Apparent Band Positions of Acridine and MeAcr. Figure 2 shows the isotropic spectra of acridine and MeAcr in the nonstretched (S=1) PVA film. In the spectrum of acridine, two peaks and three shoulders are observed in the 320—370 nm region and three humps in the 370—460 nm region. 10-Methylacridinium shows a similar spectrum, retaining most of these features, except for the 320—370 nm bands which are slightly diffused. From the studies of linear dichroism in the stretched polymer film[7,8] and the polarized fluorescence,[9,10] the short-wavelength band structure has been assigned to the ^1L_b transition and the long-wavelength one to the ^1L_a transition. It should be noted that the spectrum of AO differs from those in Fig. 2 in that it shows a deceptively simple absorption peak at 502 nm.[8] A similar change was always observed in the isotropic spectra of other 3,6-disubstituted acridine dyes: Proflavine, Trypaflavine, Acridine Yellow, and 10-Methyl Acridine Orange.[8] Although three shoulders are noticeable in the 400—490 nm region, the assignment of the polarization of AO was not so straightforward as in the case of acridine.[6,9,16] The isotropic spectrum of AO will be constituted from the individual component bands of the A_y- and A_z-spectra, in order to make the assignment of the polarization direction.

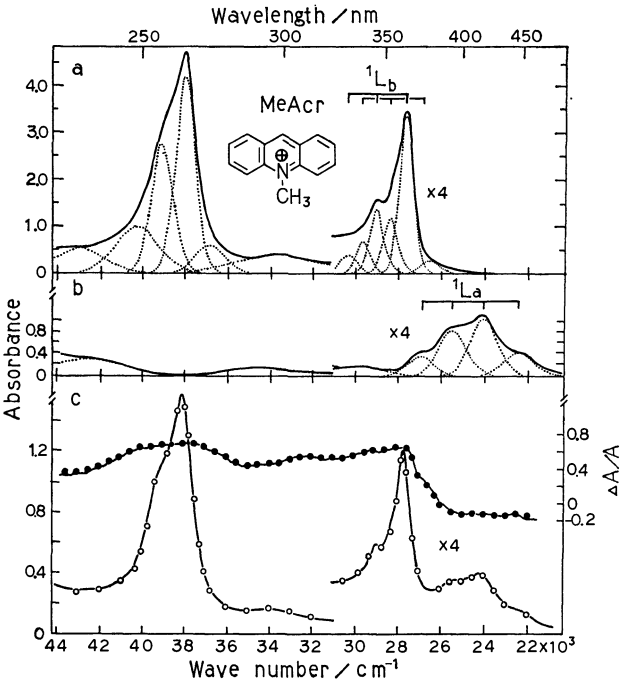

Fig. 3. Computer simulation of the dichroic data of MeAcr at ϕ=0.368. (a) Resolution of the A_z-spectrum (solid curve) into the component curves (dotted). (b) Resolution of the A_y-spectrum (solid curve) into the component curves (dotted). The absorbance scale of the ^1L_b and ^1L_a bands is four-fold expanded. (c) The results of the calculated (closed circles) and experimental (solid line) reduced dichroism in the upper half, and the reconstituted (open circles) and observed (solid line) isotropic spectrum. The numerical values for the resolution are given in Table 2.

For this purpose, the dichroic spectra of MeAcr as the base data will be analyzed with Eq. 2 in some detail below.

Computer Simulation of the Isotropic and Reduced Dichroism Spectra of MeAcr. The isotropic spectrum and the long-axis and short-axis polarized spectra (*i.e.*, the A_z- and A_y-spectra) of MeAcr are shown in Fig. 3, together with the wavelength dependence of the reduced dichroism (the RD-spectrum).[8] The A_z- and A_y-spectra of MeAcr [(a) and (b) of Fig. 3] are at first divided into the respective component bands. Then, the isotropic spectrum [(c) of Fig. 3] is reconstructed from all of those component bands by a computer synthesis, in which the band envelope, $A_i(\tilde{\nu})$, of the ith component band was conventionally assumed to be the Gaussian error function at a given wave number $\tilde{\nu}$ (Eq. 3):[17,18]

$$A_i(\tilde{\nu}) = A_{i,\max} \exp\left\{-\left(\frac{\tilde{\nu}-\tilde{\nu}_{i,\max}}{\delta_i}\right)^2\right\} \qquad (3)$$

where $\tilde{\nu}_{i,\max}$, $A_{i,\max}$, and δ_i are the peak position, the maximum intensity (absorbance) at $\tilde{\nu}_{i,\max}$, and the corresponding half-width of the ith band, respectively. The half-width is the band width in wave numbers measured at 1/2.718 of the maximum height.

The resolution of the A_z-spectrum (and also the A_y-spectrum) into the component bands was carried out with a HITAC-8700 computer according to the following procedure.[15] Both $A_{i,\max}$ and δ_i were taken as adjustable parameters. Since most of the peaks and shoulders in the A_z-spectrum (and the A_y-spectrum) are easily discernible (Fig. 3), the center of each component band, $\tilde{\nu}_{i,\max}$, was treated as a pre-determined constant and was read from the respective spectra. For the sub-bands whose peak positions were not visually clear, the following guide was observed:[19] The spacing of the sub-bands is characteristic of a particular electronic transition, but each sub-band in the transition is separated more or less evenly with an average spacing $(\Delta\tilde{\nu})_{avg}$. With the pre-determined values of $\tilde{\nu}_{i,\max}$, the values of $A_{i,\max}$ and δ_i were adjusted until a reasonable agreement was obtained between the observed and simulated A_z-spectra (and A_y-spectra). This iteration procedure was repeated with a new set of $\tilde{\nu}_{i,\max}$-values in case the agreement was poor. The value of δ_i was assumed to be constant for successive sub-bands belonging to a particular electronic transition.

Figure 3 shows the resolved component bands (dotted lines) of the A_z-spectrum (a) and the A_y-spectrum (b). With the relation $3A=A_y+A_z$,[13,20] the isotropic spectrum of MeAcr can be synthesized directly by the use of those component bands. The resultant isotropic spectrum [open circles in (c)] agrees well with the observed one (solid curve). This agreement assures the correctness of the Gaussian approximation for the profile of each component band and the assumption for the spacing of the peak positions for the component bands of a particular electronic transition.

The resolution of the A_z- and A_y-spectra into the component bands is verified by the construction of the RD-spectrum. This spectrum can be simulated by using the resolved component bands with the aid of Eq. 2, in which the transition moment angles θ_i of the component bands of the A_z-spectrum are all equal to 0° and those of the component bands of the A_y-spectrum are 90° under consideration of the C_{2v} symmetry of MeAcr.[8] The values of the orientation function Φ and the constant M_z in Eq. 2 were evaluated at the same stretch ratio of 4.3 as in a previous work: $\Phi=0.368$ and $M_z=0.75$.[13] (These values may be calculated from the values of the experimental reduced dichroism with Eq. 1, if the y-axis and the z-axis polarized transitions are well separated in an absorption spectrum, as in the case of MeAcr.[14])

The result is shown in Fig. 3c, where the simulated RD-spectrum (closed circles) agrees well with the experimental one (solid curve) in the 220—460 nm region. This agreement should be considered as a strong support for the set of all A_i, θ_i, Φ, and M_z values employed in the present simulation. Thus it is obvious that the ^1L_a transition centered at 412 nm consists of four component bands with an equal spacing of *ca.* 1.5×10^3 cm^{-1}, while the ^1L_b transition centered at 360 nm consists of about six component bands with an equal spacing of *ca.* 0.7×10^3 cm^{-1}. The UV band peaked at 263 nm was resolved into four component bands. The remaining absorption region (270—340 nm) was tentatively divided into the broad component bands.

Computer Simulation of the Isotropic and Reduced Dichroism Spectra of AO and AY. In the case of AO and AY, the energy gap between the ^1L_a and ^1L_b transitions is

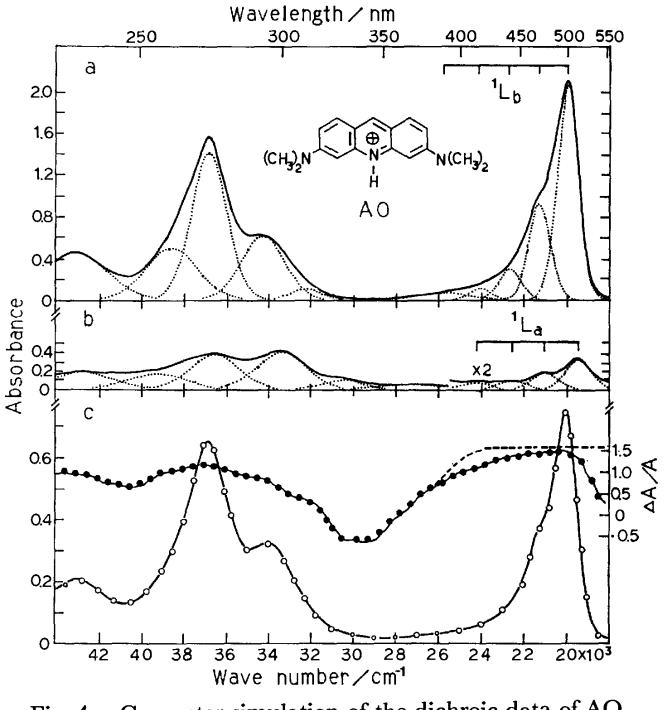

Fig. 4. Computer simulation of the dichroic data of AO at $\Phi=0.61$. Symbols are the same as in Fig. 3. The absorbance of the ^1L_a band is two-fold expanded. The thick dashed line in the visible region (c) indicates the resultant reduced dichroism under no consideration of the ^1L_a band. The presence of this band is essential to the correct reproduction of the experimental RD-spectrum.

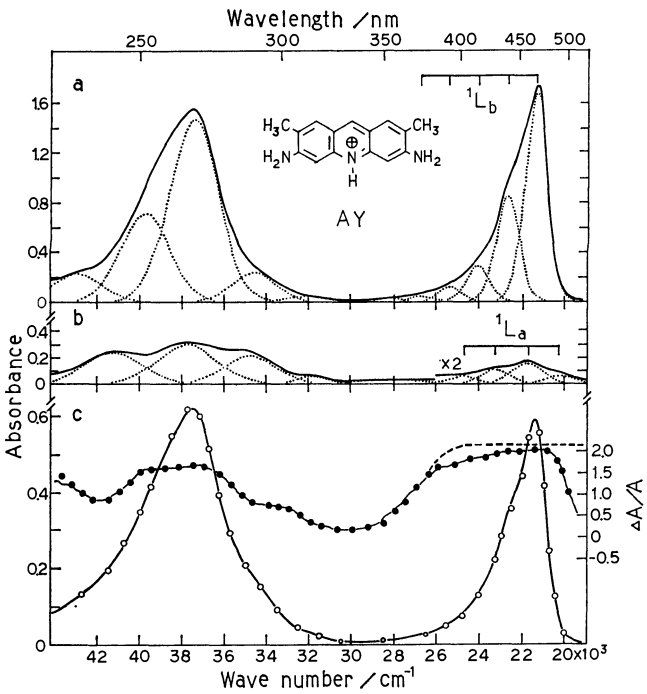

Fig. 5. Computer simulation of the dichroic data of AY at $\phi=0.72$. Symbols are the same as in Fig. 3. The absorbance of the ^1L_a band is two-fold expanded. The thick dashed line in the visible region (c) indicates the calculated reduced dichroism without the consideration of the ^1L_a band.

narrower, while the absorption intensity of the ^1L_a transition is much weaker than that of the ^1L_b transition.[8] The A_z- and A_y-spectra of AO were analyzed by the same method as used for MeAcr. The results are shown in Fig. 4, where the A_y-spectrum (b) is the average of four A_y-spectra which were obtained at four different stretch ratios. Thus the experimental error associated with the weak intensity of the A_y-spectrum was minimized. Both the A_z- and A_y-spectra of AO (a and b) were resolved into the respective component bands in the visible and UV regions. The A_z- and A_y-spectra of AY were analyzed in a manner similar to the case of AO. The results are shown in Fig. 5, which indicates that the spectral feature of AY is closely related to that of AO.

The vibrational progressions of the ^1L_a and ^1L_b bands of AY in the visible region were similar to those of AO. The A_z-spectra of AO and AY in the UV region could be divided into five component bands.[21] The highest-intensity bands at 272 nm for AO and at 266 nm for AY belong to ^1B_b transition.[9,16] However, the assignments of other bands were difficult to make. They may be either the vibrational sub-bands of the ^1B_b transition or other electronic transitions. The A_y-spectra of AO and AY in the UV region were resolved into the individual component bands. The assignments of these bands were also difficult to make. The isotropic spectra of AO and AY are finally reconstructed from those resolved bands as shown by open circles, which agree well with the observed spectra (solid curves), in Figs. 4c and 5c. The resolution of the A_z- and A_y-spectra into those component bands will be further justified by simulating the observed RD-spectrum.

The values of ϕ and M_z necessary for the simulation have already been evaluated:[13] $\phi=0.61$ (at $S=4.3$) and $M_z=0.90$ for AO, and $\phi=0.72$ (at $S=4.3$) and $M_z=1.0$ for AY. The transition moment angle θ_i is 0° for the component bands of the A_z-spectrum and 90° for the component bands of the A_y-spectrum under consideration of the molecular symmetry. The results of the simulation of the RD-spectrum are shown by closed circles for AO in Fig. 4c and for AY in Fig. 5c. The agreement between the simulated (closed circles) and the experimental (solid curve) RD-spectra is excellent over an entire wavelength region for AO and AY, which is a strong justification of both the procedure for the resolution of the A_z- and A_y-spectra into the component bands and the values of ϕ and M_z used in the simulation.

Discussion

Transition Moment Direction of an Overlapping Band and Expressions for Reduced Dichroism. If the y- and z-axis polarized electronic transitions of a molecule are isolated in the spectrum, the angle θ between either transition moment and the molecular z-axis can be determined with the aid of Eq. 1, together with the given values of M_z and ϕ. Hence, this equation yields a value of 0° for a z-axis polarized absorption band at 263 nm and 90° for a y-axis polarized band at 412 nm of MeAcr, in which these orthogonal bands are widely separated (Fig. 3). However, this is not true for the case in which two or more electronic bands are overlapped. Equation 1 is written for AO ($M_z=0.90$ and $\phi=0.61$) as

$$\frac{\Delta A}{A} = 0.915(2.4\cos^2\theta - 0.7). \qquad (4)$$

This equation yields the apparent θ-values of *ca.* 25° and 82°, which differ from 0° or 90°, for the overlapping 272 nm ($\Delta A/A=1.15$) and 330 nm ($\Delta A/A=-0.60$) bands respectively (Fig. 4). Other examples are given for the representative bands of MeAcr, AO, and AY in Table 1. Molecular orbital calculations[7,22,23] prescribe that the transition moment vector of an absorption band of the acridine dyes, which belong to the C_{2v} point symmetry group, should be polarized along the long- or short-axis in the molecular plane. Accordingly, the angle θ for the overlapping bands gives only the apparent direction of a resultant vector

Table 1. The angle of transition moment, θ_λ, for some apparent bands of MeAcr, AO, and AY calculated from Eq. 1

Dyes	θ_λ[a]		
MeAcr	$\theta_{412}=90\pm3$	$\theta_{360}=12\pm3$	$\theta_{263}=0\pm3$
AO	$\theta_{502}=13\pm2$	$\theta_{330}=82\pm3$	$\theta_{272}=25\pm2$
AY	$\theta_{467}=9\pm2$	$\theta_{295}=41\pm3$	$\theta_{266}=22\pm2$

a) θ_λ is the angle in degrees measured from the z-axis of the acridine nucleus (Fig. 1), and λ in nm indicates the observed apparent band position.

Table 2. Classification on the long-wavelength absorption bands of MeAcr, AO, and AY in the PVA film

Dyes	Bands							
	^1L_a				^1L_b			
	$A_{i,max}$	δ_i / 10^3 cm^{-1}	$\tilde{\nu}_{i,max}$ / 10^3 cm^{-1}	$\Delta\tilde{\nu}$ / 10^3 cm^{-1}	$A_{i,max}$	δ_i / 10^3 cm^{-1}	$\tilde{\nu}_{i,max}$ / 10^3 cm^{-1}	$\Delta\tilde{\nu}$ / 10^3 cm^{-1}

	0.202	0.85	25.51	1.44				
	0.086	0.85	26.95		0.068	0.46	26.90	0.75
					0.827	0.46	27.65	0.72
					0.284	0.46	28.37	0.65
					0.322	0.46	29.02	0.66
					0.169	0.46	29.68	0.71
					0.096	0.46	30.39	
AO	0.157	0.85	19.50	1.60				
	0.095	0.85	21.10	1.55	2.053	0.72	19.97	1.33
	0.049	0.85	22.65	1.54	0.925	0.72	21.30	1.37
	0.035	0.85	24.19		0.305	0.72	22.67	1.37
					0.102	0.72	24.04	
AY	0.031	1.05	20.35	1.44				
	0.075	1.05	21.79	1.47	1.667	0.75	21.41	1.32
	0.054	1.05	23.26	1.49	0.842	0.75	22.73	1.35
	0.029	1.05	24.75		0.283	0.75	24.08	1.33
					0.116	0.75	25.41	1.30
					0.035	0.75	26.71	

of some differently polarized transitions. Neglect of this fact may cause some confusion in the assignment of the direction of transition moments.

The above difficulty may be avoided by the use of Eq. 2, which is written for AO as

$$\frac{\Delta A}{A} = 0.915\left(2.4\frac{A_y\cos^2\theta_y + A_z\cos^2\theta_z}{A_y + A_z} - 0.7\right). \quad (5)$$

In this equation the correct angles of transition moments, θ_y and θ_z, can be calculated to be 90° and 0° at any wavelength, provided that both A_y- and A_z-spectra are available from the reduction procedure, together with the values of M_z and ϕ. It should be emphasized here that Eq. 2 is the general expression which describes the dichroic property of any planar, light-absorbing molecules with no out-of-plane transition and will be employed for the analysis of the observed $A_{//}$- and $A_{\perp}$-spectra, each of which contains some overlapping bands. In order to utilize Eq. 2 fully, the values of M_z, ϕ, and $A_i(=A_y$ or $A_z)$ must be available without recourse to the reduction procedure. Both M_z and ϕ may be estimated experimentally by measuring the reduced dichroism at several stretch ratios, while A_i may be obtained by equating θ_y and θ_z to 90° and 0° in Eq. 5 (or 2) for the C_{2v}-symmetric molecules.

Identification of the ^1L_a and ^1L_b Transitions of MeAcr, AO, and AY. The spectral profile of the short-axis polarized transition (^1L_a) of MeAcr could be resolved into a series of the vibrational sub-bands. The energy separation $\Delta\tilde{\nu}$ of the successive sub-bands is (1.4—1.5) × 10^3 cm^{-1} (Table 2). This spacing is very close to the previously reported values for the ^1L_a transitions of acridine[7] and some polyacenes.[24,25] The spacing of the vibrational sub-bands of the ^1L_b transition of MeAcr is (0.7—0.8) × 10^3 cm^{-1} (Table 2), as obtained from the resolution of the long-axis polarized spectrum. This energy separation is also very close to the values for the vibrational sub-bands of the ^1L_b transition of the polyacene derivatives.[25] The band profiles of the individual vibrational sub-bands associated with the electronic ^1L_b transition strongly support the notions that two different vibrational progressions are involved and that their average energy spacings are both about 1.4×10^3 cm^{-1}, as indicated in Fig. 3a. It is interesting to note that the intense, solitary peak at 360 nm is actually the second of the vibrational sub-bands. If it were the first, the RD-spectrum in Fig. 3c should ascend much more sharply from −0.2 to 0.7 in the 360—380 nm region.

From Figs, 4 and 5, it is obvious that the ^1L_a transition of AO (and AY) also consists of several vibrational sub-bands which are overlapped by the intense ^1L_b transition. If the vibrational structure were due to an error in the trial-and-error reduction search,[8,12] there would be no short-axis polarized transition (^1L_a) involved in the visible region. In this case, the calculated wavelength dependence of the reduced dichroism should differ from the experimental curve, behaving like the curve of thick dashed lines in Figs. 4c and 5c, and, hence, the experimental reduced dichroism could never be reproduced. Therefore, the short-axis polarized band must be present in the visible region of AO (and AY). The spacing of the sub-bands of the ^1L_a transition of AO (and AY) is (1.4—1.6) × 10^3 cm^{-1} (*cf.* Table 2 and Figs. 4b and 5b). This energy separation is again in good agreement with the values

for the ^1L_a transitions of MeAcr and other aromatic compounds.[25] The vibrational spacing of the ^1L_b transition of AO (and AY) is $(1.3—1.4)\times10^3$ cm^{-1} (*cf.* Table 2 and Figs. 4a and 5a) and agrees with a reported value of 1.3×10^3 cm^{-1}.[26] It is now clear from the present work why the experimental verification of the ^1L_a transition for the 3,6-disubstituted acridine dyes has long been unsuccessful. It is because the ^1L_a band is weak and completely hidden by the intense ^1L_b band.

The ^1L_a and ^1L_b bands of AO and AY are distributed over a wide wavelength region. This wide progression of the ^1L_a band of AO (and AY) may be responsible for a variety of reports on the different wavelength positions of the ^1L_a band, *i.e.*, the short-wavelength side of the principal peak (Ballard *et al.*[16] and Ito and I'Haya[23]) or the long-wavelength side of the principal peak (Wittwer *et al.*[9] and Lang and Löber[22]). The classification of the long-wavelength absorption bands of MeAcr, AO, and AY has now been completed in this work. With this result, optical studies of the interaction between acridine dyes and natural or synthetic polymers should be facilitated. The geometrical studies of the complexes between 10-Methyl Acridine Orange and deoxyribonucleic acid and sodium polyphosphate will be reported shortly.

Conclusion

The isotropic spectra of MeAcr, AO, and AY were reconstituted from the component bands obtained by resolving the long- and short-axis polarized absorption spectra (A_y and A_z). The existence of a weak absorption band (the ^1L_a band) of AO and AY could be confirmed by reproducing the experimental reduced dichroism reasonably well with the aid of a new expression for the reduced dichroism of the multiple band system. The weak ^1L_a band of both AO and AY was shown to consist of the vibrational structure with regular energy intervals. The average spacing of the successive subbands for the ^1L_a and ^1L_b transitions of MeAcr, AO, and AY could be estimated from the resolved peak positions. The general expression for the reduced dichroism of a planar molecule (Eq. 2) has proved to be useful for analyzing the linear dichroism with overlapping absorption bands in the dichroic spectra of acridine dyes of C_{2v} point symmetry.

Partner Orbitals in Hartree-Fock Theory

Kimihiko HIRAO

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 12, 1979)

The orbital ambiguity in the Hartree-Fock theory is removed in such a way as to improve the convergence property of the configuration interaction calculation. A practical proposal is made to obtain efficient orbitals for use in construction of wavefunctions. These orbitals are called the zeroth-order natural orbitals and their partner orbitals. It is also demonstrated by an illustrative calculation that use of partner orbitals rather than SCF orbitals gives much more rapid convergence and greater physical insight.

The variational condition in the Hartree-Fock (HF) theory determines the occupied and virtual manifolds, but it does not completely determine the individual orbitals belonging to each manifold.[1] This orbital ambiguity yields the possibility of obtaining a new set of orbitals within unitary transformations which may be more effective for the investigation of a particular physical problem than the SCF orbitals. Several attempts[2] were made to exploit this arbitrariness to produce physically meaningful virtual orbitals for some specific purposes. These methods, however, usually resolve the orbital ambiguity according to the criterion that the orbitals should change as little as possible under an excitation of a single electron. These orbitals are suitable to describe the singly excited states but do not help to improve the convergence in the perturbation theory and the configuration interaction (CI) calculation based on the HF equation.

The present discussion differs from these at some points in philosophy. We will consider that the orbital ambiguity should be resolved in such a way that the convergence may be improved in the CI calculation based on the HF equation. The orbitals obtained in such a way should be the zeroth-order approximation to the natural orbitals,[3] since they reduce the number of determinants required for any fixed accuracy in the wavefunction compared with most other techniques for selecting orbitals. Perturbation comparison of HF orbitals and natural orbitals indicates that the coupling of HF occupied and virtual manifolds occurs only in second order due to the Brillouin theorem.[4] This suggests the possibility that we can define zeroth-order natural orbitals by taking advantage of the arbitrariness of the manifolds. In the present study, we will define 2n zeroth-order natural orbitals for 2n-electron systems. The first n natural orbitals are determined by a unitary transformation of the HF manifold.[5] The remaining n natural orbitals are determined by a transformation of the virtual manifold involving pairing of first n zeroth-order natural orbitals with virtual orbitals. The virtual orbitals are, therefore, transformed so that each virtual orbital is largely localized in the same region as its occupied counterpart. There is no resemblance at all between any one of the SCF virtual orbitals and these transformed ones. We call these virtual orbitals as partner orbitals.

The existence of these partner orbitals is predicted in our previous study[6] of the orbital theories with the formalism of the cluster expansion method. The same kind of orbitals as partner orbitals play an important role in constructing wavefunctions of various orbital theories including electron correlation effects. Also the same kind of orbitals appear and help the HF orbitals when the HF state is unstable, that is, when the HF approximation fails to describe the system. However, when the HF solution is stable, as is usually the case, partner orbitals are embedded in the virtual manifold.

We will show how to resolve the orbital ambiguity to obtain the zeroth-order natural orbitals and their partner orbitals. We will also demonstrate that the use of partner orbitals rather than the SCF orbitals gives much more rapid convergence and greater physical insight.

Definition of Partner Orbitals

We consider the case of a determinatal wavefunction of 2n electrons with n doubly occupied orbitals

$$\Phi_0 = \|\phi_1\bar{\phi}_1 \cdots \phi_k\bar{\phi}_k \cdots \phi_n\bar{\phi}_n\| \quad (1)$$

as determined by an SCF calculation. Since we usually obtain these occupied orbitals from some kind of eigenvalue equations which give us more orbitals than needed, we have the so-called virtual orbitals. The virtual orbitals are mere mathematical by-products, so there are an infinitive number of possible choices of the virtual orbitals, the only requiring to be met being that they should be orthogonal to the HF orbitals. For a set of m orbitals (we assume $m \geq 2n$), of which n are occupied, choose pair orbital of the (m−n) virtual orbitals with each of the n occupied orbitals. Then define the Slater determinants Φ_k obtained by exciting a pair of electrons from occupied ϕ_k to its virtual counterpart orbital ϕ_{k^*},

$$\Phi_k = \|\phi_1\bar{\phi}_1 \cdots \phi_{k^*}\bar{\phi}_{k^*} \cdots \phi_n\bar{\phi}_n\|. \quad (2)$$

Throughout the paper, the indices k, l refer to the occupied orbitals, k*, l* to their virtual counterparts, u, v to the remaining virtual orbitals and i, j to general orbitals. Now consider the total wavefunction expressed as a linear combination of these determinants,

$$\Psi = C_0\Phi_0 + \sum_{k=1}^{n} C_k\Phi_k. \quad (3)$$

We assume Ψ is normalized to unity. Namely, the configuration expansion coefficients satisfy

$$C_0^2 + \sum_{k=1}^{n} C_k^2 = 1. \quad (4)$$

This expansion is different from the so-called complete MC-SCF (CMC-SCF) expansion of Clementi and

Veillard,[7] in which all possible pair excitations $\phi_k \rightarrow \phi_i$ are included for a finite set. We call this particluar expansion (3) the Selected Paired Excitational (SPE) expansion to distinguish this from other possible paired excitational expansions. The first order reduced density matrix for Φ is written

$$\rho(1|2) = 2\sum_{k=1}^{n}[(1-C_k^2)\phi_k^*(1)\phi_k(2)+C_k^2\phi_{k^*}^*(1)\phi_{k^*}(2)]. \quad (5)$$

These orbitals ϕ_k, ϕ_{k^*} constitute, therefore, the natural orbitals for Φ. The $(1-C_k^2)$ is the fractional occupation probability for ϕ_k and C_k^2 is that for ϕ_{k^*}. The configuration expansion coefficients are obtained by solving the conventional CI eigenvalue problem,

$$\boldsymbol{HC} = \boldsymbol{EC} \quad (6)$$

with $\boldsymbol{E}$ the diagonal energy matrix and $\boldsymbol{H}$ defined by the Hamiltonian matrix elements with respect to the SPE configurations.

The idea of the present method is to arrive at equations for the determination of the "best" HF occupied and virtual orbitals to be used in the SPE expansion of the wavefunction. "Best" is used here in the sense that the "best" occupied and virtual orbitals determined by a unitary transformation on each manifold will yield the lowest possible eigenvalue of (6). Thus, we predict that "best" orbitals are presumably close to the first 2n natural orbitals in the space spanned by the m orthonormal basis functions. Thus, we call the "best" occupied orbitals as the first n zeroth-order natural orbitals and the "best" virtual orbitals as partner orbitals to these occupied orbitals. The CI calculation with these "best" orbitals is called the CI with partner orbitals (CIP).

The energy expectation for Φ is given by

$$\begin{aligned} E = E_0 &- 2\sum_k C_k^2(h_{kk}-h_{k^*k^*}+G_{kk}-G_{k^*k^*}) \\ &-4\sum_{k>l}\sum[C_k^2(G_{kl}-G_{k^*l}) + C_l^2(G_{kl}-G_{kl^*}]) \\ &-2C_0\sum_k C_k K_{kk^*}, \end{aligned} \quad (7)$$

where E_0 is the HF energy

$$E_0 = 2\sum_k(h_{kk}+G_{kk}) + 4\sum_{k>l}\sum G_{kl}. \quad (8)$$

Here we set

$$G_{ij} = J_{ij} - \frac{1}{2}K_{ij}, \quad (9)$$

where J_{ij} and K_{ij} are the familiar Coulomb and exchange integrals. We use $\sum_k$ to mean summation over the occupied orbitals k and/or the partner orbitals k*. Variation of E with respect to the orbitals, subject to the condition that the occupied and virtual manifolds are kept fixed, gives

$$\langle\phi_k|(1-C_k^2)F_k-(1-C_l^2)F_l|\phi_l\rangle = 0 \quad (10a)$$

$$\langle\phi_{k^*}|C_k^2F_{k^*}-C_l^2F_{l^*}|\phi_{l^*}\rangle = 0 \quad (10b)$$

$$\langle\phi_v|F_{k^*}|\phi_{k^*}\rangle = 0, \quad (10c)$$

where

$$F_k = F_0 + (1-C_k^2)^{-1}[2\sum_{l(\neq k)} C_l^2(G_{l^*}-G_l)+C_0C_kK_{k^*}]$$

$$F_{k^*} = F_0 + 2(G_{k^*}-G_k) + C_0C_k^{-1}K_k. \quad (11)$$

Here the F_0 is the Fock operator

$$F_0 = h + 2\sum_k G_k \quad (12)$$

and

$$G_i = J_i - \frac{1}{2}K_i, \quad (13)$$

where J_i and K_i are the usual Coulomb and exchange operators. The variational conditions (10a), (10b), and (10c) determine the transformations between HF occupied orbitals, between partner orbitals, and between partner and unpaired virtual orbitals, respectively. These conditions can easily be decoupled with the use of projection operators and transformed into a pseudo-eigenvalue problem.[8]

Now let us examine the physical meaning of these variational conditions. For C_0 near unity and the rest close to zero in magnitude, the F_k can be conceptually approximated by Fock operator F_0. Hence the occupied orbitals are, to the first approximation, just the SCF orbitals. From the secular equation in (6), we have

$$E = E_0 - \sum_k(K_{kk^*})^2/(E_k-E) \quad (14)$$

and

$$C_k = -C_0K_{kk^*}/(E_k-E), \quad (15)$$

where E_k are the energies of Φ_k. Now we see C_k are negative. Hence the partner orbital ϕ_{k^*} determined by F_{k^*} is bound not only by the nuclear potential in F_0 but also by the very negative exchange potential, $C_0C_k^{-1}K_k$. As a consequence, the partner orbital ϕ_{k^*} remains strongly localized in the region of space occupied by its HF counterpart orbital ϕ_k. Thus, the partner orbitals have no resemblance to the eigenfunctions of F_0, that is, the SCF virtual orbitals. The general appearance of the partner orbitals can also be understood from the variational theorem. From (14), we see that $\delta E=0$ corresponds to finding "best" orbitals which maximize

$$\sum_k(K_{kk^*})^2/(E_k-E_0)$$

to first order approximation. This maximum property, especially maximization of $\sum_k(K_{kk^*})^2$ suggests that virtual orbitals should be transformed so that the partner orbitals are as close as possible to their HF occupied counterpart orbitals. Note here that the partner orbitals are not the localized orbitals but symmetry orbitals.

Numerical Examples

As an illustration we shall treat the He and Be atoms and HF molecule in the HF-Roothaan approximation. Optimizing Φ is carried out in a cyclic way varying C_0, C_k in accordance with the CI method and orbitals in accordance with the SCF scheme. The most important practical question is, will an SCF procedure based on (10) converge? At present it is well known that the program based on MC-SCF theory has convergence problems, so we expect that our program will have the same problems. In the present study, the orbital optimization was carried out by a two-by-two rotation technique and it presents no convergence difficulties.[9,10] Good first approximation, especially for the partner orbitals, is necessary to overcome the convergence

problems. The simple initial guess can be found on the structual analogy to the natural orbitals used in the beyond HF theories. We discussed in Appendix how to get initial orbitals.

We first perform ordinary HF-Roothaan calculation on the ground state of He and Be with STO basis functions and then transformed as above. The results can be seen in Tables 1—3 and Figs. 1—3. For He, the HF orbital ϕ_{1s} is kept fixed during the optimization of its partner orbitals ϕ_{1s^*}. The CIP covers 38.4% correlation energy for He and 14.9% for Be. Especially for He the CIP energy is 99.96% of the radial limit (−2.8790 au) and accounts for 93.5% of the radial correlation energy as defined with respect to the HF energy. The CIP results were compared with a more extensive calculations such as SPEMC-SCF (The variation that mixes occupied and virtual orbitals is considered) and CMC-SCF results. The orbital ambiguity provides 93.6 and 95.0% of the energy improvement of the CMC-SCF calculations over the HF values for He and Be, respectively, indicating the effectiveness of the partner orbital transformation. Comparison with the SPEMC-SCF method indicates that the coupling of the HF occupied and virtual manifolds makes little contribution to the energy improvement. Figures 1—3 illustrate radial dependence of each occupied and its partner orbitals for He and Be. These show the localization of each partner orbital in the region where its occupied counterpart is largest. There is no resemblance at all between any one of the SCF virtual orbitals and these partner orbitals. In view of the nodal property, the 2s* orbital of Be corresponds to the 3s Rydberg orbital and the 1s* to the 4s orbital.

We also applied the method to HF molecule. The basis set used here is Dunning's[11] (9s, 5p/4s) GTO set contracted to (4s, 3p/2s) centered on F and H. Experimental equilibrium geometry, $R=1.7328$ au is used in the present calculation of the ground state of HF. In Table 4 and 5 are presented the transformation matrices which take the SCF occupied and virtual orbitals into zeroth-order natural orbitals and their partner orbitals. The effect of zeroth-order transformation in Table 4 is surprizingly large, suggesting that the correct zeroth-order natural orbitals are not the SCF orbitals. Figure 4 shows controur maps for the zeroth-order natural orbitals and the partner orbitals in case of $R=1.7328$ au. These also illustrate that each partner orbital is localized in the region where the occupied counterpart has a high density.

Table 6 is adiabatic potentials by HF, unrestricted HF (UHF) and CIP methods for HF molecule. The HF method is inadequate for the description of the

$1\bar{\pi}$					1.0

a) The index i refers to HF orbitals, the index j to zeroth-order natural orbitals.

dissociation process since it does not give the correct dissociation limit. The usual SCF procedure of the HF method does not converge at large internuclear separations. In this region, the HF solution becomes unstable and another solution, having lower energy than the HF solution, must exist. The study of the instability problems of the HF solution tells us that the real triplet instability precedes other types of instability and the UHF solution appears when the HF solution is real triplet unstable.[6)] Thus, we can define 2n UHF natural orbitals[12)] when the HF solution is unstable. From the definition of the partner orbitals, these 2n UHF natural orbitals are similar to what we call zeroth-order natural orbitals and their partner orbitals. The determinant using the first n UHF natural orbitals is approximated as the HF determinant. Of course, they will not be identical, but this determinant differs only in second order from the HF determinant. So we employed the space spanned by these first n UHF natural orbitals as the occupied manifold when the HF solution is unstable.

Figure 5 shows the contour maps for the most important 3σ and $3\sigma^*$ orbitals at several H–F bond distances. At infinite distances of H–F bond, the wavefunction can be reduced asymptotically to the form

$$\begin{aligned}\Phi &= (1/\sqrt{2})\|\cdots(3\sigma\overline{3\sigma}-3\sigma^*\overline{3\sigma^*})\cdots\| \\ &= \|\cdots(3\sigma+3\sigma^*)/\sqrt{2}\cdot(3\sigma-3\sigma^*)/\sqrt{2}\cdot(\alpha\beta-\beta\alpha)/\sqrt{2}\cdots\| \end{aligned} \quad (16)$$

Figure 5 illustrates $(3\sigma\pm3\sigma^*)/\sqrt{2}$ orbitals at large nuclear separations converge to 1s orbital of H and 2p orbital of F, respectively. Thus, the dissociation process of the H–F bond was reproduced by the present method as most chemists had assumed.

Summary

By taking advantage of the orbital ambiguity of the HF theory, we define the zeroth-order natural orbitals and their partner orbitals. The set of HF natural orbitals which is easy to construct, is fairly good enough to give the desired accuracy and facilitates physical interpretation of the results.

The CI with partner orbitals accounts for only intrapair correlation effect of the electron correlation. A theory can be developed which involves interpair correlation effect as well as intrapair correlation, if we choose an approximate CI expansion in (3) instead of the SPE expansion. In such a theory, however, the simplicity and ease of interpretation found in the present theory may be no longer preserved.

The author would like to express his sincere gratitude to Professor A. Imamura, Professor H. Kato and Dr. H. Nakatsuji for many valuable discussions. He is also indebted to Dr. S. Yamabe for his extensive assistance in computational work. Part of this work has been supported by the Scientific Research Grants from the Ministry of Education.

Appendix (How to Get the Initial Orbitals)

The initial orthonormal orbitals are generated by the corresponding orbital transformation procedure.

Let $\hat{a}_k$ and $\hat{b}_k$ be an approximated solution and its cor-

rection to the HF solution, respectively. Then the HF natural orbitals $\hat{c}_k$ and partner orbitals $\hat{c}_k^*$ are expressed in the form[6]

$$\hat{c}_k = (\hat{a}_k + \xi_k \hat{b}_k)/(1+\xi_k^2)^{1/2}$$
$$\hat{c}_{k^*} = (\hat{b}_k - \xi_k \hat{a}_k)/(1+\xi_k^2)^{1/2}$$

where the $\hat{a}_k$ and $\hat{b}_k$ are orthonormal and ξ_k are real coefficients.

Assume that the HF solution c_k is known and we have its approximate solution a_k. Given any two sets of orbitals c_k and a_k, there exist equivalent sets $\hat{c}_k$ and $\hat{a}_k$ such that their overlap matrix is diagonal $\langle \hat{c}_{k1} | \hat{a}_1 \rangle = \delta_{k1} T_k$ through the so-called corresponding orbital transformation. Then, we can construct $\hat{c}_k^*$ using the above relations. The problem is the choice of the approximate HF solution sicne the resultant resultant $\hat{c}_k$ and $\hat{c}_k^*$ depend on the approximate solution employed. In the practical application, we used the approximate solution generated by diagonalizing the core matrix. The method is simple and relatively accurate.

When the HF solution is unstable, the UHF natural orbitals are, of course, good initial orbitals to the partner orbitals.

Thickness Measurement of Surface Layer by the Angular Dependent X-Ray Photoelectron Spectroscopy

Masamichi YAMADA and Haruo KURODA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received December 19, 1979)

A sample-holding device to study the photoelectron take-off angle dependence of XPS spectrum is described. The take-off angle dependence was studied on a silicon surface covered with an oxide layer and a contamination carbon layer, and the (thickness)/(electron attenuation length) ratio of each layer was determined from the analysis of the angular dependence of the Si2p, O1s, and C1s peak intensities.

An ordinary solid surface is often covered with an oxide layer, adsorbed materials, and so on. It is well known that the contribution from the surface layer to the XPS spectrum is enhanced while that from the substrate is depressed as the photoelectron take-off angle θ measured from the specimen surface is decreased, provided that the specimen has an atomically flat surface.[1,2] This method is useful to distinguish the photoelectron peaks due to the surface layer from those due to the substrate. Furthermore, the thickness of the surface layer t or the electron attenuation length Λ can be determined from the quantitative analysis of the angular dependent peak intensities.[1,2]

For such an analysis, it is necessary to measure signal intensities at various different photoelectron take-off angles ranging from nearly zero degree to about ninety degrees. As described later, it is predicted that the angular variation of the absolute peak intensity is determined by the (thickness)/(electron attenuation length) ratio t/Λ under the idealized experimental conditions.[1] However, this prediction has been experimentally verified only in few cases.[1,3] In most of angular dependent XPS studies performed so far, the angular variation of peak intensity was largely modified by instrumental factors such as an inhomogeneous X-ray flux,[4] a finite sample size and the misalignment of a sample, and consequently the observed total signal intensity decreased markedly at low take-off angles.[4,5] In such a case, instead of the absolute intensities, the angular dependence of the intensity ratios between photoelectron peaks of the same specimen had to be used in the analysis in order to cancell out the effect of the angular dependent instrumental factors.[2]

In this report, we describe a rather simple sample rotation device which is incorporated into a McPherson ESCA 36 photoelectron spectrometer. The utility of the device is verified by the results obtained on a silicon surface covered with oxide and contamination carbon layers. Further, the results show that, in a measurement carried out with the device, the angular variation of signal intensities can be analyzed to determine t/Λ values without any correction and without resort to intensity ratios.

Variable-angle Sample Holder

The electron energy analyzer of a McPherson ESCA 36 spectrometer is composed of two concentric spherical sectors of 360 mm mean radius, without any retarding lens system. The X-ray source and sample-treatment devices are incorporated into the sample chamber.

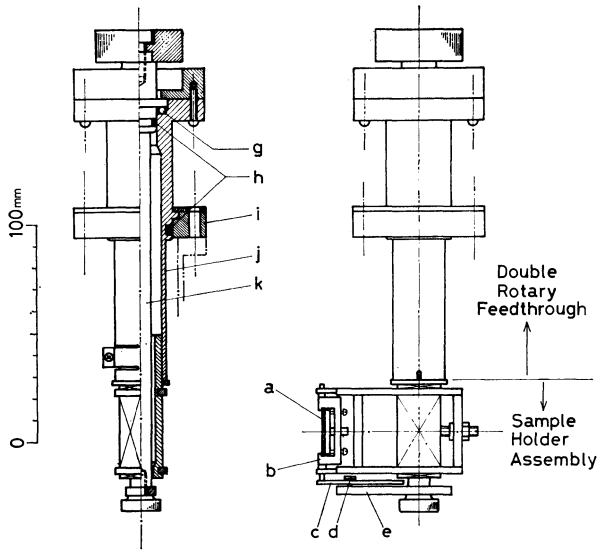

Fig. 1. Variable-angle sample-holding device. (a): Sample, (b): sample holder, (c): "tail" of sample holder, (d): pin, (e): arm, (g): stainless steel balls, (h): O-rings, (i): flange, (j): outer tube, (k): central shaft. (In the left drawing, the sample holder is omitted for brevity.)

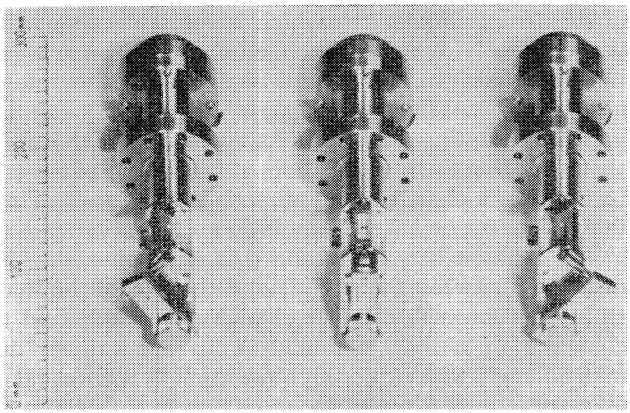

Fig. 2. Photographs showing the sample-holding device at three different sample orientations. From left to right, the photoelectron take-off angle θ is set to be *ca.* 10°, 45°, and *ca.* 80°, respectively.

Figure 1 illustrates full details of the variable-angle sample holding device. Its photographs are shown in Fig. 2. The device consists of two parts; a sample holder assembly and an O-ring-sealed double rotary

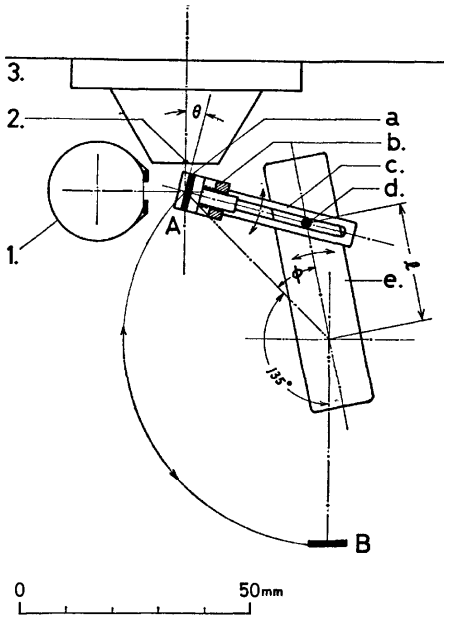

Fig. 3. Working principle of the variable-angle sample holder.
A: XPS measurement position, B: sample-treatment position, 1: X-ray source, 2: entrance slit, 3: analyzer chamber wall,
(a): sample, (b): sample holder, (c): "tail" of sample holder, (d): pin, (e): arm. (Each corresponding part is designated by the same letter as in Fig. 1.)

feedthrough which is composed of an outer tube (j) and a central shaft (k). The sample holder assembly is clamped to the outer tube (j), and can be rotated within the sample chamber by rotating the outer tube (j) from the outside. By this motion, the sample can be transferred between the measuring position (A) and the position (B) for sample deposition, argon-ion etching, and other sample treatments (see Fig. 3). In the sample holder assembly, a tail (c) is attached to the bottom of the sample holder (b) which is rotatable about the vertical axis lying in the specimen surface. The arm (e) is firmly fixed to the central shaft (k) of the rotary feedthrough so that the angle ϕ (in Fig. 3) can be varied by rotating the latter. As the angle ϕ is changed, the pin (d) on the arm (e) slides along the slit of the tail (c) causing a change of the direction of the tail. Thus the photoelectron take-off angle θ can be varied.

The relation between θ and ϕ is determined by the distance l between the pin (d) and the axis of the shaft (k). At a lower θ, a larger change of ϕ is required to change θ by a fixed amount. Thus one can set the take-off angle with rather high precision at a lower take-off angle. This is one of the great merits of this sample rotation mechanism. The pin (d) can be placed at one of the three positions on the arm (e) depending on the range of θ to be studied. Because of the narrow width (0.25 mm) of the entrance slit of the analyzer, the mispositioning of a specimen results in the large decrease of signal intensity at low θ. In the case of this device, monitoring the counting rate, we can set the specimen in the optimum position by adjusting the rotation of the outer tube (j), and thus prevent the deformation of the angular dependence. This is another merit of this device.

Angular Deapendent XPS Spectrum of a Silicon Wafer

We examined the angular dependence of the XPS spectrum of a silicon wafer with a polished (100) face. The wafer had been kept for a long time in the ordinary atmosphere without any oxidation treatment. The sample of the size 8 mm×21 mm was cut out from the wafer, and ultrasonically washed in organic solvents, distilled water, and finally trichloroethylene. After air-dried, the sample was transferred into the sample chamber of the McPherson ESCA 36 spectrometer. The XPS measurements were performed with Mg $K\alpha$ (1253.6 eV) radiation (7.4—7.5 kV, 25—27 mA) under the vacuum better than 10^{-4}Pa produced by a turbo-molecular pump. The take-off angle was varied successively from the highest (78°) to the lowest (3°) and finally again set at 78°. As compared with the initial measurement at 78°, the intensity obtained by the final measurement at the same angle was found to be slightly higher for all photoelectron peaks, which was probably due to the slight increase of the X-ray flux.

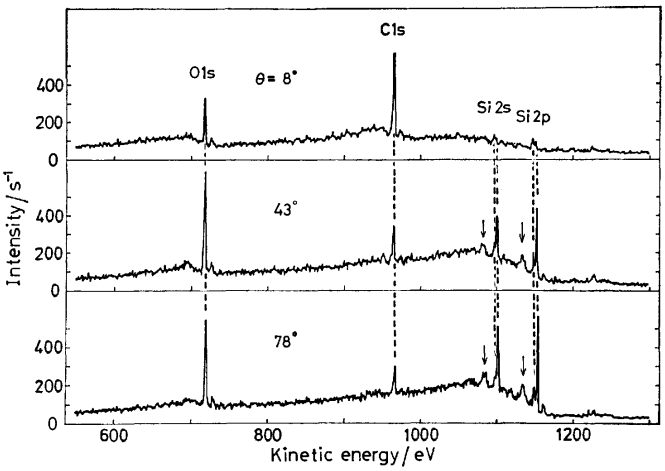

Fig. 4. Wide-scan spectra of a silicon wafer. The spectra were measured at the take-off angles, 78°, 43°, and 8°. Both Si2p and Si2s peaks are accompanied by loss peaks due to plasmon excitation (indicated by arrows).

Figure 4 shows the wide-scan spectra obtained at three different take-off angles, 8°, 43°, and 78°. The spectrum at θ=78° shows strong peaks attributable to Si2p, Si2s, and O1s, and a weak peak attributable to C1s. Both the Si2p and Si2s peaks are accompanied by energy-loss peaks. On decreasing θ, the intensities of the Si2p and Si2s peaks decrease, but that of the C1s peak increases. As can be seen in Fig. 4, the angular variation of the O1s peak intensity is different from the others. The narrow-scan spectra of the Si2p region are shown in Fig. 5, in which the higher kinetic energy peaks are due to elemental silicon and the lower kinetic energy ones are due to oxidized silicon.[6] Note that the angular dependence is different between these two components.

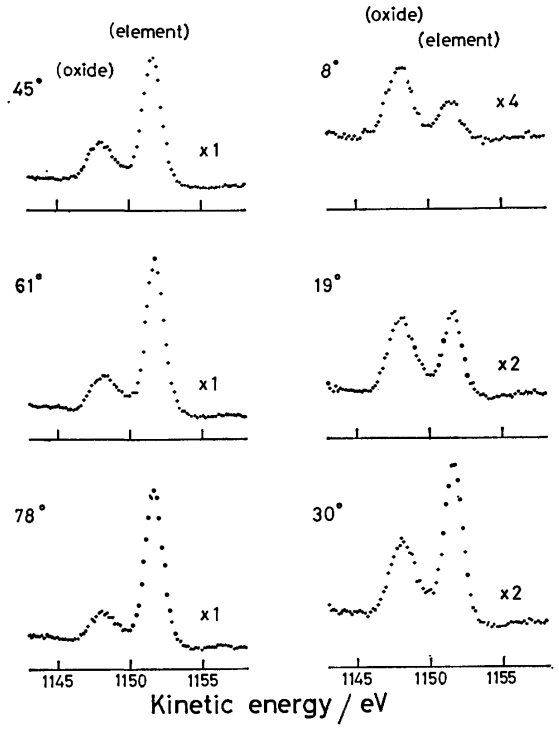

Fig. 5. Variation of the Si2p spectrum as the take-off angle changes from 78° to 8°. The higher kinetic energy peaks are due to elemental silicon and the lower kinetic energy ones are due to oxidized silicon.

Net intensities (peak height above background) of the Si2p(element), Si2p(oxide), Ols, and Cls peaks are plotted in Fig. 6 as a function of θ. We can clearly see that the θ dependences of the Si2p(oxide) and Ols peak intensities are very similar to each other, indicating that the observed Ols peak is entirely due to the silicon oxide. Thus we take the model that the silicon surface is covered with an oxide layer of the uniform thickness t_2

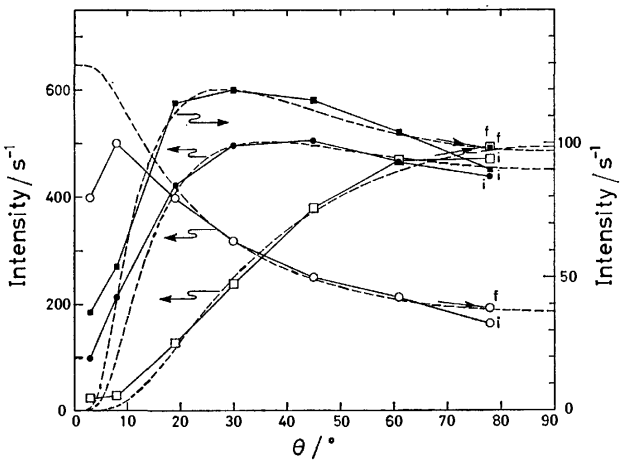

Fig. 6. Angular dependence of Cls (○), Ols (●), Si2p (oxide) (■), and Si2p (element) (□) peak intensilties (by net peak height).
At $\theta=78°$, the points designated by "i" and "f" represent the intensities obtained by the initial and final measurements, respectively. Broken lines represent the angular variations calculated for the model illustrated in Fig. 7 by using the t/Λ values in Table 1.

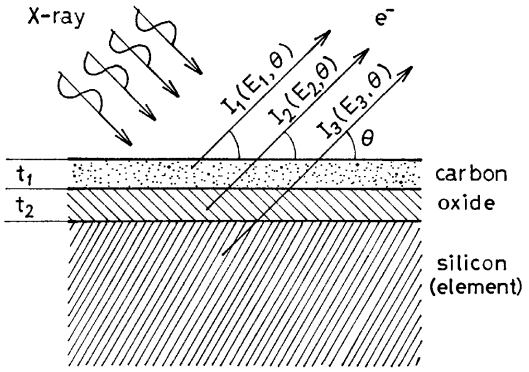

Fig. 7. Model for the surface region of the silicon wafer. $I_1(E_1, \theta)$, $I_2(E_2, \theta)$, and I_3 (E_3, θ) are the contributions from the top-most contamination carbon layer, from the silicon oxide layer, and from the elemental silicon substrate, respectively.

and a contamination carbon layer of the thickness t_1, as illustrated in Fig. 7.[7] We will assume also that no oxygen-containing species is included in the contamination carbon layer. As discussed by Fadley *et al.*,[1] on the assumptions that (a) the specimen surface is atomically flat, (b) the X-ray flux is uniformly distributed over the whole sample area, and (c) the specimen volume included in the acceptance area of the analyzer contributes uniformly to the spectrum and the portion outside the acceptance area does not contribute, the following expressions are derived for the intensity $I(E,\theta)$ of the peak (at the kinetic energy E) measured at the take-off angle θ:

$$I_1(E_1, \theta) = I_1^0[1-\exp\{-t_1/\Lambda_1(E_1)\sin\theta\}] \quad (1)$$

for the Cls peak (E_1=966 eV) due to the top-most layer,

$$I_2(E_2, \theta) = I_2^0[1-\exp\{-t_2/\Lambda_2(E_2)\sin\theta\}] \times\exp\{-t_1/\Lambda_1(E_2)\sin\theta\} \quad (2)$$

for the Si2p(oxide) (E_2=1150 eV) and Ols (E_2=718 eV) peaks due to the oxide layer, and

$$I_3(E_3, \theta) = I_3^0\exp\{-t_2/\Lambda_2(E_3)\sin\theta\} \times\exp\{-t_1/\Lambda_1(E_3)\sin\theta\} \quad (3)$$

for the Si2p(element) peak (E_3=1150 eV) due to the bulk. $\Lambda_1(E)$ and $\Lambda_2(E)$ are the electron attenuation lengths of the photoelectrons with kinetic energy E in the carbon and oxide layers respectively, and I_1^0, I_2^0, and I_3^0 are constants independent of θ. Equation 3 can be rewritten as follows:

$$I_3(E_3, \theta) = I_3^0\exp\left[-\left\{\frac{t_1}{\Lambda_1(E_3)}+\frac{t_2}{\Lambda_2(E_3)}\right\}\frac{1}{\sin\theta}\right]. \quad (3')$$

Thus $I_3(E_3,\theta)$ is expected to be exponentially dependent on $1/\sin\theta$. The observed angular dependence of the Si2p(element) peak intensity was found to be well described by Eq. 3' by using the following value:

$$\frac{t_1}{\Lambda_1(E_3)}+\frac{t_2}{\Lambda_2(E_3)} = 0.68 \quad (E_3=1150\,\text{eV}).$$

In the photoelectron kinetic energy range concerned here, $\Lambda(E)$ can be considered to be nearly proportional to $E^{1/2}$.[8] If we adopt the relation that $\Lambda(E)=\Lambda(E_3)\cdot(E/E_3)^{1/2}$, we can treat either $t_1/\Lambda_1(E_3)$ or $t_2/\Lambda_2(E_3)$ as the only one adjustable parameter, and determine its

TABLE 1. t/Λ VALUES DERIVED FROM THE ANALYSIS OF THE EXPERIMENTAL ANGULAR DEPENDENCE

	E/eV[a]	$t_1/\Lambda_1(E)$[b]	$t_2/\Lambda_2(E)$[c]

a) Approximate kinetic energy. b) The (thickness)/(electron attenuation length) ratio for the top-most contamination carbon layer. The relation $\Lambda_1(E) \propto E^{1/2}$ is assumed. c) The (thickness)/(electron attenuation length) ratio for the oxide layer. The relation $\Lambda_2(E) \propto E^{1/2}$ is assumed.

value so that the observed take-off angle dependences of other photoelectron peak intensities can be well reproduced by using Eq. 1 or Eq. 2. The t/Λ values thus obtained are listed in Table 1, and the angular dependence which is calculated for each peak by using these t/Λ values is shown in Fig. 6 with a broken line. The agreement between the observed and calculated angular dependences is very satisfactory for all peaks, except at angles below 10°. The above discrepancy at low angles may be attributed to the effect of small roughness of the surface.[9]

As described above, the angular-dependent XPS spectrum of a silicon wafer surface obtained with our variable-angle sample holder can be very satisfactorily explained by using Eqs. 1—3 on the model shown in Fig. 7. The Λ value at $E=1382$ eV (Si2p photoelectrons excited by Al $K\alpha$) in SiO_2 was reported to be 3.7 ± 0.4 nm.[7] If we take this value, the thickness of the oxide layer of the present sample is estimated to be about 1.2 nm from the value $t_2/\Lambda_2(1150\text{ eV})=0.37$.[10] Since we have not given any special oxidation treatment, this value may be considered as the typical thickness of the oxide layer that exists on the polished surface of a silicon wafer after prolonged exposure to the air, and it is in good agreement with the value <1.4 nm reported by Raider *et al.*[11] from fixed-angle XPS experiments. We do not know the materials contained in the contamination carbon layer, but most of them are likely to be hydrocarbons since the assumption that photoelectrons from the top-most layer does not contribute to the O1s peak intensity is supported by the above analysis of the angular dependent data. The electron attenuation length in a hydrocarbon layer was derived to be about 3.6 nm at $E=1117$ eV.[12] Thus from the value t_1/Λ_1 (1150 eV) $=0.31$, the thickness of the contamination carbon layer is estimated to be about 1.1 nm.

The authors wish to express their thanks to Dr. Katsuro Sugawara of Hitachi Ltd. for kindly supplying the silicon wafer used in the present study. We also would like to thank Dr. Isao Ikemoto, the University of Tokyo, for his helpful discussions.

5) For example, R. O. Ansell, T. Dickinson, A. F. Povey, and P. M. A. Sherwood, *J. Electron Spectrosc. Relat. Phenom.*, **11**, 301 (1977).

6) It is claimed that thin oxide films (<2.0 nm) on silicon substrates are not stoichiometric SiO_2 but of nonstoichiometric nature containing silicon atoms in lower oxidation states. (See for example: S. I. Raider and R. Flitsch, *IBM J. Res. Develop.*, **22**, 294 (1978); D. E. Aspnes and J. B. Theeten, *Phys. Rev. Lett.*, **43**, 1046 (1979).) Also in this study, a Si2p-(oxide) peak is broader than a Si2p(element) peak, and exhibits tailing towards higher kinetic energies (Fig. 5, $\theta=19°$).

7) An angular-dependent XPS study on oxidized silicon wafers has been performed by Hill *et al.* with a modified Hewlett-Packard 5950A spectrometer. (J. M. Hill, D. G. Royce, C. S. Fadley, L. F. Wagner, and F. J. Grunthaner, *Chem. Phys. Lett.*, **44**, 225 (1976).) Based on the same model as shown in Fig. 7, they analyzed the angular variation of the Si2p(oxide)/Si2p(element) intensity ratio.

8) C. J. Powell, *Surf. Sci.*, **44**, 29 (1974).

9) The observed C1s signal intensity at $\theta=3°$ does not lie on the smoothly extrapolated line . At $\theta=3°$, the specimen stands nearly perpendicularly in front of the entrance slit. Therefore, when viewed from the entrance slit, the area occupied by the specimen surface becomes smaller than the acceptance area of the analyzer. This is likely to be the reason for the deviation from the curve at $\theta=3°$ (see Ref. 1).

10) It is necessary to take into account the difference between the kinetic energies of photoelectrons excited by Mg $K\alpha$ and Al $K\alpha$. The Λ value at $E=1150$ eV in SiO_2 is estimated to be 3.4 nm from the $E^{1/2}$ dependence.

MO Calculation of Some Aromatic Radicals. Geometry and Spin Density of Benzyl Radical

Toshihiro AMANO, Yoshihiro OSAMURA, Eiko KAI, and Kichisuke NISHIMOTO*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received January 5, 1980)

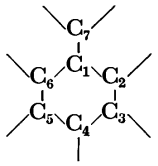
The geometry of benzyl radical, nitrobenzene anion-, benzaldehyde anion-, aniline cation-, and phenol cation-radicals is optimized by means of the energy gradient method in the framework of the CNDO/2 method, and used for the calculation of spin densities by the INDO-UHF method. The geometrical change from a neutral molecule to the ion radical can be understood by considering the shape of particular MO's. It was found that the molecular structure of benzyl radical is not a regular hexagon, the contraction of C_1–C_7 bond being remarkable. The correct order of the spin densities on ortho(ρ_2)- and para (ρ_4)-positions is obtained by the full geometry optimization. The structure of the deformed ring of benzyl radical is discussed in terms of the orbital mixing rule.

It is difficult to determine the molecular structures of radicals experimentally in most cases, because of their low stability and high reactivity. Thus, it is significant to predict the structure of unstable radicals by means of a quantum chemical method. The spin densities are determined accurately. The spin density distribution in a π radical depends considerably on its geometry.[1] Theoretical studies have been made on the spin density of benzyl radical.[2-7] However, the calculated results have not been correlated with the experimental data[8,9] (ρ_4 being greater than ρ_2) except for a few cases.[10,11] Beveridge and Guth[1] reported that the geometrical change of benzyl radical affects its spin density. Physico-chemical properties of molecules should be calculated on the basis of the most stable structure. Theoretical consideration of the geometrical distortion of benzyl radical from the regular hexagonal geometry would be applicable to the examination of that of other radical species.

In the cases of ion radicals, the structural change by electron removal from or electron attachment to neutral molecule can be explained readily in terms of the shape of the highest occupied or the lowest unoccupied MO's. However, it is difficult to expect a stable molecular structure for a neutral radical. This report describes the semi-empirical MO calculation for benzyl radical, nitrobenzene anion-, benzaldehyde anion-, aniline cation-, and phenol cation-radicals. The geometry is optimized by the energy gradient method in the framework of CNDO scheme.[12-16] Spin desities are calculated by means of the INDO-UHF method.[17]

Results and Discussion

Geometries and Spin Densities. The optimized geometry of benzyl radical is given in Table 1. The numbering of atoms is as follows.



The geometry of benzyl ring differs a great deal from that of benzene. The calculated and experimental spin densities of benzyl radical are given in Table 2. The experimental spin density of ortho-carbon, ρ_2, is less than that of para-carbon, ρ_4. However, the calculation by means of regular hexagonal geometry shows that ρ_2 is greater than ρ_4. This problem is solved by calculation with use of optimized geometry. The calculated spin density by means of fully optimized geometry is in good accordance with the experimental data. Calculation with the optimized geometry shows that the spin density of C_7 flows somewhat into the ortho-, and para-carbons in comparison with the calculated value by means of the regular hexagonal geometry.

Table 1. Optimized geometry of benzyl radical

Bond length/Å		Bond angle/°	
C_1–C_2, C_1–C_6	1.424	$\angle C_2C_1C_6$	115.8
C_2–C_3, C_5–C_6	1.371	$\angle C_1C_2C_3$, $\angle C_1C_6C_5$	122.1
C_3–C_4, C_4–C_5	1.392	$\angle C_2C_3C_4$, $\angle C_4C_5C_6$	120.0
C_1–C_7	1.365	$\angle C_3C_4C_5$	120.0
C_2–H, C_6–H	1.118	$\angle C_1C_2H$, $\angle C_1C_6H$	118.0
C_3–H, C_5–H	1.117	$\angle C_2C_3H$, $\angle C_6H_5H$	120.0
C_4–H	1.117	$\angle C_3C_4H$	120.0
C_7–H	1.112	$\angle C_1C_7H$	124.0
		$\angle HC_7H$	112.0

Since the geometry of ion radicals is not well established experimentally, it is of interest to determine the geometrical changes from their neutral molecules and

their spin densities theoretically. Figure 1 and Table 3 show the geometry and spin densities of anion radicals of nitrobenzene, and benzaldehyde. The experimental value[18,19)] of spin densities of nitrobenzene anion radical is also given in Table 3. By a comparison of these values we see that the spin density calculated by means of optimized geometry is better than that by means of neutral geometry. Since the stabilization owing to the conjugation is maximum in a neutral molecule, the radical center of anion radical tends to localize on the substituent in order to minimize the destabilization due to an extra electron. The calculated results of cation radicals of aniline and phenol are summarized in Fig. 2 and Table 4. In the cation radical its geometrical distortion from that of neutral molecule is small. The spin densities of these cation radicals increase at the ortho- and para-positions.

Consideration of Geometrical Change. Since the highest occupied and the lowest unoccupied MO's are responsible for the electron donation and the electron acceptance of the neutral molecule, respectively, the geometrical change in the ion radical may be predicted by consideration of the shape of these particular orbitals. Figure 3 shows the orbitals of neutral molecules. For example, LUMO of nitrobenzene has the bonding character at C_1–N, O–O, and C_2–C_3. The distances between these atoms decrease on accepting an electron. On the other hand, the distances associated with C_1–C_2 C_3–C_4 bonds increase.

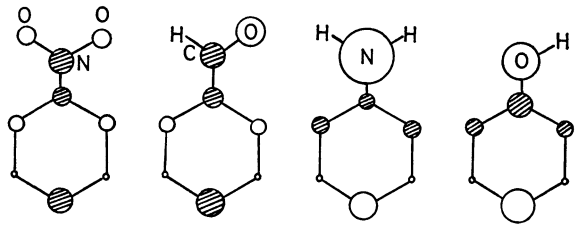

Fig. 3. The shapes of the particular orbitals of nitrobenzene, benzaldehyde, aniline, and phenol.

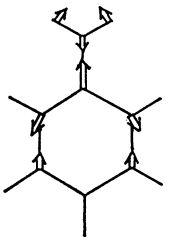
In cation radical, the distances between atoms being in-phase overlap increase and those in out-of-phase overlap decrease because of a loss of an electron in HOMO. However, the geometrical change is not so remarkable as that in the anion radical.

Let us explain the bond lengths of benzyl radical being neutral in view of the orbital mixing[20] of phenyl ring with CH_2 part. The distortion from one and half bond is visualized as follows.



The π type orbital of benzene and CH_2 part and the mode of orbital interaction are shown in Fig. 4. The p_π orbital of C_7 mixes with the symmetric orbitals about the molecular axis of benzene, π_1, π_3, π_5, and π_6. Since the energy of p orbital of carbon is located in the middle of those of the HOMO and LUMO of benzene, the singly occupied MO is formed by the following orbital phase combination.

$$\text{SOMO} = p_\pi - \pi_3 + \pi_5.$$

Thus, the amplitude of C_1 atom is very small since π_3 is combined with π_5 out-of-phase with equal weight, whereas the in-phase orbital, ϕ_2, formed by π_3 and p_π of C_7 contains the large bonding overlap at C_1–C_7 bond. This is the origin of the shortening of C_1–C_7 bond length. Since the out-of-phase orbital SOMO formed by π_3 and π_5 has the large bonding overlap between C_2 and C_6, angle C_2–C_1–C_6 becomes smaller. The shortening of C_2–C_3 bond length and the lengthening of C_1–C_2 bond length are caused by the decrease in the antibonding overlap at C_2–C_3 and the decrease in the bonding overlap at C_1–C_2, respectively. The same consideration can be applied to the expectation of geometrical changes in phenol- and aniline-cations.

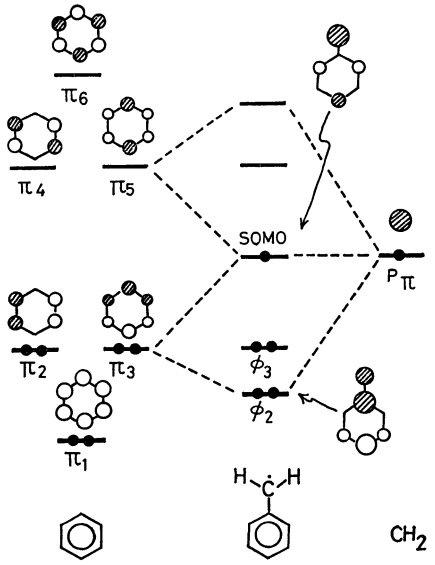


Fig. 4. The mode of the orbital interaction of benzyl radical.

The authors would like to thank Professor R. Zahradnik, Czechoslovak Academy of Sciences, for supplying the energy gradient program "DERIV" by the CNDO/2 method. Permission to use the HITAC-180 computer at the Institute for Molecular Science is gratefully acknowledged.

(Received January 5, 1980)

The concept of a "moving unit"—a group of molecules which move together for the time much longer than the velocity auto-correlation time, τ—was introduced in order to obtain information about cooperative translational motions of molecules in associated solution. The mutual diffusion coefficient was theoretically expressed in terms of the self diffusion coefficients and the number of moving units. The theoretical results were applied to the study of the mutual diffusion coefficients for methanol–carbon tetrachloride and ethanol–carbon tetrachloride solutions measured by Rayleigh scattering. It was shown that the mean number of alcohol molecules which constitute a moving unit is much smaller than the mean association number of alcohol, especially in the high concentration range of alcohol. This indicates that the hydrogen-bonded polymer of alcohol molecules cannot move without changing the polymer shape within the time τ.

Local fluctuations of concentration afford information which is useful for understanding the mixing of liquids from a molecular viewpoint. As the mean-square amplitude of concentration fluctuations is related to the spatial correlation between the positions of different molecules, it affords information about the local structure formation in solution. In the previous reports, we have discussed the local structures in various solutions on the basis of the quantitative analysis of the mean-square concentration fluctuation obtained from the Rayleigh scattering intensities.[1–8] The local structures were expressed in terms of the ordinary mean association number.

In order to discuss the state of mixing from a dynamical standpoint, however, the life-time of local structures should be taken into account in addition to the mean association number. Here, we define the "life-time" as the time during which the relative positions of molecules in a local structure change very little. The correlation time of concentration fluctuations, which is specified by a mutual diffusion coefficient, is considered to afford information about the life-time of the local structure. It is not possible, however, to obtain the life-time of the local structure directly from the mutual diffusion coefficient because too many parameters are necessary for the description of collective motions of molecules.

In the present report, we propose the existence of a group of molecules which move together for the time much longer than the velocity auto-correlation time of component molecules. We call this group of molecules a "moving unit." The mutual diffusion coefficient, which is obtained from the analysis of the Rayleigh scattering spectrum, can be expressed in terms of the number of moving units.

Binary solutions of methanol–carbon tetrachloride and ethanol–carbon tetrachloride were chosen as appropriate systems in which to determine the existence of such moving units. In these systems, the mean association numbers of hydrogen-bonded alcohol molecules increase with increasing alcohol concentration. Our main interest is to know whether these hydrogen-bonded alcohol molecules can be a moving unit particularly in the high concentration range of alcohols.

Theoretical

Mutual Diffusion Coefficient and Molecular Velocity Correlation. The spectrum of the Rayleigh light isotropically scattered by a binary solution can be approximated by two Lorentzian curves.[9] One of these corresponds to the scattering arising from the entropy fluctuations and the other to that from concentration fluctuations. Since the half-width of the latter spectrum is narrower than that of the former by a factor of about a hundred, these two curves can be identified separately, even though the band centers are overlapped. The spectrum for concentration fluctuations is expressed as[9]

$$I_c(k,\omega) \propto \frac{|k|^2 D}{\omega^2 + (|k|^2 D)^2} \tag{1}$$

where k is the scattering vector and D is the mutual diffusion coefficient. The time correlation function for concentration fluctuations is related to D:

$$\frac{\langle \Delta c(k,t)\Delta c(k,0)\rangle}{\langle |\Delta c(k)|^2\rangle} = \exp(-|k|^2 Dt) \tag{2}$$

$$\Delta c(k,t) \equiv \int_v [c(r,t) - \langle c\rangle] e^{ik\cdot r} d^3r \tag{3}$$

when temperature and pressure fluctuations are disregarded.[10] In Eqs. 2 and 3, $c(r,t)$ is the concentration at the point r at time t in the scattering volume V and the pointed brackets indicate an equilibrium ensemble average.

D is expressed in terms of the time derivative of $\Delta c(k,t)$:[11]

$$D = \lim_{s\to 0}\lim_{k\to 0} \frac{1}{|k|^2}\frac{1}{\langle |\Delta c(k)|^2\rangle}\int_0^\infty \langle \Delta\dot{c}(k,t)\Delta\dot{c}(k,0)\rangle e^{-st} dt. \tag{4}$$

We now consider a binary solution whose components are molecules A and B. If the concentration is expressed in the mole fraction of A, $\Delta X_A(r,t)$ can be approximately expressed as

$$\Delta X_A(k,t) = -\frac{i}{\rho} k\cdot[X_B J_A(k,t) - X_A J_B(k,t)] \tag{5}$$

with

$$\boldsymbol{J}_{\mathrm{A}}(\boldsymbol{k},t)=\sum_{\mathrm{a}}^{n_{\mathrm{A}}}\boldsymbol{v}_{\mathrm{a}}(t)\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_{\mathrm{a}}(t)}$$

$$\boldsymbol{J}_{\mathrm{B}}(\boldsymbol{k},t)=\sum_{\mathrm{b}}^{n_{\mathrm{B}}}\boldsymbol{v}_{\mathrm{b}}(t)\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_{\mathrm{b}}(t)} \tag{6}$$

where ρ is the number density, X_{A} and X_{B} are the mean mole fractions of A and B, respectively, and n_{A} and n_{B} are the mean numbers of molecules A and B in V, respectively. $\boldsymbol{v}_{\mathrm{a}}(t)$ is the velocity of an a-th molecule of A, and $\boldsymbol{v}_{\mathrm{b}}(t)$ that of a b-th molecule of B at time t. In the limit of small $|\boldsymbol{k}|$, $\langle|\Delta X_{\mathrm{A}}(\boldsymbol{k})|^2\rangle$ can be written as

$$\lim_{\mathrm{k}\to 0}\langle|\Delta X_{\mathrm{A}}(\boldsymbol{k})|^2\rangle=\frac{V}{\rho}N\langle(\Delta X_{\mathrm{A}})^2\rangle \tag{7}$$

where N is the mean number of total molecules in a region which is very large compared to the distances between molecules and X_{A} is the concentration fluctuation in the region. Substituing Eqs. 5—7 into Eq. 4, we can obtain

$$D=Q[X_{\mathrm{B}}\{V_{\mathrm{aa}}+(n_{\mathrm{A}}-1)V_{\mathrm{aa'}}\}+X_{\mathrm{A}}\{V_{\mathrm{bb}}+(n_{\mathrm{B}}-1)V_{\mathrm{bb'}}\}-2(n_{\mathrm{A}}+n_{\mathrm{B}})X_{\mathrm{A}}X_{\mathrm{B}}V_{\mathrm{ab}}] \qquad (\mathrm{a}\neq\mathrm{a'}\ \ \mathrm{b}\neq\mathrm{b'}) \tag{8}$$

with

$$Q=\frac{X_{\mathrm{A}}X_{\mathrm{B}}}{N\langle(\Delta X_{\mathrm{A}})^2\rangle} \tag{9}$$

$$V_{\mathrm{ij}}=\frac{1}{3}\int_0^\infty\langle\boldsymbol{v}_{\mathrm{i}}(t)\cdot\boldsymbol{v}_{\mathrm{j}}(0)\rangle\mathrm{d}t \tag{10}$$

where i and j represent a, a', b, or b'. Q is a so-called thermodynamic factor expessed in terms of mean-square concentration fluctuations, $N\langle(\Delta X_{\mathrm{A}})^2\rangle$, which can be obtained by analyzing integrated intensities of Rayleigh scattering spectra.[1] $(X_{\mathrm{A}}X_{\mathrm{B}})$ is the magnitude of $N\langle(\Delta X_{\mathrm{A}})^2\rangle$ expected for an ideal binary solution. It can be seen from Eq. 10 that V_{aa} and V_{bb} correspond to the self diffusion coefficients of A and B, respectively;

$$V_{\mathrm{aa}}=D_{\mathrm{A}}\qquad V_{\mathrm{bb}}=D_{\mathrm{B}} \tag{11}$$

$V_{\mathrm{aa'}}$, $V_{\mathrm{bb'}}$, and V_{ab} are related to the velocity correlations between different molecules. In the case where these pair-correlations are negligible, D can be written as

$$D=Q(X_{\mathrm{B}}D_{\mathrm{A}}+X_{\mathrm{A}}D_{\mathrm{B}}). \tag{12}$$

Moving Unit and Diffusion Coefficient. We consider a solution in which strong intermolecular interactions such as hydrogen bonding exist. In such a solution, the velocities of these interacting molecules are expected to be strongly correlated, that is, $V_{\mathrm{aa'}}$, $V_{\mathrm{bb'}}$ and V_{ab} can not be neglected. It is very difficult to express these quantities in terms of microscopic parameters such as intermolecular forces. Instead of studying the details of these dynamical interactions, we assume that some numbers of molecules move together as a group for a time much longer than the velocity auto-correlation time. We call this group of molecules a "moving unit." In the binary solution of A and B molecules, moving units can be represented by A_l, B_m, and $\mathrm{A}_l\mathrm{B}_m$ where l or m is the number of molecules A or B which constitutes a moving unit. We further assume that the velocity correlation between molecules belonging to different moving units can be neglected, because it is much smaller than the velocity correlation between molecules belonging to the same moving unit. Then, the velocity correlation function can be written as

$$\langle\boldsymbol{v}_{\mathrm{i}}(t)\cdot\boldsymbol{v}_{\mathrm{i}}(0)\rangle=\sum_\alpha P_{\mathrm{i}}^\alpha\langle\boldsymbol{v}_{\mathrm{i}}^\alpha(t)\cdot\boldsymbol{v}_{\mathrm{i}}^\alpha(0)\rangle \tag{13}$$

$$\langle\boldsymbol{v}_{\mathrm{i}}(t)\cdot\boldsymbol{v}_{\mathrm{j}}(0)\rangle=\sum_\alpha P_{\mathrm{ij}}^\alpha\langle\boldsymbol{v}_{\mathrm{i}}^\alpha(t)\cdot\boldsymbol{v}_{\mathrm{j}}^\alpha(0)\rangle=\sum_\alpha P_{\mathrm{ij}}^\alpha\langle\boldsymbol{v}_{\mathrm{i}}^\alpha(t)\cdot\boldsymbol{v}_{\mathrm{i}}^\alpha(0)\rangle \tag{14}$$

(i, j=a, a', b, or b')

where P_{i}^α is the probability of finding an i-th molecule in a moving unit α ($\alpha=\mathrm{A}_l$ *etc.*), P_{ij}^α the probability of finding both the i-th and the j-th molecule belonging to α, and v_{i}^α is the velocity of an i-th molecule belonging to α. Under these assumptions, V_{ij} in Eq. 8 is expressed as

$$\begin{aligned}
V_{\mathrm{aa}}&=D_{\mathrm{A}}=\sum_l P_{\mathrm{a}}^{\mathrm{A}l}D_{\mathrm{A}l}+\sum_l\sum_m P_{\mathrm{a}}^{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\\
V_{\mathrm{bb}}&=D_{\mathrm{B}}=\sum_l P_{\mathrm{b}}^{\mathrm{B}l}D_{\mathrm{B}l}+\sum_l\sum_m P_{\mathrm{b}}^{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\\
V_{\mathrm{aa'}}&=\sum_l P_{\mathrm{aa'}}^{\mathrm{A}l}D_{\mathrm{A}l}+\sum_l\sum_m P_{\mathrm{aa'}}^{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\\
V_{\mathrm{bb'}}&=\sum_l P_{\mathrm{bb'}}^{\mathrm{B}l}D_{\mathrm{B}l}+\sum_l\sum_m P_{\mathrm{bb'}}^{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\\
V_{\mathrm{ab}}&=\sum_l\sum_m P_{\mathrm{ab}}^{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}
\end{aligned} \tag{15}$$

with

$$D_\alpha=\frac{1}{3}\int_0^\infty\langle\boldsymbol{v}_{\mathrm{i}}^\alpha(t)\cdot\boldsymbol{v}_{\mathrm{i}}^\alpha(0)\rangle\mathrm{d}t \tag{16}$$

$$\begin{aligned}
P_{\mathrm{a}}^{\mathrm{A}l}&=n_{\mathrm{A}l}\frac{l}{n_{\mathrm{A}}}\qquad P_{\mathrm{aa'}}^{\mathrm{A}l}=n_{\mathrm{A}l}\frac{l}{n_{\mathrm{A}}}\frac{l-1}{n_{\mathrm{A}}-1}\\
P_{\mathrm{b}}^{\mathrm{B}l}&=n_{\mathrm{B}l}\frac{l}{n_{\mathrm{B}}}\qquad P_{\mathrm{bb'}}^{\mathrm{B}l}=n_{\mathrm{B}l}\frac{l}{n_{\mathrm{B}}}\frac{l-1}{n_{\mathrm{B}}-1}\\
P_{\mathrm{aa'}}^{\mathrm{A}l\mathrm{B}m}&=n_{\mathrm{A}l\mathrm{B}m}\frac{l}{n_{\mathrm{A}}}\frac{l-1}{n_{\mathrm{A}}-1}\\
P_{\mathrm{bb'}}^{\mathrm{A}l\mathrm{B}m}&=n_{\mathrm{A}l\mathrm{B}m}\frac{m}{n_{\mathrm{B}}}\frac{m-1}{n_{\mathrm{B}}-1}\\
P_{\mathrm{ab}}^{\mathrm{A}l\mathrm{B}m}&=n_{\mathrm{A}l\mathrm{B}m}\frac{l}{n_{\mathrm{A}}}\frac{m}{n_{\mathrm{B}}}.
\end{aligned} \tag{17}$$

Substitution of Eqs. 15—17 into Eq. 8 yields the following equation:

$$D=Q\left[\frac{X_{\mathrm{B}}}{n_{\mathrm{A}}}\left(\sum_l l^2n_{\mathrm{A}l}D_{\mathrm{A}l}+\sum_l\sum_m l^2n_{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\right)+\frac{X_{\mathrm{A}}}{n_{\mathrm{B}}}\left(\sum_l l^2n_{\mathrm{B}l}D_{\mathrm{B}l}+\sum_l\sum_m m^2n_{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\right)-\frac{2}{n_{\mathrm{A}}+n_{\mathrm{B}}}\sum_l\sum_m lmn_{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\right] \tag{18}$$

and

$$\begin{aligned}
D_{\mathrm{A}}&=\frac{1}{n_{\mathrm{A}}}\left(\sum_l ln_{\mathrm{A}l}D_{\mathrm{A}l}+\sum_l\sum_m ln_{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\right)\\
D_{\mathrm{B}}&=\frac{1}{n_{\mathrm{B}}}\left(\sum_l ln_{\mathrm{B}l}D_{\mathrm{B}l}+\sum_l\sum_m mn_{\mathrm{A}l\mathrm{B}m}D_{\mathrm{A}l\mathrm{B}m}\right).
\end{aligned} \tag{19}$$

Moving Units in Alcohol–Carbon Tetrachloride System. In the binary solutions of methanol(A)–carbon tetrachloride(B) and ethanol(A)–carbon tetrachloride(B), the existence of the moving unit of A_l-type is expected. In this case, Eq. 18 is reduced to

$$D=Q(X_{\mathrm{B}}D'_{\mathrm{A}}+X_{\mathrm{A}}D_{\mathrm{B}}) \tag{20}$$

with

$$D'_{\mathrm{A}} \equiv \frac{\sum_l l^2 n_{\mathrm{A}l} D_{\mathrm{A}l}}{\sum_l l n_{\mathrm{A}l}} = \frac{\sum_l l^2 n_{\mathrm{A}l} D_{\mathrm{A}l}}{\sum_l l n_{\mathrm{A}l} D_{\mathrm{A}l}} D_{\mathrm{A}}. \quad (21)$$

$D_{\mathrm{A}l}$ is written as

$$D_{\mathrm{A}l} = \frac{1}{3}\langle|\boldsymbol{v}_{\mathrm{A}l}|^2\rangle\tau_{\mathrm{A}l} \quad (22)$$

with

$$\tau_{\mathrm{A}l} = \int_0^\infty \frac{\langle \boldsymbol{v}_{\mathrm{A}l}(t)\cdot\boldsymbol{v}_{\mathrm{A}l}(0)\rangle}{\langle|\boldsymbol{v}_{\mathrm{A}l}|^2\rangle}\mathrm{d}t. \quad (23)$$

In the above equations, $\langle|\boldsymbol{v}_{\mathrm{A}l}{}^2|\rangle$ is expected to be inversely proportional to l at constant temperature, because this relation holds:

$$\frac{1}{2}M_{\mathrm{A}l}\langle|\boldsymbol{v}_{\mathrm{A}l}|^2\rangle \propto T \quad (24)$$

where $M_{\mathrm{A}l}$ is the mass of the moving unit A_l ($\propto l$) and T is the temperature. If we assume $\tau_{\mathrm{A}l}$ is independent of l, we have

$$D_{\mathrm{A}l} \propto \frac{1}{l}. \quad (25)$$

Substituting Eq. 25 into Eq. 21, we obtain

$$D = Q[X_{\mathrm{B}}D_{\mathrm{A}}\langle l\rangle_{\mathrm{n}}^{\mathrm{d}} + X_{\mathrm{A}}D_{\mathrm{B}}] \quad (26)$$

$$\langle l\rangle_{\mathrm{n}}^{\mathrm{d}} \equiv \frac{\sum_l l n_{\mathrm{A}l}}{\sum_l n_{\mathrm{A}l}} \quad (27)$$

where $\langle l\rangle_{\mathrm{n}}^{\mathrm{d}}$ is the mean number of A molecules which constitute one moving unit. By substituting the experimentally observed values for D, Q, D_{A}, and D_{B} into Eq. 26, we can obtain the $\langle l\rangle_{\mathrm{n}}^{\mathrm{d}}$ value at each concentration.

Experimental

The light scattering spectrometer (heterodyne detection) used in the present study was designed and constructed in our laboratory.[12] The light source was an Argon ion laser (Spectra-Physics model 165-09) which produced 100-800 mW power at 488 nm. The scattering angle, θ, was defined by two pinholes approximately 50 cm apart and 0.5 mm in diameter. The laser beam was focused into a rectangular scattering cell. Scattered light and a local oscillator beam (scattered from the cell walls) were collected onto the surface of a photomultiplier tube (HTV R-374). The photocurrent was amplified and then fed to a spectrum analyzer (Takeda-Riken TR 4120S). This analyzer is designed for the analysis of the spectral region 50 Hz-30 MHz. Details of the spectrometer have been reported elsewhere along with the reliability of the observed data.[12]

Light scattering spectra were observed by using this spectrometer at the temperature of 24 ± 0.5 °C in the scattering angle range of $6°\leq\theta\leq11°$.

All the chemicals were commerical products. The sample solutions were made dust-free by the use of a millipore filter FG of 0.2 μm pore size.

Results and Discussion

Light Beating Spectra and Mutual Diffusion Coefficients. Figure 1 shows a typical example of an observed spectrum. All spectra were found to fit a Lorentzian. By plotting the observed half-widths against $|\boldsymbol{k}|^2$, the theoretical prediction of linear dependence of a half-width on $|\boldsymbol{k}|^2$ was confirmed. A mutual diffusion coefficient was obtained from the slope of the linear plot. The mutual diffusion coefficients thus obtained are plotted against the mole fractions of methanol and ethanol, respectively, in Figs. 2 and 3 (see the circles). The dashed lines in these figures indicate the mutual diffusion coefficients calculated for Eq. 12, where Q is obtained from the observed values of $N\langle(\Delta X_{\mathrm{A}})^2\rangle$ reported elsewhere.[8] Literature values were used for D_{A} and D_{B}.[13,14] It is seen from these figures that the observed values of diffusion coefficients are larger than those predicted from Eq. 12. This disagreement between the observed and theoretical values shows that velocity pair-correlation between different molecules cannot be neglected. As the observed values are larger than the

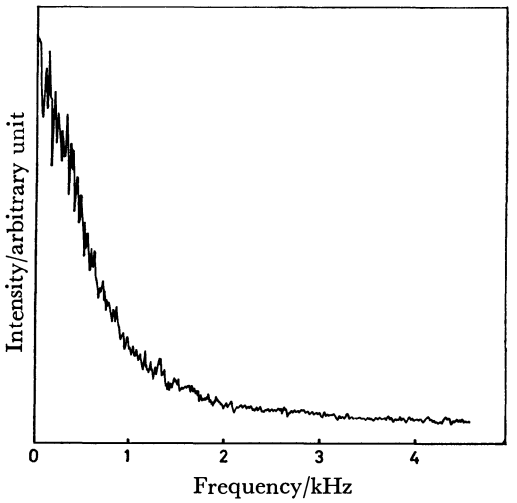

Fig. 1. Heterodyne beating spectrum of light scattered by methanol–carbon tetrachloride solution (0.3 mole fraction of methanol). Scattering angle is 7.25°.

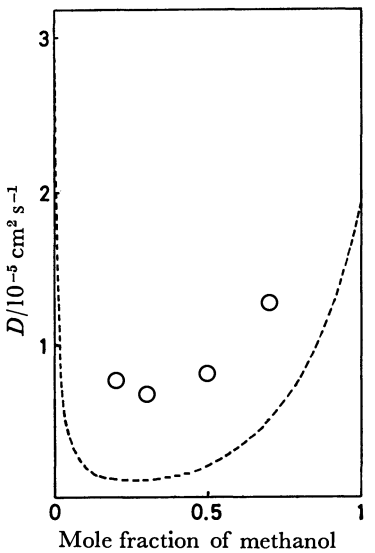

Fig. 2. Observed mutual diffusion coefficients for methanol–carbon tetrachloride system (○).
The dashed line corresponds to mutual diffusion coefficients calculated from Eq. 12.

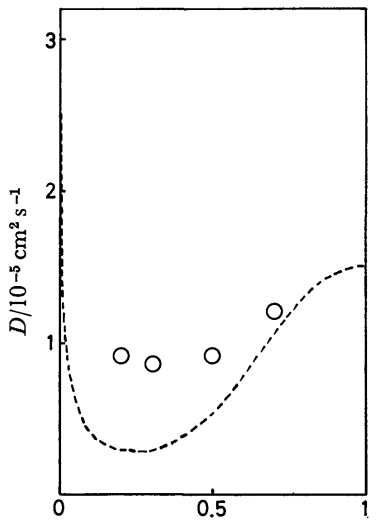

Fig. 3. Observed mutual diffusion coefficients for ethanol–carbon tetrachloride system (○). The dashed line corresponds to mutual diffusion coefficients calculated from Eq. 12.

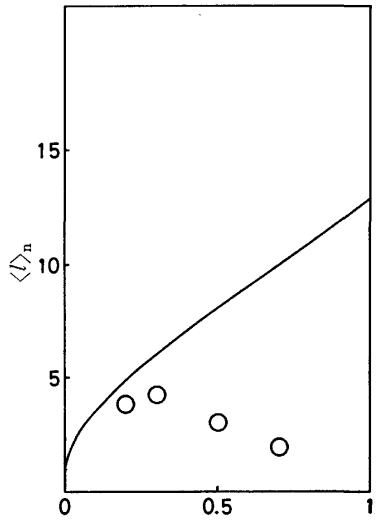

Fig. 5. Comparison of $\langle l \rangle_n^d$ (○) with $\langle l \rangle_n^p$ (——) for ethanol–carbon tetrachloride system.

theoretical ones, it can also be concluded that the velocity correlations between the molecules of the same species are stronger than between those of different species.

Moving Units and Mean Association Numbers in Alcohol–Carbon Tetrachloride System. The mean numbers, $\langle l \rangle_n^d$, were obtained from Eq. 26 using the observed mutual diffusion coefficients, D, the observed diffusion coefficients, D_A and D_B, and the observed mean-square concentration fluctuations, $N\langle(\Delta X_A)^2\rangle$. In Figs. 4 and 5 the mean numbers, $\langle l \rangle_n^d$, thus obtained are plotted against the mole fraction of alcohol for the methanol–carbon tetrachloride and ethanol–carbon tetrachloride systems, respectively.

In a previous paper,[8] we have analyzed the observed mean-square concentration fluctuations, $N\langle(\Delta X_A)^2\rangle$, by using the polymer chain model. In this model, a group of hydrogen-bonded alcohol molecules is treated as a polymer chain whose length is proportional to the association number of alcohol molecules. The solid lines in Figs. 4 and 5 shows the mean association numbers[15]

$$\langle l \rangle_n^p = \sum_l l n_{Al}^p / \sum_l n_{Al}^p$$

obtained from the above analysis, where n_{Al} is the mean number of alcohol l-mers (A_l). An "l-mer" is defined here as a group of l number of alcohol molecules which are linked by $(l-1)$ hydrogen bonds. We cannot obtain information about the life-time of local structures from $\langle l \rangle_n^p$ because the definition of an "l-mer" does not include the concept of life-time. On the other hand, $\langle l \rangle_n^d$ is the mean number of alcohol molecules which can move together for a time much longer than the velocity auto-correlation time. Therefore, $\langle l \rangle_n^d$ may be called a "dynamical mean association number." These two quantities, $\langle l \rangle_n^d$ and $\langle l \rangle_n^p$, are not necessarily equal in magnitude, as can be understood from their definitions.

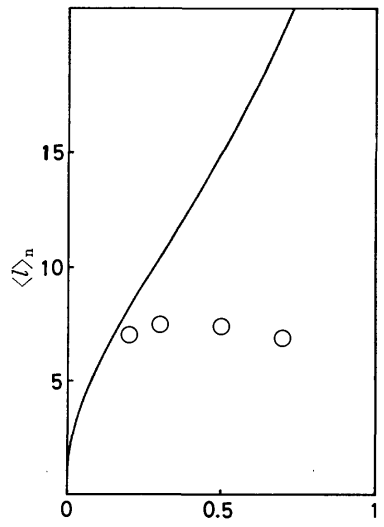

Fig. 4. Comparison of $\langle l \rangle_n^d$ (○) with $\langle l \rangle_n^p$ (——) for methanol–carbon tetrachloride system.

It is seen from Figs. 4 and 5 that $\langle l \rangle_n^d$ is only slightly smaller than $\langle l \rangle_n^p$ in the low concentration range of alcohol. As the alcohol concentration increases, however, the difference becomes very large. If all the hydrogen-bonded polymers of alcohol molecules can move for a time much longer than the velocity auto-correlation time without changing the polymer shape, each polymer can be regarded as a moving unit. Then, $\langle l \rangle_n^d$ is expected to be equal to $\langle l \rangle_n^p$. The above results indicate that a linear hydrogen-bonded polymer of alcohol molecules cannot always be a moving unit, especially in the high concentration range of alcohol. The difference between $\langle l \rangle_n^d$ and $\langle l \rangle_n^p$ may be explained as follows. Consider the velocity correlation between two alcohol molecules which form a polymer. If these two molecules are adjacent to each other, the

velocity correlation between them is expected to be strong. If these two molecules are not adjacent to each other, on the other hand, the velocity correlation between them becomes relatively weak. Therefore, it is expected that $\langle l\rangle_n^d$ cannot exceed a certain number, no matter how large the mean association number, $\langle l\rangle_n^p$.

From these results, the following picture may be drawn for the cooperative translational motion of alcohol molecules. In the low concentration range of alcohol, several alcohol molecules form a hydrogen-bonded polymer. The polymer can move for a time much longer than the velocity auto-correlation time without changing the polymer shape. The number of alcohol molecules moving together increases with the increase of the alcohol concentration in this concentration range. In the high concentration range, however, the polymer can no longer move without changing its shape as long as it could in the low concentration range. In other words, the number of molecules which can move together is much smaller than the mean association number.

Comparison with the Mean Association Number Obtained by Using an Ideal Associated Complex Model. In our previous paper,[8] the observed values of $N\langle(\Delta X_A)^2\rangle$ have been analyzed by using the ideal associated complex model. The model includes an assumption that alcohol molecules form an associated complex. The solution is regarded to be an ideal solution whose components are free molecules and the associated complexes. In other words, all the associated complexes are the same size as the carbon tetrachloride molecule and the internal degrees of the complexes are mutually independent. Under these assumptions, $N\langle(\Delta X_A)^2\rangle$ is expressed as

$$N\langle(\Delta X_A)^2\rangle = X_A(1-X_A)\{X_A+\langle l\rangle_w^c(1-X_A)\}$$
$$\langle l\rangle_w^c \equiv \sum_l l^2 n_{Al}^c / \sum_l l n_{Al}^c \qquad (28)$$

where n_{Al}^c is the mean number of associated complexes which are made up of l numbers of alcohol molecules. In the previous paper, it has been shown that this model cannot be applied to the present system (carbon tetrachloride solution of alcohols) especially in the high concentration range because the configurations of linear hydrogen-bonded polymers are not mutually independent. However, it has been also shown that $\langle l\rangle_w^c$ obtained from Eq. 28 is still a useful quantity, because the following expression can be obtained from the relation between $N\langle(\Delta X_A)^2\rangle$ and the spatial correlation of microscopic density:

$$\langle l\rangle_w^c - 1 = \int_{V^*} \rho_A g_{AA}(r)\mathrm{d}^3r - \int_{V^*} \rho_A g_{AB}(r)\,\mathrm{d}^3r$$

where A and B denote the alcohol and carbon tetrachloride molecules, respectively, ρ_A is the number density of alcohol, and $g_{\alpha\beta}(r)$ is the radial distribution function of α and β molecules (α, β=A or B). $\rho_\alpha g_{\alpha\beta}(r)\mathrm{d}^3r$ is the mean number of α molecules in a volume element d^3r, at a distance r from the center of a β molecule. Thus, $(\langle l\rangle_w^c - 1)$ represents the difference between the mean number of alcohol molecules in the neighborhood of a carbon tetrachloride molecule and that in a neighborhood of the same volume of an alcohol molecule. If the correlations between the positions of different alcohol molecules are rather strong in comparison with those between alcohol and carbon tetrachloride molecules, $\langle l\rangle_w^c$ takes larger values than unity according to the extent of the correlation. Therefore, $\langle l\rangle_w^c$ represents the number of alcohol molecules whose positions are strongly correlated.

In the case where the shape of each hydrogen-bonded species is spherical and their sizes are the same as the solvent molecules, $\langle l\rangle_w^c$ is expected to be equal to $\langle l\rangle_w^p$:[8]

$$\langle l\rangle_w^p \equiv \frac{\sum_l l^2 n_{Al}^p}{\sum_l l n_{Al}^p}.$$

This can be understood by considering that the positions of molecules which form a hydrogen-bonded species are strongly correlated in this case. In the case where the shape of each hydrogen-bonded species is like a polymer chain and various configurations are possible for the polymer chain, on the other hand, the correlation between positions of molecules which form an hydrogen-bonded species becomes relatively weak. Then, $\langle l\rangle_w^c$ is expected to be smaller than $\langle l\rangle_w^p$.

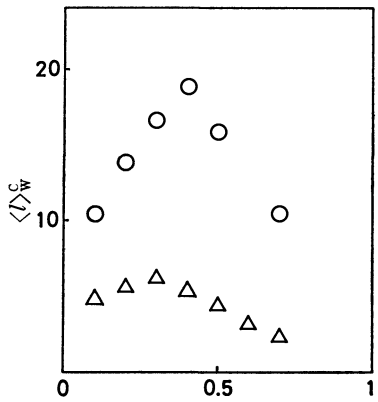

Fig. 6. Mean association numbers obtained from mean-square concentration fluctuation by using an associated complex model.
○: Methanol–carbon tetrachloride system, △: ethanol–carbon tetrachloride system.

Figure 6 shows the concentration dependences of $\langle l\rangle_w^c$ obtained from the observed $N\langle(\Delta X_A)^2\rangle$ values and Eq. 28. Comparison of $\langle l\rangle_n^d$ with $\langle l\rangle_n^p$ and $\langle l\rangle_w^c$ shows that the concentration dependence of $\langle l\rangle_n^d$ is more similar to that of $\langle l\rangle_w^c$ than to that of $\langle l\rangle_n^p$. These results can be understood by considering that the velocity time correlation between different molecules depends on the correlations of positions between these molecules.

Concluding Discussion. We have introduced the concept of a moving unit in order to obtain information about cooperative molecular motions. For the binary solutions of methanol–carbon tetrachloride and ethanol–carbon tetrachloride, we have compared the mean number of molecules which constitute an moving unit

(dynamical mean association number), $\langle l\rangle_n^d$, with two kinds of mean association number, $\langle l\rangle_n^p$ and $\langle l\rangle_w^c$. $\langle l\rangle_n^p$, the ordinary mean association number, is the mean number of molecules which are linked by hydrogen bonds. $\langle l\rangle_n^d$ is the number of molecules whose positions are strongly correlated. These parameters describe the local structure from different standpoints. We have shown that the concentration dependence of $\langle l\rangle_n^d$ is different from that of $\langle l\rangle_n^p$ for the present systems. This difference may be distinct for the solutions in which associated species of short life-time (the life-time is not much longer than the velocity auto-correlation time (10^{-12}—10^{-13} s)) exist. For the solutions in which associated species of long life-time exist, $\langle l\rangle_n^d$ is expected to approach $\langle l\rangle_n^d$. Incidentally, if all the associated species are spherical in shape and of the same size in addition to having long life-times, the relation that $\langle l\rangle_n^d \simeq \langle l\rangle_n^p \simeq \langle l\rangle_w^p \simeq \langle l\rangle_w^c$ is expected.

Although various techniques are available for studying statical structures of liquids or single molecular motions, there are few experimental methods which yield information about collective molecular motions. The measurement of mutual diffusion coefficients is useful for such study. In most of the reports on the mutual diffusion in associated solutions, however, little attention has been paid to the life-time of associated species. The observed mutual diffusion coefficients have usually been explained by using the mean association numbers such as $\langle l\rangle_n^p$ instead of $\langle l\rangle_n^d$.[18,19]

We have shown that the magnitude of the mutual diffusion coefficients depends on the life-time of the local structures formed in the solution. Though the moving unit is a fictitious concept at this stage, it is an important quantity for drawing pictures of the cooperative translational motions in associated solutions.

Light Scattering Study of Local Structures in Solutions. Mean Association Numbers and Concentration Fluctuations for Alcohol–Carbon Tetrachloride Systems

Tadashi KATO,* Toru NAKANISHI, and Tsunetake FUJIYAMA*,†

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

† *Institute for Molecular Science, Okazaki 444*

(Received January 5, 1980)

Light scattering spectra were observed for carbon tetrachloride solutions of methanol, ethanol, and 1-propanol. The Rayleigh intensities were reduced to concentration fluctuations. The observed concentration dependence of the concentration fluctuation was analyzed by using two distinct models: an ideal associated complex (IAC) model and a polymer chain (PC) model. In the IAC model, a group of hydrogen-bonded alcohol molecules is treated as a complex whose size is independent of the association number, l. In the PC model, on the other hand, the group of hydrogen-bonded molecules is treated as a linear polymer whose length is proportional to l. It was shown that the PC model can explain both the concentration fluctuation and the heat of mixing data, while the IAC model cannot be applied to the present systems. The mean association number obtained by the IAC model was discussed on the basis of the relation between the concentration fluctuation and the spatial correlation of microscopic density.

Local fluctuations of concentration afford information which is useful in understanding the mixing of a liquid from a molecular viewpoint. Thus we have carried out a series of studies to determine temperature and concentration dependences of concentration fluctuations through observation of light scattering spectra.

The relationship between the mean-square amplitude of concentration fluctuations and Rayleigh intensities has been theoretically established.[1] A method has been proposed for determining local structures in associated solutions from the observed concentration fluctuations at various concentrations and various temperatures,[2,3] and this method has been applied successfully for the studies of local structures in a few kinds of binary solutions.[4–9]

In the study of local structures which formed in the ethanol–carbon tetrachloride solution, it was found that the mean association number of ethanol increases up to about 7 with the increase of ethanol mole fraction up to 0.3 and then gradually decreases with the successive increases in ethanol concentration. On the other hand, the heats of mixing for this system have positive values at almost all the concentrations[10,11] (See Fig. 14). This suggests that the mean association number increases monotonously with the increase of alcohol concentration, because the heat of mixing can be approximately related to the change of the number of hydrogen bonds on mixing. A similar conclusion has been suggested by the studies by spectroscopic methods.[12–15] These results certainly suggest that our previous analysis of the concentration fluctuation values must be modified to some extent in the case of such associative solutions as the ethanol–carbon tetrachloride system.

In the present study, we will analyze the observed concentration fluctuations for the methanol–carbon tetrachloride and 1-propanol–carbon tetrachloride systems, in addition to the ethanol–carbon tetrachloride system, by using a model which can explain both the concentration fluctuations and the heat of mixing data. Then, the mean association number obtained by our previous analysis will be discussed on the basis of the relation between the concentration fluctuation and the spatial correlation of the microscopic density.

Experimental

The samples used in the present study were commercially available reagents. Methanol and 1-propanol were treated with zeorite A-3 in order to eliminate water. The binary solutions of methanol–carbon tetrachloride and 1-propanol–carbon tetrachloride were made dust-free by means of an Atago Abbe refractometer.

Light scattering spectra were observed at 24 ± 1 °C by using a spectrometer which is composed of He–Ne gas laser source (NEC, GLG 108, 60 mW) and a pressure-scanning Fabry-Perot interferometer.[16]

Results and Discussion

Concentration Fluctuations. The procedure for obtaining the concentration fluctuation values from the observed light scattering spectra is the same as that described in the previous reports. In Fig. 1, the observed mean-square concentration fluctuations, $N\langle(\Delta X_A)^2\rangle$, are plotted against the mole fraction, x_A, of the alcohol for the carbon tetrachloride solutions of methanol, ethanol, and 1-propanol where N is the total number of molecules included in the field within which the concentration fluctuation is considered. The dashed line in the figure corresponds to $N\langle(\Delta X_A)^2\rangle$ expected for an ideal binary solution. It is seen from the figure that observed concentration fluctuations are larger than that of an ideal solution and take maximum values at $X_A=0.3$—0.4.

Analysis of $N\langle(\Delta X_A)^2\rangle$ by Using an Ideal Associated Complex Model. In our previous reports, a method has been presented for determining local structures from the observed $N\langle(\Delta X_A)^2\rangle$.[2,3] In this method, we employed an ideal associated complex model[17] (IAC model, hereafter). This model includes an assumption that the local structure can be treated as an associated complex; the solution is regarded as an ideal solution whose components are free molecules and associated complex molecules.

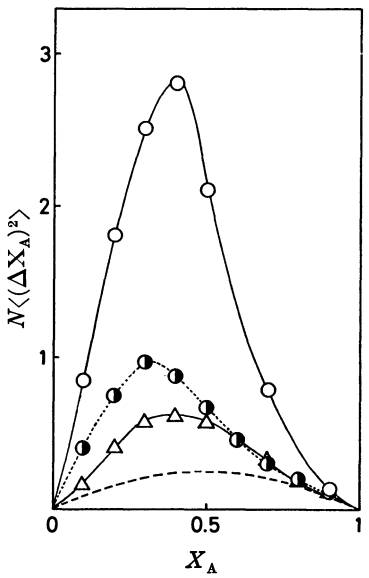

Fig. 1. Observed concentration fluctuation for methanol–carbon tetrachloride system (○), ethanol–carbon tetrachloride system (◑), and 1-propanol–carbon tetrachloride system (△).
The dashed line corresponds to the concentration fluctuation expected for an ideal binary solution.

In the present systems, we assume that associated molecules of the A_l type exist in the solution, where A represents the alcohol molecule and l is an association number. Then, $N\langle(\Delta X_A)^2\rangle$ is expressed as[7,9]

$$N\langle(\Delta X_A)^2\rangle = X_A(1-X_A)\{X_A+\langle l\rangle_w^c(1-X_A)\}$$
$$\langle l\rangle_w^c \equiv \sum_l l^2 n_{Al}^c / \sum_l l n_{Al}^c \qquad (1)$$

where n_{Al}^c is the mean number of A_l molecules. Thus, the mean association number of the alcohol, $\langle l\rangle_w^c$, can be obtained from the observed values of $N\langle(\Delta X_A)^2\rangle$ at each concentration. The results for the carbon tetrachloride solutions of methanol, ethanol, and 1-propanol are shown in Fig. 2. It is seen from the

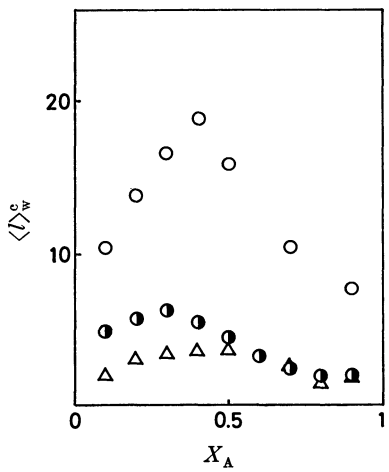

Fig. 2. Mean association numbers of methanol (○), ethanol (◑), and 1-propanol (△) in carbon tetrachloride solutions calculated from Eq. 1 and observed values of concentration flucutuation.

figures that $\langle l\rangle_w^c$ increases with the increase of alcohol mole fraction up to 0.3—0.4 and then decreases with the successive increases in alcohol concentration.

The heat of mixing per molecule, Δh^M, is expressed as

$$\Delta h^M = \frac{1}{n_A+n_B}\{\sum_l (l-1)n_{Al}^c \Delta h^c - \sum_l (l-1)n_{Al}^{c^\circ}\Delta h^c\}$$
$$= X_A \Delta h^c \left(\frac{1}{\langle l\rangle_n^{c^\circ}} - \frac{1}{\langle l\rangle_n^c}\right) \qquad (2)$$
$$\langle l\rangle_n^c \equiv \sum_l l n_{Al}^c / \sum_l n_{Al}^c$$

by using the same model, where n_A and n_B are the numbers of the alcohol and carbon tetrachloride, respectively, Δh^c is the enthalpy change for the reaction

$$A_l + A_1 \longrightarrow A_{l+1}$$

and $n_{Al}^{c^\circ}$ is the mean number of A_l molecules for the pure state. In Eq. 2, Δh^d is assumed to be independent of l. $\langle l\rangle_n^c$ and $\langle l\rangle_n^{c^\circ}$ are the mean association numbers of the alcohol for the solution and the pure state, respectively. Although $\langle l\rangle_n^c$ may differ from $\langle l\rangle_w^c$ in magnitude, they will show, in principle, the same concentration dependences. The results in Fig. 2 suggest that $\langle l\rangle_n^c$ is larger than $\langle l\rangle_n^{c^\circ}$ in magnitude over almost all the concentration range and, therefore, Δh^M will take negative values. However, the experimental values of Δh^M in the literature[10,11,18] are positive (see Fig. 14), which indicates that the IAC model cannot be applied to the present systems.

Analysis of $N\langle(\Delta X_A)^2\rangle$ by Using Polymer Chain Model. In the IAC model, it is assumed that the configurations of associated complexes are mutually independent. However, this assumption may not be appropriate for the present systems because the shapes of the complexes may be chain-like in the high concentration range of the alcohol. So we make the following assumptions in this section for a binary solution composed of alcohol(A) and carbon tetrachloride(B) molecules:

(1) Alcohol molecules form linear, hydrogen-bonded polymers A_l(l=1, 2,....), where l is an association number.

(2) The solution structure is treated by the quasi-lattice model.

(3) An alcohol l-mer, A_l, occupies the l numbers of cells in the lattice and a carbon tetrachloride molecule occupies one cell. The monomeric unit of the alcohol polymer can be exchanged with a carbon tetrachloride molecule in the lattice cells.

(4) The number of distinguishable ways of arranging the $(\sum_l n_{Al})$ numbers of polymers and n_B numbers of carbon tetrachloride molecules on the $(\sum_l n_{Al}+n_B)$ numbers of cells is given by Flory's equation for polymer solutions:[19]

$$W = \frac{(\sum_l l n_{Al}+n_B)!}{\prod_l (n_{Al}!)n_B!} \frac{1}{2^{\sum_l n_{Al}}} \left(\frac{z-1}{\sum_l l n_{Al}+n_B}\right)^{\sum_l (l-1)n_{Al}} \qquad (3)$$

where n_{Al} and n_B are the number of l-mers and carbon tetrachloride molecules, respectively, and z is the coordination number of the lattice.

(5) The internal motions of molecules belonging to different chemical species (*i.e.*, A_l and $A_{l'}$, A_l and B,

etc.) are mutually independent.

Under these assumptions, the free energy for (n_A+n_B) molecules, F, in the present system is expressed as

$$F = n_A f_A^\circ + n_B f_B^\circ + \sum_l n_{Al} f_{Al}^E + kT \ln W \quad (4)$$

$$f_{Al}^E \equiv f_{Al} - l f_A^\circ$$

where f_A° and f_A° are the free energy per molecule for the hypothetical pure states of an alcohol and carbon tetrachloride, respectively. The hypothetical pure state is defined as the state where only monomers exist and molecules are arranged on the same lattice as that of the solution. f_{Al} is the free energy for l numbers of alcohol molecules forming an l-mer.

If association equilibria are assumed, the distribution of an association number can be determined by the equilibrium conditions:

$$\mu_{Al} = l\mu_{A1} \text{ or } \mu_{Al+1} = \mu_{Al} + \mu_{A1} \quad (5)$$

where

$$\mu_{Al} = \partial F/\partial n_{Al}.$$

Combination of Eqs. 4 and 5 gives the relation

$$\frac{X_{Al+1}}{X_{Al}X_{A1}} = 2(z-1)\exp(-\Delta f_l/kT) \equiv K_l \quad (6)$$

$$\Delta f_l \equiv f_{Al+1}^E - f_{Al}^E$$

$$X_{Al} \equiv \frac{n_{Al}}{\sum_l l n_{Al} + n_B} \quad (7)$$

where Δf_l is the change of free energy due to the hydro gen bond formation:[20] $A_l + A_1 \rightarrow A_{l+1}$. For simplicity, we assume that Δf_l is independent of l, that is

$$K_1 = K_2 = \cdots \equiv K. \quad (8)$$

Then, the X_{Al} can be expressed as

$$X_{Al} = K^{l-1} X_{A1}^l. \quad (9)$$

The chemical potential of the alcohol is

$$\frac{\mu_A}{kT} = \frac{f_A^\circ}{kT} + \ln X_{A1} + KX_A X_{A1}. \quad (10)$$

Concentration fluctuations, $N\langle(\Delta X_A)^2\rangle$, are related to μ_A as

$$N\langle(\Delta X_A)^2\rangle = \left(\frac{X_B}{N}\right)^2 \langle(\Delta n_A)^2\rangle \quad (11)$$

$$\langle(\Delta n_A)^2\rangle = \frac{kT}{(\partial\mu_A/\partial n_A)_{n_B}} \quad (12)$$

where Δn_A is the fluctuation of n_A in the region which contains a constant number of B molecules. Combination of Eqs. 10, 11, and 12 gives the equation

$$N\langle(\Delta X_A)^2\rangle = \frac{X_A(1-X_A)}{X_A + (1-X_A)/\langle l\rangle_w^p} \quad (13)$$

$$\langle l\rangle_w^p \equiv \frac{\sum_l l^2 n_{Al}}{\sum_l l n_{Al}} = \frac{1+KX_{A1}}{1-KX_{A1}}. \quad (14)$$

In order to compare the present model (the polymer chain model: PC model, hereafter) with the IAC model, the theoretical values of $N\langle(\Delta X_A)^2\rangle$ calculated for various $\langle l\rangle_w^c$ or $\langle l\rangle_w^p$ values are illustrated in Figs. 3 and 4. Apparently $N\langle(\Delta X_A)^2\rangle$ increases in magnitude as $\langle l\rangle_w^c$ or $\langle l\rangle_w^p$ increases in either model. However, the rate of increase in $N\langle(\Delta X_A)^2\rangle$ for the PC model is smaller than that for the IAC model especially in the

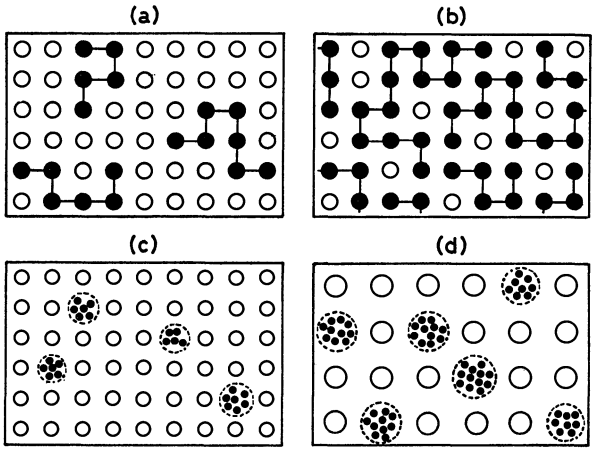

Fig. 5. Schematic representations of the ideal associated complex (IAC) model and the polymer chain (PC) model.
(a): PC model for $X_A \approx 0.3$, (b): PC model for $X_A \approx 0.8$, (c): IAC model for $X_A \approx 0.3$, (d): IAC model for $X_A \approx 0.8$. ● and ○ correspond to the alcohol molecule and the carbon tetrachloride molecule, respectively.

alcohol-rich solutions. The basic differences between the two models are schematically illustrated in Fig. 5. It may be seen from the figure that the two components mix with each other more homogeneously in the PC model than in the IAC model. Concentration fluctuations reflect sensitively the homogeneity of mixing, as can be seen from Figs. 3 and 4.

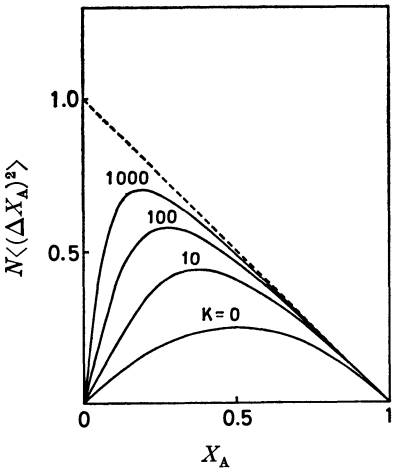

Fig. 6. Theoretical values of concentration fluctuation calculated from Eqs. 13 and 14 for $K=0$, 10, 100, and 1000.

Figure 6 shows the concentration dependences of concentration fluctuations calculated from Eq. 13 for various K values. Comparing the calculated results with the observed concentration fluctuation in Fig. 1, we can see that the PC model can explain the observed values of $N\langle(\Delta X_A)^2\rangle$ in the sense that $N\langle(\Delta X_A)^2\rangle$ takes maximum values at a mole fraction smaller than 0.5. However, the theoretical values of $N\langle(\Delta X_A)^2\rangle$ cannot exceed the values of $(1-X_A)$ even if $K=0$, which shows that the present model is still imperfect for explaining the alcohol solutions.

Modification of the PC Model. In the PC model, it is assumed that an alcohol l-mer occupies l cells in the lattice and, therefore, the number of different configurations of an l-mer is $Z(Z-1)^{l-1}$. In the IAC model, on the other hand, the sizes of associated complexes are all equal to that of a carbon tetrachloride molecule, regardless of their association numbers. It does not seem realistic to assume the ideal mixing of large linear polymers and small monomers, because the configurations of polymers are not mutually independent. In the previous calculation by using the PC model, however, these effects seem to be overemphasized because the hydrogen-bonded polymers are not entirely flexible, as we have assumed. Moreover, the sizes of an alcohol monomer and a carbon tetrachloride molecule are different. So we thought it better to assume that an alcohol l-mer occupies l/ρ cells. Then, the number of distinguishable ways of arranging molecules on the lattice becomes, instead of Eq. 3,

$$W=\frac{\{\sum_l (l/\rho)n_{Al}+n_B\}!}{\prod_l (n_{Al}!)n_B!}\frac{1}{2^{\sum_l n_{Al}}}\left(\frac{z-1}{\sum_l (l/\rho)n_{Al}+n_B}\right)^{\sum_l (l/\rho-1)n_{Al}} \quad (15)$$

and the relation among the mean number of polymers is

$$\frac{X'_{Al+1}}{X'_{Al}X'_{A1}}=2(z-1)\exp(-\Delta f_l/kT)\equiv K \quad (16)$$

$$X'_{Al}\equiv\frac{n_{Al}}{\sum_l (l/\rho)n_{Al}+n_B}. \quad (17)$$

Thus, $N\langle(\Delta X_A)^2\rangle$ is

$$N\langle(\Delta X_A)^2\rangle=\frac{X_A(1-X_A)\{X_A+\rho(1-X_A)\}^2}{X_A+(\rho/\langle l\rangle_w^p)(1-X_A)} \quad (18)$$

$$\langle l\rangle_w^p=\frac{\sum_l l^2 n_{Al}}{\sum_l l n_{Al}}=\frac{1+KX'_{Al}}{1-KX'_{Al}}. \quad (19)$$

In the case where $\rho=\langle l\rangle_w^p$, Eq. 18 is identical with the expression of $N\langle(\Delta X_A)^2\rangle$ in the IAC model, that is, $\langle l\rangle_w^p=\langle l\rangle_w^c$.

Figures 7 and 8 show the concentration dependences of $\langle l\rangle_w^p$ and $N\langle(\Delta X_A)^2\rangle$, respectively, for $K=100$ and various ρ values. Figure 8 demonstrates that the maximum position of the curve moves to the larger-mole-fraction side as ρ increases. Now we can choose the sets of K and ρ values determined for the three systems. These are summarized in Table 1 and the theoretical values of $N\langle(\Delta X_A)^2\rangle$ calculated for the typical sets of parameter in Table 1 are illustrated in Figs. 9—11. Though the agreement between theoretical and observed values was not complete, we were satisfied with the present results and did not modified the model further. The concentration dependences of $\langle l\rangle_w^p$ calculated for these K and ρ values are illustrated in Fig. 12.

The magnitudes of ρ for the three systems studied are in the order methanol>ethanol>1-propanol, as can be seen from Table 1. As ρ has been defined as the number of alcohol molecules which occupy one cell in the lattice, its magnitude is expected to increase with decreasing

the ratio of the molecular size of the alcohol to that of carbon tetrachloride.[21] The molecular sizes are in the order: carbon tetrachloride>1-propanol>ethanol>methanol. Therefore, the present results are consistent with the above expectation.

So far, ρ has been assumed to be independent of concentration. However, if its magnitude is influenced by the existence of carbon tetrachloride molecules, ρ should decrease its magnitude as the concentration of carbon tetrachloride decreases. Then, the theoretical values of $N\langle(\Delta X_A)^2\rangle$ in the high alcohol concentration range are expected to approach to the observed values, if the concentration dependence of ρ is taken into account.

Calculation of Heat of Mixing. The enthalpy for the (n_A+n_B) numbers of molecules, H, for the present system is expressed by using the PC model as

$$H = n_A h_A^\circ + n_B h_B^\circ + \sum_l n_{Al} h_{Al}^E \qquad (20)$$

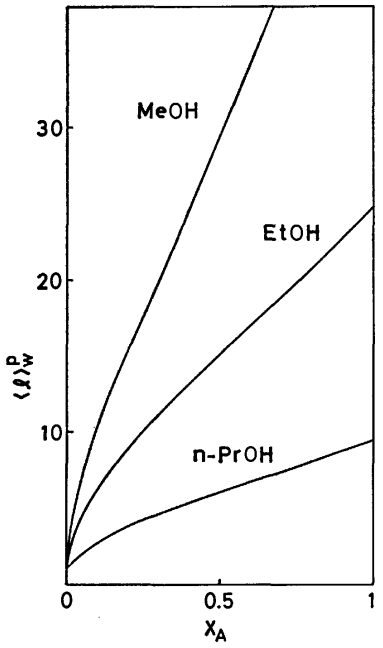

Fig. 12. Mean association numbers of methanol, ethanol, and 1-propanol in carbon tetrachloride solutions calculated from Eq. 19 for the parameters used in calculation of $N\langle(\Delta X_A)^2\rangle$ in Figs. 9—11.

$$h_\alpha^\circ \equiv kT^2\frac{\partial(f_\alpha^\circ/kT)}{\partial T} \quad (\alpha=\text{A or B})$$
$$h_{Al}^E \equiv kT^2\frac{\partial(f_{Al}^E/kT)}{\partial T}. \tag{21}$$

As we have assumed that Δf_{Al} of Eqs. 6 and 16 is independent of l, $\Delta h_l(\equiv h_{Al+1}^E - h_{Al}^E)$ is also independent of l, that is

$$\Delta h_1 = \Delta h_2 = \cdots \equiv \Delta h.$$

Then,

$$\sum_l n_{Al}h_{Al}^E = \sum_l n_{Al}(l-1)\Delta h$$
$$= \Delta h n_A\left(1-\frac{1}{\langle l\rangle_n^p}\right) \tag{22}$$

where

$$\langle l\rangle_n^p = \frac{\sum_l l n_{Al}}{\sum_l n_{Al}} = \frac{1}{1-KX_{A1}'}. \tag{23}$$

Thus the heat of mixing per molecule, Δh^M, is

$$\Delta h^M = \Delta h X_A\left(\frac{1}{\langle l\rangle_n^{p^\circ}} - \frac{1}{\langle l\rangle_n^p}\right) \tag{24}$$

where $\langle l\rangle_n^{p^\circ}$ is the mean association number in the pure alcohol. Figure 13 shows the values of $(\Delta h^M/\Delta h)$ calculated for the parameters used in the calculation of $N\langle(\Delta X_A)^2\rangle$ in Figs. 9—11. Observed values of Δh^M at 20 °C are shown in Fig. 14 in the form of $\Delta h^M/kT$. Comparing Fig. 13 with Fig. 14, we can see that the calculated values explain the experimental results in the senses that Δh^M takes positive values and that its magnitude is in the order: 1-propanol>ethanol> methanol.[22]

The calculation of $\Delta h^M/\Delta h$ in Fig. 13 is done by assuming that ρ is independent of concentration. We have also calculated $\Delta h^M/\Delta h$ for the ρ values which give the best fit between calculated and observed values of

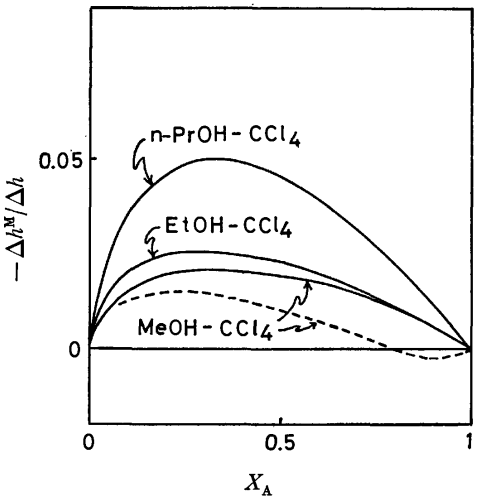

Fig. 13. Theoretical values of $-\Delta h^M/\Delta h$ calculated from Eq. 24 for the parameters used in calculation of $N\langle(\Delta X_A)^2\rangle$ in Figs. 9—11.

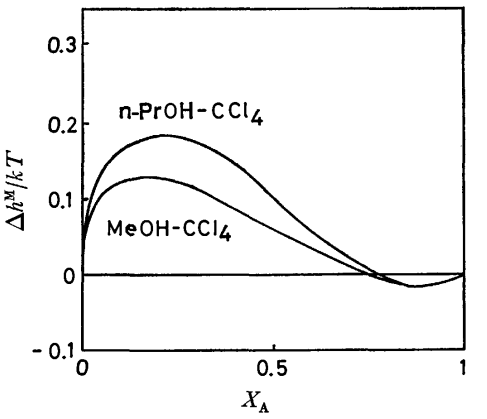

Fig. 14. Experimental values of $\Delta h^M/kT$ for methanol–carbon tetrachloride and ethanol–carbon tetrachloride systems at 20°C.[11]

$N\langle(\Delta X_A)^2\rangle$ without chaging the K value. For an example, the results for the methanol–carbon tetrachloride system are illustrated by the dashed line in Fig. 13.[23] The observed concentration dependences of Δh^M seem to be explained well by the dashed line rather than the solid line in Fig. 13. By comparing the observed values of $\Delta h^M/\Delta h$ and the observed values of Δh^M, the value of Δh has been roughly obtained as 5 kcal mol^{-1} for methanol.

Interpretation for $\langle l\rangle_w^c$. As previously described, the IAC model cannot be applied to the present systems. However, the concentration dependences of $\langle l\rangle_w^c$ seem to reflect a certain aspect of the mixing state. In this paragraph, $\langle l\rangle_w^c$ is interpreted based on the relation between $N\langle(\Delta X_A)^2\rangle$ and the spatial correlation of the microscopic density.

The fluctuation of mole fraction ΔX_A in the constant volume V^* is expressed in terms of the number fluctuation of component molecules as

$$\Delta X_A = \left(\frac{\partial X_A}{\partial n_A}\right)\Delta n_A + \left(\frac{\partial X_A}{\partial n_B}\right)\Delta n_B. \tag{25}$$

Noting that

$$\Delta n_\alpha = \int_{V^*} \rho_\alpha(\boldsymbol{r}) \mathrm{d}^3 r \qquad \Delta\rho_\alpha(\boldsymbol{r}) = \rho_\alpha(\boldsymbol{r}) - \rho_\alpha \tag{26}$$

where $\rho_\alpha(\boldsymbol{r})$ is the number density of α (α=A or B) at the point $\boldsymbol{r}$ and ρ_α the mean value of $\rho_\alpha(\boldsymbol{r})$, then $N\langle(\Delta X_\mathrm{A})^2\rangle$ is[24]

$$N\langle(\Delta X_\mathrm{A})^2\rangle = X_\mathrm{A}X_\mathrm{B}\{1+\rho X_\mathrm{A}X_\mathrm{B}(G_{\mathrm{AA}}+G_{\mathrm{BB}}-2G_{\mathrm{AB}})\} \tag{27}$$

$$G_{\alpha\beta} = \int_{V^*} [g_{\alpha\beta}(r)-1]\mathrm{d}^3 r \tag{28}$$

where ρ is the mean number density and $g_{\alpha\beta}(r)$ is the pair-distribution function of species α and β:

$$g_{\alpha\beta}(r) = \frac{\langle\rho_\alpha(0)\rho_\beta(r)\rangle - \langle\rho_\alpha\rangle\langle\rho_\beta\rangle\delta(r)\delta_{\alpha\beta}}{\langle\rho_\alpha\rangle\langle\rho_\beta\rangle}. \tag{29}$$

In our previously described treatment, the interactions between B molecules and between A and B molecules are neglected. This assumption corresponds to the relation

$$G_{\mathrm{BB}} = G_{\mathrm{AB}}. \tag{30}$$

Then, Eq. 27 is

$$N\langle\Delta X_\mathrm{A})^2\rangle = X_\mathrm{A}X_\mathrm{B}\{1+\rho X_\mathrm{A}X_\mathrm{B}(G_{\mathrm{AA}}-G_{\mathrm{AB}})\}. \tag{31}$$

On the other hand, Eq. 1 can be rewritten as

$$N\langle\Delta X_\mathrm{A})^2\rangle = X_\mathrm{A}X_\mathrm{B}\{1+(\langle l\rangle_\mathrm{w}^\mathrm{c}-1)X_\mathrm{B}\}. \tag{32}$$

By comparing Eq. 31 with Eq. 32, we obtain

$$\langle l\rangle_\mathrm{w}^\mathrm{c} - 1 = \rho_\mathrm{A}(G_{\mathrm{AA}}-G_{\mathrm{AB}})$$

$$= \int_{V^*} \rho_\mathrm{A} g_{\mathrm{AA}}(r)\mathrm{d}^3 r - \int_{V^*} \rho_\mathrm{A} g_{\mathrm{AB}}(r)\mathrm{d}^3 r. \tag{33}$$

$\rho_\alpha g_{\alpha\beta}(r)\ \mathrm{d}^3 r$ is the mean number of α molecules in a volume element $\mathrm{d}^3 r$ at a distance r from the center of a β molecule. Thus, $\rho_\mathrm{A}(G_{\mathrm{AA}}-G_{\mathrm{AB}})$ is the difference between the mean number of alcohol molecules in the entire surrounding of a carbon tetrachloride molecule and that in the entire surrounding of an alcohol molecule. If the correlations between the positions of different alcohol molecules are rather strong in comparison with those between the positions of alcohol and carbon tetrachloride molecules, $\langle l\rangle_\mathrm{w}^\mathrm{c}$ takes larger values than unity according to the extent of the correlation. Therefore, $\langle l\rangle_\mathrm{w}^\mathrm{c}$ is considered to represent the number of alcohol molecules whose positions are strongly correlated.

In the case where the shapes of the hydrogen-bonded species are spherical and their sizes are the same as that of the solvent molecule, $\langle l\rangle_\mathrm{w}^\mathrm{c}$ becomes equal to $\langle l\rangle_\mathrm{w}^\mathrm{p}$. This can be understood by considering that the positions of molecules which form a hydrogen-bonded species are strongly correlated in this case. In the case where the shape of hydrogen-bonded species is like a polymer chain and various configurations are possible for the polymer chain (*i.e.*, the polymer chain is flexible), on the other hand, the correlation between positions of molecules which form an hydrogen-bonded species becomes relatively weak. Then $\langle l\rangle_\mathrm{w}^\mathrm{c}$ is expected to be smaller than $\langle l\rangle_\mathrm{w}^\mathrm{p}$.

The concentration dependences of $\langle l\rangle_\mathrm{w}^\mathrm{c}$ and $\langle l\rangle_\mathrm{w}^\mathrm{p}$ may be interpreted as follows. In the low concentration range of alcohol, the hydrogen-bonded alcohols are isolated by carbon tetrachloride molecules. The correlation between positions of alcohol molecules increase with the increase of $\langle l\rangle_\mathrm{w}^\mathrm{p}$. In the high concentration range, however, the highly-associated alcohol molecules form a continuous medium. Then the correlation between positions of alcohol molecules becomes weak because of the decrease in the number of carbon tetrachloride molecules which perform the task of isolating the associated alcohol molecules.

Conclusion. We have analyzed the concentration dependences of the mean-square concentration fluctuations observed for carbon tetrachloride solutions of three kinds of alcohols by using two distinct models. In the IAC model, the mean association number, $\langle l\rangle_\mathrm{w}^\mathrm{c}$, can be obtained directly from the observed concentration fluctuation. However, the experimental values of heats of mixing cannot be explained by this model. On the other hand, the PC model can explain both the concentration fluctuation and the heat of mixing.

In previous reports, we have studied the local structures formed in various solutions by using the IAC model. The present study shows that this model cannot be applied to those solutions in which associative components form long chain-like local structures. For such solutions, the PC model should be used for obtaining the mean association numbers. It must be emphasized, however, that the mean association number, $\langle l\rangle_\mathrm{w}^\mathrm{c}$, obtained from the IAC model is still a useful quantity, because it represents the extent of correlations between the positions of different associative molecules and because it can be easily and uniquely obtained by measuring the mean-square concentration fluctuation.

Fluorescence Quenching Process of Anthracene by Maleic Anhydride

Hiroshi YESAKA,† Takayoshi KOBAYASHI, Kaoru SUZUKI,† and Saburo NAGAKURA*,†

The Institute of Physical and Chemical Research, Wako, Saitama 351

† *The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106*

(Received January, 9, 1980)

The time dependence of fluorescence intensity after picosecond laser excitation and the steady-state fluorescence intensity were measured in order to study the mechanism of fluorescence quenching of anthracene by maleic anhydride in 1,4-dioxane. The nonlinear relationship between the reciprocal of steady-state fluorescence intensity and quencher concentration was observed for this system and interpreted in terms of the transient effect in the quenching process. The kinetic study by picosecond laser photolysis supports this interpretation. The reaction radius (R) and the sum of diffusion constants of both reactants (D) at various temperatures were determined by applying the diffusion model of Andre *et al.* The observed values are $R=7.2$ Å, $D=1.46\times10^{-5}$ cm^2 s^{-1} (22 °C), 1.87×10^{-5} cm^2 s^{-1} (50 °C), 2.42×10^{-5} cm^2 s^{-1} (75 °C). Studies of the main path in the quenching process by nanosecond laser photolysis suggest the existence of an extra path in the quenching process which overwhelms the fluorescent exciplex formation, the photoionization, the triplet anthracene formation, and the adduct formation.

Anthracene–maleic anhydride is one of the typical systems which undergo the photochemical Diels-Alder reaction.[1] In connection with the reaction mechanism, the fluorescence quenching process is also of interest. So far, however, only a few studies have been reported on the quenching and reaction mechanisms.[1–3]

Livingston *et al.* reported that the fluorescence quenching process of anthracene by maleic anhydride in 1,4-dioxane is controlled by diffusion and that the fluorescence quenching does not result appreciably in the formation of the triplet state of anthracene.[2]

Concerning the reaction intermediate Kaupp proposed that the biradical intermediate should exist in the photochemical reaction between anthracence and maleic anhydride, from an analogy of the mechanism of the photochemical reaction between anthracene and dimethyl maleate.[3]

Anthracene and maleic anhydride form a charge-transfer complex. In some cases an excited charge-transfer complex[4] or an exciplex[5] is the intermediate of photocycloaddition reaction. So it is probable that the fluorescence quenching due to charge-transfer interaction is related to the mechanism of the photoaddition reactions. Hence we studied the fluorescence quenching process of anthracene by maleic anhydride in the present paper.

Experimental

Measurements. Steady-state fluorescence quenching experiments were carried out with a spectrophotofluorometer (Shimadzu; model 502) which has two double monochromators for excitation and emission. The 1,4-dioxane solution of anthracene (7.5×10^{-5} mol dm^{-3}) in a 1 cm square quartz cell was excited at 370 nm and the emission was measured at right angle with the excitation light. The measurements were made at room temperature (20±2 °C).

A block diagram of our picosecond emission spectroscopy apparatus was shown in Fig. 1. The excitation light pulse was the second harmonic (347.2 nm, 20 ps fwhm) of an amplified single pulse which was selected from a pulse train generated by a mode-locked ruby laser. The detection system for fluorescence from the sample was composed of a 50 cm grating monochromator, an image-converter streak camera (John Hadland; IMACON 600) coupled to a three-stage image intensifier (EMI; model 9914), and an optical multichannel analyzer (abbreviated hereafter as OMA) (PAR 1205). Fluorescence decay curves were displayed on an oscilloscope coupled to OMA. The digitized data by OMA were accumulated and processed by a desk-top computer. The fluorescence intensity of anthracene was observed at 402.5 nm. The concentration of anthracene was 7×10^{-3} mol dm^{-3} for the observation of the time profile of the fluorescence intensity.

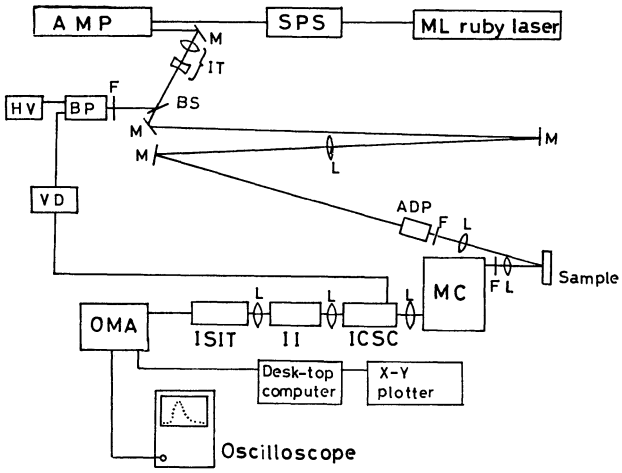

Fig. 1. Block diagram of the picosecond emission spectroscopy apparatus.
The excitation light generation system is composed of a mode-locked (ML) ruby laser, a single pulse selector (SPS), an amplifier (AMP), and an ADP crystal. The detection system is composed of a monochromator (MC), an image-converter streak camera (ICSC), an image intensifier (II), an intensified silicon intensified target tube (ISIT), an optical multichannel analyzer (OMA), an oscilloscope, a desk-top computer, and an X-Y plotter. The trigger system for ICSC is composed of a biplanar phototube (BP), a high-voltage power supply (HV), and a variable delay circuit (VD). L, M, BS, and IT represent lens, mirror, filter, beam splitter, and inverted telescop, respectively.

In the study of nanosecond laser photolysis a commercial nitrogen laser (337.1 nm, 10 ns fwhm, Molectron; model UV24) or a home-made nitrogen laser (3.7 ns fwhm) was used as an excitation light source and a Xe flash lamp with 40 μs duration was used as a monitoring light source.

The absorption spectrum measurements were carried out with a Cary 14 spectrophotometer.

Deoxygenation was done by bubbling dry nitrogen gas through the solution for 5 min.

Materials. The highly pure anthracene was a kind gift from Prof. Iwashima of Meisei University. Guaranteed reagent grade maleic anhydride (abbreviated to MA; Tokyo Kasei) and phthalic anhydride (Wako Pure Chemical) were sublimed *in vacuo* before use. Reagent grade pyromellitic dianhydride (Tokyo Kasei) was recrystallized twice from 1,4-dioxane and sublimed *in vacuo*. Acetonitrile (Wako Pure Chemical; spectrosol grade) was used without further purification. 1,4-Dioxane (Wako Pure Chemical) was let stand over iron (II) sulfate for several days. It was refluxed for 8 h with hydrochloric acid and water under nitrogen. Potassium hydroxide was added to the solution and the water layer was discarded. It was refluxed for 12 h with sodium under nitrogen, then distilled into flask and stoppered.

Results and Discussion

Steady-state Experiment. Plot of I_0/I *vs.* concentration of MA([MA]) is shown in Fig. 2 by open circles. I_0 and I are the fluorescence intensities without and with quencher, respectively. As can be seen in the figure, the plot is nonlinear. Five possible mechanisms to explain the nonlinear relation between I_0/I and [MA] are listed below: 1) (1: 1) charge-transfer complex formation in the ground state between anthracene and maleic anhydride, 2) photochemical and/or thermal reactions between anthracene and maleic anhydride, 3) internal filter effect, 4) dipole-dipole energy transfer from excited anthracene to maleic anhydride, 5) the transient effect in diffusion-controlled fluorescence quenching reaction. All but the fifth mechanism are concluded to be minor by the following considerations.

Anthracene and maleic anhydride in 1,4-dioxane form a (1: 1) ground state charge-transfer (CT) complex and its equilibrium constant is reported to be 0.05 mol^{-1} dm^3.[1] At the excitation wavelength (370 nm), not only anthracene but also the CT complex can absorb light to some extent. On the assumption that light absorption by the CT complex does not contribute to fluorescence intensity at all, I_0/I is represented as follows:

$$\frac{I_0}{I} = \frac{(1-10^{-C_0\varepsilon_A y})(1+K[\mathrm{MA}]\varepsilon_C/\varepsilon_A)(1+\tau k[\mathrm{MA}])}{1-10^{-C_0 y(K[\mathrm{MA}]\varepsilon_C+\varepsilon_A)/(1+K[\mathrm{MA}])}} \quad (1)$$

where ε_C and ε_A are the molar extinction coefficients of the complex and anthracene at the excitation wavelength, respectively. K is the equilibrium constant between free anthracene and maleic anhydride and their complex. The fluorescence lifetime of anthracene without quencher is given by τ and the quenching rate constant is represented by k. C_0 is the total concentration of anthracene and y is the optical path length of the cell.

The absorbance, A, of anthracene solution containing maleic anhydride of the concentration [MA] at the excitation wavelength (370 nm) and the absorbance, A_0, of anthracene solution without quencher at the same wavelength have the following relationship.

$$A/A_0 = \left(1+K\frac{\varepsilon_C}{\varepsilon_A}[\mathrm{MA}]\right)\Big/(1+K[\mathrm{MA}]) \quad (2)$$

Here $K=0.05$ mol^{-1} dm^3. Then we can estimate $\varepsilon_C/\varepsilon_A$ from the observed A/A_0, which is 3.4. Furthermore, from the data in the low quencher concentration region (below 0.074 mol dm^{-3}) in Fig. 2, τk is estimated to be 61.4 mol^{-1} dm^3. Combining the respective values of $\varepsilon_A(2.7\times10^6$ mol^{-1} cm^2), $C_0(7.5\times10^{-5}$ mol dm^{-3}) and y (1 cm) with K, $\varepsilon_C/\varepsilon_A$ and τk, the I_0/I values represented by Eq. 1 can be calculated as the function of [MA]. The results are shown by a dashed curve in Fig. 2. We can see from this figure that the values calculated by Eq. 1 are much smaller than the observed ones. Therefore we conclude that the ground state complex formation (mechanism 1) is a minor contributing factor in the nonlinear relationship between I_0/I and [MA].

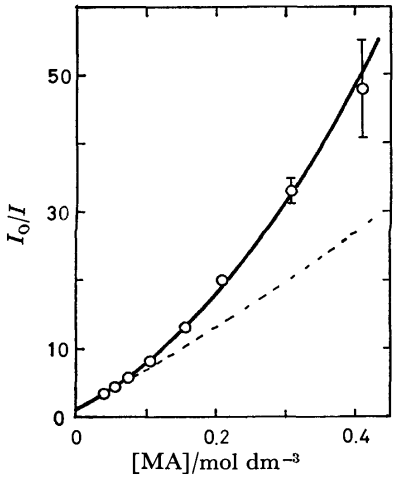

Fig. 2. Results of the steady-state intensity measurement of fluorescence from anthracene quenched by maleic anhydride in 1,4-dioxane at 20°C.
Open circles, experimental values; solid curve, calculated values for I_0/I from Eq. 3 with parameters from Table 1; dashed curve, calculated values for I_0/I from Eq. 1.

The decrease in the anthracene concentration by photochemical and/or thermal reactions with maleic anhydride during the measurement may decrease the fluorescence intensity of anthracene. The decrease was determined to be 1.6% at [MA]=0.42 mol dm^{-3} by the absorption spectrum measurement. Mechanism 2, thus, contributes little to the nonlinearity of I_0/I-[MA] plot.

The internal filter effect (mechanism 3) is estimated from the increase in absorbance brought about by the addition of maleic anhydride in the wavelength region of fluorescence. The maximum quencher concentration in the steady-state experiment is 0.42 mol dm^{-3}, and the maximum increase in absorbance in the fluorescence spectral region was 0.01 (388 nm). This means that the fluorescence intensity is reduced by this effect by 2.3%. The decrease of 2.3% in the intensity is much less than the observed decrease of 44%. Consequently mechanism 3 can be ruled out.

According to Förster's theory the rate constant for the dipole-dipole energy transfer depends on the overlap of the fluorescence spectrum of an energy donor and the absorption spectrum of an energy

acceptor. In the present case there is no overlap between the fluorescence spectrum of anthracene and the absorption spectrum of maleic anhydride. So we can rule out mechanism 4.

According to the modified theory by Andre *et al.* on the diffusion-controlled fluorescence quenching process, I_0/I is expressed by the following equation.[6]

$$I_0/I = \exp(NV[\mathrm{MA}])\ (1+4\pi RDN\tau[\mathrm{MA}])\ Y^{-1} \quad (3)$$

where R is a reaction distance. D represents the sum of diffusion constants of a fluorophor and a quencher, and N is Avogadro's number devided by 1000. Y and V are represented as follows:

$$Y = 1 - (b/a^{1/2})\pi^{1/2} \exp(b^2/a)\ \mathrm{erfc}\ (b/a^{1/2}),$$

$$\mathrm{erfc}\ (x) = \frac{2}{\sqrt{\pi}}\int_x^\infty \exp(-u^2)\mathrm{d}u, \quad V = \frac{4\pi}{3}(R^3 - R'^3),$$

$$a = \frac{1}{\tau} + 4\pi RDN[\mathrm{MA}], \quad b = 4R^2(\pi D)^{1/2}N[\mathrm{MA}]$$

where R' is a collisional distance which is taken as the sum of molecular radius of anthracene (3.51 Å) and that of maleic anhydride (2.63 Å). The molecular radii were determined from Lebas volume.[7]

R and D were determined by fitting the above theoretical expression to the observed dependence of I_0/I on [MA] shown in Fig. 2. In actuality the least-squares method was used for the determination. The values best fitted to the observed I_0/I-[MA] curve are listed in Table 1.

Table 1. The reaction distances (R's) and the sums of diffusion constants (D's)

	R/Å	$D/10^{-5}$ cm^2 s^{-1}	Temp/°C
From steady-state experiment	7.4	1.3	20±2
From decay curves			
[MA]/mol dm^{-3}			
0.214	7.2±1.4	1.56±0.4	22±1
0.428	7.2±0.7	1.36±0.2	22±1
0.208	7.2±0.7	1.87±0.2	50±1
0.202	7.2±0.7	2.42±0.2	75±1

Picosecond Emission Spectroscopy. The transient effect in the diffusion-controlled fluorescence quenching process can be observed directly by the picosecond laser photolysis technique. We can ascertain the applicability of the diffusion model to this system by comparing R and D values obtained by the picosecond photolysis technique with those obtained from the steady-state experiment.

The observed decay curves at various conditions are shown in Fig. 3 by open circles. In order to analyze these curves one must take into account the time profile of excitation pulse, $P(t)$, and the response function of the detection system, $G(t)$. The output from the detection system, $H(t)$, is given by the convolution integral as follows:

$$H(t) = \int_{-\infty}^{\infty}\int_{-\infty}^{t'} G(t-t')P(s)F(t'-s)\mathrm{d}s\mathrm{d}t', \quad (4)$$

where $F(t)$ is the undistorted response function of the fluorescent system. $P(t)$ is assumed to be a Gaussian

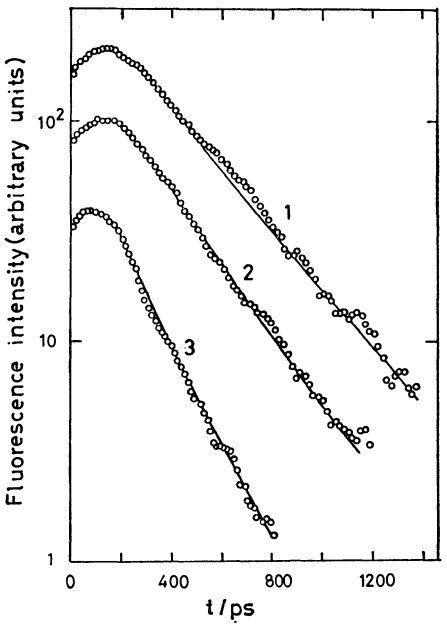

Fig. 3. Time dependence of anthracene fluorescence intensity quenched by MA in 1,4-dioxane.
Curve 1, [MA]=0.208 mol dm^{-3} at 50°C; curve 2, [MA]=0.202 mol dm^{-3} at 75°C; curve 3, [MA]=0.428 mol dm^{-3} at 22°C. Open circles are the observed values and solid lines the best fitted curves calculated by using the parameters in Table 1 and the corresponding MA concentration.

function with a parameter determined by the laser pulse width which was measured by two-photon fluorescence technique. $G(t)$ is also assumed to be a Gaussian function whose parameter is determined by the observed width of the excitation light pulse. If the fluorescent systems (anthracene molecules in the case of the present experiment) are quenched by the other molecules (maleic anhydride molecules) by the diffusion-controlled process, $F(t)$ is expressed in terms of $\exp(-at-2bt^{1/2})$. $H(t)$ was obtained numerically by computer calculation with various sets of R and D values. R and D were then estimated from the curve best fitted to the observed time profile of the fluorescence intensity.

The solid curves in Fig. 3 are the calculated curves of $H(t)$ that best fitted for the observed values. R and D values determined from these decay curves are listed in Table 1. The errors were estimated by comparing the caculated $H(t)$'s with the observed decay curves. R and D obtained from the decay curves at 22 °C agree well with those obtained from the steady-state experiment. This agreement justifies the application of the diffusion model to the fluorescence quenching process of anthracene by maleic anhydride in 1,4-dioxane.

The temperature dependence of D can be estimated by using the Stokes-Einstein equation:

$$D = \frac{k_B T}{6\pi\eta}(r_{An}^{-1} + r_{MA}^{-1}) \quad (5)$$

where k_B and T have ordinary meanings. η is the viscosity of the solvent. r_{An} and r_{MA} are the radii of anthracene and maleic anhydride, respectively. Anthracene and maleic anhydride molecules are, in fact, not

spherical. However, for the sake of simplicity we applied the above equation, and the radii of anthracene and maleic anhydride were determined by using Lebas volume.[7] The calculated D's are 1.18×10^{-5} cm^2 s^{-1} (22 °C), 2.03×10^{-5} cm^2 s^{-1} (50 °C), and 2.97×10^{-5} cm^2 s^{-1} (75 °C). A fairly good agreement is obtained with the D's obtained from the picosecond photolysis experiment.

The Main Path in Fluorescence Quenching Process. Following four possibilities for the main path in fluorescence quenching by the quencher were examined; 1) the formation of fluorescent exciplex, 2) photochemical Diels-Alder reaction, 3) the enhancement of intersystem crossing by charge-transfer interaction,[8] 4) photoionization. The possibility of formation of fluorescent exciplex was denied, because no detectable fluorescence appeared in the range from 375 nm to 750 nm by the addition of maleic anhydride to the 1,4-dioxane solution of anthracene. The adduct formation is not the main path in fluorescence quenching process because the quantum yield of the adduct formation was reported to be 0.026 at 26 °C with [MA]=0.5 mol dm^{-3}.[1]

TABLE 2. THE DEPENDENCE OF ABSORBANCE OF THE $T_n\leftarrow T_1$ TRANSITION OF ANTHRACENE IMMEDIATELY AFTER EXCITATION ON MALEIC ANHYDRIDE CONCENTRATION

[MA]/mol dm^{-3}	Absorbance of $T_n\leftarrow T_1$ transition
0	0.309
0.116	0.058
0.290	0.024
0.580	too weak to be observed

The absorbance was monitored at 425 nm. The concentration of anthracene is 3.9×10^{-3} mol dm^{-3}.

The dependence of absorbance of the $T_n\leftarrow T_1$ transition immediately after excitation on quencher concentration was studied by nanosecond laser photolysis. The results are shown in Table 2. The absorbance decreases remarkably as the quencher concentration increases. Maleic anhydride absorbs excitation light at 337.1 nm. However, the effect of this absorption upon the absorbance of the $T_n\leftarrow T_1$ transition is negligibly small, because the molar extinction coefficient at 337.1 nm is 1260 times smaller for maleic anhydride than for anthracene. Furthermore, the first excited triplet state (T_1) of anthracene was not drastically quenched by maleic anhydride, since at [MA]=0.32 mol dm^{-3} the lifetime of T_1 of anthracene was longer than 2 μs. Therefore we conclude that the intersystem crossing of anthracene cannot be enhanced by maleic anhydride.

The possibility of photoionization was examined by the nanosecond laser photolysis techniques. The anthracene cation radical, whose absorption maximum was near 720 nm,[9,10] was not observed at [anthracene]=10^{-2} mol dm^{-3} and [MA]=1 mol dm^{-3} in either 1,4-dioxane or acetonitrile. In the cases of anthracene (2.7×10^{-3} mol dm^{-3}) and pyromellitic dianhydride (2.2×10^{-2} mol dm^{-3}), and anthracene (2.4×10^{-3} mol dm^{-3}) and phthalic anhydride (1.9×10^{-2} mol dm^{-3}) in acetonitrile, the anthracene cation radical was observed by using the same experimental equipment. The quantum yield of photoionization is expected to increase with the increase in electron affinity of the acceptor. The electron affinities of pyromellitic dianhydride, maleic anhydride, and phthalic anhydride are 0.85 eV, 0.57 eV, and 0.15 eV, respectively.[11] The quantum yield of photoionization is very small for the system containing anthracene and maleic anhydride in acetonitrile compared with the others. This means that an extra channel which overwhelms the photoionization process should exist in the quenching process of excited singlet state anthracene by maleic anhydride. The process may be, for example, a formation of the biradical intermediate proposed by Kaupp,[3] or a formation of a very short-lived ion-pair whose main decay path is neither fluorescent exciplex formation, free ion formation, triplet anthracene formation, nor adduct formation.

The authors wish to express their gratitude to Mr. Hiroyuki Ohtani, The University of Tokyo, for his technical assistance in the picosecond laser photolysis experiment.

Photodissociation Spectroscopy and Photoreactions in *t*-Butylbenzene Cation and Its Daughter Cations

Yoshiya TAKENOSHITA*,† and Robert C. DUNBAR††

Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106, U.S.A.

(Received January 21, 1980)

Photodissociation spectra were observed for *t*-butylbenzene cation (*m/e* 134) and its daughter ion (*m/e* 119). Photoproduction spectra of the ions at *m/e* 119 and *m/e* 91 were observed in the visible region. It was shown that the photodissociation of *m/e* 134 yields *m/e* 119 almost 100% at wavelengths above 450 nm. Below 450 nm *m/e* 91 and *m/e* 57 appear as light-produced species. From pressure dependence and double resonance results, it was concluded that *m/e* 91 is a direct photoproduct from *m/e* 119, and that *m/e* 57 is produced in an ion-molecule reaction of *m/e* 91 with neutral *t*-butylbenzene. The photodissociation spectrum of *m/e* 119 is very similar to that of *m/e* 105 obtained by protonation of styrene, and it is reasonable to assume that *m/e* 119 has the protonated methylstyrene structure.

The photochemistry of gas-phase ions is conveniently studied using techniques of ion cyclotron resonance.[1-4] Aromatic radical ions have been particularly well explored, and many aspects of their spectroscopy and photochemical reactions have begun to be clarified, leaving a rich variety of unresolved and interesting questions.

The photodissociation spectrum of *t*-butylbenzene ion(I) was measured by Dymerski *et al.*[5] using steady-state ICR technqiues, showing, as is typical of alkylbenzene ions,[6] a broad photodissociation feature in the visible, and a peak near 270 nm. At wavelengths above about 400 nm, the only observed product was *m/e* 119, corresponding to loss of CH_3 (Eq. 1):

$$\underset{\text{I}}{C_6H_5C(CH_3)_3^+} \xrightarrow{h\nu} \underset{\text{II}}{C_9H_{11}^+} + CH_3\cdot \qquad (1)$$

(*m/e* 134) (*m/e* 119)

However, at shorter wavelengths another product ion was observed at *m/e* 57 ($C_4H_9^+$). The possibility of this being a direct photodissociation product, formed in competition with the less energetic *m/e* 119 product channel, is an interesting one. The 57^+ product channel is about 7 kcal more endothermic than the 119^+ channel;[7] competitive fragmentation to both products would be interesting, and might turn out to be indicative of non-statistical (non-RRKM) dissociation. However, the steady-state ICR technique is well known to have difficulty in distinguishing between direct photoproducts and subsequent ion-molecule reaction products,[3] and it seemed desirable to reexamine this photodissociation chemistry using the more powerful methods of pulsed ICR spectroscopy.

Experimental

The application of ion cyclotron resonance (ICR) spectroscopic techniques to studying photodissociation spectroscopy and ion photochemistry has often been described.[1-4] For one-photon photodissociations, the photodissociation cross section is obtained in the pulsed ICR technique from the extent of ion disappearance following illumination for a time τ:

$$\sigma = -[1/(I\tau)]\cdot\ln[(M_0^+ - M^+)/M_0^+] \qquad (2)$$

where M_0^+ and M^+ are the signal intensities of parent ions respectively without and with light, and I is the photon flux. Equivalent information can be obtained by observing the appearance of photoproduct ions under illumination.[8] The instrument and techniques used have been described.[2,3]

Commercial *t*-butylbenzene was used without further purification with a sample pressure ranging from 8×10^{-9} to 4×10^{-8} Torr, ionizing electron energy of 12 eV, and trapping times in the range 1—3 s. The detection radio frequency was 137.4 kHz, and the magnetic field varied from 3 to 11 kG to observe mass numbers from 41 to 134. Light from a 2.5 kW Hg–Xe arc lamp was wavelength-selected with a Schoeffel GM-250 monochromator at a resolution (FWHM) of 14 nm.

The ratio of signal intensities [119+]/[134+] was found very sensitive to electron beam parameters in the low-energy region used in this work, and varied from day to from about 1.2 to 1.8. The sum of [119+] and [134+] signal intensities was, however, kept constant within 20% in order to maintain constant ion density conditions in the cell. Representative photodissociation results are displayed in Fig. 1. All of the curves plotted in Figs. 2, 3, and 4 were obtained by measuring the extent of light-induced increase or decrease of the ap-

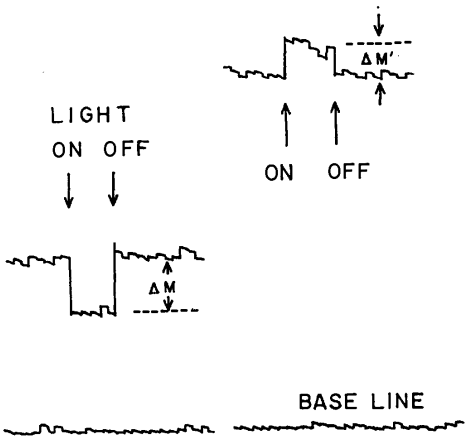

Fig. 1. Change under illumination of ICR signal intensities of *m/e* 134 (left) and *m/e* 119 for light at 440 nm. Neutral pressure was 3×10^{-8} Torr and reaction time τ was 3.0 s. ΔM denotes the signal decrease of *m/e* 134, and $\Delta M'$ denotes the signal increase of *m/e* 119.

propriate ion, and dividing by (I) for photoproduction curves, or applying Eq. 2 for photodisappearance curves.

Results and Discussion

The visible-region photodissociation (photodisappearance) spectrum of the t-butylbenzene cation (m/e 134) is shown in Fig. 2, along with the photoproduction spectra of the ions at m/e 119 and m/e 91, whose abundance increases when the light is turned on. Above 450 nm m/e 119 is the only observed photoproduct under any conditions, and accounts quantitatively for all of the photolyzed parent ion, indicating that Eq. 1 is the only photodissociation process, and that the m/e 119 ion is stable against both photodissociation and ion-molecule reaction processes.

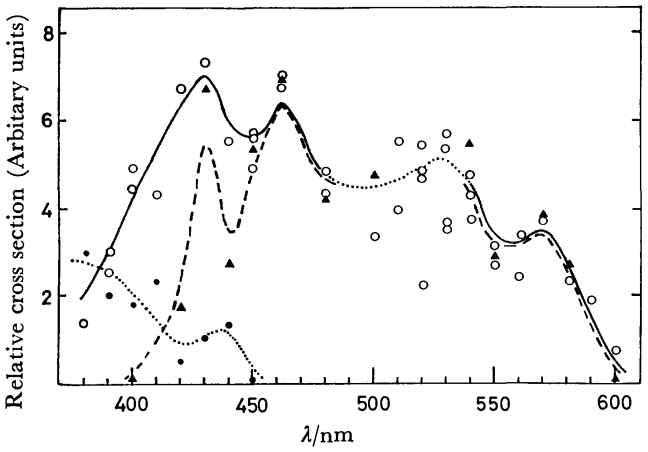

Fig. 2. Photodissociation spectrum of t-butylbenzene cation (m/e 134) (—○—), and the photoproduction spectra of its daughter ions m/e 119 (---▲---) and m/e 91 (···●···). While not absolute, the units for the three curves are consistent, so that the extent of parent-ion destruction and product-ion production may be directly compared. The pressure was 4×10^{-8} Torr, the reaction time τ was 3.0 s, and the errors of wave length are almost ±7 nm.

However, at shorter wavelengths the photochemistry becomes more complex, and ions at m/e 91 and m/e 57 become prominent as light-produced species. Figure 3 shows the complete photodisappearence spectrum of m/e 134, and shows that at shorter wavelengths, m/e 119 also decreases under illumination. Figure 4a shows that m/e 91 and m/e 57 increase under illumination parallel to the decrease in m/e 119.

The ion m/e 91 is evidently a direct photoproduct from m/e 119, but m/e 57 is not: at shorter times and lower pressure, as indicated in Fig. 4b, m/e 57 virtually disappears, and is apparently an ion-molecule reaction product from m/e 91. The photochemistry in this system is thus governed by three processes, Eqs. 1, 3, and 4.

$$\underset{(m/e\ 119)}{C_9H_{11}^+} \xrightarrow{h\nu} \underset{(m/e\ 91)}{C_7H_7^+} + C_2H_4 \qquad (3)$$

$$\underset{(m/e\ 91)}{C_7H_7^+} \xrightarrow{C_{10}H_{14}} \underset{(m/e\ 57)}{C_4H_9^+} + \text{Neutral products} \qquad (4)$$

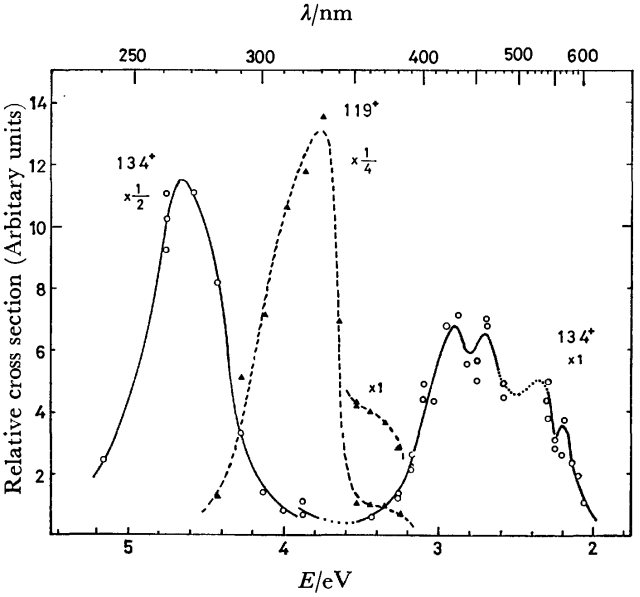

Fig. 3. Photodisappearance spectra of m/e 134 (—○—) and m/e 119 (---▲---). The intensity units are consistent for the two curves, and are also consistent with those of Fig. 2, (but note that this figure plots photodisappearance of m/e 119, while Fig. 2 plotted photoproduction of m/e 119 at the longer wavelengths involved). Pressure and τ as in Fig. 2.

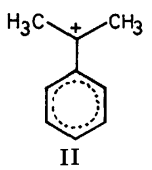
Further confirmation of this sequence is provided by the double resonance results shown in Fig. 4b: the ejection of m/e 119 results in a large decrease in m/e 91, supporting the assignment of Eq. 3 as the immediate source of m/e 91. Ejection of m/e 134 gives a lesser, but still significant decrease in m/e 91, reflecting the two-reaction sequence connecting these two ions.

Under the conditions of Fig. 4a, about half of the m/e 91 ions are converted to m/e 57 over most of the wavelength range; the sharp increase in the [57]/[91] ratio near 320 nm (where both the photon flux and the m/e 119 photodissociation cross section are large) apparently reflects the extremely rapid conversion of m/e 119 to m/e 91 at this wavelength, giving, Eq. 4 more time to move further toward completion.

The photodissociation spectrum of the m/e 119 ion reflected in Fig. 3, while subject to some distortion by photoproduction of 119 by Eq. 1, is probably reasonably faithful from 3.3 to 4.3 eV. This spectrum, with a strong peak at 3.8 eV and a small peak around 3.4 eV, is very similar to the photodissociation spectrum of m/e 105 obtained by protonation of styrene[9] (showing a strong peak at 3.9 eV, and a weaker one near 3.1 eV). It is thus reasonable to assume that the m/e 119 ion produced by electron impact from t-butylbenzene has the protonated methylstyrene structure II. Since the



II

background of electron-impact-produced m/e 119 ions

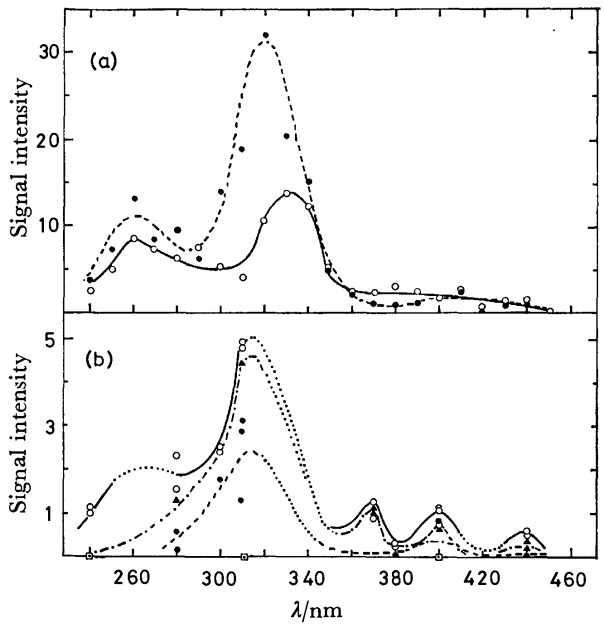


Fig. 4. a): Photoproduction curves for *m/e* 91 (—○—) and *m/e* 57 (---●---). Pressure and τ as in Fig. 2.
b): Photoproduction of *m/e* 91 using double resonance ejection of possible precursors: (—○—) shows *m/e* 91 production without double resonance; (---▲---) shows *m/e* 91 production with ejection of *m/e* 134, and (---●---) shows *m/e* 91 production with ejection of *m/e* 119. The pressure was 2.4×10^{-8} Torr, and τ was 1.0 s. Under these conditions of lower pressure and shorter τ, there was no observable signal for *m/e* (⊡).

was larger than the photoproduced *m/e* 119 ion, it was not possible to analyze separately the photoproduct ions of Eq. 1.

Reaction 4 can be visualized as a simple displacement of the *t*-butyl group by C_7H_7 on the neutral *t*-butylbenzene, although of course the present results give no information about the actual mechanism. Assuming the neutral product of this reaction to be diphenylmethane, the reaction is calculated to be exothermic by a few kcal/mol.

Conclusion

Considerable complexity has been found in the photochemistry of *t*-butylbenzene ions at shorter wavelengths, with the final product ion, *m/e* 57, terminating a sequence of two successive photodissociations and an ion-molecule reaction. No evidence was found for competitive dissociation of I into two different product channels, however, and the observed chemistry seems to be satisfactorily accounted for within the assumption that Reaction (1) is the only photoreaction of the parent ion I.

(Received January 9, 1980)

The reaction of halogenonitrobenzenes (XNBs) with electrogenerated superoxide ion in *N,N*-dimethylformamide was studied electrochemically using cyclic voltammetry (CV) and controlled potential macro-electrolysis. It was shown in the CV that electro-generated superoxide ion reacts with all of the *o*- and *p*-isomers of iodo-, bromo-, and chloronitrobenzene in the dissolved oxygen medium. However the superoxide ion did not react with the other XNBs during CV. Controlled potential macro-electrolysis of oxygen in the presence of *o*- and *p*-bromonitrobenzene yielded the corresponding nitrophenols as the main products. The reaction mechanism *via* nucleophilic attack of the superoxide ion on the XNB, in the preference to an electron-transfer mechanism, is proposed.

Electrochemical reduction of oxygen dissolved in non-aqueous organic solvents,[1-4] such as pyridine, acetonitrile, and *N,N*-dimethylformamide (DMF), occurs at *ca.* −0.85 V *vs.* silver–silver chloride (Ag/AgCl) and yields, reversibly, superoxide ion as shown in Eq. 1:[5-7]

$$O_2 + e \rightleftharpoons O_2^{\cdot-} \quad (1)$$

Recently, several studies regarding chemical reactions of electro-generated superoxide ion with organic compounds have been reported. Dietz *et al.*[8] suggested that superoxide ion in nonaqueous solvents possesses various reactivities, namely characteristics of a strong base, nucleophile, oxidant, reductant, and free radical. During the past several years we have studied the reactivity of electro-generated superoxide ion with alkylbenzenes,[9,10] methylpyridines and methylpyridine *N*-oxides.[11] Simultaneously we have studied the reaction of electro-generated superoxide ion with halogenonitrobenzenes (XNBs), expecting to observe the electron transfer reaction of superoxide ion. At the almost same time as this work was presented,[12] Rosenthal and Frimer also reported that superoxide ion solubilized in benzene by crown ether reacts rapidly with electron acceptors such as nitro substituted hydrocarbons and halides.[13]

There are several reports on the electrochemical reaction of XNBs in nonaqueous solvents, using electrochemical methods such as cyclic voltammetry and polarography.[14-17] However, electrochemical studies in the presence of oxygen have not previously been published. The cyclic voltammetric behavior of oxygen in the presence of some XNBs seemed to be interpretable in terms of the same mechanism as for catalytic reduction of aromatic halides, *via* electron transfer from the electro-generated radical anion to aromatic halides, as reported Lund *et al.*[18]

However, after detailed investigation using macro-electrolysis and cyclic voltammetry in DMF, we have concluded that the reaction mechanism of the system should be considered more in terms of a nucleophilic reaction of electro-generated superoxide ion[19-23] with XNBs than in terms of the electron transfer reaction of electro-generated superoxide ion to XNBs followed merely by elimination of halide ion. We report here the reaction of electro-generated superoxide ion with XNBs using macro-electrolysis and cyclic voltammetry in DMF solution, and discuss the results in terms of the nucleophilicity and reductant properties of superoxide ion.

† On leave from Department of Organic Chemistry, University of Aarhus, DK-8000, Aarhus C, Denmark.

Experimental

Materials. DMF was dried over anhydrous $CuSO_4$ for 24 h and then distilled under reduced pressure. Further purification was achieved by passage through a column of molecular sieve (4A 1/16) and activated alumina (both pretreated by heating at 400 °C). Tetraethylammonium perchlorate (TEAP) was synthesized and purified in the usual manner.[24] Iodonitrobenzenes (INBs), bromonitrobenzenes (BNBs), chloronitrobenzenes (CNBs), and fluoronitrobenzenes (FNBs) of E. P. grade were purchased commerically (Wako Pure Chemical Industries) and were recrystallized or distilled before use.

Cyclic Voltammetry. Cyclic voltammetry was carried out in DMF solution containing 0.1 M (1 M=1 mol dm^{-3}) TEAP as a supporting electrolyte on a hanging mercury drop electrode (HMDE). The cathode potential was referred to Ag/AgCl, aq 1 M KCl. Cyclic potential sweeps were generated by an NF Circuit Desigh Block FG-100AD function generator in connection with a potentionstat which was self-made according to the literature.[25]

Controlled Potential Macro-electrolysis. For controlled potential macro-electrolysis, a three compartment cell was employed in which the cathodic and anodic chambers were separated by two porous glass disks and a reference electrode with a Luggin capillary was put near the cathode. A mercury pool with a surface area of 16 cm^2 was used as the cathode, and platinum gauze as the anode. The electrolyte solution (0.1 M TEAP) of 60 cm^3 containing 0.06 M substrate was placed in the cathodic chamber, 40 cm^3 of electrolyte solution in the anodic chamber, and 10 cm^3 of electrolyte solution in the middle chamber. Oxygen was bubbled through the catholyte. The cathode potential was controlled with a Yanagimoto VE-8 controlled potential electrolyzer.

Separation of Products and Determination of the Yields. The main products of the electrolyses, nitrophenols, were separated and identified by the following procedure. The catholyte was poured into 200 cm^3 of 10% aqueous $NaHCO_3$ solution. Starting material and products other than nitrophenols were removed by extraction with CH_2Cl_2. The aqueous layer was evaporated to dryness *in vacuo* to remove DMF. The resulting solid was dissolved in water and acidified with 5% aqueous

HCl. The liberated nitrophenol was extracted with ether and purified by recrystallization from ethanol and weighed. The crystalline nitrophenol was identified by comparing its melting point and infrared spectrum (IR) with those of an authentic sample. The by-products of electrolysis, such as nitrobenzene and dinitrobiphenyls, were detected by using a Shimadzu gas chromatograph Model GC-6A equipped with 2 m×3ϕ SUS column packed with Silicone OV-1, and identified by comparing their retention times with those of authentic samples. Yields of products were also determined by gas chromatographic analysis.

Results and Discussion

Controlled Potential Macro-electrolysis. The reduction peak potentials of cyclic voltammograms of XNBs, together with those for oxygen, nitophenols, and nitrobenzene, are listed in Table 1. The controlled potential macro-electrolysis of oxygen in the presence of *p*-bromonitrobenzene (*p*-BNB) was carried out at −0.9 V in DMF solution. At −0.9 V, oxygen was reduced to superoxide ion while *p*-BNB was not reduced. The results of electrolysis are collected in Table 2. *p*-BNB reacted with electro-generated superoxide ion to yield *p*-nitrophenol as the main product. Trace amounts of nitrobenzene and 4,4′-dinitrobiphenyl were detected as by-prodects. In order to investigate the positional effect of the nitro group attached to the benzene ring, macro-electrolyses of oxygen in the presence of *o*- and *m*-BNB were also carried out. *o*-BNB reacted with electro-generated superoxide ion to yield *o*-nitrophenol as the main product. Trace amounts of nitrobenzene and 2,2′-dinitrobiphenyl were detected as by-products. *m*-BNB did not react with electro-generated superoxide ion and starting material was recovered.

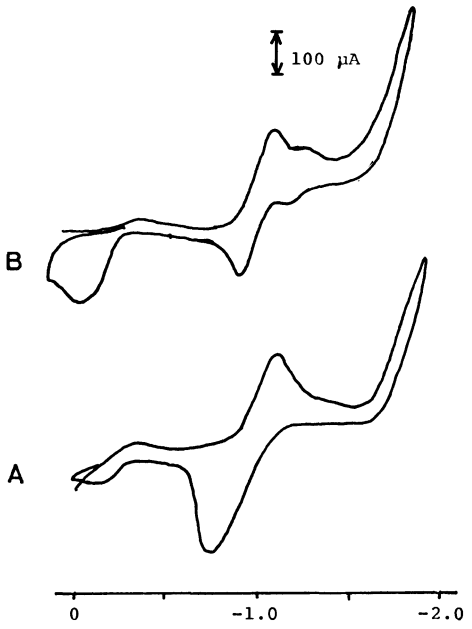

Fig. 1. Cyclic voltammograms of the catholyte in the course of the electrolysis at −0.9 V in the presence of *p*-bromonitrobenzene (oxygen is removed from the solution).
Electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}, A: after 1 h, B: after 6 h.

Cyclic Voltammetry of the Catholyte. In the course of macro-electrolysis of oxygen at −0.9 V in the presence of *p*-BNB, cyclic voltammetry of the catholyte was carried out. The result is shown in Fig. 1. A and B are the cyclic voltammograms of the catholyte after 1 h and 6 h respectively from commencement of macro-electrolysis. During these cyclic voltammetric experiments, oxygen was removed by bubbling nitrogen. Since *p*-BNB remained as a major substrate in the solution, two large reduction waves observed at *ca.* −1.1 V and −1.8 V are attributed to *p*-BNB. The oxidation wave at *ca.* −0.13 V results from bromide ion as is described later. While no reduction wave other than that for *p*-BNB is appreciable on curve A, a new reduction wave is apparent at *ca.* −1.3 V on curve B. On curve B, the oxidation peak height of bromide ion is greater in comparison with that on curve A.

Cyclic Voltammetry of Bromonitrobenzenes (BNBs). In order to clarify the reaction mechanism of the reaction of electro-generated superoxide ion with XNBs,

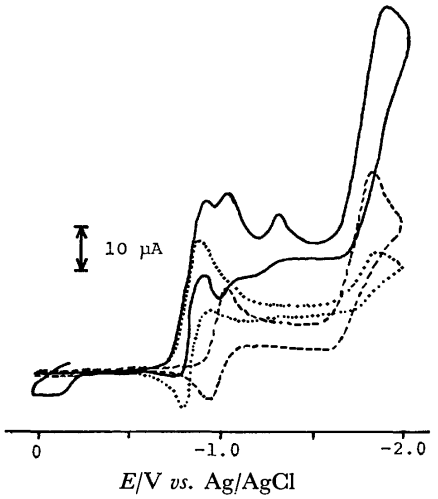

Fig. 2. Cyclic voltammograms of *p*-bromonitrobenzene. Concentration of *p*-bromonitrobenzene: *ca.* 1 mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}, ——: in the presence of air-saturated oxygen, ------: in the absence of oxygen, *cf.* ·····: cyclic voltammogram of air-saturated oxygen.

cyclic voltammetry of *o*-, *m*-, and *p*-BNB was carried out under air-saturation and under a nitrogen atmosphere. The cyclic voltammetric behaviors of *p*-BNB are shown in Fig. 2. The broken line represents the cyclic voltammogram of *p*-BNB under a nitrogen atmosphere and the solid line that under air-saturation. The dotted line represents the cyclic voltammogram of air-saturated oxygen. For *p*-BNB under a nitrogen atmosphere, only a reversible reduction wave at −1.0 V and an irreversible reduction wave at *ca.* −1.8 V were observed. On the other hand, under air saturation, a new reduction wave at *ca.* −1.3 V appeared on the first cathodic sweep, and another new wave was seen at *ca.* −0.13 V on the anodic sweep, in addition to the waves observed for oxygen alone and for *p*-BNB under nitrogen. On the subsequent cathodic sweep, a new wave, corresponding to the reduction of the oxidation product at −0.13 V, appeared at *ca.* −0.17 V. The peak potential of the new wave at −1.3 V corresponds accidentally to the first reduction peak potential of *p*-nitrophenol as is shown in Fig. 3. The first reduction wave of *p*-nitrophenol is the phenoxide formation from phenol.[26] Consequently the new reduction wave may not be that of *p*-nitrophenol because *p*-nitrophenol exists as phenoxide in such an aprotic medium as DMF even if *p*-nitrophenol is formed during cyclic voltammetry. The product showing this new reduction wave seemed to be dinitrophenyl peroxide as described later. Since the peak height of the redox wave near −0.15 V increased on addition of NaBr, this redox wave is attributed to the redox reaction of bromide ion at the mercury electrode. Consequently these additional wave of bromide and the product, observed only in the case of the simultaneous electro-reduction of oxygen, suggest the following. (1) The electro-generated superoxide ion reacted with *p*-BNB to release bromide ion and to give the redox wave during cyclic voltammetry. (2) A compound probably assigned dinitrophenyl peroxide was produced during cyclic voltammetry by the reaction of electro-generated superoxide ion with *p*-BNB.

In the cyclic voltammogram of *p*-BNB under air-saturation, the first reduction peak height of oxygen at *ca.* −0.85 V increased, and the reoxidation peak height of superoxide ion at −0.80 V diminished, in comparison with those of air-saturated oxygen in the absence of *p*-BNB (dotted line in Fig. 2). These behaviors depended on the concentration of *p*-BNB. In order to clarify the dependence of the increase of the reduction peak height of oxygen on the concentration of *p*-BNB, cyclic voltammetry of oxygen in the presence of increasing concentrations of *p*-BNB was carried out in the potential region

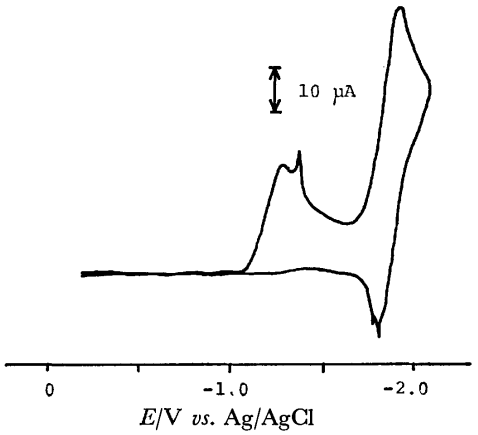

Fig. 3. Cyclic voltammogram of *p*-nitrophenol under nitrogen atmosphere.
Concentration of *p*-nitrophenol: *ca.* 10 mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}.

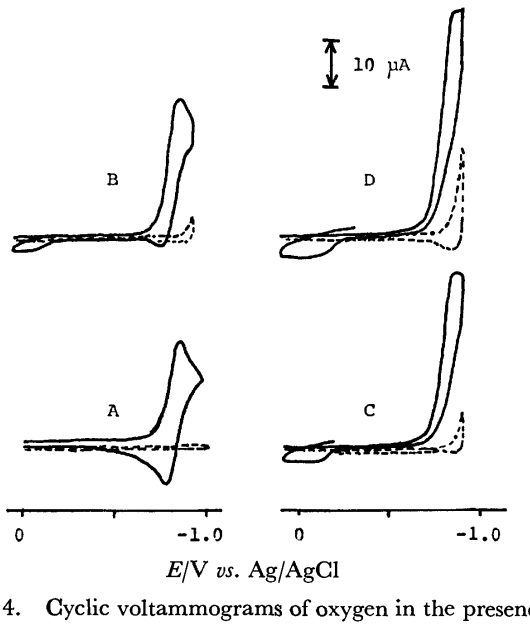

Fig. 4. Cyclic voltammograms of oxygen in the presence of increasing concentration of *p*-bromonitrobenzene. A: 0 mM, B: *ca.* 1 mM, C: *ca.* 4 mM, D: *ca.* 8 mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}, ——: air-saturation, ------: under nitrogen atmosphere.

from 0 to −1.0 V. The results are shown in Fig. 4. A is the cyclic voltammogram of air-saturated oxygen in the absence of *p*-BNB. Cyclic voltammograms of oxygen in the presence of increasing concentrations of *p*-BNB are shown in Figs. 4B, C, and D, in the order of increasing concentrations of *p*-BNB. Increasing concentration of *p*-BNB resulted in a corresponding increase in the reduction peak height of oxygen. This increase in height with increasing concentration of *p*-BNB did not continue infinitely but reached a limit. The maximum value of the ratio, i_c/i_p, for *p*-BNB is *ca.* 2, where i_c is the reduction peak height of oxygen in the presence of XNB and i_p is the peak height in the absence of XNB. Under a nitrogen atmosphere no oxidation wave corresponding to that of bromide ion appeared, as shown in Fig. 4A, while in the presence of air-saturated oxygen the oxidation wave of bromide ion was observed and the peak height increased with increasing concentration of *p*-BNB. Disappearance of the oxidation wave of superoxide ion indicates that the electro-generated superoxide ion was consumed by subsequent chemical reaction during cyclic voltammetry in the presence of a high concentration of *p*-BNB.

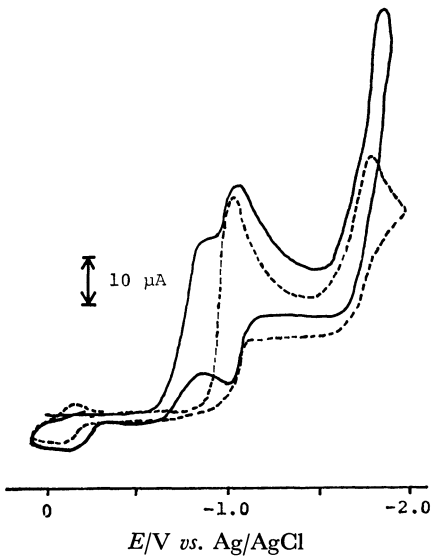

Fig. 5. Cyclic voltammograms of *o*-bromonitrobenzene. Concentration of *o*-bromonitrobenzene: *ca.* 10 mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}, ——: in the presence of air-saturated oxygen, ------: in the absence of oxygen.

In order to investigate the positional effect of the nitro group attached to the benzene ring, cyclic voltammetry of oxygen in the presence of increasing concentrations of *o*- and *m*-BNB was also carried out. The reduction peak height of oxygen increased in the presence of increasing concentration of *o*-BNB. This increase did not continue infinitly and the maximum of the i_c/i_p ratio for *o*-BNB is also *ca.* 2. Cyclic voltammetric behaviors of *o*-BNB in the presence and in the absence of oxygen are shown in Fig. 5. Under nitrogen atmosphere, the first reduction wave of *o*-BNB on the first cathodic sweep is irreversible, while that of *p*-BNB is reversible, and a redox wave corresponding to that of bromide ion appeared on the anodic sweep and on the subsequent cathodic sweep in spite of the absence of oxygen. In the presence of oxygen, the oxidation peak height of bromide ion also increased compared with that observed under a nitrogen atmosphere though the new reduction wave corresponding to the reduction of a product are not recognized. It is concluded from these results that bromide ion is released from *o*-BNB by an electrochemical reaction of *o*-BNB itself, but the reaction of electro-generated superoxide ion with *o*-BNB accelerates this release of bromide ion.

In the cyclic voltammogram of *m*-BNB in the presence of oxygen, no reduction wave appeared other than those for oxygen and *m*-BNB. An increased concentration of *m*-BNB did not results in a corresponding increase in the reduction peak height of oxygen, or in diminution of the reoxidation peak height of superoxide ion, in these cyclic voltammograms of oxygen in the presence of *m*-BNB. These results indicate that the electro-generated superoxide ion does not react with *m*-BNB during their cyclic voltammetry.

In order to investigate the difference in reactivity of electro-generated superoxide ion towards XNBs, dependent on the nature of substituted halogen, cyclic voltammetry of INBs, CNBs, and FNBs in the presence and in the absence of oxygen was carried out and is described in the following sections.

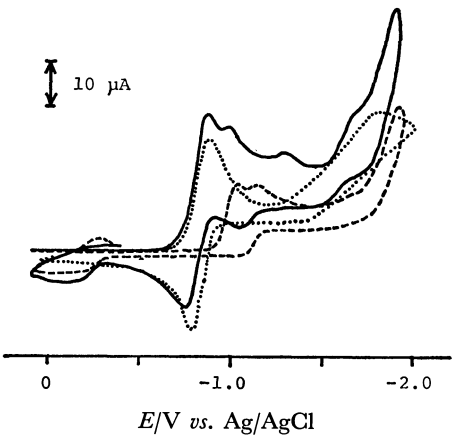

Fig. 6. Cyclic voltammograms of *p*-iodonitrobenzene. Concentration of *p*-iodonitrobenzene: *ca.* 1 mM, electrolyte: 0.1 M TEAP/DMF, electrode: HMDE, sweep rate: 0.1 V s^{-1}, ——: in the presence of air-saturated oxygen, ------: in the absence of oxygen, *cf.* ·····: cyclic voltammogram of air-saturated oxygen.

Cyclic Voltammetry of Iodonitrobenzenes (INBs). The cyclic voltammetric behavior of *p*-INB in the presence and in the absence of air-saturated oxygen is shown in Fig. 6, together with that of oxygen in the absence of *p*-INB. For *p*-INB under nitrogen, there are well-defined reduction waves near −1.0, −1.15, and −1.90 V on the cathodic sweep, and an oxidation wave near −0.2 V on the anodic sweep.[16b] On the subsequent cathodic sweep, a new reduction wave corresponding to reduction of the oxidation product apperaed at *ca.* −0.25 V. Since the oxidation peak height at −0.2 V increased on addition of NaI as

for the bromide peak described above, this oxidation wave is assigned to that of iodide ion. Under air-saturation, two new reduction waves at *ca.* −1.30 V and −1.75 V appeared as well as those for oxygen and *p*-INB, and the peak height of the oxidation wave at *ca.* −0.2 V was increased in comparison with that under a nitrogen atmosphere. The first reduction peak height of oxygen increased and the reoxidation peak height of superoxide ion diminished as compared with that for air-saturated oxygen in the absence of *p*-INB (dotted line in Fig. 6).

The cyclic voltammetric behavior of *o*-INB in the presence and in the absence of oxygen is almost identical to that of *p*-INB except absence of the new reduction wave of the product in the presence of oxygen corresponding to that appeared at −1.3 V for *p*-INB. An increase in the concentration of *o*- and *p*-INB resulted in a corresponding increase in the reduction peak height of oxygen in the cyclic voltammograms. Maximum values of the ratio, i_c/i_p, for both *o*- and *p*-INB are also *ca.* 2. In the cyclic voltammogram of *m*-INB in the presence of oxygen, no reduction wave appeared other than those for oxygen and *m*-INB as for *m*-BNB. The reduction peak height of oxygen in the presence of *m*-INB did not increase in comparison with that of air-saturated oxygen in the absence of *m*-INB.

Cyclic Voltammetry of Chloronitrobenzenes (CNBs). The cyclic voltammetric behavior of *o*-, *m*-, and *p*-CNB in the presence and in the absence of oxygen are almost identical to those of *o*-, *m*-, and *p*-BNB, respectively. Namely, *o*- and *p*-CNB readily react with electro-generated superoxide ion while *m*-CNB dose not. The ratio, i_c/i_p, for *o*- and *p*-CNB also reached a limit with increase in the concentration of *o*- and *p*-CNB, and their maximum values were *ca.* 2.

Cyclic Voltammetry of Fluoronitrobenzenes (FNBs). Reversible and irreversible reduction waves appeared near −1.1 and −2.0 V in the cyclic voltammograms of *o*-, *m*-, and *p*-FNB under a nitrogen atmosphere. In the cyclic voltammograms of *o*-, *m*-, and *p*-FNB in the presence of oxygen, no reduction waves other than those for oxygen and FNB appeared. The electro-generated superoxide ion did not therefore react with FNBs during their cyclic voltammetry. Although an increase in the reduction peak height of oxygen was observed in the presence of *o*- and *p*-FNB, the maximum values of the ratio, i_c/i_p, are close to unity, *ca.* 1.1, compared with *ca.* 2 in the presence of *o*- and *p*-isomers of other XNBs. In the presence of *m*-FNB, this increase in the reduction peak height of oxygen was not observed.

Reaction Mechanism for the Reaction of Superoxide Ion with Halogenonitrobenzenes (XNBs). A mechanism for the reaction of electro-generated superoxide ion with XNBs can be proposed as shown in Schemes 1 and 2. Scheme 1 represents S_N2 type reaction mechanism. This S_N2 type reaction of superoxide ion is well known with alkyl halides and alkyl sulfonate esters.[22,23] Electrochemically produced superoxide ion at −0.85 V attacks the carbon atom bearing halogen on the XNB to release halide ion (Eq. 2). The resulting peroxyl radical is readily reduced, by superoxide ion or at the electrode, to peroxide anion $ArOO^-$ (Eq. 3). Scheme 2 represents the electron-transfer mechanism. Electron transfer reactions between superoxide ion and aromatic nitro compounds have been reported.[13] An electron is transferred from electro-generated superoxide ion to XNB to give an anion radical $[ArX]^{\cdot}$ and oxygen is regenerated (Eq. 5). Halide ion is released from the anion radical $[ArX]^{\cdot}$ to yield phenyl radical Ar· (Eq. 6). Peroxide anion $ArOO^-$ is then produced according to Eqs. 7 and 3. In both mechanisms two electrons per molecule of oxygen are necessary to finally obtain the peroxide anion.

$$O_2 + e \rightleftarrows O_2^{\cdot} \quad (1)$$
$$O_2^{\cdot} + ArX \longrightarrow ArOO\cdot + X^- \quad (2)$$
$$ArOO\cdot + O_2^{\cdot} \longrightarrow ArOO^- + O_2 \quad (3)$$
overall: (1)×2+(2)+(3)
$$O_2 + ArX + 2e \longrightarrow ArOO^- + X^- \quad (4)$$

Scheme 1.

$$O_2 + e \rightleftarrows O_2^{\cdot} \quad (1)$$
$$O_2^{\cdot} + ArX \longrightarrow [ArX]^{\cdot} + O_2 \quad (5)$$
$$[ArX]^{\cdot} \longrightarrow Ar\cdot + X^- \quad (6)$$
$$Ar\cdot + O_2 \longrightarrow ArOO\cdot \quad (7)$$
$$ArOO\cdot + O_2^{\cdot} \longrightarrow ArOO^- + O_2 \quad (3)$$
overall: (1)×2+(5)+(6)+(7)+(3)
$$O_2 + ArX + 2e \longrightarrow ArOO^- + X^- \quad (4)$$

Scheme 2.

Since in the cyclic voltammograms of *p*-BNB and *p*-CNB under a nitrogen atmosphere the oxidation wave of halide ion did not appear, the formed anion radicals $[ArX]^{\cdot}$ are stable so that the elimination reaction as described in Eq. 6 could not occur during the period of cyclic voltammetry. In the presence of oxygen as shown in Fig. 2, the oxidation wave of halide ion appeared. These results support nucleophilic attack of superoxide ion on *p*-BNB and *p*-CNB as described in Eq. 2. In the cyclic voltammograms of INBs, *o*-BNB, and *o*-CNB, the oxidation wave of halide ion appeared even under a nitrogen atmosphere, and in the presence of oxygen these halide peaks increased further. These results indicate that these anion radicals $[ArX]^{\cdot}$ are unstable compared with those of *p*-BNB and *p*-CNB, and that the electron transfer reaction of superoxide ion to XNB (Eq. 5) proceeds forwards to some extent. If the superoxide ion reacts with XNB *via* an electron transfer mechanism, then the yield of nitrobenzene and dinitrobiphenyls should be great because of the production of radical Ar· (Eq. 6). However, as the main products of the macro-electrolysis of oxygen in the presence of *o*- and *p*-BNB were *o*- and *p*-nitrophenol respectively (Table 2), the contribution of the electron transfer reaction mechanism operating in these case is considered to be slight.

