified cyclic coordination process has been suggested for the reaction of allyltrimethylstannane with benzoyl peroxide giving allyl benzoate and trimethyl(benzoyloxy)stannane; this suggestion was based on the observations that the rate of the decomposition was apparently dependent on the concentration of the stannane, a large negative entropy value, and that only 1-methylallyl benzoate was formed from 2-butenyltrimethylstannane.[4]

Secondly, since carboxylic acid has been known to be formed by the thermolysis of diacyl peroxide in a hydrocarbon solvent,[5] protodestannylation of organostannane with the carboxylic acid is also a possible route to give acyloxystannane,[6] as has been suggested preliminarily.[7]

Such a tetraalkylstannane as tetraethylstannane has also been known to give trialkyl(benzoyloxy)stannane by means of a reaction with benzoyl peroxide.[2a] A stannane not bearing a phenyl group would resist the protodestannylation process,[8] though; hence a different mechanism would be expected for the process giving triethyl(benzoyloxy)stannane in the reaction of tetraethylstannane with benzoyl peroxide. In this paper we wish to discuss the mechanisms of the processes giving trialkyl(benzoyloxy)stannane from trialkylphenyl- and tetraalkylstannanes by means of reactions with benzoyl peroxide.

Results and Discussion

Trialkyl(benzoyloxy)stannane from Trialkylphenylstannane.[9] In order to elucidate the mechanism for the process giving trimethyl(benzoyloxy)stannane, the thermal decompositions of benzoyl peroxide were carried out under several different conditions. Reactions were carried out in evacuated sealed tubes except for that analyzing the amount of carbon dioxide formed by the thermolysis of benzoyl peroxide. Although the formations of other products such as benzene, benzoic acid, and biphenyl were observed, only the yields of carbon dioxide and trimethyl(benzoyloxy)stannane will be noted in the present study since a detailed product analysis of the reaction had been reported by Razuvaev *et al.*[2]

The rate of the thermal decomposition of benzoyl peroxide was measured in the presence and in the absence of trimethylphenylstannane. Although cyclohexane has often been used as the solvent for the thermolysis,[5] a cyclohexane–chloroform mixed solvent was used for the present kinetic study because of the poor solubility of the other additives in the hydrocarbon solvent. The rate of the decomposition was substantially depressed in the presence of styrene, while the presence of the stannane was found neither to depress nor enhance the rate of the decomposition of benzoyl peroxide. The results, given in Table 1, suggest that trimethylphenylstannane does not take a part in the decomposition of benzoyl peroxide. The possibility of the reaction giving the benzoyloxy stannane directly from trimethylphenylstannane and benzoyl peroxide can thus be ruled out.

Table 1. Rate constants for the decomposition of benzoyl peroxide (0.01 mol/dm³) in chloroform–cyclohexane (1 : 1 v/v) at 80 °C with or without an additive

Additive	Mole ratio Add./BPO	Rate constant $k_1 \times 10^5/s^{-1}$
None		4.91±0.15
$PhCH{=}CH_2$	10	3.05±0.10
Me_3SnPh	10	4.34±0.29
Me_4Sn	10	4.69±0.18
DCC[a]	2[b]	5.92±0.28
PhCOOCOPh	10	4.92±0.30
DCU[c]	2[b]	3.43±0.33

a) Dicyclohexylcarbodiimide. b) Experiments with higher concentrations could not be performed because of the limited solubility of the additive. c) *N,N'*-Dicyclohexylurea.

Dicyclohexylcarbodiimide (DCC) was added to the reaction system in order to trap the benzoic acid formed by the thermolysis of benzoyl peroxide in the hydrocarbon solvent. *N,N'*-dicyclohexylurea (DCU) was isolated by the TLC separation of the reaction mixture. The yield of trimethyl(benzoyloxy)stannane was depressed by the addition of DCC in a cyclohexane–chloroform solution. The themolysis of benzoyl peroxide in a cyclohexane–tetrahydrofuran solution in the presence of DCC gave no detectable amount of trimethyl(benzoyloxy)stannane. The amount of carbon dioxide formed by the thermolysis, however, was not affected by the addition of DCC, suggesting that DCC does not intercept the benzoyloxyl radicals during the thermolysis, although a carbodiimide has been known to intercept radicals.[10] The results shown in Table 2 indicate that the decomposition of benzoyl peroxide was not affected by the addition of DCC, they also suggest that benzoic acid might be an intermediate to give trimethyl(benzoyloxy)stannane.

In a control experiment, benzoic acid was heated with trimethylphenylstannane at 85—90 °C for 16 h.

Trimethyl(benzoyloxy)stannane was formed in yields comparable with those obtained by the reactions with benzoyl peroxide in both the solvents examined. Here again, the presence of DCC completely depressed the formation of trimethyl(benzoyloxy)stannane. These results are shown in Table 3. No serious effect of these additives, *i.e.*, DCC, DCU, and benzoic anhydride, on the rate of the decomposition of benzoyl peroxide was observed, although a slight acceleration and a little depression of the rate of the decompositions were observed in the presence of DCC and DCU respectively. The kinetic results are summarized in Table 1. These results also reveal that the thermolysis of benzoyl peroxide was not seriously affected in the presence of DCC.

On the basis of these observations, the mechanism for the process giving trimethyl(benzoyloxy)stannane may be concluded to involve the protodestannylation reaction of trimethylphenylstannane with benzoic acid, at least partially in a cyclohexane–chloroform solution or a high-concentration reaction in chloroform, and exclusively in a cyclohexane–tetrahydrofuran solution. In the reactions carried out in chloroform-containing solutions, it is not clear whether another competing process (for example, the radical process suggested by Razuvaev *et al.*[2]) was also operative concurrently or whether DCC could not effectively trap all the benzoic acid.

The mechanism for the formation of trimethyl(benzoyloxy)stannane by means of the reaction of benzoyl peroxide with trimethylphenylstannane in a cyclohexane–tetrahydrofuran solution (and the main process in the other solvent) is shown below. The observation that only the aryl–Sn bond is cleaved by

$$(PhCOO)_2 \longrightarrow 2PhCOO\cdot$$

$$PhCOO\cdot + R\text{–}H \longrightarrow PhCOOH + Ph\text{–}H,\ CO_2,\ Ph\text{–}Ph\ etc.$$

$$PhCOOH + Me_3SnPh \xrightarrow{\text{Protodestannylation}} Me_3SnOCOPh + Ph\text{–}H$$

the reaction of trimethylphenylstannane with benzoyl peroxide, giving trimethyl(benzoyloxy)stannane as the sole benzoyloxystannane, is also in accordance with the proposed mechanism.[8]

Trialkyl(acyloxy)stannane from Tetraalkylstannane. Tetraethylstannane has been known to give triethyl(benzoyloxy)stannane by the reaction with benzoyl peroxide, along with such other products as carbon dioxide, ethane, ethene, butane, and benzoic acid.[2b,d] In our present study, tetramethylstannane instead of tetraethylstannane was chosen as the tetraalkylstannane for two reasons: 1) the recovered tetramethylstannane can easily be removed from the reaction mixture by evaporation, and 2) both the starting stannane and the product, trimethyl(benzoyloxy)stannane, exhibit sharp singlet methyl signals in the NMR spectra and so can conveniently be detected.

Table 4. Reaction of benzoyl peroxide (BPO) with tetramethyl stannane (TMSn) at 85—90 °C for 16 h

Initial concentration mol/dm³			Solvent[a]	Yield/%[b] $Me_3SnOCOPh$

0.3[c]	6.0[c]	0.3[c]	none	23

a) C_6H_{12} = cyclohexane, THF = tetrahydrofuran. Mixed solvents are 1:1 v/v mixtures. b) Based on mol of BPO. c) Millimoles used for neat reactions.

The rate of the thermal decomposition of benzoyl peroxide was measured in both the presence and absence of tetramethylstannane. The results are summarized in Table 1. Neither the acceleration nor the retardation of the rate in the presence of tetramethylstannane was observed. The results suggest that the stannane does not take part in the decomposition of benzoyl peroxide. On the other hand, no detectable amount of trimethyl(benzoyloxy)stannane was formed by the thermolysis of the peroxide in the presence of tetramethylstannane under the same reaction conditions as those used for the thermolysis of benzoyl peroxide in the presence of trimethylphenylstannane. The benzoyloxystannane was formed in a moderate yield only when a large excess and a high concentration of tetramethylstannane were used. The reaction of benzoyl peroxide with tetramethylstannane without the use of the solvent gave trimethyl(benzoyloxy)stannane in a similar yield.[11] Under these conditions, DCC showed no significant effect upon the formation of trimethyl(benzoyloxy)stannane. These results are given in Table 4. Furthermore, the heating of benzoic acid with tetramethylstannane gave no detectable amount of trimethyl(benzoyloxy)stannane under any reaction conditions used for the thermal decomposition of benzoyl peroxide in the presence of the stannane. This result, together with the lack of any effect of DCC on the formation of trimethyl(benzoyloxy)stannane and the lack of any effect of tetramethylstannane on the rate of the decomposition of benzoyl peroxide, rules out the possibility that the benzoyloxystannane was formed by the decomposition of the peroxide by way of the coordination mechanism. The same results would also rule out the possibility of the benzoyloxystannane being given by the protodestannylation reaction of tetramethylstannane with benzoic acid under the reaction conditions examined. A possible mechanism for the formation of the benzoyloxystannane is a radical attack, as has been suggested by Razuvaev *et al.*[2] The formation of butane by the reaction of benzoyl peroxide with tetraethylstannane[2b,d] is clear evidence in support of the generation of the ethyl radical through the radical attack on the stannane.

$$PhCOO\cdot + Me_4Sn \longrightarrow Me_3SnOCOPh + Me\cdot$$

$$2Me\cdot \longrightarrow C_2H_6 \text{ or } \xrightarrow{R\text{-}H} CH_4 + R\cdot$$

The reactions of benzoyl peroxide with trialkylphenylstannane and with tetraalkylstannane, both giving trialkyl(benzoyloxy)stannane, have thus been found to be quite different in their mechanisms. The formation of trialkyl(benzoyloxy)stannane from trialkylphenylstannane is a more facile reaction than that from tetraalkylstannane. The reaction of tetraalkylstannane with benzoyl peroxide gives trialkyl(benzoyloxy)stannane in a moderate yield only when a high concentration of the stannane is used. The difference is undoubtedly due to the different reactivities of tetraalkyl- and trialkylphenylstannanes to a protodestannylation reaction. The phenyl–Sn bond is reactive enough to be cleaved by the reaction with benzoic acid under the conditions used for the thermolysis of benzoyl peroxide. The alkyl–Sn bond, on the other hand, is stable enough in the reaction with benzoic acid under the same conditions and is cleaved by radical attack only when a high concentration of the stannane is used.

The reaction of benzoyl peroxide with allyltrimethylstannane[4] seems to be an exception, since the stannane has two coordination centers, *i.e.*, the tin atom and the double bond, and can form a cyclic complex with the peroxide. Although trimethylphenylstannane also bears an unsaturated moiety, the interaction of the phenyl group with the electrophile might be weaker than that of the allyl group, and the formation of a cyclic complex of trimethylphenylstannane with the peroxide would not be conformationally favored. Thus, trimethylphenylstannane does not promote the decomposition of benzoyl peroxide.

Experimental

Materials. The tetramethylstannane and trimethylphenylstannane were prepared in according to the literature.[12] Commercial benzoyl peroxide was recrystallized from chloroform–ethanol before use. The solvents were purified by usual procedures

Kinetics. Six evaporated sealed tubes, each containing 2 ml of the peroxide solution (0.01 mol/dm³), were prepared for each run. The tubes were dipped in a constant-temperature bath (80 °C) and then taken up at intervals. The rate of the decomposition was calculated by measuring the remaining amount of the peroxide, which was obtained by iodometry. Experiments in the presence of additives were carried out similarly. The results are given in Table 1.

Reaction of Benzoyl Peroxide with Trimethylphenylstannane or Tetramethylstannane. Benzoyl peroxide (72.7 mg, 0.3 mmol) and trimethylphenylstannane (145 mg, 0.6 mmol) were dissolved in a chloroform–cyclohexane mixed solvent (1 : 1 v/v mixture; total, 10 ml) and sealed in an evacuated tube with or without addition of DCC.

The tube was then heated for 16 h at 85—90 °C. After heating, the solvent and volatile products were evaporated. The residue was weighed and dissolved in chloroform-*d*. A known amount of dichloromethane was added to the solution, and the whole solution was submitted to NMR analysis. The amount of trimethyl(benzoyloxy)stannane was determined by the integration of the trimethyl signal (δ 0.62 ppm) relative to that of dichloromethane (δ 5.21 ppm). A substantial amount of trimethyl(benzoyloxy)stannane (34, 15, and 103% yields in C_6H_{12}–$CHCl_3$, C_6H_{12}–THF, and $CHCl_3$ respectively) was detected by the reaction with trimethylphenylstannane, though the yield was markedly affected by the addition of DCC. The formation of trimethyl(benzoyloxy)stannane was not observed at all in the reaction with tetramethylstannane under the same conditions as that of trimethylphenylstannane. Trimethyl(benzoyloxy)stannane was formed from tetramethylstannane in a 20% yield when an excess of the stannane (1 g, 4.2 mmol) in a high concentration was allowed to react with benzoyl peroxide (51 mg, 0.21 mmol) in chloroform (10 ml); it was also formed in an 18% yield in the presence of DCC (39 mg, 0.21 mmol). The neat reaction of benzoyl peroxide (73 mg, 0.3 mmol) with tetramethylstannane (1.45 g, 6.0 mmol) gave trimethyl(benzoyloxy)stannane in a 24% yield; the yield was not affected by the addition of DCC (55 mg, 0.3 mmol). The NMR signal of trimethyl(benzoyloxy)stannane was confirmed by examining the spectrum of the authentic sample prepared from bromotrimethylstannane and silver benzoate.[13] The amount of carbon dioxide formed during thermolysis (reflux, 16 h) was measured by bubbling a nitrogen stream into the reaction solution, which was then introduced into aqueous barium hydroxide (0.1 mol/dm^3, 10 ml). After the decomposition of the peroxide, the aqueous solution was titrated by dil HCl (0.1 mol/dm^3), and the amount of carbon dioxide was obtained from the comsumption of barium hydroxide. The results are shown in Tables 2 and 4.

Reaction of Benzoic Acid with Trimethylphenylstannane or Tetramethylstannane. The acid (37 mg, 0.3 mmol) and trimethylphenylstannane (145 mg, 0.6 mmol) were dissolved in chloroform–cyclohexane (1 : 1 v/v, total, 10 ml), and then the solution was allowed to react at 85—90 °C for 16 h. The amount of trimethyl(benzoyloxy)stannane was determined by the method as described above. Trimethyl(benzoyloxy)stannane was obtained by the reaction with trimethylphenylstannane in a 26% yield, with a 74% recovery of the starting stannane. No reaction of tetramethylstannane with benzoic acid was observed, even without the use of the solvent. For example, both the starting materials were recovered nearly quantitatively after the heating of benzoic acid (37 mg, 0.3 mmol) with tetramethylstannane (1.45 g, 6.0 mmol) for 16 h at 85—90 °C. The results are given in Table 3.

Reactions of α-Aminoacetonitriles with Isothiocyanates. Synthesis of 1,3-Disubstituted 5-Imino-2-thiohydantoins

Takeshi KINOSHITA,* Hiroko WATANABE, Sadao SATO, and Chihiro TAMURA

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

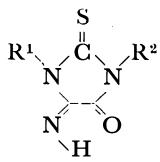
(Received April 24, 1979)

The reactions of α-aminoacetonitriles with isothiocyanates gave 1-cyanomethyl-1,3-disubstituted thioureas or 1,3-disubstituted 4-amino-4-imidazoline-2-thiones depending upon the reaction conditions. In the presence of polar organic solvents such as methanol the former products were easily cyclized to the latter. 1,3-Disubstituted 4-amino-4-imidazoline-2-thiones were autoxidized in methanol affording 1,3-disubstituted 5-imino-2-thiohydantoins.

A number of reports have been published concerning the synthesis of 1,3-disubstituted 5-iminohydantoins.[1-3] However, no synthetic study on 1,3-disubstituted 5-imino-2-thiohydantoins seems to have been reported except for the work of Kinoshita *et al.*[4] In a previous paper,[5] a report was given on the crystal structure of 1,3-dimethyl-5-imino-2-thiohydantoin prepared by the reaction of methylaminoacetonitrile with methyl isothiocyanate in the presence of atmospheric oxygen. This paper deals with the synthesis of 1,3-disubstituted 5-imino-2-thiohydantoins and the mechanism of the reaction of isothiocyanates with α-aminoacetonitriles.

Results and Discussion

Various types of isothiocyanates were allowed to react with α-aminoacetonitriles. The most basic compounds for this reaction are methyl isothiocyanate and equimolar quantities of methylaminoacetonitrile, which gave compound **1a** in methanol solution (85% yield). The structure of **1a** was confirmed to be 1,3-dimethyl-5-imino-2-thiohydantoin by the spectra data.



1, a: $R^1=R^2=CH_3$

The structure of the ring system has been established by X-ray analysis of **1a**.[5] However, the above reaction was carried out using benzene as a solvent to give compound **2a** (77% yield). The structure of **2a** was determined to be 1-cyanomethyl-1,3-dimethylthiourea by the spectral data.

When the reaction was undertaken using toluene as a solvent, compound **3a** was quantitatively precipitated (91% yield). However, when phenyl isothiocyanate

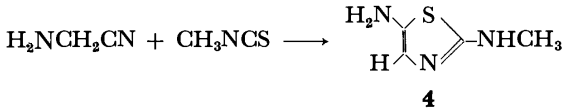
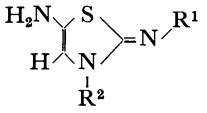
a) Measured in Nujol mulls (* shoulder). b) Observed in EtOH. c) Observed in DMSO-d_6 (**1** and **1b**), and CCl_4 (**1c**—**j**).

was used instead of methyl isothiocyanate, **2b** was not isolated even in a nonpolar solvent (benzene), **3b** being obtained in 88% yield. Whether the reaction gives **2** or **3** seems to depend upon the subtle difference in the overall polarity of the reaction system. Actually **2** was easily cyclized to **3** in a polar solvent. The structure of **3** was deduced to be 1,3-disubstituted 4-amino-4-imidazoline-2-thione by the spectral data.

In 1948, Cook *et al.*[6] examined the reaction of aminoacetonitrile with methyl isothiocyanate to give 5-amino-2-(methylamino)thiazole (**4**). It appears that the isomer **5** is also possible as the structure of **3**.

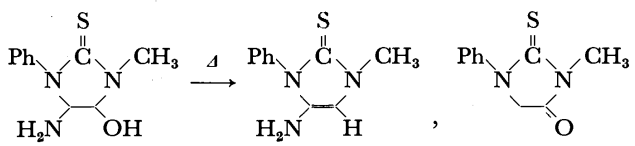


4



5, **a**: $R^1=R^2=CH_3$
b: $R^1=C_6H_5$, $R^2=CH_3$

However, convincing proof for the structure of **3** could be given by the pyrolysis of **6** prepared by the reduction of **1b** with $LiAlH_4$. The main products derived from the pyrolysis of **6** at the injection port of a gas chromatograph were determined to be a dehydration compound, 1-methyl-3-phenyl-4-amino-4-imidazoline-2-thione and a deamination compound, 1-phenyl-3-methyl-2-thiohydantoin by gas chromatography mass spectrometry (Fig. 1).



6 (*cis*/*trans*)

The retention time and the mass spectrum of the dehydration peak 2 in Fig. 1 were identical with those of **3b** (Fig. 2). Compound **3b** underwent no ring-isomerization,[7] the starting material being recovered after heating at 230 °C. The structure of **3** should be similar to that of the dehydration compound of **6**, but not that of **5**. However, we have found no definite evidence for

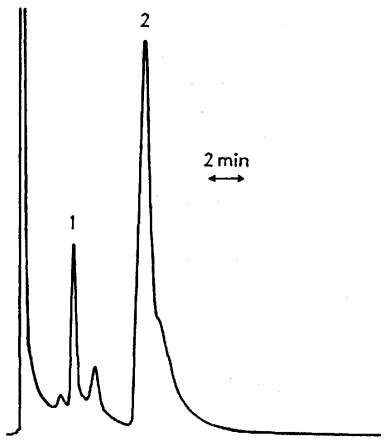


Fig. 1. Gas chromatogram of the products derived from the pyrolysis of *cis*-**6** taken by total ion current of GC-MS. Column of 2% Silicone OV-17 on Gas Chrom Q, 1 m×2 mm i.d. glass column, col. temp: 200 °C, inj. temp: 230 °C, flow rate: 23 ml/min He.

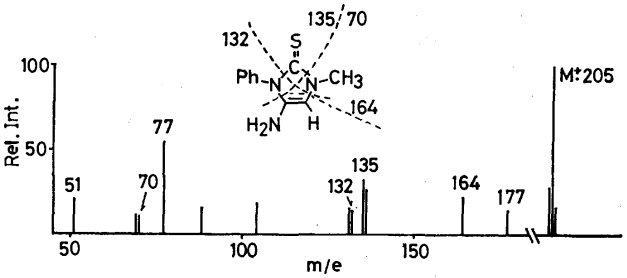

Fig. 2. Mass spectrum of peak 2 in Fig. 1.

the isomerization of **5** to **3** not occurring in the reaction process.

Even the solid of **3** is labile and turns dark-red on exposure to air producing a dimeric compound (**7**) which is insoluble in benzene, toluene, or cold methanol. Compound **7** is slightly soluble in hot methanol and is autoxidized to give **1**. Figure 3 shows the gas chromatogram derived from the autoxidation of **3a** in methanol solution. From the mass spectrum of GLC peak 2

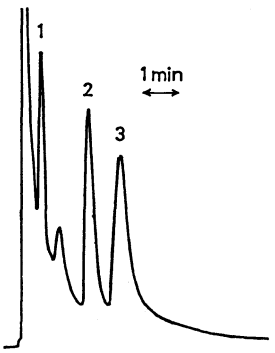

Fig. 3. Gas chromatogram of the products derived from the methanol solution of **3a** (after stirring 35 min at room temperature). Column of 2% Silicone OV-17 on Gas Chrom Q, 1 m×2 mm i.d. glass column, col. temp: 170 °C, inj. temp: 230 °C, flow rate: 32 ml/min He.

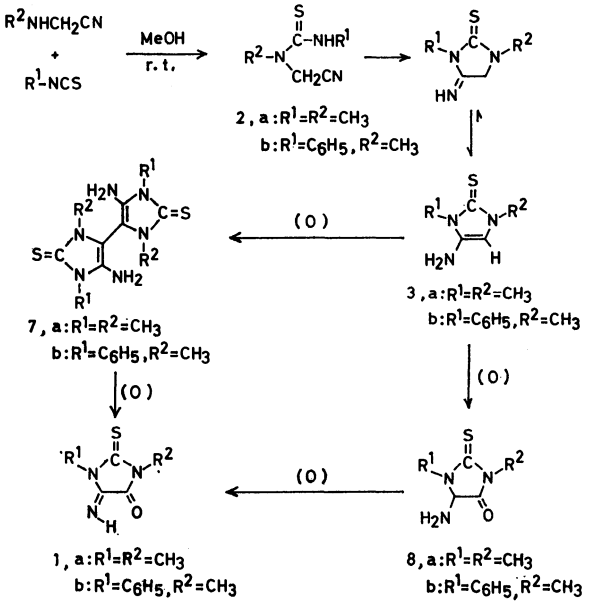
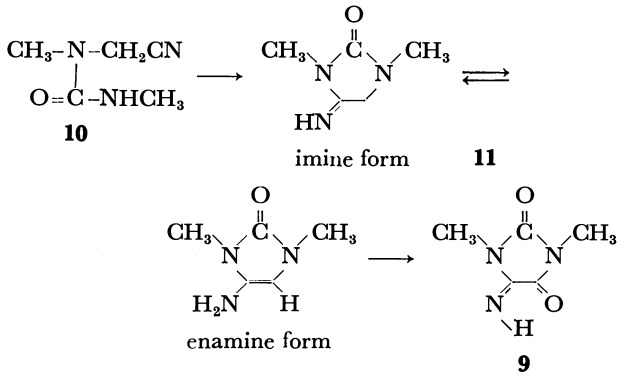
shown in Fig. 3, it was found that the peak is due to a new intermediate compound (**8a**). Attempts to isolate **8a** were unsuccessful. However, the intermediate **8b** could be isolated from the methanol solution of **3b**. In the presence of atmospheric oxygen **8b** was converted into **1b** quantitatively in a methanol solution at room temperature. The structure of **8b** was determined to be 5-amino-3-methyl-1-phenyl-2-thiohydantoin.

A plausible mechanism of the reaction of α-amino-acetonitriles with isothiocyanates in methanol is given in Scheme 1. 5-Imino-2-thiohydantoins (**1**) can be prepared from the autoxidation of two intermediate compounds (**7** and **8**) derived from the autoxidation of **3**.



Scheme 1.

The above reaction is applicable to the synthesis of 5-iminohydantoin derivatives such as 1,3-dimethyl-5-iminohydantoin (**9**) obtained by the reaction of methyl-aminoacetonitrile with methyl isocyanate. However, the reaction was extremely slow under conditions similar to those for the reaction in the preparation of **1**.



It was found that the cyclization reaction of **10** to **11** requires some kind of catalytic base such as pyridine or triethylamine, and the autoxidation of **11** to **9** requires a long period of time (*ca.* two weeks). The low reactivity of **11** toward atmospheric oxygen can be attributed to the fact that the equilibrium of **11** lies toward the imine form, whereas that of **3** lies toward the enamine form. Information on these tautomers was obtained from NMR spectra.

Experimental

All melting points are uncorrected. IR spectra were obtained on a JASCO IRA-2 spectrometer, UV spectra on a Cary 14 spectrometer, NMR spectra on a Varian A-60D spectrometer using tetramethylsilane as an internal standard, and high resolution mass spectra on a JEOL JMS-01SG mass spectrometer using a direct insertion probe and an ionization energy of 75 eV. GLC analyses were carried out on a JEOL JGC-20KFP gas chromatograph and GC-MS analyses on a JEOL JMS D-100 gas chromatograph mass spectrometer.

Materials. Commercial methyl, ethyl, butyl, phenyl, benzyl isothiocyanates, methyl isocyanate, methylaminoacetonitrile, and amines of reagent grade were used. α-Aminoacetonitriles were prepared according to the reported method.[8]

*Preparation of 1-Cyanomethyl-1,3-dimethylthiourea (**2a**).* A solution of methyl isothiocyanate (1.46 g, 20 mmol) in benzene (30 ml) was added dropwise to a solution of methylaminoacetonitrile (1.4 g, 20 mmol) in benzene (30 ml) at 5—10 °C, and the reaction mixture was stirred at 5—10 °C for 15 min and then filtered to give a colorless crystalline product (**2a**) (2.2 g, 77%); mp 75°C; MS, M. W. obsd=143.051, M. W. calcd=143.052 for $C_5H_9N_3S$; IR (Nujol), 3400 (N–H), 2270 (C≡N), 1542 (–NHCSN<) cm^{-1}; NMR (δ, ppm, DMSO-d_6), 7.91 (broad, 1H), 4.95 (s, 2H), 3.13 (s, 3H), 2.95 (d, J=4.5 Hz, 3H). Found: C, 42.09; H, 6.35; N, 29.31; S, 22.17%. Calcd for $C_5H_9N_3S$: C, 41.94; H, 6.33; N, 29.34; S, 22.39%.

*Preparation of 1,3-Dimethyl-4-amino-4-imidazoline-2-thione (**3a**).* A solution of methyl isothiocyanate (1.46 g, 20 mmol) in toluene (30 ml) was added dropwise to a solution of methyl-aminoacetonitrile (1.4 g, 20 mmol) in toluene (30 ml) at room temperature, and the reaction mixture was stirred at room temperature for 30 min and then filtered to give colorless needles (**3a**) (2.6 g, 91%); mp 96 °C; MS, M. W. obsd=143.050, M. W. calcd=143.052 for $C_5H_9N_3S$; IR (Nujol), 3320, 1645 cm^{-1}; UV (EtOH), λ_{max} 266.5 nm; NMR (δ, ppm, DMSO-d_6), 6.16 (s, 1H), 4.73 (broad, 2H), 3.38 (s, 3H), 3.33 (s, 3H); Found: C, 41.89; H, 6.47; N, 29.23; S, 22.28%. Calcd for $C_5H_9N_3S$: C, 41.94; H, 6.33; N, 29.34

S, 22.39%. In another experiment run exactly as above, except that benzene–triethylamine (27: 3) was used in place of toluene, the yield of **3a** was 2.5 g (88%).

Preparation of 1-Methyl-3-phenyl-4-amino-4-imidazoline-2-thione (3b). A solution of phenyl isothiocyanate (2.7 g, 20 mmol) in benzene (30 ml) was added dropwise to a solution of methylaminoacetonitrile (1.4 g, 20 mmol) in benzene (30 ml) at room temperature, and the reaction mixture was stirred at room temperature for 30 min and then filtered to give a pale yellow product (**3b**) (3.6 g, 88%); mp 113 °C; MS, M. W. obsd=205.067, M. W. calcd=205.068 for $C_{10}H_{11}N_3S$; IR (Nujol), 3350, 3260, 1645 cm^{-1}: NMR (δ, ppm, DMSO-d_6), 7.43 (5H, C_6H_5), 6.31 (1H, =CH–), 4.40 (2H, NH_2), 3.43 (3H, CH_3); Found: C, 58.73; H, 5.40; N, 20.23; S, 15.42%. Calcd for $C_{10}H_{11}N_3S$: C, 58.51; H, 5.40; N, 20.47; S, 15.62%.

Preparation of 1,3-Disubstituted 5-Imino-2-thiohydantoins (1). The following procedure illustrates the general method. A solution of methyl isothiocyanate (1.46 g, 20 mmol) in MeOH (30 ml) was added dropwise to a solution of methylaminoacetonitrile (1.82 g, 26 mmol) in MeOH (30 ml) at room temperature, and the reaction mixture was stirred at room temperature for 48 h in the presence of atmospheric oxygen. The solvent was evaporated *in vacuo*, and the residue was dissolved in hot ethanol, and filtered to remove the insoluble dimer (**7a**). The filtrate was then cooled to *ca.* 10 °C and filtered to give **1a** (2.67 g). An analytical sample was recrystallized from ethanol. Analytical data and physical properties of **1a** are summarized in Tables 1 and 2, respectively, along with the other derivatives (**1b**—**j**).

Isolation of the Intermediary Compound 7a. A solution of **3a** (1.5 g) in MeOH (40 ml) was stirred at room temperature for 4 h, and the solution was filtered to give a grayish product (**7a**) (230 mg, 15%); mp 246—248 °C (dec); MS, M. W. obsd=284.086, M. W. calcd=284.088 for $C_{10}H_{16}N_6S_2$; IR (Nujol), 3300, 3170, 1680, 1640 cm^{-1}; UV (EtOH), 288 nm; NMR (δ, ppm, DMSO-d_6), 5.05 (s, 4H), 3.42 (s, 6H), 3.20 (s, 6H); Found: C, 42.14; H, 5.75; N, 29.51; S, 22.47%. Calcd for $C_{10}H_{16}N_6S_2$: C, 42.23; H, 5.67; N, 29.55; S, 22.55%.

Isolation of the Intermediary Compound 8b. A solution of **3b** (0.5 g) in MeOH (20 ml) was stirred at room temperature for 4 h, and the solvent was evaporated *in vacuo*. The residue was subjected to preparative TLC on silica gel eluting with petroleum ether–benzene–ethanol (12: 4: 3) to give 5-amino-3-methyl-1-phenyl-2-thiohydantoin (**8b**) (60 mg, 11%); colorless plastic solid; MS, M. W. obsd=221.063, M. W. calcd=221.062 for $C_{10}H_{11}N_3OS$; IR (Nujol), 3390, 3310, 1747 cm^{-1}; NMR (δ, ppm, CCl_4), 7.24 (s, 5H), 4.82 (s, 1H), 3.18 (s, 3H), 1.76 (broad, 2H), Found: C, 54.08; H, 5.10; N, 18.87; S, 14.41%. Calcd for $C_{10}H_{11}N_3OS$: C, 54.28; H, 5.01; N, 18.99; S, 14.49%.

Reduction of 1b. A solution of **1b** (1.31 g, 6 mmol) in dry THF (40 ml) was added dropwise to a suspension of lithium aluminum hydride (0.5 g, 13 mmol) in dry THF (40 ml) at a rate such as to produce gentle reflux. After completing the addition, sufficient water was added dropwise with ice–water cooling to decompose the excess hydride. The reaction mixture was filtered and extracted with CH_2Cl_2, and the solution was dried over sodium sulfate and concentrated under reduced pressure. The residue was chromatographed on silica gel ($CHCl_3$–EtOH, 40: 1) to give 240 mg of *cis*-4-amino-5-hydroxy-1-methyl-3-phenylimidazolidine-2-thione(*cis*-**6**) and 20 mg of *trans*-**6**.

cis-**6**: Mp 102—103.5 °C; MS, M. W. obsd=223.079, M. W. calcd=223.078 for $C_{10}H_{13}N_3OS$; IR ($CHCl_3$), 3400, 3340 cm^{-1}; NMR (δ, ppm, DMSO-d_6), 7.35 (5H, C_6H_5), 5.12 (d, J=6 Hz, 1H, CH), 5.05 (d, J=6 Hz, 1H, CH), 3.5—3.0 (broad, 3H), 3.11 (s, 3H, CH_3). Found: C, 53.81; H, 5.66; N, 18.77; S, 14.30%. Calcd for $C_{10}H_{13}N_3OS$: C, 53.79; H, 5.87; N, 18.82; S, 14.36%.

trans-**6**: Mp 145.5—146.5 °C; MS, M^+ 223; IR ($CHCl_3$), 3380, 3330 cm^{-1}; NMR (δ, ppm, DMSO-d_6), 7.40 (5H, C_6H_5), 4.85 (d, J=3 Hz, 1H, CH), 4.63 (d, J=3 Hz, 1H, CH), 3.4—3.0 (broad, 3H), 3.08 (s, 3H, CH_3). Found: C, 53.62; H, 5.94; N, 18.71; S, 14.27%. Calcd for $C_{10}H_{13}N_3OS$: C, 53.79; H, 5.87; N, 18.82; S, 14.36%.

The assignments of *cis*/*trans*-**6** were carried out according to the reported method.[9]

Reaction of Methylaminoacetonitrile with Methyl Isocyanate. A solution of methyl isocyanate (1.6 g, 28 mmol) in benzene (30 ml) was added dropwise to a solution of methylaminoacetonitrile (2 g, 28.6 mmol) at 5—10 °C, and the reaction mixture was stirred at 5—10 °C for 10 min and then filtered to give 1-cyanomethyl-1,3-dimethylurea (**10**) (2.8 g, 78%); mp 83—83.5 °C; MS, M^+ 127; IR (Nujol), 3370 (N–H), 2250 (C≡N), 1640, 1550 cm^{-1}; NMR (δ, ppm, DMSO-d_6) 6.58 (broad, 1H, NH), 4.28 (s, 2H, CH_2), 2.84 (s, 3H, CH_3), 2.61 (d, J=4.5 Hz, 3H, CH_3). The Acetylation of Toluene and Benzene with Acetyl Chloride and Bromide and Acetic Anhydride Catalyzed by Calcined Iron Sulfate Activated by Exposure to a Mixture of Benzyl Chloride and the Aromatics[1)]

Kazushi ARATA* and Makoto HINO†
Hokkaido University of Education, Hachiman-cho, Hakodate 040
†*Hakodate Technical College, Tokura-cho, Hakodate 042*

(Received May 4, 1979)

The acetylations of toluene and benzene with acetyl halides and acetic anhydride were studied over catalysts prepared by heat-treating $FeSO_4$ in air, followed by activation on exposure to benzyl chloride in toluene or benzene at 40—80 °C for 1 h, together with $FeCl_3$ and $AlCl_3$. The sulfates treated at 700 and 800 °C showed high activity. The former, activated at 60 °C, gave 68% methylacetophenones, and the latter, more than 90%, with an isomer distribution of 2% *ortho*-, 1% *meta*-, and 97% *para*-form in the reaction of toluene with acetyl halides at room temperature, while the maximum yield was 24% with $FeCl_3$ and 29% with $AlCl_3$. A high yield of acetophenone, 77%, was obtained over the $FeSO_4$ (700 °C) catalyst in the reaction of benzene with acetyl bromide at 60 °C for 1 h. The present catalysts were also highly active for the acetylation of toluene with acetic anhydride; *e.g.*, 55% methylacetophenones were obtained over the $FeSO_4$ (800 °C) catalyst at 100 °C for 5 h. $FeCl_3$ and $AlCl_3$ gave quite low yield compared with the present catalysts.

The Friedel-Crafts acylation of aromatics with acid anhydrides and acyl halides in the presence of acidic halide catalysts has been the subject of a great many investigations during the hundred years since the discovery of the reaction. Extensive reviews have discussed the reaction mechanism.[2-5)] Alkylation with alkyl halides requires only catalytic amounts of catalysts, whereas acylation affords ketones in yields which are proportional to the amount of catalysts. The reaction is complete when little more than a molecular proportion of catalyst is used. On the other hand, more than two moles of the Lewis catalyst are consumed in the case of acid anhydride as an acylating agent.

The acetylation of toluene and benzene with acetyl halides or acetic anhydride has also been performed with, at least, an equimolar amount of a catalyst for an acetylating agent by using such Lewis catalysts as anhydrous aluminum chloride, boron trifluoride, and iron(III) chloride.[6-11)] We have found that the acetylation of toluene and benzene with acetyl halides or acetic anhydride with a new catalyst at room temperature under the heterogeneous system gave methylacetophenones and acetophenone in good yields.

Experimental

The toluene and benzene, guaranteed reagents, were purified by distillation over sodium metal. The acetyl chloride, acetyl bromide, and acetic anhydride, all guaranteed reagents of the Wako Pure Chemical Co., were used without further purification. The acetyl chloride and bromide were stored in sealed ampoules until use in order to prevent hydrolysis. The catalysts were prepared as follows: $FeSO_4 \cdot 7H_2O$ (guaranteed grade of the Kanto Chemical Co.) was heated at 150 °C for 1 h, powdered below 100 mesh, and then calcined in a Pyrex or quartz glass tube at various temperatures in air for 3 h. The prepared catalyst was sealed in an ampoule until use. The activation of the catalyst was performed by heating a mixture of 50 ml of toluene or benzene, 1 g of the catalyst, and 1 ml of benzyl chloride at 60—100 °C. After the mixture has been cooled, an acetylating reagent (0.025 mol) was added, and the whole mixture was stirred at room temperature for 15—360 min. The catalyst was then removed by filtration, and the filtrate was washed with water several times and dried over anhydrous calcium chloride. The products were identified by means of a gas-chromatographic comparison with commercially available authentic samples and analyzed, using benzene (for the acetylation of toluene) or toluene (for the reaction of benzene) as the internal standard (a 1-m column of tritolyl phosphate on Celite 545, 110 °C, He: 1.0 kg/cm²).

Results and Discussion

It was previously reported[12,13)] that the benzylation of toluene with benzyl chloride was markedly catalyzed by iron sulfates, which belong to the solid-acid type of catalysts, such as SiO–Al_2O_3 and $NiSO_4$. The iron sulfates also catalyzed the benzoylation of toluene with benzoyl chloride.[14)] The catalysts heat-treated at 700 °C showed the maximum activity in both reactions. The reaction rate in the benzoylation was, however, quite low. It took more than 50 min to complete the 30% conversion at 110 °C over the most active catalyst. Thus, the reaction rate of the acetylation of toluene with acetyl halides can be expected to be quite low because of the weak electrophilicity of the acetyl cation, CH_3CO^+. In fact, no product was detected in the gas-chromatographic analysis in the reaction of toluene with acetyl chloride at the reaction temperature of 50 °C, close to the boiling point of the chloride, over $FeSO_4$ heat-treated at 700 °C. However, the catalyst was found to be highly activated by exposure to benzyl chloride in toluene, and the acetylation proceeded at room temperature.

An example of the reaction by the activated catalyst is as follows. A mixture of toluene (50 ml), benzyl chloride (0.5 ml), and 1 g of $FeSO_4$ calcined at 700 °C was heated at 60 °C for 1 h; after cooling, acetyl chloride (0.025 mol) was added to the mixture, after which the whole mixture was stirred at room temperature. Thus, the aromatic compound for the acetylation is the toluene used in the activation of the catalyst. A

TABLE 1. YIELD(%) FOR ACETYLATION OF TOLUENE WITH ACETYL CHLORIDE AND BROMIDE AT ROOM TEMPERATURE[a)]

$AlCl_3$		CH_3COBr	22									

a) Activated at 60 °C by the addition of 1 ml of benzyl chloride; catalyst amount: 1 g. b) Without treatment with benzyl chloride, 0% for 300 min. c) Reacted at 60 °C.

mixture of *o*-, *m*-, and *p*-methylacetophenone was obtained in a 21% yield after 60 min. The longer the period of reaction the more products were given: 31% for 120 min and 34% for 180 min. The reaction with acetyl bromide under the same conditions gave a 40% yield in 30 min and a 42% yield in 60 min.

The catalytic activity was dependent on the temperature of activation; *i.e.*, mixtures of methylacetophenones were obtained in 11, 21, 29, and 30% yields for 3 h when activated at 40, 50, 70, and 80 °C respectively, 60 °C thus being the most activating temperature (34% for 3 h). The acetylation with the chloride was performed over $AlCl_3$ and $FeCl_3$, but the product amount was only 9% for 3 h with both catalysts and 11% for even a period of 11 h with $FeCl_3$ under the same reaction conditions.

Table 1 shows the yields of the products for the acetylation of toluene with acetyl chloride and bromide at room temperature catalyzed by iron sulfates calcined at various temperatures, followed by activation with benzyl chloride at 60 °C; the yields obtained with $FeCl_3$ and $AlCl_3$ are also shown for comparison. As has already been mentioned, iron sulfate calcined at any temperature was completely inactive for the acetylation at room temperature unless otherwise activated. The catalytic activity of activated $FeSO_4$ changed remarkably with the calcination temperature. The sulfates calcined at 500, 600, and 900 °C showed low activity. However, a considerable amount, 68%, of methylacetophenones was obtained over the catalyst prepared by calcining at 700 °C with both acetyl chloride and bromide, and the sulfate calcined at 800 °C gave methylacetophenones in more than a 90% yield, though its reaction rate was slower than that when using the catalyst calcined at 700 °C. $FeSO_4$(750 °C)** falls into the intermediate range between the above two catalysts. The catalysts treated at 500 and 600 °C were found to be dissolved in the reaction mixture, and $FeSO_4$(700 °C) was slightly dissolved, while the materials calcined at 800 °C and 900 °C were insoluble.

When $FeCl_3$ and $AlCl_3$ were used instead of the present catalysts under similar conditions, the maximum yields were 24% and 29% respectively, quite close to the expected maximum yields estimated from the molar amounts of these catalysts and the acetylating reagent.

The acetylations was carried out with acetic anhydride as the acetylating agent over the sulfates treated at 700 °C and 800 °C, as is shown in Table 2. The reaction was performed over 60 °C because of the slow rate of the reaction. Whereas $FeCl_3$ and $AlCl_3$ produced less than 15% of methylacetophenones in 3 h at 80 °C, $FeSO_4$(700 °C) gave a 38% yield under the same conditions and even 44% in 5 h. It should be noted that 55% methylacetophenones were obtained over $FeSO_4$(800 °C) at 100 °C in 5 h. The selectivity was lower than that in the case of acetyl halides, whose isomer distribution was 2% *ortho*-, 1% *meta*-, and 97% *para*-methylacetophenone (Table 1).

The acetylation of benzene was performed with highly active catalysts, $FeSO_4$(700 °C) and $FeSO_4$(800 °C). The results are shown in Table 3. Since the reaction rate was quite low, the reaction temperature taken was 50 °C and 60 °C in the cases of the chloride and bromide respectively, both temperatures close to their boiling points. The catalysts were almost inactive for this reaction with acetic anhydride at 80 °C. The activity of $FeSO_3$(700 °C) was higher than that of $FeSO_4$(800 °C) in contrast with the observations of the reaction of toluene. Although the reaction with acetyl chloride showed a slower rate than that with the bromide, as was seen also in the case of toluene, the $FeSO_4$(700 °C) catalyst gave a 49% conversion to acetophenone in 6 h. A high yield, 77%, was obtained over this catalyst with acetyl bromide over a period of 1 h. $FeCl_3$ and $AlCl_3$ afforded 20% and 16% yield respectively when reacted with the bromide for 1 h.

On the exposure of the catalysts to a mixture of

benzyl chloride and toluene or benzene, it appears likely that iron chloride was newly formed on the catalyst surface because of the HCl evolved by the benzylation of toluene or benzene with benzyl chloride, the iron chloride thus acting as a catalyst. After the activation of the catalysts, gas-chromatographic (GC) analysis showed the benzylation of toluene and benzene to be 100% complete. The $FeSO_4$(700 °C) catalyst was separated from the mixture of benzyl chloride and toluene after the activation, washed with toluene, and dried, and finally its IR spectrum was taken, together with that of commercial $FeCl_3$ for reference.*** The spectra showed an absorption band at 1600 cm^{-1} which is assigned to water molecule coordinated to $FeCl_3$. However, this separated catalyst produced only 10% of methylacetophenones in a reaction of 2 h with acetyl chloride. The differently prepared HCl-treated catalyst, which had been prepared by exposing $FeSO_4$(700 °C) to a stream of the mixed gas of N_2 (20 ml/min) and HCl (26 ml/min) for 20 min and then to N_2 gas for 30 min,[15] gave a 28% conversion at the highest in the acetylation of toluene with acetyl chloride. It may, therefore, be considered that the catalyst surface was activated by complicated interactions with benzyl chloride and HCl evolved by the benzylation. As for alkyl halides other than benzyl chloride, *t*-butyl and isopropyl chlorides were examined, but these halides did not activate the catalysts. GC analysis revealed that the catalysts are not active at all for the *t*-butylation and isopropylation of toluene or benzene.

The Friedel-Crafts acylation of aromatic hydrocarbons such as toluene and benzene is characterized by a generally high selectivity of the reactions reflected in high substrate-rate ratios (usually $k_{toluene}/k_{benzene} > 100$) and related predominant *para*-substitution. The competitive acetylation of toluene and benzene was studied over the present catalysts. The obtained values of k_T/k_B, the relative rate between toluene and benzene, were 99.2 with $FeSO_4$(700 °C) and CH_3COCl, 98.6 with $FeSO_4$(800 °C) and CH_3COCl, 33.6 with $FeSO_4$(800 °C) and CH_3COBr, and 65.2 with $FeSO_4$-(800 °C) and $(CH_3CO)_2O$.[16] Several workers have determined the k_T/k_B value to be 121—141 over Lewis catalysts with a high para positional selectivity (95.5—98.3% *para* isomer).[6,17,18] These high values reflect the week electrophilic nature of the acetyl cation. The present values are relatively small in comparison with those literature values, especially that in the $FeSO_4$-(800 °C) and the CH_3COBr system, in spite of the high para selectivity. This suggests that the present acetylation was not just catalyzed by iron chlorides on the catalyst surface.

*** The infrared spectra were obtained using Nujol and KBr tablets.

A ^{13}C NMR and CNDO/2 Calculation Study of the Transannular Interaction in [2.2]Cyclophanes[1)]

Kazushi TOKITA, Tetsuo TAKEMURA, Shoichi KONDO, and Nobuo MORI*

Department of Chemistry, Science University of Tokyo, Shinjuku-ku, Tokyo 162

(Received May 14, 1979)

The relationships between the aryl carbon chemical shifts and the CNDO/2 electron densities for several [2.2]cyclophanes are reported. Plots of the chemical shifts against the excess total electron densities indicate additional downfield shifts of 6—9 ppm on the average for those aryl carbons that are in close proximity to other aryl carbons. A plot of the ^{13}C shielding constant, calculated using the Karplus-Pople theory, against the chemical shift shows a downfield shift of a similar magnitude for the proximate carbons relative to the others. It is found that this difference can be essentially eliminated simply by adjusting the ΔE parameter in the Karplus-Pople equation from 10.0 eV to 9.7 eV for the proximate carbon atoms.

Although the transannular interactions in [2.2]-cyclophanes of electronically excited states have been thoroughly investigated, the interactions in the ground electronic states are still not well understood. In their photoelectron spectral study of the [2.2]para- and [2.2]-metacyclophanes, **7** and **10**, Boschi and Schmidt[2)] suggested that the interaction in **7** takes place between all the facing aryl carbons, whereas in **10** it is confined to C(8) and C(16), which are in the closest proximity to each other. In the ground state, however, no such interaction could be detected by means of ^{13}C NMR spectroscopy.[3)] Recent ^{13}C NMR results for **7** and **10**[4)] have indicated that the interacting carbons, especially C(8) and C(16) in **10**, are noticeably deshielded compared with open-chain models. Similar deshieldings were observed for other facing unsaturated carbons whose p-orbital axes were nearly colinear.[4-6)]

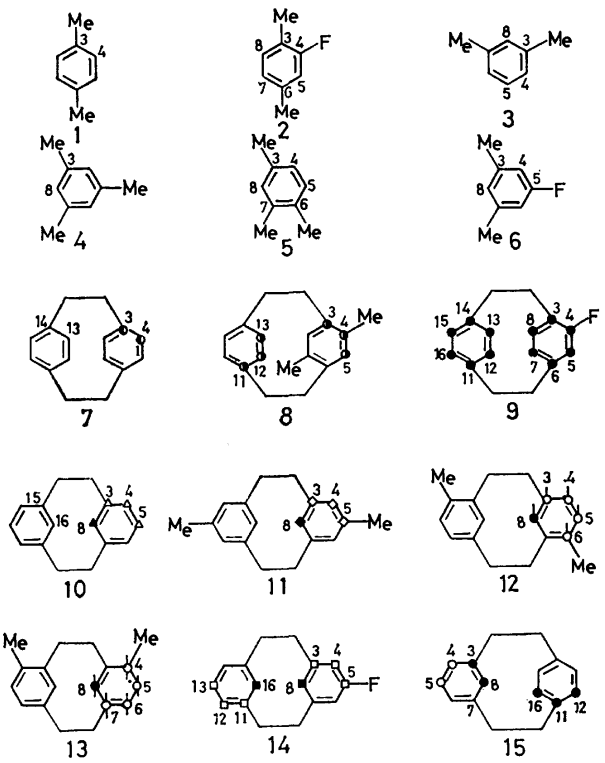

Fig. 1. The reference and [2.2]cyclophane compounds examined. The positions in **1**—**6** are numbered so as to correspond to those in **7**—**15**.

In an attempt to explain these observations we have first investigated the relationships between the aryl carbon chemical shifts and the CNDO/2 electron densities in the nine [2.2]cyclophanes, **7**—**15**, shown in Fig. 1, and in six monocyclic reference compounds, **1**—**6**. Then we have compared the observed chemical shifts with the shielding constants calculated using the Karplus-Pople theory.[7)]

Calculation

The theoretical ^{13}C shielding for an atom, σ, was calculated in terms of the Karplus-Pople theory[7)] using:

$$\sigma = \sigma_d + \sigma_p, \quad (1)$$

but the local diamagnetic term, σ_d, was estimated using:[8)]

$$\sigma_d = 4.45Zq^t, \quad (2)$$

where Z is the effective nuclear charge estimated according to Slater's rules and q^t is the total electron density on the atom. The electron densities and bond orders used in these calculations were those estimated by the CNDO/2-Molecular Orbital method.[9)] In the MO calculations for all the cyclophanes, the geometry parameters of the parent unsubstituted compounds[10)] were used in defining the input geometries, but the standard geometry parameters[11)] were used for the methyl and fluorine substituents in the methyl- and fluorocyclophanes, **8**, **9**, and **11**—**14**, and for all the monocyclic compounds.

All the computations were performed on a HITAC-8800/8700 computer at the Computer Centre of the University of Tokyo.

Results and Discussion

Table 1 gives the excess π- and total electron densities, Δq^π and Δq^t, as calculated by the CNDO/2 approximation,[9)] together with the observed and calculated aryl carbon chemical shifts, δ and σ from Eq. 1 using 10.0 eV[12)] as ΔE for all compounds.

In Models **1**—**6**, the δ value was found to bear a better linear relationship with the Δq^t than with the Δq^π value. The least-squares graph of the correlation ($r^{**}=0.972$) is drawn in Figs. 2—4, together with similar plots for the cyclophanes. The line ($s^{**}=153$) is very

** r: correlation coefficient; s: slope of the line.

a) Downfield from internal TMS (all data in $CDCl_3$). b) δ taken from J. B. Stothers, "Carbon-13 NMR Spectroscopy," Academic Press, New York (1972), p. 95. c) Obtained in this work (Ref. 15). d) Taken from Ref. 4. e) Taken from H. Horita, H. Takemitsu, T. Otsubo, Y. Sakata, S. Misumi, M. Mishima, and Y. Tsuno, Abstract presented at the 32 nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1975. f) δ taken from T. Takemura and N. Mori, *Chem. Lett.*, **1978**, 857. g) Taken from Ref. 1. h) Numbering as in Fig. 1.

close to that ($s=160$) shown by Bloor and Breen[12] for monosubstituted benzenes. Also, the correlation graph obtained between the σ and δ values of **1**, **3**, **4**, and **5** is shown in Fig. 5.

Figures 2—4 show plots of the δ against the Δq^{t} values for the **7**—**9**, **10**—**14**, and **15** cyclophanes respectively. It should be noticed in any of the figures that the aryl carbons proximate to each other show a linear relationship different from that for the remote or non-interacting carbons, as will be discussed further below (see Table 2).

In Fig. 2, the plots for all the facing carbons of the paracyclophanes lie roughly on the same correlation line,

Table 2. The least-squares linear relationships between δ and Δq^{t} for Compounds **1**—**15**

$\delta = a\Delta q^{t} + b$

Compd	a[a]	b[a]	r[b]
1—**6**	153	128.0	0.972
7—**9**	(138)	(133.4)	(0.951)
10—**14**	153 (153)	130.4 (139.4)	0.980 (0.980)
15	(113)	(135.9)	(0.953)

a) The values in parentheses are those for the proximate carbons. b) Correlation coefficient.

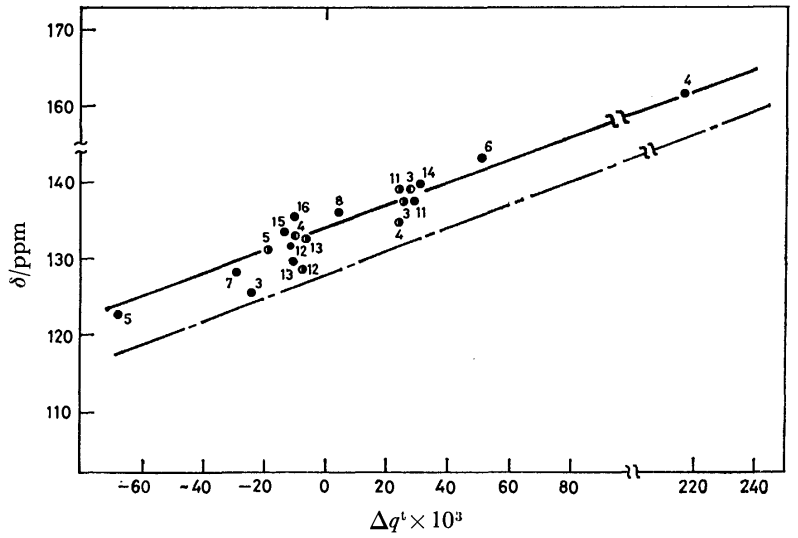

Fig. 2. Plots of δ *vs.* Δq^t for [2.2]paracyclophanes **7**—**9**. Numbering and designations as in Fig. 1. Reference line for **1**—**6**: — — —.

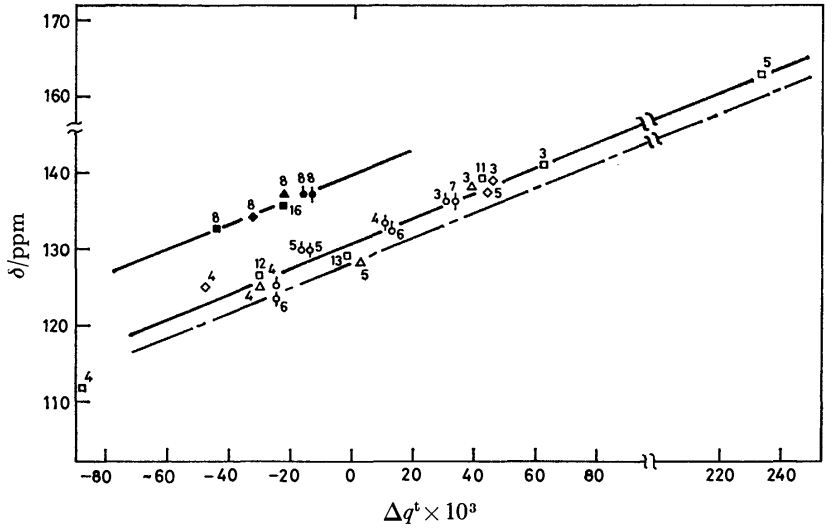

Fig. 3. Plots of δ *vs.* Δq^t for metacyclophanes **10**—**14**. Numbering and designations as in Fig. 1. Reference line for **1**—**6**: — — —.

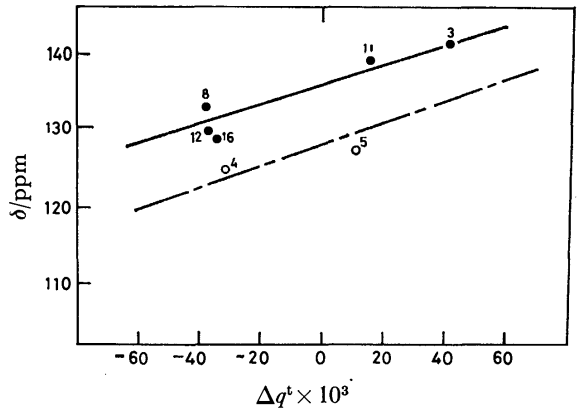

Fig. 4. Plots of δ *vs.* Δq^t for metaparacyclophane **15**. Numbering and designations as in Fig. 1. Reference line for **1**—**6**: — — —.

which is *ca.* 6 ppm upward (or downfield) from the line for the reference monocycles. Figure 3 indicates that the inner, C(8) and C(16), and the outer carbons, C(3)—C(5), of the metacyclophanes are distinguished by two separate linear relationships. The least-squares lines are parallel and are 9.0 ppm apart. The lower line for the outer carbons is only 2 ppm away from the reference line. This slight discrepancy between the latter two is unimportant, if one considers the approximate nature of the theory used to calculate the electron densities and the fact that the observed data are uncorrected for the ring current and other anisotropic shielding effects. Figure 4 shows that, in metaparacyclophane **15**, the plots for the outer carbons, C(4) and C(5), of the meta ring fall on the reference line, whereas those for the rest of the aryl carbons are on a separate line which is *ca.* 8 ppm away from the reference. From these results it may be concluded that the proximate carbons

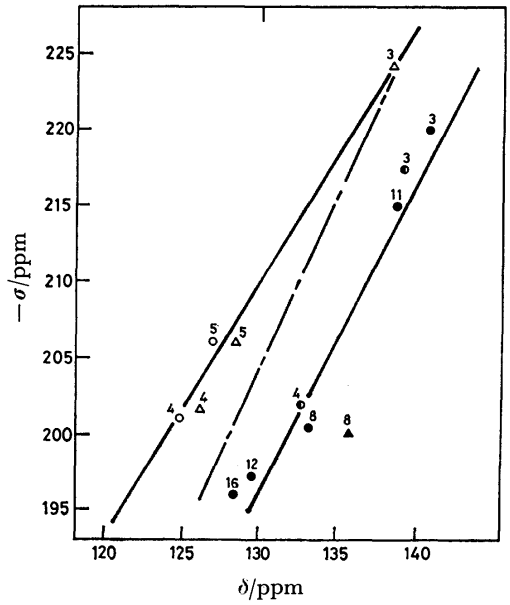

Fig. 5. Plots of σ *vs.* δ for [2.2]cyclophanes **7**, **10**, and **15**, using 10.0 eV as ΔE for all carbons. Numbering and designations as in Fig. 1. Reference line for **1**, **3**, **4**, and **5**: — - —

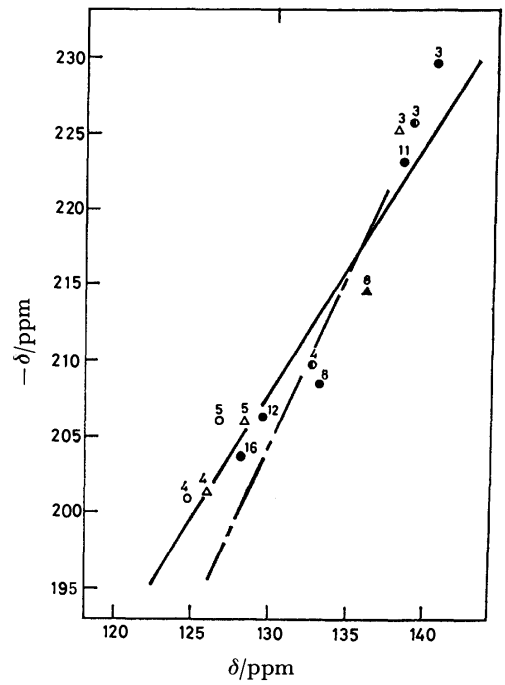

Fig. 6. The effect of using decreased ΔE for the proximate carbons, 9.5 eV for C(8) of **10** and 9.7 eV for all the others.

are shifted downfield compared with the remote carbons with the same total electron densities. The magnitude of the downfield shifts varies with the type of the cyclophane series within the range of *ca.* 6—9 ppm. This is probably attributable to decreases in the excitation energy term, ΔE, of the paramagnetic shielding expression, σ_p, as will be interpreted below.

Figure 5 shows plots of the σ values predicted from Eq. 1, using 10.0 eV as ΔE, against the δ values for the **7**, **10**, and **15** cyclophanes. Apparently, there are two different linear relationships, which are characteristic of the proximate and the remote carbons. The least-squares lines are nearly parallel, with a space of *ca.* 10 ppm between; both are in poor agreement with the reference line. Exactly, the use of the ΔE value of 10.0 eV leads to an estimation of the chemical shifts for the proximate carbons 8—12 ppm smaller than those for the remote carbons, except for the inner C(8) of **10** and **15**, which are underestimated by 20 and 14 ppm respectively (similar results were obtained by using 8.0 eV as the ΔE). The magnitude of the underestimation is seemingly correlated with the interatomic distance between the interacting carbons and the relative orientation of the p-orbitals concerned, as Table 3 shows. A possible explanation for the underestimation can be obtained by assuming decreases in ΔE caused by a transannular interaction.[13] Such decreases in the meta- and metaparacyclophanes must be highly local (Karplus and Pople[7b] suggest the possibility of localized excitations). For example, a decrease in the ΔE from 10.0 to 9.7 eV changes the σ value for C(3) of **7** from −217.3 to −225.8 ppm. The graph of Fig. 6 shows the effect of using the ΔE of 9.7 eV for all the proximate carbons except for C(8) of **10**, for which 9.5 eV is used. All the points now lie roughly on the same line, which is closer to the reference than in Fig. 5. The assumption of the local decreases in ΔE can also explain the downfield-shift trend of the proximate carbon resonances shown in Figs. 2—4, because a decrease in ΔE should cause a downfield shift. Recent studies of smaller molecules[14] indicate that the correlation between theory and experiment for ^{13}C chemical shifts is improved by using different excitation energies for individual carbons in calculating their chemical shifts.

TABLE 3. UNDERESTIMATED CHEMICAL SHIFTS, $\Delta\sigma$ AND INTERATOMIC DISTANCES, l, FOR THE PROXIMATE CARBONS

Compd	Centers	l/Å	$\Delta\sigma$/ppm[a]
7	C(3)-C(14)	2.77[10c]	8
	C(4)-C(13)	3.09	12
10	C(8)-C(16)	2.69[10a]	20
	C(3)-C(15)	3.02	0

Pseudo-sugars. 5. Synthesis of DL-Validatol and DL-Deoxyvalidatol, and Their Epimers[1,2]

Seiichiro OGAWA,* Tatsushi TOYOKUNI, Masaji OMATA,
Noritaka CHIDA, and Tetsuo SUAMI
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223
(Received May 21, 1979)

New cyclitols, validatol and deoxyvalidatol, derived by hydrogenolysis of antibiotic validamycin A, were synthesized as the racemates from readily available tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol.

In connection with a previous work,[3] we wish to report the first synthesis of racemic validatol and deoxyvalidatol, the degradation products of validamycin A,[4] from readily available tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**1**).[2]

Treatment of **1** with 1.2 molar equivalent of silver fluoride in dry pyridine at ambient temperature overnight gave exclusively tri-*O*-acetyl-(1,3/2,4)-4-bromo-6-methylene-1,2,3-cyclohexanetriol (**2**) in 60% yield. The ^{1}H NMR spectrum showed the signals of C-5 methylene protons as a one-proton broad triplet (J=12 and 14 Hz) at δ 2.61 and a one-proton doublet of doublets (J=5 and 14 Hz) at δ 3.01, confirming the assigned structure. Debromination of **2** with tributyltin(IV) hydride in toluene in the presence of α,α'-azobisisobutyronitrile gave tri-*O*-acetyl-(1,3/2)-4-methylene-1,2,3-cyclohexanetriol (**3**) in 60% yield. On the other hand, exhaustive dehydrobromination of **1** was effected by treatment with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in toluene to give an exocyclic diolefin, tri-*O*-acetyl-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol (**4**)[5] in 45% yield, which was identical with the compound obtained from **2** in a similar way in 51% yield. Its structure was determined by the ^{1}H NMR spectrum, which revealed the signals of the exocyclic methylene protons as two broad singlets at δ 5.08 and 5.21. Compounds **2**, **3**, and **4** thus obtained might be useful intermediates for the preparation of unsaturated branched cyclitols.

14	H	H	OH

Catalytic reduction of **3** or **4** in ethyl acetate with platinum oxide gave preferentially tri-*O*-acetyl-(1,3,4/2)-4-methyl-1,2,3-cyclohexanetriol (**5**) in a high yield, the ^{1}H NMR spectral data of which were identical with those of an optically active sample reported by Horii and Kameda.[6] A 4-epimer (**7**) of **5** was also prepared by hydrogenolysis of **1** with Raney nickel T-4[7] in ethyl acetate in the presence of Amberlite IR-45 (OH^-) in 92% yield. *O*-Deacetylation of **5** and **7** with methanolic sodium methoxide gave crystalline triol **6** (deoxyvalidatol) and **8**, respectively.

(1,3,4/2)-4-Hydroxymethyl-1,2,3-cyclohexanetriol (validatol) (**14**) was synthesized from **2** or **3** by hydroboration followed by the usual sequence of reactions. First, (1,3/2,4)-4-hydroxymethyl-1,2,3-cyclohexanetriol (**11**) was prepared from **1** as a reference compound. Tetra-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-hydroxymethyl-1,2,3-cyclohexanetriol (**9**)[2] derived by treatment of **1** with sodium acetate in aqueous 2-methoxyethanol was hydrogenolyzed with Raney nickel in the usual way to give a crystalline tetraacetate (**10**) of **11** in 96% yield. *O*-Deacetylation gave a crystalline **11** in 97% yield.

Hydroboration of **2** with sodium borohydride and boron trifluoride in tetrahydrofuran (THF) followed by treatment with hydrogen peroxide[8] and successive acetylation gave, after purification on a silica-gel column, a homogeneous syrupy product in 30% yield. Comparison of the ^{1}H NMR spectrum with that of **9** showed that the product consists of **9** and tetra-*O*-acetyl-(1,3,6/2,4)-4-bromo-6-hydroxymethyl-1,2,3-cyclohexanetriol (**12**) in a 1:2 ratio. Without separation, the mixture was hydrogenolyzed in the usual way to give a syrup, which was found by ^{1}H NMR spectroscopy to consist of **10** and validatol tetraacetate (**13**) in a 1:2 ratio. Compound **3** was also subjected to hydroboration similarly followed by acetylation to give a 1:2.5 mixture of **10** and **13** in 29% yield. Since both compounds showed a similar mobility on TLC in various solvent systems, separation was carried out by converting them into tetrols **11** and **14**. *O*-Deacetylated mixture was successfully fractionated by chromatography on silica gel to give **11** as crystals and **14** as a homogeneous syrup. Acetylation of **14** gave a syrupy **13** whose

^{1}H NMR spectrum was superimposable on that of an authentic optically active sample reported.[4b]

Experimental

Melting points were determined in a capillary in a silicone bath and are uncorrected. Solutions were evaporated under reduced pressure at 40—50 °C. Unless otherwise stated, the ^{1}H NMR spectra were taken on a Varian EM 360A (60 MHz) or HA 100D (100 MHz) in deuteriochloroform ($CDCl_3$) with reference to tetramethylsilane as an internal standard, the peak positions being given in terms of δ-values. Values given for coupling constants are of first-order. TLC was performed on pre-coated silica gel 60 F-254 plaques (Merck, Darmstadt; 0.25 mm thickness). Silica gel (Wakogel C-300, Wako Pure Chemical Industries, Ltd.) was used for column chromatography.

Tri-O-acetyl-(1,3/2,4)-4-bromo-6-methylene-1,2,3-cyclohexanetriol (2). A mixture of tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**1**)[2] (1 g) and silver fluoride (0.36 g, 1.2 molar equiv.) in dry pyridine (20 ml) was stirred at ambient temperature for 20 h. The brown reaction mixture was diluted with ether (100 ml) and the precipitates were removed by filtration. The filtrate was evaporated and the product purified by passage through a short column of alumina with chloroform. The eluate was evaporated and the residue was crystallized from ethanol to give **2** (0.49 g, 60%) as needles: mp 124—125 °C: ^{1}H NMR (60 MHz) δ 2.00 (3H, s), 2.05 (3H, s), and 2.10 (3H, s) (OAc), 2.61 (1H, broad t, $J_{4,5ax}=12$ Hz, $J_{5gem}=14$ Hz, H-5ax), 3.01 (1H, dd, $J_{4,5eq}=5$ Hz, H-5eq), 3.80 (1H, ddd, $J_{3,4}=9.5$ Hz, H-4), 4.7—5.5 (5H, m, H-1, H-2, H-3, and exocyclic methylene).

Found: C, 44.43; H, 4.87; Br, 23.12%. Calcd for $C_{13}H_{17}O_6Br$: C, 44.71; H, 4.91; Br, 22.88%.

Tri-O-acetyl-(1,3/2)-4-methylene-1,2,3-cyclohexanetriol (3). A solution of **2** (1.65 g) in dry toluene (50 ml) was treated with tributyltin(IV) hydride (1.6 ml) in the presence of a trace of α,α'-azobisisobutyronitrile at 80 °C for 30 min under a nitrogen stream. The reaction mixture was then evaporated and the residue was crystallized from ligroin to give **3** (0.76 g, 60%) as prisms: mp 69—71 °C; ^{1}H NMR (60 MHz) δ 1.15 (4H, m, ring methylene), 2.00 (3H, s), 2.01 (3H, s), and 2.10 (3H, s) (OAc), 4.7—5.5 (5H, m, H-1, H-2, H-3, and exocyclic methylene).

Found: C, 57.56; H, 6.71%. Calcd for $C_{13}H_{18}O_6$: C, 57.77; H, 6.71%.

Tri-O-acetyl-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol (4). a) A solution of **1** (1 g) and DBU (1.8 ml, 5 molar equiv.) in toluene (10 ml) was refluxed for 30 min. After cooling, the precipitates were removed by decantation. The solution was evaporated and the residue dissolved in ethyl acetate (50 ml). The solution was washed with 0.2 M hydrochloric acid, aqueous saturated sodium hydrogencarbonate, and water, successively, dried over anhydrous sodium sulfate, and filtered through a short column of alumina. The filtrate was evaporated and the residue was crystallized from ethanol to give **4** (0.28 g, 45%) as needles: mp 67—68 °C; ^{1}H NMR (100 MHz) δ 2.06 (3H, s), 2.08 (3H, s), and 2.15 (3H, s) (OAc), 5.08 (1H, broad s) and 5.21 (1H, broad s) (exocyclic methylene), 5.28 (1H, dd, $J=7.5$ Hz, $J=10.5$ Hz, H-2), 5.6 —5.8 (3H, m, H-1, H-3, and H-5), 6.31 (1H, m, H-6).

Found: C, 57.97; H, 5.96%. Calcd for $C_{13}H_{16}O_6$: C, 58.26; H, 6.01%.

b) A solution of **2** (1 g) and DBU (0.52 ml, 1.2 molar equiv.) in toluene (20 ml) was refluxed for 6 h. After cooling, the precipitates were removed by filtration and the filtrate was treated as described above. Crystallization of the crude product from ethanol gave **4** (0.4 g, 51%): mp 66—67.5 °C, identical with the compound obtained above.

Tri-O-acetyl-(1,3,4/2)-4-methyl-1,2,3-cyclohexanetriol (Deoxyvalidatol) (5). a) A solution of **3** (0.1 g) in ethyl acetate (10 ml) was hydrogenated in a Parr shaker apparatus in the presence of platinum oxide (10 mg) under an initial hydrogen pressure of 3 kg cm^{-2} at ambient temperature overnight. The catalyst was removed by filtration and the filtrate was evaporated to give **5** (77 mg, 76%) as a chromatographically homogeneous syrup: ^{1}H NMR (100 MHz) δ 1.05 (3H, d, $J=7$ Hz, methyl), 1.1—1.9 (4H, m, two ring methylene), 2.01 (6H, s) and 2.05 (3H, s) (OAc), 2.21 (1H, m, H-4), 4.83 (1H, dd, $J_{2,3}=9$ Hz, $J_{3,4}=5$ Hz, H-3), 5.23 (1H, t, $J_{1,2}=9$ Hz, H-2). The ^{1}H NMR spectral data were almost identical with those of an optically active sample reported,[6] showing that **5** contains a trace of its 4-epimer (**7**). (Found: C, 56.75; H, 7.31%).

b) Compound **4** (65 mg) was hydrogenated in ethyl acetate (5 ml) in a similar way to that described above to give a syrupy mixture (56 mg, 85%) of **5** and **7** in the ratio of 3: 1.

(1,3,4/2)-4-Methyl-1,2,3-cyclohexanetriol (Deoxyvalidatol) (6). A solution of crude **5** (0.1 g) in methanol (10 ml) was treated with 1 M methanolic sodium methoxide (0.2 ml) and allowed to stand at ambient temperature overnight. The mixture was then treated with Amberlite IR-120 (H^+) and concentrated to give a crystalline residue. Recrystallization from ethanol–ether gave **6** (46 mg, 86%) as colorless crystals: mp 109.5 °C (after melting partly at 93 °C). ^{1}H NMR (60 MHz in D_2O with sodium 4,4-dimethyl-4-silapentane-1-sulfonate as an internal standard) δ 0.92 (3H, d, $J=7$ Hz, methyl), 1.12—2.27 (5H, m, two ring methylene and H-4), 3.06—3.76 (3H, m, H-1, H-2, and H-3).

Found: C, 57.23; H, 9.44%. Calcd for $C_7H_{14}O_3$: C, 57.51; H, 9.65%.

Tri-O-acetyl-(1,3/2,4)-4-methyl-1,2,3-cyclohexanetriol (7). A solution of **1** (0.5 g) in ethyl acetate (10 ml) was hydrogenated in a Parr shaker apparatus in the presence of Raney nickel T-4[7] (5 ml) and Amberlite IR-45 (OH^-) (7 ml) under an initial hydrogen pressure of 3 kg cm^{-2} at ambient temperature overnight. The catalyst and resin were removed by filtration and the filtrate was evaporated to give a crystalline residue, which was recrystallized from ethanol to give **7** (0.29 g, 92%) as feathers: mp 92—93.5 °C; ^{1}H NMR (60 MHz) δ 0.92 (3H, d, $J=6$ Hz, methyl), 1.98 (6H, s) and 2.00 (3H, s) (OAc), 4.54—5.18 (3H, m, H-1, H-2, and H-3).

Found: C, 57.07; H, 7.22%. Calcd for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

(1,3/2,4)-4-Methyl-1,2,3-cyclohexanetriol (8). Compound **7** (0.1 g) was treated with methanolic sodium methoxide in the same way as in the preparation of **6**. The crude product was recrystallized from ethanol–ether to give **8** (53 mg, 99%) as colorless crystals: mp 120.5—121 °C. ^{1}H NMR (60 MHz in D_2O) δ 0.93 (3H, d, $J=5.5$ Hz, methyl), 1.09—2.04 (5H, m, two ring methylene and H-4), 2.64—3.66 (3H, m, H-1, H-2, and H-3).

Found: C, 57.27; H, 9.46%. Calcd for $C_7H_{14}O_3$: C, 57.51; H, 9.65%.

Tetra-O-acetyl-(1,3/2,4)-4-hydroxymethyl-1,2,3-cyclohexanetriol (10). A solution of tetra-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-hydroxymethyl-1,2,3-cyclohexanetriol (**9**)[2] (0.5 g) in ethyl acetate (10 ml) was hydrogenolyzed as in the preparation of **7**. Crystallization of a crude product from ethanol gave **10** (0.39 g, 96%) as prisms: mp 99.5—100 °C; ^{1}H NMR (60 MHz) δ 2.00 (9H, s) and 2.03 (3H, s) (OAc), 1.2—2.3 (5H, m, ring methylene and H-4), 3.83—4.03 (2H, AB-quartet, H-7 and H-7'), 4.62—5.12 (3H, m, H-1, H-2, and H-3).

Found: C, 54.71; H, 6.68%. Calcd for $C_{15}H_{22}O_8$: C, 54.54; H, 6.71%.

(1,3/2,4)-4-Hydroxymethyl-1,2,3-cyclohexanetriol (11). Compound **10** (0.22 g) was *O*-deacetylated with methanolic sodium methoxide as in the preparation of **6**. The crude product was recrystallized from ethanol to give **11** (0.11 g, 97%) as prisms: mp 126.5—127 °C.

Found: C, 51.93; H, 8.56%. Calcd for $C_7H_{14}O_4$: C, 51.84; H, 8.70%.

(1,3,4/2)-4-Hydroxymethyl-1.2,3-cyclohexanetriol (Validatol) (14) and Its Tetraacetate (13). a) To a stirred solution of **2** (0.5 g) and sodium borohydride (0.24 g) in THF (15 ml) was added dropwise a solution of 47% boron trifluoride etherate (2.4 ml) in THF (4.8 ml) at ambient temperature over a period of 1 h. After the reaction mixture had been set aside at ambient temperature overnight, an excess of sodium borohydride was destroyed by addition of 50% aqueous THF (5 ml). The reaction mixture was then treated with a mixture of 3 M aqueous sodium hydroxide (6 ml) and 30% hydrogen peroxide (3 ml). The resulting mixture was evaporated and the residue was treated with acetic anhydride (10 ml) and pyridine (10 ml) at ambient temperature overnight. Insoluble substance was removed by filtration and the filtrate was evaporated to give a syrup, which was purified by fractionation on a silica-gel column (50 g) with butanone–toluene (1: 10, v/v). A major product was obtained as a homogeneous syrup, 0.17 g (30%), whose ^{1}H NMR (60 MHz) spectrum showed that the product consists of **9** and tetra-*O*-acetyl-(1,3,6/2,4)-4-bromo-6-hydroxymethyl-1,2,3-cyclohexanetriol (**12**) in a 1: 2 ratio. Without further fractionation, the mixture was hydrogenolyzed as in the preparation of **7** to give a syrup (0.12 g, 85%). The ^{1}H NMR (60 MHz) spectrum showed that the product consists of **10** and **13** in a 1: 2 ratio. Since **10** and **13** showed a similar mobility on TLC in various solvent systems, attempts were made to separate them by converting them into tetrols **11** and **14**. The mixture (0.29 g) was treated with 1 M methanolic sodium methoxide in methanol (20 ml) at ambient temperature overnight. After treatment with Amberlite IR-120 (H^+), the reaction mixture was evaporated to give a syrup (0.13 g, 90%), which was shown by TLC [benzene–ethanol (3: 2, v/v)] to contain two components (R_f 0.46 and 0.32). The product was fractionated on a silica-gel column (7 g) with ethanol–toluene (2: 3, v/v) as an eluent. Fractions showing a single spot at R_f 0.46 were combined and evaporated to give **14** (55 mg) as a homogeneous syrup.

Found: C, 51.93; H, 8.50%. Calcd for $C_7H_{14}O_4$: C, 51.84; H, 8.70%.

Compound **14** was acetylated in the usual way to give **13** as a homogeneous syrup, whose ^{1}H NMR (100 MHz) spectrum was superimposable on that of an authentic optically active sample.[4b]

Fractions showing a single spot at R_f 0.32 were combined and evaporated to give **11** (30 mg) as crystals: mp 126—127 °C, identical with the compound obtained by hydrogenolysis of **10** followed by *O*-deacetylation.

b) Compound **3** (0.5 g) was hydroborated and subsequently worked up as described above. The acetylated product was chromatographed on a silica-gel column (50 g) with butanone–toluene (1: 10, v/v) to give a homogeneous syrup (0.18 g, 29%), which was shown by ^{1}H NMR (60 MHz) spectrum to consist of **10** and **13** in a 1: 2.5 ratio.

This work was carried out with financial support from the Ministry of Education. Elemental analyses were performed by Mr. Saburo Nakada, to whom our thanks are due.

Friedel-Crafts Reaction of Aromatics with Epoxides. Stereochemistry and Selectivities

Masashi INOUE, Keizo CHANO, Osamu ITOH, Toshio SUGITA, and Katsuhiko ICHIKAWA*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received May 25, 1979)

The Friedel-Crafts reaction of toluene and anisole with 2-methyloxirane and 2,3-dimethyloxiranes was examined. The inter- and intramolecular selectivities of 2-methyloxirane were between those of conventional methylation and isopropylation. It was also found that all the positional isomers formed by the aluminum chloride-catalyzed reaction of toluene and anisole had almost completely inverted configurations of the epoxide carbons. These results are explained by a mechanism of the S_N2 type. Diminished stereospecificities were observed in aluminum bromide-catalyzed reactions.

The Friedel-Crafts reaction is one of the most intensively studied organic reactions.[1] Concerning the stereochemical aspect, it had been accepted until ten years ago that the alkylation proceeds with almost complete racemization. For example, Price and Lund reported that the alkylation of benzene with 2-butanol and boron trifluoride gave 2-phenylbutane with 1% net inversion.[2] Such other catalysts as aluminum chloride, hydrogen fluoride, sulfuric acid, and phosphoric acid also gave the product with less than 0.7% net inversion. Streitwieser and Stang reexamined the stereochemistry of the reaction by the use of 2-propanol-1-d_3[3] and found that the alkylation proceeded with at least 93% net racemization and very little net inversion in the presence of BF_3.[4] They concluded that the reaction is much like an S_N1 solvolysis and has little of the character of a direct (S_N2 type) displacement.

About ten years ago, Nakajima, Suga, and two of the present authors found a stereospecific Friedel-Crafts reaction of benzene with 2-methyloxirane (PO).[5] The reaction gave 2-phenyl-1-propanol with complete inversion, and the mechanism was concluded to be of the S_N2 type. At almost the same time, Brauman *et al.* reported that the alkylation of benzene with γ-valerolactone gave 4-phenylvaleric acid with 40% net inversion.[6] Thereafter, several reports have appeared concerning the stereospecific alkylations. The alkylating agents and stereospecificities are as follows: 2-methyltetrahydrofuran, 35% net inversion;[7] 3-chloro-1-butanol, 20% net inversion;[8] 3-chlorobutyric acid, 43% net inversion;[8] 2-chloro-1-phenylpropane, 82% net retention.[9,10] All of these stereochemical investigations, however, have been restricted to the reaction of benzene, and no attention has been paid to any aromatic substrate other than benzene. Thus, a problem remains unsolved: are the stereospecificities of the alkylation of toluene at each of the three possible positions really the same as that on benzene?

On the other hand, many papers have dealt with the intramolecular selectivity, *i.e.*, the isomer distribution in the alkylation of toluene, and with the intermolecular selectivity, *i.e.*, the relative rate of reaction, $k_{toluene}/k_{benzene}$.[11,12] The reaction mechanisms are most often discussed on the basis of the sets of these two selectivities. Although the stereochemical consequence of the reaction is also an essential component of any discussion of the mechanism, no report has appeared discussing the relationship between the stereochemical behaviour and the reactivity of the alkylating agent.

This paper will report on the Friedel-Crafts reaction of toluene and anisole with PO and with *cis*- and *trans*-2,3-dimethyloxiranes (*cis*- and *trans*-BO), and will discuss the stereochemistry and the intra- and intermolecular selectivities of the reaction.

Results and Discussion

Inter- and Intramolecular Selectivities of Friedel-Crafts Reaction with 2-Methyloxirane. The reaction of toluene with PO yielded three isomeric 2-tolyl-1-propanols (**1**). Nakajima *et al.* reported that an aromatic component attacked the methyl-substituted epoxide carbon in PO.[13] Although the product distributions in the reaction of xylenes with PO have already been discussed, those in the reaction of toluene with PO have not yet been examined because of the difficulties in the

separation of the three isomeric products on GLC.

Efforts were made to separate the three isomers on GLC. It was found that a Bentone-34 column can separate three peaks, but the separation was insufficient. Therefore, we turned our attention to the determination of the product distribution by NMR. Although the NMR spectra of the isomeric mixture could not be resolved into the three components, we found that an europium shift reagent can separate the signals of the methyl protons on the aromatic ring into three peaks, as is shown in Fig. 1. The product distributions determined by this method are given in Table 1, together with the previously reported stereospecificities of the reaction of benzene and the intermolecular selectivities (*vide infra*).

The intermolecular selectivities of the reaction were determined by the usual competitive method, using benzene and toluene in a fifty-fold excess to PO. To discuss the relative rate ratio, k_T/k_B, two conditions should be satisfied: that the reaction is not diffusion-controlled, and that no subsequent reaction occurs. The latter condition seems to be satisfied, since the yields of the high-boiling materials were 5% at the highest, 1—2% usually, and negligible in the case of $TiCl_4$ catalysis. Whether or not the former condition is satisfied in the heterogeneous $AlCl_3$-catalyzed reaction is uncertain, but the fact that there is no remarkable discrepancy in the results between the heterogeneous reaction and the $TiCl_4$-catalyzed homogeneous one appears to show that the data can be used for the estimation of k_T/k_B.

Whereas aluminum bromide catalysis has been reported to result in a remarkable decrease in stereospecificity,[5] there seems to be no remarkable difference between aluminum bromide and the other catalysts as far as the selectivities are concerned. The reason for the diminished stereospecificity in $AlBr_3$ catalysis is uncertain; it is now under investigation.

Table 2 shows some typical results of the selectivities of hydroxypropylation, that is, the alkylation with PO, together with those of the usual Friedel-Crafts reactions summarized by Brown *et al.*[11] Both the intra- and intermolecular selectivities of hydroxypropylation are between those of isopropylation and methylation. Brown *et al.*[14] emphasized that a Friedel-Crafts reaction with primary and probably secondary halides involves an S_N2-type displacement reaction by the aromatics on a polarized alkyl halide-metal halide addition complex. The situation of hydroxypropylation seems to be similar to those mentioned by Brown *et al.*, because the hydroxypropylation of benzene resulted in complete inversion[5] and because the formation of fully developed carbonium ions was confirmed in only a few acid-catalyzed nucleophilic substitutions of epoxides, such as 2,2-diphenyloxirane[15] and some steroid epoxides.[16,17] In an epoxide-Lewis acid complex, the cleavage of the C–O bond of epoxide is made difficult by the presence of another C–O bond. A large nucleophilic contribution by the attacking aromatics is required, because a large covalent character remains in the C–O bond as compared with that in secondary halides and alcohols. Thus, the k_T/k_B of hydroxypropylation is larger than that of isopropylation, but smaller than that of methylation, which seems to show that a larger covalent character remains in the methyl–halogen bond than in the secondary carbon–oxygen bond of PO.

*Stereospecificities of the Formation of Isomeric (*o-, m-, *and* p-*) Products from Toluene.* To explore the specificities of the reaction of toluene, we first examined the reaction with optically active PO. An isomeric mixture of the product was optically active, but, unfortunately, they could not be separated either by column chromatography or by preparative gas chromatography. Therefore, the reaction of toluene with BO was examined. This reaction afforded a mixture of 3-chloro-2-butanols and 3-tolyl-2-butanols (**2**). The stereochemistry of the formation of the former compounds was reported previously.[18] The yields and stereochemistry of **2** are given in Table 3.

The yields of **2** in the reaction with BO were lower than those of **1** in the reaction with PO. The reaction of BO can be expected to proceed by the same S_N2 mechanism as in the case of PO. Since S_N2 reactions are sensitive to the steric factors, methyl substitution at the carbon which is in the β-position to the reacting carbon resulted in a decrease in the yield of the alkylation reaction. The fact that 2,2-dimethyloxirane gave only small amounts of a Friedel-Crafts reaction product under conditions similar to those in this paper[19] can be explained by the steric factors.

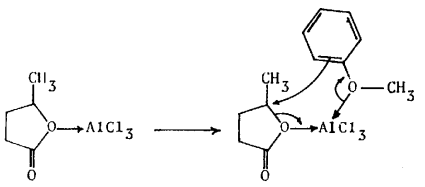
Although the retention times of the three isomers (*o*-, *m*-, and *p*-) of *erythro*-**2** on GLC were different from one another and were much larger than those of *threo*-isomers, the three isomers of *threo*-**2** could not be separated on GLC. As is shown in Table 3, only *threo*-**2** from *cis*-BO and only *erythro*-**2** from *trans*-BO were obtained in an aluminum chloride-catalyzed reaction. Therefore, all the three positional isomers of **2** were formed with complete inversion of configuration of the carbon attacked by toluene, showing that the reaction is of the S_N2 type. Aluminum bromide catalysis was found to decrease the stereospecificities, as in the reaction of benzene with PO.

Recent mechanistic works on Friedel-Crafts reactions have suggested that the transition state of the reaction of a reactive substrate resembles the nature of the π-complex[12] or the oriented π-complex,[20] which determines the substrate selectivity, the k_T/k_B value.[22] The second transition state, from the π-complex to the σ-complex, determines the positional (intramolecular) selectivity. However, the details of the structural change of the alkylating species accompanying π- and σ-complex formation have not been discussed.[21] The results reported in this paper show that the partial bond between the reacting carbon and the leaving group remains in the transition state, and that the reaction is of the S_N2 type. However, the above discussion does not answer the question whether the transition state of S_N2 alkylation involves a π-complex nature or a σ-complex one.[23]

Olah *et al.* examined the Friedel-Crafts benzylation and found that the reaction had high positional and low substrate selectivities.[28] They also found that aluminum chloride-catalyzed benzylation afforded a larger amount of the *meta* product than the other mild catalysis, they attributed this fact to the inter- and intramolecular rearrangement of the primary product. As the present hydroxypropylation has low substrate and low positional selectivities, the results might be explained by the subsequent isomerization processes, which are generally accepted as resulting in a substantial increase in the amount of the *meta* isomer. However, such an intramolecular-rearrangement mechanism that involves the cleavage of the bond between an aryl ring and an alkyl group, *e.g.*, ionization and subsequent internal return, cannot be applied to the hydroxyalkylation with epoxide, and intermolecular rearrangement or transalkylation can be excluded on the basis of the stereochemical results.

Reaction of Anisole with 2-Methyloxirane and 2,3-Dimethyloxiranes. A previous paper has described that the Friedel-Crafts reaction of anisole with epoxides proceeds by two different paths, *i.e.*, direct alkylation and the rearrangement of epoxides to carbonyl compounds, followed by condensation with anisole.[29] The products formed *via* the latter process in the reaction of anisole with PO were 1,1-bis(methoxyphenyl)propanes; the mechanisms of the reaction were discussed in some detail in the previous paper. The *o*-/*p*- isomer ratio of the 2-(methoxyphenyl)-1-propanols formed *via* direct alkylation of anisole with PO was 1.35. The reported *o*-/*p*- isomer ratio for the isopropylation of anisole with 2-propanol is 1.00—1.04, while that for methylation with methyl chloride is 1.75—1.91.[30] Thus, the present hydroxypropylation follows the general tendency of the usual primary and secondary alkylations.

The reaction of anisole with BO afforded a mixture composed of chlorohydrins,[18] 3-(methoxyphenyl)-2-butanols, and 1,1-bis(methoxyphenyl)-2-methylpropanes. The last-named compounds are formed *via* rearrangement, followed by condensation. The stereochemistries of the direct hydroxybutylation products are summarized in Table 4. As is the case of the reaction of toluene, the two isomers produced have a configuration with substantially complete inversion.

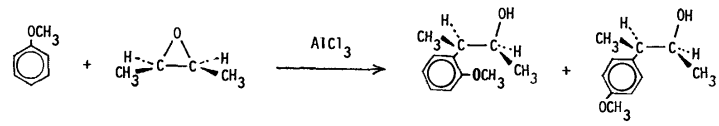


Scheme 1.

Kretchmer *et al.* proposed the mechanism depicted in Scheme 1 for the reaction of anisole with γ-valerolactone and several other alkylating agents on the basis of their finding that the proportions of the *ortho* products obtained from these reactions are higher than those from ordinary reactions.[31] This mechanism, however, cannot be applied to the reaction reported here, because the reaction mechanism expects the formation of an *ortho* product with retention of configuration.

It was demonstrated that the methylation of anisole proceeds concurrently by two paths: the direct alkylation of the aromatic nucleus and the alkylation of oxygen to form an oxonium ion, followed by inter-

TABLE 4. STEREOCHEMISTRY OF ALKYLATION OF ANISOLE WITH 2,3-DIMETHYLOXIRANE



Epoxide	Isomer distribution	Stereochemistry

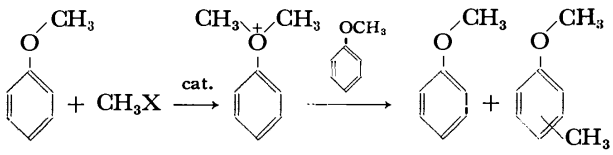
molecular transalkylation.[32] If the latter path is assumed for the present hydroxyalkylation, the stereochemistry of the product should be retention (through double inversion) or racemization. Since the results given in Table 4 show almost complete inversion, the above oxonium ion-intermediate path would be only a minor one, even if it were to occur, in hydroxyalkylation with epoxides; the products seem to be formed by the direct alkylation of the aromatic nucleus of anisole.



Scheme 2.

Experimental

Materials. *cis*- and *trans*-2,3-dimethyloxiranes (*cis*- and *trans*-BO's) were prepared by the method of Pasto and Cumbo.[34] Optically active 2-methyloxirane (PO), $[\alpha]_D^{26}$ 13.10 (neat) [lit,[37] $[\alpha]_D^{16}$ 12.72 (neat)], was prepared from chloroacetone.[35] Inactive PO was a commercially available material, and each epoxide was distilled over calcium hydride before use. Benzene and toluene were washed with sulfuric acid and were distilled before use. Anisole was dried over sodium hydroxide and distilled over calcium hydride before use. Aluminum chloride was purified by sublimation.

Authentic Samples. 2-(*m*-Tolyl)-1-propanol, bp 128—129 °C/18 mmHg, was prepared by the hydroboration-oxidation[38] of 2-(*m*-tolyl)propene, which has been prepared by the Grignard reaction of *m*-tolylmagnesium bromide with acetone, followed by dehydration with $KHSO_4$. 2-(*o*-Tolyl)-1-propanol was prepared in a similar fashion, bp 119—121 °C/13 mmHg. (*Z*)- and (*E*)-2-(*o*-, *m*-, and *p*-tolyl)-2-butenes were prepared by methods similar to those used for preparing all the isomers of 2-(methoxyphenyl)-2-butenes described by Sneeden and Zeiss.[39] The hydroboration-oxidation of (*E*)-2-(*o*-methoxyphenyl)-2-butene yielded *threo*-3-(*o*-methoxyphenyl)-2-butanol (54% yield), bp 122—123 °C/6 mmHg. *erythro*-3-(*o*-Methoxyphenyl)-2-butanol was obtained in a similar fashion from (*Z*)-2-(*o*-methoxyphenyl)-2-butene (55% yield), bp 122—123 °C/6 mmHg. Similarly, other analogs were synthesized from suitable 2-butenes except for the cases of *erythro*-3-(*o*- and *m*-tolyl)-2-butanols. In these cases, (*E*)-2-(*o*- and *m*-tolyl)-2-butenes could not be obtained in the desired purity.[40] *erythro*-3-(*m*-Tolyl)-2-butanol was prepared by the reaction of lithium bis(*m*-tolyl)cuprate with *trans*-BO (18% yield),[41] bp 126—130 °C/29 mmHg; ^{13}C NMR ($CDCl_3$), 16.1, 21.0, 21.4, 47.1, 72.4, 124.8, 127.1, 128.2, 128.5, 137.9, and 144.1 ppm from TMS. The ^{13}C NMR spectrum of the *threo*-isomer was 17.6, 20.4, 21.4, 47.8, 72.1, 124.9, 127.3, 128.3, 128.7, 137.9, and 143.6. *erythro*-*o*-Methyl and *p*-methoxyl substituted analogs were also prepared in a similar fashion. The NMR spectra of the authentic samples are given in Table 5.

Isomer Distribution. A Typical Procedure of Aluminum Chloride-catalyzed Reaction. To a stirred mixture of toluene (30 ml) and aluminum chloride (12 mmol), cooled in an ice bath, a solution of PO (10 mmol) in 20 ml of toluene was slowly added over a period of 2 h. The resulting mixture was stirred for an additional 30 min and then poured into ice water, extracted with diethyl ether, dried over $MgSO_4$, and concentrated; the crude product was distilled *in vacuo* to give a mixture of 2-tolyl-1-propanols, bp 117—129 °C/20 mmHg (60 % yield). The isomer distribution of this fraction was determined by NMR using an europium shift reagent; it is shown in Fig. 1.

Competitive Hydroxypropylation. A Typical Procedure of Aluminum Chloride-catalyzed Reaction. To a mixture of benzene (0.5 mol), toluene (0.5 mol), and aluminum chloride (12 mmol), cooled in an ice bath, a solution of PO (10 mmol) in 50 ml of 1,2-dichloroethane was added, drop by drop with vigorous stirring over a period of 2.5 h. The vigorous stirring was essential to prevent the formation of undesired oligomers of PO. After the reaction has been allowed to proceed further for 30 min, the reaction mixture was poured into ice water. After the usual work-up, the crude product was analyzed by GLC.

Hydroxypropylation of Toluene with Optically Active PO. Optically active PO (10 mmol) in toluene (20 ml) was added to toluene (30 ml) in the presence of aluminum chloride (12 mmol) at an ice-bath temperature over a period of 2 h, after which the reaction was continued for an additional 30 min. After the usual work-up, the distillation of the crude product gave a mixture of 2-tolyl-1-propanols (60% yield) which was optically active, $[\alpha]_D^{18}$ 8.02 (*c* 3.08, $CHCl_3$). Chromatography on neither silica gel nor alumina could spearate the mixture into three components.

Aluminum Chloride-catalyzed Reaction of Toluene with BO. Into a mixture of toluene (150 ml) and aluminum chloride (60 mmol), a mixture of *cis*-BO (50 mmol) and toluene (50 ml) was added over a period of 3 h with vigorous stirring in an ice bath. The stirring was then continued for an additional 30 min. After the usual work-up, the crude product was distilled giving 1.21 g (15%) of *threo*-3-tolyl-2-butanols, bp 91—94 °C/4 mmHg. GLC analysis showed that the product was not contaminated with the *erythro*-isomers.

a) Limits of error: ± 0.2 for $J_{1,2}$ and $J_{3,4}$, ± 0.5 for $J_{2,3}$.

Reaction of Anisole with BO in the Presence of Aluminum Chloride. The reaction was carried out in a procedure similar to that described in a previous paper.[29] After the usual work-up, the crude product was chromatographed on silica gel. Benzene eluted a mixture of 1,1-bis(methoxyphenyl)-2-methylpropanes. Recrystallization from hexane gave a pure bis-*para* isomer; mp 62—63 °C; NMR ($CDCl_3$) $\delta = 1.8^6$ (d, 7.8 Hz, 6H), 2.37 (m, 1H), 3.30 (d, 10.9 Hz, 1H), 3.73 (s, 6H), 6.9 (phenyl, AA'BB' type coupling, 8H); Found: C, 79.76, H, 8.42%. Further elution with 5% ethyl acetate–benzene gave a mixture of the two isomers of 3-(methoxyphenyl)-2-butanols. The isomer distribution of this fraction was determined by GLC.

23) It was demonstrated that epoxides have specific interaction with aromatics.[24] It was also reported that an aromatic solvent have some effects in the acid-catalyzed ring-

opening reaction of epoxides.[25,26] We wish to point out the possibility that epoxide and aromatics form a weak complex which may resemble the π-complex, and that the equilibrium constant of the process determines the substrate selectivity. The complex is transformed to the σ-complex with a release of the leaving group through the transition state of highest energy, which process determines the positional selectivity. The overall processes may resemble the preequilibrium complex formation demonstrated in some S_N2 reactions.[27]

The Modification of Tryptophyl Residues during the Acidolytic Cleavage of Boc-groups. I. Studies with Boc-Tryptophan[1)]

Yoshihiro MASUI,* Naoyoshi CHINO, and Shumpei SAKAKIBARA
Protein Research Foundation, Peptide Institute, 476 Ina, Minoh, Osaka 562

(Received June 16, 1979)

The formation of a component, X, was observed when a reaction mixture of *t*-butyloxycarbonyl-tryptophan (Boc-Trp), trifluoroacetic acid (TFA), and 1,2-ethanedithiol was analyzed by cellulose TLC. The side product was isolated and further separated into two components by column chromatography on silica gel. The subsequent analysis of the NMR spectra of these components confirmed that they were N^{in}-Bu^t-Trp and C^{in}-Bu^t-Trp.** The reaction of Boc-Trp with TFA and with anhydrous hydrogen fluoride (HF) was examined as model systems in order to determine conditions which would minimize the formation of the X component during the synthesis of peptides containing Trp. The addition of 10 molar equivalents of 1,2-ethanedithiol completely suppressed the formation of the X component in HF, but additives were less efficient in TFA. A combination of dimethyl sulfide and 1,2-ethanedithiol was the most effective method for suppressing the formation of the X component in TFA. The behavior of N^{in}- and C^{in}-Bu^t-Trp in acidic media was also investigated, and a possible pathway for the *t*-butylation of the tryptophyl residue will be proposed.

The acidolytic cleavage of protective groups from Trp-containing peptides is known to be accompanied by several side reactions. The first group of side reactions is the so-called oxidative destruction of the tryptophyl residue. This is a series of complicated reactions of the highly reactive indole ring characterized by coloration[2)] or by an increase in the fluorescence[3)] of the reaction mixture. These reactions can be effectively avoided by the addition of such antioxidants as 2-mercaptoethanol[4)] or 1,2-ethanedithiol[2)] to the acidic reagents. The second group of side reactions is the alkylation of the tryptophyl residue by fragments of the protective groups. The *t*-butylation of the indole ring during the deprotection of the Boc groups was first observed in 1970 by Alakhov *et al.*[5)] using mass spectrometry. Boc-Trp-Gly-OMe was treated with TFA to remove the Boc group. The newly formed amino group was acetylated, and the product was subjected to mass spectrometry. The spectrum indicated the presence of an ion at *m/e*(M+56) in addition to the original molecular ion. Alakhov *et al.* also observed that 95% TFA gave less butylated by-products, as did 2 M HCl in acetic acid or ethyl acetate. The formation of side products was still noticeable in all cases. In 1972, Wünsch *et al.*[6)] reported that a significant amount of side products was formed when a protected analog of human gastrin was treated with TFA to remove the Boc and Bu^t groups. They later isolated a side product and found that the tryptophyl residue was *t*-butylated at the NH group of the indole ring.[7,8)] Kisfaludy *et al.*[7)] observed a similar phenomenon during the synthesis of ACTH. They then examined the reaction of Trp with isobutylene under relatively drastic conditions and isolated a crystalline product, 2,5,7-tri-Bu^t-Trp. From these observations, Wünsch and Kisfaludy concluded that the tryptophyl residue is readily converted to mono-or multi-butylated Trp by isobutylene in acid or during the deprotection of Boc or Bu^t groups with TFA, and that N^{in}-Bu^t-Trp was a major product. They emphasized that HF caused more alkylation of the tryptophyl residue than did TFA and that the yield of alkylated products was as high as 50%.[7)]

We also observed that side products, detectable by TLC, were produced when Trp-containing peptides were treated with TFA to remove the Boc group, even though 1,2-ethanedithiol was added to the system. We examined the reaction of Boc-Trp with TFA and with HF as model systems. TFA and HF were chosen as acids since they are commonly used active reagents for the removal of protective groups and also since they are excellent solvents for almost all peptide derivatives.

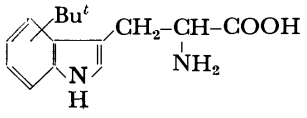
This paper will deal with the isolation of *t*-butylated products from the reaction mixture and with the evaluation of additives in the deprotection reaction, with the goal of minimizing the formation of side products. We will also discuss the different characteristics of HF and TFA as deprotecting reagents.

Results

Isolation and Structure Determination of Side Products. The cellulose TLC of reaction mixtures of Boc-Trp with TFA containing 1,2-ethanedithiol always indicated the presence of one major side component (X component) and some minor ones, as is shown in Fig. 1(A). The isolation of the X component from the reaction mixture was achieved by column chromatography on Dia-ion HP-20. The reaction mixture was placed in the top of the column, and Trp was washed out with 20% aqueous methanol. The minor components were eluted by increasing the concentration of methanol to 30%, and then to 40%. X component was eluted with 50% aqueous methanol. The yield of the X component was about 10% of the starting material. Silica gel TLC [Fig. 1(B)] revealed that the X component consisted primarily of almost equal amounts of two sub-components, Xa and Xb, which were both ninhydrin- and Ehrlich-positive. Therefore, these two components were separated by column chromatography on silica gel.

Elemental analysis showed that both components, Xa

** C^{in}-Bu^t-Trp:



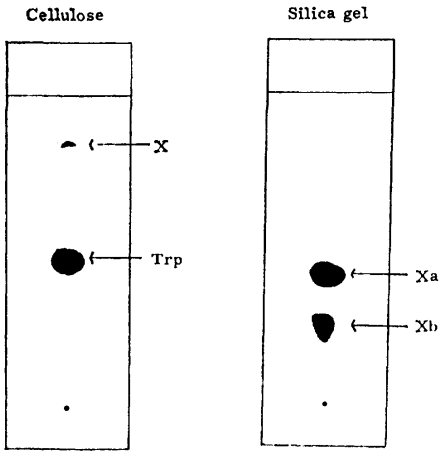


Fig. 1. TLC of products of Boc-Trp in TFA containing 1,2-ethanedithiol.

and Xb, had the same composition, mono-*t*-butylated Trp. The ^{1}H-NMR spectra of the Xa component in a mixture of C_5D_5N–D_2O (1 : 1) and in a mixture of DMSO-d_6–D_2O (1 : 1) (Fig. 2) clearly indicated that one Bu^t group was attached at the indole nitrogen of Trp. This conclusion was also confirmed by the analysis of the ^{13}C-NMR spectrum. However, the ^{1}H-NMR spectrum of the Xb component indicated 4H on the indole carbons and one Bu^t group at a carbon somewhere in the indole ring, but the location of the Bu^t group could not be determined. It was considered that the Xb component was a mixture of mono-*t*-butylated tryptophans substituted at various positions on the indole ring.

Determination of the X Component and Trp; Effect of Additives as Scavengers. The elution pattern of

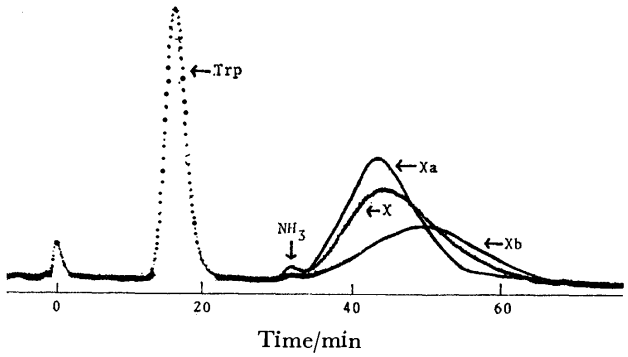

Fig. 3. Ion-exchange chromatogram of Trp, X, Xa, and Xb by amino-acid analyzer.

Xa, Xb, and Trp on an amino-acid analyzer is shown in Fig. 3. No efficient condition was found for determining Xa and Xb separately on the same chromatogram. Therefore, an isolated X component was used as a standard for measuring the total amount of mono-*t*-butylated Trp, Xa and Xb, on an amino-acid analyzer.

By using this procedure, we measured the *t*-butylated Trp and the intact Trp in reaction mixtures of Boc-Trp in TFA and in HF under various conditions (Tables 1 and 2). If no scavenger was added with the TFA, the reaction mixture turned brown, a large quantity of the X component was formed (14%), and the recovery of Trp was low (67%). The addition of 1,2-ethanedithiol effectively prevented coloration, but the addition of even 50% of this material to the TFA failed to reduce the formation of the X component to less than 4.2%. A combination of a large excess of dimethyl sulfide with 1,2-ethanedithiol was the best scavenger in TFA. This mixture gave the maximum recovery of intact Trp after deprotection, yet the formation of the X component was significant (see Table 1). The addition of anisole, which is frequently used as a scavenger during acidolysis, was ineffective in suppressing *t*-butylation.[9]

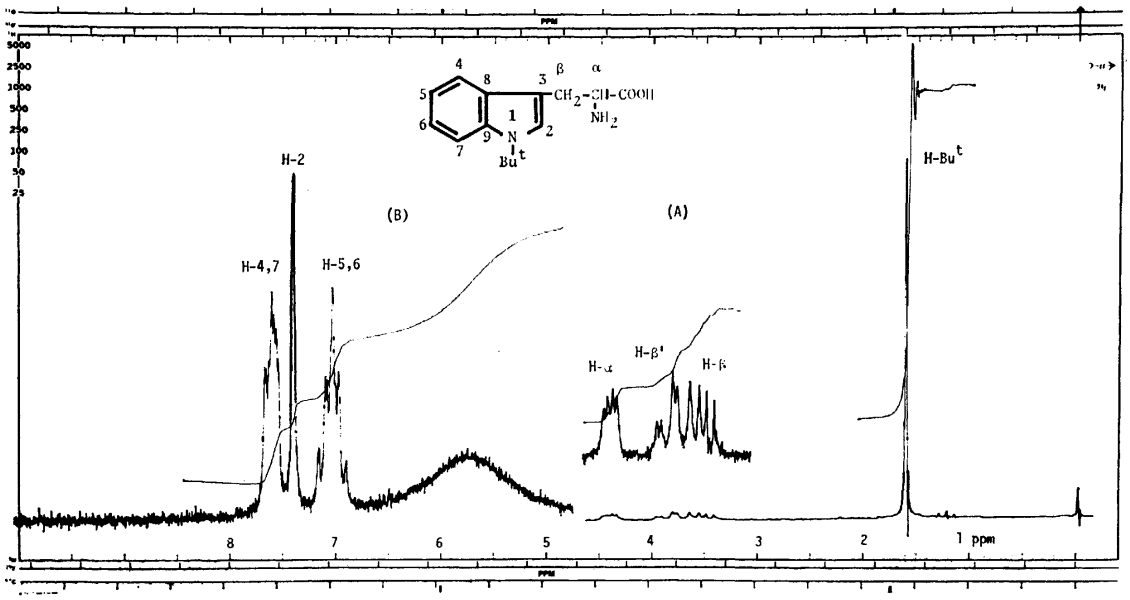

Fig. 2. NMR spectra of Xa in C_5D_5N–D_2O (1 : 1)(A) and in DMSO-d_6–D_2O (1 : 1)(B) at 100 MHz.

Table 1. Effect of additives on the formation of X component in TFA[a]

Additives			Recovery/%	
1,2-Ethanedithiol	Others		X	Trp
None			14.2	67
1.0 ml	None		4.2	93
0.3 ml			5.1	91
	Me–S–Me	1.0 ml[b]	1.1	99
0.1 ml		0.5 ml	2.6	97
		0.3 ml	4.3	96
	Me–S–Et	1.0 ml	2.6	97
	Me–S–Ph	1.0 ml	3.2	96

Table 2. Effect of additives on the formation of X component in HF[a]

Additives	Amount (equiv)[b]	Recovery/%	
		X	Trp
None		15.6	57
1,2-Ethanedithiol	10	ND[c]	99
Anisole+E[d]	10+10	ND[c]	99
Me–S–Me+E[d]	10+10	ND[c]	99
Anisole	10	2.4	94

a) For the reaction conditions, see the Experimental section. b) Equiv against Boc-Trp. c) Not detectable. d) 1,2-Ethanedithiol.

On the other hand, the formation of the X component in HF was negligible when 10 equivalents of 1,2-ethanedithiol were added to the reaction mixture, even without the addition of anisole or dimethyl sulfide (Table 2). This result differs from that reported in the absence of scavengers by Wünsch *et al.*[7,10] Scavengers seem to be effective in HF, but not in TFA.

Behavior of Xa and Xb in Acidic Reagents. The chemical stability of Bu^t groups of Xa and Xb was examined in acidic reagents. The Xa and Xb were dissolved separately in TFA and in HF in the presence of additives, and the reaction mixtures were examined with an amino-acid analyzer and by TLC. As is shown in Table 3, over 90% of the Xa was converted to Trp in HF, which indicates that the N^{in}-Bu^t-group is quite unstable in HF. In TFA, however, only 50% of the N^{in}-Bu^t-group was removed, and about 10% of the starting Xa was converted to Xb during the treatment. No formation of N^{in},C^{in}-di-*t*-butylated Trp was observed. Although a small amount of Trp was detectable in a reaction mixture of Xb with HF, Xb seemed to be fairly stable in both reagents, as was to be expected. Interestingly, the C^{in}-Bu^t-group was removable under the conditions of the acid hydrolysis of peptides.

Table 3. Stability of Bu^t groups in N^{in}-Bu^t-Trp (Xa) and C^{in}-Bu^t-Trp (Xb) in acidic media

Conditions	Xa Recovery/%		Xb Recovery/%	
	Trp	Xa+Xb	Trp	Xb
HF/HS–CH_2–CH_2–SH/ Anisole 0 °C, 1 h	92	Trace	5	90
TFA/HS–CH_2–CH_2–SH 0 °C, 10 min and rt, 50 min	50	40+10[a]	None	100
6 M HCl/Mercaptoacetic Acid[11] 108 °C, 22 h	99	None	84	Trace

a) The ratio of Xa and Xb was estimated from the silica gel TLC.

Discussion

In discussing the modification of tryptophyl residues during deprotection procedures, the contribution of scavengers cannot be eliminated. Wünsch and others have shown that the modification of the tryptophyl residues is higher in HF than in TFA when no scavenger is added to the reaction mixture. Similar results were obtained in the reactions of Boc-Trp in this study; the recovery of intact Trp was 67% in TFA and 57% in HF under the conditions used for the removal of Boc groups (see Tables 1 and 2). In the presence of scavengers, however, the situation changed dramatically. The formation of *t*-butylated Trp was negligible in HF when 10 molar equivalents of 1,2-ethanedithiol were added, but a considerable amount of modified Trp was detectable in reaction mixtures with TFA, even when an excess of promising scavengers was added. This result may be explained by the reactivity with acidic reagents of Bu^t groups attached to the N or C atom of the indole group. As can be seen in Table 3, the N^{in}-Bu^t-group is reasonably stable in TFA, but quite unstable in HF. Therefore, in HF the scavengers must compete with the C^{in}-*t*-butylation reaction. The effectiveness of scavengers in HF can be clearly explained if the *S*-*t*-butylation is much faster at 0 °C than the *C*-*t*-butylation of the indole moiety. In TFA at room temperature, however, the scavenger must compete with the N^{in}-*t*-butylation reaction and the formation of N^{in}-Bu^t-Trp may be much faster than the formation of the *S*-Bu^t-derivatives of scavengers.

In the presence of 10% 1,2-ethanedithiol in TFA, the formation of C^{in}-Bu^t-Trp from N^{in}-Bu^t-Trp was 10%, and 50% of the N^{in}-Bu^t-Trp was converted to Trp. Under these conditions, the formation of C^{in}-Bu^t-Trp from Boc-Trp was only 5%. No *t*-butylation at the indole nucleus was observed when Boc-Trp(For)*** was treated with TFA (see Experimental section). The above facts suggest that N^{in}-Bu^t-Trp is more reactive with Bu^t cations than is an unsubstituted tryptophyl residue. We therefore propose the following scheme for the formation of these side products in TFA: (1) N^{in}-*t*-butylation is the first step in the side reaction, (2) once a Bu^t group is attached to the indole nitrogen, the carbon atoms of the indole moiety become more susceptible to attack by Bu^t cations, and (3) the N^{in}, C^{in}-

*** For: N^{in}-formyl.

di-Bu^t-Trp thus formed degrades to C^{in}-Bu^t-Trp.

It must be noted that the formation of *t*-butylated Trp cannot be detected after the acid hydrolysis of the peptide (see Table 3). Thus, *t*-butylation must be detected in the intact peptide or after the enzymatic digestion of the peptide.

Since the present study used Boc-Trp as a model compound, the above observations must be confirmed with peptides which are protected with Boc or Bu^t groups. These studies are now being carried out in our laboratory.

Experimental

All melting points are uncorrected. Amino-acid analysis was performed on a JEOL JLC-6AH Amino-Acid Analyzer. The UV spectra were obtained on a Hitachi 124 Spectrophotometer, and the IR spectra, on a Hitachi EPI-G2 Grating Infrared Spectrophotometer. The optical rotations were measured with a Perkin-Elmer 141 Polarimeter. The ^{1}H-NMR and ^{13}C-NMR measurements were performed with a Varian XL-100 Spectrometer, using tetramethylsilane as the internal reference. The solvent systems used for TLC on silica gel G (Merck Art 7731) or cellulose (Merck Art 5552) were (A) 1-butanol–acetic acid–water (4: 1: 5, upper phase) and (B) chloroform–methanol–acetic acid (85: 15: 2). For silica gel-column chromatography, silica gel 60 (Merck Art 7734) was used.

Isolation of By-products, Xa and Xb. A solution of Boc-Trp (10 g, 33 mmol) in TFA (30 ml) containing 1,2-ethanedithiol (3 ml) was allowed to react at 0 °C for 10 min and then at room temperature for 50 min. The TLC of this reaction mixture is shown in Fig. 1(A). The solution was concentrated under reduced pressure, and the residue was triturated with ether and hexane to obtain a powder. The product was collected by filtration and dried in a vacuum desiccator over sodium hydroxide pellets at room temperature for 24 h. The dried material was dissolved in a mixture of water (400 ml) and methanol (20 ml), and the solution was neutralized with 5% aq sodium hydrogencarbonate. This solution was then poured into the top of a column (4×20 cm) of Dia-ion HP-20, Mitsubishi Kasei Co., Ltd., which was then eluted with 2 l of water, 1-l portions each of 20%, 30%, and 40% aq methanol, and 2 l of 50% aq methanol successively. Each fraction was monitored by TLC, the X component was found to be eluted by 50% aq methanol. This fraction was then collected and condensed. The residue was purified by reprecipitation from methanol with ether and dried over P_2O_5 at 35 °C for 24 h; yield, 1.0 g (11%); R_f 0.85 on cellulose TLC using Solvent A. Found: C, 67.79; H, 8.09; N, 10.22%. Calcd for $C_{11}H_{11}O_2N_2 \cdot C(CH_3)_3 \cdot 1/3\ H_2O$: C, 67.64; H, 7.82; N, 10.52%.

This product, X component, gave two spots on silica gel TLC, as is shown in Fig. 1(B). It was applied to the top of a column (3×20 cm) of silica gel and was eluted with a mixture of chloroform–methanol–acetic acid (85: 15: 2).

The fraction containing Xa was collected and concentrated to a residue, which was then triturated with ether to obtain a powder. The product was purified by reprecipitation from methanol with ether and dried over P_2O_5 *in vacuo* at 45 °C for 120 h; yield, 421 mg (4.9%); mp 179 °C (dec). $[\alpha]_D^{29.5}$ −29.6° (c 0.5, 80% aq ethanol). UV (H_2O) max: 286 nm (ε 6000), 223 nm (ε 37000). ^{1}H-NMR [100 MHz, C_5D_5N–D_2O (1: 1)]: H-Bu^t: δ 1.61 (9H, s), H-β: 3.55 (1H, dd, J=9.0, 16.0 Hz), H-β': 3.91 (1H, dd, J=4.0, 16.0), H-α: 4.44 (1H, dd, J=4.0, 9.0), [100 MHz, DMSO-d_6–D_2O (1:1)]: H-5, 6: 7.03 (2H, m), H-2: 7.36 (1H, s), H-4, 7: 7.62 (2H, d, J=9.0), [100 MHz, DMSO-d_6]: Absence of indole NH signal. ^{13}C-NMR [25.2 MHz, DMSO-d_6]: C-β: δ 27.1, *C*-methyl (Bu^t): 29.2, C-α: 55.0, *C*-methine (Bu^t): 55.6, C-3: 107.9, C-7: 111.5, C-4: 118.2, C-6: 119.2, C-5: 120.7, C-2: 125.6, C-8: 129.6, C-9: 135.3, C-(C=O): 171.4. IR(KBr): 2955 cm^{-1} (ν_{C-H}, Bu^t), 1215 cm^{-1} (ν_{C-C}, Bu^t). Found: C, 69.50; H, 7.63; N, 10.78%. Calcd for $C_{11}H_{11}O_2N_2 \cdot C(CH_3)_3$: C, 69.20; H, 7.74; N, 10.76%. From the above data, the Xa component was identified as N^{in}-Bu^t-Trp.

The fraction containing Xb was collected and treated in the same manner as Xa; yield, 455 mg (5.3%). ^{1}H-NMR [100 MHz, DMSO-d_6]: H-Bu^t: δ 1.32, 1.34, 1.44 (9H, three singlet signals), H-indole ring: 6.90—7.54 (4H, unresolved signals). Found: C, 69.31; H, 7.69; N, 10.73%. Calcd for $C_{11}H_{11}O_2N_2 \cdot C(CH_3)_3$: C, 69.20; H, 7.74; N, 10.76%. From the above data, the Xb component was considered to be mono-*t*-butylated Trp, substituted at various positions on C atoms of the indole ring.

Determination of X Component and Trp on the Amino-acid Analyzer. A mixture of X component (0.35 μmol) and Trp (0.20 μmol) was analyzed on the amino-acid analyzer under the following conditions: length of column with LC-R-2 resin, ϕ 0.8×15 cm; solvent, 0.5 M sodium citrate buffer at pH 5.24 containing 1% benzyl alcohol; flow rate, 1.0 ml/min; jacket temperature, 52 °C. The pattern obtained is shown in Fig. 3.

Reaction of Boc-Trp with Cleavage Reagents for the Evaluation of Additives. (A) Reaction with TFA: Boc-Trp (30.4 mg, 0.1 mmol) was dissolved in TFA (1 ml) containing various additives, and the solution was stirred at 0 °C for 10 min and at room temperature for 50 min. The reaction mixture was then concentrated *in vacuo*, and the residue was diluted with 0.5 M sodium citrate buffer (pH 5.20) to 10 μmol/ml and to 0.2 μmol/ml. These solutions were then analyzed under the conditions described above for determining the recovery of X component and Trp respectively. The analytical data are shown in Table 1.

(B) Reaction with HF: Boc-Trp (30.4 mg, 0.1 mmol) was treated with HF (1 ml) in the presence of various additives at 0 °C for 1 h in the usual manner.[12] The reaction mixture was concentrated at reduced pressure, and the residue was redissolved in acetic acid (10 ml). The solvent was evaporated *in vacuo*, and the residue was diluted with 0.5 M sodium citrate buffer (pH 5.20). The recovery of X component and Trp was determined in the same manner as has been described previously in the case of TFA treatment. X component was not detected on the chromatogram of amino-acid analysis using only 10 equiv of 1,2-ethanedithiol as an additive. The analytical data are shown in Table 2.

Reaction of Xa or Xb with Acids. (A) Reaction of Xa or Xb with TFA: Xa (26.0 mg, 0.1 mmol) was treated with TFA (1 ml) in the presence of 1,2-ethanedithiol (0.1 ml) at 0 °C for 10 min, the solution was then maintained at room temperature for 50 min and worked up as has been described for the reaction of Boc-Trp with TFA. The recovery of Trp and X was determined on the amino-acid analyzer. A part of the reaction mixture was placed in the top of the column of Dia-ion HP-20 and eluted with 20% aq methanol, and then methanol. When each fraction was monitored by TLC, only Trp was detected in the 20% aq methanol fraction. X component was found in the methanol fraction. This fraction was collected, concentrated, and analyzed by TLC on a silica gel G plate using the B solvent system. The ratio of Xa and Xb was estimated to be 4: 1, and N^{in},C^{in}-di-Bu^t-Trp was not detected. The analytical data are shown in Table 3. Xb (26.0 mg, 0.1 mmol) was treated in the same manner as Xa.

(B) Reaction of Xa or Xb with HF: Xa (26.0 mg, 0.1 mmol) was treated with HF (1 ml) in the presence of 1,2-ethanedithiol (0.1 ml) and anisole (0.1 ml) at 0 °C for 1 h and then worked up as has been described for the reaction of Boc-Trp with HF. The recovery of Trp and X component was determined on the amino-acid analyzer. The treatment of Xb (26.0 mg, 0.1 mmol) was carried out in the same manner as Xa.

(C) Reaction of Xa or Xb with 6 M HCl: Xa (2.6 mg, 10 μmol) was treated with 6 M HCl in the presence of 2% mercaptoacetic acid[11] in an evacuated, sealed ampule at 108 °C for 22 h and then analyzed on the amino-acid analyzer. Xb (2.6 mg, 10 μmol) was treated in the same manner as Xa.

Reaction of Boc-Trp(For)[13] with TFA. Boc-Trp(For) (33.2 mg, 0.1 mmol) was treated with TFA (1 ml) containing 1,2-ethanedithiol (0.1 ml) at 0 °C for 10 min, and then the mixture was maintained at room temperature for 50 min. The reaction mixture was concentrated and the residue was treated with 0.1 M piperizine (1 ml) for 1 h at room temperature to remove the For group. The solution was then applied into the top of a column of Dia-ion HP-20 and eluted with water, 20% aq methanol, and methanol. Each fraction was collected and analyzed by TLC. Only Trp was eluted by 20% aq methanol. Although other by-products were present in the methanol fractions, Xa and Xb were not detected. Thus, no *t*-butylation occurred during this reaction.

The Acid-catalyzed Reaction of the 2-Oxabicyclo[4.1.0]hept-3-en-5-one System: Isomerization from Homo-4-pyrones into 2-Furylacetone Derivatives

Hiroshi YAMAOKA, Ikuhiro MISHIMA, Mitsuko MIYAMOTO, and Terukiyo HANAFUSA*

(Received July 2, 1979)

The monocyclopropanation of 4-pyrones with dimethyloxosulfonium methylide, using a dimethyl sulfoxide–hexamethylphosphoric triamide medium in place of neat dimethyl sulfoxide, gave homo-4-pyrone derivatives, which were then rearranged into the 2-furylacetone derivatives, along with hydrated triketones or the dehydrated naphtho[2,1-*b*]furan derivative, by means of strong acid catalysis at room temperature.

In 1965 Corey *et al.* reported that dimethyloxosulfonium methylide is a convenient reagent for preparing cyclopropyl ketones starting from the corresponding α,β-unsaturated ketones.[1] Thus, the treatment of chromones (**1**), regarded as α,β-unsaturated carbonyl compounds, with the above ylide in dimethyl sulfoxide (DMSO), which has been preferentially used in cyclopropanation,[2] affords 3,4-benzo-2-oxabicyclo[4.1.0]-hept-3-en-5-one(homochromone) derivatives (**2**).[3,4] We have been investigating their mass spectra[5] and the solvolytic behavior of the corresponding secondary ester, **3**,[3] in connection with homoconjugation or homoaromaticity, two of the most interesting concepts in organic chemistry.[6]

The parent 2-oxabicyclo[4.1.0]hept-3-en-5-one (homo-4-pyrone) (**4**), free from a condensed benzene ring, may be one of the best substrates for use in order to procure further information about the structural characteristics of homochromones **2**. As homo-4-pyrones have not been mentioned to date, we now wish to report the preparation and the acid-catalyzed reactions of **4**.

Results and Discussion

Syntheses. Cyclopropanation of 4-Pyrones: According to the previously reported manner, 2,6-dimethyl-3,5-diphenyl- (**5a**), 2,3,5,6-tetramethyl- (**5b**), and 2,6-dimethyl-4-pyrone (**5c**) were prepared.[7] While the treatment of benzo-condensed 4-pyrones, **1**, with dimethyloxosulfonium methylide (**6**) for several hours gave cyclopropyl ketones (homochromones), **2**, in a fairly good yield,[3,4,8] the choice of solvent was found to be critical for the reaction when parent 4-pyrones, **5a**—**5c**, free from a condensed benzene ring, were subjected to cyclopropanation. As is shown in Table 1, tetramethyl-4-pyrone (**5b**), corresponding to the benzo-condensed compound **1a**, was intact after having been in contact with **6** in DMSO at 60 °C for many hours. When the reaction was carried out in mixtures of hexamethylphosphoric triamide (HMPA) and DMSO (1 : 1 by volume), time studies of aliquots by means of either NMR or TLC exhibited the formation of homo-4-pyrone, **4**. A change in the HMPA/DMSO ratios brought about no appreciable alterations in the yields of **4** within the region from 0.3 to 3.0, although DMSO was essential for the generation of **6** *in situ* because no evolution of hydrogen accompanied by the formation

of **6**[1] occurred when neat HMPA was chosen as the reaction medium.

The purification of the crude product was done by means of column chromatography on either deactivated neutral alumina or silica gel, using ether–light petroleum as the eluent. Thus, the diphenyl derivative **4a** was isolated as colorless prisms (mp 101—102 °C), while both **4b** and **4c** were less stable. Therefore, the structural assignments of the latter compounds may be elucidated by a comparison of the spectral data with those of **4a**.

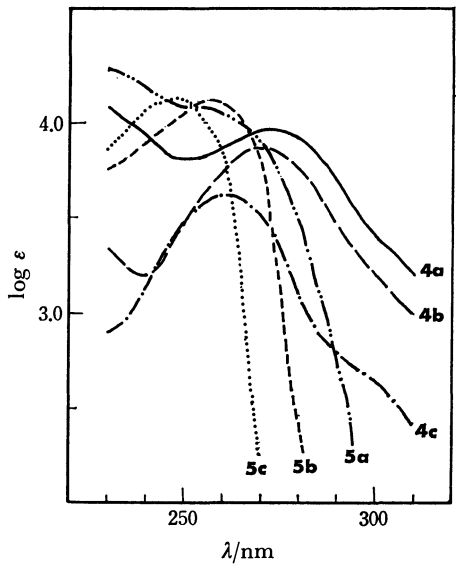

Fig. 1. UV spectra of **4a**—**c** and **5a**—**c** in methanol.

The UV spectra of **4a**—**4c** are shown in Fig. 1, along with those of the corresponding 4-pyrones, **5a**—**5c**. The change in the wave numbers for maximum absorption ($\nu_{C=O}$) according to the variation in the properties of the carbonyl function from **5** to **4** was not so remarkable as that in the benzo-condensed compounds, **2**.[3] Unlike the ambiguous information given concerning the production of cyclopropyl ketones, the mass spectra indicated an expulsion of the CHO radical from the molecular ion, M−29, which has been found to be a characteristic fragmentation in homochromones, **2**,[5] as well as in the parent ion (M^+) (see Table 2).

Table 2. Data of the mass spectra of homo-4-pyrones **4**

Compd	M^+(*m/e*)	M−15	M−28	M−29[b]	M−43

4c	138(100)	123(13)	110(8)	109(19)	95(65)

a) Relative intensity. b) Expulsion of the CHO radical.

In the NMR spectrum of **4a**, protons belonging to the cyclopropane were not obvious because of the duplication with the signal of a methyl group (δ, 1.80), but a typical AB quartet (J=6 Hz) peculiar to cyclopropyl methylene protons (δ, 1.56 and 1.82) was revealed by the treatment of **4a** with alkaline 1,2-dimethoxyethane (DME)–D_2O, in analogy with that of 2,3-dimethylchromone (**1a**), which could be deuterated at the 2-methyl group, in the β-position to the α,β-unsaturated carbonyl group, to give **1a'** in our preliminary experiment. 4-Pyrone **5a** could be converted into 2,6-bis(trideuteriomethyl)-3,5-diphenyl-4-pyrone (**5a'**) under the same conditions. However, no deuterium exchange took place in the case of the homochromone **2a**. Taking these results into account, it seems that trideuteriomethylation on **4a** cannot proceed on the methyl group attached to cyclopropane (the C-1 position at δ, 1.28), while it can on the other methyl group (δ, 1.80 for the 3-methyl group adjacent to β-carbon for the α,β-unsaturated carbonyl function). The experimental results agreed exactly with this expectation, and the chemical shifts of all the aliphatic protons suggested a monocyclopropyl ketone, **4a'**, in comparison with those of related compounds, as is shown below.

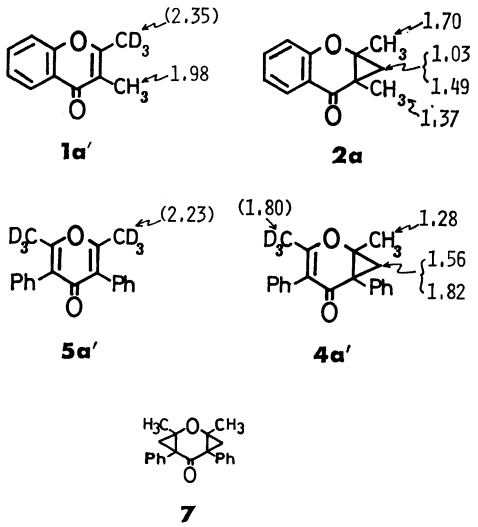

Fig. 2. ^1H NMR chemical shifts for aliphatic protons on 4-pyrones and homo-4-pyrones (δ, ppm).

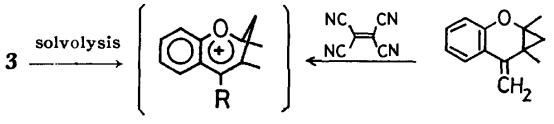
Although deuterium exchange for either **4b** or **4c** failed to yield decomposition products, structural assignments could be made on the basis of their ^1H NMR spectra as well as the mass spectra. For example, the NMR spectrum of **4c** included two methyl signals, at δ=1.93 (3-methyl) and 1.63 ppm (attached to cyclopropane); a vinyl proton at δ=5.03 ppm for the singlet, and a methine proton at δ=*ca.* 1.8 ppm for the multiplet (C-6 position). Methylene protons of cyclopropane were observed at δ=1.43—1.03 ppm for the multiplet. Three different homo-4-pyrones were prepared; the most stable, **4a**, was employed for the further reactions.

An attempt to prepare the dicyclopropyl ketone (bishomo-4-pyrone), **7**, from **4a** with **6** in HMPA–DMSO was unsuccessful to be recovered so far.

Acid-catalyzed Reaction of Homo-4-pyrone ***4a*** *by Means of Trifluoroacetic Acid*: Since it has been reported that the cationic intermediate may be highly stabilized by the homoaromatic conjugation depicted in **8** in either the solvolysis of the secondary cyclopropylmethyl ester, **3**,[3] or the electrophilic addition of tetracyanoethylene to

the 4-methylene-4*H*-homochromene derivatives, **9**,[9] we attempted to isolate secondary alcohols or vinylcyclopropanes corresponding to **3** or **9** starting from **4**, but we could not do so because of the cleavage of cyclopropane.[8] Therefore, we studied the protonation to the carbonyl function of homo-4-pyrone, **4a**, by means of acid catalysis as another way for investigating the cationic intermediate from **4a**.



8 **9**

R=H (from **3**)
R=CH_2-C(CN)$_2$-$\bar{C}$(CN)$_2$ (from **9**)

When **4a** was dissolved in trifluoroacetic acid (TFA) at room temperature for 1 d, followed by the usual work-up process, the column chromatography of the crude product on silica gel afforded three products in 6, 32, and 30% yields; they are recognized as a dehydrated, an isomeric, and a hydrated compound of **4a** respectively on the basis of both microanalyses and mass spectrometry.

*Reaction of Homo-4-pyrone, **4a**, by Means of an Other Acid Catalysis*: The same products, a dehydrated, an isomeric, and a hydrated one, were isolated in trace, 12, and 34% amounts respectively by the treatment of **4a** with *p*-toluenesulfonic acid in benzene at room temperature for 1 d, although **4a** was fairly stable in acetic acid. An acid-catalyzed reaction by the use of three polychloroacetic acids, CH_2ClCO_2H, $CHCl_2CO_2H$, and CCl_3CO_2H, afforded the hydrated product in 16, 30, and 36% yields respectively; moreover, the **4a** was recovered, judging from the NMR spectra of the mixture. As an isomeric compound could not be detected in either case, the production of an isomeric compound seems to occur by means of strong acid catalysis.

Structural Assignment of the Dehydrated Product: The IR absorptions obviously demonstrated the existence of neither hydroxyl nor carbonyl group, so this compound may possess an ether linkage. The NMR spectrum included signals for two methyl protons (δ, 2.43 and 2.57), a vinyl proton (δ, 6.80), and nine aromatic protons (δ, 7.33 to 8.25), in which the existence of a solitary multiplet (δ, 7.92 to 8.25 for 2H) in a fairly low field may be conjectured upon *peri*-(5, 8) protons in the naphthalene ring, which is probably crowded with substituents upon at least the 1,4-positions, judging from the NMR data for related naphthalenes in the literature as is shown in Table 3.[10]

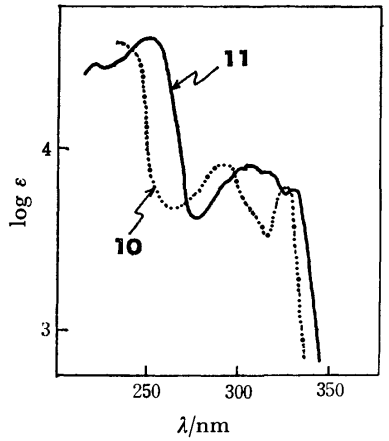


Fig. 3. UV spectra of naphtho[2,1-*b*]furans.

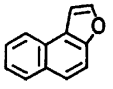
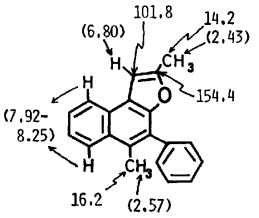
The ^{13}C NMR data at δ=154 and 102 ppm suggest the furan moiety,[11] although the other set of signals due to the furan ring cannot be found because of complicated signals between at δ=137 ppm and 122 ppm. Therefore, the structure of the ether may be speculated to be condensed furan, a so-called naphthofuran. On the basis of this speculation, the presence of α-methyl (δ_C, 14; δ_H, 2.43) and β-proton (δ_H, 6.80) on the furan moiety may be well interpreted; also the signal at 122 ppm for β-carbon shows a doublet under the off-resonance conditions in the ^{13}C NMR spectrum. The other methyl signal at δ=16 ppm was assigned to a substituent of the naphthalene; the *peri*-position is more plausible than the other positions, judging from the chemical shift of the ^1H NMR spectrum at δ=2.43 ppm (see Table 3).[10]

The UV spectrum showed maxima at 330, 304, and 249 nm (log ε 3.78, 3.94, and 4.63 respectively), nicely in accord with those of the parent naphtho[2,1-*b*]furan, **10**, reported in the literature,[12] as is illustrated in Fig. 3. On the basis of these data, the structure of the dehydrated product was identified as dimethylphenylnaphthofuran, **11**.



10



11

Chemical shifts; δ_C (δ_H)

Structural Problem of the Isomeric Product: Because of a monooxime formation as well as the IR absorption at 1720 cm^{-1}, and its freedom from a hydroxyl group, the other oxygen atom of the isomeric product probably performs an ether function. That a cleavage of the cyclopropane ring had occurred was indicated by the ^1H NMR spectrum of the product, which had signals at δ=4.92 and 6.05 ppm for each singlet instead of the AB quartet for cyclopropyl methylene (δ, 1.56 and 1.82) in **4a**. Methyl signals were transferred into somewhat lower fields (δ, 2.02 for the sharp singlet and 2.33 for the broad singlet) in comparison with those of **4a**. Then, $Eu(fod)_3$ was added in portions to the substrate dissolved in deuteriochloroform, and the ^1H NMR spectra were recorded under various molar ratios in order to ascertain structural information. If the substrate is a methyl ketone, a remarkable lanthanoid-induced downfield shift may be expected for the methyl group adjacent to the carbonyl group.[13] The experimental results of the downfield shifts are presented in Fig. 4.

The relative extents of the induced shifts for both the sharp singlet for the methyl group (δ, 2.02) and the

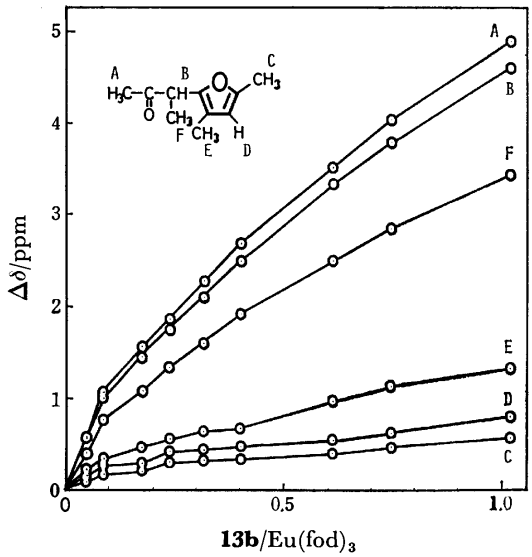

Fig. 4-2. $Eu(fod)_3$-induced shifts for **13b**.

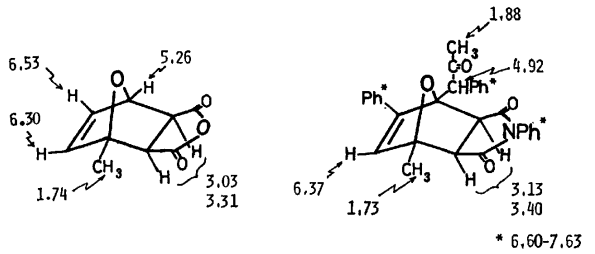
singlet for the methine proton (δ, 4.92) were much larger than any other proton signals. Accordingly, the product may possess a CH_3–C(=O)–CH(Ph)– moiety, an idea which is also supported not only by the facile disappearance of the methine signal (δ, 4.92) adjacent to the carbonyl group in its ^1H NMR spectrum after hydrogen-deuterium exchange upon treatment with alkaline DME–D_2O, but also by an intense fragment at *m/e* 247 (M−43) which may be readily accounted for by an expulsion of the acetyl group in the mass spectrum.

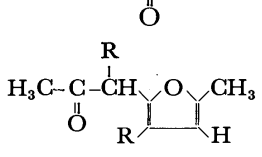
The formation of a one-to-one adduct with *N*-phenylmaleimide may be proof of the furan skeleton of the product. The stractural assignment of the adduct was carried out by means of a comparison with the adduct, **12**, which had been prepared from 2-methylfuran with maleic anhydride as reported in the literature[14] and as is demonstrated in Fig. 5. In the ^1H NMR spectrum of the *N*-phenylmaleimide adduct, one methyl signal of the isomeric product of **4a** (δ, 2.33) underwent an extraordinary upfield shift to δ=1.73 ppm, so that the methyl group changed into the substituent at α-carbon in the furan which had been obtained by the acid catalysis of **4a**.



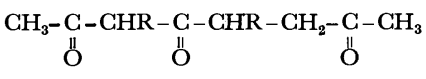
12 **adduct**

Fig. 5. ^{1}HNMR chemical shifts for Diels-Alder adducts (δ, ppm).

The conclusive information concerning the structural assignment of the isomeric product of **4a** was given by means of ^{13}C NMR measurement. In accordance with the data on the chemical shifts in the literature,[11] the singlets at both δ=152 and 145 ppm (α-carbons), and both the singlet at 125 ppm and the doublet at 108 ppm (β-carbons) under the off-resonance conditions, confirm the presence of the furan moiety. Although not all the signals could be assigned because of the duplication of signals in the region of the phenyl carbons (δ, 126 to 137), the signals at δ=203 ppm for the singlet and δ=29 ppm for the quartet (off-resonance spectrum) also showed CH_3–C(=O) function.



13



14

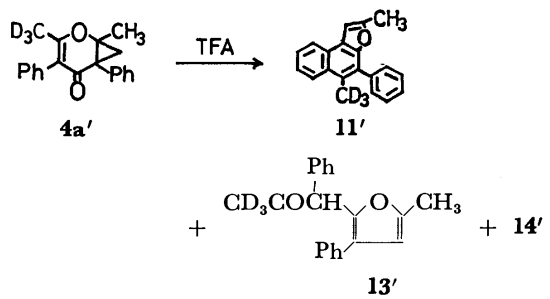
(**a**; R=Ph, **b**; R=CH_3, **c**; R=H)

As a long-range coupling of the allyl type was found between the signals of the methyl group (δ, 2.33) and the vinyl proton (δ, 6.05), the –CH=C(–)–CH_3 moiety should be included in the furan ring. After all, then, the structure of the isomeric product could be deduced to be that of the 2-furylacetone derivative, **13a**.

The Structure of the Hydrated Product: This was assigned by means of its spectroscopic data to **14a**; it was dissolved in TFA for several hours to give a dehydrated compound, **11**, in about a 10% yield, accompanied by the recovery of **14a**. For the purpose of obtaining further information about the reaction pathway, the exposure of either deuterium-labelled **4a′** or other homo-4-pyrones in TFA was carried out; also, the decisive structural assignment of the isomeric product, **13**, will be made.

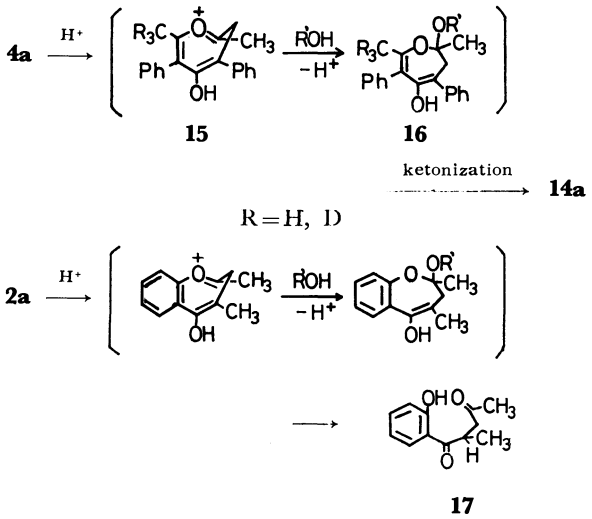
Acid-catalyzed Reaction of Trideuteriomethyl-substituted 4a′ in TFA: By using the procedure mentioned above, three products were isolated analogously. The ^1H NMR spectrum of the dehydrated one showed only one methyl signal (δ, 2.43) which could be identified as α-methyl in the furan, while the signal for the naphthylmethyl group (δ, 2.57) scarcely appeared at all. Therefore, the CD_3 group on the C-3 position in homo-4-pyrone, **4a′**, can be said to have been specifically transferred into the *peri*-position on the naphthalene ring of **11**.

On the other hand, the signal for the methyl group at a lower field (δ, 2.02) identified as acetyl protons completely disappeared, and the signal for α-methyl in the furan ring (δ, 2.33) was observed exclusively in the ^1H NMR spectrum of the isomeric product. Consequently, the α-methyl group belonging to the furan ring seems to be derived from the bridgehead methyl group (C-1 position) in 2-oxabicyclo[4.1.0]hept-3-en-5-one derivatives, **4a**, in either **11** or **13a**. In the case of 2-furylacetone, **13a**, further evidence was provided by the mass spectrum of **13a′**. Thus, accompanying the parent peak at *m/e* 293 ($C_{20}H_{15}D_3O_2$), there was a peak at *m/e* 247 (M−46, base) corresponding to the loss of the CD_3CO moiety; this peak appeared entirely cut off from any surrounding peaks, so upon acid catalysis that the CD_3 group in **4a′** seems move into the acetyl group as the side chain of the furan ring in **13a′**.

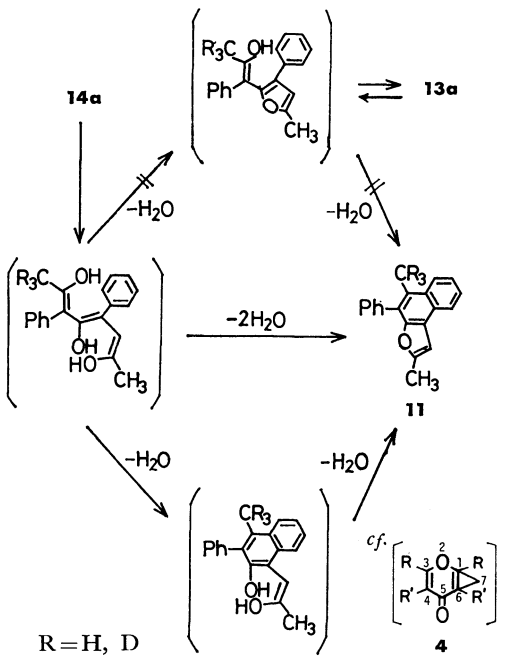


Mechanism: On the basis of the above experimental results, a plausible mode of formation that we favor for **11**, **13a**, and **14a** is illustrated below. Protonation onto the carbonyl group of **4a** occurs to give a cationic intermediate such as **15** by strong acid catalysis, *e.g.*, TFA,[15] followed by nucleophilic attack by a solvent

on the C-1 position adjacent to ether oxygen coexisting with a ring enlargement due to the cleavage of the cyclopropane. Then, the acetal **16** thus produced undergoes ketonization to yield 3,5-diphenyl-2,4,7-octanetrione (**14a**). Such a product was also obtained when the benzo-condensed compound **2a** was submitted to an acid-catalyzed reaction; in this case, one of the carbonyl groups was enolated to **17** as a phenol, as is depicted below.[4]



As it is a convenient route for furan synthesis for the dehydration of 1,4-diketones to take place under appropriate conditions, *e.g.*, in the presence of sulfuric acid (the so-called Paal-Knorr-type reaction),[16] the formation of the 2-furylacetone derivative, **13a**, may be expected in a similar manner. Support for this reaction mechanism was provided by the deuterium-labelled experiment. Thus, the 3-methyl group of **4a** was changed into acetonyl function in **13a**, while the other methyl group (the C-1 position of **4a**) was changed into the 2-furylmethyl function, as has been described above; therefore, it may be speculated that carbons belonging to the furan in **13a** originate as carbons at the 1, 5, 6, and 7 positions in **4a**.

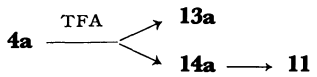


Taking this postulation into account, the conversion from triketone, **14a**, into naphthofuran, **11**, can be explained: (i) the furan moiety was made from the carbons of the C-1, 5, 6, 7 positions in **4a**; (ii) the carbons of the C-3, 4, 5, 6 positions in **4a** belong to the new benzene ring, which condenses with the phenyl group at the C-6 position in **4a** to give a naphthalene in which the CD_3 group may be assigned as a substituent at the *peri*-position in the case of the deuterium-labelled experiment, as is shown below.

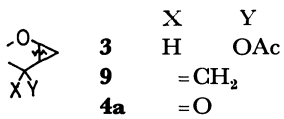
Nevertheless, the correct mechanism of 2-furylacetone **13a** formation seems to be somewhat different from the above deduction, judging from the following experimental results:[19] (i) when the reaction of **14a** with TFA was followed by means of either ^1H NMR spectroscopy or TLC at intervals, the formation of **13a** was undetectable, and (ii) interconversion from **13a** into **11** did not occur in TFA at room temperature.

Accordingly, **13a** is not given from **14a** by means of a Paal-Knorr reaction in the present case, but was directly formed from the starting material, although it seems, on the basis of the above deuterium-labelled experiment, likely that the C-1, 6 bond fission of **4a** occurred during the production of **13a**.

Thus, the interconversions among **4a**, **11**, **13a**, and **14a** may be finally expressed as below. This scheme may be well interpreted by the fact that the product ratio, **13a**/(**11**+**14a**), for the treatment of **4a** with TFA was found to be inevitably constant for at least six entries:



It is noteworthy that a similar mode of the cleavage of the cyclopropane ring has been deduced from the product studies of either the solvolysis of the secondary ester, **3**,[3] or the electrophilic addition of tetracyanoethylene to the *exo*-methylene compound, **9**,[9] and that the same characteristic cleavage of cyclopropane may also be involved in the acid-catalyzed reaction of homo-4-pyrone, **4a**.



Mode of cleavage of the cyclopropane ring

Reaction of Other Homo-4-pyrones with TFA: An isomerization of both **4b** and **4c** by means of acid catalysis took place analogously with the case of **4a** to give **13b** and **13c** in 40 and 15% yields respectively, along with a triketone **14c** (20% yield, starting from **4c**), although TFA was diluted with an equal volume of carbon tetrachloride or chloroform for the purpose of relieving a vigorous reaction moderately. The structural assignments of the products were made by means of both their ^{13}C NMR spectra, in which a furan moiety was clearly indicated, as is shown in Table 4, and their other spectral characteristics in comparison with those

Table 4. The ^{13}C NMR chemical shifts for 2-furylacetones **13**

13c[a)]	205	152	147	109	107	43	29	14	

a) Only an off-resonance spectrum was obtained.

of **13a**. The proton NMR data of **13b** including $Eu(fod)_3$ were closely analogous with those of **13a**, as is shown in Fig. 4.

In connection with reports on the chemistry of flavors, 2-furylacetone **13c** has been identified as one of the components in molasses aroma, bread aroma, meat flavor, and so on,[17] and antibiotic nonactic acid, which has been noted to have structural characteristics[18] analogous to the carbon skeleton of **13**. The production of 2-furylacetone starting from homo-4-pyrone in our present study is interesting because of the versatile utility of the product as well as the finding that aromatization into five-membered heterocycle may be one of the most suitable pathways for the cleavage of the cyclopropane of homo-4-pyrones under strong acid catalysis.

Experimental

General. All the melting and boiling points are uncorrected. The IR spectra were measured using a Hitachi 215 spectrometer; the UV spectra, on a Hitachi 124 spectrometer; the mass spectra, on a Hitachi RMU-6L spectrometer, and the ^1H NMR spectra, on a Varian T-60 spectrometer. The chemical shifts on both ^1H and ^{13}C NMR spectra are given in δ, with tetramethylsilane as the internal standard.

Materials. The preparation of 2,6-dimethyl-3,5-diphenyl-4-pyrone (**5a**) was carried out according to the procedure reported by Letsinger *et al.*[7] Mp 208—211 °C (lit, 202—206 °C)[7] (40% yield; flaky crystals, from benzene–ligroin). Analogously 2,3,5,6-tetramethyl-4-pyrone (**5b**) was synthesized from 3-pentanone in a 13% yield. Bp 154 °C/25 mmHg, mp 90—91 °C (lit, 90 °C)[7] (colorless prisms, from light petroleum). Starting from commercially available dehydroacetic acid, 2,6-dimethyl-4-pyrone (**5c**) was obtained. Mp 132—134 °C (lit, 130 °C),[7] bp 155 °C/35 mmHg (65% yield, colorless needles, from chloroform–hexane). Dimethyloxosulfonium methylide (**6**) was generated *in situ* by the treatment of sodium hydride with trimethyloxosulfonium iodide in dimethyl sulfoxide which had been distilled on calcium hydride under reduced pressure. Hexamethylphosphoric triamide was also distilled *in vacuo* before use and dried on molecular sieves.

General Procedure for the Cyclopropanation of 4-Pyrones. Dimethyldiphenylhomo-4-pyrone(1,3-dimethyl-4,6-diphenyl-2-oxabicyclo[4.1.0]hept-3-en-5-one) (4a): To mineral oil-free sodium hydride, prepared from commercial NaH (5.5 g, 0.14 mol; 61% in mineral oil) by means of triple decantation with light petroleum, we added trimethyloxosulfonium iodide (30 g, 0.14 mol) in one portion, after which we stirred in freshly distilled dimethyl sulfoxide (DMSO) (60 ml) over a period of 15 min, at first very carefully, at 20 °C. After the cessation of the violent evolution of hydrogen, the milky-white solution was kept in a nitrogen atmosphere. Into the dimethyloxosulfonium methylide generated in DMSO we poured hexamethylphosphoric triamide (HMPA) (60 ml), after which we added **5a** (15 g, 0.054 mol) in several portions, because of the poor solubility of **5a** in the medium. The solution was then allowed to stand at room temperature for 3 h under nitrogen, warmed at 40 °C for 6 h, and then cooled in an ice-bath; anhydrous ether (100 ml) was then added to the solution. The mixture was then poured into ice water and separated; the aqueous layer was extracted thoroughly with ether, and at last it was extracted once with benzene. The combined organic layer was satisfactorily washed with water and then dried on anhydrous sodium sulfate. The solution was evaporated *in vacuo*; a brown syrup (16.3 g) thus obtained was chromatographed on neutral alumina (80 g, deactivated by the addition of 10% water (w/w)) using ether–light petroleum (1: 10 by volume) as the eluent, and the solvent was evaporated *in vacuo* to give 8.31 g (53%) of **4a**. Mp 101—102 °C (colorless prisms, from light petroleum). IR (Nujol): 1655, 1515 cm^{-1}. ^1H NMR (CCl_4): 7.3—7.0 (10H, m, aromatic), 1.80 (3H, s, methyl), 1.28 (3H, s, methyl), 1.82, 1.56 (2H, AB quartet, J=6 Hz, cyclopropane). Found: C, 82.69; H, 6.29%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%. MS and UV data (see Table 2 and Fig. 1). About 15% of the **5a** was recovered in the column chromatography as a more polar fraction than **4a**.

Tetramethylhomo-4-pyrone(1,3,4,6-tetramethyl-2-oxabicyclo[4.1.0]-hept-3-en-5-one) (4b): According to the general procedure, **4b** was obtained as a colorless oil (see Table 1). IR (neat): 1640, 1625, 1440, 1400, 1195, 1035, 805 cm^{-1}. ^1H NMR (CCl_4): 1.89 (3H, s, methyl), 1.65 (3H, s, methyl), 1.57 (3H, s, methyl), 1.22 (3H, s, methyl), 1.22, 0.78, (2H, AB quartet, J=7 Hz, cyclopropane). MS and UV data (see Table 2 and Fig. 1).

Dimethylhomo-4-pyrone(1,3-dimethyl-2-oxabicyclo[4.1.0]hept-3-en-5-one) (4c): The synthetic procedure was analogous to those used for the other homo-4-pyrones mentioned above. (see Table 1). IR (neat): 1650, 1610, 1400, 1170, 965, 840 cm^{-1}. ^1H NMR (CCl_4): 5.03 (1H, s, vinyl), *ca.* 1.8 (1H, m, methine), 1.93 (3H, s, methyl), 1.63 (3H, s, methyl), 1.4—1.0 (2H, m, cyclopropane). MS and UV data (see Table 2 and Fig. 1).

General Procedure for Deuterium Exchange: A solution of the substrate (**4a**; 0.10 g) in DME (3 ml) was added to a stirred solution of a catalytic amount of sodium hydroxide in DME–D_2O (1: 1 by volume, 6 ml). After having been stirred overnight at room temperature, the solvent was evaporated *in vacuo* without heating; then the residue was extracted twice with dry ether (20 ml). The extracts were combined, washed with water, and dried over anhydrous sodium sulfate. The solution was condensed *in vacuo* to give a residue (**4a'**; 0.09 g), whose spectroscopic data have been discussed above.

General Procedure on the Treatment of Homo-4-pyrones 4 with Trifluoroacetic Acid: A wine-red solution of homo-4-pyrone **4a** (0.50 g) in trifluoroacetic acid (TFA) (5 ml) was subjected to ^1H NMR measurement, but a complicated pattern was observed. The solution was stirred at room temperature for 1 d, diluted with dry ether (50 ml), poured into an ice-cold

aqueous sodium hydrogencarbonate solution, and extracted three times with ether (100 ml); the combined organic layer was washed thoroughly with cold aqueous sodium hydrogencarbonate and with water, and then dried over anhydrous sodium sulfate. A yellow syrup (0.49 g) obtained by the subsequent evaporation of the ether was chromatographed on silica gel (15 g), using ether–light petroleum (1:9) as the eluent, to give three crystalline products: **11**, 30 mg (6%), mp 115—117 °C (from light petroleum). IR (nujol): 1600, 1580, 1360, 1230, 1180, 1010 cm^{-1}. ^1H NMR (CCl_4): 8.25—7.92 (2H, m, aromatic), 7.67—7.33 (7H, m, aromatic), 6.80 (1H, broad s, vinyl), 2.57 (3H, sharp s, methyl), 2.43 (3H, broad s, methyl). ^{13}C NMR ($CDCl_3$): 154.4 (s), 136.7 (s), 130.7, 130.2, 128.2, 127.5, 127.2, 126.5, 125.6, 124.5, 123.9, 122.4, 101.8 (d), 16.2 (q), 14.2 (q) (see also text). MS (*m/e*): 272 (M^+, base), 229. UV data (see Fig. 1). Found: C, 87.65; H, 5.94%. Calcd for $C_{20}H_{16}O$: C, 88.20; H, 5.92%. **13a**, 160 mg (32%), mp 35—37 °C (from light petroleum). IR (neat): 1720, 1600, 1570, 1450, 1150, 760, 690 cm^{-1}. ^1H NMR (CCl_4): 7.20 (10H, aromatic), 6.05 (1H, broad s, vinyl), 4.92 (1H, s, methine, disappeared when alkaline DME–D_2O) was used, 2.33 (3H, broad s, methyl), 2.02 (3H, sharp s, methyl), ^{13}C NMR ($CDCl_3$): 203.7 (s), 151.9 (s), 144.6 (s), 137.2 (s), 133.8 (s), 130.8, 130.5, 130.2, 129.0, 128.7, 128.0, 127.4, 127.1, 125.5 (s), 108.1 (d), 57.7 (d), 28.5 (q), 13.5 (q) (see also Table 4). MS (*m/e*): 290 (M^+), 247 (base). Found: C, 82.44; H, 6.34%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%. Monooxime, mp 154—156 °C (from methanol). Found: C, 78.28; H, 6.25; N, 4.50%. Calcd for $C_{20}H_{19}NO_2$: C, 78.66; H, 6.27; N, 4.59%. **14a**, 160 mg (30%), mp 75—77 °C (from light petroleum). IR (Nujol): 1715, 1600, 1160, 760, 730, 690 cm^{-1}. ^1H NMR ($CDCl_3$): 7.7—6.7 (10H, m, aromatic), 4.3—3.3 (4H, m), 2.13 (3H, s, methyl), 1.78 (3H, s, methyl). MS (*m/e*): 308 (M^+), 290 (base), 247. Found: C, 78.09; H, 6.61%. Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.5%. In addition to these products, an almost one-to-one mixture of **13a** and **14a** was also isolated (130 mg; 25%).

*Reaction of **4a** by Means of* p-*Toluenesulfonic Acid*: Homo-4-pyrone, **4a** (0.50 g), and an equal amount of *p*-toluenesulfonic acid were dissolved in benzene (5 ml) at room temperature for 1 d. The mixture was then washed with aqueous sodium hydrogencarbonate and with water, and dried on anhydrous sodium sulfate. The solution was evaporated, and the residue was subjected to chromatography to yield **11** (trace), **13a** (60 mg, 12%), and **14a** (180 mg, 34%).

*Treatment of **4a** with Polychloroacetic Acids*: To each solution of **4a** (50 mg) in $CDCl_3$ (0.4 ml), equimolar polychloroacetic acid, CCl_3CO_2H (28 mg), $CHCl_2CO_2H$ (22 mg), or CH_2ClCO_2H (16 mg), was added, after which the mixture was kept at 40 °C for 1 d. Since **14a** was the sole isolable product in each case, the yields were estimated by ^1H NMR spectroscopy on the basis of the ratio for the characteristic signals identified as **14a** to the recovered **4a**. When the reaction was carried out in neat $CHCl_2CO_2H$, **14a** was the single isolable product in addition to the reactant. The yields have been shown above.

Preparation of N-*Phenylmaleimide Adduct*: a) Homo-4-pyrone **4a** (0.50 g, 1.72 mmol), *N*-phenylmaleimide (0.30 g, 1.72 mmol), and TFA (3 ml) was stirred at room temperature for 30 h, and then diluted with dry ether (100 ml), and poured into ice-cold sodium hydrogencarbonate; the mixture was extracted twice with ether (50 ml), and the combined organic layer was thoroughly washed with aqueous sodium hydrogencarbonate, washed with water, and dried over anhydrous sodium sulfate. The subsequent evaporation of the solution gave a syrup (0.80 g) which was subjected to preparative TLC on silica gel, using methyl acetate–light petroleum (1:6) as the eluent, to yield pale yellow needles. (290 mg, 45%, from ether). Mp 125 °C. IR (Nujol): 1710, 1500, 1200, 1180, 750, 715, 690 cm^{-1}. ^1H NMR data (see the text). Found C, 77.46; H, 5.48; N, 2.91%. Calcd for $C_{30}H_{25}NO_4$: C, 77.74; H, 5.44; N, 3.02%.

b) The same product was obtained by the reaction of **13a** with equimolar *N*-phenylmaleimide in $CDCl_3$ at room temperature for several days; it was confirmed on the basis of both ^1H NMR spectrometry and the TLC analysis of the standard sample as has been described in Method a.

*Isomerization from Homo-4-pyrone **4b** into 2-Furylacetone **13b** by Means of Trifluoroacetic Acid*: Trifluoroacetic acid was diluted with chloroform (1:1 by volume). Analogously with the procedure of the reaction starting from **4a**, **13b** was isolated in a 40% yield from **4b**, along with the recovery of **4b** in an 8% yield. Purification was accomplished by column chromatography (silica gel, with ether–light petroleum (1:4) as the eluent). **13b**; colorless oil. IR (neat): 1730, 1590, 1450, 1360 cm^{-1}. ^1H NMR ($CDCl_3$): 5.65 (1H, broad s, vinyl), 3.55 (1H, q, J=6 Hz, methine), 2.20 (3H, s, methyl), 1.92 (3H, s, methyl), 1.90 (3H, s, methyl), 1.30 (3H, d, J=6 Hz, methyl). MS (*m/e*): 166 (M^+), 123 (M−43, base). Monooxime, mp 48—49 °C. MS (*m/e*): 181 (M^+).

*Acid-catalyzed Reaction of Homo-4-pyrone **4c***: Trifluoroacetic acid–carbon tetrachloride (1:1 by volume) was used as the medium. After 1 d-reaction at room temperature, the mixture was worked up as has been described above; purification was carried out by column chromatography on silica gel, using ether–light petroleum (1:3) as the eluent. **13c**; colorless oil (15%). IR (neat): 1720, 1570, 1355, 1220, 1025, 780 cm^{-1}. ^1H NMR (CCl_4): 6.03 (1H, d, J=3 Hz, vinyl), 5.90 (1H, d, J=3 Hz, vinyl), 3.57 (2H, s, methylene), 2.30 (3H, broad s, methyl), 2.10 (3H, sharp s, methyl). MS (*m/e*): 138 (M^+), 111, 95 (M−43, base). ^{13}C NMR data (see Table 4). **14c**; colorless oil (20%). IR (neat): 1710, 1610, 1400, 1360 cm^{-1}. ^1H NMR (CCl_4): 5.50 (s), 3.63 (s), 2.93—2.20 (m, total 6H), 2.20 (3H, s, methyl), 2.02 (3H, s, methyl). MS (*m/e*): 156 (M^+), 138, 123, 113 (M−43), 99, 85, 71.

We are indebted to Dr. Masaaki Mishima, Kyushu Univ., Mr. Yoshinori Ikebe, Hitachi, Ltd., and Dr. Yasuhito Uchio, Hiroshima Univ., for obtaining the ^{13}C NMR spectra; we also wish to thank to Dr. Shizuko Eguchi, Hiroshima Univ., for her measurements of the mass spectra. We are indebted to the Ministry of Education for a Scientific Research Grant-in-Aid (374168).

Asymmetric Benzoin Condensation Catalyzed by Optically Active Thiazolium Salts in Micellar Two-phase Media

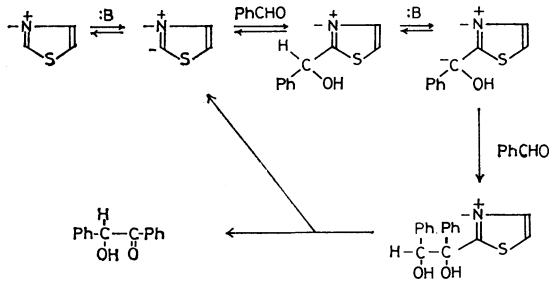
Waichiro TAGAKI,* Yoshiharu TAMURA, and Yumihiko YANO

Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received July 9, 1979)

Three thiazolium salts, 3-[2-(*l*-3-*p*-menthyloxy)ethyl]thiazolium bromide (**1**), 3-(*l*-3-*p*-menthyl)thiazolium halides (**2**), and 3-(*l*-3-*p*-menthyl)-4-methylthiazolium perchlorate (**3**) have been examined for the catalysis of benzoin condensation in micellar two-phase media. The catalytic activities on the chemical yields of benzoin were observed to be high for **1** and **2** but low for **3**. On the contrary, for the asymmetric induction, **3** gave much higher optical purity of 35.3% than in the cases of **1** and **2** (0.8—3.5%). These results are discussed in terms of micellar and conformational effects.

Thiazolium salts are well known to catalyze the benzoin condensation (Scheme 1).[1] The catalytic activity, however, is generally not large in aqueous media. Therefore, the catalysts are commonly used in organic solvents such as in methanol for the purpose of synthesis.[2] Meanwhile, we have found that *N*-(long chain alkyl)thiazolium salts are highly active catalysts when used in aqueous two-phase system.[3] We consider that such enhanced activity was produced by combined effects of micellar[4] and phase transfer[5] catalyses. For the past decade, these catalytic systems have been extensively studied as the enzyme models, and some success appears to have been achieved in the simulation of enzymic rate enhancement. However, relatively little success has been achieved in the simulation of enzymic stereospecificity, although there have been some interesting examples of stereospecific micellar[6] and phase transfer[7] reactions.

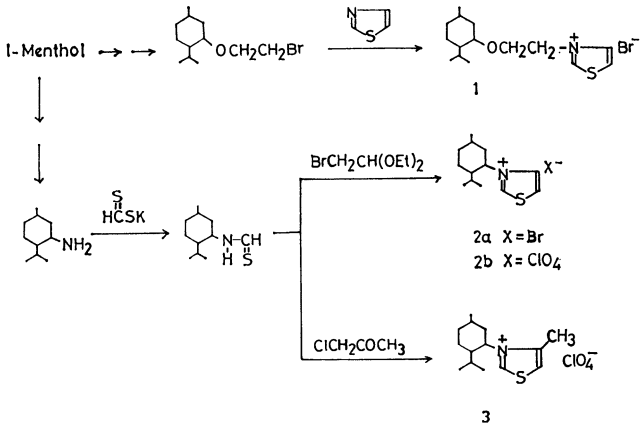


Scheme 1.

In the meantime, Sheehan and the coworkers have already studied the asymmetric benzoin condensation and obtained fairly high optical purity of 52% by using some optically active thiazolium salt of highly constrained structure.[8] Unfortunately, they examined the reactions only in methanol. Therefore, we have reexamined similar asymmetric benzoin condensation, but under micellar conditions in aqueous media.

Results and Discussion

Synthesis of the Catalysts. All catalysts were prepared starting from crystalline *l*-menthol, as outlined in Scheme 2. Synthetic procedures for **1** involve no disturbance of asymmetric center. Whereas in the syntheses of **2** and **3**, the chirality of the 3-position of *l*-menthol was once destroyed by the oxidation leading



Scheme 2.

to *l*-menthone. However, this and the subsequent transformations to (*l*-3-*p*-menthyl)amine are well established procedures.[9] The conversions of (*l*-3-*p*-menthyl)-amine to **2** and **3** were carried out according to the method of Sheehan *et al.*[8]

Benzoin Condensation. The reactions were carried out in a Thunberg tube under the nitrogen atmosphere at room temperature. The reaction mixture was homogeneous when carried out in methanol containing triethylamine. While it was heterogeneous when carried out in aqueous phosphate buffer (pH 8) because of insolubility of benzaldehyde. Each catalyst was soluble in aqueous buffer, but when stirred in the presence of benzaldehyde it was extracted nearly completely from the aqueous phase to the liquid benzaldehyde phase. The benzoin thus formed was isolated by column chromatography on silica gel. The results are compiled in Table 1.

Table 1 indicates the following features: (a) In all the cases, the benzoin yield is higher in water (heterogeneous) than in methanol (homogeneous). The yield is also higher with bromide (**2a**) than with perchlorate (**2b**). (b) Racemization of the product benzoin occurs to some extent for a prolonged reaction duration. (c) The catalyst **2a** gave rotation of opposite sign to that given by **1** and **3**. (d) The 4-methyl substituent in **3** caused the highest optical purity, but the lowest benzoin yield.

The higher benzoin yield in water has already been observed for the catalyst (**4**).[3] The **4** forms micelle (CMC $=3.3\times10^{-3}$ M in H_2O) and its H-D exchange

Table 1. Thiazolium salt catalysis of benzoin condensation[a]

Catalyst	Solvent	Time h	Benzoin yield[b] %	$[\alpha]_D^{20}$ °	Optical purity[c] %

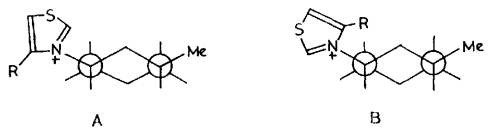
rate at the 2-position is 16 fold faster than that of non-micelle forming 3-methyl analogue.[3,11] The incorporation of **4** into benzaldehyde phase during the catalysis is also the same as observed for **1**, **2**, and **3**. Therefore, the micellar or phase transfer activation may be appropriate to account for the reactivities of these salts. The effect of counter anion (**2a** *vs.* **2b**) is also consistent with the micellar effects, since it is known that the perchlorate anion is bound more tightly to cationic micelle than bromide ion and a tighter binding causes a stronger inhibition of micellar reactivity.[4]

The 4-methyl group in **3** showed profound effects on both chemical and optical yields of benzoin. These effects may be understood in the following way. Namely, the conformations of **2** and **3** can be drawn as in the following formula **A** and **B**.[12] The CPK molecular model indicates that the isopropyl group enforces the plane of thiazolium ring to assume the conformations in such a way to bisect the plane of cyclohexane ring (C_1–C_3–C_5 and C_2–C_4–C_6). The interconversion between **A** and **B** is relatively easy when R=H (**2**), but severely restricted when R=Me (**3**) favoring **A** much more than **B**. On the other hand, the condensation should be easier through **B** than **A** since the reaction



A B

R: H, Me

at 2-position of thiazolium ring is shielded by cyclohexane ring in **A**. Thus **2** should be more reactive (more in the reactive **B**) than **3** (more in the less reactive **A**). Meanwhile, the accounting for stereospecificity is not easy, since there are two addition steps to create two asymmetric carbons (see Scheme 1), both of which should be important, although the asymmetry of the first carbon (or carbanion) is lost after the condensation. Only we can suspect is that stereochemical confinement may be more stringent for more conformationally frozen **3** than **2**.

The above observation that the highest optical purity was obtained with the lowest yield is rather disappointing, since in the enzymic catalyses the rate enhancement and stereospecificity appear to be inseparable in the same catalytic mechanism.[13] For the present micellar two-phase system, the hydrophobic interaction between the catalyst and the substrate is considered to be important for the rate enhancement. However, some more special hydrophobic or multifunctional interactions are necessary for enzymic stereospecificity.

Experimental

3-[2-(l-3-p-menthyloxy)ethyl]thiazolium Bromide (1). The salt was synthesized starting from *l*-menthol *via* the following intermediates successively: (*l*-3-*p*-menthyloxy)acetic acid, ethyl(*l*-3-*p*-menthyloxy)acetate, 2-(*l*-3-*p*-menthyloxy)ethanol, and 2-(*l*-3-*p*-menthyloxy)ethyl bromide. The last bromide 1 g (3.8 mmol) and thiazole 0.35 g (4.1 mmol) was heated (100 °C) in a sealed tube for 44 h. Crystals formed were collected and recrystallized from ethanol–ether, yield 0.74 g (56%), mp 188—189 °C, $[\alpha]_D^{20}$ −54.3° (*c* 0.97, MeOH). Found: C, 51.46; H, 7.53; N, 4.05%. Calcd for $C_{15}H_{26}BrNOS$: C, 51.71; H, 7.54; N, 4.02%.

(l-3-p-Menthyl)amine Hydrochloride. *l*-Menthol was converted to *l*-menthone by chromium trioxide oxidation followed by further conversion to *l*-menthone oxime. This oxime was reduced by metallic sodium in ethanol according to the literature procedures to give (*l*-3-*p*-menthyl)amine which was isolated as the hydrochloride, mp 255 °C, $[\alpha]_D^{20}$ −35.5° (*c* 2.0, H_2O) [lit,[9] $[\alpha]_D^{20}$ −36.1° (*c* 2.0, H_2O)].

N-thioformyl-(l-3-p-menthyl)amine was prepared by the same procedures as reported by Sheehan *et al.*[8]

3-(l-3-p-menthyl)thiazolium Bromide (2a). To a stirred solution of *N*-thioformyl-(*l*-3-*p*-menthyl)amine (5 g, 25 mmol) in benzene (40 ml) was added α-bromoacetaldehyde diethyl acetal (5 g, 25 mmol) in benzene (10 ml). The mixture was stirred overnight at room temperature. After benzene was evaporated, ether (20 ml) was added and neutralized with $NaHCO_3$ and extracted with ether to remove unreacted materials. The aqueous layer was evaporated to dryness. The residue was recrystallized from acetone–ether, 4.2 g (52%), mp 201—203 °C, $[\alpha]_D^{20}$ −31.8° (*c* 1.0, MeOH). Found: C, 51.72; H, 7.53; N, 4.64; S, 10.10%. Calcd for $C_{13}H_{22}BrNS$: C, 51.30; H, 7.30; N, 4.60; S, 10.54%.

3-(l-3-p-menthyl)thiazolium Perchlorate (2b). To a stirred

solution of **2a** 0.5 g (1.64 mmol) in methanol (5 ml) was added silver perchlorate 0.34 g (1.64 mmol). Silver bromide precipitated was filtered off and methanol was evaporated. The residue was dissolved in acetone and the insoluble silver bromide was again removed. Acetone was removed and the crystalline residue was finally recrystallized from ethanol–ether, yield 0.45 g (84%), mp 113—115 °C, $[\alpha]_D^{20}$ −32.1° (*c* 0.62, MeOH). Found: C, 48.05; H, 6.71; N, 4.28; S, 9.86%. Calcd for $C_{13}H_{22}ClNO_4S$: C, 48.21; H, 6.86; N, 4.33; S, 9.90%.

3-(l-3-p-Menthyl)-4-methylthiazolium Perchlorate (3). To a stirred solution of *N*-thioformyl-(*l*-3-*p*-menthyl)amine (4.1 g, 20.5 mmol) in benzene (40 ml) was added chloroacetone (1.9 g, 20.5 mmol) in benzene (20 ml). The mixture was stirred for 24 h and finally refluxed for 15 min. Benzene was evaporated, water was added, and neutralized with sodium carbonate (pH 7—8). The aqueous layer was extracted with ether to remove the unreacted materials. The water was evaporated to dryness. The residue was dissolved in dichloromethane to remove sodium chloride. The dichloromethane layer was dried over sodium sulfate. The dichloromethane was removed to give pasty residue. This paste was dissolved in acetone and treated with silver perchlorate in acetone. Silver chloride precipitated was filtered off and ether was added to the filtrate to give crystalline precipitates. The crystalline precipitates were collected and recrystallized from ethanol–ether, yield 0.16 g (16%), mp 199—200 °C, $[\alpha]_D^{20}$ −57.0° (*c*, 1.00, MeOH). Found: C, 50.10; H, 7.35; N, 4.07; S, 9.50%. Calcd for $C_{14}H_{24}ClNO_4S$: C, 49.76; H, 7.17; N, 4.15; S, 9.49%.

Asymmetric Benzoin Condensation. In a Thunberg tube, the solvent (10 ml) containing a catalyst (0.15 mmol) was bubbled with nitrogen for 20 min. The reaction was initiated by mixing the solvent with benzaldehyde (2.8 mmol) which was placed with a stirring rod in the upper flask of Thunberg tube. Stirring was continued at room temperature for a given time. The reaction mixture was extracted with ether, and the ether layer was dried over anhydrous magnesium sulfate. The ether was evaporated to dryness and the residue was chromatographed on a silica gel column with chloroform. The fraction containing benzoin was collected and the solvent was removed. Further recrystallization was noted to be unnecessary.

Optical rotation was recorded with a JASCO-SL automatic polarimeter, the precision of reading to be within ±0.002°.

We thank Mr. T. Higashiyama, Toyo Hakka Co., Ltd., for generous gift of *l*-menthol. We also thank Drs. Oya and Katakai for allowing the use of above polarimeter. This research was supported in part by Grant-in-Aid for Scientific Research from the Ministry of Education, Japan.

The Synthesis and Cation-complexing Ability of Alkyl Crown Ethers

Tadashi MIZUNO, Yohji NAKATSUJI, Shozo YANAGIDA, and Mitsuo OKAHARA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita 565

(Received July 11, 1979)

Alkyl-15-crown-5 and alkyl-12-crown-4 were prepared *via* polyethylene glycol β-haloalkyl ethers in two steps from terminal olefins, and their complexing ability with cations of alkali and alkaline earth metals was measured by using ^{1}H NMR; it was found to be almost identified with that of the corresponding unsubstituted crown ether. A new type of alkyl crown ether with a chloro substituent could also be synthesized according to this method.

Synthetic macrocyclic polyethers have received attention in recent years, as phase-transfer catalysts in a variety of organic reactions because they possess the ability to form complexes with salts of the alkali and alkaline earth metals to raise the reactivity of the counter anion; they are also expected to be useful selective carriers for the transport of cations through a liquid membrane.[1,2]

Modifications of their solubilities in various organic solvents by introducing lipophilic groups into the macrocyclic ring seem to be desirable for these purposes. For substituted macrocyclic compounds, the balance between lipophilic and hydrophilic parts is supposed to be one of the important factors influencing their properties; this balance can easily be adjusted by changing the substituents and the ring size.

From this standpoint, alkyl-substituted crown ethers, cryptands, and cyclic tetraamines were synthesized *via* the multi-step reactions reported by Cinquini,[3,4] Lehn,[5] and Tundo[6] and found to show high catalytic activity in several two-phase reactions. On the other hand, alkyl-substituted cyclams were synthesized and successfully used as the extraction of heavy metal ions from an aqueous solution by Tabushi.[7]

In the course of our investigation, a convenient method of synthesizing these alkyl crown ethers *via* polyethylene glycol β-haloalkyl ethers was found and previously reported in a preliminary paper.[8]

In this paper, we will describe the preparation of alkyl-15-crown-5 and alkyl-12-crown-4 and their complexing ability with alkali and alkaline earth cations, as measured by means of the ^{1}H NMR method.

Experimental

The ^{1}H NMR spectra were taken at 100 MHz on a JEOL JNM-PS-100 spectrometer, using tetramethylsilane as the internal standard, except for the measurement of the complexing ability. The infrared spectra were obtained on a JASCO IR-E spectrometer. The mass spectra were measured with a Hitachi RMU-6E mass spectrometer at an ionization potential of 70 eV. The GLC analyses were done on a Shimadzu GC-3A using a 1 m×3 mm column packed with 10% Silicone SE-30 on 60—80 mesh Celite 545. The halogen contents of the polyethylene glycol β-haloalkyl ethers were measured according to the conventional method.[9]

*Preparation of Polyethylene Glycol β-Haloalkyl Ether (**1** or **2**).* To a stirred suspension of 136.0 g (0.7 mol) of tetraethylene glycol and 35.6 g (0.2 mol) of NBS we added, drop by drop, 18.5 g (0.22 mol) of 2-methyl-1-pentene over a 15-min period at 45—50 °C; the mixture was then stirred at that temperature for 2 h until the positive halogen had been consumed. The reaction mixture was cooled to room temperature and worked up adding water and then extracting with ether. The ether extracts were dried over anhydrous magnesium sulfate and concentrated to give 47.8 g (67%) of the crude product (**1h**). Some of the results are shown in Table 1.

*Preparation of Alkyl-15-crown-5 (**3**); 2-Methyl-2-propyl-15-crown-5 (**3h**).* To a stirred suspension of 4.7 g (0.11 mol) of sodium hydroxide in 174 ml of diglyme we added, drop by drop, 35.7 g (0.1 mol) of **1h** over a 3.5-h period at 120—125 °C; the mixture was then stirred at 110—140 °C for 7 h. The reaction was followed by GLC and continued until the starting material (**1h**) had been completely consumed. The resultant mixture was cooled to room temperature, and sodium bromide was removed by filtration. The filtrate was evaporated under reduced pressure to give 29.3 g of a brown viscous liquid. A portion of the crude product (9.6 g) was distilled to give 3.83 g (43%) of a colorless liquid. The product was further purified on a silica-gel column (hexane: acetone = 10: 1) to afford the following analytical sample (**3h**): n_D^{20}, 1.4636; IR max (neat) 2980, 2880, 1465, 1360, 1297, 1200, and 1125 cm^{-1}; mass: 276 (M) and 233 (M−R); NMR (CCl_4) δ 0.90 (t, 3H), 1.06 (s, 3H), 1.38 (m, 4H), and 3.28—3.68 (m, 18H). Found: C, 60.88; H, 10.27%. Calcd for $C_{14}H_{28}O_5$: C, 60.84; H, 10.21%.

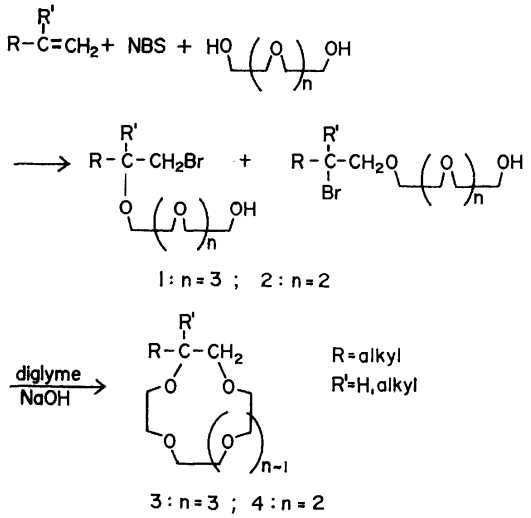
*Preparation of Alkyl-12-crown-4 (**4**); 2-Methyl-2-propyl-12-crown-4 (**4d**).* A suspended mixture of 20.0 g (0.064 mol) of **2d** and 5.92 g (0.14 mol) of sodium hydroxide in 165 ml of diglyme was stirred at 130—145 °C for 19 h until the starting material (**2d**) had been completely consumed. A brown viscous liquid (14.2 g) was then obtained according to the procedure mentioned above. A portion of the crude product (9.0 g) was distilled to give 1.93 g (21%) of **4d** as a colorless liquid. All the spectroscopic analytical results shown in Table 4 support the expected structure.

*Preparation of Crown Ether Containing a Chloro Substituent; 2-Chloromethyl-2-methyl-15-crown-5 (**3i**).* To a stirred suspension of 3.0 g (0.07 mol) of sodium hydroxide in 100 ml of diglyme we added, drop by drop, 18.2 g (0.05 mol) of **1i** in 25 ml of diglyme over a 4.5-h period at 80—125 °C, and then the mixture was stirred for 6 h at 110—120 °C. A purification procedure similar to that described above afforded the following analytical sample (**3i**): IR max (neat) 2900, 2850, 1455, 1350, 1250, 1100, 930, 770, and 730 cm^{-1}; mass: 233 (M−R); NMR (CCl_4) δ 1.18 (s, 3H) and 3.40—3.76 (m, 20H). Found: C, 51.90; H, 8.44; Cl,[9] 12.1%. Calcd for $C_{12}H_{23}O_5Cl$: C, 50.97; H, 8.20; Cl, 12.5%.

Measurement of Complexing Ability Using ^{1}H NMR. The ^{1}H NMR were measured as a 1% solution of crown ether in acetone-d_6, with 8% dioxane in benzene used as an external standard. The chemical shift of ^{1}H NMR signals of the main oxyethylene protons in the crown ether was compared with that in a sample containing an equimolar amount of the metal salt (thiocyanate).[10] The difference in the chemical shifts of these two samples was regarded as the downfield shift, based on the formation of the complex. The results are summarized in Tables 5 and 6.

Results and Discussion

Preparation of Alkyl-substituted Crown Ethers via *Polyethylene Glycol β-Haloalkyl Ethers.* The overall reaction process is shown in Scheme 1.



Scheme 1.

The polyethylene glycol β-haloalkyl ether was prepared by adding 1-alkene to a suspension of polyethylene glycol and a halogenating agent (NBS or NBA) and was then converted to the alkyl-substituted crown ether by heating with sodium hydroxide in diglyme. The β-haloalkyl ethers were obtained as a mixture of two isomers (Markownikoff and *anti*-Markownikoff adducts of the terminal olefins[11,12]). However the two isomers afford only one type of alkyl-substituted crown ether after a cyclization reaction.

Table 1 shows the halogenating agents used, the yields, and the halogen contents of the products in the preparation of polyethylene glycol β-haloalkyl ethers. Although the intermediate haloethers (**1** or **2**) were cyclized to crown ethers without further purification,[13] the halogen contents of the crude products coincided well with the calculated values.

The results of the cyclization to alkyl-15-crown-5 are shown in Table 2, while the analytical data are shown in Table 3. A reaction temperature above 100 °C was found to be optimal for the cyclization without any undesirable formation of olefins. The use of a high-dilution technique with a varied dropping rate of polyethylene glycol β-haloalkyl ether did not improve the yield appreciably. Dioxane had been used as the solvent in the preparation of alkyl-15-crown-5 in the previous paper,[8] but diglyme was preferable to dioxane from the viewpoint of making it possible to adopt higher reaction temperatures.

Table 1. Synthesis of polyethylene glycol β-haloalkyl ethers

Compd	R	R'	*n*	Halogenating agent	Yield %	Found (Calcd) Halogen(%)
1a	*n*-C_4H_9	H	3	NBA	62	22.3 (22.4)

2a	C_2H_5	H	2	NBS	24	25.6 (25.5)
2b	CH_3	CH_3	2	NBS	38	28.2 (28.0)
2c	C_2H_5	CH_3	2	NBS	76	24.9 (26.7)
2d	*n*-C_3H_7	CH_3	2	NBS	65	25.6 (25.5)
2e	CH_2Cl	CH_3	2	NBS	73	35.7 (36.3)

The yield of alkyl-12-crown-4 (**4**) was lower than that of the corresponding alkyl-15-crown-5 (**3**) in spite of the severer reaction conditions, as is shown in Tables 2 and 4; this finding suggests that the sodium cation did not function effectively as the template ion in the formation of the former.[14]

A new type of crown ether (**3i** and **4e**) with a chloro substituent, which is potentially useful for the preparation of variously functionalized crown ethers, could also be synthesized according to this method. Although the intermediate product (**1i** or **2e**) possesses two different halogen atoms, the results of the NMR and elementary analyses showed that the chlorine atom was preferentially conserved in the final product (**3i** or **4e**) after the cyclization reaction (Scheme 2).

Complexing Ability of Alkyl-substituted Crown Ethers. The lipophilicity of crown ethers may be supposed to be important, together with their complexing properties, when they are used as phase-transfer catalysts, as is the case with quaternary ammonium salts, which were discussed recently.[15] The lipophilicity of alkyl crown ethers can be controlled by changing the number or the chain length of the alkyl group. However, the introduction of the alkyl group into the crown ether rings may cause a decrease in their complexing ability toward the metal cations because of the steric effect or the loss of symmetry.[16]

Therefore, we investigated the complexing ability of some of the alkyl crown ethers prepared in this study and compared it with that of the unsubstituted crown ethers. The ^1H NMR spectrum of each alkyl crown

a) Unsubstituted 15-crown-5.

ether as a 1% solution in acetone-d_6 was measured, with or without an equimolar amount of the metal salt. An 8% solution of dioxane in benzene was used as the external standard.

The influence of the change in the alkyl group in alkyl-15-crown-5 (Table 5) and alkyl-12-crown-4 (Table 6) on the complexing ability toward sodium and potassium cations was found to be almost the same as that of the corresponding unsubstituted crown ether. This finding suggests that it is possible to adjust the lipophilic/hydrophilic balance of crown ethers without changing the complexing ability toward alkali metal cations. In other words, there is possibility of designing a suitable crown compound for a specified purpose without imparing their complexing ability and selectivity.

TABLE 6. DOWNFIELD SHIFT IN 100 MHz NMR OF ALKYL-12-CROWN-4 CAUSED BY MSCN OR $M(SCN)_2$ (Hz)

Cation	Compd			
	4[a]	**4b**	**4c**	**4d**
Na^+	15.6	13.2	15.8	14.7
K^+	10.6	8.2	9.7	9.2
Mg^{2+}	2.2	0.8	2.2	3.3
Ca^{2+}	—[b]	20.2	24.5	20.1

a) Unsubstituted 12-crown-4. b) Precipitation of insoluble salts.

Table 6 also demonstrates the complexing ability of alkyl and unsubstituted 12-crown-4 for magnesium and calcium cations. The complexing ability of unsubstituted 12-crown-4 for the calcium cation could not be measured because of the formation of an insoluble complex in the acetone-d_6 solution.[17] About a 20 Hz downfield shift was observed in the combination of 12-crown-4 and the calcium cation, but in the case of the magnesium cation the shift was little. The selectivity of alkyl-12-crown-4 for magnesium and calcium cations was similar to that of unsubstituted 12-crown-4.

Consequently, the complexing ability and the selectivity of alkyl-15-crown-5 and alkyl-12-crown-4 for alkali and alkaline earth metal cations were found to be almost equal to those of the corresponding unsubstituted one, and the raise in the lipophilicity of crown ethers can be expected to bring about a favorable result when crown ether is used as a phase-transfer catalyst or a selective carrier for the transport of cations.

Reactions of Trimethylsilyl Cyanide and *N*-(Trimethylsilyl)diphenylmethyleneamine with Nitrones and Thermal Decompositions of Their Adducts

Otohiko Tsuge,* Satoshi Urano, and Takahiko Iwasaki

Research Institute of Industrial Science, Kyushu University 86, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 16, 1979)

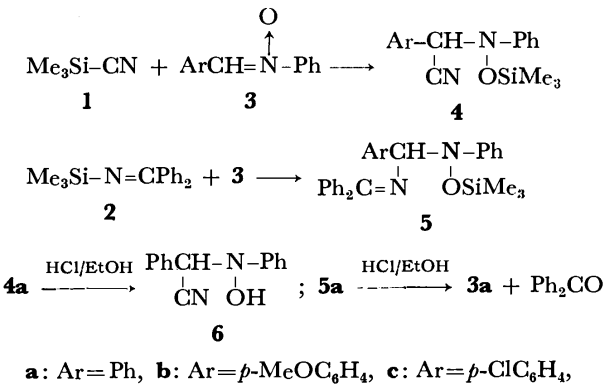
Trimethylsilyl cyanide (**1**) and *N*-(trimethylsilyl)diphenylmethyleneamine (**2**) reacted with α-aryl-*N*-phenylnitrones to afford the corresponding 1:1 adducts **4** and **5** respectively. Thermal decomposition of **4** in refluxing xylene gave azoxybenzene, stereoisomers of 2,3-diarylsuccinonitriles, α-iminonitriles and/or benzanilides, whose yields depended on the nature of substituents on phenyl group of **4**. On heating in benzene **5** afforded a mixture of azoxybenzene and *meso*-*N*,*N*′-bis(diphenylmethylene)-1,2-diarylethylenediamines. On the other hand, reactions of **1** and **2** with *N*-(diphenylmethylene)aniline *N*-oxide or *N*-(9-fluorenylidene)aniline *N*-oxide did not give the corresponding 1:1 adducts, but instead compounds arising from thermal decomposition of initial 1:1 adducts were directly obtained. The reaction of **1** with *N*-(*p*-diethylaminophenyl)-α-phenylnitrone leading to the corresponding α-imino nitrile is also described.

It is known that trimethylsilyl cyanide (**1**) is a good reagent for introducing cyano group, acylation, protecting and activating carbonyl groups in organic syntheses.[1] Recently, Ojima and his coworkers have developed versatility of **1** for syntheses of heterocyclic compounds by the reaction with isocyanates[2] or isothiocyanate,[3] and of α-amino nitriles by the reaction with Schiff bases.[4,5] It has also been reported that *N*-(trimethylsilyl)diphenylmethyleneamine (**2**) reacted with isocyanates, isothiocyanates, and benzimidoyl chlorides to give useful products for syntheses of heterocyclic compounds.[6]

However, little attention has been drawn to the reactions of **1** and **2** with nitrones. In this paper we wish to report on the reactions of **1** and **2** with α-aryl-*N*-phenylnitrones (**3**) and thermal decomposition of the adducts. In this context, the reactions of **1** and **2** with aromatic nitrones other than **3** are also described.

Results and Discussion

Reactions of Trimethylsilyl Cyanide (1) and N-*(Trimethylsilyl)diphenylmethyleneamine (2) with α-Aryl*-N-*phenylnitrones (3).* Treatment of **1** with nitrones, **3a**—**3d**, afforded the corresponding 1:1 adducts, α-[*N*-(trimethylsilyloxy)phenylamino]arylacetonitriles, **4a**—**4d**, in excellent yields respectively. Also, **2** reacted with nitrones, **3a**—**3d**, to give the corresponding 1:1 adducts, α-[*N*-(trimethylsilyloxy)phenylamino]-*N*-(diphenylmethylene)benzylamines, **5a**—**5d**, in good yields (Scheme 1).



a: Ar=Ph, **b**: Ar=*p*-$MeOC_6H_4$, **c**: Ar=*p*-ClC_6H_4, **d**: Ar=*p*-$NO_2C_6H_4$

Scheme 1.

Structural elucidation of these adducts **4** and **5** was accomplished on the basis of elemental analysis and spectral data. Detrimethylsilylation of **4a** with hydrochloric acid in ethanol afforded α-(*N*-hydroxyphenylamino)phenylacetonitrile (**6**) in good yield, whereas **5a** was readily converted into nitrone **3a** and benzophenone under similar conditions.

The reaction conditions, yields, physical and analytical data for **4** and **5** are summarized in Tables 1 and 2.

Although **1** did not react with *N*-(diphenylmethylene)aniline *N*-oxide (**7**) or *N*-(9-fluorenylidene)aniline *N*-oxide (**8**) in refluxing benzene, on heating with **7** or **8** at 120 °C without solvent **1** afforded a mixture of tetraphenylsuccinonitrile (**9**) or 9,9′-dicyano-9,9′-bifluorenyl (**10**) and azoxybenzene (**11**) respectively.

Table 1. Reaction conditions, yields, melting points, and appearance for **4** and **5**

Compound	Reaction conditions	Yield/%	Mp/°C	Appearance
4a	C_6H_6, reflux, 4 h	95[a]	88—89	colorless prisms
4b	C_6H_6, reflux, 2.5 h	97	102—102.5	colorless prisms
4c	C_6H_6, reflux, 3 h	95	94—96	colorless needles
4d	C_6H_6, reflux, 5.5 h	97	118—119.5	colorless needles
5a	CH_2Cl_2, r.t., 12 h	84	105—106	colorless needles
5b	CH_2Cl_2, r.t., 14 h	73	102—104	colorless prisms
5c	CH_2Cl_2, r.t., 16 h	83	93—95	colorless prisms
5d	CH_2Cl_2, r.t., 13 h	74	125.5—127	colorless prisms

a) In the reaction at room temperature (r.t.) for 12 h **4a** was obtained in 50% yield.

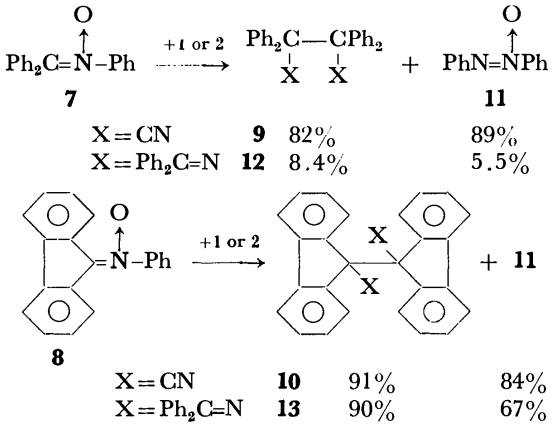
On the other hand, **2** reacted with **7** or **8** in dichloromethane at room temperature to give a mixture of **11** and *N,N'*-bis(diphenylmethylene)tetraphenylethylenediamine (**12**) or 9,9'-bis(diphenylmethyleneamino)-9,9'-bifluorenyl (**13**) respectively (Scheme 2).



Scheme 2.

Compounds **9**, **10**, **12**, and **13** were prepared by other routes respectively, but the above reactions provide a one-pot syntheses for these compounds.

Thermal Decomposition of 1:1 Adducts. It is reasonable to assume that the reactions shown in Scheme 2 proceeded through the rupture of the C–N bonds of initial adducts of types **4** and **5**. Thus, we have investigated thermal decompositions of adducts **4** and **5**.

When a solution of **4a** or **4b** in xylene was refluxed, a mixture of **11** and stereoisomers of the corresponding 2,3-diarylsuccinonitriles (**14**) respectively. Under similar conditions **4c** afforded α-phenylimino-*p*-chlorophenylacetonitrile (**15c**) and *p*-chlorobenzanilide (**16c**) together with **11** and stereoisomers of 2,3-bis(*p*-chlorophenyl)-succinonitriles (**14c**). In the thermal decomposition of **4d**, however, α-phenylimino-*p*-nitrophenylacetonitrile (**15d**) was obtained as a major product, accompanied with a small amount of *p*-nitrobenzanilide (**16d**) as shown in Scheme 3.

a: Ar=Ph, **b**: Ar=*p*-$MeOC_6H_4$, **c**: Ar=*p*-ClC_6H_4, **d**: Ar=*p*-$NO_2C_6H_4$

Scheme 3.

Structural elucidation of **14**, **15**, and **17** was accomplished on the basis of their spectral data and/or comparison with physical data of the compounds reported previously.[7]

As mentioned above, α-imino nitriles **15c** and **15d** were formed in thermal decomposition of **4c** and **4d**. It is reasonable to assume that these α-imino nitriles **15** are formed by the elimination of trimethylsilanol from the corresponding **4**, because *p*-chlorophenyl and *p*-nitrophenyl groups enhance the acidity of α-hydrogen atom of **4**. Thus, it is also expected that thermal decomposition of an adduct of type **4** possessing an electron-donating group on *N*-phenyl will give an α-imino-nitrile. In fact, α-(*p*-diethylaminophenylimino)phenylacetonitrile (**20**) was obtained directly even at room

On the other hand, thermal decomposition of **5a**—**5d** in refluxing benzene afforded a mixture of **11** and the corresponding *meso-N,N'*-bis(diphenylmethylene)-1,2-diarylethylenediamines, **17a**—**17d**, respectively (Scheme 4). Hydrolysis of **17a** gave a mixture of *meso*-1,2-diphenylethylenediamine (**18**) and benzophenone.

	Heating time/h		
5a	30	49%	84%

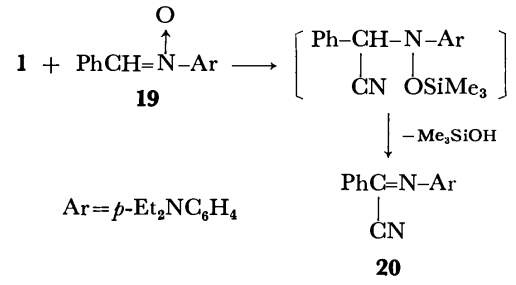
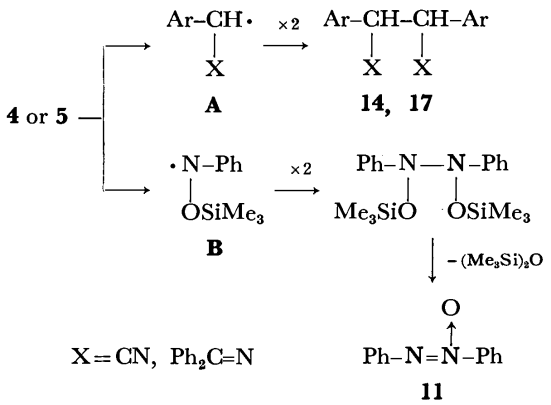
Scheme 4.

temperature by the reaction of **1** with *N*-(*p*-diethylaminophenyl)-α-phenylnitrone (**19**).



Although mechanistic considerations are still speculative, a plausible pathway for the formation of **11** and **14** or **17** from **4** or **5** is outlined in Scheme 5. The homolytic rupture of the C–N bond of **4** or **5** yields radical **A** and **B**. The radical **A** dimerizes to give **14** or **17**, and the dimerization of **B** with subsequent elimination of di(trimethyl)siloxane affords **11**.



Scheme 5.

Experimental

Melting points are uncorrected. IR, NMR, and mass spectra were obtained on a JASCO IRA-1 spectrometer, Hitachi R-40, JEOL SX-100 spectrometers, and a Hitachi RMS-4 spectrometer, respectively. IR and NMR spectra were taken in KBr disks and $CDCl_3$ solutions respectively. Mass spectra were obtained at 70 eV.

Materials. Trimethylsilyl cyanide (**1**)[8] and *N*-(trimethylsilyl)diphenylmethyleneamine (**2**)[9] were prepared from trimethylsilyl chloride and silver cyanide or lithium diphenylmethanimine by the reported methods respectively. α-Aryl-*N*-phenylnitrones **3a**—**3d**,[10] *N*-(diphenylmethylene)aniline *N*-oxide (**7**),[11] *N*-(9-fluorenylidene)aniline *N*-oxide (**8**)[11] and *N*-(*p*-diethylaminophenyl)-α-phenylnitrone (**19**)[12] were prepared according to the reported methods respectively.

General Procedure for the Reaction of 1 with 3. A solution of **1** (0.01 mol) and **3** (0.005 mol) in benzene (5 ml) was refluxed. The reaction mixture was evaporated *in vacuo*, and recrystallization of the residue from hexane afforded the corresponding α-[*N*-(trimethylsilyloxy)phenylamino]arylacetonitrile **4**. Reaction conditions, yields, physical and analytical data for **4** are given in Tables 1 and 2.

General Procedure for the Reaction of 2 with 3. A solution of **2** (0.001 mol) and **3** (0.001 mol) in CH_2Cl_2 (20 ml) was stirred at room temperature. The reaction mixture was concentrated *in vacuo* to leave a residue. The residue was triturated with hexane to give crystals, which on recrystallization from hexane afforded the corresponding α-[*N*-(trimethylsilyloxy) phenylamino]-*N*-(diphenylmethylene) benzylamine **5**. Reaction conditions, yields, physical and analytical data for **5** are also shown in Tables 1 and 2.

Detrimethylsilylation of 4a. A solution of **4a** (1.0 g) in EtOH (25 ml) was stirred with concd HCl (20 ml) at room temperature for 1 h. The reaction mixture was poured into water (100 ml) to give solid, which on recrystallization from hexane–benzene afforded 0.69 g (91%) of α-(*N*-hydroxyphenylamino)phenylacetonitrile (**6**), mp 127.5—128.5 °C, as colorless needles. IR 3280 (OH), 2240 cm^{-1} (C≡N); ^1H NMR δ 5.37 (s, 1H, >C**H**), 5.50 (s, 1H, O**H**), 7.0—7.7 (m, 10H); MS *m/e* 224 (M^+). Found: C, 75.09; H, 5.32; N, 12.50%. Calcd for $C_{14}H_{12}N_2O$: C, 74.99; H, 5.38; N, 12.49%.

Treatment of 5a with Hydrochloric Acid in EtOH. A solution of **5a** (0.5 g) in EtOH (10 ml) was stirred with concd HCl (0.5 ml) at room temperature for 0.5 h. To the reaction mixture was added water (6 ml), and filtration gave 0.13 g (61%) of **3a**. The filtrate was extracted with $CHCl_3$, and the extract was concentrated *in vacuo* to leave 0.16 g (80%) of benzophenone.

Reaction of 1 with 7. A mixture of **1** (1.5 g, 0.15 mol) and **7** (0.5 g, 0.0018 mol) was heated at 120 °C for 2 h. The reaction mixture was concentrated *in vacuo* and the residue was triturated with hexane to give crystals, which on recrystallization from AcOEt afforded 0.28 g (82%) of tetraphenylsuccinonitrile (**9**), mp 206—208 °C (lit,[13] mp 213—215 °C), as colorless prisms. IR 2240 cm^{-1} (C≡N); ^1H NMR δ 7.2—7.4 (m); ^{13}C NMR δ 59.2 (quart. C), 121.0 (**C**≡N). Found: C, 87.52; H, 5.16; N, 7.33%. Calcd for $C_{28}H_{20}N_2$: C, 87.47; H, 5.24; N, 7.29%.

The hexane filtrate was chromatographed on silica gel using hexane as eluent to give 0.16 g (89%) of azoxybenzene (**11**).

Reaction of 1 with 8. A mixture of **1** (1.5 g, 0.015 mol) and **8** (0.5 g, 0.0018 mol) was heated at 120 °C for 2 h. A similar treatment of the reaction mixture to that described above afforded 0.31 g (91%) of 9,9′-dicyano-9,9′-bifluorenyl (**10**) as colorless leaves and 0.15 g (84%) of **11**.

10: Mp 284—286 °C (lit,[14] mp 253—255 °C); IR 2240 cm^{-1} (C≡N); ^1H NMR δ 7.0—7.5 (m); ^{13}C NMR δ 53.6 (quart. **C**), 118.5 (**C**≡N). Found: C, 88.36; H, 4.21; N, 7.36%. Calcd for $C_{28}H_{16}N_2$: C, 88.40; H, 4.24; N, 7.36%.

Reaction of 2 with 7. A solution of **2** (1.8 g, 0.0071 mol) and **7** (1.5 g, 0.0055 mol) in CH_2Cl_2 (20 ml) was stirred at room temperature for 21 h. The reaction mixture was concentrated *in vacuo*, and the residue was triturated with hexane to give 1.3 g (86%) of unreacted **7**. MeOH (10 ml) was added to the hexane solution to give crystals. Filtration and recrystallization of the crystals from hexane–benzene afforded 80 mg (8.4%) of *N*,*N*′-bis(diphenylmethylene)tetraphenylethylenediamine (**12**), mp 147—149 °C, as colorless prisms. IR 1620 cm^{-1} (C=N); ^1H NMR δ 6.4—7.6 (m); ^{13}C NMR δ 80.2 (quart. **C**), 168.1 (**C**=N). Found: C, 89.98; H, 5.73; N, 4.12%. Calcd for $C_{52}H_{40}N_2$: C, 90.17; H, 5.66; N, 4.05%.

The hexane–MeOH filtrate was concentrated *in vacuo*, and the residue was chromatographed on silica gel using hexane as eluent to give 30 mg (5.5%) of **11**.

Reaction of 2 with 8. A solution of **2** (0.5 g, 0.002 mol) and **8** (0.5 g, 0.0018 mol) in CH_2Cl_2 (10 ml) was stirred at room temperature for 24 h. The reaction mixture was concentrated *in vacuo*, and the residue was triturated with hexane to give crystals, which on recrystallization from AcOEt–$CHCl_3$ afforded 0.55 g (90%) of 9,9′-bis(diphenylmethyleneamino)-9,9′-bifluorenyl (**13**), mp 206—207.5 °C

(dec), as colorless plates. IR 1610 cm^{-1} (C=N); ^1H NMR δ 6.0—8.0 (m); ^{13}C NMR δ 79.9 (quart. **C**), 167.8 (**C**≡N); MS *m/e* 344 ($M^+/2$). Found: C, 90.61; H, 5.29; N, 4.00%. Calcd for $C_{52}H_{36}N_2$: C, 90.66; H, 5.27; N, 4.07%.

Thermal Decomposition of ***4a***. A solution of **4a** (1.4 g) in xylene (12 ml) was refluxed for 30 h. On cooling to room temperature, crystals separated from solution. Filtration and recrystallization of the crystals from benzene–EtOH afforded 0.2 g (37%) of *meso*-2,3-diphenylsuccinonitrile (*meso*-**14a**), mp 240—242 °C (lit,[15] mp 238—239 °C), as colorless needles. IR 2240 cm^{-1} (C≡N); ^1H NMR δ 4.23 (s, 2H), 7.1—7.5 (m, 10H). Found: C, 82.50; H, 5.12; N, 12.19%. Calcd for $C_{16}H_{12}N_2$: C, 82.73; H, 5.21; N, 12.06%.

The xylene filtrate was concentrated *in vacuo*, and the residue was triturated with hexane to give crystals. Recrystallization from EtOH afforded 0.15 g (28%) of *dl*-2,3-diphenylsuccinonitrile (*dl*-**14a**), mp 169—171 °C (lit,[16] mp 160 °C), as yellow prisms. IR 2250 cm^{-1} (C≡N); ^1H NMR δ 4.22 (s, 2H), 7.1—7.5 (m, 10H). Found: C, 82.54; H, 5.14; N, 12.00%. Calcd for $C_{16}H_{12}N_2$: C, 82.73; H, 5.21; N, 12.06%.

The hexane solution was chromatographed on silica gel using hexane as eluent to give 0.28 g (50%) of **11**.

A similar thermal decomposition of **4b** (1.6 g) in xylene (16 ml) afforded 0.29 g (41%) of *meso*-2,3-bis(*p*-methoxyphenyl)succinonitrile (*meso*-**14b**), 0.26 g (36%) of *dl*-2,3-bis(*p*-methoxyphenyl)succinonitrile (*dl*-**14b**), and 0.46 g (95%) of **11**.

meso-**14b**: Mp 239—241 °C; IR 2260 cm^{-1} (C≡N); ^1H NMR δ 3.80 (s, 6H), 4.15 (s, 2H), 6.8—7.4 (m, 8H); MS *m/e* 292 (M^+), 146 ($M^+/2$). Found: C, 74.05; H, 5.61; N, 9.69%. Calcd for $C_{18}H_{16}N_2O_2$: C, 73.95; H, 5.52; N, 9.58%.

dl-**14b**: Mp 189—190 °C; IR 2250 cm^{-1} (C≡N); ^1H NMR δ 3.84 (s, 6H), 4.12 (s, 2H), 6.8—7.4 (m, 8H); MS *m/e* 292 (M^+), 146 ($M^+/2$). Found: C, 73.89; H, 5.54; N, 9.55%. Calcd for $C_{18}H_{16}N_2O_2$: C, 73.95; H, 5.52; N, 9.58%.

Thermal Decomposition of ***4c***. A solution of **4c** (1.9 g) in xylene (19 ml) was refluxed for 30 h. After being cooled to room temperature, filtration gave crystals which on fractional recrystallization from MeOH–$CHCl_3$ afforded 0.16 g (19%) of *meso*-2,3-bis(*p*-chlorophenyl)succinonitrile (*meso*-**14c**), mp 229—230 °C (lit,[15] mp 234—236 °C), as colorless prisms and 0.1 g (11%) of *p*-chlorobenzanilide (**16c**).

The xylene filtrate was concentrated *in vacuo*, and MeOH (12 ml) was added to the residue to give crystals. Filtration and fractional recrystallization of the crystals from MeOH afforded 0.15 g (17%) of *dl*-2,3-bis(*p*-chlorophenyl)succinonitrile (*dl*-**14c**), mp 181—183 °C, as colorless prisms and 0.38 g (27%) of α-phenylimino-*p*-chlorophenylacetonitrile (**15c**), mp 107—108 °C (lit,[17] mp 108—108.5 °C), as yellow needles. The MeOH filtrate was concentrated *in vacuo*, and the residue was chromatographed on silica gel using hexane as eluent to give 0.28 g (50%) of **11**.

meso-**14c**: IR 2250 cm^{-1} (C≡N); ^1H NMR δ 4.20 (s, 2H), 7.0—7.4 (m, 8H). Found: C, 63.68; H, 3.33; N, 9.23%. Calcd for $C_{16}H_{10}N_2Cl_2$: C, 63.81; H, 3.35; N, 9.30%.

dl-**14c**: IR 2225 cm^{-1} (C≡N); ^1H NMR δ 4.28 (s, 2H), 7.1—7.5 (m, 8H). Found: C, 63.72; H, 3.41; N, 9.18%. Calcd for $C_{16}H_{10}N_2Cl_2$: C, 63.81; H, 3.35; N, 9.30%.

15c: IR 2220 cm^{-1} (C≡N). Found: C, 69.84; H, 3.72; N, 11.56%. Calcd for $C_{14}H_9N_2Cl$: C, 69.86; H, 3.77; N, 11.64%.

Thermal Decomposition of ***4d***. A solution of **4d** (1.5 g) in xylene (16 ml) was refluxed for 30 h. On cooling to room temperature, 0.12 g (11%) of *p*-nitrobenzanilide (**16d**) crystallized out of solution. The xylene filtrate was concentrated *in vacuo*, and recrystallization of the residue from EtOH afforded 0.82 g (75%) of α-phenylimino-*p*-nitrophenylacetonitrile (**15d**), mp 121—123 °C, as yellow prisms. IR 2180 cm^{-1} (C≡N); ^1H NMR δ 7.2—7.6 (m, 5H), 8.4 (m, 4H). Found: C, 67.13; H, 3.55; N, 16.81%. Calcd for $C_{14}H_9N_3O_2$: C, 66.92; H, 3.61; N, 16.73%.

Thermal Decomposition of ***5***. A typical run is shown for the thermal decomposition of **5a**. A solution of **5a** (0.74 g) in benzene (4 ml) was refluxed for 30 h. The reaction mixture was concentrated *in vacuo*, and the residue was triturated with hexane (3 ml) to give crystals, which on recrystallization from AcOEt afforded 0.37 g (84%) of *meso*-*N,N'*-bis(diphenylmethylene)-1,2-diphenylethylenediamine (**17-a**), mp 238—239 °C (lit,[18] mp 228 °C), as colorless prisms. IR 1615 cm^{-1} (C=N); ^1H NMR δ 4.88 (s, 2H), 6.4—7.5 (m, 30H); MS *m/e* 270 ($M^+/2$). Found: C, 88.73; H, 5.96; N, 5.23%. Calcd for $C_{40}H_{32}N_2$: C, 88.85; H, 5.96; N, 5.18%.

The hexane filtrate was chromatographed on silica gel using hexane as eluent to give 79 mg (49%) of **11**.

The results on the thermal decompositions of **5b**—**5d** are shown in Scheme 4.

meso-N,N'-*Bis(diphenylmethylene)-1,2-bis(*p-*methoxyphenyl)ethylenediamine (**17b**)*: Mp 229—230 °C as colorless prisms; IR 1625 cm^{-1} (C=N); ^1H NMR δ 3.72 (s, 6H), 4.78 (s, 2H), 6.4—7.4 (m, 28H); MS *m/e* 600 (M^+), 300 ($M^+/2$). Found: C, 83.91; H, 6.07; N, 4.76%. Calcd for $C_{42}H_{36}N_2O_2$: C, 83.97; H, 6.06; N, 4.66%.

meso-N,N'-*Bis(diphenylmethylene)-1,2-bis(*p-*chlorophenyl)ethylenediamine (**17c**)*: Mp 230—232 °C as colorless prisms; IR 1625 cm^{-1} (C=N); ^1H NMR δ 4.79 (s, 2H), 6.4—7.5 (m, 28H); MS *m/e* 608, 610, 612 (M^+), 304, 306 ($M^+/2$). Found: C, 78.81; H, 4.94; N, 4.50%. Calcd for $C_{40}H_{30}N_2Cl_2$: C, 78.81; H, 4.96; N, 4.60%.

meso-N,N'-*Bis(diphenylmethylene)-1,2-bis(*p-*nitrophenyl)ethylenediamine (**17d**)*: Mp 253—256 °C (dec) as colorless prisms; IR 1620 cm^{-1} (C=N); ^1H NMR δ 4.95 (s, 2H), 6.3—8.2 (m, 28H); MS *m/e* 315 ($M^+/2$). Found: C, 76.21; H, 4.75; N, 8.93%. Calcd for $C_{40}H_{30}N_4O_4$: C, 76.17; H, 4.79; N, 8.88%.

Hydrolysis of ***17a***. A solution of **17a** (0.48 g) in EtOH (20 ml) was stirred with 12% hydrochloric acid (3 ml) at room temperature for 25 h. The reaction mixture was poured into water and extracted with benzene. The benzene extract was concentrated *in vacuo* to give 0.11 g (34%) of benzophenone. The aqueous solution was made basic with aqueous NaOH, and then extracted with $CHCl_3$. The $CHCl_3$ extract was concentrated *in vacuo*, and recrystallization of the residue from cyclohexane afforded 0.1 g (53%) of *meso*-1,2-diphenylethylenediamine (**18**), mp 119—119.5 °C (lit,[18] mp 118 °C), as colorless plates. IR 3330, 3250 cm^{-1} (NH_2); ^1H NMR δ 1.35 (s, 4H, NH_2), 4.02 (s, 2H), 7.0—7.7 (m, 10H); MS *m/e* 212 (M^+). Found: C, 79.08; H, 7.67; N, 13.14%. Calcd for $C_{14}H_{16}N_2$: C, 79.21; H, 7.60; N, 13.20%.

Reaction of ***1*** *with* ***19***. A mixture of **1** (1.0 g, 0.01 mol) and **19** (1.0 g, 0.0037 mol) in benzene (20 ml) was stirred at room temperature for 6 h, during which time the mixture turned into a red solution. The reaction mixture was concentrated *in vacuo*, and the residue was chromatographed on silica gel using $CHCl_3$ as eluent to give 0.9 g (87%) of α-(*p*-diethylaminophenyl)iminophenylacetonitrile (**20**), mp 112—113 °C, as red prisms. IR 2210 (C≡N), 1610 cm^{-1} (C=N); ^1H NMR δ 1.20 (t, 6H), 3.42 (q, 4H), 7.5—8.2 (m, 9H); MS *m/e* 277 (M^+). Found: C, 77.87; H, 6.95; N, 15.15%. Calcd for $C_{18}H_{19}N_3$: C, 77.94; H, 6.91; N, 15.15%.

^{13}C-NMR Study of the Solvent Effect of the *N*-Acetyl-L-alanine Methyl Ester

Tetsuo ASAKURA* and Atsuo NISHIOKA

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 16, 1979)

The ^{13}C-NMR spectra of the *N*-acetyl-L-alanine methyl ester in solution were observed in order to clarify the solvent effect. The assignment of the two kinds of carbonyl groups was carried out on the basis of the difference in the long-range ^{1}H–^{13}C coupling patterns and the spectral change through the hydrolysis of the ester group in a D_2O solution. The internal rotational angle around the N–C$^{\alpha}$ bond was estimated as $-94°$ from the observed value of $^{3}J_{C'-N-C^{\alpha}-H}$, using Bystrov equation. In a trifluoroacetic acid solution, the formation of strong hydrogen bonds accompanying partial protonation between the *N*-acetyl-L-alanine methyl ester and the solvent was suggested. Moreover, the acetyl C=O group tends to interact with trifluoroacetic acid more strongly than the alanyl C=O group.

High resolution NMR spectroscopy has been extensively used to study the helix-coil transition of some synthetic polypeptides induced by such organic acids as trifluoroacetic acid.[1,2]

As the cause of the chemical shift change of the α-CH proton in the backbone chain through the helix-coil transition, two possibilities have been mainly considered. One possibility is a change in the intramolecular shielding effect which is intrinsic to the polypeptide conformation, and the other one is a solvent effect of the peptide residue by the organic acids in the coil state.[1]

On the basis of a theoretical chemical-shift calculation of poly(L-alanine), taking into account only the intramolecular shielding contribution, we have suggested that the latter is more probable, since the α-CH peak in the coil state was predicted to resonate upfield slightly (by 0.1 ppm) from the helical peak position; this is, however, contrary to the observed spectral behavior.[3,4]

In order to clarify such a polypeptide-solvent interaction in solution, it seems useful to investigate the solvent effect of the dipeptide model compounds, since the flexibility of the polypeptide backbone chain originates essentially from the rotation about the N–C$^{\alpha}$ and C$^{\alpha}$–C′ single bonds adjacent to the α-carbons; also, polypeptide-solvent interaction can be expected to occur in a relatively short range along the polypeptide chain.

In our previous paper,[5] we have studied the modes of the self-association of the *N*-acetyl-L-alanine methyl ester (Ac–Ala–OMe) and *N*-acetyl-L-alanine methylamide (Ac–Ala–NHMe) in deuteriochloroform, which is widely used as a helix-supporting solvent of polypeptides, using ^{1}H and ^{13}C-NMR spectroscopies.

In this paper, the ^{13}C-NMR spectra of Ac–Ala–OMe were measured in several kinds of solvents, including trifluoroacetic acid, which is used as a coil solvent of polypeptides, in order to study the solvent effect.

Especially, the ^{13}C-NMR resonances of the carbonyl groups give useful information on the peptide-solvent interaction. However, there is a considerable problem in assigning the carbonyl resonances, since the range of the chemical shifts is relatively small and since the resonance positions of the carbonyl groups depend strongly on the solvent. Thus, the ^{13}C assignment of the acetyl and alanyl carbonyl resonances in Ac–Ala–OMe was carried out on the basis of the difference in the long-range ^{1}H–^{13}C coupling patterns[6,7] and the spectral change through the hydrolysis of the ester group in deuterium oxide.