The difference in reactivity of electro-generated superoxide ion towards XNBs dependent on the nature of substituted halogen and on the position of the nitro group attached to benzene ring is discussed next. The maximum values of the ratio, i_c/i_p, of the reduction peak heights of oxygen in the presence of *o*- and *p*-

isomers of INB, BNB, and CNB are *ca.* 2. This result corresponds well with the fact that two electrons are necessary to produce peroxide anion $ArOO^-$ from XNB in Scheme 1, but disagrees with usual EC catalytic mechanism.[27] In the cyclic voltammograms of the *m*-isomers of INB, BNB, and CNB, the reduction peak heights of oxygen did not increase in the presence of high concentrations of XNB. In the case of FNBs, the reduction peak heights of oxygen did not increase even in the presence of *o*- and *p*-FNB. It has been reported that potassium superoxide reacted with some nitrophenyl halides[13] as electro-generated superoxide reacted with XNBs in this work but did not react with phenyl halides.[22] The difference in reactivity between nitrophenyl halides and phenyl halides is interpretable in terms of activation by the nitro group on the benzene ring. In the cyclic voltammograms of XNBs in the presence of oxygen, the high reactivities of *o*- and *p*-isomers of XNB, other than FNB, to superoxide ion are manifest, but the reactivity of *m*-isomers of XNB is seen to be very low.

The wave corresponding to the oxidation of peroxide anion $ArOO^-$ did not appear in Figs. 2, 5, and 6. This is probably due to the fact that its oxidation potential may be more positive than the measured potential region, as for alkylperoxide anion,[19] and also due to its reaction with XNB to yield bis(nitrophenyl) peroxides,[19] ArOOAr (Eq. 8). In general, the reduction peaks of dialkylperoxides appear at more negative potentials than −2.0 V *vs.* SCE (Et_2O_2; −2.15 V, Bu_2O_2; −2.19 V, $Bu^t{}_2O_2$; −2.4 V *vs.* SCE).[19] Since the bis(nitrophenyl) peroxides formed in this study have two nitro groups, their reduction peak potential should be more positive than those of dialkyl compounds. The first reduction potentials of organic nitro compounds between −1.0 and −1.2 V *vs.* SCE. The reduction of bis(nitrophenyl) peroxides by electrogenerated superoxide ion cannot occur because the maximum value of the i_c/i_p ratio is not over two. Consequently the reduction potentials of bis(nitrophenyl) peroxides lie at more negative potential than that of oxygen. The reduction wave of the bis(*p*-nitrophenyl) peroxide may correspond to the new reduction wave at *ca.* −1.3 V in Figs. 2 and 6, and that of the bis(*o*-nitrophenyl) peroxide may overlap with those of *o*-XNBs, and thus the new wave are not appreciable in Fig. 5.

As probable mechanisms for formation of phenols, two mechanisms can be proposed in the same manner as

$$ArOO^- + ArX \longrightarrow ArOOAr + X^- \quad (8)$$

$$ArOOAr + O_2^{\cdot-} \longrightarrow ArO_3\cdot + ArO^- \quad (9)$$
$$\longrightarrow ArOOAr, ArO^-, O_2$$

$$ArOOAr + O_2^{\cdot-} \longrightarrow ArO\cdot + ArO^- + O_2 \quad (10)$$

$$ArO\cdot + O_2^{\cdot-} \longrightarrow ArO^- + O_2 \quad (11)$$

Scheme 3.

$$ArOO^- + CH_3\overset{\overset{O}{\|}}{S}CH_3 \longrightarrow ArO^- + CH_3\overset{\overset{O}{\|}}{S}CH_3 \quad (12)$$

Scheme 4.

for the reaction of superoxide ion with alkyl halides[28,29] as shown in Schemes 3 and 4. If Reaction 9 or 10 and 11 proceed rapidly, the ratio i_c/i_p will exceed two due to the regeneration of oxygen *via* these reactions. Since the observed ratios were *ca.* 2, these reactions might be too slow to occure in the period of cyclic voltammetry.[19] On the other hand, nitrophenols can be formed without further consumption of electron *via* reaction 12 shown in Scheme 4. However this reaction is characteristic of dimethyl sulfoxide, and it is hardly applicable to the reaction in DMF.[29] Thus in the present system nitrophenols may be formed *via* the mechanism shown in Scheme 3 rather than the mechanism in Scheme 4. However, as shown in Fig. 1B, the appearance of the new reduction peak at *ca.* −1.3 V attributed to ArOOAr are clear, while the wave corresponding to the reduction of phenoxide is difficult to appreciate due to overlapping of the expected wave to that of the abundant starting material. From these results, therefore, it is not clear yet whether phenol obtained was produced during the macro-electrolysis according to the mechanism described in Scheme 3 or it was produced during the procedure for separation and purification. However it is difficult to determine the more probable mechanism for formation of nitrophenols between the reaction path of Reaction 9 and that of Reactions 10 and 11 from our present results.

We thank the Japan Society for the Promotion of Science for the Provision of Funds during the period (Feb—April 1976) when one of us (H.L.) was a Visiting Professor at Tohoku University. The present work was partially supported by a Grant-in-Aid for Scientific Reseach No. 47017 from the Ministry of Education, Science and Culture.

(Received January 29, 1980)

The preparation and properties of a water soluble porphyrin having functional groups, α,β,γ,δ-tetrakis[1-(2-hydroxyethyl)pyridinium-4-yl]porphine, are described. This porphyrin is water soluble from below pH 0 to above pH 14. Acid-base titration revealed the diprotonated diacid-monocation equilibrium ($pK_4=1.0$) and the monocation-free base equilibrium ($pK_3=1.9$) in the acidic range and the free base-monoanion equilibrium ($pK_2=13.0\pm0.2$) in the basic region. The zinc, iron, and cobalt derivatives of the porphyrin were also synthesized and purified. Catalytic properties of the iron and cobalt complexes for reduction of molecular oxygen in water are reported in terms of cyclic voltammetry. The electrochemical reduction utilizing these complexes was interpreted to proceed *via* electrochemical catalytic regeneration mechanism as had been observed for tetrakis(1-methylpyridinium-4-yl)porphinatoiron(III). The apparent rate constants for electron transfer from the iron and cobalt porphyrins to oxygen were estimated to be $3—4\times10^7$ and 1×10^7 dm^3 mol^{-1} s^{-1}, respectively.

Since its magnificent achievement[1] by Hans Fischer as long as a half century ago, porphyrin synthesis has been constantly of primary importance among many investigators. Hitherto various porphyrin skeltons occurring naturally have been synthesized, and the use of modified or newly prepared porphyrins with simpler structure has accumulated ample information for various purposes.[2] Especially recent advent of water soluble porphyrins accelerated a new field to open in their chemistry. Their demand is expanding not only as model compounds related to living body but also from industrial point of view. Recently, in relation to the study to find effective energy conversion/storage systems such as fuel cells, an eminent catalytic capability of α,β,γ,δ-tetrakis(1-methylpyridinium-4-yl)porphinatoiron(III) (Abbr; $Fe^{III}TmP$) has attracted attention[3,4] for the reduction of molecular oxygen to hydrogen peroxide.

In this paper, preparation and spectroscopic properties of a new water soluble porphyrin having hydroxyl groups, α,β,γ,δ-tetrakis[1-(2-hydroxyethyl)pyridinium-4-yl]porphine (Abbr; ThoepyP), and its zinc, iron and cobalt derivatives (Abbr; Zn^{II}ThoepyP, Fe^{III}-ThoepyP, and Co^{III}ThoepyP, respectively) are reported. Catalytic aspects of Fe^{III}ThoepyP and Co^{III}ThoepyP for the reduction of molecular oxygen to hydrogen peroxide are also presented in terms of cyclic voltammetry, in comparison mainly with the results reported for $Fe^{III}TmP$[3] and iron and cobalt tetrakis-(*o*-aminophenyl)porphines (Abbr; Fe^{III}TapP and Co^{III}TapP, respectively).[5]

Experimental

Materials. Most of the chemicals were commercially available guaranteed reagents and used without further purification. 2-iodoethanol was prepared from 2-chloroethanol and excess sodium iodate in dry acetone under reflux. 0.05 M Sulfuric acid (abbr; H_2SO_4) for cyclic voltammetric experiments was obtained from H_2SO_4 and doubly distilled water. Glassy carbon electrodes (area 0.785 cm^2) were purchased from Tokai Carbon Co. Ltd. and polished to a bright surface with alumina powder (final polish using 0.05 μm particle size), washed with 0.05 M H_2SO_4 and distilled water.

α,β,γ,δ-Tetrakis[1-(2-hydroxyethyl)pyridinium-4-yl]-porphinatozinc(II) Tetraiodide, Zn^{II}ThoepyP. α,β,γ,δ-Tetra-4-pyridylporphinatozinc (II), Zn^{II}TpyP, was prepared by the method of Fleischer.[6] *N*-Hydroxyethylation was accomplished accoriding to the same method of *N*-methylation[7] using *ca.* 300 molar excess of 2-iodoethanol, although reaction time was 2 d rather than 10 h.[8] Yield 54%. Found: C, 41.91; H, 3.39; N, 7.91%. Calcd for $Zn_1C_{48}H_{44}N_8O_4I_4$: C, 42.09; H, 3.24; N, 8.18%.

α,β,γ,δ-Tetrakis[1-(2-hydroxyethyl)pyridinium-4-yl]porphine Hexachloride, ThoepyP. The *N*-hydroxyethylated diacid was prepared by stirring 2.36 g of Zn^{II}ThoepyP in 600 cm^3 of 1.5 M H_2SO_4. When the dark blue solid dissolved to form a green solution, 190 g of sodium perchlorate was added, immediately producing a green precipitate of perchlorate salt. The mixture was refrigerated for 12 h and the precipitate was isolated by filtration, half dried in air, and acetone was added to the still moist product to wash away extra sodium perchlorate. The residue was dissolved in distilled water and imposed on an anion–exchange resin (Dowex 2X-8, Cl form) to get chloride salt solution, which was evaporated to dryness. The crude solid was recrystallized from water–methanol–ether. Drying at 110 °C for 14 h left 1.12 g (69%) of a solid. Found: C, 56.21; H, 4.61; N, 10.37%. Calcd for $C_{48}H_{48}N_8O_4Cl_6$: C, 56.99; H, 4.59; N, 11.08%.

α,β,γ,δ-Tetrakis[1-(2-hydroxyethyl)pyridinium-4-yl]-porphinatodiaquairon(III) Pentachloride, Fe^{III}ThoepyP. ThoepyP 400 mg (0.425 mmol) and *ca.* 600 mg of $FeCl_2\cdot nH_2O$ were heated at reflux in water (50 cm^3) for 0.5 h, when metal incorporation was ascertained from absorption spectra in 450—700 nm region. The addition of 30 g of $NaClO_4$ caused dark brownish solution of the perchlorate salt of the aiming compound. The solution was chilled in a refregirator for 12 h and the product was collected on a funnel and washed with acetone containing 10 (v/v) percent ether to remove $FeCl_2\cdot nH_2O$ and $NaClO_4$. To further separate those concomitant inorganic salts more perferctly from the porphyrin, the crude solid was dissolved in a distilled water and imposed on a Sephadex LH-20 column. The elute was then passed through ion-exchange resin (Dowex 2X-8, Cl form) to get chloride salt. After evaporation of water, drying at 110 °C

for 12 h left 211 mg (48.3%) of the dark bluish solid. Found: C, 53.63; H, 4.65; N, 10.27%. Calcd for $Fe_1C_{48}H_{44}N_8O_4Cl_5(H_2O)_2$: C, 54.08; H, 4.54; N, 10.51%.

α,β,γ,δ-Tetrakis[1-(2-hydroxyethyl)pyridinium-4-yl]porphinatodiaquacobalt(III) Pentachloride, Co^{III}ThoepyP. Cobalt was incorporated into the porphyrin ring by refluxing water solution containing *ca.* 500 mg of $CoCl_2 \cdot 6H_2O$ and 300 mg (0.319 mmol) of ThoepyP for 2 h. Then the solution was treated in a manner described for Fe^{III}ThoepyP. Drying at 110 °C for 15 h in a reduced pressure left 119 mg (35%) of a bluish purple solid. Found: C, 52.44; H, 4.71; N, 10.10%. Calcd for $Co_1C_{48}H_{44}N_8O_4Cl_5(H_2O)_2$: C, 53.92; H, 4.53; N, 10.48%.

Measurement. Absorption spectra were measured with a JASCO UVIDEC-1 spectrophotometer. Cyclic potential sweeps were generated by an NF Circuit Design Block FG-100AD function generator in conjunction with a potentiostat which was home-made according to the literature.[9] Nitrogen 99.9% pure was used for dearation of all solutions, and 5 min of air bubbling was conducted in order to saturate a solution with oxygen. Potentials were referred to a saturated calomel electrode (SCE). pH values were measured with a Hitachi-Horiba M-7 pH meter.

Results and Discussion

Spectroscopy. Because of the presence of four hydroxyl groups and four quaternary ammonium groups, ThoepyP is highly water soluble from pH 0 to above 14 and slightly soluble even in methanol or ethanol. Spectrophotometric titrations were used to determine the acid-base equilibria present.

Equilibria at pH *0—7*: Table 1 lists the main absorption maxima and extinction coefficients of ThoepyP at various pH values, as well as those of some metallated

Table 1. Absorption maxima and extinction coefficients of ThoepyPs and some of its complexes in water

Compound	pH of medium	Absorption maxima/nm	Extinction coefficient (10^{-3})
Free base	5.64	422	202
		519	12.9
		557	7.0
		583	6.9
		641	2.7
Diacid	0.0	447	101
		593	8.2
		642	9.9
Monoanion	14.0	448	53.5
		578	8.3
		622	6.3
Zn^{II}ThoepyP	5.64	439	159
		563	15.2
		606	5.3
Fe^{III}ThoepyP	5.64	422	84.4
		519	9.3
		580(shoulder)	4.4
		638	3.5

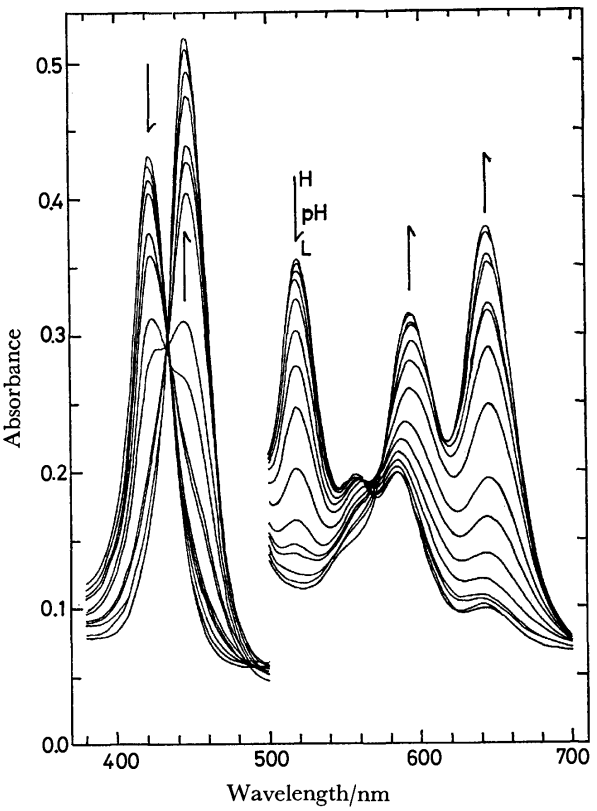

Fig. 1. Absorption spectra of ThoepyP when titrated with HNO_3 at $\mu=2.0$ ($NaNO_3$). The spectra are from pH 4.3 to 0.3. The Soret was run in 1 mm cells and visible in 10 mm cells, at the same concentration of ThoepyP (2.13×10^{-5} M). Temperature=21 °C

derivatives at neutral pH value. The four bands in the visible region from pH 4 to 7 were independent of pH value. Beer's law experiments (2×10^{-4}—3.7×10^{-6} M (1 M=1 mol dm^{-3})) conducted using the 447 and 422 nm bands at pH 0 and 7, respectively, gave linear plots at both wavelength maxima, indicating that the diacid and free base forms of the *N*-hydroxyethylated porphine are probably monomeric. Figure 1 shows spectrophotometric titrations from 380 to 700 nm of ThoepyP with nitric acid at ionic strength 2.0 ($NaNO_3$) at 21 °C. Seemingly one isosbestic point (435 nm) appeared in the Soret region, however, two isosbestic points were observed in the visible region at 562 and 575 nm corresponding to pH 4.3 to 1.6 and 1.5 to 0.3, respectively. Accordingly more than two protonated porphyrin species must be present between pH 0.3 and 4. Assuming that these species are to be diprotonated diacid (H_4P^{2+}), monocation (H_3P^+) and free base (H_2P), and that diacid-monocation, and monocation-free base equilibria

$$H_4P^{2+} = H_3P^+ + H^+ \qquad K_4 \qquad (1)$$

$$H_3P^+ = H_2P + H^+ \qquad K_3 \qquad (2)$$

are present and neglecting deviation of activity coefficients from unity, K_3 and K_4 were calculated from the visible region spectra, owing to the method by Baker *et al.*[10] That is, using the absorbance changes at high pH at 519 nm, K_3 could be obtained from the following

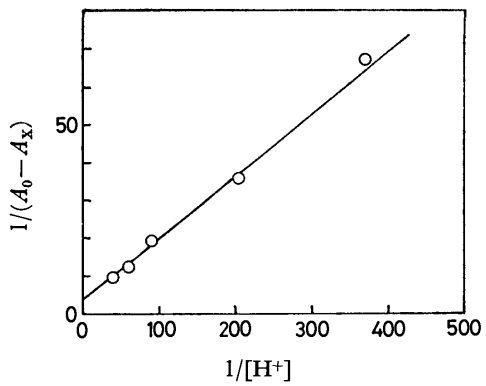

Fig. 2. Plot of $1/(A_0-A_x)$ *vs.* $1/[H^+]$ from the data in Fig. 1 to determine K_3 from Eq. 3. The wavelength is 517 nm for $\mu=2.0$. Temperature=21 °C

equation.[11]

$$\frac{1}{A_0-A_x}=\frac{K_3}{A_0-A_\infty}\frac{1}{[H^+]}+\frac{1}{A_0-A_\infty}, \qquad (3)$$

where A_0 and A_∞ are the absorbances of the free base and monocation forms of the porphyrin, and A_x is that of a mixture of H_3P^+ and H_2P at a constant wavelength. K_3 was calculated from the linear relationship between $1/(A_0-A_x)$ and $1/[H^+]$ to be *ca.* 1.3×10^{-2} (Fig. 2). K_4 was obtained from the low pH absorbances appeared at 562 nm to be *ca.* 10^{-1}. Therefore pK_4 and pK_3 of the equilibrium (1) and (2) are about 1.0 and 1.9, respectively. In agreement with the case for $\alpha,\beta,\gamma,\delta$-tetrakis(1-methylpyridinium-4-yl)porphine, TmpyP, pK_3 and pK_4 values were found to increase with ionic strength ($pK_4=1.2$, $pK_3=2.2$ at $\mu=5.0$).[10]

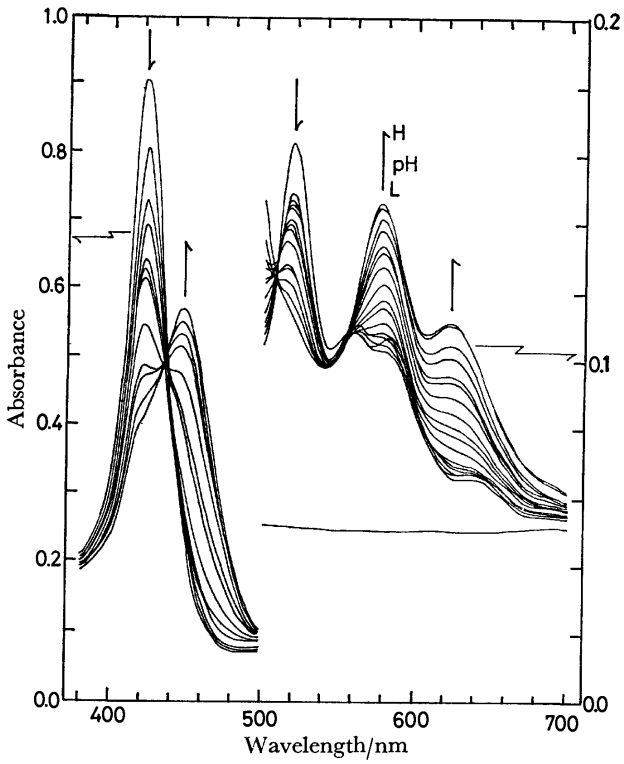

Fig. 3. Spectrophotometric titration of H_2P with NaOH forming HP^-.

Equilibria at pH *7—14*: To investigate the acidity of the free base, a spectrophotometric titration from pH 7 to 14 was performed with sodium hydroxide. Figure 3 shows the resulting titration of H_2P with sodium hydroxide and the isosbestic points at 556, 504, and 418 nm. Assuming that H_2P and monoanion, HP^-, are absorbing species, and that free base-monoanion equilibrium

$$OH^- + H_2P = HP^- + H_2O \qquad K_b \qquad (4)$$

is present, Eq. 5 is obtained.

$$\log [HP^-]/[H_2P] = \log K_b - p(OH) \qquad (5)$$

Thus the plots of the left-hand side of Eq. 5 *vs.* p(OH) should be linear with a slope of −1. The log ($[HP^-]/[H_2P]$) *vs.* p(OH) plots at 422, 578, and 622 nm (Fig. 4) showed a linear relation with an average slope of 1.0 ± 0.2 and a log K_b of 1.0 ± 0.2. Hence the dissociation constant, K_2, of the free base to monoanion and proton at 21 °C is 13.0 ± 0.2 in close accordance with the result for TmpyP (12.9 ± 0.2).[7]

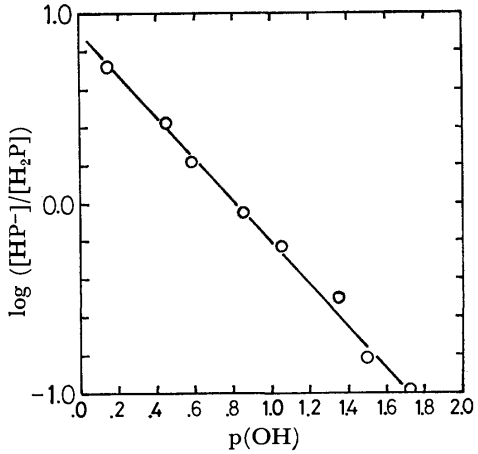

Fig. 4. Plots of log ($[HP^-]/[H_2P]$) *vs.* p(OH) at 578 nm to determine K_2 in Eq. 4.

As so far mentioned, ThoepyP as well as TmpyP[7] was found to exist from pH 0 to 7 as monomers of diacid, monocation, and free base forms in contrast to the trend that most porphyrins are apt to exist as dimers or polymers in solution, with formation constants large enough such that in the usual spectrophotometric concentration range (10^{-4} to 10^{-6} M), appreciable association occures.[12] Acid-base titmetric data were analyzed at a fixed ionic strength and temperature using Q bands because of their multiplicity. Results indicated that ThoepyP behaves apparently in the same fashion as TmpyP. The relatively low basicity and high acidity compared with other porphyrins[13] seem common aspects of porphyrins having quaternary ammonium ion and are not much influenced by the alkyl groups attached to nitrogen. A slight difference owing to side group was, however, reflected on the position of redox potential of its iron complex, a 0.020 V negative shift of ThoepyP (−0.048 V) from that of TmpyP (−0.028 V).

Cyclic Voltammetry. The cyclic voltammogram illustrated in Fig. 5 for Fe^{III}ThoepyP indicated an

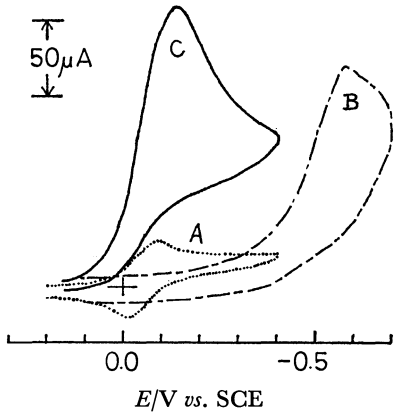

Fig. 5. Cyclic voltammetric current-potential curves at glassy carbon electrode in 0.05 M H_2SO_4. (A) 2.4×10^{-4} M Fe^{III}ThoepyP, saturated with N_2, scan rate= 64 mV s^{-1}: (B) only O_2 (air-saturated), scan rate=110 mV s^{-1}, replotted from Ref. 3; (C) 2.4×10^{-4} M Fe^{III} ThoepyP and O_2 (air-saturated), scan rate=64 mV s^{-1}.

electrochemical (*ec*) catalytic regeneration as for Fe^{III}TmP.[3]

$$Fe^{III}ThoepyP + e^- = Fe^{II}ThoepyP, \quad E_1 \qquad (6)$$

$$Fe^{II}ThoepyP + 1/2O_2 + H^+ \xrightarrow{k} Fe^{III}ThoepyP + 1/2H_2O_2, \qquad (7)$$

where Fe^{III}ThoepyP was reduced on the glassy carbon electrode and the generated Fe^{II}ThoepyP transferred its electron to oxygen, O_2, to return to the iron(III) porphyrin. The catalytic aspects of the O_2 electroreduction was recognized by comparing the cyclic voltammetric current-potential (*i-E*) curves, curve A to C in Fig. 5, (A) for a 0.05 M sulfuric acid solution containing 2.4×10^{-4} M Fe^{III}ThoepyP, (B) saturated with O_2 from the air, and (C) containing the iron porphyrin and saturated with O_2 from air, respectively. Although the O_2 reduction occurred at the peak potential, E_p, of *ca.* −0.057 V *vs.* SCE in the absence of Fe^{III}ThoepyP, the addition of the iron porphyrin shifted the reduction potential to −0.08 V which is close to redox potential of $Fe^{III/II}$ThoepyP (−0.06 V). The redox potential of $Fe^{III/II}$ThoepyP couple, trace A, was independent of scan rate, *v*, from 0.016 to 0.256 V s^{-1} and the separation between the cathodic and anodic potentials, ΔE_p, was 60—70 mV, which indicated that Reaction 6 was a diffusion controlled one-electron transfer reaction.

If the two-electron reduction of O_2 to form H_2O_2 in proton donating media is taken place rapidly, the theoretically calculated value[14,15] of the peak current versus square root of scan rate (i_p *vs.* $v^{1/2}$) would be 880 $\mu A(V/s)^{-1/2}$, assuming an O_2 concentration of 2.9×10^{-4} M[16] and a diffusion coefficient, D_{O_2}, value of 2.6×10^{-5} cm^2 s^{-1}.[17] At low concentration of the porphyrin (10^{-6}—10^{-5} M), the catalytic O_2 wave appeared as a prewave to the main O_2 wave and at potentials approximately corresponding to Reaction 6. With the increase of concentration of the iron porphyrin, the wave height dramatically increased, and at or above *ca.* 2×10^{-4} M, the i_p for the catalyzed wave became diffusion controlled in O_2. When this latter condition was satisfied, the slope of the i_p *vs.* $v^{1/2}$ approached to *ca.* 800 $\mu A(V/s)^{-1/2}$ which is close to that expected for a two-electron, diffusion controlled reduction of O_2 to hydrogen peroxide, H_2O_2, under reversible conditions. In alkaline pH solution (above *ca.* pH 11) the slope of the i_p *vs.* $v^{1/2}$ plot attained to the ideal value (880 $\mu A(V/s)^{-1/2}$). When the iron porphyrin concentration was much lower (*ca.* 10^{-6} M) than that of oxygen, the apparent rate constant for Reaction 7 was calculated using Eq. 8[18] from the height of the catalytic O_2 wave under the approximation of the pseudo first order *ec* catalytic mechanism with Reaction 7 being irreversible.

$$i_k = nFAC_{por}D_{por}^{1/2}k^{1/2}C_{O_2}^{1/2}, \qquad (8)$$

where i_k is the catalytic current observed in A, *F*; Faraday constant in C mol^{-1}, *A*; area of electrode in cm^2, C_{por}; concentration of porphyrin in mol cm^{-3}, D_{por}; diffusion coefficient of porphyrin in cm^2 s^{-1}, *k*; apparent rate constant in mol^{-1} cm^3 s^{-1} and C_{O_2}; concentration of oxygen in mol cm^{-3}. Taking the average of three independent experiments, the rate constant was calculated to be *ca.* $3—4\times10^{-7}$ dm^3 mol^{-1} s^{-1} for the 10^{-6} M iron porphyrin in air-saturated O_2 solutions (0.05 M H_2SO_4). This rate constant answers for why the catalytic wave becomes diffusion controlled in O_2 when the iron porphyrin concentration exceeds that of O_2.

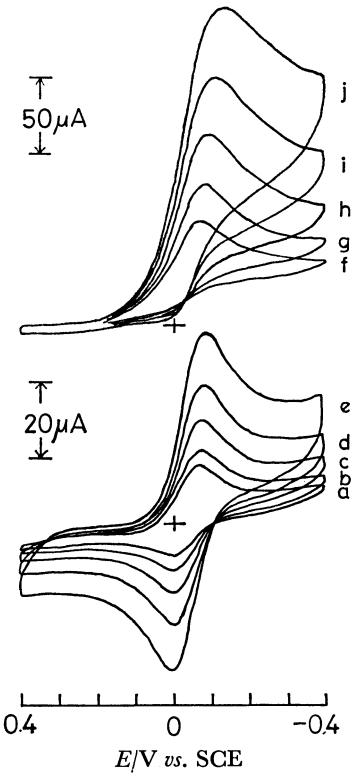

Fig. 6. Cyclic *i-E* curves of 2.4×10^{-4} M Co^{III}ThoepyP in 0.05 M H_2SO_4 at 16, 32, 64, 128, and 256 mV s^{-1}, N_2 saturated solution (a to e) and O_2 (air-saturated) solution (f to j).

Typical cyclic *i-E* curves are shown in Fig. 6 for 2.4×10^{-4} M Co(III)ThoepyP in 0.05 M H_2SO_4. In the potential range of +0.40 to −0.40 V under nitrogen, a well-defined voltammetric wave of a diffusion controlled electrode reaction was observed (line a to e). The $Co^{III/II}$ThoepyP redox potential was −0.035 V and their peak potentials (E_P = −0.07—−0.08 V) were almost independent of scan rate in the range from 0.016 to 0.256 V s^{-1}. When oxygen was introduced into the above solution (line f to j), a cathodic current increased at the peak potential of this cobalt complex and its peak height was linearly proportional to O_2 concentration at a constant scan rate. When this solution was fully saturated with air, the peak current increased at its potential with the increase of scan rate as seen for Fe^{III}ThoepyP. But the most distinct difference was the rate of increase. If we plot this peak current against $v^{1/2}$, its slope attains 490 $\mu A(V/s)^{-1/2}$ which is 56% of that theoretically expected for a two-electron, diffusion controlled reduction of O_2 under reversible conditions (880 $\mu A(V/s)^{-1/2}$). At low concentrations of the cobalt complex (10^{-6}—10^{-5} M), the catalytic O_2 wave appeared as a prewave to the main O_2 wave. As the concentration of the cobalt porphyrin increased, the wave height increased dramatically, and at or above 2.4×10^{-4} M, the i_p for the catalytic wave became saturated. Thus the above mentioned electrochemical behavior was similar in many points to that of Fe^{III}ThoepyP. So by applying *ec* catalytic regeneration mechanism, we evaluated the apparent rate constant for this system (which corresponds to k in Eq. 7) from the catalytic current when Co^{III}ThoepyP concentration is quite low. If we again assume the pseudo first order *ec* catalytic mechanism, the calculated rate constant was *ca.* 1×10^7 dm^3 mol^{-1} s^{-1} for the 10^{-6} M cobalt porphyrin in air-saturated solution (0.05 M H_2SO_4).

In the course of studies on various water soluble iron porpyrins such as Fe^{III}TpyP,[19] Fe^{III}TmP,[3] Fe^{III}-ThoepyP, and Fe^{III}TapP,[5] we could extract some electrochemically interesting features for those iron complexes as follows. (1) The redox potentials ranged between 0 and −0.06 V in 0.05 M H_2SO_4 solution and when cyclic voltammetric experiments were carried out in deaerated solution, they revealed *i-E* curves characteristic of a reversible diffusion controlled electrode reaction. (2) They could be good catalysts for the reduction of molecular oxygen and the potentials for the *ec* catalysis were governed by the $Fe^{III/II}$porphyrin redox couples which also depended on pH values; shifted to negative direction with the rise of pH value. (3) Electron transfer from electrode to oxygen by these complexes was so swift that if the porphyrin concentrations were enriched to some extent, then catalytic current became diffusion controlled in O_2, and the slope of the i_p *vs.* $v^{1/2}$ plot increased to that expected for a two-electron, diffusion controlled reduction of O_2 to H_2O_2 under "reversible conditions." (4) The apparent rate constants of the iron porphyrins to transfer electron(s) to oxygen were dissimilar among species used. For example that of Fe^{III}ThoepyP was estimated to be around 1/3—1/4 of that of Fe^{III}TmP (1.2×10^8 dm^3 mol^{-1} s^{-1}).[3]

In contrast to the case of iron porphyrins, only a few electrochemical studies[5,20] have been reported on the reduction of molecular oxygen with the cobalt incorporated water soluble porphyrins. Although we are still, in the present stage, in want of basic data if we dared to pick up what differed electrochemically from those of the corresponding iron porphyrins, they would be as follows. (1) The redox potentials were always more positive than those of corresponding iron porphyrins. (2) In common with the case of Co^{III}TapP[5] the slope of i_p vs. $v^{1/2}$ plots of O_2 reduction with Co^{III}-ThoepyP was approximately 60% of that of the corresponding iron porphyrin. Phenomenon (1) is easily understandable from the trend that potentials of metal(III/II) redox couple in the first transition metal period in the periodic table parallel to the 3rd ionic potentials, *i.e.*, metals which have less tendency to produce trivalent ions indicate more positive redox potentials.[21]

In order to estimate the apparent rate constant in Eq. 7, the assumptions have been made that these reactions proceeded *via ec* catalytic regeneration mechanism and that reactions were pseudo first order. However, we confronted the fact that these values depended on scan rates, though their degree was not so striking. For such a fact following three reasons may be casted. (1) Though reactions proceed *via ec* catalytic regeneration mechanism, O_2 concentration might be still too low compared with that of the porphyrins (10^{-6}—10^{-5} M) to postulate pseudo first order reaction. (2) Reaction in Eq. 7 *per se* may not simply be a pseudo first order. (3) Adosorption of porphyrins might be occurred. Within these possibilities, however, (3) is eliminated by the finding of the linearity of the i_p *vs.* $v^{1/2}$ plot from Fig. 6, curve a to e (not shown), because if adsorption occurred the slope would be increased with increment of scan rate.

Conclusion

It was indicated that ThoepyP behaves mostly in the same fashion as for TmpyP in water. Catalytic properties of its iron and cobalt complexes for reduction of molecular oxygen in water were recognized and interpreted to proceed *via ec* catalytic regeneration mechanism. The apparent rate constants for electron transfer from porphyrin to oxygen were calculated, assuming pseudo first order reaction, to be 3—4×10^7, and 1×10^7 dm^3 mol^{-1} s^{-1} for its iron and cobalt complexes, respectively. Simultaneously, the doubt was casted whether the above reactions were actually pseudo first order or not.

Direct Observation of the 1,4-Biradical of Benzophenone with *cis*-3-Methyl-2-pentene Excited by the Fourth Harmonic of a Nd:YAG Laser

Hisaharu HAYASHI

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received March 18, 1980)

Intermolecular biradical formation between the benzophenone triplet state with *cis*-3-methyl-2-pentene was studied by a ns laser-photolysis technique, the fourth harmonic (266 nm) of a *Q*-switched Nd : YAG laser being used as an exciting light source. We succeeded for the first time in observing the transient absorption due to the 1,4-biradical in the 380—300 nm region. Its lifetime was determined to be 25 ± 4 μs (in acetonitrile), 15 ± 4 μs (in methanol), and 6 ± 2 μs (in cyclohexane). Quenching experiments with methyl viologen dication were also carried out in order to assign the observed transient absorptions.

Photochemical reactions of benzophenone have been studied extensively as typical examples for those of carbonyl compounds.[1] Their primary processes are composed of: (1) triplet-triplet energy transfer, (2) hydrogen-abstraction reaction, and (3) biradical formation. Many studies on the processes (1) and (2) have been carried out with the aid of the time-resolved spectroscopy technique, their reaction intermediates being detected directly.[2-4] On the other hand, studies on the process (3) with the transient method are scanty.

Biradicals play important roles in photochemical reactions of carbonyl compounds.[1,5] Transient absorptions due to biradicals produced by the intramolecular hydrogen-abstraction reactions of valerophenones were recently found with the aid of the laser-photolysis technique.[6,7] Their spectra were found to resemble those of the triplet state and ketyl radical of acetophenone. The situation may be the same for the spectra of 1,4-biradicals formed from the triplet state of benzophenone with olefins.[5] Thus they may be expected to resemble the spectra of its triplet state and ketyl radical which have a strong peak at about 320 nm. However, no transient absorption due to the biradicals has ever been observed by the laser-photolysis technique using a *Q*-switched frequency doubled ruby laser (347.2 nm) or an N_2 laser (337.1 nm) as an exciting light source.[8] This is because it is very difficult to measure transient absorptions in the wavelength region shorter or slightly longer than that of the exciting light source.

Under these circumstances, we have undertaken to extend the measurement region to 300 nm by exciting samples by the fourth harmonic (266 nm) of a Nd: YAG laser and to detect the biradicals. Quenching experiments with methyl viologen dication (MV^{2+})[9] have also been carried out in order to confirm the assignment of the observed transient absorptions.

Experimental

Benzophenone (**1**) and methyl viologen hydrated were purified by repeated recrystallizations from ethanol and methanol–acetone (1 : 1) mixed solvent, respectively. *cis*-3-Methyl-2-pentene (*cis*-**2**) purified by vacuum distillation was used as olefin. Spectrograde acetonitrile, methanol, and cyclohexane were used as solvents without further purification.

Laser-photolysis measurements were made for degassed solutions at room temperature by using a Molectron UV-24 N_2 laser or the fourth harmonic of a Quanta-Ray DCR-1 Nd : YAG laser as an exciting light source. The laser pulse widths were 10 ns for the former and 5 ns for the latter. The details of the laser-photolysis apparatus have been published elesewhere.[7]

Results and Discussion

After exciting a ternary solution containing **1** and *cis*-**2** in acetonitrile with the fourth harmonic of the Nd : YAG laser, we have measured the time-dependence of its transient absorption, $I(t)$, in the 300—600 nm region. As examples the $I(t)$ curves observed at 520 and 330 nm for the solution containing **1** of 8.8×10^{-4} mol dm^{-3} and *cis*-**2** of 0.266 mol dm^{-3} are shown in Figs. 1 (a) and (b). We can see from Fig. 1(a) that the decay curve at 520 nm can be represented by a single exponential function with the lifetime (τ_1) of 15 ± 2 ns as follows:

$$I(t) = I_1 \exp(-t/\tau_1). \quad (1)$$

The decay curves at the different wavelength in the 380—600 nm region can also be represented by Eq. 1 with the same lifetime as that observed at 520 nm.

On the other hand, the decay curve at 330 nm is represented as follows:

$$I(t) = I_1 \exp(-t/\tau_1) + I_2 \exp(-t/\tau_2) + I_3. \quad (2)$$

Here τ_1 and τ_2 denote the fast and slow lifetimes, respectively, and they were determined to be 15 ± 2 ns and 25 ± 4 μs from Figs. 1(a) and (b), respectively. The fast lifetime is equal to that obtained at 520 nm. The third term on the right side of Eq. 2 is a constant component in the observed time range (shorter than 140 μs).[10] The decay curves at the different wavelength in the 300—380 nm region can also be represented by Eq. 2 with the same lifetimes as those observed at 330 nm.

It is well known that the primary photochemical processes of **1** with *cis*-**2** and MV^{2+} are shown by the following scheme:[1,5,9,11]

$$\mathbf{1} \xrightarrow{h\nu} S_1 \quad (3)$$

$$S_1 \xrightarrow{k_{ISC}} T_1 \quad (4)$$

$$T_1 \xrightarrow{k_T} \mathbf{1} \quad (5)$$

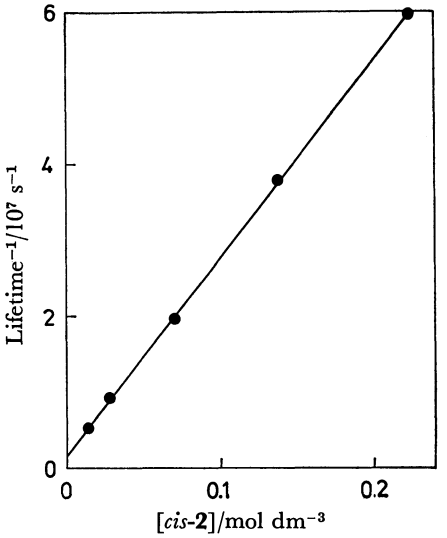

Fig. 3. Stern-Volmer relation between the inverse of the lifetime ($1/\tau_1$) observed at 520 nm and [*cis*-**2**] for the ternary solution containing **1** (8.8×10^{-4} mol dm^{-3}) and *cis*-**2** in acetonitrile

Here S_1 and T_1 are the lowest excited singlet and triplet states of **1**, respectively. RH is a hydrogen donor and K· is the benzophenone ketyl radical. The rate constants of the respective processes are represented by k_{ISC}, k_T, k_H, k_q, k_B, k_a, k_b, and k_c.

Time-resolved absorption spectra were measured before and after quenching of T_1 by *cis*-**2** with the result shown in Fig. 2. Spectrum I measured immediately after excitation of the acetonitrile solution containing **1** and *cis*-**2** is identical with that of the triplet-triplet (T_n—T_1) absorption of **1**[4] and corresponds to the spectrum before quenching of T_1, while Spectrum II measured 800 ns after excitation of the solution is a new one observed for the photochemical reaction of **1**. Thus the observed short lifetime (τ_1) corresponds to the quenching process of T_1 by *cis*-**2** and, as is shown in Fig. 3, the following Stern-Volmer relation was proved

to be fulfilled for this process:[12]

$$1/\tau_1 = k_T + k_{sv}[cis\text{-}2]. \quad (12)$$

Here k_{sv} is the slope of the $1/\tau_1$—[*cis*-**2**] plot in Fig. 3 and corresponds to either k_H or k_q. From the observed straight line in Fig. 3, the k_T and k_{sv} values were determined to be 1.4×10^6 s^{-1} and 2.7×10^8 s^{-1} mol^{-1} dm^3, respectively.

Spectrum II is not due to the triplet state of *cis*-**2** from the following reasons: (1) Upon exciting the acetonitrile solution of *cis*-**2** (0.32 mol dm^{-3}) with the fourth harmonic of the Nd : YAG laser, no transient absorption could be observed in the 300—600 nm region. (2) The energy level of its lowest triplet state is considered to be higher than that of T_1.[5] Furthermore, Spectrum II is not due to the ketyl radical of **1** from the following reasons: (1) The ratio of the absorbance of the peak at 530 nm (P_L) to that at 320 nm (P_S) for the ketyl radical was observed to be 0.25.[4] On the other hand, the P_L/P_S value for Spectrum II was observed to be nearly zero. (2) The k_{sv} value for this system is larger than the k_H one for the reaction of T_1 with cyclohexene in benzene (5.1×10^7 s^{-1} mol^{-1} dm^3),[12] in spite of the fact that the hydrogen-donating ability of cyclohexene is much larger than that of *cis*-**2**.[13] This means that Spectrum II is due to a product other than the ketyl radical. Therefore, the remaining possible assignment of Spectrum II is either due to the biradical or oxetane. But no electronic transition has been observed for 2,2-diphenyloxetanes at the wavelength longer than 300 nm.[14] Thus Spectrum II and the observed k_{sv} may be assigned to the 1,4-biradical and k_q, respectively.

In order to obtain further support to this assignment, the electron transfer experiments with MV^{2+} were carried out. Since MV^{2+} is almost insoluble in acetonitrile, wet acetonitrile was used as a solvent. The volume ratio of water to acetonitrile was 3.5×10^{-2}. The behavior of the transient absorption observed for the wet acetonitrile solution containing **1** and *cis*-**2** excited with the fourth harmonic of the Nd : YAG laser was proved to be actually the same as that in acetonitrile solution. The decay curve of the transient absorption observed at 330 nm for the ternary solution containing **1** of 8.0×10^{-4} mol dm^{-3} and *cis*-**2** of 0.29 mol dm^{-3} in wet acetonitrile is represented by Eq. 2 with the lifetimes of 14 ± 1 ns and 26 ± 5 μs. The slow decay curve is shown in Fig. 4(a).

For the laser-photolysis of solutions containing MV^{2+}, the N_2 laser was used as an exciting light source to avoid direct excitation of MV^{2+} which has a strong absorption at 266 nm but not at 337.1 nm, transient absorption being measured in the 380—650 nm region. MV^{2+} withdraws an electron from T_1, $K^{\cdot}$, or the biradical forming its radical cation ($MV^{\cdot+}$) (see Eqs. 9, 10, and 11).[9,11] $MV^{\cdot+}$ is stable in degassed solvents and has a broad absorption band at about 600 nm and a sharp one at about 390 nm.[15]

The transient absorption was measured for the ternary solution containing **1** of 2.77×10^{-2} mol dm^{-3} and MV^{2+} of 2.4×10^{-4} mol dm^{-3} in wet acetonitrile. The T_n—T_1 absorption of **1** was found to be quenched by MV^{2+} forming $MV^{\cdot+}$ The $I(t)$ curve observed at 530 nm is shown in Fig. 4(b). It is represented by the superposition of an exponential function with the lifetime of 570 ± 50 ns and a constant component in this time region. The decay part is due to the combination of the processes shown by Eqs. 5 and 9 and the constant corresponds to the absorption of $MV^{\cdot+}$.

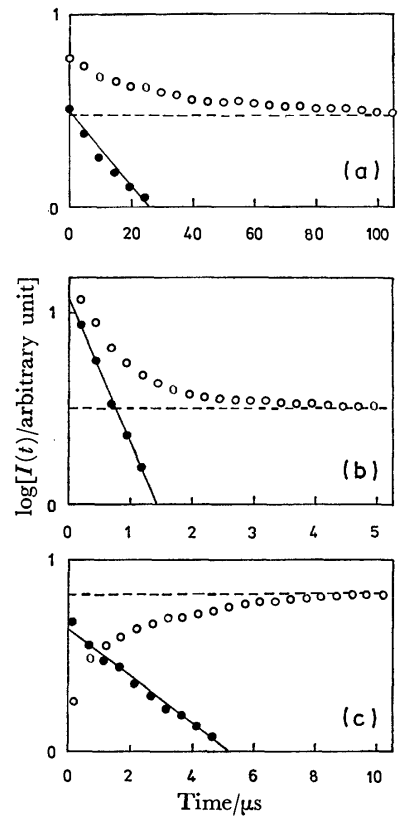

Fig. 4. Time dependence of transient absorption intensities, I (t), observed for wet acetonitrile solutions. ○: The total decay curve, ------: the constant component in this time region, ●: the difference between the total decay curve and the constant component.
(a) Decay curve observed at 330 nm for the ternary solution containing benzophenone (8.8×10^{-4} mol dm^{-3}) and *cis*-3-methyl-2-pentene (0.29 mol dm^{-3}) in wet acetonitrile. (b) Decay curve observed at 530 nm for the ternary solution containing benzophenone (2.77×10^{-2} mol dm^{-3}) and MV^{2+} (2.4×10^{-4} mol dm^{-3}) in wet acetonitrile. (c) Growth curve observed at 600 nm for the quaternary solution containing benzophenone (2.77×10^{-2} mol dm^{-3}), *cis*-3-methyl-2-pentene (0.32 mol dm^{-3}), and MV^{2+} (2.4×10^{-4} mol dm^{-3}) in wet acetonitrile.

The transient absorption was measured for the quaternary solution containing **1** of 2.77×10^{-2} mol dm^{-3}, *cis*-**2** of 0.32 mol dm^{-3}, and MV^{2+} of 2.4×10^{-4} mol dm^{-3} in wet acetonitrile. After fast quenching of the T_n—T_1 absorption of **1** by *cis*-**2** with the lifetime of 11 ns, the absorption of $MV^{\cdot+}$ appears slowly. As an example, the growth curve observed at 600 nm is shown in Fig. 4(c). It is represented by the following equation:

$$I(t) = I_4(1-\exp(-t/\tau_4)). \quad (13)$$

The growth time (τ_4) which is determined to be 3.6 ± 0.5

μs from the curve in Fig. 4(c) corresponds to the appearance time of the transient absorption of $MV^{\cdot+}$.

From the above-mentioned experimental results obtained with the wet acetonitrile solutions we conclude that, in the quaternary solution under study, *cis*-**2** quenches T_1 more effectively than MV^{2+} and an intermediate formed by the interaction between T_1 and *cis*-**2** transfers an electron to MV^{2+}. Generally speaking, either the ketyl radical or the biradical is the possible intermediate acting as an electron donor to MV^{2+}.[9,11] The spectrum of the intermediate (Spectrum II) is different from that of the ketyl radical as mentioned before. Thus it can be seen that the observed growth of $MV^{\cdot+}$ in Fig. 4(c) is brought about by the process represented by Eq. 11 and that Spectrum II is due to the 1,4-biradical.

From the above discussion, the obtained τ_2 value, 25 ± 4 μs, in acetonitrile can also be considered to be the lifetime of the biradical. Similar results were also obtained for the methanol and cyclohexane solutions containing **1** and *cis*-**2** with the laser-photolysis technique using the Nd : YAG laser. The lifetime of the biradical was determined to be 15 ± 4 μs in methanol and 6 ± 2 μs in cyclohexane. The lifetime in the polar solvents was observed to be longer than that in the nonpolar solvent. This tendency agrees well with that observed for the biradicals formed from the intramolecular hydrogen-abstraction reaction of valerophenones.[6,7]

This is the first direct observation of the transient absorption due to the biradical as a precursor of the reactions of oxetane formation and isomerization through the Yang mechanism,[5] although it has already been observed for the biradicals produced by the intramolecular hydrogen-abstraction reactions.[6,7] The reason for failure of the previous attempts to observe it[8] may be due to the fact that its strong band locates in the wavelength region shorter than 380 nm. In fact the following relation seems to hold for the absorption intensity ratio between the longer and shorter wavelength bands observed for the triplet state of **1**, its ketyl radical, and its biradical:

$$P_L/P_S(T_1) > P_L/P_S(K\cdot) \gg P_L/P_S(B). \quad (14)$$

Theoretical interpretation for this is a future problem. The constant component represented by the third term in Eq. 2 (I_3) was observed in all the solvents used in the present study. Its spectrum is similar to Spectrum II, but its origin is not yet clarified.

The author wishes to express his thanks to Professor Saburo Nagakura of The University of Tokyo for his continuous encouragement and fruitful discussion and Dr. Masao Kaneko of The Institute of Physical and Chemical Research for his kindness in informing the author of the purification method of methyl viologen hydrate. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 454135 from the Ministry of Education, Science and Culture.

(Received November 26, 1979)

In treating the lattice dynamics strictly, it is important to separate the short-range forces into various kinds according to their characters: covalent-bond, characteristic repulsive, and van der Waals. The purpose of this paper is to describe a method of separation and an appropriate treatment which is applicable to any crystal with any properties. For the repulsive and the van der Waals interactions, we apply the Jones-type potential function, varying as an inverse power of the distance. The results indicate that the repulsive force serves to emphasize the ionicity in the crystal-force field and that the covalent-bond force cannot be represented reasonably by the use of the valence force to such a crystal as the wurtzite structure, forming a coordination lattice.

We have studied the lattice dynamics of the wurtzite-type structure on the basis of the polarizable-ion model (PIM). A force-field model including the Coulomb force, where ions are assumed to be point-charge, is termed the rigid-ion model (RIM) regardless of the kind of short-range force. On the other hand, a model including the interaction of the induced electronic polarization is termed PIM. Though this model includes the effect of the electronic extension, we pay no heed to it in this paper, having submitted our ideas in an earlier paper.[1] In another earlier paper[2] the short-range force constants were estimated so as to reproduce the observed macroscopic quantities, such as, the Γ-point optical-mode frequencies, the elastic constants, and the piezoelectric constants, by the use of the effective ionic charge and the electronic polarizability, evaluated separately.[3]

In general, a crystal has two characteristics, ionicity and covalency, at the same time; this is not, however, true of the NaCl-type and the Diamond-type crystals. The atomic interaction in a partial ionic crystal will be treated as consisting of three parts, aside from the polarization part: electric Coulomb (long-range), overlap, and van der Waals.[4] By the overlap part, we mean the covalent attractive term and the characteristic repulsive term. Thus, three kinds of forces are contained in the short-range force: covalent-bond, characteristic repulsive, and van der Waals. In spite of this circumstance, they were previously not distinguished, but were treated collectively.[2] The purpose of this paper is thus to describe a method of separation and an appropriate treatment which is applicable to any crystal with any properties.

The Born-type functional form[5a] is available for use for the repulsive and the van der Waals forces, which are assumed to be expressed by a function varying as an inverse power of the atomic or ionic distance. From a formal point of view, the covalency of crystals differs from the ionicity in the greater complexity of representing explicitly the potential function. The formal theory of lattice vibrations has been described in terms of the interaction of the electrons and the nuclei involved in a solid.[6] As a phenomenological model, the shell model has been widely used in valency crystals.[7] A fornal justification of the shell model shows a rather large amount of arbitrariness possible in defining the parameters, because the number of parameters to be definde is too great. The valence-force-field model, taken from the theory of molecular vibration, describes the covalent-bond force directly.[8] While consisting of merely the nearest neighbor interaction, this is known to reproduce observed macroscopic quantities fairly well. For the covalent-bond force, therefore, we apply the valence-force-field model.

Method

Dynamical Matrix. The dynamical matrix, $\boldsymbol{D}$, for PIM is written as:

$$\boldsymbol{D} = \boldsymbol{D}^{\mathrm{N}} + \boldsymbol{D}^{\mathrm{C}} + \boldsymbol{D}^{\mathrm{P}}, \tag{1}$$

with three constituents:[5b] $\boldsymbol{D}^{\mathrm{N}}$, a short-range non-Coulomb contribution; $\boldsymbol{D}^{\mathrm{C}}$, a long-range Coulomb contribution; and $\boldsymbol{D}^{\mathrm{P}}$, a long-range electronic polarization contribution. $\boldsymbol{D}$ is the $(3n\times 3n)$ matrix, where n is the number of atoms per unit cell; it is a continuous function within the limits of the vanishing vector ($\boldsymbol{q}=0$) of the reciprocal space. It can be expanded into a MacLaurin series. The macroscopic quantities can be expressed by the use of coefficients of various orders of this series.[2]

For the short-range force, we used the valence-force-field (VFF) method in our preceding paper;[2] this method can be represented in terms of a function dependent on several force constants. Though VFF contains coupling terms between forces, we omitted these less important terms in order to simplify the procedure.[9] We have distinguished the following force constants: K_1 (parallel to the **c** axis) and K_2 (not parallel to it) for first-neighbor bond stretching, H for bending (without distinction between two sorts: cation-anion-cation and anion-cation-anion), and K_3 for second-neighbor stretching; *cf.* Fig. 1.

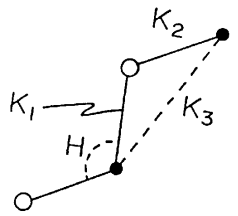

Fig. 1. The explanation of force constants used in this paper.

In this paper, the repulsive force (RF), whose role is known, together with the Coulomb force, for ionic crystals, and the van der Waals force are given separately in addition to the valence force (VF). After this separation is accomplished, the force analogous to RF and the van der Waals force are separated from VF. Accordingly, VF will denote the covalent-bond force more strictly than before. After the short-range force is separated into forces, the dynamical matrix is written as:

$$\boldsymbol{D} = \boldsymbol{D}^{\mathrm{V}} + \boldsymbol{D}^{\mathrm{R}} + \boldsymbol{D}^{\mathrm{W}} + \boldsymbol{D}^{\mathrm{C}} + \boldsymbol{D}^{\mathrm{P}}. \tag{2}$$

The van der Waals force, $\boldsymbol{D}^{\mathrm{W}}$, will not be treated separately because of its small contribution. Our new attempt is applied to the well-examined wurtzite-type structure in this paper. Though only one example, that of BeO, is treated, any other material may be treated similarly.

The repulsive force is assumed to be written as the sum of the two-body repulsive interaction. This is only approximately true. As the covalency is increased, the interactions of atoms with their different neighbors become more interdependent. Thus, the many-body interaction begins to take on an important role. As many authors have noted,[10] indeed, the many-body interaction is not negligibly small; in spite of this evidence, the interaction of the two bodies is large in comparison with it. The force, represented as a function of a force constant, H, denoting an angular rigidity, is, in a sense, the three-body force. Thus, the many-body interaction is considered to be included collectively in VF as a function of H. For the repulsive interaction, we apply the Jones-type potential function following Born's first assumption,[5a] where atoms or ions were pictured as rigid spheres mutually attracted by a force varying as an inverse power of the distance, r:

$$\beta \times r^{-s}, \tag{3}$$

where β is a strength parameter and s is a hardness parameter. s is independent of the species of ions in a given crystal. Another function of the repulsive interaction is assumed to have a form exponential with the distance; this is suited to the quantum-mechanical results more than the inverse power form. Since the exponential form is virtually equal to the inverse power form, we will employ the latter form, whose function is simple and which has been well examined mathematically.

Pauling[11] has studied the effect of relative ionic sizes on the properties of the alkali halides and has given an approximate formula providing a quantitative theory of the anion-contact and double-repulsive effect:

$$\beta_{\mathrm{AB}} B_0 e^2 (r_{\mathrm{A}} + r_{\mathrm{B}})^{s-1} r_{\mathrm{AB}}{}^{-s}, \tag{4}$$

where r_{AB} is the distance between the A and B ions, where r_{A} and r_{B} are constants representing their radii (which Pauling calls standard radii), where B_0 is a characteristic repulsive coefficient (whose value can be determined conveniently), and where β_{AB} is a constant obtained from a quantum-mechanical treatment.[11]

Characteristic Repulsive Force. The method for the calculation of RF will now be shown briefly. An expansion of the potential energy with respect to the nuclear displacement gives various orders of coefficients, which are denoted by various orders of derivatives with respect to the displacement. Among them, the second-order coefficient approximately gives the force field described by matrix elements.[5a] The definite expressions for evaluating these coefficients have scarcely been given. Now those will be given: the formula for the second-order coefficient of Eq. 4, those for the first- and second-order coefficients, given by the expansion of the second-order coefficient with repsect to the wave vector, and the method for checking the resulting values evaluated with the use of these formulas. The potential, ϕ, at a point $\boldsymbol{r}$ in a lattice space is given by summing up the influence from all lattice sites, $\boldsymbol{r}_l$:

$$\phi = \sum_l' |\boldsymbol{r} - \boldsymbol{r}_l|^{-s}. \tag{5}$$

In order to gain a rapid convergence of the summation, various methods of treatments have been given.[12] We have employed Tosi's method,[13] which is applicable to any value of s except for $s \leqq m$ (=dimension of lattice space).

The lattice summation of Eq. 5 is rewritten by Tosi[13] for the m-dimensional space as:

$$\begin{aligned} S^{(m,s)}(\boldsymbol{q}, kk') &= \sum_l' |\boldsymbol{r} - \boldsymbol{r}_l|^{-s} \\ &= \frac{1}{\Gamma(\sigma)} \left\{ \frac{2\pi^\tau \omega^{\sigma-\tau}}{v(s-m)} + \frac{\pi^\tau}{v} \sum_h' \exp\left[2\pi i (\boldsymbol{k}_h + \boldsymbol{q}) \cdot \boldsymbol{r}\right] \right. \\ &\quad \times \frac{\Gamma[\tau - \sigma, \pi^2 (\boldsymbol{k}_h + \boldsymbol{q})^2 / \omega]}{(\pi |\boldsymbol{k}_h - \boldsymbol{q}|)^{m-s}} - \frac{2}{s} \omega^\sigma \\ &\quad \left. + \sum_l' \exp\left(2\pi i \boldsymbol{q} \cdot \boldsymbol{r}_l\right) \frac{\Gamma[\sigma, (\boldsymbol{r} - \boldsymbol{r}_l)^2 \omega]}{|\boldsymbol{r} - \boldsymbol{r}_l|^s} \right\}, \end{aligned} \tag{6}$$

where $\boldsymbol{r} = \boldsymbol{x}\binom{0}{k'} - \boldsymbol{x}\binom{0}{k}$ and $\boldsymbol{r}_l = \boldsymbol{x}\binom{l}{k} - \boldsymbol{x}\binom{0}{k}$, where $\sigma = s/2$ and $\tau = m/2$, where the subindices l and h indicate, respectively, the direct-space and the reciprocal-space lattice points, where $\boldsymbol{q}$ is the wave vector, and where v is the unit-cell volume. $\Gamma(\mathrm{x})$ is the complete gamma function, and $\Gamma(\nu, \mathrm{x})$ is the incomplete gamma function. The second-order derivative of Eq. 6 with respect to the displacement comes out to:

$$\begin{aligned} S^{m,s}_{\alpha\beta}(\boldsymbol{q}, kk') &= \frac{1}{\Gamma(\sigma)} \left\{ \frac{\pi^\tau}{v} (-4\pi^2) \sum_h' (k_{h\alpha} + q_\alpha)(k_{h\beta} + q_\beta) \right. \\ &\quad \times \exp\left[2\pi i (\boldsymbol{k}_h + \boldsymbol{q}) \cdot \boldsymbol{r}\right] \frac{\Gamma[\tau - \sigma, \pi^2 (\boldsymbol{k}_h + \boldsymbol{q})^2 / \omega]}{(\pi |\boldsymbol{k}_h + \boldsymbol{q}|)^{m-s}} \\ &\quad + \sum_l' \exp\left(2\pi i\, \boldsymbol{q} \cdot \boldsymbol{r}_l\right) 4 (r_\alpha - r_{l\alpha})(r_\beta - r_{l\beta}) \\ &\quad \times \frac{\Gamma[\sigma + 2, \omega (\boldsymbol{r} - \boldsymbol{r}_l)^2]}{|\boldsymbol{r} - \boldsymbol{r}_l|^{s+4}} - 2\delta_{\alpha\beta} \sum_l' \exp\left(2\pi i \boldsymbol{q} \cdot \boldsymbol{r}_l\right) \\ &\quad \left. \times \frac{\Gamma[\sigma + 1, \omega (\boldsymbol{r} - \boldsymbol{r}_l)^2]}{|\boldsymbol{r} - \boldsymbol{r}_l|^s} + \delta_{\alpha\beta} \delta_{kk'} \frac{4}{s+2} \omega^{\sigma+1} \right\}. \end{aligned} \tag{7}$$

Though Eq. 6 is valid for $s > m$, it can be generalized for any real value of s.[12] Equation 7 is, hence, valid for any real value of s. Values evaluated according to Eq. 7 may be checked with the use of this relation:

$$\sum_{\alpha=1}^{m} S^{(m,s)}_{\alpha\alpha}(\boldsymbol{q}, kk') = s(s-1) S^{(m,s+2)}(\boldsymbol{q}, kk'). \tag{8}$$

If $s=1$ and $m=3$, there holds the well-known equation given by Born:

$$\sum_\alpha S^{(3,1)}_{\alpha\alpha}(\boldsymbol{q}, kk') = \frac{4\pi}{v}. \tag{9}$$

Moreover, the first- and the second-order derivatives with respect to the wave vector are given as:

$$S^{(m,s)}_{\alpha\beta,\gamma}(\boldsymbol{q}, kk') = \frac{2\pi i}{\Gamma(\sigma)}(A+B),$$

$$A = \frac{\pi^\tau}{v}(-2\pi i)\sum{}'_h\left\{[\delta_{\alpha\gamma}(k_{h\beta}+q_\beta)+\delta_{\beta\gamma}(k_{h\alpha}+q_\alpha)]\right.$$
$$\times\frac{\Gamma[\tau-\sigma, \pi^2(\boldsymbol{k}_h+\boldsymbol{q})^2/\omega]}{(\pi|\boldsymbol{k}_h+\boldsymbol{q}|)^{m-s}} - 2\pi^2(k_{h\alpha}+q_\alpha)(k_{h\beta}+q_\beta)(k_{h\gamma}+q_\gamma)$$
$$\left.\times\frac{\Gamma[\tau-\sigma+1, \pi^2(\boldsymbol{k}_h+\boldsymbol{q})^2/\omega]}{(\pi|\boldsymbol{k}_h+\boldsymbol{q}|)^{m-s+2}}\right\}\exp[2\pi i(\boldsymbol{k}_h+\boldsymbol{q})\cdot\boldsymbol{r}],$$

$$B = \sum{}'_l r_{l\gamma}\left\{4(r_\alpha-r_{l\alpha})(r_\beta-r_{l\beta})\frac{\Gamma[\sigma+2, \omega(\boldsymbol{r}-\boldsymbol{r}_l)^2]}{|\boldsymbol{r}-\boldsymbol{r}_l|^{s+4}}\right.$$
$$\left.-2\delta_{\alpha\beta}\frac{\Gamma[\sigma+1, \omega(\boldsymbol{r}-\boldsymbol{r}_l)^2]}{|\boldsymbol{r}-\boldsymbol{r}_l|^{s+2}}\right\}\exp(2\pi i\boldsymbol{q}\cdot\boldsymbol{r}_l), \qquad (10)$$

$$S^{(m,s)}_{\alpha\beta,\gamma\nu}(\boldsymbol{q}, kk') = \frac{-4\pi^2}{\Gamma(\sigma)}(C+D),$$

$$C = \frac{\pi^\tau}{v}\left\{(\delta_{\alpha\gamma}\delta_{\beta\nu}+\delta_{\beta\gamma}\delta_{\alpha\nu})\frac{\Gamma[\tau-\sigma, \pi^2(\boldsymbol{k}_h+\boldsymbol{q})^2/\omega]}{(\pi|\boldsymbol{k}_h+\boldsymbol{q}|)^{m-s}}\right.$$
$$-2\pi^2[\delta_{\alpha\nu}(k_{h\beta}+q_\beta)(k_{h\gamma}+q_\gamma)+\delta_{\beta\nu}(k_{h\alpha}+q_\alpha)(k_{h\gamma}+q_\gamma)$$
$$+\delta_{\gamma\nu}(k_{h\alpha}+q_\alpha)(k_{h\beta}+q_\beta)+\delta_{\alpha\gamma}(k_{h\beta}+q_\beta)(k_{h\nu}+q_\nu)$$
$$+\delta_{\beta\gamma}(k_{h\alpha}+q_\alpha)(k_{h\nu}+q_\nu)]\frac{\Gamma[\tau-\sigma+1, \pi^2(\boldsymbol{k}_h+\boldsymbol{q})^2/\omega]}{(\pi|\boldsymbol{k}_h+\boldsymbol{q}|)^{m-s+2}}$$
$$+4\pi^4(k_{h\alpha}+q_\alpha)(k_{h\beta}+q_\beta)(k_{h\gamma}+q_\gamma)(k_{h\nu}+q_\nu)$$
$$\left.\times\frac{\Gamma[\tau-\sigma+2, \pi^2(\boldsymbol{k}_h+\boldsymbol{q})^2/\omega]}{(\pi|\boldsymbol{k}_h+\boldsymbol{q}|)^{m-s+4}}\right\}\exp[2\pi i(\boldsymbol{k}_h+\boldsymbol{q})\cdot\boldsymbol{r}],$$

$$D = \sum{}'_l r_{l\gamma}r_{l\nu}\left\{4(r_\alpha-r_{l\alpha})(r_\beta-r_{l\beta})\frac{\Gamma[\sigma+2, \omega(\boldsymbol{r}-\boldsymbol{r}_l)^2]}{|\boldsymbol{r}-\boldsymbol{r}_l|^{s+4}}\right.$$
$$\left.-2\delta_{\alpha\beta}\frac{\Gamma[\sigma+1, \omega(\boldsymbol{r}-\boldsymbol{r}_l)^2]}{|\boldsymbol{r}-\boldsymbol{r}_l|^{s+2}}\right\}\exp(2\pi i\boldsymbol{q}\cdot\boldsymbol{r}_l). \qquad (11)$$

Values evaluated according to Eq. 11 may be checked by the use of this relation:

$$\sum_{kk'}z(k)z(k')S^{(m,s)}(\boldsymbol{q}, kk') =$$
$$\{s(s+1)\}^{-1}\sum_{\alpha\beta}\sum_{kk'}z(k)z(k')S^{(m,s)}_{\alpha\beta,\alpha\beta}(\boldsymbol{q}, kk'), \qquad (12)$$

which is a generalization of the equation given by Keffer *et al.*[14] for $s=1$ and $m=3$. The symbol $z(k)$ is the effective ionic charge of the kth ion. The left-hand side of Eq. 12 corresponds to the well-known Madelung constant, A, if $s=1$:

$$A = (2n)^{-1}\sum_{kk'}z(k)z(k')S^{(m,s)}(\boldsymbol{q}, kk'). \qquad (13)$$

Result

Before the evaluation of the repulsive interaction by means of Eq. 4 is made, the definite values of the repulsive parameters, B_0, ρ and s, and the ionic radii have to be given. Except for ρ, these parameters in a family of salts were determined by a simultaneous fit of the assumed expression of the lattice energy to the equation of the state and its volume derivative for the alkali halides with the NaCl structure, where the number of salts sizably exceeds the number of component ion species. ρ is independently determined by the use of the valence charge and the number of outer electrons of the pth ion following Pauling's equation:

$$\rho_{pp'} = 1 + (z_p/n_p) + (z_{p'}/n_{p'}). \qquad (14)$$

By means of the fact that the attractive forces and the repulsive forces are balanced in ionic crystals, Pauling determined B_0. The repulsive parameters for a wurtzite structure, however, can not be determined by a simultaneous fit because, in this case, the number of salts scarcely exceeds the number of component ion species. Therefore, the results for the NaCl structure are approximately applied here after converting them into the wurtzite structure.

The ionic radii for Be and O in the wurtzite-type structure are 0.293 and 1.32 Å respectively, after the values derived by Pauling in the NaCl-type structure had been modified as:[14]

$$r_{\text{Wurtzite}} = r_{\text{NaCl}} \times c,$$
$$c = [(B_{\text{W}}/B_{\text{N}})(A_{\text{N}}/A_{\text{W}})]^{1/(s-1)} = 0.944, \qquad (15)$$

where A is the Madelung constant and B is the coordination number. BeO is of the same ionic type as LiF. However, the value of the observed compressibility of BeO is not similar to that of LiF; rather, it is similar to that of MgO.[15] In spite of this evidence, $s=6$, which is the value for LiF on the average, is used so as to keep consistency with other parameters.

For a BeO compound with an ionic structure, ρ_{++}, ρ_{+-}, and ρ_{--} are taken as 3.0, 1.75, and 0.5 respectively by means of Eq. 14. If BeO has such a structure as wurtzite, the ionicity is weakened and the valence charge is deprived of its meaning. At this stage, the effective ionic charge seems to take the place of the valence charge in Eq. 14. The results are 3.0, 1.71, and 0.43—the effective ionic charge is nearly 1.0.[3] The values of the B_{AB} $[=\rho_{\text{AB}}(r_{\text{A}}+r_{\text{B}})^{s-1}]$ coefficient between like or unlike ions, then, are in this ratio:

$$B_{++}:B_{+-}:B_{--} = 1:94:276. \qquad (15)$$

The wurtzite-type structure has two "molecules," with two cations and two anions, in a unit cell (see Fig. 2).

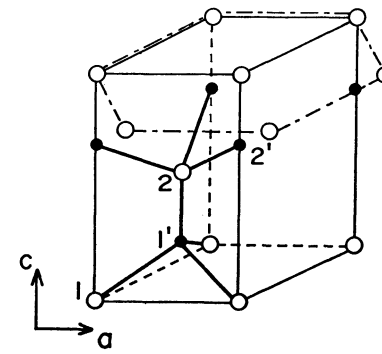

Fig. 2. Crystal structure of wurtzite type.

Since these four ions, displacing in one one and the same direction and amount, do not cause any relative displacement, that is, since the acoustic mode of frequency at the Γ point is kept at zero, the three coefficients, B_{AB}'s, should satisfy this relation:

$$B_{++}\times B_{--}/B_{+-}{}^2 = c_{\text{B}} = 1.^{\dagger\dagger} \qquad (17)$$

†† Fowler[16] has obtained the value of $B_{\text{AB}}{}^0$ $(=B_{\text{AB}}\times B_0)$ for alkali halides with the use of thermodynamical data. The approximate relation (Ref. 19, Eq. 922) suggested upon examination of the results of the study of an inert-gas mixture
$$(B_{+-}{}^0)^{1/s} = \{(B_{++}{}^0)^{1/s} + (B_{--}{}^0)^{1/s}\}/2,$$
has been used in order to estimate the ratio. Here, $(B_{+-}{}^0)^{1/s}$ is the arithmetic mean of $(B_{++}{}^0)^{1/s}$ and $(B_{--}{}^0)^{1/s}$.

That is, B_{+-} is the geometrical mean of B_{++} and B_{--}. As the ratio given in Eq. 16 does not satisfy Eq. 17 ($c_B=0.031\neq 1.$), the values of B_{AB} given in Eq. 16 seem to be unreliable; the $\beta_{++}\times\beta_{--}>\beta_{+-}^2$ relation has to be maintained, at least in order to satisfy Eq. 17. On the other hand, the ionic radii estimated by Born[13] reproduce the experimental ones quite well. It is known that the difference in ionic radius between a cation and an anion given by Pauling is too large in comparison with that derived from experiments.[13,17] The ionic radii for CsCl-type crystals derived by Hollinger *et al.*[18] with the use of observed elastic constants also show this tendency. Consequently, it is reasonable at present to treat B_{AB} as an adjustable parameter to be fitted empirically, keeping the relation in Eq. 17, just as the force constant is. After B_{AB} is estimated for compounds of salts, it can be divided into parameters, B_{AB} and β_{AB}, in a family of salts. This treatment is as follows: first, an arbitrary ratio of B_{AB} between like or unlike ions is chosen, and then the force constants of the covalent-bond force are estimated so as to reproduce the observed marcoscopic quantities. The results will be shown for four kinds of ratio:

$$B_{++}\quad B_{+-}\quad B_{--} \qquad (18.N)$$
$$=0.25\quad :0.5\quad :1.0, \qquad (18.1)$$
$$=0.01\quad :0.1\quad :1.0, \qquad (18.2)$$
$$=0.0025:0.05:1.0, \qquad (18.3)$$
$$=0.0001:0.01:1.0. \qquad (18.4)$$

If the short-range force is represented only by the use of RF, one of the calculated e_2-mode frequencies becomes a imaginary number. As the most characteristic feature of the covalent bonds is their directional nature, the force constant, H, in VF, representing an angular rigidity, is taken into account as a temporary expedient so that the imaginary number can be done away with. The effect of the ratio (B_{++}: B_{+-}: B_{--}) on the calculated macroscopic quantities is then examined. Table 1 shows the value of H, which is the limiting value to make the calculated results real, and the other parameters used here. The set of $B_0\times B_{+-}=1.6$ and $H=0.04$ ($B_0\times B_{+-}$ and H take constant values, regardless of the variable B_{+-}) are the limiting values when the imaginary number is done away with. $B_0\times B_{+-}$ being a constant value independent of the value of B_{+-} means that only the proportion of the two kinds of repulsive forces between like ions is varied, while the repulsive force between unlike ions is kept intact. The calculated results are shown in Table 2 for frequencies and elastic constants. (Since the short-range non-Coulomb contribution is not important with regard to piezoelectric constants, the results for them are omitted.) The results in the fourth column show the case where the characteristic repulsive force is not taken into account.

a) Ref. 19.

The variation in the ratio of B_{AB} is remarkable in macroscopic quantities, as can be seen in Table 2. Let us first examine the frequencies. At the Γ point, the lattice vibration can be classified, by factor-group analysis, into the $2a_1+2b_1+2e_1+2e_2$ modes. Among these, though the a_1 and e_1 modes are independent of the ratio, the two frequencies belonging to b_1 and e_2

modes are particularly interesting. Each vibrational mode is shown in Fig. 3. In the a_1 and e_1 modes, the interatomic distance remains unchanged between like ions, but is changed between unlike ions. As the repulsive force between unlike ions is kept intact, the calculated results do not vary in spite of the variety of the ratio. The variety of the ratio denotes the relation between cation-cation and anion-anion repulsive forces: as the ratio decreases, the cation-cation repulsive force is decreased and the anion-anion repulsive force is increased. As the interatomic distance between like ions is changed, on the contrary, the calculated results vary remarkably with the ratio. The case where RF makes the main contribution as the short-range force causes a large splitting of the e_2- and b_1-mode frequencies. This splitting becomes rather too large in comparison with the observed values.

Let us next discuss the elastic constants. In this case, the variation in the ratio is more remarkable. Comparing the calculated c_{11} and c_{12} species with each other, c_{12} is larger than c_{11}, in contrast with the observed values. This difference varies remarkably depending on the value of the ratio; c_{11} becomes equal to c_{12} at nearly $B_{+-}=0.04$. In Fig. 4 the contribution of RF is shown for several species of elastic constants against the ratio. As the ratio becomes smaller, RF makes a large contribution and causes a large repulsion. This tendency can also be observed in the induced internal strain of the c_{11} and c_{12} species; the contribution of the internal strain of other species is small enough to be negligible. Reflecting the variation in the calculated frequencies, the contribution of the induced internal strain of the c_{11} and c_{12} species does not approach zero, but increases as the ratio increases. It is worthy of notice that the sign of the contribution is different between these two species. The fact that the calculated c_{12} species is larger than that of c_{11} is a result of this.

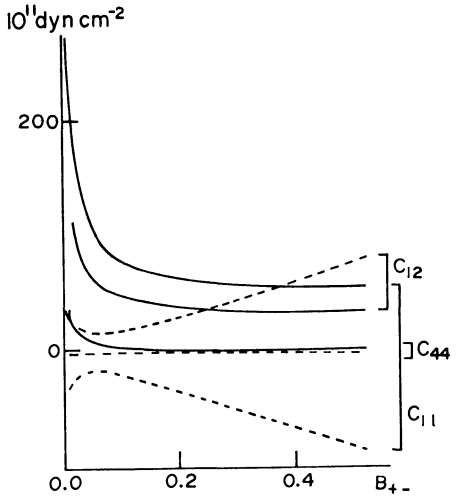

Fig. 4. The contribution of the repulsive force to elastic constants as a function of B_{+-}.

Thus far the characteristic effect of RF on calculated macroscopic quantities has been examined and only the covalent-bond force has been considered, so that the imaginary number has been done away with. Let us now take the covalency strictly into account. Before we do so, however, we must fix the value of B_{+-} by reference to the preceding results. Fortunately, the features appearing in the reproduction of e_2-mode frequencies and the relation between c_{11} and c_{12} are very specific; hence, the ratio can be roughly fixed. If we dare to estimate the approximate value for Be compounds by the use of Fowler's data,[16] in spite of the difference in the relation of B_{AB} (see footnote), the values are reduced to nearly zero except for B_{--}. This suggests that our conclusion derived from the reproduction of the macroscopic quantities is reasonable. Hence, we fix the ratio at:

$$B_{++}:B_{+-}:B_{--} = 0.01:0.1:1.0. \quad (19)$$

This result can be explained as follows: since the radius ratio is quite different from unity, the repulsion between anions is much larger than that between cations. The $B_{+-}=1.0$ ratio corresponds to the case when the ionic radii of cation and anion are nearly equal to each other. The way of treating the consideration of RF separately

	c_{44}	15.3	15.9	13.0	11.9	8.1

is thus advantageous because it brings the effect of the radius ratio into operation.

Table 3 gives the results obtained against several values of B_0 at $B_{+-}=0.1$. If we assume that the Coulomb force and the repulsive force are balanced at the equilibrium (because the covalent-bond force is not regarded as such a force as to take part in an ionic balance), $B_0=3.53$ is obtained. If we assume that the lattice energy can be represented as the sum of the Coulomb and the repulsive energies, the result is too small in comparison with the observation for the wurtzite structure. In the case of NaCl, on the contrary, the reproduction is very good. We regard the difference between the calculated and the observed values as the covalency.

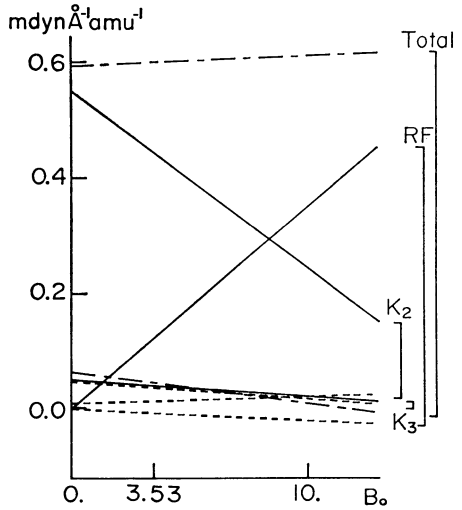

Fig. 5. The contribution of each short-range force to e_2-mode frequencies.

The increased B_0 value causes the contribution of RF to increase and the value of the force constants to decrease. The calculated results also vary appreciably in reproduction in terms of the increase. This evidence indicates that the manner of the contribution of RF is peculiar to itself. The contribution of RF and each force constant in VF to the e_2-mode frequencies is shown in Fig. 5, as examples. As can also be seen in it, RF makes a contribution not only so as to compensate VF, but also so as to give a peculiar feature.

Discussion

The short-range force was separated into the covalent-bond force and the repulsive force in the preceding chapter. On this occation, the Born-type central-force model was employed for the repulsive force. As for the covalent-bond force, on the other hand, the valence force was employed. On Born's notation, the force field occurring between the two particles of k and k' is described by the matrix elements α and β, $\phi_{\alpha\beta}(kk')$, denoting the coefficients of the derivatives with respect to the direction of the displacement, α and $\beta=x, y$, and z; the coefficients of the matrix elements are force constants. Accordingly, 3×3 kinds of force constants with respect to α and β are distinguished against each pair of atoms, k and k', —the number of them is reduced through symmetry operations. Among them, we distinguished the constants connected with the difference in the pair of particles, but identified those with a difference in the direction: as the most characteristic feature of the covalent-bond forces is their directional nature, a characteristic of this kind, expected to be involved in Born's notation in terms of the α and β elements, was considered to be put into the covalent-bond force collectively.

As can be seen in Table 3, the increased RF caused the VF to decrease; this resulted in a split of the e_2-mode frequencies and in an increase in the c_{12} and c_{13} species. Thus, the ionicity in the crystal-force field was emphasized according to the increase in RF. Even without RF, a lack of the covalent-bond force, that is, a lack of the rigidity in direction, can be observed in the calculated results, as shown in the fourth column in Table 3. However the value of H, which has been expected to represent an angular rigidity, became zero; this result reproduced the calculated results satisfactorily, but this matter seems strange. This evidence seems to indicate that each force constant in VF, which reasonably been defined by means of molecular spectroscopy, does not give the same meaning in such a crystal as a wurtzite structure forming a coordination lattice. The increase in RF causing a decrease of VF also indicates that the VF used here involves not only the covalent-bond force, but also a force similar to RF. VF is thus an inclusive force including not only the covalent-bond force, but also several other kinds of forces. Hence, we can scarcely make any progress in separating the short-range forces as long as we use an ambigous valence-force-field model. It may be supposed that we had better distinguish constants in terms of their α and β elements rather than use those defined on the basis of the molecular theory.

Conclusion

We have separated the short-range forces into various kinds of forces according to their characteristics in order to establish a suitable treatment which is applicable to any crystal with any character. By the use of an inclusive valence force, we can scarcely make any progress in separation.

The authors wish to express their thanks to Prof. Yosio Sakamoto, Hiroshima University, for his indispensable suggestions and help in the preparation of this paper.

Studies on the Aqueous Solutions of Guanidinium Salts. XIII. NMR Study of the Interactions between Guanidinium Salt and Tetraalkylammonium Salts in Water

Koichiro MIYAJIMA,* Hiromitsu YOSHIDA, Yoshihiro KURODA, and MASAYUKI NAKAGAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-shimoadachi-cho, Sakyo-ku, Kyoto 606

(Received September 14, 1979)

The quadrupole relaxation of ^{14}N nucleus of guanidinium bromide has been measured in aqueous ternary solutions containing symmetrical tetraalkylammonium salts by the ^1H NMR method. By means of Pople's line shape analysis and the Debye-Einstein equation, it has been confirmed that no complex formation takes place in the aqueous ternary solution containing symmetrical tetraalkylammonium salts. The rotational correlation time of the guanidinium ion is linearly related to the absolute viscosity of the solutions containing the homologous series of alkylammonium salts. A similar relationship was obtained for the ternary solutions with sugars or polyethylene glycols. This suggests that the correlation time depends on the microviscosity around the guanidinium ion.

In a previous work, the free energy change on mixing aqueous guanidinium bromide [GuBr] and tetrabutylammonium bromide [$(n$-Bu$)_4$NBr] solutions was determined and the mutual salting-in effect was observed.[1] The result has been interpreted in terms of the following: (a) complex formation between two kinds of solutes even in an aqueous ternary solution, and (b) alteration of the water structure, *viz.* structural salting-in. (a) is based on the fact that the guanidinium halides form crystalline complexes with symmetrical tetraalkylammonium halides in concentrated ternary solutions,[2] and (b) on the data of enthalpy of mixing of Bu_4NBr and guanidinium chloride in aqueous solution reported by Chawla *et al.*[3] The transfer of Bu_4NBr from water to guanidinium chloride solution is accompanied by a decrease in the excess partial molar heat capacity, indicating that the hydrophobic hydration around tetraalkylammonium ion is reduced in the aqueous guanidinium salt solution. Recent investigation of the volume of mixing of GuBr–Bu_4NBr–H_2O system has revealed that the reduction of the hydrophobic hydration caused by the structural breaking action of the guanidinium ion gives rise to increase in solution volume.[4] It seemed of interest to confirm whether the large salting-in effect is due to the complex formation or the structural change of water. For this purpose we measured the ^1H NMR spectra of GuBr in the aqueous ternary solution with various alkylammonium bromides, sugars or polyethylene glycol, with attention focussed on the change of shapes of amino proton signals. The results analyzed by means of Pople's theory[5] and the Debye-Einstein equation[6] support interpretation (b), the mutual salting-in effect due to the structural change of water.

Experimental

Materials. Symmetrical tetraalkylammonium bromides (Wako Chemical Co., Ltd.) were recrystallized at least twice from an appropriate solvent.[7] The other alkylammonium salts $C_iH_{2i+1}N(CH_3)_3Br$, (i=2—5), $C_6H_5N(CH_3)_3Br$, $C_6H_5N(C_2H_5)_3Cl$ (reagent grade, Tokyo Kasei Chemical Co., Ltd.) were recrystallized from ethanol several times. Sucrose, D-glucose and D-fructose of reagent grade were used without further purification. Polyethylene glycols (EG) with molecular weight 200 and 300 (Nakarai Chemical Co., Ltd.) were used without further purification. The solid solutes were dried *in vacuo* over phosphorus pentoxide before use. All solutes were dissolved in redistilled and deionized water. GuBr used was the same compound as reported previously.[8] The concentration of GuBr was 2 mol/kg·water throughout the experiments. All samples were not degassed. The pH values of these solutions were maintained in the range 4.2—4.6 with 0.01 mol dm^{-3} hydrobromic acid solution.

Method for NMR Measurement. The ^1H NMR spectra were measured on a Varian HA-100 D NMR spectrometer operating at 100 MHz. Cyclosilane-d_{18} sealed in a co-axial capillary tube was used for an internal lock signal and as an external reference for chemical shift. The temperature variation was made with a temperature variable accessory unit (V-6040) calibrated by ethylene glycol. Regulation of temperature was accurate to ± 2 °C throughout the NMR measurement.

Viscosity Measurement. The absolute viscosity of these ternary solutions, η, was measured with an Ostwald type viscometer. Temperature of the thermostat bath was controlled within ± 0.03 °C. The kinetic energy correction was made for determination of viscosity by the equation,

$$\eta/d = At - B/t,\ A = 2.628\times10^{-3}\ (\mathrm{cm^2/s^2}),$$
$$B = 15.00\ (\mathrm{cm^2}),$$

where t is the flow time and d the density of the solution, measured with Seiko SDM 421 and 422 vibration densimeters.[4]

Results and Discussion

Figure 1 shows the ^1H NMR spectra of a 2 mol/kg·water GuBr solution and a mixed aqueous solution of GuBr and R_4NBr molalities of which are 2 mol/kg·water, respectively. The broad signal at *ca.* 7—7.5 ppm is due to the NH absorption of the guanidinium ion, the sharp signal at about 5.15 ppm to the absorption of water proton. The chemical shifts are given in Table 1. The NH resonance shows a narrowing and slight shift to down field on addition of R_4NBr, the resonance of water proton remaining almost unchanged. The extent of the narrowing and shift progresses with increase in the chain lengths of the alkyl group. The sharpening accompanied by the addition of Bu_4NBr also depends on the concentration of the added salt. The down field shift seems to arise from the increase in the hydrogen bond of the guanidinium ion with water molecules. However, the absolute values of

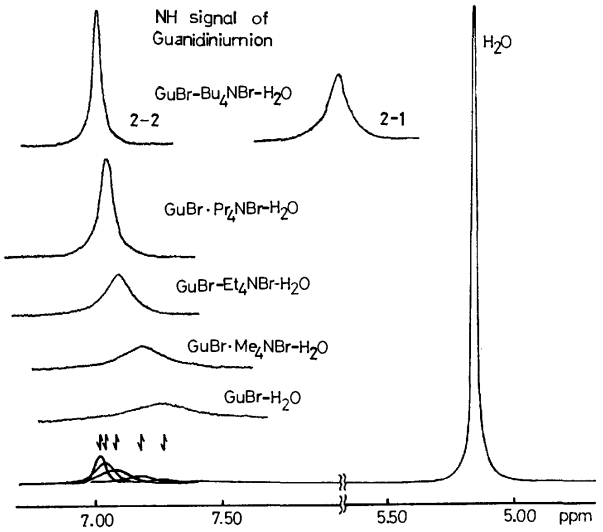

Fig. 1. ^{1}H NMR spectra of 2 mol/kg·water GuBr solution and the mixed aqueous solutions of GuBr and R_4NBr.

the shift could not be estimated since correction of the bulk susceptibility was not available. Two explanations can be considered for the narrowing: (a) change of the exchange rate of NH protons with the water proton, and (b) change of the extent of broadening by quadrupole relaxation of the ^{14}N nucleus. NMR studies of the aqueous guanidinium solutions show that the NH proton signals change depending on the pH of the solutions, the corresponding water proton signal varying simultaneously.[9] However, in the present case, the line width of the water proton is little affected in spite of the sharpening of NH signal of the guanidinium ion. Thus (a) can be eliminated and we will further consider explanation (b). The narrowing phenomenon can be treated by the equations derived by Pople for the NMR line shape of spin 1/2 nucleus relaxing by quadrupole mechanism.[5] In the following, we will discuss the change of line shapes by means of this theory.

The theoretical line shape $I(x)$ for the spectra of nuclei of spin 1/2 (^{1}H) coupled to a nucleus of spin 1 (^{14}N) is expressed by the parameter λ which is a product of spin-lattice relaxation time T_1 of the ^{14}N nucleus and the NH coupling constant $^1J_{NH}$:

$$I(x) = D\frac{45+\lambda^2(5x^2+1)}{225x^2+\lambda^2(34x^4-2x^2+4)+\lambda^4(x^6-2x^4+x^2)} \quad (1)$$

$$x = \Delta\nu/{}^1J_{NH} \quad (2)$$

$$\lambda = 10T_1\,{}^1J_{NH}, \quad (3)$$

where $\Delta\nu$ is the frequency relative to the center and D is a constant concerning the peak area. When we determine the parameter which can reproduce the best fit curve to the observed line shape, we simply take into account the half height width $\Delta\nu_{1/2}$, instead of the total line shape of the observed signal. Thus we get from Eqs. 1—3

$$I(x_0) = I(0)/2 = (45+\lambda^2)/8\lambda^2, \quad (4)$$

where x_0 is $\Delta\nu_{1/2}/2\cdot{}^1J_{NH}$. Thus λ can be so determined as to satisfy Eq. 4. This simplified treatment may be justified since the observed NH resonance is simply a single peak, suggesting that the parameter λ is approximately less than 5 (Fig. 1). In analyzing the observed line width by Eq. 4, the "natural" line width at half height in the absence of quadrupole relaxation should be substracted.[10] However, this approximation would cause no large error to the results. The theoretical curve of NH proton resonance for the GuBr–H_2O and GuBr–Bu_4NBr–H_2O systems were calculated by assuming the $^1J_{NH}$ value for both systems as 63 Hz, calculated from ^{15}NH coupling constant of urea by taking into account the difference of gyromagnetic ratio between ^{14}N and ^{15}N. The theoretical curves are shown in Fig. 2

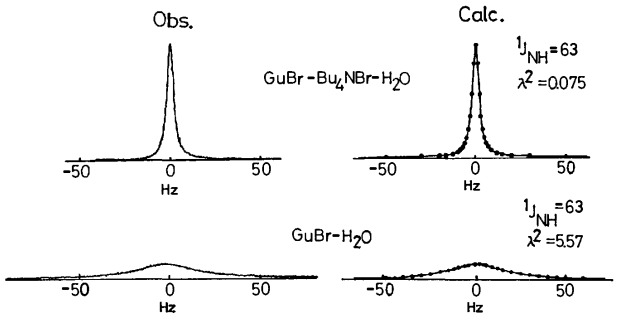

Fig. 2. Observed and calculated line shape of NH signals for the GuBr–Bu_4NBr–H_2O and GuBr–H_2O systems.

together with the observed ones. The peak height and area of the calculated signal largely depend on the assumed magnitude of λ. Accordingly, the peak height for the GuBr–Bu_4NBr–H_2O system was adjusted to that of the observed one, and the peak height for the GuBr–H_2O system was so determined as to give the same area of signal as that of the GuBr–Bu_4NBr–H_2O system. In spite of the assumption of the $^1J_{NH}$ value and approximate treatment for the line shape analysis, the calculated curve almost entirely fits the observed one.

From the adjusted parameters λ and by assuming $^1J_{NH}$ as 63 Hz, the remaining physical constant T_1, spin-lattice relaxation time of the ^{14}N nucleus can be calculated by means of Eq. 3. In the case of extreme narrowing condition ($w_0\tau_C \ll 1$, where w_0 is the Larmor frequency of ^{14}N nucleus), usually satisfied in our cases, the spin-lattice relaxation time is also related to the molecular rotational correlation time τ_C by means of the relation[11]

$$\frac{1}{T_1} = \frac{3}{2}\pi^2\left(1+\frac{\theta^2}{3}\right)\left(\frac{e^2qQ}{h}\right)^2\tau_c, \quad (5)$$

where θ is the asymmetry parameter of the field gradient tensor and e^2qQ/h the quadrupole coupling constant. T_1 and τ_C calculated for each system from the values of $^1J_{NH}$ are given in Table 1, θ and e^2qQ/h being given in the footnote. The value of T_1 obtained for the GuBr–H_2O system is comparable with those obtained by a different method, *i.e.* 0.932 ms for guanidine and 1.44 ms for urea,[13] which indicates that our assumption is reasonable. The spin-lattice relaxation times of mixed solutions are shortened with the increase of alkyl chain length of the added tetraalkylammonium bromide, *e.g.*,

TABLE 1. THE NMR DATA OF GUANIDINIUM SALT SOLUTIONS CONTAINING TETRAALKYLAMMONIUM SALTS

GuBr–(n-Bu)$_4$NBr	7.44	4.6±0.2	0.07±0.01	0.14±0.01	37.3

$^1J_{NH}$=63 Hz, θ=0.412, e^2gQ/h=3500(kHz).[12]

even an order of magnitude in the case of R=$-C_4H_9$. Since the quadrupole coupling constant would not be much influenced by the addition of R_4NBr, the relation in Eq. 5 indicates that this shortening is attributable to the increase of the rotational correlation time, τ_C, *i.e.*, slowing down of the rotational motion of the guanidinium ion. The relationship between diffusing particle size and correlation time can be expressed by the Debye-Einstein equation[6]

$$\tau_c = \frac{4\pi a^3}{3kT}\cdot\eta, \qquad (6)$$

where k is the Boltzmam constant, T absolute temperature, η the viscosity of the solution, and a the radius of the solute molecule.

In the ternary system tetraalkylammonium bromide–GuBr–H_2O, the crystalline complexes with various mole ratios were isolated from highly concentrated solutions. The excess free energy of mixing obtained from the ternary system GuBr–Bu_4NBr–H_2O at relatively high concentration where the crystalline complexes were not isolated, were negative and large in magnitude. Considerably large salting-in effect was observed in the same system even at low concentration regions. It is of interest to confirm whether the complexes with the same composition as the crystalline complexes actually exist in the ternary solution or not. If no water soluble complexes exist in aqueous ternary solution, the complex formation is not the cause of large salting-in. Equation 6 is useful for our purpose. In order to calculate the correlation time τ_C by means of this equation, we should determine the radii of the solutes, a. By assuming that the 1-1 complexes are formed between GuBr and R_4NBr in aqueous solution, the radii of complex, a', were obtained by spherical approximation of the sum of the partial molar volumes of infinite dilution, and by using these radii and the observed viscosities of the solutions, the correlation times, $\tau_C^{calc}(a')$ at 30 °C were calculated. The results are given in Table 2, together with values of a calculated from observed τ_C and η. Disagreement of the τ_C values with the corresponding observed values is remarkable. The volume ratio of guanidinium ion in water and aqueous tetrabutylammonium bromide solution obtained from the a values is 1.87. On the assumption that a 1 to 1 complex is formed between GuBr and Bu_4NBr, the ratio is calculated to be 9.52 with the a' values. This indicates that no complex between guanidinium bromide and tetraalkylammonium bromide would be formed in ternary aqueous solution.

From the thermodynamic studies of the aqueous solutions of guanidinium salts and urea, it has been shown that guanidinium halides and urea have very similar physicochemical properties in aqueous solutions.[14] The NH resonance of aqueous urea solutions

TABLE 2. COMPARISON BETWEEN THE OBSERVED AND CALCULATED VALUES OF τ_c

System	$\tau_c^{obsd}\times 10^{12}$ (s)	a' (Å)	$\tau_c^{calcd}(a')\times 10^{12}$ [a] (s)	a (Å)	η (c.p.)

a) $\tau_c^{calcd}(a')$ is calculated by means of Eq. 6 with a' value on the assumption that a 1 to 1 complex is formed between tetraalkylammonium bromides and GuBr or Urea. b) The calculation of the observed τ_c in urea solution was carried out using the following values: $^1J_{NH}$=63 Hz, e^2qQ/h=3510 kHz, θ=0,323.[13]

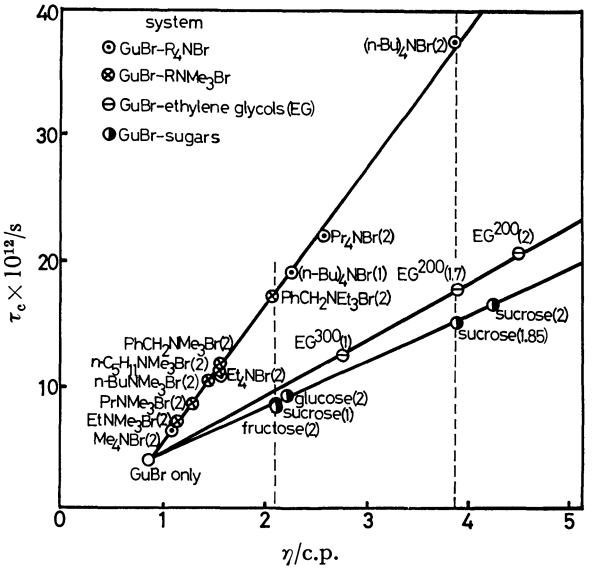

Fig. 3. Realtionships between the observed τ_c's and η's. The molalities of the second solutes are shown in parentheses.

might therefore be also expected to show narorwing to an extent similar to that of the GuBr solutions on addition of R_4NBr. This was actually observed. In the case of urea (Table 2), complex formation with tetra-alkylammonium salts in the aqueous solution[15] should be excluded as above.

With regard to the viscosity dependence of τ_C, it has been argued that microviscosity should be employed instead of macroviscosity.[16-19] The relationship between the observed τ_C of the guanidinium ion and the measured viscosity of the ternary solutions has been investigated. τ_C values are plotted against η of various ternary solutions containing alkylammonium salts, sugars or polyethylene glycols as the second solute in Fig. 3. We see that linear relationship exists between τ_C's and η values of the ternary solutions of the homologous series, irrespective of the concentration of the second solutes. The effect of the second solute on solution viscosity immediately influences τ_C. However, the τ_C values of the guanidinium ion have different values in the ternary solutions, even when the macroviscosity of the solutions is the same. This seems to indicate that τ_C is related to the quantity proportional to microviscosity around the guanidinium ion. The τ_C values seem to depend closely on the microstructure of the solution surrounding the guanidinium ion. The type of hydration of a series of alkylammonium salts was assumed to be of cage-like structure and that of a series of sugars to be purely hydrogen bonding with a definite orientation.[20] The type of hydration of polyethylene glycols is considered to be a mixed one in view of the chemical structure. Since the influence of the second solute on the water structure differs and each effect is reflected in the microviscosity surrounding the guanidinium ion, τ_C may have different values in the solutions where the macroviscosity is the same. Thus we might expect that τ_C would also influence the activation energy for the rotational motion of the guanidinium ion, E_{τ_c}. The values of τ_C at various temperatures were calculated from the line shape of NH proton (Fig. 4). E_{τ_c} values for various ternary solutions with the same viscosity (3.86 c.p.), and binary guanidinium bromide solution were determined by the temperature dependence of τ_C by means of the equation

$$\tau_c = \tau_c^0 \exp(E_{\tau_c}/RT). \quad (7)$$

The slope of $\ln \tau_C$ *vs.* $1/T$ curves determined by least squares fit gives the following activation energies: 5.3 ± 0.3 kcal/mol for GuBr–H_2O system, 7.9 ± 0.2 kcal/mol for GuBr–Bu_4NBr–H_2O system, 7.1 ± 0.2 kcal/mol for GuBr–EO_{200}–H_2O system and 7.0 ± 0.2 kcal/mol for GuBr–sucrose–H_2O system.

The activation energy of viscous flow E_η was also obtained by means of

$$E_\eta = \frac{RT\, d\ln \eta}{d\left(\frac{1}{T}\right)}. \quad (8)$$

Linear relationship holds between E_{τ_c} and E_η, indicating that the activation energy of macroviscous flow is proportional to the activation energy of the microviscous flow on the assumption that τ_C is another expression of microviscosity (Fig. 5).

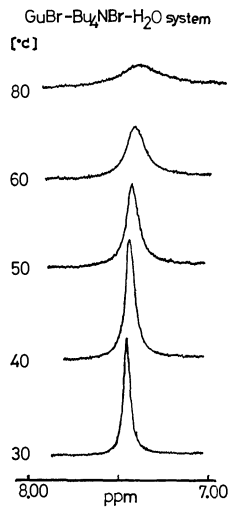

Fig. 4. Temperature dependence of the line shape of the NH proton for the ternary system GuBr–Bu_4NBr–H_2O.

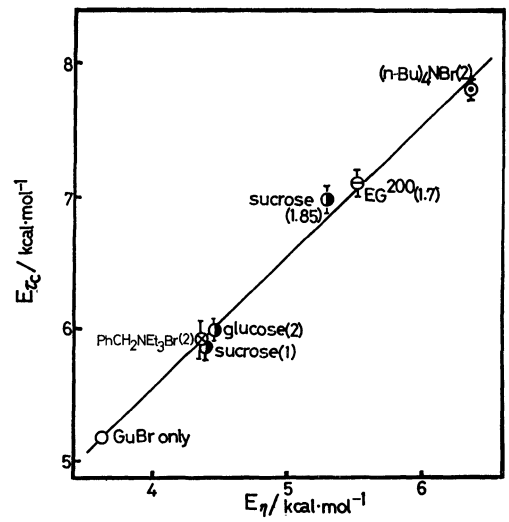

Fig. 5. Relationship between E_{τ_c} and E_η.
The molalities of the second solutes are shown in parentheses.

Negative Azeotropic Transformation in Mixed Monolayers of Octadecylammonium Chloride and Tetradecanoic Acid

Kinsi MOTOMURA,* Masaki IKEMATSU, Yoshiteru HAYAMI,
Hirosi MATUO, and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received December 7, 1979)

The surface pressure of mixed monolayers of octadecylammonium chloride and tetradecanoic acid has been measured as a function of mean area per film molecule at various compositions and temperatures. It has been observed that the transition pressure from expanded to condensed state of either constituent decreases with the addition of the other one. This behavior has been called a negative azeotropy in the two-dimensional state in contrast to the positive azeotropy observed for the ethyl heptadecanoate–tetradecanoic acid system. By applying the thermodynamic treatment, the phase diagram has been constructed and the apparent molar entropy and energy associated with the phase transition have been calculated. The results support the view that the negative azeotropic transformation in the mixed monolayer is brought about by the mutual interaction between octadecylammonium chloride and tetradecanoic acid molecules which is stronger than that between the same kind of molecules.

It has been found useful in clarifying the interaction between film-forming molecules in the monolayer state to analyze the phase transition of mixed monolayers from expanded to condensed states thermodynamically.[1-8] Recently we have shown that a positive azeotropic transformation is observed for the mixed monolayer of slightly different molecules between which the mutual interaction is weaker than that between the same kind of molecules.[6,7] It is now expected for a mixed monolayer of which the constituent molecules interact strongly with each other to exhibit a negative azeotropic transformation. Actually it has been found by Harkins *et al.*[9,10] that the equimolar mixed monolayer of fatty acid and alkylamine has the minimum area per film molecule at a given surface pressure, which can be explained in terms of the decrease of transition pressure by mixing the monolayers.

The object of this paper is to make clear the thermodynamic behavior of the mixed monolayer of tetradecanoic acid and octadecylammonium chloride by measuring the surface pressure as a function of composi tion and temperature.

Experimental

Tetradecanoic acid was purified by vacuum distillation and recrystallization from ether. Octadecylammonium chloride was synthesized from octadecylamine, which was fractionated by vacuum distillation, by the reaction with hydrochloric acid and then recrystallized from ethanol. As a spreading solvent, a mixture of benzene and ethanol (9 to 1 in volume) each purified by ordinary procedures was used. Monolayers were spread on 0.1 M sodium chloride solution which was prepared from twice distilled water and sodium chloride (Wako special grade).

Surface pressure was measured by a Wilhelmy-type surface balance. Temperature was kept constant within 0.1K by circulating thermostated water.

Results and Discussion

The surface pressure, π, of mixed monolayers consisting of octadecylammonium chloride and tetradecanoic acid was measured as a function of the mean area per film molecule, A, at various compositions at a constant temperature. The results at 298.2 K are illustrated in Fig. 1. It is observed that the break point pressure of π *vs.* A curve of either constituent decreases with the addition of the other one and becomes gradually obscure. In Fig. 2, the surface pressure of the break point, referred to as the transition pressure π^{eq}, is plotted against the mole fraction of tetradecanoic acid defined by

$$x_2^{\pi} = n_2/(n_1+n_2), \quad (1)$$

where n_i is the number of moles of film-forming component i. It is clearly seen that the value of π^{eq} of mixed monolayer deviates negatively from a straight line connecting that of the pure monolayers and have a minimum in the vicinity of $x_2^{\pi}=0.5$. This fact indicates that the mixed monolayer is homogeneous in both expanded and condensed states. Such a behavior may be called a negative azeotropic transformation in contrast with the positive azeotropic transformation

observed for the system of ethyl heptadecanoate and tetradecanoic acid of which the π^{eq} *vs.* x_2^{π} curve has a maximum.[6] There is a possibility that octadecylammonium chloride and tetradecanoic acid form the one-to-one addition compound in the condensed state. However, this possibility is denied by the fact that each π *vs.* A curves in Fig. 1 does not have more than one break point and the π^{eq} *vs.* x_2^{π} curves in Fig. 2 behave smoothly.

Measurements were made likewise at 295.7 and 293.2 K. The π^{eq} *vs.* x_2^{π} curves at these temperatures are shown in Fig. 2. It is found that these curves are similar in shape to each other and shift downward with decreasing temperature. Since the phase transition takes place from the expanded monolayer, of which the concentration is x_2^{π}, to the condensed monolayer, these curves are referred to as the π^{eq} *vs.* $x_2^{\pi,e}$ curves. Now let us consider to evaluate the composition of condensed monolayer in equilibrium with the expanded monolayer thermodynamically.

According to the thermodynamic treatment,[1,11] the mole fraction of tetradecanoic acid in the condensed monolayer $x_2^{\pi,c}$ is related to $x_2^{\pi,e}$ by the expression

$$x_2^{\pi,c} = x_2^{\pi,e} + (a^c - a^e)(\partial\pi^{eq}/\partial x_2^{\pi,e})_{T,p}/\{RT/x_1^{\pi,e}x_2^{\pi,e} + (\partial a^e/\partial x_2^{\pi,e})_{T,p,\pi}(\partial\pi^{eq}/\partial x_2^{\pi,e})_{T,p}\int_0^{\pi}[\partial^2 a^e/(\partial x_2^{\pi,e})^2]_{T,p,\pi}d\pi\}, \quad (2)$$

where a is the mean area per mole of film-forming components and the superscripts e and c represent expanded and condensed states, respectively. By applying Eq. 2 to the experimental results given in Figs. 1 and 2 on the assumption that the value of a^c may be replaced by the corresponding one of octadecanoic acid, the value of $x_2^{\pi,c}$ can be calculated numerically. The π^{eq} *vs.* $x_2^{\pi,c}$ curve obtained at 295.7 K is drawn in Fig. 3 as the curve 1, in which the corresponding π^{eq} *vs.* $x_2^{\pi,e}$ curve taken from Fig. 2 is also depicted as the curve 2. It is found that the areas denoted by the letters e and c are regions in which the expanded and condensed monolayers are stable, respectively, and the area between the curves 1 and 2 is a region in which the expanded and condensed monolayers coexist. Therefore, we may say that Fig. 3 is the phase diagram describing the equilibrium between expanded and condensed monolayers of octadecylammonium chloride–tetradecanoic acid system at 295.7 K.

Now we shall consider an apparent molar thermodynamic quantity change Δy^{γ} associated with the phase transition from expanded to condensed monolayer:

$$\Delta y^{\gamma} = x_1^{\pi,e}(\bar{y}_1^{\gamma,e} - \bar{y}_1^{\gamma,e}) + x_2^{\pi,c}(\bar{y}_2^{\gamma,c} - \bar{y}_2^{\gamma,e}). \quad (3)$$

On the right-hand side of Eq. 3, $\bar{y}_i^{\gamma}$ is the apparent partial molar quantity defined by

$$\bar{y}_i^{\gamma} = (\partial Y/\partial n_i)_{T,p,\gamma,n_{j\neq i}} \quad i = 1, 2\ (j \neq i), \quad (4)$$

where Y is the thermodynamic quantity inherent in the monolayer and γ the surface tension.[6,12]

The apparent entropy change Δs^{γ} is related to the derivative of π^{eq} with respect to T at constant $x_2^{\pi,e}$ under atmospheric pressure by

$$\Delta s^{\gamma} = [a^c - a^e - (x_2^{\pi,e} - x_2^{\pi,e})(\partial a^e/\partial x_2^{\pi,e})_{T,p,\pi}] \times [(\partial\pi^{eq}/\partial T)_{p,x_2^{\pi,e}} - (\partial\gamma^{\circ}/\partial T)_p], \quad (5)$$

where γ° is the surface tension of 0.1 M sodium chloride solution.[6,12] Since $\partial\pi^{eq}/\partial T$ is estimated on the basis of the experimental results shown in Fig. 2 and $\partial\gamma^{\circ}/\partial T$ on the basis of the value of γ° approximated by that of pure water,[13] we can calculate Δs^{γ}. In Fig. 4, the value of Δs^{γ} at 295.7 K is plotted against the mole fraction of tetradecanoic acid in the condensed monolayer. The Δs^{γ} *vs.* $x_2^{\pi,c}$ curve seems to be approximately linear over the whole range. Taking Eq. 3 into account, therefore, the apparent partial molar entropy

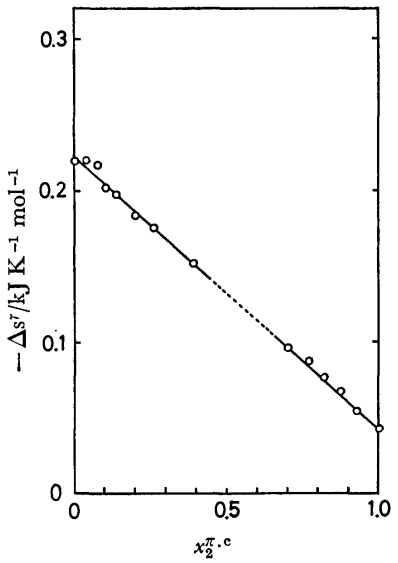

Fig. 4. Apparent molar entropy change Δs^{γ} *vs.* mole fraction of tetradecanoic acid in condensed monolayer $x_2^{\pi\cdot c}$ curve for octadecylammonium chloride–tetradecanoic acid system at 295.7 K.

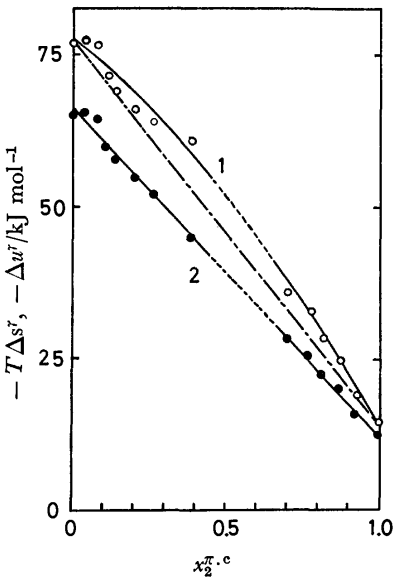

Fig. 5. Δu^{γ} *vs.* $x_2^{\pi\cdot c}$ curve (1) and $T\Delta s^{\gamma}$ *vs.* $x_2^{\pi\cdot c}$ curve (2) at 295.7 K for octadecylammonium chloride–tetradecanoic acid system.

changes of octadecylammonium chloride and tetradecanoic acid are given by intercepts of the straight line on the ordinates. This dependence of Δs^{γ} on $x_2^{\pi\cdot c}$ is quite similar to that of the system of pentadecanoic and tetradecanoic acids which is known to form an ideal mixed monolayer.[2] Furthermore, an analogous Δs^{γ} *vs.* $x_2^{\pi\cdot c}$ curve is observed for the mixed monolayer of ethyl heptadecanoate and tetradecanoic acid which exhibits the positive azeotropic transformation.[6] This fact indicates that the apparent molar entropy change associated with the phase transition has an ideal value even when the mixed monolayer behaves nonideally. This means that the apparent molar entropy change is of limited significance in the azeotropic transformation. Therefore, the azeotropic behavior of octadecylammonium chloride–tetradecanoic acid system should be explained in terms of other thermodynamic quantity changes.

Next let us consider the apparent molar internal energy change associated with the phase transition Δu^{γ} which is given by the relation

$$\Delta u^{\gamma} = -(\pi^{eq}-\gamma^{o})[a^{c}-a^{e}-(x_2^{\pi\cdot e}-x_2^{\pi\cdot e})(\partial a^{e}/\partial x_2^{\pi\cdot e})_{T,p,\pi}] - p\Delta v^{\gamma} - T\Delta s^{\gamma}, \quad (6)$$

where Δv^{γ} is the apparent molar volume change.[6] Taking into account that the $p\Delta v^{\gamma}$ term on the right-hand side of Eq. 6 is negligibly small compared with other terms under atmospheric pressure,[6,14] the value of Δu^{γ} can be evaluated by making use of the above experimental results. In Fig. 5, the Δu^{γ} *vs.* $x_2^{\pi\cdot c}$ curve is drawn. The curve is found to show a remarkable deviation from the straight line connecting the value of Δu^{γ} for the pure components as compared with the $T\Delta s^{\gamma}$ *vs.* $x_2^{\pi\cdot c}$ curve also depicted in Fig. 5. Here we notice that the value of Δu^{γ} is smaller than an ideal one for the system of octadecylammonium chloride and tetradecanoic acid, while it was larger for the system of ethyl heptadecanoate and tetradecanoic acid.[6]

In order to examine the connection of the azeotropic transformation with the interaction between film-forming molecules, it is appropriate to look closely at partial molar energies of the film-forming components. Taking account of Eq. 3, the apparent partial molar energy of component i is given by the intercept of tangent to the Δu^{γ} *vs.* $x_2^{\pi\cdot c}$ curve on the ordinate specified by $x_1^{\pi\cdot c}=1$. As seen in the previous paper,[6] the positive azeotropy of ethyl heptadecanoate–tetradecanoic acid system is characterized by the decrease of $\bar{u}_i^{\gamma\cdot c}-\bar{u}_i^{\gamma\cdot e}$ with increase in $x_1^{\pi\cdot c}$. For the octadecylammonium chloride–tetradecanoic acid system, however, we can see from Fig. 5 that the value of $\bar{u}_i^{\gamma\cdot c}-\bar{u}_i^{\gamma\cdot e}$ increases with increasing $x_1^{\pi\cdot c}$. This fact indicates that the mutual interaction between octadecylammonium chloride and tetradecanoic acid molecules in the mixed monolayer is stronger than the interactions between the same kind of constituent molecules. This finding is very reasonable.

A Thermodynamic Study on Hydrolytic Reactions of Lead(II) Ion in an Aqueous Solution and Dioxane-Water Mixtures. I. A Potentiometric Study

Takayoshi KAWAI, Shin-ichi ISHIGURO, and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received February 5, 1980)

The hydrolytic reactions of lead(II) ions were studied at 25 °C by means of potentiometric titrations by using a glass electrode in water and dioxane–water mixture (dioxane contents: 0.1 and 0.2 mol fractions) containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium. Four complexes, $Pb_3(OH)_3^{3+}$, $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$, and $Pb_6(OH)_8^{4+}$ were found in the solvent systems examined at $pH \lesssim 8$, and the formation constant $*\beta_{pq}$ for the reaction, $qPb^{2+}+pH_2O=Pb_q(OH)_p^{(2q-p)+}+pH^+$, was determined. The autoprotolysis constants K_1 in the same solvent systems were also obtained by use of a hydrogen electrode. The formation constant $\beta_{pq}(=*\beta_{pq}/K_1^p)$ for the reaction, $qPb^{2+}+pOH^-=Pb_q(OH)_p^{(2q-p)+}$ was evaluated by combining the formation constants $*\beta_{pq}$ and the autoprotolysis constants obtained. The free energy change of transfer from water to a dioxane–water mixture for the reaction could be estimates as $\Delta G_{pq}^t=-RT\ln\{\beta_{pq}(\text{mix})/\beta_{pq}(\text{aq})\}$. The values $(1/p)\Delta G_{pq}^t$ of hydroxo complexes of various metal ions such as lead(II), copper(II), nickel(II), beryllium(II), and cadmium(II) ions were approximately independent of the complexes at a given concentration of dioxane. This result suggested that the formal charge per metal ion of the complex, z' $(=z-p/q$; z: charge of a metal ion), rather than the total charge of the complex, $zq-p$, is essential for the interactions between the hydroxo complexes and solvent molecules.

The hydrolytic reactions of lead(II) ion have so far been studied in aqueous solution containing various ionic media.[1-3] Recently, Olin has reported formation of four hydrolytic species, *i.e.*, the $PbOH^+$ and $Pb_4(OH)_4^{4+}$ complexes in the relatively low pH region ($5<pH<7$) and the $Pb_3(OH)_4^{2+}$ and $Pb_6(OH)_8^{4+}$ complexes at a higher pH ($6<pH<8$).[4] The $Pb_4(OH)_4^{4+}$ and $Pb_6(OH)_8^{4+}$ complexes are predominant species and most of lead(II) ions exist as the hydroxo complexes at $pH>6$. The structures of the $Pb_4(OH)_4^{4+}$ and $Pb_6(OH)_8^{4+}$ complexes have been studied by means of X-ray diffraction.[5,6] Raman spectroscopic studies on the complexes have also been reported.[7]

We have previously reported the medium effect on the hydrolytic reactions of various divalent metal ions such as beryllium,[8] copper,[9] nickel,[10] and cadmium[11] in dioxane–water mixtures. It has been found that the composition of the hydrolytic species and the formation constant $*\beta_{pq}$ for the reaction, $qM^{z+}+pH_2O=M_q(OH)_p^{(zq-p)+}+pH^+$ are generally little affected by the solvent composition up to 0.5 mole fraction (*ca.* 88 w/w %) of dioxane in the medium.

In the present study, the hydrolytic reactions of lead(II) ions were studied in water and dioxane–water mixtures. The autoprotolysis reaction of solvent was also investigated in the same solvent systems. On the basis of the formation constants of the hydroxo complexes of lead(II) ions, together with those of other metal ions previously obtained, the medium effect for the hydrolytic reactions of divalent metal ions is discussed.

Experimental

All measurements were carried out at (25.00±0.02) °C in a liquid paraffin bath set in a room thermostated at (25±0.5)°C. Lithium perchlorate was used as an ionic medium to keep the concentration of perchlorate ions at 3 mol dm^{-3}. Total concentrations of lead(II) ions examined were changed from 0.001 to 0.08 mol dm^{-3}. The total concentration of lead(II) ions was kept constant throughout a series of potentiometric titrations. The cell used for the emf measurements of the autoprotolysis reaction of the solvent was as follows:

$$\text{Ref}\,|\,\text{Test Solution}\,|\,H_2(Pt) \qquad \text{(A)}$$

$$\text{Ref} = \left|\begin{array}{l}3\text{ mol dm}^{-3}\\LiClO_4\\\text{in Mixture}\end{array}\right|\left|\begin{array}{l}3\text{ mol dm}^{-3}\\LiClO_4\\\text{in aqueous}\\\text{solution}\end{array}\right|\left|\begin{array}{l}0.01\text{ mol dm}^{-3}\\AgClO_4\\2.99\text{ mol dm}^{-3}\\LiClO_4\\\text{aqueous}\\\text{solution}\end{array}\right|\text{AgCl–Ag} \qquad \text{(B)}$$

The emf differences between the two hydrogen electrodes immersed in the same test solution were within 0.1 mV. The emf reached a constant value within 15—20 min after the addition of $HClO_4$ solution and remained unchanged within ±0.05 mV for at least 5—6 h. The cells used for emf measurements of free-hydrogen and free-lead(II) ions were, respectively, as follows:

$$\text{Ref}\,|\,\text{Test Solution}\,|\,\text{GE} \qquad \text{(C)}$$

$$\text{Ref}\,|\,\text{Test Solution}\,|\,\text{Pb(Hg)}. \qquad \text{(D)}$$

The emfs of both glass electrode (GE) and lead amalgam electrode reached a constant values within a minute and remained unchanged within ±0.1 mV for at least 5—6 h.

Reagents and Analysis. Lead(II) Perchlorate. A stock solution of lead(II) perchlorate was prepared as follows: First, reagent grade lead(II) nitrate was recrystallized twice from water. The lead nitrate crystals thus prepared were dissolved in perchloric acid of super special grade diluted with water. Lead perchlorate was crystallized from the solution by evaporating under vacuum and crystals thus obtained were recrystallized from perchloric acid solution by repeating the above procedure. Finally, lead perchlorate thus obtained was recrystallized twice from water. The concentration of lead(II) ions in the stock solution was gravimetrically determined in the form of lead sulfate.

Lithium Perchlorate and Lithium Hydroxide were prepared by the procedures as described in the previous paper.[12]

Dioxane was purified by an ordinary method.[12]

Apparatus. Beckman (No. 40495 and 40498) glass electrodes were used in combination with an Orion Digital pH Meter Model 801. Hydrogen electrodes used were prepared according to Feltham and Spiro.[13] The hydrogen electrodes

were stored in a 0.1 mol dm^{-3} H_2SO_4 solution and were electrolyzed about 30 min in the solution before measurements. Lead amalgam electrodes were prepared as described in Ref. 14 and the electrode cell design used was described in a previous paper.[15] The Ag–AgCl electrodes used as references were prepared according to Brown.[16] The emfs of hydrogen and lead amalgam electrodes were measured by using Takeda Riken Digital Voltmeter (TR-6515). For studying hydrolytic reactions of lead(II) ions, glass electrodes were used, while lead amalgam electrodes were used for measurements of potential changes with varying concentrations of dioxane in an acidic solution containing a constant total concentration of lead(II) ions where no hydrolysis occurs.

Results

The Autoprotolysis Constant of Solvent. An H_0 mol dm^{-3} $HClO_4$ ($H_0 \simeq 0.07$) solution containing $(3-H_0)$ mol dm^{-3} $LiClO_4$ was titrated with an LiOH solution containing 3 mol dm^{-3} $LiClO_4$, the concentration of LiOH in the titrant is about 0.03 mol dm^{-3}. The emf E at equilibrium is written by the following equation:

$$\begin{aligned} E &= E_{0,H} + 59.154 \log [H^+] + 59.154 \log y_H \\ &\quad + E_j - \Delta E_p \\ &= E^*_{0,H} + 59.154 \log [H^+] + E_j - \Delta E_p \end{aligned} \quad (1)$$

where

$$\Delta E_p = 29.577 \log (P_H/P_{0,H}) \quad (2)$$

and $E_{0,H}$ is a constant and P_H and $P_{0,H}$ stand for partial pressures of hydrogen gas at each point and initial point of the emf measurements, respectively. The value log $(P_H/P_{0,H})$ was so small in a course of one series of titrations that it was neglected. E_j is the liquid junction potential between the reference electrode and the test solution. y_H denotes the activity coefficient of hydrogen ion in the solution. Equation 1 is rewritten by using the autoprotolysis constant $K_i(=[H^+][OH^-])$ as follows:

$$\begin{aligned} E &= E^*_{0,H} + 59.154 \log (K_i/[OH^-]) \\ &= E^*_{0,A} - 59.154 \log [OH^-]. \end{aligned} \quad (3)$$

Since $E^*_{0,H}$ and $E^*_{0,A}$ are constant in a constant ionic medium with a constant composition of solvent, the autoprotolysis constant was estimated by using the $E^*_{0,H}$ and $E^*_{0,A}$ values obtained by Gran's plots in relatively low acidic and basic regions of the solution, where the liquid junction potentials were negligible.

$$\log K_i = \frac{E^*_{0,A} - E^*_{0,H}}{59.154} \quad (4)$$

The autoprotolysis constants obtained in various solutions by using hydrogen electrodes are summarized in Table 1.

Formation Constants of Hydroxo Complexes of Lead(II) Ions. The hydrolytic reactions of metal ions may be written as follows:

$$qM^{z+} + pH_2O = M_q(OH)_p^{(zp-q)+} + pH^+. \quad (5)$$

The average number of hydrogen ion set free per metal ion, Z, is an experimentally determinable quantity as given by the following equation:

$$Z = \frac{[H^+] - \boldsymbol{H}}{B} = \sum_p \sum_q p {}^*\beta_{pq} [M^{z+}]^q [H^+]^{-p}/B \quad (6)$$

where ${}^*\beta_{pq}$ is the formation constant of the $M_q(OH)_p^{(zq-p)+}$ complex given by Eq. 7;

$${}^*\beta_{pq} = [M_q(OH)_p^{(zq-p)+}][H^+]^p/[M^{z+}]^q \quad (7)$$

Initial: Formation constants initially assumed. Final: Formation constants finally obtained. Fixed: The set of the complexes is fixed at that proposed by Olin, but the formation constants of the complexes are floated.
( ): Minor species and uncertain. —: Unreasonable species which is rejected in the course of the calculation.

estimate the composition of complexes formed in a relatively low pH region if there exists either $Pb_4(OH)_4^{4+}$ or $Pb_3(OH)_3^{3+}$, or both. Therefore, the composition of the complexes formed and their formation constants were determined by the least-squares method using an electronic computer (HITAC 8700). As a first guess, a number of possible species were assumed to be present in the systems, and then unreasonable species were rejected in the course of the least-squares optimization. The method used was essentially based on the principle of the LETAGROP program developed by Sillén.[17] The minimum value of the error square sum $U=\sum(Z_{obsd}-Z_{calcd})^2$ for a given system was searched by choosing the best set of the composition (p and q) and the formation constants of the complexes in the system. As is shown in Table 2, the only four complexes, $Pb_3(OH)_3^{3+}$, $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$, and $Pb_6(OH)_8^{4+}$ were finally obtained as possible species in all the solvent systems examined. Formation of the $PbOH^+$ complex proposed by Olin[4] was rather uncertain in our measurements (see Table 2). An examination of the least-squares calculation by assuming a set of complexes, $PbOH^+$, $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$, and $Pb_6(OH)_8^{4+}$, which had been proposed by Olin, gave a larger error square sum than that for a set of the complexes, $Pb_3(OH)_3^{3+}$, $Pb_4(OH)_4^{4+}$, $Pb_3(OH)_4^{2+}$, and $Pb_6(OH)_8^{4+}$, and the $PbOH^+$ complex was excluded in the course of the refinement. In Table 2, columns "Initial" and "Final" show the initially assumed and finally obtained composition and stability constants of the complexes, respectively. Lack of number in the column "Final" means that the relevant complex is rejected as an unreasonable one during the course of the refinement. "Fixed" denotes that the set of the complexes is fixed at the proposed one by Olin, and the formation constants of the complexes are allowed to change to reach the minimum error square sum. Since the Z values never exceed 1.5, possible combinations of $p/q<1.5$ are assumed as the inital sets of complexes. Values in parentheses are uncertain ones. The final results obtained for the formation constants of the hydroxo complexes of lead(II) ions are summarized in Table 3, together with the autoprotolysis constants of the solvents.

TABLE 3. AUTOPROTOLYSIS CONSTANT $K_1(=[H^+][OH^-])$ AND FORMATION CONSTANTS OF HYDROXO COMPLEXES OF LEAD(II) ION IN AQUEOUS AND DIOXANE–WATER MIXTURES CONTAINING 3 mol dm^{-3} $LiClO_4$

$qPb^{2+}+pH_2O=Pb_q(OH)_p^{(2q-p)}+pH^+$

$*\beta_{pq}=[Pb_q(OH)_p^{(2q-p+)}][H^+]^p/[Pb^{2+}]^q$

	Mole fraction of dioxane

$-\log*\beta_{86}$	−42.33 (0.02)	−40.75 (0.02)	−41.12 (0.02)

Uncertainties of the formation constants were estimated as 3σ where σ denotes the standard deviation.

Discussion

As seen in Table 3, the formation constants of all of the lead(II) hydroxo complexes, $\log*\beta_{pq}$, were only slightly changed by the addition of dioxane in an aqueous solution, the fact having been found for other divalent metal ions so far examined.[8–11] Combination of the formation constant $*\beta_{pq}$ with the autoprotolysis constant of solvent K_1 leads to the formation constant β_{pq} for the hydrolytic reaction as follows:

$$qM^{z+} + pOH^- = M_q(OH)_p^{(zq-p)+} \quad (8)$$

$$\beta_{pq} = [M_q(OH)_p^{(zq-p)+}]/[M^{z+}]^q[OH^-]^p = *\beta_{pq}/K_1^p. \quad (9)$$

Thus, the free energy change of transfer for Reaction 8 from the aqueous solution to a dioxane–water mixture is obtained as follows:

$$\Delta G^t_{pq} = \Delta G^\circ_{pq}(\text{mix}) - \Delta G^\circ_{pq}(\text{aq}) = -RT\ln\{\beta_{pq}(\text{mix})/\beta_{pq}(\text{aq})\}. \quad (10)$$

The free energy changes of transfer ΔG^t_{pq} against the mole fraction of dioxane in the mixtures are represented in Fig. 4. The values ΔG^t_{pq} were negative for all of the hydrolytic species, as well as metal and hydrogen ions, and became more negative with an increase in the concentration of dioxane. However, no clear correlation was found between ΔG^t_{pq} and the composition or the total charge of the hydroxo complexes. ΔG^t_{pq} may be expressed in terms of the partial molar free energy change of transfer of a species i, Δg^t_i, as follows:

$$\Delta G^t_{pq} = \Delta g^t_{pq} - q\Delta g^t_M - p\Delta g^t_{OH}. \quad (11)$$

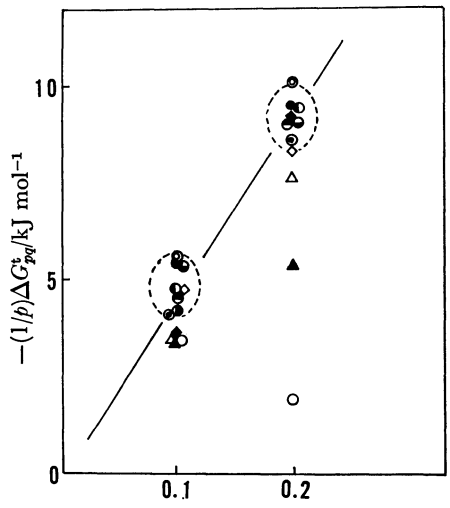

Fig. 5. Free energy changes of transfer per hydroxide ion of hydroxo complexes of divalent metal ions against the mole fraction of dioxane in mixed solvents.
Symbols are the same as those in Fig. 4.

Since the number of OH^- ion involved in a hydroxo complex depends on its composition, the values, $(1/p)\Delta G^t_{pq}$, were subsequently compared in Fig. 5 instead of ΔG^t_{pq} in Fig. 4. The values $(1/p)\Delta G^t_{pq}$ were approximately independent of the complexes examined at a given solvent composition, except for some complexes such as Cd_2OH^{3+}, Cu_2OH^{3+}, and Be_2OH^{3+}, which are all minor species in their systems. For the partial molar free energy change of transfer Δg^t_i from an aqueous solution to a dioxane–water mixture, it has been reported that Δg^t_i of a cation is usually negative and the value becomes more negative for ions with small ionic radius and that the reverse is the case for anions.[18]

In order to estimate the value of Δg^t_{pq}, the changes of the activity coefficients of lead(II) and hydrogen ions were measured at a constant total concentration of a relevant ion with varying solvent compositions by measuring emfs of cells (C) and (D). Emfs of the cells may be written as follows: for cell (C)

$$E_H = E_{0,H} + 59.154 \log [H^+] + 59.154 \log y_H + E_j \quad (12)$$

and for cell (D)

$$E_{Pb} = E_{0,Pb} + 29.577 \log [Pb^{2+}] + 29.577 \log y_{Pb} + E_j. \quad (13)$$

Since we used glass electrodes, ΔE_p equals zero. y_i denotes the activity coefficient of a species i in the solution. An activity coefficient of a species i in a given solvent may be described as follows:

$$y_i = y_i(aq) \cdot y_i(solvent) = y_i(mix) \quad (14)$$

where $y_i(aq)$ represents the activity coefficient of species i in an aqueous medium in which y_i approaches unity at infinite dilution. y_i may be reasonably assumed to be constant in a constant ionic medium of a given solvent. y_i(solvent) is a function of solvent composition in a given ionic medium and is unity in an aqueous solution.

Since $E_{0,H}$ is a constant independent of solvent composition, changes in E_H with changing solvent compositions at a constant $[H^+]$ is given as

$$\begin{aligned}\Delta E_H &= E_H(mix) - E_H(aq) \\ &= 59.154 \log \{y_H(mix)/y_H(aq)\} + \{E_j(mix) - E_j(aq)\} \\ &= 59.154 \log y_H(solvent) + \{E_j(mix) - E_j(aq)\}. \quad (15)\end{aligned}$$

Thus, ΔE_H may be independent of $[H^+]$, but depends on the solvent composition of 3 mol dm^{-3} $LiClO_4$ solution, as far as the term $\{E_j(mix) - E_j(aq)\}$ is negligibly small. Similar measurements were carried out for ΔE_{pq} by using lead amalgam lelectrodes.

The emf changes of cells (C) and (D), ΔE_H and ΔE_{Pb}, respectively, were measured at constant $[H^+]$ and $[Pb^{2+}]$. Since the measurements were carried out in an acidic solution where no hydrolysis of metal ion occurs, $[H^+]$ is equal to the total concentration of the acid in the solution, and $[Pb^{2+}]$ is equal to the total concentration of the metal ion, B.

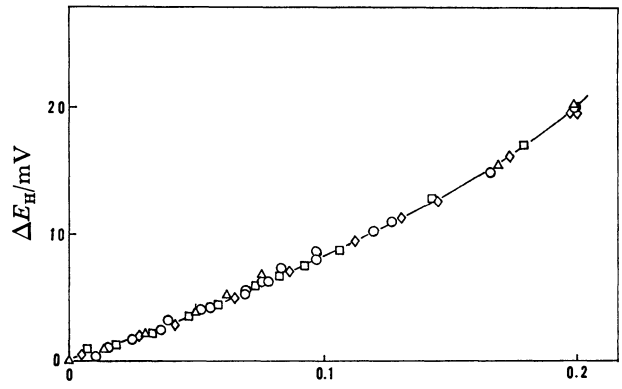

Fig. 6. Emf changes of cell (C) with varying solvent compositions.
The concentrations of hydrogen ions (in mol dm^{-3}); are; △: 0.00 (extrapolated by Gran's plot), (Ref_1), ○: 0.010 (Ref_1), □: 0.020 (Ref_1), ◇: 0.020 (Ref_2). Ref_1 and Ref_2 indicate the reference cells (E) and (F), respectively, used in the measurements.

The emf for cell (C) was measured by using two different reference electrodes in order to check the effect of the different liquid junction on potentials.

$$Ref_1 = \left| \begin{array}{l} 3 \text{ mol dm}^{-3} \\ LiClO_4 \\ \text{in aqueous} \\ \text{solution} \end{array} \right| \left| \begin{array}{l} 0.01 \text{ mol dm}^{-3} \\ AgClO_4 \\ 2.99 \text{ mol dm}^{-3} \\ LiClO_4 \\ \text{in aqueous} \\ \text{solution} \end{array} \right| AgCl\text{–}Ag \quad (E)$$

$$Ref_2 = \left| \begin{array}{l} 3 \text{ mol dm}^{-3} \\ LiClO_4 \\ \text{in 0.2 mole} \\ \text{fraction} \\ \text{dioxane–water} \\ \text{mixture} \end{array} \right| \left| \begin{array}{l} 0.01 \text{ mol dm}^{-3} \\ AgClO_4 \\ 2.99 \text{ mol dm}^{-3} \\ LiClO_4 \\ \text{in aqueous} \\ \text{solution} \end{array} \right| AgCl\text{–}Ag \quad (F)$$

As is seen from Fig. 6, ΔE_H obtained fell on one curve. Therefore, the liquid junction potentials of the cells were found to be negligible.

In these measurements, the changes of the activity coefficients or the partial molar free energy changes of transfer, Δg^t, of hydrogen and lead(II) ion in a 3 mol dm^{-3} $LiClO_4$ can be described with a good approximation as follows:

$$\Delta g_{\mathrm{H}}^{\mathrm{t}} = -RT\ln\{y_{\mathrm{H}}(\mathrm{mix})/y_{\mathrm{H}}(\mathrm{aq})\} = -F\Delta E_{\mathrm{H}} \quad (16)$$

$$\Delta g_{\mathrm{Pb}}^{\mathrm{t}} = -RT\ln\{y_{\mathrm{Pb}}(\mathrm{mix})/y_{\mathrm{Pb}}(\mathrm{aq})\} = -2F\Delta E_{\mathrm{Pb}} \quad (17)$$

where F stands for Faraday constant. The $\Delta g_{\mathrm{H}}^{\mathrm{t}}$ and $\Delta g_{\mathrm{Pb}}^{\mathrm{t}}$ values with varying mole fractions of dioxane are shown in Fig. 7.

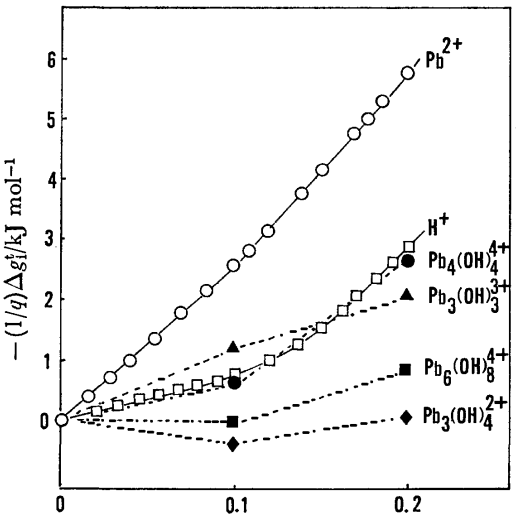

Fig. 7. Partial molar free energy changes of transfer of H^+, Pb^{2+}, and $Pb_q(OH)_p^{(2q-p)+}$ with varying solvent compositions.

The thermodynamic formation constant of the $M_q(OH)_p^{(zq-p)+}$ complex is given in terms of activities as follows:

$$*\beta_{pq}^{\circ} = (a_{pq}\cdot a_{\mathrm{H}}{}^{p})/(a_{\mathrm{M}}{}^{q}\cdot a_{\mathrm{H_2O}}{}^{p}) = \frac{[\mathrm{M}_q(\mathrm{OH})_p{}^{(zq-p)+}][\mathrm{H}^+]^p}{[\mathrm{M}^{z+}]^q}\cdot\frac{1}{[\mathrm{H_2O}]^p}\cdot\frac{y_{pq}y_{\mathrm{H}}{}^{p}}{y_{\mathrm{M}}{}^{q}f_{\mathrm{H_2O}}{}^{p}}. \quad (18)$$

$f_{\mathrm{H_2O}}$ represents the activity coefficient of water in a mixed solvent expressed by the mole fraction scale of the solvent component. If the standard state of any reacting species is so chosen that the activity coefficient of the species appraoches unity when the composition of the solution approaches 3 mol dm^{-3} $LiClO_4$ aqueous solution, $*\beta_{pq}$ obtained in the aqueous solution is given as the formation constant at the standard state ($=*\beta_{pq}^{0}$), and is independent of the solvent composition at a given temperature. The activity coefficient y is defined in terms of molarity and is independent of the concentration of the relevant species in a given constant ionic medium, but is dependent on the solvent composition, as is shown in Eq. 14.

Since the value $[\mathrm{M}_q(\mathrm{OH})_p{}^{(zq-p)+}][\mathrm{H}^+]^p/[\mathrm{M}^{z+}]^q = *\beta_{pq}$ is experimentally determinable for the complex $M_q(OH)_p^{(zq-p)+}$ in a given solvent and $*\beta_{pq}^{0}$ is defined as the formation constant of the complex in the aqueous solution, the difference between the formation constants obtained in a mixed solvent and an aqueous solution is given as follows:

$$\Delta\ln *\beta_{pq} = \ln *\beta_{pq}(\mathrm{mix}) - \ln *\beta_{pq}(\mathrm{aq}) = p\ln[\mathrm{H_2O}] + \ln(y_{\mathrm{M}}{}^{q}/y_{\mathrm{H}}{}^{p}) - \ln(y_{pq}/f_{\mathrm{H_2O}}{}^{p}). \quad (19)$$

The first two terms of the right hand side of Eq. 19 are experimentally determined, and thus, the value $\ln(y_{pq}/f_{\mathrm{H_2O}}{}^{p})$ is estimated. If we assume that $f_{\mathrm{H_2O}}=1$ as a first approach over the range of the solvent composition examined here, the values may represent the variations of the activity coefficient of the $M_q(OH)_p^{(zq-p)+}$ complex in the dioxane–water mixtures containing 3 mol dm^{-3} $LiClO_4$ at 25 °C. The partial molar free energy change of transfer of the $M_q(OH)_p^{(zq-p)+}$ complex may thus be calculated as follows:

$$\Delta g_{pq}^{\mathrm{t}} = -RT\ln[\mathrm{H_2O}]^p + q\Delta g_{\mathrm{M}}^{\mathrm{t}} - p\Delta g_{\mathrm{H}}^{\mathrm{t}} + RT\Delta\ln *\beta_{pq}. \quad (20)$$

$(1/q)\Delta g_{pq}^{\mathrm{t}}$ with varying mole fractions of dioxane are shown in Fig. 7.

As is seen from Fig. 7, $\Delta g_{\mathrm{H}}^{\mathrm{t}}$ and $\Delta g_{\mathrm{Pb}}^{\mathrm{t}}$ are both negative and become more negative with an increase in the mole fraction of dioxane. $(1/q)\Delta g_{pq}^{\mathrm{t}}$ seems to vary with a similar trend to $\Delta g_{\mathrm{H}}^{\mathrm{t}}$ and $\Delta g_{pq}^{\mathrm{t}}$. At a given mole fraction of dioxane, the $(1/q)\Delta g_{pq}^{\mathrm{t}}$ values are smaller than $\Delta g_{pq}^{\mathrm{t}}$, and the smaller the formal charge, $(zq-p)/q$, of a hydroxo complex is, the smaller $(1/q)\Delta g_{pq}^{\mathrm{t}}$ may become. The same results have previously been obtained for the hydroxo complex of cadmium.[11]

Equation 4 is rewritten as follows:

$$\frac{1}{p}\Delta G_{pq}^{\mathrm{t}} = \frac{q}{p}\left(\frac{1}{q}\Delta g_{pq}^{\mathrm{t}} - \Delta g_{\mathrm{M}}^{\mathrm{t}}\right) - \Delta g_{\mathrm{OH}}^{\mathrm{t}}. \quad (21)$$

The values $(1/p)\Delta G_{pq}^{\mathrm{t}}$ of formation of hydroxo complexes of divalent metal ions examined are approximately independent of the complexes at a given solvent composition. Since the contribution of $\Delta g_{\mathrm{OH}}^{\mathrm{t}}$ to $(1/p)\Delta G_{pq}^{\mathrm{t}}$ is the same for all the hydroxo complexes and $(1/q)\Delta g_{pq}^{\mathrm{t}}$ may vary with the formal charge of the complexes, the term $(q/p)\{(1/q)\Delta g_{pq}^{\mathrm{t}} - \Delta g_{\mathrm{M}}^{\mathrm{t}})\}$ may be independent of the complexes but dependent on the composition of solvents. Thus, at a given solvent composition,

$$\frac{q}{p}\left(\frac{1}{q}\Delta g_{pq}^{\mathrm{t}} - \Delta g_{\mathrm{M}}^{\mathrm{t}}\right) \approx k(\mathrm{constant}). \quad (22)$$

The formal charge z' per metal ion of the complex is defined as follows:

$$z' = \frac{1}{q}(zq-p) = z - p/q. \quad (23)$$

Thus, replacing $z-z'$ to p/q in Eq. 22, we rewrite the equation for free energy change of transfer of an $M_q(OH)_p^{(zq-p)+}$ complex in terms of the formal charge of the complex as follows:

$$\frac{1}{q}\Delta g_{pq}^{\mathrm{t}} \approx \Delta g_{\mathrm{M}}^{\mathrm{t}} + k(z-z'). \quad (24)$$

Since $(1/q)\Delta g_{pq}^{\mathrm{t}}$ may be less negative than $\Delta g_{\mathrm{M}}^{\mathrm{t}}$ (see Fig. 7), the value k may be positive at a given solvent composition. Thus, Eq. 24 indicates that the value $(1/q)\Delta g_{pq}^{\mathrm{t}}$ of a hydroxo complex approaches the value of $\Delta g_{\mathrm{M}}^{\mathrm{t}}$ when the formal charge z' of the complex approaches z, the charge of the free metal ion.

Medium effects on the thermodynamic parameters of the hydrolytic reactions of metal ions may be mainly due to changes in solvation structures of the species involved.[18-20] Ion-solvent interactions of the hydroxo complexes of beryllium ions in dioxane–water mixtures

were discussed in a previous paper.[20] The enthalpy changes of transfer per hydroxide ion $(1/p)\Delta H^{t}_{pq}$ $[=(q/p)\{(1/q)\Delta h^{t}_{pq}-\Delta h^{t}_{M}\}-\Delta h^{t}_{OH}$, where Δh^{t}_{i} denotes the partial molar enthalpy change of transfer of species i] strongly depended on metals.[20,21] Consequently, the value $(1/q)\Delta h^{t}_{pq}$ depends on both p/q and Δh^{t}_{M} at a given solvent composition.

The different features of the solvent effects between ΔG^{t}_{pq} and ΔH^{t}_{pq} of hydroxo complexes of divalent metal ions may be explained as follows: For a strongly solvated metal ion (*i.e.*, $(1/p)\Delta H^{t}_{pq}$ may be largely negative for such an ion), the ion may have a large ordering effect for the solvent molecules even in the secondary solvation shell of the ion, and thus, $(1/p)\Delta S^{t}_{pq}$ may become less positive. Therefore, the effect due to $(1/p)\Delta H^{t}_{pq}$ on $(1/p)\Delta G^{t}_{pq}$ may be compensated by the effect due to $(1/p)\Delta S^{t}_{pq}$, and thus, the $(1/p)\Delta G^{t}_{pq}$ value becomes practically independent of metal ion.

Equilibria of Complex Formation between Bivalent Metal Ions and 3,3′-Bis[*N*,*N*′-bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein

Sadaaki Murakami,* Kotaro Ogura, and Takashi Yoshino

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received August 27, 1979)

The complex formation equilibria between several bivalent metal ions and 3,3′-bis[*N*,*N*′-bis(carboxymethyl)-aminomethyl]-*o*-cresolsulfonphthalein (XO) have been investigated potentiometrically and spectrophotometrically. The metal ions studied here were Co(II), Ni(II), Cu(II), Zn(II), Pb(II), and Cd(II). The formation constants and visible-absorption-spectrum parameters of these metal complexes have been determined. It has been found that all these metal ions form 1: 1 and 2: 1 (metal: XO) complexes with XO. Moreover, the complex of each composition changes into one of several protonated ones depending on the pH of the solution. The probale structures of the complexes in solution are discussed.

Xylenol Orange (abbreviated as XO or H_6L; Formula I) forms stable and colored complexes with metal ions, and it has been widely used as an indicator in the chelatometric and spectrophotometric determinations of numerous metal ions.[1–5] However, despite many interesting findings concerning the solution chemistry of its metal complexes, serious discrepancies have often been noted among the data and/or conclutions reported by different authors. These discrepancies are primarily caused by the use of commercial or incompletely purified XO.[6] Recently, new methods for the purification of XO have been established,[6–9] pure XO has been used, in particular, in the investigation of the solution chemistry of XO. However, discrepancies among the data and conclusions reported seem to remain. The following two facts may be offered as explanations of this problem:

1) The metal complexes of XO have a visible absorption spectrum. The compositions and the stability constants of these complexes have, therefore, often been determined only by spectrophotometry.

2) The XO molecule has two chelating groups on each side of its large sulfonphthalein nucleus, and each chelating group reacts with metal ions independently of the other;[3] hence, several complex species have various ratios of metal and XO.[3,5] Moreover, the complex of each component changes into different types of protonated or hydroxo complexes, depending on the pH of the solution.[10–12] The complex formation equilibria between metal ions and XO must, therefore, be complicated.

The change in the visible absorption spectrum of XO accompanying its complex formation is smaller than that of 3,3′-bis[*N*,*N*′-bis(carboxymethyl)aminomethyl]-thymolsulfonphthalein,[12–14] MTB, similar sulfonphthalein indicator (Formula I), and the difference in color between XO and its complexes, especially in neutral and alkaline solutions, not clearly distinguishable except in the case of metal ions with valences of 3 or more.[1,3,12] This may be due to differences in electron-donation effects of the substituent groups, R_1 and R_2, on the sulfonphthalein nucleus, as seen in Formula I.[15] Moreover, no clearly visible change in the spectrum is obsevable in the metal complex formation with sulfonphthalein indicators when the metal ions combine with coordinating donors other than phenolic or quinolic oxygen (1 or 1′ in Formula I).[10,12,14–21] In such a case, no information can be obtained spectrophotometrically. Also, most of the measurements have been limited to the narrow pH range of the solution (pH 3 to 6) in which the spectrum change is remarkable. The following points may be made regarding on investigation of XO chemistry in solution:

i) Measurement over a wide pH range should be under taken.

ii) The results by spectrophotometry should be compared with those obtained by other instrumental methods.

The present work is a study of the complex formation equilibria of XO with several bivalent metal ions in aqueous solutions over the pH range of 1 to 14 by spectrophotometry and potentiometry, refering to the results of research by ESR[22] and electrochemical (polarography and potential sweep voltametry)[23] techniques. The metal ions examined were Co(II), Ni(II), Cu(II), Zn(II), Pb(II), and Cd(II). The results obtained were compared with those reported by other authors: Co(II),[24] Ni(II),[24] Cu(II),[11,24,25] Zn(II),[26,27] Pb(II),[28] and Cd(II).[29]

	R_1	R_2
XO	CH_3	H
MTB	$CH(CH_3)_2$	CH_3

I XO or MTB

Experimental

Xylenol Orange. XO was synthesized and purified by cellulose-column chromatography and by ion exchange using the batch method, as has been described previously.[8,16] The product was the free acid form of XO, and the purity was

nearly 100%, as measured by potentiometric titration with standard sodium hydroxide. This XO was weighed and dissolved in water in each experiment.

Metal Ion Solutions. The commercial perchlorate salt of each metal ion was dissolved in water without further purification. Each solution was standardized by EDTA titration.[1)]

The other reagents and apparatus for the potentiometric and spectrophotometric experiments were the same as have been described earlier.[14,16)] All the measurements were performed at 25±0.2 °C. The ionic strength of the solutions was maintained at 0.1 with sodium perchlorate. The pH values of the strongly acidic and alkaline media (pH<*ca.* 1.5 and pH>*ca.* 12) are difficult to measure by means of a pH meter using a glass electrode. The pH values of such media were determined directly from the concentrations of perchloric acid or sodium hydroxide, one of which was added to adjust the hydrogen ion concentrations, without account being taken of the activity coefficient.

Formation Constants. The formation constants of the complexes were calculated from the mass balances and the electroneutrality, utilizing the successive approximation method previously described in detail.[14-16)] The acid formation constants of XO used in the foregoing calculations were those determined previously[8)] ($\log k_i$: 12.23, 10.56, 6.74, 2.85, 2.32, and 1.5 from $i=1$ to 6 respectively).

Results

Complex Formation Equilibria. Potentiometric titrations of XO solutions containing 1: 1, 2: 1, and 3: 1 molar ratios of Co(II), Ni(II), Cu(II), Zn(II), Pb(II), and Cd(II) to XO were performed (the molar ratios of the metal ion to the ligand will be, hereinafter, referred to as "1/1", "2/1", and "3/1"). The visible absorption spectra of the 1/1 and 2/1 solutions for each metal ion at different pH values (pH 1—14) were measured between 350 and 700 nm, and the variation in the spectrum with the pH was investigated.

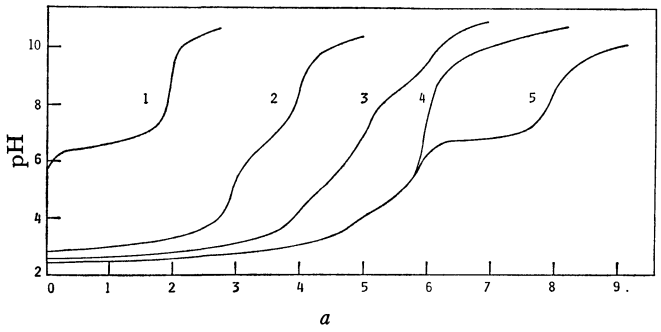

Fig. 1. Potentiomitric titration curves of Cu(II)–XO solutions.
1-Cu(II), 2-XO, 3, 4, and 5-1/1, 2/1, and 3/1 solutions, respectively. [XO]=about 1×10^{-3} mol/l and [Cu(II)] is varied.

Cu(II) Complexes. Figure 1 shows the foregoing titration curves for the Cu(II) complexes, together with the curves for the Cu(II) and XO solutions. The 1/1 Curve 3 exhibits three inflections at $a=4$, 5, and 6, indicating the formation of these three stable 1: 1 complex species: CuH_2L^{2-}, $CuHL^{3-}$, and CuL^{4-}, where a is the number of moles of base added per mole of XO. The 2/1 Curve 4 shows two inflections at $a=$ 5 and 6 (the first one is not well-defined), probably with the formation of two 2/1 complexes, $CuHL^{-}$ and Cu_2L^{2-}, at the respective a values. The 3/1 Curve 5 is quite identical with the 2/1 Curve up to $a=6$, but beyond this a value up to $a=8$ there is a buffer region in which copper(II) hydroxide is precipitated; this precipatation reaction of copper(II) hydroxide is in the same pH range as when the Cu(II) aquo ion is hydrolyzed ($a=0$ to 2 on Curve 1). The 3/1 solution may, therefore, contain the free Cu(II) ion. The extent of the buffer region over two unit of a indicates that there exists one mole of free Cu(II) ion per mol of ligand in the 3/1 solution, and that not more than two Cu(II) ions can combine with one XO molecule.[14,16)]

The absorption spectra of the 1/1 and 2/1 solutions for Cu(II) at various pH values are shown in Figs. 2 and 3 respectively. The absorbances of these spectra at a given wavelength are shown as a funtion of pH in Fig. 4. The 1/1 solutions below pH 10 show two steps of change in their absorbance (Plot 1 in Fig. 4). The first step in the pH region from 4 to 6, and the second step, from 7 to 10. Moreover, an isosbestic point for

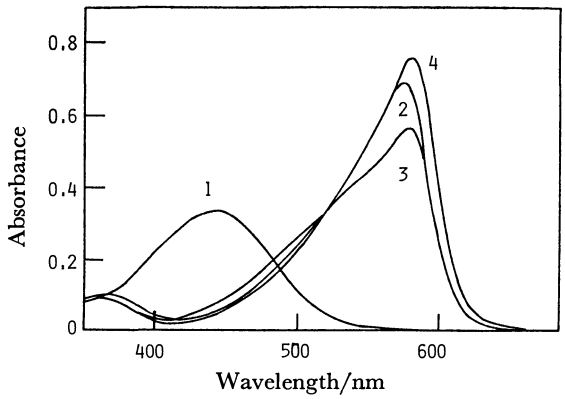

Fig. 3. Visible absorption spectra of 2/1 Cu(II)–XO solutions at various pH values.
pH: 1-2.62, 2-9.31, 3-13.42, and 4-13.57.
[XO]=1.20×10^{-5} mol/l.

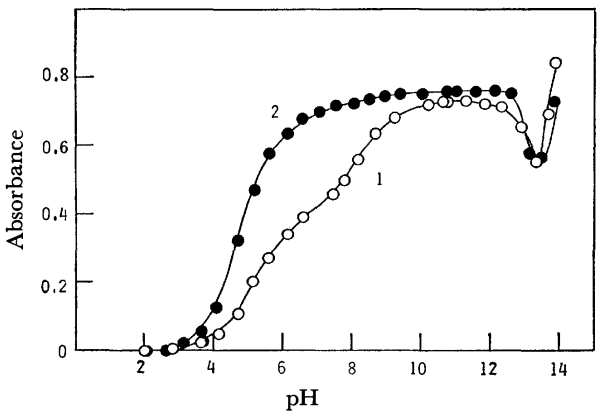

Fig. 4. Absorbances at 575 nm for Cu(II)–XO solutions as a function of pH.
1-1/1 and 2-2/1 solutions, respectively.
[XO]$=1.20\times10^{-5}$ mol/1.

the spectra in each pH range was observed at 483 and 533 nm respectively (the intercept points of Spectra 1 and 2, and of Spectra 2 and 3, respectively in Fig. 2). These pH regions are similar to those for the buffer regions of the titration curve (Fig. 1) from $a=4$ to 5 and from $a=5$ to 6 respectively. In addition, for the following reaction:

$$CuH_iL^{-4+i} \rightleftarrows CuH_{i-n}L^{-4+i-n} + nH^+$$

$$K^{nH}_{MH_iL} = \frac{[CuH_iL]}{[H]^n[CuH_{i-n}L]}.$$

The plot of $\log\{[CuH_iL]/[CuH_{i-n}L]\}$ *vs.* pH[30] gave a straight line with a slope of $n=1$ for each step of the absorbance change, as is seen in Fig. 5 for the proton dissociation from CuH_2L^{2-}. The value of each $K^{H}_{CuH_iL}$ for $i=1$ and 2 was evaluated from the pH value when the log term was equal to zero (Table 1). In the 1/1 solutions, the formation of the three complex species CuH_2L^{2-}, $CuHL^{3-}$, and CuL^{4-} may be complete around pH 3, 6.5, and 11 respectively, taking into account the change in their absorbance (Fig. 4). Spectra 1, 2, and 3 in Fig. 2, therefore, may correspond to the foregoing complex species. The wavelength, λ_{max}, and the absorptivity, ε, for the maximum absorbance of the spectrum attributed to each complex

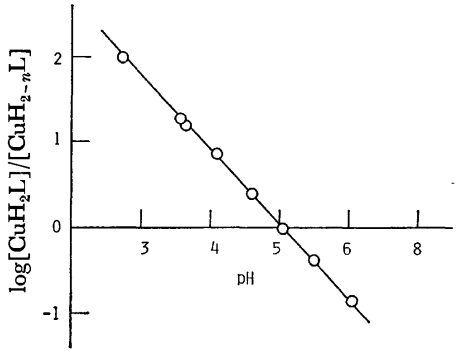

Fig. 5. Plot of $\log\{[CuH_2L]/[CuH_{2-n}L]\}$ *vs.* pH.
Wavelength: 575 nm.

species were also determined (Table 2).

The 2/1 solutions show a single step of change in their visible absorbance below pH 8 (Plot 2 in Fig. 4), and the isosbestic point was at 486 nm for the spectra in this pH range (the intercept point of Spectra 1 and 2 in Fig. 3). The plot of $\log\{[Cu_2H_iL]/[Cu_2H_{i-n}L]\}$ *vs.* pH showed a straight line, with a slope of $n=1$. The pH region for the change in this absorbance may correspond to that from $a=5$ up to 6 (Curve 4 in Fig. 1). These facts suggest that a mono-protonated complex, Cu_2HL^-, is almost complete around pH 3 (its corresponding spectrum may be seen in Curve 1 in Fig. 3). The change in the spectrum from pH 3 to 7 may be accompanied by a proton dissociation from Cu_2HL^-.

Below pH 3, no remarkable change in the spectrum as a function of pH is observed, and no observable inflections are seen on the titration curves. However, the spectra of both the 1/1 and 2/1 solutions at pH 2—3 are at slightly longer wavelengths than that of the XO solutions of the same pH (*i.e.*, λ_{max} and ε for the XO, 1/1 and 2/1 solutions are 439, 443, and 443 nm, and 2.62, 2.75, and 2.75×10^4 l mol^{-1} cm^{-1}, respectively). The results of the mole-ratio method at pH 2—3 showed the existence of the 1: 1 and 2: 1 complex species, as may be seen in Plots 1 and 2 in Fig. 9. (The results of the mole-ratio methods will be discussed below in more detail.) The ESR spectra of the 1/1 solutions indicated the existence of stable 1: 1 complex species down to around pH 1.[22] This fact suggests that more highly protonated complex species, *i.e.*, CuH_iL^{-4+i} ($i\geqslant3$), may be formed in such acidic solutions.[12,14] Around pH 1, the ESR spectra consisted of two overlapping lines attributed to the 1: 1 complex species and the Cu(II) aquo ion. Below pH 1, the spectra showed one line attributed to a Cu(II) aquo ion, indicating that the 1: 1 complex species CuH_iL^{-4+i} dissociates to a Cu(II) ion and H_6L in such strongly acidic solutions. The ESR spectra of the 2/1 solutions around pH 4 showed the existence of the 2: 1 complex species, but around pH 2—3 they consisted of three overlapping lines, attributed to the 2: 1 and 1: 1 complex species, and a Cu(II) aquo ion. Around pH 1 the ESR spectra consisted of two lines attributable to the 1: 1 complex species and Cu(II) aquo ion. These facts indicate that the 2: 1 complex species, Cu_2HL^-, begins to dissociate to CuH_iL^{-4+i} and the Cu(II) aquo ion as the pH decreases from 3, its dissociation being complete around pH 1.

Above pH 13, the visible absorbances for both 1/1 and 2/1 solutions decrease and exhibit their minimum value at almost the same pH value (*ca.* 13.2); they then increase beyond this pH value, as are seen of Spectra 3, 4, and 5 in Fig. 2 and Spectra 2, 3, and 4 in Fig. 3 for the 1/1 and 2/1 solutions respectively and in Plots 1 and 2 in Fig. 4. No precipitate of the copper(II) hydroxide was observed in the solutions. The spectra for both 1/1 and 2/1 solutions around pH 14 are quite identical with that of the XO solutions around this pH value. The ESR spectra of the 2/1 and 1/1 solutions around pH 13.2 suggested the existence of hydroxo complex species of Cu(II) with XO, while those around pH 14 were similar to that of the tetrahydroxocuprate-

(II) ion, $Cu(OH)_4^{2-}$. These findings suggest that both the 1:1 complex, CuL^{4-}, and the 2:1 complex, Cu_2L^{2-}, dissociate to $Cu(OH)_4^{2-}$ and L^{6-} through an intermediate hydroxo complex species,[12,14,15,17,19,21] such as $Cu(OH)L^{5-}$ and $[Cu(OH)]_2L^{4-}$.

Co(II), Ni(II), Zn(II), and Pb(II) Complexes. These metal complexes showed similar types of titration curves and changes in the spectra with pH value. Accordingly, the Zn(II) system will be discussed. The 2/1 and 3/1 solutions behaved similarly in their titration curves and their spectra to the Cu(II) system. However, two 1/1 titration curves for Zn(II) have the inflections, at $a=4$ and $a=5$, although the Cu(II) 1/1 curve has three inflections, at $a=4$, $a=5$, and $a=6$, as are seen in the 1/1 Curve 3 in Fig. 1. These facts suggest that the formations of their 1:1 complexes, MH_2L^{2-} and MHL^{3-}, are complete at the respective a values, but that the dissociation of a proton from MHL^{3-} occurs in more alkaline solutions at $a>5$. The 1/1 solution for Zn(II) showed only one step of change in the absorbance below pH 9. However, the absorbances decreased slightly from about pH 9 up to 11. This change may correspond to the dissociation of a proton from the MHL^{3-} complex. Both 1/1 and 2/1 solutions for the Zn(II) complexes showed a minimum absorbance at 12.5, as high as was observed in the Cu(II) system (Fig. 4).

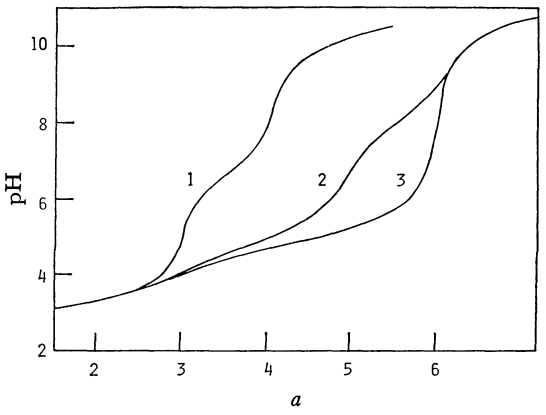

Fig. 6. Potentiometric titration curves of Cd(II)–XO solutions.
1-XO, 2-1/1, and 3-2/1 solutions, respectively.
[XO]=about 1×10^{-3} mol/l.

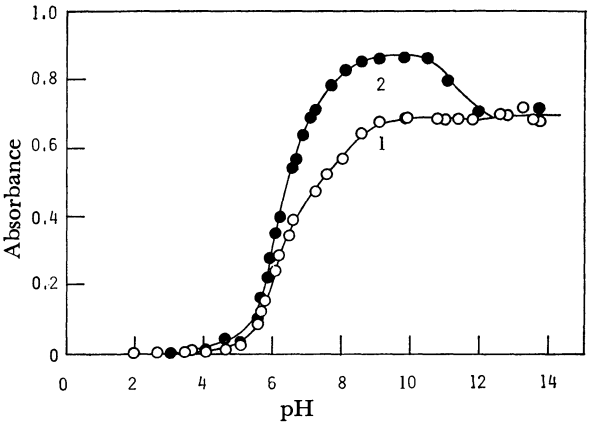

Fig. 7. Absorbances at 575 nm for Cd(II)–XO solutions.
1-1/1 and 2-2/1 solutions.
[XO]=1.20×10^{-5} mol/l.

These foregoing findings suggest that complex formation equilibria similar to those as found in the Cu(II) and XO system are also involved in both 1/1 and 2/1 (or 3/1) solutions of Co(II), Ni(II), Zn(II), and Pb(II), although the complex formation and proton dissociation reactions occur in different pH regions (see Table 1).

Cd(II) Complexes. Both the 1/1 and 2/1 titration curves for Cd(II) are identical to that for the XO solution up to around $a=3$ (Curves 1, 2, and 3 in Fig. 6). Cd(II), therefore, may not react with XO species, H_iL^{-6+i} ($i\geqslant3$),[8] in acidic media (pH 4). Beyond about $a=3$, these curves differ from that for XO and are terminated by an inflection at $a=5$ and $a=6$ for the 1/1 and 2/1 solutions respectively, indicating the formations of complex species, $CdHL^{3-}$ and Cd_2L^{2-}, at each a value. The 1/1 curve beyond $a=5$ is similar in type to that for Cu(II). The 1/1 solution showed two steps of change in the absorbance as a function of pH below 10, as is seen on Plot 1 in Fig. 7. The first step is from pH 4 to 7. The 1/1 curve shows the similar pH value between $a=3$ and 5. Accordingly, this change in absorbance may be ascribed to the complex formation of $CdHL^{3-}$. The plot of $\log\{[CdH_{3-n}L]/[H_3L]\}$ *vs.* pH gave a straight line with a slope of $n=2$ (XO exists as the H_3L^{3-} species in this pH region[8]), which suggests that a protonated complex, such as CdH_iL^{-4+i} ($i\geqslant2$), may not exist, and the complex formation reaction involved in the 1/1 solution from around $a=3$ to 5 may be as follows:

$$Cd^{2+} + H_3L^{3-} \rightleftarrows CdHL^{3-} + 2H^+.$$

The change in absorbance from pH 7 to 10 may correspond to the dissociation of a proton from $CdHL^{3-}$.

Up to about pH 6 the 2/1 solutions showed spectra almost identical with those of the 1/1 solutions (Fig. 7). In addition, the 2/1 titration curve is very similar in pH value to the 1/1 curve up to around $a=5$. These findings suggest that Cd(II) does not form the 2:1 complex until around pH 6. Beyond this pH value the 2/1 spectra differed from the 1/1 spectra. The change in the absorbance of the 2/1 solution from pH 4 to 6, therefore, may be accompanied by the formation of the 1:1 complex, $CdHL^{3-}$, while the change above pH 6 may be attributed to the formation of the 2:1 complex. The plot of $\log\{[CdH_iL]/[CdHL]\}$ *vs.* pH from 6 to 10 showed a straight line with a slope of $n=1$. Accordingly, the 1:1 protonated complex of Cd(II) does not exist until about pH 6, and the reaction involved in the 2/1 solution from pH 6 to 10 may be indicated as follows:

$$Cd^{2+} + CdHL^{3-} \rightleftarrows Cd_2L^{2-} + H^+.$$

Discussion

Problems in the Determination of the Complex Composition by Spectrophotometry. Otomo,[24,29] Hung *et al.*,[25] Studlar *et al.*,[26] Miyazima,[27] and Marchenko[28] have

Table 1. Formation constants of XO complexes at 25 °C and μ=0.1 ($NaClO_4$)

Reaction		log K					
		Co(II)	Ni(II)	Cu(II)	Zn(II)	Cd(II)	Pb(II)

concluded, from the results of the mole-ratio method and the continuous variation method, that Co(II),[24] Ni(II),[24] Zn(II),[26,27] Pb(II),[28] and Cd(II)[29] form only 1:1 complexes with XO in weakly acidic solutions (around pH 5.5—6.5). On the other hand, Yamada and Fujimoto[11] have concluded, from the results of the mole-ratio method using spectrophotometry, that Co(II) and Ni(II) form only 1:1 complexes at pH 3.5—4.5, but for Cu(II) only the 2:1 complexes are formed at pH 3.5—4.5. In the present work, it has been found that all these metal ions form both 1:1 and 2:1 complexes in all the solutions from acidic to alkaline pH. The same conclusions as offered here have been reported from the studies by ESR[22] and electrochemical[23] techniques. Thus, there are serious discrepancies among the results by different authors. Some authors[24–29] used commercial XO without further purification. However, Yamada and Fujimoto[11] used pure XO,[6,9] and so the different results might be caused not only by the purity of the XO used, but also by the experimental method.

The present results from the continuous variation method for Cu(II), Zn(II), and Cd(II) complexes in weakly acidic solutions are shown in Fig. 8. The individual plot at a given wavelength in the continuous variation method indicates the formation of either a 1:1 or 2:1 complex for each metal ion; that is, the plots at 574, 570, and 578 nm for Cu(II), Zn(II), and Cd(II) respectively in Fig. 8 exhibit an inflection at [M]/([M]+[XO])=2/3, but the plots at 498, 510, and 500 nm for these same metal ions show an inflection at 1/2. These facts indicate that the different conclusions are reached regarding the compositions of the complexes, depending on the wavelength used, in spite of testing the same metal ion at the same pH. The results of the mole-ratio method at various pH values for the Cu(II) system are shown in Fig. 9. The individual plot at a given pH exhibits either one inflection or two at [M]/[XO]=1 and/or 2, depending on the pH of the solution.

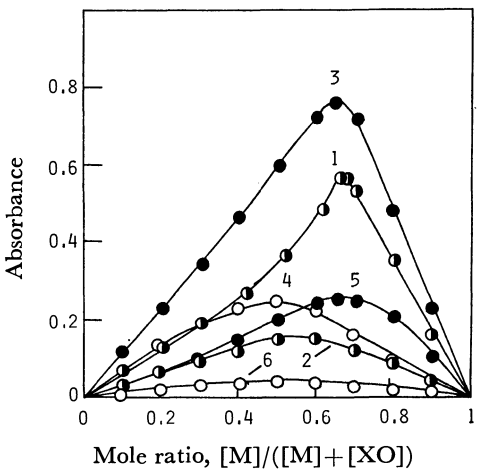

Fig. 8. Continuous variation method for Cu(II), Zn(II), and Cd(II) complexes with XO.
Cu(II): 1-574 and 2-498 nm at pH 5.86, Zn(II): 3-570 and 4-510 nm at pH 5.89, Cd(II): 5-578 and 6-500 nm at pH 6.20. [M]+[XO]=4.0×10^{-5} mol/l.

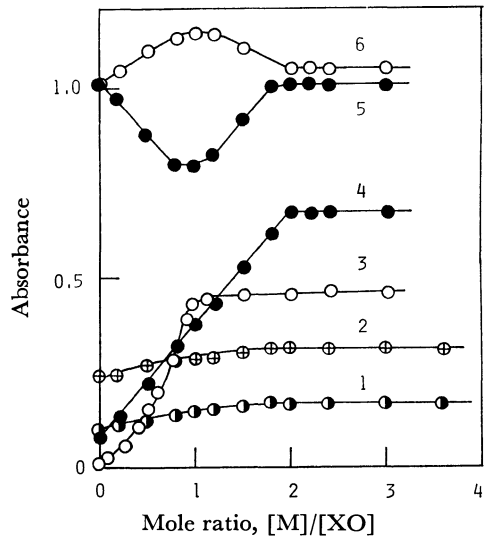

Fig. 9. Mole ratio method for Cu(II) complexes with XO at various pH values.
pH: 1-1.95, 2-3.12, 3-4.45, 4-5.58, 5-7.80, and 6-10.36.
Wavelength: 1-480, 2-500, 3-575, 4-540, 5-575, and 6-582 nm.

One of the explanations for this problem is that the 1: 1 and the 2: 1 complexes of XO formed in solutions of the same pH have absorption maxima at the same wavelength and differ only in absorptivity, as seen in Table 2. The complex of each component changes into a different type of protonated or hydroxo complex, therefore, the absorptivity, $\bar{\varepsilon}_1$ or $\bar{\varepsilon}_2$, is defined as $\bar{\varepsilon}=\sum\varepsilon_i x_i$ to express the apparent absorptivity of each component. ε_i and x_i are the absorptivity and the molar fraction of the complex species i, and the summation is performed on all the complex species of the same component which exist in the solution of a given pH. The subscript 1 or 2 indicates the 1: 1 or 2: 1 complex. The results of the mole-ratio method may be divided into the following three groups in terms of the relationship between $\bar{\varepsilon}$ and inflections on the plots:

(i) two inflections at [M]/[XO]=1 and 2 when $\bar{\varepsilon}_1 \neq \bar{\varepsilon}_2$.

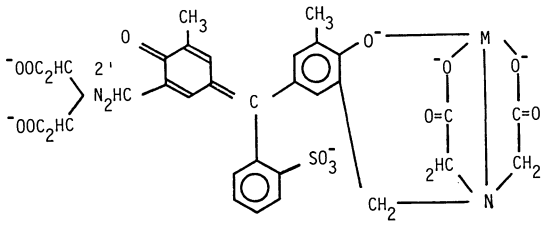
(ii) one inflection at 1 when $\bar{\varepsilon}_1=\bar{\varepsilon}_2$.

(iii) one inflection at 2 when $2\bar{\varepsilon}_1=\bar{\varepsilon}_2$.

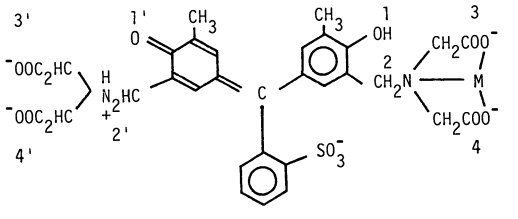
The 1, 2, 5, and 6 plots in Fig. 9 may be explained by (i), the 3 plot by (ii), the 4 plot by (iii). Accordingly, caution should be taken in determining the composition of the metal complexes with XO by spectrophotometry.

Arrangement of the Complex. The changes in the visible absorption spectrum of XO, accompanied by proton dissociation and/or complex formation, may be due to a change in the π-electron structure of its sulfonphthalein nucleus. Thus, the proton dissociation from the phenolic hydroxyl group (1 in Formula I) and the coordination of the phenolic (1) and/or quinolic oxygen (1′) lead to an important change in the absorption spectrum (the number in parentheses after the donor of the XO molecule, hereinafter, will refer to the donor, as indicated by its number in Formula I). Based on the visible absorption parameters, a discussion has been made of the coordination of the individual donor of XO, which is involved in the complex formation and/or in the proton dissociation from the acid group of the XO molecule of the protonated complex.

ML^{4-} dissociates all of the available protons; therefore, the arrangement of the complex may be presented as in Formula II. The mono-protonated complex, MHL^{3-}, dissociates its proton in alkaline solutions (with pH values of from 8 to 10.5, as seen in its acid dissociation constant in Table 1). In addition to this, the conversion from MHL^{3-} to ML^{4-} is accompanied by a slight change in ε, but almost no change in λ_{max} (Table 2). The protonated nitrogens (2 and 2′) of XO dissociate their protons in alkaline solutions, accompanied by a slight change in ε, but almost no change in λ_{max}.[8] Accordingly, the proton in MHL^{3-} may dissociate from the uncoordinating nitrogen (2′) in Formula II. The conversion from MH_2L^{2-} to MHL^{3-} accompanies the blue shift in the spectrum from around 440 to around 580 nm. This fact suggests that its proton dissociation is from phenolic oxygen (1) and that the coordinating donor involved in this reaction is the phenolic oxygen. MH_2L^{2-} exists in a weakly acidic medium. The uncoordinating phenolic oxygen (1) of XO in the MH_2L^{2-} complex would be protonated in such media, considering its pK value.[8] These considerations suggest the arrangement for the MH_2L^{2-} complex indicated in Formula III. The highly protonated complex species, H_iL^{-4+i} ($i \geqslant 3$), which are thought to exist in an acidic solution (pH 1—4), have λ_{max} around 440 nm. No remarkable change in the spectrum on its complex formation was observed, as has been mentioned above. In strongly acidic solutions with pH values from 1 to 2, carboxylic groups (3′ and 4′), which are not coordinated to metal ions, may be protonated based on their pK values.[8] Accordingly, the maximum value of i may be 4; that is, the four protons in MH_iL^{-4+i} ($i=4$) may be attached to two carboxylic oxygens (3′ and 4′) and the phenolic oxygen (1) and the amino nitrogen (2′)[12] in Formula III.



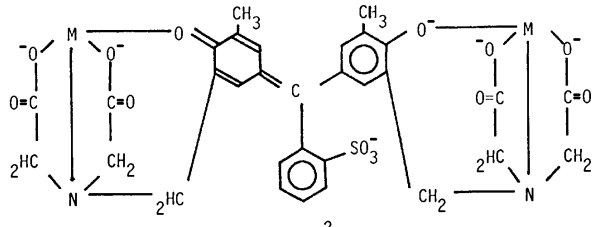
II ML^{4-}



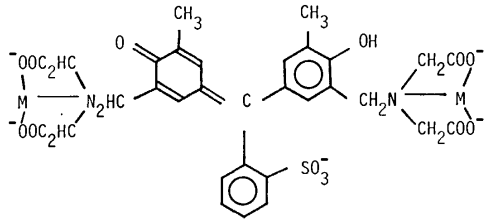
III MH_2L^{2-}

M_2L^{2-} dissociates all of the available protons; therefore, its arrangement may be offered as Formula IV. The spectra corresponding to the mono-protonated 2: 1

complex, M_2HL^-, for each metal ion have λ_{max} values of 435 to 445 nm and ε of 2.41 to 2.83×10^4 l mol^{-1} cm^{-1} respectively. There is not much difference in the spectra between this complex species and the XO species, H_iL^{-6+i} (i=3 to 6) the phenolic oxygen (1) of which is protonated, while its quinolic oxygen (1′) is not protonated (H_iL, i=3 to 6: λ_{max}=439—434 nm, $\varepsilon=2.62\times10^4$ l mol^{-1} cm^{-1}). These facts suggest that neither phenolic nor quinolic oxygens coordinate to metal ions; the arrangement indicated in Formula V is suggested for M_2HL^-.



IV M_2L^{2-}



V M_2HL^-

Yamada *et al.*[11] have established the existence of the diprotonated 2:1 complex, Cu_2H_2L, at pH 3.5—5.5 from their spectrophotometric investigation. They have proposed that the phenolic and quinolic oxygens (1 and 1′) coordinate with Cu(II), but that the amino nitrogens (2 and 2′) do not coordinate and the nitrogens are protonated. Such a structure is, however, contradictory to the following two facts: i) If the Cu_2H_2L is formed at pH 3.5—5.5, the two protons might dissociate at a higher pH. However, the 2/1 titration curve indicates only one proton dissociation above pH 5.5. ii) Iminodiacetic acid, H_2L, forms ML with Cu(II) in weakly acidic media, and all the available protons in this ligand dissociate completely by pH about 5.[31] These facts suggest that all the donors of the bis(carboxymethyl)aminomethyl group in an XO molecule may coordinate to a Cu(II) ion in such weakly acidic solutions as are indicated in Formulas III and V for the MH_2L^{2-} and M_2HL^- complexes.

It is interesting to investigate whether the phenolic (or quinolic) oxygen (1 or 1′) coordinates to metal ions at a lower or higher pH than the amino nitrogen (2 or 2′). Among the metal complexes with SXO,[32] XO, SMTB,[33] MTB, and SGCR,[34] metal ions are, in general, divided into two groups in terms of the foregoing point: 1) Alkaline earth metal ions[10,18] and trivalent metal ions, such as Fe(III),[12] Cr(III),[21] and Al(III),[19] are coordinated by their phenolic oxygen at a lower pH than by their amino nitrogen. 2) Bivalent metal ions,[14–17,20] such as Co(II), Ni(II), Cu(II), Zn(II), Pb(II), and Cd(II), are coordinated by the amino nitrogen at lower pH and by the phenolic oxygen at higher pH. The metal ions of group (1) are hard metal ions, while those of group (2) are intermediate or soft metal ions, according to the hard and soft acid and base (HSAB) theory.[35,36] The phenolic oxygen, therefore, has more affinity to harder metal ions, and the amino nitrogen, to softer metal ions, in complexation in aqueous solutions.

Formation Constants. The formation constants were calculated utilizing the suceissive approximation method;[14,16] they are listed in Table 1. The formation constants of XO complexes with these metal ions have been determined by many authors. They have, however, assumed that only one reaction was involved in the solutions, as indicated in either of following equations:

i) $M^{2+} + L^{6-} \rightleftarrows ML^{4-}$: Refs. 24—29.

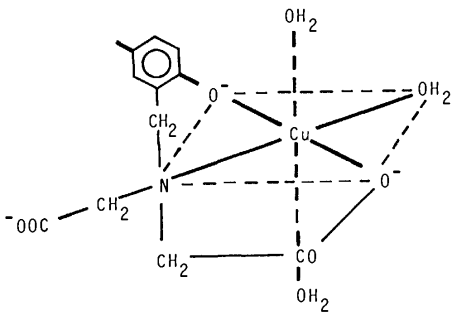
ii) $2M^{2+} + H_2L^{4-} \rightleftarrows Cu_2H_2L$: Ref. 11.

However, several reactions may be assumed to be involved, as has been determined above. This may be one reason why there are discrepancies among the formation constants calculated by the different authors. The present formation constants were calculated by taking all the probable reactions involved into account.[14,16]

The stabilities of the complexes in aqueous solutions frequently observed for the ligands, which coordinate to metal ions through oxygen and/or nitrogen donor atoms, follow this sequence: i) Co(II)<Ni(II)<Cu (II)> Zn(II) and ii) Pb(II)>Zn(II)> Cd(II). The stabilities of the XO complex species, ML^{4-}, MHL^{3-}, and M_2L^{2-}, do not follow this sequence, but that of MH_2L^{3-} does. The relative stabilities of the former three complex species for Cu(II) is considered to be lower than would be expected from the foregoing sequence. XO has two chelating groups on each side of the sulfonphthalein nucleus, consisting of phenolic (1) or quinolic (1′), amino (2 or 2′), and two carboxylic oxygens (3 and 4 or 3′ and 4′). In general, XO might act as a branched tetradentate ligand centered on the nitrogen atom. Such ligands prefer a regular octahedral or tetrahedral structure rather than a planar or tetragonal structure arising from elongation along an axis.[37] However, Cu(II) frequently forms complexes with the latter structure.[38,39] Accordingly, either of the following interpretations for the relative instabilities of the XO complexes for Cu(II) may be suggested: (i) If all of the four donor atoms of each chelating group were coordinated to such a structure, the complexes would be distorted into a lower symmetry or converted into a more regular octahedral one, resulting in the Jahn-Teller destabilization.[37,39] (ii) If the Cu(II) complexes keep a planar or tetragonal structure, it may be sterically impossible for one of the three branching donor atoms, *i.e.*, phenolic oxygen (1 and/or 1′), two carboxylic oxygens (3 and 4 and/or 3′ and 4′), to coordinate into a *trans* coordination site of the Cu(II) ion, in which another *trans* site is coordinated by the central nitrogen atom (2 and/or 2′), because it is too far away from it.[14,17] Therefore, each chelating group of XO would

act as a tridentate ligand, resulting in a decrease in the chelate effects.[39]

The relative instability of the Cu(II) complexes among the bivalent first transition metal ions has also been observed in other sulfonphthalein indicators, such as SXO,[15] MTB,[14] SMTB,[17] and SGCR.[20] Spectrophotometric and ESR studies of the Cu(II)-SXO complex[15] have suggested that the instability of this complex is explained by the foregoing interpretation (ii) and that the tetradentate ligand SXO acts as a tridentate one to Cu(II), to which one of the two carboxylic groups of SXO molecule remains uncoordinating. If the instabilities of the Cu(II)-XO complexes can be explained along the same lines as that for the Cu(II)-SXO complex, the sterical structure VI can be proposed for the $CuHL^{3-}$, CuL^{4-}, and Cu_2L^{2-} complex species. However, it still doubtful whether the explanation used for the SXO complex can also be applied to the XO complexes. The ESR study of the Cu(II)-complexes is being under taken: a valid discussion of these structure must await further investigation. The stabilities of the ML^{4-}, MHL^{3-}, and M_2L^{2-} complex species for Co(II), Zn(II), Cd(II), and Pb(II) exhibits the ordinary trend. This may be explained by the assumption that these metal ions probably take a regular octahedral or tetrahedral structure.[39] The Ni(II) complexes exhibit a property intermediate between Co(II) and Cu(II). Similar behavior of Ni(II) is encountered in connection with the other sulfonphthalein indicators.[14,15,17] The Ni(II) complexes frequently exhibit behavior similar in structure to that of the Cu(II) complexes as a result of the Jahn-Teller effect, although this effect is not so pronounced as that seen in the Cu(II) complexes.[40]



VI CuL^{4-}, $CuHL^{3-}$ and Cu_2L^{2-}

The stabilities of the MH_2L^{2-} and M_2HL^{-} complex species for all the metal ions exhibit the ordinary trend. The XO molecule in these complex species may act as a tridentate ligand; *i.e.*, the phenolic and/or quinolic oxygen may remain uncoordinated (Formulas III and V), so that its stability is not so much dependent on the coordination structures of the metal ions as the stabilities of ML^{4-}, MHL^{3-}, and M_2L^{2-} appear to be.

Three-dimensional Metal Complex Structures with Ambident Propylenediamine Ligands Serving as the Hosts of the Aromatic Guest Molecules. Hofmann-pn and pn-Td Type Clathrates

Shin-ichi NISHIKIORI, Toschitake IWAMOTO,* and Yukichi YOSHINO

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received September 29, 1979)

Novel clathrate compounds, Hofmann-pn type $Cd(pn)Ni(CN)_4 \cdot 3/2G$ (G=C_4H_5N, C_4H_4S, or C_6H_6) and pn-Td type $Cd(pn)Cd(or\ Hg)(CN)_4 \cdot 3/2C_6H_6$, have been prepared. Their host structures are analogous to those of the known Hofmann-en type $Cd(en)Ni(CN)_4 \cdot 2G$ and en-Td type $Cd(en)Cd(or\ Hg)(CN)_4 \cdot 2C_6H_6$. The propylenediamine (pn: 1,2-diaminopropane) molecule ambidently bridges six-coordinate Cd atoms, as the en (ethylenediamine) does in the latter types of clathrates. The guest molecules occupy at random three quarters of the cavities in the host structures: every remaining cavity contains two methyl groups of the pn molecules. The crystal structure of $Cd(l\text{-pn})Ni(CN)_4 \cdot 3/2C_4H_5N$ has been analyzed in order to demonstrate the structural features. The crystal is tetragonal with the space group P422, $a=7.575(2)$ and $c=7.742(2)$ Å, and $Z=1$. The degree of disorder is extremely high with regard to the arrangement and orientation of the *l*-pn molecule.

We have developed the synthetic and structural chemistry of the Hofmann type and the analogous clathrates with the general formula of $Cd(diam)M(CN)_4 \cdot 2G$ (diam=$(NH_3)_2$, en, or tn; M=square-planar Ni, Pd, or Pt, or tetrahedral Cd or Hg; G=C_4H_5N, C_4H_4S, C_6H_6, or $C_6H_5NH_2$), as has been summerized in a previous paper.[1] Among these clathrates, the Hofmann-en type (diam=en, M=Ni, Pd, or Pt), the en-Td type (diam=en, M=Cd or Hg), and the tn-Td type (diam=tn, M=Cd or Hg) have ambident α,ω-diamines bridging two six-coordinate Cd atoms in their host structures. In this paper we wish to add to them two novel series, the Hofmann-pn type $Cd(pn)Ni(CN)_4 \cdot 3/2G$ and the pn-Td type $Cd(pn)M(CN)_4 \cdot 3/2G$ (M=Cd or Hg), the hosts of which contain an ambident pn (propylenediamine) ligand as diam in the general formula of $Cd(diam)M(CN)_4 \cdot nG$ for the clathrates ($n=2$) reported previously.[1] However, the participation of the pn as a constituent of the host gives rise to a decrease in n from 2 to 3/2. Based on the present results of structural analysis, this decrement is interpreted in terms of the random distribution of a pair of pn-methyl groups with a 1/4 probability, and a guest molecule with a 3/4 probability, in the cavity formed in the metal-complex host structure. Our idea at the beginning of this investigation was to develop a stereospecific host structure using optically-active *l*-pn as one of the host constituents. Although this idea has not been realized, it has been suggested that the space volume of a cavity available for a guest molecule can be regulated by introducing bulky substituents into the ambident diamine ligand building up the three-dimensional host structure.

Experimental

Preparation. *Cd(*dl*-pn)Ni(CN)*$_4 \cdot 3/2C_4H_5N$: From a concentrated aqueous solution containing $CdCl_2$, $K_2[Ni(CN)_4]$, and racemic pn (*dl*-pn) in a 1:1:3 mole ratio, tris(*dl*-propylenediamine)cadmium tetracyanonickelate(II) $[Cd(dl\text{-pn})_3][Ni(CN)_4]$ was precipitated as pale yellow crystals. They were then recrystallized from hot water. Found: C, 30.9; H, 6.44; N, 28.2; Cd, 22.3; Ni, 11.7%. Calcd for $C_{13}H_{30}N_{10}CdNi$: C, 31.4; H, 6.08; N, 28.2; Cd, 22.6; Ni, 11.8%. The recrystallized complex was dissolved into water (0.2 g/50 cm^3) in a 300-cm^3 stoppered conical flask, and the solution was covered with an organic mixture of pyrrole and xylene (1:15 v/v). By leaving the flask in a refrigerator for a week, pale yellow plate-like crystals of the clathrate were obtained on the interface between the aqueous and the organic phases. Although the needle-like crystals of $[Cd(dl\text{-pn})_3][Ni(CN)_4]$ were occasionally mixed with those of the clathrate, it was easy to discriminate between the complex and the clathrate visually. The clathrate was filtered off on a sintered glass, washed with small amounts of water and ethanol successively, and preserved in a silica gel desiccator under the saturated vapor pressure of pyrrole.

*Cd(*dl*-pn)Ni(CN)*$_4 \cdot 3/2C_4H_4S$ and *Cd(*dl*-pn)Ni(CN)*$_4 \cdot 3/2C_6H_6$: These clathrates were prepared by procedures similar to the above one using a 1:1 thiophene–xylene mixture for the thiophene clathrate and a 1:2 benzene–xylene mixture for the benzene clathrate. They were obtained as coagulated polycrystals.

*Cd(*l*-pn)Ni(CN)*$_4 \cdot 3/2C_4H_5N$: *l*-Propylenediamine (*l*-pn) was obtained from racemic propylenediamine.[2] $[Cd(l\text{-pn})_3][Ni(CN)_4]$ and $Cd(l\text{-pn})Ni(CN)_4 \cdot 3/2C_4H_5N$ were prepared by a method similar to that used for the *dl*-pn compounds. Since $[Cd(l\text{-pn})_3][Ni(CN)_4]$ is less soluble in water than the *dl*-pn complex, an aqueous solution containing 0.1 g of the *l*-pn complex in 50 cm^3 of water was used for the preparation of the clathrate.

*Cd(*dl*-pn)Cd(CN)*$_4 \cdot 3/2C_6H_6$ and *Cd(*dl*-pn)Hg(CN)*$_4 \cdot 3/2C_6H_6$: To 25 cm^3 of a 0.2 M (1 M=1 mol dm^{-3}) $CdCl_2$ aqueous solution in a 300-cm^3 stoppered conical flask, 150 mmol of *dl*-pn and 25 cm^3 of 0.2 M $K_2[Cd(CN)_4]$ or $K_2[Hg(CN)_4]$ were added successively. After the pH had been adjusted to 8.0 by adding 6 M HCl drop by drop, the solution was covered with a benzene–xylene (1:1) mixture. After the flask had been left in a refrigerator for a week, colorless crystals of the clathrate were formed on the interface and at the bottom of the aqueous solution.

Powder X-Ray Diffraction. X-Ray diffraction patterns of powdered specimens were recorded on a JEOL DX diffractometer using Ni-filtered Cu $K\alpha$ radiation.

Structure Determination

Single crystals of $Cd(l\text{-pn})Ni(CN)_4 \cdot 3/2C_4H_5N$ (**1**) and $Cd(dl\text{-pn})Ni(CN)_4 \cdot 3/2C_4H_5N$ (**2**) were used for X-ray diffraction experiments to determine the crystal struc-

tures.

Data Collection. Each of the crystals of **1** and **2** cut into the cube with dimensions of *ca.* 0.3×0.3×0.3 mm was coated with epoxy resin in order to prevent the decomposition of the crystal under ambient conditions. Preliminary Weissenberg photographs showed 4/mmm symmetries for both **1** and **2** crystals; the lack of any systematic absences of reflections indicated that the possible space groups are P4/mmm, P422, P4mm, P$\bar{4}$2m, and P$\bar{4}$m2. As will be mentioned later, the P422 and P4/mmm space groups were adopted for **1** and **2** respectively. The precise determination of lattice parameters and the collection of the intensity data were carried out on a Philips automated four-circle diffractometer[3] for **1** and on a Rigaku automated four-circle diffractometer[4] for **2**. In both cases, the reflections with $2\theta \leq 60°$ were collected using Mo $K\alpha$ radiation. The intensities of three standard reflections recorded every fifty measurements showed no significant variations. The densities were measured by the flotation method using bromoform–xylene mixture. The crystal data are:

$C_{13}H_{17.5}N_{7.5}CdNi$,	F.W.=449.94, Tetragonal

D_x/g cm^{-3}	1.68	1.68
Number of reflections used for refinement ($\|F_o\|>3\sigma(\|F_o\|)$)	414	425

Solution and Refinement of the Structures. The structures were solved by the heavy-atom method. The refinements were carried out by successive Fourier and difference Fourier syntheses and by the block-diagonal least-squares method on a HITAC 8800/8700 computer at the Computer Center of this University, using the programs in UNICS[5] and their local versions. The atomic scattering factors used were those in the International Tables.[6]

There is no significant difference in the unit cell dimensions between **1** and **2**. The Patterson maps of **1** and **2** showed that, in both structures, Cd and Ni atoms lie at 0,0,0 and 1/2,1/2,0, and that the cyanide group bridges these atoms. The two-dimensional extension of the metal cyanide sheet on the {001} plane is similar to those observed for Hofmann type and Hofmann-en type clathrates.[1] Therefore, the pn ligands were assumed to bridge two Cd atoms in adjacent metal cyanide sheets along the fourfold axis of crystal, as the en ligand does in Hofmann-en type clathrate.[7,8]

Because the *l*-pn molecule has no symmetry, the non-centrosymmetric space group P422 was assumed for **1**. As the *l*-pn molecule is located about a special position, 0,0,1/2 with the point symmetry 42, it should have an orientational disorder. The centrosymmetric space group P4/mmm was assumed for **2**. The other three space groups, P4mm, P$\bar{4}$2m, and P$\bar{4}$m2, giving the arrangement of pn-methyl groups with an unacceptable overlapping or the arrangements of pn and pyrrole molecules about the unacceptable $\bar{4}$ axis, were discarded.

For both **1** and **2**, the Fourier syntheses phased by the Cd and Ni atoms gave the positions of the C and N atoms of the cyanide group and the pyrrole molecule. The pyrrole molecule was found in the cavity between the metal cyanide sheets; like the pyrrole molecule in Hofmann-en type Cd(en)Ni(CN)$_4$·2C$_4$H$_5$N,[8] the molecular dipole axis is arranged with an equal probability parallel and antiparallel to the c axis of crystal.

At this stage, the atomic parameters for the Cd, Ni, and C and N atoms of the cyanide and pyrrole were refined by the block-diagonal least-squares procedure to minimize $\sum w(||F_o|-|F_c||)^2$; $w=1$ for $|F_o|<F_{max}$ and $w=(F_{max}/|F_o|)^2$ for $|F_o|\geq F_{max}$, $F_{max}=35.0$ for **1**, and 50.0 for **2**. After several cycles of the calculations by applying the anisotropic temperature factors to Cd and Ni atoms, and the isotropic ones to C and N atoms, the conventional reliability index, $R_1=\sum w(||F_o|-|F_c||)/\sum|F_o|$, became 0.088 for **1** and 0.128 for **2**. At this point a trial was made to find the positional parameters for the pn molecule, though the electron density due to the pn molecule was predicted to be very low because of the great extent of orientational disorder. The electron densities appearing on the difference Fourier map of **2** were so vague that we could hardly locate any atoms. In the case of **1** we could barely find two sets of the atomic coordinates forcibly assigned to the C and N atoms of the *l*-pn molecule. However, the positional and thermal parameters of a few atoms of *l*-pn obtained after several cycles of the least-squares calculations gave too large estimated standard deviations. Therefore, we ceased to refine the structures of **1** and **2** at this stage.[9] The atomic parameters determined for **1** are listed in Table 1, while an illustrative sketch of the structure is shown in Fig. 1.

Table 1. The atomic parameters of Cd(*l*-pn)Ni(CN)$_4$·3/2C$_4$H$_5$N and their estimated standard deviations (in parentheses)[a]

Atom[b]	x/a	y/b	z/c	B_{iso}
Cd	000	000	000	—[c]
Ni	500	500	000	—[c]
C(CN)	328 (1)	328	000	3.3 (2)
N(CN)	219 (2)	219	000	4.4 (2)
N(prl)[d]	500	000	335 (5)	5.4 (6)
C(prl)[d]	500	169 (5)	422 (4)	6.8 (6)
C(prl)[d]	500	087 (5)	598 (4)	6.7 (6)

a) The positional parameters have been multiplied by 10^3. b) The parameters of the C and N atoms of the *l*-pn molecule have not been determined accurately. c) The anisotropic thermal parameters have been obtained for Cd ($B_{11}=0.0063(1)=B_{22}$, $B_{33}=0.0144(2)$, and $B_{12}=B_{13}=B_{23}=0$) and Ni ($B_{11}=0.0060(2)=B_{22}$, $B_{33}=0.0179(4)$, and $B_{12}=B_{13}=B_{23}=0$) in the form of $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+2B_{12}hk+2B_{13}hl+2B_{23}kl)\}$. d) Each of the occupancy factors of the N and C atoms of the pyrrole molecule is 0.375.

Cd(*dl*-pn)$Hg(CN)_4 \cdot 3/2C_6H_6$	31.7 (31.6)	3.29 (3.15)	14.0 (13.8)	18.1 (18.5)	

Results and Discussion

The clathrates prepared are listed in Table 2 along with their analytical results. In the earlier stage of the investigations of the Hofmann type clathrates, some clathrates were reported to have non-stoichiometric or substoichiometric compositions with regard to the number of guest molecules for a formula unit of the metal complex host, $M(NH_3)_2Ni(CN)_4$ (M=Ni, Cu, Zn, or Cd);[10–12] these observations were due to inadequate conditions in the preparation or to careless treatment of the prepared specimens.[13] It is well known that some hydrate clathrates and *p*-hydroxybenzene clathrates are non-stoichiometric.[14] However, in the novel clathrates the number of guest molecules can be counted as 3/2 for a formula unit of the metal complex host, within the limits of experimental error. As has been verified with regard to the crystal structures of **1** and **2**, the novel $Cd(pn)Ni(CN)_4$ host has linkages of the ambident CN and pn ligands substantially similar to those of the Hofmann-en type host; the structure of the Cd(pn)Cd(or Hg)$(CN)_4$ host is also concluded to be similar to that of the en-Td type, as will be discussed later. By analogy with the naming of the Hofmann-en type and the en-Td type, we can name the novel clathrates, $Cd(pn)Ni(CN)_4 \cdot 3/2G$ and Cd(pn)Cd(or Hg)$(CN)_4 \cdot 3/2G$, the "Hofmann-pn type" and the "pn-Td type" respectively.

Hofmann-pn Type Clathrates. The stoichiometry of the novel clathrates suggests that one of the four cavities is not occupied by a guest molecule. Since, in general, the crystal structure cannot be stable with vacant cavities, it is also suggested that the cavity unoccupied by a guest molecule should be occupied by another species instead of the guest. The crystal structures of **1** and **2** can be interpreted most plausibly in terms of the random distributions of the cavity occupied by a pyrrole molecule and that occupied by a pair of pn-methyl groups in a 3: 1 ratio throughout the crystal. As Fig. 1 shows, the square-planar metal cyanide sheet has a structure similar to those in the Hofmann type and the Hofmann-en type, with interatomic distances of Ni–C-(CN)=1.840(8) Å, C(CN)–N(CN)=1.17(2) Å, and Cd–N(CN)=2.35(2) Å in **1**. One of the four cavities formed between the metal cyanide sheets is occupied by a pair of methyl groups protruding from the confronting pair of pn molecules; each of the pn molecules bridges two Cd atoms in adjacent metal cyanide sheets. The other three cavities are occupied by pyrrole molecules oriented randomly upward and downward with regard to the molecular dipole axis. The apparent tetragonal symmetry of the crystal is derived from a random distribution of both kinds of cavities and from random orientations of the pn molecules.

The cause of disorder in this structure can be understood from the calculation of the void space of the cavity occupied by the methyl groups. According to Immirzi and Perini,[15] the volume of an organic molecule packed in a crystal can be approximated by a simple additivity rule within an error of *ca.* 3%. On the assumption that the pyrrole molecules have close packing in the Hofmann-en type pyrrole clathrate, $Cd(en)Ni(CN)_4 \cdot 2C_4H_5N$,[8] the volume of the Hofmann-en type host, $V_{en\text{-}host}$, is calculated to be 267.4 Å^3 by subtracting that of two pyrrole molecules, 2×95.1 Å^3, from that of the unit cell, 457.6 Å^3. By adding the volume of a methyl group, 31.7 Å^3, and that of 1.5 times pyrrole molecules, 1.5×95.1 Å^3, to, and subtracting that of a hydrogen, V_H 6.8 Å^3, from, $V_{en\text{-}host}$, we obtain the calculated unit cell volume of the Hofmann-pn type *l*-pn host clathrate **1** as 434.9 Å^3, nearly equal to the observed value, V_{cell} 444.2 Å^3. Since the approximation can be seen to be valid, we may calculate the volume of the cavity, V_{cav}, in **1** thus:

$$V_{cav} = [V_{cell} - (V_{en\text{-}host} - V_H)] \times 0.5 = 91.9 \text{ Å}^3$$

a value nearly equal to that of a pyrrole molecule. However, the volume of two methyl groups, 63.4 Å^3, is smaller by *ca.* 30 Å^3 than V_{cav}, the occupation ratio

of the cavity being 69%. The void space may give much freedom of motion to the pn molecule.

pn-Td Type Clathrates. The powder X-ray diffraction patterns of pn-Td type benzene clathrates Cd(*dl*-pn)Cd(CN)$_4$·3/2C$_6$H$_6$ and Cd(*dl*-pn)Hg(CN)$_4$·3/2C$_6$H$_6$ were assigned to the tetragonal systems, as Table 3 shows. The unit cell dimensions of these clathrates are very close to those of the corresponding en-Td type benzene clathrates.[16] Since their diffraction patterns showed a close resemblance to those of the corresponding en-Td type clathrates, the substantial structure of the pn-Td type host can be thought of as being similar to that of the en-Td type host. One of the four cavities must be occupied at random by a pair of pn-methyl groups, too. The calculated volume (117 Å^3) of a cavity in the pn-Td type host gave a *ca.* 46% void space in the cavity occupied by the methyl groups. However, the three-dimensional framework, built of the tetrahedral Cd(CN)$_4$ or Hg(CN)$_4$ moieties and the ambident pn ligands, which are linked together at the six-coordinate Cd atoms, appears to be tight enough to keep the tetragonal crystal lattice, even with the considerably large void space in the cavity occupied by the methyl groups.

Conclusion. These observations suggest that the number of cavities available for the guest molecules can be regulated by introducing bulky substituents into the ambident diamine ligand building up the host structures of these types of clathrates. 2,3-Diaminobutane (bn) has two methyl groups. In the clathrate with the Cd(bn)M(CN)$_4$·nG formula, n can be expected to be one if such a clathrate is successfully prepared using bn in place of pn. The investigations are now in progress.

Ion Pair Formation between Electro-generated 1,2-Naphtoquinone Anion Radicals and Alkali Metal Cations in Acetonitrile

Taitiro FUJINAGA, Satoshi OKAZAKI, and Tsutomu NAGAOKA*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 24, 1979)

Ion association of 1,2-naphthosemiquinone with the alkali metal cations in acetonitrile has been comprehensively studied by the use of ESR, absorption spectroscopy, polarography and with MO calculation. A continuous flow electrolysis system with a glassy carbon column electrode has been developed for the rapid quantitative preparation of organic free radicals, whose ESR spectrum or absorption spectrum was observed *in situ*. The formation constants of the ion pair with K^+, Na^+, and Li^+ were estimated as $10^{3.2}$, $10^{4.5}$, and $10^{8.0}$, respectively. By the addition of alkali metal cations, the half-wave potentials shifted to more positive potential in the order of $K^+ < Na^+ < Li^+$. The proton hyperfine splitting constants in the ESR also varied in this order. This column electrolysis method is considered to be a powerful technique, particularly for the study of short lived free radicals, because the quantitative electrolysis is performed rapidly even in a solution of extremely diluted supporting electrolyte, such as 0.1 mM (mmol/dm^3).

In most of the studies of ion pair formation between organic free radicals and alkali metal cations by means of ESR and absorption spectroscopy, radical anions were usually obtained by chemical reactions with alkali metals using solvents, such as ether, having low dielectric constants.[1-3] Therefore, it is not particularly useful to carry out discussions of the comparisons of their characteristics with those obtained in polarography, in which dipolar aprotic solvents are generally used.

Fujinaga *et al.* have studied the electrolytic preparation of organic free radicals[4] and their electrochemical behavior in *N,N*-dimethylformamide by the use of ESR and polarography.[5] The effect of metal cations on the polarographic reduction of naphtoquinone in aprotic solvents have been investigated by Fujinaga *et al.*[6] and also recently, by Kalinowski *et al.*[7]

In the present paper, the authors employed a rapid flow electrolysis using a glassy carbon column electrode[8] in order to generate radical ions and studied the ion pair formation between 1,2-naphtoquinone radical anions (β-NPQ$^{-\cdot}$) and alkali metal cations of supporting electrolyte in acetonitrile by the comprehensive analysis of their ESR spectra and polarograms.

This column electrolysis method has the following advantages over the conventional constant potential electrolysis: 1) The objective depolarizers in the sample solution are completely electrolyzed immediately after flowing into the column; 2) The concentration of the electro-generated radical anion is determined by the simple monitoring of the electrolysis current instead of charge; 3) An ESR spectrum, or an absorption spectrum corresponding to the stepwise change of the electrode potentials can be observed *in situ*.

The formation constants of the ion pairs between β-NPQ$^{-\cdot}$ and alkali metal cations were inclined to increase with decreasing ionic radii of counterions, that is, $10^{3.2}$, $10^{4.5}$, and $10^{8.0}$ for K^+, Na^+, and Li^+, respectively. The proton hfs constants of their ESR spectra and half-wave potentials of their polarograms shifted significantly in the order of $K^+ < Na^+ < Li^+$. From these results, the complexes between β-NPQ anion and counter cations seem to be contact ion pairs.

Experimental

Reagents. Reagent grade β-NPQ from Wako Pure Chemicals, Ltd., Osaka was purified by the sublimation method. The concentration of β-NPQ used was 0.35 mM unless otherwise noted. Acetonitrile from the same supply was distilled over P_2O_5 after pretreated with calcium hydride. Propylene carbonate and *N,N*-dimethylformamid (DMF) were distilled under reduced pressure, after being dried with molecular sieves 4A. Tetraethylammonium perchlorate (TEAP) was prepared by the conventional method. All metal ions added were in their perchlorates. Other chemicals used were of analytical reagent grade.

radical anion was sent into the cylindrical ESR cavity or the spectrophotometric flow-cell. The electrolysis current flowing through the cell was recorded by a National Pen Recorder Model VP 654-B. ESR spectra were measured with a JEOL JES-PE-3X, and the absorption spectra were measured with a Shimadzu UV 200 spectrophotometer. A PAR Model 174 Polarographic Analyzer was used for the measurements of polarograms. MO calculation was carried out by FACOM M-190 at the Data Processing Center of Kyoto University.

Results

Column Electrolysis and Absorption Spectroscopy. The fundamental examination of column electrolysis of β-NPQ were carried out by comparing the coulopotentiogram with its absorption spectrum. As a result, β-NPQ underwent two one-electron reductions in acetonitrile at glassy carbon electrode, and its electrolysis efficiency was 90—100% at the constant flow rate of 1.5 cm^3/min.

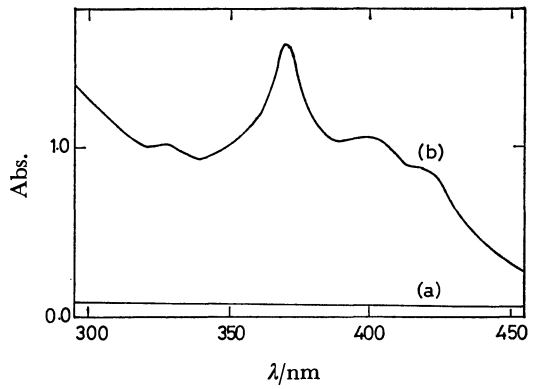

Fig. 3. UV absorption spectrum of β-$NPQ^{-\cdot}$ in acetonitrile with 0.1 M TEAP.
(a): Blank, and (b): 0.35 mM β-$NPQ^{-\cdot}$.

Figure 3 shows the absorption spectrum of electrogenerated β-$NPQ^{-\cdot}$ in acetonitrile with 0.1 M TEAP. The absorbance at 370 nm was proportional to the concentration of β-NPQ. By the addition of metal ion, the half-wave potentials of both waves shifted to more positive potentials owing to the ion pair formation effect. For the spectroscopic studies of ion pair formation of

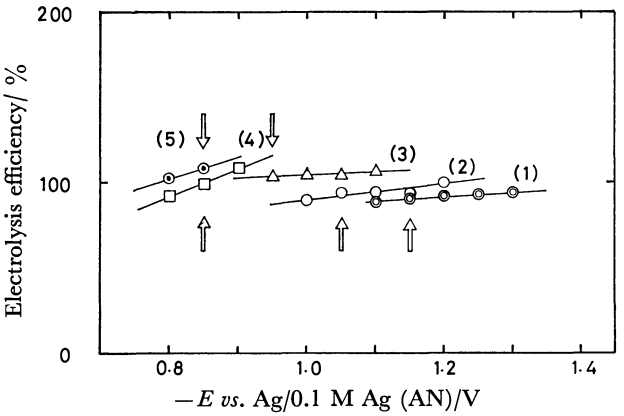

Fig. 4. Coulopotentiograms of β-$NPQ^{-\cdot}$ in acetonitrile with 0.1 M TEAP.

monoanion radical, $M^+ \cdot$β-$NPQ^{-\cdot}$, the electrode potential was adjusted to maximize the absorption peak at 370 nm, which is inherent in the monoanion radical, β-$NPQ^{-\cdot}$. The same method was also adopted in ESR measurement.

Figure 4 illustrates the effect of lithium ions on the limiting current of the first wave, in which the arrow marks indicate the optimum potentials necessary to give the maximum intensity in the ESR spectra. As shown in the figure, the higher the lithium concentration, the narrower the available potential range to produce the monoanion radical alone became. With the addition of alkali metal, the absorption peak of β-$NPQ^{-\cdot}$ shifted to the shorter wave length, but within 10 nm.

ESR Spectroscopy. Figures 5-1 to 5-4 show the

ESR spectra of β-$NPQ^{-\cdot}$ radical (5-1-A) and its potassium (5-2-A), sodium (5-3-A), and lithium (5-4-A) ion pairs together with their simulated spectra, from 5-1-B to 5-4-B, respectively. Good agreements were obtained between their observed spectra (A) and the corresponding simulated ones (B) within 20 mG (10^{-7} T). The fact that the spectrum of potassium ion pair (5-2-A) is similar to that of the free ion (5-1-A) suggests the weak association of β-NPQ radical anion with potassium cation. In the spectra of sodium and lithium ion pairs, however, each feature splits into four lines resulting from the coupling to ^{23}Na or ^{7}Li nuclei. The six ring-protons of the quinone are not equivalent, and these six proton hfs' are not all measurable. There were five protons with resolvable splittings for $Li^{+}\cdot\beta$-$NPQ^{-\cdot}$ and $Na^{+}\cdot\beta$-$NPQ^{-\cdot}$, whereas four for $K^{+}\cdot\beta$-$NPQ^{-\cdot}$.

When sodium or lithium perchlorate was added to the β-NPQ radical anion in acetonitrile, ESR signals due to both the free ion and its ion pair were observed simultaneously, as seen in Fig. 6-1-D. By the further addition of these cations, the intensity of the signal of the free anion was decreased, and only the spectrum of the ion pair was observed at the end. Figure 6-1-C shows the synthetic spectrum of β-$NPQ^{-\cdot}$ in the presence of 0.15 mM sodium ion, obtained by superimposing the simulated spectrum of the free ion (A) upon that of the sodium ion pair (B) on the assumption that the rate of the ion pair formation and dissociation of $Na^{+}\cdot\beta$-$NPQ^{-\cdot}$ is enough slow on the ESR time scale, *i.e.*, these two spectra can be simply superimposed upon each other.

In the case of the addition of potassium perchlorate, the ESR spectrum varied asymmetrically with respect

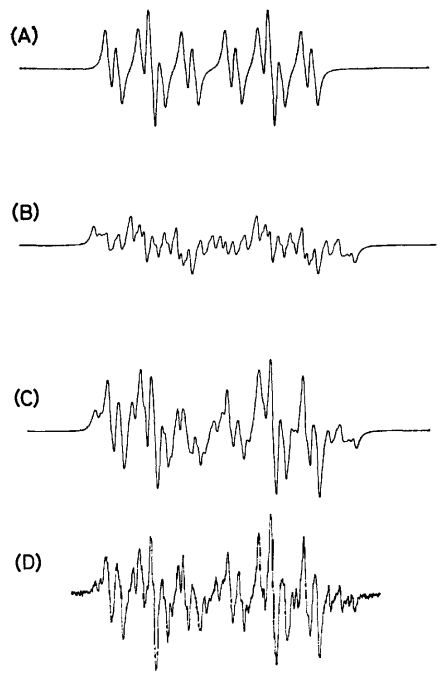

Fig. 6-1. Analysis of ESR spectrum of sodium ion pair. (A): Synthetic spectrum of free ion and (B): of sodium ion pair, (C): superimposed spectrum of (A) and (B), and (D): observed spectrum of sodium ion pair in the presence of 0.15 mM $NaClO_4$.

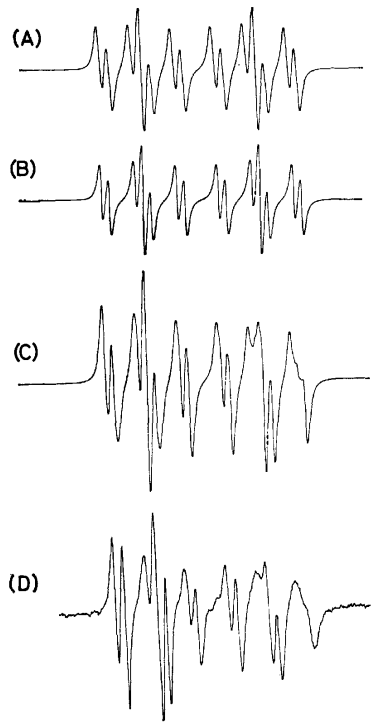

Fig. 6-2. Analysis of ESR spectrum of potassium ion pair. (A): Synthetic spectrum of free ion and (B): of potassium ion pair, (C): superimposed spectrum of (A) and (B), and (D): observed spectrum of potassium ion pair in the presence of 0.75 mM $KClO_4$.

to the line width. This asymmetry effect was most pronounced in the presence of about 0.75 mM potassium ions as seen in Fig. 6-2-D. This phenomenon suggests the coexistence of two radicals with slightly different coupling constants and *g*-values, *i.e.*, if the one having the smaller *g*-value possesses a larger coupling constant than the other, then the superposition of their ESR lines become loose at the region of high magnetic field. These two observed radicals were assigned to a free ion and an ion pair. Figure 6-2-C shows the synthetic spectrum of β-$NPQ^{-\cdot}$ in the presence of 0.75 mM potassium ion, obtained by the same method as in Fig. 6-1-C. Slight discordances were observed between the simulated (C) and observed (D) spectra owing to the line broadening at the region of high magnetic field. This fact suggests that the rate of the free ion–ion pair exchange kinetics of the potassium ion pair seems to be faster than those of the sodium and lithium ion pair, but still not to be so rapid as to give a time-averaged ESR spectrum.

MO Calculation. The proton hfs' in Table 1 were assigned by a HMO calculation adopting the McLachlan approximate configurational interaction. Table 2 summarizes the calculated results. The estimated value of the spin density of each carbon atom was very sensitive to given values of the coulomb integrals for two oxygen atoms (α_o). However, the spin density at position 6 defined in Fig. 7 was estimated still to be the largest even though the coulomb integral parameter (δ_o) was varied from 0.8 to 1.4. Therefore, the largest proton hfs constant in Table 1 is evidently assigned to the ring proton of position 6.

Variations of spin densities due to the ion pair formation can be discussed by means of the McClelland type MO calculation.[2,3,9] In this calculation, the effective Hamiltonian of the ion pair, H'_{eff} is defined by Eq. 1,

$$H'_{eff} = H_{eff} - \frac{Z\cdot e^2}{\varepsilon(r)\cdot r}, \qquad (1)$$

where, H_{eff} denotes the effective Hamiltonian in the absence of a cationic field, and $\varepsilon(r)$ is a screening factor introduced by Takeshita and Hirota[2] in order to explain the screening effect of solvent molecules on the anion. Figure 7 shows the co-ordinate system used in this calculation, in which a σ-type interaction was assumed and a positive point charge, $+e$ was approaching the anion along X-axis. Table 3 summarizes the results obtained by the use of this calculation, where $\varepsilon(r)$ was assumed to be constant, 10. The curves in Fig. 8 show the relationships between the calculated

proton hfs at position 6 for each given value of $\varepsilon(r)$ and the interionic distance. In the figure, the experimental values are indicated by circles, the interionic distances of which were estimated on the assumption of a contact ion pair. From the results, it seems reasonable to consider $\varepsilon(r)$ for these ion pairs as an adjustable parameter being changed between 1 and the macroscopic dielectric constant of the solvent. This fact suggests the solvation tendency of acetonitrile toward these ion pairs. However, the quantitative discussions about $\varepsilon(r)$ are difficult owing to the rough approximation in the calculation.

Polarography. In acetonitrile, propylene carbonate, and DMF, β-NPQ undergoes two one-electron reductions corresponding to the formations of the stable monoanion and dianion. The polarographic characteristics for the reduction of the quinone are summarized in Table 4. The first wave was fairly reversible, but the second wave was less so in the solvents investigated, provided TEAP was used as the supporting electrolyte. When alkaline earth metals were used as the supporting electrolytes, both waves became less reversible than those with alkali metals. Both waves shifted to more positive potentials with increasing the concentration of the supporting electrolytes of metal salts, owing to their complex formation effects.

This potential shift was discussed according to Peover's method.[10] After the first one-electron reduction, the following complex formation equilibrium is assumed to be,

$$p\mathrm{M}^+ + \mathrm{Q}^{-\cdot} \overset{K}{\rightleftharpoons} \mathrm{M}_p\cdot\mathrm{Q}^{(p-1)+} \qquad (2)$$

where, Q,$Q^{-\cdot}$ and $M_p\cdot Q^{(p-1)+}$ represent 1,2-naphthoquinone, its anion radical and ion pair, respectively, and p is a coordination number. The association constant K is given by Eq. 3,

$$K = \frac{[\mathrm{M}_p\cdot\mathrm{Q}^{(p-1)+}]}{[\mathrm{M}^+]^p\cdot[\mathrm{Q}^{-\cdot}]}. \qquad (3)$$

The shift of the half-wave potential, $\Delta E_{1/2}$ due to ion pair formation is given by Eq. 4,

$$\Delta E_{1/2} = -\frac{RT}{F}\ln\frac{[\mathrm{Q}^{-\cdot}]^\circ}{1/2[\mathrm{Q}]}, \qquad (4)$$

where $[Q^{-\cdot}]^\circ$ is the concentration of semiquinone at the electrode surface. When metal ions are in large excess,

$$\Delta E_{1/2} = \frac{RT}{F} \ln K + \frac{RT}{F} p \cdot \ln C_{M^+}. \quad (5)$$

A coordination number and an association constant are simply evaluated from the slope and intercept in the plot of the half-wave potential of β-NPQ *vs.* the logarithm of the concentration of metal ions, C_{M^+} as shown in Fig. 9.

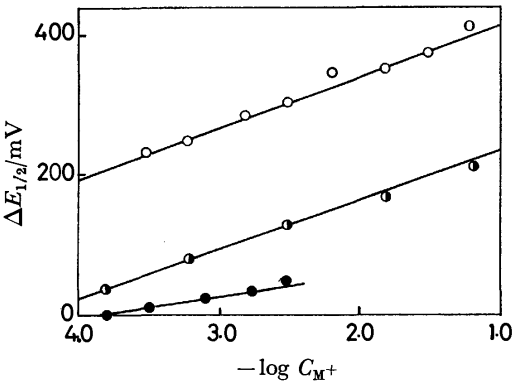

Fig. 9. Relationships between half-wave potentials of β-NPQ and concentrations of alkali metals.
Slopes in mV; 70 for Li^+ (○), 70 for Na^+ (◑) and 33 for K^+ (●).

Equation 5, however, cannot be used when a low soluble salt, *i.e.*, potassium perchlorate, is added in acetonitrile or when the coordination number varies at the low concentration of counterions. In these cases, the tentative association constant obtained from Eqs. 3 and 4, was converged by fitting p value so as to allow K to be nearly constant. This method could offer reliable association constants and coordination numbers even at a low concentration of counterions. These results are summarized in Table 5.

Discussion

The ion pair formation effects of supporting electrolyte cations with β-NPQ$^{-\cdot}$ were observed to be in the order of $TEAP^+ < K^+ < Na^+ < Li^+ < Ba^{2+} < Sr^{2+} < Ca^{2+} < Mg^{2+}$ as shown in Tables 1 and 4. The observed changes of proton hfs of ESR spectra in acetonitrile were somewhat larger than those in 1,2-dimethoxyethane (DME) reported by Warhurst *et al.*[1] This distinction between these two solvents is explained by the fact that the solvation of acetonitrile toward the ion pair is not more significant than DME as expected from their donor number; 14 for acetonitrile and 24 for DME. An unusual tendency of β-NPQ$^{-\cdot}$ for the coupling to metal nuclei also appeared in acetonitrile as well as in DME. This fact suggests the strong tendency of β-NPQ$^{-\cdot}$ toward ion pair formation, because it is not generally observed in these polar solvents. The variation of the coupling constants of ESR spectra are qualitatively well explained using a McClelland-type MO calculation. Table 3 shows a slight decrease in the spin density at position 9 but little increase at the other positions when a positive point charge approaches the β-NPQ anion along X-axis as illustrated in Fig. 7.

Polarography provides also much helpful information about the ion association equilibrium. Table 5 indicates that the association constants and the coordination numbers can be looked upon as being constant over the experimental concentration range of counterions. Therefore, it can be concluded that 1: 1 type of ion pair is formed predominately between K^+ and β-NPQ$^{-\cdot}$, though 1: 2 association may be expected from the slope of the plot in Fig. 9. The association constant for the potassium ion pair ought to be sufficiently accurate judging from a good accordance between the results obtained in polarography and ESR. As mentioned previously, the observed ESR spectrum is most asymmetric in the presence of 0.75 mM potassium ion, in which the signal intensities due to both the free ion and ion pair become almost equivalent. It is ascertained by calculation that the concentration ratio of free ion to ion pair is closed to unity in the presence of 0.75 mM potassium ion.

The relationships between the half-wave potentials and the effective ionic potentials $[\phi = Z/(r_c + S)]$[11,12] give straight lines with positive slopes as shown in Fig. 10. Though it is known that the ion pair with a contact structure gives a positive slope in this relation, a few comments will be needed here. Ion pairs may not always be in a form either solvent separated or contact, but may be intermediate between them. In this figure, the steeper slope for acetonitrile than DMF shows clearly that the association energy in acetonitrile is fairly large when compared to that in DMF, and moreover the solvation of the ion pair is more remarkable in DMF than in acetonitrile. As a result, the interionic distance between the cation and β-NPQ$^{-\cdot}$ anion may be larger in DMF than in acetonitrile. In this case, solvent molecules seem to act as pegs to separate the ion pair. In this study, the solvent effects on the half-wave potentials can be explained in terms of the difference in the solvation energies of these cations, because the solvation tendencies of DMF and acetonitrile to anions are almost equivalent.

The effect of the ionic size of the cation on the ion pair formation tendency will be discussed next. Simple MO calculations lead to the conclusion that the larger

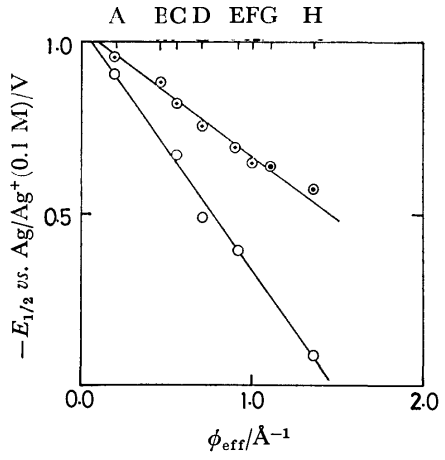

Fig. 10. Relationships between half-wave potentials of β-NPQ and effective ionic potentials of counterions.
(○): Acetonitrile, (⊙): DMF, correction parameter, S=0.8, (A): TEA$^+$, (B): K$^+$, (C): Na$^+$, (D): Li$^+$, (E): Ba^{2+}, (F): Sr^{2+}, (G): Ca^{2+}, (H): Mg^{2+}.

the radius of the counterion, the stronger the solvation of the ion pair become. That is to say, the structure of the potassium ion pair is looser than that of the lithium ion pair. As a result, the interionic distance of the potassium ion pair may be somewhat larger in fact than that given in Fig. 8. The structure of the potassium ion pair, however, is not a typical form of the solvent separated one, considering the contact structures of the ion pairs with sodium and lithium ions which have larger solvation energies than potassium.

The screening effects of the solvent molecules also seem to play an important role in this study. Toshima *et al.*[13] assume the $\varepsilon(r)$ value for the ion pair of nitrobenzene anion with alkali metal cations in DMF to be of the same order as the macroscopic dielectric constant of the solvent. In the ion pair considered here, however, $\varepsilon(r)$ should be regarded as an adjustable parameter.

It can be concluded that the smaller the ionic size of the counterion, the weaker the solvent separation of ion pairs becomes, *i.e.*, a so called contact ion pair is formed, and moreover the tendency of separation is dependent on the nature of the solvent used.

Recently, Chauhan *et al.*[14] reported on the weak association between nitromesitylene anion and tetraalkylammonium cation with the association constant of *ca.* 35. However, no complex formation effect of TEA$^+$ on the ESR spectrum of β-NPQ$^{-\cdot}$ was observed over the concentration range of TEAP from 10^{-4} M to 10^{-1} M.

It is also a great advantage of the column electrolysis that the electrolysis can be performed quantitatively even in the solution with a low concentration such as 10^{-4} M of the supporting electrolyte.

The present work was partially supported by a Grant-in-Aid for Scientific Research, No. 243010 from the Ministry of Education, Science and Culture.

Cobalt(III) complexes, $[Co(l\text{-mop=aa})_2]^-$ and $[Co(cop=aa)_2]^-$ (aa=ala$^-$, val$^-$, leu$^-$, phe$^-$), where $H_2(l\text{-mop=aa})$ and $H_2(cop=aa)$ denote amino acid–Schiff bases of *l*-menthyl 3-(*o*-hydroxybenzoyl)propionate and cholesteryl 3-(*o*-hydroxybenzoyl)propionate, respectively, were prepared in solution. The intensity of the CD peak induced at 520 nm changes with the solvent used for preparation of the complex, decreasing in the order: ethanol, methanol, dimethyl sulfoxide, *N*,*N*-dimethylformamide and acetonitrile. Since the order corresponds to the increasing order of the CH..π-interaction between the solvent and benzene, it seems that the CH..π-interaction between the chiral group and the aromatic nucleus in the ligand plays an important role in determining the configuration of the complexes.

Asymmetric transformation of racemic amino acids into an optical isomer by the use of metal complexes is important in amino acid industry and of interest in connection with the model of transamination reaction in the biological system. Amino acid coordinated to an optically active cobalt(III) complex is epimerized in alkaline solution, whereby D- or L-amino acid is produced in excess in equilibrium.[2,3] Activation of the hydrogen at the α-carbon of amino acid coordinated to a metal is attained only under high pH conditions. On the other hand, when an amino acid is incorporated into the ligand system of a complex by Schiff base formation, the hydrogen at the α-carbon atom is easily labilized in the physiological pH range, an optical amino acid being isomerized.[4-6] This is thought to be a racemase model in the biological system. If a complex with amino acid–Schiff base is formed in an asymmetric environment, DL-amino acids might be transformed into an optical isomer. This type of reaction should operate in the transamination reaction of vitamine B_6.[7] However, only a few studies have been reported on asymmetric transformation of racemic amino acid into an optical isomer by the use of Schiff base complex.[1,8,9]

It was found that in the cobalt(III) complexes, $[Co(l\text{-mop=aa})_2]^-$ (Fig. 1a), with the Schiff base obtained from *l*-menthyl 3-(*o*-hydroxybenzoyl)propionate and DL-amino acid, asymmetry around the metal is induced and DL-amino acids are partially transformed into an optical isomer.[1] The *l*-menthyl group on the side chain exerts a vicinal effect but not a Pfeiffer effect on determining the configuration of the complex, since the group no longer affects the asymmetry induction when it is detached from the ligand. However, the origin of the vicinal effect has not been clarified yet. We intended to elucidate how the *l*-menthylg roup causes the asymmetry around the metal. For this purpose new cobalt(III) complexes, $[Co(cop=aa)_2]^-$, with the amino acid–Schiff bases of cholesteryl 3-(*o*-hydroxybenzoyl)propionate were also prepared in solutions (Fig. 1b) and the effect of the cholesteryl group on the asymmetry induction was examined.

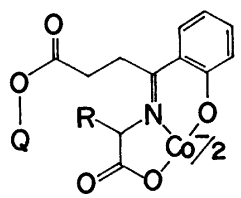

Fig. 1.
(a) Q=*l*-menthyl
(b) Q=cholesteryl

Experimental

Preparation. 3-(*o*-Hydroxybenzoyl)propionic acid was synthesized by the method of Fieser *et al.*[10] Synthesis of *l*-menthyl 3-(*o*-hydroxybenzoyl)propionate (H(*l*-mop)) was described in the preceding paper.[1]

Cholesteryl 3-(o-Hydroxybenzoyl)propionate (Hcop). 3-(*o*-Hydroxybenzoyl)propionic acid (7.2 g) and cholesterol (14.3 g) were dissolved in benzene (100 cm^3). To this was added a drop of concd sulfuric acid and the mixture was refluxed for 48 h. During the course of this reaction, water formed by esterification was eliminated as a benzene azeotrope. The solvent was evaporated and the pale brown precipitate obtained was recrystallized twice from a ethanol–benzene mixture to give colorless needles melting at 160—161 °C.

Found: C, 79.30; H, 9.81%. Calcd for $C_{37}H_{52}O_4$: C, 78.96; H, 9.67%.

Cobalt(III) Complexes. Preparation of the solutions of $[Co(l\text{-mop=aa})_2]^-$ is as follows. Racemic amino acid (5×10^{-4} mol), H(*l*-mop) (5×10^{-4} mol), cobalt(II) acetate tetrahydrate (2.5×10^{-4} mol) and triethylamine (*ca.* 60 mg) were placed in a 50 cm^3 volumemetric flask and the volume was adjusted with a solvent (ethanol, methanol, dimethyl sulfoxide, *N*,*N*-dimethylformamide, or acetonitrile). Synthesis of $[Co(cop=aa)_2]^-$ is nearly the same as that of $[Co(l\text{-mop=aa})_2]^-$ except for using a 1: 1 mixture of a solvent and carbon tetrachloride, because of low solubility of Hcop in ethanol and so on. Clear red solutions were obtained after 2 or 3 d.

Measurements. Electronic spectra and circular dichroism spectra were measured with a Shimazu multipurpose spectrophotometer Model MSP-5000 and a JASCO ORD/CD optical dispersion recorder, respectively. NMR spectra were measured with a Hitachi NMR spectrophotometer Model R-20-B in carbon tetrachloride and in benzene using tetramethylsilane as an internal standard.

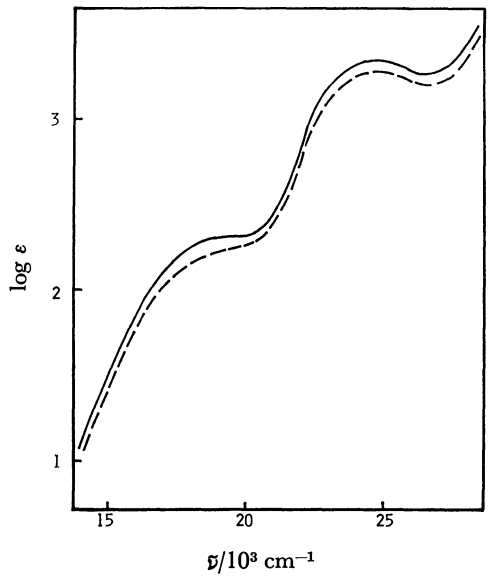

Fig. 2. Electronic spectra of (——) $[Co(l\text{-mop=ala})_2]^-$ (in methanol) and (– – –) $[Co(cop=ala)_2]^-$ (in methanol–carbon tetrachloride).

Results and Discussion

Electronic spectra of $[Co(l\text{-mop=aa})_2]^-$ and $[Co(cop=aa)_2]^-$ are similar to each other. Typical examples are shown in Fig. 2. Two absorption bands appeared near 19000 and 24500 cm^{-1}, whose extinction coefficients gradually increased and converged after 120 h to *ca.* 200 and 1500 $mol^{-1}\,dm^3\,cm^{-1}$, respectively. The frequencies and the extinction coefficients of these bands are almost independent of the amino acid and the solvent used for preparation of the complex. Although we were not successful in isolating the complexes, it seems reasonable to formulate the complexes as $[Co(l\text{-mop=aa})_2]^-$ and $[Co(cop=aa)_2]^-$.

CD spectra of $[Co(l\text{-mop=ala})_2]^-$ prepared in methanol and $[Co(cop=ala)_2]^-$ prepared in methanol–carbon tetrachloride (1 : 1) are given in Figs. 3 and 4,

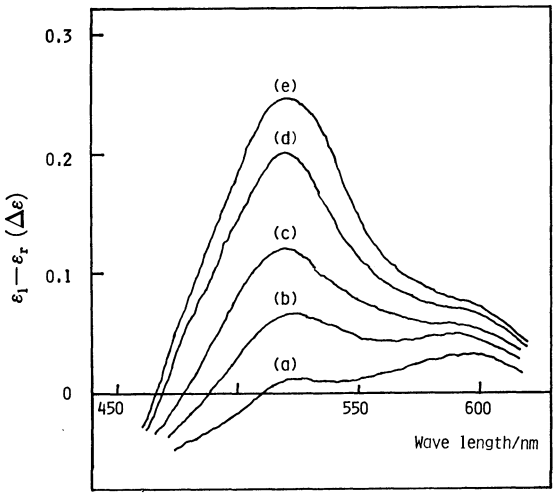

Fig. 3. CD spectra of $[Co(l\text{-mop=ala})_2]^-$ (in methanol) at various reaction times.
(a) 20, (b) 43, (c) 63, (d) 113, and (e) 230 h.

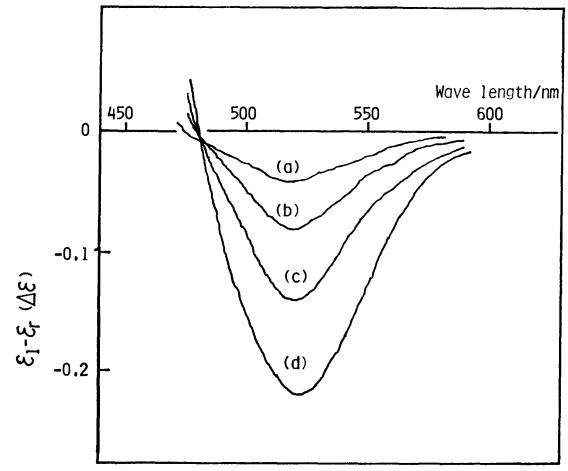

Fig. 4. CD spectra of $[Co(cop=ala)_2]^-$ (in methanol–carbon tetrachloride) at various reaction times.
(a) 20, (b) 60, (c) 120, and (d) 240 h.

respectively. In the spectrum of $[Co(l\text{-mop=ala})_2]^-$ a positive CD peak appeared near 520 nm, whose intensity gradually increased and converged after *ca.* 240 h. Similar CD spectra were observed for $[Co(l\text{-mop=val})_2]^-$ and $[Co(l\text{-mop=leu})_2]^-$. On the other hand, a negative CD peak was induced in $[Co(cop=ala)_2]^-$. A negative CD peak was also induced in $[Co(cop=val)_2]^-$ and $[Co(cop=leu)_2]^-$ prepared in methanol–carbon tetrachloride. It is likely that the cholesteryl group exerts an opposite vicinal effect to the *l*-menthyl group. Appearance of the CD band in the visible region indicates that an asymmetry around the metal is induced. We presumed that *l*-mop=aa^{2-} facially coordinates to the cobalt(III) ion form the view of Burrows and Bailar, Jr.,[11] that the *fac*-form is more stable than the *mer*-form. Belokon *et al.*[12] determined the structure of an optically active form (*Λ*(*SS*)) of potassium bis[*N*-(3-methylsalicylidene)threoninato]-cobaltate(III) and showed that the Schiff base meridionally coordinates to the metal. $[Co(l\text{-mop=aa})_2]^-$ and $[Co(cop=aa)_2]^-$ are thus presumed to also possess a *mer*-configuration. One set of optical isomers (*Δ* and *Λ*) is considered for these complexes. It seems that an isomer showing a positive CD peak at 520 nm is formed in excess for $[Co(l\text{-mop=aa})_2]^-$, while an isomer showing a negative CD peak at 520 nm for $[Co(cop=aa)_2]^-$, owing to the effect of the chiral group on the side chain.

On the basis of the Dreiding model, it is unlikely that the chiral group in the present complexes exerts any steric hindrance to the complex formation. In fact, no CD peak was detected for the copper(II) and the nickel(II) complexes with $H_2(l\text{-mop=aa})$ and $H_2(cop=aa)$. A hydrophobic interaction between the chiral group and the group attached to the α-carbon of the amino acid can not be the main effect, since the CD peak was induced in $[Co(l\text{-mop=gly})_2]^-$.[1] Thus, it is most probable that some non-covalent interaction between the chiral group and some part of the molecule or an asymmetric packing effect of the chiral group in the cavity of the molecule[13] causes the asymmetry around the metal.

Table 1. Intensities ($\Delta\varepsilon$) of CD band induced at 520 nm

	EtOH	MeOH	DMSO	DMF	AN
$[Co(l\text{-mop=ala})_2]^-$	0.40	0.24	0.14	0.12	0
$[Co(l\text{-mop=val})_2]^-$	0.21	0.20	0.06	0.05	0
$[Co(l\text{-mop=leu})_2]^-$	0.24	0.18	0.09	0.07	0
$[Co(l\text{-mop=phe})^2]^-$	0	0	0	0	0
$[Co(cop=ala)_2]^-$	−0.22	−0.11	0	0	0
$[Co(cop=val)_2]^-$	−0.04	−0.03	0	0	0
$[Co(cop=leu)_2]^-$	−0.03	−0.02	0	0	0
$[Co(cop=phe)_2]^-$	0	0	0	0	0

$[Co(cop=aa)_2]^-$ was prepared in a 1:1 mixture of a solvent and carbon tetrachloride. EtOH=ethanol, MeOH=methanol, DMSO=dimethyl sulfoxide, DMF=*N,N*-dimethylformamide, and AN=acetonitrile.

In order to elucidate the CD induction in the complexes, the complexes were prepared in various solvents (1:1 mixture of a solvent and CCl_4 in the case of $[Co(cop=aa)_2]^-$) and their CD spectra were compared. Despite the resemblance of absorption spectra of the complexes, the CD spectrum depends a great deal on the solvent used for preparation of the complex. CD intensities induced at 520 nm are summarized in Table 1. We see that the CD intensity of $[Co(l\text{-mop=aa})_2]^-$ except for $[Co(l\text{-mop=phe})_2]^-$ decreases in the order ethanol, methanol, dimethyl sulfoxide, *N,N*-dimethylformamide. No CD peak was induced in acetonitrile. On the other hand, the absolute CD intensity of $[Co(cop=aa)_2]^-$ except for $[Co(cop=phe)_2]^-$ decreases in the order: ethanol and methanol. No CD peak was induced in dimethyl sulfoxide, *N,N*-dimethylformamide and acetonitrile. Thus, the order of solvents in inducing the asymmetry around the metal is as follows: ethanol>methanol>dimethyl sulfoxide>*N,N*-dimethylformamide>acetonitrile. The solvent dependence of CD intensity indicates that the vicinal effect of the chiral group is greatly affected by the character of solvent. However, the order mentioned above can not be correlated with any property of solvent such as dielectric constant or dipole moment. From the fact that no CD induction takes place in $[Co(l\text{-mop=phe})_2]^-$ and $[Co(cop=phe)_2]^-$ even in ethanol, we presume that a certain interaction operates between the chiral group and the aromatic nucleus of the ligand. For the sake of confirmation, proton NMR spectra of ethanol, methanol, dimethyl sulfoxide, *N,N*-dimethylformamide and acetonitrile were measured in carbon tetrachloride and in benzene, and the chemical shifts of methyl proton were compared. The results are given in Table 2. Proton NMR signals are always observed at higher field in benzene as compared with in carbon tetrachloride. This can be interpreted in terms of the CH..π-interaction[14] between the methyl proton and benzene. As a measure of the CH..π-interaction we adopted the difference in methyl proton chemical shift between in carbon tetrachloride and in benzene ($\Delta\delta=\delta(CCl_4)-\delta(Bz)$). The small $\Delta\delta$ values of ethanol and methanol indicate that these molecules weakly interact with the aromatic nucleus. The $\Delta\delta$ values of dimethyl sulfoxide, *N,N*-dimethylformamide and acetonitrile are considerably large, indicating a strong CH..π-interaction with the aromatic nucleus. When we adopt the mean of the $\Delta\delta$ values for two inequivalent methyl groups of *N,N*-dimethylformamide, the increasing order in $\Delta\delta$ value (increasing order of the CH..π-interaction) of solvents is as follows: ethanol<methanol<dimethyl sulfoxide<*N,N*-dimethylformamide<acetonitrile. The decreasing order of the induced CD intensity agrees with the increasing order of the CH..π-interaction of solvents utilized for preparation of the complexes. A typical example of this correlation is given for $[Co(l\text{-mop=val})_2]^-$ in Fig. 5. It is likely that the chiral group at the side chain interacts with the aromatic nucleus of the ligand in ethanol or methanol, the CH..π-interaction causing the asymmetry of the configuration of the complex. On the other hand, in dimethyl sulfoxide, *N,N*-dimethylformamide or acetonitrile the CH..π-interaction between the solvent and the aromatic ring of the ligand is strong enough to supress the CH..π-interaction between the chiral group and the aromatic nucleus. $[Co(l\text{-mop=ala})_2]^-$ prepared in a chloroform-methanol (8:2) mixture showed a weak CD peak ($\Delta\varepsilon=0.113$) as compared with the complex prepared in methanol. This can be attributed to the fact that the CH..π-interaction between chloroform and benzene is so strong ($\Delta\delta=1.0$) as to reduce the CH..π-interaction between the chiral group and the aromatic nucleus of the ligand. The CD intensity induced in $[Co(cop=aa)_2]^-$ is much weaker than that induced in $[Co(l\text{-mop=aa})_2]^-$. It seems that the cholesteryl group is

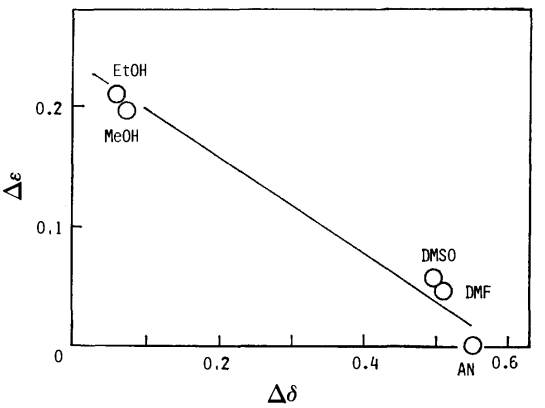

Fig. 5. Correlation between induced CD intensity ($\Delta\varepsilon$) and CH···π-interaction ($\Delta\delta$) of solvents used for preparation of $[Co(l\text{-mop=val})_2]^-$.

AN	1.96	1.41	0.55

a) $\Delta\delta=\delta(CCl_4)-\delta(Bz)$. b) Average value.

less effective than the *l*-menthyl group for introducing the asymmetry around the metal. So far we can not explain why no asymmetry was induced in $[Co(l\text{-}mop{=}phe)_2]^-$ and $[Co(cop{=}phe)_2]^-$. However, it is likely that the chiral group interacts with the phenylalanine nucleus rather than the phenolic nucleus, the interaction exerting no marked effect on asymmetry induction around the metal ions.

The authors are grateful to Assoc. Prof. T. Inazu and Dr. T. Shinmyozu for the measurement of NMR spectra and valuable discussions. The work was carried out with a Grant-in-Aid from the Ministry of Education for Scientific Research.

Thermochromism of Metal Chelates with Triphenylmethane Complexons in Aqueous Solutions. III. Copper(II)–Methylthymol Blue and -Methylxylenol Blue Systems†

Shoji NAKADA, Mutsuo YAMADA, Tasuku ITO,†† and Masatoshi FUJIMOTO*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

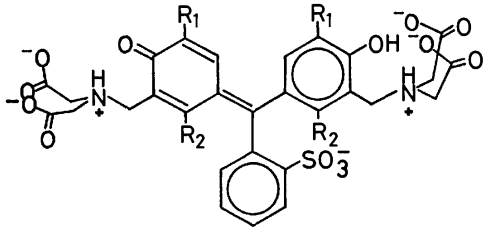
(Received December 20, 1979)

Reversible thermochromisms of copper(II) complexes with 3,3′-bis[bis(carboxymethyl)aminomethyl]thymolsulfonphthalein (Methylthymol Blue; MTB) and 3,3′-bis[bis(carboxymethyl)aminomethyl]-*p*-xylenolsulfonphthalein (Methylxylenol Blue; MXB) were studied in aqueous solutions. The thermochromisms of these complexes were primarily ascribed to the temperature-dependence of the protolytic equilibria between a complex species AH having an uncoordinated free phenolic hydroxyl group and a complex species A having a coordinated phenolate group: $AH \rightleftarrows A + H$. The equilibrium constants K of the reactions at 25 °C were determined to be $p(K/\text{mol dm}^{-3}) = 4.66$ for Cu(II)–MTB and 4.78 for Cu(II)–MXB. The thermodynamic parameters ΔH and ΔS for the reactions were calculated to be 26 ± 2 kJ mol^{-1} and -6 ± 3 J K^{-1} mol^{-1} (298 K) for both complexes, respectively. The rate constants of the proton dissociation of the phenolic hydroxyl group in the complexes AH were estimated to be 1.6×10^5 and 1.8×10^5 s^{-1} for Cu(II)–MTB and Cu(II)–MXB, respectively. The thermodynamic and kinetic data are discussed in terms of the effects of the substituents in the ligand molecules on the thermochromism.

The complexes of the multidentate ligands of the triphenylmethane complexons with various bivalent metal ions were found to be thermochromic in aqueous media.[1] In the previous papers, the thermochromism observed for the Cu(II)–Xylenol Orange (XO) system was interpreted in terms of the temperature-dependence of a protolytic equilibrium between a complex species AH having an uncoordinated free phenolic hydroxyl group and a complex species A having a coordinated phenolate group:

$$AH \rightleftarrows A + H.^{1)} \quad (1)$$

In the present paper we study the thermochromisms observed for the Cu(II) complexes of the similar ligands MTB and MXB by means of a spectrophotometric and a temperature-jump method. The data obtained for the thermochromisms of Cu(II) complexes of the ligands will be compared with that for the Cu(II)–XO system in relation to the differences in alkyl substituents in the ligand molecules (see Fig. 1).



MTB : $R_1 = CH(CH_3)_2$, $R_2 = CH_3$

MXB : $R_1 = CH_3$, $R_2 = CH_3$

XO : $R_1 = CH_3$, $R_2 = H$

Experimental

Materials. All chemicals used were of analytical grade, unless otherwise specified. Water was deionized and distilled.

Methylthymol Blue and Methylxylenol Blue were synthesized by Mannich condensation from Thymol Blue or *p*-Xylenol Blue, iminodiacetic acid (IDA), and formaldehyde, respectively.[2] The crude samples of the synthesized MTB and MXB purified beforehand by means of cellulose column chromatography were finally purified by means of high-performance liquid chromatography as in the case of XO.[3] The purity of the specimens of the ligands was confirmed by elemental analyses and melting point measurements. The purified ligands were used as a free acid form. Stock solutions of the ligands (1.0×10^{-3} mol dm^{-3}) were prepared by dissolving a desired amount of MTB and MXB in water. It should particularly be emphasized that for the quantitative studies the use of the highly purified specimens of the ligands was essential. In the pH range above 8.8, the color of the solutions of the ligands faded within one or two days because of the decomposition, whereas the solutions of the ligands were very stable in the acidic media.

Copper(II) perchlorate and sodium perchlorate were prepared and purified as described previously.[1] Acetate and phosphate buffer solutions were used for the Cu(II) complexes and the free ligands, respectively.

Measurements. The equilibria were measured with Hitachi recording spectrophotometers Model ESP-3T and Model 323 equipped with a cell thermostated at various temperatures. A 1 cm quartz cell was used. The kinetic measurements were carried out with a Union Giken co-axial-cable temperature-jump apparatus Model RA-105.[4] The pH values of the solutions were adjusted with the buffer solutions and measured with a Hitachi-Horiba pH-meter Model F-7SS. Temperature of the solution was measured with a copper-constantan thermocouple and a millivoltmeter within ± 0.2 °C. The ionic strength of the solution was adjusted to 0.1 mol dm^{-3} with sodium perchlorate.

Melting point was measured with a Rigaku Denki differential scanning calorimeter Model 8001 SL/C.

Results and Discussion

In the previous papers we ascribed the thermochromism observed for the Cu(II)–XO system primarily to the temperature-dependence of the protolytic equilibrium (1) based on the similarity of the temperature-dependence and the pH-dependence of the absorption spectra and on the results of molar-ratio method carried out at various temperatures.[1] Quite similar features were observed for the thermochromisms of the Cu(II) complexes of MTB and MXB.

As compared with XO these ligands contain two additional methyl groups R_2 and two isopropyl groups R_1 for MTB and two methyl groups R_1 for MXB (see Fig. 1). The effects of such structural factors in the ligand molecules on the phenomena of thermochromisms of their metal chelates are discussed in relation to the thermodynamic functions and the kinetic data.

Equilibria. Figures 2(a) and 2(b) show the typical examples of the temperature-dependence of the visible absorption spectra of the aqueous solution of Cu(II)–MTB at pH 4.36 and of Cu(II)–MXB at pH 4.57, respectively, the solutions containing 3.0×10^{-5} mol dm^{-3} ligand and 2.4×10^{-4} mol dm^{-3} Cu^{2+} ion.

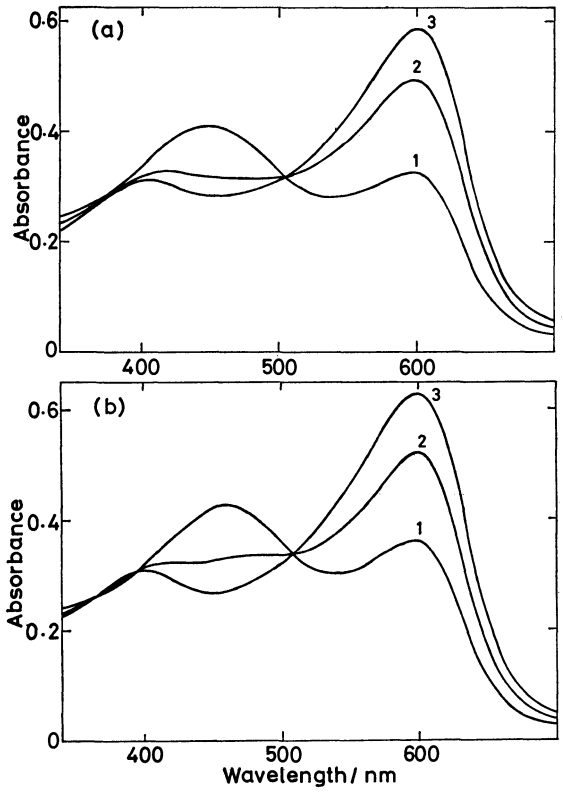

Fig. 2. Temperature-dependence of the absorption spectra of the Cu(II) complexes.
(a) Cu(II)–MTB. At 29 (1), 58 (2), and 77 °C (3). [Cu]$=2.4\times10^{-4}$ mol dm^{-3}; [MTB]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). At pH$=4.36\pm0.02$. (b) Cu(II)–MXB. At 28 (1), 54 (2), and 78 °C (3). [Cu]$=2.4\times10^{-4}$ mol dm^{-3}; [MXB]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). At pH$=4.57\pm0.02$.

The absorption spectra change reversibly with a distinct isosbestic point at 504 nm for Cu(II)–MTB and at 509 nm for Cu(II)–MXB. As the temperature rises the absorbances at 450 nm for Cu(II)–MTB and at 460 nm for Cu(II)–MXB decrease accompanied with a large increase in the absorbance at 600 nm for both systems. For the temperature-rise from 20 to 78 °C the absorbance at 600 nm increases about two-fold, the color changing from dark yellowish brown to dark blue for both systems. The increase of the absorbances at 600 nm was much the same as that of the Cu(II)–XO system at 574 nm under similar conditions. For the Cu(II) complexes of MTB and MXB the features of the temperature-dependences of the absorption spectra at a constant pH were all the same as those

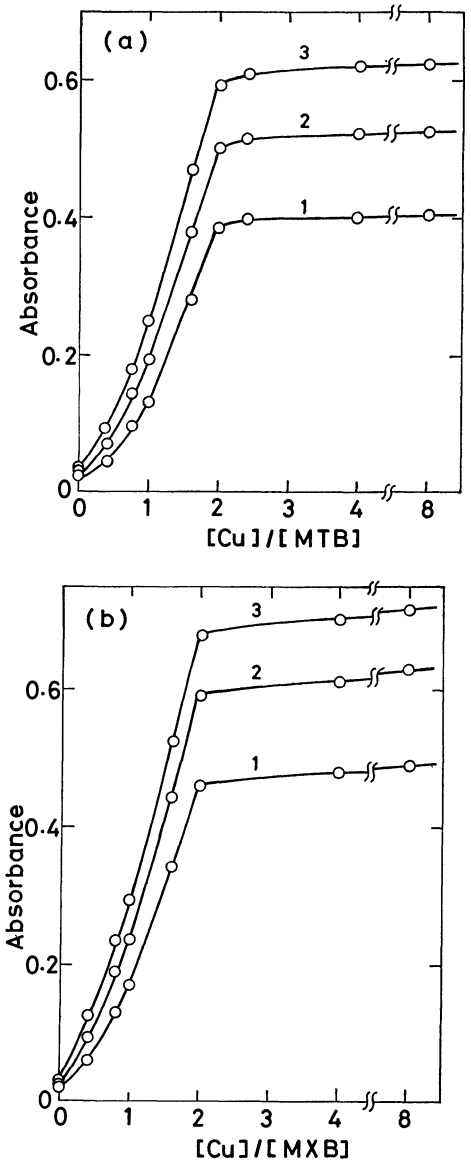

Fig. 3. Molar-ratio method at 600 nm for Cu(II) complexes at various temperatures.
(a) Cu(II)–MTB. At 25 (1), 50 (2), and 70 °C (3), [MTB]$=3.0\times10^{-5}$ mol dm^{-3}. pH$=4.57\pm0.02$. I=0.1 mol dm^{-3} ($NaClO_4$). (b) Cu(II)–MXB. At 25 (1), 50 (2), and 70 °C (3). [MXB]$=3.0\times10^{-5}$ mol dm^{-3}. pH$=4.88\pm0.02$. I=0.1 mol dm^{-3} ($NaClO_4$).

of the pH-dependences of the absorption spectra at a constant temperature.[5-9] The wavelengths of the absorption maxima and the isosbestic points observed for the two dependencies of the spectra were found to be all the same. Namely, also in the cases of the Cu(II) complexes of MTB and MXB the effect of heating the solutions essentially corresponds to the effect of the increase in pH of the same solutions.

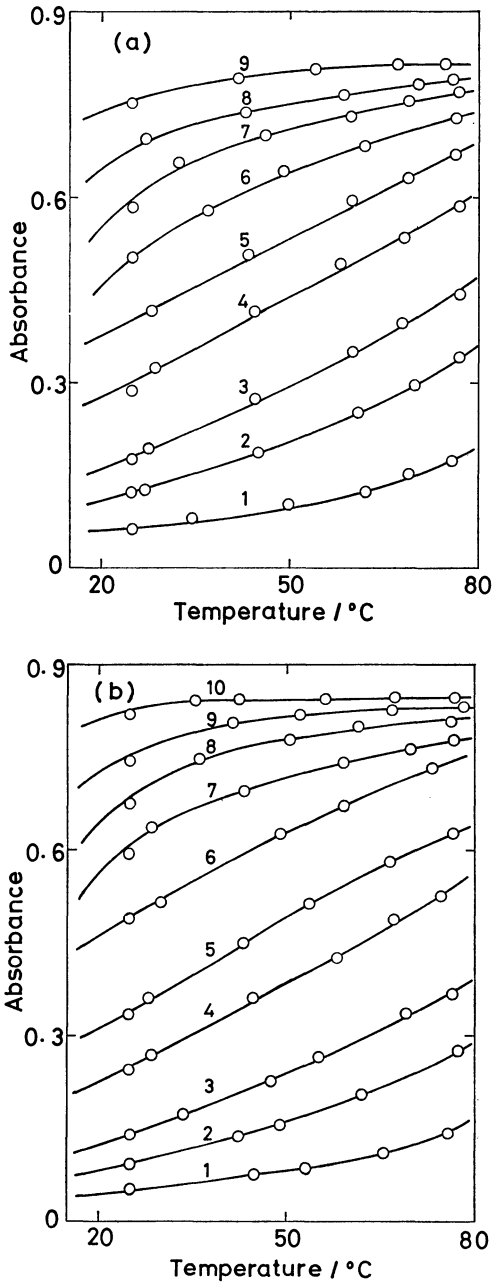

Fig. 4. The temperature-dependence of the absorbance at 600 nm of the Cu(II) complexes at various pH's.
(a) Cu(II)–MTB. At pH 3.26 (1), 3.71 (2), 3.99 (3), 4.36 (4), 4.59 (5), 4.90 (6), 5.20 (7), 5.47 (8), and 6.10 (9). [Cu]$=2.4\times10^{-4}$ mol dm^{-3}; [MTB]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). (b) Cu(II)–MXB. At 3.24 (1), 3.69 (2), 4.00 (3), 4.33 (4), 4.57 (5), 4.88 (6), 5.18 (7), 5.44 (8), 5.70 (9), and 6.08 (10). [Cu]$=2.4\times10^{-4}$ mol dm^{-3}; [MXB]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$).

Figures 3(a) and 3(b) show the results of molar-ratio method measured at 600 nm, at various temperatures, and at pH 4.57 for Cu(II)–MTB and at 4.88 for Cu(II)–MXB, respectively. The metal-to-ligand ratio of the complex species formed in the solution for both systems was found to be invariably 2: 1 irrespective of the temperature.[1]

From the results described above, we concluded that the observed thermochromisms of Cu(II) complexes of MTB and MXB are also ascribed to the temperature-dependence of the protolytic equilibrium between two 2: 1 complex species, *i.e.*, between the low-temperature and the high-temperature form of a 2 : 1 complex species (see equilibrium (1)).

Figures 4(a) and 4(b) show the temperature-dependences of the absorbances at 600 nm of the solutions of the 2 : 1 Cu(II) complexes of MTB and MXB at various pH values. Upon heating the solutions at pH higher than 5.5 or lower than 3.7 the absorbances of both systems increase only slightly. The marked increase in the absorbance was observed for both systems only in a narrow pH range, *e.g.*, between pH 4.0 and 4.9 for Cu(II)–MTB and between pH 4.3 and 5.1 for Cu(II)–MXB (see Figs. 4(a) and 4(b)).

From the temperature-dependences of the absorbance the pH-dependences of the absorbance at various temperatures were derived as reproduced in Figs. 5(a) and 5(b). From these figures the pK values for the Eq. 1 were calculated at 25, 35, 50, and 70 °C. The

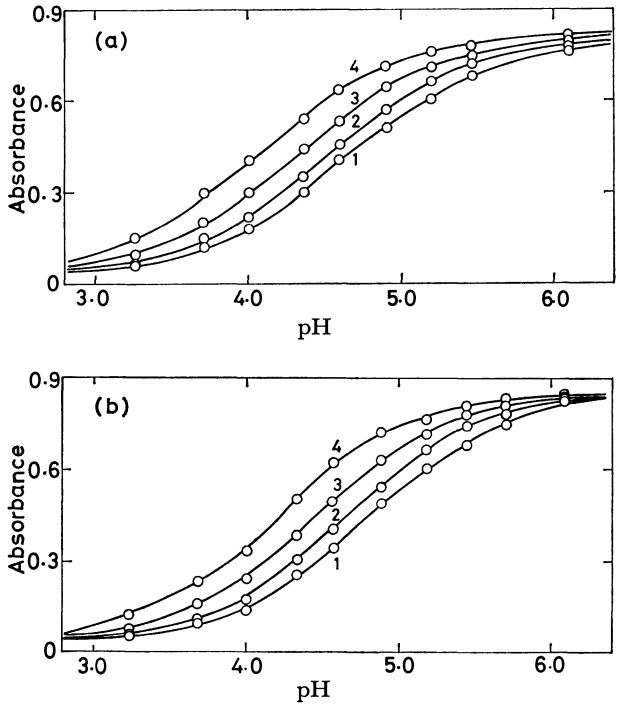

Fig. 5. The pH-dependence of the absorbance at 600 nm of the Cu(II) complexes at various temperatures.
(a) Cu(II)–MTB. At 25 (1), 35 (2), 50 (3), and 70 °C (4). [Cu]$=2.4\times10^{-4}$ mol dm^{-3}; [MTB]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$). (b) Cu(II)–MXB. At 25 (1), 35 (2), 50 (3), and 70 °C (4). [Cu] $=2.4\times10^{-4}$ mol dm^{-3}; [MXB]$=3.0\times10^{-5}$ mol dm^{-3}. I=0.1 mol dm^{-3} ($NaClO_4$).

Table 1. Temperature-dependence of the acid-dissociation constants for the Cu(II) complexes and the free ligands at I=0.1 mol dm^{-3} ($NaClO_4$)[a]

T/°C	15	25	35	50	70
Cu(II)–MTB		4.66	4.54	4.34	4.10
Cu(II)–MXB		4.78	4.65	4.45	4.20
Cu(II)–XO[b]	4.62	4.40	4.27	4.11	3.83
MTB	6.94	6.87	6.81		
MXB	7.05	6.98	6.90		
XO[b]	6.66	6.57	6.50		

a) p(K/mol dm^{-3}) for the complexes. p(K_a/mol dm^{-3}) for the free ligands. b) See Ref. 1.

data were summarized in Table 1 together with those for Cu(II)–XO.

The pK_a values of the phenolic proton of the free ligands MTB and MXB also were obtained at various temperatures by the same procedure as in the case of XO[1] (Table 1).

The temperature-dependences of the absorption spectra of the free ligands in neutral region were smaller compared with those in the Cu(II) complexes in weakly acidic region. For the temperature-rise from 25 to 45 °C the absorbance at 600 nm of the free ligands MTB at pH 6.85 and MXB at pH 6.95, *viz.*, near the pK_a values of the phenol proton of the free ligands, increased only by 11% for MTB and 14% for MXB; the absorbance at 600 nm of Cu(II) complexes of MTB at pH 4.60 and MXB at pH 4.80 increased by so large as 28 and 37%, respectively.

Table 2. Thermodynamic functions for the protonation of the Cu(II) complexes and the free ligands

	ΔH	ΔS
	kJ mol^{-1}	J K^{-1} mol^{-1} (298 K)
Cu(II)–MTB	25±2	−6±3
Cu(II)–MXB	26±2	−6±3
Cu(II)–XO[a]	26±2	1±3
MTB	12±2	−92±3
MXB	13±2	−91±3
XO[a]	14±1	−78±1

a) See Ref. 1.

The thermodynamic parameters ΔH and ΔS for the Eq. 1 for Cu(II) complexes, and for the acid-dissociation of the phenol proton for the free ligands were graphically determined by plotting the values of log K and log K_a against $1/T$, respectively. The obtained values are listed in Table 2 together with the corresponding values for the Cu(II)–XO complex and the free ligand XO.

The positive values of ΔH show that the thermochromic changes of the Cu(II) complexes of MTB and MXB also are endothermic.

The values of ΔH for the Cu(II) complexes were about twice as large as that for the free ligands; the thermochromism was not observed for the free ligands.

A relationship is observed between the thermodynamic data and the position of alkyl substituents in the ligand molecule. Namely, the thermodynamic data for the three ligands, MTB, MXB, and XO, indicate that the effect of the substituents R_2 at meta position to the phenol group is reflected on the values of ΔS, but the effect of the substituents R_1 at ortho position is not (see Table 2). Similar relationship was also observed for the Cu(II) complexes of these ligands.

Bolton and co-workers reported the increase in values of pK_a and ΔS caused by the presence of meta-methyl substituents in phenols.[10]

The difference in the substituents R_1 at ortho position to the phenol group did not affect the thermodynamic functions.

As described in our previous report,[1] the data obtained in the present study also show that the values of ΔS for the equilibrium (1) differ much from those for the protolytic equilibrium in the free ligands. The small values of ΔS for the Cu(II) complexes would be ascribed to the compensation of the increase in the entropy by water molecules released from the coordination sphere of the metal ion upon coordination of the phenolate oxygen and the decrease in the entropy by the hydration of a dissociated proton.[1] Similar discussions have been reported by Desai and Milburn[11] for the complex formation of Fe(III) with phenols, and by Wright *et al.*[12] and Brunetti *et al.*[13] for the protonation of EDTA and its bivalent metal complexes.

Molar absorptivities of the ligands MTB and MXB were found to depend on the temperature. In the pH region between 3.5 and 3.9 corresponding to the pK_a of the carboxyl proton of the ligands[6,8,9] where the absorption spectra of the free ligands show no pH-dependency, a definite temperature-dependence of the spectra was clearly observed. This temperature-dependence of the absorbance would be attributed to the change in molar absorptivity of the ligands and might also contribute to the thermochromism of the Cu(II) complexes, though the effect is not so strong.

Kinetics. The temperature-jump studies were carried out for the Cu(II) complexes of MTB and MXB, and the free ligands, according to the procedure used in the case of Cu(II)–XO.[1] Only one relaxation signal of an increasing absorbance at 600 nm was observed in 5—10 μs region for the Cu(II) complexes in acidic solutions; the corresponding signal for the ligands in nearly neutral solutions was observed in 10—20 μs region. The relaxation times for the protolytic changes can be expressed by

$$\tau^{-1} = k_1 + k_{-1}([\bar{H}]+[\bar{A}]), \quad (2)$$

where k_1, k_{-1}, and [¯] denote the forward and the backward rate constants and equilibrium concentrations, respectively. The kinetic data were listed in Table 3 together with those for Cu(II)–XO and the ligand XO.

The values of k_1 and k_{-1} for the acid-dissociation of phenol proton of the free ligands differ from those of XO. The values of quotient, k_1/k_{-1}, for free ligands were determined to be $10^{-6.7}$ and $10^{-6.9}$ mol dm^{-3} for MTB and MXB, respectively. These values are in good agreement with the values of K_a determined by the equilibrium measurements, though the errors are arge. The kinetic data for the free ligands, MTB and

TABLE 3. THE PROTONATION-DEPROTONATION RATE CONSTANTS FOR THE Cu(II) COMPLEXES AND THE FREE LIGANDS, AT 25 °C AND I=0.1 mol dm^{-3} ($NaClO_4$)

	k_1 / 10^4 s^{-1}	k_{-1} / 10^{10} mol^{-1} dm^3 s^{-1}
Cu(II)–MTB	16	—
Cu(II)–MXB	18	—
Cu(II)–XO[a)]	20	—
MTB	0.2±0.8	0.9±0.5
MXB	0.2±0.8	1.5±0.5
XO[a)]	1.0±0.6	3.0±0.1

a) See Ref. 1. —: For the complexes the values of τ^{-1} did not depend on the sum of equilibrium concentrations, $[\bar{H}]+[\bar{A}]$.

MXB, would suggest that the differences in the values of $K_a=k_1/k_{-1}$ observed may primarily be ascribed to the differences in the values of k_{-1}. This indicates that isopropyl substituent R_1 at ortho position to the phenol group slows down the rate of the proton recombination to somewhat larger extent compared with the methyl substituent R_1 at the same position.

For the Cu(II) complexes of MTB and MXB the values of k_1 estimated for reaction (1) were found to be in the same order of magnitude as that for Cu(II)–XO, *i.e.*, *ca.* 2×10^5 s^{-1}. The values of τ^{-1}, reciprocal of the relaxation times, for the protonation-deprotonation of the Cu(II) complexes of MTB, MXB, and XO are essentially independent of the sum of the equilibrium concentrations of proton and the chelate species involved. These results may be attributed to (1) an instrumental problem that the values of τ derived from the exponential signals for the Cu(II) complexes would reflect the time constant τ_c for the temperature-rise of our apparatus; (2) a possibility of a mechanism involving a contribution of a sort of intramolecular rate-determining step to the recombination of the phenolate with a central Cu(II) ion. The problems on the ambiguity of these possibilities are still open and will be reported elsewhere.

For the kindness in the DSC measurements, the authors thank Professor Yoshio Matsunaga. They also thank Professor Mitsuo Shimoji and Professor Yoshio Nakamura for aid in the use of a spectrophotometer for the measurements at high temperatures.

Stereochemistry of *Λ-uns*-(2*S*,2*S*′)-1,1′-Trimethylenedipyrrolidine-2,2′-dicarboxylato Cobalt(III) Complexes with *N*-Alkyl Substituted Amino or Cyclic Imino Acids

Minahiro Okabayashi, Ken-ichi Okamoto, and Jinsai Hidaka*

Department of Chemistry, University of Tsukuba, Ibaraki 305

(Received January 5, 1980)

((2*S*,2*S*′-1,1′-Trimethylenedipyrrolidine-2,2′-dicarboxylato)(α-amino carboxylato)cobalt(III) complexes were prepared and characterized, where the α-amino carboxylate ligand is glycinate, (*R*)- or (*S*)-alaninate, (*R*)- or (*S*)-valinate, sarcosinate, *N*-ethylglycinate, (*R*)-prolinate, or (*S*)-pipecolate((*S*)-2-piperidinecarboxylate). Of the three possible isomers, only the *Λ-uns-mer* form was prepared for each of the complexes except for the glycinato complex. The (*R*)-prolinato and (*S*)-pipecolato complexes were stereoselectively prepared by using (*RS*)-proline or (*RS*)-pipecolic acid. The pipecolate ion coordinated selectively was assigned to *S*(*C*) configuration on the basis of the CD measurement of the 2,4-dinitrophenyl-pipecolic acid. The nitrogen atom of the sarcosinate, *N*-ethylglycinate, (*R*)-prolinate, or (*S*)-pipecolate ion, which coordinated stereoselectively to Co(III) ion, took the *R*(*N*) configuration. The stereoselectivity in this work was discussed on the basis of the electronic absorption, CD, and PMR spectra.

When the ethylenediamine-*N*,*N*′-diacetate ion (edda) coordinated to Co(III) ion to form [Co(edda)(am)]-type complex (am: α-amino carboxylate ion), the edda preferred to take a symmetric coordination rather than an unsymmetric one,[1–3] while the trimethylenediamine-*N*,*N*′-diacetate ion (tmdda) preferred the unsymmetric one.[4–6] It was assumed that the preference depends mainly on the probable conformation of the backbone diamine chelate ring of the linear O–N–N–O-type ligand.[4] The linear quadridentate ligand in this work, the (2*S*,2*S*′)-1,1′-trimethylenedipyrrolidine-2,2′-dicarboxylate ion (*S*,*S*-tmpro), has two chiral centers, *S*(*C*)*S*(*C*), and two pyrrolidine rings. By coordination to Co(III) ion, therefore, the possible configurations are regulated to only two, *Δ*-symmetric and *Λ*-unsymmetric. This is useful for investigations of the stereochemical preference of the quadridentate ligand and of the selective coordination of the bidentate ligand, α-amino carboxylate, for the remaining two coordination sites.

In the present paper, some aspects of the stereochemistry of the [Co(*S*,*S*-tmpro)(am)]-type complexes are dealt with, where am denotes glycinate, (*S*)- or (*R*)-alaninate, (*S*)- or (*R*)-valinate, (*R*)-prolinate, (*S*)-pipecolate ((*S*)-2-pipelidinecarboxylate, *S*-pipec), sarcosinate (sar), and *N*-ethylglycinate (*N*-et-gly). The *S*,*S*-tmpro complexes obtained have been characterized from their electronic absorption, CD, and PMR spectra. The stereoselective coordination of the *S*,*S*-tmpro and bidentate ligands are discussed in relation to the conformational preference and their steric interaction. The absolute configurations of the coordinated pipecolate ion and of the coordinated nitrogen atoms of the sar, *N*-et-gly, *R*-pro, and *S*-pipec were assigned by means of their CD and PMR spectra.

Experimental

1) Preparation of Ligands. (2*S*,2*S*′)-1,1′-Trimethylenedipyrrolidine-2,2′-dicarboxylic acid was prepared from (*S*)-proline and 1,3-dibromopropane according to the method of Schoenberg *et al.*[7] The needle crystals obtained were recrystallized from ethanol. Found: C, 39.74; H, 6.05; N, 7.05%. Calcd for $C_{13}H_{22}N_2O_4 \cdot 2NaCl \cdot 0.5H_2O$: C, 39.40; H, 5.86; N, 7.07%.

N-Ethylglycine was prepared by the ethylation of glycine using ethyl iodie.[8] Found: C, 34.77; H, 7.24; N, 10.12%. Calcd for $C_4H_9NO_2 \cdot HCl$; C, 34.41; H, 7.17; N, 10.04%.

2) Λ-uns-*Ba*[*Co*(S,S-*tmpro*)*Cl*(*OH*)]$_2 \cdot H_2O$. To a solution containing 1.6 g of tmpro$H_2 \cdot 2NaCl \cdot 0.5H_2O$ and 1.0 g of $CoCl_2 \cdot 6H_2O$ in 20 cm^3 of water was gradually added 1.0 g of PbO_2 by means of vigorous stirring at 65 °C for 10 min. The color of the solution changed from pale red to blue. The solution was cooled to room temperature and then filtered. The filtrate was poured into an anion-exchange column (Dowex 1-X8, 200—400 mesh, Cl^- form, 5×15 cm). The absorbed band was eluted with an 1 mol dm^{-3} $BaCl_2$ aqueous solution, and the eluate was evaporated to dryness. The complex was extracted from the solid with methanol, and the blue complex was obtained by the addition of ether. The complex was recrystallized from methanol by adding a small amount of ether. The CD spectral pattern in the visible region suggested that the *S*,*S*-tmpro has a *Λ-uns* form, but the geometrical arrangement with respect to Cl^- and OH^- is still unknown.

3) Λ-uns-[*Co*(S,S-*tmpro*)(*gly*)]. To the solution of *Λ-uns*-[Co(*S*,*S*-tmpro)Cl(OH)]$^-$ in *2)* was added a solution containing 0.3 g of glycine in 10 cm^3 of water. The pH of the solution was then adjusted to 7.0 by the addition of an 1 mol dm^{-3} NaOH aqueous solution. After the addition of a small amount of activated charcoal, to the mixture was added 1.0 g of PbO_2 at 65 °C for 30 min. The reaction solution was cooled to room temperature and then filtered. The filtrate was passed through the anion-exchange column as in *2)* in order to remove the unreacted anion, *Λ-uns*-[Co(*S*,*S*-tmpro)Cl(OH)]$^-$. The eluate was evaporated to a small volume with a rotary evaporator and then chromatographed on an anion-exchange column (QAE-Sephadex A-25, (*R*,*R*)-tartrate form, 3.5×85 cm). The adsorbed band was separated into five bands: yellow, violet, violet, violet, and red, in the order of elution, by eluting with water. The first yellow band contained cationic compounds, because it was adsorbed by a cation-exchange resin (SP-Sephadex C-25, Na^+ form). It was found, from the absorption and CD spectra, that the second band contained *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(gly)]; the third one, *mer*-[Co(gly)$_3$]; the fourth one, *Λ-uns-fac*-[Co(*S*,*S*-tmpro)(gly)], and the fifth one, *fac*-[Co(gly)$_3$] (the earlier-eluted part of the fifth band consists of the *Δ-fac* isomer, and the later-eluted part, the *Λ-fac* isomer). The fourth band contained a very small amount of the complex in comparison

with the second band.

4) *Λ*-uns-mer-[*Co*(S,S-*tmpro*)(*gly*)]·H_2O. The second eluted band in *3)* was evaported to a small volume, and to the concentrated solution was added ethanol and then acetone. The solution was kept in a refrigerator overnight. The needle crystals thus precipitated were collected and recrystallized from water by the addition of ethanol and acetone. The pure crystals were collected, washed with ethanol and then ether, and dried in the air. Yield: 0.125 g.

5) *Λ*-uns-fac-[*Co*(S,S-*tmpro*)(*gly*)]·$3H_2O$. The fourth eluate in *3)* was evaporated to dryness. The violet solid was suspended in ethanol and collected by filtration. The crude complex was purified as in *4)*. Yield: 0.01 g.

6) *Λ*-uns-mer-[*Co*(S,S-*tmpro*)(S-*ala*)]·H_2O, [*Co*(S,S-*tmpro*)(R-*ala*)]·H_2O, [*Co*(S,S-*tmpro*)(S-*val*)]·H_2O, *and* [*Co*(S,S-*tmpro*)(R-*val*)]·H_2O. These complexes were prepared and isolated in the same method as that used for *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(gly)]. The *Λ-uns-fac* isomer was not detected in these complexes.

7) *Λ*-uns-mer-[*Co*(S,S-*tmpro*)(*sar*)]. The complex was prepared by the same procedure as that used for [Co(*S*,*S*-tmpro)(gly)] using 0.37 g of sarcosine. The reaction mixture being passed through the columns (Dowex 1-X8 and SP-Sephadex C-25) in order to remove the negative and positive charged compounds was chromatographed on a column (QAE-Sephadex A-25, Cl^- form, 3.5×85 cm). The only band was eluted with water and fractionated into eight parts. It was found from their absorption and CD spectra that all eight fractions contained *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(sar)]. Yield: 0.15 g.

8) *Λ*-uns-mer-[*Co*(S,S-*tmpro*)(N-*et-gly*)]·$0.5H_2O$. The complex was prepared and isolated using the same procedure as had been used for *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(sar)]. Yield: 0.10 g.

9) *Attempt to Prepare* [*Co*(S,S-*tmpro*)(S-*pro*)]. The preparation of the [Co(*S*,*S*-tmpro)(*S*-pro)] was attempted by a procedure similar to that used for the glycinato complex, but using (*S*)-proline instead of glycine. After the removal of the charged compounds as in *7)*, a small amount of the violet complex was obtained. Chromatography behavior and the absorption and CD spectra showed that the eluate contained *mer*- and *fac*-[Co(*S*-pro)$_3$], while the desired [Co(*S*,*S*-tmpro)-(*S*-pro)] was not detected.

10) *Λ*-uns-mer-[*Co*(S,S-*tmpro*)(R-*pro*)]·$2.5H_2O$. This complex was prepared by the same procedure as that used for [Co(*S*,*S*-tmpro)(gly)] using 1 g of (*RS*)-proline. The reaction mixture having been removed the negative and positive charged compounds as in *7)* was chromatographed on the column (QAE-Sephadex A-25, Cl^- form). The complex was separated into three bands: blue-violet, violet, and red, in the order of elution. The absorption and CD spectra showed that the first adsorbed band contained *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(*R*-pro)], and the second and third bands, *mer*- and *fac*-[Co(*RS*-pro)$_3$] respectively. The needle crystals were isolated from the first eluate by a procedure similar to that used for *4)*. Yield: 0.15 g. The complex was recrystallized from ethanol by adding ether and dried in a vacuum desiccator.

11) *Λ*-uns-mer-[*Co*(S,S-*tmpro*)(S-*pipec*)]·$0.5H_2O$. This complex was prepared and isolated by the same procedure as in *10)* using 0.60 g of (*RS*)-pipecolic acid. The complex was chromatographed on the column (QAE-Sephadex A-25, (*R*,*R*)-tartrate form); the CD spectra of the eight fractionated eluates were identical. The crude complex was recrystallized twice from an ethanol–methanol (1:1) mixture by the addition of ether without any change in the CD spectrum. Yield: 0.14 g. The absolute configuration of the coordinated (*R*)- and/or (*S*)-pipecolate ion was determined by the following method.

A solution containing 0.033 g of [Co(*S*,*S*-tmpro)(pipec)]·$0.5H_2O$ in 20 cm^3 of a 0.6 mol dm^{-3} $NaHCO_3$ aqueous solution was warmed at 55 °C. To the solution was added 6 cm^3 of a 0.1 mol dm^{-3} NaOH solution, whereupon the color of the solution immediately changed from blue-violet to colorless. The colorless solution was cooled to room temperature as soon as possible, neutralized by the addition of 6 mol dm^{-3} HCl, and then evaporated to dryness with a rotary evaporator. The pipecolic acid thus released was dinitrophenylated by the method reported by Yonetani *et al.*[9] The resulting dinitrophenylated pipecolic acid (DNP-pipec) showed the same CD spectrum as that of DNP-pipecolic acid described in the literature.[10] Thus, it was determined that the coordinated pipecolate ion has *S* configuration.

12) uns-mer-[*Co*(*tmdda*)(*sar*)]·$0.5H_2O$. This complex was prepared by the method described in a previous paper.[4] Only the *uns-mer* isomer was obtained, without the *uns-fac* one being formed.

Analyses. The analytical results for the complexes obtained are summarized in Table 1.

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra, with a JASCO J-20 spectropolarimeter. The PMR spectra were recorded on a JEOL JNM-MH-100 NMR spectrometer at the probe temperature in a D_2O solvent. Sodium 2,2-dimethyl-2-silapentanesulfonate (DSS) was used as the internal reference.

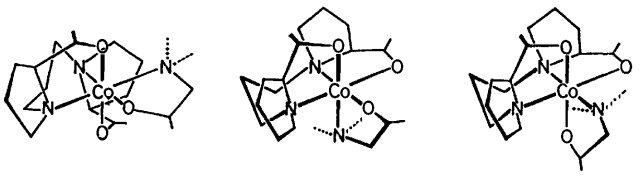
Results and Discussion

Structural Assignments. The (2S,2S')-1,1'-trimethylenedipyrrolidine-2,2'-dicarboxylate anion is an O–N–N–O-type ligand similar to the trimethylenediamine-*N,N'*-diacetate anion,[4-6] while the *S,S*-tmpro has two chiral centers, (*S*(*C*) and *S*(*C*)), and two pyrrolidine rings. Accordingly, only three chiral configurations, *Δ-s*, *Δ-uns-fac*, and *Δ-uns-mer*, are possible for the [Co(*S,S*-tmpro)(am)] complex (Fig. 1).



(a) (b) (c)

Fig. 1. Three possible isomers of [Co(*S,S*-tmpro)(am)] type complex, (a) *Δ-s*, (b) *Δ-uns-fac*, and (c) *Δ-uns-mer*.

The absorption and CD spectral data of the isolated *S,S*-tmpro complexes are summarized in Tables 2 and 3, while the representative curves are shown in Figs. 2 and 3. Of the nine complexes in this work, only the glycinato complex gave two kinds of isomers, though the later-eluted glycinato isomer formed a trace amount. The absorption curves of the nine complexes resemble each other remarkably except for the later-eluted glycinato isomer, and their CD curves all show a positive

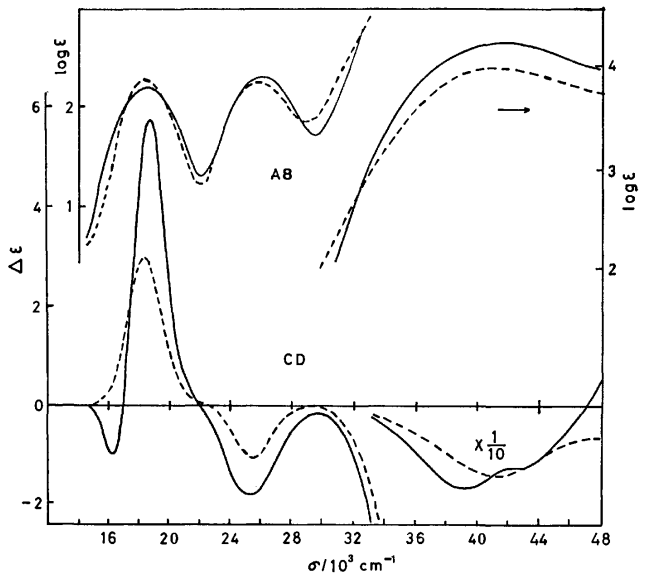

Fig 2. Absorption and CD spectra for the isomers of [Co(*S*,*S*-tmpro)(gly)], *Λ-uns-mer* (——) and *Λ-uns-fac* (----).

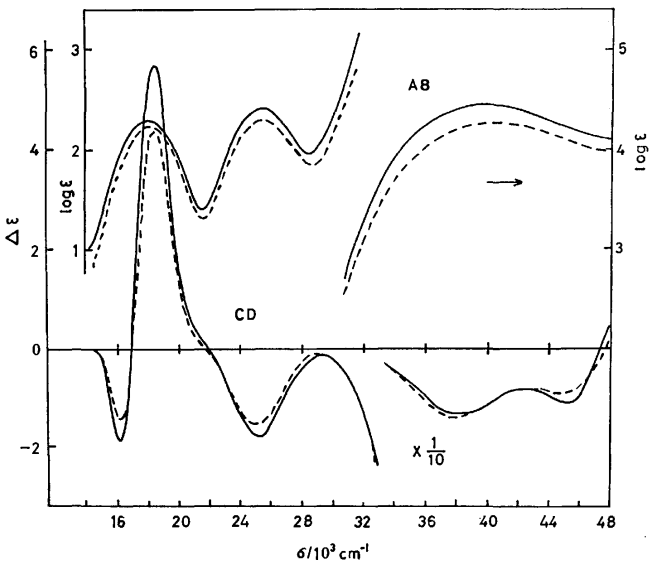

Fig. 3. Absorption and CD spectra of *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(*R*-pro)] (——) and *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(*S*-pipec)] (——).

dominant CD band in the first absorption band region, such as those of *Λ-uns-mer*-[Co(tmdda)(am)].[4] The later-eluted glycinato isomer, the absorption spectral pattern of which differs from those of the earlier-eluted isomer and the other eight complexes, also shows a positive dominant CD band in the corresponding region. This CD behavior suggests that all of the complexes isolated commonly take *Λ* configuration, namely, *Λ-uns-mer* or *Λ-uns-fac* (Fig. 1).

As is shown in Fig. 2, the first absorption band of the earlier-eluted glycinato isomer is broad, whereas that of the later one is sharp. These absorption spectral patterns indicate that the earlier-eluted isomer is *mer*(N_3O_3), and the later one, *fac*(N_3O_3).[11] The absorption spectra of the other complexes coincide with that of the earlier-eluted glycinato isomer (Figs. 2 and 3 and Table 2). Therefore, the later-eluted glycinato isomer is assigned to the *Λ-uns-fac* form, and the earlier-eluted isomer and the eight complexes, the *Λ-uns-mer* form.

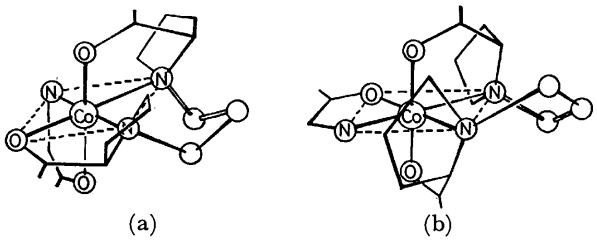

Fig. 4. Chair (a) and skew-boat (b) conformations for the trimethylenediamine chelate ring of *Λ-uns-mer-* and *Δ-s*-[Co(*S*,*S*-tmpro)(am)], respectively.

Stereospecificity. For all of the present complexes, the coordinated *S*,*S*-tmpro ligand takes the *Λ*-unsymmetric form. Furthermore, the CD spectrum of the starting complex, [Co(*S*,*S*-tmpro)Cl(OH)]$^-$, suggests that the chiral configuration is *Λ*-unsymmetric (Table 3). Molecular models reveal that the backbone trimethylenediamine ring of *S*,*S*-tmpro takes a symmetrical chair form for the *Λ*-unsymmetric coordination, while a skew-boat is most probable for the *Δ*-symmetric one (Fig. 4). From the present results, accordingly, it is possible to say that the *Λ*-unsymmetric preference of the *S*,*S*-tmpro depends mainly on the more stable conformation of the backbone trimethylenediamine ring.[12,13]

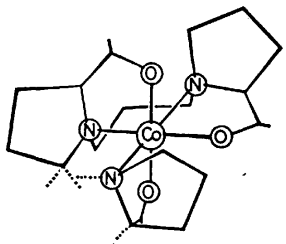

Fig. 5. Probable chiral configuration, *R*(*N*), of the (*R*)-prolinate ion in *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(*R*-pro)].

The *Λ-uns-mer* and *Λ-uns-fac* isomers were obtained only for the glycinato complex. For both the sarcosinato and *N*-ethylglycinato complexes, however, the *mer* isomer was obtained, and no *fac* isomer was detected. It seems that this preference for the *Λ*-unsymmetric *mer* is attributable to the proximity between the *N*-alkyl group of the sarcosinate or *N*-ethylglycinate ring and the chair-conformed trimethylenediamine ring of the *S*,*S*-tmpro (Fig. 1). A similar trend was also observed for the [Co(tmdda)(sar)] complex (Tables 2 and 3). Another steric factor is found between the axial pyrrolidine ring of the *S*,*S*-tmpro and *N*-alkyl group of the bidentate ligand. A typical example of this interaction is found in the *Λ-uns-mer*-[Co(*S*,*S*-tmpro)(*S*-pro)] complex (Fig. 5). The prolinato complex could not be formed by using (*S*)-proline as the bidentate ligand, though the (*R*)-prolinato complex was selectively

formed, without the forming of the (*S*)-prolinato complex, by using (*RS*)-proline. This selectivity is due to the fact that the *N* atom of (*S*)-proline is regulated to the *S* configuration by coordinating to Co(III). That is, the *S*(*N*) coordination can not be realized in the *Λ-uns-mer S,S*-tmpro complex because of the proximity between the pyrrolidine rings of (*S*)-prolinate and *S,S*-tmpro (Fig. 5). In the *R*(*N*) coordination of (*R*)-prolinate, on the contrary, the pyrrolidine ring of the (*R*)-prolinate chelate avoids that of *S,S*-tmpro. A similar selectivity can also be expected for the pipecolato, sarcosinato, and *N*-ethylglycinato complexes of the *Λ*-unsymmetric configuration. The pipecolato complex, *Λ-uns-mer*-[Co(*S,S*-tmpro)(*S*-pipec)], was selectively prepared by using (*RS*)-pipecolic acid, as in the case of *Λ-uns-mer*-[Co(*S,S*-tmpro)(*R*-pro)]. The absolute configuration of the selected pipecolate ion was determined to be *S*(*C*) by the 2,4-dinitrophenyl (DNP) method.[9,10]

From model constructions, the order of the interligand crowd for the possible isomers of *Λ-uns-mer*-[Co(*S,S*-tmpro)(*R*- or *S*-pipec)] is $S(N)S(C) \gg S(N)R(C) > R(N)S(C) \approx R(N)R(C)$. Of the four isomers, the *R*(*N*)*S*(*C*) isomer is most probable for the pipecolato complex, since the *S*(*N*)*R*(*C*) and *R*(*N*)*R*(*C*) isomers are eliminated on the basis of the DNP method described above. In the $[Co(R\text{-pipec})(NH_3)_4]^+$ complex, the pipecolate ion coordinated to Co(III) with the *S*(*N*) configuration and the piperidine ring conformation took the chair form.[14] In the *Λ-uns-mer*-[Co(*S,S*-tmpro)(*S*-pipec)] complex, therefore, it is probable that the (*S*)-pipecolate ion coordinates to Co(III) to take the *R*(*N*) configuration. This suggests that the repulsion between the pyrrolidine ring and the chair-conformed piperidine one is relaxed by the *R*(*N*) preference of the pipecolate chelate.

The *R*(*N*) preference in the sarcosinato and *N*-ethylglycinato complexes is vague in comparison with that in the (*S*)-pipecolato one, and so their PMR spectra were measured in D_2O. The singlet (at 2.28 ppm) due to the *N*-methyl group is observed for the sarcosinato complex, and the triplet (at 1.32 ppm) due to the *N*-ethyl group for the *N*-ethylglycinato complex. These spectral patterns indicate that, for both of the complexes, the nitrogen atom of the bidentate ligand takes either the *R* or *S* configuration. However, no further information was obtained. In order to estimate the configuration of the nitrogen atoms of the complexes, the vicinal CD curves due to the nitrogen atom were estimated for the (*R*)-prolinato, (*S*)-pipecolato, sarcosinato, and *N*-ethylglycinato complexes, namely, $\Delta\varepsilon(R\text{-pro}) - \Delta\varepsilon(R\text{-val})$ for *R*-pro, $\Delta\varepsilon(S\text{-pipec}) - \Delta\varepsilon(S\text{-val})$ for *S*-pipec, $\Delta\varepsilon(\text{sar}) - \Delta\varepsilon(\text{gly})$ for sar, and $\Delta\varepsilon(N\text{-et-gly}) - \Delta\varepsilon(\text{gly})$ for *N*-et-gly (Fig. 6). The vicinal CD curves are quite similar to each other. These results suggest that the nitrogen atoms of the (*S*)-pipecolate, sarcosinate, and *N*-ethylglycinate ions of the *Λ-uns-mer* type

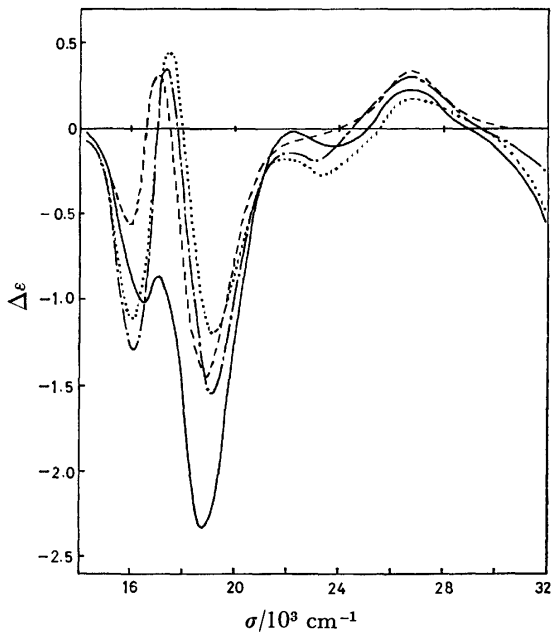

Fig. 6. Calculated vicinal CD curves of *Λ-uns-mer*-[Co(*S,S*-tmpro)(am)] complexes, *R*-pro (——), *S*-pipec (——) *N*-et-gly (-·-·-), and sar (------).

complexes coordinate selectively to Co(III) by means of the *R*(*N*) configuration.

(Received January 7, 1980)

The oxovanadium(IV), nickel(II), copper(II), and palladium(II) complexes of 5,14-dihydrodibenzo[*b,i*]-[1,4,8,11]tetraazacyclotetradecine and 7,8,15,16,17,18-hexahydrodibenzo[*b,j*][1,4,8,11]tetraazacyclotetradecine have been synthesized, and studied by electronic, vibrational, NMR, ESR, and ESCA spectroscopy. The absorption bands appearing in the energy region greater than 16800 cm^{-1} were attributed to $\pi \rightarrow \pi^*$ transitions within a ligand molecule and metal to ligand charge-transfer transitions. The ligand-field bands were not assigned for the present complexes, because all the ligand-field bands were obscured by the $\pi \rightarrow \pi^*$ and charge-transfer bands of high intensity. The metal complexes assume the square-planar configurations since no significant absorption band was detected in the region below 17000 cm^{-1}. A strong band appearing at *ca.* 1620 cm^{-1} was assigned to the C=N stretching mode, and this band was shifted to lower frequency upon metal coordination. A V=O streching band was observed at *ca.* 950 cm^{-1} for the oxovanadium complexes. The oxovanadium, nickel, copper, and palladium complexes showed a single nitrogen 1s peak by ESCA spectroscopy, whereas the metal-free ligand, 5,14-dihydrodibenzo[*b,i*][1,4,8,11]tetraazacyclotetradecine, revealed double nitrogen 1s peaks. ESR spectra were measured in xylene–benzene (2: 1 v/v) as well as in the corresponding ligand matrices at room temperature. Judging from *g* tensors, the copper complexes were confirmed to have D_{2h} coordination symmetry with an unpaired electron in the d_{xy} orbital. On the other hand, vanadium(IV) is in C_{4v} coordination symmetry with an unpaired electron in the $d_{x^2-y^2}$ orbital.

The naturally occurring macrocycles with N_4-donor atoms, porphyrins and corrins, may form metal complexes which involve four conjugated six-membered chelate rings (6^4 type) and three six- and one five-membered chelate rings (6^3-5 type), respectively. However, there are many N_4-macrocycles which can yield metal complexes having other combinations of chelate-ring sizes. The chemistry of metal porphyrins and metal corrins has been widely investigated up to the present time because of their biochemical interest.[1,2]

In the present work, we employed N_4-macrocycles which can form two six- and two five-membered chelate rings of 6-5-6-5 type; a 16 π-macrocyclic ligand, 5,14-dihydrodibenzo[*b,i*][1,4,8,11]tetraazacyclotetradecine (**1**), and a 12 π-macrocycle, 7,8,15,16,17,18-hexahydrodibenzo[*b,j*][1,4,8,11]tetraazacyclotetradecine (**2**). A number of π-electrons placed in the interior molecular skeleton of this type extends from none for the completely saturated system to 16 for complete conjugation.[3] Hiller *et al.*[4] and Green *et al.*[5] reported electronic and vibrational spectra of the nickel(II) and copper(II) of macrocyclic ligands **1** and **2** without assignments of characteristic bands. We characterized the spectral properties of the oxovanadium(IV), nickel(II), copper-(II), and palladium(II) complexes of the present macrocycles by means of electronic, vibrational, ESR, NMR, and ESCA spectroscopy. The characteristic coordination behavior of the present planar ligand has been discussed in reference to the ligand properties of porphyrins.

Experimental

5,14-Dihydrodibenzo[b,i][*1,4,8,11*]*tetraazacyclotetradecine(1).* Prepared after Hiller *et al.*[4] from 1,2-diaminobenzene (36.5 g) and 2-propynal (18.2 g)[6] in a mixed solvent composed of methanol (90 ml) and *N,N*-dimethylformamide (45 ml). The crystalline solid was washed with methanol (50 ml) and recrystallized from *N,N*-dimethylfomamide as glittering red needles; yield 11.0 g (23%). Found: C, 74.82; H, 5.57; N, 19.55%; M^+, 288.[7] Calcd for $C_{18}H_{16}N_4$: C, 74.98; H, 5.59; N, 19.43%; M, 288.35.

(Dibenzo[b,i][*1, 4, 8, 11*]*tetraazacyclotetradecinato) oxovanadium-(IV).* A mixture of **1** (0.50 g), vanadium (IV) chloride oxide (0.40 g), and *N,N*-dimethylformamide (80 ml) was heated under reflux for 5 h. To the filtrate of the hot mixture was added water (400 ml), and fine brown crystals were recovered; yield 0.47 g (77%). Found: C, 61.69; H, 4.09; N, 15.64%; M^+, 353.[7] Calcd for $C_{18}H_{14}N_4OV$: C, 61.20; H, 3.99; N, 15.86%; M, 353.28.

(Dibenzo[b,i][*1,4,8,11*]*tetraazacyclotetradecinato)nickel(II).* This complex was prepared from **1** (0.25 g) and nickel(II) acetate tetrahydrate (0.30 g) in the presence of sodium acetate trihydrate (0.50 g) and *N,N*-dimethylformamide (23 ml)

after Hiller *et al.*,[4] and recrystallized from *N,N*-dimethylformamide to give glittering violet plates; yield 0.28 g (94%). Found: C, 63.28; H, 4.11; N, 16.21%; M+, 344.[7] Calcd for $C_{18}H_{14}N_4Ni$: C, 62.66; H, 4.09; N, 16.24%; M, 345.05.

(Dibenzo[b,i]*[1,4,8,11]tetraazacyclotetradecinato)copper(II).* This was prepared from **1** (1.00 g) and copper(II) acetate monohydrate (2.25 g) in the presence of sodium acetate trihydrate (1.50 g) and *N,N*-dimethylformamide (100 ml) after Hiller *et al.*,[4] and recrystallized from *N,N*-dimethylformamide to give glittering dark red needles; yield 1.11 g (91%). Found: C, 61.85; H, 4.15; N, 15.98%; M+, 349.[7] Calcd for $C_{18}H_{14}N_4Cu$; C, 61.79; H, 4.03; N, 16.01%; M, 349.88.

(Dibenzo[b,i]*[1,4,8,11]tetraazacyclotetradecinato)palladium (II).* A mixture of **1** (0.50 g), palladium(II) chloride (0.40 g), and *N,N*-dimethylformamide (25 ml) was heated under reflux for 2 h. The hot mixture was filtered, and water (500 ml) was added to the filtrate. The precipitates were separated and washed with water (100 ml) and methanol (10 ml) to give pale brown needles; yield 0.24 g (35%). Found: C, 55.47; H, 3.91; N, 13.26%; M+, 392.[7] Calcd for $C_{18}H_{14}N_4Pd$; C, 55.05; H, 3.59; N, 14.27%; M, 392.74.

7,8,15,16,17,18-Hexahydrodibenzo[b,j]*[1,4,8,11]tetraazacyclotetradecine (2).* 1,2-Ethanediamine (1.2 ml) dissolved in methanol (100 ml) was added in 1.5 h to a mixture of zinc(II) acetate dihydrate (3.07 g), 2,2′-(ethylenediimino)dibenzaldehyde[8] (2.68 g), and methanol (300 ml) under reflux with stirring. The reaction mixture was refluxed for another 2 h with stirring. After the mixture was cooled down with ice–water, the precipitated crystalline solid was recrystallized from chloroform as colorless needles; yield 1.77 g (61%), mp 279—282 °C (dec). Found: C, 74.24; H, 6.90; N, 19.08%; M+, 292.[7] Calcd for $C_{18}H_{20}N_4$: C, 73.94; H, 6.89; N, 19.16%; M, 292.39.

(7,8,16,17-Tetrahydrodibenzo[b,j] [*1,4,8,11]tetraazacyclotetradecinato)oxovanadium(IV).* 1,2-Ethanediamine (1.07 ml) dissolved in methanol (50 ml) was added in 1 h to a mixture of vanadium (IV) chloride oxide (1.70 g), sodium acetate trihydrate (2.10 g), 2,2′-(ethylenediimino)dibenzaldehyde (1.07 g), and methanol (250 ml) under reflux with stirring. The reaction mixture was refluxed for another 1 h with stirring. After the solvent was evaporated off *in vacuo*, the residue was extracted with chloroform (300 ml), concentrated to *ca.* 10 ml *in vacuo*, and brown needles were obtained upon addition of methanol (35 ml); yield 0.08 g (6%). Found: C, 60.08; H, 5.09; N, 15.50%; M+, 357.[7] Calcd for $C_{18}H_{18}N_4OV$: C, 60.51; H, 5.08; N, 15.68%; M, 357.31.

(7,8,16,17-Tetrahydrodibenzo[b,j] [*1,4,8,11]tetraazacyclotetradecinato)nickel(II).* This was prepared from nickel(II) acetate tetrahydrate (2.49 g), 2,2′-(ethylenediimino) dibenzaldehyde (2.68 g), 1,2-ethanediamine (1.3 ml), and methanol (110 ml) after Green *et al.*,[5] and recrystallized from benzene–petroleum ether (3 : 1 v/v) as glittering dark brown needles; yield 2.38 g (68%). Found: C, 62.42; H, 5.05; N, 15.85%; M+, 348.[7] Calcd for $C_{18}H_{18}N_4Ni$: C, 61.93; H, 5.20; N, 16.05%; M, 349.08.

(7,8,16,17-Tetrahydrodibenzo [b,j][*1,4,8,11]tetraazacyclotetradecinato)copper(II).* This was prepared from copper(II) acetate monohydrate (1.00 g), 2,2′-(ethylenediimino)-dibenzaldehyde (1.34 g), 1,2-ethanediamine (0.67 ml), and methanol (40 ml) after Green *et al.*,[5] and recrystallized from benzene–petroleum ether (3 : 1 v/v) to give glittering dark brown plates; yield 0.75 g (42%). Found: C, 60.89; H, 5.09; N, 15.60%; M+, 353.[7] Calcd for $C_{18}H_{18}N_4Cu$: C, 61.09; H, 5.13; N, 15.83%; M, 353.91.

(7,8,16,17-Tetrahydrodibenzo[b,j][*1,4,8,11]tetraazacyclotetradecinato)palladium(II).* 1,2-Ethanediamine (0.33 ml) dissolved in methanol (10 ml) and sodium hydroxide (0.16 g in 0.5 ml H_2O) in methanol (10 ml) was added concurrently in 30 min to a mixture of palladium(II) chloride (0.36 g), 2,2′-(ethylenediimino)dibenzaldehyde (0.27 g), and methanol (20 ml) under reflux with stirring. The reaction mixture was refluxed for another 1 h with stirring, and cooled down with ice–water. The crystalline solid was recovered and extracted with chloroform (30 ml); upon addition of a 10-fold amount of methanol red needles were obtained; yield 0.09 g (23%). Found: C, 54.39; H, 4.49; N, 13.76%; M+, 396.[7] Calcd for $C_{18}H_{18}N_4Pd$: C, 54.49; H, 4.57; N, 14.12%, M, 396.77.

Spectral Measurements. Ultraviolet and visible spectra were recorded on a Shimadzu UV-200S double beam spectrophotometer at room temperature. Infrared spectra covering the 650—4000 cm^{-1} range were measured with a JASCO IRA-2 grating spectrophotometer at room temperature. A JEOL JNM-FX 60 spectrometer was used to obtain NMR spectra at room temperature and chemical shifts were reported in ppm from internal TMS. ESR spectra were recorded at room temperature on a JEOL JES-ME-1 X-band and a JEOL JES-ME-3 K-band spectrometer equipped with a 100 kHz field modulation unit. The copper(II) and oxovanadium(IV) complexes of **1** were doped in ($\approx$1 wt%) the isomorphous ligand, while the metal complexes of **2** were in ($\approx$1 wt%) the isomorphous nickel complex for measurements. All the ESR sensitive metal complexes were also measured in xylene–benzene (2 : 1 v/v) at room temperature. The manganese ion diffused into magnesium oxide was used to obtain standard reference signals for measurements. ESCA spectroscopy was performed on a Du Pont 650B spectrometer using a Mg $K\alpha$ irradiation unit. A signal due to Au $4f_{5/2.7/2}$ was used for calibration.

Results and Discussion

Electronic Spectra. Visible and ultraviolet spectra covering the 16000—32000 cm^{-1} region are shown in Figs. 1 and 2 for the metal chelates of 5,14-dihydrodibenzo[*b,i*][1,4,8,11]tetraazacyclotetradecine (**1**) and 7,8,15,16,17,18-hexahydrodibenzo[*b,j*][1,4,8,11]tetraazacyclotetradecine (**2**), respectively, and the absorption bands appearing in the energy region greater than 16800 cm^{-1} are reasonably attributed to $\pi \rightarrow \pi^*$ transitions within a ligand molecule and charge-transfer transitions from metal to ligand. General feature of the spectra for the 16π-macrocycle (**1**) system is similar to those observed for metal porphyrins.[9,10] An extremely intense absorption band observed in the 23000—26000 cm^{-1} region is assigned to the so-called Soret-type transition, and a pair of weaker bands in the 19000—24000 cm^{-1} region are to the α- and β-type transitions (Table 1). The α, β, and Soret bands for the metal chelates of **1** are located in a higher energy region than those for the corresponding metal porphyrins. The oxovanadium(IV), nickel(II), copper(II), and palladium(II) complexes do not show any significant absorption in the region lying below *ca.* 17000 cm^{-1}. The spectral behavior is consistent with the square-planar coordination.[11]

The spectral features for the metal complexes of 12π-macrocycle **2** are quite different from those for metal porphyrins. The nickel(II) complex shows a spectrum similar to those observed for the nickel(II)–amben complex (**3**).[5,12,13] It is rather difficult at present to make exact assignments of absorption bands observed

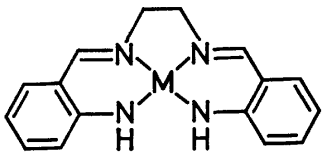
in the visible and near UV regions, we tentatively assign intensive bands in the 18000—30000 cm^{-1} region



3

to charge-transfer and/or $\pi \rightarrow \pi^*$ transitions (Table 1). A low energy band, which is attributable to a ligand-field transition was observed only for the copper(II) and palladium(II) at 16900 (ε 700) and 15400 (ε 220) cm^{-1}, respectively.

Vibrational Spectra. The characteristic IR absorption bands for the present discussion are summarized in Table 2 together with those for Ni(amben)[13] and Ni(porphine).[14] The metal-free macrocycles show a weak band at *ca.* 3200 cm^{-1} which is associated with a N–H stretching mode in a manner as observed for the metal-free porphyrins.[15] This vibrational mode disappears upon complex formation.

A strong absorption band observed in the 1600 cm^{-1} region can be attributed to the stretching mode of C=N bond. This band is most sensitive to metal-coordination among the absorption peaks appearing in the NaCl region, and shifts significantly to lower frequency upon

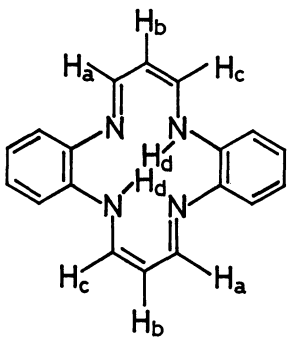
a) Measured by KBr disk method at room temperature. b) Relative intensities: s, strong; m, medium; w, weak; br, broad. c) See Table 1 for numbering the ligands **1** and **2**. d) Amben, *N,N'*-ethylenebis(*o*-aminobenzylideneiminato).

metal-coordination. Such a spectral feature has been observed for Ni(amben),[13] but is not clear for metal porphyrins.[15] The magnitude of these frequency-shifts with respect to metal ions follows the sequence in an increasing order: Cu(II)≲VO(IV)≲Ni(II)≲Pd-(II). For the 5,14-dihydrodibenzo[*b,i*][1,4,8,11]tetra-azacyclotetradecine system, this characteristic band reduces its intensity to medium upon metal coordination. On the other hand, the C=N band observed for 12π-macrocyclic ligand **2** does not lose its intensity upon complex formation. The formation of a square-planar complex with higher conjugation system seems to be responsible for such reduction in IR activity.

A strong absorption band at around 950 cm^{-1} observed for the oxovanadium(IV) complexes is attributed to the V=O stretching mode.[16,17]

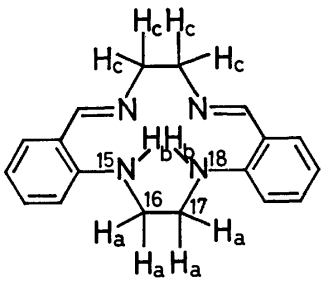
NMR Spectra. NMR data for macrocyclic ligands **1** and **2** and the nickel(II) and palladium(II) chelates of the latter ligand are listed in Table 3 along with the comparable data for Ni(II) ambtn,[13] zinc(II) dipyrromethene,[18] and nickel(II) porphyrin.[19,20] The complexes of macrocycle **1** are too insoluble to give satisfactory NMR spectra. The methine proton peak for **1** observed in the lower field region is shifted to down-field by *ca.* 1 ppm relative to that of dipyrromethenes (free base).[18] As the extent of down-field shift is smaller than that for porphyrins, the cyclic conjugation throughout the macrocyclic skeleton of **1** seems to be not so extensive as observed for porphyrins. In the case of **1**, the proton signals for methine groups (=CH–



4

NH–, –CH=N–) of the 6-, 8-, 15-, and 17-positions were observed as a quintet. The H_a-methine proton (–CH=N–) shown by **4** couples with the H_b-methine proton (–CH=CH–), and the H_a-signal is split into a symmetrical doublet. On the other hand, the H_c-methine proton (–CH=NH–) couples both with H_b-(–CH=CH–) and H_d- (N–H), the H_c-signal being split into a triplet. Consequently, the quintet signal is referred to the overlap of a doublet and a triplet signal. The coupling of H_b- (–CH=CH–) with H_a- and H_c- seems to result in a triplet signal for H_b. A signal for the H_d-amine proton (N–H) was observed as a broad triplet with equal intensity due to coupling with the nitrogen nucleus ($I=1$).

The signal (9.27 ppm) for protons attached to the aniline-type nitrogen in **2** was found to disappear upon metal-coordination. The methine proton peak (8.32 ppm) observed for macrocycle **2** in the lowest field is shifted to up-field by 0.3 (palladium complex)—0.6 ppm (nickel complex) upon complex formation. This up-field shift is comparable to that observed for the meso-methine protons of nickel(II) porphyrin (Table 3).[19] This may be attributed to reduction of the ring current by incorporation of the nickel or the palladium. The shielding effect by nickel(II)-coordination is larger than that by palladium(II)-coordination. The metal-free macrocycle (**2**) showed the H_a-signal (refer to **5**) in the highest field (3.37 ppm) with some broadening. Upon substitution of the H_b proton on the nitrogen(–NH–) with deuterium(D), the H_a-signal at 3.37 ppm turned to be sharp. A similar spectral change was observed upon nickel(II)- and palladium(II)-coordination. Accordingly, the H_a protons(–CH_2–NH–) placed at the 16- and 17-positions must couple with the H_b protons(–CH_2–NH–) placed at the 15- and 18-positions, and the H_a protons absorption is observed as a broad signal owing to a small proton spin-coupling constant (J_{ab}). The H_a- and H_c-signals(=N–CH_2–, –CH_2–NH–) show down-field shift upon formation of the palladium chelate. These down-field shifts can be attributed to the deshielding effect provided by the positive charge on palladium-(II). The H_a- and H_c-(methylene protons) peaks are shifed to up-field upon formation of the nickel(II) complex. These up-field shifts can be attributed to the significant shielding effect provided by the chelate rings rather than the deshielding effect due to the positive charge on nickel(II). This seems to indicate that the methylene groups of the nickel(II) complex are placed in a conformational space different from that occupied by those of the palladium(II) complex, most likely due to the difference in ionic radius between Ni^{2+} and Pd^{2+}.



5

ESCA Spectra. For macrocyclic ligands **1** and **2** and their complexes, binding energies of carbon(C $1s_{1/2}$), nitrogen(N $1s_{1/2}$), vanadium(V $2p_{1/2}$, $2p_{3/2}$), oxygen(O $1s_{1/2}$), nickel(Ni $2p_{1/2}$, $2p_{3/2}$), copper(Cu $2p_{1/2}$, $2p_{3/2}$), and palladium(Pd $3p_{1/2}$, $3p_{3/2}$) are listed in Tables 4 and 5 together with those for 5,10,15,20-tetraphenylporphine, phthalocyanine, and their copper(II) complexes.[21] There are these possible structure as to the location of inner hydrogen atoms in macrocycles **1** and **2** (Fig. 3). Macrocyclic ligand **1** shows two N 1s peaks

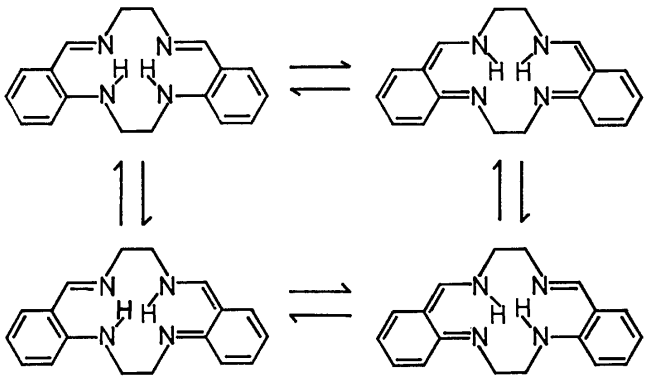
(1) (2) (3)

Fig. 3. Three possible structures arising from the location of inner hydrogen atoms of macrocycles.
(1) Two inner hydrogen atoms are directly bound to diagonally opposite nitrogen atoms.
(2) Two inner hydrogen atoms are fixed to adjacent nitrogen atoms.
(3) Two inner hydrogen atoms are shared by four equivalent central nitrogen atoms.

(396.0, 397.2 eV) (Table 4) with nearly equal intensity. The general feature of a nitrogen 1s peak is similar to those observed for porphyrins and phthalocyanine.[21,23-25] Moreover, the ^{1}H-NMR spectrum shows the presence of two kinds of nitrogen atoms as judged by the methine proton signal (Table 3). Consequently, there are two kinds of nitrogen atoms in macrocycle **1**; the one without hydrogen atom, and the other with hydrogen attached. Our result rules out any structure with hydrogen bridges, yielding equivalent nitrogens (Fig. 3-(3)), although the possibility of forming intramolecular hydrogen bonding is not eliminated. A structure of type(2) in Fig. 3 must be ruled out, since this destroys π-conjugation of the ligand. The most plausible molecular structure for macrocycle **1** is type(1) in Fig. 3; two inner hydrogen atoms are bound to nitrogen at diagonal positions.

Since macrocyclic ligand **2** shows only one N 1s peak at 397.5 eV as shown in Table 4, this feature is different from those observed for porphyrins, phthalocyanine, and macrocycle **1**. The tautomeric effect (refer to **6**) which provide only equivalent nitrogens seems to be responsible for the existance of one N 1s signal (type(3) in Fig. 3).



6

As shown in Table 4, only one N 1s peak was observed for the macrocyclic chelates; namely, the four nitrogens are chemically equivalent in these complexes. The nitrogen 1s peak observed in the 397—398 eV region for the bivalent metal chelates does not appreciably vary the peak position by changing metal species as

b) See Table 1 for numbering the ligands **1** and **2**; TPP, 5,10,15,20-tetraphenylporphine; PC, phthalocyanine.

shown in Table 4. Our result is comparable to those obtained for porphyrins.[21,23-25] The N 1s peak for porphyrins and phthalocyanine is somewhat shifted to higher energy because of high π-conjugation.

ESR Spectra. Oxovanadium(IV) Complex: In the ESR spectra of macrocyclic oxovanadium(IV) complexes measured in xylene–benzene (2 : 1 v/v) at room temperature, a set of eight hyperfine lines were observed by the magnetic interaction between an unpaired electron and vanadium nucleus ($I=7/2$). The similar spectral features have been observed for (5,10,15,20-tetraphenylporphinato)oxovanadium(IV) complex.[26] Figure 4 shows the ESR spectrum recorded at room temperature for the powdered sample of (dibenzo[*b*,*i*]-[1,4,8,11]tetraazacyclotetradecinato)oxovanadium(IV) magnetically diluted with the corresponding ligand as an example. This spectrum is composed of two sets of vanadium hyperfine lines; $g_{//}$ and $g_{\perp}$ components.

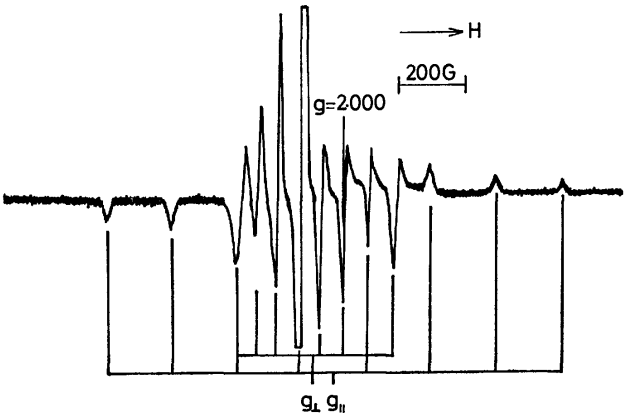

Fig. 4. ESR spectrum of (dibenzo[*b*, *i*][1, 4, 8, 11]tetraazacyclotetradecinato)oxovanadium(IV) complex magnetically diluted with the corresponding metal-free ligand at room temperature.

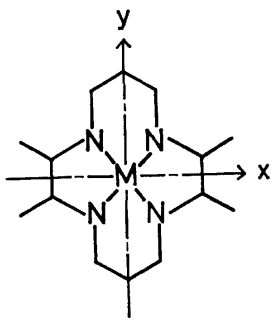
Pd-metal								559[c)]	531[c)]
1-Pd-chelate								557.0	531.5
2-Pd-chelate								561.7	534.1

a) Measured in the tablet state (5-mm diameter); for calibration, the signal of Au $4f_{5/2}$ and Au $4f_{7/2}$ was used. b) See Table 1 for numbering the ligands. c) Values reported in Ref. 22.

The superhyperfine splitting, due to magnetic interaction between an unpaired electron in V(IV) and nitrogen nuclei($I=1$), has not been observed in the present oxovanadium(IV) complexes. Consequently, the oxovanadium(IV) complexes are of square-planar type with an unpaired electron in the $d_{x^2-y^2}$ orbital. The similar spectral features have also been observed for the complexes derived from porphyrins[26–28] and phthalocyanine.[29] A plausible structure around the coordination site for the oxovanadium(IV) complexes are illustrated schematically by (**7**) except for V=O on



7

z-axis. Since the spin-orbit coupling constant is much smaller than the orbital excitation energies, the first-order perturbation can be applied to our system for evaluation of g values

$$g_z = g_0 - 8\lambda/\Delta_3 = g_{\parallel} \quad (1)$$

$$\left.\begin{aligned} g_x &= g_0 - 2\lambda/\Delta_2 \\ g_y &= g_0 - 2\lambda/\Delta_1 \end{aligned}\right\} = g_{\perp} \quad (2), (3)$$

where $\Delta_3=\Delta E(d_{xy}\leftarrow d_{x^2-y^2})$, $\Delta_2=\Delta E(d_{xz}\leftarrow d_{x^2-y^2})$, $\Delta_1=\Delta E(d_{yz}\leftarrow d_{x^2-y^2})$, and λ is the spin-orbit coupling constant of V^{4+} ion. The g ($g_{//}$ and $g_{\perp}$) and A ($A_{//}$ and $A_{\perp}$) values for the oxovanadium(IV) complex of macrocycle **1** are in agreement with those obtained for the complex of macrocycle **2** as shown in Table 6. The $g_{//}$ and $g_{\perp}$ values in this work are slightly larger in magnitude than those obtained for the complexes of 5,10,15,20-tetraphenylporphine and phthalocyanine, but the $A_{//}$ and $A_{\perp}$ values are smaller.[26,29] The $|g_0-g_{//}|$ values in this work are comparable to those obtained for the complexes of 5,10,15,20-tetraphenylporphine[26] and phthalocyanine.[29] This may be attributed to equivalent Δ_3 (refer to Eq. 1) value for the complexes of the present macrocycles, 5,10,15,20-tetraphenylporphine, and phthalocyanine. The $|g_0-g_{\perp}|$ values in this work are smaller in magnitude than those obtained for the complexes of 5,10,15,20-tetraphenylporphine and phthalocyanine (Table 6). On the basis of Eqs. 2 and 3, the Δ_1 and Δ_2 values obtained in this work are larger than those for the complexes of 5,10,15,20-tetraphenylporphine and phthalocyanine. Namely, the relative energy level of d_{xy}, d_{yz} is higher than those estimated for the 5,10,15,20-tetraphenylporphine and phthalocyanine complexes.

Copper(II) Complex. The ESR spectra of (dibenzo[*b*,*i*][1,4,8,11]tetraazacyclotetradecinato) copper(II) magnetically diluted with the corresponding metal-free ligand at room temperature are shown in Fig. 5 as an example. The general feature of spectra (A) and (B) is similar to that observed for the square-planar copper(II) complexes derived from porphyrins[26,30] and phthalocyanine.[31] In these two spectra, a set of four copper hyperfine lines on the parallel component of the g-tensor($g_{//}$), which lie in the low field region, are observed, while such hyperfine lines are not obvious on the perpendicular component of the g-tensor($g_{\perp}$) in the higher field region. The X- and K-band ESR spectra shown in Fig. 5 indicates that the $g_{\perp}$-tensor is of anisotropic nature; D_{2h} coordination symmetry. In addition, superhyperfine lines due to four chemically equivalent nitrogen donor atoms, appear on the perpendicular component of the g-tensor($g_{\perp}$, g_2, and g_3) at higher field, while such superhyperfine lines are not observed on the parallel component of the g-tensor($g_{//}$) at lower field. As judged from the general feature of superhyperfine lines, it may be concluded that an unpaired electron of the copper(II)

complex is placed in its d_{xy} orbital.

Although the $g_{//}$ and $g_{\perp}$ values are somewhat smaller in magnitude than those observed for the complexes derived from porphyrins[26,30] and phthalocyanine,[31] the Δg value ($\Delta g=g_{//}-g_{\perp}$) is approximately equal in magnitude to those of porphyrin complexes and phthalocyanine complex. Moreover, the $A_{//}$ value is somewhat larger in magnitude than those reported for porphyrin complexes[26,30] and phthalocyanine complex.[31] This is attributed to the greater electron density of the unpaired electron of copper(II) nucleus. The K-band ESR spectrum for the magnetically diluted powdered sample indicates the presence of three g values such as g_z, g_y, g_x as shown in Fig. 5-(B). If the coordination symmetry is D_{2h} (refer to **7**), these values are expected to be $g_z > g_y$, g_x ($g_x \neq g_y$). On this basis, the copper atom most plausibly assumes a distorted square-planar coordination of Cu–N_4 type due to the presence of five- and six-membered chelate rings. Furthermore, the five- and six-membered chelate rings are placed in the same plane, so that efficient π-conjugation is attained in the macrocyclic ligand moiety. The $A_{\perp}^{N}$ value for the complex of macrocycle **1** is about a half of the one observed for the complexes derived from porphyrins[26,31] and phthalocyanine,[31] but the $A_{\perp}^{N}$ value for the complex of macrocycle **2** is similar in magnitude to those for the porphyrins and phthalocyanine complexes. Consequently, the metal d-electrons in the copper(II) complex are more delocalized toward the ligand moiety through the coordinate bonds in a manner as expected for the corresponding complexes of **2**.

The Reaction Process between α-Iron(III) Oxide and Sulfur Dioxide in the Presence of Carbon

Hiromitsu Araki, Young Hong Ryoo,† Motonori Eguchi, Ryoko Matsuzaki, and Yuzo Saeki*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received January 9, 1980)

The reaction products obtained by heating a mixture of α-Fe_2O_3 and carbon in a SO_2 stream at various temperatures were examined. The possible reactions during the above process were also examined. The solid products obtained by heating a mixture of α-Fe_2O_3 and carbon in a SO_2 stream were Fe_3O_4 at 500—700 °C, pyrrhotite and Fe_3O_4 at 750 °C, and pyrrhotite ($Fe_{0.88}S$) alone at 800 °C. Sulfur was obtained outside the heating zone throughout the temperature range. The process of the formation of pyrrhotite by the reaction between α-Fe_2O_3 and SO_2 in the presence of carbon can be represented as follows: The reaction between carbon and SO_2 occurs even at 350 °C to form sulfur, and the reaction proceeds markedly above *ca.* 700 °C. Above *ca.* 500 °C, the reductions of α-Fe_2O_3 with carbon and sulfur occur to form Fe_3O_4. Above *ca.* 750 °C, pyrrhotite is formed by the reaction between Fe_3O_4 and sulfur. These results were supported by the thermodynamical consideration based on the chemical potential diagram for the Fe–S–C–O system.

As sulfidizing agents for synthesizing the transition-metal sulfides, sulfur, hydrogen sulfide and carbon disulfide have been well known. It is not only interesting from the viewpoint of the synthesis of the transition-metal sulfide itself, but also important for the development of sulfur dioxide(SO_2) utilization, to obtain knowledge of the chemical process for synthesizing the sulfide from the oxide using SO_2 as a sulfidizing agent. In this work, the reaction process between α-iron(III) oxide(α-Fe_2O_3) and SO_2 in the presence of carbon was investigated in order to understand the above chemical process.

Pechkovskii[1] has reported that iron sulfide is formed at 650—800 °C by heating a mixture of Fe_2O_3 and carbon in a SO_2 stream and that 99.7% of the charged Fe_2O_3 is sulfidized at 800 °C by using a 8 : 1 mixture of carbon and Fe_2O_3 (molar ratio). Pechkovskii and Mal'tseva[2] have carried out a differential thermal analysis for the mixture of Fe_2O_3 and carbon (Fe_2O_3: C=1: 5 by molar ratio) in a SO_2 stream and have observed the formation of pyrrhotite($Fe_{1-x}S$) above 640 °C. Also, they have estimated that the pyrrhotite may be formed through the reaction between FeO and gaseous sulfur, both substances having been formed during the reaction between Fe_2O_3 and SO_2 in the presence of carbon. The composition of the pyrrhotite formed was not mentioned.

In this work, the reaction products between α-Fe_2O_3 and SO_2 in the presence of carbon were examined. The reactions between carbon and SO_2, α-Fe_2O_3 and carbon, α-Fe_2O_3 or Fe_3O_4 and sulfur in a SO_2 stream, and Fe_3O_4 and sulfur in the presence of carbon were examined in order to elucidate the reaction process between α-Fe_2O_3 and SO_2 in the presence of carbon. Some thermodynamical consideration were also made of the formation of pyrrhotite.

Experimental

Materials. The α-Fe_2O_3 used was prepared by the thermal decomposition of the guaranteed reagent, $Fe(NO_3)_3 \cdot 9H_2O$, and confirmed as α-Fe_2O_3[3] by X-ray analysis. The chemical analysis gave Fe, 70.0$_0$% (Calcd for Fe_2O_3; Fe, 69.94%). The Fe_3O_4 was synthesized by Harber's method[4] and confirmed as Fe_3O_4[5] by X-ray analysis. The chemical analysis gave Fe, 72.2$_6$% (Calcd for Fe_3O_4; Fe, 72.36%). The carbon was prepared by the thermal decomposition of the guaranteed reagent glucose. The above materials were used as powders under 150 mesh. Gaseous SO_2 was dried by passing it through concd H_2SO_4 and over P_2O_5.

Procedures. A mixture of α-Fe_2O_3 and carbon in a quartz boat (length: 72 mm, width: 16 mm, depth: 9 mm) was placed in a transparent quartz reaction tube (inner diameter: 28 mm, length: 1000 mm). Gaseous SO_2 was then introduced into the reaction tube. The sample part was positioned in the middle of a tubular electric furnace (heating length: 300 mm) maintained at a specified temperature for 1 h. The temperature of the sample part was controlled within ±2 °C. After heating, the sample was held at 100 °C for 1 h in an argon stream in order to release the adsorbed SO_2 on unreacted carbon. The reactions between carbon and SO_2, α-Fe_2O_3 and carbon in an argon stream, α-Fe_2O_3 or Fe_3O_4 and sulfur in a SO_2 stream, and Fe_3O_4 and sulfur in the presence of carbon in an argon stream were examined in a similar manner.

Analytical. The X-ray analysis of the sample was performed with an X-ray powder diffractometer equipped with a proportional counter using Mn filtered Fe radiation.

Concerning the chemical analysis of pyrrhotite, the sample was oxidatively decomposed in HNO_3 with $KClO_3$. The iron and sulfur contents were determined by the volumetric method with $KMnO_4$ and the gravimetric method as $BaSO_4$, respectively. In the case of a mixture of pyrrhotite, unreacted carbon, and sulfur adsorbed on the carbon, the sample was oxidatively decomposed and the contents of iron and total sulfur in the filtrate were determined by the above techniques. Then, after dissolving pyrrhotite in the sample selectively with dilute HCl, the undissolved residue, which consisted of unreacted carbon and sulfur adsorbed on it, was oxidatively decomposed in HNO_3 with $KClO_3$, and the amount of sulfur adsorbed on the carbon was gravimetrically determined. The

† Present address: College of Engineering, Korea University, 1, Anam-Dong, Sungbuk-ku, Seoul 132, Korea.

amount of sulfur due to pyrrhotite was calculated as the difference between the above total sulfur and the sulfur adsorbed on the carbon. From this value and the foregoing iron content, the composition of pyrrhotite was determined.

Results and Discussion

Reaction Products between α-Fe_2O_3 and SO_2 in the Presence of Carbon. The products obtained by heating the mixture of α-Fe_2O_3 (2.00 g) and carbon (1.20 g) (Fe_2O_3: C=1: 8 by molar ratio) at various temperatures for 1 h in a SO_2 stream at a flow-rate of 100 cm^3/min were examined. The results are shown in Table 1, together with the weight changes in the samples. The solid products were identified by X-ray analysis.[3,5,6]

Table 1. Products obtained by heating a mixture of α-Fe_2O_3 and carbon in a SO_2 stream at various temperatures

Temp/°C	Weight change/%	Sample in the boat	Amount of sulfur obtained outside the heating zone/g
350	+0.2	α-Fe_2O_3	Trace
400	+0.1	α-Fe_2O_3	Trace
450	+0.1	α-Fe_2O_3	Trace
500	+0.1	α-$Fe_2O_3 \gg Fe_3O_4$	Trace
550	−0.1	α-$Fe_2O_3 \gg Fe_3O_4$	0.01
600	−0.2	α-$Fe_2O_3 \approx Fe_3O_4$	0.01
650	−1.1	$Fe_3O_4 \gg$ α-Fe_2O_3	0.06
700	−2.2	Fe_3O_4	0.14
750	−12.3	$Fe_{1-x}S > Fe_3O_4$	0.39
800	−25.5	$Fe_{1-x}S$	1.11

The formation of Fe_3O_4 was observed above 500 °C, while the formation of pyrrhotite($Fe_{1-x}S$) in addition to Fe_3O_4 was observed above 750 °C. The only solid product obtained at 800 °C was pyrrhotite. Sulfur was obtained outside the heating zone throughout the temperature range in this experiment, and the amount of sulfur markedly increased above *ca.* 700 °C. Also, the sample weight markedly decreased above *ca.* 700 °C. The slight increase in the sample weight at 350—500 °C was due to the adsorption of the sulfur formed by the reaction on the unreacted carbon, as will be described later.

The composition of the pyrrhotite obtained at 800 °C was determined by chemical analysis. The analysis gave Fe, 59.1$_4$%; S, 38.6%. From the results, the composition of the pyrrhotite formed was determined to be $Fe_{0.88}S$.

Possible Reactions during the Reaction between α-Fe_2O_3 and SO_2 in the Presence of Carbon. To elucidate the reaction process between α-Fe_2O_3 and SO_2 in the presence of carbon, the following experiments were carried out under conditions similar to those described above.

Reaction between Carbon and SO_2: Carbon (1.20 g) was heated in a SO_2 stream (100 cm^3/min) for 1 h. Under such conditions as in this experiment, sulfur is formed at temperatures below *ca.* 1000 °C.[7] Hence, the amounts of sulfur formed at various reaction temperatures were determined. A part of the sulfur was deposited outside the heating zone, while the other part was adsorbed on the unreacted carbon in the boat. The amount of adsorbed sulfur was determined by chemical analysis. The amount of sulfur formed is shown in Fig. 1, together with the weight change in the sample.

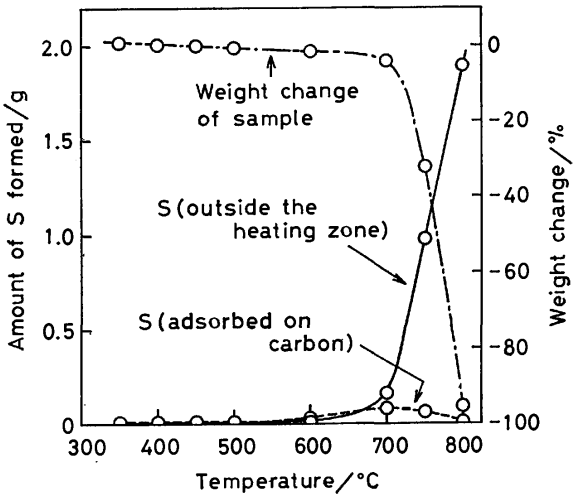

Fig. 1. Experimental results for the reaction between carbon and SO_2.

A slight amount of sulfur was formed even at *ca.* 350 °C, and the amount was markedly increased above *ca.* 700 °C. Also, the sample weight markedly decreased above *ca.* 700 °C. These facts indicate that the reaction between carbon and SO_2;

$$C(s) + SO_2(g) \longrightarrow S_n^{\dagger\dagger}(g) + CO_2(CO)(g) \quad (1)$$

occurs even at 350 °C and proceeds markedly above *ca.* 700 °C.

Reaction between α-Fe_2O_3 and Carbon: The products formed by heating a mixture of α-Fe_2O_3 (2.00 g) and carbon (1.20 g) in an argon stream (100 cm^3/min) for 1 h were examined by X-ray analysis. The results are shown in Table 2.

The results indicate that the following known reactions;

$$Fe_2O_3(s) + C(s) \longrightarrow Fe_3O_4(s) + CO(CO_2)(g) \quad (2)$$

Table 2. Reaction products between α-Fe_2O_3 and carbon at various temperatures

Temp/°C	Sample in the boat
350	α-Fe_2O_3
400	α-$Fe_2O_3 \gg Fe_3O_4$
450	α-$Fe_2O_3 \gg Fe_3O_4$
500	α-$Fe_2O_3 \gg Fe_3O_4$
550	α-$Fe_2O_3 \gg Fe_3O_4$
600	α-$Fe_2O_3 \approx Fe_3O_4$
650	$Fe_3O_4 >$ α-Fe_2O_3
700	Fe_3O_4
750	Fe_3O_4
800	$Fe_3O_4 \gg FeO$

†† Above 650 °C, the S_2 is dominant in all species. At lower temperatures the S_6, S_7, and S_8 species become important constituents.[8]

$$Fe_3O_4(s) + C(s) \longrightarrow FeO(s) + CO(CO_2)(g) \quad (3)$$

proceed above *ca.* 400 and *ca.* 800 °C respectively.

Reaction between α-Fe_2O_3 and Sulfur: The reaction between α-Fe_2O_3 and sulfur formed by the reaction of carbon with SO_2 was examined.

α-Fe_2O_3 (2.00 g) was heated in a stream of SO_2 containing a specified amount of gaseous sulfur at various temperatures for 1 h. The gaseous sulfur was formed by heating liquid sulfur and was carried by a stream of SO_2 (100 cm^3/min). The heating temperature of the sulfur was controlled so as to give the same amounts of gaseous sulfur as those obtained by the reaction between carbon and SO_2, described in the previous paragraph. The amounts of sulfur introduced were 0.01 g for the experiments at 400 and 500 °C and 0.03 g for the experiment at 600 °C.

X-Ray analyses of the samples in the boat showed them to be unreacted α-Fe_2O_3 alone at 400 °C, α-Fe_2O_3>Fe_3O_4 at 500 °C, and α-Fe_2O_3≈Fe_3O_4 at 600 °C.

These results show that, even in a SO_2 stream, the reaction between α-Fe_2O_3 and gaseous sulfur proceeds above *ca.* 500 °C to form Fe_3O_4, according to the reaction,

$$Fe_2O_3(s) + S_n(g) \longrightarrow Fe_3O_4(s) + SO_2(g). \quad (4)$$

From the above results, it could be explained that the sulfur and Fe_3O_4, formed by heating a mixture of α-Fe_2O_3 and carbon in a SO_2 stream (Table 1), were formed by Reaction 1 and by Reactions 2 and 4 respectively.

Formation Reaction of Pyrrhotite from Fe_3O_4: As has been mentioned before, when a mixture of α-Fe_2O_3 and carbon was heated in a SO_2 stream, pyrrhotite was formed above *ca.* 750 °C. Above this temperature, the amount of sulfur formed increased markedly and α-Fe_2O_3 was reduced to Fe_3O_4. Considering these results, the possible reactions giving the pyrrhotite were considered to be;

$$Fe_3O_4(s) + S_n(g) \longrightarrow Fe_{1-x}S(s) + SO_2(g), \quad (5)$$

and;

$$Fe_3O_4(s) + C(s) + S_n(g) \longrightarrow Fe_{1-x}S(s) + CO(CO_2)(g). \quad (6)$$

Therefore, Reaction 5 was examined in a SO_2 stream. Fe_3O_4 (2.00 g) was heated in a stream of SO_2 containing a specified amount of gaseous sulfur at 700—800 °C for 1 h. The amounts of sulfur introduced were controlled so as to be the same as those obtained by the reaction between carbon and SO_2, being 0.25 g for the experiment at 700 °C, 1.12 g at 750 °C, and 1.90 g at 800 °C.

X-Ray analyses of the samples in the boat showed them to be unreacted Fe_3O_4 alone at 700 °C, Fe_3O_4> Fe_{1-x}S at 750 °C, and Fe_{1-x}S>Fe_3O_4 at 800 °C. From these results, it is revealed that Reaction 5 proceeds above *ca.* 750 °C, even in a SO_2 stream.

The chemical analysis of the pyrrhotite free from unreacted Fe_3O_4, obtained at 800 °C for 2 h, gave Fe, 60.4$_5$%; S, 39.5%. From this result, the composition of the pyrrhotite formed by the reaction between Fe_3O_4 and sulfur was evaluated to be $Fe_{0.88}S$. This composition agreed with that of the pyrrhotite formed by heating a mixture of α-Fe_2O_3 and carbon in a SO_2 stream.

In order to examine Reaction 6, a mixture of Fe_3O_4 (2.00 g) and carbon (1.20 g) was heated in a stream of argon containing a specified amount of gaseous sulfur at 700—800 °C for 1 h. The amount of sulfur introduced was controlled so as to be the same (1.90 g) as that obtained by the reaction between carbon and SO_2 at 800 °C. The experimental results are shown in Table 3.

Table 3. Experimental results for the reaction between Fe_3O_4 and sulfur in the presence of carbon

Temp/°C	Sample in the boat	Amount of SO_2 formed/g
700	$Fe_{1-x}S \gg Fe_3O_4$	0.80
750	$Fe_{1-x}S \gg Fe_3O_4$	0.77
800	$Fe_{1-x}S$	0.34

Pyrrhotite and SO_2 were formed at all experimental temperatures.

From the results, it is found that the formation of pyrrhotite is due to Reaction 5, in which SO_2 is also formed. When 2.00 g of the Fe_3O_4 used is converted to $Fe_{0.88}S$ by Reaction 5, the formation of 1.11 g of SO_2 must be expected. However, the values of SO_2 formed, shown in Table 3, were less than the calculated value. This suggests that the SO_2 formed by Reaction 5 tends to react with carbon according to Reaction 1. For this reason, it is considered that carbon does not directly take part in the sulfidizing reaction, but contributes to sulfur formation by reacting with SO_2.

From the above-mentioned experimental results, the formation process of pyrrhotite by the reaction between α-Fe_2O_3 and SO_2 in the presence of carbon can be represented as follows: (i) Reaction 1 occurs even at 350 °C to form sulfur, and the reaction markedly proceeds above *ca.* 700 °C. (ii) Above *ca.* 500 °C, α-Fe_2O_3 is reduced to Fe_3O_4 by Reactions 2 and 4. (iii) Above *ca.* 750 °C, Reaction 5 occurs between Fe_3O_4 and sulfur, which are formed by the reactions mentioned above, to form $Fe_{0.88}S$.

This result disagrees with the above-mentioned estimation of Pechkovskii and Mal'tseva[2] that pyrrhotite is formed by the reaction between FeO and sulfur.

Thermodynamical Consideration. In order to discuss the present experimental results from the thermodynamical point of view, the chemical potential diagrams for the Fe–S–C–O system were constructed in a manner similar to that described by Yazawa[9] on the basis of the available thermodynamic data[10–13] and phase relations.[14] As an example, the diagram at 800 °C is shown in Fig. 2. N_S/N_{Fe} represents the atomic ratio of sulfur to iron in pyrrhotite. The broken line shows the oxygen and sulfur potentials in the gas phase formed by the reaction between carbon and SO_2, depending on the carbon content in the gas phase. The activity of carbon is unity at the dot mark. In these calculations, CO, CO_2, O_2, COS, CS_2, SO_2, SO_3, S_2, S_4, S_6, and S_8 were assumed to be gaseous products between carbon and SO_2.

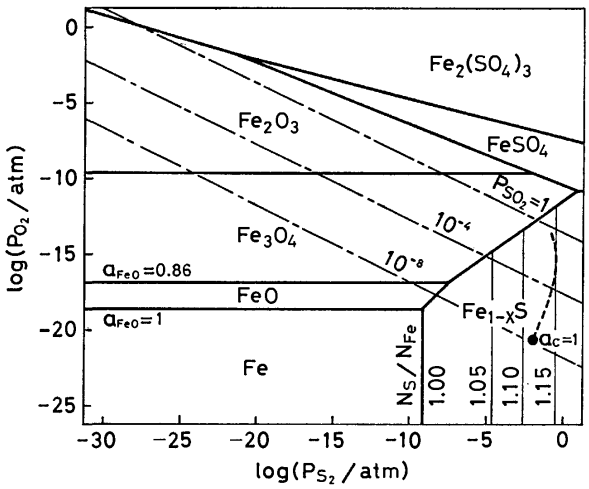

Fig. 2. Chemical potential diagram for the Fe–S–C–O system at 800 °C.

From the results shown in Fig. 2, it is clear that the reduction of Fe_2O_3 to Fe_3O_4 occurs at first when Fe_2O_3 is heated in the presence of carbon in a SO_2 stream. It is also shown that Fe_3O_4 is converted to pyrrhotite *via* FeO under a low pressure of SO_2 below *ca.* 10^{-7} atm, and that Fe_3O_4 is converted to pyrrhotite without FeO formation under a higher partial pressure of SO_2. Considering the experimental conditions in this work, the results in Fig. 2 support the above-mentioned estimation that pyrrhotite is formed through the $Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow Fe_{1-x}S$ path without any FeO formation.

$Fe_{0.88}S$ ($N_S/N_{Fe} \approx 1.14$) was obtained in this work. This composition of pyrrhotite is in the range of values shown by the broken line in Fig. 2. From this fact, it can be said that pyrrhotite with nearly an equilibrium composition is formed in this experiment.

Chiral Recognition in Catalytic Hydrogenation of α-Acylaminoacrylic Acids by Cationic Rhodium(I) Complexes of Chiral Aminophosphines Derived from (*R,R*)-1,2-Cyclohexanediamine or (*R*)-1,2-Propanediamine[1]

Kazuo KASHIWABARA, Kazuhiro HANAKI, and Junnosuke FUJITA*

(Received February 8, 1980)

Four chiral diphosphines, (*R,R*)-1,2-bis[*N*-methyl(diphenylphosphino)amino]cyclohexane, (*R,R*)-1,2-bis-[(diphenylphosphino)amino]cyclohexane, (*R*)-1,2-bis[*N*-methyl(diphenylphosphino)amino]propane, and (*R*)-1,2-bis[(diphenylphosphino)amino]propane have been prepared from the corresponding optically active diamines. The cationic 1,5-cyclooctadiene rhodium(I) complexes with these diphosphines act as effective homogeneous catalysts for the stereoselective hydrogenation of α-acylaminoacrylic acids. The optical yields and the absolute configurations of the products depend on the kind of diphosphine ligands. The (*R,R*)-1,2-bis[*N*-methyl(diphenylphosphino)amino]cyclohexane complex catalyst yields *N*-benzoyl-(*S*)-leucine, *N*-benzoyl-(*S*)-phenylalanine, and *N*-acetyl-(*S*)-phenylalanine in 94, 92, and 89% e.e., respectivcly. The other three catalysts are less effective (6—74% e.e.). The aminophosphine complexes with methyl groups on the nitrogen atoms always give (*S*)-amino acids, those with no methyl group (*R*)-amino acids. Such a difference in the chiral recognition has been discussed on the basis of circular dichroism spectra and Dreiding molecular models of the rhodium(I) complexes.

Reports have been given on the surprisingly high stereoselectivity for asymmetric hydrogenation of α-acylaminoacrylic acids catalyzed by chiral rhodium(I) diphosphine complexes.[2-4] The mechanism of the hydrogenation reactions has been found to involve oxidative addition of molecular hydrogen which takes place after the coordination of a substrate molecule to a catalyst.[5] Brown and Chaloner[6] confirmed the formation of a diastereomeric intermediate complex coordinated with a substrate molecule by ^{31}P NMR spectroscopy in solution. However, it is still not clear as to how chiral recognition operates in such asymmetric hydrogenation reactions.

Recently, three research groups reported that rhodium(I) complex catalysts of aminophosphines derived from (*R,R*)-1,2-diamines always give (*R*)-amino acid derivatives, and those from *N,N'*-dimethyl derivatives of these diamines (*S*)-amino acid derivatives.[1,7,8] The results seem to be useful for elucidating the mechanism of chiral recognition in catalytic hydrogenation reactions by rhodium(I) complexes, since a simple modification of a ligand affords an enantiomeric product. In this paper, we wish to report the results of catalytic hydrogenation reactions by rhodium(I) complexes with aminophosphines derived from chiral 1,2-diamines and to discuss factors of the chiral recognition in these reactions on the basis of circular dichroism spectra and Dreiding molecular models of the catalysts.

Experimental

NMR, absorption, and circular dichroism spectra were recorded on a JEOL JNM-PMX 60 spectrometer, a Hitachi 323 spectrophotometer, and a JASCO J-40 spectropolarimeter, respectively. Optical rotations were determined with a JASCO DIP-4 polarimeter. (*Z*)-α-Acetamidocinnamic acid,[9] (*Z*)-α-benzamidocinnamic acid,[10] and (*Z*)-β-isopropyl-α-benzamidoacrylic acid[11] were prepared according to the procedures reported.

Preparation of Ligands. *(R,R)-1,2-Bis[N-methyl(diphenylphosphino)amino]cyclohexane (1)*: To a vigorously stirred aqueous solution (40 cm^3) of sodium hydroxide (8.0 g, 0.2 mol) was added 5.0 g (0.044 mol) of (*R,R*)-1,2-cyclohexanediamine[12] ($[\alpha]_D^{22} = -36.0°$ (*c* 2.8, H_2O)) under cooling in an ice-cold bath. A solution of ethyl chloroformate (7.6 cm^3, 0.095 mol) in 40 cm^3 of benzene was then added dropwise over 30 min. The reaction mixture was allowed to stand at room temperature for 3 h. The resulting precipitate, (*R,R*)-1,2-bis(ethoxycarbonylamino)cyclohexane was filtered, washed with cold water, and dried *in vacuo*. The product was recrystallized from ethanol. Yield: 9.0 g (80%). 10 g (0.26 mol) of lithium tetrahydridoaluminate(III) and 150 cm^3 of dry tetrahydrofuran (THF) were placed in a 500-cm^3 three-necked, round-bottomed flask equipped with a mechanical stirrer and a reflux condenser with a soda lime tube. To this vigorously stirred mixture was added 9.0 g (0.035 mol) of (*R,R*)-1,2-bis(ethoxycarbonylamino)cyclohexane in small portions, the vessel being kept in an ice-cold bath. After the addition was completed, the mixture was allowed to stand at room temperature for 30 min and then refluxed overnight. The reaction mixture was cooled in an ice-bath and the unreacted hydride was carefully quenched by dropwise addition of water (30 cm^3). A white precipitate was filtered and washed three times with boiling THF (300 cm^3). The combined filtrate and washings were evaporated under reduced pressure to give an oily residue. This was neutralized with concd hydrochloric acid, mixed with acetone, and cooled in an ice bath. The resulting crystalline product, (*R,R*)-1,2-bis(methylamino)cyclohexane dihydrochloride was filtered and dried in a vacuum desiccator over diphosphorus pentaoxide. Yield: 5.0 g (67%). The product (6.6 g, 0.031 mol) and ethanol-free chloroform (200 cm^3) were placed in a 500-cm^3 three-necked, round-bottomed flask equipped with a serum cap and a nitrogen inlet. The flask was successively evacuated and filled with nitrogen while the contents were stirred. 12.5 g (0.124 mol) of triethylamine and 13.0 g (0.059 mol) of chlorodiphenylphosphine were then injected through the serum cap with syringes. The resulting solution was stirred overnight at room temperature. Chloroform was removed under reduced pressure and ether (300 cm^3) was added. The mixture was refluxed for 1 h and filtered in order to remove triethylamine hydrochloride. All the precedures were carried out under nitrogen atmosphere. The filtrate was evaporated under reduced pressure to yield

a pale yellow solid, which was recrystallized from acetone and water. Yield: 8.0 g (50%) (overall yield from the starting amine, 27%). Mp 137—139 °C, $[\alpha]_D^{22}=-7.3°$ (*c* 1.1, $CHCl_3$). Found: C, 75.09; H, 6.92; N, 5.33%. Calcd for $C_{32}H_{36}N_2P_2$: C, 75.26; H, 7.12; N, 5.49%. NMR ($CDCl_3$, TMS): δ(ppm)=1.0—2.1 (8p, CH_2), 2.63 (d, 6p, CH_3, $J_{H-P}=3.5$ Hz), 3.47 (m, 2p, CH), 7.4 (m, 20p, C_6H_5).

(R,R)-1,2-Bis[(diphenylphosphino)amino]cyclohexane (2): This ligand was prepared from (*R,R*)-1,2-cyclohexanediamine (4.0 g, 0.035 mol), triethylamine (7.1 g, 0.070 mol), and chlorodiphenylphosphine (15.4 g, 0.070 mol) by a method similar to that for aminophosphine **1**, dry benzene (100 cm^3) being used as solvent instead of chloroform. A white solid obtained was recrystallized from acetone and water. Yield: 4.25 g (25%). Mp 119—120 °C, $[\alpha]_D^{22}=-69.0°$ (*c* 1.3, $CHCl_3$). Found: C, 74.30; H, 6.92; N, 5.57%. Calcd for $C_{30}H_{32}N_2P_2$: C, 74.64; H, 6.70; N, 5.80%. NMR ($CDCl_3$, TMS): δ(ppm) =0.9—2.5 (m, 8p, CH_2), 2.7 (m, 2p, CH), 7.4 (m, 20p, C_6H_5).

(R)-1,2-Bis[N-methyl(diphenylphosphino)amino]propane (3): (*R*)-1,2-Bis(methylamino)propane dihydrochloride was prepared from (*R*)-1,2-propanediamine[13] ($[\alpha]_D^{22}=-33.8°$ (*c* 1.56, C_6H_6)) by a procedure similar to that for aminophosphine **1**. Yield: 79%. A solution of (*R*)-1,2-bis(methylamino)-propane dihydrochloride (4.0 g, 0.023 mol), triethylamine (9.3 g, 0.092 mol), and chlorodiphenylphosphine (10.1 g, 0.046 mol) in 100 cm^3 of ethanol-free chloroform was stirred overnight at room temperature under nitrogen atmosphere. Chloroform was evaporated under reduced pressure and the resulting residue was extracted with benzene (100 cm^3). The benzene solution was filtered in order to remove triethylamine hydrochloride, the filtrate being evaporated under reduced pressure to give an oily product. Yield: 7.4 g (69%) (overall yield from the starting amine, 54%). NMR ($CDCl_3$, TMS): δ(ppm)=1.18 (d, 3p, CH_3, $J_{H-H}=6.0$ Hz), 2.4 (d, 3p, NCH_3, $J_{P-H}=4.0$ Hz), 2.5 (d, 3p, NCH_3, $J_{P-H}=5.0$ Hz), 3.2 (m, 2p, CH_2), 3.8 (m, 1p, CH), 7.4 (s, 20p, C_6H_5).

(R)-1,2-Bis[(diphenylphosphino)amino]propane (4): (*R*)-1,2-propanediamine dihydrochloride (2.4 g, 0.016 mol) was added to an aqueous solution (20 cm^3) of sodium hydroxide (12.0 g). The amine was extracted with boiling benzene (100 cm^3) and the extract was dried over potassium hydroxide overnight. To the benzene solution were added triethylamine (2.3 g, 0.023 mol) and chlorodiphenylphosphine (5.1 g, 0.023 mol) with stirring under nitrogen atmosphere over a period of 30 min. The mixture was stirred at room temperature for 1 h and the triethylamine hydrochloride precipitated was removed by filtration. The filtrate was evaporated under reduced pressure to give an oily product. Yield: 3.0 g (60%). NMR ($CDCl_3$, TMS): δ(ppm)=1.11 (d, 3p, CH_3, $J_{H-H}=6.0$ Hz), 2.7—3.5 (m, 3p, CH and CH_2), 7.45 (s, 20p, C_6H_5).

Aminophosphines **3** and **4** were used for preparing rhodium (I) complexes without further purification.

Preparation of Rhodium(I) Complexes. *[Rh(cod)(1)]PF_6 (I)*: A dichloromethane solution (10 cm^3) of [Rh(cod)-Cl]$_2$[14] (0.5 g, 1 mmol, cod=1,5-cyclooctadiene) was mixed with an aqueous solution (10 cm^3) of sodium hexafluorophosphate (0.5 g, 3 mmol) with stirring under nitrogen atmosphere. To the mixture was added aminophosphine **1** (1.1 g, 2.2 mmol) and the solution was stirred vigorously for 20 min. The dichloromethane layer was washed three times with water (10 cm^3), its volume being reduced to *ca.* 5 cm^3 by passing nitrogen. On addition of ethanol (10 cm^3) and then diethyl ether (25 cm^3), the solution gave fine orange crystals which were filtered, washed with diethyl ether, and recrystallized from chloroform and diethyl ether. Yield: 1.14 g (66%). $[\alpha]_D^{25}=-79.1°$ (*c* 0.18, $CHCl_3$). Found: C, 54.78; H, 5.60; N, 3.19%. Calcd for $RhC_{40}H_{48}N_2P_3F_6$: C, 55.41; H, 5.59; N, 3.23%. NMR ($CDCl_3$, TMS): δ(ppm)= 0.8—1.9 (m, 8p, CH_2), 2.1 (m, 8p, CH_2 of cod), 2.48 (d, 6p, NCH_3, $J_{P-H}=8.0$ Hz), 4.0 and 4.6 (m, 4p, –CH=CH–), 5.0 (m, 2p, CH), 6.4—8.3 (m, 20p, C_6H_5).

The other aminophosphine complexes were prepared similarly.

[Rh(cod)(2)]$PF_6\cdot CHCl_3$ (II): Yield: 77%, orange blocks from chloroform/diethyl ether. $[\alpha]_D^{25}=-94.8°$ (*c* 0.13, $CHCl_3$). Found: C, 48.96; H, 4.68; N, 3.07%. Calcd for $RhC_{39}H_{45}N_2P_3F_6Cl_3$: C, 48.89; H, 4.74; N, 2.92%. NMR ($CDCl_3$, TMS): δ(ppm)=0.5—2.0 (m, 8p, CH_2), 2.3 (m, 8p, CH_2 of cod), 3.4 (m, 2p, CH), 4.4 and 4.9 (m, 4p, –CH=CH–), 6.9—8.2 (m, 20p, C_6H_5),

[Rh(cod)(3)]PF_6 (III): Yield: 35%, orange crystalline needles from chloroform/diethyl ether. $[\alpha]_D^{25}=-97.6°$ (*c* 0.17, $CHCl_3$). Found: C, 53.43; H, 5.66; N, 2.99%. Calcd for $RhC_{37}H_{44}N_2P_3F_6$: C, 53.74; H, 5.38; N, 3.39%. NMR ($CDCl_3$, TMS): δ(ppm)=1.24 (d, 3p, CH_3, $J_{H-H}=7.0$ Hz), 2.2 (m, 8p, CH_2 of cod), 2.34 (d, 3p, NCH_3, $J_{P-H}=9.0$ Hz), 2.51 (d, 3p, NCH_3, $J_{P-H}=7.0$ Hz), 4.4 and 5.0 (m, 4p, –CH=CH–), 7.2—8.0 (m, 20p, C_6H_5).

[Rh(cod)(4)]$PF_6\cdot CHCl_3$ (IV): Yield: 44%, orange blocks from chloroform/diethyl ether. $[\alpha]_D^{25}=-0.5°$ (*c* 0.20, $CHCl_3$). Found: C, 46.99; H, 4.29; N, 3.14%. Calcd for $RhC_{36}H_{41}N_2P_3F_6Cl_3$: C, 47.10; H, 4.51; N, 3.05%. NMR ($CDCl_3$, TMS): δ(ppm)=1.17 (d, 3p, CH_3, $J_{H-H}=7.0$ Hz), 2.3 (m, 8p, CH_2 of cod), 2.7 (m, 2p, CH_2), 2.9—3.5 (m, 1p, CH), 4.55 and 4.80 (m, 4p, –CH=CH–), 7.4—7.8 (m, 20p, C_6H_5).

Hydrogenation Procedures. Ethanol was dried overnight over molecular sieves 3A and purged with a stream of nitrogen for at least 30 min before use. In a Schlenk tube equipped with a serum cap were placed 6 mmol of a substrate and 0.03 mmol of a rhodium (I) complex. The tube was successively evacuated and filled with nitrogen. Ethanol (20—60 cm^3) was then injected. The mixture was stirred vigorously and the reaction vessel was connected to an atmospheric pressure hydrogenation apparatus. After hydrogen uptake ceased, reaction work-up and isolation of the products were carried out according to reported methods[2,15] in order to avoid undue optical enrichment. NMR spectra of all the products were measured to check the chemical conversions. Optical purities were determined by optical rotations of the products at 589 nm.

Results and Discussion

Catalysts and Hydrogenation. The optically pure aminophosphines **1**—**4** (Fig. 1) are easily obtained in a large scale since the parent 1,2-diamines can be resolved by a simple procedure with *d*-tartaric acid and the reactions proceed with full configurational retention. Aminophosphines **1** and **2** form stable white block and needle crystals, respectively, while **3** and **4** are viscous oily substances. These aminophosphines would form chelate rings with similar skeletal structures upon coordination. The absolute configurations of aminophosphines **1**—**4** are shown together with those prepared by Onuma *et al.*[7] and Fiorini and Giongo[8] (**5**—**7**), which were derived from (*S,S*)-2,3-butanediamine or (*S,S*)-1,2-diphenyl-1,2-ethanediamine (Fig. 1).

Hydrogenation was carried out with (*Z*)-α-acylamino-acrylic acid derivatives.

Solvent: Ethanol. P_{H_2}: 1.0 atm. Room temperature. Substrate/Rh=200. [Rh]: 0.5—1.5 mmol/dm^3. Hydrogenation time: 15—50 min. Chemical yield: 90—98%. Optical purity was determined based on the values given in Ref. 2. a) Rhodium (I) catalyst with aminophosphine **5** (Fig. 1) derived from (*S,S*)-1,2-diphenyl-1,2-ethanediamine, see Ref. 8. b) Rhodium(I) catalyst with aminophosphine **6** derived from (*S,S*)-1,2-diphenyl-1,2-ethane diamine, see Ref. 8. c) Rhodium(I) catalyst with aminophosphine **7** derived from (*S,S*)-2,3-butanediamine, see Ref. 7. d) Ref. 8.

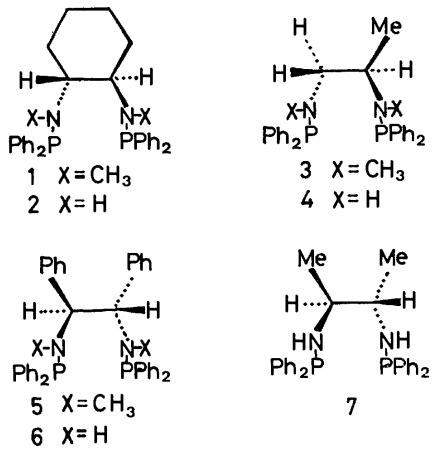

Fig. 1. Absolute configurations of chiral aminophosphines.

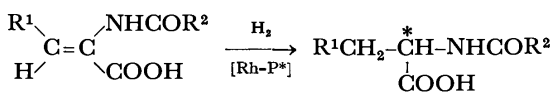

The optical purity and absolute configuration of the reaction products are summarized in Table 1 together with those reported by Onuma *et al.*[7] and Fiorini and Giongo.[8] The values were reproducible within ±2%. The addition of triethylamine did not improve the optical purity. The results can be summarized as follows, (1) The catalysts of (*R,R*)-aminophosphines with secondary amino groups, (II) *etc.*, show selectivity giving (*R*)-amino acid derivatives. Several rhodium(I) catalysts with other (*R,R*)-diphosphines[16] or -phosphites[17] whose skeletal structures are similar to those of catalysts (II) *etc.* also give the same (*R*)-amino acid derivatives. The *N*-methylation of the aminophosphines reverses the selectivity to afford (*S*)-amino acid derivatives. (2) The optical purity of the products depends on the bulkiness of substituents in a chelate ring, (I), (VI)>(V)>(III)>(II)>(VII)>(IV). (3) The products from substrate (c) show a big difference in optical purity between catalysts (I) and (II), and (III) and (IV), indicating the importance of fitness of the substrate to the catalysts. (4) The cationic catalyst (I) gives a product of higher optical purity than that obtained *in situ*,[18] suggesting that chloride ions have strong coordinating ability to the rhodium(I) ion to reduce the stereoselectivity in the hydrogenation. The cationic complexes work more effectively in asymmetric hydrogenation reactions.[19,20]

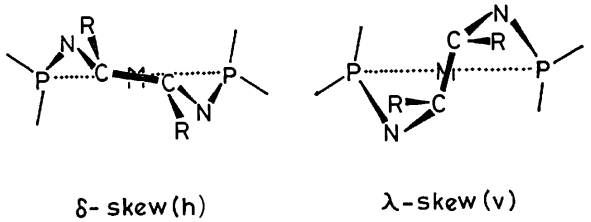

Fig. 2. Two skew conformations of a (1*R*, 2*R*)-aminophosphine chelate ring.

Chiral Recognition. Each of the aminophosphines (Fig. 1) coordinates to a rhodium(I) ion to form a seven-membered chelate ring. It will be more flexible than a five- and probably a six-membered one and can form a variety of conformations. Among the conformations, two skew forms, skew(h) and skew(v) appear to be stable (Fig. 2), since the forms would involve less intra- and inter-ligand steric interactions. The skew(h) and skew(v) imply "horizontal" and "vertical," respectively, named with reference to the direction of the central C–C bonds of the chelate rings. The skew(h) conformation was confirmed by X-ray analysis of $[Co(1,4\text{-butanediamine})_3]^{3+}$.[21] In *trans*-$[CoCl_2(1,4\text{-butanediamine})_2]^+$, one chelate ring is the skew(h), and the other the skew(v).[22] Thus, the two skew forms of a seven-membered chelate ring with no substituent group appear to have similar conformational stability.

Similar skew conformations of seven-membered chelate rings can be assumed for the aminophosphines in the rhodium(I) complexes. Aminophosphine **1** can form stereoselectively two types of chiral chelate rings, δ-skew(h) and λ-skew(v), owing to the chirality of the (*R,R*)-1,2-cyclohexanediamine moiety. However, molecular models show that the δ-skew(h) form is a less crowded

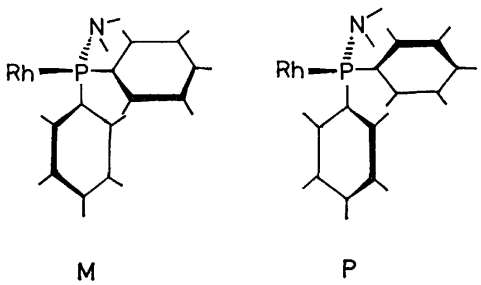

Fig. 3. Two helical orientations of two phenyl groups.

and a less strained structure than the other form. When the δ-skew(h) conformation is assumed for aminophosphine **1**, the two nitrogen atoms are forced to take (*S*)-configuration stereoselectively in order to reduce steric interactions with the phenyl groups. Furthermore the two phenyl groups on each phosphorus atom are prohibited to rotate freely around the phosphorus–carbon bonds and would be disposed in particular orientations to afford, in most cases, new helical chirality, left-handed helicity(*M*) or right-handed helicity(*P*)[23] such as seen in biaryls (Fig. 3). It is not clear from studies of molecular models which helicity is preferred for the δ-skew(h) conformation of aminophosphine **1**. However, according to X-ray analysis, the 1,2-bis-[(*R*)-(*o*-methoxyphenyl)phenylphosphino]ethane[3] and (+)-isopropylidene-2,3-dihydroxy-1,4-(diphenylphosphino)butane (diop)[24] complexes have *P* helicity and give products of (*S*)-amino acids, while the (*S*,*S*)-2,3-bis(diphenylphosphino)butane complex[25] with *M* helicity produces (*R*)-amino acids. Thus aminophosphine **1** is tentatively assumed to have *P* helicity.

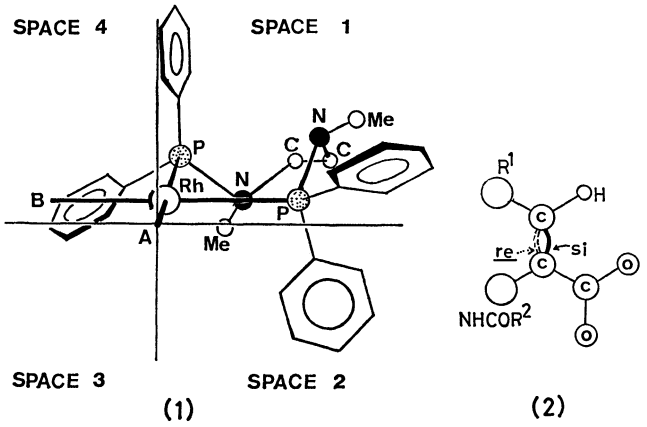

Fig. 4. (1): A schematic drawing of aminophosphine **1** coordinated to a rhodium(I) ion with the δ-skew conformation and the *P* helicity. (2): A substrate.

Figure 4 shows a schematic drawing of aminophosphine **1** coordinated to the rhodium(I) ion with the δ-skew form, viewed from the site (A) where a substrate would enter. The space 1 viewed from site (A) is occupied by the edge of one phenyl group and would be the most crowed. A substrate (Fig. 4(2)) would therefore preferentially coordinate to the rhodium(I) ion *via* the α-*re* face so that the most crowded site 1 is occupied by the small hydrogen atom on the olefinic carbon atom. The coordination through the α-*re* face of a substrate can lead to the formation of a bond between the rhodium(I) ion (site B) and the oxygen atom of the amido carbonyl of the substrate as shown by X-ray analysis on [Rh{1,2-bis(diphenylphosphino)ethane}-{methyl(*Z*)-α-acetamidocinnamate}]$^+$.[26] An (*S*)-*N*-acylamino acid is derived, when the substrate thus coordinated is hydrogenated stereoselectively from the olefinic face coordinated to the rhodium(I) ion. CH_2=C-(NHCOCH$_3$)COOH (substrate (d), Table 1) has two hydrogen atoms on one olefinic carbon atom, and hence the two coordination modes of this prochiral olefin may not be discriminated by the CH_2 group. However, the coordination through the same α-*re* face as the other olefins can similarly induce the coordination of the oxygen atom of the amido group, while that through the opposite α-*si* face introduces the bulky carboxyl group instead of the hydrogen to the most crowded space 1. Thus, substrate (d) would coordinate preferentially to the rhodium(I) ion through its α-*re* face to give (*S*)-*N*-acylalanine.

In contrast to catalyst (I), catalyst (II) gives products of (*R*)-*N*-acylamino acids, although the difference in the structure of these catalysts seems to be small. For such reverse chiral recognition, two explanations can be given. (a) The seven-membered chelate ring of aminophosphine **2** which would be less crowded and more flexible than aminophosphine **1** is in the λ-skew(v) conformation opposite to the δ-skew(h) conformation of aminophosphine **1**. (b) The stable orientation of the two phenyl groups has *M* helicity opposite to that for aminophosphine **1**, although the seven-membered chelate ring is fixed in the same δ-skew(h) form as aminophosphine **1**. Explanation (b) is more likely since molecular models indicate that the δ-skew(h) form of aminophosphine **2** is also less crowded than λ-skew(v) form, but the phenyl groups in the less crowded complex (II) can rotate more freely than those in the more crowded complex (I) and it is possible to form *M* helicity as the stable orientation. The circular dichroism (CD) spectra of the catalysts seem to support this explanation.

Figure 5 shows absorption and CD spectra of catalysts (I) and (II) in chloroform. Both catalysts exhibit similar absorption spectra over the whole region. On the other hand, the CD curves are nearly the same in the small wave number region to *ca.* 31000 cm^{-1}, but

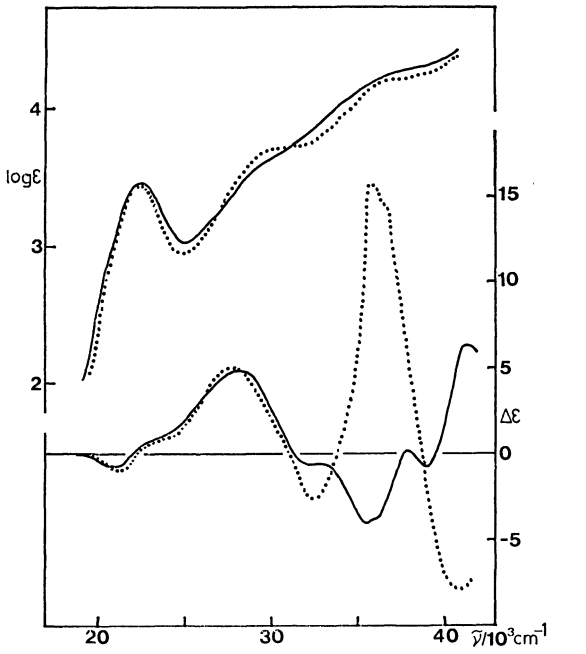

Fig. 5. Absorption and circular dichroism spectra of rhodium(I) complexes in chloroform.
——: [I], ·····: [II].

appreciably differ in the ultraviolet region. The absorption bands in the small wave number region might comprise d-d transitions in the rhodium(I) ion and charge transfer transitions from the metal ion to the ligands.[27] The CD spectra corresponding to these transitions should be affected by chiral conformation of the seven-membered aminophosphine chelate rings as observed in many cobalt(III) complexes with chiral chelate ligands.[28] The similarity in the CD spectra of catalysts (I) and (II) in this transition region suggests that the chiral aminophosphine ligands in both catalysts are in the same conformation, δ-skew(h). The CD spectra of the catalysts in the ultraviolet region differ considerably from each other. The CD bands may correspond to the intra-ligand transitions. In fact, the signs or patterns resemble those of the free ligands (Fig. 6). No definite information seems to be provided on the conformation of the chelate ligands.

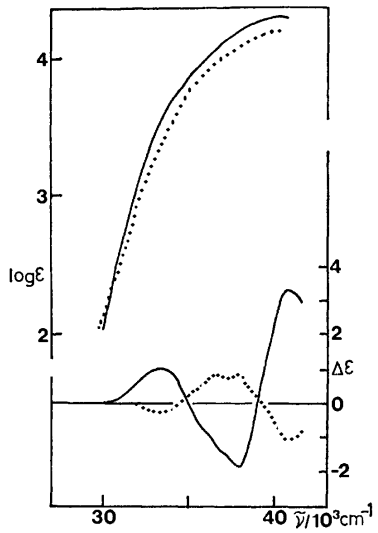

Fig. 6. Absorption and circular dichroism spectra of free aminophosphines in chloroform.
——: (**1**), ……: (**2**).

When catalyst (II) in the δ-skew(h) conformation has the phenyl groups of *M* helicity, the edge phenyl group occupies site 2. Thus site 2 is more crowded than site 1 and the substrate given in Fig. 4(2) would coordinate to the rhodium(I) ion *via* the α-*si* face to produce an (*R*)-amino acid by the same hydrogenation mechanism as that given for catalyst (I), although the optical yields are rather low. The low optical yields might be attributed to the instability of a conformer with the phenyl groups in a particular helicity resulting from the less crowded structure of catalyst (II) as compared with that of catalyst (I).

A similar chiral recognition would operate on the hydrogenation reactions with catalysts (III) and (IV) and their analogues (Table 1), since these catalysts give the same selectivity as that of catalysts (I) and (II) depending on the presence or absence of the methyl groups on the nitrogen atoms. The optical yields of catalysts (III) and (IV) are considerably lower than those of the corresponding catalysts (I) and (II), respectively, probably because of more flexible skeletones

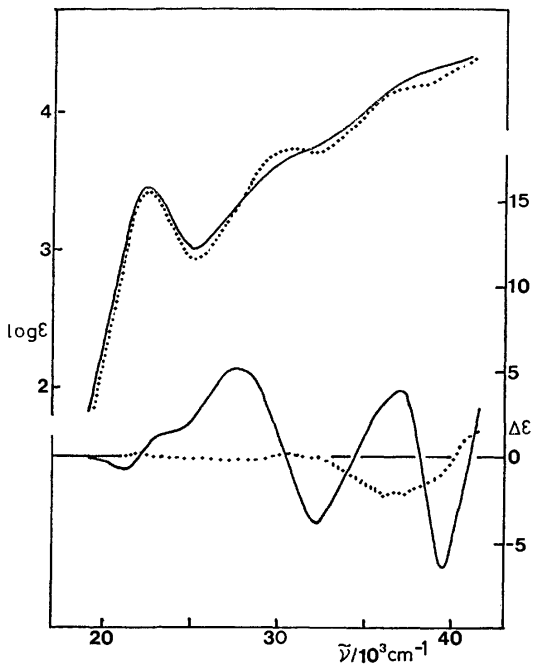

Fig. 7. Absorption and circular dichroism spectra of rhodium(I) complexes in chloroform.
——: [III], ……: [IV].

of the seven-membered chelate rings in the former catalysts. The absorption and CD spectra of catalysts (III) are similar to those of catalysts (I) and (II) in the small wave number region. On the other hand, catalyst (IV) shows very weak CD in this region, although the absorption spectrum is nearly the same as those of the other catalysts (Fig. 7). The very weak CD of catalyst (IV) suggests that the seven-membered aminophosphine **4** chelate ring is extremely flexible, existing in the two conformers of opposite chirality, δ-skew(h) and λ-skew(v), the amounts of which are almost equal at equilibrium. The conformational flexibility of catalyst (IV) is also suggested from ^{1}H NMR spectrum. The coordinated 1,5-cyclooctadiene ligand in each catalyst (I—IV) shows two kinds of vinyl proton signals probably because of the two nonequivalent phenyl groups disposed in different orientations on each phosphorus atom. The difference in chemical shift of such two vinyl proton signals would decrease with an increase in the flexibility of a diphosphine ligand.[2] The differences are 0.5—0.6 ppm for catalysts (I), (II), and (III), and only 0.25 ppm for catalyst (IV). The phenyl groups in such a flexible catalyst would hardly form a stable helical configuration, and thus the chiral recognition would not operate effectively on the hydrogenation if we assume the same mechanism as that given for catalyst (I). It seems that selectivity in the hydrogenation reactions catalyzed by rhodium(I) complexes with aminophosphines derived from chiral 1,2-diamines is most closely related with the helicity and stability of orientations of the phenyl groups on phosphorus atoms of the diphosphine ligands.

The discussion has been made on the basis of the mechanism proposed by Halpern *et al.*[5] and Brown and Chaloner[6] that a substrate coordinates to a catalyst

prior to the hydrogenation. It has also been made by assuming that the stereoselective coordination of a prochiral substrate to a vacant coordination site of a catalyst is controlled thermodynamically. In order to elucidate the selectivity of a complex catalyst, detailed kinetic studies will also be needed.[29]

(Received October 4, 1979)

2-(*p*-Bromophenacylthio)-1,3-dithiolylium bromide, when treated with triethylamine, gave 2-(*p*-bromophenacylidene)-1,3-dithiole (17%) and bis[(*p*-bromobenzoyl)(1,3-dithiol-2-ylidene)methyl] disulfide (72%). Treatment of 2-phenacylthio-1,3-dithiolylium bromide with triethylamine also gave similar results. On the other hand, 2-(*p*-bromophenacylthio)-1,3-dithiolanylium bromide yielded 1-(*p*-bromophenyl)-2-(1,3-dithiolan-2-yl)-2-thioxoethanone (12%) in addition to 2-(*p*-bromophenacylidene)-1,3-dithiolane (49%) contrary to the reported results. These results can best be rationalized by 1,3-cyclization of thiocarbonyl ylide intermediates to the valence tautomeric episulfides.

Thiocarbonyl ylides are generally unstable transient intermediates and can not be isolated under normal conditions. One of exceptions is the ylide **1** which is a thermally stable crystalline compound.[1] Unusual stability of **1** must be, at least in part, due to an aromatic sextet retained in the five membered ring. In fact the ylide **2** in which positive charge is delocalized over only a three-atom center is an unstable transient intermediate.[2] Recent ^{13}C NMR study has shown that 1,3-dithiolylium ion belongs to a typical heteroaromatic cation whose positive charge is delocalized over the entire ring.[3] Keeping this background in mind we investigated the reactions of 2-phenacylthio- and 2-(*p*-bromophenacylthio)-1,3-dithiolylium bromides (**4a** and **4b**) with base with expectation of obtaining a new class of stable thiocarbonyl ylides **3**.

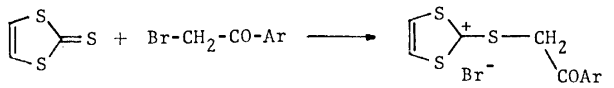
Dithiolylium salts **4a** and **4b** were conveniently prepared in good yields by treatment of 1,3-dithiole-2-thione (**5**) with phenacyl and *p*-bromophenacyl bromides, respectively.

An acetonitrile solution of **4b** was treated with a large excess of triethylamine at room temperature. Purification of products by column chromatography gave 2-(*p*-bromophenacylidene)-1,3-dithiole (**6b**) (18%),

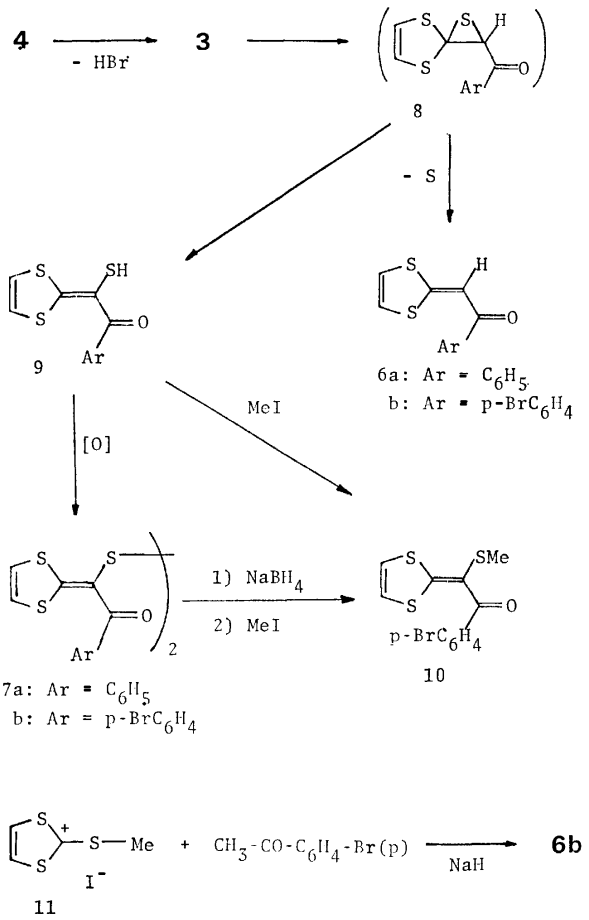


5 **4a**: Ar = C_6H_5; **b**: Ar = p-BrC_6H_4

bis[(*p*-bromobenzoyl)(1,3-dithiol-2-ylidene)methyl] disulfide (**7b**) (72%), and **5** (7%). The mass spectrum of **6b** has an M+2 peak which is almost equal in intensity to the molecular peak at *m/e* 298 because of the presence of the ^{81}Br isotope. The NMR spectrum showed a singlet of the exocyclic vinyl proton at δ 7.43 ppm, a singlet (with fine line structure) of dithiole ring protons at 6.89, and a multiplet of benzene ring protons at 7.5—8.0. The carbonyl stretching absorption appears abnormally low at 1585 cm^{-1} suggesting strong conjugation between carbonyl and 1,3-dithiol-2-ylidene groups. Campaigne and Haaf reported that the carbonyl absorptions of this type of compounds occur at 1590—1610 cm^{-1}.[4] Furthermore the structure of **6b** was confirmed by an independent synthesis; the condensation of the sodium salt of *p*-bromoacetophenone with the dithiolylium salt **11** gave **6b** in a 32% yield. The mass spectrum of **7b** has its molecular peak at *m/e* 658, M+2 peak at 660, and M+4 peak at 662 in intensity ratio of *ca.* 1:2:1 suggesting the presence of two bromine atoms. The base peak appears at *m/e* 329 which is exactly the half of the molecular peak. The NMR spectrum shows a singlet at δ 7.28 ppm and an $A'_2X'_2$ multiplet at 7.0—7.5. The UV spectrum closely resembles that of **6b** and the IR spectrum has a carbonyl absorption at 1565 cm^{-1}. These data are indicative of the symmetrical structure of **7b** with the same structural unit as **6b** and are in harmony with the presented structure. Further support for the structure of **7b** comes from its conversion to compound **10**; reduction of **7b** by sodium borohydride and methylation of the resulting product with methyl iodide gave **10** in a 61% yield.

Treatment of the dithiolylium salt **5a** with triethylamine gave results similar to those obtained with **5b**. Compounds **6a**, **7a**, and **5** were obtained in 17, 71, and 6% yields, respectively.

These results can best be explained in terms of thiocarbonyl ylide intermediate **3** produced by dehydrobromination of **4**. The ylide **3** is not so stable as was expected and cyclizes immediately to episulfide **8**, which either gives **6** with spontaneous extrusion of sulfur or isomerizes to **9**. The latter gives rise to disulfide **7** as the final product by air oxidation. Evidence for the intermediacy of **9** comes from the fact that treatment of **4b** with triethylamine in the presence of methyl iodide gives **10**, the product of methylation of **9**, in an 83% yield along with a 6% yield of **6b**.

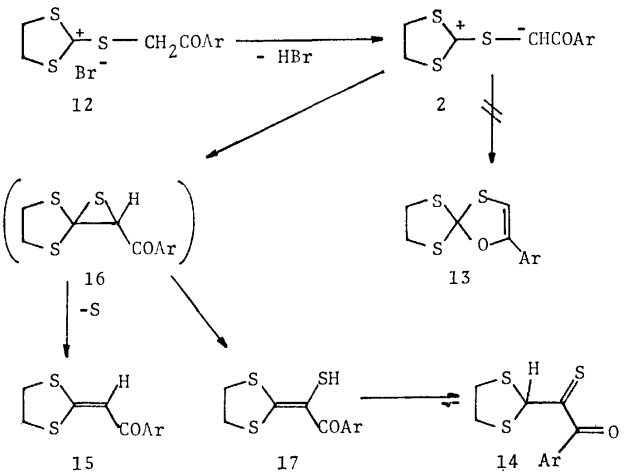


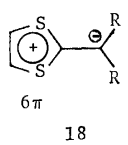
Ueno and Okawara reported that the ylide **2**, generated by deprotonation of the salt **12** with sodium hydride in acetonitrile, gives compound **13** in an excellent yield. The formation of **13** was explained as a result of 1,5-cyclization of **2**.[2] We now investigated the reaction of **12** with triethylamine in order to compare the properties of **2** and **3** under normalized conditions. Results were rather surprising. Treatment of **12** with excess triethylamine gave 1-(*p*-bromophenyl)-2-(1,3-dithiolan-2-yl)-2-thioxoethanone (**14**) (12%), 2-(*p*-bromophenacylidene)-1,3-dithiolane (**15**) (49%), and ethylene trithiocarbonate (27%). Compound **13** was not detected at all.[5] Compound **14** has its carbonyl absorption at 1560 cm^{-1}. The mass spectrum shows molecular and M+2 peaks of about equal intensity at *m/e* 332 and 334. The juncture of 1,3-dithiolan-2-yl group to thiocarbonyl group is supported by the occurence of an intense peak at *m/e* 149 (S–CH_2CH_2–S–CH–C=S).

The presence of *p*-bromobenzoyl group is evident from two peaks at *m/e* 183 and 185. The methylene protons signal appears at δ 3.38 ppm as singlet in harmony with the presented structure. The carbonyl absorption of compound **15** occurs at 1615 cm^{-1}. Reported carbonyl frequencies of this type of compounds are in the range of 1595—1630 cm^{-1}.[4] The NMR spectrum shows a multiplet of methylene protons at δ 3.36—3.62 ppm, a singlet of vinyl proton at 7.30, and a multiplet of benzene ring protons at 7.5—8.0.

The result can be explained as follows: The ylide **2** undergoes 1,3-cyclization to episulfide **16**, which either gives **15** with loss of sulfur or isomerizes to **17**. The latter further isomerizes to the final product **14**. The enol form of compound **9** may be stabilized by the contribution of the canonical structure like **18** as would be expected from unusually low carbonyl absorptions observed with compounds **6**, **7**, and **10**. As a result, compound **9** is easily methylated to give **10** or oxidized to disulfide **7**. However, such stabilization is not expected for the enol form of compound **14** and this accounts for the fact that **14** can be isolated as stable compound in the thiocarbonyl form.

We must thus conclude that (1) the ylides **3** can not be stabilized by the aromatic sextet retained in the five membered ring so that they can be isolated under usual conditions, (2) the ylides **3** undergo 1,3-cyclization to give the valence tautomeric episulfides, which is one of the characteristic reactions of thiocarbonyl ylides,[6] and (3) as far as judging from present evidence, the ylide **2** preferentially undergoes 1,3-cyclization rather than 1,5-cyclization contrary to the reported results.[2]





18

Experimental

General. All melting points were measured on a Mel-

temp capillary melting point apparatus and are uncorrected. NMR spectra were recorded on a Varian A-60 spectrometer or a Hitachi R 24B spectrometer with tetramethylsilane as internal reference. IR and UV spectra were determined with a JASCO IRA-2 spectrometer and a Hitachi EPS-3T spectrometer, respectively. Mass spectra were taken on a Japan Electron Optics Lab. Model JMS-OISJ instrument operating at 40 eV. Acetonitrile and tetrahydrofuran were refluxed over and distilled from calcium hydride and stored over molecular sieves. Merck Art 7734 (E. Merck, Darmstadt) was used for silica gel chromatography.

2-Phenacylthio- and 2-(p-Bromophenacylthio)-1,3-dithiolylium Bromides (4a and 4b). A mixture of 1.0 g (7.5 mmol) of 1,3-dithiole-2-thione[7] (**5**) and 7.2 g (36.3 mmol) of phenacyl bromide in 45 ml of anhydrous acetonitrile was stirred at room temperature. After 1.5 h of stirring, **4a** began to separate as yellowish brown crystals. The mixture was stirred for 2 d and diluted with 45 ml of anhydrous ether to complete the precipitation of **4a**. The resulting precipitate was collected and washed with ether to give **4a** in 66—71% yield. **4a**, on attempted recrystallization from hot acetonitrile or ethanol, suffered extensive decomposition to **5** and phenacyl bromide. It was therefore purified by reprecipitating it from an acetonitrile solution with ether as diluent. **4a**, thus obtained, melted at 114—115 °C.

NMR (CF_3CO_2H) δ 5.32 (2H, s, $-CH_2-$), 7.39—8.02 (5H, m, phenyl), and 8.33 (2H, s, dithiole ring); IR (KBr) $\nu_{C=O}$ 1676 cm^{-1}. Found: C, 39.52; H, 2.73; S, 28.85% Calcd for $C_{11}H_9OS_3Br$: C, 39.64; H, 2.72; S. 28.86%.