Experimental

The Ac–Ala–OMe sample was synthesized as has been described previously.[5] The carbon tetrachloride (CCl_4), sulfuric acid (H_2SO_4), and trifluoroacetic acid(CF_3COOH) were purchased from the Tokyo Kasei Company, Ltd. The benzene-d_6 (C_6D_6), dimethyl-d_6 sulfoxide (Me_2SO-d_6), deuteriochloroform ($CDCl_3$), and deuterium oxide (D_2O) were purchased from CEA, France.

The ^{1}H-decoupled ^{13}C-NMR spectra were mostly recorded at 25 °C with a JEOL PS-100 spectrometer equipped with PFT-100 Fourier transform units operating at 25.14 MHz. As for the measurement of the ^{1}H-coupled spectrum, a JEOL FX-60 spectrometer was used operating at 15.01 MHz at 40 °C. The chemical shifts were represented in ppm downfield from internal tetramethylsilane (Me_4Si) except for the D_2O solution. In the D_2O solution, only the partial spectra of the carbonyl region were observed.

Results and Discussion

Assignment of the Carbonyl Resonances in D_2O. Figures 1a) and b) show the ^{1}H-decoupled and -coupled ^{13}C-NMR spectra of the carbonyl carbons of Ac–Ala–OMe in D_2O respectively. The use of D_2O as a solvent leads to a simplification of the ^{1}H-coupled spectrum because the coupling between an exchangeable NH proton and every ^{13}C nucleus in this molecule disappears when the NH proton is exchanged with deuterium. On the basis of the difference in the long-range ^{1}H–^{13}C coupling patterns between the two kinds of carbonyl resonances, the higher-field resonance can easily be assigned to the acetyl C=O group, and the lower-field resonance, to the alanyl C=O group. The long-range ^{1}H–^{13}C coupling constants obtained from the first-order analysis of the spectrum are given as follows:

Acetyl C=O $^{2}J_{C'-C-H} = 5.9\pm0.1$ Hz

$^{3}J_{C'-N-C^{\alpha}-H} = 2.5\pm0.1$ Hz

Alanyl C=O $^{2}J_{C'-C^{\alpha}-H} = 8.1\pm0.2$ Hz

$^{3}J_{C'-C^{\alpha}-C-H} = 4.3\pm0.2$ Hz

$^{3}J_{C'-O-C-H} = 4.3\pm0.2$ Hz

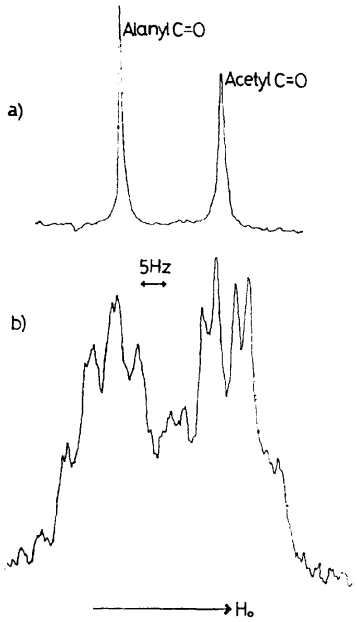

Fig. 1. ^{1}H-decoupled a) and -coupled b) ^{13}C-NMR spectra for the carbonyl region of *N*-acetyl-L-alanine methyl ester at 15.01 MHz (35 v/v % in D_2O at 40 °C). 500 and 2500 transients were collected to obtain the spectra a) and b), respectively. Pulse interval of 30 s was used.

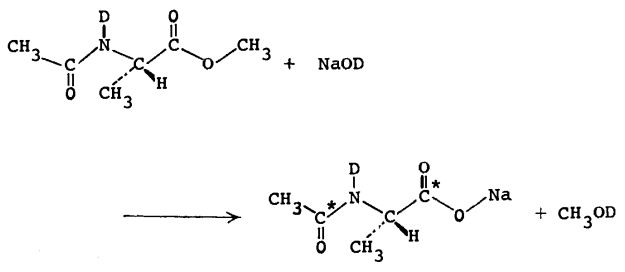
The relative shielding order of these resonances is consistent with that in neat liquid, although the chemical-shift difference between the two peaks becomes small in D_2O (1.68 ppm in 50 v/v% D_2O, 2.16 ppm in neat liquid).[8]

It should be noticed that the acetyl C=O resonance is broader than the alanyl C=O resonance in the ^{1}H-decoupled spectrum (Fig. 1a)). This might come from the coupling between the ^{14}N nucleus and the *N*-linked acetyl C=O nucleus and also the coupling between the amide deuterium and the acetyl C=O nucleus.

Moreover, these carbonyl resonances were also assigned on the basis of the spectral change through the hydrolysis of the ester group in Ac-Ala-OMe. When a trace of NaOD is added to the D_2O solution, the following hydrolysis occurs:



As is shown in Fig. 2, the C=O peaks of the expected hydrolysis product marked by an asterisk appear after the addition of a trace of NaOD to the solution. The peak shifted remarkably to a low field by the hydrolysis can be assigned to the alanyl C=O resonance. This assignment is in agreement with that carried out on

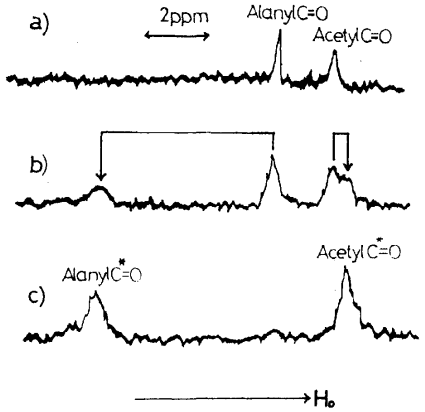


Fig. 2. ^{1}H-decoupled ^{13}C-NMR spectra for the carbonyl region of *N*-acetyl-L-alanine methyl ester at 25.14 MHz at 25 °C.
a) 50 v/v % in D_2O. b) After addition of a trace of NaOD to the solution a). c) Same as b) except for the increase of the amounts of NaOD in the solution.

the basis of the difference in the long-range ^{1}H–^{13}C coupling pattern in the ^{1}H-coupled spectrum.

Conformation of Ac-Ala-OMe in D_2O. Comparing the long-range ^{1}H–^{13}C coupling constants of acetyl C=O and alanyl C=O resonances in the Ac-Ala-OMe spectrum with the corresponding ^{1}H–^{13}C coupling constants of *N*-methylacetamide[7] and methyl acetate[9] respectively, it is found that the values of the corresponding coupling constants are almost the same except for the $^{2}J_{\underline{C}'-C-\underline{H}}$ of the alanyl C=O group. The value of the $^{2}J_{\underline{C}'-C-\underline{H}}$ of alanyl C=O in Ac-Ala-OMe is larger than that in methyl acetate[9] by about 1 Hz.

Especially, the $^{3}J_{\underline{C}'-N-C^{\alpha}-\underline{H}}$ constant is known to obey the general Karplus relation and can be used for determining the internal rotational angle around the N–C^{α} bond, ϕ.[10,11] This value of $^{3}J_{\underline{C}'-N-C^{\alpha}-\underline{H}}$, 2.5 Hz in Ac-Ala-OMe is coincident with the value of $^{3}J_{\underline{C}'-N-C^{\alpha}-\underline{H}}$, 2.5 Hz in Ac-Ala-NDMe in methanol-d_4[10] and corresponds to four angles, ϕ,[12] −94°, −146°, −6°, and 126°, using the Karplus-like equation reported by Bystrov.[10] However, Ingwall and Goodman[13] have reported a conformational energy map for Ac-Ala-OMe in which the low-energy areas enclosed by the 1 kcal mol^{-1} energy contours are spread over the range of $-50° < \phi < -180°$. Thus $\phi = -6°$ and 126° can clearly be eliminated. In our previous paper,[5] we have observed the vicinal coupling constant, $^{3}J_{\underline{H}-N-C^{\alpha}-\underline{H}}$, between the NH and C^{α}–H protons in the ^{1}H-NMR spectra of Ac-Ala-OMe as a function of its concentration in $CDCl_3$. $^{3}J_{\underline{H}-N-C^{\alpha}-\underline{H}}$ increased from 6.1 Hz in neat liquid to 6.9 Hz in 23 v/v% in a $CDCl_3$ solution with dilution. Using the Karplus-like equation reported by Ramachandran *et al.*,[14] the increase in $^{3}J_{\underline{H}-N-C^{\alpha}-\underline{H}}$ from 6.1 Hz to 6.9 Hz corresponds to the variation in ϕ from −75° to −81°. Since the value of $\phi = -94°$ is near to the value obtained from $^{3}J_{\underline{H}-N-C^{\alpha}-\underline{H}}$ in a 23 v/v% $CDCl_3$ solution, $\phi = -94°$ was chosen for the internal rotational angle around the N–C^{α} bond. Taking into account the energy map by Ingwall and

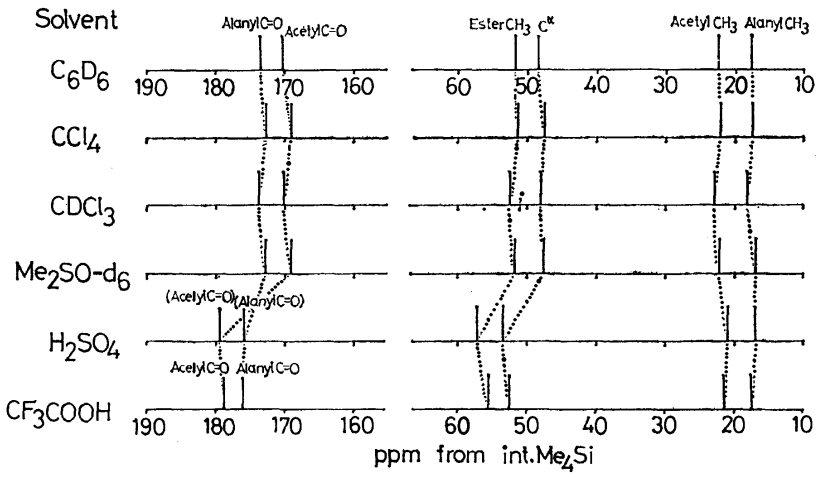

Fig. 3. ^{13}C-NMR stick spectra of *N*-acetyl-L-alanine methyl ester observed in several kinds of solvents (10 v/v %, at 25 °C). Chemical shifts were represented from internal Me_4Si.

Goodman, the value of $\phi = -94°$ may be regarded as ϕ averaged over the low-energy conformations.

Solvent Effect. The ^{13}C-NMR spectra of Ac-Ala-OMe observed in several kinds of solvents are shown in Fig. 3 as stick spectra.

In C_6D_6, CCl_4, and $CDCl_3$ solutions, the resonance positions of the ^{13}C nuclei are scarcely changed among these solvents. A similar spectrum of Ac-Ala-OMe was observed in Me_2SO-d_6. Thus, the amount of the shift induced by Me_2SO-d_6 is very small, although this solvent is well known as a good hydrogenbond-accepting solvent.[5,14-17]

On the other hand, two C=O resonances shift markedly to a low field in the H_2SO_4 solution. Since the peak positions of the acetyl and alanyl C=O groups are reversed in the CF_3COOH solution relative to those in the $CDCl_3$ solution, as will be discussed below, the relative shielding order of these peaks might be reversed in the H_2SO_4 solution compared with that in nonpolar solvents. In this solvent, protonation to the carbonyl groups of Ac-Ala-OMe would occur[18] and the ^{13}C chemical shifts of every ^{13}C nucleus in Ac-Ala-OMe would be influenced by the polarization of these carbonyl groups.[19-23] In truth, the ester CH_3 and C^α carbon resonances shift remarkably to a low field, whereas the acetyl CH_3 and alanyl CH_3 resonances shift slightly a high field.

A ^{13}C peak behavior similar to that of the H_2SO_4 solution was observed in the CF_3COOH solution. However, the amounts of the induced ^{13}C chemical shift are smaller in the CF_3COOH solution than in the H_2SO_4 solution. Thus, it is likely that strong hydrogen bonds with partial protonation[18,24-29] are formed between the solvent and the carbonyl groups of Ac-Ala-OMe in the CF_3COOH solution.

Moreover, the ^{13}C-NMR chemical shift of Ac-Ala-OMe is shown in Fig. 4 as a function of the CF_3COOH composition in the CF_3COOH-$CDCl_3$ solvent systems. With an increase in the CF_3COOH composition, the two carbonyl, ester CH_3 and C^α peaks shift gradually to a low field, while the acetyl CH_3 and alanyl CH_3 carbons shift to a high field in the region of 0—30

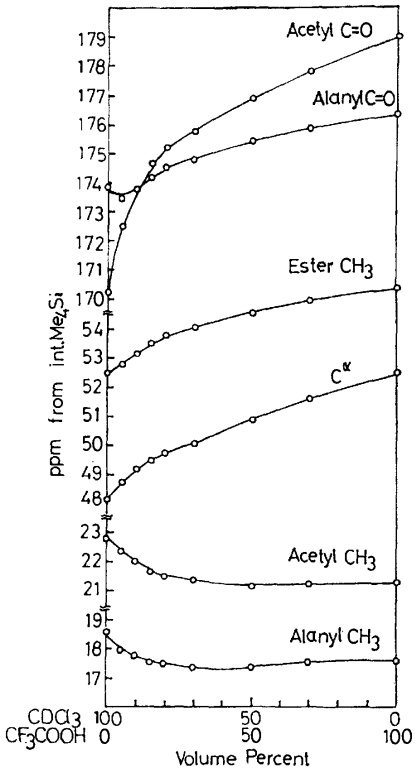

Fig. 4. ^{13}C-NMR chemical shift of *N*-acetyl-L-alanine methyl ester represented as a function of the CF_3COOH composition in $CDCl_3$-CF_3COOH solvent system (10 v/v %, at 25 °C). Chemical shifts were represented from internal Me_4Si.

v/v% CF_3COOH compositions, but do not shift upon a further increase in the CF_3COOH composition. In the two carbonyl resonances, the acetyl C=O peak shift is larger than that of the alanyl C=O peak with an increase in the CF_3COOH composition; as a result, the relative resonance position in the $CDCl_3$ solution is reversed in the CF_3COOH solution. The amount of the solvent-induced shift of the acetyl C=O carbon in Ac-Ala-OMe is comparable with that of the acetyl C=O carbon in

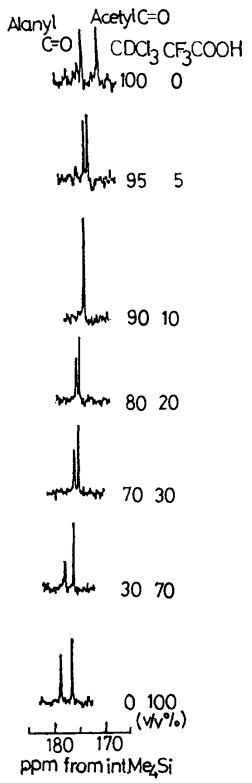

Fig. 5. ^{13}C-NMR spectra for the carbonyl region of *N*-acetyl-L-alanine methyl ester observed in $CDCl_3$–CF_3COOH solvent system (10 v/v %, at 25 °C). Chemical shifts were represented from internal Me_4Si.

N,N-diethylacetamide in the $CDCl_3$–CF_3COOH solvent system.[23] As is shown in Fig. 5, the acetyl C=O peak becomes broader in the region of 20—70 v/v% CF_3COOH composition and again becomes sharp in the 100% CF_3COOH solution, contrary to the alanyl C=O peak behavior. Thus, the acetyl C=O group tends to interact with the CF_3COOH molecule more strongly than the alanyl C=O group. A similar difference in the solvent effect by CF_3COOH is observed among the internal alanyl C=O groups and the *N*-terminal acetyl C=O group in the *N*-acetyl-L-alanyl-L-alanine methyl ester from the ^{13}C-NMR measurements.[30]

These results suggest that the interaction between trifluoroacetic acid and the internal peptide groups of poly(L-alanine) is weaker than that between the acid and simple amide molecules where protonation occurs.[23,26-28] That is, a hydrogen-bond interaction might take place.

The authors are greatly indebted to Dr. Kazuo Sato, of the Central Research Laboratory, Idemitsu Kosan Co., for the measurement of the ^{1}H-coupled NMR spectrum of Ac-Ala-OMe.

Phenanthro[4,5-*bcd*]furan Derivatives. VI. Some Electrophilic Substitution Reactions and Hydrogenation of 4*H*-Cyclopenta-[*def*]phenanthrene, Phenanthro[4,5-*bcd*]furan, and 4*H*-Benzo[*def*]carbazole

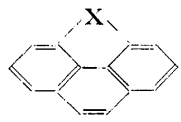
†*Department of General Education, Niigata University, Ikarashi, Niigata 950-21*

(Received July 19, 1979)

Some electrophilic substitution reactions and hydrogenation of 4*H*-cyclopenta[*def*]phenanthrene (**1a**), phenanthro[4,5-*bcd*]furan (**1b**), and 4*H*-benzo[*def*]carbazole (**1c**) have been investigated. The bromination of **1a** and **1b** with bromine gave the corresponding 8-bromo derivatives. The bromination of **1c** however gave the 1,3,5,7-tetrabromo derivative as the sole product. The benzoylation of **1a** and **1b** afforded the corresponding 1-benzoyl derivatives, but in the case of **1c**, the 1,7-dibenzoyl derivative was obtained together with the 4-benzoyl derivative. It appears that ortho- and para-orientation of the nitrogen atom in **1c** is much stronger than that of the methylene group or the oxygen atom in **1a** or **1b**. Hydrogenation of **1a**, **1b**, and **1c** with palladium–charcoal catalyst afforded the corresponding 8,9-dihydro derivatives (**4a**, **4b**, and **4c**). The reduction of **1a** and **1c** with sodium–ethanol gave **4a** and **4c**. The reduction of **1b** however gave the 3,3a,8,9,9a,9b-hexahydro derivative. It appears that facile hydrogenation of the carbon-carbon double bonds at the 8,9-positions in **1a**, **1b**, and **1c** are due to strain in the fused ring system.

The unique structures of 4*H*-cyclopenta[*def*]phenanthrene (**1a**), phenanthro[4,5-*bcd*]furan (**1b**), and 4*H*-benzo[*def*]carbazole (**1c**) are represented by the formulae **1a**—**c** which consist of phenanthrene and methylene or hetero-atom bridge linkages. Therefore, it is expected that **1a** has both the character of phenanthrene (**6**) and fluorene, **1b** has those of **6** and dibenzofuran, and **1c** has those of **6** and carbazole.



1a: X=CH_2
1b: X=O
1c: X=NH

The ultraviolet spectra of **1a**, **1b**, and **1c** are shown in Fig. 1 and those of **6** and pyrene are shown in Fig. 2. **1a** has an absorption spectrum similar to that of phenanthrene itself in the position of absorption bands and shapes suggesting that interaction (hyperconjugation) between the methylene bridge linkage and π-electrons on the phenanthrene ring is very weak. **1c** exhibits absorptions at much longer wavelengths than phenanthrene and the shapes are similar to those of pyrene which is isoelectronic with **1c** showing that interaction between non-bonding electrons on the nitrogen atom and π-electrons on the phenanthrene ring is strong. In addition the position of the absorption spectrum of **1b** lies between those of **1a** and **1c** and the shapes are similar to that of pyrene. It appears therefore that the interaction between non-bonding electrons on the oxygen atom and π-electrons on the phenanthrene ring is of medium intensity. Thus, all absorption regions of **1a**—**c** shift to longer wavelengths as X changes from the methylene group to the oxygen or the nitrogen atom. Consequently a difference in reactivity is expected upon electrophilic substitution. Additionaly it may be expected that the carbon-carbon double bonds at the 8,9-positions in **1a**, **1b**, and **1c** have abnormal character towards hydrogenation compared with the double bond at the 9,10-positions in the phenanthrene owing to the bridge linkage of X. The reactivity of phenanthro-

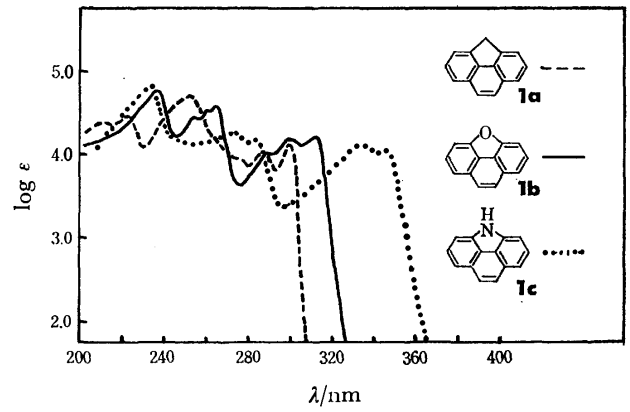


Fig. 1. The ultraviolet spectra of 4*H*-cyclopenta[*def*]-phenanthrene (**1a**), phenanthro[4,5-*bcd*]furan (**1b**), and 4*H*-benzo[*def*]carbazole (**1c**) in ethanol.

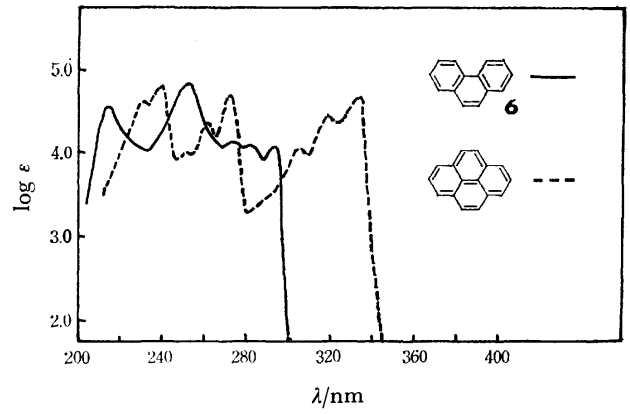

Fig. 2. The ultraviolet spectra of phenanthrene (**6**) and pyrene in ethanol.

[4,5-*bcd*]furan (**1b**) has been previously reported,[1] but there are few reports on the reactivity of **1a**[2] and **1c**.[3] Therefore, the electrophilic substitution reactions and hydrogenation of **1a** and **1c** have been examined and the reactivity of **1b** with that of **1a**, **1c**, and **6** compared.

Results and Discussion

1a was synthesized by the dehydrogenation of 1-hydroxy-1,2,3,3a-tetrahydro-4*H*-cyclopenta[*def*]phenanthrene with palladium–charcoal according to the method of Bachmann.[4] **1c** was prepared in a 53% yield by heating 4-phenanthrylamine at 560 °C using calcium oxide as the catalyst in a nitrogen atmosphere; Kruber *et al.*[3a] have obtained **1c** in a 20% yield at a reaction temperature of 400 °C.

The results of several electrophilic substitution reactions and hydrogenation of **1a**, **1b**, **1c**, and phenanthrene (**6**) are summarized in Table 1.

The bromination of **1a** with bromine gave two products, 8-bromo-4*H*-cyclopenta[*def*]phenanthrene (**2a**) and 4-bromo-4*H*-cyclopenta[*def*]phenanthrene (**2e**) in 42% and 30% yields, respectively. It appears that **2a** was produced by an addition-elimination mechanism and **2e** was formed by a radical reaction. In fact, the bromination of **1a** with *N*-bromosuccinimide gave only **2e** in a 73% yield. The bromination of **1b** and phenanthrene with bromine afforded the corresponding 8-bromophenanthro[4,5-*bcd*]furan (**2b**)[1] and 9-bromophenanthrene (**7**),[5] respectively suggesting that in the case of **1a** and **1b** bromination proceeds by an addition-elimination mechanism rather than by an aromatic substitution mechanism. The reason for this is that the electron density at the ortho- and para-positions to the methylene group or the oxygen atom in **1a** or **1b** is not sufficiently high or the double bonds at the 8,9-positions in **1a** and **1b** are more reactive than the double bond at the 9,10-positions in the phenanthrene owing to strain introduced by bridge linkages as discussed below. Though the former explanation may be reasonable for the bromination of **1a**, the latter is at least plausible for the bromination of **1b** as phenanthrene-4,5-diol afforded 1,3,6,8-tetrabromophenanthrene-4,5-diol[7] by an aromatic substitution mechanism. Therefore, **1a** and **1b** have the character of phenanthrene rather than that of fluorene[8] or dibenzofuran[9] under the bromination conditions. The bromination of **1c** gave a sole product of 1,3,5,7-tetrabromo-4*H*-benzo[*def*]carbozole (**2c**) suggesting that the ortho- and para-positions to the nitrogen atom of **1c** have high electron density by strong resonance between non-bonding electrons on the nitrogen atom and π-electrons on the phenathrene ring. Therefore, the bromination of **1c** proceeds by an aromatic substitution mechanism in preference to the addition-elimination mechanism. Thus, **1c** has the

Table 1. Electrophilic substitution reactions and hydrogenation of 4*H*-cyclopenta[*def*]phenanthrene (**1a**), phenanthro[4,5-*bcd*]furan (**1b**), 4*H*-benzo[*def*]carbazole (**1c**), and phenanthrene (**6**)

	Starting materials

character of carbazole rather than that of phenanthrene as carbazole[10] is most reactive at 3- and 6-positions under the bromination conditions. The experimental results of bromination are parallel to the shifts in the ultraviolet spectra of **1a**, **1b**, and **1c**.

The Friedel-Crafts reaction of **1a** and benzoyl chloride using aluminium chloride as the catalyst gave 1-benzoyl-4*H*-cyclopenta[*def*]phenanthrene (**3a**). The Friedel-Crafts reaction of **1b** and benzoyl chloride afforded 1-benzoylphenanthro[4,5-*bcd*]furan (**3b**).[1] The reaction of **1c** with benzoyl chloride however gave only 1,7-dibenzoyl-4*H*-benzo[*def*]carbazole (**3c**) together with 4-benzoyl-4*H*-benzo[*def*]carbazole (**3g**). The corresponding monobenzoyl derivative was not isolated. The results of the Friedel-Crafts reaction suggest that the para-position to the nitrogen atom in **1c** has higher electron density than those to the methylene group or the oxygen atom in **1a** and **1b**.

The hydrogenation of **1a**, **1b**, and **1c** in the presence of palladium–charcoal gave the corresponding 8,9-dihydro derivatives, **4a**, **4b**, and **4c**, respectively. The double bond at the 9,10-positions of phenanthrene were not hydrogenated under the reaction conditions. Gas chromatographic analysis showed that the rate of reduction from pyrene to 4,5-dihydropyrene was comparable to that of the double bond at the 8,9-positions in **1a** but the rate from 4,5-dihydropyrene to 4,5,9,10-tetrahydropyrene was very slow. This suggests that facile hydrogenation of **1a**, **1b**, and **1c** to the corresponding 8,9-dihydro derivatives (**4a**, **4b**, and **4c**) are due to strain in the fused ring system of **1a**—**c**. This explanation is supported by the fact that reduction of **1b** with lithium aluminium hydride afforded 4-phenanthrol.[1]

The reduction of **1a** with sodium–ethanol gave **4a**, and the reduction of **1b** afforded 3,3a,8,9,9a,9b-hexahydrophenanthro[4,5-*bcd*]furan (**5b**). In the case of **1c**, two products, **4c** and 3,8,9,9a-tetrahydro-4*H*-benzo[*def*]carbazole (**5c**), were obtained in 44% and 29% yields, respectively. Thus, not only the double bonds at the 8,9-positions but also the benzene rings which have hetero-atom substituents were readily reduced when the bridge linkage of X was a hetero-atom. The double bond at the 9,10-positions in phenanthrene was however not reduced under the reaction conditions. Thus, the double bonds at the 8,9-positions in **1a**, **1b**, and **1c** were readily reduced with sodium–ethanol and by catalytic hydrogenation.

Experimental

4H-Cyclopenta[def]*phenanthrene (**1a**).* Colorless plates from methanol; mp 113.5—114.5 °C (lit,[4] 114—115 °C). IR (KBr): ν_{max} 754, 817 cm^{-1} (Ar–H). ^{1}H NMR ($CDCl_3$): δ 4.22 (2H, s, $-CH_2-$), 7.45—7.78 (6H, m, Ar–H), 7.73 (2H, s, Ar–H). ^{13}C NMR ($CDCl_3$): δ 37.1 (C-4), 120.9 (C-3), 122.4, 125.1, 127.0, 127.9 (C-9), 138.2 (C-9b), 141.6 (C-3a). UV(EtOH): λ_{max} (ε) 210 (24300), 220^{sh} (26600), 222 (27800), 225 (24700), 249^{sh} (47500), 252 (50700), 261 (18400), 275 (8700), 287 (10600), 299 nm (12800).

4H-Benzo[def]*carbazole (**1c**).* Colorless plates from benzene–hexane; mp 172—173 °C (lit,[3a] 170—173 °C). IR (KBr): ν_{max} 750, 820 (Ar–H), 3445 cm^{-1} (NH). ^{1}H NMR ($CDCl_3$): δ 7.25 (2H, dd, J=3 and 6 Hz, Ar–H), 7.62—7.80 (5H, m, Ar–H+NH), 7.94 (2H, s, Ar–H). ^{13}C NMR ($CDCl_3$): δ 106.0 (C-3), 115.3, 122.3 (C-9b), 126.0, 126.8, 127.4 (C-9a), 138.8 (C-3a). UV(EtOH): λ_{max} (ε) 234 (63100), 273 (17600), 283 (13500), 332 (12200), 346 nm (10900).

1,3,5,7-Tetrabromo-4H-benzo[def]*carbazole (**2c**).* Bromine (1.1 g) in carbon tetrachloride (20 ml) was added to a carbon tetrachloride solution (30 ml) of **1c** (300 mg), and the mixture stirred for 1 h at room temperature. The precipitated crystals were collected by filtration to give 660 mg (83%) of **2c**. Recrystallization from tetrahydrofuran–benzene gave colorless needles; mp 294—295 °C (lit,[3b] mp 292—293 °C). IR (KBr): ν_{max} 808 (Ar–H), 3460 cm^{-1} (NH). UV(EtOH): λ_{max} (ε) 242 (45800), 248 (50000), 272 (18300), 288 (19000), 298 (13600), 353 (19100), 372 nm (21200). Found: C, 33.25; H, 1.14; N, 2.85%. Calcd for $C_{14}H_5NBr_4$: C, 33.18; H, 0.99; N, 2.76%.

8-Bromo-4H-cyclopenta[def]*phenanthrene (**2a**) and 4-Bromo-4H-cyclopenta*[def]*phenanthrene (**2e**).* Bromine (540 mg) in carbon tetrachloride (10 ml) was added to a carbon tetrachloride solution (30 ml) of **1a** (600 mg), and the solution stirred for 1 h at room temperature. After removal of the solvent, the resulting oil was chromatographed on silica gel and eluted with benzene–hexane (1:9). The first fraction gave 370 mg (42%) of **2a**. Recrystallization from methanol gave colorless needles; mp 91—92 °C. IR(KBr): ν_{max} 770, 780 cm^{-1} (Ar–H). NMR ($CDCl_3$): δ 4.13 (2H, s, Ar–CH_2–), 7.42—7.90 (6H, m, Ar–H), 7.96 (1H, s, Ar–H). UV (EtOH): λ_{max} (ε) 206 (26900), 223 (33900), 251 (48800), 257 (44400), 267 (22000), 283 (9600), 295 (14000), 308 nm (15500). Found: C, 66.73; H, 3.40%. Calcd for $C_{15}H_9Br$: C, 66.94; H, 3.37%.

The second fraction afforded 260 mg (30%) of **2e**. Recrystallization from methanol gave colorless needles; mp 131—132 °C. IR(KBr): ν_{max} 825 cm^{-1} (Ar–H). NMR ($CDCl_3$): δ 6.30 (1H, s, Ar–CHBr), 7.50—7.80 (8H, m, Ar–H). UV (EtOH): λ_{max} (ε) 227 (56700), 243 (21900), 257 (20700), 285 (13600), 298 nm (11700). Found: C, 66.89; H, 3.65%. Calcd for $C_{15}H_9Br$: C, 66.94; H, 3.37%.

*Bromination of **1a** with* N*-Bromosuccinimide.* *N*-Bromosuccinimide (600 mg) was added to a carbon tetrachloride solution (10 ml) of **1a** (300 mg) and the mixture refluxed for 2 h. After removal of insoluble materials by filtration the solvent was evaporated. The resulting crystals were chromatographed on silica gel and eluted with benzene–hexane (1:9) to give 320 mg (73%) of **2e**. The compound was identical with the product obtained by the bromination of **1a** with bromine.

1,7-Dibenzoyl-4H-benzo[def]*carbazole (**3c**) and 4-Benzoyl-4H-benzo*[def]*carbazole (**3g**).* Anhydrous aluminium chloride (840 mg) was added to a carbon disulfide solution (16 ml) of **1c** (400 mg) and benzoyl chloride (800 mg). The mixture was stirred for 6 h at room temperature, decomposed with dilute hydrochloric acid, and extracted with tetrahydrofuran. The solution was washed with water, dried, and evaporated. The resulting crystals were divided into a benzene-insoluble portion and a benzene-soluble portion. The benzene-insoluble portion (270 mg; 32%) was recrystallized from tetrahydrofuran–benzene to give **3c** as yellow needles; mp>300 °C. IR (KBr): ν_{max} 820 (Ar–H), 1630 (Ar–CO), 3240 cm^{-1} (NH). UV (EtOH): λ_{max} (ε) 210 (31200), 237 (41200), 258 (43500), 296 (23000), 397 nm (33500). Found: C, 84.36; H, 4.43; N, 3.55%. Calcd for $C_{28}H_{17}O_2N$: C, 84.19; H, 4.29; N, 3.51%.

The benzene-soluble portion was chromatographed on silica gel and eluted with benzene. The first fraction gave 100 mg (25%) of the starting material (**1c**), and the second fraction afforded 90 mg (15%) of **3g**. Recrystallization from ethanol

gave colorless needles; mp 141—142 °C (lit,[3a] 141—142 °C). IR (KBr): ν_{max} 825 (A–H), 1660 cm^{-1} (Ar–CON). NMR ($CDCl_3$): δ 7.36—7.77 (11H, m, Ar–H), 7.84 (2H, s, Ar–H). UV (EtOH): λ_{max} (ε) 213 (42800), 227 (43000), 256 (30600), 303 (15500), 315[sh] (13900), 338 (2800), 345 (1500), 354 nm (2000). Found: C, 85.50; H, 4.61; N, 4.60%. Calcd for $C_{21}H_{13}ON$: C, 85.40; H, 4.44; N, 4.74%.

1-Benzoyl-4H-cyclopenta[def]*phenanthrene (3a).* Anhydrous aluminium chloride (300 mg) was added to a carbon disulfide solution of **1a** (300 mg) and benzoyl chloride (330 mg). The mixture was stirred for 6 h at room temperature, decomposed with dilute hydrochloric acid, and extracted with ether. The ethereal layer was washed with water, dried, and evaporated. The resulting oil was chromatographed on silica gel and eluted with benzene–hexane (4: 1) to give 380 mg (82%) of **3a**. Recrystallization from methanol gave colorless needles; mp 129—130 °C. IR (KBr): ν_{max} 1640 cm^{-1} (Ar–CO). NMR ($CDCl_3$): δ 4.29 (2H, s, Ar–CH_2), 7.32—7.90 (7H, m, Ar–H), 8.23 (1H, d, J=9 Hz, Ar–H). UV (EtOH): λ_{max} (ε) 210 (34200), 225 (29200), 252 (51200), 321 nm (9600). Found: C, 89.54; H, 4.92%. Calcd for $C_{22}H_{14}O$: C, 89.77; H, 4.79%.

8,9-Dihydro-4H-benzo[def]*carbazole (4c).* A mixture of **1c** (400 mg), 8% palladium–charcoal (350 mg), and ethanol (30 ml) was shaken for 20 h at room temperature under a hydrogen atmosphere. After removal of the catalyst by filtration, the ethanol was evaporated under reduced pressure. The resulting crystals were chromatographed on silica gel and eluted with benzene–hexane (1: 1) to give 330 mg (82%) of **4c**. Recrystallization from benzene–hexane gave colorless plates; mp 124—125 °C (lit,[3b] 124—125 °C). IR (KBr): ν_{max} 773 (Ar–H), 3430 cm^{-1} (NH). NMR ($CDCl_3$): δ 3.27 (4H, s, $-CH_2-+-CH_2-$), 6.93 (2H, d, J=8 Hz, Ar–H), 7.01 (2H, d, J=8 Hz, Ar–H), 7.26 (2H, t, J=8 Hz, Ar–H), 7.39 (1H, broad s, NH). UV (EtOH): λ_{max} (ε) 216 (40300), 246 (34500), 255 (24000), 294 (12000), 316 (3600), 329 nm (3000). Found: C, 86.82; H, 5.83; N, 7.01%. Calcd for $C_{14}H_{11}N$: C, 87.01; H, 5.74; N, 7.25%.

8,9-Dihydro-4H-cyclopenta[def]*phenanthrene (4a).* Hydrogenation of **1a** to **4a** (89% yield) was conducted by the method employed for reduction of **1c**. Recrystallization from methanol gave colorless plates; mp 139—140 °C (lit,[3a] 138—140 °C). IR (KBr): ν_{max} 765 cm^{-1} (Ar–H). NMR ($CDCl_3$): δ 3.10 (4H, s, Ar–CH_2+Ar–CH_2), 3.83 (2H, s, Ar–CH_2), 6.99—7.34 (6H, m, Ar–H). UV (EtOH): λ_{max} (ε) 214 (37000), 228 (15100), 273 (18000), 282 nm (14000). Found: C, 93.47; H, 6.40%. Calcd for $C_{15}H_{12}$: C, 93.71; H, 6.29%.

Reduction of 1c with Sodium and Ethanol. An ethanolic solution (20 ml) of **1c** (200 mg) was heated under reflux. To the solution sodium (3.7 g) was added in limited amounts. When precipitates of sodium ethoxide were produced, additional ethanol (20 ml) was introduced into the solution and the residual sodium was added. After the sodium had disappeared (1 h), the mixture was poured into ice water, and extracted with ether. The ethereal layer was washed with water, dried, and evaporated. The resulting oil was chromatographed on silica gel and eluted with benzene–hexane (1: 1). The first fraction gave 90 mg (44%) of **4c**. The product was identical with the product obtained by the catalytic hydrogenation of **1c** in melting points and infrared spectra. The second fraction afforded 60 mg (29%) of **5c** as crystals. Recrystallization from benzene–hexane gave colorless needles; mp 127—128 °C (lit,[3a] 125—126 °C). IR (KBr): ν_{max} 3420 cm^{-1} (NH). NMR ($CDCl_3$): δ 1.13—1.53 (1H, m, $-CH_2-$), 2.12—2.35 (1H, m, $-CH_2-$), 2.70—3.32 (4H, m, $-CH_2-+-CH_2-$), 3.37—3.53 (1H, m, Ar–CH–), 5.72—6.01 (2H, m, –CH=CH–), 6.72—7.31 (4H, m, Ar–H+NH). UV (EtOH): λ_{max} (ε) 230 (31900), 283 nm (5800). Found: C, 86.25; H, 6.73; N, 7.41%. Calcd for $C_{11}H_{13}N$: C, 86.11; H, 6.71; N, 7.17%.

Reduction of 1a with Sodium and Ethanol. **1a** was reduced by a method similar to the hydrogenation of **1c** with sodium and ethanol. The resulting oil was chromatographed on silica gel and eluted with benzene–hexane (1: 9) to give 130 mg (65%) of **4a**. The product was identical with the sample obtained by the catalytic hydrogenation of **1a** with palladium–charcoal in melting points and infrared spectra.

The authors wish to express their thanks to Mr. Takao Oono for the NMR analyses.

An X-Ray Photoelectron Spectroscopic Study of Several Hydroxy Azo Compounds

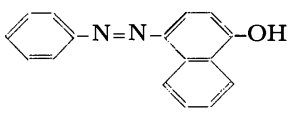
Tooru YOSHIDA

Osaka Prefectural Industrial Research Institute, 2-1-53, Enokojima, Nishi-ku, Osaka 550

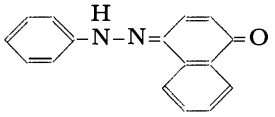
(Received July 23, 1979)

The tautomerism of several solid hydroxy azo compounds has been examined by X-ray photoelectron spectroscopy. It has been found that the proportion of enol and keto tautomers may be readily estimated from the relative intensities of the two peaks in the O(1s) electron spectrum which corresponds to the protonated and deprotonated oxygen atoms. The resonance structures of the sodium salt of 1-phenylazo-2-naphthol and 5-phenylazo-8-quinolinol have been discussed on the basis of the N(1s) and O(1s) electron binding energies.

Phenylazo derivatives of phenols and naphthols can exist either in the enol form (*e.g.* **1**) or in the keto form (*e.g.* **2**). Numerous investigations have been conducted to establish the structure in solution or solid by a variety of techniques *e.g.* visible and UV,[1] Raman,[2] IR,[3] NMR,[4] and X-ray diffraction analysis.[5] Phenylazo derivatives of phenol appear to exist in the enol form both in solution and the solid, whereas in the phenylazo derivatives of naphthols both forms coexist even in the solid state. There have been however few studies concerning a quantitative analysis of the tautomers in solid hydroxy azo compounds.[1e]



1



2

X-Ray photoelectron spectroscopy (XPS), which is sensitive to the charge distribution, is suitable for the detection of protonated atoms.[6] The purpose of the present XPS study is to determine the proportions of enol and keto form tautomers of several solid hydroxy azo compounds, and furthermore, to examine the chemical structures of two compounds; the sodium salt of 1-phenylazo-2-naphthol and 5-phenylazo-8-quinolinol. In the former compound a mobile hydrogen atom is absent in the molecule and in the latter a mobile hydrogen atom is considered fixed by an intramolecular hydrogen bond.

Experimental

The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. Mg $K\alpha$ (1253.6 eV) X-ray radiation was used as the excitation source. The samples were ground to a powder and dusted on to double-backed adhesive tape. The measurements were conducted at room temperature under a vacuum of about 10^{-7} Torr. The binding energy of the C(1s) electron peak was used as the energy standard throughout the present work and has been taken to be 285.0 eV. The reproducibilities of the values thus obtained were within ± 0.1 eV. Appreciable X-ray damage was not observed throughout the experiments. All the compounds used and their binding energies are given in Table 1. Phenylazo, naphthylazo, and quinolylazo derivatives of naphthols were prepared by the standard diazo-coupling reaction with the naphthols. 5-Phen-

TABLE 1. MEASURED BINDING ENERGIES AND PROPORTIONS OF KETO TAUTOMER

Compound	R	Binding energy/eV		R/%[a]	
		N(1s)	O(1s)	A[b]	B[c]
	*o*-OCH_3	400.4	533.3; 530.9	69

1,1′-Azonaphthalene		400.2			

a) The proportion of keto tautomer. b) The values estimated in this study. c) The reported values[1e] estimated from electronic spectra.

ylazo-8-quinolinol was obtained by diazo-coupling with 8-quinolinol in acetic acid.[7] 4-(Phenylazo)phenol and 1-(2-pyridylazo)-2-naphthol were obtained commercially and used after recrystallization from ethanol. The sodium salt of 1-phenylazo-2-naphthol was obtained by treating the naphthol with NaOH in a mixture of ethanol and water: the black crystals separated out were subject to hydrolysis by water and ethanol. Therefore, the crystals collected by filtration were rapidly washed with a small amount of alkaline ethanol and diisopropyl ether, and dried *in vacuo* at 90 °C. The salt thus obtained was brownish black. Found: C, 71.69; H, 4.42; N, 10.47%. Calcd for $C_{16}H_{11}N_2ONa$: C, 71.11; H, 4.07; N, 10.37%. 1,1'-Azonaphthalene and two nickel complexes of phenylazo derivatives of 2-naphthol as reference compounds were prepared according to the literature.[8,9] All compounds were checked by elemental analysis, and all compounds except for the sodium salt and the two metal complexes were also checked by melting point measurement.

Results and Discussion

The Determination of the Equilibria of Tautomers. The O(1s) electron spectrum of 1-phenylazo-2-naphthol is shown in Fig. 1. E_b in the figure indicates the binding energy. The spectrum clearly showed two peaks, which suggested the presence of two types of oxygen atoms in the molecule. The peaks with full-width at half-maximum height (FWHM) of approx. 1.5 eV indicated by the broken lines in the figure were obtained by graphical resolution. P_1 and P_2 indicate their peak heights in Figs. 1 and 2. The binding energy difference between the two peaks was 1.9 eV. The reported values of the difference between the O(1s) binding energies of protonated and deprotonated oxygen atoms have been in the range of 1.4—1.9 eV.[10] Furthermore, the O(1s) electron spectrum of 4-(phenylazo)phenol, which is known to exist as the pure azo compound from the IR study,[3] showed a single peak with a FWHM of 1.5 eV. The binding energy was very similar to that of the peak with the higher binding energy of 1-phenylazo-2-naphthol. Therefore, it appears to be reasonable to assign the peaks with high and low binding energies in Fig. 1 to the protonated and deprotonated oxygen atoms respectively.

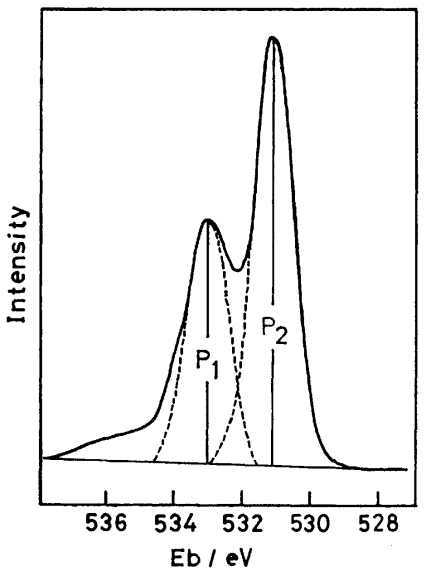

Fig. 1. O(1s) electron spectrum of 1-phenylazo-2-naphthol.

In XPS, the relative intensities of the peaks of a certain atom correspond to the relative amounts of the atom present in different states in the molecule. Therefore, it may be considered that the equation $100 \cdot P_2/(P_1+P_2)$ corresponds to the proportion(%) of the deprotonated oxygen atom and consequently, of the keto form tautomer in such a compound as 1-phenylazo-2-naphthol, which contains only two kinds of oxygen atoms in the molecule—protonated and deprotonated oxygens.

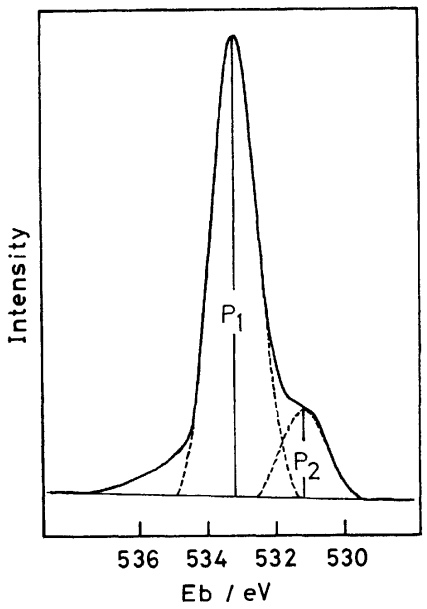

Fig. 2. O(1s) electron spectrum of 1-(*p*-methoxyphenylazo)-2-naphthol.

The O(1s) electron spectrum of 1-(*p*-methoxyphenylazo)-2-naphthol is shown in Fig. 2, as an example of a compound containing a methoxyl group in the molecule. It was found that the O(1s) binding energy of the oxygen atom of a methoxyl group was almost the same as that of a protonated oxygen atom in respect to the O(1s) electron spectra of the two nickel complexes. The O(1s) electron spectrum of bis[1-(*p*-methoxyphenylazo)-2-naphtholato]nickel(II) showed two peaks with nearly equal intensities, and that of bis(1-phenylazo-2-naphtholato)nickel(II) showed a single peak. The O(1s) electron binding energies of the former complex were 533.2 eV and 531.3 eV, and that of the latter was 531.3 eV.

Therefore, the single peak with the higher binding energy of the two in Fig. 2 can be assigned to the oxygen of the methoxyl group in addition to the protonated oxygen, and the other to the deprotonated oxygen. Consequently, in the case of a compound such as 1-(*p*-methoxyphenylazo)-2-naphthol, which contains a methoxyl group, it may be considered that the equation $100 \cdot P_2/(P_1'+P_2)$, where $P_1'=P_1-(P_1+P_2)/2$, corresponds to the proportion of the keto form tautomer.

The O(1s) electron spectra of all other naphthol derivatives showed two types of peak similarly to 1-phenylazo-2-naphthol.

The proportions of keto form tautomer estimated in the above ways are given in Table 1, together with the reported values derived from the electronic spectra by use of the potassium bromide disc.[1e] The values are comparable with the reported values. In this study, errors of approx. 5% were unavoidable due to the incompleteness of graphical resolution.

It appears that the XPS method is more suitable than the electronic spectra method for the determination of equilibria of tautomers in the solid state since the latter method involves considerable uncertainty in the values of the true energies and intensities of the bands of the individual tautomers. Furthermore, it has been said that the spectra obtained by the potassium bromide disc method are not free from the influence of the diluent.[1f]

The N(1s) electron spectra of all hydroxy azo compounds except for the three hydroxy azo compounds containing heterocyclic nitrogen atoms and the sodium salt of 1-phenylazo-2-naphthol showed a single peak with a FWHM (≈1.6 eV) and a binding energy similar to that of a reference compound 1,1'-azonaphthalene, which exists in the pure azo form. Therefore, it was impossible to examine the equilibria of the tautomers on the basis of the N(1s) spectra.

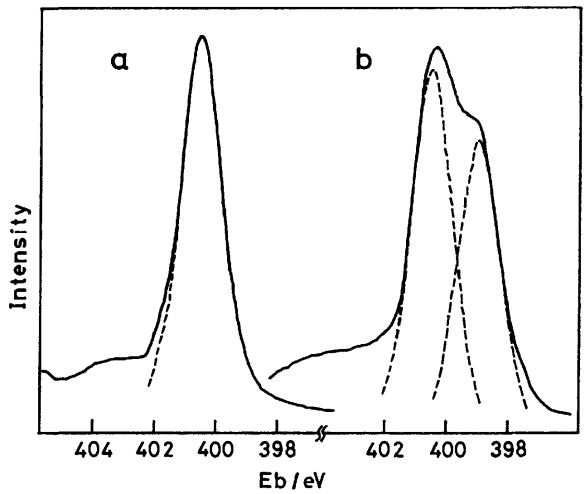

Fig. 3. N(1s) electron spectra of a: 1-phenylazo-2-naphthol and b: its sodium salt.

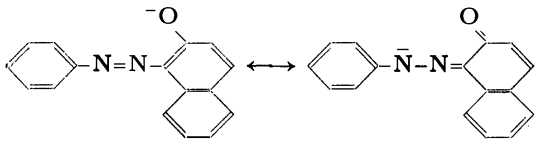
The Sodium Salt of 1-Phenylazo-2-naphthol. The N(1s) spectra of 1-phenylazo-2-naphthol and its sodium salt are shown in Fig. 3. The N(1s) spectrum of 1-phenylazo-2-naphthol showed a single peak, suggesting that the charge densities on the three types of nitrogen atoms, the nitrogen atoms of the azo group, the protonated and deprotonated nitrogen atoms of the hydrazono group, are almost equal. The spectrum of the salt showed two comparable peaks, which suggested the presence of two types of nitrogen atom. The peaks indicated by the broken lines in the figure were obtained by graphical resolution, as were those in Fig. 4. Furthermore, the O(1s) binding energy of the salt was very close to those of the keto form oxygen of hydroxy azo compounds. The results suggest the following resonance contribution:



The inequality in intensities of the two peaks of the salt in Fig. 3(b) may be due to an impurity (probably, 1-phenylazo-2-naphthol produced by hydrolysis of the salt) in the sample. The O(1s) spectrum of the salt showed a peak with some intensity around the energy (533 eV) corresponding to a protonated oxygen atom.

5-Phenylazo-8-quinolinol. The O(1s) electron spectrum of 5-phenylazo-8-quinolinol showed a single peak with a FWHM of 1.6 eV. From its binding energy, the peak was assigned to the protonated oxygen atom. This is consistent with the results[11] from the electronic spectra that 5-phenylazo-8-quinolinol exists predominantly in the enol form in solution due to the presence of an intramolecular hydrogen bond between the heterocyclic nitrogen and the hydroxyl hydrogen.

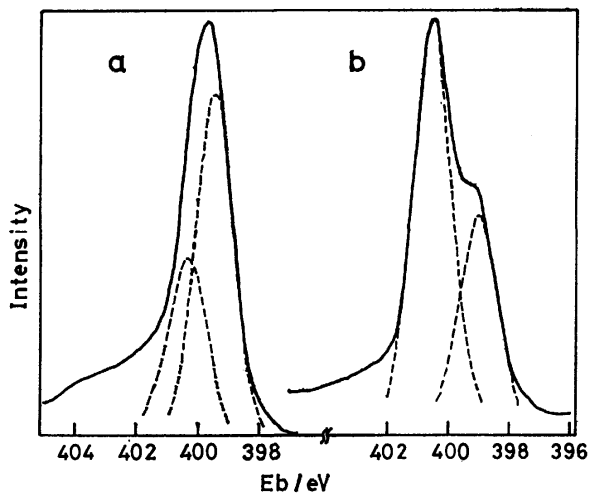


Fig. 4. N(1s) electron spectra of a: 5-phenylazo-8-quinolinol and b: 1-(2-pyridylazo)-2-naphthol.

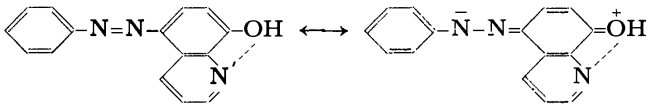
The N(1s) spectra of 5-phenylazo-8-quinolinol and 1-(2-pyridylazo)-2-naphthol are shown in Fig. 4. Both spectra showed two peaks with an intensity ratio of approx. 2: 1. The N(1s) spectrum of 1-(8-quinolylazo)-2-naphthol was very similar to that of 1-(2-pyridylazo)-2-naphthol.

The peak with the lower binding energy of the two in 1-(2-pyridylazo)-2-naphthol and 1-(8-quinolylazo)-2-naphthol can be readily assigned to the heterocyclic nitrogen atom and the other to the nitrogen atoms of the azo group, by comparison with the N(1s) spectra of 1-phenylazo-2-naphthol and 1-(1-naphthylazo)-2-naphthol. That is, the N(1s) binding energy of the heterocyclic nitrogen atom is approximately 399.0 eV.

Therefore, it appears reasonable to assign the two peaks in 5-phenylazo-8-quinolinol with high and low binding energies to the nitrogen atom adjacent to the quinoline ring in the azo group and the remaining

nitrogen atom of the azo group in addition to the heterocyclic nitrogen atom respectively. The inequality of the two nitrogen atoms of the azo group may be caused by the following resonance:[3a)]



Here, the presence of an intramolecular hydrogen bond may stabilize the dipolar form, since the N(1s) spectra of all the hydroxy azo compounds having no such intramolecular hydrogen bond did not show any inequality for the two nitrogen atoms of the azo group.

The intramolecular hydrogen bond appears to be relatively strong, since the O(1s) binding energy of 5-phenylazo-8-quinolinol was not larger than those of the other hydroxy azo compounds. In fact, the N(1s) binding energy of the heterocyclic nitrogen atom was 0.4—0.5 eV higher than those of 1-(2-pyridylazo)-2-naphthol and 1-(8-quinolylazo)-2-naphthol.

In 5-phenylazo-8-quinolinol the contribution of the resonance structure with unit negative charge on the nitrogen atom of the azo group appears to be smaller than that in the sodium salt of 1-phenylazo-2-naphthol from the following result. The differences between the N(1s) binding energies of the two nitrogen atoms of the azo group are 0.9 eV for the former compound and 1.5 eV for the latter.

The author wishes to thank Drs. Kiyoshi Yamasaki and Shigemasa Sawada and Mr. Nobuhiro Kuramoto for their help in performing this experiment and Mr. Taichiro Hirohara for the elemental analysis.

Photochemical Reactions of Aromatic Compounds. XXXIII.[1] Photoreactions of 1-Cyanonaphthalene with Indene in Various Solvents

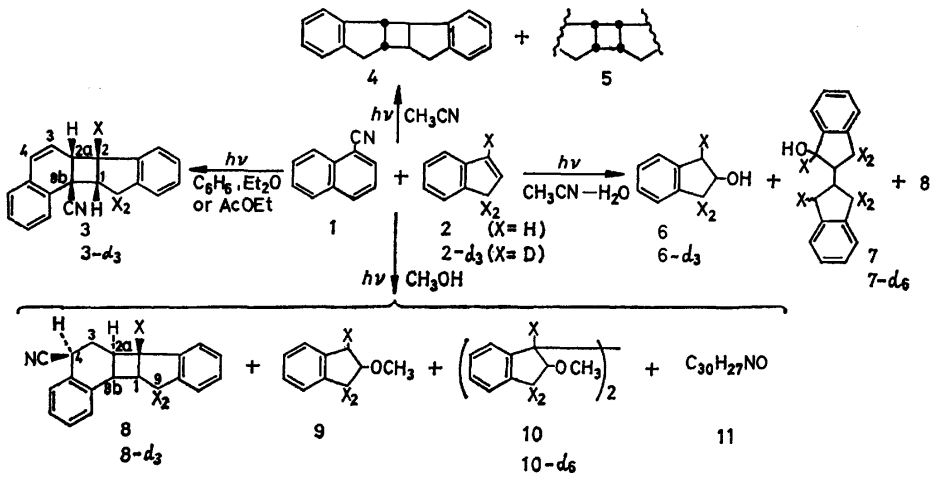
Masahide YASUDA, Chyongjin PAC,* and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received July 25, 1979)

The stereospecific photocycloaddition of 1-cyanonaphthalene to indene occured in cyclohexane, benzene, diethyl ether, tetrahydrofuran, and ethyl acetate, giving the *endo* head-to-head cycloadduct as the sole 1 : 1-adduct. The mechanism was discussed in terms of the exciplex intermediacy. In methanol or in acetonitrile in the presence of water, the photoreaction gave the dihydrocycloadduct (**8**), accompanied by the formation of 2-methoxyindan and 2,2′-dimethoxy-1,1′-biindanyl or 2-indanol and 1-hydroxy-2,2′-biindanyl. In these solvents, the reactions were suggested to be initiated by photochemical electron transfer; the methoxylated or hydroxylated compounds are formed by the nucleophilic attack of methanol or water on the indene cation. Anionic species, including the 1-cyanonaphthalene anion, were suggested to play important roles in the formation of **8**.

Photocycloadditions of aromatic nitriles to furan and olefinic compounds have been extensively investigated with regard to the chemistry of exciplexes.[2,3] The photoreactions more or less depend on the solvent polarity[2a,b,e,f,i,3b,4] and, in a few cases, afford other products in polar solvents which arise from ion radicals.[2f,4] Solvent effects on the photophysics of typical exciplexes have been well documented,[5] and the dissociation into ion radicals has been confirmed to occur in polar solvents.[5,6] The irradiation of exciplex-formation systems in very polar solvents can thus provide a convenient method for the generation of ion radicals, and synthetic applications have been increasingly reported in recent years.[7-9] However, the formation of the final products must compass complex reaction pathways since there independently or concurrently participate such various reaction intermediates as exciplexes, ion-pairs, cation radicals, anion radicals, and free radicals. For example, the photochemical *anti*-Markownikoff addition of methanol to an aromatic olefin in the presence of an electron acceptor includes, at least, a photochemical electron transfer from the olefin to the electron acceptor, the nucleophilic attack of methanol on the cation radical of the olefin, and the reduction of the methoxylated radical by the anion radical of the electron acceptor.[9] Moreover, electron acceptors which are usually aromatic nitriles are more or less consumed by unreclaimed reactions, and the products have not been fully characterized. Thus, the features of the photoreactions of exciplex-formation systems in polar solvents would often vary from system to system. During the course of our investigation of the photoreactions of aromatic nitriles with furan and olefinic compounds, we have found that the photoreactions of 1-cyanonaphthalene (**1**) with indene (**2**) depends not only on the solvent polarity, but also on the nature of the solvent, as is shown in Scheme 1, and that a novel type of photocycloaddition occurs in polar protic media to give a reduced cycloadduct (**8**), which is formed *via* the anionic species of **1**.

Results

Photoreaction in Less Polar Solvents. The irradiation of **1** and **2** in benzene through Pyrex with a high-pressure mercury arc at an ambient temperature gave **3** as the exclusive 1 : 1-adduct, accompanied by small amounts of indene dimers, though over-irradiation resulted in the formation of complex mixtures. Similar results were obtained in the photoreactions of cyclohexane, diethyl ether, tetrahydrofuran, and ethyl acetate solutions. Isomers of **3** could neither be detected



Scheme 1.

by the GLC of the photolysate nor by the NMR of a crude product which had been obtained by passing a photolysate through a short column of silica gel to remove indene dimers and polymeric materials.

The structure of **3** was indicated by its elemental composition and the spectral properties. The ^{1}H NMR spectrum consisted of two sets of double doublets for C_9-methylene protons, two sets of multiplets for H-1 and H-2a, a triplet for H-2, a doublet of doublets for H-3, a doublet for H-4, and multiplets for aromatic protons. Since the signal for H-2 appears as a triplet, **3** can be identified as a head-to-tail adduct. This assignment was further confirmed by the NMR spectrum of **3**-d_3; this compound was obtained by the photocycloaddition of **1** to indene-1,1,3-d_3 (**2**-d_3). It showed a broad singlet for H-1 and a broad doublet for H-2a at positions identical to those of the respective centers of the two sets of multiplets for **3**, while the olefinic and aromatic resonances were essentially identical to those for **3** in all respects.

The *endo*-configuration for **3** was suggested by the unusually high chemical shifts of the olefinic protons and an aromatic proton; the olefinic protons show upfield shifts of more than 0.34 and 0.27 ppm relative to the corresponding protons of similar compounds.[2b,h-j,3a,b,10] Similarly, the aromatic proton is considerably shielded (more than 0.2 ppm). The shielding effects on the protons can be reasonably understood by means of molecular models with the *endo*-configuration; the benzene ring of the indan moiety is located just over the olefinic protons and the aromatic proton of the indan moiety extends over the edge of the other benzene ring. On the other hand, the shielding effects can not be expected from the *exo*-configuration.

Photoreaction in Acetonitrile in the Presence of Water. The irradiation of an acetonitrile solution of **1** and **2** gave an *anti* head-to-head cyclobutane dimer, **4**, in a 50% yield, accompanied by only small amounts of **3** and the *syn* head-to-head cyclobutane dimer, **5**, whereas 70% of the **1** was recovered. Control experiments using 313 nm light, where **1** absorbed mostly the incident light, showed that **4** and **5** were formed in a 95: 5 ratio, while the head-to-tail dimers could not be detected.

The formation of the indene dimers was remarkably "quenched" by water. In the presence of 10 vol% of water we obtained 2-indanol, **6**, 1-hydroxy-2,2′-biindanyl, **7**, and a new cycloadduct, **8** in 58%, 23%, and 25% yields respectively, while the indene dimers were not formed. The structure of **6** was unambiguously determined by a direct comparison with an authentic sample prepared by the reduction of 2-indanone[11] with sodium borohydride.

The structure of **7** was deduced from the spectral properties. The NMR spectrum showed a broad triplet for H-1, a broad doublet for O–H, and complex signals for the other aliphatic protons and aromatic protons. On the addition of deuterium oxide, the broad doublet disappeared along with a collapse of the broad triplet into a sharp doublet. The NMR spectrum of **7**-d_6 showed a broad singlet for O–H at δ 1.7, a broad doublet for H-2 at δ 2.3, an asymmetrical broad triplet for H-2′ at δ 2.46, and two sets of doublets with small splittings for H-1′ at δ 2.86—3.24, clearly supporting the structure assigned. Probably, H-1′ is located in either a *cis* or *trans*-relationship with H-2′.

The mass spectrum of **8** which showed a very weak molecular ion peak at *m/e* 271 and strong fragment-ion peaks at *m/e* 116 and 155, indicates that **8** is a dihydro-adduct of **1** and **2**. The ^{1}H NMR spectrum consisted of signals for nine aliphatic protons and eight aromatic protons, but showed none for olefinic protons. Each signal for the aliphatic protons was resolved by means of extensive double-irradiation experiments, lanthanoid-induced shifts (LIS), and deuterium-labelling experiments. The data are listed in Table 1. For example, the doublet of doublets at δ 3.64 can easily be assigned to the signal for the proton (H-4) attached to cyanated carbon, since this signal showed the largest shift downfield on the addition of Eu(fod)$_3$ and since this signal was absent in the spectrum of **8**-*d*; this compound was obtained by refluxing a dioxane–methanol-*O*-*d* solution of **8** in the presence of sodium methoxide.

In the NMR spectrum of **8**-d_3, the signal for H-8b appeared as a broad triplet, demonstrating that **8** is a head-to-tail adduct. The *cis*-relationship between H-2a and H-4 was deduced from the vicinal couplings with H-3A (one of the C-3 methylene protons); the coupling constants are very similar to those of the axial-axial couplings for cyclohexane compounds.[12] When a solution of **8** in dioxane–methanol was refluxed in the presence of sodium methoxide, an equilibrium mixture

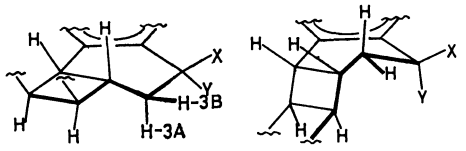
	(m)	(t)	(m)	(m)		(d-d)	(t)	(d-d)	(d-d)	$J_{3A2a}=5.0, J_{3B,2a}=6.5$

a) Aromatic signals (δ 6.9—7.5) are omitted. b) 0.4 equiv of Eu(fod)$_3$ added.

of **8** and **12** was obtained in a 1 : 4 ratio, clearly demonstrating that **8** is thermodynamically less stable than **12**.

For **8**, the half-chair conformation (A) would be much more favorable than the negative half-chair conformation (B) because of the steric repulsion between the cyano group and the cyclobutane ring. In fact, the vicinal coupling constants of H-3A and H-3B are very similar to those of the axial-axial and axial-equatorial couplings for cyclohexane compounds respectively. Similarly, the B conformer or, more probably, an equilibrium mixture of A and B would be favorable for **12**. With the *endo*-structure, however, B is extremely unstable because of the nonbonding interaction between H-4 and the benzene ring of the indan moiety, since the closest separation between them is only 1.8—2.0 Å, as is shown by the molecular models. If **8** and **12** had this structure, **8** could be expected to be more stable than **12**. Therefore, this structure can not be accepted. On the other hand, **12** can exist in either A or B with the *exo*-configuration; it is thus more stable than **8**. Therefore, the *exo*-configuration can be assigned to **8** and **12**.



A B

8 (X=H; Y=CN) **12** (X=CN;Y=H)

Photoreaction in Methanol. The irradiation of a methanolic solution of **1** and **2** gave **8** in a 35% yield, along with several other products, including mainly 2-methoxyindan (**9**) and diastereoisomeric mixture of 2,2′-dimethoxy-1,1′-biindanyl (**10**). These compounds were confirmed to be the primary photoproducts, since their formation increased linearly with the irradiation time up to *ca.* a 10% conversion.

The structure of **9** was determined by a direct comparison of its spectral properties with those of an authentic sample which had been prepared by the methylation[13] of 2-indanol with diazomethane in the presence of boron trifluoride etherate.

The repeated chromatography of mixtures of **10** on silica gel gave three isomers (**10a**, **10b**, and **10c**) contaminated by small amounts of the others and a fourth isomer (**10d**) in a mixture with an equal amount of **10b**. In the mass spectra, only **10c** showed the molecular ion peak at *m/e* 296, whereas the main fragment-ion peaks at *m/e* 262 and 198 were commonly observed for **10a**—**c**. The NMR spectra of **10a**—**c** commonly consisted of the signals for aliphatic protons, methoxyl protons, and aromatic protons in the area ratio of *ca.* 4 : 3 : 4, showing that **10a**—**c** are dimeric compounds of **2** which possess two methoxyl groups.

The signals of aliphatic protons are too complex to be assigned. Therefore, the d_6-compounds of **10** were prepared by a photoreaction using **2**-d_3; the NMR spectra were then taken (Table 2). The aliphatic resonances should be the signals for H-2 and H-2′. Since the chemical shifts are relatively low, two methoxyl groups can be said to attach themselves to C-2 and C-2′. For structural elucidation, it should be noted that H-2 and H-2′ or the two methoxyl groups are magnetically equivalent for **10c** and **10d**, but not for **10a** and **10b**. Therefore, **10a** or **10b** appears to be either isomer of the *cis*, *trans*-structure. The *trans*, *trans*- or *cis*, *cis*-structure should be reserved for **10c** and **10d**.

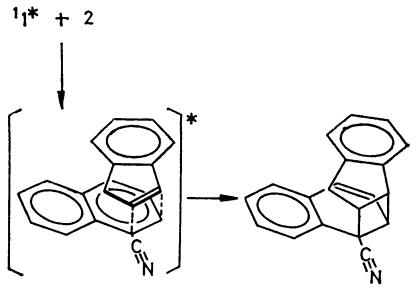
TABLE 2. ^{1}H NMR SPECTRAL DATA FOR **10**(**a**—**d**)-d_6

	H-2 and H-2′		OCH_3	
10a	3.65	3.98	2.80	3.15
10b	3.65	4.20	3.24	3.38
10c	3.60		2.96	
10d	3.88		3.25	

From complex mixtures of oligomeric and polymeric materials, a 1 : 2 : 1-adduct of **1**, **2**, and methanol (**11**) was isolated by repeated chromatography. However, the isolation was poorly reproducible because of the low yields as well as difficulties in the isolation. The structure could not be determined.

Discussion

An excited-singlet mechanism is responsible for the formation of **3**, since the fluorescence of **1** was quenched by **2** at a diffusion-controlled rate ($k_q = 1.2 \times 10^{10}$ dm^3 mol^{-1} s^{-1} in benzene) and the triplet photosensitization using benzophenone or Michler's ketone did not give **3** at all. It is of mechanical interest to note that the *endo* cycloadduct (**3**) was exclusively formed. This stereoselectivity can be interpreted in terms of the intermediacy of the **1**—**2** exciplex possessing a sandwich-type configuration. The excited singlet **1** has been known to form exciplexes with a variety of alkenes,[14] and the ionization potential of **2** is low (8.14 eV)[15] enough for the formation of the **1**—**2** exciplex. Therefore, the exciplex mechanism is not unreasonable, though exciplex emission could not be detected. Moreover, it should be noted that the head-to-tail structure of **3** can not be expected from the most stable 1,4-biradical and 1,4-dipolar intermediates. This suggests that the photocycloaddition is stereospecific in nature, as has been reported in the photocycloaddition of **1** to *cis*- and *trans*-1-phenoxypropenes.[2h]



This photocycloaddition still occurs in such a moderately polar solvent as ethyl acetate, but it does not in acetonitrile and methanol; the exciplex formation is dominant in ethyl acetate and less polar solvents. In very polar solvents, however, a complete electron-transfer reaction predominantly occurs to give the

anion radical of **1** ($\mathbf{1}^{\cdot-}$) and the cation radical of **2** ($\mathbf{2}^{\cdot+}$), a conclusion supported by the free-energy change (ΔG) calculated using Eq. 1:[16]

$$\Delta G(\text{kcal/mol}) = 23.06[E_{1/2}(\mathbf{2}/\mathbf{2}^{+}) - E_{1/2}(\mathbf{1}/\mathbf{1}^{-}) - e_{o}^{2}/\varepsilon\alpha] - E_{0-0}(\mathbf{1}) \quad (1)$$

where $E_{1/2}(\mathbf{2}/\mathbf{2}^{+}) = 1.24$ V *vs.* Ag/Ag^{+} in acetonitrile, $E_{1/2}(\mathbf{1}/\mathbf{1}^{-}) = -2.33$ V *vs.* Ag/Ag^{+} in acetonitrile, and $E_{0-0}(\mathbf{1}) = 89.1$ kcal/mol.[17] If the Coulombic term ($e_{o}^{2}/\varepsilon\alpha$) is estimated to be small (*ca.* 1.5 kcal/mol), the value of ΔG can be calculated to be *ca.* -5 kcal/mol, indicating that the electron-transfer process is substantially exothermic, probably occuring at a diffusion-controlled rate.[16]

Table 3. Isomer ratios of indene cyclobutane dimers

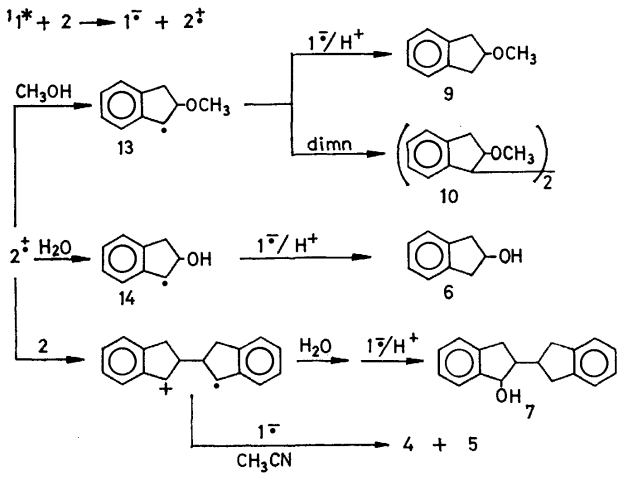
Benzophenone-sensitization[c]	3	84	5	8

a) Ref. 18. b) In the presence of 1,3-cyclohexadiene. c) W. Metzner and D. Wendisch, *Ann.*, **730**, 111 (1969).

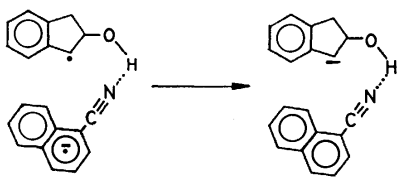
In fact, the photoreaction in acetonitrile gave the *syn* and *anti* indene dimers in a ratio very similar to that observed in the dimerization *via* $\mathbf{2}^{\cdot+}$,[18] as is shown in Table 3. This cation radical mechanism is further supported by the remarkable "quenching" of dimer formation on the addition of only a few vol% of methanol or water. This "quenching" appears to be caused by the nucleophilic attack of methanol or water on $\mathbf{2}^{\cdot+}$, which ultimately results in the formation of **9** and **10** or **6**, as is shown in Scheme 2.



Scheme 2.

Table 4 lists the product distribution of the photoreactions in methanol and in acetonitrile in the presence of methanol and water. The most notable points are (1) the slow formation of the products in methanol, (2) the poor yields of **9** and the formation of considerable amounts of **10** in either methanol or acetonitrile–methanol, and (3) the relatively good yield of **6** and the lack of any formation of a compound corresponding to **10** (*i.e.* 2,2′-dihydroxy-1,1′-biindanyl) in acetonitrile–water.

Apparently, the **13** radical can undergo the dimerization reaction competitively with the reduction by $\mathbf{1}^{\cdot-}$, while the reduction of the **14** radical by $\mathbf{1}^{\cdot-}$ is much faster than the dimerization reaction. The reduction potential of **13** is not significantly different from that of **14**, as is to be expected from their similar π-electronic structures. Therefore, the efficient reduction of **14** must be caused by factors other than the reduction potential. For example, a hydrogen-bonding between $\mathbf{1}^{\cdot-}$ and **14** would necessitate their approaching within an effective distance for the reduction and/or would facilitate the electron flow from $\mathbf{1}^{\cdot-}$ to **14**. On the other hand, such a hydrogen-bonding can not occur with **13**.

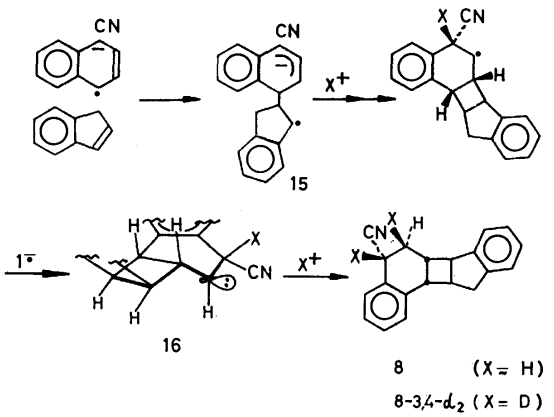


Compound **8** was confirmed to be formed *via* anionic species including $\mathbf{1}^{\cdot-}$, since the photoreaction in methanol-*O*-*d* gave **8**-3,4-d_2. In the NMR spectrum, the signals of H-4 and H-3B were completely absent, whereas that of H-3A at δ 1.16 appeared as a broad doublet ($J \simeq 13$ Hz). The NMR data demonstrate the stereospecific incorporation of the two deuterium atoms in the *cis*-relationship at C-3 and C-4. Scheme 3 delineates the possible mechanistic pathways which can interpret the stereochemistry in the formation of **8** and **8**-3,4-d_2. The anion radical of **1** would undergo a radical type of addition to **2**, giving the addend anion radical (**15**). The protonation of **15** probably occurs on the less hindered side at cyanated carbon, thus assuring the *cis*-relationship between the cyano group and the cyclobutane ring in **8**. Similarly, the deuterium incorporation at C-3 would stereospecifically occur on

Table 4. Product distribution of the photoreactions of **1** with **2** in protic media[a]

Solvent	Irradn time / h	Conversion/%		Product (yield/%)[b]	
		1	**2**		
CH_3CN–H_2O (9: 1)	15	42	≈100	**6** (55)	**7** (25)
CH_3CN–CH_3OH (9: 1)	19	42	≈100	**9** (37)	**10** (53)
CH_3OH	22	56	63	**9** (23)	**10** (23)

a) [**1**] = [**2**] = 0.1 mol dm^{-3}; irradiation at 313 nm using a merry-go-round apparatus. The yields of **8** were not determined. b) GLC yields based on the **2** consumed.



Scheme 3.

the *quasi*-equatorial position of the half-chair conformation A of the anion (**16**). On the other hand, the selective formation of **8** can not be reasonably interpreted by an alternative mechanism that includes the initial protonation at cyanated carbon of $\mathbf{1}^{\cdot-}$, followed by the addition of the protonated radical to **2**. According to this mechanism, the sterically favorable approach of **2** to the protonated radical seems to occur in the *trans*-relationship with the cyano group rather than in the *cis*-relationship, leading to the formation of **12**. Finally, it should be pointed out that this type of reductive photocycloaddition *via* the anion radical has not been reported previously, though photochemical cross-cycloadditions *via* cation radicals are known.[19]

Experimental

The following instruments were used for the spectral measurements: ^{1}H NMR, Hitachi R-24 (60 MHz) and JEOL JNM PS-100 (100 MHz); IR, Shimadzu IR-400; UV, Hitachi 124; MS, Hitachi RMU-6E; fluorescence spectra, Hitachi MPF-2A. The GLC was carried out on a Shimadzu GC-3BF apparatus using a column of SE-30 (5% on Celite 545, 0.75 m) at 195 °C for **3**, **7**, **8**, and **10** and at 180 °C for **4** and **5**, and a column of Ucon Oil LB-550X (5% on Celite 545, 0.75 m) at 170 °C for **6** and **9**. Irradiation was carried out in a Pyrex vessel with an Eikosha PIH-300 high-pressure mercury arc under cooling with water. All the solutions were bubbled with an N_2 stream for 30 min before irradiation. The melting points are uncorrected.

Materials. Commercial thiophene-free benzene was washed with sulfuric acid until no further coloration of the acid layer took place, and then washed with water and distilled from P_2O_5. Spectrograde cyclohexane (Nakarai Chemicals) was used without further purification. The dioxane was refluxed over sodium and then distilled. The tetrahydrofuran and diethyl ether were distilled from $LiAlH_4$. The acetonitrile was distilled three times from P_2O_5 and then from CaH_2. The methanol was refluxed over CaH_2 and then distilled. The indene was distilled from sodium under reduced pressure prior to use. The 1-cyanonaphthalene (Tokyo Kasei) was chromatographed on silica gel and then distilled *in vacuo*.

Preparation of Indene-1,1,3-d_3. A solution containing indene-d_0 (23 g, 0.2 mol), 1,8-diazabicyclo[5.4.0.]undec-7-ene (3 g, 20 mmol), and deuterium oxide (40 g, 2.0 mol) in dry dioxane (100 ml) was refluxed under an N_2 atmosphere for 20 h and then about one half of dioxane was distilled off. The remaining solution was poured into 1000 ml of ice-water. The oil layer was separated, washed with 1 mol dm^{-3} hydrochloric acid, with an aqueous solution of $NaHCO_3$, and three times with water, and then dried ($MgSO_4$). After filtration, the filtrate was distilled *in vacuo* to give deuterated indene. The above procedure was repeated for this indene. Finally, 12 g of indene-1,1,3-d_3 (50% yield) were obtained. The isotopic purity was confirmed to be over 95% by a study of the NMR and mass spectra.

Photoreaction in Less Polar Solvents. As a typical run, the photoreaction in diethyl ether will be described. A solution of **1** (0.47 g, 3 mmol) and **2** (7.5 g, 67 mmol) in 200 ml of diethyl ether was irradiated for 20 h. After the removal of the diethyl ether, 6.5 g of **2** was recovered by the vacuum distillation of the remaining oil. The residue was chromatographed on silica gel, using mixtures of hexane and benzene as the eluents. After **4** and **5** (*ca.* 0.1 g) had been eluted with hexane, 0.32 g of **1** was eluted with 30% benzene in hexane. Further elution by a 1: 1-mixture of hexane–benzene gave 0.1 g of **3** (38% yield based on the unrecovered **1**), which was then recrystallized from ethanol–benzene; mp 146—147 °C; IR (Nujol): 2220 (C≡N) and 1640 cm^{-1} (C=C); UV (CH_3CN): λ(log ε) = 302 (sh), 273 (3.89), and 265 nm (3.89); MS: 269 (M^+, vw), 153, and 116; NMR ($CDCl_3$): δ 2.8 and 3.2 (d-d each, 2H, $-CH_2-$), 3.9 (m, H-1), 4.1 (m, H-2a), 4.32 (t, J=8.0 Hz, H-2) 5.38 (d-d, J=4.5 and 10.0 Hz, H-3), 5.96 (d, J=10.0 Hz, H-4), 6.5 (d, 1×ArH), and 6.8—7.3 (m, 7×ArH); Found: C, 89.03; H, 5.58; N, 5.11%. Calcd for $C_{20}H_{15}N$: C, 89.18; H, 5.61; N, 5.20%.

Photoreaction in Acetonitrile. A solution of **1** (0.94 g, 6 mmol) and **2** (11 g, 100 mmol) in 250 ml of acetonitrile was irradiated for 100 h. After the removal of the acetonitrile, 9.3 g of **2** were recovered by vacuum distillation. The residue was chromatographed on silica gel; subsequent elution with hexane gave 0.85 g of the *anti* head-to-head indene dimer **4** (50% yield based on the unrecovered **2**), which was then recrystallized from ethanol; mp 109—110 °C (lit,[20] 110 °C). Further elution with 30% of benzene in hexane gave 0.7 g of **1**.

Photoreaction in Acetonitrile–Water. A solution of **1** (0.2 g, 1.3 mmol) and **2** (2.0 g, 18 mmol) in 55 ml of acetonitrile–water (10: 1) was irradiated for 50 h. GLC showed that the **1** had been completely consumed. The solids which had been precipitated during the irradiation were filtered out and then washed with 10 ml of cold methanol; 0.19 g of **7** was thus obtained. The filtrate was condensed, and then 10 ml of hot methanol were added. After cooling, the solids were again precipitated; filtration and washing with 10 ml of cold methanol gave another 0.18 g of **7**. The combined yield of **7** was 23%, based on the unrecovered **2**. The **7** was then recrystallized from ethanol; mp 182—183 °C; UV (CH_3CN): λ (log ε) = 272 (3.32), 265 (3.31), and 259 nm (sh); MS: 250 (M^+, vw), 232 ($M-H_2O$), and 116; NMR ($CDCl_3$): δ 1.8 (d, O–H), 2.14—3.46 (m, 8H), 4.96 (t, OCH), and 7.0—7.5 (m, 8H); Found: C, 86.14; H, 7.11%. Calcd for $C_{18}H_{18}O$: C, 86.36; H, 7.25%.

To the filtrate, a 20-ml portion of chloroform was added, and then the mixture was dried ($MgSO_4$). After filtration, vacuum distillation gave 0.5 g of **2** and 1.0 g of 2-indanol **6** (mp 68—69 °C, 58% yield). The residue was chromatographed on silica gel; elution with 40% benzene in hexane gave 90 mg of **8** (25% yield based on the **1** used), which were then recrystallized from ethanol–benzene; mp 207—208 °C; IR (KBr): 2220 cm^{-1} (C≡N); MS: 271 (M^+, vw), 155, and 116; UV (cyclohexane): λ (log ε) = 274 (3.11), 267 (3.11), and 262 nm (3.04); Found: C, 88.27; H, 6.28; N, 5.20%. Calcd for $C_{20}H_{17}N$: C, 88.52; H, 6.32; N, 5.16%.

Photoreaction in Methanol. A solution of **1** (1.0 g, 6.5 mmol) and **2** (6.0 g, 54 mmol) in 200 ml of methanol was

irradiated for 25 h. After the removal of the methanol, vacuum distillation gave 3.5 g of **2** and 0.4 g of 2-methoxyindan **9** (12.5% yield, based on the unrecovered **2**). The residue was chromatographed on silica gel; after a mixture of **4** and **5** (*ca.* 0.1 g, 4% yield) had been eluted with hexane, elution with 40% benzene in hexane gave a viscous oil, to which 10 ml of hot methanol were then added. Cooling while the solution was scratched gave white solids, which were then filtered and washed with 5 ml of cold methanol; 0.31 g of **8** (35% yield based on the unrecovered **1**) was thus obtained. The subsequent vacuum distillation of the filtrate gave 0.5 g of **1**. Further elution with benzene and acetone gave mixtures of **10** and polymeric materials. Vacuum distillation gave 0.6 g of **10** (160—163 °C/0.1 mmHg, 19% yield), which was chromatographed on silica gel, using benzene and 2—10% ethyl acetate in benzene as the eluents. Each fraction was further chromatographed. This procedure was repeated three times for each fraction to give 30—50 mg of **10a**, **10b**, a mixture of **10b** and **10d**, and **10c**. **10a**: mp 97—98 °C (from methanol); MS: 262 ($M-CH_3OH$) and 147 (M/2); NMR (CCl_4): δ 2.7—3.15 (m, 4H), 2.83 (s, OCH_3), 3.16 (s, OCH_3), 3.6—4.0 (m, 4H), and 7.0—7.4 (m, 8H); Found: C, 81.37; H, 7.44%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%. **10b**: mp 170—172 °C (from methanol); MS: 262 ($M-CH_3OH$) and 147 (M/2); NMR ($CDCl_3$): δ 2.7—3.1 (m, 4H), 3.24 (s, OCH_3), 3.38 (s, OCH_3), 3.55—3.75 (m, 2H), 4.13—4.35 (m, 2H), and 7.0—7.3 (m, 8H); Found: C, 81.41; H, 7.39%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%. **10c**: mp 70—73 °C (from methanol); MS: 294 (M^+, w), 262 ($M-CH_3OH$), and 147 (M/2); NMR (CCl_4): δ 2.7—3.1 (m, 4H), 2.96 (s, $2\times OCH_3$), 3.3—3.7 (m, 4H), and 6.9—7.3 (m, 8H).

In another run, a fraction which had been eluted with benzene was further chromatographed on silica gel. Subsequent elution with 30% hexane in benzene gave solids, which were then recrystallized from ethanol to give 50 mg of **11**; mp 229—231 °C; MS: 417 (M^+, vw), 301 ($M-C_9H_8$, w), 271 ($M-C_{10}H_{10}O$, w), 155, 154, 147 (100%), and 116 (24 %); NMR ($CDCl_3$): δ 1.5 (t, 1H), 2.27 (d-d, 1H), 3.02 (d-d, 1H), 3.38 (s, 3H, OCH_3), 3.3—3.8 (m, 3H), 4.0—4.4 (m, 3H), 5.68 (d, 1H), 6.7—7.6 (m, 13H); Found: C, 85.94; H, 6.44; N, 3.33%. Calcd for $C_{30}H_{27}NO$: C, 86.30; H, 6.52; N, 3.36%.

Sodium Methoxide-catalyzed Isomerization of **8**. A solution of **8** (100 mg, 0.6 mmol) and sodium methoxide (11 mg, 2 mmol) in dry dioxane–methanol (15 ml) was bubbled with an N_2 stream and then refluxed for 5 h. GLC showed that the solution contained an equilibrium mixture of **8** and **12** in a 1:4 ratio. After the evaporation of the solvent under reduced pressure, 50 ml of chloroform were added; the solution was washed three times with water and then dried ($MgSO_4$). Filtration and evaporation left a glassy material, to which 10 ml of hot methanol were added; the mixture was then allowed to stand overnight at room temperature. After the filtration of the **8** (10 mg) thus precipitated, the filtrate was condensed to *ca.* one half its original volume and allowed to stand overnight in a refrigerator; 60 mg of **12** were thus obtained; mp 79—80 °C; MS: 271 (M^+, vw), 155, and 116; IR (CCl_4): 2220 cm^{-1} (C≡N); Found: C, 88.35; H, 6.26; N, 5.22%. Calcd for $C_{20}H_{17}N$: C, 88.52; H, 6.32; N, 5.16%.

Synthesis of L-Epicapreomycidine

Tadashi TESHIMA, Kunikazu KONISHI, and Tetsuo SHIBA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 17, 1979)

A cyclic guanidino amino acid, L-epicapreomycidine, isolated from hydrolyzates of protease inhibitors such as chymostatin and elastatinal was synthesized. This amino acid is a diastereomer of L-capreomycidine which is a component amino acid of tuberactinomycin N,O and capreomycin. A new synthetic route from β-hydroxy-DL-ornithine *via* an aziridine compound to DL-capreomycidine was applied to the synthesis of L-epicapreomycidine starting from *erythro*-β-hydroxy-L-ornithine. A convenient and one-step technique to obtain L-*erythro* form from a mixture of four diastereomers of β-hydroxyornithine by means of enzymatic reaction was newly exploited. The synthetic L-epicapreomycidine obtained was identical with natural one in all respects, thus confirming the proposed structure.

A cyclic guanidino amino acid, L-epicapreomycidine, was found as a component amino acid of peptides produced by microorganism, *i.e.*, chymostatin and elastatinal which are known as protease inhibitors.[1] This amino acid is a diastereomer of L-capreomycidine which is a constituent of antibiotics capreomycin[2] or tuberactinomycin N and O.[3] DL-Capreomycidine and DL-epicapreomycidine had been synthesized by Bycroft *et al.* by the method based on an oximation of methyl (2-amino-4-pyrimidinyl)acetate followed by hydrogenation.[4]

Owing to the disadvantage in this method by which one of the diastereomers can not be secured purposely and optically active isomers for each diastereomer are not easily obtained unless an efficient technique of an optical resolution for such peculiar guanidino amino acid is developed.

In our previous work, we exploited an entirely novel approach to synthesize DL-[5] and also L-capreomycidine[6] stereoselectively employing N^{δ}-benzyloxycarbonyl-*threo*-β-hydroxyornithine as a key intermediate. In the present study, where *erythro* isomer of optically pure β-hydroxyornithine was taken as an intermediate in a similar synthetic strategy, epicapreomycidine of the natural steric configuration was successfully obtained for the first time.

3-(Benzyloxycarbonylamino)propionaldehyde **3**[7] was condensed with bis(glycinato)copper(II) to give a mixture of *erythro* and *threo* N^{δ}-benzyloxycarbonyl-β-hydroxy-DL-ornithine in a ratio of 1:1. Since use of aqua[*N*-(1-carboxylatoethylidene)glycinato]copper(II) as in the preparation of L-capreomycidine[8] has been found to give a *threo*-rich mixture, the usual copper complex of glycine was used in this case where *erythro* isomer is a desirable isomer. After fractional recrystallization of the condensed product from water was repeated six times, a pure DL-*erythro* isomer **4a** was obtained. Acetyl derivative **5a** derived from **4a** was treated with the acylase to give L-*erythro* isomer. However, since the tedious fractional recrystallization caused a low yield of the desired product, the product of the coupling reaction was directly subjected to the enzymatic resolution without fractionations of the diastereomers. Interestingly, the deacetylation of *erythro* isomer was found to proceed much faster than that of *threo* one. Thus, when the reaction was stopped just before the *threo* isomer became susceptible to the enzyme, N^{δ}-benzyloxycarbonyl-*erythro*-β-hydroxy-L-ornithine was obtained in an optically pure form without any further purification through single reaction procedure. This new procedure is very advantageous in a sense that not only the optical resolution, but also the diastereomeric separation took place simultaneously in a one-step enzymatic reaction.

Erythro isomer of β-hydroxy-L-ornithine derivative **6a** was converted to L-epicapreomycidine according to a series of the reaction which is the same in principle to that for the synthesis of L-capreomycidine.[6] Thus, successive procedures of N^{α}-tosylation, methyl esterification, amidation and *O*-mesylation gave an intermediate **10**. The acid amide form is requisite for the purpose of *O*-mesylation followed by aziridine ring formation to prevent an elimination of β-hydroxyl function.

O-Mesyl amide **10** was treated with diethylamine to give an aziridine derivative **11**. The aziridine ring in **11** was then opened with ammonia, and benzyloxycarbonyl group was removed by hydrogenolysis to give triamino amide derivative **12**.

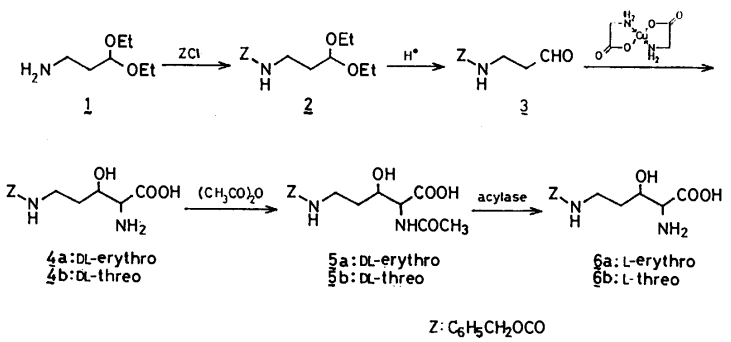

Fig. 1.

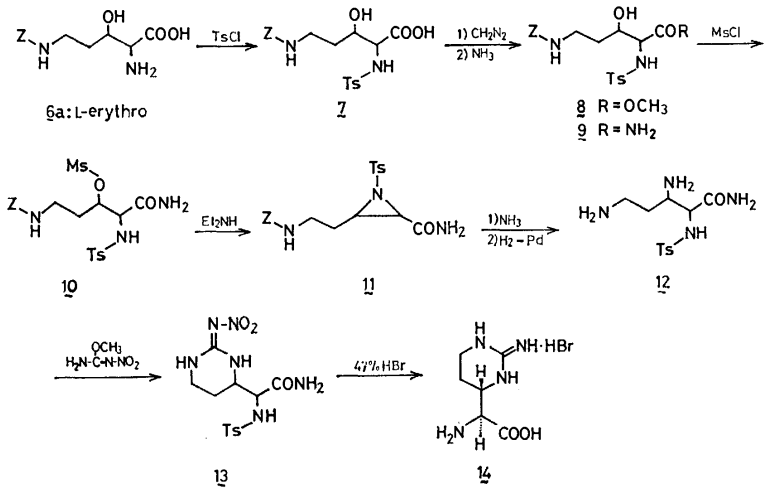

Fig. 2.

Concerning the stereoselectivity, the fact that *erythro* form of β-hydroxyornithine derivative **10** afforded *trans* aziridine **11** which turned to *erythro* form of triaminopentanamide derivative **12** was well understood by double S_N2 reaction mechanism as described in the synthesis of DL-capreomycidine.[5] The *trans* configuration of the aziridine compound **11** was supported by NMR data which showed a coupling constant of $J=$ 6 Hz for two protons at the aziridine ring.

Two free amino groups in **12** were coupled with *O*-methyl-*N*-nitroisourea in the presence of sodium hydroxide to give cyclic nitroguanidino derivative **13**. All the protecting groups of **13** were finally removed by hydrolysis with 47% hydrobromic acid to obtain epicapreomycidine hydrobromide **14**. Synthetic compound is identical with natural epicapreomycidine in all respects (mp, $[M]_D$, NMR, TLC, PC, amino acid analysis) (Table 1).

Table 1. Comparison of synthetic and natural epicapreomycidine hydrobromide

			Epicapreomycidine		Capreomycidine
			Synthetic	Natural	
Mp (dec) (°C)[a]			198—205	199—202	218—230
$[M]_D$ (*c* 1.19, 6 M HCl)			+21.0°	+18.4°	+44°
R_f	TLC[b]	a	0.11	0.11	0.11
		b	0.50	0.50	0.50

		d	0.16	0.16	0.16
Amino acid analysis (min)[c]			215	215	205

a) Melting points were compared for diflavianates. b) Developing solvent: a) 1-butanol–acetic acid–water (4: 1: 2), b) phenol–water–28% ammonia (30: 10: 1), c) *t*-butyl alcohol–acetic acid–water (2: 1: 1), d) 1-butanol–ethyl methyl ketone–28% ammonia–water (5: 3: 3: 1). c) Following conditions were applied; 27 cm column, pH 5.28, 0.35 M sodium citrate buffer.

Experimental

All melting points are uncorrected. NMR spectra were measured with a Varian XL-100-15 spectrometer. The optical rotations were measured with a Perkin-Elmer 141 polarimeter. TLC was carried out by the ascending method on silica gel G using developing solvents, 1-butanol–acetic acid–water (4: 1: 2) (solvent A) and phenol–water–28% ammonia (30: 10: 1) (solvent B). Paper chromatography was carried out on Toyo Roshi No. 51 paper using developing solvents, *t*-butyl alcohol–acetic acid–water (2: 1: 1) (solvent C) and 1-butanol–ethyl methyl ketone–28% ammonia–water (5: 3: 3: 1) (solvent D). Amino acid analysis was carried out with a Hitachi KLA-5 Amino Acid Analyzer (55 cm column, 0.20 M sodium citrate buffer pH 3.25 (92 min) and 4.25, flow rate 60 ml/h). An acylase was gifted from Tanabe Seiyaku Co., Ltd.

3-(Benzyloxycarbonylamino)propionaldehyde Diethyl Acetal (2). To a solution of 3-aminopropionaldehyde diethyl acetal (**1**) (35.3 g, 0.240 mol) and triethylamine (49.9 ml, 0.360 mol) in 500 ml of chloroform, benzyloxycarbonyl chloride (44.7 g, 0.264 mol) was added dropwise for 1.5 h with stirring at 0 °C. The mixture was stirred at 0 °C for 1 h and then at room temperature overnight. Excess benzyloxycarbonyl chloride was decomposed by addition of *N*-(2-aminoethyl)piperazine (4.5 ml, 35 mmol). The reaction mixture was washed with 20% aqueous citric acid, 4% $NaHCO_3$, and brine. The organic layer was dried over anhydrous $MgSO_4$ and concentrated *in vacuo* to give a colorless oil; yield 64.5 g (95.7%).

For elemental analysis, a small amount of this oil was distilled.

Found: C, 63.56; H, 8.23; N, 4.84%. Calcd for $C_{15}H_{23}NO_4$: C, 64.03; H, 8.24; N, 4.98%.

3-(Benzyloxycarbonylamino)propionaldehyde (3). A mixture of **2** (27.8 g, 99.0 mmol) in 800 ml of acetone and 100 ml of 0.1 M† HCl was heated under reflux for 1 h, and concentrated *in vacuo* to one eighth volume. The mixture was extracted with ethyl acetate and organic layer was washed with brine. Organic layer was dried over anhydrous $MgSO_4$ and concentrated *in vacuo*. An oily residue was triturated with hexane to give crystals; yield 17.6 g (85.9%), mp 57—58 °C. For elemental analysis, the product was converted to a 2,4-dinitrophenylhydrazone derivative, mp 161 °C.

Found: C, 52.56; H, 4.48; N, 18.07%. Calcd for $C_{17}H_{17}N_5O_6$: C, 52.71; H, 4.42; N, 18.08%.

N^5-Benzyloxycarbonyl-β-hydroxy-DL-ornithine (4). To a suspension of bis(glycinato)copper(II) (208 g, 981 mmol) and Na_2CO_3 (104 g, 981 mmol) in 1.8 l of H_2O, a solution of **3**

† 1 M = 1 mol dm^{-3}.

(81.2 g, 392 mmol) in 400 ml of dichloromethane was added dropwise at 60 °C for 15 min. The reaction mixture was stirred at 60 °C for 1.5 h and neutralized with HCl on cooling in ice bath. H_2S was bubbled through the solution with stirring for 1.5 h. Copper sulfide was filtered off and washed with 4 l of 1 M HCl. The filtrate and washings were combined and aerated to remove H_2S. The solution was neutralized with ammonia to give crystals; yield 15.7 g (14.2%) (*erythro*: *threo* (1: 1)). From the mother liquor, a further crop was recovered; yield 4.8 g (4.3%) (*erythro*: *threo* (1: 1.3)). The ratio of *erythro* and *threo* isomers were obtained by amino acid analysis (retention time: *threo*, 186 min; *erythro*, 197 min).

N$^{\delta}$-Benzyloxycarbonyl-erythro-*β-hydroxy*-DL-*ornithine (4a)*. Crude product (*erythro*: *threo* (1: 1.3)) (13.9 g) of **4** was recrystallized six times from H_2O (250—300 ml per g of the crude crystals) to give a pure *erythro* isomer **4a**: yield 1.41 g (10.1%), mp 248—248.5 °C (dec).

Found: C, 55.29; H, 6.41; N, 9.86%. Calcd for $C_{13}H_{18}N_2O_5$: C, 55.31; H, 6.43; N, 9.92%.

N$^{\alpha}$-Acetyl-N$^{\delta}$-benzyloxycarbonyl-erythro-*β-hydroxy*-DL-*ornithine (5a)*. To a solution of **4a** (539 mg, 1.90 mmol) in 1 M NaOH (1.90 ml, 1.90 mmol), acetic anhydride (0.32 ml, 3.40 mmol) and 1 M NaOH (3.80 ml, 3.80 mmol) were added dropwise at the same time with stirring at 0 °C. Keeping the pH of the solution at 9 by addition of 1 M NaOH, the mixture was stirred at 0 °C for 2 h and then at room temperature overnight. The reaction mixture was acidified with HCl and extracted with ethyl acetate. The organic layer was washed with H_2O and dried over anhydrous $MgSO_4$. The oily residue after concentration *in vacuo* was triturated with ethyl acetate and ether to give crystals: yield, 413 mg (67.0%). They were recrystallized from ethyl acetate; yield, 312 mg (50.6%), mp 123—125 °C.

Found: C, 55.46; H, 6.21; N, 8.58%. Calcd for $C_{15}H_{20}N_2O_6$: C, 55.55; H, 6.22; N, 8.64%.

N$^{\delta}$-Benzyloxycarbonyl-erythro-*β-hydroxy*-L-*ornithine (6a)*. To **5a** (283 mg, 0.873 mmol) was added 0.1 M LiOH until a clear solution was obtained, and the solution was adjusted to pH 7.1 with 0.1 M LiOH. To the solution, 1.5 ml of 0.01 M cobalt chloride and the acylase (35 mg, 20 units/mg) were added, and the solution was incubated at 37 °C for 20 h. When crystals of free *erythro*-L-form were separated out, pH of the mixture decreased to 6.4. After the solution was adjusted again to pH 7.1, the incubation was continued for further 60 h. After cooling in ice bath, crystals deposited were collected by filtration; yield 95 mg (77%). They were recrystallized from H_2O; yield, 75 mg (61%), mp 237 °C (dec), $[\alpha]_D^{20}$ +6.2° (*c* 1.0, 2 M HCl).

Found: C, 55.40; H, 6.40; N, 9.88%. Calcd for $C_{13}H_{18}N_2O_5$: C, 55.31; H, 6.43; N, 9.92%.

Convenient Preparation of N$^{\delta}$-*Benzyloxycarbonyl*-erythro-*β-hydroxy*-L-*ornithine (6a) from a Mixture of Four Diastereomers*. *N$^{\delta}$*-Benzyloxycarbonyl-*β*-hydroxy-DL-ornithine (**4**) (*erythro*: *threo* (1: 1)) (21.0 g, 74.5 mmol) was acetylated in the manner similar to that in the preparation of **5a** to give a mixture of *erythro* and *threo* isomers of *N$^{\alpha}$*-acetyl-*N$^{\delta}$*-benzyloxycarbonyl-*β*-hydroxy-DL-ornithine (**5**) as a colorless oil. The enzymatic reaction of this mixture with the acylase was carried out in the manner similar to that in the reaction of **5a**. After the reaction mixture was cooled in an ice bath, crystals separated out were collected by filtration. They were found to be pure *erythro* isomers from the result of amino acid analysis; yield 2.08 g (39.6%).

N$^{\delta}$-Benzyloxycarbonyl-N$^{\alpha}$-p-*tolylsulfonyl*-erythro-*β-hydroxy*-L-*ornithine (7)*. To a suspension of **6a** (737 mg, 2.61 mmol) in 6.5 ml of THF–H_2O (1: 2) were added triethylamine (0.82 g, 8.1 mmol) and *p*-toluenesulfonyl chloride (763 mg, 4.00 mmol) portionwise during a period of 30 min with stirring at room temperature. After stirring for 2 h, the reaction mixture was concentrated *in vacuo* and an aqueous solution of the residue was extracted with ether. The ether layer was reextracted with aqueous $NaHCO_3$. Both aqueous layers were combined and acidified with HCl to give colorless needles; yield 939 mg (82.4%). Recrystallization from ethanol–ether–hexane, gave a pure sample for elemental analysis; mp 164.5—166.5 °C, $[\alpha]_D^{19}$ +19.4° (*c* 1.13, EtOH).

Found: C, 54.92; H, 5.54; N, 6.39; S, 7.25%. Calcd for $C_{20}H_{24}N_2O_7S$: C, 55.03; H, 5.54; N, 6.42; S, 7.32%.

N$^{\delta}$-Benzyloxycarbonyl-N$^{\alpha}$-p-*tolylsulfonyl*-erythro-*β-hydroxy*-L-*ornithine Methyl Ester (8)*. To a solution of **7** (2.41 g, 5.52 mmol) in 14 ml of THF–dioxane (1: 1), was added excess diazomethane in ether and allowed to react for 1 h. Excess diazomethane was decomposed with acetic acid and the solution was concentrated *in vacuo* to give needles; yield 2.49 g (100%). For elemental analysis, they were recrystallized from ethyl acetate–hexane; mp 108—112 °C, $[\alpha]_D^{19}$ −0.1° (*c* 1.03, MeOH), $[\alpha]_{365}^{19}$ +27.0° (*c* 1.03, MeOH).

Found: C, 55.89; H, 5.95; N, 5.91; S, 6.77%. Calcd for $C_{21}H_{26}N_2O_7S$: C, 55.99; H, 5.82; N, 6.22; S, 7.10%.

N$^{\delta}$-Benzyloxycarbonyl-N$^{\alpha}$-p-*tolylsulfonyl*-erythro-*β-hydroxy*-L-*ornithinamide (9)*. A solution of **8** (2.49 g, 5.53 mmol) in 120 ml of methanol, was saturated with ammonia in a pressure bottle and kept at room temperature for 4 d. Concentration *in vacuo* gave crystals; yield 1.58 g (65.5%). For elemetal analysis they were recrystallized from methanol–ether–hexane; mp 206—208 °C, $[\alpha]_D^{19}$ +15.9° (*c* 1.10, DMF).

Found: C, 55.31; H, 5.74; N, 9.58; S, 7.48%. Calcd for $C_{20}H_{25}N_3O_6S$: C, 55.16; H, 5.79; N, 9.65; S, 7.36%.

N$^{\delta}$-Benzyloxycarbonyl-N$^{\alpha}$-p-*tolylsulfonyl-O-methylsulfonyl*-erythro-*β-hydroxy*-L-*ornithinamide (10)*. To a solution of **9** (661 mg, 1.52 mmol) in 7 ml of pyridine, methanesulfonyl chloride (0.939 ml, 12.1 mmol) was added portionwise with stirring at −25 °C during a period of 2.5 h. After an additional stirring for 2 h, the reaction mixture was concentrated *in vacuo* and extracted with ethyl acetate after addition of 30 ml of H_2O. The organic layer was washed with 5% aqueous citric acid, $NaHCO_3$ and brine successively, dried over anhydrous $MgSO_4$ and concentrated *in vacuo*. The residue was triturated with hexane to give colorless needles; yield 691 mg (91.5%). Recrystallization from acetone–hexane gave a pure sample for elemental analysis; mp 159—162 °C, $[\alpha]_D^{19}$ +34.3° (*c* 1.00, acetone).

Found: C, 49.22; H, 5.28; N, 8.19; S, 12.37%. Calcd for $C_{21}H_{27}N_3O_8S_2$: C, 49.11; H, 5.30; N, 8.18; S, 12.49%.

(2S,3R)-5-Benzyloxycarbonylamino-trans-*2,3*-[N-*(*p-*tolylsulfonyl)epimino]pentanamide (11)*. A solution of **10** and diethylamine (0.54 ml, 5.2 mmol) in 7 ml of THF was kept at 38—42 °C for 3 h, and then concentrated *in vacuo*. An aqueous solution of the residue was extracted with chloroform. After the extract was dried over anhydrous $MgSO_4$, the solvent was evaporated *in vacuo* to an oil, which was triturated with benzene to give needles; yield 267 mg (56.4%). They were recrystallized from chloroform–hexane; yield 246 mg (52.0%), mp 136—137 °C, $[\alpha]_D^{20}$ +21.8° (*c* 1.06, DMF).

Found: C, 57.18; H, 5.53; N, 9.92; S, 7.53%. Calcd for $C_{20}H_{23}N_3O_3S$: C, 57.54; H, 5.55; N, 10.07; S, 7.68%.

(2S,3R)-erythro-*3,5-Diamino-2-(*p-*tolylsulfonylamino)pentanamide (12)*. A solution of **11** (283 mg, 0.678 mmol) in 100 ml of methanol was saturated with ammonia in a pressure bottle, and allowed to stand at 30 °C for 4 d. The residue obtained after concentration *in vacuo* was dissolved in methanol and hydrogenolyzed in the presence of Pd-black. After removal of catalyst, the reaction mixture was concentrated *in vacuo* to give crystals which were recrystallized from metha-

nol–ether; yield 136 mg (52.1%), mp 200—209 °C (dec), $[\alpha]_D^{15}$ +76.5° (*c* 1.06, MeOH).

Found: C, 37.87; H, 6.13; N, 14.58; S, 8.37; Cl, 18.24%. Calcd for $C_{12}H_{22}N_4O_3SCl_2 \cdot 1/2H_2O$: C, 37.70; H, 6.06; N, 14.65; S, 8.39; Cl, 18.55%.

L-*Epicapreomycidine Hydrobromide (**14**)*. To a solution of **12** (74 mg, 0.20 mmol) in 2 ml of methanol and a trace of H_2O, were added 1 M NaOH (0.40 ml, 0.40 mmol) and *O*-methyl-*N*-nitroisourea (47 mg, 0.40 mmol) portionwise with stirring at 0 °C during a period of 2 h. The reaction mixture was stirred at 0 °C for 1 h and then at room temperature overnight. More amount of *O*-methyl-*N*-nitroisourea (20 mg, 0.168 mmol) was added to the reaction mixture. After 3 h, the reaction mixture was acidified with 1 M HCl. The residue obtained after concentration *in vacuo* was triturated with a small amount of H_2O and ethyl acetate to give a nitroguanidino derivative **13** as crystals; yield 40 mg (55%). The product was heated with 8 ml of 47% HBr and 3 ml of anisole under reflux for 5 h. An aqueous layer was separated from anisole layer and concentrated *in vacuo*. A solution of the residue in methanol was neutralized with pyridine. Addition of ethanol to the solution gave colorless prisms of monohydrobromide **14**; yield 23 mg (45%). They were recrystallized from H_2O–ethanol; yield 14 mg (28%). $[\alpha]_D^{20}$ +8.31° (*c* 1:19, 6 M HCl). For elemental analysis, the hydrobromide was converted to diflavianate of yellow prisms; mp 198—205 °C (dec).

Found: C, 38.86; H, 3.19; N, 14.00; S, 7.55%. Calcd for $C_{26}H_{24}N_8O_{18}S_2 \cdot 1/2H_2O$: C, 38.57; H, 3.11; N, 13.84; S, 7.92%.

The authors are grateful to Prof. Hamao Umezawa, Institute of Microbial Chemistry, for his gift of the natural sample of L-epicapreomycidine.

Layered Compounds. LXII.[1] Triple-layered [*m.m*][*n.n*]Paracyclophanes: Syntheses and Spectra

Tetsuo Otsubo,† Takashi Kohda, and Soichi Misumi*

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received August 7, 1979)

A series of the title cyclophanes (*m*, *n*=2—4) were synthesized by the thermal- and photo-desulfurization methods from dithia intermediates. Their absorption and emission spectra were measured to examine the transannular electronic interaction. The absorption spectra of the title compounds and their TCNE complexes gave the same order of the interaction as seen in the case of double-layered system: [2.2]>[3.3]>[4.4] in neutral state and [3.3]>[2.2]>[4.4] in CT state. The emission spectra are discussed in terms of the existence of excited trimer.

In the previous papers of this series we reported the physical and chemical properties of multilayered [2.2]paracyclophanes to be strongly affected by the transannular π-electronic interactions among the stacked benzene rings. In addition to the electronic interaction, their severe molecular strain due to rigid [2.2]phane framework gave rise to intriguing behaviors such as catalytic skeletal rearrangement.[3] In order to pursue only transannular electronic interaction without strain effect, it is more instructive to study some series of multilayered [*m. n*]paracyclophanes with longer bridging chain.

For example, [3.3]paracyclophane is much more suitable for this purpose because of far less strained sandwich framework compared to [2.2]paracyclophane. It was already pointed out that double-layered [3.3]-paracyclophane **8** is a better system for both intermolecular and intramolecular charge-transfer interactions than [2.2]paracyclophane **7**.[4,5] So, multilayered [3.3]paracyclophanes are expected to reveal more unique behaviors with the increase of layer number. In addition, it is interesting to see if [4.4]phane system exerts such a multilayer effect although [4.4]paracyclophane **9** exhibits less transannular interaction.

For the above-stated purpose, we have intended to investigate a series of triple-layered [*m.m*][*n.n*]paracyclophanes **1**—**6** with combined numbers of the bridging methylene, *i.e.*, *m* and *n*=2—4.[6] This paper presents their syntheses and spectral properties.

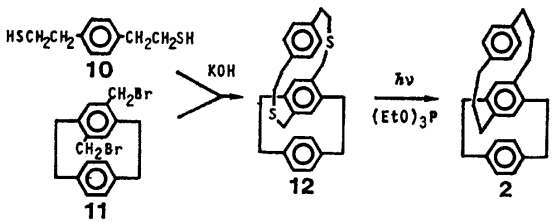
Results and Discussion

Syntheses. Although the syntheses of [3.3]- and [4.4]paracyclophanes, **8** and **9**, were difficult before, new synthetic routes through sulfur extrusion of the corresponding dithia homologs have recently developed for the general use.[7] These methods are also useful to the syntheses of the present triple-layered [*m.m*][*n.n*]-paracyclophanes **2**—**6**, that is to say, by stepwise stacking of *para*-substituted benzenes. For example, in the case of [2.2][3.3]paracyclophane **2** the [2.2]-framework was at first constructed by the Hofmann elimination method as previously reported.[2] The resulting 4,7-bis(bromomethyl)paracyclophane **11**[8] was treated with 1,4-bis(2-mercaptoethyl)benzene **10**[7a] to give dithia[2.2][4.4]paracyclophane **12** in 25% yield. Irradiation of **12** in triethyl phosphite with a high pressure mercury lamp for 6 h led to the formation of the desired cyclophane **2** in 23% yield.

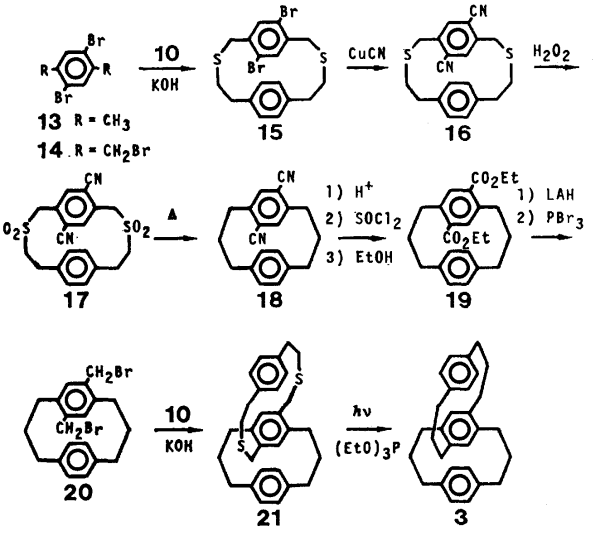


Scheme 3.

A similar route to derive [3.3][3.3]homolog **3** requires 5,8-bis(bromomethyl)[3.3]paracyclophane **20** as a key intermediate, which is not readily accessible.[9]

† Present address: Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Hiroshima 730.

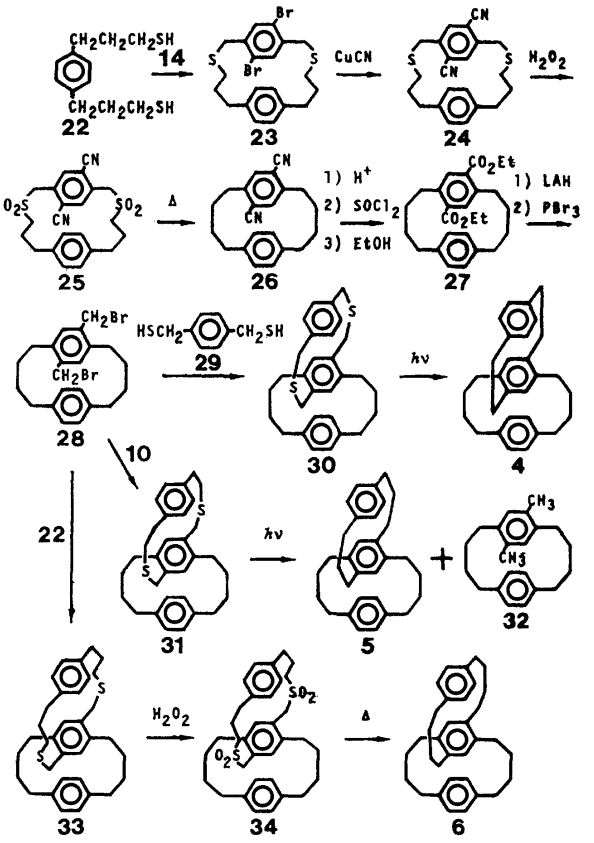
One successful but laborious approach has been developed. Treatment of 2,5-dibromo-*p*-xylene **13**[10] with NBS gave 2,5-dibromo-1,4-bis(bromomethyl)-benzene **14** in 34% yield. A coupling reaction between **10** and **14** led to 16,19-dibromo-2,13-dithia[4.4]paracyclophane **15** in 62% yield, which was treated with copper(I) cyanide in *N*-methylpyrrolidinone to afford dicyano derivative **16** in 68% yield. 5,8-Dicyano-[3.3]paracyclophane **18** was obtained in 40% yield by oxidation of **16** with hydrogen peroxide to give disulfone **17**, followed by pyrolysis. Although hydrolysis of **18** in basic conditions failed, it was hydrolyzed in a boiling solution of sulfuric acid–acetic acid, and treatment of the resulting acid with thionyl chloride and then with absolute ethanol produced 5,8-bis(ethoxycarbonyl)[3.3]paracyclophane **19** in 46% yield. Reduction of **19** with lithium aluminium hydride followed by bromination with phosphorus tribromide gave the desired bromide **20** in satisfactory yield. [3.3][3.3]Paracyclophane **3** was derived from **20** in quite similar manner as described for **2**.



Scheme 4.

For [4.4]phane series, 6,9-bis(bromomethyl)[4.4]-paracyclophane **28** was prepared according to the same reaction sequence. Dithiacyclophanes **30**, **31**, and **33** were similarly obtained by reactions of bromide **28** with dithiols **29**, **10**, and **22**, respectively, in high yields. Photodesulfurization of **30** proceeded smoothly to afford [2.2][4.4]paracyclophane **4** in 55% yield. A similar reaction of **31** was ineffective with a high pressure mercury lamp because of the poor absorbance of **31**. This was improved by use of a low pressure mercury lamp, and [3.3][4.4]paracyclophane (**5**) was formed in 12% yield together with 6,9-dimethyl[4.4]-paracyclophane (**32**) as a by-product. On the other hand, the formation of [4.4][4.4]paracyclophane (**6**) was accomplished by the pyrolytic method (5% yield), for any photochemical attempt was unsuccessful.

Electronic Absorption Spectra. It is well known that the transannular electronic interaction in cyclophane results in the bathochromic and hyperchromic shifts



Scheme 5.

of the absorption bands in its electronic spectrum and the magnitude of these shifts is simply utilized as a measure of the interaction.[2] As shown in Fig. 1, the shifts of a series of triple-layered paracyclophanes are in an order of [4.4][4.4]PC **6**<[3.3][4.4]PC **5**<[2.2]-[4.4]PC **4**<[3.3][3.3]PC **3**<[2.2][3.3]PC **2**<[2.2][2.2]-PC **1** (PC: paracyclophane). It is evidently concluded

that the transannular interactions of triple-layered paracyclophanes depend mainly on a pair of the ring-to-ring distances in each molecule and [2.2]phane system with the shortest distance is most effective. [4.4]Phane system shows no interaction even when triply layered, that is, the $^1B_{2u}$ transition of **6** still retains fine structure, characteristic of alkylbenzenes. Also the spectral shapes of **4** and **5** are essentially same as those of [2.2]paracyclophane **7** and [3.3]paracyclophane **8**, respectively.[11]

Charge-transfer Complexes. The charge-transfer spectra of cyclophane–tetracyanoethylene complexes were measured to obtain further information concerning the transannular interaction. The π-donor character of the complexing benzene in cyclophane is enhanced by a transannular electron release from the remaining faced benzene ring. Cram *et al.* reported that double-layered [3.3]paracyclophane **8** was rather stronger π-donor than [2.2]paracyclophane **7**.[4] This indicates that [3.3]phane system is favored over [2.2]phane system for the transannular interaction in charge-transfer state. The CT spectra of a series of triple-layered paracyclophanes are shown in Fig. 2 and Table 1. The order of the shifts is the same as seen in double-layered case. Thus, [3.3][3.3]paracyclophane **3** is the strongest donor of all the triple-layered cyclophanes. The presence of the transannular interaction in CT complexes of [4.4]-phane system is supported by a red shift of the CT band of [4.4][4.4]paracyclophane **6** compared with *p*-xylene or [4.4]paracyclophane **9**.

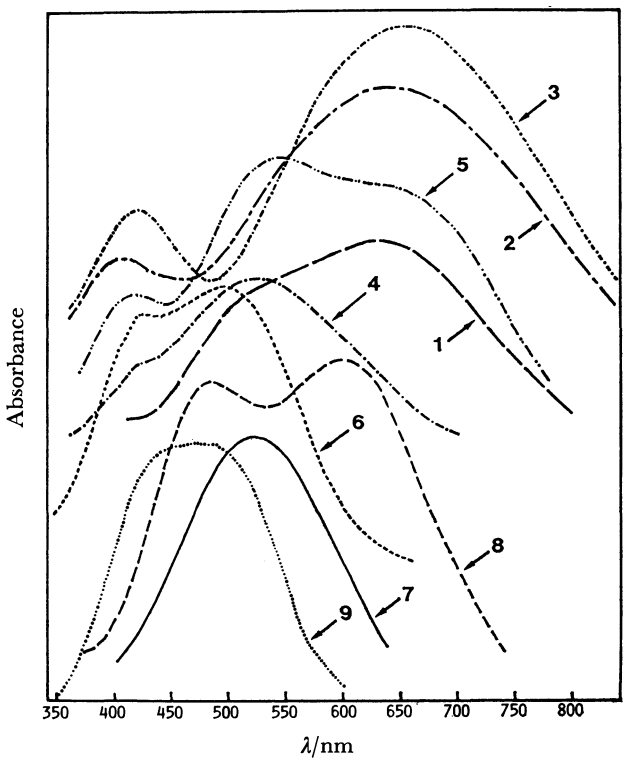

Fig. 2. Charge-transfer spectra of cyclophane–TCNE complexes in dichloromethane. Curves are all displaced on the vertical axis for separation.

Emission Spectra. Some of double-layered cyclophanes provide suitable models for the study of excimer which is well known to exist only in excited state and to show a fluorescence band in longer wavelength than the monomer fluorescence.[12] In the previous paper, we described on the basis of fluorescence spectra data that [2.2]- and [3.3]paracyclophanes, **7** and **8**, have structures resemble to the benzene excimer, whereas [4.4]paracyclophane **9** undergoes conformational change for the excimer formation.

An interesting question is whether any excited trimer exists or not. There has been found an example of termolecular exciplex composed of 2: 1 ratio of donor: acceptor.[13] The formation of neutral excited intramolecular trimer is also possible when considered a marked interaction in multilayered cyclophanes, although it is unfavorable on entropy to form intermolec-

ularly a termolecular aggregate. The present triple-layered paracyclophanes are expected to provide a helpful information about the excited trimer.

Their emission data are summarized in Table 2. The excimer fluorescences are characterized by broadening and large Stokes shift and are clearly distinguishable from ordinary monomer type of fluorescence. The excimer fluorescence bands of **1**, **2**, and **3** appear at much longer wavelength than those of double-layered paracyclophanes, **7** and **8**, indicating that the third stacked benzene obviously serves to stabilize the excited trimer state.

On the other hand, [4.4][4.4]paracyclophane **6** shows another type of excited trimer formation. It reveals monomer emission at low temperature but excimer emission at room temperature as seen for [4.4]paracyclophane **9**. However, the emission of **6** can be considered as superposition of two distinct excimer bands. Thus, the band at 330 nm is associated with excited dimer in analogy with the excimer band at 335 nm for **9** and another band at 395 nm is assigned to excited trimer emission.

Table 2 also shows large red shift of phosphorescence bands. There are rather correlated to absorption bands than fluorescence bands, indicating that the excimers are independent of triplet state.

Experimental

Melting points are uncorrected. All solvents are of reagent grade. NMR measurements were made with a Hitachi Perkin-Elmer R-20 spectrometer (60 MHz) or a JEOL JNM-FX 100 in deuteriochloroform using TMS as an internal standard. Mass spectra were determined on a Hitachi RMU-7 spectrometer at 70 eV using direct insertion technique. UV spectra were recorded on a Hitachi EPS-3T spectrophotometer. Emission spectra were taken on a Hitachi MPF-2A spectrophotometer attached with a HTV R-446F photomultiplier in EPA (diethyl ether–isopentane–ethanol of 5:5:2 volume ratio). A solution of about 1×10^{-3} M was prepared and degassed by freeze-pump-thaw method. Emission spectra were uncorrected.

Dithia[2.2][4.4]paracyclophane (12). A mixture of 1,4-bis(2-mercaptoethyl)benzene **10**[7a] (0.79 g, 4.0 mmol) and 4,7-bis(bromomethyl)[2.2]paracyclophane **11**[8] (1.73 g, 4.4 mmol) in benzene (200 ml) was slowly added into a refluxing ethanol solution (500 ml) of potassium hydroxide (0.71 g) under nitrogen. The addition took 6 h and the reflux was continued for further 6 h. The solvent was evaporated and the residue was chromatographed on silica gel with 1:1 benzene–hexane to give the desired cyclic compound **12** (0.44 g, 25%), colorless plates from benzene–hexane, mp 156.5—158 °C.

NMR ($CDCl_3$, 60 MHz) δ=6.67 (4H, s, ArH), 6.37 (4H, A_2B_2m, ArH), 5.80 (2H, s, ArH), 3.51 (2H, ABd, J=14 Hz, $ArCH_2S$), 3.07 (2H, ABd, J=14 Hz, $ArCH_2S$), 2.3—3.1 (16H, m, CH_2); MS *m/e* 430 (M^+). Found: C, 78.06; H, 7.22; S, 15.11%. Calcd for $C_{28}H_{30}S_2$: C, 78.09; H, 7.02; S, 14.89%.

Triple-layered [2.2][3.3]Paracyclophane (2). Dithiacyclophane **12** (70 mg) was dissolved in a mixture of benzene (5 ml) and triethyl phosphite (5 ml) in a quartz tube and irradiated with a high pressure mercury lamp for 6 h in a nitrogen atmosphere. After evaporation to dryness, the residue was chromatographed on silica gel with 1:9 benzene–hexane to give the desired product **2** from the first eluate, 13 mg (23%), colorless prisms from hexane, mp 161—162.5 °C.

NMR ($CDCl_3$, 60 MHz) δ=6.46 (4H, s, ArH), 6.35 (2H, A_2B_2dd, J=7 Hz, ArH), 6.14 (2H, A_2B_2dd, J=7 Hz, ArH), 5.57 (2H, s, ArH), 1.7—3.4 (20H, m, CH_2); MS *m/e* 366 (M^+). Found: C, 91.49; H, 8.29%. Calcd for $C_{28}H_{30}$: C, 91.75; H, 8.25%.

2,5-Dibromo-1,4-bis(bromomethyl)benzene (14). A mixture of 2,5-dibromo-*p*-xylene **13** (79 g, 0.3 mol) and NBS (111 g, 0.62 mol) in carbon tetrachloride (500 ml) was refluxed for 1 h using sunlight as a catalyst. The hot solution was filtered and the insoluble succinimide was washed with dichloromethane. The filtrate and the washings were combined, washed with water, and dried over anhyd magnesium sulfate. The solution was concentrated *in vacuo*, and the residue was recrystallized from benzene to give colorless columns, 43 g (34%), mp 160—161 °C.

NMR ($CDCl_3$, 60 MHz) δ=4.51 (4H, s, CH_2), 7.66 (2H, s, ArH). Found: C, 22.84; H, 1.35; Br, 75.50%. Calcd for $C_8H_6Br_4$: C, 22.78; H, 1.43; Br, 75.78%.

16,19-Dibromo-2,13-dithia[4.4]paracyclophane (15). A mixture of 1,4-bis(2-mercaptoethyl)benzene **10** (1.98 g, 0.01 mol) and 2,5-dibromo-1,4-bis(bromomethyl)benzene **14** (4.22 g, 0.01 mol) in benzene (300 ml) was slowly added into a refluxing ethanol (1 L) containing potassium hydroxide (1.78 g) under nitrogen. The addition took one day. After the addition was complete, the reflux was continued half a day. The mixture was concentrated, and the residue was chromatogphed on silica gel with 1:1 benzene–hexane. The first eluate gave the desired coupling compound **15** (8.54 g, 62%), colorless scales from benzene–hexane, mp 181.5—182.5 °C.

NMR ($CDCl_3$, 60 MHz) δ=7.00 (2H, s, ArH), 6.89 (4H, s, ArH), 3.68 and 3.26 (4H, ABq, J=14 Hz, $ArCH_2S$), 3.6—2.3 (8H, m, CH_2); MS *m/e* 458 (M^+). Found: C, 46.94; H, 3.75; S, 13.92; Br, 34.67%. Calcd for $C_{18}H_{18}S_2Br_2$: C, 47.17; H, 3.96; S, 13.99; Br, 34.88%.

16,19-Dicyano-2,13-dithia[4.4]paracyclophane (16). A suspension of dithia compound **15** (6.79 g, 14.8 mmol) in *N*-methyl-2-pyrrolidinone (28 ml) was heated at 180 °C with stirring in a nitrogen atmosphere for 1.5 d. The hot mixture was poured into 15% ammonia water (50 ml) and cooled in an ice bath. The resulting cake was filtered and dried in the air. The desired product **16** was extracted from the cake with dichloromethane by use of a Soxhlet extraction and purified by chromatography on silica gel with dichloromethane, 3.53 g (68%), colorless scales from benzene–hexane, mp 259.5—261.5 °C.

NMR ($CDCl_3$, 60 MHz) δ=7.26 (2H, s, ArH), 6.90 (4H, s, ArH), 3.80 and 3.45 (4H, ABq, J=15 Hz, $ArCH_2S$), 3.5—2.5 (8H, m, CH_2). Found: C, 68.38; H, 5.00; N, 7.96; S, 18.29%. Calcd for $C_{20}H_{18}N_2S_2$: C, 68.53; H, 5.18; N, 7.99; S, 18.30%.

5,8-Dicyano[3.3]paracyclophane (18). Dithia[4.4]paracyclophane **16** (3.19 g, 9 mmol) was mixed with acetic acid (24.3 ml) and 35% hydrogen peroxide (6.1 ml) and heated at 100 °C for 5 h. The mixture was cooled in an ice bath and resulting colorless solid of disulfone **17** was collected by filtration, washed with water, and dried, 3.09 g (82%).

Disulfone **17** (500 mg) was packed in a Pyrex tube sealed at one end. The open end was connected to a rotary pump and the system was maintained under 0.5 mmHg. The tube was placed in a furnace (15 cm in length, preheated at 650 °C) in such a way as the middle of the tube could be heated. The sample part was slidden smoothly inside the furnace. As soon as the pyrolysis started, an oily product condensed

near the opposite cool end. Column chromatography of the product on silica gel with benzene gave pure dicyano[3.3]-paracyclophane **18**, 176 mg (49%), colorless columns from benzene–hexane, mp 190.5—191.5 °C.

NMR ($CDCl_3$, 60 MHz) δ=7.11 (2H, s, ArH), 7.01 (2H, A_2B_2dd, J=8, 2 Hz, ArH), 6.79 (2H, A_2B_2dd, J=8, 2 Hz, ArH), 3.4—1.8 (12H, m, CH_2); MS *m/e* 286 (M^+). Found: C, 83.61; H, 6.05; N, 9.73%. Calcd for $C_{20}H_{18}N_2$: C, 83.88; H, 6.34; N, 9.78%.

5,8-Bis(ethoxycarbonyl)[3.3]paracyclophane (19). Dicyano compound **18** (185 mg, 0.65 mmol) was mixed with 1:1 concd H_2SO_4–H_2O (3 ml) and acetic acid (1 ml), and refluxed with stirring for one day in a nitrogen atmosphere. The mixture was diluted with 30 ml of water. The resulting precipitate of 5,8-dicarboxy[3.3]paracyclophane was collected by filtration, washed with water, and dried, 184 mg (88%).

The above dicarboxylic acid (100 mg, 0.31 mmol) was treated under reflux with thionyl chloride (2 ml) in dry benzene (10 ml) for 1.5 h. After complete removal of thionyl chloride by distillation, absolute ethanol (5 ml) was added. The mixture was refluxed for 1 h and diluted with benzene (50 ml). The solution was washed with sat. aq NaCl and dried over anhyd magnesium sulfate. After evaporation, the residue was chromatographed on silica gel with benzene to give the desired diester **19**, 61 mg (52%).

NMR ($CDCl_3$, 100 MHz) δ=1.46 (6H, t, J=7.1 Hz, CH_3), 2.05 (4H, m, CH_2), 2.70 (6H, m, CH_2), 3.65 (2H, m, CH_2), 4.42 (4H, q, OCH_2), 6.74 (4H, s, ArH), 7.34 (2H, s, ArH).

An analytical sample was purified by gel permeation liquid chromatography and recrystallized from pentane, colorless plates, mp 82.5—83 °C. Found: C, 75.81; H, 7.38%. Calcd for $C_{24}H_{28}O_4$: C, 75.76; H, 7.42%.

5,8-Bis(bromomethyl)[3.3]paracyclophane (20). Diester **19** (132 mg) was mixed with excess of lithium aluminium hydride in dry THF (20 ml) and refluxed for 30 min. After successive addition of ethyl acetate, water, dil hydrochloric acid, and NaCl, the mixture was extracted with ether. The extract was washed with sat. aq NaCl solution and dried over anyd magnesium sulfate. Evaporation of solvent gave a colorless solid of 5,8-bis(hydroxymethyl)[3.3]paracyclophane, 98 mg (96%).

NMR ($CDCl_3$, 100 MHz) δ=2.0—3.0 (12H, m, CH_2), 4.68 (4H, center of ABq, J=12.8 Hz, CH_2O), 6.72 (4H, center of ABq, J=8.0 Hz, ArH), 6.76 (2H, s, ArH).

This diol was used in the following bromination without purification.

The above diol (98 mg) was stirred with phosphorus tribromide (0.5 ml) in dry benzene (20 ml) for 1 h at room temperature. The mixture was washed with sat. aq NaCl, dried over anhyd magnesium sulfate, and evaporated. The residue was filtered through a short column of silica gel with benzene to give the pure compound **20**, 104 mg (74%), colorless plates from hexane, mp 136.5—137.5 °C.

NMR ($CDCl_3$, 100 MHz) δ=1.9—3.1 (12H, m, CH_2), 4.45 (4H, center of ABq, J=10.3 Hz, CH_2Br), 6.69 (2H, s, ArH), 6.77 (4H, center of ABq, J=8.6 Hz, ArH). Found: C, 56.74; H, 5.13; Br, 37.62%. Calcd for $C_{20}H_{22}Br_2$: C, 56.90; H, 5.25; Br, 37.85%.

Dithia[3.3][4.4]paracyclophane (21). Compound **21** was obtained in 63% yield from a coupling reaction of the above dibromide **20** and 1,4-bis(2-mercaptoethyl)benzene **10** in a similar manner as described for dithia[2.2][4.4]paracyclophane **12**, colorless prisms from benzene–hexane, mp 204—205 °C.

NMR ($CDCl_3$, 60 MHz) δ=6.63 (4H, s, ArH), 6.57 (4H, s, ArH), 6.06 (2H, s, ArH), 3.69 (2H, ABd, J=14 Hz, $ArCH_2S$), 3.11 (2H, ABd, J=14 Hz, $ArCH_2S$), 3.5—1.5 (20H, m, CH_2); MS *m/e* 458 (M^+). Found: C, 78.27; H, 7.19; S, 13.94%. Calcd for $C_{30}H_{34}S_2$: C, 78.55; H, 7.47; S, 13.98%.

Triple-layered [3.3][3.3]Paracyclophane (3). Photodesulfurization of dithia compound **21** was carried out in similar manner as described in the synthesis of [2.2][3.3]analogue **2**. [3.3][3.3]Paracyclophane **3** was obtained in 16% yield, colorless plates from hexane, mp 166—168 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.54 (4H, A_2B_2dd, J=6.7, 0.7 Hz, ArH), 6.43 (4H, A_2B_2dd, J=6.7, 0.7 Hz, ArH), 5.89 (2H, s, ArH), 3.0—1.8 (24H, m, CH_2); MS *m/e* 394 (M^+). Found: C, 91.11; H, 8.68%. Calcd for $C_{30}H_{34}$: C, 91.31; H, 8.69%.

18,21-Dibromo-2,15-dithia[5.5]paracyclophane (23). Dithia compound **23** was prepared from 2,5-dibromo-1,4-bis-(bromomethyl)benzene **14** and 1,4-bis(3-mercaptopropyl)-benzene **22**[7a] in similar manner as for dithia[4.4]analogue **15**, yield 87%, colorless plates from hexane, mp 137—138 °C.

NMR ($CDCl_3$, 60 MHz) δ=7.45 (2H, s, ArH), 6.99 (4H, s, ArH), 4.03 (2H, ABd, J=14 Hz, $ArCH_2S$), 3.44 (2H, ABd, J=14 Hz, $ArCH_2S$), 2.63 (4H, m, $ArCH_2$), 1.96 (8H, m, CH_2); MS *m/e* 486 (M^+). Found: C, 49.11; H, 4.60; S, 13.27; Br, 32.69%. Calcd for $C_{20}H_{22}S_2Br_2$: C, 49.39; H, 4.56; S, 13.19; Br, 32.86%.

18,21-Dicyano-2,15-dithia[5.5]paracyclophane (24). Dithia compound **24** was derived from dibromo derivative **23** in similar manner as for dithia[4.4]analogue (**16**), yield 53%, colorless plates from benzene, mp 164—165 °C.

NMR ($CDCl_3$, 60 MHz) δ=7.60 (2H, s, ArH), 6.94 (4H, s, ArH), 4.02 (2H, ABd, J=14 Hz, $ArCH_2S$), 3.55 (2H, ABd, J=14 Hz, $ArCH_2S$), 2.65 (4H, m, $ArCH_2$), 1.92 (8H, m, CH_2); MS *m/e* 398 (M^+). Found: C, 70.05; H, 6.12; N, 7.47; S, 16.87%. Calcd for $C_{22}H_{22}N_2S_2$: C, 69.80; H, 5.86; N, 7.40; S, 16.94%.

6,9-Dicyano[4.4]paracyclophane (26). The above dicyano dithia compound **24** was oxidized to disulfone **25** in 96% yield. The pyrolysis as described in [3.3]analogue **18** gave the desired [4.4]paracyclophane **26** in 48% yield, colorless columns from benzene–hexane, mp 206.5—207.5 °C.

NMR ($CDCl_3$, 60 MHz) δ=7.12 (2H, s, ArH), 6.76 (4H, s, ArH), 3.1—0.9 (16H, m, CH_2); MS *m/e* 314 (M^+). Found: C, 84.34; H, 7.08; N, 8.78%. Calcd for $C_{22}H_{22}N_2$: C, 84.04; H, 7.05; N, 8.91%.

6,9-Bis(ethoxycarbonyl)[4.4]paracyclophane (27). Diester **27** was derived from dicyano compound **26** in similar manner as in the case of [3.3]analogue **19**, colorless plates from pentane, mp 59.5—61.5 °C, yield 77%.

NMR ($CDCl_3$, 100 MHz) δ=7.30 (2H, s, ArH), 6.66 (4H, s, ArH), 4.37 (4H, q, J=7.2 Hz, OCH_2), 1.42 (6H, t, J=7.2 Hz, CH_3). Found: C, 76.69; H, 7.95%. Calcd for $C_{26}H_{32}O_4$: C, 76.44; H, 7.90%.

6,9-Bis(bromomethyl)[4.4]paracyclophane (28). Bromomethyl derivative **28** was prepared *via* 6,9-bis(hydroxymethyl)[4.4]paracyclophane from the above diester **27** in overall yield 72%, colorless prisms from hexane, mp 129—130 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.75 (2H, s, ArH), 6.67 (4H, s, ArH), 4.37 (4H, centered ABq, J=10.2 Hz, CH_2Br), 3.0—1.0 (8H, m, CH_2). Found: C, 58.97; H, 5.80; Br, 35.46%. Calcd for $C_{22}H_{28}Br_2$: C, 58.69; H, 5.82; Br, 35.49%.

Dithia[3.3][4.4]paracyclophane (30). The synthesis of **30** was accomplished by a reaction of dibromide **28** and 1,4-bis(mercaptomethyl)benzene **29** in similar manner as described in dithia[2.2][4.4]paracyclophane **12**, yield 88%, colorless columns from benzene–hexane, mp 206.5—208 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.76 (4H, centered A_2B_2, ArH), 6.51 (4H, s, ArH), 6.20 (2H, s, ArH), 3.79 (2H, ABd,

J=15 Hz, $ArCH_2S$), 3.71 (4H, s, $ArCH_2S$), 3.42 (2H, ABd, J=15 Hz, $ArCH_2S$), 2.9—1.0 (16H, m, CH_2); MS *m/e* 458 (M^+). Found: C, 78.29; H, 7.43; S, 13.71%. Calcd for $C_{30}H_{34}S_2$: C, 78.55; H, 7.47; S, 13.98%.

Triple-layered [2.2][4.4]Paracyclophane (4). Triple-layered cyclophane **4** was obtained in 55% yield by photodesulfurization of dithia[3.3][4.4]paracyclophane **30** as described in the case of **2**, colorless plates from pentane, mp 129—130 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.53 (4H, s, ArH), 6.35 (2H, A_2B_2dd, J=7.4, 1.0 Hz, ArH), 6.20 (2H, A_2B_2dd, J=7.4, 1.0 Hz, ArH), 5.64 (2H, s, ArH), 3.2—1.0 (24H, m, CH_2); MS *m/e* 394 (M^+). Found: C, 91.32; H, 8.58%. Calcd for $C_{30}H_{34}$: C, 91.31; H, 8.69%.

Dithia[4.4][4.4]paracyclophane (31). The synthesis of **31** was accomplished by a reaction of 6,9-bis(bromomethyl)[4.4]paracyclophane **28** and 1,4-bis(2-mercaptoethyl)benzene **10** in similar manner as described in dithia[2.2][4.4]paracyclophane **12**, yield 77%, colorless plates from benzene–hexane, mp 280—282 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.66 (4H, s, ArH), 6.53 (4H, s, ArH), 6.03 (2H, s, ArH), 3.46 (2H, ABd, J=14 Hz, $ArCH_2S$), 3.03 (2H, ABd, J=14 Hz, $ArCH_2S$), 3.2—0.9 (16H, m, CH_2). Found: C, 78.70; H, 7.63; S, 13.39%. Calcd for $C_{32}H_{28}S_2$: C, 78.96; H, 7.87; S, 13.17%.

Triple-layered [3.3][4.4]Paracyclophane (5) and 6,9-Dimethyl-[4.4]paracyclophane (32). The above dithia compound **31** (49 mg), triethyl phosphite (10 ml), and benzene (20 ml) were mixed in a Vycor tube, and the mixture was irradiated with a low pressure mercury lamp for 12 h in a nitrogen atmosphere. After evaporation of the solvent, the residue was chromatographed on silica gel with hexane. From the first eluate, compound **32** was obtained, 2 mg (7%), colorless prisms from hexane, mp 113—114.5 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.67 (4H, s, ArH), 6.47 (2H, s, ArH), 2.07 (6H, s, CH_3), 2.8—1.1 (16H, m, CH_2); MS *m/e* 292 (M^+). Found: C, 90.18; H, 9.16%. Calcd for $C_{22}H_{28}$: C, 90.35; H, 9.65%.

From the second eluate, the desired triple-layered compound **5** was obtained in 12% yield (5 mg), colorless columns from pentane, mp 170—171 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.60 (2H, ABd, J=7.1 Hz, ArH), 6.53 (2H, ABd, J=7.1 Hz, ArH), 6.51 (4H, s, ArH), 5.96 (2H, s, ArH), 2.8—1.3 (28H, m, CH_2); MS *m/e* 422 (M^+). Found: C, 91.20; H, 8.80%. Calcd for $C_{32}H_{38}$: C, 90.94; H, 9.06%.

Dithia[4.4][5.5]paracyclophane (33). Dithia compound **33** was obtained in 67% yield by the reaction of 6,9-bis(bromomethyl)[4.4]paracyclophane **28** and 1,4-bis(3-mercaptopropyl)benzene **22** in similar manner as described in dithia[2.2][4.4]paracyclophane **12**, colorless prisms from pentane, mp 120—122 °C.

NMR ($CDCl_3$, 100 MHz) δ=6.80 (4H, s, ArH), 6.62 (4H, s, ArH), 6.44 (2H, s, ArH), 3.66 (2H, ABd, J=14.1 Hz, SCH_2), 3.28 (2H, ABd, J=14.1 Hz, SCH_2), 3.1—1.0 (28H, m, CH_2); MS *m/e* 514 (M^+). Found: C, 79.40; H, 8.32; S, 12.30%. Calcd for $C_{34}H_{42}S_2$: C, 79.32; H, 8.22; S, 12.46%.

Triple-layered [4.4][4.4]Paracyclophane (6). The above dithia compound **33** (290 mg) was mixed with acetic acid (2 ml) and 35% hydrogen peroxide (0.6 ml), and heated at 100 °C for 12 h to give colorless precipitate of disulfone **34** (190 mg, 58%).

The above disulfone **34** (50 mg) was pyrolyzed by the method described for 5,8-dicyano[3.3]paracyclophane **18**. The pyrolytic product was chromatographed on silica gel with benzene–hexane and recrystallized from benzene–hexane to give colorless columns of paracyclophane **6**, 2 mg (5%), mp 250 °C (dec).

NMR ($CDCl_3$, 100 MHz) δ=6.55 (8H, s, ArH), 5.99 (2H, s, ArH), 1.6—0.8 (32H, m, CH_2); MS *m/e* 450 (M^+). Found: C, 90.61; H, 9.39%.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 847019 from the Ministry of Education, Science and Culture.

Photocyclization of 2′-Hydroxychalcones to 4-Flavanones

Ryoka MATSUSHIMA* and Ichiro HIRAO

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received September 3, 1979)

On irradiation with light of $\lambda \geqq 365$ nm, parent and methoxy-substituted 2′-hydroxychalcones undergo facile photocyclization to give corresponding 4-flavanones in high efficiencies in ethyl acetate or dioxane, whereas in low or nil efficiencies in benzene, chloroform, carbon tetrachloride, ether, acetonitrile, ethanol, or *t*-butyl alcohol. The low reactivity in benzene is, however, significantly increased by the addition of liquid paraffin to increase the solvent viscosity. 3′,4′-Benzo-2′-hydroxychalcone showed low reactivities in any solvents. The formation of 4-flavanones is neither quenched by triplet quenchers nor depressed by the addition of free radical scavengers. The reaction mechanism is discussed in terms of enolization.

It has previously been reported that the photolysis of substituted 4-flavanones undergo ring opening to give 2′-hydroxychalcones[1-3] or hydrogen atom abstraction to give dimeric products,[2,3] depending on the substituent and solvent.

The photocyclization of 2′-hydroxychalcone in benzene has been reported as a new method for flavanone synthesis (53% yield),[4] though the mechanism has little been studied. The photocyclization of 2′-hydroxychalcones is apparently the reverse process of the photochemical ring opening of 4-flavanones, and it appeared of interest to investigate further the scope of these reactions. The present investigation has emphasized on the solvent effects on the relative reactivity or yield for the photocyclization of parent and substituted 2′-hydroxychalcones.

Experimental

2′-Hydroxychalcones[5] and 4-flavanones[6] were prepared according to the literatures methods. Other reagents and solvents were of guaranteed grade (Wako Chemicals).

Each sample solution was degassed by bubbling with purified nitrogen and sealed in a 5 ml or 10 ml pyrex ampul prior to irradiation. The light source was a 400 W high pressure mercury lamp. A cut-off glass filter (Toshiba UV-35) or an aqueous copper(II) solution filter[7] was employed to eliminate short wavelength regions. The transmittance characteristics of the filters and the main emission from the light source, as well as the absorption spectra of **1a** and **1b**, are illustrated in Fig. 1. Irradiation was carried out by means of a merry-go-round apparatus in a thermostat controlled at 20±1 °C.

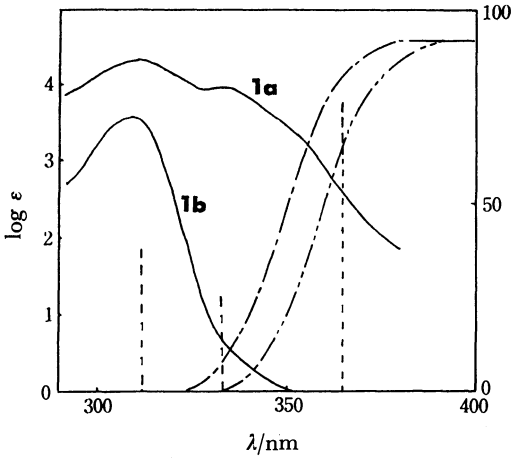

Fig. 1. Absorption spectra of **1a** and **1b** in benzene, and the transmittance characteristics of cut-off filters for selective excitation of **1a**. (— - —): Transmittance of a UV-35 glass filter, (— - - —): transmittance of aqueous copper(II) solution filter, (——): emission from a high pressure mercury lamp.

Photolyzed mixture solutions were condensed below 40 °C and separated by PLC on silica gel–benzene. The photoproducts from **1a** and **2a** were confirmed to be **1b** and **2b** respectively by comparing their NMR and IR spectra, while the photoproducts from **3a**—**5a** were assigned to be **3b**—**5b** respectively by comparing their UV spectra and TLC, with those of the authentic samples prepared independently. The amounts of the products and the reactants in the photolyzed mixtures were determined by colorimetric or gravimetric analysis after separation by PLC on silica gel–benzene. Quantum yields were measured with monochromatic 360—366 nm light from the light source by using a combination of filters (Toshiba UV-35 and UV-D2). For the estimation of the light quanta absorbed by the sample solutions, a mixture of 0.1 M benzophenone and 0.1 M benzhydrol in benzene[8] was used.

UV absorption spectra were measured by the use of a Hitachi 124 spectrophotometer. NMR and IR spectra were measured by means of a Hitachi R-24 NMR spectrometer and a Nihonbunko IRA-1 IR spectrometer, respectively.

Results

Photocyclization of 2′-Hydroxychalcones in Various Solvents. By selective excitation with light of $\lambda \geqq 365$ nm, a series of 2′-hydroxychalcones **1a**—**5a** in deoxygenated solutions underwent photocyclization to give corresponding 4-flavanones **1b**—**5b**, respectively (Scheme 1).

Photolyses of **1a**—**5a** were carried out in a variety of solvents, and the qualitative results are shown in Table 1. Both **1a** and **2a** undergo photocyclization in benzene, ether, ethyl acetate, 1,4-dioxane, acetonitrile, and ethanol, but not in chloroform and *t*-butyl alcohol. Both **3a** and **4a** photocyclize in benzene, ether, ethyl acetate, and 1,4-dioxane, but not in chloroform, carbon tetrachloride, acetonitrile, ethanol, and *t*-butyl alcohol. **5a** shows low reactivity in most solvents.

Effects of the Wavelength of Light. Irradiation of light involving shorter wavelength regions led to the complication of the reaction and the decrease in the rates. Figure 2 illustrates wavelength effects on the relative rates of **2a** and **4a** in benzene.

On irradiation with light of $\lambda \geqq 313$ nm, the consumption rate of **4a** is decreased to 2/5 of that with $\lambda \geqq 334$

a) Irradiated with a 400 W high pressure mercury lamp through a UV-35 glass filter for 10 h at 20 °C. Initial concentrations of 2′-hydroxychalcones were 1 mM. 4-Flavanones formed were detected by TLC on silica gel–benzene.

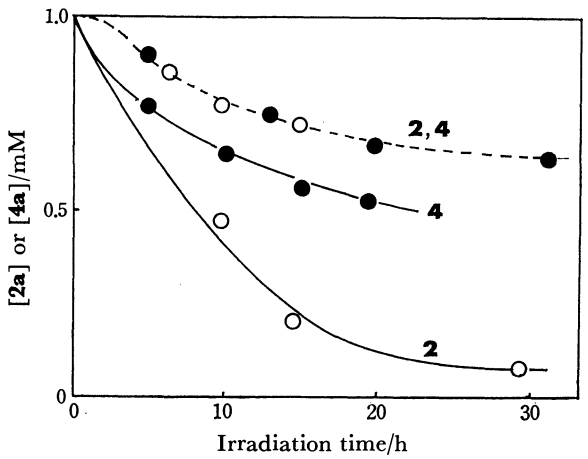

Fig. 2. Wavelength effects on the photoreaction rates of **2a** (○) and **4a** (●) in benzene. (—○—): Irradiation of **2a** with $\lambda \geqq 334$ nm, (--○--): Irradiation of **2a** with $\lambda \geqq 313$ nm, (—●—): irradiation of **4a** with $\lambda \geqq 365$ nm, (--●--): irradiation of **4a** with $\lambda \geqq 334$ nm.

nm. Similarily, the rate of **2a** on irradiation with $\lambda \geqq 334$ nm is 3/5 of that with $\lambda \geqq 365$ nm. A UV-35 (Toshiba) glass filter or an aqueous copper(II) solution filter appears to be suitable to cut shorter wavelength regions (see also Fig. 1).

Variation in the Photoreaction Rates. Relative rates of the reaction were measured in benzene, ethyl acetate, and 1,4-dioxane, since in these solvents all of the 2′-hydroxychalcones **1a—5a** undergo photocyclization (Table 1). Table 2 compares the consumption rates at a constant (5 h) irradiation time, while Figs. 3 and 4

Table 2. Variation in the relative rates with solvent and substituent[a)]

2′-Hydroxy-chalcone	Consumption of 2′-hydroxychalcone (%) in		
	Benzene	1,4-Dioxane	Ethyl acetate
1a	8.2	94	95
2a	10	97	91
3a	14	35	63
4a	30	30	84
5a	7.4	1.4	1.3

a) Initial concentration of each 2′-hydroxychalcone was 1 mM, irradiation time was 5 h.

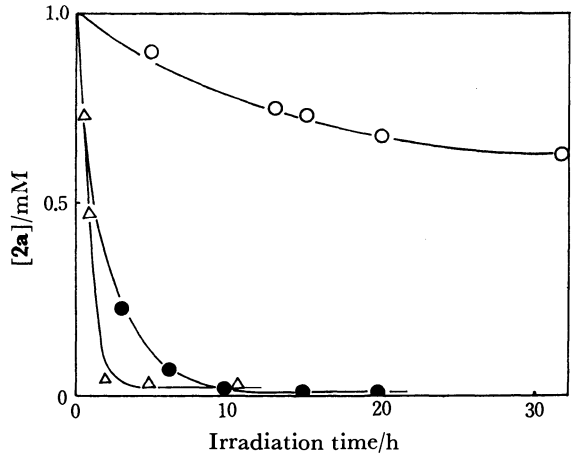

Fig. 3. Consumption of **2a** with irradiation time in benzene (○), 1,4-dioxane (△), and ethyl acetate (●). Similar plots were obtained for **1a**.

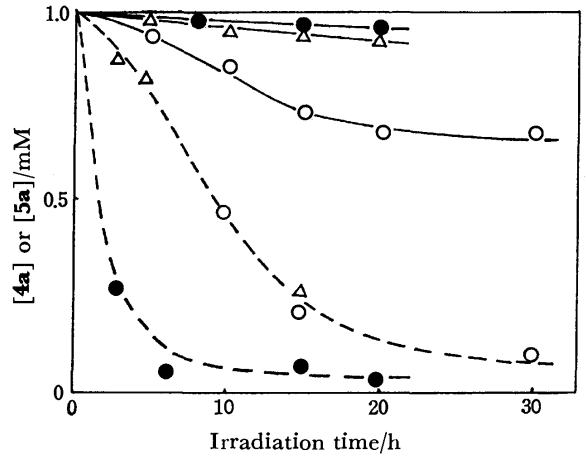

Fig. 4. Consumption of **4a** (broken line) and **5a** (solid line) with irradiation time in benzene (○), 1,4-dioxane (△), and ethyl acetate (●).

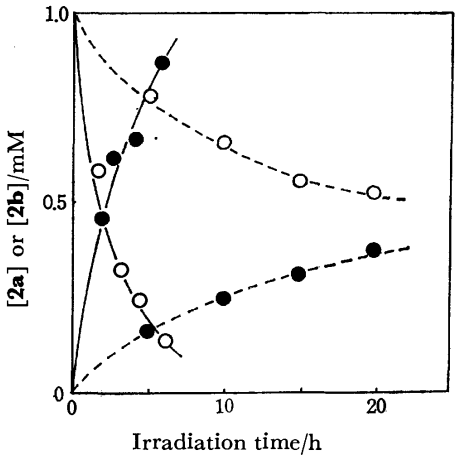

Fig. 5. Concentration changes in **2b** (●) and **2a** (○) with irradiation time in benzene (broken line) and ethyl acetate (solid line).

illustrate the concentration changes with irradiation time.

The results show that the rates are high in ethyl acetate or 1,4-dioxane, and low in benzene, though **5a** has the lowest reactivities in each solvent. It is notable that the rates of **1a** and **2a** are higher in ethyl acetate than in benzene by a factor of 20—40 (Fig. 3).

The quantum yields for the consumption of **1a** and **2a** (1 mM) excited at 365—366 nm were 0.3—0.4 in ethyl acetate and 0.01 in benzene, though they varied depending on the concentration of the reactants and on the extent of the reaction. The low reactivity of **2a** in benzene is significantly increased with the increase in the solvent viscosity (Table 3).

TABLE 3. EFFECTS OF SOLVENT VISCOSITY ON THE QUANTUM YIELD FOR THE CONSUMPTION OF **2a** IN BENZENE–LIQUID PARAFFIN

Liquid paraffin/vol%	Relative viscosity[a)]	Quantum yield × 100
0	1.0	1.0
20	1.4	1.1
40	2.3	1.7
60	4.8	2.7
80	18	3.8
100	150	11

a) Measured at 20±0.5 °C by means of an Ostwald viscositometer.

Variation in the Yields of 2b. The amounts of **2b** formed and **2a** recovered were determined at various irradiation time for the photoreaction of **2a**. Figure 5 illustrates the increasing curve of **2b** and the decreasing curve of **2a** in benzene and ethyl acetate.

The curves of **2a** and **2b** are symmetrical to each other, indicating that the reaction is *clean*. The yields of **2b** based on the consumed amounts of **2a** are listed in Table 4.

Though the values are somewhat scattered, the yields of **2b** are equal or close to unity in ethyl acetate. This implies that the quantum yield for the formation

TABLE 4. YIELDS OF **2b** AT VARIOUS IRRADIATION TIME IN BENZENE, 1,4-DIOXANE, AND ETHYL ACETATE[a)]

Solvent	Irradiation time/h	[2a]/mM Recovered	[2b]/mM Formed	Yield of 2b/%[b)]
Benzene	5	0.77	0.17	74
	10	0.66	0.24	71

	3	0.31	0.55	79
	4	0.06	0.35	58
Ethyl acetate	2	0.57	0.45	100
	3	0.32	0.62	91
	4.5	0.23	0.65	84
	6	0.14	0.86	100

a) Initial concentration of **2a** was 1 mM. Cut-off filter was a 1.5 cm-depth solution of copper(II) sulfate (80 g) and copper(II) nitrate (80 g) in 400 ml water, which had been pre-irradiated for 10 h. The amounts of **2a** and **2b** in the photolyzed mixtures were determined colorimetrically after separation by PLC. b) The yield of **2b** based on the consumed amount of **2a**.

of **2b** is equal or close to the quantum yield value for the consumption of **2a**, or 0.3—0.4 in ethyl acetate. It should be noted that longer irradiation may lower the yield, thus the practical conversion yield of **2b** is 55% at best in 1,4-dioxane. In ethyl acetate the conversion yield of **2a** into **2b** is fairly high, *e.g.*, 86% at 6 h irradiation. The high conversion yield and the cleanness of the reaction (the high yield of **2b** based on the consumed amount of **2a**) in ethyl acetate may be of preparative use, if the wavelength and the time of irradiation *etc.* are suitablly controlled. Since the reaction can be achieved in neutral (mild) media, it may be useful for cyclization of 2'-hydroxychalcones having labile groups to acid or base.

Effects of Triplet Quenchers and Radical Scavengers. The formation of **2b** by the photolysis of **2a** in aerated benzene was not significantly quenched, though unknown side products were also formed. The formation

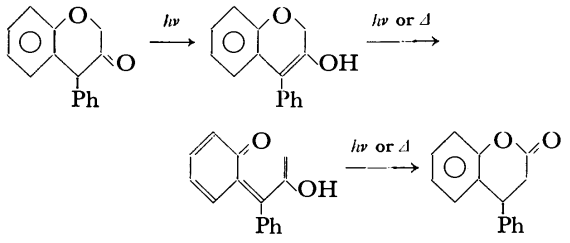
of **2b** was not quenched in the photolysis of **2a** (1 mM) in benzene in the presence of ferrocene (1 mM), *trans*-stilbene (1 mM), or acenaphthylene (2 mM). Selective excitation of **2a** in the presence of acenaphthylene gave isomeric dimers of acenaphthylene, though the formation of **2b** was not quenched. Further, the *anti*/*syn* ratio of dimers was higher than that by direct excitation of acenaphthylene. Thus, the formation of **2b** is not quenched, even when triplet energy is transferred from **2a** to the quenchers.

The addition of 2,6-di-*t*-butylphenol (1 mM) altered neither the rate nor the yield of the formation of **1b** in the photolysis of **1a** (1 mM) in ethyl acetate.

Discussion

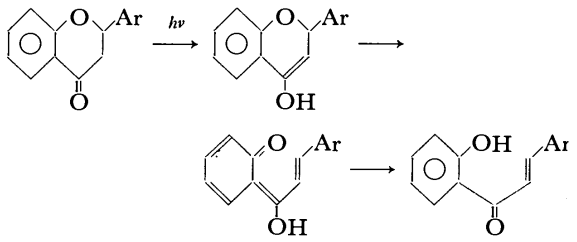
The lack of quenching by triplet quenchers and the lack of inhibition by free radical scavengers (2,6-di-*t*-butylphenol and dissolved oxygen) may imply that a mechanism involving triplet states or free radicals is unlikely. The higher reactivities in polar solvents than in nonpolar solvent (Fig. 3 and Table 2) may support that the reaction takes place through ionic or polar processes.

Though the effects of solvent and substituent on the reactivities (Table 1) are far from explainable as yet, it seems that polar solvents, particularly aprotic polar solvents (basic solvents), are effective for the reaction, while nonpolar solvents are less effective. This may suggest some role of the interactions of solvent with the hydroxyl group of 2′-hydroxychalcones. One may assume, for example, that the intramolecular hydrogen bonding of the 2′-hydroxychalcones would be broken or loosened by solvation or proton transfer from the hydroxyl group to a basic or polar solvent, affecting the structures and reactivities in their ground state or excited states. The NMR signal of the phenolic proton of **1a** at $\delta \approx 12.5$ ppm was not changed at all with the change in the solvent from benzene to ethyl acetate, 1,4-dioxane, and 1,4-dioxane–water (3: 1), implying that the intramolecular hydrogen bonding in the ground state remains unchanged even in basic or polar solvents. Thus, the ground state structures of the 2′-hydroxychalcones may be represented by **10** regardless of solvent.



Scheme 2.

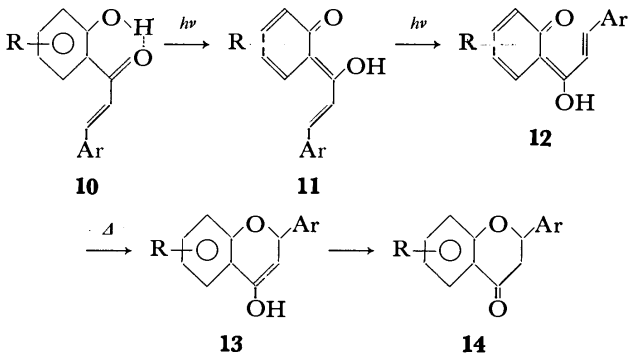
A. Padwa *et al.* have shown that the photochemical rearrangements of 3-chromanone derivatives take place *via* enolization (Scheme 2).[9] Similar mechanism has also been proposed for the photochemical ring opening reaction of the substituted 4-flavanones in benzene (Scheme 3).[3] It is noted that the photocyclization



Scheme 3.

of the 2′-hydroxychalcones to the 4-flavanones is apparently the reverse reaction of the photochemical ring opening of the 4-flavanones and that the both reactions can indeed be reversible under suitable conditions.

It seems, therefore, reasonable to assume a similar mechanism (involving enolization) for the photocyclization (Scheme 4). Photochemical excitation of **10** would lead to enolization to give **11**, which needs, however, to undergo *cis-trans* isomerization to **12** for the subsequent cyclization to occur. The cyclization of **12** to **13** may be exothermic or less endothermic due to the recovery of aromatic stability, and proceed effectively *via* a thermal 6-π electrocyclic process.



Scheme 4.

The two-photon mechanism in Scheme 4 requires that the upper limit of the quantum yield for the formation of 4-flavanone should be 0.5. The quantum yield estimated for the formation of **2b** in ethyl acetate ranges in 0.3—0.4, which is close to the upper limit. The estimated quantum yield is strikingly high despite the short lifetimes of the excited singlet states of aromatic ketones in solution. The reaction would proceed so rapidly and effectively that it dominates over rapid deactivation processes of excited singlet states, such as intersystem crossing and internal conversion *etc.* It is known that the acidities of phenols are greatly increased in the excited singlet states.[10] The increased acidity of **10** in the excited singlet state would allow facile acid-catalyzed enolization, and polar solvents may accelerate the reaction by stabilization of the enols.

In non polar solvents, such as benzene, the enols would be less stabilized and the reaction is less efficient so that deactivation processes may compete with or dominate over. The increase in the reaction efficiency with the solvent viscosity (Table 3) may imply that bimolecular deactivation processes, as well as unimolecular ones, compete well with the forward reaction in benzene.

The authors wish to thank Mr. H. Mizuno for his hospitality and considerable assistance in the preparation of the samples. They also wish to thank Dr. M. Suzuki, Mr. M. Morioka, and Miss S. Yamazaki for their comments and encouragement.

Aromatization of Ring-A in α-Bromocholestan-6-ones

SHAFIULLAH* and ISLAMUDDIN
Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India
(Received May 8, 1978)

Pyridine promoted dehydrohalogenation of 3β-chloro-5-bromo-5α-cholestan-6-one resulting in ring-A aromatization with expulsion of C-10 angular methyl group to give 19-norcholesta-1,3,5(10)-trien-6-one along with 3α,5-cyclo-5α-cholest-7-en-6-one, cholesta-2,4-dien-6-one, and 5α-cholestane-3,6-dione. Similar treatment of 3β-chloro-5,7β-dibromo-5α-cholestan-6-one ends up with the aromatization of ring-A with migration of C-10 angular methyl group to give 1-methyl-19-norcholesta-1,3,5(10)-trien-6-one.

Our understanding of principles involved in selective ring-A aromatization of steroids[1] has acquired enormous attention in recent years as a result of brilliant investigations carried out by Hora,[2] Hanson,[3] and Mazur.[4] They have enlightened the mechanistic aspect of aromatization reactions. Moreover, aromatic steroids have proved their usefulness as important starting material in the synthesis of 19-norsteroids.[5] In addition to above, 10-nor-analog steroidal hormones[5] began to receive immense attention when it was realized that the presence of the angular methyl group at C-10 was not essential to biological activity and in fact, that the removal of this group, in many cases, results in great enhancement of this reactivity. This paper is the subject of outcome of the generalizations in the light of above historical background.

Results and Discussion

The compounds **2** ($C_{27}H_{44}OClBr$) and **7** ($C_{27}H_{43}OClBr_2$) were obtained from 3β-chloro-5α-cholestan-6-one (**1**)[6] by usual α-bromination. The identity of these products were based upon spectral and chemical evidences. In IR spectra the carbonyl frequencies at 1712 cm^{-1} was indicative for the axial (α) oriented bromine at C5 in **2** and 1725 cm^{-1} for equatorially substituted at C7 in **7**.[7,8] The NMR spectra (60 MHz, $CDCl_3$) exhibited signals at δ 4.5 ($W/2$ 21 Hz) and δ 4.39 ($W/2$ 20 Hz) for (C3-αH; axial) implying trans ring junction[9] in **2** and **7**. Interestingly, C3-protons of **2** and **7** display paramagnetic shifts, compared to parent ketone (**1**) where it appears at δ 3.8, ascribable to the field effect of axial bromine at C5.[10] In the spectrum of **7** a doublet at δ 5.35 (C7-αH) very decisively supported that the bromine at C7 is equatorially introduced and the axial hydrogen is split by C8-axial hydrogen (β) with J value of 8 Hz.[10] Singlets due to C10β-methyl and C13β-methyl appeared at δ 1.0 and 2.69 in **2** and at δ 1.1 and 0.72 in **7** respectively.

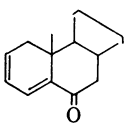
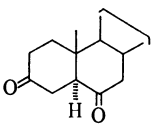
4



5

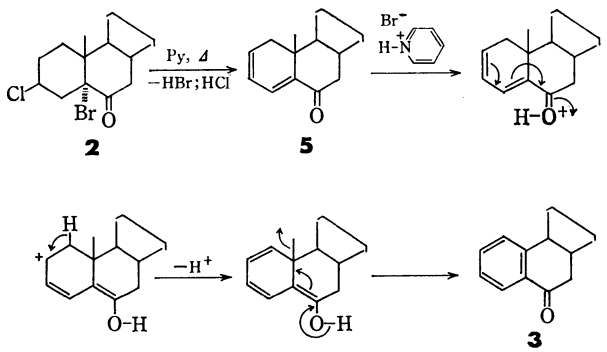


6

The halo ketone (**2**) on subjection to dehydrohalogenation provided **3** in about 38%, 3α,5-cyclo-5α-cholest-7-en-6-one (**4**), (9%) cholesta-2,4-dien-6-one (**5**)[11] (11%) and 5α-cholestane-3,6-dione (**6**)[12] (22%). The structures were established on spectral evidences and by comparison with authentic samples in known cases. The compound (**3**)[2] showed IR bands at 3060 (C=C–H), 1680 (C=O) and 1600 cm^{-1} (>C=C<).[10] The UV spectrum gave absorption maxima at 253 and 295 nm. Signals in the NMR spectrum were observed at δ 8.05 m (C4-H, J=8 Hz, o-coupled; J=2 Hz, m-coupled), 7.3m (C1-H, C2-H, C3-H). The multiplet at δ 8.05 strongly supported C4-H location β- to C6-oxo function. C13β-Methyl protons appeared as singlet at δ 0.76.

The mechanistic pathway through which **2** is converted into **3** is depicted in Scheme 1.

The product 4 in IR spectrum showed bands at 3080 (C=C–H), 1665 (C=C–C=O), 1605 cm^{-1} (>C=C<). The prominent bands at 1030 and 1010 cm^{-1} suggested the presence of cyclopropane moiety.[13] An α,β-unsaturated ketonic chromophore was also supported by absorption maximum at 253 nm (ε 8000). A signal in NMR spectrum (60 MHz) at δ 6.22s devoid of any vicinal proton, easily ascribable to a vinylic proton (C7-H). A multiplet at δ 2.55 was ascribable to protons at C9 and C14, allylic to C7-8 olefinic linkage. Signals due to C10β-methyl and C13β-methyl protons are at δ 1.22s and 0.76s. It is pertinent to mention that the



2 **5** **3**

Scheme 1.

nearby location of electron withdrawing C6-oxo function causes downfield shift of cyclopropane protons which merge with the methylene envelope.[14] The formation of **4** was, under the reaction conditions, rationalized on the basis of earlier report.[15]

On being refluxed with pyridine and after usual work up of the reaction mixture (**7**) provided exclusively **8** with 38% yield, a product of ring-A aromatization involving methyl migration from C10 to C1 owing to the presence of C6-oxo function.[3] The IR spectrum of **8** exhibited bands at 1685 (-C=O), 3010w (C=C-H) and 1600 cm^{-1} (>C=C<) and supported by UV absorption maxima at 255 and 300 nm. The NMR spectrum gave signals at δ 7.95d,d (C4-H; J=8 Hz; *o*-coupled, J=2 Hz; *m*-coupled; β to C6-oxo function), 7.35m (C2-H and C3-H). The C1-methyl and C13β-methyl protons appeared as singlet at δ 2.42 and 0.73 respectively.

Experimental

All melting points are uncorrected. IR spectra in Nujol were recorded with a Perkin-Elmer 237 spectrophotometer and UV spectra in 95% EtOH with a Beckmann DK2 spectrophotometer. NMR spectra were run in $CDCl_3$ with a Varian A60 instrument, chemical shifts (δ) being given in ppm relative to internal TMS and mass spectra were measured on an AEI MS-9 mass spectrometer. Light petroleum refers to fractions by 60—80 °C. TLC plates were coated with silica gel and sprayed with 20% perchloric acid solution.

3β-Chloro-5-bromo-5α-cholestan-6-one (2). The compound **1**[6] (4.0 g) in ether (50 ml) at 0 °C was treated with a solution of bromine in glacial acetic acid (40 ml, 5%); the addition of bromine solution was completed over a period of 1 h (catalysed with hydrobromic acid). Decolourization proceeded rapidly and crystalline material separated after the addition of approximately half of the bromine solution. The reaction mixture was further allowed to stand at 0 °C for 1/2 h to ensure complete crystallization. The solid was filtered under suction and recrystallized from light petroleum ether from which **2** (3.5 g) separated as white crystals, mp 124—125 °C, positive Beilstein halogen test (homogeneous by TLC, solvent petroleum ether–diethyl ether); Found: C, 65.54; H, 8.5%. Calcd for $C_{27}H_{44}OClBr$: C, 64.85; H, 8.8%; ν_{max} 765 (C-Cl), 740 cm^{-1} (C-Br).

3β-Chloro-5,7β-dibromo-5α-cholestan-6-one (7). To a solution of **1**[6] (4.0 g) in ether (20 ml) at room temperature was added bromine solution. The experimental technique was similar to that detailed under **2** except, the reaction mixture was allowed to stand at room temperature for three days. Recrystallization from petroleum ether afforded the halo ketone (**7**) (3.8 g), mp 174—175 °C, positive Beilstein halogen test (homogeneous TLC; solvent system petroleum ether–diethyl ether); Found: C, 55.85; H, 7.45%. Calcd for $C_{27}H_{43}OClBr_2$: C, 55.95; H, 7.59%; ν_{max} 768 (C-Cl), 736 and 655 cm^{-1} (C-Br).

Dehydrohalogenation of 2. The halo ketone **2** (10 g) in freshly distilled pyridine (70 ml) was heated under reflux for 10 h. Most of the solvent was removed by distillation under reduced pressure, the residue diluted with water and extracted with ether. The ethereal solution was washed successively with water, dilute hydrochloric acid, water, $NaHCO_3$ (5% aqueous solution) and water and dried over anhydrous sodium sulfate. Solid material (5.0 g) thus obtained was chromatographed over silica gel (100 g). Fractions of 10 ml were collected. Elutes from petroleum ether–benzene (20: 1) and (15: 1) gave cholesta-2,4-dien-6-one (**5**),[11] (1.1 g) mp and mixed mp 128—129 °C and 5α-cholestane-3,6-dione (**6**),[12] (2.2 g), mp and mixed mp 168 °C, respectively.

Further elution with petroleum ether–benzene (12: 1) gave 3α,5-cyclo-5α-cholest-7-en-6-one (**4**) which was crystallized from petroleum ether (0.9 g), mp 118—119 °C, negative Beilstein halogen test MS (10 eV) *m/e* 382 (80.3%) (M^+); Found: C, 84.6; H, 10.7%. Calcd for $C_{27}H_{42}O$: C, 84.8; H, 10.9%.

Elution with petroleum ether–ether (9: 1) gave 19-norcholesta-1,3,5(10)-trien-6-one (**3**) which was recrystallized from petroleum ether (3.76 g), mp 110 °C, negative Beilstein halogen test; MS (70 eV) *m/e* 366 (82.0%) (M^+); Found: C, 85.03; H, 10.5%. Calcd for $C_{27}H_{38}O$; C, 85.24; H, 10.38%.

Dehydrohalogenation of 7. The halo ketone **7** (5.0 g) in freshly distilled pyridine (35 ml) over KOH heated under reflux for 10 h. The reaction mixture worked up in the manner described under **2**. Removal of the solvent gave semi solid material (4.0 g) which was chromatographed over silica gel (80.0 g). Fractions of 10 ml were collected. Elutes from petroleum ether–benzene (6: 1) gave 1-methyl-19-norcholesta-1,3,5(10)-trien-6-one (**8**) which was recrystallized from petroleum ether (1.9 g), mp 140 °C, negative Beilstein halogen test; MS (70 eV) *m/e* 380 (100%) (M^+); Found: C, 85.06; H, 11.2%. Calcd for $C_{29}H_{40}O$: C, 85.26; H, 10.52%.

We thank Prof. W. Rahman, Head, Department of Chemistry for providing facilities and Prof. M. S. Ahmad for helpful discussion.

The Formation and Some Properties of Hydrous Manganese(IV) Oxide

Eiichi NARITA* and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received January 22, 1979)

The properties of two kinds of hydrous manganese(IV) oxides (abbreviated as hydrous MnO_2) prepared by the reduction of $KMnO_4$ and by the disproportionation of K_2MnO_4 in alkaline solutions were investigated by means of chemical analysis, X-ray analysis, IR spectroscopy, wide-line NMR spectroscopy, thermal analysis, magnetic susceptibility measurement, *etc.* The chemical reactivity of the hydrous MnO_2 was also evaluated from the extent of oxidation to K_2MnO_4 by the reaction with an alkaline $KMnO_4$ solution at 80 °C. The properties and reactivity of the hydrous MnO_2 predominantly depended on the pH of the suspensions. At a pH 8 or higher, amorphous ternary compounds of manganese(IV) oxide with an approximate composition of $K_2O \cdot 4MnO_x \cdot 4H_2O$ ($x = 1.97$—2.00) were formed. The IR spectra and wide-line NMR spectra showed that the chemically bound water was in two different forms. The hydrous MnO_2 had the greater chemical reactivity, being easily soluble as manganate(VI) ions by the reaction described above. The contents of the chemically bound water and alkali in the hydrous MnO_2 decreased with a decrease in the pH of the suspensions and upon the acid-treatment of the precipitates. This variation in the chemical composition caused a decrease in the reactivity and a marked variation in the thermal behavior. The structure of the hydrous MnO_2 was discussed on the basis of findings regarding the magnetic susceptibility and its temperature dependence.

The synthetic manganese(IV) oxide prepared by the reduction of $KMnO_4$ in alkaline solutions is generally called "Hydrous MnO_2"[1] because of a large content of chemically bound water. It is also a giant molecule which is seldom stoichiometric. In the chemical industries, the hydrous MnO_2 is formed only in the production of saccharin as a by-product. Therefore, studies of its properties and chemical reactivity have been performed in comparison with those of various MnO_2 substances prepared by the pyrolysis of manganese(II) compounds or by the oxidation of manganese(II) ions in acid solutions. According to Regner *et al.*[2] and Sterr and Schmier,[3] the hydrous MnO_2 has the formula of $3MnO_2 \cdot MOH \cdot 2H_2O$ (M=K, Na) and the structure of δ-MnO_2, but there remains a lack of understanding the relationship between the various properties and the conditions of preparation. The present authors have now studied the reactivity of various kinds of hydrous MnO_2 in order to develop an alkaline $KMnO_4$ solution for use in air-pollution control, such as the removal of nitrogen oxides from waste gas,[4] and have found that the properties and reactivity are greatly influenced by the conditions of formation. The main purpose of this paper is to report on the factors influencing the chemical composition, the reactivity, and some properties of the hydrous MnO_2 prepared by the reduction of alkaline $KMnO_4$ solutions and by the disproportionation of alkaline K_2MnO_4 solutions.

Experimental

Materials. $KMnO_4$ and K_2MnO_4 were used as the starting materials. The $KMnO_4$ was a commercial extra pure reagent. The K_2MnO_4 was prepared by the decomposition of $KMnO_4$, boiling it in a 6 M (1 M=1 mol dm^{-3}) potassium hydroxide solution and then keeping it dry in a desiccator over phosphorus(V) oxide.

Preparation of Hydrous MnO_2. The hydrous MnO_2 substances were prepared by the following two reactions. (1) A four-necked flask was equipped with a reflux condenser, a dropping funnel, a glass electrode of a pH meter, and a thermometer. A definite quantity of an alkaline solution of 0.1—0.2 M $KMnO_4$ in the range from 300 to 500 cm^3 was introduced into the flask, and then heated to the desired temperatures (30, 56, 86 °C). A solution of the reducing agent, such as H_2O_2, K_2SO_3, and KNO_2, in the dropping funnel was then added, drop by drop (100 cm^3/h), to the $KMnO_4$ solution during violent agitation by means of a magnetic stirrer. Potassium hydroxide was used as an alkali component, while potassium hydrogencarbonate was suitably used as a pH controller. After the completion of the addition, the suspensions were stirred for a further 30 min. The products were then separated from the suspensions by filtration, washed with distilled water, and dried overnight at 110 °C. (2) A definite quantity of an alkaline solution of 0.6 M K_2MnO_4 in the range from 300 to 500 cm^3 was introduced into the flask, and then the mixture was heated to 50 °C. A 0.5—1.0 M H_2SO_4 solution in a dropping funnel was added, drop by drop (100 cm^3/h), to the K_2MnO_4 solution with violent agitation until the pH of the suspensions attained the desired value. The subsequent treatment of the precipitated hydrous MnO_2 was the same as has been described above (1).

Analysis of Chemical Composition of Hydrous MnO_2. The hydrous MnO_2 substances were dried overnight in an electric oven in air to eliminate the adsorbed water and subsequently analyzed for available oxygen, manganese, and potassium contents. The available oxygen was determined by the standard oxalic acid method.[5] Absorption spectroscopy was used for the determination of the manganese content. In this analysis, the manganese(II) ion obtained by the reduction of the sample with oxalic acid was oxidized to the permanganate ion by potassium periodate in the presence of a mixed acid (HNO_3: H_3PO_4: H_2O=1 : 1 : 1). The x-value in MnO_x was calculated from the resulting data. The potassium content was determined by atomic absorption spectroscopy. The balance was regarded as the chemically bound water.

Characterization of Hydrous MnO_2. The X-ray diffraction patterns were obtained using a Rigaku Denki Geigerflex D-2F with Mn filtered Fe $K\alpha$ radiation, with 25 kVP and 10 mA. The IR absorption spectra were obtained using a Shimadzu I-430 spectrometer with the KBr pellet technique. The wide-line NMR absorption spectra measurements were made at 40 MHz using a Nippon Denshi JNMW-40 spectrometer equipped with a 9000 variable-frequency oscillator. The samples were pressed to form tablets in order to increase

the proton number per unit volume. The surface area was measured by means of the BET nitrogen adsorption at 78 K, after outgassing at 373 K. The samples were prepared by the acetone drying of the hydrous MnO_2 suspensions after filtration in order to keep the original particle shape. The magnetic susceptibility was measured at temperatures from 77 to 298 K using a magnetic balance with a maximum magnetic field strength of 2 T. DTA and TG were performed using a Rigaku Denki Thermoflex over the range from room temperature to 1200 °C. The rate of temperature rise was 10 °C/min.

Evaluation of Chemical Reactivity of Hydrous MnO_2. The chemical reactivity of the hydrous MnO_2 with an alkaline $KMnO_4$ solution was measured as follows. The hydrous MnO_2** (5.00×10^{-3} mol Mn) was stirred in a 200 cm^3 Erlenmeyer flask with a 100 cm^3 portion of a 6.0 M potassium hydroxide solution. Subsequently, a 1.586 g portion of fine-ground $KMnO_4$ (1.000×10^{-2} mol) was added to the hydrous MnO_2 suspension, after which the reaction was continued under violent agitation for a period of 2 h at 80 °C† as

$$MnO_2 + 2KMnO_4 + 4KOH = 3K_2MnO_4 + 2H_2O. \quad (1)$$

After having been filtered, the amount of the residual hydrous MnO_2 was determined by the absorption spectroscopy previously described. The chemical reactivity was defined as the degree of the oxidation (abbreviated as D.O. hereafter), which is given by

$$\text{D.O. (\%)} = \frac{[MnO_2]_0 - [MnO_2]_t}{[MnO_2]_0} \times 100$$

$[\ ]_0$: Initial amount, $[\ ]_t$: amount after 2 h.

Results and Discussion

The chemical composition and reactivity of the hydrous MnO_2 prepared by the reduction of alkaline $KMnO_4$ solutions and by the disproportionation of

a) The calculated chemical composition of the $K_2O\cdot4MnO_2\cdot4H_2O$ formula is as 18.3 K_2O, 67.7 MnO_2, and 14.0 H_2O (wt%).

** Because these was no difference in the reactivity between dried and undried samples, the later was used for this reaction.

† It has been found that the reaction is complete under these conditions.

alkaline K_2MnO_4 solutions are given in Tables 1 and 2 respectively.

Effects of pH. In the case of the reduction of a $KMnO_4$ solution, a low pH of the solution causes the reduction of $KMnO_4$ to the manganese(II) ion. The pH was, therefore, kept at about 8 or higher in the following reactions:

$$2KMnO_4 + H_2O_2 = 2MnO_2 + 2KOH + 2O_2 \quad (2)$$

$$2KMnO_4 + 3K_2SO_3 + H_2O = 2MnO_2 + 3K_2SO_4 + 2KOH \quad (3)$$

$$2KMnO_4 + 3KNO_2 + H_2O = 2MnO_2 + 3KMNO_3 + 2KOH \quad (4)$$

The hydrous MnO_2 obtained from the solution of pH$\gg$8 had an approximately constant composition, with the formula of $K_2O \cdot 4MnO_x \cdot 4H_2O$ (x=1.97—2.00), as is shown in Table 1. According to the X-ray diffraction patterns, they were all amorphous. The stoichiometry indicates that the hydrous MnO_2 substances shown in Table 1 are similar to the synthetic product studied by Sterr *et al.* and called δ-MnO_2, the formula of which is $KOH \cdot 3MnO_2 \cdot 2H_2O$, and to the active MnO_2 studied by Regner *et al.*, the K_2O content of which is 11.3—14.9 wt%. However, the hydrous MnO_2 obtained in this experiment had the chemically bound water and a little more K_2O than the synthetic MnO_2 in their earlier studies. These differences in the chemical composition appeared to be dependent on the conditions of the washing treatment of the hydrous MnO_2 after filtration. Especially, the K_2O are involved with the MnO_2 particles with quite small bond forces at the time of the formation of the hydrous MnO_2. Its content was, therefore, decreased by repeated washings with distilled water. The hydrous MnO_2 substances shown in Tables 1 and 2 have been washed with the minimum amount of distilled water possible to remove only physically adsorbed ions, that is, until the absorbed permanganate ion was not observed in the wash water. All of the hydrous MnO_2 substances obtained from the solutions of pH$\gg$8 at low temperatures (30, 50 °C) were chemically active in the reaction (Eq. 1), the D.O. values being high, as is shown in Table 1. The results show that the pH of the original suspensions is an important factor in getting the highly active hydrous MnO_2. In the process of removing NO_x from waste gas with an alkaline $KMnO_4$ solution,[4] the hydrous MnO_2 obtained as a by-product is regenerated to a soluble manganate(VI) by a reaction according to Eq. 1. It is easy to oxidize the manganate(VI) to permanganate by the electrolytic oxidation.

The disproportionation of K_2MnO_4 solutions was performed by the drop-by-drop addition of a H_2SO_4 solution until the pH of the suspensions attained the desired value. Although the pH successively varied during the drop-by-drop addition of the acid in the following reaction:

$$3K_2MnO_4 + 2H_2SO_4 = MnO_2 + 2KMnO_4 + 2K_2SO_4 + 2H_2O \quad (5)$$

the effect was kept negligible by keeping the hydrous MnO_2 in a mother liquor at the each last pH shown in Table 2. Figure 1 clearly indicates the chemical

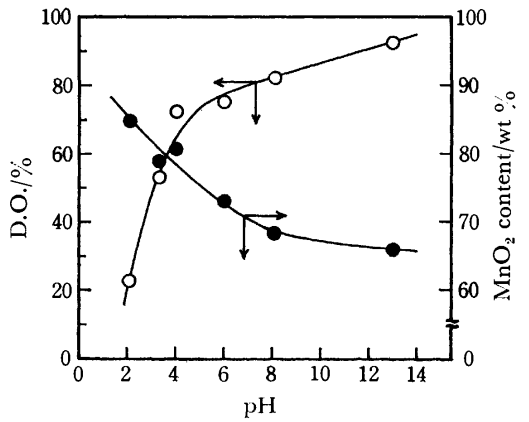

Fig. 1. The chemical reactivity, D.O. and MnO_2 content of the hydrous MnO_2 as a function of pH of suspensions obtained by disproportionation.

reactivity, D.O., and the MnO_2 content as functions of the pH of the suspensions obtained by the disproportionation. The chemical composition and reactivity of the hydrous MnO_2 were influenced by the pH, especially in the range from pH 6 down. As is shown in Table 2, the hydrous MnO_2 substances precipitated at high pHs had chemical compositions and reactivities similar to those prepared by the reduction of $KMnO_4$ solutions described above. The MnO_2 content increased with a decrease in the pH; the chemical reactivity and the x-value in MnO_x also decreased simultaneously. The same tendency was observed by the acid-treatment of the hydrous MnO_2. A typical hydrous MnO_2, Sample No. 16, was mixed with a 1 M H_2SO_4 solution for 2 h at 50 °C. The chemical composition, reactivity, and D.O. of the resulting acid-treated MnO_2, Sample No. 22, are shown in Table 2. The hydrous MnO_2 lost not only a considerable amount of the chemically bound water and alkali, but also its high chemical reactivity upon the acid treatment. The X-ray diffraction pattern suggests that Sample No. 22 was slightly crystallized as α-MnO_2. On the other hand, when a hydrous MnO_2 with a low reactivity, Sample No. 14, was mixed with a 10 M KOH solution for 3 h at 80 °C, there was no change in the chemical composition and reactivity, as is shown in Table 2. The surface state of the hydrous MnO_2 obtained from the high pH of the suspensions is thermodynamically unstable and active. However, it easily becomes stable upon the acid treatment, though it recovers its original surface state by the alkali treatments only with great difficulty.

In the reaction of the hydrous MnO_2 with an alkaline $KMnO_4$ solution for a period of 2 h at 80 °C, only the manganate(VI) was always obtained as a final soluble manganate species in spite of the differences in the chemical reactivities of the hydrous MnO_2. In addition to the dissolved manganese, the solution contained some unreacted hydrous MnO_2. The results show that the decomposition of the alkaline $KMnO_4$ solution simultaneously occurred as follows: an available oxygen of $KMnO_4$ is wastefully consumed by

$$4KMnO_4 + 4KOH = 4K_2MnO_4 + 2H_2O + O_2 \quad (6)$$

the decomposition, which is accelerated by the presence

of manganese(IV) oxides.[6,7] The hydrous MnO_2 substances with high D.O. values were, therefore, regarded as the active MnO_2 in reacting with permanganate ions. The reactivity of the hydrous MnO_2 substances with the alkaline $KMnO_4$ solution increased with increases in the chemically bound water and alkali contents. The results show that the chemically bound water and alkali play an important role in the oxidation of the hydrous MnO_2, (Eq. 1).

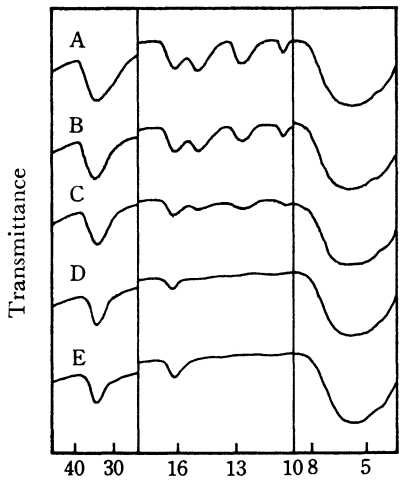

Fig. 2. IR spectra of the hydrous MnO_2 prepared at various pH of suspensions.
A: Sample No. 1—13, 16, 17 (pH>8.1), B: Sample No. 18 (pH 6.0), C: Sample No. 20 (pH 3.3), D: Sample No. 21 (pH 2.1), E: Sample No. 22 (pH<1).

IR and NMR Absorption Spectra. The IR spectra for the hydrous MnO_2 prepared at various pH values of the suspensions are given in Fig. 2. Sample No. 16, prepared at a high pH, has the typical composition of the hydrous MnO_2, and its spectrum displays five distinct bands at the frequencies of 440—620, 1050, 1280, 1510, 1630, and 3400 cm^{-1}. The bands at 1630 and 3400 cm^{-1} are the OH stretching band and the OH bending vibration band respectively. The broad band at 440—620 cm^{-1} is based on the Mn–O bond. The spectrum of the typical hydrous MnO_2 is characterized by additional three bands at 1050, 1280, and 1510 cm^{-1}. It seems likely that these three bands are based on the OH bending vibration combined with the Mn atom. However, it is possible that the bands are based on the bending vibration of the hydroxyl group containing alkali because of the correlation between the intensity of the absorbance and the K_2O content. No clear reversion could be made. Despite many studies[8] of the IR spectra of the natural MnO_2 ores and the synthetic MnO_2 obtained from the acid solutions by the use of various methods, these three bands shown in Fig. 2 have not yet been reported. The intensity of the absorbance of these three bands gradually becomes weaker with a decrease in the pH, until those for such hydrous MnO_2 substances as Sample No. 21, prepared at the lowest pH in this experiment, are ultimately not observed. A similar tendency was observed in the case of the acid-treated hydrous MnO_2, Sample No. 22. According to the chemical analysis, these hydrous MnO_2 substances still have a considerable amount of the chemically bound water, most of it in the form of the H_2O molecule. The evaluation of the chemical reactivity was possible by the measurement of the IR spectra because of the close correlation between the intensity of absorbance of the three bands and the chemical reactivity of the hydrous MnO_2.

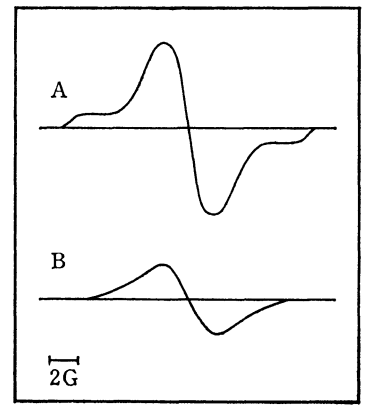

Fig. 3. Typical NMR spectra of the hydrous MnO_2.
A: Sample No. 3, B: Sample No. 22 (Acid-treated MnO_2).

A typical NMR spectrum of the hydrous MnO_2, Sample No. 3, is shown in Fig. 3(A). This spectrum consists of a narrow absorption line, ΔH 3.8 G, superimposed on a broad one, ΔH 15.5 G. The broad line and the narrow one appear to be dependent on the hydroxyl group combined with the MnO_2 polymeric structure and on the H_2O molecule with a comparatively weak interaction to the lattice atom respectively. Glemser[9] distinguished between adsorbed water and chemically bound water by NMR spectroscopy for δ-MnO_2 and γ-MnO_2. These MnO_2 substances showed a broad line, with a superimposed narrow line with a width of 2.1—2.2 G which is due to the physically adsorbed water. The proton causing the narrow line in Fig. 3(A) is not so free in the hydrous MnO_2 structure. Therefore, it appears to belong to the H_2O molecule combined with the lattice. The hydrous MnO_2 obtained from the alkaline solution is a kind of hydro-gel, for it is amorphous and contains a large amount of water and alkali. The water in such gels never has a definite form in the bond state such as the physically adsorbed water and the water of crystallization have. In the case of the hydrous MnO_2, the water may be contained in a porous structure of the MnO_2 polymer in various bond states, and the polymer chain is cleaved to form the hydroxyl group as follows:

$$\begin{array}{c} | \quad | \\ -Mn-O-Mn- \\ | \quad | \end{array} \xrightarrow{H_2O} \begin{array}{c} | \\ -Mn-OH \\ | \end{array} + \begin{array}{c} | \\ HO-Mn- \\ | \end{array}$$

The influence of the chemical composition on the reactivity of the hydrous MnO_2 indicates that the H_2O molecule in the hydrous MnO_2, which forms most of the chemically bound water, is not merely the physically adsorbed water. The NMR spectrum of the acid-

treated hydrous MnO_2 containing 5.5 wt% of chemically bound water, Sample No. 22, is shown in Fig. 3(B). While a broad absorption line vanished, a narrow one still remained with a weak intensity. These spectra indicate the same results as those of the IR spectra shown in Fig. 2.

Effects of Temperature. The chemical composition of the hydrous MnO_2 varied depending upon the temperature of the suspensions shown in Table 1, but this variation was not so remarkable as the effect of the pH. The contents of the chemically bound water and alkali in the hydrous MnO_2 slightly decreased with an increase in the temperature of the suspensions, and the chemical reactivity decreased because of the reduction of the active sites in the reaction (Eq. 1). The x-value in MnO_x of the hydrous MnO_2 prepared by reduction at a high temperature decreased to 1.90—1.93 when the H_2O_2 solution was used as a reducing agent. However, this tendency was not observed in the case of the hydrous MnO_2 prepared by the use of other kinds of reducing agents. The difference in the amount of available oxygen of the hydrous MnO_2 appeared to originate from the reducing force of the reducing agent used. The redox of the manganese ion and the replacement of O^{2-} by any other ions occur without any changes in the crystal lattice in manganese(IV) oxides, well known as typical homogeneous, solid redox systems.[10]

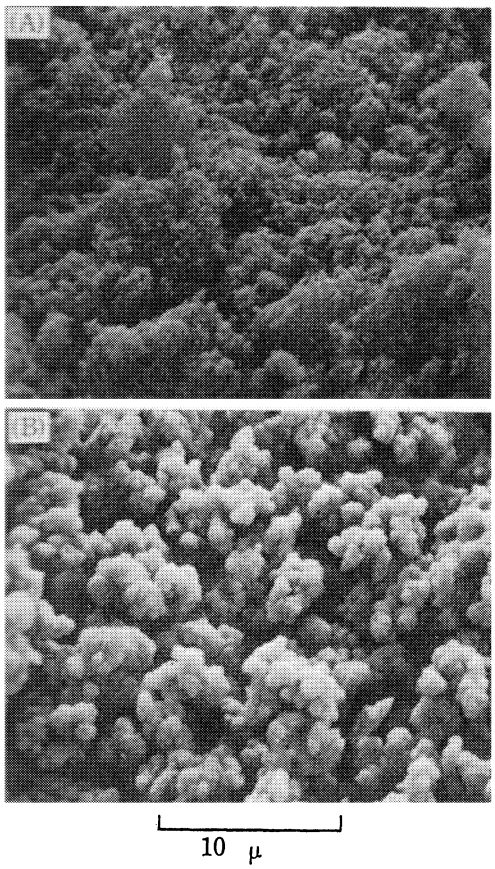

Fig. 4. Scanning electron micrographs of the hydrous MnO_2 prepared by reduction.
(A): Reduction by H_2O_2 (Sample No. 3), (B): Reduction by KNO_2 (Sample No. 8).

A H_2O_2 solution, therefore, reacts with the precipitated hydrous MnO_2 to produce the scarece oxygen hydrous MnO_2 at high temperatures because of the strong reducing force.

Effects of Reducing Agents. The particle shape of the hydrous MnO_2 varied with the kind of reducing agent in spite of the constant chemical composition and reactivity. Some typical SEM photographs of the hydrous MnO_2 are shown in Fig. 4. While the hydrous MnO_2 prepared by reduction with the H_2O_2 solution (**A**) was irregularly piled with fine amorphous particles, the one prepared with the KNO_2 solution (**B**) coagulated to quite a large spherical shape. The hydrous MnO_2 prepared with the K_2SO_3 solution also coagulated to a spherical shape, but the size of the second-order particle was smaller than that prepared with the KNO_2 solutions. A spherical-shape hydrous MnO_2 such as Sample No. 8 has been also produced as a by-product of the absorption of NO_x gas with a high alkaline solution of $KMnO_4$. The surface area of a representative hydrous MnO_2 is tabulated in Table 3. As would be from the particle shape shown in Fig. 4, the surface area varied with the conditions of preparation. The hydrous MnO_2 substances prepared both by the reduction of $KMnO_4$ with the H_2O_2 solution and by the disproportionation of the K_2MnO_4 solution have large surface areas. Figure 5 indicates the chemical reactivity, the D.O., and the MnO_2 content as functions of the surface area of the hydrous MnO_2 in Table 3. Although Samples Nos. 3, 5,

and 8 were prepared under the same conditions except for the kind of reducing agent, there was no correlation between the chemical reactivity and the surface area. Sample No. 16, obtained from the suspension with a pH of 13.0, had the same chemical composition and reactivity as Samples Nos. 3, 5, and 8. On the other hand, the chemical reactivity of Sample No. 21, obtained from a suspension with a pH of 2.1, decreased very much in spite of its large surface area. The results show that the diffusion of the permanganate ion into the particles of the hydrous MnO_2 is fast, without any correlation to the apparent surface area, and that the chemical reactivity is only influenced by the chemical composition, that is, the number of active sites as has previously been described. The hydrous MnO_2 prepared by the disproportionation of K_3MnO_4, which if formed by the oxidation of pyrolusite with KOH–KNO_3 molten salts,[11] was similar to those obtained in this experiment.

Thermal Behavior. TG and DTA curves of the hydrous MnO_2 substances obtained from suspensions with various pHs were classified into the three types shown in Fig. 6. The DTA curves varied according to the pH of the suspensions. As has been described previously, the chemical composition, especially the K_2O content of the hydrous MnO_2, also varied according to the pH of the suspensions. Therefore, the K_2O content appeared to cause the varying thermal behavior of the hydrous MnO_2. The results of the X-ray analysis and chemical analysis of the heated samples obtained at different temperatures are shown in Table 4. Sample No. 16, the K/Mn molar ratio of the chemical composition of which was about 0.5, gradually crystallized to form potassium permanganite,[12] $K_2Mn_4O_8$, during the heating process and was completely transformed to $K_2Mn_4O_8$ above 900 °C. The continuous weight loss in the heating process to about 900 °C indicated on the TG curve, which was due to the release of a large amount of the chemically bound water, corresponded with the broad endothermic peak of the DTA curve. The chemically bound water still remained in the hydrous MnO_2 at a considerable high temperature, and the IR spectrum of the sample heated at about 700 °C had the absorption bands based on the chemically bound water. On the other hand, Sample No. 19, with a K/Mn molar ratio of 0.15, rapidly crystallized to form cryptomelane,[13] KMn_8O_{16}, with a sharp exothermic peak at 450 °C. This exothermic peak was generally shown on the DTA curves of the hydrous MnO_2 with a K/Mn molar ratio of about 0.1—0.3. The nearer the K/Mn molar ratio came to the theoretical value, 0.125, the larger and sharper the exothermic peak became. On further heating, this material was decomposed into $K_2Mn_4O_8$ and bixbyte,[14] Mn_2O_3, which was then further decomposed into hausmannite,[15] Mn_3O_4, with an increase in the temperature. In the case of Sample No. 21, the K/Mn molar ratio of which was still small, the exothermic peak due to the formation of KMn_8O_{16} was not seen on the DTA curve. The thermal behavior of the hydrous MnO_2 prepared by the reduction of the $KMnO_4$ solution was quite similar to that of such a hydrous MnO_2 as Sample No. 16. Table 4 shows that the DTA curves of the hydrous MnO_2 substances continuously varied according to the change in the K_2O content. The other kinds of manganese(IV) oxide with no K_2O content, such as synthetic β-MnO_2 and γ-MnO_2, indicated similar thermal behavior, as is shown in Fig. 6, upon the addition of potassium hydroxide to the samples. Therefore, the presence and amount of potassium must be checked in advance in the study of the thermal behavior of manganese(IV) oxides.

Table 5. Magnetic susceptibilities of the hydrous MnO_2 substances and the other kinds of MnO_2

No.	$\chi/10^{-6}$, (Temp/°C)
3[a]	65.1(26.5), 74.7(−25.0), 87.5(−75.3), 105.0(−112.7), 130.8(−159.7), 167.1(−195.8)
5[a]	62.2(26.5)
8[a]	66.2(26.5)
16[b]	46.9(23.0), 68.8(−64.8), 89.3(−126.0), 108.5(−155.2), 137.5(−195.8)
19[b]	53.1(23.5)
21[b]	55.4(18.8), 57.1(−7.8), 64.6(−62.0), 77.5(−107.0), 90.7(−144.6), 118.6(−195.8)
26 (α-MnO_2)	36.6(23.5)
27 (β-MnO_2)	27.2(21.9), 27.3(−17.2), 29.6(−75.0), 30.9 (−114.4), 33.4(−150.5), 34.3(−195.8)
28 (γ-MnO_2)	33.5(22.8)
29 (δ-MnO_2)	52.9(23.4)

a) Prepared by reduction. b) Prepared by disproportionation.

Two different DTA curves have been reported for the hydrous MnO_2 substances by Sterr *et al.* and by Regner *et al.* According to Sterr *et al.*, the DTA curve of the hydrous MnO_2 has an exothermic peak at 520 °C, but the DTA reported by Regner *et al.* has no exothermic peak. In view of our results, these different phenomena of the DTA curves appear to be dependent on the K_2O content of the hydrous MnO_2.

Magnetic Susceptibility. The structures and states of manganese(IV) oxides can be investigated by the measurement of their magnetic susceptibilities because of the paramagnetic property due to the unpaired electrons in the 3 d orbit. The magnetic susceptibilities of some typical hydrous MnO_2 substances are shown in Table 5 in contrast with those of the well-known α-, β-, γ-, and δ-MnO_2. The values in Table 5 are the magnetic susceptibilities per gram of MnO_2. The magnetic susceptibilities of the hydrous MnO_2 substances were all high, especially the values of those prepared by the reduction of the $KMnO_4$ solution by the H_2O_2 solution. Selwood *et al.*[16] have measured the magnetic susceptibilities of various kinds of manganese(IV) oxides, all confined within the range of $25—45\times10^{-6}$ (25 °C). The high magnetic susceptibility of the hydrous MnO_2 substances can be attributed to the free spin of the unpaired electrons of the paramagnetic ion (Mn^{4+}). In other words, the distribution of ions is disordered, and the mutual interference of ions is extremely weak in the MnO_2 lattice. According to the magnetic classification of oxides by Selwood *et al.*, the hydrous MnO_2 substances could all be classified as typical "Disperse Oxides." The magnitude of the magnetic susceptibilities of the other MnO_2 substances was of the order of: δ->α-$\geqslant\gamma$->β-MnO_2. There is a good agreement between our results and those of earlier workers. β-MnO_2 is the most stable crystal phase of all the MnO_2, and it has the highest degree of crystallization, according to the results of X-ray analysis. Therefore, β-MnO_2 had the lowest magnetic susceptibility, and its temperature dependence was not observed because of the interruption due to the free distribution of the spin of the unpaired electron. β-MnO_2 can be magnetically classified as a typical "Massive Oxide." The relationship between the magnetic susceptibilities of the hydrous MnO_2 substances and the pH's of the suspensions obtained by the disproportionation of K_2MnO_4 solution is shown in Fig. 7. The magnetic susceptibility increased

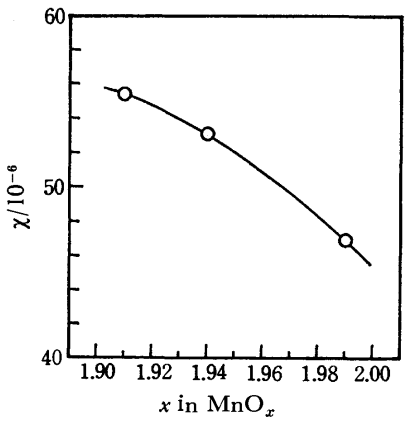

Fig. 7. Magnetic susceptibilities of the hydrous MnO_2 prepared by disproportionation as a function of x in MnO_x.

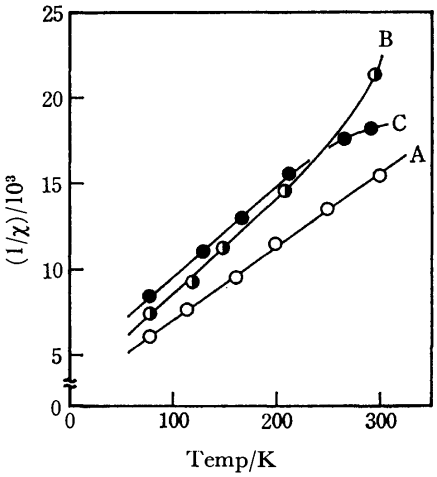

Fig. 8. Inverse magnetic susceptibilities of the hydrous MnO_2 prepared at various pH of suspensions as a function of temperature.
A: Sample No. 3 (pH 12.8), B: Sample No. 16 (pH 13.0), C: Sample No. 21 (pH 2.1).

with a decrease in the pH, which was itself due to the increase in the number of unpaired electrons in the hydrous MnO_2, namely, the decrease in the x-value of MnO_x. The temperature dependence of the magnetic susceptibility in the range from 77.4 K to room temperature is shown in Fig. 8. It was possible to calculate the

magnetic moment because any hydrous MnO_2, Sample No. 3, appeared to follow the Curie-Weiss law. The moment for the manganese in this hydrous MnO_2 was 4.00 Bohr magneton compared with a theoretical moment of 3.87 Bohr magneton, while the Weiss constant was 63°. Two other hydrous MnO_2 substances, Samples Nos. 16 and 21, also appeared to follow the Curie-Weiss law in the temperature range from 77.4 to 220 K. The magnetic susceptibility of Sample No. 21 was higher than that of Sample No. 16 because of the increase in the number of unpaired electrons, but its temperature dependence was conversely small. The moments for the manganese of Samples Nos. 16 and 21 were 3.6 and 3.7 Bohr magneton, and the Weiss constants were 54 and 89°, respectively. This tendency can be explained by the mechanism by which the distribution of the manganese ion in the MnO_2 lattice becomes more regular during the removal of the chemically bound water and alkali by means of the decrease in the pH's of the suspensions.

The authors would like to thank Mr. Takeshi Sakano of the Mitsubishi Metal Corp. for his discussion and encouragement, Dr. Masayoshi Ito of the Science University of Tokyo for his measurement of the wide-line NMR spectra, Professor Minoru Takahashi of the Department of Applied Physics, Tohoku University, for his guidance and support in the measurement of the magnetic susceptibility, and Mr. Keizo Hara for his experimental assistance.

INDO Molecular Orbital Interpretation of Thermal Singlet Oxygen-complex Generation by Strained Acetylenes

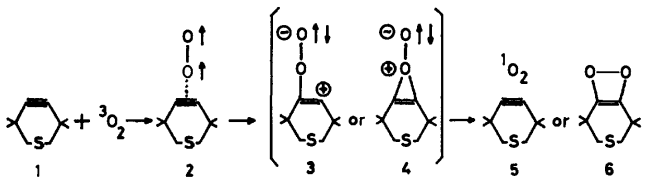
Katsutoshi OHKUBO* and Hiroyuki SATO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received February 16, 1979)

Synopsis. A three-center interaction between the $(\pi_u)_y$ of strained XC≡CX (X=H,F, or OCH_3) and the $(\pi_g)_y$ of $^3O_2$ separated the two half-occupied π_g MOs of $^3O_2$ on an energy scale of 428—494 kJ/mol causing spin inversion in $^3O_2$. A perepoxide-type $^1O_2$–XC≡CX intermediate once formed is transformed into a stable dioxetene-type $^1O_2$ complex from which the free generation of $^1O_2$ was found to be difficult.

The generation of $^1O_2$ has hitherto been realized by the reaction of sodium hypochlorite and hydrogen peroxide,[1-3] the decomposition of peroxides[4-8] and ozonides,[9-12] and the photosensitization[1,13,14] or microwave discharge[15,16] of $^3O_2$. The possibility of thermal $^1O_2$ formation from $^3O_2$ with 3,3,6,6-tetramethyl-1-thia-4-cycloheptyne **1** has recently been reported:[17]



The above reaction mechanism, however, remains obscure. Consequently an INDO-MO[18] study of the above reaction process has been conducted using a simple model of the strained acetylene **1**, XC≡CX (X=H, F, or CH_3O), in order to shorten the computation time.

Results and Discussion

The strained acetylene molecule **1** is characterized by split π MOs, and the spectrophotometrically estimated energy difference between the π MOs is 30.5 kJ/mol at the strained angle (146°) of the acetylene **1** molecule.[17,19] In the case of XC≡CX, the energy difference between the π MOs has been estimated to be 170 kJ/mol (X=H), 89.5 kJ/mol (X=F), and 612 kJ/mol (X=CH_3O) at ∠XCC=146° using standard geometric parameters.[18] The destabilization of the $(\pi_u)_y$ MO expanding on the XC≡CX molecular plane ($(\pi_u)_y$ MO is energetically kept practically constant) is monotonically promoted by widening the strained angle thereby permitting overlap between the s or p AO of X and the p_y AO of C (overlap intergral=0.27 at 146° in HC≡CH). Therefore, the deviation of the C–X bond from the linear arrangement in XC≡CX makes the ionization energy of the highest doubly-occupied $(\pi_u)_y$ MO smaller and facilitates electron transfer from the strained acetylene molecule to $^3O_2$.

In view of the most reactive MOs of the strained acetylene and $^3O_2$, *i.e.*, the $(\pi_u)_y$ MO of the former and the π_g MOs of the latter, two distinctive interacting systems (three-center and four-center) may be considered as the mode of interaction between them (Fig. 1). The formation of a dioxetene-type intermediate from the strained acetylene and $^3O_2$ *via* the four-center interacting systems is however thermally forbidden since orbital symmetry in the σ-type orbital correlation such as $(\pi_g)_y-(\pi_g)_y$ or $(\pi_u)_y-(\pi_u)_y$ in the F-type interacting system should be inversely rearranged in the reaction process.[20] Therefore, the present thermal generation of $^1O_2$ from $^3O_2$ with the strained acetylene molecule must first pass through the three-center interacting system in which electron transfer from the $(\pi_u)_y$ MO in the acetylene to the $(\pi_g)_y$ (or $(\pi_g)_z$ in the B or C system) of $^3O_2$ would be expected together with back electron donation from the $(\pi_g)_x$ (and/or $(\pi_u)_x$) of the latter to the $(\pi_g)_y$ (or $(\pi_g)_z$ in the E system) of the former.

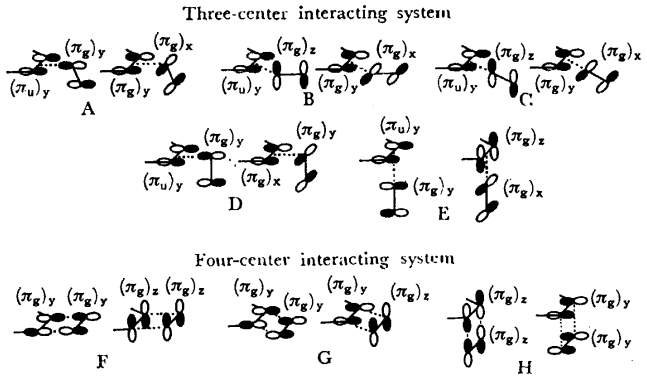


Fig. 1. Three-center and four-center interacting systems of the strained acetylene and $^3O_2$.

The three-center interacting systems of HC≡CH–$^3O_2$ were calculated utilising the geometric parameters in Table 1 and the relative stabilities of the interacting systems are given in the order: A>B>C>D>E. The one-electron attraction term (E_I) was large and negative in the order of D>A>E>B>C. The interelectronic and internuclear repulsions (E_{II} and E_N respectively) were larger and in the same order. The balance between the nuclear-electron attraction and the above repulsions results in the A-type interacting system being the most plausible mode of interaction.

The approach of the $^3O_2$ molecule to the strained acetylene in the A-type interacting system is an energy stabilization process and results in a quasi-stable perepoxide-type intermediate **2'**. For example, the potential curve for the HC≡CH–$^3O_2$ interacting system shown in Fig. 2, was obtained by optimizing the geometric parameters (see Table 1) by minimizing the total energies of the interacting systems with a repeated SCF-procedure.[21] As Fig. 2 illustrates, the change of electronic configuration from the triplet-state to the singlet-state interacting system could be expected

Table 1. Relative stabilities of the three-center interacting systems

	r_{CO}/Å[a]	r_{OO}/Å	θ/deg.	ϕ/deg.	E_I/a.u.	E_{II}/a.u.	E_N/a.u.	E_{total}/a.u.

a) Fixed values in the calculations.

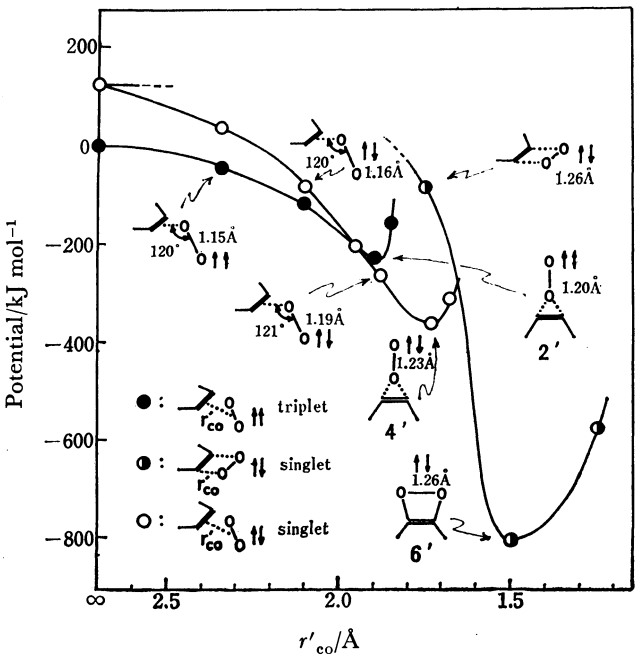

Fig. 2. Potential curves for the interacting system of the strained HC≡CH (∠HCC=146°) and $^3O_2$ or $^1O_2$. (The four-center interacting system of HC≡CH–$^1O_2$ at $r'_{CO}=\infty-1.8$ Å was not treated for shortening computation time.)

before the formation of the above-mentioned triplet-state intermediate **2'**. As the distance (r'_{CO}) between the two centers of C–C in HC≡CH and O–O in O_2 becomes smaller, the highest half-occupied MO formed by $(\pi_u)_y$ (HC≡CH)–$(\pi_g)_y(^3O_2)$ is destabilized with respect to the half-occupied MO of $(\pi_g)_y$(HC≡CH)–$(\pi_g)_x(^3O_2)$. The energy separation between the above two MOs are 194, 303, and 428 kJ/mol at r'_{CO}=2.3, 2.1, and 1.9 Å respectively. Such a remarkable energy separation between the two half-occupied MOs may result in an electronic rearrangement (*viz.*, electron migration from the $(\pi_g)_y$ MO to the $(\pi_g)_x$ MO in $^3O_2$ via spin inversion) by changing the triplet-state interacting system into the energetically more stable singlet-state system at the intersystem crossing point (r'_{CO}= 1.94 Å). In the A-type interacting system of $CH_3OC{\equiv}COCH_3$ (or FC≡C)–$^3O_2$ (∠OCC=∠FCC=146°), the electron-donative (or attractive) nature of CH_3O (or F) resulted in the intersystem crossing at a slightly longer range of r'_{CO}=1.96 Å (or at a slightly shorter range of r'_{CO}=1.91 Å) with an energy separation between the above-mentioned half-occupied MOs of 485 kJ/mol (or 494 kJ/mol). The strained acetylene-$^1O_2$ system once formed *via* spin inversion, then, moves to a quasi-stable perepoxide-type intermediate **4'** (see Fig. 2). The singlet oxygen complex of the intermediate **4'**, then, transforms into a stable dioxetene **6'** (456 kJ/mol lower in potential energy than **4'**) with an activation energy of 58 kJ/mol. The generation of free $^1O_2$ from the dioxetene-type intermediate **6'** however appears difficult because the isolation of free $^1O_2$ from **6'** requires 920 kJ/mol (Fig. 2). Therefore, the reaction between $^3O_2$ and strained acetylenes such as **1** generates a dioxetene-type $^1O_2$ complex which thermally transforms into a dione with chemiluminescence (fluorescence).[17]

Acidity and Catalytic Activity of Iron(II) Sulfate Heat-treated at High Temperature

Kazushi ARATA* and Makoto HINO†

Hokkaido University of Education, Hachiman-cho, Hakodate 040

†*Hakodate Technical College, Tokura-cho, Hakodate 042*

(Received February 23, 1979)

Synopsis. Acidity and catalytic activity of $FeSO_4$ calcined at 500—900 °C were studied. The product obtained by calcination at 700 °C showed maximum acidity at $H_0 \leqq 1.5$ and activity for isomerization of *d*-limonene oxide, polymerization of isobutyl vinyl ether and dehydration of 2-propanol. When calcined at 750 °C the product showed no acidity or activity.

Studies were carried out on the Friedel-Crafts benzylation,[1] benzoylation[2] and isopropylation[3] of toluene with their corresponding halides and polycondensation of benzyl chloride[4] catalyzed by iron sulfates heat-treated in the air at 200—900 °C. Maximum activity was found for the catalyst calcined at 700 °C. The specific surface area of the calcined sulfates indicated no relationship with their catalytic activities. The acidic property of calcined iron sulfates has not been investigated as regards relationship with catalytic activity, though several workers observed the maximum acidity of iron sulfates calcined at 120—200 °C.[5,6] In this paper we report the acidity of $FeSO_4$ calcined over 500 °C and its correlation with catalytic activities for isomerization of *d*-limonene oxide, polymerization of isobutyl vinyl ether and dehydration of 2-propanol.

Experimental

Catalysts were prepared by heating $FeSO_4 \cdot 7H_2O$ at 200—300 °C for 1—1.5 h followed by powdering below 100 mesh. Calcination was then carried out in the air in Pyrex glass tubes (quartz tubes for temperatures over 600 °C) for 3 h. The catalysts were stored in sealed ampoules.

The acidic property of the catalysts was determined by titration with butylamine using 4-phenylazodiphenylamine as a Hammett indicator: 0.05—0.2 ml of 0.1 M butylamine benzene solution was added to 0.5 g of the powder (below 100 mesh) suspended in 30 ml of benzene at intervals of 5—6 h. Since the catalyst is colored, the end point of titration was taken when a color change was observed on SiO_2–Al_2O_3 plastered on a small slip of filter paper, acidic coloration being seen with an indicator. The slip consumed 0.02—0.03 ml of 0.1 M butylamine. As the amount of consumed amine, 0.03 ml was subtracted from the titre per slip after slips were added until the acidic color of the indicator on SiO_2–Al_2O_3 remained unchanged. It took 4—5 d for titration.

Isomerization of *d*-limonene oxide was carried out with a mixture of 0.5 ml of the epoxide, 2.5 ml of toluene and 0.3 g of the catalyst with stirring at 90 °C for 15 min.[7]

Polymerization of isobutyl vinyl ether was performed with a mixture of 5 ml of the ether, 45 ml of toluene and 80 mg of the catalyst with stirring at room temperature for 30 min. Conversion (%) on the polymerization reaction was obtained on the basis of the unreacted monomer by gas chromatography using a 1-m column of tricresyl phosphate on Celite 545 (95 °C, He: 1.0 kg/cm²) with benzene as an internal standard.

Dehydration of 2-propanol was carried out at 170 °C by using a microcatalytic pulse reactor (catalyst amount: 30 mg, carrier gas: He, flow rate: 30 ml/min, pulse size: 0.4 μl). The catalyst was heat-treated in a reactor at 500 °C for 1.5 h before the reaction. Effluent products were directly introduced into a gas chromatographic column for analysis (Porapak R-2 m, 128 °C). The percentage conversion is given as the average value from the 5 to 10 th pulse reaction.