4b was prepared from **5** and *p*-bromophenacyl bromide in 65—70% yield as above; mp 138 °C (decomp), yellowish brown crystals. Although, judging from the NMR spectrum, the compound thus obtained was sufficiently pure, satisfactory elemental analysis could not be obtained (Found: C, 32.78; H, 2.18; S, 22.32%. Calcd for $C_{11}H_8OS_3Br$: C, 32.05; H, 1.96; S, 23.34%). NMR (CF_3CO_2H) δ 5.52 (2H, s, $-CH_2-$), 7.7—8.2 (4H, $A'_2X'_2m$, benzene ring), and 8.71 (2H, s, dithiole ring); IR (KBr) $\nu_{C=O}$ 1652 cm^{-1}; UV (EtOH) λ_{max} (log ε) 229 (4.02) (sh), 260.5 (4.00), and 465 nm (4.19).

Reaction of 4a with Triethylamine. Over a period of 10 min, 3 ml of triethylamine was added dropwise to a stirred suspension of 932 mg (2.8 mmol) of **4a** in 50 ml of anhydrous acetonitrile cooled at -10 °C. The mixture was warmed to room temperature and stirred for additional 2 h. The resulting red mixture was diluted with ice-water (150 ml) and extracted with 150 ml of chloroform. The extract was washed with water, dried (Na_2SO_4), and evaporated to give 813 mg of a red oil, which was subjected to column chromatography on silica gel (50 g). Elution with benzene gave 42 mg (6%) of **5**, 105 mg (17%) of 2-phenacylidene-1,3-dithiole (**6a**), and 503 mg (71%) of bis[benzoyl(1,3-dithiol-2-ylidene)methyl] disulfide (**7a**).

In a separate reaction carried out under similar conditions, **5**, **6a**, and **7a** were obtained in 7, 14, and 55% yields, respectively.

6a: Yellow needles (from hexane); mp 80—81 °C; NMR ($CDCl_3$) δ 6.82 (2H, s with fine structure, dithiole ring), 7.30—8.13 (5H, m, phenyl), and 7.47 (1H, s, vinyl); IR (KBr) $\nu_{C=O}$ 1587 and 1560 cm^{-1}. Found: C, 59.91; H, 3.69; S, 29.07%. Calcd for $C_{11}H_8OS_2$: C, 59.97; H, 3.66; S, 29.11%.

7a: Orange needles (from benzene); mp 115—116 °C. Compound recrystallized from benzene contained one molecule of benzene as solvent of crystallization. Found: C, 57.89; H, 3.45; S, 33.06%. Calcd for $C_{22}H_{14}O_2S_6 \cdot C_6H_6$: 57.94; H, 3.47; 33.08%. NMR ($CDCl_3$) δ 6.80—7.52 (14H, m); IR (KBr) $\nu_{C=O}$ 1580 and 1555 cm^{-1}.

Reaction of 4b with Triethylamine. Triethylamine (3 ml) was added dropwise during 10 min to a stirred suspension of 1.0 g 2.4 mmol) of **4b** in 40 ml of anhydrous acetonitrile cooled at -12 °C with an ice–salt bath. The bath was removed and stirring was continued for 2 h. During this period, crystals of the starting material disappered and orange crystals of product began to precipitate instead. The mixture was left overnight at room temperature and the resulting orange crystals were collected to give 485 mg of bis[(*p*-bromobenzoyl)(1,3-dithiol-2-ylidene)methyl] disulfide (**7b**). The filtrate was diluted with water and extracted with chloroform. The extract was washed with water, dried, and evaporated to leave 272 mg of a dark red oil, which was chromatographed on a column of silica gel (30 g). Elution with benzene gave 20 mg (7%) of **5**, 133 mg (18%) of 2-(*p*-bromophenacylidene)-1,3-dithiole (**6b**), and 87 mg (total yield; 72%) of **7b**.

The reaction was repeated three times. The yield of **6b** varied in the range of 18—20% and that of **7b** in the range of 65—72%.

6b: Yellowish brown crystals (from acetonitrile); mp 168 °C (decomp); NMR ($CDCl_3$) δ 6.89 (2H, s with fine line structure, dithiole ring), 7.43 (1H, s, vinyl), and 7.47—7.97 (4H, $A'_2X'_2m$, benzene ring); IR (KBr) $\nu_{C=O}$ 1585 cm^{-1}; UV (EtOH) λ_{max} (log ε) 226 (4.05), 234 (3.99) (sh), 270.5 (4.06) and 412 nm (4.49); MS *m/e* (%) 300 (M^++2, 98), 298 (M^+, 95), 185 ($^{81}BrC_6H_4CO$, 22), 183 ($^{79}BrC_6H_4CO$, 25), 157 ($^{81}BrC_6H_4$, 41), 155 ($^{79}BrC_6H_4$, 44), 149 (48), 143 (S–CH=CH–S–C=CH–C=O, 100), and 115 (S–CH=CH–S–C=CH, 18). Found: C, 44.13; H, 2.39; S, 21.41; Br, 26.79%. Calcd for $C_{11}H_7OS_2Br$: C, 44.15; H, 2.36; S, 21.43; Br, 26.71%.

7b: Orange prisms (from chloroform–hexane); mp 198—198.5 °C; NMR ($CDCl_3$) δ 7.28 (4H, s, dithiole ring) and 7.03—7.40 (8H, m, benzene ring); IR (KBr) $\nu_{C=O}$ 1565 cm^{-1}; UV (EtOH) λ_{max} (log ε) 225 4.26) (sh), 270 (3.98), 339.5 (3.78), and 425 nm (4.37); MS *m/e* 662 (M^++4), 660 (M^++2), 658 (M^+), 331, and 329. Found: C, 39.93; H, 1.84; S, 29.12%. Calcd for $C_{22}H_{12}O_2S_6Br_2$: C, 40.00; H, 1.83; S, 29.12%.

6b from 11 and p-*Bromoacetophenone.* A solution of 1.55 g (7.8 mmol) of *p*-bromoacetophenone in 20 ml of anhydrous tetrahydrofuran was added to a suspension of 0.52 g (10.9 mmol) of 50% sodium hydride dispersion in oil in 20 ml of anhydrous acetonitrile. The mixture was stirred for 1 h, and then 1.07 g (3.9 mmol) of **11**[7] was added all at once. The mixture was stirred for 1 h, poured into ice-water, and extracted with chloroform. The extract was washed with water, dried, and evaporated, The brown oily residue was purified by chromatography on a column of silica gel (40 g) with benzene as eluent to give 0.37 g (32%) of **6b**, mp 168 °C (decomp) (from acetonitrile). **6b**, thus obtained, agreed with a specimen obtained from **4b** and triethylamine in all respects.

Conversion of 7b to (p-Bromobenzoyl)(1,3-dithiol-2-ylidene)-methyl Methyl Sulfide (10). A solution of 0.50 g (0.75 mmol) of **7b** in 35 ml of tetrahydrofuran was added during 1 h to a stirred suspension of 104 mg (2.7 mmol) of sodium borohydride in 20 ml of tetrahydrofuran. After 2 h of stirring at room temperature, 0.37 g (2.6 mmol) of methyl iodide in 20 ml of tetrahydrofuran was added. The mixture was stirred for 1 h, poured into ice-water, and extracted with chloroform. The extract was washed with water, dried and evaporated to leave an orange oil. The crude product was separated by chromatography on silica gel (35 g) with chloroform as eluent to give 208 mg (61%) of **10** and 170 mg (34%) of the starting material.

10: Yellowish orange needles (from cyclohexane); mp 125—126 °C; NMR ($CDCl_3$) δ 2.09 (3H, s, Me), 6.94—7.24 (2H, m, dithiole ring), and 7.40—7.80 (4H, m, benzene ring); IR (KBr) $\nu_{C=O}$ 1564 cm^{-1}. Found: C, 41.77; H, 2.65; S, 27.77%. Calcd for $C_{12}H_9OS_3Br$; C, 41.74; H, 2.63; S, 27.86%.

*Reaction of **4b** with Triethylamine in the Presence of Methyl Iodide.* Over a period of 10 min, 3.3 ml of triethylamine was added to a stirred mixture of 1.19 g (2.9 mmol) of **4b** and 2.05 g (14.4 mmol) of methyl iodide in 30 ml of acetonitrile at −10 °C under nitrogen. The mixture was warmed to room temperature and stirred overnight. The resulting yellow crystalline precipitate was collected to give 224 mg of **10**. The filtrate was diluted with water and extracted with chloroform. The extract was washed, dried, and evaporated to leave an orange oil, which was chromatographed on silica gel (30 g). Elution with chloroform afforded 37 mg (10%) of **5**, 332 mg (total yield; 83%) of **10**, and 55 mg (6%) of **6b**. **10**, thus obtained and recrystallized from cyclohexane, melted at 128—128.5 °C and agreed in all respects with a specimen derived from **7b**.

*Reaction of 2-(p-Bromophenacylthio)-1,3-dithiolanylium Bromide[8] (**12**) with Triethylamine.* Triethylamine (4 ml) was added to a stirred solution of 828 mg (2 mmol) of **12** in 35 ml of anhydrous acetonitrile at 0 °C. The mixture was warmed to room temperature and stirred for 8 h, and then poured into ice–water and extracted with ether. The extract was washed with water, dried, and evaporated. The residue was chromatographed on silica gel (40 g). Elution with chloroform afforded 82 mg (12%) of 1-(*p*-bromophenyl)-2-(1,3-dithiolan-2-yl-)-2-thioxoethanone (**14**), 74 mg (27%) of ethylene trithiocarbonate, and 296 mg (49%) of 2-(*p*-bromophenacylidene)-1,3-dithiolane (**15**).

The reaction was repeated several times. The yield of **14** changed in the range of 7—24%, that of ethylene trithiocarbonate in the range of 20—40%, and that of **15** in the range of 49—57%.

14: Yellow prisms (from cyclohexane); mp 84.5—85 °C; NMR ($CDCl_3$) δ 3.38 (4H, s, dithiolane ring), 6.48 (1H, s, methine), and 7.52—8.00 (4H, $A'_2X'_2m$, benzene ring); IR (KBr) $\nu_{C=O}$ 1660 cm^{-1}; UV (EtOH) λ_{max} (log ε) 260 (4.31) and 350 nm (3.76); MS *m/e* (%) 334 (M^+ +2, 58), 332 (M^+, 53), 185 ($^{81}BrC_6H_4CO$, 96), 183 ($^{79}BrC_6H_4CO$, 95), 156 ($^{81}BrC_6H_4$, 91), 154 ($^{79}BrC_6H_4$, 100), 149 (S–CH_2CH_2–S–CH–C=S, 88), and 105 (S–CH_2CH_2–S–CH, 61). Found: C, 39.63; H, 2.75; S, 28.87%. Calcd for $C_{11}H_9OS_3Br$: C, 39.64; H, 2.72; S, 28.86%.

15: Yellow needles (from acetonitrile); mp 145 °C (decomp); NMR ($CDCl_3$) δ 3.36—3.62 (4H, m, dithiolane ring), 7.30 (1H, s, methine), and 7.49—7.99 (4H, $A'_2X'_2m$, benzene ring); (CF_3CO_2H) δ 3.90 (4H, s), 7.15 (1H, s), and 7.70 (4H, broad s); UV (EtOH) λ_{max} (log ε) 220 (3.89) (sh), 269 (4.00), and 349 nm (4.30). Found: C, 43.73; H, 2.99%. Calcd for $C_{11}H_9OS_2Br$: C, 43.86; H, 3.01%.

(Received October 13, 1979)

D-Nor-5α-androstan-16-one was prepared *via* seven steps from 16-diazo-3β-hydroxyandrost-5-en-17-one. The major products of the photolysis of its acetylhydrazone in dioxane containing oxygen were the parent ketone and 17-oxa-5α-androstan-16-one, accompanied by low yields of three isomeric lactams: 17-aza-5α-androstan-16-one, 16-aza-5α-androstan-17-one, and 17-aza-5α,13α-androstan-16-one. These three are the same lactams formed in the photo-Beckmann rearrangement of the corresponding oxime, *D*-nor-5α-androstan-16-one oxime. Their formation from the acetylhydrazone may have some mechanistic significance with regard to the path of the formation of lactams in the photolysis of 5α-androstan-17-one acetylhydrazone in the presence of oxygen reported previously. The mass spectrometric fragmentations of fifteen *D*-nor-5α-androstanes with functional groups at their C-16 positions are described.

In the previous paper,[2)] it was reported that *O*-acetylandrosterone acetylhydrazone and its analogue afforded a pair of lactams, 17-oxo-17a-aza-*D*-homosteroid and its 13α-isomer, in 32% yield, upon photolysis in the presence of oxygen; the corresponding hydrazone afforded no lactams and yielded the corresponding azine as the major product. To gain more insight into the pathway of the formation of lactams, we have undertaken the photolysis of *D*-nor-5α-androstan-16-one acetylhydrazone (**20**), a steroidal four-membered ring ketone acetylhydrazone. The study is described in this paper.

Results

Synthesis of D-*Nor-5α-androstan-16-one Hydrazone (18) and Its* N-*Acetyl Derivative 20.* The parent ketone, *D*-nor-5α-androstan-16-one (**16**) was synthesized by the method devised by Cava *et al.*,[3)] adopted for steroids first by Mateos,[4)] then by Meinwald *et al.*[5)] and Cava and Moroz,[6)] with some modifications. Thus, a 1 : 5.5 mixture of methyl 3β-hydroxy-*D*-norandrost-5-en-16α- and 16β-carboxylates **2** and **3** were directly obtained by photolysis of 16-diazo-3β-hydroxyandrost-5-en-17-one (**1**)[5)] in THF containing methanol in 89% yield. Recrystallization of the mixture from acetone readily afforded 16β-isomer **3** in 62% yield.

16β-Isomer **3** was hydrogenated in acetic acid in the presence of Adams' platinum catalyst to afford methyl 3β-hydroxy-*D*-nor-5α-androstane-16β-carboxylate (**5**),[7)] mp 141—142 °C, in 76% yield. Jones oxidation of **5** afforded methyl 3-oxo-*D*-nor-5α-androstane-16β-carboxylate (**7**), mp 157—158 °C, in 81% yield. This was subjected to Wolff-Kishner reduction to yield *D*-nor-5α-androstane-16β-carboxylic acid (**9**), mp 226—227 °C, in 90% yield. This sequence of the reaction was repeated on the mixture of methyl 16α- and 16β-carboxylates **2** and **3** to afford a mixture of *D*-nor-5α-androstane-16α-carboxylic acid (**8**) and the 16β-isomer **9**. These isomers could be separated by recrystallization and column chromatography.

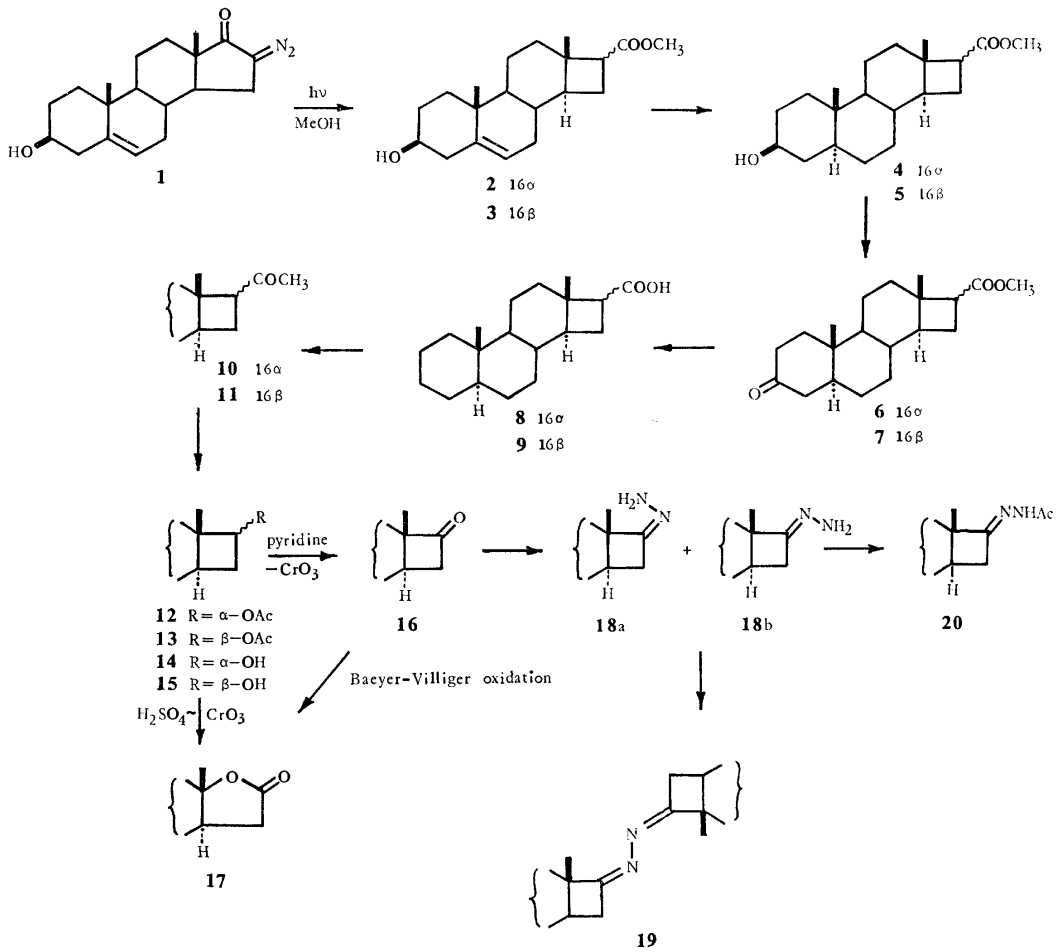
Treatment of 16β-isomer **9** with methyllithium afforded *D*-norpregnan-20-one (**11**), mp 125—127 °C, in 90% yield. A similar treatment of 16α-isomer **8**, mp 208—209 °C, gave 16α-*D*-norpregnan-20-one (**10**), mp 135—137 °C, in 68% yield.

Baeyer-Villiger oxidations of 20-ones **10** and **11** afforded *D*-nor-5α-androstan-16α-yl acetate (**12**) and the 16β-isomer (**13**) respectively. Without purification, these were hydrolyzed with methanolic potassium hydroxide to afford 16α-hydroxy-*D*-nor-5α-androstane (**14**), mp 171—173 °C, and the 16β-isomer (**15**), mp 132—135 °C, in 21 and 84% yields.

The Sarret's oxidation of 16β-isomer **15** then afforded 16-oxo-*D*-nor-5α-androstane (**16**), mp 128—129 °C. On the other hand, the Jones oxidation of **15** resulted in the formation of 17-oxa-5α-androstan-16-one (**17**). Its structure was confirmed by spectral data and through its preparation by Baeyer-Villiger oxidation of ketone **16**.

D-Nor-5α-androstan-16-one hydrazone (**18**), mp 116 °C (dec), was readily prepared by the standard method. In this procedure, evaporation of solvent from the reaction mixture caused dimerization of hydrazone **18** to give rise to the corresponding azine (**19**). Hydrazone **18** was therefore isolated by the addition of water to the solution after the formation of the hydrazone was complete. On the basis of its NMR spectrum, hydrazone **18** in solution was concluded to be a mixture of *E* and *Z* isomers although one isomer predominated; as in the case of oximes,[8,9)] it is believed that protons attached to carbon α of the $-C=N-NH_2$ group generally resonate at a lower field when the proton is eclipsed by the C=N bond and the NH_2 group *syn* to it. The NMR spectrum of **18** exhibited a multiplet signal at τ 7.14—7.56 assignable to the C-16 methylene protons and a doublet signal centered at τ 6.49 (J=6.9 and 14.3). The combined integral area of these signals corresponded to two protons and the ratio of the area of the signal at the lower field to that of the signal at the higher field was approximately 5 : 1. A double doublet signal at the lower field is assignable to the 15α-H deshielded by the eclipsed $C=N-NH_2$ group, assuming that the conformation of the ring D of **18** and the coupling constants of the 15α-H are similar to those of the parent ketone **16**. On the basis of this integral ratio of signals, the ratio of *syn* and *anti* isomers with respect to the C-13–C-16 bond was calculated

** Present address: Organic Chemistry Laboratory, Department of Chemical process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060.



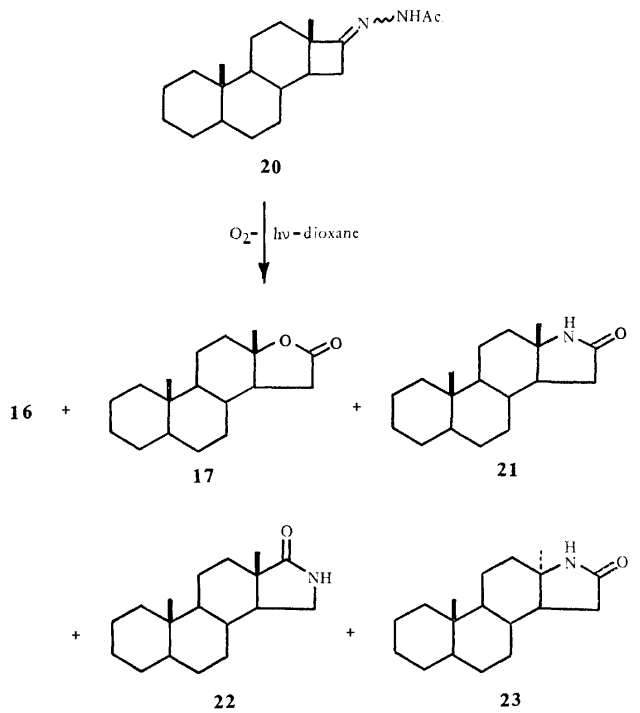
Scheme 1.

to be approximately 2 : 1.

Acetylation of the mixture of hydrazones **18a** and **18b** under controlled conditions afforded a mixture of *N*-acetyl- and *N*-diacetylhydrazones, from which *N*-acetyl derivative (**20**), mp 204—206 °C, was obtained by column chromatography in 61% yield.

Photolysis of Acetylhydrazone 20. The photolysis of acetylhydrazone **20** was carried out under the same procedure as described for the photo-rearrangement of androsterone acetylhydrazone in the previous paper.[2] Thus, acetylhydrazone **20** in dioxane was bubbled with oxygen and was irradiated with a 15-W low pressure mercury arc for 7 h. Extensive preparative TLC of the product mixture afforded lactone **17** (6%), parent ketone **16** (38%), and a mixture of lactams. The separation of the lactam mixture into its components was not possible by preparative TLC. However, the mixture could be separated into its three isomeric lactam components (**21**, **22**, and **23**) by high performance liquid chromatography. The yields of **21**, **22**, and **23** were 0.7, 1.1, and 0.7%. These lactams (**21**, **22**, and **23**) were identified as 17-aza-5α,13α-androstan-16-one by mass, IR, and NMR spectra and by direct comparisons with the authentic specimens obtained by the Beckmann and the Photo-Beckmann rearrangements of *D*-nor-5α-androstan-16-one oxime.[9] Thus, the major products in the present reaction were the parent ketone and 17-oxa-5α-androstan-16-one and the lactams were formed in only low yields. These results are in contrast to those in the photolysis of *O*-acetylandrosterone acetylhydrazone,[2] a fused cyclopentanone analogue of **20** obtained under similar conditions. In the photolysis of *O*-acetylandrosterone acetylhydrazone, 17-oxo-17α-aza-*D*-homosteroid and its 13α-isomer are formed in 32% yield.

In the previous paper,[2] some plausible paths of the formation of the lactams in the photo-reaction of the steroidal 17-one acetylhydrazone in the presence of oxygen were discussed on the basis of various available experimental results, including those of the photolysis of the corresponding hydrazone in the presence of oxygen. Thus, oxygen is required for the formation of the lactams.[2] One of the most probable paths suggested was the one involving intermediate(s) common with those involved in the formation of the lactams in the photorearrangement of the corresponding oxime, since the same lactams are formed in a comparable ratio in photo-reactions of both an oxime and the corresponding acetylhydrazone. The formation of three lactams **21**, **22**, and **23**, despite their low yields, may have a mechanistic significance. Not only two isomeric 17-azalactams, **21** and **23**, resulting from the migration of the more substituted carbon center were formed, but 16-aza-lactam **22** resulting from the migration of the less substituted carbon center was also obtained in the present reaction. These three (**21**, **22**, and **23**) are the



Scheme 2.

very lactams which arise from the photo-Beckmann rearrangement of *D*-nor-5α-androstan-16-one oxime.[9] Thus, the present results reinforce the validity of the pathway suggested in the previous paper.[2] The reason why the lactams are not major products in the fused cyclobutanone acetylhydrazone **20** is not clear at the present stage.

The formation of the parent ketone from the *N*-acetylhydrazones has been discussed in the previous paper.[2] It almost certainly involves the thermal decomposition of hydroperoxides which will be generated by either a radical-induced autoxidation, as was observed for benzaldehyde phenylhydrazones[11] and for some steroidal ketone phenylhydrazones,[12] or by the other pathway proposed for the photo-oxidation of some imines.[13] If the reaction proceeds through the autoxidation pathway, the initiator of the chain reaction can be a radical species generated by irradiation, since we found that no hydroperoxide nor any ketone derived from it was formed from steroidal ketone acetylhydrazone[2] under conditions similar to the formation of hydroperoxide of steroidal ketone phenylhydrazones[12] and that irradiation is necessary for the progress of the reaction. There is another possibility: the formation of the parent ketone by photo-oxidation with singlet oxygen, as was initially observed for acetone phenylhydrazone.[14] However, generation of singlet oxygen by sensitization with the substrate itself is not likely and this path may be excluded.

It is almost certain that 17-oxa-5α-androstan-16-one (**17**) is formed by the reaction of an oxocarbene,[15,16] generated photochemically from the ketone **16**, with molecular oxygen. Careful examination of the reaction mixture showed the absence of the 13-epimer of **17** in the product. This stereospecificity favors a concerted process for the formation of the oxocarbene from the ketone **17**, at least in this instance.[17]

Notes on the Mass Spectra of D-*Nor-5α-androstane Derivatives.* The mass spectra of 16-functionalized *D*-nor-5α-androstanes are of interest since they may give some information on the competition between the decomposition directed by their monofunctionalized cyclobutane ring and the fragmentation of the hydrocarbon framework. In Table 2, the intensities of some significant fragments are summarized. Some of the characteristic features of these results are the following:

a) Isomeric carboxylic acids **8** and **9**, isomeric methyl ketones **10** and **11**, hydrazone **18**, and azine **19** give strong molecular ion peaks.

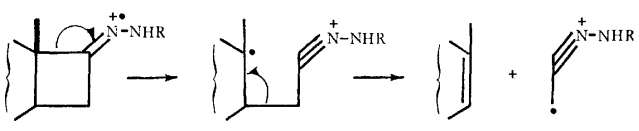
b) In the mass spectra of isomeric carboxylic acids **8** and **9**, isomeric 16-ols **12** and **13**, isomeric acetates **14** and **15**, and ketone **16**, the M^+—ring D peak (*m/e* 218)[18] is either their base peak or the second most intense fragment; a peak at *m/e* 203, which probably arises from ejections of their 10β-CH_3 and ring D from the molecular ion, is prominent. Moreover, in the mass spectra of isomeric carboxylic acids **8** and **9**, isomeric methyl ketones **10** and **11**, and a lactone **17**, a peak at *m/e* 217, arising from cleavage of ring D involving hydrogen rearrangements,[18] is also prominent.

c) The mass spectra of a pair of methyl ketones **10** and **11** exhibit the base peak at *m/e* 230, which is attributable to $M^+-Ac-CH_3$.

d) No significant difference in their fragmentation and intensity between isomers was found in a pair of isomeric 16-carboxylic acids **8** and **9**, a pair of isomeric methyl ketones **10** and **11**, a pair of 16-ols **12** and **13** and a pair of 16-ol acetates.

e) Analogous to the 3β-methoxy derivative,[19] the base peak in the mass spectrum of lactone **17** was the one attributable to the ejection of 13β-CH_3 from the molecular ion.

f) The mass spectra of hydrazone **18** and acetylhydrazone **20** exhibited the base peaks at *m/e* 56 and 98, respectively, and M^+—ring D as well as M^+—ring D—CH_3 were appreciable only in the hydrazone. Apart from the base peak, no fragment ions which exceed 3% in their intensity were found in the spectrum of acetylhydrazone **20**. The ions at *m/e* 56 and 98 may be generated *via* the pathway depicted in Scheme 3.



Scheme 3.

g) In all the *D*-nor-5α-androstanes **8**—**19** other than **20**, the mass spectra exhibited two very intense peaks at *m/e* 108 and 109 [the base peak in **14**] regardless of their 16-functional group.

Experimental

Instruments and general procedures are described in the preceding paper.[2] All the low resolution mass spectra were taken with a Hitachi RMU-6E spectrometer (ion-source temperature 200° and ionizing voltage 80 eV) in the Faculty of

Pharmaceutical Sciences, with the exceptions of compounds **18** and **20**, the spectra of which were taken with a Hitachi JMS-D 300 spectrometer. The high resolution mass spectrum of **19** was measured in the Faculty of Agriculture (ion-source temperature 220 °C and ionizing voltage 70 eV).

*Methyl 3β-Hydroxy-*D*-norandrost-3-ene-16α- and 16β-carboxylates, (2 and 3).* 16-Diazo-3β-hydroxyandrost-5-en-17-one (**1**)[7] (18 g) in dry tetrahydrofuran (720 ml) and absolute methanol (180 ml) was irradiated through a Pyrex filter with a 200-W high pressure mercury arc (Ushio UMB-200 H3) for 34 h, while nitrogen gas was bubbled slowly through the mixture. After removal of the solvent, the residue was recrystallized from acetone to yield methyl 3β-hydroxy-*D*-norandrost-5-ene-16β-carboxylate (11.29 g).[7] The residue from the filtrate (6.803 g) was subjected to column chromatography (Wakogel C-200, 90 g). Elutions with benzene afforded a 1 : 1 mixture of 16α- and 16β- carboxylates, (4.972 g).

*Catalytic Hydrogenations of Methyl 3β-Hydroxy-*D*-nor-5α-androstane-16β-carboxylate (3) and a Mixture of 16α- and 16β-Carboxylates (2 and 3).* (*a*): 16β-Carboxylate **3** (11 g), obtained as given above, in acetic acid (100 ml) in the presence

of Adams' platinum catalyst (300 mg) was hydrogenated under an atmosphere of hydrogen until absorption of hydrogen ceased (24 h). After removal of the catalyst and the solvent, the residue was dissolved in dichloromethane. The solution was washed with 5% sodium hydrogencarbonate, saturated sodium chloride solution, and water successively, and dried (Na_2SO_4). Removal of the solvent left a residue which was recrystallized from acetone to yield the hydrogenated product **5** (8.345 g), mp 141—142 °C. Found: C, 75.00; H, 10.19%. Calcd for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06%. IR (Nujol): 3527 and 3438 (OH), 1736 and 1714 ($COOCH_3$), 1258, 1198, and 1049 cm^{-1}. For NMR see Table 1. MS *m/e* (rel intensity): 320 (M^+, 10%), 305 (M^+-CH_3, 14), 287 (9), 271 (8), 234 (M^+—ring-D, 39), 219 (28), 216 (M^+—ring-D—H_2O, 49), 201 (M^+—ring-D—H_2O—CH_3, 31), 190 (28), 173 (16), 147 (26), 108 (100), 107 (67), 95 (27), 93 (37), 91 (29), 81 (36), 67 (27), 55 (42), 41 (33), and 28 (87).

(*b*): A mixture of carboxylates **2** and **3** was similarly hydrogenated to afford a mixture of the dihydro derivatives of carboxylates **4** and **5** in 95% yield.

*Oxidations of Methyl 3β-Hydroxy-*D*-nor-5α-androstane-16β-carboxylate (5) and of a Mixture of 16α- and 16β-Carboxylates (4 and 5).* (*a*): To the 3β-ol **5** (8.345 g) in acetone (180 ml), there was added dropwise Jones reagent (20 ml) at 0 °C. After stirring for 1.5 h, a saturated sodium hydrogen sulfite solution was added until the color of the solution became blue. The solution was filtered and the filtrate was partly evaporated. The crystals of ketone **7** (4.622 g) was collected by filtration and the filtrate was extracted with diethyl ether. The diethyl ether solution was worked up in the usual way. The crude product was recrystallized from acetone to yield ketone **7** (1.243 g). The residue from the filtrates of this recrystallization was purified by column chromatography (Wakogel C-200) with benzene to afford a further amount of ketone **7** (0.750 g). The total yield of **7**, mp 157—158 °C, was 81%. Found: C, 75.27; H, 9.76%. Calcd for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50%. IR (Nujol): 1731 (6-membered ring ketone), 1710 ($COOCH_3$), 1350, 1224, 1192, 1172, 1047 and 1028 cm^{-1}. For NMR see Table 1. MS *m/e* (rel intensity) 318 (M^+, 11%), 303 (5), 287 (6), 271 (9), 244 (11), 232 (M^+—ring-D, 50), 218 (75), 203 (6), 175 (11), 149 (17), 109 (27), 95 (18), 93 (18), 91 (15), 81 (25), 67 (17), 55 (36), 41 (25), and 28 (100).

(*b*): A mixture of carboxylates **4** and **5** was similarly oxidized to afford a mixture of ketones **6** and **7** in 70% yield.

Wolff-Kishner Reduction of Methyl D*-Nor-3-oxo-5α-androstane-16β-carboxylate (7) and of a Mixture of 16α- and 16β-Carboxylates (6 and 7).* (*a*): Ketone **7** (5.92 g), hydrazine (16 ml), and potassium hydroxide (16 g) were refluxed in triethylene glycol (160 ml) for 1 h. After removal of the excess of hydrazine and water, the solution was refluxed for 1.5 h. The cooled solution was poured into water–ice (200 ml). The pH of the solution was adjusted by the addition of 6 mol dm^{-3} hydrochloric acid and the solution was stirred for 0.5 h and set aside for 0.5 h. The crystals were collected by filtration and dissolved in dichloromethane. The solution was washed with water and dried (Na_2SO_4). The product was recrystallized from methanol to afford *D*-nor-5α-androstane-16β-carboxylic acid (3.16 g), mp 226—227 °C. (lit,[13] mp 207—209 °C). The residue from the filtrate afforded a further amount of the product (1.668 g) on column chromatography (Wakogel C-200, benzene). The total yield was 90%. Found: C, 78.53; H, 10.50%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%. IR (Nujol): 3200—2400 (COOH), 1692 (COOH), 1268 and 958 cm^{-1}. For NMR see Table. MS *m/e* (rel intensity): 290 (M^+, 15%), 275 (38), 230 (7), 218 (100), 217 (32), 203 (71), 189 (15), 175 (62), 161 (23), 148 (55), 109 (13), 108 (59), 95 (40), 93 (29), 91 (18), 81 (46), 79 (27), 67 (39), 55 (38), 41 (33), and 28 (72).

(*b*): A mixture of the 16α- and 16β-carboxylates (6.256 g) was similarly subjected to reduction to afford a mixture of 16α- and 16β-carboxylic acids **8** and **9**. This was recrystallized from methanol to afford 16β-carboxylic acid **9** (2.690 g). The residue (2.330 g) from the filtrate was subjected to column chromatography (Wakogel C-200) with benzene to afford three fractions: A, B, and C. The first fraction (0.988 g) was 16α-carboxylic acid **8**. An analytical specimen was obtained by recrystallizing it from methanol, mp 208—209 °C. Found: C, 78.48; H, 10.47%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%. IR (Nujol): 3600—2400 (COOH), 1695 (COOH), 1418, 1332, 1238, and 943 cm^{-1}; for NMR see Table 1. MS *m/e* (rel intensity); 290 (M^+, 13%), 275 (37), 230 (7), 218 (90), 217 (37), 203 (70), 189 (13), 175 (52), 161 (24), 148 (54), 109 (85), 108 (65), 95 (40), 93 (31), 91 (20), 81 (45), 79 (28), 67 (40), 55 (38), 41 (34), and 28 (100). The second fraction (0.3 g) was a mixture of carboxylic acids **8** and **9**. The third fraction (0.808 g) was a pure 16β-carboxylic acid **9**.

Preparation of D*-Norpregnan-20-one (11).* To 16β-carboxylic acid **9** (3.651 g) in benzene (300 ml) was added, dropwise with stirring, 1 M methyllithium (40 ml) in diethyl ether. The solution was stirred for 1 h at room temperature and was then poured into water–ice. The solution was extracted with diethyl ether and the solution was worked up as usual. After removal of the solvent, the residue was recrystallized from methanol to yield *D*-norpregnan-20-one (**11**) (3.254 g, 90%), mp 125—127 °C. (lit,[18] oil). Found: C, 83.22; H, 11.30%. Calcd for $C_{20}H_{32}O$: C, 83.27; H, 11.18%. IR (Nujol): 1715 (Ac), 1354, 1186, and 1161 cm^{-1}. For NMR see Table 1. MS *m/e* (rel intensity) 288 (M^+, 12%), 270 (12), 230 (100), 218 (39), 217 (59), 215 (35), 203 (36), 189 (11), 175 (32), 161 (26), 148 (32), 135 (28), 121 (37), 109 (78), 108 (47), 95 (40), 93 (30), 91 (19), 81 (50), 79 (29), 67 (37), 55 (40), 43 (50), and 28 (42).

Preparation of D*-Nor-16α-pregnan-20-one (10).* 16α-Carboxylic acid **8** was similarly transformed into *D*-nor-16α-pregnan-20-one (**10**), mp 135—137 °C, in 68% yield. Found: C, 83.08; H, 11.32%. Calcd for $C_{20}H_{32}O$: C, 83.27; H, 11.18%. IR (Nujol) 1697 (Ac), 1356, 1180, and 1108 cm^{-1}. For NMR see Table 1. MS *m/e* (rel intensity); 288 (M^+, 13%), 270 (11), 255 (14), 230 (96), 218 (31), 217 (47), 215 (29), 203 (29), 189 (9), 175 (25), 161 (21), 148 (28), 135 (18), 121 (26), 109 (56), 108 (26), 95 (22), 93 (19), 91 (14), 81 (28), 79 (15), 67 (22), 55 (23), 43 (21), 41 (17), and 28 (100).

The Baeyer-Villiger Oxidation of D*-Norpregnan-20-one (11).* *D*-Norpregnan-20-one (**11**) (3.408 g), *m*-chloroperbenzoic acid (3.5 g) and *p*-toluenesulfonic acid (60 mg) in dichloromethane (100 ml) in a vessel covered by an aluminium foil were stirred for 72 h at room temperature. Further amounts of the reagents [*m*-chloroperbenzoic acid (500 mg) and *p*-toluenesulfonic acid (100 mg)] were added after 26 h and 41 h. The excess peracid was decomposed by adding 5% sodium thiosulfite to the solution. The solution was washed first with 10% sodium hydrogencarbonate, then with water, and dried (Na_2SO_4). The crude acetate **13** in methanol (100 ml) was hydrolyzed by adding potassium hydroxide (3.0 g) and by stirring the solution for 2 h at room temperature. The solution was neutralized with 2 mol dm^{-3} hydrochloric acid and extracted with diethyl ether. The solution was worked up as usual. The crude product was recrystallized from acetone to yield *D*-nor-5α-androstan-16β-ol (**15**) (1.619 g), mp 132—135 °C (dec). (lit,[13] mp 103—105 °C). The residue from the filtrate was subjected to column chromatography (Wakogel C-200, benzene) to yield a further amount

of the product (0.993 g). The combined yield was 84%. Found: C, 82.38; H, 11.79%. Calcd for $C_{18}H_{30}O$: C, 82.38; H, 11.52%. IR (Nujol) 3600—3200 (OH), 1191, 1131, and 1062 cm^{-1}. For NMR see Table 1. MS *m/e* (rel intensity): 262 (M^+, 4%), 247 (5), 233 (8), 299 (5), 218 (100), 203 (54), 175 (51), 161 (27), 148 (52), 135 (17), 122 (17), 109 (85), 108 (60), 95 (30), 93 (25), 91 (13), 81 (30), 67 (30), 55 (32), and 41 (28). The acetate **13** was prepared by the standard method, mp 50—53 °C. Found: C, 78.87; H, 10.95%. Calcd for $C_{20}H_{32}O_2$: C, 78.89; H, 10.59%. IR (Nujol): 1745 (Ac), 1235 (C–O), and 1042 cm^{-1}. For NMR see Table 1. MS *m/e* (rel intensity) 304 (M^+, 1%), 289 (5), 262 (4), 244 (8), 299 (8), 218 (100), 203 (46), 175 (44), 161 (19), 148 (49), 135 (15), 121 (14), 109 (65), 108 (53), 95 (24), 93 (21), 91 (12), 81 (26), 67 (26), 55 (26), 43 (42), 41 (25), and 28 (55).

Baeyer-Villiger Oxidation of D-*Nor-16α-pregnan-20-one (**10**).* *D*-Nor-16α-pregnen-20-one (800 mg) was similarly oxidized and was hydrolyzed to yield *D*-nor-5α-androstan 16α-ol (**14**) (154 mg). This was recrystallized from acetone to yield a pure 16α-ol **14**, mp 171—173 °C (dec). Found: C, 82.43; H, 11.70%. Calcd for $C_{18}H_{30}O$: C, 82.38; H, 11.52%. IR (Nujol) 3237 (OH), 1174, 1030, 1037, 999 and 976 cm^{-1}. For NMR see Table. MS *m/e* (rel intensity): 262 (M^+, 4%), 247 (5), 233 (6), 299 (5), 218 (48), 203 (66), 175 (62), 161 (30), 148 (66), 135 (18), 122 (20), 109 (100), 108 (70), 95 (35), 93 (29), 91 (16), 81 (36), 67 (36), 55 (37), and 41 (31). The acetate **12** was prepared by the standard method, mp 56—57 °C. Found: C, 77.90; H, 10.51%. Calcd for $C_{20}H_{32}O_2$: C, 78.89; H, 10.59%. IR (Nujol): 1751 (OAc), 1239 (C–O), 1030, and 1019 cm^{-1}. For NMR see Table; MS *m/e* (rel intensity) 304 (M^+, 0.2%), 289 (1.4), 262 (3), 244 (7), 229 (7), 218 (100), 203 (45), 175 (41), 161 (17), 148 (48), 135 (14), 121 (17), 109 (65), 108 (51), 95 (21), 93 (18), 91 (10) 81 (24), 67 (25), 55 (25), 43 (42), 41 (20), and 28 (34).

Sarret's Oxidation of D-*Nor-5α-androstan-16β-ol (**15**).* *D*-Nor-5α-androstan-16β-ol (**15**) (320 mg) in pyridine (2 ml) was added dropwise to a solution of chromium trioxide (320 mg) in pyridine (2 ml) at room temperature and stirred for 48 h. The solution was then dissolved in dichloromethane and washed first with water, then with 2 mol dm^{-3} -hydrochloric acid, and again with water, and dried (Na_2SO_4). The crude product was purified by column chromatography (Wakogel C-200) with a 1: 1 mixture of hexane and benzene. The first fraction (178 mg) was a crude *D*-nor-5α-androstan-16-one (**16**) which was recrystallized from methanol to afford the pure ketone, mp 128—219 °C. Found: C, 83.15; H, 10.94%. Calcd for $C_{18}H_{28}O$: C, 83.02; H, 10.84%. IR (Nujol): 1775 (4-membered ring ketone), 1143, 1019, 987 and 973 cm^{-1}. For NMR see Table. MS *m/e* (rel intensity) 260 (M^+, 1%), 245 (1), 232 (3), 218 (100), 203 (52), 175 (50), 161 (21), 148 (26), 135 (13), 122 (17), 121 (15), 109 (76), 108 (61), 95 (21), 93 (23), 91 (11), 81 (26), 67 (26), 55 (20), and 41 (22).

The Baeyer-Villiger Oxidation of D-*Nor-5α-androstan-16-one (**16**).* The ketone **16** (50 mg), *m*-chloroperbenzoic acid (100 mg), and *p*-toluenesulfonic acid monohydrate (50 mg) in dichloromethane (5 ml) were stirred for 3.5 h at room temperature. The solution was washed with 5% sodium thiosulfite solution, sodium hydrogencarbonate solution and water successively, and dried (Na_2SO_4). After removal of the solvent, the residue (60 mg) was recrystallized from aq acetone (13 mg) to give lactone **17**, mp 185—187 °C. Found: C, 78.22; H, 10.33%. Calcd for $C_{18}H_{28}O_2$: C, 78.21; H, 10.21%. IR (Nujol): 1775 (lactonic C=O), 1210, 1161, 1050, 1003, 954, and 910 cm^{-1}. For NMR see Table. MS *m/e* (rel intensity) 276 (M^+, 7%), 261 (100), 232 (34), 217 (48), 149 (60), 109 (33), 108 (39), 95 (35), 81 (36), 67 (34), 55 (36), and 43 (38).

Jones Oxidation of D-*Nor-5α-androstan-16β-ol (**15**).* To *D*-nor-5α-androstan-16β-ol (**15**) (2.612 g) in acetone (50 ml), there was added Jones reagent (5 ml) dropwise at room temperature in the course of 1 h. After the addition of a saturated sodium hydrogensulfite solution until the color of the solution became blue, the solution was extracted with diethyl ether. The residue (2.72 g) was recrystallized from acetone to yield 17-oxa-5α-androstan-16-one (**17**), mp 185—187 °C, (400 mg). Column chromatography of the residue from the filtrate afforded a further amount (769 mg) of the lactone **17**.

Preparation of D-*Nor-5α-androstan-16-one Hydrazone (**18a** and **18b**).* Ketone **16** (500 mg) and hydrazine hydrate (5 ml) in ethanol (15 ml) were refluxed for 1.5 h. After a part of the solvent was removed, water was added to the solution. Crystals of hydrazones **18a** and **18b** were collected by filtration (302 mg). The filtrate afforded a further amount of crystals (214 mg), mp 116 °C (dec). The combined yield was 98%. Found: C, 78.93; H, 11.03; N, 9.93%. Calcd for $C_{18}H_{30}O_2$: C, 78.77; H, 11.02; N, 10.21%. IR (Nujol): 3345 (NH_2), 1162, 1112, 926, 910, and 896 cm^{-1}. For NMR see Table. MS *m/e* (rel intensity): 274 (M^+, 10%), 259 (M^+-CH_3, 7), 258 (M^+-NH_2, 5), 218 (45), 203 (35), 175 (37), 161 (8), 148 (49), 123 (9), 109 (96), 108 (66), 95 (24), 93 (22), 84 (23), 81 (26), 67 (41), 56 (100), 55 (39), and 41 (30). In this procedure, extraction of the hydrazone in aq ethanol with diethyl ether and evaporation of the solvent resulted in the formation of azine **19**, as described in the next procedure.

Preparation of D-*Nor-5α-androstan-16-one Azine (**19**).* Ketone **16** (50 mg) and hydrazine hydrate (0.5 ml) in ethanol (1.5 ml) were refluxed for 2 h. After a part of the solvent was removed by a rotary evaporator, the solution was extracted with diethyl ether. The diethyl ether solution was washed with water and dried (Na_2SO_4). Removal of the solvent left a residue which was recrystallized from methanol to yield azine **19** (5 mg), mp 220 °C (dec). Found: *m/e* 516.4460. Calcd for $C_{36}H_{56}N_2$ M^+ 516.4443. IR (Nujol): 1699 cm^{-1} (C=N–N=C). For NMR see Table. MS *m/e* (rel intensity): 516 (M^+. 8.5%), 501 (17), 314 (78), 258 (29), 218 (39), 203 (27), 175 (30), 148 (37), 109 (95), 95 (56), 93 (53), 91 (42), 81 (71), 79 (61), 67 (88), 55 (69), and 41 (100).

Preparation of D-*Nor-5α-androstan-16-one Acetylhydrazone (**20**)* Hydrazone **18** (516 mg) and acetic anhydride (2.5 ml) in pyridine (10 ml) were stirred for 16 h at room temperature. After the addition of methanol, a part of the solvent was removed. The solution was extracted with diethyl ether. The diethyl ether solution was washed with water, 5% acetic acid, and water again, and dried (Na_2SO_4). Removal of the solvent afforded a residue which was recrystallized from methanol (300 mg). The residue from the filtrate was subjected to column chromatography (Wakogel C-200) with benzene to afford two fractions. The first fraction (35 mg) was found to be *D*-nor-5α-androstan-16-one acetylhydrazone (**20**) by its NMR spectrum. The total yield was 61%. Recrystallization from methanol afforded an analytical specimen, mp 204—206 °C, Found: C, 75.79; H, 10.15; N, 8.73%. Calcd for $C_{20}H_{32}N_2O$: C, 75.90; H, 10.19; N, 8.85%. IR (Nujol): 3207 (NH), 1664 (NHCO), 1558, 1290, and 1079 cm^{-1}. For NMR see Table. MS *m/e* (rel intensity): 317 (M+1, 0.3%) 316 (M^+, 0.2), 301 (0.4), 290 (0.7), 275 (0.5), 258 (0.5), 218 (0.5), 203 (0.6), 175 (0.6), 161 (0.5), 125 (2.4), 112 (1.2), 109 (1.9), 98 (100), 67 (1.9), 55 (1.9), 43 (1.5), and 41 (1.7).

Photo-reaction of D-*Nor-5α-androstan-16-one Acetylhydrazone (**20**) in the Presence of Oxygen.* Acetylhydrazone **20** (350 mg) in dioxane (150 ml) was bubbled with oxygen. The solution

was irradiated with a 15-W low pressure mercury arc for 7 h under an atmosphere of oxygen. After removal of the solvent, the residue was dissolved in dichloromethane. The solution was washed with water and dried (Na_2SO_4). The product was subjected to preparative TLC with a 99: 1 mixture of diethyl ether and methanol to afford ten fractions (A to J) in the order of decreasing polarity. Fractions A (93 mg) and B(36 mg) were a mixture of the parent ketone and 17-oxa-5α-androstan-16-one (**17**). Fraction A was recrystallized from methanol to afford the parent ketone (47 mg). The residue from the filtrate and fraction B were combined and subjected to preparative TLC with benzene (Wako gel B-5F) to afford the parent ketone (61 mg) as the most mobile fraction (B_1). The second mobile fraction B_2 (54 mg) was subjected to preparative TLC with a 50: 1 mixture of benzene and diethyl ether to afford three fractions: B_{2a} (18 mg), B_{2b} (9 mg) and B_{2c} (1 mg). Fractions B_{2a} (5%) was 17-oxa-5α-androstan-16-one **17** and was recrystallized from acetone-water to afford 4 mg of lactone **17**, identical with the specimen prepared by the Baeyer-Villiger oxidation of ketone **16**. The third mobile fraction (171 mg) was subjected to preparative TLC with a 50 : 1 mixture of benzene and diethyl ether to afford five fractions: B_{3a} (7 mg), B_{3b} (6 mg), B_{3c} (6 mg), B_{3d} (21 mg), and B_{3e} (12 mg). The fractions B_{3d} was subjected to HPLC (column, μ-Bondapak CN; diethyl ether as the solvent; detector, JASCO UVIDEC-100; pump, Varian series 4100) to give two fractions. The fraction with a shorter retention time was evaporated to yield crystals of 16-aza-5α-androstan-17-one (**22**) (3.3 mg), mp 259—261 °C, identical with a specimen obtained by the Beckmann rearrangement of *D*-nor 5α-androstan-16-one oxime.[9] (lit,[10] mp 259—260 °C). The fraction (5.1 mg) with a longer retention time was still a mixture and this mixture was again subjected to preparative HPLC (column; μ-Bondapak NH_2, diethyl ether as the solvent). The fraction (2 mg) with the shorter retention time was 17-aza-5α-androstan-16-one (**21**),[10] identical with an authentic specimen obtained by the Beckmann rearrangement.[9] The fraction (2 mg) of a longer retention time was 17-aza-5α,13α-androstan-16-one (**23**), mp 154—157 °C(diethyl ether), identical with a specimen obtained by the photo-Beckmann rearrangement.[9]

We thank Mrs. Tomoko Okayama and Miss Hiroko Maki for the measurements of NMR spectra.

Photoreaction of *D*-Nor-5α-androstan-16-one Oxime, a Steroidal Cyclobutanone Oxime[1)]

Hiroshi SUGINOME*,** and Tsutomu UCHIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

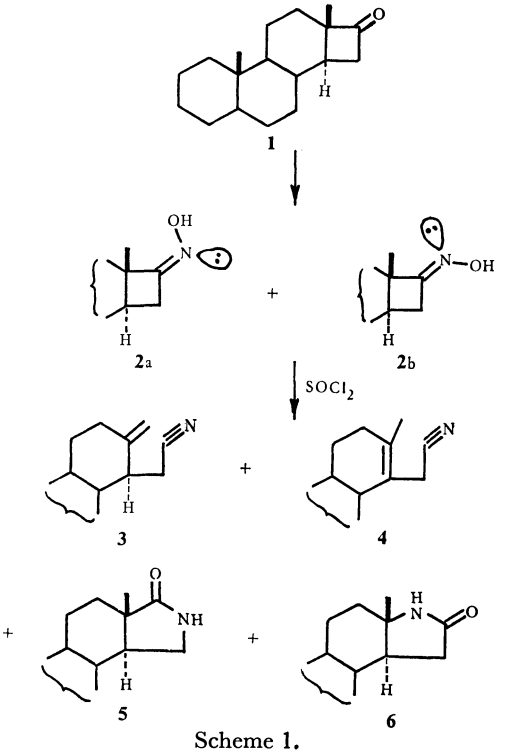
(Received January 16, 1980)

Irradiation of *D*-nor-5α-androstan-16-one oxime in methanol leads to a mixture of seco-nitriles; *D*-nor-13,16-seco-5α-androst-13(18)-ene-16-nitrile (**3**), *D*-nor-13,16-seco-5α-androst-12-ene-16-nitrile (**7**), 13ξ-methoxy-*D*-nor-13,16-seco-5α-androstane-16-nitrile (**8**), and 15-hydroxy-*D*-nor-15,16-seco-5α-androstane-16-nitrile (**9**). These result from ionic α-fissions at either of the α-bonds. Low yields of three lactams, 17-aza-5α-androstan-16-one (**6**), 17-aza-5α,13α-androstan-16-one (**11**), and 16-aza-5α-androstan-17-one (**5**), resulting from photo-Beckmann rearrangement, are also formed. The formation of **11** is the second proven example of a photo-Beckmann rearrangement in which a chirality of the migrating carbon center is not retained in the product lactam and an intervention of a ring-opened intermediate must be involved. It was found that direction of the α-cleavage of this excited four-membered cyclic ketone oxime was not governed only by the stability of cleaved ions, since seco-nitrile **9** resulting from α-fission to a less stable primary carbonium ion was formed together with seco-nitriles **3**, **7**, and **8** from a more stable tertiary carbonium ion. The Beckmann rearrangement of the mixture of *syn* and *anti* oximes with thionyl chloride afforded the two expected lactams **5** and **6** together with the products of Beckmann fission **3** and *D*-nor-13,16-seco-5α-androst-13(14)-ene-16-nitrile resulting from a cleavage to tertiary carbonium ion.

In the photo-Beckmann rearrangement of steroidal saturated ketone oximes, the chirality of the migrating center of the oximes is generally retained in the product lactams.[2)] We have found one exception to this rule: irradiation of *O*-acetylandrosterone oxime afforded a pair of lactams epimeric at the C-13.[3)] This exception implies that another mechanism, in which lactams are formed *via* rebonding of species resulting from α-fission of the oximes or the corresponding species resulting from the breakdown of the intermediate oxaziridines, is involved in the lactam formation. In order to gain more insight into the mechanism of the photoreaction of oximes, the Beckmann and the photo-Beckmann rearrangements of a steroidal cyclobutanone oxime were investigated. The results are described in this paper.

Results

D-Nor-5α-androstan-16-one oxime (**2**), prepared by the standard method, was chosen as the substrate. NMR showed that the crude oxime, as well as the one recrystallized from aqueous ethanol, were mixtures of the (*Z*) and (*E*) isomers **2a** and **2b**. Thus, a signal due to the 18-H of the oxime before the recrystallization appeared as two singlets at τ 8.87 and 8.84 (19-H as a singlet at τ 9.22), indicating it to be a mixture of geometrical isomers. This was proved more clearly by an analysis of the signals in lower fields. In the spectrum, there were a triplet centered at τ 7.34 with J=11.3 Hz, a double doublet centered at τ 7.15 with J=7.8 and 11.3 Hz, and another double doublet centered at τ 6.54 with J=7.8 and 11.3 Hz. The integrated signal areas corresponded to 1 H, 0.8 H and 0.2 H. These signals were ascribable to the 15α(or β)-H of **2a** and **2b**, the 15β(or α)-H of **2a** and the 15β(or α)-H of **2b**. As we reported previously, protons of the hydroxyimino group, which is nearly eclipsed by the C=N bond of the oximes, are deshielded[2)] when the hydroxyl group is *syn* to them and appear at *ca.* τ 6.6. The α-oriented proton at the C-15 of **2b** falls in this category; from the ratio of the signal areas of the 15β(or α)-H of **2a** and the 15β(or α)-H of **2b**, the ratio of **2a** and **2b** is estimated to be approximately 4: 1. This ratio did not change significantly after its recrystallization from aq ethanol.



Scheme 1.

Scheme 1 shows the results of ordinary Beckmann rearrangement. Treatment of oxime mixture **2a** and **2b** with thionyl chloride at room temperature afforded a product mixture, much simpler than that from the photolysis (*vide infra*). The mixture was subjected to preparative TLC to afford a mixture of two seco-nitriles **3** and **4** and a mixture of two lactams **5** and **6**. The two seco-nitriles **3** and **4** were separated by preparative TLC with silica gel containing silver nitrate. The structure of the less mobile compound **3**, mp 66—70

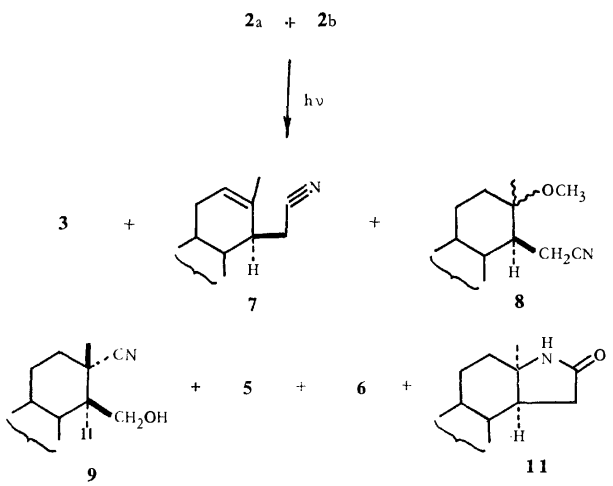
** Present address: Organic Chemistry Laboratory, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060.

°C, (35%) was confirmed to be *D*-nor-13,16-seco-5α-androst-13(18)-ene-16-nitrile (**3**) by IR, mass, and NMR spectroscopy. The molecular formula $C_{18}H_{27}N$ was confirmed by high resolution mass spectrometry. The IR spectrum exhibits a band due to the C≡N group at 2242 cm^{-1} and a series of bands due to the *exo*-methylene at 1647 and 894 cm^{-1}. The low resolution mass spectrum shows the molecular ion at *m/e* 257 (71.2%), M^+-CH_3 at *m/e* 242 (57.0%), the base peak at *m/e* 149, and the ion at *m/e* 109 (63.1%). The NMR spectrum has a singlet due to the 19-H at τ 9.28 and no signal due to the 13β-methyl group is found. Instead, the spectrum shows two broad one-proton singlets at τ 5.16 and 5.28($W_{1/2}$=4.5 Hz) and a two-proton doublet centered at τ 7.38 (J=5.3 Hz). These results are in agreement with the structure **3**; the two broad singlets are ascribed to the *exo*-methylene protons and the doublet to the C-15 methylene protons.

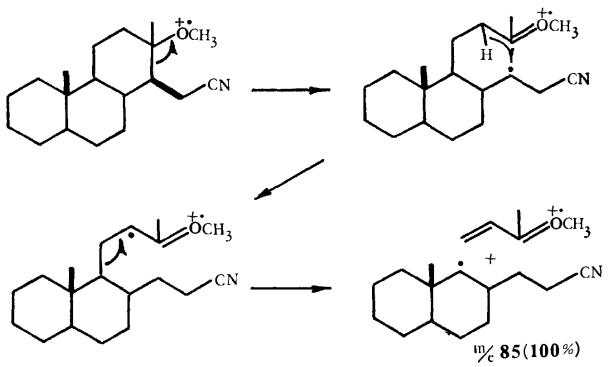
The spectral results of oily seco-nitrile **4** (8%) were in agreement with the structure of *D*-nor-13,16-seco-5α-androst-13(14)-ene-16-nitrile (**4**). The high resolution mass spectrometry proved that **4** has the molecular formula $C_{18}H_{27}N$. The low resolution mass spectrum of **4** exhibits the molecular ion at *m/e* 257 (15.7%), M^+-CH_3 peak at *m/e* 242 (5.6%), a fragment at *m/e* 149 (5.1%), and the base peak at *m/e* 109. The IR spectrum has a nitrile band at 2245 cm^{-1}. The NMR spectrum has two singlets (each 3H) at τ 9.28 and 8.32 and a two-proton singlet at τ 6.93. These signals are assignable to the 19-H, the 18-H, and the 15-H of **4**.

Lactams **5** and **6**, obtained from a less mobile fraction, were separated with the aid of HPLC. The molecular formula of lactam **5** (12%) which has a shorter retention time was confirmed to be $C_{18}H_{29}NO$ by high resolution mass spectrometry. The physical and the spectral properties were in agreement with 16-azaandrostan-17-one (**5**).[4] The molecular formula of lactam **6** (7%) which has a longer retention time, was also confirmed to be $C_{18}H_{29}NO$ by high resolution mass spectrometry. The physical and spectral properties were in accordance with 17-azaandrostan-16-one (**6**).[4]

The photo-Beckmann rearrangement of oxime **2** in methanol was carried out under the same procedure as we reported previously.[2] Irradiation of a solution of the mixture of oximes **2a** and **2b** afforded a complex mixture of the products, from which a mixture of seco-nitriles **3** and **7**, two other seco-nitriles **8** and **9**, and three lactams **5**, **6**, and **11** have been isolated by preparative TLC (Scheme 2). Although the separation of the mixture of seco-nitriles **3** and **7** to its components by means of preparative TLC was unsuccessful, spectrometry confirmed that it was a mixture of two seco-nitriles, **3** and *D*-nor-13,16-seco-5α-androst-12-ene-16-nitrile (**7**). Thus, the IR spectrum shows the molecular ion at *m/e* 257. The NMR shows all the signals due to seco-nitrile **3** obtained by the Beckmann rearrangement. Besides these signals it has two singlets at τ 9.29 and 8.34, and a broad singlet at τ 4.34. These signals are ascribed to the 19-H, the 18-H, and the 12-H of *D*-nor-13,16-seco-5α-androst-12-ene-16-nitrile (**7**). On the basis of the ratio of the integrated areas of the singlet at τ 4.34 due to the 12-H of **7** and the two singlets at τ 5.16 and 5.28 due to the *exo*-methylene protons of **3**, the ratio of **3** and **7** was estimated to be approximately 1.8 : 1.0 (2.8% and 1.5% yields). The structure of a less mobile amorphous compound (**8**) (1%) was proved to be 13ξ-methoxy-*D*-nor-13,16-seco-5α-androstane-16-nitrile by means of spectrometry. The IR spectrum shows a nitrile band at 2192 cm^{-1}. The high resolution mass spectrum of **8** proves that it has the molecular formula $C_{19}H_{31}NO$. The NMR exhibits three singlets (each 3H) at τ 9.23, 8.84, and 6.80, and a doublet (2H) centered at τ 7.84 (J=3.0 Hz). These signals are ascribable to the 19-H, the 18-H, the methoxyl group and the 15-H of **8**. The fragment ions in the mass spectrum supported this assignment. In the spectrum the base peak is present at *m/e* 85 and no other peak has an abundance of more than 7.9%. The formation of the base peak is rationalized in terms of structure **8** in a manner depicted in Scheme 3. The other crystalline compound (**9**) (2.7%) was also a seco-nitrile and its structure, 15-hydroxy-*D*-nor-15,16-seco-5α-androstane-16-nitrile (**9**), has been assigned from the analysis of the mass, IR, and NMR spectra. The molecular formula $C_{18}H_{29}NO$ was deduced from high resolution mass spectrometry. The IR spectrum exhibits a nitrile band at 2220 cm^{-1} and a hydroxyl band at 3571 cm^{-1}. The NMR shows two singlets (each 3H) at τ 9.27 and 8.24 and a doublet (2H) centered at τ 6.06 (J=2 Hz) which are ascribed to the 19-H, the 18-H, and the 15-H of **9**. The low resolution mass spectrum exhibits the parent

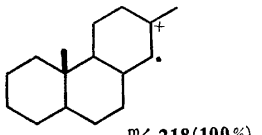


Scheme 2.



Scheme 3.

peak at *m/e* 275 (58.0%), M^+-CH_3 at *m/e* 260 (40.8%), M^+-H_2O at *m/e* 257 (25.6%), M^+-CH_2OH at *m/e* 244 (38.3%), and a base peak at *m/e* 218. Structure **10** is assigned to the last fragment ion.



10

A mixture of lactams, which were again difficult to separate by means of preparative TLC, was obtained as a less mobile fraction. This mixture could be separated, however, to 16-aza-5α-androstan-17-one (**5**), 17-aza-5α-androstan-16-one (**6**), and a new lactam **11** by HPLC. Lactams **5** and **6** were identified by direct comparisons with the authentic specimens obtained by the Beckmann rearrangement. The new lactam **11** has the molecular formula $C_{18}H_{29}NO$, as shown by its high resolution mass spectrum, and the lactam carbonyl bands at 1701 and 1675 cm^{-1} and the NH band at 3240 cm^{-1} in the IR spectrum. The most diagnostic spectral property is the mass spectrum which shows a fragmentation pattern nearly identical to that of 17-aza-5α-androstan-16-one (**6**). Thus, the structure of the new lactam is clearly 17-aza-5α,13α-androstan-16-one (**11**).

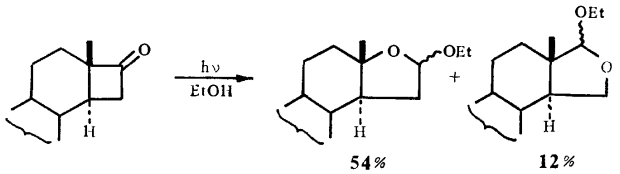
Discussion

These results confirmed that the photo-reaction of fused cyclobutanone oxime **2** leads mostly to the products resulting from α-fissions and gives only a low yield of a mixture of lactams. Although the yield of lactams is very low, the present result is the second proven example of a photo-Beckmann rearrangement in which the chirality of the migrating center of the oximes is not retained in the product lactam. The formation of lactam **11** implies that, as we described in our previous papers,[2,3] a ring-opened intermediary species should be involved in the course of the photo-rearrangement and reinforces the possibility of the presence of an exceptional mechanistic pathway for the lactam formation from the excited saturated ketone oxime.

As we pointed out in our previous papers, the α-fission reaction is rare in the photo-reaction of oximes.[7] The oximes in which α-fissions in the photo-reaction are observed[8,9] appear to be those in which an increase of non-bonded interaction or strain in the molecule is expected by the formation of the corresponding oxaziridine intermediate.

The observed α-fission in the present case is attributable to the ring strain of the four-membered ring. The present α-fission is apparently ionic in nature since all the products which result from α-fission are those expected for an ionic mechanism. Another example of ionic α-fission was recently reported by Inamoto and his colleagues.[9]

A remarkable feature in the present photo-reaction is the formation of nitrile **9** which arises from a less stable primary carbonium ion generated by a cleavage of the C-15–C-16 bond. This is contrasted to the α-fission in the ground state reaction in which the products in α-fission are nitriles **3** and **4** resulting from a more stable carbonium ion, as would be expected. This result indicates clearly the difference in behaviour of the α-fission in the ground state reaction and in the excited state reaction. The selectivity in the site of the α-fission in excited cyclobutanone oxime **2** seems to be reduced. An analogous anomalous behaviour for the α-fission has been found in an excited steroidal cyclobutanone; 3β-methoxy-*D*-nor-5α-androstan-16-one gives 12% of the acetal derived from a less stable 1,4-biradical.[10,11] (Scheme 4).



Scheme 4.

It is noted that while the photo-Beckmann rearrangement of *O*-acetylandrosterone oxime, a *trans* fused cyclopentanone oxime, afforded two isomeric lactams arising from the migration of the more-substituted carbon center and no accompanying lactams arising from the migration of the less-substituted carbon center,[3] the corresponding *trans* fused cyclobutanone oxime **2** afforded lactam **5** arising from the migration of the less substituted carbon center.

Experimental

Mps were determined with a Yanagimoto micro-melting point apparatus. IR spectra were determined for Nujol mulls with a JASCO IR-E spectrophotometer unless stated otherwise. 100 MHz ^1H NMR spectra were recorded with a JEOL PS 100 high-resolution spectrometer (solvent $CDCl_3$; Me_4Si as internal reference). Preparative TLC was carried out on Wakogel B-5F unless stated otherwise. Mass spectra were recorded in the Faculty of Pharmaceutical Sciences or the Faculty of Agriculture of this University with a Hitachi JMS-D 300 spectrometer using a direct inlet system. (Ion source temperatures: 175 °C for compounds **2**, **3**, and **8**; 180 °C for compounds **6** and **9**; 185 °C for compound **5** and 100 °C for compound **4**. Ionizing voltage, 70 eV). Only fragment peaks of relative intensities over 40% are mentioned. High resolution mass spectra were measured by Miss Y. Chiba in the Faculty of Agriculture. Dotite spectrosol methanol (Wako) was used as solvent for the photoreactions.

Preparation of D-*Nor-5α-androstan-16-one Oxime* **2a** *and* **2b**. *D*-Nor-5α-androstan-16-one (**1**) (50 mg), hydroxylamine hydrochloride (30 mg) and sodium acetate trihydrate (20 mg) in ethyl alcohol (1 ml) and water (0.2 ml) were stirred for 2 h at room temperature. After the usual work-up the product was recrystallized from aq ethanol to afford the oxime (15 mg), mp 87—90 °C, which was a mixture of geometrical isomers. Found: C, 78.31; H, 10.42; N, 5.30%. Calcd for $C_{18}H_{29}NO$: C, 78.49; H, 10.61; N, 5.09%. IR: 3260 (OH), 1705 (C=N), and 937 cm^{-1}. MS *m/e* (rel intensity) 275 (M^+, 11.7), 260 (M^+-CH_3, 39.8), 259 (M^+-16, 22.5), 258 (M^+-H_2O, 100), 109 (76.6), 95 (63.9), 81 (59.1), 67 (68.3), 55 (68.2), 41 (60.7); for NMR see text.

The Beckmann Rearrangement of D-*Nor-5α-androstan-16-one Oxime,* ***2a*** *and* ***2b***. To the amorphous oxime (41 mg) in dioxane (2 ml) was added thionyl chloride (0.5 ml) at room temperature. The solution was stirred for 20 min. The solution was extracted with dichloromethane. The organic layer was washed with water, 5% sodium hydrogencarbonate, and water again and then dried (Na_2SO_4). The residue(40 mg) was subjected to preparative TLC with a 2 : 1 mixture of dichloromethane and diethyl ether to afford two fractions (A and B). The more mobile fraction A (27 mg) was a mixture of the Beckmann fission products and was subjected to preparative TLC. The TLC plates were developed twice with hexane and benzene, once with a 9 : 1 mixture of hexane and benzene, and five times with a 99: 9 : 1 mixture of hexane, benzene, and dichloromethane to afford two fractions. The more mobile fraction A_1 (6 mg) was still a mixture of two nitriles **3** and **4**. This fraction was again subjected to preparative TLC (Wakogel B-5F containing 5% silver nitrate) with a 3: 1 mixture of benzene and diethyl ether to afford two fractions. The more mobile fraction (3 mg, 8%) was a colorless oil and was a 13,17-seco-nitrile **4**. Found: *m/e* 257.2124. Calcd for $C_{18}H_{27}N$: M, 257.2141; IR (Nujol): 2245 cm^{-1} (C≡N). For MS and NMR see text.

The less mobile crystalline fraction (2 mg) was the seco-nitrile **3**. The less mobile crystalline fraction A_2 (12 mg) was also nearly pure nitrile **3**, which gave crystals on addition of methanol, mp 66—70 °C. Found: *m/e* 257.2160. Calcd for $C_{18}H_{27}N$: M, 257.2141; IR (Nujol): 2242 (C≡N), 1773, 1647, and 894 cm^{-1} (C=CH_2); MS *m/e* (rel intensity) 257 (M^+, 71.2), 242 (M^+-CH_3, 57.0), 163 (46.6), 149 (100), 109 (63.1), 95 (60.4), 81 (68.3), 67 (59.7), 55 (64.5), and 41 (50.0). For NMR see text.

The fraction B (11 mg) was subjected to HPLC (μ Bondapak CN; JASCO UVIDEC-100 detector; pump, Varian Series 4100) with diethyl ether as the solvent. The fraction (7 mg) having the shorter retention time (7.5 min) was 16-azaandrostan-17-one (**5**). This was recrystallized from acetone to yield crystals (5 mg, 12%), mp 259—261 °C. (lit,[4] 259—260 °C). Found: *m/e* 275.2242. Calcd for $C_{18}H_{29}NO$: M,+ 275.2247; IR: 3306 (NH), 1716 and 1679 cm^{-1} (lactam carbonyl) (lit,[4] 3451, 3200, 1720, and 1700 cm^{-1}); MS *m/e* (rel intensity) (ion-source temp, 185 °C, 70 eV) 275 (M^+, 100), 260 (21.5), 230 (24.6), 218 (28.0), and 98 (33.8%) (lit,[4] *m/e* 275 (100), 260 (25), 230 (16), and 218 (26%)); NMR: τ 9.04 (3H, s, 18-H), 9.22 (3H, s, 19-H), 7.01 (1H, t, 15β-H), 6.08 (1H, dd, 15α-H) ($J_{15\alpha,15\beta}=J_{15\beta,14\alpha}=9.8$ Hz; $J_{15\alpha,14\alpha}=$ 4.5 Hz), and 3.41 (1H, br. s, $W_{1/2}$ 12 Hz, NH).

The fraction (3 mg, 7%) of longer retention time (11.5 min) was 17-azaandrostan-16-one (**6**). This was recrystallized from acetone to yield crystals (2 mg), mp 250—251 °C. (lit,[4] mp 256—257 °C). Found: *m/e* 275.2255. Calcd for $C_{18}H_{29}$-NO: M, 275.2247, IR: 3287 (NH), 1715 and 1677 cm^{-1} (lactam carbonyl) (lit,[4] 3420, 3200, 1720, and 1697 cm^{-1}); MS *m/e* (rel intensity) (ion-source temp 180 °C and ionizing voltage 70 eV) 275 (M^+, 1.2), and 260 (100%) (lit,[4] *m/e* 275 (2) and 260 (100); 8.94 (3H, s, 18-H), 9.24 (3H, s, 19-H), 7.89 (1H, d, 15α- or 15β-H), 7.91 (1-H, d, 15α- or 15β-H) ($J_{15\beta,14\alpha}=J_{15\alpha,14\alpha}=9.8$ Hz) 4.04 (1-H, br. s, $W_{1/2}$ 10 Hz).

The Photo-Beckmann Rearrangement of D-*Nor-5α-androstan-17-one Oxime.* The mixture of *syn* and *anti* oximes (300 mg) in methanol (300 ml) was irradiated for 48 h with a 15-W low pressure mercury arc. Argon was slowly bubbled during the irradiation. After the removal of the solvent, the residue was subjected to preparative TLC (Wakogel B-5F) with a 1: 4 mixture of diethyl ether and benzene to afford eight fractions A (53 mg), B (33 mg), C (21 mg), D (16 mg), E (15 mg), F (37 mg), G (24 mg), and H (80 mg) in the order of decreasing mobility. The fraction A was subjected again to preparative TLC with benzene to afford two fractions (A_1 and A_2). The fraction A_1 (34 mg) was further subjected to preparative TLC with a 5: 1 mixture of hexane and benzene. The plates were developed five times to afford a mixture of two seco-nitriles **3** and **7** (12 mg, 4.3%). Analysis of the NMR spectrum is described in the text. The fraction B was subjected to preparative TLC with benzene to afford a gummy compound (9 mg). This was again purified by preparative TLC (Merck silica gel 60 F_{254} with concentration zone) with a 4 : 1 mixture of hexane and diethyl ether to afford a colorless gum **8** (3 mg, 1%). Found: *m/e* 289.2391. Calcd for $C_{19}H_{31}NO$: M, 289.2404; IR (neat): 2192 (C≡N), 1468, 1451, 1436, 1378, 1135, and 1084 cm^{-1}; MS *m/e* (rel intensity) 289 (M^+, 3.6%), 274 (2.6), 257 (2.6), 242 (1.4), 85 (100), 72 (4.5), 67 (5.1), 55 (7.9), and 41 (5.1), for NMR see text. The fraction E was again purified by preparative TLC to afford the seco-nitrile **9** (8 mg) which was recrystallized from diethyl ether–hexane to afford crystals, mp 164—166 °C. Found: *m/e* 275.2241. Calcd for $C_{18}H_{29}NO$: M, 275.2248; IR (Nujol): 3571 (OH), 2220 (C≡N) and 1088 cm^{-1}. For NMR see text; MS *m/e* (rel intensity) (ion-source temp 180 °C, 70 eV) 275 (M^+, 58.0%), 260 (40.8), 257 (25.6), 247 (11.8), 244 (38.3), 242 (23.2), 218 (100), 200 (15.3), 190 (26.7), 175 (15.6), 149 (33.6), 135 (18.5), 121 (26.5), 110 (54.8), 109 (64.4), 95 (7.13), 81 (71.6), 67 (65.4), 55 (65.9), and 41 (62.1). The fraction F was again subjected to preparative TLC (Merck silica gel 60 F_{254} with concentration zone) with a 4 : 1 mixture of hexane and ethyl acetate. The plates were developed five times to afford two fractions (F_1 and F_2). The fraction F_1 (2 mg) was unidentified and a less mobile fraction F_2 (19 mg) was a mixture of other seco-nitriles. However, the separation to its components by preparative TLC was not successful. The fraction H was subjected to preparative HPLC, as with the case of the lactam mixture from the Beckmann rearrangement, to afford three fractions (H_1, H_2, and H_3) in the order of the retention times. The fraction H_1 (63 mg) with the shortest retention time was an unidentified gum. The second fraction H_2 (2 mg, 0.7%) was 16-aza-5α-androstan-17-one **5** identical with the specimen obtained by the Beckmann rearrangement. The fraction H_3 (8 mg, 2.7%) was a mixture of two lactams, 17-aza-5α-androstan-16-one (**6**) and 17-aza-5α,13α-androstan-16-one (**11**). This was subjected to preparative HPLC (μ Bondapak NH_2) with diethyl ether as the solvent to afford pure lactam **6** and its epimer **11** in a 3 : 1 ratio. Lactam **6** with the shorter retention time was identical with an authentic specimen of lactam **6** obtained by the Beckmann rearrangement. The new lactam **11** having a longer retention time was recrystallized from diethyl ether. It had mp 154—157 °C. Found: *m/e* 275.2249. Calcd for $C_{18}H_{29}NO$; M, 275.2249; for IR see text. NMR: τ 8.83 (3H, s, 18-H) and 9.36 (3H, s, 19-H), MS *m/e* 275 (rel intensity) (M^+, 3.9%), 260 (M^+-CH_3, 100), 136 (6.9), 109 (4.9), 81 (5.9), 79 (4.3), 67 (7.5), 55 (8.0), and 41 (8.6).

We thank Miss Hiroko Maki for the measurement of NMR spectra.

Preparation and Properties of Nitrosyl Complexes of Molybdenum[1]

Takashi TATSUMI,* Kazuhiko SEKIZAWA, and Hiroo TOMINAGA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113
(Received November 8, 1979)

Reactions of some dpe(dpe=$Ph_2PCH_2CH_2PPh_2$) complexes of molybdenum with nitrosyl hexafluorophosphate ($NOPF_6$) have been investigated. The reaction of $MoH_4(dpe)_2$ with $NOPF_6$ in benzene–methanol affords two types of complexes, a protonated species, *trans*-$[MoF(HNO)(dpe)_2]PF_6$ (**1a**) and a non-protonated species, *trans*-$MoF(NO)(dpe)_2\cdot 1/2C_6H_6$. From the nitroxyl complex **1a**, a series of nitrosyl complexes has been obtained. Some nitrosyl complexes exhibit *cis-trans* isomerism. Reactions of the nitrosyl complexes with protonic acids afford the corresponding nitroxyl complexes or the anion substitution products. Cationic nitrosyl complexes are obtained by the reactions of $Mo(CO)L(dpe)_2$ (L=N_2 or C_2H_4) and $Mo(C_2H_4)_2(dpe)_2$ with $NOPF_6$. Attempts were also made to prepare nitrosyl complexes of molybdenum by use of other nitrosylating agents.

Recently dinitrogen,[2] isonitriles,[3] thiocarbonyl,[4] and ethylene,[5] which are attached to the electron-rich site of $M(dpe)_2$ (M=Mo or W, dpe=$Ph_2PCH_2CH_2PPh_2$), have been shown to be susceptible to electrophilic attack. Such attack at coordinated dinitrogen has been extensively investigated, leading to the formation of nitrogen–hydrogen and nitrogen–carbon bonds.[2] This finding prompted us to prepare metal complexes containing nitrogen monoxide activated by coordination to this site. We describe below the nitrosylation of some dpe complexes of molybdenum by use of versatile nitrosylating agents[6,7] and the protonation of the nitrosyl complexes thus obtained. Chatt *et al.* briefly commented on the formation of $MoX(NO)(dpe)_2$ (X= F and Br) from $MoX(N_2H)(dpe)_2$ and nitrogen monoxide.[8] Very recently King and Leigh reported the preparation of a series of nitrosyl complexes of molybdenum and tungsten with only halide and tertiary phosphine as coligands.[9] The reactions of nitrosyl compleses with electrophiles such as HCl, HBr, $PhCH_2Br$, O_2, and NO have recently been reviewed.[10]

Results and Discussion

Reaction of Phosphine Complexes of Molybdenum with $NOPF_6$. The reaction of a hydride complex, $MoH_4(dpe)_2$, with $NOPF_6$ ($NOPF_6$/Mo=1.05) in benzene–methanol solution gives *trans*-$[MoF(HNO)(dpe)_2]PF_6$ (**1a**) and *trans*-$MoF(NO)(dpe)_2\cdot 1/2C_6H_6$ (**2a**). Complex (**1a**) is a purple crystalline diamagnetic solid. The ^{31}P NMR spectrum of **1a** exhibits a doublet (J_{P-F}=39 Hz) at −45 ppm (relative to PPh_3) assigned to the four equivalent phosphorus nuclei, suggesting a *trans* configuration. Complex **2a** is a yellow crystalline diamagnetic solid which also has a *trans* configuration since its ^{31}P NMR spectrum shows a doublet (J_{P-F}= 27 Hz) at −58 ppm. This complex appears to be identical with that prepared by an alternative route.[8] Without methanol as a cosolvent, the starting material was recovered almost quantitatively. Complex (**1a**) is apparently a protonation product of **2a** by HPF_6. Treatment of **2a** with a benzene–methanol solution of $NOPF_6$ gives **1a** in good yield. HPF_6 must have been formed *in situ* by Eq. 1.[7] Expectedly, reaction of **2a** with aqueous HPF_6 in benzene affords **1a**.

$$NOPF_6 + MeOH \rightleftarrows HPF_6 + MeONO \quad (1)$$

In the reactions of nitrosonium salts with transition metal complexes, three types of reaction products have been found;[7] *i.e.*, formation of cationic nitrosyl species, one-electron oxidation, and protonation affording metal hydrides (in methanol). The basic character of the NO ligand of **2a** (see below) results in its rapid protonation but prevents the selective preparation of its complex by addition of 1 mol eq. of $NOPF_6$ to the hydride. One might expect that as the $NOPF_6$/Mo ratio is increased, **1a** would be exclusively obtained. In fact, however, the yield of **1a** decreased, whereupon benzene-soluble unknown complexes were obtained.

Treatment of the dinitrogen complex, *trans*-$Mo(N_2)_2(dpe)_2$, with $NOPF_6$ afforded no nitrosyl complex; dark red crystals of $[MoF(N_2H_2)(dpe)_2]PF_6$ (**3a**) were obtained which show the antisymmetric and symmetric N–H stretching frequencies at 3350 and 3260 cm^{-1}, respectively. Presumably the ligating dinitrogen was protonated by the *in situ*-formed HPF_6. This complex seems to be analogous to the hydrazido(2−) complex $[MoF(NNH_2)(dpe)_2]BF_4$.[11] Complex **3a** is isoelectronic to **1a**. Chatt *et al.* isolated $MoF(N_2H)(dpe)_2$, which is isoelectronic to **2a** and can be protonated in a similar way with **2a** to afford N_2H_2 complexes.

In contrast, *trans*-$Mo(CO)(N_2)(dpe)_2\cdot 1/2C_6H_6$ reacted with $NOPF_6$ to yield the known $[Mo(CO)(NO)(dpe)_2]PF_6$ (**3b**).[12] In this reaction, we have also detected *cis*-$[Mo(CO)_2(dpe)_2]PF_6$ and *cis*-$Mo(CO)_2(dpe)_2$ by IR. $Mo(CO)(C_2H_4)(dpe)_2$ showed a similar behavior toward $NOPF_6$. It should be noted that **3b** cannot obtained from *cis*-$Mo(CO)_2(dpe)_2$ and $NOPF_6$.[13] In the reactions of *trans*-$Mo(CO)(N_2)(dpe)_2\cdot 1/2C_6H_6$ and $Mo(CO)(C_2H_4)(dpe)_2$, *cis*-$[Mo(CO)_2(dpe)_2]PF_6$ would be formed by way of *cis*-$Mo(CO)_2(dpe)_2$ since these monocarbonyl complexes slowly changed to the *cis*-dicarbonyl in the absence of $NOPF_6$. In the reaction of $Mo(C_2H_4)_2(dpe)_2$ with $NOPF_6$, $[Mo(C_2H_4)(NO)(dpe)_2]PF_6$ (**3c**) was obtained in very poor yield.

Reaction of trans-*$Mo(N_2)_2(dpe)_2$ and $MoH_4(dpe)_2$ with NO Gas and Some NO Sources* Treatment of *trans*-$Mo(N_2)_2(dpe)_2$ in benzene with NO at atmospheric pressure afforded an orange yellow solution, from which yellow crystals were obtained. Elemental analysis suggests the empirical formula $[Mo(NO)(dpe)]_2\cdot 2C_6H_6$ (**4**) for the complex. The complex $[Mo(NO)(dpe)_2]_2\cdot CH_2Cl_2$ has been prepared previously from $[Mo(CO)_3(NO)(dpe)]PF_6$ and dpe.[13] Since **4** reacts successively

TABLE 1. NITROSYL COMPLEXES OF MOLYBDENUM

	Complex	Found (Calcd), %				IR, cm^{-1} a)	Color
		C	H	N	Halogen	ν(NO)	
2a	*trans*-MoF(NO)(dpe)$_2$·1/2C_6H_6	68.0 (67.4)	5.4 (5.2)	1.2 (1.4)	1.5 (1.9)	1528	yellow
2b	*cis*-MoCl(NO)(dpe)$_2$	64.6 (65.2)	5.0 (5.0)	1.5 (1.5)	3.5 (3.7)	1567	yellow

a) Recorded in KBr.

with NO to afford a brown powder, contaminated with the phosphine oxide(IR), the yield of **4** is low, but it can be isolated under appropriate conditions. The reaction of MoH_4(dpe)$_2$ with NO under similar conditions gave no nitrosyl complexes; MoH_4(dpe)$_2$ being recovered unchanged. With *N*-methyl-*N*-nitroso-*p*-toluenesulfoamide, the reagent known to be capable of nitrosylating metal hydrides,[7] MoH_4(dpe)$_2$ was recovered quantitatively.

The reaction of *trans*-Mo(N_2)$_2$(dpe)$_2$ with NOCl (NOCl/Mo=10) was carried out in toluene giving a greenish yellow solid, the IR spectrum of which suggested that it was a mixture of two known complexes, $MoCl_3$(NO){Ph_2P(=O)$CH_2CH_2PPh_2$(=O)},[14] $MoCl_2$(NO)$_2${Ph_2P(=O)$CH_2CH_2PPh_2$(=O)},[15] and free phosphine oxide. In the case of NOCl/Mo=1, a yellow solid was obtained, whose IR spectrum shows the presence of **2f′** (see below), $MoCl_2$(NO)$_2${Ph_2P(=O)-$CH_2CH_2PPh_2$(=O)}, and the starting dinitrogen complex. In either case the components of these mixtures were inseparable by crystallization and thus as a nitrosylating agent NOCl is not suitable for the clean synthesis of nitrosyl complexes.

*Product Derived from the Nitroxyl Complex (**1a**).* The reaction of **1a** with appropriate alkali metal salts (MX) in acetone afforded MoX(NO)(dpe)$_2$ [X= Cl(**2b**), Br(**2c**), I(**2d**), and NCS(**2e**)] (Table 1). With NaN_3 and NaNCO, **1a** gives **2a**. From the position of the C–S frequencies at 840 cm^{-1}, it was concluded that in the complex (**2e**) the nitrogen of the thiocyanate group is coordinated to molybdenum. With $NaBH_4$, **1a** gives **4** in good yield.

In CH_2Cl_2 the ^{31}P NMR spectrum of **2b** shows a broad multiplet centered at −60 ppm, suggesting a *cis* configuration. Refluxed in benzene, **2b** is converted into yellow crystals analyzing as *trans*-MoCl(NO)(dpe)$_2$·1/2C_6H_6 (**2f**). The ^{31}P NMR spectrum of **2f** shows a sharp singlet at −58 ppm, suggesting a *trans* configuration. Preliminary X-ray data of **2f** also shows the presence of benzene as a crystal solvent, and essentially linear M–N–O system.[16] Dissolved in CH_2Cl_2, **2f** is slowly converted into **2b** (Eq. 2).

$$\underset{(\mathbf{2b})}{\textit{cis}\text{-MoCl(NO)(dpe)}_2} \underset{CH_2Cl_2}{\overset{C_6H_6\ \text{reflux}}{\rightleftharpoons}} \textit{trans}\text{-MoCl(NO)(dpe)}_2\cdot 1/2C_6H_6 \quad (2)$$
$$(\mathbf{2f})$$

In the *trans* compound ν(NO) is shifted to lower frequency by 20 cm^{-1}. These data are compatible with Feltham and Nyholm's interpretation.[17] They prepared a series of six-coordinate nitrosyl complexes [CoX(NO)(diars)$_2$]X (X=Cl, Br, I, and NCS; diars= *p*-$Me_2AsC_6H_4AsMe_2$) in which there were two NO frequencies present. On the basis of examination of bands in the 900 cm^{-1} region in their IR spectra, they suggested that these complexes were a mixture of *cis* and *trans* isomers. The isomer with lower NO frequency was assigned to the *trans* configuration, while the isomer with the higher frequency was assigned to the *cis* one. Since both the molybdenum nitrosyls and the cobalt nitrosyls are six-coordinate complexes having the ligands such as NO, halogen, and four group VB donors, it is natural that the ν(NO) frequencies are assumed to shift similarly on change of configuration. On refluxing in benzene the bromo analog (**2c**) was not converted into its *trans*-isomer. But we could find the presence of *trans*-MoBr(NO)(dpe)$_2$ (ν(NO)=1547 cm^{-1}) in a separate experiment (see below). The iodo (**2d**) and NCS (**2e**) analogs exhibit no such isomerism. Unfortunately the low solubility of the complexes in usual organic solvents precluded the direct determination of their molecular structure by NMR spectroscopy.

In the $[CoX(NO)(diars)_2]X$ complexes, Feltham and Nyholm observed an effect of the halogen ligand (X) on the preference of one configuration over the other. Their data are indicative of increasing stability of the *trans* configuration up the halogen group. The tendency observed holds in our $MoX(NO)(dpe)_2$ (X=F, Cl, and Br) series as well. Graham estimated the order of σ-inductive strength F>Cl>Br>I and π-donor strength F>Cl>Br>I.[18] Since the NO ligand has a strong π-acidity, we expect that the ligand which has a considerable π-donor ability may be preferred for the *trans* ligand to NO. We may conclud that is the reason why we can obtain only the *trans* isomer of the fluoro complex. The ν(NO) of the *trans* complexes are lowered with increasing π-donor strength of halogens.

Table 2. XPS data for some molybdenum nitrosyl complexes

Complex	N 1s(eV)	Mo 3p3/2(eV)
cis-$MoCl(NO)(dpe)_2$ (**2b**)	400.4	394.5
trans-$MoCl(NO)(dpe)_2 \cdot 1/2C_6H_6$ (**2f**)	400.0	394.4
$Mo(NO)_2Cl_2(PPh_3)_2$	401.6	396.5
$Mo(CO)_5(PPh_3)$		393.5
$MoCl_2(CO)_3(PPh_3)_2$		395.7

The XPS data of **2b**, **2f**, and related complexes are given in Table 2. Hughes and Baldwin have observed a linear relationship between 3d and 3p binding energies of molybdenum and a charge parameter q calculated as the sum of the partial ionic characters over the metal-ligand bonds.[19] The observed 3p3/2 binding energy for the complexes (**2b**) and (**2f**) corresponds to a q_{Mo} value nearly intermediate between $Mo(CO)_5(PPh_3)$ and $MoCl_2(CO)_3(PPh_3)_2$, indicating a substantial electroneutrality for the NO ligand. In terms of a formal oxidation state, the molybdenum would be closest to Mo(I). The nitrogen 1s binding energies for **2b** and **2f** are fairly low as expected from the low ν(NO) in their IR spectra. As stated above, however, the M–N–O system is found to be essentially linear. The low N 1s energy of these complexes is responsible for their reactivity to protonic acids, which will be described in the following section.

Reaction of Nitrosyl Complexes with Protonic Acids. As stated above, **1a** is prepared from the reaction of **2a** with aqueous HPF_6 in benzene. Similarly with HBF_4, **2a** gives $[MoF(HNO)(dpe)_2]BF_4$ (**1b**). $[MoF(HNO)(dpe)_2]I_3$ (**1c**) was obtained by the reaction of **1a** with I_2. It has been tried to prepare some cationic HNO (nitroxyl) complexes by using common protonic acids (Table 3). King and Leigh reported that in CH_2Cl_2, $MoCl(NO)(dpe)_2$ did not react with hydrogen chloride.[9] Treatment of **2b** with an excess of dry hydrogen chloride in benzene, however, gives the complex formulated as $MoCl_2(HNO)(dpe)_2$ (**1d**) as a violet precipitate. From **2f**, **1d** was also obtained similarly. We can not determine whether **1d** is a seven-coordinate 18-electron species or a cationic complex. So far suitable crystals for X-ray crystal structure determination have not been obtained. The one chlorine atom is labile and easily replaced by a non-coordinating anion, *i.e.*, PF_6 or BPh_4 to afford stable crystalline products, $[MoCl(HNO)(dpe)_2]X$ [X=PF_6(**1e**) and BPh_4(**1f**)]. In contrast with **1e** and **1f**, the protonic H of the HNO ligand of **1d** is very labile; dissolved in acetone, **1d** releases hydrogen chloride spontaneously to afford *trans*-$MoCl(NO)(dpe)_2$ (**2f'**).

With dry hydrogen bromide, **2c** gives $MoBr_2(HNO)(dpe)_2$ (**1g**) as a violet precipitate. Complex **1g** decomposed easily in acetone to afford a mixture of yellow and orange yellow crystals. The IR spectrum of the former indicated that it was the starting material (**2c**). That of the latter show ν(NO) at 1547 cm^{-1} and its elemental analysis suggests that it has the same composition as **2c**. We may conclude that it is the *trans* isomer of $MoBr(NO)(dpe)_2$ and that the isomer with higher NO

Table 3. HNO complexes of molybdenum

a) Recorded in KBr.

frequency (**2c**) is the *cis* one. The mixture was recrystallized from CH_2Cl_2 to give pure crstals of **2c**. The *trans* isomer could not be obtained free from the *cis* isomer.

Complex **2a** reacts similarly with dry hydrogen chloride or hydrogen bromide giving the complex consisting almost entirely of **1d** or **1g**, fluorine content being negligible. The reaction of **2f'** with dry hydrogen bromide affords a complex approximately formulated as $MoClBr(NO)(dpe)_2$ (**1h**). But chlorine seems to be partially replaced by bromine. In contrast, treatment of **2a** with an excess of aqueous hydrochloric or hydrobromic acid gives the neutral complex **2b** or **2c**. Complex **2a** was also treated with benzoyl chloride, with the aim of isolating compounds incorporating the organic moiety, but the formation of such derivatives was not observed, **2f** being the only product isolated. Protonation of N_2H, N_2R, or N_2COR ligands in the complexes formally isoelectronic to **2a** took place even with aqueous hydrochloric acid.[8,21,22] This means that the ligating NO is a weaker base than those ligands. Trifluoroacetic acid reacted with **2a** giving yellow crystals of $Mo(OCOCF_3)(NO)(dpe)_2$ (**2g**). IR bands for $\nu_{asym}(CO_2)=1700\ cm^{-1}$ and $\nu_{sym}(CO_2)=1410\ cm^{-1}$ are characteristic of those of the unidentate trifluoroacetate-complexes.[23]

Complex **4** also reacts with aqueous HPF_6 in toluene–methanol to yield **1a** and H_2. With aqueous hydrogen chloride, **4** gives the mixture of **2b** and **2f** with the evolution of H_2. In contrast with $MoX(NO)(dpe)_2$ (X=F, Cl, and Br) and **4**, the complexes such as **3b**, **3c**, and $MoCl_2(NO)_2(PPh_3)_2$ did not react with HPF_6. These results are consistent with the expectation that the protonation of the nitrosyl group leading to HNO derivatives is possible only in the case of nitrosyl complexes of particularly low ν(NO), *i.e.*, with a substantial negative charge localized on the NO ligand.[20] The nitrosyl complexes (**2a**—**g**) were unreactive to other electrophiles such as NO or O_2.

On treatment of **2a** with benzoyl bromide, a blue solid was obtained, which although slightly impure, proved to be $MoFBr(HNO)(dpe)_2$ (**1i**). The simple addition of hydrogen bromide, which was presumably provided by adventitious moisture, seems to have occurred.[22]

Characterization of Nitroxyl Complexes. Protonation of the NO ligand may occur at either the nitrogen or oxygen atom. The ^1H NMR spectrum of **1a** shows a doublet, integrating for one proton, centered at 10.1 ppm, which is assigned to the N–H proton. This assignment is consistent with the observation that the H atom attached to a nitrogen atom adjacent to a transition metal ion exhibits a ^1H NMR resonance at much lower field than δ 6 ppm.[24] This resonance disappared on addition of ^2H_2O. The HNO resonance of a previously reported cobalt complex is δ 7.9.[25] The anomalously large coupling constant ($J=130$ Hz) is tentatively assigned to the long-range coupling with the Mo–F fluorine atom. Unfortunately, the ^{19}F NMR spectrum of **1a** showed only a P–F signal and no Mo–F was observed possibly because of its multiplicity. The doublet pattern of ^{31}P NMR spectrum of the DPE ligands is ascribed to the coupling not with the N–H proton but with the Mo–F fluorine atom. The N–H proton NMR resonance was observed only for **1a**. In the other complexes the N–H proton resonance may coincide with other resonance or be very broad,[26] or the measurement was impossible due to their instability.

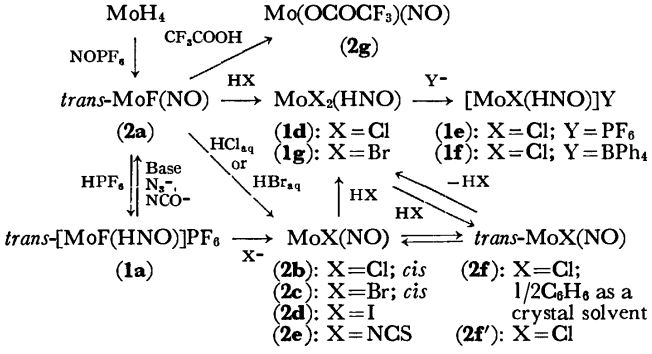
All the HNO complexes show a strong band at 1600—1650 cm^{-1} assigned to ν(NO) in their IR spectrum, in the ν(NO) region observed for $RhCl(HNO)(PPh_3)_3$.[27] The complex $RhCl(NOH)(PPh_3)_3$, which is the only one example of a proton attack at oxygen, was reported to have no band ascribable to ν(NO). It is noticiable that ν(NO) of the complexes containing fluorine ligands is lower than those containing chlorine or bromine. We were able to detect very weak N–H IR absorptions only in **1c** (2400 cm^{-1}) and **1i** (2386 cm^{-1}). In the other complexes, perhaps because of an electronic effect, the IR absorptions may be very weak and broad. Similar behavior was observed in the diazenido complexes of Mo and W,[8] and HNO complexes of Re.[26]

Based upon the ^1H NMR and IR data, we propose that the protonation of the NO ligand occurred at the nitrogen atom. Several examples of protonation of metals to give hydrides have been reported in reactions with NO^+ in the presence of methanol.[7] No signals, however, were observed in the hydride region. The presence of protonic H in **1a** was also supported by the reaction with triethylamine, which afforded $[NEt_3H]PF_6$ with the formation of Complex (**2a**) (Eq. 3).

$$\underset{(\mathbf{1a})}{trans\text{-}[MoF(HNO)(dpe)_2]PF_6} \underset{HPF_6}{\overset{NEt_3}{\rightleftharpoons}} trans\text{-}MoF(NO)(dpe)_2\cdot 1/2C_6H_6 \quad (3)$$
$$(\mathbf{2a})$$

Other complexes having a non-coordinating anion also react with the amine to afford the corresponding nitrosyl complex with concomitant formation of ammonium salts. As stated above, the others decompose spontaneously to the neutral nitrosyls in solution, whereas evolved hydrogen halides can be trapped as ammonium halides in the presence of triethylamine.

Reaction Pathways of the Interconversion of Nitrosyl and Nitroxyl Complexes. The reactions of the nitrosyl and nitroxyl complexes are summarized in Scheme 1. We observed the selective formation of *trans*-nitrosyl complex (**2f'**) by decomposition of **1d** in acetone,



dpe ligands are omitted for clarity.

Scheme 1.

whereas *cis* isomer (**2b**) was exclusively obtained by the reaction of **1a** with LiCl. The stereochemistry of **1d** is unknown because of its instability. For the seven-coordinate polyhedra, geometrical isomers are not yet established by X-ray diffraction, as shown in a recent review.[28] If **1d** is seven-coordinate with both the chlorine atoms *trans* to the HNO ligand, loss of one chlorine with concomitant proton dissociation would result in the formation of *trans*-nitrosyl complex.

Preferential formation of *cis* isomer from **1a** and LiCl makes a marked contrast with the finding above. Two possible pathways are conceivable in the fluoride displacement reaction; a dissociative path and an associative path.[29] The simple case is that of a dissociative mechanism. If the intermediate is a square-pyramid having an open face where the leaving group was located, one would expect that the addition of a new group yields 100% *trans* product. The trigonal-bipyramidal intermediate is expected to yield a mixture of *cis* and *trans* product.

One possible elucidation of selective formation of *cis* isomer is that the entering group X attacks the complex by an associative mechanism and furthermore that Y attacks through any one of the edges of the octahedron *trans* to the leaving group, that is, from the back of the complex. If attack of X had been *cis* to the leaving group, 100% *trans* product would be obtained. We consider that the back side attack of X does occur since it is possible that X makes some hydrogen bond to H of the HNO ligand. That is, the entering group X is anchored to the back side of the complex, attack from the front side having been made impossible. In fact such hydrogen bonding of N_2H_2 ligand with BF_4^-,[11] and I^- [30] was observed from X-ray analysis.

Fluorine displacement was widely observed in the reactions in Scheme 1: simple anion exchange, **2a**→**2b**, **2c**; nitroxyl formation with anion exchange, **2a**→**1d**, **1g**; nitrosyl formation with anion exchange, **1a**→**2b**, **2c**, **2d**, **2e**. In these reactions a seven-coordinate complex must be included as the intermediate or at least in the transition state. In contrast, fluorine was retained in the reactions of **1a** with N_3^- or NCO^-. The product selectivity in these reactions may be apprehensible in terms of pK_a of the conjugated acid (HX) of the anion X. The pK_a of HX is as follows: HF, 3.14; HCl, −7, HBr, −9; HI, −10; HNCS, 0.85; HOCN, 3.46; HN_3, 4.72; CF_3COOH, <0.6. The anion X with pK_a(HX) lower than pK_a(HF) undergoes substitution of the fluorine ligand by X, whereas those with greater pK_a results in the retention of the fluorine, elimination of the weaker acid having occurred preferentially. That is, direct correlation was found between pK_a of various acids in water and the propensity to add to metal complexes.

Experimental

All operations were conducted under nitrogen at room temperature or as otherwise stated. $MoH_4(dpe)_2$, *trans*-$Mo(N_2)_2(dpe)_2$, *trans*-$Mo(CO)(N_2)(dpe)_2$, $Mo(CO)(C_2H_4)(dpe)_2$, $Mo(C_2H_4)_2(dpe)_2$, and *cis*-$Mo(CO)_2(dpe)_2$ were prepared accoding to the published methods. ^1H (100 MHz), ^{19}F (94.2 MHz), and ^{31}P (40.5 MHz) NMR spectra were recorded on a computer-assisted EOL PS-100 spectrometer. IR spectra were recorded on a JASCO IRA-2 spectrophotometer. X-ray photoelectron binding energies were recorded on a JASCO ESCA-1 electron spectrometer and were referenced to the carbon ls line (taken to be 285.0 eV) of each sample. The Mg K_α X-ray line (1253.6 eV) was used as a photoelectron excitation source.

Reaction of $MoH_4(dpe)_2$ with $NOPF_6$. To a suspension of $MoH_4(dpe)_2$ (4.4 g) in benzene (350 ml) was added a freshly prepared solution of $NOPF_6$ (0.9 g) in methanol (10 ml). The evolution of hydrogen was observed. The mixture was stirred at room temperature for 4 h. After the mixture turned dark brown, a dark red solid precipitated. Addition of hexane to the mixture deposited an additional quantity of the complex. The precipitate was filtered, washed with ether, recrystallized from acetone–ether and dried *in vacuo* to yield dark red crystals of **1a** (2.3 g, 43%). Further addition of hexane to the mother liquor precipitated yellow crystals. The crystals were filtered, washed with methanol, recrystallized from benzene–hexane and dried *in vacuo* to yield **2a** (0.70 g, 15%). The presence of benzene as the crystal solvent was confirmed by gas chromatography of a toluene solution of the complex.

Reaction of Diphosphine Complexes of Mo (0) with $NOPF_6$. To a solution of *trans*-$Mo(N_2)_2(dpe)_2$ (0.95 g) in benzene (50 ml) was added a freshly prepared solution of $NOPF_6$ (0.35 g) in methanol (5 ml). After the mixture was stirred at ambient temperature for 4 h, the mixture deposited dark red crystals, which were filtered, washed with hexane and dried *in vacuo* to yield 0.59 g (54%) of $[MoF(N_2H_2)(dpe)_2]PF_6$ (Found: C, 58.0; H, 4.7; N, 2.3%. Calcd for $C_{52}H_{50}N_2F_7P_5Mo$: C, 57.5; H, 4.6; N, 2.6%). Similarly, the reaction of *trans*-$Mo(CO)(N_2)(dpe)_2 \cdot 1/2C_6H_6$ with $NOPF_6$ afforded **3b** [ν(CO) = 1934 cm^{-1}] (17%) and a mixture of *cis*-$Mo(CO)_2(dpe)_2$ and *trans*-$[Mo(CO)_2(dpe)_2]PF_6$. The reaction of $Mo(CO)(C_2H_4)(dpe)_2$ afforded **3b** (16%) and a mixture of the dicarbonyl complexes. The reaction of $Mo(C_2H_4)(dpe)_2$ afforded **3c** (5%).

$[Mo(NO)(dpe)_2]_2 \cdot 2C_6H_6$. To a solution of *trans*-$Mo(N_2)_2(dpe)_2$ (200 mg) in benzene (30 ml) was bubbled NO_2-free NO. When the reaction was complete, as indicated by the color, the undissolved brown solid [IR ν(NO) = 1775 and 1665 cm^{-1}] were removed from the solution by filtration. Addition of hexane to the filtrate deposited yellow crystals, which were filtered, washed with hexane and dried *in vacuo* to yield 42 mg (20%) of **4**. The presence of benzene as the crystal solvent was checked by gas chromatographic analysis of a toluene solution of the complex. The undissolved brown solid increased with time; apparently it is a product of successive reaction of **4** with NO. Its purification, however, was unsuccessful.

Reaction of trans-$Mo(N_2)_2(dpe)_2$ with NOCl. To a solution of *trans*-$Mo(N_2)_2(dpe)_2$ (155 mg) in toluene (10 ml) was added 6% NOCl in toluene (2 ml) (NOCl/Mo = 10). The mixture was stirred for 40 min during which time dinitrogen was evolved. A greenish brown solid precipitated, which was filtered, washed with hexane and recrystallized from CH_2Cl_2–hexane, yield 80 mg. The IR spectrum of the product showed that it was a mixture of two complexes, $MoCl_3(NO)\{Ph_2P(=O)CH_2CH_2PPh_2(=O)\}$ [ν(NO) = 1690 cm^{-1}], and $MoCl_2(NO)_2\{Ph_2P(=O)CH_2CH_2PPh_2(=O)\}$ [ν(NO) = 1770 and 1660 cm^{-1}]. In the case of NOCl/Mo = 1, a mixture of three complexes, 2f′ [ν(NO) = 1543 cm^{-1}], $MoCl_2(NO)_2\{Ph_2P(=O)CH_2CH_2PPh_2(=O)\}$], and the starting material was obtained.

*Reaction of **1a** with Alkali Metal Salts.* Acetone (20 ml) was added to the mixture of **1a** (500 mg) and LiCl (240 mg).

The resulting orange brown suspension was quickly filtered. From the filtrate yellow crystals deposited on standing, which were filtered, washed with acetone and dried *in vacuo* to yield 221 mg (50%) of **2b**. Similar procedures using LiBr, LiI, NaSCN, NaNCO, and NaN_3 afforded **2c** (55%), **2d** (17%), **2e** (50%), **2a** (48%), and **2a** (41%), respectively.

Reaction of 1a with $NaBH_4$. Tetrahydrofuran (50 ml) was added to **1a** (385 mg) and $NaBH_4$ (43 mg), and the mixture was stirred for 8 h. Solvent was then evaporated off *in vacuo* to leave a brown solid, which was recrystallized from benzene–hexane to yield yellow crystals of **4** (156 mg, 44%) (Found: C, 70.1, H, 5.6; N, 1.1%. Calcd for $C_{116}H_{108}O_2N_2P_8Mo$: C, 69.6; H, 5.4; N, 1.4%).

Interconversion of 2b and 2f. The solution of **2b** (52 mg) in benzene (5 ml) was refluxed for 1 h. On addition of hexane, yellow crystals precipitated, which were filtered, washed with hexane and dried *in vacuo* to yield 34 mg (63%) of **2f**. Similarly, dissolved in CH_2Cl_2, **2f** was converted to **2b** (61%) after 1 d.

Reaction of 2a with Protonic Acids. To a solution of **2a** (30 mg) in benzene (3 ml) was added a 65% aqueous solution of HPF_6 (0.1 mg). The mixture, which turned orange brown immediately, was stirred for 1 h at room temperature. Solvent was then evaporated off *in vacuo* to leave a reddish brown powder, which was recrystallized from acetone–ether to yield dark red crystals of **1a** (23 mg, 70%). Similar procedures using $NOPF_6$–MeOH, HBF_4, and I_2 afforded **1a** (76%), **1b** (72%), and **1c** (24%), respectively.

$MoCl_2(HNO)(dpe)_2$. On bubbling HCl gas into a solution of **2a** (91 mg) in benzene (10 ml) for 30 min, a violet powder precipitated. The complex, which was too unstable for recrystallization, was filtered, washed with benzene and hexane, and dried *in vacuo*, to yield 74 mg (80%) of **1d**. The complex contained no fluorine and complete displacement by chlorine seems to have occurred (Found: Cl, 7.0; F, 0%. Calcd for $C_{52}H_{49}ONP_4Cl_2Mo$: Cl, 7.1; F, 0%). Similarly the reactions of **2b** and **2f** with HCl gas afforded **1d** in 87 and 85% yield, respectively. The reactions of **2a**, **2c**, and **2f′** with HBr gas afforded **1g** (70%), **1g** (82%), and **1h** (73%), respectively.

Conversion of 1d and 1g into Nitrosyl Complexes. Complex **1d** (122 mg) was dissolved in acetone (5 ml). The initial violet suspension became a yellow solution, from which a yellow precipitate was obtained and analyzed as **2f′** (91 mg-77%) (Found: C, 64.6; H, 4.9; N, 1.2%. Calcd for $C_{52}H_{48}ONP_4ClMo$: C, 65.2; H, 5.0; N, 1.5%). The IR spectrum shows ν(NO) at 1543 cm^{-1}. Recrystallization of **2f′** from benzene–hexane yielded yellow crystals containing 1/2 mol solvated benzene. Similarly, **1g** was converted into a mixture of yellow crystals[ν(NO) = 1567 cm^{-1}] and orange yellow crystals[ν(NO) = 1547 cm^{-1}]. The former was formulated as **2c**. The latter was also analyzed as $MoBr(NO)(dpe)_2$ and supposed to have the *trans* configuration (Found: C, 62.0; H, 5.0; N, 1.2; Br, 7.8%. Calcd for $C_{52}H_{48}ONP_4BrMo$: C, 62.3; H, 4.8; N, 1.4; Br, 8.0%). Recrystallization of the mixture from CH_2Cl_2–ether gave yellow crystals of **2c** (60%).

Reaction of 1d with Non-coordinating Anions. Acetone (10 ml) was added to the mixture of **1d** (124 mg) and KPF_6 (50 mg). After stirring for 10 min the mixture was filtered. The filtrate, a light-green solution was evaporated to dryness and the solid residue was recrystallized from acetone–ether to give 100 mg (73%) of **1e** as violet crystals. A similar procedure using $NaBPh_4$ afforded **1f** (79%).

Anion Substitution of 2a. Aqueous hydrogen chloride (0.5 ml, 35% solution) was added to **2a** (80 mg) in acetone (5 ml). After stirring for 1 h, the precipitate was filtered, recrystallized from CH_2Cl_2–ether to yield 47 mg (60%) of **2b**. Similar procedures using aqueous hydrogen bromide, benzoyl chloride, and trifluoroacetic acid afforded **2c** (54%), **2b** (83%), and **2g** (41%), respectively. The reaction of **2a** with benzoyl bromide afforded **1i** (39%), but no satisfactory analyses were obtained for the product (see Table 3), which was found to be contaminated with a small amount of **1g** (IR).

Reaction of 4 with Protonic Acids. On addition of 65% aqueous solution of HPF_6 (0.07 ml) to a solution of **4** (80 mg) in toluene (5 ml)–methanol (1 ml), an immediate reaction took place yielding a reddish brown solution. Evolution of hydrogen was confirmed by GLC. Addition of hexane deposited dark red crystals, which were filtered to yield 61 mg (70%) of **1a** (Found: C, 57.7; H, 4.8; N, 1.2%. Calcd for $C_{52}H_{49}ONF_7P_5Mo$: C, 57.4; H, 4.5; N, 1.3%). A similar procedure using aqueous hydrogen chloride afforded a mixture of **2b** and **2f**, which was recrystallized from CH_2Cl_2–ether to give **2b** (45%) (Found: C, 64.9; H, 5.2; N, 1.2%. Calcd for $C_{52}H_{48}ONP_4ClMo$: C, 65.2; H, 5.0; N, 1.5%).

Reaction of 1a with Triethylamine. To a solution of **1a** (99 mg) in acetone (5 ml) was added triethylamine (0.5 ml) in benzene (3 ml). On standing the resulting yellow solution, a yellow powder precipitated, which was filtered, washed with ether and dried *in vacuo* to yield 41 mg (46%) of **2a**. Addition of hexane to the filtrate deposited an additional quantity of **2a** contaminated with $[NEt_3H]Cl$ (IR) which was washed with methanol and dried. The combined yield amounted to 68%.

Photochemistry of Host-Guest Complex. III.[1] Effect of Guest Cation on the Photoreactivity of Acetophenone Oxime Derivatives Having Crown Ether Moiety

Masaru TADA,* Hideki HIRANO, and Atsushi SUZUKI

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received November 12, 1979)

The *syn-anti* isomerization of acetylbenzocrown ether oximes was stimulated by the complex-formation with sodium ion. The photolysis of these oximes gave mother ketones and amides through an oxaziridine intermediate. The photolysis of the oximes was depressed by the formation of host–guest complexes. Reactivity in the photolysis of the crown ether oximes corresponds to that of 3,4-dimethoxyacetophenone oxime, whereas the reactivity of the complexed crown ether oxime with sodium ion corresponds to that of *p*-cyanoacetophenone oxime. Such behavior is explained by the change of the electronic properties of excited states of acetophenone oxime chromophore, which enhances the intersystem crossing.

Few photochemical reactions of crown ether and cryptand have been reported, though these classes of compounds are the targets of active current research.[2] Hautala and Hasting[3] observed the stimulated type II fission of monovalery-dibenzo-18-crown-6 by the formation of the complexes with alkali metal ions. In our earlier study,[4] the photochemical cross coupling between 18-crown-6 and alkyl aryl ketones was enhanced by the introduction of a cyano group or a potassium salt of carboxylato-group at the terminal position of the alkyl aryl ketone. These groups form complexes with crown ether and can hold radical pairs nearby by host–guest interaction or Coulomb interaction. Now we report the photochemical behavior of acetylbenzocrown ether oximes.

Experimental

Syntheses of Oximes. A mixture of benzo-15-crown-5 (930 mg, 3.5×10^{-3} mol), acetic acid (240 mg, 4.0×10^{-3} mol), and polyphosphoric acid (15 ml) was heated to 80 °C for 3 h under stirring. After cooling, the mixture was diluted with 30 ml of water under further cooling and stirred for 30 min to hydrolyse the polyphosphoric acid. The precipitate was combined with the chloroform extract and washed with saturated sodium hydrogencarbonate solution and water. Evaporation of chloroform after drying over magnesium sulfate gave a pale yellow solid. Recrystallization of the solid from ethanol gave acetylbenzo-15-crown-5 (**3b**) (40% yield). Mp, 93—95 °C: IR($CHCl_3$), 1665 cm^{-1}; NMR ($CDCl_3$) (δ), 2.50 (3H, s), 3.67—4.30 (crown ether), 6.78 (1H, d, J=9 Hz), and 7.51 (2H, m).

A mixture of acetylbenzo-15-crown-5 (**3b**) (200 mg, 6.5×10^{-4} mol), hydroxylamine hydrochloride (70 mg, 1.0×10^{-3} mol), and potassium acetate (100 mg, 1.5×10^{-3} mol) was heated under reflux for 2 h in a mixed solvent of ethanol, chloroform, and water (10: 3: 2). After cooling, the reaction mixture was diluted with 10 ml of water. Chloroform extraction (20 ml×3) of the mixture gave a pale yellow solid after conventional work-up. Recrystallization from methanol gave a colorless acetylbenzo-15-crown-5 oxime (**1b**) in 75% yield. Mp, 133—135 °C. Found: C, 58.75; H, 7.02; N, 4.38%. Calcd for $C_{16}H_{23}NO_6$: C, 59.06; H, 7.13; N, 4.31%. $\lambda_{max}^{CH_3CN}$ 263 (17300) and 294 nm (7050); IR ($CHCl_3$): 3560, 3450—3100, 1599, 1503, 1419, and 1130 cm^{-1}; NMR ($CDCl_3$) (δ): 2.21 (3H, s), 3.69—4.22 (crown ether), 6.78 (1H, d, J=9 Hz), 7.10 (1H, dd, J=9 and 1 Hz), 7.21 (1H, d, J=1 Hz), and 8.75 (1H, br, s).

The same procedure gave acetylbenzo-18-crown-6 oxime (**1c**). Mp, 106—107 °C. Found: C, 58.21; H, 7.67; N, 3.84%. Calcd for $C_{18}H_{27}NO_7$: C, 58.52; H,7.37; N, 3.79%. IR ($CHCl_3$): 3560, 3450—3100, 1602, 1510, 1432, and 1140 cm^{-1}; NMR ($CDCl_3$) (δ): 2.24 (3H, s) 3.68—4.34 (crown ether), 6.84 (1H, d, J=9 Hz), 7.12 (1H, dd, J=9 and 1 Hz), 7.23 (1H, d, J=1 Hz), and 9.20 (1H, br, s).

Acetophenone Oxime Derivatives. 3,4-Dimethoxyacetophenone oxime (**1a**), acetophenone oxime, *p*-chloroacetophenone oxime, *p*-methoxyacetophenone oxime, and *p*-cyanoacetophenone oxime were synthesized from the mother ketones in the manner used for the preparation of acetylbenzo-15-crown-5 oxime (**1b**); these oximes have the reported physical constants.

General Procedure of Photochemical Reaction. One of the oximes in 10 ml of appropriate solvent was placed in a Pyrex tube (unless otherwise mentioned) and irradiated externally by using a Rikosha rotary irradiation-apparatus equipped with a 450 W high pressure mercury lamp mounted in a quartz cooling jacket. The distance between tubes and the lamp was *ca.* 5 cm. The absorption spectra of the oximes (**1a**, **1b**, and **1c**) show large extinction coefficients around the emission lines of the lamp at 302.5 and 313 nm and no absorption is seen at 366 nm. The spectra were changed only slightly by addition of sodium, potassium, or tetramethylammonium salts. The concentration of the oximes for irradiation were arranged to absorb more than 99.9% of the emission-light from the lamp at 302.5 and 313 nm, so that all samples in the rotary irradiation-apparatus absorb essentially equal number of photons.

Geometrical Isomerization. A preparative scale experiment was carried out in acetonitrile by irradiation of one of the oximes (5.0×10^{-2} mol/dm^3, 10 ml) for 6 h. The reaction mixture was separated by chromatography on a silica gel plate eluted with chloroform–ethyl acetate (2: 1). The *syn*-isomer of 3,4-dimethoxyacetophenone oxime (**1a**) gave almost identical IR and NMR spectra to its *anti*-isomer, but the chemical shift of acetoxime methyl is slightly different. 3,4-Dimethoxyacetophenone oxime (**1a**): *anti*-isomer (δ,2.26); *syn*-isomer (δ, 2.19). Acetylbenzo-15-crown-5 oxime (1b) has a similar spectral property: *anti*-isomer (δ, 2.21); *syn*-isomer (δ, 2.19). Recrystallization of the *syn*-isomer formed photochemically gave original *anti*-isomer.

A solution (1.6×10^{-1} mol/dm^3) of one of the oximes (**1a** or **1b**) placed in an NMR sample tube was irradiated in the presence of sodium perchlorate, and the ratio of *syn*- and *anti*-oxime was determined by NMR analysis using the relative intensity of the acetoxime methyls.

Photolyses in Acetic Acid. One of the oximes (**1a** or **1b**)

in anhydrous acetic acid was irradiated until the starting material disappeared. Evaporation of the solvent *in vacuo* and chromatography on an alumina column eluted with chloroform gave the products. The products were further separated by chromatography on a silica gel plate. This was eluted with chloroform–ethyl acetate (2 : 1) for the products from dimethoxyacetophenone oxime (**1a**) and with chloroform–ethyl acetate–methanol (2: 1: 0.1) for the products from acetylbenzo-15-crown-5 oxime (**1b**). The mother ketones were obtained as major products (*ca.* 70%) and two types of amide (**4a**, **4b**), with arene migration and methyl migration respectively, were obtained in *ca.* 30% yield.

An acetic acid solution (6.25×10^{-2} mol/dm^3, 10 ml) of one of the oximes (**1a** or **1b**) combined with various amounts of sodium acetate was irradiated for only 10 min. Within this period less than 0.1% of the starting oxime was converted to oxaziridine. Immediately after irradiation the solution were combined with an aqueous solution of potassium iodide and starch under magnetic stirring; then the mixture was allowed to stand for 10 min. These solutions were titrated with aqueous sodium thiosulfate. The results are shown in Table 1.

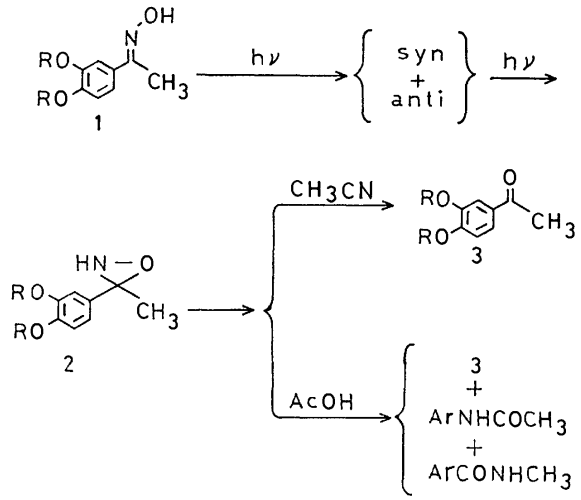
Photolysis in Acetonitrile. One of the oximes (**1a**, **1b**, **1c**) (5.0×10^{-2} mol/dm^3) in acetonitrile–water (20 : 1) was irradiated until the starting oxime disappeared. Evaporation of the solvent and chromatography gave the mother ketone in quantitative yield.

Various amounts of sodium, potassium, or tetramethylammonium salts were added to an acetonitrile solution (5.0×10^{-2} mol/dm^3, 10 ml) of one of the oximes. The mixture was irradiated until 30—40% of the starting oxime disappeared (10—15 h), then the reaction mixture was condensed *in vacuo*. The residue was extracted three times with chloroform (20 ml×3). After drying over magnesium sulfate the combined extract was condensed to about 3 ml and the precipitated sodium perchlorate was removed. The filtrate was further condensed and analyzed by NMR spectroscopy in deuteriochloroform containing measured amount of tetrachloroethane as an internal reference. This procedure can extract both complexed and non-complexed acetylbenzo-15-crown-5 (**1b**) almost completely and hence the relative yield of **3** can be determined with reasonable accuracy. The results thus obtained for **1b** and **1c** are shown in Figs. 2 and 3.

Photolysis of Acetophenone Oxime Derivatives. An acetonitrile solution (5.0×10^{-2} mol/dm^3, 10 ml) of one of the oxime derivatives was irradiated for 16 h; less than 20% of the starting oximes were consumed within this period. The work-up used for the photolysis of the oximes (**1a**, **1b**, **1c**) and NMR analyses using tetrachloroethane as an internal reference gave the results shown in Fig. 4.

Results and Discussion

Irradiation of 3,4-dimethoxyacetophenone oxime (**1a**) caused *syn-anti* isomerization at the early stage. Further irardiation gave the mother ketone (**3a**) in quantitative yield in acetonitrile containing or not containing water. Prolonged irradiation of (**1a**) in glacial acetic acid gave two amides, formed by photochemical Beckmann rearrangement, as minor products (*ca.* 30%) in addition to the mother ketone (**3a**) (*ca.* 70%). In the same manner, acetylbenzo-15-crown-5 oxime (**1b**) and acetylbenzo-18-crown-6 oxime (**1c**) gave similar products to those obtained in the case of oxime (**1a**). One type of amide was identical to the authentic sample prepared by Beckmann rearrangement of the *anti*-oximes by the



1a, 2a, 3a: R=CH_3
1b, 2b, 3b: R=$-(CH_2CH_2O)_3CH_2CH_2-$

Scheme 1.

catalysis of sulfuric acid. This type of amide must be formed by migration of arene moiety. Though the structure of the other type of amide has not been studied in detail, its NMR spectra show clearly the existence of the *N*-methyl group (δ, 2.95), and hence the amide must be formed by methyl migration. The photoreactivity of oximes should be the same, whether or not they contain crown ether moiety.

Geometrical Isomerization. The effect of sodium perchlorate on *syn-anti* isomerization is changed by the introduction of crown ether moiety into the oxime. As shown in Fig. 1, the isomerization of acetylbenzo-15-crown-5 oxime (**1b**) in chloroform–methanol (3 : 4) was stimulated in the presence of sodium perchlorate. On the other hand, the isomerization of 3,4-dimethoxyacetophenone oxime (**1a**) was only slightly affected. These results clearly show that the complexation of

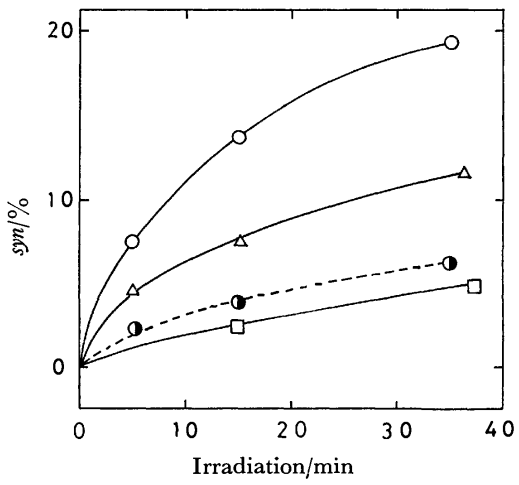

Fig. 1. Geometrical isomerization of **1a** and **1b** (1.6×10^{-1} mol dm^{-3}) in $CHCl_3$–CH_3OH (3: 4).
□—□: **1a** or **1b** without added salt, ◑···◑: **1a**+$NaClO_4$ (1.06 mol dm^{-3}), △—△: **1b**+$NaClO_4$ (0.16 mol dm^{-3}), ○—○: **1b**+$NaClO_4$ (1.06 mol dm^{-3}).

sodium cation stimulates the isomerization of crown ether oxime (**1b**). Geometrical isomerization of an oxime has been reported to take place from a triplet excited state.[5] The complexation of (**1b**) must therefore increase the quantum yield of this triplet state.

Oxaziridine Formation. A mother ketone and two amides are believed to form photochemically through an oxaziridine intermediate.[5,6] We analyzed the oxaziridine by iodometry[6] at the very early stage of photolysis (10 min) in glacial acetic acid. Only 0.1% of oxaziridine was formed within this period, so secondary photolysis to produce the mother ketone and amides shoud be negligible. Therefore, the values obtained by iodometry must be a good measure of relative quantum yield of the oxaziridine intermediate (**2**) in the presence of sodium acetate (see Table 1).

TABLE 1. RELATIVE QUANTUM YIELDS OF OXAZIRIDINE FORMATION FROM **1a** AND **1b** IN THE PRESENCE OF SODIUM ACETATE

Added NaOAc[a]	Starting oxime	
	1a[b]	**1b**[b]
0.0	1.00	1.00
5.0	0.76	0.82
10.0	0.60	0.68
15.0	0.53	0.48
20.0	0.51	0.29

a) Molecular equivalents of NaOAc to the oxime. b) 6.25×10^{-2} mol dm^{-3} solution of **1a** and **1b** in acetic acid was used.

The relative quantum yield of oxaziridine formation from acetylbenzo-15-crown-5 oxime (**1b**) deviates from those of 3,4-dimethoxyacetophenone oxime (**1a**) in somewhat higher concentrations of the added sodium acetate. The formation constant of the complex between **1b** and sodium acetate was determined by Benesi-Hildebrand method;[7] the value is very small (K=2—3 M^{-1}) in acetic acid. The small formation constant must be one of the major factors of the salt effect only in the higher concentration range.

The photochemical formation of oxaziridine from an oxime has been reported to occur from a singlet state.[5,6] Hence the complexation seems to retard the process involving a singlet excited state of crown ether oxime (**1b**). The similar decrease in the quantum yields for both **1a** and **1b** in the lower concentration range of the added salt must be due to the basic nature of sodium acetate. It has been established that a base inhibits the photolysis of an oxime.[8]

Formation of Mother Ketones. Prolonged irradiation of the oximes (**1a**, **1b**, and **1c**) in acetonitrile containing or not containing water gave only the mother ketones. Fig. 2 shows the effect of sodium salts on photolyses, The mother ketone must be derived from the oxaziridine intermediate by a photochemical or thermal process.[6] Since no other product than the mother ketone was obtained, the relative quantum yield of the ketone must be a reasonable reflection of the formation of oxaziridine intermediate, whatever the

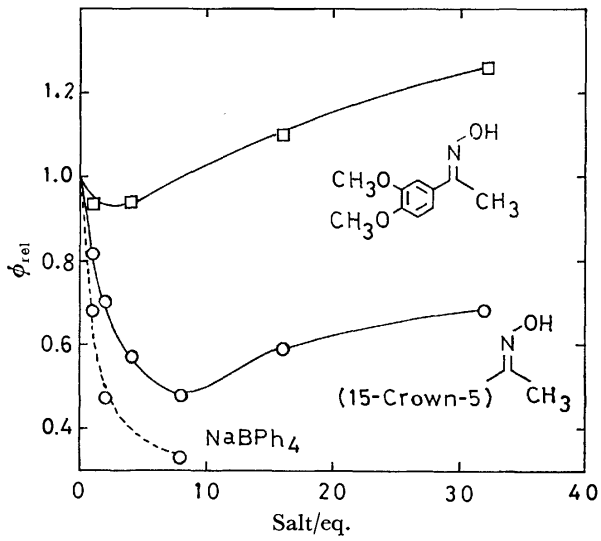

Fig. 2. Relative quantum yield of the mother ketone on photolysis of **1a** (1.3×10^{-1} mol dm^{-3}) and **1b** (5.0×10^{-2} mol dm^{-3}) in CH_3CN–H_2O (20: 1) in the presence of sodium salt.
□—□: **1a**+$NaClO_4$, ○—○: **1b**+$NaClO_4$, ○···○: **1b**+$NaBPh_4$.

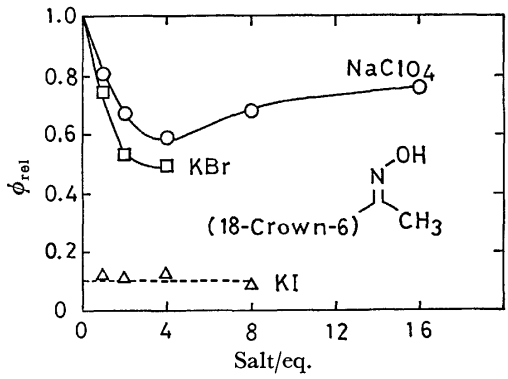

Fig. 3. Relative quantum yield of the mother ketone on photolysis of **1c** (5.0×10^{-2} mol dm^{-3}) in CH_3CN–H_2O (20: 1) in the presence of alkali metal salts.
○—○: $NaClO_4$, □—□: KBr, △···△: KI.

mechanism of formation is. The photolysis of acetyl-15-crown-5 oxime (**1b**) was depressed by sodium salts in the lower concentration range. By contrast, 3,4-dimethoxyacetophenone oxime (**1a**) showed only a slight effect. Recovery of the reactivity is seen in both types of oxime in higher concentration range of the added sodium perchlorate; this effect can be accounted for by the enhanced acidity or the polarity of the reaction media. It is well established that the photolysis of oxime is stimulated by acidic or polar conditions.[8-10] The effect of complex formation on the reactivity, therefore, must be limited to the lower concentration range of the added sodium perchlorate. The Benesi-Hildebrand method[7] gave the formation constant of *ca.* 5×10^2 M^{-1} for the complex between crown ether oxime (**1b**) and sodium ion from perchlorate in acetonitrile. Sodium tetraphenylborate depressed the photolysis strongly, though the effect in higher concentration could not be tested due to the insolubility of the

salt. A similar result was obtained with crown ether oxime (**1c**). Potassium salts were more effective. In the case of potassium iodide, however, a different mechanism must be operative to account for its powerful quenching. An electron transfer from iodide ion to the excited oxime is the most probable mechanism.[11]

Mechanism of Salt Effect. Hitherto discussed phenomena suggest that the effect of alkali metal salts on the photoreactivity of crown ether oximes differs to some extent according to the counter ion of the salts. So we can not deny the effect of perchlorate anion on the reactivity of crown ether oximes in the presence of sodium perchlorate, but the photolysis of 3,4-dimethoxyacetophenone oxime (**1a**) and acetylbenzo-15-crown-5 oxime (**1b**) were little affected by the addition of tetramethylammonium perchlorate. Therefore, it is clear that the difference in the effect of sodium perchlorate on **1a** and **1b** must be due to the formation of host–guest complexes between crown ether oxime and sodium cation. The slightly concave curve for oxime (**1a**) in Fig. 2 may indicate a weak chelation of sodium ion by the dimethoxybenzene moiety of **1a**.

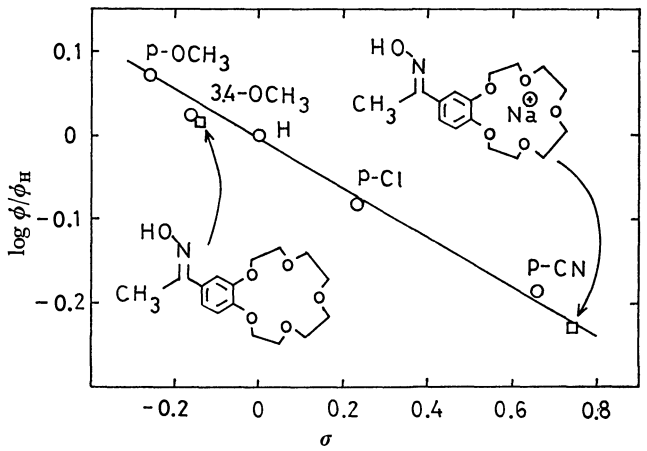

Fig. 4. Relative quantum yield of the mother ketones from acetophenone oxime derivatives (5.0×10^{-2} mol dm^{-3}) in CH_3CN.

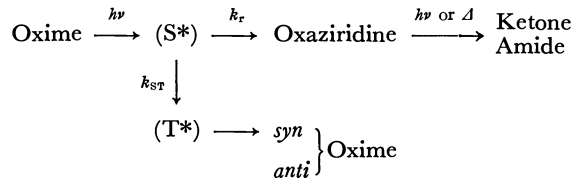
Complexation of a cation in the cavity of crown ether must reduce the electron donating ability of alkoxyl groups. Such a change must affect the nature of both the excited state and the ground state of aromatic oximes. Actually the photoreactivity of acetophenone oxime derivatives varies depending on the electronic nature of the substituent on the benzene ring (see Fig. 4). The oxime having an electron donating substituent has higher reactivity than the oxime having an electron withdrawing substituent. Though we can not clarify the exact nature of the excited state responsible for the photolysis, the relative quantum yields of the ketone formation from acetophenone oxime derivatives in acetonitrile show a linear correlation with Hammet σ-constant. The photoreactivity of free crown ether oxime (**1b**) corresponds to that of oxime (**1a**), and the reactivity of the complexed **1b** with sodium ion, obtained by extrapolation of the curve in Fig. 2, corresponds to *p*-cyanoacetophenone oxime. The complexation of crown ether oxime (**1b**) with sodium ion induces a slight change in its electronic absorption spectrum, a small hypsochromic shift (*ca.* 3 nm) and a small decrease in extinction coefficient, but the complexation may affect the nature of the excited state more profoundly.

The photochemistry of oximes can be summarized by the scheme shown below, which was established by



Mukai and Oine[6] and de Mayo *et al.*[5] A singlet state of oxime gives an oxaziridine, which affords a mother ketone and an amide on further photolysis or thermal process. A triplet excited state, on the other hand, causes geometrical isomerization. Our findings show that the formation of a host–guest complex stimulates the geometrical isomerization and depresses the formation of oxaziridine. The present results and the general scheme indicate that the ratio of the rate of intersystem crossing to the rate of oxaziridine formation (k_{ST}/k_r) becomes larger with the host–guest complex than with the free crown ether oxime. There are a several possible explanations of this behavior. First, the spin-orbital coupling may vary by complex formation due to a heavy atom effect and modify the rate of intersystem crossing (k_{ST}); but a light atom such as sodium usually does not show such a heavy atom effect.[12] Second, the difference in energy gap between a singlet and a triplet excited state (ΔE_{ST}) may alter the rate of intersystem crossing (k_{ST}). Unfortunately, these oximes are non-emissive, at least in the solvent system used for photoreaction, and no direct information on the excited state was available. However, the change in electronic absorption spectra was not remarkable by complex formation—a small hypsochromic shift of *ca.* 3 nm—and we do not consider this factor to be important. Third, any electronic property of the excited state must affect both k_r and k_{ST}. In analogy with alkyl aryl ketones,[13] the excited state of the acetophenone oxime derivatives must reduce the $n\pi^*$ character of the singlet state by introduction of an electron donating substituent such as alkoxyl group and diminish the rate of intersystem crossing, $(n\pi^*)^1\rightarrow(\pi\pi^*)^3$. On the other hand, an electron withdrawing substituent such as cyano group enhances an $n\pi^*$ nature of the singlet state and hence the rate of intersystem crossing. This concept is reasonable, since the intersystem crossing $(n\pi^*)^1\rightarrow(\pi\pi^*)^3$ is larger than the intersystem crossing $(\pi\pi^*)^1\rightarrow(\pi\pi^*)^3$.[14] This is the most reasonable explanation for the depression of the formation of oxaziridine which affords the mother ketone and amides, and the stimulated geometrical isomerization from $(\pi\pi^*)^3$. We believe the variation in the electronic property of the excited states is the most important factor in characterizing the photochemical behavior of the host–guest complex of acetylbenzocrown ether oximes.

(Received November 12, 1979)

Several *N,O*-diacyl-*N*-*t*-butylhydroxylamines and *O*-acyl-*N*-*t*-butylhydroxylamines were prepared, and their thermal decompositions were studied. The thermal decompositions of *N,O*-diacyl-*N*-*t*-butylhydroxylamines in tetralin gave substituted *N*-*t*-butylbenzamides, carboxylic acids, 1,1′-bitetralyl, and 1,2-dihydronaphthalene as the major products, together with small amounts of carbon dioxide, *t*-butylamine, and benzanilides. In the thermal decompositions of *O*-acyl-*N*-*t*-butylhydroxylamines, the products were *t*-butylamine, carboxylic acids, substituted *N*-*t*-butylbenzamides, 1,1′-bitetralyl, and 1,2-dihydronaphthalene.

It is well known that such chemical bonds as the O–O bonds in diacyl peroxides are cleaved on heating in both homolytic and heterolytic manners.[1] Although a number of workers have investigated the thermal decomposition of diacyl peroxides, few surveys of the thermal properties of the acylated hydroxylamines have appeared in the literature.[2] *N,O*-Dibenzoylhydroxylamine decomposes thermally, giving mainly phenyl isocyanate and benzoic acid (Lossen rearrangement), and the decomposition initiates the polymerization of methyl methacrylate.[2a] Horner and Steppan examined the thermal decomposition of *N,O*-diacyl-*N*-arylhydroxylamines at 180—190 °C and found *N,O*-diacyl-*o*-aminophenols as the main products, together with 20—30% of carbon dioxide. They suggested that at least 20—30% of the decomposition underwent the homolytic cleavage of the N–O bond. On the other hand, the thermal decomposition of *N,O*-diacyl-*N*-*t*-alkylhydroxylamines has not yet been studied. The alkyl group on the nitrogen atom would suppress such reactions as the Lossen rearrangement and the migration of the acyloxyl group; hence, a different type of thermolysis would result. In order to obtain further information about the thermal properties of the N–O bond in hydroxylamine derivatives, we have studied the thermal decompositions of *N*-*O*-diacyl-*N*-*t*-butylhydroxylamines and *O*-acyl-*N*-*t*-butylhydroxylamines, with tetralin as the solvent.

Results and Discussion

Preparation of N,O-*Diacyl*-N-t-*butylhydroxylamines.* The *N,O*-diacyl-*N*-*t*-butylhydroxylamines (**1**) and *O*-acyl-*N*-*t*-butylhydroxylamines (**2**) were prepared by the reactions of *N*-*t*-butylhydroxylamine and the corresponding acyl chlorides in the presence of pyridine. The reactions of *N*-*t*-butylhydroxylamine with an excess of acyl chlorides gave **1a**—**d**; the results are summarized in Table 1. On the other hand, the reaction of *N*-*t*-butylhydroxylamine with an equivalent of acyl chloride afforded **2** as the main product. The results are summarized in Table 2. Under reduced pressure, *O*-benzoyl-*N*-*t*-butylhydroxylamine (**2a**) and *O*-*p*-toluoyl-*N*-*t*-butylhydroxylamine (**2b**) could be isolated by distillation, although the distillation was accompanied by a slight decomposition. The other hydroxylamines

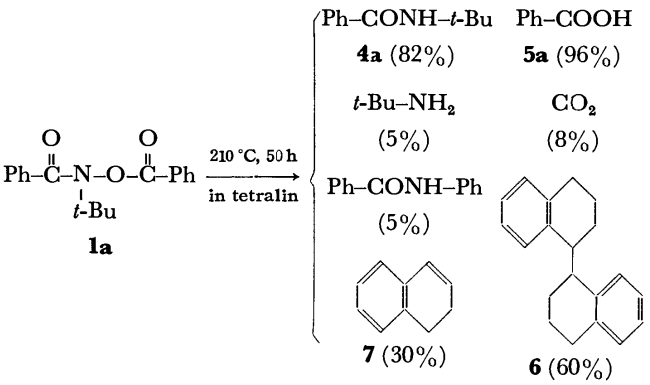
Scheme 1.

Thermal Decomposition of N,O-*Diacyl*-N-t-*butylhydroxylamines.* *N,O*-Diacyl-*N*-*t*-butylhydroxylamines (**1**) were quite stable in comparison with *N,O*-dibenzoylhydroxylamine[2a] or *N,O*-diacyl-*N*-arylhydroxylamines,[2b] and no detectable decomposition was observed below 180 °C. Therefore, the thermal decompositions of **1** were carried out in tetralin as the solvent above 205 °C. In the thermal decompositions of **1a—d**, bearing the same acyl groups on the N and O atoms, the corresponding substituted *N*-*t*-butylbenzamides (**4**) and carboxylic acids (**5**) were formed as the products in good yields. These products were isolated by extraction from the reaction mixture with an alkaline solution and by means of column chromatography, and then identified by comparing their properties with those of authentic samples. The yields of the products were estimated by means of GLC; the results are summarized in Table 3. A detailed product analysis was performed for the thermal decomposition of **1a**; *N*-*t*-butylbenzamide (**4a**) and benzoic acid (**5a**) were found along with minor amounts of *t*-butylamine as the salt of benzoic acid, benzanilide, and carbon dioxide. 1,1'-Bitetralyl (**6**) and 1,2-dihydronaphthalene (**7**) were also obtained as the products derived from tetralin. On the gas chromatogram of the reaction mixture, the stereoisomers of **6** showed two distinct peaks of approximately equal intensities, as had been reported by Williams.[3]



Scheme 2.

In each of the thermal decompositions of **1e—k**, bearing different acyl groups on the N and O atoms, two kinds of amides (**4**) and acids (**5**), originating from the two different acyl groups, were formed. These results are also given in Table 3. For example, on heating in tetralin at 210 °C for 26 h, **1e** was completely decomposed, giving *N*-*t*-butylbenzamide (**4a**) (82%) and *p*-toluic acid (**5b**) (82%) as the major products plus small amounts of *N*-*t*-butyl-*p*-toluamide (**4b**) (13%), benzoic acid (**5a**) (9%), and carbon dioxide (4%).

Oae and Sakurai studied the reaction of *N*-aroyl-*O*-3,5-dinitrobenzoyl-*N*-phenylhydroxylamines with sodium cyanide in dipolar aprotic solvents at room temperature.[4] The products were aroylanilides and a small amount of carbon dioxide. They suggested that the reaction proceeds *via* the decarboxylation of a Meisenheimer-type complex formed as an intermediate, as in the displacement reaction of polynitro aromatics. Although the formation of the anilides is quite comparable to the present results of thermal decompositions, the mechanisms of those two reactions must be quite

different, since no efficient nucleophile is present and since a nonpolar solvent was used in the present reaction. Moreover, in the present case, the *O*-acetyl derivative (**1h**) can not form such a complex. It is also unlikely that the *O*-benzoyl, *O*-*p*-toluoyl, and *O*-*p*-methoxybenzoyl derivatives, without bearing such an electron-withdrawing substituent as a nitro group, would form a complex in tetralin. In addition, the product, **6**, derived from tetralin could not be explained in terms of such ionic mechanisms. The precursors of **6** are obviously the tetralyl radicals formed by the abstraction of a hydrogen atom from tetralin. Dihydronaphthalene (**7**) would also be formed from the tetralyl radicals by disproportionation. Thus, the formation of these products suggests a homolytic decomposition of **1**, giving the acylaminyl radical and the acyloxyl radical. However, the amount of carbon dioxide formed by the thermal decomposition is too small to be accounted for by the decarboxylation of the acyloxyl radical formed by the homolysis of the N–O bond of **1**.

In order to compare the yields of carbon dioxide, the thermal decomposition of benzoyl peroxide was carried out under the same conditions as in the thermolysis of **1a**. When benzoyl peroxide was heated in tetralin (0.05 M, 1 M=1 mol dm^{-3}) at 210 °C for 2 h, benzoic acid and carbon dioxide were formed in 37 and 60% yields respectively, based on benzoyl peroxide. These results indicate a facile decomposition of the benzoyloxyl radical at that temperature to give carbon dioxide rather than the abstraction of a hydrogen atom from the solvent to give benzoic acid. Moreover, no detectable amount of benzene was formed in the thermal decomposition of **1a**. It is also highly unlikely that the acetoxyl radical efficiently abstracts a hydrogen atom from tetralin to give acetic acid at this temperature, because the acetoxyl radical has been known to be unstable and more easily decarboxylates than the benzoyloxyl radical.[5] On the contraly, acetic acid was formed in a high yield by the decomposition of *N*-benzoyl-*O*-acetyl-*N*-*t*-butylhydroxylamine (**1h**). These results rule out the mechanism involving homolytic fission of the N–O bond of **1**, giving the acylaminyl radical and the acyloxyl radical, as the main process of the reaction.

A probable mechanism for the thermal decomposition of **1** which is in accordance with the present results is shown in Scheme 3. The thermal decomposition of **1** would be initiated by the attack of a nucleophile, which may consist of some trace impurities or the products formed by the thermal decomposition of the hydroxylamine itself. This is suggested on the basis of the facts that a certain induction period was observed in the thermal decomposition of **1e** at 205 °C, as is shown in Fig. 1. The addition of a small amount of *t*-butylammonium benzoate to the reaction solution obviously depressed the induction period and accelerated the rate

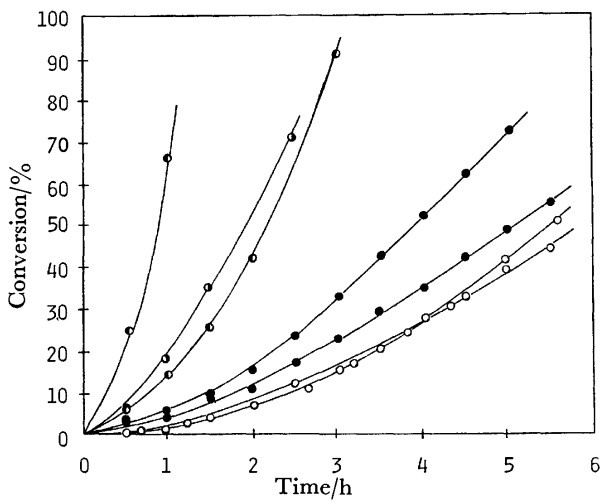

Fig. 1. Thermal decomposition of *N*-benzoyl-*O*-*p*-toluoyl-*N*-*t*-butylhydroxylamine in tetralin (0.1 M) at 205.0±0.2 °C.
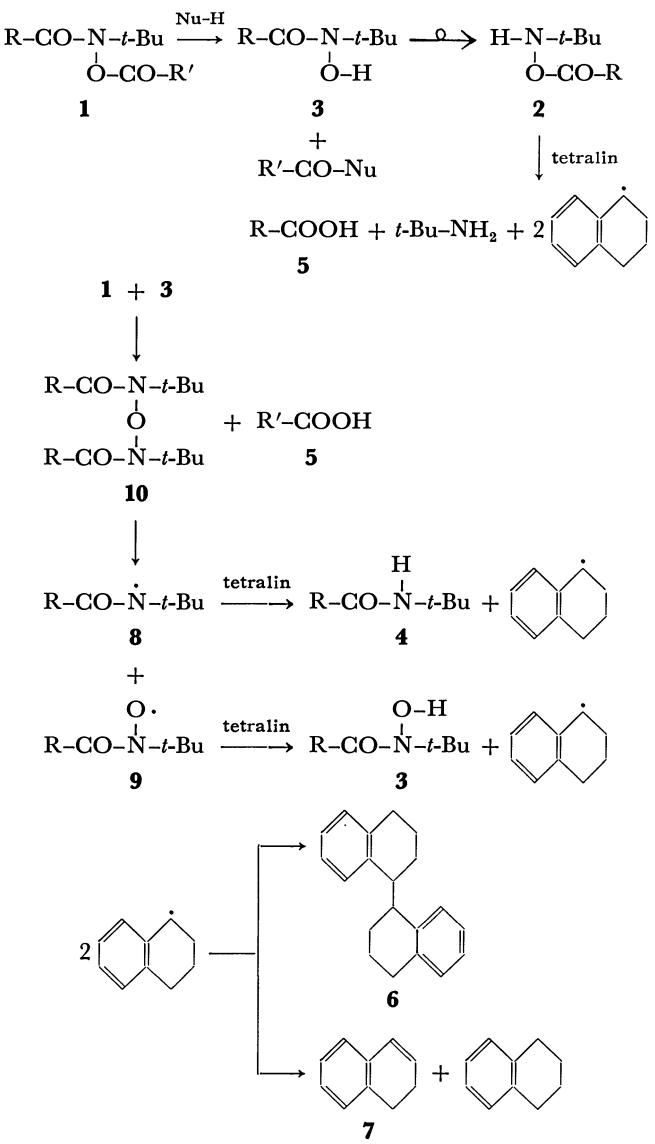
○: No additive, ●: in the presence of an equilolar amount of benzoic acid, ◐: in the presence of 10 mol% of *t*-butylammonium benzoate, ◑: in the presence of 10 mol% of *N*-benzoyl-*N*-*t*-butylhydroxylamine (**3a**).

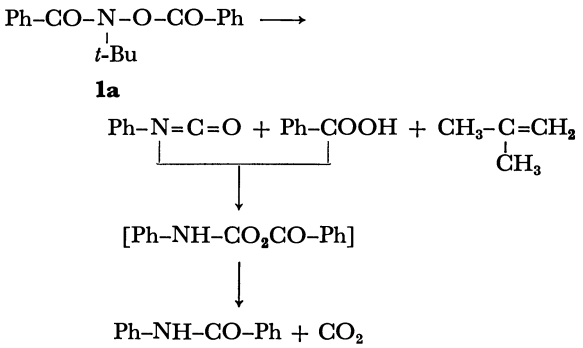


Scheme 3.

of the decomposition. The reactions of some *N,O*-diacylhydroxylamines with amines,[6] sodium methoxide, sodium azide, thiophenols, and sodium cyanide[4] have been studied. In those reactions, the nucleophiles attack the carboxylic carbonyl carbon atom of the reactant. By analogy, the nucleophile would attack the carboxylic carbonyl carbon atom of **1e** in the present reaction, giving *N*-benzoyl-*N*-*t*-butylhydroxylamine (**3a**) in the initiation reaction.

Although *t*-butylammonium benzoate accelerated the rate of the decomposition, the mechanism of the thermal decomposition of **1** requires the formation of radical species, because the hydrocarbons, **6** and **7**, are formed from the solvent. This can be explained by a mechanism in which the initial reaction gives *N*-acyl-*N*-*t*-butylhydroxylamine (**3**), which then reacts with **1** to give the acylaminyl radical (**8**), the acylaminoxyl radical (**9**), and carboxylic acid (**5**). These radicals and acid may be formed by the nucleophilic attack of **3** upon the N atom of **1**, thus forming **5** and the intermediate (**10**). This process was confirmed by the observation that the thermolysis of **1e** was apparently accelerated by the addition of a small amount of **3** as is shown in Fig. 1. The intermediate (**10**) probably collapses rapidly into the radicals (**8** and **9**) under the conditions used. The radicals (**8** and **9**) would then abstract hydrogen atoms from the solvent to form amide (**4**) and to regenerate **3** respectively. A similar substitution reaction on the nitrogen atom has been established in the reaction of *O*-acetyl-*N*-benzoyl-*N*-(*p*-methoxyphenyl)hydroxylamine with phenols, pyrrole, and indoles.[7]

The mechanism shown in Scheme 3 does not involve the formation of carbon dioxide. In detailed product studies of the thermal decomposition of **1a**, benzanilide was found (5%). This suggests that a part of the **1a** undergoes Lossen rearrangement to form benzoic acid, phenyl isocyanate, and 2-methylpropene. The isocyanate would rapidly react with benzoic acid, giving benzanilide and carbon dioxide as follows:[8]



Under the same conditions, slow acyl-exchange reactions between the amides and acids were observed. That is, after the heating of **4a** with an equivalent of **5b** at 210 °C for 30 h, **4b** and **5a** were formed, both in 7% yields. On the other hand, the reaction of **4b** with **5a** under the same conditions gave **4a** and **5b** in 8 and 8% yields respectively. These results suggest that a route to give the minor amides (for instance, **4b** and **4c** from **1e** and **1f** respectively) and acids (for instance, **5a** and **5b** from **1e** and **1i** respectively) would be the subsequent acyl-exchange reaction between the major amide and the acid formed by the decompositions of **1e—k**.

In order to examine the prosess giving *t*-butylamine, which was found as a minor product in the thermal decomposition of **1a**, *N*-benzoyl-*N*-*t*-butylhydroxylamine (**3a**) was heated in tetralin. On heating **3a** in tetralin at 150 °C, a rearranged product (**2a**) was isolated and characterized. The further heating of the reaction mixture at 210 °C for 2 h gave *t*-butylammonium benzoate (50%). These results suggest that *t*-butylamine was derived from **3a** *via* **2a** during the thermal decomposition of **1a**. The same results also suggest an alternative route for the formation of minor amides (**4**) and minor acids (**5**) in the decomposition of **1e—k**, bearing different acyl groups on the N and O atoms. In the initiation reaction of the decomposition of **1**, the attack of *t*-butylamine upon the carboxylic carbonyl carbon atom of **1** gives the minor amide and **3**, which then subsequently decomposes to afford a minor acid and *t*-butylamine. The amounts of the minor amide and the minor acid, which appeared to be somewhat higher

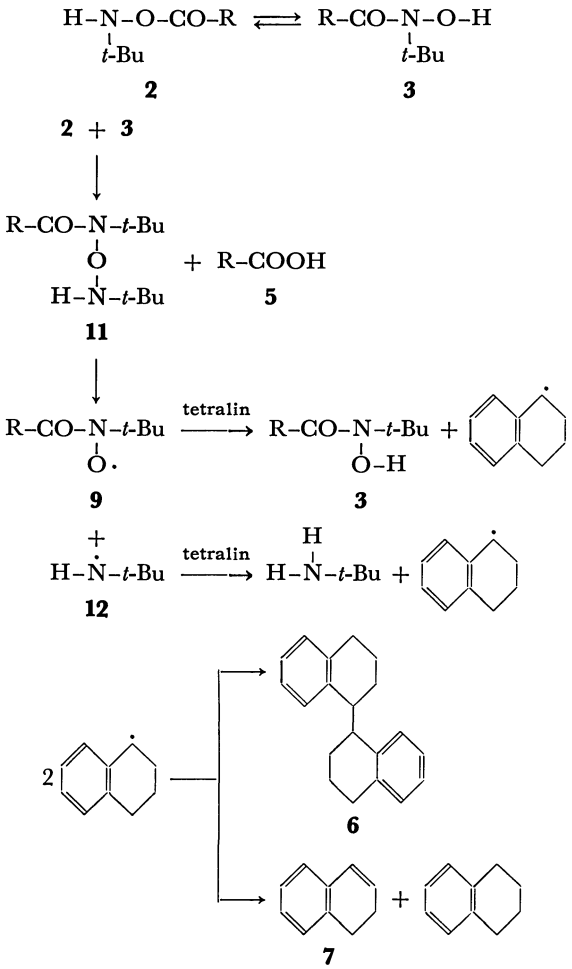
than would be expected from the slow acyl-exchange reaction alone, may be explained by these two processes, *i.e.*, the acyl-exchange reaction and the rearrangement reaction.

Thermal Decomposition of O-*Acyl*-N-t-*butylhydroxylamines.* In order to study the thermal properties of *O*-acyl-*N*-*t*-butylhydroxylamines (**2**), and also to prove the intermediacy of **2** during the thermal decomposition of **1**, several **2** were prepared and subjected to thermal decomposition. On heating at 210 °C for 4 h in tetralin, **2** decomposed completely, giving *t*-butylamine and carboxylic acid as a salt in high yields, together with a small amount of the amide (**4**). The products derived from tetralin, **6** and **7**, were also obtained in substantial yields. These results are summarized in Table 4. No



Scheme 4.

detectable amount of carbon dioxide was formed in the thermal decomposition of **2**. Thus, we can eliminate the possibility which involves the homolytic fission of the N–O bond of **2** to yield aminyl and acyloxyl radicals. The mechanism involving the nitrene intermediate is unlikely because *t*-butylnitrene does not afford *t*-butylamine in a good yield.[9] These results suggest that the decomposition of **2** involves the initial formation of *N*-acyl-*N*-*t*-butylhydroxylamine (**3**), which subsequently reacts with the starting material, resulting in the formation of an aminyl radical (**12**) and an acylaminoxyl radical (**9**), as is shown in Scheme 4. These radicals would abstract hydrogen atoms from tetralin to yield *t*-butylamine and to regenerate **3** respectively.

Experimental

All the melting points and the boiling points are uncorrected. The IR spectra were recorded on a Shimadzu IR-430 infrared spectrometer. The tetralin was washed succesively with concd H_2SO_4, aq NaOH, and water, dried over $CaCl_2$ and distilled under reduced pressure. The distillate was passed through a column of alumina and redistilled before use.

Preparation of N,O-*Diacy*-N-t-*butylhydroxylamines (1).* *(a)*: Benzoyl chloride (112.5 g, 0.800 mol) was added to a solution of *N*-*t*-butylhydroxylamine (30.0 g, 0.337 mol) and pyridine (63.3 g, 0.800 mol) in dry benzene (700 cm^3) at room temperature with stirring. The mixture was then heated at 60 °C for 15 h with stirring. The mixture was cooled, washed with aq NH_4OH, dil aq NaOH, dil HCl, and water, and dried over Na_2SO_4. The solvent was evaporated *in vacuo*, and the residue was recrystallized from CH_2Cl_2–petroleum ether, thus giving **1a** (69.3 g, 69%); mp 98.0—99.0 °C (lit, 98—99 °C).[10] By the reaction of *N*-*t*-butylhydroxylamine with the corresponding acyl chloride, **1b—d** were prepared similarly. The yields, physical properties, and elemental analyses are shown in Table 1.

(b): *p*-Toluoyl chloride (19.7 g, 0.127 mol), was added to a solution of **3a** (22.4 g, 0.116 mol) and pyridine (10.0 g, 0.127 mol) in dry benzene (200 cm^3), after which the whole mixture was stirred at 75 °C for 12 h. The reaction mixture was washed with aq NH_4OH, dil aq NaOH, dil HCl, and water, and dried over Na_2SO_4. The solvent was evaporated *in vacuo*, and the residue was recrystallized from CH_2Cl_2–petroleum ether, thus giving **1e** (29.5 g, 82%). By the same procedures, **1f**, **1g**, and **1h** were prepared by the reactions of **3a** with the corresponding acyl chlorides. The reactions of **2a** with the corresponding acyl chlorides gave **1i**, **1j**, and **1k**. The yields, physical properties, and elemental analyses are shown in Table 1.

Preparation of O-*Acyl*-N-t-*butylhydroxylamines (2).* Benzoyl chloride (127 g, 0.90 mol) was added to a solution of *N*-*t*-butylhydroxylamine (80 g, 0.90 mol) and pyridine (78 g, 1.0 mol) in dry ether (500 cm^3), after which the mixture was refluxed with stirring for 15 h. The reaction mixture was then washed with aq NH_4OH, dil aq NaOH, dil HCl, and water, and dried over Na_2SO_4. The solvent was evaporated, and the residue was distilled under reduced pressure to give *O*-benzoyl-*N*-*t*-butylhydroxylamine (**2a**) (135 g, 78%); bp 101—104 °C/3 mmHg** (lit, 73 °C/0.5 mmHg).[10] The distillate was then further purified by chromatography on silica gel, with CH_2Cl_2 as the eluent. By the same procedure

** Through this paper 1 mmHg=133.322 Pa.

as has been described above, **2b—d** were prepared. The yields, physical properties, and elemental analyses are shown in Table 2.

Preparation of N-*Benzoyl*-N-t-*butylhydroxylamine (3a).* A solution of NaOH (10.2 g, 0.255 mol) in water (40 cm³) was added to a stirred suspension of **1a** (43.7 g, 0.147 mol) in methanol (200 cm³). The mixture was then stirred at room temperature for 1.5 h. After the evaporation of the methanol under reduced pressure, water (200 cm³) and ether (50 cm³) were added to the residue. The separated water layer was acidified with HCl. The formed crystals were taken in ether, and the ethereal solution was washed with saturated $NaHCO_3$ and water, and dired over Na_2SO_4. The ether was then evaporated, and the residue was recrystallized from CH_2Cl_2–petroleum ether to give **3a** (23.4 g, 82%); mp 108—109 °C (lit, 109 °C).[10]

Thermal Decomposition of 1. A solution of **1** in tetralin (0.1 M, 20 cm³) was sealed in a degassed tube with break-off tips at both ends and then heated in a constant-temperature bath at 210 °C. The tube was opened in a vacuum system, and the carbon dioxide formed by the decomposition was introduced into an aq $Ba(OH)_2$ solution (0.1 M, 50 cm³) after having been passed through a cold trap by a nitrogen stream. The $Ba(OH)_2$ solution was filtered, and the filtrate (40 cm³) was titrated with HCl (0.1 M). An excess of an ethereal solution of diazomethane was added to the decomposition mixture, and the mixture was allowed to stand for 1 h. After the evaporation of the ether *in vacuo*, the reaction mixture was subjected to GLC analysis, with the addition of a known amount of biphenyl as an internal standard. The following three columns were used a 2-m column packed with Apiezon Grease L (30%) on Cerite 545 to analyze methyl benzoate; a 2-m column packed with Thermon 1000+H_3PO_4 (5+0.5%) on Chromosorb W to analyze the amides, bitetralyl, and methyl esters, and a 5-m column packed with polyethylene glycol 20 M (25%) on Shimalite 101 to analyze dihydronaphthalene. The results are summarized in Table 3.

Thermal Decomposition of 2. A solution of **2a** in tetralin (0.1 M, 20 cm³) sealed in a degassed ampule was heated in a constant-temperature bath at 210 °C for 4 h. After cooling, the precipitated *t*-butylammonium benzoate was collected by filtration, and washed with petroleum ether. The filtrate was subjected to GLC analysis after methylation with diazomethane.

Kinetic Procedure. A solution of **1e** (0.1 M, 25 cm³) in tetralin was placed in a reaction vessel fitted with a gas-inlet tube and a reflux condenser. It was heated in a constant-temperature bath (205.0±0.2 °C) after nitrogen had been bubbled into, for 30 min. Aliquots were withdrawn at scheduled intervals and quenched by chilling to 0 °C. The aliquot (100 mm³) and methanolic NaOH (0.25%, 10 cm³) were placed in a volumetric flask (25 cm³), and the mixture was heated in a water bath at 65 °C for 30 min. After a methanolic iron(III) chloride solution (10 cm³) had been added, the solution was diluted to the volume of the flask with methanol and the absorbance at 510 nm was measured. The iron(III) chloride solution was prepared by dissolving 5 g of $FeCl_3 \cdot 6H_2O$ in 1 dm³ of methanol containing HCl (0.0321 M) to prevent iron(III) hydroxide formation.[11]

The Confirmation of the Configuration of Ethyl 2-Bromo-3-nitro-2-alkenoate by ^{13}C NMR Spectroscopy

Chung-gi SHIN, Yasuchika YONEZAWA, Katsumi AJISAKA,† and Juji YOSHIMURA*,††

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

††*Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227*

(Received November 26, 1979)

The configuration of the ethyl 2-bromo-3-nitro-2-alkenoate formed by the elimination of hydrogen bromide from ethyl 2,3-dibromo-3-nitroalkanoate was determined to be (*Z*) by the examination of the ^{13}C NMR spectra.

In a previous paper, it was found that the base-catalyzed elimination of hydrogen bromide from a *threo* and *erythro* mixture of ethyl 2,3-dibromo-3-nitroalkanoate (**1**) afforded only one kind of geometric isomer of ethyl 2-bromo-3-nitro-2-alkenoate (**2**).[1] The same phenomenon was also observed in the case of a *threo* and *erythro* mixture of ethyl 2-acetoxy-3-nitroalkanoate.[2] The configuration of **2** was deduced to be (*Z*) from the fact that the reduction of **2** with diethyl phosphonate gave ethyl 3-nitro-2-alkenoate (**3**) with the (*E*)-configuration,[3] the geometry of which was determined by ^1H NMR spectroscopy.[1]

In the present investigation, the authors measured the ^{13}C NMR spectra of **2** and related compounds in order to confirm the configuration of **2** and then discussed the reaction mechanism.

Results and Discussion

The ^{13}C NMR chemical shifts of Compounds **2** and **3** and of ethyl (*E*)- and (*Z*)-2-nitro-2-alkenoates [(*E*)-**4**, and (*Z*)-**4**] are presented in Table 1. It is noticeable that, in every (*E*), and (*Z*) isomeric pair of 3-nitro-2-alkanoate, **3**, each carbon at positions C-1, C-2, and C-3 (for numbering, see Table 1) of the (*Z*)-isomer always resonates at a higher field than does the corre-

a) The carbons were commonly numbered as follows: $\overset{6}{C}\text{–}\overset{5}{C}\text{–}\overset{4}{C}\text{–}\overset{3}{C}X{=}\overset{2}{C}Y\text{–}\overset{1}{C}OO\overset{1'}{C}H_2\overset{2'}{C}H_3$.

† Present address: Ajinomoto Co., Inc., Central Research Laboratories, 1-1 Suzuki-cho, Kawasaki-ku, Kawasaki 210.

sponding carbon of the (*E*)-isomer. This tendency is, however, less pronounced in the case of 2-nitro-2-alkenoate, **4**.

Savitsky *et al.*[4] reported that the chemical shift of olefinic carbons of 3-substituted alkenoate with two bulky substituents in a *cis* orientation deviates from the expected value due to the alteration in the electron density by the steric inhibition of the resonance. Consequently, the above facts are attributed to the diminished electron-withdrawing effect of the nitro and ethoxycarbonyl groups of (*Z*)-**3** in the *cis* orientation. This empirical fact is a useful clue for the determination of the configuration of the isomeric pair of **2**; however, it is not applicable when only one isomer is available, as in the present case. Therefore, the observed ^{13}C shifts of olefinic carbons in **2** were compared with those calculated from the results of (*E*)- and (*Z*)-**3** and the substituent effect. The substituent effects for a series of 2-alkenoates have been studied by Lippmaa *et al.*[5,6] and by Brower and Stothers,[7] and the substituent parameter of the bromine atom suggested by Lippmaa *et al.* was used for the calculation here; that is, the shifts of the C-2 and C-3 of **3** were corrected by 8.0 ppm to an upper field by the bromination of C-2. The results are presented in Table 2. The observed shifts agree well with the calculated values for the (*Z*)-isomer, but not with those of the (*E*)-isomer. This is in accordance with our previous deduction.[1] However, it should be noticed that the observed shifts of the C-2 of (*Z*)-**2** deviate comparatively much from the calculated shifts. This deviation might also be attributed to the *cis* configuration between the bromine atom and the nitro group in (*Z*)-**2**, because such crowded compounds were not used by Lippmaa *et al.*[5,6] in determining the substituent parameters.

An analogous tendency is found in the differences in the chemical shifts ($\Delta\delta$/ppm) of the olefinic carbons of **3** or **4** and the corresponding 2-alkenoates with no nitro group[7] (Table 3). In the case of **4** with a nitro group on C-2 both (*Z*)- and (*E*)-isomers showed a similar trend. That is, the substituent shifts for both isomers were 23—25 ppm lower for C-2, to which a nitro group is attached, and 10—13 ppm higher for C-3. On the other hand, in the case of **3**, where the nitro group is attached to C-3, the substituent shifts exhibited quite different profiles. For the (*E*)-isomer, C-2 showed field shifts higher by 6—7 ppm and C-3 field shifts lower by 4—10 ppm, as was observed in the case of **4**. In contrast, the C-2 and C-3 of the (*Z*)-isomer shifted to fields lower by 0.5—1.5 and 4—14 ppm respectively. These anomalous shifts may be attributed to the factor mentioned above.

In conclusion, it can be said that the substitution shifts are strongly affected by the configuration and the position of the substituent. If the stereoelectronic influence is taken into account in the estimation of the substituent shift of the bromine atom, a much better consistency will result than is found in Table 2.

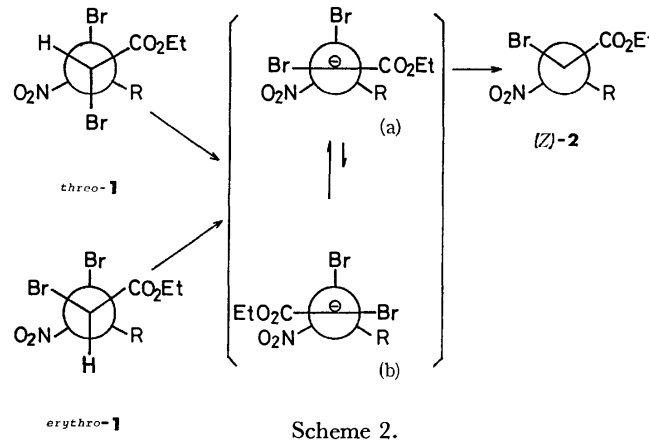
Table 2. Calculated and observed ^{13}C chemical shifts of the olefinic carbons of **2**

R	Calcd and obsd	^{13}C shifts (δ/ppm) C-2	C-3
Et	Calcd (*Z*)	112.9	156.1
	Calcd (*E*)	105.9	154.4
	Obsd	118.9	155.9
i-Pr	Calcd (*Z*)	110.9	156.1
	Calcd (*E*)	103.8	154.4
	Obsd	113.5	160.4
n-Pr	Calcd (*Z*)	113.4	156.3
	Calcd (*E*)	106.5	152.4
	Obsd	119.6	155.0

Table 3. The substituent shift[a] of C-2 and C-3 caused by the nitro group on the C-3 of **3** and on the C-2 of **4**

Compound	R	(*Z*) C-3	(*Z*) C-2	(*E*) C-3	(*E*) C-2
3	Me	14.2	0.5	9.9	−6.1
	Et	8.9	1.2	8.7	−6.8
	i-Pr	4.6	1.3	4.2	−7.1
	n-Pr	11.2	1.5	8.2	−7.0
4	Me	−10.1	25.1	−9.9	23.3
	Et	−13.7	25.3	−12.2	24.3
	n-Pr	−9.8	25.4	−12.4	23.8

a) The differences in chemical shifts between **3** or **4** and the correspondlng 2-alkenoates are shown in δ/ppm. Consequently, the negative sign implies a higher field shift upon substitution with a nitro group.



Scheme 2.

The above results show that both the *erythro* and *threo* isomers of **1** afforded only the (*Z*)-isomer of **2**. It means that the elimination from the two isomers proceeds *via* a common intermediate, analogous to the *E1cB* mechanisms proposed by Cummings and Kreuz[8] and by Kaplan *et al.*[9,10] As is shown in Scheme 2, the deprotonation of both diastereomers of **1** will result in the formation of a common, resonance-stabilized carbanion. Although two conformations, in which the leaving bromine atom is in a proper disposition for elimination, are possible for this anion, (a) will predominate over (b) because of the electrostatic repulsion between nitro and ethoxycarbonyl groups. Thus, the predominant formation of (*Z*)-**2** will result.

Experimental

The ^{13}C NMR spectra were recorded at 30 °C on a JEOL

JNM FX-100 spectrometer in the pulse Fourier transform mode at 25.15 MHz. Each spectrum was obtained after 1000 transients with a frequency range of 6250 Hz. The pulse angle of 45° was used, with an acquisition time of 0.8 s and a pulse delay of 0.7 s. All the measurements were carried out in a deuteriochloroform solution containing a drop of TMS as the internal standard. The chemical shifts were recorded in δ/ppm.

Enolate Anions. III. Substituent Effects of Sodium Diethyl Alkylmalonates in DMSO[1]

Syun-ichi KIYOOKA,* Tsukasa KODANI, and Kojiro SUZUKI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received November 30, 1979)

The conformations of sodium enolate anions, derived from diethyl malonate and diethyl alkylmalonates (alkyl=methyl, ethyl, propyl, isopropyl, butyl, isobutyl, and *s*-butyl), have been determined to be *Z,Z*-type by the analysis of their ^{1}H-NMR spectra in DMSO. In the case of diethyl *t*-butylmalonate, such a *Z,Z* type contributes to the lesser extent to the conformations of the sodium enolate anion because of repulsion between the *t*-butyl substituent and the two ethoxyl groups, which exist in three types (*Z,Z*, *Z,E*, *E,E*) of conformation, as is evident in the ^{1}H-NMR spectra. The IR spectra of sodium diethyl malonate in DMSO showed two characteristic absorption bands at 1679 and 1556 cm^{-1}. The IR isotope shifts upon the use of the enolates of diethyl malonate-2-^{13}C and diethyl malonate-1,3-$^{13}C_2$ suggested that these two bands are attributable to the C=O and C=C=C bonds. All sodium diethyl alkylmalonates except for the *t*-butyl derivative have two characteristic IR bands in the region of 1500—1700 cm^{-1}, the bands on the high-frequency side of which have nearly equal wave numbers, while those on the low-frequency side have a good correlation with the substituent constant, σ^*.

Since the reaction rates in the alkylation of enolate anions have been reported to be rapidly accelerated by the addition of dipolar aprotic solvents, such as DMSO and DMF,[2] the effect of the difference in the solvation state on the reactivity has been investigated for various reactions.[3] Because of the mutual electrostatic-interaction between a cation and an enolate anion, almost all enolate anions tend to be present as ion pairs.[4] Moreover, it is generally expected that the degree of this ion-pairing association would be altered by the extent of the solvation of the cation.

Recently, Raban *et al.* discussed the effect of the ion-pairing on the structures of the enolate anions of β-diketones on the basis of their ^{1}H- and ^{13}C-NMR spectra.[5] The relations between the reactivity of the enolate anions derived from β-diketones and the ion-pairing were reported in detail by DePalma *et al.*[6] In order to evaluate the reactivity of the enolate anions with ester groups, which are very important for organic synthesis, various spectral studies of them have been continued.[1]

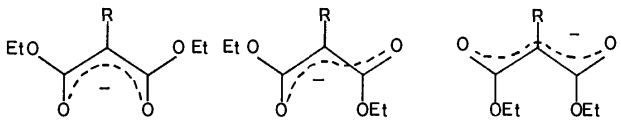
The substituent effects on the electron density at the delocalized anionic moiety of the enolate anions and on the conformations of them in DMSO were examined using the sodium enolates of ethyl substituted-phenylacetates.[1b] The ^{13}C-NMR spectra of sodium diethyl alkylmalonates were shown to correspond to a single conformer except in the case of the *t*-butyl derivative.

This report deals with alkyl substituent effects on the electron density at the delocalized anionic moiety of sodium diethyl malonates and on their conformations by means of IR and ^{1}H-NMR measurements.

Results and Discussion

The enolate anions produced from acetylacetone were found to be 100% in the *Z,Z* conformation for lithium enolate and 34% in the *Z,Z* conformation for sodium enolate in methanol-d_4.[5a] Further, the enolate anions from acetoacetaldehyde and ethyl acetoacetate exist exclusively in the *Z,Z* conformation for lithium enolates in DMF, and in the latter enolate anion, a *Z,Z* conformer is predominant even for sodium and potassium enolates.[7] The sodium enolate of ethyl 2-methylacetoacetate in DMF was shown to exist 66% in the *Z,Z* conformation, which is slightly destabilized by the introduction of the α-methyl group.[7]

Three arrangements are possible for the structures of enolate anions derived from diethyl alkylmalonates. Compared with the stereomodels of other enolate anions, such as acetylacetonato-alkali metals, those of sodium diethyl alkylmalonates are so crowded that the most preferred conformation can not be presumed by the inspection of their stereomodels alone.



Z,Z *Z,E*(⇌*E,Z*) *E,E*

Table 1 shows the ^{1}H-NMR chemical shifts of diethyl alkylmalonates and their enolate anions in DMSO. The ^{1}H-NMR spectra of the enolates with the alkyl substituents other than the *t*-butyl group can be correlated to one conformation, as has been deduced from their ^{13}C-NMR spectra;[1a] the number of conformers existing in the enolate anion can be determined simply by the inspection of the spectra of the ethoxyl groups. Upon enolate-anion formation, the chemical shifts of the methylene and methyl protons of the ethoxyl groups are shifted to a higher field, $\Delta\delta$ being +0.25—+0.30 and +0.09—+0.15 ppm respectively, while down-field shifts ($\Delta\delta$ −0.31——0.81 ppm) are observed for the β-protons. The alkyl-substituent effects for these $\Delta\delta$ values can not, however, interpreted quantitatively.

On the other hand, the unusual chemical shifts of the enolate anion with a *t*-butyl substituent are very informative in estimating the structures of these enolate-anion series in DMSO. In this enolate anion, the chemical shifts of the methylene protons in ethoxyl groups are observed at 3.44 and 3.98 ppm, where the former is a quartet and the latter consists of two overlapping quartets. This result suggests the existence of three different conformers of the enolate anion in DMSO. In the case of the isopropyl substituent, the quartet

TABLE 1. ^{1}H-NMR CHEMICAL SHIFTS OF DIETHYL ALKYLMALONATES AND THEIR ENOLATES $(CH_3{}_b\text{–}CH_2{}_a\text{–}O\text{–}\overset{\overset{O}{\|}}{C}\text{–})_2\text{–}CH\text{–}R_{\alpha\ \beta.\gamma.\delta.\varepsilon}$

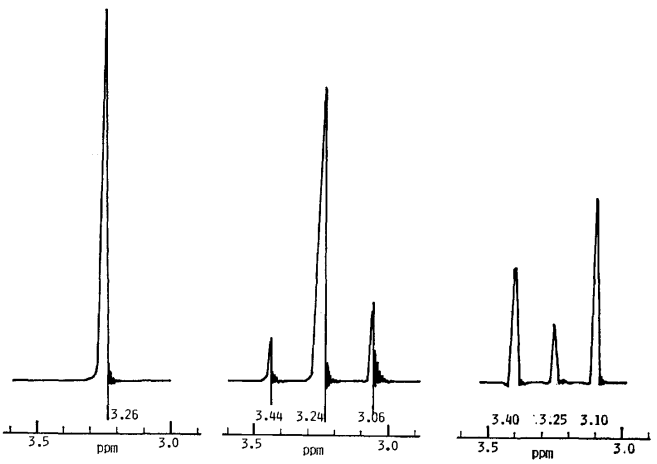
	+0.66 +0.12	+0.03		+0.02			

a) Parent esters. b) Enolate anions. c) Differences (a—b); a minus sign denotes down-field shift. d) After 24 h, the quartet at 3.86 ppm separated into two signals, at 3.45 (q) and 3.90 (dq) ppm. The integral intensity of the signal at 3.45 ppm was about half of that at 3.90 ppm. e) The ratio of the integral intensity of the signal at 3.44 ppm to that at 3.98 was about 2/3. The signal at 3.98 ppm is a multiplet similar to that at 3.90 ppm of the isopropyl derivative.

signal of methylene protons in the ethoxyl groups appeared at 3.86 ppm immediately after the enolate-anion preparation, but separated into two signals at 3.45 (a quartet) and 3.90 ppm (a double-quartet) after 24 h. This spectral change also suggests a change in the conformational distribution from a single conformational entity to a mixture of three different conformations closely related to the case of the *t*-butyl derivative. The conformational change might be attributable to the bulkiness of an alkyl group at α-carbon, which induces repulsions between the alkyl substituent and the ethoxyl groups.

If the same phenomenon could be observed for the sodium dimethyl alkylmalonate system, more precise information would be obtained, since far more simplified spectra are obtained for methoxyl groups. In practice, the ester-methyl parts of the ^{1}H-NMR spectra of the enolates were found to be in circumstances similar to those of the diethyl-ester system, as is illustrated in Fig. 1. The methoxyl parts of the ^{1}H-NMR spectra of the enolates with isopropyl or *t*-butyl substituents consisted of three singlet peaks with different intensities,



1) Ethyl derivative 2) Isopropyl derivative 3) *t*-Butyl derivative

Fig. 1. The methoxyl parts of the ^{1}H-NMR spectra of sodium enolates derived from dimethyl alkylmalonates in DMSO.

their chemical shifts closely corresponding to each other. On the other hand, only one singlet peak, corresponding to the central peaks of the three peaks described above, was observed in the enolate with an ethyl substituent. Again, in the case of the isopropyl derivative, methoxyl signals other than that at 3.24 ppm did not appear in the spectrum observed immediately after the enolate-anion preparation. The two signals at 3.44 and 3.06 ppm gradually appeared after the solution had been allowed to stand for 24 h at room temperature.

In order to determine the conformation to which the singlet peak in the case of ethyl derivative is to be ascribed, the spectral changes upon the addition of 18-crown-6 were investigated with the enolates of diethyl ethylmalonate, dimethyl isopropylmalonate, and dimethyl *t*-butylmalonate. Though the ^{1}H-NMR signal of 18-crown-6 and that of the lowest-field peak in the three singlet peaks of the enolates overlap each other, the integral intensities of the other two peaks could be measured and compared with those of the α-alkyl moieties. Thus, the intensities of the singlet peak in the ethyl derivative and of the central singlet peaks in the isopropyl and *t*-butyl derivatives were decreased by the addition of 18-crown-6. This spectral change caused by 18-crown-6 is a result of the dissociation of the ion pairs, facilitated by the ability of 18-crown-6 to capture the cation.[5a]

Among the three possible arrangements, the most stable conformation for the non-dissociated ion pairs is thought to be the *Z,Z* type. Zaugg *et al.* have discussed how *Z,E* and *E,E* types are more dissociated than the *Z,Z* type.[8] It has generally been accepted that, in the absence of compelling steric interactions, the *Z,Z* conformers exist only as ion pairs; chelation by the counter-cation is necessary to offset the coulombic repulsions between the two oxygen atoms.[7] The small central peak in the case of the *t*-butyl substituent can also be assigned to the *Z,Z* conformer, while the outer two peaks may be ascribed to the *Z,E* and *E,E* conformers, although their assignment remains to be definitely settled.

Vibrational spectroscopy is useful in estimating the electron density of bonds. Zook *et al.* found that the typical C=O stretching frequency (1710 cm^{-1}) of pinacolone shifts to a much lower region (1575 cm^{-1}) on conversion to its sodium derivative.[3a] A similar lower frequency shift, from 1724 to 1589 cm^{-1}, has also been observed when ethyl phenylacetate was converted to its sodium enolate.[1b]

Table 2 shows the IR absorption frequencies of diethyl alkylmalonates and their sodium enolates in DMSO in the region of 1800—1500 cm^{-1}. These enolate anions have two characteristic absorption bands, except that the *t*-butyl substituent, which has a broad absorption band at 1600 cm^{-1}, presumably because its complex conformational composition is different from those with the other substituents. The enolate anions of β-dicarbonyl compounds have been established to have two absorption bands in this region.[9] Acetylacetone forms a metal chelate, and the chelate ring (*Z,Z* conformation) is planar and symmetrical; the two C=O bonds are equivalent, as are the C=C bonds in the ring. The IR spectra of bis(acetylacetonato)copper(II) showed two bands (1578 and 1527 cm^{-1}) in the carbonyl region; they were assigned to the C=O stretching and C=C=C stretching modes of vibration respectively, on the basis of their ^{13}C isotope shifts; the original 1578 and 1527 cm^{-1} absorptions were found to shift to frequencies lower by 30 and 7 cm^{-1} respectively in the 2,4-$^{13}C_2$ derivative and by 3 and 1 cm^{-1} respectively in the 1,3,5-$^{13}C_3$ derivative.[10]

TABLE 2. IR SPECTRA OF DIETHYL ALKYLMALONATES AND THEIR SODIUM ENOLATES IN DMSO IN THE REGION OF 1800—1500 cm^{-1}

Alkyl	Wave numbers		
	Parent ester	Sodium enolate	
Hydrogen	1732	1679	1556
Methyl	1729	1677	1524
Ethyl	1731	1675	1521
Propyl	1729	1671	1519
Isopropyl	1728	1667	1512
Butyl	1727	1670	1517
Isobutyl	1728	1668	1516
s-Butyl	1732	1665	1509
t-Butyl	1731	1600	

a) The wave numbers were given as the mean values of two split absorptions, which were identified as symmetrically and *anti*-symmetrically coupled vibrations; R. A. Abramovitch, *Can. J. Chem.*, **36**, 151 (1958); **37**, 361 (1959).

TABLE 3. IR SPECTRA OF SODIUM DIETHYL MALONATES LABELED BY ^{13}C AND THE ISOTOPE-SHIFTS VALUES IN THE REGION OF 1700—1500 cm^{-1}

^{12}C Compound	1,3-^{13}C Compound	2-^{13}C Compound
1679	(1659 sh.)	1675 ($\Delta\delta$ 4)
	1640[a] ($\Delta\delta$ 39)	
	1630[a]	
(1564 sh.)		
1556	1519 ($\Delta\delta$ 37)	1552 ($\Delta\delta$ 4)

a) The intensity of the absorption at 1640 cm^{-1} is slightly smaller than that at 1640 cm^{-1}; this may be caused by combination vibrations.

Isotope-labeling experiments were employed to assign the two absorption bands of sodium diethyl malonate. In the IR spectrum of sodium diethyl malonate-1,3-$^{13}C_2$, the absorption bands at 1679 and 1556 cm^{-1} of the ^{12}C compound shifted to a frequency region lower by 39 and 37 cm^{-1} respectively, as is shown in Table 3. On the other hand, the sodium diethyl malonate-2-^{13}C gave only a small isotope shift ($\Delta\delta$ −4 cm^{-1}), which indicated that the C-2 carbon atom participates little in these two vibrations, such as in the case of the β-diketone system. Consequently, the two absorptions of sodium diethyl malonate at 1679 and 1556 cm^{-1} are assigned to vibrations of the C=O and C=C=C bonds respectively.[10] The assignment of the latter is further verified by the examination of the alkyl-substituent effect on the positions of the two absorptions of the sodium

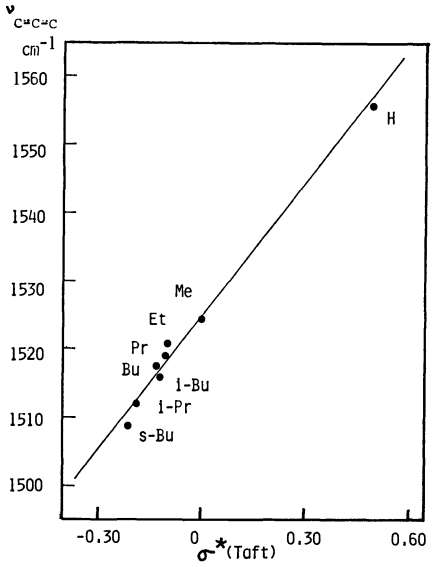


Fig. 2. Correlation of $\nu_{C=C=C}$ (cm^{-1}) in the IR spectra of sodium diethyl alkylmalonates in DMSO to Taft's σ*.

enolate of diethyl alkylmalonates. While the absorptions at higher frequencies of the two remain rather unaffected by the alkyl substituent, those at lower frequencies are nicely correlated ($r=0.994$) to the substituent constants, σ*, as is shown in Fig. 2. The inductive effect of α-alkyl substituents will affect the C=C=C group more intensely than the C=O group, a bond away from the α-carbon.

Experimental

The diethyl and dimethyl esters of alkylmalonic acids were synthesized according to the literature[12] and were identified by elementary analysis and by means of the ^{1}H-NMR spectra. Diethyl malonate-1,3-$^{13}C_2$ and diethyl malonate-2-^{13}C, from the British Oxygen Company, Limited, labeled with 93.0 and 92.0 atom% respectively, were used.

The preparation of enolate anions and the IR and ^{1}H-NMR measurements of them were carried out in a manner similar to that described in a previous report.[1b]

Stereochemistry of Nucleophilic Addition Reactions. 10.[1] Preparation of 2-*C*-Diacetylmethyl and 2-*C*-Acetylmethyl Derivatives with the *Altro*, *Gluco*, and *Manno* Configuration from Methyl 4,6-*O*-Benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside

Tohru SAKAKIBARA,* Akinori SETA, Yoshifusa TACHIMORI, and Rokuro SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 11, 1979)

Reaction of the title compound with acetylacetone in the presence of a catalytic amount of sodium hydroxide afforded the 2-*C*-diacetylmethyl and 2-*C*-acetylmethyl derivatives having the *altro*, *gluco*, and *manno* configurations. The 2-*C*-diacetylmethyl derivative with the *altro* configuration exceptionally exists in a skew boat form. The product ratio depends on solvent and the amount of THF.

The reaction of an α-nitro olefin with active methylene compounds predominantly affords a thermodynamically more stable product, because of its reversible character.[2] However, it has been found that phase transfer catalyzed, heterogeneous reactions of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside (**1**) with active methylene compounds give the thermodynamically less stable mannopyranoside in good yields.[3] These results prompted us to investigate a similar reaction in a homogeneous system. In a preliminary communication,[4] we reported the preparation of the altropyranoside **8** from **1** and acetylacetone; in spite of the high tendency of the nitro group to occupy an equatorial orientation in nitro sugars,[5] the nitro group of **8** is orientated axially. Studies have been carried out in order to clarify kinetically controlled protonation. In this paper, we report the preparation of 2-*C*-diacetylmethyl and 2-*C*-acetylmethyl derivatives having the *altro*, *gluco*, and *manno* configuration as well as solvent effects.

Results and Discussion

Treatment of **1** (0.1 mmol) with dimethyl malonate (0.11 mmol) in THF (2 ml) in the presence of 0.05 M (1 M=1 mol dm^{-3}) NaOH (0.2 ml) for 1 h at room temperature resulted in the recovery of **1**, while in the presence of 5.0 M NaOH (0.2 ml) it afforded a complex mixture, from which isolation of the adduct **2** or **3** was unsuccessful. A similar reaction, however, with 0.2 M NaOH (0.1 ml) predominantly afforded the mannopyranoside **2**; similar results were obtained in the reaction with diethyl malonate in the heterogeneous system.[3] A similar reaction of **1** with malononitrile afforded mannopyranoside **4** and glucopyranoside **5** in a 9 : 1 ratio, the highest ratio being 1 : 1.3 in the heterogeneous reaction.[3]

Although in the heterogeneous system the reaction of **1** with acetone resulted in the introduction of a hydroxyl group instead of an acetylmethyl group at the C-2 position, homogeneous reaction afforded the desired

a) Methine or methylene proton(s) of the substituent at C-2. b) Recorded in acetone-d_6.

2-*C*-acetylmethyl derivative **6**, together with a small amount of the nitro alcohol **7**.

Reaction of **1** (0.1 mmol) with acetylacetone (0.15 mmol) in THF (2 ml) in the presence of 0.2 M NaOH (0.1 ml) at 21 °C for 1 h afforded a mixture consisting mainly of the altropyranoside **8** and mannopyranoside **9** in an approximately 4: 1 ratio. These compounds were separated by fractional crystallization. The *altro* configuration with a skew boat form was assigned to **8** by NMR data (Fig. 1). The assignment of signals, carried out by INDOR method, was confirmed by comparison with the spectrum of 3-deuterated derivative of **8**; i) $J_{1,2}$=10.5 Hz indicating the diaxial relationship between H-1 and H-2, ii) $J_{2,3}$=2.5 Hz and $J_{3,4}$=4.5 Hz the equatorial orientation of H-3, and iii) $J_{4,5}$=$J_{5,6a}$= 10 and $J_{5,6e}$=5.0 Hz the benzylidene acetal ring with normal chair conformation.

When dioxane (12 ml) was used as a solvent instead of THF (2 ml), a similar reaction of **1** (20 mg) with acetylacetone afforded predominantly the glucopyranoside **10**, the configuration of which was determined from the coupling constants; $J_{1,2}$=3.1, $J_{2,3}$=11.9, and $J_{3,4}$= 10 Hz.

Treatment of **1** (20 mg) with acetylacetone (10 mg) in THF (1.3 ml) in the presence of 1 M NaOH (0.1 ml) at 21 °C for 1 h afforded a deacetylated product, methyl 2-*C*-acetylmethyl-4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-mannopyranoside (**6**), in 89% yield. When the reaction was stopped at 15 min, the nitro olefin **1**, mannopyranoside **6**, and altropyranoside **8** were detected in an approximate ratio of 1: 1.2: 14, but only a trace of diacetylmethyl derivative with *manno* configuration **9** was detected by NMR spectroscopy. Under the same conditions, deacetylation of **9** was slow; the ratios of **9** to **6** were 8: 1 and 2.5: 1 after 15 min and 1.5 h, respectively. On the other hand, the altropyranoside **8** was completely converted into **6** within 1.5 h. It is noteworthy that a small amount of **8** was detected during the course of deacetylation of **9**.

A similar treatment of the glucopyranoside **10** with 1 M NaOH for 15 h gave the glucopyranoside **11** in a high yield, structure of which was deduced by coupling constants; $J_{1,2}$=3.0, $J_{2,3}$=11, and $J_{3,4}$=10 Hz. Deacetylation of **10** occurred slowly; the ratios of **10** to **11** were 4: 1 and 1.3: 1 after 40 min and 1.5 h, respectively.

When the mixture of **8** and **9** (*ca.* 5: 1, 200 mg) in THF (2.3 ml) was treated with 0.2 M NaOH (0.7 ml) for 50 h, a complex mixture was formed, from which the mannopyranoside **9** and glucopyranoside **10** were isolated in 75 and 12.5% yield, respectively. In addition to these compounds, a small amount of a new compound **12** was isolated. Elemental analysis and the NMR spectrum show that it was a 2-*C*-acetylmethyl derivative. The possibility of **12** being *allo* configuration was chemically excluded; treatment of **12** with 0.2 M NaOD in acetone-d_6 exclusively afforded the C-3 deuterated derivative of the mannopyranoside **6**.[6] Thus, compound **12** should be the altropyranoside; appearance of the H-5 signal at a low field (δ 4.72) as that of **8** (δ 4.60)[7] supports the axial orientation of the nitro group. However, in contrast to the case of **8**, the NMR data strongly suggest that it has the chair conformation;[8] $J_{1,2}\leq$1.0, $J_{2,3}$=1.9, $J_{3,4}$=4.1, $J_{4,5}$=$J_{5,6a}$=10, and $J_{5,6e}$=5.0 Hz (Fig. 1). The reason why compound **8** has a skew boat conformation and compound **12** a chair conformation is not clear. If such assignments were correct, compound **12**, having unfavorable 1,3-diaxial interaction between the nitro and methoxyl group, should be less stable than compound **8**. In fact epimerization of **12** to the mannopyranoside **6** occurred more readily than that of **8** to **9**.

In these reactions no evidence for formation of the allopyranoside was obtained. Attempts for epimerization of the glucopyranoside **10** with 1 M NaOH or sodium hydride in THF failed, only glucopyranosides **10** and **11** being detected.

Re-examination of phase transfer catalyzed, heterogeneous reaction of **1** (benzene–0.2 M NaOH) with acetylacetone showed the formation of a trace of altropyranoside **8** besides the mannopyranoside **9** (main product). In the heterogeneous system, about half the amount of **8** epimerized to **9** within 2 min. In the homogeneous system the epimerization was much slower.

This seems to be the first example to isolate the kinetically controlled product of not only the addition of nucleophile but also the following protonation, in the Michael reaction of nitro olefin derivatives. Then we have studied the reaction in detail and found two remarkable solvent effects.

As seen from Table 2, the relative ratios of the altropyranoside **8** to the mannopyranoside **9** increase with an increase in the amount of THF or acetone. Nearly equal amounts of **8** and **9** are formed, when 0.3 ml of THF is used (Entry 1), whereas a 4.2: 1 ratio is obtained for 3 ml of THF (7). From the fact that all of **9** and most of **8** were recovered under the same conditions (2 and 3), the formation of nearly equal

a) A solution of the nitro olefin **1** (20 mg, 0.068 mmol) in the solvent indicated was stirred at 21 °C with acetylacetone (10 mg, 0.1 mmol) in the presence of 0.2 M NaOH (0.1 ml). b) Determined by NMR spectroscopy: —, product not detected; t, trace. c) Twenty-six mg (0.066 mmol) of starting material used. The same results were obtained in the absence of acetylacetone. d) Instead of 0.2 M NaOH, 0.2 M NaOD used. e) The C-3 position completely deuterated. f) Amount of sodium hydroxide (0.2 M) reduced to 0.03 ml.

amounts of **8** and **9** reflected, at least mostly, kineticall controlled reaction. Treatment of **9** with 0.2 M NaOD for 1 h at 21 °C gave undeuterated **9**, whereas the same treatment of **8** afforded a mixture of **8** and **9** in a 5: 1 ratio, where the C-3 position of both compounds was completely deuterated. This suggests that the protonation at C-3 of the intermediary nitronate derived from **8** is more favorable from the face *cis* to the C-2 substituent, giving the altropyranoside **8**.

Epimerization of **8** to **9** in acetone-d_6 in the presence of 0.2 M NaOD was monitored by NMR spectroscopy. As shown in Fig. 2, epimerization of the mannopyranoside **9** to the altropyranoside **8** occurred more slowly than that of **8** to **9**.

The proportion of axial and equatorial approach of the nucleophile to the nitro olefin **1** varies with solvent. In such a polar solvent as DMSO and acetone, no glucopyranoside **10** was detected, whereas in a less polar solvent such as dioxane, **10** became the major product. Under the conditions for formation of **10** (23), epimerization of **8** or **9** to **10** was negligible as judged from NMR spectroscopy. When the amount of dioxane was decreased to 1.3 ml or a small amount of water was added, the ratio of **10** considerably decreased (Table 3).

A similar but not conspicuous trend was observed in

a) A solution of **1** (20 mg, 0.068 mmol) in the solvent indicated was stirred at 21 °C with dimethyl malonate (13.2 mg, 0.1 mmol) in the presence of 0.2 M NaOH (0.1 ml). b) Determined by NMR spectroscopy; —, product not detected.

the reaction of **1** with dimethyl malonate (Table 4).

In the nucleophilic addition reaction to **1**, previous examples always showed a favorable axial approach under kinetically controlled conditions. This was explained in terms of steric hindrance and stereoelectronic control.[9] However, predominant equatorial approach in less polar medium is not explained in terms of these factors. Abramovitch and Struble found that such a bulky nucleophile as anion of diethyl malonate exceptionally approaches from the equatorial side of 4-*t*-butyl-1-cyanocyclohexene[10] and ethyl 4-*t*-butylcyclohexene-1-carboxylate.[11] They explained the results on the basis of 1,3-interaction between the axial hydrogen atom and an approaching nucleophile. The explanation is not applicable to the present reaction; steric hindrance due to the methoxyl group is apparently more serious than that due to the lone pair on the ring oxygen atom.

Experimental

Melting points were determined in capillaries and are uncorrected. IR spectra were recorded for KBr discs and NMR spectra were determined in chloroform-*d* and/or acetone-d_6 with tetramethylsilane as an internal standard on either a Varian XL-100-15 or a JEOL-PS-100 spectrometer. Column chromatography was carried out on silica gel (C-300, Wakogel). TLC was performed using Merck (Darmstadt) silica gel GF 254. Solutions were concentrated under reduced pressure.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-[bis(methoxycarbonyl)-methyl]-3-nitro-α-D-mannopyranoside (2). To a solution of **1**[12] (29.3 mg, 0.1 mmol) and dimethyl malonate (13.8 mg, 0.11 mmol) in THF (2 ml) was added 0.2 M NaOH (0.1 ml) at 21 °C. The mixture was stirred for 2 h and then deionized with cation exchange resin (Amberlite IR-120, H^+). After removal of the resin, the filtrate was concentrated to yield a syrup (42 mg), its NMR spectrum showing it to be almost pure **2**. The syrup (42 +40 mg) was chromatographed on silica gel eluted with benzene–ethyl acetate (20 : 1, v/v) to afford 70 mg of **2** (82%), $[\alpha]_D^{31}$ −30.2° (*c* 1, $CHCl_3$); IR 1750, 1740 (COOMe), and 1560 cm^{-1} (NO_2).

Found: C, 54.02; H, 5.62; N, 3.01%. Calcd for $C_{19}H_{23}NO_{10}$: C, 53.64; H, 5.45; N, 3.29%.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-[bis(methoxycarbonyl)-methyl]-3-nitro-α-D-glucopyranoside (3). To a solution of **1** (60 mg, *ca.* 0.2 mmol) and dimethyl malonate (42 mg, 0.32 mmol) in dioxane (36 ml) was added 0.2 M NaOH (0.3 ml) at 21 °C, and the mixture was stirred for 6 h. Similar work-up to that for **2** afforded a residue consisting of **2** and **3** in a 1.5: 1 ratio as shown by NMR spectroscopy. The residue (85 +87 mg) was chromatographed on silica gel eluted with benzene–ethyl acetate (20: 1, v/v). The fast running fraction was 83.5 mg of **2** (48%), which was found to be identical with an authentic sample by NMR spectroscopy. The slow running fraction was 57 mg of **3**, which was recrystallized from ethanol to give 52.2 mg of **3** (30%), mp 133—134 °C; $[\alpha]_D^{22}$ +126° (*c* 1, $CHCl_3$); IR 1742, 1722 (COOMe), and 1558 cm^{-1} (NO_2).

Found: C, 53.86; H, 5.50; N, 3.26%. Calcd for $C_{19}H_{23}NO_{10}$: C, 53.64; H, 5.45; N, 3.29%.

Methyl 4,6-O-Benzylidene-2-C-dicyanomethyl-2,3-dideoxy-3-nitro-α-D-mannopyranoside (4). To a solution of **1** (29.3 mg) and malononitrile (7.9 mg, 0.12 mmol) in THF (2 ml) was added 0.2 M NaOH (0.1 ml). The mixture was stirred for 2 h and deionized in a similar way to that for **2**. After removal of the resin, the filtrate was concentrated to give a syrup (34 mg), NMR spectrum of which revealed the presence of **4** and **5** in a ratio of 9 : 1. The same reaction was performed three more times and the combined residue was chromatographed on silica gel.[3] The mannopyranoside **4** and the glucopyranoside **5** isolated were identical with respective authentic samples in IR and NMR spectra.

Methyl 2-C-Acetylmethyl-4,6-O-benzylidene-2,3-dideoxy-3-nitro-α-D-mannopyranoside (6). To a solution of **1** (29.3 mg) in acetone (2 ml) was added 1 M NaOH (0.2 ml) at 21 °C. The mixture was stirred for 2 h and subjected to a similar work-up to that for **2**, giving a residue (32 mg). Recrystallization of the residue (32 +30 mg) from ethanol afforded 53 mg of **6** (75%), which was identical with an authentic sample by IR and NMR spectroscopy.[3]

The mother liquor mainly consists of **11** and 3-nitro alcohol **7**, as judged from NMR spectroscopy and TLC.

A similar reaction of **1** (20 mg, 0.068 mmol) with acetylacetone (10 mg, 0.1 mmol) in THF (1.3 ml) in the presence of 1 M NaOH (0.1 ml) at 21 °C for 1 h afforded a residue (24 mg). Recrystallization of the residue (24 +26 mg) from ethanol gave 47.7mg of **6** (89%).

Methyl 4,6-O-Benzylidene-2-C-diacetylmethyl-2,3-dideoxy-3-nitro-α-D-altropyranoside (8). To a solution of **1** (29.3

mg) and acetylacetone (15 mg, 0.15 mmol) in THF (2 ml) was added 0.2 M NaOH (0.1 ml) at 21 °C. The mixture was stirred for 20 min and then deionized with cation exchange resin. After removal of the resin, the filtrate was concentrated to give a white powder (36 mg). The powder (36 +35 mg) was recrystallized from isopropyl alcohol to give 55.8 mg of **8** (71%), mp 163—164 °C; $[\alpha]_D^{22}$ +26.8° (*c* 1, acetone); IR 1725, 1700 (CO), and 1555 cm^{-1} (NO_2).

Found: C, 57.91; H, 5.87; N, 3.62%. Calcd for $C_{19}H_{23}NO_8$: C, 58.01; H, 5.89; N, 3.56%.

The mother liquor mainly consists of the mannopyranoside **9**, which was isolated as a second crop (10.2 mg, 13%).

Methyl 4,6-O-Benzylidene-2-C-diacetylmethyl-2,3-dideoxy-3-nitro-α-D-glucopyranoside (10). To a solution of **1** (20 mg, 0.068 mmol) and acetylacetone (10 mg, 0.1 mmol) in dioxane (12 ml) was added 0.2 M NaOH (0.1 ml) at 21 °C. After the solution had been stirred for 1 h, the mixture was treated in a similar way to that for **8**, giving a crystalline residue. The same reaction was carried out two more times and the combined residues were recrystallized from ethanol to afford 60 mg of **10** (75%), mp 198—199 °C; $[\alpha]_D^{22}$ +30.2° (*c* 0.5, DMSO); IR 1730, 1700 (CO), and 1555 cm^{-1} (NO_2).

Found: C, 57.74; H, 5.88; N, 3.72%. Calcd for $C_{19}H_{23}NO_8$: C, 58.01; H, 5.89; N, 3.56%.

Methyl 2-C-Acetylmethyl-4,6-O-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopyranoside (11). To a solution of **10** (26 mg, 0.066 mmol) in THF (1.3 ml) was added 1 M NaOH (0.1 ml) at 21 °C. The mixture was stirred for 15 h and deionized in a similar way to that for **8**. After removal of the resin, the filtrate was concentrated to give a pure powder by NMR spectroscopy. Recrystallization from ethanol afforded 21 mg of **11** (91%), mp 187—188 °C; $[\alpha]_D^{22}$ +84.3° (*c* 0.5, $CHCl_3$); IR 1710 (CO) and 1545 cm^{-1} (NO_2).

Found: C, 57.95; H, 6.00; N, 4.02%. Calcd for $C_{17}H_{21}NO_7$: C, 58.11; H, 6.02; N, 3.99%.

Methyl 2-C-Acetylmethyl-4,6-O-benzylidene-2,3-dideoxy-3-nitro-α-D-altropyranoside (12). A mixture of **8** and **9** (in a ratio of *ca.* 5: 1, 200 mg, 0.51 mmol) was dissolved in THF (2.3 ml). To this solution was added 0.2 M NaOH (0.7 ml). The resulting solution was stirred at 21 °C for 50 h and worked up in a similar way to that for **8**, affording a powder. Recrystallization from ethanol gave 150 mg (75%) of platelet crystals of **9** as the first crop, 25 mg (12.5%) of needles of **10** as the second crop, and 23 mg of granular crystals as the third crop. A small amount of chloroform was added to the last crystals and the insoluble material was filtered and recrystallized from ethanol to give 10 mg of **12** as needles (5.6%), mp 204—205 °C; $[\alpha]_D^{22}$ +15.4° (*c* 0.5, acetone); IR 1717 (CO) and 1560 cm^{-1} (NO_2).

Found: C, 58.39; H, 6.00; N, 4.05%. Calcd for $C_{17}H_{21}NO_7$: C, 58.11; H, 6.02; N, 3.99%.

Attempts for Epimerization of 10. To a solution of **10** (26 mg, 0.066 mmol) in THF (1.3 ml) was added *ca.* two equiv NaH (6.4 mg, purity *ca.* 50%) at 21 °C. The mixture was stirred for 1.5 h and worked up in a similar way used for **8** to give a residue, NMR spectrum of which showed the presence of **11** and **10** in a ratio of 2 : 1, but no evidence for formation of the allopyranoside.

A similar treatment of **10** (26 mg) with 1 M NaOH (0.1 ml) in THF (1.3 ml) at 21 °C for 1.5 h also gave a mixture of **11** and **10** in a 1: 1.3 ratio. No evidence was again obtained for formation of the allopyranoside.

Epimerization of 12 to 6. To an acetone-d_6 solution of **12** (13 mg, 0.033 mmol) was added 0.2 M NaOD (0.05 ml). Within 20 min, **12** was completely epimerized to give the 3-deuterated derivative of **6**, the C-2 position of which was not deuterated.

Under the same conditions, epimerization of the altropyranoside **8** was much slower; even after 45 min *ca.* 16% of **8** was epimerized to the mannopyranoside **9**, revealing that compound **12** is much less stable than **8**.

6) If the epimerization occurred *via* the nitro olefin intermediate, the possibility of **12** as being an allopyranoside was not excluded. However, this is not likely since no acetylmethyl group of the product was completely deuterated, *i.e.*, this group did not come from the solvent, and the nitro alcohol **7**, formed (**6** : **7**=3 : 1) by the reaction of the nitro olefin **1** with acetone-d_6 under the same conditions, was not detected by NMR spectroscopy.

7) The H-5 signal of 3-nitro sugar with the *gluco* and *manno* configuration resonated at around δ 3.6.

8) A strongly distorted chair conformation like $^4H_5$ form is also possible from the NMR data.

Synthesis of *dl*-12,15-Ethylene-13,14-dihydro-prostaglandin-$F_{2\alpha}$ Methyl Ester

Nobuyuki HAMANAKA,* Hisao NAKAI, and Masayasu KURONO

Ono Pharmaceutical Co., Ltd., Research Institute, 3-1-1, Sakurai, Shimamoto-cho, Mishima-gun, Osaka 618

(Received January 10, 1980)

A report is given on the synthesis of a spiro prostaglandin analog *via* triketone obtained by the double Michael addition of 1,3-cyclopentanedione to 1,4-pentadien-3-one.

Prostaglandin (PG) is a highly active autacoid which might act as a mediator in many physiological activities.[1] The synthesis of 12-methyl[2] and that of 15-methyl PGs[3] have been described in investigations carried out to find stable PG analogs having higher biological activities than natural PG. In the present report we describe the synthesis of a spiro PG analog in which an ethylene linkage is introduced between the C-12 and C-15 positions, Δ^{13}-double bond being saturated.

The starting bicyclic triketone **3** was obtained as follows. The sodium salt of 1,3-cyclopentanedione was treated with 1,4-pentadien-3-one (1 equiv, −40 °C, 4 h, then −20 °C, 1.5 h) to afford the intermediate anion **2**. Cyclization of **2**, which rapidly polymerized during the course of isolation, was accomplished by treatment *in situ* with AcOH (5 equiv, −20 °C, 20 h) to give the bicyclic triketone **3**[4] in 56% yield on the basis of 1,3-cyclopentanedione. Selective protection of the C-8 carbonyl group in six-membered ring of **3** with ethylene glycol (1 equiv, TsOH, benzene, reflux, 30 min) afforded monoacetal **4** quantitatively. Dehydrogenation of **4** with SeO_2 in dioxane (92—93 °C, 20 h) gave 1,3-cyclopentanedione **5** in 88% yield. Addition of two carbon units (corresponding to C-6 and C-7 of PG) was achieved by treatment of **5** with $LiCH_2COOBu^t$[5] in benzene (1.2 equiv, 25 °C, 30 min) to give hydroxy ester **6** in 79% yield. Treatment of **6** with $SOCl_2$ (4.4 equiv)–pyridine (5.6 equiv) in CH_2Cl_2 at −40 °C for 30 min gave the deconjugated α-chloro ketone **7** quantitatively. Reductive dechlorination of **7** with Zn–CH_3OH (40—43 °C, 3.5 h) gave the conjugated ketone **9** in 84% yield. Treatment of **9** with TsOH in toluene gave unstable lactone **10** which was directly reduced with *i*-Bu_2AlH in toluene (−70 °C, 5 min) to give the hydroxy hemiacetal **11** in 77% yield on the basis of **9**. Condensation of **11** with $Ph_3P{=}CH(CH_2)_3COONa$ (9.5 equiv) in DMSO (34 °C, 75 h) followed by esterification with CH_2N_2 gave methyl ester **13** in 50% yield. Geometry of the two hydroxyl groups of **13** was confirmed by lanthanoid induced ^1H NMR shifts (Fig. 1). Since the proton signals at C-9 and C-11 of **13** showed the same gradient while two protons of C-10 showed different gradients, 9- and 11-hydroxyl groups of **13** are *cis* as expected from the synthetic route of **13**. Compound **13** was deprotected with TsOH–acetone (reflux, 2 h) to give **14** quantitatively. The α-chain was introduced by treatment of **14** with *n*-$C_5H_{11}MgBr$ to give the desired *dl*-12,15-ethylene-13,14-dihydro-$PGF_{2\alpha}$ methyl ester **1** in 60% yield. Treatment of **1** with AcOH (50 °C, 2 h) exclusively gave **15** possessing exocyclic double bond [*m/e* 378 (M^+), 335 ($M^+-C_3H_7$)]. *m/e* 321 ($M^+-C_4H_9$) was not observed among fragment ion peaks of **15**. This suggests that the hydroxyl group of C-15 occupies an equatorial position, and **18**

a) Recrystallization solvents.

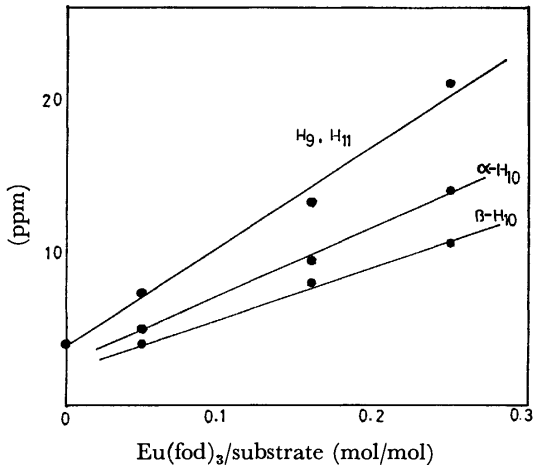

Fig. 1. Lanthanoid induced ^{1}H-NMR shifts of **13**.

or **19** are the possible stereoisomers of **1**. We tentatively assigned the stereochemistry of **1** to **19** on the basis of the following. i) Conformer **17** is more stable as compared with **16**, the steric repulsions between the C-11 OH and six-membered ring of **17** being less than those between α-chain carbons and the six-membered ring of **16**; ii) Axial attack of Grignard reagent to the six-membered cyclic ketone **17** favors approach from axis a.

After intravenous administration, PG analog **1** showed no effect on uterine contractile activity in a pregnant rat at a dose of 200 γ/kg or on blood pressure in rabbit and dog at a dose of 50 γ/kg.

Experimental

General. Melting and boiling points are uncorrected. ^{1}H-NMR spectra were recorded on a Varian XL-100 spectrometer with Me_4Si as an internal standard, and IR spectra on a Hitachi EPI-G2 spectrophotometer. MS data were obtained on a JEOL JMS-01 SG at 75 eV.

Spiro[4.5]decane-1,4,8-trione (3). To a suspension of 230 mg (10.0 mmol) of NaH in DMF (90 ml) was added 980 mg (10.0 mmol) of 1,3-cyclopentanedione at −35 °C over a period of 10 min. To the resulting mixture was added a solution of 820 mg (10.0 mmol) of 1,4-pentadien-3-one in DMF (10 ml) at −35 °C over a period of 5 min. The resulting solution was allowed to stand at −35 °C for 4 h, then at −20 °C for 1.5 h and then treated with AcOH (3 ml) at −20 °C for 20 h. The reaction mixture was poured into 1 mol dm^{-3} HCl (300 ml) and extracted with CH_2Cl_2. The organic layer was washed with H_2O and dried (Na_2SO_4). After removal of the solvent, the residue obtained was purified by column chromatography on silica gel using a mixture of benzene and AcOEt as an eluent to afford 1.01 g (56%) of **3** as colorless crystals; MS *m/e* 180 (M^+).

8,8-(Ethylenedioxy)spiro[4.5]decane-1,4-dione (4). A mixture of 100 mg (0.556 mmol) of triketone **3**, 34.5 mg (0.556 mmol) of ethylene glycol, 1 mg of TsOH and benzene (5 ml) was refluxed for 1 h. The resulting mixture was diluted with benzene (20 ml) and was shaken with saturated aqueous $NaHCO_3$ solution. The organic layer was dried ($MgSO_4$) and evaporated *in vacuo* to afford 125 mg (100%) of **4** as colorless crystals; MS *m/e* 224 (M^+).

8,8-(Ethylenedioxy)sprio[4.5]dec-2-ene-1,4-dione (5). A solution of 70 mg (0.312 mmol) of monoacetal **4** in dioxane (2 ml) was treated with 35 mg (0.315 mmol) of SeO_2 at 92—93 °C for 20 h. The resulting mixture was diluted with AcOEt (15 ml) and washed with H_2O and saturated aqueous $NaHCO_3$ solution. The organic layer was dried ($MgSO_4$) and evaporated under reduced pressure to afford 82 mg of oily residue which was purified by column chromatography on silica gel using Et_2O as an eluent to afford 61 mg (88%) of **5** as colorless crystals; MS *m/e* 222 (M^+).

1-(t-Butoxycarbonylmethyl)-1-hydroxy-8,8-(ethylenedioxy)spiro-[4.5]dec-2-en-4-one (6). To a stirred solution of 30 mg (0.135 mmol) of **5** in benzene (1 ml) was added dropwise a solution of 20 mg (0.164 mmol) of $LiCH_2COOBu^t$ in benzene (2 ml) at 0 °C over a period of 30 min. The resulting solution was diluted with benzene (20 ml) and washed with water and dried ($MgSO_4$). After removal of the solvent under reduced pressure, the residue obtained was purified by thin layer chromatography on silica gel using Et_2O as a developing solvent to afford 36 mg (79%) of **6** as colorless crystals; MS *m/e* 338.1707 (Calcd for $C_{18}H_{26}O_6$: 338.1729).

1-(t-Butoxycarbonylmethyl)-3-chloro-8,8-(ethylenedioxy)spiro[4.5]-dec-1-en-4-one (7). To a stirred solution of 150 mg (0.443 mmol) of **6** in CH_2Cl_2 (1 ml) were added dropwise a solution of 155 mg (1.96 mmol) of $SOCl_2$ in CH_2Cl_2 (7 ml)

and then a solution of 195 mg (2.45 mmol) of pyridine in CH_2Cl_2 (7 ml) at −40 °C over a period of 30 min. The resulting mixture was diluted with CH_2Cl_2 (20 ml) and washed with H_2O, dried (Na_2SO_4) and evaporated under reduced pressure to afford an oily residue which was purified by thin layer chromatography on silica gel using Et_2O as a developing solvent to give 151 mg (100%) of **7** as an oil; MS *m/e* 356.1376 (Calcd for $C_{13}H_{25}O_5Cl$: 356.1390).

1-(t-Butoxycarbonylmethyl)-8,8-(ethylenedioxy)spiro[4.5]dec-1-en-4-one (8). A solution of 580 mg (1.63 mmol) of **7** in MeOH (25 ml) was treated with 4.00 g (61.2 mmol) of Zn dust at 60 °C for 2 h. After removal of the Zn dust by filtration, the filtrate was evaporated. The resulting residue was extracted with CH_2Cl_2. The organic layer was washed with H_2O, dried (Na_2SO_4) and evaporated. Purification of the residue by column chromatography on silica gel using Et_2O as an eluent afforded 520 mg (100%) of **8** as an oil; MS *m/e* 322.1780 (Calcd for $C_{18}H_{26}O_5$: 322.1780).

1-(t-Butoxycarbonylmethyl)-8,8-(ethylenedioxy)spiro[4.5]dec-2-en-4-one (9). A solution of 50 mg (0.155 mmol) of **8** and 5.04 mg (0.0933 mmol) of NaOMe in MeOH (3 ml) was treated at 40—43 °C for 3.5 h. After removal of MeOH *in vacuo*, the residue was extracted with AcOEt. The organic layer was washed with H_2O, dried ($MgSO_4$) and evaporated. Purification of the residue by column chromatography on silica gel using a mixture of benzene and AcOEt as an eluent gave 42 mg (84%) of **9** as colorless crystals; MS *m/e* 322.1800 (Calcd for $C_{18}H_{26}O_5$: 322.1780).

(4S,8S)-4',4'-Ethylenedioxy-5-oxaspiro[bicyclo[3.3.0]octane-1,1'-cyclohexane]-2,6-dione (10). A solution of 120 mg (0.372 mmol) of **9** in benzene (10 ml) was treated with 2 mg of TsOH at 60 °C for 16 h. The resulting solution was diluted with benzene (30 ml), washed with H_2O and saturated aqueous $NaHCO_3$ solution and dried ($MgSO_4$). After removal of benzene *in vacuo*, the residue obtained was purified by column chromatography on silica gel using AcOEt as an eluent to afford 62 mg (63%) of **10** as colorless crystals; MS *m/e* 266.1130 (Calcd for $C_{14}H_{18}O_5$: 266.1154).

(4S,6R,8S,2R)- and/or (4S,6S,8S,2R)-4'4'-Ethylenedioxy-6-oxospiro[bicyclo[3.3.0]octane-1,1'-cyclohexane]-3,7-diol (11) Directly from (9). A solution of 100 mg (0.310 mmol) of **9** in toluene (3 ml) was treated with 64 mg (0.340 mmol) of TsOH at 40 °C for 3 h and then cooled to −70 °C. To the resulting solution was slowly added 4.80 mmol of *i*-Bu_2AlH in toluene (3 ml) over a period of 30 min. After the addition of MeOH (3 ml), the reaction mixture was treated with H_2O (9 ml) at 25 °C and stirred vigorously. After removal of the gel by filtration, the filtrate was dried ($MgSO_4$) and evaporated *in vacuo* to afford 65 mg (77% based on **9**) of **11** as an oil.

1-(cis-6-Methoxycarbonyl-2-hexenyl)-8,8-(ethylenedioxy)spiro-[4.5]decane-2,4-diol (13) Directly from (11). To a stirred solution of 2.5 g (5.65 mmol) of (4-carboxybutyl)triphenylphosphonium bromide in DMSO (3 ml) was added a solution of 2.0 mmol of sodium methylsulfinylmethide in DMSO (5 ml) at 10 °C. To the above solution was added a solution of 160 mg (0.592 mmol) of the crude hemiacetal **11** in DMSO (5 ml) at 25 °C. The resulting solution was allowed to stand at 34 °C for 45 h. The reaction mixture was quenched with H_2O (50 ml) and then extracted with a mixture of Et_2O and AcOEt (1: 1). The aqueous layer was acidified with oxalic acid (≈pH 5) and then extracted with a mixture of Et_2O and pentane (1: 1). The organic layer was dried ($MgSO_4$) and evaporated *in vacuo*. The residue was purified by thin layer chromatography on silica gel using a mixture of AcOEt and AcOH (98: 2) as a developing solvent to afford 120 mg of **12** which was treated with CH_2N_2 in MeOH and then evaporated *in vacuo* to afford 109 mg (50% based on **11**) of **13** as an oil after purification by column chromatography on silica gel using AcOEt as an eluent; MS *m/e* 368.2188 (Calcd for $C_{20}H_{32}O_6$: 368.2198).

1-(cis-6-Methoxycarbonyl-2-hexenyl)-2,4-dihydroxyspiro[4.5]-decan-8-one (14). A solution of 56 mg (0.152 mmol) of **13** and 1 mg of TsOH in acetone (5 ml) was refluxed for 5 h. The resulting solution was diluted with AcOEt and washed with saturated aqueous $NaHCO_3$ solution. The organic layer was dried ($MgSO_4$) and evaporated under reduced pressure to give 52 mg (100%) of **14** as an oil; MS *m/e* 324 (M^+).

dl-*12,15-Ethylene-13,14-dihydro-PGF$_{2\alpha}$ Methyl Ester (1).* To a stirred solution of 52 mg (0.160 mmol) of **14** in Et_2O (10 ml) was added dropwise a solution of 0.500 mmol of *n*-$C_5H_{11}MgBr$ in Et_2O (1 ml). After being left to stand at 25 °C for 30 min, the resulting mixture was diluted with AcOEt, washed with aqueous NH_4Cl solution and dried ($MgSO_4$). After removal of the solvent under reduced pressure, the residue obtained was purified by thin layer chromatography on silica gel using AcOEt as a developing solvent to afford 36 mg (60%) of **1** as an oil; MS *m/e* 396.2866 (Calcd for $C_{23}H_{40}O_5$: 396.2875).

Retardation of the Cleavages of Nitrophenyl 1-Adamantanecarboxylates by Cyclodextrins

Makoto KOMIYAMA* and Shohei INOUE

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received January 21, 1980)

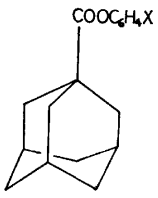
Cleavages of *p*- and *m*-nitrophenyl 1-adamantanecarboxylates (**1** and **2**) were carried out in the presence of α-, β-, and γ-cyclodextrins at 16 °C. The complex formation of **1** with α-, β-, and γ-cyclodextrins decelerated its cleavage by 3.2, 28, and 13 fold, respectively, in the 99 : 1 (v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile. All α-, β-, and γ-cyclodextrins showed decelerations of the cleavages of **1** and **2** also in the 66 : 34 mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile, although the magnitudes of the rate effects were smaller. The decelerations of the cleavages of **1** and **2** by cyclodextrins were markedly in contrast with the accelerations of the cleavages of other phenyl esters by cyclodextrins previously reported, and were ascribed to the formation of the complexes, in which **1** and **2** were protected sterically and/or electrostatically by cyclodextrins.

Cyclodextrins (CDs), cyclic oligosaccharides composed of 6—8 glucose units, have been used as an enzyme model, since they form complexes with substrates prior to their catalytic functions, resulting in many specificities exhibited by enzymes. The stereochemistry in the complex formation was shown to have quite important roles in the catalyses by CDs.[1]

Of many kinds of catalyses by CDs, hydrolyses of esters have been most widely and precisely studied, and much information has been obtained, especially on the effects of different leaving groups on the catalyses by CDs. Thus, CDs accelerated cleavages of phenyl esters of acetic acid,[2] benzoic acids,[2] and 3-carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl.[3] The cleavages of trifluoroethyl benzoate[4] and *S*-ethyl thiobenzoate[5] were also accelerated by CDs, whereas the cleavages of ethyl and methyl esters of benzoic acids and cinnamic acids were retarded or totally inhibited by CDs.[2,6,7]

However, little is known about the role of the acyl portions of esters in the catalyses by CDs.

In this paper, the effects of α-, β-, and γ-cyclodextrins (α-, β-, and γ-CD) on the cleavages of *p*-nitrophenyl 1-adamantanecarboxylate (**1**) and *m*-nitrophenyl 1-adamantanecarboxylate (**2**) are described. The acyl portions of **1** and **2**, adamantanecarbonyl groups, are much more bulky and apolar than the acyl portions of any esters ever studied. Furthermore, a ^{13}C-NMR spectrometry on the CD–1-adamantanecarboxylate (**3**) system was carried out to shed light on the interactions of the adamantane moieties of **1** and **2** with CDs.



1 : X= p-NO_2
2 : X= m-NO_2

Experimental

Materials. **1** and **2** were synthesized from 1-adamantanecarbonyl chloride and the corresponding phenols and were recrystallized from ethanol. **1**: mp 132.5—132.8 °C (lit, 130—131 °C[8]). **2**: mp 137.8—138.3 °C. Found: C, 67.79; H, 6.37; N, 4.59%. Calcd for $C_{17}H_{19}NO_4$: C, 67.76; H, 6.36; N, 4.65%. α-CD and β-CD were recrystallized from water. γ-CD was purchased from Nakarai Chem. Co. and was used without further purification.

Kinetics. The cleavage of **1** was carried out at 16 °C in the 99 : 1 (v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile. The small amount of acetonitrile was due to the initiation of the reaction by the addition of the 30 μl stock solution of **1** in acetonitrile to 3 ml 0.1 mol dm^{-3} NaOH aqueous solution.

The attempt to examine the cleavage of **2** in the similar way, however, was not successful because of poor solubility of **2** in aqueous solution.

For the purpose of comparison, the cleavages of both **1** and **2** were carried out in the 66 : 34 (v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile. The reactions were also initiated by the addition of 30 μl stock solutions in acetonitrile to the mixture of 2 ml 0.1 mol dm^{-3} NaOH aqueous solution and 1 ml acetonitrile.

The initial concentrations of **1** and **2** were approximately 2×10^{-5} and 10^{-4} mol dm^{-3}, and their cleavages were followed by the release of the corresponding phenols at 410 and 390 nm, respectively. The rate constant of the cleavage, k_{obsd}, was determined by the usual first-order plot.

^{13}C-NMR Spectrometry. ^{13}C-NMR spectra were taken in D_2O solutions at pDs 9 and 13 at 60 °C on a JEOL PFT-100 spectrometer operating at 25.03 MHz by use of a deuterium lock. The chemical shifts were referenced to external benzene and the accuracy was within ±0.03 ppm.

Results

All α-, β-, and γ-CDs retarded the cleavages of both **1** and **2**. Figure 1 shows the dependence of k_{obsd} on the concentrations of CDs ($[CD]_0$) for the cleavage of **1** in the 99 : 1(v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile. Obviously, k_{obsd} asymptotically decreased with $[CD]_0$. Similar results were observed also in the cleavages of **1** and **2** in the 66 : 34(v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile.

These retardations of the cleavages of **1** and **2** by CDs are markedly in contrast with the accelerations of the cleavages of phenyl esters by CDs previously reported.[1-3]

The dependences of k_{obsd} on $[CD]_0$ were analyzed according to the Scheme 1 involving the complex

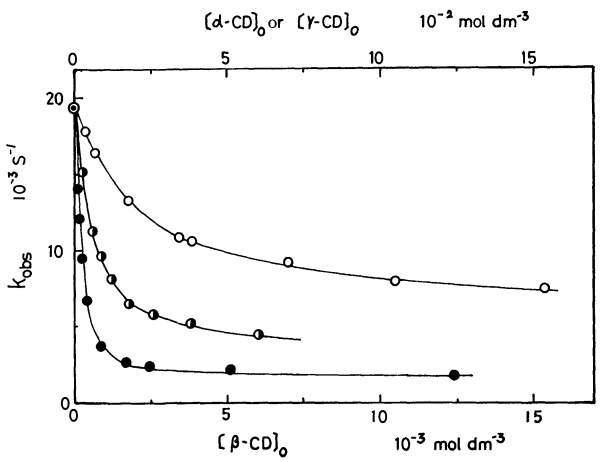


Fig. 1. Dependences of the rate constants of the cleavage of **1** (k_{obsd}) upon the initial concentrations of cyclodextrins ([CD]$_0$); in the 99 : 1 (v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile at 16 °C. ●: β-CD (the lower scale), ○: α-CD, ◑: γ-CD (the upper scale).

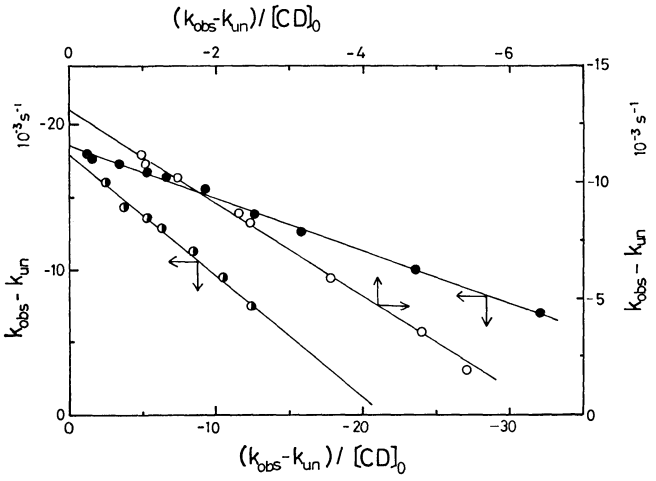

Fig. 2. Plots of $(k_{obsd}-k_{un})$ *vs.* $(k_{obsd}-k_{un})/[CD]_0$ in the cleavage of **1** in the presence of CDs. ○, ●, and ◑ refer to α-, β-, and γ-CDs, respectively; the data in Fig. 1 are used here.

formation of the substrate (S) with CD prior to the reaction:

$$S + C \underset{K_d}{\rightleftharpoons} S\cdot C \xrightarrow{k_c} \text{products}$$
$$\downarrow k_{un}$$
$$\text{products}$$

Scheme 1.

The rate constants of the cleavage of the substrate in the S·C complex, k_c, and the dissociation constant of the S·C complex, K_d, were determined by use of the Eadie-type plot Eq. 1:

$$(k_{obsd}-k_{un}) = -K_d(k_{obsd}-k_{un})/[CD]_0 + (k_c-k_{un}). \quad (1)$$

Table 1 lists the values of k_c and K_d, determined from the slope and intercept of the straight lines in the Eadie-type plots as shown in Fig. 2.

Table 1. Values of k_c, k_c/k_{un}, and K_d for the cleavages of *p*- and *m*-nitrophenyl 1-adamantanecarboxylates (**1** and **2**) in the presence of cyclodextrins (CDs)

Substrate	CD	k_c / 10^{-4} s^{-1}	k_c/k_{un}	K_d / 10^3 mol dm^{-3}

	β-CD	28±5	0.60	2.2±0.5
	γ-CD	45.2[c]	—	—

a) In the 0.1 mol dm^{-3} NaOH aqueous solution–acetonitrile mixture (99 : 1 in volume), at 16 °C; k_{un} under these conditions was 1.93×10^{-2} s^{-1}. b) In the 0.1 mol dm^{-3} NaOH aqueous solution–acetonitrile mixture (66: 34 in volume) at 16 °C; k_{un}'s of **1** and **2** under these conditions were 4.75×10^{-3} and 4.65×10^{-3} s^{-1}, respectively. c) k_{obsd} in the presence of 3×10^{-2} mol dm^{-3} CD.

It was found that the complex formation of **1** with α-, β-, and γ-CDs decelerated its cleavage by 3.2, 28, and 13 fold, respectively, in the 99 : 1(v/v) mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile. Similarly, the cleavages of **1** and **2** were retarded by 3.3 and 1.7 fold, respectively, by the complex formations with β-CD in the 66 : 34 mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile.

Determinations of k_c and K_d for the cleavages of **1** and **2** by α- and γ-CDs in the 66 : 34 mixture by use of the Eadie-type plots were not successful because of small magnitudes of effects by CDs, although these CDs showed decelerations in these reactions.

The magnitudes of the deceleration of the cleavage of *p*-nitrophenyl ester **1** by CDs were similar to those of the cleavage of *m*-nitrophenyl ester **2** by CDs. These small effects of the positions of the phenyl substituents on the rate constants of their cleavages in the presence of CDs were also in contrast with the predominant roles of the positions of the phenyl substituents in the acceleration of the cleavages of phenyl acetates by CDs. For example, the cleavages of *p*- and *m*-nitrophenyl acetates were accelerated by α-CD by 3.4 and 300 fold, respectively.[6]

Table 2 shows the changes of the ^{13}C-NMR chemical shifts on the complex formation of CDs with **3** in D_2O. At pDs 9 and 13, the secondary hydroxyl groups of CDs are overwhelmingly in the unionized and ionized states, respectively, since their pK_a is around 11 at 60 °C.[9]

Furthermore, at pD 9, almost all of CD and **3** form complexes under the experimental conditions, in consideration of the previously determined dissociation constants of these complexes (for the α-CD–**3** complex, 1.1×10^{-3} mol dm^{-3} and for the β-CD–**3** complex, 1.4×10^{-3} mol dm^{-3} at 60 °C[10]).

On the complex formation of **3** with α-CD at pD 9, the C-4 atoms showed shifts toward the lower magnetic field, whereas the C-2 and C-3 atoms showed shifts

TABLE 2. CHANGES OF THE ^{13}C CHEMICAL SHIFTS ON THE COMPLEX FORMATION BETWEEN CYCLODEXTRINS (CDs) AND 1-ADAMANTANECARBOXYLATE (**3**)[a]

CD

c) Assignment following Ref. 11. d) The values in parentheses show the results of the duplicate experiments.

toward the higher magnetic field. The C-1 atom, however, exhibited little shift.

At pD 13, where virtually all of α-CD is in the anionic form, however, no changes of the chemical shifts for both α-CD and **3** were observed considering experimental error. This indicates that no complex is formed between α-CD and **3** at pD 13.

Larger changes of the chemical shifts of both the guest and host molecules were observed on the complex formation between β-CD and **3** at pDs 9 and 13.

Discussion

The retardation of the cleavages of **1** and **2** by CDs in spite of the acceleration of the cleavages of many other phenyl esters previously studied is attributable to the apolar and bulky properties of the adamantane moieties of **1** and **2**. These groups can be included in the cavity of β-CD (and also the cavity of γ-CD) as indicated by the considerable changes of the ^{13}C-NMR chemical shifts on the complex formation of **3** with β-CD. The adamantane moieties of **1** and **2**, however, can not be included in the small cavity of α-CD and only sit on the top of the cavity, as proposed by the study using the molecular models.[6] This is consistent with the small changes of the ^{13}C chemical shifts on the complex formation of **3** with α-CD. In the hydrolyses of phenyl esters accelerated by CDs, the phenyl portions are included in the cavity, followed by the nucleophilic attack of CDs at the substrates.[1]

Two Structures A and B are possible for the complex of **1** or **2** with β-CD or γ-CD, both of which are nonproductive or less productive. Structure A is formed by the inclusion of **1** and **2** in the cavity from the secondary hydroxyl side with their phenyl portions first, whereas Structure B is formed by the inclusion of **1** and **2** in the cavity from the same side with their adamantane portions first.[12] In Structure A, the carbonyl carbon atoms of the substrates should be located deeply in the cavity, since the apolar property of the adamantane portions require most of them as well as the phenyl portions to be included in the cavity. Consequently, nucleophilic attack of the secondary alcoholate anion of CDs at the carbonyl carbon atoms is sterically unfavorable. Furthermore, steric protection by the walls of CDs and electrostatic repulsion by the negative charges of CDs retard alkaline hydrolyses of **1** and **2**.

In Structure B, nucleophilic attack by the secondary alcoholate anions of CDs can not produce the acyl-CD (the intermediate) with the release of the phenols, since the acyl-CD with the acyl portion inside the cavity involves too drastic distortion(s) in bond(s). Furthermore, alkaline reactions are retarded sterically and electrostatically in the similar way as in Structure A.

The retardation of the cleavages of **1** and **2** by α-CD indicates that the phenyl portions of **1** and **2** are included in the cavity with the adamantane portions sitting on the top of the cavity. In this structure, nucleophilic attack both by the secondary alcoholate anion of CD and by hydroxide ion are prevented sterically and/or electrostatically. If the adamantane portions alone is located in the cavity and the phenyl portion is outside, any retardation by α-CD is unlikely.

Much smaller deceleration effects by CDs on the cleavages of **1** and **2** in the 66 : 34 mixture of 0.1 mol dm^{-3} NaOH aqueous solution and acetonitrile than in the 99: 1 mixture is attributable to shallower inclusions of the substrates in the cavities of CDs because of apolar properties of the adamantane portions. In this structure, any effect by CDs should be small. This interpretation is supported by the 13 fold large K_d of the β-CD–**1** complex (corresponding to less stable complex) in the 66: 34 mixture than that in the 99: 1 mixture.

In conclusion, the cleavages of **1** and **2** were retarded by CDs, which is in contrast with the acceleration of the cleavages of many other phenyl esters by CDs. The present results show that the acyl portions of the substrates can have a predominant effect on the catalyses by CDs.

We would like to thank Prof. Teiji Tsuruta at the University of Tokyo for his valuable comments.

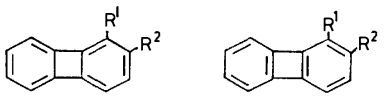
Reaction of 1,2-Dimethoxybiphenylene with Dichlorocarbene. Chemical Detection of the Bond Fixation in Biphenylene Derivatives

Masaru SATO, Keiko INABA, Seiji EBINE,* and Josuke TSUNETSUGU
Department of Chemistry, Saitama University, Urawa, Saitama 338
(Received January 26, 1980)

1,2-Dimethoxybiphenylene reacted with dichlorocarbene to give three chloro(methoxy)-6*H*-benzo[3,4]-cyclobuta[1,2]cyclohepten-6-one derivatives, two chloro(methoxy)fluorenones and two dimethoxyfluorenones. The reaction with dibromocarbene gave similar products. The formation of these products serves as unequivocal chemical evidence for bond fixation of 1,2-dimethoxybiphenylene. The chloro(methoxy)-6*H*-benzo[3,4]cyclobuta-[1,2]cyclohepten-6-one was led to 9-chloro-5-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one, the first tropolone analogue of biphenylene. This compound was shown to exist in only one of the two possible tautomers in contrast with general monocyclic tropolones.

Delocalization of π-electrons in benzene nucleus of aromatic compounds can be perturbed by some demands of an electronic environment or the incorporation of steric strain. The former is demonstrated in such molecules as naphthalene, phenanthrene, and other condensed-ring aromatic compounds, where some bond fixation in one benzene ring results from the fusion with the other benzene rings. The latter is illustrated in benzocyclobutene derivatives. Biphenylene provides the special case of double bond fixation in which both electronic and steric factors are participated: biphenylene prefers one canonical structure (**1a**) over the others, especially the structure (**1b**) carrying an anti-aromatic cyclobutadiene ring. Such a partial bond fixation of biphenylene was proved by electron diffraction[1] and X-ray analysis,[2] and suggested from the proton-proton coupling constant of the aromatic ring[3] and some chemical reactions.[4] It is also well-known that the carbene addition may be valuable as a chemical probe for the detection of bond fixation in aromatic molecules.[5] The carbene addition to naphthalenes, for example, takes place at C_1–C_2 and C_3–C_4 double bond but does not at C_2–C_3 double bond,[6] and methoxycarbonylcarbene reacts with biphenylene preferentially at the C_2–C_3 double bond.[7] In connection with our work on chemistry of small ring-annelated non-benzenoid aromatics, we are investigating the reaction of dichlorocarbene with methoxybiphenylenes, because the reaction can provide a convenient synthetic route to the troponoid analogues of biphenylene. The addition of dichlorocarbene to 1- (**2**) and 2-methoxybiphenylenes

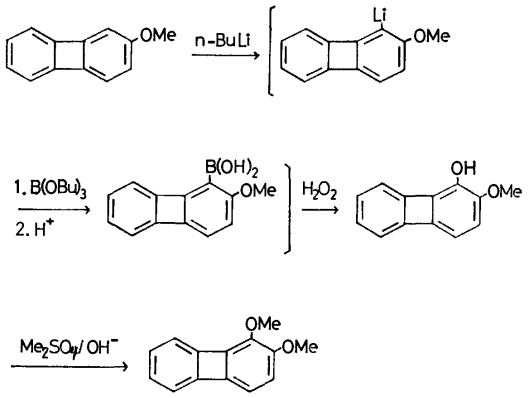


(1) $R^1=R^2=H$ (2) $R^1=OMe$, $R^2=H$ (3) $R^1=H$, $R^2=OMe$
(4) $R^1=R^2=OMe$

(**3**) takes place at C_2–C_3 and C_1–C_{8b}, or C_2–C_3 and C_4–C_{4a} double bonds, respectively, as previously reported.[8] We now wish to report the details about the addition of dihalocarbene to 1,2-dimethoxybiphenylene (**4**).[9]

Results and Discussion

2-Methoxybiphenylene (**3**)[10] was metalated with butyllithium and the lithio intermediate was allowed to react with tributyl borate, and the resulting 1-biphenylenylboronic acid was subsequently oxidized with hydrogen peroxide to give 1-hydroxy-2-methoxybiphenylene. This fact is parallel to the predominant α-metalation of biphenylene.[11] 1-Hydroxy-2-methoxybiphenylene was treated with dimethyl sulfate and alkali to afford 1,2-dimethoxybiphenylene (**4**) is a nearly quantitative yield.



1,2-Dimethoxybiphenylene (**4**) reacted with dichlorocarbene, generated from chloroform (3 equiv.) and 33% aqueous sodium hydroxide in the presence of catalytic amount of hexadecyltrimethylammonium chloride,[12] to give three chloro(methoxy)-6*H*-benzo[3,4]cyclobuta-[1,2]cyclohepten-6-ones (**8a**, **9a**, and **10a**), two chloro-(methoxy)fluorenones (**11a** and **12a**), and two dimethoxyfluorenones (**13** and **14**), along with the recovered starting material (70.0%). The yields, IR, NMR, and electronic spectra of these compounds are summarized in Table 1. Similarly, the reaction of **4** with dibromocarbene generated by the Dehmlow's method[13] gave two bromo(methoxy)-6*H*-benzo[3,4]cyclobuta[1,2]-cyclohepten-6-ones (**9b**) and (**10b**), two bromo-(methoxy)fluorenones (**11b**) and (**12b**), and 3,4-dimethoxyfluorenone (**14**). The yields, IR, ^{1}H-NMR, and electronic spectra of those products are summarized

a) See Ref. 14.

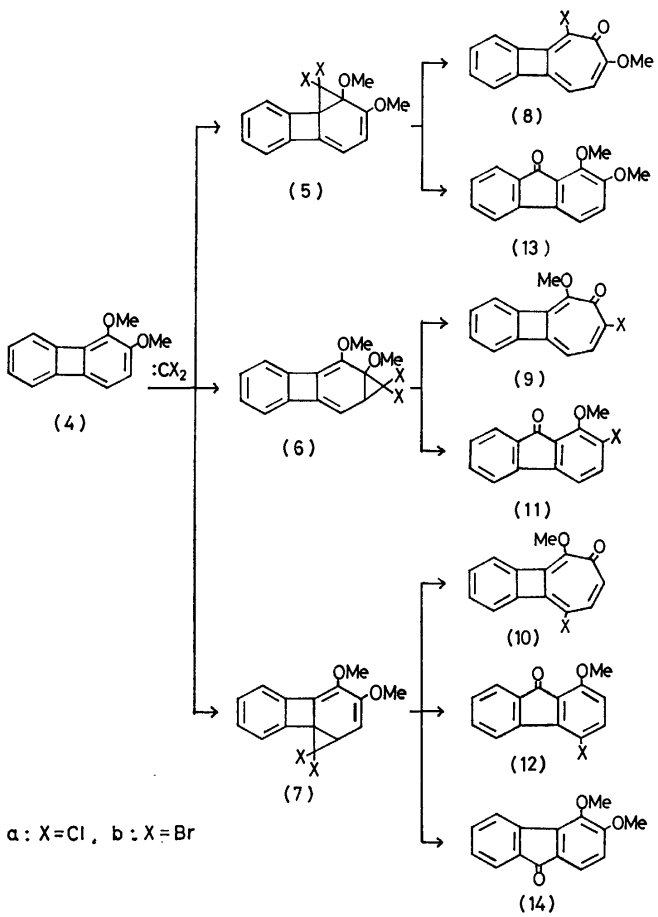
in Table 2. Chloro(methoxy)-6*H*-benzo[3,4]cyclobuta-[1,2]cyclohepten-6-one derivatives (**8a**, **9a**, and **10a**) had the molecular ion at *m/e* 244, and the corresponding bromo derivatives **9b** and **10b** had the molecular ion at *m/e* 290 in their mass spectra. These tropone derivatives showed the strong absorption near 1600 cm^{-1} in their IR spectra. Their electronic spectra were closely similar to each other and moreover to those of other 6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one derivatives reported previously.[8] In the NMR spectra, **10a** showed two olefinic doublets (AB type) at δ 6.37 and 6.71 ppm (J=13.2 Hz), and similarly **9a** at δ 6.20 and 7.42 ppm (J=9.0 Hz). The large coupling constant in the former and the small one in the latter mean the intervention of a double bond and a single bond, respectively, between the vicinal protons. Hence **10a** and **9a** can be assigned to 9- and 7-chloro-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-ones, respectively. The two olefinic protons in **8a** appeared accidentally as a singlet at δ 6.29 ppm but on addition of the shift reagent (Eu-fod) the singlet separated into two doublets (J=9.0 Hz), whereby **8a** is assigned to 5-chloro-7-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one. The NMR spectra of **10b** and **9b** showed two doublets at δ 6.28 and 6.79 (J=13.2 Hz), and 6.13 and 7.77 (J=8.5 Hz), respectively. Therefore, in a similar manner, **10b** and **9b** were assigned to 9-bromo- and 7-bromo-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-ones, respectively. Two dimethoxyfluorenones (**13** and **14**), and two chloro(methoxy)-fluorenones (**11a** and **12a**) were identified as 1,2- and 3,4-dimethoxyfluorenones,[14] and 2- and 4-chloro-1-methoxyfluorenones, respectively, by the mixed mp and IR spectral coincidence with the authentci samples. The latter two authentic compounds were prepared by another route: 1-methoxyfluorenones[15] was chlorinated with sulfuryl chloride in the presence of azobis-(isobutyronitrile) to give 2- and 4-chloro-1-methoxyfluorenones in 23 and 57% yields, respectively. 2-Bromo- (**11b**) and 4-bromo-1-methoxyfluorenones (**12b**) were assigned by the close similarity of their IR, UV, and ^{1}H-NMR spectra to those of **11a** and **12a**, respectively.

The formation of these products seems to be elucidated best as proceeding through the reaction path shown in Scheme 1. Dichlorocarbene added to **4a** giving the intermediate adducts **5**, **6**, and **7**. The adduct **7** converted spontaneously to **10** and, on the other hand, was attacked by a hydroxide ion at C_{4a} and C_{8b} to give **12** and **14**, respectively. The path to fluorenone derivatives is similar to that in the reaction between 1-methoxybiphenylene and dichlorocarbene.[8] Similarly, the adduct **5** afforded **8** and **13**, and the adduct **6** did **9** and **11**. Thus, the addition of dichlorocarbene must have taken place at the fixed C_{8b}–C_1, C_2–C_3, and C_4–C_{4a} double bonds of the canonical structure **4a** of 1,2-dimethoxybiphenylene, although dibromocarbene cannot add to the corresponding C_{8b}–C_1 double bond. No adduct from another canonical structure **4b** was obtained. This is the first example in the reaction of

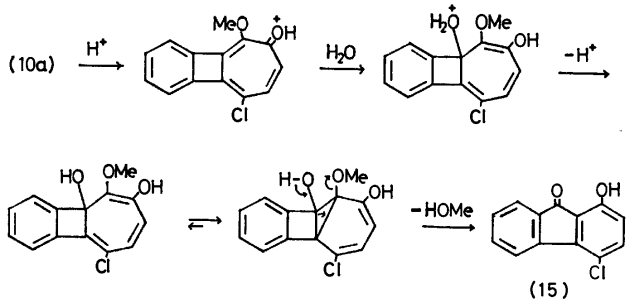


Scheme 1.

biphenylene series where all the possible products resulting from one of the Kekule's canonical structures are obtained, and this observation serves as unequivocal chemical evidence for the bond fixation of biphenylene system.

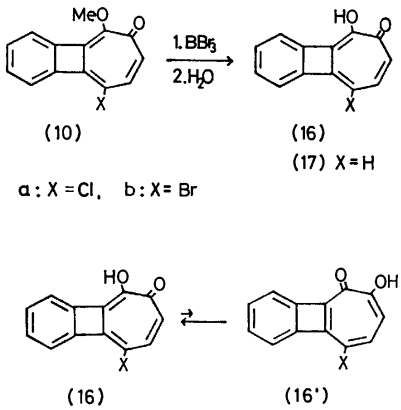
The addition of dichlorocarbene to C_{8b}–C_1, C_2–C_3, and C_4–C_{4a} double bonds of **4a** gave 2.2, 5.3, and 8.3% yields of the products, respectively, while the addition of dibromocarbene to the corresponding double bonds did in 0, 4.4, and 12.4% yields, respectively. In the reaction of **4** with dihalocarbene, the addition of the carbene to C_4–C_{4a} double bond was most favorable. The observation may be explained by the absence of steric hindrance in the approach of the carbene and by the best stabilization of the intermediate **7** in term of both conjugated methoxyl groups compared with others **5** and **6**. The predominant addition of dihalocarbene to C_4–C_{4a} double bond is also observed in the dichlorocarbene-addition to 2-methoxybiphenylene[8] but is in contrast with the exclusive addition of ethyl diazoacetate to the C_2–C_3 double bond of biphenylene itself.[7] In the latter, the addition of the carbene may be controlled by the electron-deficiency of C_{8b}–C_1 double bond induced with rehybridization of the junction carbon (C_{8b}).[16] The similar conjugative effect of methoxyl group was observed in the addition of dichlorocarbene to methoxynaphthalenes.[17,18] The less addition of dichlorocarbene to the C_{8b}–C_1 double bond than to the C_4–C_{4a} double bond seems to be in part due to the steric hindrance of the methoxyl group. Dibromocarbene added in the best yield to C_4–C_{4a} double bond and did not add to the most crowded double bond (C_{8b}–C_1). Therefore, the difference in yields between dichloro- and dibromocarbene addition to 1,2-dimethoxybiphenylene is probably due to the bulkiness of dibromocarbene compared with dichlorocarbene.

Attempted hydrolysis of the tropolone methyl ether **10a** with concentrated hydrochloric acid in boiling ethanol led to the hydroxyfluorenone derivative **15**. This facile rearrangement may be due to the release of the central four-membered ring strain, according to Scheme 2.



Scheme 2.

The tropolone methyl ether **10a** was treated with boron tribromide in dichloromethane at −65 °C and subsequently hydrolyzed to give 9-chloro-5-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**16a**), that is, the tropolone analogue of biphenylene in 93% yield. Similarly, bromo derivative **10b** was hydrolyzed to 9-bromo-5-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]-cyclohepten-6-one (**16b**) in 55% yield. Attempts to debrominate **10b** with tributyltin hydride[19] or zinc-copper couple in aqueous THF[20] in order to develope the route to the parent 5-hydroxy-6*H*-benzo[3,4]-cyclobuta[1,2]cyclohepten-6-one (benzo[3,4]cyclobuta-[1,2-*c*]tropolone) (**17**) were not successful. Catalytic hydrogenation of **16b** to **17** was also tried in vain.



The tautomerism **16**⇄**16'**, like monocyclic tropolones, is potentially expected. The equilibrium, however, proved to be imposed predominantly or exclusively to the tautomer **16** by the following facts. The electronic spectrum of **16a** is closely similar to that of the methyl

ether **10a**. The NMR coupling constant $J_{7,8}=13.3$ Hz of **16a** is nearly the same as that of the corresponding protons of **10a** ($J=13.2$ Hz). If the rapid equilibrium **16**⇄**16′** exsists, the coupling constant $J_{7,8}$ in **16** should be reduced to the corresponding value ($J_{6,7}=10.9$ Hz) of tropolone.[21] If the tautomer **16′** exists, the high-field shift of the benzenoid protons would be expected due to the paramagnetic ring current of the central four-membered ring, but actually this was not observed in **16a**. The absence of the contribution of **16′** is probably due to the instability of anti-aromatic cyclobutadiene structure in the central four-membered ring. The tropolone derivative **16a** gave a red coloration in chloroform layer with aqueous iron(III) chloride, like monocyclic tropolones. The tropolone **16a** could not be extracted with aqueous sodium hydrogen carbonate but reacted with aqueous sodium carbonate to give a red precipitate from which **16a** was recovered by neutralization with hydrochloric acid (2 mol dm^{-3}). The acidic property of **16a** is also shown by the fact that **16a** reacted with diazomethane to give the methyl ether **10a**, an alternate tautomeric methyl ether of **16a′** not being detected after careful search of the reaction mixture.

Experimental

1-Hydroxy-2-methoxybiphenylene. To a solution of 2-methoxybiphenylene (9.10 g, 0.05 mol) in dry ether (100 ml) was added the solution of butyllithium prepared from lithium (1.29 g, 0.186 mol) and butyl bromide (10.3 g, 0.075 mol) in dry ether (10 ml) under nitrogen. After the mixture was stirred for 1 h at room temperature, it was refluxed for 20 h. The resulting mixture was dropwise added to a solution of tributyl borate (19.1 g, 0.083 mol) in dry ether (60 ml) at −78 °C under nitrogen. After the addition had been completed, the cooling bath was removed and the mixture was stirred for 1 h at room temperature. To the mixture was added 10% HCl (25 ml). The ethereal layer was separated and the aqueous layer was extracted with ether. The ethereal solution combined was washed with water and then transfered to a 2-necked round-bottomed flask equipped with a reflux condenser. To the ethereal solution was added 30% hydrogen peroxide (22 ml) dropwise at such a rate that mild reflux was maintained. After the addition had been completed, the mixture was stirred for 0.5 h. The ethereal layer was separated and the aqueous layer was extracted with ether. The ethereal solution combined was washed with water and dried over anhydrous magnesium sulfate. Evaporation of the ether gave yellow crystals, the silica gel chromatography of which gave the recovered starting material (0.81 g, 8.9%) and 1-hydroxy-2-methoxybiphenylene (yellow needles, mp 94—95 °C) (6.03 g, 60.9%). Found: C, 78.83; H, 5.27%. Calcd for $C_{13}H_{10}O_2$: C, 78.77; H, 5.09%. IR(KBr): 3380, 1498, 1438, 1138, and 739 cm^{-1}. NMR ($CDCl_3$): δ 3.77 (s, 3H), 5.6 (broad s, 1H), 6.08 (d, 1H, $J=7.6$ Hz), 6.25 (d, 1H, $J=7.6$ Hz), 6.42—6.83 (m, 4H). MS (75 eV): *m/e* 198 (M^+, 100%), 183 (M^+-CH_3, 75.5%), and 155 (M^+-CH_3-CO, 58%).

1,2-Dimethoxybiphenylene (4): To a solution of 1-hydroxy-2-methoxybiphenylene (5.94 g, 0.03 mol) and dimethyl sulfate (60.5 ml, 0.64 mol) in methanol (33 ml) was slowly added a solution of sodium hydroxide (54.9 g) in water (65 ml) under stirring at such a rate as the temperature of the solution was kept at 20—30 °C. After the addition had been completed, the mixture was warmed at 60 °C for 1 h. To the mixture was added water (465 ml). The crystals precipitated were collected by filtration and recrystallized from ethanol to give white-yellow leaflets (5.97 g, 94%), mp 132.5—133.5 °C. Found: C, 79.14; H, 5.74%. Calcd for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%. IR (KBr): 1488, 1407, 1292, 1240, 1228, 802, and 736 cm^{-1}. NMR($CDCl_3$): δ 3.77 (s, 3H), 3.98 (s, 3H), 6.13 (d, 1H, $J=7.5$ Hz), 6.88 (d, 1H, $J=7.5$ Hz), and 6.5—6.83 (m, 4H). MS(75 eV): *m/e* 212 (M^+ 100%), 197 (M^+-CH_3, 70%), and 169 (M^+-CH_3-CO, 59%).

Reaction of 1,2-Dimethoxybiphenylene (4) with Dichlorocarbene. A mixture of 1,2-dimethoxybiphenylene (**4**) (1.70 g, 8 mmol), chloroform (2 ml, 24 mmol), dichloromethane (5 ml), 33% aqueous sodium hydroxide (4 ml), and hexadecyltrimethylammonium chloride (25 mg) was stirred for 3 h at room temperature. The resulting red mixture was diluted with water and extracted with dichloromethane. The extract was washed twice with saturated aqueous sodium chloride and dried over sodium sulfate. After the solvent had been evaporated, the red-orange crystalline residue was chromatographed on silica gel with elution of benzene–ether. The following compounds were in turn eluted and purified with thin-layer chromatography and recrystallization. Their spectral data were summarized in Table 1. 2-Chloro-1-methoxyfluorenone (**11a**)(90 mg, 4.7%), yellow needles, mp 122—122.5 °C. Found: C, 68.84; H, 3.71%. Calcd for $C_{14}H_9ClO_2$: C, 68.72; H, 3.71%. 1,2-Dimethoxybiphenylene (**4**) (recovery 70.0%). 3,4-Dimethoxyfluorenone (**14**) (36 mg, 1.9%), mp 142.5 °C, yellow rods (lit,[14] 145.5 °C). 4-Chloro-1-methoxyfluorenone (**12a**) (16 mg, 0.8%), fine yellow needles, mp 152—152.5 °C. Found: C, 68.68; H, 3.74%. Calcd for $C_{14}H_9ClO_2$: C, 68.72; H, 3.71%. 1,2-Dimethoxyfluorenone (**13**) (17 mg, 0.9%), orange-yellow plates, mp 113—114 °C (lit,[14] 113 °C). 7-Chloro-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**9a**) (12 mg, 0.6%), fine yellow needles, mp 142—143 °C. Found: C, 68.68; H, 3.89%. Calcd for $C_{14}H_9ClO_2$: C, 68.72; H, 3.71%. 9-Chloro-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]-cyclohepten-6-one (**10a**) (110 mg, 5.6%), yellow needles, mp 135—136 °C. Found: C, 68.60; H, 3.79%. Calcd for $C_{14}H_9ClO_2$: C, 68.72; H, 3.71%. 5-Chloro-7-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**8a**) (26 mg, 1.3%), yellow crystals, mp 150—151 °C. Found: C, 68.76; H, 3.76%. Calcd for $C_{14}H_9ClO_2$: C, 68.72; H, 3.71%.

Reaction of 1,2-Dimethoxybiphenylene (4) with Dibromocarbene. To a mixture of 1,2-dimethoxybiphenylene (**4**) (1.70 g 8 mmol), dichloromethane (3 ml), 33% aqueous sodium hydroxide (9 g), and hexadecyltrimethylammonium chloride (30 mg) was dropwise added bromoform (3.5 ml, 40 mmol) for a period of 15 min on an ice–water bath. After the mixture was stirred for 30 min, the ice–water bath was removed. The mixture was further stirred for 1.5 h at room temperature. The resulting mixture was treated in the same work-up as that in the reaction of **4** with dichlorocarbene described above. The following products were isolated: 2-Bromo-1-methoxyfluorenone (**11b**) (95 mg, 4.1%), yellow needles, mp 72.8—73.8 °C. Found: C, 58.33; H, 3.10%. Calcd for $C_{14}H_9BrO_2$: C, 58.16; H, 3.14%. 1,2-Dimethoxybiphenylene (**4**) (1.07 g, 70% recovery). 3,4-Dimethoxyfluorenone (**14**) (96 mg, 5.0%), yellow needles, mp 139.7—140.2 °C (lit,[14] 145.5 °C). Found: C, 74.74; H, 5.05%. Calcd for $C_{15}H_{12}O_2$: C, 74.79; H, 5.03%. 4-Bromo-1-methoxyfluorenone (**12b**) (27 mg, 1.2%), yellow needles, mp 134.8—135.8 °C. Found: C, 58.16; H, 3.15%. Calcd for $C_{14}H_9BrO_2$: C, 58.16; H, 3.14%. 7-Bromo-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**9b**) (9 mg, 0.4%), yellow nee-

dles, mp 147—148 °C. Found: C, 58.00; H, 3.06%. Calcd for $C_{14}H_9BrO_2$: C, 58.16; H, 3.14%. 9-Bromo-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**10b**) (143 mg, 6.2%), yellow needles, mp 144.3—144.8 °C. Found: C, 58.17; H, 3.45%. Calcd for $C_{14}H_9BrO_2$: C, 58.16; H, 3.14%. The spectral data were summarized in Table 2.

2- *(11a) and 4-Chloro-1-methoxyfluorenones (12a).* A solution of 1-methoxyfluorenone[16] (210 mg, 1 mmol), sulfuryl chloride (160 mg, 1.2 mmol), and azobis(isobutyronitrile) (small amount) in dichlormethane (10 ml) was stirred for 1.5 h. After the solvent was evaporated up, the residue was chromatographed on silica gel with elution of benzene–ether. The first elute gave pale yellow crystals (mp 191—192 °C, 11 mg). The second elute gave 2-chloro-1-methoxyfluorenone (56 mg, 23%) as yellow needles (mp 120—121 °C). Found: C, 68.73; H, 3.61%. Calcd for $C_{14}H_9ClO_2$: C, 68.72; H, 3.71%. The third fraction was 4-chloro-1-methoxyfluorenone (136 mg, 57%), as yellow needles, mp 152.5—153 °C. Found: C, 68.27; H, 3.67%. Calcd for $C_{14}H_9ClO_2$: C, 68.72; H, 3.71%.

4-Chloro-1-hydroxyfluorenone (15). *A*: To a solution of 4-chloro-1-methoxyfluorenone (**10a**) (65 mg) in dichloromethane was added boron tribromide (0.12 ml) at −65 °C under nitrogen. The red-brown solution was stirred for 45 min at the same temperature. The solution was warmed up to room temperature and poured into water. The mixture was extracted with dichloromethane. The extract was washed with water and dried over anhydrous sodium sulfate. After evaporation, the residue was sublimed under reduced pressure (110 °C/10 mmHg) to give a yellow crystalline product (55 mg, 90%), which was recrystallized from hexane, mp 158.5—159.5 °C. Found: C, 67.67; H, 2.99%. Calcd for $C_{13}H_7ClO_2$: C, 67.70; H, 3.06. UV (EtOH): 254 (log ε 4.76), 299 (3.35), 382 (3.61) nm. IR (KBr): 3387, 1699, 1614, 1297, 1183, and 741 cm^{-1}. NMR ($CDCl_3$): δ 6.74 (d, 1H, J=9.0 Hz), 7.29 (d, 1H, J=8.9 Hz), 7.3—7.8 (m, 3H), 8.13 (m, 1H), and 8.64 (broad s, 1H).

B: A mixture of 9-chloro-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**10a**) (37 mg), concd HCl (2 ml), and ethanol (5 ml) was refluxed for 4 h. The solution was poured into water, and the resulting mixture was extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. After evaporation, the residue was chromatographed on silica gel to give, along with the starting material (16 mg, 45%), 4-chloro-1-hydroxyfluorenone (**15**) (18 mg, 52%), yellow needles, mp 158—159 °C. Admixed mp 158—159 °C.

*9-Chloro-5-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (16a).* To a solution of 9-chloro-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**10a**) (105 mg, 0.43 mmol) in dichloromethane (15 ml) was added boron tribromide (0.2 ml) at −65 °C under nitrogen. After being stirred for 30 min at the same temperature, the solution was warmed gradually to room temperature and poured into water. The mixture was extracted with dichloromethane. The extract was dried over anhydrous sodium sulfate. After the solution had been evaporated up, the residue was sublimed at about 140 °C/2 mmHg to give yellow crystals (92 mg, 93% yield), which were recrystallized from ethanol to give bright-yellow needles, mp 207—208 °C. Found: C, 67.87; H, 2.98%. Calcd for $C_{13}H_9ClO_2$: C, 67.70; H, 3.06%. UV (EtOH): 278 (log ε 4.27), 312 (4.64), 348 (3.86), 386sh (3.40), and 419 (3.10) nm. IR (KBr): 3250, 1602, 1569, 1373, 1215, 833, and 729 cm^{-1}. NMR (DMSO-d_6): δ 6.49 (d, 1H, J=13.3 Hz), 7.02 (d, 1H, J=13.3 Hz), 7.2—7.45 (broad s, 4H), and 10.3 (1H). MS (60 eV): *m/e* 230 (M^+, 63%) and 202 (M^+−CO, 100%).

*9-Bromo-5-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (16b).* To a solution of 9-bromo-5-methoxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**10b**) (118 mg, 0.41 mmol) in dichloromethane (15 ml) was added boron tribromide (0.4 ml) at −65 °C under nitrogen. After the solution had been stirred for 30 min at the same temperature and then poured into water. The mixture was extracted with dichloromethane. The extract was dried over anhydrous sodium sulfate and then evaporated up. The residue was sublimated under reduced pressure. The crystals obtained were recrystallized from ethanol to give yellow needles, mp 199—200 °C. Found: C, 56.61; H, 2.37%. Calcd for $C_{13}H_7BrO_2$: C, 56.76; H, 2.56%. UV (EtOH): 213 (log ε 4.47), 280 (4.27), 313 (4.63), 347 (4.01), and 392 (3.42) nm. IR (KBr): 3260, 1595, 1570, 1375, 1220, and 750 cm^{-1}. NMR ($CDCl_3$): δ 6.49 (d, 1H, J=13.5 Hz), 7.04 (d, 1H, J=13.5 Hz), and 7.20—7.42 (m, 4H).

Reaction of (16a) with Diazomethane. To a solution of diazomethane in ether (20 ml) prepared from *N*-nitrosomethylurea (103 mg, 1 mmol) was added 9-chloro-5-hydroxy-6*H*-benzo[3,4]cyclobuta[1,2]cyclohepten-6-one (**16a**) (40 mg, 0.17 mmol) on an ice-water bath. The solution was stirred for 6 h. The solution was extracted with aqueous sodium carbonate. The ethereal layer was dried over anhydrous sodium sulfate, and then evaporated up. The residue was chromatographed on silica gel with elution of dichloromethane to give the methyl ether **10a** as yellow crystals (38 mg, 90%). The aqueous layer was acidified with HCl (2 mol dm^{-3}) and then extracted with ether. From the ethereal extract the starting material was recovered (3 mg, 7%).

The auther thanks Prof. L. Horner (Universitat Mainz) for kindhearted offer of the authentic samples and their NMR spectra of dimethoxyfluorenones, and also Prof. K. Suzuki (Utsunomiya Univ.) for kindhearted offer of 1-methoxyfluorenone. The author is also grateful to Dr. K. Takahashi and Prof. K. Takase (Tohoku Univ.) for 100 MHz-NMR measurements.

Mechanism of Base Catalyzed Oxidation of 2-(1-Hydroxyalkyl)-thiazolium Ion with 3-Methyllumiflavin

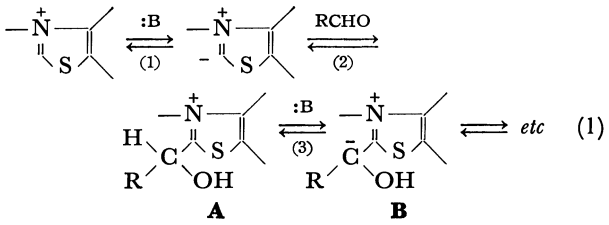
Yumihiko YANO, Yoshiharu TAMURA, Yutaka HOSHINO, and Waichiro TAGAKI*

Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received January 30, 1980)

The oxidation of 2-(α-hydroxybenzyl)- and 2-(1-hydroxyethyl)thiazolium ions with 3-methyllumiflavin was studied kinetically in an aqueous buffer solution. The results indicate that the rate-determining step is carbanion formation followed by rapid oxidation. The carbanion formation was subjected to general base catalysis.

The mechanism of catalysis of thiamine coenzyme involves the formation of active aldehyde as a key intermediate[1] as shown in the following equation.



(1)

A **B**

The first step (1) of ionization of 2-hydrogen of thiazolium ring was thoroughly investigated.[2] However, the mechanism of the subsequent deprotonation of **A** (step 3) has remained unclarified, whether it is subjected to a general base or a specific base catalysis, although α-hydrogen exchange of 2-(1-hydroxyethyl)thiazolium ion (**A**, R=CH_3) had been confirmed by NMR.[3] Recently, it has been shown by NMR that carbanion formation from 2-(1-hydroxyethyl)- and 2-(α-hydroxybenzyl)thiazolium ions is subjected to general base catalysis in aqueous buffer solutions.[4]

Flavins are reduced by carbanions such as those generated from α-hydroxy ketones. Usually, the reduction is so fast that the rate limiting step is the formation of carbanion.[5] Namely, the rate of carbanion formation can be measured spectrophotometrically by observing oxidation-reduction of flavin. The method allows the use of a much lower concentration of substrate than that for NMR. In addition to such a merit, the use of flavin is of interest as a model reaction of flavin pyruvate oxidase. This enzyme catalyzes the oxidative decarboxylation of pyruvate to give acetate and CO_2,[6] the flavoprotein being reduced by 2-(1-hydroxyethyl)-thiamine diphosphate.[7]

As a part of studies on the model thiamine catalysis,[8] a kinetic study was carried out on the reaction of 2-(α-hydroxybenzyl)- and 2-(1-hydroxyethyl)thiazolium ions (**1** and **2**) with flavin (**3**), together with the H-D exchange reaction of **1** for comparison.

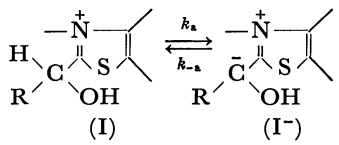
3 (Flox)

Results and Discussion

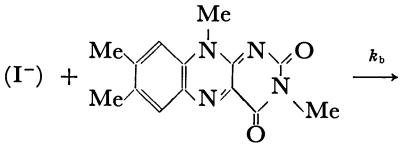
Carbanion Oxidation by Flavin. The reaction was followed by monitoring the decrease in absorption of **3** (Flox) at 443 nm under anaerobic conditions. The disappearance of Flox was found to be linear with the reaction time to 75% reaction. The reaction is of zero order with respect to flavin concentration as observed in the other α-hydroxy carbanion oxidations by flavins.[5] The bubbling of O_2 after the reaction regenerated more than 95% Flox in all the runs.

The results are in line with the mechanism of Eqs. 2 and 3, *i.e.* the rate limiting formation of carbanion (I^-) followed by a rapid oxidation. Thus, on the assumption of steady state with respect to (I^-), Eq. 4 can be derived resulting in the zero order dependency in [Flox] (Eq. 6) under the conditions of Eq. 5. The rates were also confirmed to be of first order with respect to (I) to give first order rate constant, k_a (Fig. 1).

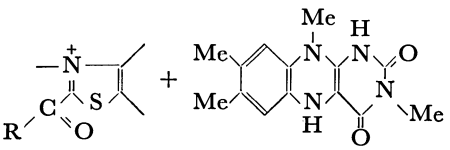


(2)

(I) (I^-)



3 (Flox)



(3)[9]

$$-\frac{d[Flox]}{dt} = \frac{k_a k_b [I][Flox]}{k_{-a} + k_b[Flox]} \quad (4)$$

$$k_b[Flox] \gg k_{-a} \quad (5)$$

$$-\frac{d[Flox]}{dt} = k_a[I] \quad (6)$$

$$k_a = k_{OH^-}[OH^-] + k_B[B] \quad (7)$$

The k_a values obtained under various conditions are summarized in Table 1. The pH-log k_a plots for compound **1** give a straight line of slope=0.93 (Fig. 2). The buffer concentrations were changed for Tris and carbonate buffers. The rate increase is linear with the

		0.25	12.6
		0.4	13.8
		0.5	15.9
	9.23[b]	0.1	13.9
	9.45[d]	0.1	22.5
		0.2	24.5
		0.4	30.5
	9.53[b]	0.1	25.6
	9.78[b]	0.1	44.3
2	9.46[d]	0.1	0.392
		0.25	0.751
		0.5	1.14

a) [Flox]=6.9×10^{-5}M, [**1**]=[**2**]=2.07×10^{-3}M, μ=0.5 (NaCl). b) Borate buffer. c) Tris buffer. d) Carbonate buffer.

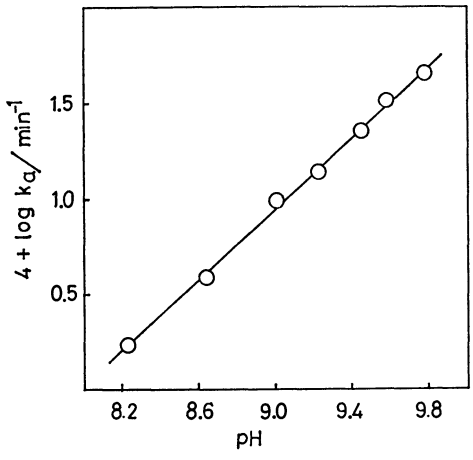

Fig. 2. pH-log k_a plots for **1** (see Table 1).

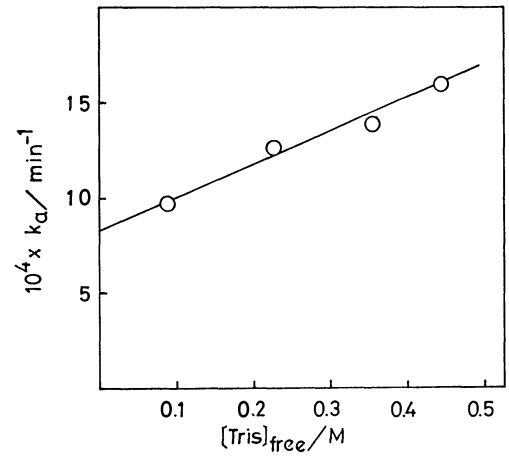

Fig. 3. Plots of k_a *vs.* Tris buffer concentration for **1** (pH=9.01, see Table 1).

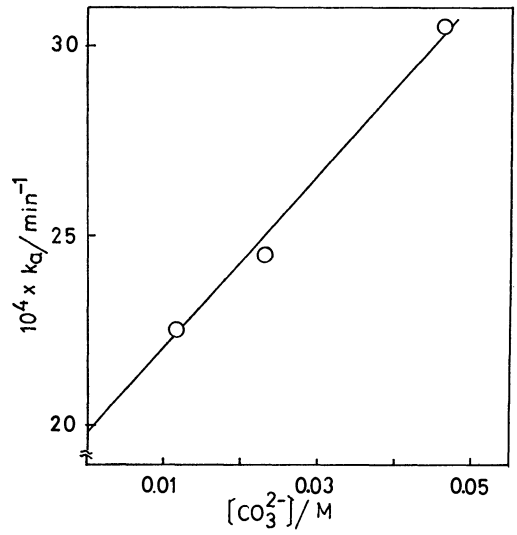

Fig. 4. Plots of k_a *vs.* carbonate buffer concentration for **1** (pH=9.45, see Table 1).

increase of buffer concentration in both cases (Figs. 3 and 4). Thus, k_a is represented by Eq. 7, where k_{OH^-} and k_B are the hydroxide ion and buffer (general base) catalyzed second order rate constants, respectively. The k_{OH^-} and k_{Tris} values for **1** are 91.3 and 1.66×10^{-3} M^{-1} min^{-1}, respectively in the Tris buffer (Fig. 3). For the carbonate buffer, k_{OH^-} and $k_{CO_3^{2-}}$ are 72 and 2.3×10^{-2} M^{-1} min^{-1}, respectively (Fig. 4). Since k_{OH^-} values should be the same, the average value, 82 M^{-1} min^{-1} can be used as the k_{OH^-} for **1**. In a similar way, k_{OH^-} and $k_{CO_3^{2-}}$ for **2** can be calculated to be 0.80 and 1.68×10^{-3} M^{-1} min^{-1}, respectively. The reactivities of **1** and **2** can then be compared by the ratio of k_{OH^-} (**1**)/k_{OH^-} (**2**)=10^2 and $k_{CO_3^{2-}}$ (**1**)/$k_{CO_3^{2-}}$ (**2**)=14, respectively. The ratios seem to be reasonable, since the carbanion formation should be much easier from **1** than from **2**.

The β value of the Brönsted plots could be regarded as a criterion to distinguish a general base from a specific base catalysis; the β value is close to unity in the case of specific base catalysis and *ca.* 0.5 for general base catalysis.[10] As shown in Fig. 5, the Brönsted plots of log k_a *vs.* pK_a of bases for **1** give a straigh line of slope=0.63 (β values). The β value for **2** can be calculated to be 0.5, from the available two data of k_{OH^-}

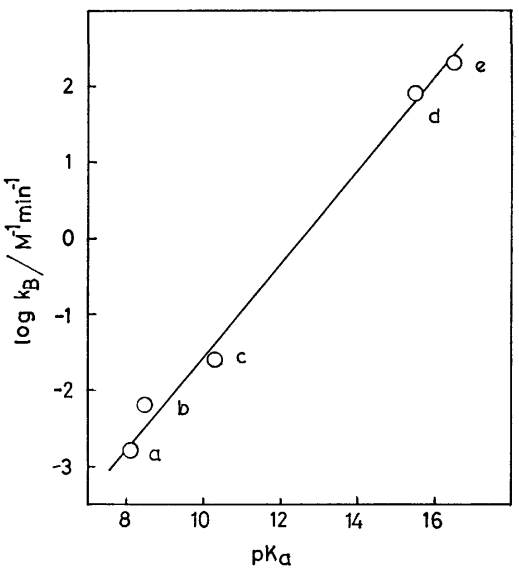

Fig. 5. The Brönsted plots for carbanion formation of **1**.
a) k_{Tris}, $pK_a=8.10$,[11] b) k_{Tris} (NMR), $pK_a=8.50$,[12] c) $k_{CO_3^{2-}}$, $pK_a=10.3$,[13] d) k_{OH^-}, $pk_a=15.6$,[14] e) k_{OD^-} (NMR), $pK_a=16.5$.[14]

and $k_{CO_3^{2-}}$. The β values indicate that the carbanion formation is a process of general base catalysis for both **1** and **2**.

H-D Exchange of 1. Since the carbanion formation is rate limiting in the above flavin reduction, the rates should be the same as those of H-D exchange of α-hydrogen of **1** and **2**. Thus, H-D exchange of **1** was also examined by means of NMR. The rate was followed by determining the relative intensities of the α-hydrogen and unexchangeable hydrogens of phenyl ring of **1**. First order kinetics was observed, although measurement of 1: 5 proton ratio involves large experimental error. The rate constants (k_{obsd}) thus obtained, however, were found to involve the rate term of decomposition of **1** to the corresponding thiazolium ion and benzaldehyde as shown by $k_{obsd}=k_{ex}+k_{dec}$. Therefore, in order to obtain k_{ex}, the rate of decomposition of **1** (k_{dec}) was determined spectrophotometrically by following the decrease of **1** at λ_{max} 267 nm ($\varepsilon=10{,}000$ $M^{-1}cm^{-1}$) under the same conditions as those of H-D exchange reaction. The results are given in Table 2. Although we have only two data, the k_{ex} values give $k_{OD^-}=2.0\times10^2$ $M^{-1}min^{-1}$ and $k_{Tris}=6.0\times10^{-3}$ M^{-1} min^{-1} on the basis of Eq. 7. These rate constants should involve considerable error. Nevertheless, they fit reasonably on the straight line of Fig. 5, when we consider the relationship, $pK_a(D_2O)=pK_a(H_2O)+0.4$.[12]

The results indicate that the deprotonation of active aldehyde such as **1** and **2** proceeds *via* general base catalysis. It should be noted that the present method is superior to the usual NMR method. The rate of carbanion formation can easily be determined by the spectrophotometric method. Substrate concentration required (2×10^{-3} M) is much lower than that (0.2 M) for NMR method. Furthermore, the time necessary for rate measurement can be reduced a great deal. For example, if the rate constant (k_a or k_{ex}) is 4×10^{-3} min^{-1}, the half-life is 170 min in the H-D exchange reaction, whereas, in the flavin reduction, zero order rate is $V_{obsd}=\Delta OD/\Delta t=k_a[I]\varepsilon=(4\times10^{-3})\times(2.07\times10^{-3})\times(1.2\times10^4)=0.099$, and when [Flox] is 6.9×10^{-5} M (OD=0.83), the half-life is only 4.6 min (=0.415/0.099). This makes the decomposition of **1** negligible during the course of rate determination.

Table 2. Rate constants of H-D exchange of **1**

pD[a]	[Tris]/M	$10^3\times k_{ex}/min^{-1}$[b]
9.20	0.1	1.4
9.20	0.4	2.9

a) $pD=pH_{obsd}+0.4$. b) $k_{ex}=k_{obsd}-k_{dec}$; $k_{dec}=4.76\times10^{-4}$ min^{-}, [**1**]=0.2 M, μ=0.5(NaCl) at 30 °C.

Experimental

Materials and Methods. All melting points were uncorrected. UV and visible spectra were recorded with a Shimadzu UV 200 spectrophotometer, and NMR spectra with a Varian A-60 spectrometer. pH was measured with a Hitachi-Horiba F-7DE pH meter. Water used for kinetics was purified by treating deionized water with potassium permanganate and by distillation twice. Buffer reagents were of commercial special grade.

3,4-Dimethyl-2-(α-hydroxybenzyl)-5-(2-hydroxyethyl)thiazolium iodide (**1**) was prepared by the method reported. Mp 113—115 °C (from ethanol-acetone) (lit,[15] mp 111—113 °C).

2-(1-Hydroxyethyl)-4-methylthiazolium iodide (**2**) was prepared from the corresponding thiazole and methyl iodide in ethanol. Mp 149—151 °C (from methanol-ether) (lit,[2a] mp 149—150 °C).

3-Methyllumiflavin (**3**) was prepared by the method reported. Mp 315 °C (from DMF) (lit,[16] mp 318 °C).

Kinetics. All kinetic measurements were carried out in an aqueous buffer solution containing 1% acetonitrile at 30 °C. 30 μl of the substrate (**1** or **2**) solution (1×10^{-1} M) was placed in the upper compartment of a Thunberg cuvette, and 3 ml of an aqueous buffer solution and 30 μl of Flox (6.9×10^{-3} M in acetonitrile) in the lower cell. Each solution was bubbled for 30 min with nitrogen which had been scrubbed with vanadous ion solution[17] and prehumidified with water. In the case of Tris buffer, nitrogen bubbling was performed in the dark to avoid the light-reduction of flavin. After equilibration at 30 °C for 15 min, the reaction was initiated by mixing the two solutions, the reaction being followed by observing the decrease of optical density at 443 nm. The slopes of optical density *vs.* time plots ($\Delta OD/\Delta t$) are plotted against substrate concentration (Fig. 1, 1 M=1 mol dm^{-3}).

Kinetics for H-D Exchange. The reaction mixtures for the kinetics were prepared as follows. The thiazolium salt (0.1 mmol) was weighed accurately in a microtube, and 0.5 ml of buffer solution added, the tube being capped with septum-rubber. Nitrogen was bubbled for 5 min through an injection needle. The solution was transfered to the NMR tube with syringe and capped quickly. The rate constants were determined by following the relative intensities of α-proton and phenyl ring protons in a similar manner to that reported.[18]

(Received February 8, 1980)

The synthesis of biopterin, D(and L)-*erythro*-neopterins, and their derivatives having a substituent at the 2-amino group *via* the 2-methylthio analogues is described. The 2-(methylthio)pteridines were synthesized by condensation of 4,5-diamino-6-hydroxy-2-(methylthio)pyrimidine with 5-deoxy-L-arabinose and D(and L)-arabinose phenylhydrazones, followed by oxidation with $K_3[Fe(CN)_6]$ and O_2 in the presence of KI in an acidic solution, respectively. Aminolysis of these thioethers with ammonia and other amines in the presence of acetic acid gave the title compounds.

The aromatic amino acid hydroxylases, phenylalanine hydroxylase,[2] tyrosine hydroxylase,[3] and tryptophan hydroxylase,[4] play key roles in the biosynthesis of catecholamine neurotransmitters or indoleamine neurotransmitter. Since these hydroxylases require tetrahydrobiopterin as cofactor, defficiency of the biopterin cofactor causes serious neuropathological disorders. Indeed, hyperphenylalaninemia due to defficiency of biopterin has been reported as a variant form of phenylketonuria.[5,6] In order to diagnose such disease, assay of biopterin in serum or urine is required.

Recently we studied a radioimmunoassay for biopterin (**3a**) by employing 6-[[4-hydroxy-6-(L-*erythro*-1,2-dihydroxypropyl)-2-pteridinyl]amino]hexanoic acid–bovine serum albumin conjugate (**1a**) as the immunogen and *N*-[2-(4-hydroxy-3-[^{125}I]phenyl)ethyl]-6-[[4-hydroxy-6-(L-*erythro*-1,2-dihydroxypropyl)-2-pteridinyl]-amino]hexanamide (**1b**) as the radioactive antigen.[7] The antiserum produced by rabbits against **1a** showed high specificity toward biopterin and did not cross-react with other pteridines including D- and L-*erythro*-neopterins (**4a** and **5a**) and 6,7-dimethylpterin. During a preliminary experiment, we found that the sensitivity of the radioimmunoassay increased about ten-fold on preincubating the antiserum with 6-[(4-hydroxy-6,7-dimethyl-2-pteridinyl)amino]hexanoic acid (**2**); most probably, antibodies having specificity against the hexanoic acid moiety were removed by the preincubation.

This finding suggests that the sensitivity of the assay could be more increased even when the time-consuming preincubation procedure is omitted, if a radioactive antigen having no hexanoic acid moiety were used. In order to examine this possibility, we synthesized several biopterin and neopterin derivatives to be used as antigen carrying a hydroxyphenyl or methoxyphenyl group linked to the amino nitrogen of biopterin and neopterin directly or indirectly through a carbon chain smaller than a pentyl group.

In the present paper, we studied a synthetic route for such biopterin derivatives by a nucleophilic replacement of 4-hydroxy-6-(L-*erythro*-1,2-dihydroxypropyl)-2-(methylthio)pteridine (**3b**) with an appropriate amine to save reaction steps and time. The required common intermediate (**3b**) was synthesized by condensation of 4,5-diamino-6-hydroxy-2-(methylthio)pyrimidine and 5-deoxy-L-arabinose phenylhydrazone, followed by oxidation of the unstable condensate with potassium hexacyanoferrate(III) and oxygen in the presence of a small amount of potassium iodide.[8,9] Two blue fluorescent compounds were obtained in this reaction. The minor

a) Negative figures are H_0 values. b) Wave length in nm measured in aqueous buffer of given pH; shoulders or influexions in italics. c) Ionic species are shown by + (cation), ○ (neutral molecule), − (mono-anion), and 2 − (dianion).

product was found to be 4-hydroxy-2-(methylthio)-pteridine (**6**) which was unambiguously synthesized by condensation of 4,5-diamino-6-hydroxy-2-(methylthio)-pyrimidine and glyoxal. The structure of the main product was determined to be **3b** from the elemental analyses and UV spectra similar to those of **6** (Table 1). This conclusion was further confirmed by aminolysis of the main product into biopterin (**3a**). The 6-(D-*erythro*-1,2,3-trihydroxypropyl) and 6-(L-*erythro*-1,2,3-trihydroxypropyl) analogues (**4b** and **5b**) of **3b** were similarly synthesized by condensation of 4,5-diamino-6-hydroxy-2-(methylthio)pyrimidine with D- or L-arabinose phenylhydrazone and oxidation of the condensates with the above oxidizing agents; their structures were confirmed by aminolysis to the known D- or L-*erythro*-neopterin (**4a**, **5a**),[10] respectively. A considerable amount of the condensate again lost the trihydroxypropyl substituent during the oxidation. It is to be noted that an analogous condensate from 2,4,5-triamino-6-hydroxypyrimidine and D-arabinose phenylhydrazone did not loose the trihydroxypropyl group even when the condensate was oxidized by air in an alkaline solution;[10] under such conditions, the present condensate entirely lost the trihydroxypropyl group to give **6**.

The (methylthio)pteridine (**3b**) proved to be a good precursor for the synthesis of the present required biopterin derivatives carrying a substituent at the 2-amino group. When **3b** was heated with tyramine in 2-methoxyethanol or *N,N*-dimethylformamide in the presence of acetic acid, **3b** was easily converted into 4-hydroxy-2-[2-(*p*-hydroxyphenyl)ethylamino]-6-(L-*erythro*-1,2-dihydroxypropyl)pteridine (**3c**); in the absence of acetic acid, decomposition of **3b** into several unclarified substances took place to a fair extent. Analogous treatment of **3b** with *p*-methoxybenzylamine, *p*-anisidine, or aniline gave the biopterin derivatives (**3d**—**f**) possessing respectively a *p*-methoxybenzyl, *p*-methoxyphenyl, or phenyl group at the 2-amino nitrogen. The thioethers (**4b** and **5b**), on aminolysis with those amines, gave the corresponding derivatives of D-*erythro*-neopterin (**4c**—**f**) and L-*erythro*-neopterin (**5c**—**f**).

The (methylthio)pteridines (**3b**, **4b**, and **5b**) showed very weak basicity (pK_a −1.0) and a characteristic bathochromic shift on protonation (see Table 1). The aminolysis products exhibited two pK_a values at about 1.6 and 7.5: the former is attributed to the protonation of the pteridine ring to form cations and the latter to the ionization of the 4-hydroxyl group to form anions. Both values are slightly lower than those of biopterin (pK_a 2.23 and 7.89[9]). An additional pK_a value at 10 was observed with **3c**, **4c**, and **5c** owing to the ionization of the phenolic hydroxyl group. However, the ionization changed the UV spectra only slightly, because the hydroxyl group is not conjugated to the main pteridine chromophore.

A study of radioimmunoassay for biopterin and neopterin using the present synthesized compounds will be reported eleswhere.

Experimental

The elemental analyses were conducted at The Analytical Section, Meijo University, Nagoya. The pK_a values were determined by a spectroscopical method,[11] and the UV spectra in an appropriate buffer solution on a Shimadzu UV-300 spectrophotometer.

*4-Hydroxy-6-(*L-erythro-*1,2-dihydroxypropyl)-2-(methylthio)-pteridine (**3b**) and the Trihydroxypropyl Analogues (**4b** and **5b**).* 4-Amino-6-hydroxy-2-methylthio-5-nitrosopyrimidine[12] (18 g) was hydrogenated over 5% palladium on carbon (10 g) in 0.5 M KOH (500 ml) at room temperature and atmospheric pressure till the calculated amount of hydrogen was absorbed. The catalyst was removed by filtration and the filtrate was adjusted to pH 3—4 with formic acid. A considerable amount of colorless needles of the 5-aminopyrimidine deposited on neutralization. Without isolating the needles, the mixture was added to 5-deoxy-L-arabinose phenylhydrazone[9] (32 g) in methanol (400 ml). The resulting solution was stirred under nitrogen at 25 °C for 90 min, and then under reflux for 30 min. After chilling, it was added to a solution of potassium hexacyanoferrate(III) (100 g), potassium iodide (5 g), and formic acid (10 ml) in water (500 ml). The solution was stirred under bubbling oxygen at pH 3—4 and 25 °C for 20 h. The solution was concentrated to about 500 ml under reduced pressure and made alkaline (pH 9—10) with ammonia. The nonfluorescent precipitate was removed by filtration and the filtrate was fractionated on a Florisil column (5×60 cm) using water as the elution solvent to give two blue fluorescent fractions. The major fraction, after concentration to about 150 ml, was chromatographed again on Florisil in the same way as above. The eluate was evaporated to dryness under reduced pressure and the residue was extracted with hot methanol (500 ml). Concentration of the extract to about 50 ml and chilling gave colorless needles (5.5 g) of 4-hydroxy-6-(L-*erythro*-1,2-dihydroxypropyl)-2-(methylthio)pteridine (**3b**), which decomposed above 210 °C without melting (from water) (Found: C, 40.27; H, 4.45; N, 18.65%. Calcd for $C_{10}H_{12}N_4O_3S \cdot 2H_2O$: C, 39.46; H, 5.31; N, 18.41%). The minor fraction, after purification as above, yielded 1.9 g of 4-hydroxy-2-(methylthio)pteridine (**6**), mp 268—269 °C (dec) (from water) (Found: C, 43.59, H, 3.08; N, 28.72%. Calcd for $C_7H_6N_4OS$: C, 43.29; H, 3.11; N, 28.85%). This compound was synthesized alternatively by heating 4,5-diamino-6-hydroxy-2-(methylthio)pyrimidine and equimolar glyoxal in water under reflux for 30 min (68% yield).

By employing D- or L-arabinose phenylhydrazone in palce of 5-deoxy-L-arabinose phenylhydrazone in the above reaction, 4-hydroxy-6-(D-*erythro*-1,2,3-trihydroxypropyl)-2-(methylthio)-pteridine (**4b**) [70% yield, mp 156—158 °C (dec) (from water) (Found: C, 39.63; H, 4.68; N, 18.03%. Calcd for $C_{10}H_{12}N_4O_4S \cdot H_2O$: C, 39.72; H, 4.68; N, 18.54%)] and the L-isomer (**5b**) [62% yield, mp 156—158 °C (dec) (from water) (Found: C, 39.75; H, 4.63; N, 18.17%. Calcd for $C_{10}H_{12}N_4O_4S \cdot H_2O$: C, 39.72; H, 4.68; N, 18.54%)] were respectively obtained.

*Biopterin (**3a**) and* D *(and* L*)*-erythro-*Neopterins (**4a** and **5a**).* A solution of **3b** (200 mg), ammonium acetate (0.6 g), and 28% aqueous ammonia (5 ml) was heated under reflux for 4 h. The solution was adjusted to pH 2 with hydrochloric acid and fractionated on a Florisil column (3.5×20 cm) using water as the elution solvent. The eluate was evaporated to dryness under reduced pressure and the residue was extracted with 1% ammonia (50 ml). The extract was concentrated to about 10 ml, adjusted to pH 3, and chilled to give ivory needles (90 mg) of biopterin, which was identified with

the authentic sample.[9])

In a similar way, **4b** and **5b** were converted to D-*erythro*-neopterin (**4a**) (62% yield) and L-*erythro*-neopterin (**5a**) (72% yield), respectively.

*4-Hydroxy-2-[2-(p-hydroxyphenyl)ethylamino]-6-(*L-erythro-*1,2-dihydroxypropyl)pteridine (3c) and the Trihydroxypropyl Analogues (4c and 5c).* A solution of **3b** (1.0 g), tyramine (3 g), and acetic acid (0.8 g) in 50% aqueous 2-methoxyethanol (8 ml) was heated at 100—105 °C for 6 h. The solution was adjusted to pH 1—2 with hydrochloric acid and placed on a Florisil column (3.5×40 cm). The column was washed with 2 M formic acid (0.5 l) and water (0.5 l) to remove the excess tyramine and a small amount of **3b**. The column was then eluted gradiently with 0—2% ammonia (1 l). The eluate, after concentration to about 150 ml, was again chromatographed in the same way as above and the final eluate was evaporated to dryness. The residue was extracted with 2% ammonia (200 ml), which was concentrated to about 100 ml. The solution was adjusted to pH 3 with formic acid and chilled to give yellow needles (34% yield) of **3c**, which decomposed at 165 °C (from water) (Found: C, 54.56; H, 5.62; N, 18.38%. Calcd for $C_{17}H_{19}N_5O_4 \cdot H_2O$: C, 54.39; H, 5.64; N, 18.66%).

Similar treatnent of **4b** and **5b** with tyramine gave **4c** [30% yield, mp 180—182 °C (dec) (from water) (Found: C, 49.88; H, 5.05; N, 16.72%. Calcd for $C_{17}H_{19}N_5O_5 \cdot 2H_2O$: C, 49.87; H, 5.66; N, 17.11%)] and **5c** [32% yield, mp 180—182 °C (dec) (from water) (Found: C, 49.88; H, 5.23; N, 16.90%. Calcd for $C_{17}H_{19}N_5O_5 \cdot 2H_2O$: C, 49.87; H, 5.66; N, 17.11%)], respectively.

*4-Hydroxy-6-(*L-erythro-*1,2-dihydroxypropyl)-2-(*p-*methoxybenzylamino)pteridine (3d) and the Trihydroxypropyl Analogues (4d and 5d).* A mixture of **3b** (1.0 g), *p*-methoxybenzylamine (2 g), and acetic acid (0.6 g) was heated at 100—105 °C for 4 h. The solution was adjusted to pH 3 with 50% formic acid and placed on a Florisil column (3.5×30 cm). The column was washed with 2M formic acid (500 ml) and then eluted gradiently with 0—2% ammonia (2 l). The eluate was concentrated to about 100 ml, made acid with formic acid, and then evaporated to dryness. The residue was extracted with hot methanol (100 ml). Concentration of the extract to about 5 ml and dilution with water (5 ml) gave pale yellow needles (50% yield) of **3d**, mp 226—227 °C (dec) (from 50% aqueous methanol) (Found: C, 54.70; H, 5.35; N, 18.33%. Calcd for $C_{17}H_{19}N_5O_4 \cdot H_2O$: C, 54.39; H, 5.64; N, 18.66%).

A similar reaction of **4b** and **5b** with *p*-methoxybenzylamine gave respectively **4d** as pale yellow needles [26% yield, darkened above 230 °C without melting (from methanol) (Found: C, 54.60; H, 5.02; N, 18.56%. Calcd for $C_{17}H_{19}N_5O_5$: C, 54.68; H, 5.13; N, 18.76%)] and **5d**[50% yield, darkened above 230 °C without melting (Found: C, 54.57; H, 5.06; N, 18.44%. Calcd for $C_{17}H_{19}N_5O_5$: C, 54.68; H, 5.13; N, 18.76%)].

*4-Hydroxy-6-(*L-erythro-*1,2-dihydroxypropyl)-2-(*p-*methoxyphenylamino)pteridine (3e) and the Trihydroxypropyl Analogues (4e and 5e).* A solution of **3b** (1.0 g), *p*-anisidine (8 g), and acetic acid (3 g) in *N,N*-dimethylformamide (15 ml) was heated at 80 °C for 8 h. The solution was fractionated on Florisil as above to give pale yellow needles (78% yield) of **3e**, which decomposed at 273 °C (from water) (Found: C, 56.08; H, 4.86; N, 20.23%. Calcd for $C_{16}H_{17}N_5O_4$: C, 55.97; H, 4.99; N, 20.40%).

In a similar way, the D-trihydroxypropyl analogue (**4e**) [43% yield, decomposed above 250 °C without melting (Found: C, 53.43; H, 4.63; N, 19.28%. Calcd for $C_{16}H_{17}N_5O_5$: C, 53.48; H, 4.77; N, 19.49%)] and the L-trihydroxypropyl analogue (**5e**) [30% yield, decomposed above 250 °C without melting (Found: C, 53.30; H, 4.64; N, 19.24%. Calcd for $C_{16}H_{17}N_5O_5$: C, 53.48; H, 4.77; N, 19.49%)] were obtained from the respective 2-(methylthio)pteridines (**4b** and **5b**).

*4-Hydroxy-6-(*L-erthro-*1,2-dihydroxypropyl)-2-phenylaminopteridine (3f) and the Trihydroxypropyl Analogues (4f and 5f).* These compounds were synthesized from the corresponding 2-methylthio precursors (**3b**, **4b**, and **5b**) and aniline in a way similar to that for the *p*-methoxybenzylamino analogues. The (1,2-dihydroxypropyl)pteridine (**3f**) was obtained as pale yellow needles (22% yield), mp 270—271 °C (dec) (from methanol) (Found: C, 57.38; H, 4.77; N, 21.83%. Calcd for $C_{15}H_{15}N_5O_3$: C, 57.50; H, 4.83; N, 22.34%). The (D-*erythro*-trihydroxypropyl)pteridine (**4f**) was obtained in 57% yield as pale yellow needles which decomposed above 260 °C without melting (Found: C, 54.80; H, 4.37; N, 21.04%. Calcd for $C_{15}H_{15}N_5O_4$: C, 54.71; H, 4.59; N, 21.27%). The (L-*erythro*-trihydroxypropyl)pteridine (**5f**), obtained in 33% yield as pale yellow needles, decomposed above 260 °C without melting (Found: C, 54.82; H, 4.46; N, 21.12%. Calcd for $C_{15}H_{15}N_5O_4$: C, 54.71; H, 4.59; N, 21.27%).

The authors would like to thank Mrs. Noriko Nishioka for the measurement of pK_a values and UV spectra.

Neighboring Group Participation in Solvolysis. X. Dissection of Ar_1-5 and Ar_2-6 Pathways in Trifluoroacetolysis of 4-Arylbutyl 6-Methyl-2-naphthalenesulfonates[1]

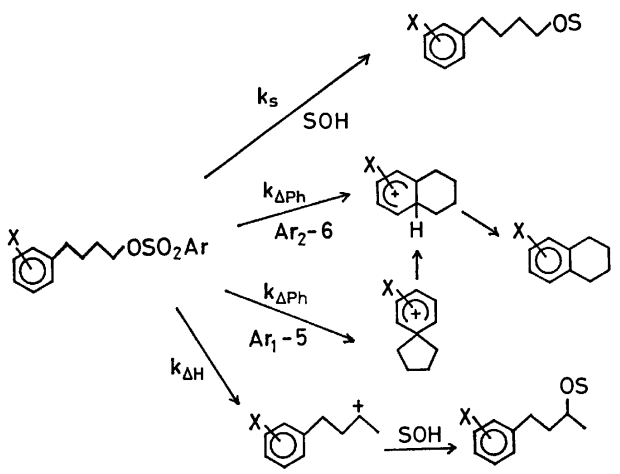
Takashi Ando,* Junko Yamawaki, Yoshimasa Saito, Yoshio Takai, and Hiroshi Yamataka

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Osaka 565

(Received February, 9, 1980)

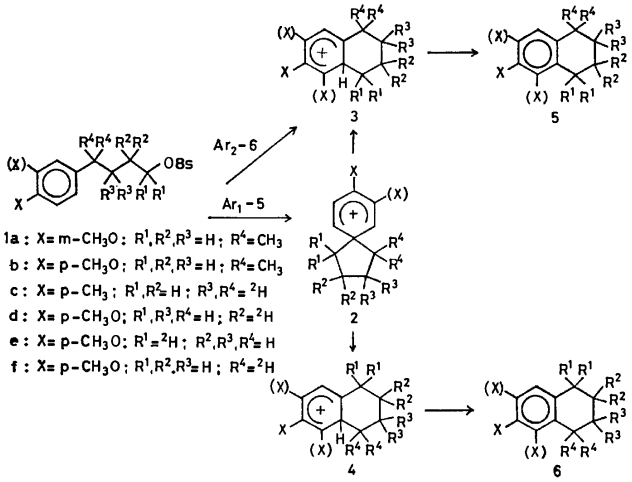
Trifluoroacetolysis rates and products were determined for eleven 4-(*m*- and *p*-substituted phenyl)butyl 6-methyl-2-naphthalenesulfonates. Most substrates solvolyze predominantly or even exclusively with aryl assisted (k_Δ) pathway. Dissection of k_Δ into Ar_1-5 and Ar_2-6 components was performed by means of quantitative ^{13}C NMR study of suitably labeled *p*-methyl and *p*-fluoro derivatives; the results were 32.4% Ar_1-5 and 67.6% Ar_2-6 for the former and 43.3% Ar_1-5 and 56.7% Ar_2-6 for the latter. For other substrates the dissection was carried out by postulating two independent linear free energy relationships (LFER) for the two pathways determined by the above four partial rates. Ar_2-6 is much prefered over Ar_1-5 through the series; for the unsubstituted derivative 90.6% Ar_2-6 *vs.* 9.4% Ar_1-5 was determined. A completely different approach by means of non-linear regression analysis of k_Δ as a sum of two independent LFER gave fairly different and rather unsettled results, limitations of such an approach being suggested. The characteristics of remote aryl participation are discussed based on the above data.

Recent study in this laboratory has shown that participation of a remote phenyl group is much more enhanced in a solvent of low nucleophilicity and high ionizing power such as trifluoroacetic acid than in an ordinary solvent.[2] 4-Phenylbutyl 6-methyl-2-naphthalenesulfonate (menasylate; Mns)[3] was found to solvolyze exclusively *via* the phenyl assisted pathway with 26.2 times rate enhancement relative to the standard, butyl menasylate. Heck and Winstein, who studied remote aryl participation in solvolysis systematically for the first time, proposed that δ-aryl participation proceeds with two possible modes; participation by the phenyl-1 (ipso) carbon forming a five-membered ring (Ar_1-5) and that by the phenyl-2 (ortho) carbon forming a six-membered ring (Ar_2-6) (Scheme 1).[4]



Scheme 1.

While anchimerically unassisted solvolysis gives a primary alkyl product, either mode of phenyl assisted solvolysis gives rise to 1,2,3,4-tetrahydronaphthalene (tetralin) as a final product. The rate constant of the former was designated k_s and that of the latter $k_{\Delta ph}$ as distinguished from $k_{\Delta H}$, the rate constant of neighboring hydrogen assisted solvolysis, which was found important in trifluoroacetic acid (Scheme 1, S= CF_3CO).[2,4] The identity of the products from the two modes of the $k_{\Delta ph}$ pathway makes its dissection difficult. The dissection is possible, however, by the double labeling technique, one lable on the phenyl ring and the other on the alkyl chain (Scheme 2).



Scheme 2.

Two differently substituted tetralins will be produced from a *p*-substituted substrate, and four from a *m*-substituted one. If we can accurately analyze the composition of tetralin isomers and also if we can reasonably estimate the migration ratio of CR^1R^1 and CR^4R^4 groups from the Ar_1-5 intermediate (**2**) to two types of protonated tetralins (**3** and **4**), then the two modes of $k_{\Delta ph}$ can be dissected quantitatively. Thus, Winstein and Heck studied the formolysis of 4-(*m*- and *p*-methoxyphenyl)butyl *p*-bromobenzenesulfonates (brosylates; Bs) utilizing methyl groups as a label on the alkyl chain (**1a** and **b**).[5] They postulated that only the $C(CH_3)_2$ group could migrate to the ortho position and the CH_2 group could not in the spiro intermediate **2**. Thus, the product ratio of **5** *vs.* **6** was considered to

be equal to the path ratio of Ar_2-6 *vs.* Ar_1-5. Introduction of two methyl groups on the chain, however, allows the intervention of a tertiary cation produced by ring opening of **2**, making the product analysis rather complicated. Furthermore, substitution with methyl groups is too large to be regarded as a perturbation. It is risky to estimate the behavior of the unperturbed substrate from the results of the dimethylated ones.

Jackman and Haddon,[6] and Gates and his coworkers[7] studied this dissection problem by use of deuterium as a label on the chain (**1c**—**f**). Although their analyses seem reasonable and substitution by deuterium is small enough a perturbation, the produced tetralins had to suffer rather drastic reaction such as oxidation or reduction before isotope analysis by means of mass spectroscopy was performed. These operations are tedious and may cause serious errors.

Carbon-13 NMR spectroscopy has become a familiar technique for organic chemists in recent years. Although quantitative application of FT NMR has so far been little exploited because of the widespread belief that the peak area does not give any information about the number of nuclei, it is actually quite useful in the quantitative and nondestructive analysis if enough precautions are taken. The large chemical shift range of ^{13}C NMR becomes one of the principal advantages in the quantitative analysis too. In this paper we report our study of the dissection of $k_{\Delta ph}$ in the trifluoroacetolysis of 4-(*p*-methyl- and *p*-fluorophenyl)butyl brosylates into Ar_1-5 and Ar_2-6 pathways by applying ^{13}C NMR to the analysis of the tetralins produced from suitably isotope-labeled substrates.

Although the double labeling technique with ^{13}C on the chain and a substituent on the ring is a sound method for evaluating the two reaction pathways, preparation of all the substituted phenylbutyl derivatives labeled with ^{13}C is laborious and expensive. Furthermore, the technique is not generally applicable because the quantitative analysis is only possible when tetralin isomers give a sufficient chemical shift difference. Among others $k_{\Delta ph}$ of the unsubstituted substrate can never be dissected by this method. On the other hand, if the two pathways are discrete and the partial rates of the both pathways follow individual LFER, a study of the substituent effects on the rate constants $k_{\Delta ph}$, when combined with the results of the double labeling technique, must give a possibility of a new and general approach to the dissection problem. Thus, $k_{\Delta ph}$ of substituted and unsubstituted substrates can reasonably be dissected to the two partial rates in such a manner as they follow two Hammett-type relationships, which have been determined by the data obtained from the double labeling method utilizing ^{13}C NMR spectroscopy. Two LFER thus obtained may give further information on the characteristics of remote aryl participation.

If the two independent LFER hold for the individual partial rates as postulated above, $k_{\Delta ph}$ can be described as a sum of them. Then, a completely different approach by means of non-linear regression analysis of substituent effects on $k_{\Delta ph}$ may become another possibility. It is a pure kinetic approach in contrast to the combination of the kinetic and product analyses described above. The results of this computer-programmed analysis are compared with those from the above combinational one, and the soundness of the two approaches is discussed.

Results

Trifluoroacetolysis rates of eleven 4-(*m*- and *p*-substituted phenyl)butyl menasylates (**7a**—**k**) were determined by the spectrophotometric method as described earlier.[2,3] The observed rate constants together with the corresponding activation parameters are given in Table 1, in which the data of butyl menasylate (**8**)[2] are also included. Each reported rate constant is the average value of duplicate to quadruplicate runs. The individual runs gave linear first-order rate plots over two half-lives for all the compounds with correlation coefficients greater than 0.9995.

$X\text{-}C_6H_4(CH_2)_4OMns$ $CH_3(CH_2)_3OMns$

7a: X=*m*-CH_3 **g**: X=*p*-F **8**
b: X=*p*-CH_3 **h**: X=*m*-Cl
c: X=*m*-CH_3O **i**: X=*p*-Cl
d: X=*p*-CH_3O **j**: X=*p*-Br
e: X=H **k**: X=*m*-CF_3
f: X=*m*-F

Reaction products were analyzed by gas chromatography after more than six half-lives under the same conditions as those for the kinetic runs. Reaction solutions containing dodecane as an internal standard were injected directly into a gas chromatograph. The yields of the products corrected with their respective sensitivities are summarized in Table 2. Control experiments showed that typical tetralins (unsubstituted and 6-CH_3) and a primary trifluoroacetate (unsubstituted) were stable under the reaction conditions.[2]

In the trifluoroacetolysis of [1,1-$^2H_2$]-4-(*p*-methoxyphenyl)butyl menasylate (**7d**-1,1-$^2H_2$), no deuterium scrambling was detected in the recovered menasylate after one half-life. The same observation was already reported for **7e**-1,1-$^2H_2$.[2]

^{13}C NMR study was performed with 4-(*p*-methyl- and *p*-fluorophenyl)butyl brosylates (**9b** and **g**, respectively) instead of menasylates **7b** and **g**. Although the menasylate is an excellent leaving group for the rate study,

menasyl chloride is commercially unavailable. As the difference in the leaving group is reasonably expected to have no effect on the fractions of the two neighboring aryl assisted pathways, **9b** and **g** both labeled with 90% ^{13}C at 1-position as well as the unlabeled ones were prepared and solvolyzed. ^{13}C-Enriched and "natural abundance"[8] tetralins with a substituent on the 6-position (**10b** and **g**) were isolated from the reaction solutions after more than seven half-lives and then purified by column chromatography and molecular distillation (Scheme 3).

FT NMR spectra were taken with great care under the conditions adequate for quantitative analysis,[9,10] particularly with a long pulse interval and a small pulse flip angle (*cf.* Experimental Section). Under these conditions the peak area ratio of the two benzylic carbons, 1- to 4-position, of the 6-methyl "natural abundance" tetralin (**10b**) was 1/1.016, and that of the 6-fluorotetralin (**10g**) was 1/1.097. The inequality in the latter may be attributed to the peak splitting of the C_4 by the long-range coupling with the fluorine (1.6 Hz). The peak area ratio of the ^{13}C-enriched tetralin was 1/4.950 for the 6-CH_3 derivative and 1/3.817 for the 6-F one under the same conditions as above.

Discussion

Table 1 shows that the trifluoroacetolysis rates of 4-arylbutyl menasylates **7** vary more than 10^2 depending on the substituents of the phenyl ring. This large substituent effect of the aryl group remote from the reaction center clearly indicates the development of the direct interaction between these two groups in the transition state of the reaction. It is consistent with the fact that most substrates gave tetralins as principal products in the yields more than 90% (Table 2). Thus, it is concluded undoubtedly that the trifluoroacetolyses of most of 4-arylbutyl menasylates proceed predominantly or even exclusively with remote aryl group participation.

As being implied qualitatively in the above discussion, it is generally accepted that aryl assisted ($k_{\Delta ph}$) and aryl unassisted (k_s) reactions are discrete in 4-arylbutyl solvolysis just like as in 2-arylethyl solvo-

Table 2. Trifluoroacetolysis products of 4-arylbutyl menasylates[a]

Substituent	6-Tetralin[b]	5-Tetralin[c]	1-ROTFA[d]	2-R'OTFA[e]

a) Yields in %. No analysis was performed for the *p*-CH_3O derivative (**7d**). The *m*-CF_3 derivative (**7k**) did not give a clear-cut result. b) 6-Substituted tetralin. c) 5-Substituted tetralin. d) 4-Arylbutyl trifluoroacetate. e) 3-Aryl-1-methylpropyl trifluoroacetate. f) Only relative yields were determined, but methyltetralin was confirmed to be stable under the reaction conditions. g) An unknown compound (*ca.* 5%) was detected. h) The isomers could not be separated by gas chromatography. ^{13}C and ^{19}F NMR spectra showed that the mixture contained 75±1% 6-fluoro- and 25±1% 5-fluorotetralins.

lysis.[2,5,6,11] Thus, the yields of tetralins correspond to the fractions of $k_{\Delta ph}$ in k_t. Furthermore, the lack of deuterium scrambling in the samples of **7d-** and **e**-1,1-$^2H_2$ recovered from the reaction solutions revealed that ion-pair return from the spiro Ar_1-5 intermediate to the starting menasylate, either directly or *via* the Ar_2-6 intermediate, is prohibited. Friedlich and Winstein also reported their observation that ring expansion of the spiro Ar_1-5 intermediate was very much faster than ring opening or solvolysis.[12] These facts suggest that the two pathways of $k_{\Delta ph}$ are also discrete, and that the ratio of the two partial rate constants can be described as a function of the relative amounts of two isomeric tetralins. Thus, the two partial rate constants, k_1 and k_2 in Scheme 3, are able to be calculated from the combined data of the titrimetric rate constants k_t (Table 1), the yields of tetralins determined by gas chromatography (Table 2), and the fractions of the two pathways estimated quantitatively from the contents of isomeric tetralins.

From the two sets of the ^{13}C NMR data on **10b** and **g**, the ratio of the two pathways, k_1 *vs.* k_2, can be calculated for both **9b** and **g**. A "natural abundance" tetralin was obtained from **9** labeled with 1.1% each of 1-^{13}C and 4-^{13}C, and an enriched tetralin from **9** labeled with 90% 1-^{13}C and 1.1% 4-^{13}C. Since k_1/k_2 and k_{12}/k_{13} are common for each isotopic substrate, the rate ratio k_1/k_2 can be described as a function of k_{12}/k_{13} and the peak area ratios of the two benzylic carbons in the two types of tetralins, "natural abundance" and ^{13}C-enriched. By assuming no kinetic isotope effect at the migration step ($k_{12}/k_{13}=1.00$), the fractions of the two pathways were determined 32.4% Ar_1-5 and 67.6% Ar_2-6 for the *p*-CH_3 derivative and 43.3% Ar_1-5 and 56.7% Ar_2-6 for the *p*-F one. The isotope effect can reasonably be neglected because an effect of 5% ($k_{12}/k_{13}=1.05$) could alter the fractions of the pathways by only 0.3%. Then, by neglecting the difference in the leaving group, four partial rate constants, $k_1^{p\text{-}CH_3}$, $k_2^{p\text{-}CH_3}$, $k_1^{p\text{-}F}$, and $k_2^{p\text{-}F}$, in the trifluoroacetolysis of **7** can be obtained. The ^{13}C NMR measurement was repeated for **10g** with two other FT instruments and even with a CW one in order to confirm the above results. The fractions of the two pathways thus obtained agreed with each other within a range of ±1.0%.

It is interesting to compare the present results in the trifluoroacetolysis of **9b** with those in the formolysis of **1c** reported by Jackman and Haddon.[6] Their results, 30.6—33.6% Ar_1-5 and 69.4—66.4% Ar_2-6 varying with an assumed kinetic isotope effect in the migrating step of **2**, is in complete agreement with ours. It suggests the accuracy of their results in spite of the difficulty in their experiment as well as the absence of the solvent effect on the fractions of the two pathways. The latter conclusion is reasonable because the two pathways are both neighboring aryl assisted ones and the susceptibilities of the two transition states to the nature of the solvent must be similar. It is in contrast with the solvent effect on the ratio of k_Δ *vs.* k_s as we demonstrated already.[2]

It is well known that reactivities of *m*- and *p*-substituted benzene derivatives generally follow the Hammett-type LFER.[13] Substituent effects on the rates of the neighboring aryl assisted solvolysis of 2-arylethyl derivatives have also been treated successfully in this manner.[11] As a quite natural extension of 2-arylethyl solvolysis, the two pathways of remote aryl participation are expected to follow their individual LFER. The four partial rate constants of **7b** and **g** obtained above must give rise to two Hammett-type relationships for the two pathways, which then must hold for other substrates.[14] Thus, the rate constants $k_{\Delta ph}$ of other substrates can be divided into k_1 and k_2 in such a manner as their ratios hold the ones determined by the above two LFER.

Yukawa and Tsuno proposed the LArSR (linear aromatic substituent reactivity) relationship (Eq. 1)

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \qquad (1)$$

as a generalized equation of the extended Hammett relationship for reactions with nucleophilic character.[15] According to Tsuno, most k_Δ pathways of 2-arylethyl and related substrates have *r* values (resonance parameters) about 0.5.[16] Schadt, Lancelot, and Schleyer reported that the substituent constants obtained from the acetolysis of substituted neophyl brosylates, σ(neophyl), are effective for all other related solvolyses; σ(neophyl) correspond to the substituent constants with $r=0.58$ in the Yukawa-Tsuno treatment, Eq. 1.[11] Thus, we assumed that similar substituent constants, $\sigma^0+0.5\Delta\bar{\sigma}_R^+$ ($\equiv\sigma^\Delta$), are also effective for the two remote aryl participation reactions, and carried out the kinetic dissection using these σ^Δ.

Contrast to the Ar_1-5 pathway, in which *m*- and *p*-substituents behave naturally as *m*- and *p*-ones, respectively, in the Ar_2-6 pathway *m*-substituents affect the reaction center as *o*- or *p*-ones, and *p*-substituents as *m*-ones, respectively (Scheme 2). As σ_o has not been

well established as σ_p, only σ_p was used for the Ar_2-6 pathway of the *m*-CH_3 and *m*-Cl derivatives, for which the reactivities of the *o*- and *p*-positions were estimated similar from the relative yields of 5- and 6-substituted tetralins (Table 2). The dissection of $k_{\Delta ph}$ of the *m*-F derivative, in which the reactivity of the *o*-position is apparently lower than that of the *p*-one[17] (*cf.* footnote h of Table 2), was carried out by modifying the σ_p value in order to reflect this decreased reactivity. Since the substituent constants of a methoxyl group are not clear in trifluoroacetic acid, which is a strongly acidic solvent prone to form a hydrogen bond with the methoxyl oxygen, the dissection was unable to be performed. In fact, the rate enhancement in **7c** and **d** was much smaller than that expected for substrates with a strongly electron-donating substituent. Furthermore, the product study of **7c** revealed that an unknown compound other than methoxytetralins was detected in the reaction solution. Methoxytetralins may be unstable under the reaction conditions. The dissection was also impossible for the *m*-CF_3 derivative **7k**, because its product analysis did not give a clear-cut result. Thus, the dissection by means of the combination of the product and kinetic analyses was carried out for **7a**, **b**, **e**, **f**, **g**, **h**, **i**, and **j**. The results are summarized in Table 3.

Table 3. Dissection of $k_{\Delta Ph}$ into Ar_1-5 and Ar_2-6 pathways

Substituent	$k^{70}_{\Delta Ph}\times 10^5/s^{-1}$	$k_1\times 10^5/s^{-1}$	$k_2\times 10^5/s^{-1}$	% Ar_1-5	% Ar_2-6
m-CH_3 (**7a**)	27.0	1.0	26.0	3.7	96.3
p-CH_3 (**7b**)	23.7	7.7	16.0	32.4[a]	67.6[a]
H (**7e**)	7.45	0.70	6.75	9.4	90.6
m-F (**7f**)	0.930	0.009	0.921	1.0	99.0
p-F (**7g**)	1.17	0.51	0.66	43.3[a]	56.7[a]
m-Cl (**7h**)	0.750	0.009	0.741	1.2	98.8
p-Cl (**7i**)	0.563	0.132	0.431	23.4	76.6
p-Br (**7j**)	0.567	0.122	0.445	21.5	78.5

a) Determined by NMR analysis.

The four partial rate constants of **7b** and **g** gave ρ values of -4.07 for Ar_1-5 and -3.29 for Ar_2-6. After the dissection for the other substrates were performed, the linear regression of the calculated partial rate constants of all the substrates except **7f** gave the two LFER, Eqs. 2 and 3, in which k_1^X and k_2^X represent the rate constants of the Ar_1-5 and Ar_2-6 pathways, respectively, of the X-substituted **7**, and k^H ($=k_1^H+k_2^H$) denotes the overall rate constant of **7e**. The two LFER are plotted in Fig. 1.

$$\log k_1^X/k^H = -4.42\sigma^\Delta - 0.99 \quad \text{(correlation coeff: 0.985)} \quad (2)$$

$$\log k_2^X/k^H = -3.05\sigma^\Delta - 0.07 \quad \text{(correlation coeff: 0.978)} \quad (3)$$

The successful dissection of the rate constants of the neighboring aryl assisted reaction, $k_{\Delta ph}$, into k_1 and k_2, which are described by the two independent LFER, suggests a possibility of completely different approach. Since the two LFER are represented as Eqs. 4 and 5,

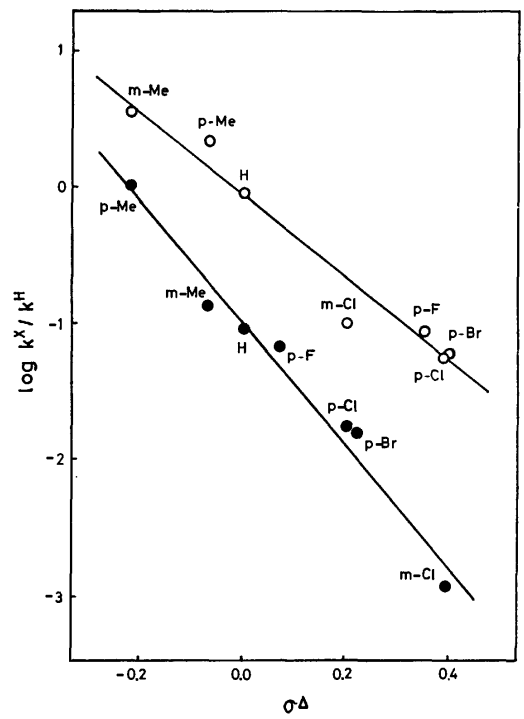

Fig. 1. LFER plots of dissected rate constants *vs.* σ^Δ.
●: k_1 (for Ar_1-5), ○: k_2 (for Ar_2-6).

the substituent effects on $k_{\Delta ph}$ ($\equiv k=k_1+k_2$) can be written as Eq. 6.

$$\log k_1^X/k_1^H = \rho_1\sigma_1^\Delta; \quad k_1^X = k_1^H\, 10^{\rho_1\sigma_1^\Delta} \quad (4)$$

$$\log k_2^X/k_2^H = \rho_2\sigma_2^\Delta; \quad k_2^X = k_2^H\, 10^{\rho_1\sigma_1^\Delta} \quad (5)$$

$$k^X/k^H = k_1^X/k^H + k_2^X/k^H = k_1^H\, 10^{\rho_1\sigma_1^\Delta}/k^H + k_2^H\, 10^{\rho_1\sigma_1^\Delta}/k^H \quad (6)$$

When the Ar_1-5 fraction of **7e**, k_1^H/k^H, is designated α, Eq. 6 can be substituted by Eq. 7.

$$k^X/k^H = \alpha 10^{\rho_1\sigma_1^\Delta} + (1-\alpha)10^{\rho_1\sigma_1^\Delta} \quad (7)$$

Non-linear regression analysis utilizing Eq. 7 was thus performed by putting in k^H and sets of k^X, σ_1^Δ, σ_2^Δ in order to determine the optimum values of α, ρ_1, and ρ_2. Computer-programmed calculations by means of the simplex[18] and Powell methods[19] gave a same answer, Eqs. 8 and 9.

$$\log k_1^X/k^H = -3.95\sigma^\Delta - 0.54 \quad \text{(correlation coeff: 0.996)} \quad (8)$$

$$\log k_2^X/k^H = -3.53\sigma^\Delta - 0.24 \quad \text{(correlation coeff: 0.997)} \quad (9)$$

Although the linearity of each LFER is excellent, fractions of the two pathways for all the substrates are quite different from those obtained by the combinational approach of product and kinetic analyses (Table 3). In particular, the calculated results for **7b** and **g**, 67% Ar_1-5 and 33% Ar_2-6 for **7b** and 83% Ar_1-5 and 17% Ar_2-6 for **7g**, did not coincide with the values determined directly by the NMR analysis at all.

Since the substituent constants are variable as shown in Eq. 1 and we are unaware how large the resonance parameter r should be in the two LFER, the non-linear regression analysis was extended to include the sets of

r_1 and r_2 both varied independently from 0 to 1 in Eq. 10.

$$k^X/k^H = \alpha 10^{\rho_1(\sigma_1^0 + r_1\Delta\bar{\sigma}_{R1}^+)} + (1-\alpha)10^{\rho_2(\sigma_2^0 + r_2\Delta\bar{\sigma}_{R2}^+)} \quad (10)$$

The results varied to a large extent depending on the r values used. However, any combination of r_1 and r_2 was unable to reproduce the observed data of the fractions of the two pathways for **7b** and **g** simultaneously. Furthermore, when the non-linear regression analysis by use of Eq. 10 was performed by treating r_1 and r_2 also as variables, it converged on an improbable point where r_1 was close to 0 and r_2 was larger than 1. The observed data for **7b** and **g** were again not reproduced at this point. Thus, the nonlinear regression analysis was unsuccessful in this case.

We do not regard the failure of the non-linear regression analysis in this case as the fundamental defect of the method. This type of analysis must be easier when the two reactions have different types of characters.[11,20,21] Unfortunately, ρ_1 and ρ_2 are both negative and similar in magnitude in this case. Strict accuracy of all the data used for the analysis, *i.e.*, $k_{\Delta ph}$ and σ, is an indispensable condition in such a case. However, $k_{\Delta ph}$ are estimated values from k_t and the product yields, and the identity of σ_o and σ_p was postulated in some cases. Such uncertainties in the data used, although they must be not large, may cause the analysis very difficult in the present case.

The idea of variable substituent constants (Eq. 10) is also applicable to the combinational approach of product and kinetic analyses. Calculations were thus performed using variable r values. Fractions of the two pathways obtained for each substrate certainly varied as expected according to the sets of the r values used. However, the extent of the variation was not so large as in the case of the non-linear regression analysis with variable r. The reason is obviously because the four partial rate constants were fixed to the experimental values throughout the calculations.

The above calculations with variable r revealed some characteristic features: (i) ρ_1 is always larger than ρ_2. (ii) The linearity of the two LFER is governed mostly by the value of r_2; the correlation coefficient becomes too small (<0.97) when r_2 larger than 0.5 is employed. (iii) There is a tendency that a better linearity is obtained when r_1 is larger than r_2. Further search for a point of best fit is apparently meaningless in the present case when the risk of statistical approach such as those encountered in the non-linear regression analysis is considered. We regard the results shown in Table 3 and Eqs. 2 and 3 as a reasonable answer to the dissection problem, although some uncertainties still remain.

It is apparent from Table 3 that the Ar_2-6 pathway is much favored than Ar_1-5. For the unsubstituted ester **7e** the former is 4.5 times more rapid than the latter after the statistical correction. Since the former pathway can be regarded as a kind of electrophilic aromatic substitution at the ortho position to the alkyl chain and the latter as the one at the ipso, the above result must reflect a difference in the reactivity of these positions toward a potential electrophile. A low π-electron density at the ipso position of toluene in comparison with the other positions was calculated by Libit and Hoffmann as an extended Hückel result.[22] Recently, *ab initio* STO-3G calculations of the relative energies of "late" and "early" transition state models for attack of a proton on benzene and the various positions of toluene were reported by Santiago *et al.*[23] The results show that the relative energies are para>ortho>H(benzene)>ipso for both the late and early transition state models. Our result indicating the unfavorable Ar_1-5 pathway is thus compatible with the theoretical calculations.

Santiago *et al.* also suggested that the ipso position is deactivated toward formation of an early transition state.[23] Thus, it is expected that the ipso substitution has a later transition state than the ortho substitution. Our conclusions that ρ_1 is larger than ρ_2 and, though not secured enough, r_1 may be larger than r_2 can be attributed to the development of a positive charge to a larger extent in the case of the ipso substitution, Ar_1-5. Another possible explanation that the lower electron density at the ipso position may cause a larger electron demand in the substitution reaction can also rationalize the larger substituent effect on Ar_1-5. A larger substituent effect on the chemical shifts of the ipso carbons in ^{13}C NMR spectra was reported in the case of *p*-substituted toluenes (**11**) compared with those of the para carbons of substituted benzenes (**12**).[24,25]

11 **12**

The relative ease of remote aryl participation is affected by the ring size of the transition state other than the electronic effect. The ring size effect can be discussed in two aspects, *i.e.*, entropy and strain energy.

According to Page, the standard entropy loss on cyclization of terminal olefins is larger for a six-membered ring than for a five-membered one by *ca.* 8 cal K^{-1} mol^{-1} (=33 J K^{-1} mol^{-1}) at 298 K.[26] The corresponding difference in the ring-size corrections in Benson's thermochemical analysis[27] is also 8.5 cal K^{-1} mol^{-1}. Thus, the activation entropy must be in favor of the five-membered transition state. On the other hand, the strain energy of cyclopentane is 6 kcal mol^{-1} larger than that of cyclohexane.[28] Thus, the activation enthalpy must be in favor of the six-membered transition state. The preponderance of the Ar_2-6 pathway may be the outcome of the relative importance of the ethalpy term, but the firm conclusion is difficult because of the simultaneous operation of the electronic effect described above.

In connection with the above discussion, it is interesting to compare the activation parameters of the pairs of the substrates with same substituents at the *m*- and *p*-positions, namely **7a**, **c**, **f**, and **h** *vs.* **7b**, **d**, **g**, and **i**, respectively (Table 1). Throughout the series of these pairs, the *m*-substituted esters have smaller enthalpies

and smaller (more negative) entropies of activation than the corresponding *p*-substituted isomers. The activation enthalpy of **7f** must be raised slightly because of the peculiar deactivation at the ortho position of the fluorine substituent (*vide supra*).[17] It is apparent from Table 3 that the *m*-substituted esters solvolyze almost exclusively *via* the Ar_2-6 pathway. This must be also true for the *m*-CH_3O ester **7c**.[5] On the contrary, the solvolyses of the *p*-isomers proceed considerably *via* the Ar_1-5 pathway. Thus, the differences in the activation parameters are in perfect harmony with the differences in the reaction pathways. Furthermore, these observations secure our first assumption that the two modes of remote aryl participation are discrete.

Finally, the magnitude of the ρ values should be discussed briefly. The value for the Ar_1-5 pathway, *ca.* −4, is well in the range of the ρ values for the k_Δ pathway of 2-phenylethyl solvolysis (Ar_1-3).[11] Ouellette *et al.* reported that the ρ^+ values of the acetolyses decreased in the order benzyl>2-phenylethyl>4-phenylbutyl systems.[21] However, in their analysis of the acetolysis rates of 4-arylbutylmercury(II) perchlorates, they regarded all the k_Δ pathway as Ar_1-5. Since it is not the case as revealed in the present study, their ρ^+ value, −1.2, must be in serious error. Similar magnitudes of the ρ values for the Ar_1-5 and Ar_1-3 pathways rather indicate that the electronic natures of the aromatic rings in these through-space interactions with the potential electrophiles are almost identical independently of the ring size.

Experimental

General. All melting points were determined on a Yanagimoto MP-S2 hot stage melting point apparatus and not corrected. ^1H NMR spectra were obtained on a Hitachi R-20 or R-24 instrument at 60 MHz using tetramethylsilane as an internal standard.

Preparation of 4-Aryl-1-butanols. All the 4-(*p*-substituted phenyl)-1-butanols were prepared by the Friedel-Crafts reaction of substituted benzenes with succinic anhydride and aluminum chloride,[29] followed by the Wolff-Kishner reduction,[30] esterification, and lithium aluminum hydride reduction, successively. All the 4-(*m*-substituted phenyl)-1-butanols except the *m*-CH_3 derivative were prepared from the corresponding 3-(*m*-substituted phenyl)-1-propanols *via* chlorides,[31] cyanides,[32] acids, and esters, successively. The propanols were prepared by the Knoevenagel reaction of the corresponding *m*-substituted benzaldehydes with malonic acid,[33] followed by esterification and lithium aluminum hydride reduction.[34] 4-(*m*-Tolyl)-1-butanol was prepared by the hydroboration-oxidation[35] of 4-(*m*-tolyl)-1-butene, which was obtained by the coupling reaction of *m*-tolylmethylmagnesium chloride with allyl bromide.[36,37]

4-(m-Tolyl)-1-butanol: Bp 130.5 °C/7.5 Torr (1 Torr= 133.322 Pa). Found: C, 80.17; H, 9.99%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.82%.

4-(m-Fluorophenyl)-1-butanol: Bp 90—92 °C/5.5 Torr. Found: C, 71.12; H, 7.87%. Calcd for $C_{10}H_{13}FO$: C, 71.40; H, 7.79%.

4-(p-Fluorophenyl)-1-butanol: Bp 138.5—139.5 °C/15 Torr. Found: C, 71.17; H, 7.97%. Calcd for $C_{10}H_{13}FO$: C, 71.40; H, 7.79%.

4-(m-Chlorophenyl)-1-butanol: Bp 133 °C/5.0 Torr. Found: C, 64.89; H, 7.32; Cl, 19.02%. Calcd for $C_{10}H_{13}ClO$: C, 65.04; H, 7.10; Cl, 19.20%.

4-(p-Chlorophenyl)-1-butanol: Bp 140—148 °C/4.5 Torr. Found: C, 65.16; H, 7.21; Cl, 19.11%. Calcd for $C_{10}H_{13}ClO$: C, 65.04; H, 7.10; Cl, 19.20%.

4-(p-Bromophenyl)-1-butanol: Bp 157—158 °C/5.0 Torr. Found: C, 52.26; H, 5.75; Br, 34.58%. Calcd for $C_{10}H_{13}BrO$: C, 52.42; H, 5.72; Br, 34.88%.

4-(m-Trifluoromethylphenyl)-1-butanol: Bp 119—120 °C/40 Torr. Found: C, 60.25; H, 5.89; F, 25.78%. Calcd for $C_{11}H_{13}F_3O$: C, 60.55; H, 6.01; F, 26.12%.

Preparation of Labeled Alcohols. Both [1-^{13}C]-4-(*p*-tolyl)-1-butanol and [1-^{13}C]-4-(*p*-fluorophenyl)-1-butanol were prepared by carbonation of the corresponding Grignard reagents with $^{13}CO_2$ gas,[38] followed by esterification and reduction. [1,1-$^2H_2$]-4-(*p*-Methoxyphenyl)-1-butanol was prepared by the reduction of ethyl 4-(*p*-methoxyphenyl)-butanoate with lithium aluminum deuteride.

[*1*-^{13}C]-*4*-(p-*Tolyl*)-*1*-*butanol*: Bp 102—103 °C/3.5 Torr. ^{13}C Enrichment was 89.4% as measured by ^{1}H NMR.

[*1*-^{13}C]-*4*-(p-*Fluorophenyl*)-*1*-*butanol*: Bp 127—128 °C/10 Torr. ^{13}C Enrichment was 90.4% as measured by ^{1}H NMR.

[*1,1*-$^{2}H_2$]-*4*-(p-*Methoxyphenyl*)-*1*-*butanol*: Bp 151—152 °C/7.0 Torr. Deuterium content was better than 99% as measured by ^{1}H NMR.

Preparation of 4-Arylbutyl Arenesulfonates. The menasylates and brosylates were prepared by the standard procedures from alcohols with menasyl chloride and brosyl chloride, respectively, at 0 °C in pyridine as a solvent.[3,39] Physical properties and analytical data of these esters are summarized in Table 4.

Preparation of Solvolysis Products. 4-(p-*Chlorophenyl*)-*butyl Trifluoroacetate*: Three molar equivalents of trifluoroacetic anhydride was added dropwise to 4-(*p*-chlorophenyl)-1-butanol under stirring at 0 °C. After stirring further 2 h at room temperature, the excess of the anhydride was removed under reduced pressure. Distillation of the residual oil gave the trifluoroacetate: bp 101—111 °C/5.0 Torr. Found: C, 51.27; H, 4.25%. Calcd for $C_{12}H_{12}ClF_3O_2$: C, 51.35; H, 4.31%.

3-(p-*Chlorophenyl*)-*1*-*methylpropyl Trifluoroacetate and 3-*(m-*Trifluoromethylphenyl*)-*1*-*methylpropyl Trifluoroacetate*: These secondary trifluoroacetates were prepared by heating 4-(*p*-chlorophenyl)-1-butene and 4-(*m*-trifluoromethylphenyl)-1-butene, respectively, in trifluoroacetic acid at 80 °C for 6 h.[37] After removing the excess of trifluoroacetic acid, these materials were used as the authentic samples for identification of solvolysis products by gas chromatography without further purification.

5-Methoxytetralin: The Wolff-Kishner reduction[30] of 25.0 g (0.142 mol) of 3,4-dihydro-5-methoxy-1(2*H*)-naphthalenone with 23.3 g of potassium hydroxide and 16.5 ml of 90% hydrazine hydrate in 200 ml of diethylene glycol gave 14.0 g of 5-methoxytetralin: bp 109.5 °C/10 Torr (lit,[40] 85—88 °C/3 Torr).

*6-Methyltetralin (**10b**)*: This material was isolated from the trifluoroacetolysis solution of **9b**. ^{13}C NMR (C_6D_6) δ (from external tetramethylsilane)=21.1 (Me), 23.8 (C_2 and C_3), 29.3 (C_1), 29.7 (C_4), 126.9 (C_7), 129.5 (C_8), 130.2 (C_5), 134.2 (C_6), 134.9 (C_9), and 137.0 (C_{10}); ^{1}H NMR ($CDCl_3$) δ=1.89 (4H, m, CH_2), 2.38 (3H, s, Me), 2.84 (4H, m, $ArCH_2$), and 7.04 (3H, br s, Ar). Found: C, 90.09; H, 9.52%. Calcd for $C_{11}H_{14}$: C, 90.35; H, 9.65%.

*6-Fluorotetralin (**10g**)*: This material was isolated from the trifluoroacetolysis solution of **7g**. ^{13}C NMR (C_6D_6) δ (from external tetramethylsilane)=23.1 (C_2 or C_3), 23.4 (C_3 or C_2), 28.9 (C_1), 29.6 (d, J_{CF}=1.6 Hz, C_4), 112.9 (d, J_{CF}=22.0 Hz, C_7), 115.7 (d, J_{CF}=20.7 Hz, C_5), 130.9 (d, J_{CF}=7.3 Hz, C_8), 132.8 (d, J_{CF}=3.6 Hz, C_9), 139.3 (d, J_{CF}=7.3 Hz, C_{10}), and 161.7 (d, J_{CF}=240.7 Hz, C_6); ^{1}H NMR ($CDCl_3$) δ=1.76 (4H, m, CH_2), 2.72 (4H, m, $ArCH_2$), and 6.67—7.05 (3H, m, Ar). Found: C, 79.72; H, 7.26%. Calcd for $C_{10}H_{11}F$: C, 79.97; H, 7.38%.

Trifluoroacetolysis Media. Trifluoroacetic acid containing 1 wt% of trifluoroacetic anhydride and 0.125 M (1M=1 mol dm^{-3}) of sodium trifluoroacetate was prepared according to the procedure described before.[3]

Kinetic Procedures. The usual ampule technique described before was employed.[3] Absorbance at about 326 nm was measured with a Hitachi Perkin-Elmer 139 or a Hitachi 100-30 UV-visible spectrophotometer. The absorbance after more than seven half-lives was used as that at "infinity."

Product Analyses. Reaction solutions containing 0.01 M of dodecane after more than six half-lives were directly injected into a Varian Aerograph Model 2850-30 gas chromatograph with a flame ionization detector and a Hewlett-Packard 3370B digital integrator. Columns packed with Silicone DC550 on Celite 545, Silicone OV-1 on Chromosorb W AW-DMCS, or PEG 20M on Chromosorb W NAW were used. Sensitivities were determined using authentic samples for tetralin, 6-methyltetralin, 5-methoxytetralin, and 4-(*p*-chlorophenyl)butyl trifluoroacetate. For other compounds sensitivities were calculated by the method described by Sternberg *et al.*[41] Accuracy of the calculated sensitivites were confirmed for the above authentic samples.

Trifluoroacetolyses of [*1*-^{13}C]-*4*-(p-*Tolyl and* p-*Fluorophenyl*)-*butyl Brosylates (**9b**-*1*-^{13}C *and* **9g**-*1*-^{13}C)* A reaction solution of 3.0 g **9b**-1-^{13}C in 100 ml of the same media as that for kinetic runs was heated at 70 °C for 14 h. The solvent was removed under reduced pressure, water being added to the residue. Extraction with ether gave a reaction product as an oil. Column chromatography through silica gel and molecular distillation gave 890 μl of a pure sample of [1,4-^{13}C]-6-methyltetralin (**10b**-1,4-^{13}C). Found: C, 89.82; H, 9.70%. Calcd for $C_{11}H_{14}$ containing 0.9 atom of ^{13}C: C, 89.80; H, 9.59 %. A similar reaction of **9g**-1-^{13}C at 85 °C for 22 h gave [1,4-^{13}C]-6-fluorotetralin (**10g**-1,4-^{13}C). Found: C, 79.28; H, 7.24% Calcd for $C_{10}H_{11}F$ containing 0.9 atom atom of ^{13}C: C, 79.50; H, 7.34%.

Trifluoroacetolysis of [*1,1*-$^{2}H_2$]-*4*-(p-*Methoxyphenyl*)*butyl Menasylate (**7d**-*1,1*-$^{2}H_2$)*. A solution of 970 mg of **7d**-1,1-$^{2}H_2$ in 50 ml of trifluoroacetic acid containg 1 wt% of trifluoroacetic anhydride was heated at 80 °C for 120 min. After the removal of the solvent under reduced pressure, the residue was poured into ice–water. Precipitates were recovered by filteration and purified by recrystallization. No scrambling of the deuterium in the recovered **7d**-1,1-$^{2}H_2$ was indicated by the absence of any signal due to the α-hydrogen.

Quantitative ^{13}C NMR Measurements. The measurements were performed on a JEOL JNM-FX 100 instrument at 25.05 MHz in normal FT mode. All spectra were run on 0.56 M (^{13}C-enriched) and 1.12 M (natural abundance) samples in perdeuteriobenzene solution contained in a 10-mm tube. The spectrometer was locked on the deuterium resonance of the solvent. Spectra were obtained at a spectral width of 1000 Hz with 16K data points using a normal pulse sequence (decoupling on at all the time). A pulse width was 4 μs, which corresponds to a flip angle of 30 °. A pulse repetition time was 25 s and an acquisition time was 8.192 s. Relaxation time of benzylic carbons is 5.1 s for both C_1 and C_4 of **10b**, and 5.4 and 5.5 s for C_1 and C_4, respectively, of **10g**. A longer pulse repetition time (60 s) did not alter the results. Number of pulses was 800 for the natural abundance samples and 100 for the ^{13}C-enriched ones. Relative peak areas integrated were described in the text.

Quantitative ^{13}C NMR spectra of **10g** were also obtained on another JEOL JNM-FX 100 instrument (25.05 MHz) and a Hitachi R22-FT one (22.633 MHz) both in FT mode, and on a Hitachi R20 instrument (15.085 MHz) in CW mode. Measurements were carried out using the same samples as above but in deuteriochloroform and under different conditions. All the results were identical to within a range of ±1.0%.

Non-linear Regression Analyses. The calculations were carried out using the ACOS 900 computer at the Computation Center of Osaka University.

We thank Professor Y. Tsuno of Kyushu University for his valuable discussion and Dr. K. Uozaki of Osaka University for his helpful suggestions on the statistical

analysis. We also thank Professors Y. Sasaki and Y. Kyogoku of Osaka University for making the NMR spectrometers available for the quantitative analysis. The present work was partially supported by a Grant-in-Aid (Nos. 747018, 964097, and 274154) for science research from the Ministry of Education.

Stereochemical Studies on the Nucleophilic Substitution in the Reaction of Allylic Phosphates with Organoaluminum Reagents

Akira Itoh, Shuji Ozawa, Koichiro Oshima,* Shizuka Sasaki, Hajime Yamamoto, Tamejiro Hiyama, and Hitosi Nozaki

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received February 25, 1980)

The reaction of *cis*- or *trans*-5-isopropenyl-2-methyl-2-cyclohexenyl diethyl phosphate (**1**) with Me_2AlX (X= OPh, SPh, NHPh) in hexane results in substitution of the $-O-PO(OEt)_2$ group with X under predominant inversion. In contrast, treatment of *cis*- or *trans*-**1** with trialkylaluminum produces predominantly the allyl-nonallyl couplingproducts of the same (thermodynamically more stable) configuration. Similar alkylation of *endo*- and *exo*-2-acetoxynorcarane gave *endo*-2-methylnorcarane, exclusively.

The reaction of geranyl and neryl phosphates with R_2AlX type organoaluminum reagents[1] or trialkylaluminum compounds[2] results in nucleophilic substitution. The interest in stereoselectivity of these unique "ionic" reactions proceeding in nonpolar or less polar solvents has motivated the present studies on (1) the reaction of *cis*- or *trans*-5-isopropenyl-2-methyl-2-cyclohexenyl diethyl phosphate (**1**) with R_2AlX and (2) the reaction of *cis*- or *trans*-**1** with R_3Al.[3]

(1) Reaction of cis- *or* trans-*1 with R_2AlX.* Much attention has been paid to the conversion of esters to RCOX by means of R_2AlX (X=NR^1R^2,[4] SR,[5] SeR[6]). However, few examples are known for the nucleophilic substitution on a saturated carbon. The reaction of geranyl and neryl diethyl phosphates with R_2AlX (X=SPh, S^{t}Bu, OPh, NHPh) reagents results in the replacement of the $OPO(OEt)_2$ group by X group without affecting both olefinic bonds in any sense of the words. No allylic migration, no *E,Z*-isomerization, and no cyclization occur. Notably, this ionic reaction proceeds in *hexane*, which is a poor solvent of the reaction system and the whole forms a white suspension.

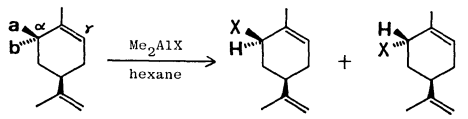
Further investigation of this kind of substitution with *cis*- and *trans*-**1** has clarified the steric course of the reaction. Treatment of *cis*- or *trans*-**1** with a heterogeneous white suspension of Me_2AlX (2 equiv) in hexane at 0 °C for 2 h gave substitution products **2** in good yields, as summarized in Table 1.

Invariably, substitution occurs under extensive configurational inversion and accompanies considerable allylic migration in contrast to the open chain geranyl and neryl diethyl phosphates. In order to determine the α/γ ratios, or S_N2/S_N2' ratios, products in the reaction of α-deuterio-*cis*-**1** or *trans*-**1** have been analyzed by NMR method.[7]

Solvent effect on the reaction between α-deuterio-*cis*-**1** and Me_2AlOPh is shown in Table 2. All the solvents except hexane gave clear solutions, in which ions should be much more free than in hexane. In the extreme tetrahydrofuran solvent, the retention product was predominant and the α/γ ratio was almost close to unity. Possibly an intimate ion-pair in a solvent cage could explain the findings. The similar solvent effect was observed in the reaction of *cis*-**1** with Me_2AlSPh or $Me_2AlNHPh$ (Table 3).

Assignments of the products were based on the examination of those NMR spectra. All the *trans* isomers, **2a**, **2b**, and **2c**, exhibited the narrow signals for the protons attached to carbon bearing X group at higher field than those for protons in *cis* isomers. The spectra are consistent with the postulated configuration

Table 1. Reaction of *cis*-**1** or *trans*-**1** with Me_2AlX in hexane[a]



cis-**1**: **a**=O-PO(OEt)$_2$, **b**=H(D)
trans-**1**: **a**=H(D), **b**=O-PO(OEt)$_2$

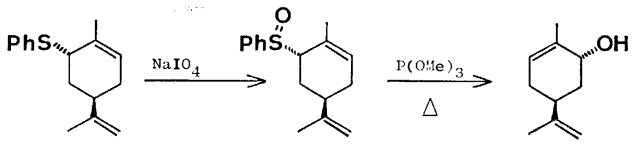
assuming those chair conformations in which the isopropenyl group is equatorial and the H–C–X protons therefore pseudo-equatorial. On the other hand, the much broader, lower field proton signals of *cis* isomers are ascribed to pseudo-axial ones.[8] Further support for the assignment has been given by the following transformation of *trans*-**2b** to *trans*-carveol (Scheme 1).



Scheme 1.

(*2*) *Reaction of* cis- *or* trans-*1 with* R_3Al. An investigation of the reaction of allylic phosphates with organoaluminum reagents has provided an exceptionally mild procedure to effect allyl-nonallyl coupling.[2] This C–C bond formation is now found to be characterized by carbocationic intermediates being produced from allylic phosphates in hexane.

Treatment of *cis*- or *trans*-**1** with trialkylaluminum (3 equiv) in hexane at 0 °C for 20 min gave a mixture of **4** and **5**. The results are summarized in Table 4, which indicates that the alkylation occurs predominantly from the side opposite to the isopropenyl group.

Table 4. Alkylation of *cis*-**1** or *trans*-**1** with R_3Al

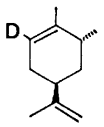
10	*cis*-**1**	Me	THF	63	8:92

a) Isolated yields refer to the epimeric mixtures. b) Isomeric ratios were determined by GLPC.

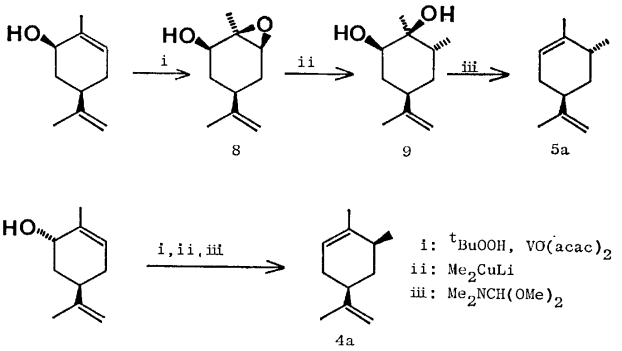
It is worth noting that this alkylation takes place also with carboxylic esters (runs 3 and 4) instead of the phosphate as a leaving group. A synthetically useful transformation of alcoholic substrates R^1OH into the coupling products R^1–R^2 [9] is thus based on the reaction of the corresponding esters R^1–OCOR with organometallic reagents R^2Mtl. No carbonyl attack[10] is observed with trialkylaluminum reagents.

The α-deuterio-*cis*-**3** and *trans*-**3** gave mainly *trans*-methylated products, **5** and its regioisomer **6** being produced in a ratio of 45: 55 and 40: 60 respectively. The product distribution of the alkylation was also independent of the solvent (runs 1, 9, and 10). The reaction of allylic phosphates with trialkylaluminum is in sharp contrast to the substitution reaction of those with Me_2AlX reagents described in section 1, where S_N2 type introduction of the X group predominates with inversion of the configuration.[11]



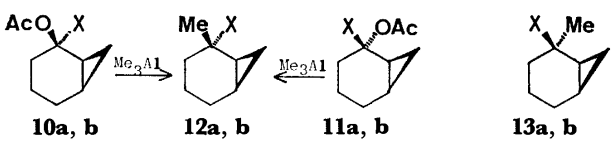
6

The structures of the products were unambiguously confirmed by the alternative synthesis of **4a** and **5a** according to Scheme 2.[12]



Scheme 2.

Similar stereochemistry was observed in the transformation of *endo*-2-acetoxynorcarane **10a** and its epimer **11a**. Subjection of the acetate **10a** to the action of trimethylaluminum in dichloromethane for 2 h at room temperature gave **12a** (contaminated with less than 7% of its epimer **13a**) in 80% yield. The exclusive product from **11a** was again **12a** (80%). As the deuterated acetates (**10b** and **11b**, a 22 : 78 mixture) gave



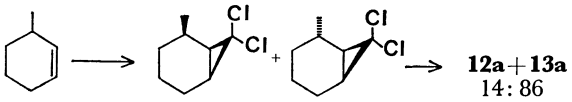
10a, b **12a, b** **11a, b** **13a, b**

a: X=H; **b**: X=D

Scheme 3.

12b (>93%), a mechanism involving rearrangement with ring opening can be rejected.[14]

Authentic samples of the products were prepared from 3-methylcyclohexene (Scheme 4). The stereochemical identities were established by hydrogenating this mixture (H_2, 1 atm, PtO_2, AcOH) to 1:5 mixture of *cis*- and *trans*-1,2-dimethylcyclohexane, each of which was separated by GLPC and compared spectrometrically with the corresponding authentic sample.[15]



Scheme 4.

Experimental

The optical rotations were measured using a Yanaco-OR-50 polarimeter. The infrared spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra on a Hitachi RMU-6L machine; the GLPC analyses on a Yanagimoto GCG-550F; and the NMR spectra on a JEOL-C-60H or Varian EM-390H spectrometer. The chemical shifts are given in δ in ppm with TMS as the internal standard. Splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. The microanalyses were carried out by the staffs at the Elemental Analyses Center of Kyoto University. All experiments were carried out under an atmosphere of dry argon. Tetrahydrofuran was dried by distillation from sodium–benzophenone. Thin layer or thick layer plates were made of E. Merck PF-254, and preparative column chromatography on silica gel E. Merck Art. 7734.

Preparation of cis-*Carveol.* (−)-Carvone (21.0 g, 140 mmol) was reduced by lithium aluminum hydride (2.66 g, 70 mmol) in THF (300 ml) at −15 °C.[16] The crude carveol (*cis*: *trans*=92:8, determined by GLPC, 10% PEG 20M on Celite 545, 2 m, 140 °C) was then treated with 3,5-dinitrobenzoyl chloride (37.8 g, 164 mmol) in pyridine (120 ml) at 25 °C. The mixture was stirred at the same temperature for 12 h, poured into precooled 1 M (1 mol dm^{-3}) HCl, and extracted with ethyl acetate twice. The organic phase was washed with 1 M HCl, and brine, dried, and concentrated. The crude product was passed through a short column of silica gel and the *cis*-benzoate was recrystallized from ethanol–ethyl acetate (3 : 1) twice (mp 92.5 °C). Hydrolysis (5% KOH in methanol, 100 ml, 20 min at reflux) followed by purification by column chromatography on silica gel (hexane: ethyl acetate=3 : 1) afforded *cis*-carveol (6.84 g, 32%) contaminated by <0.5% *trans* isomer.

Preparation of trans-*Carveol.* According to the reported procedure,[17] the title compound (>99.5% pure) was prepared from (−)-carvone by reduction with aluminum triisopropoxide in isopropyl alcohol and purification by recrystallization of 3,5-dinitrobenzoate (mp 111.5 °C) followed by hydrolysis.

*Preparation of α-Deuterio-*cis*-carveol.* (−)-Carvone (3.0 g, 20 mmol) was reduced by lithium aluminum deuteride (0.42 g, 10 mmol, Merck 98% d) in THF (25 ml) at −15 °C and the product was further purified by the method described above.

*Preparation of α-Deuterio-*trans*-carveol.* A solution of diethyl phosphate of α-deuterio-*cis*-carveol (1.15 g, 4.0 mmol) in 1,2-dimethoxyethane (3.0 ml) was added to a mixture of potassium superoxide (0.98 g, 13.8 mmol), 18-crown-6 (2.43 g, 9.2 mmol), dimethyl sulfoxide (10.0 ml), and 1,2-dimethoxyethane (10.0 ml) at 25 °C. After 16 h, the reaction mixture was poured into water and the organic phase was extracted with ethyl acetate three times. The combined extracts were washed with brine, dried, and freed of the solvent. Purification by column chromatography on silica gel afforded α-deuterio-*trans*-carveol (0.19 g, 1.3 mmol, contaminated by <5% *cis* isomer) in 32% yield. Absence of γ-deuterio-carveol was confirmed by the examination of its NMR spectrum.

cis-*5-Isopropenyl-2-methyl-2-cyclohexenyl Diethyl Phosphate* (cis-***1***). Butyllithium in hexane (1.5 M, 31.4 ml, 47.2 mmol) was added to a solution of *cis*-carveol (6.82 g, 44.9 mmol) in ether (40 ml) at −23 °C. After 20 min, a solution of diethyl phosphorochloridate (13.0 ml, 89.8 mmol) and triethylamine (12.5 ml, 89.8 mmol) in ether (30 ml) was added. The mixture was stirred for 2 h at the same temp, poured into ice–water, and extracted with ethyl acetate three times. The organic phase was washed with brine, dried, and freed of the solvent. Purification by column chromatography on silica gel (hexane: ethyl acetate=3: 1) afforded *cis*-**1** (9.54 g, 33.1 mmol) in 74% yield as a colorless oil: NMR (CCl_4) δ 1.33 (t, J=7.2 Hz, 6H), 1.74 (s, 6H), 1.6—2.3 (m, 5H), 4.03 (m, 4H), 4.69 (s, 2H), 4.85 (m, 1H), 5.49 (m, 1H).

trans-*5-Isopropenyl-2-methyl-2-cyclohexenyl Diethyl Phosphate* (trans-***1***): NMR (CCl_4) δ 1.33 (t, J=7.2 Hz, 6H), 1.74 (s, 6H), 1.6—2.3 (m, 5H), 4.03 (m, 4H), 4.57 (m, 1H), 4.69 (s, 2H), 5.60 (m, 1H).

General Procedure for the Reaction between Me_2AlX (X=OPh,[18] *SPh,*[19] *NHPh,*[20]*) and* ***1*** *in Hexane.* The substitution of *cis*-**1** with Me_2AlOPh is representative. Phenol (0.18 ml, 2.0 mmol) was added dropwise to a solution of trimethylaluminum (1.0 M solution in hexane, 2.0 ml, 2.0 mmol) in hexane (10 ml) at 0 °C. After stirring for 30 min, a solution of *cis*-**1** (0.29 g, 1.0 mmol) in hexane (3.0 ml) was added to the resulting white suspension at 0 °C and the mixture was held there for 2 h. Workup (1 M HCl and ether) followed by column chromatography on silica gel with ether–hexane (1: 50) afforded a mixture of *trans*-**2a** and *cis*-**2a** (0.18 g, 80% yield) in a ratio of 98 : 2 as determined by GLPC (PEG 20 M 10% on Celite 545, 2 m, 195 °C). Further purification by preparative TLC (hexane, three developments) gave pure *trans*-**2a**: bp 152 °C (bath temp, 2 Torr); IR (neat) 1645, 1600, 1590, 1495, 1235 cm^{-1}; NMR (CCl_4) δ 1.70 (s, 3H), 1.76 (s, 3H), 1.83—2.50 (m, 5H), 4.48 (m, 1H), 4.66 (s, 2H), 5.63 (m, 1H), 6.75—7.33 (m, 5H); MS *m/e* (%) 228 (M^+, 3), 185 (2), 135 (18), 134 (71), 119 (50), 107 (62), 93 (100).

Found: C, 83.94; H, 8.93%. Calcd for $C_{16}H_{20}O$: C, 84.16; H, 8.83%.

cis-*5-Isopropenyl-2-methyl-3-phenoxycyclohexene* (cis-***2a***): Bp 160 °C (bath temp, 2 Torr); IR (neat) 1645, 1595, 1585, 1492, 1238, 1030, 888 cm^{-1}; NMR (CCl_4) δ 1.71 (s, 3H), 1.76 (s, 3H), 1.9—2.4 (m, 5H), 4.67 (s, 2H), 4.76 (m, 1H), 5.53 (m, 1H), 6.72—7.23 (m, 5H); MS *m/e* (%) 228 (M^+, 3), 185 (3), 135 (17), 134 (51), 119 (47), 107 (78), 93 (100).

Found: C, 84.38; H, 8.96%. Calcd for $C_{16}H_{20}O$: C, 84.16; H, 8.83%.

trans-*5-Isopropenyl-2-methyl-3-(phenylthio)cyclohexene* (trans-***2b***): Bp 155 °C (bath temp, 2 Torr); IR (neat) 1645, 1583, 1479, 889 cm^{-1}; NMR (CCl_4) δ 1.7—2.6 (m, 5H), 1.73 (s, 3H), 1.90 (s, 3H), 3.56 (m, 1H), 4.67 (s, 2H), 5.53 (m, 1H), 7.1—7.5 (m, 5H); MS *m/e* (%) 245 (1), 244 (M^+, 4), 134 (62), 119 (28), 107 (64), 93 (100).

Found: C, 84.56; H, 9.38%. Calcd for $C_{16}H_{21}N$: C, 84.53; H, 9.31%.

General Procedure for the Reaction between Me_2AlX *and* **1** *in Various Solvents.* Me_2AlX (2.0 mmol) was prepared in hexane and the solvent was removed *in vacuo* to leave a white solid. Dichloromethane (ether, DME, THF) (10 ml) was added and the mixture was stirred for 5 min at 25 °C. A solution of *cis*-**1** (0.29 g, 1.0 mmol) in the same solvent (3.0 ml) was added at 0 °C. After 2 h, the mixture was worked up as previously described.

Transformation of trans-**2b** *into* trans-*Carveol.* A solution of **2b** (*trans*: *cis*=97: 3, 1.54 g) in methanol (20 ml) was treated with sodium periodate (2.8 g, 13.1 mmol) at 25 °C for 2 d. The mixture was filtered and the filtrate was concentrated *in vacuo*. The residue was chromatographed on silica gel (hexane: ethyl acetate=5: 1) to give a diastereomeric mixture of the sulfoxide (0.91 g, 3.5 mmol) in 66% yield. A mixture of trimethyl phosphite (2.1 ml, 17.8 mmol, freshly distilled from sodium), the sulfoxide (0.91 g, 3.5 mmol), and methanol (3.3 ml) was heated to reflux for 1 h. The mixture was poured into saturated aqueous sodium hydrogencarbonate and extracted with ethyl acetate three times. The combined extracts were washed with brine, dried, and concentrated. Purification by column chromatography on silica gel (hexane: ethyl acetate=10 : 1) afforded *trans*-carveol (0.28 g, 1.9 mmol, contaminated by $<2\%$ *cis*-carveol) in 53% yield.

General Procedure for the Alkylation of **1** *or* **3** *with Trialkylaluminum.* Trialkylaluminum (1.0 M solution in hexane, 3.0 ml, 3.0 mmol) was added dropwise to a solution of **1** or **3** (1.0 mmol) in hexane, dichloromethane or tetrahydrofuran (7.0 ml) at 0 °C. After 20 min, ethanol (1.0 ml) was added to decompose the excess trialkylaluminum. The mixture was poured into 1 M HCl and extracted twice with pentane. The combined extracts were washed with brine, dried, and freed of the solvent. Purification by preparative TLC (hexane) afforded a mixture of **4** and **5** whose ratio was determined by GLPC (PEG 20 M 10% on Celite 545, 2 m, 72 °C (R=Me), 88 °C (R=Et), 114 °C (R=^{t}Bu)). Pure samples of **4** and **5** were obtained by preparative GLPC (PEG 20 M 30% on Celite 545, 3 m, 98 °C (R=Me), 110 °C (R=Et), 120 °C (R=^{t}Bu)).

cis-*2,3-Dimethyl-5-isopropenylcyclohexene* (**4a**): Bp 130 °C (bath temp, 20 Torr); IR (neat) 3185, 1645, 888, 800 cm^{-1}; NMR (CCl_4) δ 0.94 (d, J=6.9 Hz, 3H), 1.57 (s, 3H), 1.65 (s, 3H), 1.8—2.3 (m, 6H), 4.57 (s, 2H), 5.28 (m, 1H); MS *m/e* (%) 151 (3), 150 (M^+, 16), 135 (19), 121 (26), 108 (100), 107 (73), 93 (89), 82 (24), 67 (99).

Found: C, 88.17; H, 11.84%. Calcd for $C_{11}H_{18}$: C, 87.93; H, 12.07%.

trans-*2,3-Dimethyl-5-isopropenylcyclohexene* (**5a**): Bp 130 °C (bath temp, 20 Torr); IR (neat) 3185, 1645, 888, 800 cm^{-1}; NMR (CCl_4) δ 1.07 (d, J=6.9 Hz, 3H), 1.64 (s, 3H), 1.72 (s, 3H), 1.6—2.3 (m, 6H), 4.64 (s, 2H), 5.29 (m, 1H); MS *m/e* (%) 151 (4), 150 (M^+, 20), 135 (11), 121 (10), 107 (100), 93 (39), 82 (54), 67 (92).

Found: C, 87.72; H, 11.97%. Calcd for $C_{11}H_{18}$: C, 87.93; H, 12.07%.

Alternative Synthesis of **4a** *and* **5a**. Epoxidation of (−)-*cis*-carveol (0.61 g, 4.0 mmol) by the method of Sharpless afforded epoxy alcohol **8**[21] (0.42 g, 64% yield). A solution of **8** (0.10 g, 0.61 mmol) in ether (2.0 ml) was treated with lithium dimethylcuprate(I) (3.7 mmol) in ether (6.0 ml) at 0 °C.[22] After 1.3 h at 0 °C and 1 h at 25 °C, the mixture was poured into ice–water and filtered. The filtrate was washed with 1 M HCl, saturated sodium hydrogencarbonate, and brine, dried, and concentrated. The residue was submitted to column chromatography on silica gel to afford the diol **9** (0.11 g, 97% yield) as a colorless solid: mp 68 °C; IR (Nujol) 3340, 3080, 1645, 1130, 1077, 1043, 887 cm^{-1}; NMR (CCl_4) δ 0.95 (d, J=7.5 Hz, 3H), 1.22 (s, 3H), 1.70 (s, 3H), 1.3—2.2 (m, 6H), 2.88 (bs, 2H, –OH), 3.52 (dd, J=5.7 and 10.4 Hz, 1H), 4.65 (s, 2H); MS *m/e* (%) 184 (M^+, 6), 166 (26), 151 (22), 140 (29), 122 (58), 97 (65), 69 (100), 57 (65), 55 (67). A mixture of the diol **9** (70 mg, 0.38 mmol), *N,N*-dimethylformamide (1.0 ml), and *N,N*-dimethylformamide dimethyl acetal (0.5 ml) was heated at 150 °C for 1 h. Acetic anhydride (1.0 ml) was added and the

resulting mixture was heated for another 3.5 h.[23] Purification of the product by column chromatography on silica gel (pentane) afforded **5a** (20 mg, $[\alpha]_{25}^{D}$ +125° (*c* 0.84, MeOH)) in 36% yield.

In similar fashion, the authentic sample of **4a** ($[\alpha]_{25}^{D}$ +28° (*c* 0.78, MeOH)) was obtained from (−)-*trans*-carveol *via* a corresponding diol: mp 104 °C; IR (CCl_4) 3410, 3090, 1645, 1139, 1102, 1041, 886 cm^{-1}; NMR (CCl_4) δ 0.90 (d, J=7.1 Hz, 3H), 1.05 (s, 3H), 1.71 (s, 3H), 1.1—2.5 (m, 6H), 3.60 (m, 1H), 3.93 (bs, 2H, -OH), 4.62 (s, 2H); MS *m/e* (%) 184 (M^+, 3), 166 (30), 151 (11), 140 (13), 125 (15), 124 (20), 123 (21), 122 (23), 97 (26), 85 (100), 72 (79).

exo- *and* endo-*2-Norcaranol.* The title compounds were prepared from 2-cyclohexenol following the method reported by Dauben and Berezin.[24] Acetylation (acetic anhydride and pyridine) of these alcohols gave **10a** and **11a**.

2-Norcaranol-2-d. Lithium aluminum deuteride reduction of 2-norcaranone gave a mixture of *endo*-alcohol-2-*d* and *exo*-isomer (*endo* : *exo*=22 : 78).

Alkylation of ***10a*** *or* ***11a*** *with Trimethylaluminum.* A solution of trimethylaluminum in hexane (1.0 M, 3.0 ml, 3.0 mmol) was added to a solution of **10a** or **11a** (1.0 mmol) in dichloromethane (3.5 ml) at 0 °C. After 2 h at 25 °C, the mixture was worked up in a usual way. A ratio of **12a**: **13a** was determined by GLPC (Apiezone 10% on Celite 545, 3 m, 100 °C). Purification by preparative GLPC (PEG 20 M 20% on Celite 545, 2 m, 50 °C) gave pure samples of **12a** and **13a**: IR (neat) 3100, 3025, 2950, 2880, 1468, 1015 cm^{-1}; NMR (CCl_4) δ 0.33—0.59 (m, 2H), 0.60—2.13 (m, 9H), 0.94 (d, J=4.4 Hz, for **12a**) and 1.08 (d, J=4.4 Hz, for **13a**).

endo-*2-Methylnorcarane-2*-d (***12b***): NMR (CCl_4) δ 0.26—0.66 (m, 2H), 0.71—2.12 (m, 8H), 0.95 (d, J=0.6 Hz, 3H); MS *m/e* (%) 111 (M^+, 10), 110 (3), 96 (76), 82 (100), 69 (59), 68 (94), 67 (58), 54 (76), 41 (53).

Alternative Synthesis of a Mixture of ***12a*** *and* ***13a***.[25] A solution of 3-bromocyclohexene (8.1 g, 50 mmol) in ether (20 ml) was treated with lithium dimethylcuprate (I) (50 mmol) in ether (200 ml) at −20 °C for 1.5 h. A mixture of the resulting crude 3-methylcyclohexene, hexadecyltrimethylammonium bromide (0.5 g), and chloroform (30 ml) was treated with aqueous NaOH (50%, 30 g) at 50 °C. After stirring for additional 40 min, the mixture was diluted with ice-water and 10% HCl and extracted with dichloromethane. Distillation under reduced pressure (bp 95 °C, 20 Torr) afforded a mixture of 7,7-dichloro-*endo*-2-methylnorcarane and its 2-epimer (4.3 g, 48% yield). The mixture was reduced with sodium (0.91 g, 39 mg-atoms) in liquid ammonia(25 ml)-ethanol (0.24 g) to give *endo*-2-methylnorcarane **12a** and *exo*-epimer **13a** in 14: 86 ratio (0.22 g, 35% yield).

Stereochemical Assingnment of ***12a*** *and* ***13a***. A mixture of **12a** and **13a** (96 mg, 0.87 mmol, **12a**: **13a**=14: 86), platinum(IV) oxide (20 mg), and acetic acid (2.0 ml) was stirred at 25 °C for 12 h under hydrogen atmosphere to yield a mixture of *cis*- and *trans*-1,2-dimethylcyclohexane (*cis*: *trans*=17: 83). Both isomers were separated by preparative GLPC (Apiezone 5% on Celite 545, 3 m, 100 °C) and their IR spectra were compared with published data.

The authors wish to thank the Ministry of Education, Science, and Culture, Japan, for the Grant-in-Aid (203014, 303023, 335042, 403022).

Preferential Solvation of Ag(I) Bromate and Iodate in Dimethyl Sulfoxide-Water Mixtures

Sivasankaran nair JANARDHANAN and Chatty KALIDAS*

Department of Chemistry, Indian Institute of Technology, Madras 600 036, India

(Received June 18, 1979)

The selective solvation of Ag(I) bromate and iodate was studied in dimethyl sulfoxide–water mixtures at 30 °C by solubility and EMF measurements. The solubility of silver bromate decreases down to $X_{DMSO}=0.2$ and thereafter increases with addition of dimethyl sulfoxide, the solubility of silver iodate continuously decreasing under the same conditions. The transfer free energy of silver cation decreases while that of halate ions increases with the addition of dimethyl sulfoxide. The solvent transport number, Δ, passes through a maximum around $X_{DMSO}=0.5$ in both cases. These results were interpreted in terms of a heteroselective solvation of both the salts, the silver ion being preferentially solvated by dimethyl sulfoxide and the halate ions selectively hydrated by water in the mixtures.

Investigations on ion solvation have largely been confined to aqueous[1] and pure non-aqueous solvents,[2] only few studies being carried out[3-5] in binary mixed solvents. In mixed solvents containing an electrolyte, there are two possibilities[6] depending on whether (a) both the ions of the electrolyte are solvated by the same solvent component, *i.e.*, a homoselective solvation or (b) one ion is bound more strongly by one solvent component while the other ion prefers the second solvent, *i.e.*, a heteroselective solvation. The present work deals with the selective solvation of two salts. The behavior of silver bromate and silver iodate in DMSO–water mixtures of varying composition was studied by means of electromotive force and solubility measurements in order to study the solvation of these salts and also the effect of solvent-solvent interactions on ion solvation.

Experimental

Materials. Dimethyl sulfoxide (BDH, LR Grade) was purified by the method of Maricle and Hodgson.[7] The middle fraction boiling at 60 °C under a pressure of 12 mm of Hg was collected and stored out of contact with air. Doubly distilled water was used in the preparation of DMSO–water mixtures. Ferrocene (E. Merck) was purified by sublimation in a vacuum. Silver bromate and silver iodate were prepared by the reaction of silver nitrate with the corresponding potassium salt. The precipitated silver halates were first thoroughly washed with water and then with acetone, and dried in a vacuum at 70—80 °C for several hours. The purity of the salts was checked by estimation of their silver content.

Solubility Measurements. The solubility measurements on the salts were performed at 30±0.1 °C in accordance with the general procedure.[4] The silver content of the saturated solution was determined by the addition of excess standard aqueous potassium iodide, the remaining potassium iodide being estimated by potentiometric titration with a standard solution of silver nitrate. A Metrohm Multidosimat (Type E 415) automatic titrator in conjunction with a Knick pH meter (for recording the EMF data) was employed. Oxidation of the iodide ion by iodate was found to be negligible.

Electromotive Force Measurements. The concentration cell was of the following type:[8]

$$\mathrm{Ag}\left|\begin{array}{l|l} x_1'\ \mathrm{H_2O} & x_1''\ \mathrm{H_2O} \\ x_2'\ \mathrm{DMSO} & x_2''\ \mathrm{DMSO} \\ \text{saturated with } \mathrm{AgXO_3} & \text{saturated with } \mathrm{AgXO_3} \end{array}\right|\mathrm{Ag} \qquad (1)$$

X=Br or I

EMF measurements were carried out over the complete range of DMSO–water mixtures keeping the mole fraction difference $x_2''-x_2'$ at 0.1. A U-type cell fitted with ground joints at the top and a G_3 frit in the middle to avoid direct contact of the solution was used in the EMF measurements. Silver electrodes freshly prepared according to the method of Carmody[9] were used. The EMF of cell 1 was measured at 30 °C with a Keithley (Model 602) Solid State Electrometer having an input impedence $>10^{14}$ Ω, reproducible with accuracy better than ±1 mV.

Results and Discussion

Solubility Measurements. The solubility and the transfer free energies of the salt (for transfer from water to DMSO–water mixtures) was calculated from the relation

$$\Delta G^{\circ}_{t(\mathrm{salt})} = 2.303RT\log\frac{K_{sp(\mathrm{water})}}{K_{sp(\mathrm{solvent})}} \qquad (2)$$

in different compositions of DMSO–water mixtures for both the salts. The results are given in Table 1, together with the free energy of transfer of silver ion in these mixtures.[11] The transfer free energy of the salts is related to that of the corresponding ions by

$$\Delta G^{\circ}_{t(\mathrm{AgXO_3})} = \Delta G^{\circ}_{t(\mathrm{Ag^+})} + \Delta G^{\circ}_{t(\mathrm{XO_3^-})}. \qquad (3)$$

The transfer free energies of the anions calculated from Eq. 3 are given in Table 1, the results being plotted in Fig. 1. K_{sp} in Eq. 2 represents the thermodynamic solubility product of the salt in water or the solvent mixtures and the mean activity coefficients required in these calculations were obtained from the extended Debye-Hückel equation with $a=6.5$ Å. The solubility of silver bromate decreases down to $X_{DMSO}=0.2$ and subsequently increases with the addition of DMSO, the solubility of silver iodate decreasing continuously under the same conditions. Thus $\Delta G^{\circ}_{t(\mathrm{salt})}$ increases up to $X_{DMSO}=0.2$ and thereafter decreases down to $X_{DMSO(\mathrm{pure})}$ in the case of silver bromate; it increases continuously in the case of silver iodate. However, the transfer free energy of silver ion (on the basis of ferrocene reference method, Table 1) shows a continuous decrease with the addition of DMSO, indicating that silver ion is preferentially solvated by DMSO. On the contrary, the transfer free energy of the anions is positive and continuously increases with the addition of DMSO indicating that they are selectively hydrated. Thus a

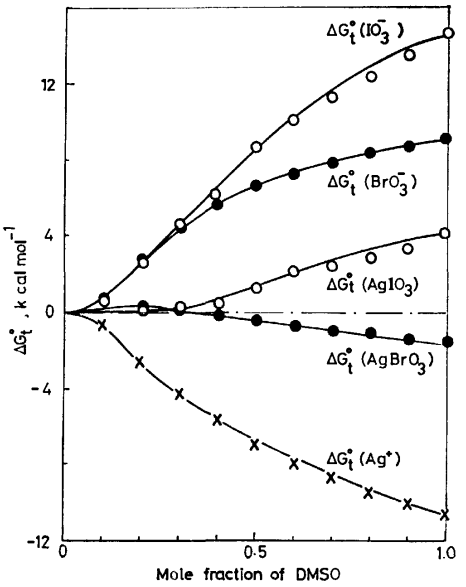

Fig. 1. Variation of ΔG_t° for silver bromate, silver iodate, Ag^+, BrO_3^-, and IO_3^- ions (from water to water–DMSO mixtures) with the mole fraction of DMSO at 30 °C.

heteroselective solvation of the salts in these mixtures may be inferred. Harakany and Schneider[8] arrived at a similar conclusion in the case of Ag_2SO_4–DMSO–water system.

We see from Table 1 that in aqueous solutions containing small amounts of DMSO ($X_{DMSO} \approx 0.1$), $\Delta G^\circ_{t(Ag^+)}$ is nearly equal to zero or slightly negative indicating that Ag^+ ion behaves as if it were in pure aqueous solution because of the strong interactions of DMSO with water molecules at low mole fractions of DMSO.[12,13] These strong solvent-solvent interactions result in a decrease of solubility of both salts at low mole fractions of DMSO. At higher mole fractions of DMSO, the relatively strong hydration of IO_3^- over that of BrO_3^- has a profound effect on the observed solubility of the two salts. The large positive ΔG_t° values of the bromate and iodate ions agree with earlier results,[14] the unusually strong hydration of these ions being attributed to their pyramidal structure with the halogen at the apex.

Solvent-transport Number Δ, from EMF Measurements. The emf data obtained from cell (1) utilised to calculate the solvent transport number, Δ of DMSO in these mixtures is expressed[12] by

$$E = \frac{-RT}{F} \frac{(x_2'' - x_2')\Delta}{X_2(1-X_2)} \left(1 + \frac{\partial \ln f_2}{\partial \ln X_2}\right), \qquad (4)$$

where $X_2 = (x_2'' + x_2')/2$ and $\partial \ln f_2 / \partial \ln X_2$ represents the variation of the activity coefficient of DMSO with the mole fraction in these mixtures, taken from the work of Cox and Mctigue[15] for the calculation of Δ. The other terms have their usual meanings. Δ may be defined as the net increase in the number of moles of DMSO in the cathode compartment, with the mean molar velocity of the solvent mixtures as a reference, when one faraday of electricity is passed through the cell during the course of electrolysis at the given solvent composition. The EMF data, values of $\partial \ln f_2 / \partial \ln X_2$ and the calculated Δ values of DMSO in the case of the two salts are given in Table 2 and Fig. 2. The values are positive throughout, passing through a maximum at $X_{DMSO} = 0.45$ ($\Delta = 1.6$) in the case of silver bromate and at $X_{DMSO} = 0.55$ ($\Delta = 2.1$) in the case of silver iodate. The Δ_{max} values provide direct information on ion solvation. The considerable positive values of Δ for both salts is in line with the conclusion arrived at from the transfer

free energy data of the two salts in the mixtures. The transport of DMSO into the cathode compartment occurs largely through the silver ion while the anions transport water into the anode compartment. The two effects are combined, characterising the heteroselective solvation with significantly large Δ.

Oxidation Studies with Peroxomonophosphoric Acid. III. A Kinetic and Mechanistic Study of Oxidation of Dialkyl Sulfides

Ganesh Prasad PANIGRAHI* and Radhasyam PANDA
Department of Chemistry, Berhampur University, Berhampur 760 007, Orissa, India
(Received August 25, 1979)

The kinetics of oxidation of dialkyl sulfides by peroxomonophosphate in aqueous medium at 308 K and μ= 0.4 mol dm^{-3} follow the rate expressions (i) $-$d[peroxomonophosphate]/dt=$\{k_1[H_2PO_5^-]+k_2[HPO_5^{2-}]\}$[sulfide] in the pH region 6.8—8.7 where k_1 and k_2 values are 336.5 and 0.95, 69.7 and 0.254, and 27.5 and 0.126 dm^3 mol^{-1} s^{-1} for dimethyl, diethyl and dipropyl sulfides, respectively, (ii) $-$d[peroxomonophosphate]/dt=$k_2[HPO_5^{2-}]$·[sulfide] in the pH region 8.5—12.5, where the average k_2 values are 0.86, 0.247, and 0.128 dm^3 mol^{-1} s^{-1} for dimethyl, diethyl, and dipropyl sulfides, respectively, and (iii) $-$d[peroxomonophosphate]/dt=$\{k_2[HPO_5^{2-}]+k_3$·$[PO_5^{3-}]\}$[sulfide] in the pH region 12.5—13.7, the k_2 and k_3 values being 0.947 and 0.107, and 0.233 and 0.018 dm^3 mol^{-1} s^{-1} for dimethyl, and diethyl sulfides, respectively. The mechanism of the reaction is in line with a nucleophilic attack of the sulfide-sulfur on the peroxo oxygen, giving rise to S_N 2-type transition states which undergo oxygen–oxygen bond fission to give the corresponding sulfoxide and phosphate.

Organic sulfides have been oxidised[1–14] by various peroxo compounds. Howard and Levitt[6] pointed out that in the oxidation of diethyl sulfide by persulfate at pH 8 the reaction sequence should be sulfide→sulfoxide→sulfone, the second step of oxidation of the sulfoxide to sulfone being very slow. Electrophilic nature of the peroxo oxygen in this oxidation was suggested.

Curci and Modena[11,12] carried out studies on the steric and polar influences on peroxide oxidation rates of organic sulfides. In the oxidation of methyl phenyl sulfides and diphenyl sulfides by H_2O_2 in acidic ethanol solution,[8] the nucleophilic nature of the sulfide molecule was well established. Modena[9] observed the effects of alkyl group structure in alkyl phenyl sulfides, alkyl benzyl sulfides being predominantly steric.

Various reports have appeared on the oxidation of organic sulfides by peroxo compounds. However, no work seems to have been carried out on the oxidation of sulfides by peroxomonophosphoric acid. In continuation of our work[15,16] on the oxidation of organic substrates by peroxomonophosphoric acid in acid and alkaline pH, we are reporting the study on the oxidation of dialkyl sulfides by peroxomonophosphoric acid.

The oxidation was studied over the pH range 6—14, contribution of the various peroxomonophosphoric acid species being estimated. It is of interest that the pH dependence of the oxidation rate is quite contrary to that observed in the dimethyl sulfoxide oxidation.[16]

Experimental

All the chemicals were of AnalaR grade. Peroxomonophosphoric acid (PMPA) was prepared by the acid hydrolysis[17–20] of potassium peroxodiphosphate. Perchloric acid, used for hydrolysis, was neutralised by addition of a requisite amount of sodium hydroxide. The ionic strength of the medium was maintained with sodium perchlorate. The pH of the solution, adjusted with standard buffers or carbonate-free hydroxide, was determined with a Systronics digital pH-meter 335. Reactions were followed by measuring the rate of disappearance of peroxomonophosphoric acid, the estimation of which was made in an acetic acid–acetate buffer at a pH≈ 4—5 with a drop of ammonium molybdate solution (to avoid the diffused end point due to the presence of 2—3% of H_2O_2 formed during the course of hydrolysis) by the usual iodometric procedure. The self-decomposition of peroxomonophosphate (PMP), which occurs to some extent in the presence of higher [OH$^-$] due to

$$PO_5^{3-} \longrightarrow PO_4^{3-} + 1/2O_2$$

was found to be either nil or negligibly small. However, in a few cases, due allowance has been made to account for the self decomposition of the oxidant.

Results and Discussion

The kinetics of oxidation of dialkyl sulfides by PMP in alkaline pH have been investigated at 308 K. Kinetic runs with PMP in the range 2.91—9.26×10^{-4} mol dm^{-3} in the presence of excess [sulfide] at fixed pH and μ show a first-order disappearance of PMP. This follows from the constancy of the first-order rate constants (k_1') up to at least 60% completion of the reaction with respect to the disappearance of PMP in any single run when [sulfide]>[PMP].

The oxidation also exhibits a first order dependence on [sulfide] as seen from the constancy of the second-order rate constants k_2' (Table 1), calculated either by: $k_2'=k_1'$/[sulfide] (when [sulfide]>[PMP]) or from the usual second-order rate expression (when [sulfide]≈ [PMP]).

The variation of ionic strength using $NaClO_4$ was found to have negligible effect on the oxidation rate, indicating the rate determining slow step to involve at least one neutral molecule.[21] The oxidation rate is insensitive to the addition of acrylamide, indicating the absence of radicals in the reaction system.

Temperature dependence in the range 298—318 K for different dialkyl sulfides at pH 13.01 is given in Table 1. Activation parameters have been evaluated from the linear Arrhenius plots of log k_2' *vs.* T^{-1} (Table 2).

The influence of pH on oxidation rate has been studied in the pH ranges 7.36—13.7 for dimethyl sulfide, 6.76—13.7 for diethyl sulfide, and 6.87—13.0 for dipropyl sulfide. The results are interesting. Plots of pH *vs.* log k_{obsd}(=log k_2') for different dialkyl sulfides are shown in Fig. 1. The plots in sigmoid form suggest the participation of various species of PMP in the oxidation. The pH $-$log k_{obsd} plots can be

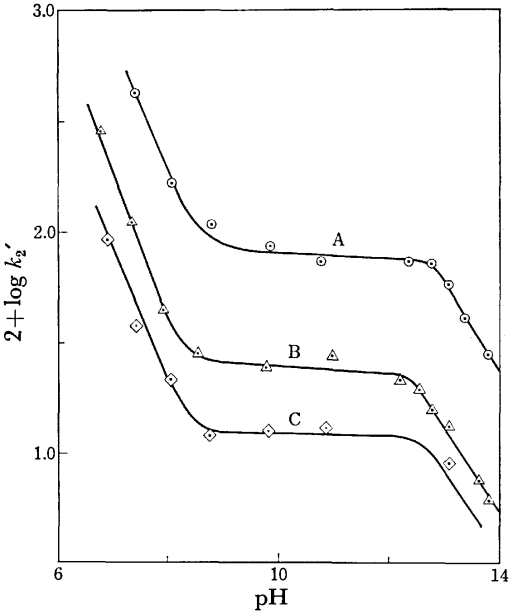

Fig. 1. Plots of log k_2' *vs.* pH (pH range 6.8 to 13.7).
A: Dimethyl sulfide, B: diethyl sulfide, C: dipropyl sulfide.