Results and Discussion

Figure 1 shows the acid amount ($pK_a \leqq 1.5$) of $FeSO_4$ calcined at 500—800 °C. The substance obtained by calcination at 700 °C was found to be the most acidic. It is of interest that the acid amount was zero when calcined at 750 °C. The substance obtained by treatment at 900 °C also showed no acidity. The acidic amount of $FeSO_4$ treated at 700 °C was 0.052 mmol/g at $pK_a \leqq -3.0$.

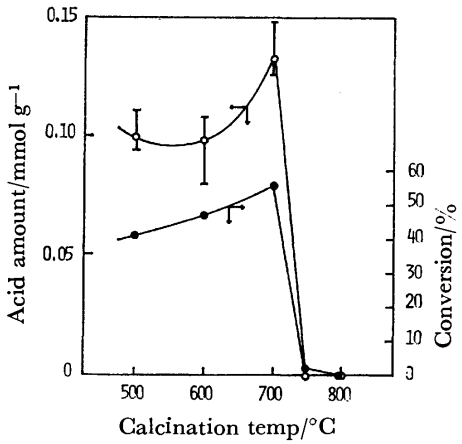

Fig. 1. Acidity of calcined $FeSO_4$ and its catalytic activity for isomerization of *d*-limonene oxide.
(○): Acid amount at $pK_a \leqq 1.5$,
(●): isomerization of *d*-limonene oxide.
Selectivity was 20% 1-methyl-3-isopropenylcyclopentyl-1-carboxaldehyde (I), 66% dihydrocarvone (II), 7% *exo*-carveol (III) and 7% *endo*-carveol (IV) in all runs.

Since the acidity could not be determined accurately because of the coloration of the substance, catalytic activities by several acid-catalyzed reactions were examined. The activity for isomerization of *d*-limonene oxide is shown in Fig. 1. We see that the activity is in line with acidity, the catalyst calcined at 750 °C being quite inactive in spite of the remarkable activity attained by heat treatment at 700 °C.[8]

The following two reactions were carried out (Fig. 2): (1) polymerization of isobutyl vinyl ether, which is known to be catalyzed by Lewis catalysts such as BF_3-

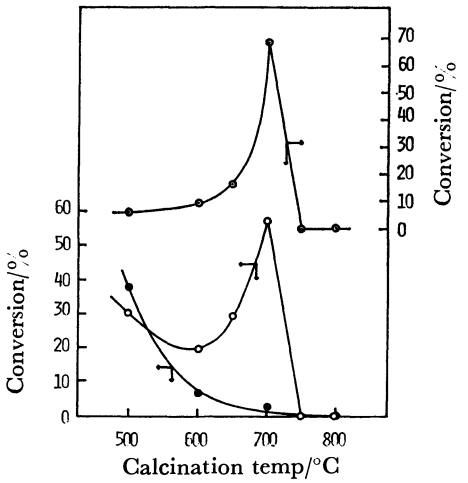

Fig. 2. Catalytic activities for polymerization of isobutyl vinyl ether (⊙) and for dehydration of 2-propanol (○). (●): dehydration of 2-propanol over $NiSO_4$ at 190 °C.

etherate and $TiCl_4$,[9] and (2) the dehydration of 2-propanol to propylene, which is generally catalyzed by acidic sites at $-3<H_0\leqq+1.5$.[10] Both reactions give maximum activity by calcination at 700 °C. Both activities are in line with the acidity (Fig. 1), the catalyst calcined at 750 °C being inactive.

In order to examine such a rapid decrease in catalytic activity for other metal sulfate, $NiSO_4$ was subjected to reaction with 2-propanol. The activity decreased rapidly by calcination above 500 °C. The catalysts calcined above 700 °C were almost inactive. The acidity of $NiSO_4$ increases initially with rise in temperature of heat-treatment, reaching a maximum at *ca.* 350 °C, and decreasing subsequently.[11] It seems that activity is related with acidity. The amount of diisopropyl ether formed by the dehydration of 2-propanol was almost negligible for all the catalysts of $FeSO_4$ and $NiSO_4$.

In the polymerization of isobutyl vinyl ether, $FeSO_4$ (700 °C) gave 91% conversion for 2 h. The yield insoluble in an excess amount of methanol was 74% with 0.96 dl/g of the reduced viscosity.[12]

ESCA studies of $FeSO_4$ showed that the sulfate completely decomposes to form α-Fe_2O_3 at 675—700 °C, recrystallization proceeding rapidly.[13] A small amount of sulfur (0.12—0.15 wt %), which remains in the catalyst after decomposition, exists as SO_4^{2-} on the surface treated at 700 and 750 °C.[14] $NiSO_4$ reveals its acidity on the sulfate configuration between the monohydrate and anhydrous forms.[15] Other metal sulfates, $Al_2(SO_4)_3$, $ZnSO_4$, $MgSO_4$, and $CdSO_4$, also show surface acidity on the sulfate salts, the maxima appearing at 180—400 °C.[11] The creation of acid sites on the Fe_2O_3 catalyst by decomposition of the sulfate at 700 °C is specific, and the inactivity caused by calcination at a slightly higher temperature, 750 °C, is noteworthy.

As regards the polymerization of isobutyl vinyl ether, solid acid catalysts such as $NiSO_4$ (calcined at 350 °C), SiO_2–Al_2O_3 (500 °C, Al_2O_3: 15 wt %, Nikki Chemical Co.), Al_2O_3 (500 °C, KAT6, Nishio Chemical Co.) and TiO_2 (hydrogel) were found to be almost inactive under the present reaction conditions.

The Mössbauer Effect of ^{119}Sn in the Dimethylbis(8-quinolinolato)-tin(IV) Single Crystal

Hisao NEGITA,* Ryukei BOKU, and Sumio ICHIBA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received June 8, 1979)

Synopsis. The Mössbauer absorption spectrum of ^{119}Sn in the single crystal of dimethylbis(8-quinolinolato)tin-(IV) was studied by an intensity-tensor method. The orientation of the principal axes of the electric-field gradient (EFG) was discussed from the point of view of point-charge formalism.

For the octahedral coordination, all the signs of V_{zz}, the principal component of EFG, are in good agreement with those to be expected from the point-charge formalism with the exception of the *cis* configuration.[1-4] From the magnetic perturbation study of a powder sample of dimethylbis(8-quinolinolato)tin(IV), $Sn(Me)_2(oxin)_2$, which has a distorted *cis*-octahedral configuration, Parison and Johnson[4] have proposed that this inconsistency comes from a deviation from a regular octahedral geometry. The sign of V_{zz} as well as the orientation of the EFG axes can be inferred from the single crystal absorption spectra.[5-10] The purpose of the present study is to examine their proposition in more detail by means of Mössbauer experiments on the single crystal of $Sn(Me)_2(oxin)_2$. The method employed here was first suggested by Zimmermann and applied by him to $FeCl_2 \cdot 4H_2O$,[11] and recently it has also been applied to $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$.[12] It is based on the fact that the quadrupole line intensities can be characterized by means of an intensity tensor.

Crystal Structure and Experimental

$Sn(Me)_2(oxin)_2$ has monoclinic symmetry, and its space group is $P2_1/c$.[13] The dimensions of the unit cell are $a=9.44$, $b=13.28$, and $c=15.67$ Å, with $\beta=110.0°$. A unit cell consists of four $Sn(Me)_2(oxin)_2$ molecules, as is shown in Fig. 1. These four molecules can be grouped into two sites, I and II, with different orientations of the EFG relative to the crystal axes. The symmetry relation between Site I and Site II is a 180° rotation about the b axis.

A single crystal of the complex was cut parallel to the 001 plane, and a crystal plate of *ca.* 13×8 mm^2 was polished to a thin plate, the surface density of which was 27.5 mg of Sn per cm^2. The Mössbauer spectra were obtained in the manner described in our previous paper,[10] except that the absorber was kept at 110 K and the source was $Ca^{119m}SnO_3$.

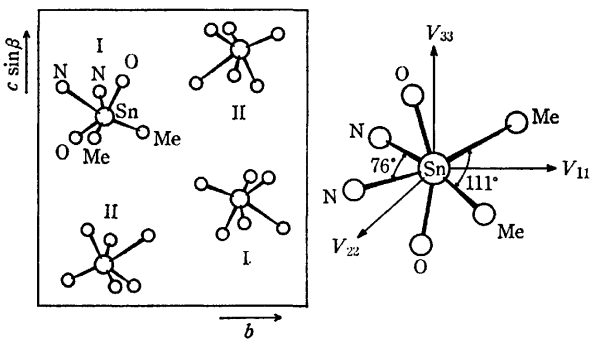

Fig. 1. The molecular geometry of the $SnMe_2N_2O_2$ unit in dimethybis(8-quinolinolato)tin(IV) and the orientations in the unit cell.

Results and Discussion

A typical Mössbauer spectrum with computer-fitting Lorenzian curves is shown in Fig. 2. The parameters obtained from these spectra are presented in Table 1. In the table, the values of A^h/A^{tot}, the intensity of the higher energy peak line divided by the total intensity, were obtained from the observed spectra, whereas those of I^h/I^{tot} were calculated from Eq. 1 using a recoilless fraction of $f'=0.11$, estimated from powder samples:

$$\frac{A^h}{A^{tot}}-\frac{1}{2}=F\left(\frac{I^h}{I^{tot}}-\frac{1}{2}\right) \quad (1)$$

where $F=[1+0.125T_a(1-4a^2)]^{-1}$, with $T_a=nf'\sigma_0$, the effective thickness of absorber, and $a=I^h/I^{tot}$.

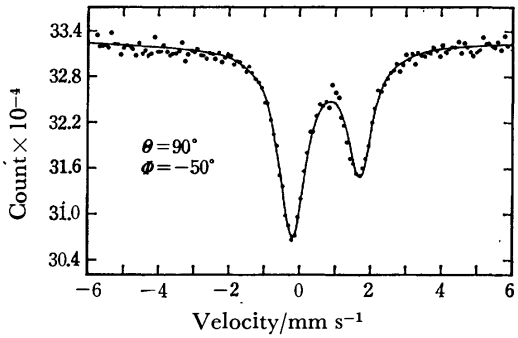

Fig. 2. Mössbauer absorption spectrum of dimethylbis-(8-quinolinolato)tin(IV) single crystal at 110 K. The γ-ray is in the pq plane and $-50°$ from the p axis.

Table 1. Experimental parameters for $Sn(Me)_2(oxin)_2$

a) The polar angles of the γ-ray relative to O_{pqr}.

Since the crystal axes, a, b, and c, are not orthogonal with each other, a orthogonal system, O_{pqr}, is introduced. The base vectors, $\boldsymbol{p}$, $\boldsymbol{q}$, and $\boldsymbol{r}$, are parallel to $\boldsymbol{a}\times\boldsymbol{b}$, $\boldsymbol{a}$, and $\boldsymbol{b}$ respectively. The components of the

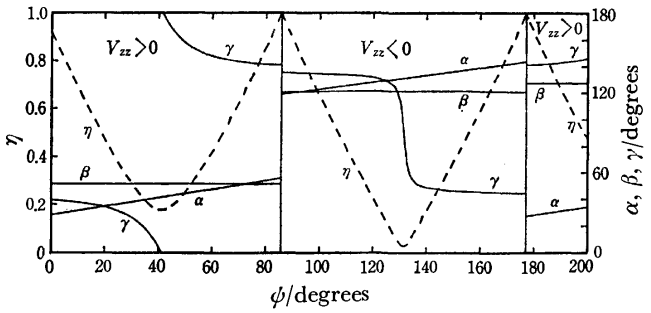

Fig. 3. Sign of V_{zz}, α, β, γ, and η as a function of the parameter ϕ.

macroscopic-intensity tensor obtained by a least-squares analysis from the data of Table 1 are $I^{m}_{pp}=0.005\pm0.002$, $I^{m}_{qq}=-0.029\pm0.006$, $I^{m}_{rr}=0.024\pm0.006$, $I^{m}_{pq}=0.133\pm0.002$, and $I^{m}_{pr}=I^{m}_{qr}=0$. The observable tensor thus has monoclinic symmetry, and two components of the local site tensor are not recorded. However, the introduction of an unknown parameter, ϕ (see Ref. 11 for the definition), makes it possible to represent the local intensity tensor. Figure 3 shows the values of the asymmetry parameter (η) and the Euler angles (α, β, γ), designating the orientation of the principal-axes system of EFG relative to O_{pqr}, as a function of the ϕ angle. Although the values of ϕ are restricted to $0°\leqslant\phi\leqslant200°$, the solutions for $\pi\leqslant\phi\leqslant2\pi$ are obtained by the following transformation from those for $0\leqslant\phi\leqslant\pi$:

$$\eta\rightarrow\eta,\ (\alpha,\beta,\gamma)\rightarrow(\alpha,\pi-\beta,\pi-\gamma)\ \text{for}\ \phi\rightarrow\pi+\phi.$$

From the point-charge model for *cis*-R_2SnX_4 structures, it is expected that, for bond angles of R–Sn–R greater than the tetrahedral angle (109.5°), V_{zz} lies on the R–Sn–R plane, and is normal for a bisector of the R–Sn–R, and has the sign opposite to that expected for a regular *cis* geometry, *i.e.*, a negative sign.[4]

Although the 2Me, 2N, and Sn of the complex are not on a common plane, the local symmetry about the tin in $Sn(Me)_2(oxin)_2$ is approximately C_{2v}. We take an unweighted least-squares plane through the four ligand atoms (2Me and 2N) for the Sn atom as the Me_2SnN_2 plane and define V_{11} as the field gradient in the direction of the bisector of projection which two Sn–Me bonds form on the plane, and V_{33}, as that in the normal direction of the plane (see Fig. 1). The direction of V_{22} is normal with regard to V_{11} and V_{33}. The Me–Sn–Me angle is opened out to 111°, so that V_{zz} can be expected to coincide with V_{22}. However, the uncertainty as to the directions of V_{xx} and V_{yy} remains.

We shall refer only to the I site in the following discussion. Two possible cases are considered:

$$V_{xx}//V_{11},\ V_{yy}//V_{33},\ \text{and}\ V_{zz}//V_{22} \quad \text{(i)}$$

$$V_{xx}//V_{33},\ V_{yy}//V_{11},\ \text{and}\ V_{zz}//V_{22} \quad \text{(ii)}$$

The Euler angles for (i) and (ii) are $\alpha=93°$, $\beta=128°$, and $\gamma=135°$ and $\alpha=93°$, $\beta=128°$, and $\gamma=45°$ respectively (the corresponding values for the II site are obtained by the transformation of $(\alpha,\beta,\gamma)\rightarrow(\alpha,\pi-\beta,\pi-\gamma)$ in each case). Though the point symmetry of the tin sites imposes no restrictions on η, the value of η is expected to be large judging from the point-charge model (*cf.* Fig. 3 in Ref. 4). This value is seen, along with the values of α, β, and γ, in the $V_{zz}<0$ range in Fig. 3. The solutions for $86°\leqslant\phi\leqslant132°$ correspond to (i), and those for $132°\leqslant\phi<177°$, to (ii). The α values in the range of the former are closer to 93° than those of the latter. This suggests that the direction of the principal axes of the EFG may be as in Case (i). If η is found by an additional investigation, as in the case of $FeCl_2\cdot4H_2O$,[11] the precise orientation of the EFG axes can be established.

The Isomerization of 1-Butene over the ReO_3 Catalyst

Tsutomu YAMAGUCHI, Nobuo TSUDA,** and Kozo TANABE*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

***National Institute for Research in Inorganic Materials, Namiki, Niihari-gun, Ibaraki 300-31*

(Received July 2, 1979)

Synopsis. The catalytic activity of the single crystals of ReO_3 was examined by using the isomerization of 1-butene as a test reaction. The results indicate that there are two types of surfaces: one is sensitive to the introduction of hydrogen, and the other is not.

The isomerization of butenes has been investigated extensively over various metal oxides, including both acidic and basic oxides, such as silica-alumina[1] and alkaline earth metal oxides.[2] In contrast with work with such oxides, little work has been done on single crystals of oxides. This report will deal with the catalytic properties of the single crystals of ReO_3, which have been prepared by different methods.

Experimental

Materials. Rhenium(VI) oxide (ReO_3) was prepared by the following methods. Rhenium(VII) oxide (Re_2O_7) was obtained by oxidizing Re metal (Hermann C. Starck, Berlin, 99.9%) in an oxygen stream.

Sample #1: Rhenium(VII) oxide was dissolved in methanol and heated in a CO atmosphere at 90 °C to yield ReO_3. The resulting oxide was washed with water, acetone, and methanol, and then dried under a vacuum at room temperature. An X-ray analysis revealed the oxide to be ReO_3, and an electron-micrographic analysis showed that the particles were in the form of a rectangle. An electron-diffraction pattern and a lattice image of a ReO_3 particle showed that the sample was a single crystal with {100} surfaces.

Sample #2: Rhenium(VII) oxide was reduced to yield ReO_3 as in the case of #1. The resulting oxide was annealed in air for 1 d at 230 °C, and then washed by acetone, water, and methanol and dried in air at 120 °C. An X-ray analysis revealed the oxide to be ReO_3.

Sample #3: Rhenium(VII) oxide was dissolved in water and reduced with H_2 at 300—320 °C. The resulting oxide was ennealed in air at 230 °C for 138 h, washed with water, and dried in air at 120 °C.

Sample #4: Rhenium(VII) oxide was dissolved in methanol and reduced with CO and H_2 at 280 °C. The resulting oxide was annealed in air at 230 °C for 1 d.

Sample #5: The impregnation of a Re_2O_7-methanol-water solution with silica gel and subsequent CO treatment at 280 °C yielded the oxide, which was washed with methanol and water, heated in air at 230 °C to remove the Re_2O_7, and annealed in air at 180 °C for one night. The atomic ratio of Re/Si was estimated to be 1/3.

Reaction. The isomerization of 1-butene was carried out in a closed recirculation system at 200 °C. The sample oxide was evacuated *in situ* at 300 °C for 3 h prior to use.

Results and Discussion

The results are summarized in Table 1. Samples #1 and #2 are characterized by intermediate activity, a large hydrogen effect, and no metathesis activity. Samples #3 and #4 have very low activity. Sample #5 shows high activity in the isomerization and the metathesis reaction.

TABLE 1. REACTION OF 1-BUTENE OVER ReO_3 CATALYSTS

Catalyst	Rate[a] / 10^{-5} mol min^{-1} g^{-1}	*cis*/*trans*	H_2 effect	Surface area / m^2 g^{-1}
#1	1.6	1.1	large	12
#2	3.9	1.2	large	—
#3	<0.3	—	—	1.7
#4	<0.3	—	no	—
#5	23[b]	1.1	—	136

a) Initial rate; estimated on the basis of the disappearance of 1-butene. b) *Ca.* 20% of the metathesis reaction is included.

A distinct Re line with 4±1G of a full width at half the maximum was obtained by NMR at 300 K for the samples prepared similarly as in Samples #3 and #4; this indicates that the structure of both samples is pure ReO_3, since this line was not observed in a defective structure of ReO_3, even when the oxide has been identified as ReO_3 by X-ray spectrometry.

A higher activity was obtained when Samples #1 and #2 were evacuated at a higher temperature (about 500 °C) for a short period during the standard pretreatment. A drastic change in the isomerization rate upon the addition of 100 Torr of hydrogen during the reaction was observed only when the catalyst was evacuated

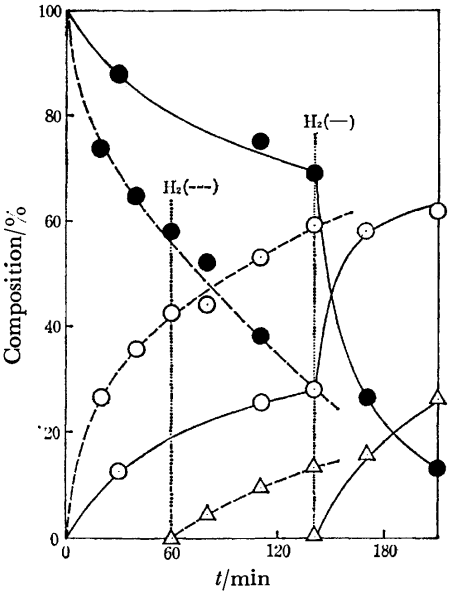

Fig. 1. Reaction of 1-butene over ReO_3 (#2) catalyst. ——: Evacuated at 300 °C for 3 h, ——: evacuated at 300 °C for 2.5 h and 500 °C for 0.5 h. ●: 1-Butene, ○: 2-butene. △: butane. H_2 (—), H_2 (——): addition of 100 Torr of H_2, corresponding to the lines — and ——, respectively.

under the standard pretreatment conditions (Fig. 1).

Those observations indicate that the isomerization takes place on two types of surfaces; one (Surface I) is sensitive to the nitroduction of hydrogen, while the other (Surface II) is not. The former surface is dominant when the catalyst is prepared by methanol reduction and treated by successive evacuation at 300 °C. The introduction of hydrogen onto Surface I during the reaction caused a large enhancement of the reaction rate, with the formation of butane. This suggests that the isomerization proceeds *via* an alkyl intermediate (probably secondary-alkyl). The addition of one hydrogen atom to the C–C double bond gives the alkyl intermediate, and the following removal of one hydrogen from the intermediate yields 2-butene, or the addition of another hydrogen results in the production of butane.

Surface II is not sensitive to the introduction of hydrogen, and so its proportion may increase upon evacuation at an elevated temperature. This type of surface can be obtained by removal of the oxygen atoms from the surface lattice or by the partial decomposition of ReO_3 to ReO_2; the resulting surface will be highly defective. The exposed Re atom may act as a Lewis acid center. An increase in the region of the Surface II may be accompanied by the destruction of the Surface I.

Catalysts #3 and #4 showed low activity. This could be attributed to their lower surface area. However, if we consider the observation that even the addition of hydrogen during the reaction did not bring about any increase in the reaction rate, it seems more likely to conclude that the pure single crystals of ReO_3 do not have the Surface I and are tolerant of such a reduction upon evacuation that will bring about catalytically active sites.

The highest activity was obtained in Catalyst #5. This catalyst was the only one that gave the metathesis products. The acidic centers, which were produced by the combination of two oxides, may be responsible for the isomerization reaction, since it is known that the combination of two oxides can produce a new acidic center,[3] which will then act as an active center for the isomerization.

Kinetics of Dissociation of the Hydrogen Bond in the (n, π^*) Singlet State of 9,10-Diazaphenanthrene

Iwao YAMAZAKI,* Hiroyuki TAKEDA, and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received July 6, 1979)

Synopsis. Changes of fluorescence properties with temperature have been examined for 9,10-diazaphenanthrene (DAP) in proton-donating solvents. From a kinetic analysis, the rate constant for dissociation of the hydrogen bond in the (n, π^*) singlet state of DAP is evaluated to be 4.3×10^8 s^{-1} at 113 K, and the activation energy of the dissociation is 10.0 kJ/mol.

In proton-donating solvents the n→π^* absorption spectrum of 9,10-diazaphenanthrene (DAP) exhibits a large blue shift which is attributable to formation of a hydrogen bond between solute and solvent molecules.[1] On the contrary, the n←π^* fluorescence shows only a small shift, indicating that the hydrogen bond is broken in the (n, π^*) excited singlet state within its lifetime.[1]

Baba and Mugiya[2] reported that a large blue shift occurs in the fluorescence spectrum of DAP in an aprotic polar solvent at low temperature. They interpreted the blue shift as due to the fact that the relaxation process from the Franck-Condon excited to the equilibrium excited state, with respect to the orientation of solvent dipoles, is inhibited at such a low temperature that the solvent becomes rigid. For DAP in proton-donating solvents at low temperature, Rau and Bisle[3] suggested that the dissociation of the hydrogen bond in the excited state is more or less inhibited owing to an increase in solvent viscosity with lowering temperature.

In this study, the fluorescence spectrum and lifetime have been examined for DAP in a mixture of alcohols at temperatures ranging from 300 to 77 K with a view to obtaining quantitative information as to the kinetic behavior of the hydrogen bond in the ^{1}(n, π^*) state.

Experimental

A mixture of methanol and ethanol (volume ratio, 1: 1) and that of isopentane and methylcyclohexane (volume ratio, 4: 1) were used as a proton-donating solvent and a nonpolar reference solvent, respectively. These mixtures, hereafter referred to as ME and PM, respectively, give good rigid glasses at 77 K. A DAP concentration of less than 10^{-4} M was adopted to prevent the formation of a dimer of DAP in PM at low temperature.[4]

Fluorescence decay measurements were made with a single-photon counting apparatus using a time-to-amplitude converter.[5] The lifetime could be determined quantitatively down to 0.5 ns on the basis of the deconvolution method.

Results and Discussion

Table 1 gives the frequencies of n→π^*absorption and n←π^* fluorescence maxima, denoted by ν_a and ν_f respectively, and the fluorescence lifetimes τ_f for DAP in PM and proton-donating solvents at 300 and 77 K. The table gives also the frequency shifts, $\Delta\nu_a$ and $\Delta\nu_f$, relative to the frequencies in PM at 300 K. The values of ν_a in proton-donating solvents were estimated on the assumption that the shape and half-width of the n→π^* absorption curve are the same as those in PM. When the solvent is changed from PM to ME at 300 K, the absorption spectrum is greatly displaced to the blue, whereas the fluorescence shows only a small blue shift, *i.e.*, $\Delta\nu_a=1550$ cm^{-1} and $\Delta\nu_f=220$ cm^{-1}. On the contrary, at 77 K the fluorescence shift in ME is almost as large as the absorption shift, *i.e.*, $\Delta\nu_f=1330$ cm^{-1}. It should be emphasized that the absorption and fluorescence spectra in PM containing a small amount (0.5% by volume) of ethanol are essentially the same as those in ME. The fluorescence in PM has a constant lifetime of about 4 ns irrespective of temperature. In ME the fluorescence lifetime varies distinctly according to the temperature; the lifetime in ME at 300 K is comparable to the one in PM, whereas it is 1.2 ns at 77 K. All these results indicate that at 300 K the hydrogen-bonded complex between solute and solvent molecules dissociates in the ^{1}(n, π^*) state of DAP, but that at 77 K the breakage of the hydrogen bond is inhibited owing to the high viscosity of the solvent. Thus the fluorescence spectra in ME at 77 and 300 K originate from the hydrogen-bonded complex and the free DAP molecule, respectively.

Table 1. Frequencies of absorption and fluorescence maxima and fluorescence lifetimes of DAP in different solvents

Solvent	ν_a / cm^{-1}	ν_f / cm^{-1}	$\Delta\nu_a$ / cm^{-1}	$\Delta\nu_f$ / cm^{-1}	τ_f / ns
PM					
300 K	24630	19940	0	0	4.9
77 K[a]	24950	20280	320	340	3.6

a) A small amount of ethyl ether (5% by volume) was added to prevent the formation of DAP dimer.
b) Estimated values (see text).

The changes of the fluorescence spectrum and lifetime in ME with temperature occur in the range 150—77 K. The spectrum shifts rapidly to the blue as the temperature is lowered from 150 K, as is seen in Fig. 1. Furthermore, at the intermediate temperatures, the fluorescence lifetimes were found to exhibit different values depending on the wavelength where the fluorescence was monitored. Therefore, each of the fluorescence spectra obtained at temperatures between 150 K and 77 K is regarded as a superposition of two kinds of spectra: one originating from the hydrogen-bonded complex and the other from the free DAP molecule. On the assumption that

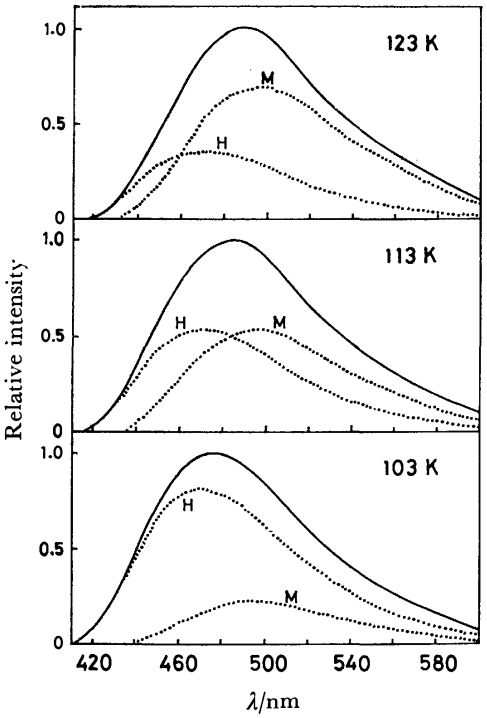

Fig. 1. Fluorescence spectra of DAP in ME at different temperatures (solid lines), and analysis of the individual spectra into the components (dotted lines) of the hydrogen-bonded complex (H) and the free DAP molecule (M). For each of the observed spectra the maximum fluorescence intensity is normalized to a unit relative intensity.

the spectral shape of each fluorescence component is independent of temperature in this temperature range, one can analyze the whole spectrum into separate components; the results are shown in Fig. 1 for three temperatures. It is seen that, as the temperature is lowered, the contribution from the fluorescence component of the hydrogen-bonded complex increases, while that from the component of the free DAP molecule decreases. This means that on lowering the temperature the solvent becomes rigid and the dissociation of the hydrogen bond is inhibited in varying degrees, depending upon the viscosity of the solvent.

The deactivation processes in the excited state involving the dissociation of the hydrogen bond are represented by the following kinetic scheme:

$$\begin{array}{ccc} \text{DAP*}\cdots\text{H} & \xrightarrow{k_d(T)} & \text{DAP*} \\ \downarrow k_{fH},\ k_{qH} & & \downarrow k_{fM},\ k_{qM} \end{array}$$

where DAP* and DAP*···H denote the excited singlet states of the free DAP molecule and hydrogen-bonded complex, respectively; k_{fH}, k_{qH}, k_{fM}, and k_{qM} are the radiative (f) and radiationless (q) decay constants for the hydrogen-bonded complex (H) and free molecule (M); $k_d(T)$ is the rate constant for the dissociation of the hydrogen bond as a function of temperature, T. The rate constants other than $k_d(T)$ are assumed to be independent of T in the range concerned here (150—77 K). Then the ratio of the fluorescence quantum yield of the free molecule to that of the hydrogen-bonded complex, $\Phi_M(T)/\Phi_H(T)$, is expressed as

$$\Phi_M(T)/\Phi_H(T) = (k_{fM}/k_{fH})k_d(T)/(k_{fM}+k_{qM}). \quad (1)$$

In this equation, $k_{fM}+k_{qM}\simeq 1/\tau_f(150\text{ K})=3\times10^8\text{ s}^{-1}$ and $k_{fM}/k_{fH}=0.69$; these values are obtained by using the ratio (0.5) of Φ_H(77 K) to Φ_M(150 K) and the lifetimes at 77 and 150 K (1.2 and 3.5 ns, respectively). The quantum yield ratio $\Phi_M(T)/\Phi_H(T)$ can be evaluated from the analysis of the spectrum as shown in Fig. 1. Thus, the rate of the hydrogen-bond dissociation, $k_d(T)$, can be calculated from Eq. 1. At 113 K where the two quantum yields Φ_M and Φ_H are nearly equal (Fig. 1), $k_d=4.3\times10^8\text{ s}^{-1}$, which value is comparable to $k_{fH}+k_{qH}\simeq 1/\tau_f(77\text{ K})=8.3\times10^8\text{ s}^{-1}$. The k_d value becomes smaller at lower temperatures and negligible at 77 K compared with $k_{fH}+k_{qH}$, while at higher temperatures k_d becomes larger and at 150 K it dominates over $k_{fH}+k_{qH}$. This means that, within the lifetime of the $^1(n, \pi^*)$ state, the dissociation of the hydrogen bond is completed at temperatures higher than 150 K, but that practically no dissociation occurs at 77 K.

In the previous study by Baba and Mugiya[2] concerning the Franck-Condon blue shift of the fluorescence of DAP in an aprotic solvent, it was noted that the reorientation of solvent dipoles occurs with the rate which follows an equation of the Arrhenius type, and that the activation energy for the reorientation process is about 17 kJ/mol. The rate constants at different temperatures obtained in the present study for the hydrogen-bond dissociation were found to be well described in terms of the Arrhenius equation with an activation energy of 10.0 kJ/mol. This somewhat small value of activation energy is consistent with the view that in the case of hydrogen-bonding interaction in the $^1(n, \pi^*)$ state a repulsive force is operative between the proton donor and acceptor. Furthermore, the smaller activation energy is favorable for the expectation that the hydrogen bonding interaction would be localized at a limited portion of the donor–acceptor system concerned.

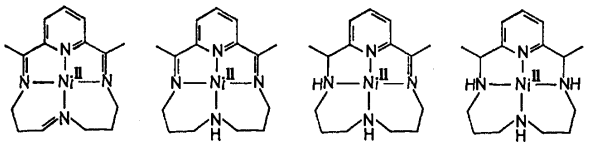
Synopsis. Formation of 5-coordinate Ni(II) complexes of the title quadridentate ligands and halide ions (Cl^-, Br^-, and I^-) in nitromethane was investigated. Some of the formation constants were estimated by means of curve-fitting method.

Nickel(II) complexes of the title ligand, L, and its analogs, $[Ni(L+nH)](ClO_4)_2$ ($n=-2$ (**1**), 0 (**2**), 2 (**3**), and 4 (**4**)) form 5- and 6-coordinate complexes with halide ions in nitromethane solutions. In the absence of halide ions, these complexes exist as 4-coordinate, diamagnetic species in nitromethane, which were confirmed by means of the ^1H NMR and electronic spectra. The present note discusses the solution equilibria between the complexes **1**—**4** and halide ions (Cl^-, Br^-, and I^-) in nitromethane.



1 **2** **3** **4**

The electronic spectra of the complexes **1**—**4** in nitromethane solutions were measured in the presence of various amounts of tetraethylammonium halides. The equilibria attained rapidly under the experimental conditions.[1]

Figure 1 shows the typical spectra of $[Ni(L+2H)](ClO_4)_2$ in the absence and the presence of halide ions. The results of the molar-ratio methods are shown in Fig. 2(a). In the chloride system, a 6-coordinate 1 : 2 complex forms predominantly, a small amount of a 1 : 1 complex being also formed. The decrease in the spectral intensity of the chloride system as compared with that

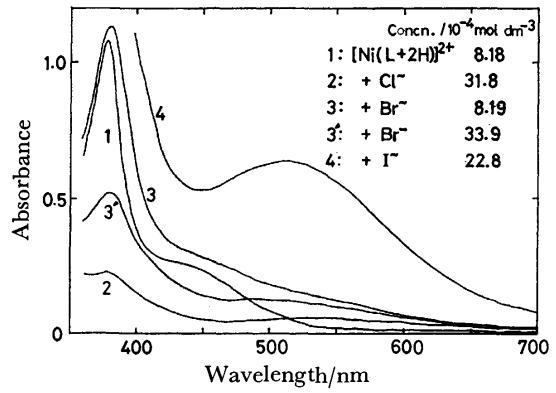


Fig. 1. Absorption spectra of the nitromethane solutions of $[Ni(L+2H)](ClO_4)_2$ (1) and in the presence of Et_4NX (2, 3, 3′, and 4) at 25±0.2 °C.

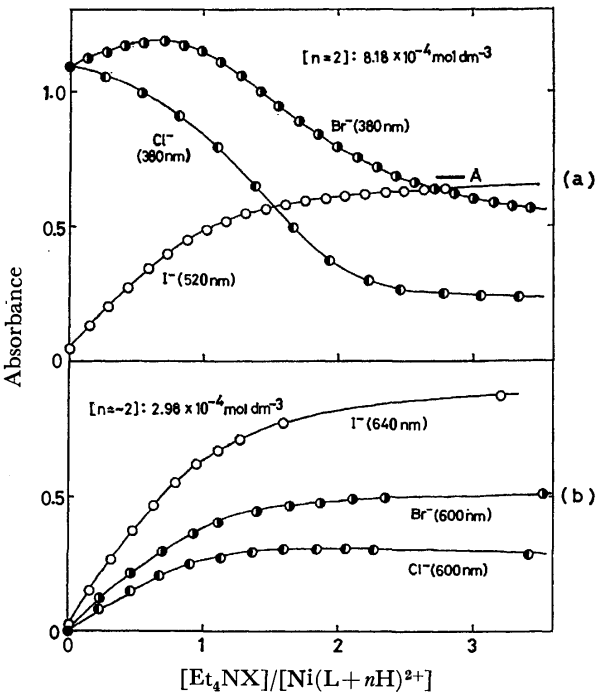

Fig. 2. The molar-ratio method applied to the systems, $[Ni(L+nH)](ClO_4)_2$ and Cl^-(◐), Br^-(◑), and I^-(○) for $n=2$ (a) and -2 (b). The horizontal line **A** indicates the calculated limiting value (see the text).

of the 4-coordinate species also supports the above result.[7] In the iodide system, the spectrum is quite different from both that of a 4-coordinate and of a 6-coordinate complex, *viz.*, a single broad absorption with much larger extinction coefficient is observed around 520 nm. This feature suggests the formation of a 5-coordinate complex with a square-pyramidal structure.[2] The formation of a 5-coordinate 1 : 1 iodo complex was confirmed by the molar-ratio method (Fig. 2(a)). The behavior of the bromide system was intermediate between those of the chloride and the iodide systems. The spectrum changed markedly, depending on the amount of the added Et_4NBr. As is clear from Fig. 2(a), the 5-coordinate complex and then the 6-coordinate complex form with an increase in the concentration of the added Et_4NBr.

In contrast to the $[Ni(L+2H)](ClO_4)_2$ system, the complexes in $[Ni(L-2H)](ClO_4)_2$–halide system exist predominantly as 5-coordinate species, regardless of the kind of halide ions (Fig. 2(b)). Incorporation of the double bonds in the macrocyclic skeleton causes an increase in the in-plane ligand field strength.[3] The tendency to form the 6-coordinate complex would be thereby decreased in the $[Ni(L-2H)]^{2+}$ system.

Table 1. Equilibrium constants at 25±0.2 °C for the reactions, $[Ni(L+nH)]^{2+}+X^- \rightleftharpoons [Ni(L+nH)X]^+$ (X=Cl⁻, Br⁻, and I⁻), and the molar extinction coefficients of $[Ni(L+nH)I]^+$

	$K_1(Cl^-)$ / 10^4 mol^{-1} dm^3	$K_1(Br^-)$ / 10^4 mol^{-1} dm^3	$K_1(I^-)$ / 10^3 mol^{-1} dm^3	ε_p / mol^{-1} dm^3 cm^{-1} (λ / nm)
Ni(L+4H)[a]	—	—	1—2	108—123 (550)
Ni(L+2H)	—	—	8.5	831 (520)[b]
Ni(L)	—	3.2	140	2500 (600)
Ni(L−2H)	3—4	2.6	19	3138 (640)

a) α-*C*-*meso* isomer (see Ref. 7). b) See the text and Fig. 2(a).

As a result of similar experiments for other systems, it was found that a relatively large amount of 5-coordinate complex forms in the systems, $[Ni(L-2H)]^{2+}$–I^-, $-Br^-$, $-Cl^-$; $[Ni(L)]^{2+}$–I^-, $-Br^-$; and $[Ni(L+2H)]^{2+}$–I^-.

For the equilibria of $[Ni(L+nH)]^{2+}$,

$$[Ni(L+nH)]^{2+} + X^- \overset{K_1}{\rightleftharpoons} [Ni(L+nH)X]^+, \quad (1)$$

the formation constant of the 5-coordinate complex, K_1, and the observed absorbance of the solution, A, are expressed as follows.[4]

$$K_1[X^-] = \frac{A-\varepsilon_s[Ni(L+nH)^{2+}]_t}{\varepsilon_p[Ni(L+nH)^{2+}]_t - A} = Y, \quad (2)$$

where [ ] and [ ]$_t$ denote the equilibrium and the total concentration, respectively, and ε_s and ε_p the molar extinction coefficient for the 4- and 5-coordinate species, respectively. The values of $[X^-]$ and Y can be calculated on the basis of the assumed ε_p. The values of K_1 and ε_p were determined by varying values of ε_p until a straight line was obtained for the plot of Y against $[X^-]$. The values of K_1 and ε_p thus obtained are listed in Table 1. For some of the systems, the linear plots were not obtained due to the predominant formation of the more stable 6-coordinate 1:2 complex.

For the $[Ni(L+2H)]^{2+}$–I^- system, the value of ε_p seemed to be reasonable judging from the position of the horizontal line **A** in Fig. 2(a), which indicates the limiting value of the absorbance for the 5-coordinate iodo complex as calculated from the evaluated ε_p. The values of $K_1(I^-)$ and $K_1(Br^-)$ lie in the range 10^3—10^5 mol^{-1} dm^3. These values are in the same order of magnitude as corresponding values of $K_1^{-1}=2.5\times10^{-4}$ mol dm^{-3} for the analogous reaction of 1,4,8,11-tetrathiacyclotetradecane, ttp, $[Ni(ttp)I]^+ \rightleftharpoons [Ni(ttp)]^{2+}+I^-$.[5] The values of the equilibrium constants in Table 1 indicate that the 5-coordinate complexes $[Ni(L)X]^+$ and $[Ni(L-2H)X]^+$ are more stable than $[Ni(L+4H)X]^+$ and $[Ni(L+2H)X]^+$. In fact, the isolation of crystalline $[Ni(L)Br]Br\cdot H_2O$ was reported.[6] The relative stabilities of the 5-coordinate complexes should be related also to the values of the equilibrium constants, $K_2(X^-)$, for the step $[Ni(L+nH)X]^+ + X^- \rightleftharpoons [Ni(L+nH)X_2]$. The value of $K_2(Br^-)$ for the formation of $[Ni(L)Br_2]$ was evaluated by an analogous method to be *ca.* 3×10^3 mol^{-1} dm^3. This value is nearly 1/10 of $K_1(Br^-)$, suggesting that the increased relative stability of 5-coordinate species compared with the 6-coordinate species in the solution containing comparable concentrations of $[Ni(L)]^{2+}$ and Br^-.

The tendency to form the 5-coordinate complexes depends on the nature of the axial as well as the in-plane ligands, and also on the easiness with which the 6-coordinate species form. For the present systems in the nitromethane solutions, 5-coordinate complexes form predominantly when the in-plane ligand field is strong and the axial ligand field is weak.

Experimental

Reagent grade nitromethane (Wako) was dried with calcium chloride and distilled. Reagent grade tetraethylammonium halides were dried over phosphorus pentaoxide and kept in the dark. The complexes **1**—**4** were prepared according to the literature.[7] The purity was confirmed by elemental analysis. The absorption spectra were measured at 25±0.2 °C with a Hitachi recording spectrophotometer model EPS-3T.

Synopsis. The reductions of tetradecylammonium, tetradodecylammonium, benzyldimethyl(tetradecyl)ammonium, and ammonium ions were examined in hexamethylphosphoric triamide. The reduction behavior of these ions was found to be a function of the size and the charge of the cation of the supporting electrolytes.

The present authors have studied the polarographic reductions of various metal ions in hexamethylphosphoric triamide (HMPA) which is the most basic solvent in the aprotic solvents available thus far. The reduction behavior of certain kinds of metal ions is remarkably influenced by the cations of the supporting electrolyte. For example, in a 0.05 M (1 M = 1 mol dm^{-3}) tetraethylammonium perchlorate (Et_4NClO_4) solution, the sodium ion is not reduced until the reduction of the supporting electrolyte is observed. In contrast, in a lithium perchlorate ($LiClO_4$) solution, the reduction of sodium ion is diffusion-controlled.[1] From the measurements of the electrolytic conductivities, it was found that the solvated radius of the lithium ion is much larger than that of the tetraethylammonium ion, while that of the sodium ion is between them.[2] With the use of the larger cation as the supporting electrolyte, the reduction of the metal ion is promoted.

The above phenomena suggest that the relative difference in size between the supporting electrolyte cation and the depolarizing ion must control the electrode reaction. If various ammonium ions are used as the depolarizing ions, the situation is as follows; the chemical character and charge are the same, and there is only a difference in size. Therefore, it is expected that the relationship between the cation of the supporting electrolyte and that of the depolarizing ion could be made more clear.

The physical characters of various ammonium ions in HMPA have already been investigated.[3] Some of them are reduced at a very negative potential, while the others are reduced at a less negative potential. The latter were used as the depolarizing ions for the purposes of this research.

Experimental

The equipment used was a Yanagimoto polarograph, Type P8-DP. All the experiments were carried out at 25 °C±0.1 °C. All the potentials were referred to a freshly-prepared Ag/0.1 M $AgClO_4$(HMPA) electrode. The dropping mercury electrode used had the following characteristics in 0.05 M Et_4NClO_4–HMPA at h=62 cm: m=1.760 mg s^{-1} with an open circuit and t=1.450 s at −2.6 V *vs.* Ag/0.1 M Ag^+.

All the solutions were prepared from the perchlorate salts. The supporting electrolytes were 0.05 M Et_4NClO_4, tetrabutylammonium perchlorate (Bu_4NClO_4), and $LiClO_4$. As the depolarizing cation, the ammonium, benzyldimethyl(tetradecyl)ammonium (BDT^+), tetradecylammonium (Dec_4N^+), and tetradodecylammonium (Dod_4N^+) cations were used. The methods of preparing these reagents and the purification of HMPA have been described in previous papers.[1]

Results and Discussion

In Figs. 1 and 3, the polarograms of various ammonium ions in Et_4NClO_4, Bu_4NClO_4, and $LiClO_4$ solutions are shown.

Ammonium Ion: In the Et_4NClO_4 solution, the reduction of the ammonium ion was very irreversible, judging from the log-plot of the wave analysis, which was obtained by means of the plots of the values of $\log i/(i_l - i)$ and E (where i is the current at potential E and where i_l is the limiting current) (see Fig. 1 and Table 1).

When Bu_4NClO_4 was used as the supporting electrolyte, the reduction potential shifted in the positive direction. In the solution of $LiClO_4$, the potential of the reduction was shifted towards a more positive value. As the reduction wave showed a large maximum in this case, the measurement of the current heights was impossible (see also Table 1). The value of the I ($=i_l c^{-1} m^{-2/3} t^{-1/6}$; c is the concentration) of NH_4^+ in the Bu_4N^+ solution showed 0.67 $\mu A\ s^{1/2}\ mM^{-1}\ mg^{-2/3}$ (1 mM = 10^{-3} mol dm^{-3}). The caesium ion in Et_4NClO_4 has the I value of 0.74 $\mu A\ s^{1/2}\ mM^{-1}\ mg^{-2/3}$, as was shown in previous papers.[1] The reduction of the caesium ion is reversible and diffusion-controlled. From the value of the caesium ion, the diffusion coefficient should be assumed to be $1.486 \times 10^{-6}\ cm^2\ s^{-1}$. Using this, the value of n (the mol equivalent electron number) in the case of NH_4^+ reduction was obtained as 0.88 in Bu_4N^+. Therefore, the reduction, by one electron, to the neutral radical ($NH_4 \cdot Hg$) seems to have occurred, as has been reported in other aprotic solvents.[4]

Figure 2 shows the dependence of the limiting current of the ammonium ion on the square root of the height of the mercury column in the Et_4NClO_4 and Bu_4NClO_4 solutions. In the Bu_4NClO_4 solution, the height of the limiting current (i_l) was proportional to the square root of the mercury height. This means that, in this solution, the reduction process of the ammonium ion was diffusion-controlled. On the other hand, in the 0.05 M Et_4NClO_4 solution the value of i_l was proportional to $h^{1/2}$, but the line did not pass through the point of origin. In this case, therefore, the limiting current of the ammonium ion was not fully diffusion-controlled.

Benzyldimethyl(tetradecyl)ammonium (BDT^+) Ion: In the Et_4NClO_4 solution, the log-plot analysis of the

	$E_{1/2}$/V vs. Ag/Ag+	log-plot mV	$E_{1/2}$/V vs. Ag/Ag+	log-plot mV	$E_{1/2}$/V vs. Ag/Ag+	log-plot mV
Dec_4N^+ (4.94)	−1.98	338	−2.24	330	*ca.* −2.25	280
Dod_4N^+ (4.34)	−2.03	280	−2.23	250	−2.10	180
BDT^+ (5.07)	−2.57	87	−2.45	77	*ca.* −2.50	—
NH_4^+ (4.86)	−2.48	106	−2.31	150	*ca.* −2.26	—

The values in parentheses show the solvated radii in HMPA (Ref. 3).

reduction wave of BDT^+ ion showed 87 mV. This means that the BDT^+ ion was reduced irreversibly. When Bu_4N^+ or Li^+ was used as the supporting electrolyte cation, the reduction potential of the BDT^+ ion was shifted toward a positive value. In the $LiClO_4$ solution, its reduction wave was accompanied by a large maximum, as is shown in the case of NH_4^+. The measurement of the limiting current was impossible. From the relationship between $h^{1/2}$ and i_l shown in Fig. 2, the reduction current of BDT^+ in the Et_4NClO_4 solution was found to be partly controlled by a kinetic process. On the other hand, in the Bu_4NClO_4 solution its reduction process was completely diffusion-controlled and the log-plot showed 77 mV.

Tetradecylammonium (Dec_4N^+) Ion: The polarographic reduction of Dec_4N^+ in HMPA is shown in Fig. 3. The slope of the reduction wave in any supporting electrolyte examined was very gentle, showing the process to be fairly irreversible. The values of the log-plot were 280 mV, 330 mV, and 338 mV in $LiClO_4$, Bu_4NClO_4, and Et_4NClO_4 respectively. The reduction process in $LiClO_4$ was most reversible among these three solutions, judging from the values of the log-plot. However, the values of the half-wave potential showed that Dec_4N^+ was reduced at a more positive potential in the Et_4N^+ than in the Bu_4N^+ and Li^+ solutions. In this sense, the effect of size of the supporting electrolyte cation was not the same as with ammonium or BDT^+ ion.

Tetradodecylammonium (Dod_4N^+) Ion: The polarographic behavior of Dod_4N^+ resembled that of the Dec_4N^+ ion. The reduction was most reversible in $LiClO_4$ among the three solutions, judging from the values of the log-plot of the wave analysis. The values of the half-wave potential showed that Dod_4N^+ was reduced at a more positive potential in the Et_4N^+ than in the Bu_4N^+ and Li^+ solutions. In this case, the effect of the size of the supporting electrolyte cation was the same as that for Dec_4N^+.

The relationship between the size of the supporting electrolyte cation and that of the depolarizing ion could be generally the same as in the case of the reductions of metal ions. Especially in the case of the ammonium and BDT^+ ions, the potentials of reduction shifted in the positive direction, and the process of the reduction was more reversible, when the larger cation of the supporting electrolyte was used. However, in the cases of Dod_4N^+ and Dec_4N^+, the effect of the supporting electrolyte cation was different: in Et_4N^+, the potential of $E_{1/2}$ was the most positive, though the reduction process was very irreversible. The reductions of these two cations occurred at around −2.0 V, though other normal tetraalkylammonium ions, such as the tetramethylammonium, Et_4N^+, tetrapropylammonium, Bu_4N^+, tetrahexylammonium, and tetraheptylammonium ions, were reduced at around −3.0 V.[3] Therefore, the reductions of the higher tetraalkylammonium ions, such as Dec_4N^+ and Dod_4N^+, seem to be different from those of ammonium, BDT^+, and metal ions.

Effect of Plasticizer on the Selectivity of Potassium-selective PVC Membrane Electrodes Based on Bis(crown ether)s

Hiroshi TAMURA, Keiichi KIMURA,* and Toshiyuki SHONO*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received July 16, 1979)

Synopsis. Potassium-selective PVC membrane electrodes based on bis(crown ether)s containing benzo-15-crown-5 moiety were prepared, *o*-nitrophenyl octyl ether (NPOE) or dipentyl phthalate (DPP) being used as a plasticizer. Selectivity coefficients for various monovalent ions were measured. The preference of potassium over sodium in the bis(crown ether) (I; $n=5$)–NPOE electrode system is close to that in the valinomycin system.

Neutral carrier type ion-selective electrodes have been remarkably developed, attempts being made to prepare electrodes based on valinomycin and macrocyclic polyethers.[1,2] A report was given on the preparation of potassium-selective PVC membrane electrodes based on bis- and poly(benzo-15-crown-5)s.[3] However, the electrodes of poly(crown ether)s were impractical due to the poor response to activity change of potassium ion and the long response time, whereas the bis(crown ether)s were found to be high-selective active components.

In this note, we would like to report on the effect of plasticizers upon the selectivity of potassium-selective PVC membrane electrodes based on bis(benzo-15-crown-5)s.

Experimental

Chemicals. The syntheses of crown ether derivatives (I, II) were reported.[3] (Hexanoyloxymethyl)benzo-15-crown-5 (III) was synthesized from 4-hydroxymethyl-15-crown-5 and hexanoyl chloride in chloroform in the presence of triethylamine, and purified by recrystallization from petroleum ether. The plasticizers, NPOE and DPP were prepared according to reported methods.[4,5]

Electrode. The PVC membrane electrode was prepared as reported.[3] The electrochemical cell can be represented as follows: Ag, AgCl/0.001 M KCl/PVC membrane/measured solution/0.1 M NH_4NO_3/KCl (sat.)/Hg_2Cl_2 (s), Hg.

Measurements. All the measurements of e.m.f. were made at 25±0.1 °C using Corning pH meter 130. Standard potassium solutions for calibration plots were obtained by gradual dilution of 1 M potassium chloride solution. Selectivity coefficient k_{KM} was calculated by FIM (fixed interference method).[6] The constant concentrations of Na^+, Rb^+, Cs^+, and NH_4^+ are 1×10^{-1}, 1×10^{-3}, 1×10^{-3}, and 1×10^{-2} M, respectively.

(III)

Results and Discussion

In order to elucidate the effect of plasticizer upon the electrode property, potassium-selective PVC membrane electrodes based on bis(crown ether)s (I; $n=1$, 3, 5, 7) were prepared with use of NPOE or DPP as the plasticizer. For comparison, benzo-15-crown-5 II, (hexanoyloxymethyl)benzo-15-crown-5 (III), and valinomycin (IV) were also employed as a neutral carrier. The electrode properties are sumarized in Table 1.

The electrodes of bis(crown ethers) (I; $n=1$, 3, 5, 7) showed a linear response to the activity of potassium chloride in the range 10^{-5}—10^{-1} M (1 M=1 mol dm^{-3}). The slopes of calibration plots were 55—59 mV per decade of activity change at 25 °C. These electrodes showed the same tendency in selectivity coefficients as reported.[3] The electrode of bis(crown ether) (I; $n=5$) showed the highest selectivity, which might be partly due to dependence of the chain length connecting two crown ether moieties upon the complex formation constant.[7]

The electrodes of monomeric analogs, II and III, also showed a linear response with a near-Nernstian slope in the activity range 10^{-5}—10^{-1} or -3×10^{-1} M KCl. However, the potassium-selectivity of the electrodes of I surpasses that of II about one to two order of magnitude, reflecting the high extractability of bis(benzo-15-crown-5) for potassium as compared to the monomeric analog.[8,9] Modification by a lipophilic chain such as III improves the potassium selectivity of benzo-15-crown-5.

It should be noted that the selectivity coefficients of the NPOE systems are generally much smaller than those of the DPP systems in the crown ether-based electrodes. The DPP systems are nearly equal in the selectivity coefficient to the dibutyl phthalate systems. NPOE was found to be the best plasticizer of the three in our PVC membrane electrode systems. Partition of cation to membrane should affect the selectivity of electrode, which depends on dielectric constant of plasticizer. NPOE which has a higher dielectric co sta t tha DPP is considered to increase the selectivity of electrode.

Thus, the selectivity coefficient of potassium over sodium (k_{KNa}) for the bis(crown ether) (I; $n=5$)–NPOE system is close to that for the valinomycin system. In the selectivity coefficients of potassium over other interfering ions, this system is also superior to the valinomycin system. Our potassium-selective electrodes can be compared favorably with the electrode based on valinomycin in the selectivity, electrode response, and response time (within 10 s). Moreover, they have an advantage over valinomycin-based electrodes since the

Synthesis and Magnetism of $M^{II}Cu^{II}_3$-type Tetranuclear Complexes, the Nickel(II) and the Cobalt(II) Complexes with *N,N'*-Bis(aminoalkyl)oxamidatocopper(II)

Hisashi Okawa,* Yukitaka Kawahara, Masahiro Mikuriya, and Sigeo Kida
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812
(Received September 3, 1979)

Synopsis. Hetero-metal tetranuclear complexes, tris-[*N,N'*-bis(aminoalkyl)oxamidatocopper(II)]cobalt(II) and tris[*N,N'*-bis(aminoalkyl)oxamidatocopper(II)]nickel(II) perchlorate (or nitrate), were synthesized and characterized. Cryomagnetic investigation demonstrated that a considerably strong antiferromagnetic spin-exchange interaction is operating between copper(II) and cobalt(II) or nickel(II) ions.

Use of metal complexes as a ligand is one of the effective methods for synthesizing hetero-metal polynuclear complexes. *N,N'*-Bis(aminoalkyl)oxamidatocopper(II) acts as a bidentate ligand with its two carbonyl oxygens, and binuclear metal complexes bridged by the oxamide group were first prepared by Ojima and Nonoyama.[1] Subnormal magnetic moments of these complexes are indicative of antiferromagnetic spin-exchange interaction operating between the metal ions.[1] However, cryomagnetic investigation of the oxamide-bridged polynuclear complexes has not yet been reported.

We report here the synthesis and magnetic property of the $M^{II}Cu^{II}_3$-type tetranuclear complexes of *N,N'*-bis(aminoalkyl)oxamides, where copper(II) ions lie at the corners of a triangle with a M(II) ion at the center. *N,N'*-Bis(3-aminopropyl)oxamidatocopper(II) (abbreviated as Cu(apoxa)) and *N,N'*-bis(2-aminoethyl)-oxamidatocopper(II) (Cu(aeoxa)) were used as a ligand in this study.

Experimental

Syntheses. Cu(apoxa) and Cu(aeoxa)·$2H_2O$ were prepared by the method of Ojima and Yamada.[2] Syntheses of the tetranuclear complexes are exemplified by Co[Cu(apoxa)]$_3$(ClO_4)$_2$·$4H_2O$. Cu(aeoxa) (790 mg) and cobalt(II) perchlorate hexahydrate (366 mg) were dissolved in water (20 ml). The purple solution thus obtained was slowly concentrated at a temperature below 30 °C to give purple crystals. They were collected and dried under reduced pressure.

Elemental analyses of the complexes are given in Table 1.

Measurements. IR spectra were measured with a Hitachi IR spectrophotometer Model 215 on a KBr disk. Electronic spectra were measured with a Shimazu Multipurpose spectrophotometer Model MSP-5000 by a reflection on a powder sample. Magnetic susceptibilities were measured by the Faraday method in the temperature range 80—300 K. The apparatus was calibrated using $HgCo(NCS)_4$.[3] Magnetic moments were determined by the expression, $\mu_{eff} = 2.828\ (\chi_M \times T)^{1/2}$.

IR spectra of the tetranuclear complexes exhibit the C=O stretching band at 1590 cm^{-1}, which is practically the same in frequency as that of Cu(apoxa) and Cu(aeoxa)·$2H_2O$. On the other hand, the C=O deformation at 720 cm^{-1} of the ligand complexes[2] disappeared in the spectra of the tetranuclear complexes. This fact may be attributed to the coordination of the carbonyl oxygens to the nickel(II) and the cobalt(II) ions. The bands due to free perchlorate and nitrate ions were found around 1110 and 1380 cm^{-1} respectively.

Visible spectra of the tetranuclear complexes are characterized by a band at 18000 cm^{-1}, which is assigned to a d-d band of the copper(II) ion. The corresponding band of the mononuclear complexes is found near 20000 cm^{-1}. The shift of this band indicates that the ligand field of the [CuN_4]-chromophore is weakened when the carbonyl oxygens coordinate to the M(II) ion. The bands at 9000 and 13000 cm^{-1} for Co[Cu(apoxa)]$_3$(ClO_4)$_2$·$4H_2O$ are assigned to the $^4T_{2g} \leftarrow {}^4T_{1g}$ and the $^4A_{2g} \leftarrow {}^4T_{1g}$ transitions, respectively, of a cobalt(II) ion under O_h symmetry. The bands at 8500 and 13500 cm^{-1} for the $Ni^{II}Cu^{II}_3$-complexes are assigned to the $^3T_{2g} \leftarrow {}^3A_{2g}$ and the $^3T_{1g} \leftarrow {}^3A_{2g}$ transitions, respectively, of an octahedral nickel(II) ion. Based on the IR and visible spectral data, we assumed that the complexes possess the structure shown in Fig. 1.

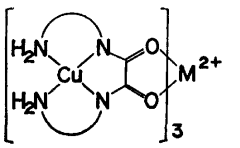

Fig. 1. Structure of complexes.

Magnetic moments of the complexes at room temperature are given in Table 1. Each moment is lower than the value expected for a magnetically non-interacting $Co^{II}Cu^{II}_3$-system (5.85 BM) and $Ni^{II}Cu^{II}_3$-system (4.53 BM), assuming the moments for copper(II), cobalt(II), and nickel(II) ions at 1.85, 4.90, and 3.20 BM, respectively. Furthermore, the moments decrease with lowering of temperature. These

a) Moment per molecule at room temperature.

facts imply that an antiferromagnetic spin-exchange interaction is operating in the molecules.

The magnetic susceptibility expression for the $M^{II}Cu^{II}_3$-system with M(II) ion at the center and copper(II) ions at the corners of a triangle (Fig. 2) was derived by extension of Kambe's approach.[4] The Hamiltonian for this system is given by $\mathcal{H}=-J(S_T^2-S_{123}^2)$, where $S_T=S_0+S_1+S_2+S_3$ and $S_{123}=S_1+S_2+S_3$. J is the exchange integral between M(II) and copper(II) ions. The states, (S_T, S_{123}; E), formed by the spin-spin coupling for the $Co^{II}Cu^{II}_3$-system are as follows: (3, 3/2; $-6J$), $2\times$(2, 1/2; $-3J$), (2, 3/2; 0), $2\times$(1, 1/2; J), (1, 3/2; $4J$), and (0, 3/2; $6J$). By applying the Van Vleck equation,[5] the susceptibility expression for this system is given by

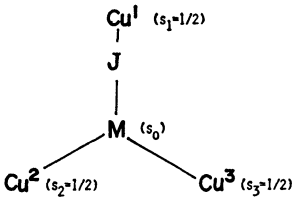

Fig. 2.

$$\chi_M = \frac{2Ng^2\beta^2}{kT} \times \frac{14\exp(6J/kT)+10\exp(3J/kT)+5+2\exp(-J/kT)+\exp(-4J/kT)}{7\exp(6J/kT)+10\exp(3J/kT)+5+6\exp(-J/kT)+3\exp(-4J/kT)+\exp(-6J/kT)} \quad (1)$$

where each symbol has its usual meaning. In the same way the states, (5/2, 3/2; $-5J$), $2\times$(3/2, 1/2; $-3J$), (3/2, 3/2; 0), $2\times$(1/2, 1/2; 0), and (1/2, 3/2; $3J$), are formed for the $Ni^{II}Cu^{II}_3$-system. The magnetic susceptibility expression for this system is given by

$$\chi_M = \frac{Ng^2\beta^2}{2kT} \times \frac{35\exp(5J/kT)+20\exp(3J/kT)+12+\exp(-3J/kT)}{6\exp(5J/kT)+8\exp(3J/kT)+8+2\exp(-3J/kT)} + N\alpha. \quad (2)$$

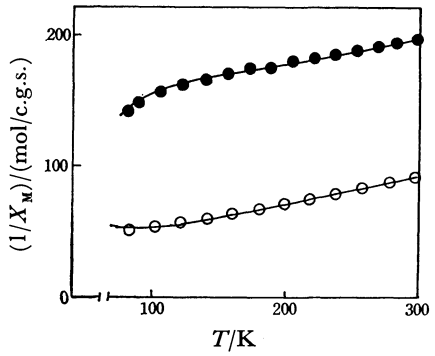

Fig. 3. Temperature variations of inverse magnetic susceptibilities of (○) $Co[Cu(apoxa)]_3(ClO_4)_2\cdot 4H_2O$ and (●) $Ni[Cu(aeoxa)]_3(ClO_4)_2\cdot 6H_2O$. Solid lines represent the theoretical values drawn on the basis of the expression (1) with $J=-23$, $g=2.29$ and $N\alpha=450\times 10^{-6}$ (top) and the expression (2) with $J=-75\ cm^{-1}$, $g=2.20$ and $N\alpha=400\times 10^{-6}$ c.g.s./mol (bottom).

Magnetic susceptibilities of $Co[Cu(apoxa)]_3(ClO_4)_2\cdot 4H_2O$ and $Ni[Cu(aeoxa)]_3(ClO_4)_2\cdot 6H_2O$ were well interpreted in terms of the expressions (1) and (2), respectively. The best fits between the experimental and the theoretical inverse susceptibilities are shown in Fig. 3. Magnetisms of $Ni[Cu(apoxa)]_3(ClO_4)_2\cdot 5H_2O$ and $Ni[Cu(apoxa)]_3(NO_3)_2\cdot 4H_2O$ also obeyed the expression (2). The magnetic parameters determined are as follows. $Ni[Cu(apoxa)]_3(ClO_4)_2\cdot 5H_2O$: $-J=42$, $g=2.49$, and $N\alpha=400\times 10^{-6}$; $Ni[Cu(apoxa)]_3(NO_3)_2\cdot 4H_2O$: $-J=49\ cm^{-1}$, $g=2.40$, and $N\alpha=400\times 10^{-6}$ c.g.s./mol. However, the g values of these complexes are large compared with 2.20 of $Ni[Cu(aeoxa)]_3(ClO_4)_2\cdot 6H_2O$. This would be indicative of the presence of paramagnetic impurity such as hexaaquanickel(II) ion. If this is taken into consideration, the $-J$ values for these complexes might exceed the values obtained above. Thus, we may conclude that a considerably strong antiferromagnetic spin-exchange interaction operates between the copper(II) and M(II) ions through the oxamidebridge.

Complexation of Arenediazonium Ions with a Macrocyclic Polyether. The Stability Constants for the Complexes

Yoji HASHIDA* and Kohji MATSUI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received May 10, 1979)

Synopsis. The stability constants for 18-crown-6 complexes with arenediazonium salts have been determined spectrophotometrically. The Hammett plot for *m*- and *p*-substituted benzenediazonium salts showed good correlation with a reaction constant 0.98 in methanol. The solvent effect on the stability of the complexes has been discussed.

Complexation of arenediazonium ions with macrocyclic polyethers, *i.e.* crown ethers, have been elucidated by NMR[1,2] and IR[3] spectroscopy. Such complexation with the appropriate crown ether reduces the thermal[4] and photochemical[5] decomposition of arenediazonium ions. Several preparative uses for crown ethers which include halogen displacement[6] and effective arylation[7,8] of aromatic substrates have been explored. This note will deal with the stability constants (K_S) for the 18-crown-6 complexes with arenediazonium salts:

$$Ar\text{-}N_2^+BF_4^- + P \overset{K_s}{\rightleftharpoons} Ar\text{-}N_2^+,\ P,\ BF_4^- \qquad (1)$$

$$K_s = [Ar\text{-}N_2^+,\ P,\ BF_4^-]/[Ar\text{-}N_2^+BF_4^-][P]$$

where P denotes the crown ether. 18-Crown-6 was chosen as the host, since it has an appropriate cavity size for the diazonium ion,[2] and is transparent in the UV region.

It has been found that the absorption maxima of arenediazonium ions shift to shorter wavelengths on complexation with the crown ether. Figure 1 shows a typical spectral change for the *p*-methoxybenzenediazonium salt in chloroform with increasing addition of 18-crown-6. The difference in UV spectra was used as an analytical tool to determine the stability constant, by adding known amounts of diazonium salt and crown compound into the solvent (see Experimental).

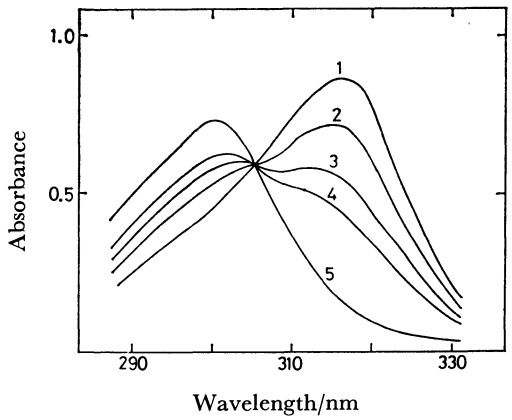

Fig. 1. UV spectrum of *p*-methoxybenzenediazonium tetrafluoroborate in chloroform in the absence and presence of 18-crown-6; $[Ar\text{-}N_2^+BF_4^-]_0 = 2.19 \times 10^{-5}$ M, (1), $[P]_0 = 0$, (2) $[P]_0 = 1.2 \times 10^{-4}$ M, (3), $[P]_0 = 2.3 \times 10^{-4}$ M, (4) $[P]_0 = 4.7 \times 10^{-4}$ M, (5) $[P]_0 = 5.2 \times 10^{-2}$ M (Further addition of the crown ether did not change the spectrum).

The stability constants measured in several organic solvents are given in Table 1, together with the spectral properties of diazonium ions and their complexes. The

a) Dielectric constant of solvent (from Ref. 16). b) Ref. 13. c) Ionization constant of conjugate acid of solvent (from Ref. 16). d) K_S: M^{-1} e) Maximum wavelength for the free diazonium ion (λ_{max}^{Dz}) and its complex (λ_{max}^{Cx}). f) Ref. 9.

observed stability constants are in reasonable agreement with those determined by titration calorimetry (Nos. 5, 6).[9]

One interesting aspect in Table 1 is the structural effect of diazonium salts on the stability of the complexes. The stability constant depended on the nature of the substituent in the diazonium salt as expected, *i.e.* as the electrophilicity of the diazonio group increases, the stability of the complex increased. The Hammett plot for the *m*- and *p*-substituted compounds (Nos. 1—8) shows a good correlation; a least-squares treatment gives an equation, $\log K_s = 0.98\sigma + 2.43$ with a correlation coefficient (r) of 0.986. The ρ value found is relatively low compared with those in other diazo-equilibrium systems, such as arenediazocyanide-($\rho = 3.53$),[10] arenediazosulfone-($\rho = 3.76$),[11] arenediazosulfonate)-($\rho = 5.5$),[12] and arenediazotate-formation ($\rho = 6.58$).[10] Ortho-substitution on the diazonium ion considerably reduces complex stability; the introduction of the *o*-methyl (No. 16) and 2,6-dimethyl groups (No. 17) lowered the pK_s by *ca.* one and three units respectively. This behavior undoubtedly results from steric hindrance.[2]

It was shown that the solvent has a pronounced effect on the stability (Nos. 7, 9—14). As can be seen, there is no observable correlation between stability of the complex and the common solvent properties such as dielectric constant and E_T-value.[13] Rather, the stability of the complex appears to be influenced by the basicity of the solvent, *i.e.* relatively stable complexes were formed in less basic solvents such as acetone and chlorinated alkanes.[14] This is explainable since the free diazonium ion is more stabilized by significant solvation in a solvent of higher basicity.

Experimental

Materials. 18-Crown-6 was prepared as described in the literature[15] (mp 38—40 °C). Arenediazomiun fluoroborates were prepared using reagent grade aromatic amines and purified by dissolving them in the minimum amount of acetonitrile, followed by reprecipitation with the addition of diethyl ether. The solvents were purified by standard procedures.[16]

pK_s *Measurement.* A solution of the diazonium salt *ca.* 2×10^{-4} M (1 M = 1 mol dm^{-3}) was prepared. In a typical run, a sample (5 ml) of this solution was added to a mixture of MeOH–H_2O (1 : 1, in volume) containing the R-salt (2-naphthol-3,6-disulfonic acid) and sodium carbonate; the solution was subsequently diluted to a specified volume and the absorbance measured, in order to determine the original concentration of diazonium salt. The remaining diazonium solution was employed for pK_s measurements; known quantities of the solution were added to a solution containing specified amounts of crown ether and the optical spectrum recorded at 15 °C. The stability constant K_s based on the Eq. 1 was calculated using a spectrally determined [Ar–N_2^+, P, BF_4^-]/[Ar–$N_2^+BF_4^-$] ratio under a given condition, in conjuction with the following equations;

$$[\text{Ar–N}_2^+\text{BF}_4^-]_0 = [\text{Ar–N}_2^+\text{BF}_4^-] + [\text{Ar–N}_2^+, \text{P}, \text{BF}_4^-]$$

$$[\text{P}]_0 = [\text{P}] + [\text{Ar–N}_2^+, \text{P}, \text{BF}_4^-]$$

where [Ar–$N_2^+BF_4^-$]$_0$ and [P]$_0$ denote the original concentrations of diazonium salt and the crown ether, respectively.

(Received May 28, 1979)

Synopsis. Phenyl- and tolylthallium(III) bis(trichloroacetate)s [$ArTl(OCOCCl_3)_2$, **1** (Ar=phenyl or tolyl)] were prepared from thallium(III) oxide, trichloroacetic acid, benzene, and toluene. The replacement of the thallium moiety in **1** with iodo, chloro, cyano, selenocyanato, and nitro groups and the aromatic coupling of **1** proceeded smoothly to give the corresponding aromatic derivatives in good yields. In the presence of $PdCl_2$–NaOAc, **1** (Ar=phenyl) reacted with acrylonitrile and methacrylonitrile to afford cinnamonitriles(*trans* and *cis*) and a mixture of α-benzylacrylonitrile and β-phenylmethacrylonitriles(*Z* and *E*) respectively.

Direct aromatic thallation by thallium(III) acetate–$HClO_4$ in acetic acid[1] or thallium(III) trifluoroacetate in trifluoroacetic acid[2] is an effective method for the preparation of arylthallium(III) compounds, which are useful in organic syntheses. However, trifluoroacetic acid is an expensive and hazardous reagent, and the method using $HClO_4$ is dangerous in some cases because of the danger of explosion.[3] We have now found a simple method for direct aromatic thallation using trichloroacetic acid, useful for large-scale syntheses in the cases of benzene and toluene. We wish to report the preparation of phenyl- and tolylthallium(III) bis(trichloroacetate)s [$ArTl(OCOCCl_3)_2$, **1** (Ar=phenyl or tolyl)] and their use in organic syntheses.

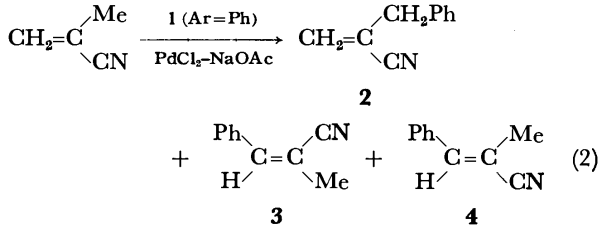
A mixture of benzene or toluene, thallium(III) oxide, and trichloroacetic acid was stirred at 65—70 °C for 1—5 h to give a white solid of **1** (Scheme 1). The reaction conditions, the yields of **1**, the melting points,

$$2ArH + Tl_2O_3 + 4CCl_3CO_2H \longrightarrow 2ArTl(OCOCCl_3)_2 \quad (1)$$

1

the isomer ratios, and the analytical and ^1H-NMR data are shown in Table 1. The scope of this aromatic thallation is, unfortunately, very limited; thus, **1** could not be obtained from anisole, thiophene, nitrobenzene, benzaldehyde, or methyl benzoate.[4] No aromatic thallation of benzene and toluene occurred when acetic, chloroacetic, or dichloroacetic acid was used under the conditions shown in Table 1.

The replacement of the thallium moiety in arylthallium(III) compounds with halogen,[5] pseudohalogen,[6] and a nitro group[7] and the aryl-coupling reaction[8] have been reported to give the corresponding aromatic derivatives. Although the yields of the products have depended on the kind of ligand on the thallium (*i.e.*, the yield of ArX is sometimes very low when the ligand is CN, Cl, OAc, or SCN), **1** where a ligand is CCl_3CO_2 was subjected quite successfully to all such reactions. Some typical results of the application of these reactions to **1** are summarized in Table 2. It has been known that arylthallium(III) compounds reacted with styrene and methyl acrylate in the presence of Li_2PdCl_4, the overall reaction being the replacement of an olefinic hydrogen by the aryl group.[9] When **1** (Ar=phenyl) was treated with styrene, ethyl acrylate, acrylonitrile, and methacrylonitrile in acetic acid or methanol in the presence of palladium(II) chloride or palladium metal and sodium acetate, *trans*-stilbene, ethyl cinnamate, cinnamonitriles(*trans*: *cis*=59: 41), and a mixture of α-benzylacrylonitrile (**2**) and (*Z*)- and (*E*)-β-phenylmethacrylonitriles (**3** and **4**) (**2**: **3**: **4**=55: 26: 19)



2

(Scheme 2) were produced respectively in good to excellent yields.[10] The product distributions in the latter two reactions were very close to those obtained in the reaction of phenylmercury(II) chloride under similar conditions, showing the presence of the same reactive species, probably the phenylpalladium(II) species. This is the first example of the arylation of α,β-unsaturated nitriles by the use of arylthallium(III) compounds and also of the arylation of olefins by arylthallium(III) compounds by the use of palladium metal as a catalyst. Some typical results are listed in Table 2.

a) Determined by GLC. b) Isomer ratio not determined. c) Preparative scale experiment. **1** (Ar=Ph), 162 mmol. The yield is the isolated one (see Experimental). d) *o*: *m*: *p*=9: 5: 86. e) *trans*: *cis*=59: 41. Reaction with PhHgCl (for 1 h) afforded an 80% yield of a mixture of *trans*- and *cis*-cinnamonitriles (*t*: *c*=65: 35). f) **2**: **3**: **4**=55: 26: 19. Reaction with PhHgCl (for 1 h) gave a 57% yield of a mixture of **2**, **3**, and **4** (**2**: **3**: **4**=46: 31: 23).

Experimental

All the organic materials were commercial products and were distilled before use. Commercial inorganic materials were used without further purification. The organic product mixtures were analyzed by GLC by the use of a Shimadzu 4BMPF apparatus on EGSS-X-(15%)-Chromosorb-W (1 or 3 m) and Apiezon-L (1 m) columns (carrier gas, N_2). The NMR spectra were recorded on a Varian EM-360 spectrometer in CH_3OD, $CDCl_3$, or CCl_4, using tetramethylsilane as the internal standard.

Preparation of **1** *(Ar=phenyl).* A brown heterogeneous mixture of thallium(III) oxide (Tl_2O_3, 13.7 g, 30 mmol), trichloroacetic acid (19.6 g, 120 mmol), and benzene (70 ml) was stirred at 70 °C for 5 h to give a white, heterogeneous mixture. After the mixture had been cooled down to room temperature, the solid was filtered off, washed with benzene, and dried *in vacuo* over silica gel. Almost pure **1** (Ar=phenyl) was thus obtained; 24.0 g (39.6 mmol, 66% yield based on Scheme 1). This is soluble in alcohols, tetrahydrofuran, dimethyl sulfoxide, *N*,*N*-dimethylformamide, and pyridine and insoluble in chloroform, carbon tetrachloride, diethyl ether, and hexane.

The reaction of toluene was similarly carried out to give pure **1** (Ar=tolyl, *o*: *m*: *p*=9: 5: 86) in a 64% yield.

Preparation of Phenyl Selenocyanate from **1** *(Ar=phenyl).* The following is a typical example of the reactions of **1** with various reagents on a preparative scale. A black suspension of **1** (Ar=phenyl) (98.4 g, 162 mmol) and $Cu(SeCN)_2$ (76.2 g, 279 mmol) in dioxane (200 ml) was stirred at reflux for 0.5 h. After the mixture had then been cooled to room temperature, the precipitated dark grey solid was filtered off and washed with ether (*ca.* 50 ml). Water (200 ml) was added to the combined solution of the filtrate and the ether washing, and then it was extracted with ether (200 ml×3). The ether extract was washed with aqueous NaCl and dried over $MgSO_4$. Distillation afforded 21 g (115 mmol, 71% yield) of almost pure phenyl selenocyanate; bp 110—120 °C/4 mmHg (lit,[11] bp 134 °C/10 mmHg).

We wish to thank Dr. Takuzo Funabiki for kindly supplying *trans*- and *cis*-cinnamonitriles, **3**, and **4** for GLC analysis. This research is partly supported by a grant from the Ministry of Education.

A New Catalytic System for the Preparation of Chromanols

Yoji TACHIBANA

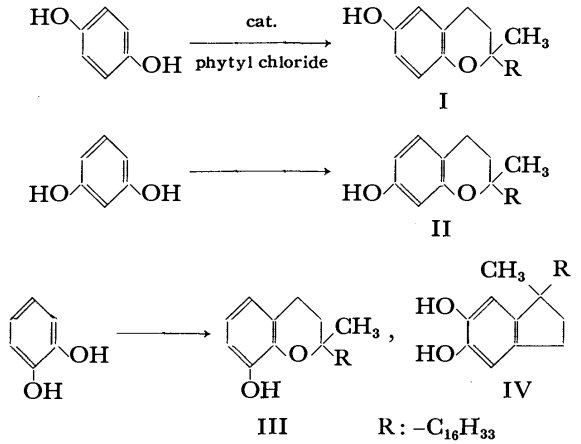
Ueda Factory, Nisshin Chemical Co., Ltd., Kamishiodiri, Ueda, Nagano 386

(Received June 6, 1979)

Synopsis. In the presence of the cation exchange resin complexes of metal ions, hydroquinone, resorcinol, and catechol reacted with phytyl chloride to give chromanols in good yields. The enhanced activity of the catalysts compared with the corresponding metal halides has been ascribed to the participation of the sulfonyl group in the abstraction of the proton on the benzene ring or the hydroxyl group. The catalysts were recycled several times with little loss of activity.

The study of anchoring homogeneous catalysts to a solid support has been developed on account of the ease in separation of product, the ability to carry out sequential catalytic reaction and positional selectivity.[1-3] It has been reported that the cation exchange resin complexes of metal ions are useful catalysts for the preparation of vitamin E.[4] In the course of studying the uses of the metal resin catalysts, it was found that these catalysts showed enhanced selectivity in the preparation of other chromanols compared with the corresponding metal halides.

In the presence of metal resin catalysts, the reaction of phytyl chloride with hydroquinone, resorcinol and catechol afforded I, II, and III, IV in good yields, respectively. Each product was characterized by elemental analysis, IR, NMR, and mass spectroscopy, the results of which are given in Table 1. The catalysts were recycled for use several times with little loss of activity, the results of which are summarized in Table 2, together with the results using metal halides for comparison. In the preparation of vitamin E from trimethylhydroquinone, little difference in selectivity was observed between the metal resin catalyst and metal halide.[4] The use of hydroquinone, resorcinol, and catechol in place of trimethylhydroquinone gave chromanols in poor yields when catalyzed by metal halides. The low selectivity has been attributed to the lower electron density of the benzene rings of hydroquinone, resorcinol, and catechol compared to trimethylhydroquinone. Therefore, the degradation of phytyl chloride by metal halides is more likely to occur than with trimethylhydroquinone. The yield of chromanol decreased in the order; resorcinol> hydroquinone> catechol which agrees with the order of electron density on the ortho or para position for the hydroxyl group.



The metal resin catalysts appear to enhance the activity of the substrate, resulting in higher yields of chromanols. The enhanced selectivity in the reaction catalyzed by the metal resin catalysts has been explained by assuming the participation of the sulfonyl group of the resin in the abstraction of the proton on the benzene ring (Scheme 1) or the hydroxyl group[5] (Scheme 2),

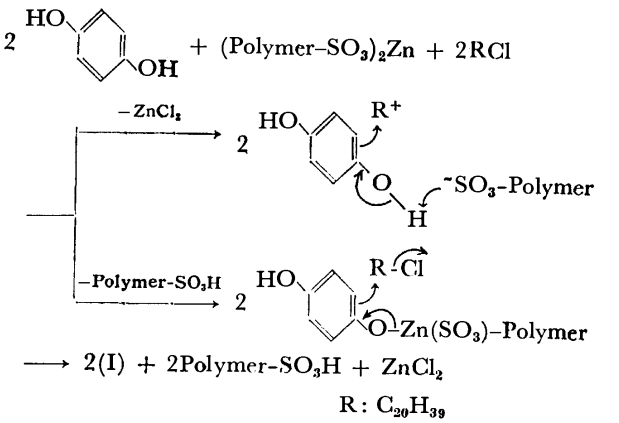
thereby facilitating substitution of the cation derived from phytyl chloride. In Scheme 2, the interaction of the $Zn(SO_3)$-polymer with the oxygen atom of the hydroxyl group may be included to activate the substrate. The latter mechanism (Scheme 2) appears however to be more plausible considering the ease of proton abstraction. The formation of IV is thought to be due to chelation between the two hydroxyl groups of catechol rather than a steric factor. The chelation presumably prevents the participation of the hydroxyl group in the formation of III.



Scheme 2.

Further studies on the detailed mechanism of this system are now in progress.

Experimental

GLC and atomic absorption spectra were recorded on a Hitachi 023 gas chromatograph equipped with a flame ionizer detector and a Hitachi 208 atomic absorption spectrometer, respectively. Amberlyst 15 (Rohm and Haas, 4.8 meq/g dry resin, in $-SO_3H$ form) was employed as cation exchange resin. The metal resin catalysts were prepared in the same way as described in a previous paper.[4]

A typical procedure is described for the preparation of III and IV; A benzene solution (100 ml) containing catechol (9.9 g), phytyl chloride (28.5 g) and zinc resin catalyst (20 g, 2.25 mmol of zinc ion/g dry resin) was allowed to reflux for 3 h. After standing overnight, the catalyst was filtered off and washed with benzene and acetone. The filtrate was washed with 10% $NaHCO_3$ solution and water, dried over anhydrous Na_2SO_4 and concentrated under reduced pressure. The residue was purified by silica gel column chromatography using benzene/hexane solution (1/2) as eluent, to give 12.1 g of III and 7.9 g of IV, respectively. The catalyst was again applied for the subsequent reaction.

In a similar way, other chromanols (I, II) were isolated.

Selective Decarboxylation of 1-Methyl-4,5-imidazoledicarboxylic Acid

Kazuyuki TAKAHASHI* and Keiryo MITSUHASHI

Department of Chemistry, College of Technology, Seikei University, Kichijoji, Musashino-shi, Tokyo 180

(Received June 22, 1979)

Synopsis. The selective decarboxylation of 1-methyl-4,5-imidazoledicarboxylic acid was carried out in various solvents. 1-Methyl-5-imidazolecarboxylic acid was obtained by heating in acetic or propionic anhydride, whereas 1-methyl-4-imidazolecarboxylic acid was obtained in *N,N*-dimethylformamide, *N,N*-dimethylacetamide, or *N*-methylpyrrolidone or by pyrolysis. The reaction mechanism is discussed.

The exhaustive decarboxylation of 4,5-imidazoledicarboxylic acids is well known, whereas the monodecarboxylation of the 1-substituted derivatives, which must lead to an isomeric product, has seldom appeared in the literature.

We have reported in a previous paper that the treatment of 1-methyl-4,5-imidazoledicarboxylic acid in an excess of boiling aniline at about 200 °C for 6—8 h gave 1-methyl-4-imidazolecarboxanilide in a yield of 56%.[1] On the other hand, Nematollahi reported the cyclic dimerization *via* the monodecarboxylation of 4,5-imidazoledicarboxylic acid in boiling acetic anhydride, yielding 5*H*,10*H*-diimidazo[3,4-*a*: 3′,4′-*d*]pyrazine-5,10-dione.[2]

The latter reaction conditions were then applied to 1-methyl-4,5-imidazoledicarboxylic acid in order to ascertain which isomer could be obtained by monodecarboxylation. The treatment in boiling acetic anhydride for only one hour gave 1-methyl-5-imidazolecarboxylic acid in a yield of 63.5%, while that at 100 °C for 4 h gave the same product in an almost quantitative yield. For the further investigation of the decarboxylation, acetic anhydride was replaced with various media; the results are summerized in Table 1.

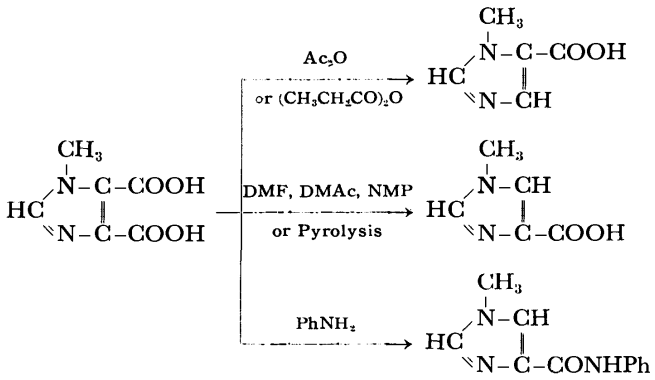

Fig. 1.

The successful effect of acetic anhydride on the selective decarboxylation seemed to suggest that the acylation of nitrogen at the 3-position is needed to promote the reaction. However, the use of anhydrides other than propionic anhydride, glacial acetic acid, acetyl chloride, and chloroacetyl chloride resulted in failure, probably because of the insolubility of the substrate in these acylating media.

On the other hand, the monodecarboxylation in such solvents as *N,N*-dimethylformamide, *N,N*-dimethylacetamide, *N*-methylpyrrolidone, and aniline, or by pyrolysis, where, in all cases, no electrophilic species was present, occurred at the 5-carboxyl group, giving the 4-carboxylic acid or its anilide. The reaction in *N,N*-dimethylaniline was hard to control.

TABLE 1. PRODUCTS AND CONDITIONS OF DECARBOXYLATION

Reaction media	Reaction temp/°C	Reaction time/h	Product	Yield/%

a) Heated until the reaction mixture became homogeneous. b) Most of the substrate was recovered.

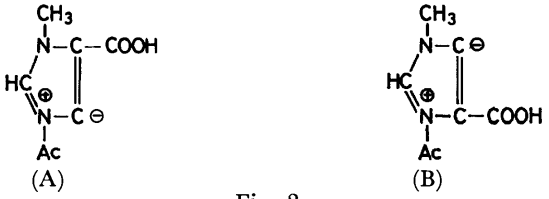

Fig. 2.

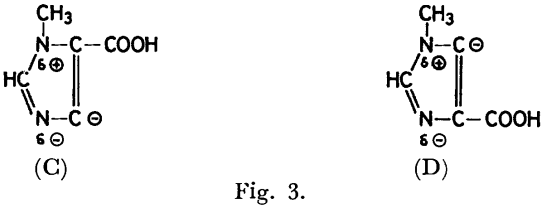

Fig. 3.

From the above results, the reaction mechanism can be thought to be as follows, on the basis of the adjacent charge effect: in the presence of such electrophilic species as acetic anhydride, the decarboxylated transition state (A) must be more stable than (B), consequently yielding the 5-carboxylic acid, while in the absence of electrophilic species, (D) must be preferable to (C), giving the 4-carboxylic acid or its derivative. Such a consideration on the basis of the electrostatic interaction has appeared in a paper by Cohen and his coworkers.[3] They studied the exchange reaction of ring hydrogens in 1-methylimidazole by NMR and concluded that the 5-carbanion was preferable to the 4-carbanion because of the electrostatic repulsion.

The present work provides a route to synthesize 1-methyl-4- and -5-imidazolecarboxylic acids and their derivatives which is more convenient than the known syntheses.[4]

Experimental

Decarboxylation in Acetic Anhydride. Into 100 ml of acetic anhydride, 3.4 g (0.02 mol) of 1-methyl-4,5-imidazoledicarboxylic acid was added, after which the suspension was heated at 100 °C for 4 h. After the reaction mixture became homogeneous, it was concentrated to dryness under reduced pressure. The resulting residue was washed with acetone and recrystallized from ethanol to give 1-methyl-5-imidazolecarboxylic acid in a yield of 2.5 g (99%); mp 256—257 °C (dec) (uncorr.) (lit,[4] 275—277 °C (dec)).

Decarboxylation in Propionic Anhydride. 1-Methyl-4,5-imidazoledicarboxylic acid (1.7 g, 0.01 mol) in 100 ml of propionic anhydride was heated, after which the reaction mixture was treated in the same way as that in acetic anhydride.

Decarboxylation in N,N-*Dimethylformamide.* Into 50 ml of *N,N*-dimethylformamide, a 1.7 g portion(0.01 mol) of 1-methyl-4,5-imidazoledicarboxylic acid was added, after which the suspension was heated under reflux for 3 h. The reaction mixture was then concentrated to dryness under reduced pressure. The resulting residue was washed with benzene and recrystallized from ethanol to give 1-methyl-4-imidazolecarboxylic acid in a yield of 0.5 g(39.7%); mp 246—247 °C (dec)(uncorr.)(lit,[2] 246—247 °C(dec)).

Decarboxylations in N,N-*Dimethylacetamide and* N-*Methylpyrrolidone.* The decarboxylations in *N,N*-dimethylacetamide and *N*-methylpyrrolidone were carried out in the same way as that in *N,N*-dimethylformamide.

Pyrolysis. In a test tube, 0.85 g (0.005 mol) of 1-methyl-4,5-imidazoledicarboxylic acid was placed and heated in a silicone oil bath at 250 °C for 1 min. The reaction mixture was then washed with benzene and recrystallized from ethanol to give 1-methyl-4-imidazolecarboxylic acid in a yield of 0.19 g (30%).

Isomeric Identification of the Monocarboxylic Acids. The carboxylic acids obtained were transformed to their methyl esters, which were then compared gas-chromatographically with authentic methyl 1-methyl-4- and -5-imidazolecarboxylates.

Methylation of 1-Methyl-4- and -5-imidazolecarboxylic Acids. Into 50 ml of thionyl chloride, a 2.5 g portion(0.02 mol) of 1-methyl-5-imidazolecarboxylic acid was added; the suspension was then heated under reflux for about 6 h till the mixture became clear. Immediately after the thionyl chloride has been distilled off, a 50 ml portion of methanol was added and the mixture was refluxed for 1 h. The reaction mixture was then cooled in an ice bath, and powdery sodium carbonate was added to make it alkaline. The solution was concentrated to dryness under reduced pressure, and the residue was extracted with chloroform. The chloroform layer was concentrated again, and the resulting residue was recrystallized from hexane to give methyl 1-methyl-5-imidazolecarboxylate in a yield of 1 g (35.7%); mp 54—56 °C (uncorr.) (lit,[4] 56—57 °C, 68—70 °C, 39—40 °C).

The methylation of the 4-carboxylic acid was carried out in a similar way. The methyl ester was obtained in a yield of 45%; mp 103—104 °C (lit,[1] 103—104 °C).

Preparation of Authentic Samples. Methyl 1-methyl-5-imidazolecarboxylate was prepared from methyl 4-imidazolecarboxylate with dimethyl sulfate according to Pyman's method,[4] while the 4-isomer was prepared from 1-methyl-4-imidazolecarboxanilide through hydrolysis, followed by esterification.[1] The isomeric structure of these authentic samples has previously been determined by a study of the Nuclear Overhauser Effect on NMR.[1]

Gas Chromatography. Gas chromatography was performed on a Shimadzu GC-6AMP instrument equipped with a 3 mm × 1000 mm glass column of OV-17 (5%) on DMCS. The column temperature was raised at a rate of 4 °C/min starting from 100 °C, and the flow rate was 30 ml of helium/min. The retention times of methyl 1-methyl-4- and -5-imidazolecarboxylates were 21 and 10 min, respectively.

Infrared Spectra and Intramolecular Hydrogen Bonding of *p*-(Substituted phenoxy)-*α*-(dialkylamino)acetanilides

Kazuhisa ABE,* Minoru HIROTA, Michiharu SUGIURA,** and Yoshiki HAMADA**

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

***Faculty of Pharmacy, Meijo University, Tempaku-ku, Nagoya 468*

(Received June 28, 1979)

Synopsis. The title compounds were synthesized with pharmaceutical interests, and their infrared spectra in the NH and carbonyl stretching regions were measured. By comparing the spectra with those of *p*-phenoxyacetanilide, intramolecular hydrogen bonds are shown to exist between the amide NH and the α-dialkylamino groups.

The structures and the conformations of many amides and peptides have been discussed on the basis of their infrared spectra and several absorption bands are shown to be characteristic of amide functional group.[1] Among these characteristic absorptions, NH stretching bands and carbonyl stretching bands (amide I bands) are most extensively studied, and the former bands are proved to be very sensitive to the stereochemistry and to the participation in hydrogen bond formation.[2,3]

On pharmaceutical interests, a series of *p*-(substituted phenoxy)-*α*-(dialkylamino)acetanilides (**1**) were synthesized[4] and their hydrogen bonding behaviors were studied by measuring their infrared spectra in the NH and carbonyl stretching regions. Since the intra- and intermolecular hydrogen bonds often have remarkable effect on solubility, it can also affect on their biological activities.

Experimental

Syntheses of the *p*-(substituted phenoxy)-*α*-(dialkylamino)-acetanilides were reported previously.[4] Infrared spectra in solutions were measured with a Hitachi 225 recording spectrophotometer. Concentrations of the solutions were about 1×10^{-3} mol/l for the measurements in NH stretching region and about 5×10^{-4} mol/l for the measurement in C=O stretching region, at which concentrations the association of the solute is negligible. Measurement of ^{1}H-NMR spectra were carried out by a JOEL JNM C60-H spectrometer with solutions of which concentrations were about 0.5 mol/l. The chemical shifts (in ppm) of the NH proton siginals are rather insensitive to the changes in concentrations probably due to the formation of strong intramolecular hydrogen bonds.

Results and Discussion

Their infrared spectra were measured in a carbon tetrachloride solution enough dilute to avoid the effect of association in practice and were given in Tables 1 (NH stretching region) and 2 (C=O stretching region). The NH absorption bands of all amides in Table 1 are located at considerably lower frequencies and rather broad with half-widths ranging from 70 to 120 cm^{-1}. On the other hand, *p*-phenoxyacetanilide (**2**) has an NH band at 3448 cm^{-1} ($\varepsilon=188$), being by far a narrower band with a half-width of 10.3 cm^{-1}. In general, the amide group takes predominantly the trans conformation in which NH and C=O groups are anti to each other, and the NH band of trans conformer appears at a higher frequency than that of cis conformer. For example, the trans conformer of acetanilide absorbs at 3446 cm^{-1}, while the cis at 3402 cm^{-1}.[2,5] However the low frequency shifts observed with **1**'s are more than 100 cm^{-1} with reference to the NH frequency of **2**, being too large to attribute to the privileged cis con-

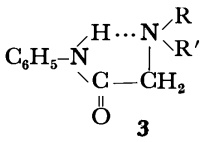
former. Thus the NH group of **1** is suspected to be involved in a strong hydrogen bond. Since the NH absorptions of these amide are not concentration dependent and measured at very low concentrations, the hydrogen bond must be intramolecular (as illustrated by **3**).



3

The NH stretching frequencies of **1**'s are mainly controlled by the nature of the α-dialkylamino groups. As shown in Table 1 and also in Fig. 1, the NH stretching frequencies generally decrease in the order: morpholino >dimethylamino>piperidino>diethylamino >2-methylpiperidino derivatives. The pK_a values of the parent amines are 8.33 for morpholine, 10.77 for dimethylamine, 11.22 for piperidine, and 10.93 for diethylamine.[6,7] Stronger base usually acts as stronger hydrogen acceptor and will cause larger low frequency shift of the stretching vibration of hydrogen donating NH group in hydrogen bond formation. The effect of the α-dialkylamino group is in line with this interpretation. The anomalously low frequency shifts observed with diethylamino derivatives, and presumably with 2-methylpiperidino derivatives, are explained that the bases are weakened by the so-called B strain probably operating when the ammonium ions are formed from these nitrogen bases. Hydrogen bonds are formed without considerable change in geometries of the acceptor molecules, the effect being negligible. The

a) Chemical shifts (in ppm downfields from internal TMS reference) are given.

pK_a's of diethylamine and 2-methylpiperidine are lower than expected from the electronic effect alone.

The hydrogen bond was also proved by ^{1}H-NMR spectra of **1**'s in chloroform-*d* (Table 3). The amide NH signals resonate in the range 8.9—9.5 ppm (downfield from TMS reference signal), which is obviously lower fields than the NH chemical shift of **2** (7.85 ppm) which is impossible to form intramolecular hydrogen bond. The NH stretching frequency (ν_{NH}) *vs.* NH chemical shift (δ_{NH}) plots in Fig. 1 are almost linear in all cases illustrated, and support evidently the fact that the low frequency shifts of ν_{NH} and the low field shifts of δ_{NH} are both due to the hydrogen bond formation, and the hydrogen bonds are formed with the α-dialkylamino group intramolecularly.

The NH stretching absorption bands of free amide group was not observed with any of **1**'s, and the α-dialkylamino-*p*-phenoxyacetanilides are supposed to exist solely as the intramolecularly hydrogen bonded conformers.

Asymmetric Synthesis of Aspartic Acid by Hydrogenation of Optically Active 1,4-Oxazine Derivative[1]

Minoru TAMURA and Kaoru HARADA*

Department of Chemistry, The University of Tsukuba, Niihari-gun, Ibaraki 305

(Received July 25, 1979)

Synopsis. The asymmetric hydrogenation of an optically active heterocyclic compound, (*R*)-3-methoxycarbonylmethylene-5-phenyl-3,4,5,6-tetrahydro-2*H*-1,4-oxazin-2-one(**2**), was studied. The compound **2** was hydrogenated with several catalysts, and was converted into optically active aspartic acid. The configuration of the resulting aspartic acid proved to be (*S*), and the optical yield was in the range 12—17%.

Recently we have reported[2] an asymmetric synthesis of alanine by hydrogenolytic transamination by the use of (*R*)-2-amino-2-phenylethanol (**1**) as a chiral reagent. The effects of the asymmetric moieties as well as the solvents on the optical yields were explained by the chelation hypothesis based on the interaction between the substrate and the catalyst.

In the present work, in order to study the effect of the structure of substrate on the optical yield, the optically active heterocyclic compound **2** was prepared from amino alcohol **1** and dimethyl acetylenedicarboxylate, and the asymmetric hydrogenation of **2** was carried out.

Kagan *et al.*[3,4] reported an efficient asymmetric synthesis by hydrogenation of the cyclic compound prepared from (1*S*,2*R*)-2-amino-1,2-diphenylethanol and dimethyl acetylenedicarboxylate. However, since asymmetric hydrogenation of **2** was not described in detail, we would like to report the results of the hydrogenation of **2** with aluminum amalgam, Raney nickel, and other catalysts.

TABLE 1. ASYMMETRIC SYNTHESIS OF ASPARTIC ACID BY HYDROGENATION OF **2**

Temp °C	Catalyst	Time h	Solvent	Route (A or B)	Yield[b]	$[\alpha]_D^{25}$ DNP-Asp[c]	Optical yield[d] (confign.)

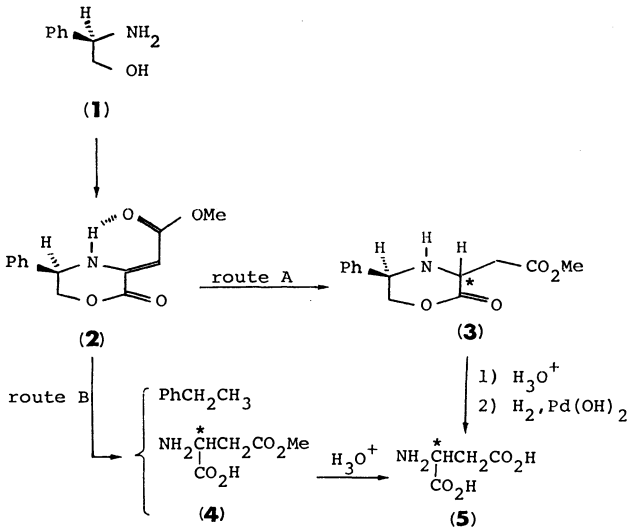
20	Pd on C	48	Dioxane	B	48	+10.8 (0.573)	12 (*S*)

a) DME is 1,2-dimethoxyethane. b) The yields of **3** (route A) or **4** (route B). c) The specific rotations were measured in 1 mol dm^{-3} NaOH. d) Optical yield is defined as ($[\alpha]_D$ obsed/$[\alpha]_D$ lit) × 100, DNP-(*S*)-Asp, $[\alpha]_D^{25}$ +91.9° (1 mol dm^{-3} NaOH).

Cyclic compound **2** was prepared through the condensation of optically active amino alcohol **1** and dimethyl acetylenedicarboxylate at room temperature. The IR spectra of **2** indicated the presence of an intramolecular hydrogen bond.[5] In the NMR spectra of **2**, the chemical shift of the NH proton also suggested an intramolecular hydrogen bond.[6] From the results described above, it was concluded that compound **2** is of *Z*-configuration.

Compound **2** was hydrogenated with aluminum amalgam or Raney nickel (Scheme 1; route A). Product **3** was purified by the use of silica gel column chromatography without fractionation. The yield of **3** was



Scheme 1.

44—62%. Hydrolysis and subsequent hydrogenolysis of **3** gave optically active aspartic acid in 74—75% yields from **3**. The optical yields of the aspartic acid were determined as *N*-(2,4-dinitrophenyl)aspartic acid (DNP-Asp).[7] The configuration of aspartic acid was (*S*). The optical yields ranged from 14 to 17%. In the reaction with aluminum amalgam, the reaction temperature was lowered, however, no change of the optical yield was observed.

When palladium black or 5% palladium on charcoal was used as a catalyst, hydrogenation and hydrogenolysis took place simultaneously and β-methyl hydrogen aspartate (**4**) was obtained in 42—70% yields (route B). According to the time-course checked by TLC of the reaction mixture, it seems that hydrogenation takes place prior to hydrogenolysis.

It was found that the reductive cleavage of the benzylic C–N bond and also the homobenzylic C–O bond (Ph–CH_2–CH_2–O)[8] took place in route B. The existence of ethylbenzene in the reaction mixture, which was confirmed by gas-liquid chromatography, would support the hydrogenolytic cleavage of the homobenzylic C–O bond.

Compound **4**, which was obtained by the route B, was hydrolyzed to form optically active aspartic acid. The optical yield of DNP-aspartic acid ranged from 12 to 16%. And the configuration of aspartic acid was (*S*). The results are summerized in Table 1.

The examination of the conformation by the Dreiding model showed that the preferential formation of (*S*)-isomer was caused by the steric effect of the phenyl group on substrate **2**, and that the steric effect would be larger when the phenyl group is pseudo axial than pseudo equatorial. The optical yields obtained by

these reactions suggested that substrate **2** could largely take the conformation in which the phenyl group is pseudo equatorial.

Experimental

The NMR spectra were obtained by using a Hitachi H-60 and R-24 A spectrometers, and the IR spectra were measured with a Hitachi 215 type grating infrared spectrophotometer. The gas chromatography was carried out with a Hitachi 163 type gas chromatograph. The specific rotations were measured with a JASCO DIP-181 type digital polarimeter using a 50 mm cell. The amino acids were analyzed with a Yanagimoto LC-5 S instrument. The mass spectra were obtained by a Hitachi RMU-6 MG type high resolution mass spectrometer.

(R)-3-Methoxycarbonylmethylene-5-phenyl-3,4,5,6-tetrahydro-2H-1,4-oxazin-2-one (2). A solution of (*R*)-2-amino-2-phenyl-ethanol (**1**) ($[\alpha]_D^{25}$ −27.3° [c=1.08, methanol])[2] (0.5 g, 3.65 mmol) in 10 ml of MeOH was added dropwise to a solution of dimethyl acetylenedicarboxylate (0.518 g, 3.65 mmol) in 7 ml of MeOH with stirring for 20 min. After being stirred for additional 2.5 h, the mixture was evaporated and purified by silica gel column chromatography (30×210 mm, E. Merck No. 9385), eluted with benzene–AcOEt (9: 1 v/v) solvent. Compound **2** was obtained as colorless oil (0.791 g; 88%), which crystallized on cooling in a refrigerator. The recrystallization from ether–petroleum ether gave colorless needles. Mp 67—68 °C, $[\alpha]_D^{20}$ −259° (c=0.590, $CHCl_3$). Found: C, 63.11; H, 5.10; N, 5.83%. Calcd for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.29; N, 5.66%. IR($CHCl_3$): 3300 (NH), 3000, 1740 (lactone), 1660 (ester), 1620 (C=C) cm^{-1}. δ($CDCl_3$): 3.65 (3H, s), 4.30—4.85 (3H, ABC m), 5.70 (1H, s, $-\underset{|}{C}=CH$), 7.30 (5H, s), 8.50 (1H, s, NH). The H–D exchange of the proton on NH was very slow (half life $T_{1/2}$: 2 d). Mass: M^+ (247), λ_{max}: 325 nm (ε=8330).

(R)-3-Methoxycarbonylmethyl-5-phenyl-3,4,5,6-tetrahydro-2H-1,4-oxazin-2-one (3) (Route A). An aluminum amalgam prepared from 500 mg of aluminum foil[9] was added to an ice-cooled magnetically stirred solution of **2** (500 mg, 2.02 mmol) in 30 ml of 1,2-dimethoxyethane. The mixture was treated with 4 ml of distilled water, and the stirring was continued for 6 h at 0 °C under nitrogen atmosphere. To the reaction mixture, Celite 545 (0.1 g) was added and filtered under suction, and the residue was washed with 1,2-dimethoxyethane (25 ml) and MeOH (25 ml). After evaporation of the solvent at 0—5 °C, the residue was dissolved in ethyl acetate and was dried (Na_2SO_4). After removal of the solvent at 0—5 °C, the residual oil was purified by silica gel column chromotography mentioned above. The combined fractions were evaporated at 0—5 °C to furnish colorless oli. Yield: 0.307 g (61%). IR (NaCl): 3300 (NH), 2950, 1750 (lactone), 1730 (ester) cm^{-1}. δ($CDCl_3$): 2.71 (1H, s, NH), 2.80—3.10 (2H, 6 peaks, $-C\underline{H}_2-CO_2CH_3$), 3.70 (3H, s), 4.00—4.45 (4H, m), 7.38 (5H, s). Mass: M^+ (249). In the case of Raney nickel, **2** (400 mg, 1.62 mmol) was dissolved in 20 ml of abs EtOH and Raney nickel (W-2 type, 600 mg) was added. Hydrogenation was carried out at room temperature for 48 h (initial pressure of hydrogen was 3 atm).

(S)-Aspartic Acid (Route A). The compound **3** was hydrolyzed with 6 mol dm^{-3} hydrochloric acid (10 ml) under reflux for 5 h. After evaporation, the hydrolyzate was dissolved in a small amount of distilled water and the pH was adjusted to about 4.5 with sodium hydrogen carbonate. Palladium hydroxide on charcoal (0.2 g) was added to the solution and the hydrogenolysis was carried out for 13 h. The catalyst was removed by filtration and the filtrate was evaporated to dryness. The residue was dissolved in a small amount of water and the solution was applied to a Dowex 50 column (H^+ form). The column was eluted with 3 mol dm^{-3} aqueous ammonia and the eluent was evaporated to dryness. A part of the solution was diluted appropriately and analyzed with an amino acid analyzer (yield: 74%). A part of aspartic acid was converted to DNP-Asp, which was purified by a Celite column (Hyflo-super-cel); $[\alpha]_D^{25}$ +16.0° (c=0.702, 1 mol dm^{-3} NaOH), optical purity 17%. The DNP-aspartic acid was further confirmed by TLC (MeOH: AcOEt=5: 1 v/v).

(S)-β-Methyl Hydrogen Aspartate (4) (Route B). To a solution of **2** (200 mg, 0.810 m mol) in 5 ml of abs. MeOH, palladium black (300 mg) was added, and the mixture was stirred for 48 h under hydrogen (1 atm). The catalyst was removed by filtration and a small part of the filtrate (1 μl) was applied on a gas-liquid chromatography, which showed the presence of ethylbenzene. The residual filtrate was evaporated to dryness and the residue crystallized by addition of a small amount of chloroform. Yield: 83.2 mg (70%); mp 199—200 °C; δ (D_2O): 2.80—3.35 (2H, ABX), 3.77 (3H, s), 4.35 (1H, dd); IR (KBr): 3400 (br), 3000 (br), 2070, 1720, 1650, 1600 cm^{-1}. Found: C, 40.80; H, 6.01; N, 9.22%, Calcd for $C_5H_9NO_4$: C, 40.81; H, 6.16; N, 9.52%.

(S)-Aspartic Acid (Route B). Crude **4** was refluxed with 6 mol dm^{-3} hydrochloric acid (10 ml) for 3 h. After evaporation, the residue was dissolved in a small amount of water and the solution was applied to a Dowex 50 column. The yield of aspartic acid was determined by an amino acid analyzer (91%), and the optical purity of the aspartic acid was determined as DNP-(*S*)-aspartic acid; $[\alpha]_D^{25}$ +14.7° (c 0.422, 1 mol dm^{-3} NaOH), optical purity 16%.

The authors wish to express their thanks to Dr Takenori Kusumi for his valuable discussions. We also would like to thank Dr. Shinya Nomoto for his discussion.

Stereochemical Control Exerted by Methoxyl Group on the Diiodomethane-Copper Methylenation of Cyclic Olefins Containing Methoxyl Group

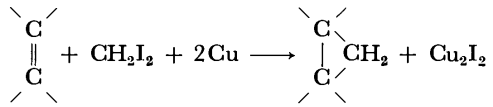
Nariyoshi KAWABATA* and Naoki IKEDA

Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

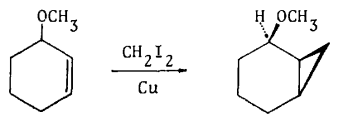
(Received July 25, 1979)

Synopsis. In the diiodomethane-copper methylenation of 3- and 4-methoxycyclopentenes and 3-methoxycyclohexene, the cis isomers of the cyclopropane derivatives predominated over the corresponding trans isomers, the trans isomer of cyclopropane derivatives being predominantly obtained from 3-methoxycyclooctene.

Reports have been given on the synthesis of cyclopropane derivatives from olefins by the reaction with diiodomethane and copper.[1,2] The reaction gave



cyclopropane derivatives in good yields as in the corresponding Simmons-Smith reaction.[3] The reaction proceeded stereospecifically, *i.e.*, cis and trans olefins afforded cyclopropane derivatives whose configurations with respect to the olefin substituents were cis and trans, respectively. Moreover, the ether functions controlled the stereochemistry of the cycloaddition, *cis*-2-methoxybicyclo[4.1.0]heptane being exclusivel obtained from 3-methoxycyclohexene.[2] This type of

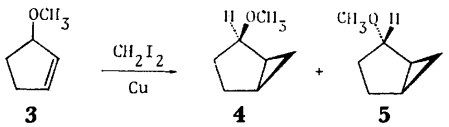


1 **2**

stereospecific synthesis of cyclopropane derivatives in the Simmons-Smith reaction has been widely used in synthesis.[4] The present work deals with an investigation of the stereochemistry of the diiodomethane-copper methylenation with olefins containing oriented ether functions.

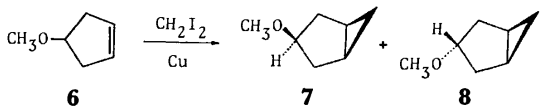
Results and Discussion

Reaction of 3-methoxycyclopentene with diiodomethane and copper powder gave an 88: 12 mixture of *cis*- and *trans*-2-methoxybicyclo[3.1.0]hexane in 75% yield. Reaction of 4-methoxycyclopentene with diiodomethane and copper powder gave a 90: 10 mixture of



3 **4** **5**

88: 12

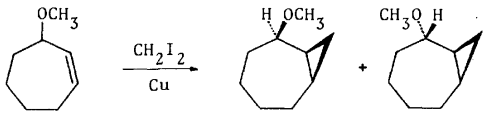


6 **7** **8**

90: 10

cis- and *trans*-3-methoxybicyclo[3.1.0]hexane in 70% yield. The structures of these cyclopropane derivatives were determined by comparison of their spectral data with those of authentic materials.[5]

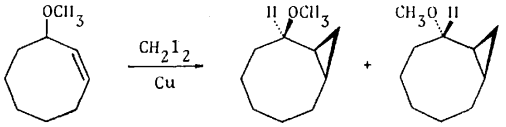
Reaction of 3-methoxycycloheptene with diiodomethane and copper powder gave a 57: 43 mixture of *cis*- and *trans*-2-methoxybicyclo[5.1.0]octane in 77% yield. The relative configurations of these cyclopropane derivatives were assigned on the basis of their ^{1}H NMR spectra. The cis isomer **10** and the trans isomer **11** showed absorptions due to the protons geminal to the methoxyl group at δ 3.65 with a width at half-height of 13 Hz and δ 2.70 with a width at half-height of 17 Hz, respectively. This is in line with the cis and trans configurations of the cyclopropane ring to the methoxyl group, respectively. In the case of 2-hydroxybicyclo[5.1.0]octanes, the peak due to the hydrogen atom geminal to the hydroxyl group of the trans isomer appears at δ 3.3 with a width at half-height of 15 Hz, the corresponding peak of the cis isomer appearing at δ 4.2 with a width at half-height of 10 Hz.[6]



9 **10** **11**

57: 43

The reaction of 3-methoxycyclooctene with diiodomethane and copper powder gave an 18: 82 mixture of *cis*- and *trans*-2-methoxybicyclo[6.1.0]nonane in 83% yield. The relative configurations of these cyclopropane derivatives were also determined on the basis of their ^{1}H NMR spectra. The cis isomer **13** and the trans isomer **14** showed absorption due to the protons geminal to the methoxyl group at δ 3.78 with a width at half-height of 11 Hz, and δ 2.72 with a width at half-height of 18 Hz, respectively. This is in line with the cis and trans configurations of the cyclopropane ring to the methoxyl group, respectively.[6]



12 **13** **14**

18: 82

In brief, preferential cis-directive addition was observed in reactions with the methoxycyclopentenes and the methoxycyclohexene, and preferential trans-directive addition being observed in the reaction with the methoxycyclooctene. Stereochemical control of the

methoxyl group was weak in the reaction with the methoxycycloheptene.

The stereospecific synthesis in the Simmons-Smith reaction with cyclic allylic alcohols was explained in terms of the attack of organozinc reagent on the nearest face of the neighboring double bond after coordination to the oxygen atom of the substrate.[7] Models of the 3- and 4-methoxycyclopentenes and 3-methoxycyclohexene indicate that the methoxyl group can only function as a cis-director. The model of 3-methoxycyclooctene shows that addition in the trans-direction is favored. On the other hand, the model of 3-methoxycycloheptene is less useful for determining which face of the double bond is more accessible.

In the Simmons-Smith reaction with cyclic allylic alcohols,[7] the cis isomers of the corresponding cyclopropane derivatives were exclusively obtained from 2-cyclopenten-1-ol and 2-cyclohexen-1-ol, the trans isomers of the cyclopropane derivatives being exclusively obtained from 2-cycloocten-1-ol and 2-cyclononen-1-ol. A 90: 10 mixture of the cis and trans isomers of the cyclopropane derivatives was obtained from cyclohepten-1-ol.[7]

The methoxyl group shows a tendency in stereochemical control in the cycloaddition of copper carbenoid to cyclic olefins containing the methoxyl group similar to that in the Simmons-Smith reaction with cyclic allylic alcohols, although the control was weak in the diiodomethane–copper methylenation. This can be interpreted in terms of the weaker interaction of the methoxyl group with copper carbenoid in the transition state than that of the hydroxyl group with the organozinc intermediate in the Simmons-Smith reactions, since copper halides are weaker Lewis acids than zinc halides.

Experimental

Elemental analyses were performed at the Elementary Analyses Center of Kyoto University. ^{1}H NMR spectra were taken on a Varian T-60-A spectrometer in carbon tetrachloride using tetramethylsilane as an internal standard, IR spectra on a Hitachi 215 grating spectrophotometer, and mass spectra on a Hitachi Model RMU-6 mass spectrometer. VPC analyses were performed on a Shimadzu GC-4C gas chromatograph.

Materials. 3-Methoxycyclopentene was prepared according to the conventional procedure.[8] 4-Methoxycyclopentene, 3-methoxycycloheptene, and 3-methoxycyclooctene were prepared by the conventional method[9] from 3-cyclopenten-1-ol,[10] 2-cyclohepten-1-ol,[11] and 2-cycloocten-1-ol,[12] respectively. Commercial copper powder was used without further purification. Diiodomethane and benzene were purified by distillation. Other chemicals were used without further purification.

Procedure. Reactions of cyclic olefins containing methoxyl group with diiodomethane and copper powder were carried out as reported.[1,2] Yields were determined by VPC analysis of the reaction mixture on the basis of olefin. Products were isolated by collection from the reaction mixture by VPC, and analyzed.

2-Methoxybicyclo[3.1.0]hexane. Reaction of 3-methoxycyclopentene (0.20 g, 2.05 mmol), diiodomethane (1.05 g, 3.97 mmol), copper powder (0.58 g, 9.16 mmol), and iodine (0.015 g, 0.12 mmol) in 1.5 ml of benzene at 75 °C for 72 h gave an 88: 12 mixture of *cis*- (**4**) and *trans*-2-methoxybicyclo-[3.1.0]hexane (**5**) in 75% yield based on the olefin.

2-Methoxybicyclo[3.1.0]hexane. Reaction of 4-methoxycyclopentene (0.18 g, 1.85 mmol), diiodomethane (1.07 g, 4.00 mmol), copper powder (0.58 g, 9.13 mmol), and iodine (0.017 g, 0.14 mmol) in 1.5 ml of benzene at 75 °C for 72 h gave a 90: 10 mixture of *cis*- (**7**) and *trans*-3-methoxybicyclo-[3.1.0]hexane (**8**) in 70% yield based on the olefin.

2-Methoxybicyclo[5.1.0]octane. From 3-methoxycycloheptene (0.25 g, 1.95 mmol), diiodomethane (1.03 g, 3.86 mmol), copper powder (0.58 g, 9.16 mmol) and iodine (0.015 g, 0.12 mmol) in 1.5 ml of benzene at 75 °C for 96 h was obtained a 57: 43 mixture of *cis*- (**10**) and *trans*-2-methoxybicyclo[5.1.0]octane (**11**) in 77% yield based on the olefin. Found: C, 77.00; H, 11.62%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%. The cis isomer (**10**): ^{1}H NMR (CCl_4) δ 0.2—2.5 (m, 12H), 3.20 (s, 3H), 3.65 (m, 1H, width at half-height = 13 Hz). The trans isomer (**11**): ^{1}H NMR (CCl_4) δ 0.2—2.5 (m, 12H), 2.70 (m, width at half-height = 17 Hz), 3.35 (s, 3H).

2-Methoxybicyclo[6.1.0]nonane. From 3-methoxycyclooctene (0.25 g, 1.81 mmol), diiodomethane (1.04 g, 3.90 mmol), copper powder (0.61 g, 9.53 mmol), and iodine (0.015 g, 0.12 mmol) in 1.5 ml of benzene at 75 °C for 96 h was obtained an 18: 82 mixture of *cis*- (**13**) and *trans*-2-methoxybicyclo[6.1.0]nonane (**14**) in 83% yield based on the olefin. The cis isomer (**13**): $n_D^{30} = 1.4705$; ^{1}H NMR (CCl_4) δ 0.2—2.3 (m, 14H), 3.21 (s, 3H), 3.78 (m, 1H, width at half-height = 11 Hz); MS *m/e* (rel intensity) 154 (1.0, M^+), 93 (59), 81 (65), 80 (74), 79 (100). Found: C, 78.12; H, 11.83%. Calcd for $C_{10}H_{18}O$: C, 77.87; H, 11.76%. The trans isomer (**14**): $n_D^{30} = 1.4665$; ^{1}H NMR (CCl_4) δ 0.0—2.3 (m, 14H), 2.72 (m, 1H, width at half-height = 18 Hz), 3.29 (s, 3H); MS *m/e* (rel intensity) 154 (1.0, M^+), 93 (59), 81 (67), 80 (50), 79 (100); Found: C, 77.75; H, 11.79%. Calcd for $C_{10}H_{18}O$: C, 77.87; H, 11.76%.

Quaternary Ammonium Periodate as a New Oxidizing Agent

Katsuhiko INOMATA,* Yukiharu NAKAYAMA, and Hiroshi KOTAKE
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received July 28, 1979)

Synopsis. Quaternary ammonium periodate has been found to be a useful oxidizing agent to convert a 1,2-diol and an olefin to the corresponding carbonyl compound in anhydrous aprotic solvents. The resulting carbonyl compounds have been reacted with alkyllithium to prepare alcohols in one-pot from a 1,2-diol or an olefin.

Sodium and potassium periodate are useful oxidants to convert sulfides and 1,2-diols to the corresponding sulfoxides and carbonyl compounds. The necessity of employing water as a solvent or as a cosolvent mixed with an organic solvent such as methanol, however, places some restrictions on the use of periodates.[1]

In order to overcome the restrictions, the alkali salt has been converted to the quaternary ammonium salt. The quaternary ammonium periodate does not require water to oxidize a 1,2-diol and an olefin to the corresponding carbonyl compounds in aprotic solvents.

Three quaternary ammonium periodates (**2a**—**c**) were readily prepared from equimolar quantities of sodium periodate and the corresponding quaternary ammonium halides (**1a**—**c**) in aqueous solutions at 0 °C.

$$NaIO_4 + [R^1R^2R^3R^4N]^+X^- \xrightarrow{-NaX} [R^1R^2R^3R^4N]^+IO_4^-$$

1a; $R^1=CH_3(CH_2)_{15}$, $R^2=C_6H_5CH_2$, R^3, $R^4=CH_3$, $X=Cl$ — **2a**; 90%

1b; $R^1=C_6H_5CH_2$, R^2, R^3, $R^4=CH_3CH_2$, $X=Br$ — **2b**; 84%

1c; R^1, R^2, R^3, $R^4=CH_3(CH_2)_3$, $X=Br$ — **2c**; 94%

Each compound has similar oxidizing ability,[2] but benzylhexadecyldimethylammonium periodate (**2a**) was used in the following experiments since **2c** changed color yellow on storage at room temperature and **2b**, although readily soluble in dichloromethane, is sparingly soluble in ethereal solvents such as THF and dioxane.

2a was allowed to react with an equimolar amount of *dl*-1,2-diphenyl-1,2-ethanediol (**3dl**) in refluxing THF for 6 h, and almost all the **3dl** disappeared on TLC and a new spot of benzaldehyde appeared. The resulting benzaldehyde was isolated as a semicarbazone (81% yield).

$$C_6H_5CH(OH)\text{-}CH(OH)C_6H_5 + \mathbf{2a} \xrightarrow[-H_2O]{}$$

3dl

$$2C_6H_5CHO + [CH_3(CH_2)_{15}N(CH_3)_2CH_2C_6H_5]^+IO_3^-$$

81% (as semicarbazone) — **4**

The above reaction produces one equivalent of water, and so the oxidation was conducted in the presence of molecular sieves to remove the water. The resulting benzaldehyde (**5**) was subsequently allowed to react with an alkyllithium to give the corresponding alcohol in one-pot. For example, a mixed solution of **3dl** and **2a** in dioxane was refluxed in the presence of molecular sieves[3] for 2 h and the resulting benzaldehyde

$$\mathbf{3dl} + \mathbf{2a} \longrightarrow [C_6H_5CHO]$$

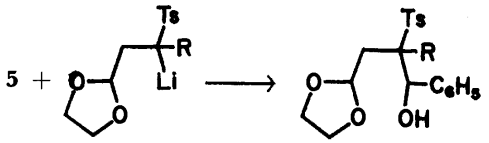
5

$$\xrightarrow{CH_3(CH_2)_3Li} C_6H_5CH(OH)(CH_2)_3CH_3$$

6, 71%

was treated with butyllithium without isolation to give 1-phenyl-1-pentanol (**6**) (71% yield).

Similarly the alcohol **8a**, **b**,[4] precursors of furan derivatives, were prepared from **3** and the corresponding alkyllithiums **7a**, **b**[5,6] in good yields.



7a, R=H — **8a**, 82% from **3meso**

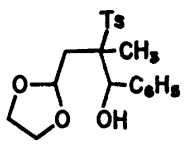
7b, R=CH_3 — **8b**, 87% from **3meso**, 84% from **3dl**

Pappo *et al.* have reported a procedure for the cleavage of olefinic bonds with sodium periodate and a catalytic amount of osmium tetraoxide. It was noted that water was required in all the reactions to effect hydrolysis of the intermediary osmate ester.[7] Consequently **2a** was used in the place of sodium periodate in this procedure in anhydrous aprotic solvents.

To a mixture of *trans*-stilbene and two molar quantities of **2a** in dioxane was added a catalytic amount of osmium tetraoxide at room temperature under nitrogen. The clear solution became green and then yellow and accompanied by the precipitation of **4**. After stirring for 3 h at room temperature and subsequent addition of THF, the reaction mixture was cooled to −78 °C and allowed to react with alkyllithium **7b** to give the expected alcohol **8b** (95% yield from stilbene).

$$C_6H_5CH{=}CHC_6H_5 + 2\,\mathbf{2a} \xrightarrow[r.t.,\ 3\,h]{cat.\ OsO_4}$$

$$[C_6H_5CHO] \xrightarrow[-78\,°C,\ 2\,h]{7b}$$



8b, 95%

This oxidation reaction was also conducted with equimolar quantities of *trans*-stilbene and **2a** and 36% of the stilbene was recovered and 51% of benzaldehyde (as semicarbazone) was obtained. The diol **3** was not detected on TLC.

From the above results, it is evident that water is not required in the oxidative cleavage of a diol or an olefin with quaternary ammonium periodate in aprotic solvents. Work is now in progress to determine the scope and limitation of this oxidation reaction.

Experimental

All melting points are uncorrected. The NMR and IR spectra were recorded on JEOL JNM/MH-60 and JASCO IRA-1 spectrometers, respectively.

Materials. All the solvents were distilled according to the standard methods and stored over a drying agent. Thin-layer chromatography (TLC) was performed on Merck's Kieselgel 60 PF_{254} (Art. 7749).

Benzylhexadecyldimethylammonium Periodate (2a). Benzylhexadecyldimethylammonium chloride (**1a**, 2.407 g, 6 mmol) and sodium periodate (1.070 g, 6 mmol) were dissolved in a minimal amount of water, respectively, and mixed at 0 °C. Whereby a white precipitate separated out immediately. After vigorous stirring for 30 min, the precipitated **2a** was filtered and dried under vacuum (3.168 g, 96%, mp 74—77 °C). Recrystallization from benzene–hexane gave pure **2a** (90% yield; 2.963 g). Mp 76—77 °C. Found: C, 54.15; H, 8.46; N, 2.54%. Calcd for $C_{25}H_{46}INO_4$: C, 54.44; H, 8.41; N, 2.54%.

In a similar manner, **2b** and **2c** were prepared from the corresponding quaternary ammonium halides and sodium periodate in excellent yields.

2b: Mp 149—150 °C. Found: C, 40.66; H, 5.79; N, 3.71%. Calcd for $C_{13}H_{22}INO_4$: C, 40.73, H, 5.74; N, 3.66%.

2c: Mp 193 °C (dec). Found: C, 44.18; H, 8.58; N, 3.30%. Calcd for $C_{16}H_{36}INO_4$: C, 44.34; H, 8.37; N, 3.23%.

Reaction of 2a with 3dl. A mixed solution of **3dl** (107 mg, 1/2 mmol) and **2a** (304 mg, 1.1/2 mmol) in THF (7 ml) was refluxed for 6 h under nitrogen. After evaporation of the solvent, the residue was partitioned between ether and water. To the ethereal layer was added a solution of semicarbazide hydrochloride (112 mg, 1 mmol) in water–methanol followed by the addition of several drops of pyridine and the mixture worked up in the usual way to give benzaldehyde semicarbazone (81% yield, 131 mg). Mp 223—224 °C (lit, 224—225 °C).

1-Phenyl-1-pentanol (6). A mixed solution of **3dl** (107 mg, 1/2 mmol) and **2a** (304 mg, 1.1/2 mmol) in dioxane (4 ml) was refluxed for 2 h in the presence of molecular sieves[3] under nitrogen. After the addition of THF (10 ml) at room temperature (the precipitated benzylhexadecyldimethylammonium iodate (**4**) was dissolved), the reaction mixture was cooled to −78 °C followed by the addition of butyllithium (1.1 mmol) and allowed to warm to room temperature and kept overnight. After the addition of buffer solution (pH 7) and filtration, the filtrate was evaporated to remove the organic solvent and saturated with sodium chloride followed by extraction with ether. The crude residue obtained by evaporation of the extract was subjected to preparative TLC (ethyl acetate/hexane=1/5) to give the expected alcohol **6** (116 mg, 71% yield). The compound exhibited IR and NMR spectral data in accordance with assigned structure.

Oxidative Cleavage of trans-*Stilbene with 2a.* To a mixed solution of *trans*-stilbene (90 mg, 1/2 mmol) and **2a** (606 mg, 2.2/2 mmol) in dioxane (2 ml) was added a catalytic amount of osmium tetraoxide (*ca.* 1.5 mg) dissolved in dioxane (2 ml) at room temperature under nitrogen. The clear solution became green and then yellow accompanied by the precipitation of **4**. After stirring for 3 h at room temperature followed by the addition of THF (10 ml), the reaction mixture was cooled to −78 °C and the lithium salt **7b** (1.1 mmol, THF solution) added. The pale yellow mixture was stirred for 2 h at −78 °C and treated with pH 7 buffer solution at −78 °C. After the similar work-up as described above, the expected alcohol **8b** (345 mg)[4] was obtained in a 95% yield from stilbene.

Photo-induced Reaction of 2-Bromo-3-methoxy-1,4-naphthoquinone with 1,1-Dicyclopropylethylenes

Kazuhiro MARUYAMA,* Masahiro TOJO, and Tetsuo OTSUKI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received August 22, 1979)

Synopsis. 2-(2,2-Dicyclopropylethenyl)-3-methoxy-1,4-naphthoquinone was isolated as a major product, accompanied by 2,2-dicyclopropyl-2,3-dihydronaphtho[2,3-*b*]furan-4,9-dione in the photochemical reaction of 2-bromo-3-methoxy-1,4-naphthoquinone with 1,1-dicyclopropylethylene. An ionic pathway to lead these products was suggested.

Photochemical reaction of 2-bromo-3-methoxy-1,4-naphthoquinone with a variety of 1,1-diarylethylenes was found to yield polycyclic aromatic *p*-quinones such as 5-arylbenz[*a*]anthracene-7,12-diones *via* 2-(2,2-diarylethenyl)-3-methoxy-1,4-naphthoquinone as their precursor (see an example in Scheme 1).[1]

To see a profound insight into the mechanistic aspects of the photochemical reaction —radical process or not— the photochemical reactivity of 1,1-dicyclopropylethylenes (**2**) with 2-bromo-3-methoxy-1,4-naphthoquinone (**1**) was examined here, because the radical generated at the α-position of cyclopropyl group was reported to cause the ring-opening reaction of cyclopropane, resulting in the isomerization to substituted 3-pentenyl radical in good yield (Scheme 2).[2]

When 2-bromo-3-methoxy-1,4-naphthoquinone (**1**) (1 mmol) and 1,1-dicyclopropylethylene (**2a**) (2 mmol) dissolved in benzene (25 ml) were irradiated by a high pressure Hg arc lamp (300 W), 2-(2,2-dicyclopropylethenyl)-3-methoxy-1,4-naphthoquinone (**3a**) (25%) and 2,2-dicyclopropyl-2,3-dihydronaphtho[2,3-*b*]furan-4,9-dione (**4a**) (5%) were isolated from the reaction mixture, accompanied by 4-cyclopropyl-3-pentenyl bromide (**5a**) (30% as a mixture of *E*- and *Z*-isomers) (Scheme 3). Moreover, 1,1-bis(2-methylcyclopropyl)-ethylene (**2b**) gave the similar mixture of products **3b** (25%) and **5b** (30%) in its reaction with **1**. **5** may be produced *via* the acid-catalyzed ring-opening reaction by hydrogen bromide liberated during the formation of **3** and/or **4**.

Although the present evidences are not conclusive because of the rather poor yield of the products isolated from the reaction mixture,[3] no products which are originated from the radical ring-opening reaction of 1,1-dicyclopropylethylenes can be identified so far. By analogy to the photochemical reaction of 1,1-diarylethylene with **1**, the charge transfer interaction between quinone **1** and 1,1-dicyclopropylethylene (**2**) may play a role in the initial stages of the reaction, leading to the formation of intermediate **6** *via* **7** by eliminating bromide ion.[4] **6** is a possible intermediate which could be stabilized finally as **3** or **4**. Thus, the ionic pathway including radical ions may be dominant at least in the photochemical reaction of 1,1-dicyclopropylethylenes (**2**) with 2-bromo-3-methoxy-1,4-naphthoquinone (**1**).

Experimental

Starting Materials. The synthesis of 2-bromo-3-methoxy-1,4-naphthoquinone (**1**) was described in the previous report.[1b] 1,1-Dicyclopropylethylene (**2a**) and 1,1-bis(2-methylcyclopropyl)ethylene (**2b**) were synthesized by the Wittig reaction[5] of the corresponding dicyclopropyl ketones.[6] 1,1-Dicyclopropylethylene (**2a**): colorless oil, bp 36—38 °C/22 mmHg. NMR (CCl_4): δ: 0.3—0.8 ppm (8H, m), 1.0—1.5 (2H, m), 4.41 (2H, s). IR (liq. film): 3100, 890 cm^{-1}. 1,1-Bis(2-methylcyclopropyl)ethylene (**2b**); colorless oil, bp 79—80 °C/62 mmHg. NMR (CCl_4): δ; 0.2—0.4 ppm (2H, m), 0.6—1.4 (4H, m), 1.10 (6H, d, J=5 Hz), 1.6—2.1 (2H, m), 4.36 (2H, s). IR (liq. film): 3100, 890 cm^{-1}.

Photochemical Reaction. A benzene solution (25 ml) of 2-bromo-3-methoxy-1,4-naphthoquinone (**1**) (1 mmol) and 1,1-dicylopropylethylene (**2**) (2 mmol) was irradiated by a high pressure Hg arc lamp (300 W). A half amount of quinone was consumed on irradiating the reaction mixture for 10 h at room temperature. After concentrated *in vacuo*, the reaction mixture was further purified by column chromatography on silica gel. The physical properties of the products were as follows. 2-(2,2-Dicyclopropylethenyl)-3-methoxy-1,4-naphthoquinone (**3a**): orange yellow needles, mp 84—86 °C. NMR ($CDCl_3$): δ; 0.6—0.8 ppm (8H, m), 1.2 (2H, m), 4.07 (3H, s), 5.97 (1H, s), 7.5—7.8 (2H, m), 7.9—8.2 (2H, m). IR (KBr): 3100, 1675 cm^{-1}. UV (C_2H_5OH): 424 nm (log ε: 3.15), 327 (3.34), 272 (4.11), 255 (sh) (4.06). MS: *m/e* (relative intensity); 294 (M^+, 36), 279 (M^+-15, 13), 266 (M^+-28, 57), 251 (M^+-43, 100). 2-[2,2-Bis(2-methylcyclopropyl)-ethenyl]-3-methoxy-1,4-naphthoquinone (**3b**): orange yellow needles, mp 98—100 °C. NMR ($CDCl_3$): δ; 0.4—1.4 ppm (14H, m), 3.92 (3H, s), 5.71 (1H, s), 7.3—7.6 (2H, m),7.7—8.0 (2H, m). IR (KBr): 3100, 1670 cm^{-1}. UV (C_2H_5OH): 427 nm (log ε: 3.18), 326 (3.32), 274 (4.13), 256 (sh) (4.04). MS: *m/e* (relative intensity): 322 (M^+, 14), 280 (M^+-42, 100), 266 (M^+-56, 53). 2,2-Dicyclopropyl-2,3-dihydronaphtho-[2,3-*b*]furan-4,9-dione (**4a**): yellow needles, mp 134—135 °C. NMR ($CDCl_3$): δ; 0.5—0.7 ppm (8H, m), 1.3 (2H, m), 2.85 (2H, s), 7.5—7.8 (2H, m), 7.9—8.2 (2H, m). IR (KBr): 3100, 1680 cm^{-1}. UV (C_2H_5OH): 397 nm (log ε: 2.94), 334 (3.30), 287 (3.95), 254 (4.23), 249 (sh) (4.21). MS *m/e*: (relative intensity); 280 (M^+, 26), 252 (M^+-28, 100), 224 (M^+-56, 28). 4-Cyclopropyl-3-pentenyl bromide (**5a**) as a mixture of *E*- and *Z*-isomers (the relative ratio of the two isomers, 40/60 (A/B),[7] was estimated on the basis of their NMR signals): colorless oil. NMR (CCl_4): δ; 0.5 ppm (4H, m), 1.46 (3H, s), 1.5 (1H, m), 2.6 (2H, m), 3.40 (2H, t, J=1.7 Hz), 5.2 (1H, m) for an isomer A. 0.5 ppm (4H, m), 1.56 (3H, s), 1.5 (1H, m), 2.6 (2H, m), 3.34 (2H, t, J=1.7 Hz), 5.2 (1H, m) for another isomer B. IR (liq. film): 3100 cm^{-1}. MS: *m/e* (relative intensity); 190 (M^+, 27), 188 (M^+, 27), 109 (M^+-Br, 100). 5-Bromo-2-(2-methylcyclopropyl)-2-hexene (**5b**) as a mixture of *E*- and *Z*-isomers (the relative ratio of the two isomers, 40/60 (A/B),[7] was estimated on the basis of their NMR signals): colorless oil. NMR (CCl_4): δ; 0.2—1.8 ppm (7H, m), 1.46 (3H, s), 1.72 (3H, d, J=4 Hz), 2.4—2.8 (2H, m), 3.8—4.2 (1H, m), 4.9—5.3 (1H, m) for an isomer A. 0.2—1.8 ppm (7H, m), 1.56 (3H, s), 1.66 (3H, d, J=4 Hz), 2.4—2.8 (2H, m), 3.8—4.2 (1H, m), 4.9—5.3 (1H, m) for another isomer B. IR (liq. film): 3100 cm^{-1}.

2) E. S. Heyser and T. D. Taliaferro, *J. Org. Chem.*, **28**, 3442 (1963).

3) The poor yields of the products could be partly due to the trivial reactions such as the demethylation of the starting quinone caused by hydrogen bromide liberated during the course of the reaction.

4) When 1,1-diarylethylene such as 1-(*p*-chlorophenyl)-1-phenylethylene, 1-phenyl-1-(2-thienyl)ethylene or 1-phenyl-1-(2-*N*-methylpyrrolyl)ethylene was submitted to the reaction (*cf.* Scheme 1), one of two aryl groups donating highly its π-electrons cyclizes preponderantly to give polycyclic aromatic *p*-quinone (see Refs. (1b), (1c), and (1d)). By inspection of molecular model it is clear that the isomeric distribution of the final products can be determined by the configuration of the intermediate, 2-(2,2-diarylethenyl)-3-methoxy-1,4-naphthoquinone. Therefore, these results indicate that the charge-transfer interactions between quinone and the aryl group of reacting ethylene in the initial stages are playing a role for determining the isomeric distribution of final products.

In addition, an important contribution of the similar charge-transfer interactions has been confirmed in the photosubstitution reaction of halogenated 1,4-naphthoquinones. (see K. Maruyama and T. Otsuki, *Chem. Lett.*, **1977**, 851, *Bull. Chem. Soc. Jpn.*, **50**, 3249 (1977)).

Coordinative Role of Alkali Cations in Organic Reactions. IV. Benzoylation, Phenacylation, and Benzylation of Kojic Acid

Narinder S. Poonia,* Ashok K. Arora, and Amritlal V. Bajaj
Department of Chemistry, University of Indore, Khandwa Road, Indore 452001, India
(Received April 21, 1979)

Synopsis. Using kojic acid (5-hydroxy-2-hydroxymethyl-4-pyrone) as a substrate, the title reactions were carried out with various alkali metal hydroxides. Whereas phenacylation (with KOH or NaOH) and benzylation (with KOH, NaOH, or LiOH) are possible only on the phenolic hydroxyl, benzoylation can be carried out selectively as well as collectively on both the hydroxyl group (in 80% aq EtOH). The results were discussed in terms of the interactive role of alkali cations with the substrate.

In earlier communications[1,2] we reported that an organic reaction involving the use of alkali hydroxide (MOH) is triggered by the alkali cation (M^+) and that the efficiency and the course of the reaction can be controlled by changing either M^+ or the conditions which influence the coordinative role of the latter. In this article we introduce, in addition, that during benzoylation (with benzoyl chloride), phenacylation (with phenacyl bromide), and benzylation (with benzyl chloride) of kojic acid (5-hydroxy-2-hydroxymethyl-4-pyrone, abbr. HO**k**CH_2OH, **1**), (i) MOH is not present just to neutralize the acid byproduct of the reaction but reacts with the substrate (**1**) (see **5**[3,4]) and determines the invitation to the electrophilic reagent, and (ii) the ion-association (insolubility) of the leaving alkali halide ion pair in the reaction medium determines the efficiency of the reaction.

The synthetic procedures for the derivatives of kojic acid, namely, 5-benzoyloxy-2-hydroxymethyl-4-pyrone (**2a**), 5-hydroxy-2-benzoyloxymethyl-4-pyrone (**2b**), 5-benzoyloxy-2-benzoyloxymethyl-4-pyrone (**2c**), 5-phenacyloxy-2-hydroxymethyl-4-pyrone (**3**) and 5-benzyloxy-2-hydroxymethyl-4-pyrone (**4**) have been standardized to maximize the product yields.

4, $R_1=PhCH_2$; $R_2=H$

Results and Discussion

Benzoylation. As against the laborious procedures adopted earlier,[5] we provide herein one-step procedures involving the rather convenient use of MOH in EtOH–H_2O medium for obtaining **2a** (81%), **2b** (65%), and **2c** (79%) in higher yields (see Table 1).

Benzoylation reactions on **1** are possible on the phenolic or both the hydroxyl groups using appropriate amounts of PhCOCl and MOH; the reactions fail in the absence of MOH. The reactions are most favored when MOH of the lowest charge density M^+ (KOH) is used in an ionizing medium (EtOH–H_2O), *i.e.*, under the conditions favoring formation of the loose K^+–O**k**-$CH_2O^-K^+$ ion pairs which allow a facilitated M^+/-PhC^+O exchange at each negative site.

With an excess MOH of a high charge density M^+ (NaOH and especially LiOH), which can ensure an effective protection of the phenoxide through M^+, benzoylation of the $-CH_2OH$ group can be carried out using **1** and PhCOCl in equimolecular proportions. This reaction is novel. When the high charge density Li^+ is used, the reaction appears to involve Li^+–O**k**CH_2OH ($\downarrow Li^+$) coordinated species as an intermediate because **2b** can also be synthesized (in 32% yield) employing one mole each of **1**, LiOH, $LiClO_4$, and PhCOCl wherein whole LiOH is expected to be consumed by the phenolic hydroxyl while Li^+ ions of $LiClO_4$ carry out the reaction on the alcoholic hydroxyl. If $-CH_2O^-Li^+$ should have formed as an intermediate (alkoxide mechanism), the Li^+/PhC^+O exchange becomes rather difficult to visualize because such an exchange is not possible even at the comparatively delocalized phenoxide as evident from the lack of benzoylation of the phenolic hydroxyl under these conditions. Various sugars coordinate[6] with alkali and alkaline earth cations in water through the $-CH_2OH$ groups (NMR studies) and X-ray diffraction analysis reveals coordination of the cation with the $-CH_2OH$ group in the complexes $KI(3)_2$,[4a] $NaI(3)_2 \cdot 2H_2O$,[4b] and $NaClO_4$(1,4-anhydroerythritol).[7]

Phenacylation. As in methanol,[8] the direct product of the reaction in ethanol or acetone is the complex $MBr(3)_2$ instead of **3**; on decomposing the complex with water, **3** is recovered in a hydrated form (mp 90 °C and not 144—145 °C as reported earlier[9,10]) which can be dehydrated (mp 145 °C) by recrystallization from absolute ethanol. Using KOH in EtOH–H_2O (4: 1) the reaction efficiency is maximum with 77% yield of **3** (liberated from the complex).

In the presence of MOH only phenolic hydroxyl undergoes phenacylation as known earlier.[8] In the absence of MOH, **1** and $PhCOCH_2Br$ are recovered unreacted under all conditions. Condensation also fails when pyridine is used instead of MOH; the direct $PhCOCH_2Br$–pyridine reaction,[11] was avoided by mixing pyridine with **1** and adding $PhCOCH_2Br$ later. These observations indicate that MOH does not only function to neutralize HBr but reacts with the substrate to produce the reactive M^+–O**k**CH_2OH and that the nature of M^+ determines the reactivity of the phenoxide with $PhCOCH_2Br$.

The yield of **3** increases as media of increasing polarity and M^+ of decreasing charge density are used. This indicates that the C–Br bond is attacked in accordance with the "liberation" of the cation-controlled

Table 1. Reaction of **1** with $PhCOCl$, $PhCOCH_2Br$, and $PhCH_2Cl$ in the presence of different MOH[a)]

— poor or no reaction. c_1 and c_2 stand for the first and the second crop; in case crops are not mentioned, product was the same in both. a) Each reaction has been investigated extensively under varied conditions but only those experiments are included here which either afforded the highest yield or threw light on the reaction mechanism. b) The reagent preceding the arrow was added to the mixture of the other two. c) Optimum conditions recommended for synthesis. d) **2d** represents M^+-**Ok**CH_2OH. e) Derivative recovered from the complex—$M^+(\mathbf{3})_2Br^-$. f) When 1:1:2 or 1:2:2 reaction mixture was employed or water was eliminated, yield of the product was decreased for each MOH; when both the changes were made at a time then particularly for NaOH and LiOH phenolic hydroxyl also failed to react and M^+-**Ok**CH_2OH was recovered.

phenoxide through loosening of the M^+-**Ok**CH_2OH ion pair; if the sequence of addition of the reactants is varied and **1**–MOH complexation is not allowed to occur prior to the addition of $PhCOCH_2Br$, the yield of the product is decreased.

Benzylation. Only phenolic hydroxyl can be benzylated (*cf.* phenacylation) and the **1**–$PhCH_2Cl$ reaction fails in the absence of MOH. Compound **4** is obtained in the highest yield (68%) when KOH is used and the reaction medium (EtOH) contains water. In a less ionizing medium (EtOH) the reaction is poor (KOH) or is completely stopped (NaOH or LiOH) especially in the presence of excess MOH due to the protection of phenoxide with the cation. This and that the reaction is favored in the order LiOH, NaOH, and KOH indicate that M^+/PhC^+H_2 exchange is facilitated as M^+-**Ok**CH_2OH ion pair loosens. The reaction on the phenolic hydroxyl in the presence of LiOH is possible with $PhCH_2Cl$ but not with $PhCOCH_2Br$ (see Table 1). The enhanced reactivity of $PhCH_2Cl$ with respect to that of $PhCOCH_2Br$ on a common substrate (Li^+-**Ok**CH_2OH) is interestingly significant because $PhCH_2Cl$ is expected to be a relatively inert reagent due to Ph^+ being a less electron withdrawing agent than PhC^+O and the C–Cl bond being a stronger bond than the C–Br one. The facilitated benzylation can only be because insolubility[14] and hence[15] solution stability of the leaving ion pair for $PhCH_2Cl$ (*i.e.*, LiCl) is higher than that for $PhCOCH_2Br$ (*i.e.*, LiBr) which forces an SN^1 contribution of $PhCH_2Cl$ to aid displacement of Li^+ from phenoxide.

Experimental

Recommended Procedure for Benzoylation, Phenacylation, and Benzylation. To a solution of **1** (1.42 g, 10 mmol) in EtOH–H_2O (4:1, v/v) (15 ml) was added the required amount of MOH. The clear reaction mixture was treated with the reagent concerned, and refluxed for 1 h on steam-bath. The product was crystallized by cooling, collected and authenticated. Specific conditions for the synthesis of compounds **2**—**4** are outlined below.

Synthesis of 2a. Compound **1** was taken in EtOH–H_2O (4:1) and treated with KOH (0.56 g, 10 mmol) followed by benzoyl chloride (1.41 g, 10 mmol). Yield 1.99 g (81%), mp 143 °C. *Synthesis of 2b.* Compound **1** was taken in EtOH–H_2O (4:1) and treated with excess LiOH (0.84 g, 20 mmol) followed by benzoyl chloride (1.41 g). Yield 1.59 g (65%), mp 174—175 °C. *Synthesis of 2c.* Compound **1** was taken in EtOH–H_2O (4:1) and treated with KOH (1.12 g, 20 mmol) followed by benzoyl chloride (2.81 g, 20 mmol). The isolated product was recrystallized from 10 ml acetone–water (1:1, v/v) to remove the traces of the by-product (benzoic acid). Yield 2.76 g (79%), mp 133—134 °C.

Synthesis of 3. Compound **1** was taken in EtOH–H_2O (4:1) and treated with KOH (0.56 g) followed by phenacyl bromide (1.99 g, 10 mmol). The isolated product was a crystalline complex $K^+(\mathbf{3})_2Br^-$ (mp 208 °C). The complex was decomposed with boiling water (20 ml) to get the hydrated form of **3** (mp 90 °C) which was recrystallized from ethanol to obtain anhydrous **3** (mp 145 °C). Yield 2.00 g (77%).

Synthesis of 4. Compound **1** was taken in EtOH–H_2O (4:1) and treated with KOH (0.56 g) followed by benzyl chloride (1.27 g, 10 mmol). Yield 1.57 g (68%), mp 133 °C.

Authentification of the Products. All the products are known compounds. They were authenticated with the help of elemental analysis, hot stage microscopic examination of melting points and IR spectroscopy. Absorption characteristics of >C=O in **2a**, **2b**, and **2c** deserve a mention in that the pyrone carbonyl of each compound absorbs at ≈1670 cm^{-1} whereas carbonyl of the benzoyl moieties absorbs at a higher position probably due to the presence of an oxygen in the vicinity. The benzoyl carbonyl near the phenolic oxygen absorbs at the highest —**2a** at 1755 cm^{-1}, **2b** at 1735 cm^{-1}, and **2c** at 1740 and 1667 cm^{-1}.

Hydration Numbers of Sodium Chloride in Dioxane–Water Mixtures and the Volume Change Accompanying Hydration

Tsunemichi Okuwa

Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received February 5, 1979)

The density and the ultrasonic velocity were measured for dioxane–water solutions of sodium chloride at 25 °C. The hydration numbers of sodium chloride were estimated and were compared with those determined by electrical-conductivity measurements. The difference between them was discussed. The volume change caused by the dissociation of sodium chloride in a 60 wt % aqueous dioxane solution was determined from the data of the apparent molal volume. This value is in good agreement with that calculated from the excess ultrasonic absorption.

In a dioxane–water mixture with a lower dielectric constant than water, NaCl would dissociate incompletely and a dissociation equilibrium may be attained between the Na^+ ions, the Cl^- ions, and the undissociated NaCl molecules. If the water molecules bound to ions are considered to be incompressible, then a volume change attributable to ionization would be found. The volume change was estimated from density measurements of aqueous dioxane solutions of sodium chloride and was compared with that calculated from excess ultrasonic absorption, as reported in the previous paper.[1] The sound velocity increases with an increase in the concentration of NaCl in dioxane–water mixtures. This increase reflects a decrease in the compressibility of the solvent caused by hydration. The hydration numbers due to the ionization of NaCl were calculated using some assumptions.

Experimental

The densities were measured by a float method similar to that used by Desnoyers and Arel.[2] A float was suspended in the pan of a balance by means of a nylon thread 0.1 mm in diameter and was then placed in the solution in a thermostated cell. The volume of the float used was about 230 cm^3.

The difference between the density of a solution, d, and that of water, d_0, is related to the weights, W and W_0, of the float in the solution and in water respectively by

$$d - d_0 = (W_0 - W)/V, \quad (1)$$

where V is the volume of the float. Measurements were made at 25 °C.

The ultrasonic velocities were measured by the interference method of the pulse wave and the continuous wave at 5 MHz. The molalities of sodium chloride in mixed solvents containing 0 to 60 wt % dioxane were in the range of 0.1—1.0 m.

Results

The ultrasonic velocities in solutions of NaCl in dioxane–water mixtures are shown in Fig. 1.

The apparent molal volume, ϕ_v, and the apparent molal compressibility, ϕ_k, are given by

$$\phi_v = \frac{V - V_s}{n_2} = \frac{1000}{mdd_s}(d_s - d) + \frac{M}{d}, \quad (2)$$

and

$$\phi_k = -\left(\frac{\partial \phi_v}{\partial p}\right)_T = \frac{\beta V - \beta_s V_s}{n_2} = \frac{1000(\beta - \beta_s)}{md_s} + \beta\phi_v, \quad (3)$$

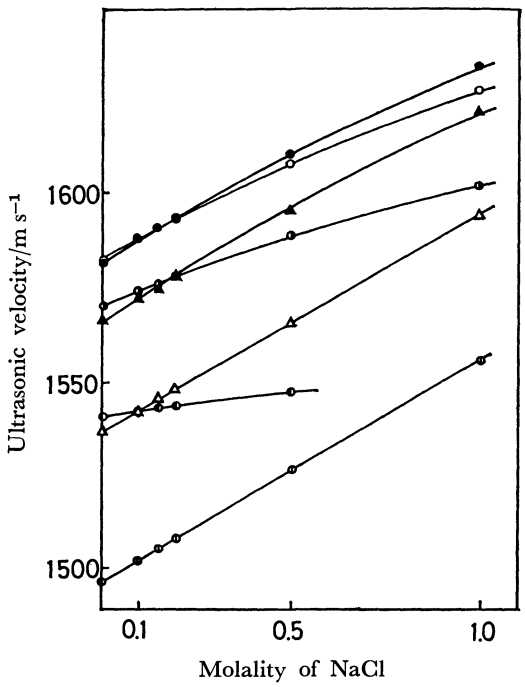

Fig. 1. Ultrasonic velocity in solutions of NaCl in dioxane-water mixtures at 25 °C.
Dioxane wt %: ⓘ 0, △ 10, ▲ 20, ● 30, ○ 40, ◑ 50, ◐ 60.

where n_2, m, and M are the number of moles, the molality (mole per 1000 g of solvent), and the molecular weight of NaCl respectively. V, d, and β are the volume, density, and compressibility of the solution respectively. The subscript s denotes the solvent. A typical example of the plot of ϕ_v *vs.* $(\text{molality})^{1/2}$ is shown in Fig. 2.

Discussion

Hydration Number of Sodium Chloride. In the solution of NaCl in a dioxane–water mixture, both water and dioxane molecules may participate in the formation of solvation shells around ions. As the dipole moment of a dioxane molecule is much smaller than that of water, the electrostrictive effect of the ions on dioxane molecules in the solvation shells might be negligible[3] in comparison with the electrostriction on water molecules. Therefore, the volume of dioxane molecules would be unchangeable in the solution. Assuming that the compressibilities of the ions and water molecules bound to the ions are equal to zero,

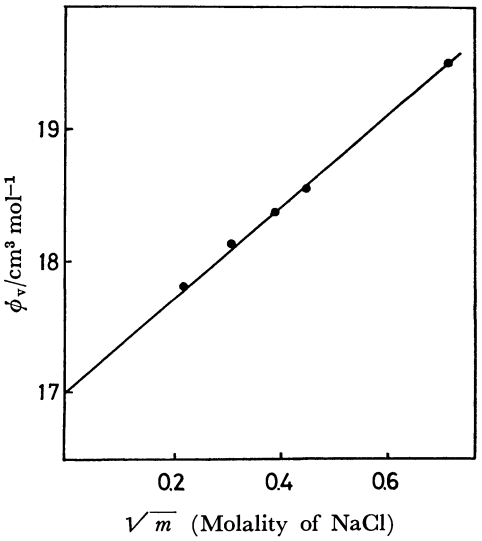

Fig. 2. Apparent molal volume of NaCl in 60 wt % aqueous dioxane solution at 25 °C.

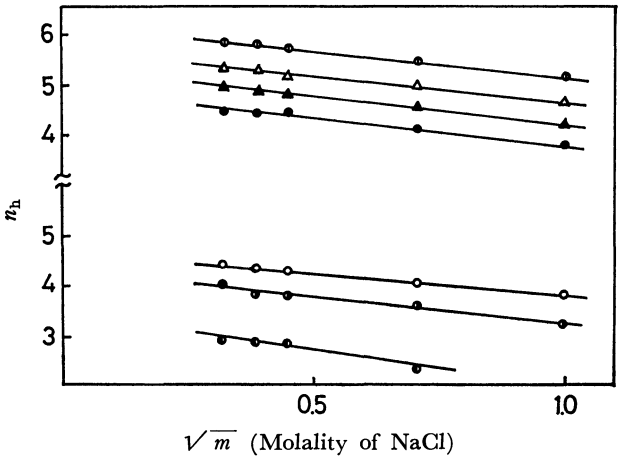

Fig. 3. Hydration numbers of NaCl in dioxane-water mixtures at 25 °C.
Dioxane wt %: ⦶ 0, △ 10, ▲ 20, ● 30, ○ 40, ◑ 50, ◐ 60.

the compressibility of the solution, β, is given by

$$\beta = -\frac{1}{V}\frac{\partial}{\partial p}\{V_0(n_1-n_i)+V_3n_3\}$$
$$= -\frac{1}{V}\{n_i\beta_0V_0-\beta_sV_s\}, \quad (4)$$

where n_1 is the total number of moles of water in the solution, n_i is the number of water molecules bound to the ions, V_0 is the molal volume of free water not bound to the ions, β_0 is the compressibility coefficient of pure water, and V_3 and n_3 are the molal volume and the number of moles of dioxane.

According to Eqs. 3 and 4, the hydration number, n_h, of sodium chloride in a dioxane–water mixture is expressed as

$$n_h = \frac{n_i}{\alpha n_2} = -\frac{\phi_k}{\alpha\beta_0V_0}, \quad (5)$$

where α is the degree of dissociation of NaCl. The values of n_h are shown in Fig. 3. In 0, 10, 20, and 30 wt % dioxane aqueous solutions, α is assumed to be approximately 1.

The dissociation equilibrium constants of NaCl in dioxane–water mixtures were obtained by electrical conductance measurements.[4–6] NaCl is considered to be in an equilibrium[6] such as

$$NaCl(aq) + kH_2O \overset{K^\circ}{\rightleftharpoons} Na(aq)^+ + Cl(aq)^-,$$
$$K^\circ = \frac{K}{C_{H_2O}^{k}}, \text{ and } K = \frac{C_{Na^+}\cdot C_{Cl^-}}{C_{NaCl}}, \quad (6)$$

where C_{H_2O} is the molar concentration of water and where k is the net change in the waters of solvation upon the dissociation of NaCl and corresponds to the hydration number. K° and k are found to be independent of C_{H_2O} and to vary only with the temperature:

$$\log K^\circ = -10.00, \quad k = 6.4 \ (25\,^\circ C)^{6}$$
$$\log K^\circ = -11.13, \quad k = 7.0 \ (50\,^\circ C)^{6} \quad (7)$$

As may be seen in Fig. 3, the hydration number, n_h, of NaCl in an aqueous solution is close to k (=6.4) at an infinite dilution, but n_h in dioxane–water mixtures decreases with an increase in the concentration of dioxane. The difference between n_h and k in a dioxane–water mixture might be caused by differences in the models used for the hydrated ion and the assumptions associated with these models. If the hydration number is constant and independent of the concentration of dioxane in dioxane–water mixtures, the compressibilities of hydrated ions must have definite values. The existence of dioxane molecules might influence the electrostriction of the ions in relation to the surrounding water molecules.

Volume Change Accompanying the Dissociation of Sodium Chloride. It is useful to estimate further the volume change which accompanies the ionization of NaCl in dioxane–water mixtures. The apparent molal volume of NaCl, ϕ_v, derived from Eq. 2, is related to the degree of dissociation, α, by

$$\phi_v = (1-\alpha)\phi_u + \alpha\phi_i, \quad (8)$$

where ϕ_i and ϕ_u are the apparent molal volumes of NaCl in the ionized and un-ionized states respectively.

The volume change caused by hydration, ΔV, is given by

$$\Delta V = \phi_i - \phi_u. \quad (9)$$

NaCl in dioxane–water mixture might be ionized completely at an infinite dilution; therefore, ϕ_i, can be approximately determined by the extrapolation of ϕ_v to zero concentration:

$$\phi_i \simeq \phi_v^\circ, \quad (10)$$

where ϕ_v° is the apparent molal volume at an infinite dilution.

As may be seen in Fig. 2., the value of ϕ_v° in a 60 wt% dioxane aqueous solution is 17.0 cm^3/mol. This value is a little larger than the ϕ_v° value of 16.628 cm^3/mol[7] in water. From Eqs. 8, 9, and 10, we obtain $\Delta V \approx -7$ cm^3/mol.

On the other hand, ΔV was estimated on the basis of ultrasonic absorption measurements.[1] In this paper, ΔV was calculated by considering the enthalpy change,

ΔH, for the reaction. The maximum excess ultrasonic absorption per wavelength at the relaxation frequency, μ_{max}, is given by[8,9]

$$\mu_{max} = \frac{\pi}{2\beta RTV}\left(\Delta V - \frac{l}{dC_p}\Delta H\right)^2 \frac{1}{\chi}$$

$$\chi = \left(\frac{1}{n_{Na^+}} + \frac{1}{n_{Cl^-}} + \frac{1}{n_{NaCl}}\right), \quad (11)$$

where l is the coefficient of thermal expansion, C_p is the heat capacity at a constant pressure, and n_{Na^+}, n_{Cl^-}, and n_{NaCl}, are the numbers of the moles of the sodium ion, the chloride ion, and undissociacted sodium chloride. The value of l/dC_p in a 60 wt % dioxane aqueous solution at 25 °C was estimated by interpolation of the literature values.[9]

The variation in the dissocication constant with the temperature is given by

$$\left(\frac{\partial \ln K}{\partial T}\right)_p = \frac{\Delta H}{RT^2}.$$

Taking the values derived from Eqs. 6 and 7, we find:

$$\Delta H \approx -6.6 \text{ kcal/mol}$$

Using these values in Eq. 11, we calculate $\Delta V \approx -8$ cm^3/mol. This value is in better agreement with the ΔV estimated from the density measurements than with $\Delta V \approx -5$ cm^3/mol, which was determined by neglecting ΔH in Ref. 1.

Adsorption of *n*-Aliphatic Alcohols on Mercury Electrode and Their Effect on Electrode Kinetics

Katsumi NIKI* and Yumiko TAKIZAWA

Department of Electrochemistry, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

(Received May 11, 1979)

The adsorption parameters of butyl alcohol, amyl alcohol, and hexyl alcohol at mercury electrode were evaluated by means of the electrocapillary measurements and compared with those obtained by differential capacity measurements. A marked difference is observed both in the interaction parameters between adsorbed molecules and in the maximum surface excess, Γ_{max}. The inhibition effect by these alcohols on the electrode kinetics of the vanadium(III)/vanadium(II) couple in 0.5 M H_2SO_4 and of the europium(III)/europium(II) couple in 1.0 M HCl depends only on the surface coverage, $\theta=\Gamma/\Gamma_{max}$, of the electrode and is independent of the chain length of the adsorbed alcohol. The blocking effect is predominant in the inhibition of the electrode process by these alcohols.

The neutral surfactants adsorbed on the electrode surface often have a marked influence on electrode kinetics. The role of these surfactants can be interpreted by one of three classes of inhibition mechanisms. These involve: (a) a blocking effect, (b) an electrostatic effect, the change in the ϕ_2 potential, and (c) the effect on the activation energy for the charge transfer step. Lipkowski and Galus extensively discussed and compared the present theories with the available experimental data.[1] It has been shown that the interaction between the activated complex and the adsorbed surfactants may be described by the equation derived from Flory-Huggins, Frumkin or Blomgren-Bockris adsorption isotherms for the activated complex. It was found from the statistical analysis of the experimental data that the Flory-Huggins type equation[2,3] was better than the other two, namely:

$$k_\theta = k_0(1-\theta)^n \quad (1)$$

where k_θ is the apparent rate constant in the presence of adsorbed layer, k_0 the rate constant without surfactants, θ the surface coverage, and n is a constant.

In the present work, the effect of aliphatic alcohols on the electrode kinetics of the V(III)/V(II) and Eu(III)/Eu(II) couples has been studied in connection with the adsorption behavior of these alcohols on the dropping mercury electrode.

Experimental

Reagent grade butyl, amyl, and hexy alcohols (Tokyo Kasei) were used without further purification after their purity had been checked by gas chromatography. These alcohols were dissolved in either 0.5 M H_2SO_4 or 1.0 M HCl solutions. The base solutions were pre-treated with a purified activated charcoal. The electrocapillary curves for these solutions were obtained with a modified capillary electrometer and the radius of the capillary was determined by standardization against a solution of known surface tension as previously described.[4]

The V(III)/V(II) system in 0.5 M H_2SO_4 solution was prepared by reducing $VOSO_4$ *in situ* on a mercury pool cathode. The Eu(III)/Eu(II) system in 1.0 M HCl solution was prepared by dissolving Eu_2O_3 (electronic grade, 99.9%) and Eu(II) was generated cathodically *in situ*. The electrode kinetic parameters of the V(III)/V(II) and Eu(III)/Eu(II) systems were measured by conventional dc polarographic and pulse polarographic methods (Fuso Model 312 Polarograph). The detailed experimental procedure has been previously described.[5]

Measurements were made at (25±0.5) °C and, the electrode potential was referred to SCE.

Results and Discussion

Adsorption Isotherms. As shown in Table 1, the maximum surface excess of these alcohols is considerably smaller than that calculated from the projected area of the perpendicular orientation (7.90×10^{-10} mol cm^{-2}) and decreases linearly with the chain length of the alcohol. This is probably due to either the deviation of the alcohol dipole from vertical orientation at the electrode surface or the contamination of water molecules in the electrical double layer saturated by the alcohol. These results also suggest that the shift of the point of zero charge with respect to the surface excess of these alcohols at the electrode surface deviates from the curve predicted by the Frumkin model.[7]

The adsorption isotherms are well characterized by the Frumkin isotherm[5]

$$B_0c = \frac{\theta}{1-\theta}\exp(-2a_0\theta) \quad (2)$$

and

$$-\Delta G_A^\circ = RT\ln(55.5\,B_0) \quad (3)$$

where B_0 is the adsorption equilibrium constant, a_0 is the attraction constant between adsorbed molecules (a positive value of a_0 corresponds to the presence attraction between the adsorbed species, and *vice versa*), θ ($=\Gamma/\Gamma_{max}$) is the surface coverage of the mercury electrode, ΔG_A° is the standard free energy of adsorption of the alcohol, and c is the bulk concentration of the alcohol. The values of these parameters listed in Table 1 were obtained at the point of zero charge. The free energies of adsorption obtained by the present work agrees reasonably well with those obtained by Damaskin *et al.* from the differential capacity measurements.[8] However, both the maximum values of surface excess Γ_{max}, and the attraction constants a_0, in the present results differ markedly from their values.[8]

Figure 1 shows the dependence of θ on the relative concentration $c/c_{\theta=0.5}$ calculated from Eq. 2 in terms of the attraction constant. It is obvious from these plots that the higher the values of a_0 are, the lower the values of θ when $c<c_{\theta=0.5}$ and *vice versa* when

Table 1. Adsorption parameters of aliphatic alcohols on mercury electrode

	Γ_{max} / 10^{-10} mol cm^{-2}	$-\Delta G_A^\circ$ / kcal mol^{-1}	a_0
Butyl alcohol	6.67 (5.18)[a]	3.88 (3.83)[a]	0.39[3] (1.28)[a]
Amyl alcohol	5.9 (4.85)[a]	4.76 (4.58)[a]	0.42[6] (1.48)[a]
Hexyl alcohol	5.0 (4.64)[a]	5.68 (5.39)[a]	0.69[5] (1.68)[a]

a) The values in the parentheses are quoted from Ref. 8.

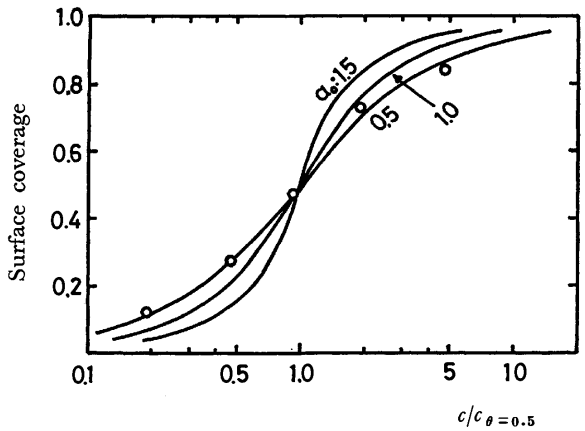

Fig. 1. Dependence of surface coverage of mercury electrode on the relative concentration, $c/c_{\theta=0.5}$, for butyl alcohol in 0.5 M H_2SO_4.

θ is greater than 0.5. The isotherms obtained by various investigators with the capillary electrometer generally agreed well[6] and the attraction constants calculated from these adsorption isotherms were always smaller than unity. On the other hand, the attraction constants evaluated from the differential capactiy measurements were much greater than unity. As was mentioned in the previous work,[6] the surface coverages evaluated from the differential capacity measurements are smaller than those evaluated from the electrocapillary measurements when the surface coverage of the electrode surface is less than 0.5 and *vice versa* when θ is greater than 0.5.

The concentration of the alcohol needed to give a certain coverage ($\theta=\Gamma/\Gamma_{max}$) at the point of zero charge decreases regularly with an increase in the chain length of the alcohols. This factor, Traube's factor, is about 5.1. On the other hand, the value reported by Kaganovich and Gerovich[9] and Damaskin *et al.*[8] were 3.0 and 3.7, respectively.

There are certain regularities in the solubility of n-aliphatic alcohols in water and in electrolyte solutions. The solubility of these alcohols decreases by the ratio of 3.9 in water[8] and 4.5 in 1 M KCl[9] for each additional CH_2 group. Therefore, the adsorption isotherms (the electrocapillary curves) are superimposable when the relative concentration, c/c_{satd} where c_{satd} is the solubility of the alcohol, of these alcohols is used as a measure of the concentration.

Electrode Kinetics. The standard rate constant of the V(III)/V(II) ($E^\circ=-0.505$ V, 0.5 M H_2SO_4) and Eu(III)/Eu(II) ($E^\circ=-0.612$ V, 1 M HCl) couples is not proportional to the uncovered electrode area, $1-\theta$, as stated in the previous work.[3] The inhibition

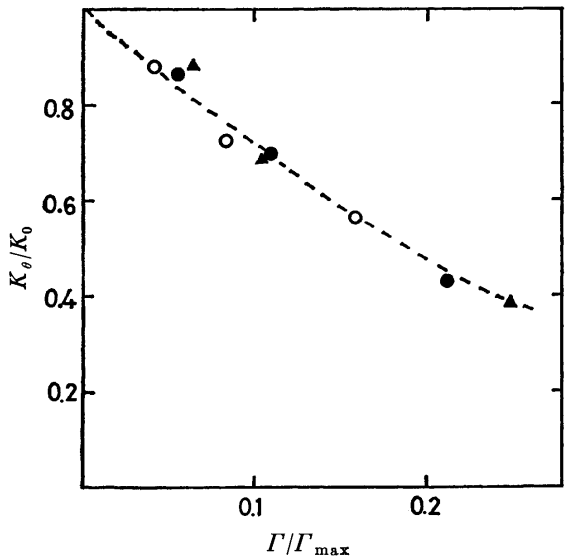

Fig. 2. Variation of the standard rate constants of V(III)+e=V(II) in 0.5 M H_2SO_4 with the surface coverage by alcohols.
○: Butyl alcohol, ●: amyl alcohol, ▲: hexyl alcohol.
----: $k_\theta=k_0(1-\theta)^{3.3}$.

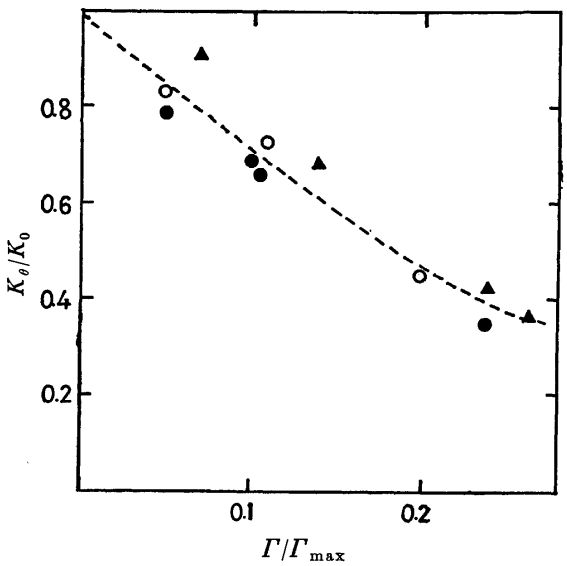

Fig. 3. Variation of the standard rate constants of Eu(III)+e=Eu(II) in 1.0 M HCl with the surface coverage by alcohols.
○: Butyl acohol, ●: amyl acohol, ▲: hexyl alcohol.
----: $k_\theta=k_0(1-\theta)^{3.3}$.

effect of butyl alcohol on the electrode kinetics is the least among these alcohols and that of hexyl

alcohol is the highest at a given surface excess. In the plot of the ratio of the standard rate constants, k_θ/k_0, against the surface coverage, θ, however, the variation of the rate constants of the V(III)/V(II) and Eu(III)/Eu(II) couples with respect to the surface coverage are superimposable regardless of the chain length of the alcohol as shown in Figs. 2 and 3. The standard rate constant of the uncovered electrode is denoted by k_0 and that at the electrode with the coverage of θ is denoted by k_θ. The plots of Figs. 2 and 3 are also superimposable. A similar electrode kinetic behavior of the vanadium couple to the europium couple is reasonable because the ionic charges of these couples are identical and the ionic sizes of these systems are roughly the same.

The transfer coefficient of the vanadium system and of the europium system does not depend on the nature of the alcohols and the extent of the coverage of the electrode surface. The transfer coefficient in the presence of the alcohols coincides with that without alcohols.

Andreev and his coworkers[13] noticed that the transfer coefficient decreases in the presence of the alcohols and is almost twice smaller than that in the solutions without alcohols in the reduction of cadmium ions in 0.5 M H_2SO_4. In the plot of $\log k_\theta$ against θ^2 in the range of $\theta=0.4$—0.9, the experimental data fit well on straight lines.[12] However, the linear plots with different alcohols were not superimposable. In the reduction of zinc ion in 0.1 M $NaClO_4$, on the other hand, amyl and hexyl alcohols have about equal inhibiting effect whereas the effect of butyl alcohol is somewhat weaker.[13]

The inhibition effect on the electrode kinetics depends only on the surface coverage, θ, of the electrode and is independent of the chain length of the adsorbed alcohol molecule. This evidence suggests that the "blocking effect" is predominant in the inhibition of the electrode process when aliphatic alcohols adsorbed on the electrode surface. The effect due to the interaction between the adsorbed alcohol molecules predicted by Biegler and Laitinen,[14] Sathyanarayana,[2] and Parsons[3] is negligible in the present experiments.

It is also interesting to note that the values of n in Eq. 1 calculated by Lipkowski and Galus[1] for various systems agree reasonably well when we employ the surface excess of the alcohols determined by the present work. The results are shown in Table 2. In the previous work,[5] on the other hand, the value of the closed packed coverage, $\Gamma_{max}=7.9\times10^{-10}$ mol cm^{-2} was used so that large values of n were obtained.

Table 2. The n value for the electrode reaction rate constant equation of $k_\theta=k_0(1-\theta)^n$

System	Alcohol	n	Ref.
V(III)/V(II)	amyl	4.2[a]	
		6.4	5
V(III)/V(II)	butyl, amyl, hexyl	3.3	present work
Eu(III)/Eu(II)	butyl, amyl, hexyl	3.3	present work
Cd(II)	butyl	4.0[a]	
		4.5	5
$HPbO_2^-$	butyl	4.8[a]	
		4.9	5
		2.8	1
$Fe(CN)_6^{3-}$	amyl	5.1[a]	
		3.0	1
Cu(II)	butyl	3.6[a]	
		2.1	1
$S_2O_8^{2-}$	amyl	6.0[a]	
		3.5	1

a) The n values were calculated by using the data in Ref. 6.

Polar Fluorescent State of 1- and 2-Acylanthracenes. II.[1] The Perturbation of Protic Solvents

Takashi TAMAKI

Research Institute for Polymers and Textiles, Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received May 18, 1979)

The steady-state and time-resolved fluorescence spectra were measured for protic solutions of 1- and 2-acetyl- or 1- and 2-benzoylanthracenes at various temperatures. It has been demonstrated that the perturbation of protic solvents on the fluorescence spectra is caused by a combination of the orientational dipolar solvent-solute relaxation and the hydrogen bond interaction. Based on the time-dependent spectral shift and the temperature dependence of fluorescence polarization observed for 2-acylanthracene, the relaxation process of the excited solute has been supposed to involve the level inversion of dual fluorescent states, which respond differently to the solvation of the system.

The solvent perturbation on the solute emission has been subject of continuing interest in recent years.[2] The solvent dipole-solute dipole interaction is very important in the excited-state relaxation of a fluorescent solute which is electronically neutral in the ground state, but it led to a highly polar state upon photoexcitation. This solvent relaxation process occurs on the nanosecond time scale subsequent to a rapid ($>10^{-12}$ s) vibrational relaxation from the excited Franck-Condon (F.C.) state to the excited equilibrium (e.q.) state. In a fluid solution in which the solvent relaxation is much faster than the fluorescence decay, the excited e.q. state is eventually stabilized by the orientational relaxation of the surrounding solvent molecules. The fluorecsence spectrum becomes diffuse and red-shifted as a result of solvent reorientation, where as the absorption spectrum remains unchanged. The more polar the solvent, the greater the stabilization energy, leading to the larger red shift of the fluorescence maximum. As the solvent-relaxation time increases, *e.g.*, in a viscous solution at a low temperature, the time-dependent spectral shift of the fluorescence associated with the solvent relaxation becomes experimentally observable, for which time-resolved emission spectroscopy is promising.[3]

Some anthracene derivatives are known to reveal the related spectral shift in polar solvents.[4-7] Very recently, we have studied the solvent dependence of the fluorescence spectra of 1- (**1a**) and 2-acetyl- (**2a**) or 1- (**1b**) and 2-benzoylanthracene (**2b**) in aprotic solvents.[1] The structured spectra in nonpolar solvents have been found to become structureless and red-shifted in solvents with a higher polarity than ethyl ether. This solvent dependence was consistent with the well-established mechanism which involves orientational dipolar solvent-solute interaction. The dipole moment of the excited state has been estimated to be about 10 D for the compounds examined.

We wish now to report the perturbation of protic solvents on the fluorescence of these compounds. The steady-state and time-resolved fluorescence measurements indicate that the compounds are subjected to hydrogen bonding with the solvents in addition to the general orientational relaxation. Of particular interest is the observation concerning the time-dependent spectral shift for 2-acylanthracenes (**2a** and **2b**), because there is not only a peak shift, but also a significant change in the spectral shape. This finding is discussed in terms of the level inversion of the dual fluorescent states, which consist of the lowest excited state perturbed by the hydrogen bond and the excited CT state.

Experimental

The acylanthracenes (**1** and **2**) were the same as those used before.[1] The hexane, 1-propanol, and propylene glycol were spectro- or GR-grade reagents and were used without further purification. The ethanol was dried by refluxing over calcium hydride and distilled fractionally.

The steady-state fluorescence measurements were made using a Hitachi MPF 2A spectrofluorometer. The excitation wavelength was 390 nm. The time-resolved fluorescence and lifetime measurements were done using an Ortec SP-3X nanosecond spectrometer. The photoexcitation was done by means of the 337-nm light supplied by a 0.5-atm air-saturated flash lamp through a Corning 7-60 filter. The bandwidth of the monitoring wavelength was 2 nm for the time-resolved measurements and 5 nm for the lifetime measurements. The outputs from a multichannel analyser were displayed on an X-Y plotter (Hewlett-Packard). The fluorescence lifetime was determined from the slope of the decay curve drawn. The sample solutions were deoxygenated by the flushing of argon gas for 10 min prior to measurements. The sample absorbance in a 1-cm square quartz cell was made *ca.* 0.1 at the excitation wavelength, an optical density corresponding to the concentration of the order of 10^{-5} mol dm^{-3}. The measurements for the temperature dependence were carried out with sample cells placed in a cryostat (Oxford DN-704) combined with a temperature controller (Oxford DTC-2). The degree of fluorescence polarization (P) was measured by the ordinary method using the linearly polarized exciting radiation.[8] Since the instrument responded differently to the light quanta of the two polarized components, correction was done for the polarized fluorescence intensities ($I_{\parallel}$ and $I_{\perp}$) by measuring the corresponding fluorescence intensities ($I'_{\parallel}$ and $I'_{\perp}$) for a horizontally polarized exciting radiation, which can be expected to be the same. The value of P was calculated from this equation:

$$P = \frac{I_{\parallel} - I_{\perp}(I'_{\parallel}/I'_{\perp})}{I_{\parallel} + I_{\perp}(I'_{\parallel}/I'_{\perp})}$$

Results and Discussion

Hydrogen-bond Contribution. The fluorescence maxima of 1- and 2-acylanthracenes (**1** and **2**) in protic solvents move to lower frequencies than ex-

pected from the properties of solvent polarity.[1] It appears probable that this extraordinary peak shift is attributable to hydrogen-bond formation, since these compounds have a carbonyl-type oxygen as a hydrogen-accepting site. Such protic solvent perturbation has been clearly demonstrated by the observation concerning the effect of very dilute concentrations of alcohols on the spectra of the compounds dissolved in a nonpolar solvent like hexane. As is shown in Fig. 1, the fluorescence spectra become structureless and red-shifted as the concentration of 1-propanol is increased. When perturbed by very small amounts of added alcohol (<0.01 M), which are insufficient to alter the absorption spectrum or the dielectric properties of the solvent, the spectrum does not only shift, but also broadens considerably (Fig. 1a). This suggests the appearance of new emission band(s). The emission spectra shown in Fig. 1a are normalized on the short-wavelength side, where the contribution of the new band is negligible. The subtraction of the unperturbed spectrum from the perturbed gives

Table 1. Peak positions of the fluorescence spectra of hydrogen-bonded 1- and 2-acylanthracenes

Compounds	λ_f/nm
1-Acetylanthracene (**1a**)	448
1-Benzoylanthracene (**1b**)	466
2-Acetylanthracene (**2a**)	420, 444
2-Benzoylanthracene (**2b**)	430, 454

rise to the emission band, presumably corresponding to a hydrogen-bonded species. The band peaks of all the compounds examined are listed in Table 1. On a further increase in the alcohol concentration, the fluorescence peak moves further to the red, the bandwidth remaining almost constant until the spectra coincide with that of the pure alcohol solution (Fig. 1b). This shift may be attributed to the general dipolar solvent-solute interaction. Thus, the protic solvent perturbation is due to a combination of the nonspecific dipolar and the specific hydrogen-bond interactions.

It can be noted that the hydrogen bond is facilitated in the excited state, because the photoexcitation leads to preferential electron migration from the anthryl group to the carbonyl group,[1] resulting in an increase in the carbonyl basity. Since the electron migration induces a resonance contribution to the π-electron conjugation of these two groups, a coplanar geometry of the molecular conformation is most likely to be attained, thus ensuring the delocalization of the π-electron.[9] The situation reported for methyl anthracenecarboxylate[6] is analogous to that in this study. It is of interest to mention the possibility of a change in geometry associated with photoexcitation, as was pointed out for methyl anthracenecarboxylate.[6] A difference in ground-state geometry appears among the three positional isomers of substituted anthracenes if the substituent lacks spherical or cylindrical symmetry.[10] Carbonyl-substituted anthracenes are just the same. It is known that the carbonyl group of the 9-isomer is perpendicularly torsional with respect to the plane of an anthryl ring because of the repulsive forces of two *peri*-hydrogen atoms.[10,11] Therefore, a significant geometry change is induced upon photoexcitation.[6a] On the other hand, the ground-state geometry of the 1- and 2-isomers stays rather coplanar because of these being less steric hindrance. This has been also confirmed for the compounds concerned by IR and UV absorption measurements. The carbonyl-stretching frequencies for **1a** and **2a** in $CHCl_3$ are 1675 cm^{-1} and 1678 cm^{-1} respectively, whereas the frequency for the 9-isomer is 1693 cm^{-1}. The lesser double-bond character of the carbonyl bond for the former compounds is consistent with a coplanar geometry.[10] The UV measurement indicates that all the acylanthracenes except the 9-isomer exhibit a fundamentally different spectrum from that of the parent substance, anthracene.[1] The observed spectral deformation can be explained as being due to an effective resonance contribution, which may lead to the same conclusion with respect to the ground-state geometry. In conclusion, the geometry change can be regarded as less

important in the cases we are studying than in the cases of methyl 1- and 2-anthracenecarboxylates.[6b]

Temperature and Time-dependent Spectral Shifts. The steady-state fluorescence spectra of **2b** in ethanol at various temperatures are shown in Fig. 2. At room temperature the spectrum is structureless and largely red-shifted, arising from a fully relaxed e.q. state. As the temperature is lowered, the spectra move to the blue and develop some structure, with a gradual increase in the emission intensity. At 77 K the spectrum is the same in both shape and peak position as that in a nonpolar solvent. No phosphorescence could be detected. The spectra of the other compounds (**1a**, **1b**, and **2a**) reveal a similar temperature dependence. In contrast with the emissive behavior, the absorption spectra show no corresponding change, except for the sharpening and slight intensifying of the bands at lower temperatures. The absence of the isoemissive point supports the view that the temperature-dependent spectral shift is due to solvent reorientation around the excited solute which is subjected to a hydrogen bond.

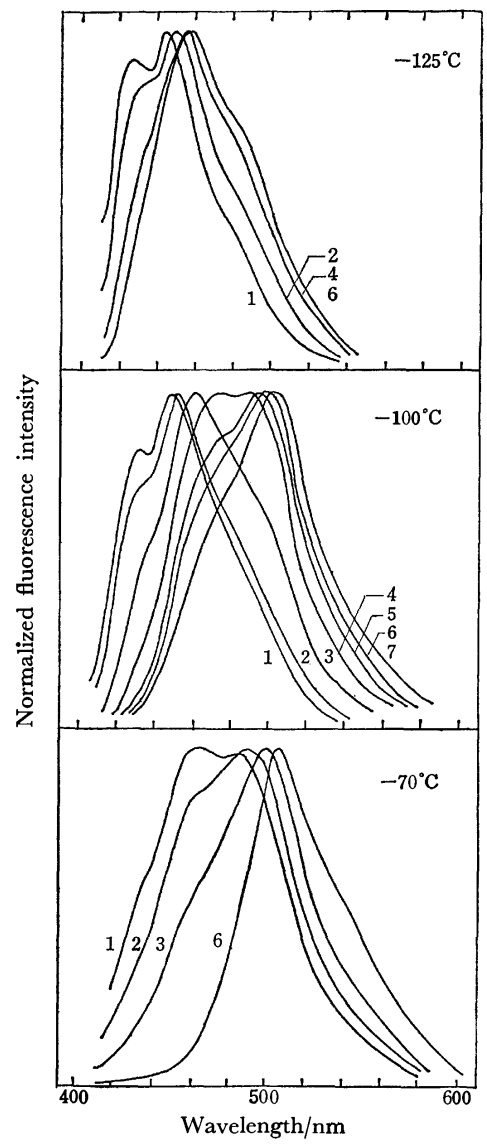

Fig. 4. Time-resolved fluorescence spectra of 2-benzoylanthracene in propylene glycol at the temperature indicated. 1, 5 ns; 2, 15 ns; 3, 20 ns; 4, 30 ns; 5, 40 ns; 6, 50 ns; 7, 70 ns.

The temperature-dependent spectral shift is, in fact, associated with the time-dependent spectral shift. The time dependence of the spectra is very intimate for each family of **1** or **2**. Some typical results for **1b** and **2b** in 1-propanol are shown in Figs. 3 and 4 respectively. Each spectrum is given at each delay time after the onset of a nanosecond flash lamp. The time-dependent spectral shifts amount to several tens of nanometers at −70 °C——100 °C. In this temperature range, the dielectric relaxation time of the solvent (τ_ρ=2.0—47×10^{-8} s[12]) is comparable in

order of magnitude to the fluorescence lifetime of $\tau_f \simeq 10^{-8}$ s. The wavelength span in which the spectra shift decreases on either further lowering or raising of the temperature, since the dielectric relaxation time becomes far from the fluorescence lifetime. At extreme temperatures, such as room temperature or 77 K, where the solvent relaxation is complete or totally inhibited, the spectrum is practically time-independent.

The wavelength region over which the spectral shift is observed moves to the blue with a decrease in the temperature. The extrapolation of the peak shift found at −125 °C to zero time provides the peak maxima of 450 nm for **1b** and 445 nm for **2b**. Although the dielectric relaxation at this temperature ($\tau_\rho \simeq 2 \times 10^{-5}$ s[12]) is much slower than the fluorescence decay, these peak positions lie about 20 nm to the red relative to the positions of the spectra at 77 K, which correspond nearly to the F.C. solvent configuration. This suggests that, even at −125 °C, the appreciable subnanosecond relaxation occurs. From the close resemblances of the zero-time spectra with the hydrogen perturbed spectra (Fig. 1a), it is clear that the hydrogen-bond interaction is responsible for this rapid relaxation.

The observed time-dependent spectral shifts are in many respects analogous for the systems of **1** and **2**. However, the difference between them is apparent at a glance in Figs. 3 and 4. While the spectra observed for **1b** retain, to a good approximation, their band width and shape during the progress of the peak shift (Fig. 3), it is striking that the spectra observed for **2b** exhibit a significant change in their structure (Fig. 4). In the latter case, there are at least two emissions with different solvent configurations. At −100 °C both emission spectra are observable: the one arises in the early stage of the delay time, and the other, in the later stage. The conversion of these two emissions occurs at an intermediate delay time of 30 ns. Each spectrum can be separately measured when the temperature is varied. At −125 °C only the early stage emission is predominant; it is attributed to the hydrogen bonded species. On the contrary, at −70 °C the later stage emission prevails, and it approaches the room-temperature spectrum. This temporal variation in the fluorescence spectra is very interesting, because it gives direct evidence of the solvent-induced change in the excited electronic structure.

At temperatures where there are time-dependent spectral shifts, the fluorescence lifetime is dependent on the excitation wavelength. For the system of 1-benzoylanthracene–propanol, which shows a continuous time-dependent spectral shift, the kinetics of the wavelength-dependent decay can be explained by the Bakhshiev formulation.[13] If the fluorescence quantum yield and the transition probability are time-independent, the decay law which describes the continuous orientational dipolar solvent-solute relaxation can be written as

$$I(\bar{\nu}, t) = \text{const} \cdot \exp(-t/\lambda) \cdot f(\bar{\nu}, t), \quad (1)$$

where $\exp(-t/\lambda)$ is a damping function which defines the electronic relaxation of the system and where $f(\bar{\nu}, t)$ represents the effects of the time-dependent spectral shifts on the observed fluorescence decay. $f(\bar{\nu}, t)$ can be estimated at a given wavelength from the normalized time-resolved spectra. The calculation of the decay time associated with $I(\bar{\nu}, t)$ can be made assuming an appropriate value for λ. The values calculated for **1b** at various wavelengths are listed in Table 2. The agreement between the measured and calculated values is gratifying.

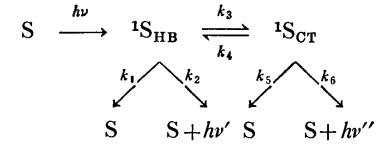
540	12	11

Excited-state Level Inversion. The temporal variation in the fluorescence spectra found for the 2-benzoylanthracene-propanol system indicates that this system involves at least two fluorescent species which are chemically the same, but electronically different. The acylanthracenes may be viewed as forming an intramolecular donor–acceptor system in which the anthryl group is a donor, and the carbonyl group, an acceptor. A previous study of the solvent dependence of the fluorescence suggests that the excited state in highly polar solvents has a character of charge transfer.[1] Consequently, the appearance of the two emissions may be interpreted in terms of two excited states, $^1S_{HB}$ (the lowest excited state perturbed by the hydrogen bond) and $^1S_{CT}$ (the excited CT state), which respond differently to the solvent relaxation. The conversion of $^1S_{HB}$ to $^1S_{CT}$ is an intramolecular electron-transfer reaction.

These considerations are summarized in the following reaction scheme:



The transient populations of $^1S_{HB}$ and $^1S_{CT}$ are given by the following equations:[3]

$$[^1S_{HB}] = C_1 \exp(-t/\lambda_1) + C_2 \exp(-t/\lambda_2), \quad (2)$$

$$[^1S_{CT}] = C_3\{\exp(-t/\lambda_1) - \exp(-t/\lambda_2)\}, \quad (3)$$

where

$$1/\lambda_1,\ 1/\lambda_2 = (1/2)[k_1+k_2+k_3+k_4+k_5+k_6 \mp \{(k_1+k_2+k_3-k_4-k_5-k_6)^2+4k_3k_4\}^{1/2}].$$

It is of interest to examine whether or not this reaction scheme is consistent with the wavelength-dependent kinetic behavior measured for the 2-benzoylanthracene–propanol system. In this respect, it was confirmed that the decay law of Eq. 1 in itself was no longer applicable to the observed time-dependent spectral

Table 3. Observed and calculated fluorescence decay times for 2-benzoylanthracene in propylene glycol at −100 °C, taking $\lambda_1=15$ ns and $\lambda_2=12$ ns

change (Fig. 4), apparently indicating that the fluorescence lifetime and/or the transition probability is time-dependent. We have analyzed the experimental results in ways similar to those presented above, but on the assumption that the damping function in Eq. 1 is biexponential, as is presented in Eq. 2 or 3. Since it was difficult to measure the rise in the curve of the $^1S_{CT}$ fluorescence, the calculation for this fluorescence has been done only for the decay time. We have also assumed, for the sake of simplicity, that the conversion of the two excited states is irreversible, *i.e.*, $k_3 \gg k_4 \simeq 0$, and therefore, $[^1S_{HB}]$ is represented only by the second term of Eq. 2. Table 3 shows the values calculated at various wavelengths, taking $\lambda_1=15$ ns and $\lambda_2=12$ ns together with the measured values. While it is to be expected that the calculated value deviates from the measured value in the wavelength region where the two emission spectra are greatly overlapping, these two values agree to a good precision at the other wavelengths. This supports the validity of the reaction scheme postulated.

Since the level inversion involves a change in the dipole moment, the photoselection technique is helpful to characterize the phenomenon. On the basis of this technique, Suzuki and his coworkers have extensively investigated the fluorescence level inversion of the dual fluorescence for indole and such 1-naphthyl derivatives as hydroxyl, cyano, or amino.[14] Similarly, we have measured the degree of the fluorescence polarization (P) for the compounds of **1** and **2** at various temperatures. In Fig. 5, the excitation polarization spectra for **1a** and **2a** in an ethanol glass at 77 K are compared with those in glycerol at room temperature. In the case of **1a**, the general shapes of the polarization spectra for the two temperatures are substantially the same, though the absolute value of P in ethanol at 77 K is larger than that in glycerol at room temperature. The increase in P at low temperatures is due to the depletion of the rotational depolarization, as is to be expected from the solvent viscosity. On the other hand, the two polarization spectra for **2a** are significantly different. It is noted that, while the spectra in the long wavelength region (>340 nm) have the ordinary temperature effect, the effect occurs in the opposite direction at the shorter wavelengths.

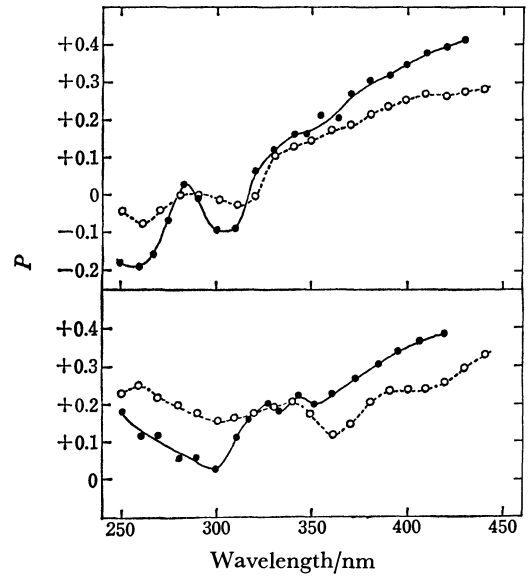

Fig. 5. Fluorescence excitation polarization spectra of 1-acetylanthracene (upper) and 2-acetlyanthracene (lower) in glycerol at 20 °C monitored at 510 nm (open circle) or in ethanol at 77 K monitored at 450 nm (closed circle).

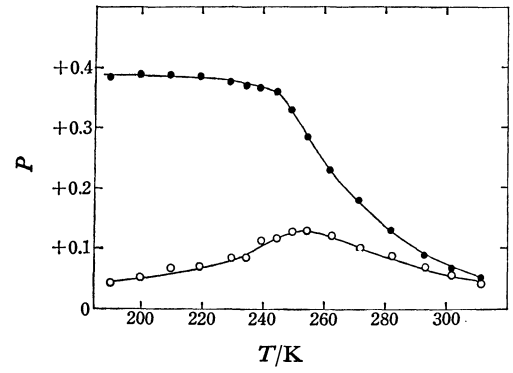

Fig. 6. Temperature dependence of the degree of fluorescence polarization of 2-acetylanthracene in propylene glycol monitored at 440 nm. The excitation wavelength was 400 nm (closed circle) and 300 nm (open circle).

The anomaly of the temperature effect is further evident from the measurement of P in propylene glycol by varying the temperature from 300 K to 200 K. As is shown in Fig. 6, when excited at 300 nm, the value of P first increases with a decrease in the temperature, reaching its maximum at about 250 K. On a further lowering in the temperature, though, it in turn decreases. This temperature dependence of P is in contrast with that for the excitation at a long wavelength, *e.g.*, 400 nm, which indicates a plateau in the values of P below 250 K. The decrease in P at low temperatures is characteristic of fluorescence-level inversion.[14]

There is an intense band near 300 nm in the absorption spectra of **2**. Since no corresponding band is present in the spectrum of the parent anthracene, this band may be identified as a CT transition band. However, it is reasonable that this CT band is too

high in energy to be ascribed to the emissive state in highly polar solvents at room temperature. An alternative band responsible for the polar fluorescence may subside in the longer-wavelength bands.

As has been demonstrated above, the temperature- and time-dependent spectral changes observed for **2** in protic solvents are partly due to the level inversion of dual fluorescence arising from the lowest excited singlet and excited CT states. Although the spectral shifts observed for **1** conform to a relaxation mechanism which involves the continuous orientational dipolar solvent-solute interaction, the possibility of a level inversion can not be excluded at this stage of the investigation. If the relevant energy levels are closely related, it appears unlikely that a drastic change in the fluorescence spectra is necessarily required.

Microscopic Evaluation of Surfactant–Water Interaction in Apolar Media

Junzo SUNAMOTO,* Tomiko HAMADA, Takafumi SETO, and Shinji YAMAMOTO

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received May 23, 1979)

Under the very limited conditions where the mole ratio of water to surfactant is about unity or so, the tightness of the interaction between various ionic surfactants and water solubilized in apolar media was evaluated using the O–H vibrational mode of water in the near infrared spectral region. Water solubilized in apolar solvents containing surfactant exhibited two absorption bands in the region. One of the two arises from water existing in bulk organic phase and appears around 1900—1910 nm. Another band arises from water bound to surfactant and appears over a range of 1920—2020 nm; it is affected primarily by the ionic head group of surfactant rather than by the counter ion. The cationic surfactants were thought to form more rigid micelles than the zwitterionic or anionic ones. The copper(II) ion cosolubilized in the system hardly altered the O–H vibrational energy of water. The dependence of the near infrared absorption band on water, the chemical shift and line width of water proton resonance in NMR, and the fluorescence intensity of terbium chloride all displayed an inflection at the point where the mole ratio of water to surfactant is about unity. This was interpreted in terms of the two step hydration mechanism.

The term "reversed micelles" describes aggregates of surfactants and polar solutes formed in aprotic media. Although reversed micelles have been investigated intensively, the structure of aggregates remains poorly understood even on the elementary level. Much of the interest in "the aggregates" or "reversed micelles" stems from their use as models of enzyme pockets or cell membranes.

Favorable substrate cosolubilization, orientation, and the unique properties of the system have been proposed to be responsible for the effects on reaction rates, paths, and equilibria occurring in the interior core.[1,2] Aggregates formed in apolar media certainly provide a specific and restricted field. The rigidity-flexibility or hardness-softness of the field is thought to be affected by the kind of surfactants and the amount of water added.[2] Depending on concentrations of surfactant and water added, the tightness of surfactant–water interaction,[2] the size of water pool,[3] the microscopic viscosity[4] and polarity of the interior[5] can be varied over a considerable range. However, the problem of rigidity and tightness of aggregates in conjunction with the structure of surfactants has been not investigated thoroughly thus far. Considering the correlation between the motion of reactants and reaction rates or pathways, we can not discard the problem of the "rigidity" of the reaction field. Certainly, several efforts to rationalize the correlation between the motional freedom and the amount of water added within interior cores have been made through NMR,[4] spin label,[6] and fluorescence studies.[3] However, one has scarecely paid attention to the state and nature of aggregates formed under the very limited condition where the mole ratio of water to surfactant is about unity or less.[7]

Very recently, we found that the configurational change between tetrahedral and octahedral species of cobalt(II) complexes takes place in reversed micelles formed by the several kinds of surfactants.[2] The phenomenon was interpreted in terms of solvochromism and thermochromism which were accompanied by the elimination-addition equilibrium of water between the metal ion and the surfactant.[2] Moreover, it seemed to be certainly connected with the rigidity (or flexibility) of the surfactant–water aggregates. In this work we would like to report the correlation between the structure of surfactants and the tightness of the surfactant-water interaction in apolar media as evaluated using the near infrared O–H vibrational mode of water bound to surfactants. We limited the amount of water to an extremely small extent so that the mole ratio of water to surfactant was about unity or so. It is sure that a portion of water is dispersed in the bulk phase of organic solvent. Of course, the surfactant molecule also may partly exist as the monomeric form in bulk solvent. We do not know, therefore, whether the 1:1 aggregate between water and surfactant in apolar media can be considered as a true reversed micelle.[7]

Experimental

Materials. Surfactants, hexadecyltrimethylammonium bromide (CTAB), dimethyldioctadecylammonium chloride (QD-Cl), egg phosphatidylcholine (EL), dodecylammonium propionate (DAP), and sodium 1,2-bis(2-ethylhexyloxycarbonyl)-1-ethanesulfonate (AOT), were the same as those used in previous studies.[2] 3-(Hexadecyldimethylammonio)-1-propanesulfonate (SB-16:3) was prepared by quarternizing *N,N*-dimethylhexadecylamine with propanesultone and purified according to the method described in literature.[8] Hexadecyltrimethylammonium chloride (CTACl) was a gift from Kao Soap Co., Ltd., Tokyo. Sodium dodecylbenzenesulfonate (DBS) was purchased from Wako Pure Chemicals Co., Ltd., Tokyo and purified by recrystallization from benzene prior to the use. Purity of all the surfactants adopted was inspected by TLC or HLC and elemental analysis.

Measurements. All the visible and near infrared spectra were measured on a Hitachi 323 recording spectrophotometer equipped with a thermoregulated cell compartment. NMR studies were run on a JEOL MH-100 spectrometer with TMS as an internal standard. Fluorescence measurements were carried out on a Hitachi 512 fluorospectrometer.

In all runs, the amount of water added was carefully determined every time after the spectroscopic measurements on a Karl-Fischer Moisture Automatic Titration Apparatus Model MK-A (Kyoto Electronics MFG Co., Ltd.) using Karl-Fischer reagent SS "Mitsubishi" ($f=0.3$ mg/mL) with standard water–methanol solution ($f=0.5$ mg/mL) for Karl-Fischer reagent, Mitsubishi Chemical Industries Ltd., Tokyo.

Results and Discussion

Near Infrared Spectra of O–H Vibrational Modes. In the near infrared region, water exhibits relatively strong absorption bands due to the ν_2 (scissoring) plus ν_3 (asymmetric stretching) combination mode of vibration.[9] The band observed in vacuum is 5332.0 cm^{-1} (1875 nm) arises from the B_1 species, which corresponds to the band at 5330.6 cm^{-1} (1876 nm) theoretically calculated.[9] This is completely freed from the hydrogen bonding itself. If the water molecule hydrogen-bonds or interacts with other polar molecules or ions, the band will shift toward the lower energy state or the longer wavelength. In pure bulk water the force constant of the O–H bond is compensated owing to the dual character of water as both proton donor and acceptor properties.[10] Bulk water shows, therefore, the band at 5181 cm^{-1} (1930 nm) in the near infrared region. In nonpolar solvents containing ionic surfactants, a part of cosolubilized water locates in the bulk organic phase, where the water molecules are mostly freed from hydrogen bonding themselves, and others interact with the ionic head of surfactant. In the near infrared region, the former exhibits absorption bands around 1900 nm and the latter over a range of 1920—2020 nm.[11,12] Figure 1 shows the near infrared spectra of water in chloroform containing different kinds of surfactant. In chloroform containing anionic surfactants such as AOT or DBS, the position of two bands is close to each other, and at larger amount of water both absorptions overlap to create a broad single band. Intensities of bands in the system containing anionic surfactants are usually stronger than those with zwitterionic and cationic surfactants.

Effect of Bulk Solvent. The near infrared spectra of water vary with the bulk solvents as well as the type of surfactants. In chloroform containing surfactants, the O–H vibrational mode in near infrared region separates into two distinct bands as described above. In less polar solvents such as hexane or carbon tetrachloride, only a single absorption band is observable in the corresponding region irrespective of the surfactants (Fig. 2). In hexane containing no surfactants, we could not obtain any reliable spectra because of the extremely low solubility of water in the solvent. Since the dipole moment of the O–H bond depends on the dielectric constant of the field,[13] the intensity of these bands should be affected by the polarity of bulk solvents. Seno and his coworkers also previously observed similar results on the absorption band arising from water dispersed in bulk solvents.[12] That the dipole moment of the O–H bond changes with solvents and/or surfactants means that the quantitative treatment in spectroscopic studies on the system is not feasible.[14] We can, therefore, interpret the data only in a qualitative manner.

Temperature Effect. There exists an equilibrium in the translocation between two different kinds of water existing in bulk solvents and bound to surfactants. Increasing temperature causes a decrease in intensity of the band arising from water bound to surfactants

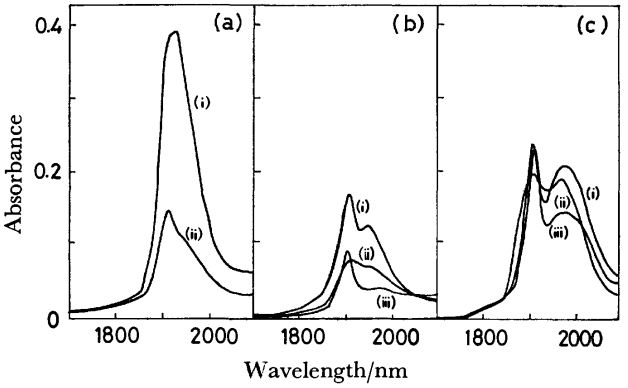

Fig. 1. Near infrared spectra of water solubilized in chloroform containing various kinds of surfactants at 25 °C: (a) anionic surfactants, (i) 0.20 M AOT/0.20 M H_2O and (ii) 0.10 M DBS/0.084 M H_2O; (b) zwitterionic surfactants, (i) 0.040 M SB-16:3/0.037 M H_2O, (ii) 0.045 M EL/0.055 M H_2O, and (iii) 0.20 M DAP/0.20 M H_2O; (c) cationic surfactants, (i) 0.20 M CTACl/0.20 M H_2O, (ii) 0.20 M CATB/0.22 M H_2O, and (iii) 0.20 M QD-Cl/0.18 M H_2O.

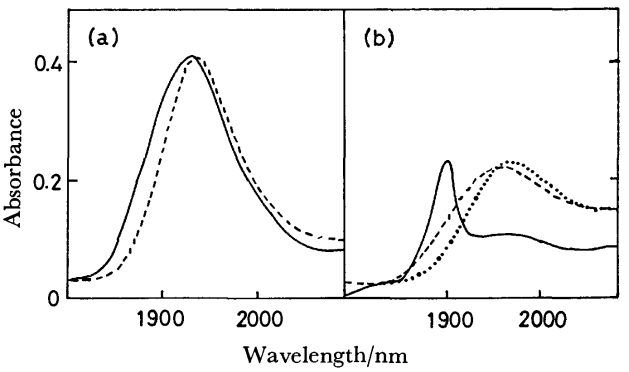

Fig. 2. Effect of bulk solvent on the distribution of water solubilized in apolar solvents containing surfactants at 25 °C: (a) 0.20 M AOT with 0.20 M water in chloroform (——) and 0.20 M AOT with 0.24 M water in carbon tetrachloride (----); (b) 0.20 M DAP with 0.20 M water in chloroform (——), 0.20 M DAP with 0.22 M water in carbon tetrachloride (----), and 0.20 M DAP with 0.22 M water in hexane (·····).

with a concomitant increase in the intensity of the absorption of water in the solvent phase (Fig. 3). A temperature increase enhances the mobility of water bound to surfactants, resulting in easier dispersion into the bulk organic phase. The result coincides with that previously observed on the thermochromism of the cobalt(II) complexes in the reversed micelles.[2]

Effect of Cosolubilized Metal Ion. The energy states of the O–H vibration in three different surfactant systems, AOT, DAP, and CTAB, with or without the copper(II) ion were determined as a function of added water (Fig. 4). The configuration of the copper(II) complexes in reversed micelles is drastically affected by the kind of surfactants and the amount of water present.[2,15] On the other hand, the O–H vibrational energy of water is not so significantly affected by cosolubilizing the copper(II) ion. In three sur-

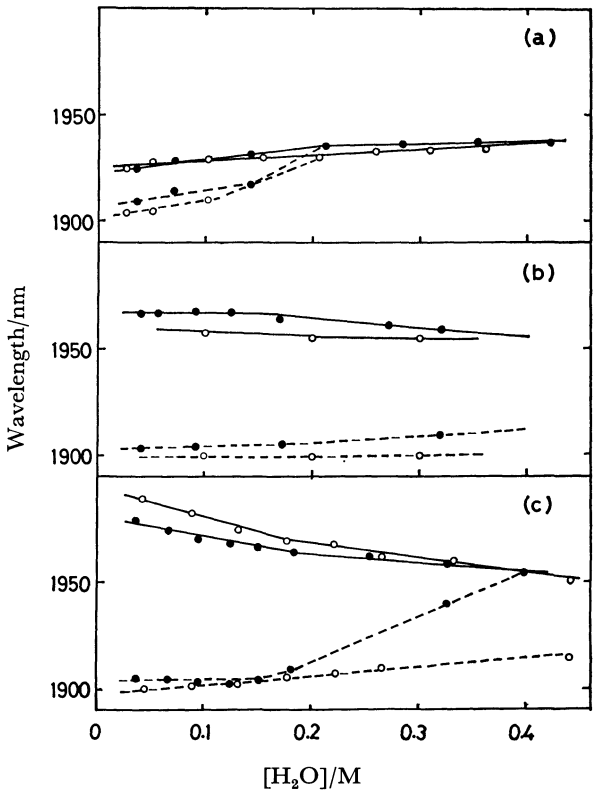

Fig. 4. Effect of the Cu(II)-ion on the near infrared absorption bands of water solubilized in three different surfactants/chloroform system as a function of water added at 25 °C: (a) 0.20 M AOT in chloroform without Cu(II) ion (○) and with 4.6×10^{-4} M Cu(II) ion (●); (b) 0.20M DAP in chloroform without Cu(II) ion (○) and with 2.7×10^{-3} M Cu(II) ion (●); (c) 0.20 M CTAB in chlorofrom without Cu(II) ion (○) and with 5.9×10^{-4} M Cu(II) ion (●). The copper-(II) ion was cosolubilized as the aqueous nitrate in all the systems. Solid lines are absorption bands of water bound to surfactant, while broken lines are those of water existing in bulk organic solvent.

factant systems, the energy state of the O–H bond of water changed as a function of water content, giving an inflection around the point where the mole ratio of water to surfactant is about unity. The addition of the metal(II) ion is expected to force water molecules into the interior core of reversed micelles from the bulk phase.[16] However, a concomitant increase of water bound to surfactants was not observed. Because of low solubility of the metal salt under the adopted conditions, it was impossible to cosolubilize more salts. Very recently, we reported solvochromisms of the cobalt(II)[2] and copper(II)[15] complexes in reversed micellar systems, where the configurational change between T_d and O_h takes place when water is added to the system. The present result coincides with those obtained for both the solvochromism of the metal(II) ions[2,15] and the hydrolysis of an amino acid ester as promoted by the copper(II) ion in the AOT/CCl_4 reversed micelles.[15,17]

Effect of Water Content and Tightness of Surfactant–Water Interaction. The interaction of water and various surfactants in apolar media was examined as a function of water amount added using the O–H vibrational modes in the near infrared region (Fig. 5). If water located in bulk solvents were completely free from any interactions with other polar or ionic molecules, the O–H vibrational mode of the water molecule would be identical irrespective of surfactants and/or bulk solvents. Since the band under consideration is affected a little by surfactants, however, the state and nature of water molecules in bulk phase seem to be altered by the solubility of surfactants in the bulk solvent and the polarity of the bulk phase (Fig. 5(b)). On the other hand, the vibrational energy of the O–H bond of water interacting with surfactants depends largely on the head group structure of surfactants (Figs. 1 and 5(a)). If the argument is limited to a series of surfactants under the same conditions, then it is reasonable to postulate that the shift in frequency of the O–H vibration reflects the relative strength of the interaction between water and surfactants.[18] Therefore, we can regard the difference ($\Delta\lambda$) between the theoretically calculated and observed wavelength as a semiquantitative parameter measuring the tightness of the interaction between water and other molecules under consideration:

$$\Delta\lambda = \lambda_0 - 1876\ (\mathrm{nm}), \qquad (1)$$

where λ_0 stands for the intrinsic absorption band which is graphically estimated, using data given in Fig. 5, by extrapolating the observed wavelength to the point where the mole ratio of water to surfactant is zero. Results are summarized in Table 1.

In dried apolar media, ionic surfactants will exist as intimate ion pairs. The interaction between water and surfactants, therefore, looks like a dipole-dipole interaction, especially under very limited conditions

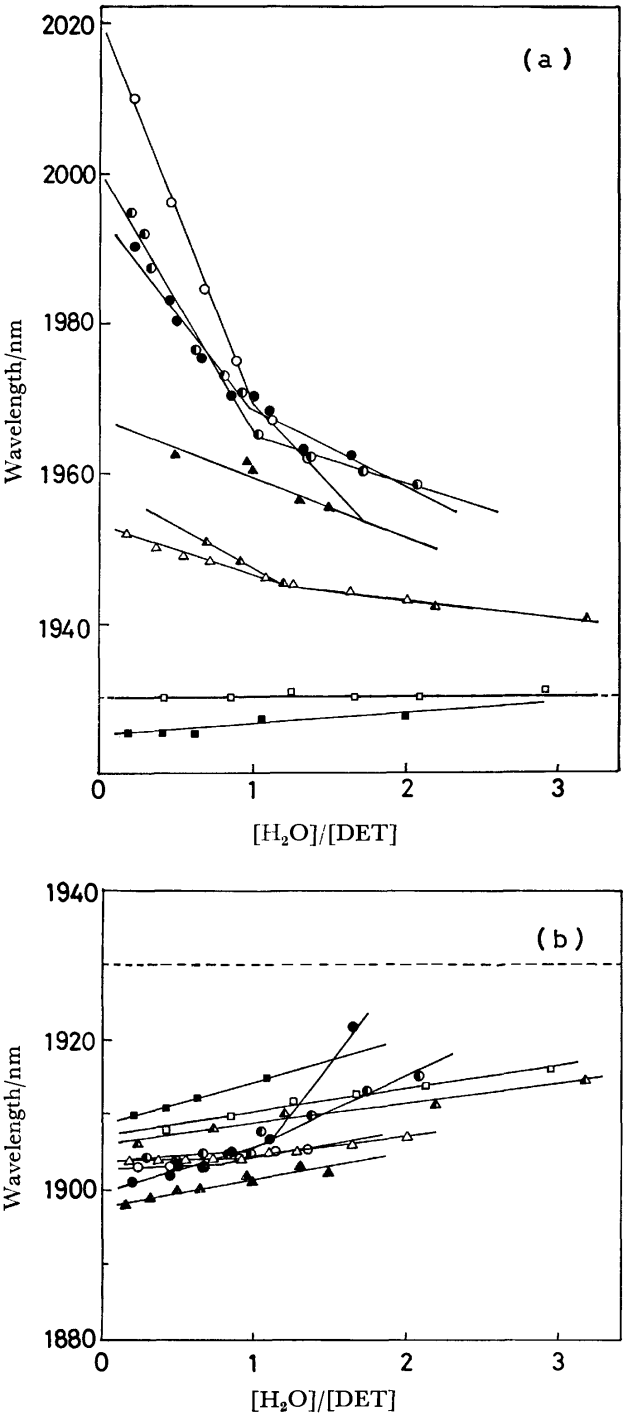

Fig. 5. Effect of water content on the near infrared spectra of water solubilized in chloroform containing various surfactants: (a) the absorption band of water bound to surfactants and (b) the absorption band of free water locating in bulk chloroform containing various surfactants; QD-Cl (○), CTACl (◐), CTAB (●), DAP (▲), EL (◭), SB-16:3 (△), DBS (□), and AOT (■). A broken line in (b) stands for the position of the absorption band of pure water (1930 nm).

where the mole ratio of water to surfactants is unity or less. It is of interest to clarify which ion species, the ion head group of surfactants or the counter ion, predominantly affects the interaction with water. Seno and his coworkers deduced that the carboxylato group in the DAP reversed micelles predominantly interacts with water from the shift of stretching frequency of carbonyl group as a function of water added.[12] If this is the case, water interacting with QD-Cl and CTACl must exhibit the absorption band at the same wavelength because both surfactants bear same counter anion, Cl^-. Furthermore, water interacting with AOT and DBS also will show the same absorption band since both surfactants bear the sulfonato group and sodium ion. Contrary to what would be expected, water interacting with CTACl in chloroform behaves similarly to that interacting with CTAB rather than QD-Cl. Water interacting with AOT exhibits different bands from those interacting with DBS. These results suggest that in apolar media the ion head of surfactant molecules, in spite of being more bulky, predominantly affects the force constant of the O–H bond of water. In order to secure more information of this point, we prepared hexadecylammonium chloride, sulfate, and perchlorate, sodium dihexadecyl phosphate, and potassium salts of anionic surfactants and tried to investigate the effect of small counter ions. Unfortunately, we were unable to utilize these surfactants owing to their diminished solubility in the usual apolar solvents.

Table 1. Intrinsic absorption bands of free water locating in bulk chloroform and water bound to various surfactants in the near infrared region at 25 °C[a]

Surfactant	Free water		Bound water		$\Delta\lambda_{0,(b-f)}$[b]
	$\lambda_{0,f}$	$\Delta\lambda_f$[c]	$\lambda_{0,b}$	$\Delta\lambda_b$[c]	
AOT	1908	32	1924	48	16
DBS	1907	31	1930	54	23
SB-16:3	1904	28	1953	77	49
EL	1906	30	1962	86	56
DAP	1897	21	1967	91	70
CTAB	1901	25	1996	120	95
CTACl	1903	27	2000	124	97
QD-Cl	1903	27	2020	144	117

a) Intrinsic absorption bands were graphically estimated using data given in Fig. 5 (see text). b) Difference between $\lambda_{0,f}$ and $\lambda_{0,b}$. Subscripts, f and b, refer to free water and water bound to surfactants, respectively. c) Calculated using Eq. 1.

Results given in Table 1 and Fig. 5 suggest to us that the tightness of interaction of water with surfactants in apolar media can be roughly classified into three categories depending on the head group structure of surfactants. CTAB, CTACl, and QD-Cl belong to the first category. Of surfactants adopted in this work, these cationic surfactants shift the O–H vibrational energy of the bound water most largely toward the lower energy state (longer wavelength). This means that these cationic surfactants interact tightly with water to reduce the force constant of the O–H bond of water and seem to form the most rigid reversed micelles. The second category includes DAP, EL, and SB-16:3. On the basis of the near infrared data,

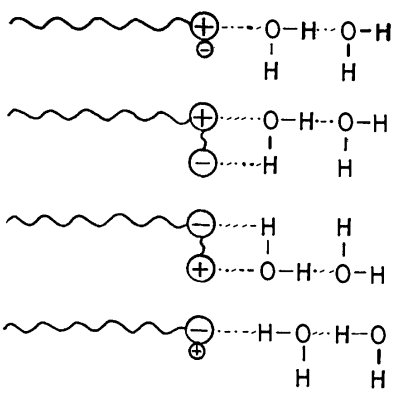

Fig. 6. Schematic representation of the mode of the interaction between water and surfactant in apolar media. From top to bottom, interactions of water with cationic surfactant, two different kinds of zwitterionic surfactants, and the anionic surfactant are shown, respectively.

DAP behaves as a zwitterionic surfactant rather than as cationic or anionic one. The anionic surfactants, AOT and DBS, belong to the different category from above two kinds of surfactants. The anionic surfactants seem to form the softest reversed micelles with water. These three distinct modes of the interaction between water and surfactants are represented schematically in Fig. 6. Assuming that in apolar media water predominantly interacts with the head group of surfactants, the interaction with the anionic surfactants is essentially hydrogen bonding,[19] while that with the cationic ones is the coordination type. In fact, water interacting with the anionic surfactants exhibits the band at the wavelength very close to that of pure bulk water. For the zwitterionic surfactants, two distinct types of interaction will compensate with each other. The difference in the absorption bands between the free water and water bound to surfactants, $\Delta\lambda_{b-f}$, decreases as one goes from cationic to zwitterionic and to anionic surfactant. The larger difference in the energy state between both state of water suggests a greater difficulty in the translocation of water between both states. This means that the surfactant-water aggregate under the circumstances may be relatively rigid. The hypothesis is not inconsistent with results obtained in previous studies on the solvochromism and the thermochromism of the cobalt(II) complexes in reversed micelles.[2] Both bands of free water and water bound to surfactants seem to approach the value of pure bulk water (1930 nm) as increasing the amount of water added (Fig. 5).[19] The state and nature of water in the cationic and the zwitterionic systems drastically change in the region where the mole ratio of water to surfactant is less than unity. The shift of absorption bands as a function of water content reveals an inflection point, where the $[H_2O]/[surfactant]$ ratio is about unity. The absorption bands of water bound to the cationic and the zwitterionic surfactants shift from the longer wavelength toward the shorter wavelength with increasing the amount of water, while the corresponding bands of the anionic surfactants move in the opposite direction. This reveals that between the cationic and anionic surfactant–water aggregates the nature of interaction of water with surfactants is different.

Evidences for the Two Step Hydration Mechanism. NMR of Water Interacting with Cationic Surfactant in Apolar Media: The chemical shift of the water proton in deuterochloroform containing CTAB was determined as a function of water amount added (Fig. 7 (b)). Over the range of water concentration examined, signals from methyl and methylene protons on the alkyl chain did not move, while *N*-methyl proton signal shifted a little toward the higher magnetic field with an inflection at the point of $[H_2O]/[CTAB] \fallingdotseq 1$. The proton signal of water moved substantially to the lower magnetic field with increasing water content, and again the inflection point appeared around the point where the mole ratio of water to CTAB is nearly unity. Increasing the water content in the system produces more hydrogen bonding between water molecules and causes the paramagnetic shift of the proton signal. The chemical shift of the water proton under consideration seems to finally reach the value of pure water (δ=4.66 ppm). Extrapolating the chemical shift to the point where the water content is zero gives 2.80 ppm. Water in deuterochloroform containing no surfactants shows a signal at 1.96 ppm. Interaction of the oxygen atom of water with the strongly electronegative cation-head of CTAB causes, therefore, a deshielding effect on the hydrogen atom of water molecule, resulting in the down-field shift of the proton signal. In contrast to the near infrared spectra, only one signal of water proton was observed by NMR. This means that the life time of both water protons, located in bulk phase and interacting with surfactant, is faster than the NMR time scale. In case of the phosphatidylcholine/diethyl ether micelles[20] and the AOT/heptane micelles,[4a] over a range where the mole ratio of water to surfactants is larger than 2, the line width of water proton resonance in NMR decreased as increasing the amount of water. Contrary to previous findings in the anionic and zwitterionic systems,[4a,20] in the present cationic system increasing water broadens the line width (Fig. 7 (a)). Again, we would like to note that the mode of interaction of water with cationic surfactants is different from that with anionic surfactants.

In the present system two possibilities must be considered to elucidate the broadening of the water proton signal: the viscosity of the medium and the proton exchange between free water and water bound to CTAB. Increased viscosity generally leads to line broadening by increasing the correlation time. In the reversed micellar system, in fact, adding a very little amount of water increases the macroscopic viscosity of the medium despite the decrease of the microscopic viscosity in the interior core.[21] Therefore, we can not eliminate the first possibility in interpreting our line broadening. Protons of water interacting with surfactants would have a shorter transversed relaxation time, T_2, than free water protons located in the bulk phase. When the rate of proton exchange between free water and the bound water is sufficiently

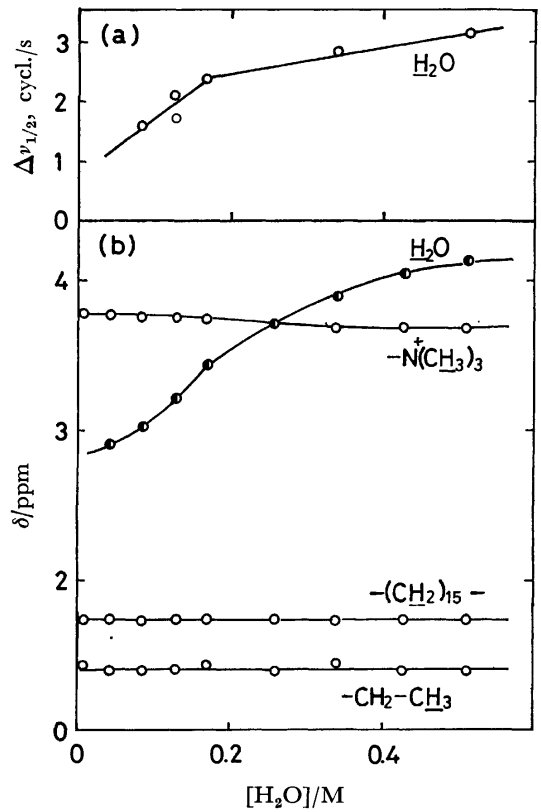

Fig. 7. NMR studies on the interaction of water with 0.20 M CTAB in deuterochloroform as a function of water content at 25 °C: (a) the line width of water proton signal at halfpeak height and (b) chemical shifts of proton signals of water, choline methyl, methylene, and terminal methyl, respectively.

great compared with the reciprocal of the relaxation time, the apparent line width ($\nu_{1/2}=1/T_2$) can be written as

$$1/T_2 = x_f(1/T_2)_f + x_b(1/T_2)_b, \quad (2)$$

where x is the mole fraction and the subscripts f and b refer to the free and bound water, respectively.[22] Since it is reasonable to assume that $(1/T_2)_b \ll (1/T_2)_f$, the line width will be affected mostly by water bound to surfactants. Increasing the hydrogen bonding of water very probably diminishes the mobility of water molecules and will cause the further line broadening of water proton signals. Anyway, the correlation between the mobility of water bound to surfactant and the strength of interaction of water and surfactant can be discussed only about the same ionic series of surfactants.

Fluorescence Intensity of Tb(III) in DAP Reversed Micelles: The fluorescence emission from the excited Tb^{3+} is strongly quenched in aqueous solution.[23] Removing some of water molecules from its hydration shell tends to enhance the fluorescence emission.[23] We found a significant enhancement of the fluorescence emission from the Tb^{3+}-ion when the concentrated aqueous solution of $TbCl_3$ was cosolubilized in hexane containing DAP. The relative fluorescence intensity decreased with increasing water content and an obvious inflection point was again observed where the mole ratio of water to DAP was about unity. Through the investigation of the state and nature of water interacting with surfactants in apolar media, we always observe an obvious inflection at the point where the mole ratio of water to surfactant is about unity. This is true for the O–H vibrational energy of water molecules in the near infrared spectra, the chemical shift and line width of water proton signal in the NMR, and the fluorescence intensity of terbium chloride. The most plausible explanation is a two step hydration mechanism.[2,15,17,20] When water is first introduced into the specific system, water tends to interact with surfactants irrespective of the presence of other polar or ionic solutes. Upon completion of the first hydration on the surfactants, water molecules start to interact with themselves by the hydrogen bonding or binding to other polar solutes cosolubilized in the interior core. Results obtained in this work coincide with those obtained in previous studies: the solvochromism of the metal(II) ion,[2,15] the hydrolysis of an amino acid ester as promoted by the copper(II) ion in the AOT/CCl_4 reversed micelles,[15,17] and the general acid-base catalysis of DAP on the hydrolysis of alkyl aryl carbonates in apolar media.[24]

We might conclude that in a very restricted field formed by reversed micelles or surfactant-water aggregates the situation closely resembles the hydrophobic pocket of enzymes or biomembranes. And also that the O–H vibrational modes of water in the near infrared region as well as the chemical shift and/or the line width of water proton resonance in NMR[4,20] can give an useful information on the tightness of the interaction of water with polar or ionic groups in the hydrophobic domain.

Professor Fredric M. Menger, Department of Chemistry, Emory University, is profoundly thanked for his reading through the manuscript and beneficial discussion. We are also grateful to Professor Syozaburo Takekiyo, Nagasaki University, for his comments.

Complex Formation and Ionization in 3,5-Dialkyl-4-hydroxybenzylidenemalononitrile in the Ground State, and Non-radiative Relaxation in the Excited State

Hiroko Mizukoshi and Michiya Itoh*

Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920

(Received May 28, 1979)

The interaction of 3,5-dialkyl-4-hydroxybenzylidenemalononitrile (HO-BMN) with ethanol, pyridine, and triethylamine in hexane gives rise to a hydrogen bonding complex formation in a low concentration of ethanol (pyridine and triethylamine) at room temperature. For ethanol concentration >5 mol dm^{-3}, the H-bonded complex exhibits further interaction with another ethanol (pyridine and triethylamine) molecule leading to the formation of anion form of this compound. However, no excited-state proton transfer was observed in several solvents. HO-BMN is fairly fluorescent in a solid solution of boric acid glass at room temperature, as well as in the rigid organic solution at 77 K, but almost non-fluorescent in fluid media at room temperature ($\phi \approx 10^{-4}$). The non-radiative process of HO-BMN in fluid media is discussed in terms of torsional relaxation of the excited state.

It was reported that 3,5-di-*t*-butyl-4-hydroxybenzylidenemalononitrile (*t*-Bu$_2$-HO-BMN) is the most potential uncoupler of oxidative phospholylation.[1,2] This is attributed to the properties of the proton transfer and conduction in phospholipid bilayer.[3] Yamaguchi *et al.* reported that the *t*-Bu$_2$-HO-BMN shows a ternary complex formation with valinomycin and potassium ion. On the other hand, this compound exhibits the dimer formation in 3-methylpentane at low temperature and the excited-state proton transfer in the dimer.[4] The unusual property of this compound seems to be attributable to the strong electron acceptor group (malononitrile) as a substituent of phenol.

This paper describes unusual spectroscopic properties of various 3,5-dialkyl-4-hydroxybenzylidenemalononitrile (HO-BMN) both in the ground and excited states. HO-BMN exhibits hydrogen bonded complex formation with ethanol (pyridine and triethylamine) in a dilute ethanol solution (*ca.* 1 mol dm^{-3}) in hexane. The ground-state ion-pair formation occurs by the further interaction between the H-bonded complex and another ethanol molecule in ethanol concentration greater than 5 mol dm^{-3}. However, no proton transfer was observed in the excited state of these compounds. Although HO-BMN shows fairly strong fluorescence in boric acid glass at room temperature and in several glassy or rigid solutions at low temperature, the compounds are almost non-fluorescent in the fluid solution at room temperature. Remarkable temperature dependence of fluorescence intensity and lifetime of the compounds dependent on rigidity of the solution was interpreted in terms of torsional relaxation of the excited state.

Experimental

The purification of materials and solvents was described.[4] Ethanol (Nakarai, 99.5%) was purified by distillation after refluxing over magnesium metal. Pyridine (Nakarai GR) and triethylamine (Nakarai GR) were distilled twice after refluxing over potassium metal for 3—5 h. Solid solution of boric acid glass was prepared as follows. Boric acid was heated and melted in a porcelain dish at 150—180 °C, transparent liquid being obtained. The samples were then dissolved into liquid glass at this temperature (the samples were stable in this process). Solid-glass solution was obtained after the temperature had fallen to room temperature.

Since materials are insoluble in aqueous solution, determination of pK_a was performed in aqueous ethanol solution (50, 40, and 30 w/v %). The pK_a in 100% aqueous solution (Table 1) was obtained by an extrapolation from values in the mixed solution.[5]

Measurement of fluorescence and absorption spectra was made as described previously.[4] Fluorescence quantum yield was determined using quinine sulfate (2.1×10^{-5} mol dm^{-3} in 0.5 mol dm^{-3} H_2SO_4) as a standard ($\phi = 0.546$ in the excitation at 365 nm).[6] Determination of fluorescence lifetimes was made by N_2 laser (Molectron UV-12) excitation and analysis of exponential decay curve. The data were analyzed by a convolution method.[4]

Results and Discussion

Complex and Ion-pair Formations in the Ground State. The absorption spectrum of 3,5-dialkyl-4-hydroxybenzylidenemalononitrile (HO-BMN) shows an absorption band at 350—370 nm in aprotic solvent and in an acidic ethanol–water mixed solution, and another band at 465 nm in basic ethanol–water. The former and the latter were attributed to the neutral form and to the anion form of the compound, respectively.[4] Absorption spectra of 3,5-dimethyl- and 3,5-di-*t*-butyl-4-hydroxybenzylidenemalononitrile (Me$_2$- and *t*-Bu$_2$-HO-BMN) were measured in hexane solution in the presence of various amounts of ethanol (Figs. 1 and 2). The spectral change of Me$_2$-HO-BMN exhibiting an isosbestic point at 345 nm indicates the complex formation between this compound and ethanol in concentration greater than 0.1 mol dm^{-3}, while the spectra exhibit a conspicuous red-shift owing to the change of solvent polarity (general solvent effect) by the addition of small amount of ethanol. In 3,5-diisopropyl-4-methoxybenzylidenemalononitrile (Pr$_2$-MO-BMN),[7] however, no significant ethanol concentration dependence of absorption spectra was detected, though a considerable red-shift of the absorption band owing to the general solvent effect was observed with increasing ethanol concentration. Thus, the electronic interaction of HO-BMN with ethanol can be attributed to the hydrogen bonding between the OH

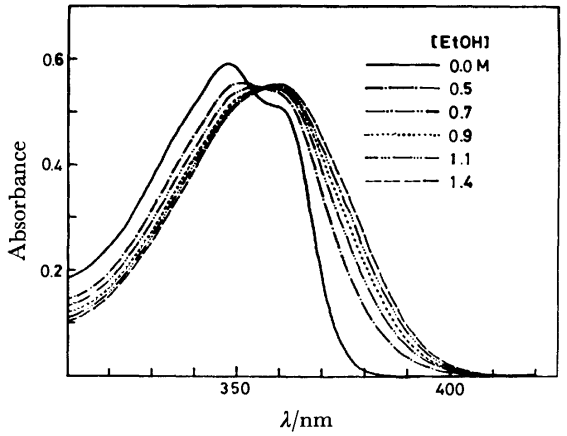

Fig. 1. Absorption spectra of t-Bu_2-HO-BMN (1.7×10^{-5} mol dm^{-3}) in hexane containing various amount of ethanol at room temperature (ethanol concentration <2 mol dm^{-3}) (1 M = 1 mol dm^{-3}).

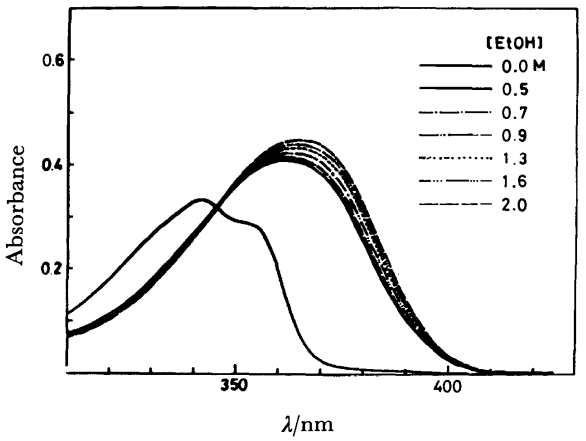

Fig. 2. Absorption spectra Me_2-HO-BMN (2.3×10^{-5} mol dm^{-3}) in hexane containing various amounts of ethanol (concentration $\simeq2$ mol dm^{-3}) (1 M = 1 mol dm^{-3}).

group in HO-BMN and ethanol molecule. With increase in ethanol concentration (>5 mol dm^{-3}), the absorption band of the H-bonded complex at 370 nm gradually decreased and another band at 465 nm appeared, increasing with an isosbestic point at 400 nm (Fig. 3). The second band corresponds to that of the anion form of the compound, mentioned above.

Here, the equilibria are expressed as follows:

$$\underset{C_f}{\text{HO-BMN}} + \underset{C_B}{\text{EtOH}} \overset{K_1}{\rightleftharpoons} \underset{C_b}{\text{H-bonded complex}}$$

$$\underset{C_b}{\text{H-bonded complex}} + \underset{C_B}{\text{EtOH}} \overset{K_2}{\rightleftharpoons} \underset{C}{\text{Anion form}}$$

$$\text{HO-BMN} + 2\,\text{EtOH} \overset{K_3}{\rightleftharpoons} \text{Anion form} \qquad (1)$$

where K_1, K_2, and K_3 are the corresponding equilibrium constants, and $K_1\times K_2=K_3$. The constants were obtained by the following equations:[8,9]

$$(\varepsilon-\varepsilon_f)/C_B = K_1\varepsilon_b - K_1\varepsilon \qquad (2)$$

$$1/C_B^2 = c/A - K_3,\ c=\text{const} \qquad (3)$$

where C_f, C_B, and C_b are the equilibrium concentrations

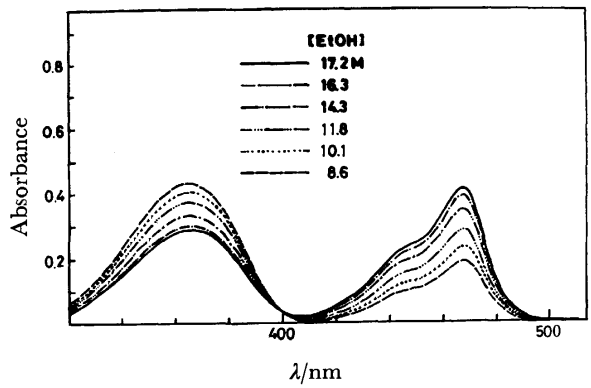

Fig. 3. Absorption spectra t-Bu_2-HO-BMN (1.7×10^{-5} mol dm^{-3}) in hexane containing various amounts of ethanol at room temperature (concentration >8 mol dm^{-3}) (1 M = 1 mol dm^{-3}).

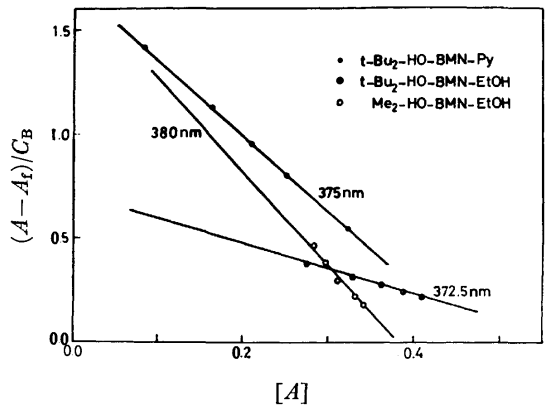

Fig. 4. Plots of $(A-A_f)/C_B$ *vs.* A, where ε and ε_f in Eq. 2 were replaced by the corresponding absorbance A and A_f, respectively (concentration of HO-BMN, 1—3 mol dm^{-3}).

of the free HO-BMN, ethanol and the H-bonded complex, respectively; and ε_f and ε_b are molar extinction coefficients of free HO-BMN and the complex, respectively; ε is apparent extinction coefficient. In Eq. 3, A is the absorbance of the anion form at 465 nm. A linear relationship of $(\varepsilon-\varepsilon_f)/C_B$ *vs.* A at 370 nm suggesting a 1:1 interaction of HO-BMN and ethanol is shown in Fig. 4. Plots of $1/C_B^2$ *vs.* $1/A$ suggesting also the reaction mechanism for the anion formation are shown in Fig. 5. The concentration dependence of the anion band at 465 nm shows remarkable deviation from Scot plots and Benesi Hildebrand plots of an ordinary 1:1 interaction between HO-BMN and ethanol molecule. Slopes of these linear plots (Figs. 4 and 5) afford equilibrium constants K_1 and K_3, respectively. The results are summarized in Table 1. Equilibrium constants K_1 and K_3 in the t-Bu_2-HO-BMN–ethanol system were determined at temperatures 5, 15, 20, and 30 °C. Conventional plots of ln K *vs.* $1/T$ showing a linear relation afford enthalpy changes of respective equilibrium ($\Delta H_1=-1.8$, $\Delta H_2=-1.0$, and $\Delta H_3=-2.8$ kcal mol^{-1}). The H-bonded complex formation of the other HO-BMN with ethanol was also observed (Table 1). Since the absorption band of the anion pair of the other HO-BMN was

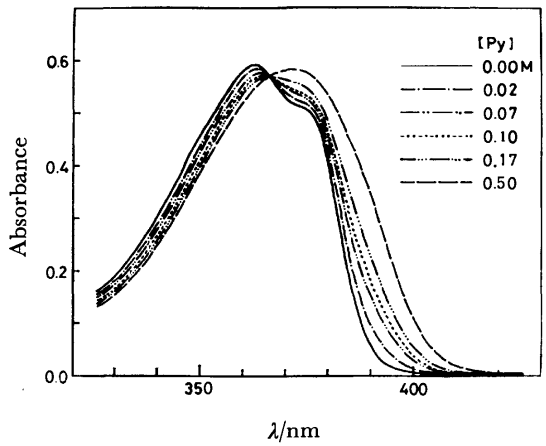

Fig. 6. Absorption spectra of *t*-Bu_2-HO-BMN (8.7×10^{-6} mol dm^{-3}) in hexane contaning various amounts of pyridine (1 M=1 mol dm^{-3}).

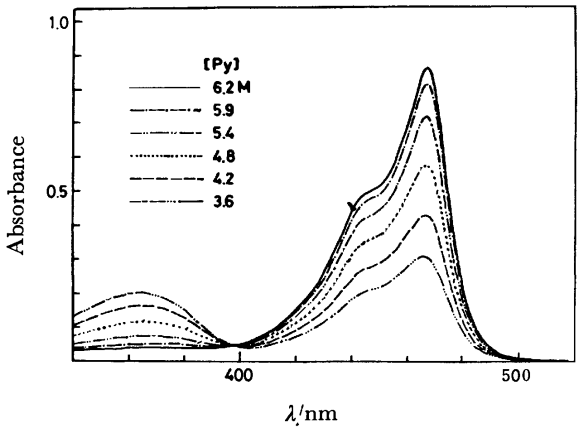

Fig. 7. Absorption spectra of *t*-Bu_2-HO-BMN (8.7×10^{-6} mol dm^{-3}) in hexane containing various amounts of pyridine (concentration >3 mol dm^{-3}) at room temperature (1 M=1 mol dm^{-3}).

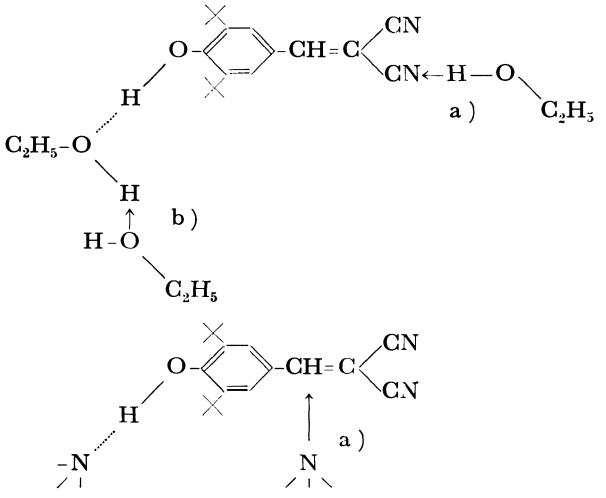
small in intensity even in ethanol, the exact equilibrium constant K_3 was not obtained.

The H-bonding formation of *t*-Bu_2-HO-BMN and further anion pair formation were also observed in the interaction with pyridine and triethylamine (TEA). Figures 6 and 7 show the absorption spectra of *t*-Bu_2-HO-BMN in hexane with various concentrations of pyridine. Similarly, plots of $(\varepsilon-\varepsilon_f)/C_B$ *vs.* A, and of $1/C_B^2$ *vs.* $1/A$ afford K_1 and K_3, respectively. In the *t*-Bu_2-HO-BMN and TEA system, the concentration dependence of TEA upon the absorption band of the H-bonded complex in hexane exhibits no significant isosbestic points because of considerable red shift with increasing concentration of TEA (<2 mol dm^{-3}). Therefore, K_1 was not obtained in this system. Figure 8 shows absorption spectra of the anion band of *t*-Bu_2-HO-BMN in various concentrations of TEA (>4 mol dm^{-3}) in hexane. It is seen that the increase of the anion band follows Scheme 1 and not the ordinary 1:1 interaction. Plots of $1/C_B^2$ *vs.* $1/A$ (Fig. 5) afford K_3 (Table 1). The constants K_3 obtained in the three systems show almost similar values, though ethanol, pyridine and TEA differ considerably in dielectric property.

Baba *et al.*[8] reported the H-bonded complex formation between *p*-nitrophenol and TEA in several solvents, and subsequent proton transfer in the ground state. The proton transfer *i.e.*, anion pair formation of phenol in the H-bonded complex, takes place from nitrophenol to amine to yield a H-bonded ion pair, no further concentration dependence of amine upon the ion pair formation being detected. In these HO-BMN–ethanol, –pyridine, and –TEA systems, another ethanol (pyridine and TEA) molecule is involved in the ion pair formation from the H-bonded complex. The concentration dependence of the anion formation might be ascribed to the change of the dielectric property of the solvent system by the addition of ethanol (dielectric constant, ε=24.6),[10,11] pyridine (12.4) and TEA (2.42) in the hexane solution (1.88). However, the results of the anion pair formation in the interaction with three proton acceptors do not seem to be correlated with their dielectric constants. This shows that the ionization of the H-bonded complex can be attributed to a specific interaction between the complex and ethanol (pyridine and TEA) molecule.

Hoshino and Koizumi[12] reported a two-step interaction of ethanol molecule with *p*-amino- and *p*-dimethylaminobenzophenone in cyclohexane. They suggested the interactions of one ethanol molecule to the NH_2 group (or $N(CH_3)_2$) and one molecule to C=O of these compounds. The first specific interaction of ethanol with HO-BMN is ascribed to the hydrogen bonding with OH group, since ethanol, as well as TEA and pyridine, is a proton acceptor. In the interaction of the second ethanol molecule leading to the ion pair formation, there seem to be two possibilities: (a) a specific interaction of another ethanol molecule with malononitrile group, and (b) further interaction of the second ethanol molecule with an oxygen atom of the H-bonded OH group of HO-BMN or with a hydrogen atom of the first ethanol. However, since TEA and pyridine exhibit almost the same behavior as ethanol, (a) seems preferable.



Fluorescence and Non-radiative Process. The neutral and anion forms of HO-BMN show very weak fluorescence spectra in 410—430 and 460—500 nm regions, respectively, at room temperature. The fluorescence intensity of the neutral form exhibits no

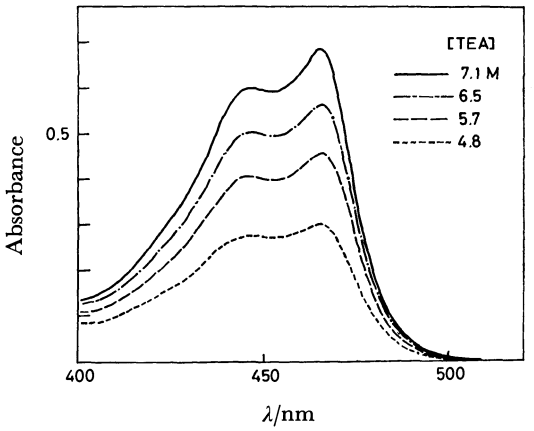


Fig. 8. Absorption spectra of *t*-Bu_2-HO-BMN in hexane containing various concentrations of TEA at room temperature (concentration of *t*-Bu_2-HO-BMN, 3.7×10^{-5} mol dm^{-3}) (1 M=1 mol dm^{-3}).

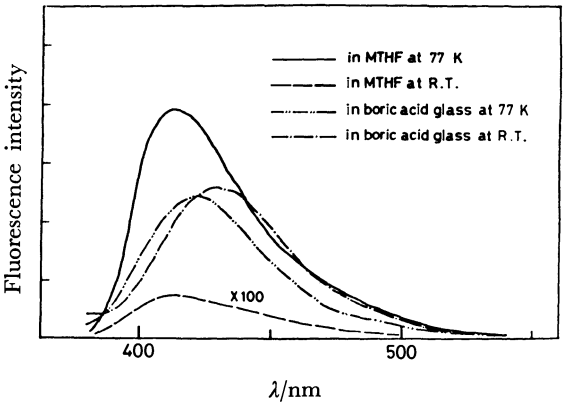

Fig. 9. Fluorescence spectra of *t*-Bu_2-HO-BMN in 2-methyl-tetrahydrofuran and in boric acid glass; Intensities are arbitrary unit.

significant difference between free (λ_{max} 410 nm in hexane) and H-bonded HO-BMN (λ_{max} 430 nm in ethanol). Fluorescence quantum yields of HO-BMN (neutral form) and MO-BMN in several solvents were determined approximately to be $1—5\times10^{-4}$ at room temperature. The fluorescence intensity of these compounds in various solvents remarkably increased with decreasing temperature at 150—77 K. Figure 9 shows fluorescence spectra of *t*-Bu_2-HO-BMN (neutral form) in MTHF, at 77 K and at room temperature. Figure 10 shows the temperature dependence of fluorescence intensity of *t*-Bu_2-HO-BMN in various solvents. Fluorescence intensity of *t*-Bu_2-HO-BMN increased in the temperature region below $\approx$100 K in MTHF and in methylcyclohexane (MCH). However, in 3-methylpentane–MCH mixed system (1:3), it increased markedly at temperatures below $\approx$90 K. A similar temperature dependence of fluorescence was also observed in MO-BMN. The temperature region in which fluorescence intensities increase seems to correspond to the increase of solvent rigidity (viscosity) from fluid to rigid glass. In order to confirm the influence of the rigidity of solution on fluorescence intensity, the fluorescence spectrum of HO-BMN in the solid solution of boric acid glass was determined at room temper-

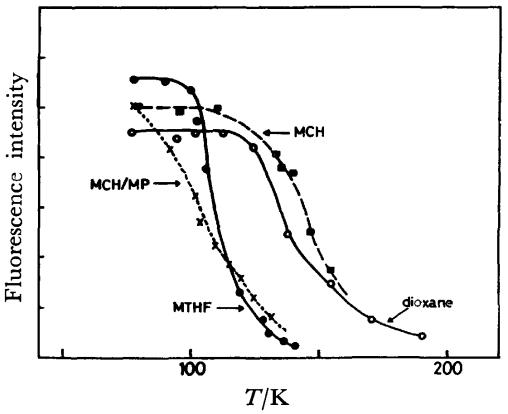

Fig. 10. Temperature dependence of fluorescence intensity (arbitrary unit) of t-Bu_2-HO-BMN in various solvents.

ature.[13] The spectrum shows fairly strong fluorescence at room temperature (Fig. 9), but no significant temperature dependence. Fluorescence lifetimes of these compounds in various solvents were determined to show also remarkable temperature dependence. The lifetimes in the rigid glass at 77 K are 1—3 ns (Table 1), while those decrease to within a duration of a laser pulse in fluid medium at 100—150 K. Fluorescence lifetimes of these compounds may be in the order of picosecond at room temperature.

Semi-empirical molecular orbital calculation (Pariser-Parr-Pople type) indicates that the first electronic transition of HO-BMN as well as MO-BMN is allowed, corresponding to an absorption band at 340—360 nm. Thus, natural radiative lifetimes τ_0 of these compounds were obtained as $1—3\times10^{-9}$ s (in ethanol, THF, and hexane) from absorption bands at 340—360 nm. The lifetimes of these compounds were estimated to be $10^{-12}—10^{-13}$ s from fluorescence quantum yield ($\approx10^{-4}$) and τ_0 ($\approx10^{-9}$ s). This suggests that the decay process of the compounds is mostly non-radiative. In the non-radiative process of HO-BMN in fluid medium, there are two possible mechanisms: (a) the excited-state proton transfer of OH group leading to the anion formation, *i.e.*, a photoionization, and (b) a torsional non-radiative relaxation process of the excited state.[14] (a) is ruled out from similar fluorescence behavior of MO-BMN to HO-BMN. Thus, (b) can be attributed to the non-radiative process, since the torsional non-radiative process seems to be frozen out in rigid solution at 77 K and in the boric acid glass at room temperature.

Hui and Rice reported a torsional non-radiative process in the excited state of styrene.[15] The non-radiative process of styrene consists of $S_1\rightarrow T_1$ and cis-trans isomerization, suggesting a plausible schematic potential energy surface for the torsional motion that leads to cis-trans isomerization. On the other hand, El-Bayoumi reported torsional relaxation of the excited state of 1,1,4,4-tetraphenylbutadiene (TPB).[16] In fluid media, TPB exhibits large Stokes shifts and their fluorescence spectra are diffuse, while the fluorescence maximum shifts to higher energy, and the vibrational structure being resolved by preventing this torsional relaxation in the rigid medium at low temperature. In HO-BMN, however, no longer-wavelength fluorescence corresponding to the large Stokes shift was observed in fluid medium. If the torsional equilibrium of S_1 state of this compound is in a low level and the intersystem crossing from S_1 to T_1 is predominant in the decay process, no fluorescence would be observed. According to this argument, HO-BMN dimer (or MO-BMN) as well as the double proton transfer species (or the excimer) should be fluorescent.[4] This is becuase the torsional relaxation in a component molecule of the dimer can be prevented by its sandwich-type structure. However, no exact potential energy curves concerned with C–C bond rotations of malononitrile double bond and of phenyl-malononitrile single bond were obtained at the present stage.

The authors wish to thank Dr. Kiyokazu Fuke for his valuable discussion on torsional non-radiative relaxation. The work was partly supported by a Grant-in Aid from the Ministry of Education.

Topological Ligand Design. II. The Definition and Derivation of Extended and Complex Ligand Graphs*

Susumu TAKAMOTO

Department of Chemistry, Faculty of Sciences, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

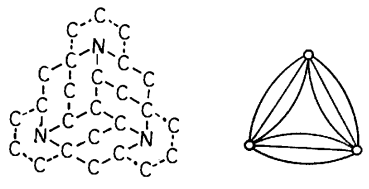
(Received June 16, 1979)

An extended ligand graph is a set of several points corresponding to donor atoms, where each pair of points is connected by *n* lines when these atoms are able to form *n* chelate rings with a metal ion. These graphs can cover all the ligands, but they may not express the geometrical patterns of some complicated ligands clearely enough for them to be discriminated. A complex ligand graph is a set of some main points and sub-points connected by sub-lines, where the main points, sub-points, and sub-lines correspond to donor atoms, carbon atoms forming chelate bonds, and chemical bonds among them respectively. All the complex ligand graphs can then be systematically derived from donor-atomic graphs, which are composed of only main points and main lines and are equivalent to the simple ligand graphs previously designed. Another designing method of ligands is proposed for a certain coordination sturcture. A complex ligand graph to which no more sub-points or sub-lines can be added is called a parent ligand graph. Then all the complex ligand graphs for such a coordination are derived from the parent ligand graphs by neglecting some sub-points or by removing some sub-lines successively.

In the previous paper[1] a simple ligand graph was defined and all of the lower members were systematically derived. This is one of the most useful methods for designing and classifying ligands and can bring us various information about future ligands. However, it cannot cover some kinds of ligands containing special kinds of branched carbon atoms, where branches form their several chelate rings with a metal ion, since any branch point in a simple ligand graph should be not a carbon atom, but a donor atom. To cover these complicated ligands, the definition of the ligand graph must be further extended.

Theoretical

Extended Ligand Graph. An "extended ligand graph" is a set of several points corresponding to donor atoms, where each pair of points is connected by *n* lines when these atoms are able to form *n* chelate rings with a metal ion. For example, a complicated terdentate ligand (A) in Fig. 1 is expressed by the



(A) (B)

Fig. 1. An example of the extended ligand graph. (A): Ligand, (B): its extended ligand graph.

extended ligand graph (B); some carbon chains connected by broken lines are neglected in this graph, because they cannot become the chelate ring. Therefore, branched carbon atoms may be commonly used for different chelate rings. These extended ligand graphs may contain some double or triple lines; the maximum degree of their points is nine, since every pair of points may have triple lines. They can represent all the chelate ligands and can be derived systematically

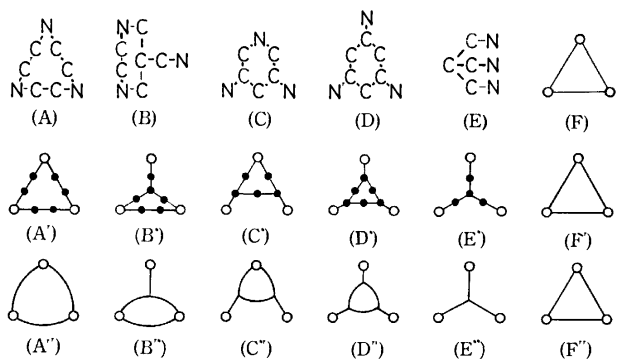


Fig. 2. Various graph expressions for some ligands. (A) to (E): ligands, (F): their extended ligand graph, (A′) to (E′): their several complex ligand graphs, (A″) to (E″): their several complex pattern graphs, (F′) and (F″): their composite pattern and donor-atomic graph.

from the simple ligand graphs by substituting some of their lines for double or triple lines. However, they do not express the geometrical patterns of complicated ligands well enough for them to be discriminated. For example, the ligands from (A) to (E) in Fig. 2 are expressed by the same extended ligand graph (F). In order to correct this defect, a complex graph should be applied which is a set of main points and main lines, with each main line also a graph composed of sub-points and sub-lines.

Complex Ligand Graph. A "complex ligand graph" is a set of several main points and sub-points connected by sub-lines, where the main points, sub-points, and sub-lines correspond to donor atoms, carbon atoms forming chelate bonds, and chemical bonds among these atoms respectively. Examples of the complex ligand graphs are shown as (A′) to (E′) in Fig. 2. The degree of the main points does not exceed three, while that of the sub-points is only two or three, since no carbon atom can be an end-point. The complex ligand graph contains neither multiple sub-lines nor self-loops, and is naturally a connected planar graph as well as a simple ligand graph.

On the complex ligand graph, a graph-theoretical path between two main points containing only two

* A preliminary report on this work was presented at the ACS/CSJ Chemical Congress, Honolulu, April 1979.

or three sub-points is called a "chelate path." For example, every N–C–C–N or N–C–C–C–N chain of the ligands in Fig. 1 or Fig. 2 is a chelate path. Accordingly, each line on an extended ligand graph corresponds to a chelate path. Every main point is a common terminal point of a maximum of nine chelate paths; this is obvious from the maximum degree of the points in the extended ligand graph. Every sub-point belongs to one, two, or three chelate paths.

When all the sub-points of degree two are neglected in a complex ligand graph, what is left is called a "complex pattern graph" and its lines are called a "series"; these definitions are equivalent to those in the simple ligand graph. Some examples are shown in Fig. 2, (A″) to (E″).

Then new terms are defined in order to derive these complex graphs from some simpler, non-complex graphs which have already been designed. When a pair of main points have at least one chelate path, they are connected by a "main line," while a set of several main points connected by several main lines is called a "donor-atomic graph," which is quite equivalent to the simple ligand graph, since it has neither sub-points, sub-line, multiple-line, nor self-loop. As the main line is not related to the number of the chelate paths or the branched carbon atoms contained in it, all the ligands in Figs. 1 and 2 can be represented by the same trigonal-shaped donor-atomic graph, as is shown in Fig. 2 (F″).

When several chelate paths between each pair of main points in a complex pattern graph are observed, there are four kinds of simple patterns (shown in Fig. 3) as far as ligands for five- or six-membered chelate rings are concerned; they are called "unit patterns." The (A), (B), (C), and (D) unit patterns contain one, two, two, and three chelate paths respectively.

(A) (B) (C) (D)

Fig. 3. Unit patterns.

When each main line of a donor-atomic graph is displaced by one of the unit graphs, the complex graph thus produced is called a "composite pattern." As each main line in the complicate ligand in Fig. 1 contains three chelate paths, for example, the composite pattern for this ligand is obtained by displacing three main lines by the unit pattern (D) in Fig. 3. For the ligands from (A) to (E) in Fig. 2, their composite patterns are represented by the same trigonal graph (F′), which is identical to their donor-atomic graph (F″), since every main line contains only one chelate path; its unit pattern is the same as (A) in Fig. 3.

A composite pattern is not always identical to its complex pattern graph, for two adjacent unit patterns have some common sub-lines and sub-points. For example, all the ligands in Fig. 2 have the same composite pattern (F′); however, they are represented by several complex pattern graphs, (A″) to (E″), because they have different parts in common. In these complex pattern graphs in Fig. 2, the common parts of the unit patterns are expressed by straight lines, and the others, by curved lines.

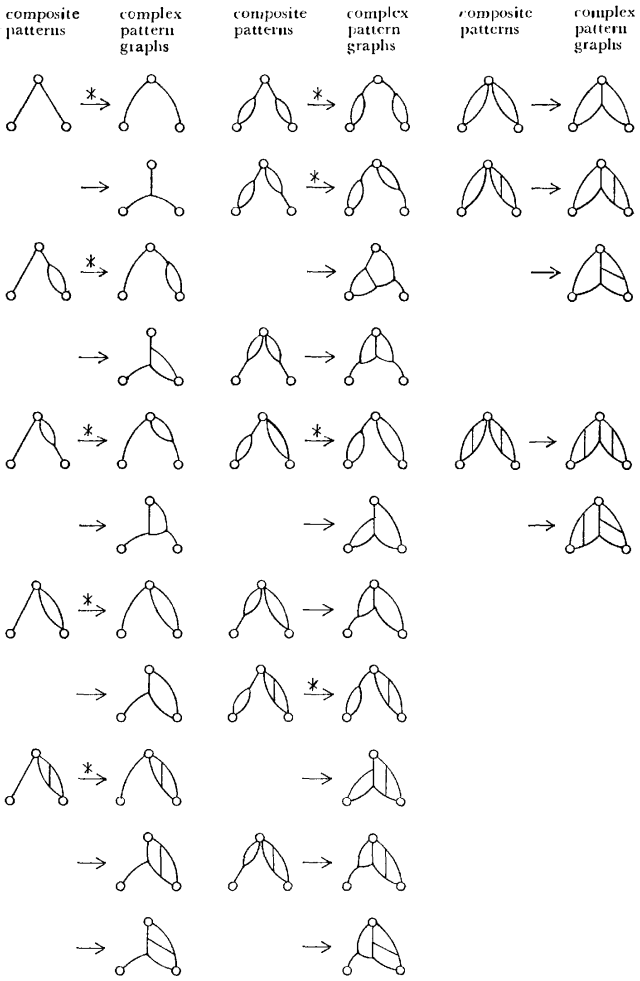

Fig. 4. Condensations between two unit patterns.
*: Without condensation.

Thus, a new concept of "condensation" should be introduced; it means a partial fusing of two patterns, as when the condensation of two benzene rings produces a naphthalene frame. All the condensations between a pair of adjacent unit patterns are summarized in Fig. 4. By various combinations of four kinds of unit patterns, many composite patterns are obtained from a donor-atomic graph, and by various condensations among the unit patterns, further, more complex pattern graphs are obtained. The condensation is not always necessary, but if the degree of a main point exceeds three in a composite pattern, the condensation must not be neglected.

Finally, the complex ligand graphs can be derived by allotting some sub-points of degree two to some series of a complex pattern graph, so that each chelate path may have two or three sub-points. Thus, all the complex ligand graphs can be obtained systematically from the donor-atomic graphs, which have already been designed.

On the contrary, any ligands can be reduced to their donor-atomic graphs. For example, a complicated quadridentate ligand (A) in Fig. 5 is represented

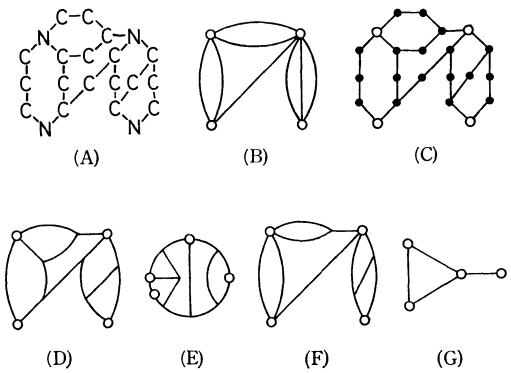

Fig. 5. Reduction of a ligand structure into its donor-atomic graph. (A): Ligand, (B): extended ligand graph, (C): complex ligand graph, (D): complex pattern graph, (E): its schematical illustration, (F): composite pattern, (G): donor-atomic graph.

by both the extended ligand graph (B) and the complex ligand graph (C). Then, (C) is reduced to the complex pattern graph (D) by neglecting all the sub-points of degree two. (E) is a schematical illustration of (D). When all the condensed chelate paths in (D) are separated into the unit patterns, its composite pattern (F) is obtained. Finally, (F) is reduced to its donor-atomic graph (G) by substituting each unit graph for a main line.

Ligand Design for a Certain Coordination Structure. The above derivation method for the complex ligand graphs is sufficiently systematic and can cover all of these graphs, but a ligand graph derived mechanically cannot always fit a special coordination structure, and in a computer manipulation it is not easy to select them. Furthermore, one often needs knowledge about all the ligands for a special coordination, such as octahedral, tetrahedral, or square planar.

When all the donor-atomic graphs which are fit for such special coordination are found, all the composite patterns, complex pattern graphs, and complex ligand graphs may be derived successively. The donor-atomic graphs for any planar coordinations are always only linear or circular graphs, while those for tetrahedral or octahedral coordination are equivalent to all the simple ligand graphs with $m=4$ or $m=6$, as was illustrated in Table 3 in the previous paper.[1] Therefore, all the ligands for such purposes may be designed by the above-described procedure, but they may still contain some useless ligands which cannot coordinate to a metal ion easily because of intricate carbon-chains. Therefore, an alternate designing method for these complex ligand graphs will be proposed.

In a certain coordination structure, a complex ligand graph to which no more sub-points or sub-lines can be added, *i.e.*, a high density complex graph, is called a "parent ligand graph." Several kinds of parent ligand graphs may exist in each coordination structure. If all of them are found, all the complex ligand graphs for such a coordination can be derived as their "daughter ligand graphs" by neglecting some sub-points or removing some sub-lines.

Planar Coordinations: The donor-atomic graph of the parent ligand graphs for an n-polygonal planar coordination is an n-polygonal graph. These parent ligand graphs are, then, obtained by displacing each edge of the n-polygon with one of the three "linear unit graphs" shown in Fig. 6. This procedure is similar to that used in deriving the composite patterns, but these unit graphs contain three sub-points of degree two or three on each chelate path. In this case, the condensation between two unit graphs would not occur, since two unit graphs surrounding a metal ion cannot approach each other so closely. For example, all the parent ligand graphs for the square planar coordination can be obtained by the combination of four unit graphs, so that every main point may have degree three as is shown in Fig. 7.

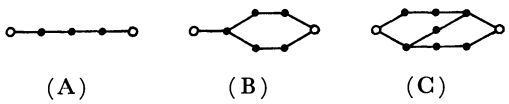

Fig. 6. Linear unit graphs.

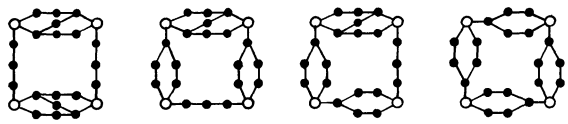

Fig. 7. Parent ligand graphs for the square planar coordination.

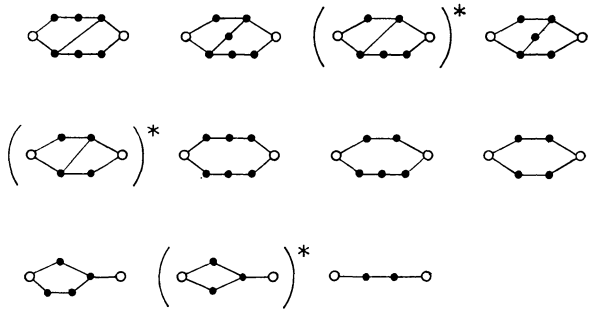

Fig. 8. Daughter unit graphs for the planar coordination. *: Omitted here because of containing less than five-membered ring.

In order to derive the daughter ligand graphs, all the "daughter unit graphs" of three unit graphs are found by neglecting sub-points or removing sub-lines from the unit graphs, as is shown in Fig. 8. Then a circular daughter ligand graph might be derived by substituting each edge of the n-polygon for one of those daughter unit graphs. All the linear daughter ligand graphs are derived by removing one unit graph or one daughter unit graph from those circular daughter ligand graphs and parent ligand graphs.

Polyhedral Coordinations: An m-polyhedron is covered with mn-polygons (sometimes different polygons). Then its parent ligand graphs are obtained when every surface is covered by n-polygonal unit graphs, with condensations on some edges. As a popular example, a tetrahedron or an octahedron is covered with four or eight equilateral triangles. The parent ligand graphs for such coordination are derived by covering all surfaces with five kinds of trigonal unit graphs, as is shown in Fig. 9.

The adjacency of two trigonal unit graphs is geo-

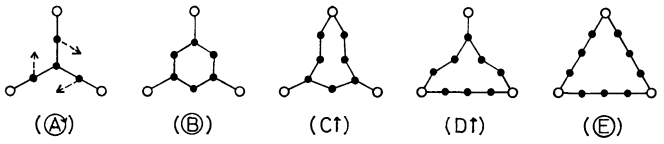

Fig. 9. Trigonal unit graphs.

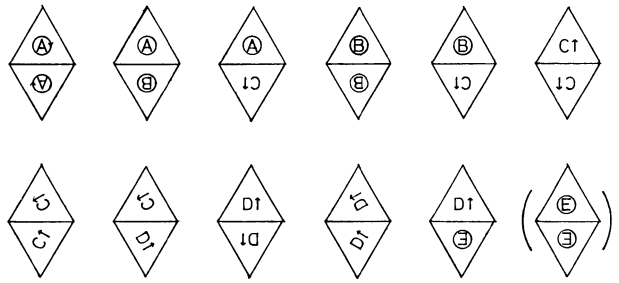

Fig. 10. Adjacency of two trigonal unit graphs.

metrically restricted. Every edge of the (A), (B), or (E) unit graph in Fig. 9 is equivalent by symmetry, but (C) or (D) has two kinds of edges. When two (A) graphs are adjacent, new sub-point and sub-lines are added along the arrow. The two rotational isomers of (A) were neglected here. All the possible geometries for a pair of adjacent unit graphs are shown in Fig. 10. As the unit graph (E) has less density, it can be used for the parent ligand graph only when it is surrounded with three unit graphs (D). Therefore, (E)-(E) adjacency is of no use, although possible geometrically.

Under these conditions, nine parent ligand graphs for the tetrahedral coordination are obtained, as is shown in the development diagrams in Fig. 11. They all have quite rigid cage structures in spite of being composed of three-membered carbon chains. If their metal chelates could ever be prepared, the cations would be spherical with a extreme stability and quite a hydrophobic nature.

Similar procedures can be applied to other polyhedral coordinations covered by any polygons other than a triangle when proper unit graphs for such polygon have been constructed. Furthermore, this method is also applicable to the polynuclear coordinations, since they are considered to be combined polyhedral coordinations.

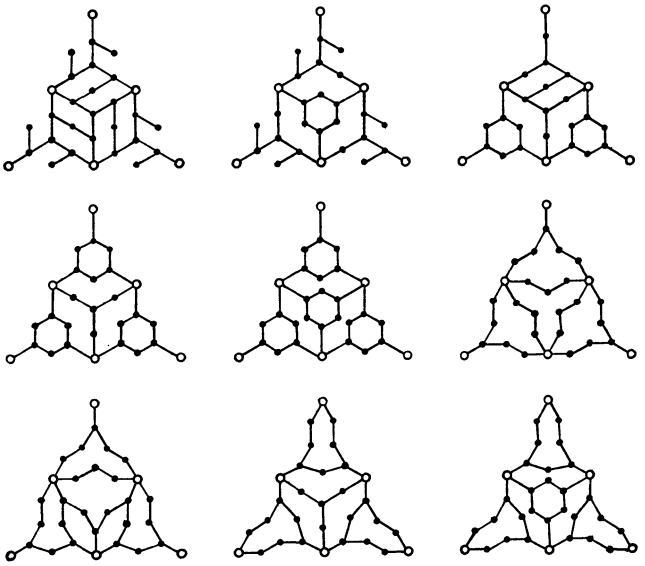

Fig. 11. Parent ligand graphs for the tetrahedral coordination.

The author wishes to express his thanks to professor Takeshi Iizuka of Gunma University and Mr. Nobuhide Tanaka of Gakushuin University for their valuable suggestions and discussions. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Solution Properties of Phycocyanin. VI. The Characterization of the Phycocyanin Monomer†

Takahide Saito, Naomichi Iso,* Haruo Mizuno, Fumiaki Ozeki, and Yoshiyuki Matsui

Department of Food Science and Technology, Tokyo University of Fisheries, Konan, Minato-ku, Tokyo 108

(Received July 7, 1979)

The monomer molecular weight of phycocyanin was determined by sedimentation equilibrium measurements in 6 mol/l guanidine hydrochloride (GndCl) and by sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis. The former measurement gave the monomer molecular weight of 4.0×10^4. From the latter, the phycocyanin was found to be composed of two kinds of subunits, the molecular weights of which were 1.7×10^4 and 2.0×10^4. Assumimg that the phycocyanin monomer consists of two polypeptide chains, the molecular weight becomes 3.7×10^4. These values coincide with the value of 4.2×10^4 assumed in our previous works, which corresponds to one-sixth of the hexamer molecular weight. The sedimentation coefficient, s_{25w}, was 2.21 Svedberg unit, and the intrinsic viscosity in 6 mol/l GndCl was 19.5 ml/g, at 25.0 °C. From these values, it was clear that the phycocyanin monomer was unfolded in the solvent.

Phycocyanin, isolated from red- or blue-green algae, undergoes reversible self-associating reactions according to changes in the environment, such as in the pH, the ionic strength, the temperature, and the protein concentration of the solution.

In our previous papers,[1,2] we postulated, on the basis of the results of the sedimentation equilibrium measurements at various temperatures, that the dissociation-association behavior of phycocyanin could be explained by assuming a monomer⇌trimer⇌tetramer equilibrium system at pH 6.8 and the ionic strength (I) of 0.1. On the other hand, the dissociation-association of the same sample at pH 5.4 and I 0.1 was determined to follow a monomer⇌hexamer equilibrium system. The approach used in the estimation of the equilibrium constant from the centrifugal data requires the value of the monomer molecular weight, M_1. The molecular weight of the phycocyanin hexamer has been obtained as 2.56×10^5 from osmotic measurements at pH 5.4 and I 0.1.[3] However, the value of M_1 could not be determined in aqueous solutions because of the dissociation behavior in a lower-concentration region and because of the association behavior in a higher-concentration region. Thus, the value of 4.2×10^4 was assumed for M_1 in the previous works; this value corresponds to one-sixth of the value of 2.56×10^5 for hexamer.

This work was undertaken in order to decide the molecular weight of the phycocyanin monomer experimentally. For this purpose, two methods were employed; sedimentation equilibrium measurements in 6 mol/l guanidine hydrochloride (GndCl) and the sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis. Moreover, the sedimentation coefficient and the intrinsic viscosity were measured in 6 mol/l GndCl.

Experimental

Protein Preparation. The crystalline phycocyanin from *Porphyra tenera* used in this study was isolated and purified as has been described previously.[4] The proper amount of GndCl was dissolved in phycocyanin phosphate buffer solution, the pH of which was 6.8 and with I value of 0.1. The solution was dialysed against a GndCl–phosphate buffer (pH 5.4, I 0.1) at 5 °C for 72 h. The concentration of GndCl in the external solution was then adjusted to be the same as that of the phycocyanin solution. The external solution was used as a solvent in this work.

Sedimentation Equilibrium Measurements. The sedimentation equilibrium experiments were performed with a Hitachi Model UCA-1 ultracentrifuge using interference optics. The rotor speed was set at 19780 rpm, and the temperature was maintained at 25.0 °C. All the runs were made at that speed for approximately 24 h so as to ensure that an equilibrium was established in a liquid column of 1.5 mm. Since the solution has a blue color, it was difficult to decide the fringe numbers at the cell bottom exactly. Therefore, the Nazarian method[5] was used for the determination of the molecular weight from sedimentation interference patterns. According to the Nazarian method, the apparent molecular weight, M^a, is given by the following equation:

$$M^a = \frac{2RT}{(1-\bar{v}\rho)\omega^2}\frac{\mathrm{d}\ln \Delta_Q J}{\mathrm{d}(r^2)},$$

where R is the gas constant; T, the absolute temperature; $\bar{v}$, the partial specific volume of the solute; ρ, the density of the solvent; ω, the angular velocity of rotation, and r, the radial distance from the axis of rotation. $\Delta_Q J$ is the displacement of a fringe in the distance of the fixed Q and indicates the number of fringes crossed in traversing the interference pattern from r^2 to r^2+Q.

Sedimentation Velocity Measurements. The sedimentation velocity experiments were performed with the same ultracentrifuge as was used in the sedimentation equilibrium experiments, although Schlieren optics were used instead of the interference optics in those measurements. In all runs the rotor speed was set at 51200 rpm, and the temperature was maintained at 25.0 °C. The synthetic boundary cell was used, since the actual sedimentation rates of the solute were quite slow in 6 mol/l GndCl. The sedimentation coefficient, s, is represented by the following equation:

$$s = \frac{\ln(r_p/r_m)}{\omega^2(t-t_0)},$$

where r_p is the boundary position measured from the second moment of the refractive index gradient; r_m, the position of the meniscus; t, the time, t_0, the initial time correction.

Partial Specific Volume. The partial specific volume of phycocyanin in 6 mol/l GndCl was calculated by the

† Some of the experimental results in this paper were presented at the 28 th Annual Meeting of The Society of Polymer Science, Japan, Tokyo, May 1979.

usual method from the densities of the solvent and solutions at 25.0 °C; using the solvent density of 1.1426 g/ml, the value of 0.746 ml/g was thus obtained. The densities were measured with a Shibayama Densimeter, SS-D-200 Ext. Type.

SDS-Polyacrylamide Gel Electrophoresis. The SDS–polyacrylamide gel electrophoresis was done by the Weber-Osborn procedure.[6] The phycocyanin sample was incubated at 37 °C for 2 h in a 0.01 M sodium phosphate buffer, 1% in SDS, and 1% in 2-mercaptoethanol. The gel buffer was a 0.1 M sodium phosphate–1% SDS solution. Electrophoresis was performed at a constant current of 8 mA per gel. The proteins used as the references were obtained from Boehringer Marnheim: cytochrom C (molecular weight M=12500), chymotrypsinogen A (M=25000), ovalbumin (M=45000), and bovine serum albumin (M=67000).

Viscosity Measurements. The viscosity measurements were made with an Ubbelohde dilution-type viscometer. Kinetic energy corrections were not made. The intrinsic viscosity was obtained by using Huggins' equation.

Results and Discussion

Figure 1 shows the absorption spectra of phycocyanin at various concentration of GndCl. From Fig. 1, the denaturation of phycocyanin may be considered to be complete in a 1 mol/l GndCl solution. On the basis of these results, the concentration of GndCl of 6 mol/l was used in the sedimentation measurements and the viscosity measurements in this work.

Figures 2 and 3 show the results of the sedimentation equilibrium measurements. Plot of ΔJ (the displacement of a fringe) *versus* r^2 is shown in Fig. 2. The $\Delta_Q J$'s were estimated by selecting the Q value of 1 cm^2; they are plotted against r^2 in Fig. 3. As is shown, the plot is linear, and the apparent molecular weight, M^a can be estimated from the slope of the plot. As Ohta and Kawahara[7] have pointed out, the monodispersity of the solute cannot be decided even if the Nazarian plot is linear, and the molecular weight thus calculated is the z-average molecular weight in the case of a polydisperse solute. In this work, the sample was assumed to be monodiperse in the denaturated solvent. The reciprocals of M^a thus obtained are plotted against the protein concentration, c, in Fig. 4. The true molecular weight of the phycocyanin monomer could be estimated by the linear extrapolation of the plot to infinite dilution; the molecular weight of 4.0×10^4 was obtained. In previous studies, the monomer molecular weight was assumed to be 4.2×10^4, a value arrived at on the basis of the results of the osmotic measurements performed at pH 5.4 and I 0.1; this value was about one-sixth of the molecular weight of the phycocyanin hexamer. The assumed value coincides with the value of 4.0×10^4 obtained in this work.

The results of the SDS–polyacrylamide gel electrophoresis are shown in Fig. 5. The mobility, R_f, was calculated by using the following equation:

$$R_f = \frac{\text{distance of protein migration}}{\text{length after destaining}} \times \frac{\text{length before staining}}{\text{distance of dye migration}}$$

The electrophoresis pattern of the phycocyanin sample

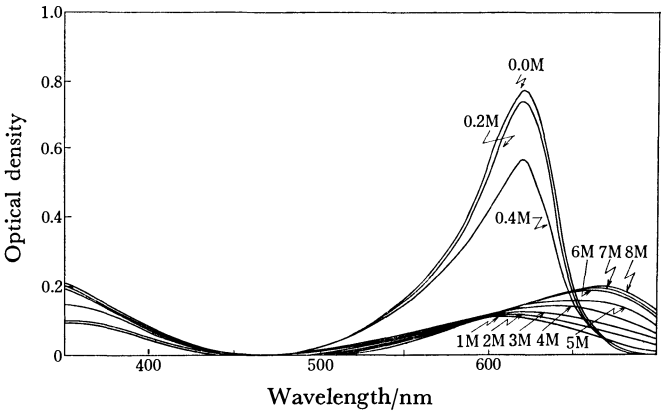

Fig. 1. The absorption spectra of phycocyanin at various concentrations of GndCl.

shows two bands, the quantities of which are nearly equivalent. Several investigators have reported that the phycocyanin monomer consisted of two kinds of subunits. For example, Glazer and Fang[8] reported that the phycocyanin from a blue-green alga (*Synechococcus sp.*) was composed of an α subunit (molecular weight, 1.77×10^4) and a β subunit (molecular weight, 1.9×10^4). The molecular weights of the two kinds of

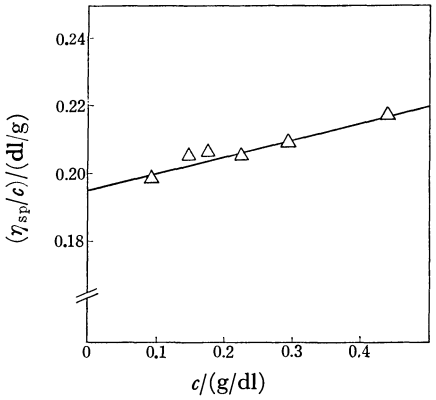

Fig. 7. A plot of η_{sp}/c *versus* c.

subunits in this work were calculated to be 1.7×10^4 and 2.0×10^4 on the basis of the data in Fig. 5. Assuming that the phycocyanin monomer is composed of two polypeptide chains, the molecular weights of which are 1.7×10^4 and 2.0×10^4, the molecular weight of the monomer becomes 3.7×10^4. The value of 3.7×10^4 corresponds to the value of 4.0×10^4 obtained by the sedimentation equilibrium measurements. The results show that the assumption that the phycocyanin monomer is composed of the two subunits is reasonable. In view of the fact that the sedimentation equilibrium measurements form an absolute method for the determination of the molecular weight, the monomer molecular weight of the phycocyanin should be 4.0×10^4.

The hydrodynamic measurements, sedimentation velocity measurements and viscosity measurements will be described below.

All of our sedimentation velocity patterns showed a single peak. Figure 6 shows the sedimentation coefficient of phycocyanin as a function of the protein concentration. From Fig. 6, the values of the sedimentation coefficient at an infinite dilution, s_0, and the concentration-dependence coefficient, k_s, were determined to be 0.88 S (Svedberg unit) and 1.53 respectively. The value of s_{25w}, the s-value in water at 25 °C, was calculated to be 2.21 S by the usual method.

The viscosity data for phycocyanin in 6 mol/l GndCl at 25.0 °C are shown in Fig. 7. The intrinsic viscosity, $[\eta]$, was determined by the linear extrapolation of the plot of η_{sp}/c, where η_{sp} is the specific viscosity and where c is the concentration of phycocyanin. From this extrapolation, the values of $[\eta]$ and of the Huggins' constant, k', for the phycocyanin monomer in 6 mol/l GndCl at 25.0 °C were found to be 19.5 ml/g and 1.29 respectively.

The Scheraga and Mandelkern parameter, β, was calculated by means of the following equation;

$$\beta = \frac{N_A s[\eta]^{1/3}\eta_0}{M^{2/3}(1-\bar{v}\rho)},$$

where N_A is the Avogadro number and η_0, the solvent viscosity (1.481×10^{-2} poise). The β-value of 2.6×10^6 was obtained for the phycocyanin monomer in 6 mol/l GndCl. Jennings[9] proposed a monomer model which was a prolate ellipsoid 35 Å in diameter and 105 Å in length. On the basis of this monomer model, the s- and $[\eta]$-values have been calculated to be 3.5 S and 4.2 ml/g respectively.[3] Using the s- and $[\eta]$-values, 2.0×10^6 is calculated for the β-value. The discrepancy of the β-values may be attributed to the fact that the conformation of the phycocyanin monomer in 6 mol/l GndCl was different from that of the monomer model proposed by Jennings; that is, the protein in 6 mol/l GndCl can be considered to be unfolded and to be expanded hydrodynamically.[10]

Reflection Spectrum of the Single Crystal of Wurster's Blue Perchlorate

Yasushi Iyechika, Kyuya Yakushi, and Haruo Kuroda*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 9, 1979)

The visible and near-infrared reflection spectrum of the single crystal of Wurster's blue perchlorate was measured at various temperatures over the range of 30—300 K, by using the microspectrophotometric method. The absorption spectra were derived by Kramers-Kronig transformation of the reflection spectra. The intensity ratio of the (0-0) and (0-1) vibronic bands of the local-excitation associated with the π-π^* ($^2B_{1u} \leftarrow {}^2B_{2g}$) transition of $TMPD^+$ was found to be anomalous when the spectrum was measured with the light polarized parallel to the b-axis, while not in the spectrum polarized parallel to the a-axis. The Davydov splitting between B_{3u} and B_{2u} components of this absorption band was found to be about 400 cm^{-1}. In the antiferromagnetic (low temperature) phase below 190 K, the charge-transfer band appeared in the a-axis spectrum, showing its absorption maximum at 11.6×10^3 cm^{-1}, and its intensity increased on lowering the temperature. At the same time, a marked temperature dependence was observed in the local-excitation band. These changes are interpreted in terms of the singlet-triplet model of the dimeric interaction of $TMPD^+$ ions in the low-temperature phase.

N,N,N',N'-Tetramethyl-*p*-phenylenediamine perchlorate (Wurster's blue perchlorate, WBP) is a well-known example of stable cation radical salts, of which magnetic behaviors have been extensively studied.[1-8] This salt exhibits a phase transition between the paramagnetic (high-temperature) phase and the antiferromagnetic (low-temperature) phase, the specific heat peak corresponding to this phase transition having been observed at 189.9 K.[9] The temperature dependence of the spin susceptibility in the low-temperature phase was interpreted in terms of the singlet-triplet model assuming a dimeric interaction of the cation radical of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD).[3] This model was also shown to be consistent with the change of the absorption spectrum of WBP powder at low temperatures.[8,10] The dimeric arrangement of $TMPD^+$ ions was confirmed later by de Boer and Vos from the crystal structure analysis of the low-temperature phase of WBP.[11]

The optical properties of WBP crystal have been previously studied by several authors.[8,10,12-15] The polarized absorption spectrum of WBP crystal at room temperature was observed some years ago by Sakata and Nagakura[8] and by Tanaka and Mizuno,[13] both by employing a microspectrophotometric method for the observation of transmission spectrum. The polarized absorption spectrum of the low-temperature phase and its temperature dependence were studied in our laboratory also by use of a microspectrophotometer for transmission spectroscopy of small single crystal.[15] Although several important aspects have been revealed by those studies, the absorption spectra which were reported in these works, are not very satisfactory in the following respects: First, the resolutions of the spectra were not high enough to reveal the details of absorption bands, and, second, there remained some ambiguities as regards the crystallographic characters of the crystal faces on which the observations were carried out. The reflection spectrum of a crystal offers informations complementary to those obtainable from the absorption spectrum observed by transmission method, and, furthermore, in the case of a strongly-absorbing crystal like WBP, the reflection spectroscopy has several experimental advantages over the observation of transmission spectrum. The preliminary study of the reflection spectrum of WBP at low temperatures was carried out earlier by Anderson,[14] who made the observation on a mosaic arrangement of needle crystals of WBP without making any attempt to identify the crystallographic characters of the observing crystal faces.

In the present study, we constructed an apparatus to measure the polarized reflection spectrum of a single crystal of microscopic size at low temperatures, incorporating a cryostat with a microspectrophotometer for reflection spectroscopy. Using this apparatus, we have studied the polarized reflection spectrum of WBP crystal and its temperature dependence over the temperature range of 30—300 K.

Experimental

Material. WBP was prepared according to the method reported by Michaelis and Granick.[16] Small single crystals of WBP were grown by slowly cooling a hot methanol solution of WBP. The crystals thus obtained were either a needle having (011) crystal face, or a plate with the developed face of (001).

Microspectrophotometer and Cryostat. The reflection microspectrophotometer used in the present study, is the same as the one which was previously constructed and used by us to study the reflection spectrum of benzidine-TCNQ complex. The details of this apparatus were described in our previous paper.[17] The optical system of Olympus MMSP is used as the reflection microscope optical system of this apparatus. In order to carry out the measurement at low temperatures, we took off the rotatable sample stage of the microspectrophotometer and installed a cryostat as shown in the photograph of Fig. 1.

The main body of the cryostat is a cryogenic refrigerator, CTi SPECTRIM^{tm}, made by Cryogenic Technology Inc. It is horizontally supported on a specially designed stage with a mechanism to adjust its position in three directions X, Y, and Z, with an accuracy of 10 μ. At the cold head of the refrigerator, we installed the sample-holding device which is illustrated in Fig. 2. The sample crystal is fixed on a miniature goniometer head, so that we can adjust the crystal orientation with respect to the optical axis. The crystal is cooled by means of the heat conduction through the goniometer head and the copper block on which the former is fixed. The temperature is controlled by adjusting the current of the electric heater installed at the cold head, and measured with a Au(Fe)–chromel thermo-couple fixed at the goniometer head. For the purpose of the radiation

(b) Structure of the miniature goniometer head.

shield and to avoid the water condensation on the crystal faces, we put a copper cup with a quartz window over the goniometer head. The face of the window is tilted from the horizontal plane by 30° to avoid the disturbance arising from the light reflection at the window. The system described above is covered with a vacuum-tight cover, and the inside of the above sample chamber was evacuated by the combined action of a rotary vacuum pump and a sorption pump. The pressure measured without the operation of the cryogenic refrigerator was about 5×10^{-5} Torr. Under the operation of the refrigerator, the pressure must be appreciably lower than the above value because of the cryogenic-pumping action of the cold head.

In the present study, we used an objective lens of the magnification of $\times5$. We had to use this lens of rather low magnification because of the requirement of a long working distance due to the geometry of our cryostat. The smallest size of the crystal face that can be used for the measurement of reflection spectrum, is 0.18 mmϕ under the condition adopted in the present study. The aperture angle of the used objective lens is 5.8°, so that we can safely treat the observed reflectance data as those obtained under the normal incidence condition.[18]

Analysis of Reflection Spectrum. Two different methods were employed in the present study to obtain optical constants from the measured reflectance data. The one was the dispersion analysis method (or curve-fitting method). In this case, we express the complex dielectric function as follows,

$$\varepsilon(\omega) = \varepsilon_c + \sum_j \frac{S_j\omega_j^2}{(\omega_j^2-\omega^2)-i\gamma_j\omega_j\omega} \tag{1}$$

and look for the parameter set, ε_c and (ω_j, γ_j, S_j), which gives the best agreement between the observed and calculated reflectance, using the following relation between the reflectance $R(\omega)$ and the complex dielectric function $\varepsilon(\omega)$.

$$R(\omega) = \frac{|\varepsilon(\omega)|+1-2\{|\varepsilon(\omega)|+\mathrm{Re}[\varepsilon(\omega)]\}^{1/2}}{|\varepsilon(\omega)|+1+2\{|\varepsilon(\omega)|+\mathrm{Re}[\varepsilon(\omega)]\}^{1/2}} \tag{2}$$

The optical constants, $n(\omega)$ and $k(\omega)$ of the crystal, can be obtained from $\varepsilon(\omega)$ by the following relations

$$\mathrm{Re}[\varepsilon(\omega)] = n(\omega)^2 - k(\omega)^2 \tag{3}$$

$$\mathrm{Im}[\varepsilon(\omega)] = 2n(\omega)k(\omega) \tag{4}$$

The details of the procedure of this analysis has been described in our previous paper.[17] The second method was the Kramers-Kronig analysis. To perform a direct Kramers-Kronig transformation, we need to know the reflectance over a very wide frequency range. However, our measurement of reflection spectrum was limited only in the near-infrared and visible region. Therefore, instead of carrying out a direct Kramers-Kronig transformation, we used the modified method which was proposed by Ahrenkiel.[21] This method was able to be successfully used in the present case. In order to see the spectrum corresponding to the absorption spectrum, we plotted the imaginary part of the complex dielectric constant, Im[$\varepsilon(\omega)$] against the frequency or wave number.

The method of obtaining the oscillator strength of an absorption band was as follows. In the case of dispersion analysis, we used one dispersion term.

$$\varepsilon_{[j]}(\omega) = S_j\omega_j^2/[(\omega_j^2-\omega^2) - i\gamma_j\omega_j\omega],$$

for each absorption bands.[19] Then the oscillator strength of the band (j) was calculated by the following equation.

$$f_{(j)} = \frac{m}{2\pi^2e^2N}\int_0^\infty \mathrm{Im}\,\varepsilon_{[j]}(\omega)\omega\,\mathrm{d}\omega,$$

where N is the number density of electrons concerned with the j-th transition, m is the electron mass, and e is the electron charge.

In the case of Kramers-Kronig analysis, the oscillator strength was calculated as follows,

$$f_{(j)} = \frac{m}{2\pi^2e^2N}\int_{\omega_a}^{\omega_b}\varepsilon_2(\omega)\omega\mathrm{d}\omega$$

where ω_a and ω_b are the low- and high-wave number limits of the concerned band. When absorption bands are overlapping on each other, there remains some arbitrariness as regards their decomposition. This gives a slight uncertainty of the oscillator-strengths of decomposed bands.

Results and Discussion

Spectrum at Room Temperature. The crystal of

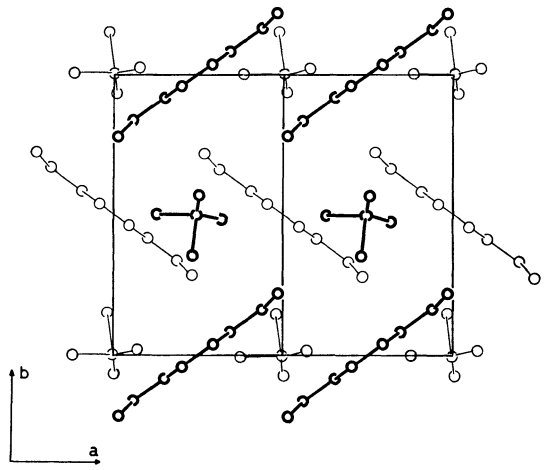

Fig. 3. Projection of the crystal structure of the high-temperature phase of WBP onto the (001) plane.

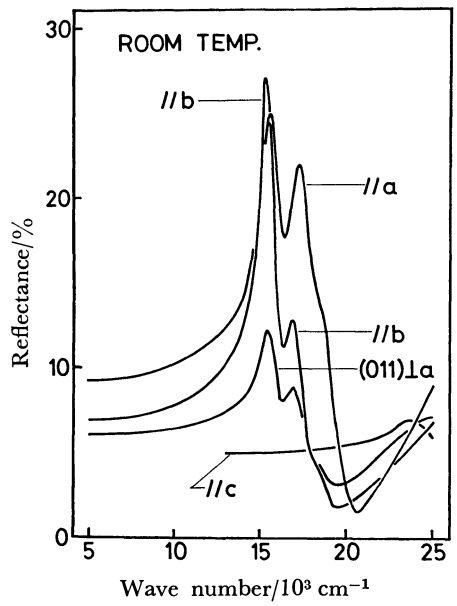

Fig. 4. Room-temperature reflection spectra observed on the (001), (011) and (010) crystal faces.

WBP is orthorhombic with the space group Pnnm, and the lattice constants, $a=5.956$ Å, $b=10.229$ Å, and $c=10.187$ Å.[11] Two molecular units of $TMPD^{+}\cdot ClO_4^{-}$, which are mutually related by the symmetry operation of a glide plane, are contained in the unit cell. The projection of the crystal structure, reported by de Boer and Vos,[11] is reproduced in Fig. 3.

Figure 4 shows the reflection spectra measured on the (001) face for the //a and //b polarizations and those measured on the (011) face for the //a and $\perp$a polarizations. A prominent dispersion of reflectance appears in the region of 13×10^3—20×10^3 cm^{-1}. This is the region where the absorption band due to the lowest π-π^* transition ($^2B_{1u}\leftarrow{}^2B_{2g}$) of $TMPD^{+}$ ion appears in the solution spectrum of WBP. The polarization direction which gives the strongest dispersion, agrees with the one that is expected for the local excitation band associated with the $^2B_{1u}\leftarrow{}^2B_{2g}$ transition which has its transition moment parallel to the long molecular axis. Below 14×10^3 cm^{-1}, the observed

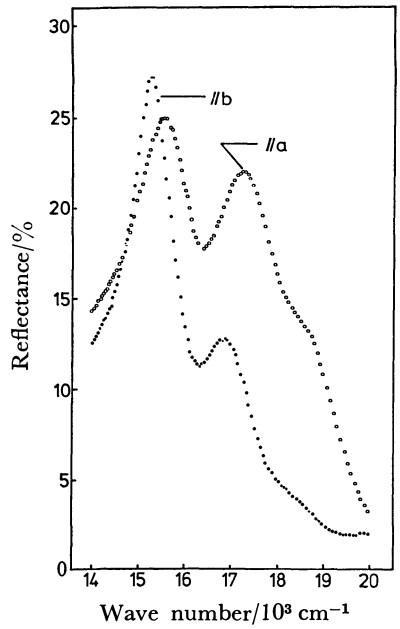

Fig. 5. Reflection spectra measured with 1.6 nm resolution at room temperature.

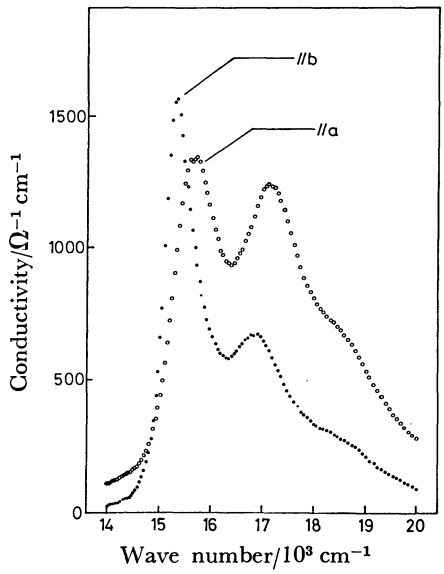

Fig. 6. Optical conductivity spectra obtained by the Kramers-Kronig transformation of the reflection spectra shown in Fig. 5.

reflection spectra show no distinct dispersion except a slight indication of the presence of a shoulder on the low-wave number tail of the //a spectrum of the (011) face, although a dispersion clearly appears around 11×10^3 cm^{-1} in the //a reflection spectrum observed at low temperatures as we will show later. The shape of the //a reflection spectrum which was reported by Anderson,[14] resembles to our //a spectrum of the (011) face, but the reflectance values reported by him, are significantly lower as compared with those obtained in the present study. This is naturally expected since his data were obtained on a mosaic arrangement of needle crystals, not on a good single crystal.

In order to reveal the details of the structure ap-

pearing in the reflection spectrum, we carried out the measurement with an increased resolution over the region from 14×10^3 cm^{-1} to 20×10^3 cm^{-1} [20]. The results are shown in Fig. 5. Figure 6 shows the optical conductivity spectra† which were obtained by the Kramers-Kronig transformation of the reflectance data given in Fig. 5. As we have already mentioned, the absorption band appearing here can be safely attributed to the local excitation (LE) associated with the $^2B_{1u}\leftarrow{}^2B_{2g}$ transition of $TMPD^+$. The obtained optical conductivity spectra resemble to the solution spectrum of $TMPD^+$ ion, having the vibrational progression of about 1530 cm^{-1} which can be attributed to an intramolecular vibration of $TMPD^+$. We decomposed the observed absorption band into vibronic bands, and estimated the oscillator strength of each vibronic band. The results are given in Table 1, together with the corresponding values of the solution spectrum. In Table 1, we give also the total oscillator strength f_t and the square of the direction cosines of the long molecular axis of $TMPD^+$ with respect to the a- and b-axes. The ratio of the observed oscillator strengths, $f_t(//b)/f_t(//a)=0.63$, is in good agreement with the value, 0.56, that is expected on the basis of the oriented-gas model. This is in accord with what one can expect for a LE band due to a strong, long-axis polarized transition of $TMPD^+$ ion. In the case of this absorption band, a deviation of the oscillator-strength ratio $f_t(//b)/f_t(//a)$ from the oriented-gas value, could arise either from the crystal-induced mixing of some intramolecular transition which are polarized perpendicular to the long molecular axis, or from the mixing of an intermolecular charge-transfer (CT) transition. However, in WBP crystal, the mixing of a short-axis polarized transition of $TMPD^+$ with a long-axis polarized transition is forbidden by the site symmetry of $TMPD^+$. Although the n-π^* transition of $TMPD^+$ and the intermolecular CT transition between $TMPD^+$ ions could mix with the long-axis polarized transition of $TMPD^+$, the mixings of these transitions can not significantly affect the polarization ratio of the above LE band, because the oscillator strengths of the n-π^* and CT transitions are quite small in the present case.[22] As for the absolute value of oscillator strength, we note that the values determined from the //a and //b spectra of WBP crystal are about twice the oriented-gas values calculated by use of the oscillator strength of the $^2B_{1u}\leftarrow{}^2B_{2g}$ band of the solution spectrum of $TMPD^+$ ion.[23] Seemingly, this fact indicates that the oscillator strength of the above LE band has been significantly enhanced in WBP crystal. This enhancement of oscillator strength is likely to be due to the crystal-induced mixing of higher-energy, long-axis polarized, strong transitions of $TMPD^+$.

The most interesting aspect that can be noted in Fig. 6 (or in Table 1), is that the intensity ratio of the (0-0) and (0-1) vibronic bands is significantly different between the //a and //b optical conductivity spectra. The band shape in the //b spectrum is very much different from that of the solution spectrum, while the band shape in the //a spectrum resembles to the solution spectrum. In the //b spectrum, the (0-0) vibronic band is appreciably sharper and its intensity relative to the (0-1) vibronic band is significantly higher as compared with the solution spectrum. This phenomenon is similar to the *J*-band of the helix polymer of the pseudo-isocyanine dye, where the (0-0) band becomes sharp and markedly strong as compared with other vibronic bands when the spectrum is observed with the light polarized parallel to the direction of the helix.[24] This characteristic feature of *J*-band has been explained in terms of the collective excitation along the chain. A possible explanation for the shape of the LE band of WBP can be given from the consideration of the exciton-phonon coupling and the exciton band width. The shape of an absorption band of a molecular crystal was theoretically discussed by Sumi,[25] who showed by the model calculation that the intensity of an absorption band will be more and more concentrated into its (0-0) band on increasing the strength of the intermolecular interaction. He introduced two parameters, S and B, which are determining the band shape, S being the parameter related to the coupling between the electronic transition and the intramolecular vibration, and B being the one corresponding to the half-width of the exciton band. For a free molecule, the oscillator strength of the (0-n) vibronic band can be approximately given by Eq. 5.

† For the purpose to compare with the theoretical band shapes predicted by Sumi, we plotted here optical conductivity, not $\mathrm{Im}[\varepsilon(\omega)]$, against wave number. The optical conductivity was calculated from $\mathrm{Im}[\varepsilon(\omega)]$ by the following relation;

$$\sigma(\omega)=8.854\times10^{12}\omega\cdot\mathrm{Im}[\varepsilon(\omega)] \qquad [\Omega^{-1}\,cm^{-1}]$$

where $\mathrm{Im}[\varepsilon(\omega)]$ is expressed in c.g.s. units.

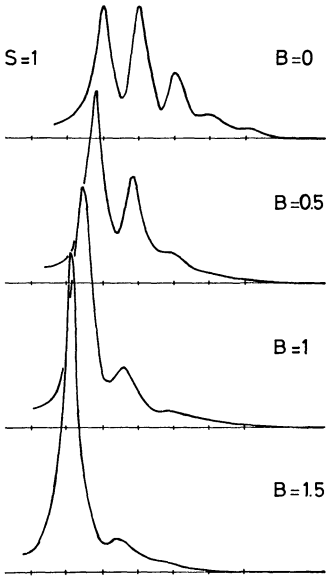

Fig. 7. Vibronic band shapes in optical conductivity spectra, theoretically predicted for various values of B, assuming that $S=1$. The spectra have been a little broadened than the original ones given in the paper by Sumi.[25]

$$f_{0-n} = A\frac{S^n}{n!}e^{-S} \tag{5}$$

When we apply the above relation to the $^2B_{1u}\leftarrow{}^2B_{2g}$ band of the solution spectrum of $TMPD^+$ ion, the S value is estimated to be 1.0 in the unit of a quantum of the intramolecular vibration.[26] Assuming that the same S value can be used for the corresponding LE band of WBP crystal, we compared the observed band shapes with the theoretical band shapes given by Sumi for different B values. The band shapes which are expected by Sumi's theory for the cases of $B=0$—1.5,[27] are illustrated in Fig. 7, where the width of each vibronic band has been a little broadened than the spectra given in Sumi's paper, for the purpose to compare with the observed spectra. When we compare the observed band shapes (Fig. 6) with the theoretical ones shown in Fig. 7, we can see that the observed band shape of the //b spectrum corresponds to the case of $B=0.5$—1.0 while that of the //a spectrum corresponds to the case of $B=0$—0.5.[27]

Since there are two sites of $TMPD^+$ in the unit cell, the exciton band associated with $^2B_{1u}$ molecular excited state splits into two bands, in which symmetries are B_{3u} and B_{2u}, respectively. The optical transition to B_{3u} exciton band is allowed for the a-axis polarized light, and that to B_{2u} exciton band is allowed for the b-axis polarized light. As shown in Table 1, the Davydov splitting of these two exciton states is about 400 cm^{-1}. The band shape analysis described above suggests that B_{2u} exciton band has a witdh of 1500—3000 cm^{-1} while B_{3u} exciton band has a considerably narrower band width, less than 1500 cm^{-1}.

Temperature Dependence of the Spectrum. WBP crystal undergoes a phase transition at about 190 K. The crystal of the low-temperature phase is monoclinic with the space group $B2_1/d$, the lattice constants being

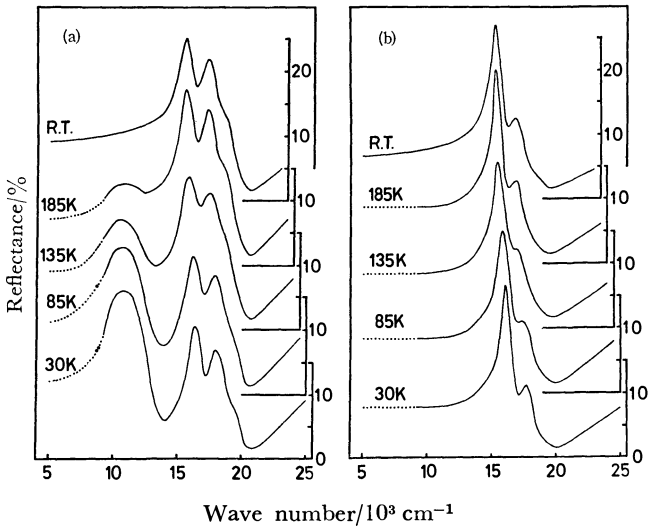

Fig. 8. Low-temperature reflection spectra of WBP. (a) //a spectra, (b) //b spectra.

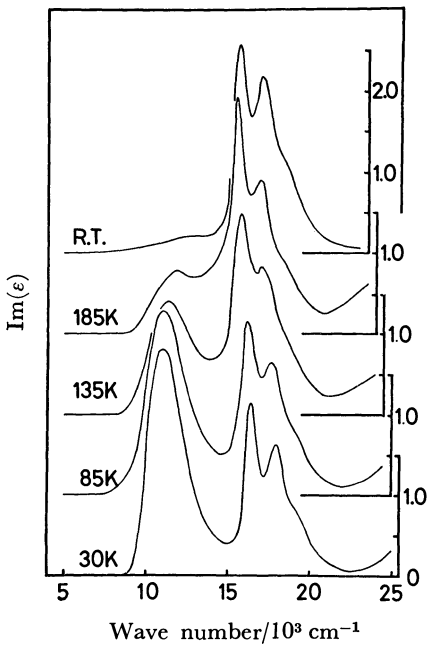

Fig. 9. $Im[\varepsilon(\omega)]$ spectra (//a) obtained by the Kramers-Kronig transformation of the reflection spectra shown in Fig. 8.

$a=11.655$ Å, $b=10.147$ Å, $c=20.130$ Å, and $\beta=92.57°$ at 110 K.[11] As compared with the high-temperature phase, the lengths of the a- and b-axes are doubled in the low-temperature phase, and the unit cell contains eight molecular units of $TMPD^+\cdot ClO_4^-$. The $TMPD^+$ ions are stacked along the a-axis as in the high-temperature phase, but with an alternation of intermolecular spacing showing definitely the character of a dimeric arrangement. The reflection spectra measured for the //a and //b polarizations at various temperatures are shown in Fig. 8. It should be noted that, in the low-temperature phase, a new broad dispersion of reflectance appears in the region of 9×10^3—15×10^3 cm^{-1}, and its amplitude increases on lowering the temperature. This dispersion can be observed most

TABLE 2. TEMPERATURE DEPENDENCE OF THE OSCILLATOR STRENGTH OF THE CHARGE-TRANSFER BAND AND THE TRIPLET POPULATION ESTIMATED BY VARIOUS METHOD

T/K	Oscillator strength		Triplet population/%

strongly when the light is polarized parallel to the a-axis which is the direction of the $TMPD^+$ stack, and is not observable when the light is polarized perpendicular to it. This fact indicates that the dispersion mentioned above is associated with the charge transfer between $TMPD^+$ ions. Figure 9 shows the $Im[\varepsilon(\omega)]$ spectra obtained by Kramers-Kronig transformation of the //a reflection spectra. The general features of the obtained $Im[\varepsilon(\omega)]$ spectra are very similar to the low-temperature spectrum of WBP powder reported by Sakata and Nagakura.[10] The first absorption band is the charge-transfer band, which is very broad and structureless even at 30 K, having its absorption maximum at 11.6×10^3 cm^{-1}. Sakata and Nagakura pointed out that there is a close correlation between the decrease of the paramagnetic susceptibility and the increase of the intensity of the charge-transfer band.[8,10] Assuming the dimeric arrangement in $TMPD^+$ chain, they concluded that there is a thermally accessible triplet state (T_0) of $TMPD^+$ dimer above the ground singlet state (S_0), and since the optical transition to the charge-transfer (singlet) state of the dimer is allowed only from S_0, the decrease of the intensity of the CT band must be proportional to the increase of the triplet population, hence to the spin concentration. From the analysis of the temperature dependence of the CT band, they derived 230 ± 50 cm^{-1} for the singlet-triplet separation of the $TMPD^+$ dimer, which was in good agreement with the value (≈235 cm^{-1}) determined by Thomas *et al.*[3] from ESR data. We determined the oscillator strength of the CT band at each temperature from the observed spectrum, and estimated the fraction of $TMPD^+$ dimers which are in the triplet state, assuming that the transition moment of the CT transition does not vary with temperature. The results are given in Table 2. The triplet population $N_t(T)$ derived from the paramagnetic susceptibility χ_H by means of Eq. 6 and that calculated by the singlet-triplet model assuming the singlet-triplet separation of 235 cm^{-1}, are also given in the same table.

$$\chi_H = \frac{g^2\beta^2S(S+1)}{3kT}\cdot N_t(T) \qquad (6)$$

As shown in Table 2, the results by Kramers-Kronig analysis and curve-fitting analysis are a little different from each other. Seemingly this disagreement arised

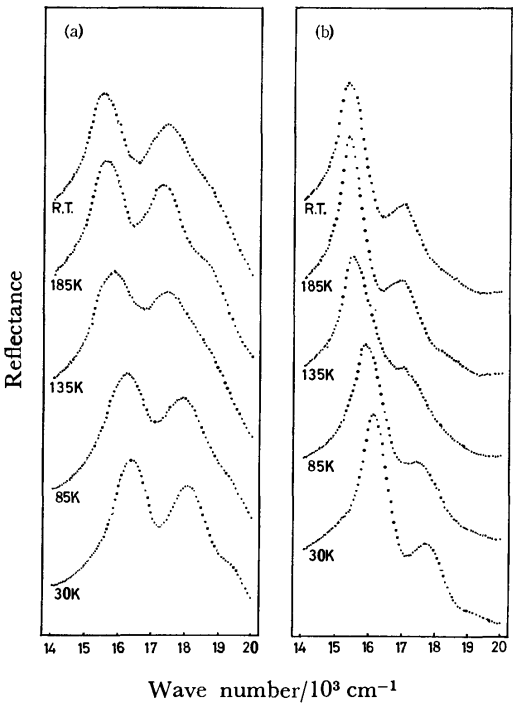

Fig. 10. Low-temperature reflection spectra, in the visible region, measured with 1.6 nm resolution.

from the inherent difficulty in determining the absolute value of oscillator strength from the reflectance data when an absorption band is very broad and weak as in the case of the CT band of WBP. No such discrepancy was found between the results of the two analysis methods in the case of the strong LE band of WBP crystal. The triplet population derived from the oscillator-strength values obtained by curve-fitting analysis, are in very good agreement with those derived from the paramagnetic susceptibility data. But this fact does not necessarily mean that the data by curve-fitting method are more reliable than those by Kramers-Kronig analysis, since the above agreement with the magnetic data looks too good if we take into account the situation that the transition moment of the CT excitation must vary to some extent with temperature accompanying the lattice contraction on lowering the temperature. Although there remains such a problem as regards the quantitative anaylsis of the

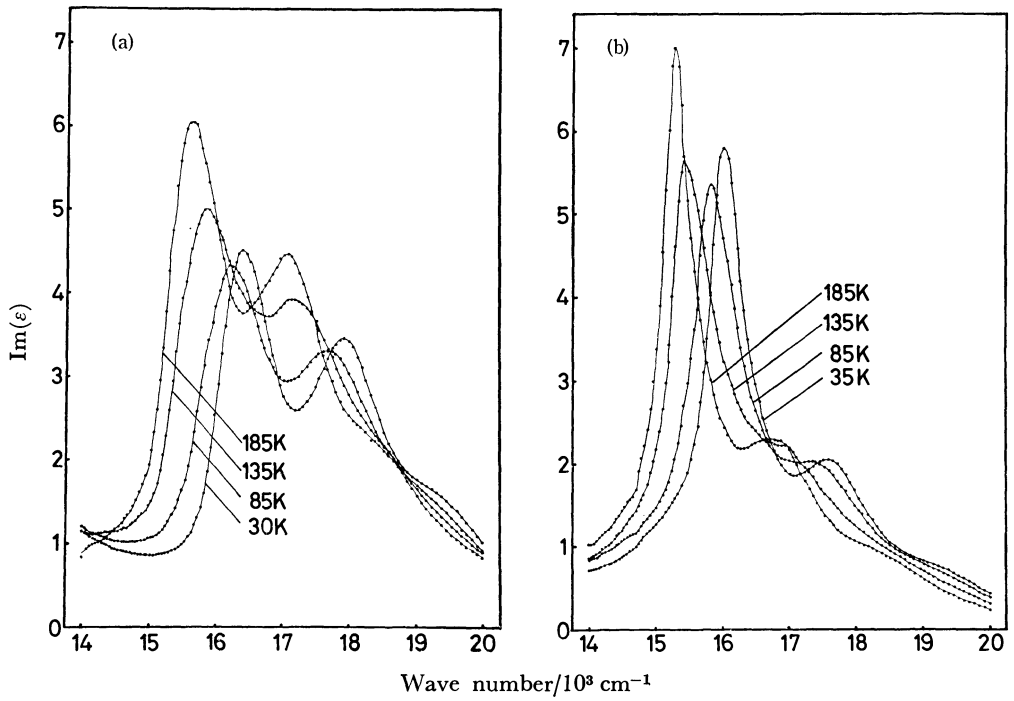

Fig. 11. Im[$\varepsilon(\omega)$] spectra obtained by the Kramers-Kronig transformation of the reflection spectra shown in Fig. 10: (a) //a spectra, (b) //b spectra.

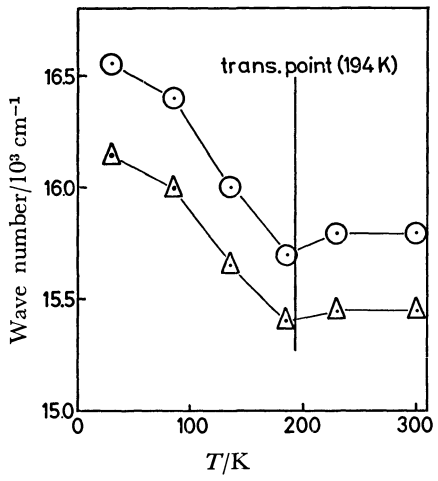

Fig. 12. Shift of the (0-0) band with temperature.

intensity change of the CT band, the results shown in Table 2 clearly indicate that the essential feature of the temperature dependence of the CT band can be well understood in terms of the singlet-triplet model as discussed by Sakata and Nagakura.[10] Incidentally, if we take up only the change, not the absolute value, of the oscillator strength with temperature, the results by the two analysis methods exactly agree with each other, and are also in good agreement with the data reported by Sakata and Nagakura for the spectrum of WBP powder.

The reflection spectrum in the region of 14×10^3—20×10^3 cm^{-1} was measured with an increased resolution, the resolution being 1.6 nm. The results are shown in Fig. 10. Figure 11 shows the Im[$\varepsilon(\omega)$] spectra obtained by Kramers-Kronig analysis of the above reflectance data. As we have mentioned in the case of the room-temperature spectrum, the absorption band appearing here is the LE band associated with the lowest π-π^* ($^2B_{1u}\leftarrow{}^2B_{2g}$) transition of TMPD$^+$. We can see three characteristic features of temperature dependence both in the //a spectrum and in the //b spectrum. The first is the shift of the absorption peaks with temperature. In Fig. 12, we plotted the wave number of the (0-0) band against temperature. One can clearly see that the position of the (0-0) band does not appreciably change with temperature in the high temperature phase, but is markedly blue-shifted on lowering the temperature in the low-temperature phase. The second is the change of the width of vibronic band. On lowering the temperature, the width gradually increases, shows the maximum broadness at 135 K, and then decreases at lower temperature. The third is the fact that the peak heights of the (0-0) and (0-1) bands gradually decrease on lowering the temperature from 185 K to 85 K and then increase at 30 K. In the case of a typical molecular crystal like anthracene, the (0-0) band shows a red-shift on lowering the temperature, the magnitude of this shift having been reported to be about 150 cm^{-1} between the room temperature and 4.2 K in the case of anthracene,[28] and usually the width of a vibronic band monotonously decreases on lowering the temperature. The temperature dependence observed for the LE band of WBP is very much different from the one mentioned above.

Examining the temperature dependence of the absorption spectrum of WBP powder, Sakata and Nagakura[10] reported that the spectra measured at different temperatures exhibited isosbestic points. They concluded that the singlet-singlet transition and the triplet-triplet transition of TMPD$^+$ dimer are overlapp-

ing on each other to give the observed LE band of the absorption spectrum of the powder, and the temperature dependence of its band shape can be understood by considering the thermal equilibrium between the singlet and triplet states of the dimer. The single-crystal spectra obtained in the present study show that the temperature dependence of the $\mathrm{Im}[\varepsilon(\omega)]$ spectrum of WBP crystal is, in reality, a little more complicated than described by the above authors. The observed spectra did not exhibit isosbestic points, so that it was not possible to carry out a simple quantitative analysis of the band shape in terms of the thermal equilibrium between the singlet and triplet states of $TMPD^+$ dimer. But the main feature of the observed temperature dependence can be understood, at least qualitatively, by the same model. As shown in Table 2, the triplet population becomes to be almost negligible at 30 K. Thus the band shape at 30 K can be regarded to be the one entirely due to the singlet-singlet transition, while, at higher temperatures, the band due to triplet-triplet transition is overlapping with the absorption band due to the singlet-singlet transition. Possibly, the band shape at just below the transition temperature is largely determined by the triplet-triplet absorption band. Seemingly this is the reason why the LE band is broader at intermediate temperatures. The shifts of absorption peaks and the change of the band shape suggest that the triplet-triplet absorption band is located at the wavenumber lower by 600—800 cm^{-1} than the singlet-singlet absorption band. We tried to reproduce the observed band shapes as the superposition of the singlet-singlet and triplet-triplet absorption bands, and found it necessary, in order to explain the observed band shapes, to consider that both the singlet-singlet and triplet-triplet absorption bands shift to higher wave number on lowering the temperature. This situation prevented us to carry out a further quantitative analysis of band shape, but we were able to conclude that the observed temperature dependence of the LE band is consistent with the change of the triplet population derived from the magnetic data or that from the intensity of the CT band.

The authors are grateful to Olympus Optical Co., Ltd. for their generous offer of the Olympus MMSP-RK system used in the present study. The authors wish to thank Dr. Koichi Ohno, Faculty of Education, The University of Tokyo, for helpful discussion.

Electrophoresis and Diffusion Studies of the Solubilization of Polar and Nonpolar Oily Compounds with Sodium Dodecyl Sulfate. II

Keizo OGINO* and Nobuo TAKESHITA

Faculty of Science and Technology, Science University of Tokyo, 2641 Yamazaki, Noda, Chiba 278

(Received July 12, 1979)

The solubilization of polar and nonpolar oily materials into an aqueous sodium dodecyl sulfate (SDS) solution with and without sodium chloride was studied. Normal paraffins and their derivatives, with carbon numbers of C_7, C_8, and C_{10}, were used as solubilizates, the extents of solubilization, the relative viscosities of the solutions, the diffusion coefficients, and the electrophoretic mobilities of the micelles in the solutions were observed, and the effective specific volumes, the effective radii, the ζ-potentials, and the effective charge of the micelles were derived assuming that the micelles were spherical. The micelles of SDS showed increasing mobilities when they incorporated octanoic acid, 1-octanol, and decanoic acid, while the mobilities decreased when they incorporated heptane, octane and 1-decanol. On the basis of these results, we discussed the mechanism of the solubilization of polar and nonpolar oily compounds with SDS.

The behavior of the micelles of surfactants have been studied extensively by many investigators for SDS,[1] mixed ionic-nonionic surfactants,[2] polyether sulfate, and other surface-active agents,[3] but only a few investigations have been devoted to the micelles incorporating solubilizates in them.

In a previous paper[4] we observed the electrophoretic mobilities of micelles of SDS, $|U_M|$ in aqueous solutions, and showed that the $|U_M|$ increased with an increase in the concentration of octanoic acid and decreased with that of octane. We further studied the behavior of the micelles of SDS including polar or nonpolar oily materials in an aqueous medium in the presence or absence of electrolytes in order to elucidate the mechanisms of the solubilization of the oily materials. We suggest that strongly polar compounds are adsorbed on the outer surface, weakly polar compounds penetrate deeply into the palisade layers, and nonpolar compounds are occluded in the hydrocarbon cores of the micelles.

Experimental

Materials. *Surface-active Agent*: Sodium dodecyl sulfate (SDS) of a reagent grade was purchased and was purified by extraction with petroleum ether, followed by recrystallization from ethanol.

Solubilizates (Oily Materials): Octanoic acid, decanoic acid, 1-octanol, and 1-decanol were used as polar oily materials, and heptane and octane as nonpolar ones, all obtained in a purity of better than 99% from Wako Pure Chemical Industries.

Apparatus and Conditions. Sodium dodecyl sulfate was dissolved into a 0.2 M NaCl solution or into water at the concentrations of 0.3 and 1.5% (wt), which were higher than the critical micelle concentration (CMC) of SDS. The solubilization limits of the oily materials into the SDS solutions were determined as follows. Into 100-ml glass-stoppered Erlenmeyer flasks containing 50 ml of SDS solutions (0.3% and 1.5%), various amounts of one of the oily materials were added; the mixtures were stirred for 12 h at 25 °C and then left standing for 24 h until the solubilization equilibria were established. Then, the turbidities of the mixtures were measured with a spectrophotometer of the Hirama Type-2B at the wavelength of 655 nm. The turbidities of the solutions were plotted against the concentrations of the solubilizates, and the solubilization limits were determined from the break points of the relating curves. After that, the solubilizates were added until the solubilizing limit was reached and then submitted to dialysis by the use of cellulose tubing for 36 h at 25 °C.

The electrophoretic mobility and the diffusion coeffecient for the SDS solutions saturated with the oily materials were determined at 25 °C by a Schlieren method using a Hitachi Model HTB-2A Tiselius apparatus in combination with a Tsukasa Neurath cell, with the usual precautions.[2,3] The concentrations of both the upper and lower layers were chosen to be higher than the CMC in order to eliminate the contribution of the monomers to the diffusion coefficient; the initial concentration difference between layers was 1.2 g/dl. Then, a pair of 0.3 and 1.5% SDS solutions were set as the upper and the lower layers in the cell to minimize the boundary disturbance often encountered in electrophoresis and diffusion measurements. The electrophoretic measurements were performed under the following conditions: voltage the 50 V; current, 10 mA; migration time, 30—50 min. The calculation of diffusion coefficient was based on the maximum ordinate-area method.

The relative viscosities of the solutions containing the oily materials were measured at 25 °C with an Ubbelohde viscometer.

The specific gravity was determined using a pycnometer with a capacity of about 25 ml.

Results and Discussion

The Solubilized Amounts and the Susceptibilities to Solubilization. Figure 1 shows the solubilized amounts of the oily materials in the aqueous solutions of SDS with or without 0.2 M NaCl. The solubilized amounts widely changed according to the kinds of solubilizates in the aqueous solutions without NaCl, but it remained around a constant value in the presence of NaCl. The results also show that octanoic acid, 1-octanol, and decanoic acid are solubilized to greater extents, whereas 1-decanol, octane, and heptane are present to smaller extents in water than in 0.2 M NaCl solution. From the results presented in Fig. 1, the susceptibilities of the substances to the solubilization are determined as the moles solubilized by the mole of SDS in the solutions. The susceptibilities depend on the structures of the compounds much as they depend on the solubilized amounts. Klevens[5] found that the solubilized amounts of nonpolar compounds in aqueous surfactant solutions increased when electrolytes were added, and that some polar compounds

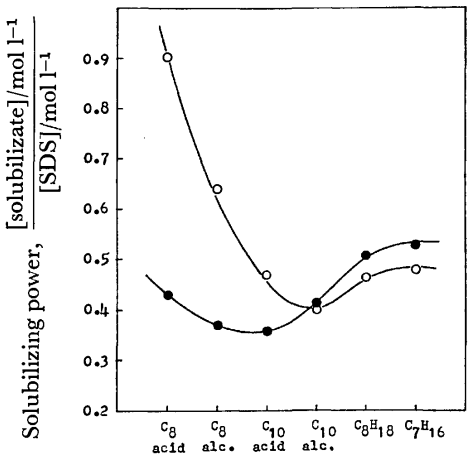

Fig. 2. The susceptibility to the solubilization of the solubilizates in 0.2 M NaCl and pure water at 25 °C.
○: In pure water, ●: 0.2 M NaCl.

with large alkyl groups and only weakly polar groups, such as 1-decanol, showed a solubilization similar to these of nonpolar compounds.

The plots in Figs. 1 and 2 indicate that carboxyl is a stronger solubilizing group than hydroxyl for the compounds of the same carbon number, probably because of its stronger depolarizing power. Furthermore, the electrolyte in the solution has effects not only on the solubilized amount, but also on the susceptibility to the solubilization of the materials in the SDS solution.

Relative Viscosities and Effective Specific Volume of the Micelles. The relative viscosities, η_r, of the solutions saturated with the solubilizates in 0.3 or 1.5% SDS solutions containing 0.2 M NaCl are plotted in Fig. 3. The relative viscosities of 0.3 and 1.5% SDS solutions both decreased in the following order of the dissolved compounds; octanoic acid>1-octanol>decanoic acid>1-decanol>octane>heptane. The viscosities changed over a wider range in the 1.5% SDS

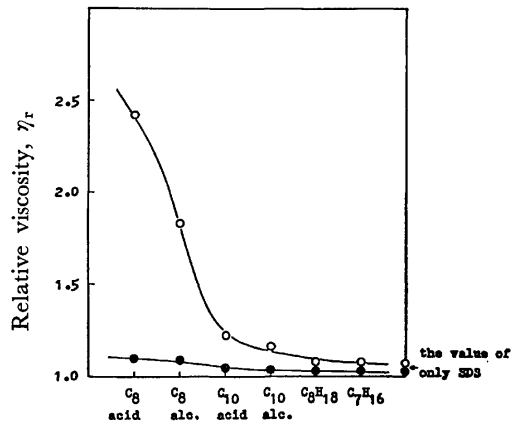

Fig. 3. Relative viscosty of the solubilized solution in 0.2 M NaCl at 25 °C.
○: SDS 1.5%, ●: SDS 0.3%.

solution than in the 0.3% solution. The relative viscosities of the solutions showed a larger change than the solubilized amounts of the components in the SDS solutions containing NaCl; the change seems to be related to the structures of the solubilizates. The solutions containing octanoic acid showed the largest viscosity. This large viscosity due to octanoic acid may be attributed to the adsorption of octanoic acid on the surface of the micelles of SDS, which would cause the increase in the mutual interaction of the micelles. On the other hand, nonpolar compounds are deeply occluded into the palisade layers and are occluded in the hydrocarbon cores of the micelles; consequently, the mutual interaction of the micelles is not influenced, and the relative viscosities of the solutions do not change because of the dissolution of the solubilizates.

Based on the Guth and Simha equation (Eq. 1),[6-9] which is an extension of Einstein's equation to the higher concentration range of the micelles in aqueous solution,

$$\eta_r = 1 + 2.5\,\phi + 14.1\,\phi^2, \quad (1)$$

the volume fraction of the spherical particles, ϕ, can be calculated from the relative viscosity, η_r. The effective specific volume, V, of SDS containing an oily material is given by[7,10]

$$V = \phi/C, \quad (2)$$

where C is the concentration of the solution presented in g/cm^3.

Figure 4 shows the effective specific volume, V, of the micelles of SDS containing solubilizates in 0.2 M NaCl solutions.

Nakagawa has suggested that the effective specific volume of micelles in various concentration ranges of the surfactant from 0.3 to 3.0% was nearly constant.[11,12] Our experimental results agreed approximately with this suggestion. For a solution of the surfactant alone, it can be said that, above the CMC, the number of micelles increases with an increase in the amount of the surfactant, whilst the size of the micelle remains almost unchanged (aggregates of 50—100).[13]

As is evident in Fig. 4, the effective specific volumes of the micelles containing octanoic acid and 1-octanol

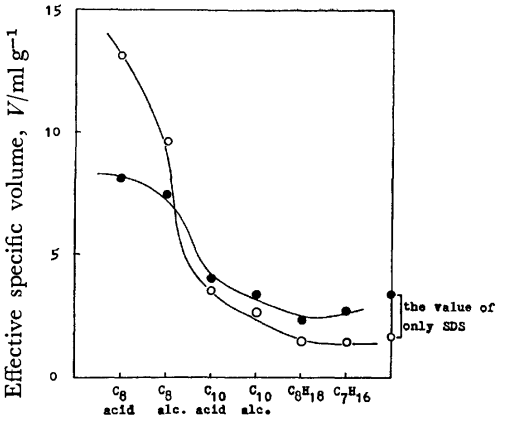

Fig. 4. Effective specific volume of the solubilized micelle in 0.2 M NaCl at 25 °C.
○: SDS 1.5%, ●: SDS 0.3%.

were larger than those of the micelles containing less polar or nonpolar compounds. Besides, the effective specific volumes of SDS micelles containing decanoic acid, 1-decanol, octane, and heptane were almost the same as that of SDS-single-component-micelles. The increase in the effective specific volume of the micelles upon the addition of polar solubilizates may be attributed to the adsorption of the solubilizate molecules on the surface of micelles, as if needles with bulky heads are inserted into a spherical needle pad.

Diffusion Coefficients and Effective Radii of the Micelles Containing Solubilizates. The diffusion coefficients, D, were calculated by means of the following equation, based on the maximum ordinate-area method,[14]

$$D = \frac{A^2}{4\pi t(H_m)^2} \cdot \frac{1}{G^2}, \tag{3}$$

where A is the area under the concentration gradient curve, H_m is maximum ordinate, t is the migration time, and G is the optical magnification (here $G=1$)

Figure 5 shows the diffusion coefficients, D, and effective radii of micelles, a, in 0.2 M NaCl solutions. Since a charged colloid interacts with an ionic medium, the diffusion of a hydrophilic-charged colloid is usually retardated in the presence of electrolytes in solutions, but this effect is suppressed in the concentration range of electrolytes higher than 0.2 M.[3,13]

The effective radii of micelles, a, can be calculated by means of the Stokes-Einstein's equation:[15,16]

$$a = kT/6\pi\eta D, \tag{4}$$

where k is the Boltzmann constant and η is the viscosity of the medium. The diffusion coefficient of the micelles of SDS containing solubilized octanoic acid was the smallest, while that of SDS containing heptane was the largest, though the incorporated amounts in the micelles were almost the same for the two solubilizates, as has been mentioned above. On the other hand, the effective radii of the micelles of SDS containing octanoic acid were the largest, and those containing heptane was the smallest. These results are in accordance with the results of the relative viscosities and the effective specific volumes of micelles of the systems.

Electrophoresis. From the measurements of the

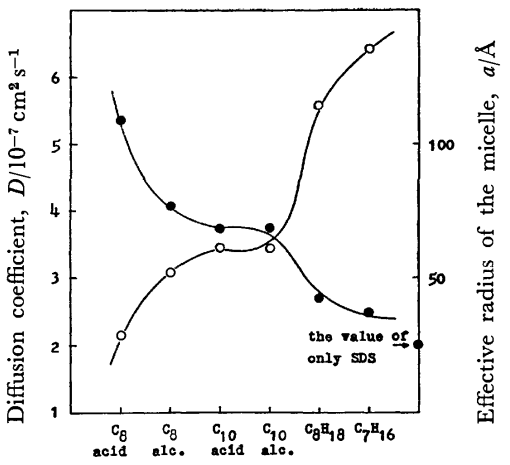

Fig. 5. Diffusion coefficient and effective radius of the solubilized micelle in 0.2 M NaCl at 25 °C.
○: Diffusion coefficient, ●: effective radius of the micelle.

migration velocities of micelles from the upper layer to the lower layer (V_a) or in the reverse direction (V_d) in a cell of the Tiselius apparatus, the electrophoretic mobility of micelles, $|U_M|$, was calculated by means of following equation:[2,17-19]

$$U_M = V_d\tau^\beta - \frac{V_a\tau^\alpha - V_d\tau^\beta}{(T_M{}^\beta/T_M{}^\alpha) - 1}, \tag{5}$$

where T_M is the transference number of micelles, and τ is the specific conductance of the solution, while the superscripts α and β refer to the upper and lower layers respectively.

$T_M{}^\beta/T_M{}^\alpha$ in Eq. 5 is expressed as

$$T_M{}^\beta/T_M{}^\alpha = \frac{C_M{}^\beta/\tau^\beta}{C_M{}^\alpha/\tau^\alpha}, \tag{6}$$

where $C_M{}^\alpha$ and $C_M{}^\beta$, which are the concentrations of the M^- ions in the α and β phases respectively, are given by

$$C_M{}^\alpha/C_M{}^\beta = \frac{(C-\mathrm{CMC})^\alpha}{(C-\mathrm{CMC})^\beta}, \tag{7}$$

where C is the concentration of the surfactant.

Figure 6 shows the electrophoretic mobilities of the micelles containing various solubilizates. The absolute value of the electrophoretic mobilities of the micelles solubilizing octanoic acid, 1-octanol, and decanoic acid were larger than that of SDS alone (presented by the dotted line), while those of the micelles containing 1-decanol, octane, and heptane were smaller. The $|U_M|$ of the micelles containing 1-decanol was smaller than that of SDS alone in the presence of NaCl; this is a result of the behavior of 1-decanol, like that of normal paraffins in a medium containing electrolytes.

The ζ-potential was calculated from U_M by the use of Henry's equation:[20]

$$\zeta = \frac{6\pi\eta}{\varepsilon f(\kappa a)} \cdot U_M, \tag{8}$$

where $f(\kappa a)$ is the Henry function, κ is the Debye-Hückel parameter, a is the radius of the micelle, and η and ε are the viscosity and dielectric constant of

the medium respectively.

Furthermore, the number of the effective charge of micelles, Q, is estimated by means of the following equation:[20]

$$Q = \frac{1}{e} \cdot \frac{1+\kappa a+\kappa r_1}{1+\kappa r_1} \cdot \varepsilon a \zeta, \qquad (9)$$

where e is the elementary charge and r_1 is the radius of the counter ion, for which we adopted 0.22 nm in the present system.

Table 1 shows the results of electrophoretic and diffusion measurements for the micelles containing various solubilizates. The absolute value of the ζ-potential follows the order of $|U_M|$. As is evident from Table 1, the numbers of the effective charges of micelles containing polar solubilizates are larger than those of the micelles containing nonpolar solubilizates or no solubilizates, with that of the micelles of SDS containing octanoic acid being the largest. These results suggest that the micelles containing octanoic acid aggregate with each other to form the larger micelles, whereas the micelles containing nonpolar solubilizates seem not to aggregate, showing a charge similar to that of the micelles of SDS alone.

The large number of the charge of the octanoic acid-containing micelles may be attributed to the hydration of carboxyl groups. From the point of view of energy, the hydrated carboxyls would better remain on the surface of the micelles than be incorporated into the hydrocarbon cores of the micelles. The alkyl group of octanoic acid is considered to penetrate into the palisade layer of the micelles. This mechanism of the solubilization of polar oily compounds is shown schematically in Fig. 7. In this figure, **a** indicates octanoic acid; **b**, 1-octanol; **c**, decanoic acid, and **d**, 1-decanol. Since nonpolar compounds, such as octane and heptane, are not hydrated, all the molecules are thought to be incorporated into the hydrocarbon cores of the micelles, like needles buried in a spherical pad. The generally accepted model of the solubilization of oily materials by the micelles of a surfactant was proved to be consistently true in the present systems.[21,22]

Cotton Effect Induced in Optically Inactive Molecules and Molecular Complexes by Optically Active Environment. II. Acridine and Phenazine in Cellulose Diacetate Film

Yasumasa J. I'HAYA,* Taka-aki AOI, and Tatsuji SANO

Department of Materials Science and Laboratory for Magneto-Electron Physics, The University of Electro-Communications, Chofu-shi, Tokyo 182

(Received August 6, 1979)

Ultraviolet absorption spectra and induced circular dichroism (ICD) of acridine and phenazine were measured in cellulose diacetate film. The induced Cotton effect corresponding to each absorption maxima of these systems appeared. From the correspondence between the maxima of ICD and the peaks of the resolved absorption spectra, it was found that the sign of ICD is negative in the region where the molecular long-axis polarized transition plays a part in the CD induction and it is positive in the region where short-axis polarized transition does. A mechanism of CD induction tentatively proposed is that a dye molecule is imprisoned in a cage formed by an assembly of the folded chains of cellulose diacetate and the Cotton effect is induced by an electrostatic interaction between electronic transition dipole moments of the dye and of the chromophores involved in the cellulose diacetate cage.

The origin of the ICD (induced circular dichroism) spectra of optically inactive molecules dissolved in optically active medium is still controversial. The oldest explanation was a complex formation including hydrogen bonding between an achiral molecule and chiral solvent molecules,[1] but later on there have been discovered a variety of cases where the mechanism of ICD is not explained systematically. Among others, those which are worth notice are (a) due to the stereoregular arrangement of chiral host molecules such as cholesteric solvents[2] and helical biopolymers[3] along which achiral molecules are forced to line up in a regular way and (b) due to a formation of clathrates in which achiral species are imprisoned in an optically active cage.[4]

Part I of this series[5] has demonstrated that aromatic hydrocarbons and their molecular complexes embedded in acetylcellulose films exhibit the induced Cotton effect in their π-π^* absorption region and charge-transfer absorption region, respectively. The advantage of the experiment is that even very weak and/or closely overlapped vibrational bands and charge-transfer bands unresolved by the usual solution spectroscopy may be observed in such ICD spectra. We then tried to resolve vibrational bands in ICD spectra of several dye molecules in a film state and correlate them to the corresponding broad absorption spectra taken in solution. However, even when we used a high resolution spectropolarimeter together with a data processing computer, we found it difficult to resolve unambiguously each vibrational band in ICD spectra for filmed molecules which show rather broad absorption spectra in solution. Instead, we found an interesting correlation between the signs of ICD spectra and the direction of electronic transition moments of guest molecules. In the following, we report the ICD spectral feature of acridine and phenazine embedded in cellulose diacetate matrices, with specific emphasis on the correlation mentioned above.

Experimental

Acridine and phenazine, all commercial reagent grade, were purified by sublimation. Cellulose diacetate (Eastman Chemical, E-398-3, degree of polymerization 171) was used without further purification. An acetone solution of each dye was added to an acetone solution of cellulose diacetate, then the viscous solution was drawn onto a fused quartz plate and baked slowly in an oven to remove acetone. Original concentrations of the dyes and cellulose diacetate were held in the range $1—3\times10^{-4}$ mol dm^{-3}. The arrangement of the matrix, cellulose diacetate, was examined by the observation under a polarizing microscope. Films which were not opaque and showed no birefringence were selected. They were 5—15 μm in thickness with excellent transparency. The film thickness was roughly estimated from birefringence and retardation using a polarizing microscope. It was estimated that the dyes were doped at the ratio of 1:20—1:40 against the number of the sugar residues of cellulose diacetate.

Absorption spectra were taken on a JASCO UVIDEC-505 digital double-beam spectrophotometer. A JASCO model J-40S spectropolarimeter was used for the measurement of CD spectra of the sample films. In each measurement, the CD spectrum was calibrated with reference to the base line of the pure cellulose diacetate film whose thickness was identical with that of the sample film. An S/N ratio in a CD spectrum was improved by using a JASCO data processing machine DP-500 through repeated runs.

Results and Discussion

The UV and CD spectra of acridine embedded in a cellulose diacetate film are shown in Figs. 1 and 2 and those of phenazine in Figs. 3 and 4. The thickness of the sample film was 8 μm for acridine and 15 μm for phenazine when the spectra were taken in the longer wavelength region (280—500 nm), and it was 7 μm for acridine and 5 μm for phenazine when the spectra were taken in the shorter wavelength region (200—300 nm). The scales of the ordinate are the ellipticity (θ) for CD and the optical density (*O.D.*) for UV spectra. These quantities were not converted into the corresponding molecular characteristics, *i.e.*, molecular extinction coefficient and molecular ellipticity, since the thickness and concentration of each sample film could not be determined accurately. Incidentally, the same dyes dissolved in an acetone solution of cellulose diacetate did not show any induced Cotton effect.

The overall UV spectra of acridine and phenazine

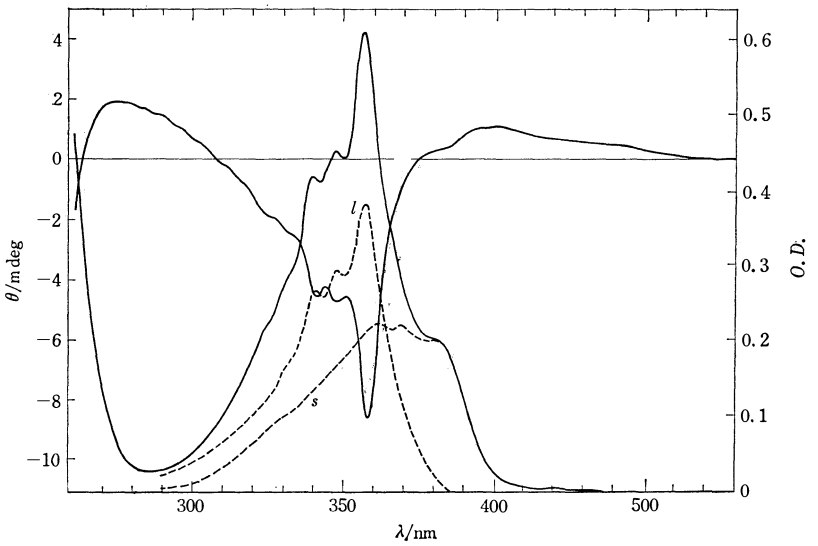

Fig. 1. UV and CD spectra of acridine in cellulose diacetate film in longer wavelength region. Film thickness: 8 μm. Dotted curves show the resolution of UV spectrum into the components of molecular long-axis polarized (*l*) and short-axis polarized (*s*) transitions.

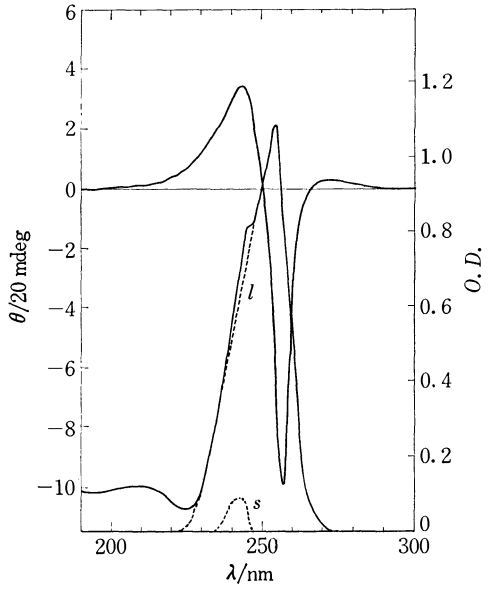

Fig. 2. UV and CD spectra of acridine in cellulose diacetate film in shorter wavelength region. Film thickness: 7 μm. Dotted curves are the same as in Fig. 1.

in film states shown in Figs. 1—4 are not very much different from those observed in CCl_4 and ethanol solutions; the overall spectral shifts to the red are 200 cm^{-1} at most. We also measured the infrared spectra of the sample films, which were not very much different (1—3 cm^{-1}) from those of the corresponding dyes in solution and in powder states. These suggest that the dye molecules embedded in cellulose diacetate films are the same and/or the like surroundings as those in solution. The calibration of CD curves with reference to the base line of the pure cellulose diacetate film is important, since cellulose diacetate itself has optical activity. The UV absorption and CD spectra of a typical cellulose diacetate film (thickness 10 μm) are shown in Fig. 5.

As seen in Figs. 1 and 2, the ICD spectrum of acridine is divided into five bands; a weak and trailing positive band peaked at around 400 nm (band I), an intense negative band whose vertex lies at 358 nm, being spread over 6000 cm^{-1} and rich in vibrational structures (band II), a weak positive band at 265—310 nm (band III), an intense and sharp negative band at 257 nm (band IV), and a positive band centered at 243 nm (band V). From Figs. 3 and 4, the ICD spectrum of phenazine is analyzed into the following; a weak and trailing positive band whose peak lies at around 405 nm (band I), an intense and broad negative band centered at 366 nm (band II), a medium positive band at 276 nm (band III), an intense and sharp negative band peaked at 255 nm (band IV), and a rather strong positive band whose maximum lies at 242 nm (band V).

It is well known that in these dye molecules the relatively weak ^1L_b bands (molecular long-axis polarized) overlap with the intense ^1L_a bands (short-axis polarized) in the wavelength region 300—400 nm, and the very weak ^1B_a bands (short-axis polarized) are hidden in the very intense ^1B_b bands (long-axis polarized) in the wavelength region 200—300 nm.[6] Furthermore, the longer wavelength region of these bands might be overlapped with very weak n→π* bands. Since there has been made no accurate experimental analysis so far, we tentatively try to resolve the overlapped bands into their components, consulting the dichroic spectral analyses of these dyes embedded in stretched poly (vinyl alcohol) sheets made by Inoue *et al.*[7] The divided spectra of acridine and phenazine are shown by the dotted lines in Figs. 1—4, where we have paid no regard for n→π* transitions.

From these band resolutions, we can safely say that in acridine and phenazine bands II and IV (negative) correspond to the long-axis polarized ^1L_b and ^1B_b bands, respectively. Band II of acridine has a detailed

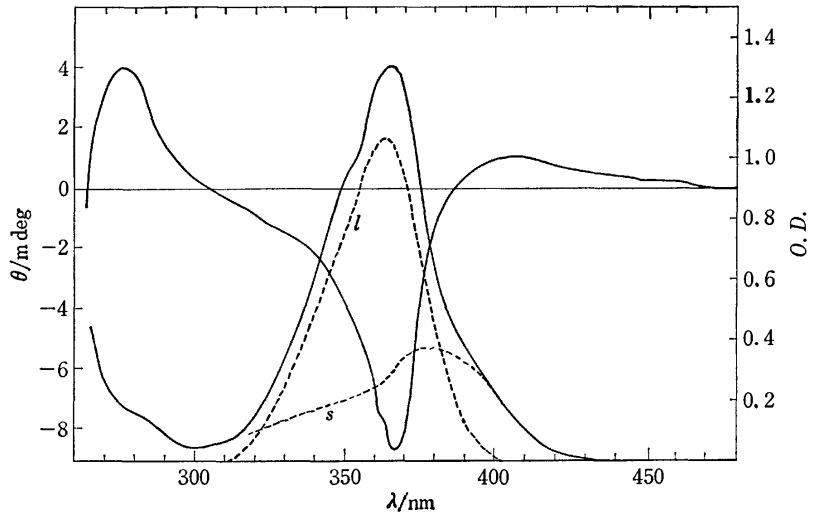

Fig. 3. UV and CD spectra of phenazine in cellulose diacetate film in longer wavelength region. Film thichness: 15 μm. Dotted curves are the same as in Fig. 1.

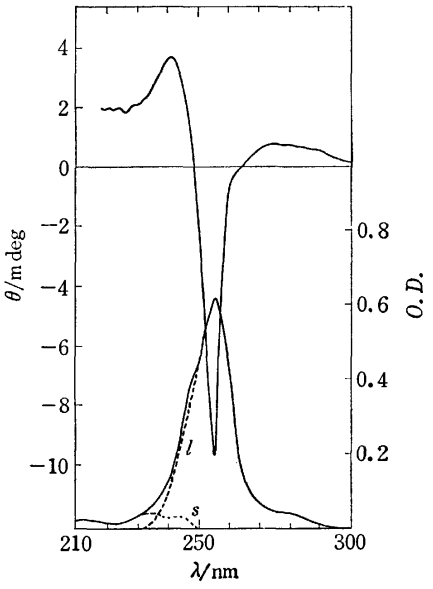

Fig. 4. UV and CD spectra of phenazine in cellulose diacetate film in shorter wavelength region. Film thickness: 5 μm. Dotted curves are the same as in Fig. 1.

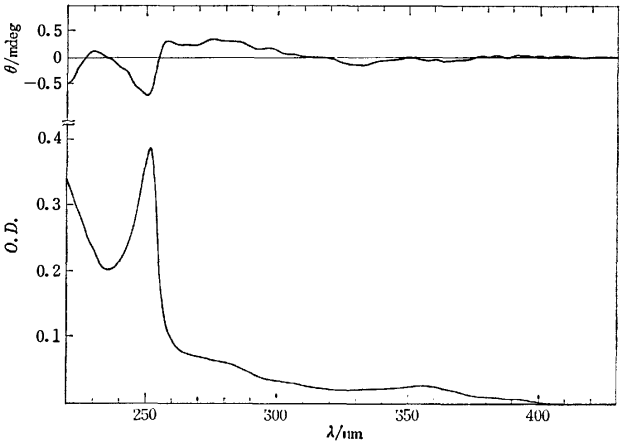

Fig. 5. UV and CD spectra of pure cellulose diacetate film.

structure, the ellipticity of each minimum being roughly proportional to the intensity of the corresponding vibrational absorption maximum in the UV spectrum. The peak of band I in the acridine film keeps at a distance from the maximum of the short-axis polarized ^1L_a transition, though the separation is not very large (*ca.* 2000 cm^{-1}), and its magnitude of ellipticity is too small if the origin of band I is assigned to be ^1L_a. This is probably because the originally rather intense positive band due to ^1L_a, which might be assumed to have a peak at around 370 nm, is partly cancelled out by very intense band II and then the resultant overlapped bandshape of Fig. 1 is observed. The same explanation applies to band I of the phenazine film (Fig. 3).

Band V of both acridine and phenazine is tentatively assigned to have an origin in the short-axis polarized ^1B_a transition. The question why the ellipticity of band V is so large while the resolved ^1B_a is very weak remains untouched. More inexplicable situation is the case of band IV. In the phenazine film, there appears a shoulder at about 280 nm in the absorption spectrum which roughly corresponds to the positive maximum of band III. Incidentally, such a shoulder is not observed in the solution spectrum of pure phenazine and phenazine+cellulose diacetate. On the contrary, even a shoulder does not appear in the 260—290 nm region of the absorption spectrum of the acridine film.

The whole spectral features mentioned above are summarized in Table 1. An obvious fact is that the long-axis polarized transition induces a *minus* CD and the short-axis polarized transition a *plus* CD. Furthermore, it may be safely said that the intensities of ICD bands I, II, and IV are proportional to those of the corresponding absorption spectra which have origins of CD induction.

We now discuss about a mechanism of the ICD in the present systems. A possibility of forming a charge-transfer complex between cellulose diacetate and the dye molecules is scarce, since we have not

Table 1. Correlation between the sign of induced circular dichroism (ICD) and the direction of polarization of allowed transitions

Band	$\frac{CD_{max}}{nm}$	CD sign	$\frac{\lambda_{max}}{nm}$	Direction of polarization	Tentative assignment
Acridine					
I	≈400 (w) [a]	+	370 (s)	short-axis	B_1
II	358 (s)	−	358 (s)	long-	A_1
III	275	+			
IV	257 (vs)	−	254 (vs)	long-	A_1
V	243 (s)	+	243 (vw)	short-	B_1
Phenazine					
I	≈405 (w)	+	380 (m)	short-	B_{2u}
II	366 (s)	−	365 (s)	long-	B_{1u}
III	265 (m)	+	(280) [b]		
IV	255 (vs)	−	255 (vs)	long-	B_{1u}
V	242 (m)	+	242 (vw)	short-	B_{2u}

a) Letters in parentheses are abbreviations for spectral intensities. b) A weak shoulder.

observed any absorption and CD spectra that are expected to be caused by a charge-transfer mechanism. Next, it is possible that the matrix partially forms a spatially regular helical structure along which the dye molecules are lined up just as mentioned in item (a) of the early paragraph. The entire cellulose diacetate matrix may be composed of a part where the cellulose chains line up regularly, probably in a helical structure in a certain spot, and a part where such chains are folded for some reason.[8] However, there were not enough dye molecules in our sample to induce CD through the dipole-dipole interaction between the helically stacked and/or intercalated dye molecules. Of course, it is still possible that the sparsely embedded dye monomer exhibits an ICD, being involved in a complicated interaction with the asymmetric environment of the matrix.[9] It will be mentioned later that even this will not be the case.

The remaining possibility is item (b) mentioned in the early paragraph. Our tentative model structure is that the dye molecule is imprisoned in a cage of a suitable spatial extent formed by an assembly of the folded chains of cellulose diacetate, and the Cotton effect is induced in the allowed transition region of the dye molecule due to the asymmetric perturbation of cellulose diacetate. It is hard to make proof of this model, but the following consideration might be of service to credit that the model is not an offhand one. First, the CD spectral shapes look closely like those induced in the β-cyclodextrin cage in which case we have succeeded in predicting the signs and magnitudes of ICD by making use of an approximate polarizability theory.[10] If a geometrical conformation of the cellulose diacetate cage were known, the very similar method could be applied to the present system in order to guess the ICD signs and intensities. Second, the relationship between the signs and intensities of the ICD spectra and the UV absorption spectral intensities in the present system can be compared with that observed for the DNA–dye and the RNA–dye systems.[9] In the latter systems we found two types of induced Cotton effect; one appearing at low P/D ratios (DNA phosphate residue/dye concentration) results from an interaction between dye dimers aggregated along the nucleic acid helices, which shows a quite different CD spectral feature from that of the present system, and the other appearing at high P/D ratios is probably due to an interaction between a dye monomer and an asymmetric perturber in DNA, which yields a CD spectral shape that closely resembles the present case. In the present study, we tried to find out whether the shape, sign, and intensity of the ICD are dependent on concentration, but we could not succeeded in getting a transparent film when the concentration of the dyes was increased. There is an evidence from polarized infrared measurements of a cellulose triacetate film that the folding of the cellulose chain occurs at a certain temperature in the vicinity of room temperature;[11] this fact suggests the existence of a spatial cavity in a cellulose film, either a perfect cage or mere vacant space.

At this stage of discussion, we must mention about our experimental detail, because there has often been asked the difficult problem of whether a strain effect remaning even in an unstretched film produces a spurious CD spectrum due to the linear dichroism of the sample;[12] the usual spectropolarimeter is unable to exclude a considerable amount of the linearly polarized beam passing through a sample. Strictly speaking, every film tested had an anisotropic portion which showed somewhat different absorption spectra when a linearly polarized light was illuminated and the film was rotated perpendicularly to the incident light. However, about two third of the whole surface of a good film selected under the inspection of a polarizing microscope were isotropic with regard to a linearly polarized light, and UV and CD spectra were obtained with reproducibility of 2%. These spectral data were not dependent on the film thickness (3—20 μm) and the dye and cellulose diacetate concentrations (1—8 $\times$ 10^{-4} mol dm^{-3} in acetone). We did not investigate the rate of vaporization of acetone, though it was considered to be important in order to prepare a film which is most suited for the study of this type. In-

cidentally, a sample made by immersion of the pure cellulose diacetate film in an acetone solution of the dyes did not show any CD spectrum. This way of preparing films are usally used in a linear dichroism observation for dyes embedded in stretched polymer films.[7,13] Therefore, the phenomenon demonstrated in the present article is not ascribable to a regular arrangement of the dye adhered to a distorted matrix as mentioned before.

Looking at a problem of CD induction in the present system from all angles just as mentioned hitherto, it admits of no doubt to believe that the circular dichroism to be induced in optically inactive molecules by optically active matrices is due to a complex formation between one molecule and one certain segment of the matrix. If this segment forms a cage in which the optically inactive molecule is imprisoned, the situation will be more favarable, though this is not a necessary condition. A direct mechanism of appearance of the ICD spectrum then is attributable to an electrostatic interaction between electronic transition dipole moments of the included molecule and of the chromophores involved in the segment cage. Unfortunately, a quantitative comparison between the signs and intensities of the observed ICD bands and those to be predicted along this line of theoretical consideration cannot be made unless a definite atomic arrangement of the cage in a film state is known. On the other hand, we will be able to do this with a clathrate compound whose three dimensional structure has been determined accurately and/or can be guessed without ambiguity. One of such systems is the clathrate between β-cyclodextrin and aromatic compounds, an analytical result of which will be presented soon.[10]

The Crystal and Molecular Structure of Tetracyclo[6.4.3.0.0^{2,7}]-pentadec-4-en-13-one

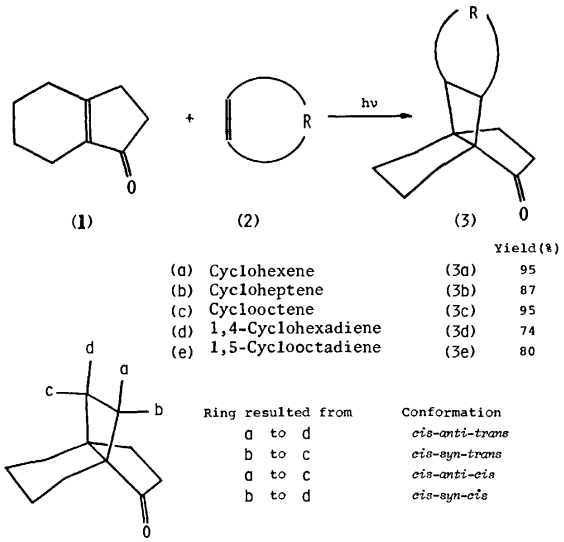
Shigeru KOSHIBE,† Yasushi KAI, Noritake YASUOKA,†† and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received August 13, 1979)

The X-ray molecular structure of the photocycloadduct of bicyclo[4.3.0]non-1(6)-en-7-one with 1,4-cyclohexadiene has been determined. The crystals belong to the monoclinic system, space group $P2_1/c$, $Z=4$, $a=8.108(1)$, $b=8.836(1)$, $c=17.095(1)$ Å, and $\beta=95.38(1)°$ at 22 °C; $a=7.975(1)$, $b=8.760(1)$, $c=16.949(2)$ Å, and $\beta=94.85(1)°$ at −160 °C. The structure was solved by the direct method and refined by the least-squares procedure to $R=0.052$ (22 °C) and 0.053 (−160 °C) for 1777 and 2349 non-zero reflections respectively. The ring junction between the four- and six-membered rings is *trans*. The molecule has the *cis-anti-trans* structure. No essential difference is observed between the molecular structure at 22 °C and −160 °C except for the thermal motions.

Odaira and his coworkers[1] have found that a photoreaction between bicyclo[4.3.0]non-1(6)-en-7-one (**1**) and aliphatic cycloolefins (**2**) gave a single cycloaddition product (**3**) although four types of isomers were expected to be formed.



In order to determine the stereochemistry of the photocycloadducts, X-ray analyses of **3a**,[2] **3d**, and **3e**[3] have been carried out. This paper will deal with the molecular structure of **3d** at 22 °C and −160 °C. Interest in the effect of the ring size on the detailed structure of the photocycloadducts also prompted this study.

Experimental

Colorless, square-prismatic crystals were kindly supplied by Professor Y. Odaira and his coworkers of this University.

A Rigaku automated, four-circle diffractometer was used for the measurement of the unit-cell dimensions and the integrated intensities. Graphite-monochromatized Cu $K\alpha$ and Mo $K\alpha$ radiations were used at 22 °C and −160 °C respectively. The low temperature was attained by the gas-flow method of liquid nitrogen. Crystals with approximate dimensions of $0.25\times0.25\times0.3$ mm (22 °C) and $0.3\times0.3\times0.3$ mm (−160 °C) were used; they were coated with collodion to prevent sublimation. The crystal data are given in Table 1.

Table 1. Crystal data of **3d**

$C_{15}H_{20}O$, monoclinic	*F.W.* 216.3, mp 80—81 °C, space group $P2_1/c$	
	22 °C	−160 °C
a/Å	8.108(1)	7.975(1)
b/Å	8.836(1)	8.760(1)
c/Å	17.095(1)	16.949(2)
β/°	95.38(1)	94.85(1)
V/Å^3	1219.3(1)	1179.8(3)
D_m/g cm^{-3}	1.18	
Z	4	4
D_c/g cm^{-3}	1.18	1.218
μ/cm^{-1}	5.56 (for Cu $K\alpha$)	0.795 (for Mo $K\alpha$)

The unit-cell dimensions were determined by the least-squares fit of 2θ values of high-angle reflections.

The intensity data were collected by the θ-2θ scan technique at a 2θ rate of 2° min^{-1}. The scan widths were $\Delta2\theta=(2.0+0.28\tan\theta)°$ at 22 °C for Cu $K\alpha$ and $(2.0+0.70\tan\theta)°$ at −160 °C for Mo $K\alpha$. The backgrounds were counted for 10 s before and after the scan of each peak. Totals of 1808 ($\theta\leqq120°$ at 22 °C, Cu $K\alpha$) and 2730 ($\theta\leqq55°$ at −160 °C, Mo $K\alpha$) unique data were collected, of which 83 (22 °C) and 381 (−160 °C) less than $3\sigma(F)$ were classed as unobserved. Three standard reflections (400, 1,1,$\bar{1}\bar{0}$, and 040) were measured at every 60 reflections at both temperatures; no intensity decrease was observed during the data collection. Corrections for the usual Lp effect was carried out, but not for absorption [μ(Cu $K\alpha$)=5.56 and μ(Mo $K\alpha$)=0.795 cm^{-1}].

Structure Solution and Refinement

The structure was solved by the direct method with the *MULTAN* program,[4] using intensity data obtained at 22 °C. All the non-hydrogen atoms appeared clearly in the E map based on the set of signs with the highest figure of merit. All the hydrogen atoms were located by difference synthesis. The structure was refined

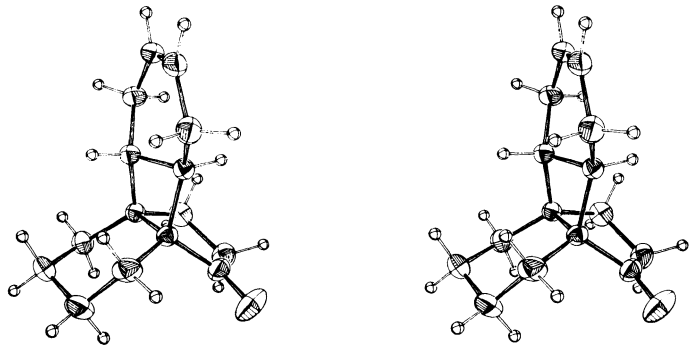

Fig. 1. An *ORTEP* drawing[9] of the molecule. Non-hydrogen atoms are represented by thermal ellipsoids at 20% probability level.

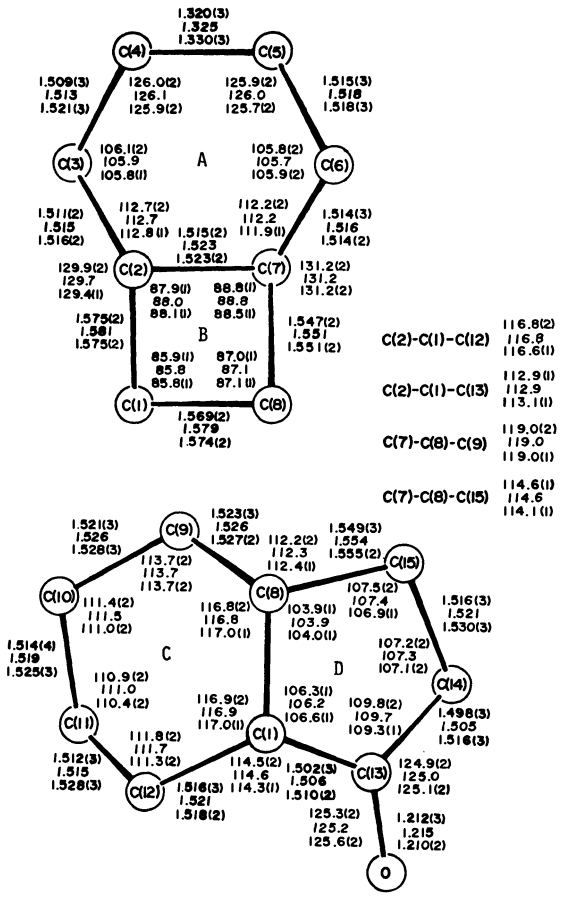

Fig. 2. Bond lengths and bond angles with e.s.d.'s in parentheses.
Upper figure: room temperature structure (22 °C). Middle figure: as above, corrected for the thermal motion by the rigid body approximation.[8] Lower figure: low temperature structure (−160 °C).

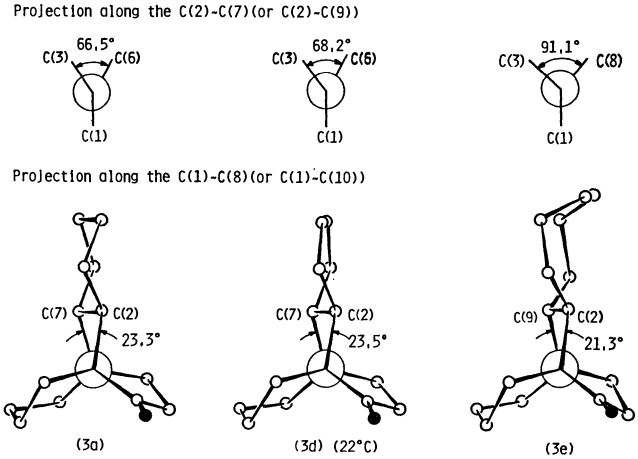

Fig. 3. A view of the three related molecules projected along the C(1)–C(8) or the corresponding C(1)–C(10) bond, and Newman projections along the C(2)–C(7) or the corresponding C(2)–C(9) bond. Oxygen atoms are expressed as dark circles.

with the weight unity by means of the block-diagonal least-squares procedure (*HBLS*-V program[5]). Anisotropic and isotropic thermal parameters were applied for non-hydrogen and hydrogen atoms respectively. The final R value was 0.052 for 1725 non-zero (0.055 for all 1808) reflections.

The anisotropic refinement of the low-temperature structure was started by using the atomic parameters obtained by the use of the room-temperature data. The locations of all the hydrogen atoms were confirmed by the difference systhesis, the parameters of which were refined isotropically. The final R value was 0.053 for 2349 non-zero (0.070 for all 2730) reflections. The weighting schemes used were $w=(\sigma^2(F_o)+a|F_o|+b|F_o|^2)^{-1}$ for $|F_o|>0$ and $w=c$ for $|F_o|=0$. In the case of $a|F_o|+b|F_o|^2<0$, $w=\sigma^{-2}(F_o)$ was used instead. The values of a, b, and c used at the final refinements were 0.026, −0.000, and 0.564. The computations were carried out on a NEAC 2200-700 computer at Osaka University.

The atomic scattering factors for non-hydrogen atoms were taken from Hanson *et al.*,[6] and for hydrogen, from Stewart *et al.*[7] The final atomic parameters are listed in Table 2.†††

Results and Discussion

Molecular Structure. A perspective view of the molecule is shown in Fig. 1, while the bond lengths and bond angles are given in Fig. 2.

No essential difference is observed between the molecular structures at 22 °C and −160 °C except for the

††† The tables of the structure factors (22 °C and −160 °C) are kept as Document No. 8005 at the Chemical Society of Japan.

thermal motions. The room-temperature structure shows a shortening of the bond lengths far from the center of the molecule due to the thermal motion of atoms. This shortening could be rather well corrected by the rigid body approximation of the molecule,[8] and the corrected values can be compared with those of the low-temperature structure (Fig. 2). However, some discrepancies are seen in the bond lenths of C(11)–C(12), C(13)–C(14), and C(14)–C(15). This may be due to the non-rigidity of the molecule.

The most distinctive feature of the molecular structure is that the A/B ring junction is *trans*, while the photocycloadduct has the *cis-anti-trans* structure (Scheme). The present compound has a structure very similar to those of **3a** and **3e** except for the local structure of the A ring. The similarity and difference in the room-temperature structures of the three related molecules may clearly be seen in Fig. 3. The torsional angle about the C(2)–C(7) bond in the present molecule [68.2°] is similar to that in **3a** [66.5°], but they are much smaller than that about the corresponding C(2)–C(9) bond in **3e** [91.1°]. This can be interpreted as being due to the size difference of the A ring. The torsional angle about the C(1)–C(8) bond [23.5°] is equal to that in **3a** [23.3°]; these values are slightly larger than that about the corresponding C(1)–C(10) bond in **3e** [21.3°].

The central cyclobutane ring (B Ring) is puckered, and such a puckering is also observed in the other two compounds; these structures are compared in Table 3. The longest C–C bond, a [1.575(2) Å], is much longer than the normal C–C single bond. The c bond [1.547(2) Å], the length of which is equal through the three compounds, is slightly longer than the usual length. No significant difference is observed between the corresponding bond lengths nor bond angles in **3a** and **3d**. However, some deviations from these are seen in **3e**; the b bond [1.544(3) Å] is longer, d [1.549(3) Å] is shorter, and the α [86.9(1)°] and γ

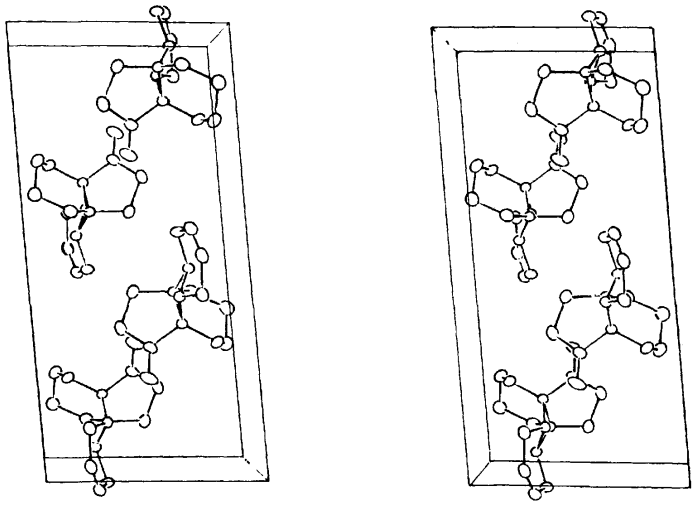

Fig. 4. A stereoscopic drawing of the crystal structure of **3d** (Present study).

(c)

Fig. 5. Crystal structure of the three related molecules viewed down along the b axis.
(a) **3a**, (b) **3d**(Present study), (c) **3e**.
Oxygen atoms are expressed as dark ellipses.

[88.9(1)°] angles are larger than the corresponding bond lengths and angles in the other two compounds.

Almost all the bond lengths and bond angles in Rings C and D in the present compound (**3d**) are equal to the corresponding lengths and angles in **3a** and **3e**, within the limits of error, except for the bond lengths, f and k, and bond angles involving the bridgehead carbon atoms, ζ, ϕ, and χ (Table 4).

Crystal Structure. A stereoscopic drawing[9] of the molecular packing is given in Fig. 4. Some close atomic contacts are observed between molecules related

Table 5. Short intermolecular atomic contacts [*l*/Å] (less than 3.6 Å), with e.s.d.'s in parentheses

by a two-fold screw axis. The carbon atom next to the carbonyl group of the D ring, C(6), has the closest contact between the carbonyl oxygen atoms of the adjacent molecules along the 2_1 axis [3.406(3) Å at 22 °C]. The other close contacts are listed in Table 5.

The packings of the **3a** and **3d** molecules are compared with that of the present crystal in Fig. 5.[9] In the **3a** crystal, the carbonyl oxygen atoms have close atomic contacts between atoms in the adjacent molecules related by the 2_1 axis and the center of symmetry (Table 5). In the **3e** crystal, close intermolecular atomic distances are noticed between the two adjacent molecules related by the center of symmetry (Fig. 5(c) and Table 5). Throughout the three related compounds, it can be concluded that the carbonyl oxygen atoms of the D ring play an important role in the packing of molecules.

The authors wish to express their deep thanks to Professor Yoshinobu Odaira and his coworkers of this university for their kindness in supplying the crystals. The authors' thanks are also due to Miss Nobuko Kanehisa, who helped them with the *ORTEP* drawings.

(Received August 20, 1979)

The structure of [(*R*)-1-cyanoethyl][(*S*)(−)-α-methylbenzylamine]bis(dimethylglyoximato)cobalt(III) has been determined by X-ray analysis at 293 K and 173 K. The crystal is monoclinic; the space group is $P2_1$; $Z=2$, with $a=8.665(2)$, $b=13.485(3)$, $c=9.584(3)$ Å and $\beta=96.95(3)°$ at 293 K, and $a=8.786(2)$, $b=13.500(2)$, $c=9.243(2)$ Å, and $\beta=98.09(3)°$ at 173 K. The structures were deduced by the heavy-atom method and refined by the block-diagonal least-squares technique to the final R values of 0.055 and 0.038 for 1940 and 1948 observed reflections at 293 K and 173 K respectively. The bis(dimethylglyoximato)cobalt moiety is twisted around its long axis because of the steric repulsion from the (*R*)-1-cyanoethyl group and the optically active amine. The degree of the twist is the same as that observed in the structure of [(*R*)-1-(methoxycarbonyl)ethyl][(*R*)(+)-α-methylbenzylamine]bis(dimethylglyoximato)cobalt(III). The conformation of the amine ligand was ascertained to be influenced by the substituted alkyl group through the bis(dimethylglyoximato)cobalt moiety.

The complexes of bis(dimethylglyoximato)cobalt (abbreviated to $Co(dmg)_2$ or cobaloxime) and optically active amine catalyze the asymmetric hydrogenation of olefins.[1-6] In order to clarify the mechanism of inducing the asymmetry, several crystal structures of related complexes have been determined by X-ray analysis.[7-9] In Part III of this series on the crystal structure of [(*R*)-1-(methoxycarbonyl)ethyl] [(*R*)(+)-α-methylbenzylamine] bis (dimethylglyoximato) cobalt-(III) (abbreviated to the R–R ester complex), it has been shown that the $Co(dmg)_2$ plane is twisted around its long axis because of the steric repulsion from the (*R*)-1-(methoxycarbonyl)ethyl group and the optically active amine, α-methylbenzylamine.[9] We proposed in that paper that the twist is one of the factors inducing asymmetry in the reaction step of σ-bond formation.

To examine whether or not the twist exists in other complexes, we have determined the crystal structure of the title complex, the R–S cyano complex, in which the methoxycarbonyl group is replaced by the cyano group. Preliminary experiments revealed that the crystal changes its unit-cell dimensions upon X-ray exposure without the degradation of a single-crystal form. The change was proved to reflect the racemization of the cyanoethyl group.[10] When the crystal was cooled, it contracted in an abnormally anisotropic manner and the gradual change of its unit-cell dimensions upon X-ray exposure was no longer detectable below 173 K.[11] The crystal structures at 293 K and 173 K were determined to confirm the mechanism of the racemization, which has already been reported.[11,12] This paper will present the twist of the $Co(dmg)_2$ plane caused by the short contacts with the cyanoethyl group and the conformation of the amine ligand.

Experimental

Dark red plate-like crystals of the R–S cyano complex, whose preparation will be reported elsewhere, were obtained from an aqueous methanol solution. The selection of the crystal was carefully made on a microscope because the preliminary photographic technique could not be used. A crystal $0.14\times0.20\times0.60$ mm in size was set up on a Rigaku four-circle diffractometer, Mo $K\alpha$ radiation monochromated by graphite being used ($\lambda=0.71069$ Å). The unit-cell dimensions were obtained by means of the least-squares technique with 15 reflections ($2\theta>20°$). Their values before and after the data collection are shown in Table 1. The average values in the last column were used in this work. The crystal data are summarized in Table 2. During the intensity-

Table 1. The change in the unit-cell dimensions

	Start 1[a]	Start 2[b]	End[c]	Average[d]
a/Å	8.665(2)	8.661(2)	8.657(2)	8.659

data collection, the orientation matrix was redetermined if the intensities of three monitor reflections were significantly deteriorated. The intensities of the independent reflections with $2\theta \leqq 50°$ were measured with an $\omega/2\theta$ scan, a scanning rate of $8°(2\theta)\ \mathrm{min}^{-1}$, and a scan range of $(1.0+0.35\tan\theta)°$. Stationary background counts were accumulated for 5 s before and after each scan. A total of 1940 independent reflections, $|F_o| \geqq 3\sigma(|F_o|)$, were obtained.

For the experiment at low temperatures, the nitrogen-gas-flow method was used. The experimental details were the same as those at room temperature, using a crystal $0.15 \times 0.25 \times 0.40$ mm in size. 1948 independent reflections, $|F_o| \geqq 3\sigma(|F_o|)$, were obtained. Corrections for the Lorentz and polarization factors were made, but no correction for absorption was applied.

Structure Determination

The structure at 293 K was deduced by the heavy-atom method and was refined by the block-diagonal least-squares technique. All the hydrogen atoms were found on the difference map. The final refinement was made with the anisotropic and isotropic temperature factors for non-hydrogen and hydrogen atoms respectively. The weighting scheme of $w=0.3$ if $|F_o| > 70.79$ and $|F_o| < 7.08$ and $w=(0.0023F_o^2-0.17906|F_o|+4.48559)^{-1}$ if $7.08 \leqq |F_o| \leqq 70.79$ was employed. The final R became 0.055 for 1940 reflections. No peaks higher than 0.25 e Å^{-3}, except a peak of 0.45 e Å^{-3} around the cobalt atom, were found on the final difference map.

The procedure of the structure determination at 173 K was the same as that at 293 K. The weighting scheme of $w=0.2$ if $|F_o| > 100.69$ and $|F_o| < 7.55$ and $w=(0.00185F_o^2-0.19964|F_o|+6.40248)^{-1}$ if $7.55 \leqq |F_o| \leqq 100.69$ was applied. The final R was 0.038 for 1948 reflections. No peaks higher than 0.23 e Å^{-3}, except the peaks of 0.58 e Å^{-3} around the cobalt atom, were found on the final difference map. The atomic-scattering factors were taken from the International Tables for X-Ray Crystallography.[13] The final atomic coordinates and their standard deviations at 293 K and 173 K are given in Tables 3 and 4 respectively. The lists of the thermal parameters and the observed and calculated structure factors are kept in the office of the Chemical Society of Japan (Document No. 8006). The computation was done on M-180 and M-160 computers at this Institute.

Description of the Structure

The equations of the mean planes of four nitrogen atoms and two dmg's are given in Table 5, together

a) Atoms included in the least-squares calculation.

with the deviations of the atoms from the planes. The projection of the structure at 293 K in the (I) plane is shown in Fig. 1, in which the short contacts between the non-bonded atoms are also given. The $Co(dmg)_2$ plane is twisted around its long axis, as is observed in the R–R ester complex. A fairly strong repulsion between N(1) and C(18) tilts the plane (II), whereas the contacts between N(4) and C(9) and between N(4) and C(11) tilt the plane (III) in the opposite sense. The deviations of the four nitrogen atoms at 293 K are the same as those of the R–R ester complex. However, the deviations of C(1), C(2), and C(3) are not so large. In the ester complex,

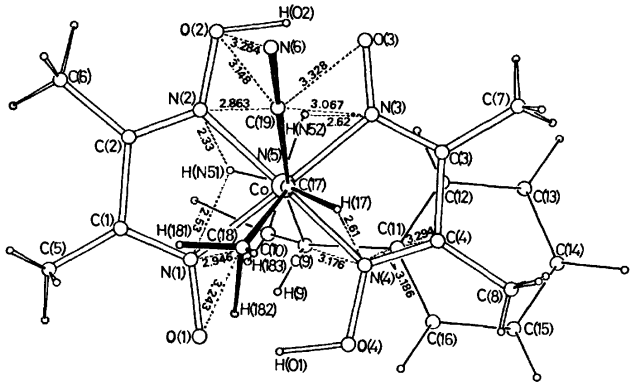

Fig. 1. Projection of the complex onto the mean plane of four nitrogen atoms of $Co(dmg)_2$ and the short contacts between non-bonded atoms (l/Å) at 293 K, their threshold values being 3.400 Å for distances between the non-bonded atoms and 2.70 Å for those including hydrogen atoms.

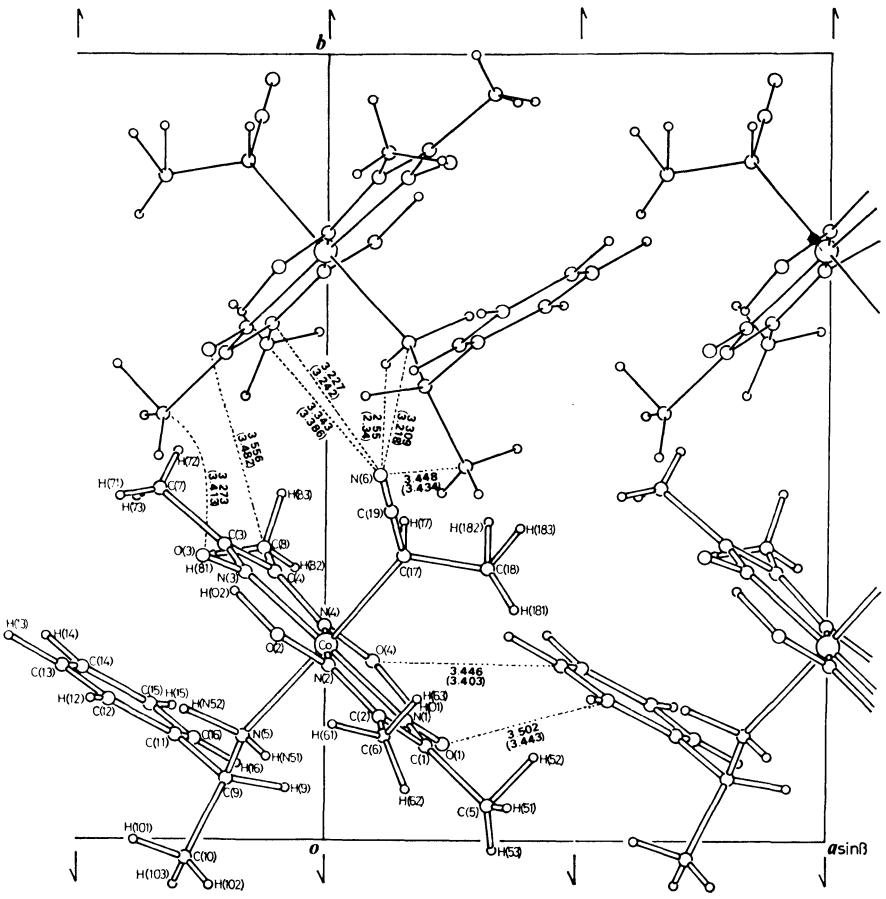

Fig. 3. Projection of the crystal structure along the c axis and short contacts bweteen complexes. The short contacts at 173 K are in the parentheses.

both of the methoxycarbonyl and methyl groups lie on the dmg planes. The carbon atoms of the dmg rings must deviate from the planes as a result of the steric repulsion from the methoxycarbonyl and methyl groups. The cyano and methyl groups in the present complex, on the other hand, are located over the gaps between the two dmg's. Therefore, only the nitrogen atoms should be affected by the steric repulsion from the cyanoethyl group.

The deviations of the atoms of the $Co(dmg)_2$ moiety from the plane (I') at low temperatures becomes smaller than those at room temperature. The short contacts between the non-bonded atoms at 173 K are compared with the corresponding ones at 293 K in Table 6. The distances at 173 K are rather smaller than those at 293 K.

The deviation of the cobalt atom from the mean plane of $Co(dmg)_2$ is small at both temperatures. The Co atom in the methyl complex is shifted by 0.04 Å from its mean plane of $Co(dmg)_2$ toward the amine ligand, whereas the Co atom in the ester complex deviates toward the ester group by 0.04 Å. This indicates that the deviation of the Co atom from the mean plane of $Co(dmg)_2$ is affected by the relative bulkiness of the axial ligands.

The bond distances at 293 K are shown in Fig. 2, and they are compared with the corresponding ones at 173 K in Table 7. The bond angles at both temperatures are listed in Table 8. The Co–C(17) and Co–N(5) bonds at 293 K are shorter by 0.02 Å and longer by 0.018 Å respectively than the corresponding ones at 173 K. The sums of the two bonds, however, are nearly equal at both temperatures. As the C(17) atom comes close to the cobalt atom at high temperatures, the angles of Co–C(17)–C(18) and Co–C(17)–C(19) become larger and the $Co(dmg)_2$ plane may be twisted more.

The three bonds around N(3), Co–N(3), N(3)–O(3), and N(3)–C(3), and the two bonds around N(4), Co–N(4), and N(4)–O(4) at 293 K have different distances from the corresponding ones at 173 K. The two angles around N(3), Co–N(3)–O(3), and O(3)–N(3)–C(3), have different values between the two temperatures. These differences may indicate that the resonance state of dmg is changed by the modified electronic state of Co, which is itself caused by the short Co–C distance at high temperatures.

The C(17)–C(18) distance at 293 K is significantly shorter then that at 173 K, probably because of the large thermal vibration of the C(18) atom. The other bond distances and angles are in fair agreement between the two temperatures.

The crystal structure viewed along the c axis is shown in Fig. 3, in which the short contacts are given. There is a short contact between N(5) and N(6) in the unit of $(-x, -0.5+y, 1-z)$. The N···N distances are 3.309 and 3.218 Å for 293 and 173 K respectively. The distanecs of H(N51)···N(6) and the angles of

Table 9. Characteristic dimensions of the amine in the various complexes

Bending of C(9)-C(11) from the phenyl ring	2.2°	4.0	4.0	2.9	3.3	4.8	3.5

a) Ref. 16. b) The value of the R-R ester is omitted. c) Distances of C(4)···C(11), the others being N(4)···C(11).

N(5)-H(N51)···N(6) are 2.55 Å and 149° for 293 K, and 2.34 Å and 152° for 173 K. This seems to be a weak hydrogen bond, judging from the previously reported N-H···N hydrogen bond.[14] The other contacts are not unusually short.

Discussion

In this serial study attempting to clarify the mechanism of inducing asymmetry, the distortion of the $Co(dmg)_2$ moiety has been examined for various substituted alkyl ligands. The optically acitve amine, α-methylbenzylamine, is kept unaltered except for its absolute configuration, because it seems necessary first to elucidate the effect of the substituted alkyl ligand on the $Co(dmg)_2$ moiety. For this purpose, it is assumed that the conformational change, if any, of the amine ligand is not seriously influenced by the intermolecular force or crystalline field, while it is influenced by the intramolecular force.

In Table 9, the characteristic dimensions and conformations of the amine in the crystal structures thus far determined are compared. As the crystals of the cyano complexes exhibit an abnormal thermal expansion, the values at 173 K are also listed. The Co–N(5) bond lengths range from 2.054 to 2.088 Å. Such variation seems to be brought about by the *trans* Co–C bond and will be discussed in detail in the following paper. The average length of N(5)–C(9) is in good agreement with the usual distance, 1.472± 0.005 Å.[15] The average distance of C(9)–C(11) is slightly longer than the usual one, 1.505±0.005 Å.[15] Bond distances, however, have relatively large variations. This may be due to the short contacts between the amine and the $Co(dmg)_2$ moiety.

The angles of N(4)–Co–N(5) and Co–N(5)–C(9) deviate from the right and tetrahedral angles respectively to avoid the short contact between N(4) and C(9). The average value of Co–N(5)–C(9)–C(11) is 78.3°. The torsion angle of the ester complex is significantly larger than the average value. This is due to the fact that the $Co(dmg)_2$ moiety is bent toward the amine. To avoid the short contacts between C(11)···N(4) and C(11)···C(4), the N(5)–C(9) bond rotates from the stable staggered form toward the eclipsed form.

The rotation around the Co–N(5) bond, that is, the torsion angle of N(4)–Co–N(5)–C(9), varies from 0.8° to 39.7°. In Part II of this series,[8] the most stable conformation was calculated to be 13°, and the potential energy curve against the torsion angle closely resembled a quadratic in the vicinity of 13°. For both cyano complexes, the deviations from the stable conformation are in the opposite direction, but are nearly equal. The energies should be practically the same for both complexes. The amine ligand in each cyano-complex crystal comes in contact with the cyanoethyl group of the neighbouring molecule. Such deviations in the opposite direction, therefore, should be brought about by the opposite configuration of the cyanoethyl group. The $Co(dmg)_2$ plane is bent toward the methyl group in the methyl complex, whereas it is bent toward the amine in the ester complex. The conformation around the Co–N(5) bond in the former complex is close to the stable one, whereas the bond in the latter rotates from the stable conformation to a considerable extent. These facts suggest that (i) the Co–N bond distance is apparently affected by the *trans* Co–C bond; (ii) although the conformation around the Co–N bond is affected by the crystalline field, the potential energy caused by such a conformation is nearly equal if the substituted alkyl group is the same except for its absolute configration, and (iii) the torsion angle of N(4)–Co–N(5)–C(9) depends on the bulkiness of the substituted alkyl group, showing 13+5° for the methyl group, 13±10° for the cyanoethyl group, and 13+27° for methoxycarbonyl group. The assumption mentioned above, therefore, holds good for the determined crystal structures. This seems to indicate that the difference in energy between the σ-complexes containing *R*- and *S*- substituted alkyl groups is attributable to the structure of the $Co(dmg)_2$ moiety or the Co–N and Co–C distances. These points will be discussed in detail in the following paper.

The Deuteron Magnetic Resonance of Tin(II) Chloride Dihydrate Single Crystals in High- and Low-temperature Phases

Hideko KIRIYAMA* and Osamu NAKAMURA**

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

***Government Industrial Research Institute, Osaka, Midorigaoka 1, Ikeda, Osaka 563*

(Received September 3, 1979)

The deuteron magnetic resonance spectra of $SnCl_2 \cdot 2D_2O$ single crystals have been measured from 208 to 300 K in order to elucidate the static and dynamic structures of water molecules in connection with the phase transition occuring at 234 K. The deuteron quadrupole coupling constants (asymmetry parameters) were determined at 208 K for four non-equivalent water deuterons. These values are 194.2±0.3 (0.066±0.004), 193.2±0.5 (0.112±0.003), 223.3±0.4 (0.206±0.003), and 244.0±0.4 kHz (0.058±0.003), depending largely on the hydrogen-bond strength or the D···O distance. The deuteron arrangements deduced from the EFG tensors agreed well with the ordered structure reported by an earlier ND study. The dynamical process of deuterons responsible for the high-temperature disordered structure was analyzed with the aid of the ND results and was ascribed to a combination of the flip motion of water molecules about each two-fold axis and their rotational motion around each pseudo-three-fold axis.

The phase transition in $SnCl_2 \cdot 2H_2O$ (abbreviated as SCD) was first found at 218 K (at 234 K for its deuterium analogue) from an anomaly in the dielectric constant measured by Kiriyama and Kiriyama.[1] An earlier X-ray work showed that two kinds of water molecules are arranged alternately to form a characteristic H-bonded layer in the crystal lattice, and also that the phase transition is accompanied by no distinct change in the structure of non-hydrogen atoms.[2] A subsequent neutron diffraction (ND) experiment determined the ordered and disordered arrangements of deuterons below and above the phase-transition temperature, T_t, respectively.[3,4] On the other hand, proton (PMR) and deuteron (DMR) magnetic resonance studies provided direct evidence that the phase transition is due to the ordering of hydrogen (or deuterium) atoms in the H-bonded network.[5] A closer X-ray examination of the structure has disclosed that, in the vicinity of T_t, the [100] and [001] axial lengths and, consequently, the three H-bonded O···O distances steeply change in association with the ordering of the hydrogen atoms.[4]

The ordering process of water hydrogens and the various critical phenomena upon the phase transition were investigated in detail by means of heat-capacity[6] and dielectric measurements[7] as well as by Raman spectroscopies.[8,9] A statistical theory developed for use with the two-dimensional H-bonded network by Salinas and Nagle is helpful in understanding the mechanism of the phase transition as well.[10]

In order to locate the hydrogen atoms in the low-temperature phase and to clarify their dynamic nature, involving the motion of the water molecules in the high-temperature phase, DMR and PMR experiments were carried out using single crystals. Some of these results have been reported previously.[1,5,11]

Experimental

Sample. A commercially available extra-pure reagent, SCD, was ground into a fine powder and then dehydrated in a vacuum desiccator for 12 d at room temperature. The anhydrous sample so obtained was identified by means of its X-ray powder patterns and IR spectra. For the present DMR work, large single crystals were needed to obtain suitable signals. About $20 \times 15 \times 40$ mm^3 in size, they were grown by very slow cooling from saturated aqueous (D_2O) solution of the anhydrate, $SnCl_2$, which had been acidified with DCl. The crystal shape was an elongated prism parallel to the [001] axis, with well-developed side planes, (100) and (110). All the interfacial angles of a deuterated crystal were identical to those of the non-deuterated one, within the limits of experimental error, in accord with the fact that the lattice constants of the two compounds are almost the same.[4] The single crystals were cut and shaped into cylindrical rods, typically 15 mm in diameter × 20 mm long. The axes of the three cylinders were chosen to be parallel to the crystallographic b and c axes, and the normal, to the (100) plane; the last direction will, hereinafter, be referred to as a* axis for convenience.

Measurements. The deuteron magnetic resonance spectra were measured at the Larmor frequency of 6.9 MHz with a frequency-variable, Pound-Watkins-type spectrometer and at 8 MHz with a bridge-type spectrometer (JNM-8, JEOL). The quadrupole effect on NMR or quadrupole splitting was measured at five-degree intervals of rotation angle about each of the mutually perpendicular axes, a*, b, and c. The temperature of a sample was measured by the use of a calibrated copper-constantan thermocouple and was controlled to ±0.3 K throughout the experiments.

Preliminary Remarks

Crystal Structure. The previous X-ray examination showed that no significant isotope effects on the lattice parameter and on the crystal structure are observed on deuterium substitution. Therefore, unless otherwise noted, the description of the structure will be concerned with ordinary $SnCl_2 \cdot 2H_2O$. The crystal is monoclinic, with the space group $P2_1/c$ and with $Z=4$. The lattice parameters are $a=9.158$, $b=7.156$, $c=8.942$ Å, and $\beta=114.50°$ at 88 K, and $a=9.320$, $b=7.277$, $c=8.970$ Å, and $\beta=114.91°$ at 293 K.[2,4] The unit cell contains two kinds of water molecules; the first, $H_2O(1)$, coordinates to a tin(II) atom to form a trigonal pyramid of the dichloroaquatin(II) complex, $SnCl_2 \cdot OH_2$, whereas the second, $H_2O(2)$, does not (Fig. 1). These two kinds of water molecules are alternately connected by three O–H···O-type H-bonds, and the resulting sheets run parallel to the (100) plane. On the assumption of a double-minimum

potential for each H-bond, the seven sites shown in Fig. 1 are possible for four independent water–hydrogens.

Analytical Method. The quadrupole interaction in the present study can be treated as a first-order perturbation to the Zeeman energy, because the deuteron quadrupole coupling constant, e^2qQ/h, of about 200 kHz for a stationary water deuteron is much smaller than both Larmor frequencies of measurements. When a single crystal is turned about the z-axis, *i.e.*, for the z-axis rotation, the quadrupole splitting measured from the Larmor frequency, $\Delta\nu_z$, is expressed in the following convenient form:[12]

$$\Delta\nu_z = (3/8)(eQ/h)[V^1_{zz}-(V^1_{xx}-V^1_{yy})\cos 2\phi - 2V^1_{xy}\sin 2\phi] \quad (1)$$

where V^1_{ij} is the electric-field gradient (EFG) tensor at a given deuteron site in the laboratory coordinate system (x, y, z) fixed to a probe head and where ϕ is the angle of the static magnetic field, H_0, measured from the reference axis (x-axis) on the rotation plane. The angular dependence or the rotation pattern of $\Delta\nu_z$ around the z-axis yields only the first three of the five independent EFG components, V^1_{xx}, V^1_{yy}, V^1_{xy}, V^1_{yz}, and V^1_{zx}. For this reason, the rotation patterns were measured around the three a*, b, and c axes, and then combined in the usual way. By diagonalizing the tensors thus obtained, the principal values and the direction cosines of the principal axes for every

EFG were determined in the crystallographic coordinate system.[13]

When a water molecule reorients rapidly at high temperatures, as in the present case, the EFG tensor for the moving deuteron should be averaged over the several sites spent by it. This averaging is actually performed by superposing the individual EFG's.

Results and Discussion

DMR Spectra in the Low-temperature Phase. Below the transition temperature (234 K), eight, four, and eight pairs of lines were observed about the a*, b, and c axes respectively, with a maximum splitting of about 180 kHz. These facts indicate that two nonequivalent water molecules are stationary in the low-temperature phase on the DMR scale. Every rotation pattern is consistent with the space group $P2_1/c$, which is the same as in the high-temperature phase. Thus, the present results provided no evidence in support of the antiferroelectric nature below T_t proposed by Mognaschi *et al.*,[7] in accord with the X-ray and ND results.

The rotation patterns measured at 208 K are presented in Fig. 2. As the figure shows, two independent pairs of sine curves cross at nearly the same point on each diagram when the magnetic field is along either the a*, b, or c axis. Therefore, the EFG tensors were calculated for 80 possible combinations of the sine curves. Such a large number of possibilities, however, was first reduced to one-half its initial number by assuming an e^2qQ/h value of about 200 kHz and an η value of nearly zero for a stationary water deuteron. Secondly, the number was further reduced to ten from the viewpoint of crystal symmetry involving the two-fold axis and the c-glide plane.

Then, we tried to assign the obtained EFG tensors to the individual deuterons on the basis of the following empirical rules:[12,14]

(1) the principal z axis of an EFG tensor is nearly

TABLE 3. RELATION BETWEEN THE DIRECTIONS OF THE PRINCIPAL AXES OF THE EFG TENSORS AT 208 K AND THE CONFIGURATION OF THE WATER MOLECULES IN SCD (standard deviations in parentheses)

		O(1)		O(2)	
		D(2)	D(4)	D(5)	D(7)
ϕ_z/°	Model I	6.9(16)	11.2(15)	3.0(39)	—

	Model II	112.5(1)		107.6(1)	
	ND	104.0(5)		106.4(5)	

parallel to the direction of an O–D bond, and

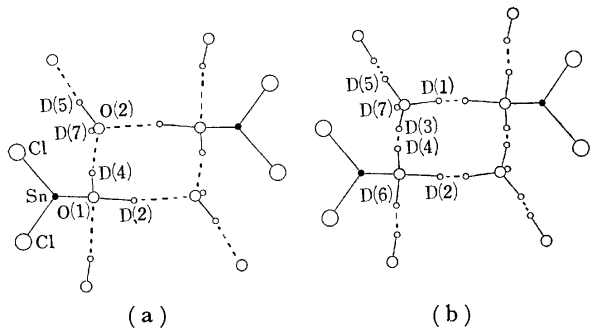
(2) the principal y axis is nearly perpendicular to the molecular plane of D_2O.

The assignment based on the empirical rules successfully reduced the combination number to only two. For these models, I and II, the values of e^2qQ/h and η are summarized in Tables 1 and 2, where the direction cosines of each EFG principal axis are also included. In practice, however, no significant difference is observed between them in regard to the deuteron arrangement, *viz.*, the configuration of the water molecules of interest.

Configuration of Water Molecules. As has been described previously, the crystal structure suggests three and four available deuteron sites in the neighborhoods of O(1) and O(2) respectively.[2] If the Bernal and Fowler rules hold for the H-bonded water layers in SCD, then three of deuteron arrangements or of H-bonding schemes may be anticipated for an ordered state below T_t. Of these, only one type of scheme could be judged by the assignment of EFG for either model. The results obtained were in good agreement with the ND results, in turn supporting our assignment (Fig. 3a).

In Table 3, the configurations of water molecules for Models I and II are compared with those from the ND work, by using four characteristic angles, ϕ_z, ψ_z, θ_{yy}, and θ_{zz}; ϕ_z is the angle between the principal z-axis and the assigned O(D)···O direction of a deuteron; ψ_z, the angle between the principal z-axis and the O–D direction determined by ND; θ_{yy}, the angle between the principal y axes at two deuteron sites of a water molecule, and θ_{zz}, the corresponding angle between the two principal z axes.

The ϕ_z angle is widely spread, from 3° to 14°, and its maximum was found at $D_2O(1)$, probably because of its small acceptor angles, O···O(1)···O, such as 90.2° at 88 K (88.2° at 297 K).[4] On the other hand, the values of ψ_z are nearly zero, within the limit of experimental error, except for D(2). These facts provide additional evidence for the validity of the empirical rule (1) which has been used for suggesting O–D directions on the basis of the DMR results. The θ_{yy} values of $D_2O(1)$ in both models are about 21°,



(a) (b)

Fig. 3. Configuration of water molecules in (a) low- and (b) high-temperature phases.

considerably larger than the experimental values in the literature. The θ_{zz}'s of $D_2O(2)$ for both models are very close to the average bond-angle (108°) for water molecules of crystallization, and also to the ND results. Concerning the θ_{zz}'s of $D_2O(1)$, a slight but significant difference was disclosed between the two models. That is, the θ_{zz} values are 98.5° for the configuration Model I and 112.5° for II, compared with the D–O–D angle of 104.0° at 88 K (102.7° at 297 K) obtained from the ND results. In addition to the fact that the bond angle of a water molecule may be affected by forming O–D···O hydrogen bonds only a little, the EFG at the deuteron site may be influenced to some extent by the H-bonded-acceptor oxygen. It is, therefore, probable that the θ_{zz} of $D_2O(1)$ is smaller than the D–O(1)–D bond angle determined by ND; for this reason, Model I has been chosen as the basis for further discussion.

As has been mentioned earlier, Salinas and Nagle proposed a statistical model of the two-dimensional H-bonded network in SCD. They succeeded in predicting the temperature dependence of hydrogen occupancy at individual sites as well as the deuteron arrangements in the ordered structure.[10] On the other hand, Wang *et al.* demonstrated that the intensity of the Raman spectra associated with H-bonded vibrations changes gradually and continuously near T_t. They discussed this feature on the basis of the occupation probabilities of hydrogens at the various sites.[9] Under these circumstances, it became necessary to confirm whether or not the present DMR data are of the completely ordered state, because the temperature of the measurements, 208 K, is lower than T_t by only 26 K. However, the experimental results regarding the two-fold b-axis showed that the resonance line assignable to D(5) has almost the same intensity as those of the remaining three lines and that no absorption due to D(6) can be detected. It is, therefore, certain that the ordered arrangements of deuterium atoms are well established, even at 208 K, at least on the DMR scale. Unfortunately, no spectra could be observed below 200 K, possibly because of the very long spin-lattice relaxation times.

H-bonds in the Ordered-phase below T_t. It has been recognized that the quadrupole coupling constant of a deuteron, e^2qQ/h, reflects the H-bond strength and, consequently, depends on the O···O distance or, more precisely, on the D···O distance. Soda and

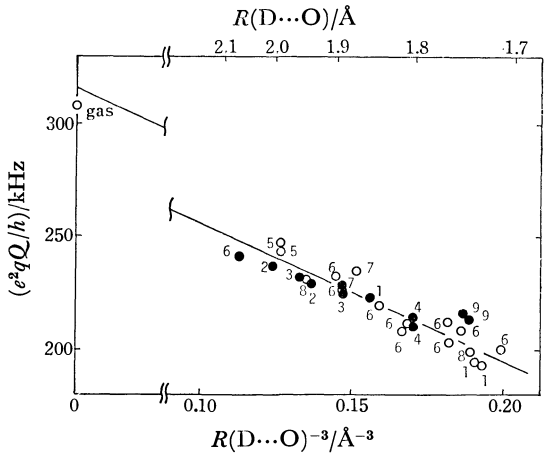


Fig. 4. Correlation between the observed quadrupole coupling constants and the reciprocal cube of hydrogen bond length R(D···O) in O-D···O type of hydrogen bonds. Black circles indicate the plot for non-coordinated water molecules. The plots correspond to 1: $SnCl_2 \cdot 2D_2O$ (this work and Ref. 4), 2: α-$(COOD)_2 \cdot 2D_2O$,[17,18] 3: β-$(COOD)_2 \cdot 2D_2O$,[17,18] 4: $(KCOO)_2 \cdot D_2O$,[19,20,21] 4: $Ba(ClO_3)_2 \cdot D_2O$,[12,22,23] 6: $CuSO_4 \cdot 5D_2O$,[15,24] 7: $NaHC_2O_4 \cdot D_2O$[25] 8: $LiHCOO \cdot D_2O$,[26,27] and 9: D_2O(Ice).[28,29]

Chiba first derived a useful relation based on the available DMR and ND results:[15]

$$e^2qQ/h = 310.0 - 3.0 \times \frac{190.6}{R(\mathrm{D}\cdots\mathrm{O})^3} \quad \text{(in kHz)}, \qquad (2)$$

where R(D···O) is the D···O distance in Å units. The coefficient, 190.6(kHz), is the e^2qQ/h value of a deuteron due to a unit charge placed apart from it by 1 Å. It is noteworthy that the constant, 310.0 kHz, is close to the e^2qQ/h value (307.95 kHz)[16] for a free water molecule in spite of the lesser reliablity of the early ND data. By using more reliable, three-dimensional ND results, including those in SCD, value of e^2qQ/h is plotted again as a function of R(D···O) in Fig. 4. The least-squares fitting on the 27 data points of nine hydrated crystals as well as of ice gave the following relation:

$$e^2qQ/h = 317.1 - 3.0 \times \frac{200.2}{R(\mathrm{D}\cdots\mathrm{O})^3} \quad \text{(in kHz)}, \qquad (3)$$

where, the coefficient, 200.2 kHz, is based on a recent, experimental value of eQ (2.875×10^{-27} cm^2).[30] As can be seen in Fig. 4, no discrimination between coordinated water molecules and non-coordinated ones is necessary at all for relating e^2qQ/h to R(D···O). The above relationship will be used below to estimate the unknown value of e^2qQ/h from a known R(D···O).

DMR Spectra in the High-temperature Phase. The pair separation, $2\Delta\nu$, and the width of each component line were almost unchanged up to T_t (234 K), above which the whole spectra disappeared. As the temperature was further raised up to about 280 K, the signal again became observable. Figure 5 represents a typical temperature dependence of the quadrupole splitting at a rotation angle of $\phi_b = 95°$ around the two-fold b axis where the ϕ_b angle is measured away from the positive c axis toward the positive a axis

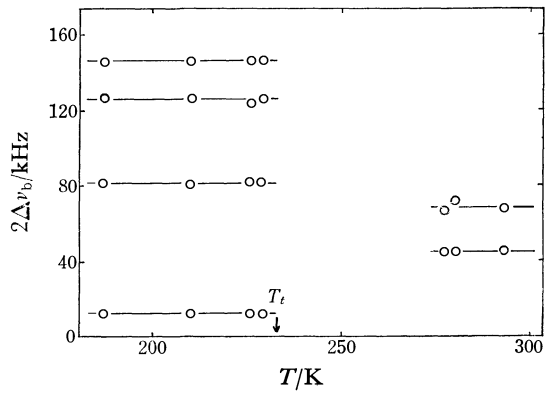

Fig. 5. The temperature dependence of quadrupole splittings around b-axis. $\phi_b = 95°$.

on the b plane (010). It should be noted that, in the high-temperature phase, the number of splitting is reduced by half and the pair separation, $2\Delta\nu$, decreases to less than half its low-temperature, rigid-lattice value. These facts indicate that all the deuterons are in some motional state above T_t and that their rate becomes fast enough to make the high-temperature spectra observable above 280 K. Since the S/N ratio of the signal was very poor, no motional parameter of deuterons could be estimated from the collapse of the splitting lines or line broadening. The above feature of the spectra, however, can be explained by assuming that the correlation time for deuterons is of the same order as for protons; the values determined from the pulsed PMR measurement are 2.3×10^{-5} and 2.3×10^{-7} s at 230 and 280 K respectively.[5]

Additionally, the high-temperature signal was observable only in a restricted angular region of less than 50° around the a* direction, which is perpendicular to the H-bonded water layer. The angular dependences of the experimental quadrupole splitting about the b and c axes are reproduced in Fig. 6.[5] The spectrum about the b axis clearly splitted into two pairs of lines. This finding, together with the symmetry relation, allowed us to expect the observation of four pairs of lines for the c-axis rotation. The outermost lines indeed showed the doublet structure at ϕ_c's of 105° and 110°, corroborating this expectation.

Deuteron Motion in the High-temperature Phase. The maximum splitting at room temperature is only about 40 kHz, much smaller than that expected for the two-fold reorientation, *i.e.*, the 180° flipping of water molecules. In the present case, however, the average EFG tensors for moving deuterons cannot be deduced because of the incomplete data above T_t. In order to clarify the dynamic process responsible for the deuteron disordered structure, we tried to simulate the rotation pattern for various types of motion suggested by the ND results (Fig. 3b). The average EFG for the moving deuteron in question was computed by using the method described previously. In this calculation, the empirical rules (1) and (2), and either the typical, found or expected values for e^2qQ/h and η in the stationary state were used. Then, the validity of each motional model was judged by the number of component lines about

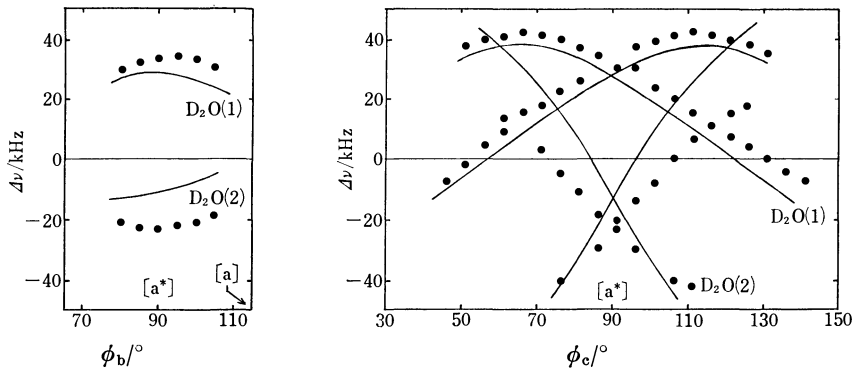

Fig. 6. Rotation patterns around (a) b-axis and (b) c-axis at room temperature. Soild curves indicate the calculated ones for Motion 5.

the unique b-axis, the width of quadrupole splitting, $\Delta\nu$, and its angular dependence.

First, the following three types of motion were checked:

Motion 1: *The 180°-flip of water molecules about each two-fold axis, as is found in many hydrated crystals.* The rotation pattern simulated about the b axis coincides with the observation in the number of splitting, but it differs greatly from the measurement in its magnitude and angular dependence.

Motion 2: *The jump motion of deuterons between two equilibrium positions in an O–D···O deuteriun bond, as is recognized in some H-bonded crystal like ferroelectric KH_2PO_4 substances.* This type of motion leads to four pairs of lines, which are assigned to the D(1)–D(2), D(3)–D(4), D(5)–D(6), and D(7) sites illustrated in Fig. 3b, in disagreement with the observation of only two pairs.

Motion 3: *The hindered rotation of both kinds of water molecules about their pseudo-three-fold axes, as proposed from the earlier ND results.*[5] In such a case, because one deuteron of $D_2O(2)$ is fixed at the D(7) site, three pairs of lines are expected; they are assigned to the D(7) and D(1)–D(3)–D(5) sites for $D_2O(2)$ and the D(2)–D(4)–D(6) sites for $D_2O(1)$, with an intensity-ratio of 1 : 1 : 2. This motion can also be excluded in view of the number of splitting.

Hence, it became necessary to combine either two or three of the above three types of motion in order to explain the experimental results. The following models were further examined:

Motion 4: *The combination of Motions 1 and 2.* This model gives rise to only a single spectral line, because all deuterons can move from one to another throughout all the seven deuteron sites, D(1)—D(7). Therefore, this can not be the case.

Motion 5: *The combination of Motions 1 and 3.* Two pairs of spectral lines are anticipated, because two deuterons of $D_2O(1)$ exchange their sites among the D(2), D(4), and D(6) sites, while those of $D_2O(2)$ do so among the D(1), D(3), D(5), and D(7) sites. The rotation pattern for this model was tentatively calculated by using the typical values of e^2qQ/h (=220 kHz) and $\eta(=0)$ for all the deuterons, regardless of the difference in H-bond strength discussed above. On averaging the EFG tensors, it must be taken into account that the molecular planes of both $D_2O(1)$ and $D_2O(2)$ change their orientations through Motion 5, with the probabilities depending on the occupancy factors of the individual deuteron sites, which are determined by the ND study. The occupancies of the D(2), D(4), and D(6) sites for $D_2O(1)$ were initially approximated by 2/3, while those of the D(1), D(3) and D(5) sites were approximated by 1/3 and that of D(7); by 1 for $D_2O(2)$.[3] Thus, the simulated rotation patterns around the b and c axes resemble to the experimental ones, especially in the magnitude of splitting and number (Fig. 3 in Ref. 5). This adequacy of the model led us to compute the rotation pattern based on the reasonable coupling constants derived from Eq. 3 and on the occupancies obtained from the ND study.[4] The results are shown in Fig. 6. The fit to the observation is not very good, but the agreement between them seems satisfactory enough in view of the oversimplified model and the uncertainty in both DMR and ND experiments at room temperature.

Motion 6: *The combination of Motions 2 and 3.* Two pairs of lines with the intensity ratio of 1 : 3 are to be expected for the b-axis rotation; the former is assigned to the D(7) site, and the latter, to all the other sites from D(1) to D(6). Since the observed intensity ratio was almost 1 : 1, this model is not adequate.

Motion 7: *The combination of Motions 1, 2, and 3.* Because all deuterons can travel to all the deuteron sites, from D(1) to D(7), the b-rotation pattern may be expected to consist of only one pair of lines, in conflict with the observation.

It is, therefore, concluded that the motion of deuterium atoms in the high-temperature, disordered phase of SCD is best described as a combination of the 180°-flip and the hindered rotation about the Sn–O(1) and D(7)–O(2) bonds for $D_2O(1)$ and $D_2O(2)$ respectively. The direction of Sn–O(1) makes an angle of 16° with the axis normal to the H-bonded water layer, *viz.*, the a* axis, while the corresponding angle for D(7)–O(2) amounts to 41°.

The proton dynamics associated with the phase transition, as has been mentioned previously, have been investigated by Mognaschi *et al.*[7] They explained the critical phenomena of the dielectric constant in terms of a "critical slowing down" of the electric polarization, which was ascribed to the proton

transfer along an H-bond in a double-minimum potential. We cannot discuss such critical behavior from the viewpoint of DMR, since our data are lacking in the vicinity of T_t. On the other hand, a logarithmic plot of the proton spin-lattice relaxation times *vs.* the reciprocal temperature showed a deep, cusp-shaped reduction around T_t, in contrast to the prediction by Mognaschi *et al.*[5,7] The structural information from X-ray results may be significant in this regard. On passing through the transition, the distances of the three non-equivalent H-bonds vary with the temperature in different ways. Consequently, the resulting change in the potential energy makes the critical dynamics too complex to discuss in the light of the present theories.

The present DMR study has shown that the dynamic process occuring in the high-temperature phase well above T_t is assignable to Motion 5, that is, the combination of the 180°-flip and pseudo-C_3 reorientation of water molecules, excluding the deuteron transfer. Therefore, even if the jump motion along an H-bond is involved in the disordered phase, its rate must be too slow to affect the DMR spectra. In the earlier paper we pointed out that the noticeable d.c. conductivity found in SCD is attributable to the proton mobility, as with ice.[1] Mognaschi *et al.* have recently provided strong evidence for the protonic conduction and proposed a combination of the translation of protons along H-bonds and the rotation of water molecules as the conduction mechanism.[31] Another striking feature of our model is that the deuteron at D(7), whcih is free from any deuterium-bond, is not stationary, but travels among the four allowed sites around D(2). The occupancy factor at D(7) is expected to be unity, the same as in the low-temperature, ordered state, this being consistent with the ND results.

The authors wish to express their thanks to Professor Emeritus Ryôiti Kiriyama of Osaka University for his continued interest and fruitful discussion.

Dielectric Study of Aliphatic Esters in Cyclohexane Solutions at the Frequency of 100 GHz

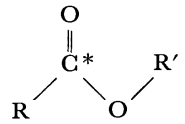
Yoshikazu KANO, Ryuichi MINAMI, and Hiroaki TAKAHASHI*

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received August 29, 1979)

The dipole relaxation mechanism of carboxylic esters has been studied through the dielectric measurements of seventeen aliphatic esters in cyclohexane solution at 25 °C. The dielectric relaxation times obtained in this experiment are compared with those obtained for a number of rigid molecules under the same conditions. This result indicates that the dipole relaxation process of these esters RC*OOR′ is dominated by intramolecular rotation around the C–C bonds and/or the O–C bond rather than that around the C*–O bond.

This paper deals with the results of dielectric measurements of seventeen aliphatic esters in cyclohexane solution at 25 °C at the frequency of 100 GHz. The dielectric data obtained in this experiment and those by Crossley and Koizumi[1] obtained for the same esters under the same conditions using lower microwave frequencies were examined to explore the mechanism of the dielectric absorption of aliphatic esters RC*OOR′ (hereafter, C* means the carbon atom in a carbonyl group). All the results indicate that the dielectric



absorption of these esters is dominated by intramolecular relaxation. However, in contrast to Crossley and Koizumi[1] who considered that the dipole orientation of the methoxyl and ethoxyl groups around their C*–O bonds is very important especially for a few esters, the present authors reached the conclusion that rotations of groups around the C–C bonds and/or the O–C bond play the dominant role in the dielectric absorption of the aliphatic esters.

Experimental

The apparatus and procedure used to determine dielectric constants (ε') and losses (ε'') at 100 GHz have been described previously.[2] Static dielectric constants (ε_0) were measured at 1 MHz and refractive indices (n) were determined at the frequency of Na-D line. The slopes a_0, a', a'', and a_D were obtained from ε_0, ε', ε'', and n_D^2 of the solvent and solutions as in the previous papers.[2,3] The units of weight fraction were used to express the concentration of the solute in solution.

Results

The values of a_0, a', a'', and a_D obtained for the aliphatic esters in cyclohexane solution at 25 °C are listed in Table 1. Two relaxation times $\tau(1)$ and $\tau(2)$ given by

$$\tau(1) = \frac{1}{\omega}\frac{a''}{a'-a_D}; \quad \tau(2) = \frac{1}{\omega}\frac{a_0-a'}{a''}$$

are recorded in Table 1—ω denotes the angular frequency. The physical significance of $\tau(1)$ and $\tau(2)$ have been discussed in previous reports.[3,4] As a large error seems to arise from the bold assumption that a_D is equal to a_∞ (the slope at the extremely high frequency), we shall not place much reliance on values of $\tau(1)$.

For each of the esters Cole-Cole plots were made by use of a' and a'' of this experiment at 100 GHz together with those recalculated from Crossley and Koizumi's data obtained at *ca.* 35, 24, 16, 9, 6, 4, and 2 GHz. Crossley and Koizumi made the following remark concerning the highest frequency they employed. "In many cases the frequency of maximum loss is in the region of the highest experimental frequency, and thus the high frequency side of the dispersion is not well characterized." It may be added here that the high frequency side of the dispersion is examined first by the present experiment. The mean relaxation times (τ_0) and the distribution parameters (α) obtained in this way were compared with those given by Crossley and Koizumi using lower microwave frequency data alone (Table 2). We find our τ_0 values are slightly smaller than τ_0 obtained by Crossley and Koizumi in some esters but they compare well on the whole. Further we find values $\tau(2)$ to be sometimes smaller than our values for τ_0.

Discussion

If the Debye theory[5] of dielectric relaxation is correct, the relaxation times (τ_0) of all the rigid polar molecules measured in the same solvent at the same temperature should be proportional to the molecular volume of the solutes. This prediction is examined in Fig. 1 for a number of rigid molecules (code number 21—39; Table 3) in cyclohexane at 25 °C—the molecular volume is obtained by the ratio of the molecular weight (M) to the density (d). We find Debye's theory to be only qualitatively valid. The points for 21—39 scatter in a wide range and the fluctuation appears to be much larger than the error in estimating the molecular volume.[6] There exists a general tendency shown by curve A that the points for rigid molecules move upward with increasing molecular volume.

The relaxation times (τ_0) of seventeen aliphatic esters (code numbers 1—17) are also examined in a similar manner — as an exception, $\tau(2)$ is taken for methyl acetate since τ_0 is not available for this molecule. We can draw curve B through the points for esters. We notice that curve B is situated below curve A and is almost parallel to the abscissa for esters of large molecular volumes. This is a common feature of all flexible polar molecules.[7]

Two curves A and B intersect each other in the

region of molecules with small molecular volumes. One finds that point 1 for methyl acetate is quite close to point 23 for furan.[8] Does this mean that methyl acetate should be considered to have a rigid planar configuration? We have strong evidence from microwave spectroscopy that methyl acetate[9] as well as methyl and ethyl formates[10,11] have plane configurations. Perhaps we can say that rotation of the methyl group around the C*–O bond is not completely free and that it does not dominate the dielectric relaxation. At least we cannot refute the view from our evidence that this C*–O bond is strongly hindered and hence the molecule has a planar configuration. On the other hand, point 9 (ethyl acetate) and 16 (amyl acetate) are on curve B. That is, their relaxation process is the intramolecular one. If the acetyl group cannot rotate around the C*–O bond, rotation of the acetoxy group around the O–C bond should occur instead. And the latter rotation is supposed to be the dominant mechanism for these molecules since the main dipole moment of the ester originates from the carbonyl group.

Lastly attention must be paid to the fact that point 15 for ethyl lactate is on the curve A between points

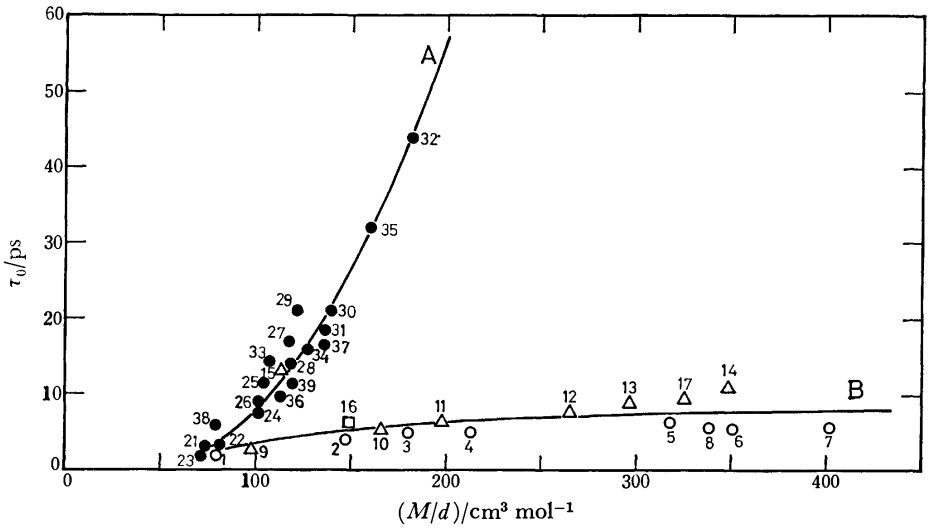

Fig. 1. Plot of relaxation time τ_0 in cyclohexane solution at 25 °C against the molecular volume: Code 1—17 aliphatic esters; 21—39 rigid molecules. M/d of esters 5, 7, and 17 are estimated values.

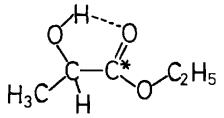
25 (bromobenzene) and 28 (*m*-chlorotoluene) or between points 33 (*N*-methylaniline) and 39 (nitrocyclohexane). Planar configuration appears to be stabilized on account of formation of an intramolecular hydrogen bond in ethyl lactate.[12] Here, rotation of the groups around the central C–C* bond is hindered by the hydrogen-bond formation, and rotation of the ethoxyl group around the C*–O bond is also hindered on account of its partial double bond character. This phenomenon seems to be very important in understanding the nature of dielectric relaxation of flexible aliphatic esters.



In conclusion, it should be pointed out that dielectric relaxation of aliphatic esters is largely dominated by intramolecular rotation around the C–C bonds and/or the O–C bond rather than that around the C*–O bond.

The authors would like to express their sincere thanks to Professor K. Higashi for his guidance throughout the course of this research, and to Professor N. Koizumi of Kyoto University for his very constructive critisism of the manuscript.

Absorption Spectra of the Polyacetylene Films Doped with BF_3

Masashi TANAKA,* Atsushi WATANABE, and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received September 13, 1979)

Optical absorption measurements are carried out on pure and BF_3 doped polyacetylene films over a wide wavelength region (200 cm^{-1}—54000 cm^{-1}). In the lightly doped polymer, the extra peak appears at 870 cm^{-1} and it is assigned to the transition from the valence band to the impurity level. This band becomes more intense at low temperature. For the heavily doped films, the dc conductivity of the $(CH)_x$ fibril is optically estimated to be $\sigma_0 = 10^4\ \Omega^{-1}\ cm^{-1}$. This value is in good agreement with the calculated value ($\sigma_0 = 0.8 \times 10^4\ \Omega^{-1}\ cm^{-1}$) due to the tight binding model.

Polyacetylene is one of the simplest linear conjugated polymers with a single chain structure. Accordingly, many theoretical and experimental studies[1] were reported upon the electronic structure of polyacetylene as a quasi one-dimensional conductor. Shirakawa and coworkers[2-4] succeeded in synthesizing high quality polycrystalline films of $(CH)_x$. The conductivity measured by the four point probe technique was about $10^{-9}\ \Omega^{-1}\ cm^{-1}$ for the *cis*-rich polyacetylene film. Recently, Shirakawa, Heeger, and MacDiarmid and coworkers[5-7] found out that, when flexible, crystalline silvery films of the *cis*-$(CH)_x$ or *trans*-$(CH)_x$ polymer were doped with controlled amounts of electron-attracting species such as chlorine, bromine, iodine, or AsF_5, their electrical conductivity could be systematically varied over a wide range from that of an insulator ($\sigma = 10^{-9}\ \Omega^{-1}\ cm^{-1}$) to a metal ($\sigma = 10^3\ \Omega^{-1}\ cm^{-1}$). Furthermore, the IR[8] and visible-UV[9-11] absorption spectra were measured upon exposure to vapors of chlorine, bromine, iodine, or AsF_5. Tanaka *et al.*[12] studied the infrared reflection spectra of oriented polyacetylene films, doped with varying concentrations of AsF_5 and iodine, and discussed about the relation between the reflectivity and the conductivity of doped $(CH)_x$ films.

In the present paper, we report the absorption spectra in the 200 cm^{-1}—54000 cm^{-1} region of *cis*-rich polyacetylene films doped with BF_3 and discuss about the electronic structure of the heavily doped $(CH)_x$ films.

Experimental

The *cis*-rich polyacetylene films were prepared from acetylene by treatment of the Ziegler catalyst in hexane at −80 °C as described by Shirakawa and coworkers.[2-4] The films were doped by exposure to the vapor of BF_3 at room temperature. The dopant concentration were determined by weight change of the sample.[17]

The IR transmission measurement of the thick films (*ca.* 5×10^{-3} cm) were taken with Hitachi EPI-L (200 cm^{-1}—700 cm^{-1}) and JASCO IRA-3 (330 cm^{-1}—5000 cm^{-1}) spectrophotometers at room temperature and with a JASCO DS-402G (600 cm^{-1}—4000 cm^{-1}) spectrophotometer at low temperature.

The visible and UV transmission data of the thin films (*ca.* 200 Å) polymerized on the inner surface of the 1 cm quartz cell were measured with JASCO IRA-3 (2500 cm^{-1}—5000 cm^{-1}) and Carl Zeiss M4Q (4000 cm^{-1}—54000 cm^{-1}) spectrophotometers.

Results and Discussion

Linear polyacetylene, $(CH)_x$, is the simplest conjugated organic polymer and the π-electrons on each carbon atom delocalize to form a band. The energy of the π-electrons is calculated by the MO theory,[1,11]

$$\varepsilon(k) = \pm\sqrt{t_1^2 + t_2^2 + 2t_1t_2\cos(ka)} \quad (1)$$

where t_1 and t_2 (>0) are the transfer integrals between successive sites, a the C–C bond length, and k the wave vector. In the absence of bond alternation ($t_1 = t_2$), the energy eigenvalues form a band of width $4t$ (Fig. 1-1) which is half-filled with the π-electrons. On the other hand, if one bond is longer than the

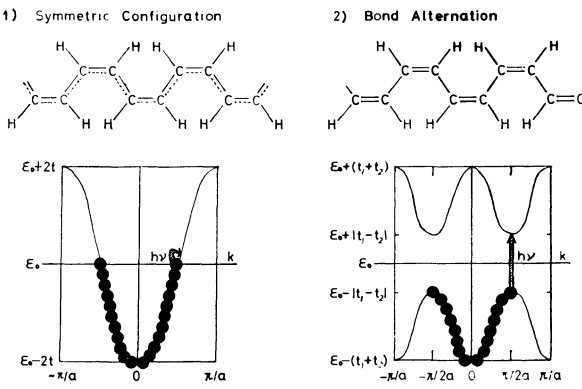

Fig. 1. Energy band diagram for the polyacetylene system.

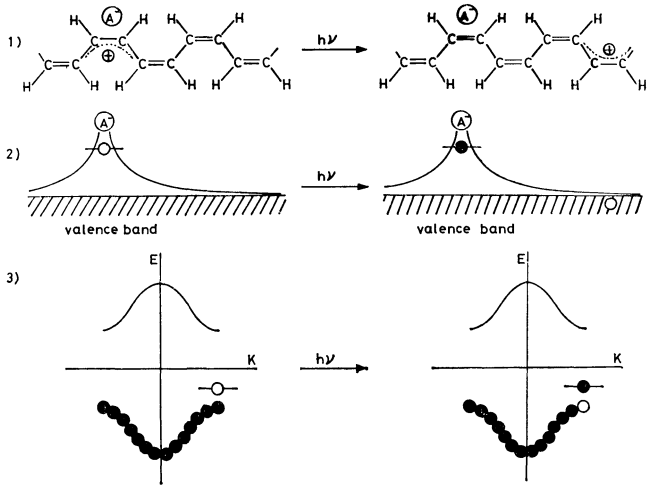

Fig. 3. Character of the 870 cm^{-1} band.
(1) Schematic diagram of acceptor ion (A^-) near a $(CH)_x$ chain. (2) The resulting hole on the polymer chain is bound by the Coulomb potential. (3) The resulting bound state is in the energy gap.

other ($t_1 \neq t_2$), a set of bonding (valence band) and antibonding (conduction band) orbitals is formed and the energy gap in the electronic spectrum is expected as shown in Figs. 1—2.

The absorption spectrum of the undoped polymer has the sharp absorption edge at 12000 cm^{-1} and the peak at 17000 cm^{-1} (Fig. 5, $y=0$). Accordingly, this absorption band can be assigned to the interband transition from the valence band to the conduction band, and shows that the bond alternation is present in the polymer.

In the lightly doped polymer, two infrared peaks of the additional absorption over the undoped sample are observed at 1370 cm^{-1} and 870 cm^{-1} (Fig. 2). The narrow mode at 1370 cm^{-1} was explained by Su, *et al.*[13] as the result of soliton formation in the long chain polyenes.

The broad band at 870 cm^{-1} can be assigned to the transition from the valence band to the hole level by applying the traditional approach in semiconductors. That is, the cation (hole) in the $(CH)_x$ chain is tightly bound to the charge center (A^-) by Coulomb force in a dielectric medium as shown in Fig. 3. Then, the binding energy E of the hole in the screened Coulomb field are given by the following equation,[8,16]

$$-\frac{\hbar^2}{2m^*}\frac{d^2}{dx^2}\psi_n - \frac{e^2}{\varepsilon|x|}\psi_n = E_n\psi_n \tag{2}$$

$$E_n = -\frac{m^*e^4}{2\hbar^2\varepsilon^2}\frac{1}{n^2}. \tag{3}$$

Taking the measured dielectric constant to be $\varepsilon=11$[8] and assuming $m^*/m=1$, the transition from the valence band to the impurity 1s level can be estimated to occur in the vicinity of 900 cm^{-1}. In the thermal equilibrium at room temperature, a few π-electrons can excite from the valence band to the impurity levels. This means that the optical absorption intensity increases at the low temperature. Figure 4 shows the temperature dependence of the 870 cm^{-1} band. The peak is observed at 870 cm^{-1} and located

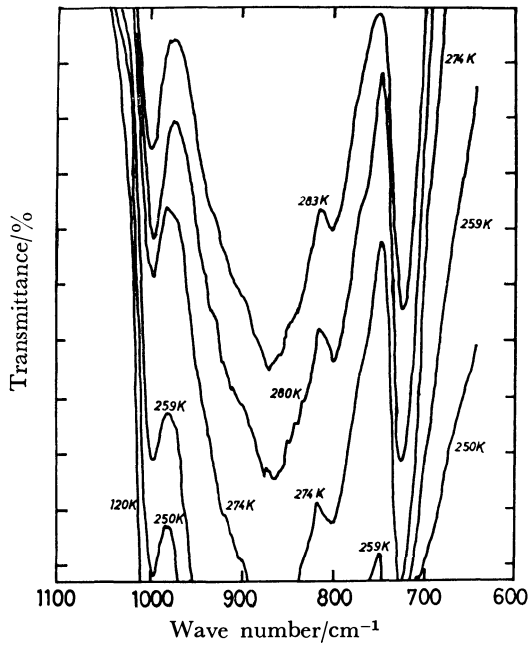

Fig. 4. IR transmission spectra of $[CH(BF_3)_{0.01}]_x$ at various temperature.

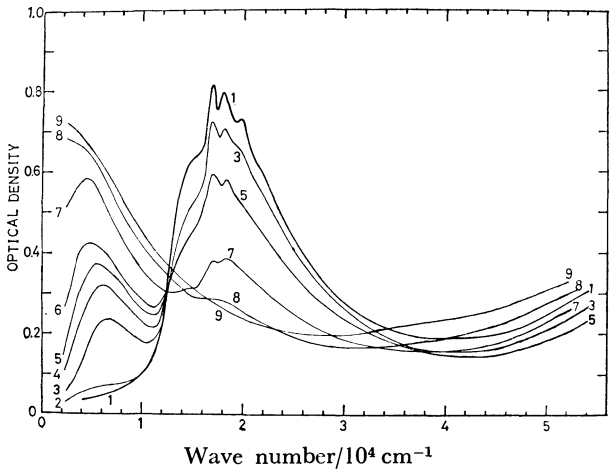

Fig. 5. Absorption spectra of the thin films of $[CH(BF_3)_y]_x$, (1) $y=0$, (2) $y=0.0045$, (3) $y=0.0095$, (4) $y=0.018$, (5) $y=0.025$, (6) $y=0.029$, (7) $y=0.038$, (8) $y=0.051$, (9) $y=0.077$.

between two C–H out of plane bending modes (1015 cm^{-1} in the *trans* isomer and 740 cm^{-1} in the *cis* isomer) and the transmittance of the 870 cm^{-1} band becomes smaller as the temperature decreases.

In addition to the 1370 cm^{-1} and 870 cm^{-1} bands, a broad band appears in the region of 8000 cm^{-1} and the absorption intensity of the interband transition at about 17000 cm^{-1} decreases (Fig. 5). The fact that there is an isosbestic point at 12000 cm^{-1} in the spectra clearly indicates that there is an equilibrium between two absorbing species. Furthermore, the red shift of the broad band suggests that doping removes the bond alternation leading to a uniform bond length as shown in Figs. 1 and 3. That is, the energy gap between the valence and conduction bands becomes small and the metallic state is formed in the heavily doped films. The maximum absorption coefficient of

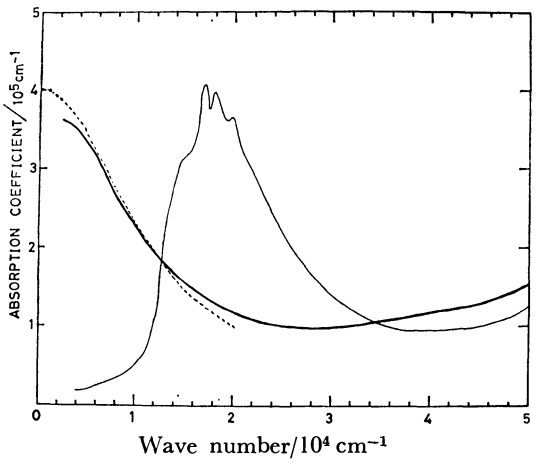

Fig. 6. Comparison between the calculated and observed absorption spectra of the intraband transition band of the metallic doped $(CH)_x$ film.
——: Pure $(CH)_x$, ——: $[CH(BF_3)_{0.077}]_x$, ----: calculated spectra.

the interband transition was determined to be 4×10^5 cm^{-1} near 17000 cm^{-1} by Fincher, *et al.*[11] Accordingly, the absorption coefficient of the intraband transition of the heavily doped films ($y=0.077$) can be estimated as shown in Fig. 6.

The relation between the absorption coefficient $\alpha(\omega)$ and the conductivity $\sigma_1(\omega)$ is given in the following equation,[14]

$$\alpha(\omega)=\frac{4\pi}{n(\omega)c}\sigma_1(\omega)=\frac{4\pi}{n(\omega)c}\frac{\sigma_0^{\text{film}}}{1+\omega^2\tau_0^2} \tag{4}$$

where $n(\omega)$ is the refractive index and c the velocity of light. σ_0^{film} and τ_0 are the dc conductivity of the $(CH)_x$ film and the relaxation time, respectively. These parameter were determined by the optimum fit of Eq. 4 to the experimental data where the refractive index $n(\omega)$ is taken to be unity. The fit was obtained with $\sigma_0^{\text{film}}=1070\ \Omega^{-1}$ cm^{-1} and $\tau_0=0.43\times 10^{-15}$ s. The calculated absorption spectrum based on these values is plotted for comparison with the experimental curves in Fig. 6.

Electron microscopy photographs of $(CH)_x$ films show a fibril structure with typical fibril diameter of about 200 Å. The individual fibrils are randomly oriented and the polymer has the volume filling factor of about $f=1/3$.[11] Then, the dc conductivity σ_0 of the fibrils is given by the next equation,

$$\sigma_0=\sigma_0^{\text{film}}/(f\delta)=10^4\ \Omega^{-1}\text{cm}^{-1} \tag{5}$$

where δ is the fractional alignment factor ($\delta=1/3$).

In the tight binding approximation, the effective mass m^* of the free carrier is calculated as follows,[15]

$$\frac{m}{m^*}=\frac{4ta^2m}{\pi\hbar^2}=1.1 \tag{6}$$

where t and a are taken to be 3.0 eV and 1.4 Å, respectively. From the measured density of $(CH)_x$ (0.4 g/cm^3) and the filling factor $f=1/3$, the number of π-electrons per unit volume of the fibril can be estimated to be $N=6\times 10^{22}$ cm^{-3}. Then, the plasma frequency ω_p and dc conductivity σ_0 for a metal are written in the conventional form,[15]

$$\omega_p^2=4\pi Ne^2/m^* \tag{7}$$

and

$$\sigma_0=\omega_p^2\tau_0/4\pi. \tag{8}$$

Using the above values for N, m^* and τ_0, ω_p is estimated to be 1.46×10^{16} s^{-1} ($\hbar\omega_p=9.1$ eV) and σ_0 to be $0.8\times 10^4\ \Omega^{-1}$ cm^{-1}. The calculated value of σ_0 is in good agreement with the optically determined value.

Catalytic Properties of Iron Oxide. III. Oxidative Dehydrogenation of Butenes over Iron Oxide Catalysts

Makoto Misono,* Kanji Sakata, Fumio Ueda, Yasuaki Nozawa, and Yukio Yoneda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 13, 1979)

Oxidative dehydrogenation of butenes was investigated by use of a flow reactor over three iron oxide catalysts having different structures, *i.e.*, α-Fe_2O_3, γ-Fe_2O_3, and Fe_3O_4, which were prepared *in situ* by controlled reduction and reoxidation with a pulse method. Under the working conditions of catalytic oxidation, the structures of α- and γ-Fe_2O_3 remained unchanged, while Fe_3O_4 was oxidized to γ-Fe_2O_3, the oxidation state of iron being Fe(III) in all of three iron oxide catalyst. These results are consistent with the kinetics that the reaction was of zeroth order in the partial pressure of oxygen and of nearly first order in the butene partial pressure. γ-Fe_2O_3, as well as γ-Fe_2O_3 formed from Fe_3O_4 under the catalytic conditions, was very active and selective for the reaction, as expected from the results obtained previously with a pulse reactor. It was concluded from the following facts that the oxygen species responsible for this reaction is lattice oxygen of γ-Fe_2O_3 and that the reaction proceeds by the redox cycles of γ-Fe_2O_3 $\rightleftharpoons$$\gamma$-$Fe_2O_{3-x}$. i) Reactivity of γ-iron oxide surface in the stoichiometric oxidation of butenes to butadiene did not change, when the surface oxygen was stepwisely removed by CO-pulses from γ-Fe_2O_3 to γ-$Fe_2O_{2.8}$. ii) Formation of butadiene from a butene pulse was little affected by whether butenes were pulsed with oxygen or not.

Iron oxide is widely used in oxidation reasctions a single or mixed oxides. However, as for allylic oxidation of olefin, it is not a selective catalyst.[2] Recently, we found by use of a pulse method that metastable γ-Fe_2O_3(maghemite) was very active and selective in oxidative dehydrogenation of butenes.[3] Reactivity and oxygen mobility of γ-Fe_2O_3 were already investigated in detail in relation to the oxidation of carbon monoxide.[1]

In the present study, we attempted to confirm the relationship between the structure and oxidation state of iron oxide and the catalytic activity for oxidative dehydrogenation. It was of prime interest whether or not the high activity and selectivity of γ-Fe_2O_3 observed by a pulse method can be reproduced in a flow reactor. Kinetic studies, structure determination of iron oxide under working conditions, and comparison of catalytic and stoichiometric oxidations were also carried out, in order to clarify the reaction mechanism and the nature of the active oxygen species.

Experimental

Apparatus and Procedure. Apparatus for the reaction was a combination of a pulse reactor and a flow reactor. The pulse reactor was the same that described previously,[3] in which carrier gas (He) was deoxygenated by a molecular-sieve trap kept at liquid nitrogen temperature. After the structure and oxidation state of iron oxide was controlled by its reduction and oxidation with the pulse method described previously,[3] the system was changed to a flow system by the operation of valves, and reaction gas mixtures (butene, oxygen, and helium) were introduced to pass over the catalysts. The reaction system was carefully designed, so that the catalyst was never exposed to any trace of oxygen during the valve operation. For example, a 6-way valve was covered by a metal jacket in which a stream of dry helium was continuously passed, to avoid oxygen diffusion from air into the flow of the feed gas. After 1 h of the flow experiment (usually reaction became almost stationary within 1 h), the system was changed again to the pulse system to examine the oxidation state and the structure of catalysts. Ordinary pulse-experiments were also carried out in some cases.

Reagents and Catalysts. α-Fe_2O_3, γ-Fe_2O_3, and Fe_3O_4 were the same as described in Part II.[1] $MgSO_4$–SiO_2 (abbreviated as Mg–S) and CaO were also the same as used before.[4,5] Butenes (Takachiho Shoji, >99.9%) and pentenes (Tokyo Kasei, >99%) were obtained commercially and used without further purification.

Results and Discussion

Comparison of α-Fe_2O_3, γ-Fe_2O_3, and Fe_3O_4 in Oxidative Dehydrogenation of 1-Butene (Flow Method). Reaction of 1-butene over iron oxides having different initial structures and oxidation states, which were prepared *in situ* as described in Experimental section was measured by the flow method at 300 °C. Typical results are given in Table 1. Reaction became nearly stationary within 1 h, the conversion becoming 1/2—2/3 of the initial value within this period. Deactivation was small when butene pressure was low and oxygen pressure was high. This deactivation was probably due to carbon deposit, since the initial activity was restored by burning off of the carbon deposit by oxygen pulses at 300 °C. The selectivity to butadiene was almost constant during the flow experiments.