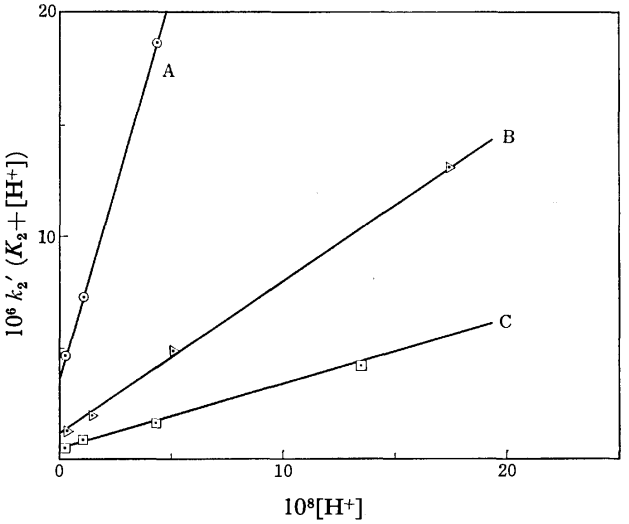

Fig. 2. Plots of k_2' ($K_2+[H^+]$) *vs.* $[H^+]$ (pH range 6.8 to 8.7).
A: Dimethyl sulfide, B: diethyl sulfide, C: dipropyl sulfide.

divided into three distinct pH regions 6.8—8.7, 8.7—12.5, and 12.5—13.7. The oxidation rate in the case of sulfides decreases with increasing $[OH^-]$, quite contrary to the oxidation of dimethyl sulfoxide by PMP where the rate increases with the increasing $[OH^-]$ (Table 3).[16]

Various equilibria[19] involving peroxomonophosphoric acid in solution are:

$$H_3PO_5 \overset{K_1}{\rightleftharpoons} H_2PO_5^- + H^+ \quad (1)$$

$$H_2PO_5^- \overset{K_2}{\rightleftharpoons} HPO_5^{2-} + H^+ \quad (2)$$

$$HPO_5^{2-} \overset{K_3}{\rightleftharpoons} PO_5^{3-} + H^+ \quad (3)$$

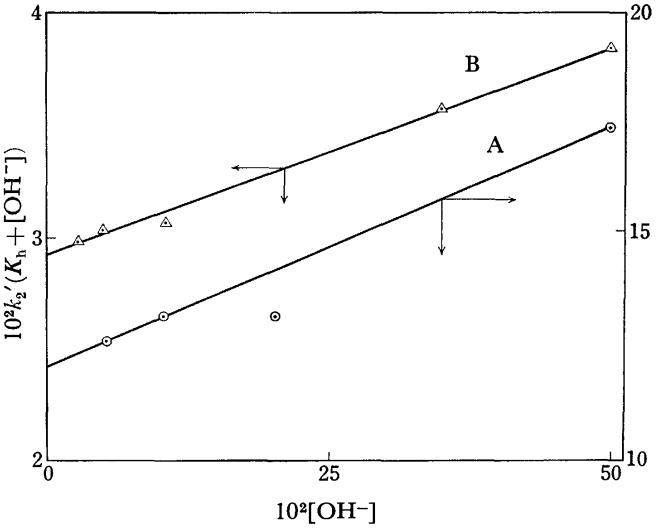

Fig. 3. Plots of k_2' ($K_h+[OH^-]$) *vs.* $[OH^-]$ (pH range 12.5 to 13.7).
A: Dimethyl sulfide, B: diethyl sulfide.

The dissociation constants, K_1, K_2, and K_3 are 8.0×10^{-2}, 4.2×10^{-6}, and 1.6×10^{-13}, respectively[19] at 298 K and $\mu=0.2$ mol dm^{-3}.

Since the species H_3PO_5, $H_2PO_5^-$, HPO_5^{2-}, and PO_5^{3-} become predominant with increasing pH in the order specified and the electrophilic character of these species decreases, it is evident from the pH dependence of the sulfide oxidation that the rate of oxidation decreases with decreasing electrophilic character of PMP species. A reverse trend has been observed in the case of DMSO oxidation[16] by PMP in the pH range 10—13.6; this has been rationalised on the basis of a nucleophilic attack of the PMP species on the sulfur of the sulfoxide.

The oxidation rate decreases in the order: dimethyl> diethyl>dipropyl sulfide. This could be attributed to the steric factor rather than to the polar effects which arises from the fact that in the oxidation[9] of alkyl phenyl sulfides and alkyl benzyl sulfides the effect of alkyl group structure is postulated to be predominantly steric. Although it is hard to sort out the polar and steric effects in the case of the dialkyl sulfides, the rate enhancement observed by the electron-releasing substituents on the aromatic rings of the alkyl phenyl sulfides is in the expected order of reactivity for the sulfide acting as a nucleophile.

On the other hand peroxides acting as electrophiles are not uncommon;[22,23] the observed second-order kinetics, the high negative entropies of activation and catalysis by acid support the electrophilic nature of the peroxide.

The sulfide molecule can be envisaged to participate in a nucleophilic attack on the peroxo oxygen, giving rise to the corresponding sulfoxide which does not undergo further oxidation. This arises from the fact that (i) TLC-analysis of the reaction mixture after about 80% completion of the reaction with respect to the consumption of PMP does not show the presence of any sulfone, and (ii) the rate of oxidation of dimethyl sulfoxide[16] is much lower than that of the dimethyl

sulfide under similar conditions (Tables 1 and 3).

Since PMPA exists[19] as $H_2PO_5^-$ and HPO_5^{2-} in the pH range 4—7, the reaction sequence can be presented as

$$R_2S: + H_2PO_5^- \xrightarrow{k_1} R_2SO + H_2PO_4^- \quad (4)$$

$$R_2S: + HPO_5^{2-} \xrightarrow{k_2} R_2SO + HPO_4^{2-} \quad (5)$$

Table 2.[a] Oxidation of dialkyl sulfides by peroxomonophosphate (Thermodynamic parameters).

20.5	4.29	10.84	0.53
20.3	4.41	10.65	0.40

a) Ref. 16, in aqueous medium at 308 K and μ=0.4 mol dm^{-3}. b) Observed second-order rate constant. c) At μ=0.45 mol dm^{-3}.

The reaction sequence in the pH range 12—14 in which PMP exists[19] as HPO_5^{2-} and PO_5^{3-} would be

$$HPO_5^{2-} + OH^- \overset{K_4}{\rightleftharpoons} PO_5^{3-} + H_2O \quad (6)$$

$$R_2S: + HPO_5^{2-} \xrightarrow{k_2} R_2SO + HPO_4^{2-} \quad (7)$$

$$R_2S: + PO_5^{3-} \xrightarrow{k_3} R_2SO + PO_4^{3-} \quad (8)$$

These equations suggest the rate laws corresponding to pH regions 6.8—8.7 and 12.5—13.7, respectively, as

$$-\text{d[peroxomonophosphate]}/dt = \{k_1[H_2PO_5^-] + k_2[HPO_5^{2-}]\}[\text{sulfide}] \quad (8a)$$

and

$$-\text{d[peroxomonophosphate]}/dt = \{k_2[HPO_5^{2-}] + k_3[PO_5^{3-}]\}[\text{sulfide}] \quad (8b)$$

from which we get:

$$-\frac{\text{d[PMPA]}}{dt} = \frac{k_1[H^+] + k_2K_2}{K_2 + [H^+]}[\text{PMPA}][\text{sulfide}] \quad (9)$$

where

$$k_2' = \frac{k_1[H^+] + k_2K_2}{K_2 + [H^+]}, \quad (9a)$$

$$-\frac{\text{d[PMP]}}{dt} = \frac{k_2K_h + k_3[OH^-]}{K_h + [OH^-]}[\text{PMP}][\text{sulfide}] \quad (10)$$

where

$$k_2' = \frac{k_2K_h + k_3[OH^-]}{K_h + [OH^-]} \quad (10a)$$

and

$$\frac{[H_2O]}{K_4} = K_h \quad (11)$$

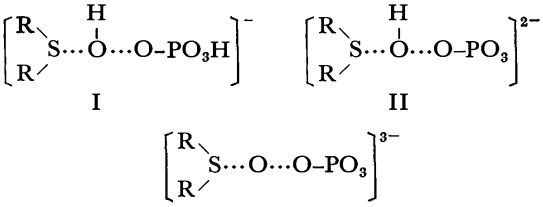
Plots (Fig. 2) of $k_2'\{K_2 + [H^+]\}$ against $[H^+]$ (Eq. 9a) in the pH range 6.8—8.7 give straight lines (r=0.999, 0.999, and 0.998 for dimethyl, diethyl, and dipropyl sulfides respectively). From the intercepts and slopes of these least-square plots the values of k_1 and k_2 are respectively calculated to be 336.5 and 0.95 dm^3 mol^{-1} s^{-1} for dimethyl sulfide, 69.7 and 0.254 dm^3 mol^{-1} s^{-1} for diethyl sulfide, and 27.5 and 0.126 for dipropyl sulfide. The second-order rate constants (k_2' calcd) obtained from Eq. 9a with these k_1 and k_2 values, are given in Table 1.

Similarly from Eq. 10a, plots (Fig. 3) of $k_2'\{K_h + [OH^-]\}$ against $[OH^-]$ (with $K_h = K_w/K_3$, where K_w is the ionic product of water and K_3 is the dissociation constant of HPO_5^{2-}) for dimethyl and diethyl sulfides in the pH region 12.5—13.7 are found to be straight lines (r=0.97 and 0.99 respectively). The values of k_2 and k_3 as obtained from the intercepts and slopes of the above plots are respectively 0.947 and 0.107, and 0.233 and 0.018 dm^3 mol^{-1} s^{-1} for dimethyl and diethyl sulfides. With these k_2 and k_3 values, k_2' calcd values have been obtained from Eq. 10a (Table 1).

The k_2 values corresponding to the pH regions 6.8—8.7 and 12.5—13.7 agree excellently with the average k_2' values (0.86, 0.247, and 0.128 for dimethyl, diethyl, and dipropyl sulfides, respectively) in the pH region 8.5—12.5. This leads us to conclude that the PMP species predominantly exists as HPO_5^{2-} in the pH region 8.5—12.5. Thus the oxidation in this pH region can be expressed by

$$-\text{d[PMP]}/dt = k_2[HPO_5^{2-}][\text{sulfide}] \quad (12)$$

The oxidation of dialkyl sulfides by PMP in the pH range 6.8—13.7 can be visualised to involve a nucleophilic attack of the sulfide-sulfur atom on the peroxo-oxygen giving rise to S_N2-type transition states I, II, and III corresponding to steps (4), (5 and 7), and (8) respectively, which undergo oxygen-oxygen bond fission to form the products.



I II

III

This mechanism is in line with the thermodynamic parameters,[7] the magnitude of reactivity of different PMP species and the steric factor[9] involved in the sulfide.

The authors are thankful to Prof. P. S. Radhakrishna Murti, Dr. S. N. Mohapatro, and Dr. R. K. Panda of this department for helpful discussions and encouragement. One of the authors (R. S. P.) is grateful to C. S. I. R. (New Delhi) for the award of a Senior Research Fellowship.

Concentration Dependence of Flow Properties of Molten Salt Systems

Nurul Islam* and Anwar Ali
Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India
(Received December 15, 1979)

The concentration dependence of fluidities and conductances of molten calcium nitrate tetrahydrate–MNCS ($M=Na^+$ or NH_4^+) systems was quantitatively explained by the isoenergetic and isoentropic equations essentially based on the Vogel-Tammann-Fulcher (VTF) and the Configurational Entropy Model (CEM) equations. The pre-exponential terms of the VTF and the Doolittle's equations were found to depend linearly on the values of the corresponding parameters, *i.e.*, T_0, the zero mobility temperature and those of V_0, the molar intrinsic volume at T_0, respectively. The linear interdependence of the two thermodynamic parameters, T_0 and V_0 on each other has been demonstrated. In addition to the linear dependence of the corrected energy of activation, E_{cor} on V_0, a physically meaningful linear dependence of E_{cor} on T_0 has also been demonstrated.

A solute experiences strong interionic effects due to the close proximity of charged species even in extremely dilute solutions of molten salts as is the case with very concentrated electrolytes. This renders such solutions to behave differently from those of the aqueous solutions. Attention has recently been drawn to the fact that the great majority of solutions which reach concentrations approaching their maximum solubility become very viscous on cooling to their melting temperatures and may readily supercool to the vitreous state.[1-4] This has led to the examination of relaxation processes in glass-forming melts in order to have greater insight into the nature of the transport behaviour in highly concentrated solutions and to provide new empirical description for the concentration dependence of such properties.

In order to achieve this aim Angell[2] transformed the Vogel-Tammann-Fulcher (VTF) equation[5] to an isothermal expression for the variation of transport properties with concentration by assuming the pre-exponential, A_Y, and the exponential, k_Y, parameters as concentration independent while taking only the T_0 as varying linearly with concentration. The resulting expression is of the form,

$$Y = A_Y T^{-1/2} \exp\left[-k_Y/Q_Y(N_0-N)\right], \quad (1)$$

where Y stands for the fluidity, $\phi=\eta^{-1}$, or the conductance, Λ, Q_Y (denoted by Q_{2Y} in Eq. 2) is the slope of the linear plot of T_0 *versus* N being in mol% and is given as,

$$T_0 = T_{0(0)} \pm Q_{2Y}N \quad (2)$$

The parameter N_0 is the characteristic concentration at which the isothermal temperature, T becomes the glass transition temperature T_g of the system, *i.e.*, the concentration at which the particle mobilities would fall to zero at the isothermal temperature. Recent studies on a large varieties of molten salt systems[6-8] have revealed that the parameter A_Y also varies linearly with concentration and may be expressed as,

$$A_Y = A_{0Y} \pm Q_{1Y}N, \quad (3)$$

in which Q_{1Y} represents the slope of the plot of A_Y *versus* N and A_{0Y} is the value of A_Y for the pure solvent. By accounting for such a dependence of A_Y Eq. 1 was modified[8] to

$$Y = (A_{0Y}\pm Q_{1Y}N)\,T^{-1/2} \exp\left[-k_Y/Q_{2Y}(N_0-N)\right]. \quad (4)$$

The above isothermal equation has been satisfactorily employed to explain the concentration dependence of transport properties of many molten salt mixtures. The limitations of this equation may, however, be pointed out. This equation has been found to be meaningfully applicable only within the T_0 values of the two components of the melts. If we try to go beyond this range of temperature the values of N_0 will be either less than zero or more than 100 mol% which are physically meaningless. For example, in the case of $Ca(NO_3)_2\cdot 4.09H_2O$–$Cd(NO_3)_2\cdot 4.07H_2O$[6] melts the T_0 values of the solvent and that of the solute range between 205 and 193 K. Therefore, the concentration dependence of transport properties obtained above 205 K cannot be explained by such an isothermal equation. Similar difficulties arise in applying the above isothermal equation to the mixtures of alkali metal nitrates in molten $Cd(NO_3)_2\cdot 4H_2O$[9] and $Ca(NO_3)_2\cdot 4H_2O$.[10] In view of such an inherent difficulty with Eq. 4 another expression based on the VTF equation was obtained[11] at equal values of T/T_0 $(=c)$. This results in an isoenergetic equation,

$$Y = (A_{0Y}\pm Q_{1Y}N)c^{-1/2}(T_{0(0)}\pm Q_{2Y}N)^{-1/2} \times \exp\left[-k_Y/(T_{0(0)}\pm Q_{2Y}N)(c-1)\right]. \quad (5)$$

Similarly, such behaviours may also be quantitatively explained in terms of the essentially configurational entropy model,[12]

$$Y = (A'_{0Y}\pm Q'_{1Y}N)\exp\left[-k'_Y/(T_{0(0)}\pm Q_{2Y}N)c\ln c\right]. \quad (6)$$

Some of the melts employed for this purpose have inherent glass-forming ability while others are induced by the presence of high concentrations of solute. In the latter category, the solubility of solutes, namely transition metal salts, in a given molten salt solvent depends upon several factors, *e.g.*, the ease of ionization, complex ion forming ability and their energetics, solvation, equilibria among several chemical species, *etc.* Furthermore, these molten salt mixtures could either be grouped as ideal with respect to the intrinsic volume, $V_{0,i}$ as well as to the zero mobility temperature, $T_{0,i}$ or as non-ideal. The former is marked by the absence of reactions involving complex-ion formation while the latter seems to have been caused by the presence of either tetrahedral or octahedral complex-ions as a result of pronounced interactions among the components of the melts.

The purpose of this paper is to examine the ability of generalized Eqs. 5 and 6 to explain the concentration dependence of the transport properties without being

restricted by the T_0 values of the two components and the role of the relevant parameters including the derived ones in understanding the successive variations in their behaviour with concentration.

The mixed molten salt systems, calcium nitrate tetrahydrate–ammonium thiocyanate and calcium nitrate tetrahydrate–sodium thiocyanate have been selected for the present investigation. In addition to these melts, reported[12,13] data on the concentration dependence of the flow processes in the cases of non-ideal melts containing either tetrahedral or octahedral complex-ions have also been analysed.

Experimental

Calcium nitrate tetrahydrate (BDH; mp 42.7 °C) was used as solvent in the molten state. Ammonium thiocyanate (BDH; mp 149.6 °C) and sodium thiocyanate (BDH; mp 287 °C, recrystallized twice from double distilled water) were used as solutes.

Samples were prepared in a thermostated paraffin bath at about 333 K. During the samples' preparation all the chemicals were handled with extra care in an atmosphere of pure and dry nitrogen. Several samples of different concentrations were prepared. Calcium nitrate tetrahydrate was found to dissolve approximately 60 mol% of ammonium thiocyanate, and 24 mol% of sodium thiocyanate.

Density measurements were made using a calibrated dilatometer of approximately 6.0 ml capacity with graduated stem of 0.01 ml divisions. The viscosities of the melts were determined with the help of a Cannon-Ubbelohde[14] type viscometer (viscometer constant, 6.26 cSt/s). The conductance measurements were made with conductivity bridge of Philips Model PR 9500 type. The cells used were of capillary-type[15,16] of cell constant values as 542 cm^{-1} and 730 cm^{-1} at 298 K.

Densities, viscosities, and conductivities were measured within $\pm 0.3\%$, $\pm 0.1\%$, and $\pm 1.5\%$ accuracy, respectively, in a thermostated paraffin bath of ± 0.1 °C thermal stability under dry nitrogen atmosphere.

Table 1. Equivalent conductance ($10^4\ \Lambda$, $Sm^2\ equiv^{-1}$) and fluidity ($10^{-1}\ \phi$, $N^{-1}\ m^2\ s^{-1}$) data as a function of temperature for molten (a) $Ca(NO_3)_2 \cdot 4.23H_2O$–$NH_4NCS$ and (b) $Ca(NO_3)_2 \cdot 4.1H_2O$–NaNCS systems

Results and Discussion

The waters of hydration in the melts were determined by the method[17] of comparison of densities.

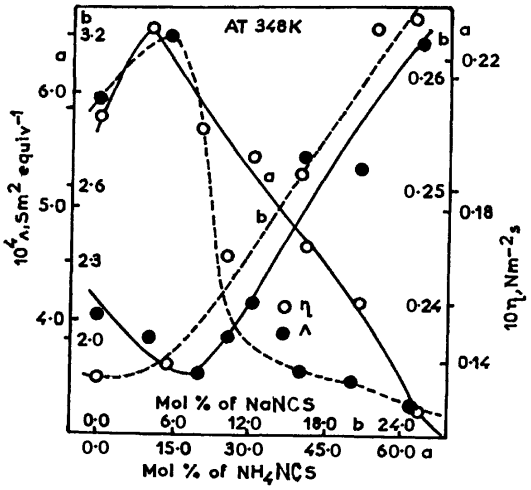

Fig. 1. Viscosity and conductance isotherms for molten (a) $Ca(NO_3)_2 \cdot 4.23H_2O$–$NH_4NCS$ and (b) $Ca(NO_3)_2 \cdot 4.1H_2O$–NaNCS systems.

The fluidities and conductances of the systems (Table 1) under investigation are found to change quite markedly with concentration (Fig. 1). The viscosity of a system is determined mainly by the bulky or less mobile entities while the ions of higher mobilities appear to be mainly responsible for the conductance behaviour. Therefore, both are expected to show an opposite trend in their behaviour with concentration as has actually been found.

In the case of the system, $Ca(NO_3)_2 \cdot 4.23H_2O$–$NH_4NCS$ fluidity and conductance both increase with increase in concentration of NH_4NCS. In this melt the hydrated solvent cation, $Ca(H_2O)_4^{2+}$ seems to be less mobile than the added solute cation, NH_4^+. Therefore, on adding NH_4NCS we are increasing the concentration of the conducting NH_4^+ ions which increase the conductance value with $[NH_4^+]$. It may, however, be pointed out that in the cases of ideal systems the resultant viscosities of the mixtures of molten salts may also depend upon the respective values of the two components. The above fact may be responsible for the increase in fluidity with $[NH_4^+]$. Both fluidity and conductance decrease with increase in the concentration of solute for the system, $Ca(NO_3)_2 \cdot 4.1H_2O$–NaNCS. Here the substitution of less mobile Na^+ for $(1/2)Ca^{2+}$ appears to be responsible for the decrease in the conductance value with increase in [NaNCS]. Decrease in the viscosity with concentration may presumably be due to an increase in the compactness or rigidity of the system.

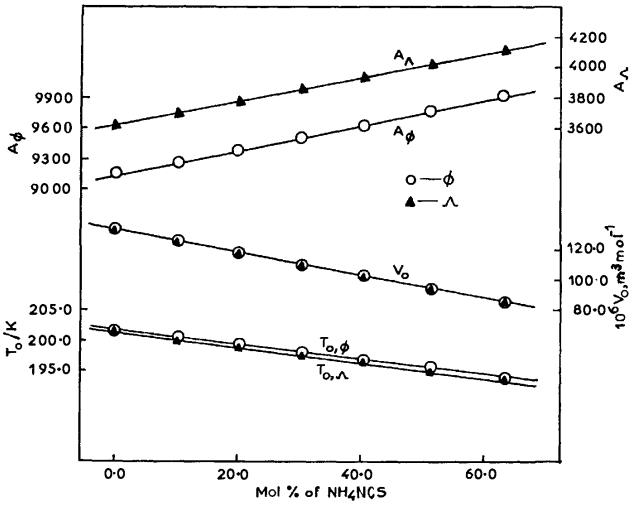

Fig. 2. Variation of A_Y, V_0, and T_0 with $[NH_4NCS]$ in molten $Ca(NO_3)_2 \cdot 4.23H_2O$–$NH_4NCS$ system.

In order to analyse the concentration dependence of fluidities and conductances the data were first least-squares fitted to the VTF and the CEM equations. The values of the parameters A_Y, A_Y', and T_0 thus obtained gave linear plots (Fig. 2) with N as expected from Eqs. 2 and 3.

Having examined the linear concentration variations of A_Y, A_Y', and T_0 the fluidities and conductances were

a) The density equation is $10^{-2}\,\rho(\mathrm{kg\ m^{-3}})=a-bT(\mathrm{K})$.

least-squares fitted to Eqs. 5 and 6 at several values of constant T/T_0 $(=c)$. The corresponding temperature, T lying in the experimental range and the value of c which gave reasonably good fits were selected. The values of the relevant parameters thus obtained along with the standard deviations in $\ln\phi$ and $\ln\Lambda$ are listed in Tables 2 and 3. It should be noted that the computed values of the parameters A_{0Y}, Q_{1Y}, k_Y, Q_{2Y}, and $T_{0(0)}$ from Eq. 5 and those of A'_{0Y}, Q'_{1Y}, k'_Y, Q_{2Y}, and $T_{0(0)}$ from that of Eq. 6 are very close to those obtained from the corresponding plots (Fig. 2). Furthermore, the values of $T_{0(0)}$ obtained from Eqs. 5 and 6 are in good resemblance with those obtained by extrapolating the plots of T_0 *versus* N to zero mol% of solute in the respective melts.

It may be emphasized that the isoenergetic[18] as well as an apparently isoentropic[19] conditions used in the present systems satisfactorily represent the concentration dependence of viscosities and conductances in the glass-forming melts irrespective of the nature of the melt, whether they are ideal or non-ideal.[8] However, the isoenergetic condition appears to have a direct experimental relevance as compared to that involving an apparently constant entropy (the latter, however, is far from constant). Such an analysis emphasizes further the importance of choosing T/T_0 as a better corresponding state for the comparison of liquid properties.

Furthermore, an interesting relationship for the dependence of A_Y on T_0 obtained[11] by combining Eqs. 2 and 3,

$$A_Y=[A_{0Y}-(Q_{1Y}/Q_{2Y})T_{0(0)}]+(Q_{1Y}/Q_{2Y})T_0 \qquad (7)$$

is found (Fig. 3) to be applicable to the systems under investigation. This equation may be applied to any system in which A_Y and T_0 both vary linearly with concentration.

In view of the significance of another thermodynamic parameter, V_0 of Doolittle's equation[20] in explaining the transport behaviour, variations in the values of the parameters A''_Y and V_0 with concentration have similarly been examined. The molar volumes were obtained from the corresponding densities (Table 4). The pre-exponential term A''_Y of Doolittle's equation like those of A_Y and A'_Y terms shows a linear dependence on concentration and is, therefore, expressed as,

$$A''_Y=A''_{0Y}\pm Q_{3Y}N, \qquad (8)$$

where A''_{0Y} is the value of A''_Y for the pure solvent and Q_{3Y} is the slope of the plot of A''_Y *versus* N. It is also apparent from the plots of V_0 *versus* N (Fig. 2) that the V_0 varies linearly with concentration and may similarly be represented as,

$$V_0=V_{0(0)}\pm Q_{4Y}N, \qquad (9)$$

where $V_{0(0)}$ is the value of V_0 for the pure solvent and Q_{4Y} is the slope of the plot of V_0 *versus* N. Equations 8 and 9 may be combined to yield,

$$A''_Y=[A''_{0Y}\mp(Q_{3Y}/Q_{4Y})V_{0(0)}]\pm(Q_{3Y}/Q_{4Y})V_0 \qquad (10)$$

for the linear dependence of A''_Y on V_0.

Finally, combining Eqs. 2 and 9 a meaningful correlation between the two thermodynamic variables T_0 and V_0 may be obtained as,

$$T_0=[T_{0(0)}\mp(Q_{2Y}/Q_{4Y})V_{0(0)}]\pm(Q_{2Y}/Q_{4Y})V_0. \qquad (11)$$

The Eqs. 7, 10, and 11 represent the linear dependence of A_Y on T_0, A''_Y on V_0, and T_0 on V_0, respectively, as has actually been found in the cases of ideal (Fig. 3)

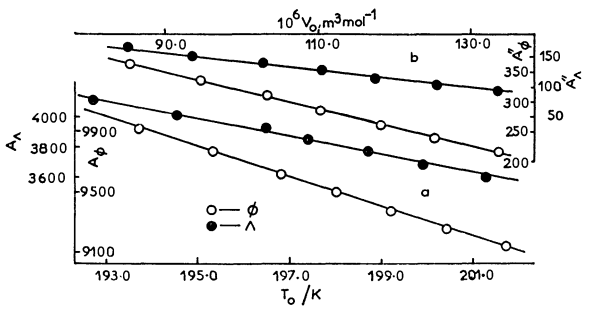

Fig. 3. Variations of (a) A_Y with $T_{0,Y}$, (b) A''_Y with $V_{0,Y}$, and (c) $T_{0,Y}$ with $V_{0,Y}$ for molten $Ca(NO_3)_2\cdot4.23H_2O$–NH_4NCS system.

as well as non-ideal systems containing either tetrahedral or octahedral complex-ions. The data for these parameters were least-squares fitted to the above derived equations and the computed values of the corresponding slopes and the intercepts are comparable with those obtained from the plots of A_Y, A''_Y, and T_0 against T_0, V_0, and V_0, respectively.

Furthermore, it is equally interesting to examine the relationship between the corrected activation energy, E_{cor} and T_0 value especially in view of their linear variations with concentration, *i.e.*, Eq. 2 and the following equation,

$$E_{cor} = E'_{cor} + Q_{5Y}N, \quad (12)$$

where E'_{cor} is the intercept while Q_{5Y} is the slope of E_{cor} *versus* N plot. Thus, combining Eqs. 12 and 2, we get,

$$E_{cor} = [E'_{cor} \mp T_{0(0)}(Q_{5Y}/Q_{2Y})] + (Q_{5Y}/Q_{2Y})T_0, \quad (13)$$

which suggests a linear increase in the corrected activation energies with T_0 as has actually been found (Fig. 4) in all the systems under investigation and also in those reported earlier.[12,13]

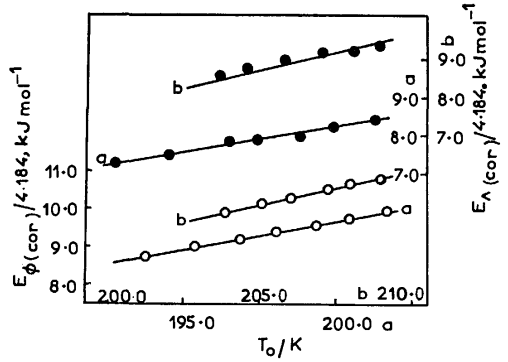

Fig. 4. Variation of E_Y with $T_{0,Y}$ for molten (a) $Ca(NO_3)_2 \cdot 4.23H_2O$–$NH_4NCS$ and (b) $Ca(NO_3)_2 \cdot 4.1H_2O$–NaCNS systems.

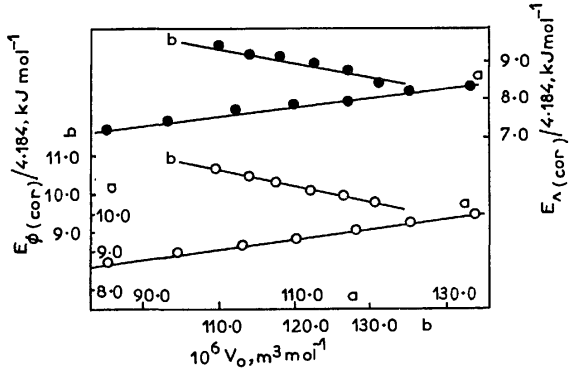

Fig. 5. Variation of E_Y with $V_{0,Y}$ for molten (a) $Ca(NO_3)_2 \cdot 4.23H_2O$–$NH_4NCS$ and (b) $Ca(NO_3)_2 \cdot 4.1H_2O$–NaNCS systems.

Similarly, in view of Eq. 11, E_{cor} may be expected to vary linearly with increase in the value of V_0 (Fig. 5) depending upon the sign in Eq. 11 for the dependence of T_0 on the V_0. Thus Eqs. 9 and 12 yield,

$$E_{cor} = [E'_{cor} \mp V_{0(0)}(Q_{5Y}/Q_{4Y})] \pm (Q_{5Y}/Q_{4Y})V_0. \quad (14)$$

It may be noted that Eq. 13 always envisages the same trend in the behaviour of E_{cor} with T_0 and is also physically understandable.

The authors wish to thank Professor W. Rahman, Head of the Chemistry Department, for providing the facilities. The financial assistance from the Council of Scientific and Industrial Research (New Delhi) to one of us (A. A.) is gratefully acknowledged.

18) The corrected activation energies, E_{cor}, for conductance and viscous flows were obtained as, $E_{cor}/Rk_Y = [T/(T-T_0)]^2$ from the derivative of VTF equation. R is the gas constant and k_Y is the empirical constant. Now, if we take T_0 as basis for the corresponding temperature, T in fused salts, then at constant values of T/T_0 we have, $E_{cor} = [(T/T_0)/\{(T/T_0)-1\}]^2 Rk_Y$. Therefore, E_{cor} may have a constant value at equal T/T_0 values.
19) According to the CEM, the configurational entropy of the system is given as $S_c = \Delta C_p \ln(T/T_0)$ where ΔC_p is the difference in heat capacities for the liquid and the glassy state which may be regarded as almost invariant with concentration. Therefore, at equal values of T/T_0 the configurational entropy of the system may apparently be treated as constant.
20) The Doolittle's equation is of the form.

$$Y = A''_Y \exp[-k''_Y/(V-V_0)]$$

where V is the molar volume and V_0 is the molar intrinsic volume of the melt.

Determination of Uranium and Thorium with Arsenazo III after Sequential Extraction from Acid-deficient Aluminium Nitrate Medium

T. V. RAMAKRISHNA* and R. S. SHREEDHARA MURTHY
Department of Chemistry, Indian Institute of Technology, Madras 600 036, India
(Received August 14, 1979)

Uranium has been quantitatively extracted into IBMK from ≈2.2 mol dm^{-3} aluminium nitrate solution at pH 0.8—0.9. Coextracted thorium (≈10%) is returned to the aqueous phase by addition of benzene. Subsequently, thorium is extracted into IBMK in the presence of hexadecyltrimethylammonium bromide (CTAB). This separation method has been applied to the analysis of uranium and thorium content of monazite sand.

Extensive work has been carried out on the extractive separation of uranium and thorium from each other and from accompanying elements.[1-5] A review of these methods indicates that in many instances the methods are selective either for uranium or thorium, and are therefore useful for the separation of any one of them from accompanying elements. Extraction methods have not been extensively explored for the sequential separation of uranium and thorium probably because their extraction takes place from medium of widely differing composition. This is illustrated by the studies of Cospito and Rigali[6] who extracted uranium from sulfate medium into trioctylamine in xylene and thorium with Aliquat 336, after making the aqueous phase 4 mol dm^{-3} with respect to nitric acid.

The selectivity of the extraction of uranium from 2.7 mol dm^{-3} acid-deficient aluminium nitrate into isobutyl methyl ketone (IBMK) proposed by Nietzel and De Sesa[7] was found to be far superior as compared to extraction from highly acid medium.[8] However, thorium has been coextracted to varying extents, no attempt being made to use this extraction for the separation of uranium from thorium.

The present investigation was undertaken to find suitable conditions for the selective and sequential extraction of uranium and thorium from acid-deficient aluminium nitrate solution into IBMK. The extraction behaviour of these metal ions was spectrophotometrically followed using arsenazo III.[9] The results indicate that coextracted thorium (≈10%) can be selectively returned to the aqueous phase by the addition of benzene. Further, addition of CTAB enabled the quantitative extraction of thorium into IBMK. The method was applied to the analysis of monazite sand.

Experimental

Reagents. Standard uranium and thorium solutions (10 ppm) Saturated aluminium nitrate solution Hexadecyltrimethylammonium bromide solution (0.5%) Arsenazo III solution (0.02%).

Apparatus. A Carl Zeiss PMQ II spectrophotometer with 10 mm quartz cells.

Recommended Procedure. *Separation*: Transfer a 5 cm^3 aliquot of the sample solution to a 25 cm^3 beaker. Add 10 g of aluminium nitrate and stir to dissolve. Adjust the pH to 0.8—0.9 using powdered ammonium carbonate under a pH-meter. Transfer the solution quantitatively to a 60 cm^3 separatory funnel using 1 cm^3 of saturated aluminium nitrate solution for rinsing. After extraction into 5 cm^3 of IBMK for 3 min, separate the aqueous phase (I) and treat the organic phase with 5 cm^3 each of saturated aluminium nitrate solution and benzene. Shake for 1 min. Separate the aqueous phase (II) and retain the organic phase for the recovery of uranium.

To the combined aqueous phase (I and II) in a 60 cm^3 separatory funnel, add 1 cm^3 of CTAB solution and extract into 10 cm^3 of IBMK for 5 min. Discard the aqueous phase. Retain the organic phase for the recovery of thorium.

Determination: Strip each organic phase containing uranium or thorium twice with 5 cm^3 of 0.1 mol dm^{-3} HCl and collect the resulting aqueous phases separately in a 25 cm^3 standard flask and make upto the mark with distilled water. Discard the organic phases.

Transfer an aliquot of the made-up solution containing not more than 30 μg of uranium or thorium to a 25 cm^3 conical flask. Add a few drops of concd H_2SO_4 and evaporate until fumes of sulfur trioxide evolve. For the determination of uranium, treat the residue containing uranium with 1 cm^3 of water, 5 cm^3 of concd HCl and 2 g of zinc granules. Allow the reduction to proceed for 5 min. Filter the solution through glass wool and wash thoroughly with 1: 1 HCl, collecting the filtrate and washings in a 25 cm^3 standard flask. Add 5 cm^3 of arsenazo III solution and make upto the mark with 1: 1 HCl. For the determination of thorium, dissolve the residue containing thorium in 5 cm^3 of water and transfer the solution to a 25 cm^3 standard flask using 1: 1 HCl for rinsing. Add 5 cm^3 of arsenazo III solution and dilute to the mark with 1: 1 HCl. Measure the absorbance in a 10 mm cell at 665 nm against a reagent blank. Estimate the concentration of uranium or thorium by reference to the respective calibration graphs prepared by directly subjecting 5—30 μg of uranium or thorium using 0.5—3.0 cm^3 of standard metal solution for development of coloration.

Results and Discussion

Initial studies on the extractive separation of uranium and thorium were made using 100 μg of each element. Extraction was carried out from 10 cm^3 of aqueous phase into 5 cm^3 of IBMK for 5 min, the percentage extraction of uranium or thorium being estimated.

Separation of Uranium: The effect of variation of aluminium nitrate concentration at pH 0.9 on the extraction of uranium and thorium is shown by curves A and B, respectively, in Fig. 1. It is evident that uranium extraction is quantitative provided that the aqueous phase is at least 2 mol dm^{-3} in aluminium nitrate. However, a significant amount of thorium (5—50%) was also extracted when the aluminium nitrate concen-

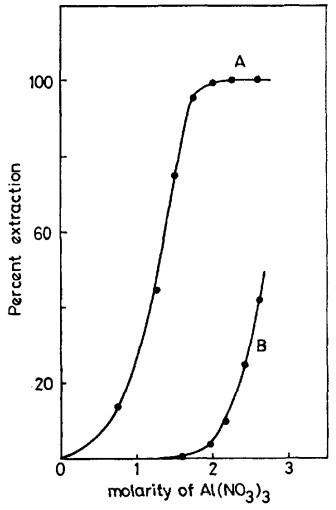

Fig. 1. Effect of aluminium nitrate concentration on the extraction of uranium (curve A) and thorium (curve B) into IBMK; pH of aqueous phase 0.9.

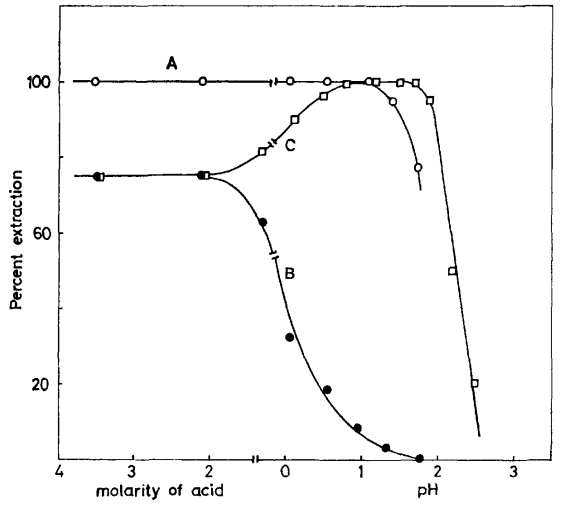

Fig. 2. Effect of acidity on the extraction of uranium (curve A), thorium (curve B), and thorium–CTAB (curve C) from 2.2 mol dm^{-3} aluminium nitrate solution into IBMK.

tration was varied from 2 to 2.6 mol dm^{-3}.

Figure 2 shows the effect of acidity on the extraction of uranium (curve A) and thorium (curve B) from aluminium nitrate solution (≈2.2 mol dm^{-3}). Variation in acidity was brought about by using concd HNO_3 or ammonia solution. It is evident that thorium extraction decreases rapidly with decreasing acidity; at pH 1.2, where uranium extraction is quantitative, only 5% of thorium is extracted. To ensure the quantitative extraction of uranium, the pH should be maintained at 0.8—0.9 where the extraction of thorium is 10—15%. Satisfactory conditions for the extraction can be conveniently brought about by dissolving 10 g of aluminium nitrate in a 5 cm^3 aliquot of the sample solution (whose volume increased to 10 cm^3) and by adjusting the pH to 0.8—0.9 using powdered ammonium carbonate with a pH-meter.

Attempts to make the organic uranium extract free from thorium revealed that retrograde extraction with a fresh aqueous phase of ≈2.2 mol dm^{-3} aluminium nitrate at pH 0.9 is ineffective, since it did not bring down thorium to the aqueous phase completely. As solvent to the organic extract in order to return the coextracted thorium selectively to the aqueous phase, benzene was chosen since it does not extract uranium or thorium. Equilibration of the phases after the addition of 5 cm^3 benzene, however, caused 10% decrease in the recovery of uranium. This was overcome by replacing the aqueous phase by 5 cm^3 of saturated aluminium nitrate solution (acidity ≈1 mol dm^{-3}) and equilibrating for 1 min with the IBMK extract after the addition of 5 cm^3 benzene. Uranium and thorium separation, however, was not quantitative when extraction was carried out from saturated aluminium nitrate solution directly into a 1 : 1 IBMK : benzene mixture, as uranium upto 20% remained in the aqueous phase along with thorium.

A shaking time of 1 min was found to be sufficient for the quantitative extraction of uranium into IBMK. Later equilibration upto 3 min with saturated aluminium nitrate and benzene did not affect the recovery of uranium.

Other solvents examined for the extraction of uranium included 1-butanol, ethyl acetate, butyl acetate, pentyl acetate, and cyclohexanone. Though extraction was quantitative with ethyl acetate and cyclohexanone, IBMK was preferred because it coextracted only 10% of thorium, while the percentage coextraction of thorium was 30% in ethyl acetate and 42% in cyclohexanone.

Separation of Thorium: Since thorium in nitrate medium would be present as the species $[Th(NO_3)_6]^{2-}$ its extraction from aluminium nitrate medium containing a cationic surfactant was considered.[10] This was examined by adding 1 cm^3 of 0.5% solution of CTAB to 10 cm^3 of ≈2.2 mol dm^{-3} of aluminium nitrate solution containing 100 μg of thorium. Extraction was carried out for 5 min using 10 cm^3 of IBMK, 1-butanol, ethyl acetate, butyl acetate, or cyclohexanone, of which only ethyl acetate and IBMK quantitatively

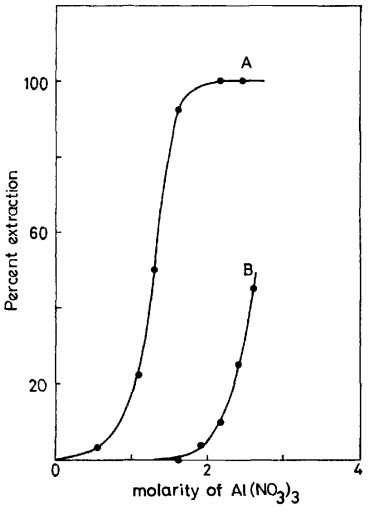

Fig. 3. Effect of aluminium nitrate concentration on the extraction of thorium–CTAB (curve A) and thorium (curve B) into IBMK; pH of aqueous phase 0.9.

extracted thorium. IBMK was preferred because of its lower solubility in the aqueous phase and rapid separation of both phases.

The effect of various parameters on the extraction of thorium indicates that the aqueous phase containing CTAB should be at least ≈2.2 mol dm^{-3} in aluminium nitrate (curve A, Fig. 3) and that the pH maintained over the pH range 0.8—1.6 for the quantitative extraction of thorium (curve C, in Fig. 2). Equilibration for 4 min and addition of at least 1 cm^3 of 0.3% solution of CTAB were sufficient for transferring thorium from the aqueous to organic phase.

TABLE 1. RECOVERY STUDIES FOR THE SEQUENTIAL EXTRACTION OF URANIUM AND THORIUM

Metal taken, μg		Metal found, μg		% Recovery	
U	Th	U	Th	U	Th
100	100	99	99	99	99
20	100	20.3	98	101.5	98
100	20	99.5	19.8	99.5	99
20	20	20	19.6	100	98
500	20	490	19.8	98	99
20	500	20.6	490	102.5	98

Sequential Extraction of Uranium and Thorium: The above results are promising for the sequential extraction of uranium and thorium. The sample solutions were subjected to extraction and determination (Experimental). The results (Table 1) indicate that the proposed method works satisfactorily.

Interference Studies: The extent of extraction of metal ions present in monazite sand which interfere with the arsenazo III procedure like zirconium, titanium and rare earths was examined. One mg of each ion (gadolinium was chosen as a representative rare earth) was subjected to extraction separately in the absence of thorium and uranium. After stripping the organic phases with 1 : 1 HCl, the concentrations of zirconium and gadolinium were estimated by the arsenazo III[9] procedure and that of titanium by the hydrogen peroxide method.[11] The interfering effect of anions such as sulfate and phosphate which are not removed by the usual means was also studied. The results (Table 2) indicate that the extraction procedure is quite selective, only phosphate inhibiting the extraction of both uranium and thorium.

Iron(III) hydroxide was used for collecting thorium and accompanying elements as hydroxide in order to overcome the interference of phosphate.[12] Aluminium hydroxide was also found to be effective for collecting thorium. The precipitate could be dissolved simply by treatment with saturated aluminium nitrate solution, so that subsequent separation and determination could be effected with no particular modification. 5 drops of saturated aluminium nitrate solution was added to samples containing uranium, thorium and phosphate. Dilute ammonia solution was then added until aluminium hydroxide precipitation was complete. The precipitate was centrifuged, washed with dilute ammonia (1 : 10) and dissolved in 8 cm^3 of saturated aluminium nitrate solution. The pH was then adjusted to 0.8—0.9 with solid ammonium carbonate and subjected to extraction. The results (Table 2) indicate that the method works satisfactorily.

Analysis of Monazite Sand: The thorium and uranium content of two monazite sand samples was determined after the removal of phosphate with aluminium hydroxide. 0.500 g of the finely ground sand was heated with 2 cm^3 of concd H_2SO_4 upto fuming of sulfur trioxide on a hot plate for 2 h. The residue was leached with ice-cold water and the leachate made up to 100 cm^3 with distilled water. A 1.0 cm^3 aliquot of the solution thus obtained was subjected to phosphate removal, then to extraction. The results (Table 3) indicate that the method works satisfactorily. In the present study, though the extraction behavior of rare earths other than gadolinium was not investigated, successful application of the extraction procedure to the analysis of monazite sand indicates that other rare earths behave in a similar way to that of gadolinium.

Concentration and Spectrophotometric Determination of Molybdenum with Thiocyanate and Rhodamine 6G

T. Prasada Rao and T. V. Ramakrishna*
Department of Chemistry, Indian Institute of Technology, Madras 600 036, India
(Received August 14, 1979)

A method is described for the determination of molybdenum based on reaction with potassium thiocyanate and Rhodamine 6G in 0.55—0.8 mol dm^{-3} hydrochloric acid medium. The method is sensitive ($\varepsilon=2.63\times10^5$ l mol^{-1} cm^{-1}) and obeys Beer's law over the range 0.04—0.24 ppm of molybdenum. Selectivity can be considerably improved by collecting molybdenum on iron(III) hydroxide. In conjunction with the collection procedure, the method is useful to determine as low as 5 ppb of molybdenum present in 100 cm^3 of aqueous samples.

A number of ternary systems have been proposed for the spectrophotometric determination of molybdenum[1-5] and, amongst these, the method based on its reaction with thiocyanate and Rhodamine B in the presence of copper–thiourea complex[3] is attractive as it possesses high sensitivity ($\varepsilon=1.10\times10^5$ l mol^{-1} cm^{-1}), selectivity and, in addition, allows the determination to be completed directly in aqueous medium. Our investigation on these lines revealed that the use of Rhodamine 6G instead of Rhodamine B is advantageous, as the reaction proceeds in dilute hydrochloric acid medium without the addition of copper–thiourea complex and providing much superior sensitivity ($\varepsilon=2.63\times10^5$ l mol^{-1} cm^{-1}). Furthermore, Rhodamine 6G is less susceptible to colour changes due to slight changes in the acidity of the medium. Detailed study on this colour system showed that the few ions that interfere in the determination can be conveniently overcome by selectively collecting molybdenum(VI) on iron(III) hydroxide precipitate. In conjunction with the collection procedure, the method was found useful to determine as low as 5 ppb of molybdenum present in aqueous samples.

Experimental

Reagents. *Molybdenum(VI) Solution*: Dissolve 0.115 g of ammonium molybdate in water and dilute to 250 cm^3. Dilute appropriate volumes of this stock solution (250 ppm) with water to provide a 1.0 ppm solution.

Potassium Thiocyanate Solution (3%): Dissolve 3 g of potassium thiocyanate in water and dilute to 100 cm^3.

Rhodamine 6G Solution (0.01%): Dissolve 0.1 g of reagent (chrom a Gesellschaft, Schmid and Co., Stuttgart) in water and dilute to 1 dm^3.

Gelatin Solution (1%): Dissolve 1 g of gelatin in boiling water and dilute to 100 cm^3.

Apparatus: A Carl Zeiss PMQ-II spectrophotometer with 10 mm quartz cells and a Knick pH-meter with an Ingold combined glass-calomel electrode were used.

Recommended Procedure. *Determination*: Transfer a suitable aliquot (upto 10 cm^3) of the sample solution containing not more than 6 μg of molybdenum to a 25 cm^3 volumetric flask. Adjust the acidity to 0.55—0.8 mol dm^{-3} with hydrochloric acid and add with mixing 5 cm^3 each of potassium thiocyanate and Rhodamine 6G solution. Allow the reaction to proceed for 1 h and then add 1 cm^3 of 1% gelatin. Dilute the solution to mark with distilled water and measure the absorbance in 10 mm cells at 570 nm against a reagent blank. Prepare a calibration graph for 1—6 μg of molybdenum by the above procedure.

Concentration and Separation: To a suitable aliquot (upto 100 cm^3) of the sample add 2 mg iron(III) and adjust the pH to 4.0 under a pH-meter. Add 5 cm^3 of acetone, stir well and centrifuge the suspension. Discard the centrifugate and wash the suspension twice with 5 cm^3 of a 2% solution of ammonium chloride. Dissolve the precipitate by digesting with 5 cm^3 of 0.2 mol dm^{-3} hydrochloric acid and then treat with 2.5 cm^3 of 0.5 mol dm^{-3} sodium hydroxide to reprecipitate the iron. Centrifuge, wash the precipitate twice with 5 cm^3 of water and combine the centrifugate and washings. If the molybdenum content is large, make up the solution to a known volume and subject an aliquot to molybdenum determination. Otherwise, evaporate the solution to a small volume and complete the determination as given under "Procedure."

Results and Discussion

Preliminary Studies. Initial experiments indicated that after the addition of thiocyanate and Rhodamine 6G to molybdenum solution in 0.6 mol dm^{-3} hydrochloric acid, if the solutions were immediately diluted to 25 cm^3 with water, the colour development was quite incomplete. Omission of dilution with water caused both test and blank solution to acquire an intense pink colour but on standing, the colour of the blank slowly changed to orange red. However, later dilution with water as above to 25 cm^3 caused the pink colour of the test solution also to fade off gradually. Systematic investigation revealed that the colour system is colloidal in nature and stabilization can be achieved by the addition of small amounts of gelatin prior to dilution with water. In preliminary experiments, therefore, after the addition of reagent solutions, the reaction was allowed to proceed for 60 min to facilitate complete disappearence of the pink colour of the blank, and then treated with 1 cm^3 of 1% solution of gelatin and sufficient water to 25 cm^3.

The spectra of gelatin-stabilized solutions in 10 mm cells against distilled water is shown in Fig. 1. It is evident that the reagent blank absorbs maximally at 530 nm. In the presence of molybdenum, there is, in addition to this maximum, a new shoulder at 570 to 575 nm. The difference between the spectra of the complex and the reagent blank showed that 570 nm is the optimum wavelength for measurement.

Considerable enhancement in the absorbance of the sample at 570 nm was noticed when Rhodamine 6G concentration was increased to 5 cm^3 of 0.01%. This is

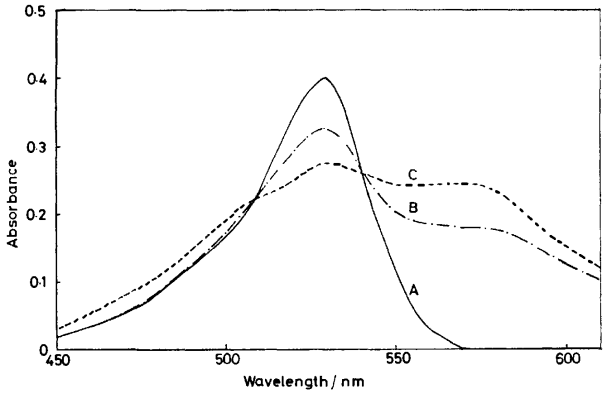

Fig. 1. Absorption spectra of molybdenum–thiocyanate–Rhodamine 6G system (0.6 mol dm^{-3} in HCl; total volume 25 cm^3; 10 mm cells).
A: 1.0 cm^3 of 2.1×10^{-4} mol dm^{-3} (0.01%) Rhodamine 6G, 1 cm^3 of 10% potassium thiocyanate and 1 cm^3 of 1% gelatin, reference: water, B,C: as in A, with 0.5 and 1 cm^3 of 1.05×10^{-4} mol dm^{-3} molybdenum, reference: water.

apparently due to increased association of the complex. Under these conditions, the blank showed an absorbance of 0.06 at 570 nm as against 0.28 and 0.61 obtained with solutions containing 0.2 and 0.5 cm^3 of 1.05×10^{-4} mol dm^{-3} of molybdenum present in 25 cm^3 respectively when measured in 10 mm cells.

Optimization of Experimental Conditions. Maximum absorbance was obtained when the acidity of the reaction medium, containing 3 μg of molybdenum, 5 cm^3 each of 3% potassium thiocyanate and 0.01%. Rhodamine 6G, was maintained from 0.55 to 0.8 mol dm^{-3} in hydrochloric acid. Similar studies at 0.6 mol dm^{-3} acidity on the variation of potassium thiocyanate and Rhodamine 6G concentration showed that the addition of 2 cm^3 of 5% potassium thiocyanate and 4 cm^3 of 0.01% solution of Rhodamine 6G was sufficient to provide maximum absorbance. Though 1 cm^3 of 0.75% solution of gelatin was found to be sufficient to stabilize the colour system, further addition did not affect the absorbance. When the recommended concentration of reagent solutions were added, maximum colour was produced after a standing time of 45 min, which after dilution remained stable for 90 min and the addition of as high as 5 cm^3 of saturated sodium chloride solution did not affect the absorbance. Under these conditions, the calibration graph was a straight line for 1—6 μg of molybdenum and passed through the origin. The molar absorptivity and Sandell sensitivity were established to be 2.63×10^5 dm^3 mol^{-1} cm^{-1} and 0.36 ng cm^{-2} respectively for the colour system at 570 nm.

Ten replicate determination of standard solutions containing 3.0 μg of molybdenum(VI) gave an average recovery of 102.5% with a relative standard deviation of 2.5%.

Effect of Diverse Ions. The effect of 40 diverse ions on the determination of 3.0 μg of molybdenum was examined. A few ions that interfered were overcome by adding thiourea, ascorbic acid or tartrate. The results obtained are summarized in Table 1. The interference due to zinc and cobalt(II) could not be masked.

Table 1. Effects of diverse ions[a)]

Ion	Amount Added (mg)	Molybdenum Found (μg)	Ion	Amount Added (mg)	Molybdenum Found (μg)

Ba^{2+}	1	3.1	Arsenite	1	3.2

a) Molybdenum taken was 3.0 μg. b) 1 cm^3 of 5% thiourea. c) 1 cm^3 of 2% ascorbic acid. d) 1 cm^3 of 10% tartrate.

Composition of the Complex. The ratio of molybdenum to Rhodamine 6G was determined by both mole ratio and Job's continuous variation methods. The results obtained (Figs. 2 and 3) showed that the molar ratio of molybdenum to Rhodamine 6G is 1 : 2. The molar ratio of molybdenum to thiocyanate could not be established, as no colour developed upon treating with Rhodamine 6G, evidently due to instability of the molybdenum–thiocyanate binary complex.

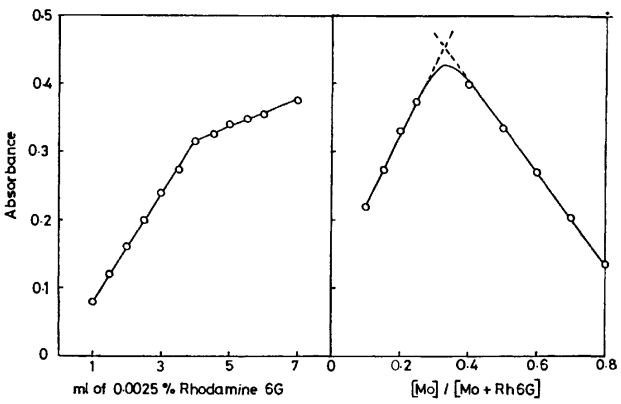

Fig. 2. Mole-ratio method (0.6 mol dm^{-3} in HCl, total volume 25 cm^3; 10 mm cells; 570 nm).
[Mo] = 1 cm^3 of 1.05×10^{-4} mol dm^{-3}, [Rh6G] = 1 to 7 cm^3 of 5.25×10^{-5} mol dm^{-3}.

Fig. 3. Continuous variation method (0.6 mol dm^{-3} in HCl; total volume 25 cm^3; 10 mm cells; 570 nm).
$[Mo+Rh6G]_{total}=2.1\times10^{-5}$ mol dm^{-3}.

With Rhodamine B colour system,[3] it has been indicated that Mo(VI) is reduced to Mo(V) by copper–thiourea complex in sulfuric acid medium to form $[MoO(SCN)_5]^{2-}$ to facilitate association with 2 molecules of Rhodamine B cation. However, with the Rhodamine 6G colour system, as the presence of copper–thiourea did not affect the sensitivity, it appeared reasonable to conclude that the reduction of molybdenum(VI) proceeds smoothly in dilute hydrochloric acid medium in the presence of thiocyanate to form $[MoO(SCN)_5]^{2-}$ which then associates with 2 molecules of Rhodamine 6G cation to produce the observed spectral shift.

Evaluation of Iron(III) Hydroxide Collection. Though solvent extraction and ion-exchange find common use to separate interferents from the desired constituent, collection of molybdenum on a sparingly soluble metal hydroxide was considered for its separation from interfering elements. Earlier studies have shown that for the collection of molybdenum from weakly acidic solutions, thorium hydroxide (99.5% collected in 30 min)[6] is much superior to iron(III) hydroxide (96.5% in 2h),[7] aluminium hydroxide (7.8% in 2 h)[6] or manganese dioxide (100% in 24 h).[8] Iron(III) hydroxide collection, however, was chosen in the present study. Detailed investigations revealed that the addition of miscible organic solvents such as acetone, methanol, ethanol, 2-propanol, 4-hydroxy-4-methyl-2-pentanone, acetonitrile, 1,4-dioxane, and *N,N*-dimethylformamide to weakly acidic solution of molybdenum promoted rapid and quantitative collection on ferric hydroxide. Addition of acetone was chosen for further investigations. Later studies revealed that the molybdenum collected on iron(III) hydroxide was quantitatively released by dissolving the precipitate in dilute hydrochloric acid and reprecipitating it with alkali.

Systematic study of collection of molybdenum was made by adding 2 mg of iron(III) to 20 cm^3 aliquots of solution and using dilute sodium hydroxide to precipitate iron(III) hydroxide. The suspensions obtained were centrifuged and the supernatant liquid was rejected. In each instance the precipitate, after washing twice with 5 cm^3 of 2% ammonium chloride, was dissolved by digesting with hydrochloric acid ($\approx$5 cm^3 of 0.2 mol dm^{-3}) and then the pH was raised to >10.0 using sodium hydroxide ($\approx$2.5 cm^3 of 0.5 mol dm^{-3}) to reprecipitate the iron. The suspension was centrifuged and washed twice with 3 cm^3 portions of water. The centrifugate and washings were combined and evaporated to about 5 cm^3. Molybdenum content was then established by the procedure described under "Experimental."

Figure 4 shows the effect of variation of pH of the medium containing 5 cm^3 of acetone on the collection of 3 μg of molybdenum by iron(III) hydroxide. It is evident that the recovery is quantitative over the pH range 4.0 to 4.5 and that iron(III) hydroxide is ineffective at pH's greater than 9.0. Subsequent studies at pH 4.0 using 2 mg of iron(III) revealed that the addition of 5 cm^3 of acetone was sufficient to recover quantitatively 0.5 μg to 1 mg of molybdenum present in 100 cm^3 of sample. Collection of molybdenum was unaffected

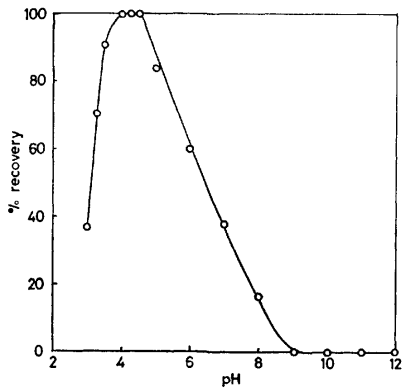

Fig. 4. Effect of pH on the collection of molybdenum on iron(III) hydroxide; 3 μg of molybdenum in 100 cm^3, 2 mg of iron(III) and 5 cm^3 of acetone.

by the presence of 5 g of sodium chloride present in 100 cm^3 of sample.

Synthetic sample solutions containing 1—6 μg of molybdenum(VI) present in 100 cm^3 were taken through the collection and determination procedure and a calibration graph was prepared. A linear relationship was obtained over the whole range and the slope was identical to that obtained from aliquots of the standard molybdenum solution analysed without the collection step. The absorbance of blanks prepared with and without the collection step were also found to be comparable.

The ions that were found to interfere in the determination of molybdenum in the absence of masking agents were re-examined in conjunction with the collection procedure. Excepting tungsten, none of the ions at 1 mg level interfered in the determination of 3 μg of molybdenum. Small quantity of tungsten was found to accompany molybdenum as was evident from the enhancement in the absorbance value (0.33 to 0.90). Addition of tartrate, as described earlier, eliminated the interference due to tungsten.

Recovery Studies. As no standard samples were available for testing the collection and determination procedure developed, it was decided to examine the recovery of molybdenum added to soil and sea water samples collected at random. 5 g of finely ground soil samples dried at 110 °C were treated with 0, 5, and 10 μg of molybdenum(VI). Each sample was heated in a platinum crucible at 400—450 °C for 3 h to decompose any organic matter present. Then 10 cm^3 of water, 2 cm^3 of concentrated sulphuric acid and 10 cm^3 of concentrated hydrofluoric acid were added and heated gently until most of the liquid was evaporated. The crucible was then heated strongly to expel the residual sulphuric acid. The residue was dissolved in 6 mol dm^{-3} hydrochloric acid, rinsed into a beaker, and heated nearly to boiling, to bring all soluble material into solution.[9] The solution was filtered through Whatman No. 42 filter paper, washed with dilute hydrochloric acid collecting the filtrate and washings in a 100 cm^3-flask. The volume was then made up with water.

Aliquots of soil solution and sea water samples were

Table 2. Recovery of molybdenum added to soil and sea water samples

Sample	Aliquot taken (cm^3)	Mo added ($\mu g/100\ cm^3$)	Mo Found (μg)	Recovery (%)
Soil extract	25	—	—	—
	25	5	1.3	104
	25	10	2.4	96
Sea water	50	—	—	—
	100	—	—	—
	50	10	5.1	102
	100	10	10.0	100
	100	1	1.05	105
	100	5	4.90	98

subjected to collection and determination procedure as described under "Experimental." The results are summarised in Table 2 which clearly indicate satisfactory recovery of molybdenum from both soil and sea water samples.

Polyfunctionality of α-$Zr(HPO_4)_2 \cdot H_2O$. Case of H^+/Ag^+ and H^+/Tl^+ Ion Exchange Processes†

Umberto Costantino,* Armando Isernia, and Giovanni De Meo
Dipartimento di Chimica, Università di Perugia, Via Elce di Sotto, 10-06100 Perugia, Italy
(Received August 7, 1979)

A detailed investigation of the ion exchange processes of silver and thallium(I) ions on α-$Zr(HPO_4)_2 \cdot H_2O$ has been carried out. The H^+/Ag^+ exchange occurs in $AgNO_3$ or CH_3COOAg solution with a single phase transition and leads to $Zr(AgPO_4)_2 \cdot H_2O$ (interlayer distance 8.4 Å). The H^+/Tl^+ ion exchange process has been performed by titrating the exchanger with 0.1 M ($TlNO_3$+TlOH) solution, owing to the great ionic size of Tl(I). The titration curve shows essentially a single plateau. In a similar way to that for H^+/Ag^+ exchange, the process takes place with a single phase transition, leading to $Zr(TlPO_4)_2 \cdot H_2O$ (interlayer distance 9.0 Å). Since the processes are new examples in which a univalent cation is exchanged with a single phase transition in α-$Zr(HPO_4)_2 \cdot H_2O$, the so called "polyfunctionality" of this exchanger has been discussed, considering the high polarizability of Ag^+ and Tl^+ ions. The catalytic potential applications of zirconium phosphate loaded with Ag^+ ions are outlined.

The crystal structure of α-zirconium bis(monohydrogen-orthophosphate) monohydrate, α-$Zr(HPO_4)_2 \cdot H_2O$, hereafter referred to as α-$HH \cdot H_2O$††, has been refined[1] and the position of the exchangeable hydrogen atoms and water molecule determined by means of powder neutron diffraction data[2]. From these works it was concluded that: a) the exchangeable hydrogen atoms are covalently bonded to phosphate oxygens; b) the water molecule lies in the center of the cavity formed by the arrangement of the layers and it is hydrogen-bonded to tetrahedral ≥P–OH groups belonging to the same layer; c) there are no hydrogen-bonds between the layers that are held by van der Waals forces.

Knowledge of the position of the exchangeable hydrogen atoms would help in understanding the so called "polyfunctionality" of α-$HH \cdot H_2O$. It is known that the titration curves of the exchanger with alkali metal hydroxides, in the presence of the respective chlorides, exhibit various steps at different pH values for each cation (*i.e.* 3 steps for Li^+ and Rb^+, 2 steps for Na^+ and K^+, 4 steps for Cs^+; Fig. 3, Ref. 3), as if the hydrogen atoms of α-$HH \cdot H_2O$ have different acidities for the different cations. Albertsson *et al.*[2] suggested that the exchange sites are created by the hydroxide ion, that may freely diffuse in the crystals and reacts with the ≥POH groups. The energy supplied by this reaction should allow the metal ion to be sorbed by the exchanger as hydrated ions. Troup and Clearfield[1] attributed the different acidities of the hydrogen atoms to defects of the structure that would lead to a range of hydrogen bond energies and to the shift of the phosphate groups from their normal position. Disorder would thus create exchange sites of different energies. According to Allulli *et al.*[4] the polyfunctionality of zirconium phosphate is related to the growth of various solid phases.

As a contribution to the knowledge of the exchange behaviour of α-$HH \cdot H_2O$, this paper reports two examples in which monovalent cations having a high polarizability, such as Ag^+ and Tl^+, are taken up by crystalline zirconium phosphate in one step. Furthermore the H^+/Ag^+ ion exchange process provides the first example in which a univalent cation is entirely exchanged at room temperature without addition of hydroxide ions.

Experimental

Chemicals. All reagents, except $ZrOCl_2 \cdot 8H_2O$ supplied by "Merck", were R.P.E. "C. Erba". Thallium(I) hydroxide was prepared by adding a Tl_2SO_4 solution to a hot barium hydroxide solution in a closed system filled with nitrogen.

Crystalline zirconium phosphate was prepared according to the method of slow decomposition of zirconium fluorocomplexes in the presence of phosphoric acid.[3] The microcrystals were sedimented in a countercurrent apparatus[5] and the various fractions were stored over P_4O_{10}. The fraction with a mean radius of particles of 3—5 μm was used throughout the experiments.

Ion Exchange Procedure. In order to attain different percentages of Ag^+-exchange, several samples of α-$HH \cdot H_2O$ (1 g) were equilibrated with increasing volumes of 0.100 M $AgNO_3$ or 0.050 M CH_3COOAg solutions at 25±1 °C. The thallium-uptake, as a function of pH, was obtained from the batch titration performed by contacting several samples of α-$HH \cdot H_2O$ (0.500 g) with 100 ml of 0.100 M ($TlNO_3$+TlOH) solutions. After equilibration (4 d) the solid samples were filtered off and their X-ray diffractograms recorded, the clear solutions being analyzed for their pH value and metal ion content. Kinetic experiments were performed as reported.[6]

Analytical Procedure. Silver ion was determined with a Perkin-Elmer A.A. spectrophotometer. Thallium was titrated with standard potassium bromate at 60 °C. Hydration water content was obtained by the percent-weight loss at 180 °C of the samples, previously conditioned over a NaCl saturated solution ($P/P_0 \approx 0.7$). X-Ray powder diffraction patterns were obtained with a General Electric diffractometer using Ni-filtered Cu $K\alpha$ radiation.

Results

Ag^+-uptake. The ion-exchange mechanism of Ag^+ on $HNa \cdot 5H_2O$ suggests that in acidic media Ag^+ might replace the protons of $HH \cdot H_2O$ obtained from the partial regeneration of the monosodium

† This work was supported by the National Research Council of Italy (C. N. R.).

†† The ionic forms of α-$Zr(HPO_4)_2 \cdot H_2O$ will also be indicated by their counter-ions and water content.

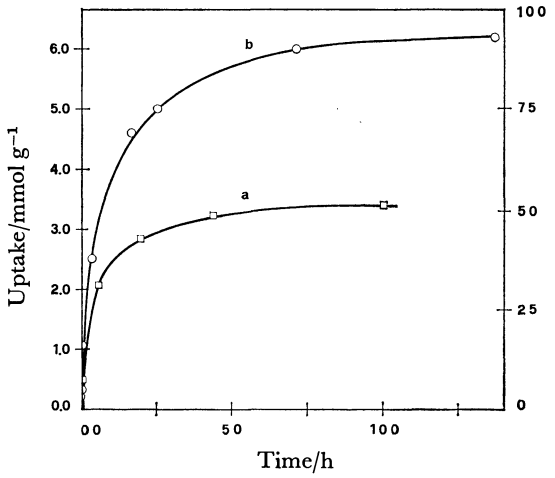

Fig. 1. Ag^+-uptake on α-$HH \cdot H_2O$ as a function of time.
Conditions: 1 g of ecxhanger equilibrated with 200 ml of 0.100 M $AgNO_3$ solution (curve a) or with 200 ml of 0.050 M CH_3COOAg solution (curve b), $t=25 \pm 1$ °C.

form.[6] For the sake of confirmation an attempt was made to convert the zirconium hydrogen phosphate into silver form by contacting the exchanger with $AgNO_3$ or CH_3COOAg solutions. Figure 1 shows the Ag^+-uptake of 1 g of $HH \cdot H_2O$, as a function of time, when the exchanger is equilibrated at 25±1 °C with 200 ml of 0.100 M $AgNO_3$ solution (curve a) or with 200 ml of 0.050 M CH_3COOAg solution (curve b). In nitrate media the uptake suddenly slows down after 20 h of equilibration, because of the accumulation in solution of the protons replaced by silver ions (after 70 h the pH was ≈1.8). Maximum Ag^+-conversion of 50% was obtained.

In acetate media, owing to the presence of the Brönsted base, CH_3COO^-, the pH of the solution remains higher than 4. The H^+/Ag^+ exchange seems to proceed in only one step, a maximum Ag^+-conversion of ≈95% being reached within 150 h.

X-Ray diffractograms of the sample withdrawn from the nitrate solution showed the presence of a not exchanged $HH \cdot H_2O$ phase and a new phase having an interlayer distance of 8.4 Å; the one withdrawn from the acetate solution showed the presence of only the 8.4 Å phase. In order to obtain further information on the ion-exchange mechanism, equilibrium experiments were carried out by contacting several samples (1 g) of $HH \cdot H_2O$ with increasing volumes of $AgNO_3$ or CH_3COOAg solution.

Figure 2 shows the millimoles of Ag^+ taken up by 1 g of exchanger against the millimoles of Ag^+ initially present in the equilibrating 0.100 M $AgNO_3$ solution (curve a) or 0.050 M CH_3COOAg solution (curve b). The following comments are given.

i) Up to 80—90% Ag^+-conversion the H^+/Ag^+ ion-exchange process seems to take place in a single step both in acetate and nitrate media; after this value of conversion the selectivity of exchanger towards Ag^+ ions strongly decreases and higher volumes of equilibrating solutions are needed to obtain the full Ag^+-phase.

ii) In the acetate medium, in the range 0—85% Ag^+-conversion the exchanger shows a high selectivity for silver ions and virtually all the added Ag^+ ions are taken up. As expected from the constancy of the H^+/Ag^+ rational selectivity coefficient, in the nitrate medium much greater amounts of silver ions (larger volumes of equilibrating solution) must be added to the exchanger in order to reach a Ag^+-conversion identical to that attained in the acetate medium.

X-Ray diffraction patterns of samples having the same Ag^+-conversion but obtained from the nitrate and acetate equilibrating solutions were found to be similar, confirming the view that the same ion exchange mechanism holds in both cases.

X-Ray powder patterns of samples at various Ag^+-loading (Fig. 3a) show that a new phase with interlayer distance 8.4 Å is present already at 10% Ag^+-conversion. This phase and the original $HH \cdot H_2O$ (7.6 Å) phase are present up to 85% Ag^+-conversion, the latter being transformed into the former as the conversion proceeds. After this value of conversion is reached, only the 8.4 Å phase is present and 100% of Ag^+-conversion is obtained without appreciable change in the X-ray diffractograms.

The water content of several samples with increasing Ag^+-loading was also determined (Fig. 4). It can be seen that the water content of the exchanger remains practically equal to one mole per mole of exchanger in all the range of composition. X-Ray powder patterns of hydrated and anhydrous silver forms are given in Table 1.

Tl^+-uptake. Preliminary experiments showed that, in constrast to silver ion, Tl^+ can not diffuse

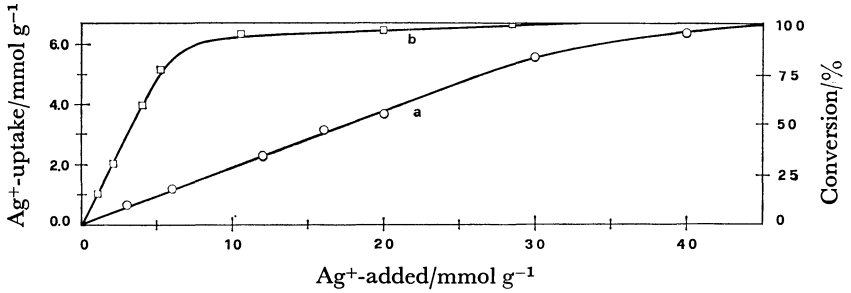

Fig. 2. Ag^+-uptake on α-$HH \cdot H_2O$ as a function of the m·moles of Ag^+ initially added.
Conditions: 1 g of exchanger equilibrated with increasing volumes of 0.100 M $AgNO_3$ solution (curve a) or 0.050 M CH_3COOAg (curve b).

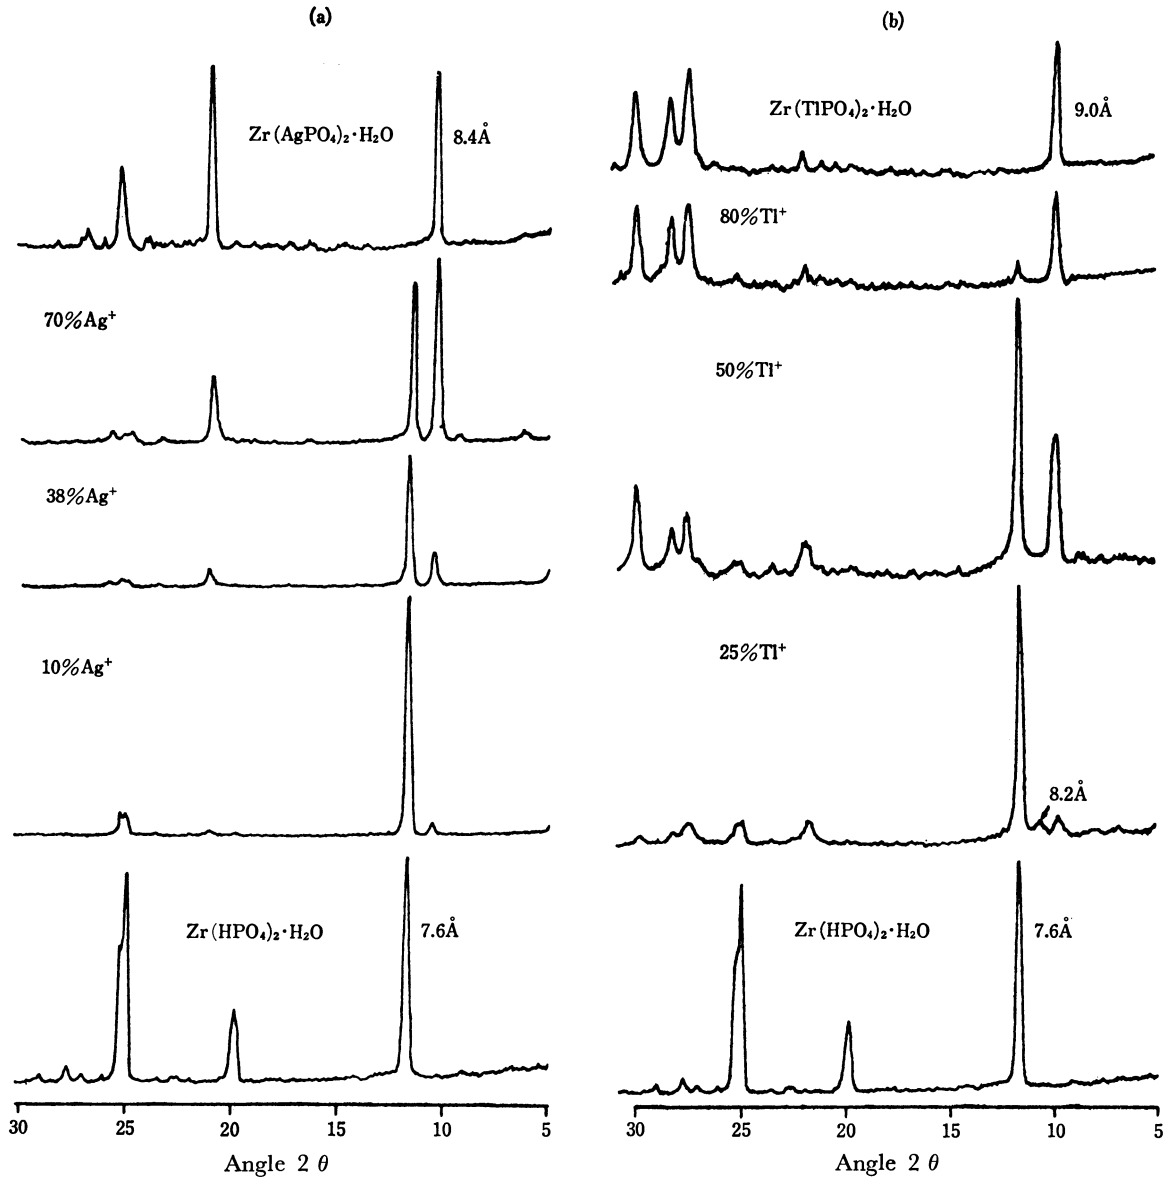

Fig. 3. Some X-ray diffractograms relative to H^+/Ag^+ (a) or H^+/Tl^+ (b) ion exchanges on α-$HH \cdot H_2O$.

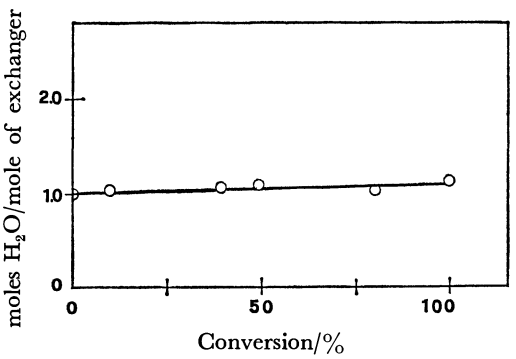

Fig. 4. Water content of α-zirconium phosphate at various stages of Ag^+-conversion.

(or diffuses very slowly owing to its greater ionic radius) within the layers of the exchanger from nitrate solutions.

When the steric hindrance prevents the free diffusion of a counter-ion in the $HH \cdot H_2O$ lattice (in this case the ionic diameter of Tl^+ ion, 3.0 Å, is much greater than the free diameter[1] of the openings connecting the cavities, 2.61 Å) it is possible to force the cations to cross these openings and to enlarge the layers of the exchanger,[3] if sufficient energy is supplied. This energy can be provided by the neutralization of the protons of the exchanger if the soluble cation hydroxide is available.

Figure 5 shows the Tl^+-uptake curve of $HH \cdot H_2O$ obtained by titrating the exchanger with 0.100 M ($TlNO_3$+TlOH) solutions at 25±1 °C. Apart from the sloping regions between 0—20% and 80—100% of Tl^+-conversion, the curve shows a single plateau at pH≈5.

X-Ray diffractograms of samples with increasing Tl^+-conversion (Fig. 3b) show that in the range 0—25% of conversion the phases, with interlayer distance of 7.6, 8.2, and 9.0 Å, are present.

In the approximate range 25—80%, two phases with interlayer distance 7.6 and 9.0 Å, respectively, are co-existent, one transforming into the other. After

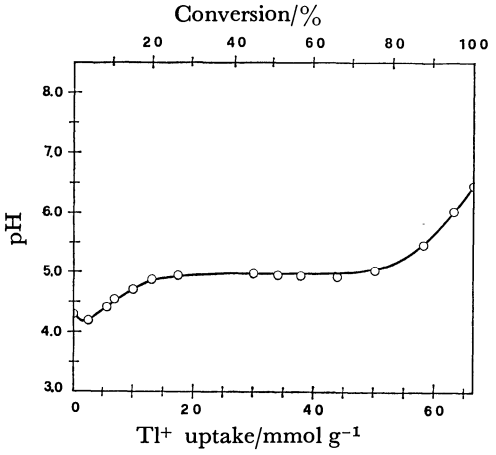

Fig. 5. Tl^+-uptake curve on α-$HH \cdot H_2O$ obtained from the batch titration curve of the exchanger with ($TlNO_3$ + TlOH) 0.100 M solutions.

80% conversion only the 9.0 Å phase is present, full conversion being reached without drastic modifications of the X-ray patterns. Determination of the water content of samples having different Tl^+-conversion, shows that as in the case of H^+/Ag^+, the H^+/Tl^+ exchange takes place without changes in water content that remains equal to one mole per mole of exchanger. The X-ray powder patterns of hydrated and anhydrous thallium forms are given in Table 1.

Discussion

The results obtained indicate that the H^+/Ag^+ and H^+/Tl^+ ion exchange processes on α-$HH \cdot H_2O$ occur in a single step with the direct transformation of the dihydrogen phase into the about fully exchanged phase. Thus, without considering the solubility of the Ag^+ ion in the $Ag_{1.7}H_{0.3} \cdot H_2O$ phase or the solubility of Tl^+ in the $Tl_{1.6}H_{0.4} \cdot H_2O$ phase, the ion exchange processes may be schematically described by the reactions:

$$\underset{7.6\,Å}{HH \cdot H_2O} + 2Ag^+ \longrightarrow \underset{8.4\,Å}{AgAg \cdot H_2O} + 2H^+ \quad (1)$$

$$\underset{7.6\,Å}{HH \cdot H_2O} + 2Tl^+ + 2OH^- \rightarrow \underset{9.0\,Å}{TlTl \cdot H_2O} + 2H_2O. \quad (2)$$

Only in the case of H^+/Tl^+ ion exchange process, the weak reflection at d=8.2 Å, present in X-ray diffractograms of samples having a Tl^+-conversion ranging from 5 to 25%, suggests that a small percentage of the HTl phase could be obtained.

In the case of the alkali metal ions, the ion exchange process on $HH \cdot H_2O$ occurs in several steps, thus the H^+/Ag^+ and H^+/Tl^+ are the first examples in which a univalent cation is taken up by α-$HH \cdot H_2O$ with a single phase transition.††† This cannot be explained in terms of ionic size, since Ag^+ and Tl^+ have effective ionic radii very similar to those of Na^+ and Rb^+, respectively, involving the difference in polarizability.

If polarizable ions constitute a ionic solid there is a further contribution to the lattice energy and discrepancies are generally found between the calculated and experimental values of lattice energy. The discrepancy is usually attributed to dispersion forces and to the possibility of some covalent bonding. The salt forms of crystalline zirconium phosphate may be considered covalent-ionic solids because the counter-ions present within the layer are ionically bonded to the macro-anions, constituting the layers themselves, that are of covalent nature.

Thus, it can be assumed that Ag^+ and Tl^+, owing to their polarizability much higher than that of alkali metal ions, give rise to higher interaction energy with the fixed groups of the matrix. Allulli *et al.*[4] found that crystalline zirconium phosphate, in molten salts, strongly prefers Tl^+ to K^+.

The strong interaction between Ag^+ and Tl^+ and

††† It should be recalled that H^+/Li^+ ion exchange on an another layered inorganic ion exchanger, α-$Ti(HPO_4)_2 \cdot H_2O$, occurs in a single step.[7,8]

the $\geq P-O^-$ groups of the exchanger, and thus their low mobility in the crystal lattice, could explain why a single step in the ion exchange processes has been obtained, in a manner similar to that recently outlined for the H^+/K^+ exchange on α-$HH\cdot H_2O$.[5,9]

Let us suppose that the energy required for exchanging the proton of the hypothetical, *i.e.* $HAg\cdot H_2O$, is lower than that furnished by the pH of equilibrating solution, in other words that the eventual second plateau of exchange lies at pH value lower than ≈ 6. In the first stages of the H^+/Ag^+ exchange, both the protons present in each cavity would be replaced by the silver ions. An appreciable amount of $AgAg\cdot H_2O$ is thus formed in the external parts of the crystals. According to the model of co-existing solid phases[3] in a single crystal of $HH\cdot H_2O$, a situation similar to that schematically shown in Fig. 6 may occur. The Ag^+ ions of the 8.4 Å phase should have a strong tendency to diffuse into the $HH\cdot H_2O$ phase, arranging themselves in a regular mode. Thus, for each cavity of the exchanger there would be one silver ion, giving rise to the HAg phase. However, if the rate of this internal diffusion is very low and the pH of the external solution remains higher than that required for the exchange of the second proton, other Ag^+ ions would be furnished by the solution, the exchange taking place, with low activation enery, in the region of separation between the $AgAg\cdot H_2O$ and $HH\cdot H_2O$ co-existing phases. In this region the cavities are very likely irregular, and the exchange of both the protons may occur with a rate greater than the diffusion of Ag^+ in the $HH\cdot H_2O$ to give the HAg phase. Thus the exchange process goes on with an advancing phase bondary (Fig. 6). This mechanism requires that, if the exchange is stopped and a crystal of zirconium phosphate, half converted into silver form, is left standing for a long time, it should be transformed into the monosilver phase according to the reaction occurring in the crystal:

$$\underset{7.6\,\text{Å}}{HH\cdot H_2O} + \underset{8.4\,\text{Å}}{AgAg\cdot H_2O} \rightarrow 2HAg\cdot H_2O. \qquad (3)$$

A sample half converted into silver form and heated at 180 °C, for 2 d, showed no co-existence of the anhydrous AgAg (7.78 Å) and HH (7.41 Å) phases. Only one phase, with inter-layer distance 7.46 Å, very likely the anhydrous HAg, was detected. This indicates that the rate of the proposed transformation (3) is very low at room temperature. Several other experiments, such as the H^+/Ag^+ exchanges performed in buffered media at different pH values for very long periods, are expected to confirm this point.

Zirconium phosphate loaded with silver ion is considered to be a promising material for catalytic processes. La Ginestra *et al.*[10] were able to reduce reversibly the silver counter-ions present between the layers of crystalline zirconium phosphate and obtain materials containing dispersed silver atoms in the structure.

The authors thank Prof. G. Alberti for helpful discussions.

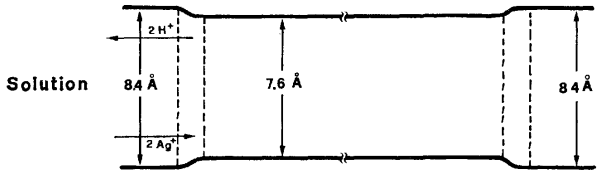

Fig. 6. Schematic representation of the co-existence of $Zr(AgPO_4)_2\cdot H_2O$ (8.4 Å) and $Zr(HPO_4)_2\cdot H_2O$ (7.6 Å) in a single crystal of the exchanger. The advancement of the phase bondary during the H^+/Ag^+ ion exchange is shown.

Studies on Synthesis of 6-Bromo-2,3-disubstituted 4(3*H*)-Quinazolinones and Their Thiones

Mahmoud Zarif Amin BADR,* Hassan Ahmed Hassan EL-SHERIEF, and Abdallah Mohamed MAHMOUD

Department of Chemistry, Faculty of Science, Assiut University, Assiut, Egypt

(Received December 20, 1978)

Synthesis of some 2,3-disubstituted 6-bromo-4(3*H*)-quinazolinones is described. Treatment of some 4-quinazolinones with phosphorus pentasulfide gave the corresponding 4-quinazolinethiones. The reaction of 6-bromo-2-methyl-3,1-benzoxazin-4-one with hydroxylamine hydrochloride gave 6-bromo-3-hydroxy-2-methyl-4(3*H*)-quinazolinone which on treatment with alkyl halides, acyl chlorides and sulfonyl chlorides gave the corresponding ethers, esters, and sulfonates respectively. 2-Styryl-4(3*H*)-quinazolinone derivatives are obtained by condensation of aromatic aldehydes and corresponding 3-substituted-6-bromo-2-methyl-4(3*H*)-quinazolinones. Their antibacterial affinities are of considerable efficiency.

4(3*H*)-Quinazolinones have become of increasing importance in recent years owing to their interesting pharmacological properties,[1] and their use as analgesics,[2] potential anticonvalsant,[3] muscle relaxant,[4] and long-acting sedatives.[5]

6-Bromo-2-methyl-3,1-benzoxazin-4-ones (**1**) are known to react with amines to give the corresponding 4-quinazolinones,[6–8] which were condensed[7,9] with aromatic aldehydes to afford the corresponding 6-bromo-2-(2-arylvinyl)-4(3*H*)-quinazolinones (**2b—f**) (*cf.* Table 1).

Reaction of 6-bromo-4-quinazolinones (**2a,c—e**) with phosphorus pentasulfide in boiling pyridine gave the corresponding 4-quinazolinethiones[10–12] (**3a,c—e**) (*cf.* Table 1). The structures of **3** were established by their elemental and spectral analyses. Their IR spectra showed the stretching vibration bands of C=S (1230—1250 cm^{-1}) and C=N (1615—1630 cm^{-1}).

These compounds were reconverted to **2** by boiling with dilute hydrochloric acid. Also, condensation of **1**

(**8a,e—g**) were also obtained by condensing (**6c,e,d**) with the corresponding aromatic aldehydes.

The IR spectra of **6a** and **7a—d** showed stretching vibration bands of OH (3360—3340 cm^{-1}), C=O (1720—1680 cm^{-1}), and C=N (1650—1620 cm^{-1}). However, the IR spectra of **6b—k** and **8a—h** did not show stretching vibration bands of OH groups.

The UV spectra of **2a,b**, **3a**, **4c**, **5a,b**, and **8d** in ethanol are similar to those of 2,3-disubstituted 4(3*H*)-quinazolinones,[9] showing two main bands in the region 280—288 and 325—350 nm, (*cf.* Table 5).

Table 5. UV spectral data of 2,3-disubstituted 4(3*H*)-quinazolinones

Compound	λ_{max} nm (ε)			
2a	285 (7000)	325 (3000)	—	—
2b	282 (9000)	350 (10000)	—	—
3a	287 (5000)	353 (4000)	370 (5000)	383 (3000)
4c	287 (7000)	340 (5000)	—	—
5a	287 (9000)	335 (4000)	—	—
5b	282 (8000)	340 (11000)	—	—
8d	287 (27000)	350 (41000)	—	—

The higher red shifts of the electronic absorption bands for the compound (**3a**) compared with that of the corresponding compound (**2a**) become understandable in view of the higher energy level of nonbonding electrons in sulfur compared to oxygen.[18] The band at 370 nm presumably arises from π-π* and n-π* transitions in the C=S group.[18]

Biological screening results: The antimicrobial activities of the prepared compounds against a variaty of microbes were determined.[19] These microorganisms include Gram-positive and Gram-negative bacteria.

The bacteria used are: *Bacillus subtilis*, *Staphylcoccus aureus*, *Escherichia coli*, *Pesudomonas aeruginosa*, *Mycobacterium pheli*, *Proteus morganii*, *Serratia* and *Bacillus megaterium*.

The results showed that most of the prepared compounds (**3a**, **4a**—**c**,**e**, **5b**, and **6c**,**g**,**h**,**k**) show from a little to a strong activity on the Gram-positive and Gram-negative bacteria. The activity expressed in percent range 40—70% inhibition was found at concentration 10^{-3} M. The more strong active compounds against *Staphylcoccus aureus* are **6c**,**g**,**h**, that against *Pesudomonas aeruginosa*, *Mycobacterium pheli* and *Escherichia coli* is **6h** and those against *Eschericha coli* are **4a**—**c** and **6k** and those against *Serratia*, *Bacillus megaterium* and *Staphylcoccus aureus* are **3a**, **4a**—**c**,**e**, and **5b**, respectively.

Experimental

Melting points reported are uncorrected. Elemental analysis was carried out on a Colman C, H, and N analyser. IR spectra were recorded on a Perkin-Elmer infracord. The biological screening was carried out at the Microbiological Laboratory, Department of Botany, Assiut University.

6-Bromo-2-methyl-3,1-benzoxazin-4-one (1).[7] Pale yellow needles from carbon tetrachloride, mp 130—131 °C.

*6-Bromo-2-methyl-3-*p*-tolyl-4(3*H*)-quinazolinone (2a).*[8] Colourless needles from ethanol, mp 131—132 °C.

*3-Substituted 6-Bromo-2-(2-arylvinyl)-4(3*H*)-quinazolinones (2c—f and 7, 8):* 3-Substituted 6-bromo-2-methyl-4(3*H*)-quinazolinone (**2a**, **b**, or **6a**) was refluxed with corresponding aldehydes for 10 min. The cooled reaction mixtures gave precipitates on adding ethanol, which were filtered and crystallized from ethanol. The yield was about 80—90%. The results are listed in Table 1.

*2,3-Disubstituted 6-Bromo-4(3*H*)-quinazolinethiones (3):* A mixture of **2a**—**f** (0.01 mol) and phosphorus pentasulfide (0.01 mol) in 100 ml pyridine was refluxed for 5 h. The reaction mixture was cooled and poured into dilute acetic acid. The crude product was filtered, washed with water and recrystallized from the proper solvent. The results are listed in Table 1.

Reaction of 1 with Heterocyclic Amines (2h, i, 4, and 5): A mixture of 1 (0.01 mol) and corresponding heterocyclic amines (0.013 mol) in 100 ml dry pyridine was refluxed for 5 h. The solvent was evaporated to dryness, and the residue was washed with dilute acetic acid followed by water. The crude product was filtered, dried and recrystallized from the proper solvent. The results are listed in Tables 1 and 2.

*6-Bromo-2-methyl-3-hydroxy-4(3*H*)-quinazolinone (7a).* To a mixture of 1 (0.01 mol) and hydroxylamine hydrochloride (0.03 mol), a dilute solution of potassium hydroxide (0.05 mol) was slowly added with vigorous shaking. The reaction mixture was heated on a water bath for 30 min and then acidified with dilute acetic acid. The crude product was filtered, dried and crystallized from ethanol–benzene mixture as white needles, mp 245 °C (sublimed).

Reaction of 6a and 7 with Alkyl Halides, Acyl Chlorides, and Sulfonyl Chlorides (6b—k and 8). To a suspension of **6a** or **7a**—**d** (0.01 mol) in dry acetone (50 ml), was added 0.011 mol of anhydrous potassium carbonate and 0.011 mol of alkyl halides, acyl chloride, or sulfonyl chlorides. The mixture was heated on a steam bath for 3 h. After filtration acetone was evaporated. The crude product was recrystallized from the proper solvent, yield being about 80%. The results are listed in Tables 3 and 4.

The Solvent Extraction of Alkali Metal Picrates by 12-Crown-4

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received January 11, 1980)

Synopsis. The overall extraction equilibrium constants (K_{ex}) for 1: 1: 1 complexes of 12-crown-4 (12C4) with alkali metal picrates between benzene and water have been determined at 25 °C. The K_{ex} series for the 12C4 for the alkali metal ions are given by $Na^+ > Li^+ > K^+ > Rb^+ \geq Cs^+$.

Solvent-extraction studies of crown ether complexes with various metal ions, particularly with the alkali and alkaline earth metal ions, have been reported.[1] In some of the studies, the overall extraction equilibria have been analyzed by means of the constituent equilibria, and the extractability of the crown ether complex as well as that of the metal ion has been discussed in detail.[1b,1c,1d] Moreover, crown ethers have been used for extraction analysis.[2]

In this paper, the overall extraction equilibrium constant values for the 12-crown-4 (12C4)–alkali metal picrate system have been determined between benzene and water at 25 °C, and these extraction constant values have been compared with those of 15-crown-5 (15C5), in order to clarify the role of 12C4 in the extraction process.

Experimental

Materials. The 12C4 was obtained from Wako-Pure Chemicals, Ltd., and was used without further purification. The concentrations of the alkali metal hydroxides and picric acid solutions were determined by means of acid and basic titrations respectively. The benzene (analytical-grade) was washed twice with distilled water.

Apparatus and Procedure. The organic phase of the crown ether (1.2×10^{-2}—2.5×10^{-1} M; 1 M = 1 mol dm^{-3}) and the aqueous phase of the alkali metal hydroxide (1.1—1.7×10^{-2} M) and the picric acid (6.0×10^{-3}—1.1×10^{-2} M) in stoppered glass tubes (30 ml) were shaken in a thermostated water bath for approx. 35 min at 25±0.2 °C and then centrifuged. The initial volume of each phase was 10 ml in all cases. A portion of the aqueous phase (8 ml) was transferred into a 10-ml beaker, and the hydrogen-ion concentration determined by means of a Hitachi-Horiba F-5 pH meter. The extractions were conducted at pH 9.1—11.9. The picrate in the organic phase was back-extracted into 8 ml of a 0.01 M NaOH aqueous solution, and the picrate concentration was determined at 356 nm by means of a Shimadzu UV-200 spectrophotometer ($\varepsilon = 1.45\times10^4$ cm^{-1} M^{-1}). In blank experiments, no detectable extraction was found in the absence of 12C4.

The Distribution Coefficient of 12C4. A portion (13 ml) of a benzene solution containing 12C4 and an equal volume of distilled water were placed in a stoppered glass tube and shaken under the conditions given above. The range of concentration of the 12C4 was from 1.3×10^{-1} to 2.3×10^{-1} M. After centrifuging, a portion (12 ml) of the organic phase was transferred to a 20-ml beaker, and allowed to evaporate over several days, and the residue weighed. Since 12C4 is very hygroscopic, the water content of the residue was determined by Karl Fischer titration. The average distribution coefficient, determined in this way, was 0.15.

Results

In an equilibrium between an aqueous solution of a univalent metal ion, M^+, a picrate ion, A^-, and a benzene solution of a crown ether, L, the equilibrium constants may be defined by the following equations:

$$K_{ex} = [MLA]_o[H^+]/[M^+][L]_o[HA]_o \quad (1)$$

$$K_{D,L} = [L]_o/[L] \quad (2)$$

$$K_{ex}(HA) = [HA]_o/[H^+][A^-] \quad (3)$$

$$K_{ML} = [ML^+]/[M^+][L] \quad (4)$$

$$K_{ex'} = [MLA]_o/[ML^+][A^-] \quad (5)$$

where the subscript "o" and the lack of subscript designate the organic phase and the aqueous phase respectively; square brackets indicate the molar concentrations. Thus, K_{ex} can be written as follows:

$$K_{ex} = K_{D,L}^{-1}K_{ex}(HA)^{-1}K_{ML}K_{ex'}. \quad (6)$$

The distribution ratio of the univalent metal may be represented by:

$$D_M = [MLA]_o/([M^+]+[ML^+]) \quad (7)$$

In the case of $[M^+] \gg [ML^+]$, Eq. 7 becomes:

$$D_M = K_{ex}K_{ex}(HA)[L]_o[A^-]. \quad (8)$$

The $-\log(D_M/[A^-])$ *vs.* $-\log[L]_o$ plot in Fig. 1 shows a linear relationship with a slope of 1 in every case, indicating that 12C4 forms the 1: 1 complex with the alkali metal ion. The values of $[L]_o$ and $[A^-]$ in Eq. 8 were calculated by means of Eqs. 9 and 10 respectively:

$$[L]_o = ([L]_t-[MLA]_o)/(1+K_{D,L}^{-1}) \quad (9)$$

$$[A^-] = ([HA]_t-[MLA]_o)/\{1+(K_{HA}+K_{ex}(HA))[H^+]\} \quad (10)$$

TABLE 1. EQUILIBRIUM CONSTANTS AT 25 °C, CRYSTAL IONIC RADII OF ALKALI METALS, AND CAVITY RADII OF CROWN ETHERS

Crown ether	Cavity radius (Å)[4]	$K_{D,L}$	Cation	Crystal ionic radius (Å)[5]	log K_{ex}
12C4	0.5—0.65	0.15			
			Li^+	0.60	−1.62
			Na^+	0.95	−1.44
			K^+	1.33	−1.82
			Rb^+	1.48	−2.10
			Cs^+	1.69	−2.18
15C5	0.85—1.1	0.15[6][1d]			
			Li^+	0.60	−1.10[1d]
			Na^+	0.95	1.51[1d]
			K^+	1.33	0.19[1d]
			Rb^+	1.48	−0.25[1d]
			Cs^+	1.69	−0.49[1d]

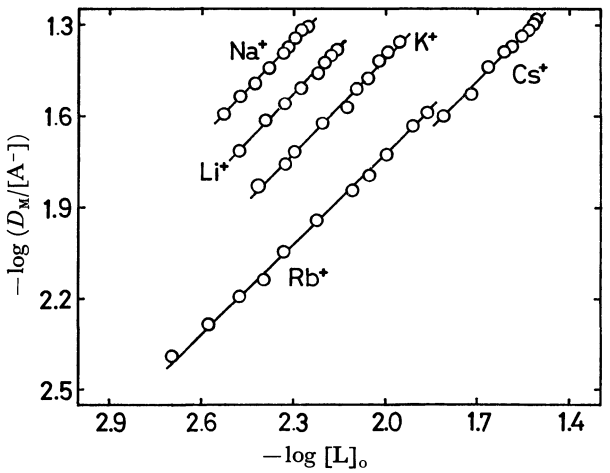

Fig. 1. Plots of $-\log (D_M/[A^-])$ *vs.* $-\log [L]_o$ for the alkali metals–12C4 system at 25 °C.

where the subscript "t" denotes the total concentration. The value of K_{ex}(HA) was spectrophotometrically determined to be 247 by using the association constant of picric acid ($K_{HA}=1.9_5$[3]). The equilibrium constants obtained from these data are summarized in Table 1, together with the literature values.

Discussion

The log K_{ex} series for the 12C4 for the alkali metal ions are given by $Na^+ > Li^+ > K^+ > Rb^+ \geq Cs^+$, indicating that the nearer the crystal radius of the alkali metal ion approaches to the cavity radius of 12C4, the more extractable the alkali metal ion is except for Li^+ (Table 1). In a previous paper,[1d] we have demonstrated that, in each case of 15C5 and 18-crown-6 (18C6), the alkali metal ion which has the optimum size for the crown ether cavity and the corresponding alkali metal ion–crown ether complex are the most extractable of all the alkali metal ions and the alkali metal ion–crown ether complexes respectively. In the case of 12C4, Na^+ is more extractable than Li^+, although Li^+ fits more closely into the 12C4 cavity than Na^+. This may be attributed to the fact that Li^+ is much more strongly hydrated than Na^+. 14-Crown-4 (14C4) and 12C4 have four donor oxygen atoms. 14C4 has a slightly larger cavity radius (0.6—0.75 Å[4]) than 12C4. However, Li^+ is the most favorable fit for the 14C4 cavity of all the alkali metal ions. It is interesting that 14C4 extracted Li^+ most effectively among the alkali metal ions.[1a] 15C5 and 18C6 show the most remarkable selectivity for Na^+ and K^+ respectively among the alkali metal ions.[1d] On the other hand, 12C4 displays no pronounced selectivity for any alkali metal ion.

Equation 6 shows that the series for K_{ex} for the same univalent metal ion for different crown ethers reflects the magnitude of $K_{D,L}$, the stability, and the extractability of the univalent metal ion–crown ether complex in the aqueous phase. It may be noted from Table 1 that the log K_{ex} value of 12C4 for the same alkali metal ion is smaller than that of 15C5. Since the $K_{D,L}$ value of 12C4 is nearly equal to that of 15C5, this may be due to the fact that the size of the 12C4 complex with the same alkali metal ion is smaller than that of the 15C5 complex and that the ability of 12C4, which has fewer donor oxygen atoms (four) than 15C5 (five), to form the complex with the same alkali metal ion in the aqueous phase is poorer than that of 15C5.

An ESR Study of *N,N*-Bis(arylthio)aminyls. ^{33}S Hyperfine Splittings[1]

Yozo MIURA* and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received October 4, 1979)

Synopsis. In the ESR spectra of *N,N*-bis(phenylthio)-, *N,N*-bis(phenyl-d_5-thio)-, and *N,N*-bis(3,5-dichlorophenylthio)aminyls, ^{33}S hyperfine splittings were detected. The spin densities in the aminyls were calculated by using the HMO calculations with and without McLachlan's correction, and the results were compared with the values derived from the ^{1}H, ^{14}N, and ^{33}S hyperfine splittings by use of the relationship $a=Q\rho$.

In a previous report on an ESR study of *N,N*-bis(arylthio)aminyls (**2**),[2,3] it was shown from the ^{1}H and ^{14}N hyperfine splitting (hfs) constants that in **2** the spin resides mainly on the central nitrogen atom and the two adjacent sulfur atoms. In continuing this study, we have tried to detect satellites due to ^{33}S (I=3/2) in ESR signals of **2**. It is well known that

$$\underset{\mathbf{1}}{\text{Ar–S–NH–S–Ar}} \xrightarrow{-H\cdot} \underset{\mathbf{2}}{\text{Ar–S–}\dot{\text{N}}\text{–S–Ar}}$$

a: Ar=C_6H_5, **b**: Ar=C_6D_5, **c**: Ar=3,5-$Cl_2C_6H_3$

the detection of satellites due to ^{33}S in natural abundance is very difficult because of the small amount present (0.74%). Fortunately, we have been successful in the detection of the satellites due to ^{33}S in the spectra of **2** without an enrichment of ^{33}S atoms. From the ^{1}H, ^{14}N, and ^{33}S hfs constants for **2**, we derived the spin densities in **2** by use of the relationship $a=Q\rho$, and compared the values with those obtained from the HMO calculations with and without McLachlan's correction.[4] In this report these results are described.

Results and Discussion

The aminyls **2** were generated by oxidation of *N*-(arylthio)arenesulfenamides (**1**) with lead dioxide and potassium carbonate.[2,5,6] Since **2** are fairly persistent, we could easily obtain high concentration solutions of **2** by this procedure. A typical ESR spectrum of **2b** is illustrated in Fig. 1a. The signal is composed of a simple 1:1:1 triplet with a small line-width (0.035 mT). On recording under high amplification, the satellite due to ^{33}S in natural abundance was detected, together with the satellite due to ^{15}N (I=1/2) in natural abundance (0.37%). The ratio of the observed splittings of $a_{^{15}N}/a_{^{14}N}$ (1.40) agrees with that of the magnetic moments of the nuclei (1.40). In the spectrum of **2a**, the satellite due to ^{33}S was also detected, but it was significantly masked by the main spectrum because of the large line-width of the spectrum (0.16 mT). However, the obtained value was in good agreement with that for **2b**. In the spectrum of **2c**,

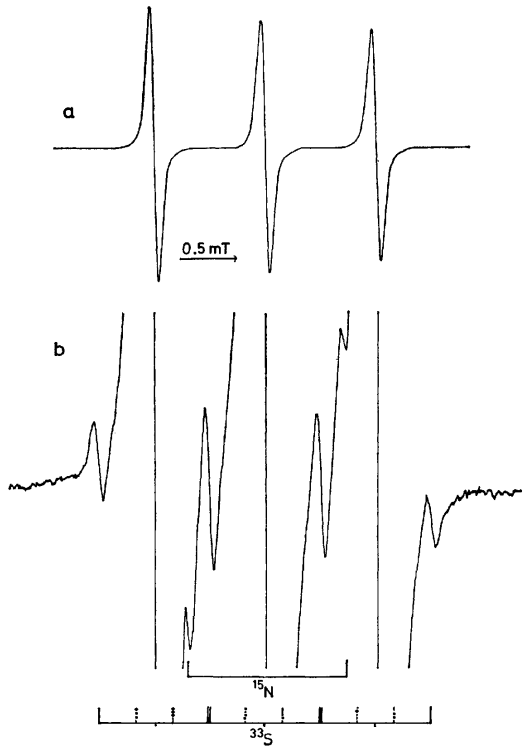

Fig. 1. ESR spectra of **2b** in benzene solution at room temperature.
(a): The main spectrum recorded under low amplification; (b): satellites due to ^{33}S and ^{15}N recorded under high amplification (100 times). The stick diagrams represent the theoretical reconstruction of satellites due to ^{33}S and ^{15}N. The experimentally observed satellites are shown by the full lines and those lost in the main spectrum are shown by the dotted lines.

TABLE 1. HYPERFINE SPLITTING CONSTANTS AND λ_{max} FOR **2**

	Solvent	$a_{^{14}N}$/mT	a_{other}/mT	*g*-value	λ_{max}/nm
2a	Benzene	1.141[a]	0.39(^{33}S)	2.0075[b]	538[a]
2b	Benzene	1.144	0.39(^{33}S), 1.60 (^{15}N)	2.0075	538

6	0.058(^{1}H)[b]	0.021	0.025	0.015

a) The spin densities (ρ) were derived from the hfs constants (a) using the relationship: $a=Q\rho$; $Q^{\pi}_{^{14}N}=2.3$ mT,[8c,d] $Q_{^{1}H}=-2.7$ mT,[10] $Q^{\pi}_{^{33}S}=3.3$ mT,[8b,11] $\lambda=0.7$. b) The value observed for **2c**.

the satellite due to ^{33}S was split into a septet, with an interval of 0.058 mT, by the interaction with the six magnetically equivalent protons. The ^{1}H, ^{14}N, ^{15}N, and ^{33}S hfs constants are listed in Table 1.

The ^{14}N hfs constant and the λ_{max} for **2b** were measured in some nonpolar and polar solvents in order to examine solvent effects on these values. As can be seen in Table 1, these values are independent of solvent. Thus, the spin distribution in **2** is little affected by the polarity of the solvent.

The HMO calculations with and without McLachlan's correction were made for **2a** using the following parameters:[8,9] $\alpha_N=\alpha+0.9\beta$, $\alpha_S=\alpha+1.3\beta$, $\beta_{NS}=0.7\beta$, $\beta_{CS}=0.75\beta$, $\lambda=0.7$; these parameters are chosen on the basis of the previously used values, but are slightly varied to give the best fit with the experimental results. In Table 2 the results are compared with the experimental values. Since, in the spectrum of **2a**, the splittings due to the ring protons were not detected, the values for **2c** are shown in Table 1. As can be seen from the comparison of the ^{14}N and ^{33}S hfs constants for **2a** with those for **2c**, the spin distributions in these aminyls are almost identical with each other. Thus, we can derive the spin densities on the phenyl rings of **2a** from the ^{1}H hfs constants for **2c**. As can be seen from Table 2, better agreement between the experimental and calculated values of the spin densities is obtained from the HMO calculation. The results indicate that in **2** *ca.* 50% of the spin resides on the central nitrogen atom and *ca.* 12% resides on each sulfur atom. The large g-values observed for **2** and other *N,N*-bis(arylthio)aminyls[2,7] (2.0073—2.0076) are well explained by this considerable delocalization of the spin onto the adjacent sulfur atoms, which have a large spin-orbit coupling parameter (382 cm^{-1}).[12,13]

Experimental

The visible spectra were obtained with a Hitachi Model ESP-3T spectrometer. The ESR spectra were obtained with a JES-ME-3X spectrometer equipped with an X-band microwave unit and 100 kHz field modulation. The hfs constants and g-values were determined in comparison with the ^{14}N hfs constant (1.309 mT) and the g-value (2.0055) of Fremy's salt. *N*-(Phenylthio)benzenesulfenamide (**1a**) and *N*-(3,5-dichlorophenylthio)-3,5-dichlorobenzenesulfenamide (**1c**) were prepared by the reported method.[2]

N-(Phenyl-d_5*-thio)benzene-*d_5*-sulfenamide (1b).* The amide was prepared in a similar manner to **1a**. Into dry ether (200 ml) was bubbled ammonia gas at −30——40 °C. To the solution was added dropwise freshly distilled benzenesulfenyl-d_5 chloride[14] (73—75 °C/3 Torr, 0.026 mol) in dry ether (30 ml). After addition, the bubbling of ammonia gas was stopped and the reaction mixture was raised to room temperature. Filtration of the reaction mixture and evaporation of solvent afforded an orange crystalline mass, which was recrystallized from hexane to give pale pink plates: mp 123—126 °C; yield 1.26 g (38%). IR (KBr): 3270 cm^{-1} (NH). Found: C, 58.85; H, 4.39; N, 5.68%. Calcd for $C_{12}HD_{10}NS_2$: C, 59.22; H, 4.56; N, 5.76%.

Generation of 2. Sulfenamide **1** (10 mg) was treated in solvent (3 ml) with lead dioxide (0.5 g) and potassium carbonate (0.5 g). After filtration, 0.5 ml of the purple solution was placed in an ESR cell and the solution was degassed by three freeze-and-thaw cycles; then the cell was sealed. ESR spectra were recorded at room temperature.

Spin density calculations were carried out on a FACOM 230-60 computer.

Electronic States of Crystalline Cation Radical Salts. Simple Salt of Phenothiazine$^{+\cdot}$Br$^-$ and Complex Salt of (Phenothiazine)$_2^{+\cdot}$Br$^-$

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 7, 1980)

Synopsis. Phenothiazine forms not only simple cation radical salt of Phenothiazine$^{+\cdot}$ Br$^-$ but also complex salt of (Phenothiazine)$_2^{+\cdot}$ Br$^-$. In this paper, less-than-half occupied Hubbard model was applied to the complex salt in order to explain its crystal electronic state.

The prominent magnetic, electrical, and optical properties of solid ion radical salts have been the subject of many theoretical and experimental investigations over the past seventeen years.[1] In such solid ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated stacking into columns so as to make a large overlap between their half-occupied molecular orbitals. In this case, any individual radical molecule interacts through charge transfer most strongly with two other neighboring radicals, and the electronic and magnetic properties of the solid salt differ distinctly from those of ion radical monomer. Moreover, in some cases, we can obtain complex ion radical salts, which include not only ion radical molecule but also its parent neutral molecule.[1-4] The optical and magnetic properties of crystalline complex ion radical salts are very interesting in comparison with those of the corresponding simple salts. In the present paper, we shall examine the electronic state of complex cation radical salt, (Phenothiazine)$_2^{+\cdot}$ Br$^-$, together with that of simple salt, Phenothiazine$^{+\cdot}$ Br$^-$.

Phenothiazine (PT) is a strong electron donating molecule and forms chemically stable cation radical salts with various diamagnetic counter anions. A simple cation radical salt of PT$^{+\cdot}$ Br$^-$ is a kind of such compounds. The electronic spectrum of solid PT$^{+\cdot}$ Br$^-$ shows a strong low-energy band at 12900 cm^{-1} and high-energy bands at 20500, 23000, and 28600 cm^{-1}.[2-5] The high-energy bands are known to come from the monomer absorptions of phenothiazine cation radical in solution, while the low-energy band at 12900 cm^{-1} is characteristic of the solid salt and was assigned to the charge-transfer transition between cation radicals.[3-5] The magnetic susceptibility of this salt was found to be almost diamagnetic, indicating that strong antiferromagnetic spin exchange interaction acts between adjacent cation radicals. According to Sato *et al.*,[6] the change in the paramagnetic susceptibility with temperature was found to fit well the curve calculated from regular one-dimensional Ising model, for which the spin-exchange coupling parameter, J, was taken to be 970 cm^{-1}. In order to understand those optical and magnetic properties, a regular one-dimensional half-occupied Hubbard model is applied to the segregated stack of phenothiazine cation radicals in simple cation radical salt of PT$^{+\cdot}$ Br$^-$. This model is a simplification of the real crystal and is described by two parameters I and T.[5] T is the transfer matrix element of an unpaired electron which describes hopping between adjacent molecular sites, while I is the on-site Coulomb repulsion between two electrons with up and down spins on the same molecule. Then, T favors electron delocalization through band formation, whereas I favors localization due to electron-electron repulsions. On the basis of this model, we can explain the reason why the intermolecular charge-transfer absorption appears in the solid-state spectrum of PT$^{+\cdot}$ Br$^-$. The peak energy of the charge-transfer absorption corresponds to $\omega=I$, and if the electron transfer matrix element, T, is not zero, the absorption has observable intensity.[5,7] As for the magnetic property of this system, Takahashi showed that, in the case of $I \gg |T|$, the half-occupied Hubbard model becomes equivalent to the following effective Hamiltonian,[8]

$$\mathcal{H}_{\text{eff}} = \frac{4T^2}{I}\sum_i \left(\boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1} - \frac{1}{4}\right) + 0\left(\frac{T^3}{I^2}\right), \qquad (1)$$

where $\boldsymbol{S}_i$, $(S=1/2)$, is the spin operator of an electron at the i-th site. In other words, if the value of I is much larger than $|T|$, we can neglect such higher terms as $0(T^3/I^2)$, and the one-dimensional half-occupied Hubbard model is reduced to one-dimensional Heisenberg antiferromagnetic model with exchange interaction, $J=2T^2/I$. In this respect, our application of Hubbard model receives strong support from the fact that in PT$^{+\cdot}$ Br$^-$ there acts antiferromagnetic spin exchange interaction between adjacent PT$^{+\cdot}$ cation radicals.[6] Rigorously speaking, the J value of Heisenberg model should correspond to $2T^2/I$. However, since only the J value estimated with linear Ising model is available, we approximately use the estimated $J=970$ cm^{-1} value as $J \approx 2T^2/I$. If we use the $I=12900$ cm^{-1} value obtained spectroscopically, the T value was determined as $T \approx -2500$ cm^{-1} for the one-dimensional system of PT$^{+\cdot}$ cation radicals in simple PT$^{+\cdot}$ Br$^-$ salt.

Next, we consider the crystal electronic state of complex cation radical salt of (PT)$_2^{+\cdot}$ Br$^-$. The existence of this complex salt was earlier suggested by Matsunaga and Shono and by the present author,[2,3] and was later confirmed by Doi and Matsunaga.[4] In the electronic spectrum of the solid complex salt, the charge-transfer absorption due to the transition between cation radicals appears at 12600 cm^{-1}. In addition, a broad absorption is observed at 5200 cm^{-1}, which was assigned to the electronic transition from neutral phenothiazine to its cation radical.[4] In the complex salt, it appears that the positive charge is equally shared by the two molecules of phenothiazine and that phenothiazine molecules form, in themselves, a segregated stacking into infinite one-dimensional columns. Then, we can apply regular one-dimensional

less-than-half occupied Hubbard model to the segregated stack of phenothiazine molecules.

Shiba[9] and Klein and Seitz[10] have shown that the magnetic susceptibility of a uniform stack of lessthan-half occupied molecules (average number of unpaired electrons per site is ρ) is related to the susceptibility of a uniform stack of half-occupied molecules ($\rho=1$) in simple ion radical salt. It is assumed that the values of I and T in less-than-half occupied Hubbard model are common to those in half-occupied system, respectively. If the value of I is much larger than that of $|T|$, the less-than-half occupied one-dimensional Hubbard model becomes identical to an antiferromagnetic Heisenberg chain with exchange interaction,[11]

$$J=\frac{2T^2\rho}{I}\left(1-\frac{\sin 2\pi\rho}{2\pi\rho}\right). \quad (2)$$

In fact, if we take $\rho=1$ in Eq. 2 for half-occupied Hubbard model, we simply obtain $J=2T^2/I$, which is identical with the J value of simple ion radical salt in Eq. 1. For the complex cation radical salt of $(PT)_2^{+\cdot}$ Br^-, we can choose $\rho=1/2$, $I=12900\ cm^{-1}$ and $T\approx -2500\ cm^{-1}$ because of the assumption that the I and T values of the complex salt are almost the same as those corresponding to the simple salt of $PT^{+\cdot}$ Br^-. Then, using Eq. 2, the J value of the complex salt of $(PT)_2^{+\cdot}$ Br^- was estimated to be $485\ cm^{-1}$. Temperature dependence of the magnetic susceptibility, χ, of the complex salt can be given by Bonner and Fisher's theoretical equation with $J=485\ cm^{-1}$.[12] More practically, as an excellent fit to their equation, Torrance proposed an analytical expression of χ *versus* temperature and J.[11] If we compare the $J=970\ cm^{-1}$ value of the simple salt with the $J=485\ cm^{-1}$ value of the complex salt, we note marked decrease of the J value in the complex salt. This will give more paramagnetism to the susceptibility of the complex salt. The strong dependence of J on ρ means that the antiferromagnetic spin exchange interaction between unpaired electrons is caused mostly by the charge-transfer interaction between unpaired electrons and that less density of unpaired electron in the complex salt gives smaller J value, compared to the J value in the simple salt.

As for the optical property of the complex salt, $(PT)_2^{+\cdot}$ Br^-, the above-mentioned Hubbard model can also explain the observed charge-transfer absorption due to the transition between cation radicals. This absorption is observed at $12600\ cm^{-1}$, which is close to the $12900\ cm^{-1}$ value of the simple salt. Theoretically speaking,[7] the regular one-dimensional less-than-half occupied Hubbard model leads to the charge-transfer absorption spectrum of $\mathrm{Re}\,\sigma_{xx}(\omega)\propto \mathrm{Re}\,\sigma^+(\omega)+\mathrm{Re}\,\sigma^-(\omega)$;

$$\mathrm{Re}\,\sigma^{\pm}(\omega)=\frac{e^2}{4}\frac{I^2\rho\left(1-\frac{1}{2}\rho\right)}{\omega^2\sqrt{\omega^2-2I^2\rho\left(1-\frac{1}{2}\rho\right)}}$$
$$\times\sqrt{4T^2-\left\{-(\rho-1)I\pm\sqrt{\omega^2-2I^2\rho\left(1-\frac{1}{2}\rho\right)}\right\}^2}, \quad (3)$$

where we neglected the term of Fermi distribution function. For the simple salt of $PT^{+\cdot}$ Br^- with $\rho=1$ and $I=12900\ cm^{-1}$, the charge-transfer absorption, $\mathrm{Re}\,\sigma_{xx}(\omega)$, has a divergent peak at $\omega=I$; this spectroscopic feature was mentioned previously. For the complex salt of $(PT)_2^{+\cdot}$ Br^-, however, if we put $\rho=1/2$, $I=12900\ cm^{-1}$ and $T\approx -2500\ cm^{-1}$, the absorption peak of $\mathrm{Re}\,\sigma_{xx}(\omega)$ will take place around $\omega=\sqrt{4T^2+2IT+I^2}=11300\ cm^{-1}$. Therefore, the charge-transfer absorption of the complex salt will show red-shift in comparison with that of the simple salt. The experimental peak energy, $12600\ cm^{-1}$, of the complex salt shows a little red-shift compared to the $12900\ cm^{-1}$ value of the simple salt, but this magnitude of the red-shift is not so large as that predicted theoretically. One of the reasons for this is that the I value of the complex salt may be a little larger than that of the simple salt and that the role of counter anion of Br^- in the complex salt may be less effective to decrease on-site Coulomb repulsion than in the simple salt, because average number of Br^- anions per one site of phenothiazine in the complex salt is just half of that in the simple salt.

A Further Evidence of the Vibronic Coupling through b_{3g} Vibrational Modes in the Fluorescence Spectrum of Anthracene[1)]

Tomoyuki TERADA, Motohiko KOYANAGI,* and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 8, 1980)

Synopsis. Angular dependence of the fluorescence polarization spectra of anthracene was investigated in polyethylene films using a sample rotation technique. An important role of a nontotally symmetric vibration, the b_{3g} ring vibration at 1655 cm^{-1}, was further confirmed by a combination of this technique and the modulation polarization technique developed previously.

Despite many studies on the fluorescence polarization spectra of anthracene, only a partially successful experiment for the assignment of b_{3g} nontotally symmetric vibrational bands has been reported by Bree and Katagiri.[2)] Very recently Ohta and Ito measured the intensity of Raman lines of crystalline anthracence in the pre-resonance excitation region and found a marked intensity enhancement of the b_{3g} Raman line at 1630 cm^{-1} for such a "resonant" excitation.[3)] The enhancement was then attributed to the vibronic coupling between two $\pi\pi^*$ excited states, *i.e.*, ^1L_a and ^1B_b, of the molecule. Previously we developed a new polarization method, *i.e.*, a modulation polarization (MP) method, and reported its application to studies of emission polarization spectra of some molecules in mixed crystals[4)] and in stretched polyethylene films.[5)] Anthracene was one of these molecules. Several bands of the long molecular axis polarization were clearly confirmed to exist in the fluorescence by the MP method. However, there remained a few ambiguous points about the molecular orientation in the stretched polyethylene films and the degrees of self-polarization of the apparatus. In the present work we examined the angular dependence of the MP spectra and confirmed the validity of the previous conclusion.

Experimental

The MP spectra were observed in a similar way to those described previously.[5)] The axis of an analyzing polarizer was fixed as inclined by 45° from the vertical axis of a Dewar for possible diminution of the systematic error of polarizations coming from the curvature of the Dewar. A sample-rotation device is homemade and it makes the 0°—180° rotation of sample films possible. An angle precision of the device is estimated to be ±3°. An angle θ is defined as that between the stretching film axis and the analyzing polarizer axis.

Results and Discussion

Anthracene is assumed to be embedded in stretched polyethylene films in such a way that its long molecular axis is oriented along the stretching film direction.[6)] Thus this system should roughly approximate a model of the oblate-spheroidal orientation of the molecule, allowing overlapping vibronic bands to be possibly separated by such polarization studies. Since $\pi\pi^*$ transitions of aromatics are of in-plane polarization,[7)] an application of such polarization techniques to oblate or prolate aromatics enables us to discriminate between the short and long molecular axis polarizations. A previous work on the MP spectrum of anthracene has partly demonstrated this possibility.[5)]

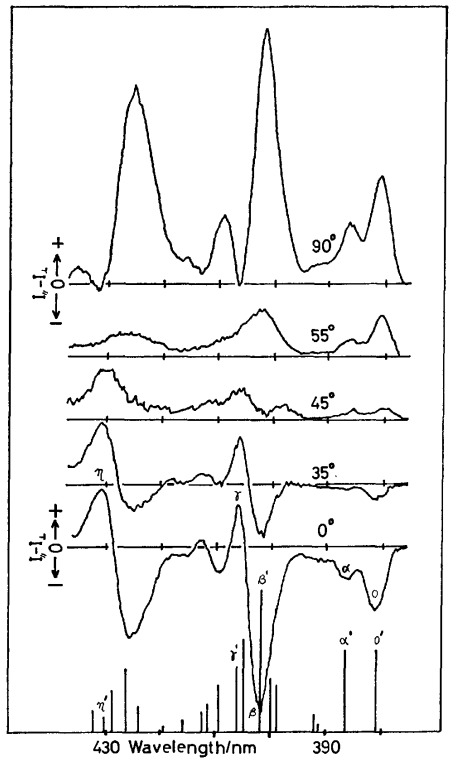

Fig. 1. Angular dependence of the fluorescence polarization spectra of anthracene in stretched polyethylene films at 77 K. For comparison, the fluorescence spectrum in heptane matrix at the same temperature is schematically shown at the bottom of this figure. The spectrum is evenly shifted so that the origin bands of both systems may coincide with one another. See text or the caption of Fig. 2 for band designations.

An angular dependence of the MP polarized fluorescence spectrum of anthracene is shown in Fig. 1. The spectrum at $\theta=0°$ resembles Fig. 3c of Ref. 5 except a better band resolution in the present work and a similar vibrational analysis is made possible by comparing the extrema of the MP spectrum with the vibrational bands of the fluorescence spectrum in heptane. Here let us devote our attention to the following extrema of the MP spectrum: the extrema at 380.6 nm (o in Fig. 1), 386.4 nm (α), 402.2 nm (β), 406.2 nm (γ), and 431.3 nm (η). These correspond nicely to five prominent bands in the anthracene/heptane system. They are the bands 0—0 (o' in Fig. 1), 0—393 cm^{-1} (α'), 0—1405 cm^{-1} (β'), 0—1637 cm^{-1} (γ'), and 0—1405—1637 cm^{-1} (η'), respectively.

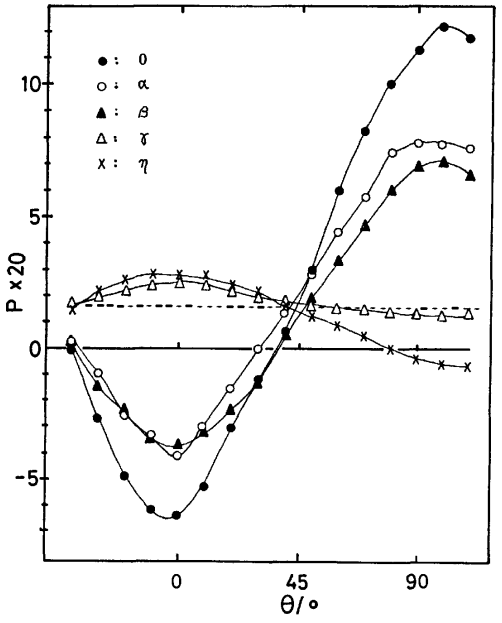

Fig. 2. Angular dependence of the polarizations of five prominent fluorescence bands. Band designations are: o, 0—0; α, 0—395 cm^{-1}; β, 0—1410 cm^{-1}; γ, 0—1655 cm^{-1}; η, 0—1655—1410 cm^{-1}.

With respect to the abscissa axis the spectrum at $\theta=0°$ is, as a whole, symmetrical to that at $\theta=90°$, as can be expected. The spectrum at $\theta=35°$, however, is seen far from such a symmetrical relation to that at $\theta=55°$. The spectrum at $\theta=45°$ shows several weak polarization peaks. These peaks were found to come mainly from the instrumental self-polarizations whose correction factor was not equal to unity, but nearly to 1.15 on an average in the present optical arrangement. This correction factor also explains the asymmetric relationship between the MP spectra at $\theta=35°$ and 55°.

Angular dependence of the polarizations of the five prominent fluorescence bands is shown in Fig. 2. Evidently there are four characteristic features to be pointed out. [1] Two types of the polarization angular dependence are found for the bands (o, α, β) and the others (γ, η). [2] All the polarization curves of the bands cross at $\theta\approx45°$. [3] The extreme value of the polarization of each band appears at $\theta\approx0°$ or $\theta\approx90°$, depending on the polarization nature of the vibrational band. [4] An even upward shift of the base-line by $P=+0.08$ seems to bring about a nice symmetric situation for the curves. The items [2] and [3] demonstrate that the molecule in the stretched polyethylene film is oriented in such a way that the long molecular axis is nearly parallel to the stretching film axis.[6] An experimental fact described in the item [4] is reasonably explained by the instrumental self-polarizations. The angular dependence of the bands γ and η (the item [1]) clearly proves these bands are certainly of b_{3g} vibrational modes.[5]

Infrared Studies of the Oxidation of 2-Propanol on ZnO

Hisashi MIYATA,* Kazuo HATA,† Takashi NAKAJIMA, and Yutaka KUBOKAWA
Department of Applied Chemistry, University of Osaka Prefecture, Mozuumemachi, Sakai, Osaka 591
(Received February 21, 1980)

Synopsis. The oxidation of 2-propanol and acetone on ZnO has been studied by IR spectroscopy. Surface isopropoxide was oxidized to acetate and formate ions *via* enolate complex of acetone. Formation of α-diketone-like species was proposed for oxidation with dinitrogen oxide.

By investigation of the reaction of oxygen with olefins, 2-propanol, acetone, and 2-methyloxirane on metal oxides, such as ZnO, MgO, and NiO, by IR spectroscopy,[1-3] it was found that the compounds are oxidized to carboxylates on the surface. No C–C bond scission took place in the oxidation with dinitrogen oxide.[2,3] In order to clarify the mechanism of the oxidation and the role of adsorbed oxygen species, the oxidation of 2-propanol adsorbed on zinc oxide with oxygen or dinitrogen oxide has been investigated by IR spectroscopy.

Details of the apparatus, procedures, and materials were reported.[1-3] After 0.25—0.4 cm^3/g of 2-propanol or acetone had been introduced into the IR cell, the weakly adsorbed reactants were removed by immersing the trap in liquid nitrogen. Oxygen or dinitrogen oxide of 2 kPa was then circulated over the ZnO, the temperature of which being raised in stages. Infrared spectra were recorded at ambient temperature after each treatment of the sample.

The infrared spectrum of 2-propanol adsorbed on the zinc oxide (0.35 cm^3/g) exhibited bands at 2964, 2922, 2866, 1458, 1366, 1165, and 1134 cm^{-1} (Fig. 1a), which did not change significantly on evacuation at 353 K. The bands agree with those due to the surface isopropoxide formed on metal oxides,[1,4-7] confirming the formation of the stable isopropoxide species on zinc oxide.

The temperature of the zinc oxide containing isopropoxide was raised in stages under circulation of oxygen. The bands due to isopropoxide species were slightly reduced in intensity at 353 K and disappeared at 423 K. New bands appearing at 3038, 1576, 1548, 1498, 1428, and 1308 cm^{-1} at 353 K grew with an increase in temperature of the disk to 423 K. Figure 2A shows the change in intensity of these bands with increase in temperature. The behavior is almost the same as that of the reaction of oxygen with propene and 2-methyloxirane on ZnO[2,3] and with 2-propanol on MgO.[1] Thus, the same assignment is applicable. The bands at 2976, 1548, and 1432 cm^{-1} are due to $\nu_{as}(CH_3)$, $\nu_{as}(COO)$, and $\nu_s(COO)$ of surface acetate ions, respectively, and those at 2872, 1576, and 1366 cm^{-1} to the corresponding vibrations of surface formate ions.

The spectra of acetone-d_6 adsorbed on ZnO, pretreated with D_2O, were investigated for the bands at 1498 and 1308 cm^{-1} (Fig. 1de). Bands appearing at 2666, 2502, 2245, 2216, 1464, 1352 cm^{-1} are attributed to the dissociatively adsorbed acetone, *i.e.*, the enolate complex.[7] The bands at 1466 and 1352 cm^{-1} (1498 and 1308 cm^{-1} for acetone) are assigned to the C=O and C=C coupled vibrations of $(O{=}C{=}CD_2)$-groups in the enolate complex.[7-10] CD_2= vibrations appeared at 2245 cm^{-1} (3040 cm^{-1} for acetone). The bands at 2666 and 2502 cm^{-1} are due to the surface OD groups. Similar spectra have been reported by Koga, Onishi, and Tamaru,[7] and Nagai and Miyahara.[9] Thus, the bands at 1498 and 1308 cm^{-1} can be assigned to the enolate complex. The change in intensity of the bands with increase in temperature resembles that of the isopropoxide except for the alkoxyl bands. The results together with the fact that acetone was detected during the course of temperature rise of the ZnO containing 2-propanol in the presence of oxygen leads to the following conclusion: 2-propanol is dehydrogenated to form acetone, which was oxidized to acetate and formate ions *via* the enolate complex.

Similar experiments were carried out for isopropoxide adsorbed on ZnO using dinitrogen oxide instead of oxygen. After admission of dinitrogen oxide to the ZnO containing isopropoxide, its temperature was raised in stages. The resulting spectra are shown in Fig. 3. The intensity of the bands due to the isopropoxide

decreased with increase in temperature, disappearing completely at 523 K. The bands due to the enolate complex appeared at 353 K and passed through a maximum in intensity at 423 K (Fig. 2B). New bands appeared simultaneously at 1550 and 1436 cm^{-1} at 423 K, the ratio of intensity being constant up to 573 K. This suggests that these bands arise from the same adsorbed species. Results of similar experiments for acetone adsorbed on ZnO are also shown in Fig. 3. Essentially the same spectra are observed except for the alkoxyl bands.

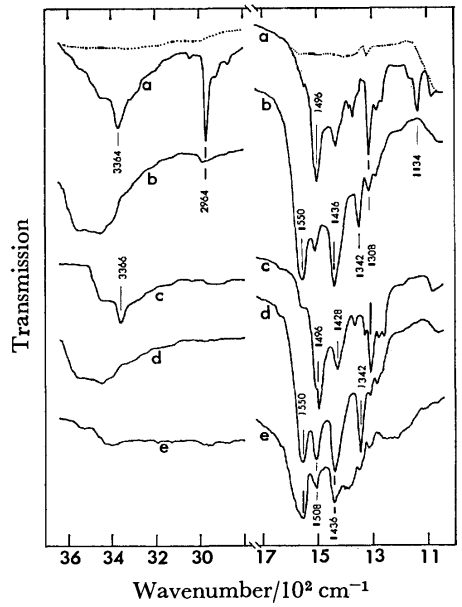

Fig. 3. Interaction of dinitrogen oxide with 2-propanol or acetone adsorbed on ZnO.
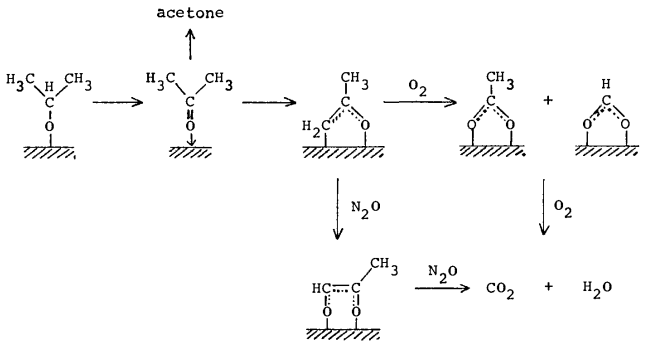
(a) After 1 h adsorption of 2-propanol (0.3 cm^3/g) at 293 K followed by 1 h at 393 K in dinitrogen oxide (2.2 kPa); (b) followed by 1 h at 523 K; (c) after 1 h adsorption of acetone (0.28 cm^3/g) at 293 K followed by 1 h at 393 K in dinitrogen oxide (2.3 kPa); (d) followed by 1 h at 523 K in dinitrogen oxide; (e) after 1 h adsorption of biacetyl (0.25 cm^3/g) followed by 1 h at 353 K in oxygen.

It was found in the reactions of dinitrogen oxide with 2-propanol or acetone that an appreciable amount of oxygen had been incorporated by the ZnO before carbon dioxide was formed. In contrast to the oxidation by oxygen, no cleavage of the C–C bond occurred, since no bands due to the formate ions appeared in the COO or CH stretching region. The results together with the change in intensity of the bands with increase in temperature (Fig. 2B) suggests that the enolate complex incorporate oxygen to form a new oxygen-containing compound having absorption at 1550 and 1436 cm^{-1}. Although the position of these bands is very similar to that for propionate ions on ZnO, the intensity of the CH stretching and the bending vibrations of the CH_3 groups is very low, in disagreement with what is expected from the propionate ions. The spectra of a number of oxygen-containing compounds such as alcohols, aldehydes, acids, and ketone were examined. Only biacetyl was found to give essentially the same spectra as those shown in Fig. 3. Thus, these bands are tentatively assigned to α-diketone-like species. Presumably, oxidation proceeds by the following scheme:



Scheme 1.

Studies of the Separation Mechanism in Ion-exchange Chromatography. II. Inversion of the Elution Order of Tri- and Divalent Complex Cations with Increasing Concentration of the Eluent

Hayami YONEDA,* Chang Eon OH, and Shigeo YAMAZAKI
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received January 11, 1980)

Synopsis. Two pairs of tri- and divalent complex cations $[Co(en)_3]^{3+}$, $[Ni(en)_3]^{2+}$ and $[Co(phen)_3]^{3+}$, $[Fe(phen)_3]^{2+}$ were chromatographed through the SP-Sephadex cation-exchange column using various concentrations of aqueous KBr and K_2SO_4 solutions as eluent, and the inversion of the elution order was observed for the pair of the phen complexes when eluted with KBr and for that of the en complexes when eluted with K_2SO_4.

In the first paper of this series,[1] it was reported for *cis* and *trans* isomeric pairs of some complex cations that the usual elution order in ion-exchange chromatography was reversed with the addition of dioxane to the eluent. This was interpreted as a result of the enhancement of the electrostatic interaction in the moving phase which overtook the interaction in the fixed phase. If this interpretation is valid, the inversion of the elution order is expected also for the pairs of differently charged cations under suitable conditions. This expectation was ascertained in the present study.

Experimental

All the complexes were prepared according to the literature, and identified by UV absorption spectra. Complexes used were $[Co(en)_3]Cl_3$, $[Ni(en)_3]Cl_2$, $[Co(phen)_3]Cl_3$, and $[Fe(phen)_3]Cl_2$. All the works were carried out on a laboratory-built chromatographic unit at room temperature. The column size was 10.8 cm long and 1.1 cm in diameter. SP-Sephadex C-25 (K^+-form) was used as a packing material. The detector was operated at an appropriate wavelength in the visible region for each complex. The adjusted retention volume was measured from the elution curve thus obtained. Blue dextran 2000 was used as a marker.

Results and Discussion

Figure 1 shows the adjusted retention volumes of the en and phen complex pairs as a function of KBr concentration. At low KBr concentration, both trivalent complexes, $[Co(en)_3]^{3+}$ and $[Co(phen)_3]^{3+}$ show greater retention volumes than the corresponding divalent complexes, $[Ni(en)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$. This means that the trivalent complex is adsorbed more strongly on the $-SO_3^-$ group of the resin than the corresponding divalent complex. However, the retention volume of the tri- and divalent complexes decreases with increasing concentration of the eluent, and the rate of decrease in the retention volume is much larger for the trivalent complex than for the divalent complex. Thus, the inversion of the elution order can be expected for both pairs above a certain eluent concentration.[2] Here, it is worth noting that this critical concentration

at which the inversion takes place is different for different pairs; while the inversion takes place at 0.3 mol dm^{-3} KBr for the phen complex pair, it does not even at 1 mol dm^{-3} KBr for the en complex pair. On the contrary, as shown in Fig. 2, when K_2SO_4 solution is used as eluent, the inversion takes place at *ca.* 0.18 mol dm^{-3} for the en complex pair, but it does not even

at 0.20 mol dm^{-3} for the phen complex pair. These trends can be interpreted in the following way.

In quantitative consideration, it is convenient to use the distribution coefficient D, the ratio of the concentration of a sample ion in the resin phase to that in the moving phase, which has been demonstrated[3] to equal the adjusted retention volume per unit resin volume. Thus, we have

$$D = [M]_R/[M] = V_{adj}/V_{resin}$$

where $[M]_R$ and $[M]$ represent the concentration of a sample ion M^{m+} in the resin phase and in the moving phase, respectively, and V_{adj} and V_{resin} represent the adjusted retention volume and the volume of the ion-exchange resin packed in the column, respectively. If it is assumed that a small amount of a sample ion M^{m+} is distributed between the B^+-formed resin and the aqueous solution of an electrolyte B_nX used as an eluent, D is given by

$$D = K_B^M([B]_R)^m/[B]^m$$

where K_B^M is the selectivity coefficient of M^{m+} relative to B^+.[3] When the ion-association between M^{m+} and X^{n-} is taken into account, the distribution coefficient D of M^{m+} is expressed as[3]

$$D = K_B^M([B]_R)^m/\{[B]^m(1+\beta[X])\} \quad (1)$$

where β is the association constant. With this final equation, the elution order of the tri- and divalent complex cations can be compared.

Let D_3 and D_2, $K(3)$ and $K(2)$, and $\beta(3)$ and $\beta(2)$ represent the distribution coefficients, the selectivity coefficients, and the ion-association constants for tri- and divalent complexes, respectively. If we take the ratio of these distribution coefficients D_3 and D_2 for a particular pair, we obtain

$$D_3/D_2 = (K(3)/K(2))([B]_R/[B])(1+\beta(2)[X])/(1+\beta(3)[X]). \quad (2)$$

Here, $K(3)$ is in general larger than $K(2)$. At low concentration of B_nX, $[B]_R$ is larger than $[B]$, and $\beta[X]$ can be neglected in Eq. 2. Therefore, the value of D_3/D_2 is larger than unity, indicating that the trivalent ion is adsorbed on the resin more strongly than the corresponding divalent ion. However, as the concentration of B_nX increases, the value of $[B]_R/[B]$ becomes smaller and smaller and finally it becomes less than unity so as to make its product with $K(3)/K(2)$ very close to unity at fairly high concentration of B_nX. Thus, in principle, the value of D_3/D_2 for a particular pair can be smaller than unity at very high eluent concentration. However, when the ion-association effect is added, D_3/D_2 becomes smaller than unity at relatively low eluent concentration, since the value of $(1+\beta(2)[X])/(1+\beta(3)[X])$ in Eq. 2 is always smaller than unity for a particular pair. Using Eq. 2, our experimental results can now be explained in the following way.

Bromide anion is poorly hydrated in aqueous solution because of its large size and low electric charge, and therefore is considered to be a water-structure breaker.[4] Such a structure-breaking anion is antagonistic[4] to a water-structure-making cation like $[M(en)_3]^{m+}$ which attracts many water molecules with its many N–H bonds, and has little tendency toward association with $[M(en)_3]^{m+}$. Thus, the effect of ion-association need not be considered for the en complex pair when eluted with KBr solution and the elution order is not reversed in the ordinary concentration range of the eluent. On the other hand, SO_4^{2-} is strongly hydrated and has a great tendency to associate with a strongly hydrated complex cation like $[M(en)_3]^{m+}$ through S–O···H–N–M hydrogen bonds.[5] Thus, when the en complexes are eluted with K_2SO_4, the effect of ion-association, that is, the term $(1+\beta[X])$ becomes dominant in Eq. 2. Since the term $(1+\beta(2)[X])/(1+\beta(3)[X])$ is less than unity, the value of D_3/D_2 will become smaller than unity from a certain concentration of K_2SO_4 solution, resulting in the reversed elution order.

For the elution of the phen complex pair, we have to consider a reverse situation. Since the phen complex has no N–H bonds for hydrogen bonding and its size is large, it is poorly hydrated and is known to be a typical hydrophobic ion.[4] Such a hydrophobic cation has a big tendency toward association with a hydrophobic anion or a water-structure-breaking anion. Thus, the ion-association takes place to a considerable extent with Br^- ion, resulting in the inversion of the elution order from a certain concentration of KBr solution. On the other hand, there is little tendency toward association between a hydrophobic cation and a hydrophilic anion.[5] So, for the phen complex pair eluted with K_2SO_4 solution, the value of D_3/D_2 does not become smaller than unity, that is, the inversion of the elution order does not take place.

(Received September 14, 1979)

Synopsis. Relative reactivities of *N-t*-butoxycarbonyl-(Boc)amino acids (Gly, Val, Ile, Leu, Tyr, and Phe) and Boc-oligopeptide acids having various numbers of amino acid residues (n=2, 4, 5, 8, and 10) were determined by competitive esterification in reaction with chloromethylated polystyrene. Increase of peptide-chain lengths reduced reactivity of *C*-terminal carboxylates.

In peptide synthesis on a polymer support, the first step involves an attachment of the *C*-terminal of *N*-protected amino acid to the polymer support *via* a benzyl ester linkage.[2] Studies have been reported on the improvement of this first step in the solid phase peptide synthesis by stepwise elongation.[3-6] However, only a few studies have been made on the esterification step in peptide synthesis by fragment condensation on a polymer support.[6,7] In this paper, we report relative reactivities of Boc-amino acids in the esterification with soluble chloromethylated polystyrene and the influence of peptide-chain lengths of Boc-oligopeptide acids on the reactivity of their *C*-terminal amino acids in the esterification.

Taking advantage of polymer reaction, relative reactivities of Boc-amino acids (Gly, Val, Ile, Leu, Tyr, and Phe)[8] in their esterification with the polymer were determined by competitive esterification with use of amino acid ratios in the acid hydrolysate of the resulting resin (Table 1). We used the recovery of Gly as a standard with the intention of estimating roughly the influence of the *C*-terminal amino acid residue on the esterification. Four methods of esterification were used to obtain information on which differences in reactivity can be compensated: (1) use of potassium carbonate as a base, (2) use of potassium carbonate and 18-crown-6 as a base and catalyst, respectively,[3] (3) use of potassium fluoride as a catalyst,[4] and (4) use of potassium fluoride and 18-crown-6 as catalysts. Reactions proceeded heterogeneously in (1) and (3) and homogeneously in(2) and (4). Relative reactivities of Boc-amino acids in (1) and (3) (heterogeneous reactions) were in line with those in (2) and (4) (homogeneous reactions), respectively. In each case, Boc-amino acids having β-branched substituents (Val and Ile) and a more hydrophobic substituent (Phe) showed higher reactivity.

In order to understand the influence of the peptide-chain lengths of Boc-oligopeptide acids on the reactivity of their *C*-terminal amino acids in esterification, relative reactivities of Boc-oligopeptide acids having various numbers of amino acid residues (n=2, 4, 5, 8, and 10) and the same *C*-terminal amino acid were determined by competitive esterification using Boc-amino acid (Val or Ile) as a reference. The competitive reactions were carried out for the following.

Series A: Boc–Phe–OH (n=1), Boc–Gly–Phe–OH (n=2), Boc–Tyr–Gly_2–Phe–OH (n=4), and Boc–[Tyr(Bzl)–Gly_2–Phe]$_2$–OH (n=8)

Series B: Boc–Leu–OH (n=1), Boc–Leu_2–OH (n=2), Boc–Ala_2–Leu_3–OH[1] (n=5), and Boc–Ala_2–Leu_3–Pro_2–Leu_3–OH[1] (n=10)

Boc-oligopeptide acids of series A and B have Phe and Leu as the *C*-terminal amino acids, respectively.

Methods (1), (2), and (3) were used to estimate the effect of different reactive species on esterification. Relative reactivities of Boc-peptide acids were determined using the ratios of the carboxyl components in the resulting peptide resins taking the recovery of Val or Ile as a standard. The results are shown in Figs. 1 and 2. Total yields in the competitive esterification of the polymer with Boc-peptide acid and Boc-amino acid were 72—95%. In series A, each method showed

TABLE 1. AMINO ACID ANALYSES OF RESINS ESTERIFIED WITH BOC-AMINO ACIDS BY COMPETITIVE REACTIONS AND RELATIVE REACTIVITIES OF BOC-AMINO ACIDS

Esterification method (reaction time, h)	Amino acid content (μmol/g-resin)						Relative reactivities (Gly=1.00)

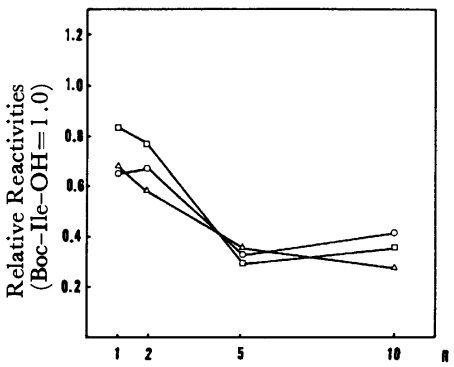

Fig. 2. The influence of the peptide-chain lengths of Boc-oligopeptide acids of series B on the esterification reaction with the chloromethylated polystrene (Boc-Ile-OH was used as a reference for the competitive reactions).
$n=1$, Boc-Leu-OH; $n=2$, Boc-Leu_2-OH; $n=5$, Boc-Ala_2-Leu_3-OH; $n=10$, Boc-Ala_2-Leu_3-Pro_2-Leu_3-OH. —○—, K_2CO_3; —□—, K_2CO_3+18-crown-6; —△—, KF.

the peptide-chain lengths of Boc-peptide acids to decrease the reactivities of their *C*-terminal carboxylates with increase in the number of amino acid residues. In series B, a similar tendency was observed except for Boc-Ala_2-Leu_3-Pro_2-Leu_3-OH, whose secondary structure was estimated to be random coil by the method of Chou and Fasman.[9] That of other Boc-peptide acids ($n=4$, 5, and 8) might be in β-sheet structure.[1] As shown in Fig. 1, an abnormal behavior was observed in the competitive reaction of Boc-Val-OH and Boc-[Tyr(Bzl)-Gly_2-Phe]$_2$-OH with the chloromethylated polystyrene using KF as a catalyst; the amount of Val incorporated was lower (total yield of Boc-Val-OH and Boc-octapeptide, 13.1%) and relative reactivity of Boc-[Tyr(Bzl)-Gly_2-Phe]$_2$-OH higher. Addition of 18-crown-6 to the reaction mixture made the reaction system homogeneous, a similar behavior being observed with methods (1) and (2) (Fig. 1).

Experimental

Relative Reactivities of Boc-amino Acids in Esterification with the Chloromethylated Polystyrene (General Method). Starting with chloromethylated polystyrene (1.00 g; chloromethyl content, 0.89 mmol/g),[10] three-fold equivalents (2.67 mmol) each of Boc-amino acids (Gly, Val, Ile, Leu, Tyr, and Phe) and an equivalent amount of potassium carbonate (8.34 mmol) with the total of the acids were added to 80 ml of DMF. The mixture was allowed to equilibrate at 40 °C in a thermostatted bath (*ca.* 30 min with magnetic stirring), followed by addition of the polymer (1.00 g) and left at 40 °C with stirring. As base and/or catalyst the following compounds were used. Method (2), an equivalent each of potassium carbonate (8.00 mmol) and 18-crown-6 (16.0 mmol). Method (3), an equivalent of anhydrous KF (16.0 mmol). Method (4), an equivalent each of anhydrous KF (16.0 mmol) and 18-crown-6 (16.0 mmol). Portions of the reaction mixture were poured into water at the reaction time given in Table 1. The precipitated resin was filtered off, washed successively with water and methanol in order to remove soluble reactants, and dried *in vacuo* at 50 °C. The resulting resin was subjected to acid hydrolysis with propionic acid–12 M HCl (2 : 1 v/v) for 72 h at 115 °C followed by amino acid analysis.

Relative Reactivities of Boc-oligopeptide Acids in Esterification with the Chloromethylated Polystyrene Using Boc-amino Acid (Val or Ile) as a Reference (General Method). The chloromethylated polystyrene (1.00 g; chloromethyl content, 0.89 mmol/g) was reacted with three equivalents (2.67 mmol) each of Boc-oligopeptide acid and Boc-amino acid in 25 ml of DMF at 40 °C. The reaction times in methods (1), (2), and (3) were 45 h, 24 h, and 45 h, respectively. The work-up was the same as that mentioned above.

Formation of Ketone Diperoxides from Ozonation of *O*-Methyloximes

Yoshikatsu Ito,* Hiroaki Yokoya, Yasutoshi Umehara, and Teruo Matsuura

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received February 8, 1980)

Synopsis. The ozonation of the *O*-methyloximes has been investigated. Besides the corresponding ketones, ketone diperoxides, and *N*-methoxyamides were produced. The stereochemistry of the ketone diperoxides was studied by the NMR technique.

In our previous paper,[1] it has been shown that the ozonation of valerophenone *O*-methyloxime (**1c**) in carbon tetrachloride at −20 °C gives as the major products valerophenone diperoxide (**2c**) and *N*-methoxyamides **4c** and **5c**, in addition to the corresponding ketone **3c**. Erickson *et al.*, however, reported[2] that the ozonation of acetophenone *O*-methyloxime (**1a**) in dichloromethane at −78 °C led to only the carbon–nitrogen double bond cleavage affording the corresponding ketone **3a**. This and our interest in a chemi-energized process occurring from **2c**[3] led us to study the ozonation of *O*-methyloximes in more detail.

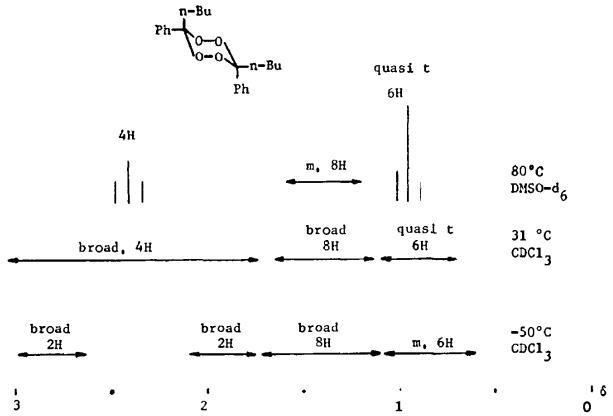
Table 1 shows the results of the ozonation of *O*-methyloximes **1a**—**d** in carbon tetrachloride or dichloromethane at low temperatures. In addition to the corresponding ketones **3a**—**d**, the ketone diperoxides **2a**—**c** and *N*-methoxyamides **4a**—**c** and **5a**—**d** were isolated, as we found previously.[1] In the case of **1d**, however, many by-products were also formed and only benzoic acid was characterizable.

The ketone diperoxides **2b** and **2c** were formed as a mixture of *cis* (**2b**-*c* and **2c**-*c*) and *trans* (**2b**-*t* and **2c**-*t*) isomers, while **2a** was obtained as a single isomer.[4] The yields of the *cis* and *trans* isomers were almost

a) *cis*-Valerophenone diperoxide (**2c**-*c*)



b) *cis*-Propiophenone diperoxide (**2b**-*c*)

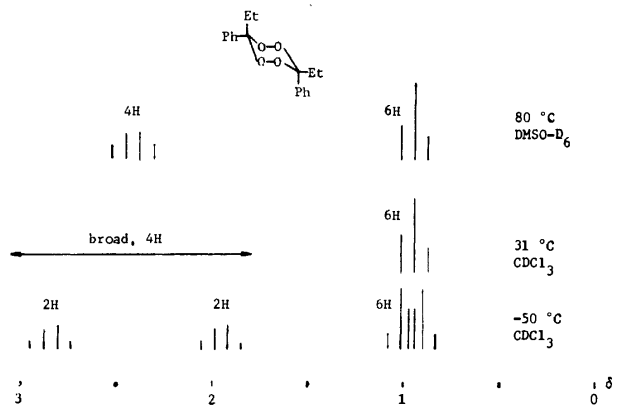


Fig. 1. NMR spectra (100 MHz) of *cis*-propiophenone diperoxide (**2b**-*c*) and *cis*-valerophenone diperoxide (**2c**-*c*) at different temperatures.

equal, *i.e.* **2b**-*t*/**2b**-*c*=1 and **2c**-*t*/**2c**-*c*=1.2. From their NMR spectra at a number of temperatures the higher melting isomers were assigned to be *trans* and the lower melting isomers to be *cis*. Similarly, the stereochemistry of acetophenone diperoxide (**2a**) was assigned to be *trans*.

The chair-to-chair conformational isomerism of acetone diperoxide was studied by Murray and coworkers by the NMR technique.[5] The NMR spectra

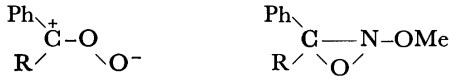
1b (24.0)	CCl_4[a]	6.5	13[d]	51	11	10
1c (5.5)	CCl_4[a]	27	20[d]	34	13	16
1d (23.0)	CCl_4[c]	5.6	0	6	0	10[e]

a) At −20 °C. b) At −78 °C. c) At 0 °C. d) A combined yield of the *cis* and *trans* isomers. e) $PhCO_2H$ (15%) as a by-product.

of the *cis* isomers **2b**-*c* and **2c**-*c* (Fig. 1) indicated that they also underwent the conformational isomerization at room temperature and that the isomerization process was slowed down at low temperature (−50 °C) to the point where the chemical shifts of the axial and equatorial methylene groups can be discerned (Fig. 1. δ: **2b**-c_{eq} 2.85; **2b**-c_{ax} 1.96; **2c**-c_{eq} 2.78; **2c**-c_{ax} 1.92). According to Murray *et al.*,[5] the equatorial methylene group should be more deshielded (larger δ values). At 80 °C the peaks of the axial and equatorial methylene groups completely coalesced due to the rapid conformational isomerization (Fig. 1. δ: **2b**-*c* 2.42; **2c**-*c* 2.41). The *trans* isomers **2a**, **2b**-*t*, and **2c**-*t* showed essentially no dependency of their NMR spectra on temperatures between −50 °C and 140 °C, indicating that each of these *trans* isomers has a rigid conformation, as was found with other *trans* ketone diperoxides.[6] The alkyl substituents of the *trans* peroxides **2b**-*t* and **2c**-*t* can be regarded to be axial on the basis of the small δ values of the methylene groups adjacent to the tetroxane rings (δ: **2b**-*t* 1.62; **2c**-*t* 1.56).

The present reaction would be a convenient method for the preparation of ketone diperoxides which are not easily accessible. For example, we failed to prepare **2c** by the usual procedures for the synthesis of ketone diperoxides,[7] *i.e.*, from ozonolysis of 5,6-diphenyl-5-decene or from the reaction of valerophenone with hydrogen peroxide in the presence of sulfuric acid. As we have suggested previously,[1] a carbonyl oxide **6** seems to be a precursor of the ketone diperoxides **2**. In fact, when the ozonation of **1c** was carried out in the presence of excess acetaldehyde, the formation of **2c** was completely suppressed.[8] An oxaziridine **7** is the most probable intermediate of the *N*-methoxyamides **4** and **5**. Bailey *et al.* isolated the corresponding oxaziridine from the ozonation of *N*-benzylidene-*t*-butylamine in dichloromethane.[9]



6 **7**

Experimental

O-Methyloximes **1a—d** were prepared from the corresponding ketones and *O*-methylhydroxylamine hydrochloride according to the method of Karabatsos and Hsi.[10] Pivalophenone *O*-methyloxime (**1d**) was obtained as colorless crystals from ethanol, mp 64—66 °C. NMR ($CDCl_3$) δ 1.16 (9 H, s, *t*-Bu), 3.69 (3H, s, OCH_3), 6.8—7.6 (5H, m, ArH). IR (nujol) 1480, 1070, 880 cm^{-1}. MS *m/e* 191 (M^+, relative intensity 19), 175 (9), 160 (25), 104 (100), 77 (28), 57 (69), Found: C, 75.53; H, 9.13; N, 7.05%. Calcd for $C_{12}H_{17}NO$: C, 75.35; H, 8.96; N, 7.32%.

The ozonation and isolation procedures with **1c** were described previously.[1] Similar procedures were followed with **1a** (concentration 1.5 g/150 ml of CCl_4, ozonation time 2 h), **1b** (1.6 g/40 ml of CCl_4, 2 h), and **1d** (5.0 g/120 ml of CCl_4, 2 h). The physical and spectral properties of new substances are summarized below. The NMR and IR spectra of **2a**[11] and **5a**[12] were identical with those of the authentic sample.

4a. A colorless oil, bp 44.0—45.5 °C/0.1 mmHg. NMR ($CDCl_3$) δ 2.25 (3H, s, CH_3–CO), 3.66 (3H, s, CH_3O), 7.0—7.55 (5H, m, ArH). IR (neat) 1680 cm^{-1}. MS *m/e* 165 (M^+, 12), 122 (100), 77 (64), 43 (75). Found: C, 65.20; H, 6.70; N, 8.21%. Calcd for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48%.

2b-*t*. Colorless crystals from acetone, mp 136.5—138 °C. NMR ($CDCl_3$ at 31 °C) δ 0.55 (6H, t, J=7 Hz, CH_3) 1.62 (4H, q, J=7 Hz, CH_2), 7.24—7.72 (10 H, m, ArH). The similar NMR spectra were obtained at −50 °C ($CDCl_3$), 80 °C (DMSO-d_6), and 140 °C (DMSO-d_6).

2b-*c*. A colorless viscous oil which resisted to crystallization. NMR ($CDCl_3$ at −50 °C) δ 0.91 (3H, t, J=7 Hz, CH_3), 1.01 (3H, t, J=7 Hz, CH_3), 1.96 (2H, q, J=7 Hz, CH_2), 2.85 (2H, q, J=7 Hz, CH_2), 7.02—7.90 (10H, m, ArH). ($CDCl_3$ at 31 °C) δ 0.94 (6H, t, J=7 Hz, CH_3), 1.8—3.1 (4H, broad, CH_2), 7.27 (10H, broad s, ArH). (DMSO-d_6 at 80 °C) δ 0.94 (6H, t, J=7.5 Hz, CH_3), 2.42 (4H, q, J=7.5 Hz, CH_2), 7.40 (10H, s, ArH).

4b. A colorless oil, bp 51—52 °C/0.1 mmHg. IR (neat) 1675 cm^{-1}. NMR ($CDCl_3$) δ 1.10 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 2.58 (2H, q, J=7 Hz, $CH_3C\underline{H}_2$), 3.70 (3H, s, CH_3O), 7.0—8.1 (5H, m, ArH). MS *m/e* 179 (M^+, 6), 57 (100). Found: C, 67.23; H, 7.52; N, 7.85%. Calcd for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82%.

5b. A colorless oil, bp 49—51 °C/0.1 mmHg. IR (neat) 1640 cm^{-1}. NMR ($CDCl_3$) δ 1.28 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 3.51 (3H, s, CH_3O), 3.72 (2H, q, J=7 Hz, $C\underline{H}_2$), 7.0—7.7 (5H, m, ArH). MS *m/e* 179 (M^+, 7), 105 (100), 77 (100). Found: C. 66.89; H, 7.52; N, 7.80%. Calcd for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82%.

5d. A colorless oil, bp 83—84 °C/0.1 mmHg. IR (neat) 1645 cm^{-1}. NMR ($CDCl_3$) δ 1.55 (9H, s, *t*-Bu), 3.35 (3H, s, CH_3O), 7.2—8.2 (5H, m, ArH). MS *m/e* 207 (M^+, 4), 105 (100), 77 (32), 57 (16). Found: C, 69.31; H, 8.29; N, 6.60%. Calcd for $C_{12}H_{17}NO_2$: C, 69.54; H, 8.27; N, 6.76%.

The physical and spectral properities of **2c**-*t*, **2c**-*c*, **4c**, and **5c** were reported Previously.[1] The temperature dependences of the NMR spectra of the *cis*-diperoxide **2c—c** and the *trans*-diperoxides **2c**-*t* and **2a** were analogous to those of **2b**-*c* and **2b**-*t*, respectively.

Oxidation of Thujopsene with Lead Tetraacetate

Katsumi Yokoi* and Yoshiharu Matsubara

Department of Applied Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashiosaka 577

(Received September 20, 1979)

Synopsis. We inveatigated the oxidation of thujopsene with lead tetraacetate. In the hydrolysis product, two new sesquiterpenoids were found to be afforded: 6α,10,10-trimethyl-4β-acetyltricyclo[4.4.0.0^{1,3}]decane and its $C_{(4)}$-stereoisomer.

It has been reported by Nagahama *et al.*[1] that the lead tetraacetate oxidation of **1** was accompanied by ring contraction; this was a new reaction. However, the structures of the oxidation product were not well-defined. In the course of our investigation of the oxidation, therefore, we have now isolated the components of the oxidation product and defined their structures well on the basis of the MS, IR, and NMR spectra.

Results and Discussion

The reaction was carried out by adding minium trilead tetraoxide to a mixture of thujopsene, **1**, acetic acid, and acetic anhydride. The reaction product was hydrolyzed to give three components (**2**: **3**: **4**=6: 87: 7 in GLC). The hydrolysis product was fractionated by distillation under reduced pressure, and each component was isolated by GLC. Their products are shown in Fig. 1. Compound **4** was identified with authentic widdrol on the basis of the MS, IR, and NMR spectra.

Compound **2** was determined to have a molecular formula of $C_{15}H_{24}O$ on the basis of the MS spectra and the results of the elemental analysis, and it was characterized as a saturated ketone on the basis of the IR (C=O, 1700 cm^{-1}) absorption band. The ^{1}H-NMR spectra revealed the presence of the following functional groups: a *gem*-dimethyl (6H, two s), a tertiary methyl (3H, s), an acetyl (3H, s), a methine (1H, dd), and a methylene of a cyclopropane ring (2H, m). The ketone

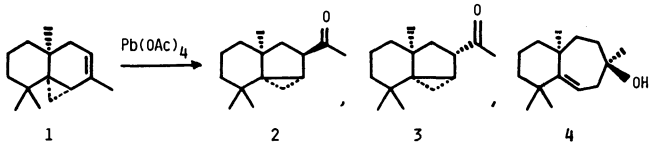

Fig. 1. Oxidation products of thujopsene **1**.

was deduced to be 6α,10,10-trimethyl-4-acethyltricyclo-[4.4.0.0^{1,3}]decane.

Compound **3** was determined to have a molecular formula of $C_{15}H_{24}O$ on the basis of the MS spectra and the results of the elemental analysis; it was characterized on the basis of the close resemblance to most of the fragment ions of the MS spectrum of **2**. Also the ^{1}H-NMR spectra revealed the presence of the same functional groups as **2**. These findness supported the idea that **3** was the $C_{(4)}$stereoisomer of **2**.

In order to define each configuration of the acetyl group and the $C_{(2)}$-methylene of **2** and **3**, the coupling constant of $C_{(4)}$-methine, the variation in the chemical shift of each proton with an increase in the concentration of the shift reagent (Eu(dpm)$_3$: Tris(dipivaloylmethanato)europium(III)), and the NOE were measured in the ^{1}H-NMR spectra (Table 1). As a result, the $C_{(4)}$-methine of **2** revealed double doublet (J=2.5 Hz, 10 Hz), while the $C_{(4)}$-methine of **3** revealed a double quartet (ddd, J=5 Hz, 8.5 Hz, 10 Hz). The chemical shift of the $C_{(10\alpha)}$-methyl of **3** was enlarged further in comparison with those of **2** with an increase in the concentration of Eu(dpm)$_3$. Besides the NOE was observed on **3**, because, when the $C_{(2)syn}$-proton of **3** at 0.33 was irradiated, the integration of the acetyl proton of **3** at δ 2.19 was increased (44% of NOE), while the $C_{(6\alpha)}$-methyl of **3** at δ 1.09 was enlarged (42% of NOE). This behavior showed their structures

Table 1. Variation in the chemical shift for different protons of (**2**) and (**3**) (1×10^{-4} mol in 0.5 ml of $CDCl_3$) with an increase in Eu(dpm)$_3$

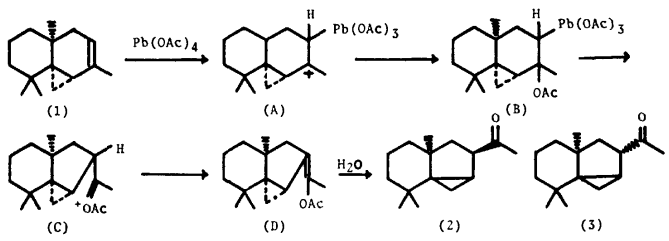

Fig. 2. Mechanism for the formation of **2** and **3**.

to be 6α,10,10-trimethyl-4-acetyltricyclo[4.4.0.0^{1,3}]-decane **2** and its $C_{(4)}$-stereoisomer, **3**.

In the reaction, the formation of the products, **2** and **3**, could be explained by the reaction sequence shown in Fig. 2: firstly, the addition of lead tetraacetate to the olefin of **1** may give an intermediate (**B**); the degration of **B** will give an enol acetate (**D**) (it was difficult to isolate **D**), accompanied by ring-contraction. The resulting stereoisomers (**2** and **3**) may be formed by the hydrolysis of **D**.

Experimental

Materials. Thujopsene, **1**, was obtained by distillation from chinese cedar wood oil (provided by the Takasago Perfumary Co., Ltd.); bp 118—120 °C/10 Torr, $d_4^{25}=0.9316$, $n_D^{25}=1.5019$, $[\alpha]_D^{29}=-77.4°$ (neat), purity in GLC 99%.

Measurements. The MS spectra were measured on a Shimadzu LKB 9000 gas chromatography mass spectrometer (acceleration voltage, 3500V; ionization potential 70 eV). The IR spectra were recorded on a Nihonbunko IRA-2 apparatus (Diffraction Grating Infrared Spectrophotometer). The ^{1}H-NMR spectra were recorded on a Hitachi Parkin-Elmer R-24 (60 MHz) spectrometer, using TMS as the internal standard, unless otherwise mentioned, in $CDCl_3$. The column chromatography depended on silica gel (Wako-gel C-300). The GLC was carried out with a separation column (3 mm×4 m) packed with 5% PEG-20M or 5% OV-17 on Chromosorb AW-DMCS (60—80 mesh).

Reaction of Thujopsene (1) with Lead Tetraacetate. To a mixture of 5 g (0.025 mol) of **1**, 48 g of acetic acid, and 17 g of acetic anhydride, we added 17.2 g of minium trilead tetra oxide in portions over a period of 1.5 h, the temperature being kept below 60 °C. Stirring was then continued for one additional hour. Water was added, and the solution was neutralized with sodium carbonate, filtered, and extracted with benzene. This benzene solution was washed with water again and dried over sodium sulfate. When the solvent was then removed, 6.4 g of a residue were obtained. $n_D^{25}=1.4941$, $d_4^{25}=0.9838$, $EV=10.6$, $[\alpha]_D^{25}=-0.07°$ (neat), The residue (3.5 g) was hydrolyzed with a 2 mol dm^{-3} sodium hydroxide–ethanol solution. After the ethanol had been removed, water and benzene were added with shaking and the organic layer was separated. This organic layer was washed and dried over sodium sulfate. The benzene was then removed; subsequent distillation gave 3.1 g of products which had three components (**2**: **3**: **4**=6: 87: 7). Bp 134—139 °C/2 Torr, $n_D^{25}=1.4975$, $d_4^{25}=0.9836$, $[\alpha]_D^{25}=-0.05°$(neat). Semicarbazone: mp 236—237 °C (dec, from 90% ethanol). A ketone regenerated from the semicarbazone had two components (**2**: **3**=2: 98) in GLC.

6α,10,10-Trimethyl-4β-acetyltricyclo[4.4.0.0^{1,3}]decane (2). Found: C, 81.59; H, 11.05%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.98%. Additivity Parameters for Anodic Peak Potentials in [2.2]Metacyclophanes and Tetrahydropyrene Formation[1]

Koichi TORIZUKA and Takeo SATO*

Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received December 6, 1979)

Synopsis. The first anodic peak potentials $E_{pa}(O_1)$ for sixteen [2.2]metacyclophanes were surveyed in order to correlate the peak potential with the number and position of the alkyl groups. The analysis of the data gives the additivity parameters, which call for cathodic shifts of 0.14 and 0.035 V per methyl group for R_2 or R_5 (5- or 13-position) and for substitution at the rest of the positions respectively. The controlled-potential electrolysis of the representative metacyclophanes gave excellent yields of the corresponding tetrahydropyrenes.

The anodic oxidation of [2.2]metacyclophane and derivatives at the first anodic potential $E_{pa}(O_1)$ have previously been shown[2] to be a highly efficient and selective reaction to give the corresponding 4,5,9,10-tetrahydropyrenes. The current efficiency reached almost 100% as a two-electron process, and the selectivity was far better than the alternative photolytic method.[3] In this investigation, we surveyed the peak potentials, $E_{pa}(O_1)$, for a series of [2.2]metacyclophanes (**1a**—**1p**) to ascertain the effect of alkyl substitution on the one-electron transfer.

The preparation of **1** was carried out by the pyrolysis of disulfone, **3**, which had been obtained from disulfide, **2**. The cyclic voltammetry was determined in acetonitrile containing 0.1 mol dm^{-3} of Bu_4NClO_4(TBAP) at various scan rates. Of the three anodic peaks, the first peak was found to be sensitive to the impurity contained in acetonitrile. Accordingly, we carried out redeterminations for those compounds the data of which had been reported earlier.[2]

The data determined at 250 mV/s are shown in Table 1. The inspection of the data revealed the following facts:

Table 1. Observed and calculated peak potentials E_{pa} (O_1) for compound **1**

Table 2. The scan-rate dependence of the peak potential shifts

Scan rate / mV/s	**1a**/V	**1c**/V	ΔE_{pa}/V	**1f**/V	ΔE_{pa}/V	**1i**/V	ΔE_{pa}/V
50	1.32	1.05	−0.27	1.26	−0.06	1.12	−0.20
100	1.34	1.07	−0.27	1.29	−0.05	1.16	−0.18
250	1.37	1.09	−0.28	1.33	−0.04	1.18	−0.19
500	1.40	1.11	−0.29	1.36	−0.04	1.20	−0.20

a) The introduction of a methyl group at the R_2 and/or R_5 positions causes a significant cathodic shift, amounting to −0.14 V per methyl group.

b) On the other hand, a methyl group at other positions (R_1, R_3, R_4, and R_6) causes less of a cathodic shift. The extent of the cathodic shift is normal for alkylated aromatics.[4] The shift is approximately one-fourth as large as that of R_2 or R_5, namely, −0.07 V for two methyl groups or −0.14 V for four methyl groups. The situation is similar for inner methyl derivatives, **4**, of which C-8, 16 methyl groups show cathodic shifts similar in magnitude to the above.

c) The cathodic shift is essentially similar for ethyl, isopropyl, and *t*-butyl derivatives, as with the corresponding methyl compound.

The predicted E_{pa} values for **1a**—**1p** are shown in Table 1. These were calculated by assuming incremental cathodic-shift changes caused by alkylation on **1a**. Such calculation at the scan of 250 mV/s is derived by means of:

$$E_{pa}(O_1) = 1.37 + m(-0.14) + n(-0.035)$$

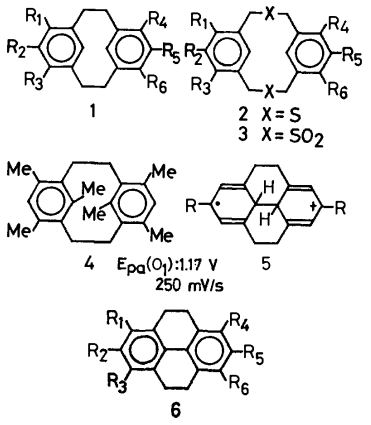
where

m=the number of R_2 and R_5 alkyl groups

n=the number of alkyl groups other than R_2 and R_5.

For example, the effect of R_2 and R_5 methyl groups in compounds **1b**—**1e** is shown by a large cathodic shift, either by −0.14 or −0.28 V. By contrast, the cathodic shifts for **1f** and **1g** are smaller (−0.07 V). Compounds **1h** and **1i** are isomeric and contain both types of substitution, criterion a) and b), thus resulting in the potential shift of −0.21 V.

The anomalously large stabilization effect caused by



R_2 and R_5 alkyl groups is taken as an indication that the O_1 peak corresponds to the formation of the transannular cation radical, **5**, proposed earlier.[2]

The peak potentials vary with the scanning rates. Incremental changes caused by alkyl substitution were, however, found to be constant within the usual scan

rates. Table 2 shows the scan-rate dependence on $E_{pa}(O_1)$ and the shift differences.

When electrolyzed anodically at the potential of O_1, these [2.2]metacyclophanes gave the corresponding 4,5,9,10-tetrahydropyrenes in high yields (Table 3).

Experimental

The following compounds were prepared as previously reported: **1a**,[2a] **1c**,[2a] **1d**,[2b] **1f**,[5] **1g**,[6] **1j**,[2b] **1l**,[7] **1m**,[7] **1n**,[7] and **1p**.[7] The unsymmetrical [2.2]metacyclophanes, **1b**, **1h**, **1i**, **1k**, and **1o**, were prepared by the pyrolysis of disulfone (**3**), which had been obtained from disulfide (**2**). The physical properties and analytical data of these are summarized in Table 4. As a typical example, the preparation of 4,5,6,12,-14-pentamethyl[2.2]metacyclophane (**1o**) will be described.

5,6,7,14,16-Pentamethyl-2,11-dithia[3.3]metacyclophane (2o). A solution of 1,3-bis(chloromethyl)-4,5,6-trimethylbenzene (3.0 g, 13.8 mmol) in 200 ml of benzene and a solution of 1,3-bis(mercaptomethyl)-4,6-dimethylbenzene (2.74 g, 13.8 mmol) in 200 ml of benzene were added simultaneously and at the same rate to boiling ethanol (1 l) containing sodium hydroxide (1.1 g, 28.3 mmol) under good stirring over the course of 27 h. After a usual work-up,[2c] compound **2o** (4.0 g, 85.5%) was obtained as colorless needles; mp 195—196 °C (from benzene–hexane); ^{1}H NMR ($CDCl_3$) δ 2.10s (3H), 2.19s (6H), 2.24s (6H), 3.80s (8H), 6.62s (1H), and 6.77m (2H).

4,5,6,12,14-Pentamethyl[2.2]metacyclophane (1o) Disulfide **2o** (1.27 g) was oxidized to disulfone **3o** (mp>300 °C), using 30% hydrogen peroxide in acetic acid-benzene. The pyrolysis of **3o** used a vacuum pyrolysis furnace similar to that described by Staab *et al.*[8] at 500 °C. The purification of the sublimate gave **1o** (0.75 g, 73%) as colorless plates; mp 197—198 °C; ^{1}H NMR δ 1.77d (4H), 2.31s (15H), 3.32q (4H), 4.22s (1H), 4.28s (1H), and 7.00s (1H).

The controlled potential electrolysis of (**1**) was carried out as has been described before.[2] A typical run is as follows.

Controlled Potential Electrolysis of 1o. A solution of **1o** (55.7 mg, 0.20 mmol) in acetonitrile (60 ml) containing TBAP (0.1 mol dm^{-3}) was electrolyzed at the O_1 potential supplied from a potentiostat until 38.6 C (2.0 F mol^{-1}) had been consumed. A usual work-up and chromatography (silica gel) gave **6o** (55.0 mg, 99.5%) (mp 168.5—170 °C), which was further purified and recrystallized from hexane, thus yielding analytical samples as colorless needles; mp 173—174 °C; ^{1}H NMR δ 2.29s (15H), 2.78s (8H), and 6.90s (1H).

The physical properties and analytical data of the newly prepared tetrahydropyrenes are listed in Table 3.

Naphthalene-sensitized Photolysis of Dibenzoyl Peroxide

Akihide KITAMURA, Hirochika SAKURAGI, Masayuki YOSHIDA,** and Katsumi TOKUMARU*

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305

***Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received March 11, 1980)

Synopsis. Naphthyl benzoates and phenylnaphthalenes were produced, on naphthalene-sensitized photolysis of dibenzoyl peroxide, in different distribution of their isomers from its thermolysis in the presence of naphthalene, suggesting that naphthalene as sensitizer interacts with dibenzoyl peroxide in a specific orientation in the sensitization process.

Aromatic hydrocarbon-sensitized photolysis of dibenzoyl peroxide (BPO) has previously been shown to proceed by way of a singlet exciplex.[1,2] Although most photosensitized reactions are supposed to take place without any chemical change of sensitizers, the present work is concerned with the products from naphthalene-sensitized photolysis of BPO, particularly with the fate of the sensitizer.

Thus, in the sensitization process, the excited sensitizer molecule will take a favourable orientation with respect to the peroxide molecule to form efficiently an exciplex, which will subsequently undergo cleavage of the peroxide moiety into free radicals. Therefore, immediately after the cleavage, the resulting free radicals will attack the sensitizer molecule, still located in a close proximity of the radicals in a specific orientation, to give reaction products in a different distribution from random encounters of the free radicals with the sensitizer molecules. The investigation of these reaction products will give insight into the favourable orientation of the sensitizer and peroxide molecules in the exciplex, and this attempt is described below.

Results and Discussion

A solution of BPO (0.03 M) and naphthalene (0.04 M) in benzene was irradiated under nitrogen atmosphere at room temperature with a 400-W high pressure mercury lamp through a Pyrex wall. For comparison, BPO (0.03 M) was allowed to decompose thermally in the presence of naphthalene (0.04 M) in benzene at 80 °C. The products were quantitatively analyzed by GLPC. The results are summarized in Table 1.

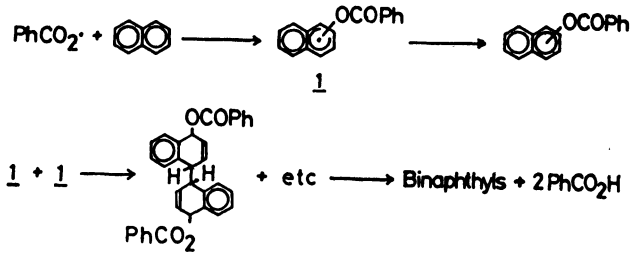
TABLE 1. YIELD OF PRODUCTS IN PHOTOLYSIS AND THERMOLYSIS OF DIBENZOYL PEROXIDE IN THE PRESENCE OF NAPHTHALENE IN BENZENE

Product	Yield[a]	
	Photolysis	Thermolysis
Biphenyl	0.28	0.40
Phenyl benzoate	0.23	0.029
1-Phenylnaphthalene	0.036	0.006
2-Phenylnaphthalene	0.011	0.004
1-Naphthyl benzoate	0.036	0.013
2-Naphthyl benzoate	0.007	0.013
Benzoic acid	0.15[c]	
Naphthalene[b]	0.77	0.70
1,1′-Binaphthyl[b]	0.014	0.003
1,2′-Binaphthyl[b]	0.009	0.003
2,2′-Binaphthyl[b]	0.016	0.008

a) Yields in mol/mol peroxide unless otherwise noted. Average values of data obtained by duplicate runs. b) Yields in mol/mol naphthalene. c) Determined by isolation.

Production of biphenyl, phenyl benzoate, and benzoic acid is reasonably understood by a mechanism previously postulated.[3] Thus, the peroxide moiety decomposes through simultaneous two-bond cleavage into a benzoyloxyl radical and a phenyl radical, which subsequently undergo geminate recombination into phenyl benzoate or diffusion out of the solvent cage to react with benzene finally affording biphenyl and benzoic acid.

As Table 1 shows, it is remarkable that the photolysis produced larger amounts of naphthyl benzoates (1-naphthyl and 2-naphthyl benzoate) and phenylnaphthalenes (1-phenyl- and 2-phenylnaphthalene) than the thermolysis. Moreover, among the above compounds 1-naphthyl derivatives were produced in several times higher yields than their corresponding 2-naphthyl derivatives in the photolysis, in contrast with the thermolysis which gave nearly equal amounts of 1-naphthyl and 2-naphthyl derivatives. A possibility that this fact would be due to more rapid change of the resulting 2-naphthyl benzoate and 2-phenylnaphthalene than their respective 1-naphthyl derivatives under the photolytic conditions was eliminated by control experiments.



It is certain that naphthyl benzoates result from addition of benzoyloxyl radicals to naphthalene followed by loss of a hydrogen atom from the resulting cyclohexadienyl radicals (**1**).[4] Phenylnaphthalene must be similarly formed through addition of phenyl radicals to naphthalene. Production of 1,1′-, 1,2′-, and 2,2′-binaphthyl is presumably through recombination of the cyclohexadienyl radicals (**1**) followed by elimination of two moles of benzoic acid for each mole of binaphthyls formed.[4]

As mentioned above, it is reasonably supposed that when the two-bond cleavage of the peroxide moiety in the exciplex generates simultaneously benzoyloxyl and phenyl radicals in the proximity of the naphthalene

molecule, which has worked as sensitizer, these radicals will be captured by the naphthalene molecule in competing with their diffusion out of the solvent cage into the bulk of the solvent benzene. This reasoning can explain the formation of higher yields of phenylnaphthalenes and naphthyl benzoates from the photolysis than from the thermolysis, in which these compounds would result from random encounters of the radicals and naphthalene. Furthermore, the aforementioned finding that the production of higher yields of 1-phenylnaphthalene and 1-naphthyl benzoate than their respective 2-naphthyl derivatives from the photolysis might suggest that, immediately after the cleavage of the peroxide moiety, the radical centres of benzoyloxyl and phenyl radicals would be located closer to the C-1 carbon of naphthalene than to the C-2 carbon. This orientation can be taken as reflecting the conformation of the exciplex, as supposed by the construction of the molecular model, where the aromatic nucleus of the peroxide would overlap with the naphthalene molecule and the C-1 ring carbon of the peroxide would be close to the C-1 carbon of the naphthalene.

Experimental

Photolysis and Thermolysis of Dibenzoyl Peroxide with Naphthalene in Benzene. A solution of dibenzoyl peroxide (3.00 g, 0.012 mol) and naphthalene (2.00 g, 0.016 mol) in benzene (400 ml) was irradiated under nitrogen atmosphere for 2.3 h (five times half-life periods determined by iodometry) by a 400-W high pressure mercury lamp immersed in a Pyrex cooling well. Thermolysis was carried out at a half scale of photolysis at 80 °C in an oil bath for 21.7 h (five times half-life periods) under nitrogen gas bubbling. After the reaction was completed, the solution was concentrated to one-tenth of its original volume. Naphthalene, biphenyl, phenylnaphthalenes, naphthyl benzoates, and binaphthyls were determined quantitatively by GLPC. Benzoic acid was isolated by extraction with aqueous sodium hydrogencarbonate solutions and determined by gravimetry.

Irradiation of Naphthyl Benzoates in Benzene. A solution of 1-naphthyl benzoate (35.7 mg, 0.14 mmol) and 2-naphthyl benzoate (77.4 mg, 0.31 mmol) in benzene (40 ml) was similarly irradiated by a 400-W high pressure mercury lamp for 2.4 h. GLPC analysis of the irradiation mixture revealed the ratio of remaining 1-naphthyl benzoate/2-naphthyl benzoate to be 0.25.

Synthesis of 1-Benzothiopyrylium Perchlorates and Related Compounds

Hiroyuki NAKAZUMI* and Teijiro KITAO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received February 5, 1980)

Synopsis. The blue colored 1-benzothiopyrylium perchlorates were synthesized by the reduction of thiocoumarins with lithium aluminium hydride followed by the treatment with acid. A number of new thiocarbonyl derivatives of thiocoumarins and thiochromones were also synthesized, the spectral characterization of which has been described.

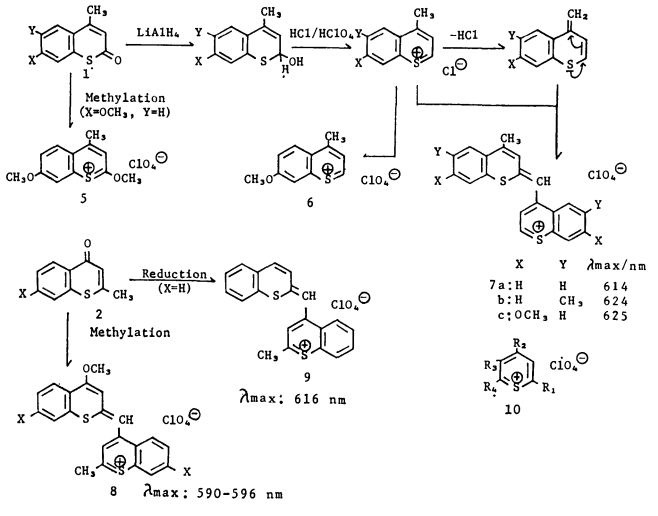
In our previous papers, we have reported the syntheses and methylation of 2*H*-1-benzothiopyran-2-ones (thiocoumarins) (**1**) and 4*H*-1-benzothiopyran-4-ones (thiochromones) (**2**), an isomer of **1**.[1,2]

In this paper, we wish to report (i) the reduction of thiocoumarins (**1**) with lithium aluminium hydride ($LiAlH_4$) and synthesis of 2*H*-1-benzothiopyran-2-thiones (**3**) and 4*H*-1-benzothiopyran-4-thiones (**4**) as reactants to prepare 1-benzothiopyrylium salts, and (ii) spectral characterization of **3** and **4** to distinguish them.

Results and Discussion

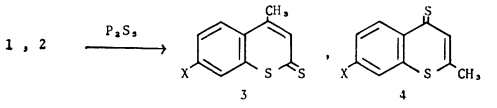
Preparation of 1-Benzothiopyrylium Perchlorates (7). In the previous paper,[2] we reported that the methylation of **2** with dimethyl sulfate gave the dimerized product **8**, while in the case of isomeric thiocoumarin **1** (X=OCH_3), none of the dimerized product but *O*-methylated product **5** was isolated by the same reaction.

We now found that a blue colored 1-benzothiopyrylium perchlorate **7** could be obtained in yields of 22—72%, by the reduction of thiocoumarin **1** with $LiAlH_4$ followed by the treatment with acid. Similar reduction of **2** with aluminium hydride or $LiAlH_4$ also gave an isomeric blue colored 1-benzothiopyrylium salt **9**.[2] Mckinnon[3] has already reported that some of thiopyrylium salts (**10**) were obtained from 2*H*(or 4*H*)-thiopyran-2(or 4)-ones under the same conditions. In the case of **1c** (X=OCH_3), both of 1-benzothiopyrylium salts **7c** and **6**, as the precursor of **7c**, were isolated in yields of 30 and 39%, respectively. Compounds **7a** and **6** also could be obtained by the cyclization of 4-(phenylthio)-2-butanones with PPA or perchloric acid.[4] A possible mechanism for the formation of **7** is given in a similar manner as described in the case of thiochromones (Scheme 1). It is shown that the condensation takes place between 4-methyl group of **1** and 2-carbon atom of the other molecule in this reaction.



Scheme 1.

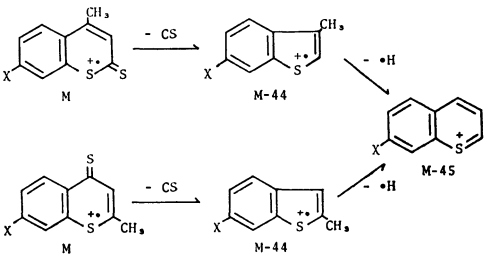
On the other hand, it is also known that the oxidation of 2*H*(or 4*H*)-thiopyran-2(or 4)-thiones give thiopyrylium salts (**10**). Then, we synthesized a number of new thiocarbonyl derivatives **3** and **4** as reagents to prepare **7** and **9**. Compounds **3** and **4** were obtained by the usual reaction of **1** and **2** with P_2S_5, respectively (Scheme 2), but an attempt to prepare **7** from **3** was failed. That is, the oxidation of **3a** with hydrogen peroxide gave an undetermined product, which showed the two λ_{max}'s of 579 and 626 nm in acetone solution and complex peaks in the NMR spectra.



Scheme 2.

Spectral Characteristics. The spectral data of **3** and **4** are summarized in Table 1. We proposed some spectral characterization of **1** and **2** to distinguish. From **3** and **4**, the additional distinction between thiocoumarin and thiochromone nuclei became possible as follows. In the NMR spectra, the characteristic deshielding effect of benzenoid proton at the 5-position of **4** was observed similar to that of thiochromones (**2**). The proton showed the chemical shift at *ca.* 9.00 ppm. In the series of thiocoumarin **3**, however, such a proton showed the chemical shift at *ca.* 7.80 ppm. This difference may be utilized to distinguish them as well as that of **1** and **2**. The proton at the 3-position of both derivatives **3** and **4** showed the chemical shift in the aromatic region (above 7.00 ppm), compared to that of **1** and **2** in the range of 6.48—6.75 ppm, except for **3c** and **4c**.

In the mass spectra, the major fragmentation pathway for each of **3** and **4** was elimination of C=S, followed by the loss of a hydrogen atom leading to the formation of 1-benzothiopyrylium ion (Scheme 3). The series of



Scheme 3.

a) In EtOH.

thiochromone **4** were characterized by abundant molecular ion as the base peak and the M−1 fragment ion, formula of which was not assigned. In the case of **3**, such an M−1 fragment ion was very small (below 12 (rel. intensity)). It was observed that in the case of **3** the M−44 fragment ion was much stronger than that of M−45. The M−40 fragment ion was not observed in **4**, which was found characteristically in the mass spectra of **2**.[1]

The absorption maxima of the longest wavelength of **3** were longer by *ca.* 10 nm than those of **4**.

Experimental

All the melting points are uncorrected. ^{1}H-NMR spectra were taken on a Hitachi R-24A spectrometer with tetramethylsilane as an internal standard. Absorption spectra were obtained with a Hitachi EPS-3T spectrometer. Mass spectra were taken on a Hitachi RMU-6E mass spectrometer operating at 80 eV. Elemental analyses were performed on a Yanaco CHN recorder MT-2.

The Reduction of ***1*** *with Lithium Aluminium Hydride.* Powdered $LiAlH_4$ (0.1 g) was added to a stirred solution of **1a** (1.0 g) in anhydrous diethyl ether (100 ml) at room temperature. After 1 h, ethyl acetate (2 ml) was added, and after 10 min, addition of 10% dilute HCl (10 ml) gave a blue colored mixture. After 30 min, diethyl ether was evaporated below 30 °C. The residue was dissolved in glacial acetic acid (30 ml) and 60% perchloric acid (0.5 ml) was added. After standing for 20 h at room temperature, the mixture was diluted with diethyl ether, and the resulting solid was separated and washed with a mixture of acetone and benzene (1: 2) and EtOH. The crude product was recrystallized from glacial acetic acid (80 ml) containing a small amount of perchloric acid to give **7a** (X=H, Y=H). **7a**:[4] 72%, NMR (CF_3COOH): δ=3.30 (3H, s), 5.95 (2H, s), and 7.50—9.10 (≈10H, m). Found: C, 57.01; H, 3.77%. Calcd for $C_{20}H_{15}O_4ClS_2$: C, 57.35; H, 3.58%. λ_{max} (acetone): 614 nm (ε 8.30×10^4); **7b** (X=H, Y=CH_3): 22%, NMR (CF_3-COOH): δ=2.83 (6H, s), 3.30 (3H, s), 5.88 (2H, s), and 8.0—8.8 (≈8H, m). Found: C, 58.61; H, 4.28%. Calcd for $C_{22}H_{19}O_4ClS_2$: C, 59.13; H, 4.26%. λ_{max} (acetone): 624 nm (ε 4.3×10^4). In the case of **1c** (X=OCH_3), the residue from diethyl ether was washed with glacial acetic acid (50 ml) containing perchloric acid and dissolved in glacial acetic acid (100 ml) at 70 °C. After cooling, diethyl ether was added to this solution, and then **7c** was isolated in 30% yield. The other 1-benzothiopyrylium salt **6** was isolated in 39% yield from the filtrate (washed with AcOH). **7c**: NMR (CF_3COOH): δ=3.20 (3H, s), 4.12 (3H, s), 4.22 (3H, s), 5.65 (2H, s), and 7.50—9.00 (≈8H, m). Found: C, 55.13; H, 4.03%. Calcd for $C_{22}H_{19}O_6ClS_2$: C, 55.17; H, 3.97%. λ_{max} (acetone): 625 nm (ε 6.2×10^4); **6**:[4] dec 200 °C (lit, 205 °C), NMR (CF_3COOH): δ=3.25 (3H, s), 4.20 (3H, s), 7.50—8.00 (2H, m), 8.35 (1H, d, J=10 Hz), 8.70 (1H, d, J=10 Hz), and 9.60 (1H, d, J=10 Hz). Found: C, 45.52; H, 3.85%. Calcd for $C_{11}H_{11}O_5SCl$: C, 45.44; H, 3.79%. λ_{max} (acetone): 415 nm (ε 6.4×10^3).