After the flow experiments, the system was changed again to the pulse system by the procedure described in the Experimental section, carefully avoiding the contamination of the catalysts. Then the oxidation states of the catalysts were determined from the amounts of oxygen uptake by the catalysts from O_2-pulses. Although the structures of iron oxides were not determined by X-ray diffraction analysis, they were easily estimated from the oxidation state, color, and magnetic properties. These results are also given in Table 1. The oxidation states and structures of α-Fe_2O_3 and γ-Fe_2O_3 did not change during the flow experiments, when oxygen was present more than 0.5%. On the other hand, Fe_3O_4 was oxidized to γ-Fe_2O_3.

Table 1 clearly shows, in spite of the presence of deactivation, that the catalytic activity and selectivity

TABLE 1. OXIDATIVE DEHYDROGENATION OF 1-BUTENE OVER IRON OXIDE CATALYSTS BY A FLOW METHOD AT 300 °C

Starting iron oxide	Feed gas (% in He)		Stationary conversion	Selectivity to butadiene	Structure after run
	O_2	1-Butene	%	%	
α-Fe_2O_3	5.1	6.5	3	38	α-Fe_2O_3
γ-Fe_2O_3	5.4	5.5	12	89	γ-Fe_2O_3
γ-Fe_2O_3	0	4.8	0	—	mainly Fe_3O_4
Fe_3O_4	7.6	7.7	17	91	γ-Fe_2O_3

Total flow rate: 30 cm^3 min^{-1}, amount of catalyst: 150 mg.

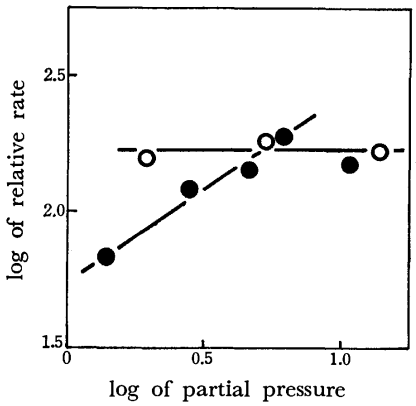

Fig. 1. Dependence of the rate on the partial pressure of 1-butene or oxygen.
Partial pressures are expressed by % in feed gas (1 atm). Reaction temperature: 300 °C, W/F: 5.0×10^{-2} g min cm^{-3}, ○: dependency on O_2 (butene: 4.5%), ●: dependency on butene (O_2: 4.5%).

were much higher with γ-Fe_2O_3 than with α-Fe_2O_3. Fe_3O_4 was little active at first, but it soon became comparable with γ-Fe_2O_3. This is natural, since Fe_3O_4 was oxidized to γ-Fe_2O_3 during the run. These results are in complete agreement with the results obtained by use of a pulse method.[3] Thus, it was confirmed also with a flow method that iron(III) oxide exhibits quite different behavior in allylic oxidation of olefin depending on its structure, γ-Fe_2O_3 (maghemite) being very active and selective.

Sazonova *et al.*[6] also studied the structural change of iron oxide during the oxidative dehydrogenation, and reported that iron oxide was in the states of α-Fe_2O_3 and Fe_3O_4 at high and low pressures of oxygen, respectively. However, the iron oxide they assigned to Fe_3O_4 could be γ-Fe_2O_3 in view of the present study. The X-ray powder diffraction patterns of Fe_3O_4 and γ-Fe_2O_3 are very close with each other. The selectivity they reported was not very high, probably because of the higher reaction temperature (365 °C).

Kinetics of Oxidative Dehydrogenation of 1-Butene over γ-Fe_2O_3 (Flow Method). Reaction mechanism was examined by a kinetic study. Figure 1 shows the dependency of the rate on the partial pressures of oxygen and 1-butene. As obvious from the figure, the reaction is of zeroth order with respect to oxygen. Selectivity of butadiene formation was nearly unchanged in this range of oxygen pressure. As for the rate dependency on the butene partial pressure, the rate data deviate from the straight line at high pressure. This was caused by significant deactivation of catalyst at this pressure region. At lower pressure-region, the reaction order was 0.7th. If the deactivation were properly taken into account, the reaction order would become closer to first order.

If the catalytic oxidation proceeds by a reduction-oxidation cycles of catalyst (redox mechanism), the result that kinetics was zeroth order in oxygen and first order in 1-butene means that the oxidation step of catalyst is much more rapid than the reduction step, and, therefore, the catalyst should be in a high oxidation state under the working conditions. This is in accord with the oxidation state actually found (Table 1). Furthermore, it was observed in the case of pulse experiments that the rate of reduction of γ-Fe_2O_3 by butene was slower than that of oxidation of γ-Fe_2O_{3-x} by oxygen. The reduction step was also slower than the oxidation step in the case of the oxidation of carbon monoxide over γ-Fe_2O_3.[1]

Comparison of the Rates of Catalytic and Stoichiometric Oxidation of 1-Butene (Pulse Method). In the redox mechanism, in which the reduction of catalyst is the slow step, the rate of stoichiometric oxidation of substrate by catalyst (oxidation of 1-butene by γ-Fe_2O_3 in the present system) is expected close to the rate of catalytic oxidation (1-butene+O_2 over γ-Fe_2O_3). This statement is valid when the oxidation states of the catalyst are the same in the stoichiometric and catalytic processes. Therefore, it is necessary that the rate of the former process is correctly measured for γ-Fe_2O_{3-x} having the same oxidation state as in the catalytic oxidation.

We measured the rate of the stoichiometric process by the reaction of a very small amount (usually 0.2 cm^3) of 1-butene pulsed over γ-Fe_2O_3 (50 mg), and measured the rate of catalytic process by a small pulse of a mixture of 1-butene and oxygen (usually, 1.0 cm^3 of 1 : 4 mixture). Under the working conditions, x of γ-Fe_2O_{3-x} was close to zero as described above, and the rate of butadiene formation in the stoichiometric oxidation was nearly independent of x in the range of x from 0 to 0.2 (*cf.* Fig. 3), so that the comparison by the present method is meaningful. We already reported the two rates were close enough to support the redox mechanism.[3] In the present study, the comparison was made in a little more accurate way.

Typical results are shown in Fig. 2, where % conversions to butadiene of 1-butene pulsed sequentially (with or without oxygen) are given, together with the extents of isomerization to 2-butenes. The trends seen in Fig. 2 were sufficiently reproducible. In runs

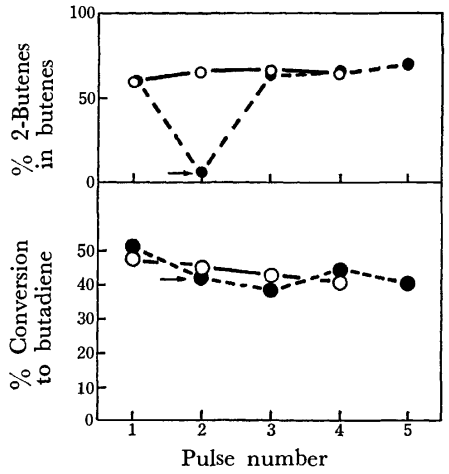

Fig. 2. Reactivity of 1-butene pulse with and without oxygen over γ-Fe_2O_3.
——: Run 1, ----: Run 2
Size of butene pulses was 0.2 cm^3. Data indicated by arrows are for the pulse of 1-butene (0.2 cm^3) pulsed with O_2 (0.8 cm^3).

1 and 2, the second pulses were 1-butene with oxygen and without oxygen, respectively, and all the other pulses contained only 1-butene. Conversion to butadiene decreased slightly by repeated pulses, due to carbon deposit. Results in Fig. 2 clearly show that the rates of two processes (stoichiometric and catalytic) were very close with each other (see the second pulse), supporting the redox mechanism.

The dependency on reaction temperature of butadiene formation in the stoichiometric process was small, apparent activation energies obtained from the conversions of first pulses being 15 kJ mol^{-1} (200—300 °C) and 25 kJ mol^{-1} (270—320 °C) for γ- and α-Fe_2O_3, respectively.

When the reaction temperature was raised to 350 °C, the rate of catalytic oxidation became significantly higher than the stoichiometric oxidation and the formation of carbon dioxide increased. At higher temperatures a mechanism which involves gaseous or adsorbed oxygen and favors complete oxidation is probably operative besides the redox mechanism.

As for the isomerization, two facts are noted: (i) the catalytic activity was much enhanced by the decrease in the oxidation state, butene composition from the second and subsequent pulses (without O_2) being in equilibrium, and (ii) the presence of gaseous oxygen greatly suppressed the isomerization rate. These two phenomena are probably both related to the number of iron sites exposed on the surface, which the reduction of catalyst may increase and (physical) adsorption of oxygen may decrease.

Reactivity of γ-Fe_2O_3 with 1-Butene as a Function of the Extent of Pre-reduction. Reaction of 1-butene pulse in the stoichiometric oxidation by iron oxide was measured over γ-Fe_2O_3, which was pre-reduced to various extents *in situ* by pulses of carbon monoxide. Reduction by CO-pulses minimized contamination of iron oxide during the reduction procedure. Figure 3 shows % conversions of 1-butene to butadiene plotted as a function of the extent of pre-reduction expressed by x of Fe_2O_{3-x}. The conversion remained unchanged in the range of x from 0 to 0.2 (Fe_2O_3 to $Fe_2O_{2.8}$). This is in contrast to the gradual decay of reactivity observed when γ-Fe_2O_3 was pre-reduced by butene itself (see Fig. 2). The decay in the latter case is, therefore, likely due to oxidation or polymerization products from butadiene. Further pre-reduction decreased the reactivity and finally to null at Fe_3O_4. Isomerization increased rapidly upon the pre-reduction as was before.

Reduction of Fe_2O_3 to $Fe_2O_{2.8}$ corresponds to the removal of several layers of oxygen from the surface of Fe_2O_3 (Fe ion going into inner bulk[1,8]). Therefore, the constant reactivity observed in the region between Fe_2O_3 and $Fe_2O_{2.8}$ was not the reactivity of adsorbed oxygen but that of lattice oxygen, since, if the adsorbed oxygen were responsible, the reactivity should have decreased much more rapidly when the oxygen was removed from the surface.

Reactivity and quantity of adsorbed oxygen on α-Fe_2O_3 were studied recently by Iwamoto *et al.* by means of thermal desorption.[7] They found several different adsorbed species, but the total oxygen atoms adsorbed was only about 2% of the surface layer (1.5×10^{19} O-atom m^{-2}).[1] Oxygen adsorbed reversibly on γ-Fe_2O_3 was about 20% of the surface layer at 12 kPa and 300 °C, as determined by a static measurement. But this was reversibly desorbed and not present when 1-butene was pulsed. Therefore, the amount of adsorbed oxygen present in the pulse experiments was probably much smaller than that utilized in butadiene formation from a butene pulse (without O_2). Then, also from this consideration, we can say that the contribution of adsorbed oxygen must be small in the stoichiometric pulse experiments. Actually, the % conversion to butadiene little changed when the pulse size was increased from 0.1 to 0.4 cm^3, indicating that the effect of small quantity of adsorbed oxygen is very low.

Oxygen Responsible for Selective Oxidation. Figure 2 demonstrated that the catalytic oxidation and the stoichiometric oxidation are governed by the same oxygen species, and the results in Fig. 3 indicate that the oxygen species responsible for the stoichiometric oxidation is lattice oxygen. If these two results are combined, it may be concluded that the oxygen species responsible for the catalytic oxidation of butenes over γ-Fe_2O_3 is the lattice oxygen. Possible reasons why γ-Fe_2O_3 was highly active and selective have been discussed previously.[1,3] It may be remarked that γ-Fe_2O_3 has an inverse spinel structure with cation deficiency and that reduction-oxidation between γ-Fe_2O_3 and Fe_3O_4 proceeds readily by the diffusion of Fe ion.[1,3,8] Spinels containing iron (ferrites) are already known as good catalysts for oxidative dehydrogenation of butenes.[9]

Here, the following may be worthy to remark as for the meaning of "lattice oxygen." (i) "Lattice oxygen" in the bulk cannot participate directly in the oxidation reaction. Of course, oxygen must be on the surface when it reacts with a substrate. (ii) "Lattice oxygen" on the surface is never in the same

electronic state as in the bulk. In some cases, surface "lattice oxygen" might be better described as O^- than as O^{2-}. Even in the bulk, it is not correct to regard oxide ion as having double negative charge, since electron is more or less delocalized to cation. Thus, it is not easy to determine in a general way whether the oxygen on the surface is lattice or adsorbed oxygen and whether the oxygen species responsible for catalytic oxidation is lattice or adsorbed oxygen. Sometimes, differentiation of lattice oxygen from adsorbed oxygen may not be meaningful. However, we may be able to state that the oxygen responsible for the catalytic oxidation is "lattice oxygen," when the rates of stoichiometric and catalytic processes agree and the oxygen used in the former process is not adsorbed oxygen from gas phase, as discussed in the preceding paragraph based on the results in Figs. 2 and 3.

Relative Reactivities of Olefins (δ_R-effect).[10] Effects of substituents on the reactivity provide useful information on the nature of reaction intermediate. In Fig. 4, reactivities of several olefins measured by the pulse method over α-Fe_2O_3 at 270 °C are plotted against the rate of hydrogen abstraction at allyl position at 65 °C, following Voge and Adams.[11] The data were obtained from the first pulses over freshly prepared iron oxides. According to the discussion of Voge and Adams,[11] the linear plot in Fig. 4 indicates that the formation of allylic intermediate is rate-determining. Relative reactivity normalized to one hydrogen atom at allylic positions was calculated from the reactivities of six olefins to be primary : secondary : tertiary = 1 : 4 : 12. However, the very rapid isomerization often observed over iron oxides is not consistent with the idea that the formation of allylic species is also the rate-determining step of isomerization.

We speculate on the basis of the discussion described below that the oxidation proceeds *via* an allyl radical (or cation) and the isomerization *via* an allyl anion.[12] Allylic species is likely the intermediate of oxidation

because of the results in Fig. 4 and because it seems difficult that butadiene is formed *via* an intermediate other than allylic species. Evidence which suggests a different intermediate for isomerization is also obtained from the δ_R-effects summarized in Table 2. Results obtained for typical solid acid (Mg–S) and base (CaO) are also given in this table. Since two reactions (oxidation and isomerization) proceeded over iron oxide simultaneously and could be competitive, the δ_R-effects observed might have been obscured to some extent. However, the following qualitative discussion may be made.

It is remarkable in Table 2 that in the case of iron oxides the methyl substitution at 3-position (3-methyl-1-butene) increased the rate of oxidation but decreased the isomerization. Suppressive effect of the 3-methyl group on isomerization was also observed over $Fe_2O_{2.9}$ at 120 °C, where the competitive oxidation was negligible. Therefore, the opposite behavior of oxidation and isomerization upon the methyl substitution is meaningful and suggests that two reactions proceed *via* different intermediates. Alkyl cations are not likely the intermediate for isomerization, because, if the alkyl cation were the intermediate, 2-methyl-1-butene should have been far the more reactive as in the case of Mg–S, due to the stability of tertiary cation.

The reactivity patterns of isomerization of iron oxides were more like that of CaO than that of Mg–S, so that allyl anions are presumably the intermediates as in the case of CaO.[5] The fact that the *cis*/*trans* ratio of 2-butene from the isomerization of 1-butene was about 1.5 at 150—200 °C is not in conflict with the allyl anion intermediate. If one assumes allyl radicals (or cations) for oxidation and allyl anions for isomerization, the opposite effects of 3-methyl group on oxidation and isomerization can reasonably be explained, since a methyl group destabilizes the anion but stabilizes the cation or radical.[13,14] Co-existence of two allylic intermediates, anionic and covalent, has been proposed for the isomerization of butene over chromia.[15] Change in the selectivity from acrolein to benzene in the allylic oxidation of propene over several oxide catalysts was also explained by the change in the charge of allylic intermediate.[2a]

Solvent Effect on the Adsorption of 1-Octadecanol at Oil/Water Interface

Takayuki IKENAGA, Norihiro MATUBAYASI, Makoto ARATONO,
Kinsi MOTOMURA, and Ryohei MATUURA*
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received December 11, 1978)

In order to study the effect of solvent on the adsorption at interfaces, interfacial tension was measured as a function of temperature and compositon for the systems of water and solutions of 1-octadecanol in cyclohexane, cyclohexene, mesitylene, toluene, and benzene. The interfacial density of 1-octadecanol and the entropy and energy of interface formation were calculated thermodynamically. It was found that cyclohexane causes a significant adsorption of 1-octadecanol and marked decreases in the entropy and energy changes, giving rise to phase transition from expanded to condensed film, while benzene, toluene, and mesitylene cause only a slight adsorption and small decrease in thermodynamic quantities. Cyclohexene was found to give rise to an intermediate adsorptive behavior of 1-octadecanol. The results were interpreted in terms of the mutual solubility between water and solvents and that of 1-octadecanol in the solvents.

The adsorption of various kinds of non-ionic surface active materials at oil/water and air/water interfaces has been investigated by many workers.[1-8] However, their thermodynamic treatment seems insufficient. Recently we have shown that the structure and property of the interface are clarified by applying rigorous thermodynamic treatment to the interfacial tension measured as a function of temperature, pressure, and concentration and evaluating the changes of the thermodynamic quantities associated with adsorption of long chain fatty alcohols at the hexane/water interface.[9-11]

It is evident that the adsorption of surface active substances to the interface is affected not only by temperature, pressure, and concentration but by properties of the solvent. However, the solvent effect on the behavior of the adsorbed film at oil/water interface has hardly been investigated systematically in spite of its importance.[12] The object of the present study is to obtain information on the solvent effect by use of the above treatment for systems consisting of water and the 1-octadecanol solutions in various organic solvents. The organic solvents employed in this work are hydrocarbons of six-membered ring structure differing in degree of saturation and in the side chain: cyclohexane, cyclohexene, benzene, toluene, and mesitylene.

The interfacial tension was measured as a function of temperature and mole fraction under atmospheric pressure. The entropy change, energy change, and the partial molar entropy change were estimated.

Experimental

Materials. 1-Octadecanol was purified by distillation under reduced pressure and triple recrystallization from hexane. Its purity was 99.9% as estimated by gas-liquid chromatography.

Benzene and toluene were purified by shaking with sulfuric acid and refluxing with metallic sodium for 8 h and by distillation under atmospheric pressure. Cyclohexane, cyclohexene, and mesitylene were purified by passing through a column of activated alumina (Woelm neutral activity grade I) and by distillation under atmospheric pressure.

Water was triply distilled, the second and third stages being done from dilute alkaline potassium permanganate solution. Water and each pure organic solvent were saturated mutually before measurements, but it was found to have little influence on the interfacial tension. The purity of water and each organic solvent was checked by the interfacial tension between them before use.

Interfacial Tension Measurements. The pendant drop technique[13,14] was used for the determination of equilibrium interfacial tension with an experimental error of *ca.* 0.05 mN m^{-1}. The values of interfacial tension were calculated by use of Fordham's correction table.[15] Measurements were carried out at fixed concentration and temperature under atmospheric pressure. The temperature was held constant within 0.05 K by circulating thermostated water around the pendant drop cell. The densities of water and pure organic solvents[16-18] were used for calculation of interfacial tension because of their small mutual solubility and low concentrations of solutions.

Results and Discussion

The interfacial tension γ of the system of cyclohexane solution of 1-octadecanol and water is plotted in Fig. 1 against temperature T at a constant mole fraction of 1-octadecanol x_1^0 in the cyclohexane solution, in which the solubility of water is neglected. At lower concentrations γ decreases linearly with increasing T, while at moderately high concentrations γ increases with increase in T. At higher concentrations there exists a point where the γ *vs.* T curve distinctly breaks at a lower temperature. The behavior of this system is very similar to that of hexane solution and water.[11] We conclude that the phase transition occurs from expanded to condensed film at the break point. It is seen that the slope of the γ *vs.* T curve, which is related to the entropy change, becomes larger from negative to positive with increase in concentration.

The interfacial tension, which is the interpolated value at constant temperature given in Fig. 1, is shown as a function of the mole fraction in Fig. 2. The γ *vs.* x_1^0 curve decrease monotonically at higher temperatures, the break point lying at 293.15 K.

Figure 3 shows the γ *vs.* T curves at constant x_1^0 for the system of cyclohexene solution and water. Cyclohexene gives rise to the phase transition of the adsorbed film of 1-octadecanol at very high concentrations and very low temperatures. Comparing cyclohexene and cyclohexane with hexane, we see that the temperature and concentration at which the condensed

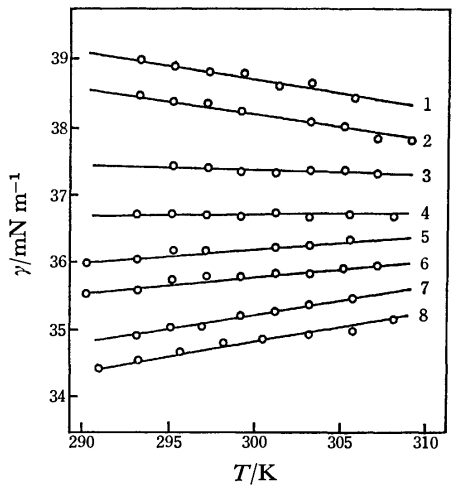

Fig. 4. Interfacial tension *vs.* temperature curves of 1-octadecanol at the mesitylene/water interface at constant mole fraction: (1) $10^3 x_1^0=0$, (2) 0.363, (3) 0.991, (4) 2.002, (5) 2.827, (6) 3.423, (7) 4.247, (8) 4.863.

film is formed becomes lower and higher, respectively, in the order of hexane, cyclohexane, and cyclohexene. It was also found that for the pure cyclohexene/water interface the slope of the γ *vs.* T curve is more gradual and the interfacial tension is smaller than for the pure cyclohexane/water and hexane/water interfaces.

In Fig. 4 γ *vs.* T curve is given for the system of mesitylene solution and water. Comparing Fig. 4 with Figs. 1 and 3 we see that the adsorptive behavior of 1-octadecanol from mesitylene seems similar to that from cyclohexane and cyclohexene at lower concentrations. However, no break point is observed over the whole range measured, the variation of γ with T being very small.

The γ *vs.* T curve for the system of toluene solution and water (Fig. 5) shows the system to behave virtually in the same manner as that of mesitylene, though the interfacial tension is smaller than that of mesitylene.

From the γ *vs.* T curve for the system of benzene solution and water (Fig. 6), we see that the variation of γ with T is steeper than that of toluene and the slope of γ *vs.* T curve is negative over the whole range measured, while the values of γ are smaller than those of toluene.

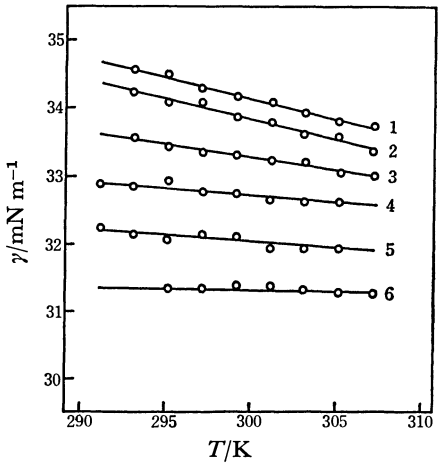

Fig. 6. Interfacial tension *vs.* temperature curves of 1-octadecanol at the benzene/water interface at constant mole fraction: (1) $10^3 x_1^0=0$, (2) 0.296, (3) 0.987, (4) 1.571, (5) 2.117, (6) 3.718.

In order to visualize the effect of solvent on the adsorption of 1-octadecanol at the interface, the γ *vs.* x_1^0 curves for the five solvents in the present study and hexane[11] at 293.15 K are compared in Fig. 7. Benzene, toluene, and mesitylene have a similar effect on the adsorption, but their effect differs a great deal from that of hexane and cyclohexane. The effect of cyclohexene seems to be intermediate between that of the two groups of solvents.

Let us now estimate the interfacial density of 1-octadecanol Γ_1^{H} which is calculated by applying the following equation to the γ *vs.* x_1^0 curve:

$$\Gamma_1^{\mathrm{H}} = -(x_1^0/RT)(\partial\gamma/\partial x_1^0)_{T,p}, \quad (1)$$

where the solution is assumed to be ideal.[10] The values of $\partial\gamma/\partial x_1^0$ are obtained by fitting the γ *vs.* x_1^0 data to the polynomial

$$\gamma = c_3 x_1^{03} + c_2 x_1^{02} + c_1 x_1^0 + c_0 \quad (2)$$

for cyclohexane and cyclohexene and to the function

$$\gamma = A\exp(Bx_1^0) + C \quad (3)$$

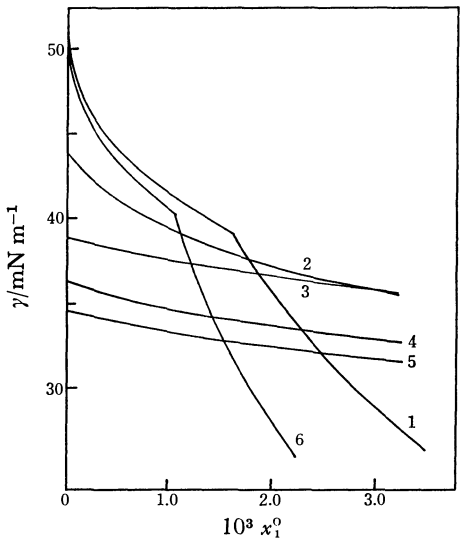

Fig. 7. Interfacial tension *vs.* mole fraction curves at 293.15 K: (1) cyclohexane, (2) cyclohexene, (3) mesitylene, (4) toluene, (5) benzene, (6) hexane.

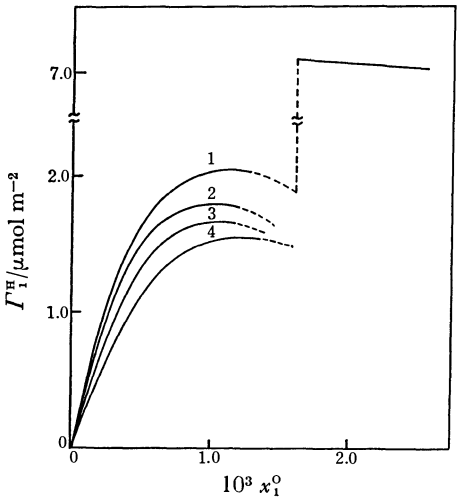

Fig. 8. Interfacial density *vs.* mole fraction curves of 1-octadecanol at the cyclohexane/water interface at constant temperature: (1) 293.15 K, (2) 298.15 K, (3) 303.15 K, (4) 308.15 K.

for benzene, toluene, and mesitylene by means of the least square method, where c_3, c_2, c_1, c_0, A, B, and C are constants.

The value of Γ_1^{H} calculated at constant temperature for the system of cyclohexane solution and water is plotted against x_1^0 in Fig. 8. Γ_1^{H} becomes smaller with rise in T. The Γ_1^{H} *vs.* x_1^0 curves seem to have maximums. The abnormal behavior may be due to the assumption of the ideal solution for Eq. 1. Practically alcohol molecules are known to undergo strong autoassociation in nonpolar solvents.[19] It is obvious that the discontinuity on the Γ_1^{H} *vs.* x_1^0 curve at 293.15 K corresponds to the first-order phase transition from expanded to condensed film.

In a similar manner we can calculate the values of Γ_1^{H} for the systems of cyclohexene, mesitylene, toluene, and benzene. For the sake of comparison the Γ_1^{H} *vs.* x_1^0 curves at 303.15 K are given for the five organic

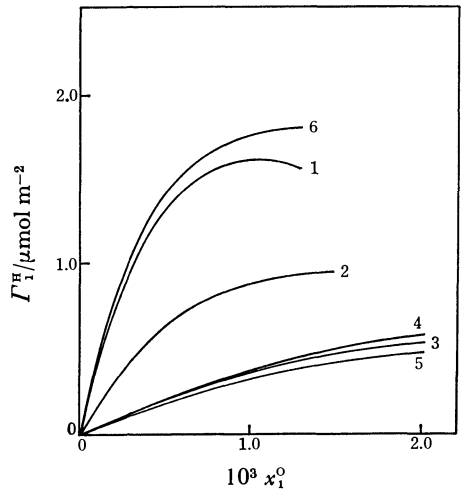

Fig. 9. Interfacial density *vs.* mole fraction curves at 303.15 K: (1) cyclohexane, (2) cyclohexene, (3) mesitylene, (4) toluene, (5) benzene, (6) hexane.

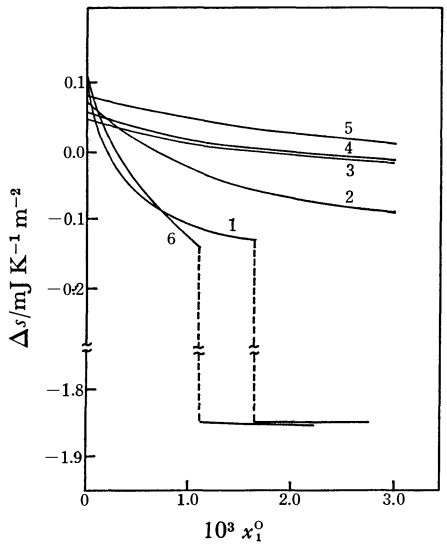

Fig. 10. Entropy of interface formation *vs.* mole fraction curves at 293.15 K: (1) cyclohexane, (2) cyclohexene, (3) mesitylene, (4) toluene, (5) benzene, (6) hexane.

solvents and hexane in Fig. 9. The value of Γ_1^H is remarkably large for cyclohexane and hexane while benzene and its derivatives give very small values. As expected, cyclohexene has an intermediate value. This suggests that the affinity of aromatic solvent molecules to water molecules is strong enough to reduce the adsorption of 1-octadecanol.

Next let us consider the entropy of interface formation, Δs. It is related to the slope of γ *vs.* T curve by[10]

$$\Delta s = -(\partial\gamma/\partial T)_{p,x_1^0}. \tag{4}$$

By estimating $\partial\gamma/\partial T$ graphically from the γ *vs.* T curve, the values of Δs are obtained which are given against x_1^0 at 293.15 K in Fig. 10. It is thought that the dependence of Δs on T is negligibly small since the γ *vs.* T curves are approximately linear. We find that in the cases of hexane and cyclohexane Δs

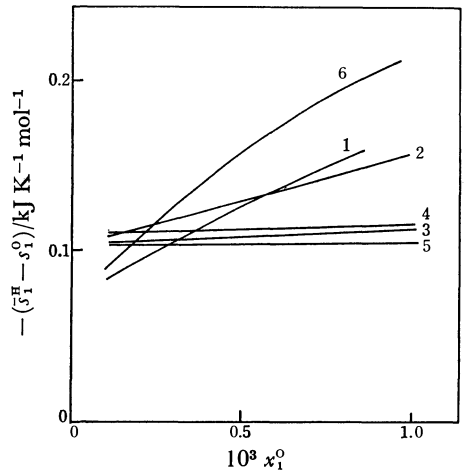

Fig. 11. Partial molar entropy change of 1-octadecanol *vs.* mole fraction curves at 303.15 K: (1) cyclohexane, (2) cyclohexene, (3) mesitylene, (4) toluene, (5) benzene, (6) hexane.

decreases rapidly with increasing x_1^0 from the positive value of pure interface to a negative value in a low concentration region. On the other hand, the extent of variation of Δs for mesitylene, toluene, and benzene is very small as compared with that for the above two solvents, the value of Δs becoming small in the order mesitylene, toluene, and benzene. It is clear that the formation of pure interface causes increase in the entropy of the whole system but the adsorption of 1-octadecanol diminishes it.

Comparing Figs. 9 and 10, we see that the value of Δs decreases as the value of Γ_1^H increases, indicating that the adsorption of 1-octadecanol to the interface is characterized by a negative change in entropy. The discontinuity in the Δs *vs.* x_1^0 curve for cyclohexane also indicates first-order phase transition from the expanded to the condensed film. The negative large value of entropy suggests that the freedom of motion of 1-octadecanol molecules is restrained a great deal in the condensed state.

The decrease in entropy leads us to expect a more regular conformation of 1-octadecanol in the interfacial region, which can be clarified by estimating the change in partial molar entropy of 1-octadecanol. The partial molar entropy change can be calculated from experimental data with the aid of

$$\bar{s}_1^H - s_1^0 = -[(\partial\gamma/\partial T)_{p,x_1^0} - (1-\Gamma_1^H\bar{a}_1)(\partial\gamma/\partial T)_{p,\Gamma_1^H}]/\Gamma_1^H, \tag{5}$$

where $\bar{a}_1$ is the partial molar area of 1-octadecanol.[10] In Fig. 11 the values of $\bar{s}_1^H - s_1^0$ are given against x_1^0 at 303.15 K for the low concentration region where the solutions are supposed to be ideal. It is of great significance that the value of the partial molar entropy change is definitely negative over the whole range of concentration and becomes more negative as the concentration increases. This indicates that the molecules of 1-octadecanol are compelled to take a more restricted conformation in the interface than in the bulk solution. The dependence of the partial molar entropy change on the bulk concentration seems to

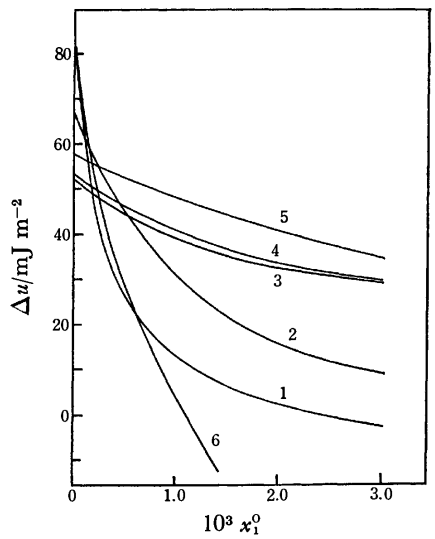

Fig. 12. Energy of interface formation *vs.* mole fraction curves at 303.15 K: (1) cyclohexane, (2) cyclohexene, (3) mesitylene, (4) toluene, (5) benzene, (6) hexane.

differ among the solvents. However, the difference is not so remarkable when the difference in the values of Γ_1^{II} shown in Fig. 9 is taken into consideration.

Let us calculate the energy of interface formation, Δu. We have the thermodynamic relation[9]

$$\Delta u = \gamma + T\Delta s - p\Delta v, \quad (6)$$

where Δv is the volume of interface formation. Since the term $p\Delta v$ is negligibly small as compared with the other terms on the right side of Eq. 6,[10] the value of Δu is determined by the values of γ and Δs. In Fig. 12 Δu is given against x_1^0 at 303.15 K for all the solvents. The values of Δu decrease steeply with x_1^0 for cyclohexane and hexane and decrease gradually for mesitylene, toluene, and benzene. Such a behavior is qualitatively similar to that of the Δs *vs.* x_1^0 curves (Fig. 10) except for the discontinuous changes of Δs attributable to the phase transition observed at 293.15 K. This indicates that the decrease in Δu by the adsorption of 1-octadecanol overcomes the disadvantage brought about by the decrease in Δs irrespective of the solvent.

The interfacial tension between organic liquid and water is related to their mutual solubility.[20] Thus, the small value of the interfacial tension between benzene and water is accounted for by the large affinity which the π electron system on the benzene ring possesses for water. When hydrophobic side chains are introduced in benzene molecule, interfacial tension increases and the entropy and energy of interface formation decrease. However, in spite of such a difference among benzene, toluene and mesitylene, the adsorptive behavior of 1-octadecanol at the interfaces between these solvents and water is very similar. The appreciable affinity of the aromaticity of the solvents for water plays a dominant role in the adsorption of 1-octadecanol.

On the other hand, the adsorption from the saturated hydrocarbons like cyclohexane and hexane is in striking contrast to that from the above aromatic solvents. It is characterized by the large value of Γ_1^{II}, the significant dependence of Δs and Δu on the concentration, and the phase transition from expanded to condensed film. Such a behavior is understandable on the basis of the low mutual solubility of saturated hydrocarbon and water, the high affinity of hydroxyl group of 1-octadecanol for water, and the strong lateral force between 1-octadecanol molecules. In terms of the solubilities of 1-octadecanol in cyclohexane and hexane, which are 1.81 and 0.47 in weight percent at 303.15 K, respectively, the slight difference in the adsorptive behavior between cyclohexane and hexane is also interpreted. For cyclohexene, we can expect an intermediate behavior between cyclohexane and benzene, which has been confirmed experimentally.

A Plot of the pH *vs.* the Logarithm of the Titrant Volume in Potentiometric Titration. The Determination of Phenol in Water

Katsuyoshi KAMAKURA

Department of Industrial Chemistry, Toyama Technical College, Hongo-cho, Toyama 930-11

(Received April 23, 1979)

The determination of phenol in water was successfully carried out by means of a new plot of the potentiometric titration data. The plot of the pH *vs.* the logarithm of the titrant volume gave a titration curve with an inflection between two linear portions, and the center of the inflection obtained by a graphical method was found to correspond to the equivalence point. In the titration of phenol, the data fitted well to the theoretical curve by taking into account the hydrolysis of the phenol ion. The mean of the results obtained from the apparent equivalence point in the concentration range of 1.0—7.7×10^{-3} mol dm^{-3} was 101.2% of the results obtained iodometrically after the bromination of phenol, and the precision of the results was ±2.7% (S.D.).

Nonaqueous solvents have been used for the titration of very weak acids,[1] but they are somewhat troublesome to use. This paper will discuss the titration data of aqueous phenol. In a plot of the pH *vs.* the titrant volume for the potentiometric titration of a very weak acid in water, the inflection at the equivalence point is not sharp, or even disappears. Gran's plot is well known as a special method for the determination of the equivalence point in potentiometric titration, but it can not apply to a solution containing a weak acid or a weak base. It was found that the plot of the pH *vs.* the logarithm of the titrant volume has an inflection between two linear portions, and that the center of the inflection obtained from a graphical method corresponds to the equivalence point. Measurements were made on the titrating solutions in the range from 1.0×10^{-3} to 7.7×10^{-3} mol dm^{-3} with the titrant of 1.1 mol dm^{-3} NaOH.

Theoretical

Titration Curve. We will first discuss the titration of aqueous phenol with aqueous sodium hydroxide, assuming that the volume change due to the addition of titrant is very small. The equilibrium for the ionization of phenol (AH) may be written as

$$AH \rightleftarrows A^- + H^+, \tag{1}$$

$$K_a = \frac{[A^-][H^+]}{[AH]}, \tag{2}$$

where K_a is the ionization constant of phenol. The hydrolysis reaction of sodium phenoxide during the titration is expressed as

$$A^- + H_2O \rightleftarrows AH + OH^-. \tag{3}$$

The equilibrium constant, K_h, in this case is

$$K_h = \frac{[AH][OH^-]}{[A^-]}. \tag{4}$$

Equation 2 may be written in logarithmic form as

$$\log [H^+] = \log \frac{[AH]}{[A^-]} + \log K_a. \tag{5}$$

The material balance for the dissociation of phenol is

$$[AH]_0 = [A^-] + [AH], \tag{6}$$

where $[AH]_0$ is the concentration of phenol in the solution before titration. Before the equivalence point, the material balance for hydrolysis is

$$[A^-] = [NaOH](1-h), \tag{7}$$

where [NaOH] is the concentration of titrant in the solution titrated and where h is the degree of hydrolysis. From Eqs. 5—7 we obtain

$$\log [H^+] = \log \left\{\frac{[AH]_0}{[NaOH](1-h)} - 1\right\} + \log K_a. \tag{8}$$

On substituting the numerical value,[2] $pK_a = 9.998 \approx 10$, into Eq. 8, pH is expressed as

$$pH = -\log \left\{\frac{[AH]_0}{[NaOH](1-h)} - 1\right\} + 10. \tag{9}$$

Beyond the equivalence point, the material balance for hydrolysis is

$$[A^-] = [AH]_0(1-h). \tag{10}$$

From Eqs. 5, 6, and 10, we obtain

$$\log [H^+] = \log \frac{h}{1-h} + \log K_a. \tag{11}$$

On substituting the same numerical value as Eq. 9, the pH is expressed as

$$pH = -\log \frac{h}{1-h} + 10. \tag{12}$$

Next, we will deal with the relation between h and [NaOH]. The concentration, $[OH^-]$, of the hydroxide ion before the equivalence point is expressed as follows:

$$[OH^-] = h[NaOH]. \tag{13}$$

The following equation was obtained by eliminating $[OH^-]$, $[A^-]$, and [AH] from Eqs. 4, 6, 7, and 13:

$$[NaOH]h^2 + ([AH]_0 - [NaOH] + K_h)h - K_h = 0. \tag{14}$$

Beyond the equivalence point, $[OH^-]$ is expressed as follows:

$$[OH^-] = h[AH]_0 + [NaOH] - [AH]_0. \tag{15}$$

Similarly, the following equation was obtained from Eqs. 4, 6, 10, and 15:

$$[AH]_0h^2 + ([NaOH] - [AH]_0 + K_h)h - K_h = 0. \tag{16}$$

When the numerical values of $[AH]_0$, [NaOH], and K_h ($=K_w/K_a$) are substituted into Eq. 14 or 16, we can estimate h. Then, the relation between pH and log [NaOH] is determined from Eq. 9 or 12. Assuming that the volume of the titrating solution is 100 cm^3 and that the volume change due to the addition of the titrant is very small, [NaOH] is expressed as follows;

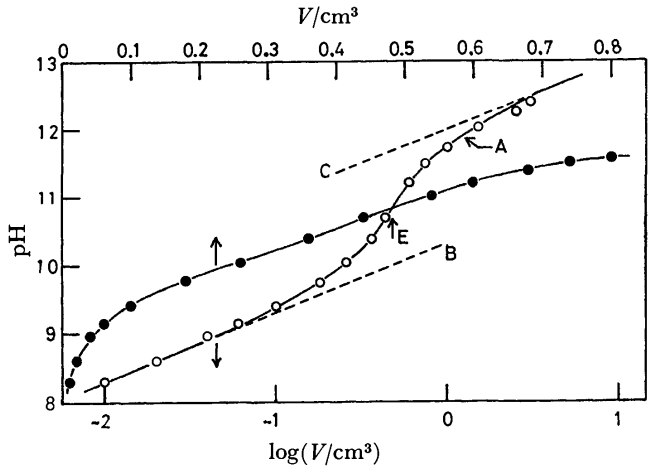

Fig. 1. Theoretical curve and experimental data.
○: Experimental data.
A: Theoretical curve, B and C: asymptotes obtained from Eqs. 18 and 21, respectively. E: Equivalence point, common to Figs. 1—5. Solution titrated: 5.2×10^{-3} mol dm^{-3} phenol, titrant: 1.1 mol dm^{-3} NaOH, temp: 25 °C.

$$[\mathrm{NaOH}] = [\mathrm{NaOH}]_t\frac{V}{100}. \tag{17}$$

Here, $[\mathrm{NaOH}]_t$ is the concentration of the titrant and V is the titrant volume. Therefore, we could obtain the relation of the pH *vs.* the logarithm of the titrant volume as is shown in Fig. 1 (A). The curve, quite consistent with the experimental data, consists of two linear portions.

The asymptotic equation for the linear portion at the beginning of titration is thus obtained for $h\rightarrow0$ in Eq. 9:

$$\mathrm{pH} \simeq \log[\mathrm{NaOH}] - \log[\mathrm{AH}]_0 + 10. \tag{18}$$

The asymptotic equation for the linear portion far beyond the equivalence point is thus obtained for $h\rightarrow0$ in Eq. 12:

$$\mathrm{pH} \simeq -\log h + 10. \tag{19}$$

Here, h is approximated for $[\mathrm{NaOH}]\gg[\mathrm{AH}]_0$ in Eq. 16 as follows:

$$h \approx \frac{K_h}{[\mathrm{NaOH}]}. \tag{20}$$

Consequently, the following asymptotic equation is obtained from Eqs. 19 and 20:

$$\mathrm{pH} \simeq \log[\mathrm{NaOH}] - \log K_h + 10. \tag{21}$$

The slopes of the two linear portions in the theoretical curve were proved identical from Eqs. 18 and 21.

Effect of pK_a *and Concentration of Acid on the Titration Curve.* The method presented above is based on the hydrolysis of the titrating agent, *i.e.*, phenol. Figures 2 and 3 show the relation between h and log V, while Figs. 4 and 5 show the relation between pH and log V. As the equivalence point corresponds to the peak in the curve of h *vs.* log V, the equivalence point is at the maximum of dpH/dlog V. When pK_a is large or the concentration of titrating agent is low, the curve of h *vs.* log V becomes unsymmetrical and the maximum of dpH/dlog V becomes obscure. If

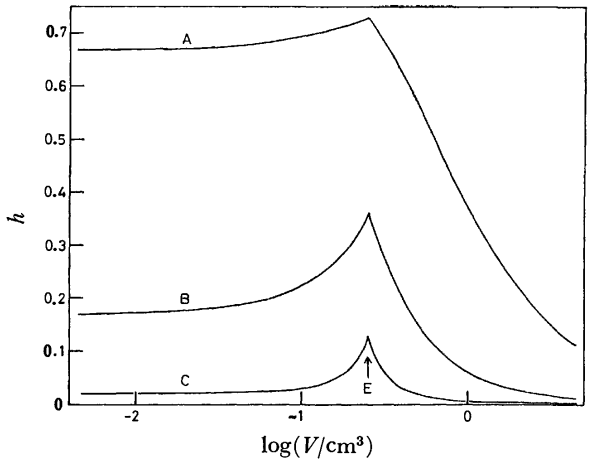

Fig. 2. Theoretical curves; the relation between h and log V.
$[\mathrm{AH}]_0$: 0.005 mol dm^{-3}, concn of titrant: 2 mol dm^{-3}.
pK_a; A: 12, B: 11, C: 10.

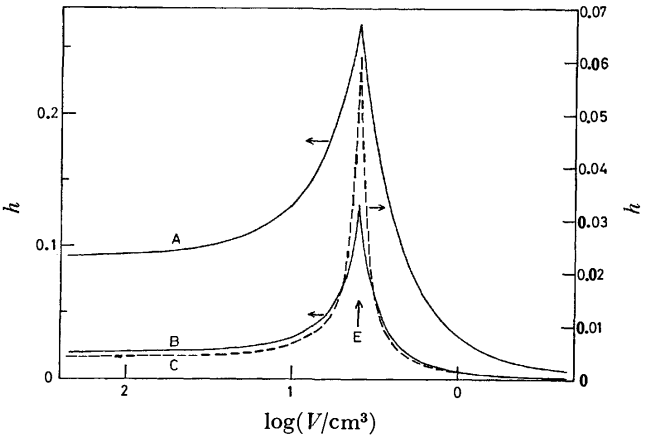

Fig. 3. Theoretical curves; the relation between h and log V.
pK_a: 10. $[\mathrm{AH}]_0$ and concn of titrant; A: 0.001 mol dm^{-3} and 0.4 mol dm^{-3}, B: 0.005 mol dm^{-3} and 2 mol dm^{-3}, C: 0.025 mol dm^{-3} and 10 mol dm^{-3}.

the curve of h *vs.* log V is symmetrical, the maximum of dpH/dlog V becomes much clearer and the equivalence point can be obtained by either the mathematical or the graphical method. We can designate the relation between the pK_a and the concentration of the titrating agent by drawing such curves as are shown in Figs. 2—5. Consequently, the concentration of the titrating agent must be higher than about 0.001 mol dm^{-3} for $pK_a=10$.

Experimental

Materials. All the chemicals were reagent grade and were used without further purification. The CO_2-free solution of NaOH was prepared from a saturated solution.

Titration Apparatus. A pH meter (Toa Electronics HM-5B) was used to obtain the titration curve. The buret was a pipet with a capacity of 0.2, 1, or 2 cm^3. The titration cell was a 120-cm^3 wide-mouthed bottle, in which the solution was stirred with a magnetic stirrer. All the titrations were carried out in a water bath at 25±0.1 °C. Nitrogen was passed slowly through the solution being titrated in order

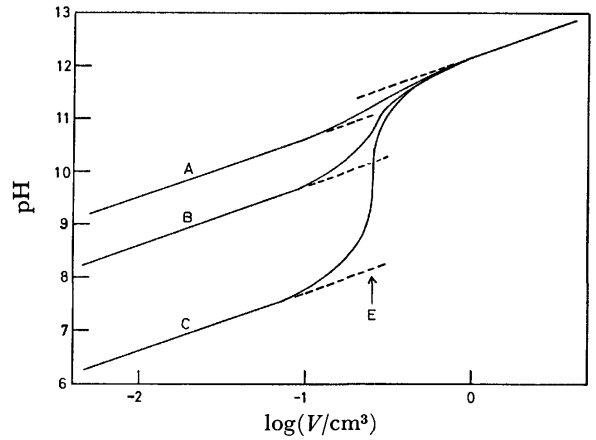

Fig. 4. Theoretical curves; the relation between pH and log V.
$[AH]_0$ and concn of titrant are the same as Fig. 2. pK_a; A: 11, B: 10, C: 8.

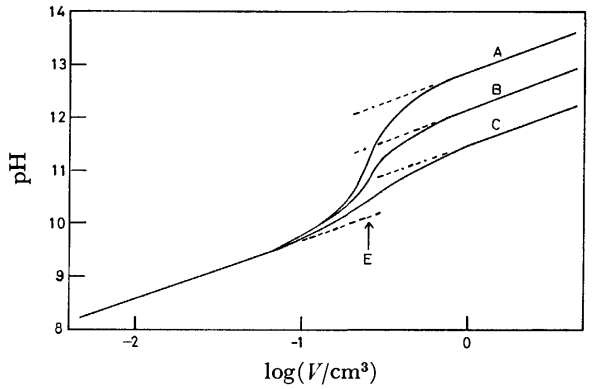

Fig. 5. Theoretical curves; the relation between pH and log V.
pK_a: 10. $[AH]_0$ and concn of titrant; A: 0.025 mol dm^{-3} and 10 mol dm^{-3}, B: 0.005 mol dm^{-3} and 2 mol dm^{-3}, C: 0.001 mol dm^{-3} and 0.4 mol dm^{-3}.

to avoid the absorption of CO_2. The electrodes, buret, and nitrogen inlet were inserted into the titration cell through a rubber stopper.

Titration Procedure. The pH meter was standarized with standard buffers of pH 4.01 and pH 6.86 at 25 °C. Distilled water (100 cm³) and concentrated phenol (0.2—1.5 cm³) were placed in the titration cell, and allowed to stand about ten minutes with stirring and while wet nitrogen gas was bubbled in for temperature equilibration at 25 °C. A correction for the volume change due to the addition of titrant has not been made.

Results and Discussion

Graphical Determination of the Equivalence Point. Figure 6 shows a typical potentiometric titration curve of phenol in water. The apparent equivalence point was determined graphically as follows: Line A was drawn at the initial part of the titration curve; Line B was then drawn parallel to A, tangent to the final portion of the titration curve; Line C was then drawn with a maximum slope tangent to the region of the equivalence point; Lines E and F were drawn vertically so as to pass through the intersections of Line C with

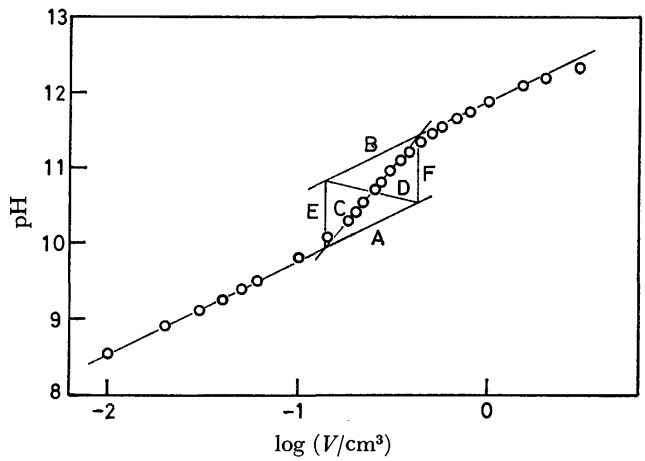

Fig. 6. Typical potentiometric titration curve of phenol in water and graphical determination of equivalence point. The solution titrated is 2.6×10^{-3} mol dm^{-3} phenol and other conditions are the same as those in Fig. 1.

Table 1. Determination of phenol in water

c_1[a] / 10^{-3} mol dm^{-3}	c_2[b] / 10^{-3} mol dm^{-3}	c_2/c_1 / %
1.04	1.08	103.8
1.04	1.10	105.8
2.60	2·68	103.1
2.60	2.62	100.8
5.17	5.12	99.0
5.17	5.00	96.7
7.72	7.76	100.5
7.72	7.69	99.6

a) c_1 is the concn of phenol obtained iodometrically after the bromination of phenol. b) c_2 is the concn determined by this method.

A and B; Line D was drawn from the intersection of Lines A and F to the intersection of Lines B and E. The intersection of Lines C and D was then taken to be the equivalence point.

Accuracy of the Method. Table 1 shows the results of the titration of phenol in water. The value of c_2/c_1 is the ratio of the amount of phenol obtained from this method to that obtained iodometrically after the bromination of phenol.[3] The average value of c_2/c_1 was 101.2% in the concentration range (1.0—7.7×10^{-3} mol dm^{-3}) of phenol, and the precision was ±2.7% (standard deviation).

Precise Complexometric Coulometric Titration of Disodium Dihydrogen Ethylenediaminetetraacetate Dihydrate and Aluminium†

Tatsuhiko TANAKA,* Kousei HOTTA, and Takayoshi YOSHIMORI
Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received June 11, 1979)

The purity of recrystallized disodium dihydrogen ethylenediaminetetraacetate dihydrate was determined accurately by titration with zinc ion coulometrically generated from an amalgamated zinc anode. The reagents used were of 99.446%±0.002% homogeneity when the sample was dehydrated and stored in a hygrostat (relative humidity, *ca.* 58% at 20 °C) over 1 year. Aluminium of high purity (99.99%) was coulometrically titrated with the purified reagent. Aluminium was allowed to react with a certain amount of the reagent, excess of the reagent being titrated with zinc ion anodically generated. The end point was determined potentiometrically using a mercury electrode. The purity was found to be 99.976% with a standard deviation of 0.010% for 6 degree of freedom. Cause of the lower result (0.01%) is discussed.

Marinenko reported on an accurate coulometric determination of gallium for the measurements of the stoichiometric composition of gallium arsenide and of the atomic weight of Ga.[1] The sample containing gallium was allowed to react with excess disodium dihydrogen ethylenediaminetetraacetate dihydrate (Na_2H_2edta) of known composition and the excess of the reagent was back-titrated with coulometrically generated zinc ion. The method requires standard Na_2H_2edta (as a solid) of sufficient purity and homogeneity. However, no mention was given on the quality of Na_2H_2edta.

H_4edta (free acid) of high purity (J. T. Baker Chemical Co., U.S.A.)[2] is insoluble in water and inadequate for the present investigation. Dihydrated disodium salt of the acid of high purity is not available owing to the uncertainty of the content of water of crystallization.

The purity of Na_2H_2edta has been determined by acidimetric[3] or complexometric[1,4–10] coulometry. Several electrogenerated metallic ions, zinc(II),[1,4] lanthanum(III),[5] bismuth(III),[6,7] lead(II),[8] mercury(II),[9] and copper(II)[10] ions, were used as complexometric titrants. The current efficiency for the generation of the titrants, except zinc(II), has not been measured accurately, some electrode materials of high purity not being available. On the other hand, metallic zinc of high purity is available and the current efficiency for the generation of zinc(II) ion has been measured accurately.[11] Moreover, zinc(II) ion is useful as a back-titrant for the determination of metallic ions which have a larger stability constant with edta than that of zinc–edta complex.

The Analytical Methods Committee in the U.K. reported recently the procedure for accurate standardization of Na_2H_2edta by spectrophotometric titration with the use of pure bismuth[12] or zinc[13] metal. However, it gives no satisfactory accuracy because of the difficulty in the detection of the end point.

Only the complexometric procedure can be applied to determine aluminium by coulometric titration. Several coulometric investigations with use of 8-quinolinol complex have been reported.[14–18] The precision attained was higher than 0.1%(as standard deviation), not being sufficient for determining the aluminium content in pure aluminium metal. On the other hand, Na_2H_2edta has high equivalent weight and its use is particularly advantageous for precise determination of metals of small atomic weight such as aluminium. So far, however, it has not been used for complexometric coulometric determination of aluminium.

In this investigation, Na_2H_2edta was purified by recrystallization from ethanolic solution,[19] and by storage in a hygrostat for a long time. Its purity was determined by coulometric titration, and the purity of metallic aluminium was coulometrically determined with the purified Na_2H_2edta.

Experimental

Apparatus and Reagents. Apparatus for coulometric generation of the titrant and for measurement of the time interval of the electrolysis as well as precautions in the weighing of sample were the same as reported.[20] As the Faraday constant, 96484.6 C mol^{-1} was used.

A tall lipless beaker (*ca.* 200 ml) made from quartz plugged with a silicone rubber stopper was used as the electrolytic cell. The generator anode was an amalgamated zinc rod (*ca.* 6 cm^2 in area), and the generator cathode a platinum plate (1×1 cm). The zinc rod was prepared from zinc metal (99.999%, guaranteed by the Industrial Inspection Institute of Japan as a standard reference material for titrimetric analysis). The diaphragm under the cathodic compartment was prepared as follows: the bottom of a polyethylene tube was closed with a polyethylene plate with many fine holes. An agar-agar gel saturated with potassium nitrate was plugged on the bottom, the thickness of the agar layer being about 2 cm.

The end point for titration of Na_2H_2edta was determined by an amperometric procedure using a mercury-plated platinum electrode[21] (applied voltage −1.25 V *vs.* SCE), and that for aluminium was determined potentiometrically with a mercury cup electrode[22] and an "Expandomatic" pH meter (Beckman Instruments, Inc.). A salt bridge of potassium nitrate–agar was used for connection of the electrolytic cell with a saturated calomel electrode in an outside compartment, since chloride ion interferes with the indication of the potential of mercury cup electrode.

All reagents were of analytical grade, and were used (except Na_2H_2edta) without further purification. A 0.5 mol dm^{-3} acetate buffer of pH 6.2 was used as the anolyte for the determination of purity of Na_2H_2edta. Small amounts

† Presented at the 37 th National Meeting of the Chemical Society of Japan, Yokohama, Japan, April 1978, the 27 th Annual Meeting of the Japan Society for Analytical Chemistry, Kanazawa, Japan, October 1978, and the ACS/CSJ Chemical Congress, Hawaii, U. S. A., April 1979.

of solid tungstic acid and 1 mol dm^{-3} potassium nitrate solution (*ca.* 15 ml) were placed in the cathodic compartment.

Procedure. *Coulometric Titration of Na_2H_2edta*: Residual oxygen in the anolyte specified above was removed by passing oxygen-free nitrogen gas for *ca.* 2 h under vigorous stirring. The gas was then allowed to flow over the anolyte throughout the titration.

As pretitration, *ca.* 50 mg of Na_2H_2edta was added to the cell and titrated with anodically generated zinc ion at a constant current of *ca.* 150 mA. Near the end point of titration, the generating current was cut off, the indicator current being measured with a microammeter (full-scale deflection: 10 μA). This was repeated after the end point had been determined. The end point was determined graphically. An Na_2H_2edta sample (*ca.* 400 mg accurately weighed) was then transferred to the cell. After dissolution, it was titrated with coulometrically generated zinc ion by the same procedure as above. The time interval of titration was measured from the two titration curves.

Preparation of Solution of Aluminium Sample: Small pieces of aluminium metal (99.99%) were dipped into hot 7% sulfuric acid for a few minutes, washed successively with water and ethanol, dried *in vacuo* and stored in a desiccator containing magnesium perchlorate. *Ca.* 150 mg of the sample was weighed into a decomposition flask (*ca.* 50 ml) fitted with a reflux condenser[23] to prevent loss by spitting, and dissolved in 10 ml of 6 mol dm^{-3} nitric acid in the presence of platinum wires as a catalyst. The solution was then transferred to the electrolytic cell and evaporated to a small volume (*ca.* 20 ml). A weighed amount of the Na_2H_2edta (solid, standardized) was added in slight excess and the pH of the solution was adjusted to 3.5 by gradual addition of solid sodium acetate trihydrate. The solution was heated nearly to boil for *ca.* 15 min on a hot plate to ensure the complete complexation reaction of aluminium ion with edta. After cooling, the pH of the solution was adjusted to 6.2 by the dropwise addition of 20% sodium hydroxide solution. The solution was finally diluted to *ca.* 150 ml with deaerated water.

Coulometric Titration of Aluminium: After deoxygenation of the solution of aluminium, the solution was cooled below 3 °C in an ice bath. Excess edta was back-titrated with electrogenerated zinc ion. Because of sluggish attainment of the equilibrium condition near the end point of the titration, the constant current was cut off near the end point, and the potential of the indicator electrode was measured after it became stable. This was repeated in order to obtain the titration curve. The end point was determined by means of the differential titration curve. A blank experiment was carried out throughout the procedure.

Results and Discussion

Standardization of Na_2H_2edta. The purity and pretreatment of commercial Na_2H_2edta were first investigated by the procedure described previously. Three different lots of analytical-grade Na_2H_2edta A, B, and C were analyzed (a) without any treatment and (b) after drying, the assay values being given in Table 1.

The results for both (a) and (b) indicate low purity and considerable inhomogeneity. Wendlandt pointed out that the composition of crystalline water among commercial Na_2H_2edta is not stoichiometric.[24] The results (Table 1) indicate similar phenomena. Duval found the evolution of water at 60 °C on heating Na_2H_2edta.[25] However, Blaedel and Knight recommended 80 °C as the optimum temperature for air-drying of the hydrated salt without decomposition.[19] The values of relative standard deviation seem to support 80 °C, since constant weight of Na_2H_2edta was obtainable by heating at the temperature for 4 d. JIS(Japanese Industrial Standard) recommends heating of the reagent at 80 °C for 5 h,[26] but the time is not sufficient to attain constant weight.

TABLE 1. ASSAYS OF ANALYTICAL-GRADE Na_2H_2edta

Sample	No. of detns.	Purity (%)	s_R / %
A	3	99.280	0.061
	3	99.653[a]	0.024
B	3	99.585	0.076
	3	99.961[a]	0.063
C	3	99.629	0.049
	3	99.728[a]	0.022
	10	99.697[b]	0.009[c]

a) Dried at 80 °C for 4 d. b) Stored in hygrostat (*ca.* 58% rel. humidity) for 6 months. c) $\sqrt{V}$ value.

TABLE 2. ASSAYS OF Na_2H_2edta RECRYSTD. FROM REAGENT B

Method of pretreatment	No. of detns.	Purity %	s_R %
Without drying	5	97.607	0.054
Dried at 80 °C for 4 d	6	98.981	0.080
Dried at 80 °C for 4 d[a]	4	99.211	0.017
Stored in hygrostat[b] for 6 months	4	99.268	0.010
Dehydrated *in vacuo* and stored in hygrostat[b]			
for 12 months	1	99.445	—
for 15 months	6	99.446	0.002

a) Ground prior to drying. b) About 58% rel. humidity.

The hydrated salt is stable over a wide range of humidity.[19] The weight of the reagent left under ordinary atmospheric conditions (35—60% relative humidity) changed from −0.017% to +0.025%. Thus, one of the reagents (Sample C, Table 1) was gently ground with an agate mortar, dried at 80 °C for 4 d, and stored in the hygrostat containing a saturated solution of sodium bromide at ordinary temperature (relative humidity *ca.* 58%) with frequent mixing. The results of assay of the Na_2H_2edta stored for 6 months in the hygrostat (Table 1) indicate that the reagent shows sufficient homogeneity.

Na_2H_2edta(Sample B, Table 1) of analytical grade was purified by recrystallization from ethanolic solution[19] in order to obtain pure Na_2H_2edta. The results obtained for the recrystallized reagent (Table 2) are somewhat lower than those of the original material. This may be mainly due to the contamination from glassware and distilled water. Since the recrystallized reagent may contain occluded water, it was dehydrated completely in a vacuum oven overnight at 120 °C,[19] and rehydrated by being kept in the hygrostat (relative humidity *ca.* 58%) until the purity became constant.

Table 3. Determination of high-purity aluminium (99.99%)[a]

Sample taken (mg)	Al found (mg)	Purity %
137.611	137.576	99.975
150.915	150.871	99.971
156.859	156.836	99.985
169.583	169.512	99.958
143.749	143.725	99.983
127.214	127.182	99.975
150.650	150.624	99.983
		Mean = 99.976±0.009%[b]
		R = 0.027%
		s_R = 0.010%

a) Value estimated by the manufacturer. b) The 95% confidence interval for the mean.

Excellent homogeneity could be attained by storing for more than 1 year.

In conclusion, the recrystallized reagent is suitable for use as a complexometric standard, when it is once dehydrated and then stored in a hygrostat, for example a desiccator containing a saturated solution of sodium bromide, for more than 1 year with frequent mixing.

Assay of Aluminium. The purity of the metallic aluminium (99.99%) was determined by the procedure described previously. When the electrolyte was not cooled, the aluminium content exceeded 100%. This may be caused by the displacement reaction of aluminium–edta complex to zinc–edta complex with the electrogenerated zinc ion, since the stability constant of aluminium–edta complex is similar to that of zinc–edta complex. The electrolyte was, therefore, cooled below 3 °C during the course of titration in order to prevent the displacement reaction. The results for the aluminium sample obtained by the proposed method are given in Table 3.

The purity was somewhat less than 99.99% (estimated by the manufacturer), though the standard deviation was small. The cause of this result was investigated.

Impurities in the sample were first examined. Semi-quantitative spectrographic analysis indicates that the sample contains in total *ca.* 30 ppm of metallic impurities, iron, copper, manganese, magnesium, silicon, and antimony. Oxygen was determined by bromine–methanol dissolution followed by spectrophotometric measurement (8-quinolinol extraction method),[27] the content being *ca.* 40 ppm. Thus, the purity of this sample can be evaluated as 99.99%.

Marinenko and Foley reported that the anodic oxidation of zinc proceeds at 100.000% current efficiency with current density between 10^{-2} and 10^3 mA cm^{-2}.[11] In the present investigation, the current density was *ca.* 25 mA cm^{-2}, no error due to the current efficiency being present. The error due to the location of end point was considered. Sharp potential breaks were usually obtained at the end point (*ca.* 12 mV per 1 μg of aluminium). The difference of 0.1 s in the duration of electrolysis corresponds to *ca.* 15 ppm of aluminium. Thus, the uncertainty of the graphical location of the end point is below several ppm. The standard deviation in the measurement of the generating current was not greater than 0.005%. Thus, the titration error can not be the cause of the lower result. Some displacement reaction between aluminium– and zinc–edta complexes might be the main source of *ca.* 0.01% error.

The authors express their thanks to Mr. Syuiti Ishiwari, Hitachi Co. Ltd., for the spectrographic analysis of the aluminium sample. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Kinetic Studies of the Acid Hydrolysis of Aquaoxo[*N*-(2-pyridylmethyl)-iminodiacetato]vanadium(IV) and Aqua(nitrilotriacetato)-oxovanadate(IV) in Aqueous Perchloric Acid Solution

Masato NISHIZAWA and Kazuo SAITO*

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received June 29, 1979)

Acid hydrolysis of aquaoxo[*N*-(2-pyridylmethyl)iminodiacetato]vandium(IV) [VO(pmida)H_2O], ([H^+]= 0.1—2.0 M, 1M= 1 mol dm^{-3}) and aqua(nitrilotriacetato)oxovanadate(IV) [VO(nta)H_2O]$^-$, ([H^+]=0.2—2.0 M) has been studied by the stopped-flow method in aqueous perchloric acid solution at an ionic strength 2.0 ($LiClO_4$). The pseudo first-order rate constant k_o is dependent on the proton concentration. The rate formula is expressed by $k_o=(k_1K_1[H^+]+k_2K_1K_2[H^+]^2)/(1+K_1[H^+]+K_1K_2[H^+]^2)$. A simulation curve fitting treatment gave the figures: k_1=0.02 and 0 s^{-1}, k_2=6 and 3000 s^{-1}, K_1=1.5 and 0.2 M^{-1}, and K_2=0.2 and 0.004 M^{-1} at 25 °C for [VO(pmida)-H_2O] and [VO(nta)H_2O]$^-$, respectively. These data indicate that the rate determining step corresponds to the dissociation of the second basal bond of the singly or doubly protonated oxovanadium(IV) complexes.

The ligand substitution reaction of oxovanadium(IV) complexes includes several kinds of mechanistically discriminated reaction on different coordination sites (Fig. 1).[1] We have determined the structure of a new complex aquaoxo[*N*-(2-pyridylmethyl)iminodiacetato]vanadium(IV) [VO(pmida)H_2O]·$2H_2O$ by X-ray crystallography to find that the tertiary amine occupies the trans site to oxo.[2] The anation reaction of this complex[1] with thiocyanate and azide proceeded much slower ($\simeq 10^{-1}$ s^{-1} at 25 °C) than the reported basal site substitutions[3] ($\simeq 10^3$ s^{-1} at 25 °C). We have thus considered that the hitherto known rates would not represent those of direct basal site substitution but involve the rearrangement from the apical to the basal site.

This new compound is stable toward acid hydrolysis above pH 3, but loses the quadridentate ligand in a more acid solution. Nitrilotriacetate(nta^{3-}) gives aqua(nitrilotriacetato)oxovanadate(IV) [VO(nta)-H_2O]$^-$ which was found also stable toward acid hydrolysis above pH 3.[4] Acid hydrolysis of these two complexes involve various steps but must include the dissociation of basal metal-ligand bond. This paper deals with the kinetic studies of aquation of [VO-(pmida)H_2O] and [VO(nta)H_2O]$^-$ in perchloric acid solutions containing 0.1 to 2.0 and 0.2 to 2.0 M (1 M= 1 mol dm^{-3}) acid, respectively, at an ionic strength 2.0 ($LiClO_4$). The overall reaction is expressed by Eq. 1 (L^{n-2} stands for the quadridentate ligand with n=0 or 1).

$$[VO(L)H_2O]^n + mH^+ \underset{k_f}{\overset{k_d}{\rightleftharpoons}} [VO_{aq}]^{2+} + H_mL^{m+n-2} \quad (1)$$

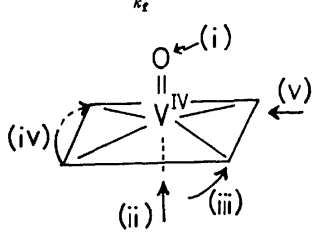

Fig. 1. Different substitution rates at various coordination sites of oxovanadium(IV) ion.
i) Very slow exchange of the oxo ligand, ii) very rapid substitution at the apical site, iii) fairly rapid intramolecular rearrangement from the apical to the basal site, iv) chelate formation at the basal site, v) rather slow direct basal substitution.

Experimental

Materials. The complex [VO(pmida)H_2O]·$2H_2O$[2] and K[VO(nta)H_2O]·H_2O[4] were prepared by the given methods, and the purity was checked by IR, UV, and visible absorption spectra and elemental analysis of carbon, hydrogen, and nitrogen. The ionic strength was adjusted with Special Grade sodium perchlorate and lithium perchlorate. The latter was prepared from the carbonate and perchloric acid and doubly recrystallized. Perchloric acid (Wako Chem. Co., Special Grade 60%) was used without further purification. The acid concentration was determined by the titration with sodium hydroxide.

Kinetic Runs. The UV absorption spectra at the initial and the final stage of the acid hydrolysis reaction are shown in Fig. 2. The rate was measured by monitoring the decrease of absorbance at 350 and 330 nm for the pmida and nta complexes, respectively, by the stopped-flow technique mainly at 25 °C and I=2.0 ($LiClO_4$). The difference in absorption at the given wave lengths before and after the acid hydrolysis coincided with those calculated from pure

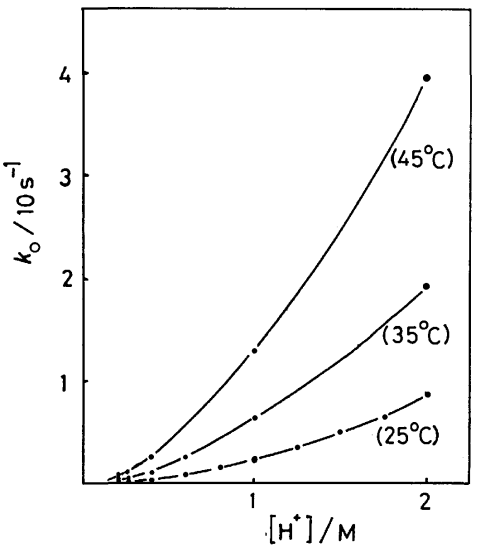

Fig. 4. Dependence of the first-order rate constant k_o upon the acid concentration for [VO(nta)H$_2$O]$^-$ (I= 2.0, LiClO$_4$ at 25, 35, and 45 °C).

solutions of [VO(L)H$_2$O]^n and [VO(H$_2$O)$_5$]$^{2+}$, and the free ligand. The absorption spectra of all the reaction mixtures 5 min after mixing were the same with those of the complexes in 5 M perchloric acid solutions. Plots of $\ln(A_t - A_\infty)$ against time were linear until the reaction reached 85% completion, where A_t and A_∞ stand for the absorptions at the given wave length at time t and infinity, respectively. The first-order rate constants k_o were obtained from the slopes by the least squares method. The apparatus (Union Giken, RA 601 stopped-flow spectrometer) was used on different time scales, and the reproducibility was satisfactory within an error ±3%.

Results

The Overall Rate. The observed rate constant, k_o is expressed by Eq. 2, where [VO] stands for the concentration of the original complex.

$$-\mathrm{d[VO]}/dt = k_o[\mathrm{VO}] \quad (2)$$

Since the acid hydrolysis proceeded to completion under the given conditions, only the k_d in Eq. 1 was observed. Addition of excessive H$_3$nta did not change the k_o values at [H$^+$]=0.2 M. Addition of H$_2$pmida to the [VO(pmida)H$_2$O] solution at [H$^+$]=0.1 M increased the observed first-order rate constant and the formula was expressed by Eq. 3. ([H$_x$pmida] stands for the sum of concentration of variously protonated species of free pmida^{2-})

$$k'_o = k_d + k_f[\mathrm{H}_x\mathrm{pmida}] \quad (3)$$

The observed k_d was 0.012 s^{-1}, coinciding with the k_o (0.012 s^{-1}) in the absence of excess of H$_2$pmida. Hence the formation reaction does not affect the rate of acid hydrolysis and no attention was paid to k_f.

Kinetic Formulae. The observed first-order rate constants for the two complexes showed rather complicated dependence on the acid concentration. (Figs. 3 and 4)

The pmida Complex: The curves in Fig. 3 suggests the participation of two routes involving one and two protons as shown by Eqs. 4, 5, and 6.

$$[\mathrm{VO(L)H_2O}]^n \overset{K_1(\mathrm{H^+})}{\rightleftarrows} [\mathrm{VO(HL)H_2O}]^{n+1} \overset{K_2(\mathrm{H^+})}{\rightleftarrows} [\mathrm{VO(H_2L)H_2O}]^{n+2} \quad (4)$$

$$[\mathrm{VO(HL)H_2O}]^{n+1} \xrightarrow{k_1} [\mathrm{VO_{aq}}]^{2+} + \mathrm{H}_x\mathrm{L} \quad (5)$$

$$[\mathrm{VO(H_2L)H_2O}]^{n+2} \xrightarrow{k_2} [\mathrm{VO_{aq}}]^{2+} + \mathrm{H}_x\mathrm{L} \quad (6)$$

On the basis of Eqs. 4 to 6, the rate formula is written by

$$k_o = (k_1K_1[\mathrm{H^+}] + k_2K_1K_2[\mathrm{H^+}]^2)/(1 + K_1[\mathrm{H^+}] + K_1K_2[\mathrm{H^+}]^2). \quad (7)$$

Individual values of k_1, k_2, K_1, and K_2 were obtained by the trial and error method from the experimental values and shown in Table 1. They may involve rather large errors. The broken lines in Fig. 3 drawn by use of these calculated values, however, fit the experimental plots well.

The nta Complex: When the same analysis was applied to the nta complex, the individual values of equilibrium and rate constants were calculated as shown in Table1. It seems as if there is no contribution of the route shown by Eq. 5. The usefulness of such an analysis was verified as follows. The simulated value of k_1 is almost zero, and the product $K_1K_2[\mathrm{H^+}]^2$ is very small

Table 1. Results of the simulation curve fitting

	pmida			nta	
Temp/°C	45	35	25	25	25[a]
K_1/M^{-1}	1.7	1.6	1.5	0.20	0.26
K_2/M^{-1}	0.1	0.1	0.2	0.004	$k_2 \cdot K_2$
k_1/s^{-1}	0.1	0.05	0.02	0.00	12±2
k_2/s^{-1}	40	20	6	3000	(M^{-1} s^{-1})

a) By use of Eq. 9; the apparent ΔH^* and ΔS^* calculated for the product k_2K_2 at 25, 35, and 45 °C are 38±17 kJ mol^{-1} and −96±50 J mol^{-1} K^{-1}, respectively.

TABLE 2. SALT EFFECTS ([H+]=0.2 M, 25 °C)

I	k_o/s^{-1}	
	pmida	nta
0.2	0.020	0.14
1.2	0.037	0.13
2.0	0.042	0.11

under the experimental conditions. Hence the first term of the numerator and the third term of the denominator of Eq. 7 can be ignored to give Eq. 8.

$$k_o = k_2K_1K_2[H^+]^2/(1+K_1[H^+]) \quad (8)$$

This is converted into Eq. 9.

$$[H^+]/k_o = 1/k_2K_1K_2[H^+] + 1/k_2K_2 \quad (9)$$

Plots of $[H^+]/k_o$ against $[H^+]^{-1}$ gave straight lines at the three temperatures, and the K_1 and the product k_2K_2 were obtained from the intercepts and gradients. The K_1 values obtained by such a plot and by the simulation method coincided with each other.

Medium Effects. The salt effect[5] was studied by changing the ionic strength, and the results are included in Table 2. A positive and a slightly negative effect were found for the pmida and the nta complex, respectively.

The chloride ion concentration did not affect the rate. The thiocyanate ion slightly accelerated the reactions of both complexes. The kinetic formula is too complicated to be analysed, but the anion seems to replace, at least partly, the coordinated water of the original complexes.[1,4]

Discussion

Whenever a substitution reaction of oxovanadium(IV) complexes is to be analysed, participation of mechanistically discriminated reactions should be considered (Fig. 1). They include i) very inert oxoanion exchange,[6] ii) extremely labile apical site substitution,[7,8] iii) basal ligand substitution involving intramolecular rearrangement of a ligand from apical to basal site,[3] iv) chelation at basal site,[9] and v) direct basal substitution.[1,4] For the present reactions, process iii and v should be considered.

Kinetic formulae for both the complexes indicate that proton catalysed bond breaks are the rate determining steps. Since coordinated nitrogen atoms have no lone pair of electrons, the protonation should take place on the oxygen of the acetate branch of the ligand.[10]

The pmida Complex. The X-ray structure has been determined and the bond lengths are known. The kinetic formula suggests the presence of two parallel paths, accompanied by single and double protonation. For the process iii to operate, break of at least two basal bonds should be needed. A plausible reaction mechanism is illustrated in Fig. 5.

The V–O bond lengths are 2.02 and 1.98 Å at the trans and cis site of the aqua ligand, respectively, in the crystalline state (Fig. 6). If the difference were preserved in the aqueous solution, the first protonation should take place at the trans site. The protonated acetate branch will leave the coordination sphere rapidly, so that the observed K_1 corresponds to the product of the equilibrium constant of the first protonation (I to II) and the break of the trans V–OH bond to the aqua (II to III).[11] The k_1 step can take place at either the V–O (cis to aqua) or the V–N (pyridine) bond. Their lengths are 1.98 and 2.11 Å respectively in the crystalline state. If a similar difference existed in the aqueous solution, the V–N bond would be broken at a rate k_1 [III]. The observed k_1 value is not very different from the ordinary rate constant of direct basal bond break (process v).[1]

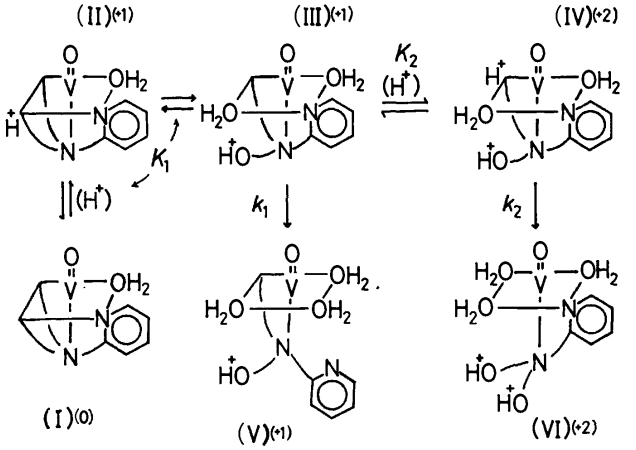

Fig. 5. Plausible reaction mechanism for [VO(pmida)-H_2O]. (The overall charges of the complex and the intermediates are in parentheses).

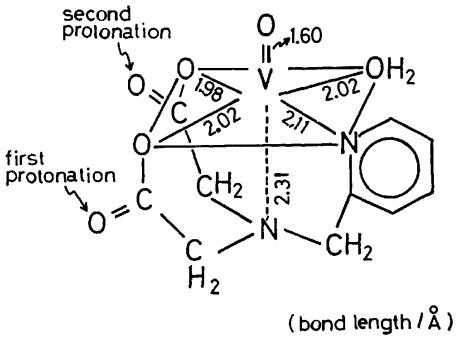

Fig. 6. X-Ray structure data of [VO(pmida)H_2O]·$2H_2O$ and plausible protonation site in solution.

The k_2 step involving the doubly protonated complex (IV) must be the break of the acetate arm cis to the aqua ligand. The larger k_2 than k_1 must be due to protonation. After the two basal bonds are broken, the tertiary nitrogen can dissociate very quickly (process ii) and the third basal bond (V–O and V–N(pyridine) for the intermediates V and VI, respectively) can move to the apical site (process iii) to result in complete dissociation of $H_x$pmida.

The contribution of the two paths depends on the acid concentration. The k_2 is much greater than k_1, but the small K_2 decreases its contribution, which however predominates at a high acid concentration.

The nta Complex. The X-ray structure of this complex is not known, but the tertiary amine was believed to occupy the apical position.[4] The simulated

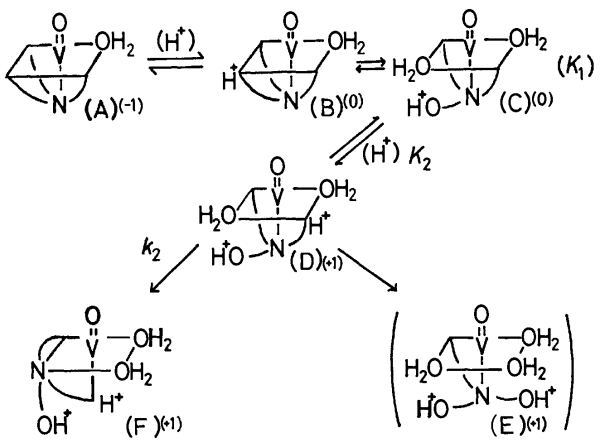

Fig. 7. Plausible reaction mechanisms for [VO(nta)-H_2O]$^-$ (see the text). (The overall charges of the complex and the intermediates are in parentheses).

small k_1 implies that the singly protonated species (C in Fig. 7) does not allow the dissociation of the complex. Whenever a similar process is assumed for this complex as for the pmida complex, the K_1 represents the overall equilibrium constant for the two processes, the protonation (form A to B) and the dissociation of a V–OH bond trans to aqua (B to C). The simulated K_1 is much smaller than that for the pmida complex. This fact may result from either the difficulty in first protonation or the ease of the backward reaction from C to B, suggesting in either case a stronger V–O bond than that for the pmida complex. The K_2 value indicating the ease of second protonation at the cis site to the aqua ligand is also smaller than that for the pmida complex. This fact also suggests a stronger V–O bond than that for the pmida complex. These observations are also reflected in the high acid concentration region, in which the acid hydrolysis can be measured. The simulated k_2 vaule ($\simeq 3000\ s^{-1}$) is, on the other hand, much greater than that of the pmida complex ($\simeq 6\ s^{-1}$). Although there can be complication from the difference in overall charge, it is unlikely that a stronger bond is more readily broken than a weaker bond under a similarly protonated circumstance. Hence the k_2 must reflect some other process than a mere break of V–OH bond (from D to E in Fig. 7). If the doubly protonated intermediate D underwent intramolecular rearrangement to give F, the protonated arm at the apical site would be readily broken (processes iii and ii). Such an intramolecular change is not generally feasible for a terdentate ligand. Molecular model studies, however, suggest that the nta complex is highly strained. The second protonation will elongate the V–O bond and can bring about the rearrangement of H_2nta^- to give F. The simulated k_2 is in the same region as those for the process iii.[12]

Comparison of the Two Complexes. The faster acid hydrolysis of the more stable nta complex than that of the pmida complex may be accounted for by considering different rate determining steps for both complexes as shown above. The reason why the pmida complex undergoes the intramolecular rearrangement to give F-type intermediate with difficulty may be attributed to the more highly oriented V–N (pyridine) bond brought about by the delocalization of electron between d_{xy} orbital of vanadium(IV) and the π-orbital of pyridine.

The influence of ionic strength upon k_o indicates the interactions between species with the same and opposite ionic sign for the pmida and the nta complex, respectively. Since interactions involving species without electric charge do not exhibit significant dependence on the ionic strength, the equilibrium constants K_2 and K_1 will be subject to the influence (see Figs. 5 and 7). The K_2 for the pmida complex will increase and the K_1 for the nta complex will decrease with increase in ionic strength. Since the second and third terms of the denominator of Eq. 7 are much less than unity, the influence of ionic strength will be predominating on the numerator. Hence the results of Table 2 are reasonably interpreted by the mechanisms shown in Figs. 5 and 7.

11) The absorption change corresponding to the step from species (II) to (III) seems too small to be detected. The rate of the bond break from II to III must be greater than those for the k_1 and k_2 paths but can be of similar order to that of the k_2 path.

12) This interpretation is based on the assumption that the first protonation takes place at the trans site to the aqua ligand as presumed for the pmida complex. If the first protonation occurred on the cis site, on the contrary, the intermediate product would involve a facially terdentated $Hnta^{2-}$ species. The nitrogen at the apical site would be labile, and the second protonated acetate arm can squeeze into the apical site while the nitrogen tentatively leaves the apical site. Such a mechanism is also in accord with the given kinetic formula and the simulated values of K_1, K_2, and k_2. So far as the bond lengths remain unknown the two possible reaction mechanisms cannot be discriminated.

Equilibrium Study of Iron Vanadium Sulfides in the Iron-rich Portion of the Composition Triangle of FeS–VS–S

Hiroaki WADA

National Institute for Researches in Inorganic Materials, Namiki, Sakura-mura, Niihari-gun, Ibaraki 305

(Received August 2, 1979)

An equilibrium study of a part of the Fe–V–S system at sections with atomic Fe:V ratios of 1:0, 9:1, and 4:1 was carried out by means of thermogravimetry. The thermochemical data which were obtained in the range of $\log(P_{S_2}/\text{atm}) = -4$ to -0.8 at temperatures between 520 and 814 °C are presented. The compositional limits of the univariant assemblage of $Fe_{1-\delta}S$-FeS_2-$(Fe,V)_3S_4$ were determined at 570 °C on the basis of X-ray analyses of the quenched specimens. The rate of FeS_2 formation under the experimental conditions employed was studied qualitatively from the point of view of the sulfidation kinetics of iron vanadium sulfides.

The results of equilibrium studies of the ternary compounds of Fe–V–S with the constant V/(Fe+V) ratio in the range of 0.29 to 1 were presented in earlier publications.[1-3] The author wishes to report in this paper the experimental results for a further series of samples with the V/(Fe+V) ratios of 0.20, 0.10, and 0. In this part of the Fe–V–S system, the following compounds are included: the hexagonal $(Fe,V)_{1-\delta}S$ solid solution, the monoclinic $(Fe,V)_3S_4$ solid solution, and the cubic FeS_2 (pyrite). With respect to the phase relations, it is known that the ternary univariant assemblage, which is composed of a three-phase mixture of FeS_2, the $(Fe,V)_3S_4$ solid solution, and $Fe_{1-\delta}S$, is stable over wide compositional ranges at 570 °C.[2] However, the compositional data on the phase boundary of the univariant assemblage have not yet been determined precisely in detail.

The primary aims of this study were to obtain the thermochemical data of iron vanadium sulfides under equilibrium conditions and to determine the phase relations and its compositional limits in detail. Considerable attention has been focussed on the determination of the univariant field of FeS_2–$Fe_{1-\delta}S$–$(Fe,V)_3S_4$ s.s.–vapor. In this connection, the sulfidation kinetics of iron vanadium sulfides was examined in order to obtain fundamental knowledge on the rate of FeS_2 formation under the experimental conditions employed.

The main thermochemical study was carried out with a gravimetric method by using a quartz spring balance at temperatures between 500 and 814 °C. The sulfur pressure in the N_2–sulfur vapor system was controlled by temperature regulation. The present paper is concerned with the P_{S_2} (equilibrium sulfur pressure)-T (temperature)-X (composition) relations, the phase relations, and the sulfidation rate of iron vanadium sulfides in the case of FeS_2 formation.

Experimental

Materials. Sulfide samples with atomic Fe : V ratios of 9 : 1 and 4 : 1 were synthesized by heating the mechanical mixtures of reagent-grade $VOSO_4 \cdot 3H_2O$ and $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ in an H_2S atmosphere at 1050 °C for 4 h. The iron sulfide samples were synthesized by means of a direct reaction from the elements. The iron powder (99.99%) and sulfur powder (99.9999%) were used for preparation. The mixture in desired quantities was sealed in an evacuated silica tube, heated at high temperatures, and quenched in water. Two samples with different compositions were used for the study of the Fe–S system. One was $FeS_{1.12}$, which had been synthesized at 800 °C for a week. The other was $FeS_{2.01}$, which had been heated at first at 450 °C for a week and then homogenized at 600 °C for a week. These artificial sulfides were used as the starting materials for the equilibrium study.

General Procedure. The equilibrium study of iron vanadium sulfide was carried out by both thermogravimetry and the rigid tube, quench-type, annealing experiment at temperatures between 520 and 814 °C. The general experimental procedures, the apparatus, and the methods of the chemical analyses and of the phase identification of quenched specimens are the same as those described in previous papers.[1-2]

Results and Discussion

Composition versus P_{S_2} Diagram in an Iron-rich Portion of the Composition Triangle of FeS–VS–S. The results of equilibrium studies of the Fe–V–S system at sections with atomic Fe:V ratios of 4:1, 9:1, and 1:0 are shown graphically in Figs. 1—3. The isothermal curves are drawn by a smooth fitting of data points which represent the relation of the equilibrium sulfur pressure, P_{S_2}, to the composition of the sulfides (X=S/(Fe+V)) at the selected temperature. Also, the phase relations which were revealed by the X-ray diffraction of the quenched specimens are given in Table 1 and Figs. 1—3. Below, a solid solution will be abbreviated as

Table 1. Results of X-ray identification of the specimens quenched from 570 °C

Composition Fe/(Fe+V)	Composition S/(Fe/V)	Time/h	Products
1.000	1.120	720	$Fe_{1-\delta}S$ (hexagonal:3c)
	1.150	90	$Fe_{1-\delta}S$
	1.170	90	$Fe_{1-\delta}S+FeS_2$
0.900	1.146	182	$(Fe_{0.90}V_{0.10})_{1-\delta}S$
	1.168	144	$(Fe,V)_{1-\delta}S+(Fe,V)_3S_4$
	1.220	109	$(Fe,V)_{1-\delta}S+(Fe,V)_3S_4$
	1.230	109	$Fe_{1-\delta}S+(Fe,V)_3S_4+FeS_2$
	1.750	111	$Fe_{1-\delta}S+FeS_2+(Fe,V)_3S_4$
	1.800	111	$FeS_2+(Fe,V)_3S_4$
0.800	1.146	182	$(Fe_{0.80}V_{0.20})_{1-\delta}S$
	1.160	95	$(Fe,V)_{1-\delta}S+(Fe,V)_3S_4$
	1.216	109	$(Fe,V)_{1-\delta}S+(Fe,V)_3S_4$
	1.500	1536	$(Fe,V)_3S_4+FeS_2+Fe_{1-\delta}S$
	1.550	127	$FeS_2+(Fe,V)_3S_4$

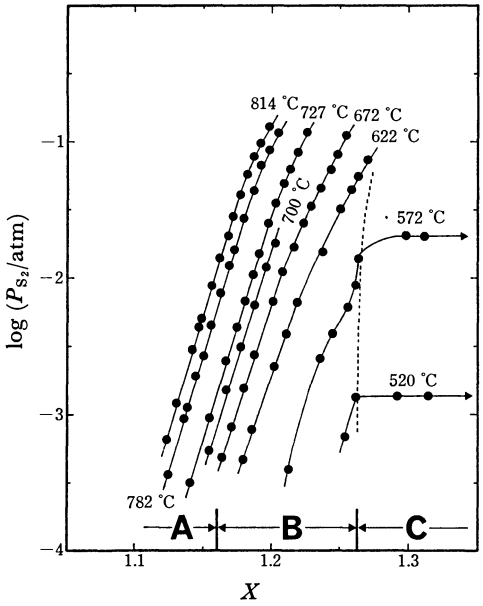

Fig. 1. P_{S_2}-composition (X=S/(Fe+V)) isotherm of $Fe_{0.80}V_{0.20}S_X$. Phase identifications of quenched specimens by X-ray powder diffraction method are shown in lower part of figure as follows A: $(Fe_{0.80}V_{0.20})_{1-\delta}S$. B: $(Fe,V)_{1-\delta}S+(Fe,V)_3S_4$ s.s. C: $Fe_{1-\delta}S+FeS_2+(Fe,V)_3S_4$ s.s. The dashed line indicates the phase boundary of the univariant field.

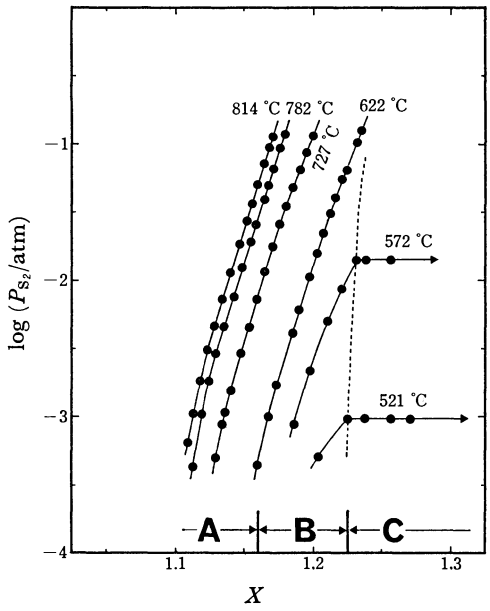

Fig. 2. P_{S_2}-composition isotherms of $Fe_{0.90}V_{0.10}S_X$. A: $(Fe_{0.90}V_{0.10})_{1-\delta}S$. B: $(Fe,V)_{1-\delta}S$ s.s.$+(Fe,V)_3S_4$ s.s.. C: $Fe_{1-\delta}S+FeS_2+(Fe,V)_3S_4$ s.s.

s.s. for convenience.

Figure 1 shows isotherms with the composition of $Fe_{0.80}V_{0.20}S_X$, where X ranges between 1.12 and 1.32. As listed in Table 1, the following phase relations are obtained at 570 °C: $(Fe_{0.80}V_{0.20})_{1-\delta}S$ phase, a two-phase mixture of $(Fe,V)_{1-\delta}S$ s.s. and $(Fe,V)_3S_4$ s.s., and a three-phase mixture of FeS_2, $Fe_{1-\delta}S$, and $(Fe,V)_3S_4$ s.s. in the compositional ranges of $X<1.16$, $1.16\leqq X<1.263$, and $1.263\leqq X<1.55$ respectively.

As is shown in Fig. 1, the isothermal curves for 814, 782, 727, and 700 °C exhibit continuous and gradual changes in the sulfur pressure with the composition. Although the sulfur-rich limit of the hexagonal $(Fe_{0.80}V_{0.20})_{1-\delta}S$ phase was determined to be about $X=1.16$ from the X-ray measurements of the quenched specimens, no characteristic curvature change in the isotherms is observed at $X=1.16$. This behavior of the isotherms seems to be indicative of the existence of a high-temperature phase, as has been reported previously.[2,3] There is the possibility that the homogeneity range of the $(Fe_{0.80}V_{0.20})_{1-\delta}S$ becomes broadened with an increase in the temperature and that its sulfur-rich limit has a composition with a value higher than $X=1.16$.

With respect to the isotherms for 572 and 520 °C, an abrupt change in the slope is observed at the composition of about $X=1.262$. In the compositional range of $X>1.262$, the isotherms become horizontal due to the formation of FeS_2, as has been discussed previously.[2] On the basis of the phase relations which were determined from the X-ray studies of the quenched specimens, it is suggested that the horizontal parts of the isotherms mean a univariant field of the Fe–V–S system, where $Fe_{1-\delta}S$, FeS_2, and $(Fe,V)_3S_4$ s.s. coexist at equilibrium.

Figure 2 shows the isothermal curves of the composition of $Fe_{0.90}V_{0.10}S_X$, where X ranges from 1.11 to 1.31. The phase relations obtained at 570 °C are as follows: $(Fe_{0.90}V_{0.10})_{1-\delta}S$ phase, a two-phase mixture of $(Fe,V)_{1-\delta}S$ and $(Fe,V)_3S_4$ s.s., and a three-phase mixture of $Fe_{1-\delta}S$, FeS_2, and $(Fe,V)_3S_4$ s.s., in the compositional ranges of $X<1.16$, $1.16\leqq X<1.23$, and $1.23\leqq X<1.75$ respectively.

The isothermal curves of $Fe_{0.90}V_{0.10}S_X$ are similar in shape to that of $Fe_{0.80}V_{0.20}S_X$ except that the entire curves are shifted to the sulfur-poor side with regard to the composition. As is evident in Fig. 2, no curvature changes are observed in the isotherms for 814, 782, and 727 °C at the sulfur-rich phase boundary of $(Fe_{0.90}V_{0.10})_{1-\delta}S$. It is noted that the isotherms for 521 and 572 °C become horizontal due to the FeS_2 formation at $X=1.225$ and $X=1.230$ respectively. However, no such change is observed in the isotherm for 622 °C in the present experimental compositional range. This suggests that the sulfur-poor limits of the three-phase field recedes toward the sulfur-rich side with an increase in the temperature.

Figure 3 shows the isotherms of the binary compound, FeS_X, where X lies in the range from 1.07 to 1.25. In this compositional range, only two phases were detected by the X-ray powder diffraction of the quenched specimens (Table 1). One is the hexagonal $Fe_{1-\delta}S$ (pyrrhotite), whose X-ray diffraction patterns exhibit 3c-type supper structure lines[4] in addition to the fundamental reflection lines of the NiAs type, while the other is the cubic FeS_2 (pyrite). The following phase relations were confirmed at 570 °C: the $Fe_{1-\delta}S$ phase, and a two-phase mixture of $Fe_{1-\delta}S$ and FeS_2, in the compositional ranges of $X<1.16$ and $X\geqq 1.16$ respectively.

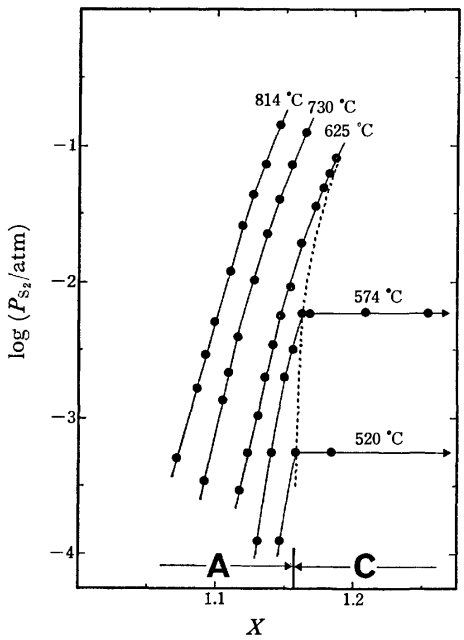

Fig. 3. P_{S_2}-Composition isotherms of FeS_X. A: $Fe_{1-\delta}S$. C: $Fe_{1-\delta}S+FeS_2$. The phase boundary of $Fe_{1-\delta}S$ is represented as the broken line.

With respect to the isotherm feature, it is noted that the horizontals associated with a two-phase equilibrium of $Fe_{1-\delta}S$ and FeS_2 appear at the compositions of $X=1.155$ and $X=1.160$ for 520 and 574 °C (Fig. 3). However, the isotherm for 625 °C does not show such horizontals in the range of $X<1.19$. Those results indicate that the homogeneity range of the $Fe_{1-\delta}S$ phase tends to be broadened to the sulfur-rich side with an increase in the temperature.

A few remarks should be made here regarding the equilibrium sulfur pressure of a two-phase mixture of $Fe_{1-\delta}S$ and FeS_2. For example, in the experiments for 574 and 520 °C, the sulfur pressure was controlled to bring the composition to a higher sulfur content than at the beginning of that series. The sulfidation of the specimens proceeded with an increase in the sulfur pressure, and isotherms became horizontal in a two-phase field due to the considerable increase in the sulfur content in the solids, associated with the FeS_2 formation. In this case, however, the values of the sulfur pressure at the horizontal parts of the isotherms are not regarded as truly resulting from a two-phase equilibrium of $Fe_{1-\delta}S$ and FeS_2, because a slightly higher sulfur potential than the equilibrium one is needed on the formation of FeS_2 in order to supply the activation energy of the reaction of $Fe_{1-\delta}S$ with sulfur vapor. Therefore, it is designated here as the upper limit of the equilibrium sulfur pressure.

The relation of the decomposition pressure of FeS_2 to temperature was examined in order to determine the lower limits of the equilibrium sulfur pressure of $Fe_{1-\delta}S$–FeS_2 mixtures. Experiments were carried out by thermogravimetry using $FeS_{2.01}$ as the starting material. When a significant weight loss of specimens was observed within the time interval of 30 min at the selected temperature and pressure, it was judged

Fig. 4. that FeS_2 begins to decompose to $Fe_{1-\delta}S$ and sulfur vapor. The experimental results are listed in Table 2 and shown in Fig. 4, together with the results reported by other investigators.[5-8] The data points obtained in this study are well represented by the following equation (least-squares treatment): $\log(P_{S_2}/\text{atm})=-16477/(T/\text{K})+16.96$, where 1 atm=101.325 kPa. This result is in good agreement with that of Toulmin and Barton,[5] as is shown in Fig. 4. The upper limit of the equilibrium sulfur pressure which was obtained on the sulfidizing specimens (Fig. 3) is given in Fig. 4 for comparison.

The true equilibrium value probably lies within the range between the upper and lower limits of sulfur pressure at a given temperature. The difference in the sulfur pressure between the formation and the reduction of FeS_2 is about $0.25=\log(P_{S_2}/\text{atm})$ at 574 °C. It may be considered that this discrepancy is derived from the sluggishness of the reaction rate of

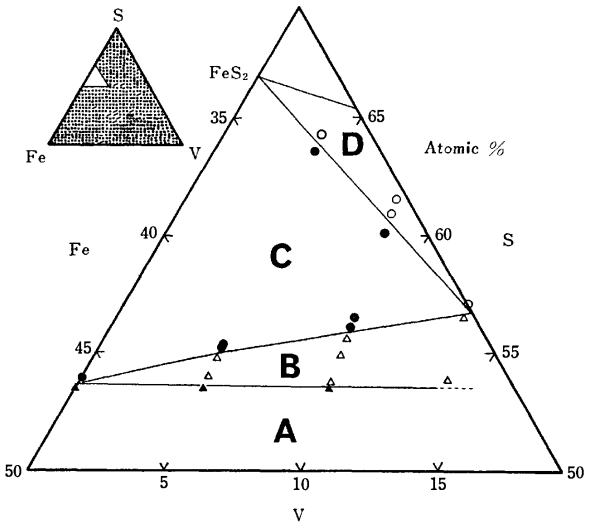

Fig. 5. Tentative phase diagram of the iron-rich portion of the composition triangle of FeS–VS–S at 570 °C. Phase relations are represented as follows. ▲: $(Fe,V)_{1-\delta}S$ s.s. △: $(Fe,V)_{1-\delta}S$ s.s.+$(Fe,V)_3S_4$ s.s. ●: $Fe_{1-\delta}S+FeS_2+(Fe,V)_3S_4$ s.s. ○: $FeS_2+(Fe,V)_3S_4$ s.s.

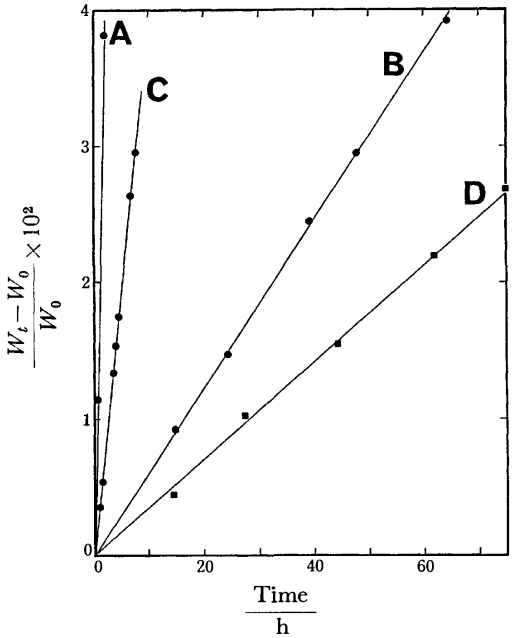

Fig. 6. The relation of the weight gain of the sample with time.

the formation or the reduction of FeS_2 under the present experimental conditions. On the assumption that the true equilibrium sulfur pressure of the $Fe_{1-\delta}S$–FeS_2 mixture is halfway between the upper and lower limits, the Gibbs free energy of the $[2/(1-2\delta)]Fe_{1-\delta}S+S_2=[2(1-\delta)/(1-2\delta)]FeS_2$ reaction was calculated in the temperature range of 520—580 °C: $\Delta G_r^\circ=-67100+68.5\,T$ cal_{th}, where 1 $cal_{th}=4.184$ J.

The Tentative Phase Diagram at 570 °C. The tentative isothermal phase diagram in the iron-rich portion of the composition triangle FeS–VS–S was constructed on the basis of the results of both thermogravimetry and rigid-tube, annealing, quench-type experiments. The phase relations and phase boundaries are shown in Fig. 5.

With respect to the Fe–S binary system, the sulfur-rich limit of $Fe_{1-\delta}S$ is determined to be 46.3 atom% Fe at 570 °C (Fig. 3). This value is in good agreement with the sulfur-rich limit of $Fe_{1-\delta}S$ (46.2 atom% Fe), which was reported by Arnold.[9] As is shown in Fig. 6, it is assumed that the $Fe_{1-\delta}S$ and $V_{1-\delta}S$ phases form a complete $(Fe,V)_{1-\delta}S$ solid solution (A region) at 570 °C. The sulfur-rich phase boundary of the $(Fe,V)_{1-\delta}S$ field is extended nearly parallel with the line joining FeS–VS from the Fe–S side to the V–S side in the $0\leqq V/(Fe+V)<0.3$ range.

The univariant field (C region) is determined by a smooth fitting of data points. The sulfur-poor boundary of the univariant field recedes progressively toward sulfur-poor compositions with an increase in the Fe content; its limits are 55.1 and 55.9 atom% S in the sections with atomic Fe:V ratios of 9:1 and 4:1 respectively. On the other hand, the sulfur-rich boundary of the univariant field is shifted progressively toward a sulfur-rich composition with an increase in the Fe content; its limits are about 63.9 and 60.6 atom% S in the sections with atomic Fe:V ratios of 9:1 and 4:1 respectively. It should be noted that the sulfur-rich boundary line intersects the line joining Fe–S at the composition of FeS_2.

The two-phase fields (B region) of $(Fe,V)_3S_4$ and $(Fe,V)_{1-\delta}S$ are present in the middle part between the A and C regions. However, the compositional relation of $(Fe,V)_{1-\delta}S$ to the coexisting $(Fe,V)_3S_4$ has not been determined in this study.

Sulfidation Kinetics of Iron Vanadium Sulfides. In a series of reports,[1-3] the phase relations and P_{S_2}-X-T relations of the Fe–V–S system have been presented without any particular regard for the reaction kinetics. In general, it is well known that the time required for equilibriation increases with the decrease in the temperature with respect to the phase equilibria. Therefore, it may be suggested that the thermochemical data reported in this series are perhaps somewhat less accurate at lower temperatures, such as 520 °C, because the establishment of the equilibrium could not be checked precisely. It is necessary to obtain experimental data on the sulfidation kinetics of iron vanadium sulfides in order to have a comprehensive understanding of the Fe–V–S system at lower temperatures.

In the course of the equilibrium study of the Fe–V–S system, the sulfidation rate was examined supplementally. Considerable attention has been focussed on the rate of FeS_2 formation in the univariant field (FeS_2–$Fe_{1-\delta}S$–$(Fe,V)_3S_4$ s.s.–vapor). The sulfidation kinetics of powder samples were determined by means of thermogravimetry.

The variation in the sample weight with time was examined along the horizontal parts of the isotherms (Figs. 1—3) in order to ascertain the sulfidation rate of the sulfide powder. The composition at the sulfur-poor limit of the horizontal line was selected as the starting composition in the sulfidation experiments. About 300 mesh and 1 g of powder samples were used.

The degree of the weight gain of the sample is shown in Fig. 6 for periods up to 80 h. The experimental results may be represented well as the following linear relation: $W_t=W_0(1+\alpha t)$, where α, t, W_t, and W_0 denote the gain in the sample weight per a unit of time, time/h, the sample weight at time $t=t$, and $t=0$ respectively. As a first approximation, it can be proposed that the slope of the linear equation, α, is related to the rate of FeS_2 formation. From Fig. 6, the following values are obtained for the slopes of Lines A, B, C, and D: for $FeS_{1.156}$, $\alpha_A=1.98\times10^{-2}$/h at 520 °C and $P_{S_2}=10^{-2.08}$, and $\alpha_B=0.06\times10^{-2}$/h at 520 °C and $P_{S_2}=10^{-3.26}$, for $FeS_{1.161}$, $\alpha_C=0.40\times10^{-2}$/h at 574 °C and $P_{S_2}=10^{-2.22}$, and for $Fe_{0.90}V_{0.10}S_{1.225}$, $\alpha_D=0.04\times10^{-2}$/h at 520 °C and $P_{S_2}=10^{-3.02}$. It should be noted that sulfidation rate of $Fe_{1-\delta}S$ (pyrrhotite) at 520 °C increases with an increase in the sulfur pressure in the P_{S_2} range from $10^{-3.26}$ to $10^{-2.08}$. On the basis of the assumption that the P_{S_2} values of Experiments B, C, D are very close to the equilibrium values at a given temperature, the following conclusions are obtained: (1) the sulfidation rate of $Fe_{1-\delta}S$ increases with an increase in the temperature, and (2) there is the tendency for the FeS_2 formation to be inhibited by the presence of vanadium in sulfides.

The over-all reaction rate of pyrrhotite for FeS_2 formation was calculated according to the $FeS_x+yS_2=FeS_2$ sulfidation reaction, where x and y are 1.156 and 0.422 respectively at 520 °C. In this case, the sulfidation rate was represented by the following equation; $-d[P]/dt=K_{obsd}[P]$ where [P] is the concentration of FeS_x with the composition at the sulfur-rich limit and where K_{obsd} is the apparent first-order rate constant. From the experimental results, the following K_{obsd} values were obtained from the slopes in the first-order plots in a region of low conversion ($0.87<P/P_0\leqq1$): $K_A=1.98\times10^{-5}$/s, $K_B=6.26\times10^{-7}$/s, and $K_C=4.13\times10^{-6}$/s. The activation energy of FeS_2 formation was calculated to be 191.6 kJ/mol by using values of K_B and K_C according to the Arrhenius equation. This value is much larger than that of the sulfidation of Fe metal (113.0 kJ/mol) under the sulfur pressure of 1 atm, which was reported by Narita and Nishida.[10] The reaction mechanism of iron vanadium sulfides on the sulfidation process could not be clarified in this study. Further detailed studies of the sulfidation kinetics will be necessary for a comprehensive understanding of the Fe–V–S system.

The author wishes to express his deep gratitude to Professor Mitsuoki Nakahira of Okayama College of Science for his encouragement and helpful discussions throughout this study.

Transition Metal Alkoxides. Preparation and Properties of Bis(aryloxo)-iron(II) and Bis(alkoxo)iron(II) Complexes Having 2,2′-Bipyridine Ligands

Sanshiro KOMIYA, Shoshiro TANE-ICHI, Akio YAMAMOTO, and Takakazu YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received August 23, 1979)

A series of bis(aryloxo)iron(II), **2a**—**2g**, and bis(alkoxo)iron(II), **2h**—**2k**, complexes with 2,2′-bipyridine ligands ($Fe(OC_6H_4X)_2(bpy)_n$ and $Fe(OR)_2(bpy)_n$) have been prepared by the reactions of diethylbis(2,2′-bipyridine)-iron(II) (**1**) with corresponding *p*-substituted phenols and alcohols, respectively. (X=NO_2, CN, Cl, C_6H_5, H, and CH_3; R=CH_3, C_2H_5, *iso*-C_3H_7, and $CH_2C_6H_5$). These compounds were characterized by IR and NMR spectroscopies and elemental analyses as well as by chemical reactions. Kinetic investigation of the reactions of **1** with phenols by a visible spectroscopic method supports a mechanism involving partial dissociation of the 2,2′-bipyridine ligand, followed by coordination of phenol and activation of the Fe–C_2H_5 bonds giving the bis(phenoxo)iron(II) compound. Thermolysis of bis(alkoxo)iron(II) complexes gives not only disproportionation products of the alkoxo ligands (alcohols and aldehydes) but also organic products which are obtained as the result of C–O bond cleavage of the alkoxo groups. Interactions of **2** with acyl and alkyl halides lead to the formation of corresponding esters and ethers. Reactions of these iron(II) complexes with various organic acetates give corresponding acetates *via* an alkoxo exchange reaction. Bis(aryloxo)iron(II) complexes, **2**, are hydrolyzed with H_2O to yield phenols. Catalytic trans-esterification between ester and alcohol and Tishchenko type dimerization of benzaldehyde are effectively promoted under mild conditions by the bis(phenoxo)iron(II) and bis(benzyloxo)iron(II) complexes, respectively.

In contrast to non-transition metal alkoxides,[1] which are known to promote the catalytic reactions of carbonyl compounds such as Tishchenko reaction and Meerwein-Pondorf reaction, and to early transition metal alkoxides, which have been studied mainly from structural interest, the chemistry of Group VIII transition metal alkoxides has been much less explored. Formation of Group VIII transition metal alkoxides as intermediates has been implicitly postulated in reduction of transition metal halides on reactions with alcohols to low valent transition metal complexes,[2] or in oxidation of alcohols[3] as well as in trans-esterification reactions.[1a] The lack of well-characterized group VIII transition metal alkoxides has hindered our understanding of the mechanisms of these reactions. Although a growing number of Group VIII metal alkoxides have been synthesized and their properties studied,[4] more information is obviously needed concerning the chemistry of the Group VIII transition metal alkoxides to shed light on the mechanisms of transition metal promoted transformation of organic compounds.

We have found that diethylbis(2,2′-bipyridine)-iron(II), $Fe(C_2H_5)_2(bpy)_2$ (**1**) serves well as a starting material for preparing a variety of iron(II) aryloxides and alkoxides and studied their properties including catalytic activities. This paper also deals with the kinetic study of the reaction of **1** with alcohols and substituted phenols to form the alkoxides and aryloxides.

Results and Discussion

Preparation and Spectroscopic Properties of Bis(aryloxo)- and Bis(alkoxo)iron(II) Complexes. A variety of *p*-substituted phenols react with diethylbis(2,2′-bipyridine)iron(II), $Fe(C_2H_5)_2(bpy)_2$ (**1**)[5] to give bis-(phenoxo)iron(II) complexes having bpy ligands, $Fe(OC_6H_4X)_2(bpy)_n$ (**2**) (n=1 and 2) with evolution of two equivalents of ethane at ambient conditions. The bis(phenoxo)iron complexes are highly air sensitive, but thermally very stable.

$$Fe(C_2H_5)_2(bpy)_2 + 2HOC_6H_4X \longrightarrow Fe(OC_6H_4X)_2(bpy)_n + 2C_2H_6 \quad (1)$$

n=2; X=NO_2(**2a**), CN(**2b**)
n=1; X=CN(**2c**), Cl(**2d**), C_6H_5(**2e**), H(**2f**), CH_3(**2g**)

These complexes were characterized by elemental analyses, IR, and NMR spectroscopies, as well as by chemical reactions. The phenoxide complex **2f** was also prepared *via* an independent route by the reaction of $FeCl_2$ with $NaOC_6H_5$ in the presence of bpy, but the contamination of the product with salts prevented isolation of the pure material. Table 1 summarizes the elemental analyses and the yields of the complexes. The number of coordinating bpy ligand in the bis-(phenoxo)iron(II) complexes varies depending on the *p*-substituent in the phenoxo ligand. Electron-withdrawing substituents such as nitro and cyano groups favor the coordination of electron-donating two bpy ligands and less electron-withdrawing substituents give mono-bpy coordinated complexes. Bis(*p*-cyanophenoxo)iron(II) complex lies on the border between the two groups favoring mono- and bis-bpy complexes and both complexes **2b** and **2c** can be isolated under suitable conditions (see Experimental). Complexes **2a** and **2b** having two bpy ligands have considerable solubilities but the other complexes having one bpy ligand are much less soluble in organic solvents. Many metal alkoxides and phenoxides are known to be aggregated,[1a] and the coordinatively unsaturated complexes having only one bpy ligand per iron may well have polymeric structures accounting for the poor solubilities. In fact addition of excess bpy to a heterogeneous system of **2c** having one bpy ligand in acetone or toluene with heating caused dissolution of **2c** to give a homogeneous solution from which dark

d, doublet; m, multiplet; br, broad; s, singlet.

red crystals of **2b** having two bpy ligands were obtained on cooling the solution to −78 °C. The bpy ligand may be acting to break the bridging phenoxo bonds.

IR spectra of these (*p*-substituted phenoxo)iron(II) complexes showed a strong characteristic ν(C-O) band at 1260—1340 cm^{-1} which is shifted to higher frequency by 10—15 cm^{-1} compared with ν(C-O) of free phenols (Table 2). Cyano and nitro groups in the present complexes do not seem to have an interaction with iron, since no frequency change of ν(CN) and $\nu(NO_2)$ from the starting phenols was observed.

^1H NMR spectra of these bis(*p*-substituted diphenoxo)iron(II) complexes (Table 2) showed two doublets assignable to ortho and meta hydrogens in the *p*-substituted phenoxo ligands and three groups of multiplets for the bpy ligand. Bis(phenoxo) complex **2f** showed two kinds of broad signals in a 2 to 3 ratio, one being attributable to ortho hydrogens and the other to meta and para hydrogens. These spectroscopic results suggest that the phenoxo ligand is normally bonded with iron through oxygen unlike the π-bonding between ruthenium and phenoxo ligand in $RuH(OC_6H_5)(PPh_3)_2$ as observed by Wilkinson *et al.*[6]

In the presence of free bpy ligand, ^1H NMR of **2f** in CD_3OD showed only averaged peaks of bpy ligands coordinated and uncoordinated at room temperature, indicating fast intermolecular exchange process between them in the solution. On the contrary, ^1H NMR of a mixture of **2a** and free bpy showed separated signals for free and coordinated bpy ligands, respectively. Ligand exchange rate of **2a** with free bpy is considered to be slow enough in NMR time scale to separate the peaks. The configuration of the six coordinated complex with two bpy ligands, **2a** and **2b**, is considered to be cis, because of the steric requirement. ^1H NMR of bpy ligand in the cis configuration has been reported to show two kinds of pyridyl rings giving complicated multiplets.[7] However, the observed ^1H NMR of the coordinated bpy in **2a** showed a relatively simple pattern. Fast intramolecular exchange of bpy ligands may account for this observation, while a trans structure for **2a** is not completely excluded.

The reactions of **1** with aliphatic alcohols (ROH) afforded bis(alkoxo)iron(II) complexes analogously to the reactions with phenols.

$$Fe(C_2H_5)_2(bpy)_2 + ROH \xrightarrow{-2C_2H_6} Fe(OR)_2(bpy)_n \quad (2)$$

$n=1$ for $R=CH_2C_6H_5$(**2h**), C_2H_5(**2i**), *iso*-C_3H_7(**2j**),
$n=0$ for $R=CH_3$(**2k**)

The alkoxoiron complexes are extremely sensitive to air to preclude the microanalysis and have been characterized mainly by chemical reactions (*vide infra*). IR spectra of **2h**—**2j** showed a characteristic strong ν(C-O) band at *ca.* 1000 cm^{-1} in addition to the bands attributable to the bpy ligand. On the other hand, the IR spectrum of **2k** showed only bands assignable to the methoxo ligands. The aliphatic alkoxoiron complexes, **2h**, **2i**, and **2j**, are all quite insoluble in organic solvents suggesting polymeric structures as are common among other metal alkoxides. Formation of polymeric iron(II) methoxide has been reported by Klein.[8]

Chemical Reactivities of Iron(II) Aryloxides and Alkoxides. The phenoxoiron complex **2f** smoothly reacted with alkyl and acyl halides to give corresponding ethers and esters, respectively (Table 3). The resulted solid product formed in the reaction of **2f** with CH_3COCl was identified as $FeCl_2(bpy)$ by comparing its IR spectrum with that of the sample prepared by the acidolysis of **1** with HCl.

2j	$CH_3CO_2C_6H_5$ (4)	$CH_3CO_2C_3H_7{}^i$ (1.64)
2k	$CH_3CO_2C_6H_5$ (4)	$CH_3CO_2CH_3$ (1.52)

a) Reactions were carried out at 50 °C in THF for 5 h.

$$\mathbf{2f} \xrightarrow[CH_3COCl]{} CH_3COOPh + FeCl_2(bpy) \qquad (3)$$
$$\mathbf{2f} \xrightarrow[CH_3I]{} CH_3OPh + FeI_2(bpy)$$

Other bis(*p*-substituted phenoxo)- and bis(alkoxo)iron(II) analogs also gave corresponding organic acetates on reaction with acetyl chloride (Table 3).

Table 4 summarizes the results of the reactions of aryloxoiron(II) and alkoxoiron(II) complexes with various organic esters. *p*-Substituted phenyl acetates reacted with the phenoxoiron(II) complex, **2f**, to give phenyl acetate. Benzyl and ethyl acetates had no tendency to exchange with the phenoxo ligand under the same conditions. On the other hand, phenyl acetate underwent the exchange reaction with the benzyloxo, isopropoxo, and methoxoiron(II) complexes giving benzyl, isopropyl, and methyl acetates, respectively in good yields. The more electrophilic alkoxo ligand seems to have stronger affinity with iron(II). Hydrolysis of **2a**—**2g** with water gave corresponding *p*-substituted phenols.

A greenish grey bis(phenoxo)iron(II) complex, **2f**, is highly air sensitive and it turns red brown immediately on exposure to air at room temperature both in solution and in the solid state. Oxygen uptake by **2f** in solution was roughly half a mol per iron. The resultant red brown complex **2f′**, is almost insoluble in usual solvents and is paramagnetic with a μ_{eff} value of 4.3 B.M., suggesting a high spin Fe(III) species. IR spectrum of **2f′** is very close to that of **2f** indicating the existence of the intact phenoxo and bpy ligands in **2f′**. No absorption band attributable to ν(O–O) was detected, whereas most of the dioxygen complexes show the strong characteristic band at 800—900 cm^{-1}.[9] Therefore, the present complex **2f′** may be considered as a polymeric oxygen bridged complex having the bpy ligand. An oxygen bridged iron(II) complex has been reported by Teyssie *et al.*[10]

Although thermal decomposition of metal alkoxides usually affords exclusively disproportionation products of the alkoxo ligands,[1] alcohols and aldehydes, thermolysis of **2h**—**2k** in the solid state gave unusual products besides the disproportionation products as shown in Table 5.

$$\underset{\mathbf{2h}}{Fe(OCH_2C_6H_5)_2bpy} \longrightarrow C_6H_5CH_2CH_2C_6H_5 + C_6H_5CH_3 + C_6H_5CHO + C_6H_5CH_2OH + H_2 \qquad (4)$$

$$\underset{\mathbf{2j}}{Fe(OC_3H_7{}^i)_2(bpy)} \longrightarrow C_3H_6 + CH_3COCH_3 + iso\text{-}C_3H_7OH + H_2 \qquad (5)$$

$$\underset{\mathbf{2k}}{Fe(OCH_3)_2} \longrightarrow CH_4 + H_2 + etc. \qquad (6)$$

Formation of bibenzyl and toluene from **2h** indicates the involvement of the C–O bond cleavage on thermolysis, whereas benzaldehyde and benzyl alcohol were obtained by the usual disproportionation reaction of the alkoxo ligands. Thermolysis of **2j** gave propylene in addition to the disproportionation products, also suggesting a similar decomposition pathway. Compound **2k** mainly gave methane on thermolysis. The present unusual C–O bond fission may have arisen from the great affinity of iron metal with oxygen. Formation of an alkyl radical by the C–O bond cleavage probably accounts for the pyrolysis products. Analogous C–O bond breakage in a transition metal alkoxo compound is known.[11] On the other hand, thermolysis of **2i** and **2f** afforded ethanol and phenol as a major product respectively, although the hydrogen source is not clear.

Catalytic Reactions Promoted by Alkoxoiron(II) Complexes. The phenoxo complex **2f** was found to catalyze the trans-esterification. Isopropenyl acetate and benzyl alcohol were converted into benzyl acetate and acetone in a 73% yield in the presence of **2f** at room temperature.

$$CH_3CO_2C(CH_3)=CH_2 + C_6H_5CH_2OH \xrightarrow[\mathbf{2f}]{} CH_3CO_2CH_2C_6H_5 + (CH_3)_2CO \qquad (7)$$

In the trans-esterification reaction isopropene-2-ol may

Table 5. Thermal decomposition of alkoxoiron(II) complexes in solid state[a)]

Complex		Dp/°C	Product (mol/Fe)
$Fe(OCH_2C_6H_5)_2(bpy)$	**2h**	210—220	H_2(0.05), $C_6H_5CH_3$(0.30), C_6H_5CHO(0.52), $C_6H_5CH_2OH$(0.23), $C_6H_5CH_2CH_2C_6H_5$(0.20)
$Fe(OC_2H_5)_2(bpy)$	**2i**	170	H_2(0.03), C_2H_5OH(0.87)
$Fe(OC_3H_7^i)_2(bpy)$	**2j**	185	H_2(trace), C_3H_6(0.28), i-C_3H_7OH(0.24), $(CH_3)_2CO$(0.04)
$Fe(OCH_3)_2$	**2k**	200—220	H_2(0.10), CH_4(0.50), C_2H_6(trace)

a) The compounds were heated up to 220 °C.

be first formed and transformed to its tautomer, acetone. Methyl methacrylate and ethanol also gave ethyl methacrylate and methanol in a 38% yield in the presence of **2f**.

$$CH_2{=}C(CH_3)CO_2CH_3 + C_2H_5OH \xrightarrow[\mathbf{2f}]{} CH_2{=}C(CH_3)CO_2C_2H_5 + CH_3OH \quad (8)$$

The phenoxoiron(II) catalyst used was unchanged after the reaction as revealed by IR analysis, suggesting the phenoxo ligand in **2f** is not involved in the catalytic trans-esterification. A similar type of trans-esterification using Cu phenoxide[12] has been reported and a mechanism involving metal assisted nucleophilic replacement was postulated.

Non-transition metal alkoxides, especially aluminum isopropoxide, are known to catalyze Tishchenko reaction.[1] Among the iron alkoxides prepared in the present study dibenzyloxo(2,2'-bipyridine)iron complex **2h** was found to be most effective for the Tishchenko reaction, converting benzaldehyde into benzyl benzoate.

$$C_6H_5CHO \xrightarrow[80\,°C,\ 6\,h]{\mathbf{2h}} C_6H_5COOCH_2C_6H_5\ (63\,\%) \quad (9)$$

Recently a few transition metal complexes of Ru(II),[13] Fe(II),[14] and Mn(II)[15] have been reported to serve as catalysts for the dimerization of aldehyde, and formation of alkoxo-transition metal intermediates has been postulated.

Kinetic Study of the Formation of ***2f***. The rate of the formation of complex **2f** by the reaction of **1** with excess of phenol in THF was studied by following the change in the visible spectrum of the reaction mixture *in vacuo*. The decrease in the absorbance of a band at 590 nm which is known to be a CT band of **1**,[16] was used to estimate the rate of disappearance of **1**. Plot of $\log(A_t - A_\infty)$ against time gave a linear relationship indicating a first-order dependence of the rate on the concentration of **1**.

$$\frac{d}{dt}[\mathbf{2f}] = -\frac{d}{dt}[Fe(C_2H_5)_2(bpy)_2] = k[Fe(C_2H_5)_2(bpy)_2] \quad (10)$$

Figure 1 shows the dependence of the pseudo-first-order rate constant k on the phenol concentration. It is seen that the rate increase with the increase in the phenol concentration is leveled off at higher concentration of phenol and addition of the bpy ligand shows a marked effect to retard the rate of decomposition

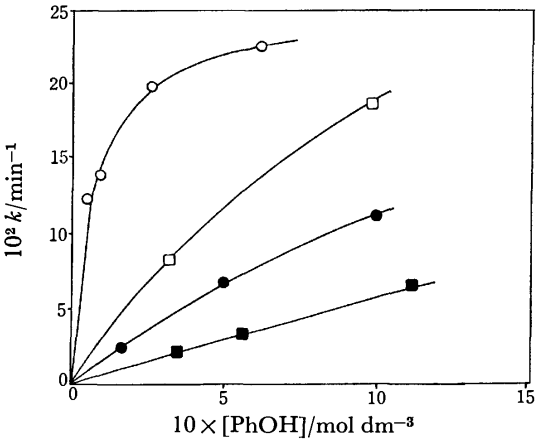

Fig. 1. Effect of [PhOH] on the first order rate constant k in various bpy concentrations for the reaction of **1** with phenol in THF at 23.2 °C. [bpy]=0 mol/dm³, ○; 0.90×10^{-3} mol/dm³, □; 2.71×10^{-3} mol/dm³, ●; 9.02×10^{-3} mol/dm³, ■.

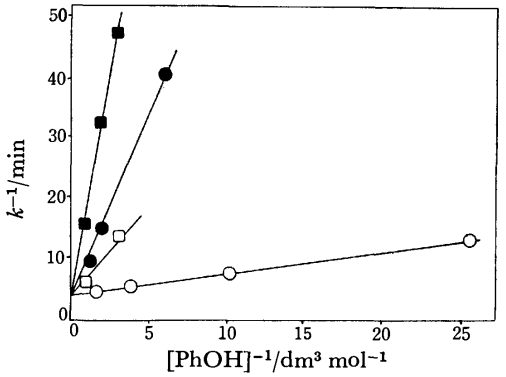

Fig. 2. Plot of the reciprocal of k *vs.* the reciprocal of [PhOH] in Fig. 1.

of **1**. The both reciprocal plots of k and phenol concentration at various bpy concentration shown in Fig. 2 gives straight lines. The effect of variation of the added bpy concentration on the slopes in Fig. 2 is shown in Fig. 3. These experimental results can be summarized by the following equation;

$$\frac{1}{k} = A + \frac{B + C[\mathrm{bpy}]}{[C_6H_5OH]} \quad (11)$$

where A, B, and C represent constants. A similar kinetic behavior has been previously observed by Yamamoto *et al.*[16] in the reaction of **1** with olefins. The present kinetic behavior can be explained by

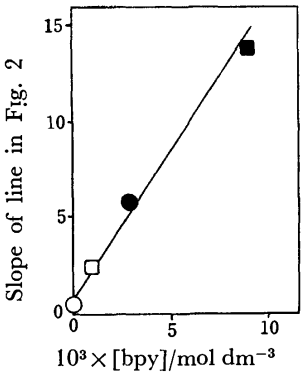

Fig. 3. Plot of the slope of line in Fig. 2 against [bpy].

assuming the following reaction mechanism.

$$\mathrm{Fe(C_2H_5)_2(bpy)_2} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\mathbf{3}}{\mathrm{Fe(C_2H_5)_2(bpy)(bpy)^*}} \quad (12)$$
$$\mathbf{1}$$

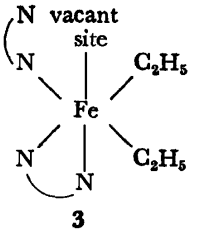
$$\mathbf{3} + \mathrm{C_6H_5OH} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{\mathbf{4}}{\mathrm{Fe(C_2H_5)_2(bpy)(bpy)^*(C_6H_5OH)}} \quad (13)$$

$$\mathbf{4} \xrightarrow[-\mathrm{C_2H_6}]{k_3} \xrightarrow[+\mathrm{C_6H_5OH}\ -\mathrm{C_2H_6}]{\text{fast}} \underset{\mathbf{2f}}{\mathrm{Fe(OC_6H_5)_2(bpy)}} \quad (14)$$

$$\mathbf{3} + \mathrm{bpy} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \underset{\mathbf{5}}{\mathrm{Fe(C_2H_5)_2(bpy)(bpy)_2^*}} \xrightarrow{k_5} \mathbf{1} \quad (15)$$

(bpy)*: partially dissociated bpy ligand

A partial dissociation of bpy from **1** takes place to give coordinatively unsaturated species **3** which presumably has a structure as shown below:



3

where $\widehat{\mathrm{N\ N}}$ represents the bpy ligand. Phenol then coordinates at the vacant site in **3** affording **4**. Activation of the Fe–Et bond by coordination of phenol leads to splitting of the ethyl group to give ethane as the rate-determining irreversible process. Further rapid reaction of phenol may follow to give **2f**. A competitive coordination of phenol and bpy toward **3** should be considered; Eq. 15 accounting for the inhibition effect of bpy on the reaction.

Since the starting material **1** and the final product **2f** are the only species observable during the reaction (actually 1:1 reaction mixture of **1** and phenol gave a 1:1 mixture of **1** and **2f**, indicating the absence of isolable reaction intermediates), the concentration of **3**, **4**, and **5** are considered to be negligible. Therefore by applying the steady state approximation for these species the following rate equation is derived.

$$\text{Rate} = -\frac{\mathrm{d}}{\mathrm{d}t}[\mathbf{1}] = k[\mathbf{1}]$$

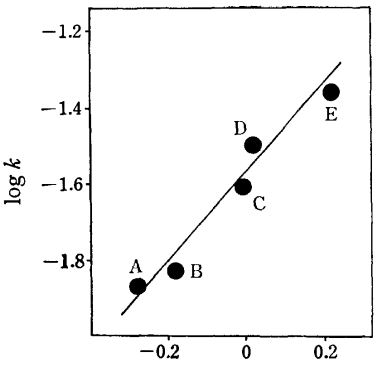


Fig. 4. Relation between log k in THF at 23.2 °C and Hammett substituent constant. $[\mathrm{XC_6H_4OH}] = 1.66 \times 10^{-1}$ mol/dm^3; A, X=CH_3O; B, X=CH_3; C, X=H; D, X=C_6H_5; E, X=Cl. $[\mathrm{bpy}] = 2.71 \times 10^{-3}$ mol/dm^3. Under these conditions, k increases with increasing the phenol concentration and does not level off.

$$k = \frac{k_1k_2k_3[\mathrm{C_6H_5OH}]}{k_{-1}(k_{-2}+k_3)+k_2k_3[\mathrm{C_6H_5OH}]+\dfrac{\bar{k}_4k_5(k_{-2}+k_3)[\mathrm{bpy}]}{k_{-4}+k_5}} \quad (16)$$

When k_{-2} is much greater than k_3, the observed pseudo-first-order rate constant k is given by

$$\frac{1}{k} = \frac{1}{k_1} + \frac{k_{-1}k_{-2}+\bar{k}[\mathrm{bpy}]}{k_1k_2k_3[\mathrm{C_6H_5OH}]} \quad (17)$$

$$\bar{k} = \frac{k_4k_5k_{-2}}{k_{-4}+k_5}$$

The experimental results expressed by Eq. 11 is in agreement with Eq. 17 supporting the validity of assumptions as expressed by Eqs. 12—15. Thus from constants A, B, and C in Eq. 11 rate constants and their ratios $1/k_1$, $k_{-1}k_{-2}/k_1k_2k_3$, and $\bar{k}/k_1k_2k_3$ may be obtained. The $1/k_1$ value of 4.0 min obtained from the intercept in Fig. 2 roughly agrees with the value observed in the reaction of **1** with olefins.[16] The agreement may be taken as additional support for that the similar reaction mechanism involving the partial dissociation of bpy ligand from **1** is operative in the reactions of **1** with phenols and with olefins.

The rates of the reactions of **1** with various *p*-substituted phenols were examined under the same conditions. The relation between log k and Hammett substituent constant σ[18] of X is demostrated in Fig. 4 ($\rho = +1.17$). More electron-withdrawing substituent facilitates the reaction, indicating electrophilic attack of phenols to **1**.

The pseudo-first-order rate constant k was estimated in various solvents such as acetone, THF, and toluene, having dielectric constants of 20.7, 7.6, and 2.4.[18] Figure 5 shows the results under various phenol concentrations. The fact that all the $1/k$ values lie on the same line as plotted *vs.* phenol concentration indicates the absence of solvent effect on the rate. This result suggests that non-polar active intermediate is involved in the rate determining step.[19]

Two types of interactions of iron(II) complex with phenol for **4** such as (A) and (B) are plausible.

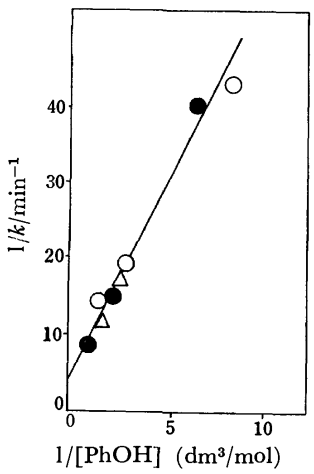

Fig. 5. Plot of the reciprocal of k *vs.* the reciprocal of [PhOH] at 23.2 °C in various solvents. Acetone, ○; THF, ●; toluene, △.

In the usual electrophilic cleavage of metal alkyls by acids, the three centered intermediate (B) has been suggested.[20] However, the intermediate (B) is not reasonable in the present reaction of **1** with phenols. The nucleophilic participation by $OC_6H_5^-$ to give four centered intermediate (A) is preferred by the following reasons, although the substituent effect of the phenols on the reaction rate suggests electrophilic attack of phenols at the ethyl ligand bonded to iron(II). Firstly, the absence of solvent effect agrees with the non-polar four centered intermediate rather than the ionic one (B). Secondly, the kinetic behavior of the present reaction is quite similar to that found in the reaction of **1** with olefin, in which facile Fe–C bond activation by the coordination of electron-defficient olefin to iron(II) has been reported.[17] On the other hand, however, the possibility of oxidative addition of phenol to Fe(II) giving Fe(IV) species in **4** followed by the reductive elimination of alkane can not be excluded.[21]

Experimental

All the procedures were carried out under nitrogen or *in vacuo*. The nitrogen gas used was deoxygenated by passing through a trap cooled to −196 °C in order to avoid the contamination by a trace of oxygen. Solvents were purified by usual manners under nitrogen and were stored under nitrogen or argon. $Fe(C_2H_5)_2(bpy)_2$ was prepared by the method previously reported.[5] Phenols and esters were commercial products and used without further purification. Alkyl and acyl halides were used after simple distillation of commercial products. IR and visible spectra were recorded on a Hitachi 295 infrared spectrometer and a Hitachi Type 200 spectrometer, respectively. ^1H NMR spectra were measured on a JEOL PS-100 spectrometer by Mr. Y. Nakamura. Micro analyses of C, H, N, and Cl were performed by using Yanagimoto CHN Corder Type MT-2 by Mr. T. Saito in our laboratory. Magnetic susceptibility was measured with Shimadzu Magnetic Balance Type MB-100. Gases were analysed by gas chromatography after collecting the gases evolved by a Toepler pump by which the gas volumes were measured. Amounts of the organic products were determined quantitatively by gas chromatography using suitable internal standards.

Preparation of the Bis(aryloxo)- and Bis(alkoxo)iron(II) Complexes and Their Reactions with H_2O and O_2. Phenol (497 mg, 5.3 mmol) was added to a THF (20 ml) solution of $Fe(C_2H_5)_2(bpy)_2$ (860 mg, 2.0 mmol) at −78 °C. After the evacuation of the reaction vessel, the mixtures was allowed to react at room temperature for 1 d. The color of the solution changed from deep purple to greenish grey and ethane (4.2 mmol) was detected in the gas phase. The solution was concentrated to *ca.* 10 ml and diethyl ether (30 ml) was added to give a greenish grey powder, which was washed with hexane and diethyl ether a few times and was dried *in vacuo*. (Yield 415 mg, 51%). The compounds **2a**, **2c**, **2d**, **2e**, **2g**, **2h**, **2i**, **2j**, and **2k** were prepared similarly. Elemental analyses, yields, and IR and ^1H NMR spectra of **2a**—**2g** are summarized in Tables 1 and 2, respectively. Micro analyses of **2h**—**2k** failed because of their extreme sensitivity toward oxygen. Results of thermolysis of **2h**—**2k** are listed in Table 5. Hydrolysis of **2f** (170 mg, 0.43 mmol) by distilled water (0.5 ml) in THF (6 ml) gave phenol (0.56 mmol) at 50 °C after 10 h. Hydrolysis of the other aryloxides, **2a**, **2b**, **2c**, **2d**, **2e**, and **2g** under similar conditions gave corresponding *p*-substituted phenols, the amount of respective phenols liberated being trace, 1.14, 0.85, 1.09, 1.18, 1.30, and 1.10 mol/complex. Dry air was introduced into the toluene suspension of complex **2e** (310 mg, 0.78 mmol) to give a brown heterogeneous solution. Oxygen absorbed (0.39 mmol) was measured by a gas burette. Resulted brown complex was filtered and dried *in vacuo* (100%). Found: C, 64.9; H, 4.6; N, 6.5%. Calcd for $C_{22}H_{18}N_2O_3Fe$: C, 63.8; H, 4.4; N, 6.8%. μ_{eff}=4.3 B.M. IR. ν(C–O)= 1260 cm^{-1}.

Preparation of $Fe(OC_6H_4CN\text{-}p)_2(bpy)_2$ (2b). The mixture of **2c** (440 mg) and bpy (320 mg) in dry toluene (10 ml) was heated to 100 °C to give a dark red homogeneous solution. After the filtration of this hot solution, it was kept in dry-ice temperature to deposit slowly dark red crystals. The resulted red crystals were filtered off, washed with diethyl ether containing free bpy and dried *in vacuo*.

Reactions of Bis(aryloxo)iron(II) Complexes with Organic Halides. Complex **2e** (41 mg, 0.10 mmol) in THF was treated with CH_3COCl (100 μl, 1.4 mmol) to cause immediate color change from greenish grey to dark red. After 1 d phenyl acetate (0.15 mmol) was detected in the solution. The red compound was obtained by removing all the volatile matter and was identified as $FeCl_2(bpy)$ by comparing its IR spectrum with that of an authentic sample which was prepared by **1** and HCl. (Yield 10 mg, 25%) Found: C, 42.5; H, 2.0; N, 10.0; Cl, 25.1%. Calcd: C, 43.2; H, 3.0; N, 10.1; Cl, 24.1%. Other reactions of various bis(aryloxo)iron(II) complexes with $PhCH_2Br$, CH_3I, and CH_3COCl were performed similarly and the results are summarized in Table 3.

Reaction of the Bis(aryloxo)iron(II) Complexes with p-Nitrophenyl Acetate. Complex **2f** (210 mg, 0.50 mmol) in THF (10 ml) was treated with *p*-nitrophenyl acetate (350 mg, 1.9 mmol) to give a dark red heterogeneous solution. After 5 h at room temperature phenyl acetate (0.83 mmol) was found in the solution by gas chromatography. The reactions of iron phenoxides and alkoxides with other organic acetates were carried out analogously and the results are shown in Table 4.

Catalytic Trans-esterification. Isopropenyl acetate (1 ml)

was mixed with benzyl alcohol (1 ml) in the presence of **2f** (90 mg, 0.23 mmol) to give immediately a red purple solution. After 2 d at room temperature acetone (6.6 mmol) and benzyl acetate (6.6 mmol) were detected in solution. (73% based on isopropenyl acetate). IR spectrum of the catalyst recovered was identical with that of **2f**. Transesterification of methyl methacrylate (3 ml) and ethanol (3 ml) in the presence of **2f** (110 mg, 0.28 mmol) also gave ethyl methacrylate (11.2 mmol) and methanol (11.2 mmol) in 1 d at room temperature (38% based on methyl methacrylate).

Tishchenko Type Reaction of Benzaldehyde Promoted by ***2h***. Benzaldehyde (5 ml, 50 mmol) was heated to 80 °C for 6 h in the presence of **2h** (120 mg) to afford a homogeneous blue solution. Benzyl benzoate (16 mmol, 63%) was found in the liquid phase by gas chromatography.

Kinetics. The rate of the formation of **2f** from **1** and phenol in THF was estimated by following the disappearence of the visible spectrum of **1** at 590 nm under vacuum. The pseudo-first order rate constants obtained by measuring the change at various wave lengths gave the same values. The solvent for spectroscopic measurements was dried over benzophenone ketyl and was introduced by a trap-to-trap distillation into the reaction mixture containing **1** and phenol.

Reactions of CO_2 with Cu(I) Alkoxides and Amides to Give Alkylcarbonato-, μ-Carbonato-, Hydrogencarbonato-, and Carbamato-copper Complexes

Takakazu YAMAMOTO, Minoru KUBOTA, and Akio YAMAMOTO*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received September 13, 1979)

Carbon dioxide reacts with $ROCu(PPh_3)_2$ ($R=C_2H_5$, $C_6H_5CH_2$; PPh_3=triphenylphosphine) to produce $ROCO_2Cu(PPh_3)_2$. Hydrolysis or thermolysis of the alkylcarbonatocopper(I) complexes gives a binuclear carbonatocopper(I) complex $(PPh_3)_2CuOCO_2Cu(PPh_3)_2$, which is further converted into a hydrogencarbonatocopper(I) complex $[HOCO_2Cu(PPh_3)_2]_n$ by the reaction with CO_2 in moist solvents. The IR spectrum of $[HOCO_2Cu(PPh_3)_2]_n$ shows association of the $HOCO_2Cu(PPh_3)_2$ units through hydrogen bonds. The IR spectrum of $[HOCO_2Cu(PPh_3)_2]_n$ also reveals that the mode of the association depends on conditions of the crystallization of the complex. The reaction of $(PPh_3)_2CuOCO_2Cu(PPh_3)_2$ with CH_3I gives $(CH_3O)_2CO$ and the reaction of $[HOCO_2Cu(PPh_3)_2]_n$ with $C_6H_5NH_2$ affords $C_6H_5NHCO_2Cu(PPh_3)_2$ in high yields. Carbon dioxide reacts also with an amidocopper(I) complex $C_6H_5NHCu(PPh_3)_2$ to yield a carbamatocopper(I) complex $C_6H_5NHCO_2Cu(PPh_3)_2$. The reaction of $CH_3Cu(PPh_3)_2$(diethyl ether)$_{0.5}$ with CO_2 in the presence of $HN(C_2H_5)_2$ affords $(C_2H_5)_2NHCO_2Cu(PPh_3)_2$. The isocyanate group of phenyl isocyanate is inserted into the C_2H_5O–Cu bond of $C_2H_5OCu(PPh_3)_2$ to give a (ethyl *N*-phenylcarbamato)copper complex.

Considerable attention has been focused on the reactions of carbon dioxide with transition metal complexes from the interest of utilizing carbon dioxide for organic syntheses promoted by transition metal complexes.[1-6] Carbon dioxide has been reported to be inserted into metal–carbon,[1d,7-13] –hydride,[1d,14-16] –alkoxide,[17] –hydroxide,[18] and –amide[19] bonds to form carboxylato, alkylcarbonato, hydrogencarbonato, and carbamato complexes.

As a part of our program of studies on the reactivity of copper(I) complexes having Cu–C,[20] Cu–N,[21] Cu–O[22] or Cu–S[11] bonds we have studied[23] also the reaction of CO_2 with $ROCu(PPh_3)_2$ ($R=C_2H_5$, $CH_2C_6H_5$) and expanded the work to investigate the chemical properties of the produced alkylcarbonatocopper(I) complex. The result was compared with the reaction of CO_2 with copper(I) amides and with the reaction of phenyl isocyanate, an isoelectronic compound of CO_2, with a copper ethoxide.

Results and Discussion

Reactions of CO_2 with Alkoxocopper(I) Complexes. Reactions of carbon dioxide with alkoxocopper(I) complexes containing triphenylphosphine are summarized in Scheme 1.

Reactions of $C_2H_5OCu(PPh_3)_2$(**1a**)[22a] and $C_6H_5CH_2OCu(PPh_3)_2$(diethyl ether)(**1b**)[22a] with CO_2 at atmospheric pressure and at low temperatures afforded $C_2H_5OCO_2Cu(PPh_3)_2$(**2a**) and $C_6H_5CH_2OCO_2Cu(PPh_3)_2$ (**2b**) (Reaction 1). Very recently a similar reaction of CO_2 with copper(I) *t*-butoxide, *t*-C_4H_9OCu, in the presence of ligands was reported.[17a] Analytical data of **2a** and **2b** (Table 1) agree with the compositions for the alkylcarbonato copper having two PPh_3 ligands. The color and diamagnetism of **2a** and **2b** indicate that the oxidation state of copper is one. Table 2 summarizes the IR absorption bands of the alkylcarbonatocopper(I) and related complexes. Complexes **2a** and **2b** show strong ν(C=O) and ν(C–O) bands at 1660 cm^{-1} and in the region of 1380—1280 cm^{-1}, respectively, and $\pi(CO_3)$ near 800 cm^{-1}.[24] The IR pattern is consistent with the molecular formula and can be compared with those of alkylcarbonatomagnesiums, *t*-butylcarbonatocopper(I),[17a] bis(methylcarbonato)copper(II),[17b] and methyl(methylcarbonato)palladium[25] complexes. The appearance of the ν(C=O) band at a relatively high frequency suggests the coordination of the $ROCO_2$ ligand through one oxygen as represented by Form I.

a) Solvent: C_6D_6 for **2a**, **2b**, and **7**; CD_2Cl_2 for **3** and **5**; toluene-d_8 for **6**.

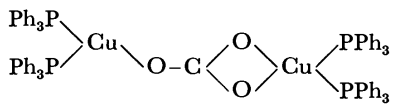
However, the coordinating mode of the alkylcarbonato ligand to Cu changes depending on delicate conditions of crystallization. For example, addition of hexane to a diethyl ether–ethyl alcohol (1:1) solution of **2a** gives complex **2a'** with the same composition as **2a** but with the different IR spectrum of **2a'** showing the ν(C=O) bands at considerably lower frequency, 1600 cm^{-1}. The lowering of ν(C=O) band suggests that the $C_2H_5OCO_2$ ligand in **2a'** coordinates to Cu through two oxygens as represented by Form II or the C–O oxygen has intermolecular interaction with Cu to form a polymeric compound in the solid state. Complex **2a'** can be reverted to **2a** by crystallization of **2a'** from toluene–ether. Cryoscopic molecular weight determination of **2a** and **2b** in dioxane (Table 2) reveals that they exist as monomers in the solutions. The somewhat lower observed values than the calculated molecular weights suggest partial dissociation of PPh_3 from the complexes. The reaction of ethyl bromide with **2a** affords diethyl carbonate in 10% yield. Although the formation of the alkylcarbonato complexes can be formally explained as insertion of CO_2 into the RO–Cu bond, the possibility of an indirect route as shown below promoted by intervention of a small amount of water cannot be ruled out.

$$ROCuL_2 + H_2O \rightarrow HOCuL_2 + ROH \quad (12)$$

$$ROH + CO_2 \rightleftharpoons ROCO_2H \quad (13)$$

$$ROCO_2H + HOCuL_2 \rightarrow ROCO_2CuL_2 + H_2O \quad (14)$$

Hydrolysis of **2a** or **2b** yields a μ-carbonatocopper(I) complex formulated as $(PPh_3)_2CuOCO_2Cu(PPh_3)_2$ (Reaction 2). Heating of **2a** and **2b** at 110 °C and 122 °C respectively also gives the carbonato complex, CO_2, and ROH (Reaction 3), but the source of hydrogen for ROH and stoichiometry of Reaction 3 have not been clarified. Recently similar dinuclear complexes having μ-carbonato ligand coordinated through one and two oxygens to two transition metals have been reported.[26,27] Similarlity of the IR spectrum of **3**, showing carbonato bands at 1480, 1370, and at 835 cm^{-1}, with those of $Pd_2Me_2(CO_3)(PPh_3)_3$[26] and $Rh_2(CO_3)(PPh_3)_5$,[27] for which the singly and doubly O-bonded structures have been established, suggests an unsymmetric structure as shown below.



3

The IR spectrum of a symmetrical singly O-bonded μ-carbonatorhodium complex $Rh_2(CO)_2(CO_3)L_4$,[28] showing the carbonato bands at 1533, 1300, 1275, and 829 cm^{-1}, is somewhat different from those of the unsymmetrical carbonato complexes. The presence of two PPh_3 per Cu in **3** has been confirmed not only by elemental analysis but also by an NMR technique using acetone as a reference. Cryoscopic molecular weight determination in dioxane demonstrates that **3** remains binuclear in the solvent, although the somewhat low observed value for **3** suggests a partial dissociation of PPh_3 from **3** in the solution. The carbonato complex **3** has a higher thermal stability than **2a**, **2b**, and a hydrogencarbonatocopper(I) complex $HOCO_2Cu(PPh_3)_2$ **4** (*vide infra*) and thermolysis at 162 °C liberates *ca.* 1 mol of CO_2 per **3**.

Although the postulated structure for **3** indicates the presence of two different $Cu(PPh_3)_2$ moieties, ^{31}P-NMR shows only one sharp peak at 1.62 ppm (half width=7 Hz) downfield from external PPh_3 even at −83 °C in toluene. Rapid intramolecular exchange of the CO_3 group between two CuL_2 moieties or rapid exchange of the coordinated PPh_3 with free PPh_3 partly liberated from **3** accounts for the ^{31}P-NMR data. The rapid exchange between the coordinated PPh_3 and free PPh_3 certainly takes place in the presence of PPh_3 added as the ^{31}P-NMR spectrum of a mixture of **3** and PPh_3 (1:4 molar ratio) shows only one relatively broad signal at 1.16 ppm (half width=38 Hz) downfield from external PPh_3 at −63 °C. The reaction of **3** with CH_3I affords dimethyl carbonate in 82% yield (Reaction 4).

The reaction of **3** with H_2O in the presence of CO_2 in *N,N*-dimethylformamide (DMF) yields a hydrogencarbonatocopper(I) complex **4** (Reaction 5). Since **2a** and **2b** are converted into **3** (Eq. 2) by the hydrolysis and **3** is converted into **4** (Eq. 5) on standing them in solutions containing H_2O and CO_2, prolonged reaction of the alkoxocopper(I) complexes, **1a** and **1b**, with CO_2 in moist solvents is expected to yield directly the final product **4** through the serial Reactions 1, 2, and 5. This actually occurs in the reaction of **1a** with CO_2.

Similar reactions of a phenoxocopper(I) complex $PhOCu(PPh_3)_2$ **1c** with CO_2 in moist solvents also affords the hydrogencarbonatocopper(I) complex directly (Reaction 7a), but the IR spectrum of the complex varies depending on the preparative conditions and it was revealed that there are three types of complexes **4**, **4'**, and **4''** with the same composition $HOCO_2Cu(PPh_3)_2$.

$C_6H_5OCu(PPh_3)_2 + CO_2$ in moist THF

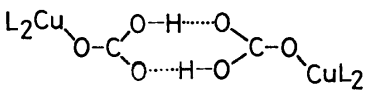
1c → **4** (7a) [−10—0 °C]

→ **4'** (7b)

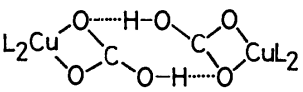
→ **4''** (7c) [−10—0 °C, $+10C_6H_5OH$; −30 °C]

In the case of the reaction of **1c** attempts for the isolation of the complexes of type **2** and **3** were not successful even by using solvents dried over Na, presumably due to the high reactivities of **2** and **3** with water under the preparative conditions by using **1c** as the starting material and to the difficulty to remove a trace of water from the solvents and CO_2 gas employed.

The IR absorption bands in the region of 2600 cm^{-1} ascribable to the bridging ν(O–H···O) band observed in the three hydrogencarbonato complexes **4**, **4'**, and **4''** suggest the presence of associated species for these complexes. There are at least two ways of association as depicted below, which have been established by X-ray crystallography for $[PdR(OCO_2H)L_2]_2$[29,30] and $[RhH_2(OCO_2H)L_2]_2$.[28]

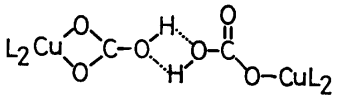


Form A[29]



Form B[28]

Other modes of association as illustrated below may be also possible.



Form C

Assignment of the hydrogencarbonato complexes **4**, **4'**, and **4''** to the respective associated forms is not possible solely on the basis of the IR spectra, but the complex **4'** showing the high ν(C=O) band at 1640 cm^{-1} may be related to a species having non-interacting C=O group such as that represented by Form C. On deuteriation of **4** by treating with D_2O (Reaction 8), the ν(O–H···O) bands at 2670 and 2600 cm^{-1} are shifted to 2100 and 2040 cm^{-1}, while a δ(OHO) band hidden under absorption bands of PPh_3 in a region of 1400—1500 cm^{-1} appears at 1060 cm^{-1} and a coupled vibration ν(C–O)+ν(C=O)+δ-(OHO) at 1325 cm^{-1} is shifted up to 1365 cm^{-1}. These trends are consistent with those observed for $[Rh(CO)(O_2COH)L_2]_2$[28] and hydrogencarbonato dimer anion.[31]

Formation of the hydrogencarbonato complexes **4**, **4'**, and **4''** depends on slight differences in experimental conditions. Complex **4'** or **4''** in a moist DMF solution can be converted into **4** by addition of a 1:1 mixture of hexane and diethyl ether to crystallize out **4** (Reaction 9). The existence of the hydrogencarbonatocopper(I) complexes **4'** and **4''** predominantly as a monomer in solution is demonstrated by the cryoscopic molecular weight determination of **4'** and **4''** as well as by the IR spectrum of **4''** in $CHCl_3$. The ν(O–H···O) band of **4''** at 2600 cm^{-1} disappears whereas new bands at 3300 cm^{-1} (ν(O–H)) and 1660 cm^{-1} (ν(C=O)) emerge on dissolving in $CHCl_3$, indicating that the hydrogen bond is cleaved in the solution.

$$[HOCO_2Cu(PPh_3)_2]_n \xrightarrow{\text{organic solvent}} n\,H\text{-}O\text{-}\overset{\overset{O}{\|}}{C}\text{-}O\text{-}Cu(PPh_3)_2 \quad (15)$$

Complexes **4**, **4'**, and **4''** can be also obtained in the reactions of CO_2 with various organocopper(I) complexes such as cyanoethyl-,[32] nitroalkyl-,[32] and methylcopper(I)[20] complexes. Although it was previously reported that the reaction of the methylcopper-(I) complex $CH_3Cu(PPh_3)_2$(diethyl ether)$_{0.5}$ with CO_2 afforded $CH_3COOCu(CO_2)(PPh_3)_2$, whose characterization was based on the liberation of CH_3COOH and CO_2 upon acidolysis,[11] it has been later found that the product of the reaction was a mixture of $CH_3COOCu(PPh_3)_2$, **4'**, and **4''**. Heating of **4** at *ca.* 100 °C for 1.5 h yields the carbonato complex **3** (Reaction 6). The reaction of **4** with aniline affords a phenylcarbamatocopper(I) complex **5** in 79% yield (Reaction 10). The analytical data of **5** (Table 1) roughly agree with the formulation and the appearance of the ν(C=O) band at a relatively low frequency (Table 2) suggests the coordination of the carbamato ligand to copper through two oxygens. It is reported that the ν(C=O) absorption appears in a region of 1636—1680 cm^{-1} when a carbamato ligand coordinates to transition metal through one oxygen whereas the carbamato ligand coordinated through two oxygen gives rise to the ν(C=O) at lower frequencies.[19a]

Complex **5** may be formed through the condensation reaction between $C_6H_5NH_2$ and $HOCO_2$ ligand of **4** (Eq. 16) or through the formation of a phenylcarbamic acid by the reaction of $C_6H_5NH_2$ and CO_2 partly liberated from **4** (Eqs. 17a—17c).

$$C_6H_5\overset{H}{N}\text{-}H + HO\text{-}CO_2CuL_2 \longrightarrow C_6H_5NHCO_2CuL_2 + H_2O \quad (16)$$

4 **5**

$$\mathbf{4} \rightleftharpoons \underset{A}{HOCu(PPh_3)_2} + CO_2 \quad (17a)$$

$$\text{or} \quad \left.\begin{array}{l} C_6H_5NH_2 + CO_2 \rightleftharpoons C_6H_5NHCOOH, \\ 2C_6H_5NH_2 + CO_2 \rightleftharpoons C_6H_5NH_3{}^+C_6H_5NHCO_2{}^- \end{array}\right\} \quad (17b)$$

$$\text{or} \quad \left.\begin{array}{l} C_6H_5NHCOOH + A \rightleftharpoons \mathbf{5} + H_2O \\ C_6H_5NH_3{}^+C_6H_5NHCO_2{}^- + A \\ \qquad \rightarrow \mathbf{5} + C_6H_5NH_2 + H_2O \end{array}\right\} \quad (17c)$$

Equilibria of type 17b are known[33] and formation of carbamic acid has been proposed as the key step in an amine catalyzed exchange reaction between CO_2 and transition metal carbamates.[19b] Complex **5** affords a small amount (5 mol % per **5**) of ethyl phenylcarbamate by the reaction with C_2H_5I.

Reactions of Amidocopper(I) Complexes with CO_2. The reaction of phenylamidocopper(I) complex C_6H_5-$NHCu(PPh_3)_2$[21] with CO_2 gives the phenylcarbamatocopper(I) complex **5**. (Reaction 11). Reaction 11 may proceed through direct insertion of CO_2 into the Cu–N bond or an indirect route involving partial liberation of $C_6H_5NH_2$ from $C_6H_5NHCu(PPh_3)_2$ by the reaction with a trace of H_2O (Eq. 18) and formation of the carbamic acid (Eq. 17b).

$$C_6H_5NHCu(PPh_3)_2 + H_2O \rightleftharpoons HOCu(PPh_3)_2 + C_6H_5NH \quad (18)$$

$$C_6H_5NH_2 + CO_2 \rightleftharpoons C_6H_5NHCOOH \quad (17b)$$

$$HOCu(PPh_3)_2 + C_6H_5NHCOOH \rightarrow \mathbf{5} + H_2O \quad (19)$$

The formation of a carbamatocopper complex through the equilibrium of type 17b seems to occur in the reaction of $CH_3Cu(PPh_3)_2$(diethyl ether)$_{0.5}$ with diethylamine and CO_2.

$$CH_3Cu(PPh_3)_2(\text{diethyl ether})_{0.5} + (C_2H_5)_2NH + CO_2 \rightarrow \underset{\mathbf{6}}{(C_2H_5)_2NCOOCu(PPh_3)_2} \quad (20)$$

Although the interaction of the methylcopper complexes with N–H compounds generally affords amidocopper(I) complexes such as $C_6H_5NHCu(PPh_3)_2$ with

liberation of CH_4, the interaction of the methylcopper complex with diethylamine does not lead to the corresponding amidocopper(I) complex due to the too weak acidity of the hydrogen in $(C_2H_5)_2NH$.[21] Therefore the formation of **6** by Reaction 20 is considered to proceed most probably through the formation of diethylcarbamic acid which has acidic hydrogen. Similar behavior of methylpalladium complexes has been observed in the reactions with amines and CO_2.[26] The analytical data and IR and NMR spectral data of **6** agree with the formulation for **6**. Formation of methyl diethylcarbamate by the reaction of **6** with CH_3I in 58% yield also supports the formation of the carbamatocopper(I) complex.

Reactions of $CH_3Cu(PPh_3)_2$(diethyl ether)$_{0.5}$ with NH_3 and $C_6H_5NHNH_2$ under the bubbling of CO_2 also afford white copper complexes whose IR spectra show the formation of similar carbamatocopper(I) complexes. However, full characterization of the complexes were not successful due to the instability of complexes. The reaction of C_2H_5Br with the product of the reaction with NH_3 gives ethyl carbamate (20% based on copper).

$$CH_3Cu(PPh_3)_2(\text{diethyl ether})_{0.5} + NH_3 + CO_2 \rightarrow [NH_2COOCu(PPh_3)_2] \xrightarrow{C_2H_5Br} NH_2COOC_2H_5 \ (20\%) \quad (21)$$

It is reported that the reaction of $CuN(Si(CH_3)_3)_2$ with CO_2 affords copper(I) isocyanate.[34] However, no indication for the formation of copper(I) isocyanate complex was obtained in the reactions described above.

Insertion of Phenyl Isocyanate into the Cu–O Bond of ***1a***. Since phenyl isocyanate can be regarded as an isoelectronic compound of CO_2 and some examples of insertion of isocyanate into a metal–oxygen bond are known,[35] a reaction of phenyl isocyanate with the ethoxocopper(I) complex **1a** was examined to find out that **1a** undergoes a ready insertion of the isocyanate into the Cu–O at −10 to 0 °C to afford (ethyl phenylcarbamato-*N*-)copper(I) complex **7**.

$$\mathbf{1a} + C_6H_5\text{-}N{=}C{=}O \rightarrow C_6H_5\text{-}\underset{\displaystyle Cu(PPh_3)_2}{\underset{|}{N}}\text{-}COOC_2H_5 \quad (22)$$

7

As for the direction of the insertion of the isocyanate group into the C–O bond, a reverse type of insertion to afford $C_6H_5N(OC_2H_5)COCu(PPh_3)_2$ is possible, although it is less likely in view of the probable polarization of the Cu–O bond as $Cu^{\delta+}$–$O^{\delta-}$.

Experimental

General Procedure and Material. Preparation and recrystallization of copper complexes were carried out under deoxygenated nitrogen or argon or under vacuum. Solvents were dried by usual methods, distilled, and stored under argon or nitrogen. IR spectra were recorded on a Hitachi Model 295 spectrometer. ^{1}H-NMR spectra were recorded on a Japan Electron Optics Lab. JNM-PS-100 spectrometer. TMS was used as the internal standard. ^{31}P-NMR spectra were obtained in the pulsed Fourier transform mode at 40.50 MHz. Identification of the evolved gas was made with a Hitachi RMU 5B mass-spectrometer and a Shimadzu GC-5B gas chromatograph, and the amount of gas was measured with a Toepler pump. The microanalysis of carbon, hydrogen, and nitrogen was performed by Mr. T. Saito in our laboratory with a Yanagimoto CHN Autocorder Type MT-2. The alkoxo and phenoxo copper complexes **1a**, **1b**, and **1c** were prepared as previously reported.[22a] Carbon dioxide was dried by passing through a cold trap cooled to −78 °C.

*Preparation of Ethylcarbonatobis(triphenylphosphine)copper(I) (**2a** and **2a′**).* The ethoxocopper(I) complex **1a** (630 mg, 1.0 mmol) was dissolved in a mixture of diethyl ether (5 ml) and ethyl alcohol (5 ml). The atmosphere in the reaction vessel was replaced with CO_2 (50 ml) at −40 °C. The mixture was stirred at −40——30 °C for 1 h to yield a transparent colorless solution. Concentration of the solution to about 5 ml by evaporation and addition of excess hexane gave a white precipitate. Recrystallization from toluene–diethyl ether yielded white crystals of **2a** (550 mg, 81%). Drying the white precipitate obtained from diethyl ether–ethyl alcohol–hexane in vacuum gave **2a′**.

*Preparation of Benzylcarbonatobis(triphenylphosphine)copper(I) (**2b**).* The benzyloxocopper(I) complex **1b** (1.3 g, 2.0 mmol) was dissolved in a mixture of diethyl ether (3 ml) and benzyl alcohol (2 ml). The gas in the reaction vessel was evacuated and then CO_2 (50 ml) was introduced at −30 °C. Stirring the mixture for 1 h at −30——20 °C afforded a transparent solution. Condensing the solution and addition of hexane (15 ml) gave a white precipitate. Recrystallization from diethyl ether–toluene containing a small amount of PPh_3 yielded 530 mg (yield=36%) of **2b**.

*Preparation of Tetrakis(triphenylphosphine)(μ-carbonato)dicopper-(I) (**3**).* The ethylcarbonatocopper(I) complex **2a** (250 mg, 0.37 mmol) was dissolved in 20 ml of THF. Water (14 mg, 0.75 mmol) was added to the solution and the solution was stirred for 0.5 h at room temperature to yield a white precipitate with liberation of C_2H_5OH (0.34 mmol) and CO_2 (0.17 mmol). Recrystallization from CH_2Cl_2–hexane gave **3** (150 mg, yield=88%).

*Preparation of Hydrogencarbonatobis(triphenylphosphine)copper(I) (**4**).* Complex **3** (310 mg, 0.25 mmol) was dissolved in 15 ml of DMF containing 0.5 ml of H_2O. The gas in the reaction vessel was evacuated and CO_2 (50 ml) was introduced at −30 °C. After stirring the solution for 2 h at −30 °C, an excess amount of diethyl ether was added and the solution was cooled to −70 °C to obtain a white precipitate, which was washed with diethyl ether repeatedly and dried in vacuum to yield 160 mg (yield=49%) of **4**. Deuteriation of **4** was performed by stirring a suspension of **4** in excess D_2O at room temperature.

*Preparation of Complex **4′**.* Immediately after addition of 0.5 ml of water into a THF solution (5 ml) containing $C_6H_5OCu(PPh_3)_2$ **1c** (0.34 g, 0.5 mmol) and C_6H_5OH (5 mmol), CO_2 gas was bubbled into the solution at −10 to 0 °C for 5 min to produce a white precipitate. The precipitate was washed repeatedly with diethyl ether and dried under vacuum to give a white complex of **4′** (272 mg, yield 84%).

*Preparation of Complex **4″**.* CO_2 gas was bubbled into a THF solution (5 ml) of a mixture of **1c** (340 mg, 0.5 mmol) and 0.5 ml of water at −30 °C for 5 min to produce a white precipitate, which was washed repeatedly with diethyl ether and dried in vacuum to yield 280 mg (yield=91%) of **4″**. Complexes **4**—**4″** were also prepared through the pathways described in the text.

*Preparation of Phenylcarbamatobis(triphenylphosphine)copper(I) (**5**).* The hydrogencarbonato complex **4** was dissolved in 10 ml of DMF containing 0.5 ml (5.5 mmol) of aniline. The mixture was stirred at −30 °C in an atmosphere of

CO_2. After 10 h diethyl ether and hexane were added to the solution and the mixture was cooled to −78 °C to produce a white solid, which was collected by filtration and dried in vacuum to yield 190 mg (yield=79%) of **5**.

Preparation of Diethylcarbamatobis(triphenylphosphine)copper(I) (6). Diethylamine (71 μl, 0.69 mmol) was added to $CH_3Cu(PPh_3)_2$ (diethyl ether)$_{0.5}$[20] suspended in 10 ml of diethyl ether. After evacuation of the gas in the reaction vessel, 100 ml of CO_2 was introduced at −20 °C and the mixture was stirred for 30 min at the temperature. The color of the solution turned from light yellow to white. Addition of hexane to the solution yielded 420 mg (yield=89%) of **6**.

Preparation of (Ethyl Phenylcarbamato-N-)bis(triphenylphosphine)-copper(I) (7). Phenyl isocyanate (2 mmol) was added into a flask containing **1a** (630 mg, 1 mmol) and the white emulsion was stirred at −10—0 °C for 5 h to produce a white precipitate. Recrystallization from diethyl ether–toluene gave white crystals of **7** (600 mg, yield=80%).

Thermolysis of the Complexes. A Schlenk type tube containing 260 mg (0.39 mmol) of **2a** was immersed in an oil bath and the temperature was raised gradually. The color of the complex was slightly changed from white to brown at 110 °C and evolution of CO_2 started at the temperature. Heating of the complex at 110 °C afforded 0.16 mmol of CO_2 (41 mol%/**2a**), 0.36 mmol of C_2H_5OH (92 mol%/**2a**), and 210 mg of a brownish solid, whose IR spectrum essentially coincided with that of **3** prepared by the acidolysis of **2a**. Heating of **2a** at higher temperature, 162 °C, caused further liberation of CO_2 (0.92 mol%/**2a**) coordinated to Cu. The other thermolyses of the complexes were carried out in similar manners and the amount of CO_2 evolved is given in Table 1.

Reactions of the Complexes with Alkyl Halides. Methyl iodide (5 ml) was added to a flask containing 640 mg (0.52 mmol) of **3** and the mixture was stirred overnight at room temperature. Gas chromatographic analysis of the reaction mixture showed the formation of 0.43 mmol (82 mol%/**3**) of dimethyl carbonate. The other reaction of the complexes with alkyl halides were carried out in similar manners.

Effect of pH and buffer concentrations on Brdička currents produced by horse heart cytochrome c was investigated in the presence of hexaamminecobalt(III) chloride in ammonia, tris(hydroxymethyl)aminomethane, *N,N*-dimethylglycine, borate, and carbonate buffer solutions at pH varying between 8.2 and 10.7. The Brdička current-activity of the protein varied with pH and the kind and concentration of buffers, but, if corrected for the effect of the buffer salts, showed a sigmoidal pH-dependence. The pH-dependence was interpreted as due to the protonic dissociation of Lys-79 of the protein. Brdička currents of the protein were observed also in unbuffered solutions containing no proton donor except water. The current intensity was explained by taking into account the change of pH at electrode surface. The results indicate that a main proton donor in the Brdička reaction is a water molecule.

Effect of the electrolyte pH and the kind and concentration of buffers on Brdička currents produced by SS- and/or SH-containing proteins has been studied extensively.[1-6] However, an understanding of the effect of these factors is far from complete. We have shown[7] that cytochrome c gives Brdička currents in ammoniacal buffers of pH 9.4 containing cobalt salts and that the heme group and its sixth ligand are important in determining the Brdička current-activity of the protein. Since the structure at heme moiety changes with pH,[8] it seems interesting to study the effect of pH on the Brdička current produced by cytochrome c. In this study we have investigated the pH effect on the Brdička current produced by horse heart cytochrome c in the presence of hexaamminecobalt(III) chloride in buffer solutions of various kinds at pH varying between 8.2 and 10.7 and shown that the pH-dependence of the Brdička current-activity can be interpreted as due to the protonic dissociation of Lys-79 of the protein. The results and discussion are presented in this paper. Importance of water molecule as a proton donor in the Brdička reaction is also described.

Experimental

Chemicals and Apparatus. Horse heart cytochrome c (cyt-c) was a product of Sigma Chemical Co. (Type IV, Lot No 78c-7040). The purity of the cyt-c was checked by SDS-disk electrophoresis. Stock solutions, usually 0.5% in cyt-c were stored at 5 °C. The concentrations were checked spectrophotometrically.[9] Other chemicals used were of a reagent grade quality. D.c. polarograms were recorded on a Yanagimoto P8 polarograph. The characteristics of the dropping mercury electrode (DME) were $m=1.60\ \mathrm{mg\ s^{-1}}$ and $\tau=6.3$ s at open circuit in ammoniacal buffer at 70 cm height of mercury reservoir.

Electrochemical Measurements. All measurements were made in an H-type cell immersed in a thermostat controlled at 25 °C. All potentials were measured against a saturated calomel electrode (SCE). Buffer solutions (0.06—0.30 M ammonium chloride–ammonia for pH 8.4—10.1, 0.06—0.25 M hydrogen chloride–tris(hydroxymethyl)aminomethane for pH 8.2—9.2, 0.06—0.24 M boric acid–potassium hydroxide for pH 9.1—9.4, 0.05—0.20 M *N,N*-dimethylglycine–potassium hydroxide for pH 9.7—10.7, and 0.025—0.10 M sodium hydrogencarbonate–disodium carbonate for pH 9.9) were used as the base solution. The ionic strength of the base solution was adjusted to 0.2 mol $\mathrm{dm^{-3}}$ with potassium chloride. Other details of the electrochemical measurements have been described previously.[7]

Results

Brdička Currents in Ammoniacal Buffers. Figure 1 shows polarograms of Brdička current of 0.34 μM cyt-c in the presence of 2×10^{-4} M hexaamminecobalt(III) chloride (Co(III)) in ammoniacal buffers at various pH-values. Two Brdička waves were observed in the pH range covered in Fig. 1, the first one exhibiting a peak. The peak potential of the first wave was shifted negatively with increasing pH, that is, from −1.31 V at pH 8.4 (Fig. 1a) to −1.38 V at pH 10.1 (Fig. 1g), whereas the potential of the second peak (or a shoulder) was almost independent of pH and appeared at −1.52 V. The height of the waves increased with increasing pH. Figure 2 shows the dependence of the Brdička current on the ammonia buffer concentration, $c_{amm}=(NH_4^+)+(NH_3)$, at pH 10.1. The height of the first wave increased greatly with increasing c_{amm} from 0.06 M (Fig. 2a) to 0.30 M (Fig. 2c), whereas the height of the second one was hardly influenced by c_{amm}. With decreasing pH the effect of c_{amm} on the Brdička current became smaller.

Brdička Currents in Tris(hydroxymethyl)aminomethane Buffers (Tris Buffers). Figure 3A shows a polaro-

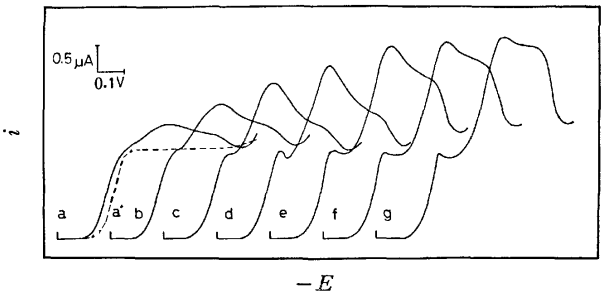

Fig. 1. Polarograms of Brdička current of 0.34 μM cyt-c in the presence of 2×10^{-4} M Co(III) in ammoniacal buffers; a) $c_{amm}=0.11$ M, pH 8.4, b) $c_{amm}=0.12$ M, pH 8.7, c) $c_{amm}=0.15$ M, pH 9.1, d) $c_{amm}=0.10$ M, pH 9.4, e) $c_{amm}=0.08$ M, pH 9.7, f) $c_{amm}=0.07$ M, pH 9.9, and g) $c_{amm}=0.06$ M, pH 10.1. Each curve starts from −0.9 V. (Broken line represents polarogram in the absence of cyt-c.)

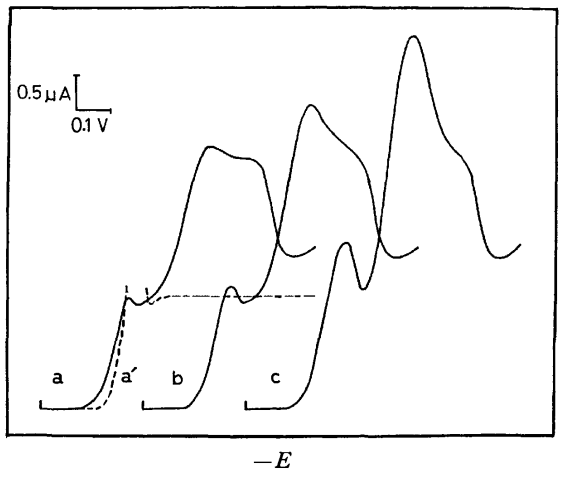

Fig. 2. Dependence of Brdička current of cyt-c on c_{amm} at pH 10.1; c_{amm}: a) 0.06 M, b) 0.12 M, and c) 0.30 M. Each curve starts from −0.9 V.

gram of Brdička current of cyt-c in the presence of Co(III) in 0.12 M tris buffer at pH 8.9. A rounded hump was observed at −1.34 V, followed by a shoulder at −1.52 V. The shape of the wave was similar at pH varying between 8.2 and 9.2, whereas the height of the wave increased with increasing pH. The shape and the height of the wave were hardly influenced by the concentration of tris buffer, c_{trls}, in the range 0.06—0.25 M at constant pH.

Brdička Currents in Borate Buffers. Figure 3B shows a polarogram of Brdička current of cyt-c in the presence of Co(III) in 0.24 M borate buffer at pH 9.1. Two waves of nearly equal wave height were observed at −1.32 and −1.52 V, respectively. At pH 9.4 the Brdička waves were similar in shape to but larger in height than those at pH 9.1. The shape and the height of the waves were hardly influenced by the concentration of borate buffer, c_{borate}, in the range 0.06—0.24 M at constant pH.

Brdička Currents in N,N-*Dimethylglycine Buffers.* Figure 3C shows a polarogram of Brdička current of cyt-c in 0.05 M *N,N*-dimethylglycine buffer at pH 10.0. Two waves observed at −1.36 and −1.52 V grew up to a certain limit with increasing pH from 9.7 to 10.7. With increasing concentration of *N,N*-dimethylglycine buffer, c_{dimet}, from 0.05 to 0.20 M at constant pH, the height of the two waves decreased slightly. In these buffer solutions the polarogram of Co(II) to Co(0) reduction step in the absence of cyt-c (Fig. 3C') appeared at the potential more negative by about 130 mV than that in ammoniacal buffer solutions (see Fig. 2a'). Similar negative shift of the reduction step of Co(II) to Co(0) has been reported[3] in glycine buffer solutions.

Brdička Currents in Carbonate Buffers. Figure 3D shows a polarogram of Brdička current of cyt-c in 0.025 M carbonate buffer at pH 9.9. Two waves were observed at −1.36 and −1.52 V, respectively. The height of the waves decreased with increasing concentration of carbonate buffer, c_{carb}, from 0.025 to 0.10 M. The polarogram of Co(II) to Co(0) reduction step in the absence of cyt-c (Fig. 3D') appeared at the

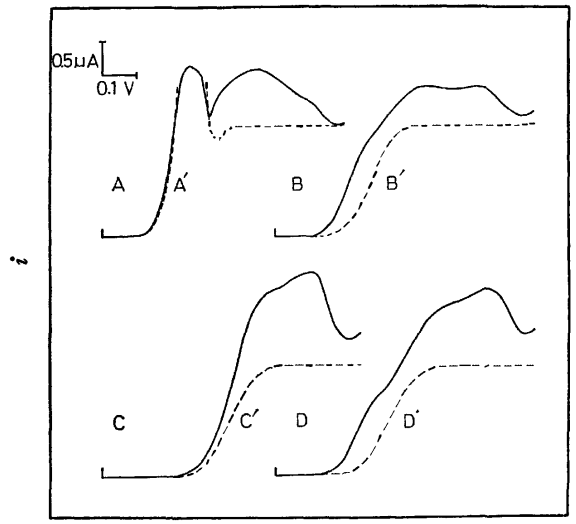

Fig. 3. Polarograms of Brdička current of 0.33 μM cyt-c in the presence of 2×10^{-4} M Co(III) in A) 0.12 M tris buffer, pH 8.9, B) 0.24 M borate buffer, pH 9.1, C) 0.05 M dimethylglycine buffer, pH 10.0, and D) 0.025 M carbonate buffer, pH 9.9. Each curve starts from −0.9 V. (Broken lines represent polarograms in the absence of cyt-c.)

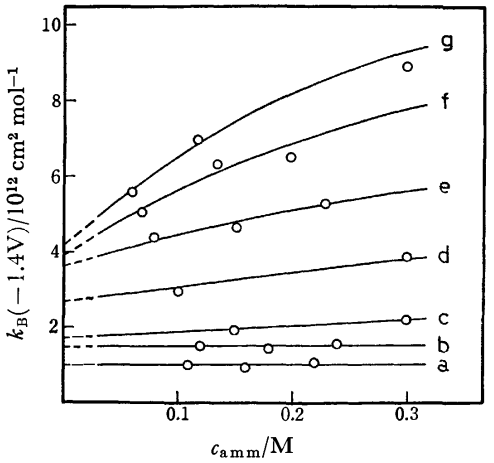

Fig. 4. Plots of k_B (−1.4 V) against c_{amm} at pH= a) 8.4, b) 8.7, c) 9.1, d) 9.4, e) 9.7, f) 9.9, and g) 10.1.

potential more negative by about 100 mV than that in ammoniacal buffer solutions.

$k_B(-1.4\,V)$-Value. It has previously been shown[7,10] that the Brdička current of cyt-c in ammoniacal buffers of pH 9.4 containing Co(III) at the concentration lower than 2×10^{-4} M can be expressed by

$$i_B = FAk_B\Gamma f_{Co}, \quad (1)$$

where F is Faraday, A the surface area of the DME, k_B a proportionality constant representing the Brdička current-activity of cyt-c, Γ the surface concentration of cyt-c adsorbed on the DME surface, and f_{Co} the flux of Co(III) ions at the electrode surface. Further it has been shown[7,10] that the adsorption of cyt-c on the DME surface at low bulk concentrations of cyt-c and at −1.4 V is cntrolled by diffusion and that

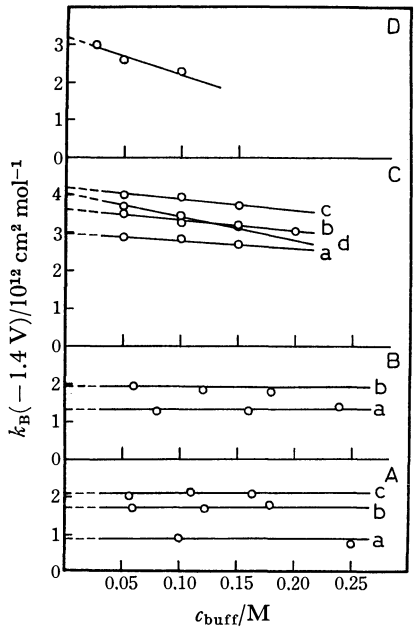

Fig. 5. Plots of k_B (−1.4 V) against A) c_{tris} at pH= a) 8.2, b) 8.9, and c) 9.2, B) c_{borate} at pH=a) 9.1 and b) 9.4, C) c_{dimet} at pH=a) 9.7, b) 10.0, c) 10.3, and d) 10.7, and D) c_{carb} at pH=9.9.

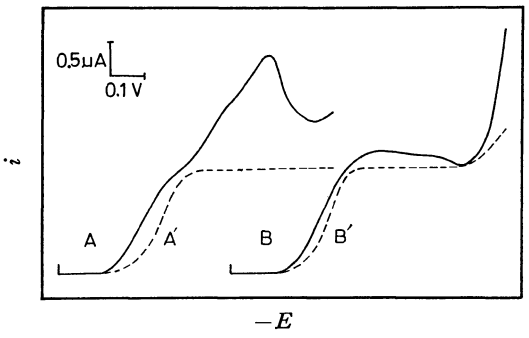

Fig. 6. Polarograms of Brdička current of 0.33 μM cyt-c in the presence of 2×10^{-4} M Co(III) in A) 0.2 M KCl solution and in B) 0.2 M NH_4Cl solution. Curves start from −0.9 V. (Broken lines represent polarograms in the absence of cyt-c.)

Γ can be estimated by Koryta's equation.[11] It was found that the Brdička currents of cyt-c measured under the present experimental conditions also obeyed Eq. 1 and that Γ at −1.4 V was able to be determined by Koryta's equation. The cobalt ion flux at the DME is given by the Ilković theory.[12] Thus, we determined the k_B-values of cyt-c in various buffer solutions by applying Eq. 1 to the Brdička currents at −1.4 V. The k_B(−1.4 V)-values are plotted against the buffer concentrations, c_{buff}, in Figs. 4 and 5.

Brdička Currents in Unbuffered Solutions. Figure 6 shows polarograms of Brdička current of 0.33 μM cyt-c in the presence of 2×10^{-4} Co(III) in 0.2 M KCl solution (Fig. 6A) and in 0.2 M NH_4Cl solution (Fig. 6B). Characteristic Brdička waves were observed in these solutions. The height of the waves in 0.2 M KCl solution was very much greater than that in 0.2 M NH_4Cl solution.

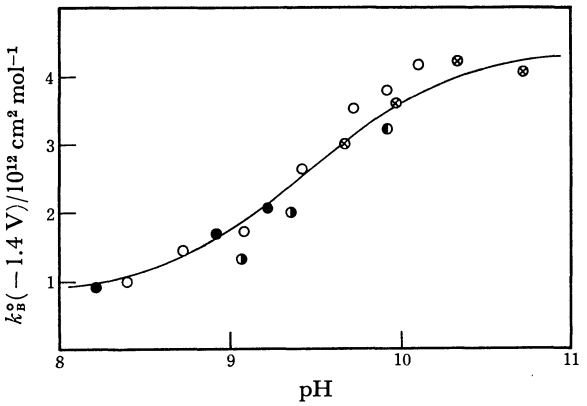

Fig. 7. Plots of k_B° (−1.4 V) against pH; data obtained in ○ ammonia buffer, ● tris buffer, ◑ borate buffer, ◐ carbonate buffer, and ⊗ dimethylglycine buffer. Solid line was calculated on the basis of equation and assumption in the texst.

Discussion

Experimental results show that the shape and the height of the Brdička waves of cyt-c vary with the electrolyte pH and the kind and concentration of buffers. Equation 1 predicts that the Brdička currents are controlled by two factors, k_B and Γ. As reported previously[7,10] at −1.4 V cyt-c is very strongly adsorbed on DME surface, so that at low bulk concentrations of cyt-c Γ can be estimated by Koryta's equation. With increasing negative potential, however, the protein becomes less strongly adsorbed on DME surface and Γ can no longer be evaluated by Koryta's equation. Accordingly, in the following we shall limit the quantitative analysis of the effects of pH and buffers on the Brdička currents to k_B-values at −1.4 V.

Figures 4 and 5 show the dependence of the k_B-(−1.4 V)-values on the buffer concentrations at various pH-values. In ammoniacal buffers, the k_B(−1.4 V) increases with increasing c_{amm} (Fig. 4). On the contrary, in *N,N*-dimethylglycine and carbonate buffers k_B(−1.4 V) decreases with their concentrations, whereas it is hardly affected in tris and borate buffers (Fig. 5). To eliminate these buffer effects, each k_B(−1.4 V) *vs.* c_{buff} plot was extrapolated to $c_{buff}=0$. Values of $k_B^\circ(-1.4\,V) \equiv \lim_{c_{buff}\to 0} k_B(-1.4\,V)$ thus estimated are plotted against pH in Fig. 7. They are on a single sigmoidal curve, independent of the kind of buffers.

In the pH range covered in Fig. 7 ferricytochrome c has two different conformational states depending on pH.[8] At the dme ferricytochrome c in the two states is adsorbed and reduced to ferrocytochrome c at the electrode surface.[7] Assuming that the ferrocytochrome c also has two states, state I and state II, and that the two states are in equilibrium as expressed by

$$\Gamma^{II}(H^+)/\Gamma^{I} = K_1, \qquad (2)$$

where Γ^{I} and Γ^{II} are the surface concentrations of state I and state II in the adsorption layer, respectively, and K_1 the protonic dissociation constant, we can get the following expression for the Brdička current;

$$i_B = FA(k_B^I \Gamma^I + k_B^{II} \Gamma^{II}) f_{Co}$$
$$= FA((k_B^I(H^+) + k_B^{II} K_1)/((H^+) + K_1)) \Gamma f_{Co}, \quad (3)$$

where k_B^I and k_B^{II} represent the Brdička current-activities of state I and state II, respectively. Thus, k_B in Eq. 1 is given by

$$k_B = (k_B^I(H^+) + k_B^{II} K_1)/((H^+) + K_1),$$

or

$$pH = pK_1 + \log((k_B - k_B^I)/(k_B^{II} - k_B)). \quad (4)$$

Solid line in Fig. 7 was calculated by Eq. 4 with $pK_1 = 9.45$, $k_B^I = 0.8 \times 10^{12}$ cm^2 mol^{-1}, and $k_B^{II} = 4.4 \times 10^{12}$ cm^2 mol^{-1}.

Previously we have shown that heme moiety is important in determining the Brdička current-activity of cyt-c.[7] Ferricytochrome c undergoes a transition with an apparent pK, pK_a, of 9.35, which corresponds to the heme-linked deprotonation of ε-amino group of Lys-79.[8] The value of pK_a has been reported to decline with the ionic strength, I, from 9.2 at $I=0.02$ to 8.9 at $I=0.3$.[13] In case of ferrocytochrome c the pK value for the deprotonation of Lys-79 has not been reported so far as we know, but it should have a higher value than the pK_a value of ferricytochrome c, since Lys-79 of ferrocytochrome c is free from bonding to the heme iron.[8] Accordingly, we may conclude that the equilibrium of Eq. 2 corresponds to the equilibrium for the deprotonation of Lys-79 in ferrocytochrome c adsorbed on the DME surface and that the lysine residue together with heme group contributes to the Brdička current-activity of cyt-c.

It has been supposed that the effect of buffer concentration on Brdička currents is due to an acidic component which works as a proton donor.[6,12] This implies that k_B increases with the concentration of an acidic component of buffer salt. However, as shown in Fig. 4 the $k_B(-1.4\text{ V})$-values of cyt-c are almost independent of c_{amm} at pH's lower than 9 at which the concentration of the acidic component, (NH_4^+), is in large excess over that of the basic component, (NH_3), indicating that the effect of (NH_4^+) is negligibly small. Tris and borate buffers also have negligible effect on the $k_B(-1.4\text{ V})$-values (Figs. 5 A and B). Even a decreasing effect is found in dimethylglycine and carbonate buffers (Figs. 5 C and D). As will be reported elsewhere,[14] Brdička current of a protein can be interpreted as due to the catalytic action of protein–Co(0) complex[12] which is transiently formed on electrode surface and the k_B-value depends on the catalytic activity constant, k_c, and the stability constant, k_f/k_d, k_f, and k_d being the formation and decomposition rate constants of the protein–Co(0) complex, respectively. The complicated effects of the buffers described above should be explained by taking into account the contribution of the buffers (probably the basic components) to the k_c and/or the k_f/k_d.

The results that $k_B^\circ(-1.4\text{ V})$ increases with increasing pH and that $k_B(-1.4\text{ V})$ is hardly influenced by the acidic components of the buffer salts indicate that a main proton donor in the Brdička reaction is a water molecule.

In order to get further evidence for the validity of this indication we measured polarograms of Brdička current of cyt-c in unbuffered solutions. As shown in Fig. 6A, in 0.2 M KCl solution containing only 2×10^{-4} M Co(III) cyt-c gave distinct Brdička waves of which $k_B(-1.4\text{ V})$-value was estimated as 3.0×10^{12} cm^2 mol^{-1} by Eq. 1. In 0.2 M NH_4Cl solution containing 2×10^{-4} M Co(III) the protein gave rather small Brdička waves (Fig. 6 B), of which $k_B(-1.4\text{ V})$-value was estimated as 0.8×10^{12} cm^2 mol^{-1}. In an unbuffered solution, pH of the solution in the vicinity of electrode surface must be different from that in the bulk of solution, since Brdička reaction (catalytic hydrogen evolution reaction) produces hydroxide ions, OH^-, and simultaneously the reduction of hexaamminecobalt(III) ions liberates NH_3 molecules. The OH^- and NH_3 molecules diffuse into the solution, so that their surface concentrations, $(OH^-)^\circ$ and $(NH_3)^\circ$, are related[15] to the Brdička current and the limiting current of Co(III), $i_{lim.Co}$, respectively, by the Ilković equations:

$$i_B = \kappa_{OH^-}(OH^-)^\circ \quad (5\text{-a})$$

and

$$i_{lim.Co} = \kappa_{Co}(Co(III))^* = \kappa_{NH_3}(NH_3)^\circ, \quad (5\text{-b})$$

where κ_{OH^-}, κ_{Co}, and κ_{NH_3} are the Ilković constants for OH^-, Co(III), and NH_3, respectively, depending on their respective diffusion coefficients, D_{OH^-}, D_{Co}, and D_{NH_3}, and $(Co(III))^*$ the bulk concentration of Co(III). By Eq. 5-a with $D_{OH^-} = 5.2 \times 10^{-5}$ cm^2 s^{-1} [12] and $i_B(-1.4\text{ V}) = 0.97$ μA (Fig. 6A), $(OH^-)^\circ$ is estimated as 9.5×10^{-5} M, which corresponds to pH 10.0. By Eq. 5-b $(NH_3)^\circ$ is estimated as 7.0×10^{-4} M at $(Co(III))^* = 2 \times 10^{-4}$ M, where $D_{Co} = 7.5 \times 10^{-6}$ cm^2 s^{-1} [10] is used; D_{NH_3} is assumed to be equal to the diffusion coefficient of NH_4^+: $D_{NH_4} = 1.9 \times 10^{-5}$ cm^2 s^{-1}.[12] The pH of 7.0×10^{-4} M NH_3 solution is calculated to be approximately 10. Accordingly, it will be safe to estimate the electrode surface pH as about 10, under the condition under which the Brdička current in Fig. 6 A is observed. In 0.2 M NH_4Cl solution OH^- ions produced by the Brdička reaction at the DME surface can react with NH_4^+ ions to form NH_3 molecules. The reduction of Co(III) ions also liberates NH_3 molecules. Thus, using Eqs. 5-a and 5-b, the ratio $(NH_4^+)/(NH_3)$ may be estimated as 2.5×10^2 at the electrode surface. This value of $(NH_4^+)/(NH_3)$ ratio corresponds approximately to pH 7. The results that $k_B(-1.4\text{ V}) = 3.0 \times 10^{12}$ cm^2 mol^{-1} in 0.2 M KCl (electrode surface pH$\approx$10) and $k_B(-1.4\text{ V}) = 0.8 \times 10^{12}$ cm^2 mol^{-1} in 0.2 M NH_4Cl (electrode surface pH$\approx$7) can reasonably be explained by the $k_B^\circ(-1.4\text{ V})$-pH curve in Fig. 7.

(Received September 17, 1979)

The preparation and structural assignments of *N*-methyl-(*S*)- and -(*R*)-alaninatocobalt(III) complexes with a few chiral derivatives of 2,3,2-tet (=3,7-diazanonane-1,9-diamine) and triethylenetetramine are described. The hydroxide ion-catalyzed epimerizations of these complexes are examined at pH 10. In the *N*-methylalaninato complexes the isomer ratio for *Λ*-*S*/*Λ*-*R* ranged from 76/24 to 90/10. In the most favorable case where tetramine is 2(*S*)10(*S*)-4,8-diazaundecane-2,10-diamine (abbreviated as 2(*S*)10(*S*)-Me_2-2,3,2-tet) the energy differences among the four possible diastereomers are discussed in relation to the prediction from strain energy minimization calculations.

In recent papers, bis(ethylenediamine)cobalt(III) complexes or triethylenetetraminecobalt(III) complexes of *N*-substituted amino acidate (sarcosinate,[2-5] *N*-methyl-(*S*)- and -(*R*)-alaninate,[3,6-9] and *N*-benzylglycinate[10]) have been investigated from stereochemical points of view. Buckingham and coworkers reported[2] the stereoselective coordination of the secondary nitrogen atom in the sarcosinatobis(ethylenediamine)cobalt(III) complex due to steric repulsions between the *N*-methyl group and the adjacent ethylenediamine chelate ring. The coordinated secondary N center of sarcosinate in the *Δ*-[Co(sar)$(en)_2$]$^{2+}$ ion was assumed to have the *S* configuration stereoselectively, which was confirmed later by an X-ray crystal structure analysis.[11] Though the presence of less stable isomer, *Δ*-[Co(*R*-sar)$(en)_2$]$^{2+}$ was predicted on the basis of strain energy minimization calculations, some earlier attempts to obtain the isomer failed.[3] Recently, the *Δ*-*R* isomer was isolated by Yamatera and coworkers,[4] so that the presence of all four isomers (*Δ*-*R*, *Δ*-*S*, *Λ*-*R*, and *Λ*-*S*) were proved.

In the case of the *N*-methyl-(*S*)- or -(*R*)-alaninato complex there are two chiral centers in the *N*-methylalaninate moiety: *N*-methyl and *C*-methyl groups. Consequently, nonbonded repulsive interactions possibly occur not only between the *N*-methyl group and the adjacent chelate ring but also between the *N*-methyl group and the *C*-methyl group in the *N*-methylalaninate. In the *Λ* configuration it was shown that the *N*-methyl-(*S*)-alaninato complex with the *N*-methyl group trans to the *C*-methyl group was obtained stereospecifically owing to these nonbonded interactions, while in the *N*-methyl-(*R*)-alaninato complexes (*Λ*-*R*) with trien[7] or trien derivatives[8,9] two diastereomers were found to coexist: the trans configuration involving considerable steric repulsion between the *N*-methyl group and the adjacent chelate ring, and the cis configuration having alternatively significant nonbonded repulsion between the two methyl groups.

Sargeson and coworkers showed[12] that the α-proton of chelated α-amino acidate moieties in chiral complex ions undergoes hydroxide ion-catalyzed exchange in basic aqueous solution, and gives rise to a diastereomeric mixture after the establishment of equilibrium. It was found that an equilibrated solution of the *Δ*-β_2-[Co(*N*-Me-ala)(trien)]$^{2+}$ (at pH 12) contains *Δ*-β_2-(*RRS*)-[Co(*N*-Me-(*R*)-ala)(trien)]$^{2+}$ (≈60%), *Δ*-β_2-(*RRS*)-[Co(*N*-Me-(*S*)-ala)(trien)]$^{2+}$ (≈20%), and *Δ*-β_2-(*RRR*)-[Co(*N*-Me-(*S*)-ala)(trien)]$^{2+}$ (≈20%).[7] From the viewpoint of asymmetric transformation at the C center, the isomer ratio for *Δ*-*R*/*Δ*-*S* was 60/40 in the *Δ*-β_2-[Co(*N*-Me-ala)(trien)]$^{2+}$ system. Further, the *Δ*-[Co(*N*-Me-ala)$(en)_2$]$^{2+}$ system gave an improved ratio *Δ*-*R*/*Δ*-*S*=80/20.[6] The strain energy minimization study on the *Δ*-[Co(*N*-Me-ala)$(en)_2$]$^{2+}$ and *Δ*-β_2-[Co(*N*-Me-ala)(trien)]$^{2+}$ isomers correctly predicted the stability order and the energy difference among the diastereomers.[3]

In order to obtain further information about the asymmetric transformation of *N*-methylalaninate, a few chiral derivatives of triethylenetetramine (=trien) and 3,7-diazanonane-1,9-diamine (=2,3,2-tet) were employed for quadridentate ligand (=N_4), and *Λ*-β_2-[Co(*N*-Me-(*S*)- and -(*R*)-ala)(N_4)]$^{2+}$ complexes were prepared. The structure and abbreviations for these tetramines are summarized in Table 1. The epimerization of the amino acidato complexes were accomplished in basic solution. Each equilibrated mixture contained three isomers *Λ*-β_2-(*R*)-*S*, *Λ*-β_2-(*R*)-*R*, and *Λ*-β_2-(*S*)-*R*, as shown in Fig. 1. The isomer ratios for *Λ*-*S*/*Λ*-*R* were obtained, and the results are discussed in relation to the prediction of strain energy minimization calculations.

amine (=(*R*)-baetchxn),[9] 2(*S*),10(*S*)-4,8-diazaundecane-2,10-diamine (=2(*S*)10(*S*)-Me_2-2,3,2-tet),[15] and 2(*S*),8(*S*)-dimethyl-3,7-diazanonane-1,9-diamine (=3(*S*)9(*S*)-Me_2-2,3,2-tet)[1] were prepared by the methods described previously. The dichlorocobalt(III) complexes (*trans*-[$CoCl_2$(3(*S*)8(*S*)-dimetrien)]ClO_4,[16] *Λ*-*β*-[$CoCl_2$(5(*R*)-metrien)]$Cl\cdot 0.5H_2O$,[14] *Λ*-*β*-[$CoCl_2$((*R*)-baetchxn)]$Cl\cdot 0.5H_2O$,[14] *trans*-[$CoCl_2$(2(*S*)-10(*S*)-Me_2-2,3,2-tet)]ClO_4,[1] and *trans*-[$CoCl_2$-(3(*S*)9(*S*)-Me_2-2,3,2-tet)]ClO_4[1]) were prepared according to the methods reported previously. *N*-Methyl-(*S*)-alanine and *N*-methyl-(*R*)-alanine were synthesized by the method of Quitt, *et al.*,[17] using (*S*)- and (*R*)-alanine, respectively.

Λ-*β*$_2$-[*Co*(N-*Me*-(S)- *or* -(R)-*ala*) (3(S)8(S)-*dimetrien*)]*Cl*·*ClO*$_4$·*0.5H*$_2$*O*. *N*-Methyl-(*S*)-alanine (or *N*-methyl-(*R*)-alanine) (0.26 g) was added to 5 ml of hot water, followed by $LiOH\cdot H_2O$ (0.088 g). The mixture was warmed to 70 °C until the compound dissolved. To the resulting solution was added *trans*-[$CoCl_2$(3(*S*)8(*S*)-dimetrien)]ClO_4 (0.80 g). The mixture was warmed for 15 min on a water bath at 70 °C. Solid $LiClO_4\cdot 3H_2O$ (0.48 g) was added to the solution, and the mixture was cooled in a refrigerator overnight. The orange-red crystals were collected, washed with methanol and acetone, successively, and air dried. The porduct was recrystallized from hot water. Calcd for [Co-($C_4H_8NO_2$)($C_8H_{22}N_4$)]$Cl\cdot ClO_4\cdot 0.5H_2O$: C, 30.07; H, 6.30; N, 14.61%. Found: for *N*-Me-(*S*)-ala complex, C, 30.33; H, 6.42; N, 14.81%, and for *N*-Me-(*R*)-ala compex, C 29.76; H, 6.45; N, 14.84%.

Λ-*β*$_2$-[*Co*(N-*Me*-(S)-*ala*)(5(R)-*metrien*)]$(ClO_4)_2$ was prepared by the method described previously.[8]

Λ-*β*$_2$-[*Co*(N-*Me*-(R)-*ala*)(5(R)-*metrien*)]$I_2\cdot 5H_2O$ was prepared by the method used for the preparation of *Δ*-*β*$_2$-[Co(*N*-Me-(*S*)-ala)(5(*S*)-metrien)]$I_2\cdot 2H_2O$ except that *Δ*-*β*-[$CoCl_2$-(5(*R*)-metrien)]$Cl\cdot 0.5H_2O$ and *N*-methyl-(*R*)-alanine were employed in place of the corresponding 5(*S*)-metrien complex and *N*-methyl-(*S*)-alanine, respectively.

Calcd for [$Co(C_4H_8NO_2)(C_7H_{20}N_4)$]$I_2\cdot 5H_2O$: C, 19.86; H, 5.76; N, 10.73%. Found: C, 19.83; H, 6.08; N, 10.46%.

Λ-*β*$_2$-[*Co*(N-*Me*-(S)-*ala*)((R)-*baetchxn*)]$(ClO_4)_2$ and *Λ*-*β*$_2$-[*Co*(N-*Me*-(R)-*ala*)((R)-*baetchxn*)]$ZnCl_4$ were prepared according to the method described previously.[9]

Λ-*β*$_2$-[*Co*(N-*Me*-(S)- *or* -(R)-*ala*)(2(S)10(S)-*Me*$_2$-2,3,2-*tet*)]$(ClO_4)_2\cdot H_2O$ and *Λ*-*β*$_2$-[*Co*(N-*Me*-(S)- *or* -(R)-*ala*)-(3(S)9(S)-*Me*$_2$-2,3,2-*tet*)]$(ClO_4)_2\cdot H_2O$ were prepared by the method used for the preparation of the *Λ*-*β*$_2$-[Co((*S*)-ala)(*SS*-pyht)]$(ClO_4)_2\cdot 2H_2O$.[1] Calcd for [$Co(C_4H_8NO_2)$-($C_9H_{24}N_4$)]$(ClO_4)_2\cdot H_2O$: C, 27.57; H, 6.05; N, 12.37%. Measurements. Visible absorption spectra were measured with a Shimadzu UV-210 spectrophotometer. Circular dichroism curves were obtained with a JASCO-J20 recording spectropolarimeter. Proton NMR (PMR) spectra (90 MHz) were obtained on a Hitachi R-40 spectrometer using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an internal standard reference. FT carbon-13 NMR (CMR) spectra were obtained at 25.03 MHz with broad-band proton decoupling on a JEOL PS-99.5 MHz spectrometer employing the solvent deuterium signal as an internal lock. A pulse angle of 45 ° was employed with no pulse delay. The ambient temperature was 39 °C. Me_4Si sealed in a capillary was used as an external reference.

The perchlorate salts were suspended in the solvent (D_2O) and treated with twice the molar amount of tetraphenylarsonium chloride. The white precipitates were removed by filtration, and the filtrates were employed for NMR measurements.

Measurements of Isomer Ratios for Epimerization Reactions. (i) *N*-Methylalaninato complexes with the trien derivatives: Weighed samples (25 mg) of the *N*-methyl-(*S*)- or -(*R*)-alaninatocobalt(III) complexes with the trien derivatives were dissolved in 25 ml of 0.02 mol/dm^3 Na_2CO_3+0.02 mol/dm^3 $NaHCO_3$ buffer (pH 10.1), and the solution was warmed at 40 °C for 25 h. The solution was poured on a small column of SP-Sephadex C25 cation-exchange resin in the sodium form. The complex was eluted with 0.1 mol/dm^3 NaCl. Two bands were collected. The first

a) Ref. 8. b) Ref. 9.

pink band (bottom of the column) moved at a rate consistent with a univalent cation was assumed to be a hydrolysis product. The second orange-red 2+ band (top) which was a mixture of Λ-β_2-(*N*-Me-(*R*)-ala)Co(III) and Λ-β_2-(*N*-Me-(*S*)-ala)Co(III) complexes was concentrated to near dryness with a rotary evaporator, and excess NaCl was filtered off. After removing most of NaCl by addition of methanol, final desalting was carried out by gel permiation chromatography on a column (2.5×40 cm) of SP-Sephadex G15. The solution was passed down the column and collected. The resuting solution was evaporated to an appropriate concentration, then the CD curves was obtained. The best fitted curve with the observed CD curve of the equilibrated mixture was calculated by mixing the authentic CD curves of corresponding (*R*)- and (*S*)-amino acidato complex (in H_2O) between 560 nm and 400 nm using least-squares method, and the isomer ratio (Λ-*S*/Λ-*R*) was obtained. The agreement between the observed and calculated curves was satisfactory. Attempts to separate the diastereomeric isomers, (*R*)- and (*S*)-amino acidato complexes, failed.

(ii) *N*-Methylalaninato complexes with the 2,3,2-tet derivatives: Weighed samples (100 mg) of the *N*-methyl-(*S*)- or -(*R*)-alaninatocobalt(III) complex with the 2,3,2-tet derivatives were dissolved in 100 ml of 0.02 mol/dm^3 Na_2CO_3+0.02 mol/dm^3 $NaHCO_3$ buffer, and the compound was equilibrated and desalted by the above-mentioned procedure. The resulting solution was loaded on a SP-Sephadex C25 cation-exchange resin (2.5×40 cm), and eluted with 0.1 mol/dm^3 sodium L-tartratoantimonate(III). Since the length of the column was not sufficient for the complete separation, the eluate was recycled by a rotary pump. After 5—6 cycles the complexes separated cleanly into two bands. The bands were washed with 500 ml of water, eluted with 0.1 mol/dm^3 NaCl, and evaporated to near dryness. After desalting by a similar procedure as above their absorption spectra and CD curves were obtained. The first minor (bottom) and second major band (top) were assigned to the *N*-methyl-(*R*)-alaninato and *N*-methyl-(*S*)-alaninato complexes, respectively. The isomer ratio was estimated spectrophotometrically. Attempts to separate chromatographically the cis and trans isomers of the *N*-methyl-(*R*)-alaninato complexes failed.

In both methods the isomer ratios were reproducible to better than within ±2%.

Strain Energy Minimization Calculations. The minimized strain energies of the complexes Λ-β_2-[Co(*N*-Me-(*R*)- and -(*S*)-ala)(2(*S*)10(*S*)-Me_2-2,3,2-tet)]$^{2+}$ were calculated by the method reported previously.[1] The starting models were generated from the Λ-β_2-[Co(ala)(2(*S*)10(*S*)-Me_2-2,3,2-tet)]$^{2+}$ cations.[1] Calculations were carried out on a HITAC 8700/8800 computer at the Computer Center of this University.

Results and Discussion

β_2-[Co(*N*-Methyl-(*S*)- or -(*R*)-alaninato)(N_4)]$^{2+}$ complexes were prepared from *trans*-[$CoCl_2(N_4)$]$^+$ complexes or Λ-β-[$CoCl_2(N_4)$]$^+$ complexes by the methods described previously.[1,8,9]

The absolute configuration for the complexes was assigned to the Λ configuration based on their circular dichroism spectra. The complexes prepared by the present methods were expected to have the β_2 configuration.[1,18] The electronic and circular dichroism spectral data of Λ-β_2-[Co(*N*-Me-(*S*)- and -(*R*)-ala)(N_4)]$^{2+}$ complexes are listed in Table 2.

As described in the Introduction, only one isomer was anticipated for Λ-β_2-[Co(*N*-Me-(*S*)-ala)(N_4)]$^{2+}$ complexes, in which the *N*-methyl group was trans

a) ppm from DSS. b) Ref. 8. c) Ref. 9.

to the *C*-methyl group in the *N*-methylalaninate (=Λ-β_2-(*R*)-*S*). The PMR spectra of Λ-β_2-[Co(*N*-Me-(*S*)-ala)(N_4)]$^{2+}$ in D_2O exhibited a doublet at about 1.5 ppm and a singlet at 2.4—2.6 ppm arising from the *C*-methyl and *N*-methyl groups, respectively (Table 3 and Figs. 2b and 3a). These spectra are similar to those of other Λ-β_2 isomers of *N*-methyl-(*S*)-alaninato complexes with trien[7] and trien derivatives.[8,9] The ^{13}C-NMR spectrum of the Λ-β_2-[Co(*N*-Me-(*S*)-ala)-(3(*S*)9(*S*)-Me_2-2,3,2-tet)]$^{2+}$ complex exhibited twelve signals with one broad peak corresponding to two carbons, which was consistent with the number of the carbons expected for one kind of the isomer (Fig. 4b).

On the other hand, the presence of two isomers for Λ-β_2-[Co(*N*-Me-(*R*)-ala)(N_4)]$^{2+}$ has been reported.[3,7-9] The PMR spectrum of the *N*-methyl-(*R*)-alaninato complex with 3(*S*)8(*S*)-dimetrien showed two *N*-methyl resonances at 2.36 and 2.58 ppm, which were assigned to those of the *N*-methyl groups of the Λ-β_2-(*R*)-*R* and Λ-β_2-(*S*)-*R* complexes, respectively (Table 3 and Fig. 2a). The isomer ratio for Λ-β_2-(*R*)-*R*/Λ-β_2-(*S*)-*R* at equilibrium (pH 7) was estimated as about 3/1. This value is in contrast to those in the corresponding *N*-methyl-(*R*)-alaninato complexes with other tetramines, in which the isomer ratios for Λ-β_2-(*R*)-*R*/Λ-β_2-(*S*)-*R* were close to 1/1.[7-9] An X-ray structure analysis of the Λ-[$CoCO_3$(3(*S*)8(*S*)-dimetrien)]$^+$ ion[19] revealed that the apical five-membered chelate ring of the tetramine has the λ conformation with an axial *C*-methyl group in the crystal. If the apical chelate ring of the *N*-methylalaninato complex takes similarly the λ conformation, severe nonbonded repulsions will occur between the *N*-methyl group and the axial *C*-methyl group. Actually, the conformer

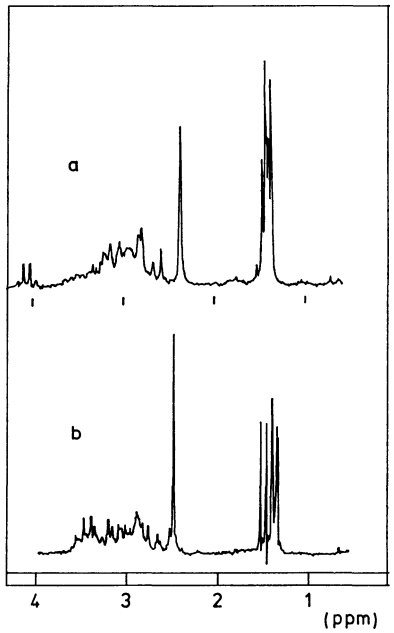

Fig. 2. PMR spectra of Λ-β_2-[Co(*N*-Me-ala)(3(*S*)8(*S*)-dimetrien)]$^{2+}$ ions in D_2O; (a) *N*-Me-(*R*)-ala and (b) *N*-Me-(*S*)-ala.

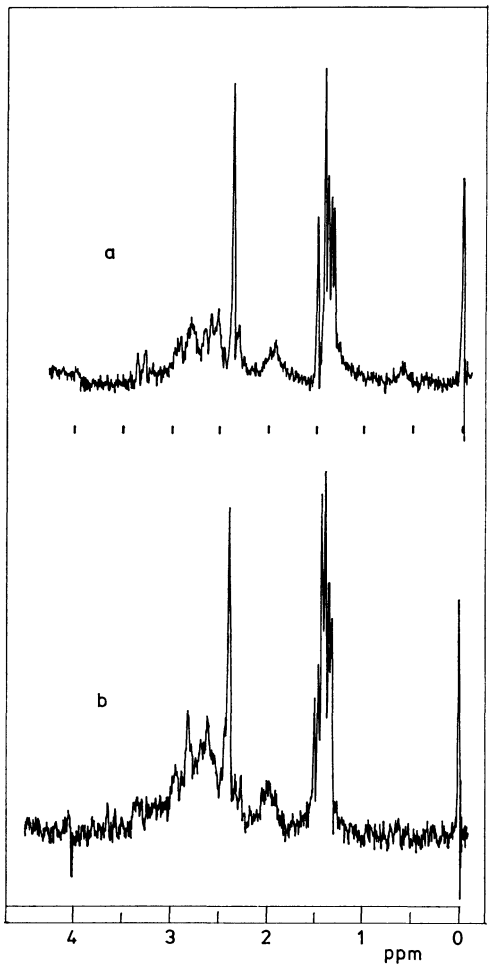

Fig. 3. PMR spectra of Λ-β_2-[Co(*N*-Me-ala)(3(*S*)9(*S*)-Me_2-2,3,2-tet)]$^{2+}$ ions in D_2O; (a) *N*-Me-(*S*)-ala and (b) *N*-Me-(*R*)-ala.

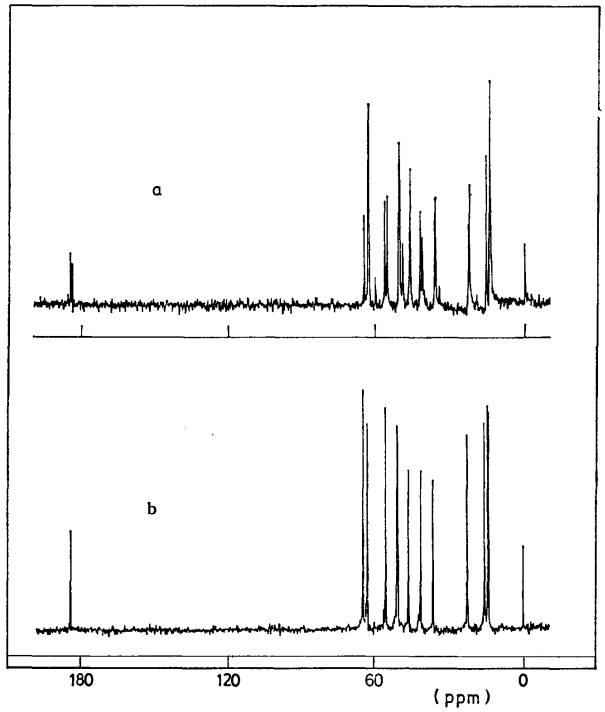

Fig. 4. CMR spectra of Λ-β_2-[Co(*N*-Me-ala)(3(*S*)9(*S*)-Me_2-2,3,2-tet)]$^{2+}$ ions in D_2O; (a) *N*-Me-(*R*)-ala and (b) *N*-Me-(*S*)-ala.

with the δ conformation with respect to the apical chelate ring will coexist in solution. It is probable that the steric repulsions between the *N*-methyl group and the axial *C*-methyl group in the apical chelate ring contribute properly to the destabilization of the Λ-β_2-(*S*)-*R* isomer in comparison with the Λ-β_2-(*R*)-*R* for the 3(*S*)8(*S*)-dimetrien complex.

In the PMR spectra of the *N*-methyl-(*R*)-alaninato complexes with the 2,3,2-tet derivatives the *N*-methyl resonance appeared as a singlet at about 2.4 ppm, while the PMR signals for the *C*-methyl group in the *N*-methyl-(*R*)-alaninate showed two kinds of doublets (Table 3 and Fig. 3b). This indicates that the chemical shift of the *N*-methyl signals of the Λ-(*R*)-*R* and Λ-(*S*)-*R* isomers are incidentally identical. The CMR spectrum of the Λ-β_2-[Co(*N*-Me-(*R*)-ala)(3(*S*)9(*S*)-Me_2-2,3,2-tet)]$^{2+}$ complex showed more complicated feature than that of the corresponding *N*-methyl-(*S*)-alaninato complex (Fig. 4a). Both signals at 184.4 and 185.0 ppm were assigned to the carboxyl carbon in the *N*-methyl-(*R*)-alaninate. It indicates the presence of the two species for the *N*-methyl-(*R*)-alaninato complex. The ratio of Λ-(*R*)-*R*/Λ-(*S*)-*R* at equilibrium (at pH 7) was estimated as about 1/1 from the CMR data.

It has been shown[6,7] that the epimerization at the C center of the *N*-methylalaninate ligand in the complexes occurs in basic aqueous solution. As Fig. 5 shows the PMR spectrum of the Λ-β_2-[Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)]$^{2+}$ at about pH 10 exhibited a new *C*-methyl doublet at 1.50 ppm and a new *N*-methyl singlet at 2.58 ppm. The equilibrated mixture should contain three isomers Λ-(*R*)-*S*, Λ-(*R*)-*R*, and Λ-(*S*)-*R*.[7-9] From the viewpoint of asymmetric transformation, the isomer ratios Λ-*S*/Λ-*R*, after the epimerization

a) At 40 °C, pH 10.1. b) Ref. 6. c) Ref. 7. d) Ref. 12. e) Ref. 1.

The isomer ratios for *Λ*-*S*/*Λ*-*R* are listed in Table 4. The isomer ratios for *Λ*-(*R*)-*R*/*Λ*-(*S*)-*R* at pH 10 were assumed to be the same as those at pH 7. The *Λ*-β_2-[Co(*N*-Me-ala)(N_4)]$^{2+}$ systems generally showed a considerable stereoselectivity on the epimerization. The degree of the stereoselectivity ranges from 85/15 to 90/10 ($\Delta G = -1.1 \sim -1.4$ kcal/mol) in this study except for the 5(*R*)-metrien complexes (76/24). These values are considerably larger than that for the [Co(*N*-Me-ala)(trien)]$^{2+}$ system (*Λ*-*S*/*Λ*-*R*=60/40),[7] and a little larger than for the [Co(*N*-Me-ala)$(en)_2$]$^{2+}$ system (80/20).[6]

As described in the Introduction, significant nonbonded repulsive interactions were anticipated in the *Λ*-*R* isomers between the *N*-methyl group and the adjacent chelate ring or alternatively between the *N*-methyl and the *C*-methyl groups in the *N*-methylalaninate. The effects of these two steric repulsions seem to be approximately equal, since the ratios for *Λ*-(*R*)-*R*/*Λ*-(*S*)-*R* are about 1/1 in all cases except for that of the 3(*S*)8(*S*)-dimetrien complexes. The observed thermodynamic preference of *Λ*-β_2-[Co(*N*-Me-(*S*)-ala)(N_4)]$^{2+}$ isomer over *Λ*-β_2-[Co(*N*-Me-(*R*)-ala)-(N_4)]$^{2+}$ isomer should be due to the absence of such steric disadvantage. The isomer ratio of the *Λ*-β_2-[Co(*N*-Me-ala)(5(*R*)-metrien)]$^{2+}$ complex is similar to that of the [Co(*N*-Me-ala)$(en)_2$]$^{2+}$ system, while those of the 3(*S*)8(*S*)-dimetrien or (*R*)-baetchxn complexes are considerably larger than that of the trien ones. Though the reason for these high selectivity with the substituted trien complexes is uncertain, it is probable that the relative stability is influenced by the *C*-methyl group substituted in the apical chelate ring of the 3(*S*)8(*S*)-dimetrien or by the increased rigidity due to the fused cyclohexane ring in the central chelate ring of the (*R*)-baetchxn.

The technique of strain energy minimization calculation was applied to the *Λ*-β_2-[Co(*N*-Me-(*R*)- and -(*S*)-ala)(2(*S*)10(*S*)-Me_2-2,3,2-tet)]$^{2+}$ complexes, the isomer ratio *Λ*-*S*/*Λ*-*R* in which was 90±2/10±2 ($\Delta G = -1.35 \pm 0.15$ kcal/mol). The 2,3,2-type tetramine ligands have the same geometrical structure in the cis configuration, while the *cis*-complexes with trien adopt two geometrical isomers.[20] Further, the conformation of 2,3,2-tet or its derivatives is assumed to be more rigid than that of trien series. Actually, a recent

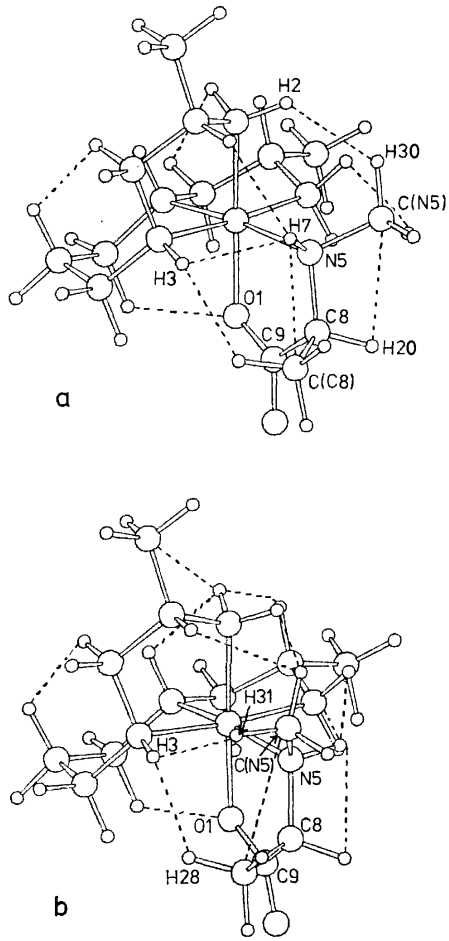

Fig. 7. Minimized structures for *Λ*-β_2-[Co(*N*-Me-(*S*)-ala)(2(*S*)10(*S*)-Me_2-2,3,2-tet)]$^{2+}$ ions; (a) *Λ*-(*R*)-*S* and (b) *Λ*-(*S*)-*S*. Dotted lines show interatomic repulsions greater than 0.3 kcal/mol.

X-ray analysis study revealed[21] that in the crystal of *cis*-β_2-[Co(gly)(trien)]$^{2+}$ two conformers coexist, the apical chelate rings of which have both the δ and λ conformations. On the other hand, the outer five-membered chelate rings of the methyl-substituted 2,3,2-tet employed in this study have the δ conformation due to the preference of the equatorial orientation of the *C*-methyl groups. Since the conformation and configuration of the 2,3,2-tet are thus fixed in the cis form, the stereoisomerism for the [Co(*N*-Me-ala)(2(*S*)10(*S*)-Me_2-2,3,2-tet)]$^{2+}$ system is simpler than the [Co(*N*-Me-ala)$(en)_2$]$^{2+}$ or the [Co(*N*-Me-ala)(trien)]$^{2+}$ systems.

The final minimized structures for the diastereomeric isomers are shown in Figs. 7 and 8, and the final energy terms are listed in Table 5. The most stable isomer is *Λ*-(*R*)-*S* with the *N*-methyl group trans to the *C*-methyl group, as shown in Fig. 7a. The calculated stability order, *Λ*-(*R*)-*S*, *Λ*-(*S*)-*R*, *Λ*-(*R*)-*R*, *Λ*-(*S*)-*S* is the same as that for the [Co(*N*-Me-ala)$(en)_2$]$^{2+}$ system. However, compared with the [Co(*N*-Me-ala)(trien)]$^{2+}$ system, the relative stabilities of the *Λ*-(*S*)-*R* with trans methyl groups and *Λ*-(*R*)-*R* with cis methyl groups are reversed (Table 6).

The starting models of the *N*-methylalaninate moiety was generated from both puckered and near-planar

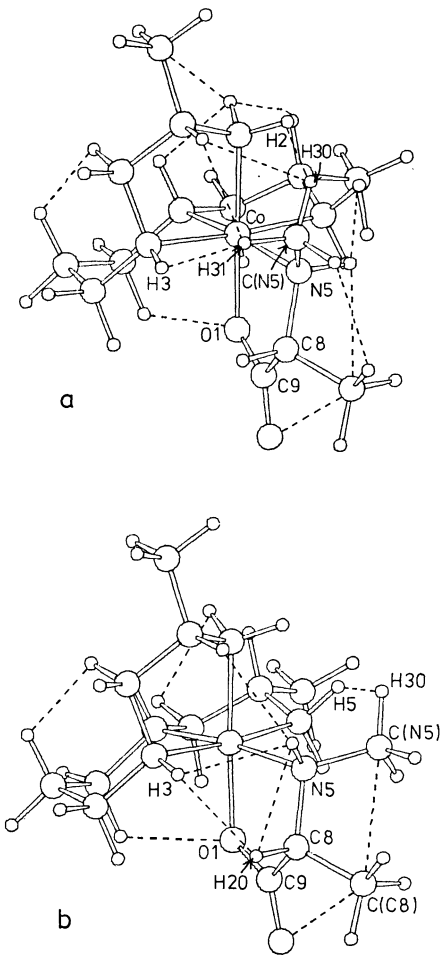

Fig. 8. Minimized structures for Λ-β_2-[Co(*N*-Me-(*R*)-ala)(2(*S*)10(*S*)-Me_2-2,3,2-tet)]$^{2+}$ ions; (a) Λ-(*S*)-*R* and (b) Λ-(*R*)-*R*. Dotted lines show interatomic repulsions greater than 0.3 kcal/mol.

conformation.[3] Except for the Λ-(*R*)-*S* isomer the planar conformation was unstable. In the case of the Λ-(*R*)-*S* ion the planar form was a little more stable than the puckered one (8.56 kcal/mol). Normally, the puckered conformation with a pseudo-equatorial *C*-methyl group was stable for the alaninate. However, in the Λ-(*S*)-*S* isomer the puckered form with a pseudo-axial *C*-methyl group was much more stable than the pseudo-equatorial form (13.1 kcal/mol). The dihedral angles, ϕ(Co–N5–C8–C9), were 6.7° Λ-(*R*)-*S*, 27.3° Λ-(*S*)-*R*, 30.1° Λ-(*R*)-*R*, 18.8° Λ-(*S*)-*S*, and ϕ(N5–C8–C9–O1) were 3.0° Λ-(*R*)-*S*, 22.6° Λ-(*S*)-*R*, 26.7° Λ-(*R*)-*R*, 18.7° Λ-(*S*)-*S*.

The introduction of the *N*-methyl group to the alaninate moiety produces significant strains in the complex. The calculated strain energies of the corresponding alaninato complexes were *ca.* 4 kcal/mol more stable than the most stable isomer of the *N*-methylalaninato complex.[1] Comparisons of the strain energy contributions among the isomers of the Λ-β_2-[Co(*N*-Me-ala)(2(*S*)10(*S*)-Me_2-2,3,2-tet)]$^{2+}$ ions show that the difference derives mainly from the bond-angle deformations, torsional strain, and nonbonded interactions. The Λ-(*R*)-*S* isomer has the smallest strain energy contributions in the bond-angle deformations

Table 5. Final energy terms[a] for the four isomers of the *N*-methylalaninato complexes

	trans-N(*R*)-C(*S*)	*trans*-N(*S*)-C(*R*)	*cis*-N(*R*)-C(*R*)	*cis*-N(*S*)-C(*S*)
Bond deformations	1.61	1.59	1.76	1.64
Angle deformations	6.22	7.30	7.52	8.98

Table 6. Strain energy differences[a] for [Co(*N*-Me-ala)(N_4)]$^{2+}$ systems

(N_4)	Λ-(*R*)-*S* (*trans*)	Λ-(*S*)-*R* (*trans*)	Λ-(*R*)-*R* (*cis*)	Λ-(*S*)-*S* (*cis*)
$(en)_2$[b]	0.0	1.0	1.3	3.8
trien[b]	0.0	1.9	0.6	4.0
2(*S*)10(*S*)-Me_2-2,3,2-tet	0.0	0.7	1.4	2.8

a) kcal/mol. b) Ref. 3.

and nonbonded interactions, though the *N*-methyl-(*S*)-alaninate ring adopts a strained, near-planar, conformation: Torsional strain for N5–C8 bond is 1.5 kcal/mol Λ-(*R*)-*S*, 0.6 Λ-(*S*)-*R*, 0.8 Λ-(*R*)-*R* and 0.8 Λ-(*S*)-*S*. The strain due to the *N*-methyl group extends the Co–N5 bond (2.02 Å, 0.6 kcal/mol) in all isomers, and distorts the Co–N5–C(N5) angle, Λ-(*R*)-*S* 118° (0.6 kcal/mol), Λ-(*S*)-*R* 120° (1.0), Λ-(*R*)-*R* 115° (0.3), and Λ-(*S*)-*S* 122° (1.3). The *N*-methyl group causes significant nonbonded interactions in all four isomers. In the case that the *N*-methyl group has the *S* configuration, nonbonded interactions between the *N*-methylalaninate and the adjacent chelate ring are considerably large: the H2···H30 (2.16 Å, 0.5 kcal/mol) and H3···H31 (2.14 Å, 0.6) in the *N*-methyl-(*R*)-alaninato complex, and H3···H28 (2.09 Å, 0.7) and H3···H31 (2.14 Å, 0.6) in the *N*-methyl-(*S*)-alaninato complex. In the complexes with *N*(*R*)-methyl group close contacts arise between the N–H proton and the *N*-methylalaninate ring: the C(C8)···H7 (2.45 Å, 0.5 kcal/mol), C(N5)···H20 (2.42 Å, 0.6), H2···H30 (2.11 Å, 0.7), and H3···H7 (2.09 Å, 0.7) in the *N*-methyl-(*S*)-alaninato complex, and the C(C8)···C(N5) (2.80 Å, 0.7), H3···H20 (2.13 Å, 0.6), and H5···H30 (2.12 Å, 0.6) in the *N*-methyl-(*R*)-alaninato complex.

The stability order and the calculated strain energy differences are in good agreement with the experimental results, though the strain energy of the Λ-(*S*)-*R* isomer was underestimated. This result suggested that the main source of the destabilization of the Λ-β_2-[Co(*N*-Me-(*R*)-ala)(N_4)]$^{2+}$ ions and the absence of the Λ-(*S*)-*S* isomer was due mostly to serious intramolecular strain energy. From the viewpoint of asymmetric transformation, *N*-substitution of the alaninate results in a striking improvement of the chiral selectivity in the *N*-methylalaninato complexes, in comparison with that for the

corresponding alaninato complexes.[1)]

Gas Chromatography under the Column Outlet Pressure Higher than Atmospheric

Koji Takeuchi, Kunio Ohzeki, and Tomihito Kambara*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 18, 1979)

The effects of column outlet pressures on the HETP *vs.* carrier gas velocity curves are discussed on the basis of KOS theory. It is shown that when a column is operated at a constant outlet pressure higher than atmospheric the minimum of H-$\bar{u}$ curve shifts towards lower HETP and $\bar{u}$ values, and on the contrary the operation at reduced outlet pressure results in the shift of the minimum towards higher HETP and $\bar{u}$ values. The separation factor and number of theoretical plates obtained by a column operated at the outlet pressure of 4.0 atm are superior by *ca.* 10% to those obtained by normal gas chromatography.

Gas chromatographic columns are almost always operated under the constant outlet pressure of atmospheric. On the one hand, Haruki[1] investigated the gas chromatography under reduced pressure and concluded that the reduced pressure operation offered no advantage over normal atmospheric pressure operation. Recently, Hatch and Parrish[2] using capillary columns reported that at the optimum flow velocity, the reduced pressure operation produced efficiencies *ca.* 30% lower than those of normal gas chromatographic operation. On the other hand, Halasz *et al.*[3] and Novak and Bocek[4] reported that the column operation under the outlet pressure higher than atmospheric resulted in an improved column efficiencies. The problems were discussed theoretically on the basis of the van Deemter equation.[5,6] However, the equation being derived from the assumption of a uniform mobile phase velocity,[7] the application of the theory to gas chromatography requires an essential revision especially with respect to the pressure drop along the column.

In our previous papers,[8,9] a new equation for HETP was derived from the kinetic viewpoint, in which the pressure dependence of the diffusion coefficient in gas phase and the non-linear carrier gas velocity distribution along the column were dealt with mathematically. The validity of KOS theory[9] was confirmed experimentally in the study of the dependencies of HETP on carrier gas flow rate[9] and column length.[10] The present work aims at obtaining a clearer understanding of the effects of column outlet pressure higher than atmospheric on the HETP. The column efficiencies of the reduced pressure gas chromatography are also discussed theoretically.

Theoretical

According to KOS theory, the HETP is given by

$$H = \frac{l}{n} = \frac{9D^*l}{2w} \times \frac{(p_i^4 - p_o^4)}{(p_i^3 - p_o^3)^2} + \frac{3wF_s^2\beta^2}{2\alpha FK^2l} \times \frac{(p_i^2 - p_o^2)^2}{(p_i^3 - p_o^3)}, \quad (1)$$

where n the number of theoretical plates of a column of length l, D^* the diffusion constant under unit pressure, w permeability coefficient, p_i and p_o the inlet and outlet pressures, F and F_s the volume fractions occupied by the mobile and stationary phases, K the distribution coefficient (the ratio of concentration in the mobile phase to that in the stationary phase), α the rate constant of dissolution and β is given by

$$\frac{1}{\beta} = \frac{t_R}{t_0} = 1 + \frac{F_s}{KF}, \quad (2)$$

where t_R is the retention time of a given component and t_0 is that of air peak. The latter corresponds to the passing time of carrier gas through the whole column, and is the function of p_i and p_o,[11] namely,

$$t_0 = \frac{4l^2(p_i^3 - p_o^3)}{3w(p_i^2 - p_o^2)^2} \quad (3)$$

The average carrier gas velocity $\bar{u}$, is given by

$$\bar{u} = \frac{l}{t_0}. \quad (4)$$

The carrier gas flow-rate v, is given by the famous Darcy equation:

$$v = qu_op_oF = \frac{wqF(p_i^2 - p_o^2)}{2l}, \quad (5)$$

where q is the proportionality factor and u_o is the outlet linear velocity.

Equation 1 can be rearranged into

$$y = a + bx, \quad (6)$$

where

$$y = \frac{(p_i^3 - p_o^3)^2}{n(p_i^4 - p_o^4)} \quad (7)$$

$$x = \frac{(p_i^2 - p_o^2)(p_i^3 - p_o^3)}{(p_i^2 + p_o^2)} \quad (8)$$

$$a = \frac{9D^*}{2w} \quad (9)$$

and

$$b = \frac{3wF_s^2\beta^2}{2\alpha FK^2l^2}. \quad (10)$$

Experimental

The measurements were carried out with a Hitachi Model 063 gas chromatograph equipped with a Hitachi 056 recorder, thermal conductivity detertor being used. The sample cell outlet was connected to a pressure gauge and a needle valve, so that the column outlet pressure is controlled, the arrangement being almost the same as reported by Novak and Bocek.[4] Helium was used as carrier gas. The flow-rate was measured with a soap-film meter and corrected for the water vapor pressure. The stainless steel column of 1 m by 0.3 cm i.d. was packed with 25% dinonyl phthalate on 80—100 mesh Shimalite BT. The packed column was preconditioned for 10 h at 130 °C under an appropriate helium flow. The measurements of HETP were carried out at

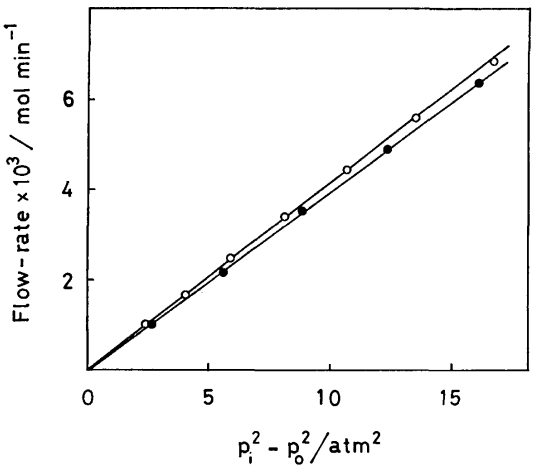

Fig. 1. Helium flow-rate plotted against $(p_i^2-p_o^2)$ at the constant outlet pressures: (○) p_o 1.0 atm, p_i 1.8—4.2 atm; (●) p_o 3.0 atm, p_i 3.4—5.0 atm. Column: 1 m by 0.3 cm i.d., 25% DNP on Shimalite BT, 74.0 °C.

the column temperature of 74.0 °C, employing benzene as a solute. The sample sizes of 0.8, 0.6, 0.4, and 0.2 μl were injected twice at each level. The numbers of theoretical plates were calculated from the formula[12]

$$n = 5.55(t_R/W_{1/2})^2, \quad (11)$$

where t_R and $W_{1/2}$ designate the peak maximum distance from the start line and the peak width at the half peak height, respectively, and extraporated to zero charge of sample amount. Peak asymmetry was estimated from the skewness which is defined as the ratio of the slopes of tangents at the inflection points of both sides of the peak.[13] The mean carrier gas velocity was evaluated from the retention time of air peak. The effect of column outlet pressure on the separation of adjacent peaks 1 and 2 was estimated from the value:[12]

$$R = \frac{2(t_{R-2}-t_{R-1})}{W_1+W_2} \quad (12)$$

Results and Discussion

In Fig. 1, the carrier gas flow-rate was plotted against $(p_i^2-p_o^2)$ for the column operations under atmospheric and increased outlet pressures. Both lines showed good linearity as expected from Eq. 5, only a slight difference in the slopes being found. The dependence of passing time of air peak on the pressure differences was shown in Fig. 2. The relationship between $\bar{u}$ and pressure drop given by Eqs. 3 and 4 can be now written as

$$\bar{u} = \frac{4.8(p_i^2-p_o^2)^2}{p_i^3-p_o^3}, \quad (13)$$

where $\bar{u}$ is expressed in cm s^{-1} and the coefficient 4.8 is evaluated from dividing the column length of 100 cm by the slope of plot in Fig. 2.

The effects of column outlet pressure on column efficiency were illustrated in Figs. 3 and 4. In Fig. 3, the validity of Eq. 6 was confirmed, the linear regression equation being determined as

$$y = 1.73\times10^{-3} + 2.29\times10^{-4}\,x$$

for atmospheric outlet pressure operation and

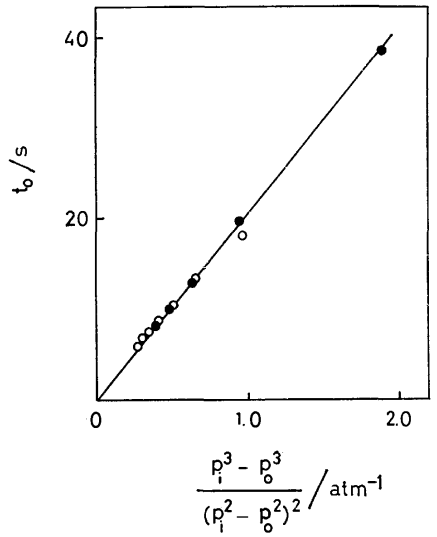

Fig. 2. Dependence of passing time of carrier gas on the inlet and outlet pressures. The open and closed circles have the same meanings as in Fig. 1.

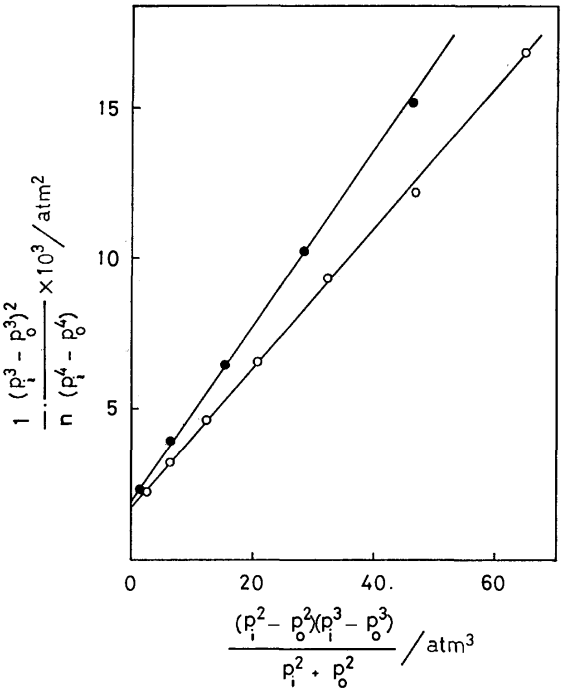

Fig. 3. Effect of column inlet and outlet pressures on HETP (*cf.* Eq. 6). The symbols on each line are the same as in Fig. 1.

$$y = 1.98\times10^{-3} + 2.88\times10^{-4}\,x$$

for the elevated outlet pressure of 3.0 atm. The 95% confidence limits of the expected value of y when $x=0$ were $(1.73\pm0.29)\times10^{-3}$ and $(1.98\pm0.22)\times10^{-3}$, respectively. No significant difference was found between the intercepts at the significance level of 5% (t-test). On the other hand, the regression coefficients with 95% confidence limits being $(2.29\pm0.08_6)\times10^{-4}$ and $(2.88\pm0.08_7)\times10^{-4}$, respectively, the difference between the slopes was highly significant. The β value and hence the K value being constant and independent of pressure drop as shown in Table 1, the variation in the slopes of lines may be due to the change

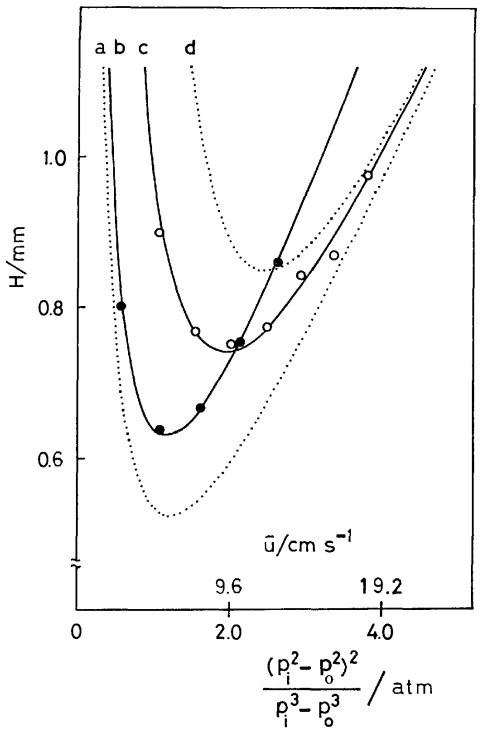

Fig. 4. Dependence of H-$\bar{u}$ curves on the column inlet and outlet pressures. Solid lines b and c are experimentally obtained H-$\bar{u}$ curves. The symbols have the same meanings as in Fig. 1. Dotted lines denote theoretically obtained H-$\bar{u}$ curves by the combination of Eqs. 13 and 14, inserting the values: (a) p_o 3.0 atm, p_i 3.3—6.6 atm; (d) p_o 0.1 atm, p_i 1.5—4.4 atm.

in the rate constant α of dissolution caused by the pressure change.

Inserting the numerical values obtained from the atmospheric outlet pressure operation into Eq. 1, the column length being 1000 mm, one derives

$$H/\text{mm} = \frac{1.73(p_i^4-p_o^4)}{(p_i^3-p_o^3)^2} + \frac{0.23(p_i^2-p_o^2)^2}{p_i^3-p_o^3}. \quad (14)$$

The so-called H-$\bar{u}$ curves were shown in Fig. 4, in which the solid lines on the plots were obtained from the regression equations. The dotted lines were illustrated by combining the calculated values of Eqs. 13 and 14. When Eq. 14 holds for the operation at column outlet pressure of 3 atm, curve a in Fig. 4 is given. The shift of the minimum towards lower $\bar{u}$ and H values is obviously found in the theoretically predicted H-$\bar{u}$ curve and experimentally obtained one, although the curves do not coincide completely each other as discussed previously. On the other hand, in the case of gas chromatography under the reduced column outlet pressure of 0.1 atm, the shift of the minimum towards higher $\bar{u}$ and H values is predicted as shown by curve d in Fig. 4. This tendency was already experimentally observed by Hatch and Parrish.[2]

The column operation under the increased pressure resulted in peaks with leading shape, the skewness decreasing with decreasing sample amount as shown in Fig. 5. It is interesting to compare the results

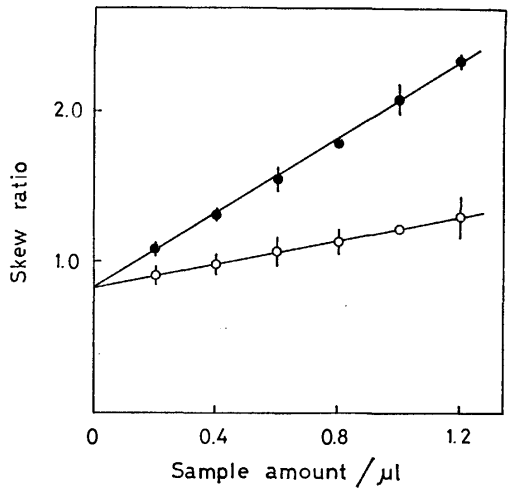

Fig. 5. Effects of pressure drop and sample amount on the skew ratio of benzene peak. The column inlet and outlet pressures are: (○) p_o 1.0 atm, p_i 2.4 atm; (●) p_o 4.0 atm, p_i 4.8 atm. Other conditions are the same as in Fig. 1. The vertical line on each plot denotes 95% confidence limits.

Table 1. Constancy of β value

Pressure/atm	$1/\beta = t_R/t_0 = 1+F_s/KF$
$p_o=1.0$	
$p_i=1.8-4.2$	$17.0_8 \pm 0.1_2$ $(n=7)$
$p_o=3.0$	
$p_i=3.4-5.0$	$16.9_7 \pm 0.3_8$ $(n=5)$

with that reported by Haruki,[1] who observed that the gas chromatography under the reduced pressure gave the peaks with trailing shape with decreasing inlet and outlet pressures.

An attempt was made to find the effect of the increased column pressure on the resolution. A 0.6 μl portion of a mixture containing 0.3 μl benzene, 0.1 μl ethylbenzene, 0.1 μl of *m*- and *o*-xylenes was chromatographed at 94.4 °C under the various outlet and inlet pressures, namely, one combination is $p_o=1.0$ and $p_i=1.8-3.6$ atm and the other is $p_o=4.0$ and $p_i=4.4-4.5$ atm. The resolution of ethylbenzene from *m*-xylene and the number of theoretical plates for *o*-xylene were calculated. At the optimum flow-rate, the elevated pressure operation resulting in the peaks with longer retention time produced both the column efficiency and the resolution *ca.* 10% higher than those of normal operation.

(Received September 20, 1979)

Alkali and alkaline earth metal salts of 2,2′,4,4′,6,6′-hexanitrodiphenylamine (HND) were extracted into nitrobenzene in the absence or presence of several crown ethers or cryptands which differ from one another in hole size. The quantity of water transferred to the nitrobenzene phase was determined by means of the Karl-Fischer method. The NMR and near-infrared spectra show that the coextraction of water is caused by the hydration of the cations. The number of water molecules attached to the cations increases upon going from Cs^+ (0.6) to Li^+ (5.6) and from Ba^{2+} (10.5) to Ca^{2+} (13.0). The complexation between these cations and the crown ethers causes a clear decrease in the hydration number; *e.g.*, in the 1:1 metal–crown ether complexes, more than half of the water molecules are removed, and in the 1:1 metal–cryptand complexes, less than one water molecule remains unremoved. The complexes of a 1:2 stoichiometry are also found; some are stable and carry virtually no water molecules. The number and type of donor atoms have no significant effect on the coextraction of water. The presence of fused benzo rings on the crown ether also has no influence on the number of water molecules.

Recently, interest in the coextraction of water into organic solvents with ion-pairs has been increasing.[1–5] In a previous paper,[6] it was shown that, when aqueous solutions containing alkali metal salts of 2,2′,4,4′,6,6′-hexanitrodiphenylamine (HND) are shaken with nitrobenzene, the water molecules strongly associated with the salts are transferred to the nitrobenzene phase.

It is well known that crown ethers and cryptands combine stoichiometrically with alkali and alkaline earth metal cations to form complexes, in which the cation is accommodated into the molecular hole of the ligand. Depending on the relative size of the hole and the metal ion, 1:1, 1:2, and 2:3 complexes are formed. In some complexes of small crown ethers, the cation lies in or slightly above the donor plane in the solid state;[7,8] a few of them are known to have the same structure in solution as well.[9] This 'metal in the hole' structure does not require a stripping of the entire hydration shell of the ion, since the contact of water molecules with the cation is still possible in the direction perpendicular to the plane of the donor ring. With regard to some solid cryptates, the cation has been found to be enclosed in the molecular cage of the ligand.[10] The cation, therefore, can be expected to exist as an unhydrated or only slightly hydrated state.

In the present study, the number of water molecules attached to alkali and alkaline earth metal complexes with several crown ethers and cryptands has been determined in order to make clear the effect of the ligands on the cation hydration. The number of the water of crystallization was also determined with the alkaline earth metal salts of HND and their complexes with dibenzo-18-crown-6 by means of thermogravimetric analysis.

Experimental

Materials. Commercial HND was purified by repeated recrystallizations from acetone. *N*-(2,4,6-trinitrophenyl)-2,4-dinitro-1-naphthylamine (TDN) was obtained by the reaction between 2-chloro-1,3,5-trinitrobenzene and 1-naphthylamine, followed by nitration.[11] 1,3,7,9-Tetranitrophenothiazine 5-oxide (TPO) was prepared by the nitration of phenothiazine.[12,13] The TDN and TPO thus obtained were recrystallized from acetic acid; their alkali and alkaline earth metal salts were prepared by treating these amines with the corresponding metal carbonate or hydroxide.

The crown ethers used were benzo-12-crown-4 (B12C4), 15-crown-5 (15C5), benzo-15-crown-5 (B15C5), 18-crown-6 (18C6), benzo-18-crown-6 (B18C6), dibenzo-18-crown-6 (DB18C6), dibenzo-24-crown-8 (DB24C8), and 5,6-benzo-4,7,13,16-tetraoxa-1,10-diaza-5-cyclooctadecene (2.2B). 15C5, 18C6, and DB24C8 were obtained from the Nisso Co., Ltd. The first two were used without further purification. DB24C8 was recrystallized from chloroform and then ethanol. B12C4, B15C5, B18C6, and DB18C6 were synthesized and purified by the method of Pedersen.[14] 2.2B was obtained from 3,6-dioxa-1,8-octanediamine and 1,2-bis(chloroformylmethoxy)benzene by the method of Dietrich *et al.*;[15] the product obtained was recrystallized from 4-methyl-2-pentanone. 2.2B was found to be a monohydrate by measuring the weight loss on heating.

The cryptands, 4,7,13,18-tetraoxa-1,10-diazabicyclo[8.5.5]-eicosane (2.1.1), 4,7,13,16,21-pentaoxa-1,10-diazabicyclo-[8.8.5]tricosane (2.2.1), 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane (2.2.2), and 5,6-benzo-4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacos-5-ene (2.2.2B), were purchased from Merck and well used without further purification.

Some crown ether complexes were crystallized from methanol–water mixtures.

The nitrobenzene was treated with an aqueous sodium carbonate solution and washed with water several times prior to use.

Measurements. A nitrobenzene solution (20 cm^3 for crown ethers and 5 cm^3 for cryptands) containing the ligands (0—0.03 mol dm^{-3}) and HND or the other polynitro-substituted amines (0—0.01 mol dm^{-3}) was shaken with an equal volume of an aqueous alkali or alkaline earth metal chloride solution for 1 h at (25±0.01) °C in a thermostated water bath, the ionic strength being adjusted to 0.1 mol dm^{-3}, and the pH, to about 12, with the corresponding metal chloride (or sulfate) and hydroxide (or carbonate).

a) z^2/r_c values.

The water-content in the nitrobenzene phase was determined by the use of a Mitsubishi Kasei CA-01 Karl-Fischer titrator. Nitrobenzene was treated with an aqueous solution under the same conditions, and the water-content increments, Δs, were obtained. The total metal concentration in the nitrobenzene phase, $[M(t)]_o$, was calculated from the difference between the total quantity of HND and the quantity of HND anions found in the aqueous phase by the use of Hitachi 124 spectrophotometer. The total concentration of the ligand, L, in the nitrobenzene phase, $[L(t)]_o$, was obtained by measuring the quantity of L left unextracted in the aqueous phase in the following manner: to the aqueous phase, a large excess of potassium chloride (sodium chloride for 15C5 and B15C5; lithium chloride for B12C4) and an excess of HND were added. L was then extracted as the potassium complex into benzene (1,2-dichlorobenzene for B12C4, 15C5, and B15C5). The concentration of the complex in the benzene phase was determined spectrophotometrically. From the total quantity of L and the concentration of the complex thus obtained, $[L(t)]_o$ was calculated.

The conductance measurements in nitrobenzene were carried out at (25±0.005) °C by the use of a universal bridge (Ando Electric Co., Ltd., LCR 10) equipped with platinized platinum electrodes.

The thermogravimetric curves were obtained on a Rigaku Denki TG unit under a nitrogen flow of about 30 cm³/min. The temperature rise was 0.625 °C/min.

Results and Discussion

Hydration of the Uncomplexed Cations. Nitrobenzene dissolves water at a concentration of 0.178 mol dm^{-3} at 25 °C, while a nitrobenzene solution containing the alkali or alkaline earth metals dissolves a slightly greater quantity of water. The quantity of water coextracted increases linearly with the increase in the metal concentration, as is shown in Fig. 1. From the slope of each line, the quantity of water coextracted, $h(M^{n+})$, is calculated.

Table 1 shows that the values of $h(M^{n+})$ increase linearly with the ratio of the charge to the ionic radii of the cations, z^2/r_c, except for those of the heavy alkali metals (K^+, Rb^+, and Cs^+). The $h(M^{n+})$ values are found not to be dependent on the anion species used. In general, bulky univalent anions are believed not to be hydrated in solution. These values, therefore, are assumed to be identical with the hydration numbers of the cations.

Stokes and Robinson, on the other hand, obtained the hydration numbers of the alkali and alkaline earth metal chlorides in an aqueous solution by means of activity measurements (Rb^+ 1.2, K^+ 1.9, Na^+ 3.5, Li^+ 7.1, Ba^{2+} 7.7, Sr^{2+} 10.7, and Ca^{2+} 12.0).[16] These

$Ca(HND)_2$: 0.01 mol dm^{-3}.

values are similar in magnitude to the corresponding $h(M^{n+})$ values listed in Table 1. This fact suggests that the cations in the aqueous phase carry water into the nitrobenzene phase without being stripped

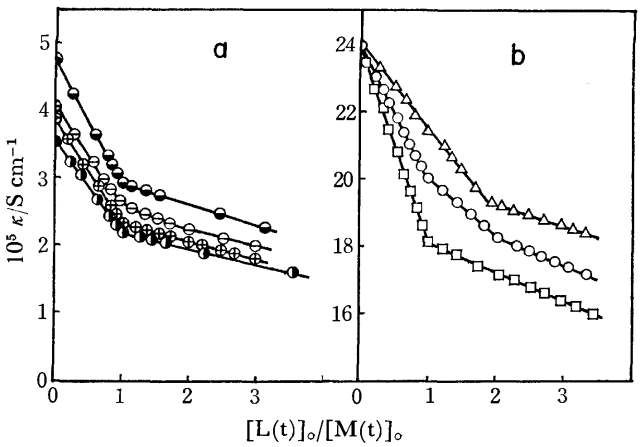

Fig. 3. Conductometric titration curves of the alkali metal and Ba^{2+} salts of HND.
a: DB18C6 complexes with Na^+ (⊕), K^+ (◒), Rb^+ (◑), and Cs^+ (⊖). Concentrations of the HND salts: Na^+ 0.01, K^+ 0.02, Rb^+ 0.01, and Cs^+ 0.012 mol dm^{-3}. b: Ba^{2+} complexes with 15C5 (△), 18C6 (○), and DB24C8 (□). The concentration of Ba(HND)$_2$: 0.005 mol dm^{-3}.

of the water molecules attached to them when they pass through the interface.

In a previous paper,[17] it was shown that the NMR and near-infrared spectra gave information concerning the behavior of water in a nitrobenzene solution containing the calcium salt of HND. The infrared spectra were also found to be useful for the investigation of water in the nitrobenzene solution. The transmittance, T %, of a 0.01 mol dm^{-3} solution of anhydrous Ca(HND)$_2$ in dry nitrobenzene was measured in the presence of varying amounts of water at 3660 cm^{-1}. The T % decreases with an increase in the water concentration, as is shown in Fig. 2. The curve obtained can be approximated by two line portions; the value of 13.3, which is obtained from the concentration ratio of water to Ca^{2+} at the intersection, agrees quite well with the $h(M^{n+})$ value for Ca^{2+}. It can thus be concluded that, when water is added to the nitrobenzene solution of Ca(HND)$_2$, the water binds exclusively to Ca^{2+}, and that the excess water then disperses into the solvent.

Complex Formation. The stoichiometries of the complexes in nitrobenzene were determined by means of conductometric titration. As an illustration, the conductometric titration curves for alkali metal–DB18C6 complexes and for some Ba^{2+}–crown ether complexes are shown in Fig. 3. The addition of ligands to the salts on HND in nitrobenzene results in a decrease in the specific conductance, κ. All the curves except for $Ba(15C5)^{2+}$ break at the first equivalence point, indicating the formation of stable complexes of a 1:1 stoichiometry. $Cs(DB18C6)^{2+}$ may be less stable than the others, because its titration curve shows no clear change at the equivalence point; this finding does not, however, necessarily mean the absence of the 1:2 complexes, as will be seen later.

The conductivity data of the alkali metal and ammonium–DB18C6 complexes in nitrobenzene were analyzed by means of the method of Schedlovsky.[18]

Table 2. Λ° and λ° values (S cm^2 mol^{-1}), together with the ion-pair formation constants, K

M^+	Λ°(M(L)HND)	$\lambda^\circ(ML^+)$	$\lambda^\circ(M^+)$	K/mol^{-1} dm^3 [a]
Na	21.4	9.6	16.3[b]	10
K	21.4	9.6	17.8[b]	7
Rb	21.5	9.7	—	8
NH_4	21.1	9.3	18.4[b]	5

a) $K=[M(L)HND]/[ML^+][HND^-]$. b) From Ref. 19.

The limiting equivalent conductivities, Λ°, were found to differ not all from one another. The limiting ionic equivalent conductivity for the anion of HND could be determined to be $\lambda^\circ(HND)=11.8$ S cm^2 mol^{-1}. The values of $\lambda^\circ(ML^+)$, therefore, were determined by using the $\lambda^\circ(M^+)$ values reported by Witschonke and Kraus.[19] Table 2 shows that the $\lambda^\circ(ML^+)$ values are not affected by the size of the central cation and are smaller than the λ° values for the uncomplexed cations. The K values in Table 2 show that virtually no ion-pairs are formed between ML^+ and the anion of HND. It is clear that ML^+ is much bulkier than M^+ and that the effective size of ML^+ is exclusively determined by the ligand size. These findings strongly support the view that ML^+ exists as a complex with the 'metal in the hole' structure, even in a dissolved state.

Hydration of the Free Ligands. As can be seen from Fig. 1, water is also coextracted with uncomplexed DB18C6. The Δs values for L were measured by means of the extraction method in the absence of HND. Under such conditions, the transfer of ligand as complexes was neglected. The number of water molecules attached to a molecule of a ligand, h(L), can be calculated from the slope of the plot. The data thus obtained, together with the hole diameters,[20,21] are summarized in Table 3.

Table 3 shows that the free ligands exist in a slightly hydrated form in the nitrobenzene phase. The benzo derivatives seem to be less hydrated. It should be noted that 2.2B exists as a monohydrate not only in the nitrobenzene phase, but also in the solid state. 18C6 and the uncomplexed potassium ion have 1.6 and 1.3 water molecules respectively, while the complex has only 0.3 water molecule. From these data, it is possible to assume that 1.6 water molecules are bound inside the ligand hole.

Hydration of the Complexed Cations, ML^{n+}. The number of water molecules attached to the complexed cations, $h(ML^{n+})$, is obtained from the slope of the Δs-$[M(t)]_0$ plot (Fig. 1) when 1:1 complexes alone are known to exist in the nitrobenzene phase. The $h(ML^{n+})$ values can also be obtained from an h-a plot, as is shown in Fig. 4, where $h=\Delta s/[M(t)]_0$ and $a=[L(t)]_0/[M(t)]_0$.

For a given metal cation, the h value at $a=0$ in Fig. 4, for example, is identical with the $h(M^{n+})$ value. Since ML^{n+} is less hydrated than M^{n+}, the h values decrease with the addition of L to a solution containing M^{n+} and HND anions ($a<1$). The intensity of the orange-red color of the aqueous phase, which shows the presence of HND anions, also decreases upon the addition of L. At the first equivalence point ($a=1$),

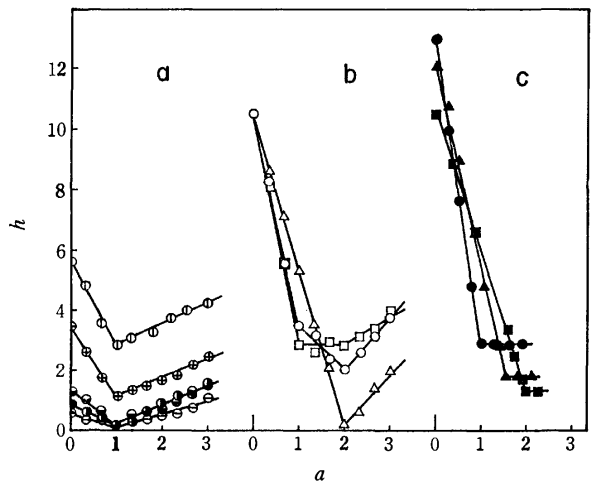

Fig. 4. Effect of the ligands on the coextraction of water.
a: Alkali metal complexes with DB18C6, Li^+ (◐), Na^+ (⊕), K^+ (◒), Rb^+ (◑), and Cs^+ (⊖). b: Ba^{2+} complexes with 15C5 (△), 18C6 (○), and DB24C8 (□) c: Alkaline earth metal complexes with 2.1.1, Ca^{2+} (●), Sr^{2+} (▲), and Ba^{2+} (■).

the aqueous phase becomes colorless, indicating the complete transfer of the HND anions as ion-pairs, M(L)HND or $M(L)HND_2$, from the aqueous to the nitrobenzene phases. As regards the Ba^{2+} complex with 15C5, the curve in Fig. 4(b) shows no change at $a=1$. This is also the case for the other 1:2 complexes listed in Table 4. The conductometric titration curves (Fig. 3) for these complexes also fall off smoothly until $a=2$, indicating that the 1:1 complexes do not exist or are not so stable as the 1:2 complexes. Figure 4(b) shows that the alkaline earth metals form 1:2 complexes with the crown ethers, whereas, in some instances, the formation of the 1:2 complexes is not clear from the conductometric titration curves. In the crown ether complexes, the h values calculated from the slopes of the third line portions ($a>2$) are identical with the h(L) values; this indicates that no 1:2 complexes undergo further complexation.

The cryptands used form stable 1:1 complexes with the alkali and alkaline earth metals. It must be noted that 2.1.1 forms the 1:2 complex with Ba^{2+} and the 2:3 complex with Sr^{2+} (Fig. 4(c)). The fact that these 1:1 complexes are not formed between these cations and the cryptand is evident from the observation of the color change in the aqueous phase.

The h values obtained with the 1:1 complexes, together with those for the 1:2 and 2:3 complexes, are listed in Table 4. If the 1:2 alkaline earth metal–crown ether complexes are sufficiently stable, the $h(ML_2^{2+})$ values can be determined from h values at $a=2$, but they are omitted from Table 4 because the stability data are lacking.

Table 4 shows that the number of water molecules attached to the metal cations decreases on complexation; roughly speaking, the $h(ML^{n+})$ values are reduced to less than one-half the $h(M^{n+})$ values. The number of water molecules released, for example, amounts roughly to as much as 6—8 for the alkaline earth metals. The heavy alkali metal complexes lose virtually all the water molecules on complexation. It is noteworthy that Sr^{2+} and Ba^{2+} complexes with 15C5 and B15C5 have no water molecules. B12C4 forms no stable complex with any of the cations tested except for Li^+, as can be expected from its small hole size (*cf.* Table 3). 2.2B also forms no complex with Cs^+, though the reason for this is not known.

The h values for the metal–cryptand complexes (cryptates) are listed in Table 5. It is clear that the cryptates are much less hydrated than the crown ether complexes. Two important features are that the cryptates always have about one water molecule and

Table 5. The number of water molecules coextracted with the 1:1 cryptands, $h(ML^{n+})$

M^{n+}	L			
	2.1.1	2.2.1	2.2.2	2.2.2B
Li	0.7	0.9	1.0	1.2
Na	0.4	0.8	0.5	0.5
Ca	2.9	0.6	1.0	1.3
Sr	1.8[a)]	0.7	1.2	1.2
Ba	1.3[b)]	0.8	1.2	1.0

a) M:L=2:3. b) M:L=1:2.

the h values are not affected by the cation size.

Complex Structures. For some crown ether complexes, the 'metal in the hole' structure is proved in the crystalline state and in solution. The complex formation, therefore, does not necessarily require a stripping of the entire hydration shell of the cation. The molecular holes of 15C5 and B15C5 are so small that Sr^{2+} and Ca^{2+} can not be well accommodated. Hence, these crown ethers form 1:2 complexes of a sandwich-type structure, in which the metal cation is located between the two parallel rings consisting of five donor atoms. In the complexes of this type, the number of donor atoms is twice as many as that in the 'metal in the hole' structure. It is, therefore, not likely that no binding sites of the metal cation are left for the further coordination of water molecules. In the alkaline earth metal–crown ether complexes, it can also be noted that the number of water molecules released by complexation is roughly equal to that of the donor atoms.

Table 5 shows that all the 1:1 cryptates except for $Ca(2.1.1)^{2+}$ are associated with only 0.4—1.3 water molecules; this finding is in striking contrast to the results obtained with the crown ether complexes. Such a marked decrease in the h values strongly supports the 'metal in the cage' structure. In solid complexes of 2.2.2 with $CaBr_2$[22] and $BaSCN_2$,[23] the cations are known to be coordinated by one water molecule in each case. It, therefore, likely seems that the 0.4—1.3 water molecules are attached to the central cation by coordination, even in the nitrobenzene phase.

As can be seen from Table 5, $Ca(2.1.1)^{2+}$ is highly hydrated; the fact may suggest that Ca^{2+} is surrounded by the ligand, as in typical crown ether complexes. Ba^{2+} is much larger than the hole size of 2.1.1 and forms 1:2 complexes with it. From analogy with potassium B15C5,[24] a sandwich structure is inferred for the cryptate. A 'club sandwich' structure is postulated for a 2:3 crown ether complex, in which three ligands are arranged as planes in three tires, each separated from the next by a metal cation.[20] With regard to the cryptate formed between Sr^{2+} and 2.1.1, however, such a structure is unlikely, because 2.1.1 is not a planar molecule like crown ethers.

Thermogravimetric Analysis. Li^+, Ca^{2+}, Sr^{2+}, and Ba^{2+} salts of HND were found to have 4, 11, 4, and 4 molecules of water of crystallization respectively. For the Ba^{2+} salt, a crystal with two molecules of water of crystallization was found. The stoichiometries of the crystalline solids of the alkaline earth metal–crown ether complexes were determined from the thermogravimetric curves by the help of the spectrophotometric method ($Ca(DB18C6)_2HND_2\cdot 6H_2O$, $Sr(DB18C6)_2HND_2\cdot 6H_2O$, and $Ba(DB18C6)_2HND_2\cdot 5.5H_2O$).

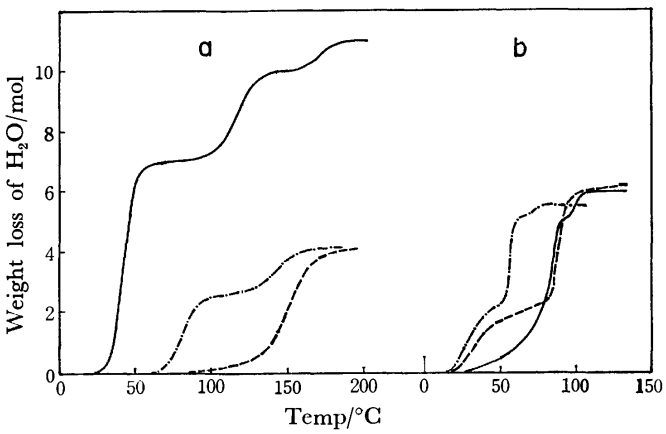

Fig. 5. Thermogravimetric analysis of water of crystallization.
a: $Ca(HND)_2\cdot 11H_2O$ (—), $Sr(HND)_2\cdot 4H_2O$ (----), and $Ba(HND)_2\cdot 4H_2O$ (——). b: $Ca(DB18C6)_2HND_2\cdot 6H_2O$ (——), $Sr(DB18C6)_2HND_2\cdot 6H_2O$ (— — —), $Ba(DB18C6)_2HND_2\cdot 5.5H_2O$ (——).

As an illustration, the thermogravimetric curves are shown in Fig. 5. In most cases, the thermal dehydration occurs in multistages in the range from about 30 to 180 °C. The DB18C6 complexes are found to lose their water of crystallization completely below about 100 °C; such is the case with 18C6. The uncomplexed salts still have some molecules of water of crystallization above 100 °C. It can be concluded that alkaline earth metal cation–water molecule bonds are much weaker in the complexes than in the uncomplexed salts. There are some instances in which h values are closely related to the number of water of crystallization. For example, Yamamoto *et al.* found that the ion-pairs formed between $Fe(phen)_3^{2+}$ (where phen refers to 1,10-phenanthroline) and ClO_4^-, SCN^-, I^-, and Br^- are accompanied by 1, 2, 2, and 6 water molecules respectively in the solid state and in the nitrobenzene phase as well.[25] In the present investigation, however, no such fine correlation was found. It can be recognized that large cations are at least less hydrated than smaller ones, both in the solid state and in the nitrobenzene phase.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture.

The Thermal Cycloaddition of Dispiro[2.2.2.2]deca-4,9-diene to Isolated Carbon-Carbon Multiple Bonds

Tohru SHIBATA, Takashi TSUJI,* and Shinya NISHIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 26, 1979)

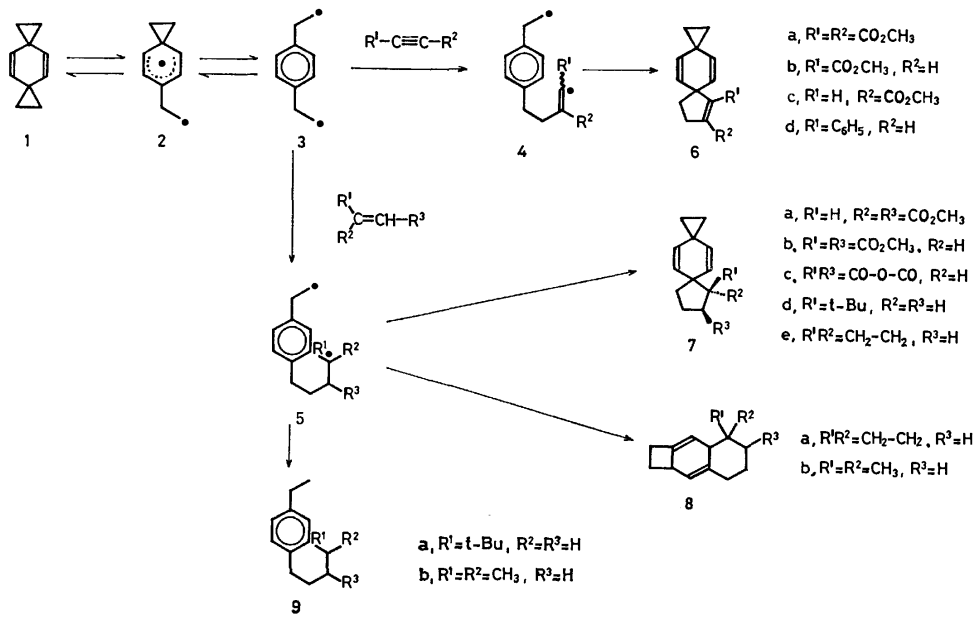
The cycloadditions of dispiro[2.2.2.2]deca-4,9-diene (**1**) to isolated carbon-carbon multiple bonds have proceeded in two different modes, giving dispiro[2.2.4.2]dodeca-4,11-diene and tricyclo[6.4.0.0^{3,6}]dodeca-2,7-diene derivatives. Mono- and 1,2-disubstituted olefins and acetylenes gave the former adducts, whereas 1,1-disubstituted olefins gave the latter, as the major products. Evidence for the intermediacy of biradicals is provided. The observed difference in the mode of the cycloaddition is explained in terms of the stereoelectronic and/or steric effects in the transition state for the cyclization of the intermediate. The addition of **1** to tetracyanoethylene (TCNE) in wet acetone has proceeded *via* a zwitterionic intermediate(s), giving a 1:1:1 adduct of **1**, TCNE, and water.

We have previously reported the thermal cycloaddition reactions of dispiro[2.2.2.2]deca-4,9-diene (**1**) with some conjugated unsaturated compounds[1] which demonstrated the one-step production of [8]paracycloph-4-enes,[1] [4.2]paracyclophanes,[2] and 3-oxa[8]paracycloph-4-enes.[3] As a further inverstigation of the chemistry of **1**, we have now studied the reactions of **1** with compounds possessing an isolated carbon-carbon multiple bond. In the present paper, two novel types of the cycloadditions of **1**, giving dispiro[2.2.4.2]dodeca-4,11-diene and tricyclo[6.4.0.0^{3,6}]-dodeca-2,7-diene derivatives (**7** and **8**) will be described, and the evidence supporting the intermediacy of biradicals will be presented. We will also report the reaction of **1** with tetracyanoethylene (TCNE), which seems to proceed *via* dipolar intermediate(s).

Results

Addition Reactions Giving Dispiro[2.2.4.2]dodeca-4,11-diene Derivatives (7). As was reported briefly in the previous report,[1] **1** adds to dimethyl maleate (**10**) and dimethyl acetylenedicarboxylate (**11**) to give dispiro[2.2.4.2]dodecane derivatives, **7a** (42%) and **6a** (62%) respectively, under conditions (*ca.* 155 °C) giving rise to the homolytic scission of the cyclopropane ring in **1**. We have now further investigated the cycloaddition reactions of **1** to other unsaturated compounds possessing an isolated carbon-cabon multiple bond in order to examine the generality and the stereochemistry of the reactions.

The reactions were carried out as has previously been reported in *t*-butyl alcohol at 150 °C under a nitrogen atmosphere.[2] The reaction mixture of **1** with dimethyl fumarate (**12**) consisted of one major and five minor products and was quite similar in composition to that resulting from the reaction with **10**. Thus, the major product, isolated in an 11% yield, was found to be **7a**, identical with that produced in the reaction with **10**. On the other hand, the reaction with maleic anhydride (**13**) gave a single cycloadduct (**7c**) in a 29% yield. The successive treatment of **7c** with methanol and then with diazomethane afforded the dimethyl ester (**7b**) which was apparently different from **7a**, but which was identical with one of the minor products found in the product mixtures from both **10** and **12** in a proportion of six-hundredths of **7a**. The triethylamine-catalyzed epimerization at 155



Scheme 1.

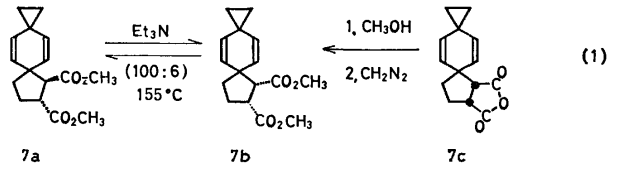
16	0.20	0.40	*t*-butyl alcohol	**6b** (21), **6c** (2.3), **27** (2.7)[c]
17	0.20	0.40	*t*-butyl alcohol	**6d** (13), **28** (2.3)[d]

a) The reactions were carried out at 155—160 °C for 9—13 h under nitrogen or argon. b) The yields were determined by GLC analysis. c) Methyl 3,4-dihydro-7-ethyl-1-naphthalenecarboxylate. d) [4.2]Paracycloph-1-ene. e) *p*-Diethylbenzene.

°C gave an equilibrium mixture composed of **7a** and **7b** in a 100:6 ratio starting from either compound. No epimerization, however, was observed in the absence of triethylamine.



(1)

7a 7b 7c

These results show unequivocally that the substituents in **7b** and **7c** have a *cis* geometry with respect to the five-membered ring, whereas those in **7a** have a *trans* geometry.[4] Therefore, it may be concluded that the cycloadditions of **1** with **10** and with **12** are nonstereospecific and give mixtures of **7a** and **7b** in the same proportion as that in the equilibrium mixture.

In these reactions, it was noticed that the yields of the cycloadducts were remarkably dependent on the reactant concentrations and reached their maxima at 0.01—0.02 M (1 M=1 mol dm^{-3}) for **12**, at 0.1 M for **10** (**7a** in *ca.* 50% yields from both **10** and **12**), and at 0.03 M for **13** (**7c** in a 45% yield) when the reactions were carried out with the **1**/olefin molar ratio of 1/4. At concentrations lower or higher than the above optimums, the reactions resulted in lower yields. At a higher concentration, the addition of a second olefin molecule to the biradical intermediate, **5**, might become competitive with the ring closure of **5** to the product; hence the decreased yields might result. At a lower concentration, the interception of the biradical, **3**, (the interception of the biradical, **2**, would not be important; *vide infra*) by the solvent and/or the impurities prior to the addition of the olefin might reduce the product yield. According to Szwarc,[5] **12** is nearly five times as reactive as **10** toward alkyl radicals. The optimum concentration for **12** was, indeed nearly one-fifth of that for **10**.

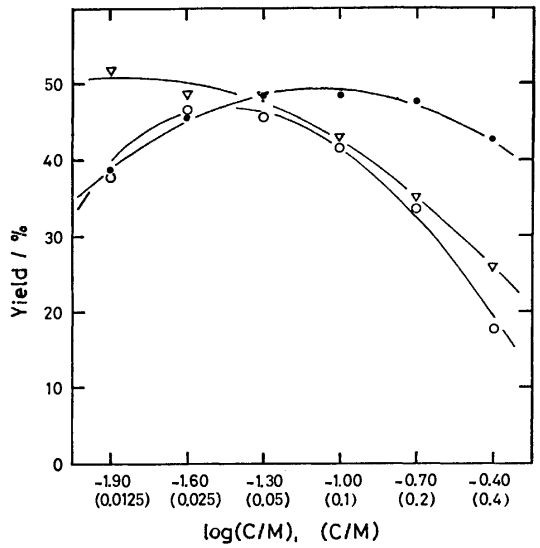


Fig. 1. Yields of the cycloadduct, **7a** or **7c**, *vs.* concentrations of the reactant, **10**, **12**, or **13**. The reactions were carried out maintaining the **1**/olefin molar ratio at a quarter.
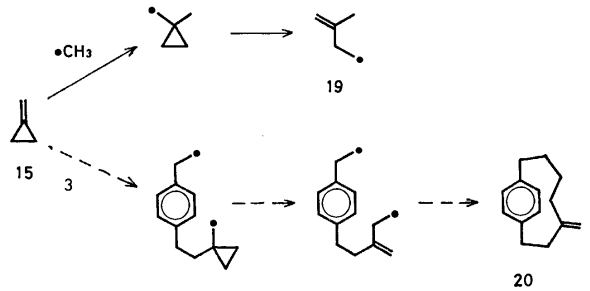
●: Yields of **7a** from **1** and **10**, ▽: yields of **7a** from **1** and **12**, ○: yields of **7c** from **1** and **13**.

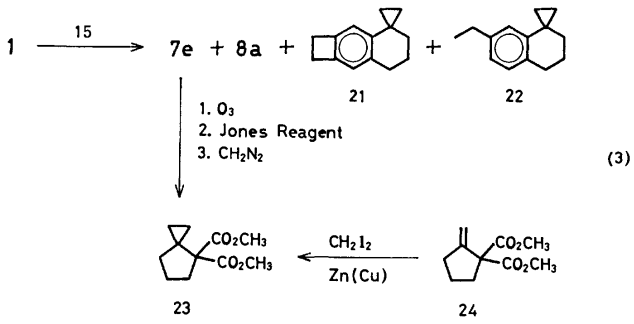
As is shown in Table 1, 3,3-dimethyl-1-butene (**14**) and methylenecyclopropane (**15**) underwent an analogous cycloaddition to give the dispiro products, **7d** and **7e**, though in lower yields. In addition to **11**, the acetylenic compounds, methyl propiolate (**16**) and ethynylbenzene (**17**),[2] also gave the dispiro adducts, **6b** and **6c**, and **6d**, respectively.

Addition Reactions Giving Tricyclo[6.4.0.0^{3,6}]dodeca-2,7-diene Derivatives (8). Two olefins, **15** and 2-methylpropene (**18**), gave tricyclic compounds as the major product. Kawamura *et al.* have reported the addition of methyl radical to **15** at the inner carbon atom and the subsequent rearrangement to the 3-methyl-3-butenyl radical (**19**).[6] If the addition of **1** to **15** proceeds analogously, the formation of 3-methylene-[7]paracyclophane (**20**) may be expected, as is de-



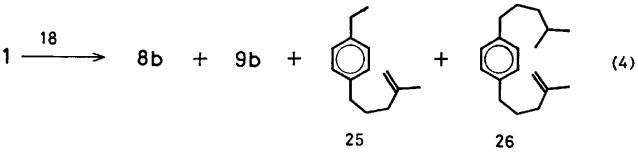
(2)

picted in Eq. 2. The reaction of **1** with **15**, however, gave a mixture of adducts which were isolated and assigned the structures represented by **7e**, **8a**, **21**, and **22**, but no cyclophane. The ozonolyiss of **7e** in methanol at −70——80 °C followed by an oxidative workup and subsequent treatment with diazomethane afforded the dimethyl dicarboxylate (**23**), in a 23% yield, this product was identical in all respects with the ester synthesized *via* an independent route, from **24** to **23**.

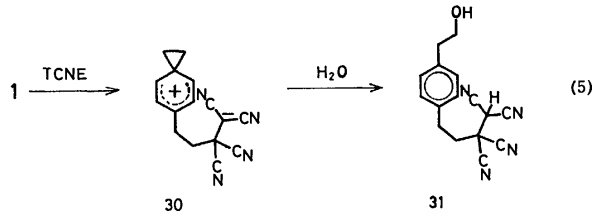


The product, **8a**, which showed two signals of olefinic protons at δ 4.88 and 5.29 in the NMR spectrum, could not be isolated in an analytically pure state because of its gradual conversion into **21** and a polymeric material during the purification. In the mass spectrum of **21**, the molecular ion peak appeared at *m/e* 184, indicating a loss of two hydrogens from a 1:1 adduct. The UV spectrum of **21** exhibited a characteristic fine structure which was very similar to those observed in the spectra of symmetrically substituted tetraalkylbenzenes,[7] but this structure was shifted considerably to a longer wave length (by 7 nm compared to 1,2,3,4,5,6,7,8-octahydroanthracene) and the NMR spectrum showed two singlets at δ 6.21 and 6.55, abnormally high field for aromatic proton. These observations are best accommodated by the structure identified as **21**, in which the spiro cyclopropane ring can give rise to the bathochromic shift in the UV spectrum and the high-field shifts of the aromatic proton signals in the NMR spectrum to the extents observed; hence, **8a**, a precursor of **21**, was assigned the 1,4-cyclohexadiene structure.[8] Compound **22**, as expected, also exhibited characteristic shifts in the UV and NMR spectra similar to those in the spectra of **21**.

The reaction of **1** with **18** afforded the tricyclic product, **8b**, in a 5% yield. The major product was *p*-(4-methyl-4-pentenyl)ethylbenzene (**25**) (15%), which was probably formed through the rapid intramolecular disproportionation. No dispiro adduct, however, was detected in the reaction mixture.



Reaction with TCNE. As has been reported previously, **1** reacts with tetracyanoquinodimethane to give [3.3]paracyclophanetetracarbonitrile *via* a zwitterionic intermediate.[1] TCNE is well known to add to electron-rich olefins,[9] and **1** is known to be an olefin possessing an unusually low ionization potential.[10] Therefore, it is of interest to investigate how **1** behaves toward TCNE. The reaction of **1** with TCNE proceeded rapidly in various solvents, such as acetonitrile, nitromethane, acetone, ethyl acetate, tetrahydrofuran, dichloromethane, and ether, accompanied by an apparent transient coloration of the mixtures in some of the solvents, and was completed in a few minutes at room temperature. In wet acetone, a 1:1:1 adduct of **1**, TCNE, and water, **31**, was obtained in a quantitative yield. In all other solvents, whether anhydrous or wet, however, the reactions gave only amorphous materials.



Discussion

Evidences for the Biradical Pathway for the Formation of Dispiro and Tricyclic Adducts. The cycloaddition of **1** to the olefins giving the dispiro[2.2.4.2]dodecane and tricyclo[6.4.0.0^{3,6}]dodecane derivatives, **6**, **7**, and **8**, can be reasonably explained by the pathway outlined in Scheme 1. Various observations support the above mechanism: 1) the occurrence of the reaction only above the temperature at which the homolytic cleavage of the cyclopropane ring in **1** commences; 2) the formation of the by-products characteristic to radical reactions, *i.e.*, a 1:2 adduct, **26**, hydrogen abstraction products, **9**,[11] and disproportionation products, **25** and **26**; 3) the inhibiting effect of the hydrogen donors, such as thiophenol, 2-propanol, and 2,2,4-trimethylpentane,[12] and 4) the nonstereospecificity of the reaction. The reactions of **1** with **10** and with **11** in methanol, as expected, did not show any notable differences in the product compositions.

Although the two biradicals, **2** and **3**, could react with the unsaturated compounds to produce the adducts, the major part, if not all, of the products would derive from **3**. The structure of **2** represents that **2** corresponds to the transition state (or the short-lived intermediate) for the 1,2-aryl shift in **3**.[13] Therefore, **2**, after its formation, would very rapidly rearrange to **3**[14] and have hardly any chance to react with the unsaturated compounds. The reaction of **1** with the styrene derivatives afforded only [4.2]paracyclophanes.[2] Neither dispiro[2.2.4.2]dodeca-4,11-diene nor tricyclo[6.4.0.0^{3,6}]dodeca-2,7-diene derivatives were detected. These results, in accord with the above reasoning, strongly support the ideas that the biradical reacting with the unsaturated compounds is **3** and that the cyclization of the resulting biradicals occurs in **5** (**32**).[15]

Two Modes of Ring Closure. The dispiro compound, **1**, underwent the cycloadditions in two different modes, depending on the unsaturated compounds.

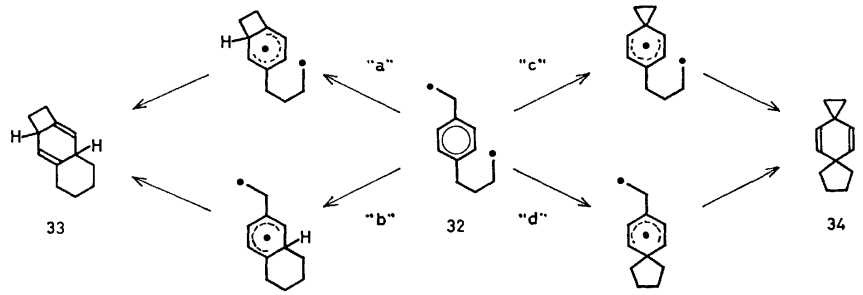


Fig. 2. Four possible cyclization routes for **32** to **33** and **34**. The substituents are omitted for clarity.

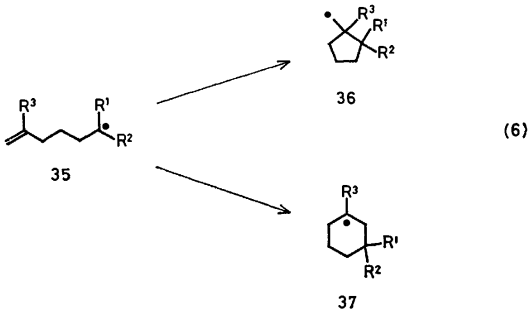
There could be four cyclization routes for the biradical intermediate, **32**, leading to two kinds of products, **33** and **34**, as is shown in Fig. 2. The (a) route, however, may be ruled out, since few, if any, instances of such a mode of cyclization of 2-arylethyl radicals have been established, whereas the other three cyclization modes are well documented.[13] In the reactions of the 1,2-disubstituted olefins and the acetylenes, **32** cyclized by the (c) and/or (d) pathways, which would be favored over the (b) pathway because of stereoelectronic[16] and/or steric[17a] effects. These cyclization pathways, (c) and (d), imply intramolecular trappings of the intermediates postulated for 1,2- and 1,4-aryl shifts in radical rearrangements, though the two possible pathways are not differentiated at present.

In the reaction with the 1,1-disubstituted olefins, however, the cyclization to the spiro compounds would be hindered by the repulsive interaction between the central six-membered ring and the two substituents, as is depicted in Fig. 3; hence, a less sterically hindered cyclization to the tricyclic products would result. The above explanation is supported by the finding that methylenecyclopropane, which seems to have less bulky substituents than 2-methylpropene,[18] afforded a mixture of the dispiro and tricyclic adducts. A similar substituent effect on the reaction mode has been known for the ring closure of 5-hexenyl radicals; that is, the less substituted **35** tend to rearrange to cyclopentylmethyl radicals, **36**, but increasing substitution results in an increasing **37**/**36** ratio.[16,17]



(6)

The cycloadditions leading to the dispiro products are formally insertions of the olefins into the cyclopropane ring. Although some analogous reactions producing five-membered rings from olefins and cyclopropane rings have been reported,[19] they are bimolecular or metal-catalyzed reactions. The present reactions are initiated by the unimolecular scission of the cyclopropane ring into the biradical, **3**, to which the unsaturated compounds then add. There is no precedent, to the best of our knowledge, for such an intermolecular cycloaddition of a biradical formed by the homolytic cleavage of a cyclopropane ring to a carbon-carbon multiple bond giving a five-membered ring, probably because 1,3-biradicals are generally too short-lived to be intercepted by unsaturated compounds.[20] In the present reactions, the biradical species reacting with the unsaturated compounds would be the 1,8-biradical, **3**, rather than the incipient 1,3-biradical, **2**; therefore, it would be sufficiently long-lived to add to the multiple bonds.[13]

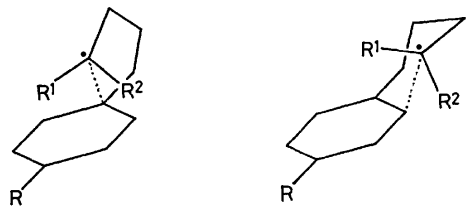


Fig. 3. Probable transition states for the two types of cyclization.

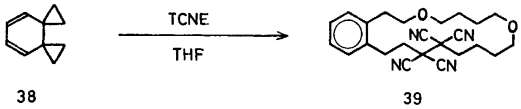
Reaction with TCNE. The rapid reaction of **1** with TCNE is clearly differentiated from the reactions initiated by the unimolecular ring scission in **1**. The formation of the water-incorporated product, **31**, is also incompatible with a radical mechanism and indicates the generation of the zwitterion, **30**. The ring-opening addition of TCNE to **1** rather than the usual addition to unsaturated bonds, and the low reactivity of **1** toward methylenemalononitrile, which adds no less rapidly than TCNE to such electron-rich olefins as vinyl ethers *via* zwitterions,[9b] coupled with the low ionization potential of **1**, suggest the electron transfer from **1** to TCNE prior to the formation of **30**.[9c]

The peculiar observations that **31** was produced only in wet acetone and that the reactions in many other kinds of solvents resulted in amorphous products are rather puzzling. De Meijere *et al.* have reported the reaction of TCNE with dispiro[2.0.2.4]deca-7,9-diene, **38**, a structural isomer of **1**, in tetrahydrofuran giving **39**,[21] but no related product was detected in the reaction of **1** with TCNE in tetrahydrofuran.



(7)

Experimental

General. The melting points are corrected. The NMR spectra were obtained with JEOL PS-100 and Hitachi R-24 spectrometers at 100 and 60 MHz respectively; the chemical shifts are given in ppm from $Si(CH_3)_4$. The IR spectra were taken on a Hitachi Model 215 grating spectrometer and are given in cm^{-1}. The mass spectra were recorded on a Hitachi Model RMU-6E spectrometer at an ionizing voltage of 80 eV, with the exception of that of **23**, which was recorded on a JEOL Model JMS-D300 spectrometer at an ionizing voltage of 70 eV; the ions of each spectrum were normalized to the spectrum's most intense ion, set equal to 100. The UV spectra were taken on a Cary Model 17 spectrophotometer and are given in nm. The GLC work was done on a Hitachi Type 063 gas chromatograph with a thermal conductivity detector, using helium as the carrier gas. The following glass columns were used: A, 20% Apiezon Grease L on Celite 545, 3 mm×1 m; B, 15% Apiezon Grease L on Celite 545, 3 mm×2 m; C, 20% PEG succinate on Celite 545, 4 mm×4 m; D, 15% Apiezon Grease L on Celite 545, 6 mm×1.5 m; E, 20% PEG 20M on Celite 545, 4 mm×1.8 m; F, 15% Apiezon Grease L on Celite 545, 3 mm×1 m; G, 5% Silicone Gum SE-30 on Chromosorb W, 3 mm×0.7 m; H, 20% Silicone DC-550 on Celite 545, 4 mm×1.5 m; I, 5% PEG phthalate on Celite 545, 4 mm×3 m; J, 20% Apiezon Grease L on Celite 545, 4 mm×2 m. The yields were calculated on the basis of the **1** used in the reaction.

Materials. The preparation of dispiro[2.2.2.2]deca-4,9-diene was carried out as has been described previously.[1] Methyl propiolate (**16**),[22] methylenecyclopropane (**15**),[23] 5-iodo-1-pentyne,[24] 3,3-dimethyl-1-butene,[25] TCNE,[26] and Zn–Cu couple[27] were prepared according to the procedures described in the literature. The other reagents were obtained from commercial sources and were purified by fractional distillation or by recrystallization except for 2-methylpropene (**18**), which was purchased from the Tokyo Kasei Co. and used without further purification.

*Reaction of **1** with Dimethyl Fumarate (**12**).* A solution of 132 mg of **1** (1.00 mmol) and 288 mg of **12** (2.00 mmol) in 50 ml of *t*-butyl alcohol was heated at 155 °C for 13.8 h under nitrogen. The solvent was then removed *in vacuo* and the residue was chromatographed on silica gel and eluted with chloroform. The first fraction contained 26 mg of **12**. From the second fraction, which weighed 100 mg, 66 mg of a crystalline mixture were separated by crystallization from petroleum ether. The removal of **12** by sublimation and the recrystallization of the residue from petroleum ether afforded **7a**; mp 68.2—68.7 °C (29 mg, 11%). The third fraction gave 231 mg of an intractable, viscous oil. The adduct obtained above showed no depression of its melting point in a mixed-melting-point measurement with that obtained from **1** and **10**.

*Reaction of **1** with Maleic Anhydride (**13**).* A solution of 132 mg of **1** (1.00 mmol) and 196 mg of **13** (2.00 mmol) in 50 ml of *t*-butyl alcohol was heated as above. After the solvent had been removed, the residue was distilled. The first fraction (bp 140 °C at 15 mmHg) (1 mmHg=133.322 Pa) was 24 mg of **13**. The second fraction (bp 170 °C at 0.02 mmHg) was 169 mg of a pale yellow liquid, from which 66 mg of crystalline **7c** were obtained (29%) by recrystallization from diethyl ether and preparative GLC separation (Column A, 200 °C). A mixture consisting of two components (15 mg) was separated by the preparative GLC, but the structures could not be determined. The residue of the distillation weighed 169 mg. **7c**, mp 79.0—80.5 °C; NMR (CCl_4, 100 MHz): 0.85 (m, 4H), 1.75 (m, 2H), 2.25 (m, 2H), 3.08 (d, J=9.5 Hz, 1H), 3.52 (m, 1H), 5.0—5.6 (m, 4H); mass: *m/e* 230 (M^+, 4), 130 (78), 129 (55), 118 (49), 117 (100), 115 (40), 91 (40); IR (KBr): 1862, 1773, 1222, 917. Found: C, 72.92; H, 6.25%. Calcd for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13%.

Dimethyl cis-*Dispiro[2.2.4.2]dodeca-4,11-diene-7,8-dicarboxylate (**7b**).* A solution of 22 mg of **7c** (0.096 mmol) in 1.5 ml of methanol was heated at 100 °C for 10 h. After the solvent had been removed *in vacuo*, a solution of diazomethane in ether was added until the yellow color persisted. The subsequent distillation of the reaction mixture yielded 25 mg of **7b** (95%) (bp 150 °C at 0.02 mmHg), a colorless oil which differed from **7a** in GLC retention time and its spectral properties. **7b**, NMR (CCl_4, 100 MHz): 0.77 (s, 4H), 1.4—2.6 (complex m, 4H), 2.86 (d, J=8 Hz, 2H), 3.1 (m, 1H), 3,55 (s, 3H), 3.58 (s, 3H), 4.96 (d of m, J=10 Hz, 2H), 5.40 (m, 2H); mass: *m/e* 276 (M^+, 1), 216 (39), 158 (17), 157 (100), 156 (27), 129 (37), 117 (27); IR (liquid film): 1740, 1728. Found: C, 69.20; H, 7.26%. Calcd for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30%.

*Epimerization between **7a** and **7b**.* A solution of **7b** in *t*-butyl alcohol (0.27 M) was heated at 155 °C for 22 h, but no epimerization was detected on GLC analysis (Column B, 200 °C). Similarly, a solution of **7a** in *t*-butyl alcohol (0.27 M) was stable at the above temperature. They, however, epimerized when they were heated at 155 °C in a 0.5 M methanolic solution of triethylamine. The ratio of **7b** to **7a** was found to be 0.06:1 after 10 h heating, regardless of the stereochemistry of the starting material; this ratio remained unchanged after 20 h heating. Reaction of **1** with **12** in methanol (155 °C, 12 h) gave the product mixture, in which the ratio of **7b** to **7a** was 0.05.

*Effect of the Reactant Concentration on the Yield of the Adducts, **7a** and **7c**.* To an aliquot (0.5 ml) of a solution of **1** in *t*-butyl alcohol in an accurately known concentration (*ca.* 0.1 M), were added 0.20 mmol of **10** or **12** and the following amount of the solvent; 0, 0.5, 1.5, 3.5, or 7.5 ml. These mixtures were heated in sealed ampoules at 151—153 °C for 14 h under nitrogen. After the reaction, the solvent was removed and the yields of the adducts were determined on GLC (Column B, 200 °C), using benzophenone as the internal standard. Similarly, hexane solutions of **1** and **13** were heated at 158 °C for 12 h under nitrogen and the product yields were determined. In the reactions of **1** with both **10** and **12**, the product ratio, **7b**/**7a**, was 0.06, regardless of the amount of the solvent added.

*Effect of Hydrogen Donors on the Reaction of **1** with **10**.* Five 200-μl aliquots were withdrawn from a solution of 35.5 mg of **1** (0.27 mmol) and 57.6 mg of **10** (0.40 mmol) in 1.00 ml of ether. From each aliquot, the solvent was removed and the following materials were added to the residue: (1) 2.00 ml of *t*-butyl alcohol, (2) 2.00 ml of *t*-butyl alcohol and 11 mg of thiophenol, (3) 2.00 ml of *t*-butyl alcohol and 55 mg of thiophenol, (4) 2.00 ml of 2-propanol, and (5) 2.00 ml of 2,2,4-trimethylpentane. These solutions were heated at 152—155 °C for 11 h under nitrogen, and then the relative yields of **7a** were determined on GLC, using benzophenone as the internal standard (Column B, 200 °C). The yield of **7a** in Run 1 was set equal to 100%. (1) 100%, (2) 38%, (3) 6.3%, (4) trace amount, and (5) 89%.

*Reaction of **1** with 3,3-Dimethyl-1-butene (**14**).* A solution of 132 mg of **1** (1.00 mmol) and 168 mg of **14** (2.00 mmol) in 5.0 ml of *t*-butyl alcohol was heated at 158 °C for 11.5 h under nitrogen. After the removal of the solvent, the residue was subjected to silica gel column chromato-

graphy and subsequently to preparative GLC (Column C, 170 °C), which yielded 4.7 mg of **9a** (2.2%), 5.3 mg of **7d** (2.5%), and 1.9 mg of an unidentified liquid. **7d**, NMR (CCl_4, 60 MHz): 0.65 (s, 4H), 0.86 (s, 9H), 1.2—1.8 (m, 7H), 4.75 (d, J=10 Hz, 2H), 5.26 (d, J=10 Hz, 1H), 5.54 (d, J=10 Hz, 1H). **9a**, NMR (CCl_4, 60 MHz): 0.80 (s, 9H), 1.0—1.8 (m containing t at 1.18, J=7 Hz, 9H), 2.45 (q, J=7 Hz, 4H), 6.83 (s, 4H).

*Reaction of **1** with Methyl Propiolate (**16**).* A solution of 132 mg of **1** (1.00 mmol) and 173 mg of **16** (2.06 mmol) in 5.00 ml of *t*-butyl alcohol was heated at 158 °C for 11.5 h under argon. After the reaction, 0.47 mmol of **16** remained. On GLC analysis (Column F, 170 °C), one major and six minor peaks were observed. The solvent was then removed, and the residue was chromatographed on silica gel. Elution with dichloromethane and then with a mixture of dichloromethane and ether (4:1) gave 53 and 164 mg of the product mixtures respectively. The preparative GLC (Column F, 170 °C) of the former mixture afforded 8.5 mg of **6b**, 4.9 mg of **6c** (2.3%), 5.9 mg of **27** (2.7%), and 1.6 mg of an unidentified product. That of the latter mixture gave 36.3 mg of **6b** (total 44.8 mg, 21%) and 5.9 mg of an unidentified product. An analytical sample of **6b** was obtained by recrystallization from petroleum ether, and those of others by preparative GLC (**6c**, with Column F and subsequently with Column I; **27**, with Column H and subsequently with Column I). Further elution with ether and with ethanol only produced an intractable, amorphous yellow solid. **6b**, mp 65.9—66.5 °C; NMR (CCl_4, 100 MHz): 0.76 (s, 4H), 1.97 (t, J=7.5 Hz, 2H), 2.46 (t of d, J=7.5 and 2.5 Hz, 2H), 3.61 (s, 3H), 4.96 (d, J=10 Hz, 2H), 5.34 (d, J=10 Hz, 2H), 6.67 (t, J=2.5 Hz, 1H); mass, *m/e* 216 (M^+, 8), 198 (25), 157 (21), 156 (24), 141 (27), 129 (100), 128 (36); IR (KBr): 1704, 1628. Found: C, 77.85; H, 7.48%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%. **6c**, NMR (CCl_4, 100 MHz): 0.76 (s, 4H), 1.93 (t, J=7.5 Hz, 2H), 2.59 (t of d, J=7.5 and 2.0 Hz, 2H), 3.68 (s, 3H), 4.96 (d, J=10 Hz, 2H), 5.38 (d, J=10 Hz, 2H), 6.29 (t, J=2 Hz, 1H); mass: *m/e* 217 (10), 216 (M^+, 75), 157 (100), 156 (24), 141 (42), 129 (93), 128 (42), 115 (29); IR (liquid film): 1713, 1626. **27**, NMR (CCl_4, 100 MHz): 1.24 (t, J=7.5 Hz, 3H), 2.40 (m, 2H), 2.5—2.9 (complex m, 4H), 3.79 (s, 3H), 6.89 (s, 2H), 7.03 (t, J=4.5 Hz, 1H), 7.58 (s, 1H).

*Reaction of **1** with Methylenecyclopropane (**15**).* A solution of 396 mg of **1** (3 mmol) and 400 mg of **15** (7.4 mmol) in 21 ml of *t*-butyl alcohol was heated at 152—155 °C for 8 h under nitrogen. The reaction mixture was found by GLC analysis to consist of four major and four minor products, besides *p*-diethylbenzene. Distillation (bath temp, 170 °C at 2 mmHg) and subsequent separation by preparative GLC (Column D, 180 °C) yielded 27.2 mg of **7e** (4.9%), 26.0 mg of **8a** (4.7%), 31.6 mg of **21** (5.7%), and 72.3 mg of **22** (13%). Analytical samples of **7e**, **21**, and **22** were obtained through further purification by GLC (**7e** and **21**, with Column E at 180 °C; **22**, with Column H at 200 °C). The NMR spectrum of **8a** was recorded, but other spectral and analytical data could not be obtained because of the decomposition, which gave **21** and a polymeric material. **7e**, NMR (CCl_4, 100 MHz): 0.34 (AA′ BB′ m, 4H), 0.68 (s, 4H), 1.6—1.9 (m, 6H), 4.91 (d, J=11 Hz, 2H), 5.37 (d, J=11 Hz, 2H); mass: *m/e* 186 (M^+, 4), 158 (35), 157 (40), 143 (25), 130 (100), 129 (80), 128 (34), 115 (34), 91 (30). Found: C, 90.33; H, 9.71%. Calcd for $C_{14}H_{18}$: C, 90.26; H, 9.74%. **8a**, NMR (CCl_4, 100 MHz); −0.1—0.7 (complex m, 4H), 0.8—1.2 (two m, 2H), 1.2—3.0 (complex m, 9H), 3.16 (m, 1H), 4.88 (m, 1H), 5.29 (m, 1H). **21**, NMR (CCl_4, 100 MHz): 0.76 (AA′ BB′ m, 4H), 1.48—1.72 (m, 2H), 1.72—2.00 (m, 2H), 2.81 (t, J=6.5 Hz, 2H), 3.04 (s, 4H), 6.20 (s, 1H), 6.54 (s, 1H); mass: *m/e* 185 (17), 184 (M^+, 100), 183 (46), 169 (55), 156 (38), 155 (70), 141 (41); IR (liquid film): 3075, 1478, 890, 857; UV (hexane), max: 277 (ε=2610), 282 (3360), 287 (3400), 292 (3450). Found: C, 91.13; H, 8.79%. Calcd for $C_{14}H_{16}$: C, 91.25; H, 8.75%. **22**, NMR (CCl_4, 100 MHz): 0.81 (AA′ BB′ m, 4H), 1.18 (t, J=7.7 Hz, 3H), 1.55—1.75 (m, 2H), 1.75—2.05 (m, 2H), 2.51 (q, J=7.7 Hz, 2H), 2.82 (t, J=6 Hz, 2H), 6.34 (s, 1H), 6.77 (AB q, J=8 Hz, 2H); mass: *m/e* 186 (M^+, 43), 158 (40), 157 (100), 129 (56), 128 (19), 115 (17), IR (liquid film): 3075, 1493, 1450, 810; UV (hexane), max: 268^{sh} (ε=670), 274 (1030). 283 (330). Found: C, 90.32; H, 9.78%. Calcd for $C_{14}H_{18}$: C, 90.26; H, 9.74%.

*Yields of the Adducts of **1** and **15**.* To 6.6 mg of **1** and 40 μl of a 50 vol % hexane solution of **15** was added a specified volume of *t*-butyl alcohol bubbled with argon, after which the mixture was heated at 155 °C for 9 h under argon. The yields of the adducts were determined by GLC (Column B, 180 °C), using benzophenone as the internal standard. In Run 2, the yield of *p*-diethylbenzene and the amount of **1** remaining were also determined to be 7.7 and 7.2% respectively, using tetralin as the internal standard.

Run	[1]/M	[15]/M	Yields of adducts/%			
			7e	**8a**	**21**	**22**
1	0.032	0.12	3	7	7	2
2	0.10	0.46	8	13	12	4
3	0.25	1.0	7	8	13	5

*Ozonolysis of **7e**.* Compound **7e** (8.0 mg) was dissolved in 5.0 ml of anhydrous methanol, after which ozone/oxygen was bubbled through the solution held at −70—−80 °C for 30 min. After bubbling nitrogen to displace the excess ozone, the methanol was removed *in vacuo* (2 mmHg). The residue was dissolved in 10 ml of acetone, cooled in an ice bath, and treated with 0.5 ml of a 2.67 M Jones reagent. After 20 min, 1.0 ml of methanol was slowly added to destroy the excess oxidizing reagent and the solvent was removed. The residue was dissolved in 5.0 ml of ether, treated with anhydrous magnesium sulfate, and decanted, and the precipitate was washed with another 5.0 ml of ether. The combined ethereal solutions were extracted with two 2-ml portions of aq potassium hydrogencarbonate (2.5 M). The combined extracts were acidified with dil sulfuric acid, saturated with sodium sulfate, and extracted with two 5-ml portions of ether. To the combined ethereal solutions dried with anhydrous magnesium sulfate, was added diazomethane in ether under ice cooling until the yellow color persisted. After standing for 15 min, the excess diazomethane was removed by bubbling nitrogen, and then the ether was evaporated. The isolation of the products by preparative GLC (Column G, 90—130 °C) yielded 2.2 mg of dimethyl 1,1-cyclopropanedicarboxylate, 2.1 mg of **23**, and 0.5 mg of an unidentified material. The Compound **23** thus obtained was identical to that synthesized *via* an independent route (*vide infra*) in all respects.

*Dimethyl 2-Methylene-1,1-cyclopentanedicarboxylate (**24**).* To 40 ml of anhydrous methanol was added 1.6 g of sodium (0.07 mol), and then 8.8 g of dimethyl malonate (0.066 mol) was slowly added to the stirred solution. After heating under reflux for 10 min, 9.7 g of 5-iodo-1-pentyne (0.05 mol) was added slowly and heating was continued for 4 h. Most of the methanol was removed under reduced pressure, the residue was dissolved in 200 ml of water, and the solution was extracted with ether three times. The ethereal extracts

were dried with anhydrous magnesium sulfate and distilled through a spinning-band column *in vacuo* to give 3.1 g of **24** (bp 34 °C at 0.02 mmHg), 2.2 g of dimethyl 4-pentyne-1,1-dicarboxylate (bp 46 °C at 0.02 mmHg), and 1.6 g of a mixture of the two compounds. **24**, NMR (CCl_4, 60 MHz): 1.65 (apparent quintet, J=7 Hz, 2H), 2.05—2.55 (complex m, 4H), 3.60 (s, 6H), 5.20 (m, 2H); IR (liquid film): 1665.

Dimethyl Spiro[2.4]heptane-4,4-dicarboxylate (23). A mixture of 645 mg of **24** (3.25 mmol), 2.7 g of diiodomethane (10 mmol), and 2.0 g of Zn(Cu) couple (30 mmol) in 17 ml of absolute ether was vigorously stirred under reflux. (A small amount of iodine was added at the start.) Two additional 2.7-g portions of diiodomethane were added after 21 and 45 h. After 78 h of reaction (then, the ratio of the product to the starting material was nearly 1, on the basis of GLC analysis), the ethereal solution was decanted, washed with saturated aq ammonium chloride four times, saturated aq potassium carbonate, and saturated aq sodium chloride, and dried with anhydrous magnesiun sulfate. After the removal of the solvent, distillation gave 611 mg of a liquid (bath temp, 140 °C at 3 mmHg), which was subjected to preparative GLC, affording 200 mg of the starting material (32%), 64 mg of an unidentified product, and 200 mg of **23** (30%). **23**, NMR (CCl_4, 100 MHz): 0.40—0.70 (AA′ BB′ m, 4H), 1.58—1.88 (m, 4H), 2.35 (s, 2H), 3.63 (s, 6H); mass: *m/e* 212 (M^+, 2), 153 (48), 152 (100), 121 (22), 120 (39), 93 (80); IR (liquid film): 3080, 1735, 1150. Found: C, 62.25; H, 7.70%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

Reaction of 1 with 2-Methylpropene (18). Into a solution of 133 mg of **1** (1.01 mmol) in 5.0 ml of *t*-butyl alcohol was bubbled **18** at 20 °C until the absorption of the gas became slow. (*Ca.* 5 mmol of **18** was dissolved, judging from the change in weight.) The mixture was heated at 156 °C for 12 h under argon. Then the solvent was removed, and the residue was divided by column chromatography on silica gel with petroleum ether into five fractions, which weighed 24, 12, 5, 31, and 92 mg respectively. They were subjected to preparative GLC (Column B, 170 °C). Thus, 9.5 mg of **8b** (5%) and a small amount of **9b** were obtained from the first fraction, a small amount of **9b** (total 3.0 mg, 1.6%) from the second, 2.7 mg of **25** and 5.8 mg of **26** (2.3%) from the fourth, and 25 mg of **25** (total 27.7 mg, 15%) from the fifth. Analytical samples of these compounds were obtained through further purification by GLC (Column B). **8b**, NMR (CCl_4, 100 MHz): 0.65 (s, 3H), 0.93 (s, 3H), 1.2—2.9 (complex m, 11H), 3.13 (m, 1H), 5.17 (m, 1H), 5.37 (broad s, 1H); mass: *m/e* 188 (M^+, 1), 145 (100), 118 (43), 117 (66), 91 (25); IR (liquid film): 1704, 1643; UV (hexane), max: 212^{sh} (ε=12000). Found: C, 89.41; H, 10.58%. Calcd for $C_{14}H_{20}$: C, 89.29; H, 10.71%. **9b**, NMR (CCl_4, 60 MHz): 0.82 (d, J=6 Hz, 6H), 1.0—1.8 (complex m containing t, J=7.5 Hz at 1.15, 8H), 2.42 (apparent quintet, J=7.5 Hz, 4H), 6.86 (s, 4H); mass: *m/e* 190 (M^+, 22), 120 (19), 119 (100), 105 (10), 91 (15). **25**, NMR (CCl_4, 100 MHz): 1.23 (t, J=7.7 Hz, 3H), 1.6—1.9 (m containing s at 1.71, 5H), 2.00 (t, J=7.5 Hz, 2H), 2.57 (q, J=7.7 Hz, 4H), 4.67 (s, 2H), 7.00 (s, 4H); mass: *m/e* 188 (M^+, 2), 133 (12), 132 (100), 119 (17), 117 (49), 91 (17); IR (liquid film): 1646; UV (hexane), max: 255^{sh} (ε=180), 260 (310), 266 (420), 268 (400), 274 (480). Found: C, 89.34; H, 10.70%. Calcd for $C_{14}H_{20}$: C, 89.29; H, 10.71%. **26**, NMR (CCl_4, 100 MHz): 0.88 (d, J=7 Hz, 6H), 1.0—1.4 (m, 2H), 1.4—1.9 (complex m containing s at 1.70, 8H), 2.00 (t, J=8 Hz, 2H), 2.52 (m, 4H), 4.64 (s, 2H), 6.92 (s, 4H); mass: *m/e* 244 (M^+, 3), 189 (17), 188 (99), 175 (18), 118 (20), 117 (100), 91 (19); IR (liquid film): 1646; UV (hexane), max: 255^{sh} (ε=245), 260 (370), 266 (490), 268 (400), 275 (540).

Reaction of 1 with TCNE. TCNE (33 mg, 0.26 mmol) and **1** (33 mg, 0.25 mmol) were each dissolved in 1 ml of simply distilled acetone, and nitrogen was bubbled through each solution for 5 min. When the two solutions were then mixed, a pale violet color appeared, but it then faded within a few min. After standing for 5 d, the reaction mixture was worked up. The crystallization of the product from chloroform yielded 69 mg of **31** (≈100%); mp 104.5—106.5 °C. Successive recystallization from ether and from a 5:1 mixture of ether and acetone gave an analytical sample melting at 107.8—109.0 °C. **31**, NMR (acetone-d_6, 100 MHz): 2.6—3.3 (complex m, 7H), 3.69 (t, J=7 Hz, 2H), 5.97 (broad s, 1H), 7.08—7.32 (m, 4H); mass: *m/e* 251 (M^+—HCN, 9), 221 (18), 135 (33), 105 (79), 104 (100), 103 (11), 91 (11); IR (KBr): 3550, 2120. Found: C, 69.25; H, 4.96; N, 20.06%. Calcd for $C_{14}H_{14}ON_4$: C, 69.05; H, 5.07; N, 20.13%. When the reaction of **1** with TCNE was repeated without bubbling nitrogen and for a shorter reaction time (15 min), **31** melting at 107.7—109.0 °C was obtained in an 85% yield after crystallization from ether. If the acetone distilled through a fractionation column and stored over a Linde 4A Molecular Sieve was used as the solvent, the product was an intractable yellow liquid.

(Received June 28, 1979)

The tautomeric behavior of 5-nitro-2-anilinopyridine and 2-anilinopyrimidine was studied. 2-(*N*-Methylanilino) and 1-methyl-2-(phenylimino)-1,2-dihydro derivatives were prepared as models for the amino and imino tautomers, respectively, and their spectra were compared. The results and the assumed tautomeric equilibrium constants strongly suggest the equilibria to be favorable to the amino tautomers, the K_t values being considerably smaller than that of the parent 2-anilinopyridine.

Tautomeric equilibria of aminopyridines have been discussed by several investigators. From experimental evidences and theoretical consequences[1-5] it was concluded that the amino tautomers are considerably more stable than the imino tautomers. As regards 2-anilinopyridines, however, Bell *et al.*[6] and Rud'ko *et al.*[7] claimed the presence of a measurable amount of the imino tautomer on the basis of the splitting of their N–H stretching bands. Cook *et al.* discussed the tautomeric behavior from the ultraviolet spectra.[8] Studies were made on this problem and it was concluded that the tautomeric equilibria by far favor to the amino tautomer[9-10] and that the splitting of the N–H stretching bands is due to the presence of rotational isomers.[11] The tautomeric behavior of the title compounds was studied, since the introduction of the electron-withdrawing group, especially on the pyridine nucleus, might contribute to stabilize the imino tautomers.

Experimental

Preparation of Materials. 2-Anilino-5-nitropyridine (**1**) and 2-anilinopyrimidine (**4**) are known compounds and were prepared by condensing 2-chloropyrimidine and 2-chloro-5-nitropyridine with aniline. *N*-Methylanilino derivatives **2** and **5** were prepared similarly with use of *N*-methylaniline. 1-Methyl-5-nitro-2-(phenylimino)-1,2-dihydropyridine (**3**) and 1-methyl-2-(phenylimino)-1,2-dihydropyrimidine (**6**) are new compounds, and were prepared by the method previously reported.[10] **2**, mp 101 °C. Found: C, 62.80; H, 4.98; N, 18.15%, M^+, 229. Calcd for $C_{12}H_{11}N_3O_2$: C, 62.87; H, 4.84; N, 18.33%; M^+, 229. **3**, mp 119—120 °C. Found, C, 62.61; H, 5.10; N, 19.14%; M^+, 229 (an isomer of **2**). **5**, bp 125—126 °C/11 mmHg. Found C, 71.53; H, 6.16; N, 22.75%; M^+, 185. Calcd for $C_{11}H_{11}N_3$: C, 71.33; H, 5.99; N, 22.69% M^+, 185. **6**, mp 88—90 °C. Found: C, 71.80; H, 5.84; N, 22.51%; M^+, 185 (an isomer of **5**)

Measurement of Spectra. Ultraviolet and infrared spectra were measured with Hitachi EPS-3T and Hitachi 225 recording spectrophotometers, respectively. NMR spectra were obtained with a JEOL JNM C60-H spectrometer and, when necessary, $Eu(fod)_3$ was used to separate the overlapping signals. Details of the spectral measurement were imilar to those previously reported.[10]

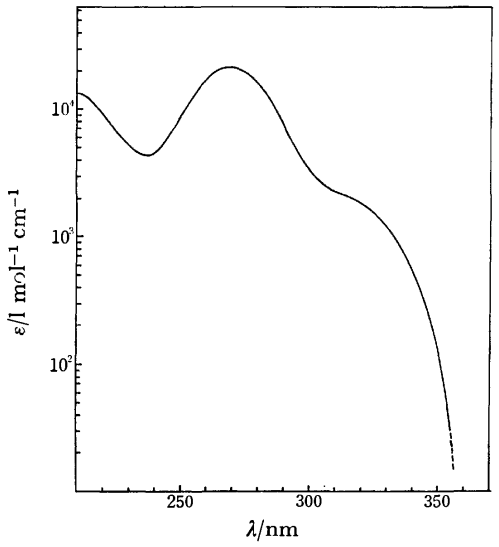

Fig. 1. Ultraviolet spectrum of **4** in aqueous ethanol (1:1).

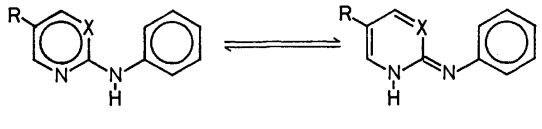
Results and Discussion

Ultraviolet Spectra. The ultraviolet spectra of 2-anilino-5-nitropyridine (**1**), 2-anilinopyrimidine (**4**) and their *N*-methyl derivatives are given in Table 1. The spectra of **1** and **4** resemble considerably those of the corresponding *N*-methylanilino derivatives **2** and **5**, differing a great deal from those of the corresponding 1-methyl-2-(phenylimino)-1,2-dihydro derivatives **3** and **6**. Even when the measurements were carried out in highly polar solvents, **1** and **4** showed no absorption bands in the longer wavelength region in which the characteristic absorption bands of the pyridoneimine chromophores appear (Fig. 1). This suggests that **1** and **4** exist almost exclusively as the amino tautomer. Measurement in several other solvents also gave similar results.



(I) (II)

In order to estimate the tautomeric equilibrium constants of **1** and **4**, the dissociation constants (K_a) of the amino (**2** and **5**) and the imino (**3** and **6**) model compounds were determined by means of the pH

dependence of their ultraviolet spectra. The tautomeric equilibrium constants obtained from the K_a values by the equation $K_t=K_a$(amino)/K_a(imino) are given in Table 2. As expected, the K_t value of **1** and **4** is remarkably smaller than that of unsubstituted 2-anilinopyridine. The electron withdrawing nitro-group on the heterocyclic ring gives rise to the displacement of the unshared electrons on the exocyclic nitrogen atom towards the ring, favoring the imino tautomer. The effects is more pronounced when another carbon atom constituting the ring is substituted by a nitrogen atom. This is due to the electronegative nature of nitrogen atom. From the K_t value obtained, 2-anilinopyrimidine is expected to exist as a tautomeric mixture containing *ca.* 0.2% of the imino tautomer in aqueous ethanol solution. The amount of the imino tautomer corresponds to the apparent molar absorption coefficient of *ca.* 3 l mol^{-1} cm^{-1} in the longer wavelength region, being too low an intensity to be detected by the usual measurement of ultraviolet spectrum.

NMR Spectra. The NMR spectra of the heterocyclic ring protons of 2-anilino-5-nitropyridine, 2-anilinopyrimidine, and their *N*-methyl derivatives are given in Table 3.

The assignment of the signals was carried out by comparison with similar compounds, by using their lanthanoid induced shifts by Eu(fod)$_3$, and by the estimation from the electron densities. As has been shown from MO calculations,[10] the imino tautomer is expected to have considerable bond alternation in the heterocyclic part of its molecule. This causes a decrease in aromaticity of the heterocyclic ring, resulting in chemical shifts of the protons on the ring to displace towards higher fields. The effect is observed in the imino model compounds **3** and **6**, which is in line with the case of the imino models of 2-anilinopyridine and 2-anilino-4-methylquinoline. The spectra of **1** and **4** resemble as a whole the corresponding amino model compounds (**2** and **5**), there being no indication of the presence of the imino tautomers. Analogous to the case of unsubstituted 2-anilinopyridine, the hy-

drogen atom at the 3-position of the heterocyclic ring resonates at a higher field and is attributed to the anisotropy effect caused by the phenyl ring of anilino moiety, since the 3-H is located close on the phenyl ring in one (III) of the two possible rotational isomers. This is reasonable, since the effect is not predominant with **5** which is void of such steric hindrance and the molecule is supposed to be nearly planar.

Infrared Spectra and the Existence of Rotational Isomers. Existence of the tautomeric equilibrium is often presumed on the basis of the splitting in the N–H stretching bands of these and related aminopyridines. Surely it can be an indication of the tautomeric equilibria if other possibilities are excluded. However, the presence of rotational isomers (III and IV) has been suggested on several nitro-substituted 2-anilino-pyridines and -quinolines to explain the splitting of N–H absorptions.[11] As regards 2-anilinopyrimidine (**4**), the two rotational isomers are degenerate and the appearance of a single absorption band is predicted if the splitting is caused by rotational isomerism. In accord with this prediction, **4** has actually a single symmetrical absorption band at 3432 cm^{-1} in the N–H stretching region.

(III) (IV)

The imino compounds **3** and **6** exhibit very strong C=N stretching absorptions at 1649 and 1630 cm^{-1}, respectively. On the other hand, other compounds including **1** and **4** have no remarkable absorptions when the spectra were measured in carbon tetrachloride solutions.

From the results, the amino tautomers are found to be by far more favorable in the tautomeric equilibria of both **1** and **4**. As expected, the tautomeric equilibrium constants of these compounds are considerably lower than the tautomeric equilibrium constant ($K_t = 2 \times 10^{-5}$) of the parent 2-anilinopyridine.

This research was supported in part by a Grant-in-Aid for Special Project Research from the Ministry of Education, Science and Culture.

An ESR Study of *N*-(Alkylthio)arylaminyls. Substituent Effects on ESR Parameters[1)]

Yozo MIURA,* Hidetsugu ASADA, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 28, 1979)

A series of *N*-(alkylthio)arylaminyls, ArNSR, were generated by hydrogen-abstraction from *N*-(alkylthio)-anilines or by the photolysis of *N*,*N*-bis(*t*-butylthio)anilines, and were studied by ESR spectroscopy. *N*-(*t*-Butylthio)aminyls were fairly long-lived, and their lifetimes were scarcely affected by oxygen. Substituent effects on the ESR parameters were also studied, and the results were compared with those for *N*-alkoxyarylaminyls.

A variety of *N*-alkoxyarylaminyls (**5**), ArNOR, were produced by hydrogen-abstraction from *N*-alkoxy-anilines,[2)] by addition of alkyl or metal radicals,[3)] and by the photolysis of peroxyoxalates,[4)] and they were studied in detail by means of ESR spectroscopy. Since the aminyls prossess an aromatic ring and an oxygen atom adjacent to the central nitrogen, they are significantly stabilized by such contributing resonance forms as $-\dot{N}-\ddot{O}\leftrightarrow\ddot{N}^{-}-\overset{+}{O}-$.

N-(Alkylthio)arylaminyls (**3**) are structurally very close to **5**; therefore, the comparison of their ESR parameters and stabilities with those for **5** is interesting. However, the aminyls **3** have never been reported on. In this paper we wish to report on the generation of **3** and their ESR spectroscopic investigation. In addition, the results will be compared with those for **5**.

Results and Discussion

The aminyls **3** were generated by hydrogen-abstraction from *N*-(alkylthio)anilines (**1**) by the *t*-butoxyl radical, which were produced by the thermal decomposition of di-*t*-butyl diperoxyoxalate (Method A) or by the photolysis of *N*,*N*-bis(*t*-butylthio)anilines (**2**) (Method B).

The precursors, **1**, were prepared by the reaction of the appropriate anilines with sulfenyl chlorides in the presence of triethylamine; **1a** and **1b** were obtained as yellow crystals, while **1f**, **1n**, and **1o** were each obtained as a viscous oil.[5)]

Hydrogen-abstraction from **1** was performed by the reaction with di-*t*-butyl diperoxyoxalate at room temperature; relatively strong ESR signals were thus obtained. The assignment of the signals were performed on the basis of their splitting patterns and also on the basis of their relatively large *g*-values (2.0061—2.0071). For example, the ESR spectrum of **3f** (Fig. 1) is split into 1 : 2 : 1 triplets (3.68 G), 1 : 1 doublets (4.20 G), and a 1 : 1 : 1 triplet (9.93 G). The 1 : 1 : 1 triplet is obviously due to the central nitrogen nucleus, while the 1 : 1 doublets and the 1 : 2 : 1 triplets are due to the para- and ortho-protons respectively. In the cases of **3n** and **3o**, splittings due to the γ protons were observed in addition to the splittings due to the nitrogen nucleus and the ring protons.

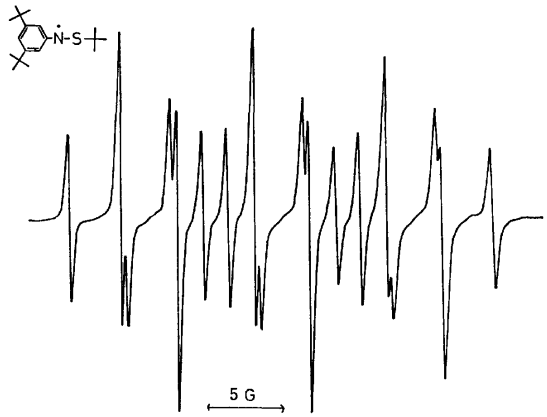

Fig. 1. ESR spectrum of **3f** recorded for the benzene solution containing **1f** and di-*t*-butyl diperoxyoxalate (17 °C).

The compounds **2** were prepared by the reaction of the appropriate anilines with more than two equivalents of sulfenyl chloride and were isolated as colorless crystals. The compounds **1** are relatively unstable because of the presence of the active hydrogen (NH). On the other hand, **2** are very stable and can be stored for a long time without any detectable decomposition.

The compounds **2** absorb light at 239—328 nm (ε: 2170—22500 in benzene) and, on irradiation with a high-pressure mercury lamp, undergo homolysis to give **3** in a moderate concentration. Therefore, this procedure (Method B) is excellent for the generation of **3**. However, when the irradiation was continued, secondary radicals often appeared and the analysis of the spectra was disturbed. For this reason, an appropriate period of irradiation, usually 0.5—3 min, is required in order to obtain clean ESR spectra of **3**. The aminyls, **3a**, **3b**, **3n**, and **3o**, were obtained by

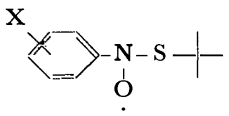
a) In benzene at 17 °C. b) The splitting constants were determined by computer simulation. c) The two ortho-protons seem to be magnetically unequivalent, but their a_H values were apparently equivalent because of the relatively broad hyperfine line. d) Absorbs at 556 nm (benzene).

Method A, while **3c**—**e** and **3g**—**m** were generated by method B and **3f** was obtained by both methods. The ESR parameters for the **3f** generated by Method A were identical with those for the **3f** obtained by Method B. The ESR parameters for **3** are summarized in Table 1.

In order to confirm that the present aminyls differ from the corresponding nitroxides **4**, **4a** was generated by the addition reaction of *t*-butylthiyl radical to nitrosobenzene and its ESR parameters were compared with those for **3c**. The ESR parameters for **4a** (in benzene) are 12.64 (a_N); 1.87 ($a_{o\text{-H}}$); 0.85 ($a_{m\text{-H}}$); 2.01 G ($a_{p\text{-H}}$); 2.0061 (*g*-value),[6] quite different from those for **3c**. Thus, the possibility that the present aminyls may be **4** was completely excluded.



4 (**4a**: X=H)

The aminyl **3f** was also generated in some polar solvents (chloroform, THF, acetonitrile, and ethanol), and the ESR parameters were measured in order to examine the solvent effect on the splitting constants for **3**. The a_N values obtained for **3f** in these solvents are in the range of 9.89—9.93 G, indicating that the magnitudes of the a_N values are independent of the solvent polarity. From this result, it can be said that the spin distribution in **3** is scarcely influenced by the solvent polarity.

When R in **3** is *t*-butyl, the corresponding aminyls are fairly long-lived. The results of the decay kinetic studies are illustrated in Fig. 2. The aminyl, **3e**, decayed with clean second-order kinetics (k=1.7 l mol^{-1} s^{-1}), while **3c** and **3f** persisted for more than one day ($\tau_{1/2}$>half a day). The high persistence observed for

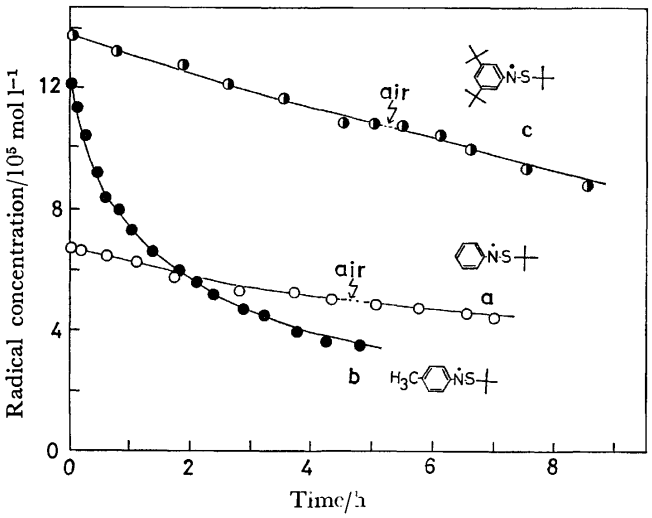


Fig. 2. Decay plots of **3c** (a), **3e** (b), and **3f** (c) in deoxygenated benzene and in benzene saturated with air (17 °C).

these aminyls is comparable to those of the oxygen analogs, **5**.[2-4]

The ESR signal intensity of **3f** in toluen, when the temperature was lowered to *ca.* −75 °C, became weaker, while when the temperature was raised to room temperature (20 °C), it was again restored, and this cycle was reversible. From this observation, it seems that **3** exist in equilibrium with a dimer.[2d]

In order to know whether **3** react with oxygen or not, the decay kinetics was also examined in the presence of oxygen. The results are shown in Fig. 2. After the measurement of the decay rate of **3** for 5 h under deoxygenated conditions, air was bubbled into the solution of **3** and the measurement was again carried out. As can be seen from the figure, the decay rates after

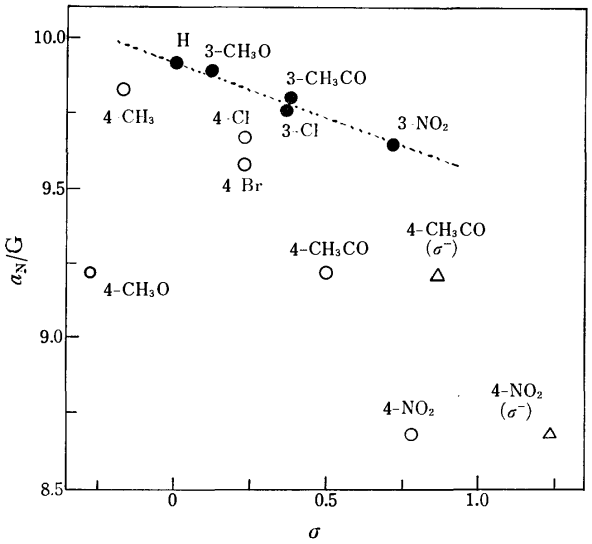

Fig. 3. Plots of a_N values *vs.* σ (○ and ●) and σ^- (△) for **3**.

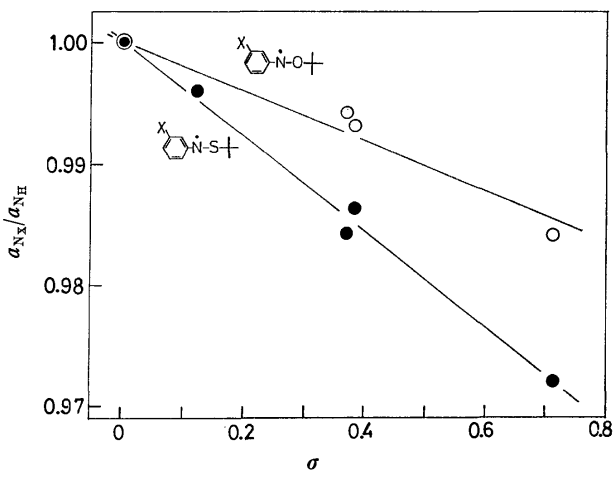

Fig. 4. Plots of a_{N_X}/a_{N_H} *vs.* σ for **3** (●) and **6** (○). a_{N_X}:a_N value for meta-substituted **3** and **6**; a_N:a_{N_H} value for unsubstituted **3** and **6**.

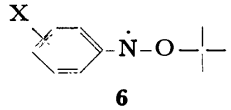
this point are almost identical with those observed under the deoxygenated conditions, suggesting that **3** do not react with oxygen much, if at all. Since **3** are typical nitrogen-centered free radicals, this result is of interest.

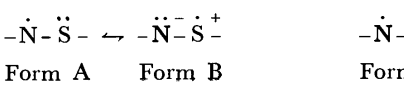
Substituent Effects. The a_N values for **3** lie in the range of 8.68—9.93 G, in the range of magnitude expected for nitrogen-centered free radicals in a π-electronic ground state.[7]

When we consider the substituent effects on ESR parameters, two limiting cases may be envisioned; that is, in terms of Walter's criteria, Class O and Class S.[8] Numerous ESR spectroscopic investigations of substituent effects have been reported, and aryl nitroxide radicals and nitrobenzene anion radicals have been classified as Class O,[9] while *N*-*t*-butylarylaminyls,[10] *N*-*t*-butoxyarylaminyls (**6**),[4] *N*-aryl-*N*-(arylthio)-aminyls (**7**),[11] *etc.* have been classified as Class S.

In Fig. 3, the a_N values for **3** are plotted against the Hammett σ and σ^- constants.[12] As can be seen from the figure, the a_N values do not correlate with these constants: both the electron-donating and electron-accepting substituents reduce the a_N values, and the unsubstituted aminyl, **3c**, exhibits the largest a_N value. Such a behavior of **3** in relation of the σ and σ^- constants indicates that **3** belong to Class S, where a_N values are determined predominantly by the extent of the delocalization of the unpaired electron onto the substituent. In the present aminyls, however, the substituents may also influence the relative importance of the resonance forms, A and B, just in the cases of **6**[4] and **7**.[11] That is, substituents not only delocalize the unpaired electron, but also influence the relative importance of the resonance forms, A and B, as has been pointed out by Danen *et al.*[4] When more powerful electron-accepting substituents are introduced, the polar form B becomes more important, resulting in a reduction of the spin density on the central nitrogen with an increase in the spin density on the sulfur. In the case of the para-substituted **3**, the two effects compete with each other in the determination of the magnitude of the a_N value. That is, when σ and σ^->0, both the effects reduce the a_N value. On the other hand, when σ<0, the former effect reduces the a_N value, while the latter effect (inductive effect) increases the a_N value. As can be seen from the figure, the a_N values are reduced in any case. From these results, it can be said that the magnitudes of the a_N values are determined predominantly by the extent of the delocalization of the unpaired electron onto the substituent, while the inductive effect is of secondary importance.



6



Form A Form B Form C Form D

On the other hand, in the case of the meta-substituted **3**, the extent of the delocalization of the unpaired electron onto the substituent is small. Therefore, the magnitudes of the a_N values are determined only by the inductive effect of the substituent; thus, the a_N values for the meta-substituted **3** are correlated with the σ constants (see Fig. 3). In conclusion, the magnitudes of the a_N values for **3** are determined predominantly by the extent of the delocalization of the unpaired electron onto the substituent; therefore, **3** belongs to Class S.

The aminyls **3** are structurally very close to **6**.[2d,4] The a_N values reported for **6** are in the range of 9.95—11.00 G, which are larger by *ca.* 1 G than those for **3**.[13] Similarly, the $a_{o\text{-H}}$ (4.34—4.80 G) and $a_{p\text{-H}}$ values (4.90—5.15 G) for **6** are also larger by *ca.* 1 G than those for **3**. This reduction in the magnitude of the splitting constants observed in going from **6** to **3** can be interpreted in terms of the greater ability of the sulfur to remove the spin from the central nitrogen compared with that of the oxygen.[14] In **3** and **6**, the spin is delocalized onto the sulfur or the oxygen by the contribution of the polar resonance form, B

or D.[15] When the relative importance of B in **3** is superior to that of D in **6**, the sulfur would remove the spin from the central nitrogen to a greater extent than the oxygen in **6**, and the central nitrogen in **3** would be charged more negatively than that in **6**. The greater ability of the sulfur to remove the spin compared with the oxygen can be explained from the results of the present study on the substituent effects. In Fig. 4, the ratio of a_{N_X}/a_{N_H} (a_{N_X} : a_N value for *meta*-substituted **3** and **6**; a_{N_H} : a_N value for unsubstituted **3** and **6**) are plotted against the σ constants. The slopes in the figure are determined by the amount of the negative charge on the central nitrogen in **3** or **6**. That is, the greater the negative charge on the central nitrogen, the larger becomes the slope. The slope obtained for **3** is −0.038, while it is −0.020 for **6**, indicating that the relative importance of B in **3** is superior to that of D in **6**. From this result, the greater ability of the sulfur to remove the spin from the central nitrogen can be explained by the greater contribution of B in **3** compared with that of D in **6**.

Experimental

All melting points are uncorrected. IR spectra were run on a JASCO Model IR-G spectrometer. UV and visible spectra were recorded with a Hitachi recording spectrometer, Model ESP-3T, and NMR spectra with a Hitachi Perkin Elmer R-20 spectrometer using TMS as an internal standard.

3,5-Di-*t*-butylaniline[16] and di-*t*-butyl diperoxyoxalate[17] were prepared by the reported methods. 2-Methyl-2-propanesulfenyl chloride was prepared as follows:[18] chlorine was bubbled into di-*t*-butyl disulfide (4.8 g, 0.027 mol) in hexane (50 ml) at 30±3 °C for 30—50 min, and then an excess of chloride dissolved in the reaction mixture was expelled by bubbling nitrogen. The hexane solution of the chloride thus obtained was used in the following reaction without any further purification. 1-Methylethanesulfenyl and butanesulfenyl chlorides were also prepared similarly. Other reagents were obtained commercially and were used without purification. Column chromatography was performed on alumina (E. Merck, Art 1097; column-size: 3×30 cm).

*N-(t-Buthylthio)-4-nitroaniline (**1a**).* A hexane solution of 2-methyl-2-propanesulfenyl chloride, prepared as has been described above, was added dropwise to a stirred solution

of 4-nitroaniline (7.0 g, 0.051 mol) and triethylamine (6.0 g, 0.059 mol) in dry THF (400 ml) at 0—5 °C. After the addition, the reaction mixture was stirred for 2 h at the same temperature and then filtered. The filtrate was concentrated under reduced pressure, and the resulting residue was chromatographed [eluent: benzene–hexane (10:1)]. Recrystallization from hexane gave yellow needles; mp 124—125 °C: yield, 1.3 g (11%). IR (KBr): 3310 cm^{-1} (NH). NMR (CCl_4): δ 1.31 (s, *t*-Bu, 9H), 6.08 (br s, NH, 1H), and 7.25 and 8.23 (d, J=10 Hz, aromatic, 4H). Found: C, 52.90; H, 6.04; N, 12.52%. Calcd for $C_{10}H_{14}N_2O_2S$: C, 53.07: H, 6.23; N, 12.38%.

N-*(t-Butylthio)-3-nitroaniline (**1b**)*. The aniline was obtained analogously to **1a**. Yellow plates; mp 100—102 °C; yield, 2.4 g (21%). IR (KBr): 3350 cm^{-1} (NH). NMR (CCl_4): δ 1.30 (s, *t*-Bu, 9H), 5.38 (br s, NH, 1H), and 7.35—8.01 (m, aromatic, 4H). Found: C, 52.98; H, 5.93; N, 12.56%. Calcd for $C_{10}H_{14}N_2O_2S$: C, 53.07; H, 6.23; N, 12.38%.

N-*(t-Butylthio)-3,5-di-t-butylaniline (**1f**)*.[5] A hexane solution of 2-methyl-2-propanesulfenyl chloride, prepared as has been described above, was added dropwise to a stirred solution of 3,5-di-*t*-butylaniline (10.4 g, 0.051 mol) and triethylamine (6.0 g, 0.059 mol) in dry ether (400 ml) at 0—5 °C. After the addition, the reaction mixture was stirred for 2 h at the same temperature and then filtered. The filtrate was concentrated under reduced pressure, and the resulting residue was chromatographed (eluent: hexane), giving a pale yellow oil of **1f** containing a slight amount of impurities. Yield, 2.4 g (15%). IR (neat): 3300 cm^{-1} (NH). NMR (CCl_4): δ 1.30 (s, *t*-Bu, 27H), 4.86 (br s, NH, 1H), and 6.92 (b, aromatic, 3H).

N-*(Isopropylthio)-3,5-di-t-buytlaniline (**1n**)*.[5] The aniline was prepared analogously to **1f** and was separated by column chromatography as a pale yellow oil containing a slight amount of impurities. Yield, 1.2 g (8%). IR (neat): 3320 cm^{-1} (NH). NMR (CCl_4): δ 1.20 (d, J=7 Hz, CH_3, 6H), 1.29 (s, *t*-Bu, 18H), 3.06 (sept. J=7 Hz, $CHMe_2$, 1H), 4.70 (br s, NH, 1H), and 6.75 (s, aromatic, 3H).

N-*(Butylthio)-3,5-di-t-butylaniline (**1o**)*.[5] The aniline was prepared analogously to **1f** and was separated by column chromatography as a pale yellow oil containing a slight amount of impurities. Yield, 1.8 g (12%). IR (neat): 3350 cm^{-1} (NH). NMR (CCl_4): δ 0.90—1.46 (br m, $CH_3CH_2CH_2$, 7H), 1.28 (s, *t*-Bu, 18H), 2.57 (*t*, J=8 Hz, SCH_2, 2H), 6.70 (s, aromatic, 3H).

General Procedure for the Preparation of N,N-*Bis(t-butylthio)-aniline (**2**)*. A hexane solution of 2-methyl-2-propanesulfenyl chloride, prepared as has been described above, was added dropwise to a stirred solution of aniline (0.015 mol) and triethylamine (0.069 mol) in dry ether (400 ml) at 0—5 °C. After the addition, the reaction mixture was stirred for 20 h at room temperature and then filtered. The filtrate was concentrated under reduced pressure, and the resulting oily residue was chromatographed on alumina [eluent: hexane for **2c—k** and benzene–hexane (1:2) for **2l** and **2m**]. Subsequent recrystallization from methanol afforded needles of **2**.[19] The yield, and physical and analytical data are summarized in Table 2.

*Generation of **3** from **1**.* Aniline **1** (20 mg), di-*t*-butyl diperoxyoxalate (20 mg), and benzene (0.20 ml) were placed in an ESR cell, degassed by three freeze-and-thaw cycles, and then sealed. The ESR spectra were recorded at 17 °C.

*Generation of **3** by Photolysis of **2**.* An aniline, **2** and a solvent (0.20 ml) were placed in an ESR cell, degassed as has been described above, and then sealed. After photolysis for 0.5—3 min in the cavity of an ESR instrument with a high-pressure mercury lamp (JES-UV-1, 100 W), the ESR signal was recorded.

*Generation of Nitroxide **4a**.* Nitrosobenzene (10 mg), 2-methyl-2-propanethiol (10 mg), di-*t*-butyl diperoxyoxalate (10 mg), and benzene (0.20 ml) were placed in an ESR cell, degassed as has been described above, and then sealed. The ESR signal was recorded at 20 °C.

Decay Kinetics. A degassed benzene solution (0.20 ml) of **2** in an ESR cell was irradiated for 0.5—3 min as has been described above. The decay rates of **3** were measured at 17 °C in the dark by monitoring the ESR signal intensities. The concentrations of **3** were determined as follows: integrated signals were recorded on the ESR instrument eqipped with a JES-ID-2 integrator. The areas under integrated curves were determined by means of their weights. The calibration curves were obtained using benzene solutions of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl as a standard.[20] Integrated signals of the samples and the references were recorded with the same instrument settings. The concentrations are believed to be accurated to ±10%.

The ESR spectra were recorded on a JES-ME-3X spectrometer with an X-band microwave unit and 100 kHz field modulation. The splitting constants and the *g*-values for **3** were determined by comparison with the a_N value (13.09 G) and the *g*-value (2.0057) of Fremy's salt. The computer simulations of the ESR spectra were performed using a FACOM 230-60 computer equipped with a FACOM F-6201D plotter.

Reactions of Aryldiazomethanes with Chloranil

Takumi OSHIMA and Toshikazu NAGAI*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

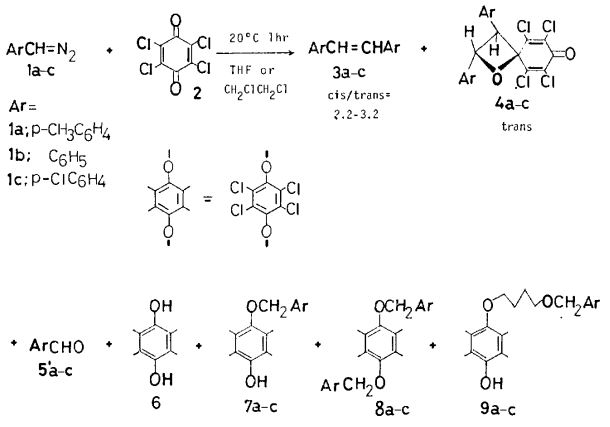
(Received July 3, 1979)

The reactions of several aryldiazomethanes (**1a**: *p*-tolyl; **1b**: phenyl; **1c**: *p*-chlorophenyl) with chloranil gave stilbenes (**3**) and spiro-oxetanes (**4**) at 20 °C in tetrahydrofuran or 1,2-dichloroethane. The isomer ratios of **3** were *ca.* 2 to 3:1 in favor of *cis*, depending on the solvents and on the substituents of **1**. In the case of **4**, however, stable *trans*-isomers were selectively formed. On the other hand, the presence of added CH_3OH suppressed the formations of **3** and **4** and, instead, induced redox reactions giving α,α-dimethoxyarylmethanes and tetrachlorohydroquinone (**6**). In these redox reactions, the acid decompositions of **1** with **6** were also found. However, the presence of CF_3CH_2OH allowed the formation of considerable amount of **3** and **4**, along with the redox products. The mechanism of these reactions will be discussed.

Diazoalkanes are useful synthetic intermediates in organic chemistry and are best represented as resonance hybrid structures with opposing dipoles.[1] These compounds, therefore, behave as 1,3-dipoles[2] or as nucleophiles[3] because of the high electron density on diazo carbon. On the other hand, quinones have conjugated two C=O and two C=C double bonds to be considered as dipolarophiles.[4] Moreover, halogen and/or cyano substituted quinones, such as chloranil and dichlorodicyano-*p*-benzoquinone, become strong electron acceptors.[5] Therefore, the reactions of diazoalkanes with quinones are interesting from the viewpoint of mechanistic study or synthetic application. For example, Pechmann[6] has reported the formation of a pyrazoline derivative through the 1,3-dipolar cycloaddition of diazomethane to the C=C bond of *p*-benzoquinone. In the case of tetrahalo-substituted quinones, epoxides were isolated in the reactions with diazomethane because the C=O bond is more reactive than the C=C bond in these quinones.[7] In this paper, we want to describe the reactions of some aryldiazomethanes(**1**) with chloranil(**2**) with or without added CH_3OH or CF_3CH_2OH.[8]

Results and Discussion

*The Reactions of Aryldiazomethanes (**1a**—**c**) with Chloranil (**2**) in THF or CH_2ClCH_2Cl.* The reactions of **1a**—**c** with **2** gave mainly *cis*- and *trans*-stilbenes(**3a**—**c**) and *trans*-spiro-oxetanes(**4a**—**c**), as is shown in Scheme 1. Besides **3** and **4**, small amounts of several products were isolated: benzaldehydes(**5′ a**—**c**), tetrachlorohydroquinone(**6**), tetrachloro-4-(benzyloxy)phenols(**7a**—**c**), tetrachloro-1,4-bis(benzyloxy)benzenes(**8a**—**c**), and tetrachloro-4-[4′-(benzyloxy)butoxy]phenols (**9a**—**c**). The **9** products were obtained only in the THF solution because these compounds incorporated the THF molecule. Since these by-products were afforded by the action of the residual water present in the solvent, a detailed mechanism will be presented later for the case of the reactions in the presence of CH_3OH or CF_3CH_2OH. The reaction conditions and the product distributions are summarized in Table 1.

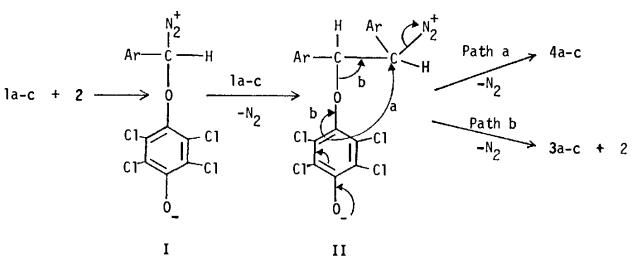


Scheme 1.

In both THF and 1,2-dichloroethane, **3** were major products. The yield of **4** was considerably greater in 1,2-dichloroethane than in THF. Here, particular attention should be paid to the stereochemistry of **3** because the thermodynamically less stable *cis*-isomers were about 2 to 3 times more numerous than the *trans*-isomers, depending on the solvents and on the substituents of **1**. On the other hand, **4** were shown to be the only stable *trans*-isomers by comparison with an authentic sample produced by the photoaddition of *trans*-**3b** and **2**, and also by the fact that the thermal decomposition of **4** at slightly over their melting points for several minutes gave *trans*-**3** and **2**. As is exemplified in the case of **1b** in THF, the ratio of **1** to **2** had no essential influence on the product distributions.

Mechanistically, the formation of **4** needs an intermediate because *cis*- or *trans*-**3** was quantitatively recovered after 5-hs' mixing with an equimolar amount of **2** in THF or 1,2-dichloroethane at room temperature. The most reasonable process is the occurrence of the diazonium betaine intermediate(II) which can produce **4** or **3** by way of Path(a) or Path(b), as is shown in Scheme 2.

Though II may be formed through the nucleophilic attack of **1** on the first diazonium betaine(I, or carbonium betaine given by the loss of N_2), the mechanism



Scheme 2.

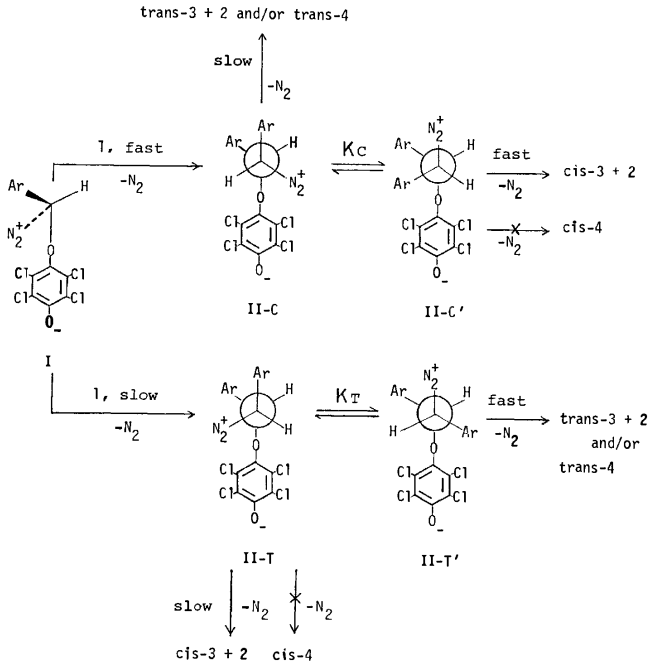
a) Reaction time 1 h. b) Yield as mole percentage based on **1**.

giving I remains unknown. However, three possible routes can be suggested. The first one is the radical-ion formation, followed by the simultaneous recombination presumed in our previous communication.[9)] Radical cations of diazoalkanes have already been postulated or actually detected in the electrochemical oxidation[10)] or in the reaction with copper(II) perchlorate.[11)] However, no direct evidence for the presence of the radical cation of **1** could be obtained in our system, though the radical anion of **2** was detected in the measurements of ESR and electronic absorption spectra.[9)] The second possible route is the formation of 2,5-dihydro-1,3,4-oxadiazole through 1,3-dipolar cycloaddition between **1** and **2**; the follow-up ring opening or the loss of N_2 gives I or carbonium betaine. In fact, 1,3,4-oxadiazole was isolated in the reaction of diazomethane with duroquinone.[12)] Other examples of the favoring of the 1,3,4-structure of oxadiazole were found in the reactions of diphenyldiazomethane with diphenylketene[13)] and of aryldiazomethanes with hexa- and pentafluoroacetones.[14)] The last possible route is the direct attack of the diazo carbon on the oxygen atom of **2**. Whichever route is adopted, it has to explain the observation that the qualitaitve N_2 evolution or disappearance of diazo-color was accelerated in the order of **1c**<**1b**<**1a**.

Stereochemistry in the Formations of ***3*** *and* ***4***. The high *cis*-to-*trans* ratio of stilbenes in the decomposition of **1a—c** with catalytic ammonium cerium(IV) nitrate has already reported by Trahanovsky and his coworkers.[15)] However, an unequivocal explanation of the high yield of the *cis*-isomer is lacking.

Why does the major path(b) preferentially yield *cis*-isomers rather than *trans*-ones, while the minor path(a) selectively yields *trans*-isomers? These stereochemical phenomena can be well interpreted by considering the transition state leading to II and the subsequent N_2 elimination process giving **3** and **4**. The nucleophilic attack of **1** on I should occur favorably through the transition state where the steric repulsion is as small as possible and where the opposite charges which appear attract each other.

As is pictured in Scheme 3, I contains a large chloranil moiety with a negative charge, a medium-sized aryl group, and a small H atom on the side remote from the N_2^+ group. Therefore, the approach of **1** to I from this side predominantly give such stable conformers as II-C



Scheme 3.

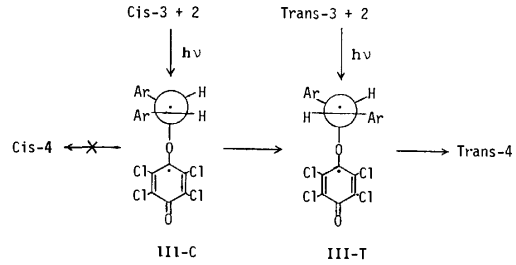
and II-T, avoiding the most striking steric repulsion between the chloranil moiety and the aryl group of **1**, and also satisfying the electronic requirement mentioned above. It should be noted here that the II-C has a lower free energy than II-T because the former can release some of the steric repulsion by placing the small H atom on the most hindered space between the chloranil moiety and the aryl group. Accordingly, the formation of II-C is more accelerated than II-T. However, in the conformational rotation to II-C′ and II-T′, the equilibrium constant, K_C, is apparently smaller than K_T because II-C′ has the highest free energy amoung these four isomers from the sterical point of view(Scheme 3). In view of the steric orientations of these isomers, it may be thought that the stereochemistry of the produtcs depends on how great extent the respective isomers contribute to the product formations. As is represented in Scheme 3, II-C and II-T may produce *trans*-**3** and *cis*-**3** respectively *via* a cis-type elimination; also, II-C may produce *trans*-**4** *via* an intramolecular S_N1-type reaction. On the other hand, II-C′ and II-T′ may produce *cis*-**3** and

Table 2. Product distributions in the reactions of **1a—c** with **2** in THF-CH_3OH or THF-CF_3CH_2OH and in the reaction of **1b** with **6** in THF at 20 °C[a]

1a—c, **2**, and **6** (mmol)		Additive[b]	Yield/%[c]						
			3(*cis*/*trans*)	**4**	**5′**	**6**	**7**	**8**	**9**
1a (7.35)	**2** (6.10)	CH_3OH	trace	ND[d]	53	23	22	2	7
1b (8.47)	**2** (8.50)	CH_3OH	trace	ND	52	13	19	3	18
1c (6.58)	**2** (6.10)	CH_3OH	trace	ND	46	12	15	2	17
1b (8.47)	**2** (8.50)	CF_3CH_2OH	58 (2.6)	6	24	11	3.5	1	3.5
1b (8.47)	**6** (8.47)	—	—	—	—	—	43	7	47

a) Reaction time 1 h. b) A four-fold excess was added with respect to **1**. c) Yield as mole percentage based on **1**. d) Not detected.

trans-**3** respectively *via* a trans elimination; also, II-T′ may produce *trans*-**4** *via* an intramolecular S_N2-type displacement. However, II-C′ or II-T can not give *cis*-**4**, probably because of the highly crowded model, which has the two aryl groups on the same side. In accordance with this idea, we obtained *trans*-**4b** alone in a 77.8 or 79.2% yield on the 3-h irradiation of a benzene solution of *trans*- or *cis*-stilbene containing an equimolar amount of **2**(50 mmol dm^{-3}), using a high-pressure mercury lamp at 20 °C: photochemical oxetane formation from olefins and C=O compounds is well known to proceed *via* a biradical intermediate,[16] such as III-C(from *cis*-stilbene) and III-T(from *trans*-stilbene); the former seems to afford no *cis*-**4** because of the highly crowded orientation as well as II-T and II-C′, but it does afford *trans*-**4** after pre-transformation into the stable III-T(Scheme 4).

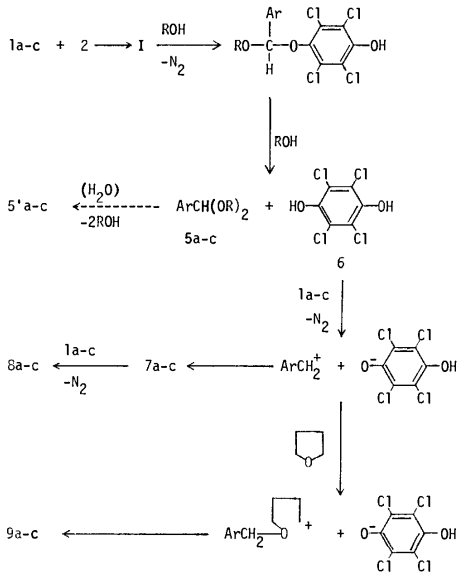


Scheme 4.

From these stereochemical considerations, the present high yield of *cis*-**3** can be reasonably explained as being responsible for the significant contribution of II-C′. Otherwise, the product distributions from the other conformers, II-C, II-T, and II-T′, would result in an excess formation of *trans*-**3** relative to *cis*-**3**, conflicting with the present results (Table 1). Therefore, it may be suggested that the rate of the product formation from II-C′ and II-T′ is much more rapid than that from II-C and II-T.

A further examination of Table 1 indicates the presence of the solvent and the substituent effects on the product distributions. The significant increase in *trans*-**4** in 1,2-dichloroethane compared with the amount in THF may be attributable to the lower solvating ability of the former medium, where the opposite charges of II should come close together, thus retarding the conformational rotation. This phenomenon results in the increase in path(a) and also in the increase of the product formation from II-C and II-T, giving more *trans*-**3** and *trans*-**4**. On the other hand, the substituents of **1** affect the relative ratio of II-C to II-T, since the stronger the nucleophilicity of **1**, the weaker the stereoselective attack of **1** on I becomes, as is supposed by the reactivity selectivity principle.[17] This assumption is in good agreement with the facts that the *cis*/*trans* ratio of **3** decreases, while *trans*-**4** increases, with the increase in the nucleophilic activity of **1**.

Reactions of ***1a—c*** *with* ***2*** *in THF-CH_3OH or THF-CF_3CH_2OH.* To establish the validity of the I intermediate, it is useful to attempt capturing it with suitable nucleophilic reagents. Indeed, marked changes in the product distributions were found on the addition of CH_3OH or CF_3CH_2OH, as is summarized in Table 2. The reactions in the presence of CH_3OH gave only a trace amount of **3**; instead, they afforded mainly acetals(**5**) and **6**, along with **7**, **8**, and **9**. **5** were isolated as benzaldehydes(**5′**) because of the easy degradation under the present acidic conditions as exhibited in the NMR measurement (see Experimental). These phenomena indicate that I undergoes a nucleophilic attack by CH_3OH rather than by **1** to turn into the redox products, as is formulated in Scheme 5. Furthermore, in this Scheme the forma-



Scheme 5.

tion of **6** may be responsible for the products, **7**, **8**, and **9**, because this hydroquinone is so acidic as to decompose **1**, as was confirmed in a comparative experiment using **1b** and **6** (Table 2). Both **7** and **8** are simple mono- and dietherification products of **6** with **1**; however, **9** noticiably arises from the THF ring opening caused by the attack of the resulting benzyl cations.

On the contrary, the presence of CF_3CH_2OH allowed the substantial formation of **3b** and **4b** because of the lesser nucleophilic ability of this alcohol compared with CH_3OH. Keeping these results in mind, the appearance of small amounts of **5'**, **6**, **7**, **8**, and **9** in the absence of an additive may be attributed to the action of the residual water (ROH, R=H) present in the solvent in spite of careful drying; here unstable *gem*-diols seem to be produced instead of **5**.

In summary, aryldiazomethanes behave differently toward chloranil than in the epoxide formation in the case of diazomethane.[7] Stilbenes and spirooxetanes were formed from the intermediate, I, under the stereocontrolled conditions which furnished *cis*-rich for **3** and only the *trans*-isomer for **4**. However, the introduction of CH_3OH markedly changed these reaction features to the redox ones giving acetals and hydroquinone.

Experimental

The NMR spectra were obtained with a Varian EM-360 instrument. The IR and UV spectra were recorded with a Hitachi 215 infrared spectrometer and a 323 spectrophotometer respectively. The ESR spectra were observed with a JEOL JES-NE2X instrument.

Materials. The tetrahydrofuran(THF) was refluxed over lithium aluminum hydride and fractionated. The dichloroethane was dried over anhydrous calcium chloride for several days and fractionated. The methanol was treated with magnesium and fractionated. The 2,2,2-trifluoroethanol(Wako Pure Chemical Co., Ltd. >99%) was used without further purification. The chloranil was commercially obtained and was purified by recrystallization from dry THF; mp 290 °C. The oily aryldiazomethanes (**1a—c**) were prepared just before use by the method of Closs and Moss[18] and were used without further purification. Hence, small amounts of benzaldehyde azines given by the spontaneous decomposition of the diazo compounds were detected in the NMR purity check in the cases of **1a** and **1b**; therefore, these azines were discarded in calculating the reaction yields. The NMR signals of the aliphatic protons of these diazo compounds and the corresponding azines (in parentheses) are as follows: δ ($CDCl_3$) **1a**; 4.88 (8.26), **1b**; 4.90 (8.67), **1c**; 4.87.

*Reactions of Aryldiazomethanes (**1a—c**) with Chloranil (**2**).* These reactions were carried out in THF and 1,2-dichloroethane. The general procedures are exemplified in the case of **1a** in THF as follows. To a stirred solution of **2** (0.5 g, 2.03 mmol) in 20 ml of dry THF, we added, drop by drop, a THF solution (10 ml) containing **1a** (0.97 g, 7.35 mmol) over a 10-min period at 20 °C. The color of the solution was suddenly darkened by the addition of **1a**, and then it gradually faded with the vigorous evolution of N_2. After 1 h's standing, the removal of the solvent *in vacuo* gave a pasty reaction mixture. The washing of this mixture with 3×20 ml pentane and then with a small portion of ether left recovered **2** (130 mg) and **4a** (260 mg, 15.6%); the amount of **4a** was determined by the NMR measurement using an internal standard ($CHCl_2CHCl_2$, δ=5.8 (s)), while its analytical sample was obtained by fractional crystallization from benzene–petroleum ether. The evaporation of the solvent (pentane–ether) gave an oily residue (1.21 g), which was submitted to NMR measurement. The spectrum showed the formation of excess *cis*-**3a** compared with its *trans*-isomer, as was confirmed by subsequent chromatographic treatment (silica gel). Elution with pentane gave, successively, *cis*-**3a** (374 mg, 49%) and *trans*-**3a** (155 mg, 20%), while elution with a petroleum ether–benzene mixture gave **8a** (8 mg, 0.5%), **2** (55 mg), **5'a** (53 mg, 6%), **7a** (103 mg, 4%), and **9a** (16 mg, 0.5%), and subsequent elution with a benzene–ether mixture gave **6** (40 mg, 2%) and a small amount of an unidentified solid. The structures of **3a—c**, **4a—c**, **7a—c**, **8a—c**, and **9a—c** were determined by elemental analyses, and the IR and NMR spectra.

p,p'-Dimethylstilbene(*cis*-**3a**); colorless oil. NMR (δ, $CDCl_3$): 2.28 (6H, s, CH_3), 6.45 (2H, s, vinyl H), 6.88—7.20 (8H, q, aromatic H). Found: C, 92.13; H, 7.82%. Calcd for $C_{16}H_{16}$: C, 92.26; H, 7.74%.

p,p'-Dimethylstilbene(*trans*-**3a**); colorless leaflets (ether); mp 179—180 °C. NMR (δ, $CDCl_3$): 2.30 (6H, s, CH_3), 6.90 (2H, s, vinyl H), 6.95—7.40 (8H, q, aromatic H). Found: C, 92.24; H, 7.80%. Calcd for $C_{16}H_{16}$: C, 92.26; H, 7.74%.

Stilbene (*cis*-**3b**); colorless oil. NMR (δ, $CDCl_3$): 6.57 (2H, s, vinyl H), 7.22 (10H, s, aromatic H). Found: C, 92.94; H, 6.69%. Calcd for $C_{14}H_{12}$: C, 93.29; H, 6.71%.

Stilbene(*trans*-**3b**); colorless leaflets (ether); mp 123—124 °C. NMR (δ, $CDCl_3$): 7.07 (2H, s, vinyl H), 7.17—7.57 (10H, m, aromatic H). Found: C, 93.20; H, 6.70%. Calcd for $C_{14}H_{12}$: C, 93.29; H, 6.71%.

p,p'-Dichlorostilbene(*cis*-**3c**); colorless oil. NMR (δ, $CDCl_3$): 6.47 (2H, s, vinyl H), 7.07 (8H, s, aromatic H). Found: C, 67.38; H, 4.06%. Calcd for $C_{14}H_{10}Cl_2$: C, 67.50; H, 4.02%.

p,p'-Dichlorostilbene(*trans*-**3c**); colorless leaflets (ether); mp 178—181 °C. NMR (δ, $CDCl_3$): 7.0 (2H, s, vinyl H), 7.37 (8H, s, aromatic H). Found: C, 67.09; H, 4.11%. Calcd for $C_{14}H_{10}Cl_2$: C, 67.50; H, 4.02%.

*2,3,5,6-Tetrachloro-*trans-*3',4'-di-*p-*tolylspiro[2,5-cyclohexadiene-1,2'-oxetan]-4-one (**4a**).* Colorless prisms (benzene–petroleum ether); mp 154 °C (dec). IR (KBr): 1675, 1111, 953, 800, 718 cm^{-1}. NMR (δ, $CDCl_3$): 2.35 (3H, s, CH_3), 2.40 (3H, s, CH_3), 4.93 (1H, d, J=9.3 Hz), 6.67 (1H, d, J=9.3 Hz), 6.83—7.60 (8H, m, aromatic H). UV: λ_{max} (THF) 260, 306.5 nm (ε=12900, 6270). Found: C, 58.48; H, 3.56%. Calcd for $C_{22}H_{16}Cl_4O_2$: C, 58.18; H, 3.55%.

*2,3,5,6-Tetrachloro-*trans*-3',4'-diphenylspiro[2,5-cyclohexadiene-1,2'-oxetan]-4-one (**4b**).* Colorless prisms (benzene–petroleum ether); mp 150 °C (dec). IR (KBr): 1671, 1092, 955, 762 cm^{-1}. NMR (δ, $CDCl_3$): 4.98 (1H, d, J=9.1 Hz), 6.72 (1H, d, J=9.1 Hz), 6.90—7.83 (10H, m, aromatic H). UV: λ_{max} (THF) 259, 295 nm (ε=11400, 6995). Found: C, 56.62; H, 2.91%. Calcd for $C_{20}H_{12}Cl_4O_2$: C, 56.37; H, 2.84%.

*2,3,5,6-Tetrachloro-*trans*-3',4'-bis(*p*-chlorophenyl)spiro[2,5-cyclohexadiene-1,2'-oxetan]-4-one (**4c**).* Colorless prisms (benzene–petroleum ether); mp 172 °C (dec). IR (KBr): 1676, 1100, 952, 821, 726 cm^{-1}. NMR (δ, $CDCl_3$): 4.87 (1H, d, J=8.9 Hz), 6.60 (1H, d, J=8.9 Hz), 6.83—7.50 (8H, m, aromatic H). UV: λ_{max} (THF) 260.5, 296 nm (ε=13600, 7320). Found: C, 48.74; H, 2.13%. Calcd for $C_{20}H_{10}Cl_6O_2$: C, 48.52; H, 2.04%.

*2,3,5,6-Tetrachloro-4-(*p*-methylbenzyloxy)phenol (**7a**).* Colorless needles (benzene–petroleum ether); mp 134—135

°C. IR (KBr): 3390, 1437, 1391, 958, 708 cm^{-1}. NMR (δ, $CDCl_3$): 2.35 (3H, s), 4.92 (2H, s), 5.83 (1H, s, OH), 7.05—7.50 (4H, q, aromatic H). Found: C, 47.81; H, 2.88%. Calcd for $C_{14}H_{10}Cl_4O_2$: C, 47.76; H, 2.86%.

*2,3,5,6-Tetrachloro-4-(benzyloxy)phenol (**7b**).* Colorless prisms (benzene–petroleum ether); mp 142—143.5 °C. IR (KBr): 3390, 1436, 1386, 945, 708 cm^{-1}. NMR (δ, $CDCl_3$): 4.92 (2H, s), 5.85 (1H, s, OH), 7.13—7.50 (5H, m, aromatic H). Found: C, 46.09; H, 2.44%. Calcd for $C_{13}H_8Cl_4O_2$: C, 46.14; H, 2.37%.

*2,3,5,6-Tetrachloro-4-(p-chlorobenzyloxy)phenol (**7c**).* Colorless needles (benzene); mp 174—175 °C. IR (KBr): 3400, 1344, 1152, 1082, 808 cm^{-1}. NMR (δ, $CDCl_3$): 4.93 (2H, s), 5.95 (1H, s, OH), 7.40 (4H, s, aromatic H). Found: C, 41.88; H, 1.97%. Calcd for $C_{13}H_7Cl_5O_2$: C, 41.91; H, 1.89%.

*2,3,5,6-Tetrachloro-1,4-bis(p-methylbenzyloxy)benzene (**8a**).* Colorless needles (benzene); mp 211—212 °C. IR (KBr): 2911, 1424, 1352, 956, 799 cm^{-1}. NMR (δ, $CDCl_3$): 2.38 (6H, s), 5.00 (4H, s), 7.17—7.67 (8H, q, aromatic H). Found: C, 58.06; H, 4.02%. Calcd for $C_{22}H_{18}Cl_4O_2$: C, 57.92; H, 3.98%.

*2,3,5,6-Tetrachloro-1,4-bis(benzyloxy)benzene (**8b**).* Colorless needles (ether); mp 169—171 °C. IR (KBr): 1421, 1358, 959, 752, 694 cm^{-1}. NMR (δ, $CDCl_3$): 4.97 (4H, s) 7.1—7.35 (10H, m, aromatic H). Found: C, 56.04; H, 3.38%. Calcd for $C_{20}H_{14}Cl_4O_2$: C, 56.10; H, 3.30%.

*2,3,5,6-Tetrachloro-1,4-bis(p-chlorobenzyloxy)benzene (**8c**).* Colorless needles (benzene); mp 236—237 °C. IR (KBr): 1418, 1355, 959, 801 cm^{-1}. NMR (δ, $CDCl_3$): 4.96 (4H, s), 7.15 (8H, s, aromatic H). Found: C, 48.63; H, 2.46%. Calcd for $C_{20}H_{12}Cl_6O_2$: C, 48.33; H, 2.43%.

*2,3,5,6-Tetrachloro-4-[4'-(p-methylbenzyloxy)butoxy]phenol (**9a**).* Pale yellow prisms (benzene); mp 86—87 °C. IR (KBr): 3150, 1441, 1381, 1168, 1030, 709 cm^{-1}. NMR (δ, $CDCl_3$): 1.66—2.07 (4H, m, CH_2CH_2), 2.33 (3H, s, CH_3), 3.33—3.73 (2H, m, OCH_2), 3.76—4.17 (2H, m, OCH_2), 4.45 (2H, s, OCH_2Ar), 5.93 (1H, s, OH), 7.13 (4H, s, aromatic H). Found: C, 51.08; H, 4.31%. Calcd for $C_{18}H_{18}Cl_4O_3$: C, 50.97; H, 4.28%.

*2,3,5,6-Tetrachloro-4-[4'-(benzyloxy)butoxy]phenol (**9b**).* Pale yellow prisms (benzene); mp 84—85 °C. IR (KBr): 3240, 1445, 1384, 1171, 1041, 714 cm^{-1}. NMR (δ, $CDCl_3$): 1.70—2.10 (4H, m, CH_2CH_2), 3.40—3.8 (2H, m, OCH_2), 3.80—4.10 (2H, m, OCH_2), 4.43 (2H, s, OCH_2Ar), 5.83 (1H, s, OH), 7.18 (5H, s, aromatic H). Found: C, 49.78; H, 4.03%. Calcd for $C_{17}H_{16}Cl_4O_3$: C, 49.78; H, 3.93%.

*2,3,5,6-Tetrachloro-4-[4'-(p-chlorobenzyloxy)butoxy]phenol (**9c**).* Pale yellow prisms (benzene); mp 77—78 °C. IR (KBr): 3140, 1425, 1371, 1152, 1025, 699 cm^{-1}. NMR (δ, $CDCl_3$): 1.70—2.07 (4H, m, CH_2CH_2), 3.40—3.70 (2H, m, OCH_2), 3.80—4.10 (2H, m, OCH_2), 4.77 (2H, s, OCH_2Ar), 5.90 (1H, s, OH), 7.23 (4H, s, aromatic H). Found: C, 45.99; H, 3.36%. Calcd for $C_{17}H_{15}Cl_5O_3$: C, 45.92; H, 3.40%.

*Reactions of **1a—c** with **2** in THF–CH_3OH.* The reactions were carried out in THF containing CH_3OH. The general procedures may be illustrated by the case of **1a**. To a stirred solution of **2** (1.50 g, 6.10 mmol) in THF (50 ml) containing CH_3OH (1.0 g) we added a THF solution (10 ml) of **1a** (0.97 g, 7.35 mmol) over a 10-min period at 20 °C. After 1 h's standing, the removal of the solvent *in vacuo* gave a pasty reaction mixture. The washing of this mixture with 3×20 ml ether left only the recovered **2** (0.49 g); the subsequent evaporation of the ether solution gave oily products. The NMR spectrum of the oily products showed the presence of α,α-dimethoxy-*p*-tolylmethane (**5a**); (δ, $CDCl_3$), 3.28 (6H, s, OCH_3) and 5.30 (1H, s, $CH(OR)_2$). However, this acetal was easily degradated to *p*-tolualdehyde on work-up. Therefore, the acetal was identified as the aldehyde (**5'a**). The column chromatographic treatment of the oily products gave, successively, **3a** (trace), **8a** (35 mg, 2%), **2** (60 mg), **5'a** (470 mg, 53%), **7a** (565 mg, 22%), **9a** (220 mg, 7%), and **6** (420 mg, 23%).

*Reaction of **1b** with **2** in THF–CF_3CH_2OH.* To a stirred solution of **2** (2.09 g, 8.50 mmol) in THF (50 ml) containing CF_3CH_2OH (3.4 g) we added a THF solution (10 ml) of **1b** (1.0 g, 8.47 mmol) over a 10-min period at 20 °C. After 1 h's standing, the removal of the solvent *in vacuo* gave a pasty reaction mixture. The washing of the reaction mixture with 3×20 ml ether left **2** (1.2 g) and **4b** (110 mg, 6%). The ether was evaporated *in vacuo*, and the residue (1.7 g) was chromatographed. Contrary to the case of CH_3OH, a relatively large amount of **3b** (442 mg, 58%, *cis*/*trans*=2.6) was obtained, together with **5'b** (220 mg, 24%), **6** (230 mg, 11%), **7b** (100 mg, 3.5%), **8b** (20 mg, 1%), and **9b** (120 mg, 3.5%).

*Reaction of **1b** with **6** in THF.* An equimolar mixture of **1b** (1.0 g, 8.47 mmol) and **6** in THF (50 ml) gave **7b** (1.23 g, 43%), **8b** (0.13 g, 7%), and **9b** (1.63 g, 47%).

Bromination of 9-Allyltriptycenes: Bromoolefin Formation and Lifetime of an Intervening Bromonium Ion

Shiro HATAKEYAMA, Tsutomu MITSUHASHI, and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received July 7, 1979)

The bromination of 9-allyl-1,2,3,4-tetrachlorotriptycene affords a mixture of bromoolefins together with a minor quantity of the corresponding dibromide. By the examination of the reactions of model compounds, it is concluded that the first attack of bromine on the olefinic bond takes place in the *meso* rotamer and the resulted bromonium ion collapses either by attack of the tribromide ion to produce the dibromide or by internal rotation about the C_9–C_{allyl} bond followed by attack of the tribromide ion to produce the bromoolefin. Examination of the bromoolefin/dibromide ratios at various temperatures suggests that the activation energy for the attack of the tribromide ion on the bromonium ion is *ca.* 3 kcal/mol higher than the rotational barrier.

Since Roberts and Kimball postulated the intermediacy of a bridged ion in the bromination of alkenes,[1] there have been numerous studies on the behavior, of this ion[2] and its presence is now generally accepted. Curiously enough, however, no information about the lifetime of the bromonium ion has been available, although there has been a report that a bromonium ion formed during the bromination of a highly hindered alkene, adamantylideneadamantane, is stable.[3]

As a result of our work on restricted rotation,[4] we have been interested in reactivities of rotamers[5] and have extended the work to triptycene systems which show medium barriers to rotation. As has been briefly reported,[6] the bromination of 9-allyl-1,2,3,4-tetrachlorotriptycene (**2**) was found to afford substitution products together with a normal adduct. This is a striking fact since substitution is known to occur during the bromination if the olefin is conjugated[7] but no instance is reported for such substitution, to the best of our knowledge, in the case of unconjugated olefins. Thus the finding prompted us to investigate the driving force for the substitution reaction by carrying out similar reactions with related compounds.

We wish to furnish evidence in this paper for that the bromoolefin is produced because an intermediate bromonium ion formed from the *meso* rotamer of the compound in question undergoes internal rotation and the *dl*-rotamers subsequently formed are stabilized by the participation of the neighboring chloro group. As a by-product of the investigation, rough estimation of the lifetime of the bromonium ion becomes possible. The process of the estimation will be discussed in detail.

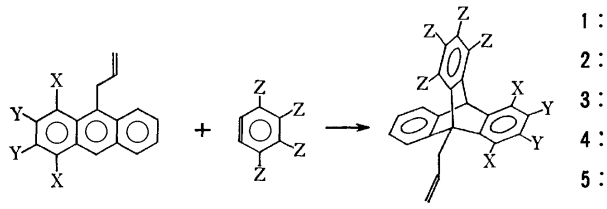
Experimental

Materials. 9-Allyltriptycenes were prepared by the Diels-Alder reactions of 9-allylanthracenes with benzynes, as illustrated in the scheme below. 9-Allylanthracenes were obtained, according to the procedure presented by Mosnaim *et al.*,[8] by the Grignard reaction of allylmagnesium chloride with substituted anthrone, followed by dehydration of the products. The purity of allylanthracenes was checked by ^{1}H NMR spectra and they were directly used for subsequent reactions.

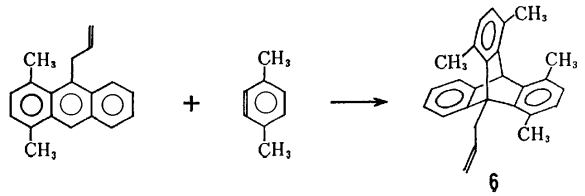
9-Allyl-1,4-dimethylanthracene. 1,4-Dimethylanthrone[9] (5 g, 0.02 mol) was added in small portions to a stirred solution of allylmagnesium chloride (0.07 mol) in ether. After the addition was completed, 50 ml of dry tetrahydrofuran was added and the mixture was refluxed for another hour. The mixture was cooled and the Grignard complex was decomposed with dilute hydrochloric acid. Organic layer was separated, treated with concentrated hydrochloric acid for dehydration of the product, and washed with water. The dried solution was evaporated and the residue was chromatographed on silica gel, using hexane as an eluent. ^{1}H NMR ($CDCl_3$, δ): 2.76 (3H, s), 2.99 (3H, s), 4.3—5.4 (4H, m), 6.0—6.8 (1H, m), 7.15 (2H, s), 7.3—8.3 (4H, m), 8.49 (1H, s).

9-Allyl-2,3-dichloroanthracene was prepared similarly by using 2,3-dichloroanthrone.[10] ^{1}H NMR ($CDCl_3$, δ): 3.9—4.2 (2H, m), 4.5—5.2 (2H, m), 5.7—6.4 (1H, m), 7.1—8.2 (7H, m).

9-Allyl-1,2,3,4-tetrachloroanthracene was also prepared by using 1,2,3,4-tetrachloroanthrone.[11] In this case, phosphorus pentaoxide was used for dehydration in place of concentrated hydrochloric acid. ^{1}H NMR ($CDCl_3$, δ): 4.3—4.5 (2H, m), 4.7—5.4 (2H, m), 6.0—6.6 (1H, m), 7.3—8.3 (4H,



1 : X=Y=Z=H
2 : X=Y=H, Z=Cl
3 : X=CH_3, Y=Z=H
4 : X=Z=H, Y=Cl
5 : X=Y=Z=Cl



6

m), 8.60 (1H, s).

9-Allyltriptycene (1). To a refluxing solution of 3.5 g (0.03 mol) of isopentyl nitrite and 4.4 g (0.02 mol) of 9-allylanthracene in 30 ml of dichloromethane was added 4.1 g (0.03 mol) of anthranilic acid in 20 ml of acetone over a period of 2 h. The reaction mixture was heated for 1 h and cooled. The solvent was evaporated *in vacuo* and the residue was taken up in benzene. Chromatography on alumina, using hexane as an eluent, gave 4 g (68% yield) of **1**. The compound was recrystallized from hexane, mp 148—148.5 °C. Found: C, 93.65; H, 5.88%. Calcd for $C_{23}H_{18}$: C, 93.82; H, 6.18%. ^{1}H NMR ($CDCl_3$, δ): 3.6—3.9 (2H, m), 5.2—5.8 (2H, m), 5.36 (1H, s), 6.0—6.8 (1H, m), 6.8—7.6 (12H, m).

9-Allyl-1,4-dimethyltriptycene (3), mp 134—134.5 °C, was similarly prepared by using 9-allyl-1,4-dimethylanthracene. The yield was 65%. Found: C, 93.21; H, 6.60%. Calcd for $C_{25}H_{22}$: C, 93.12; H, 6.88%. ^{1}H NMR ($CDCl_3$, δ): 2.39 (3H, s), 2.54 (3H, s), 4.0—4.3 (2H, m), 5.0—5.7 (2H, m), 5.58 (1H, s), 5.8—6.7 (1H, m), 6.65 (2H, q, J_{AB}= 8.0 Hz, $\Delta\delta_{AB}$=4.1 Hz), 6.8—7.6 (8H, m).

9-Allyl-2,3-dichlorotriptycene (4), mp 234.5—235 °C, was similarly prepared in 65% yield and was recrystallized from dichloromethane–hexane. Found: C, 75.74; H, 4.30; Cl, 19.99%. Calcd for $C_{23}H_{16}Cl_2$: C, 76.04; H, 4.44; Cl, 19.52%. ^{1}H NMR ($CDCl_3$, δ): 3.6—3.9 (2H, m), 5.30 (1H, s), 5.2—5.8 (2H, m), 6.0—6.7 (1H, m), 6.9—7.6 (10H, m).

9-Allyl-1,2,3,4-tetrachlorotriptycene (2) was obtained by the reaction of 9-allylanthracene with tetrachlorobenzyne which was generated by the action of isopentyl nitrite on tetrachloroanthranilic acid.[12] The yield was 15%. It was recrystallized from chloroform–ether–hexane, mp 257.5—258 °C. Found: C, 64.17; H, 3.10; Cl, 32.61%. Calcd for $C_{23}H_{14}Cl_4$: C, 63.92; H, 3.27; Cl, 32.81%. ^{1}H NMR ($CDCl_3$, δ): 4.2—4.6 (2H, m), 5.1—5.7 (2H, m), 5.8—6.3 (1H, m), 6.02 (1H, s), 6.9—7.7 (8H, m). ^{13}C NMR ($CDCl_3$, ppm from TMS): 34.1, 52.6, 56.5, 59.8, 115.8, 123.0, 123.8, 123.9, 124.0, 124.4, 124.8, 126.7, 129.7, 135.7, 142.6, 142.8, 145.5.

9-Allyl-1,4,5,8-tetramethyltriptycene (6), mp 187.5—188.5 °C was prepared from 9-allyl-1,4-dimethylanthracene, isopentyl nitrite, and 3,6-dimethylanthranilic acid[13] in 60% yield. Found: C, 92.68; H, 7.56%. Calcd for $C_{27}H_{26}$: C, 92.52; H, 7.48%. ^{1}H NMR ($CDCl_3$, δ): 2.41 (3H, s), 2.50 (3H, s), 2.62 (6H, s), 4.0—4.7 (2H, m), 5.0—5.7 (2H, m), 5.7—6.3 (1H, m), 5.88 (1H, s), 6.5—7.7 (8H, m).

9-Allyl-1,2,3,4,5,6,7,8-octachlorotriptycene (5), mp 256.5—257.5 °C, was prepared from 9-allyl-1,2,3,4-tetrachloroanthracene, isopentyl nitrite, and tetrachloroanthranilic acid in 10% yield. It was recrystallized from dichloromethane–hexane and its purity was checked by the ^{1}H NMR spectrum. Mass spectrum showed widely distributed molecular ion peaks at 566, 568, 570, 572, 574, and 576 in accord with the natural abundance of ^{35}Cl and ^{37}Cl. The most intensive peak was 570. ^{1}H NMR ($CDCl_3$, δ): 4.0—4.3 (1H, m), 5.0—5.9 (4H, m), 6.70 (1H, s), 7.0—7.9 (4H, m).

Bromination. 9-Allyltriptycenes were brominated with a large excess of bromine in chloroform with stirring overnight. To the reaction mixture, an excess of pentenes was added and the solvent was evaporated *in vacuo*. In the cases of dimethyl and tetramethyl derivatives, the brominations were carried out by using equimolar amounts of bromine with stirring for 3 d since the substitution at the benzene nuclei occurred in the presence of excessive bromine. The ^{1}H NMR spectra of the resulting residue showed that the bromination was almost complete under the reaction conditions. A typical example follows.

To a solution of 0.15 g (0.94 mmol) of bromine in 20 ml of chloroform was added 10 ml of a chloroform solution containing 42.0 mg (0.095 mmol) of **2** and the mixture was stirred overnight at 0 °C. After treated with pentenes, the mixture was evaporated. The residue was chromatographed on alumina with hexane as an eluent. The first fraction contained *trans*- and *cis*-bromoolefins (**10**), and the second afforded dibromide (**9**). Careful chromatography and repeated recrystallization of the bromoolefin mixture from dichloromethane–hexane gave *trans*-**10** as a pure specimen.

trans-**10**, mp 239—239.5 °C. Found: C, 53.90; H, 2.38; Br, 15.50; Cl, 27.51%. Calcd for $C_{23}H_{13}BrCl_4$: C, 54.05; H, 2.57; Br, 15.63; Cl, 27.75%. ^{1}H NMR ($CDCl_3$, δ); 4.2—4.5 (2H, m), 6.04 (1H, s), 6.1—6.8 (2H, m), 6.9—7.7 (8H, m).

The following ^{1}H NMR data for the *cis* isomer were obtained by subtracting the signals due to the *trans* isomer from those of the *cis-trans* mixture: 4.2—4.5 (2H, m), 6.03 (1H, s), 6.4—6.6 (2H, m), 7.0—7.6 (8H, m).

9, mp 195—196.5 °C (from dichloromethane–hexane). Found: C, 46.69; H, 2.27; Br, 27.42; Cl, 24.33%. Calcd for $C_{23}H_{14}Br_2Cl_4$: C, 46.67; H, 2.38; Br, 27.00; Cl, 23.95%. ^{1}H NMR ($CDCl_3$, δ): 3.6—4.2 (2H, m), 4.2—4.6 (2H, m), 4.7—5.2 (1H, m), 6.01 (1H, s), 6.9—8.0 (8H, m).

Bromination of **1** gave 9-(2,3-dibromopropyl)triptycene only. It was recrystallized from chloroform–hexane, mp 201—202 °C. Found: C, 60.89; H, 3.82; Br, 35.48%. Calcd for $C_{23}H_{18}Br_2$: C, 60.82; H, 4.00; Br, 35.18%. ^{1}H NMR ($CDCl_3$, δ): 3.84 (2H, d, J=6.5 Hz), 4.0—4.6 (2H, m), 5.0—5.4 (1H, m), 5.32 (1H, s), 6.8—7.6 (12H, m).

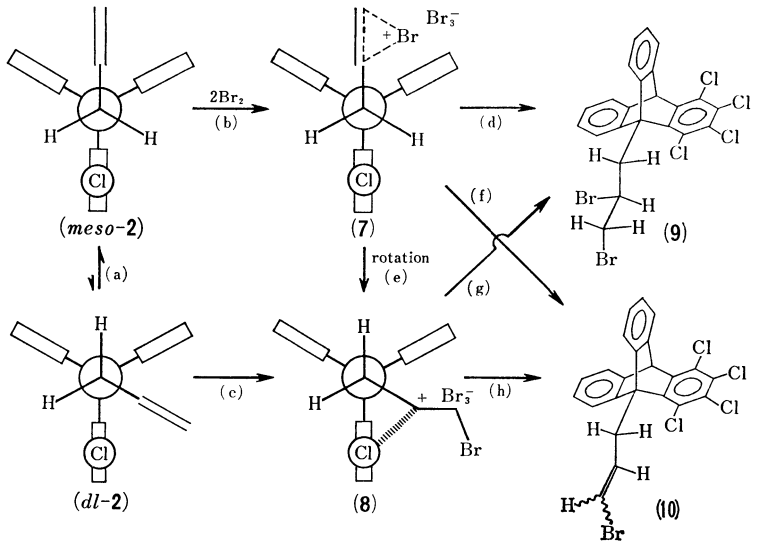
Bromination of **5** gave a product which did not show any NMR signals ascribable to the corresponding dibromide but those consistent with the structure of bromoolefins. The mixture of bromoolefins resisted to separation. Mass spectrum showed widely distributed molecular ion peaks at 644, 646, 648, 650, 652, 654, 656, and 658 in accord with the olefinic structure and the natural abundance of ^{35}Cl, ^{37}Cl, ^{79}Br, and ^{81}Br. The most intensive peak was 648. ^{1}H NMR ($CDCl_3$, δ): 3.7—4.3 (1H, m), 4.9—5.5 (1H, m), 6.0—6.7 (2H, m), 6.69 (1H, s), 7.0—7.8 (4H, m).

Bromination of **4** gave 9-(2,3-dibromopropyl)-2,3-dichlorotriptycene only. It was recrystallized from dichloromethane–hexane, mp 103—104 °C. Found: C, 52.97; H, 3.18; Br, 31.01; Cl, 13.76%. Calcd for $C_{23}H_{16}Br_2Cl_2$: C, 52.81; H, 3.08; Br, 30.55; Cl, 13.56%. ^{1}H NMR ($CDCl_3$, δ): 3.7—4.3 (4H, m), 5.0—5.4 (1H, m), 5.27 (1H, s), 6.9—7.6 (10H, m).

Bromination of **3** afforded 9-(2,3-dibromopropyl)-1,4-dimethyltriptycene only. It was recrystallized from dichloromethane–hexane, mp 199—200 °C. Found: C, 62.23; H, 4.37; Br, 33.51%. Calcd for $C_{25}H_{22}Br_2$: C, 62.26; H, 4.60; Br, 33.14%. ^{1}H NMR ($CDCl_3$, δ): 2.33 (3H, s), 2.49 (3H, s), 3.5—4.3 (4H, m), 4.8—5.2 (1H, m), 5.55 (1H, s), 6.47 (2H, s), 6.8—7.9 (8H, m).

Kinetics. Competitive reactions were carried out as follows. An equimolar mixture of **1** and one of other 9-allyltriptycenes was added to a solution of an equimolar amount of bromine in chloroform which was pre-cooled to 0 °C. The mixture was stirred for 3 d at 0 °C. Relative reaction rate was calculated by measuring the amount of unreacted starting materials with a Waters M-6000 high pressure liquid chromatography apparatus, using hexachlorobenzene as the internal standard. The following equation was used to obtain relative rates.

$$k_N/k_1 = \log\frac{[N]}{[N]_0} \Big/ \log\frac{[\mathbf{1}]}{[\mathbf{1}]_0}$$



where N denotes the compound in question and subscript 0 the initial state.

The following is a typical procedure. A solution of 15.5 mg (5.3×10^{-5} mol) of **1**, 22.9 mg (5.3×10^{-5} mol) of **2**, 8.4 mg (5.3×10^{-5} mol) of bromine, and 10.7 mg of C_6Cl_6 in 7 ml of chloroform was stirred for 3 d at 0 °C. Then an excessive amount of pentenes was added and the solution was submitted for analysis. The relative rate of **2** to **1** was 0.47.

Temperature Dependence of the Product Ratio in the Bromination of 2. Bromination of **2** (8 mg of **2** and 27 mg of bromine in 6 ml of chloroform) was carried out at 40 °C, 20 °C, 0 °C, and −17 °C. After 1 h the unreacted bromine was removed by pentenes. Under these conditions, a considerable amount of **2** was recovered. The product ratio was determined by means of high pressure liquid chromatography.

Spectral Measurement. ^{1}H NMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz. ^{13}C NMR spectra were obtained on a JEOL FX-60 spectrometer operating at 15.4 MHz.

Discussion

9-Allyl-1,2,3,4-tetrachlorotriptycene gave a mixture of *cis-trans* bromoolefins as a major product along with a normal adduct. This is anomalous in that the bromination of normal unconjugated olefins gives addition products and it is conjugated olefins that gives substitution products. The bromoolefin might be considered to be not a primary product: it may be formed as a result of dehydrobromination of a primary product, which is the normal product. Therefore, the dibromide was treated under the reaction conditions. No bromoolefin was found, however. Thus the bromoolefin must be a primaty product.

Possible pathways leading to the dibromide and the bromoolefin are shown in the above scheme. Advantages and disadvantages of these paths will be discussed by the experimental and available data.

As to the conformations of the molecule, the triptycene skeleton is rigid and thus there are two axes about which conformational changes are possible: C_9–C_{allyl} and C_{CH_2}–C_{vinyl} bonds. Although it is generally recognized that the most stable conformation of propene is that in which the C=C bond and one of the C–H's in the methyl eclipse with each other,[14] that kind of conformation is not stable in the present case because of the repulsion between the vinyl moiety and the peri-substituents. Rather it may be reasonable to assume that, as was the case in 9-benzyltriptycenes,[15] the vinyl group takes a conformation in which the π-system bisects the H–C–H angle of the allyl-methylene group. There are still two possible conformations after assuming the relation between the methylene and the vinyl groups: a =CH inside conformation and a C=C inside conformation. We are convinced that the C=C inside conformation is much less stable due to the steric effects.[16]

Since both the ^{1}H NMR spectra of 9-allyl-1,2,3,4-tetrachlorotriptycene (**2**) at ambient and low temperatures did not show any of the AB type signal but a rather sharp signal for the CH_2 group in the allyl, the compound may be assumed to exist as the *meso* form exclusively. The ^{13}C NMR spectrum of **2** supported the assumption: at −34 °C, where the internal rotation should be frozen,[17] the ^{13}C NMR spectrum gave lines in accordance with the molecular structure of C_{2v} symmetry. Thus the equilibrium shown as (a) in the scheme is lopsided in favor of the *meso* form.

However, these observations may not be taken as direct evidence for that the reaction takes place from the *meso* form, since the *dl* form, being more reactive due to the chloro participation, might react exclusively albeit their trace population. Therefore, another support is, at least, needed to exclude the reaction in the *dl*-conformation (path c).

We took advantage of reactions of model compounds to diagnose the presence or the absence of the reaction paths. As described in the Experimental section, brominations of 9-allyltriptycene (**1**) and its 2,3-dichloro (**4**) and 1,4-dimethyl (**3**) derivatives afforded only the corresponding addition products: formation of the substituted products is limited to the system carrying a peri-chloro group. The results indicate that the bromoolefin formation is not a result of the steric hindrance of the peri-substituent, since, if it were the case, the 1,4-dimethyl derivative should have given a bromoolefin. Neither the bromoolefin forma-

TABLE 1. RELATIVE BROMINATION RATES OF SUBSTITUTED 9-ALLYLTRIPTYCENES

Substrate	Substituent	Relative rate
1	none	1.00
2	1,2,3,4-Cl_4	0.47
3	1,4-$(CH_3)_2$	0.74
4	2,3-Cl_2	0.76
5	1,2,3,4,5,6,7,8-Cl_8	≈ 0
6	1,4,5,8-$(CH_3)_4$	<0.09

tion is attributed to the inductive effect, because the 2,3-dichloro derivative failed to give any of the corresponding bromoolefin. The formation of the bromoolefin from the *meso* bromonium ion (**7**) may thus be unlikely (path f). A logical intermediate will then be a chloronium ion (**8**) or a carbocation stabilized by a neighboring chloro group.

Neighboring chloro participation is present if the group is in the vicinity of a cationic center[18] and 5-membered cyclic chloronium ion have been postulated.[19] Since the cationic center and the chloro group are to form a 6-membered ring, this kind of stabilization is expected. Then a problem arises: is the stabilized cation directly formed from the *dl* form (path c) or is it formed by the attack of bromine on the *meso* form followed by the internal rotation (paths b and e)?

9-Allyl-1,2,3,4,5,6,7,8-octachlorotriptycene (**5**) was used as a model compound for the diagnosis. ^1H NMR spectra of this compound showed an AB pattern split by the adjacent protons but no signal ascribable to CH_2 protons of the *meso* form was observed. This is reasonable because the *meso* form, having the vinyl group inbetween the two tetrachlorobenzo bridges, is unstable relative to the *dl* form in this compound. The action of a large excess of bromine on **5** in chloroform at room temperature afforded the corresponding substituted product only in an almost quantitative yield after standing overnight. This observation suggests that the *dl* form of **2**, if reacted at all, affords only the substitution products and could in principle mean that the reaction occurs from the *dl* form of **5**.

We then ran competitive reactions to obtain further information about the reaction rates. The results are shown in Table 1. The relative rates, taken that of unsubstituted 9-allyl-triptycene (**1**) as a standard, suggest that substitution by chloro groups remote from the reaction site retards the reaction to a small extent (compare **1** and **4**). Therefore, the less reactivity of compound **2**, compared to **3**, must be derived by the electronic effect, because the steric effects in these compounds are almost the same. Another example of this sort is found in the defference in reactivities of **5** and **6**: **5** showed almost zero reactivity in the presence of **1**, whereas **6** reacted definitely, although a little, in spite of their similar steric environments. The low reactivities of **5** and **6** may now be taken as evidence for that the bromination of **2** does not take place in the *dl* form but in the *meso* form exclusively. Thus we rule out the path c: the bromination of **2** must proceed *via* path b.

As to the formation of two kinds of products, the dibromide and the bromoolefin, two pathways are still possible, although the intervention of the *dl* form of **2** is now excluded. A bridged bromonium ion (**7**) formed by the attack of bromine on the olefin in the *meso* form may react with the tribromide anion to afford the adduct (path d). Alternatively, **7** may undergo internal rotation to form the *dl* form which may quickly change to the chloronium ion (**8**) (path e). The chloronium ion may be attacked by the tribromide ion at the inside carbon to form the dibromide (path g) or at the proton of the outside carbon to form the bromoolefin (path h). The formation of the dibromide from the chloronium ion (path g), however, may be rejected for the following reasons. The octachloro compound (**5**) failed to give any of the corresponding dibromide. Since a bromonium ion formed from **5** may collapse to a chloronium ion easily, a dibromide should have been found in the bromination products, if the chloronium ion were to produce the dibromide. This is reasonable because the inside carbon in the chloronium ion (**8**) is sterically protected and more exposed protons of the bromomethyl group will be vulnerable to the attack.

Although it is not possible to rigorously exclude the possibility that the once-formed chloronium ion undergoes internal rotation to revert to the *meso* bromonium ion (**7**), we believe this will not occur because of the stability of the chloronium ion. The chloronium ion will be attacked to give the bromoolefins before the internal rotation.

Having established the paths of the reaction, we come to an interesting problem. It is most likely that both the internal rotation and the attack of the bromonium ion by the tribromide occur from the bromonium-tribromide ion pair.[20] The reasons are three fold: bromide salts are not added which would enhance the attack by the bromide ion, the bulkiness of the triptycyl group efficiently hinders the solvation of the charge center of the bromonium ion to disfavor the formation of free ions, and the low polarity of the solvent should be unfavorable for the formation of free ions. We may then approximate that both the internal rotation and the formation of the dibromide are unimolecular competitive reactions occurring from the same ion pair, although it can be argued, strictly saying, that the ion pair may have to dissociate for the rotation, the collapse of the solvent-separated ion pair is not purely unimolecular, *etc.* Then examination of the temperature dependence of the product ratio (**10**/**9**) will produce the ratio of rate constants and the difference in kinetic parameters of the two processes.

The results of the temperature dependence study of the ratios **10**/**9** are shown in Table 2. The ratio increases with the decreasing temperature. The Arrhenius polt of the data yields the difference in the activation energies as 3.0 kcal/mol and that in the entropies of activation as 8.0 e.u. The absolute value of the activation energy for rotation can not be obtained at the present time, but we tentatively assume that the size of the ion pair is roughly the same with that of a phenly group. Then the barrier to rotation

Table 2. Formation ratios of the bromoolefins *vs.* the adduct in the bromination of compound **2** at various temperatures

Temp/°C	Ratio (substitution/addition)
40.7	1.54
20.0	2.40
0.0	3.09
−17.0	7.36

(E_a 13.1 kcal/mol, ΔS^* −6.0 e.u.) is known for a model compound, 9-benzyl-1,2,3,4-tetrachlorotriptycene.[21] This indicates that the collapse of the ion pair requires thermal energy corresponding to these kinetic parameters: the energy of activation for rotation will be about 13 kcal/mol and that for the reaction of the ion pair about 16 kcal/mol. Using these values, we estimate the half life of the bridged bromonium ion as 0.1 s at 0 °C. This is by no means the general half life of bromonium ions but, we feel, is a special case where the lifetime of the intermediate is exceptionally long due to the steric conditions.

The change in entropies of activation, as observed from the ratio (**10**/**9**) is nearly equal to that for the rotation of 9-benzyl-1,2,3,4-tetrachlorotriptycene. If we rely upon the entropy of activation obtained by the DNMR method,[22] it follows that the activation entropy for the reaction of the bromonium ion with the tribromide ion is close to zero. This value seems to be plausible since the collapse of an ion pair is a unimolecular reaction and concurrent occurence of the bond formation (C–Br) and the bond cleavage (Br–Br_2) will compensate to result in a small entropy change.

The lack of the reactivity of the bromoolefins toward an excess of bromine is not limited under the conditions mentioned above. The isolated bromoolefins are also inert to bromine. Although the reason for this inertness is not well understood at the present time, we believe the steric effects must be playing an important role.

Base-catalyzed Autoxidation of Fluorene in the Presence of Phase Transfer Catalysts[1)]

Junzo YAMASHITA,* Shinji ISHIKAWA, and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980

(Received July 9, 1979)

Base-catalyzed autoxidation of fluorene to fluorenone has been carried out in an aqueous potassium hydroxide-benzene two-phase system in the presence of 18-crown-6 as a phase transfer catalyst. The initial rate of oxidation is proportional to the amount of fluorene. The addition of 18-crown-6 leads to the increased concentration of potassium hydroxide and water in the benzene phase, which is responsible for the increased rate of oxidation. Increasing the concentration of potassium hydroxide in the aqueous phase increases the concentration of 18-crown-6 and potassium hydroxide in benzene, resulting in a large increase in the rate of oxidation. The ease of oxidation with respect to the base is KOH>NaOH>LiOH>$Ba(OH)_2$. Less polar solvents such as cyclohexane used as an organic phase decrease the oxidation rate.

Fluorene, diarylmethanes, and other weak carbon acids that are unreactive toward oxygen in an aqueous or alcoholic solution can be oxidized in dimethyl sulfoxide or other dipolar aprotic solvents.[2)] For example, the oxidation of fluorene by molecular oxygen in the presence of potassium *t*-butoxide in *t*-butyl alcohol–dimethyl sulfoxide solution is known to proceed through fluorenide anion to yield fluorenone (Scheme 1).[2b)]

$$R_2CH_2 + B^- \longrightarrow R_2CH^- + BH$$
$$R_2CH^- + O_2 \longrightarrow R_2CH\cdot + O_2^{\cdot-}$$
$$R_2CH\cdot + O_2 \longrightarrow R_2CHOO\cdot$$
$$R_2CHOO\cdot + R_2CH^- \longrightarrow R_2CHOO^- + R_2CH\cdot$$
$$R_2CHOO\cdot + O_2^{\cdot-} \longrightarrow R_2CHOO^- + O_2$$
$$R_2CHOO^- \longrightarrow R_2CO + OH^-$$

R_2CH: 9-Fluorenyl

Scheme 1.

Recently the oxidation of fluorene, xanthene, 9,10-dihydroanthracene, and other aromatic weak carbon acids was successfully carried out in an aqueous sodium hydroxide–benzene or –tolune two-phase system in the presence of phase transfer catalysts.[3)]

In the present paper we describe the reaction as regards the function of 18-crown-6 as a phase transfer catalysts.

Results and Discussion

Benzene was chosen as an organic phase containing fluorene and 18-crown-6. An aqueous phase contained a large amount of potassium hydroxide as a base. The two-phase system of water(10 ml) and benzene (40 ml) in a 100 ml flask was vigorously shaken under oxygen pressure(1 atm) at 40.0 °C and the rate of oxygen absorption was measured by the usual constant pressure oxygen absorption apparatus.[2b)] Despite the complexities of the two-phase system, the oxidation rates were reproducible within ±5%. The shaking speed between 150 and 200 strokes/min did not affect the rate of oxidation; therefore, that of 170—180 strokes/min was used in determination of the kinetic effects.

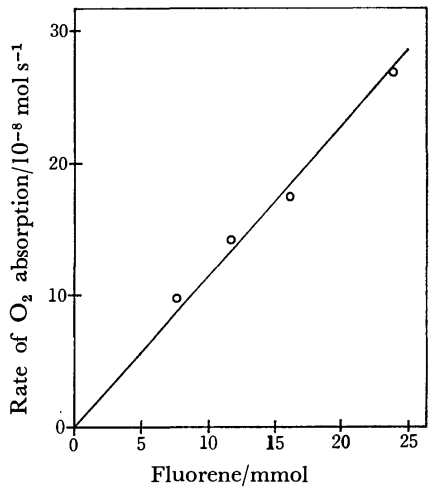

Fig. 1. Relation between fluorene used and the rate of O_2 absorption. Reaction conditions: benzene 40 ml, KOH 7.50 mol dm^{-3} in H_2O 10 ml, 18-crown-6 1.59 mmol, 40 °C.

TABLE 1. EFFECT OF TEMPERATURE[a)]

Temp °C	Fluorene mmol	KOH mol dm^{-3}	18-Crown-6 mmol	k[b)] 10^{-5} s^{-1}
30	16.2	7.50	1.56	1.04
40	16.3	7.50	1.59	1.07
50	16.2	7.50	1.57	1.31

a) Benzene 40 ml, H_2O 10 ml. See Fig. 1 for other reaction conditions. b) k=[rate of O_2 absorption (mol s^{-1})]/[fluorene (mol)].

The initial rate of oxidation is proportional to the amount of fluorene (Fig. 1), which agrees with other base-catalyzed autoxidation.[2)] The effect of temperature on the rate of oxidation is not very great since the partial pressure of oxygen in the reaction flask decreases with rise in temperature (Table 1).

Effects of various bases on the rate of oxidation are given in Table 2. As expected, potassium hydroxide is the most active, the order of activity being consistent with that of the stability of the corresponding metal complexes of 18-crown-6.[4)]

The solvent effects on the oxidation rate (Table 3)

Table 2. Effects of bases[a)]

	Base / mmol	Fluorene / mmol	k / s^{-1}
LiOH	34.4	3.06	5.1×10^{-6}
NaOH	59.9	3.04	7.8×10^{-4}
KOH	75.2	2.67	1.9×10^{-3}
$Ba(OH)_2$	46.5	3.01	small

a) Benzene 40 ml, 18-crown-6 5.0×10^{-5} mol. See Fig. 1 for other reaction conditions.

Table 3. Effects of solvents[a)]

Solvent	18-Crown-6 / mmol	k / 10^{-5} s^{-1}
Benzene	1.59	1.19
t-Butylbenzene	1.59	1.14
Cyclohexane	1.54	0.283

a) Fluorene 16.2 mmol, solvent 40 ml, KOH 7.50 mol dm^{-3} in H_2O 10 ml, 40 °C. See Fig. 1 for other reaction conditions.

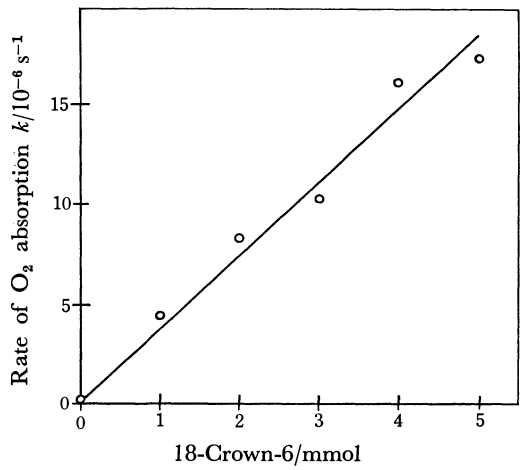

Fig. 2. Effect of 18-crown-6. Reaction conditions: fluorene 16.2 mmol, KOH 7.98 mol dm^{-3}, 40 °C. See Fig. 1 for other reaction conditions.

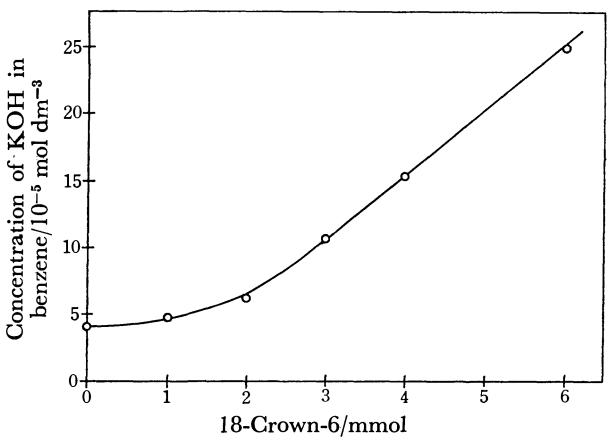

Fig. 3. The effect of 18-crown-6 on the concentration of KOH in benzene. Reaction conditions: See Fig. 1.

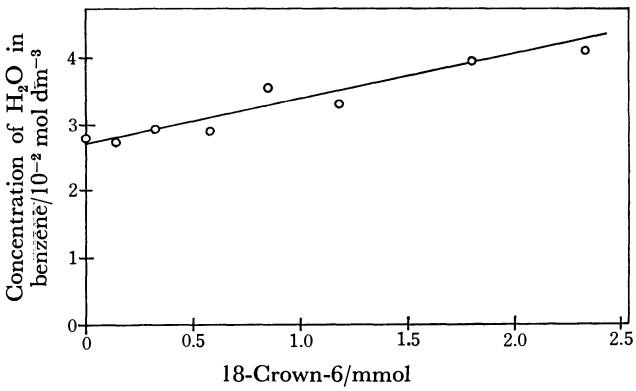

Fig. 4. The effect of 18-crown-6 on the concentration of H_2O in benzene. Reaction conditions: See Fig. 1.

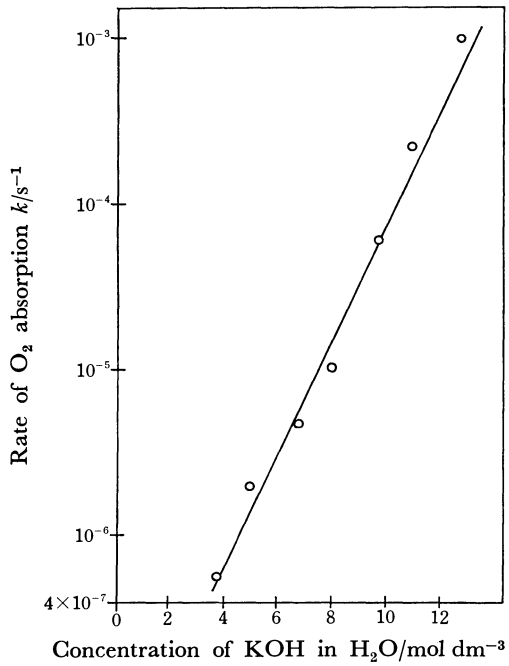

Fig. 5. Effect of the concentration of KOH. Fluorene 16.2 mmol, 18-crown-6 1.50 mmol, 40 °C. See Fig. 1 for other reaction conditions.

may be consistent with Scheme 1, since the less polar solvent or cyclohexane is presumed to involve the less amount of potassium hydroxide responsible for the formation of the fluorenide anion.

The Effect of Concentration of 18-Crown-6. The rate of oxidation is proportional to the amount of 18-crown-6 used, *ca.* 97% of which is distributed into the benzene phase (Fig. 2). The result can be predicted from Fig. 3 which shows the proportional relationship between the concentration of potassium hydroxide in benzene and that of 18-crown-6, since the rate of base-catalyzed autoxidation is known to be proportional to the concentration of bases.[2)] The extremely low concentration of potassium hydroxide in benzene as compared with that in the aqueous phase indicates that 18-crown-6 is not very effective in complexing and solubilizing potassium hydroxide into benzene.

The amount of water involved in benzene increases linearly with the concentration of 18-crown-6 (Fig. 4).

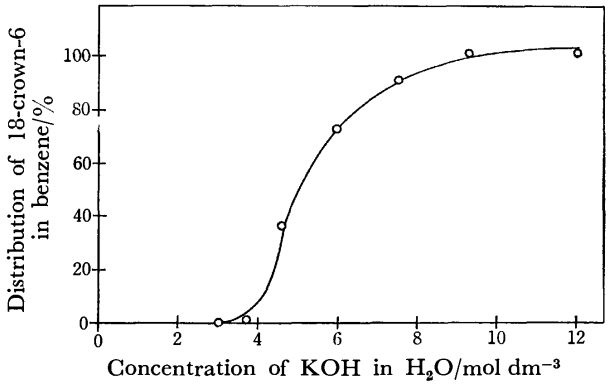

Fig. 6. Relation between the concentration of KOH in water and 18-crown-6 in benzene. Reaction conditions: See Fig. 5.

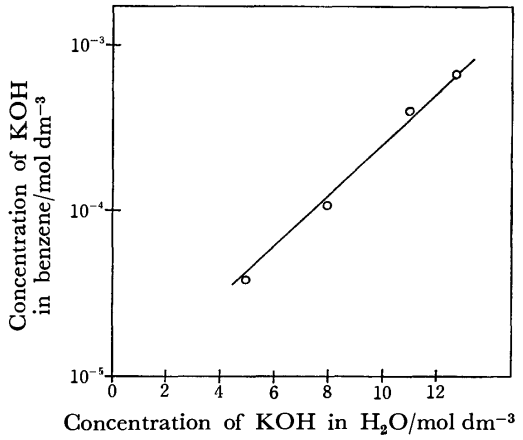

Fig. 7. Relation between the concentration of KOH in water and in benzene. Reaction conditions: See Fig. 5.

This might cause the decreased basicity of potassium hydroxide in benzene leading to a decrease in the rate of oxidation. The results shown in Figs. 2 and 4 indicate that the basicity of potassium hydroxide in benzene is almost constant at a high molar ratio of water to potassium hydroxide in benzene, calculated to be *ca.* 160—700 from Figs. 3 and 4.

Effect of the Concentration of Potassium Hydroxide in an Aqueous Phase. The concentration of potassium hydroxide in an aqueous phase has a large effect on the rate of oxidation (Fig. 5). The concentration of 18-crown-6 and potassium hydroxide in benzene increases rapidly with rise in that of potassium hydroxide in the aqueous phase. The large increase of the oxidation rate with the increasing concentration of potassium hydroxide in benzene (Fig. 9) suggests the increased basicity in the benzene phase. From Figs. 7 and 9, the molar ratios of water to potassium hydroxide in benzene are calculated to be *ca.* 1700 and 20, where the concentration of potassium hydroxide in the aqueous phase are 4.0 and 12.5 mol dm^{-3}, respectively. This indicates that the molar ratio decreases by a factor of 1/85 at the higher concentration of potassium hydroxide in the aqueous phase, which may be responsible for the increased basicity.[5] Thus, the increase of potassium hydroxide in the aqueous phase is doubly

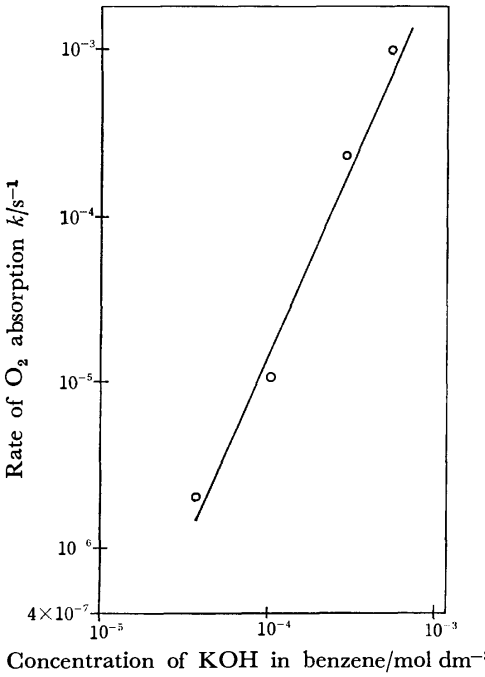

Fig. 8. Relation between KOH in benzene and the rate of oxidation. Reaction conditions: See Fig. 5.

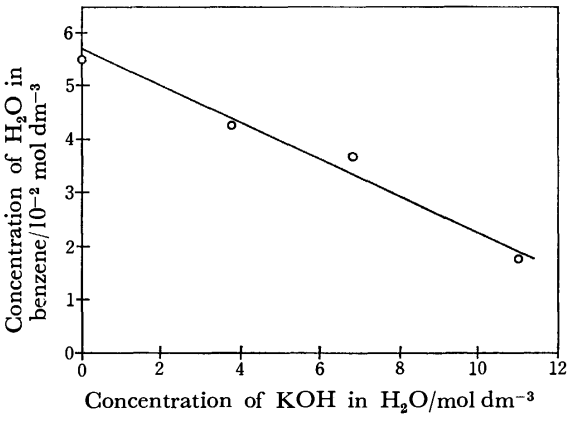

Fig. 9. Relation between the concentration of KOH in water and H_2O in benzene. Reaction conditions: See Fig. 5.

reflected on the rate of oxidation by increasing both the amount and base strength of potassium hydroxide in the benzene phase.

Experimental

Materials. Reagent grade fluorene was recrystallized twice from ethanol and dried *in vacuo*. 18-Crown-6 was prepared according to the reported procedure: mp 34.5—35.5 °C (lit, 36.5—38.0 °C).[6] Found: C, 54.61; H, 8.85; O, 36.54%. Calcd for $C_{12}H_{24}O_6$: C, 54.53; H, 9.15; O, 36.32%. Reagent grade benzene, *t*-butylbenzene and cyclohexane were shaken with sulfuric acid, washed, dried with sodium, and distilled. Hydroxides of lithium, sodium, potassium, and barium were of guaranteed grade.

Standard Oxidation Procedure. A 100 ml flask with a side arm containing 40.0 ml benzene solution of fluorene 2.71 g (16.3 mmol) and 18-crown-6 0.396 g (1.50 mmol) and 10.0 ml aqueous solution of potassium hydroxide (7.50 mol

dm^{-3}) was connected by rubber tubing to a gas buret, evacuated, and filled with oxygen a number of times. The flask was then shaken at a rate of 170—180 strokes/min with a movement of 10 cm in a thermostated water bath. The oxygen absorption was measured at 1 atm by the gas buret with an automatic pressure control apparatus.[2b] After 3 h, the reaction mixture was extracted with benzene and the extracts were used for analysis. The rate of oxygen absorption was not appreciable in the absence of fluorene or 18-crown-6.

Analysis. *Fluorenone*: The yield of fluorenone was determined on a Hitachi 163 type gas chromatograph using a 25 m Chemi-column coated with Silicone SF 96. The oxidation of 1 mol of fluorene to fluorenone under the reaction conditions mentioned above consumed *ca.* 1 mol of oxygen. No appreciable amount of other oxidation products of fluorene was detected.

Water in Benzene: The reaction mixture containing 40 ml of benzene phase and 10 ml of aqueous phase was shaken at 40.0 °C for 20 min and then left to stand for 10 min. A 10 ml sample pipetted from the benzene phase was used for the determination of water content by the Karl-Fischer method.

Potassium Hydroxide in Benzene: A 10 ml sample pipetted from the benzene phase was distilled off benzene *in vacuo* and then added with 10 ml of 0.035 mol dm^{-3} hydrochloric acid solution for measuring potassium ion on a Hitachi 207 type atomic absorption spectrometer.

18-Crown-6 in Benzene: A 5 ml sample pipetted from the benzene phase was diluted with 3 ml of benzene containing 1.44×10^{-2} g ml^{-1} of fluorenone and was determined at 180 °C on a Hitachi 163 type gas chromatograph using a 25 m Chemi-column coated with Silicone SF 96.

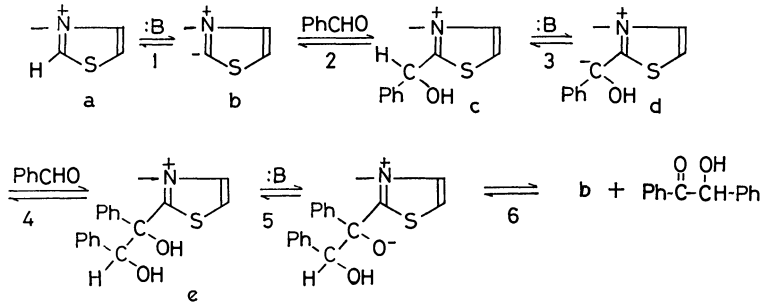
(Received July 20, 1979)

The rates of benzoin condensation catalyzed by thiazolium salts of varying structures have been determined in methanol containing triethylamine as the base by the method of gas chromatography. The condensation activity was observed not to be linearly correlated with the acidities of 2-position of catalyst thiazolium ring. The dimethylamino substituent was found not to act as an internal base for benzoin condensation, but rather exerted an inhibitory effect. In general, the effects of *N*-substituent on the rate of benzoin condensation were small. However, a large steric hindrance was observed for 3-methyl-4-menthylthiazolium perchlorate.

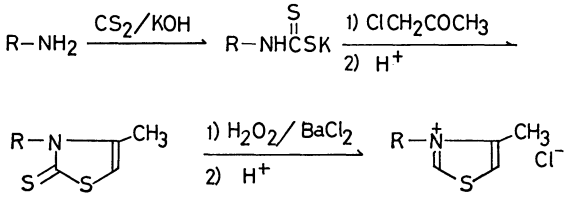
The mechanism of benzoin condensation catalyzed by a thiazolium salt is generally accepted as to involve multistep reaction pathways shown in Scheme 1.[1,2] In Scheme 1 are involved three ionization steps 1, 3, and 5, of which steps 1 and 5 were investigated and considered to be subject to lyate ion catalysis.[1c,3] However, the mechanism of base catalysis in step 3 has remained uncertain until recently as to whether it is subject to general base or lyate ion catalysis, although it has been demonstrated that the α-proton of 2-(1-hydroxyethyl)thiamine (analog of **c**) is exchangeable with solvent proton at pH 8.1.[4] Very recently, it has been shown that carbanion formation from 2-(1-hydroxyethyl)- and 2-(1-hydroxybenzyl)-thiazolium ions (analog of **c**) proceeds *via* a general base catalysis in aqueous buffer solutions.[5]



Scheme 1.

Meanwhile, we have observed general base catalysis in the H–D exchange reactions of 2,3,4-trimethylthiazolium iodide in methanol in the presence of amine.[6] This exchange reaction may also be the model of the above step 3 ionization process. Then one may expect an improved catalytic activity by attaching an appropriate basic group to the thiazolium ring which can act as an internal base. Another aspect of interests is the steric effect which we have also noted to be a determining factor for the asymmetric synthesis of benzoin.[7]

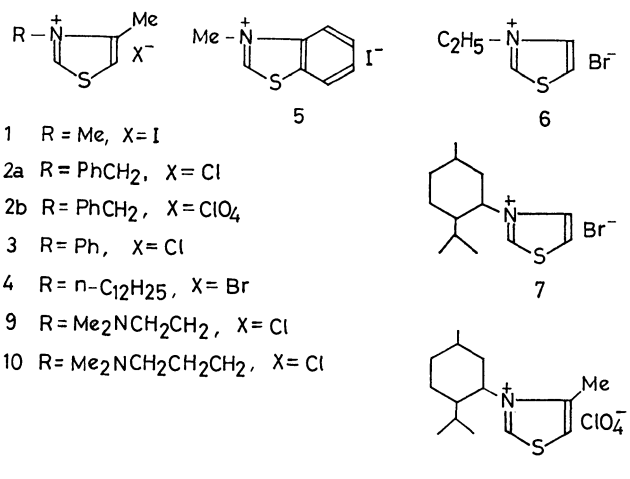
In this paper, we describe the kinetics of benzoin condensation in methanol containing triethylamine. The study was concerned with the structure-reactivity relationship of thiazolium salt catalysts such as mentioned above. It is surprising that there has been no report on the overall kinetics of benzoin formation from benzaldehyde catalyzed by thiazolium salt, although the kinetics of cyanide ion catalysis was studied in detail by Schowen and the coworkers.[8]



Scheme 2.

Results and Discussion

Synthesis of Thiazolium Salts. The thiazolium salts, **1**, **2**, **4**, **5**, and **6** were prepared by reacting the corresponding halides with thiazoles. 3-Phenyl (**3**), 3-[2-(dimethylamino)ethyl] (**9**), and 3-[3-(dimethylamino)propyl] (**10**) derivatives were synthesized from the corresponding amines, as shown in Scheme 2.[9] The preparation of menthyl derivatives, **7** and **8**, was described in a previous paper.[7]



1 R = Me, X = I
2a R = $PhCH_2$, X = Cl
2b R = $PhCH_2$, X = ClO_4
3 R = Ph, X = Cl
4 R = n-$C_{12}H_{25}$, X = Br
9 R = $Me_2NCH_2CH_2$, X = Cl
10 R = $Me_2NCH_2CH_2CH_2$, X = Cl

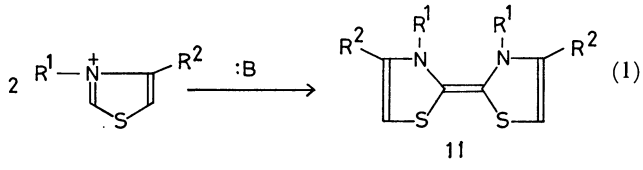
Rates of Benzoin Condensation. In the cyanide ion-catalyzed benzoin condensation in methanol, Schowen *et al.* employed spectrophotometric method to follow the formation of benzoin at 320 nm.[8a] Unfortunately, however, in the thiazolium ion-catalyzed condensation in methanol containing triethylamine, the partial dimerization of thiazolium ion to form *N,N'*-disubstituted 2,2'-bithiazolinylidene[10] (**11**, Eq. 1) was encountered



(1)

11

which disturbed the absorbance measurement at 320 nm. Therefore, we were forced to employ gas chromatography for the analysis of product benzoin by using 1,2-diphenylethane as an internal standard. The time courses of benzoin formation are illustrated in Fig. 1. The corresponding second order rate plots ($[PhCHO]_t^{-1} - [PhCHO]_0^{-1} = k_{obsd}t$) are shown in Fig. 2. Good linear plots were obtained up to more than 50% of the reaction for **1** and 70% for **2a**, although deviations were noted at the later half or one third of reaction due to the partial loss of catalytic activity by the dimerization of catalyst.

Table 1. The rate constants and benzoin yield after 20 h at 51 °C

Catalyst	$10^2 k_{obsd}$ / $l\,mol^{-1}\,min^{-1}$	k_{rel}	Benzoin yield / %
1	1.4[a]	1	66
2a	3.2[a]	2.3	79
2b	2.9[a]	2.0	67
3	1.3[a]	0.9	45
4	1.1[a]	0.8	67
5	≈0.03[a]	0.02	10
6	1.1[a]	0.8	61
	0.6[b]		—
	0.30[c]		46
7	0.94[a]	0.7	62
8	≈0.01[a]	0.01	3

a) PhCHO=0.31 M, catalyst=0.06 M, Et_3N=0.06 M. b) Et_3N=0.03 M. c) $Et_3N \cdot HCl$(0.06 M) was added.

The gas chromatographic method may be less accurate than the spectrophotometric method. Nevertheless, fairly reproducible second order rate constants were obtained. The results are listed in Table 1. In general, the rates are not very much sensitive to the *N*-substituent. Aliphatic methyl (**1**), ethyl (**6**), dodecyl (**4**), menthyl (**7**), and aromatic phenyl (**3**) substituents have almost the same effect. The effect of benzyl substituent is the largest one for the rate enhancement, but only 2—3 fold. The effect of the counter anion is also small as seen in **2a** and **2b**. The values for **5** are not accurate because of considerable decomposition of the catalyst . The activity of **8** is unusually low which is difficult to account for simply by the electronic effect, since the activity of **7** appears to be normal. As discussed in the previous paper,[7] CPK molecular model suggests that steric repulsion between 4-Me of thiazolium ring and isopropyl groups of *N*-menthyl part constrains the thiazolium ring to an unfavorable conformation for the catalysis.

Acidity of 2-Hydrogen. For several thiazolium salts, the rate constants of H–D exchange of 2-hydrogen were determined by NMR in D_2O buffered by 0.1 M acetate (mostly, pD=4.80) at 40 °C. The results are listed in Table 2.

The k_{OD^-}=5.84×10^5 $l\,mol^{-1}\,s^{-1}$ (40 °C) for **1** is reasonable in agreement with the value of 5.0×10^5 $l\,mol^{-1}\,s^{-1}$ (38 °C) reported by Haake *et al.*[3a] Such relative rates in Table 2 appear to be accounted for in terms of the electronic effects (inductive and resonance) except for that of **4**. An enhanced rate of **4** is apparently due to the micellar effect, as we had reported in a previous communication that **4** is highly active in water for benzoin condensation.[11] The salt **4** forms micelles at concentrations of the NMR measure-

TABLE 3. THE RATE CONSTANTS OF BENZOIN CONDENSATION CATALYZED BY **9** AND **10**[a]

[Et_3N]/[cat]	$10^2 k_{obsd}$/l mol^{-1} min^{-1}	
	9	**10**
1	— (trace)	— (5.6)
2	0.06 (12)[a]	0.14 (15)
3	0.14 (15)	0.20 (22)
4	0.24 (21)	0.29 (29)

a) PhCHO=0.31 M, catalyst=0.06 M. The number in parenthesis are the benzoin yields/% after 20 h.

ment which are much higher than the CMC of **4** (3.3×10^{-3} M in water). The micellar effect, of course, does not operate in methanol. Hence the rate constant for **4** in Table 1 is nearly the same as those of non micelle forming **1** and **6**, *etc.*

At any rate, Tables 1 and 2 indicate a poor correlation between the relative rates of H-D exchange of 2-hydrogen and those of benzoin condensation. Presumably, a ylide formed from **5** may be stabilized too much and lose activity for condensation.

Effect of Internal Base for Benzoin Condensation. We have suggested a possibility of general base catalysis by externally added base for the abstraction of α-hydrogen of the intermediate **c** (step 3 in Scheme 1).[5,6] Such general base catalysis would be much more favored when the reacting groups are arranged in appropriate intramolecular positions. Thus we have examined the catalytic activities of **9** and **10** for the benzoin condensation, where the dimethylamino group was expected to act as internal base as illustrated in the structure **12** for the addition intermediate. Meanwhile, Hine *et al.* demonstrated a remarkable bifunctional catalysis by 3-(dimethylamino)propylamine and 2-(dimethylaminomethyl)cyclopentylamine in dedeuteration of acetone-d_6.[12] These primary amines catalyze the reaction through the formation of iminium ion intermediate as illustrated in the structure **13** for the latter amine. Hine *et al.* proposed that the intramolecular general base catalysis by dimethylamino group occurs favorably when the reacting groups can be held in an eight-membered cyclic transition state, in which the carbon-deuterium bond being broken is in a plane nearly perpendicular to the plane of the iminium double bond as depicted in the structure **14**. The structural analogy between **12b** and **13** appears to be almost perfect if one ignores the difference of α-C–OH and α-C–D bond.

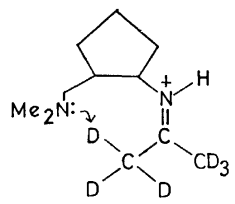
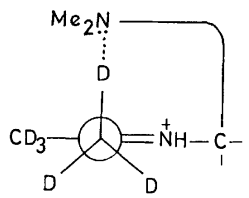
12b n=3



13



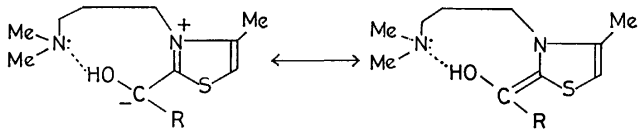
14

The pK_a values of the conjugated acids of dimethylamino group of **9** and **10** in water were determined to be 6.1 and 8.1 respectively by the NMR method.[13] They are very close to the pK_a values of the first ionization of 1,2-(dimethylamino)ethane (5.85[14]) and 1,3-(dimethylamino)propane (7.9[15]) in water. Thus it appears that the positive charge effect of thiazolium ring on the ionization of nearby protonated amino group is nearly the same as that of protonated dimethylamino group. At any rate, these pK_a values suggest the dimethylamino group, at least of **10**, to be basic enough for the ionization of α-CH bond.

Naturally, the hydrochlorides of **9** and **10** showed no activity of benzoin condensation in methanol. When an equimolar amount of triethylamine was added, the formation of benzoin was observed, but the yields of benzoin were trace for **9** and 5.6% for **10** after 20 h reaction. The increase of triethylamine concentration increased the rates and yields of benzoin formation as shown in Table 3. However, their values were unexpectedly low.

The pK_a of triethylamine is 10.78 in water[16] which is 3—5 units larger than the pK_a of **9** and **10**. These pK_a differences in water may also exist in methanol since a linear relationship is known between the pK_a values of amines in water and methanol.[17] Therefore, the dimethylamino group of **9** or **10** should be completely free in the presence of equimolar amounts of triethylamine, as verified qualitatively by NMR spectra. Yet the activity of both **9** and **10** was negligibly small. Meanwhile, as shown in Table 1, the rate constant for 3-ethyl analogue (**6**) was reduced from 1.1×10^{-2} to 0.3×10^{-2} l mol^{-1} min^{-1} in the presence of the equimolar amount of triethylamine hydrochloride (*i.e.*, $Et_3N=Et_3N\cdot HCl=0.06$ M). Thus the low activity of **9** and **10** appears partly due to this salt effect. For example, the addition of twice molar amount of free Et_3N over the catalyst hydrochloride should give a mixture of equimolar amounts of Et_3N, $Et_3N\cdot HCl$, and free dimethylamino group. However, with this salt effect alone, it seems difficult to account for such low activity. Namely, the rates of **9** and **10** are only about one fourth of that of **6** in spite of the same salt concentration. The use of **10** with partially free

amino group did not increase the rate appreciably. Electron-withdrawing inductive effect of free dimethylamino group should be small (σ_I=0.10). The CPK molecular model indicates no such steric hindrance for both **9** and **10** as noted for **8**. Both of **9** and **10** were quite stable under the present experimental conditions as far as the NMR spectra indicate. Thus we are unable to offer any reasonable explanation for the above low reactivity of **9** and **10**. However, it may be conceivable that the dimethylamino group in **9** and **10** can in fact act as internal general base as in **12b**, but the resulting carbanion loses reactivity for further condensation due to stabilization by charge delocalization which is favored to occur by ring formation involving hydrogen bonding (**12c** and **12d**).



12c 12d

Experimental

NMR was recorded by a Varian A-60 spectrometer. Triethylamine was distilled on sodium hydroxide pellets, and methanol was refluxed with calcium oxide overnight and distilled. Benzaldehyde was distilled under N_2 prior to use.

Preparation of Thiazolium Salts. *3,4-Dimethylthiazolium iodide (**1**)* was prepared by reaction of 4-methylthiazole[18] with excess methyl iodide in ethanol, mp 119—121 °C (ethanol–ether) (lit,[19] mp 119—120 °C).

*3-Benzyl-4-methylthiazolium chloride (**2a**)* was prepared from benzyl chloride and 4-methylthiazole, mp 190 °C (lit,[3a] mp 191—192 °C).

*3-Benzyl-4-methylthiazolium perchlorate (**2b**)* was obtained by anion exchange of (**2a**) with silver perchlorate in ethanol. Recrystallized from ethanol–ether, mp 111—113 °C. Found: C, 45.50; H, 4.19; N, 4.84%. Calcd for $C_{11}H_{12}ClNO_4S$: C, 45.60; H, 4.18; N, 4.83%.

*3-Dodecyl-4-methylthiazolium bromide (**4**)* was prepared from 4-methylthiazole and dodecyl bromide in ethanol, mp 102—104 °C (ethanol–ether). Found: C, 55.00; H, 8.56; N, 3.98%. Calcd for $C_{16}H_{30}BrNS$: C, 55.15, H, 8.68; N, 4.02%.

*3-Methylbenzothiazolium iodide (**5**)* was prepared from benzothiazole and methyl iodide in ethanol, mp 210 °C, (lit,[10] mp 208—210 °C).

*3-Ethylthiazolium bromide (**6**)* was prepared from thiazole and ethyl bromide, mp 160—161 °C (ethanol–ether). Found: C, 30.81; H, 4.33; N, 7.10; S, 16.39%. Calcd for C_5H_8BrNs: C, 30.94, H, 4.15; N, 7.22; S, 16.52%.

3-Phenyl-4-methyl-4-thiazoline-2-thione. To a stirred solution of ammonium phenyldithiocarbamate[20] (10 g, 58 mmol) in methanol (100 ml) was added chloroacetone (5.4 g, 58 mmol) dropwise at room temperature and stirring was continued overnight. Then, 3—4 drops of concd hydrochloric acid was added and the solution refluxed for 30 min. Methanol was evaporated and water (100 ml) was added. After neutralization with $NaHCO_3$ solid, the solution was extracted with ether. The ether layer was dried over $MgSO_4$ and was evaporated to dryness. The crude crystals were recrystallized from methanol, yield 8.0 g (67%), mp 146—148 °C, NMR (CCl_4) δ 2.08 (3H, d, J=1.6 Hz) 6.50 (1H, d, J=1.6 Hz), 7.28—7.80 (5H, m).

*3-Phenyl-4-methylthiazolium Chloride (**3**).* A mixture of the above thione (2 g, 9.66 mmol), 30% hydrogen peroxide (4.4 g, 38.6 mmol) and one drop of concd hydrochloric acid in H_2O (20 ml) was stirred for 30 min at room temperature. $BaCl_2 \cdot 2H_2O$ (2.36 g, 9.66 mmol) was added and stirring was continued overnight. The precipitate ($BaSO_4$) was separated by centrifugation. The solution was evaporated to dryness. The crystals were recrystallized from ethanol–ether, yield 1.3 g (60%), mp 205—210 °C (dec). NMR (D_2O) δ 2.4 (3H, s), 7.55—7.88 (5H, m), 8.06 (1H, s), 10.10 (1H, s). Found: C, 56.70; H, 4.50; N, 6.45%. Calcd for $C_{10}H_{10}ClNS$: C, 56.73; H, 4.76; N, 6.62%.

3-[2-(Dimethylamino)ethyl]-4-methyl-4-thiazoline-2-thione. To a stirred solution of potassium 2-(dimethylamino)ethyldithiocarbamate (5.0 g, 25 mmol), which was prepared from the corresponding amine, potassium hydroxide and carbon disulfide in methanol (150 ml) was added chloroacetone (2.3 g, 25 mmol) at room temperature. Stirring was continued overnight and concd hydrochloric acid was added until the solution became acidic and stirred further for 30 min. Enough ether was added to give precipitates. The precipitates were filtered and recrystallized from ethanol–ether, yield 4.2 g (82% as HCl salt), mp 200—205 °C NMR (D_2O) δ 2.40 (3H, d, J=1.6 Hz), 3.09 (6H, s), 3.58 (2H, t, J=8.0 Hz), 4.72 (2H, t, J=8.0 Hz), 6.77 (1H, d, J=1.6 Hz).

*3-[2-(Dimethylamino)ethyl]-4-methylthiazolium Chloride (**9**).* The above thione (3.0 g, 13 mmol) and $BaCl_2 \cdot 2H_2O$ (3.1 g, 12.7 mmol) were dissolved in 10 ml of water with one drop of concd HCl and 30% hydrogen peroxide (4.9 g, 43 mmol) was added under ice-cooling. Stirring was continued overnight at room temperature. The precipitate was separated by centrifugation. The water layer was evaporated to dryness. The residue was dissolved in methanol (5 ml) and treated with charcoal and ether was added to give crystals. The crystals thus formed were recrystallized from methanol–ether, 2.6 g (84%), mp 200 °C (dec). NMR (CD_3OD) δ 2.75 (3H, s), 3.09 (6H, s), 3.84 (2H, t, J=8.0 Hz), 5.12 (2H, t, J=8.0 Hz), 8.07 (1H, m), 10.44 (1H, d, J=2.7 Hz). Found: C, 39.55; H, 6.60; N, 11.75%. Calcd for $C_8H_{16}Cl_2N_2S$: C, 39.51; H, 6.63; N, 11.52%.

3-[3-(Dimethylamino)propyl]-4-methyl-4-thiazoline-2-thione was prepared by the same procedures as described for the above 3-[2-(dimethylamino)ethyl]-4-methyl-4-thiazoline-2-thione. Yield 35%, mp 205 °C (as HCl salt). NMR (D_2O) δ 2.00—2.50 (2H, m), 2.42 (3H, d, J=1.6 Hz), 2.99 (6H, s), 3.37 (2H, t, J=7.5 Hz), 4.40 (2H, t, J=7.5 Hz), 6.80 (1H, d, J=1.6 Hz).