Oxidation of ***3a*** *with Hydrogen Peroxide.* 30% Hydrogen peroxide (0.7 ml) was added to a suspended solution of **3a** (0.5 g) in acetic acid (27 ml), and the mixture was stirred at 30 °C. After 2 h, perchloric acid (0.8 ml) was added to the solution. Dilution with diethyl ether gave a crude product, which was recrystallized from acetic acid. Found: C, 56.35; H, 3.06%. NMR (CF_3COOH): δ=2.40—3.40 (m) and 7.50—9.50 (m).

2H-1-Benzothiopyran-2-thiones (3) and 4H-1-Benzothiopyran-4-thiones (4). 4-Methyl (thiocoumarin) **1a**[5] (1.35 g, 7.7 mmol) and P_2S_5 (7.5 g, 34 mmol) were added to benzene (50 ml). The mixture was heated under reflux for 7 h and was filtered. The filtrate was evaporated, and the residue was extracted with diethyl ether. The extract was evaporated, and the resulting solid was recrystallized from EtOH to give **3a** (1.1 g, 74%). The other **3** and **4** were obtained similarly. **3a**:[6] mp 111—112 °C, Found: 62.86; H, 4.26%. Calcd for $C_{10}H_8S_2$: C, 62.50; H, 4.17%. **3b**: 67%, mp 136—137 °C, Found: C, 64.03; H, 4.94%. Calcd for $C_{11}H_{10}S_2$: C, 64.08; H, 4.85%. **3c**: 42%, mp 150—151 °C. Found: C, 59.10; H, 4.57%. Calcd for $C_{11}H_{10}OS_2$: C, 59.46; H, 4.50%. **4a**:[7] 40%, mp 107—108 °C, Found: C, 62.57; H, 4.26%. Calcd for $C_{10}H_8S_2$: C, 62.50; H, 4.17%. **4b**: 15%, mp 134—136 °C, Found: C, 63.87; H, 4.76%. Calcd for $C_{11}H_{10}S_2$: C, 64.08; H, 4.85%. **4c**: 21%, mp 138—140 °C, Found: C, 58.97; H, 4.56%. Calcd for $C_{11}H_{10}OS_2$: C, 59.46; H, 4.50%.

The Stoichiometry and Promoter Role of Chlorosulfuric and Fuming Sulfuric Acids for α-Halogenation of Aliphatic Acid[1)]

Yoshiro OGATA* and Shinya WATANABE

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 27, 1979)

Synopsis. The stoichiometry for the chlorosulfuric acid promoted α-halogenation and the role of fuming sulfuric acid instead of chlorosulfuric acid have been studied. In the α-bromination with molecular bromine, 1 mol of halogen afforded 2 mol of aliphatic α-bromo acid just as the α-iodination, but it is different from α-chlorination which affords only 1 mol of α-chloro acid. Fuming sulfuric acid instead of chlorosulfuric acid was found to be effective for α-bromination, but the yield was lower, while no α-iodination was observed with fuming sulfuric acid.

We have reported a novel method for the preparation of aliphatic α-halo acids by the reaction of molecular halogen in the presence of strong acid, *e.g.*, $ClSO_3H$,[2)] through probable intermediary formation of ketenes.[3)]

$$RR'CHCO_2H + ClSO_3H \overset{\text{fast}}{\rightleftharpoons} RR'C{=}C{=}O + HCl + H_2SO_4 \quad (1)$$

$$RR'C{=}C{=}O + X_2 \overset{\text{slow}}{\longrightarrow} \underset{\mathbf{1}}{RR'CXCOX} \quad (2)$$

The product in iodination (**1**, X=I) was found to regenerate iodine.[2g)]

$$RR'CXCOX + H_2SO_4 \longrightarrow RR'CXCO_2H + HX + SO_3 \quad (3a)$$

$$2HX + SO_3 \text{ (or } ClSO_3H) \longrightarrow X_2 + H_2O + SO_2 \ (+HCl) \quad (3b)$$

Hence 1 mol of iodine can give 2 mol of α-iodo acid (Eq. 4), but the stoichiometry is unknown for bromination and chlorination.

$$RR'CHCO_2H + 0.5I_2 + ClSO_3H \longrightarrow RR'CICO_2H + HCl + 0.5SO_2 + 0.5H_2SO_4 \quad (4)$$

Also we found that fuming H_2SO_4 could be used as an acidic promoter for the α-chlorination, but nothing is known about the yield of α-bromination and α-iodination, when fuming H_2SO_4 is used instead of $ClSO_3H$. The present note discloses these obscurities in the halogenation.

Stoichiometry of Bromination. It is known that HBr is oxidized by $ClSO_3H$ to form Br_2,[4)] so that Br_2 formed may be used again for the bromination. In fact, we confirmed that 1 mol of Br_2 can give *ca.* 2 mol of aliphatic α-bromo acid as shown in Table 1 (Runs 1, 4, and 5). Hence the stoichiometry of bromination is analogous to that of iodination (Eq. 4).

$$RR'CHCO_2H + ClSO_3H + 0.5Br_2 \longrightarrow RR'CBrCO_2H + HCl + 0.5H_2SO_4 + 0.5SO_2 \quad (5)$$

Runs 4 and 5 imply that an additional amount of aliphatic acids is consumed by the side reaction with $ClSO_3H$[5)] (*e.g.*, α-sulfonation), but since there is little difference between the yields in Runs 4 and 5, the rate of α-bromination should be faster than the side reaction.

On the other hand, unless excess aliphatic acid and $ClSO_3H$ based on Eqs. 4 and 5 are used, the yield of iodination is rather low; *e.g.*, Run 8 gives 43% and Run 9 gives 55% of iodo acid, probably because the rate of iodination is lower than that of bromination and comparable to that of the side reaction.[2h)] But when excess aliphatic acid and excess $ClSO_3H$ to iodine are used (Run 7), the yield of α-iodination based on the used iodine increases in spite of the increased side reaction.

When a mixture of halogen and aliphatic acid in a stoichiometric ratio according to Eqs. 4 and 5 was used,

Table 1. Yields of α-halogenation of aliphatic acids[a)]

14	0.2	—	0.2	—	0.13	0.0[b)]	
15	1.7	—	0.15	—	0.6	0.0	

a) The yields were calculated on the basis of molecular halogen according to the stoichiometry of Eqs. 4 and 5.
b) Ref. 2b. c) Ref. 2f.

the yield of bromination (Run 1) was higher (88.9%) than the yield of iodination (54.5%) under analogous conditions. This is ascribed to the higher electrophilic reactivity of bromine than iodine toward C=C bond of ketene as apparent from our previous kinetic data.[2h]

Under conditions of $2[Br_2]_0 > [ClSO_3H]_0$ (Runs 2, 3 and 6), the molar yield of α-bromo acid is approximately equal to the moles of $ClSO_3H$ used, whereas the molar yield of α-chloro acid is *ca.* four fold of the moles of $ClSO_3H$ used in spite of the otherwise analogous reaction conditions.[2e] This phenomenon is tentatively explained by the following mechanism for chlorination.

$$RR'CClCOCl + RR'CHCO_2H \rightleftharpoons RR'CClCO_2H + RR'CHCOCl \quad (6a)$$

$$RR'CHCOCl \longrightarrow RR'C{=}C{=}O + HCl \quad (6b)$$

Here, α-chloroacyl chloride, which has been formed through addition of Cl_2 to ketene (Eqs. 1 and 2), can convert unreacted aliphatic acid into acyl chloride (Eq. 6a);[6] the acyl chloride thus formed is known to give again ketene (Eq. 6b),[7] which should react with Cl_2, giving again α-chloroacyl chloride.[2f] Thus only catalytic amount of $ClSO_3H$ can give a high yield of α-chloro acid because of the easier elimination of HCl from acyl chloride (Eq. 6b). On the other hand, the oxidation of α-bromoacyl bromide with chlorosulfuric acid affording Br_2 occurs at 80 °C (Eq. 3) because of the lower oxidation potential of Br^- (+1.066 V for $Br^- \rightarrow 1/2\ Br_2$; +1.358 V for $Cl^- \rightarrow 1/2\ Cl_2$); hence the bromination obeys the stoichiometry of Eq. 5, regenerating Br_2.

Bromination and Iodination with Fuming Sulfuric Acid as a Promoter. As has been observed with α-chlorination,[2a,d] the α-bromination could be carried out with fuming H_2SO_4 (Runs 10 and 11) *via* a ketene formed as shown in Eq. 7.

$$RR'CHCO_2H + SO_3 \rightleftarrows RR'C{=}C{=}O + H_2SO_4 \quad (7)$$

Since 30% fuming H_2SO_4 is expressed as H_2SO_4–$0.5SO_3$, the yield 53% of α-bromo acid in Run 11 corresponds to the moles of SO_3 contained in fuming H_2SO_4 used.

On the other hand, no iodination occurred with fuming H_2SO_4; this is ascribed to the easy decomposition of α-iodo acid with fuming H_2SO_4. In fact, when 15 mmol of fuming H_2SO_4 was introduced into the 1,2-dichloroethane solution of 4.2 mmol of α-iodobutyric acid, 0.63 mmol of iodine were easily liberated at room temperature after 5 min, but only 0.016 mmol of iodine were liberated with $ClSO_3H$. Similar decomposition giving I_2 was observed with α-iodobutyryl chloride and fuming H_2SO_4.

Also the lower yield of bromination with fuming H_2SO_4 than that with $ClSO_3H$ may be due to the slower yet noticeable decomposition of α-bromoacyl bromide by fuming H_2SO_4. Indeed, 1.8 mmol of α-bromopropionyl bromide mixed with 5 mmol of fuming H_2SO_4 gave 0.42 mmol of bromine and 0.23 mmol of α-bromopropionyl bromide at 80 C° after 30 min. But 1.4 mmol of α-bromopropionyl bromide mixed with 5 mmol of $ClSO_3H$ gave only 0.05 mmol of bromine and 0.78 mmol of α-bromopropionyl bromide at 80 °C after 30 min.

On the other hand, no molecular chlorine was detected in the reaction of chloroacetyl chloride ($CH_2ClCOCl$) with fuming H_2SO_4 or $ClSO_3H$, hence chlorine as acyl chloride produced during chlorination cannot be recycled by oxidation with $ClSO_3H$.

Experimental

Materials. Commercial first grade octanoic acid (bp 147—148 °C/35 mmHg), butyric acid (bp 73—74 °C/20 mmHg) and chlorosulfuric acid (bp 86—88 °C/33 mmHg) were distilled before use. Commerical first grade bromine, iodine, chloroacetyl chloride, and fuming H_2SO_4 were used without futher purification. α-Iodobutyric acid (mp 39—40 °C) and α-iodobutyryl chloride (bp 36—38 °C/0.38 mmHg) were prepared in thionyl chloride by the literature method.[8] α-Bromopropionyl bromide (bp 154—155 °C) was prepared by the literature method.[9] Methyl esters of those aliphatic acids had single GLC peaks. The physical properties of methyl α-bromooctanoate were: bp 136—138 °C/24 mmHg; NMR (CCl_4): δ 3.71 (s, 3H, OCH_3), 4.09 (t, J=7.8 Hz, 1H, α-H). The physical properties of other products were reported previously.[2f,h]

Products. A 1,2-dichloroethane solution (50 ml) containing aliphatic acid and halogen was thermostated at 80 °C and $ClSO_3H$ (or fuming H_2SO_4) was introduced and heated at 80 °C for 2 h. After an appropriate time, 2 ml of the solution was treated with $Na_2S_2O_3$ to remove halogen, and esterified by an ethereal solution of diazomethane.

The yield was measured by means of GLC using a Yanagimoto GCG-550 gas chromatograph equipped with a H-flame ionization detector employing a copper column 3 mm × 100 cm packed with PEG 20 M (10%) on Chromosorb WAW (60—80 mesh) with methyl caprate as an internal standard. The isolated methyl α-bromooctanoate was identified by GLC and NMR (a 60 MHz Hitachi R-24 B NMR spectrometer).

Photoinduced Decomposition of Peracetic Acid in Isopropylbenzene[1)]

Yoshiro OGATA* and Kohtaro TOMIZAWA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 16, 1980)

Synopsis. Irradiation of peracetic acid in isopropylbenzene with 254 nm and over 290 nm lights gave as aromatic products mainly *t*-butylbenzene, 2-phenyl-2-propanol, and 2,3-dimethyl-2,3-diphenylbutane. The yield of *t*-butylbenzene was higher in 254 nm photolysis than that with >290 nm, while the yield of hydroxylated aromatics, *i. e.*, 2-phenyl-2-propanol, was much higher with >290 nm than that with 254 nm. The distribution of products was little affected by the intensity of light. These results are discussed by a mechanism involving radicals of different reactivity derived from peracetic acid decomposition.

As reported by us previously, the photolysis of peracetic acid in aromatic hydrocarbons gives fairly stable radicals (*e.g.*, benzyl radical), which in >290 nm photolysis react with peracetic acid through an induced reaction to give hydroxylated product (*e.g.*, benzyl alcohol), but in 254 nm photolysis the contribution of this induced decomposition was less than that at >290 nm.[2-4)]

The change of decomposition rate of peracid with changing light intensity affects the rate of radical formation but affects little the distribution of products.[4)] Therefore, the marked difference in yields in 254 nm and >290 nm photolyses may depend on the wavelength.[4)]

In this paper, we selected isopropylbenzene because α-H-atom of isopropylbenzene is easily abstracted to give a stable radical, $PhMe_2C\cdot$; this solvent is suitable for examination of the possibility of exciplex formation.

Results and Discussion

The photolysis of peracetic acid (**1**) in isopropylbenzene was carried out with three sorts of light sources, *i.e.*, a 30 W low-pressure Hg lamp (254 nm light), a 300 W (>290 nm light), and a 1 kW high-pressure Hg lamp (>290 nm light). Table 1 shows the product yields which are average of six runs at $1.2—30.9\times10^{-2}$ M peracid concentration. These products were identified by GLC and GC-MS in comparison with their authentic samples.

Formed butylbenzenes (side chain methylation products) are consisted of *s*- and *t*-butylbenzene, the ratio of yields for *s*: *t* being 1: 5—7. The low ratio is due to the easier abstraction of tertiary H-atom of the side chain than that of primary H-atom. Isopropyltoluenes (cymenes), which were formed by an attack of methyl radical on the ring, gave yields of three isomers in the order; ortho>meta≈para at both 254 nm and >290 nm.

2-Phenylpropanols were formed by side chain hydroxylation. The yield of 2-propanol was much higher than 1-propanol. Isopropylphenols were obtained by hydroxylation of the ring in the order of yield: ortho≳para>meta. 2,3-Dimethyl-2,3-diphenylbutane was formed by the coupling of radical $PhMe_2C\cdot$; furthermore, an adduct of radical $PhMe_2C\cdot$ to the ring, $PhMe_2C-C_6H_4-CHMe_2$, was detected by GC-MS (see Experimental).

Table 1. Products and yields in photolysis of peracetic acid (**1**) in isopropylbenzene (**2**)[a)]

Isopropylphenols[d)]	3.9	3.5	1.4
2,3-Dimethyl-2,3-diphenylbutane	24.6	31.1	28.1

a) The average of six runs. b) (Mol of product/mol of decomposed **1**) × 100, except with oxygen, ethane, and 2,3-dimethyl-2,3-diphenylbutane, for which this figure is doubled. c) Total amounts of *s* and *t*-isomers. d) Total amounts of ortho, meta, and para-isomers. e) Total amounts of 2-phenyl-1-propanol and -2-propanol. f) This value containes that of $PhMe_2C-C_6H_4-CHMe_2$.

In this photolysis, there were little time dependence within 80% conversion of **1** and little effect of the peroxy acid concentration on the product yields, except for 2,3-dimethyl-2,3-diphenylbutane, a dimerization product of $PhMe_2C\cdot$, yield of which increased (≈10%) with decreasing peroxy acid concentration. This decrease of peracid concentration favors the fraction of addition of $PhMe_2C\cdot$ to isopropylbenzene to form $PhMe_2C-C_6H_4-CHMe_2$ rather than coupling of $PhMe_2C\cdot$ with other radicals.

The half-times for decomposition of peracetic acid depend on the lamp in the order: 1 kW(>290 nm)<30 W(254 nm)<300 W(>290 nm); *e.g.*, *ca.* 2 h with a 1 kW lamp(>290 nm), *ca.* 4 h with a 30 W lamp(254 nm), and *ca.* 8 h with a 300 W (>290 nm) at 2.19×10^{-1} M peracid. The highest concentration of radicals is expected with a 1 kW lamp.

As apparent from Table 1, the product distribution with >290 nm(1 kW) is similar to that with >290 nm(300 W), but different from that with 254 nm; these results are inconsistent with the rate of peroxy acid decomposition, *e.g.*, the yields of butylbenzenes were higher at 254 nm than those at >290 nm, but the yields of 2-phenylpropanols were reversed. Therefore, this discrepancy between the yields and the rate of peracid decomposition suggests that, even in isopropylbenzene, the product distribution depends on the wave length rather than the light intensity.

This is explicable by the difference of excited species, *i.e.*, aromatic solvent which is in large excess is mainly excited with 254 nm light, transferring the excited energy to peroxy acid (Eqs. 1—3), but peracetic acid is excited directly by >290 nm light (Eq. 4), in view of no absorbance of >290 nm light by aromatics.

$$[PhCHMe_2] \xrightarrow{h\nu\ (254\ nm)} [PhCHMe_2]^* \qquad (1)$$

$$[PhCHMe_2]^* + CH_3CO_3H \longrightarrow PhCHMe_2 + [CH_3CO_3H]^* \quad (2)$$

$$[CH_3CO_3H]^* \longrightarrow CH_3CO_2\cdot + HO\cdot \longrightarrow CH_3\cdot + CO_2 + HO\cdot \quad (3)$$

$$CH_3CO_3H \xrightarrow{h\nu\,(>290\ nm)} CH_3CO_2\cdot + HO\cdot \longrightarrow CH_3\cdot + CO_2 + HO\cdot \quad (4)$$

Active species generated *via* Eqs. 1—3 with 254 nm light are identical with those *via* Eq. 4 with >290 nm light. Therefore, assuming that all products are formed *via* these species, the product distribution should be similar in 254 nm and >290 nm photolyses, but this is not the case (Table 1). The higher yield of methylated aromatics with 254 nm may be explained by the formation of a sort of exciplex (Eqs. 5—6).[4]

$$[PhCHMe_2]^* + CH_3CO_3H \longrightarrow [PhCHMe_2\cdot CH_3CO_3H]_{ex} \quad (5)$$

$$[PhCHMe_2\cdot CH_3CO_3H]_{ex} \longrightarrow PhCMe_3 + CO_2 + H_2O \quad (6)$$

On the other hand, a main path for *t*-butylbenzene at >290 nm may be radical coupling between $PhMe_2C\cdot$ and Me·.

The reactivity of radical HO· is higher than that of Me·; *i.e.*, both the H-abstraction by HO· and the addition of HO· to the ring are faster than those of Me·,[5] but in spite of the higher decomposition rate of peracetic acid with >290 nm(1 kW), the yields of water and isopropylphenols at >290 nm(1 kW) are lower than the yields at 254 nm. Therefore, the preferential formation of 2-phenylpropanol at >290 nm is attributable to the effective reaction of HO-group of peracetic acid; *i.e.*, to the induced decomposition of peracetic acid by $PhMe_2C\cdot$ (Eq. 7) beside radical coupling (Eq. 8) and the pathway *via* 1-methyl-1-phenylethylhydroperoxide (Eq. 9).

$$CH_3CO_2\text{–}OH + PhMe_2C\cdot \longrightarrow PhMe_2C\text{–}OH + CH_3CO_2\cdot \quad (7)$$

$$PhMe_2C\cdot + HO\cdot \longrightarrow PhMe_2C\text{–}OH \quad (8)$$

$$PhMe_2C\cdot + O_2 \longrightarrow PhMe_2C\text{–}OO\cdot \longrightarrow\longrightarrow PhMe_2C\text{–}OH \quad (9)$$

The pathway *via* Eq. 9 is possible, because the reaction of radical R· with O_2 gives ROO·, followed by the formation of hydroxylated compound.[6]

Oxygen evolved in this system may be formed *via* dark disproportionation of peroxy acid and/or decomposition of acetylperoxyl radical.[7] Therefore, the induced decomposition (Eq. 10) was confirmed by the evolution of O_2 and by the higher yields of methane and water than the total yields of aromatic products. Hence, peracetic acid is one of H-atom sources.

$$CH_3CO_3\text{–}H + R\cdot \longrightarrow CH_3CO_3\cdot + RH \quad (10)$$

These results have been observed with toluene and ethylbenzene. In conclusion, (i) the yields of methylated aromatics are higher at 254 nm than those at >290 nm. (ii) Hydroxylation of side chain occurs probably *via* Eqs. 7, 8, and 9. The higher yields of hydroxylated products at >290 nm than at 254 nm may be due to the Eq. 7, which needs CH_3CO_3H and hence favored at >290 nm than at 254 nm. Therefore, hydroxylation of side chain is a preferential pathway at >290 nm.

Experimental

Materials. The synthses of peracetic acid (**1**) and a water-free peracetic acid–isopropylbenzene solution were described in our previous paper.[2-4] Samples of commercial guaranteed reagent grade were used as authentic samples of GLC.

Apparatus. GLC analyses were performed on a Yanagimoto gas chromatograph with FID and TCD, Model G 180. A Shimadzu GC-MS 7000 gas chromatograph-mass spectrometer was used to determine and identify the photolysis products. A Halos low-pressure 30 W Hg lamp, a Halos high-pressure 300 W Hg lamp, and a Halos high-pressure 1 kW Hg lamp were used as light sources. All experiments were carried out in a cylindrical quartz vessel (2×12 cm) or a cylindrical Pyrex vessel (2×12 cm) and were repeated in triplicate.

Photolysis of Peracetic Acid in Isopropylbenzene. Peracetic acid in isopropylbenzene was photolyzed in a quartz vessel with a 30 W low-pressure Hg lamp or in a Pyrex vessel with a 300 W high-pressure Hg lamp or with a 1 kW high-pressure Hg lamp through a water jacket. After estimation of peracid remained in the solution, a given amount of Me_2SO–benzene was added to the photolysate to avoid the contamination caused by the peracid thermolysis during GLC. Gaseous products were analyzed by the method previously described[2,3] and the products in the solutions were identified and estimated by GLC with FID and TCD (Porapak QS, Bentone 34-DIDP and PEG 20M-Silicone DC 550) in comparison with authentic samples.

GC-MS Analysis of Aromatic Products. Photolysis products were characterized by means of GC-MS employing a column packed with Bentone 34-DIDP for aromatic hydrocarbons as follows: *t*-butylbenzene, *m/e* 134 (M^+), 119 (base peak), 41, and 39; *s*-butylbenzene, *m/e* 134 (M^+), 106, 105 (base peak), and 91; isopropyltoluene, *m/e* 134 (M^+), 119 (base peak), and 91, the elution order of isopropyltoluenes by GLC was para, meta, and ortho-isomer. Other aromatic products were characterized by a column packed with PEG 20M-Silicone DC 550; 2-phenyl-1-propanol, *m/e* 136 (M^+), 106, 105 (base peak), 103, 92, and 91; 2-phenyl-2-propanol, *m/e* 136 (M^+), 121, 118, 117, 115, 108, 91, and 43 (base peak); isopropylphenols, *m/e* 136 (M^+) and 121 (base peak); coupling product, 2,3-dimethyl-2,3-diphenylbutane, *m/e* 238 (M^+) and 119 (base peak); $PhMe_2\text{–}C_6H_4\text{–}CHMe_2$, *m/e* 238 ($M^+$) and 223 (base peak).

Photo-CIDNP Observed in *O*-Methylbenzoin-Carbon Tetrachloride System

Kazuhiro MARUYAMA, Hiroyuki FURUTA, and Tetsuo OTSUKI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received February 19, 1980)

Synopsis. Photo-induced decomposition of *O*-methylbenzoin in carbon tetrachloride was investigated. A reaction scheme is proposed with the aid of photo-CIDNP technique and product analysis.

Photodecomposition of benzoin and its derivatives has been investigated mainly from the standpoint as initiators of photo-polymerization.[1a-f] By means of CIDNP photo-induced α-cleavage of benzoin has already been examined in correlation with photochemical reaction of benzaldehyde, because both processes generate common radical pair, *i.e.*, pair of benzoyl radical and α-hydroxybenzyl radical.[2a-c] Though these studies were carried out in rather inert solvent, *e.g.*, benzene, methanol, or acetonitrile, here we investigated the photo-induced decomposition of *O*-methylbenzoin in good chlorine atom donor; carbon tetrachloride. From the viewpoint to investigate the escaping feature of the incage radical pair, carbon tetrachloride is a helpful solvent. In actual, chlorine atom and trichloromethyl radical incorporated with the photodecomposition processes of *O*-methylbenzoin.

When a carbon tetrachloride solution of *O*-methylbenzoin **1** was deaerated and irradiated with a high pressure Hg arc lamp for 30 min, **1** decomposed completely. Benzoyl chloride **2** (94 mol%), benzaldehyde **3** (41 mol%), 1-methoxy-1-phenyl-2,2,2-trichloroethane **4** (28 mol%), an equimolar mixture of diastereomeric *O,O'*-dimethylbenzopinacol **5** (7 mol%), hexachloroethane **6** (48 mol%), and α,α,α-trichloroacetophenone **8** (a trace) were identified in the reaction mixture (yields were calculated on the basis of **1**) (Scheme 1). This product distribution is quite different from that observed in other solvents as benzene or acetonitrile.[1b,c,d] In the latter cases, **5** is a major product (60—70%, quantum yield;≈0.35), accompanied by less amounts of benzil (<10%). This fact clearly indicates participations of chlorine atom and trichloromethyl radical in the escaping process of the incage radical pair.

The CIDNP spectrum observed during the irradiation of carbon tetrachloride solution of **1** is illustrated in Fig. 1(A). Polarized emission was observed in the methine proton of the starting material **1** (siganl 2). Besides the signal 2, three distinct polarized signals (indicated as signal 1, 3, and 5) were observed. In comparison of their chemical shifts with those of the authentic samples, the polarized signals 1 and 3 are assignable to the methine proton of 1-methoxy-1-phenyl-2,2,2-trichloroethane **4** (δ: 4.58 ppm) and that of α-chlorobenzyl methyl ether **7** (δ: 6.36 ppm), respectively. The polarized signal 5 is originated from the formyl proton of benzaldehyde **3**. Although the

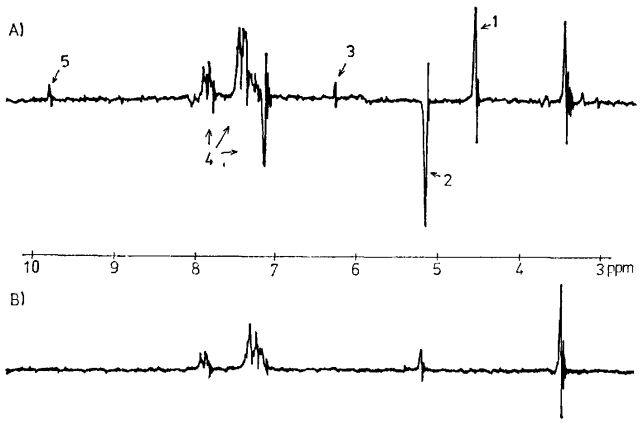

Fig. 1. Photo-CIDNP spectra of *O*-methylbenzoin in carbon tetrachloride.
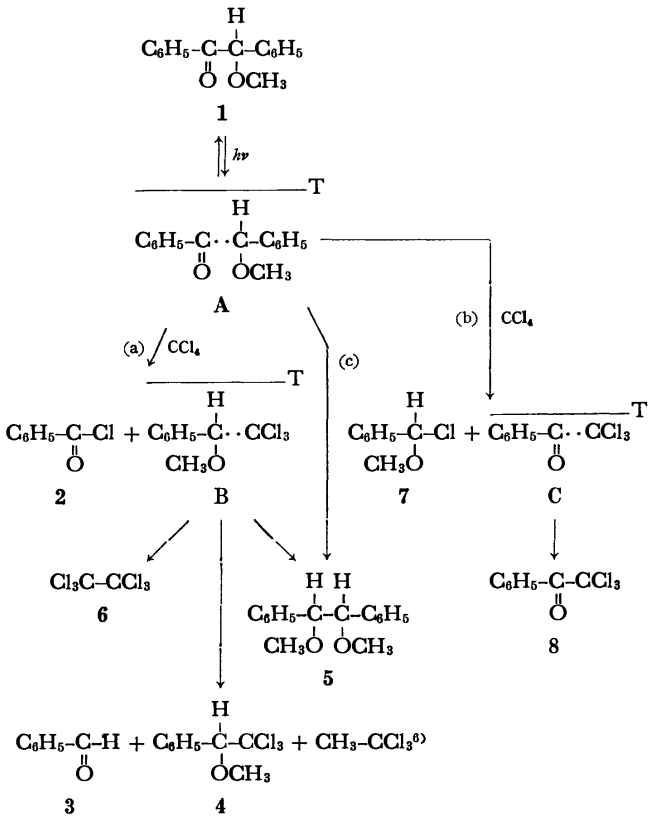
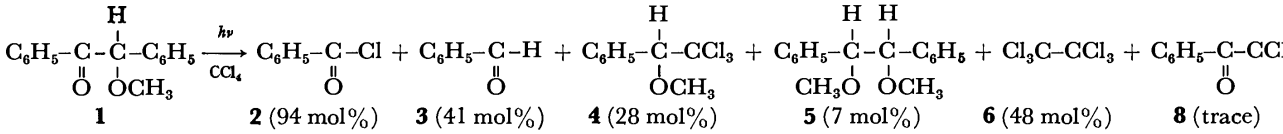
A): During irradiation, B): before irradiation.



Scheme 2.



Scheme 1.

polarized signals in the region of aromatic protons cannot be assigned unambiguously, they consist of the overlapped aromatic proton signals of **1**, **2**, **3**, **4**, **7**, and **8**. The directions of the polarizations were in good agreement with the expected from the simple rule by Kaptein,[3] assuming the radical pair **A**, **B**,[4] and **C**[4] which have triplet multiplicity[5] (Scheme 2).

Observation of CIDNP signal due to **1** indicates the presence of the back process of α-cleavage, that is, regeneration of **1** from radical pair **A** once produced. Apart from the regeneration of **1**, the radical pair **A** could collapse *via* paths (a), (b), and (c) (Scheme 2). Almost quantitative yield of benzoyl chloride **2** (94 mol%) clearly shows that the major path is the path (a). α-Methoxybenzyl radical, the other moiety of the radical pair **A**, is also stabilized as benzaldehyde **3** (41 mol%), 1-methoxy-1-phenyl-2,2,2-trichloroethane **4** (28 mol%), and *O*,*O*′-dimethylbenzopinacol **5** (7 mol%). On the other hand, minor path (b) is taking place, because of detections of α-chlorobenzyl methyl ether **7** by CIDNP (signal 3) and α,α,α-trichloroacetophenone **8** by GLC.[6] Even if in part, path (b) as well as path (c) might contribute to the formation of hexachloroethane **6**. The relative intensity of polarized CIDNP signals (signal 1/signal 3) suggests again the preponderance of path (a), though the polarized intensity of CIDNP signals doesn't directly reflect the amounts of the corresponding products.

As described above photodecomposition of **1** in carbon tetrachloride takes a quite different path (path (a)) compared with those observed in other inert solvents, allowing a greater participation of carbon tetrachloride in it. This is highly suggesting that the use of carbon tetrachloride as an additive of "sensitizer," *O*-methylbenzoin, in photo-polymerization system is promising to raise the initiation rate.

Experimental

Materials. Commercially available benzaldehyde, benzoyl chloride, and hexachloroethane were used as the authentic samples without further purification. *O*-Methylbenzoin was a gift from Nippon Gosei Kagaku Co., Ltd., (Osaka, Japan) and used without further purification. 1-Methoxy-1-phenyl-2,2,2-trichloroethane,[7] *dl*- and *meso*-*O*,*O*′-dimethylbenzopinacol,[8] α-chlorobenzyl methyl ether,[9] and α,α,α-trichloroacetophenone[10] were synthesized according to the literatures. Carbon tetrachloride was dehydrated by refluxing the commercially available reagent-grade of the reagent in the presence of calcium hydride and distilled under nitrogen atmosphere.

Photochemical Reaction. A carbon tetrachloride solution (15 ml) of *O*-methylbenzoin **1** (0.13 mmol) was irradiated with a high pressure Hg arc lamp (300 W) under nitrogen atmosphere at room temperature. After the complete consumption of **1**, the reaction mixture was analyzed by GLC (Silicone DC 550-column) compared with the authentic samples. Yields of the products were estimed by means of GLC.

CIDNP Measurement. The PS-100 type of NMR spectrometer manufactured by JEOL was modified for CIDNP measurement as described previously.[11]

Reaction of Phenacyltriphenylarsonium Bromides with *N*-Methylaniline and *N,N*-Dimethylaniline

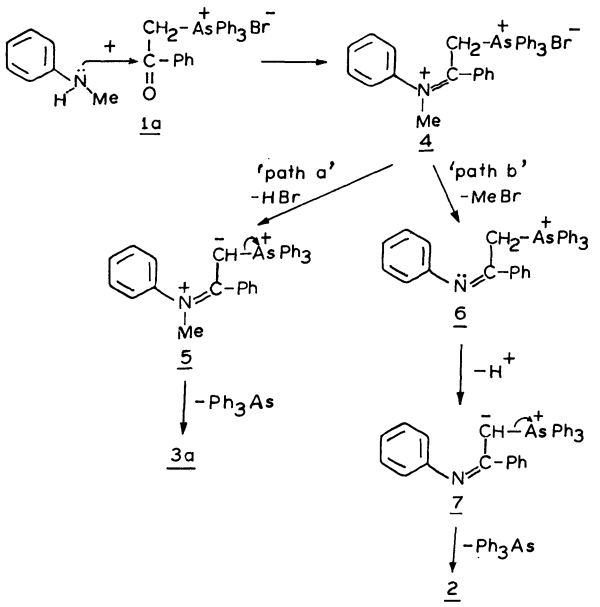
Raj Kumar BANSAL* and Gope BHAGCHANDANI
Department of Chemistry, University of Rajasthan, Jaipur-302004, India
(Received February 12, 1980)

Synopsis. Reaction of phenacyltriphenylarsonium bromide with *N*-methylaniline furnished 2-phenylindole predominantly together with 1-methyl-2-phenylindole. The corresponding reaction of the arsonium salt with *N,N*-dimethylaniline did not give any indole, instead a simple nucleophilic substituted product, α-4′-(dimethylamino)deoxybenzoin was obtained. But, the latter reaction on being carried out in presence of hydrobromic acid afforded 1-methyl-2-phenylindole by the demethylation of *N,N*-dimethylaniline.

In an earlier communication,[1] we reported the reaction of phenacyltriphenylarsonium bromide with anilines leading to the formation of 2-arylindoles and it was shown that the nucleophilic addition of aniline to the carbonyl group of the arsonium salt preceded the formation of the ylide. In an attempt to extend this reaction to aromatic secondary and tertiary amines, we carried out the reactions of phenacyltriphenylarsonium bromide(s) with *N*-methylaniline and *N,N*-dimethylaniline. The results obtained were quite interesting and could be explained on the basis of the mechanism we proposed earlier.[1]

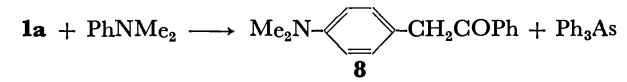
Results and Discussion

Phenacyltriphenylarsonium bromide (**1a**) reacted with *N*-methylaniline to give 2-phenylindole (**2**, 50%) and 1-methyl-2-phenylindole (**3a**, 5%). *N*-Methylaniline, like aniline, acting as a typical nucleophile interacts with the arsonium salt to form the alkylideneammonium species, **4** (Scheme 1). The formation of **2** indicates that **4** does not follow exactly the same route as observed in the case of aniline[1] because in that event 1-methyl-2-phenylindole would have been obtained exclusively. It appears that the species **4** follows two routes: (i) deprotonation of **4** gives the ylide **5** which subsequently undergoes cyclization *etc.* as observed in the case of aniline,[1] to afford **3a** (path a) and (ii) demethylation of **4** precedes the formation of the ylide **7**, the latter finally gives **2** by cyclization *etc.* (path b). The excess formation of **2** in comparison to **3a** indicates that demethylation of species **4** (path b) is preferred over its deprotonation (path a). An alternative possibility of the initial formation of **3a** followed by its demethylation to **2** is ruled out on the basis of the observations made by Chambers and Pearson[2] in connection with the dealkylation of cyclic amines.



Scheme 1.

N,N-Dimethylaniline behaved in a different manner; it reacted with **1a** to afford simple nucleophilic substitution product, α-4′-(dimethylamino)deoxybenzoin (**8**) and no indole was obtained. This is in accordance with the general behaviour of $PhNMe_2$ towards nucleophilic displacement.[3] When $PhNMe_2$ was refluxed with **1a**



in presence of hydrobromic acid, **3a** was obtained in 36% yield. Similarly $PhNMe_2$ reacted with **1b—d** in the presence of HBr to give the corresponding 1-methyl-2-arylindoles (**3b—d**) (Table 1). The results obtained

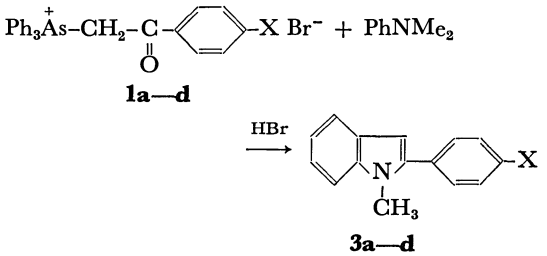


Table 1. 1-Methyl-2-arylindoles

Compound	X	Yield %	Mp/°C	Lit[4], Mp/°C
3a	H	36	100	99—100
3b	Cl	41	119	118—120
3c	Br	39	115	114—116
3d	OCH_3	35	117—118	118—119

with $PhNMe_2$ can be explained like this. The presence of two bulky methyl groups on nitrogen prevents the donation of its electron pair to the carbonyl group of the arsonium salt. But, in the presence of HBr, *N*,*N*-dimethylanilinium bromide is formed which undergoes facile demethylation to *N*-methylaniline.[2] The latter subsequently reacts with the arsonium salt as described earlier. Further, in the presence of HBr, path b is blocked due to the formation of MeBr from demethylation of $PhNMe_2$ and therefore only **3a** is formed.

$$PhNMe_2 + HBr \longrightarrow Ph\overset{+}{N}HMe_2Br^- \rightleftharpoons PhNHMe + MeBr$$

Experimental

General Procedure. Arsonium salt (10 mmol) and PhNHMe or $PhNMe_2$ (20 ml) were refluxed for 7 h. The reaction mixture was taken in chloroform, washed with 10% aqueous hydrochloric acid solution and then with water. The chloroform extract was chromatographed on silica gel. Elution with pet. ether (60—80 °C) and pet. ether–benzene (1: 1) furnished Ph_3As (mp 60 °C) and the corresponding indole(s) respectively. Reaction of the arsonium salt with $PhNMe_2$ in the presence of HBr (4 ml) was carried out in a similar manner.

We are indebted to Dr. G. Srivastava for helpful discussions. Financial support from C.S.I.R., New Delhi is gratefully acknowledged.

Photocyclization of *o*-Nitrophenyl Alkyl Ethers

Shōshichi OGUCHI* and Hiroshi TORIZUKA

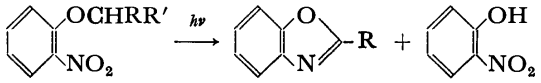
Department of Chemistry, Faculty of Education, The Tokyo Gakugei University, Koganei-shi, Tokyo 184

(Received January 5, 1980)

Synopsis. *o*-Nitrophenyl alkyl ethers **1a**, **1b**, and **1c** undergo photocyclization to give benzoxazoles **2a**, **2b**, and **2c**, respectively.

Nitro functions are known to undergo intermolecular and intramolecular hydrogen abstractions from the n,π^* state.[1,2] Although photochemical reaction of *o*-nitrophenyl alkyl ethers have been reported by McMahon, he didn't mention about photo-products other than dealkylation products.[3]

We here report that *o*-nitrophenyl alkyl ethers undergo photocyclization through intramolecular hydrogen abstraction by the excited nitro group. Irradiation of *o*-nitrophenyl benzyl ether **1a** in benzene under nitrogen atmosphere with a high pressure mercury lamp gave 2-phenylbenzoxazole **2a** in 62% yield together with *o*-nitrophenol **3** (trace) and benzaldehyde (4%). The latter compounds are resulted from dealkylation processes.[2] Similarly, irradiation of *o*-nitrophenyl



1 **2** **3**

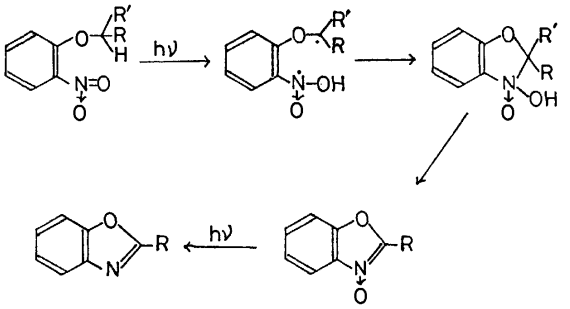
ethers **1b** and **1c** under the same conditions gave benzoxazoles **2b** and **2c** respectively, and *o*-nitrophenol **3**. In these cases aldehydes could not be isolated. In the case of **1d**, no cyclization product was obtained.

TABLE 1. THE YIELDS OF **2** AND **3**

	1		Yield(%) of **2**	Yield (%) of **3**
	R	R′		
1a	Ph	H	62	trace
1b	CH_3	H	61	trace
1c	H	H	trace	21
1d	CH_3	CH_3	0	trace

Photocyclization of **1b** was efficiently quenched by 1,3-pentadiene (E_T=58—59 kcal, 1 cal_{th}=4.184 J),[4] and the reaction was effectively sensitized by benzophenone (E_T=69 kcal) and 4,4′-bis(dimethylamino)-benzophenone (62 kcal).[4] These results indicate that cyclization occurs from the triplet state of the nitrophenyl alkyl ethers. Nitrophenyl alkyl ethers **1b** and **1c** showed peaks of the ultraviolet absorption at 325 nm (ε 3470) and 317 nm (ε 2850), respectively, in ethanol. The peak shifted to 309 nm (ε 4200) and 304 nm (ε 2500), respectively, in cyclohexane. These results indicate that the absorptions are attributable to the π,π^* transition. Therefore, the ethers are initially excited to the π,π^* states.

Intramolecular hydrogen abstraction proceeds from the n,π^* state of aromatic nitro compounds.[1,2] The formation of benzoxazoles from the nitrophenyl alkyl ethers may be explained in terms of photocyclization through δ-hydrogen abstraction by the nitro group from the n,π^* triplet state (Scheme 1). Similar mechanism of photocyclization of *N*-substituted *o*-nitroanilines has been reported by Field *et al.*[5]



Scheme 1.

Experimental

Materials. The *o*-nitrophenyl alkyl ethers **1a**—**1d** were prepared by the usual methods from *o*-nitrohalobenzene and the corresponding sodium alkoxide. Benzoxazoles were commercially available.

General Procedure for Photolysis of o-Nitrophenyl Ether. A nitrophenyl ether (**1**) (600 mg) in hexane (400 ml) was irradiated with a high-pressure mercury vapor 450W lamp (Ushio elect. Co.) for 1.5 h. After removal of the solvent the residue was chromatgraphed on silica gel. Elution with a mixture of chloroform–benzene (volume ratio 7: 1) gave a benzoxazole (**2**) and nitrophenol (**3**). The structure of **2** was determined by comparison with an authentic sample.

Hydrates of Organic Compounds. V. The Clathrate Hydration of Alcohols

Haruo NAKAYAMA* and Masayuki HASHIMOTO

Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

(Received November 27, 1979)

A new method for examining the ability of a given substance to form a hydrate with the same structure as that of a reference substance has been established. By using this method, for a series of alcohols ranging from methyl alcohol to pentyl alcohol, including their isomers, the ability to form a clathrate hydrate of either Structure I or Structure II has been investigated. It has been found that: (1) methyl alcohol has the ability to form both Structure I and II hydrates; (2) ethyl alcohol has the ability to form a Structure II hydrate; (3) all C_3-alcohols (propyl, isopropyl, allyl, and propargyl alcohol) can actually form Structure II hydrates with relatively high (around -10 °C) incongruent melting points, and (4) among the C_4- and C_5-alcohols, only *t*-butyl alcohol has the ability to form a Structure II hydrate. However, it is uncertain for methyl and ethyl alcohols whether they actually can form such hydrates even in the absence of a reference substance. These results strongly suggest that the size and/or shape limitation plays an important role in the formation of alcohol hydrates with a gas-hydrate structure, just as has been found for the formation of ether and ketone hydrates.

A group of polar substances, such as ethers (dimethyl ether,[1-3] tetrahydrofuran,[1,4-9] ethylene oxide,[1,8,9] 2,5-dihydrofuran,[4-6,9] propylene oxide,[4-6,9] trimethylene oxide,[4-6,9] and 1,3-dioxolane[5,6,9,10]) or ketones (cyclobutanone[5,6,11] and acetone[12-14]), are new known to form so-called "gas hydrates" with von Stackelberg's Structures I and II,[15] in which hydrogen-bonded water molecules form host lattices with specific polyhedral voids, such as tetrakaidecahedron and hexakaidecahedron.

Among a group of polar substances whose clathrate hydration has not been extensively studied is a series of alcohols. The formation of a solid different from ordinary ice in concentrated aqueous solutions of alcohols (such as ethyl alcohol, propyl alcohol, isopropyl alcohol, and allyl alcohol) was reported as early as 1896,[16] and later works have also suggested the existence of ethyl alcohol hydrate.[17] An extensive study by Potts *et al.*[18] in 1965 showed the existence of an ethyl alcohol hydrate below -73.5 °C. Its composition was near $C_2H_5OH \cdot 17H_2O$, similar to the Structure-II gas hydrates. On the other hand, from crystallographic studies Sargent *et al.*[5] concluded that the hydrate formed in the $C_2H_5OH+H_2O$ system was not Type II, and Calvert *et al.*[19] showed that there were more than one hydrate: Type I, with a structural disorder similar to that of ethylene oxide hydrate, and a modified Type II hydrate. Thus, even now there is some uncertainty concerning the structure and properties of ethyl alcohol hydrate. Of the other alcohols, though some irregular behavior has been found in the phase diagrams of alcohol+water binary systems,[20,21] no clathrate hydration has so far been reported.

In this investigation, in order to identify the clathrate hydration of alcohols phase-diagrammatically, we made use of the phenomenon of the "mixed hydrate" formation of alcohols with a reference substance like tetrahydrofuran. Since Structure II hydrates are exclusively formed by molecules with diameters in the range of 5.6—6.6 Å,[22] and since the molecular diameters of the alcohols examined in this study, except for methyl alcohol, are greater than 6 Å, we will primarily discuss the formation of a hydrate of Structure II except for the case of the clathration of methyl alcohol. In Structure II hydrates, as is also true in Structure I hydrates, the structures of the hydrogen-bonded water frameworks are all essentially the same, apart from a slight distortion caused by the nature of the individual guest molecule; they comprize an iso-structural series with similar unit-cell dimensions[5] and crystal symmetry. Thus, it can be anticipated that, when two components have molecules of a size that form Structure II hydrates, a solid solution which has an intermediate decomposition temperature will be formed by mixing them. In reality, the formation of a solid solution of this kind has already been confirmed in several systems.[23-25]

Another striking feature possessed by these hydrates is that the guest molecules nearly fully occupy large voids (16-hedra in Structure II hydrate). This means that most of these hydrates are stoichiometric[22] and that, therefore, the composition of Structure II hydrate is close to $M \cdot 17H_2O$, in which M stands for the guest molecule. From these considerations, it can reasonably be anticipated that the mixed hydrate formed from a binary-liquid mixture of M+M′, each component of which can form, for example, a Structure II hydrate ($M \cdot 17H_2O$ and $M' \cdot 17H_2O$), will have properties characteristic of a solid solution with complete miscibility and will be expressed by the $(M)_\alpha(M')_{1-\alpha} \cdot 17H_2O$ formula. Each 16-hedron will be occupied by either M or M′, and the relative content of the two will be varied continuously with the change in the conditions, such as the temperature and the composition of the mixture from which the solid solution is formed.

We have developed a new method which enables us to conclude whether one substance M′ can form a hydrate with the same structure as that of M by examining a solid-liquid-phase diagram of a ternary mixture of M+M′+water prepared under specific conditions. Palmer *et al.*[23] also selected, as a criterion for hydrocarbon-type hydrates, the condition that hydrates of mixtures exhibit behavior typical of soild solutions. However, their conclusions, derived from

thermal analyses, are not in agreement with the facts found in subsequent experiments; their method, for example, cannot lead to the fact that acetone forms a Structure II hydrate.

Experimental

Procedure. The procedure is summarized as follows: (1) A substance which has been known to form a congruently melting hydrate of a known structure is chosen as the reference component, M. It is preferable that its congruent melting point be as high as possible. (2) A solid is formed from a series of mixtures of various compositions X ($=X_M+X_{M'}$), with the restriction that the $X_M : X_{M'}$, ratio is kept constant, where X_M and $X_{M'}$, are the mole fractions of M and M′ respectively. (3) For a series of the solids, the temperature (T) at which the solid phase completely disappears is observed and is plotted against X. (4) If the value of X which gives a maximum temperature in the T-X plot for a series of mixtures is independent of the molar ratio, $X_M : X_{M'}$, and is the same as that found for the binary mixture, M+water, we may conclude that the M′ component has at least the ability to form a hydrate of the same structure as that of M, since such behavior should be observed only when a solid solution is formed between M-hydrate and M′-hydrate. In this investigation, as a reference substance (M) we chose tetrahydrofuran (which is abbreviated by THF hereafter) for a Structure II hydrate and ethylene oxide (EO) for a Structure I hydrate.

Materials and Measurements. All the organic reagents used in this report, except for ethylene oxide, were extra-pure reagent-grade and were purified by conventional methods. The ethylene oxide was kindly supplied by the Nihon Shokubai Co., Ltd., and was used without further purification. The water was doubly distilled in an all-Pyrex still. Ternary mixtures of an alcohol, either tetrahydrofuran or ethylene oxide, and water were made up by weight. No attempt was made to remove the air dissolved in the solution. Each solution (about 1—2 cm^3) was sealed in a small glass ampoule and was cooled until the solid phase appeared. Then the ampoule was gradually warmed and was kept standing for more than 10 h at a temperature several degrees lower than its approximate dissolving temperature (which had been determined by a preliminary survey) in order to obtain a well-grown solid phase in equilibrium with its solution phase. Then the ampoule was slowly warmed again (at the rate of 0.2—0.3 °C/h), with frequent shaking in a constant-temperature bath. The solid-liquid-phase diagrams were determined by measuring the temperature at which the solid phase completely disappeared. Such methods as cooling-curve measurements and temperature and calorimetric measurements by the use of a differential scanning calorimeter (Shimadzu Seisakusho, SC-20) were also employed when necessary. In order to confirm the conclusion obtained from the phase-diagrammatic behavior, the approximate content of the alcohol existing in a solid phase, as well as those of tetrahydrofuran and water, was determined by means of gas chromatography (Shimadzu Seisakusho, GC-4APT), using either a 1-m polyethylene glycol column at 60 °C or a 3-m diglycerol column at 100 °C, with a flow rate of the carrier gas (He) of 40 cm^3/min.

Results and Discussion

Confirmation of Validity of the Method. First, in order to test the validity of our method, we obtained the T-X plots for systems containing M′, which had previously been established to form a Structure II hydrate. In Fig. 1 the T-X plots are shown for the THF+1,3-dioxolane system. The 1,3-dioxolane molecule is another example whose hydrate is Structure II and which has a congruent melting point.[5,6,9,10] The top curve (marked with 1:0) and the bottom curve (marked with 0:1) indicate the solid-liquid-phase diagrams of binary mixtures of THF+water and 1,3-dioxolane+water respectively. These two curves clearly show the formation of the THF hydrate and the 1,3-dioxolane hydrate, both of which have a hydration number of 17 (X=1/18=0.056), characteristic of a Structure II hydrate. The observed congruent melting points of these hydrates (5.1 °C for the THF hydrate and −1.5 °C for the 1,3-dioxolane hydrate) are somewhat different from the reported values (4.38 °C[26] and 5.1 °C[4] for the THF hydrate; −5 °C[5] and −3 °C[10] for the 1,3-dioxolane hydrate). This discrepancy may be due to the presence of air in the hydrate, as has often been pointed out.[7] The absolute value of the melting point, however, does not have any influence on the analyses below. The other three curves in Fig. 1 are T-X plots for systems in which the molar ratios of THF:1,3-dioxolane are 1:1, 1:3, and 1:9. It is noteworthy that the dotted line which connects the points of the highest temperature in each curve is vertical around X=0.056, which corresponds to a hydration number of 17. This behavior is exactly the same as was anticipated in the above discussion.

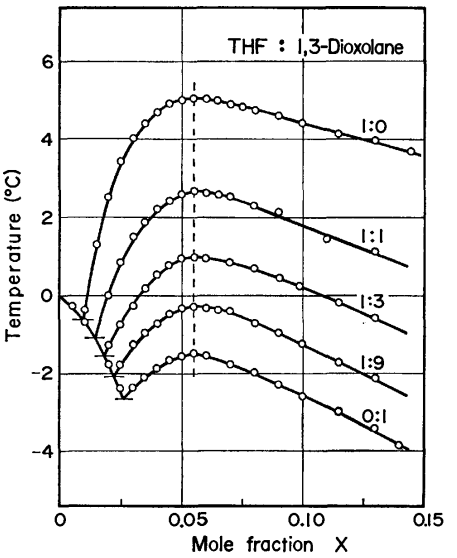

Fig. 1. The solid-liquid-phase diagrams for the THF+1,3-dioxolane+water systems.
The temperatures at which solid phase completely disappears are plotted against total mole fraction (X) of THF and of 1,3-dioxolane. The ratio attached to each curve indicates the molar ratio of THF:1,3-dioxolane in the original solution. Thus the curve marked with 1:0 is a solid-liquid equilibrium curve for THF+water binary system and one with 0:1 is that for 1,3-dioxolane+water binary system. All the following figures are made in a similar manner.

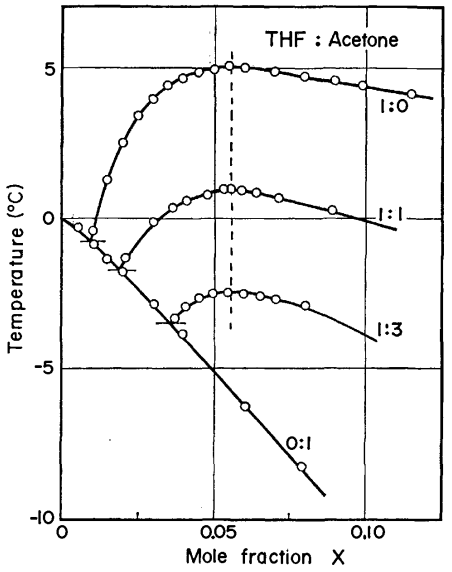

Fig. 2. The solid-liquid-phase diagrams for THF+acetone+water systems.
Explanations are given in Fig. 1.

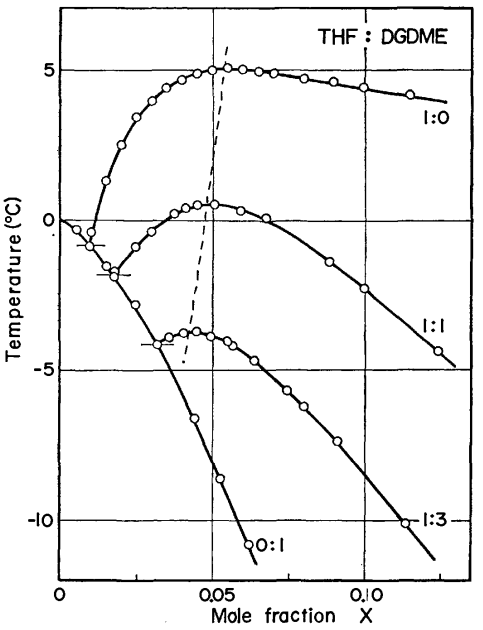

Fig. 3. The solid-liquid-phase diagrams for THF+diethylene glycol dimethyl ether+water systems.
Explanations are given in Fig. 1.

Analogous plots for the THF+acetone system are shown in Fig. 2. Since acetone forms a Structure II hydrate with an incongruent melting point (−19.8 °C[11]), we cannot, of course, observe a peak at X= 0.056 in the T-X plots for the acetone+water binary system. Only an ice-solution equilibrium curve can be obtained at a temperature higher than its incongruent melting point. However, Fig. 2 clearly shows that the T-X plots for mixtures of acetone with THF behave in the same manner as in the case shown in Fig. 1. The X which corresponds to a maximum temperature in each curve is independent of the molar ratio of THF: acetone and is around 0.056, as expected. This indicates that our principle can also be applied to a component which forms an incongruently melting hydrate. As can obviously be seen from Figs. 1 and 2, the maximum temperature in each mixture is quite high as compared with the one calculated from the proportional distribution of the melting points of both hydrates on the molar-ratio basis. This is presumably due to an enrichment of one component with a high melting point in the solid phase, as is often observed in completely miscible solid–solution systems. This effect provides a suitable condition for a temperature peak to appear beyond an ice-solution equilibrium curve, as is exemplified in Fig. 2 and in many other systems to be discussed later.

Figure 3 shows similar T-X plots for the system of THF+diethylene glycol dimethyl ether (DGDME). The latter component, which is too large to form a Structure II hydrate, was deliberately chosen in order to see the phase-diagrammatic behavior of a mixture of a hydrate former+a hydrate non-former. Figure 3 clearly shows different behavior from that found in hydrate former+hydrate former mixtures, as shown in Figs. 1 and 2; the X's which give the maximum temperatures (connected with a dotted line) depend on the THF:DGDME ratio and decrease with an increase in the DGDME content. This may be interpreted as a result of the much-depressed activities of the water molecule due to a strong interaction between water and DGDME, which is partly exemplified by the ice-solution equilibrium curve of the binary DGDME+water system. The decrease in the maximum temperature with the increase in the DGDME content may be simply interpreted as a melting-point depression of the THF hydrate upon the addition of DGDME.

From these confirmations, we may certainly conclude that the procedure employed in this report can provide information about whether or not a given substance has the ability to form a hydrate with the same structure as that of a reference substance.

Ethyl and C_3-Alcohol Hydrates. In view of the fact that the size and/or the shape of the guest species are/is the most important factor for the formation of the hydrate with a gas-hydrate structure, ethyl alcohol and a variety of C_3-alcohols are compounds which can be expected to very likely form a Structure II hydrate. The T-X plots for the systems of THF+ethyl alcohol, THF+propyl alcohol, THF+isopropyl alcohol, THF+allyl alcohol, and THF+propargyl alcohol are shown in Figs. 4—6. Despite the rather intricate discussion of the formation of ethyl alcohol hydrate with Structure II presented in an earlier section, the results shown in Fig. 4 clearly indicate that ethyl alcohol has the ability to form a Structure II hydrate with an incongruent melting point. Although it is impossible to estimate the exact value of the incongruent melting point, it is certain, by a comparison of Fig. 4 with Fig. 2, that it is considerably lower than that of acetone hydrate (−19.8 °C[11]).

As may be seen from Figs. 4—6, all the C_3-alcohols behave in a similar manner: (1) in each mixture

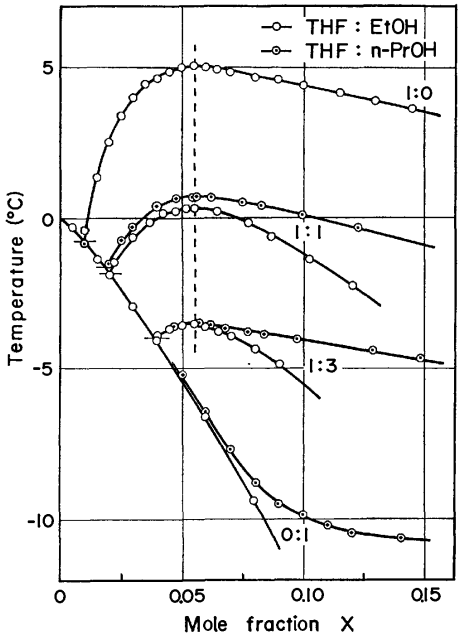

Fig. 4. The solid-liquid-phase diagrams for THF+ethyl alcohol+water systems (—○—) and THF+propyl alcohol+water systems (—⊙—). Explanations are given in Fig. 1.

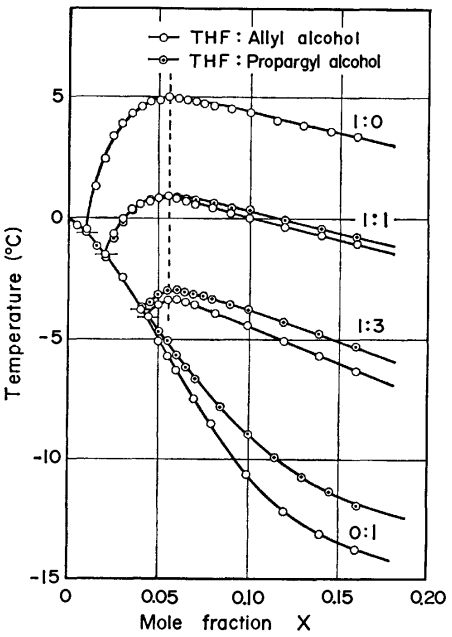

Fig. 6. The solid-liquid-phase diagrams for THF+allyl alcohol+water systems (—○—) and THF+propargyl alcohol+water systems (—⊙—). Explanations are given in Fig. 1.

with THF, the X's corresponding to the maximum temperature have the same value, around 0.056, within the limits of experimental error; (2) in each binary mixture of the alcohol+water, the equilibrium curve (marked with 0:1) bends at around −10 °C for propyl, allyl, and propargyl alcohols and at about −18 °C for isopropyl alcohol. Both of these phenomena suggest that all the C_3-alcohols can form hydrates of the Structure II type. In fact, thermal analysis by means of a differential scanning calorimeter also revealed that the solid made by cooling the alcohol+water binary mixture showed a marked absorption of heat at about −11 °C for propyl alcohol, −16 °C for isopropyl alcohol, −12 °C for allyl alcohol, and −10 °C for propargyl alcohol when each solid was gradually heated. These temperatures seem to correspond to the incongruent melting point of each alcohol hydrate. In addition, more elaborate thermal analyses[30] for the propyl alcohol+water system strongly indicated that the hydration number of the propyl alcohol hydrate was 17 (Structure II). As far as we know, no formation of a C_3-alcohol hydrate with a Structure II has been reported explicitly. It is noteworthy that the incongruent melting points of these C_3-alcohol hydrates are surprisingly high as compared with that of the ethyl alcohol hydrate reported by Potts *et al.* (−73.5 °C[18]).

C_4- and C_5-Alcohols. From the standpoint of size and/or shape limitations of a guest molecule on the formation of a Structure II hydrate, it seems to be difficult for C_4-alcohols to form such hydrates. In fact, there exists no proof for its formation. The T-X plots for the THF+*t*-butyl alcohol (TBA)+water mixtures are shown in Fig. 7. The solid-liquid equilibrium curve (marked with 0:1) for the TBA+water binary system clearly shows no formation of a hydrate of Type II. The solid phase formed at high concentrations (above X=0.064) seems to be $TBA \cdot 2H_2O$, as was pointed out by Ross.[20] The T-X plots for ternary mixture of THF+TBA+water, however, behave in a manner similar to that in the systems containing ethyl alcohol and C_3-alcohols (Figs. 4—6); each T-X curve for these systems has a maximum temperature at X=0.056. Thus, from our criterion, it may be concluded that the TBA molecule has the

Explanations are given in Fig. 1.

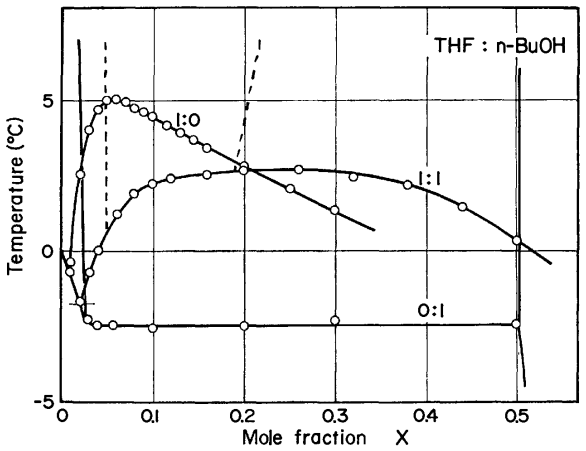

Fig. 8. The solid-liquid-phase diagrams for THF+butyl alcohol+water systems.
Explanations are given in Fig. 1.

ability to form a Structure II hydrate. Chemical analysis by means of gas chromatography also shows that the TBA molecule exists in the solid phase formed from such a ternary mixture. This can be interpreted by the following considerations. Although the TBA molecule cannot form a stable Structure II hydrate by itself because of its molecular diameter is a little larger than the limiting value of 6.6 Å, the lattice distortion caused by the TBA molecule is not so severe that the formation of a solid solution of a Structure II hydrate containing TBA is possible by incorporating the THF molecule as much as possible. The fact that TBA can form a double hydrate (Structure II) with H_2S,[31] $TBA \cdot 2H_2S \cdot 17H_2O$, gives other evidence in support of the slight distortion effect of the TBA molecule on the water structure: in this hydrate the stabilization due to the occupation of the H_2S molecule in vacant 12-hedra seems to overcome the unfavorable distortion effect of the TBA molecule.

The behavior of the *T-X* plots for the other three C_4-alcohols (butyl, isobutyl, and *s*-butyl alcohols) is quite different from that shown in Figs. 4—7. As an example, the *T-X* plots for the THF+butyl alcohol+water system are illustrated in Fig. 8. Because of the low solubility of butyl alcohol in water, the equilibrium curve (marked with 0:1) for the binary mixture with water shows the existence of a two-liquid-phase region and shows no indication of the formation of a Structure II hydrate. In Fig. 8, only the *T-X* plot for an equimolar mixture of THF+butyl alcohol is shown. Two liquid phases also exist in the region between two dotted lines. It is noteworthy that the 1:1 curve has quite a broad peak around X=0.25: this is quite different from the value corresponding to the THF+water system (0.056), indicating that the butyl alcohol does not have the ability to form a Structure II hydrate at all. The behavior of this 1:1 curve can be interpreted as follows: the solid phase formed is a simple THF hydrate (its melting point is depressed by the existence of butyl alcohol), and a high THF concentration is needed to maintain the THF hydrate in the solution since a considerable amount of THF is either distributed between the two liquid phases or extracted by liquid phase containing a large amount of butyl alcohol. The analysis by means of gas chromatography indicates, for example, for the system of X=0.14 (two liquid region) which is kept at 1.1 °C, that the molar ratio of THF:butyl alcohol:water is 1:0.04:18 for a solid sample separated from the liquid phase (the small amount of butyl alcohol may be ascribed to the incorporation of the mother liquid), 1:2.0:7.0 for an upper-liquid phase, and 1:0.75:2.2 for a lower-liquid phase (the volumes of the two phases are almost the same, and a small amount of the solid phase wafts in the upper portion of the lower-liquid phase). These results strongly support the above anticipation.

All the *T-X* plots for ternary mixtures of THF+C_5-alcohol+water also showed the same behavior, as is shown in Fig. 8.

Methyl Alcohol Hydrates. Since the molecular diameter of methyl alcohol is around 5.2—5.3 Å,[22] we first examined the possibility of the formation of a methyl alcohol hydrate of Structure I by using ethylene oxide (EO) as the reference substance. It has been known that ethylene oxide hydrate[27-29] is a Structure I with a congruent melting point of 11.1 °C.[27] The *T-X* plots for the EO+methyl alcohol+water system are shown in Fig. 9. The solid-liquid equilibrium curve (marked with 1:0) for the EO+water binary system was taken from the literature.[27] Three *T-X* curves (marked with 1:1, 1:3, and 1:5) for the ternary mixtures show the same behavior as in Figs. 4—7, indicating that methyl alcohol has the ability to form a Structure I hydrate. It is uncertain, however, whether methyl alcohol can actually form a Structure I hydrate without the assistance of EO.

On the other hand, the *T-X* plots for the ternary mixture of THF+methyl alcohol+water, shown in Fig. 10, also show that the methyl alcohol hydrate can form a solid solution with a THF hydrate of Struc-

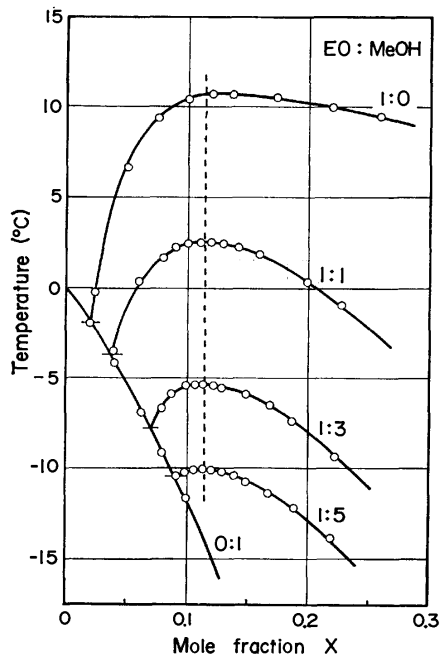

Fig. 9. The solid-liquid-phase diagrams for ethylene oxide+methyl alcohol+water systems.
Explanations are given in Fig. 1.

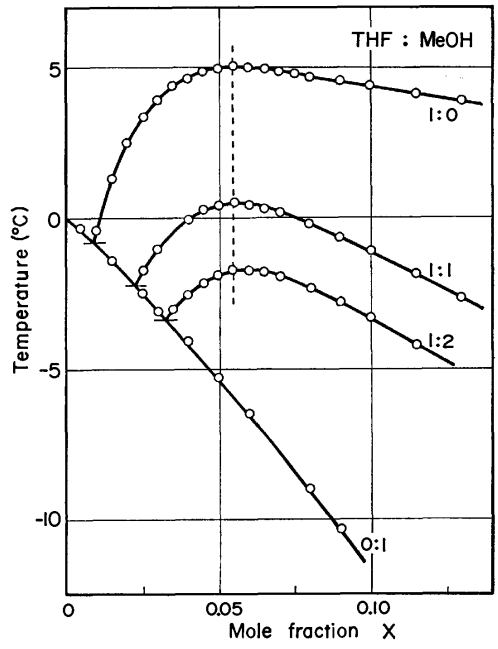

Fig. 10. The solid-liquid-phase diagrams for THF+methyl alcohol+water systems.
Explanations are given in Fig. 1.

ture II. Gas chromatographic analysis also supports this conclusion. For example, the molar ratio of THF:methyl alcohol:water is 1.0:0.85:31.0 for the solid phase formed from a solution containing X=0.07 (the molar ratio of THF:methyl alcohol is 1:3) and kept at −10.3 °C. This composition can reasonably be explained by looking upon the solid phase as a mixture of 1 mol of the THF·17H_2O hydrate and 0.85 mol of the MeOH·17H_2O, hydrate. However, this Structure II hydrate, MeOH·17H_2O, seems to be found only when a suitable other molecule such as THF coexists with methyl alcohol, since the methyl alcohol is not large enough to stabilize a Structure II hydrate by itself: stable Structure II hydrates are formed for guest molecules of 5.6—6.6 Å, as has been mentioned earlier.[22]

Summary. From these results we may classify the series of alcohols into the following four groups: (1) methyl and ethyl alcohol—these alcohols have at least the potential ability to form clathrate hydrates of either Structure I (for methyl alcohol) or Structure II (for both alcohols). It is uncertain, however, whether they can actually form such hydrates from the alcohol+water binary mixtures alone; (2) propyl, isopropyl, allyl, and propargyl alcohol—all these C_3-alcohols can form a Structure II hydrate with relatively high incongruent melting points around −10 °C; (3) *t*-butyl alcohol—though this alcohol has the potential ability to form a Structure II hydrate, it cannot form such a hydrate from the *t*-butyl alcohol+water mixture alone; and (4) other C_4- and C_5-alcohols—these alcohols do not have any potential possibilities to form the hydrates of the gas-hydrate type. These results strongly support the idea that the size and/or shape of a guest molecule also plays an important role in the formation of alcohol hydrates of Structure I and II, just as in the case of ether and ketone hydrates, and further, that the existence of a polar OH group has little influence on their formation. It is noteworthy that the experimental method employed in this study can also be applied to any other types of clathrate hydrates.

The authors wish to express their thanks to Mr. Manabu Sakai and Mr. Akira Kaneko for their preliminary experiments.

Studies of the Anodic Oxidation of the Cyanide Ion in the Presence of the Copper Ion. III. Identification of the Reaction Intermediate by Means of ESR Spectroscopy

Seiji Yoshimura, Akira Katagiri,** Yasuo Deguchi,** and Shiro Yoshizawa*

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

***Department of Chemistry, College of Liberal Arts and Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606*

(Received December 7, 1979)

The formation of the tetracyanocuprate(II) ion ($Cu(CN)_4^{2-}$), which was expected as a reaction intermediate in the anodic oxidation of the cyanide ion in the presence of the copper ion, has been investigated by means of ESR measurement. When a potassium cyanide solution containing a small amount of copper(I) cyanide was electrolyzed, an intermediate copper(II) species was found at the anode in the dissolved state. The ESR spectrum of the intermediate in the solidified state was obtained by freezing the solution in the resonant cavity. The intermediate was identified as $Cu(CN)_4^{2-}$ by a comparison of its spectrum to that of $Cu(CN)_4^{2-}$ already reported by other authors. When the ratio of the total copper(I) concentration to the total cyanide concentration in the solution was not too small, solid copper(II) cyanide was deposited on the anode during electrolysis.

In the investigation of the anodic oxidation of the cyanide ion, we have found a marked catalytic effect of the copper ion on this reaction.[1] We have postulated the formation of the tetracyanocuprate(II) ion ($Cu(CN)_4^{2-}$) as an intermediate in this catalytic electrochemical reaction, and have proposed the following mechanism, which is consistent with the results of several other electrochemical measurements:[2]

$$Cu^{I}(CN)_4^{3-} \longrightarrow Cu^{II}(CN)_4^{2-} + e^- \quad (1)$$

$$Cu^{II}(CN)_4^{2-} + CN^- \longrightarrow Cu^{I}(CN)_4^{3-} + \frac{1}{2}(CN)_2 \quad (2)$$

On the other hand, Longo and Buch[3] have studied the ESR and optical spectra of the unstable species produced in the chemical reaction between Cu^{II} and CN^-, and have identified the species as $Cu^{II}(CN)_4^{2-}$. The aim of the present paper is to confirm the formation of $Cu(CN)_4^{2-}$ in the anodic cyanide oxidation in the presence of the copper ion by means of ESR measurement.

Experimental

The ESR spectra were measured by the use of a JEOL JES-ME-3X spectrometer with X-band microwaves and with a field-moduration frequency of 100 kHz. A cylindrical resonant cavity of the TE_{011} mode was used. The temperature of the cavity was held constant by controlling the cold nitrogen-gas flow. In order to determine the g-values and hyperfine-coupling constants of the spectra, Mn^{2+} doped into MgO was used as the standard substance.

Two types of electrolysis cells, shown in Fig. 1, were used for the measurement of the ESR spectra during electrolysis. Both cells were made from a quartz tube (0.72 mmϕ in inner diameter) and were equipped with a platinum wire anode (0.4 mmϕ) coaxially. A platinum plate was used as the cathode. Cell (a) was set in the ESR spectrometer so that the anode was located at the center of the resonant cavity. By using this cell, the ESR spectrum of a paramagnetic substance, which was formed on the surface or in the vicinity of the anode, was measured. In the case of Cell (b) the platinum wire anode was located above the cavity, and the electrolyte was forced to flow downward. Thus, a paramagnetic substance, which was formed in the dissolved state, was detected. The temperature was kept constant at 25 °C in both cases. Electrolysis was performed at a constant current between 30 μA and 120 μA by means of a Hokuto Denko HA-104 galvanostat whose maximum output voltage was 50 V.

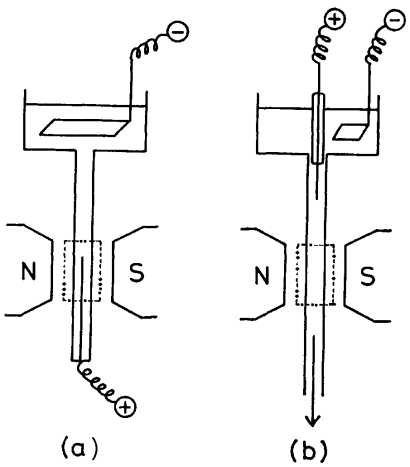

Fig. 1. Electrolysis cells for measurement of ESR absorption spectra at 25 °C.

For the purpose of measuring the ESR spectrum of a frozen solution, a polyethylene cell (2.5 mmϕ in inner diameter) was used. While a constant current was passed through at the platinum wire anode (0.4 mmϕ), the cell was brought into the cavity, whose temperature was held at −100 °C, whereby the electrolytic solution was frozen within a short time.

Electrolytic solutions were prepared from reagent-grade potassium cyanide and copper(I) cyanide. No supporting electrolyte was used, because the concentration of cyanide was sufficiently high. The compositions of the solutions were expressed in terms of the total cyanide concentration (C_{CN^-}) and the total copper(I) concentration ($C_{Cu(I)}$). C_{CN^-} and $C_{Cu(I)}$ were varied from 1.3 to 3.3 mol·dm^{-3}, and from 0.1 to 0.3 mol·dm^{-3}, respectively, while the $C_{Cu(I)}/C_{CN^-}$ ratio was varied from 1/3 to 1/33. Solid copper(II) cyanide was synthesized either by the chemical reaction of aqueous copper(II) sulfate with aqueous potassium cyanide[4] or

by the anodic oxidation of copper in an aqueous potassium cyanide solution.[5]

Results

ESR Measurement during Electrolysis. When electrolysis was started in Cell(a) at a constant anodic current of 100 μA in a solution in which $C_{Cu(I)}$ and C_{CN^-} were 0.1 and 3.0 mol·dm^{-3} respectively, ESR absorption was observed immediately. Its intensity increased with the time at first, and then a steady state was reached. Figure 2 shows the ESR spectrum in the steady state. The spectrum shows four hyperfine lines which suggest the formation of a certain copper(II) species. The same spectrum was obtained in other experiments, where the current was 30, 60, or 120 μA, and where C_{CN^-} was 1.3, 2.3, or 3.3 mol·dm^{-3}, but $C_{Cu(I)}$ was constant at 0.1 mol·dm^{-3}. The steady-state intensity of the absorption was higher for the larger current, and for the higher concentration of the total cyanide, if the total copper(I) concentration was constant. When the current was switched off, the spectrum soon disappeared.

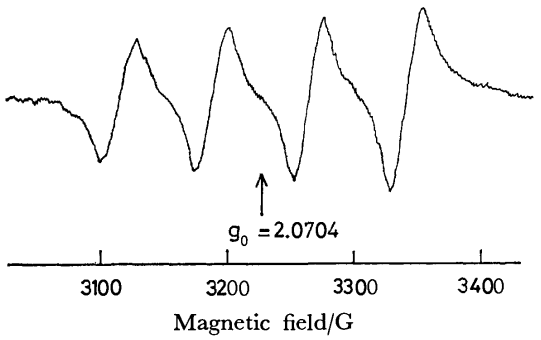

Fig. 2. ESR absorption spectrum during electrolysis at small $C_{Cu(I)}/C_{CN^-}$ ratio.
$C_{Cu(I)}$: 0.1 mol·dm^{-3}, C_{CN^-}: 3.0 mol·dm^{-3}, temp: 25 °C.

The same spectrum was observed when electrolysis was performed in a flowing solution in Cell(b), with the other conditions being the same. This indicates that the paramagnetic species was formed in the dissolved state in the solution.

Figure 3 shows the ESR spectrum measured with Cell (a) at a constant anodic current of 100 μA for the solution in which $C_{Cu(I)}$ and C_{CN^-} were 0.3 and 0.9 mol·dm^{-3} respectively. The same spectrum was obtained when the current was reduced to 50 μA and then further to 10 μA. The ESR absorption intensity increased continuously with the electrolysis time, and no steady state was reached. This spectrum agreed with that obtained independently for solid copper(II) cyanide.

ESR Measurement of the Reaction Intermediate in a Frozen Solution. Electrolysis was made in the polyethylene cell at a constant anodic current (100 μA) for a solution in which $C_{Cu(I)}$ and C_{CN^-} were 0.1 and 3.0 mol·dm^{-3} respectively. While the electrolysis was continued, the cell was inserted into the resonant cavity, held at a temperature of −100 °C, so that the anode was

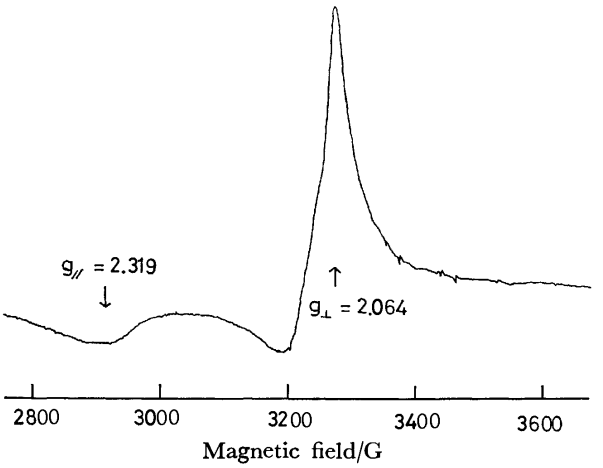

Fig. 3. ESR absorption spectrum during electrolysis at not too small $C_{Cu(I)}/C_{CN^-}$ ratio.
$C_{Cu(I)}$: 0.3 mol·dm^{-3}, C_{CN^-}: 0.9 mol·dm^{-3}, temp: 25 °C.

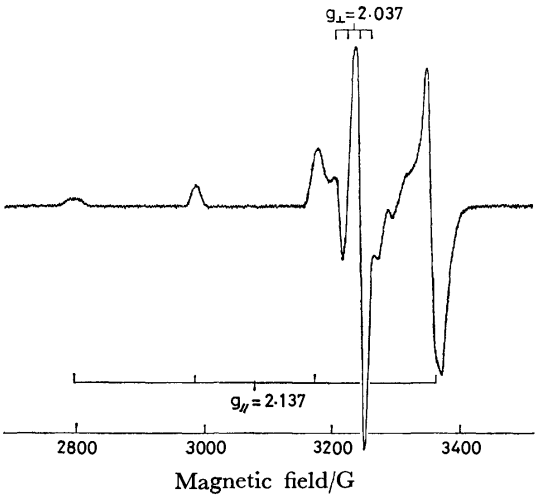

Fig. 4. ESR absorption spectrum of the frozen solution of small $C_{Cu(I)}/C_{CN^-}$ ratio.
$C_{Cu(I)}$: 0.1 mol·dm^{-3}, C_{CN^-}: 3.0 mol·dm^{-3}, temp: −100 °C.

positioned at the center of the cavity. When the solution was frozen, the current became zero. Figure 4 shows the ESR spectrum of the frozen solution thus obtained. No change was observed in the spectrum so long as the sample was held in the frozen state.

Discussion

The ESR spectrum (Fig. 2) which was observed in the case of a small $C_{Cu(I)}/C_{CN^-}$ ratio exhibits an isotropic character. This is ascribed to a certain compound of divalent copper (^{65}Cu and ^{63}Cu) with nuclear spin $I=3/2$, because the spectrum has four absorption lines equally separated. Since the anisotropic terms of spin Hamiltonian are averaged out to zero for a solution spectrum, the positions of the absorption lines are determined only by isotropic terms. The isotropic g-facter, g_0, and the isotropic hyperfine-coupling constant. A_0, are obtained from Fig. 2 with reference to the standard Mn^{2+} sample; they are shown in the left-hand column of Table 1.

Table 1. ESR parameters of the intermediate investigated in this work and of $Cu^{II}(CN)_4^{2-}$

	The intermediate investigated in this work (Figs. 2 and 4)	$Cu^{II}(CN)_4^{2-}$ (Longo and Buch)
g_0	2.0704	2.071[a]
$g_{//}$	2.137	2.146
$g_\perp$	2.037[a]	2.033
$\|A_0\|$ (10^{-4} cm^{-1})	71.4	81[a]
$\|A_{//}\|$ (10^{-4} cm^{-1})	188	190
$\|A_\perp\|$ (10^{-4} cm^{-1})	13[a]	27

a) Calculated by means of Eqs. 3 and 4.

The spectrum of the frozen solution (Fig. 4) shows the features of an axially symmetrical compound in a random orientation. The parallel and perpendicular components of the g-tensor, $g_{//}$ and $g_\perp$, and the parallel and perpendicular components of the hyperfine- coupling tensor, $A_{//}$ and $A_\perp$, are obtained from Fig. 4; they are shown in the left-hand column of Table 1. Thus, $g_{//}$ and $A_{//}$ are determined from the three low-field peaks on the spectrum. However, $g_\perp$ and $A_\perp$ are difficult to determine directly from the spectrum; therefore, they are calculated by the use of Eqs. 3 and 4,[6] together with the values of g_0 and A_0:

$$g_0 = \frac{1}{3}(g_{//}+2g_\perp) \tag{3}$$

$$A_0 = \frac{1}{3}(A_{//}+2A_\perp) \tag{4}$$

It has been known for a long time that an unstable purple compound is formed in the reaction between cyanide and the copper(II) ion (Eq. 5):

$$Cu(II) + CN^- \longrightarrow Cu(I) + \frac{1}{2}(CN)_2 \tag{5}$$

Several authors have postulated the composition of this compound from the kinetics of the reaction.[7,8] Longo and Buch[3] conducted a reaction between copper(II) sulfate and potassium cyanide in methanol, dimethylformamide, and water at a low temperature. They measured the ESR spectra of the unstable purple compound in the liquid methanol solution and in the frozen solution in each solvent, the latter being obtained by freezing the reaction mixture quickly. They thus obtained spectra with an axially symmetrical character, and concluded the purple compound to be square-planar $Cu^{II}(CN)_4^{2-}$ from a consideration based on the crystal-field theory. The ESR parameters of the compound in an aqueous solution obtained by Longo and Buch are shown in the right-hand column of Table 1. Here, the values of g_0 and A_0 are calculated from Eqs. 3 and 4, because the spectrum of a liquid solution was not measured due to the instability of the compound in an aqueous solution. Taking account of the differences in the experimental conditions, the ESR parameters obtained by Longo and Buch and those in the present work are regarded as being in substantial agreement. It is, therefore, confirmed that $Cu^{II}(CN)_4^{2-}$ is formed as a reaction intermediate in the anodic oxidation of cyanide in the presence of the copper ion.

The spectrum (Fig. 3) which was observed during electrolysis in the solution with not too small a $C_{Cu(I)}/C_{CN^-}$ ratio exhibits an anisotropic character. No hyperfine structure can be seen because of the broad linewidth. From Fig. 3, $g_{//}$ and $g_\perp$ are found to be 2.319 and 2.064 respectively. The same spectrum was obtained for solid copper(II) cyanide. Therefore, it is concluded that solid copper(II) cyanide deposits on the anode during electrolysis under these conditions. This conclusion is consistent with the fact that the intensity of the ESR absorption grows continuously with the electrolysis time. The electrode potential, which was measured under the same conditions in the H-type cell,[2] did not reach a steady value at any current, substantiating the above conclusion.

We would like to thank professor Saburo Kako for his helpful discussions, and Mr. Hideo Fujita for his assistance in measuring the ESR spectra. The present work was partly supported by a Grant-in-Aid for Scientific Research (Environmental Science) from the Ministry of Education, Science and Culture (No. 303525).

(Received February 15, 1980)

The kinetics and mechanism of the decomposition of the tetracyanocuprate(II) ion ($Cu^{II}(CN)_4^{2-}$) have been investigated by ESR measurements. Aqueous solutions of potassium cyanide with a small amount of copper(I) cyanide were electrolyzed in a cell the platinum anode of which was set in the resonant cavity of an ESR spectrometer. Since $Cu^{II}(CN)_4^{2-}$, which is formed as an intermediate, gives a definite ESR spectrum, its concentration in the anode compartment is estimated from the intensity of the first-derivative spectrum at a fixed magnetic field. From the decay curves of the ESR intensity after the steady-state electrolysis currents have been switched off, a rate equation for the decomposition of $Cu^{II}(CN)_4^{2-}$ is derived; $v=k_0[Cu^{II}(CN)_4^{2-}]^2/[CN^-]^2$, where k_0 is calculated to be 74 mol·dm^{-3}·s^{-1} at 25 °C. This rate equation is also confirmed by ESR measurements during steady-state electrolysis, where the value of $k_0=60$ mol·dm^{-3}·s^{-1} is obtained. On the basis of the kinetics, two possible mechanisms are proposed: the formation of $Cu^{II}(CN)_3^-$, followed by the rate-determining bimolecular reaction of $Cu^{II}(CN)_3^-$ to give $2Cu^{I}(CN)_2^-+(CN)_2$ (Mechanism A), and the formation of a binuclear complex, $Cu^{II}_2(CN)_6^{2-}$, followed by the rate-determining decomposition of $Cu^{II}_2(CN)_6^{2-}$ to give $2Cu^{I}(CN)_2^-+(CN)_2$ (Mechanism B). The kinetics and the mechanism are compared with those of the chemical reaction between the copper(II) ion and the cyanide ion.

In our previous investigations of the anodic oxidation of the cyanide ion in the presence of the copper ion, we have proposed the following catalytic mechanism:[2,3]

$$Cu^{I}(CN)_4^{3-} \longrightarrow Cu^{II}(CN)_4^{2-} + e^- \quad (1)$$

$$Cu^{II}(CN)_4^{2-} + CN^- \longrightarrow Cu^{I}(CN)_4^{3-} + \frac{1}{2}(CN)_2 \quad (2)$$

We have detected the intermediate tetracyanocuprate (II) ion ($Cu^{II}(CN)_4^{2-}$) by ESR measurement.[1] However, the rate of the chemical reaction, Eq. 2, was too high to be measured by chronopotentiometry or by the rotating-electrode technique under the conditions adopted.[2] In the present work, the kinetic behavior of the intermediate $Cu^{II}(CN)_4^{2-}$ have been investigated by ESR measurement, and the mechanism of the reaction, Eq. 2, discussed.

Experimental

ESR measurement was made by use of a JEOL JES-ME-3X spectrometer with X-band microwave and with a field-modulation frequency of 100 kHz. A cylindrical resonant cavity of the TE_{011} mode was used.

Figure 1 shows the electrolysis cell used. The cell was made from a quartz-glass tube (0.72 mmϕ in inner diameter) and was equipped coaxially with the platinum-wire anode (0.4 mmϕ). A platinum plate was used as the cathode. The effective surface area of the anode was controlled by means of a polyethylene sheath, as is shown in the right-hand part of Fig. 1. The cell was fixed in the spectrometer so that the working anode was positioned at the center of the resonant cavity. All experiments were made at a constant temperature of 25 °C.

The electrolytic solutions were prepared from reagent-grade potassium cyanide and copper(I) cyanide. No supporting electrolyte was used, because the concentration of cyanide was sufficiently high. The concentrations are expressed in the unit of 1 M=1 mol·dm^{-3} throughout this paper. Copper(I) must have been present almost entirely as $Cu^{I}(CN)_4^{3-}$ under the experimental conditions in this work, as can be calculated from the formation constants of the cyano copper(I) complexes.[4] Therefore, the concentration of the free cyanide ion, [CN$^-$], was simply calculated from the concentrations of the total cyanide, C_{CN^-}, and the total copper(I), $C_{Cu(I)}$, according to this equation: $[CN^-]=C_{CN^-}-4C_{Cu(I)}$.

Results and Discussion

Relationship between the ESR Absorption Intensity and the Quantity of $Cu^{II}(CN)_4^{2-}$. When a potassium cyanide solution containing a small amount of copper(I) cyanide was electrolyzed in the cell shown in Fig. 1, an ESR absorption spectrum was observed, as shown in Fig. 2, which can be ascribed to the intermediate $Cu^{II}(CN)_4^{2-}$ ion.[1] Though copper(II) species other than $Cu^{II}(CN)_4^{2-}$ might possibly be formed during electrolysis, the ESR spectra did not show any evidence of such species at all under the experimental conditions in this work. In the following analysis, therefore, copper(II) is considered to be present almost totally as $Cu^{II}(CN)_4^{2-}$.

The signal intensity of the first-derivative spectrum can be regarded as proportional to the quantity of $Cu^{II}(CN)_4^{2-}$ formed,[5] because the spectrum exhibited the Lorentzian line-shape, because the peak positions did not vary with the intensity, and because the local difference in sensitivity due to the inequality of microwave field was negligible in the small anode compartment. On the basis of the above considerations, the signal intensity, I, was measured under different conditions at a fixed magnetic field, H_0, where the peak was the highest, as is shown in Fig. 2. In these experiments the conditions of the ESR spectrometer were kept strictly constant, and the unit scale (1 div) on the recorder chart was used as the unit of the signal intensity.

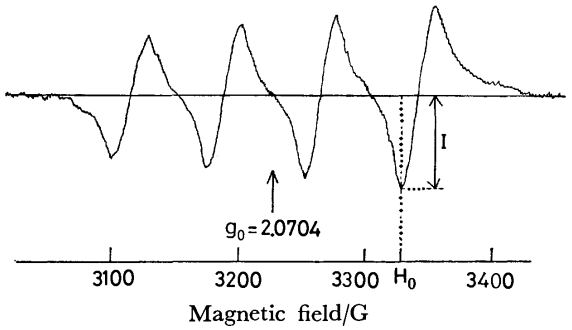

Fig. 2. ESR absorption spectrum $Cu^{II}(CN)_4^{2-}$.

Figure 3 shows a typical change in the ESR signal intensity after the switching-on and switching-off of the constant electrolysis current for a solution with a small $C_{Cu(I)}/C_{CN^-}$ ratio. The signal intensity was zero before starting electrolysis, since $Cu^{II}(CN)_4^{2-}$ was not present. When a constant anodic current was switched on, the intensity increased linearly with the time at first, and then reached a steady value. After the current was switched off, the intensity decreased, quickly at first and then slowly, to zero. Figure 4 shows the initial rate of increase in the signal intensity at the beginning of electrolysis, against the applied current. A proportionality is seen between them. It has been confirmed by other experiments that the initial rate of increase in the signal intensity is independent of the other conditions, *i.e.*, the concentrations of the free cyanide and the total copper(I), and the electrode length.

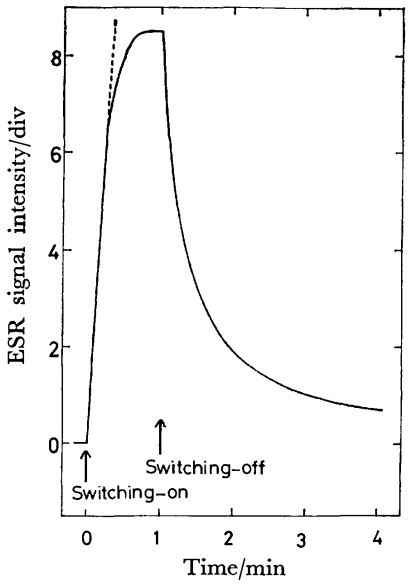

Fig. 3. Intensity of ESR absorption signal of $Cu^{II}(CN)_4^{2-}$ after switching-on and switching-off of the constant electrolysis current. (The unit intensity (1 div) corresponds to 1.55×10^{-9} mol of $Cu^{II}(CN)_4^{2-}$, *cf.* the text).

As a method for determining the quantity of a paramagnetic species from the ESR absorption intensity, Faraday's law has been applied by some workers. Hirasawa *et al.*[6] have applied this method to the formation of the anion radical of nitrobenzene, and Dohrmann and Gallussen,[7] to the formation of the copper(II) ion. A similar method is used in this work. The results shown in Figs. 3 and 4 indicate that at the beginning of electrolysis, the rate of the decomposition of $Cu^{II}(CN)_4^{2-}$ is negligible in comparison with the rate of the formation of $Cu^{II}(CN)_4^{2-}$, and that the current efficiency of the formation (Eq. 1) of $Cu^{II}(CN)_4^{2-}$ is almost 100%. Therefore, the quantity of $Cu^{II}(CN)_4^{2-}$, m, corresponding to the unit

intensity of the ESR signal is calculated from the slope of the line in Fig. 4, on the basis of Faraday's law, as follows:

$$m = 1.55 \times 10^{-9}\ \text{mol/div.} \quad (3)$$

It may reasonably be assumed that the concentration of the intermediate $Cu^{II}(CN)_4^{2-}$ is substantially uniform in the anode compartment along the length, L (Fig. 1), because the gap between the electrode surface and the glass wall is relatively small (0.16 mm), and because the current-density distribution may be nearly uniform due to the small current and the large electrolytic conductivity of the solution. For example, the concentration of $Cu^{II}(CN)_4^{2-}$ during the steady-state electrolysis shown in Fig. 3 is calculated to be 7.8×10^{-3} M by using the value, m, of Eq. 3 and the volume, $V=1.69\times10^{-3}$ cm^3, of the anode compartment. Kinetic analyses will be made on the above assumption in the following two sections. The validity of the assumption will be discussed in more detail in a later section.

Kinetics and Mechanism of the Decomposition of $Cu^{II}(CN)_4^{2-}$. In order to investigate the kinetics of the decomposition of $Cu^{II}(CN)_4^{2-}$, the decay of the ESR signal was followed after the electrolysis current has been switched off at certain steady state. The lower the CN^- concentration, the faster the signal decayed. Figure 5 shows the reciprocal of the signal intensity against the time for three different concentrations of CN^-. A linear relationship is found, indicating that the kinetics is second-order with respect to $Cu^{II}(CN)_4^{2-}$. Thus, the rate of the reaction, which is defined as the rate of the disappearance of $Cu^{II}(CN)_4^{2-}$, may be formulated as follows:

$$v = -\frac{d[Cu^{II}(CN)_4^{2-}]}{dt} = k_2[Cu^{II}(CN)_4^{2-}]^2. \quad (4)$$

The rate constant, k_2, is calculated from the slope of each line in Fig. 5 by using the "m" and "V" values, while log k_2 is plotted against log [CN^-] in Fig. 6. Since k_2 is found to be inversely proportional to the square of [CN^-], the rate equation, Eq. 4, can be

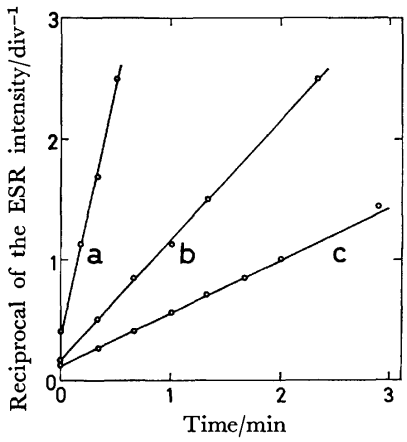

Fig. 5. Relationship between the reciprocal of ESR absorption signal intensity and time at different CN^- concentrations.
[CN^-]; a: 1 M, b: 2 M, c: 3 M, $C_{Cu(I)}$: 0.1 M, electrode length: 6 mm.

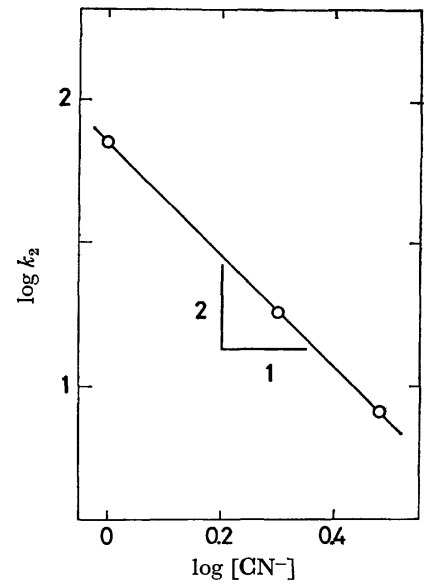

Fig. 6. Dependence of the second-order rate constant, $k_2(M^{-1}s^{-1})$ upon the CN^- concentration (M).

rewritten as Eq. 5, where k_0 is calculated to be 74 $M\cdot s^{-1}$:

$$v = k_0\frac{[Cu^{II}(CN)_4^{2-}]^2}{[CN^-]^2}. \quad (5)$$

Two types of reaction mechanisms can be considered, both of which are consistent with the rate equation, Eq. 5:

Mechanism A:

$$Cu^{II}(CN)_4^{2-} \overset{K_a}{\rightleftharpoons} Cu^{II}(CN)_3^- + CN^- \quad (6a)$$

$$2Cu^{II}(CN)_3^- \xrightarrow{k_a} 2Cu^{I}(CN)_2^- + (CN)_2 \quad (7a)$$

Mechanism B:

$$2Cu^{II}(CN)_4^{2-} \overset{K_a}{\rightleftharpoons} Cu^{II}_2(CN)_6^{2-} + 2CN^- \quad (6b)$$

$$Cu^{II}_2(CN)_6^{2-} \xrightarrow{k_b} 2Cu^{I}(CN)_2^- + (CN)_2 \quad (7b)$$

If the reaction, Eq. 6a or 6b, is in quasi-equilibrium when $[Cu^{II}(CN)_4^{2-}]\gg[Cu^{II}(CN)_3^-]$ or $[Cu^{II}(CN)_4^{2-}]\gg[Cu^{II}_2(CN)_6^{2-}]$, and if the reaction, Eq. 7a or 7b, is rate-determining, the rate equation may be described as follows:

$$v = k_aK_a^2\frac{[Cu^{II}(CN)_4^{2-}]^2}{[CN^-]^2}, \quad (8a)$$

or:

$$v = k_bK_b\frac{[Cu^{II}(CN)_4^{2-}]^2}{[CN^-]^2}. \quad (8b)$$

Here, K_a and K_b are the equilibrium constants of the reactions, Eqs. 6a and 6b, and k_a and k_b are the rate constants of the reactions, Eqs. 7a and 7b, respectively. Both Eqs. 8a and 8b agree with the experimental rate equation, Eq. 5. At present, it is not possible to decide which of the two mechanisms is correct. Another experiment has been made on this point, however, and a further discussion will be presented in a succeeding paper.

Since cyano copper(I) complexes are labile,[8] the following equilibrium may always exist:

$$Cu^{I}(CN)_2^- + 2CN^- \longrightarrow Cu^{I}(CN)_4^{3-}. \quad (9)$$

During a steady-state electrolysis, the over-all reaction may proceed through the reaction cycle of Eqs. 1, 6a, 7a, and 9, or Eqs. 1, 6b, 7b, and 9.

Kinetics during Steady-state Electrolysis. In order to confirm the rate equation, Eq. 5, the steady-state intensity of the ESR signal was measured under different conditions. Figures 7, 8, and 9 show the dependencies of the signal intensity, I, upon the anodic current, j; the electrode length, L, and the concentration of the free cyanide ion, [CN⁻]. It can be noticed from these figures that the signal intensity is proportional to $j^{1/2}$, $L^{1/2}$, and [CN⁻].

It has been assumed that the intermediate $Cu^{II}(CN)_4^{2-}$ exists uniformly in the anode compartment whose volume is $V=\pi(R^2-r^2)L$, where R is the inner radius of the quartz-glass tube and where r is the radius of the platinum-wire electrode. In a steady state when the rates of the formation and decomposition of the intermediate $Cu^{II}(CN)_4^{2-}$ are equal, the following expression should hold:

$$\frac{j}{F} = k_0 \frac{[Cu^{II}(CN)_4^{2-}]^2}{[CN^-]^2} \pi(R^2-r^2)L. \quad (10)$$

On the other hand, the steady-state intensity of the ESR signal is expressed by Eq. 11:

$$I = \frac{1}{m}[Cu^{II}(CN)_4^{2-}]\pi(R^2-r^2)L. \quad (11)$$

By combining Eqs. 10 and 11, the following equation is obtained:

$$I = \frac{1}{m}\left\{\frac{\pi(R^2-r^2)}{k_0 F}\right\}^{1/2} \cdot j^{1/2}L^{1/2}[CN^-]. \quad (12)$$

Thus, the intensity should be proportional to $j^{1/2}$, $L^{1/2}$, and [CN⁻]. These relationships are satisfied experimentally, as has been mentioned above. The rate constant, k_0, is calculated to be 60 $M \cdot s^{-1}$ from the results of Figs. 7, 8, and 9 on the basis of Eq. 12. This value is in satisfactory agreement with the value, 74 $M \cdot s^{-1}$, obtained in the previous section.

Distribution of the Concentration of $Cu^{II}(CN)_4^{2-}$ in the Anode Compartment. Kinetic analyses have been made in the preceding sections on the assumption that the concentration of $Cu^{II}(CN)_4^{2-}$ was uniform in the anode compartment. The validity of this assumption will now be discussed.

It is known that cyanogen is primarily formed in the anodic oxidation of the cyanide ion and is then hydrolyzed according to Eq. 13:[9]

$$(CN)_2 + H_2O \longrightarrow HCN + HOCN. \quad (13)$$

When the concentration of CN⁻ is sufficiently high, the hydrogen cyanide polymerizes, according to Eq. 14, to give a brown polymer, which is called "azulmin":[10]

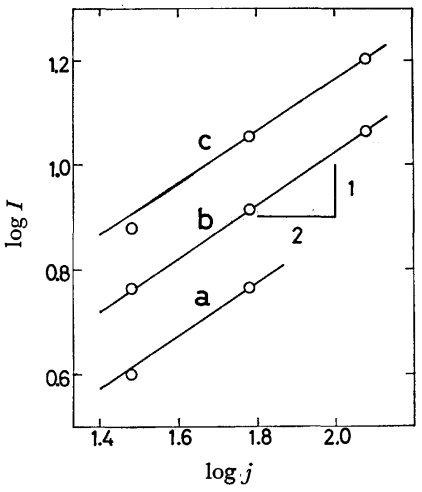

Fig. 7. Relationship between the logarithm of steady-state ESR intensity (div) and the logarithm of current (μA).

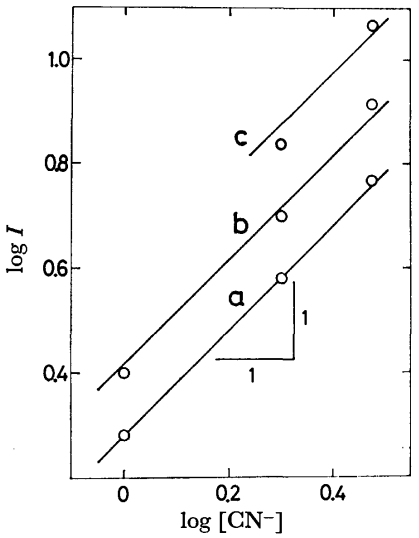

Fig. 9. Relationship between the logarithm of steady-state ESR intensity (div) and the logarithm of CN⁻ concentration (M).
$C_{Cu(I)}$: 0.1 M, electrode length: 6 mm, current; a: 30 μA, b: 60 μA, c: 120 μA.

$$x\mathrm{HCN} \longrightarrow (\mathrm{HCN})_x. \quad (14)$$

Such a brown polymer was often observed after long-time electrolysis in the present work, too. The formation of the brown polymer was almost uniform along the length of the anode, indicating that the current-density distribution was almost uniform.

The distribution of the concentration of $Cu^{II}(CN)_4^{2-}$ in the radial direction, *i.e.*, the direction normal to the electrode surface, can be calculated for steady-state electrolysis by using the rate equation, Eq. 4, and an appropriate differential equation. If the x-axis is chosen in the radical direction, with the origin at the electrode surface, and if an approximation of the linear diffusion is made, a differential equation with respect to the concentration, C, of $Cu^{II}(CN)_4^{2-}$ is established as follows:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - k_2 C^2. \quad (15)$$

Here, D is the diffusion coefficient of $Cu^{II}(CN)_4^{2-}$, while k_2 is the rate constant in Eq. 4. At a steady state, when $\partial C/\partial t=0$, Eq. 15 gives Eq. 16:

$$\frac{d^2C}{dx^2} - \frac{k_2}{D}C^2 = 0. \quad (16)$$

Boundary conditions, Eqs. 17 and 18, hold:

$$\frac{dC}{dx} = -\frac{J}{DF} \quad \text{and } C=C_0 \text{ at } x=0 \quad (17)$$

$$\frac{dC}{dx} = 0 \quad \text{and } C=C_a \text{ at } x=a \quad (18)$$

where J is the current density, where a is the distance between the electrode surface and the glass wall ($a=R-r$), and where the subscripts 0 and a indicate the electrode surface and the glass wall respectively. By integrating Eq. 16 under the conditions of Eqs. 17 and 18, the following equations are derived:

$$\frac{dC}{dx} = -\sqrt{\frac{2k_2}{3D}(C^3-C_a^3)} \quad (19)$$

$$C_0^3 - C_a^3 = \frac{3}{2}\frac{J^2}{k_2DF^2}. \quad (20)$$

The integration of Eq. 19 gives Eq. 21:

$$\frac{1}{\sqrt[4]{3}}F\left\{\arccos\frac{\frac{C}{C_a}-(\sqrt{3}+1)}{\frac{C}{C_a}+(\sqrt{3}-1)}, \frac{\sqrt{3}-1}{2\sqrt{2}}\right\} = \left(\frac{2k_2C_a}{3D}\right)^{1/2}(a-x), \quad (21)$$

where $F(\varphi, k)$ indicates the elliptic integral of the first kind.[11] The concentration distribution can be calculated numerically from Eqs. 20 and 21. A typical example is shown by Curve a in Fig. 10, in which the values of $k_0=74\ \mathrm{M\cdot s^{-1}}$ and $D=10^{-5}\ \mathrm{cm^2\cdot s^{-1}}$† are used.

The horizontal line (Curve b) shows the average concentration, which was obtained from the ESR absorption intensity. The fact that Curve a lies near

† This value is estimated from the diffusion coefficients of Cu^{2+} ($D=0.72\times10^{-5}\ \mathrm{cm^2\cdot s^{-1}}$)[12] and $Cu^{II}(NH_3)_4^{2+}$ ($D=0.95\times10^{-5}\ \mathrm{cm^2\cdot s^{-1}}$),[13] both of which have the same square-planar configuration as $Cu^{II}(CN)_4^{2-}$.

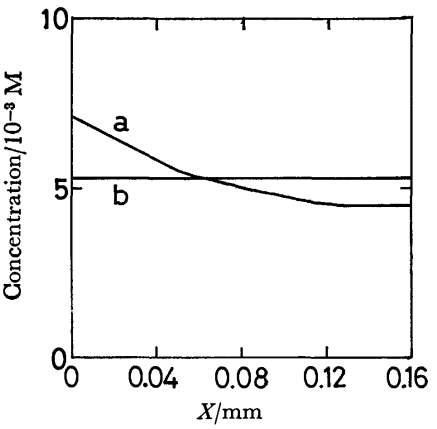

Fig. 10. Calculated concentration distribution (a) of $Cu^{II}(CN)_4^{2-}$ in the cell, compared with the experimentally observed average-value (b).
[CN⁻]: 3 M, $C_{Cu(I)}$: 0.1 M, electrode length: 6 mm, current: 30 μA.

Curve b shows the approximate validity of the assumption that the $Cu^{II}(CN)_4^{2-}$ concentration is uniform in the radial direction in the cell.

Comparison with the Kinetics and Mechanisms of the Chemical Reaction between Cu^{2+} and CN^- Ions. It is known that the copper(II) ion reacts with the cyanide ion in an aqueous solution to give copper(II) cyanide as a yellowish-brown precipitate, which then decomposes to copper(I) cyanide and cyanogen, according to Eqs. 22 and 23:[14,15]

$$Cu^{2+} + 2CN^- \longrightarrow Cu^{II}(CN)_2 \quad (22)$$

$$2Cu^{II}(CN)_2 \longrightarrow 2Cu^{I}CN + (CN)_2. \quad (23)$$

The cyanogen thus formed is evolved as a gas from an acidic solution, or it is decomposed in an alkaline solution as follows:

$$(CN)_2 + 2OH^- \longrightarrow CN^- + OCN^- + H_2O. \quad (24)$$

When the concentration of the copper(II) ion is much lower than that of the cyanide ion, not copper(II) cyanide but a purple intermediate is formed, which then gives cyanogen and a copper(I) species. Several papers have reported about this purple compound.[16–19]

The rate of the reaction between the copper(II) ion and the cyanide ion is too high under ordinary conditions to be measured by conventional methods. Duke and Courtney[20] have used the ammine copper (II) complex to diminish the reaction rate in their kinetic study, while Tanaka *et al.*[21] have used the ethylenediaminetetraacetatocopper(II) complex. Bjerrum *et al.*[22,23] have studied the kinetics in a methanol–water mixture at a low temperature. These three groups of workers have, from their kinetic considerations, expected the existence of $Cu^{II}(CN)_4^{2-}$ as an intermediate. From their measurements of ESR and optical spectra, Longo and Buch[24] have concluded the purple intermediate to be $Cu^{II}(CN)_4^{2-}$ with a square-planar configuration.

Nord and Matthes[25] have applied the stopped-flow technique to the reaction between the copper(II) ion and the cyanide ion in aqueous solutions at ambient temperatures. Thus by following the concentration of

the intermediate $Cu^{II}(CN)_4^{2-}$ by using an optical spectrometer and a oscilloscope, they obtained a rate equation, Eq. 25, from which they have proposed a reaction mechanism, Eqs. 26 and 27, the latter being rate-determining:

$$v = k_1 \frac{[Cu^{II}(CN)_4^{2-}]^2}{[CN^-]} \quad (25)$$

$$Cu^{II}(CN)_4^{2-} \rightleftharpoons Cu^{II}(CN)_3^- + CN^- \quad (26)$$

$$Cu^{II}(CN)_4^{2-} + Cu^{II}(CN)_3^- \longrightarrow \text{Product.} \quad (27)$$

There is an agreement between their work and ours in that the reaction rate is proportional to the square of $[Cu^{II}(CN)_4^{2-}]$. However, there is a disagreement in the dependency upon $[CN^-]$.

Baxendale and Westcott[26] have studied the kinetics at rather low pH values, where the concentration of the free cyanide ion is so small that the reaction rate is relatively small and can easily be measured. Thus, they followed the change in the concentration of the reaction product, $Cu^I(CN)_2^-$, by means of a UV spectrometer, and obtained the result that the reaction rate is proportional to the 6th power of $[CN^-]$ and to the square of $[Cu^{2+}]$. From this kinetic data, they have proposed the following mechanism, in which the Eq. 29 reaction is rate-determining:

$$Cu^{2+} + 3CN^- \rightleftharpoons Cu^{II}(CN)_3^- \quad (28)$$

$$2Cu^{II}(CN)_3^- \longrightarrow 2Cu^I(CN)_2^- + (CN)_2. \quad (29)$$

Their result is compatible with that of our present work. Equation 29 is the same as Eq. 7a, while their kinetic data can also be explained by the formation of $Cu^{II}_2(CN)_6^{2-}$, followed by the rate-determining reaction, Eq. 7b.

A more detailed discussion of the kinetics and the mechanisms of the chemical reaction between the copper(II) ion and the cyanide ion will be presented in a succeeding paper.

We would like to thank Professor Saburo Kako for his helpful discussions, and Mr. Hideo Fujita for his assistance in measuring the ESR spectra. The present work was partly supported by a Grant-in-Aid for Scientific Research (Environmental Science) from the Ministry of Education, Science and Culture (No. 403523).

The Reactions of NH($a^1\Delta$) with Ethane, Propane, and Isobutane in the Liquid Phase

Shigeru Tsunashima,* Jun-ichi Hamada, Mitsuhiro Hotta, and Shin Sato
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received December 25, 1979)

The photolysis of HN_3 was studied in liquid ethane, propane, and isobutane at the temperature of Dry Ice–methanol. In the reaction mixtures, quaternary ammonium salts were formed between the basic products and HN_3. The products were analyzed after having been passed through a trap containing NaOH, in which the salts were decomposed. The main products observed were nitrogen and amines: ethylamine from ethane, propyl- and isopropylamine from propane, and *i*-butyl, and *t*-butylamine from an isobutane solution. Ammonia and hydrogen were also formed as minor products. Possible reaction mechanisms are discussed. It is suggested that about 80% of the singlet NH is inserted into the C–H bond of paraffin to form amine and that 20% of it is deactivated to the ground triplet state by the reactions with paraffin. The relative efficiencies of the insertion into primary, secondary, and tertiary C–H bonds were estimated to be 1.0, 1.9, and 2.3 respectively.

The reactions of O and CH_2 with hydrocarbons have been extensively investigated. There are many similarities between O and CH_2 in the reactions. Triplet O(^{3}P) and $CH_2(^3B_1)$ are added to the double bond of olefin and abstract a hydrogen atom from paraffin. Singlet O(^{1}D) and $CH_2(^1A_1)$ are inserted into the C–H bond of paraffin and are added to the double bond of olefin.[1–6]

Since NH is isoelectronic with O and CH_2, the reactions of NH can be expected to be similar to those of O and CH_2.[7] Although there have been many studies of NH using the spectroscopic method,[8] the reactions of NH with hydrocarbons have not yet been established.[9–12] The main reason for this is that, except in a few studies, no NH-containing products could be detected.[13,14] This may be due to the following facts: (1) the insertion or addition products initially formed have so large an energy that only decomposition products can be observed and (2) a basic NH-containing product, if formed, may react with NH_3 or HNCO, which is often used as a source of NH, to form a quaternary ammonium salt. Because of its low vapor pressure, the salt is hard to analyze with GLC.

With these factors in mind, HN_3 was photolyzed in liquid ethane at the temperature of Dry Ice–methanol, as was briefly shown in a previous letter.[15] When less volatile products were treated with NaOH, the formation of ethylamine and ammonia could be detected. Propyl- and isopropylamine could also be detected from the propane solution. These amine formations were attributed to the insertion of the singlet NH ($a^1\Delta$) into the C–H bond of paraffin. In this paper, a kinetic study will be described and new results obtained with isobutane will be presented.

Experimental

The experimental method was the same as was briefly shown in the previous letter.[15] The details will now be given here.

HN_3 was prepared *in vacuo* by heating a mixture containing sodium azide (Koso Chemical Co.) and an excess amount of stearic acid (Tokyo Kasei Kogyo Co.) to approximately 100 °C. The HN_3 was dried with a trap containing P_2O_5, and the fraction condensable at −120 °C was stored in a Pyrex bulb covered with Al foil. The purified HN_3 was kept at a pressure of less than 50 Torr and/or was condensed at the temperature of liquid nitrogen. Pure-grade ethane, propane, and isobutane (Takachiho Shoji Co.) were used after distillation at −130, −120, and −110 °C respectively.

The mixture of HN_3 and hydrocarbon was prepared in a quartz tube 8 mm in o.d. using a mercury-free vacuum line equipped with calibrated volumes and a Wallace-Tiernan dial manometer (Nagano Keiki Co.). The quartz tube has a stopcock and a ground joint attached to it so that it was detachable from the vacuum line. The mixture was liquefied in a transparent quartz Dewar flask at the temperature of Dry Ice–methanol. The amount of the solution was about 1 ml. The solution of HN_3 thus prepared was irradiated with a medium-pressure mercury lamp (Wako Denki Co.) through a filter which cuts off the light shorter than 250 nm (Toshiba UV 27). Thus, the effective light was limited to between 320 and 250 nm.

After the irradiation, non-condensable gases at the temperature of liquid nitrogen were analyzed with a combination of a Toepler pump, a gas burette, and a CuO furnace at 300 °C. The solvents (ethane, propane, and isobutane) were evacuated at −130, −120, and −110 °C respectively, Less volatile products, including unreacted HN_3, were passed through a trap packed with NaOH-coated glass wool at 80 °C. The products thus obtained were analyzed by GLC using a column packed with amine 220 on Celite 545 (Gasukuro Kogyo Co., 5 m in length) at 40 °C. For the separation of ammonia and propane, a column packed with NaOH-coated Porapak Q (30 cm in length) was used at 80 °C. A mass spectrometer was also used for the identification of the product.

Results

When HN_3 was photolyzed in liquid ethane, propane, or isobutane at the temperature of Dry Ice–methanol, a white precipitant was observed to be formed. The non-condensable products at the temperature of liquid nitrogen were nitrogen and hydrogen. The amounts of hydrogen formed from the ethane, propane, and isobutane solutions were independent of the changes in the concentration of HN_3 and were, respectively, 5.6±1.0, 4.3±2.0, and 5.3±1.4% of that of the nitrogen formed. No methane formation was found in any case examined.

The condensable products observed were ammonia and amines: ethylamine from ethane, propyl- and isopropylamine from propane, and *i*-butyl- and *t*-

butylamine from isobutane solutions. Without having been passed through the NaOH trap, the peak of neither ammonia nor amine was observed on the gas chromatogram. Probably, a quaternary ammonium salt was formed in the reaction mixtures between the basic products and the reactant HN_3. The complete recovery of the products was checked by using authentic samples of amine and HN_3 dissolved in liquid hydrocarbon at the temperature of Dry Ice–methanol.

Because of the formation of a white precipitant in the solution and dew on the wall of the Dewar flask, the amount of the product was not reproducible; however, the product ratio was found to be reproducible. Figure 1 shows the plots of the product ratios, NH_3/N_2 and RNH_2/N_2, as functions of $[HN_3]/[RH]$. Here, R represents C_2H_5, C_3H_7, or C_4H_9. As is shown in Fig. 1, the ratio of RNH_2/N_2 decreased with an increase in the concentration ratio of $[HN_3]/[RH]$, while the ratio of NH_3/N_2 increased.

In the cases of propane and isobutane solutions, we obtained no evidence of the formation of C_6 or C_8 hydrocarbons, which are possible products of the C_3H_7 or C_4H_9 radicals, if formed. For both cases, two kinds of amines were formed, corresponding to the two types of C–H bonds present. Figure 2 shows plots of the product ratios, propylamine/isopropylamine and *i*-butylamine/*t*-butylamine, as functions of $[HN_3]/[RH]$. The product ratios were independent of the changes in the concentration ratio; they were 1.6± 0.2 and 4.0±0.4 in propane and isobutane solutions respectively.

Figure 3 shows plots of $(RNH_2+3H_2+4NH_3)/N_2$ as functions of the concentration ratio of $[HN_3]/[RH]$. The ratios were less than unity in every case examined.

Discussion

As was discussed in the previous letter, the following reaction mechanism can explain the results obtained in the ethane and propane solutions of HN_3 at the temperature of Dry Ice–methanol:[15]

$$HN_3 + h\nu \longrightarrow {}^1NH + N_2 \qquad \alpha \qquad (1)$$

$$\longrightarrow H + N_3 \qquad (1-\alpha) \qquad (2)$$

$$^1NH + HN_3 \longrightarrow NH_2 + N_3 \qquad k_a \qquad (3)$$

$$^1NH + RH \longrightarrow RNH_2 \qquad k_h \qquad (4)$$

$$NH_2 + HN_3 \longrightarrow NH_3 + N_3 \qquad (5)$$

$$H + HN_3 \longrightarrow H_2 + N_3 \qquad (6)$$

$$2NH_2 \longrightarrow N_2H_4 \qquad (7)$$

$$2N_3 \longrightarrow 3N_2, \qquad (8)$$

where ^1NH represents an NH radical in the first excited singlet state ($a^1\Delta$).

Baronavski *et al.* showed that the 266 nm-laser photolysis of HN_3 gives rise to NH fragments exclusively in the $a^1\Delta$ state without being vibrationally excited.[14] They also showed that a similar thing could be said when HN_3 was photolyzed with the light of wavelengths

between 290 and 310 nm. Their conclusions agree well with the results obtained in the study of the flash photolysis of HN_3 using light longer than 200 nm.[16]

In the absence of added hydrocarbon, the main reaction of the singlet NH is the abstraction of a hydrogen atom from HN_3 to form an excited NH_2 which can fluoresce.[14,17] In the presence of hydrocarbon, the insertion reaction of the singlet NH into the C–H bond of paraffin is assumed for the formation of amine. The insertion reaction is similar to that observed in the case of the singlet O and CH_2.[1-6] An alternative mechanism for the amine formation is the so-called "radical-abstraction recombination" mechanism:

$$^1NH + RH \longrightarrow NH_2 + R \quad (9)$$

$$NH_2 + R \longrightarrow RNH_2. \quad (10)$$

If these reactions are predominant, more isopropylamine should be formed than propylamine and more *t*-butylamine should also be formed than *i*-butylamine, since the bond-dissociation energy of the secondary or tertiary C–H bond is smaller than that of the primary C–H bond.[18] If we found C_6 or C_8 hydrocarbons as products, Reaction 9 would be important. This was not the case in the present study, as was shown in the Results section. That is, the amine is formed mainly by Reaction 4.

Konar *et al.* proposed a reaction mechanism in which a part of the primary photodissociation of HN_3 is to N_3 and H, followed by a hydrogen-atom abstraction from HN_3. This mechanism can explain the hydrogen formation in the 213.9 nm photolysis of HN_3 at room temperature.[11] By measuring the decay of the concentration of hydrogen atoms, Bras and Combourieu have estimated the rate constant of the reaction of hydrogen atoms with HN_3 to be $1.5\times 10^{13}\exp(-2300/T)$ $cm^3\ mol^{-1}\ s^{-1}$.[19] As the exit channel of the reaction of hydrogen atoms, they proposed the formation of NH_2 and N_2, which is different from Reaction 6:

$$H + HN_3 \longrightarrow NH_2 + N_2. \quad (11)$$

When Reaction 11 is included in the mechanism instead of Reaction 6, it is necessary to consider a reaction mechanism which can explain the hydrogen formation. It was difficult to construct such a mechanism. We, therefore, conclude that the rate constant estimated by Bras and Combourieu is that for Reaction 6, but not for Reaction 11.

The abstraction of a hydrogen atom from paraffin by H or NH_2 is a possible reaction:

$$H + RH \longrightarrow H_2 + R \quad (12)$$

$$NH_2 + RH \longrightarrow NH_3 + R. \quad (13)$$

These reactions, however, can be neglected under the present experimental conditions, because of the following reasoning: (1) the bond dissociation energy of $H–N_3$ is smaller than that of R–H,[18] (2) since the activation energies of the reactions are about 20 to 40 kJ mol^{-1},[20,21] the rates of these reactions should be very slow at the temperature of Dry Ice–methanol, and (3) no possible products formed from the recombination of R could be detected in the present study, as was shown in the Results section.

In Reaction 7, a hydrazine formation was assumed, although we failed to detect the hydrazine formation. Without including Reaction 7, the following equation can be expected to hold between the amounts of the products:

$$RNH_2 + 3H_2 + 4NH_3 = N_2. \quad (14)$$

As was shown in Fig. 3, the ratios of $(RNH_2+3H_2+4NH_3)/N_2$ were less than unity for any solvent examined. That is, about 30 to 40% of the NH-containing products are missing in this study. When Reaction 7 is included in the mechanism, the following relation can be expected to hold:

$$RNH_2 + 3H_2 + 4NH_3 + 5N_2H_4 = N_2. \quad (15)$$

A steady-state treatment of the above mechanism gives the following relations:

$$\alpha = X/(X+H_2) \quad (16)$$

$$X/RNH_2 = 1 + k_a[HN_3]/k_h[RH]. \quad (17)$$

Here, X is defined as follows:

$$X = N_2 - 3(H_2+NH_3+N_2H_4). \quad (18)$$

The amount of N_2H_4 formed can be estimated using Eq. 15. The relations of Eqs. 16 and 17 are plotted in Figs. 4 and 5 respectively as functions of the concentration ratios, $[HN_3]/[RH]$.

As is shown in Fig. 4, the ratio of $X/(X+H_2)$ is independent of the changes in the $[HN_3]/[RH]$ ratio and also the changes in the solvent examined. The values of α is estimated to be 0.91 ± 0.03 from the ratio in Fig. 4. That is, about 91% of the primary photodissociation of HN_3 gives rise to the first excited singlet state, while the remaining part corresponds to the dissociation into H and N_3. This part is slightly larger than that estimated in the gas-phase photolysis of HN_3 at 213.9 nm.[11] Bradley *et al.* pointed out that the fraction of the primary photodissociation of HNCO into H and NCO decreases with the decrease in the excitation wavelength in the gas-phase photolysis of HNCO.[22] A similar effect of the wavelength might explain the difference between the results obtained by Konar *et al.* and those of the present study.

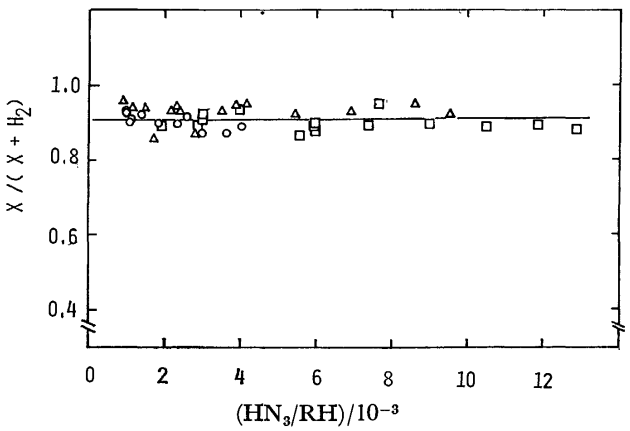

Fig. 4. Plots of $X/(X+H_2)$ as functions of concentration ratio of $[HN_3]/[RH]$.
○: $R=C_2H_5$, △: $R=C_3H_7$, □: $R=C_4H_9$.

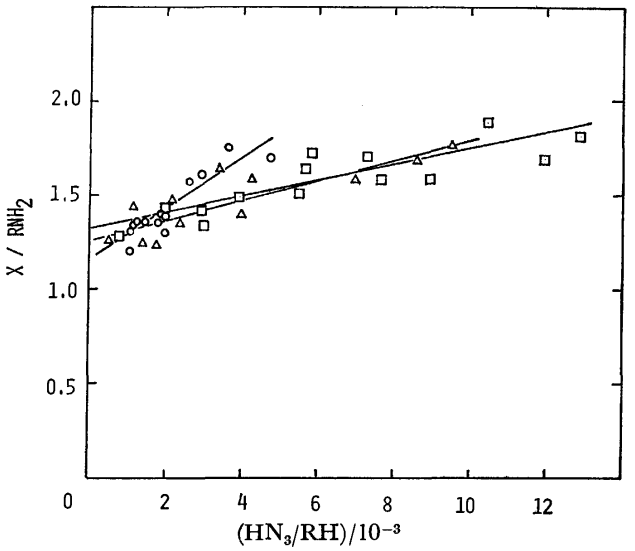

Fig. 5. Plots of X/RNH_2 as functions of concentration ratio of $[HN_3]/[RH]$.
○: R=C_2H_5, △: R=C_3H_7, □: R=C_4H_9.

As is shown in Fig. 5, the plots of X/RNH_2 give straight lines for any solvent examined, as was expected from Eq. 17. The intercepts, however, are different from unity. In order to explain the non-unity intercepts, the following reactions are considered to hold:

$$^1NH + RH \longrightarrow {}^3NH + RH \qquad k_h' \qquad (19)$$

$$^3NH + HN_3 \longrightarrow NH_2 + N_3. \qquad (20)$$

Here, ^3NH denotes NH in the ground triplet state, ($X^3\Sigma^-$). A similar deactivation process has been considered in the reactions of the singlet O and CH_2.[1-6] The triplet NH will abstract a hydrogen atom preferentially from HN_3, as was considered to hold in the case of the singlet NH. The rate constant of Reaction 20 has been estimated, in the study of the shock-wave decomposition of HN_3, to be 3.0×10^{11} exp $(-800/T)$ $cm^3\,mol^{-1}\,s^{-1}$.[23] Because of its low activation energy, Reaction 20 may be more important than Reaction 21 under the present experimental conditions:

$$^3NH + RH \longrightarrow NH_2 + R. \qquad (21)$$

By the inclusion of Reactions 19 and 20 in the mechanism, Eq. 17 changes its form as follows:

$$X/RNH_2 = (k_h+k_h')/k_h + k_a[HN_3]/k_h[RH]. \qquad (22)$$

From the slope and the intercept of the straight line in Fig. 5, the values of $k_h/(k_h+k_h')$ and k_a/k_h can be estimated. The results are summarized in Table 1. As is shown in Table 1, about 80% of the singlet NH is inserted into the C–H bond of paraffin, while the remaining part is deactivated to the ground triplet state by the reaction with paraffin. The rate constant of the reaction of the singlet NH with paraffin is about two orders of magnitude smaller than that with HN_3 at the temperature of Dry Ice–methanol.

Table 1. Summary of the rate constant ratios

Reactant	$k_h/(k_h+k_h')$	k_a/k_h	$k_h/k_{a\,rel}$	$k_{h\,rel}$
C_2H_6	0.86±0.04	125±21	1.0	1.0
C_3H_8	0.79±0.02	49± 9	2.6	1.6
i-C_4H_{10}	0.75±0.04	40± 9	3.1	1.9

The value of k_a has been estimated to be 5.6×10^{13} $cm^3\,mol^{-1}\,s^{-1}$ in the gas phase at room temperature.[14,16] Paur and Bair estimated the activation energy to be very small, if present at all.[16] In the liquid phase at the temperature of Dry Ice–methanol, the rate of Reaction 3 (k_a) may be expected to be fast and close to the diffusion-controlled rate. That is, k_a depends on the nature of the solvent, such as the viscosity. In the third column of Table 1, the relative values of k_h/k_a are listed.

Using the values of the product ratios shown in Fig. 2, it is possible to estimate the relative efficiencies of the insertion per C–H bond, k_s/k_p and k_t/k_p. Here, the subscripts p, s, and t represent the primary, secondary, and tertiary C–H bonds of paraffin respectively:

$$6k_p/2k_s = \text{propylamine/isopropylamine} = 1.6 \pm 0.2 \qquad (23)$$

$$9k_p/k_t = i\text{-butylamine}/t\text{-butylamine} = 4.0 \pm 0.4. \qquad (24)$$

Thus, $k_s/k_p=1.9\pm0.2$ and $k_t/k_p=2.3\pm0.2$. That is, the efficiencies of the insertion into the secondary and tertiary C–H bonds are about twice that into the primary C–H bond. In the case of the singlet O (^1D), a non-discriminative insertion has been observed.[24] On the other hand, the efficiency of the insertion of the singlet CH_2 ($^1A_1$) into the secondary or tertiary C–H bond is slightly larger than that into the primary C–H bond.[25] The reason for these differences is not clear at present.

The relative insertion rate of the singlet NH into ethane, propane, and isobutane can be estimated using the values of k_s/k_p, k_t/k_p and by including the numbers of the C–H bond. The results thus obtained are listed in the fourth column of Table 1. The difference between the third and fourth columns is within the factor of two and may be mainly due to the difference in k_a.

Since we included Reactions 19 and 20 in the reaction mechanism, the NH_2 radicals are formed *via* two reaction paths, Reactions 3 and 20. If Reaction 7, the formation of N_2H_4, is not included in the mechanism, the ratio of the yield, $(NH_3/RNH_2)_0$, should be equal to the k_h'/k_h ratio, where the subscript 0 denotes the value obtained by extrapolation to a zero concentration of HN_3. This is not the case, as is expected from the results shown in Fig. 1. If Reaction 7 is included, the following relations are expected to hold:

$$NH_3/(N_2H_4)^{1/2} = k_5[HN_3]/k_7^{1/2} \qquad (25)$$

$$((NH_3+2N_2H_4)/RNH_2)^{1/2} = k_h'/k_h. \qquad (26)$$

Since the yield ratios, N_2H_4/N_2, calculated were nearly independent of the change in the concentration of HN_3, the NH_3/N_2 ratio should linearly increase with an increase in the concentration of HN_3. This is the case shown in Fig. 1. Using the data of Figs. 1 and 3, the $((NH_3+2N_2H_4)/RNH_2)_0$ ratios were estimated to be 0.2, 0.3, and 0.3 respectively for the cases of ethane, propane, and isobutane. These values

are consistent with those estimated from the $k_h/(k_h+k_h')$ ratios shown in Table 1; *i.e.*, the assumption of the N_2H_4 formation well explains all of the experimental results obtained here.

The Flotation of Cd^{2+} Ions in the Presence and Absence of Zn^{2+} Ions

Koichi KOBAYASHI,*,† Yoshiko SHIMIZU,†† and Tsunetaka SASAKI†††

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received December 27, 1979)

The flotation of Cd^{2+} ions was investigated in the presence and absence of Zn^{2+} ions. It was found that the flotation efficiency of Cd^{2+} ions in the Cd^{2+}–anionic surfactant system is markedly small in the presence of Zn^{2+} ions, but the flotation efficiency of Cd^{2+} ions in the Cd^{2+}–bentonite–cationic surfactant system (adsorbing particle flotation) decreased only slightly in the presence of Zn^{2+} ions. The flotation efficiency in the latter case was further increased by the addition of 3 ppm of polyacrylamide. The doubling of the flotation reagents and time did not effectively increased the flotation efficiency of Cd^{2+} ions in the presence of Zn^{2+} ions, but the two-stage flotation did. It was confirmed that the adsorbing particle flotation of Cd^{2+} ions would be an excellent method in the presence of Zn^{2+} ions.

In previous papers,[1,2] we reported that Cd^{2+} ions were effectively removed by using an anionic surfactant, a cationic surfactant with bentonite, or a cationic surfactant with bentonite and polyacrylamide.

Generally, mine water contains such heavy metal ions as Cd^{2+}, Cu^{2+}, and Zn^{2+}. In the case of removal of Cd^{2+} ions, the flotation is greatly influenced by co-existing ions.

Shimoiizaka *et al.*[3] have studied the removal of Cd^{2+} ions by precipitation flotation in the presence of co-existing ions, such as Fe^{2+} and Zn^{2+} ions, and have indicated that Cd^{2+} ions could be effectively removed by xanthate in the presence of these co-existing ions. However, no other studies have been reported on the adsorbing particle flotation of Cd^{2+} ions in the presence of co-existing ions.

In the present paper, the flotation of Cd^{2+} ions in the presence and absence of Zn^{2+} ions will be reported.

Experimental

Materials. The zinc(II) nitrate used was of an extra-pure grade $Zn(NO_3)_2 \cdot 6H_2O$; it was recrystallized twice from distilled water, and a stock solution with a concentration of 1.78×10^{-3} mol/dm^3 was prepared. For the determination of the concentration of Zn^{2+}, the chelate-titration method was carried out using Cu-PAN.[4] A stock solution of Cd^{2+} ions was prepared by dissolving Cd metal of a 99.999% purity in nitric acid. All the other reagents, such as disodium α-sulfonatododecanoate (α-SLNa), dodecyltrimethylammonium chloride (DTAC), and bentonite (Bt), were the same as have been described previously.[1] The polyacrylamide (PAA) used as a coagulating agent was a product of the Mitsubishi Kasei Co., Ltd., its average molecular weight was seven million.

Apparatus and Procedure. The apparatus and the method of flotation measurements were the same as have been reported previously.[1] The concentration of the Cd^{2+} ions was measured by using an atomic absorption spectrometer (Techtron Pty., Model-AA-100). A glass electrode pH meter (Toadenpa Co., Ltd., HM-5A) was used to measure the pH. The gas-flow rate was kept at 10 ml/min, while the gas-flow time was kept at 7 or 14 min, as the case required. The measurements of the flotation were carried out at a room temperature of about 25 °C.

The flotation efficiency of Cd^{2+} ions (F) is conventionally expressed by:

$$F = (C_i - C_f)/C_i \times 100\ (\%),$$

where C_i and C_f are the initial and final concentrations of the Cd^{2+} ions respectively.

Results and Discussion

The adsorbing particle flotation was carried out for a solution containing 1.78×10^{-5} mol/dm^3 Cd^{2+}, 1.78×10^{-5} mol/dm^3 DTAC, or 1.78×10^{-4} mol/dm^3 DTAC and 100 ppm Bt. The results are shown in Fig. 1. As can be seen in Fig. 1, the flotation efficiency of the Cd^{2+} ions increased with an increase in the pH, showed a maximum at about pH 11, and decreased with an increase in the pH above about pH 11. The maximum flotation efficiencies of the Cd^{2+} ions were 73% and 96% in the cases of 1.78×10^{-5} mol/dm^3 DTAC and 1.78×10^{-4} mol/dm^3 DTAC respectively. In the former case, the Cd^{2+} ions may be completely adsorbed on the Bt particle, considering the results presented in a previous paper,[2] but the Bt particle

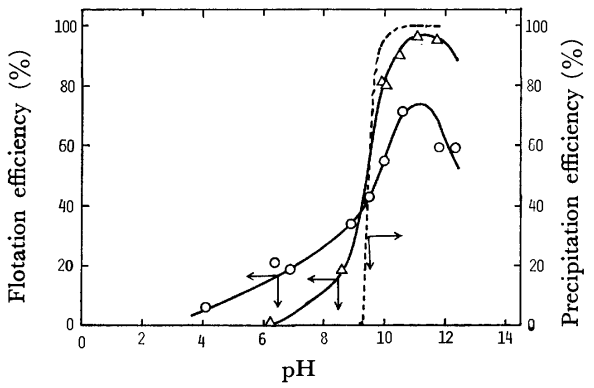

Fig. 1. Flotation efficiency *vs.* pH for Cd^{2+}–Bt–DTAC system. Cd^{2+}: 1.78×10^{-5} mol/dm^3, Bt: 100 ppm, DTAC (○: 1.78×10^{-5} mol/dm^3; △: 1.78×10^{-4} mol/dm^3), gas-flow time: 7 min, gas-flow rate: 10 ml/min. ----: Precipitation efficiency *vs.* pH curve.

† Present address: Laboratory of Chemistry, Musashi Institute of Technolgy, 1-28-1, Tamatsutsumi, Setagaya, Tokyo 158.

†† Present address: 2-7-6, Shiomidai, Isogo-ku, Yokohama, Kanagawa 247.

††† Present address: Department of Chemistry, Faculty of Science, Tokai University, Hiratsuka, Kanagawa 259-12.

could not be floated because the amount of DTAC was insufficient. When the concentration of DTAC increased to 1.78×10^{-4} mol/dm^3 DTAC, a nearly complete flotation of Bt particle could be attained. The broken curve in Fig. 1 represents the precipitation efficiency *vs.* pH curve obtained from the solubility product (7.6×10^{-15}) of $Cd(OH)_2$. It was confirmed that the flotation efficiency *vs.* pH curve of Cd^{2+} ions was in accord with the precipitation efficiency *vs.* pH curve of $Cd(OH)_2$. Judging from these facts, the polynuclear cations of Cd^{2+} may be formed and subsequently adsorbed on Bt particles. The Bt particles coagulated by DTAC are floated by bubbles.

The flotation of the Cd^{2+} ions was further carried out for the system prepared by adding 1.78×10^{-4} mol/dm^3 Zn^{2+} to a solution containing 1.78×10^{-5} mol/dm^3 Cd^{2+}, 1.78×10^{-5} mol/dm^3 DTAC, and 100 ppm Bt. The results are shown in Fig. 2(I). The flotation efficiency of the Cd^{2+} ions decreased to 62% when ten times as many Zn^{2+} ions were added as compared with 73% for the system without Zn^{2+} ions (Fig. 1). The decrease in the flotation efficiency of the Cd^{2+} ions may be due to Cd^{2+} being hindered by the adsorption of Zn^{2+} on the Bt surface. The flotation efficiency *vs.* pH curve of the system with Zn^{2+} ions shifts toward a lower pH as compared with that of the system without Zn^{2+} ions (Fig. 1). This shift in pH may be caused by the coprecipitation of Cd^{2+} with $Zn(OH)_2$, which was formed at about pH 7.7.

Figure 2(II) shows the results of the flotation of Cd^{2+} ions from a solution containing 1.78×10^{-5} mol/dm^3 Cd^{2+}, 1.78×10^{-5} mol/dm^3 α-SLNa, and 1.78×10^{-4} mol/dm^3 Zn^{2+}. The maximum flotation efficiency of 38% was obtained at pH 8.3. As may be seen, the flotation efficiency of the Cd^{2+}–α-SLNa system was lower than that of the Cd^{2+}–Bt–DTAC system in the presence of Zn^{2+} ions.

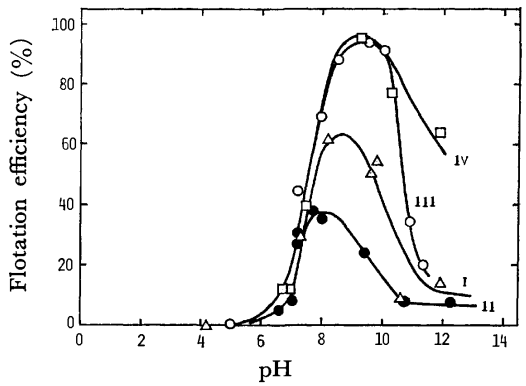

Fig. 2. Flotation efficiency *vs.* pH for Cd^{2+}–Zn^{2+}–Bt–DTAC system(I), Cd^{2+}–Zn^{2+}–α-SLNa system(II), Cd^{2+}–Zn^{2+}–Bt–DTAC–PAA system(III), and Cd^{2+}–Zn^{2+}–Bt–DTAC–PAA system(IV). Cd^{2+}: 1.78×10^{-5} mol/dm^3, Zn^{2+}: 1.78×10^{-4} mol/dm^3, gas-flow rate: 10 ml/min.
(I) DTAC: 1.78×10^{-5} mol/dm^3, Bt: 100 ppm, gas-flow time: 7 min. (II) α-SLNa: 1.78×10^{-5} mol/dm^3, gas-flow time: 7 min. (III) DTAC: 1.78×10^{-5} mol/dm^3, Bt: 100 ppm, PAA: 3 ppm, gas-flow time: 7 min. (IV) DTAC: 3.56×10^{-5} mol/dm^3, Bt: 200 ppm, PAA: 6 ppm, gas-flow time: 7 min.

In order to study the effect of PAA on the flotation efficiency, the flotation was carried out for a system prepared by adding 3 ppm PAA to a solution containing 1.78×10^{-5} mol/dm^3 Cd^{2+}, 1.78×10^{-4} mol/dm^3 Zn^{2+}, 1.78×10^{-5} mol/dm^3 DTAC, and 100 ppm Bt. As compared with Fig. 2(I) for the system without PAA, a sharp maximum of 95% flotation at about pH 9.5 is shown in Fig. 2(III). Thus, it was confirmed that the flotation efficiency of the Cd^{2+} ions increased further upon the addition of PAA.

The adsorbing particle flotation was further carried out by doubling the amount of reagents and the gas-flow time for the above system. However, the flotation efficiency of Cd^{2+} ions was not increased significantly. As can also be seen from Fig. 1 and other data,[1] the 1.78×10^{-4} mol/dm^3 DTAC is required to increase effectively the removal of 100 ppm Bt. Therefore, the further addition of DTAC is considered to increase the flotation efficiency of Cd^{2+} ions in the case of Fig. 2(IV).

As can also be seen from Fig. 1 and Fig. 2(I), the influence of the Zn^{2+} addition to the Cd^{2+}–Bt–cationic surfactant system is small in terms of the flotation efficiency. In the case of the presence of Zn^{2+}, the flotation efficiency of the Cd^{2+} ions of the Cd^{2+}–α-SLNa system was lower than that of the Cd^{2+}–Bt–DTAC system, as is shown by Fig. 2(I) and Fig. 2(II). These facts show that the adsorbing particle flotation is an effective method in the presence of Zn^{2+} ions. Further, the addition of 3 ppm PAA to the Cd^{2+}–Bt–DTAC system markedly increases the flotation efficiency of the Cd^{2+} ions, as may be seen by comparing the systems of Fig. 2(I) and Fig. 2(III). As can be seen in Fig. 2(IV), the maximum flotation efficiency of 96% was obtained when the concentration of each reagent was twice that of Fig. 2(III). Therefore, the flotation efficiency of the Cd^{2+} ions is not significantly increased by doubling the amount of the reagents and the gas-flow time.

It has also been known that the two-stage flotation is effective for the ion flotation.[5,6] Therefore, the flotation of Cd^{2+} ions from a solution containing 1.78×10^{-5} mol/dm^3 Cd^{2+}, 1.78×10^{-5} mol/dm^3 DTAC, 1.78×10^{-4} mol/dm^3 Zn^{2+}, 100 ppm Bt, and 3 ppm PAA was carried out at pH 9.55 in two stages. The flotation efficiency of Cd^{2+} ions in the first stage was 92.5%. After the underlying solution had been removed from the flotation cell, the second-stage flotation of the solution was carried out with the further addition of 1.78×10^{-5} mol/dm^3 DTAC, 100 ppm Bt, and 3 ppm PAA. It is evident from Table 1 that the flotation efficiency of the Cd^{2+} ions was 99%. From these facts, the removal of the Cd^{2+} ions can be said to have been almost complete after the two-stage flota-

Table 1. Flotation efficiency in two stages

pH	F (%)		Relative time and amount of reagents
	1st	1st+2nd	
9.55	92.5	99.0	2

tion.

In conclusion, the Cd^{2+} ions were effectively removed by using Bt and DTAC rather than the α-SLNa, and the flotation efficiency was further increased by the addition of PAA to the former system in the presence of Zn^{2+} ions. A two-stage flotation was found to be most effective.

The Effect of Sugars on the Thermal Denaturation of Lysozyme

Hatsuho UEDAIRA* and Hisashi UEDAIRA

Research Institute for Polymers and Textiles, 1-1-4, Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received January 5, 1980)

Thermal denaturation of lysozyme (hen egg-white) in aqueous sugar solution was studied by DSC measurements at pH 5 and by CD measurements at pH 2.12. All of the sugars investigated show a stabilizing influence on the native conformation. The effect of sugars on the transition temperature of lysozyme almost linearly increased with the increase of the numbers of equatorial hydroxyl groups per molecule of sugars. The ellipticity of the solutions at 294 nm of lysozyme and glucose or arabinose was additive in the value of each component at pH 5. The effect of sugars in stabilizing the protein structure may be due to the intensification of the hydrophobic interactions inside the protein molecule.

There have been many investigations on the effects of alcohols and sugars on the stability of globular proteins to elucidate the nature of the interactions that stabilize the native conformation of proteins.

The effects of mono- and polyhydric alcohols on the reversible thermal denaturation of enzymes were investigated by Gelsma and Stuur,[1] Velicelebi and Sturtevant,[2] and Gekko, Morikawa and Noguchi.[3] The thermal stability of tropocollagen in these alcohols has also been measured by Harrap.[4]

A retarding effect of sucrose and glycerol on the rate of change of the optical rotation of ovalbumin in urea solution was found by Simpson and Kauzmann.[5] The effect of glucose on the denaturation of haemoglobin by urea was also tested and characterized by Simons and Naftalin.[6] The influence of polyhydric alcohols and sugars on the rate of subunit dissociation of tetrameric L-asparaginase in the presence of urea was investigated by Shifrin and Parrott.[7] In general, polyhydric alcohols have stabilizing influences on the native conformation of proteins.

No systematic investigations are available concerning the relation between the molecular conformation of sugars and their effect on the stability of globular proteins. In this work an attempt was made to explain the relation by studying the effect of various sugars on the thermal denaturation of lysozyme by differential scanning calorimetry. The interactions between some sugars and lysozyme were also studied by circular dichroism spectrometry.

Experimental

Materials. The hen egg-white lysozyme used in the present experiments was a six times recrystallized preparation obtained from Seikagaku Kogyo Co. The molecular weight of lysozyme was assumed to be 14307 and its average residue weight to be 110.9. Saccharides (G. R.) were recrystallized once or twice from water–ethanol solutions. Solutions were prepared with deionized and distilled water. The concentration of lysozyme was determined spectrophotometrically using an extinction of $E^{1\%}_{1cm}=26.9$ at 280 nm.[8] A Hitachi automatic recording spectrophotometer, model ESP-3T, or a Shimadzu double beam spectrophotometer UV 220 was used.

DSC Measurements. A Perkin-Elmer DSC Model II Calorimeter was used. 20 μl samples were packed in a stainless steel cell for high pressure use. Concentration of lysozyme was 6.188—7.986% at pH 5.0 (adjusted by adding HCl) and ionic strength was adjusted to be 0.1 by adding NaCl. It is known that aggregation of native lysozyme is favored at high pH values, above about 5.[9] On the other hand the stainless steel pan reacts with the acid solution at high temperature. Consequently, the thermal denaturation of lysozyme was measured at pH 5 with DSC.

CD Measurements. CD spectra were measured using a JASCO J-40A spectropolarimeter with a J-DPZ data processor. The recording of each spectrum was repeated four times, and the averaged spectra were obtained on the data processor. The temperature of the sample was controlled by using a Thermocircular TC-100 (Tokyo Riko Co.). The spectra were measured at protein concentrations of 0.1—0.5% in the spectral region above 250 nm and of 0.013% in the region between 200—250 nm.

Results and Discussion

Thermal Denaturation of Lysozyme without Sugars. The heating rate dependence of the denaturation temperature was observed by DSC. In Fig. 1, the foot and peak temperatures in the DSC curves for the denaturation of lysozyme at pH 5 are plotted against heating rate. The denaturation temperature increased linearly with heating rate; the extrapolated foot and peak temperatures were 64.5 and 75.4 °C, respectively. According to Velicelebi and Sturtevant,[2] T_d, the temperature at which the transition is half completed, and T_p, the temperature of maximal excess heat capacity, do not coincide, even for a two-

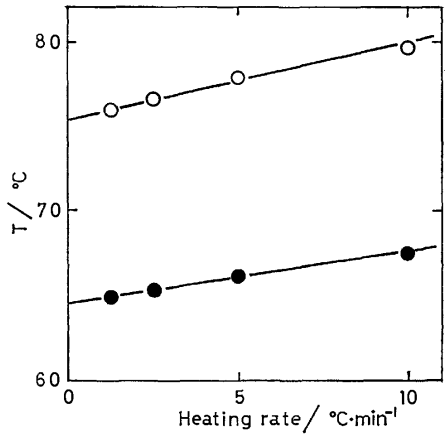

Fig. 1. Heating rate dependency of the foot (—●—) and peak (—○—) temperatures in the DSC curves for the thermal denaturation of lysozyme at pH 5 and $I=0.1$.

state process with no permanent change in heat capacity. In their work, T_d differs from T_p by 0.75—1.0 °C, but our results show the difference is within 0.1 °C. The calibration was made using the melting of In (156.7 °C) and water (0 °C). The foot and peak temperatures extrapolated to zero heating rate show 0.5 and 0.8 °C higher values for In (0.269 mg) and 1.2 and 2.3 °C higher values for water (0.7 mg), respectively. Consequently, the value of 75.4 °C of the extrapolated T_p for the denaturation of lysozyme may be a higher value still. However, due to the large difference in sample weight of lysozyme solution and of calibration substances, we use the T_p values extrapolated to zero heating rate as the denaturation temperature of lysozyme.

In Table 1, the denaturation temperature, T_d, obtained by various methods is shown. Our results are in good agreement with those in the literature.

TABLE 1. COMPARISON OF THE DENATURATION TEMPERATURES OF LYSOZYME AT pH 2.12 AND 5.0 OBTAINED BY VARIOUS METHODS

pH	2.12	5.0
T_d/°C	59.3[a]	78.5[a]
	46.8[b]	75.0[b]
	52.0[c]	
	55.8[d]	
	53.8[e]	75.4[f]

a) Calorimetry: Ref. 10. b) ORD: Ref. 11. c) UV: Ref. 1. d) Viscometry: Ref. 15. e) CD: Results of this study. f) DSC: Results of this study.

Considering the S/N ratio, we chose the heating rate of 5 degrees per minute under these conditions: The DSC sensitivity of 1 mcal/s, 20 μl of sample volume, at lysozyme concentration of 8% and ionic strength of 0.1. At this heating rate, as shown in Fig. 1, the meausured value for denaturation temperature is higher than the extrapolated value by 2.2 °C. The base line was not perfectly straight, so the evaluation of the peak area contains some uncertainty. The calorimetric enthalpy of denaturation, ΔH_{cal}, obtained from the area of DSC curve was not changed for heating rates from 1.25 to 20 degrees per minute, within experimental errors; the average value was 477±8 kJ/mol. The denaturation temperature was not changed at repeated heating about 24 h after the first run.

As most investigations are made at a more acidic condition, the denaturation was also measured by CD spectrum at pH 2.12 and ionic strength at 0.1. The value of molar ellipticity of the native lysozyme was in good agreement with the data of Shimaki *et al.*[12] and of Chen *et al.*[13]

Changes in the values of molar ellipticity, $[\theta]$, with temperature for lysozyme solution at pH 2.12 are shown in Fig. 2. The values of $[\theta]$ at 294 nm decrease with temperature and the transition temperature is 54 °C. The value of $[\theta]$ at 206 nm increases with temperature and the transition temperature is 54 °C too. The values of $[\theta]$ at 294 and 206 nm are caused by trp 62 and 108, and by the helix portion of lysozyme, respectively.[13,14] Figure 2 shows the cooperative nature of the thermal denaturation. The transition temperature T_d is taken as the temperature at which the transition is half complete. The obtained T_d values are compared with the literature values in Table 1. Table 1 shows that our results are within the values in the literature. The value of $[\theta]$ at 294 nm for the sample which was kept at 25 °C for more than 15 h after heating became the same value as that of the initial native one.

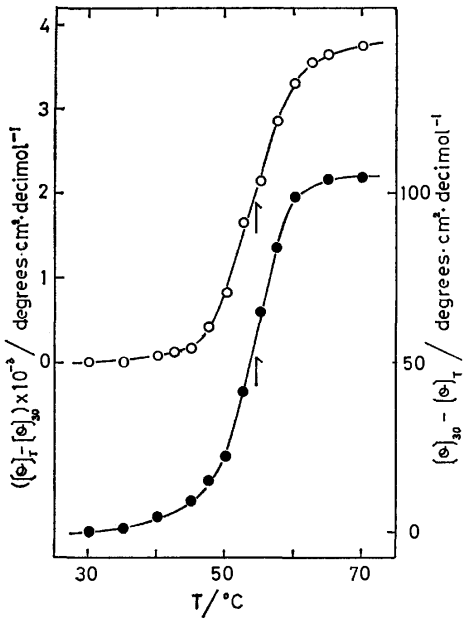

Fig. 2. Changes in the values of molar ellipticity for the lysozyme with temperature at pH 2.12 and I=0.1. —○—: At 206 nm, —●—: at 294 nm.

Plots of ln K against $1/T$, where K is the equilibrium constant for the denaturation obtained from the CD measurements, were almost linear. The values of van't Hoff enthalpy of denaturation, ΔH_{vh}, obtained from the plots were 280±8 kJ/mol from the absorption at 206 nm and 267±16 kJ/mol from the absorption at 294 nm, respectively. These values and the value of ΔH_{cal} are less than that which are obtained by Privalov[10] and by Velicelebi and Sturtevant,[2] but close to the values observed by O' Reilly and Karasz[15] and others.[16–19]

Thermal Denaturation of Lysozyme in the Presence of Sugars. DSC curves for the thermal denaturation of lysozyme (8.04%) in 1 mol kg^{-1} sugar solutions at pH 5 and I=0.1 at the heating rate of 5 degrees per minute are shown in Fig. 3. In every case studied, the thermal denaturation temperature is elevated by the addition of sugars. The values of the increasing temperature of the denaturation of lysozyme by 1 mol kg^{-1} sugar solution, ΔT_d (°C/mol), are plotted against the numbers of equatorial OH groups per molecule of sugars in Fig. 4. The numbers of equatorial OH groups are calculated from the NMR data of Angyal *et al.*[20] The values of ΔT_d are found to be closely related to the molecular conformation of sugars. From the slope in Fig. 4, T_d of lysozyme is raised about 0.8 °C per equatorial OH group. The values of ΔT_d of lysozyme by 1 mol dm^{-3} polyhydric alcohol

solutions are measured by Gelsma and Stuur,[1] and their results show that the T_d is raised by 0.8 °C per OH group, regardless of which polyhydric alcohol is added.

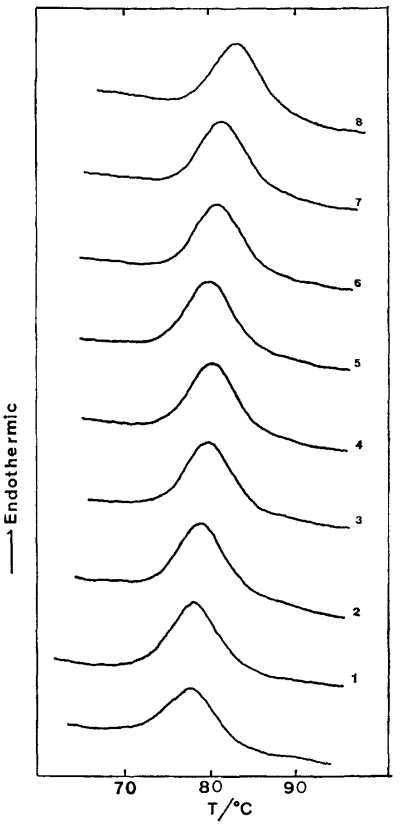

Fig. 3. DSC curves for the thermal denaturation of lysozyme in 1 mol kg^{-1} sugar solutions at pH 5 and I=0.1.
The lowest curve is for a solution without a sugar. Curves 1: with deoxyribose, 2: ribose, 3: lyxose, 4: arabinose, 5: xylose, 6: fructose, 7: glucose, and 8: sucrose.

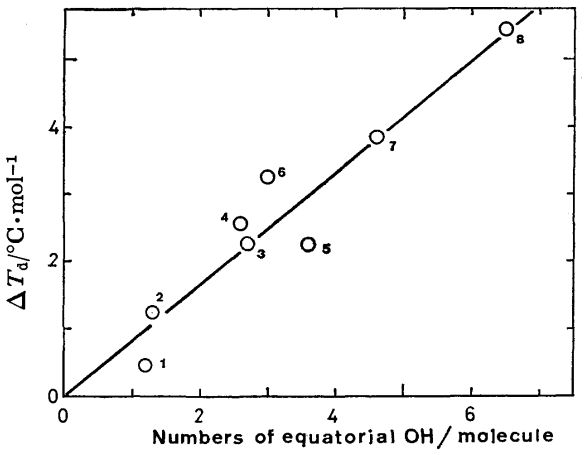

Fig. 4. The relation between the changes in the denaturation temperature of lysozyme in the presence of 1 mol kg^{-1} sugar solutions and the numbers of equatorial OH groups in a sugar molecule.
The numbers in the figure denote the same sugar as in Fig. 3.

The values of ΔH_{cal} of lysozyme in sugar solutions did not show a clear relation to the number of equatorial OH groups per added sugar molecule. In every case, sugars increased the value of ΔH_{cal} by about 10%.

Thermal denaturation for the lysozyme solution at pH 2.12 in 1 mol dm^{-1} glucose solution was also measured by the change in the values of molar ellipticity of lysozyme at 294 nm. Denaturation temperature and ΔH_{vh} were 58.5 °C and 310±16 kJ/mol, respectively. In this case, the molar ellipticity for renatured lysozyme solution was slightly lower than that for the native one. Comparing the data obtained for lysozyme with and without glucose, T_d is increased by about 5 degrees, and ΔH_{vh} increased by about 10%. The effect of the increase of T_d and ΔH_{vh} at pH 2.12 is nearly equal to the effect obtained at pH 5 by DSC measurements. The effect of polyhydric alcohols on the thermal denaturation of lysozyme is also found to be independent of pH.[1]

The Interaction between Lysozyme and Sugars. To elucidate the cause of the stabilizing effect of sugars we measured CD spectra at various concentrations of glucose and arabinose at pH 5, ionic strength 0.1, and 25 °C. CD spectra for lysozyme and arabinose solutions at various concentrations of arabinose are shown in Fig. 5. Arabinose shows a fairly negative broad band in these region, as curve h shows. Curve a is the CD spectrum for lysozyme solution and curves from b to g are the CD spectra for the mixed solutions of lysozyme and arabinose with increasing concentration of arabinose. Similarly, CD spectra for lysozyme in glucose solutions showed slightly less positive

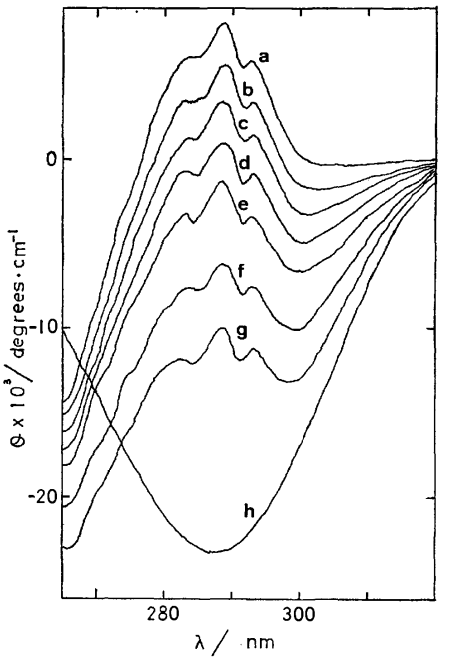

Fig. 5. The ellipticity, θ, for lysozyme and arabinose solutions at pH 5, I=0.1 and 25 °C.
Concentration of lysozyme is 8.782×10^{-3} residue mol dm^{-3}. Concentrations of arabinose are, a: 0 M (1 M=1 mol dm^{-3}), b: 0.1613 M, c: 0.3226 M, d: 0.4839 M, e: 0.6452 M, f: 0.9678 M, g: 1.290 M, and h: 1.613 M (h: without lysozyme).

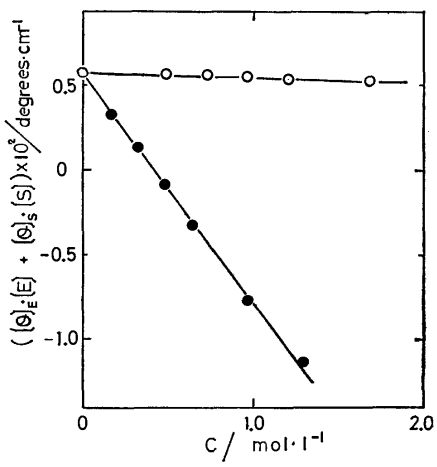

Fig. 6. The changes in the value of $[\theta]_E[E]+[\theta]_S[S]$ with sugar concentration.
Where $[\theta]_E$ and $[\theta]_S$ are molar ellipticity of lysozyme and a sugar, respectively, and [E] and [S] are molar concentrations. —O—: With glucose, —●—: with arabinose.

absorption by glucose in these wave lengths. The values of the ellipticity for the mixed solutions at 294 nm obtained by these experiments are plotted against sugar concentration in Fig. 6. Solid lines are values calculated on the assumption that the mixed solution shows the ellipticity which is simply the sum of the values of each component. The agreement between experimental and calculated values is good. These data suggest that sugars may not be bound to lysozyme at pH 5.

There have been many investigations which show the complex formation of lysozyme with sugars. Ikeda and Hamaguchi[21] found that sucrose enhanced the CD band of lyxozyme at 294 nm at pH 7.4, and that 1 mol of sucrose interacts with 1 mol of lysozyme, the association constant for the interaction was 0.4 (M^{-1}) at 25 °C. Kuramitsu *et al.*[22] showed that the binding constant for glucose and α-methyl xyloside to lysozyme was 0.5 and 1.6, respectively, from the absorption in CD spectra at 295 or 305 nm at pH 7.3 and 25 °C. Visible excited Raman spectra of lysozyme showed considerable differences in the relative intensities between that for lysozyme–glucose system and pure lysozyme, suggesting glucose–lysozyme complex formation.[23]

On the other hand, Rupley *et al.*[24] found that monosaccharide binding requires an acetamide group, and that glucose and maltose did not bind measurably. The binding constant for glucose to lysozyme is tabulated to be less than 0.1 (M^{-1}) by Chipman and Sharon.[25]

At pH 7.0, the values of ellipticity of the mixed solution of glucose and lysozyme at 304 and 294 nm are higher (less negative) that the values calculated on the assumption of additivity of $[\theta]$ of each component, in agreement with the results of Kuramitsu *et al.*[22] Also according to them, the molar ellipticity of lysozyme–α-methyl xyloside complex at 295 nm is nearly equal to that of lysozyme. The possibility remains that at pH 5, a complex is also formed but the molar ellipticity of the complex is the same as the sum of the values of each component.

As the reference values of the association constant for the complex formation of lysozyme and the saccharides studied here are very small, even if the complexes are formed, we would like to point out that there exist other interactions which stabilize the native conformation of protein in the system protein–sugar–water. The results of isopiestic measurements for the model systems[26,27] indicate that the sucrose solution environment is a more unfavorable solvent than water for amino acid with aliphatic and aromatic side chains. Consequently, it would require much more work for nonpolar groups in the interior of the protein to be exposed in the sucrose solution than in water; they would thus be caused by the sucrose solution to enter into the interior of the protein. Bull and Breese[28] suggest that the substances which stabilize proteins, such as sucrose, enhance the water structure in the immediate neighborhood of the protein and consequently contribute to protein stability. According to Tait *et al.*,[29] the distance between O–O atoms in equatorial hydroxyl groups of β-D-glucose coincides with the distance between O–O atoms in the tridimite structure of water. The structure making effect of sugars in aqueous solutions is more marked for the one which has more equatorial OH groups in the molecule.[30] Figure 4 shows that the sugars which strongly enhance the water structure raise the denaturation temperature of lysozyme more markedly. Thus in the presence of sugars the environmental effect or intensification of hydrophobic interaction inside a protein may promote a resistance against thermal denaturation of a protein.

Fluctuation of Local Field and Depolarization Degree of the ν_1 Line of Carbon Tetrachloride

Shi-aki Hyodo and Tsunetake Fujiyama*,†

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

†*Institute for Molecular Science, Okazaki 444*

(Received January 8, 1980)

The depolarization degree of a molecule having a T_d symmetry was expressed in terms of the mean square fluctuation of the local field which is felt by a molecule in the condensed phase. By the use of the mean square amplitude values observed by the X-ray diffraction method, the depolarization degree of liquid carbon tetrachloride was calculated to be 0.0021, which agrees well with the observed value of 0.0039 ± 0.0002.

The depolarization degree of Raman scattering, ρ, can be expressed in terms of a Raman scattering tensor, $\alpha'_{\rho\sigma}$, as

$$\rho = \frac{3\gamma^2}{45\bar{\alpha}^2+4\gamma^2} \tag{1}$$

where

$$\bar{\alpha} = \frac{1}{3}(\alpha'_{xx}+\alpha'_{yy}+\alpha'_{zz})$$

$$\gamma^2 = \frac{1}{2}[(\alpha'_{yy}-\alpha'_{zz})^2+(\alpha'_{zz}-\alpha'_{xx})^2+(\alpha'_{xx}-\alpha'_{yy})^2].$$

Therefore, the depolarization degree ρ should be exactly zero if the relation $\alpha'_{xx}=\alpha'_{yy}=\alpha'_{zz}$ is satisfied. The ν_1 Raman line of carbon tetrachloride is just such a case, because the vibration belongs to an a_1 symmetry of a tetrahedral molecule. The depolarization degree for the ν_1 line of liquid carbon tetrachloride, however, is not observed to be zero. With the improvement of Raman spectrometers and related attachements, the depolarization degree for this line has been observed at smaller and smaller values. But it was never observed to be zero. The most reliable value at present is $\rho=0.0039\pm0.0002$ which is reported by Murphy *et al.*[1] The finite ρ-value for the ν_1 line is believed to be real, in other words, it cannot be ascribed to any experimental errors.

There were several reports which emphasized the effect of the symmetry degradation due to the existence of the natural abundant Cl^{37}. According to the theoretical estimation of Chantry,[2] however, this effect is too small to explain the observed finite value of ρ. Douglas and Rank observed the depolarization degree of the ν_1 line of tin tetrachloride and the related isotope species and concluded that the ρ values for the three isotopic species ($SnCl_4^{35}$, $SnCl_3^{35}Cl^{37}$, $SnCl_2^{35}Cl_2^{37}$) agreed with each other within the experimental error.[3] This finite magnitude of depolarization degree has been thought to originate from some kinds of intermolecular interactions in the condensed phase, although no detailed mechanisms have been established yet. It will be shown in the present report that the fluctuation of local field is the main cause of the finite magnitude of depolarization degree observed for the ν_1 line of liquid carbon tetrachloride.

Intensity Expression for Raman Scattering. Consider a molecule irradiated by an incident light beam. In the condensed system, the electric field which is felt by the molecule is not the same as that of the incident light, because of the existence of the electric field produced on the surrounding molecuoes. Taking into account this situation, we first derive the Raman intensity expression for the liquid sample.

Imagine a space-fixed Cartesian coordinate system (x, y, z). A z-polarized incident light beam irradiates molecules along the negative x-direction (see Fig. 1). The electric vector of the incident light is expressed by $\boldsymbol{E}=\boldsymbol{E}_0\cos\omega_0 t$ ($\boldsymbol{E}_0=(0, 0, E_{0z})$). Consider now the scattering in the positive y-direction. The position vector of a molecule (i) is expressed by $\boldsymbol{r}_i$.

Generally, a polarizability $\boldsymbol{\alpha}$ is expanded as a power series of a normal coordinate Q_k as:

$$\boldsymbol{\alpha} = \boldsymbol{\alpha}^\circ + \sum_k \left(\frac{\partial\boldsymbol{\alpha}}{\partial Q_k}\right)_0 Q_k + \text{higher terms} \tag{2}$$

where Q_k is a normal coordinate corresponding to the k-th vibrational mode whose frequency is ω_ν^k, *viz.*,

$$Q_k = Q_0{}^k\cos\omega_\nu^k t.$$

If we focus our attention on a particular vibrational mode and neglect the terms higher than quadratic,

$$\boldsymbol{\alpha} = \boldsymbol{\alpha}^\circ + \boldsymbol{\alpha}'\cos\omega_\nu t \tag{2'}$$

where

$$\boldsymbol{\alpha}' = \left(\frac{\partial\boldsymbol{\alpha}}{\partial Q}\right)_0 Q_0.$$

In the case of the ν_1 vibration of carbon tetrachloride, the tensors $\boldsymbol{\alpha}^\circ$ and $\boldsymbol{\alpha}'$ have a spherical symmetry. Therefore, we can use the scalar expressions α° and α' instead of the tensors $\boldsymbol{\alpha}^\circ$ and $\boldsymbol{\alpha}'$.

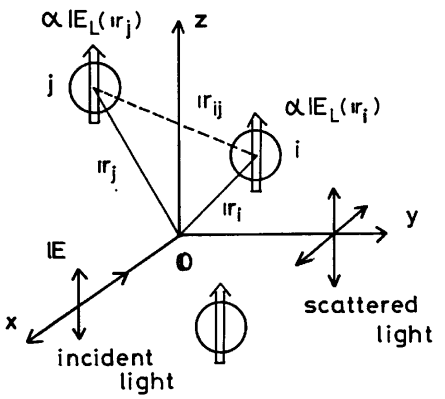

Fig. 1. Polarization of light and induced dipoles on molecules (i) and (j).

Consider a molecule (j) at $\boldsymbol{r}_j$ in the liquid phase. This molecule (j) feels the electric field $\boldsymbol{E}_L(\boldsymbol{r}_j)=\boldsymbol{E}_{L0}(\boldsymbol{r}_j)\cos\omega t$ whose frequency is the same as that of the incident light. The induced dipole, $\alpha^\circ\boldsymbol{E}_L(\boldsymbol{r}_j)$, then produces an electric field $\boldsymbol{f}(\boldsymbol{r}_i, \boldsymbol{r}_j)$ on the molecule (i) at $\boldsymbol{r}_i$. The $\boldsymbol{f}(\boldsymbol{r}_i, \boldsymbol{r}_j)$ is expressed as;

$$\boldsymbol{f}(\boldsymbol{r}_i, \boldsymbol{r}_j) = -\frac{\alpha^\circ\boldsymbol{E}_L(\boldsymbol{r}_j)}{r_{ij}^2}+\frac{3\{(\alpha^\circ\boldsymbol{E}_L(\boldsymbol{r}_j))\cdot\boldsymbol{r}_{ij}\}\boldsymbol{r}_{ij}}{r_{ij}^5} = \alpha^\circ\boldsymbol{E}_L(\boldsymbol{r}_j)\boldsymbol{l}(\boldsymbol{r}_{ij}) \quad (3)$$

where

$$\boldsymbol{r}_i \equiv \boldsymbol{r}_j-\boldsymbol{r}_i$$
$$\boldsymbol{r}_{ij} \equiv |\boldsymbol{r}_{ij}|$$
$$\boldsymbol{l}(\boldsymbol{r}_{ij}) \equiv \frac{3\boldsymbol{r}_{ij}\boldsymbol{r}_{ij}-r_{ij}^2\mathbf{I}}{r_{ij}^5}$$

and $\mathbf{I}$ is an unit tensor. As the molecule (i) is surrounded by many other molecules designated by (j), the electric field, $\boldsymbol{E}_L(\boldsymbol{r}_i)$, which is felt by the molecule (i) is

$$\boldsymbol{E}_L(\boldsymbol{r}_i) = \boldsymbol{E}+\sum_j \boldsymbol{f}(\boldsymbol{r}_i, \boldsymbol{r}_j). \quad (4)$$

As the $\boldsymbol{f}(\boldsymbol{r}_i, \boldsymbol{r}_j)$ of Eq. 4 is also the function of $\boldsymbol{E}_L(\boldsymbol{r}_j)$ which also has an expression like Eq. 4, the detailed expression of Eq. 4 becomes

$$\boldsymbol{E}_L(\boldsymbol{r}_i) = \boldsymbol{E}+\sum_j \alpha^\circ\boldsymbol{E}_L(\boldsymbol{r}_j)\boldsymbol{l}(\boldsymbol{r}_{ij}) = \boldsymbol{E}+\sum_j\{\boldsymbol{E}+\sum_k \alpha^\circ\{\boldsymbol{E}+\ldots\}\ldots\}\ldots\boldsymbol{l}(\boldsymbol{r}_{jk})\boldsymbol{l}(\boldsymbol{r}_{ij}). \quad (5)$$

If we truncate Eq. 5 at the second term,

$$\boldsymbol{E}_L(\boldsymbol{r}_i) \cong \boldsymbol{E}+\sum_j \alpha^\circ\boldsymbol{E}\boldsymbol{l}(\boldsymbol{r}_{ij}) \quad (5')$$

and

$$\boldsymbol{f}(\boldsymbol{r}_i, \boldsymbol{r}_j) = -\frac{\alpha^\circ\boldsymbol{E}}{r_{ij}^3}+\frac{3\{(\alpha^\circ\boldsymbol{E})\cdot\boldsymbol{r}_{ij}\}\boldsymbol{r}_{ij}}{r_{ij}^5}. \quad (6)$$

We consider that the dipole moment, $\alpha'\boldsymbol{E}_L(\boldsymbol{r}_i)\cos\omega_v t$, induced onto the molecule (i) scatters Raman light following the classical scattering theory. If the phases of the molecular vibrations of component molecules are independent of each other, the Raman scattering intensity from this system is proportional to the mean square amplitude of this oscillating dipole, $\alpha'\boldsymbol{E}_{L0}(\boldsymbol{r}_i)$. It sometimes happens, however, that the oscillating dipoles induced onto different molecules have the same phase; this mechanism will be shown in what follows.

The oscillating dipole induced by the electric field $\boldsymbol{E}_L(\boldsymbol{r}_i)$ onto the molecule (i), in turn, produces the electric field, $\boldsymbol{f}'(\boldsymbol{r}_j, \boldsymbol{r}_i)$, onto the molecule (j). This electric field has the same frequency as the Raman frequencies $((\omega_0+\omega_v)$ and $(\omega_0-\omega_v))$. $\boldsymbol{f}'(\boldsymbol{r}_j, \boldsymbol{r}_i)$ is expressed as

$$\boldsymbol{f}'(\boldsymbol{r}_j, \boldsymbol{r}_i) = \left[-\frac{\alpha'\boldsymbol{E}_L(\boldsymbol{r}_i)}{r_{ij}^3}+\frac{3\{(\alpha'\boldsymbol{E}_L(\boldsymbol{r}_i))\cdot\boldsymbol{r}_{ij}\}\boldsymbol{r}_{ij}}{r_{ij}^5}\right]\cos\omega_v t \cong \left[-\frac{\alpha'\boldsymbol{E}}{r_{ij}^3}+\frac{3\{(\alpha'\boldsymbol{E})\cdot\boldsymbol{r}_{ij}\}\boldsymbol{r}_{ij}}{r_{ij}^5}\right]\cos\omega_v t = \alpha'\boldsymbol{E}\boldsymbol{l}(\boldsymbol{r}_{ij})\cos\omega_v t. \quad (7)$$

The electric field, $\boldsymbol{f}'(\boldsymbol{r}_j, \boldsymbol{r}_i)$, produces an oscillating dipole $\alpha^\circ\boldsymbol{f}'(\boldsymbol{r}_j, \boldsymbol{r}_i)$ on the molecule (j). This oscillating dipole again scatters light following the classical scattering theory. It is important that the phase of this scattered light coincides with that of the molecular vibration of the molecule (i). This sort of light can be scattered from all the molecules (i). Thus, the observed Raman intensity is proportional to the mean square amplitude of the two kinds of oscillating induced dipoles, namely, $\alpha'\boldsymbol{E}_L(\boldsymbol{r}_i)\cos\omega_v t$ and $\alpha^\circ\boldsymbol{f}'(\boldsymbol{r}_j, \boldsymbol{r}_i)$. The sum of these induced dipoles is

$$\begin{aligned}&\alpha'\boldsymbol{E}_L(\boldsymbol{r}_i)\cos\omega_v t+\alpha^\circ\sum_j \alpha'\boldsymbol{E}\boldsymbol{l}(\boldsymbol{r}_{ij})\cos\omega_v t\\ &= \alpha'\boldsymbol{E}\cos\omega_v t+\sum_j \alpha'\alpha^\circ\boldsymbol{E}\boldsymbol{l}(\boldsymbol{r}_{ij})\cos\omega_v t+\sum_j \alpha^\circ\alpha'\boldsymbol{E}\boldsymbol{l}(\boldsymbol{r}_{ij})\cos\omega_v t\\ &= \alpha'\boldsymbol{E}\{1+2\sum_j \alpha^\circ\boldsymbol{l}(\boldsymbol{r}_{ij})\}\cos\omega_v t\\ &= \alpha'\boldsymbol{E}\{1+2\alpha^\circ\mathbf{L}(\boldsymbol{r}_{ij})\}\cos\omega_v t \quad (8)\end{aligned}$$

where

$$\mathbf{L}(\boldsymbol{r}_i) = \sum_j \boldsymbol{l}(\boldsymbol{r}_{ij}). \quad (9)$$

Thus, the polarized and depolarized components, I_z and I_x, of Raman scattering intensity from the liquid system can be expressed as

$$I_z \propto (\alpha')^2\{1+4\alpha^\circ\langle L_{zz}(\boldsymbol{r}_i)\rangle+4(\alpha^\circ)^2\langle(L_{zz}(\boldsymbol{r}_i))^2\rangle\}E_{0z}^2 \quad (10\text{-a})$$

$$I_x \propto 4(\alpha'\alpha^\circ)^2\langle(L_{xz}(\boldsymbol{r}_i))^2\rangle E_{0z}^2 \quad (10\text{-b})$$

where $L_{ij}(\boldsymbol{r}_i)$ represents the i,j-element of the tensor $\mathbf{L}(\boldsymbol{r}_i)$ and $\langle\ \rangle$ represents an ensemble averge. The intensity representation of Eqs. 10-a and 10-b shows that the effects of the local field on Raman intensity are completly expressed in terms of the mean and mean square values of the tensor elements, $L_{ij}(\boldsymbol{r}_i)$. In order to know $L_{ij}(\boldsymbol{r}_i)$, we have to know the relative molecular configuration of component molecules in the liquid system.

Calculation of $\langle L_{zz}(\boldsymbol{r}_i)\rangle$, $\langle(L_{zz}(\boldsymbol{r}_i))^2\rangle$, $\langle(L_{xz}(\boldsymbol{r}_i))^2\rangle$. The X-ray diffraction study of pure liquid carbon tetrachloride has clarified the existence of a local bcc lattice in the liquid at room temperature, as is shown in Fig. 2.[4] On the basis of this result,

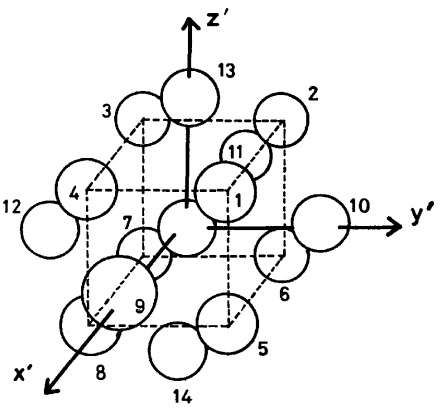

Fig. 2. Local bcc lattice structure of carbon tetrachloride obtained by X-ray diffraction study.[4] (x', y', z') refers to the lattice-fixed coordinate system. The moleucles (1—8) and (9—14) correspond, respectively, to the first and second nearest neighbours.

we calculate $\langle L_{zz}(\boldsymbol{r}_i)\rangle$, $\langle (L_{zz}(\boldsymbol{r}_i))^2\rangle$, and $\langle (L_{xz}(\boldsymbol{r}_i))^2\rangle$ values originating from displacements of component molecules from the bcc structure. Putting the molecule (i) at the center, we express the relative configuration of molecules by a vector group $\{\boldsymbol{r}_{ij}\}$, where $\boldsymbol{r}_{ij}=\boldsymbol{r}_j-\boldsymbol{r}_i$. If the lattice points of the bcc lattice is represented by a vector $\boldsymbol{r}^\circ_{ij}$, the vector $\boldsymbol{r}_{ij}$ can be written as,

$$\boldsymbol{r}_{ij} = \boldsymbol{r}^\circ_{ij} + \Delta\boldsymbol{r}_{ij} \tag{11}$$

where $\Delta\boldsymbol{r}_{ij}$ is a vector which describes the relative displacement of the surrounding molecules (j) due to thermal motion from the individual lattice points.

Now, expression of $L_{zz}(\boldsymbol{r}_i)$ or $L_{xz}(\boldsymbol{r}_i)$ with respect to $\Delta\boldsymbol{r}_{ij}$ leads to:

$$\begin{aligned} L_{zz}(\boldsymbol{r}_i) &= \sum_j l_{zz}(\boldsymbol{r}_{ij}) \\ &= \sum_j \left[l_{zz}(\boldsymbol{r}^\circ_{ij}) + \left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{ij}}\right)_0 \Delta\boldsymbol{r}_{ij} + \text{higher terms} \right] \\ &= L^\circ_{zz}(\boldsymbol{r}_i) + \sum_j \left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{ij}}\right)_0 \Delta\boldsymbol{r}_{ij} \end{aligned} \tag{12-a}$$

and

$$L_{xz}(\boldsymbol{r}_i) = L^\circ_{xz}(\boldsymbol{r}_i) + \sum_j \left(\frac{\partial l_{xz}}{\partial \boldsymbol{r}_{ij}}\right)_0 \Delta\boldsymbol{r}_{ij} \tag{12-b}$$

where

$$L^\circ_{zz}(\boldsymbol{r}_i) = \sum_j l_{zz}(\boldsymbol{r}^\circ_{ij}) \tag{13-a}$$

$$L^\circ_{xz}(\boldsymbol{r}_i) = \sum_j l_{xz}(\boldsymbol{r}^\circ_{ij}) \tag{13-b}$$

$$\left(\frac{\partial l_{\sigma\rho}}{\partial \boldsymbol{r}_{ij}}\right)_0 \Delta\boldsymbol{r}_{ij} \equiv \left(\frac{\partial l_{\sigma\rho}}{\partial r^x_{ij}}\right)_0 \Delta r^x_{ij} + \left(\frac{\partial l_{\sigma\rho}}{\partial r^y_{ij}}\right)_0 \Delta r^y_{ij} + \left(\frac{\partial l_{\sigma\rho}}{\partial r^z_{ij}}\right)_0 \Delta r^z_{ij}. \tag{14}$$

In the above equations, $l_{\sigma\rho}$ is a $\sigma\rho$-element of the tensor $\boldsymbol{l}(\boldsymbol{r}_{ij})$, and the shoulder index put on r_{ij} or Δr_{ij} distinguishes among the x, y, or z element of the vector. More detailed expressions of Eqs. 13-a and 13-b are

$$L^\circ_{zz}(\boldsymbol{r}_i) = \sum_j \frac{3(r^{\circ x}_{ij})^2 - (r^\circ_{ij})^2}{(r^\circ_{ij})^5} \tag{13-a'}$$

and

$$L^\circ_{xz}(\boldsymbol{r}_i) = \sum_j \frac{3(r^{\circ x}_{ij})(r^{\circ z}_{ij})}{(r^\circ_{ij})^5} \tag{13-b'}$$

where $r^{\circ x}_{ij}$ and $r^{\circ z}_{ij}$ are the x- and z-elements of a vector $\boldsymbol{r}^\circ_{ij}$.

We assume here that the molecular motions of component molecules are mutually independent and that all the displacement vectors are isotropic. This is equivalent to assuming the relations:

$$\langle \Delta\boldsymbol{r}_{ij}\rangle = 0$$

$$\langle (\Delta r^x_{ij})^2\rangle = \langle (\Delta r^y_{ij})^2\rangle = \langle (\Delta r^z_{ij})^2\rangle = \frac{1}{3}\langle (\Delta\boldsymbol{r}_{ij})^2\rangle$$

and

$$\begin{aligned} &\langle \Delta r^x_{ij}\Delta r^y_{ij}\rangle = \langle \Delta r^y_{ij}\Delta r^z_{ij}\rangle = \langle \Delta r^z_{ij}\Delta r^x_{ij}\rangle = \cdots \\ &\quad = \langle \Delta r^x_{ik}\Delta r^x_{ij}\rangle = \langle \Delta r^x_{ik}\Delta r^y_{ij}\rangle = \cdots = 0. \end{aligned} \tag{15}$$

Then, the mean values in question can be expressed as:

$$\begin{aligned} \langle L_{zz}(\boldsymbol{r}_i)\rangle &= \left\langle L^\circ_{zz}(\boldsymbol{r}_i) + \sum_j \left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{ij}}\right)_0 \Delta\boldsymbol{r}_{ij} \right\rangle \\ &= L^\circ_{zz}(\boldsymbol{r}_i) + \sum_j \left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{ij}}\right)_0 \langle \Delta\boldsymbol{r}_{ij}\rangle \\ &= L^\circ_{zz}(\boldsymbol{r}_i) \end{aligned} \tag{16-a}$$

$$\langle (L_{zz}(\boldsymbol{r}_i))^2\rangle = \{L^\circ_{zz}(\boldsymbol{r}_i)\}^2 + \frac{1}{3}\sum_j \left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{ij}}\right)^2_0 \langle (\Delta\boldsymbol{r}_{ij})^2\rangle \tag{16-b}$$

and

$$\langle (L_{xz}(\boldsymbol{r}_i))^2\rangle = \{L^\circ_{xz}(\boldsymbol{r}_i)\}^2 + \frac{1}{3}\sum_j \left(\frac{\partial l_{xz}}{\partial \boldsymbol{r}_{ij}}\right)^2_0 \langle (\Delta\boldsymbol{r}_{ij})^2\rangle. \tag{16-c}$$

On the other hand, $\langle (\Delta\boldsymbol{r}_{ij})^2\rangle$ for a molecule (j) can be expressed by the use of a polar coordinate system $(\Delta r_{ij}, \theta, \phi)$ whose origin is fixed at the individual lattice point as:

$$\langle (\Delta\boldsymbol{r}_{ij})^2\rangle = \frac{\int_0^{2\pi}\int_0^{\pi}\int_0^{\infty} (\Delta r_{ij})^2 \exp\left(-\frac{\ln 2}{a_j^2}(\Delta r_{ij})^2\right)(\Delta r_{ij})^2 \sin\theta \, d(\Delta r_{ij})d\theta d\phi}{\int_0^{2\pi}\int_0^{\pi}\int_0^{\infty} \exp\left(-\frac{\ln 2}{a_j^2}(\Delta r_{ij})^2\right)(\Delta r_{ij})^2 \sin\theta \, d(\Delta r_{ij})d\theta d\phi}. \tag{17}$$

Here we assumed a Gaussian distribution for the distribution of Δr_{ij}. a_j of Eq. 17 is the half-width of the Gaussian distribution for the molecule (j). The integration of those terms related with Δr_{ij} leads to

$$\int_0^\infty (\Delta r_{ij})^2 \exp\left(-\frac{\ln 2}{a_j^2}(\Delta r_{ij})^2\right) d(\Delta r_{ij}) = \frac{1}{4}\sqrt{\pi}\left(\frac{\ln 2}{a_j^2}\right)^{-3/2}$$

and

$$\int_0^\infty (\Delta r_{ij})^4 \exp\left(-\frac{\ln 2}{a_j^2}(\Delta r_{ij})^2\right) d(\Delta r_{ij}) = \frac{3}{8}\sqrt{\pi}\left(\frac{\ln 2}{a_j^2}\right)^{-5/2}.$$

Therefore, the mean square value of the displacement vector is

$$\langle (\Delta r_{ij})^2\rangle = \frac{3a_j^2}{2\ln 2}. \tag{18}$$

In the liquid carbon tetrachloride, it is hardly possible at room temperature that the orientations of these local bcc lattices coincide with each other. It is more reasonable to assume the random orientation of the local bcc lattices. Therefore Eqs. 16-a, 16-b, and 16-c should be averaged over all the orientations of the local bcc lattices. The terms which should be averaged over all orientations are $L^\circ_{zz}(\boldsymbol{r}_i)$, $\{L^\circ_{zz}(\boldsymbol{r}_i)\}^2$, $\{L^\circ_{xz}(\boldsymbol{r}_i)\}^2$, $(\partial l_{zz}/\partial \boldsymbol{r}_{ij})^2_0$, and $(\partial l_{xz}/\partial \boldsymbol{r}_{ij})^2_0$. It is obvious from Eqs. 13-a′ and 13-b′, that $L^\circ_{zz}(\boldsymbol{r}_i)$, $\{L^\circ_{zz}(\boldsymbol{r}_i)\}^2$, and $\{L^\circ_{xz}(\boldsymbol{r}_i)\}^2$ are all zero, because $L^\circ_{zz}(\boldsymbol{r}_i)$ and $L^\circ_{xz}(\boldsymbol{r}_i)$ are zero as long as the molecular configuration has a point symmetry

with respect to $\boldsymbol{r}_1$. Thus, it is enough to consider $(\partial l_{zz}/\partial \boldsymbol{r}_{1j})_0^2$ and $(\partial l_{xz}/\partial \boldsymbol{r}_{1j})_0^2$.