*3-[3-(Dimethylamino)propyl]-4-methylthiazolium Chloride (**10**).* was synthesized by the same manner as described for **9**. The yield was 61% from the corresponding thione, mp 200 °C (dec). NMR (CD_3OD) δ 2.30—2.80 (2H, m), 2.73 (3H, s), 3.00 (6H, s), 3.43 (2H, t, J=7.0 Hz), 4.70 (2H, t, J=7.5 Hz), 8.07 (1H, m), 10.50 (1H, d, J=3.0 Hz). Found: C, 42.00; H, 7.13; N, 10.88%. Calcd for $C_9H_{18}Cl_2N_2S$; C, 42.03; H, 7.05; N, 10.90%.

Kinetics of H-D Exchange of 2-Hydrogen. Deuterium oxide (99.75%, Merck) was used. The pH was measured on a Horiba (F-7DE) pH meter. The pD was then calculated by adding 0.40 to the observed pH.[21] The exchange was followed by the NMR method. The solutions for kinetics were prepared by weighing thiazolium salt (0.25 mol) in a NMR tube and by adding 0.5 ml of 0.1 M acetate buffer solution. The rate constants were calculated from the integrated areas of 2-hydrogen and those of non-exchangeable hydrogens (4-methyl, 5-hydrogen or phenyl).

pK_a *Determination.* The pK_a values of dimethylamino group of **9** and **10** in water were determined by NMR method described by Grunwald.[12] Namely, chemical shifts of dimethyl group from tetramethylammonium bromide (internal standard) were measured at seven pH's from pH 3 to 7.62 (0.2 M, citric acid–Na_2HPO_4 buffer). The pK_a values were calculated by the best fit of experimental points by using equation: $pH=pK_a+\log(\delta_{obsd}-\delta)/(\delta_{H^+}-\delta_{obsd})$, where δ_{H^+}, δ_{obsd}, δ are the chemical shifts from internal standard of fully protonated, partially dissociated at a given pH and free dimethylamino groups which were estimated because of instability of thiazolium ring at higher pH, respectively.

Kinetics of Benzoin Condensation. Into a 5 ml of septum-rubber capped flask were placed 2 ml of 0.62 M benzaldehyde, 0.5 ml of 0.48 M triethylamine and 1 ml of 0.30 M 1,2-diphenylethane (internal standard for GLC analysis). The flask was bubbled with N_2 saturated with methanol vapor for 10 min. After temperature equilibration at 51 °C for 10 min, 0.5 ml of 0.48 M solution of given catalyst was added under N_2 with appropriate time intervals, *ca.* 0.2 ml of reaction mixture was pipetted out by syringe and poured into a mixture of 2 ml of H_2O and 0.5 ml of benzene. After vigorous shaking, benzene layer was dried over $MgSO_4$. This layer was subjected to GLC analyses (column; 5% DMCS on Cromosorb WAW, 2 m, 200 °C). The amount of benzoin was determined by comparing the relative peak area of benzoin *vs.* internal standard with those of the calibration chart.

This research was supported in part by Grant-in-Aid for Scientific Research from the Ministry of Education, Japan.

Cyclodehydrogenation of 3-Isopropenyl- and 3-(1-Phenylvinyl)-tropolones to 8*H*-Cyclohepta[*b*]furan-8-one Derivatives

Kimiaki IMAFUKU,* Kazuko YAMAGUCHI, and Hisashi MATSUMURA

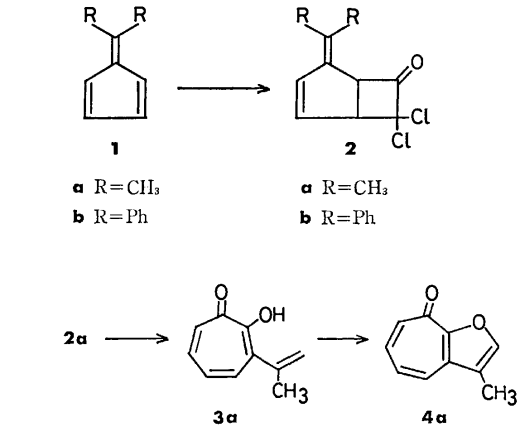
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received August 2, 1979)

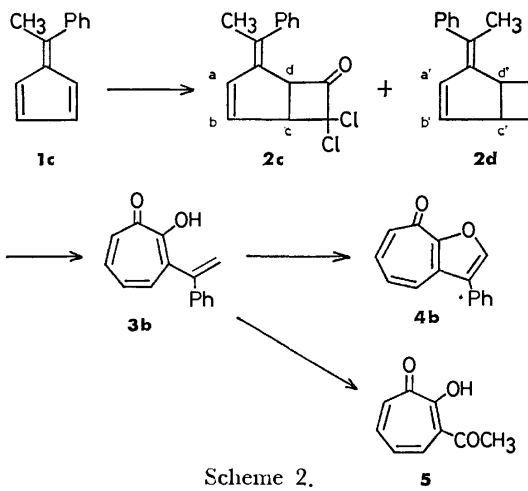
3-(1-Phenylvinyl)tropolone (**3b**) was prepared by the hydrolysis of cycloadducts of 6-methyl-6-phenylfulvene with dichloroketene. 3-Isopropenyltropolone and **3b** were treated with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone or performic acid to give 3-methyl- and 3-phenyl-8*H*-cyclohepta[*b*]furan-8-one, respectively. Reaction of **3b** with hydrazoic acid afforded an unexpected 3-acetyltropolone.

Several heterocycle-condensed troponoid skeletons have been found in natural products, but not troponoid condensed with furan ring. Kitahara and Funamizu[1] reported the formation of a furotropone, 2-methyl-8*H*-cyclohepta[*b*]furan-8-one, by peroxy acid oxidation of 3-propenyltropolone. Takase[2] also obtained the same compound by treatment of 3-acetonyltropolone with sulfuric acid. Papers have appeared concerning the synthesis of furotropone derivatives, prepared from tropone derivatives[3,4] and from furan derivatives.[5,6]

In this communication, we wish to report the synthesis of 3-methyl- and 3-phenyl-8*H*-cyclohepta[*b*]furan-8-one (**4a** and **4b**) by 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) or performic acid treatment of the corresponding 3-($\Delta^{\alpha,\beta}$-alkenyl)tropolones (**3a** and **3b**).



Scheme 1.



Scheme 2.

Results and Discussion

Synthesis of 3-(1-Phenylvinyl)tropolone (3b). Tropolones having an $\Delta^{\alpha,\beta}$-alkenyl group at C-3 position are of interest as synthetic precursors, being obtained by hydrolysis of cycloadducts of 6-alkyl-substituted fulvenes with dichloroketene,[7] which is an advantageous method of preparation.

Most cycloaddition reactions of fulvenes result in a 1,4-monoadduct. The formation of 1,2-monoadduct is little known except for the addition of benzonitrile oxide[8] and diazomethane[9] to 6,6-dimethylfulvene. 1,2-Cycloaddition reactions of dichloroketene to 6,6-dimethyl- (**1a**)[7] and 6,6-diphenylfulvene (**1b**)[10] were reported. The cycloadduct (**2a**) from dimethylfulvene was hydrolyzed to afford 3-isopropenyltropolone (**3a**),[7] a useful intermediate for the synthesis of 3-acetyltropolone.[11] The strucutre of the cycloadducts(**2b**) from diphenylfulvene was also established by detailed PMR spectral investigation.

We obtained the cycloadducts from the reaction of 6-methyl-6-phenylfulvene (**1c**)[12] with dichloroketene. The reaction of **1c** with dichloroketene (generated *in situ*) afforded an oily substance. The IR spectrum shows a strong carbonyl absorption at 1800 cm^{-1}, which is very similar to that of **2a** and **2b** and is reasonable for a saturated four-membered ring.[13] The PMR spectrum (Fig. 1) shows the oily substance to consist of two isomeric substances which may be produced by the presence of unequivalent methyl and phenyl groups at the C-6 position of the fulvene (**1c**). The two products were assigned to (*Z*)- and (*E*)-7,7-dichloro-4-(α-methylbenzylidene)bicyclo[3.2.0]hept-2-en-6-one (**2c** and **2d**), respectively, in comparison with the spectra of **2a** and **2b**. The assignments fit perfectly the structures (**2c**): δ/ppm: 2.21 (s, 3H, CH_3), 4.0—4.2 (m, 1H, H-c), 4.86 (d, 1H, J_{dc}=7.9 Hz, H-d), 5.8—6.1 (m, 1H, H-b), 6.47 (dd, 1H, J_{ab}=

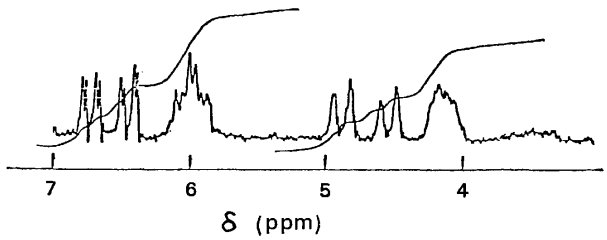


Fig. 1. PMR spectrum of mixture of cycloadducts (**2c** and **2d**).

6.0 Hz, J_{ac}=1.8 Hz H-a), 7.2—7.5 (m, 5H, Ph) and (**2d**): δ/ppm: 2.21 (s, 3H, CH_3), 4.0—4.2 (m, 1H, H-c'), 4.52 (d, 1H, $J_{d'c'}$=7.0 Hz, H-d'), 5.8—6.1 (m, 1H, H-b'), 6.72 (dd, 1H, $J_{a'b'}$=6.0 Hz, $J_{a'c'}$=1.8 Hz, H-a'), 7.2—7.5 (m, 6H, Ph). The spectrum (Fig. 1) also shows the formation of equimolar **2c** and **2d** isomers. However, the separation of the isomers was not achieved by distillation, column and TLC chromatography, and gas chromatography.

Hydrolysis of a mixture of the adducts (**2c** and **2d**) afforded 3-(1-phenylvinyl)tropolone (**3b**). The PMR spectrum of **3b** shows peaks at δ 5.34 (s, 1H), 5.81 (s, 1H), 6.70—7.65 (m, 4H), and 7.28 ppm (s, 5H), supporting the structure. The elemental analysis also gave a satisfactory result.

Cyclodehydrogenation with DDQ. Recently attempts have been made to synthesize 2*H*-chromenes by cyclodehydrogenation of 2-($\Delta^{\beta,\gamma}$-alkenyl)phenols with DDQ.[14] However, little is known about the cyclodehydrogenation of 2-($\Delta^{\alpha,\beta}$-alkenyl)phenols except for the reactions of 2-(3-methyl-1-butenyl)phenol and 2-(1-phenyl-1-propenyl)phenol.[15] The former gave 2,2-dimethyl-2*H*-chromene and the latter 2-methyl-3-phenylbenzofuran.

A solution of 3-isopropenyltropolone (**3a**) in dry benzene was refluxed for 20 h with DDQ to afford 3-methyl-8*H*-cyclohepta[*b*]furan-8-one (**4a**) in 22% yield. The UV spectrum [λ_{max}/nm (log ε): 227 (4.18), 273(4.27), 340 (3.57)] is very similar to that of 2-methyl isomer.[2] The IR spectrum of **4a** shows absorptions at 1639 (C=O) and 1090 cm^{-1} (C–O–C). These results indicate the formation of **4a**.

Reaction of 3-(1-phenylvinyl)tropolone (**3b**) with DDQ gave 3-phenyl-8*H*-cyclohepta[*b*]furan-8-one (**4b**) in 51% yield. The UV spectrum of **4b** is also very similar to that of **4a** and its 2-methyl isomer. The IR spectrum shows absorptions at 1638 (C=O) and 1102 cm^{-1} (C–O–C).

Oxidative Cyclization with Performic Acid. Nozoe and Hayashi[16] found that **3a** gives **4a** by peroxy acid oxidation, but their results have not been published.

We have carried out the same reaction of **3a** with performic acid and obtained **4a** (51%). 3-(1-Phenylvinyl)tropolone (**3b**) also reacted with performic acid to afford **4b** (62%). On the other hand, **3a** was not oxidized with alkaline hydrogen peroxide, **3a** being recovered (91%).

*Treatment of **3b** with Hydrazoic Acid.* In a previous paper,[11] it was reported that the reaction of **3a** with sodium azide in sulfuric acid gives 3-acetyltropolone (**5**). Phenyl derivatives (**3b**) was similarly treated with sodium azide in concentrated sulfuric acid to give 3-acetyltropolone (**5**) in 44% yield, the desired 3-benzoyltropolone not being obtained.

Experimental

The melting points were measured on a Yanagimoto MP-S2 melting point measuring apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, UV spectra on a Hitachi EPS-3T spectrophotometer, and PMR spectra on a Hitachi R-24 spectrometer (60 MHz).

*6-Methyl-6-phenylfulvene (**1c**).* 6-Methyl-6-phenylfulvene (**1c**) was prepared by the method of Thiele.[12] Bp 143.5 °C/18 Torr (lit,[12] 130.5 °C/10.5 Torr). PMR ($CDCl_3$) δ: 2.50 (s, 3H, CH_3), 6.05 (m, 1H), 6.35 (m, 1H), 6.48 (s, 2H), 7.30 ppm (s, 5H, Ph).

*Cycloaddition to 6-Methyl-6-phenylfulvene (**1c**).* A solution of triethylamine (18 ml) in anhydrous hexane (83 ml) was added dropwise to a solution of **1c** (10.2 g) and dichloroacetyl chloride (7 ml) in anhydrous hexane (83 ml) over a period of 3 h with stirring at room temperature. After additional stirring for 1 h, the mixture was allowed to stand overnight. The reaction mixture was filtered, the filtrate evaporated off and the residue distilled under reduced pressure to give a dark red oil. Yield 6.8 g (41%). Bp 169 °C/2 Torr. This oily substance was a mixture of (*Z*)- and (*E*)-7,7-dichloro-4-(α-methylbenzylidene)bicyclo[3.2.0]hept-2-en-6-one (**2c** and **2d**).

*3-(1-Phenylvinyl)tropolone (**3b**).* A mixture (16.7 g) of the cycloadducts (**2c** and **2d**) was refluxed for 16 h in acetic acid (71.5 ml)–water (7.2 ml) containing sodium hydroxide (13.2 g). The mixture was steam-distilled and the distillate was extracted with chloroform. The extract was washed with sodium hydrogencarbonate solution, water, and saturated sodium chloride solution. Evaporation of chloroform from the dried extract (over sodium sulfate) gave 3-(1-phenylvinyl)-tropolone (**3b**) as pale yellow scales (from hexane). Yield 1.8 g (14%). Mp 108—111 °C. IR ($CHCl_3$): 1620 cm^{-1} (C=O); PMR ($CDCl_3$) δ: 5.34 (s, 1H, =CH–H). 5.81 (s, 1H, =CH–H), 6.70—7.65 (m, 4H), 7.28 ppm (s, 5H, Ph). Found: C, 80.38; H, 5.40%. Calcd for $C_{15}H_{12}O_2$: C, 80.33; H, 5.40%.

Cyclodehydrogenation with DDQ. a): A mixture of 3-isopropenyltropolone (**3a**) (162 mg, 1 mmol) and DDQ (454 mg, 2 mmol) was refluxed for 6 h in dry benzene (20 ml). The reaction mixture was filtered, concentrated, chromatographed on a Wakogel B-10 plate (30×30 cm^2) with ethyl acetate, and recrystallized from hexane to afford 3-methyl-8*H*-cyclohepta[*b*]furan-8-one (**4a**) as pale orange prisms. Yield 15 mg (9.4%). Mp 95—96 °C. IR ($CHCl_3$): 1639, 1580, 1090 cm^{-1}; UV (MeOH) λ_{max}/nm (log ε): 227 (4.18), 273 (4.27), 340 (3.57); PMR ($CDCl_3$) δ: 2.24 (s, 3H, CH_3), 6.8—7.5 (m, 4H), 7.63 ppm (m, 1H, H-2). Found: C, 74.99; H, 5.01%. Calcd for $C_{10}H_8O_2$: C, 74.99; H, 5.03%.

b): Prolonged reaction (20 h) of **3a** (162 mg, 1 mmol) and DDQ (454 mg, 2 mmol) in dry benzene (20 ml) gave **4a** (35 mg, 22%) after the work-up mentioned above.

c): A mixture of 3-(1-phenylvinyl)tropolone (**3b**) (224 mg, 1 mmol) and DDQ (454 mg, 2 mmol) was refluxed for 20 h in dry benzene (20 ml). The reaction mixture was worked up in a similar way to that for *a)* and recrystallized from cyclohexane to give 3-phenyl-8*H*-cyclohepta[*b*]-furan-8-one (**4b**) as pale yellow needles. Yield 114 mg (51%). Mp 146—148 °C. IR ($CHCl_3$): 1638, 1580, 1102 cm^{-1}; UV (MeOH) λ_{max}/nm (log ε): 232 (4.35), 282 (4.20), 338^{sh} (3.67), 356^{sh} (3.45); PMR ($CDCl_3$) δ: 6.7—7.6 (m, 4H), 7.38 (s, 5H, Ph), 7.89 ppm (s, 1H, H-2). Found: C, 81.21; H, 4.47%. Calcd for $C_{15}H_{10}O_2$: C, 81.06; H, 4.54%.

Cyclization with Performic Acid. a): **3a** (420 mg, 2.6 mmol) was added to a performic acid solution, prepared from 85% formic acid (5 ml) and 30% hydrogen peroxide (1 ml), and heated on a water bath for 2 h. The reaction mixture was heated again with 6 M sodium hydroxide solution, neutralized with 3 M hydrochloric acid, and extracted with chloroform. The chloroform extract was dried over sodium sulfate and evaporated to dryness. The residue was recrystallized from hexane to afford **4a** (212 mg, 51%).

b): **3b** (448 mg, 2 mmol) was heated in performic acid, prepared in the same way as for *a)*, for 2 h and worked up as mentioned above. Crude product was recrystallized from cyclohexane to afford **4b** (227 mg, 62%).

*Treatment of **3b** with Hydrazoic Acid.* Sodium azide (200 mg) was added to a stirred mixture of **3b** (360 mg), concentrated sulfuric acid (1 ml), and chloroform (2 ml). The mixture was stirred at 50 °C for 3 h. After removal of chloroform layer, the acid layer was diluted with water (4 ml) and then left overnight. The crystals deposited were collected and recrystallized from methanol to afford 3-acetyltropolone (**5**)[11] as pale yellow needles. Yield 120 mg (44%). Mp 131—132 °C.

Vinyl Polymerization. 393. Radical Polymerization of Vinyl Monomer Initiated by Aliphatic Aldehyde

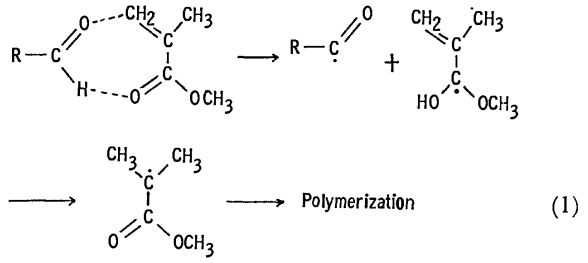
Tatsuro OUCHI,* Noriyuki MURAYAMA, and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama Suita, Osaka 564

(Received August 6, 1979)

The homogeneous polymerization of methyl methacrylate (MMA) initiated with butanal (PrCHO), pentanal (BuCHO), and hexanal ($C_5H_{11}CHO$) was carried out in dioxane. It was found that the rate of polymerization can be expressed by $R_p=k[MMA]^{1.5}[RCHO]^{0.5}$. The polymerization was confirmed to proceed through a radical mechanism. Overall activation energies, when PrCHO, BuCHO, and $C_5H_{11}CHO$ were used, were estimated to be 37.2, 36.3, and 36.0 kJ mol^{-1}, respectively. Instead of MMA, many kinds of vinyl monomer were applied. Various methacrylates and acrylates could be polymerized, but not styrene and acrylonitrile. The effect of solvent on the rate of polymerization was studied.

Imoto, Oishi, and Ouchi found that poly(acrylaldehyde-co-styrene)(AL/St)[1] and poly(methyl vinyl ketone-co-styrene)[2] can initiate the radical polymerization of methyl methacrylate (MMA). When the CHO group of AL/St was hydrogenated with $NaBH_4$ to CH_2OH group, the polymerization activity of AL/St was lost. It was thus concluded that the active center of AL/St is the pendent CHO group. Imoto, Maeda, and Ouchi reported that not only macromolecular aldehyde compounds, such as poly(formylstyrene)(*m*-: *p*-, 68:30)[3] and vanacryl,[4] but also low-molecular aldehydes of vanillin[4] or benzaldehyde (PhCHO)[5] can initiate the radical polymerization of MMA, the following mechanism of initiation being proposed.[4,5]



(1)

The present paper deals with the radical polymerization of vinyl monomers, particularly MMA, initiated by aliphatic aldehydes.

Experimental

Materials. Propanal (EtCHO, bp 49 °C), butanal (PrCHO, bp 74.8 °C), pentanal (BuCHO, bp 51.2 °C/121 mmHg), hexanal ($C_5H_{11}CHO$, bp 48 °C/40 mmHg) and benzaldehyde (PhCHO, bp 51 °C/5 mmHg), all of commercial special grade, were used. They were dried over anhydrous Na_2SO_4, distilled twice in a nitrogen atmosphere and furthermore distilled before use. No peroxyl group was found by the KI-method.

Vinyl monomers were purified by the usual methods. Dioxane was passed through a column filled with alumina and distilled, other solvents being purified by the usual methods.

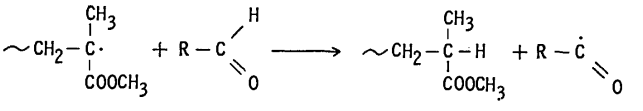
Procedures. Vinyl monomer and aldehyde were dissolved in solvent and placed in a tube. The tube was thawed by nitrogen and sealed in a vacuum. The tube was shaken in a thermostat. After a certain time, the contents of the tube were poured into a large amount of methanol in order to precipitate the polymer produced. The conversion of the monomer was calculated from the weight of the polymer.

Number-average degree of polymerization, $\overline{P}_n$, of poly(MMA) was estimated by GPC-method (Type 501, ALC/GPC of Waters Ltd.).

ESR Measurement. The ESR spectrum was measured at room temperature by using a JES-FE 1X spectrometer with 100 kHz field modulation.

Results and Discussion

Effect of the Concentration of Aldehyde on the Polymerization of MMA. Polymerization of MMA was carried out by keeping the concentration of MMA constant at 2.79 mol dm^{-3} and varying the concentration of aldehyde (Fig. 1). The formyl group retards the radical polymerization by the following chain-transfer reaction:



(2)

Thus with increase in the concentration of RCHO, the rate of chain-transfer reaction of MMA-radical to the aldehyde becomes greater, the conversion of MMA tending to decrease. The chain length of the alkyl group of RCHO remarkably affects conversion and rate of polymerization. The conversion increases, according to the order $C_2H_5<C_3H_7<C_4H_9$, but C_5H_{11} shows a lower activity than C_3H_7 or C_4H_9. EtCHO may have much higher activity for the chain-transfer reaction than the initiating reaction.

Figure 2 shows the decrease in $\overline{P}_n$ of poly(MMA)

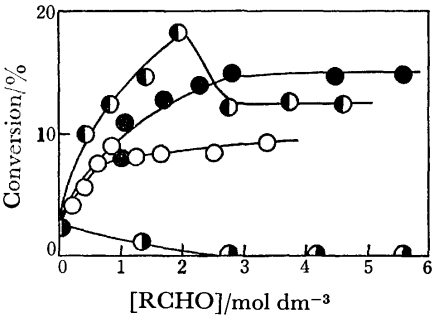


Fig. 1. Conversion of MMA *vs.* concentration of RCHO. [MMA]=2.79 mol dm^{-3}, in dioxane; 85 °C, 3 h. (◑) EtCHO, (●) PrCHO, (◐) BuCHO, (○) $C_5H_{11}CHO$.

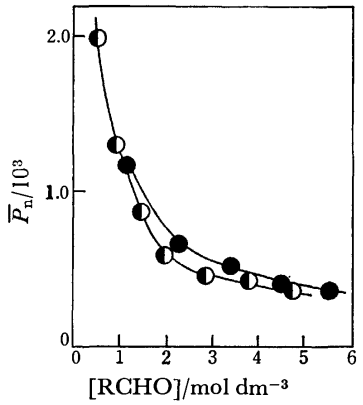

Fig. 2. Decrease of $\overline{P}_n$ of poly(MMA) with RCHO. [MMA]=2.79 mol dm^{-3}, in dioxane; 85 °C, 3 h. (●) PrCHO, (◐) BuCHO.

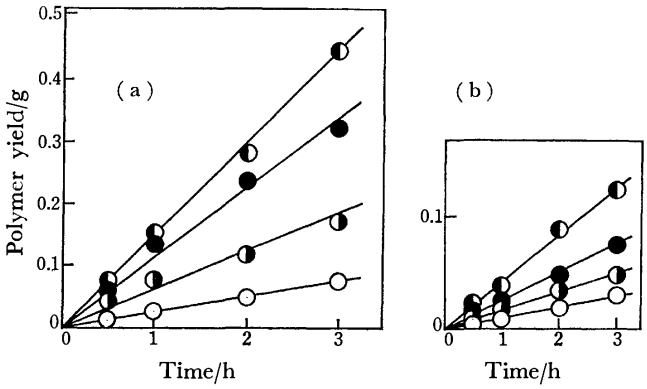

Fig. 3. Time-conversion curves.
(a) Overall conversion obtained in the presence of BuCHO *vs.* time. (b) Thermal conversion obtained in the absence of BuCHO *vs.* time. [BuCHO]= 0.94 mol dm^{-3}, in dioxane; 85 °C.
(○) [MMA]=0.93 mol dm^{-3}, (◑) [MMA]=1.86 mol dm^{-3}, (●) [MMA]=2.79 mol dm^{-3}, (◐) [MMA]= 3.72 mol dm^{-3}.

produced. This is due to the chain transfer reaction.

Reaction Orders with Respect to MMA and RCHO. Figures 3(a) and 3(b) show the time-conversion curves of MMA in the presence and absence, respectively, of BuCHO. From the straight lines in Fig. 3(a), the overall rate of polymerization, R_p(overall), can be calculated by dividing conversion by time. R_p-(thermal) is the rate of polymerization in the absence of BuCHO. Accordingly, the polymerization initiated with RCHO, R_p, was calculated by the equation.

$$R_p^2 = R_p^2(\text{overall}) - R_p^2(\text{thermal}) \quad (3)$$

The relationship between R_p and [MMA] or [RCHO] is shown in Figs. 4 and 5. From the slopes of the straight lines, the reaction orders with respect to MMA and RCHO were calculated (Table 1).

Table 1. Reaction order[a)]

RCHO	m	n
PrCHO	—	0.45
BuCHO	1.41	0.44
$C_5H_{11}CHO$	1.50	0.50

a) $R_p=k[\text{MMA}]^m[\text{RCHO}]^n$.

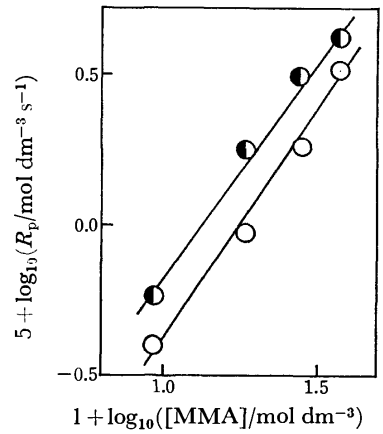

Fig. 4. Relationship between R_p and [MMA]. (◐) [BuCHO]=0.94 mol dm^{-3}, (○) [C_5H_{11}CHO]= 0.72 mol dm^{-3}, in dioxane; 85 °C.

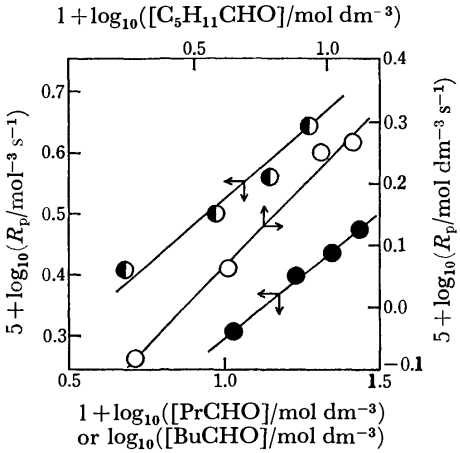

Fig. 5. Relationship between R_p and [RCHO]. [MMA]=2.79 mol dm^{-3}, in dioxane; 85 °C. (●) PrCHO, (◐) BuCHO, (○) $C_5H_{11}CHO$.

Table 2. Values of r_1 and r_2

RCHO	r_1	r_2
PrCHO	0.59	0.53
BuCHO	0.56	0.46
$C_5H_{11}CHO$	0.51	0.49

In the case of benzaldehyde, the rate equation was found to be $R_p=k[\text{MMA}]^{1.5}[\text{PhCHO}]^{0.5}$. Similarly in the present case of RCHO, the rate equation of the polymerization obeys the equation.

$$R_p = k[\text{MMA}]^{1.5}[\text{RCHO}]^{0.5} \quad (4)$$

Proofs of Radical Mechanism. That the polymerization of MMA initiated with RCHO proceeds through a radical mechanism was confirmed by two methods, (a) complete inhibition of the polymerization by 2,2-diphenyl-1-picrylhydrazyl (DPPH) (Fig. 6) and (b) copolymerization of MMA and St (Fig. 7). The calculated values of r_1 and r_2 are given in Table 2.

From these two experiments it was confirmed that the polymerization of MMA initiated with RCHO proceeds through a radical mechanism.

Selectivity of Vinyl Monomers. Instead of MMA, many kinds of methacrylate were used in the polymeri-

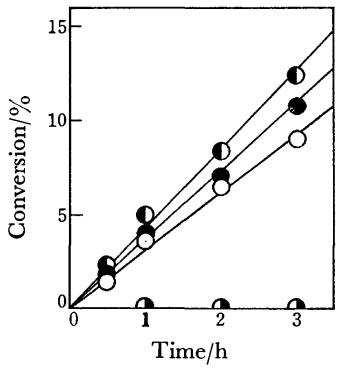

Fig. 6. Inhibition of the polymerization by DPPH. MMA 3 cm³, RCHO 1 cm³, in dioxane; 85 °C. (●) PrCHO, (◐) BuCHO, (○) $C_5H_{11}CHO$. The symbol ◑ includes the three results obtained by BuCHO, PrCHO or $C_5H_{11}CHO$.

zation initiated with BuCHO. Methacrylates were always easily polymerized (Table 3).

Vinyl monomers other than methacrylate were also examined (Table 4).

We see that acrylates and acrylamide can be more easily polymerized than methacrylates. Styrene, α-methylstyrene and acrylonitrile could not be polymerized. The results are in line with the proposed mechanism (1). Styrene and acrylonitrile form no adequate complex with RCHO.

a) MMA 3 cm³, BuCHO 1 cm³, solvent 6 cm³; 85 °C. b) H_2O 10 cm³; Heterogeneous polymerization.

Effect of Solvent on Polymerization. Twelve solvents were used in the polymerization of MMA initiated with BuCHO. The results obtained are given in Table 5, where *k* is calculated from the conversion of

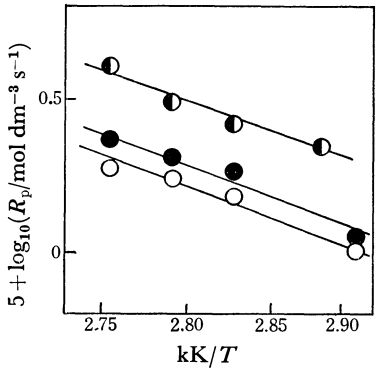

Fig. 9. Arrhenius plots.
[MMA]=2.79 mol dm^{-3}, (●) [PrCHO]=1.11 mol dm^{-3}, (◐) [BuCHO]=0.94 mol dm^{-3}, (○) [C_5H_{11}CHO]=0.72 mol dm^{-3}, in dioxane; 70—90 °C.

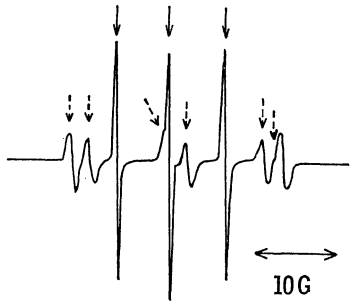

Fig. 10. ESR spectrum of the system of BuCHO/MA/BNO after reaction at 30 °C. [BuCHO]=9.4×10^{-1} mol dm^{-3}, [MA]=2.6 mol dm^{-3}, [BNO]=5.5×10^{-2} mol dm^{-3}, in benzene. ——→: (**3a**), ---→: (**4**).

MMA by the rate equation, $R_p=k[\text{BuCHO}]^{0.5}[\text{MMA}]^{1.5}$.

The effect of solvent on R_p could not be interpreted in terms of dielectric constants (ε). However, as Fig. 8 shows, R_p increased with the viscosity of the solvent, except in the cases of water (unhomogeneous polymerization) and chloroform (high chain transfer constant, 4.54×10^{-5}).

Estimation of Overall Activation Energy. The polymerization of MMA initiated with three kinds of RCHO was carried out in dioxane at 70—90 °C. The logarithms of the calculated R_p were correlated with the reciprocals of the polymerization temperature. The results obtained are shown in Fig. 9. The overall activation energy E_a was calculated from the slopes of the lines (Table 6).

Spin Trapping of Free Radicals with 2-Methyl-2-nitrosopropane (BNO). Attempts were made to detect the radicals produced in the polymerizing system of aldehyde and methyl acrylate (MA) by spin trapping technique.

Figure 10 shows the ESR spectrum observed from the system of BuCHO/MA/BNO in benzene at 30 °C. Two sets of ESR signals were observed; a triplet with A_N=8.0 G and a sextuplet with A_N=14.3 G, A_H^β=2.7 G. The former is considered to be due to (**3a**) and the latter to (**4**), which are derived from the reaction of BNO with acyl radical (**1a**) or 1-(methoxycarbonyl)ethyl radical (**2**), respectively.

When PhCHO was used instead of BuCHO, a similar spectrum was obtained; a triplet with A_N=8.2 G and a sextuplet with A_N=14.4 G, A_H^β=2.7 G.

Table 6. Overall activation energies

The Low-temperature Photolysis of Diazo Compounds. The Utility of Tertiary Alcohol in Matrix Studies of Carbene Chemistry

Hideo Tomioka,* Takaaki Miwa, Shinji Suzuki, and Yasuji Izawa

Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received August 20, 1979)

Carbene processes within the *t*-BuOH matrix at −196 °C were investigated in order to show the utility of the matrix as a tool for the study of carbene chemistry. The photolysis of several aryldiazomethane derivatives in the *t*-BuOH matrix gave the olefinic dimer as the main product, probably arising from a combination of two triplet arylcarbenes in the aggregate of molecules. The similar photolysis of other diazo compounds (*e.g.*, N_2CHCOR, R=OR′, NEt_2, and Ph) resulted in no detection of the olefinic dimer. This was explained in terms of the structural effect on the ground-state multiplicity of carbene. The photolysis of Ph_2CN_2 in *t*-BuOH containing 5% EtOH at −196 °C gave almost exclusively O–H and C–H insertion products with the solute alcohol at the expense of the O–H insertion product with the host, *i.e.*, Ph_2CHOBu^t, which was the major product in the liquid-phase photolysis. This is ascribable to the co-aggregation of the carbene precursor with the solute alcohol because of the relatively large guest hole provided by the bulky tertiary alcohol matrix. A more general utility of this matrix was shown in the reaction of Ph_2C with Ph_2CO to give oxirane, in which the intervention of carbonyl ylide was demonstrated at low temperatures.

The low-temperature photolysis of organic compounds has attracted much attention from the standpoint of physical as well as organic chemistry because of its usefulness in detecting reaction intermediates which are suspected to be involved in processes carried out at much higher temperatures. It has been noted, however, that some of the photochemical processes at low temperatures are highly sensitive to matrix properties, *e.g.*, polarity. For example, Kolc has reported[1] that the photolysis of benzocyclobutene-1,2-dione in the EPA matrix at −196 °C underwent bisdecarbonylation to give benzyne, whereas a similar photolysis in the 3-methylpentane matrix gave no sign of benzyne being formed. A similar striking effect of matrix properties on the course of low-temperature photochemical reactions has been suggested[2] to account for some of the reported discrepancies between the results of different authors.[3,4]

In the course of our study of the low-temperature photolysis of diazo compounds, we also found[5] a striking host effect; arylcarbenes generated in the *t*-BuOH matrix at −196 °C give almost exclusively coupling products, *e.g.*, $Ph_2C{=}CPh_2$ and $Ph_2C{=}N{-}N{=}CPh_2$, despite the fact that they give mainly C–H and O–H insertion products with host molecules in other alcoholic matrices (*i.e.*, MeOH—*i*-PrOH). This striking effect of the host on the course of carbene reactions in the matrix is especially noteworthy from the viewpoint of recent growing interest in the behavior of carbene in a rigid matrix.[5-7] We wish now to report developments in the application of the method in synthetic and mechanistic studies of carbene chemistry and, more generally, in synthetic photochemistry at low temperatures.

Results and Discussion

In order to examine the general utility of the low-temperature synthesis of olefin *via* the dimerization of carbene within crystalline matrices, we have irradiated several diazo compounds in a *t*-BuOH matrix and found that olefinic dimer formation is extremely sensitive to the structure of the carbenes (Table 1). Thus,

2: R=R′=CO_2Me	13.2
3a: R=H, R′=CO_2Me	n.d.[b,c]
3b: R=H, R′=$CONEt_2$	n.d.[b,d]
3c: R=H, R′=COPh	n.d.[b,e]

a) Based on the $RR'C{=}N_2$ used. b) Not detected. c) The main products were O–H insertion and Wolff rearrangement products. d) The main products were *β*- and *γ*-lactam. See Ref. 10. e) The main product was a Wolff rearrangement product.

the formation of the olefinic dimer was observed in the low-temperature photolysis of the aryldiazomethane derivatives (**1a**—**c**), which are known[8] to yield carbenes with triplet ground states. A similar photolysis of **2** also gave ethylene tetracarboxylate. Markedly to the contrary, however, no trace of olefin was detected in the photolysis of **3a**—**c**, even after all the diazo compounds had been destroyed. The main products detected were Wolff rearrangement products[9] in the cases of **3a** and **b**, and intramolecular C–H insertion products[9,10] in the case of **3c**. It is very interesting

$PhCN_2R$	$N_2C(CO_2Me)_2$	N_2CHCOR
1	**2**	**3**
a, R=H		**a**, R=OMe
b, R=Ph		**b**, R=Ph
c, R=CO_2Me		**c**, R=NEt_2

to note that some of the carbenes derived from **3** have been frequently postulated[11] as having singlet ground states. One would not expect triplet carbene chemistry to occur in the low-temperature direct-photolytic method if one assumes that the carbene has a singlet ground state separated by somewhat more than 5 kcal mol^{-1} from an upper triplet state, and that the

intersystem crossing process of the diazo compound does not compete with the dissociation.[12] Furthermore, although it is highly improbable that a reactive carbene can meet with another carbene to form olefin in the liquid phase before it attacks the substrate, evidence has been accumulating which shows that olefin could be formed by the combination of two triplet carbenes in the case where the carbenes are highly stabilized by structural[13] and/or environmental[5] effects. Recently, the flash photolysis of **1b** in benzene at 25 °C has been shown[14] to give tetraphenylethylene as the major product; this substance has not been observed in the steady-state photolysis. The fact that there is no spectroscopic evidence for any significant concentration of another transient except the triplet diphenylmethylene indicates that tetraphenylethylene is formed *via* the dimerization of the triplet carbene. Theoretical consideration also shows[15] that the least-motion formation of ethylene from triplet methylenes is an allowed process. Thus, it is reasonable to assume that the dimerization of the carbenes within a crystalline matrix would be affected by the ground-state multiplicity. The present method may, then, be expected to give us important information on the reactivity and multiplicity of the ground-state carbene,[16] although, as with most negative results, there might be several possible explanations for the failure to observe the olefinic dimer. Quite recently, for example, Roth *et al.* have shown,[17] by EPR study, that **3a** has a ground-state triplet or a triplet state that lies a maximum of 10 cal above the singlet state. Interestingly, its EPR signals follow the Curie law in the temperature range of 10—40 K, but vanish at higher temperatures, presumably by means of the reaction of the triplet with a matrix or by the conversion of the triplet state to a more reactive state capable of undergoing intra- and intermolecular reactions.[9] This is in marked contrast with that phenomenon observed in arylcarbene systems, in which the triplet state has been shown[8] to be fairly stable even at 77 K. Our results for **3a** might indicate, then, that the 77 K matrix is not cool enough to populate the triplet **3a** by quenching the singlet reaction; hence, more extensive temperature experiments would be desirable to form a more widely applicable method.

The photolysis of Ph_2CN_2 in *t*-BuOH containing a small amount of EtOH (up to 10%) at 25 °C gave Ph_2CHOBu^t almost exclusively. Surprisingly, however, when photolysis was performed in the solid phase at −77 °C, O–H insertion with the solute alcohol increased dramatically at the expense of the product formed from the host alcohol (Table 2). *t*-Butyl ether was almost completely suppressed in −196 °C photolysis, with a concomitant formation of C–H and O–H insertion products of the solute alcohol. The coupling products were also greatly reduced with an increase in the concentration of EtOH in the −196 °C photolytic runs. Similar phenomena were also observed with other solute alcohols (*e.g.*, MeOH, *i*-PrOH) in other tertiary alcohols (*e.g.*, *t*-$C_5H_{11}OH$).

A parallel series of irradiations in the EtOH–*i*-PrOH mixed matrix (Table 3) showed, however, that no

selective reaction of carbene with the solute alcohol was observed in this system. This implies that tertiary alcohols provide a special environment for carbene reactions.

Several possible explanations may be offered for the selective reaction of carbene with solute alcohol in a *t*-BuOH matrix. First, it may be that the Ph_2C generated in a matrix at −196 °C migrates through the host matrix and reacts with the more reactive solute alcohol molecules, as has been proposed[18] in the tunnelling effect in the selective H-abstraction by an H atom in a crystalline alkane mixture at −196 °C. This is less likely, however, since it has been shown[19] that the cage about the precursor severely restricts the molecular motion of such large molecules. Further, phenyl migration has been shown to be highly unfavorable in a rigid matrix, even in intramolecular 1,2-shifts, while the 1,2-H shift was relatively easy under the same conditions.[20] Secondly, one may propose that most of the Ph_2C reacts when the matrix is thawed in the dark with the more reactive, and more rapidly melting, solute alcohol. There has been accumulating evidence,[6,7] however, which demonstrates that most of the reaction of the carbene in the matrix occurs while the reaction mixtures are still frozen (see below). A more probable explanation would be that the co-aggregation of the carbene precursor and the solute alcohol is occurring in the crystalline matrix. Similar striking effects of the host on the course of low-temperature photochemical reactions have been explained[1,2] in terms of such aggregation. Such co-aggregation might be attributable, at least in part, to the limited solubility of the solute molecules in the *t*-BuOH crystal at low temperatures. However, this is by no means unavoidable, since similar selective reactions between solute molecules has been noted in a 10% EtOH–*t*-$C_5H_{11}OH$ mixed matrix which does not crystallize, but which forms a glass at −196 °C. Also noteworthy is that all crystalline matrices were not unreactive to carbene at −196 °C. C–H insertion products were obtained[6b] in reasonable yields (40—50%) in the low-temperature photolysis of $PhCH{=}N_2$ in a crystalline matrix, *e.g.*, pentane, butane, and isobutane. The interpretation of these results we favor is that the guest cavity provided by bulky tertiary alcohol has enough space to bind a molecular aggregate inside it.

Finally, an example to show the more general utility of the *t*-BuOH matrix was obtained in the reaction of Ph_2C with Ph_2CO. The irradiation (>300 nm) of Ph_2CN_2 in a 5% Ph_2CO–*t*-BuOH mixture at −196 °C resulted in a rapid and splendid change in the original wine-red color of the reaction mixture to a

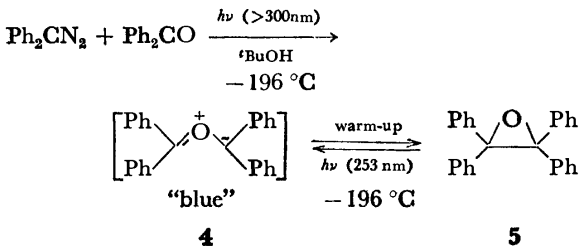

Table 4. Product distributions in the photolysis[a] of diphenyldiazomethane in the presence of benzophenone in *t*-butyl alcohol matrix at −196 °C

a) The yields were determined by GC and are based on the Ph_2CN_2 used.

deep blue, which rapidly faded to a light yellow solution when the matrix was then thawed in the dark. The GC analysis of the resulting mixture showed the presence of oxirane (**5**) as the main product (Table 4). The transient formation of a blue-colored species is very reminescent of the carbonyl ylide (**4**) which has been detected[21] in the low-temperature photolysis (253 nm) of the oxirane (**5**), although our attempt at the spectroscopic identification of **4** was not successful because of the extremely low transmission of the matrix. This strongly indicates the intervention of carbonyl ylide in the reaction of Ph_2C with the Ph_2CO, probably formed by the initial attack of carbene on carbonyl oxygen. Such an intermediate had been postulated[22] in the addition of carbene to a carbonyl compound, but it had not been detected before. It should be noted again that neither blue-colored species nor oxirane can be observed in similar photolyses within other alcoholic matrices, which form glass. The main products in this case are those formed from the host alcohol. The spin multiplicity of the attacking carbene poses a very interesting question. The attack by the triplet, followed by electron demotion, could explain the formation of ylide. However, the one-step formation of the electrophilic attack of the singlet could equally well be applied, since it has been shown that the presence of Ph_2CO as a sensitizer does not change the singlet/triplet ratio of carbene at −196 °C. This is ascribable to the rapid and reversible singlet-triplet equillibrium involved[9] in this carbene system. Note that the experimental[14] value for $E_S - E_T$ is ≤ 3 kcal/mol. Further studies to show the general usefulness of this matrix are in progress.

Experimental

The IR spectra were determined on a JASCO IR-G recording spectrometer. The H^1 NMR spectra were determined on a JEOL JNM-MH-100 NMR spectrometer. The GC-MS spectra were obtained on a Shimadzu GC-MS 1000 spectrometer using a column consisting OV-17 on Shimalite (5.0 mm×2.0 m). The GC analyses were performed on a Yanagimoto instrument, Model G-180, with a flame ionization detector. The following columns were used: A, 5.0 mm×2.0 m 10% OV-17 on 60—80 mesh Diasolid L; B, 5.0 mm×2.0 m 5% PEG 20 M on 60—80 mesh Diasolid L.

Materials. All the diazo compounds employed (**1a**,[23] **1b**,[23] **1c**,[24] **2**,[25] **3a**,[26] **3b**,[27] and **3c**,[28]) were prepared according to the literature procedures and were purified just prior to use. The *trans*-dibenzoylethylene was prepared

by means of the Friedel-Crafts reaction[29] with fumaryl chloride. The dimethyl α,β-diphenylmaleate was obtained by the reaction[30] of methyl α-bromophenylacetate with Na-NH_2. The *N,N,N',N'*-tetraethylfumaramide was prepared by the treatment of fumaryl chloride with diethylamine. The preparations of the other authentic specimens have been reported elsewhere.[6c] Satisfactory spectroscopic data have been obtained for all authentic compounds. The commercial alcohols were purified prior to use.

Photochemical Reactions and Analyses. All the irradiations were conducted using a Halos 300 W high-pressure mercury lamp with a water-cooled quartz jacket. In the general procedure, 0.06 mmol of Ph_2CN_2 was added to 2 ml of *t*-butyl alcohol with or without a second alcohol or Ph_2CO in a Pyrex tube with a capacity of 5 ml. The tube was suspended in a transparent Pyrex Dewar flask filled with coolant and irradiated until all of the precursor molecules had been destroyed. The coolants were water (24 °C), solid CO_2–EtOH (−77 °C), and liquid nitrogen (−196 °C). For solid-phase irradiations, the mixture was periodically warmed in the dark until the rigid glass or solid melted, so that mixing could occur. Control experiments ruled out the interconversion of the product during the irradiations and also showed that no reaction occurred in the absence of light in the range of temperatures studied.

The product identification and relative yields were easily determined by standard GC and/or GC-MS techniques.

The authors wish to express their thanks to Professor Gary W. Griffin, University of New Orleans, for the supply of tetraphenyloxirane.

Photocycloaddition Reaction of Alkyl-substituted 1,4-Naphthoquinones with Olefins. Substituent Effects on Controlling the Orientation of Cycloaddition Reaction

Kazuhiro MARUYAMA* and Noritsugu NARITA
Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawaoiwake-cho, Sakyo-ku, Kyoto 606
(Received August 23, 1979)

Photolysis of a benzene solution of 2-alkyl- or 2,3-dialkyl-substituted 1,4-naphthoquinone mixed with an aryl-substituted ethylene afforded 3,4-benzobicyclo[4.2.0]octene-2,5-dione derivatives (cyclobutane type adducts) in a good yield without any other types of products. The orientation of the cycloaddition was likely to control by the adverse van der Waals repulsion of the substituents of the quinone and olefin in addition to the electronic effects of the substituents. The predominant factor orientating the cycloaddition seems to play the van der Waals repulsion due to the substituents both of quinone and olefin.

Photochemical reaction of 1,4-naphthoquinones with olefins have been investigated by several workers[1-3]. Especially the photoaddition reactions are of versatile possibilities, for it consists from one-step C–C or C–O bond formation reaction. The photo-addition products of quinone and olefins can be classified into the following three structural types; cyclobutane type adduct **A**, spiro-oxetane type adduct **B** *via* $2\pi+2\pi$ cycloaddition processes, and cyclohexane type adduct **C** *via* $2\pi+2\pi+2\pi$ cycloaddition process.

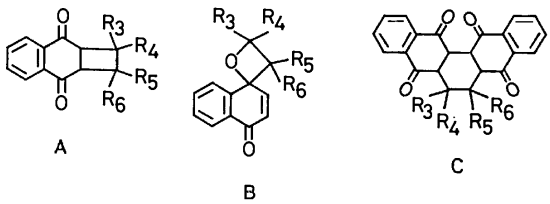

Fig. 1. The photo-addition products of 1,4-naphthoquinone and olefins.

The mechanism of the formation of type **C** products has been investigated in details by Maruyama, *et al.*[4]

Although photochemical reactions of substituted 1,4-naphthoquinones with some olefins have reported to yield cyclobutane type adducts **A**,[5,6] the systematic investigations in the fields have been sparse. In this paper, the present authors investigated the photochemical reactions of alkyl-substituted 1,4-naphthoquinones with aryl-substituted ethylenes and intended to clarify the substituent effects of quinones and olefins on the orientation of the photocycloaddition reaction.

Results and Discussion

Photocycloaddition Reaction of Alkyl-substituted 1,4-Naphthoquinones with Aryl-substituted Ethylenes. Irradiation of a solution of 2-methyl-1,4-naphthoquinone (**1a**) with styrene (**2a**) in benzene with the light through a Pyrex filter gave the mixture of three cycloaddition products in a high yield. The major product was isolated by thin layer chromatography (silica gel) and purified by recrystallization as white crystals. The structure was determined on the basis of spectroscopy (see Experimental) to be *anti*-1-methyl-8-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione(**3a**). The second

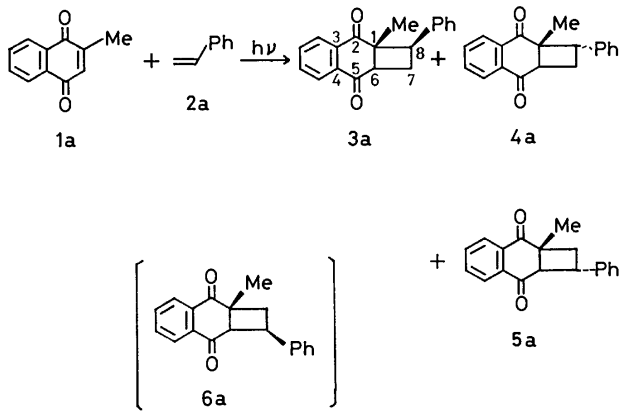

Fig. 2. Photochemical reaction of 2-methyl-1,4-naphthoquinone **1a** with styrene **2a**.

product was obtained as a mixture with **3a**. The structure was assigned to *syn*-1-methyl-8-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione(**4a**) on the basis of spectral data. The third product was obtained as pure crystals which structure was assigned to *syn*-1-methyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione(**5a**).

All of three products were cyclobutane type adducts *via* $2\pi+2\pi$ cycloaddition process. But, the corresponding *anti*-7-phenyl isomer expected(**6a**) was not detectable. These three products were unchanged by treatment with basic alumina, showing that the six-four ring fusion is cis.[8]

In a similar fashion, the photoreaction of 2-ethyl-1,4-naphthoquinone(**1b**) with styrene **2a** afforded three products **3b**, **4b**, and **5b**. No *anti*-7-phenyl isomer **6b** was obtained, too.

In these cases, the major products were the 8-phenyl isomers and the ratio of 7-phenyl isomer to 8-phenyl isomers was smaller for 2-methyl-1,4-naphthoquinone–styrene system, 1/6, than that for 2-ethyl-1,4-naphthoquinone–styrene system, 1/3.5.

The slow photo-induced isomerization between these two isomers (7-phenyl and 8-phenyl isomers) was realized, which was followed by means of NMR spectroscopy, but the rates of photo-isomerization were so slow that the distribution of the products was controlled kinetically.

The orientation of the addition could be affected

TABLE 1. RELATIVE YIELDS OF PHOTOPRODUCTS

Quinone	Olefin	Total yield %	7-Phenyl		8-Phenyl	
			Anti(%)	Syn(%)	Anti(%)	Syn(%)
1a	**2a**	80	(**6a**) 0	(**5a**) 15	(**3a**) 55	(**4a**) 30
1b	**2a**	73	(**6b**) 0	(**5b**) 24	(**3b**) 50	(**4b**) 26
1a	**2b**	95	(**6c**) 42	(**5c**) 10	(**3c**) 29	(**4c**) 19
1b	**2b**	95	(**6d**) 50	(**5d**) 14	(**3d**) 23	(**4d**) 13
1a	**2c**	73		(**5e**) 66	(**3e**) 34	
1b	**2c**	57		(**5f**) 80	(**3f**) 20	

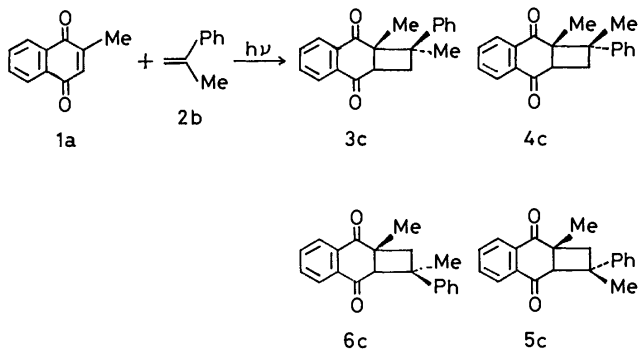

Fig. 3. Photochemical reaction of **1a** with 2-phenylpropene **2b**.

by both steric and electronic interactions between two substrates, 1,4-naphthoquinone and olefin. The results found in the 2-alkyl-1,4-naphthoquinone–styrene system indicate that the dipole-dipole interaction between the alkyl group on the quinone molecule and the phenyl group on styrene molecule presumably overcome the adverse van der Waals repulsion of these substituents.

The photocycloaddition of 2-methyl-1,4-naphthoquinone **1a** with 2-phenylpropene(**2b**) in bezene gave four cycloadducts. The major product (39%) was isolated as white crystals which structure was determined as *anti*-1,7-dimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]-octene-2,5-dione(**6c**). The second product (28%) was *anti*-1,8-dimethyl-8-phenyl-3,5-benzobicyclo[4.2.0]-octene-2,5-dione(**3c**).

The *syn*-7-phenyl (**5c**) (9%) and *syn*-8-phenyl isomer (**4c**) (18%) were obtained as the mixture, and the yields were determined by means of NMR spectroscopy. The ratio of 7-phenyl isomers to 8-phenyl isomers was about 1.

The photochemical reaction of 2-ethyl-1,4-naphthoquinone **1b** with 2-phenylpropene **2b** gave similarly two 8-phenyl derivatives (**3d**) and (**4d**), and two 7-phenyl derivatives (**5d**) and (**6d**). The major product (48%) was *anti*-ethyl-7-methyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**6d**). The *anti*-8-phenyl isomer was obtained in a yield of 22%. The syn isomers were obtained as a mixture. The ratio of 7-phenyl derivatives to 8-phenyl ones was about 1.5, which was larger than that of isomers in the case of **1a** and **2b**.

When 2-phenylpropene was employed as olefin, the methyl group on C-2 carbon of olefin would cancel out the dipole-dipole interaction caused by the phenyl group, and the adverse van der Waals repulsion of the substituent groups on the quinone and olefin may force to reverse the orientation of addition. Thus the ratio of 7-phenyl/8-phenyl adducts increased in accordance with the bulkiness of substituent groups, *i.e.* from hydrogen to methyl group. To support this conclusion, the photocycloadditions of 2-methyl- and 2-ethyl-1,4-naphthoquinone with 1,1-diphenylethylene (**2c**) were investigated under the same conditions.

A benzene solution containing 2-methyl-1,4-naphthoquinone **1a** and 1,1-diphenylethylene **2c** was irradiated through a Pyrex filter. The products were 1-methyl-7,7-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5e**) (48%) and 1-methyl-8,8-diphenyl-3,4-benzobicyclo-[4.2.0]octene-2,5-dione (**3e**) (25%). Similarly, 2-ethyl-1,4-naphthoquinone **1b** reacted photochemically with 1,1-diphenylethylene **2c** to give 1-ethyl-7,7-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5f**) (45%) as the major product and 1-ethyl-8,8-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3f**) (12%).

In these cases, the major product was the 7,7-diphenyl derivative and the ratio of 7,7-diphenyl/8,8-diphenyl isomer was 2 for 2-methyl-1,4-naphthoquinone–1,1-diphenylethylene system, and 4 for 2-ethyl-1,4-naphthoquinone–1,1-diphenylethylene system.

The results were illustrated in Table 1.

These results given in Table 1 indicated that the adverse van der Waals repulsion among the substituent groups in transition state could overcome sometimes the electronic attractive interaction caused by the substituents of reactants.

In the photoadducts of the quinone and 1,1-diphenylethylene, one of the two phenyl groups was situated above the quinone moiety from molecular model examination. The π-π interaction between quinone moiety and one of the two phenyl groups could be expected, but not with the other.

To substantiate the fact, the photocycloaddition of 2-methyl-1,4-naphthoquinone **1a** and 1,1-bis(*p*-methylphenyl)ethylene was carried out under the same irradiation conditions. The major product (46%) was 1-methyl-7,7-bis(*p*-methylphenyl)-3,4-benzobicyclo-[4.2.0]octene-2,5-dione (**5g**). The minor product was assigned the structure as 1-methyl-8,8-bis(*p*-methylphenyl)-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3g**) (28%).

The NMR spectra of these products showed that the signals due to two methyl groups on the two phenyls appeared at δ 2.0 and 2.3 ppm in chloroform-*d*, respectively. The phenyl protons appeared in the region

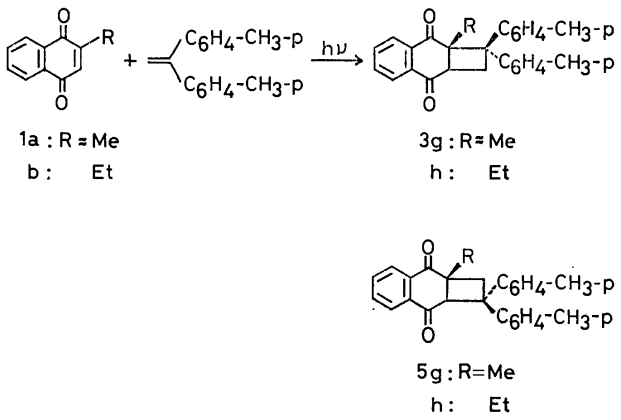

Fig. 4. Photochemical reaction of 2-alkyl-1,4-naphthoquinone with 1,1-bis(*p*-methylphenyl)ethylene.

of 6.9—7.1 and 7.2—7.3 ppm with two AB type quartets (see Experimental).

Analogous products, 1-ethyl-7,7-bis(*p*-methylphenyl)-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5h**) and 1-ethyl-8,8-bis(*p*-methylphenyl)-3,4-benzobicyclo[4.2.0]-octene-2,5-dione (**3h**) were obtained from the photoreaction of 2-ethyl-1,4-naphthoquinone **1b** with 1,1-bis(*p*-methylphenyl)ethylene.

The NMR spectra of both **3h** and **5h** also showed respectively two different *p*-methylphenyl signals. This fact clearly shows that between the one of two phenyl groups and quinone moiety the π-π interaction is operating.

The products ratio of two isomers, *i.e. anti* and *syn*, could reflect the steric or electronic courses of this type $2\pi+2\pi$ cycloaddition reaction. Further, the symmetrical 2,3-dialkyl-1,4-naphthoquinones were employed to investigate the substituent effects on the *anti*/*syn* isomers ratio of the products.

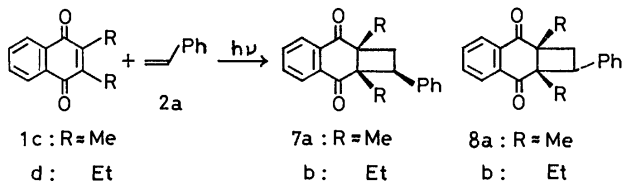

Fig. 5. Photochemical reaction of 2,3-dialkyl-1,4-naphthoquinone with styrene **2a**.

The photocycloaddition of 2,3-dimethyl-1,4-naphthoquinone (**1c**) with styrene **2a** gave *anti*-1,6-dimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7a**) in a yield of 84%, and the corresponding *syn* isomer (**8a**) in a yield of 16%.

The photoreaction of 2,3-diethyl-1,4-naphthoquinone (**1d**) with styrene **2a** gave *anti*-1,6-diethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7b**) in a yield of 93% and the *syn* isomer (**8b**) in a yield of 7%.

The photoreaction of 2,3-dimethyl-1,4-naphthoquinone **1c** with 2-phenylpropene **2b** afforded two products, one of which was assigned as *anti*-1,6,7-trimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7c**)(38%) and the other was its *syn* isomer (**8c**) (20%). Similarly, the photocycloaddition of 2,3-diethyl-1,4-naphthoquinone **1d** and 2-phenylpropene **2b** gave *anti*-1,6-diethyl-7-methyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7d**) in a yield of 77% and the corresponding *syn* isomer (**8d**) in a yield of 13%.

Table 2. Anti/syn ratio of photoproducts

Quinone	Olefin	7-Phenyl adducts	8-Phenyl adducts
1a	**2a**	0	1.88
1a	**2b**	4.20	1.56
1b	**2a**	0	2.00
1b	**2b**	3.69	1.69
1c	**2a**	5.25	
1c	**2b**	1.52	
1d	**2a**	13.33	
1d	**2b**	6.00	

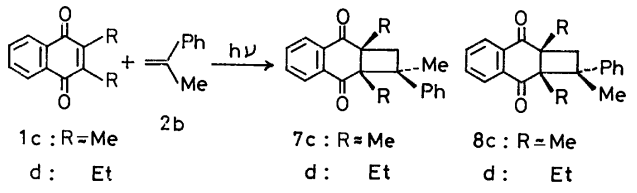

Fig. 6. Photochemical reaction of 2,3-dialkyl-1,4-naphthoquinone with 2-phenylpropene **2b**.

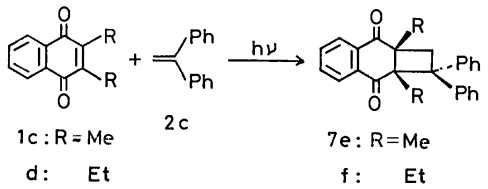

Fig. 7. Photochemical reaction of 2,3-dialkyl-1,4-naphthoquinone with 1,1-diphenylethylene **2c**.

The photocycloadditions of these symmetrical substituted 1,4-naphthoquinones(**1c** and **1d**) with 1,1-diphenylethylene **2c** gave 1,6-dialkyl-7,7-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7e** and **7f**) in high yields.

The results of the *anti*/*syn* ratio of photoproducts are given in Table 2.

The *anti*/*syn* ratio was larger than 1 with exception of the case of 7-phenyl derivatives obtained from 2-alkyl-1,4-naphthoquinone (**1a** and **1b**) and styrene **2a**. The ratio was reduced when the methyl group was introduced to C-1 carbon of styrene. The results found in these systems showed that the *anti* transition state was favored over the *syn* one, and that the adverse van der Waals repulsion of these substituents overcame the attractive force due to π-π overlap interaction between quinone moiety and phenyl group of olefin.

From the results it was shown that one of the major factors in determining the orientation of the photocycloaddition of alkyl-substituted 1,4-naphthoquinone and substituted styrene was the steric hinderance of the substituents of quinone and olefin.

Determination of Quantum Yields. The quantum yields were determined by using potassium tris(oxalato)-ferrate(III) as the chemical actinometer.[9] The light from a 300 W high pressure mercury-arc lamp was

TABLE 3. QUANTUM YIELDS FOR QUINONE DISAPPEARANCE (Φ_d) AND THE PRODUCT FORMATION (Φ_p)

a) The values are isolated yields based on the amount of quinone used.

filtered through a potassium chromate–sodium carbonate solution[10] (transmission: 300—330 nm).

Photochemical reactions for the determination were carried out holding the reaction at a low conversion to prevent an appreciable light absorption by the products. Quantum yields of the photochemical reactions measured in benzene solution were given in Table 3. Quantum yields for quinone disappearance were decreased in accordance with the larger steric repulsion of the substituent groups on quinone and olefin.

These results showed that the adverse van der Waals repulsion of substituent groups was playing an important role not only for controlling the orientation of the cycloaddition, but also for determining the rate of the reaction.

Reaction Mechanism. The absorption spectra of alkyl-substituted 1,4-naphthoquinones exhibited maxima (in chloroform) at 440 nm (ε: <100), 330 nm (ε: 2500—3000), and 245 nm(ε: *ca.* 15000). The lowest $\pi\pi^*$ absorption band of the quinones exhibited at 330 nm and $n\pi^*$ absorption was almost masked by the long wavelength tail of the $\pi\pi^*$ band, and was apparently observed as a shoulder. When the photoreaction of 2-alkyl- or 2,3-dialkyl-1,4-naphthoquinone with olefins was undertaken by using the longer wavelength light than 400 nm, then none of photoadduct could be detected by means of NMR spectroscopy, and the quinone was recovered almost quantitatively.

The photocycloaddition of 2-methyl- **1a** or 2,3-dimethyl-1,4-naphthoquinone **1c** with 1,1-diphenylethylene **2c** was not quenched by addition of fluoranthene as a triplet quencher[12-14] (E_T=54.2 kcal/mol) in the system. The present experimental results are likely to indicate the photocycloaddition between quinone and olefin proceeds *via* $\pi\pi^*$ singlet excited state of quinone, but to determine the true nature of the excited state responsible for the present cycloaddition reaction the further detailed mechanistic investigations should be done.

Experimental

The photolysis solution in a Pyrex test tube was irradiated externally with the light from a 300 W high pressure mercury-arc lamp (Eikosha, Halos PIH-300).

The melting points of photochemical products isolated were uncorrected.

The elemental analyses of photochemical products were performed at the Microanalysis Center of Kyoto University.

NMR spectra were observed with a JEOL PS-100 spectrometer at 100 MHz using TMS as the internal standard. Infrared spectra were observed with a JASCO IR-G spectrometer. Ultraviolet and visible spectra were observed with a Shimadzu UV-200 spectrometer,

The filter (Toshiba color glass filter VY-42) was employed for cutting the shorter wavelength light than 400 nm.

The 2-alkyl- and 2,3-dialkyl-1,4-naphthoquinones were prepared from 1,4-naphthoquinone and the corresponding carboxylic acid, acetic acid or propionic acid, according to the modification of Jacobsen and Torssell's method.[7]

A solution containing 20 mmol of 1,4-naphthoquinone, 80 mmol of carboxylic acid and 0.5 g of silver nitrate in 40 ml of acetonitrile–water (50% v/v) was allowed to stir

at 65 °C for the addition of 30 mmol of ammonium persulfate dissolved in 30 ml of water for 2 h. The mixture was allowed to stir for an additional 30 min. After neutralization with sodium carbonate, the solution was extracted with ether. The ethereal solution dried over magnesium sulfate was concentrated, and the crude residue was chromatographed through a silica-gel column using petroleum ether as the eluent. The yellow solid obtained was recrystallized from ethanol. The yields and physical data of alkyl-substituted 1,4-naphthoquinones were given in Table 4.

Styrene, 2-phenylpropene, and 1,1-diphenylethylene were purified by distillation under reduced pressure under nitrogen atomosphere. 1,1-Bis(*p*-methylphenyl)ethylene was prepared according to the method of Allen and Converese[15] from *p*-bromotoluene and *p*-methylacetophenone.

General procedure of photoreaction of alkyl-substituted 1,4-naphthoquinone with olefin was as follows. A solution containing 2 mmol of quinone and 4 mmol of olefin in 20 ml of benzene was irradiated in a Pyrex test tube for 12 to 24 h. After removal of the solvent under a reduced pressure, the residual yellow oil was separated by thin layer chromatography on silica gel.

Photolysis of 2-methyl-1,4-naphthoquinone **1a** with styrene **2a** afforded three products. The first product was *syn*-1-methyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5a**) in a yield of 11%. **5a**; white crystals, mp 94.0—95.0 °C; IR (KBr disk) 1670 cm^{-1}; UV (chloroform) λ_{max} 340 (ε:210), 308 (1540), 299 (1660), 254 (12000), and 244 nm (11100); NMR ($CDCl_3$) δ 1.68 (s, 3), 2.44 (dd, 1, J=8 and 10 Hz), 2.86 (dd, 1, J=8 and 10 Hz), 3.62 (d, 1, J=10 Hz), 4.24 (q, 1, J=10 Hz), 6.8—7.2 (m, 5), 7.4—7.7 (m, 3), and 7.9—8.1 ppm (m, 1); MS *m/e* 276 (M^+) and 104.

The second product was assigned the structure of *anti*-1-methyl-8-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3a**) (45%). **3a**; white crystals, mp 112.0—113.0 °C, IR (KBr disk) 1675 cm^{-1}; UV ($CHCl_3$) λ_{max} 335 (ε:250), 308 (2170), 298 (2300), and 255 nm (12900); NMR ($CDCl_3$) δ 1.14 (s, 3), 2.40—2.70 (m, 1), 2.90—3.25 (m, 2), 3.80—4.04 (m, 1), 7.0—7.4 (m, 5), 7.70—7.90 (m, 2), and 8.0—8.24 ppm (m, 2); MS *m/e* 276 (M^+) and 104; EA: Found; C, 82.52; H, 6.02%; Calcd for $C_{19}H_{15}O_2$; C, 82.58; H, 5.84%.

The third component was obtained as a mixture with **3a** and assigned as *syn*-1-methyl-8-phenyl-3,4-benzobicyclo-[4.2.0]octene-2,5-dione (**4a**) on the basis of the NMR spectroscopy. **4a**; NMR ($CDCl_3$) δ 1.36 (s, 3), 2.1—2.4 (m, 1), 2.8—2.95 (m, 1), 3.4—3.6 (m, 2), 7.0—7.2 (m, 5), 7.6—7.8 (m, 2), and 7.9—8.1 ppm (m, 2); MS *m/e* 276 (M^+) and 104.

The NMR signal of methyl proton of **3a** appeared at the higher field due to the shielding effect of *cis*-phenyl group than that of **4a**, of which phenyl group was *trans* to the methyl group.

The photoadduct **3a** (50 mg) was stirred with basic alumina (3.0 g) in ether (30 ml) for 40 h at room temperature. The alumina was removed by filteration, and the filtrate was concentrated to give a light yellow solid (48 mg). The NMR analysis showed that there was no change during this treatment, confirming the *cis* four-six ring fusion in **3a**.

The photoadduct **3a** (30 mg) in benzene-d_6 (0.5 ml) in NMR tube was irradiated with a high pressure mercury-arc lamp for 12 h. The NMR spectrum of the material showed that the isomerization of **3a** to **4a** occurred by 5% at most.

When 2-ethyl-1,4-naphthoquinone **1b** with styrene **2a** was irradiated in benzene, three products were obtained. The first component was the mixture of *anti*- and *syn*-1-ethyl-8-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3b** and **4b**, respectively) (isomer ratio: 2:1) (total yield; 57%). The NMR spectrum of this component was very complex.[16]

The second component was obtained as white crystals. The structure was assigned *syn*-1-ethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5b**). **5b**; white crystals, mp 126.5—127.0 °C; IR (KBr disk) 1670 cm^{-1}; UV ($CHCl_3$) λ_{max} 335 (ε:270), 308 (2200), 300 (2360), 253 (16600), and 242 nm (15600); NMR ($CDCl_3$) δ 0.94 (t, 3, J=8 Hz), 1.6—2.44 (m, 2), 2.54 (dd, 1, J=12 and 8 Hz), 2.82 (dd, 1, J=12 and 8 Hz), 3.72 (d, 1, J=10 Hz), 3.9—4.4 (m, 1), 6.8—7.3 (m, 5), 7.4—7.8 (m, 3), and 7.9—8.2 ppm (m, 1).

Photoreaction of **1a** and 2-phenylpropene **2b** afforded four addition products. The first product was obtained as white crystals in a yield of 39%. The structure was assigned as *anti*-1,7-dimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**6c**). **6c**; white crystals, mp 109.0—110.0 °C; IR (KBr disk) 1685 and 1675 cm^{-1}; UV ($CHCl_3$) λ_{max} 335 (ε:200), 307 (1780), 298 (1880), and 256 nm (12900); NMR ($CDCl_3$) δ 1.12 (s, 3), 1.36 (s, 3), 2.69 (ABq, 2, J=26 and 16 Hz), 3.64 (s, 1), 7.0—7.44 (m, 5), 7.56—7.8 (m, 2), and 7.9—8.2 ppm (m, 2); EA; Found; C, 82.97; H, 6.17%; Calcd for $C_{0}H_{18}O_2$; C, 82.73; H, 6.25%.

The second product was assigned *anti*-1,8-dimethyl-8-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3c**). **3c**; white crystals mp 143.0—144.0 °C; IR (KBr disk) 1670 cm^{-1}; UV ($CHCl_3$) λ_{max} 330 (ε:200), 307 (1710), 298 (1920), 254 (13000), and 242 nm (11200); NMR ($CDCl_3$) δ 1.20 (s, 6), 2.18 (d, 1, J=10 Hz), 2.88—3.24 (m, 2), 7.2—7.4 (m, 5), 7.6—7.8 (m, 2), and 7.96—8.2 ppm (m, 2); EA: Found; C, 82.88; H, 6.09%; Calcd for $C_{20}H_{18}O_2$; C, 82.73; H, 6.25%.

The third component was obtained as the mixture of two products. They were assigned *syn*-1,7-dimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5c**) and *syn*-1,8-dimethyl-8-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**4c**) (9 and 18%, respectively) on the basis of the NMR spectra. **5c**; NMR ($CDCl_3$) δ 1.52 (s, 3), 1.74 (s, 3), 2.22 (d, 1, J=12 Hz), 3.50 (s, 1), 6.8—7.2 (m, 5), 7.4—7.7 (m, 3), and 7.7—8.0 ppm (m, 1). **4c**; NMR ($CDCl_3$) δ 1.18 (s, 3), 1.24 (s, 3), 2.6—3.1 (m, 3), 6.8—7.3 (m, 5), 7.4—7.8 (m, 3), and 7.8—8.0 ppm (m, 1).

Irradiation of **1b** and **2b** afforded four cycloaddition products. The major product (48%) was assigned the structure of *anti*-1-ethyl-7-methyl-7-phenyl-3,4-benzobicyclo-[4.2.0]octene-2,5-dione (**6d**). **6d**; NMR ($CDCl_3$) δ 0.72 (t, 3, J=8 Hz), 1.20 (s, 3), 1.40—2.10 (dq, 2, J=8 and 8 Hz), 2.72 (ABq, 2, J=18 and 14 Hz), 3.80 (s, 1), 7.2—7.6 (m, 5), 7.7—8.0 (m, 2), and 8.1—8.4 ppm (m, 2).

The second product (22%) was obtained as white crystals, of which structure was assigned *anti*-1-ethyl-8-methyl-8-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**4d**). **4d**; white crystals, mp 137.0—138.0 °C; IR (KBr disk) 1675 and 1665 cm^{-1}; UV ($CHCl_3$) λ_{max} 340 (ε:270), 308 (1770), 297 (2000), and 255 nm (13700); NMR ($CDCl_3$) δ 0.68 (t, 3, J=8 Hz), 0.8—1.4 (m, 1), 1.24 (s, 3), 1.8—2.2 (m, 1), 2.2—2.6 (m, 1), 3.0—3.4 (m, 2), 7.2—7.6 (m, 5), 7.7—8.0 (m, 2), and 8.1—8.4 ppm (m, 2); EA: Found; C, 82.98; H, 6.47%; Calcd for $C_{21}H_{20}O_2$; C, 82.86; H, 6.62%.

Photolysis of **1a** with 1,1-diphenylethylene **2c** gave two products. The first product (48%) was assigned the structure of 1-methyl-7,7-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5e**). **5e**; white crystals, mp 112.5—113.5 °C; IR (KBr disk) 1685 and 1670 cm^{-1}; UV ($CHCl_3$) λ_{max} 310 (ε:1980), 302 (2080), 252 (12800), and 242 nm (13300); NMR ($CDCl_3$) 1.40 (s, 3), 2.58 (d, 1, J=12 Hz), 3.80 (d, 1, J=12 Hz), 4.16 (s, 1), 6.6—7.6 (m, 12), and 7.6—8.0 ppm (m, 2), MS *m/e* 352 (M^+) and 180; EA: Found; C, 85.50; H, 5.86%; Calcd for $C_{25}H_{20}O_2$; C, 85.20; H, 5.72%.

The second product (25%) was obtained as white crystals, assigned the structure 1-methyl-8,8-diphenyl-3,4-benzobicyclo-

[4.2.0]octene-2,5-dione (**3e**). **3e**; white crystals, mp 141.0—142.0 °C; IR (KBr disk) 1670 cm^{-1}; UV ($CHCl_3$) λ_{max} 302 (ε:2050), 252 (13500), and 243 nm (13700); NMR ($CDCl_3$) δ 1.60 (s, 3), 3.14 (dd, 1, J=10 and 2 Hz), 3.42 (dd, 1, J=12 and 10 Hz), 3.74 (dd, 1, J=12 and 2Hz), 6.4—7.0 (m, 5), 7.0—7.6 (m, 7), and 7.7—8.0 ppm (m, 2), MS *m/e* 352 (M^+) and 180; EA: Found; C, 85.00; H, 5.59%; Calcd for $C_{25}H_{20}O_2$; C, 85.20; H, 5.72%.

Irradiation of **1b** with **2c** afforded two photoadducts. The first product (45%) was assigned the structure of 1-ethyl-7,7-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5f**). **5f**; white crystals, mp 135.0—136.0 °C; IR (KBr disk) 1665 cm^{-1}; UV ($CHCl_3$) λ_{max} 310 (ε:1800), 302 (1890), 250 (11900), and 242 nm (12700); NMR ($CDCl_3$) δ 0.72 (t, 3, J=8 Hz), 1.50—2.30 (m, 2), 2.64 (d, 1, J=12 Hz), 3.84 (d, 1, J=12 Hz), 4.30 (s, 1), 6.6—7.6 (m, 12), and 7.7—8.0 ppm (m, 2); MS *m/e* 366 (M^+) and 180; EA: Found; C, 84.94; H, 6.16%; Calcd for $C_{26}H_{22}O_2$; C, 85.21; H, 6.05%.

The second product was assigned the structure of 1-ethyl-8,8-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3f**). **3f**; white crystals, mp 105.0—106.0 °C; IR (KBr disk) 1675 cm^{-1}; UV ($CHCl_3$) λ_{max} 300 (ε:1800), 250 (13800), and 242 nm (14000); NMR ($CDCl_3$) δ 0.78 (t, 3, J=8 Hz), 1.38 (dq, 1, J=8 and 8 Hz), 2.76 (dq, 1, J=8 and 8 Hz), 3.1—3.7 (m, 3), 6.7—7.7 (m, 12), and 7.7—8.0 ppm (m, 2); MS *m/e* 366 (M^+) and 180; EA: Found; C, 85.10; H, 6.12%; Calcd for $C_{26}H_{22}O_2$; C, 85.21; H, 6.05%.

When **1a** was irradiated with 1,1-bis(*p*-methylphenyl)-ethylene, two products were obtained. The major product (46%) was assigned the structure of 1-methyl-7,7-bis(*p*-methylphenyl)-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5g**). **5g**; white crystals, mp 145.0—146.0 °C; NMR ($CDCl_3$) δ 1.44 (s, 3), 2.00 (s, 3), 2.32 (s, 3), 2.62 (d, 1, J=12 Hz), 3.84 (d, 1, J=12 Hz), 4.24 (s, 1), 6.82 (ABq, 4, J=18 and 8 Hz), 7.22 (ABq, 4, J=12 and 8 Hz), 7.4—7.6 (m, 2), and 7.7—8.0 ppm (m, 2); EA: Found; C, 85.35; H, 6.23%; Calcd for $C_{27}H_{24}O_2$; C, 85.23; H, 6.36%.

The minor product (28%) was obtained as white crystals, of which structure was assigned 1-methyl-8,8-bis(*p*-methylphenyl)-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3g**). **3g**; white crystals, mp 174.0—175.0 °C; NMR ($CDCl_3$) δ 1.60 (s, 3), 1.96 (s, 3), 2.28 (s, 3), 3.06 (dd, 1, J=10 and 2 Hz), 3.28 (t, 1, J=10 Hz), 3.62 (dd, 1, J=10 and 2 Hz), 6.66 (d, 2, J=8 Hz), 7.0—7.4 (m, 6), 7.4—7.6 (m, 2), and 7.8—8.0 ppm (m, 2); EA: Found; C, 85.01; H, 6.18%; Calcd for $C_{27}H_{24}O_2$; C, 85.23; H, 6.36%.

When **1b** and 1,1-bis(*p*-methylphenyl)ethylene were irradiated in benzene, two photoadducts were obtained. The major product (36%) was assigned the structure of 1-ethyl-7,7-bis(*p*-methylphenyl)-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**5h**). **5h**; white crystals, mp 125.0—126.0 °C; IR (KBr disk) 1670 cm^{-1}; NMR ($CDCl_3$) δ 0.68 (t, 3, J=8 Hz), 1.76 (dq, 2, J=30 and 8 Hz), 1.90 (s, 3), 2.20 (s, 3), 2.42 (d, 1, J=12 Hz), 3.58 (d, 1, J=12 Hz), 3.98 (s, 1), 6.52 (ABq, 4, J=24 and 8 Hz), 6.92 (ABq, 4, J=20 and 8 Hz), 7.16—7.40 (m, 2), and 7.48—7.7 ppm (m, 2), MS *m/e* 394 (M^+) and 208; EA: Found; C, 85.38; H, 6.64%; Calcd for $C_{28}H_{26}O_2$; C, 85.24; H, 6.64%.

The minor product (25%) was obtained as a light yellow viscous oil. The structure was assigned 1-ethyl-8,8-bis(*p*-methylphenyl)-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**3h**) on the basis of the NMR spectroscopy. **3h**; NMR ($CDCl_3$) δ 0.78 (t, 3, J=8 Hz), 1.10—1.50 (m, 1), 2.00 (s, 3), 2.30 (s, 3), 2.5—2.9 (m, 1), 3.1—3.7 (m, 3), 6.70 (d, 2, J=8 Hz), 7.0—7.4 (m, 6), and 7.5—7.6 ppm (m, 2), MS *m/e* 394 (M^+) and 208.

Photolysis of 2,3-dimethyl-1,4-naphthoquinone **1c** with styrene **2a** afforded two products. The major product (84%) was assigned the structure of *anti*-1,6-dimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7a**). **7a**; white crystals, mp 107.0—108.0 °C; IR (KBr disk) 1655 cm^{-1}; UV ($CHCl_3$) λ_{max} 332 (ε:280), 306 (1900), 297 (2050), and 253 nm (13200); NMR ($CDCl_3$) δ 1.08 (s, 3), 1.12 (s, 3), 2.56 (d, 1, J=12 Hz), 2.58 (d, 1, J=12 Hz), 3.66 (dd, 1, J=12 and 8 Hz), 6.8—7.2 (m, 5), 7.6—7.8 (m, 2), and 8.0—8.2 ppm (m, 2); EA: Found; C, 82.86; H, 6.17%; Calcd for $C_{20}H_{18}O_2$; C, 82.73; H, 6.25%.

The minor product (16%) was assigned the structure of *syn*-1,6-dimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**8a**). **8a**; white crystals, mp 103.0—104.0 °C; IR (KBr disk) 1665 cm^{-1}; UV ($CHCl_3$) λ_{max} 337 (δ:200), 305 (1450), 295 (1600), and 250 nm (10900); NMR ($CDCl_3$) δ 1.54 (s, 3), 1.60 (s, 3), 2.22 (dd, 1, J=12 and 8 Hz), 2.74 (dd, 1, J=12 and 10 Hz), 3.72 (dd, 1, J=10 and 8 Hz), 6.76—7.2 (m, 5), 7.4—7.6 (m, 3), and 7.84—8.04 ppm (m, 1); EA: Found; C, 82.74; H, 6.54%; Calcd for $C_{20}H_{18}O_2$; C, 82.73; H, 6.25%.

Irradiation of 2,3-diethyl-1,4-naphthoquinone (**1d**) with styrene **2a** gave two photoadducts. The major product (93%) was obtained as a light yellow viscous oil. The structure was assigned *anti*-1,6-diethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7b**) on the basis of the NMR spectrum. **7b**; NMR ($CDCl_3$) δ 0.78 (t, 3, J=8 Hz), 0.82 (t, 3, J=8 Hz), 1.4—2.1 (m, 4), 2.48 (dd, 1, J=12 and 10 Hz), 2.68 (dd, 1, J=12 and 8 Hz), 3.54 (dd, 1, J=10 and 8 Hz), 7.0—7.4 (m, 5), 7.5—7.8 (m, 2), and 7.9—8.2 ppm (m, 2).

The minor product (7%) was obtained as a yellow oil, of which structure was assigned *syn*-1,6-diethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**8b**) on the basis of the NMR spectroscopy. **8b**; NMR ($CDCl_3$) δ 0.56 (t, 3, J=8 Hz), 0.74 (t, 3, J=8 Hz), 1.2—2.8 (m, 5), 2.88 (dd, 1, J=12 and 8 Hz), 3.64 (dd, 1, J=10 and 8 Hz), 7.0—7.6 (m, 8), and 7.80 ppm (d, 1, 8 Hz).

Irradiation of **1c** with 2-phenylpropene **2b** afforded two products. The major product (38%) was obtained as white crystals. The structure was assigned *anti*-1,6,7-trimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7c**). **7c**; white crystals, mp 125.0—126.0 °C; IR (KBr disk) 1660 cm^{-1}; UV ($CHCl_3$) λ_{max} 330 (ε:230), 296 (1880), and 254 nm (12900); NMR ($CDCl_3$) δ 1.12 (s, 3), 1.16 (s, 3), 1.26 (s, 3), 2.68 (s, 2), 7.0—7.4 (m, 5), 7.64—7.84 (m, 2), and 8.0—8.2 ppm (m, 2); EA: Found; C, 82.97; H, 6.53%; Calcd for $C_{21}H_{20}O_2$; C, 82.86; H, 6.62%.

The minor product (20%) was obtained as the mixture with **7c**. The former was assigned *syn*-1,6,7-trimethyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**8c**). **8c**; NMR ($CDCl_3$) δ 1.44 (s, 3), 1.52 (s, 3), 1.66 (s, 3), 2.16 (d, 1, J=14 Hz), 3.14 (d, 1, J=14 Hz), 6.8—7.2 (m, 5), 7.4—7.7 (m, 3), and 7.8—8.1 ppm (m, 1).

Photolysis of **1d** with **2b** gave two products. The major product (77%) was obtained as white crystals, of which structure was assigned *anti*-1,6-diethyl-7-methyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7d**). **7d**; white crystals, mp 162.0—163.0 °C; IR (KBr disk) 1670 cm^{-1}; UV ($CHCl_3$) λ_{max} 330 (ε:240), 295 (1610), and 250 nm (11400); NMR ($CDCl_3$) δ 0.72 (t, 3, J=8 Hz), 0.88 (t, 3, J=8 Hz), 1.18 (s, 3), 1.1—2.1 (m, 4), 2.64 (s, 2), 7.1—7.5 (m, 5), 7.64—7.9 (m, 2), and 7.9—8.1 ppm (m, 2); EA: Found; C, 83.17; H, 7.23%; Calcd for $C_{23}H_{24}O_2$; C, 83.10; H, 7.28%.

The minor product (13%) was obtained as the mixture with **7d**. The structure of the former was assigned *syn*-1,6-diethyl-7-methyl-7-phenyl-3,4-benzobicyclo[4.2.0]octene-

2,5-dione (**8d**) on the basis of the NMR spectroscopy. **8d**; NMR ($CDCl_3$) δ 0.72 (t, 3, J=8 Hz), 0.96 (t, 3, J=8 Hz), 1.52 (s, 3), 1.6—2.2 (m, 3), 2.20 (d, 1, J=12 Hz), 2.4—2.8 (m, 1), 3.30 (d, 1, J=12 Hz), and 7.3—8.0 ppm (m, 9).

Photolysis of **1c** with 1,1-diphenylethylene **2c** afforded a white crystalline product. The sptructure was assigned as 1,6-dimethyl-7,7-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7e**) in a yield of 87%. **7e**; white crystals, mp 170.0—171.0 °C; IR (KBr disk) 1675 and 1665 cm^{-1}; UV ($CHCl_3$) λ_{max} 302 (ε:2200), 254 (14000), and 243 nm (13600); NMR ($CDCl_3$) δ 1.24 (s, 3), 1.52 (s, 3), 2.80 (d, 1, J=12 Hz), 3.90 (d, 1, J=12 Hz), 6.60—7.0 (m, 4), 7.0—7.6 (m, 6), 7.74—7.9 (m, 1), and 7.96—8.1 ppm (m, 1), EA: Found; C, 85.09; H, 6.17%; Calcd for $C_{26}H_{22}O_2$; C, 85.21; H, 6.05%.

When **1e** was irradiated with **2c** in benzene, white crystals were obtained after purification by thick layer chromatography. The strucutre was assigned 1,6-diethyl-7,7-diphenyl-3,4-benzobicyclo[4.2.0]octene-2,5-dione (**7f**) in a yield of 92%. **7f**; white crystals, mp 180.0—181.0 °C; IR (KBr disk) 1685 and 1670 cm^{-1}; UV ($CHCl_3$) λ_{max} 300 (ε:2240), 252 (14200), and 243 nm (14100); NMR ($CDCl_3$) δ 0.80 (t, 3, J=8 Hz), 0.88 (t, 3, J=8 Hz), 1.32—2.08 (m, 3), 2.4—2.9 (m, 1), 2.80 (d, 1, J=12 Hz), 3.82 (d, 1, J=12 Hz), 6.6—7.84 (m, 13), and 7.96—8.12 ppm (m, 1), EA: Found; C, 85.39; H, 6.65%; Calcd for $C_{28}H_{26}O_2$; C, 85.24; H, 6.64%.

All measurements of quantum yields were made on a rotating assembly with a central light source (internal water-cooler mercury-arc lamp, Eikosha, Halos PIH-300). Samples in 15 mm Pyrex ampoules were placed in holders on the assembly placed at approximately 5 cm apart from the immersion well. The light was filtered by circulation of a solution containing 0.27 g of potassium chromate and 1.0 g of sodium carbonate in 1000 ml of distilled water. All studies were made at room temperature. After the irradiation, the degree of reaction was determined by means of quantitative ultraviolet absorption spectroscopy. The conversions in quinone quantities were run at highest to 15% or less. The mass balance in these runs was generally better than 90%.

Solutions of the quinone and the olefin in benzene containing excess amount of fluoranthene as a triplet quencher were irradiated under the conditions where more than 95% of the light was absorbed by the quinone. The reaction was monitored by TLC and in no case was the amount of products formed affected by addition of fluoranthene.

(Received August 24, 1979)

Benzophenone photo-sensitized addition of indene to chlorofluoroethylenes [trichlorofluoroethylene, 1,2-dichloro-1,2-difluoroethylene, 1,1-dichloro-2,2-difluoroethylene, chlorotrifluoroethylene, tetrafluoroethylene] afforded 6,6,7,7-tetrahalogeno-2,3-benzobicyclo[3.2.0]hept-2-enes as corresponding cycloadducts. The structure of the cycloadducts obtained from unsymmetrical chlorofluoroethylenes shows that the addition reaction proceeds with good regioselectivity. Some reactions such as oxidation, reduction, dechlorination, and halogenation of the cycloadducts were also examined.

Fluoro olefins are known to undergo cycloaddition reaction upon heating.[1] In fact, most fluorine-containing cyclobutane derivatives have been synthesized by the thermal cycloaddition of fluoro olefins and by subsequent reactions of these cycloadducts. In contrast, only a few investigations on photo-cycloaddition of fluoro olefins have been reported.[2-4] Since the photo-cycloaddition reaction would be expected to give different results from the thermal reaction, we investigated the photo-sensitized addition of indene to chlorofluoroethylenes [trichlorofluoroethylene (TCFE), 1,2-dichloro-1,2-difluoroethylene (*sym*-DCDFE), 1,1-dichloro-2,2-difluoroethylene (*unsym*-DCDFE), chlorotrifluoroethylene (CTFE), tetrafluoroethylene (TFE)] as a part of our studies on syntheses of fluorine-containing fused polycyclic compounds.[5] It is known that the cycloadditions of *unsym*-DCDFE, CTFE, and TFE take place thermally but those of indene, *sym*-DCDFE and TCFE do not.[1] The effect of fluorine recently has become of considerable interest in photochemistry[4,6] in light of the fact that 5-fluorouracil has been reported to have superior regioselectivity compared with unsubstituted uracil in the photo-cycloaddition reaction with several olefins. Accordingly, we have investigated the regioselectivity and stereoselectivity in the photo-cycloaddition of indene to chlorofluoroethylenes by elucidating the structure of the cycloadducts by means of NMR spectroscopy.

Results and Discussion

Irradiation (>300 nm) of indene and an excess of chlorofluoroethylenes in the presence of benzophenone as a sensitizer gave 6,6,7,7-tetrahalogeno-2,3-benzobicyclo[3.2.0]hept-2-enes as the corresponding cycloadducts (**1**—**5**).

Four different reaction conditions were employed (Methods A—D). In Methods A and B, irradiations were carried out in a Pyrex ampoule, while in Methods C and D, an immersion well photo-reactor was used. In order to study the effect of dilution with solvent, no solvent was used in Method B. Since TFE has a very low boiling point and polymerizes explosively, in Method D, TFE was bubbled into a solution of indene and benzophenone in 1,1,2-trichloro-1,2,2-trifluoroethane followed by irradiation in an immersion well reactor. In this procedure, the concentration of absorbed TFE was not determined. The reaction conditions and product yields are shown in Table 1.

As compared with Method A, Method B gave slightly higher conversion and slightly lower yield of cycloadduct. Hence, there are no marked differences in results from Methods A and B. When an immersion well photo-reactor was used (Method C), the conversions and yields were high even with shorter irradiation times.

Using Method A, the reaction of *unsym*-DCDFE gave high conversion (98.3%), while reactions of other chlorofluoroethylenes showed somewhat lower conversions (63—70%). In all cases, the yields of the cycloadducts **1**—**4** were similar (55—65%). Using Methods C and D, most of the indene (94%) was consumed and cycloadducts were obtained in good yields (84—85%) from TCFE and *unsym*-DCDFE. With TFE, the yield of cycloadduct (**5**) was very low and large amounts of high-boiling products were obtained.

The yields of the cycloadducts obtained from chlorofluoroethylenes are as following order: $CF_2{=}CCl_2 > CClF{=}CCl_2 > CClF{=}CClF \fallingdotseq CF_2{=}CClF > CF_2{=}CF_2$. This trend can be rationalized by considering the relative stability of the intermediate biradicals (see below) and steric factors. The indene dimer was a main by-product, obtained as a high-boiling residue. Tarry polymeric products were also generated, especially in the case of TFE, CTFE and *unsym*-DCDFE.

In thermal cycloadditions, it has been known[1] that a structual requirement for the fluoro olefins is the presence of a terminal difluoromethylene group. Fluoro olefins such as TFE, CTFE, and *unsym*-DCDFE undergo thermal cycloaddition to form cyclobutanes with themselves and other unsaturated compounds,

Table 1. Photo-sensitized addition reaction of indene to chlorofluoro olefins

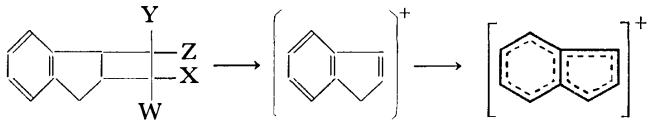
a) Methods A and B: The reaction carried out in a Pyrex ampoule. Methods C and D: The reaction carried out by using an immersion well photo-reactor. b) The yields were calculated by the amounts of indene consumed.

but *sym*-DCDFE and TCFE do not cycloadd thermally. In contrast, there is no such a structural requirement in the photo-cycloaddition with indene. All chlorofluoroethylenes examined gave the corresponding cycloadducts. Thermal cycloaddition of indene has not been known.

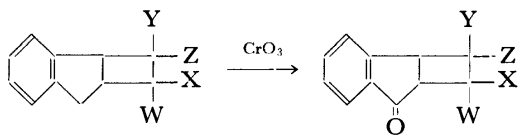
The structures of the cycloadducts were elucidated by means of their elemental analyses, IR, NMR and mass spectra. In the mass spectra, the strongest peak of the cycloadducts corresponds to indene (*m/e*: 116, C_9H_8), which is formed by the cleavage of four-membered ring shown as follows:



m/e : 116 *m/e* : 115

The presence of several stereoisomers of the cycloadducts was indicated in ^{19}F NMR spectra. The stereoisomers could not be separated by distillation or GLC. However, partial separation was achieved by fractional crystallization. The ratio of the isomers calculated from the intensity of ^{19}F NMR spectra are shown in Table 2 together with their ^{19}F chemical shifts.

The configurations of the stereoisomers were assigned by means of NMR spectra of their oxidized products. The cycloadducts (**1**—**5**) were oxidized by chromium trioxide to give the corresponding 6,6,7,7-tetrahalogeno-2,3-benzobicyclo[3.2.0]hept-2-en-4-ones (**6**—**10**).



1—**5** **6**—**10**

In addition to the more easily interpreted NMR of these oxidized products, **6**—**10**, they are more easily crystallized due to the presence of the carbonyl group. The assignments of configuration of the stereoisomers, estimated from the values of chemical shifts, coupling constants and nuclear Overhauser effect (NOE) are shown in Table 3 together with ^{19}F chemical shifts.

Table 2. The isomer ratios and fluorine-19 chemical shifts of the cycloadducts

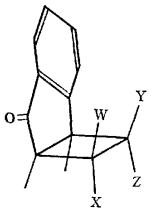
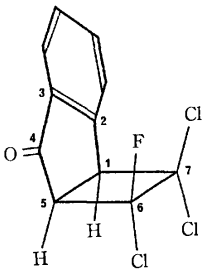
TABLE 3. FLUORINE-19 CHEMICAL SHIFTS AND MELTING POINTS OF THE OXIDIZED PRODUCTS OF THE CYCLOADDUCTS

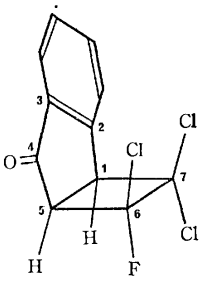
Compound	Fluorine-19 chemical shifts/ppm				Mp
	W	X	Y	Z	°C
6a	F 20.3	Cl	Cl	Cl	132.1
6b	Cl	F 7.7	Cl	Cl	119.6
6c	Cl	Cl	F 16.6	Cl	not isol.
6d	Cl	Cl	Cl	F 11.3	not isol.
7a	F 26.7	Cl	F 19.8	Cl	113.4
7b	F 36.0	Cl	Cl	F 33.4	110.6
7c	Cl	F 14.4	F 21.7	Cl	114.3
7d	Cl	F 30.9	Cl	F 27.7	not isol.
8a	F 19.6	F 12.6	Cl	Cl	96.6
9a	F 31.8	F 15.6	F 37.7	Cl	94.8
9b	F 23.1	F 26.8	Cl	F 37.4	64.6
10	F 34.6	F 29.9	F 32.6	F 34.8	86.8



Thus, the resonance peak of fluorine of **6a** is shifted 9.5 ppm down-field from that of **1a**. The shift is due to the electric field effect of the neighboring carbonyl group. On the other hand, ^{19}F chemical shift of **6b** did not differ from that of **1b**. Similar shifts are observed only for the fluorines in the W position of other isomers. When the fluorine nucleus of **6b**



6a

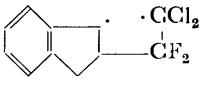


6b

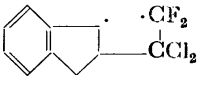
was irradiated, the integral intensity of hydrogen on the 5 position increased (14%). However, no NOE was observed in the other isomer, **6a**. Similarly, for the other isomers, when the fluorine nucleus in the X position was irradiated, the integral intensity of hydrogen on the 5 position increased (more than 10%), and irradiation of fluorine in the Z position increased (10%) that of hydrogen on the 1 position. The NMR of the series of the compounds (**6**—**10**) will be reported elsewhere in more detail.[7]

As shown in Table 2, the distribution of the stereoisomers reflects good regioselectivity and poor stereoselectivity of the reaction. In the addition of TCFE, four cycloadducts, **1a**, **1b**, **1c**, and **1d**, were obtained in the ratio of 38:46:6:10. Two isomers (**1a** and **1b**) with a fluorine on the 6 position were obtained in higher yields than the other two isomers (**1c** and **1d**) with a fluorine on the 7 position. The reaction thus shows a minimum of 84% regioselectivity. In the case of *unsym*-DCDFE, only one isomer (**3a**) with two fluorines on the 6 position was formed, and the other isomer (**3b**) was not detected. From CTFE, two isomers (**4a** and **4b**) with a chlorine on the 7 position were obtained in the ratio of 52:48, but the other two isomers (**4c** and **4d**) were not detected. *unsym*-DCDFE and CTFE show complete regioselectivity in the reactions. *sym*-DCDFE gave four stereoisomers, **2a**, **2b**, **2c** and **2d**, in the ratio of 30:12:37:21.

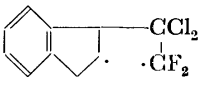
The observed results for these photo-cycloadditions may be explained by a mechanism in which biradical intermediates are formed as shown below in the case of *unsym*-DCDFE.



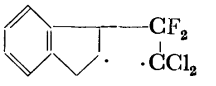
I



II



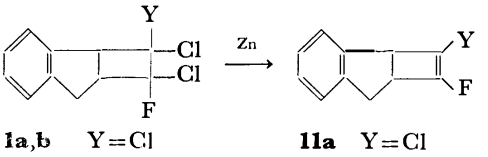
III



IV

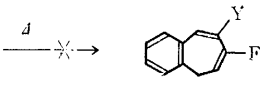
A triplet state-excited indene would attack the *unsym*-DCDFE and four different biradicals might be generated as intermediates. These would lead to the cycloadducts by intramolecular coupling. Since the stabilities of halogenated carbon radicals follow the order: $\cdot CCl_2 > \cdot CClF \gg \cdot CF_2$, and the benzyl type radicals (I and II) are more stable than III and IV, the intermediate I would be formed preferentially to give **3a**. Presumably, the stereochemistry of this cycloaddition is mainly controlled by the stabilities of the intermediate biradicals. Other cofactors might be steric effects and fluorine hyperconjugation which has been proposed as an important factor in the increased amount of ring closure of the intermediate biradicals.[6]

The cycloadducts (**1a**, **b**, and **2a**—**d**) were dechlorinated with zinc powder and the corresponding cyclic olefins (**11a**, **b**) were obtained in high yields. Dechlorination of **2a**—**d** is more difficult than for **1a**,**b**



1a,**b** Y=Cl
2a—**d** Y=F

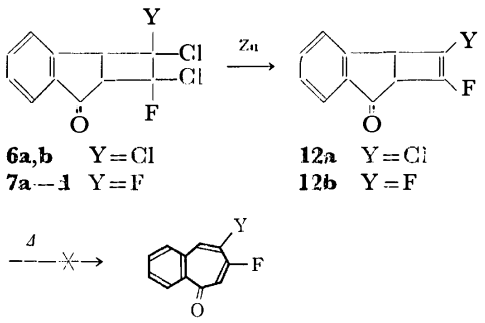
11a Y=Cl
11b Y=F



with only 15% of **2a—d** being dechlorinated under the conditions used for **1a,b**. Higher reaction temperature (140 °C) was required for complete dechlorination of **2a—d**.

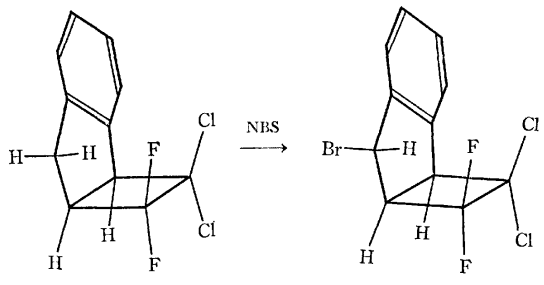
The thermal ring expansion reaction of **11a** and **11b** did not occur at 200 °C. This is in accordance with the Woodward-Hoffmann's rule which predicts that the thermal cleavage of cyclobutenes will occur in a conrotatory fashion. In the case of **11a** and **11b**, which have the cyclobutene ring fused to the five membered ring, the conrotatory cleavage would lead to the sterically untenable *trans*-cycloheptatriene.

Similarly, the cyclic ketones (**6a,b** and **7a—d**) obtained from oxidation of the cycloadducts (**1a,b** and **2a—d**) gave the corresponding olefins (**12a,b**) by dechlorination with zinc. Longer reaction time was required for the dechlorination of **7a—d**. Upon heating **12a** and **12b** at 200 °C, thermal ring expansion to benzotropone again did not occur.



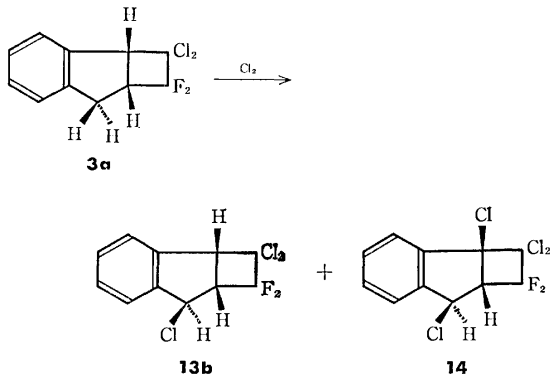
6a,b Y=Cl **12a** Y=Cl
7a—d Y=F **12b** Y=F

The cycloadduct (**3a**) was brominated with *N*-bromosuccinimide to give the monobromide (**13a**) almost quantitatively. The NMR signal of the hydrogen on the 4 position appears as a singlet at 5.51 ppm being shifted downfield by the geminal bromine. The singlet peak reflects a small H^4–H^5 coupling constant (less than 1 Hz). From the Karplus' relationship between vicinal H–H coupling constants and dihedral angles, H^4 is considered to be on the opposite side of the five membered ring plane from H^5. Hence, bromine substitution occurred on the sterically favorable position of the methylene group with high selectivity.

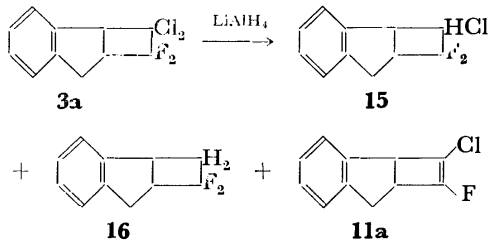


3a **13a**

Photo-chlorination of **3a** afforded the monochloride (**13b**) in 84.4% yield together with a small amount (6.3% yield) of the dichloride (**14**). Similar to bromination, the same hydrogen was replaced by chlorine in the first step with further chlorination taking place on the 1 position.



Reduction of **3a** with lithium aluminum hydride afforded **15**, **16** and **11a**, which presumably resulted from the elimination of hydrogen fluoride from **15**.



Experimental

The melting points were determined on a Mettler FPl with the elevating rate of 2 °C/min. The IR and mass spectra were measured using a Hitachi Model EPI-2 grating spectrometer and Model RMU-7 double-focusing mass spectrometer at 70 eV, respectively. The NMR spectra were obtained on a Hitachi Model R-22 apparatus (90 MHz) using TMS as an internal standard for ^1H, and on a Model R-20 B apparatus (56.45 MHz) using trifluoroacetic acid as an external standard for ^{19}F.

Materials. Commercially available indene was used after distillation under an argon atmosphere. The chlorofluoroethylenes were prepared by dechlorination from the corresponding chlorofluoroethanes.

Trichlorofluoroethylene (TCFE): Dechlorination of pentachlorofluoroethane by zinc powder in ethanol gave TCFE, which was distilled through 50 cm column packed with glass helices (bp 71—72 °C).

1,1-Dichloro-2,2-difluoroethylene (unsym-*DCDFE)*: 1,1,1,2-Tetrachloro-2,2-difluoroethane was prepared by the isomerization of 1,1,2,2-tetrachloro-1,2-difluoroethane using aluminum trichloride catalyst.[8] Dechlorination of 1,1,1,2-tetrachloro-2,2-difluoroethane gave *unsym*-DCDFE (bp 18—19 °C).

1,2-Dichloro-1,2-difluoroethylene (sym-*DCDFE) and Chlorotrifluoroethylene (CTFE)*: Dechlorination of 1,1,2,2-tetrachloro-1,2-difluoroethane and 1,1,2-trichloro-1,2,2-trifluoroethane gave *sym*-DCDFE (bp 19—20 °C) and CTFE (bp —26—27 °C), respectively.

Tetrafluoroethylene (TFE): TFE was prepared by debromination of 1,2-dibromotetrafluoroethane with zinc and introduced into a photo-reator immediately.

Photo-cycloaddition. Photo-cycloadditions were carried out using four different reaction conditions (Method A, B, C, and D). A typical procedure is described for each Method.

Method A; Reaction of Indene and Trichlorofluoroethylene (TCFE): A solution of indene (11.6 g, 0.100 mol), TCFE

a) Recrystallized from ethanol.

(74.7 g, 0.500 mol) and benzophenone (1.8 g, 0.010 mol) in 1,1,2-trichlorotrifluoroethane (187 g, 1.00 mol) was sealed under an argon atmosphere in a 300 ml Pyrex ampoule, and irradiated with a 100 W high pressure mercury lamp at room temperature for 168 h. After recovery of the solvent and TCFE by distillation, the residue was distilled *in vacuo* to give indene (4.3 g, 38.1% recovered), a cycloadduct (10.9 g, 65.3% yield) boiling at 131 °C/4 mmHg and a high-boiling residue, which contained benzophenone. The cycloadduct crystallized after standing overnight. The ^{19}F NMR spectrum of the cycloadduct indicated that it consisted of four isomers, **1a**, **1b**, **1c**, and **1d**, in the ratio of 38:46:6:10. Two of these, **1a** and **1b**, were isolated by fractional recrystallization. Indene dimer was also isolated from the high-boiling residue as colorless needles (mp 109.5 °C).

Method B; *Reaction of Indene and Trichlorofluoroethylene (TCFE)*: A mixture of indene (11.6 g, 0.100 mol), TCFE (74.7 g, 0.500 mol) and benzophenone (1.8 g, 0.010 mol) was irradiated in a 100 ml Pyrex ampoule with a 100 W high pressure mercury lamp for 168 h. The product was separated by distillation to give indene (3.5 g, 30.2% recovered), a cycloadduct (11.4 g, 61.5% yield, bp 120—122 °C/3 mmHg) and a high-boiling residue (4.9 g).

Method C; *Reaction of Indene and Trichlorofluoroethylene (TCFE)*: A solution of indene (11.6 g, 0.100 mol), TCFE (74.7 g, 0.500 mol) and benzophenone (1.8 g, 0.010 mol) in 1,1,2-trichlorotrifluoroethane (187 g, 1.00 mol) was irradiated for 20 h in an immersion well Pyrex photo-reactor (300 ml capacity with a water-cooled 100 W mercury lamp) under an argon atmosphere. All indene was consumed and a cycloadduct (22.6 g, 85.1% yield) and a high-boiling residue (3.0 g) were obtained.

Method D; *Reaction of Indene and Tetrafluoroethylene (TFE)*: A solution of indene (11.6 g, 0.100 mol) and benzophenone (1.8 g, 0.010 mol) in 1,1,2-trichlorotrifluoroethane (280 g) was placed in a 300 ml immersion well Pyrex photo-reactor, and cooled in an ice bath. TFE, which was generated from the debromination reaction of 1,2-dibromotetrafluoroethane (130 g, 0.500 mol) and zinc (100 g) in ethanol, was bubbled and absorbed into the solution. Then the solution was irradiated as in Method C for 20 h. Distillation gave indene (0.7 g, 6.0% recovered), a cycloadduct (1.0 g, 4.9% yield, bp 60—65 °C/3 mmHg) and a high-boiling residue (12.8 g).

Oxidation of the Adducts. The cycloadducts (**1**—**5**) were oxidized with chromium trioxide to the corresponding ketones (**6**—**10**). The oxidation of 6,6,7,7-tetrafluoro-2,3-benzobicyclo[3.2.0]hept-2-ene (**5**) is described as a typical experimental procedure.

*6,6,7,7-Tetrafluoro-2,3-benzobicyclo[3.2.0]hept-2-en-4-one (**10**)*: To a solution of chromium trioxide (2.4 g, 24 mmol) in water (5 ml) was added a solution of **5** (1.3 g, 6 mmol) in acetic acid (15 ml) and the mixture was heated at reflux for 8 h. After cooling, the solution was poured into an ice-cooled aqueous sodium hydrogensulfite solution and was extracted with two 30 ml portions of ether. The combined extracts were dried over sodium sulfate and evaporated. The residue crystallized after standing overnight. Recrystallization of the product from ethanol gave **10** (1.3 g, 94.1% yield) as colorless columns: mp 86.8 °C.

Dechlorination. The cycloadducts (**1a, b** and **2a—d**) and ketones (**6a, b** and **7a—d**) obtained by oxidation were dechlorinated with zinc powder to the corresponding olefins (**11a, b** and **12a, b**). The following procedures are illustrative.

*7-Chloro-6-fluoro-2,3-benzobicyclo[3.2.0]hepta-2,6-diene (**11a**)*: To a solution of the mixture of the isomers (**1a** and **1b**, 2.7 g,

10 mmol) in absolute ethanol (40 ml) was added zinc powder (6.4 g). The mixture was heated at reflux with stirring for 8 h. After removal of solid material by filtration, the filtrate was poured into diluted hydrochloric acid and was extracted with three 50 ml portions of dichloromethane. The combined extracts were dried over magnesium sulfate and evaporated to give an oily residue (2.6 g). Further purification was effected by preparative GLC (at 100 °C using an aluminum column, 6 m long × 10 mm diameter, packed with Silicone DC-QFl-Chromosorb W) to give **11a** (1.7 g, 87.3% yield) as colorless oil: n_D^{20} 1.5509, d_4^{20} 1.251, IR $\nu_{C=C}$ 1705 cm^{-1}.

*6,7-Difluoro-2,3-benzobicyclo[3.2.0]hepta-2,6-diene (**11b**)*: The synthesis of **11b** from the mixture of isomers (**2a—d**, 2.5 g, 10 mmol) followed the procedure used with **1a** and **1b**, except that a higher reaction temperature (140 °C) was adopted using ethylene glycol (25 ml) as a solvent. The product (**11b**, 1.3 g, 73.0% yield) was obtained as a colorless oil: n_D^{20} 1.5189, IR $\nu_{C=C}$ 1764 cm^{-1}.

*7-Chloro-6-fluoro-2,3-benzobicyclo[3.2.0]hepta-2,6-dien-4-one (**12a**)*: The synthesis of **12a** from the mixture of isomers (**6a** and **6b**, 2.8 g, 10 mmol) followed the procedure used with **1a** and **1b**. The product (1.7 g, 81.5% yield) was obtained as colorless prisms (from ethanol): mp 58.2 °C, IR $\nu_{C=C}$ 1705 cm^{-1}, $\nu_{C=O}$ 1721 cm^{-1}.

*6,7-Difluoro-2,3-benzobicyclo[3.2.0]hepta-2,6-dien-4-one (**12b**)*: The synthesis of **12b** from the mixture of isomers (**7a—d**) followed the procedure used with **1a** and **1b**, except that the reaction time was prolonged to 18 h. The product (**12b**, 83.3% yield) was obtained as a colorless oil: d_D^{20} 1.5410, IR $\nu_{C=C}$ 1773 cm^{-1}, $\nu_{C=O}$ 1724 cm^{-1}.

Halogenation of the Adduct. Bromination with *N*-bromosuccinimide and photo-chlorination of a cycloadduct (**3a**) gave corresponding 4-halides (**13a** and **13b**).

*4-Bromo-7,7-dichloro-6,6-difluoro-2,3-benzobicyclo[3.2.0]hept-2-ene (**13a**)*: To a solution of **3a** (2.5 g, 10 mmol) in tetrachloromethane (30 ml), were added *N*-bromosuccinimide (1.8 g, 10 mmol) and a small amount of benzoyl peroxide (*ca.* 3 mg). The mixture was heated at reflux under an argon atmosphere for 2 h. The white precipitate generated was filtered off and the filtrate was evaporated to give a yellow oil. Further purification was effected by liquid chromatography (silica gel, tetrachloromethane as an eluting solvent) to give **13a** (3.2 g, 97.6% yield) as a colorless oil: n_D^{20} 1.5612.

*4,7,7-Trichloro-6,6-difluoro-2,3-benzobicyclo[3.2.0]hept-2-ene (**13b**) and 1,4,7,7-Tetrachloro-6,6-difluoro-2,3-benzobicyclo[3.2.0]-hept-2-ene (**14**)*: Chlorine (1.5 g, 20 mmol) was absorbed by bubbling through a solution of **3a** (2.5 g, 10 mmol) in tetrachloromethane (200 ml). The solution was exposed to sun light for 10 min until the yellow color disappeared. After removal of the solvent by evaporation, the residue was distilled under reduced pressure to give **13b** (2.4 g, 84.4% yield) as a slightly yellow oil: bp 115—116 °C/2 mmHg, n_D^{20} 1.5523. Purification of the higher boiling products by using the preparative GLC gave **14** (0.2 g, 6.3% yield) as colorless prisms (from ethanol): mp 84.4 °C.

Reduction of the Adduct. The cycloadduct (**3a**) was reduced with lithium aluminum hydride.

*7-Chloro-6,6-difluoro-2,3-benzobicyclo[3.2.0]hept-2-ene (**15**)*: To a solution of **3a** (2.5 g, 10 mmol) in absolute ether (100 ml) was added lithium aluminum hydride (1.2 g, 30 mmol) and the mixture was heated at reflux for 20 h with stirring. The mixture was poured into ice-cooled diluted sulfuric acid. The organic layer separated was dried over magnesium sulfate and evaporated. The residue crystallized after standing overnight. The product was recrystallized from ethanol to give **15** (1.1 g, 51.2% yield)as colorless plates: mp 136.2 °C. Analysis of the mother liquid by a mass spectrometer coupled with GC showed the existence of by-products, 6,6-difluoro-2,3-benzobicyclo[3.2.0]hept-2-ene (**16**) and 7-chloro-6-fluoro-2,3-benzobicyclo[3.2.0]hepta-2,6-diene (**11a**).

Carbon–Carbon Bond Formation by the Use of Chloroiodomethane as a C_1 Unit. II.[1] The Preparation and Synthetic Application of 1-Chloro-3-iodoheptane[2]

Sotaro Miyano,* Hiroshi Hokari, Yoshiharu Umeda, and Harukichi Hashimoto

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980

(Received August 24, 1979)

Terminal alkenes, R–CH=CH_2 (R=Et, *n*-Pr, *n*-Bu, *n*-Hex), were readily transformed into 1-chloro-3-iodoalkanes by the AIBN-induced free radical addition of chloroiodomethane. Thus, 1-chloro-3-iodoheptane was obtained from 1-hexene in an 88% yield; this in turn was allowed to react with dialkyl malonates in the presence of alkoxides in alcohols to give dialkyl 2-butylcyclobutane-1,1-dicarboxylates and dialkyl (*E*)-3-octene-1,1-dicarboxylates (**7**), either of which could be obtained preferentially by the choice of the experimental parameters. The olefinic product, **7**, was further utilized for the synthesis of (*E*)-5-decenyl acetate and/or 1,4-nonanolide.

The free radical-induced addition of polyhalogenated methanes to alkenes to give 1:1 products (Kharasch reaction) has been well known.[3] This reaction had, however, been practically restricted to those halides which contained no less than three halogen atoms unless they had other activating substituents, such as –CO– and –CN.[3a] In fact, only a few successful Kharasch reactions had been documented for dihalomethanes[4,5] before Walton *et al.* recently reported the peroxide- or photochemically initiated addition of chloroiodomethane and diiodomethane to ethylene and several fluoroalkenes from the mechanistic point of view.[6] Several other papers have claimed the formation of cyclopropanes *via* the reaction of diiodomethane with alkenes under the free radical reaction conditions.[7]

As part of a program directed toward a study of carbon–carbon bond formation by the use of chloroiodomethane as a C_1 unit,[1] we wish to report here a facile synthesis of 1-chloro-3-iodoalkanes (**1**) *via* the 2,2′-azobisisobutyronitrile (AIBN)-initiated addition of CH_2ClI to terminal alkenes. Also to be described is the utilization of 1-chloro-3-iodoheptane (**1c**) as an intermediate for several synthetic transformations, including a synthesis of (*E*)-5-decenyl acetate (**15**), a kind of insect pheromone.

Results and Discussion

AIBN-initiated Addition of Chloroiodomethane to Terminal Alkenes. A mixture of CH_2ClI and AIBN in 1-alkene was stirred and heated at 80 °C for 6 h in a stainless steel autoclave. Employing *ca.* a 1/10 molar amount of AIBN to CH_2ClI, almost all of the halide was consumed to give 1-chloro-3-iodoalkanes in *ca.* 80—90% yields (Eq. 1 and Table 1).

Part of the AIBN was consumed in the formation of tetramethylsuccinonitrile **2**. Thus, when the molar ratio of AIBN to CH_2ClI was 1/20 or 1/100, the yield of 1-chloro-3-iodoheptane **1c** from 1-hexene was reduced to 38% or 17% respectively, leaving unchanged CH_2ClI, while appreciable amounts of the adduct (**1c**) were also obtained (6.2% yield) in the absence of the initiator.

$$\mathrm{R{-}CH{=}CH_2 + CH_2ClI \xrightarrow{AIBN} R{-}\underset{\displaystyle I}{\underset{|}{CH}}{-}CH_2{-}\underset{\displaystyle Cl}{\underset{|}{CH_2}}} \quad (1)$$

The structure of the 1:1 adduct **1** was confirmed on the basis of its NMR spectra, which showed two hydrogens of $-CH_2Cl$ comprised of four lines of a double doublet centered at *ca.* δ 3.6 (A_2 portion of an A_2MM' system, $J_{AM}\approx5.5$ Hz, $J_{AM'}\approx6.5$ Hz) and one hydrogen of –CHI– at δ 4.5—4.0 as a mulitplet. The dehydroiodination reaction of the 1:1 adduct by potassium hydroxide in aq methyl alcohol also supported the 1-chloro-3-iodoalkane structure; **1d** gave (*E*)-1-methoxy-2-nonene (**5a**) and (*E*)-1-chloro-3-nonene (**6a**) as the major products. Small amounts of a substance

Table 1. AIBN-induced addition of CH_2ClI to R–CH=CH_2[a]

	R–CH=CH_2 R	R–CH(I)–CH_2–CH_2(Cl) (1) Yield[b]/%	Bp °C/mmHg	Found (Calcd)% C	H
a	Et	81 (54)	74—76/9.5	25.91 (25.83)	4.26 (4.34)

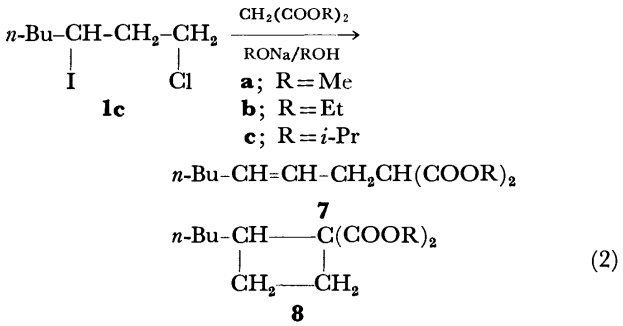
a) R–CH=CH_2, 15—20 ml; CH_2ClI, 3.0 ml (43 mmol); AIBN (mol)/CH_2ClI (mol)=1/10; 80 °C, 6 h. b) GLC yield based on CH_2ClI. Figures in parentheses show isolated yields. c) Halogen, 61.84%. Calcd for $C_7H_{14}ClI$: Cl, 13.61; I, 48.71%.

having a slightly longer GLC retention time than **1** were also detected (less than 4% of **1**). The substance was not isolated, but it seemed to have a branched chain structure, **3**, as was indicated by the reaction products from the dehydroiodination with potassium hydroxide in aq methyl alcohol (see Experimental). The isolation of the iodo nitrile **4** suggests that the initiation step of the radical chain involves mainly the attack of the isobutyronitrile radical from AIBN on the terminal carbon atom of the 1-alkenes.

Kaplan obtained cyclopropanes *via* a radical-induced methylene transfer from CH_2I_2 to alkenes using quite large amounts of peroxide initiators (more initiators than CH_2I_2 or alkenes).[7c] On the other hand, the AIBN-initiated addition of CH_2I_2 to 1-hexene gave 1,3-diiodoheptane in a 62% isolated yield under the reaction conditions of this work, while CH_2Br_2 was recovered unchanged.

An attempted addition to styrene resulted in the formation of a polymeric product, leaving CH_2ClI intact. Though little effort was made to optimize the reaction, extension to internal alkenes, including 2-heptenes, (*E*)-2-butene, (*E*)-stilbene, and cyclohexene, was not practical, either; large amounts of **2** were formed, and more than 80% of the CH_2ClI was recovered in these cases.

*Reaction of 1-Chloro-3-iodoheptane (**1c**) with Dialkyl Malonates/Alkoxides in Alcohols.* The treatment of **1c** with dimethyl malonate in the presence of sodium methoxide in methyl alcohol gave several products, as evidenced by GLC; among them we obtained dimethyl (*E*)-3-octene-1,1-dicarboxylate, **7a**, and dimethyl 2-butylcyclobutane-1,1-dicarboxylate, **8a**, as the major products in yields of 71% and 6.5% respectively (Eq. 2). Among other by-products were also identified (*E*)-1-methoxy-2-heptene, **5b**, and (*E*)-1-chloro-3-heptene, **6b**.



(2)

Tables 2 and 3 show the effects of the reaction variables on the relative yield of the olefinic products, **7**, to the ring-closure products, **8**. By the use of potassium *t*-butoxide or sodium isopropoxide, **1c** was preferentially transformed into the cyclobutanes, **8**, while dehydroiodination preceded when sodium methoxide or ethoxide was utilized, especially in lower concentrations. These results may be explained in terms of the base strength and steric bulkiness of the alkoxides used; these are both in the order of $MeO^- < EtO^- < i\text{-}PrO^- < t\text{-}BuO^-$. The E2-type dehydroiodination to **7** becomes unfavored as the base becomes bulkier, while the concentration of the malonate carbanion will increase with the basicity of the alkoxide. These

Table 2. Reaction of **1c** with $CH_2(COOR)_2$/RONa[a]

a) **1c**, 19 mmol; $CH_2(COOR)_2$, 45 mmol; RONa, 44 mmol; Reflux, 3 h.

factors facilitate nucleophilic displacement at the iodine-bearing carbon atom in **1c** by the malonate anion. Subsequent intramolecular S_N2 attack on the terminal chlorine-carrying carbon atom leads to ring closure. On the other hand, where the carbanion concentration is not so much prevailing with the less strong bases of smaller bulk, dehydroiodination by alkoxides preceds to give allylic chloride, which is then displaced in a nucleophilic manner by the malonate anion to give **7**.

Synthesis of γ-Butyrolactones. The hydrolysis of **7a** with potassium hydroxide in boiling aq methyl alcohol gave the free dicarboxylic acid, **9a**, a pure sample of which was obtained as white crystals after recrystalization from petrol. ether. Heating at reflux in aq H_2SO_4 (2:1) changed **9a** into 1,4-nonanolide, **10a**; this is the so-called "coconut aldehyde," one of the most important lactones in perfumes and flavors, having a delicately fruity and coconutty odor of an excellent tenacity.[8] Starting from 1-octene, a similar treatment of **9b** gave 1,4-undecanolide, **10b**, the so-called "peach aldehyde," which has high quality, peach-like taste.

Utilization of the trans-*1,2-Disubstituted Olefinic Structure of 7 as a Synthetic Intermediate.* *trans*-1,2-Disubstituted olefinic bonds are common functional groups which are found in many synthetically useful intermediates and naturally occurring compounds.[9] Although the dehydroiodination-alkylation of **1c** with malonate/alkoxide should give rise several possible products in respect to stereo- and regiochemistry, the preferential formation of the *trans*-1,2-disubstituted alkene, **7a**, in a reasonable yield seemed to have some synthetic utility.

The thermolysis of **9a** at *ca.* 150 °C caused its decarboxylation to (*E*)-4-nonenoic acid, **11**.[10] The series of well-established transformations shown in Scheme 1 converted **11** to (*E*)-5-decen-1-ol, **14**, and its acetate, **15**, both of which are constituents of the sex pheromone for the male peach twig borer moth, *Anarsia lineatella Zeller*.[11] Another synthesis of **15** has been briefly reported, without any detailed physical or spectral data.[11] A synthesis of the (*Z*)-counterpart of **15** has appeared recently; (*Z*)-**15** is a sex attractant for the

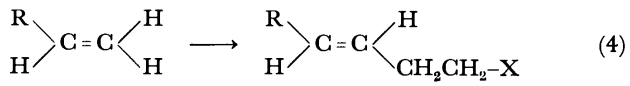
In conclusion, the net effect of the above transformations can be visualized as the displacement of the terminal *trans*-hydrogen atom with an alkyl moiety of more than two methylene units (Eq. 4).



(4)

Experimental

The IR spectra were obtained using a Shimadzu IR 430 grating spectrophotometer. The NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz), using carbon tetrachloride as the solvent (1—5% solution) unless otherwise noted. The absorption peaks were recorded in ppm units downfield from hexamethyldisiloxane as an internal standard. The analytical GLC was conducted on a Shimadzu GC 3AF and Hitachi 163 gas chromatograph equipped with flame-ionization detectors; a 300×0.3 cm stainless steel column packed with Silicone DC 550 (20%), Apiezon Grease L (20%), Silicone DC 410 (20%), or FFAP (10%) on Diasolid M (60—80 mesh), or a 20-m glass capillary column (0.25 mm i.d.) coated with silicone oil (OV-1 column), was used. The GLC yields of the reaction products were determined on the basis of the molar response, as determined from standard solutions of the products and appropriate internal standards. Preparative GLC separations were achieved with a Shimadzu GC 2C gas chromatograph using the appropriate column from among those noted above.

Materials. The chloroiodomethane was obtained by the procedure described before;[13] it was stored over a few tin pellets in the dark. The alkenes were distilled from sodium wire before use. The AIBN (dec 102 °C) and (*E*)-stilbene were used without further purification. The commercial dialkyl malonates were dried over $MgSO_4$ and distilled under reduced pressure. The solvents were purified as usual before use.

Addition of Chloroiodomethane to 1-Alkenes by Means of AIBN. A dry, 100-ml-inner-volume stainless steel autoclave equipped with a magnetic stirrer and a thermometer was charged with 4 mmol of AIBN, evacuated, and refilled with nitrogen. Then, 15—20 ml of 1-alkene and 3.0 ml (7.6 g, 43 mmol) of CH_2ClI were added by means of hypodermic syringe through a three-way cock under nitrogen. (1-Butene was distilled from a pressure bottle into the reaction vessel containing AIBN and CH_2ClI.) The mixture was stirred and heated in the course of 0.5 h to 80 ± 5 °C in an oil bath; that temperature was then maintained for 6 h. At the end of the reaction, the vessel was cooled in a water bath. The mixture was then subjected to distillation; after the excess alkene and tetramethylsuccinonitrile (**2**) had been removed *in vacuo*, the residue was fractionated through a short, packed column to give the corresponding 1-chloro-3-iodoalkane, **1**. Table 1 lists the results.

Diiodomethane was used in place of chloroiodomethane to give 1,3-diiodoheptane from 1-hexene: bp 105—107 °C/3.8 mmHg; yield, 62%. Found: C, 24.08; H, 3.91%. Calcd for $C_7H_{14}I_2$: C, 23.88; H, 4.01; I, 72.11%. NMR: δ 0.6—1.1 (3H, H_3C-), 1.1—2.0 (6H, H_3C-(CH_2)$_3$-), 2.0—2.5 (2H, -CH_2-CH_2I), 3.1—3.5 (2H, -CH_2I), 3.8—4.4 (1H, -CHI-).

Tetramethylsuccinontirile (2): An analytical sample was purified by sublimation: mp, 166—168 °C (lit,[14] 170.5—171.5 °C). The IR spectrum of the sample was superimposable upon that of the authentic one[14]; (KBr), 2220 cm^{-1} (νC≡N). NMR: δ 1.6 ($4\times H_3C$-).

2-Methyl-2-cyano-4-iodoheptane (4a): After 1-chloro-3-iodohexane had been recovered from the reaction mixture of 1-pentene, the distillation of the residue afforded a 0.6-g sample of **4a** boiling at 85—90 °C/1.5 mmHg. NMR: δ 0.7—1.1 (3H, H_3C-CH_2-), 1.3 and 1.4 (3H (s) and 3H (s), -C(CN)(CH_3)$_2$), 1.3—2.0 (4H, H_3C-(CH_2)$_2$-), 2.25 (2H, d, J=6.4 Hz, -CH_2-C(CN)(CH_3)$_2$), 3.9—4.4 (1H,

-CHI-). IR (neat): 2250 cm^{-1} (νC≡N).

A substantial rotational barrier, as judged by the PCK molecular model, may cause a magnetic non-equivalence between the two methyl groups of $-C(CN)(CH_3)_2$. The chemical shift of the C_3 methylene protons was assigned as above, because the irradiation of the sample at the -CHI- proton caused a collapse of the δ 2.25 doublet to a sharp singlet.

The **4a** was further transformed to (*E*)-2,2-dimethyl-3-heptenoic acid by heating at reflux for 5 h with KOH in ethylene glycol. NMR: δ 0.6—1.0 (3H, H_3C-CH_2-), 1.2 (6H, s, $-C(COOH)(CH_3)_2$), 1.1—1.7 (2H, H_3C-CH_2-), 1.7—2.4 (2H, $-CH_2-CH=CH-$), 5.3—5.6 (2H, -CH=CH-), 11.5 (1H, s, -COOH). IR (neat): 1700 (νC=O), 980 cm^{-1} (δ =CH_{trans}).

*Reaction of 1-Chloro-3-iodononane (**1d**) with Potassium Hydroxide in Aq Methyl Alcohol.* A heterogeneous mixture of **1d** (5.2 g) in a KOH (4 g) solution in MeOH (15 ml)-H_2O (4 ml) was stirred and then heated at reflux for 3 h. The cooled mixture was diluted with water and extracted with portions of ether. The ether extracts were then combined, washed successively with 2 M HCl and water, and dried over $MgSO_4$. The GLC analysis of the solution showed the presence of seven peaks (Apiezon Grease L column) (the following information is the compound, the percent of peak area on GLC, and the relative retention time); 1,3-nonadiene, 2.0%, 0.50; 3-methoxy-1-nonene, 0.4%, 0.72; 2-(methoxymethyl)-1-octene, 3.3%, 0.86; (*E*)-1-methoxy-3-nonene, 1.4%, 0.95; (*E*)-1-methoxy-2-nonene. 82.1%, 1.00; (*E*)-1-chloro-3-nonene, 10%, 1.15; unidentified, 0.8%, 1.33.

After the solvents had been removed by distillation, the residue was subjected to preparative GLC. A pure sample of (*E*)-1-methoxy-3-nonene was not isolated, but it was inferred from the fact that the treatment of (*E*)-1-chloro-3-nonene with KOH in aq MeOH increased the GLC peaks of the retention times of 0.50 (*i.e.*, 1,3-nonadiene) and of 0.95.

1,3-Nonadiene: NMR: δ 0.6—1.1 (3H, H_3C-), 1.1—1.7 (6H, $H_3C-(CH_2)_3-$), 1.7—2.4 (2H, $-CH_2-CH=CH-$), 4.6—6.8 (5H, $-CH=CH-CH=CH_2$). IR (neat): 1650 and 1605 ($\nu C=C_{diene}$), 1000 and 900 cm^{-1} (δ =CH_{vinyl}).

3-Methoxy-1-nonene: NMR: δ 0.6—1.0 (3H, H_3C-CH_2-), 1.0—1.8 (10H, $-(CH_2)_5-$), 3.0—3.5 (1H, $-CH(OCH_3)-$), 3.1 (3H, s, H_3CO-), 4.7—5.9 (3H, $-CH=CH_2$). IR (neat): 1640 (νC=C), 995 and 915 cm^{-1} (δ =CH_{vinyl}).

2-(Methoxymethyl)-1-octene: NMR: δ 0.7—1.1 (3H, H_3C-), 1.1—1.6 (8H, $H_3C-(CH_2)_4-$), 1.6—2.2 (2H, $-CH_2-CH_2-CH=$), 3.2 (3H, s, H_3CO-), 3.6—3.7 (2H, $-CH_2-OCH_3$), 4.6—4.9 (2H, $>C=CH_2$). IR (neat): 1650 (νC=C), 900 cm^{-1} (δ =$CH_{terminal\ methylene}$).

(E)-1-Methoxy-2-nonene: NMR: δ 0.7—1.1 (3H, H_3C-), 1.1—1.7 (8H, $H_3C-(CH_2)_4-$), 1.7—2.3 (2H, $-CH_2-CH_2-CH=$), 3.2 (3H, s, H_3CO-), 3.6—3.8 (2H, H_3CO-CH_2-), 5.3—5.7 (2H, -CH=CH-). IR (neat): 1670 (νC=C), 970 cm^{-1} (δ =CH_{trans}). Found: C, 76.61; H, 13.19%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%. The assignment of the *E* structure was based on the strong IR absorption at 970 cm^{-1}.

(E)-1-Chloro-3-nonene: NMR: δ 0.7—1.1 (3H, H_3C-), 1.1—1.7 (6H, $H_3C-(CH_2)_3-$), 1.7—2.2 (2H, $-CH_2-CH_2-CH=$), 2.2—2.7 (2H, $-CH_2-CH_2Cl$), 3.4 (2H, t, J=6.8 Hz, $-CH_2Cl$), 5.2—5.6 (2H, -CH=CH-). IR (neat): 970 cm^{-1} (δ =CH_{trans}).

Treatment of 1-Chloro-3-iodoheptane with Dimethyl Malonate/Sodium Methoxide in Methyl Alcohol. To a 200-ml, round-bottomed flask equipped with a condenser topped with a nitrogen inlet, a pressure-equalized dropping funnel, a thermometer, and a magnetic stirrer were added, under a nitrogen atmosphere, 50 ml of methyl alcohol and 1.0 g (43.5 mg-atom) of sodium metal. After the dissolution of the sodium, a 6.0 g (45 mmol) portion of dimethyl malonate was added. The mixture was heated to gentle reflux, and then a 5.0-g (19 mmol) portion of 1-chloro-3-iodoheptane **1c** was added dropwise. Stirring was continued for 3 h under gentle reflux. At the end of the reaction, the mixture was cooled, diluted with 30 ml of water, and extracted rapidly with portions of ether. The ether extracts were combined, washed successively with aq NH_4Cl and water, and dried over $MgSO_4$. An aliquot of the solution was used for the quantitative determination of the dimethyl (*E*)-3-octene-1,1-dicarboxylate, **7a**, and the dimethyl 2-butylcyclobutane-1,1-dicarboxylate, **8a**, by GLC. After the solvents and small amounts of the fore-run had been removed *in vacuo*, the residue was fractionated through a short, packed column. The yield of **7a** boiling at 100—104 °C/2 mmHg was 2.22 g, including small amounts of **8a** and trace amounts of an unidentified product; the retention time on GLC was in the order of **8a**, the unidentified, and **7a** (FFAP column). Pure sample of **7a** and **8a** were collected by preparative GLC.

The recovered solvent and the fore-run portion was concentrated to *ca.* a 1-ml volume, from which were detected and collected by preparative GLC 1-methoxy-2-heptene (**5b**) and 1-chloro-3-heptene (**6b**) among several other unidentified products.

*Dimethyl 2-Butylcyclobutane-1,1-dicarboxylate (**8a**)*: NMR: δ 0.6—1.0 (3H, H_3C-CH_2-), 1.0—1.5 (6H, $H_3C-(CH_2)_3-$), 1.5—2.1 (4H, ring-$(CH_2)_2-$), 2.1—2.6 (1H, -CH-), 3.6 (6H, $2\times H_3CO-$). IR (neat): 1730 cm^{-1} (νC=O).

*Dimethyl (E)-3-Octene-1,1-dicarboxylate (**7a**)*: Bp, 117 °C/2 mmHg; n_D^{15}, 1.4453. NMR: δ 0.6—1.0 (3H, H_3C-), 1.0—1.5 (4H, $H_3C-(CH_2)_2-$), 1.6—2.1 (2H, $-CH_2-CH_2-CH=$), 2.2—2.6 (2H, $=CH-CH_2-CH-$), 3.0—3.4 (1H, -CH-), 3.6 (6H, s, $2\times H_3CO-$), 5.0—5.5 (2H, -CH=CH-). IR (neat); 1740 (νC=O), 970 cm^{-1} (δ =CH_{trans}). Found: C, 63.01; H, 8.75%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

*(E)-3-Octene-1,1-dicarboxylic Acid (**9a**)*: The diester **7a** was hydrolyzed by refluxing it in aq MeOH in the presence of KOH. Mp, 65.5 °C (petr. ether) (lit,[10] 60—63 °C). Found: C, 60.28; H, 8.23%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%. NMR ($CDCl_3$): δ 0.6—1.0 (3H, H_3C-), 1.0—1.5 (4H, $H_3C-(CH_2)_2-$), 1.7—2.2 (2H, $-CH_2-CH_2-CH=$), 2.3—2.8 (2H, $=CH-CH_2-CH<$), 3.4 (1H, t-like, $-CH<$), 5.1—5.7 (2H, -CH=CH-), 11.8 (2H, s, $2\times$-COOH). IR (KBr): 1710 (δC=O), 965 cm^{-1} (δ =CH_{trans}).

*1-Methoxy-2-heptene (**5b**)*: NMR: δ 0.6—1.1 (3H, H_3C-), 1.1—1.7 (4H, $H_3C-(CH_2)_2-$), 1.7—2.4 (2H, $-CH_2-CH_2-CH=$), 3.2 (3H, s, H_3CO-), 3.6—4.0 (2H, H_3CO-CH_2-), 5.2—5.7 (2H, -CH=CH-). IR (neat): 1670 (νC=C), 970 cm^{-1} (δ =CH_{trans}).

*1-Chloro-3-heptene (**6b**)*: NMR: δ 0.7—1.1 (3H, H_3C-), 1.1—1.7 (2H, H_3C-CH_2-), 1.7—2.2 (2H, $Et-CH_2-$), 2.2—2.7 (2H, $ClCH_2-CH_2-$), 3.4 (2H, t, J=6.5 Hz, $ClCH_2-$), 5.1—5.6 (2H, -CH=CH-). IR (neat): 975 cm^{-1} (δ =CH_{trans}).

Similar treatment of **1c** with diethyl and diisopropyl malonate gave the corresponding alkene **7** and cyclobutane **8** (see Table 2); all the compounds exhibited satisfactory IR and NMR spectra.

*Diethyl (E)-3-Octene-1,1-dicarboxylate (**7b**)*: Bp, 117—120 °C/2 mmHg; n_D^{17}, 1.4405 (lit,[10] n_D^{25}, 1.4410). Found: C, 65.75; H, 9.62%. Calcd for $C_{14}H_{24}O_4$: C, 65.60: H, 9.44%.

*Diethyl 2-Butylcyclobutane-1,1-diacrboxylate (**8b**)*: Bp, 98—100 °C/2 mmHg; n_D^{17}, 1.4403. Found: C, 65.89; H, 9.52%. Calcd for $C_{14}H_{24}O_4$: C, 65.60; H, 9.44%.

*Diisopropyl 2-Butylcyclobutane-1,1-dicarboxylate (**8c**)*: Bp, 115—117 °C/2 mmHg; n_D^{15}, 1.4390. Found: C, 67.90; H, 9.59%. Calcd for $C_{16}H_{28}O_4$: C, 67.60; H, 9.89%.

*Reaction of (E)-3-Octene-1,1-dicarboxylic Acid (**9a**). (E)-4-Nonenoic Acid (**11**)*: A sample of the dicarboxylic acid **9a** (37.7 g, 0.19 mol) was heated to 150—160 °C. After gas evolution had ceased, the mixture was analyzed by GLC to show that it consisted of *ca.* 95% of (*E*)-4-nonenoic acid (**11**) and *ca.* 5% of 1,4-nonanolide (**10a**) (*vide infra*). The mixture was dissolved in 2 M Na_2CO_3 and extracted with portions of ether to remove the **10a**. The aqueous phase was acidified with 2 M HCl; the regenerated free acid was extracted with ether. The ether extracts were combined, washed with water, and dried over $MgSO_4$. Distillation gave (*E*)-4-nonenoic acid boiling at 98—102 °C/2.5—3 mmHg (lit,[10] bp, 112—113 °C/5 mmHg); 18.7 g (yield, 64%). NMR: δ 0.6—1.1 (3H, H_3C–), 1.1—1.6 (4H, H_3C–(CH_2)$_2$–), 1.6—2.1 (2H, *n*-Pr–CH_2–), 2.1—2.6 (4H, –(CH_2)$_2$–CO–), 5.1—5.5 (2H, –CH=CH–), 11.9 (1H, –COOH). IR (neat): 1710 (νC=O), 965 cm^{-1} (δ =CH_{trans}).

*1,4-Nonanolide (**10a**)*: The dicarboxylic acid **9a** (0.83 g) was refluxed in H_2O (40 ml)–H_2SO_4 (20 ml) for 10 h. After steam distillation, the distillate was worked up as usual. Bp, 105—107 °C/2 mmHg; 0.65 g; n_D^{13}, 1.4473 (lit,[15] n_D^{20}, 1.4462). Found: C, 69.15; H, 9.94%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.33%. NMR: δ 3.9—4.6 (1H, –CH–). IR (neat): 1770 cm^{-1} (νC=O).

*1,4-Undecanolide (**10b**)*: The method described above was applied to 1-chloro-3-iodononane (**1d**) to give **10b**. Bp, 132—135 °C/2 mmHg; n_D^{13}, 1.4512 (lit,[16] n_D^{20}, 1.4512). Found: C, 71.85; H, 11.33%. Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%. NMR: δ 3.9—4.6 (1H, –CH–). IR (neat): 1770 cm^{-1} (νC=O).

*Synthesis of (E)-5-Decenyl Acetate (**15**)*. To a stirred suspension of $LiAlH_4$ (0.6 g) in 300 ml of ether, we added a solution of (*E*)-4-nonenoic acid (**11**) (18.7 g, 0.12 mol) in ether (250 ml) over a 40-min period. The mixture was heated at reflux for another 3 h and then treated as usual. The subsequent evaporation of solvents left a 12.6 g sample of (*E*)-4-nonen-1-ol (**12**), the purity of which was *ca.* 97% as judged by GLC. NMR: δ 0.6—1.1 (3H, H_3C–), 1.1—1.7 (6H, 3×–CH_2–), 1.7—2.3 (4H, –CH_2–CH=CH–CH_2–), 2.5—2.8 (1H, –OH), 3.5 (2H, t, J=6.5 Hz, –CH_2–OH), 5.1—5.5 (2H, –CH=CH–). IR (neat): 970 cm^{-1} (δ =CH_{trans}).

Into an ice-chilled solution of triphenylphosphine (36 g) in 200 ml of acetonitrile was dropped 21.9 g of bromine (0.14 mol) to give triphenylphosphine dibromide, to which was then added the alcohol **12** (12.6 g). After the mixture had been stirred and heated at reflux for 1 h, the acetonitrile was evaporated *in vacuo*. The crude product (*E*)-1-bromo-4-nonene (**13**) was collected as a portion boiling at 50—55 °C/2—3 mmHg (*ca.* 85% yield); it was then filtered through a silica-gel column to give 5.03 g of a pure sample. NMR: δ 0.6—1.0 (3H, H_3C–), 1.0—1.5 (4H, –(CH_2)$_2$–CH_3), 1.5—2.5 (6H, 3×–CH_2–), 3.2 (2H, t, J=6.4 Hz, –CH_2Br), 5.1—5.5 (2H, –CH=CH–). IR (neat): 965 cm^{-1} (δ =CH_{trans}).

The bromide **13** (5.0 g) was treated with 1.5 g of magnesium turnings (62 mg-atom) in 80 ml of ether, to which was passed formaldehyde gas (prepared from 5 g of paraformaldehyde). A conventional work-up gave a 3.0-g portion distilling out at 78—84 °C/2—3 mmHg, which was finally purified by preparative GLC (FFAP column) to give **14** with a purity of 98% plus, as judged by the OV-1 capillary column GLC. Bp, 95—96 °C/2 mmHg; n_D^{15}, 1.4513. Found: C, 77.03; H, 12.66%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%. NMR: δ 0.6—1.0 (3H, H_3C–), 1.0—1.6 (8H, 4×–CH_2–), 1.5—1.7 (1H, –OH), 1.7—2.2 (4H, 2×–CH_2–), 3.3—3.6 (2H, t-like, –CH_2–OH), 5.1—5.3 (2H, –CH=CH–). IR (neat): 965 cm^{-1} (δ =CH_{trans}).

The treatment of the alcohol **14** with an excess amount of acetyl chloride in pyridine-benzene gave (*E*)-5-decenyl acetate, **15**: bp, 110—115 °C/16—17 mmHg; n_D^{19}, 1.4393. Found: C, 73.00; H, 11.22%. Calcd for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%. NMR: δ 0.6—1.0 (3H, H_3C–CH_2–), 1.0—1.6 (8H, 4×–CH_2–), 1.6—2.2 (7H, –OH+3×–CH_2–), 3.9 (2H, t, J=6.6 Hz, –CH_2–O–), 5.1—5.4 (2H, –CH=CH–). IR (neat): 1745 (νC=O), 970 cm^{-1} (δ =CH_{trans}).

Physical Properties and Various Reactions of Thionitrites and Related Substances

Shigeru OAE,* Kōichi SHINHAMA, Ken FUJIMORI, and Yong Hae KIM

Department of Chemistry, University of Tsukuba, Niiharigun, Ibaraki 305

(Received August 27, 1979)

Several new sulfenyl or sulfonyl derivativives, thionitrates ($RSNO_2$), sulfonyl nitrites (RSO_2NO), were successfully isolated by treating corresponding thiols and sulfinic acids with dinitrogen tetraoxide (N_2O_4). Spectroscopic data of both stable and many rather unstable compounds were determined and compared with those of corresponding alkyl nitrites (RONO) or alkyl nitrates ($RONO_2$). Chemical reactivities of these uncommon, novel *S*-nitroso and *S*-nitro compounds were investigated.

Preparation of Thionitrites and Related Substances. We reported recently that various thionitrites (RSNO) (**2**) were prepared quantitatively by the reaction of thiols (**1**) with dinitrogen tetraoxide (N_2O_4)[1,2] (Eq. 1). Red colored thionitrites **2** were not so stable as to be isolated in pure form except *t*-alkyl or *s*-alkyl derivatives.

We found that stable *t*-alkyl thionitrates (**3a**—**c**) can be prepared in good yields by treating thiols with excess dinitrogen tetraoxide (Eq. 2). *t*-Pentyl thionitrate (**3b**) and 1,1-dimethylheptyl thionitrate (**3c**) are new additions in the literature. We also found that the novel aryl thionitrates (**3d**—**f**) can be isolated as unstable white crystals upon treating the corresponding thiols with excess dinitrogen tetraoxide in hexane at low temperatures (*ca.* −60 °C). However, these aryl thionitrates **3d**—**f** were found to decompose readily at room temperature. All the *t*-alkyl thionitrates **3a**—**c** were stable at room temperature and some aryl thionitrates **3d**—**e** were stable at low temperature, however, other thionitrates were found to be not stable enough to be isolated in pure form. Reaction

conditions and isolated yields of thionitrates **3a**—**f** are listed in Table 1.

Sulfonyl nitrites (**5**) were considered to be the reaction intermediates in the reaction of sulfinic acids with alkyl nitrites.[3] Nevertheless these compounds have not been isolated. We now have found that sulfonyl nitrites **5a**—**f**, new sulfonyl derivatives, can be isolated as brown unstable crystals upon treating sulfinic acids (**4a**—**f**) with dinitrogen tetraoxide. Corresponding sulfonic acids (**6a**—**f**) were also obtained nearly in the same yields (Eq. 3). Sulfonyl nitrites **5a**—**f** isolated had strong SO_2 absorption bands near 1840 cm^{-1}. Mass spectrum of sulfonyl nitrite **5b** showed the corresponding fragment ion peaks: *m/e* (rel intensity), 155 (9, *p*-Tol†SO_2^+), 91 (20, *p*-Tol^+), and 30 (100, NO^+). However, no molecular ion peak was observed due to the weak S–N bond of this compound.

Spectroscopic Data of Thionitrites and Related Substances. Spectroscopic data of *t*-butyl nitrite (**7**), *t*-butyl nitrate (**8**), *t*-butyl thionitrite (**2a**), *t*-butyl thionitrate (**3a**) and methanesulfonyl nitrite (**5a**) were obtained and compared with each other. Infrared absorption bands of these compounds are listed in Table 3. Thionitrite **2a** and thionitrate **3a** showed the infrared absorption bands at longer wavelengths than corresponding alkyl nitrite **7** and alkyl nitriate **8**. The same trend is known in C=O stretching of ester and thioester, and is explained in terms of the electronegativity difference between S and O.[4] This inductive effect may also play a major role in our case.[5] Thus the presence of a strongly electronegative sulfonyl group may be responsible for the shift of N=O stretching frequency of sulfonyl nitrite **5a** up to 1842 cm^{-1}. In this case lack of resonance between S and N may be partly responsible for the large wave number because

3a		1510	1300, 1257	820
5a	1842			a)

a) Several absorption bands were observed at 750—960 cm^{-1}.

the sulfur atom in sulfonyl nitrite **5a** has no lone pair to conjugate with nitroso group.

^{1}H-NMR of alkyl nitrite **7**, alkyl nitrate **8**, thionitrite **2a** and thionitrate **3a** were measured. Chemical shifts are listed in Table 4. Chemical shifts of *t*-butyl groups of thionitrite **2a** and thionitrate **3a** shifted toward the lower fields than corresponding alkyl nitrite **7** and alkyl nitrate **8** due to the effect of sulfur atom. UV spectra of these compounds were also recorded and shown in Fig. 1, while the numerical values of the UV spectra are listed in Table 5. Thionitrite **2a** showed a rather strong absorption at a visible wavelength region and had a greenish red color. Alkyl nitrite **7** showed a very weak absorption at a visible wavelength. All these compounds had N=O or NO_2 absorption bands at 250—180 nm.

Chemical Reactivities and Synthetic Applications of Thionitrites. Both aromatic and alkyl thiols (**1d**, **1j**, **1k**, **11**, **1e**, **1g**, **1h**, and **1i**) reacted readily with excess

dinitrogen tetroxide at a low temperature to afford the corresponding thiosulfonic *S*-esters (**10b—i**) in good yields (Eq. 6). Symmetrical thiosulfonic *S*-esters have generally been synthesized by the oxidation of disulfides[6] or by the reaction of sulfinic acids with sulfenyl chlorides.[7] These methods, however, involve two or more reaction steps and form such side products as thiosulfonic *S*-esters and sulfonic acids. Our new method is simple and involves only one pot reaction. When thiols **1d**, **1j**, **1k**, **11**, **1e**, **1g**, **1h**, and **1i** were mixed with excess dinitrogen tetraoxide at *ca.* −20—0 °C and then quenched with *t*-butyl alcohol, the corresponding thiosulfonic *S*-esters **10b—i** were obtained

Table 6. Reactions of thiols with dinitrogen tetraoxide

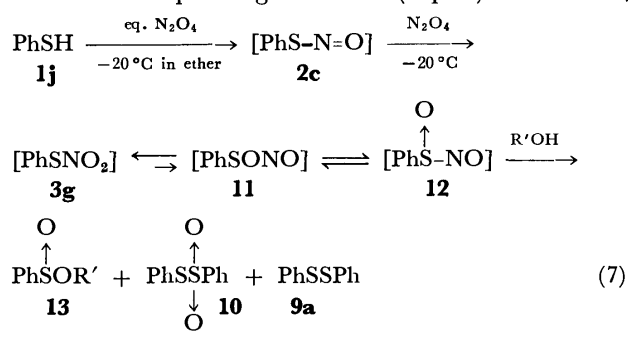
a) Mole ratio.

in good yields in such an inert solvent as ethyl ether. A solution of dinitrogen tetraoxide (in CCl_4) was added to a solution of a certain thiol in anhydrous ethyl ether at *ca.* −20 °C. Immediately, the mixture colored to bright red, characteristic of thionitrite **2**, which solution was stirred further for 1—5 min until the red color disappeared. The mixture was quenched with *t*-butyl alcohol. The *crude* product was purified by a preparative TLC. The results are summarized in Table 6. The yields of the thiosulfonic *S*-ester **10b**—**i** were markedly high when the reaction temperature was controlled at *ca.* −20 °C and quenched with excess *t*-butyl alcohol.

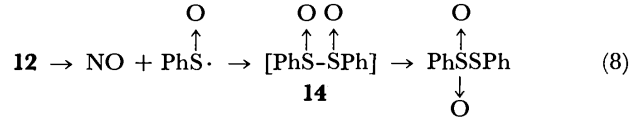
When the reaction mixture of thiol **1j** with dinitrogen tetraoxide was quenched with methanol or isopropyl alcohol instead of *t*-butyl alcohol, methyl benzenesulfinate (**13a**) (22% of yield) or isopropyl benzenesulfinate (**13b**) (10% of yield) was obtained at the expense of the intermediate such as benzenesulfinyl nitrite (**12**), which is probably in an equilibrium with phenyl thionitrate (**3g**), and methanol or isopropyl alcohol probably attacks the sulfinyl sulfur atom to form the corresponding sulfinate (Eq. 7). However,



(7)

13a: R′=Me
13b: R′=Me_2CH

bulky *t*-butyl alcohol may not attack the sulfinyl sulfur atom due to the steric hindrance. When the reaction mixture was quenched with *t*-butyl alcohol, *t*-butyl benzenesulfinate could not be detected. Probably, homolytic scission of the unstable intermediate **12** may form the sulfinyl radical which is converted to the corresponding diphenyl α-disulfoxide (**14**), which then would be converted to the corresponding *S*-phenyl benzenethiosulfonate (**10c**)[8,9] (Eq. 8).



(8)

Meanwhile treatment of the thiol **1d**, and **1j** with 6 eq. dinitrogen tetraoxide at room temperature followed by quenching with excess *t*-BuOH gave the sulfonic acids (**6a**,**b**) quantitatively (Eq. 5), whereas treatment of thiol **1j** with 1 eq. with dinitrogen tetraoxide at −70 °C gave diphenyl disulfide (**9a**) quantitatively after decomposition of unstable phenyl thionitrite(**2c**) at room temperature (Eq. 4). Treatment of thiol **1a** with 3 eq. dinitrogen tetraoxide, however, gave thionitrate **3a** in an excellent yield. Therefore, the corresponding thiosulfonic *S*-ester **10b**—**i**, sulfonic acids **6a**,**b**, and disulfide **9a** can be prepared selectively by the simple and selective oxidation of the thiol **1** with dinitrogen tetraoxide when the reaction temperature, time and the concentration of dinitrogen tetraoxide are carefully controlled.

We reported in the previous paper that thionitrites reacted with thiols to afford the unsymmetrical disulfides nearly quantitatively.[2] When thionitrites **2a**,**b** were allowed to react with sodium benzenethiolate (**15**), the corresponding unsymmetrical disulfides (**16a**, **b**) were also obtained in good yields (Eq. 9).

(9)

2a, **16a**: R=*t*-Bu **2b**, **16b**: R=*p*-Tolyl

Chemical Reactivities and Synthetic Applications of Thionitrates. Thionitrate **3a**, one of the stable thionitrates, was also found to react with benzenthiolate **15** at room temperature to afford *t*-butyl phenyl disulfide (**16c**) in 69% isolated yield (Eq. 10).

(10)

When thionitrate **3a** was heated in carbon tetrachloride for 1 h at 130 °C in a sealed tube, di-*t*-butyl disulfide (**9c**) was obtained as the major product, whereas decomposition of thionitrate **3d** at room temperature gave thiosulfonic *S*-ester **10b** as the main product together with a small amount of disulfide **9b** (Eq. 11). On the other hand, when thionitrates **3a**, **3d**, and **3e** were treated with a catalytic amount of pyridine, corresponding thiosulfonic *S*-esters **10j**, **10b**, and **10k** were obtained selectively in good yields (Eq. 12). Evolution of NO gas was confirmed by GC mass-spectroscopic analysis. When thionitrate **3d** was quenched with excess methanol, methyl *p*-toluenesulfinate **17** was obtained in 17% yiled (Eq. 13).

We also found that the reaction of isolated thionitrates **3a**—**e** with various *p*-aminophenols (**18a**—**i**) readily afforded the corresponding *N*-(*t*-alkylthio)-*p*-benzoquinone imines (**19a**—**i**) (Eqs. 14 and 15).

Only a few *N*-(alkylthio)-*p*-benzoquinone imines were prepared previously from *N*-chloro-*p*-benzoquinone imines and thiols.[10] Our new synthetic

method of quinone imines **19a**—**i** is simple and especially useful for the syntheses of *N*-*t*-alkylthio derivatives.

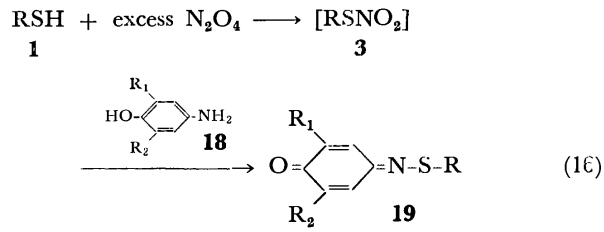
18i	**3f**	**19i**	11[d]
18j	**3h**	**19j**	10[c,d]
18k	**3d**	**19k**	6[c,d]

a) In this case $CuCl_2$ was not added. Chromatographic separation gave a poor result and the yield was determined by GLC. b) HCl salt was used as the starting material. c) An oxidative mixture of the thiol with 2 eq. N_2O_4 was used due to the instabilities of these thionitrates. d) $CuCl_2$ was not used in these cases for instabilities of these thionitrates in the presence of $CuCl_2$.

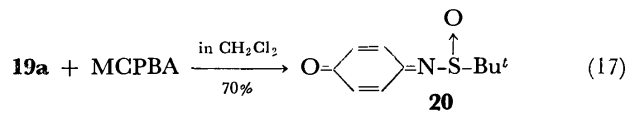
An oxidative mixture of *s*-BuSH (**1m**) or thiol **1d** with excess dinitrogen tetraoxide probably contains *s*-butyl thionitrate (**3h**) or thionitrate (**3d**), respectively, because of the formation of *N*-(*s*-butylthio)-*p*-benzoquinone imine (**19j**) or *N*-(*p*-tolylthio)-*p*-benzoquinone imine (**19k**) from the corresponding *p*-aminophenols (**18j**, **18k**) (Eq. 16). All these new compounds **19a**—**k** are quite stable and have vivid yellow colors due to the strong absorption band ($\varepsilon_{max}>10^4$) near 400 nm. Structures of the products **19a**—**k** were identified by IR, NMR, UV, and mass spectrocopies. Elemental analyses of these compounds **19a**—**k** all agree with these formulae. Isolated yields of compounds **19a**—**k** are listed in Table 7.



(16)

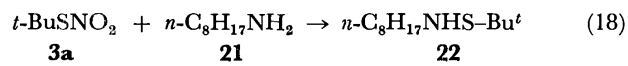
1m, **3h**: R=*s*-Bu
1d, **3d**: R=*p*-Tolyl
18j, **19j**: R=*s*-Bu, $R_1=R_2=Cl$
18k, **19k**: R=*p*-Tolyl, $R_1=R_2=H$

When compound **19a** was oxidized with an equivalent amount of *m*-chloroperbenzoic acid, a red colored unstable *N*-(*t*-butylsulfinyl)-*p*-benzoquinone imine **20** was obtained (70%) upon column chromatography (Eq. 17). This sulfinyl derivative **20** showed a strong absorption at 1080 cm^{-1} (SO) in IR spectrum, however, was found to decompose readily (*ca.* 1 h) at room temperature.



(17)

We also found that thionitrate **3a** reacted readily with octylamine (**21**) at room temperature for 10 min to give *N*-(*t*-butylthio)octylamine (**22**) in a good yield (Eq. 18).



(18)

Chemical Reactivities of Sulfonyl Nitrites. When *p*-toluenesulfonyl nitrite (**5b**) was heated in dioxane or neat, vigorous evolution of gas was observed and white crystals were obtained. After recrystallization from acetic acid, elemental analysis of this crystalline compound showed the formula of $(p\text{-TolSO}_2)_3(NO)$ (**23**)[11] and IR spectroscopic data and melting point were identical with those of a known compound which was reported as tris(*p*-tolylsulfonyl)amine oxide by Kresze and Kort.[3] Other several sulfonyl nitrites **5a**, **5c**, **5d**, and **5e** were also found to undergo thermodecomposition to give white crystals described as formula $(RSO_2)_3(NO)$ (**23a**, **23c**—**e**) by elemental analyses (Eq. 19). However, since the compound **23a** gives two distinctly different peaks of metyl groups on both ^1H and ^{13}C-NMR spectra (integral ratio=2:1 on^1 H-NMR), the structure of these compounds **23a**—**e**

is belived to be represented by $(RSO_2)_2N$–O–SO_2R rather than $(RSO_2)_3NO$, and further detailed structure assignment is now underway. Meanwhile, the gas formed by thermal decomposition of sulfonyl nitrite **5b** showed a strong peak at *m/e* 30 (NO) in its mass spectrum. These results are listed in Table 8.

Sulfonyl nitrites **5a—e** were unstable compounds in protic solvents such as alcohols or thiols and decomposed in a few minutes (Eqs. 20 and 21). When sulfonyl nitrite **5b** was stirred in methanol, *N,N*-bis(*p*-tolylsulfonyl)hydroxylamine (**24**) was obtained in a good yield. Sulfonyl nitrite **5b** also reacted with thiol **1a** in dioxane to give hydroxylamine **24**. The reaction

$$2\,p\text{-}TolSO_2NO + MeOH \rightarrow (p\text{-}TolSO_2)_2NOH + MeONO \qquad (20)$$
5b **24**

$$2\,p\text{-}TolSO_2NO + t\text{-}BuSH \rightarrow \mathbf{24} + t\text{-}BuSNO \qquad (21)$$
5b **1a** **2a**

mixture of sulfonyl nitrite **5b** and thiol **1a** was found to turn to red in a few minutes due undoubtedly to the formation of thionitrite **2a**.

Sulfonyl nitrite **5b** also reacted with thionitrite **2a** in dioxane to give *S*-*t*-butyl *p*-toluenethiosulfonate (**25**) in 20% yield (Eq. 22). This reaction was slow and

$$p\text{-}TolSO_2NO + t\text{-}BuSNO \xrightarrow[1-3\,h]{25^\circ C} p\text{-}TolS(O)\text{-}S\text{-}Bu^t \qquad (22)$$
5b **2a** **25**

required for over 1 h at room temperature.

When sulfonyl nitrite **5b** was reduced with sodium borohydride, *N*-(*p*-tolylsulfonyl)hydroxylamine (**26**) was obtained in 16% yield (Eq. 23). Other major product was compound **23b**.

$$\mathbf{5b} + \text{excess } NaBH_4 \rightarrow p\text{-}TolS(O)NHOH + \mathbf{23b} \qquad (23)$$
26

Experimental

All the melting points and boiling points were uncorrected. Elemental analysis of sulfur was carried out by Sagami Chemical Research Center and the analyses of other elements were carried out by the Chemical Analysis Center at this University. Analytical determination by GLC were performed on a Hitachi 163 gas chromatograph fitted with the following column (3 mm o.d.×3 m): 10% SE-30 on Chromosorb W. ^{1}H-NMR spectra were taken at 60 MHz on a Hitachi R-24A apparatus. ^{13}C-NMR spectra were measured on a Bruker FXD 4-100 NMR spectrometer. Mass spectra were recorded with a Hitachi RMU-6M spectrometer.

The following compounds were obtained according to the known procedures which are described in the literature: Dinitrogen tetraoxide,[2] **8**,[12] **4a**,[13] **4d**,[14] **4e**,[15] **4f**.[16]

t-Butyl Thionitrite (2a). Dinitrogen tetraoxide[2] (0.1 mol) in carbon tetrachloride (11 ml) was added to a stirred solution of thiol **1a** (9.02 g, 0.1 mol) in dry ethyl ether (100 ml) for a few minutes at −70 °C. The solution was stirred further for several minutes and poured into the cold 5% $NaHCO_3$ aq solution and extracted with ethyl ether. The ethereal extract was dried ($MgSO_4$) in dark at 0 °C, and the solvent was evaporated *in vacuo* giving almost pure thionitrite **2a** (7.0 g, 59%), which was pure enough for the reaction over several months at −20 °C with molecular sieves: (lit,[17] bp 36 °C/48 mmHg). IR (neat): 1490 (NO), 1360, 1298, 1157, and 760 cm^{-1}. NMR (CCl_4): δ=1.85 (s). Thionitrite **2a** was usually used without distillation.

Other thionitrites were prepared similarly by the method already reported by Oae *et al.*[2] Generally thionitrites were not stable enough to be isolated in pure form, and they were usually used in ethereal solution after washing (5% aq $NaHCO_3$ solution) and drying ($MgSO_4$).

t-Butyl Thionitrate (3a). The following is a typical procedure to prepare stable *t*-alkyl thionitrates.

This reaction required a relatively large flask (2 l) fitted with a reflux condenser, which is open for air escape, since the reaction took place vigorously. Dinitrogen tetraoxide[2] (1.5 mol) in carbon tetrachloride (135 ml) was added dropwise to a stirred solution of thiol **1a** (55.3 g, 0.6 mol) in dry ethyl ether (500 ml) for over 30 min at the rate that ethyl ether slowly refluxed. After the addition was over, the solution was stirred further for *ca.* 30 min. The solution was washed with ice cold water and dried ($MgSO_4$), concentrated, and distilled (with molecular sieves) giving 67.5 g (84%) of thionitrate **3a** which had a stimulant odor.

Spectroscopic data, boiling points and elemental analytical data of stable thionitrates (**3a—c**) are listed in Tables 9 and 10.

p-Chlorophenyl Thionitrate (3e). The following is a typical procedure to prepare unstable aryl thionitrates.

Dinitrogen tetraoxide (0.15 mol) in carbon tetrachloride (13.5 ml) was added dropwise to a stirred suspension of thiol **1e** (15.7 g, 0.1 mol) in hexane (100 ml) for 5 min at −60 °C. Immediately the mixture colored to bright red, characteristic of the thionitrite. After the red color of thionitrite disappeared (*ca.* 2—3 min), the white crystalline thionitrate **3e** was collected by filtration in a cold room (*ca.* 0 °C) and recrystallized with ethyl ether at −70 °C to give 13.1 g (65%) of thionitrate **3e**. IR spectrum was measured in a cold room (maintained at *ca.* −20 °C) because of the instability of thionitrate **3e**. IR spectroscopic data and melting points of thionitrate **3d—f** were listed in Table 9.

Syntheses of Sulfonyl Nitrites (5a—f). A typical procedure is as follows. A solution of dinitrogen tetraoxide (0.1 mol) in carbon tetrachloride (11 ml) was added to a stirred suspension of sulfinic acid **4b** (15.6 g, 0.1 mol) and dry ethyl ether (50 ml) at 0 °C in a few minutes. The suspension soon turned to a pale brown color in a few minutes forming

the precipitate of sulfonyl nitrite **5b**. The mixture was stirred further for 10 min at 0 °C. Then the brown precipitate was filtered, washed with dry ethyl ether and dried *in vacuo* giving 11.2 g (61%) of pure sulfonyl nitrite **5b**. IR and NMR spectra of sulfonyl nitrites **5a**—**f** are listed in Table 11, while elemental analyses of sulfonyl nitrites **5b**—**e** are listed in Table 12.

*Thiosulfonic S-Ester (**10b**—**i**).* A typical procedure is as follows. A solution of dinitrogen tetraoxide (20 mmol, in CCl_4) was added to a solution of thiol **1e** (723 mg, 5.0 mmol) in anhydrous ethyl ether (15 ml) with stirring at *ca.* 0 °C in the dark. Immediately, the mixture colored to bright red, characteristic of the thionitrite, which was stirred further for 1 min until the red color disappeared. The mixture was quenched with *t*-butyl alcohol (5 ml) for several minutes at 0—20 °C and then washed with 5% aq $NaHCO_3$ solution to remove nitric acid formed during the reaction. The *crude* product from the organic layer was purified by preparative TLC (silica gel, hexane:ether=20:1) to give 615 mg (77%) of thiosulfonic *S*-ester **10f**.

Table 12. Elemental analyses of sulfonyl nitrites **5b**—**e**[a]

Compound	Found (%)[b]				Calcd (%)

10h	1332	1135	0.7—2.5 (m, 20H), 2.9 (br, m, 1H), 3.3 (br, m, 1H)	Oil (lit,[23] 37—38)
10i	1325	1129	0.7—2.1 (m, 30H), 2.9—3.3 (m, 4H)	Oil (lit,[24] Oil)

Spectroscopic data of thiosulfonic *S*-esters **10b**—**i** are summarized in Table 13. Melting points or boiling points of thiosulfonic *S*-esters **10b**—**i** were identical with those of literatures.

*p-Toluenesulfonic Acid (**6a**).* A solution of dinitrogen tetraoxide (15 mmol, in CCl_4) was added to a solution of thiol **1d** (310 mg, 2.5 mmol) in anhydrous ethyl ether (7.5 ml) with stirring at *ca.* 0 °C. The solution was further stirred for 2.5 h at room temperature. After quenching the solution with *t*-butyl alcohol (5 ml) for 5 min, the volatile material was evaporated *in vacuo* giving 487 mg (quantitative) of sulfonic acid **6a**. IR and NMR spectra were identical with those of authentic samples.

*Diphenyl Disulfide (**9a**).* Dinitrogen tetraoxide (5

mmol, in CCl_4) was added to a stirred solution of thiol **1j** (550 mg, 5 mmol) in dry ethyl ether (10 ml) at −70 °C. After a few minutes the red colored solution was poured into the 5% $NaHCO_3$ aq solution. After the mixture was warmed to room temperature. After the red color of the thionitrite disappeared, the ethereal layer was separated, dried ($MgSO_4$) and evaporated giving 540 mg (quantitative) of disulfide **9a**. Spectroscopic data were identical with those of authentic sample.

*Methyl Benzenesulfinate (**13a**) and Isopropyl Benzenesulfinate (**13b**).* Dinitrogen tetraoxide (7.6 mmol, in CCl_4) was added to a solution of thiol **1j** (421 mg, 3.8 mmol) at −20 °C. After a few minutes, the solution was quenched with methanol (1.2 ml) and stirred further for 5 min at 0 °C. After evaporation of the solvent and TLC (hexane:ether=10:1) gave 65 mg (22%) of sulfinate **13a**: bp (bath temp) 90—100 °C/2 mmHg (lit,[25] 76—81 °C/0.45 mmHg). IR (neat): 1130 (SO), 965, 758, and 696 cm^{-1}. NMR (CCl_4): δ=3.33 (s, 3H, $-C\underline{H}_3$) and 7.54 (m, 5H, ring-protons). Other isolated products were disulfide **9a** (25%) and *S*-phenyl thiosulfonate (**10**) (43%), and spectroscopic data of these compounds were identical with those of authentic samples.

Sulfinate **13b** was also isolated by a similar procedure: bp (bath temp) 120—130 °C/2 mmHg (lit,[26] 110—117 °C/0.5 mmHg). IR (neat): 1143 (SO), 1102, 920, 845, and 735 cm^{-1}. NMR (CCl_4): δ=1.13 (d, J=6 Hz, 3H, $-C\underline{H}_3$), 1.34 (d, J=6 Hz, 3H, $-C\underline{H}_3$), 4.14 (m, 1H, $C\underline{H}$), and 7.47 (m, 5H, ring-protons). Other isolated products were disulfide **9a** (20%) and thiosulfonic *S*-ester **10c** (42%).

*Disulfides (**16a—c**).* Dinitrogen tetraoxide (5 mmol, in CCl_4) was added to a stirred solution of thiol **1d** (620 mg, 5 mmol) in 10 ml of ethyl ether at −70 °C. After a few minutes, 5% aq $NaHCO_3$ solution was added and extracted with 10 ml of ethyl ether. The ethereal solution was dried ($MgSO_4$) and filtered at 0 °C. Sodium benzenethiolate **15** (661 mg, 5 mmol) in methanol (6 ml) was added to the ethereal solution and the solution was stirred for 12 h at −10 °C. The solution was washed with $NaHCO_3$ aq solution and dried ($MgSO_4$). The solvent was evaporated and water was added. The mixture was extracted with ethyl ether. Ethereal extract was dried and evaporated to give 898 mg (77%) of disulfide **16a**.

A similar treatment of thionitrite **2a** or thionitrate **3a** with benzenethiolate **15**, gave disulfide **16b** (74%) and **16c** (69%), respectively. Stable thionitrite **2a** and stable thionitrate **3a** were used after purification, unlike unstable thionitrite **2b**.

IR and NMR spectroscopic data of disulfides **16a—c** were identical with those of authentic samples.

*Thermal Decomposition of t-Butyl Thionitrate (**3a**).* The solution of thionitrate **3a** (30 mg, 0.22 mmol) in carbon tetrachloride (0.25 ml) was heated in an oil bath at 130 °C in a sealed tube for NMR. After 1 h, NMR spectrum showed that nearly all the starting material was converted to di-*t*-butyl disulfide **9c**: NMR, IR, and mass spectroscopic data were identical with those of authentic sample.

*Reactions of Thionitrates (**3a**, **3c**, and **3d**) with Pyridine.* Thionitrate **3a** 1.89 g (14 mmol) was added dropwise to a stirred solution of pyridine (554 mg, 7 mmol) in carbon tetrachloride (20 ml) for 5 min. The solution was stirred further for 30 min. Distillation gave 1.03 g (70%) of thiosulfonic *S*-ester **10j**, 280 mg of pyridine, and 246 mg of solid which could not be characterized. Thiosulfonic *S*-ester **10j**: mp 22—24 °C, bp (bath temp) 80 °C/5 mmHg. IR (neat): 1445, 1360, 1290 (SO_2), 1140, and 1100 cm^{-1} (SO_2). NMR (CCl_4): δ=1.40 and 1.58. MS (70 eV), *m/e* (rel intensity), 210 (1, M^+), 89 (10, *t*-BuS^+), and 57 (100, *t*-Bu^+). Found: C, 45.59; H, 8.61; S, 30.29%. Calcd for $C_8H_{18}O_2S_2$: C, 45.68; H, 8.62; S, 30.48%.

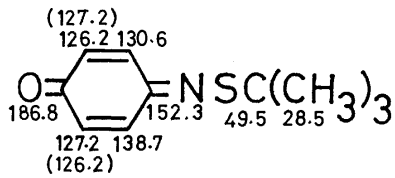
Thiosulfonic *S*-ester **10b** (65%) and thiosulfonic *S*-ester **10k** (89%) were obtained from thionitrate **3d** and thionitrate **3c**, respectively. IR spectroscopic data of thiosulfonic *S*-ester **10b** were identical with those of authentic sample. Thiosulfonic *S*-ester **10k**: bp (bath temp) 80 °C/3 mmHg. IR (neat): 1455, 1295, and 1100 cm^{-1}. NMR (CCl_4): δ=1.00 (t, 6H, $CH_2-C\underline{H}_3$), 1.35 (s, 6H, $SC(C\underline{H}_3)_2$), and 1.88 (q, 4H, $C\underline{H}_2$). Found: C, 50.39; H, 9.43%. Calcd for $C_{10}H_{22}O_2S_2$: C, 50.38; H, 9.30%.

*Methyl p-Toluenesulfinate (**17**).* Methanol (5 ml) was added dropwise for a few minutes onto the crystals of thionitrate **3e** at −20 °C. After vigorous reaction, the *crude* material was purified by TLC to give 222 mg (17%) of sulfinate **17**: MS (70 eV) *m/e* (rel intensity), 170 (56, M^+), 139 (100, *p*-$TolSO_2^+$), and 91 (28, *p*-Tol^+). IR and NMR spectroscopic data were identical with those of literatures.[27] The other products were the corresponding thiosulfonic *S*-ester **10f** (36%) and di-(*p*-chlorophenyl) disulfide (**9d**) (12%).

*N-(t-Butylthio)-p-benzoquinone Imine (**19a**).* *p*-Aminophenol 546 mg (5 mmol) was added for 5 min into a stirred suspension of well-dried anhydrous copper(II) chloride (810 mg, 6 mmol) and thionitrate **3a** (1020 mg, 7.5 mmol) in anhydrous acetonitrile (15 ml). The mixture was stirred for 1 h at room temperature, and then hydrochloric acid solution (20%, 100 ml) was added to the suspension and the mixture was extracted with ethyl ether. The ethereal extract was dried ($MgSO_4$) and evaporated. After purifying the extract on silica gel TLC (hexane:ether=10:1) bright yellow crystals of benzoquinone imine **19a** were obtained (390 mg, 40%).

Compound **19a** was obtained nearly in the same yield, even without copper(II) chloride, however, separation of the products was quite difficult. When *p*-hydroxyaniline was treated with thionitrate **3a** without copper(II) chloride, excess thionitrate **3a** was not converted to corresponding disulfide **9c** but to the thiosulfonic *S*-ester **10j** by undesirable oxidation. Since the thiosulfonic *S*-ester formed was quite difficult to be removed completely unlike the disulfide by distillation or TLC from the benzoquinone imine **19a**, copper(II) chloride is a useful reagent especially in separating benzoquinone imine **19a** in pure form.

The ^{13}C-NMR spectrum (in $CDCl_3$, ppm) of compound **19a** is depicted in the following structure.



UV and IR spectra and elemental analytical data of compound **19a** and its derivatives are listed in Table 14. NMR and mass spectroscopic data of compound **19a** and its derivatives are listed in Tables 15 and 16, respectively.

*N-(s-Butylthio)-2,6-dichlorobenzoquinone Imine (**19j**).* Dinitrogen tetraoxide (30 mmol) in carbon tetrachloride (3 ml) was added to a stirred solution of *s*-BuSH (1.35 g, 15 mmol) at 0 °C. The solution turned immediately red, characteristic for *s*-butyl thionitrite and soon the red color disappeared, due undoubtedly to the formation of *s*-butyl thionitrite. Aminophenol **18j** (1.78 g, 10 mmol) was then added for a few minutes and the solution was stirred further for 1.5 h. The mixture was filtered[28] and the filtrate was diluted with ethyl ether, washed with aq $NaHCO_3$ solution, dried ($MgSO_4$), evaporated and the usual TLC separation

Table 14. Spectroscopic data (UV, IR) and elemental analyses of quinone imines **19a—k**

Compound	UV (hexane, λ_{max}, nm)	IR (νC=O, cm^{-1})	Found (%)				Calcd (%)

(hexane:ether=7:1) gave 256 mg (10%) of benzoquinone imine **19j**. Spectroscopic data and elemental analytical data are listed in Tables 14, 15, and 16.

Oxidation of N-(t-*Butylthio*)-p-*benzoquinone Imine* (**19a**) *with* m-*Chloroperbenzoic Acid.* *m*-Chloroperbenzoic acid (360 mg, 1.88 mmol) was added to a stirred solution of benzoquinone imine **19a** in dichloromethane (15 ml) at 0 °C. The solution was further stirred for 30 min at 0 °C. The solvent was evaporated *in vacuo*. Column chromatography (hexane: chloroform=2:1—0:1) gave 276 mg (70%) of sulfinyl derivative **20**. IR (neat): 1080 cm^{-1} (SO). UV (hexane): λ_{max}= 415 nm. NMR (CCl_4): $\delta=1.32$ (s, 9H, *t*-Bu), 6.48 (d, $J=10$ Hz, 2H, O=C-CH), and 6.93 (d, $J=10$ Hz, 2H, O=C-C=CH). MS (70 eV), *m/e* (rel intensity), 211 (1, M$^+$), 154 (100, O=⟨=⟩=NSO$^+$), and 57 (17, *t*-Bu$^+$). Sulfinyl derivative **20** was unstable at room temperature, and soon

decomposed (*ca.* 1 h) to give dark material.

N-*(t-Butylthio)octylamine (22).* Thionitrate **3a** (2.02 g, 15 mmol) in acetonitrile (10 ml) was added to a stirred solution of amine **21** in acetonitrile (20 ml) for 10 min at 0 °C. The solution was further stirred for 1 h. The solvent was evaporated. TLC (hexane:ether=10:1) gave 524 mg (24%) of sulfenamide **22**: bp (bath temp) 85—95 °C/4 mmHg. IR (neat): 1460, 1135, and 910 cm^{-1}. NMR (CCl_4): δ=0.6—2.0 (m, 15H, $CH_3(CH_2)_6$–), 1.17 (s, 9H, *t*-Bu), 2.36 (br, 1H, NH), and 2.86 (br, 2H, –$C\underline{H}_2$–NH). Found: C, 65.95; H, 12.41; N, 6.32%. Calcd for $C_{12}H_{17}NS$: C, 66.29; H, 12.52; N, 6.44%. The other main product was *t*-$BuSO_2S$-Bu^t (814 mg, 3.87 mmol). Di-*t*-butyl disulfide (180 mg, 1.01 mmol) was also obtained.

Thermal Decomposition of p-*Toluenesulfonyl Nitrite (5b).* Sulfonyl nitrite **5b** (1.85 g, 10 mmol) in dioxane (25 ml) was stirred for a few minutes at *ca.* 70 °C. Vigorous evolution of gas was observed and the brown color of the solution soon vanished. The solution was concentrated, and the product was recrystallized from acetic acid giving 1.06 g (64%) of compound **23b**. Spectroscopic data, melting points, and elemental analyses of compound **23b** and related compounds are listed in Tables 19 and 20.

N,N-*Bis(p-tolylsulfonyl)hydroxylamine (24).* *A)*: Sulfonyl nitrite **5b** (185 mg, 10 mmol) was stirred in methanol for 5 min. The solvent was evaporated *in vacuo* to give 170 mg (quantitative) of almost pure hydroxylamine **24**: mp 124—126 °C (from ether), (lit,[3] 126 °C). IR (KBr): 3260 (OH), 1380 (SO_2), 1190 (SO_2), 855, and 673 cm^{-1}. IR spectroscopic data were identical with those of authentic sample prepared by the method in the literature.[3]

B): Sulfonyl nitrite **5b** (185 mg, 10 mmol) was added to a stirred solution of thiol **1a** in dioxane (20 ml). The solution slowly turned red, characteristic for thionitrite **2a**, and the mixture was further stirred for 30 min. Then, volatile materials were evaporated to give 180 mg of hydroxylamine **24**.

S-t-*Butyl* p-*Toluenethiosulfonate (25).* Sulfonyl nitrite **5b** (725 mg, 5 mmol) was added to a stirred solution of thionitrite **2a** (595 mg, 5 mmol) in dioxane (20 ml) at 0 °C. The mixture was further stirred for 1 h. Then the mixture was concentrated and upon TLC (hexane:ether=5:1) gave 241 mg of thiosulfonic *S*-ester **25**: mp 68 °C (from ethanol), (lit,[29] 69 °C). IR (KBr): 1591, 1460, 1318, 1140, 811, and 702 cm^{-1}. NMR (CCl_4): δ=1.43 (s, 9H, *t*-Bu), 2.42 (s, 3H, $C\underline{H}_3$), 7.28 (d, J=8 Hz, 2H, ring proton), and 7.75 (d, J=8 Hz, 2H, ring proton). MS (70 eV), *m/e* (rel intensity), 244 (5, M^+), 187 (9, *p*-$TolSO_2S^+$), 155 (10, *p*-$TolSO_2^+$), 91 (27, *p*-Tol^+), 89 (5, *t*-BuS^+), and 57 (100, *t*-Bu^+).

N-*(p-Tolylsulfonyl)hydroxylamine (26).* Sodium borohydride 1.89 g (50 mmol) was added to a stirred solution of sulfonyl nitrite **5b** (1.85 g, 10 mmol) in dioxane (25 ml) at 0 °C. The mixture was stirred further for 40 min at *ca.* 5—10 °C, then excess borohydride was decomposed with acetone (10 ml) at 0 °C. After nearly all the volatile material was evaporated *in vacuo* saturated NaCl aq solution was added into the residue, which was extracted with ethyl ether. Etherial extract was dried ($MgSO_4$), evaporated and upon TLC (hexane:ether=2:1) 304 mg (16%) of hydroxylamine **26** was obtained: mp 129—130 °C (recrystallized from benzene and ether). IR (neat): 3360 (OH), 1345 (SO_2), 985, 815, and 730 cm^{-1}. NMR ($CDCl_3$): δ=2.45 (s, 3H, –$C\underline{H}_3$), 3.88 (br, 2H, N$\underline{H}$ and O$\underline{H}$), 7.32 (d, J=9 Hz, 2H, ring proton), and 7.82 (d, J=9 Hz, 2H, ring proton). Found: C, 44.76; H, 4.73; N, 7.11%. Calcd for $C_7H_9NO_3S$: C, 44.90; H, 4.84; N, 7.48%.

Structure of a Guaioxide-type Sesquiterpene from "San-shion"[1]

Hiroshi HIROTA, Yoshiaki TANAHASHI, and Takeyoshi TAKAHASHI*

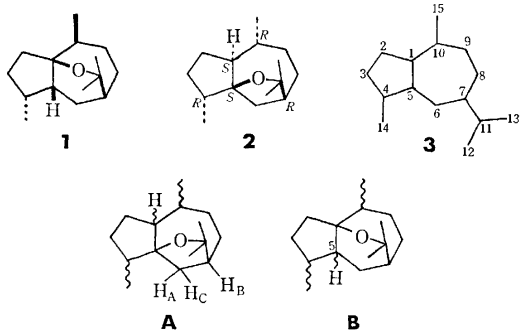
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received September 13, 1979)

The structure including absolute stereochemistry of "LB", one of the volatile constituents of "San-shion" (the roots of *Ligularia* species), was found to be (1*S*,4*R*,5*S*,7*R*,10*R*)-5,11-epoxyguaiane.

In connection with chemical investigations on plants of the genus *Ligularia* (Compositae),[2] we examined the constituents of a Chinese drug "San-shion," the roots of a *Ligularia* genus,[3,4] and isolated five volatile constituents named tentatively LA-LE,[4] along with furanoligularenone[3] and ligularenolide.[5] Four of the volatile constituents, LA, LC, LD, and LE, were found to be identical with cyperene, liguloxide, *p*-cymene, and limonene, respectively.[4a,b] The identity of LB with ogarukaya-ether A, isolated from *Cymbopogon Goeringii* (STEUD.) A. CAMUS, was confirmed by Fujita and Fujita,[6] structure **1** being proposed for ogarukaya-ether A based on biogenetic considerations.[6b] This paper deals with the structure determination leading to **2** for LB.

The molecular formula $C_{15}H_{26}O$ of LB was determined by elemental analysis and the appearance of a molecular ion peak at *m/e* 222 in the mass spectrum.[4a] The IR spectrum showed neither hydroxyl nor carbonyl absorption, the NMR spectrum suggesting the presence of two secondary and two tertiary methyl groups and the absence of olefinic proton (Experimental). The absence of unsaturated carbon–carbon linkage was revealed by treatment of LB with trifluoroperacetic acid which showed no consumption of the reagent. Thus, LB is a tricyclic saturated sesquiterpene containing an oxygen atom as a part of ether linkage. The absence of –O–CH– signal in the NMR spectrum suggests that both carbon atoms attached to the ether oxygen should be tertiary. Dehydrogenation of LB with palladium–charcoal gave *S*-guaiazulene as a major product and *Se*-guaiazulene as a minor one.[4a,b] Thus, two alternative structures (**A** and **B**; without stereochemical consideration) relating to a guaiane skeleton (**3**) can be suggested for LB.[4]



In the NMR spectrum of 1-epiguaioxide (**4**),[7,8] a double doublet signal due to $C_{(6\beta)}$–H (H_A; J=13 and J=6 Hz) appeared at δ 2.32 with small splittings (J=*ca.* 2 Hz). INDOR experiments[9] showed the presence of ABC-type spin-spin couplings for **4** (Fig. 1); the H_A proton couples with both the H_B proton (δ 1.87, dd, J=8 and J=6 Hz; $C_{(7\alpha)}$–H) and the H_C proton (δ 1.63, d, J=13 Hz; $C_{(6\alpha)}$–H). The small splittings are due to a W-letter long-range coupling between H_A and a proton on $C_{(8\beta)}$. The H_B proton couples further with the vicinal $C_{(8\beta)}$–proton (J=8 Hz). The presence of the same ABC-type spin-spin couplings was revealed for LB by INDOR experiments (Fig. 2). The H_A proton (δ 2.28, dd, J=13 and J=6.5 Hz; $C_{(6\beta)}$–H^{10}) was found to couple with both the H_B proton (δ 1.96, dd, J=9[11] and J=6.5 Hz; $C_{(7\alpha)}$–H^{10}) and the H_C proton (δ 1.69, d, J=13 Hz; $C_{(6\alpha)}$–H^{10}); the coupling constant between H_B and H_C was almost null. The structure **A** can only account for these results, excluding the structure **B** with a $C_{(5)}$–proton for LB.

Eight diastereomers (**2** and **4**—**10**) can be present for structure **A** without consideration of their enantiomers. Six of them, 1-epiguaioxide (**4**),[7,8] guaioxide (**5**),[12] bulnesoxide (**6**),[13] liguloxide (**7**),[8] 10-epiliguloxide (**8**),[8] and 1-epiliguloxide (**9**),[14] have so far been reported. None of the spectral data of the six known

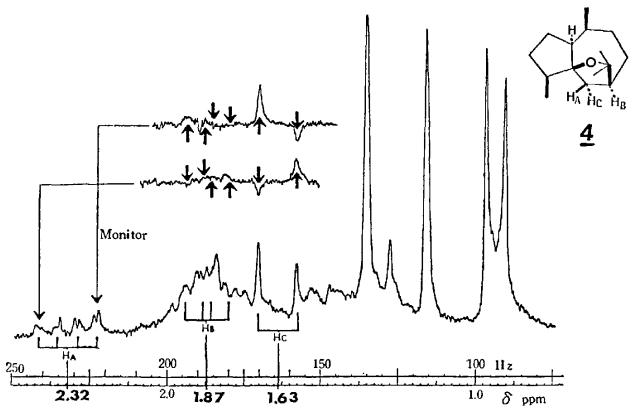


Fig. 1. INDOR experiments (100 MHz) for 1-epiguaioxide (**4**) in $CDCl_3$.

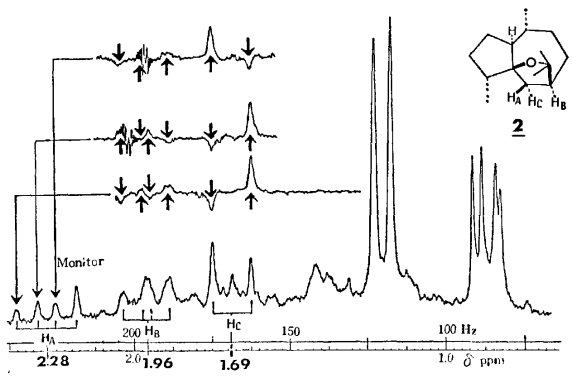

Fig. 2. INDOR experiments (100 MHz) for LB (**2**) in $CDCl_3$.

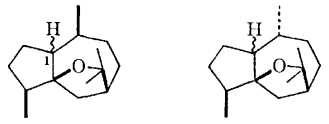
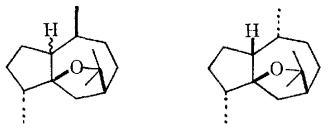
isomers are identical with those of LB. Thus, the structure of LB should be represented by either **2** or**10**, or by one of their enantiomers; the $C_{(1)}$-hydrogen atom and the $C_{(10)}$-methyl group are both oriented to the side opposite to the ether bridge for each of these structures.



5 1β-H **6** 1β-H
4 1α-H **10** 1α-H



7 1β-H **8**
9 1α-H

Treatment of guaioxide (**5**) with *N*-bromosuccinimide (NBS) gave 4-bromoguaioxide which in turn afforded 3-dehydroguaioxide.[15] When LB was heated with 1.1—1.5 equivalent mol of NBS in carbon tetrachloride under reflux, a monobromide (**11**; $C_{15}H_{25}OBr$) and the unchanged LB were obtained in 8—17% and 67—83% yields, respectively. The NMR spectrum of **11** showed the presence of a secondary methyl and three tertiary methyl groups. One of the tertiary methyl signals appearing at δ 1.76 is due to $C\underline{H}_3$–$\underset{|}{C}$–Br. The bromide (**11**) was heated under reflux with potassium hydroxide in ethanol to give an olefin (**12**; $C_{15}H_{24}O$) in 76% yield. Hydroboration of **12** afforded an alcohol (**13**, $C_{15}H_{26}O_2$; 75% yield), which was oxidized with Jones reagent to give a ketone (**14**, $C_{15}H_{24}O_2$) in 81% yield. The IR spectrum ($\nu_{C=O}$ 1740 cm^{-1}) of **14** indicated the presence of five-membered ring ketone. This shows that the bromination of LB took place on $C_{(4)}$. The ketone (**14**) isomerized on a column of alumina into a hydroxy α,β-unsaturated ketone [**15**; λ_{max} 242 nm (ε 16700)] in 93% yield.[16] The NMR spectrum of **15** showed the presence of an olefinic methyl group (δ 1.70) and the absence of olefinic proton. The formation of the conjugated cyclopentenone derivative with an α-methyl group (**15**) from the ketone (**14**) provides further support for the location of an ether oxygen atom between $C_{(5)}$ and $C_{(11)}$ (structure **A**) rather than between $C_{(1)}$ and $C_{(11)}$ (structure **B**) for LB.

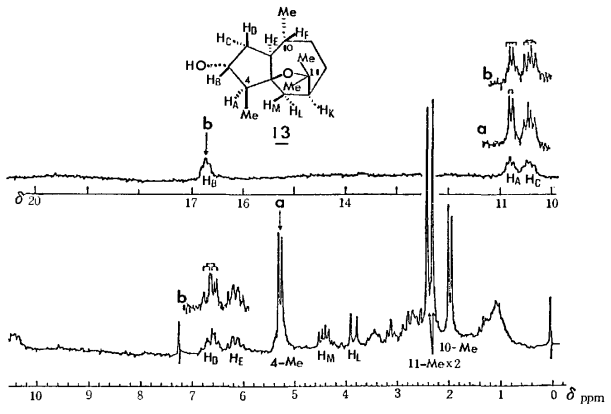


Fig. 3. NMR spectrum (100 MHz) of the alcohol (**13**) in $CDCl_3$ using $Eu(fod)_3$-d_{27} as a shift reagent [shift reagent/**13**=0.7 (M/M)]. NMDR experiments by irradiation of (a) $C_{(4)}$-CH_3 and (b) H_B are registered.

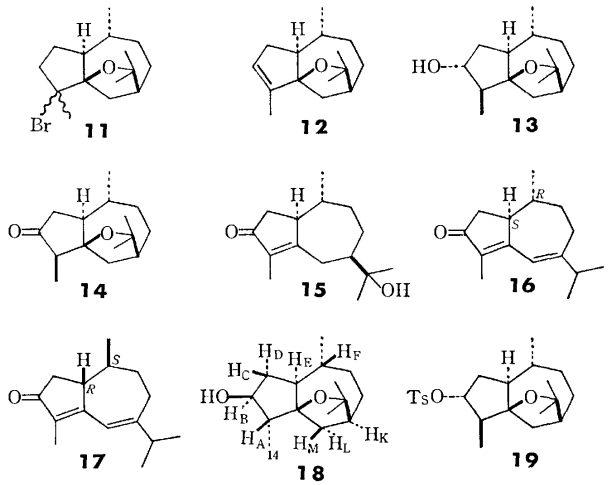
The hydroxy unsaturated ketone (**15**) was dehydrated to give an α,β: γ,δ-unsaturated ketone (**16**) quantitatively by refluxing with *p*-toluenesulfonic acid in benzene. The dienone (**16**) was found to be an enantiomer of known (1*R*,10*S*)-4,6-guaiadien-3-one (**17**)[15b] derived from guaioxide (**5**). This leads to a (1*S*,10*R*)-stereochemistry for LB and its derivatives (**11**—**16**).



The stereochemistry of the 3-hydroxy derivative (**13**) was determined as follows. Since a *cis*-relationship between the hydroxyl group and a hydrogen atom on $C_{(4)}$ is required by the mode of formation, two alternative structures, **13** and **18**, can be suggested for the alcohol. The NMR measurements using $Eu(fod)_3$-d_{27} as a shift reagent coupled with NMDR experiments lead to the assignment of signals as shown in Fig. 3, when a $C_{(2)}$-hydrogen atom *cis* to the hydroxyl group is designated as H_C. The coupling constants in a first-order approximation were determined to be $J_{A,14}$=7, $J_{A,B}$=7, $J_{B,C}$=2, $J_{B,D}$=8.5, $J_{C,D}$=13.5, $J_{C,E}$=8, $J_{D,E}$=10.5, and $J_{E,F}$=10 Hz. The structure of **13** rather than **18** is shown for the alcohol, since $J_{D,E}$ was found to be greater than $J_{C,E}$ and a large lanthanoid induced shift was observed for H_E. The structure **14** fits the ketone which exhibited a negative Cotton effect ($[\theta]_{295}$ −12900), while 3-oxo-4-epiguaioxide (3-oxoliguloxide) showed a positive Cotton effect (a +273[12]).

Hydrogenation of 3-dehydro LB (**12**) over platinum catalyst gave a saturated ether (4-epi LB) as the sole product in 60% yield, which was found to be not identical with LB; no LB was formed. The alcohol (**13**) was converted into a tosylate (**19**) in 90% yield. Treatment of **19** with lithium aluminium hydride gave a saturated ether (**10**) and the hydroxy ether (**13**) in 18 and 67% yields, respectively. Compound (**10**)

was found to be identical with 4-epi LB mentioned above. Thus, the structure of 4-epi LB is shown by **10**, in which the $C_{(4)}$-methyl group should be in a $\beta(4S)$-configuration. This leads to the structure **2** with the $C_{(4)}$-methyl group in an $\alpha(4R)$-stereochemistry for LB.

In conclusion, the structures including absolute configuration of LB and 4-epi LB are found to be (1*S*,4*R*,5*S*,7*R*,10*R*)-5,11-epoxyguaiane (**2**) and (1*S*,4*S*,5*S*,7*R*,10*R*)-5,11-epoxyguaiane (**10**), respectively. Thus, all the diastereomers (**2** and **4**—**10**) represented by **A** (5,11-epoxyguaiane) have now been recorded.

Experimental

IR and UV spectra were measured with a Hitachi EPI-G2 spectrometer and a Hitachi 340 spectrophotometer, respectively, ^{1}H-NMR spectra with a JEOL PS-100 (100 MHz), a Varian HA-100 (100 MHz), or a Hitachi R-20B (60 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, low resolution mass spectra with a Hitachi RMU-6-Tokugata mass spectrometer and high resolution mass spectra with a Hitachi RMH-2 or a JEOL D-300 mass spectrometer, with direct inlet system operating at 70 eV. CD spectra were carried out on a JASCO model J-20. For column chromatography Wakogel C-200 (Wako Pure Chemical Industries) was used. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness, and vapor-phase chromatography (VPC) on a Shimadzu gas chromatograph model GC-2C.

Isolation of LB (2). LB (**2**; 340 mg) was isolated by the reported procedure[4a] from the benzene extract of the drug (7.7 kg) in a 0.0046% yield: a colorless oil, $[\alpha]_{578}$ −45° (*c* 2.0, $CHCl_3$); IR (film): 1380, 1365, 1160, 1150, 1100, 1020, 1010, 980, and 895 cm^{-1}; NMR: δ 0.87 (3H, d, J=5.5 Hz) and δ 0.89 (3H, d, J=7.5 Hz; $C_{(4)}$-CH_3 and $C_{(10)}$-CH_3), δ 1.18 and 1.24 [each 3H, s; $C_{(11)}$-$(CH_3)_2$].

Bromination of LB (2) with NBS. NBS (1.00 g; 5.62 mmol) was added to a solution of LB (**2**, 970 mg; 4.37 mmol) in carbon tetrachloride (15 ml), and the mixture was heated under reflux for 2.5 h with an infrared lamp. The reaction mixture was cooled and filtered. After removal of solvent under reduced pressure, the resulting residue was chromatographed on a column of silica gel. Elution with petroleum ether–benzene (*ca.* 4:1) gave a 4-bromo LB (**11**, 140 mg; 11% yield), an oil, IR (film): 1150, 1020, 1000, 895, and 805 cm^{-1}; NMR: δ 0.85—0.95 (3H, diffused d; $C_{(10)}$-CH_3), δ 1.20 and 1.22 [each 3H, s; $C_{(11)}$-$(CH_3)_2$], and δ 1.76 (3H, s; $C_{(4)}$-CH_3); MS: *m/e* 302 and 300 (relative abundance, each 15%; M^+), *m/e* 287 and 285 [each 100%; $(M-CH_3)^+$], and *m/e* 221 [40%; $(M-Br)^+$]. Found: *m/e* 302.1070. Calcd for $C_{15}H_{25}O^{81}Br$: M, 302.1069. Found: *m/e* 300.1115. Calcd for $C_{15}H_{25}O^{79}Br$: M, 300.1089. Successive elution with the same solvent mixture gave the starting compound (LB; **2**, 800 mg; 82.5%). Bromide (**11**), obtained in 8—17% yields, showed one spot on thin-layer chromatogram. The NMR spectrum showed methyl signals corresponding to one configurational isomer; the configuration at $C_{(4)}$ of **11** was left undetermined.

Dehydrobromination of the 4-Bromo LB (11). The bromide (**11**; 170 mg; 0.56 mmol) in an ethanolic potassium hydroxide (KOH 350 mg, EtOH 8 ml) was heated under reflux for 1.5 h and the reaction mixture was treated in the usual way to give a residue which was chromatographed on a column of silica gel. Elution with petroleum ether–benzene (1:1) gave an olefin (3-dehydro LB; **12**; 95 mg; 76% yield), an oil, IR (film): 1155, 1010, 995, 885, and 820 cm^{-1}; NMR: δ 0.88 (3H, d, J=6 Hz; $C_{(10)}$-CH_3), δ 1.20 and 1.27 [each 3H, s; $C_{(11)}$-$(CH_3)_2$], δ 1.74 (3H, br s; $C_{(4)}$-CH_3), and δ 5.65 (1H, m; $C_{(3)}$-H); MS: *m/e* 220 (52%; M^+), *m/e* 205 [77%; $(M-CH_3)^+$], *m/e* 202 [66%; $(M-H_2O)^+$], *m/e* 187 [63%; $(C_{14}H_{19})^+$], and *m/e* 159 [100%; $(C_{12}H_{15})^+$]. Found: *m/e* 220.1824. Calcd for $C_{15}H_{24}O$: M, 220.1827.

Hydroboration of the 3-Dehydro LB (12). A solution of diborane (3 mmol) in tetrahydrofuran (3 ml) was added dropwise to a solution of the olefin (**12**, 62 mg; 0.28 mmol) in tetrahydrofuran (4 ml) under a nitrogen atmosphere. After the mixture had been stirred at room temperature for 40 min, a small quantity of water, 2 ml of 3 M aqueous solution of sodium hydroxide, and 2 ml of 30% aqueous hydrogen peroxide solution were added in succession. The resulting mixture was stirred at 50 °C for 1.5 h, and then treated in the usual way to give a residue which was chromatographed on a column of silica gel. Elution with benzene–ether (4:1) gave a 3α-hydroxy 4-epi LB (**13**, 49 mg; 75% yield), white crystals, mp 84—85 °C (crystallized from benzene); IR (KBr disk): 3250 (br), 1150, 1100, 1065, 990, 980, 890, 800, and 770 cm^{-1}; NMR: δ 0.85 (3H, diffused d; $C_{(10)}$-CH_3), δ 1.04 (3H, d, J=7 Hz; $C_{(4)}$-CH_3), δ 1.17 and 1.26 [each 3H, s; $C_{(11)}$-$(CH_3)_2$], and δ 3.93 (1H, m; $C_{(3)}$-H); the NMR spectrum with addition of $Eu(fod)_3$-d_{27} (Fig. 3); MS: *m/e* 238 (73%; M^+), *m/e* 223 [100%; $(M-CH_3)^+$], *m/e* 220 [28%; $(M-H_2O)^+$], and *m/e* 205 [64%; $(C_{14}H_{21}O)^+$]. Found: *m/e* 238.1920. Calcd for $C_{15}H_{26}O_2$: M, 238.1932.

Oxidation of 3α-Hydroxy 4-Epi LB (13). A few drops of Jones reagent were added slowly to a stirred solution of the alcohol (**13**, 25 mg; 0.10 mmol) in acetone (1 ml) at 0—10 °C, and the mixture was further stirred for 10 min at the same temperature. The reaction mixture was treated in the usual way to give a residue which was chromatographed on a column of silica gel. Elution with benzene–ether (10:1) gave a ketone (3-oxo 4-epi LB; **14**; 20 mg; 81% yield), white crystals, mp 63—64 °C (crystallized from benzene); IR: (KBr disk): 1740, 1180, 1120, 1010, 995, 990, 890, 875, and 820 cm^{-1}; CD (*c* 1.17×10^{-3}, EtOH): $[\theta]_{330}$ ±0, $[\theta]_{295}$ −12900, $[\theta]_{250}$ ±0; NMR: δ 0.89 (3H, d, J=6 Hz; $C_{(10)}$-CH_3), δ 1.03 (3H, d, J=7 Hz; $C_{(4)}$-CH_3), δ 1.16 and 1.25 [each 3H, s; $C_{(11)}$-$(CH_3)_2$], and δ 2.20 (1H, q, J=7 Hz, $C_{(4\alpha)}$-H); MS: *m/e* 236 (90%; M^+), *m/e* 221 [100%; $(M-CH_3)^+$], *m/e* 218 [29%; $(M-H_2O)^+$], and *m/e* 203 [40%; $(C_{14}H_{19}O)^+$]. Found: *m/e* 236.1786. Calcd for $C_{15}H_{24}O_2$: M, 236.1776.

Isomerization of 3-Oxo 4-Epi LB (14) on Alumina. The ketone (**14**; 10 mg; 0.04 mmol) in a small amount of ether (*ca.* 3 ml) was placed on the top of a column of neutral alumina (5 g). After 4 h, elution with ether gave a hydroxy α,β-unsaturated ketone (**15**, 9.3 mg; 93% yield) as white crystals, mp 57—58.5 °C (crystallized from AcOEt); IR (KBr disk): 3450, 3250, 1675, 1610, 1140, and 970 cm^{-1}; UV (EtOH): λ_{max} 242 nm (ε 16700); NMR: δ 1.06 (3H, d, J=5 Hz; $C_{(10)}$-CH_3), δ 1.24 and 1.28 [each 3H, s; $C_{(11)}$-$(CH_3)_2$], and δ 1.70 (3H, s; $C_{(4)}$-CH_3); MS: *m/e* 236 (1%; M^+), *m/e* 221 [5%; $(M-CH_3)^+$], *m/e* 218 [100%; $(M-H_2O)^+$], and *m/e* 178 [18%; $(C_{12}H_{18}O)^+$]. Found: *m/e* 236.1783. Calcd for $C_{15}H_{24}O_2$: M, 236.1776.

Dehydration of the Hydroxy α,β-Unsaturated Ketone (15). *p*-Toluenesulfonic acid (18 mg; 0.10 mmol) was added to a solution of the hydroxy α,β-unsaturated ketone (**15**, 8.5 mg; 0.036 mmol) in benzene (5 ml) and the solution was heated under reflux for 1.5 h under a nitrogen atmosphere. The

reaction mixture was treated in the usual way to give a single product, (1*S*, 10*R*)-4,6-guaiadien-3-one (**16**; 7.6 mg; quantitative yield), an oil; IR (film): 1690, 1625, 1590, 1340, 1285, 1055, and 875 cm^{-1}; UV (EtOH): λ_{max} 293 nm (ε 20800); CD (c 3.50×10^{-4}, EtOH): $[\theta]_{365}$ ±0, $[\theta]_{295}$ −20300, $[\theta]_{240}$ ±0; NMR: δ 1.06 (3H, d, J=6 Hz; $C_{(10)}$-CH_3), δ 1.09 [6H, d, J=7 Hz; $C_{(11)}$-$(CH_3)_2$], δ 1.75 (3H, s; $C_{(4)}$-CH_3), and δ 6.35 (1H, br s; $C_{(6)}$-H); MS: *m/e* 218 (100%; M^+), *m/e* 203 [27%; $(M-CH_3)^+$], and *m/e* 175 [37%; $(M-C_3H_7)^+$]. Found: *m/e* 218.1682. Calcd for $C_{15}H_{22}O$: M, 218.1671.

The IR, UV, NMR, and mass spectra of **16** were found to be identical with those of known (1*R*, 10*S*)-4,6-guaiadien-3-one (**17**).[15b] The dienone (**16**) exhibits a negative Cotton effect and **17** a positive CD maximum ($[\theta]_{295}$ +18300).[15b]

Hydrogenation of 3-Dehydro LB (12). 3-Dehydro LB (**12**, 15 mg; 0.07 mmol) and platinum catalyst (prepared from platinum oxide; 10 mg) in a mixture of ethyl acetate (5 ml) and acetic acid (0.3 ml) were stirred under a hydrogen atmosphere at room temperature for 5 h. The catalyst was removed by filtration and the solvents evaporated to give a residue, which was purified by chromatography on a column of silica gel. Elution with petroleum ether–benzene (5:1) gave 4-epi LB (**10**, 9 mg; 60% yield). No LB (**2**) was obtained. On VPC examination (7% SE-30; 2.3 m; 125 °C; N_2 50 ml/min), the retention time of 4-epi LB (**10**) was found to be 12.3 min, and that of authentic LB (**2**) 11.1 min under the same conditions. 4-Epi LB (**10**), an oil; IR (film): 1150, 1140, 1020, 995, and 895 cm^{-1}; NMR: δ 0.85 (3H, diffused d) and δ 0.95 (3H, d, J=6 Hz; $C_{(4)}$-CH_3 and $C_{(10)}$-CH_3), δ 1.19 and 1.29 [each 3H, s; $C_{(11)}$-$(CH_3)_2$], and δ 2.15 (1H, dd, J=5 Hz and 12 Hz; $C_{(6\beta)}$-H); MS: *m/e* 222 (20%; M^+), *m/e* 207 [100%; $(M-CH_3)^+$], *m/e* 189 [40%; $(C_{14}H_{21})^+$], and *m/e* 164 [45%; $(C_{12}H_{20})^+$]. Found: *m/e* 222.1948. Calcd for $C_{15}H_{26}O$: M, 222.1983.

Tosylation of 3α-Hydroxy 4-Epi LB (13). A mixture of the alcohol (**13**, 49 mg; 0.21 mmol) and *p*-toluenesulfonyl chloride (100 mg; 0.53 mmol) in dry pyridine (1 ml) was left at 0 °C for 72 h under a nitrogen atmosphere. After the usual treatment, a tosylate (**19**, 75 mg; 90% yield) was obtained as white crystals. 3α-Tosyloxy 4-epi LB (**19**), mp 119—121 °C (dec.) (crystallized from MeOH–$CHCl_3$); IR (KBr disk): 1640 (w), 1335, 1175, 1100, 985, 955, and 865 cm^{-1}; NMR: δ 0.82 (3H, d, J=4 Hz) and δ 0.83 (3H, d, J=7 Hz; $C_{(4)}$-CH_3 and $C_{(10)}$-CH_3), δ 1.14 and 1.28 [each 3H, s; $C_{(11)}$-$(CH_3)_2$], δ 2.46 (3H, s; aromatic CH_3), δ *ca.* 4.5 (1H, m; $C_{(3\beta)}$-H), and δ 7.37 and 7.84 (each 2H, d, J=8.5 Hz; aromatic H's); MS: *m/e* 392 (1%; M^+), *m/e* 377 [2%; $(M-CH_3)^+$], *m/e* 237 [95%; $(C_{15}H_{25}O_2)^+$], *m/e* 220 [49%; $(C_{15}H_{24}O)^+$], and *m/e* 205 [100%; $(C_{14}H_{21}O)^+$]. Found: *m/e* 392.2021. Calcd for $C_{22}H_{32}O_4S$: M, 392.2021.

Reaction of the Tosylate (19) with Lithium Aluminium Hydride. A mixture of the tosylate (**19**, 20 mg; 0.05 mmol) and lithium aluminium hydride (50 mg; 1.3 mmol) in dry tetrahydrofuran (6 ml) was heated under reflux for 10 h under a nitrogen atmosphere. The reaction mixture was treated in the usual way to give a residue, which was chromatographed on a column of silica gel. Elution with benzene gave 4-epi LB (**10**, 2 mg; 18% yield), identical [TLC, VPC (SE-30), IR, and MS] with an authentic specimen. Successive elution with benzene–ether (2:1) gave 3α-hydroxy 4-epi LB (**13**, 8 mg; 67% yield).

The authors wish to thank Dr. Ken'ichi Takeda, Dr. Kazuo Tori, and Dr. Hiroshi Ishii, Shionogi Research Laboratory, Osaka, and the late Dr. Yasuji Fujita, Government Industrial Institute, Osaka, for their valuable discussions. Thanks are also due to Dr. Hiroshi Ishii for the supply of spectral data of the diastereomers (**4**, **6**, **8**, and **9**) of guaioxide.

Optical Resolutions and Configurations of Benzylmethylphenylsilylmethylamine and Its Derivatives

Daiyo Terunuma,* Katsutoshi Murakami, Masanori Kokubo, Kazuhisa Senda, and Hiroyuki Nohira

Department of Applied Chemistry, Faculty of Engineering, Saitama University, Urawa, Saitama 338

(Received September 10, 1979)

New optically active α-amino organosilanes, such as benzylmethylphenylsilylmethylamine, benzylmethyltolylsilylmethylamines, and anisylbenzylmethylsilylmethylamines, were obtained by the fractional crystallization of the salts of the amines and (+)-tartaric acid. Benzylmethylphenylsilylmethylamine was converted into benzylmethyl-1-naphthylphenylsilane, of which the configuration had been known. From these observations, it was found that benzylmethylphenylsilylmethylamine, benzylmethylphenylsilane, and benzylmethoxymethylphenylsilane had *S*(+), *S*(−), and *S*(+) configurations respectively.

The progress of the stereochemistry of organosilicon compounds owes much to the studies of L. H. Sommer and his co-workers of the reaction mechanism of the asymmetric silicon center using the optically active methyl-1-naphthylphenylsilyl systems.[1] However, only a few successful methods for obtaining optically active organosilanes in a high optical purity have been reported.[2] The difficulty of the resolution of organosilanes can be ascribed in part to the nature of their poor crystallizability. On the other hand, in the course of our studies of the synthesis of silacyclopentane derivatives, it was found that *trans*-3,3,5-trimethyl-3-silacyclopentylamine formed crystalline salts with (+)-tartaric acid.[3] In this paper, we wish to describe the resolution[4] of such α-amino silanes as benzylphenylmethylsilylmethylamine (**2a**), benzylmethyl-(*p*-, *m*-, *o*-)-tolysilylmethylamine(**2b**, **2c**, **2d**), (*p*-, *o*-)-anisylbenzylmethylsilylmethylamine(**2e**, **2f**), and benzylbutylmethylsilylmethylamine(**2g**) by using (+)-tartaric acid as a resolving reagent, and to describe the chemical interconversion of **2a** into benzyl-1-naphthylphenylmethylsilane.

Results and Discussion

Optical Resolution. The α-chlorosilanes (**1a**—**1g**) were synthesized by the step-by-step treatment of dichloromethylsilylmethyl chloride with the corresponding Grignard reagents. Then the chlorides were treated with excess ammonia in a stainless steel autoclave for 1.5 h at 100 °C.[4,6] The α-amino silanes (**2a**—**2g**) were obtained in 50—60% yields (Scheme 1 and Table 1).

Fig. 1. Fractional crystallization of **2a**.

The optical resolutions of the amine **2** were carried out by using (+)-tartaric acid as the resolving reagent (Table 2). Since the less soluble salts obtained by the method of fractional crystallization appeared to be unstable in methanol solution above 40 °C, further recrystallization of the salts was not undertaken. Instead, the partially resolved amines, which had been liberated from the less soluble salts by treating them with a caustic alkali solution, were treated with an equimolar amount of (+)-tartaric acid in methanol. Some typical results of the resolution of **2a** are shown in the flowing chart (Fig. 1). The optical resolutions

Table 4. The dependence of the specific rotations of the salts on the concentration in DMF

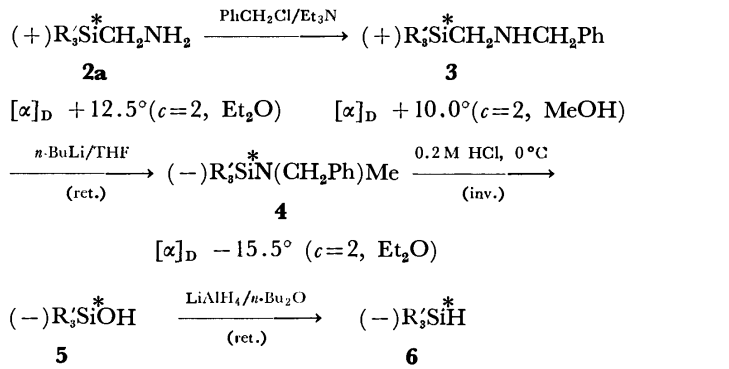
	$[\alpha]_D$(°)		
	c=1	c=2	c=4
2a	+30.8	+38.0	+40.7
2b	−40.0	−41.5	—
2c	+23.0	+28.0	+34.5
2d	+10.6	+14.5	+25.5

were carried out in this manner until the specific rotations of the salts became constant (Table 3).

In the course of these experiments, it was noticed that the specific rotation of the salts changed remarkably in their dependence on the concentration of the salts in DMF (Table 4).

The partial discrepancy of the data in Table 3 with that of our preliminary communication[4] may result from the variability in the specific rotation of the salts. The optical purities of the **2a**—**2f** obtained from the first step of fractional crystallization (Table 2) were 75, 64, 93, 82, 66, and 81% respecitvely, based on the corresponding specific rotations in Table 3. These results indicate that the optically active organosilanes obtained from the first step of resolution are quite sufficient to be used for stereochemical studies.

Chemical Conversion of 2a. Recently, an interesting intramolecular rearrangement reaction which converts α-aminosilanes, such as *N*-benzyl- and *N*-cyclohexyltrimethylsilylmethylamine, into aminosilanes appeared in the literature.[7] We considered that



Scheme 2.

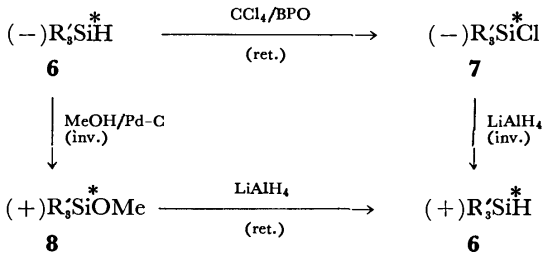
this reaction could be used to convert the optically active amine **2a** ($R'_3SiCH_2NH_2$) into siliconfunctional aminosilane. In this section, we wish to describe our attempt at the chemical interconversion of **2a** into benzylmethyl-1-naphthylphenylsilane (**9**), the absolute configuration of which is known.[5]

(+) - *N* - Benzylbenzylmethylphenylsilylmethylamine (**3**) was obtained by treating the (+)-**2a** with an equimolar amount of benzyl chloride in triethylamine. After the mixture of (+)-**3** and butyllithium in THF had been stirred 10 h at room temperature, (−)-*N*-benzyl-*N*-methylbenzylmethylphenylsilylamine (**4**) was obtained in a good yield. Although the steric course of this reaction has not yet been established, it may be assumed that this reaction proceeds with a retention of the configuration by considering to be an intramolecular rearrangement.[7] Then (−)-**4** was treated with 0.2 M (1 M=1 mol dm^{-3}) HCl at 0 °C to give (−)-benzylmethylphenylsilanol (**5**). It was observed that considerable racemization took place when the reaction was carried out at a temperature above 0 °C. The reduction of (−)-**5** with $LiAlH_4$ in dibutyl ether gave (−)-benzylmethylphenylsilane (**6**). The stereochemistry of these two reactions has been clarified by using methyl-1-naphthylphenylsilyl systems; *i.e.*, the former proceeds with inversion,[8] while the latter proceed with a retention of configuration[9] (Scheme 2).

Although optically active silane (**6**) had already been obtained by the partial reduction of (±)-benzylmethoxymethylphenylsilane (**8**) with asymmetric reduc-

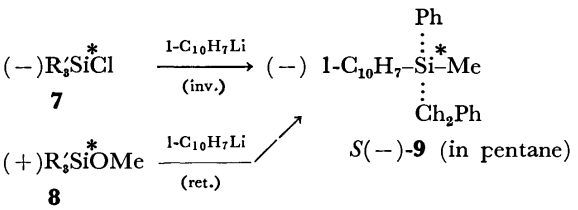
tion reagents, *i.e.*, $LiAlH_4$–alkaloid systems, the specific rotation of **6** reported in the litrature is $-7.8°$,[10] which corresponds to the optical purity of 40% (e.e.) based on our sample $[\alpha]_D$ $-17.8°$ ($c=2$, Et_2O).

Some reactions of (−)-**6** were carried out in order to establish its configuration (Scheme 3). The chlorination of (−)-**6** in CCl_4 in the presence of a small amount of benzoyl peroxide[11] gave (−)-benzyl(chloro)methylphenylsilane (**7**). On the other hand, the methanolysis of (−)-**6** in the presence of Pd-C in pentane[12] at 0 °C afforded (+)-**8**. The reduction of (−)-**7** and (+)-**8** by $LiAlH_4$ in ether gave (+)-**6**. These results are in accordance with those of similar reactions of the methyl-1-naphthylphenylsilyl systems reported in the literature.[11,12]



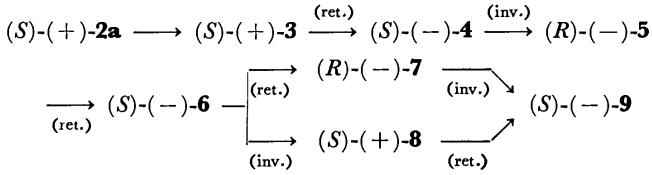
Scheme 3.

Further, the reactions of (−)-**7** and (+)-**8** with 1-naphthyllithium in ether were carried out; both reactions gave the same product, *i.e.*, (*S*)-(−)-benzylmethyl-1-naphthylphenylsilane (**9**)[5] (Scheme 4).



Scheme 4.

From these observations, it has become apparent that **7** and **8** have the *R*(−) and *S*(+) configurations respectively. Consequently, the configurations of the benzylmethylphenylsilyl systems treated in this paper are assigned as follows Scheme 5:

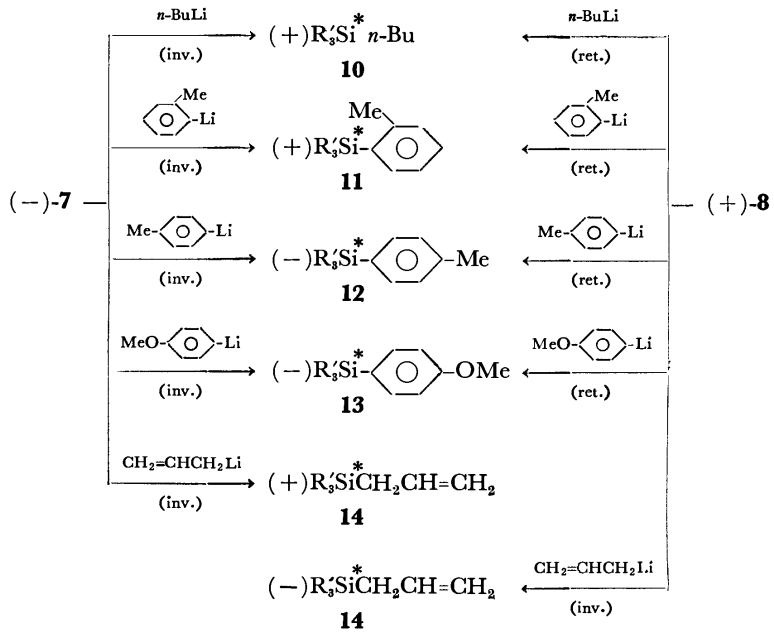


Scheme 5.

However, our results on the configuration of **6** and **8** are not in accordance with those of the previously reported assignments.[10,13] The configuration of **8** was previously determined based on the inversion reaction of **8** with the Grignard reagent of 1-bromonaphthalene in ether. Unfortunately, we could not succeed in following the reaction of **8** with 1-naphthylmagnesium bromide in ether. Therefore, some reactions of (−)-**7** and (+)-**8** with such organolithium reagents as butyllithium, (*p*-, *o*-)-tolyllithium, *p*-anisyllithium, and allyllithium were carried out in order to investigate the steric course of these reactions (Scheme 6).

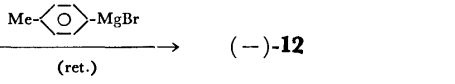
From these observations, it is clear that the reactions of the alkyl- and the aryllithium with (+)-**8** proceed with a retention of the configuration, whereas that of allyllithium with (+)-**8** proceeds with an inversion of the configuration, if the reactions of the organolithium reagents with (−)-**7** are assumed to proceed with an inversion of the configuration. These results are in fair agreement with those for methyl-1-naphthylphenylsilyl systems.[14]

On the other hand, when the reaction of *p*-tolylmagnesium bromide with (+)-**8** was carried out, (−)-**12** was obtained as the product. Although it has been described in the literature[13] that the reactions



Scheme 6.

of such aryl Grignard reagents as mesityl-, and 1-naphthylmagnesium bromide with a methoxysilane proceed with an inversion of the configuration, our results indicate that the Grignard reaction with (+)-**8** proceeds with a retention of the configuration (Scheme 7). Many detailed studies of the Grignard reactions with (+)-**8** are in progress.



(+)-**8** → (−)-**12**

Experimental

The melting points and boiling points are uncorrected. The IR spectra were determined with a JASCO IR-A2 spectrometer. The NMR spectra were determined at 60 MHz with a Varian A-60D spectrometer in CCl_4, using TMS as the internal standard. The optical rotations were measured with a JASCO DIP-181 polarimeter. All the reactions of the chlorosilanes and the methoxysilane with Grignard and organolithium reagents were carried out under a dry nitrogen atmosphere. The column chromatography was carried out using silica gel (200 mesh).

*Benzylmethylphenylsilylmethyl Chloride (**1a**).* In a three-necked flask, equipped with a magnetic stirrer and a reflux condenser, dichloromethylsilylmethyl chloride (114.5 g, 0.7 mol) and dry ether (150 ml) were placed. To the flask was added the Grignard reagent prepared from bromobenzene (121.2 g, 0.77 mol) and Mg (20 g, 0.82 mol) in ether (150 ml). The mixture was refluxed for 3 h with stirring. After the subsequent addition of THF (70 ml) to the mixture, the Grignard reagent prepared from benzyl chloride (96.6 g, 0.77 mol) and Mg (20 g, 0.82 mol) in ether (150 ml) was added, and the mixture was refluxed a further 5 h with stirring. Then the mixture was hydrolyzed with dil HCl. The organic layer was washed with water and dried ($CaCl_2$). Subsequent evaporation and distillation gave **1a** in 90% (164.6 g) yield. Bp 153—157 °C/3 Torr. NMR δ 0.30 (s, 3, Si-CH_3), 2.43 (s, 2, CH_2-Ph), 2.88 (s, 2, CH_2-Cl), 7.3—7.7 (m, 10, Ph).

The compounds (**1b**—**1g**) were obtained in manners similar to that described above. The yields and boiling points are as follows (yield (%), Bp (°C/Torr)): **1b** 74, 171—172/1, **1c** 78, 160—163/1, **1d** 64, 158—162/2, **1e** 78, 165—169/3, **1f** 77, 150—156/3, **1g** 87, 132/25.

*Benzylmethylphenylsilylmethylamine (**2a**).* In a stainless steel autoclave (200 ml), **1a** (26.8 g, 0.10 mol) and liquid ammonia (70 g, 4.1 mol) were added under a nitrogen atmosphere. The autoclave was then maintained for 1.5 h at 100 °C. The excess ammonia was liberated from the autoclave, and the contents were washed out with aqueous alkali (52 g, NaOH/ 300 ml H_2O) and benzene. The organic layer was separated, washed with aqueous alkali several times, and dried (Na_2SO_4). Subsequent evaporation and distillation gave **2a** in a 66% (16.5 g) yield. Bp 160—163 °C/4 Torr. IR (neat) 3400, 3300 cm^{-1} (w, -NH_2), 1250 cm^{-1} (s, Si-CH_3). NMR δ 0.32 (s, 3, Si-CH_3), 1.20 (s, 2, NH_2), 2.33 (s, 4, Si-CH_2-Ph, Si-CH_2-N), 6.7—7.5 (m, 10, Ph). Found: N, 5.74%. Calcd for $C_{15}H_{19}NSi$: N, 5.80%.

The amines (**2b**—**2g**) were obtained in manners similar to that described above. The boiling points and yields of the amines are listed in Table 1. **2b** NMR δ 0.14 (s, 3, Si-CH_3), 1.30 (s, 2, NH_2), 2.15—2.30 (7, CH_3-Ph, Si-CH_2Ph, Si-CH_2-N), 6.7—7.4 (m, 9, Si-C_6H_4-, Si-Ph). Found: N, 5.34%. Calcd for $C_{16}H_{21}NSi$: N, 5.48%. **2c** NMR δ 0.20 (s, 3, Si-CH_3), 0.57 (s, 2, NH_2), 2.10—2.25 (7, CH_3-Ph, Si-CH_2-Ph, Si-CH_2-N), 6.4—7.0 (m, 9, Si-C_6H_4-, Ph). Found: N, 5.54%. Calcd for $C_{16}H_{21}NSi$: 5.48%. **2d** NMR δ 0.26 (s, 3, Si-CH_3), 0.77 (s, 2, NH_2), 2.30—2.40 (7, CH_3-Ph, Si-CH_2-Ph, Si-CH_2-N), 6.6—7.4 (m, 9, Si-C_6H_4-, Ph). Found: N, 5.38%. Calcd for $C_{16}H_{21}NSi$: N, 5.48%. **2e** NMR δ 0.27 (s, 3, Si-CH_3), 1.63 (s, 2, NH_2) 2.4 (4, Si-CH_2-C, Si-CH_2-N), 3.80 (s, 3, O-CH_3), 6.8—7.5 (m, 9, Si-C_6H_4-, Ph). Found: N, 5.22%. Calcd for $C_{16}H_{21}NOSi$: N, 5.16%. **2f** NMR δ 0.20 (s, 3, Si-CH_3), 1.68 (s, 2, NH_2), 2.4 (4, Si-CH_2-C, Si-CH_2-N), 3.78 (s, 3, O-CH_3), 6.6—7.5 (m, 9, Si-C_6H_4-, Ph). Found: N, 5.21%. Calcd for $C_{16}H_{21}NOSi$: N, 5.16%. **2g** NMR δ 0.29 (s, 3, Si-CH_3), 0.62—1.67 (m, 11, Si-Bu, NH_2), 2.39 (s, 2, Si-CH_2-N), 7.3—7.5 (m, 5, Ph).

*Optical Resolution of **2a**.* To the solution of (+)-tartaric acid (8.18 g, 0.054 mol) in methanol (600 ml) in a 1 litre Erlenmeyer flask was added a solution of (+)-**2a** (13.05 g, 0.054 mol) in methanol (13 ml). A white crystalline precipitate started to separate almost immediately. The flask was then allowed to stand overnight at room temperature. The crystalline precipitate was filtered off, washed with a small amount of cold methanol, and then dried *in vacuo*. To the salt we added a 10% aqueous solution of NaOH at 0 °C. The liberated amine was extracted three times with 30 ml portions of ether. The extract was then dried (Na_2SO_4). Evaporation and distillation gave (+)-**2a** in a 35% (4.6 g) yield. $[\alpha]_D$ +9.5° (c=4, Et_2O).

The resolution of **2b**—**2g** were carried out in manners similar to that described above; the yields and specific rotations are shown in Table 2.

*(+)-N-Benzylbenzylmethylphenylsilylmethylamine (**3**).* A solution of **2a** (17.5 g, 0.0726 mol) $[\alpha]_D$ +12.5° (c=2, Et_2O), benzyl chloride (9.2 g, 0.0727 mol), and triethylamine (22.0 g,

0.257 mol) was stirred for 5 h at 100 °C. A large amount of a white solid was precipitated at the end of the reaction. Into the reaction mixture, water (20 ml) and hexane (100 ml) were then added. The organic layer was separated, washed with a 10% NaOH solution until the white precipitate could not be observed, and then dried (Na_2SO_4). Evaporation and distillation gave (+)-**3**. Bp 155—160 °C/0.07 Torr. Yield, 20.1 g (83.6%). $[\alpha]_D$ +10.0° (c=2, MeOH). NMR δ 0.25 (s, 3, Si-CH_3), 1.05 (broad s, 1, NH), 2.30 (s, 2, Si-CH_2-N), 2.40 (s, 2, Si-CH_2-Ph), 3.75 (s, 2, N-CH_2-Ph), 7.0—7.5 (m, 15, Ph). Found: N, 4.32%. Calcd for $C_{22}H_{25}NSi$: N, 4.22%.

(−)-N-Benzyl-N-methylbenzylmethylphenylsilylmethylamine (4). To a solution of (+)-**3** (20.1 g, 0.0606 mol) $[\alpha]_D$ +10.0 (c=2, MeOH), in THF (150 ml) we added *n*-BuLi (5 ml of a 10% wt/v hexane solution, *ca.* 8 mmol) by means of a syringe under a nitrogen atmosphere. The color of the solution changed to red immediately. After the solution had been stirred for 10 h at room temperature, water (50 ml) was added to the red solution. The organic layer was separated, washed with water, and then dried (K_2CO_3). Subsequent evaporation and distillation gave (−)-**4**. Bp 150 °C/0.04 Torr. Yield, 15.5 g (77.1%). $[\alpha]_D$ −15.5° (c=2, Et_2O). NMR δ 0.32 (s, 3, Si-CH_3), 2.36 (s, 3, N-CH_3), 2.52 (d, 2, Si-CH_2-Ph), 3.86 (s, 2, N-CH_2-Ph), 6.8—7.7 (m, 15, Ph). Found: N, 4.38%. Calcd for $C_{22}H_{25}NSi$: N, 4.22%.

(−)-Benzylmethylphenylsilanol (5). A solution of (−)-**4** (15.8 g, 0.0477 mol) $[\alpha]_D$ −15.5° (c=2, Et_2O) in ether (150 ml) was treated with 0.2 M HCl (150 ml) in a separating funnel at 0 °C. The organic layer was washed with water and then dried (K_2CO_3). Evaporation of the solvent gave (−)-**5**. The silanol, (−)-**5**, was used in the next reaction without further purification. $[\alpha]_D$ −13.2° (c=2, Et_2O). IR (neat) 3250 cm^{-1} (OH). NMR δ 0.25 (s, 3, Si-CH_3), 2.30 (s, 2, Si-CH_2-Ph), 2.7—3.0 (1, OH), 6.8—7.5 (m, 10, Ph).

(−)-Benzylmethylphenylsilane (6). A solution of (−)-**5**, obtained from the experiment described above, in dibutyl ether was added to a suspension of $LiAlH_4$ (6.0 g, 0.158 mol) in ether (150 ml). The mixture was kept at 90 °C for 30 min and then the solvent was removed. Then the mixture was stirred for 3 h at 140—145 °C. After satu. aqueous Na_2SO_4 had been carefully added to the mixture with ice cooling, the organic layer was separated, washed with dil HCl with water, and then dried ($CaCl_2$). Subsequent evaporation and distillation gave (−)-**6**. Bp 150—154 °C/20 Torr. Yield, 8.0 g (79.2% based on (−)-**4**). $[\alpha]_D$ −17.8° (c=2, Et_2O). IR (neat) 2100 cm^{-1} (Si-H). NMR δ 0.29 (d, J=3.5 Hz, 3, Si-CH_3), 2.34 (d, 2, Si-CH_2-Ph), 4.43 (sixted, 1, Si-H), 6.8—7.5 (m, 10, Ph).

(−)-Benzyl(chloro)methylphenylsilane (7). A solution of (−)-**6** (1.0 g, 0.0047 mol) and BPO (84 mg, 0.3 mmol) in CCl_4 (5 ml) was sealed in a sample tube under nitrogen atmosphere. The tube was then maintained for 11 h at 80 °C. The subsequent evaporation of the solvent gave (−)-**7**, $[\alpha]_D$ −25.0° (c=1, CCl_4). From the IR spectrum of the product, it was observed that the product contained about 10% of unreacted (−)-**6**. The chlorosilane (−)-**7** was extremely moisture-sensitive, and racemization occurred immediately in the presence of a trace of moisture. The product was used without further purification.

(+)-Benzylmethoxymethylphenylsilane (8). To a mixture of (−)-**6** (2.0 g, 0.0094 mol) $[\alpha]_D$ −17.8° (c=2, Et_2O), 5% Pd-C (0.2 g) in pentane (20 ml) we added methanol (1.0 g, 0.031 mol) at 0 °C. The evolution of hydrogen occurred over a period of 3 h. After bubbling had stopped, the reaction mixture was filtered to remove the catalyst. Subsequent evaporation and distillation gave (+)-**8**. Bp 158—160 °C/20 Torr. Yield, 1.8 g (78.9%). $[\alpha]_D$ +4.4° (c=2, pentane), $[\alpha]_D$ +5.3° (c=2, Et_2O). NMR δ 0.24 (s, 3, Si-CH_3), 2.32 (s, 2, Si-CH_2-Ph), 3.60 (s, 3, O-CH_3), 6.8—7.6 (m, 10, Ph).

When the reaction was carried out at a temperature above 0 °C, it was observed that racemization took place.

Reduction of (−)-7 with $LiAlH_4$. To a suspension of $LiAlH_4$ (1 g, 0.026 mol) in ether (15 ml) was added (−)-**7**, $[\alpha]_D$ −18.9° (c=2, CCl_4). The mixture was refluxed for 2 h with stirring and then hydrolyzed with satur. Na_2SO_4. The organic layer was separated, washed with dil HCl, water, and then dried ($CaCl_2$). Subsequent evaporation and distillation gave (+)-**6**. Bp 150 °C/20 Torr. Yield, 0.45 g (45%). $[\alpha]_D$ +8.3° (c=2, Et_2O). The IR spectrum of the product was identical with that of (−)-**6**.

Reduction of (+)-8 with $LiAlH_4$. A solution of (+)-**8** (2.0 g, 0.0083 mol) $[\alpha]_D$ +2.7° (c=2, Et_2O) in ether (20 ml) was added to a suspension of $LiAlH_4$ (1 g, 0.026 mol) in ether (15 ml). The mixture was then refluxed for 3 h, followed by hydrolysis with satur. Na_2SO_4. The organic layer was separated, washed, and then dried ($CaCl_2$). Subsequent evaporation and distillation gave (+)-**6**. Yield, 1.5 g (86%). $[\alpha]_D$ +7.6° (c=2, Et_2O). The IR spectrum of the product was identical with that of (−)-**6**.

Reaction of (−)-7 with 1-Naphthyllithium. To a solution of 1-bromonaphthalene (2 g, 0.0097 mol) in ether (100 ml) we added *n*-BuLi (4 ml of a 10% wt/v solution in hexane, *ca.* 0.0063 mol) by means of a syringe under a nitrogen atmosphere.[15] The mixture was then stirred for 30 min at room temperature. After a solution of (−)-**7** (1.0 g, 0.0047 mol) $[\alpha]_D$ −15.0° (c=1, CCl_4) in ether (5 ml) had been added to this mixture, it was stirred for 4 h at room temperature and then hydrolyzed. The organic layer was separated, washed with dil HCl, water, and then dried ($CaCl_2$). The subsequent evaporation of the solvent gave a pale yellow residue. Column chromatography of the residue was carried out (silica gel, hexane:benzene=4:1). The eluent was evaporated, and the viscous residue was distilled. Bp 182 °C/0.08 Torr. Yield, 0.8 g (54%). $[\alpha]_D$ −2.0° (c=3, pentane) (lit,[5] $[\alpha]_D$ −6.68° (c=2.8, pentane)). IR (neat) 1595, 1495, 1210, 985 cm^{-1}. NMR δ 0.57 (s, 3, Si-CH_3), 2.81 (s, 2, Si-CH_2-Ph), 6.7—8.1 (m, 18, Ph, 1-$C_{10}H_7$).

Reaction of (+)-8 with 1-Naphthyllithium. To a solution of 1-naphthyllithium prepared from 2 g (0.0097 mol) of 1-bromonaphthalene in ether (100 ml) and 4 ml of 10% wt/v *n*-BuLi in hexane as described above, we added (+)-**8** (1.0 g, 0.0041 mol) $[\alpha]_D$ +2.1° (c=2, pentane) in ether (5 ml). After the mixture had been stirred for 4 h at room temperature, it was hydrolyzed. The organic layer was separated, washed with dil HCl, water, and then dried ($CaCl_2$). The subsequent evaporation of the solvent gave an oily product. Chromatography (silica gel, hexane:benzene=4:1) and subsequent distillation gave (−)-**9**. Bp 191 °C/0.1 Torr. $[\alpha]_D$ −1.9° (c=2, pentane). The IR spectrum of the product was identical with that of (−)-**9**, obtained from the reaction of (−)-**7** with 1-naphthyllithium.

Reaction of (−)-7, and (+)-8 with n-BuLi. To a solution of (−)-**7**, $[\alpha]_D$ −19.0° (c=3, CCl_4), prepared from (−)-**6** (1 g, 0.0047 mol), $[\alpha]_D$ −13.5° (c=2, Et_2O) in ether (100 ml) we added 4 ml of a 10% wt/v solution of *n*-BuLi by means of a syringe at 0 °C. After having been stirred for 1 h at 0 °C, the mixture was hydrolyzed. The usual work-up of the mixture gave (+)-**10**. Bp 155—160 °C/14 Torr. Yield, 67.2%. $[\alpha]_D$ +5.0° (c=3, CH_2Cl_2). NMR

δ 0.20 (s, 3, Si-CH_3), 0.5—1.5 (m, 9, Bu), 2.28 (s, 2, Si-CH_2-Ph), 6.7—7.5 (m, 10, Ph). The reaction of (+)-**8** (1 g, 0.0041 mol) $[\alpha]_D$ +2.7° (c=2, Et_2O) with n-BuLi was carried out in the same manner. The compound (+)-**10** was thus obtained in a 72% (0.8 g) yield. $[\alpha]_D$ +5.8° (c=3, CH_2Cl_2). The IR and NMR spectra of the product were identical with those of (+)-**10**, obtained from the reaction of (−)-**7** with n-BuLi, as has been described above.

Reaction of (−)-7, and (+)-8 with o-*Tolyllithium.* To a solution of o-bromotoluene (1 g, 0.0058 mol) in ether (70 ml) we added 3 ml (*ca.* 0.0047 mol) of a 10% wt/v hexane solution of butyllithium by means of a syringe.[16] After the mixture has been stirred for 30 min at room temperature, (−)-**7** (1 g, 0.0041 mol) $[\alpha]_D$ −10.6° (c=2, CCl_4) in ether (5 ml) was added to the mixture at 0 °C. The usual work-up of the mixture gave (+)-**11** in a 75% (0.92 g) yield. Bp 155 °C/0.2 Torr. $[\alpha]_D$ +5.0° (c=4, CH_2Cl_2). NMR δ 0.43 (s, 3, Si-CH_3), 2.18 (s, 3, C-CH_3), 2.64 (s, 2, Si-CH_2-Ph), 6.7—7.5 (m, 10, Ph).

The reaction of (+)-**8** (1.0 g, 0.0041 mol) $[\alpha]_D$ +2.7° (c=2, Et_2O) with o-tolyllithium was carried out in a similar manner. The compound (+)-**11** was obtained in an 80% (0.99 g) yield. $[\alpha]_D$ +7.3° (c=2, CH_2Cl_2). The IR and NMR spectra of the product were identical with those of the product obtained by the reaction of (−)-**7** with o-tolyllithium.

Reaction of (−)-7, and (+)-8 with p-*Tolyllithium.* To a solution of p-bromotoluene (1.0 g, 0.0058 mol) in ether (100 ml) we added 3 ml (*ca.* 0.0047 mol) of a 10% wt/v hexane solution of butyllithium.[15] The mixture was stirred for 20 min at room temperature, and then (−)-**7** (1.0 g, 0.0041 mol) $[\alpha]_D$ −17.5° (c=1, CCl_4) was added to the mixture at 0 °C. The usual work-up of the mixture gave (−)-**12** in a 58% (0.7 g) yield. Bp 160 °C/0.2 Torr. $[\alpha]_D$ −4.5° (c=2, CH_2Cl_2). NMR δ 0.41 (s, 3, Si-CH_3) 2.33 (s, 3, C-CH_3), 2.55 (s, 2, Si-CH_2-Ph), 6.7—7.5 (m, 10, Ph).

The reaction of (+)-**8** (1.0 g, 0.0041 mol) $[\alpha]_D$ +4.4° (c=2, pentane) with p-tolyllithium was carried out in a similar manner. The compound (−)-**12** was thus obtained in a 48% (0.6 g) yield. $[\alpha]_D$ −5.5° (c=2, CH_2Cl_2).

Reaction of (−)-7, and (+)-8 with p-*Anisyllithium.* To a solution of p-anisyllithium prepared from p-bromoanisole (1.0 g, 0.0053 mol) in ether (100 ml) and 3 ml of 10% wt/v solution of butyllithium, we added (−)-**7** (1.0 g, 0.0041 mol) $[\alpha]_D$ −17.5° (c=1, CCl_4). After the mixture had been stirred for 2 h at room temperature, the usual work-up of the mixture gave (−)-**13** in a 50% (0.65 g) yield. Bp 175—180 °C/0.2 Torr. $[\alpha]_D$ −7.7° (c=2.5, CH_2Cl_2). NMR δ 0.40 (s, 3, Si-CH_3), 2.55 (s, 2, Si-CH_2-Ph), 3.75 (s, 3, O-CH_3), 6.7—7.5 (m, 10, Ph).

The reaction of (+)-**8** (1.0 g, 0.0041 mol) $[\alpha]_D$ +3.5° (c=2, pentane) with p-anisyllithium was carried out in a similar manner. The compound (−)-**13** was obtained in a 54% (0.7 g) yield. $[\alpha]_D$ −7.8° (c=3, CH_2Cl_2).

Reaction of (−)-7, and (+)-8 with Allyllithium. To a solution of allyllithium,[18] prepared from allyltriphenyltin (3.2 g, 0.0082 mol) and PhLi (0.0080 mol) in ether (70 ml), we added (−)-**7** (1.0 g, 0.0041 mol) $[\alpha]_D$ −11.0° (c=2, CCl_4) in ether (5 ml) with stirring at 0 °C. After the mixture had been stirred for 2 h at 0 °C, the precipitated tetraphenyltin was filtered off. The organic layer was washed with water and then dried ($CaCl_2$). Subsequent evaporation and distillation gave (+)-**14** in a 68% (0.7 g) yield. Bp 132—135 °C/0.2 Torr. $[\alpha]_D$ +0.82° (c=3.6, CH_2Cl_2). IR (neat) 1625 cm^{-1} (C=C). NMR δ 0.20 (s, 3, Si-CH_3) 1.75 (d, J=7.5 Hz, 2, Si-CH_2-C), 2.28 (s, 2, Si-CH_2-Ph), 4.5—5.0 (m, 2, =CH_2), 5.3—6.1 (m, 1, -CH=C), 6.7—7.5 (m, 10, Ph).

The reaction of (+)-**8** (1.0 g, 0.0041 mol) $[\alpha]_D$ +3.5° (c=2, pentane) with allyllithium was carried out in a similar manner. The compound (−)-**14** was thus obtained in a 59% (0.6 g) yield. $[\alpha]_D$ −1.0° (c=7, CH_2Cl_2).

Reaction of (+)-8 with p-*Tolylmagnesium Bromide.* To a solution of p-tolylmagnesium bromide, prepared from p-bromotoluene (5.0 g, 0.029 mol) and Mg (0.85 g, 0.035 mol) in ether (50 ml), we added a solution of (+)-**8** (1.0 g, 0.0041 mol) $[\alpha]_D$ +3.5° (c=2, pentane) in ether (5 ml). The mixture was refluxed for 30 h with stirring. The usual work-up of the mixture gave (−)-**12** in a 45% (0.46 g) yield. $[\alpha]_D$ −3.7° (c=6, CH_2Cl_2). The IR and NMR spectra of the product were identical with those of the product obtained by the reaction of (+)-**8** with p-tolyllithium.

The authors wish to thank the Shin-etsu Chemical Industry Co. for the gift of the organosilanes.

The Study of Surfactant-Alcohol Mixed Micelles Using Conductance, Viscosity, and Electromotive Force Measurements

Toshihiro TOMINAGA,† Theodore B. STEM, Jr., and D. Fennell EVANS*

Department of Chemical Engineering, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213, U.S.A.

(Received April 28, 1979)

Conductance, viscosity, and EMF measurements were used to characterize solutions containing surfactant–alcohol micelles. The materials studied included sodium dodecyl sulfate (SDS), sodium octyl sulfate (SOS), decyltrimethylammonium bromide (DTAB), hexadecyltrimethylammonium bromide (CTAB) and the alcohols 1-pentanol through 1-octanol. The addition of alcohols caused the conductance of a 2% SDS solution to increase, and of a 3% solution of DTAB and of a 7% solution of SOS to decrease. CTAB showed both increases and decreases upon addition of alcohol. The EMF measurements permitted the concentration of free surfactant monomer and of unbound counterion in equilibrium with the micelle to be determined. When combined with the viscosity data, the change in conductance upon addition of alcohol can be interpreted in terms of changes in micellar shape and in the concentration of involved ions.

The aqueous solubility of many sparingly soluble organic compounds such as long-chain alcohols, lipids or hydrocarbons can be increased considerably by the addition of surfactant.[1] At surfactant concentrations above the critical level at which aggregation into micells occurs, such solubilization may have a profound influence on the physical properties of the solution. For example, the conductance of such mixed micellar solutions can decrease or increase by as much as 50% upon the addition of aliphatic alcohols. In spite of the importance of mixed micellar solutions in many industrial and biological processes such as detergency, polymeric synthesis and digestion, they have received far less attention than the simple binary surfactant–water systems. In order to study mixed micellar solutions in more detail we have carried out conductance, viscosity, and EMF measurements upon alkyltrimethylammonium bromide and sodium alkyl sulfate solutions as a function of added aliphatic alcohols.

Experimental

Apparatus and Technique. The conductance measurements were carried out in two cells: a Kraus-Erlenmeyer-type cell[2] with a cell constant equal to 2.383 for dilute solutions and a Mysels donut-type cell[3] with a cell constant equal to 47.87 for concentrated solutions. The electrodes were slightly platinized in order to minimize the frequency dependence of the measured resistance. The solution in the cell was stirred with a Teflon-coated magnetic stirring bar, to facilitate the dissolution of alcohol. The conductance cells were immersed in a constant temperature oil bath controlled to 25±0.005 °C. A 100 W light bulb was placed above the cell in order to prevent condensation of water in the top of the conductance cell. A shielded Shedlowsky conductance bridge was used to measure the solution resistance.

A conductance run was made by placing the surfactant solution in the cell and adding small increments of alcohol to the surfactant solution using a 10 ml Pyrex weight burette. After each addition the conductance was followed until a steady resistance reading was obtained. When the mole fraction of alcohol was small, approximately half an hour was required to dissolve the alcohol. As the alcohol concentration was increased, a considerably longer time was required.

The viscosity of the surfactant–alcohol solutions was measured using Cannon-Ubbelohde viscometers. The measurements were carried out in a constant temperature water bath at 25 °C±0.01 °C.

EMF measurements were carried out on the surfactant solution using surfactant and counterion electrodes.[4] The liquid membrane surfactant electrodes contained an ion exchanger, tributylhexadecylammonium ion for the anion surfactant and cholanate ion for cation surfactant. The ion exchanger was dissolved in a membrane solution consisting of a mixture of *o*-dichlorobenzene–hexachlorobenzene–bromoacetanilide. An Orion 92-00-00 electrode body with an Orion porous membrane support comprised the surfactant electrode. The EMF concentration cell for the dodecyl sulfate, an ion (Ds^-), is given by

$$\mathrm{Ag/AgCl}\,\Big|\,\begin{matrix}\mathrm{NaCl}\\ \mathrm{SDS}\end{matrix}\,\Big|\,\begin{matrix}\mathrm{Bu_3N(C_{16}H_{33})Ds}\\ \text{in}\\ \text{o-dichlorobenzene}\end{matrix}\,\Big|\,\begin{matrix}\mathrm{SDS}\\ \text{sample}\end{matrix}\,\Big|$$

$$\begin{matrix}\mathrm{NH_4NO_3}\\ (5\mathrm{M})\end{matrix}\,\Big|\,\begin{matrix}\text{Orion}\\ \#90\text{-}00\text{-}02\\ \text{inner filling solution}\end{matrix}\,\Big|\,\mathrm{Ag/AgCl}$$

The sodium, bromide and reference electrodes were Orion #94-11A, #94-35A, and #90-02-00 respectively.

The EMF's were measured with an Orion Research Meter (Model 801A). In pure surfactant solution and in SDS–alcohol solution steady and reproducible values of EMF were obtained with the surfactant electrodes. However, reproducible results for DTAB–alcohol solution could not be obtained with the surfactant electrode. The counterion electrodes, however, did give satisfactory results in all surfactant–alcohol combinations studied. Reproducibility was determined by repeatedly measuring the EMF in pure micellar and mixed micellar solutions. This was conveniently done with an Orion Research Manual Electrode Switch (Model 605) which permitted up to six ion electrodes to be used with one common reference electrode. Detailed procedures are given elsewhere.[4]

Results and Discussion

Conductance measurements were carried out on sodium dodecyl sulfate (SDS), sodium octyl sulfate (SOS), decyltrimethylammonium bromide (DTAB), and hexadecylmethylammonium bromide (CTAB) as a function of added alcohol. The results are given in

† Present address: Department of Fundamental Natural Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700.

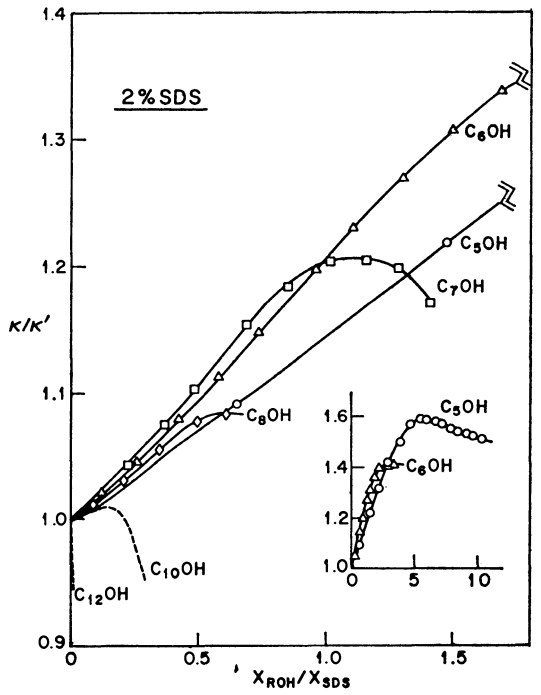

Fig. 1. The change in specific conductance of a 2% sodium dodecyl sulfate (SDS) solution upon addition of the aliphatic alcohols, pentanol through 1-octanol. The small insert shows the behavior upon addition of 1-pentanol and 1-hexanol up to the concentration at which the solution becomes cloudy.

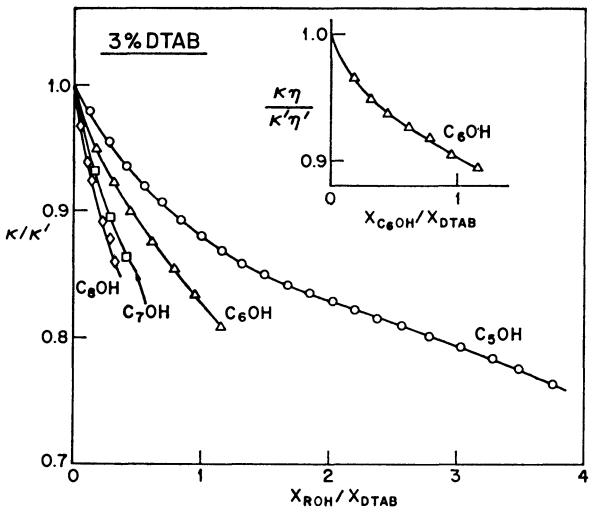

Fig. 2. The change in specific conductance of a 3% decyltrimethylammonium bromide (DTAB) solution upon addition of the aliphatic alcohols, 1-pentanol through 1-octanol. The small insert shows how the specific conductance-viscosity product for DTAB–1-hexanol solutions changes with composition.

Figs. 1—4. The initial concentration of surfactant was in all cases above the critical micelle concentration. The measurements extend up to the concentration of alcohol at which the solution becomes cloudy. Viscosity measurements were carried out on 21% SDS (0.069M), 3% DTAB (0.107M), and 2% (0.055M) and 5%

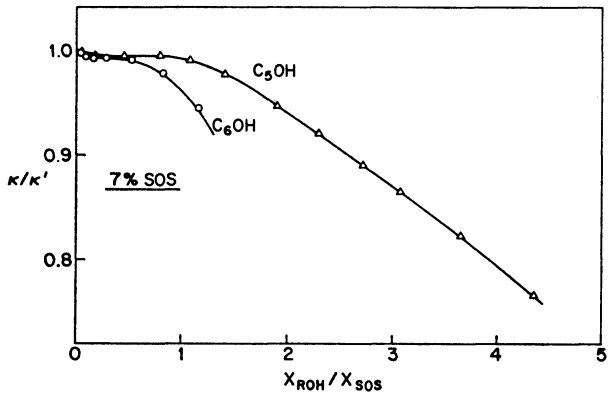

Fig. 3. The change in specific conductance of a 7% sodium octylsulfate (SOS) solution upon addition of 1-pentanol and 1-hexanol.

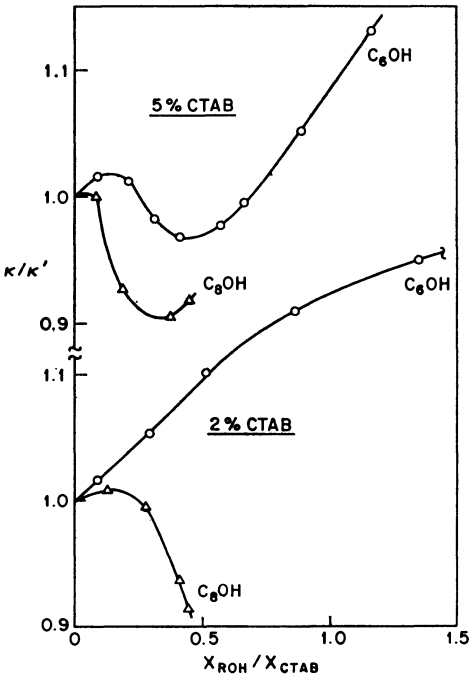

Fig. 4. The effect of surfactant concentration and alcohol chain length upon the specific conductance of hexadecyltrimethylammonium bromide (CTAB).

(0.137M) CTAB as a function of added 1-hexanol or 1-octanol and are shown in Fig. 5. EMF measurements were carried out on 2% SDS and 3% DTAB solutions as a function of added 1-hexanol and are given in Figs. 6 and 7 below.

In Figs. 1—4 the changes in specific conductance of the surfactants as a function of added alcohol are shown. The ratio of the specific conductance with and without added alcohol, κ/κ', is plotted *versus* the molar ratio of the alcohol to surfactant, x_{ROH}/x_S. If the change in surfactant concentration upon addition of alcohol is ignored, the value of κ/κ' can be replaced by the corresponding ratio of equivalent conductances. The figures show that the conductance curves are complex with initial slopes that increase in some cases, decrease in others and which may have maxima and minima.

Although it is unlikely that a single simple explanation will account for the variety of behavior, we will delineate the main factors that are responsible for the observed conductance.

In SDS solutions, while the conductance increases for all of the alcohols studied, the rate of increase and the maximum value attained depend upon the alcohol chain length. Our results for pentanol through heptanol are in agreement with the results given in graphical form by Lawrence and Pearson.[5] They measured the conductance of SDS upon addition of the alcohols, 1-ethanol through 1-heptanol. Their results show that the maximum conductance is observed for the SDS–1-pentanol solution at a mole ratio of 6 and that a 60% increase in conductance is observed. Our results show that the maximum initial slope is observed for 1-heptanol.

The conductance may be analyzed in more detail by taking into account the distribution of the alcohols between bulk water and micelles. From vapor pressure measurements of alcohols in equilibrium with a micellar solution, Hayase and Hayano[6] determined a distribution coefficient defined as

$$K = x_a/y_a = j/(S-\mathrm{CMC}(C_a)+C_a j/[(1-j)/55.5])$$

where y_a and x_a are the mole fractions in the aqueous phase and the micellar phase, respectively. The values of $1-j$ and j are the alcohol fractions in the aqueous and micellar phases, S is the total concentration of SDS, $\mathrm{CMC}(C_a)$ is the critical micelle concentration in the presence of alcohol, and C_a is the total concentration of the alcohol. Using the results for $\mathrm{CMC}(C_a)$ and K, the values of j shown in Table 3 can be calculated. For 1-pentanol most of the alcohol is in the aqueous phase while for 1-heptanol most is solubilized by the micelle. The partition coefficients in Table 1 permit the amount of alcohol solubilized at each value of x_{ROH}/x_{SDS} to be calculated. When these corrections are made, the values of the slope $d(\kappa/\kappa')/d(x_{ROH}/x_{DS})$ given in Table 1 are obtained. The corrected initial slopes for 1-pentanol, 1-hexanol, and 1-heptanol are very similar suggesting that these have identical effects upon the micelles. However, the initial slope is smaller for 1-octanol, and decreases further with increasing chain length.[7]

The initial increase in conductance of SDS upon the addition of alcohols can be attributed to the orientation of solubilized polar molecules with the polar head group remaining near the micellar surface and the hydrocarbon tails extending into the micellar interior. In pure SDS, the micelles are spherical and each surfactant molecule occupies approximately 60 Å^2 of surface.[8] The micelle exterior can thus be viewed as consisting of a number of surface sites. The incorporation of an alcohol molecule results in the surfactant molecules moving apart. This reduces the concentration of surfactant anions, lowers the surface charge density, and results in a release of bound counter ions.

Table 1. Effect of alcohols on the conductance of 2% SDS solution

Alcohols	K[a]	Uncorrected slope[b]	j[c]	Corrected slope[d]
C_5OH	722	0.14_4	0.50	0.25_5
C_6OH	2250	0.19_5	0.76	0.24_7
C_7OH	6020	0.21_0	0.90	0.23_7
C_8OH	16000	0.15_5	0.95	0.16_7

a) From Ref. 6. K for C_8OH was obtained by extrapolation of log K *vs.* alcohol-carbon-number curve. b) Initial slope of (κ/κ') *vs.* (x_{ROH}/x_{SDS}). c) (ROH, in micelle)/(ROH, total) at $x_{ROH}/x_{SDS}=0.3$. d) Initial slope of (κ/κ') *vs.* $(j\cdot x_{ROH}/x_{SDS})$.

Examination of the viscosity of the SDS–1-hexanol solutions supports this explanation. In Fig. 5, is shown the ratio η/η_{H_2O}, the relative viscosity for the micellar solution to that for water, *versus* the volume fraction of surfactant or surfactant plus alcohol. The surfactant volume was taken from the density data of Desnoyers.[9] For the alcohols, volumes were estimated using density data of pure substances.[10] The data for pure SDS fall on a straight line which extrapolates back to the intercept of η/η_{H_2O} close to unity. The data for SDS–1-hexanol fall on the same straight line indicating no change in micellar shape upon addition of alcohol.

In order to understand the behavior of these mixed micelles in more detail, we determined the activities of the sodium ions and dodecyl sulfate ions using ion electrodes. Since such electrodes give the activities of free ions, information about the sodium ions and dodecyl sulfate ions in equilibrium with the micelle can be determined.

We first measured the EMF of pure SDS solution and in Fig. 6 EMF *versus* log concentration of SDS is shown. In dilute solution, slopes close to the Nernst value of 59 mV per decade are obtained. At the CMC (8×10^{-3} M) a sharp break is observed. Above this concentration, the sodium activity continues to increase but with a smaller slope, reflecting the binding of counter ion to the micelle. The dodecyl sulfate activity decreases above the CMC. A positive slope corresponds to a decrease in activity for this ion. Assuming that activity coefficients can be ignored, the concentration

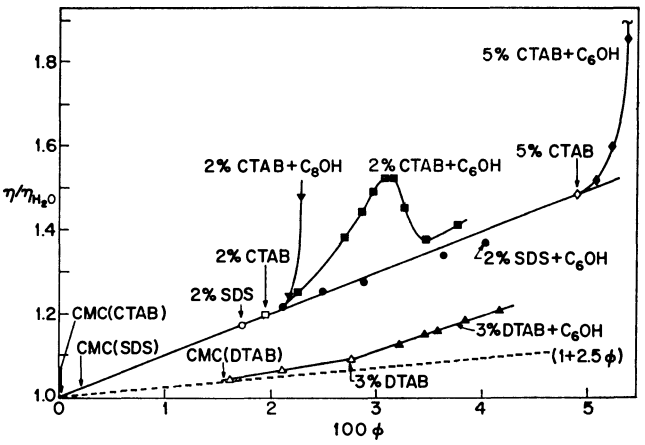

Fig. 5. The change in relative viscosity, η/η_{H_2O}, of SDS. DTAB and CTAB solutions upon addition of aliphatic alcohols as a function of volume fraction of added solute. The open points are for pure surfactant, the closed points are for surfactant plus alcohol; the dashed line represents $\eta=\eta_{H_2O}(1+2.5\,\varphi)$.

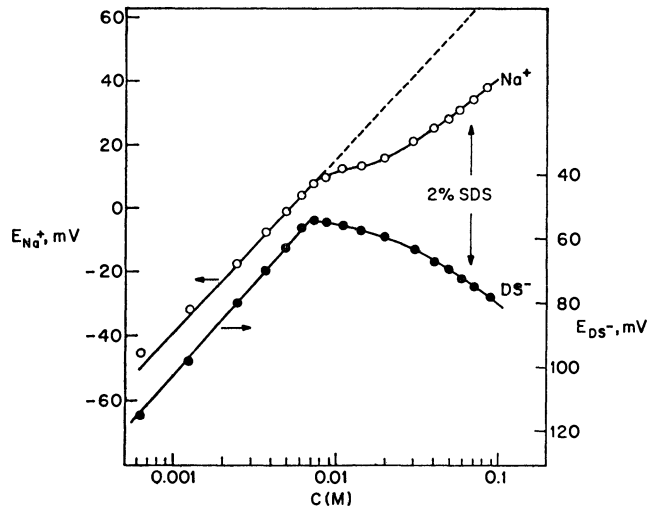

Fig. 6. The electromotive force (EMF) for sodium and dodecyl sulfate ions in 2% SDS solution. The break at 8×10^{-3} M corresponds to the CMC. Above this concentration the activities of Na^+ and Ds^- in equilibrium with the micelle can be determined.

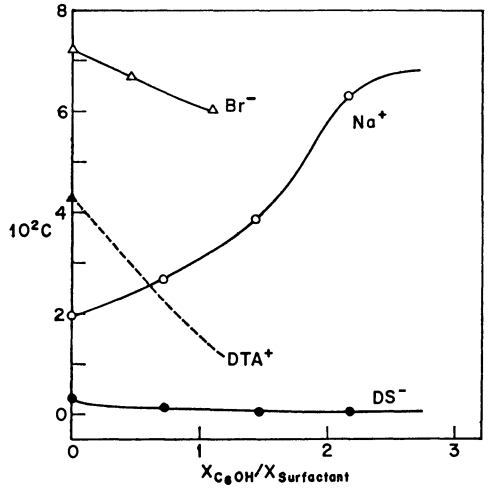

Fig. 7. The change in concentration of surfactant ions and counterions upon addition of 1-hexanol to 2% SDS and 3% DTAB as estimated from ionspecific electrodes.

of free monomer and unbound counter ion can be roughly estimated. In 2% SDS solution (0.068 M), the values of 0.02 M and 0.003 M are obtained for sodium ion and dodecyl sulfate ions respectively.

When 1-hexanol is added to 2% SDS, the ion activities change dramatically. The sodium ion concentration increases by a factor of 3 while the dodecyl sulfate concentration decreases by a factor of 10 as is seen in Fig. 7. Our results for the sodium ion activity are in substantial agreement with those of Lawrence and Pearson.[5] Since the initial concentration of free dodecyl sulfate ion is so small, even a major decrease has only a negligible effect on the conductance. However, the sodium electrode results show that the micelles release most of the bound counter ions, which results in a substantial increase in the conductance.

The conductance of DTAB–alcohol solutions is very different from that observed for SDS since it decreases upon addition of alcohol. One would expect that similarly to SDS, addition of polar compounds to DTAB should result in a release of counter ions. A decrease in the conductance of micellar solutions upon addition of non-polar solutes such as hydrocarbons is generally observed.[11] Such material appears to be solubilized entirely in the hydrocarbon interior of the micelle. The decrease in conductance arises from a corresponding increase in micellar size and perhaps by increases in counter ion binding.

One possible reason for the decrease in conductance of DTAB is that the addition of alcohol results in an increase in solution viscosity. However, the viscosity of DTAB increases by 10% up to a mole ratio, x_{ROH}/x_{DTAB}, of 1.1 while the conductance decreases by 20%. Alternatively, addition of alcohol could result in micellar reorganization such as a sphere to rod transition. This would cause the charged head groups to move closer together, increasing the micellar charge density and binding additional counter ions. That such a major reorganization does not occur can be seen from the relative viscosity shown in Fig. 5. There is a slight increase in the ratio, (η/η_{H_2O}), as 1-hexanol is added to 3% DTAB, however the increase is not as large as is usually observed for a major reorganization of micellar shape. Thus the viscosity measurements show that neither an increase in solution viscosity nor a change in micellar shape will account for the observed conductance behavior.

EMF measurements provide a clearer picture of what is happening. In a 3% (0.107M) DTAB solution the concentration of free Br^- is 0.072 M while that for DTA^+ is 0.043. Addition of 1-hexanol results in a small decrease in bromide concentration, when x_R/x_{DTAB} equals 1.1, the Br^- concentration drops to 0.060 M (see Fig. 7). Although we were not able to obtain reproducible EMF's with the DTA^+ ion electrode, the EMF decreased approximately 30 ± 10 mV suggesting a threefold decrease of monomer surfactant concentration. Since the initial concentration of free surfactant and counter ion are reasonably large, a substantial decrease in either species will have a pronounced effect on the conductance. Even in the case of 22% (0.33 M) DTAB solution the decrease in conductance is observed (Table 1) when 1-hexanol is added. This is mainly because surfactant monomer concentration is still reasonably high (0.032 M from EMF) even in such a concentrated solution.

A comparison of the SDS and DTAB results suggests that there may be major differences in the behavior of cationic and anionic surfactants upon the addition of aliphatic alcohols. However, when 1-pentanol and 1-hexanol are added to 7% (0.306 M) sodium octyl sulfate, the specific conductance decreases (Fig. 3). Similarly to DTAB, this suggests that the decrease in surfactant monomer concentration more than compensates for any change in sodium concentration. However, when the behavior for SDS and SOS are compared, the results suggest that the relative lengths of aliphatic chains in alcohol and surfactant may be an important factor in determining whether the conductance increases

or decreases. Inspection of Table 1 shows that when 1-octanol is added to SDS the increase in conductance is less than when 1-heptanol is added.

When the cationic surfactant chain becomes sufficiently long, addition of an alcohol can result in an initial increase in conductance as is shown in Fig. 4 for the addition of 1-hexanol to hexadecyltrimethylammonium bromide, CTAB. However, when 1-octanol is added the conductance increases slightly and then decreases rapidly. For 5% CTAB the addition of either 1-hexanol or 1-octanol results in both decreases and increases in the conductance. The viscosity of these solutions (Fig. 5) increases rapidly upon the addition of alcohol to either the 2% or 5% CTAB solution suggesting sphere to rod transitions.[12] In some cases the conductance rises even though the viscosity is also increasing. The behavior of 1-hexanol in 2% CTAB is pecular in this regard. Up to a mole ratio of 1.5 both the conductance and viscosity increase, above 1.5 they decrease. In general one would anticipate that an increase in viscosity would result in a decrease in conductance.

Conclusions

The results for SDS–alcohol and DTAB–alcohol micellar solutions show that when information from several experimental techniques is combined the main factors that determine the solution properties can be delineated. The two examples that we have considered in detail give reasonably simple behavior. The initial results in SOS and CTAB solution show that there are a number of complexities such as relative lengths of aliphatic chains in alcohol and surfactant, micellar reor anization and solution viscosity changes that are difficult to interpret unambiguously.

A Valence Structural Study of the Electronic Structure of S_2N_2

Hiroshi FUJIMOTO* and Takashi YOKOYAMA
Faculty of Engineering, Kyoto University, Kyoto 606

(Received December 6, 1978)

Synopsis. A valence structural analysis of S_2N_2 has been performed within the framework of the INDO approximation. The fractional double-bond character has been suggested to be the consequence of the interaction between nonionic and ionic structures, counterbalanced in part by the overlap repulsions in the ring.

The strength of pi-bonds in polar conjugated systems is a matter of great concern both experimentally and theoretically. For instance, the dimeric sulfur nitride, S_2N_2, decomposes very rapidly above −80 °C to give larger rings and polymeric materials.[1] In order to explain the weak pi-bond character of the four equivalent sulfur–nitrogen bonds, Patton and Raymond proposed that the ionic structures, II, III, IV, and V, shown in Fig. 1 should be dominant in the ground state of the S_2N_2 molecule.[2] In the course of our studies of the mechanisms of the formation and breaking of chemical bonds, we obtained a somewhat different view of the pi-bonds in S_2N_2. In this note, we wish to report the results of our qualitative calculation.

Results of Calculation

The S_2N_2 ring was assumed to be square-planar, with sulfur and nitrogen alternating at the bond distance of 1.619 Å.[3] The 3d atomic orbitals of the sulfur atoms were disregarded tentatively, since their participation has been reported to be insignificant.[4] The distribution of sigma electrons was determined by the INDO MO calculation without configuration interaction.[5] Then, this distribution was used to constitute the sigma core in the evaluation of the diagonal and off-diagonal matrix elements of the secular equation for the pi-electron configurations, I—X, in the valence-bond calculation. Table 1 gives the energies of these structures, as calculated within the framework of the INDO approximation. The nonionic structure, I, was found to lie lower than the other structures. Table 2 indicates clearly that the structures I and VI participate significantly in the ground state of S_2N_2. The linear combination of the structures II, III, IV, and V was found to be a poor representation, yielding an energy which was 7.7 eV higher than the ground state in the present calculation.

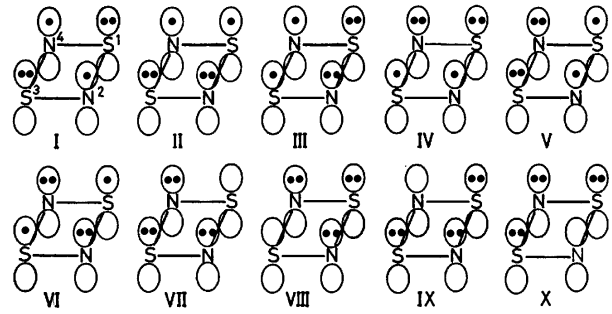

Fig. 1. Pi-electron configurations of S_2N_2.

The interactions of the valence structures I and VI with the structures II, III, IV, and V are obviously the major source of the pi character of the S–N bonds. The double-bond character is partially lifted because of the overlap repulsions which are inherent in the ring containing six pi-electrons on four centers.[6] In particular, the structures II—V themselves contribute to the weakening of the S–N bonds.

The Crystal Structure of the β Form of *p*-Chlorobenzamide

Taiichi HAYASHI, Kazuaki NAKATA,* Yoshito TAKAKI, and Kiichi SAKURAI
Department of Physics, Osaka Kyoiku University, Tennoji-ku, Osaka 543

(Received August 20, 1979)

Synopsis. The crystal of the title compound is monoclinic, with space group $P2_1/a$, $a=9.11$, $b=9.54$, $c=8.18$ Å, $\beta=93.8°$, $Z=4$. The structure was solved by a packing analysis based on an ellipsoid-model and refined by block-diagonal least-squares calculations to $R=0.115$. The amide group makes a dihedral angle of 2.0° with the benzene ring.

p-Chlorobenzamide, C_7H_6ClNO, exhibits two polymorphs at room temperature.[1] They are triclinic with space group $P\bar{1}$ (α form) and monoclinic with $P2_1/a$ (β form). The structures of the α form at room temperature and −120 °C have been determined by Taniguchi *et al.*[2] Harada *et al.*[1] obtained crystals of the β form from an acetone solution, but they gave only crystal data. Therefore in this paper we deal with the structure determination of the β form.

Experimental

Many attempts were made to obtain crystals of the β form from acetone and other solutions, but they were all unsuccessful. Intensity data were then collected from Weissenberg photographs about the b axis ($k=0$—6) which have been prepared by Harada *et al.*,[1] although the quality of the photographs was rather poor. The intensities of 1067 reflections were measured visually and corrected for Lorentz and polarization factors. The cell dimensions were reconsidered on closer examination of the oscillation and Weissenberg photographs. The revised crystal data are: $a=9.11$ (10), $b=9.54$ (7), $c=8.18$ (15) Å, $\beta=93.8(5)°$, $Z=4$, space group $P2_1/a$.

A trial structure was successfully obtained from a packing analysis based on an ellipsoid-model[3] including a centrosymmetric dimer. The structure was refined by successive Fourier and by block-diagonal least-squares calculations[4] with a weighting scheme $w=1-\exp(-20\,s^2)$ with $s=\sin\theta/\lambda$. All the H atoms located from a difference Fourier map were included in the structure-factor calculations with an isotropic temperature factor of $B=4.0$ Å^2. The final R value was 0.115. The final atomic coordinates and thermal parameters are listed in Table 1.[5] All computations were made on an ACOS System 800 computer of the Computation Center of Osaka University.

Results and Discussion

Bond lengths and angles for the non-hydrogen atoms are shown in Fig. 1. The mean estimated standard deviations are 0.01 Å and 0.7°. The dihedral angle between the plane of the amide group and the mean plane of the benzene ring is 2.0°. This value is very close to that in *p*-nitrobenzamide[6] (2.3°), but unusually small as compared with those in the related amides, which vary from about 23°[7] to 29°.[8] The very small dihedral angle may give rise to a marked 'in-plane' bending of the C(1)–C(2) bond to reduce the interaction of the ortho-hydrogen with one of the NH_2 pro-

tons.[6] In fact, the difference between the C(1)–C(2)–C(3) and C(1)–C(2)–C(7) bond angles in the present compound and *p*-nitrobenzamide are remarkably large (6.0 and 6.7° respectively) as compared with those in the related amides.

The crystal structure viewed along the b axis is shown in Fig. 2. It consists of a stacking of hydrogen-bonded layers parallel to (001). Within a layer, two molecules are linked by NH···O hydrogen bonds of 3.06 Å to form a centrosymmetric dimer, and these dimers are linked by the other type of NH···O hydrogen bonds of 3.19 Å. This type of hydrogen-bond network (classified as 'screw-axis packing' by Leiserowitz and Schmidt[9]) is very rare in aromatic amides. The only case so far reported is that of *p*-chlorocinnamide.[10]

The Cl–Cl distance of 3.24 Å is appreciably shorter than those found in the α form of *p*-chlorobenzamide[2] at −120 °C (3.29 Å) and at room temperature (3.31 Å).

The Crystal Structures of the α and β Forms of DL-Methionine

Tomohiko TANIGUCHI,* Yoshito TAKAKI, and Kiichi SAKURAI
Department of Physics, Osaka Kyoiku University, Tennoji-ku, Osaka 543

(Received September 10, 1979)

Synopsis. The crystal structures of the α and β forms of DL-methionine have been refined by block-diagonal least-squares calculations using three-dimensional X-ray data to $R=0.118$ and 0.088 respectively. The structures of both the forms are essentially the same as those previously reported by Mathieson (*Acta Crystallogr.*, **5**, 332 (1952)).

Mathieson[1] has determined the crystal structures of the α and β forms of DL-methionine, $C_5H_{11}NO_2S$, from two-dimensional X-ray data. Recently, Taniguchi *et al.*[2] found that crystals of the β form undergo a reversible solid phase transformation at about 326 K to the α form accompanied with characteristic diffuse scattering during the transformation. In the course of their X-ray study of the phase transformation, it seemed that the structures given by Mathieson[1] were too deficient in accuracy to interpret quantitatively the diffuse scattering patterns. Therefore, in this paper, we deal with a reexamination of the structures of the α and β forms.

Experimental

Plate-like crystals elongated along the b axis were obtained from aqueous solutions at room temperature. Weissenberg photographs showed that all the crystals examined were β form, but they gave diffraction patterns showing various degrees of streaking along the reciprocal-lattice rows parallel to c*. Therefore a crystal showing very weak streaks was selected for the data collection. A crystal of the α form with no streaking could be obtained from that of the β form by heating in a stream of hot air through the transition point, the crystal being kept at 333 K (±2 K) during X-ray exposure. Note that a few crystals of the α form obtained in this way did not transform to the β form even at room temperature but they were all poor in quality. Cell dimensions of the β form were determined from photographs taken with a Buerger back-reflection Weissenberg camera, and those of the α form were determined by examining double-exposure Weissenberg and oscillation photographs taken with the same crystal at room temperature (β form) and 333 K (α form). Crystal data obtained are: α form at 333 K, $a=9.89(2)$, $b=4.70(2)$, $c=16.74(3)$ Å, $\beta=102.3(7)°$, space group $P2_1/a$, $Z=4$; β form at 293 K, $a=9.912(5)$, $b=4.700(7)$, $c=33.13(2)$ Å, $\beta=106.3(3)°$, I2/a, $Z=8$.

Intensities of 1310 independent reflections for the α form at 333 K and 1494 reflections for the β form at 293 K were collected on equi-inclination Weissenberg photographs for $k=0$ to 3 (α form) and for $k=0$ to 4 (β form). The intensities were measured visually and corrected for Lorentz and polarization factors. No correction for absorption was made.

The structures of the α and β forms given by Mathieson[1] were refined by block-diagonal least-squares calculations[3] with unit weights. The H atoms for both forms were included in the least-squares calculations with fixed positional parameters deduced from the geometry of the molecules and fixed isotropic thermal parameters ($U=0.057$ and 0.044 Å^2 for the α and β forms respectively). At a later stage of refinement, the positions of the H atoms for both forms were confirmed from difference syntheses except those of terminal methyl groups. The final R values for the α and

β forms were 0.118 and 0.088 respectively. Positional and thermal parameters are given in Table 1.[4] Bond lengths and angles and torsion angles are given in Table 2. All computations were made on a NEAC 2200-700 computer of the Computation Center of Osaka University.

Discussion

The structures of both the α and β forms are essentially the same as those given by Mathieson.[1] No significant difference between the molecules of the α and β forms is observed in bond lengths and angles except for the torsion angles C(3)–C(4)–S–C(5) (68.9 and 185.6° for the α and β forms respectively), which define the conformation of the terminal C(5) atom to the C(3) atom as *gauche* in the α form and *trans* in the β form.

A fundamental difference between the crystal structures of the α and β forms lies in the arrangements of layers along the c axis. The α form consists of a single-layer unit, P, with a stacking sequence $PPP\ldots$, while the β form consists of a double-layer unit, $Q\overline{Q}$, with a sequence $Q\overline{Q}Q\overline{Q}\ldots$, where $\overline{Q}$ is related to Q by the translation $(\mathbf{a}+\mathbf{b})/2$. The structures of layers P and Q are very similar to each other except for the positions of the terminal methyl groups; both P and Q layers consist of molecules connected by three types of NH···O hydrogen bonds (2.83, 2.80, and 2.77 Å in layer P and 2.82, 2.80, and 2.79 Å in layer Q). The closest interlayer contacts are C(5)··· C(5) of 3.46 and 3.81 Å for the α and β forms respectively.

By comparing the structures of the two forms, the major change of the structure occurring on the phase transformation from the β to α forms may be explained in terms of the translation $(\mathbf{a}+\mathbf{b})/2$ of every second layer accompanied with the repositioning of the terminal methyl groups from *trans* to *gauche* to the C(3) atoms. A similar structural change can be seen on the phase transformation of DL-α-aminobutyric acid from the A to D forms.[5]

A Cation-exchange Study of Cerium(III) and Thulium(III) Tartrate Complexes

Emiko OHYOSHI* and Akira OHYOSHI†
Yatsushiro College of Technology, Yatsushiro 866
†*Department of Industrial Chemistry, Kumamoto University, Kumamoto 860*
(Received May 18, 1979)

Synopsis. The tartrate complexes of Ce(III) and Tm(III) were studied by the cation-exchange method, where a series of solutions prepared so as to keep the [Htart$^-$] value nearly constant, while the [tart^{2-}] value was varied, was used for the estimation of the protonated complexes. Three kinds of complexes, M(Htart)$_2^+$, M(Htart)(tart), and M(tart)$_2^-$, were found in the lower pH region of the solutions.

When we use some dibasic or tribasic acids as complexing agents, there must be various kinds of protonated complexes equilibrated in a solution. However, most investigators seem to have neglected or underestimated these protonated complexes. Potentiometry can not be used for these studies since it is difficult to analyze various protonated complexes from a pH titration curve indicating a high degree of overlapping of the successive equilibria. In these cases, it is useful to estimate the amounts of free metal and ligand species equilibrated in a solution. As has previously been reported, it has been found that the citrate complexes of some lanthanoids[1] and actinoids[2,3] involving various types of protonated complexes could readily be analyzed by the cation-exchange method using a series of solutions prepared so as to keep the amount of one of the protonated ligands constant, while the other one was varied. In this note, we will discuss how we applied this method to the study of tartrate complexes of Ce(III) and Tm(III).

Experimental

Materials. The tracers, ^{144}Ce and ^{170}Tm in the chloride form, were obtained from the New England Nuclear Corporation. To a portion of each of the tracer solutions, a carrier was added to prepare stock solutions of 10^{-3} M (1 M= 1 mol dm^{-3}). A cation exchanger, Dowex 50W-X8 (100—200 mesh), in the sodium form was used. All the chemicals used were of a G. R. grade. Tartrate solutions were made in the following way: (1) To 0.1 M NaHtart solution, various amounts of H_2tart were added to prepare solutions containing a nearly constant amount of Htart$^-$ and various quantities of tart^{2-}. The ionic strength governed by the amount of the salt, NaHtart, was also maintained at 0.1 M. The compositions of the solutions are given in Table 1. The acid-dissociation constants used for the calculation of the respective ion concentrations were $pK_1=2.88\pm0.02$ and $pK_2=4.02\pm0.02$, which were determined by potentiometric titration at I=0.1 M and 25 °C. (2) Solutions containing various amounts of tartrate at the constant pHs of 2.74 and 3.90 were prepared by diluting a mixture of equal volumes of 0.1 M Na_2tart and 0.34 M H_2tart, and one of 0.1 M Na_2tart and 0.05 M H_2tart, with a 0.1 M $NaClO_4$ solution.

Table 1. The compositions of tartrate solutions prepared so as to maintain [Htart$^-$] nearly constant (0.1 mol dm^{-3})

pH	[H_2tart] mol dm^{-3}	[Htart$^-$] mol dm^{-3}	[tart^{2-}] 10^{-3} mol dm^{-3}
2.12	0.595	0.104	1.31
2.21	0.476	0.102	1.59
2.32	0.359	0.099	1.99
2.49	0.239	0.098	2.92
2.59	0.182	0.095	3.52
2.74	0.124	0.091	4.78

Procedure. The cation-exchange experiments were carried out in a manner similar to that described previously.[2] The distribution coefficient, K_d, was calculated as follows:

$$K_d = \frac{\text{Activity in the resin phase}}{\text{Activity in the solution phase}} \times \frac{\text{Volum of solution (ml)}}{\text{Mass of dry resin (g)}}. \quad (1)$$

Results and Discussion

Considering the formation of M(Htart)$^{2+}$ and M(tart)$^+$, the adsorption of these species on the cation exchanger was studied at I=0.1 and 0.2 mol dm^{-3} and was found to be negligible compared with that of the M^{3+} species.[4] Thus, the following equation is derived:

$$K_d^0/K_d - 1 = \sum K_{M(Htart)_i}[Htart^-]^i + \sum K_{M(Htart)_j(tart)_k}[Htart^-]^j[tart^{2-}]^k + \sum K_{M(tart)_l}[tart^{2-}]^l \quad (2)$$

where K_d^0 denotes K_d in the absence of the complexing agent, and where $K_{M(Htart)_i}$, $K_{M(Htart)_j(tart)_k}$, and $K_{M(tart)_l}$ are the formation constants of the M(Htart)$_i$, M(Htart)$_j$(tart)$_k$, and M(tart)$_l$ respectively. If we can set conditions so as to keep [Htart$^-$] nearly constant and to vary [tart^{2-}], Eq. 2 may be written as a function of [tart^{2-}] alone, thus:

$$K_d^0/K_d - 1 = A + B\sum K_{M(Htart)_j(tart)_k}[tart^{2-}]^k + \sum K_{M(tart)_l}[tart^{2-}]^l, \quad (3)$$

where A and B are constant. From a plot of $K_d^0/K_d - 1$ *vs.* [tart^{2-}], we can conclude which of the two species, Htart$^-$ and tart^{2-}, is the actual complexing ligand. It is difficult, however, to decide the type of complexes formed from only this plot. For example, if the plot shows a straight line with an intercept, we can not conclude whether $k=1$, $l=0$; $k=0$, $l=1$, or $k=l=1$. To make the difference clear, it is necessary to know the ratio of metal to ligand; this can be found by studying the relation between K_d^0/K_d-1 and $[\text{tartrate}]_{total}$ at a constant pH.

Figure 1 shows the plots of K_d^0/K_d-1 *vs.* [tart^{2-}], where [Htart$^-$] is kept constant (nearly 0.1 mol dm^{-3} for Ce(III) and Tm(III)). The fact that straight lines are obtained indicates the presence of two different type of complexes; one consists of only Htart$^-$, and while in the other the ratio of the metal to the ligand, tart^{2-}, is 1:1. As is shown in Fig. 2, the plots of $\log(K_d^0/K_d-1)$ *vs.* $\log[\text{tartrate}]_{total}$ at pH 2.74 give straight lines with the slope of 2, indicating that all

			3.84[c]	5.58±0.05[f]	8.4±0.2[b]
			3.09[d]		6.72[c]
Tm(III)		4.10±0.05	5.3[g]	5.99±0.05[e]	6.35±0.05
				5.97±0.05[f]	

a) Ref. 6. b) Ref. 7. c) Ref. 8, I; variable. d) Ref. 9, I=0.2 mol dm^{-3}. e) The values obtained from the plot in Fig. 1. f) The values obtained from the plot of log (K_d^0/K_d-1-A) *vs.* log [H$^+$]. g) Ref. 5. I=0 mol dm^{-3}.

the complexes formed in this pH region have a 1:2 metal-to-ligand ratio. On the basis of this, the two complexes, M(Htart)$_2^+$ and M(Htart)(tart), for Ce(III) and Tm(III) are considered. Their formation constants, $K_{M(Htart)_2}$ and $K_{M(Htart)(tart)}$, calculated from the intercepts and the slopes of the straight lines in Fig. 1, are listed in Table 2. Equation 3 can be simplified and reformed in this case:

$$K_d^0/K_d - 1 = A + BK_{M(Htart)(tart)}[tart^{2-}], \quad (3')$$

$$\log (K_d^0/K_d-1-A) = \log B^2k_2K_{M(Htart)(tart)} - \log [H^+], \quad (4)$$

where k_2=[H$^+$][tart^{2-}]/[Htart$^-$]. The $K_{M(Htart)(tart)}$ values are also obtained from the intercepts of the straight lines obtained from the plots of log(K_d^0/K_d-1-A) *vs.* log [H$^+$]. These values, also listed in Table 2, are found to be close to those presented above.

To examine another type of complexes, the experiments were carried out at a pH of 3.90. The plots of log (K_d^0/K_d-1) *vs.* log[tartrate]$_{total}$ given in Fig. 2 indicate the presence of 1:2 complexes, that is, M(Htart$^-$)(tart^{2-}) and M(tart^{2-})$_2$. The intercepts of the plots in Fig. 2 correspond to $\{K_{M(Htart)(tart)}k_1^2k_2\times[H^+]+K_{M(tart)_2}\times(k_1k_2)^2\}/([H^+]^2+k_1[H^+]+k_1k_2)^2$, where k_1=[H$^+$][Htart$^-$]/[H$_2$tart].

Since the $K_{M(Htart)(tart)}$ values are already known, the formation constants of Ce(tart)$_2^-$ and Tm(tart)$_2^-$ are determined to be as listed in Table 2. To confirm the reliability of these formation constants, we tried to obtain the relationships between log (K_d^0/K_d-1) and log[tartrate]$_{total}$ at pH 2.74, using these values for the calculation. The results are in good agreement with the solid lines shown in Fig. 2. The formation constants of other types of complexes reported in the literature are also listed in Table 2. It is of interest that, for both Ce(III) and Tm(III), the two complexes, M(Htart)(tart) and M(tart)$_2^-$, have stabilities of the same order. From this, M(Htart)(tart) is found to be the predominant species in solutions of the lower pH region.

The complex of the M(tart)$^+$ type, whose formation constants for Ce(III) and Tm(III) are listed in Table 2, was not found under these experimental conditions. There are no protonated couples other than Ce(Htart)$^{2+}$ in the literature. From our results, the type of M(Htart)(tart) is found to be appreciably stable. If this species is neglected in the estimations of other species, the resulting formation constants may involve a considerable error. This might be one of the reasons why there has been a remarkable disagreement among the values reported for the formation constants of Ce(tart)$^+$ and Ce(tart)$_2^-$.

The Kinetics of the Thermal Deammonation of $[RhX(NH_3)_5]X_2$ in the Solid State

Susumu KOHATA,* Hitoshi KAWAGUCHI,** Noriko ITOH,** and Akira OHYOSHI**

Yatsushiro College of Technology, Hirayamashin-machi, Yatsushiro 866

(Received May 19, 1979)

Synopsis. The isothermal kinetics of the substitution reaction of an ammonia with an outer-sphere anion was studied in the solid state; $[RhX(NH_3)_5]X_2(s) \rightarrow [RhX_2(NH_3)_4]X(s) + NH_3(g)$ (X=Cl, Br, I). The kinetic parameters provided some evidence for a dissociative mechanism.

The metal ammine complexes, $[MX(NH_3)_5]X_2$ (M=Cr(III), Co(III), Ru(III), or Rh(III); X=Cl, Br, and I), are known to liberate ammonia molecules in the initial part of thermal degradation in the solid state.[1-3] We can classify their reactions into two types: in ammine cobalt(III) complexes, the release of the ammonia molecule is initiated by electron-transfer, while it is initiated by a replacement of an ammonia with an anion in the outer-sphere in the other metal complexes. It is of interest to compare the deammonation reactions among these transition-metal complexes with different electronic configurations. Unfortunately, there have been few reports on kinetic studies of deammonation considering the mechanism. In the present work, the kinetics of the deammonation reaction of $[RhX(NH_3)_5]X_2$ (X=Cl, Br, or I) has been investigated; the mechanism will be discussed.

Experimental

The pentaamminehalogenorhodium(III) complexes were prepared according to the method given in the literature.[4] They were identified by elemental analyses and by UV spectral measurements. The pyrolyses were made in a constant helium stream of 70 ml/min under the heating rate of 5 °C/min. About a 10-mg portion of the sample, which has been ground with a mortar into a fine, homogeneous powder, was used in each kinetic run. In the isothermal kinetic measurements, the complex was heated for 50—300 min at a temperature just below where the mass-loss begins to appear in the respective complexes. The temperatures were 296, 282, and 226 °C for the chloro, bromo, and iodo complexes respectively. The apparatus used for the pyrolyses or spectroscopic measurements are the same as those described in a previous paper.[2]

Results and Discussion

In our experiments, the temperatures at which the mass-loss begins to appear were 242 °C for $[RhI(NH_3)_5]I_2$, 281 °C for $[RhBr(NH_3)_5]Br_2$, and 300 °C for $[RhCl(NH_3)_5]Cl_2$. Wendlandt and Franke have reported the values of 290, 320, and 340 °C as the corresponding temperatures for the iodo, bromo, and chloro complexes respectively.[3] The difference may be attributable to differences in experimental conditions, such as in the apparatus and the atmosphere. Although the values of the temperature obtained by the present authors are different from the corresponding ones reported by Wendlandt and Franke, the orders of increasing thermal stability coincide with each other.

The analytical data of the reaction products, which are shown in Table 1, demonstrate that the thermal degradation can be expressed by Eq. 1:

$$[RhX(NH_3)_5]X_2(s) \rightarrow [RhX_2(NH_3)_4]X(s) + NH_3(g) \quad (X=Cl, Br, I) \qquad (1)$$

The plots of the first-order rate equation gave straight lines, with a good reproducibility, up to *ca.* 70% of Reaction 1. Reaction 1 can, therefore, be regarded as first-order with respect to the reactant. The rate constant obtained from the slopes and the activation parameters evaluated from the Arrhenius plots (Fig. 1) are given in Table 2.

The order of increasing rate constants is: $[RhCl(NH_3)_5]Cl_2 < [RhBr(NH_3)_5]Br_2 < [RhI(NH_3)_5]I_2$; the rate constants of the bromo and iodo complexes are, respectively, *ca.* 3 and 20 times greater than that of the chloro complex. If Reaction 1 proceeds through an associative mechanism, the rate constant should clearly increase along with the smaller size and the larger electronegativity of the entering group;[5] that is, the expected order of increasing rate constants is iodo-iodide<bromo-bromide<chloro-chloride. This assumption, however, is not consistent with the experimental results.

On the other hand, the values of the activation energies, (E^*/kJ mol^{-1}) for $[RhCl(NH_3)_5]Cl_2$ (196±1) and $[RhBr(NH_3)_5]Br_2$ (210±3), are close to each other; also, they are larger than that of $[RuCl(NH_3)_5]Cl_2$, for which an S_N1-type mechanism has been proposed.[2] These Rh(III) complexes also revealed a positive entropy change, ΔS^*, suggesting a five-coordinate complex in the activated state. In this case, therefore, the

	18.1	(219)		
	25.6	(226)		

a) Error recorded is e.s.d.

$Rh–NH_3$ bond-breaking is the rate determining step. It can, therefore, be considered that the deammonation-anation reactions of $[RhX(NH_3)_5]X_2$ (X=Cl and Br) proceed through a dissociative mechanism.

The remaining complex, $[RhI(NH_3)_5]I_2$, gives smaller values of E^* (156±1) and ΔS^* (−5±2/J K^{-1} mol^{-1}) than those of $[RhX(NH_3)_5]X_2$ (X=Cl and Br), though the former values are rather close to those of $[RuCl(NH_3)_5]Cl_2$. The deammonation of the iodo complex, then, proceeds *via* a partially associative mechanism. It may be explained by the strong basicity of the iodide ion, which causes the large value of the rate constant. In conclusion, the deammonation mechanism of $[RhX(NH_3)_5]X_2$ (X=Cl, Br, or I) seems, fundamentally, to belong to the category of dissociation mechanisms.

It is, then, of interest to shed light on the relation between the reaction mechanism and the product obtained from the solid-state reaction. By means of spectroscopic measurements, the main product was found to be *trans*-$[RhX_2(NH_3)_4]X$ (X=Cl and I), although the configuration of the corresponding bromo complex could not be determined. The reaction mechanism proposed in this work (dissociative mechanism) suggests the exertion of a "trans-effect" of halogen, although Evans *et al.*[7] have found no octahedral trans-effect of halogen in $[RhX(NH_3)_5]X_2$ (X=Cl or Br).

The mechanism in this sort of reaction shows a striking contrast among the Rh(III), Ru(III), and Co(III) ammine complexes. In $[CoX(NH_3)_5]X_2$ (X=Cl, Br, and I), an electron-transfer reaction takes place initially and is followed by a degradation reaction, while a replacement of ammonia with the outer-sphere anion initially takes place in $[RuX(NH_3)_5]X_2$ (X=Cl and Br) and $[RhX(NH_3)_5]X_2$ (X=Cl, Br, and I).

This difference might be explained by comparing the third-ionization potential of each metal ion, corrected with the CFSE based upon the optical data of each hexaammine complex.[8,9] The values are 32.0, 30.3, and 28.6 eV for Co, Ru, and Rh respectively; this suggests, then, that the $3d^6$ cobalt complex is more electron-acceptable than the other $4d^5$ and $4d^6$ metal complexes. This may, consequently, elucidate the difference in the thermal-degradation reactions of Co and Ru, Rh complexes described above.

Syntheses and Electronic Spectra of 4,4′-Diacetyl-2,2′-isopropylidenedi-8-quinolinol, Its Nickel(II), Copper(II), and Zinc(II) Chelates

Yoshinori YAMAMOTO,* Kunio SHIBAHARA, and Shinsuke TAKEI

(Received July 2, 1979)

Synopsis. The title nickel chelate, which has a planar four-coordinated form, gave an intense new band, no corresponding band of which was observed with the other chelates, at the position between the first and second π-π^* bands. The spectra were compared with those of the corresponding compounds free from the acetyl group.

The crystalline compounds, Ni-, Cu-, and Zn(aipdq), have been obtained readily by the reaction of each of the metal ions with the ligand. The absorption data are given in Tables 1 and 2. The intra-ligand transition bands, termed the A-, B-, and C-bands, of each of the M(aipdq) can well be compared with those[1] of the corresponding chelates free from the acetyl group, M(ipdq), in the same solvents. Both Cu- and Zn(aipdq) in all the solvents and Ni(aipdq) in pyridine give similar spectral shapes (Table 1). When the solvents listed in Table 2 are used, the spectral shapes of the A- and C-bands of Ni(aipdq) are remarkably changed, together and an intense new band appears. A similar behavior was observed with the M(ipdq). The new band of Ni(aipdq) can be compared with an unassigned small shoulder band observed with planar four-coordinated Ni(ipdq).

On the basis of the d-d spectrum, Ni(aipdq) in pyridine is found to be coordinated by two pyridine molecules (Table 1). Both in the solid state and in *N*,*N*-dimethylformamide (DMF) (8×10^{-3} M, 1 cm cell), Ni(aipdq) gives no peak near 10000 cm^{-1}, suggesting[2] that the compound has a planar four-coordinated form (*cf.* Table 2). With the other solvents for Ni(aipdq), the measurement could not be performed because of their low solubilities, but a planar form can be expected because these solutions give intense bands similar to those in DMF (Table 2).

For the spectra of the planar nickel chelates, it is observed that, upon acetylation, both the C-band and the new band shift to the red, 1.3—1.6 and *ca.* 2×10^3 cm^{-1} respectively, in the same solvents. The C-bands of the M(ipdq) have been described in terms of the movement of the electronic charge from the phenol ring to the pyridine ring.[1] The decrease in the electron density in the pyridine ring upon the acetylation explains the movement of the C-bands to lower energies, though it should be noted that the quantity of the shift of the planar nickel chelate is less than those ($2.2—2.4\times10^3$ cm^{-1}) of the other chelates. The new band of planar Ni(aipdq) is not a part of the B- or C-band, since, when the solvent is changed to MeOH, the new band shifts strongly to the blue, despite the small shift of the B-band, while upon changing to the solid state the new band shows only a little change, despite a complex splitting of the C-band (Table 2). These observations suggest that the new band is to be described in terms of the charge transfer from metal to the ligand (MLCT). In the other chelates, the lack of the corresponding band near the B- or C-band is in contrast with the well-known MLCT of the Cu(II), Ni(II), *etc.* complexes with pyridine *N*-oxide and its derivatives, whose positions change slightly when the central metal is changed.[3] From the viewpoint of the development of *selective* colorimetric reagents for nickel analysis, it would be interesting to search for a modification of the ligand which would cause such a new band to appear in a lower energy range than the first π-π^* bands of the chelates.

Experimental

The measurement and analyses were made by the same methods as in the previous paper.[1] Zn(ipdq) was prepared in a way similar to that[1] used for of Cu(ipdq); it was dried at 120 °C to give a deep yellow, crystalline powder. Found: Zn, 16.48%. Calcd: 16.60%.

4,4′-Diacetyl-2,2′-isopropylidenedi-8-quinolinol: This was prepared by a method similar to that developed by an Italian group.[4] To a solution of Ni(ipdq) (or ipdq) (10 mmol) in 40 cm^3 of EtOH and 8 cm^3 of concd H_2SO_4, $AgNO_3$ (0.4 g) in 80 cm^3 of water was added; the mixture was then heated at 40—50 °C and stirred for 2 h. During heating, pyruvic acid (8 cm^3) and $(NH_4)_2S_2O_8$ (10 g in 80 cm^3 of water) were added in two equal portions at hourly intervals. After cooling, the precipitate was collected, treated with 60 vol% aq EtOH (150 cm^3) containing AcOK (3.6 g), recollected, washed with water, and dried to give the crude product. Repeated recrystallization from toluene (45 cm^3 per 1.0 g), using activated characoal, gave yellow needles (1.3 g, 31%): mp 200.5—201.5 °C. Found: C, 72.17%; H, 5.20%. Calcd for $C_{25}H_{22}N_2O_4$: C, 72.45%; H, 5.35%. PMR ($CDCl_3$): δ=2.06 (6H, s, $>C(CH_3)_2$), 2.59 (6H, s, $-COCH_3$), 7.15—7.90 (8.8H, m, ring proton and a part of OH). IR (KBr): 3415 (OH), 1699, and 1678 cm^{-1} (C=O). UV_{max}: (Cyclohexane) 37.17×10^3 cm^{-1} (log ε 4.68) (A-band), 30.35 (3.67) and 29.33 (3.69) (B-band), 27.0 (sh 3.46) (C-band); (MeOH) 37.59 (4.67), 30.8 (sh 3.75) and 29.85 (3.76), 27.4 (sh 3.50); (0.1 M aq NaOH) 35.27 (4.59), 30.3 (sh 3.66) and 29.2 (sh 3.61), 25.2 (3.55); (6.0 M aq HCl) 36.36 (4.70), 30.8 (sh 3.86) and 29.67 (3.94), 25.3 (3.40).

(4,4′-Diacetyl-2,2′-isopropylidenedi-8-quinolinolato)nickel(II), Ni(aipdq): To a warmed solution of $Ni(OAc)_2\cdot4H_2O$ (1 mmol in 30 cm^3 of EtOH), a hot solution of the ligand (1 mmol in 20 cm^3 of acetone) was added. From the mixture shiny needles immediately separated out; they gradually

Studies of the Hydrous Titanium Oxide Ion Exchanger. V. The Stability of the Hydrogen Form in Air

Yasushi INOUE* and Hiromichi YAMAZAKI

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received July 6, 1979)

Synopsis. After being allowed to stand in air at room temperature, the exchanger in the hydrogen form showed an abrupt decrease in its ion-exchange capacity between 3 and 6 months after the preparation. This is attributable to the preferential destruction of the most acidic hydroxyl groups by dehydrating condensation.

In the previous paper,[1] it was pointed out that the hydrous titanium oxide in the hydrogen form lost about a half of its ion-exchange capacity when it was allowed to stand for 1.5 years after the preparation. Despite the importance of this observation from the practical point of view, the decrease in the ion-exchange capacity has not yet been stuied in detail as a function of the lapse of time. The present paper will describe the results of our study of this subject.

Experimental

Materials. The hydrous titanium oxide ion exchanger prepared by the method reported previously[1] was used after having been conditioned by the following procedure. The exchanger, sieved to obtain a desired particle size (100—200 mesh), was poured into a glass column, 10 mm in inside diameter and 20 cm high, with glass wool for column support. Then at least thirty times the column volume of 0.1 M (1 M=1 mol dm^{-3}) HCl, 0.1 M NaOH, and 0.1 M HCl were passed through, in this order, at a rate of about 1.0 cm^3/min. After each step, the column was washed with water until the effluent became neutral. The exchanger in the hydrogen form thus prepared was air-dried and stored in a desiccator containing a saturated NH_4Cl solution. A part of the exchanger was heated to a constant weight at 80 °C and stored in the same desiccator. As the result of the above treatment, two kinds of exchangers were obtained:

Sample A: Hydrogen form dried at room temperature,

Sample B: Hydrogen form subjected to thermal treatment at 80 °C.

Their composition and ion-exchange capacities are shown in Table 1.

Titration Curves. In 50 cm^3 of a solution (ionic strength: 0.10 M), 0.5 g of the sample was immersed for 5 d at room temperature, with intermittent shaking. This was followed by the pH measurement of the solution and by the determination of the sodium ions in the solution. The sodium ions were converted to pure sodium chloride and indirectly determined by titrating the chloride ions by means of the Fajans' method. To obtain a titration curve, this procedure was repeated for various solutions which had been prepared using the desired combinations of 0.1 M NaOH and 0.1 M NaCl. The ion-exchange capacity was calculated from the amount of sodium ions taken up from the 0.1 M NaOH solution.

Results and Discussion

The dependence of the ion-exchange capacity of Sample A on the standing period is shown in Fig. 1. The capacity first decreased slightly with the lapse of time for about 95 d after the preparation, this decrease amounted to 0.25 meq/g in this period. Thereafter, it decreased abruptly until about 180 d, at which point about a half of its original value was lost. Thereafter, the capacity continued to decrease gradually with the lapse of time. This phenomenon may be understood by considering that such a gelatinous material as hydrous titanium oxide is in the metastable state, which tends to be stabilized on standing. If this argument is true, the material which has been forced to age by thermal treatment will behave differently. Therefore, the exchanger treated thermally at 80 °C (Sample B) was also examined in a similar way. The reason for selecting this temperature for the thermal treatment is that the release of water is accompanied by a certain degree of stabilization of

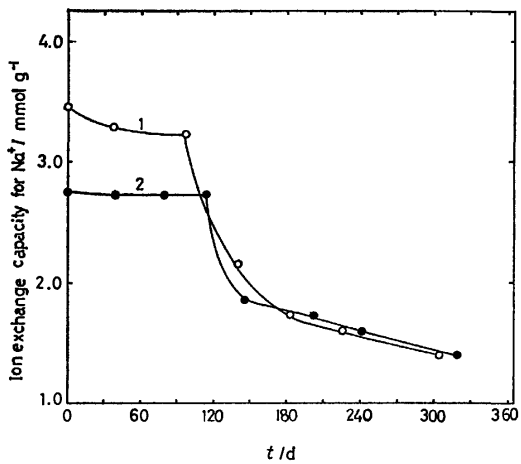

Fig. 1. Variation of ion-exchange capacity with time. ○: H^+ form, air-dried, ●: H^+ form, 80 °C heat-treatment.

the network structure[1] and that the material does not suffer so much loss in capacity as to become useless as an ion exchanger. A comparison of Curves 1 and 2 indicates that the capacity of Sample B decreased in the same way as that of Sample A. Besides, the capacities of Samples A and B reached the same value after standing for 180 d in spite of the difference in the initial values between the two samples. These facts suggest that the stabilization of the network structure does not play an important role in the stability of the exchange sites. In order to examine the effect on the acid-base property brought about by aging, the titration curves were measured for the samples stored for 320 d after the preparation, as is shown in Fig. 2. The titration curves for these samples were almost all the same. The breaking points in the curves were, however, observed at smaller amounts of OH^- for the aged samples than for the original ones. The titration curves in the pH range higher than that point ran parallel with each other. These findings strongly suggest that the most acidic exchange sites are liable to be destroyed upon standing. The preferential destruction of the most acidic sites was also observed when the exchanger was thermally treated in air.[1] The change in the composition of the exchanger was then studied by estimating the content of water from the weight loss on ignition to TiO_2. Table 1 shows that an appreciable amount of water was lost from the exchanger which had been stored for a long time. Accordingly, in a study of this kind, the exchange capacity normalized per unit amount of titanium should be used instead of the capacity defined on the basis of the unit mass of the exchanger thus far used, because, when using the latter, we can not exactly compare the capacity based on the same amounts of the original materials. The normalized capacity is represented in the last column in Table 1. The results in Table 1 are compatible with the general relationship that an exchanger with a higher water content has a larger ion-exchange capacity.[2-4] A sample which had been allowed to stand for 320 d was subjected to conditioning once again in order to examine the possibility of recovering the ion-exchange capacity. The reconditioning, however, was found not to be effective for that purpose. These facts clearly indicate that the destruction of the exchange site proceeds by means of an irreversible dehydrating condensation of the hydroxyl group with the loss of water. This change, however, was not accompanied by crystallization, because X-ray analysis exhibited no such diffraction pattern as appeared when the exchanger was thermally treated at 324 °C.[1] From these considerations, we can conclude that the exchanger is subjected to a drastic change in its ion-exchange property when it is allowed to stand for three months in air and that this deterioration results basically from the same mechanism as that observed when the exchanger was thermally treated at a temperature below 159 °C.[1]

Structure Determination of the Fluorescent Base from *Geotrichum candidum* Phenylalanine tRNA

Akihiko Mochizuki,* Yoshiaki Omata, and Yuji Miyazawa
Department of Chemistry, Science University of Tokyo, Shinjuku-ku, Tokyo 162
(Received February 7, 1979)

Synopsis. The chemical structure of the fluorescent base purified from *Geotrichum candidum* phenylalanine tRNA was determined as peroxywybutine by the use of MS, UV, and NMR measurements.

Modified nucleosides found in tRNA have been considered to play an important role in the functioning of tRNA. Hypermodified fluorescent bases, classified as "W," are located at the position adjacent to the 3′ side of the anticodon. The chemical structures of these fluorescent bases were determined as follows: α-(carboxyamino)-4,9-dihydro-4,6-dimethyl-9-oxo-1*H*-imidazo[1,2-*a*]purine-7-butyric acid dimethyl ester for wybutine obtained from yeast phenylalanine tRNA ($tRNA^{Phe}$),[1] 4,9-dihydro-4,6-dimethyl-9-oxo-1*H*-imidazo[1,2-*a*]purine for wye from *Torulopsis utilis* $tRNA^{Phe}$,[2] and α-(carboxyamino)-4,9-dihydro-β-hydroperoxy-4,6-dimethyl-9-oxo-1*H*-imidazo[1,2-*a*]purine-7-butyric acid dimethyl ester for peroxywybutine from rat liver $tRNA^{Phe}$.[3] Peroxywybutine was also found in wheat germ and bovine liver $tRNA^{Phe}$ by chromatographical[4] and spectrometrical[5] measurements respectively.

In this study, the hydrophobic and fluorescent base was purified from $tRNA^{Phe}$ of *G. candidum*[6,7] that is one of the simplest eukaryotic organisms and is classified as an aquatic fungus. The chemical structure of the base was determined to be peroxywybutine by the use of MS, UV, and NMR measurements.

Experimental

Preparation. Wet *G. candidum* cell[7] (10 kg) gave 4 g of crude tRNA by phenol extraction followed by the procedure of Miyazaki.[8] The crude tRNA was applied on a benzoylated DEAE-cellulose column and chromatographed as described by Gillam *et al.*[9] The rechromatography of the fraction eluted at 10% ethanol using the same column, as described by Litt,[10] showed a slight difference in the separation of $tRNA^{Phe}$ as compared with yeast $tRNA^{Phe}$. The specific activity of the $tRNA^{Phe}$ fractionated increased to 16 times that of the crude tRNA. The fraction containing 120 mg of $tRNA^{Phe}$ in 50 ml of water was incubated at 37 °C for 3.5 h at pH 2.9.[11,12] After neutralization, the fluorescent base liberated was extracted by ethyl acetate and purified by chromatography on Toyo No. 51A paper with a developing solvent prepared as the upper phase of a mixture of ethyl acetate : 1-propanol : water=4:1:2. The R_f value of the fluorescent base was 0.43. The base was extracted from the paper with water doubly distilled in a glass vessel. The base was then extracted again with the same volume of distilled chroloform six times and dried to an amorphous powder.

Measurements of Mass, UV, and NMR Spectra. The mass spectrum was measured with JMS-D300 on a lined JMA-2000 mass data system operated at 70 eV; PFK standard; $m/\Delta m=5000$; error, ±5 milli mass unit; 190 °C. The UV spectra were measured in water at pHs 2.42, 6.56, and 11.72 with the use of a Hitachi 200-20 spectrophotometer. The NMR spectrum was measured with JNM-PFT-100A in $CDCl_3$ containing 1% of C_2D_5OD, using TMS as the internal standard.

Results and Discussion

Table 1 shows the data of high-resolution MS of the base and elemental compositions. The ion peaks **1** and **c** are the parent and the base peaks respectively. The degradations of ions from the parent ion to the ion **2** and also from the ion **a** to the ion **b** correspond to a reduction of the mass unit equivalent to one oxygen atom. Fragmentations of the base can reasonably be presented by two pathways. The oxygen atom liberated would be originally found in the hydroperoxide group of the base, since hydroperoxides are known to lose an oxygen atom in mass spectrometry.[13] The results obtained by MS in this experiment show that the base contained the same fragment ion of $C_5H_8O_4N$ and the ion **c** as compared with those of wybutine previously reported,[1] though it contains two more oxygen atoms in the ion **a**. These results may be compared to the papers[3,5] reported for the chemical structure of peroxywybutine with quite a close agreement.

The UV spectra measured at each pH were very close to those of wybutine, and the absorption maxima were observed at 232 and 285 nm at an acidic pH, at 235, 262, and 311 nm at a neutral pH, and at 235, 265, and 303 nm at a basic pH. The comparison of the absorption maxima between the base measured in this experiment and the synthetic analogous compounds previously reported[1,14] suggests that the chromophore structure of this base is similar to that of wybutine.

In the NMR spectrum, the detection of four signals at 2.29, 3.71, 3.76, and 3.95 ppm was made possible by a scan repeated 17200 times. These peaks were close to those assigned to 6-C Me, methyl esters, and 4-N Me respectively, as reported for wybutine,[1,15] wye,[2] and peroxywybutine.[16]

As a result, discussions of the data obtained by MS, UV, and NMR lead to the conclusion that the fluorescent base purified from *G. candidum* $tRNA^{Phe}$ has the structure of the peroxide of wybutine.

Wye, wybutine, and peroxywybutine, all classified as "W," share the same 4,6-dimethylimidazopurine as a nucleus and have various side chains at the C-7 position of the nucleus. Wye and wybutine are found in simpler eukaryotic organisms, such as *Torulopsis utilis* and yeast $tRNA^{Phe}$'s respectively. On the other hand, peroxywybutine is found in such higher organisms as mammalian liver, *Lupinus luteus*, and wheat germ $tRNA^{Phe}$'s. It is interesting to find that $tRNA^{Phe}$ isolated from an aquatic fungus of *G. candidum* also gave the fluorescent base peroxywybu-

Table 1. Pertinent ions observed in the MS of the fluorescent base from *G. candidum* $tRNA^{Phe}$

Ion peaks	*m/e*	Elemental composition (mol wt)	Relative abundance/%
1	408.1358 (M^+)	$C_{16}H_{20}O_7N_6$ (408.1390)	3

Structural Dependence in a One-electron Transfer Process: Naphthalene *peri* Ketones[1)]

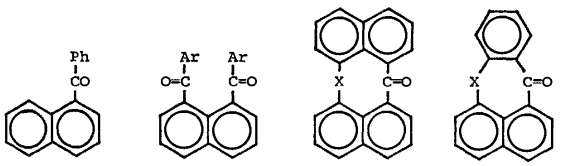
Takeo SATO,* Masao KUBO, and Kenji NISHIGAKI

Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received June 1, 1979)

Synopsis. The cyclic voltammetry of several naphthalene *peri* ketones was carried out in anhydrous DMF containing TBAP. The cathodic peak potential for carbonyl reduction was found to be shifted toward a more anodic potential when carbonyl, oxygen, and sulfur groups were present in the *peri* position. The controlled potential electrolysis of *peri* diketones gave an intramolecular coupling product *via* a bis-anion radical.

We have been exploring the relation between the oxidation-reduction potentials and the molecular geometry.[1,2)] It is particularly interesting to know how proximity effects influence an electron-transfer process. Since the *peri* positions in a naphthalene nucleus are only 2.4—2.5 Å apart,[3)] a series of those compounds with peri substituents will serve as good model substances for such studies. We examined the cyclic voltammetry (CV) of several naphthalene *peri* ketones in an aprotic solvent in order to elucidate the effect of the *peri* substituents on the carbonyl reduction.



1 **2**, Ar=Ph **3**, Ar=α-naphthyl **4**, X=CO **5**, X=O **6**, X=S **7**, X=CH_2 **8**, X=CO

The *peri* ketones used in the present study are **1**—**8**. The CV measurements were carried out in anhydrous DMF, containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate (TBAP) as a supporting electrolyte. The results are summarised in Table 1. For those compounds that gave a reversible voltammogram, such as **1** and **8**, the CV measurements were carried out at various scanning speeds. The results are shown in Table 2, together with several electrochemical parameters.

1-Benzoylnaphthalene (**1**) exhibited a quasi-reversible wave at $E^\circ=-1.71$ V *vs.* SCE. The peak-to-peak potential difference, $E_{pc}-E_{pa}$, was 220 mV at the scanning rate of 500 mV/s, but it became much smaller for lower scanning rates, which improve the reaction reversibility (Table 2). The current ratio, i_{pc}/i_{pa}, was nearly equal to unity. An interpretation that the reversible couple may correspond to a one-electron transfer process was derived by calculating n by using Randles-Cevcik equation[4)] (Table 2). When the scanning range was further extended to the cathodic side, another cathodic peak appeared at −2.5 V. For this second peak, however, no corresponding anodic peak was observed by reversed scanning. The addition of methanol caused E_{pc} to shift to the anodic side (Table 1). These results are considered to be specific for an aromatic ketone which has undergone succesive electron-transfer steps to give an anion radical and a dianion.[5)]

Compared with the monobenzoyl compound **1**, the *peri* diketones **2**, **3**, and especially **4** showed E_{pc}'s at an appreciably anodic potential. For example, the E_{pc} for **4** was −1.52 V compared with that of −1.8 V for **1**. These compounds also showed less reversible waves, as was assumed from the high i_{pc}/i_{pa} ratio of

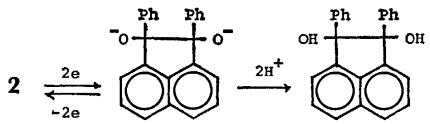
	100	180 190	1.2 1.3	23 22	0.88 0.84
	250	220 250	1.2 1.3	22 19	0.84 0.77

a) Determined in DMF-TBAP (0.1 mol dm^{-3}) at 25 °C. For the calculation of the n value, the Randles-Cevcik equation was used assuming $D=7.9\times10^{-7}$ cm^2/s (benzophenone); see Ref. 3.

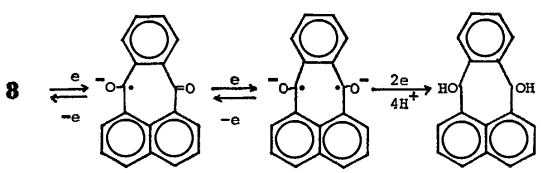
2.3—3.2. The results can be well interpreted to indicate a two-electron reduction, giving the pinacolate dianion **9**, since the intramolecular radical coupling of the bis-anion radical is geometrically favored. In fact, an intramolecular coupling product, **10**, was obtained by the controlled potential electrolysis of **1** at −2.0 V in ethanol containing potassium hydroxide, using a lead cathode. Similar results using a mercury cathode in aq ethanol have been reported.[6)] The unique geometry of **4** is assumed to be responsible for the anodic shift of the E_{pc}. It is considered that the steric strain in **4** caused by the steric interaction between the two parallel carbonyl groups is relieved by its being reduced to a dianion analogous to **9**.



9 **10**

The presence of hetero atoms, such as oxygen or sulfur, at the peri position was found to cause a further anodic shift of the cathodic waves. Both **5** and **6** showed E° at −1.4 V, the ΔE° from **1** being 0.3 V, reflecting the intramolecular stabilization effect of the hetero atom toward the one-electron reduction of a nearby carbonyl group.

Unlike **2**, **3**, and **4**, 7,12-pleiadenedione (**8**) showed two reversible redox couples at −1.2 and −1.7 V, each corresponding to a one-electron transfer (Table 2). The controlled potential electrolysis of **8** gave a diol, **13**. In **8**, the intramolecular coupling of the bis-anion radical is sterically disfavored and results in a two-step reduction. It became evident that pleiadenone, **7**, was more readily reduced than benzoylnaphthalene, **1**.



11 **12** **13**

Experimental

CV Measurements. The cyclic voltammetry was carried out in anhydrous DMF containing TBAP (0.1 mol dm^{-3}) using a two-compartment cell equipped with a nitrogen bubbler and SCE. A platinum inlay electrode (Beckman 32273) and a platinum wire were used as the working and counter electrodes respectively. The surface area of the working electrode was 0.204 cm^2. The electrochemical equipment used was the same as that described before.[2)]

Materials. The preparation of the *peri* ketones **1**—**8** has been reported elsewhere.[7)]

Controlled Potential Electrolysis of 2 and 8. A solution of 476 mg (0.96 mmol) of **2** in 200 ml of 2 mol dm^{-3} ethanolic potassium hydroxide was electrolyzed at −2.0 V using a lead cathode. The electrolysis was continued until 9 F/mol of electricity had been consumed. Compound **10** was then obtained in a 27.3% yield by chromatography on alumina eluted with hexane–benzene.

When compound **8** was similarly electrolyzed at −2.0 V, a 17% yield of the diol, **13**, was obtained; this was identical with the authentic sample (mp 197—200 °C), prepared by the sodium borohydride reduction of **8**.[8)] The electricity required was 4 F/mol.

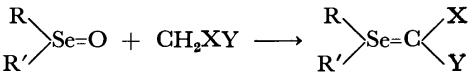
A Convenient Synthesis of Telluronium Ylides

Seizo TAMAGAKI,* Ryuji AKATSUKA, and Seizi KOZUKA
Department of Applied Chemistry, Faculty of Engineering,
Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558
(Received June 15, 1979)

Synopsis. Several telluronium ylides were readily prepared by mixing the corresponding telluroxides and a variety of active methylene compounds in $CHCl_3$ at ambient temperature or under reflux. Arylselenonium ylides could also be obtained in a similar way.

We recentry reported a convenient procedure to prepare several alkyl and arylalkyl selenonium ylides by treating the corresponding selenoxides and active methylene compounds at room temperature.[1] Mean-



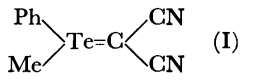
X, Y=CN or COOMe

while, only a few publications have been available on the general synthesis of telluronium ylides. Sadekov *et al.* reported that diaryl tellurium dichlorides gave the ylides when allowed to react with 5,5-dimethyl-1,3-cyclohexanedione (dimedone) in the presence of base in refluxing benzene.[2]

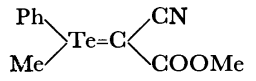
In this article it is described that the method previously developed by us for the synthesis of selenonium ylides can be applied successfully to the preparation of telluronium analogs starting from telluroxides which are easily available.

Results and Discussion

A typical reaction is as follows: phenyl methyl telluroxide was treated with a 3-fold excess of malononitrile and methyl cyanoacetate in $CHCl_3$ at ambient temperature. After 12 h, evaporation of the solvent afforded solids of phenylmethyltelluronium dicyanomethylide (I) and cyano(methoxycarbonyl)methylide (II), respectively.



(I)



(II)

As was observed in the IR spectrum of the corresponding selenonium dicyanomethylide,[1,3] the cyano groups in the telluronium dicyanomethylide (I) also exhibited two absorption bands with comparable intensity at 2120 and 2160 cm^{-1}. The IR bands due to the cyano and carbonyl groups in II shift to lower wavelengths as compared to those of methyl cyanoacetate.

Meanwhile, when diphenyl telluroxide was utilized as a telluroxide, any reaction did not take place at room temperature. However, upon refluxing a chloroform solution of the oxide and an equimolar amount of methylene compounds for 10 h, the formation of

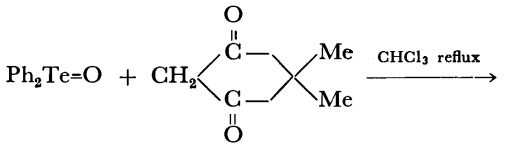
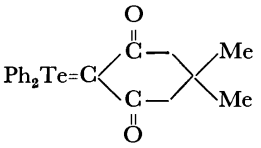
the ylides was attained in excellent yields. For instance, dimedone upon treatment with diphenyl telluroxide, afforded quantitatively the corresponding ylide (V).





(V)

The yields and physical data of these ylides are summarized in Table 1.

In a similar way, the attempt to prepare diarylselenonium counterparts, which were not obtained previously by the reaction at room temperature, can be realized in good yields.

The method described here is a useful and convenient alternative for the preparation of telluronium ylides, since it involves merely mixing reagents under mild conditions and only simple work-up of the reaction mixture as compared with that of Sadekov *et al.*[2]

Experimental

Preparation of Ylides. A mixture of phenyl methyl telluroxide (1 mmol, 235 mg) and a 3-fold excess of malononitrile in 20 ml of $CHCl_3$ was kept standing at room temperature for 12 h. After evaporation of the solvent, the resulting solid was recrystallized from $CHCl_3$–ether, giving 82% of phenylmethyltellurium dicyanomethylide (I): Found: C, 41.86; H, 2.88; N, 9.68%. Calcd for $C_{10}H_8N_2Te$: C, 42.31, H, 2.82; N, 9.87%. Similarly, the corresponding cyano(methoxycarbonyl)methylide(II) was prepared: Found: C, 41.29; H, 3.80; N, 4.71%. Calcd for $C_{11}H_{11}NO_2Te$: C, 41.62; H, 3.51; N, 4.46%. III: Found: C, 43.44; H, 3.86, N, 4.29%. Calcd for $C_{12}H_{13}NO_2Te$: C, 43.56, H, 3.93; N, 4.23%.

Compounds (IV—VII) were prepared by refluxing a $CHCl_3$ solution of diaryl telluroxides (1 mmol) and one equivalent of methylene compounds for 15 h. After the solvent was stripped off, V and VII were purified by recrystallization from benzene–hexane and ether, respectively. V: Found: C, 57.05; H, 4.78%. Calcd for $C_{20}H_{20}O_2Te$: C, 57.18, H, 4.80%. VII: Found: C, 65.89; H, 5.91%. Calcd for $C_{22}H_{24}O_2Se$: C, 66.14; H, 6.06%. IV and VI were purified by precipitation with ether from their $CHCl_3$ solutions.

Electrolytic α-Bromination of Some α-Substituted Active Methylene Compounds

Sigeru Torii,* Kenji Uneyama, and Noritsugu Yamasaki
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received June 29, 1979)

Synopsis. Electrolytic α-bromination of methyl α-substituted malonates and methyl α-substituted acetoacetates was accomplished in 73—84% yields in dichloromethane containing tetraethylammonium bromide as an electrolyte and sodium methoxide as an enolizing reagent.

Electrolytic bromination and bromohydrination of olefins proceed *via* electrophilic attack by electrochemically generated bromonium ion or bromine.[1] Enolate **2** would be brominated in principle by electrolysis to give the corresponding bromo compounds **3**. Reports have appeared on the electrolytic α-halogenation of acetone,[2] cyclohexanone, acetophenone,[3] and acetic acid[4] in a strong acidic medium such as hydrochloric acid. However, α-bromonation of active methylene and methine of malonates and acetoacetates dose not seem to have been studied.[5,6] During the course of studies on the reaction by electrochemically generated halonium ion, we found a typical electrolytic condition which enables us to trap the electrochemically generated bromonium ion with active methylene compounds and also prevents oxidation of the enolate **2**, leading to dimerization. Although direct bromination with bromine gives the corresponding bromo compounds, active methylene compounds bearing an olefinic functional group may suffer bromination of the carbon-carbon double bond in the reaction. In this article we describe

an electrolytic α-bromination of **1** which is characterized by (1) bromination without use of molecular bromine or hydrobromic acid and (2) selective bromination at α-possition of olefinic active methylene compounds.

Compounds **1a—1f** were prepared by the alkylation of methyl malonate and methyl acetoacetate.[7] The reaction conditions and results of electrolysis of **1** are given in Table 1. The compounds gave α-brominated products **3** in 73—84% yields. Alkenylated substrate **1c** gave **3c** in 83% yield without modifying the carbon-carbon double bond. Dichloromethane was found to be a useful solvent for most of the substrates. Methanol and a mixed solvent of MeCN–H_2O were chosen for **1b** and **1d**, respectively, to attain the optimum yields of **3b** and **3d**. The quantity of sodium methoxide required for the electrolysis seems to be variable depending on the acidity of the substrate and polarity of the solvent.[8]

A characteristic feature of the electrolysis is that high current densities are required (87—133 mA/cm²) to terminate the reaction within a few minutes for the mili mole scale experiment. The yield of **3a** was unsatisfactory (42%) at lower current densities and several byproducts being obtained, one of which was the corresponding dimeric malonate (21%).[9] A soluble brominating reagent (electrolyte) was used. The behavior of **1d** in CH_2Cl_2 differed electrolysis with use of Et_4NBr (10—20 eq) affording *ca.* 50% of **3d** along with methyl α-chloromalonate (10—20%) as a byproduct. The yield of the chloro compound reached 50—60% at a lower concentration of Et_4NBr (1—2 eq). The use of sodium bromide in methanol resulted in a poor yield of **3d**. In contrast, electrolysis using Mg(II) or Cu(II) bromide in a mixed solvent of MeCN/H_2O (1/7 v/v) was successful.

Experimental

IR spectra were obtained with a JASCO IRA-1 spectrometer, and ^1H NMR spectra with a JNM FX-100 fourier

transform spectrometer at 100 MHz in $CDCl_3$ using Me_4Si as an internal standard.

*Methyl α-(3-Methyl-2-butenyl)malonate (**1c**).* Compound **1c** was prepared by alkylation of methyl malonate with 1-chloro-3-methyl-2-butene: IR (neat) 2960, 1760, 1740, 1460, 1246, 1155 cm^{-1}; NMR δ 1.63 (3H, s, CH_3), 1.68 (3H, s, CH_3), 2.58 (2H, t, J=7.4 Hz, CH_2), 3.36 (1H, t, J=7.7 Hz, CH), 3.73 (6H, s, CH_3O), 5.03 (1H, t, J=7.3 Hz, CH=). Found: C, 59.70; H, 8.25%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

*Methyl α-Bromo-α-butylmalonate (**3a**) (Electrolysis of **1a**).* A mixture of **1a** (30 mg), Et_4NBr (850 mg), and MeONa (45 mg) dissolved in dry CH_2Cl_2 (7 ml) was electrolyzed using Pt foils (2×1.5 cm^2) at 6—8 °C with a constant current (260 mA) for 3.5 min. On passing electricity, the mixture turned yellow. After evaporating the solvent, the residue was mixed with water and acidified with 5% HCl. The organic substances were extracted with ether, treated with CH_2N_2, and chromatographed (SiO_2, benzene) to give **3a** (37 mg, 84%) as a colorless oil; IR (neat) 2966, 2880, 1743, 1435, 1254, 1130 cm^{-1}; NMR δ 0.92 (3H, t, J= 6.5 Hz, CH_3), 1.10—1.52 (4H, m, CH_2), 2.10—2.40 (2H, m, CH_2), 3.82 (6H, s, CH_3). Found: C, 40.34; H, 5.38%. Calcd for $C_9H_{15}O_4Br$: C, 40.47; H, 5.66%.

*Methyl α-Bromo-α-(3-methyl-2-butenyl)malonate (**3c**)*: IR (neat) 2945, 1747, 1434, 1243 cm^{-1}; NMR δ 1.64 (3H, s, CH_3), 1.73 (3H, d, J=1.2 Hz, CH_3), 3.01 (2H, d, J=7.3 Hz CH_2), 3.81 (6H, s, CH_3O), 5.10 (1H, t, J=7.3 Hz, CH=). Found: C, 42.83; H, 5.47%. Calcd for $C_{10}H_{15}O_4Br$: C, 43.03; H, 5.42%.

*Methyl 2-Acetyl-2-bromohexanoate (**3e**)*: IR (neat) 2960, 1730, 1439, 1250 cm^{-1}; NMR δ 0.92 (3H, t, J=6.5 Hz, CH_3), 1.10—1.50 (4H, m, CH_2), 2.08—2.32 (2H, m, CH_2), 2.40 (3H, s, CH_3), 3.82 (3H, s, CH_3O). Found: C, 43.25; H, 5.73%. Calcd for $C_9H_{15}O_3Br$: C, 43.05; H, 6.02%.

*Methyl 2-Benzyl-2-bromo-3-oxobutanoate (**3f**)*: IR (neat) 3040, 2965, 1730, 1440, 1255, 705 cm^{-1}; NMR δ 2.35 (3H, s, CH_3), 3.47 (1H, d, J=17.0 Hz, CH_2), 3.64 (1H, d, J=17.0 Hz, CH_2), 3.75 (3H, s, CH_3O), 7.24 (5H, m, ArH). Found: C, 50.70; H, 4.76%. Calcd for $C_{12}H_{13}O_3Br$: C, 50,55; H, 4.60%.

Bromo compound **3b** has been reported.[10]

New Effective Nickel(II) Catalysts for the Cross-coupling of an Aryl Grignard Reagent with Aryl Halide

Eiichi IBUKI, Shigeru OZASA, Yasuhiro FUJIOKA,* Motofumi OKADA, and Katsutoshi TERADA

Department of Organic Chemistry, Kyoto College of Pharmacy, Misasagi, Yamashina-ku, Kyoto 607

(Received July 9, 1979)

Synopsis. It has been found that seventeen nickel complexes of the Ni–O_4, Ni–S_4, Ni–O_2N_2, Ni–O_3N_3, Ni–N_4, Ni–N_6, and Ni–$(C_5)_2$ types exhibit a high catalytic activity for the selective cross-coupling reaction of an aryl Grignard reagent with aryl iodide, which make possible the synthesis of unsymmetrical aromatics of a high purity and in a high yield.

In connection with the search for an effective method of C_{ar}–C_{ar} bond formation, Corriu and Masse[1] have reported that bis(acetylacetonato)nickel(II) catalyzes the selective cross-coupling reaction between aromatic Grignard reagents and aryl or alkenyl halides. Tamao *et al.*[2] have independently found a high catalytic activity of nickel-phosphine complexes for similar cross-coupling reactions. The present study was undertaken in order to develop a new, efficient catalyst for the synthesis of unsymmetrical biaryls by means of a Kharasch-type reaction.

The catalytic activity of a variety of nickel complexes was examined using a cross-coupling reaction of phenylmagnesium bromide with 2-iodobiphenyl as a model under a standard set of conditions. The activities of seventeen complexes and those of the four known representative catalysts, determined as the yield of *o*-terphenyl[I], are given in Table 1. The seventeen complexes showed a fairly high activity (a 70—90% yield of I), eleven of them exhibiting an activity superior to that of the four known catalysts used for comparison (57—78%; **12**, **19**, **20**, and **21**). Although in all cases, I was accompanied by 16—43% of biphenyl[II] and no, or only a small amount of, *o*-quaterphenyl[III]. I could easily be separated from these contaminants. Thus, the seventeen complexes, particularly eleven of them, were found to be preferential catalysts for the synthetic production of unsymmetrical aromatics of a high purity and in a high yield.

The seventeen new catalysts are classified briefly into the following groups: i) the Ni–O_4 complexes of the β-diketones and aldehyde ligands (**2**, **10**, **14**, **16**, and **8**); ii) the Ni–S_4 complex of the β-dithioketone ligand (**11**); iii) the Ni–O_2N_2 complexes of the β-keto imines and Schiff-base ligands (**1**, **6**, and **4**); iv) the Ni–O_3N_3 complex of the amino acid ligand (**9**); v) the Ni–N_4 and Ni–N_6 complexes of substituted amides, dioxime, and the diamine ligands (**3** and **5**; **15**; **17**, **13**, and **18**), and vi) the Ni–$(C_5)_2$ complex of the carbanion ligand (**7**). Although most of the new catalysts are diamagnetic square-planar complexes of bis-bidentate or quadridentate ligands (**1**,[3] **2**,[4] **3**,[5] **4**,[6a] **5**,[5] **11**,[6b] and **15**), a few octahedral complexes of tris-bidentate ligands (**9**,[6c] **13**, and **18**) as well as strongly paramagnetic complexes (**7**[7] and **8**[8]) are also included in the new catalysts. In contrast to the trimeric octahedral structure of **12**[9a,b] and **14**[9c] in solution, **2** has been reported to exist as a monomeric structure, presumably because of the steric hindrance of the ligand.[4a] It seems of interest to note that the catalytic activity of coordinately saturated complexes (**9**, **13**, and **18**) is nearly comparable to that of unsaturated ones. Another result of considerable significance is the observation that the activities of a series of four closely related complexes (**10**, **12**, **14**, and **16**), the logarithms of their formation constants,[10] and the negative logarithms of the acid dissociation constants of the ligands[10] show a rather fair correlation, as is shown in Table 2.

The foregoing results suggest that the catalytic activity of the complexes has no remarkable relation with such factors as the kind and number of coordinate atoms, the size and number of chelate rings, the aggregation degree of complexes, and the steric effect of the ligands, or, consequently, with the configuration and magnetic susceptibility of the complexes. Ultimately, for the excellent catalytic activity of the complexes, the presence of Ni(II) as the central metal can be regarded

as essential,[11] and an appropriate range of stability may be attributable to one of the invaluable factors.

Experimental

Instruments. The melting points were determined with a Mettler FP-51 or FP-52 apparatus. The UV spectra were measured on a Shimadzu MPS-50L spectrophotometer in cyclohexane solutions. The ^{1}H NMR spectra were obtained with a Varian A-60A spectrometer in a $CDCl_3$ solution, using TMS as an internal standard. Quantitative GLPC was performed on a Shimadzu GC-5APTF gas chromatograph using a 1 m×3 mmϕ glass column 3% Dexsil 300GC or Silicone OV-17 on Chromosorb W AW-DMCS.

Materials. The following complexes used as catalysts, except those available commercially (**7**, **12**, and **15**), were prepared according to the references or by known methods, and all gave satisfactory physical data and acceptable results in elemental analyses.

N,N'-Bis(1-methyl-3-oxobutylidene) ethylenediaminatonickel(II)[3c] (**1**), bis(dipivaloylmethanato)nickel(II)[4b] (**2**), *N,N'*-dipicolinoyl-1,3-propanediaminatonickel(II) hydrate[5] (**3**), bis[*N*-(2-furylmethyl)salicylideneaminato]nickel(II)[6a] (**4**), *N,N'*-dipicolinoyl-1,2-propanediaminatonickel(II) trihydrate[5] (**5**), bis(4-imino-2-pentanonato)nickel(II)[12b] (**6**), bis(η-cyclopentadienyl)nickel(II) (**7**), bis(salicylaldehydato)-nickel(II) dihydrate[8] (**8**), potassium tris(L-prolinato)-niccolate(II) trihydrate[6c] (**9**), bis(trifluoroacetylacetonato)-nickel(II) (**10**), bis(dithioacetylacetonato)nickel(II)[6b] (**11**), bis(acetylacetonato)nickel(II) (**12**), tris(ethylenediamine)-nickel(II) chloride dihydrate[12a] (**13**), bis(benzoylacetonato)-nickel(II) hydrate[13] (**14**), bis(dimethylglyoximato)nickel(II) (**15**), bis(dibenzoylmethanato)nickel(II)[14] (**16**), dichloro-[bis(ethylenediamine)]nickel(II)[15] (**17**), tris(bipyridine)nickel-(II) chloride heptahydrate[16] (**18**), dichloro[1,3-bis(diphenylphosphino)propane]nickel(II)[17] (**19**), dichloro[bis(triphenylphosphine)]nickel(II)[18a] (**20**), dichloro[1,2-bis(diphenylphosphino)ethane]nickel(II)[17] (**21**).

Coupling Reactions. To an ethereal solution of phenylmagnesium bromide (20 mmol), prepared in the usual manner, we added, all at once, a mixture of 2-iodobiphenyl[18b] (10 mmol) and a catalyst **12** (0.5% of C_6H_5MgBr) in benzene at 0 °C under a nitrogen atmosphere. The mixture was stirred for 1 h, refluxed for 3 h, and hydrolyzed, and then the product was extracted with benzene. The organic layer was separated, washed with water, and then dried. Upon the withdrawal of a tenth part of the solution for analysis, the remainder was subjected to the isolation of the products. After the removal of the solvent, the resulting solid was separated into three fractions by chromatography on alumina, with cyclohexane as the eluent. Upon the evaporation of the solvent, the fractions afforded II, I, and III, which were identified by means of mixed-melting-point measurements and by means of a spectral comparison with each of the authentic samples.

o-*Terphenyl*[*I*]: Mp 56.7 °C (lit,[19] mp 56—57 °C); yield, 1.65 g (79.7%). NMR: δ 7.16 (10H, s, C_6H_5), 7.40 (4H, s, C_6H_4). UV: λ_{max} (ε) 197 (48300), 207 (46500), 233 (29100), 251 nm (sh) (13300).

Biphenyl[*II*]: Mp 69.4 °C; yield, 0.37 g (26.7%). NMR: δ 7.16—7.70 (10H, m, C_6H_5).

o-*Quaterphenyl*[*III*]: Mp 118 °C (lit,[18b] mp 118—119 °C); yield, 0.03 g (2.2%). UV: λ_{max} (ε) 201 (60600), 230 (34100), 245 nm (sh) (25600).

The yields of the coupling products were determined by quantitative GLPC, using *m*-terphenyl as an internal standard calibrated against the pure samples.

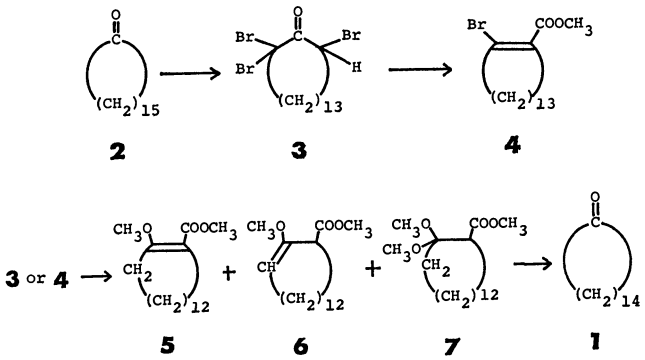
Synthesis of Cyclopentadecanone by Ring Contraction of Cyclohexadecanone

Tetsuya KATO,* Hisao KONDO, and Akihisa MIYAKE
Basic Research Laboratries, Toray Industries, Inc., Tebiro, Kamakura 248
(Received August 10, 1979)

Synopsis. Cyclopentadecanone has been synthesized from cyclohexadecanone. 2,2,15-Tribromocyclohexadecanone, upon treatment with sodium methoxide, underwent the Favorskii rearrangement *via* methyl 2-bromo-1-cyclopentadecene-1-carboxylate to produce a mixture of methyl 2-methoxy-1-cyclopentadecene-1-carboxylate, methyl 2-methoxy-2-cyclopentadecene-1-carboxylate, and methyl 2,2-dimethoxycyclopentadecane-1-carboxylate which was converted into cyclopentadecanone.

Cyclopentadecanone **1** occurs naturally as a secretion of the musk rat[1] and has attracted considerable interest due to its usefulness as a valuable perfume base. Many synthetic routes have been developed for the synthesis of cyclopentadecanone **1** from various starting materials.[2] In relation to our own interest in devising simplified approaches to the synthesis of cyclopentadecanone **1**, we have investigated the ring contraction of cyclohexadecanone **2** by applying the Favorskii rearrangement of trihalogenated ketones.[3] Our synthetic route is outlined in the following scheme.



Cyclohexadecanone **2** was easily prepared according to the method developed by Nishino *et al.*[4] Bromination of the ketone **2** with 3.5 molar equiv of bromine in dichloromethane at 25—30 °C for 20 h gave 2,2,15-tribromocyclohexadecanone **3** as colorless crystals in 92% yield.

The Favorskii rearrangement of the tribromo ketone **3** was carried out by using 2.2 molar equiv of sodium methoxide in methanol at 20 °C to afford methyl 2-bromo-1-cyclopentadecene-1-carboxylate **4** as a mixture of *cis*- and *trans*-isomer in 83% yield. The distinction between the *cis*- and *trans*-isomer has been made on the basis of a comparison of the difference in the NMR chemical shifts of the allylic methylene protons.[5] The allylic methylene protons of the *cis*-isomer resonate at 2.16—2.60 ppm whereas those of the *trans*-isomer resonate at 2.20—3.30 ppm. Bases such as magnesium methoxide, triethylamine, or calcium hydroxide also gave satisfactory results.[6] Further treatment of the bromo ester **4** with 3.3 molar equiv of sodium methoxide in methanol afforded three major compounds **5**, **6**, and **7** in 88% yield (**5**+**6**, 71%; **7**, 17%). The reaction proceeded smoothly under reflux. In preparative runs the tribromo ketone **3** was directly converted into a mixture of the methoxy esters **5**, **6**, and **7**, without any separation of the bromo ester **4**, by using 5.2 molar equiv of sodium methoxide in methanol. Each methoxy ester was isolated by chromatographic purification on silica gel. The mixture of **5**, **6**, and **7** was then saponified with sodium hydroxide in refluxing aqueous methanol for 7 h to give the corresponding enol ether carboxylic acid and ketal carboxylic acid derivatives. Acid-catalyzed hydrolysis and subsequent decarboxylation of the resulting carboxylic acids with hydrochloric acid in methanol afforded cyclopentadecanone **1** in 80% yield.

Experimental

Melting and boiling points are uncorrected. Gas-liquid chromatography (GLPC) analyses were preformed on a Shimadzu 3BT instrument using 2% silicone SE-52 coated on Chromosorb GHP (80—100 mesh) packed in glass columns (3 mm×1.2 m). The following spectrometers were used: IR, Hitachi EPI-S-2; NMR, Varian XL-100 and HA-100 (TMS as internal standard); mass spectra, Hitachi RMU-7M and RMS-4. Silica gel (Merck, 70—230 mesh) was used for column chromatography.

*2,2,15-Tribromocyclohexadecanone (**3**).* Bromine (320 g 2.00 mol) was added dropwise over a period of 1.5 h to a cold (0—5 °C) stirred solution of cyclohexadecanone **2** (136 g. 0.571 mol) in dichloromethane (300 ml). After the addition was completed, stirring was continued at 25—30 °C for 20 h. The reaction mixture was poured into water and extracted with dichloromethane. The dichloromethane extracts were washed succesively with aqueous sodium hydrogensulfite solution and water and dried over anhydrous magnesium sulfate. Evaporation of the solvent under reduced pressure gave 273 g of yellow oil which was crystallized from methanol (−30 °C) to afford 250 g of tribromo ketone **3** (92%): mp 41—42 °C; IR (KBr) 1715 cm^{-1}; NMR ($CDCl_3$) δ 0.5—2.5 (m, 26H with a s at 0.77), 4.73 (dd, J=6 and 7.5 Hz, 1H). Found: C, 40.41; H, 5.50; Br, 50.68%. Calcd for $C_{16}H_{27}OBr_3$: C, 40.45; H, 5.73; Br, 50.48%.

*Methyl 2-Bromo-1-cyclopentadecene-1-carboxylate (**4**).* To a solution of tribromo ketone **3** (39.2 g, 82.5 mmol) in anhydrous methanol (220 ml) was added dropwise a solution of sodium methoxide in methanol (0.88 mol/l, 207 ml, 182 mmol) over a period of 1.5 h at 20 °C. After the addition was completed, stirring was continued at 20 °C for an additional 1 h. The reaction mixture was poured into cold water and extracted with hexane. The hexane extracts were washed with water and dried over anhydrous magnesium sulfate. After the solvent had been removed the residue was distilled (oil bath 180 °C/0.5 Torr) to give 26.3 g of yellow oil. GLPC analysis (165 °C) showed two major peaks due to *cis*- (50.1%) and *trans*-bromo ester **4** (39.8%). The yield was 83%. Each isomer was isolated by silica gel chromatography (benzene/hexane, 1/3—1/5).

4 (*trans*-isomer): bp 155—156 °C/0.8 Torr; $n_D^{20}=1.5120$; IR (neat) 1724, 1614 cm^{-1}; NMR ($CDCl_3$) δ 1.1—1.9 (s, 22H), 2.20—3.30 (m, 4H), 3.76 (s, 3H); *m/e* 346, 344 (M^+). Found: C, 59.14; H, 8.35; Br, 23.21%. Cacld for $C_{17}H_{29}O_2Br$: C, 59.13; H, 8.47; Br, 23.14%. **4** (*cis*-isomer): bp 159—160 °C/0.6 Torr; $n_D^{20}=1.5127$; IR (neat) 1727, 1641 cm^{-1}; NMR ($CDCl_3$) δ 1.1—1.8 (s, 22H) 2.16—2.60 (m, 4H), 3.77 (s, 3H); *m/e* 346, 344 (M^+). Found: C, 59.12; H, 8.24; Br, 23.23%. Calcd for $C_{17}H_{29}O_2Br$: C, 59.13; H, 8.47; Br, 23.14%.

*Methoxy Esters (**5**, **6**, and **7**).* A solution of sodium methoxide in methanol (3.0 mol/l, 50 ml, 150 mmol) was added to bromo ester **4** (17.25 g, purity 89.9%, 150 mmol) at 20 °C. The mixture was refluxed for 5 h, cooled, poured into cold water and dried over anhydrous sodium sulfate. After the solvent had been removed the residue was distilled (oil bath 180 °C/0.4 Torr) to give 12.25 g of oil. GLPC analysis showed that methoxy esters **5**, **6**, and **7** were obtained in 88% yield (**5**+**6**, 71%; **7**, 17%). Each ester was isolated by silica gel chromatography (benzene/hexane, 1/5—1/1). **5**: IR (neat) 1705, 1613 cm^{-1}; NMR ($CDCl_3$) δ 0.9—1.8 (s, 22H), 2.0—2.7 (m, 4H), 3.58 (s, 3H), 3.63 (s, 3H), *m/e* 296 (M^+). Found; C, 72.89; H, 10.63%. Calcd for $C_{18}H_{32}O_3$: C, 72.93; H, 10.88%. **6**: bp 142—143 °C/0.5 Torr; $n_D^{20}=1.4880$; IR (neat) 1737, 1655 cm^{-1}; NMR ($CDCl_3$) δ 1.1—2.3 (m, 24H with a s at 1.30), 3.38—3.60 (m, 1H), 3.46 (s, 3H), 3.64 (s, 3H), 4.48 (t, J=7 Hz, 1H); *m/e* 296 (M^+). Found: C, 72.94; H, 10.95%. Calcd for $C_{18}H_{32}O_3$: C, 72.93; H, 10.88%. **7**: IR (neat) 1739 cm^{-1}; NMR (CCl_4) δ 1.0—2.0 (m, 26H with a s at 1.38), 2.73 (dd, J=3 and 11 Hz, 1H), 3.12 (s, 3H), 3.19 (s, 3H), 3.62 (s, 3H); *m/e* 328 (M^+). Found: C, 69.69; H, 10.89%. Calcd for $C_{19}H_{36}O_4$: C, 69.47; H, 11.04%.

*Cyclopentadecanone (**1**).* A solution of sodium hydroxide (10.0 g, 250 mmol) in aqueous methanol (H_2O/MeOH, 1/3, 75 ml) was added to the ester mixture (14.8 g, **5**+**6** 90.9%, 45.4 mmol; **7** 6.7%, 3.0 mmol) and refluxed for 7 h. The reaction mixture was cooled and made acid to Bromophenol Blue by the addition of concentrated hydrochloric acid. After hydrochloric acid (35%, 30 ml) had been added, the reaction mixture was refluxed for 1 h, cooled, and extracted with benzene. The benzene extracts were washed with water and dried over anhydrous sodium sulfate. After the solvent had been removed the residue was distilled (oil bath 180 °C/0.4 Torr) to give 10.79 g of crude cyclopentadecanone. GLPC analysis showed one major peak due to cyclopentadecanone **1** (80% yield). Pure cyclopentadecanone was obtained by fractional distillation. The IR, NMR, and mass spectral data were identical with those of an authentic sample.

Synthesis of 1-Substituted 3-(Dialkylaminoalkoxy)-4,5,6,7-tetrahydro-1*H*-indazoles

Takeo Soga,* Hirosuke Niwa, and Takanori Shiraishi

Oomiya Research Laboratory of Nikken Chemicals Co., Ltd., Kitabukuro-cho, Oomiya-shi, Saitama 330

(Received August 25, 1979)

Synopsis. 4,5,6,7-Tetrahydro-3-indazolone was prepared by catalytic hydrogenation of 3-indazolone, and its reaction with dialkylaminoalkyl chloride was studied. In addition, a number of 1-substituted 3-(dialkylaminoalkoxy)-4,5,6,7-tetrahydro-1*H*-indazoles were prepared.

Indazole[1] nucleus is of high therapeutic interest and benzydamine[2] represents an antiinflammatory drug with this heterocyclic nucleus. Barbaz *et al.*[3] reported the synthesis of 1-substituted 3-hydroxy-4,5,6,7-tetrahydro-1*H*-indazoles (**8**) by cyclization of *N*-substituted 2-chlorocyclohexene-1-carbohydrazides and the 3-*O*-alkylation of **8** to give 1-substituted 3-(dialkylaminoalkoxy)-4,5,6,7-tetrahydro-1*H*-indazoles (**7**). In this paper, we describe a new synthesis of a series of 3-(dialkylaminoalkoxy)-4,5,6,7-tetrahydro-1*H*-indazoles (**3**) and its 1-substituted derivatives (**7**). We have prepared 4,5,6,7-tetrahydro-3-indazolone (**2**) in good yield by catalytic hydrogenation of 3-indazolone (**1**) with palladium catalyst and identified it by comparison with an authentic specimen prepared by the procedure of Dieckmann.[4]

As to alkylation of **2**, Alt and Chupp[5] reported that the alkylation of **2** with alkyl halides in aqueous ethanolic sodium hydroxide gave 1-substituted derivatives (**8**). We have found that, when the reaction of **2** with 3-(dimethylamino)propyl chloride is carried out in a nonaqueous medium, a 3-*O*-monosubstituted derivative, namely, 3-[3-(dimethylamino)propoxy]-4,5,6,7-tetrahydro-1*H*-indazole (**3a**) is mainly produced in 57% yield. A minor product in this reaction was 1,3-*O*-disubstituted derivative, namely, 3-[3-(dimethylamino)propoxy]-1-[3-(dimethylamino)propyl]-4,5,6,7-tetrahydro-1*H*-indazole (**5**). Similar treatment of **2** with 2-(diethylamino)ethyl chloride in dioxane gave 3-[2-(diethylamino)ethoxy]-4,5,6,7-tetrahydro-1*H*-indazole (**3b**). The structures of **3a** and **3b** were deduced mainly from the NMR spectra, which exhibited signals at δ 4.10—4.12 (t, 3-O-C<u>H</u>$_2$-CH$_2$-), indicating the 3-*O*-substitution.

As an alternative possibility to the above mentioned synthesis of 3-*O*-substituted 4,5,6,7-tetrahydro-1*H*-indazolones (**3**), we studied the catalytic hydrogenation of 3-(dialkylaminoalkoxy)-1*H*-indazoles (**4**)[6] previously reported by us, and obtained **3a** from 3-[3-(dimethylamino)propoxy]-1*H*-indazole (**4a**) in 92% yield. Compound **3b** was further obtained by the similar catalytic hydrogenation of 3-[2-(diethylamino)ethoxy]-1*H*-indazole (**4b**).[6] The above mentioned compound **5** was also obtained by catalytic hydrogenation of 3-[3-(dimethylamino)propoxy]-1-[3-(dimethylamino)-propyl]-1*H*-indazole (**6**).[6]

Thus, the 3-*O*-substituted 4,5,6,7-tetrahydro-1*H*-indazolones (**3**) have been synthesized by the route (**1**)→(**2**)→(**3**) and another route (**4**)→(**3**). In addition, the 3-*O*-substituted compounds (**3**) were led to 1,3-*O*-disubstituted 4,5,6,7-tetrahydro-1*H*-indazolones (**7**) by reaction of the sodium salt of **3** with alkyl halides or other halides in liquid ammonia or hexamethylphosphoric triamide. The structures of **7** were confirmed by their NMR, IR, and UV spectra.

Experimental

4,5,6,7-Tetrahydro-3-indazolone (2). A solution of 3-indazolone (**1**,[7] 0.89 g) in acetic acid (30 ml) was hydrogenated in the presence of Pd–carbon (Pd 5%) (2.67 g) under hydrogen atmosphere at 50 °C for about 7 h. The catalyst was filtered off and the filtrate was evaporated *in vacuo* to give **2**, crystals, mp 289.5—291.5 °C (0.79 g, 86%). Recrystallization from methanol gave mp 293.5—295.0 °C. UV$_{max}$(C_2H_5OH): 250 nm (ε 6350). This material was identified by the determination of mixed melting point with an authentic specimen.[4]

3-[3-(Dimethylamino)propoxy]-4,5,6,7-tetrahydro-1H-indazole (3a). By Reaction of 2 with 3-(Dimethylamino)propyl Chloride: A sample of **2** (5.53 g) was dissolved in an aqueous 1 M sodium hydroxide (40 ml) with stirring. The solution was evaporated under reduced pressure to give a solid of sodium salt, which was further dried in an oven. The salt was powdered and suspended in dry dioxane (134 ml). A solution of 3-(dimethylamino)propyl chloride (5.11 g) in dry dioxane (66 ml) was added under stirring and refluxing over a 1.5 h period. Refluxing and stirring were further continued for 4.5 h. The reaction mixture was worked up in the usual way to give an oily product (6.65 g), which consisted of two components, **3a** and **5**, as judged by GLC

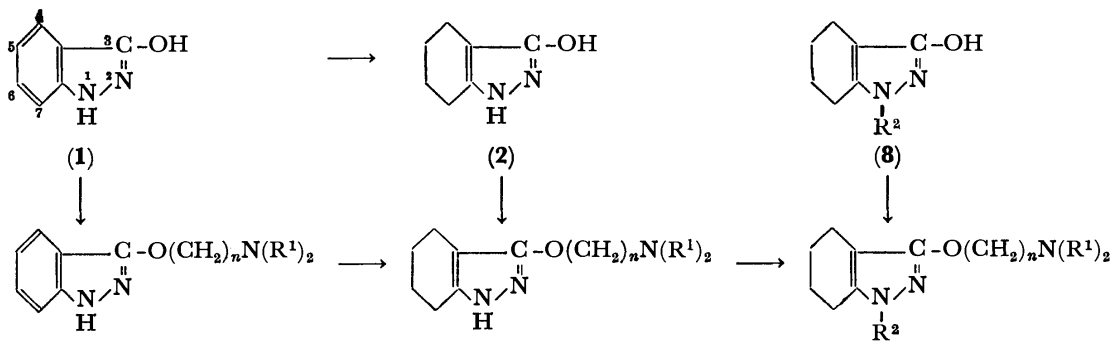

Table 1. 1-Substituted (R^2) 3-[3-(dimethylamino)-propoxy]-4,5,6,7-tetrahydro-1*H*-indazoles (**7c—i**)

No.	R^2	Yield[a] %	Formula[b]	Mp[b] °C	Found[b] (Calcd) (%) C	H	N	Cl

a) Free base. b) Hydrochloride. $UV_{max}(H_2O)$: **7c**,[b] 229 nm (ε 6820); **7d**,[b] 230 nm (ε 6650).

analysis. Chromatography on silica gel with benzene–diethylamine (9:1) afforded **3a**, an oil, 5.05 g (57%) as main product. $UV_{max}(C_2H_5OH)$: 226 nm (ε 5460). IR (neat): ν_{NH} 3150 and $\nu_{C=N}$ 1500 cm^{-1}. NMR (CCl_4): δ 2.19 (6H, s, $-N(C\underline{H}_3)_2$), 4.12 (2H, t, 3-O-$C\underline{H}_2$-CH_2-) and 10.1 (1H, broad, >N$\underline{H}$). Hydrochloride was recrystallized from methanol–ethyl acetate, mp 189.5—191.0 °C. Found: C, 55.53; H, 8.38; N, 16.21; Cl, 13.57%. Calcd for $C_{12}H_{22}ClN_3O$: C, 55.48; H, 8.54; N, 16.18; Cl, 13.63%.

A minor product, 3-[3-(dimethylamino)propoxy]-1-[3-(dimethylamino)propyl]-4,5,6,7-tetrahydro-1*H*-indazole (**5**), (an oil, 1.16 g, 9%) was obtained from the initial eluate with the same solvent. Hydrochloride was recrystallized from methanol–ethyl acetate, mp 194.0—195.0 °C.

*By Catalytic Hydrogenation of 3-[3-(Dimethylamino)propoxy]-1H-indazole (**4a**)*:[6] A solution of **4a** (6.22 g) in acetic acid (160 ml) was hydrogenated in the presence of Adams' catalyst (2.80 g) at room temperature for 12 h. The reaction mixture was worked up in the usual way to give **3a**, an oil, 5.80 g (92%). UV_{max} (C_2H_5OH): 226 nm (ε 5700). IR (neat): ν_{NH} 3160 and $\nu_{C=N}$ 1500 cm^{-1}. NMR (CCl_4): δ 4.10 (2H, t, 3-O-$C\underline{H}_2$-CH_2-). Hydrochloride: mp 188.0—189.0 °C.

*3-[3-(Dimethylamino)propoxy]-1-[3-(dimethylamino)propyl]-4,5,6,7-tetrahydro-1H-indazole (**5**).* Compound **6**[6] (1.00 g) was hydrogenated with Adams' catalyst (1.00 g) at 50 °C for 20 min in acetic acid (15 ml) to give **5** (0.94 g, 93%). UV_{max} (C_2H_5OH): 232 nm (ε 6800). IR (neat): ν_{CH} 2920—2750 and $\nu_{C=N}$ 1500 cm^{-1}. NMR (CCl_4): δ 2.12 (6H, s, 1-$(CH_2)_3N(C\underline{H}_3)_2$), 2.16 (6H, s, 3-O-$(CH_2)_3N(C\underline{H}_3)_2$), 3.75 (2H, t, 1-$C\underline{H}_2$-$CH_2$-) and 4.08 (2H, t, 3-O-$C\underline{H}_2$-$CH_2$-). Hydrochloride: mp 194.0—195.0 °C. Found: C, 52.23; H, 8.63; N, 14.02; Cl, 18.27%. Calcd for $C_{17}H_{34}Cl_2N_4O \cdot 1/2H_2O$: C, 52.30; H, 9.03; N, 14.35; Cl, 18.16%.

*3-[2-(Diethylamino)ethoxy]-4,5,6,7-tetrahydro-1H-indazole (**3b**). By Reaction of **2** with 2-(Diethylamino)ethyl Chloride*: A sample of **2** (2.76 g) was caused to react with 2-(diethylamino)-ethyl chloride (2.85 g) in dioxane (100 ml) as described for the preparation of **3a**. The oily product (3.97 g) was chromatographed on silica gel with cyclohexane–diethylamine (9:1) to afford **3b**, 3.10 g (65%). UV_{max} (C_2H_5OH): 225 nm (ε 6170). IR (neat): ν_{NH} 3180 and $\nu_{C=N}$ 1500 cm^{-1}. NMR (CCl_4): δ 1.00 (6H, t, J=7 Hz, $-N(CH_2C\underline{H}_3)_2$), 2.55 (4H, q, J=7 Hz, $-N(C\underline{H}_2CH_3)_2$), 2.73 (2H, t, J=6 Hz, 3-O-CH_2-$C\underline{H}_2$-N◇) and 4.12 (2H, t, J=6 Hz, 3-O-$C\underline{H}_2$-CH_2-N◇). Hydrochloride was recrystallized from methanol–ethyl acetate, mp 130.0—131.0 °C. Found: C, 56.85; H, 8.81; N, 15.34; Cl, 12.67%. Calcd for $C_{13}H_{24}ClN_3O$: C, 57.03; H, 8.84; N, 15.35; Cl, 12.95%.

*By Catalytic Hydrogenation of 3-[2-(Diethylamino)ethoxy]-1H-indazole (**4b**)*:[6] A sample of **4b** (1.17 g) was hydrogenated with Pd–carbon (Pd 5%) (2.00 g) at 60 °C for 10 h in propionic acid (30 ml) to give **3b**, 1.03 g (87%). IR (neat): ν_{NH} 3170 and $\nu_{C=N}$ 1500 cm^{-1}. NMR (CCl_4): δ 4.10 (2H, t, J=6 Hz, 3-O-$C\underline{H}_2$-CH_2-N◇). Hydrochloride: mp 130.0—131.0 °C.

*1-Benzyl-3-[3-(dimethylamino)propoxy]-4,5,6,7-tetrahydro-1H-indazole (**7a**).* A mixture of sodium metal (0.61 g) and iron(III) nitrate (20 mg) in liquid ammonia (60 ml) was shaken to precipitate sodium amide. A solution of **3a** (5.14 g) in liquid ammonia (40 ml) was added and kept at room temperature for 1h under shaking. Benzyl chloride (2.92 g) was added and, after shaking, the mixture was stood at room temperature overnight. After evaporation of ammonia, the residue was worked up in the usual way to give an oily product (6.24 g), which was chromatographed on silica gel with cyclohexane–diethylamine (9:1) to afford **7a**, 4.80 g (66%). UV_{max} (C_2H_5OH): 233 nm (ε 9050). IR (neat): $\nu_{C=N}$ 1500 cm^{-1}. NMR (CCl_4): δ 4.10 (2H, t, 3-O-$C\underline{H}_2$-CH_2-) and 4.90 (2H, s, 1-$C\underline{H}_2$-C_6H_5). Hydrochloride was recrystallized from 2-propanol–ethyl acetate, mp 149.0—150.0 °C (lit,[3] 143 °C). UV_{max} (H_2O): 232 nm (ε 8590) (lit,[3] 232 nm (ε 8900)). Found: C, 65.19; H, 7.88; N, 12.07; Cl, 10.13%. Calcd for $C_{19}H_{28}ClN_3O$: C, 65.22; H, 8.07; N, 12.00; Cl, 10.13%.

*1-Benzyl-3-[2-(diethylamino)ethoxy]-4,5,6,7-tetrahydro-1H-indazole (**7b**) and Others (**7c—i**).* To a solution of **3b** (1.60 g) in HMPT (4 ml), sodium hydride (50% in oil) (0.28 g) was added and the solution was heated at 100 °C with stirring for 30 min. After cooling, benzyl chloride (0.74 g) was added and stirred at room temperature for 1 h. The reaction mixture was worked up in the usual way to give **7b**, an oil, 2.04 g (93%). UV_{max} (C_2H_5OH): 232 nm (ε 8810). IR (neat): $\nu_{C=N}$ 1500 cm^{-1}. NMR (CCl_4): δ 4.11 (2H, t, J=6 Hz, 3-O-$C\underline{H}_2$-CH_2-N◇) and 4.90 (2H, s, 1-$C\underline{H}_2$-C_6H_5). Citrate was recrystallized from acetone, mp 77.5—81.5 °C. Found: C, 60.28; H, 7.38; N, 8.30%. Calcd for $C_{26}H_{37}N_3O_8$: C, 60.10; H, 7.18; N, 8.09%.

The other compounds (**7c—i**) shown in Table 1 were similarly prepared from **3a** and acid halides or alkyl halides.

The authors wish to thank Professor Sumio Umezawa, Director of the Institute of Bioorganic Chemistry, for his helpful guidance and Dr. Tsutomu Hatakeyama, Director of this Laboratory, for his support and encouragement.

Catalysis by Heteropolyacid. I. Polymerization Reaction of Benzyl Alcohols

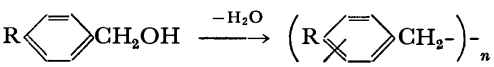
Kenji NOMIYA, Tetsuo UENO, and Makoto MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino-shi, Tokyo 180

(Received September 3, 1979)

Synopsis. Benzyl alcohol and its derivatives catalyzed by heteropolymolybdic acids such as $H_3PMo_{12}O_{40}$ and $H_4SiMo_{12}O_{40}$ have been found to polymerize, leading to the formation of polyaromatics. The properties of the polymers obtained and the function of catalysts have been studied.

Heteropolyacid has high oxidation activity and strong acidic property.[1] From its structure it can be regarded as a polynuclear metal complex and also as a molecular model for solid catalyst.[2] Recently we found a new type of polymerization reaction of benzyl alcohol and its derivatives catalyzed by 12-heteropolymolybdic acids leading to aromatic polymers. The typical stoichiometry is as follows.



Heteropolyacids, $H_4SiM_{12}O_{40}$ and $H_3PM_{12}O_{40}$ (M= Mo, W), were examined as catalyst. These catalysts promote the reaction, but neither the tetraalkylammonium salts of their acids nor the mononuclear acids (H_2MoO_4 and H_2WO_4) show catalytic activity. In this paper the Mo system is discussed.

In all catalytic reactions, the catalyst undergoes the color change yellow→green→blue, corresponding to the various reduced states of molybdenum ions.[3] However, the reduction of catalyst, as indicated by the color change, would not be substantial in the coupling reaction since initial activity of catalyst, selectivity and yields of products were not influenced by the addition of an excess amount of reactants to the reduced blue acid obtained. Since the tetrabutylammonium salts of both the unreduced yellow anion and the reduced blue anion provide no catalytic activity, remarkably strong acidity of catalyst would be important. The reduction mechanism from yellow to blue has not been clarified as yet.

Characteristics of the reaction are as follows: (a) The amorphous polymer obtained has a low molecular weight. (b) No solvent is employed. (c) The reaction is carried out by merely passing a gas (oxygen, nitrogen *etc.*) through a benzyl alcohol solution of heteropolyacids at ambient temperature. (d) The reaction does not proceed in a sealed tube. (e) The temperature of the reaction depends on the flow rate of a passing gas, *e.g.*, under atmospheric oxygen the temperature is 195 °C, whereas with increase in flow rate it is lowered to 110 °C. (f) The reaction time for obtaining the polymer in 100% yield is a few minutes. (g) The catalyst is very stable, not being decomposed during the course of polymerization.

In (c) the role of the passing gas may be only to remove the water produced and keep the reaction mixture anhydrous; oxygen and inert gas fulfill this purpose. The refluxing of benzyl alcohol in the presence of a solvent such as benzene, toluene, or anisole also gives the same polybenzyl as that obtained in a solvent-free system. However, the yield is lowered because of the simultaneously promoted side-reaction such as alkylation and condensation-etherization.

In a typical experiment, 12.4 ml of benzyl alcohol (0.12 mol) and 73.0 mg of $H_4SiMo_{12}O_{40}$ (0.4 mmol) were added to a 100 ml wide-mounted Erlenmeryer flask equipped with a gas inlet tube and a thermometer on a hot-plate at 110 °C. The gas was passed (150 ml/min) through the vigorously stirred solution. The color of the reaction mixture changed from yellow to green, and finally to blue. While the reaction mixture turned green, it began to bubble slightly, the bubbling becoming drastic as soon as the color turned blue. Within a few seconds the vigorous bubbling ceased, the system becoming highly viscous. With fall of temperature the mixture began to solidify. On cooling, a resinous and brittle substance was obtained. It was found that the reduced blue catalyst is homogeneously dissolved in the system, above 40 °C, the polymer becoming stringy. The resionoid is soluble in chloroform and the catalyst contained can be readily removed by shaking the chloroform solution with water. The pure polymer was isolated by dissolving the reaction mixture in 50 ml DMF containing LiCl (1%) and adding the solution dropwise to 150 ml methanol. The precipitate was purified by reprecipitation. The almost colorless polymer obtained was dried *in vacuo* for *ca.* 30 h. The yield was 9.7 g (75%) of pure polymer having intrinsic viscosity $[\eta]=0.19$ dl/g (in *N,N*-dimethylacetamide containing 1% LiCl at 25 °C). Thermogravimetric analysis shows that the polymer is thermally stable up to 525 °C; in air it begins to lose weight at 375 °C.

The derivatives of benzyl alcohol as monomer reactant; 4-chlorobenzyl alcohol, 4-methylbenzyl alcohol, and 2,4,6-trimethylbenzyl alcohol gave the corresponding polyaromatics. However, no corresponding polymers were obtained from triphenylmethanol and 1- and 2-phenylethanols.

The IR spectra of polymers obtained show the disappearance of the original alcoholic OH group. ^{1}H-NMR intensities of benzene moieties, methyl substituents and benzyl methylenes in the polymers indicate that the polycondensation takes place on the elimination of one H of the benzene moiety of one reactant and one OH group of another reactant. Thus the highly branched species are not dominant. Analytical data, intrinsic viscosities, melting points and decomposition temperatures of the polymers are given in Table 1 and ^{1}H-NMR data in Table 2. Viscosities and melting points indicate that the polymers have low molecular

weight.

The electronic and MCD spectra in the 240—300 nm region of the polymer were measured in comparison with those of the corresponding monomer. The characteristic vibronic structure of the monomer is largely diminished, the whole spectral shape broadening. The maximum absorption of polymer shifted to the longer wavelength region by *ca.* 10 nm. This is also the case in the MCD spectra. In both the polymer and its monomer, the sign of MCD is negative, except in the case of poly(2,4,6-trimethyl-1,3-phenylenemethylene) and 2,4,6-trimethylbenzyl alcohol, in which the positive MCD of monomer turns to the negative MCD of polymer.

In the first run of the experiment, the reduced blue compound, converted from the initial yellow catalyst, is isolated as a tetraethylammonium salt having the formula $[Et_4N]_4[SiMo_{12}O_{40}H_n]$ (n=2—4). This was determined on the basis of the observed value of elemental analysis; C, 16.43; H, 3.30; N, 2.32%.

During the course of the reaction, no evidence was obtained of the direct coordination of arene ring of reactant to the molybdenum ion in the blue catalyst. The type of polymerization might be a carbonium ion mechanism brought about by the remarkably strong Brønsted acidity of catalyst.

The heteropolyacids also give the same polybenzyl from benzyl chloride by dehydrohalogenation as that obtained from benzyl alcohol in relatively high yields. Thus the acids appear to possess an analogous function to that of $Mo(CO)_6$ and arene-$Mo(CO)_3$ as "Friedel-Crafts" like catalyst.[4,5] However, particular advantages of the reduced blue heteropolyacid over $Mo(CO)_6$ and $ArMo(CO)_3$ have been observed in the undiminished activity for repeated use of the same catalyst with no decomposition. This remarkable stability of the reduced acid would be related to the fact that it does not dissociate into sexivalent molybdenum as in the case of unreduced form of the complex because of its resonant state in the molecule as a whole making each molybdenum have a mean valency less than +6.[3]

In this reaction, the heteroatoms Si and P of heteropolymolybdic acids would play no direct important role; rather they would contribute to the maintenance of Keggin-structure of catalyst and the complete valency saturation leading to the strong Brønsted acidity.

The authors wish to thank Dr. I. Ojima and Mr. T. Noguchi, Sagami Chemical Research Center, for their help in clarifying the structures of the products we obtained.

Grignard Reaction of Peroxides Containing Neighboring Nitrogen Atom

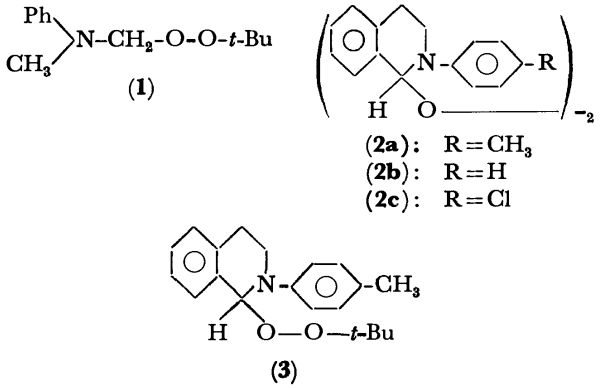
Masao Ōkubo,* Takutomo Komatsu, Kyōko Tsuruta, and Yasuyo Sonoda
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received September 3, 1979)

Synopsis. The substituent effect on the reaction of bis(2-aryl-1,2,3,4-tetrahydro-1-isoquinolyl) peroxide with PhMgBr as well as the product obtained on the reaction of 2-*p*-tolyl-1,2,3,4-tetrahydro-1-isoquinolyl *t*-butyl peroxide with PhMgBr were interpreted in terms of the coordination of the neighboring nitrogen atom to Mg atom.

In the previous report on the Grignard reaction of neighboring oxygen- and/or nitrogen-containing peroxides,[1] the effect of coordination of the hetero atoms to the Mg atom was emphasized. However, it was doubted that the high reactivity of the previously studied *N*-methylanilinomethyl *t*-butyl peroxide (**1**) was due to its sterically unhindered and flexible molecular structure but not due to the effect of the neighboring nitrogen atom. This consideration led us to examine the Grignard reaction of peroxides having sterically crowded and rigid structures. The results of the study on the substituent effect of bis (2-aryl-1,2,3,4-tetrahydro-1-isoquinolyl) peroxides (**2**)[2] and the product obtained from 2-*p*-tolyl-1,2,3,4-tetrahydro-1-isoquinolyl *t*-butyl peroxide (**3**)[3] will be reported in this paper. These peroxides were selected from several nitrogen-containing ones reported by Rieche and his coworkers[4] on the basis of the molecular structure appropriate for the present purpose: the peroxides 1) having "neighboring" nitrogen atom and 2) having neither >NH nor –OOH groups were selected.

The reaction of **2a**, **2b**, and **2c** with one and a half molar equivalents of PhMgBr in THF at 10 °C under nitrogen was followed by iodometry. The results thus obtained are shown in Fig. 1 (a), which indicate that the higher electron-density on the nitrogen atom facilitates its coordination to the Mg atom and thus accelerates the decomposition.



The similar plots obtained from the reaction of **3** are shown in Fig. 1 (b). When 1.30 molar equivalents of PhMgBr were used (Fig. 1 (b)-i), 36.4% of **3** remained even after stirring for 48 h at 15 °C. On the other hand, when 2.50 molar equivalents of the reagent were used (Fig. 1 (b)-ii), almost all (92.7%) of **3** was consumed after 24 h. As shown in Fig. 1 (b)-ii, the high decomposition velocity at the initial stage is clearly distinguished from the low velocity at the later stage. On the basis of the previous discussion given for the similar feature observed in the Grignard reaction of aroyl peroxides,[5] the low velocity at the later stage is ascribable to the aggregation of the unreacted peroxide with the reaction products: the aggregation could retard the attack of the Grignard species.[5]

The crude oily product obtained in a 91% yield after the treatment of **3** with three molar equivalents of PhMgBr for 24 h followed by the usual work-up, crystallizes on standing overnight. Purification by column chromatography (silica gel, petroleum benzine) and recrystallization from petroleum ether afforded colorless crystals, mp 76—77.5 °C. The product gave no ν_{OH} absorption band in its IR spectrum, and a large amount of phenol was detected by GLC after the treatment with dilute hydrochloric acid. The structure (**4**) can be given on the basis of NMR data (CCl_4): δ=6.58—7.15 (13H, m, aromatic), 5.20 (1H, s, >CH), 3.48 (2H, m, >N–CH_2–CH_2–), 2.82 (2H, t, –CH_2–Ar), and 2.09 (3H, s, CH_3–Ar). The chemical shift of the benzylic methine proton appeared in the remarkably lower field may be reasonable, because the methine carbon has both the neighboring oxygen and

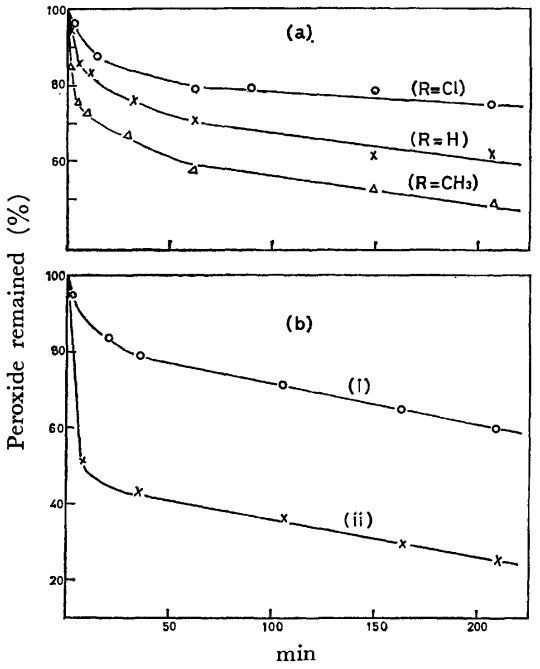


Fig. 1. Decomposition velocity of peroxides **2a**, **2b**, **2c**, and **3** on the reaction with PhMgBr.
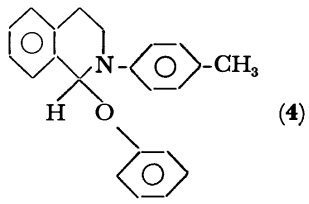
(a) Peroxides **2a**, **2b**, **2c**: 0.0023 mol; PhMgBr: 0.0035 mol. At 10 °C; in 50 ml THF.
(b)-i) Peroxide **3**: 0.0064 mol; PhMgBr: 0.00835 mol.
ii) Peroxide **3**: 0.0096 mol; PhMgBr: 0.024 mol. At 15 °C; in 59 ml THF.



(4)

nitrogen atoms. If being stood for a few days, the product **4** decomposed gradually and gave pale yellow polymeric material insoluble in CCl_4 and benzene. Contrary to the products of the reaction of **1**,[1] the phenyl group of the Grignard reagent combines with the α-oxygen atom which is nearer to the nitrogen atom of **3**. This result is explicable if it is considered that the rigid structure of **3** requires the attack by the dimeric or trimeric aggregate of the reagent as illustrated in Fig. 2. The coordination of the nitrogen atom to Mg atom could induce some positive charge on the α-oxygen atom. This effect allows the exclusive attack of the anionic phenyl group of another Grignard molecule. This suggestion is compatible with the discussion given above for the substituent effect on the decomposition velocity.

Though the peroxides **2** and **3** are less reactive than the less crowded **1** which can be decomposed by the equimolar PhMgBr,[1] the results obtained are interpreted in terms of coordination of the neighboring nitrogen atom. In addition, the peroxides **2** and **3** were found to be titrated in the simplest manner by the use of KI and acetic acid.[6] The previously proposed correlation between the reactivity of peroxides toward alkali halides and that toward Grignard reagent[1] is thus confirmed.

Experimental

Materials. The peroxides **2**[2] and **3**[3] were prepared by the reported methods from the corresponding 2-aryl-3,4-dihydroisoquinolinium bromides[7] which were synthesized from isochroman. Tetrahydrofuran was dried over sodium wire, distilled, and stored on sodium wire.

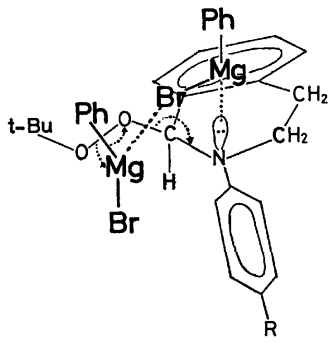


Fig. 2. Illustration of the reaction of peroxide **3** with the dimeric aggregate of PhMgBr.

Procedures. The THF solution (25 ml) of PhMgBr (0.0289 mol) was prepared under nitrogen. The peroxide **3** (0.00965 mol) dissolved in THF (40 ml) was added at once. The mixture was stirred for 24 h, and quenched by saturated aqueous NH_4Cl. The crude product obtained was purified in the manner described in the text.

The plots given in Fig. 1 were obtained by taking out the 1 ml portions of the respective reaction mixtures at definite time intervals followed by iodometric titration by the reported method.[6]

Elemental analysis of **4**: Found: C, 83.92; H, 6.72; N, 4.36; O, 5.02%. Calcd for $C_{22}H_{21}NO$: C, 83.80; H, 6.67; N, 4.44; O, 5.08%.

Synthesis of 5,7-Dihydroxy-2′,4′,5′-trimethoxyisoflavone and Its 7-Methyl Ether (Robustigenin)

Mitsuru NAKAYAMA,* Susumu OHIRA, and Takanao MATSUI†

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

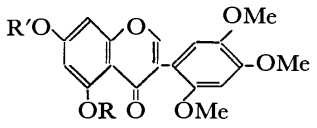
†*Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Kirishima, Miyazaki 880*

(Received September 5, 1979)

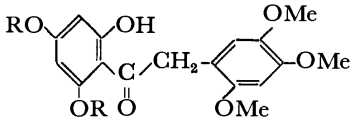
Synopsis. The treatment of 2,4,6-trihydroxy-2′,4′,5′-trimethoxydeoxybenzoin with benzyl chloride gave a dibenzyl ether. The condensation of the ether with ethyl formate, followed by the debenzylation of the resulting isoflavone, afforded 5,7-dihydroxy-2′,4′,5′-trimethoxyisoflavone, which was then converted into a pentamethoxyisoflavone. The partial demethylation of the pentamethoxyisoflavone gave 5-hydroxy-2′,4′,5′,7-tetramethoxyisoflavone, which was identical with natural robustigenin.

Recently, robustigenin, $C_{19}H_{18}O_7$, was isolated from seed shells of *Derris robusta*. Its structure was identified as 5-hydroxy-2′,4′,5′,7-tetramethoxyisoflavone (**1**) on the basis of spectral evidence.[1] We attempted the synthesis of **1** in order to confirm the proposed structure. This paper will describe the synthesis of 5,7-dihydroxy-2′,4′,5′-trimethoxyisoflavone (**2**), which may be expected to occur in nature, and 7-methyl ether of **2** (**1**, robustigenin).

The treatment of 2,4,6-trihydroxy-2′,4′,5′-trimethoxydeoxybenzoin (**3**)[2,3] with benzyl chloride and anhydrous potassium carbonate in acetone gave a dibenzyl ether (**4**). The condensation of **4** with ethyl formate in the presence of sodium gave 5,7-bis(benzyloxy)-2′,4′,5′-trimethoxyisoflavone (**5**). The debenzylation of **5** by hydrogenolysis with palladium on charcoal afforded a dihydroxyisoflavone (**2**), which was then easily converted into a dimethyl ether (**6**). The isoflavone (**6**) was also prepared by the following procedure. The Hoesch reaction of phloroglucinol dimethyl ether and 2,4,5-trimethoxyphenylacetonitrile,[4] or the treatment of phloroglucinol dimethyl ether and homoasaronic acid (2,4,5-trimethoxyphenylacetic acid)[5] in the presence of boron trifluoride etherate, yielded 2-hydroxy-2′,4,4′,5′,6-pentamethoxydeoxybenzoin (**7**). The reaction of **7** and ethyl formate yielded the isoflavone (**6**).



(**1**) R=H, R′=Me
(**2**) R=R′=H
(**5**) R=R′=$C_6H_5CH_2$
(**6**) R=R′=Me



(**3**) R=H
(**4**) R=$C_6H_5CH_2$
(**7**) R=Me

The partial demethylation of **6** with anhydrous aluminium chloride in acetonitrile[6] gave the desired isoflavone (**1**). The spectral properties of the two synthetic samples **2** and **6** were superimposable upon those recorded for natural robustigenin and its methyl ether.[1]

Experimental

The melting points are uncorrected. The IR spectra were measured in nujol, while the UV spectra were measured in an ethanol, unless otherwise stated. The NMR spectra were recorded on either a Hitachi R-20 (60 MHz) or JEOL JNM MH-100 (100 MHz) spectrometer, and the chemical shifts are reported in δ values, with TMS as the internal standard.

4,6-Bis(benzyloxy)-2-hydroxy-2′,4′,5′-trimethoxydeoxybenzoin (4). A mixture of 2,4,6-trihydroxy-2′,4′,5′-trimethoxydeoxybenzoin (**3**)[2,3] (1.0 g), anhydrous potassium carbonate (6.0 g), and benzyl chloride (0.9 ml) in dry acetone (60 ml) was refluxed for 6 h. The reaction mixture was then filtered, and the filtrate was evaporated *in vacuo*. The residue was recrystallized from acetone to give colorless needles of **4** (1.1 g) (mp 198—199 °C), which showed a pale brown color with ethanolic $FeCl_3$. IR: 1633 cm^{-1}. Found: C, 72.07; H, 6.18%. Calcd for $C_{31}H_{30}O_7$: C, 72.36; H, 5.88%.

5,7-Bis(benzyloxy)-2′,4′,5′-trimethoxyisoflavone (5). A solution of **4** (500 mg) in anhydrous ethyl formate (35 ml) was added to powdered sodium (600 mg) at 0 °C, and then the mixture was left at room temperature for 12 h. The mixture was treated with ice water and acidified with 6 M HCl. After almost all the ethyl formate had been evaporated *in vacuo*, the resulting semi-solid was dried and heated with acetic anhydride (10 ml) for 0.5 h. The reaction mixture was diluted with cold water to give pale yellow precipitates. The precipitates were collected and recrystallized from methanol to give colorless needles of **5** (200 mg); mp 163—164 °C; IR: 1650 cm^{-1}; UV λ_{max} nm (log ε): 255 (4.46), 291 (4.20). Found: C, 72.98; H, 5.66%. Calcd for $C_{32}H_{28}O_7$: C, 73.27; H, 5.38%.

5,7-Dihydroxy-2′,4′,5′-trimethoxyisoflavone (2). A solution of **5** (180 mg) in ethyl acetate (30 ml) was submitted to catalytic hydrogenolysis in the presence of Pd–C (10%: 100 mg) at room temperature. After the catalyst had been filtered, the filtrate was evaporated *in vacuo*. The residue was recrystallized from methanol to give colorless needles of **2** (110 mg) (mp 243—244 °C), which showed a brown color with ethanolic $FeCl_3$. IR: 3350, 1655 cm^{-1}; UV λ_{max} nm (log ε): 260.5 (4.42), 296 (4.16). Found: C, 62.52; H, 4.77%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

Diacetate of 2: Hot acetic anhydride–pyridine method; mp 204—205 °C (colorless needles from methanol). IR: 1763, 1650 cm^{-1}; UV λ_{max} nm (log ε): 294.5 (4.11); NMR ($CDCl_3$): δ 2.38, 2.43 (each 3H, s, CH_3CO), 3.79, 3.88, 3.96 (each 3H, s, CH_3O), 6.67, 6.91 (each 1H, s, 3′-, 6′-H), 6.94, 7.29, (each 1H, d, J=2 Hz, 6-, 8-H), 7.93 (1H, s,

2-H). Found: C, 61.34; H, 4.90%. Calcd for $C_{22}H_{20}O_9$: C, 61.68; H, 4.71%.

2-Hydroxy-2',4,4',5',6-pentamethoxydeoxybenzoin (7). *Hoesch Reaction*: A mixture of phloroglucinol dimethyl ether (800 mg), 2,4,5-trimethoxyphenylacetonitrile[4] (1.0 g) and anhydrous zinc chloride (1.0 g) in dry ether (35 ml) was saturated with anhydrous hydrogen chloride at 0 °C for 3 h and then allowed to stand at room temperature for 12 h. The ethereal solution was decanted from the oily layer of ketimine hydrochloride which had separated. This oily layer was washed with dry ether and then heated with water on a steam bath for 1 h. After cooling and standing, the precipitates were collected and recrystallized from ethanol to give colorless needles of **7** (200 mg), mp 145—146.5 °C (lit, mp 143 °C,[2] mp 144—145 °C[3]), which showed a yellowish violet color with ethanolic $FeCl_3$. IR: 1645 cm^{-1}; UV λ_{max} nm (log ε); 289 (4.35). Found: C, 62.96; H, 6.09%. Calcd for $C_{19}H_{22}O_7$: C, 62.97; H, 6.12%.

BF_3 Method: A mixture of phloroglucinol dimethyl ether (1.0 g) and homoasaronic acid[5] (1.47 g) in dry ether (35 ml) was saturated with anhydrous boron trifluoride gas at 0 °C for 3 h and then heated on a steam bath for 0.5 h. After cooling and standing, the reaction mixture was diluted with water. The resulting precipitates were collected and recrystallized to give **7** (320 mg), mp 144—145 °C, whose IR spectrum was identical with those of the sample described above.

2',4',5,5',7-Pentamethoxyisoflavone (6). *From 2*: A mixture of **2** (100 mg), anhydrous potassium carbonate (500 mg), and methyl iodide (0.5 ml) in dry acetone (30 ml) was refluxed for 5 h. The reaction mixture was then filtered, and the filtrate was evaporated *in vacuo*. The residue was recrystallized from methanol to give colorless needles of **6** (90 mg), mp 190—191 °C (lit,[1] mp 192—193 °C); IR: 1658 cm^{-1}; UV λ_{max} nm (log ε): 255 (4.42), 291 (4.15); NMR ($CDCl_3$): δ 3.74, 3.83, 3.88, 3.92, 3.93 (each 3H, s, CH_3O), 6.39, 6.49 (each 1H, d, J=2 Hz, 6-, 8-H), 6.60, 6.98, 7.80 (each 1H, s, 3'- 6'-, 2-H), whose IR and NMR spectra were identical with those of the corresponding derivative from natural robustigenin.[1] Found: C, 64.21; H, 5.44%. Calcd for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41%.

From 7: A solution of **7** (200 mg) in anhydrous ethyl formate (11 ml) was added to powdered sodium (300 mg) at 0 °C, and then the mixture was left at room temperature for 24 h. The reaction mixture was then worked up in the same manner as in the case of **5** to give **6** (180 mg), which was subsequently recrystallized from methanol as colorless needles; mp 189—191 °C. It was identical with the sample described above.

Robustigenin 5-Hydroxy-2',4',5',7-tetramethoxyisoflavone (1). A mixture of **6** (30 mg), anhydrous aluminium chloride (110 mg), and acetonitrile (7 ml) was stirred under gentle refluxing for 16 h. After the removal of the solvent, dilute hydrochloric acid was added to the residue. The resulting solid was collected, washed with water, dried, and then chromatographed on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give colorless needles of **1** (10 mg), mp 177—178 °C (lit,[1] mp 174—175 °C), which showed a dark violet color with ethanolic $FeCl_3$. IR (KBr): 3090, 1660 cm^{-1}; UV λ_{max} nm (log ε): 260 (4.41); NMR ($CDCl_3$): δ 3.75 (3H, s, CH_3O), 3.83 (6H, s, CH_3O ×2), 3.89 (3H, s, CH_3O), 6.36 (2H, s, 6- and 8-H), 6.59, 6.86, 7.85 (each 1H, s, 3'-, 6'-, 2-H), 12.92 (1H, s, OH), whose IR, UV, and NMR spectra were identical with those of natural robustigenin.[1] Found: C, 63.82; H, 5.21%. Calcd for $C_{19}H_{18}O_7$: C, 63.68; H, 5.06%.

Chemiluminescence of a *Cypridina* Luciferin Analogue, 2-Methyl-6-phenyl-3,7-dihydroimidazo[1,2-*a*]pyrazin-3-one, in the Presence of the Xanthine–Xanthine Oxidase System[1]

Toshio GOTO* and Tetsuyuki TAKAGI

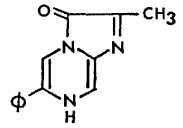
(Received September 27, 1979)

Synopsis. The title compound chemiluminesces in aqueous solutions (pH 5—6.5) in the presence of xanthine–xanthine oxidase system; O_2^- and not $^1O_2$ was proven to be the active species. Quantitative determination of xanthine and xanthine oxidase as low as 5 nmol and 10^{-5} unit, respectively, is possible by measurement of the chemiluminescence light yield and the reaction rate.

In the case of the bioluminescence of *Cypridina* system, light is emitted during the oxidation of *Cypridina* luciferin (LH) with molecular oxygen by catalysis of an enzyme, *Cypridina* luciferase. It was suggested that the substrate reacts with molecular oxygen ($^3O_2$) when it is taken in a hydrophobic pocket of the enzyme,[2] since the luciferin reacts with molecular oxygen and emits light when it is dissolved in aprotic polar solvents such as dimethyl sulfoxide, diethylene glycol dimethyl ether, *etc.*, but in aqueous solutions no luminescence is observed without the enzyme. The chemiluminescence reaction in the aprotic solvents is second order with respect to the concentrations of the substrate (LH) and molecular oxygen;[3] a suggested mechanism involves a non-chain reaction between the luciferin anion and oxygen giving a hydroperoxide anion through a radical pair intermediate:[2]

$$LH \rightarrow L^- \xrightarrow{O_2} [L\cdot \cdot O_2^-] \rightarrow L\text{-}OO^- \rightarrow \text{products} + h\nu.$$

Similarly its analogue, 2-methyl-6-phenyl-3,7-dihydroimidazo[1,2-*a*]pyrazin-3-one (LA), chemiluminesces with molecular oxygen in the aprotic solvents but not in aqueous solutions.[2] It becomes chemiluminescent, however, even aqueous solutions when the reaction mixture contains some oxidants such as H_2O_2 and catalytic amounts of $K_3[Fe(CN)_6]$ or Fe^{3+}.[4] In these cases the active oxidant may be either superoxide (O_2^-) or singlet oxygen ($^1O_2$) produced by superoxide annihilation ($2\,HOO\cdot \rightarrow {}^1O_2 + H_2O_2$). To see if the superoxide can be the oxidant for the luminescence in aqueous solutions, we have examined the xanthine–xanthine oxidase (X–XOD) system since the system has been proven to produce superoxide ions.[5]



LA

Indeed, the luciferin analogue (LA) gives light in aqueous solutions in the presence of the X–XOD system (Fig. 1). The best pH range for the luminescence is between 5 and 6.5 (Fig. 2).[6] The light yield is decreased but rate of luminescence is increased as pH increases. Using 0.1 μmol of X in a 2.5 ml solution the linear relationship is obtained between the amount of LA and the total light yield up to 0.01 μmol of LA (Fig. 3). Thus, the maximum efficiency can be obtained when the molar ratio of X and LA is *ca.* 10:1.[7] When LA is present in more than 0.035 μmol, the total light yield is proportional to the amount of X ($X < 0.3$ μmol), whereas the rate of luminescence is independent of the concentration of X (Fig. 4).

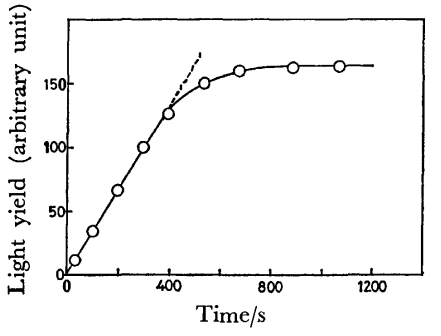


Fig. 1. Luminescence of LA in the presence of X–XOD system. X: 0.1 μmol; XOD: 0.05 unit; LA 0.01 μmol; pH 5.5.

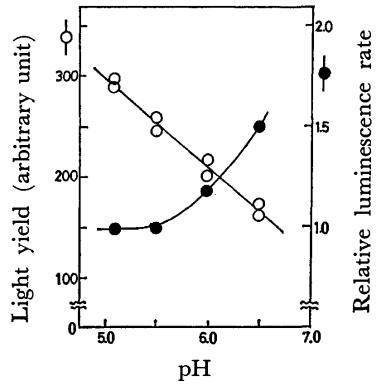

Fig. 2. pH dependence of light yield and luminescence rate. X: 0.4 μmol; XOD: 0.2 unit; LA: 0.04 μmol.

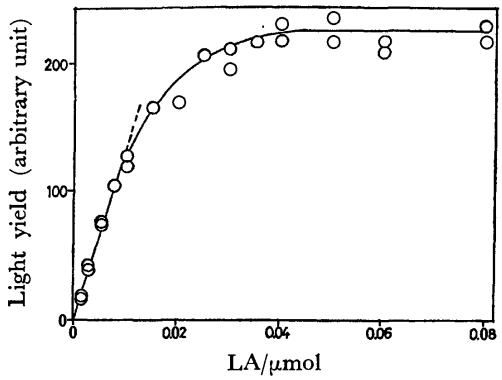

Fig. 3. Total light yield *vs.* quantity of LA. X: 0.1 μmol; XOD: 0.05 unit; pH 5.5.

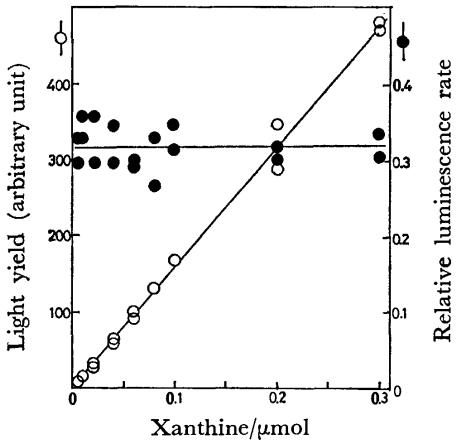

Fig. 4. Light yield and luminescence rate *vs.* quantity of xanthine. XOD: 0.05 unit; LA: 0.035 μmol; pH 5.5.

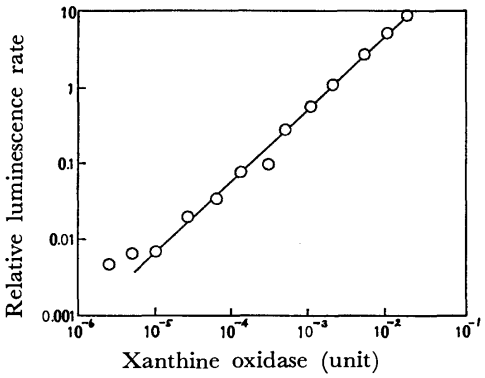

Fig. 5. Luminescence rate *vs.* quantity of xanthine oxidase. X: 0.01 μmol; LA: 0.001 μmol; pH 5.5.

Thus, the amount of X as low as 5 μmol in a 2.5 ml solution can be quantitatively determined by measuring the total light yield. On the other hand, by measurements of the initial rate of luminescence it is possible to determine the quantity of XOD as small as 10^{-5} unit (Fig. 5).

These results led to the conclusion that the reactive species of the luminescence is superoxide and not singlet oxygen;[8] if singlet oxygen were the reactive species the reaction rate must not be proportional to the amount of XOD. This was further supported by examination of the effect of sodium azide (a singlet oxygen quencher)[9] on the luminescence rate; additon of 1×10^{-3} M sodium azide did not affect the rate (4×10^{-5} M X and 0.05 unit XOD in 2.5 ml).

Involvement of superoxide was also demonstrated by addition of superoxide dismutase (SOD),[10] which is well known to decompose superoxide by the following equation: $2\cdot O_2^- + 2H^+ \xrightarrow{SOD} {}^3O_2 + H_2O_2$. SOD strongly inhibited the luminescence reaction, whereas little effect was observed with SOD preheated at 100 °C for 10 min.[11] Thus, the chemiluminescence of the luciferin analogue by the xanthine–xanthine oxidase system in aqueous solution involves superoxide as the reacting species.[12]

$$ {}^3O_2 \xrightarrow{\text{X-XOD}} \cdot O_2^- \xrightarrow{\text{LA}} h\nu $$

$$ v = k[\cdot O_2^- \text{ or } \cdot OOH] = k'[XOD] $$

The luciferin analogue may be widely applicable for detection of superoxide in physiological systems.

Experimental

Xanthine oxidase was purchased from the Boehringer Mannheim Co. The luciferin analogue (LA) was synthesized according to the literature.[13] The light yields and luminescence rates were measured with an automatic recording photomultiplier (Hamamatsu type R105)-amplifier system. Condition: 2.5 ml of 1/30 M phosphate buffer containing 10^{-4} M EDTA at 25 °C. No marked difference was observed when the buffer solution is changed from the phosphate to 0.1 M acetate.

We thank Dr. M. Nakano, Gumma University, for the generous gift of superoxide dismutase.

On the Choice of Adsorptives for the Application of a Modified Dubinin-Radushkevich Equation

Fritz STOECKLI*, André PERRET, and Ueli HUBER†
Institute de Chimie de l'Université, CH-2000 Neuchâtel, Switzerland
†*GRD Laboratorium, CH-3752 Wimmis, Switzerland*
(Received June 9, 1979)

Synopsis. It is shown that great care has to be taken in the choice of the adsorptives for the assessment of microporosity and its heterogeneity. Methanol, for which selective interactions may occur, is not a suitable adsorptive to be used in the framework of the generalized Dubinin-Radushkevich equation proposed by Stoeckli.

A paper has been published recently in this Journal by Tsunoda,[1] on the application of a modified Dubinin-Radushkevich equation to adsorption on active carbons with heterogeneous micropore systems. It is based on a generalization of the Dubinin-Radushkevich equation, originally proposed by Stoeckli,[2] and fully investigated by Stoeckli *et al.* in a recent paper.[3]

On the basis of experimental evidence from the adsorption of simple gases on various active carbons, we showed that the following equation could be used

$$W = W_0 \exp\{-B_0 y\} \cdot \exp\{y^2 \Delta^2/2\} \cdot [1-\mathrm{erf}(x)]/2 \quad (1)$$

where

$$y=(T/\beta)^2 \log^2(p_0/p) \text{ and } x=(y-B_0/\Delta^2)\,\Delta/\sqrt{2}.$$

W_0 is the total volume of the micropores, and W represents the volume filled at (T, p).

Equation 1 is based on the idea of a Gaussian distribution of the micropore volume W with the structural constant B,

$$f(B)=[W_0/\Delta(2\pi)^{1/2}] \exp\{-(B-B_0)^2/2\Delta^2\} \quad (2)$$

combined with the original equation of Dubinin and Radushkevich,[4]

$$W = W_0 \exp\{-B(T/\beta)^2 \log^2(p_0/p)\}. \quad (3)$$

The quantity Δ, a measure of the spread of B around B_0, is related to the heterogeneity of the micropore system under investigation. This is a direct consequence of the empirical relation which exists between B and the gyration radius R_g of the micropores, derived from the scattering of X-rays at small angles.[5]

The so-called affinity coefficient, β, is a characteristic of the adsorptive. It is calculated[4] from the ratios of the parachores, benzene being the reference vapor with $\beta=1$. With the use of β, the isotherms of different gases on a given microporous carbon can be reduced to a single isotherm. As shown by Stoeckli *et al.*[3] this is also the case for the generalized equation (Eq. 1), when a number of non-specific adsorptives are used. (A representation of $\ln(W)$ *versus* y yields a single curve for heterogeneous carbons). Typical values of B_0 and Δ, obtained from our experimental data,[3] are shown in Table 1.

The smaller values of B_0 correspond to narrow systems of micropores, where the spread Δ is also reduced or equal to zero (molecular-sieves). The recent work of Tsunoda is essentially an extension of a generalized equation (Eq. 1), taking into account possibility of a non-negligeable fraction of the Gaussian distribution (Eq. 2) existing in the region of $B<0$, which is physically unrealistic.

Table 1. Parameters of Eq. 1 for various carbons

Carbon	Origin	W_0 / cm³ g⁻¹	B_0 / 10⁻⁶ K⁻²	Δ / 10⁻⁶ K⁻²
U-02	Mineral	0.43	0.92	0.21
F-02	Vegetable	0.64	1.03	0.29
F-85	Vegetable	0.75	0.98	0.35
Carbosieve	Polymer	0.51	0.57	—
AC-400 (7)	Mineral	0.42	0.73	0.21
AC-900 (7)	Mineral	0.43	0.72	0.28

Although this possibility is mathematically conceivable, our extended investigations have not revealed it so far. The typical values of B_0 and Δ given in the table correspond to negligeable contributions from the region $B<0$, since B_0 is close to 3Δ. Even for $B_0=2\Delta$, this contribution would only represent 2% of the total area of the normalized Gaussian (Eq. 2).

Relatively larger values were reported by Tsunoda[1] for the spread Δ, which may justify the use of his modification of Eq. 1. However, a closer examination reveals that his approach is based on the adsorption of methanol alone, and at a single temperature (30 °C). As found in our own investigation, methanol is not a suitable adsorptive. The main reason, as in the case of water, is the possibility of selective interactions with chemical groups on the surface of the carbon.

The isotherms may often be ill-defined, or of type III or V, not described by Eqs. 1 or 3. Therefore, they show a deviation from linearity in the classical Dubinin-Radushkevich plot of $\ln(W)$ *versus* $\log^2(p_0/p)$, reflecting specific differences in the mode of adsorption. This is fundamental difference with the usual collection of molecules without specific interactions, to which the theory of micropore filling essentially applies.

In the case of carbon U-02, well characterized by N_2, Xe, SF_6, N_2O, C_6H_6, and CCl_4, one finds the average values of Table 1.

The adsorption of methanol at 230 K, on the other hand, interpreted through Eq. 1, leads to $B_0=1.71\times10^{-6}$ K^{-2} and $\Delta=0.54\times10^{-6}$ K^{-2}, using the value $\beta(CH_3OH)=0.40$. The difference with the results from the other gases is evident, and it is also found that the ratio Δ/B_0 is larger for methanol. The results of a single gas like methanol, are therefore not necessarily representative for a range of adsorptives. This suggests that great care has to be taken in the choice of adsorptives for the assessment of microporosity.

We also would like to point out, that in the case of Tsunoda's modification of Eq. 1, the quantity B_0 is no longer comparable with ours, or with the structural constant B of the D-R equation (Eq. 3). This is due to the fact that the affinity coefficient β has been omitted, implying that methanol is now the reference vapor.

Polyelectrolyte Complexes of Chitosan with Sodium Carboxymethylcellulose

Hiroshi FUKUDA

Faculty of Home Economics, Hiroshima Women's University, Uzina-machi, Hiroshima 734

(Received February 27, 1979)

A new water-insoluble precipitate was obtained by mixing chitosan with sodium carboxymethylcellulose, an anti-thrombogenic agent. The mole ratio of N/COO^- in the polyelectrolyte complexes was estimated to be 0.3935—0.9071. It was found that pH, mole ratio of N/Na in the reaction mixture and the order of mixing play an important role in determining the composition ratio of N/COO^-. In order to clarify the relationship between the molecular conformation of the polyelectrolyte complexes and their properties, IR spectroscopic studies, elementary analyses, color reaction with Toluidine Blue, studies on solubility and blood clotting test *in vitro* were performed. The polyelectrolyte complex, prepared at higher pH, differed from that prepared at lower pH, particularly in the density of -COOH group site. These results were interpreted in terms of the variation in the degree of electrolytic dissociation of the weak polyelectrolytes, caused by pH change. All the polyelectrolyte complexes revealed clot-inhibition *in vitro*. The clot-inhibiting behavior seems to be due to the clot-inhibiting surface of the polyelectrolyte complex, not to the elution of the activity from the surface.

A solution of charged polyelectrolyte reacts with one of oppositely charged polyelectrolyte to form a water-insoluble hydrous complex whose property is determined by various factor such as the degree of electrolytic dissociation of polyelectrolyte, composition of reaction mixture, order of mixing, pH and the polyion concentration. The polyion interaction or intermolecular reaction is remarkable not only as a model reaction *in vivo*, such as polyion interaction between charged polysaccharide and protein, but also as functional polymers or biomedical materials. Studies have been made on this subject.[1-3] However, the mechanism of polyion interaction and the probable structure of the polyelectrolyte complex (PEC) remains unclarified. Only a few papers[4,5] deal with the polyion interaction between polysaccharides or polysaccharide and synthetic macromolecule in spite of its importance as regards model reaction *in vivo* or biomedical applications.[6,7] The property of PEC can be made to satisfy the requirement.

Reports have appeared on novel reactions of sodium dextran sulfate with chitosan [poly(N-deacetylated chitin)],[8-11] sodium dextran sulfate with [2-(diethylamino)ethyl] dextran,[12] and sodium carboxymethyldextran with chitosan.[13] This paper describes a novel chemical interaction of sodium carboxymethylcellulose (CMC) with chitosan and studies on the PEC.

Experimental

Materials. CMC (Wako Pure Chemical Industries Co. Ltd., sodium content 7.79%, degree of substitution 0.753/A.G.U) and chitosan (Tokyo Kasei Co. Ltd., nitrogen content 7.95%) were used, the latter being purified by reprecipitation from its acidic solution with sodium hydroxide solution, but not CMC because of its high purity.

Preparation of PEC. When the pH of solution is below 2.0, no precipitates are formed by mixing chitosan with CMC, and when the pH of the chitosan solution is higher than 6.5, chitosan remain insoluble. When the pH of the chitosan solution is higher than 5.5, gelation of precipitate takes place. The reactions were thus carried out at pH 2.5 and 5.0, respectively. CMC was dissolved in water, and the pH of solution was adjusted to 2.5 and 5.0 with hydrochloric acid solution. Purified chitosan was dissolved in a 0.1 M hydrochloric acid solution, the pH of solution being adjusted to 2.5 and 5.0 with sodium hydroxide solution. These chitosan solutions were added dropwise to the corresponding CMC solutions, with stirring (rate of addition about 50 ml/30 min) under the conditions given in Table 1. Water-insoluble precipitates, the polyelectrolyte complexes PEC, were obtained. After standing for a half hour, the precipitates were washed with 0.01 M hydrochloric acid, water and methanol, and then separated by centrifugation, dried *in vacuo* for a week, until a constant weight was attained.

The elementary analyses of the PEC were performed at the Institute of Physical and Chemical Research, Wako-shi, Saitama, and the infrared spectra were taken by the KBr method. Nitrogen analysis was carried out by the Kjeldahl method.

Color Reaction of PEC with Toluidine Blue. The color change of PEC was examined in two ways: (a) addition of Toluidine Blue solution to PEC, (b) soaking of PEC in water for 1 day, and addition of Toluidine Blue solution to the filtrate. (a) was to confirm whether the surface of PEC is clot-promoting or clot-inhibiting, and (b) to see whether the clot-promoting or clot-inhibiting activities are transferred from the surface of PEC, since the reaction of anti-thrombogenic CMC with Toluidine Blue gives purple coloration.

Blood Clotting Test in Vitro. The blood clotting test was carried out according to the procedure of Imai and Nose[14] by gravimetrically measuring the amount of the clot formed at appropriate time intervals, after adding a calcium chloride solution (0.1 M, 0.02 ml) to ACD blood (0.2 ml), which had been in contact with a sample tablet: 200 mg PEC was pressed (8 t/4.5 cm^2) with poly(vinyl chloride) powder in a vacuum for 10 min. The ACD blood was prepared by adding blood (type A supplied by the Red Cross Hospital Blood Center) to an anti-coagulant citrate dextrose solution consisting of sodium citrate, citric acid and dextrose. The clotting tests were carried out concurrently under comparable conditions using the same method and the same ACD blood, after the blood had been stored for 3 days in a thermostat at 4—6 °C.

Solubility of PEC. Polyelectrolyte complexes are hardly soluble in most organic solvents. However, in order to clarify the property of PEC, it is necessary to find an appropriate solvent. Solubility tests were made on formic acid, dimethyl sulfoxide, *N,N*-dimethylformamide and two different ternary solvent mixtures (acetone/potassium bromide/water), (dioxane/water/hydrochloric acid).

Results and Discussion

Experimental conditions and yields in the preparation of PEC are given in Table 1, and, elementary analyses and compositions of PEC and pH of solutions after reaction in Table 2. Primarily, CMC is a salt of weak acid and chitosan is a salt of weak base, so that in a solution of lower pH the number of binding site $-OCH_2COO^-$ is smaller and that of binding site $-NH_3^+$ larger, as compared with a solution of higher pH.

$$-OCH_2COO^-Na^+ + H^+ \rightleftarrows -OCH_2COOH + Na^+$$

$$-NH_3OH + H^+ \rightleftarrows -NH_3^+ + H_2O$$

Thus, provided that $-COO^-$ groups in CMC participate just sufficiently to bind with $-NH_3^+$ in chitosan, in the lower pH condition (series A) the number of binding site $-NH_3^+$ is significantly larger than that of binding site $-OCH_2COO^-$. Consequently, the smaller the mole ratio of N/Na in the reaction mixture, the larger the yield for PEC. On the other hand, at pH 5.0 (series B) the number of binding site $-OCH_2COO^-$ in CMC increases and that of binding site $-NH_3^+$ decreases as compared with those at pH 2.5 (series A), so that the yield of PEC is not much affected by the mole ratio of N/Na. In general, the yield of PEC of series A is larger than that of series B. The tendency is similar to that in the PEC of chitosan with carboxymethyldextran[13] or chitosan with dextran sulfate.[10] The yield of PEC is influenced by the mixing order. When a polyelectrolyte of a large mole fraction in the reaction mixture is mixed with a polyelectrolyte solution, of a small mole fraction, the yield of PEC is larger than that obtained by reversing the order of mixing. In the case of polyelectrolyte, it seems that changes in the reaction mechanism, which affects the yield or molecular conformation of the PEC, are caused by the change in the order of mixing. The pH of reaction mixture tends to drop slightly after completion of PEC in both series. This indicates that the proton is liberated from the PEC on its formation.[6] In the pH range 2.5—5.0, the degree of electrolytic dissociation in polycation is significantly larger than

that in polyanion, all protons favoring release from the undissociated carboxyl groups. The nitrogen content in the PEC is not much influenced by the difference in the order of mixing or the mole ratio of N/Na. These results differ from those in the PEC, chitosan with carboxymethyldextran.[13] However, the nitrogen, sodium and chlorine contents in the PEC of B series are larger than those of series A, the results being similar to those in the PEC, chitosan with carboxymethyldextran[13] and chitosan with dextran sulfate.[10] However, the deviation of nitrogen content in the PEC, chitosan with carboxymethyldextran, with pH is larger than that in the PEC, chitosan with CMC. The results might be related to the fact that the difference in their viscous behavior,[15] or in effective molecular volume of polyelectrolyte in reaction solution, is caused by the pH change in carboxymethyldextran and CMC. The mole ratio of N/COO^- in the PEC, consequently, the nitrogen content in the PEC of series A should be smaller than that of series B. The results given in Table 2 (the mole ratios of N/COO^- in the PEC are calculated from the nitrogen contents in chitosan and PEC, and from the degree of substituent $-OCH_2COOH$ in CMC) are in line with the above consideration. This is also supported by IR spectra.

IR spectra of the PEC in series A are roughly similar to those of the PEC in series B and to those of blend polymer (blended chitosan with CMC in the same ratio as the complex composition), differing from each other in detail (Fig. 1). The absorption band around 1740 cm^{-1}, assigned to -COOH group, arises from the PEC, but not from the blend polymer. The absorption band around 1740 cm^{-1} in the PEC of series A is stronger than that of series B. This is in line with the electrolytic dissociation of $-OCH_2COO^-Na^+$ groups, the stronger the absorption band around 1740 cm^{-1}, the smaller the nitrogen content. The absorption band around 3500 cm^{-1}, attributable to -OH group in the blend polymer, seems to shift slightly towards lower wave number in the PEC. The absorption bands in the PEC of series A are assumed to become broader than those in the PEC of series B and in the blend polymer. The -OH groups in the PEC interact sparsely with other PEC molecules, probably through its -COOH groups. No such interaction was observed in the PEC of chitosan with carboxymethyldextran.[13] From the difference in absorption intensity of -COOH groups between the PEC of series A and series B, it seems that the intermolecular interactions in the PEC of series A through its -OH groups with other -COOH groups, are stronger than those of series B. This is supported by the results of solubility measurements. A weak absorption band around 1520 cm^{-1} assigned to $-NH_3^+$ groups is observed in the PEC, but none in the blend polymer. The sodium and chlorine contents in the PEC are distinctly smaller than those in CMC and chitosan, suggesting that the $-NH_3^+$ groups in chitosan participate in the binding with CMC

Table 3. Color reaction of PEC with Toluidine Blue

Sample code	Color of PEC itself	Color of solution in contact with PEC
A-1	blue	light blue
A-2	blue	light blue
A-3	blue	light blue
A-4	blue	light blue
A-5	blue	light blue
A-6	blue	light blue
B-1	light bluish purple	light blue

B-4	light bluish purple	light blue
B-5	bluish purple	light blue
B-6	bluish purple	light blue

probably through its $-COO^-$ groups, although the number of the ionic binding sites is small. The IR spectra of PEC are similar to those of CMC, being strongly affected by CMC rather than by chitosan. However, this might not be related to the fact that the mole ratio of N/COO^- in the PEC is small (Table 2).

Table 3 gives the results of color reactions of PEC with Toluidine Blue. No elution of CMC is observed in the solutions in contact with each PEC. The color reaction takes place not only on the surface but throughout the bulk of the complex, indicating a homogeneous dispersion of CMC into the PEC. The tint of the PEC differs with the conditions for the preparation of PEC. This seems to be closely related to the difference in the conformation in PEC.

TABLE 4. SOLUBILITIES OF PEC

Sample code	Formic acid			Dimethyl sulfoxide		
	R.T.	B	D.H.	R.T.	B	D.H.
A-1	×	△	▲	×	×	×
A-2	×	△	▲	×	×	×
A-3	×	△	▲	×	×	×
A-4	×	△	▲	×	×	×
A-5	×	△	▲	×	×	×
A-6	×	△	▲	×	×	×

B-2	△	▲	○	×	×	×
B-3	△	▲	○	×	×	×
B-4	△	▲	○	×	×	×
B-5	△	▲	○	×	×	×
B-6	△	▲	○	×	×	×

All PEC are insoluble, even on direct heating, in N,N-dimethyl formamide and two sorts of ternary solvent mixture [acetone/potassium bromide/water (20: 20: 60 wt %)] [(dioxane/water/hydrochloric acid (50: 5: 45 wt %)], other than dimethyl sulfoxide. ○: almost soluble, ▲: considerably soluble, △: partially soluble, × : insoluble, R.T.: room temperature, B:heating on a water bath, D.H.: direct heating.

All PEC are insoluble in most organic solvents, even on heating, such as dimethyl sulfoxide, N,N-dimethylformamide and two different ternary solvent mixtures {[acetone/potassium bromide/water (20: 20: 60 wt%)] [dioxane/water/hydrochloric acid (50: 5: 45 wt%)]} (Table 4), but become partially soluble in formic acid on heating. There is an appreciable difference in solubility between the PEC of series A and series B. It seems that the number of intermolecular binding sites through -OH groups with -COOH groups in the PEC of series B is smaller than that of series A. This is in line with the IR spectra.

The PEC of series A and B show clot-inhibition *in vitro*; they suppress the coagulation of blood (Fig. 2). The amount of thrombus on the PEC is 10—20% of that on glass and 30—50% of that on poly(vinyl chloride) as a reinforcing agent. The difference in anti-thrombogenic behavior between the PEC of series A and that of series B can hardly be observed. The anti-thrombogenic property may be due to the clot-inhibiting surface of the PEC and not to the eluted

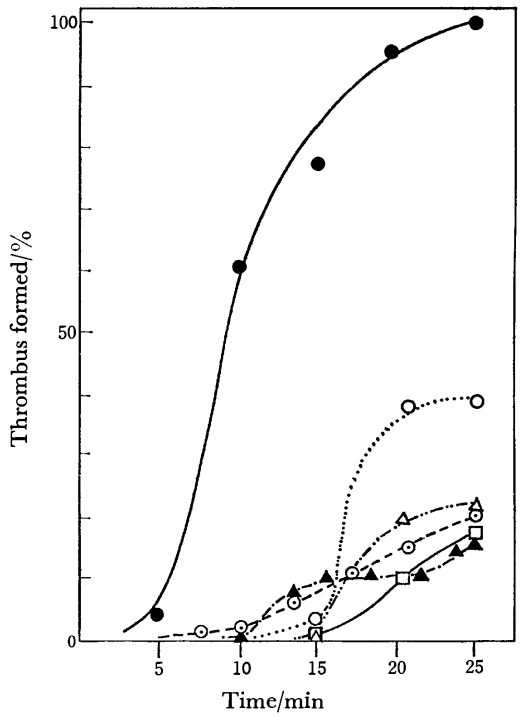

Fig. 2. Quantity of thrombus formed on polyelectrolyte complexes (PEC) compared with that on glass after a lapse of 25 min as a criterion.
●: Glass, □: A-3, △: A-4, ⊙: B-3, ▲: B-4, ○: poly(vinyl chloride) correspond to the PEC in Table 1.

activity from the surface as considered from the color reaction with Toluidine Blue. The clot-inhibiting factors of the PEC might be related to its molecular conformation or configuration.

An ESR Study of Hydrogen Atoms in Methane-Air Flame

Shoji NODA, Masazumi MIURA, and Hiroshi YOSHIDA*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received June 7, 1979)

In order to give a basis for the utilization of ESR in combustion chemical studies, both diffusion flames and premixed flames of a methane–air mixture have been studied by the flame-in-cavity ESR method. A pair of spectral lines separated by 51.0 mT due to H atoms and a very weak single line due to unidentified reaction intermediates have been recorded from combusting gases in a modified Bunsen burner. The H atoms in the diffusion flame give the spectral linewidth of 0.15 mT and populate a confined region near the luminous cone. In the premixed flame, the H atom concentration is the highest at the outside of the luminous inner cone (reaction zone), but it is distributed as long as 4 cm along the gas stream. The profile of the local concentration has been obtained by the deconvolution method from the observed dependence of the spectral intensity on the location of the flame in the resonant cavity. The maximum concentration can be estimated to be 2.4×10^{15} atoms/cm^3, which is much higher than the equilibrium concentration calculated from the flame temperature, 1200 K, and the oxygen excess ratio, 0.67. The spectral linewidth (0.01—0.04 mT) and the microwave power saturation of the H atoms depend on the location in the flame. These results strongly suggest that the line broadening and the spin relaxation are principally determined by the collision between the H atoms and the molecular oxygen.

Combustion in high-temperature flames is a complex reaction system which comprises branched-chain reactions carried by free atoms and free radicals as essential reaction intermediates.[1-4] These reaction intermediates have been studied by the optical absorption and emission spectrometric methods and incorporated in elucidating the flame structure.[1,5] Electron spin resonance (ESR) is a powerful technique for studying atomic and free radical intermediates in gas-phase reactions,[6,7] and it has been utilized, though not very extensively, for the study of combustion chemistry. Systematic studies have been reported by Russian workers,[8-21] who have succeeded in detecting the ESR spectra of several free atoms and free radicals from rarefied flames. Westenberg and Fristrom[22] and Eberius *et al.*[23] have studied H and O atoms generated in low-pressure C_2-hydrocarbon and hydrogen–air flat-flames by using the point-by-point sampling of combustion gases. Bennett *et al.*[24] have briefly communicated the detection of H atoms from hydrogen, methane, and propane free-burning flames under ordinary pressure set in an ESR resonant cavity (by the flame-in-cavity method). Later, Samoilov *et al.*[25-28] applied the flame-in-cavity method to study the kinetic aspects of H atoms, mostly in hydrogen–air free-burning flames, though they have not focussed their attention on the nature of the H atoms in the ESR observations. These studies as a whole show that the ESR technique is promising, but must still be developed for studying the intermediates in combustion reactions.

The present investigation is an extention of those by Bennett *et al.* and Samoilov *et al.* It is aimed at fully elucidating the ESR-spectroscopic nature of H atoms in methane–air free-burning flames by the flame-in-cavity method and giving a basis for utilizing this method for combustion-chemical studies. The methane–air flames are the simplest model of hydrocarbon combustion. The present experimental conditions allow us to detect only H atoms, because neither non-S-state atoms nor free radicals in the gas phase can be detected by ESR unless the pressure is so low that the collision broadening is effectively removed.[7,29] However, the study of the H atom concentration and distribution in the flames by themselves are interesting from the combustion-chemical point of view, since H atoms are known to be one of the major reaction intermediates in the fuel-rich combustion of hydrocarbons.[30]

Experimental

The burner used is a modified Bunsen burner, made of thin quartz tubes, the inner and outer tubes of which are 0.4 and 0.9 cm in diameter respectively. It was directly inserted into the cylindrical TE_{011} resonant cavity and fixed by means of a specially designed adapter. Cooling air could flow through a hole in the adapter when required. The burner could be moved up and down along the axis of the resonant cavity.

Methane of a 99.9% purity (research grade) was used as a fuel gas. Air flowed in from a conventional air compressor. These gases were controlled with a glass capillary-flow meter combined with a precise needle valve. Premixed flames were obtained by supplying methane–air mixed gas into the inner tube and then stabilized by letting secondary air flow into the outer tube. Diffusion flames were obtained by letting methane flow into the inner tube, and air into the outer tube. A rough estimate of the flame temperature was made by using a fine Pt–Rh thermocouple covered with quartz.

The ESR measurements were carried out with an X-band straight-detection-type spectrometer with a 100 kHz magnetic-field modulation. The resonant cavity was water-cooled when

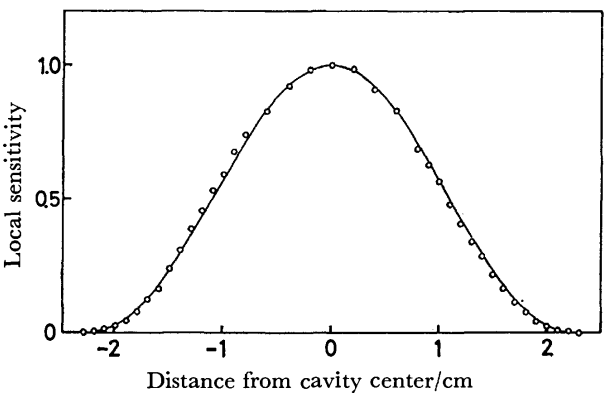

Fig. 1. Local sensitivity of ESR within the resonance cavity of TE_{011} mode.

the flame was set in it. The local sensitivity of the ESR within the resonant cavity was experimentally determined from the observed spectral intensity of a small piece of DPPH by moving it along the axis of the cavity. The sensitivity curve fit well with a sine-square function, as is shown in Fig. 1. The magnetic field inhomogeneity was checked by recording the sharp hyperfine lines of Fremy's salt in an aqueous solution; it was less than 0.002 mT within the effective volume in the cavity. The ESR saturation effect at a high microwave power level was studied at a 100 kHz magnetic-field modulation. The change in the power level was compensated for by an attenuator additionally set immediately before the crystal microwave detector, so that the crystal current was kept constant. This saturation measurement gives signals directly proportional to χ''.[31]

Results and Discussion

ESR Spectra from Diffusion Flames. A methane–air diffusion flame in a burner (with a flow rate of methane of 48 $cm^3\ min^{-1}$ and one of air of, 490 $cm^3\ min^{-1}$) formed a blue cone *ca.* 0.5 cm high and was stationary only for a limited methane/air ratio. The ESR signal recorded from this diffusion flame was composed of a pair of sharp lines with a separation of 51.0 mT around 330 mT, with a very sharp line at the center (g=2.005). The former is the spectrum due to H atoms. The latter spectrum was too weak for its nature to be studied, so that the entities responsible for this spectrum could not be identified. However, the inverted phase of the spectrum may be said to be due to the emission spectrum caused by the CIDEP effect of short-lived entities. Both the spectra were unquestionably due to unstable reaction intermediates in the flame, because they disappeared when the flame was extinguished.

The width (peak-to-peak of the derivative spectral curve) of the H atom spectrum was 0.15 mT; it remained unchanged when the burner was moved up and down along the cavity axis. In contrast, Bennett *et al.*[24] have reported the width of 0.08 mT for the H atoms in methane–air and propane–air diffusion flames. The difference in the width between the two observations is likely to result from the interaction of the H atoms with different concentrations of paramagnetic entities, such as carbons and soot compounds. The carbons and the soot compounds are the major products in the incomplete combustion of hydrocarbons, and they are generated in the reaction region of the diffusion flames.[32]

The intensity of the H-atom spectrum depended on the position of the burner in the cavity. The maximum intensity was obtained when the top of the luminous cone was situated at the center of the cavity. The variation in the intensity with the burner position almost completely followed the local sensitivity curve shown in Fig. 1. This indicates that the H atoms in the diffusion flame populate a limited region near the luminous cone, though the measurements were carried out for only a limited number of burner positions because of the poor signal-to-noise ratio.

ESR Spectra from Premixed Flames. The methane–air premixed flame, typically with a methane flow rate of 95 $cm^3\ min^{-1}$, a primary air flow rate of 600 $cm^3\ min^{-1}$, and a secondary air flow rate of 500 $cm^3\ min^{-1}$, in the burner was composed of a bell-shaped, luminous

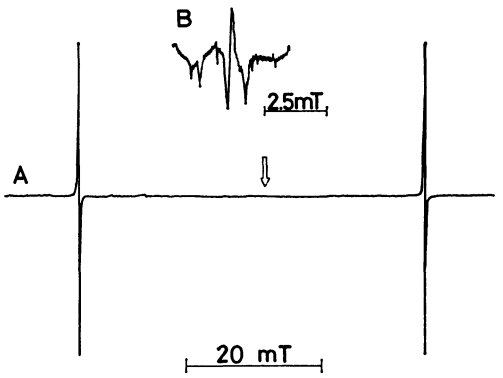

Fig. 2. ESR spectrum from a methane–air premixed flame (A) and the enlarged spectrum of the very weak signal whose resonance field is indicated by the arrow (B).

inner-cone flame *ca.* 1 cm high and of a faint-blue outer-cone flame. The outer-cone flame seemed to be partially quenched chemically and/or thermally on the wall of the outer quartz tube. The ESR signal from the premixed flame (Fig. 2) was qualitatively the same as that from the diffusion flame; it was composed of a pair of sharp lines due to H atoms and a very weak central, single line due to unidentified entities.

The linewidth and the intensity of the H atom spectrum varied depending on the position of the burner in the cavity. The microwave-power saturation behavior of the H-atom spectrum also depended on the burner position. These features of the premixed flame contrast with those of the diffusion flame.

The stationary premixed flame in the burner quartz tube could be obtained only within a limited methane/air composition range, that is, only for fuel-rich mixtures.

Concentration Profile of the H Atoms in the Premixed Flame. The intensity of the H-atom spectrum observed from the premixed flame is shown in Fig. 3 (open circles) as a function of the location of the burner in the cavity. The coordinate axis in the absolute concentration was

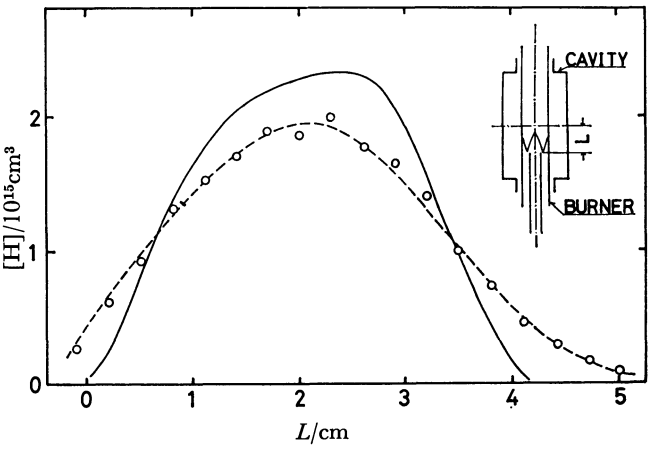

Fig. 3. The concentration profile of the hydrogen atom in a methane–air premixed flame: ○, observed signal intensities; solid line, true profile calculated by the deconvolution, dashed line, reconstructed apparent profile, where L is the distance between the cavity center and the top of the inner tube. (See Text for the details.).

calibrated with reference to the signal intensity of the molecular oxygen of the controlled concentration in the burner[7] by assuming that the H-atom concentration was uniform on a vertical cross-section plane of the burner. The maximum temperature was measured to be 1200 K, which was taken into account in the concentration calibration under the assumption that the temperature was uniform within the flame. The variation in the spectral intensity does not give the concentration profile of the H atom in the flame directly, because the local sensitivity curve of the resonant cavity (Fig. 1) causes the true concentration profile to deteriorate.

In order to get the true profile, the following deconvolution calculation was performed, using the Burger-Cittert method:[33]

$$g(L) = \int a(x)f(L-x)\mathrm{d}x, \qquad (1)$$

where $g(L)$ is the observed intensity variation, $a(x)$, the local sensitivity curve (Fig. 1), and $f(L)$, the true concentration profile. The $f(L)$ thus calculated is apparently narrower than $g(L)$, as is shown in Fig. 3 (solid curve). The convergence of the deconvolution treatment was checked by reconstructing $g(L)$, which agreed well with the original data (the reconstructed $g(L)$ is shown by the dashed curve in Fig. 3). The maximum local concentration of the H atoms shifts slightly compared with the maximum signal intensity; it is located 2.5 cm down-stream from the top of the inner tube. Comparing this with the 1 cm height of the luminous inner cone, one can see that the H atoms are located mostly in the down-stream region of the premixed flame.

The above concentration profile was obtained from a Bunsen flame confined in a narrow tube, not from a flat flame (a one-dimensional flame), for which the theoretical calculation of the flame structure is much easier. However, the present results obtained by the flame-in-cavity method are qualitatively consistent with the H atom concentration profile expected from the point-by-point sampling study for flat flames.[22,23]

In the present study, the flame was stationarily obtained for the oxygen excess ratio, α, in the narrow range of 0.63—0.75. The maximum H-atom concentration, *ca.* 2.4×10^{15} atoms/cm^2, was found for $\alpha=0.67$ in the fuel-rich region. This concentration amounts to only 0.4% of the total combustion products, in qualitative agreement with the previous results.[26,34] The equilibrium concentration of the H atoms for $\alpha=0.67$ and $T=1200$ K can be calculated to be 2×10^{-7} % of the total combustion products.[35] The observed H atom concentration is much higher than the equilibrium concentration, as has previously been reported for hydrogen-air flames.[28]

Linewidth of the H Atoms in the Premixed Flame. The spectral linewidth of the H atoms decreased monotonously, as is shown in Fig. 4; the width was 0.04 mT for the H atoms near the top of the inner tube, while it approached the instrumental resolution limit, 0.01 mT, in the down stream region of the flame. The spectral line was much narrower than that in the diffusion flame, anyway.

The H atoms possess an angular momentum of only

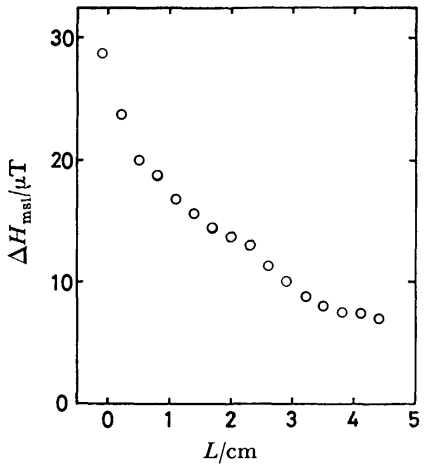

Fig. 4. The variation of the line width of the hydrogen atom in a methane–air premixed flame along the gas stream. L is the distance between the cavity center and the top of the inner tube.

spin. The collision with paramagnetic entities causes the relaxation of the spin states of the H atoms. The linewidth is determined by spin-exchange interaction between the H atoms themselves, magnetic interaction with other paramagnetic entities, magnetic-field inhomogeneity, and a broadening due to high-frequency magnetic-field modulation.[29] Among these factors, the spin-exchange interaction is unimportant, because the variation in the linewidth (Fig. 4) does not run parallel with the concentration profile of the H atoms shown in Fig. 3. There exist a variety of paramagnetic entities in hydrocarbon combustion, *i.e.*, stable molecular oxygen, reactive atomic oxygen, and several free radical intermediates. However, the H atoms are much more abundant than the atomic and free radical intermediates in fuel-rich combustion, so that the interaction between the H atoms and other paramagnetic reaction intermediates contributes little to the line broadening of the H-atom spectrum. On the other hand, the concentration of the molecular oxygen far exceeds that of the reaction intermediates. The interaction with the molecular oxygen will result in the spectral line-broadening of the H atoms. Although Westenberg and de Haas[29] have demonstrated that the molecular oxygen has little effect on the line-broadening when the oxygen concentration is comparable with the H-atom concentration, the linewidth variation observed from the present premixed flame can be attributed to the local concentration of the molecular oxygen, which is consumed mainly in the reaction zone of the premixed laminar flame and which gradually decays in concentration afterwards.[34] The reaction zone of the Bunsen flames is the luminous inner-cone flame.[32]

The variation in the linewidth along the gas stream in flames has been observed for the H atoms in hydrogen–air flames. This has been attributed to the variation in the molecular-oxygen concentration in the flames.[25] In the hydrogen–air flames, the linewidth changes drastically at the stoichiometric mixture ratios from 0.015 to 0.25 mT when the air/fuel ratio is increased. This also suggests the significant contribution of the

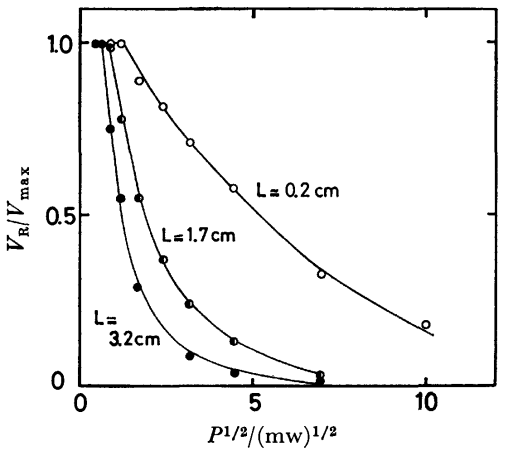

Fig. 5. Power saturation of the hydrogen atom in the different flame position of the methane–air premixed flame.

molecular oxygen to the line-broadening of the H atoms.[24]

Microwave-power Saturation of the H-atom Spectrum in the Premixed Flame. With an increase in the microwave power incident into the resonant cavity, the spectral lines of the H atoms became broader and the spectral intensity decreased simultaneously. The saturation of the spectral intensity is shown in Fig. 5 by simply plotting the peak-to-peak height of the spectrum as a function of the square-root of the microwave power. Although the analysis of the saturation curves is essentially complex because of the high-frequency field modulation (rapid passage condition), the plotted intensity is recorded so as to be parallel with χ'', as was mentioned in the Experimental section.

It is obvious from Fig. 5 that the H atoms in the luminous inner cone (reaction zone) are comparatively little saturated, while those in the down-stream region in the flame are readily saturated, with the increase in the microwave power. According to Westenberg and de Haas,[29] the spin-exchange collision between the H atoms and the molecular oxygen causes a remarkable reduction in the T_1 of the former. The observed dependence of the saturation behavior on the location in the flame is attributable to the local concentration of the molecular oxygen: the concentration initially decreases remarkably in the reaction zone, so that the T_1 of the H atoms becomes longer in down stream. This result is consistent with that of the linewidth variation.