The more explicit expression of $(\partial l_{zz}/\partial \boldsymbol{r}_{1j})_0^2$ or $(\partial l_{xz}/\partial \boldsymbol{r}_{1j})_0^2$ is

$$\left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{1j}}\right)_0^2 = \frac{9}{(r_{1j}^\circ)^{12}}\{5(r_{1j}^{\circ z})^4 - 2(r_i^{\circ z})^2(r_{1j}^\circ)^2 + (r_{1j}^\circ)^4\} \tag{19-a}$$

$$\left(\frac{\partial l_{xz}}{\partial \boldsymbol{r}_{1j}}\right)_0^2 = \frac{9}{(r_{1j}^\circ)^{12}}\{(r_{1j}^{\circ x})^2(r_{1j}^\circ)^2 + (r_{1j}^{\circ z})^2(r_{1j}^\circ)^2 + (r_{1j}^{\circ z})^2(r_{1j}^\circ)^2 + 5(r_{1j}^{\circ x})^2(r_{1j}^{\circ z})^2\}. \tag{19-b}$$

Equetions 19-a and 19-b show that these quantities are proportional to r_{1j}^8, where r_{1j} is an intermolecular distance and, therefore, the effect of the molecules (j) rapidly decreases with the increase of the distance r_{1j}. Therefore, it is enough to consider the contribution from the first nearest neighbors (8 molecules) and the second nearest neighbors (6 molecules) in the bcc lattice. So far the relative configuration of molecules has been described in the lattice-fixed coordinate system. As Eqs. 19-a and 19-b are described in the space-fixed coordinate system, however, we have to transform the coordinates used for the expression of relative configuration from the lattice-fixed to the space-fixed coordinate system. Let the Cartesian coordinates of the molecule (i) be (x_1', y_1', z_1') and (x_1, y_1, z_1) in the lattice-fixed and space-fixed coordinate systems, respectively. If the orientation of the local bcc lattice is specified by the Eulerian angles (α, β, γ) of Fig. 3, the transformation of coordinates from (x', y', z') to (x, y, z) system is given by:

$$\begin{aligned} x &= x'(\cos\alpha\cos\beta\cos\gamma - \sin\beta\sin\gamma) \\ &\quad - y'(\cos\alpha\cos\beta\sin\gamma + \sin\beta\cos\gamma) + z'\sin\alpha\cos\beta \\ y &= x'(\cos\alpha\sin\beta\cos\gamma + \cos\beta\sin\gamma) \\ &\quad - y'(\cos\alpha\sin\beta\sin\gamma - \cos\beta\cos\gamma) + z'\sin\alpha\sin\beta \\ z &= -x'\sin\alpha\cos\gamma + y'\sin\alpha\sin\gamma + z'\cos\alpha. \end{aligned} \tag{20}$$

Let the distances from the center of the molecule (i) and to the centers of its first and second nearest neighbors be d_1 and d_2, respectively. Then, the coordinates of the neighboring molecues (j) in the lattice-fixed system can be calculated easily. Insertion of these coordinate values into the relations, *e.g.*, for the eight nearest neighboring molecules,

$$\sum_j (r_{1j}^{\circ x})^2 = \sum_j x_j^2 = \frac{8}{3}d_1^2$$

$$\sum_j (r_{1j}^{\circ z})^2 = \sum_j z_j^2 = \frac{8}{3}d_1^2$$

$$\sum_j (r_{1j}^{\circ z})^4 = \sum_j z_j^4 = \frac{8}{9}d_1^4\{1 + 4\sin^2\alpha\,(\sin^2\alpha\cos^2\gamma\sin^2\gamma + \cos^2\gamma)\}$$

$$\begin{aligned} \sum_j (r_{1j}^{\circ x})^2(r_{1j}^{\circ z})^2 &= \sum_j (x_j z_j)^2 \\ &= \frac{8}{9}d_1^4\{4\sin^2\alpha\cos^2\alpha\cos^2\beta(\cos^2\gamma\sin^2\gamma - 1) \\ &\quad + 1 - 4\sin^2\alpha\sin^2\alpha\cos^2\gamma\sin^2\gamma \\ &\quad + 4\sin^2\alpha\cos\alpha\sin\beta\cos\beta(\cos^3\gamma\sin\gamma \\ &\quad - \cos\gamma\sin^3\gamma)\}. \end{aligned} \tag{21}$$

If we assume that the orientation of the local bcc lattice is random, the averaging of a function $G(\alpha, \beta, \gamma)$ over all orientations is defined by

$$\overline{G}(\alpha, \beta, \gamma) = \frac{\int G(\alpha, \beta, \gamma)\,d\Omega}{\int d\Omega} \tag{22}$$

where

$$d\Omega = \sin\alpha\,d\alpha\,d\beta\,d\gamma.$$

Inserting Eq. 21 into Eqs. 19-a and 19-b, we obtain, *e.g.*, for the eight nearest neighbors

$$\begin{aligned} \overline{\sum_j \left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{1j}}\right)_0^2} &= \frac{9}{d_1^8}\int\left[\frac{40}{9}\{1 + 4\sin^2\alpha(\sin^2\alpha\cos^2\gamma\sin^2\gamma + \cos^2\alpha)\} - \frac{16}{3} + 8\right]d\Omega \Big/ \int d\Omega \\ &= 96\frac{1}{d_1^8} \end{aligned} \tag{23-a}$$

$$\overline{\sum_j \left(\frac{\partial l_{xz}}{\partial \boldsymbol{r}_{1j}}\right)_0^2} = 72\frac{1}{d_1^8} \tag{23-b}$$

and for the six second nearest neighbors

$$\overline{\sum_j \left(\frac{\partial l_{zz}}{\partial \boldsymbol{r}_{1j}}\right)_0^2} = 72\frac{1}{d_2^8} \tag{23-c}$$

$$\overline{\sum_j \left(\frac{\partial l_{xz}}{\partial \boldsymbol{r}_{1j}}\right)_0^2} = 54\frac{1}{d_2^8}. \tag{23-d}$$

Putting $a_j = l_1$ (j=1—8) for the first nearest neighbors and $a_j = l_2$ (j=9—14) for the second nearest neighbors and inserting Eqs. 18 and 23 into Eq. 16, we obtain

$$\langle L_{zz}(\boldsymbol{r}_1)\rangle = 0 \tag{24-a}$$

$$\langle (L_{zz}(\boldsymbol{r}_1))^2\rangle = \frac{1}{2\ln 2}\left\{96\frac{l_1^2}{d_1^8} + 72\frac{l_2^2}{d_2^8}\right\} \tag{24-b}$$

$$\langle (L_{xz}(\boldsymbol{r}_1))^2\rangle = \frac{1}{2\ln 2}\left\{72\frac{l_1^2}{d_1^8} + 54\frac{l_2^2}{d_2^8}\right\}. \tag{24-c}$$

Depolarization Degree. We finally obtain the expression for depolarization degree by inserting Eqs. 24-a, 24-b, and 24-c into Eq. 10:

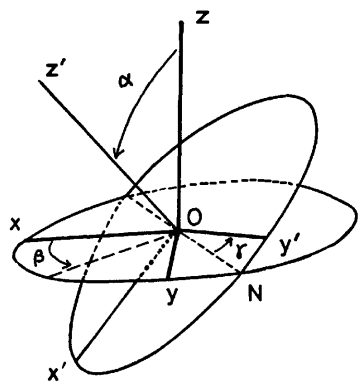

Fig. 3. Definition of Eulerian angles.
ON: Positive direction of line of nodes, the intersection of the xy and x' y' planes. α: Angle from Oz to Oz' ($0 \le \alpha \le \pi$). β: Angle in xy plane from Ox to the projection Oz on the xy plane. Also angle from Oy to ON ($0 \le \beta \le 2\pi$). γ: Angle in x' y' plane from ON to Oy'. Also angle from projection of -z on x' y' plane to Ox' ($0 \le \gamma \le 2\pi$).

$$\rho = \frac{I_x}{I_z} = \frac{\frac{2(\alpha^\circ)^2}{\ln 2}\left\{72\frac{l_1^2}{d_1^8}+54\frac{l_2^2}{d_2^8}\right\}}{1+\frac{2(\alpha^\circ)^2}{\ln 2}\left\{96\frac{l_1^2}{d_1^8}+72\frac{l_2^2}{d_2^8}\right\}}. \quad (25)$$

Eq. 25 shows that the depolarization degree ρ can be expressed in terms of the mean intermolecular distances, d_1 and d_2, the mean square amplitudes of the first and second nearest neighbors l_1 and l_2, and the polarizability, α°.

Putting the observed values of $\alpha^\circ=10.5$ Å^3,[5] $l_1=0.3$ Å, $l_2=0.35$ Å, $d_1=5.77$ Å, and $d_2=6.77$ Å,[4] into Eq. 25, ρ is calculated to be

$$\rho = 0.0021$$

for pure liquid carbon tetrachloride at room temperature. As the observed value is 0.0039 ± 0.0002, the present calculation explains the observed value very well.

Concluding Discussion. The quantities calculated in Eqs. 24-b and 24-c correspond to the magnitude of the mean square fluctuation of the local field. These fluctuations of local field are originating from the thermal displacement of carbon tetrachloride molecules from the mean local bcc structure. In other words, the main cause of the finite ρ value of the ν_1 line of liquid carbon tetrachloride is the fluctuation of local field originating from the thermal displacement of the molecular configuration.

The beautiful agreement between the observed and calculated values of depolarization degree, in turn, suggests the possibility of determining the magnitude of the thermal displacement of component molecules in the condensed system by observing the depolarization degree of liquid samples.

Some New Relationships between the Molecular Electron Densities and the Intensities of Electrons and X-Rays Scattered by Gases

Yorihiko SASAKI, Shigehiro KONAKA, and Masao KIMURA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 16, 1980)

Some new relations connecting the molecular electron densities and the intensities of electrons and X-rays scattered by gases have been derived by integrating analytically the scattered intensities multiplied by some functions of the momentum transfer, s, over ds.

The intensities of the electrons and X-rays scattered by gases have been known to provide information on atomic or molecular electron densities.[1] It has been proved that, in principle, the unique three-dimensional electron densities of molecules can not be derived directly from the one-dimensional scattering intensities.[2] However, the qualities of given molecular wave functions can be examined by comparing the experimental intensities with the theoretical ones calculated from the wave functions. Because of the considerably long computing time needed for such calculations, however, the theoretical scattering intensities based on molecular wave functions have been reported for only a very limited number of molecules.

A more convenient way of making such an examination is to make use of the integral relationships between the scattering intensities and the electron densities in molecules. A close connection between the integrated intensities of the total electron scattering and the total energies of molecules proved by Tavard *et al.* is an example of such a relationship.[3,4] Some relationships have also been reported by Bonham, who has mentioned the existence of other, similar relations.[5] These relations are obtained as the integral transforms of the scattering intensities by several kernels, which are functions involving momentum transfer, s. The purpose of the present paper is to present some new relations connecting the molecular electron densities with the scattered intensities by means of the integral transformation of the intensities, as well as to bring together the relations thus far reported in the form of analytical integration.

If the four σ functions are defined in terms of the elastic and total intensities of electrons (ED) and X-rays (XR) scattered by a free molecule as follows:[1,5]

$$\sigma_{\mathrm{E}}^{\mathrm{ED}}(s) = s^4 I_{\mathrm{E}}^{\mathrm{ED}}(s) - \sum_i Z_i^2, \tag{1}$$

$$\sigma_{\mathrm{T}}^{\mathrm{ED}}(s) = s^4 I_{\mathrm{T}}^{\mathrm{ED}}(s) - \sum_i Z_i^2 - N, \tag{2}$$

$$\sigma_{\mathrm{E}}^{\mathrm{XR}}(s) = I_{\mathrm{E}}^{\mathrm{XR}}(s), \tag{3}$$

$$\sigma_{\mathrm{T}}^{\mathrm{XR}}(s) = I_{\mathrm{T}}^{\mathrm{XR}}(s) - N, \tag{4}$$

to the first Born approximation, they are expressed in connection with the electron density in the molecule by:

$$\sigma_{\mathrm{E}}^{\mathrm{ED}}(s) = \sigma_{\mathrm{nn}}(s) - \sum_i Z_i^2 + \sigma_{\mathrm{ne}}(s) + \sigma_{\mathrm{E}}^{\mathrm{XR}}(s), \tag{5}$$

$$\sigma_{\mathrm{T}}^{\mathrm{ED}}(s) = \sigma_{\mathrm{nn}}(s) - \sum_i Z_i^2 + \sigma_{\mathrm{ne}}(s) + \sigma_{\mathrm{T}}^{\mathrm{XR}}(s), \tag{6}$$

where:

$$\sigma_{\mathrm{nn}}(s) - \sum_i Z_i^2 = \sum_{i\neq j}\sum Z_i Z_j \langle \mathrm{j}_0(sr_{ij})\rangle_{\mathrm{vlb}}, \tag{7}$$

$$\sigma_{\mathrm{ne}}(s) = -2\sum_i Z_i \left\langle \int \mathrm{d}\boldsymbol{r}\, \mathrm{j}_0(sr)\, \rho(\boldsymbol{r}+\boldsymbol{r}_i) \right\rangle_{\mathrm{vlb}}, \tag{8}$$

$$\sigma_{\mathrm{E}}^{\mathrm{XR}}(s) = \left\langle \int \mathrm{d}\boldsymbol{r}\, \mathrm{j}_0(sr) \int \mathrm{d}\boldsymbol{r}'\, \rho(\boldsymbol{r}')\, \rho(\boldsymbol{r}+\boldsymbol{r}') \right\rangle_{\mathrm{vlb}}, \tag{9}$$

and

$$\sigma_{\mathrm{T}}^{\mathrm{XR}}(s) = \left\langle \int \mathrm{d}\boldsymbol{r}\, \mathrm{j}_0(sr)\, \rho_{\mathrm{c}}(\boldsymbol{r}) \right\rangle_{\mathrm{vlb}}. \tag{10}$$

Here, the subscripts E and T denote elastic and total respectively; s is the momentum transfer given by $(4\pi/\lambda)\sin(\theta/2)$ (λ: wavelength, θ: scattering angle); N, the total number of electrons in the molecule; $\boldsymbol{r}_i$, the position vector of the i-th atom; Z, the atomic number; r_{ij}, an interatomic distance; $\mathrm{j}_0(x)$, the zero-order spherical Bessel function, $\sin x/x$; $\rho(\boldsymbol{r})$, the one-electron density, and $\rho_{\mathrm{c}}(\boldsymbol{r})$, the electron-pair correlation density; the brackets, $\langle\ \rangle_{\mathrm{vlb}}$, denote the averaging over thermal vibration.

To begin with, the integral of this type:

$$\Lambda(\alpha,\lambda) = \int_0^\infty \mathrm{d}s\, \sigma(s) s^\alpha \mathrm{e}^{-\lambda s}, \quad \lambda > 0 \tag{11}$$

will be considered. The factor, $\mathrm{e}^{-\lambda s}$, acts as a damping factor to reduce the error due to the termination of the integral. This type of integral has been mentioned in the literature[5] for the case where α is an integer. In general, for $\alpha \leqq -1$, the integral diverges, but for $\alpha > -1$ the integral can be expressed in terms of a hypergeometric function, ${}_2\mathrm{F}_1$.[6] By the use of the properties of ${}_2\mathrm{F}_1$, the integrals for the four kinds of σ are reduced to:[7]

$$\Lambda_{\mathrm{E}}^{\mathrm{ED}}(\alpha,\lambda) = \sum_{i\neq j}\sum Z_i Z_j \langle \mathrm{L}(\alpha,\lambda,r_{ij})\rangle_{\mathrm{vlb}} - 2\sum_i Z_i \left\langle \int \mathrm{d}\boldsymbol{r}\mathrm{L}(\alpha,\lambda,r)\, \rho(\boldsymbol{r}+\boldsymbol{r}_i) \right\rangle_{\mathrm{vlb}} + \Lambda_{\mathrm{E}}^{\mathrm{XR}}(\alpha,\lambda), \tag{12}$$

$$\Lambda_{\mathrm{T}}^{\mathrm{ED}}(\alpha,\lambda) = \sum_{i\neq j}\sum Z_i Z_j \langle \mathrm{L}(\alpha,\lambda,r_{ij})\rangle_{\mathrm{vlb}} - 2\sum_i Z_i \left\langle \int \mathrm{d}\boldsymbol{r}\mathrm{L}(\alpha,\lambda,r)\, \rho(\boldsymbol{r}+\boldsymbol{r}_i) \right\rangle_{\mathrm{vlb}} + \Lambda_{\mathrm{T}}^{\mathrm{XR}}(\alpha,\lambda), \tag{13}$$

$$\Lambda_{\mathrm{E}}^{\mathrm{XR}}(\alpha,\lambda) = \left\langle \int \mathrm{d}\boldsymbol{r}\mathrm{L}(\alpha,\lambda,r) \int \mathrm{d}\boldsymbol{r}'\, \rho(\boldsymbol{r}')\, \rho(\boldsymbol{r}+\boldsymbol{r}') \right\rangle_{\mathrm{vlb}}, \tag{14}$$

$$\Lambda_{\mathrm{T}}^{\mathrm{XR}}(\alpha,\lambda) = \left\langle \int \mathrm{d}\boldsymbol{r}\mathrm{L}(\alpha,\lambda,r)\, \rho_{\mathrm{c}}(\boldsymbol{r}) \right\rangle_{\mathrm{vlb}}, \tag{15}$$

with

$$\mathrm{L}(\alpha,\lambda,r) = \frac{1}{r}\frac{\Gamma(\alpha+1)}{(r^2+\lambda^2)^{\alpha/2}}\frac{\sin(\alpha\varphi)}{\alpha}, \quad \alpha > -1, \tag{16}$$

$$\varphi = \tan^{-1}\left(\frac{r}{\lambda}\right).$$

In the sense

$$\Sigma(\alpha) = \int_0^\infty ds\sigma(s)s^\alpha = \lim_{\lambda\to 0}\int_0^\infty ds\sigma(s)s^\alpha e^{-\lambda s}, \quad (17)$$

$\Sigma_T^{ED}(\alpha)$ *etc.* are obtained by replacing $L(\alpha,\lambda,r)$ in Eqs. 12—15 by:

$$F(\alpha,r) = \frac{\Gamma(\alpha+1)\sin(\alpha\pi/2)}{r^{\alpha+1}} \quad \alpha, \qquad 2>\alpha>-1, \quad (18)$$

and

$$F(2,r) = \frac{\pi}{r^2}\delta(r), \quad \alpha=2.$$

The result for $\Sigma_T^{ED}(0)$ is Tavard's energy relationship,[3,4] and those for $\alpha=1$ and 2 have already been given in the literature.[1,5] For $\alpha>2$, the integral over ds will diverge.

If λ in Eq. 11 is replaced by a complex number $(\lambda+ir')$, the integral over ds is expressed by a hypergeometric function, ${}_2F_1$, of $-r'^2/(\lambda+ir')^2$. By taking the imaginary part and letting λ tend to zero, in a sense similar to Eq. 17 we can obtain this integral:

$$J(\alpha,r') = \int_0^\infty ds\sigma(s)s^\alpha j_0(sr'), \quad 2\geqq\alpha>0. \quad (19)$$

This is a modification of Weber-Schafheitlin's discontinuous integral.[9] A useful relationship is obtained only for $\alpha=2$.

$$\begin{aligned} J_T^{ED}(2,r') &= \int_0^\infty ds\sigma_T^{ED}(s)s^2 j_0(sr') \\ &= \frac{\pi}{2}\sum_{i\neq j}\sum Z_iZ_j\langle r'^{-2}\delta(r'-r_{ij})\rangle_{vib} \\ &\quad - \pi\sum_i Z_i\left\langle\int d\Omega_{r'}\rho(r'+r_i)\right\rangle_{vib} \\ &\quad + \frac{\pi}{2}\left\langle\int d\Omega_{r'}\rho_e(r')\right\rangle_{vib}. \end{aligned} \quad (20)$$

Similar relations hold for the other scattering intensities, some of which have previously been reported in the literature.[10] The second and third terms of Eq. 20 are the averages over solid angles of the one-electron density around each nucleus and the electron-pair correlation density respectively. The latter is a radial inter-electron density function.[10]

In order to reduce termination errors, another integral:

$$M(\alpha,\ \mu) = \int_0^\infty ds\sigma(s)s^\alpha e^{-\mu s^2}, \quad \mu>0, \quad (21)$$

is considered, where $e^{-\mu s^2}$ is a damping factor often used in the calculations of radial distribution curves in electron-diffraction studies of gas molecules. This integral can be obtained in terms of a confluent hypergeometric function, ${}_1F_1$, of $r^2/4\mu$. For an even integer of α, $M(\alpha,\mu)$ can conveniently be expressed by replacing $L(\alpha,\lambda,r)$ in Eqs. 12—15 by the following $G(\alpha,\mu,r)$:

$$G(\alpha,\mu,r) = \frac{\partial^{(\alpha-2)/2}}{\partial\mu^{(\alpha-2)/2}}\left(\frac{1}{4}\sqrt{\frac{\pi}{\mu^3}}e^{-r^2/4\mu}\right), \quad \alpha\geqq 2. \quad (22)$$

Finally, relationships based upon finite integrals:

$$\Sigma_0(n) = \int_a^b ds\sigma(s)s^n, \quad (23)$$

and

$$\Lambda_0(n,\lambda) = \int_a^b ds\sigma(s)s^n e^{-\lambda s}, \quad (24)$$

may sometimes be used, where n is an integer. The functions, $F_0(n,r)$ and $L_0(n,\lambda,r)$, corresponding to $F(n,r)$ and $L(n,\lambda,r)$ are:

$$\begin{aligned} F_0(1,r) &= r^{-2}(\cos(ar) - \cos(br)), \\ F_0(2,r) &= r^{-1}(b^2 j_1(br) - a^2 j_1(ar)), \\ L_0(n,\lambda,r) &= (-1)^{n-1}\frac{\partial^{n-1}}{\partial\lambda^{n-1}}\{[(\lambda\sin(ar)+r\cos(ar))e^{-\lambda a} \\ &\quad -(\lambda\sin(br)+r\cos(br))e^{-\lambda b}]/r(r^2+\lambda^2)\}, \quad n\geqq 1. \end{aligned} \quad (25)$$

The various quantities closely related to the molecular electron density are obtainable from the experimental intensities. Except for small α values, the accuracy of $\Sigma(\alpha)$ is limited mainly by experimental errors at large scattering angles and the termination error at s_{max}. Such uncertainties are reducible by using $M(\alpha,\mu)$ and $\Lambda(\alpha,\lambda)$ with an appropriate choice of the parameters, μ and λ. There is no termination-error problem in $\Sigma_0(n)$ and $\Lambda_0(n,\lambda)$.

Since the calculation of the right-hand side of the above equations takes much less computing time than the calculation of the scattering intensities themselves from the molecular wave functions, these relationships must be of great use. The $J_T^{ED}(2,r')$ given by Eq. 20 is computed most easily; accordingly, it is most suitable for the first examination of a molecular wave function.

The authors wish to express their thanks to Professor Takao Iijima, Gakushuin University, for his helpful advice.

Direct Measurement of the Interaction Energy between Solids and Gases. VI. Calorimetric Studies on Acidic Properties of Solid Super Acids Prepared from Silica-Alumina

Hitofumi TANIGUCHI,† Tatsuo MASUDA,†† Kazuo TSUTSUMI,* and Hiroshi TAKAHASHI
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received January 17, 1980)

Solid super acids were prepared by the reaction of gaseous antimony pentafluoride with silica–alumina and heats of adsorption of ammonia on their surfaces were measured. Solid super acids gave about 170 kJ/mol of an initial differential heat of adsorption and their adsorption energies were mainly distributed in the vicinity of 137 kJ/mol, while the initial differential heat of adsorption on original silica–alumina was about 150 kJ/mol and its adsorption energy was chiefly distributed in the vicinity of 117 kJ/mol. Therefore, it was shown that solid super acid had stronger, more homogeneous and much more acid sites than original silica–alumina.

An acid of which the strength is higher than that of 100 wt% H_2SO_4 ($H_0=-10.6$) is called "super acid," which seems to play an important role in catalyst chemistry.[1-3] The representative liquid super acids are $SbF_5 \cdot FSO_3H$ and $SbF_5 \cdot HF$, whose acid strengths were measured to be $H_0<-18$ and $H_0=-15.1$ respectively,[1-3] and others were also investigated by Gillespie *et al.*[4,5] Since liquid super acids are very difficult to deal with as catalysts in the practical reaction system, the synthesis of solid super acids has been required because of easy separation of products from a reaction system and of other advantages. Tanabe and Hattori[6,9] succeeded in the synthesis of several solid super acids such as SbF_5–TiO_2–SiO_2 and SbF_5–SiO_2–Al_2O_3 whose acid strengths are $-13.16 \geqq H_0 > -13.75$ and $-13.75 \geqq H_0 > -14.52$ respectively and which are catalytically active for the reaction of butane and isobutane at room temperature.

In this study, solid super acids (SbSA(I)—(V)) were prepared by the reaction of gaseous antimony pentafluoride with silica–alumina and heats of adsorption of ammonia on their surfaces were measured so as to clarify their surface acidic properties.

Experimental

Silica–alumina cracking catalyst (alumina 13 wt%, SA-13) supplied by Catalysts and Chemicals Ind. Co., Ltd., was evacuated at 500 °C under 10^{-3} Pa for 5 h before treatment with antimony pentafluoride. Antimony pentafluoride (SbF_5) supplied by PCR Research Chem., Inc. was used after distillation.

Solid super acids were prepared by contacting pretreated SA-13 with vapor of SbF_5 in a reaction tube made of pyrex glass for 10 minutes at room temperature, subsequently evacuating for about 20 minutes at 50 °C and repeating the above procedure twice (SbSA(I)), four times (SbSA(II)), eight times (SbSA(III)), thirteen times (SbSA(IV)) or twenty times (SbSA(V)). All of the samples were stored in the desiccator before use.

Gas adsorption calorimetries and infrared measurements were carried out as described in previous papers.[7,8] The content of antimony was determined as follows. A solid super acid was immersed into 1 mol dm^{-3} hydrochloric acid in order to extract completely surface antimony; extracted antimony was analysed by atomic absorption method.

Results

Antimony contents of each sample shown in Table 1 increased with an increase in the number of the treatment. Figure 1 shows differential heat of adsorption of ammonia on SbSA samples, which are extremely higher than that on orginal silica–alumina. Moreover, adsorbed amount of ammonia in the region of high differential heats of adsorption was much greater than that for SA-13. These results indicate the appearance of higher strong acid sites on silica–alumina surface by the treatment with SbF_5 vapor. The initial heat of readsorption of ammonia on SA-13 which was NH_3-preadsorbed and evacuated overnight at 25 °C was about 75 kJ/mol and equal to that on each of SbSA samples which were similarly pretreated. The adsorbed amount of ammonia increased linearly with an increase in antimony content as shown in Fig. 2, where A shows the adsorbed amount above

TABLE 1. ANTIMONY CONTENT OF SOLID SUPER ACID

Sample	SbSA(I)	SbSA(II)	SbSA(III)	SbSA(IV)	SbSA(V)
Number of the treatment run	2	4	8	13	20
Sb Content / mmol g^{-1}	0.69	0.94	1.31	1.72	2.22

75 kJ/mol, B that above 130 kJ/mol and C that between 75 and 130 kJ/mol. Therefore, antimony atoms may be involved in the generation of acid sites on SbSA.

In Fig. 3, ammonia gas adsorption energy distributions on SbSA samples are shown. Fairly sharp maxima were observed for each of SbSA samples at the same heat of adsorption, 137 kJ/mol, and the number of acid sites at this region increased with antimony content. This suggests that the acid sites generated by the treatment with SbF_5 may be homogeneously distributed.

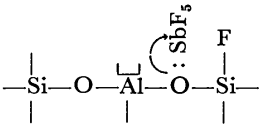
Discussion

Tanabe *et al.*[9] proposed the following surface model of solid super acid (SbF_5–SiO_2–Al_2O_3).



The acid strength of Lewis sites on surface aluminum ions becomes higher by an inductive effect of SbF_5 coordinated on neighboring oxygen ion. Lewis acid amount of SA-13 dehydrated at 500 °C *in vacuo* was determined to be about 180 μmol/g (from adsorbed amount of ammonia) based on the assumption described in previous paper[8] that only Lewis acid sites are present above 115 kJ/mol of differential heat of adsorption of ammonia in the case of silica–alumina (SA-13). If the surface model of SbSA is explained only by Tanabe's proposal, the adsorbed amount of ammonia above 130 kJ/mol should be about 180 μmol/g. The observed value shown in Fig. 2 implies that an another model of the acid generation would also be possible.

Infrared spectra of pyridine adsorbed on some solid super acids are shown in Fig. 4. The measurements were carried out at 25 °C after contacting SbSA samples evacuated at 50 °C with pyridine vapor for 10 min

Table 2. Ratio of the number of Brönsted acid sites to that of Lewis ones

Sample	SA-13	SbSA(II)	SbSA(III)	SbSA(IV)
B-site / L-site	4	9	11	16

and subsequent evacuation at 100 °C. All SbSA samples gave absorption peaks both at 1545 cm^{-1} and 1450 cm^{-1}, which indicates the presence of Brönsted and Lewis acid sites. The ratio of the number of Brönsted acid sites to that of Lewis ones was determined by their absorption intensity on the basis of the assumption that the ratio of the absorption coefficient of the 1450 cm^{-1} band to that of the 1545 cm^{-1} band, $\varepsilon_{1450}/\varepsilon_{1545}$, is 8.8,[10] and is shown in Table 2. The results show that the fraction of Brönsted sites on SbSA sample was greater than that on SA-13 and increased with antimony content. Hydrogen atoms are mostly present as surface hydroxyl groups on the original silica–alumina and may be involved in the generation of Brönsted acid sites by the interaction with SbF_5 molecules. The amount of residual hydroxyl groups of SA-13 after evacuation at 500 °C was gravimetrically determined to be 1.4 mmol/g by successive ignition loss *in vacuo* from 500 °C to 1200 °C by use of a Cahn electromagnetic microbalance. The transformation of surface hydroxyl groups into acid sites would be enhanced by an increase in the number of the treatment times with SbF_5 vapor, which was suggested by the finding that the site distribution at 137 kJ/mol became large with the treatment times. The maximum at 117 kJ/mol for original SA-13 disappeared by the treatment with SbF_5, accompanied by an appearance of the maximum at 137 kJ/mol. This suggests that the nature of inherent acid sites on SA-13 changed with the treatment with SbF_5.

The highest acid strength of SbF_5–SiO_2–Al_2O_3 prepared by Tanabe *et al.* was reported to be $-13.75 \geqq H_0 > -14.52$[6,9], while SbSA samples in this study gave about 170 kJ/mol of an initial differential heat of adsorption and their adsorption energies were mainly distributed in the vicinity of 137 kJ/mol. The differential heat value, $q=137$ kJ/mol, seems to correspond to the acid strength, $H_0 \fallingdotseq -14$, on the basis of the relation between q and pK_a value described in a previous paper,[11] which is similar to the value measured by Tanabe *et al.* The finding that SbF_5–SiO_2–Al_2O_3 exhibited high activity for the reaction of butane at 20 °C[6,9] might be attributed to the presence of a great number of acid sites with high differential heat of adsorption of ammonia above 130 kJ/mol.

It was concluded that solid super acid (SbSA samples) had stronger, more homogeneous and much more acid sites than original SA-13 and that most of acid sites on the former are Brönsted sites.

This work was partly supported by a Grant-in-Aid for Science Research from the Ministry of Education, Science and Culture (No. 343017).

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

†*The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106*

(Received January 22, 1980)

The triplet-triplet energy transfer between like molecules was investigated for the system of quinoxaline in ethanol by using the method of optical detection of zero-field magnetic resonance at 1.4 K. The concentration dependence of the spin state population indicates that the energy transfer between quinoxaline molecules takes place at concentrations higher than about 2×10^{-2} mol/dm^3.

The triplet-triplet energy transfer between like molecules has so far been studied by the method of the concentration depolarization of phosphorescence[1,2] or by magnetophotoselection.[3] However, these methods are subject to the masking effect due to the singlet-singlet energy transfer, since molecules are initially excited into singlet states in most cases. Two of the present authors (AI and NE) have also developed a method which eliminates the effect of the S-S energy transfer by making use of isotopic mixtures.[4,5]

A more sophisticated approach would be to apply the method of optical detection of zero-field magnetic resonance (ZF ODMR), in which the use of an isotopic mixture is not necessary. As the perturbation causing the T-T energy transfer does not depend on the spin variables, the direction of the spin angular momentum is conserved during the energy transfer. Hence, the relative populations initially prepared in the spin states by optical pumping, followed by intersystem crossing, are modified as a result of the energy transfer according to the relative orientations of the solute molecules. Therefore, the modified relative populations may be used as an indication of the presence of the energy transfer, if the populations are compared with those obtained in the absence of energy transfer (*i.e.*, those in a sufficiently dilute solution).

In the present communication, we will describe an application of this method to a study of the T-T energy transfer among quinoxaline molecules dissolved in ethanol.

Experimental

Quinoxaline was distilled under reduced pressure. Ethanol was distilled after passing it through silica gel columns. The equipment for the ZF ODMR experiments has been described elsewhere.[6] Samples were excited with light from a high-pressure mercury lamp through an appropriate filter, and the phosphorescence was monitored at 474 nm.

Results and Discussion

The phosphorescent triplet state of quinoxaline has been thoroughly studied by ZF ODMR.[7] It is well established that the ordering of the spin sublevels is $T_x<T_y<T_z$ and that the phosphorescence emission occurs predominantly from T_z, where the x axis is defined as the normal to the molecular plane; the y axis, as the short axis, and the z axis, as the long axis. Most studies so far reported have been made in mixed crystals, such as quinoxaline in durene and in naphthalene-d_8.[7]

In the ethanol rigid glass solution (3×10^{-3} mol/dm^3) at 1.4 K, we observed MIDP (microwave-induced delayed phosphorescence) signals at 3.49 and 1.12 GHz; these signals indicate that the zero-field splitting parameters are not much different from those in the mixed crystals. On the other hand, the decay-rate constants were obtained as 1.2, 1.3, and 6.5 s^{-1} for the T_x, T_y, and T_z states respectively. Apparently, these values are affected by the spin-lattice relaxation. Therefore, the kinetic parameters given in Table 1 should be considered to represent just apparent properties. It is reasonable to assume that the spin-lattice relaxation does not depend on the concentration of quinoxaline. As a matter of fact, it will turn out that the spin-lattice relaxation does not significantly affect our main conclusion, since we focus our attention only on the concentration dependence of the parameters.

The steady-state population ratio, r_{ij}, of the sublevel, i, with large radiative and total decay rates, to another sublevel, j, is given by:

Table 1. The phosphorescence decay rates, k_i, relative radiative decay rates, k_i^r, and relative steady-state populations, N_i^0, of quinoxaline

	k_x/s^{-1}	k_y/s^{-1}	k_z/s^{-1}	k_x^r/k_z^r	k_y^r/k_z^r	N_x^0/N_z^0
In ethanol[a)]	1.2	1.3	6.5	0.040	0.035	0.30
In naphthalene-d_8[b)]	0.42	0.80	12.0	0.013	0.013	0.36
In durene[b)]	0.40	0.59	11.1	0.015	0.020	0.68

a) 3×10^{-3} mol/dm^3 and at 1.4 K. b) From Ref. 7.

†† Present address: Institute for Molecular Science, Myodaiji, Okazaki 444.

$$r_{ij} = N_j^0/N_i^0 \simeq h_{ij}(t_1) \exp(k_j t_1)/fI_0 + \exp(k_j - k_i)t$$

where $h_{ij}(t_1)$ is the magnitude of the MIDP signal at time t_1 ($t_1 \simeq 1$ s), where I_0 is the steady-state phosphorescence intensity tacitly approximated to be proportional to $k_i^r N_i^0$, and where f is the transfer efficiency of the population from T_j to T_i by means of a microwave pulse. In the present case, the concentration dependence of this quantity was measured for the T_x-T_z transition. The value thus obtained, r_{zx}, is also the apparent ratio of the steady-state population of T_x to that of T_z, because the above equation is valid only under the isolation conditions.

The observed r_{zx} values are plotted against the concentration in Fig. 1. The values remain almost constant ($\simeq 0.3$) in the range of 10^{-3} mol/dm^3. This indicates that the population in the T_z state is larger than that in the T_x state in the absence of any energy transfer. When the concentration is increased, the T-T energy transfer gradually becomes effective and results in *population randomization* among the spin states. As a result, the value of r_{zx} may be expected to increase, as we observed.

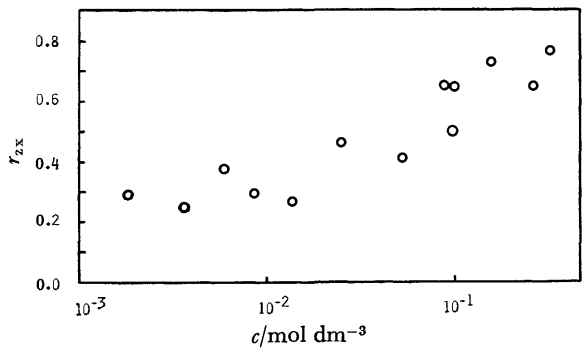

Fig. 1. Variation of the population ratio, r_{zx}, with concentration at 1.4 K.

However, before drawing any conclusion, we should discuss various possibilities which might influence the value of r_{zx} at high concentrations. As the values of f and I_0 changed from sample to sample, we used the values obtained in each measurement to estimate the value of r_{zx} from the equation. Therefore, the results in Fig. 1 cannot be due to the change in these quantities. Changes of the decay rates, k_x and/or k_z, might also affect the value of r_{zx}. However, it was found that the value of k_x does not show a significant variation in the concentration range studied. This is shown in Fig. 2. The values in Fig. 2 were obtained by plotting $\ln h_{zx}(t)$ *vs.* t in the region comparable to t_1 (*i.e.*, $\simeq 1$ s); the plots gave good straight lines. This means that, at both low and high concentrations, the effect of k_z on the magnitude of $h_{zx}(t)$ is not important and that, therefore, the second term of the equation can be neglected in this time region.

The rigid glass solutions were transparent, although cracked, at the highest concentration of 0.4 mol/dm^3, and the formation of microcrystals was not observed visually. Furthermore, the T_x-T_z transition was observed at nearly the same microwave frequency (3.48 GHz) in the 0.1 mol/dm^3 solution as in the solutions of lower concentrations. The phosphorescence spectrum of the same solution showed little difference compared with that of the samples of lower concentrations. These results suggest that the observed variation of r_{zx} is not due to a dimer or aggregate formation at high concentrations.

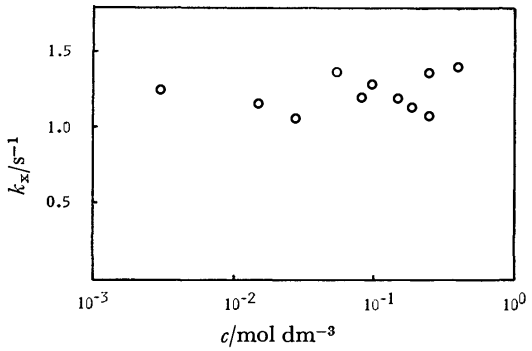

Fig. 2. Concentration dependence of the phosphorescence decay rate, k_x.

Triplet-triplet annihilation is an alternative possibility which might be responsible for the observed variation in r_{zx} with the concentration, because the population in T_z would be most effectively diminished by the annihilation. To check whether or not this possibility is operative, we measured the population ratios at different excitation light intensities and the phosphorescence decay curves at different concentrations. The intensity of the incident light was reduced to about a half by the use of an appropriate filter. The values of r_{zx} were found to be 0.55 and 0.50 for the 0.1 mol/dm^3 solution with and without the attenuation of light intensities respectively. These values are essentially in agreement with each other within the range of experimental error. The possibility of T-T annihilation is thus eliminated.

From these considerations, it may be concluded that the observed increase of r_{zx} at high concentrations is caused by the randomization of the relative populations in the spin states as a result of the triplet-triplet energy transfer among the randomly oriented quinoxaline molecules in the ethanol rigid glass. The energy transfer was found to become efficient at concentrations higher than 2×10^{-2} mol/dm^3; this finding essentially coincides with the corresponding concentration for the T-T energy transfer between dissimilar molecules.[18]

Microwave Spectrum of Propyl Silane

Michiro HAYASHI,* Jun NAKAGAWA, and Yasunori AGUNI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received January 28, 1980)

The microwave spectra of propyl silane and its four deuterated species were measured. The structure of the antiperiplanar isomer was so obtained as to reproduce the observed moments of inertia. The dipole moment and its direction were determined by Stark-effect measurements of several low J transitions.

In continuation of studies on the molecular structures of organosilicone molecules such as allyl silane[1] and ethyl fluorosilane,[2] the antiperiplanar isomer of propyl silane has been investigated by means of microwave spectroscopy.

The infrared and Raman spectra of the molecule were obtained by Murata *et al.*[3] who gave evidence of the existence of two rotational isomers, the antiperiplanar and synclinal isomers, in the gaseous phase. According to their Raman spectra, the antiperiplanar isomer is more stable than the synclinal isomer in the liquid state. We expected the structure of the synclinal isomer to be adequate for comparing it with that of allyl silane, but the observed microwave spectra of the synclinal isomer were so weak that assignments were possible for only the antiperiplanar isomer. In the present paper, the structure and the dipole moment of the antiperiplanar isomer are discussed.

Experimental

Samples of propyl silane and its deuterated species $CH_3CH_2CH_2SiD_3$ were prepared by reducing propyl trichlorosilane with lithium aluminium hydride or deuteride in dibutyl ether. Samples of $CD_3CH_2CH_2SiH_3$, $CH_3CD_2CH_2SiH_3$, and $CH_3CH_2CD_2SiH_3$ species were prepared by reacting appropriate propyl Grignard reagents with iodosilane.

The Grignard reagents were prepared in dibutyl ether from appropriate deuterated propyl bromides (98 atom % D, Merck Sharp & Dohme, Canada). Iodosilane was prepared by the method of Sternbach and MacDiarmid.[4]

The microwave spectra of the samples were measured in the region 8000—35000 MHz with a conventional Stark modulation spectrometer at the temperature of Dry Ice.

Results and Discussion

Microwave Spectra. The antiperiplanar isomer of propyl silane is a nearly prolate symmetric top molecule with the μ_a and μ_b-dipole moment components. However, the b-type transitions are actually very weak because of the smallness of the μ_b-dipole component. The observed frequencies of the transitions are given in Table 1. The rotational constants were obtained by a least-squares fit of all the observed frequencies with use of a rigid rotor formula modified by adding the first term of the centrifugal distortion $-d_J[J(J+1)]^2$. The results are given in Table 2.

Molecular Structure. The present data are not sufficient to determine the r_s structure by the substitution method. Only a part of the r_s coordinate values of the hydrogen atoms could be obtained from the solutions of the Kraitchman equations. They are given in Table 4.

In order to find a plausible structure of the molecule, five skeletal parameter values alone were adjusted so as to well reproduce the fifteen observed moments of inertia, the other parameter values being transferred from those of analogous molecules.

For the CCH_2SiH_3 part of the molecule, a set of parameter values was transferred from those of ethyl silane.[5] Since the reported parameter values of the methyl group for propane[6] gave a slightly asymmetric group, the parameter values were so corrected as to give a symmetric methyl group before the transfer of the values to the CH_3C part of our molecule.

As regards the parameter values of the CCH_2C part, r(CH) and α(HCC) values were transferred from those of the corresponding parameter values of the methyl group in ethyl silane. Since the α(CCC) value to be adjusted was related closely to the other five angle values, the change of α(CCC) was compensated by the change of α(HCH). The parameter values are given in Table 3.

When the r_s structure of a molecule is well established, the differences between the observed and calculated moments of inertia are small positive values and approximately constant for all the measured species. This was taken into consideration for the adjustment of the skeletal parameter values.

The differences between the observed and calculated moments of inertia (Table 2) are considered to be as small as those usually obtained from the r_s structure. The coordinate values of the hydrogen atoms calculated from the set of the skeletal parameter values reproduce the r_s coordinate values (Table 4).

The present set of skeletal parameter values can be regarded as the best set but their reliability cannot be shown clearly since the ambiguity arising from the transfer of the parameter values between molecules prevents estimation of the definite reliability of the values obtained.

However, even when maximum uncertainty is assumed, the r(CC) value of the CH_3C group is greater than that of propane, and the r(CC) value of the CH_2CSi group smaller than that of ethyl silane. The r(SiC) value is much greater than those of methyl silane[7] (1.8668 Å) and ethyl silane (1.866 Å).

The angle values are almost equal to those of the corresponding angle values for analogous molecules.

Dipole Moment. The dipole moments were determined by Stark-effect measurements of six low J transitions for the antiperiplanar isomers of propyl

silane and its two deuterated sepcies ($CH_3CH_2CH_2SiD_3$ and $CH_3CD_2CH_2SiH_3$). The spectrometer was calibrated with OCS[8)] on the measurements. The results are given in Table 5.

The dipole moment of the $CH_3CH_2CH_2SiH_3$ species is slightly larger than that of the $CH_3CH_2CH_2SiD_3$ species though 99% reliability intervals of the dipole moments for these species slightly overlap each other. Thus the silyl group is considered to be situated at the side of the negative pole of the dipole moment.[9)]

There are two possible directions for the dipole moment (Table 5), making angles of i) 5°46′ and ii) 143°54′ with the SiC bond, respectively. The angle between the b-inertial axis and the SiC bond of the $CH_3CD_2CH_2SiH_3$ species is smaller by ca. 40′ than that of the $CH_3CH_2CH_2SiH_3$ species. The angle of $\alpha((C–Si)\times\mu)$ for the $CH_3CH_2CH_2SiH_3$ and CH_3CD_2-CH_2SiH_3 species agree with each other within experimental error for i), and disagree beyond experimental error for ii).

The dipole moment of the antiperiplanar isomer of propyl silane is thus concluded to incline by 5°46′ from the SiC bond towards the SiH bond in the symmetry plane.

The dipole moment of the antiperiplanar isomer of propyl silane (0.811 D) is close to that of ethyl silane (0.81 D),[5)] larger than that of methyl silane (0.7351 D).[9)] The angle between the dipole moment and the SiC bond is much larger than that for ethyl silane (1°18′).

Spectra due to the Excited Vibrational States. Several groups of spectra attributable to those in the excited vibrational states can be found around the ground state lines. Among them, the group of spectra

predictable by the rotational constants $(A, B, C)=$ (19700, 2251, 2158) MHz for the normal species were assigned to that arising from the first excited skeletal torsional state. Actually, rough measurements of the relative intensity of the spectra gave the vibrational frequency of *ca.* 100 cm^{-1} which is close to the observed Raman frequency (102 cm^{-1}) in the liquid state for the $CH_3CH_2CH_2SiD_3$ species.[3)]

Assignments of the spectra attributed to those of the excited CH_3 and SiH_3 torsional states were attempted in order to evaluate the barrier to internal rotation of the CH_3 and SiH_3 groups. However, we have found no spectra with reasonable splittings.

The authors wish to express their thanks to Associate Professor Akinori Hasegawa for his kindness in supplying the samples.

Spectroscopic and Kinetic Study of an Intramolecular Aromatic Nucleophilic Photosubstitution. Reaction Mechanism of a Photo-Smiles Rearrangement

Kenji YOKOYAMA, Ryoichi NAKAGAKI, Junko NAKAMURA, Kiyoshi MUTAI,** and Saburo NAGAKURA*

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received January 25, 1980)

Photo-Smiles rearrangement reaction of *N*-[ω-(*p*-nitrophenoxy)alkyl]aniline was studied by measuring the absorption spectra of transient species. Two intermediates **A** and **B** were observed and were assigned to a solvated ion pair and the Meisenheimer complex, respectively. The reaction scheme, starting material→intramolecular charge transfer on excitation→**A**→**B**→final product, was derived from the relative yields and lifetimes of **A** and **B** as well as from the effects of solvent polarity, of triethylamine and oxygen, and of the alkyl chain length on each step of reaction.

A great number of studies on aromatic nucleophilic photosubstitution have been carried out, main interest being focused on the orientation rule.[1] However, works in which the reaction mechanism has been elucidated through direct observation of intermediates are only a few. Cornelisse *et al.*[2] and also Duddel and Richards[3] studied the reactions of 3,5-dinitroanisole and *o*-, *m*-, and *p*-nitroanisoles, respectively, with the hydroxide ion by flash and laser photolysis. They concluded that the reaction proceeded *via* the triplet state except for *m*-nitroanisole.

A photo-Smiles rearrangement is known as an intramolecular nucleophilic photosubstitution reaction in which a nucleophile and a reaction center coexist within a molecule. Mutai *et al.*[4] studied the reaction in which *N*-[ω-(*p*-nitrophenoxy)alkyl]aniline (abbreviated hereafter to $(I)_n$, *n* being the number of methylene in the alkyl chain) converted into an alcohol $(II)_n$ in polar solvents by irradiation with light of about 300 nm (see Fig. 1). They reported that the reaction proceeded unimolecularly and proposed a tentative reaction scheme. In the present study, we have intended to elucidate the reaction mechanism by observing directly the intermediates with the aid of laser photolysis.

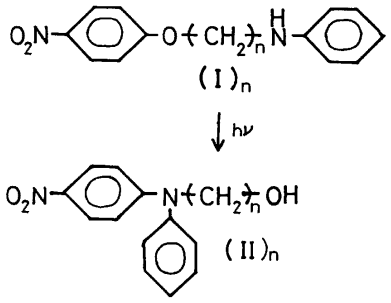

Fig. 1. Photo-Smiles rearrangement of *N*-[ω-(*p*-nitrophenoxy)alkyl]aniline, $(I)_n$.

Experimental

The starting material $(I)_n$ with $n=2$, 3, and 4 were prepared as mentioned previously[5] and purified by chromatography. Acetonitrile, benzene, cyclohexane (Wako, Spectrograde), ethanol (Nakarai, Spectrograde), and tetrahydrofuran (Wako, Special Grade) were used as solvents without further purification. Sample solution for the transient absorption measurements (about 1×10^{-3} mol·dm^{-3}) were degassed by repeating freeze-pump-thaw cycles. *N*-Methylaniline (NMA) (Wako, Special Grade) and *p*-nitroanisole (PNA) (Tokyo Kasei, Special Grade) which were regarded as two components of $(I)_n$ were used as references after distillation *in vacuo* and recrystallization, respectively.

An N_2 laser (Molectron UV-24 with peak height of 900 kw and pulse duration of 10 ns) was used as a pulse excitation source of reaction. A monitor light source was designed and constructed using a Xe flash lamp (EG & G 3CP-2). This system was able to emit rectangular shaped radiation pulses with 50 μs duration by the discharge through an LC delaying circuit.[6] By the use of this system, the transient absorption in μs region was measured with enough accuracy. A current regulated I_2-W lamp, chopped with a mechanical shutter, was used for the measurement of longer lived species (≈1 ms).

Time profile and spectra of transient species were measured by using a Jarrell-Ash JE-25 monochromator equipped with an HTV R-666S photomultiplier. A Hitachi 200-20 spectrophotometer was used for ordinary absorption measurements. All the experiments were made at room temperature.

Results and Discussion

Spectral change caused by 365 nm light irradiation of $(I)_2$ in acetonitrile is shown in Fig. 2. $(II)_2$ was produced by the irradiation of the sample in acetonitrile with the 313 or 365 nm light of Hg lamp or the defocused N_2 laser beam. Several isosbestic points were observed. This indicates that the reaction is clean and straightforward, being suited for the kinetic study of the reaction. The spectra of $(I)_2$ are safely reproduced by the superposition of those of PNA and NMA, whereas Mutai found a weak CT absorption band at 360 nm for the compounds of $n=2$ and 3.[7] This implies the existence of weak interaction in the ground state molecule. Thus it is suggested that considerable amounts of the molecules take sandwich configuration in their ground state.

Figure 3 shows the time dependence of the transient absorption of $(I)_2$ observed at 450 nm in acetonitrile.

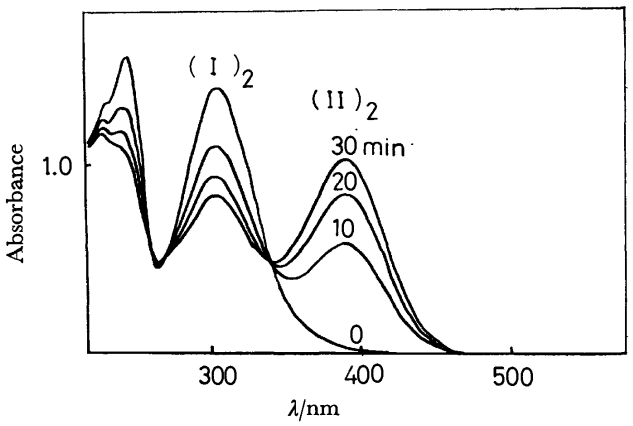

Fig. 2. Spectral change of $(I)_2$ in acetonitrile irradiated at 365 nm for 0, 10, 20, and 30 min, respectively.

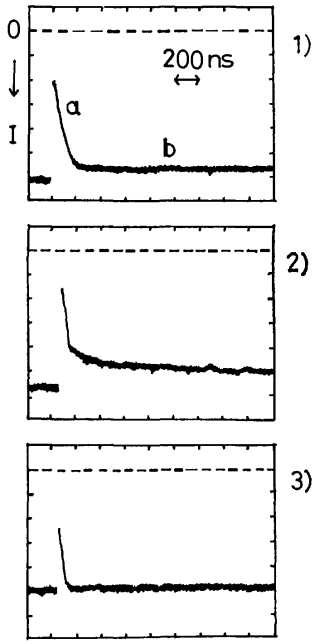

Fig. 3. Decay curve of transient absorption of $(I)_2$ in acetonitrile at 450 nm.
1) $(I)_2$ only, 2) with $N(C_2H_5)_3$ ($\approx 1\times10^{-1}$ mol·dm^{-3}), 3) with O_2.

The decay curve of the absorption can be analyzed as composed of two components, **a** and **b**. Component **a** absorbs strongly but decays very fast, whereas component **b** is weak but long lived. The observation of these two components indicates the existence of two kinds of intermediates. Hereafter the intermediates which show the **a** and **b** components are referred to as **A** and **B**, respectively.

Figure 4 shows the absorption spectrum of **A**, which has a maximum at 450 nm, a shoulder in the shorter wavelength region, and a long tail in the longer wavelength region. The spectrum was not observed when either PNA or NMA was irradiated separately by the N_2 laser under the present experimental condition. The masking of nitrogen of the NMA component by addition of 0.1 mol·dm^{-3} hydrochloric acid also resulted in the nonoccurrence of **A**. The absorption spectrum of **A** is independent of *n*, the number of the methylene group in the alkyl chain. Thus, it is concluded that decay component **a** is caused by the coexistence of PNA and NMA moieties.

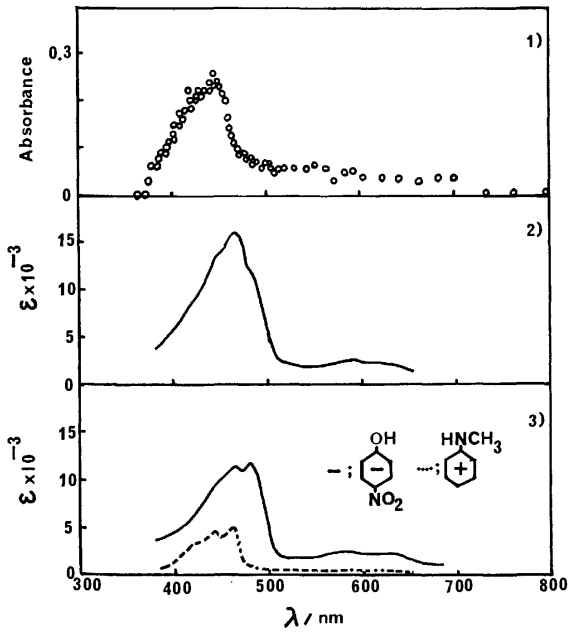

Fig. 4. Absoprtion spectra of **A** and the authentic species.
1) Absorption spectrum of **A** of $(I)_2$ in acetonitrile solution 10 ns after the excitation, 2) the 1:1 superposition of the absorption spectra of the NMA cation radical and the *p*-nitrophenol anion radical, 3) absorption spectra of the *p*-nitrophenol anion radical (Ref. 8b) and the NMA cation radical (Ref. 8a).

Transient intermediate **A** was observed clearly in polar solvents such as acetonitrile, ethanol and tetrahydrofuran, but not in nonpolar solvents such as benzene and cyclohexane. This solvent effect on the occurrence of **A** suggests the highly polar character of **A**.

Shida *et al.* reported the spectra of the *p*-nitrophenol anion radical and the NMA cation radical obtained by γ-ray irradiation at low temperature.[8] The 1:1 superposition of the spectra of both ions which are reproduced in Fig. 4, 3 is similar to the spectrum of **A** (compare Fig. 4, 1) with Fig. 4, 2)). Since the spectrum of the PNA anion radical is expected to be similar to that of the *p*-nitrophenol anion radical, the spectrum of **A** may be regarded as a superposition of those of the PNA and NMA ions. From this fact and the above-mentioned necessity of the coexistence of PNA and NMA moieties for the occurrence of **A**, we can conclude that **A** is a solvated ion pair in which both ions are bridged with the methylene chain.

Transient intermediate **A** is formed within the excitation pulse time (10 ns). Its lifetime is about 60—100 ns in the degassed acetonitrile solutions and reduces to about 20 ns after bubbling of the solution with O_2 gas for 3 min (see Table 1). In spite of the oxygen effect, **A** cannot be assigned to the lowest triplet state of $(I)_2$ in view of the fact that the spectrum of **A** is different from the T-T absorption spectra of nitro-

TABLE 1. EFFECTS OF $N(C_2H_5)_3$ AND O_2 ON THE INTERMEDIATES

	Lifetime of **A**	The relative yield of **B** to **A**

anisoles,[3] aniline and *N,N*-dimethylaniline.[9] The oxygen effect on the decay of **A** may be interpreted as the quenching of the aromatic anion by O_2.

Mutai *et al.* observed that the reaction $(I)_2 \rightarrow (II)_2$ was accelerated by addition of $N(C_2H_5)_3$.[4] We studied the effect of O_2 besides $N(C_2H_5)_3$ on the rate of the reaction by monitoring the absorbance at the peak of $(II)_2$ (at 395 nm) and the results are shown in Fig. 5. The addition of O_2 was found to decrease the rate.

Furthermore, we studied the effects of $N(C_2H_5)_3$ and O_2 on the decay of transient absorption and the results are shown in Fig. 3. The observed values of lifetime are listed in Table 1, together with the relative yield of **B** to **A** which is the ratio of absorbance of **B** observed 1 μs after the excitation to that of **A** observed 10 ns after irradiation. The addition of O_2 decreases the lifetime of **A** as well as the relative yield of **B**. The addition of $N(C_2H_5)_3$ decreases the lifetime of **A** but increases the relative yield of **B**. These results mean that O_2 quenches the ion pair and intercepts formation of **B** from **A** whereas $N(C_2H_5)_3$ accelerates the formation. The retarding effect of O_2 and the accelerating effect of $N(C_2H_5)_3$ were observed for formation of the final product, too. This is one of the evidences that intermediates **A** and **B** observed spectroscopically really participate in the reaction.

Figure 6 shows the absorption spectrum of **B** produced from $(I)_2$ in the presence of $N(C_2H_5)_3$ (1 μs after excitation). A similar spectrum of **B** was also observed in the absence of $N(C_2H_5)_3$ although S/N

ratio became worse. As a stable intermediate of aromatic substitutions, the Meisenheimer complex (see Fig. 6) is well known. Ohsawa observed the absorption spectrum of the complex of PNA with amine with the results shown in Fig. 6.[10] We can see from the figure that the spectrum of **B** is similar to that of the complex. Therefore **B** is assigned to the Meisenheimer complex. The lifetime of **B** in the presence of $N(C_2H_5)_3$ is about 1—several ms for n=2, 3, and 4. Furthermore the spectral feature was found to be almost independent of n.

Figure 7 shows a conclusive mechanism of the reaction. A slight interaction may occur between the two ending groups in the ground state of the starting material $(I)_2$, as suggested by the appearance of a weak charge transfer band. When the sandwich type molecule is excited, a charge separation takes place efficiently through the orbital overlap and then the charge-transfer complex is solvated to form an ion pair.[11]

The process **A**→**B** corresponds to the Meisenheimer complex formation probably accompanied with abstraction of H^+ and **B** is converted into $(II)_2$ gradually by abstracting H^+ from $HN(C_2H_5)_3^+$. At the stage of **A** to **B**, the basicity of the NMA cation may be considered to be weaker than that of $N(C_2H_5)_3$. Therefore H^+ transfers from **A** to $N(C_2H_5)_3$. This may reasonably explain the enhancement of the relative yield of **B** by the addition of $N(C_2H_5)_3$. The above explanation implies that the presence of H^+ acceptor such as amine is necessary for the forward reactions. Actually, when the solvent acetonitrile was distilled repeatedly with P_2O_5, the photo-Smiles reaction rate was markedly slow. The fact that commercially available spectroscopic grade acetonitrile is positive solvent for the reaction suggests the presence of impurities which act as catalysts in thermal reaction steps, although they are not detectable by gas and liquid chromatography.

As a whole, the photosensitized Smiles rearrangement is such a reaction that a substitution takes place between the cation and anion radicals produced by irradiation of light. Nagakura and Tanaka predicted theoretically that the radicals formed by charge transfer interaction played an important role in the aromatic substitution reaction.[12] The observation of the ion pair as the reaction intermediate in the present study shows that the photo-Smiles reaction is a typical example for their prediction.

Generally speaking, the orientation rule is known to be different for thermal and photo aromatic substitutions. Mutai *et al.*, however, reported that the photo-Smiles reaction is para directing with regard to the NO_2 group as is usual for the thermal nucleophilic substitution.[4] This agrees with the theoretical prediction by Nagakura and Tanaka[12a] that the free valency of the nitrobenzene anion is largest at the para position. In other words, photo-Smiles reaction is triggered by irradiation of light and the substitution takes place through interaction between the ground state cation and anion radicals in pair.

(Received February 22, 1980)

Photochemistry of [2.2]paracyclophane in glassy solvents at 77 K was studied. With irradiation, a species in which two benzyl radicals are linked together with an ethylene bridge was produced. From the ESR study, the radicals were found to form the benzyl radical pair in harder solvents. The emission spectrum and the emission lifetime of the radical species showed remarkable dependence on the solvent viscosity. In harder solvents, a new broad emission was observed on the longer wavelength side of the structured emission of the benzyl radical. From the studies of the excitation spectrum and the emission lifetime, this broad band was concluded to be the intramolecular excimer fluorescence of the radical pair. The photo-reaction of [2.2]paracyclophane was found to be biphotonic, occurring from a higher triplet state excited *via* the lowest triplet state.

[2.2]Paracyclophane (PC) is a typical molecule for studying the transannular interaction, and its electronic structure was studied by several authors both experimentally and theoretically.[1] Photochemistry of PC is also interesting in connection with its electronic structure. The biradical and the zwitter ion *etc.* were assumed by Helgeson and Cram as photochemical intermediates in the photolysis of PC in solution at room temperature.[2]

We studied the photochemistry of PC in glassy solvent at 77 K. Our main interest was laid on the confirmation of a photo-reaction intermediate, benzyl radical pair, and also on the transannular effect in the emissive state of this species.

Experimental

Materials. PC (the Aldrich Chemical Company) was purified by column chromatography and vacuum sublimation. 2-Methylpentane and 2-methyltetrahydrofuran (Tokyo Kasei) which were used as solvents, were distilled from lithium aluminium hydride. Isopentane (Tokyo Kasei) was used without further purification. The concentration of the sample was about 10^{-3} mol dm^{-3} throughout the experiment except the case of the absorption spectrum (10^{-4} mol dm^{-3}). Solutions were degassed by freeze-pump-thaw cycles. We used 2-methyltetrahydrofuran (MTHF), 2-methylpentane (2-MP), isopentane (IP), and mixed solvents of 2-MP and IP (10:0.3, 10:1, 4:1, 3:2, 1:1, and 3:7) as solvents. IP initially forms glass but gradually becomes snowy at 77 K, while other solvents form clear glass. The viscosities of these solvents at 77 K are greatly different from one another; 3.7×10^{20} cp at 77.5 K for MTHF,[3] 2.4×10^{13} cp at 77.5 K for 2-MP,[3] and $<8.9\times10^{5}$ cp at 77 K for IP.[4]

Absorption Measurements. Ultraviolet and visible absorption spectra of photolysis products of PC were measured with a Cary 14 recording spectrophotometer. For the generation of *p*-methylbenzyl radical from *p*-xylene, a light of fourth harmonics (266 nm) of a YAG laser (Quanta Ray DCR-1) was used as an exciting source, and the absorption spectrum was measured.

ESR Measurements. The ESR spectra were recorded on a JEOL JES-FE-3AX spectrometer. The magnetic field was calibrated by measuring the resonance frequency of ^{1}H NMR.

Emission and Excitation Measurements. Emission spectra of the PC photoproduct were measured by using a 100 W super high-pressure mercury lamp and a Jarrell-Ash 1/4 M monochromator as an exciting system and a Spex 1700-111 monochromator and a Hamamatsu TV R636 photomultiplier as a detecting system. As an exciting source for the excitation spectrum measurement, a 500 W xenone lamp and the Spex monochromator were used.

Emission Lifetime Measurements. A nitrogen laser (Molectron UV24) pumped dye laser (DL-14) and the second harmonic generator (KDP (KH_2PO_4) crystal) were used for the emission lifetime measurement. The excitation wavelengths are 421 nm (*p*-bis(*o*-methylstyryl)benzene), 457 nm (7-diethylamino-4-methylcoumarin), and 322 nm (Rhodamin B and Cresyl Violet Perchlorate/KDP crystal). The duration of pulse is 4—8 ns and the line-width is about 0.01 nm. The emission was observed with a Nikon G-250 monochromator and a Hamamatsu TV R666S photomultiplier.

Results and Discussion

PC in glassy solvents was irradiated at 77 K with the use of 313 nm light of a super high-pressure mercury lamp. Initially green phosphorescence of PC with long lifetime was observed. By continuing irradiation, the yellowish emission with short lifetime was observed instead of the phosphorescence of PC. After irradiation, the glassy solution was colored yellow as observed previously by Bramwell and Gendell.[5] The yellowish emission was also observed by using the longer wavelength light (365, 436 nm) for excitation. The absorption, ESR, emission, and excitation spectra of the species produced by photolysis of PC were measured and analyzed as follows.

Absorption Spectra of PC Photoproduct. By photolysis of PC in glassy solvent at 77 K, a new species was produced and existed stably in the solvent matrix. Absorption spectra of this new species produced at irradiation times of 2, 5, and 8 min in 2-MP were measured with the results shown in Fig. 1. There appear a few peaks in 260—270 nm, distinct peaks in 300—322 nm, and weak but distinct peaks near 450 nm. Kaupp *et al.* reported recently that a new species was produced by photolysis of PC in MTHF at 77 K, the absorption spectrum of which showed peaks near 320 and 450 nm.[6] Their result is consistent with ours except for the wavelength region below 300 nm which was not measured by them.

The observed spectrum consisting of the three bands at 270, 320, and 450 nm is very similar to that of the

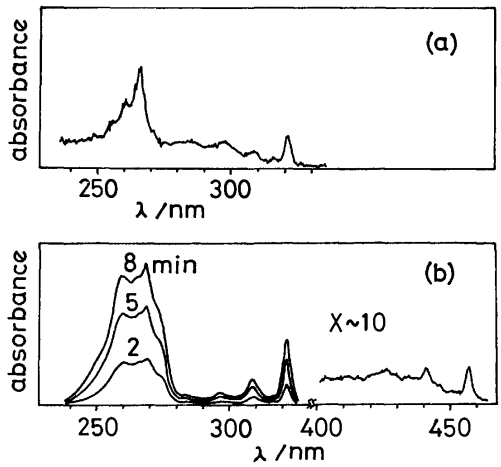

Fig. 1. Absorption spectra of (a) the *p*-methylbenzyl radical produced from *p*-xylene, (b) the PC photoproduct at respective irradiation times (2, 5, and 8 min) in 2-MP at 77 K.

benzyl radical produced from toluene or its methyl derivatives in glassy solvents at 77 K.[7] For the purpose of comparison, the observed absorption spectrum (240—340 nm) of the *p*-methylbenzyl radical produced from *p*-xylene is also shown in Fig. 1. It is evident that a species with the structure very similar to the *p*-methylbenzyl radical is produced by photolysis of PC.

It is reasonable to consider that a C–C ethylene bridge of PC is dissociated at the primary reaction step and a biradical species in which two benzyl radicals are linked together by an ethylene bridge in the *p*-position (·CH_2–C$_6$H$_4$–CH_2–CH_2–C$_6$H$_4$–CH_2·) is produced. This biradical is expected to show the absorption spectrum similar to that of the *p*-methylbenzyl radical in agreement with the above-mentioned observation. This point has been investigated further with the aid of ESR spectroscopy.

ESR Spectra of PC Photoproduct. We measured the ESR spectra of PC photoproduct in glassy solvents at 77 K in order to certify the assignment to a biradical (two benzyl radicals linked with an ethylene bridge) and to elucidate its structure.

In MTHF, 2-MP, and the harder mixed solvents of 2-MP and IP (4:1, 3:2, and 1:1), two signals are observed in the $g \approx 4$ region. One is the signal of PC in the lowest triplet state, and this signal decreases its intensity with the increasing irradiation time (PC decreases by reaction) and decays slowly with the cut-off of exciting light. Its lifetime is the same as the phosphorescence lifetime. The other signal observed in the $g \approx 4$ region increases its intensity with the increasing irradiation time and does not decay with the cut-off of exciting light. The signal can be regarded as due to the $\Delta m=2$ transition of the radical pair in triplet. There are two possibilities for the radical pair. One is that of two benzyl radicals produced from PC, and the other is that of the benzyl radical with a solvent radical which is created by reaction of the radical with solvent. By the following considerations about the reactivity of the radical with solvlent, we confirm that the $\Delta m=2$ signal is due to the radical pair, ·CH_2–C$_6$H$_4$–CH_2–CH_2–C$_6$H$_4$–CH_2·, produced by photolysis of PC, and not owing to the interaction between the benzyl radical and the solvent radical.

The absorption spectrum in each solvent does not change compared with that of the *p*-methylbenzyl radical although small shifts are observed. Consequently, the production of the radical added to the solvent is unconceivable. A possible process of reaction with solvent is the abstraction of hydrogen atom. However, it is known that the benzyl radical produced from toluene does not abstract hydrogen atom from hydrocarbon, and not even from EPA.[8] The low reactivity of benzyl radical is due to the fact that benzyl radical is π-radical and the unpaired electron density at $-CH_2$ is decreased by resonance effect. (According to Hückel MO theory, unpaired electron densities are calculated to be 4/7 on the $-CH_2$ carbon and 1/7 on each of *o*- and *p*-carbons of the benzene ring.)

From the species where unpaired electron densities exist at each *p*-position of two benzyl radicals, the remaining C–C bridge can dissociate and two molecules of quinodimethane can be produced.

CH_2=C$_6$H$_4$·–CH_2–CH_2–C$_6$H$_4$·=CH_2 ⟶

CH_2=C$_6$H$_4$=CH_2 + CH_2=C$_6$H$_4$=CH_2

Kaupp reported that quinodimethane was produced by photolysis of PC in MTHF at 85 K.[9] The reported absorption spectrum of quinodimethane has many peaks below 300 nm[9] but the production of such species could not be detected in our experiment (photolysis at 77 K).

Therefore, the photoproduct of PC is expected to remain as the biradical at 77 K without the abstraction of hydrogen atom from the solvent used here nor the degradation to smaller fragments. It is considered that the biradical with an interaction between the two benzyl radicals was observed as a radical pair in the ESR spectrum. However, there is no strong interaction between the two benzyl radicals in the ground state, because the spectral shape of the absorption spectrum is the same as that of the *p*-methylbenzyl radical produced from *p*-xylene and the spectral shift is fairly small.

In contrast with the case in the $g \approx 4$ region of the ESR spectrum, a signal increases its intensity in the $g \approx 2$ region with the increasing irradiation in all solvents used. The spectra in various solvents are broad and the detailed analysis is difficult, but the following trends can be pointed out.

1. In MTHF, an intense and broad signal in which the splitting of fine structure is about 150 G (1 G=10^{-4} T) is observed together with weak but sharply structured signals. The structured signals are considered to be due to MTHF radical. The origin of the broad signal can be assigned to the radical pair in triplet because of its spectral shape.
2. In 2-MP, only a broad signal the origin of which

can be assigned to the radical pair is observed.
3. The spectral shapes in the 4:1 and the 3:2 mixed solvents of 2-MP and IP are similar to that in 2-MP. In the softer mixed solvent (1:1), a sharp signal overlaps the broad signal. In the 3:7 mixed solvent and in IP, the sharp signal has the rather complicated structure, but it may be partly due to the benzyl radical without the interaction with the other radical linked together. These results observed in the $g \approx 2$ region also support the scheme that a biradical produced by photolysis of PC is forming a benzyl radical pair.

The Structure of the Biradical as Revealed from ESR Spectra. The homolytic cleavage of one of the C–C bridges of PC at the benzyl radical pair formation increases freedom in the motions of the benzyl radicals. Consequently, in soft matrices, the biradical is expected to take an open structure in which the two benzene rings are not parallel but separate from each other. In the hard glassy solvents, however, the molecular motion of the rings is restricted and the biradical takes a structure in which a weak interaction between the two benzyl radicals is effective. From this view, we can expect that the zero-field splitting parameter, D^*, decreases with the increasing softness and the $g \approx 4$ signal disappears in some soft solvents. This expectation is fulfilled by the present observation. The $g \approx 4$ signal is observed in MTHF, 2-MP, and in harder mixed solvents of 2-MP and IP (4:1, 3:2, and 1:1), but cannot in the soft mixed solvent (3:7) and in IP. Furthermore, the D^* value has a tendency to be larger in harder solvents, as is seen in Table 1 in which the D^* values estimated from the positions of the $g \approx 4$ signals are tabulated.

TABLE 1. D^* AND CALCULATED r VALUES OF PC PHOTOPRODUCT

Solvent	D^*/cm^{-1} a)	r/Å b)
MTHF	0.015	5.6
2-MP	0.014	5.7
4 : 1 c)	0.012	6.0
3 : 2 c)	0.013	5.8
1 : 1 c)	0.010	6.4

a) The error is estimated as ± 0.001 cm^{-1}. b) ± 0.2 Å.
c) Mixed solvent of 2-MP and IP.

In a model in which two localized radicals are separated from one another in the distance of r, D^* and r are related by the following equation:

$$D^* = 3/2(g^2\beta^2/r^3).$$

On an assumption of g=2.0023, we calculated r from observed D^* with the aid of the equation. The result is shown in Table 1. With the use of the Hückel MO theory, the center of unpaired electron distribution is calculated to locate on the C–C bond connecting $-CH_2$ and the benzene ring (see Fig. 2). r is considered to correspond approximately to the distance between the centers of unpaired electron distribution in the two benzyl radicals. As the result of cleavage of one of the C–C bridges the two benzene rings of PC gain motional freedom, facing obliquely and rotating about the remaining C–C bridge. In the non-twisted

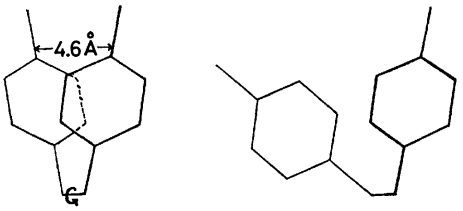

Fig. 2. Structure of the PC photoproduct in glassy solvents.
(a): Non-twisted, (b): twisted.

structure ((a) in Fig. 2), r is estimated to be about 4.6 Å. From the observed r, the two benzene rings are considered to take the twisted structure ((b) in Fig. 2). In harder solvents, the r value is smaller and this suggests that the twist angle is smaller compared with the case in softer solvents. In the 3:7 mixed solvent and in IP, the two benzyl radicals must be separated largely, so that the signal cannot be observed because of the scarce interaction.

Hope *et al.* mentioned that the better fittings of crystal structure analysis was attained for PC by assuming a small twist of two benzene rings.[10] Andrews and Westrum suggested that from an anomaly in the heat capacity (C_p) near 50 K, the twisting motion became an active vibrational mode over 50 K.[11] These facts indicate that the two benzene rings may twist after cleavage of a C–C bridge.

Emission Spectra of PC Photoproduct. The benzyl radical produced from toluene or its methyl derivatives exhibits green emission and its spectrum is sharply structured. Kaupp *et al.* mentioned that the emission of PC photoproduct was similar to that of the *p*-methylbenzyl radical, and that the excimer-like emission was not observed.[6] However, in the present experiment new excimer emission of the benzyl radical pair produced from PC was observed in some solvents.

The emission spectra of PC photoproduct in MTHF, 2-MP, IP, and in mixed solvents of 2-MP and IP are shown in Fig. 3. The emission spectrum in IP is similar in the vibrational structure to that of the benzyl radical monomer produced from toluene. The excitation spectrum of the emission is the same as the absorption spectrum of benzyl radical, and this emission is caused by the excitation of either of the two benzyl radicals produced from one PC molecule.

In solvents harder than IP, a broad emission overlaps a monomer-like emission. Especially in 2-MP and MTHF, a clear peak appears in the longer wavelength region. Because of the appearance of the new band, the emission in 2-MP and in MTHF becomes yellow rather than green. The excitation spectrum measured by monitoring the sharp band is the same as the absorption spectrum, and that measured by monitoring only the broad band component (>600 nm) also exhibits the peaks around 320 nm and 450 nm, and is the same as the absorption spectrum. Therefore, the origin of the broad band is also the benzyl radical, and not the reaction product of PC with solvent. The new broad emission is considered to be caused by the interaction in the excited state between two benzyl radicals linked with the ethylene bridge.

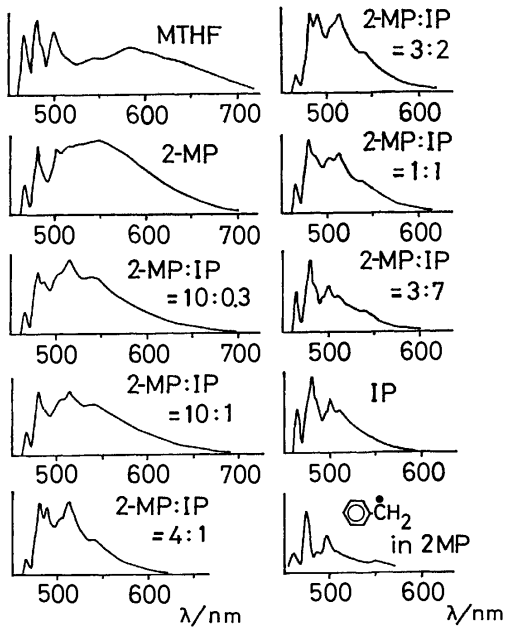

Fig. 3. Emission spectra of the benzyl radical in 2-MP and of the PC photoproduct in MTHF, 2-MP, IP, and mixed solvents of 2-MP and IP (10:0.3, 10:1, 4:1, 3:2, 1:1, and 3:7).

Both the sharp band and the broad band show single exponential decay and their decay constants are equal to each other. Furthermore they are independent of excitation wavelengths. The rise time of the broad emission is too short to be observed within the exciting pulse duration, 4 ns. These kinetic results are consistent with the case of ordinary intramolecular excimer in solution where there exists rapid equilibrium between the excited monomer state and the excimer state. Therefore, it is reasonable to consider that the broad emission observed in 2-MP and MTHF is the intramolecular excimer fluorescence of the benzyl radical pair.

The peak of the excimer band is 580 nm in MTHF and 550 nm in 2-MP. In softer solvents, the excimer band moves toward the monomer band, although the peak wavelength of excimer band cannot be determined unambiguously. This may indicate that the stabilization energy of excimer is larger in harder solvents.

The emission lifetimes of PC photoproduct in several solvents are shown in Table 2 in the decreasing order of solvent viscosity. The emission lifetime in IP is about 1.1 μs, and the emission lifetime of the benzyl radical produced from toluene is reported to be 1.28 μs in EPA.[7d] In IP, the emitting species is the benzyl radical without the interaction with the other radical, and the lifetime in IP may become similar to that of monomer. The emission lifetimes in solvents harder than IP are shorter (see Table 2). A possible reason for this is that the recombination of the two benzyl radicals is enhanced in harder solvents. In harder solvents, the two radicals are located in the closer position (from the ESR study). The probability of the recombination process from the excited states of radical (monomer or excimer) may be larger in harder solvents, and the emission lifetime of radical may be more shortened.

Table 2. Emission lifetime of PC photoproduct

Solvent	Lifetime/ns[a]
MTHF	55
2-MP	350
3 : 7[b]	560
IP	1100

a) The values cited are typical ones of several experiments. They are not always reproducible, depending on the condition of radical formation, *e.g.* irradiation time. b) Mixed solvent of 2-MP and IP.

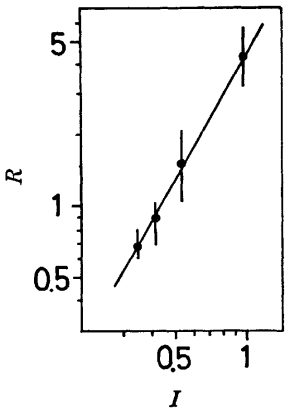

Fig. 4. Dependence of reaction rate, *R*, upon the intensity of exciting light, *I*.

Light Intensity Dependence of Reaction Rate. The absorbance at 322 nm of the PC photoproduct (biradical) increases at the initial stage linearly with irradiation time, and the initial reaction rate for the formation of the biradical can be determined. Figure 4 shows the dependence of this reaction rate, *R*, upon the exciting light intensity, *I*. The log-log plot of *R vs. I* shows a straight line, the slope of which is 1.8. This suggests the biphotonic mechanism for the formation of the biradical from PC. Therefore the photolysis of PC does not occur directly from the lowest excited state, S_1 or T_1, because of the energy deficiency. In the rigid media at low temperature, T_1 has a long lifetime (a few seconds). The higher triplet states which are populated by photon absorption of T_1 have sufficient energy for the photolysis of PC.

According to our previous paper on the $T_n \leftarrow T_1$ absorption spectrum of PC,[1b] we have a very weak band around 550 nm ($T_3 \leftarrow T_1$), an intense band around 380 nm ($T_4 \leftarrow T_1$), and a weak band around 340 nm ($T_5 \leftarrow T_1$). The 313 nm excitation corresponds to the $T_5 \leftarrow T_1$ transition the parentage of which is the local excitation corresponding to the $^3E_{2g}^- \leftarrow {}^3B_{1u}^+$ transition of the benzene ring. Therefore the locally excited T_5 state is considered to be the reactive state. Helgeson and Cram reported the wavelength-dependent photochemistry of PC in alcoholic solutions.[2] From the analysis of photoproducts at various exciting wavelengths, they proposed that the biradical composed of two benzyl radicals was produced only by the exciting light the wavelength of which is shorter than 230 nm, and that the zwitter ion (benzyl cation and

anion) is produced by the excitation with 253.7 nm light. Their suggestion that the biradical is produced from higher excited states with sufficient energy is consistent with our conclusion.

The authors should like to express their sincere thanks to Dr. Hisaharu Hayashi, the Institute of Physical and Chemical Research, for his kind advice in measuring ESR spectra.

(Received March 19, 1980)

CNDO/2 calculations of pentaammine complexes, $[M(NH_3)_5X]$ (both low and high spin states), where M= Co^{2+}, Co^{3+}, Fe^{2+}, and Fe^{3+}, and X=FH, OH_2, CO, NH_3, pyridine, OH^-, F^-, and CN^-, have been carried out in order to investigate the mutual influence between ligands. The present calculation shows that the σ-type mutual influence is remarkably affected by the oxidation number and the spin state of the metal ion and scarecely affected by the number of d electron (d electron configuration). Furthermore, the calculated results show the metal-ligand bond distance of a complex in the low spin state should be shorter than that in the high spin state.

Many experimental evidences of the trans influences in the transition metal complexes have been found in the field of inorganic chemistry from long time ago. Most of them were found at Pt complexes.[1] Recently, some experimental works have been done about the trans influence in the first transition metal complexes.[2] Shustorovich *et al.* carried out quantum chemical calculations in order to solve this problem.[3] They applied the perturbation theory based on the simple MO method to several types of complexes.

In this paper, we have investigated the trans influences in the various pentaammine complexes, $[M(NH_3)_5X]$ (both low and high spin states) where M=Co^{2+}, Co^{3+}, Fe^{2+}, and Fe^{3+}, and X=FH, OH_2, CO, NH_3, pyridine(py), OH^-, F^-, and CN^-, using CNDO/2 method. We have studied how the trans influence is affected by the oxidation number and the spin state of the metal ion and the kinds of metals and ligands.

Calculations

In the previous paper,[4] we proposed new bonding parameters associated with 4s and 4p AO's of the first transition metals in the CNDO/2 method, which give satisfactory results for the binding energies of coordination bonds of various hexaammine and hexaaqua complexes. In the present study, we have carried out CNDO/2 calculations (unrestricted SCF scheme) of pentaammine complexes (see Fig. 1) using these new parameters.

We take five neutral ligands, FH, OH_2, CO, NH_3, and py, and three ionic ones, OH^-, F^-, and CN^- into consideration. In coordination chemistry, the spin state of the transition metal complex has an important role in its physico chemical properties. Therefore, we have also calculated the electronic structure of the complexes in the low and high spin states.

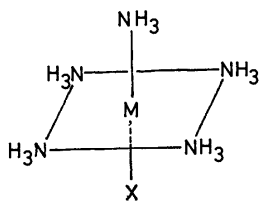

Fig. 1. Pentaammine complexes, where M=Co^{2+}, Co^{3+}, Fe^{2+}, and Fe^{3+}, X=FH, OH_2, CO, NH_3, py, OH^-, F^-, and CN^-.

We used the experimental data for Co–N distances, 2.11 Å(Co^{2+}–N)[5] and 1.97 Å(Co^{3+}–N),[6] and estimated ones for Fe–N distances, 2.15 Å(Fe^{2+}–N)[4] and 2.00 Å (Fe^{3+}–N). We have employed the experimental geometry[7] of the free molecule for that of the ligand. For the simplicity, we have put the distance of M–X bond same as that of M–N bond, that is ,we assumed a regular octahedral geometry for each complex.

Results and Discussion

The mutual influence between the trans ligands is not affected only by the characteristics of the ligand such as the ionization potential, electron affinity *etc.*, but also by the electronic structure of the central metal ion such as the oxidation number, the spin state and the number of d electrons. The mutual influence should be appeared in the charge densities of the central metal ion and the ligands and the bond orders between the metal and the ligands. The charge distribution in the complex reflects sharply the characteristics of the ligand and the central metal ion. However, it is difficult to measure experimentally the change of the charge density on the atom caused by trans influence. Many experimental evidences[2] of the mutual influence have been found by the measurement of bond distances between the metal and the ligands. However, the charge density on the atom is important for the discussion of the reactivity of the complex. Therefore, we will discuss the mutual influence from the standpoint of both the charge density and the bond order.

The most important factors affecting on the mutual

influence are the ionization potential and the electron affinity of the ligand, so that, in Table 1 the highest occupied and the lowest unoccupied orbital energies of isolated ligands calculated by the CNDO/2 method are given as a reference.

Charge Density. From the chemical intuition, we expect the 4s, $4p_z$, $3d_{z^2}$, $3d_{xz}$, and $3d_{yz}$ orbitals of metal ion make the most important contribution to the trans influence. Our results show that only the variations of the charge densities associated with these orbitals are considerably large and others are negligible when ligand X is varied. Figures 2(a)—(d) show the plots of the charge densities associated with 4s, $4p_z$, and $3d_{z^2}$ orbitals of cobalt (Co^{2+} and Co^{3+}) against the highest occupied orbital energy of the ligand X, $\varepsilon^{X}_{HOMO}(\sigma)$.

From these figures, it is found that the charge density associated with $4p_z$ orbital is varied largely at the bivalent metals, while the charge density associated with $3d_{z^2}$ orbital is changed remarkably at the tervalent metals. The reason for this may be due to the following facts. In the bivalent metal, two 4s electrons are removed, so that the electrons come back to 4s and 4p orbitals by the formation of com-

plex. Because the coordination bond is largely polarized, the contribution of $4p_z$ orbital to this bond should be large. This might be the reason why the variation of population of $4p_z$ with respect to the change of the ligand is large. In the tervalent metal, the third electron is removed from 3d orbital. Therefore, by the formation of the complex, an electron comes back at first to 3d orbital. $3d_{z^2}$ orbital contributes largely to the coordination bond, X–M–N, formed by the trans ligands and the metal, but other d orbitals contribute slightly. Consequently, the variation of the population in $3d_{z^2}$ orbital is largely varied by the trans influence.

In tervalent metal complexes, when we plot the charge density associated with $3d_{z^2}$ orbital against $\varepsilon^{X}_{HOMO}(\sigma)$, we obtain two lines. One of them contains py, CO, and CN^-, and another line contains FH, OH_2, NH_3, OH^-, and F^-. The ligands belonging to the former have unoccupied π-orbitals, however, those belonging to the latter no unoccupied π-orbitals. These π-orbitals will affect $3d_{z^2}$ orbital indirectly through the interaction with $3d\pi$ orbital.

The tendency of the charge density variation of the iron (Fe^{2+} or Fe^{3+}) complex (Figs. 3(a)—(d)) is

Marks: see Fig. 2.

similar to that of the corresponding cobalt complex.

Comparing the calculated charge densities of Co complex with those of the corresponding Fe complex (*cf.* Figs. 2(a)—(d) and Figs. 3(a)—(d)), we conclude that the charge population at the central metal ion is determined mainly by the oxidation and spin states of the complex.

Bond Order. The total bond order associated with the metal-ligand bond is consisted of the contributions of various orbital pairs. In Table 2, all possible orbital pairs are given. Similar to the results of charge density as mentioned above, the contributions of the particular pairs of orbitals to the trans influence are important, while those associated with other orbital pairs are negligibly small.

First of all, let us investigate about σ-type interac-

tion between the metal and the ligand. In this case, the ligand acts as an electron donor, so that $\varepsilon^{X}_{HOMO}(\sigma)$ plays a key role. Figures 4(a)—7(d) show the plots of the bond orders associated with all possible orbital pairs against $\varepsilon^{X}_{HOMO}(\sigma)$. It is interesting to note that the gross feature of the figure of Co^{n+} at the high spin state or Co^{n+} at the low spin state is very similar to that of the corresponding Fe complex (see *cf.* Figs. 4(a) and 6(a)). Consequently, we can say that in Fe and Co complexes the nature of the coordination bond is determined mainly by the oxidation number and the spin state (low or high), but is not by the number of d electrons of the metal. It is well known that Fe, Co, and Ni form similar complexes, so that they are called a triad. Actually, our calculation shows the electronic states of Fe and Co complexes resemble each other.

In the bivalent metal complexes, the bond orders pertaining to $4p_z$ orbital are prominently varied by the trans ligand X. Figures 4(a)—(d) show that the bond orders associated with $4p_z$-$2p_z$ and $4p_z$-2s pairs are decreased with the increase of $\varepsilon^{X}_{HOMO}(\sigma)$.

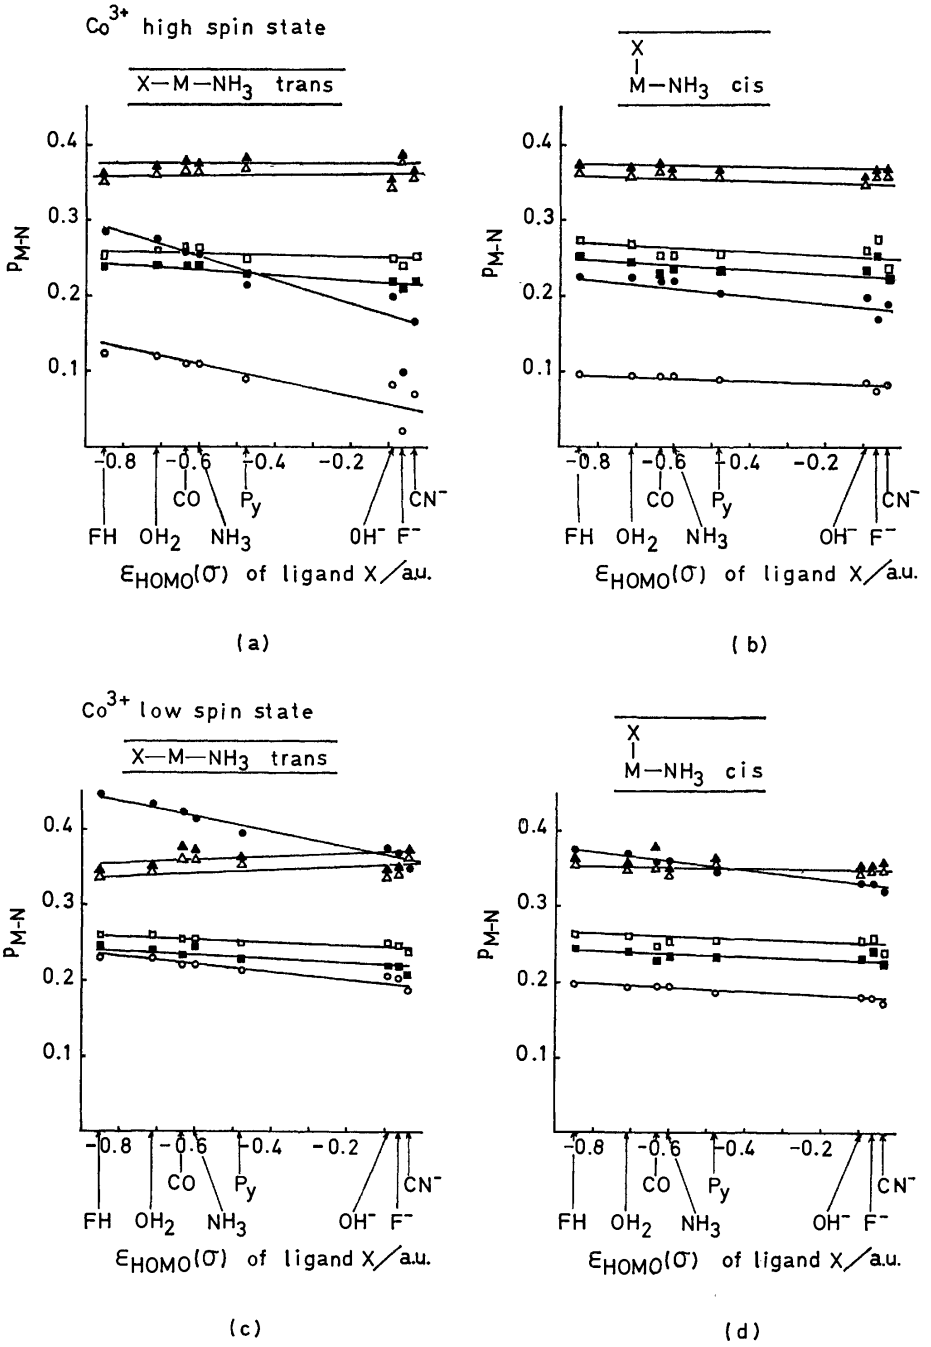

Fig. 5. The bond orders associated with various orbital pairs of M–N bond in tervalent cobalt complex.

Marks: see Fig. 4.

This result can be understood from the standpoint of the simple MO theory. Let us consider the coordination bond X–M–N. The orbital energy, α_M, associated with metal's AO increases when $\varepsilon^X_{HOMO}(\sigma)$ is increased. Second order perturbation theory calculates this increase, $\Delta\alpha_M$, by the following equation,

$$\Delta\alpha_M = \frac{\beta_{MX}^2}{\alpha_M^0 - \varepsilon^X_{HOMO}(\sigma)}$$

where α_M^0 is the orbital energy of metal's AO in the hexaammine complex. The increase of $\Delta\alpha_M$ causes the decrease of bond order, Δp_{MN}, associated with M–N bond in the following manner,

$$\Delta p_{MN} \simeq -p_{MN}^0 \frac{\Delta\alpha_M(\alpha_M^0 - \alpha_N^0)}{4\beta_{MN}^2} = k\Delta\alpha_M,$$

where $k = -\frac{p_{MN}^0(\alpha_M^0 - \alpha_N^0)}{4\beta_{MN}^2}$ (<0) and α_N^0 is the orbital energy of the lone pair of ligand NH_3. p_{MN}^0 means the bond order of M–N bond in the hexaammine complex. On the other hand, the change of the bond order, Δp_{MX}, associated with M–X bond can be written by

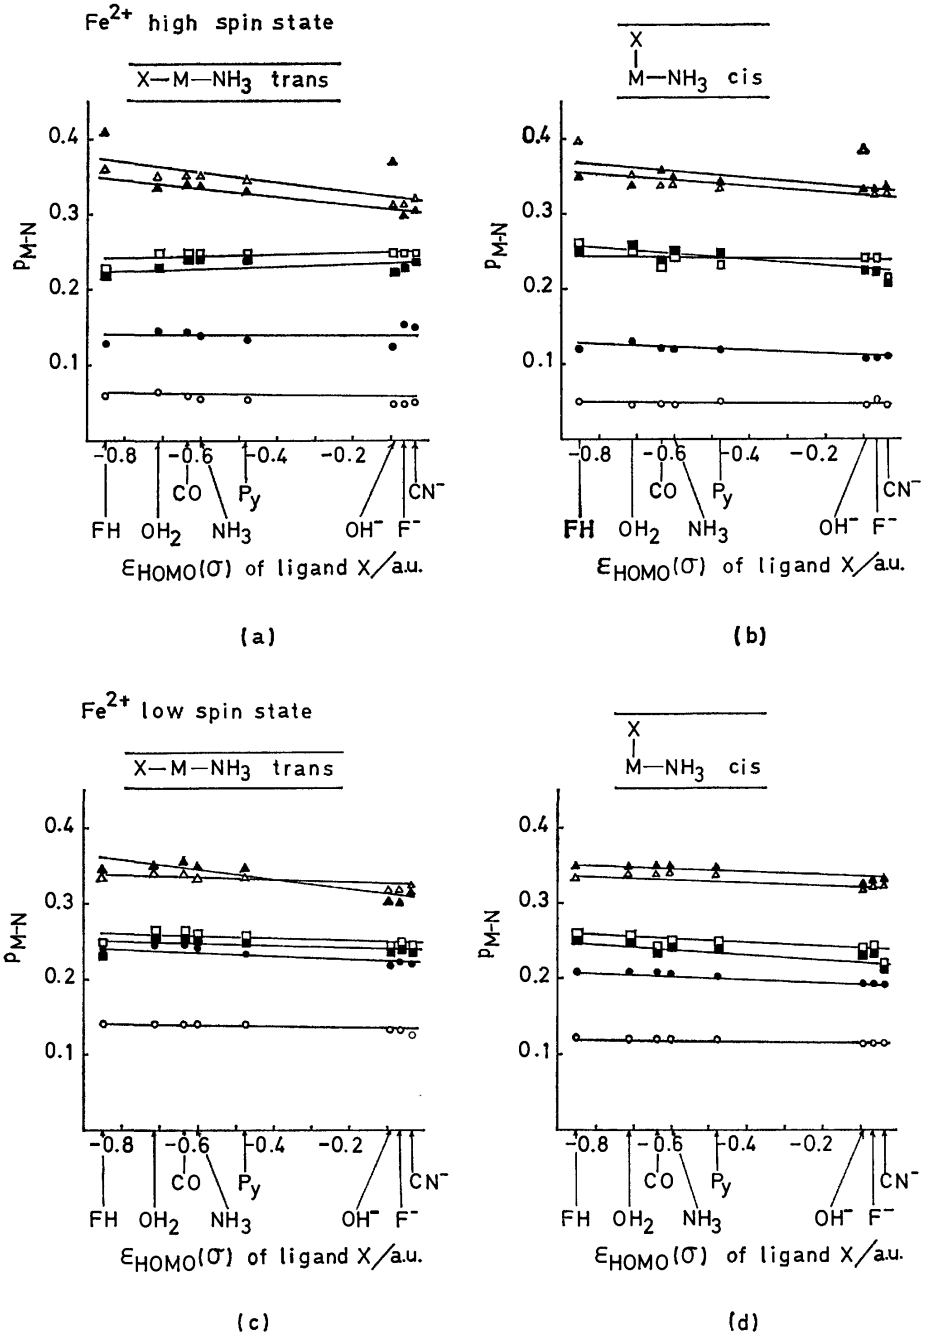

Fig. 6. The bond orders associated with various orbital pairs of M–N bond in bivalent iron complex.
(a): Fe^{2+}–*trans*N (high spin), (b): Fe^{2+}–*cis*N (high spin), (c): Fe^{2+}–*trans*N (low spin), (d): Fe^{2+}–*cis*N (low spin).
Marks: see Fig. 4.

$$\Delta p_{MX} \simeq p_{MN}{}^{0}\frac{\Delta\alpha_X(\alpha_M{}^{0}-\varepsilon^{X}_{HOMO}(\sigma))}{4\beta_{MX}{}^{2}}$$

because of $\Delta\alpha_X=\Delta\varepsilon^{X}_{HOMO}(\sigma)=\varepsilon^{X}_{HOMO}(\sigma)-\alpha_N{}^{0}=-\Delta\alpha_M$. Therefore, the bond order associated with M–N bond is decreased, when that associated with M–X bond is increased. In other words, when M–X bond is strengthened, the M–N bond is weakened.

It should be noted that the bond order associated with $3d_{z^2}$-$2p_z$ and $3d_{z^2}$-2s pairs are almost constant against the variation of $\varepsilon^{X}_{HOMO}(\sigma)$. This result is consistent with the charge variation of the bivalent metal ion. That is, in the bivalent metal complex, $4p_z$ orbital plays more important role than $3d_{z^2}$ orbital.

It is of interest to consider the effect of the spin state on the trans influence. M–*trans*N bond is greatly affected by the spin state of the metal (see Figs. 6(a) and (c)). Namely, the bond order associated with M–*trans*N bond in the low spin state is much larger than that in the high spin state. In other words, the bond distance of M–*trans*N bond in the low spin state is shorter than that in the high spin state. This

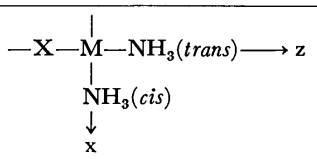
Table 2. The various orbital pairs contributing to M-N bond

σ-Type interaction	
M-*trans*N	M-*cis*N
$4s-2s$	$4s-2s$
$4s-2p_z$	$4s-2p_x$
$4p_z-2s$	$4p_x-2s$
$4p_z-2p_z$	$4p_x-2p_x$
$3p_{z^2}-2s$	$3d_{x^2-y^2}-2s$
$3d_{z^2}-2p_z$	$3d_{x^2-y^2}-2p_x$



is in accord with the experiment.[8] In M–*cis*N bond, the effect of the ligand X is very small (see Figs. 4(b) and (d)).

In the M–*trans*N bond, the variation of the bond order associated with $4p_z$-2s or $4p_z$-$2p_z$ is large, but that associated with 4s-2s or 4s-$2p_z$ is rather small. Whereas, in the M–*cis*N bond, that associated with 4s-2s or 4s-$2p_x$ is considerably large (see Figs. 4(a) and (b)). From these results, we might conclude that when a p-character of M–*trans* ligand bond increases, that of M–*cis* ligand bond decreases, so that the s-character of M–*cis* ligand bond should increase and *vice versa*. In other word, when the bond distance of M–*trans* ligand bond increases, that of M–*cis* ligand bond becomes to decrease, if the contribution of $3d_{z^2}$ orbital is unchanged. This rule can be applied to the bivalent metal complexes, because the contribution of $3d_{z^2}$ orbital is very small. However, in the tervalent metal complexes, the contribution of $3d_{z^2}$ orbital is rather large, so that this rule may not be applied.

In the tervalent metal complexes, the contribution of each orbital pair to M–*trans*N bond is much complicated (see Figs. 5(a)—(d)). The bond order associated with M–*cis*N bond is also varied considerably by the change of the spin state (see Figs. 5(b) and (d)). An interesting result is that the bond order associated with $3d_{z^2}$-$2p_z$ is increased with the decrease of $\varepsilon^{x}_{\mathrm{HOMO}}(\sigma)$, while, that associated with $4p_z$-$2p_z$ is decreased. The bond order associated with M–*trans*N bond in the low spin state is larger than that in the high spin state. It is interesting to note that the contribution of $4p_z$-$2p_z$ pair to M–*trans*N bond in the low or the high spin state is almost same, but the contribution of $3d_{z^2}$-$2p_z$ or $3d_{z^2}$-2s in the low spin state is almost double of that in the high spin state. Therefore, we expect that the bond distance of M–*trans*N bond in the low spin state is shorter than that in the high spin state, and also that of M–*cis*N bond in the low spin state is shorter than that in the high spin state.

Let us consider, next, π-type influence in a complex. The ligands FH, OH_2, NH_3, OH^-, and F^- have no unoccupied π-orbitals. On the other hand, CO, py and CN^- have unoccupied π-orbitals which can accept charge from the central metal ion. Therefore, we will find some differences between the bond order p_{MX} associated with the former ligand and that associated with the latter ligand. However, the change of p_{MN} against $\varepsilon^{x}_{\mathrm{HOMO}}(\pi)$ of the ligand X is very small, because NH_3 has no available π-orbital. Thus, the ligand X having unoccupied π-orbitals has an effect on the charge density variation of the central metal ion, but no effect on the bond order of M–N bond.

The authers would like to express their gratitude to the Data Processing Center of Kyoto University for the use of the FACOM M190 computer.

Resonance Raman Spectra of Intermolecular Vibrations of Würster's Cation Dimers

Kenji YOKOYAMA,* Yoshitaka TAJIMA, Masao TAHARA, and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuda, Midori-ku, Yokohama 227

(Received March 24, 1980)

The resonance Raman spectra of some Würster's cation dimers were measured in alcohol solution at 201 K and in glassy matrix at 77 K. The spectra of the dimer of *p*-phenylenediamine cation showed the resonance enhancement of the Raman line assigned to the intermolecular stretching vibration and supported the D_{2h} symmetry for the dimer. However, for the dimer of 2,3,5,6-tetramethyl-*p*-phenylenediamine cation and *N,N*-dimethyl-*p*-phenylenediamine cation, it was supposed that D_{2h} symmetry was broken down in alcohol solution and in glassy matrix, because the dimers had two Raman lines in the region of the intermolecular vibration.

Resonance Raman effect is a well known phenomenon where the Raman lines related to an electronic transition show enhancement of their intensities when wavelength of an exciting line approaches to the corresponding absorption band. Recently, the authors found the resonance enhancement of the Raman lines assigned to the intermolecular stretching vibrations for the dimers of some aromatic ion radicals, *p*-phenylenediamine cation (PD^+), 2,3,5,6-tetramethyl-*p*-phenylenediamine cation ($TMPD^+$),[1] *p*-benzosemiquinone anion[2] and tetracyanoethylene anion ($TCNE^-$),[3] by the excitation at the long wavelength absorption bands characteristic of the dimer formation. These results not only indicated the strength of the intermolecular bondings directly, but brought fine informations about the behavior of dimerization, with the detailed feature of their spectra taken into account. In the present study, the resonance Raman effect of Würster's cation dimers was further reinvestigated to study the mechanism of dimerization and the relation between the nature of the intermolecular bondings and the values of force constant for the corresponding bondings of the dimers.

Experimental

PD^+ and $TMPD^+$ were prepared with Br_2, as previously reported.[1] *N,N*-Dimethyl-*p*-phenylenediamine bromide ($DMPD^+Br^-$) was prepared by the method of Michaelis and Granick.[4] *N,N,N',N'*-Tetradeuterated PD (PD-d_4) and *N,N,N',N'*-tetradeuterated TMPD (TMPD-d_4) were prepared by repeating of dissolution and crystallization in CH_3OD. Methanol and ethanol were used as solvents for measurement at 201 K. A mixed solvent, EPA (ethanol: isopentane: diethyl ether = 10:1:1), was used for measurement at 77 K. The conditions of spectroscopic measurement were almost equal to the previous report,[1] except that the satellite lines of the exciting source were eliminated by using a prism system.

Results and Discussion

Figure 1 a) shows the resonance Raman spectrum of the dimer of PD^+Br^- in ethanol solution at 201 K by the excitation at the absorption band characteristic of the dimer at 605 nm.[1] A broad line at 161 cm^{-1} showed a striking resonance enhancement together with its progression, and a weak line appeared at 523 cm^{-1} in resonance condition. These Raman lines were all polarized, and the depolarization ratio of the line at 161 cm^{-1} was 0.31. Therefore, they were assigned to totally symmetric vibrations.

Kimura *et al.* studied the electronic structure of the dimer of PD^+ by using LCMO method, assuming a parallel structure of D_{2h} symmetry, as shown in Fig. 2[5] and showed that the absorption band at 605 nm characteristic of the dimer was assigned to a transition from ϕ_+ to ϕ_-, which had a transition dipole along the out-of-plane axis, z. A significant difference between ϕ_+ and ϕ_- is that ϕ_+ has a bonding character whereas ϕ_- has an antibonding character on the intermolecular bonding. Therefore, according to the Franck-Condon mechanism of Raman intensity, the resonance enhancement of the Raman line assigned

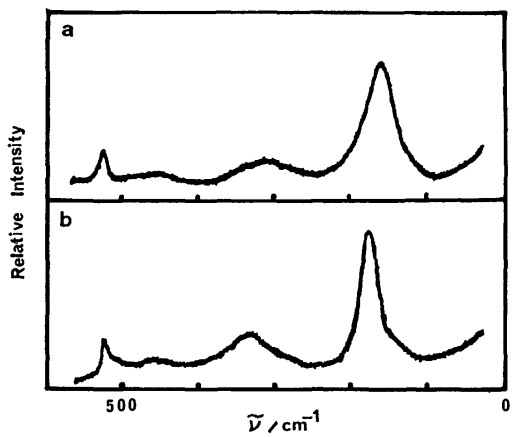

Fig. 1. Resonance Raman spectra of PD^+Br^- by the excitation with 605 nm line.
a) In ethanol solution at 201 K, b) in EPA glassy matrix at 77 K.

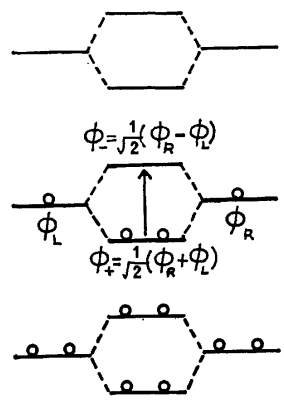

Fig. 2. MO scheme of the dimer of ion radical.

to the intermolecular stretching vibration is expected to take place by the excitation at this absorption band.

Consequently, the 161 cm^{-1} line was assigned to the intermolecular stretching vibration, as previously reported.[1] The broad line shape indicates the nature of the intermolecular vibration and the value of depolarization ratio shows the contribution of α_{zz} component to the resonance enhancement.

On the other hand, an out-of-plane NH_2 bending vibration may appear in the region about 200 cm^{-1},[6] while this mode probably increases in frequency when PD is converted to PD^+ because the conjugation between benzene ring and NH_2 is increased.[7,8] If the line is the out-of-plane NH_2 vibration, it must decrease in frequency about 6 cm^{-1} according to the deuteration. However, in the present study, the resonance Raman spectrum of the dimer of PD-d_4^+ did not show any considerable change in frequency, compared with that of the dimer of PD-h_4^+. Therefore, it was confirmed that the line observed at 161 cm^{-1} is not assigned to the out-of-plane NH_2 bending vibration.

Figure 3 a) shows the resonance Raman spectrum of the dimer of $TMPD^+Br^-$ in methanol solution at 201 K by the excitation at 605 nm. In the previous report,[1] the shoulder at 145 cm^{-1} was regarded as due to a satellite line of the exciting source. However, this shoulder did not disappear even if the satellite line was eliminated. Therefore, we have revised the assignment of this shoulder as a Raman line of the dimer of $TMPD^+$, and confirmed that the dimer of $TMPD^+$ has two lines in the region of the intermolecular vibration. Both lines at 117 and 145 cm^{-1} showed no change in spectral feature when $TMPD^+$ was converted to TMPD-d_4^+. The depolarization ratio of the band consisting of the two lines was 0.23, which is smaller than that of the dimer of PD^+, slightly.

Figure 3 b) shows the resonance Raman spectrum of the dimer of $TMPD^+Br^-$ in EPA glassy matrix at 77 K. Two lines in the region of low frequency region appeared more clearly and became to be more distiguishable from each other. Table 1 shows the observed frequencies of the Raman lines for the dimer

of $TMPD^+$ at 77 K, together with those at 201 K. Both lines at 117 and 145 cm^{-1} at 201 K shifted to 128 and 156 cm^{-1} in glassy matrix, respectively. These deviations are larger than those for the lines at 250 and 655 cm^{-1}. These results mean that both lines at 117 and 145 cm^{-1} are more sensitive to the surrounding condition than the other lines, which shows that these lines relate to the intermolecular bonding closely.

As shown in the previous study,[3] the resonance Raman spectra of the dimer of $TCNE^-$ showed the resonance enhancement of two lines in the frequency region of the intermolecular stretching vibration. The two lines were assigned to the respective intermolecular stretching vibrations of two kinds of the dimers, because the relative intensities of the two lines showed remarkable alternation when the counter cation was changed from Na^+ to Cs^+. However, the two Raman lines for the dimer of $TMPD^+$ did not show any considerable change of their intensities when the counter anion was changed among Br^-, I^-, and ClO_4^-. Therefore the origin of the two lines for the dimer of $TMPD^+$ must be different from that for the dimer of $TCNE^-$.

These results are interpreted reasonably by considering that D_{2h} symmetry is broken down for the dimer of $TMPD^+$. When the D_{2h} symmetry of the dimer is degraded, vibrations belonging to other symmetry species become totally symmetric and the transition from ϕ_+ to ϕ_- becomes to contain in-plane components beside z component. Therefore the both lines at 117 and 145 cm^{-1} were assigned to mixed modes between two intermolecular vibrations. One is surely the intermolecular stretching vibration, and the other is probably the ring tilting vibration. The break down of D_{2h} symmetry for the dimer of $TMPD^+$ is probably attributed to the repulsion between the H atoms of CH_3 substituents of component radicals. The value of depolarization ratio, 0.23, is reasonably interpreted to be owing to the mixing of α_{xx} or α_{yy} to the scattering tensor, derived from the lowering

of symmetry. The alternation of intensity for these lines at 201 K and 77 K (see Fig. 3) shows that the configuration of the dimer of $TMPD^+$ is sensitive to the surrounding condition. Figure 3 b) shows that there are some weak lines at 280, 415, and 445 cm^{-1}. These lines can be assigned to combination lines, $156+128=284$, $156+258=414$, and $156\times2+128=440$ cm^{-1}, respectively. These assignments show a good correspondence with the interpretation that both lines at 128 and 156 cm^{-1} in glassy matrix should be attributed to the same species.

Figure 1 b) shows the resonance Raman spectrum of the dimer of PD^+Br^- in EPA glassy matrix at 77 K. The spectral feature at 77 K was almost the same as that at 201 K, with slight differences that 161 cm^{-1} line was observed to increase in frequency slightly and narrow its band width, and a new weak shoulder appeared at 130 cm^{-1}. These results show that the deviation of configuration from D_{2h} symmetry for the dimer of PD^+ is slight in glassy matrix.

The resonance Raman spectra of $DMPD^+Br^-$ in EPA glassy matrix at 77 K are shown in Fig. 4. The dimer of $DMPD^+$ has the absorption band characteristic of dimerization at 680 nm.[5] As the wavelength of excitation line approached to the absorption band two Raman lines appeared with resonance enhancement, same as for the dimer of $TMPD^+$. This result indicates that the dimer of $DMPD^+$ does not take D_{2h} symmetry in glassy matrix, either. Tanaka and Sakabe reported that in the crystal of $DMPD^+Br^-$, one component cation radical was displaced relatively to the other.[7] The present result is in good agreement with their conclusion.

Table 1 shows the observed values of frequency for the dimers at 77 K, together with those at 201 K.

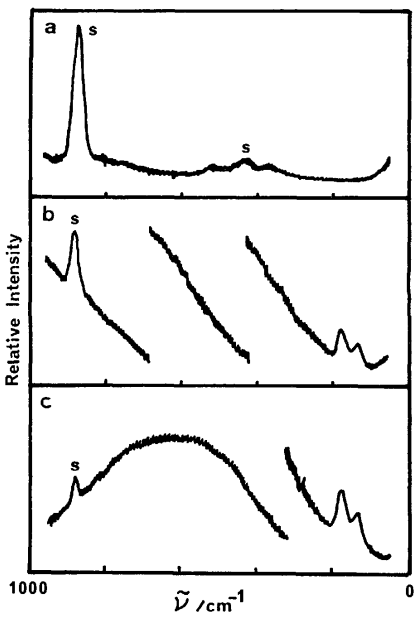

Fig. 4. Resonance Raman spectra of $DMPD^+Br^-$ in EPA glassy matrix at 77 K by the excitation with 514.5 nm a), 584 nm b), and 605 nm c) lines, respectively.
s: Solvent lines.

The Raman lines in the region of low frequency were assigned to the intermolecular vibrations, as discussed above. A 250 cm^{-1} line of the dimer of $TMPD^+$ was assigned to an out-of-plane CH_3 bending vibration because the corresponding line did not appear for the dimer of PD^+. Lines at 523 cm^{-1} for the dimer of PD^+ and 655 cm^{-1} for the dimer of $TMPD^+$ were assigned to respective ring bending vibrations because they were observed for both dimers. The corresponding line for the dimer of $DMPD^+$ was not confirmed because S/N ratio was wrong. These lines at 250, 523, and 655 cm^{-1}, assigned to intramolecular vibrations, probably borrow their intensities from the intermolecular vibrations through the mixing of vibrational modes.

Table 2 shows the force constants of the intermolecular stretching vibrations of three dimers on the basis of diatomic model. The values for the dimer of $TMPD^+$ and $DMPD^+$ were derived from the averaged frequency of the two Raman lines. Nakayama and Suzuki reported that the values of enthalpies of the dimer formation, $-\Delta H$, were nearly equal for PD^+ and $DMPD^+$, 8.0 and 8.2 kcal/mol, respectively.[9] These values show a good correspondence with the values of force constants of the dimers.

Table 2. The values of force constants for the intermolecular stretching vibrations

Species	201 K	77 K
$(PD^+)_2$	0.82 md/Å	0.96 md/Å
$(TMPD^+)_2$	0.83	0.97
$(DMPD^+)_2$		1.12

It is well known that the values of force constant of the stretching vibrations are related to the corresponding bond distances among bondings with similar nature. The values of force constant for the intermolecular bonding of these ion radical dimers are 0.8—1.1 md/Å, as shown in Table 2, and their bond distances are expected to be about 3.1 Å, according to the result of X-ray study on $DMPD^+$ crystal.[7] Yada *et al.* reported that the force constant of intermolecular stretching vibration for a CT complex, trimethylamine–iodine ($TMA-I_2$), was 0.546 md/Å, though the corresponding bond distance was 2.27 Å.[10] The inclination of force constants between these ion radical dimers and $TMA-I_2$ is not parallel to that of their bond distances. Therefore the nature of intermolecular bondings of the ion radical dimers is expected to be different from that of the CT complex. On the other hand, ferrocene is a well known sandwitch type molecule and similar with the ion radical dimers because the π orbitals of aromatic rings form a kind of covalent bond, directly. For ferrocene, the metal-ring distance is 1.66 Å and the force constant of metal-ring stretching vibration is 3.07 md/Å on the basis of linear triatomic molecule model.[11,12] At least, the inclination of their force constants are parallel to that of their bond distances. This result indicates that the intermolecular bonding of the ion radical dimer is owing to the covalency between

two π orbitals rather than CT interaction.

(Received March 24, 1980)

Precipitation and microflotation of egg albumin and of hemoglobin was studied as a function of pH in the presence of dioctadecyldimethylammonium chloride (DOAC). The "DOAC concentration-pH" stability domains for both protein solutions (0.05 wt%) exhibited similar boundaries. Efficient separation by precipitation (more than 80% after 24 h) occurs at pH>5.0 for albumin and at pH>6.3 for hemoglobin. The same amount of removal by microflotation required 5 min under otherwise similar conditions. The DOAC concentration for optimal separation of proteins (from 0.05 wt% solutions) is 0.02 wt% at pH 6—8 for albumin and 0.015 wt% at pH 6.5—8 for hemoglobin. It is noteworthy that both proteins can be precipitated and also foam separated even in strongly alkaline media, such as at pH 12, where the usual flocculents (*e.g.*, aluminum salts) cannot be employed. This work points out the usefulness of infinitely aggregating surfactants as microflotation agents.

Since proteins, such as hemoglobin and albumin, are major components in waste waters of food processing and related industries, their removal and/or recovery is highly desirable. It has been shown that microflotation, which is characterized by the application of small bubbles, could be successfully applied for the separation of inorganic and organic colloidal impurities from their suspensions.[1-4] In this process the materials to be removed must be in flocculated state, which can be accomplished either by the addition of a coagulant or by a change of solution pH. The precipitate is then floated with the help of a surfactant (collector).

Various types of flocculents have been applied to protein solutions, such as lignin[2] and its derivatives,[5] sodium polyacrylate,[6] cationic surfactants (*e.g.*, dodecylpyridinium bromide),[7] anionic surfactants (*e.g.*, sodium alkylbenzenesulfonate or sodium dodecyl sulfate),[7-9] nonionic surfactants,[10,11] and simple inorganic salts.[11,12] Among the listed additives the high molecular weight flocculents (such as lignin) and freshly precipitated metal hydroxides proved to be most suitable for efficient flotation.[2]

The solubility of proteins in water may be reduced by certain reagents which form a less soluble complex with the protein. In this investigation, dioctadecyldimethylammonium chloride, $(C_{18}H_{37})_2N(CH_3)_2Cl$ (DOAC), was used to precipitate and to float egg albumin and hemoglobin. Owing to two long alkyl chains in the DOAC molecules, its solution behavior is quite different from that of ordinary cationic surfactants.[13] Instead of forming micelles these long chain molecules infinitely aggregate yielding multilayer structures in aqueous media over a broad pH range. This property of DOAC makes it a useful precipitant for proteins and it also enhances their floatability by microbubbles.

Experimental

Materials. Egg albumin and hemoglobin were obtained from Tokyo Kasei Kogyo Ltd. and were used without further purification. Dioctadecyldimethylammonium chloride (DOAC), the purity of which with respect to the alkyl chain length was 98.6%, was kindly supplied by Kao Soap Co. Since the proteins used had a certain amount of impurities as shown below, DOAC was also used without further purification. To prepare the stock solutions, the precalculated amount of the protein (either albumin or hemoglobin) was dissolved in 200 cm³ of a NaOH solution (pH 11.0), stirred for 24 h, and filtered through an 1.0 μm pore membrane (Tōyō Roshi Co., TM-100P). A known amount of the filtrate was dried to constant weight *in vacuo* at 70°C from which the weight, obtained by the same procedure using only the solvent, was subtracted. The analysis showed that 1.5% of albumin and 3.2% of hemoglobin remained insoluble in the alkaline media; thus, the concentrations of the solutions of these proteins were corrected accordingly. Stock solutions of DOAC were prepared by dissolving appropriate amount of the solid surfactant in distilled water under stirring at 50 °C for 24 h.

Analyses. Since DOAC scattered light in the visible region and weakly absorbed light in the ultraviolet region, the protein concentrations in solutions containing DOAC were determined by the Lowry method[14] as described previously.[2] The absorbance at 750 nm increased linearly with the DOAC concentration; however, this increase was small and amounted to only 0.08 at 0.05 wt% DOAC, which was the maximum amount of the surfactant in most experiments. The measured absorbance of protein solutions was corrected for the presence of the surfactant.

The concentration of DOAC was determined independently in solutions containing protein by the methyl orange method developed by Wang *et al.*[15] The volume of a sample solution (usually 0.2—1.0 cm³) in a 500-cm³ separatory funnel was adjusted with distilled water to 10 cm³ and then 1.0 cm³ of a buffer solution (pH=3),[16] 0.1 cm³ of a 0.1 wt% Methyl Orange aqueous solution, and 10 cm³ of chloroform were added. After vigorous shaking for 30 sec, the mixture was allowed to stand for about 30 min to achieve complete separation of the chloroform from the water phase. The absorbance of the chloroform solution was then determined spectroscopically at 415 nm. The presence of protein in the sample did not interfere, (even at a 50 fold excess with respect to DOAC) except that it took much longer time for the phase to separate. The absorbance was linearly proportional to the DOAC concentration over the range 0—0.002 wt%; it had a value of ≈1.0 for a 0.002 wt% DOAC solution when a cell of 1.00 cm light path was used.

Stability and Microflotation Measurements. The stability of the protein was very much affected by both the pH and the DOAC concentration. Thus, a series of solutions was prepared at a constant pH and protein concentration (0.05 wt%) whereas the concentration of DOAC was varied systematically.

Desired quantities of stock solutions of the protein and of DOAC were mixed with distilled water to give a final volume of 30 cm^3. The pH was then adjusted with NaOH and HCl, as necessary, and the resulting solution was allowed to settle for 24 h after which time the visual appearance of the system, the relative volume of settled flocs, and the concentrations of both the protein and DOAC in the supernatant solutions were determined.

The microflotation apparatus and the procedure were essentially the same as described earlier[2] except that a 300 cm^3 instead of a 600 cm^3 glass Buchner funnel was employed as the flotation cell. Precalculated amounts of protein and DOAC solutions and of distilled water, which would yield a final volume of 200 cm^3, were introduced into the cell and the pH was adjusted with either NaOH or HCl. As frother/collector served 0.5 cm^3 of ethanol containing 5 mg of lauric acid.

Results

Figure 1 gives the concentration of albumin in supernatant solutions as a function of pH, 24 h after mixing the reacting components. Each curve is for a different initial DOAC concentration whereas the albumin content was kept constant (0.05 wt%) in all systems. In the absence of the surfactant, some precipitation of the protein occurs only over a relatively narrow pH range of 4.4—5.7; the maximum amount of the protein separated by gravity settling after 24 h amounted to only 26% at pH ≈ 5.0. The addition of DOAC affects the precipitation of albumin as follows: (1) no precipitation of albumin is observed at pH<4.4, regardless of the amount of DOAC present; (2) with increasing DOAC concentration, the amount of separated albumin becomes larger and the pH range over which the protein precipitates broadens; (3) although albumin dissolves at high pH, it remains precipitated even at a pH as high as 12, provided the DOAC concentration is ≥0.05 wt%; and (4) a domain of high turbidity exists over the pH region of ≈4.5—5.0 (hatched area in Fig. 1), presumably due to stable albumin–DOAC dispersions.

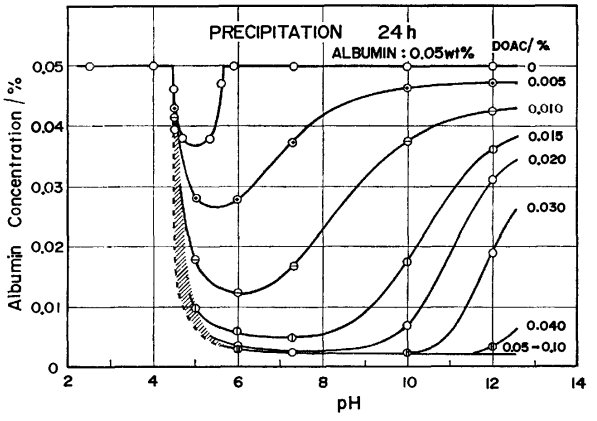

Fig. 1. The concentration of albumin left in the supernatant solutions after gravity settling as a function of pH. Each curve represents systems containing a constant concentration of albumin (0.05 wt%) but different concentrations (0—0.10 wt%) of dioctadecyldimethylammonium chloride (DOAC) 24 h after mixing of the reacting components. Hatched area indicates conditions yielding stable dispersions.

The upper part of Fig. 2 gives the concentration of albumin in the supernatant solutions, 24 h after mixing the reacting components as a function of the initial concentration of DOAC. The two curves refer to systems containing 0.05 wt% albumin at constant pH of 4.5 and 5.0, respectively. The center part of the figure shows the corresponding concentrations of DOAC in the supernatant solution. Finally, the lower part gives the percent of albumin removed after 5 min of microflotation in the same systems at pH 5.0. In Fig. 3 analogous plots refer to samples at pH 7.3 and 12.0

At pH 4.5 the addition of DOAC to protein solutions causes high turbidities. Obviously, a stable protein–DOAC precipitate is formed, which shows little tendency to settle, especially if the concentration of the surfactant exceeds 0.04 wt%. At somewhat higher pH (5.0) the removal of albumin by precipitation with DOAC and gravity settling is considerably enhanced. In these systems most of the added surfactant molecules combine with albumin leaving, for example, 0.0014 wt% and 0.0011 wt% DOAC in the supernatant solutions, at initial concentrations of 0.010 wt% and 0.015 wt%,

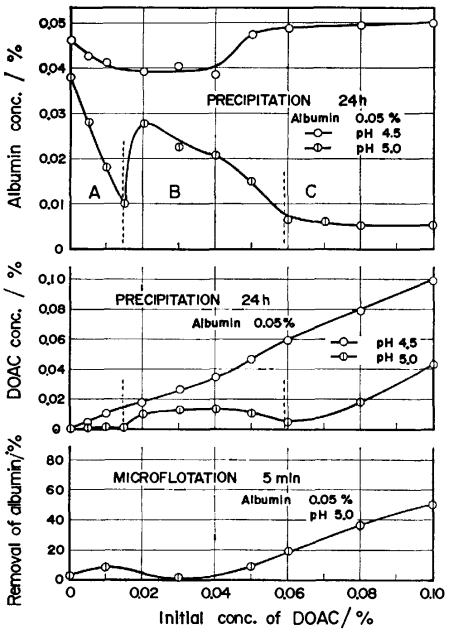

Fig. 2. The concentrations of albumin (upper part) and of dioctadecyldimethylammonium chloride (DOAC) (center part) remaining in the supernatant solutions above the precipitate separated by gravity settling 24 h after mixing of the reacting components. Lower part: the percentage removal of albumin by microflotation after 5 min. All systems contained a constant concentration of albuimn (0.05 wt%) at a constant pH (○, 4.5; ◑, 5.0), by varying amounts of added DOAC.

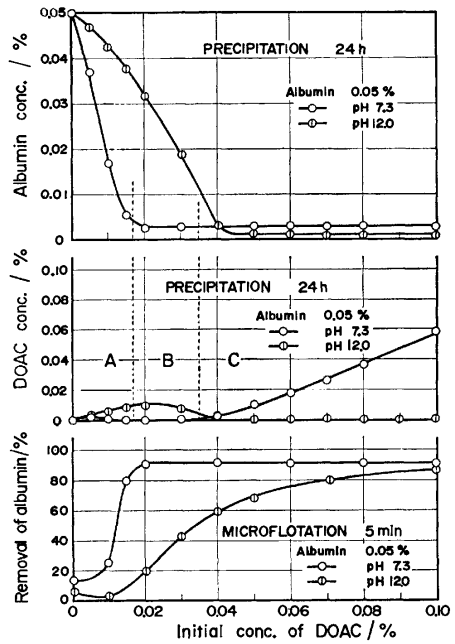

Fig. 3. Same plot as Fig. 2 for systems at pH 7.3 (○) and pH 12.0 (◐).

respectively. At intermediate amounts of DOAC a part of the precipitated albumin is peptized, giving somewhat higher concentrations of albumin and DOAC in the supernatant liquids. However, in contrast to the systems at pH 4.5, the separated albumin–DOAC phase at pH 5.0 coagulates and settles when the initial concentration of DOAC is $\geq \approx 0.06$ wt%.

The removal of albumin after 5 min of microflotation is much lower than by gravity settling after 24 h. For example, at the initial concentration of DOAC of 0.01 wt% only 8% of albumin is separated, whereas more than 60% settles out. Although the floatability of albumin improves with increasing DOAC concentration, only 50% is removed at best (in the presence of 0.10 wt% DOAC); under the same conditions $\approx$ 90% of the protein settles out.

As the pH is raised to 7.3 (upper part of Fig. 3) $\approx$ 94% of the protein is removed by settling at DOAC concentration $\geq$0.02 wt%. The surfactant content in the supernatant solutions (middle part of Fig. 3) remains low at initial concentrations <0.035 wt%, but increases nearly linearly when more DOAC is added. At this higher pH the separation of albumin by microflotation is comparable to that of settling (92% after 5 min) except that the time required is considerably shorter. The time dependence of the removal of albumin by microflotation in the absence and in the presence of different concentrations of DOAC at a constant pH of 7.3 is shown in Fig. 4.

Figure 3 also shows that at still higher pH (12.0) the precipitation and the microflotation of albumin in the presence of DOAC becomes again less efficient; thus, a minimum of 0.042 wt% of surfactant is needed for complete removal of the protein in contrast to 0.017 wt% at pH 7.3. Furthermore, at pH 12 no peptization in the presence of DOAC is detected over the concentration range studied (0—0.26 wt%).

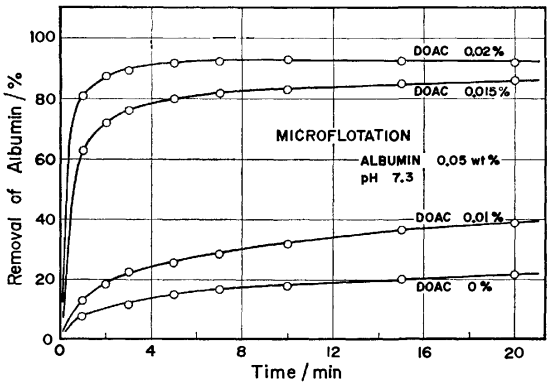

Fig. 4. Percentage removal of albumin from a 0.05 wt% protein solution at a pH of 7.3 as a function of time, in the absence and in the presence of DOAC in different concentrations.

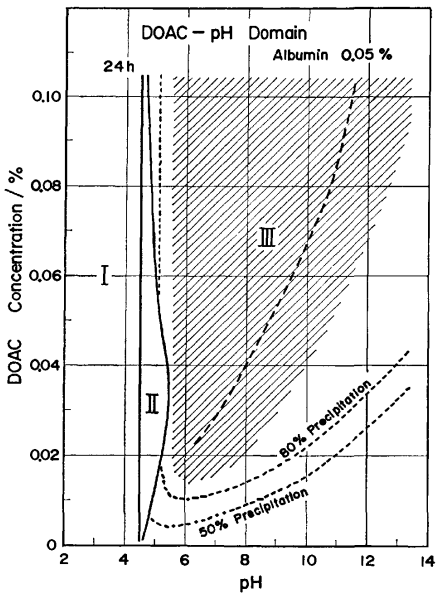

Fig. 5. DOAC-pH domain for the systems containing 0.05 wt% albumin. The solid lines delineate regions of various degree of stability, 24 h after mixing of the components. In I no precipitation takes place; in II the sols are stable; in III the albumin–DOAC floc readily settles. Dotted lines indicate the boundaries over which 50 and 80% albumin, respectively, is separated by gravity settling. Hatched area gives the conditions of 80% or greater removal of albumin after 5 min of microflotation.

In the system containing 0.20 wt% DOAC, for example, the surfactant concentration in the supernatant solution, 24 h after preparation, is only 0.0009 wt% although the settled precipitate occupies >50% of the total volume of the system. When DOAC concentration is >0.24 wt%, the entire system is solidified; *i.e.*, no supernatant solution appears 24 h after mixing the components. However, if the latter system is kept undisturbed for a longer period of time (more than 3 d), the precipitated phase gradually separates out from a transparent solution and floats as a jelly-like phase.

Figure 5 gives the entire DOAC concentration-pH

stability domain for a system containing a constant concentration of albumin (0.05 wt%), 24 h after mixing the reacting components. This plot is constructed from the data shown in Figs. 2 and 3 as well as from the analogous information for systems at pH 6.0 and 10.0. The heavy solid lines delineate conditions of different stability of albumin: in region I no precipitation is observed; in II stable albumin–DOAC aggregates are found (high turbidity); in III the complex precipitates settle by gravity. The dotted lines drawn within region III and labeled "50% precipitation" and "80% precipitation" indicate the boundary above which more than 50% (or 80%) of albumin is removed by settling 24 h after mixing. The hatched area indicates the conditions which result in 80% or better removal of albumin after 5 min of microflotation. Finally, above the dashed line an excess of DOAC is detected in the supernatant liquids (separated from the settled precipitates).

The results obtained with 0.05 wt% hemoglobin solutions are summarized in Figs. 6 and 7. A comparison with the corresponding data for albumin shows that DOAC reacts with both proteins in essentially the same manner. Minor differences noted are: (1) DOAC precipitates hemoglobin more efficiently than albumin, (2) the domain of stable dispersion (region II in Fig. 7) for hemoglobin system extends over a wider pH range than for albumin, and (3) the effective precipitation (and corresponding microflotation) region of hemoglobin is shifted by about one pH unit towards the higher pH as compared with that for albumin.

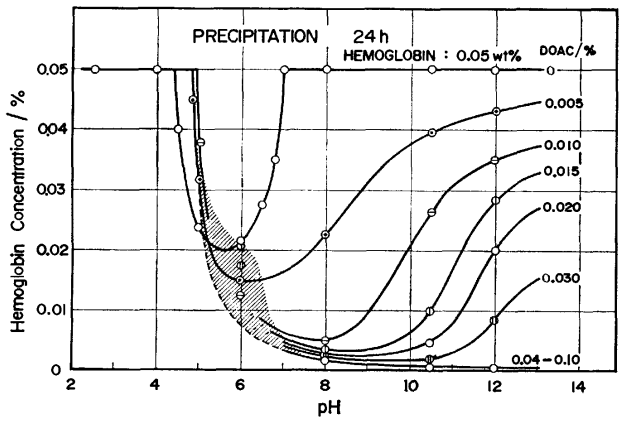

Fig. 6. Same as Fig. 1 for the hemoglobin–DOAC system.

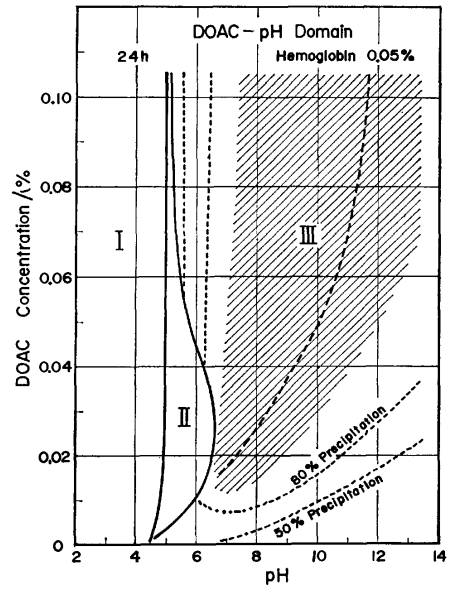

Fig. 7. Same as Fig. 5 for the hemoglobin–DOAC system.

Discussion

Dioctadecyldimethylammonium chloride (DOAC) was chosen because of its property to form very stable dispersions of liquid crystal particles that could interact with the proteins. There dispersions can be produced in aqueous solutions above or below the melting point (37 °C) of the hydrated solid DOAC. The positively charged particulate system is readily supercooled and remains unchanged for long time (over one month), even at room temperature. Thus, liquid crystals are expected to be suitable flocculents for the negatively charged proteins. The very low saturation concentration of the monomeric DOAC (2.7×10^{-4} wt% at 30 °C)[13] and the insensitivity of its liquid-crystalline phase to pH (except at a rather high concentration of base) are additional convenient properties of this surfactant for the intended purpose.

The data presented here show that the interactions between albumin (or hemoglobin) and DOAC depend strongly on the concentration of the surfactant and on the pH. Typical effects of the added DOAC on the stability of albumin are distinguished in Fig. 3 as regions *A*, *B*, and *C*. In *A* the mixing of albumin and DOAC yields rapidly settling flocs and the amount of removed albumin by gravity settling is approximately proportional to the quantity of DOAC added. The DOAC concentration in the supernatant solution is very low; the slight turbidity of the latter is most likely due to finally dispersed systems which did not settle during the 24 h of aging. In region *B* nearly the entire amount of albumin is precipitated and settled, and very little DOAC (less than 0.001 wt%) is left in the supernatant solution, even though there is an excess of the surfactant over what is necessary to react with the protein. The precipitate in this region is more voluminous than under conditions of region *A*. Finally, in *C* most of albumin is in the settled floc, but some of the DOAC can be found in the supernatant solution, the amount of which becomes larger with increasing concentration of the added surfactant.

In region *A* the negatively charged albumin reacts most likely with positively charged liquid-crystalline fragments of DOAC, as evidenced by the following observations: (1) no precipitation of albumin with DOAC takes place at pH < the isoelectric point[17] (Figs. 1 and 5); (2) the amount of DOAC which is needed to precipitate a certain amount of albumin

increases with increasing pH, *i.e.*, with increasing net negative charge on the albumin molecules (Figs. 1 and 3); and (3) at a constant pH, the amount of DOAC necessary to completely precipitate albumin is proportional to the initial protein concentration. For example, at pH=12.0, the systems containing 0.015, 0.030, and 0.05 wt% albumin, required 0.013, 0.025, and 0.042 wt% DOAC, respectively.

Although the pH dependence of the net charge on an albumin molecule (Z) is not fully established, one may assume Z to be approximately 14, 18, and 30 at pH 7.3, 10.0, and 12.0. These values are estimated by averaging the data obtained from electrophoretic mobilities[17] and from titrations.[18] Using these Z values and assuming that 60% of the positive charge on a liquid-crystalline aggregate of DOAC is electrostatically shielded by gegenions (such as Cl^- and OH^-),[19] one may calculate the DOAC content which is necessary to neutralize the negative charge on a definite amount of albumin molecules. The calculated values for a 0.05 wt% albumin solution are 0.015, 0.02, and 0.033 wt% at pH 7.3, 10.0, and 12.0, respectively. These results are in reasonable agreement with the observed DOAC concentrations (0.017, 0.022, and 0.042 wt%), which correspond to the boundary between the regions *A* and *B*.

In region *B* liquid-crystalline aggregates of DOAC may adhere to the electrically neutral albumin–DOAC floc; the onset of region *C* could, therefore, correspond to the saturated adsorption of the DOAC aggregates. The efficient multi-layer adsorption of a lammelar liquid-crystalline phase of DOAC to a surface, such as fabrics or hair, is noted elsewhere.[13] The resultant aggregate still remains in a settled state and is efficiently removed by microflotation if pH is appropriately adjusted ($\approx$6—$\approx$10). Ahmad[11] showed that the liquid-crystalline phase formed by surfactants and glycerides in association with protein was effective in the foam separation of albumin although a direct comparison with the experiments described in this work is not possible. Furthermore, some preliminary experiments indicated that the addition of $C_{18}H_{37}N(CH_3)_3Cl$, which forms micelles but does not form liquid crystalline phase in dilute aqueous solution, could also cause precipitation and settling of albumin at pH$>\approx$5. However, in excess of this surfactant, over what was needed to neutralize electric charge of the protein, peptization occurred due to the charge reversal of particles. The finely dispersed system could not be floated with microbubbles.

Stable dispersions in region *B* at pH 5 may also consist, at least in part, of small fragments of DOAC in liquid crystalline form. Since the aggregates of this surfactant contain up to 96% water, their density is very close to that of the liquid medium. Furthermore, the slight positive charge of these fragments would prevent an interaction with the finely dispersed albumin–DOAC floc of the same sign of charge. The addition of a small amount of electrolyte (*e.g.*, 1 wt% NaCl) causes a decrease in the amount of water in the swollen liquid crystals of DOAC from 96 to 70%, so that a separation of the surfactant aggregates occurs more readily. This result would indicate that the use of hard tap water rather than distilled water would be beneficial in the removal of albumin by DOAC.

Region *B* at pH 12 is considerably wider, which may be due to destabilization of liquid-crystalline aggregates of DOAC in the medium of high ionic strength. For instance, if a 0.10 wt% DOAC solution at pH 12 was aged for 24 h, a white creamy layer appeared in the upper part of the liquid; the amount of the separated phase increased with time and with increasing concentration of the surfactant.

Figure 5 shows that the conditions for an effective removal of albumin by microflotation ($\geq$80%) in the presence of DOAC coincide fairly well with those giving a floc that readily settles. The exception are either systems containing lesser amounts of the surfactant or systems at higher pH values of the media. Indeed, the higher the pH the more DOAC is needed to float the protein. The failure to separate the floc by microbubbles in this region may be due to the nature of its composition, which consists predominantly of liquid-crystalline DOAC fragments. Apparently, bubbles do not adhere to these solids sufficiently well unless the ionic strength is high enough. The addition of electrolytes (or using tap water) could improve the efficiency of microflotation under these conditions.

Since hemoglobin behaved in a very similar manner in the presence of DOAC as albumin, analogous explanation of the observed phenomena apply.

This work was supported by a joint NSF-JSPS Grant No. 01P74—24291 as a part of the United States-Japan Cooperative Science Program, by the National Science Foundation Grant CHE77 02185, and by Westvaco Foundation.

Effect of Pressure on Mesomorphic Transitions in Cholesterol Esters of Unsaturated C_{18} Aliphatic Acids

Masaru NAKAHARA,* Katsumi MAEDA, and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received March 31, 1980)

The smectic to cholesteric, cholesteric to isotropic liquid, and solid to isotropic liquid transitions in the following cholesterol esters are determined by an optical method as a function of pressure up to 1 kbar; cholesteryl oleate, cholesteryl linoleate, and cholesteryl linolenate. The pressure dependence of the transition temperatures (dT/dP) is in the range of 21 to 36 K kbar^{-1}, and the volume changes (ΔV) computed by means of Clapeyron's equation are between 0.42 and 1.3 cm^3 mol^{-1} at 1 bar. The volume change for the smectic to cholesteric transition increases with the number of the double bonds in the acids, while that for the cholesteric to isotropic liquid is little affected by the double bonds.

A study of the effect of pressure on the phase behaviors of liquid-crystal forming materials was begun by Hulett[1] just 10 years after the discovery of liquid crystals.[2,3] Similar kinds of work were undertaken by Puschin and Grebenshchikov[4] and by Robberecht[5] in the former half of this century. Researches of liquid crystals at high pressure revived one decade ago, and recently developed in various ways with the aid of more advanced techniques for measurements, as briefly reviewed elsewhere.[6] A useful optical method for detecting mesomorphic transitions at high pressure was invented and applied to cholesteryl stearate in a previous paper.[6] Cholesterol esters of a homologous series of unsaturated C_{18} aliphatic acids are investigated in the present work. Hydrocarbon chains in the cholesterol esters of saturated aliphatic acids are stretched in the solid(So), smectic(Sm), and cholesteric(Ch) phases and in the isotropic liquid(IL) phase near the Ch-IL transition; all the conformations are in the *S-trans* form.[7] The conformation about a double bond is considered to be *cis* in the acids studied here.[8,9] Thus, it is interesting to see how the deviation from the linear conformation (rod-likeness) influences the phase behaviors and volume changes associated with the phase transitions.

Experimental

Cholesteryl oleate(CO), cholesteryl linoleate(CL), and cholesteryl linolenate(CLN) were obtained from Eastman Kodak. The esters were recrystallized from 1-pentanol, washed by a water-ethanol mixture (50 v/v%) and by water, and dried before use *in vacuo* for more than 10 h. As seen in Table 1, the transition temperatures at 1 bar (1 bar=10^5 Pa) of the purified materials agree well with the literature values[9] except for CLN.

The transition temperatures were determined by using an apparatus designed previously in which a He-Ne gas laser (wavelength 632.8 nm and power 3 mW) and a phototransistor were used as a source and a detector, respectively. Pressure was measured to ± 1 bar by a Heise Bourdon gage, and temperature to ± 0.1 °C by a chromel-alumel thermocouple fixed in the high-pressure optical cell. The transition temperatures were reproducible within ± 0.5 °C under any condition. The high-pressure apparatus and experimental procedure were described in detail elsewhere.[6]

Results and Discussion

A typical example of the transparency variation below and above the Sm–Ch transition is shown in Fig. 1; the transparency increases slightly with increasing temperature in the smectic phase, drops at the transition, and increases more rapidly in the cholesteric phase. The transparency minimum is reported also for the mesomorphic transition in other liquid crystals.[10–12] Causes for the appearance of the minimum would be strong light scattering and reflection at the boundaries of optically anisotropic domains being reorganized to form the cholesteric order. The positional order in the direction normal to the smectic layer is lost during the smectic to cholesteric transition. Thus, the diffusive motion of a molecule in this direction has something to do with the rate of the transparency drop. The manner how the transparency rose with time (cooling) from the minimum to its

smectic value was taken as a criterion to judge a tricritical point of the Ch–Sm transition in cholesteryl oleyl carbonate.[12] No corresponding phenomena were observed in these esters at any pressure. Taschek and Williams[13] ascribed the transparency increase with temperature in liquid crystals to the decrease in the birefringent factor, the square of the difference between ordinary and extraordinary indices. Changes in the size of domains and in the pitch of the helical structure in the cholesteric phase would also contribute to the transparency increase. These factors cause the transparency jump finally at the Ch–IL transition, as seen in Fig. 2. Similar changes in transparency took place when material densities were decreased by reducing pressure at almost constant temperature. The transitions in these esters are monotropic with respect to the solid state as,

$$\text{—So}\leftarrow\text{Sm}\leftrightarrow\text{Ch}\leftrightarrow\text{IL}\leftarrow\text{ .}$$

The So←Sm transition could not be detected by the present method. The smectic phase of CO and CLN were apt to be supercooled below 0 °C, so that their So→IL transitions were not examined. The absolute value of the transparency in the smectic or cholesteric phase differed from one to another run, especially depending on the cooling rate.

The transition temperatures determined thus are plotted against pressure in Figs. 3, 4, and 5. In Fig. 4, the liquid crystalline phases look as if they were supercooled. Every boundary line in the phase diagrams is straight under the present experimental conditions. The values of the slopes (dT/dP) for the transitions are summarized together with other transition parameters at 1 bar in Table 1. In each ester, the larger the slope the higher the transition point;

$$(dT/dP)_{\text{Sm-Ch}} < (dT/dP)_{\text{Ch-IL}}[<(dT/dP)_{\text{So-IL}}].$$

In other words, the temperature range over which the liquid crystalline phases are stable is widened by the application of pressure. The trend found often experimentally is predicted by the order-disorder transition theories based on a lattice model.[14–16]

The volume changes ΔV at 1 bar accompanying the transitions are computed by putting the slopes (dT/dP) and the literature values[9] of the enthalpy changes ΔH into Clapeyron's equation,

$$\Delta V = \Delta H T^{-1}(dT/dP). \quad (1)$$

The values of ΔV computed thus are listed in the last column of Table 1. The volume change for the

	Sm–Ch	43.0 (41.8)	1.01	23	0.73
Cholesteryl linoleate	So–IL	42.3 (42.6)	29.9	36	34
	Ch–IL	36.3 (35.1)	0.543	28	0.50
	Sm–Ch	33.6 (34.0)	1.47	21	1.0
Cholesteryl linolenate	Ch–IL	38.0 (34.8)	0.433	30	0.42
	Sm–Ch	30.6 (33.0)	1.84	22	1.3

a) The transition points in the parentheses and enthalpy changes are from Ref. 9.

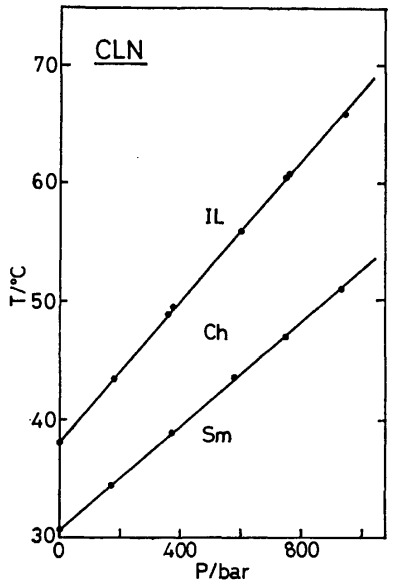

Fig. 5. Phase diagram of cholesteryl linolenate.

So–IL transition in CL is much larger than that for the Sm–Ch or Ch–IL transition, because in the former transition, the positional and rotational orders inherent in the solid state are completely lost at the same time. The ratio of the volume changes, $\Delta V_{\text{Sm-Ch}}/\Delta V_{\text{Ch-IL}}$ is larger than unity in every case, and increases as the molecular shape deviates further from rod-likeness. The former tendency indicates that one translational freedom brings about a larger volume change than two rotational freedoms. The volume change for the Sm–Ch transition increases with the number of the double bonds, while that for the Ch–IL transition is little affected. The volume changes for the Sm–Ch transition can be linearly correlated to the corresponding entropy changes in the homologous series, because the slopes (dT/dP) in Eq. 1 are all in the narrow range of 21 to 23 K kbar^{-1}.

On the Origin of Differences in the Phosphorescence Band Patterns of *p*-Benzoquinone in *p*-Dihalobenzene Crystals[1)]

Yusei MIYAGI, Motohiko KOYANAGI,* and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 7, 1980)

The phosphorescence spectra of *p*-benzoquinone (PBQ) have been studied at 4.2 K in isostructural crystals such as *p*-dichlorobenzene (DCB), *p*-bromochlorobenzene (BCB), and *p*-dibromobenzene (DBB); and in their binary mixed crystals. The variable phosphorescence band patterns observed are interpreted in terms of anisotropic local-field effects of the host environmental molecules. A similarity of the phosphorescence intensity distribution between two systems of PBQ/BCB and PBQ/(0.5 molar fraction of DCB+0.5 molar fraction of DBB) is a manifestation of the existence of effective local-fields in the crystals.

Extensive spectroscopic studies have been carried out on the lowest excited triplet state of *p*-benzoquinone (hereafter abbreviated as PBQ) in rigid matrices[2-9)] and have served as the basis for understanding emission spectra of more complex quinoidal compounds, *e.g.*, the emission spectra of 9,10-anthraquinone[10-12)] and 1,4-naphthoquinone.[13)] No widely accepted theoretical work on the energy splitting $\Delta E(n_+ - n_-)$ has appeared so far despite a great interest in knowledge about the extent of interaction between the two zeroth order n orbitals on the two carbonyl oxygens. The energy separation between the two $n\pi^*$ states of the same spin-multiplicity, which originate mainly in the $\pi_5 \leftarrow n_+$ and $\pi_5 \leftarrow n_-$ excitations, is also controversial.[14,15)]

The phosphorescence is expected sensitive even to a feasible perturbation because PBQ has a small energy gap between $T_1(n_-\pi_5^*)$ and $T_2(n_+\pi_5^*)$ states, *e.g.*, 0.002—0.04 eV depending on environments.[3-9,14)] The perturbation may be external (*e.g.*, environmental), or internal (*e.g.*, vibrational), or a combination of both. The objectives of this paper are to examine a change in the phosphorescence spectral pattern of PBQ with a change in environmental force-fields and to demonstrate a great dependence of the PBQ spectral pattern upon environments.

Experimental

All chemicals of extra pure grade were obtained from Tokyo Kasei Co. Ltd. The guest substance PBQ was recrystallized at least twice from petroleum ether prior to several vacuum sublimations. All the host substances, *i.e.*, *p*-dibromobenzene (abbreviated as DBB), *p*-dichlorobenzene (DCB) and *p*-bromochlorobenzene (BCB), were sublimed *in vacuo* and then zone-refined more than 70 passes. The guest concentration of about 10^{-3} in mol/mol ratios was generally employed. All mixed crystals were grown using the usual Bridgman method. The apparatus and experimental conditions are similar to those described previously.[16)] No intensity correction was carried out for photomultiplier response, grating reflection property, and quantum efficiency difference because the locations of the phosphorescence origin bands in the three matrices are close to each other and only their relative intensities are referred to in this paper.

Crystal Structure of DBB, DCB, and BCB

All hosts have well been known to crystallize in the same space group of $C_{2h}^5(P2_{1/a})$ with two molecules in the unit cell and to have nearly identical unit cell dimensions.[17-19)] The representative crystal structure of these hosts is shown in Fig. 1 and the dimensional data cited are given in Table 1. If a mixed crystal is grown very slowly from the melt mixed with two types of these *p*-dihalobenzenes, each lattice point of the mixed crystal can be regarded as a statistical average of the two types of molecules.[20)] As for the BCB crystal itself, the halogen positions are filled at random by bromine or chlorine.[19,21)] Since the space group has four general positions, only a statistical symmetry is possible with a center of symmetry at the center of the average molecule. Its benzene ring is assumed as a regular hexagon of 1.41 Å in side and the C–X (halogen) bond lengths of 1.77 Å are intermediate between C–Cl (1.69 Å in DCB) and C–Br (1.88 Å in DBB).[19,22)] The permanent diplole moment of BCB has been reported to be 0.1 D.[23)] This is very close to an estimated value of 10^{-1} D from a vector combination of the dipole moments available for chlorobenzene and bromobenzene.[24)]

Results

Phosphorescence Spectra. The phosphorescence spectra of PBQ in BCB, DCB, and DBB at 4.2 K are shown in Fig. 2. Here two characteristic bands are designated as *a* and *q*. The band *a* lying at the shortest wavelength of the emission systems contains the origin band and the band *q* both the ν(C=O) symmetric and antisymmetric vibrational bands. At a glance the phosphorescence band pattern of PBQ/BCB resembles that of the $^3B_{1g} \rightarrow {}^1A_g$ phosphorescence of PBQ/toluquinone reported previously.[9] On the other hand, the spectra of PBQ/DCB and PBQ/DBB are of the "forbidden-type" spectral pattern whose features have been discussed somewhat minutely in the phosphorescence spectrum of PBQ/naphthalene.[9] The phosphorescence spectrum of PBQ/DCB resembles those reported previously.[2,3] However, all the spectra of this system seem to contain additional emission components with broad band feature. Such additional emissions have also been reported for other guest molecules in the same DCB host and attributed to different phases of the host crystal.[25,26] Except the band broadness, the spectral intensity distribution of PBQ/DCB is rather close to that of PBQ/DBB. The strongest band in both systems is ascribed to the ν(C=O) antisymmetric b_{1u} vibrational mode.[2,3,6-8]

Another intensity aspect is given through a study on the phosphorescence spectra of PBQ in a binary-component crystal system, *i.e.*, PBQ/(DCB–DBB). In Fig. 3 are shown the phosphorescence spectra of PBQ at various molar fractions of DCB in DBB. For convenience' sake, all the emission spectra were roughly normalized in the peak height of the band *q* around 16750 cm^{-1}. Obviously the band *a* increases in intensity, relative to the intensity of the band *q*, with an increase in DCB molar fraction x_{DCB} from 0 to 0.5. A similar concentration dependence was also observed with an increase in DBB concentration x_{DBB} from 0 to 0.5. It should be noted that the phosphorescence band pattern at $x_{DCB}=x_{DBB}=0.5$ is very similar to that of PBQ/BCB (compare the spectral curve (6) in Fig. 3 with that given in Fig. 2a).

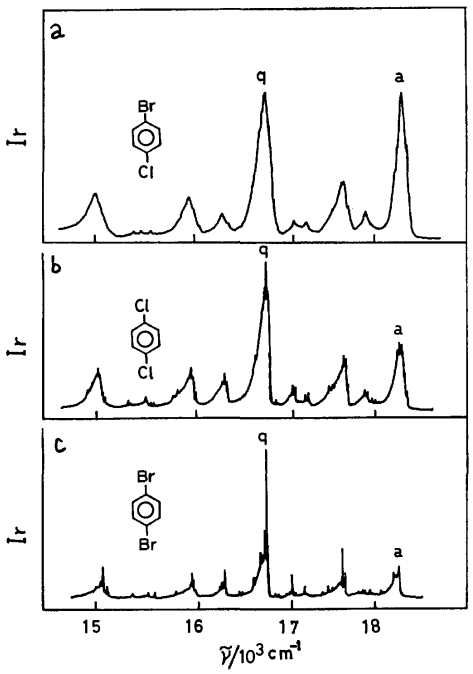

Fig. 2. Phosphorescence spectra of PBQ in (a) BCB, (b) DCB, and (c) DBB at 4.2 K. An apparent band *a* represents the origin band region containing some phonon modes and *q* the ν(C=O) band region. The ordinate I_r means a relative output signal intensity. No intensity correction is given in this Figure.

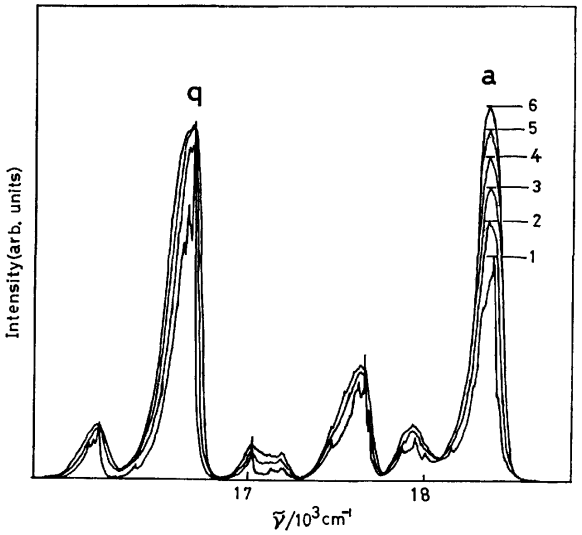

Fig. 3. Phosphorescence spectra of PBQ in binary host crystals of DCB/DBB at 4.2 K. The guest concentration is almost constant, *i.e.*, $\approx 10^{-3}$ mol/mol. The molar fractions of DCB in DBB are (1) 0.05, (2) 0.1, (3) 0.2, (4) 0.3, (5), 0.4, and (6) 0.5. To avoid the confusion of band overlappings, we employ a suitable abbreviation in this Figure.

Intensity Correlation in Binary Host Crystals. A meaningful correlation is obtained between the intensity increment of the apparent band *a* and the molar fraction of x_{DCB} (hereafter abbreviated simply as x unless noted especially) in the binary host system, *i.e.*, DCB/DBB. Since estimation of the absolute intensity of emission spectra is generally difficult, we take only a relative intensity. The intensity of the band *a* may approximately be represented as

$$\int_{\tilde{\nu}_a-\Delta}^{\tilde{\nu}_a+\Delta} f(\tilde{\nu}, x)\mathrm{d}\tilde{\nu} = F_a(x), \tag{1}$$

where $f(\tilde{\nu},x)$ is the uncorrected shape-function of the observed phosphorescence spectrum at a solvent constituent x and Δ is taken as a region much greater than any *hwhm* in all mixed crystal systems but less than 400 cm^{-1} since a next prominent band might usually appear around 400 cm^{-1} region from the band in question and we must exclude such an unnecessary component from the intensity estimation. Similarly the intensity of the band *q* is given by

$$\int_{\tilde{\nu}_q-\Delta}^{\tilde{\nu}_q+\Delta} f(\tilde{\nu}, x)\mathrm{d}\tilde{\nu} = F_q(x). \tag{2}$$

Since these bands are extremely strong in intensity and the intensities of other bands as combination

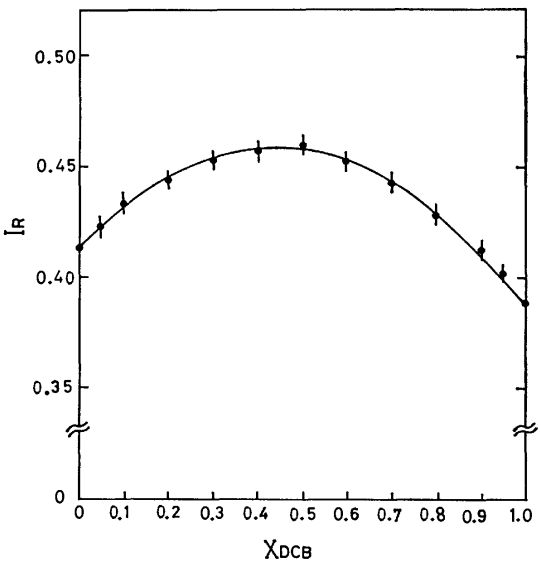

Fig. 4. A correlation between the relative intensity of the "origin" band, I_R, and the concentration of DCB in the binary host system of DCB–DBB, x. ●: Observed value, —: simulated parabola (the analytical details are given in the article).

bands are closely related to either the origin band or the false origin band, it will be reasonable to employ an approximate relative intensity of the band a as follows:

$$I_R(x) = F_a(x)/\{F_a(x)+F_q(x)\}. \quad (3)$$

The observed values of I_R against x are plotted in Fig. 4. An analytical expression for the empirical plot is given by

$$I_R(x) = -0.236x^2 + 0.212x + 0.413. \quad (4)$$

The solid curve in Fig. 4 shows this parabola.

Theoretical Consideration

General Spectral Behaviors in a Binary A–B Host System. Now let us assume that a guest molecule is surrounded by n solvent molecules. Each solvent site is occupied by either an A or a B molecule. It is, of course, statistical which molecule of them takes a certain site i. There are $N(=2^n)$ arrangements of the binary host molecules unless any symmetrical simplification is taken into account. In general the observed shape function $f(\tilde{\nu}, x)$ is represented as the arithmetic mean over all these arrangements:[27]

$$f(\tilde{\nu}, x) = \frac{1}{N}\sum_{R}^{N} f_R(\tilde{\nu}, x). \quad (5)$$

Here $f_R(\tilde{\nu}, x)$ denotes the shape function of a certain host arrangement R and is developed in terms of the binomial distribution function with two parameters n and m:

$$f_R(\tilde{\nu}, x) = \sum_m \binom{n}{m} x_A^n x_B^{n-m} f^\circ_{mR}(\tilde{\nu}), \quad (6)$$

where $f^\circ_{mR}(\tilde{\nu})$ signifies the shape function of the arrangement R with m sites of the A molecule and n-m sites of the B molecule. The actual emission shape is thus developed as a polynomial of x with degree n:

$$f(\tilde{\nu}, x) = K_n(\tilde{\nu})x^n + K_{n-1}(\tilde{\nu})x^{n-1} + \cdots + K_1(\tilde{\nu})x + K_0(\tilde{\nu}). \quad (7)$$

Here each of the expansion coefficients, K's, is constant for a fixed $\tilde{\nu}$-value:

$$K_i(\tilde{\nu}) = \sum_{m=0}^{i} \frac{n!(-1)^{i-m}}{(n-i)!(i-m)!} f^\circ_{mR}(\tilde{\nu}) \quad (8)$$

with the boundary conditions,

$$K_0(\tilde{\nu}) = f(\tilde{\nu}, 0) = f^\circ_A(\tilde{\nu}) \quad (9)$$

and

$$\sum_n K_n(\tilde{\nu}) = f(\tilde{\nu}, 1) = f^\circ_B(\tilde{\nu}). \quad (10)$$

Case of n=2. For a special case n=2 in Eq. 7, the following coefficients are obtained from Eq. 8:

$$K_2(\tilde{\nu}) = f^\circ_{0R}(\tilde{\nu}) + f^\circ_{2R}(\tilde{\nu}) - f^\circ_{1R}(\tilde{\nu}), \quad (11)$$

$$K_1(\tilde{\nu}) = 2\{f^\circ_{1R}(\tilde{\nu}) - f^\circ_{0R}(\tilde{\nu})\}, \quad (12)$$

and

$$K_0(\tilde{\nu}) = f^\circ_{0R}(\tilde{\nu}). \quad (13)$$

Discussion

If a PBQ molecule is located substitutionally at any of centrosymmetric sites in the DCB or DBB lattice of monoclinic $P2_{1/a}$, the zero-phonon origin band in the $^3B_{1g}\rightarrow{}^1A_g$ phosphorescence of the PBQ molecule is forbidden by the electric dipole selection rule. The weak origin band observed in these hosts[2,3] seems to support the assumption mentioned above for the molecular location in the hosts. When a PBQ molecule is located at any of noncentrosymmetric sites in the BCB or toluquinone lattice, however, the intensification of the origin band is remarkable (see Fig. 2a and also Ref. 9).

The intensity change observed in the binary solvent system of DCB and DBB is extremely suggestive (*cf.* Figs. 3 and 4). Supposing that one of the host molecules is substituted with a guest PBQ molecule, we can, as the zeroth approximation, consider a model in which the PBQ molecule is surrounded by eighteen neighbor host molecules: Six of them are located at "translationally equivalent" sites and the others at "translationally nonequivalent" ones. In the present case any possible guest-guest interaction is neglected since the concentration of the guest employed is dilute enough. As has been demonstrated in the previous works on the Stark experiments,[5,6,16,28] the most effective electric perturbation for the interstate coupling between $^3B_{1g}(n\pi^*)$ and $^3A_u(n\pi^*)$ states is the electric field change along the C=O axis of the guest molecule. This will be true for environmental dipolar perturbations or asymmetric host locations. As a matter of fact, a preliminary model calculation shows that the effective electric field of a permanent host molecule with 10^{-1} D over a guest molecule distant by 8 Å from it amounts to $\approx 10^6$ V/cm in external bulk scales.[29]

It is thus expected that the host arrangements concerning with four translationally equivalent molecules along the crystallographic b and c axes (*e.g.*, the molecule I′ for the assumed guest molecule I in Fig. 1) give

little contribution to the interstate mixing between $^3B_{1g}$ and ^3A_u states as well as those concerning with six translationally nonequivalent molecules (*e.g.*, the molecule II'). Furthermore, two translationally equivalent molecules along the a-axis are located too far from the guest molecule to be taken into account. There remain six translationally nonequivalent molecules on which the effective C=O axis perturbations should be assessed (*e.g.*, see the molecules II at (a/2, b/2, −c), (a/2, b/2, 0), and (a/2, b/2, c); and their inversion sites with respect to the site I). However, several investigations on the phosphorescence spectra have suggested that the $\pi_5^*\leftarrow n_\pm$ excitations are localized on the C=O groups.[6,14] Since the closest halogen-halogen intermolecular distances of DCB and DBB have been reported to be 3.85 Å and 3.76 Å, respectively, between the molecule I at (0, 0, 0) and the molecule II at (a/2, b/2, 0),[17] it seems reasonable to consider the molecule II and its inversion site molecule $\overline{\text{II}}$ at (−a/2, −b/2, 0) as the most effective components of anisotropic force-fields. There are four ways in which the molecules of DBB(B) and DCB(C) occupy these sites:

$$\text{II(B)}\text{-}\overline{\text{II}}\text{(B)},\ \text{II(C)}\text{-}\overline{\text{II}}\text{(C)},\ \text{II(B)}\text{-}\overline{\text{II}}\text{(C)},$$
$$\text{and II(C)}\text{-}\overline{\text{II}}\text{(B)}.$$

If we define the emission shape functions for these host arrangements as $f_B(\tilde{\nu})$, $f_C(\tilde{\nu})$, $f_{BC}(\tilde{\nu})$, and $f_{CB}(\tilde{\nu})$, respectively, an actual emission shape $f(\tilde{\nu}, x)$ will be represented by means of the usual statistical treatment:

$$\begin{aligned} f(\tilde{\nu}, x) &= x_{DBB}^2 f_B(\tilde{\nu}) + x_{DCB}^2 f_C(\tilde{\nu}) \\ &\quad + x_{DBB}x_{DCB}\{f_{BC}(\tilde{\nu}) + f_{CB}(\tilde{\nu})\} \\ &= x^2 f_B(\tilde{\nu}) + (1-x)^2 f_C(\tilde{\nu}) + 2x(1-x) f_{BC}(\tilde{\nu}). \end{aligned} \quad (14)$$

This just corresponds to what is given for the special case of $n=2$ in the preceding section (*cf.* Eqs. 11—13). Certainly, intensity contributions from higher orders of x than x^2 are expected small for small values of x, but this good agreement between the observed intensity change and the simulation curve of $n=2$ around $x\approx 1$ strongly supports our assumption for effective host arrangements. Since each lattice point of the mixed crystal is regarded as a statistical average of the binary components of molecules,[20] the resemblance between the phosphorescence spectra of PBQ/BCB and PBQ/(0.5 molar fraction of DCB+0.5 molar fraction of DBB) seems to be reasonable. It is suggested that the asymmetric arrangement between the molecular location II in Fig. 1 and its inversion one $\overline{\text{II}}$ is very effective for increasing the "origin band" of the PBQ phosphorescence in intensity. Similar intensification of "forbidden" bands of molecules in environments have extensively been discussed and importance of the environmental effects has been emphasized.[30-33]

The authors would like to thank Professor D. S. McClure for donating a copy of Klump's thesis (Ref. 2) and Professor H. P. Trommsdorff for sending a copy of his thesis (Ref. 4). This work has been supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture. One of the authors (Y. M.) has been financially supported during his graduate course by the Uehara Education Foundation Fund.

Studies of the Ion Flotation by Poly(ethyleneimine) Resin

Tsunetaka Sasaki,* Hisayo Kurosawa, Keiichi Miyasaka, and Minoru Mizushima

Department of Chemistry, Faculty of Science, Tokai University, 1117 Kitakaname, Hiratsuka 259-12

(Received April 1, 1980)

Flotation of Crystal violet (CV^+), neucoccin (NC^-), CrO_4^{2-}, PO_4^{3-}, Fe^{3+}, and Cu^{2+} ions was studied with use of poly(ethyleneimine) resin (PEI) as an adsorbent, Na-polyacrylate or polyacrylamide as a coagulant and sodium dodecyl sulfate or hexadecyltrimethylammonium chloride as a frother. In line with the results of adsorption studies, NC^-, PO_4^{3-}, and CrO_4^{2-} ions were effectively floated from their dilute solutions but CV^+ was not floated so much. The most effective flotation was attained for CrO_4^{2-} ions, a rapid initial decrease in concentration due to the flotation within 30 s being followed by a gradual decrease and nearly 100% flotation achieved within 10 min for a dilute solution. The rate of flotation follows a bimolecular reaction. The activation energy of flotation, 28.03 kJ mol^{-1}, is equal to that of CrO_4^{2-} ion adsorption by PEI. Flotation of Fe^{3+} and Cu^{2+} ions was effectively carried out through chelate formation of these ions with PEI.

Adsorbing particle flotation has been reported as an effective method of ion flotation,[1] bentonite being used as a cation exchange adsorbent. Further, poly(ethyleneimine) (PEI) was found to be a good anion exchange adsorbent as well as a chelating agent for metallic cations.[2] The adsorbing particle flotation of organic and inorganic anions and cations using PEI is reported in this paper.

Experimental

Materials. PEI used was supplied by Shunan Petroleum Company. The sample was prepared in a similar way to that reported.[2] Crystal Violet (CV^+) was precipitated by the addition of diethyl ether to an ethanol solution of CV^+. The precipitate was filtered and dried under reduced pressure. Neucoccin (NC^-) was recrystallized from its aqueous solution by the addition of anhydrous sodium carbonate. Crystals were filtered, washed with ethanol and dried. Potassium chromate, trisodium phosphate, Fe(III) chloride and Cu(II) sulfate of guaranteed grade were used without purification. Sodium polyacrylate (NaPA) of the degree of polymerization 2200—6600 and polyacrylamide (PAA) (Sanfloc AA-300P of Sanyo Chemical Industry Product) were used as coagulants. Pure hexadecyltrimethylammonium chloride (HTAC) (KAO Soap Co.) and sodium dodecyl sulfate (SDS) (Nikko Chemical Co.) were used.

Measurement. Flotation was carried out by adding PEI, coagulant and surfactant to the solution containing ions to be floated and shaking the solution in a stoppered test tube equipped with a stopcock at the bottom. Floatability (F) of dissolved ions was calculated from the concentrations of the solute before and after flotation by

$$F = \frac{C_i - C_f}{C_i} \times 100\%$$

where C_i and C_f denote the initial and final concentration of solute ions, respectively.

The concentrations of CV^+ and NC^- ions were measured with a Shimazu Spectronic Colorimeter 20 at wave lengths of 480 nm and 580 nm, respectively. The concentrations of CrO_4^{2-}, Fe^{3+}, and Cu^{2+} ions were measured with a Hitachi Atomic Absorption Spectrometer at wave lengths 357.9 nm, 248.3 nm, and 324.7 nm, respectively. Concentration of phosphate was determined by colorimetry at wave length 700 nm of ammonium phosphomolybdate formed by the addition of ammonium molybdate to the sample solution.

Results and Discussion

Flotation of PEI. In order to carry out the adsorbing particle flotation of ions by PEI, conditions for the flotation of PEI were studied. Flotation by hand-shaking of PEI suspension with addition of SDS alone, SDS and NaPA, and HTAC and NaPA was studied. In the flotation of PEI–SDS system, 15 cm^3 of a solution containing 0.1 g of PEI and varying amounts of SDS was shaken in a test tube for 10 s and left to stand for 5 min. The floatability was measured from the amount of PEI remaining as a suspension after flotation. In the flotation of PEI–NaPA–SDS and PEI–NaPA–HTAC systems, 15 cm^3 of the solution containing 0.1 g of PEI, 5.3 ppm of NaPA and varying amounts of SDS or HTAC was subjected to a similar treatment and the floatability was measured. All the experiments were carried out at room temperature, *ca.* 25 °C. The results are shown in Fig. 1.

The flotation percentage of PEI increases with increasing concentration of SDS or HTAC. The minimum concentration of surfactant of 100% flotation and the time required for the flotation are given in Table 1. Adsorbing particle flotation can be carried out under the conditions given. However, NaPA–SDS and NaPA–HTAC systems are preferable since flotation is quickly completed. NaPA–HTAC was used in the ion flotation studies of CV^+, NC^-, CrO_4^{2-}, and PO_4^{3-}, and PAA–SDS in the case of Fe^{3+} and Cu^{2+}

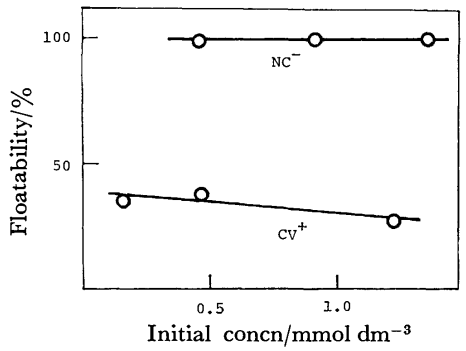

Fig. 2. Flotation of dyes.

ion flotation, neither NaPA–SDS nor NaPA–HTAC being effective in the latter case.

Flotation of Dye Ions. A 20 cm^3 solution containing 0.1 g of PEI, 14 ppm of NaPA in the case of NC^-, 40 ppm of NaPA in the case of CV^+, 20 ppm of HTAC and varying amounts of NC^- or CV^+ ions was shaken frequently for 7 min. After complete float-up of PEI, concentrations of NC^- and CV^+ ions in the underlying layers were measured, the floatability calculated being plotted against the initial concentration of respective ions (Fig. 2). Floatability of ions is nearly 100% up to the initial concentration of about 1.5 mmol dm^{-3}, while a maximum of 35% floatability was obtained for the dilute solution of CV^+ ions. Such a difference in floatability between NC^- and CV^+ ions can be expected from the anion exchange nature of PEI.[2]

Flotation of CrO_4^{2-} Ions. Since CrO_4^{2-} ions are significant as regards environmental contamination, removal of CrO_4^{2-} ions from aqueous solution by ion flotation was studied in detail.

Rate of CrO_4^{2-} Ion Flotation. A 150 cm^3 solution containing 1 g of PEI 13 ppm of NaPA, 3.3 ppm of HTAC and varying amounts of CrO_4^{2-} ions was put into an Erlenmeyer flask. Magnetic stirring for 5 min and shaking by hand was repeated. Residual concentration of Cr in the solution below PEI floated after each shaking was measured and plotted against time. Figure 3 shows the result for the solution of initial Cr concentration of 61.47 ppm.† The initial rapid fall of concentration within 30 s was followed by a gradual decrease, the concentration falling below 1/10 of the initial value within the first 10 min. Figure 4 shows the floatability of Cr after flotation for 10 min plotted against the initial concentration. The floatability increases with decreasing concentration of Cr, 98% of Cr being removed from 10.7 ppm Cr solution by flotation for 10 min.

† Concentration of Cr and the following P are expressed by ppm instead of mol dm^{-3}.

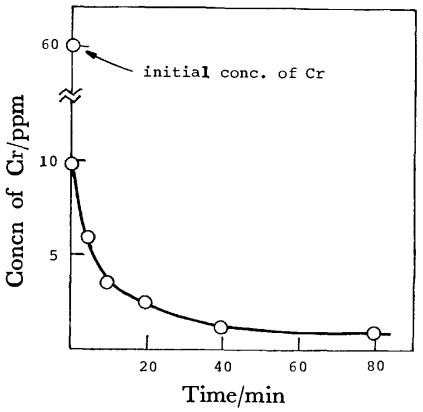

Fig. 3. Rate of CrO_4^{2-} ion flotation.

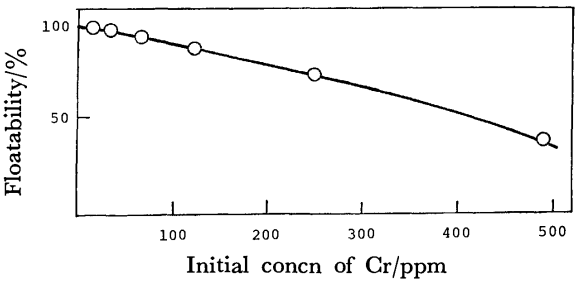

Fig. 4. Flotation of Cr.

In order to study the temperature dependence of the rate of CrO_4^{2-} ion flotation, a 500 cm^3 solution containing 54.5 ppm of Cr, 1 g of PEI, 14 ppm of NaPA and 4 ppm of HTAC was put into the Erlenmeyer flask. Stirring and shaking were carried out as mentioned above. The residual concentration determined after each flotation by shaking was measured, the result being plotted against time at a constant temperature in the range 25 °C—50 °C. Diagrams similar to that in Fig. 3 were obtained. From the results $1/(C-C_\infty)$ *vs.* t plots were made as in the case of CrO_4^{2-} ion adsorption by PEI,[2] where C and C_∞ denote the concentrations of Cr at time t and after a sufficiently long time, respectively. The results obtained at 30 °C are shown in Fig. 5. A linear relation

$$\frac{1}{C-C_\infty} = Kt + L$$

where K and L are constants, was confirmed to hold. This indicates that the reaction is bimolecular as in the case of CrO_4^{2-} ion adsorption by PEI.[2] The logarithm of K, considered as a reaction rate constant

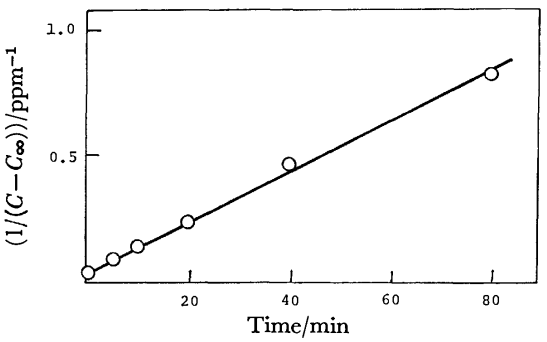

Fig. 5. $(1/C-C_\infty)$ *vs.* t plots.

of ion flotation, is plotted against the reciprocal of the absolute temperature T (Fig. 6). A straight line was obtained, the slope of which gave the activation energy of 28.03 kJ mol^{-1} in agreement with the value obtained for CrO_4^{2-} ion adsorption by PEI.[2] This suggests that the ion exchange adsorption is the rate determining step of the flotation of CrO_4^{2-}.

Effect of the Amount of PEI on CrO_4^{2-} Ion Flotation. In order to determine the amount of PEI necessary for CrO_4^{2-} ion flotation, a 500 cm^3 solution containing 5 ppm of Cr,†† 14 ppm of NaPA, 4 ppm of HTAC and varying amounts of PEI was stirred and shaken in an Erlenmeyer flask, and the residual concentration of Cr after flotation for 10 min was measured. The result is plotted against the amount of PEI in Fig. 7. It was confirmed that 0.5 g of PEI is sufficient to reduce Cr concentration from 5 ppm to below 0.5 ppm in a 500 cm^3 solution. Since neither the NaPA–HTAC–CrO_4^{2-} system nor the HTAC–CrO_4^{2-} system showed any perceptible flotation of Cr, PEI together with HTAC and NaPA is considered necessary to float Cr. A suggested model to explain the mechanism of adsorbing particle flotation of CrO_4^{2-} ions is shown in Fig. 8.

Flotation of PO_4^{3-} Ions. A 500 cm^3 solution containing 1 g of PEI, 14 ppm of NaPA, 8 ppm of HTAC and varying amount of PO_4^{3-} was treated as in the case of CrO_4^{2-} ion flotation. The residual concentration of P, determined by the measurement of PO_4^{3-} ion concentration, was plotted against the flotation time. Figure 9 shows results obtained for PO_4^{3-} solution containing 8.15 ppm of P. An abrupt decrease in the residual concentration of P within a minute is followed by a gradual decrease, the concentration becoming nearly constant after 20 min flotation. Figure 10 shows the floatability of P after 20 min flotation plotted against the initial concentration. The floatability does not reach 90% even in a dilute solution of PO_4^{3-} ions. Further experiment showed that 1 g of PEI is necessary to reduce the concentration of P from 3.26 ppm to 0.23 ppm in 500 cm^3 solution by 40 min flotation.

Rate of Fe^{3+} and Cu^{2+} Ion Flotation. While the use of NaPA and HTAC was found to be unfavorable, that of PAA and SDS was effective. Preliminary experiments showed 57 ppm of SDS and 10 ppm of

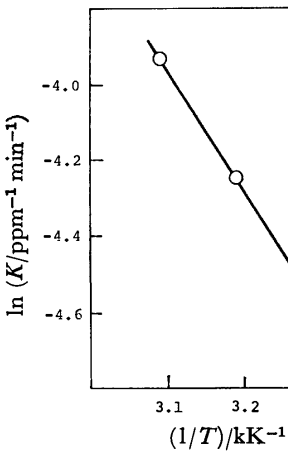

Fig. 6. Arrhenius plots.

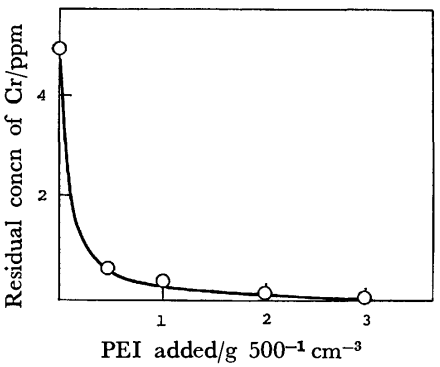

Fig. 7. Removal of Cr by flotation.

†† Ten times the maximum permissible concentration of Cr in environmental water.

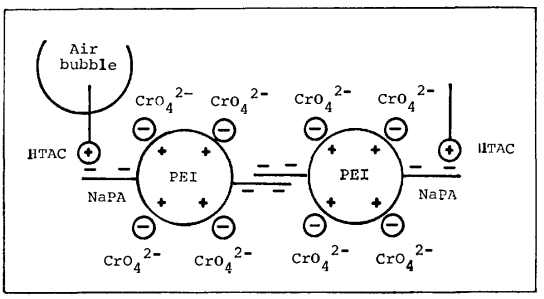

Fig. 8. Model of CrO_4^{2-} ion flotation by PEI, NaPA, and HTAC.

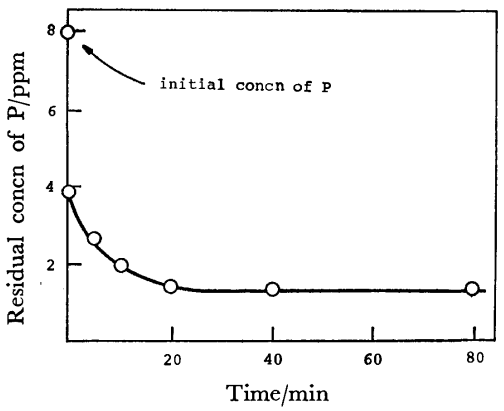

Fig. 9. Rate of flotation of P.

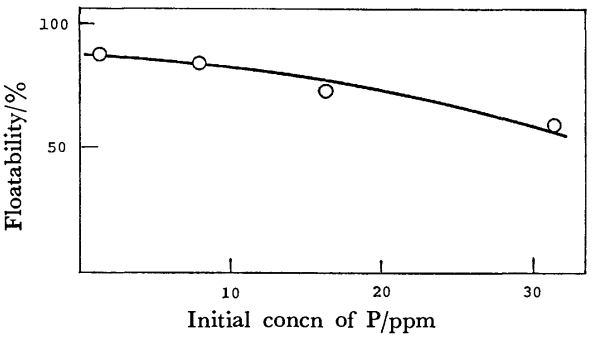

Fig. 10. Concentration *vs.* floatability of P.

PAA to be necessary.

For the measurement, a 20 cm^3 solution containing 1×10^{-4} mol dm^{-3} of Fe^{3+} ions at pH 8 or Cu^{2+} ions at pH 7, 0.06 g of PEI, 57 ppm of SDS and 10 ppm of PAA was gently shaken in a test tube for varying periods of time and then shaken vigorously for 3 s. PEI underwent flotation. The concentrations of Fe^{3+} and Cu^{2+} ions in the underlying layers after shaking were determined, floatability calculated being plotted against time. It was found that the maximum floatability reaches nearly 100% and 90% after 30 s of flotation for Fe^{3+} and Cu^{2+} ions, respectively.

Effect of pH *on* Fe^{3+} *and* Cu^{2+} *Ion Flotation.* The pH of a 20 cm^3 solution containing 1×10^{-4} mol dm^{-3} of Fe^{3+} or Cu^{2+} ions, 57 ppm of SDS, 10 ppm of PAA and 0.06 g of PEI was controlled by the addition of HCl and NaOH. The solution was gently shaken for 30 s, then vigorously for 3 s and PEI was floated. Fe^{3+} and Cu^{2+} ion concentrations were measured and the floatability calculated. The floatability is plotted against pH in Fig. 11. Flat maximum of floatability is attained in the pH range 5—9 for Fe^{3+} and 4—9 for Cu^{2+} ions. The pH dependence of floatability of Fe^{3+} and Cu^{2+} ions without the addition of PEI is also given for the sake of comparison. The floatability is far smaller than that of the system with PEI, showing the marked effect of PEI for the flotation

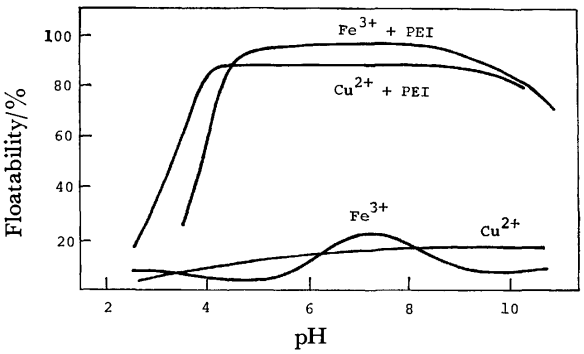

Fig. 11. pH *vs.* floatabilities of Fe^{3+} and Cu^{2+}.

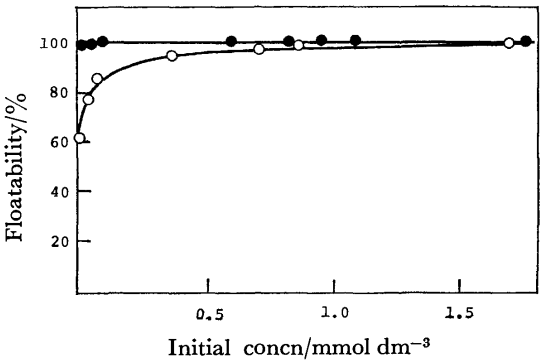

Fig. 12. Flotation of Fe^{3+} (●) and Cu^{2+} (○) ions.

of these ions.

Concentration Dependence of Fe^{3+} *and* Cu^{2+} *Ion Flotation.* A 20 cm^3 solution containing 57 ppm of SDS, 10 ppm of PAA, 0.06 g of PEI and varying amounts of Fe^{3+} ions at pH 8 or Cu^{2+} ions at pH 7 was gently shaken for 30 s, then vigorously for 3 s and PEI was floated. Fe^{3+} and Cu^{2+} ion concentrations of underlying layer were measured, the floatability calculated being plotted against the initial concentration of these ions (Fig. 12). Nearly 100% flotation was observed in wide concentration ranges of these ions, except for a lower concentration of Cu^{2+} ions where a decrease in floatability was observed. The decrease may be due to the hydrolytic formation of hydroxide which is neither adsorbed by PEI nor floated without PEI.

Studies of Thermochemical Hydrogen Production. VII. Vapor-Liquid Equilibrium for Sulfur Dioxide-Bromine-Hydrobromic Acid-Sulfuric Acid-Water System

Hiroshi Ishikawa,* Eiichi Ishii, Itsuki Uehara, and Masanori Nakane
Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received October 4, 1979)

In order to eliminate SO_2 from HBr gas produced by the reaction between SO_2, Br_2, and H_2O, vapor-liquid equilibrium measurements of the Br_2–H_2SO_4–H_2O system saturated with HBr have been made over a wide range of the constituent concentrations. Experiments were carried out in a semi-flow system at 25 °C under atmospheric pressure. The relative concentration of HBr saturated in the liquid phase decreased from 0.31 to 0.05 [mol]/[mol] with an increase in the relative H_2SO_4 concentration from 0.0 to 0.40 [mol]/[mol]. The solubility of Br_2, as defined by Henry's law constant, varied from 1.1 to *ca.* 150 atm/mol/mol with the above-mentioned decrease in the HBr concentration. The relation between the partial pressure of SO_2 in the gas phase and the composition of the liquid phase was found to be expressed by the following empirical formula: $P_{SO_2}=K\cdot C_{HBr}\cdot C_{H_2SO_4}/C_{Br_2}$, where the value of K is 8×10^{-4} when C is expressed as a relative molar concentration for each species in the liquid phase. The unconverted SO_2 can be effectively removed by bringing the effluent gases from the reactor into contact with a HBr-saturated aqueous solution containing an excess of Br_2.

The research and development of thermochemical hydrogen production from water by the iron-bromine family cycle has previously been carried out by the present authors.[1-3] One of the most feasible iron-bromine thermochemical cycles consists of the following four chemical reactions:

$$SO_2 + Br_2 + 2H_2O \longrightarrow H_2SO_4 + 2HBr \quad (1)$$

$$H_2SO_4 \longrightarrow H_2O + SO_2 + 1/2O_2 \quad (2)$$

$$3FeBr_2 + 4H_2O \longrightarrow Fe_3O_4 + 6HBr + H_2 \quad (3)$$

$$Fe_3O_4 + 8HBr \longrightarrow 3FeBr_2 + 4H_2O + Br_2 \quad (4)$$

Each reaction step has been investigated experimentally on a laboratory scale, and our earlier works have dealt with Reactions 2, 3, and 4.

The reaction between SO_2, Br_2, and H_2O is relatively well known as a usual method for preparing gaseous HBr in a laboratory-scale operation.[4] Recently, equilibrium determinations and reaction kinetic measurements have been carried out by Velzen *et al.*[5] during the course of the development of the electrochemical hybrid-water-splitting cycle, Mark-13, presented by Schuetz *et al.*[6] It has also been confirmed by the present authors that gaseous HBr and concentrated sulfuric acid could be prepared by using a packed column reactor.[7]

One of the problems to be solved, however, is the removal of the small quantity of unconverted SO_2 contained in the HBr gas produced in a flow reactor of SO_2 with Br_2 and H_2O. This is because the HBr gas produced by Reaction 2 is circulated for use in the bromination of Fe_3O_4, *i.e.*, Reaction 4, and the contamination of HBr by SO_2 would cause the formation of $FeSO_4$ as an undesirable side reaction. The continuous operation of the cycle would cause $FeSO_4$ to be accumulated as a by-product, and its thermal decomposition to Fe_2O_3 would be additionally required. On the other hand, the contamination of HBr by Br_2 matters little. The requirement for SO_2-free HBr gas seems to be fulfilled by bringing the effluent HBr gas from the reactor into contact with a HBr-saturated aqueous solution containing an excess of Br_2. Therefore, prior to the kinetic measurements, vapor-liquid equilibrium measurements of the HBr-saturated Br_2–H_2SO_4–H_2O system have been made over a wide range of constituent concentrations.

Some equilibrium data have already been reported by Velzen,[5] but they were confined to the liquid phase with a high concentration of H_2SO_4.

Experimental

The experiments were carried out in a semi-flow system at 25 °C under atmospheric pressure. The apparatus shown in Fig. 1 is composed of a cylindrical vessel 4 cm in diameter and 13 cm in height and equipped with a HBr-gas dispersion tube (ball filter No. 1), three PTFE tubes 1.0 mm in inner diameter for the addition of Br_2 and sulfuric acid and for the withdrawing of a liquid-phase sample, and a magnetic stirrer. The vessel was immersed in a water bath thermostatted at 25 °C.

After the liquid had been saturated with HBr, given quantities of Br_2 and 98 wt% sulfuric acid were introduced into the agitated liquid phase. Simultaneously, HBr gas was passed in at a rate of 50 ml/min. The outlet gas was led to a sampling cell of a derivative spectrophotometer (Yanagimoto Co. Ltd., Type UO-2) for the quantitative analysis of Br_2 as well as of the SO_2 evolved by the oxidation of HBr with H_2SO_4. Figure 2 shows examples of the variation in the Br_2 and SO_2 concentrations in the gas phase

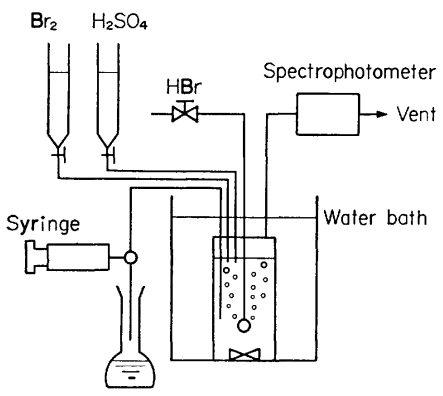

Fig. 1. Experimental appparatus for equilibrium determinations.

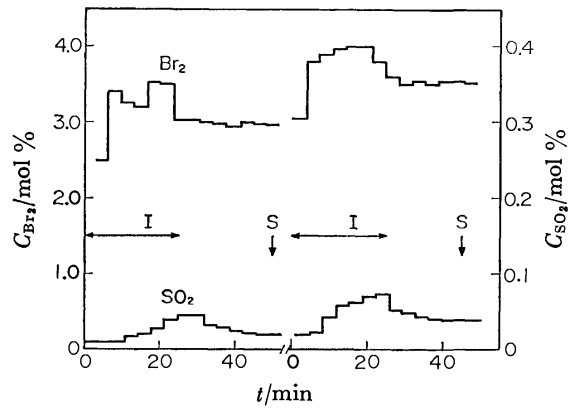

Fig. 2. Variation of Br_2 and SO_2 concentrations in gas phase.
I: Injection of sulfuric acid, S: sampling of liquid phase and determination of gas phase and liquid phase compositions.

monitored alternatively at regular intervals of 3.5 min. After about 20 min, when both the Br_2 and SO_2 concentrations had reached an equilibrium condition, the feed of the HBr gas was stopped, and the composition of the gas phase, considered to consist of only HBr, Br_2, and SO_2, was determined. At the same time, a sample of the liquid phase was taken out by using a syringe, and a weighed aliquot was diluted with a large excess of water in a volumetric flask. The composition of the liquid phase, consisting of HBr, H_2SO_4, Br_2, and H_2O, was calculated by determining the free Br_2, the total acidity, and the sulfuric-acid content. Thus, a given volume of the liquid-phase sample was taken and analyzed for Br_2 iodometrically, after which the total acid content was determined by titration with an NaOH solution. Another sample was analyzed for H_2SO_4 as follows: hydrogen bromide was oxidized by adding nitric acid. After the resulting Br_2 and the excess HNO_3 had been evaporated in a water bath, the remaining sulfuric acid was titrated. Then the HBr content was determined by subtracting the H_2SO_4 content from the total acid content.

Results and Discussion

Experiments were carried out on the liquid phase in concentrations of H_2SO_4 ranging from 0.0 to 80 wt% and in concentrations of Br_2 up to 10 wt%. The equilibrium data at 25 °C under atmospheric pressure are shown in Table 1. The content of SO_2 dissolved in the liquid phase was neglected, since the partial pressure of SO_2 evolved in the gas phase was very low. Moreover, the solubility of SO_2 in these liquid phases can be estimated to be small from the solubility data in sulfuric acid,[8] in a mixture of hydrochloric and sulfuric acids,[9] and in a mixture of hydrobromic and sulfuric acids.[5]

Solubility of HBr. The solubility data of the gaseous-phase components of the reaction mixture in the corresponding liquid phase are indispensable for the control of the mass balance of the HBr-producing system. Run No. 1 in Table 1 is an example carried out to determine the solubility of HBr in water. The numerical value obtained, 67.5 wt%, was a little higher than that of 66.0 wt% given by Haase *et al.*[10] The relation between the concentration of HBr and that of H_2SO_4 in the HBr-saturated liquid phase is shown in Fig. 3. The "relative concentration" is defined

a) Also present: liquid bromine insoluble in the liquid phase.

by [mol]/[mol] or [wt]/[wt], where [mol] and [wt] are the concentrations expressed in mol% and wt% respectively. The concentration of HBr saturated in the solution was reduced from 0.31 to 0.05 [mol]/[mol] with an increase in the H_2SO_4 concentration from 0.0 to 0.40 [mol]/[mol].

Henry's law constant (H) is also useful in defining the vapor-liquid equilibrium:

$$H = P_A/X_A \quad \text{(atm/wt/wt or atm/mol/mol)} \qquad (5)$$

where P_A is the partial pressure of a gas, A, in the gas phase and where X_A is the concentration of a species, A, in the liquid phase, expressed in a weight fraction or a mole fraction. Figure 4 shows the relation between Henry's law constant for HBr and the H_2SO_4 concentration in the liquid phase. The values

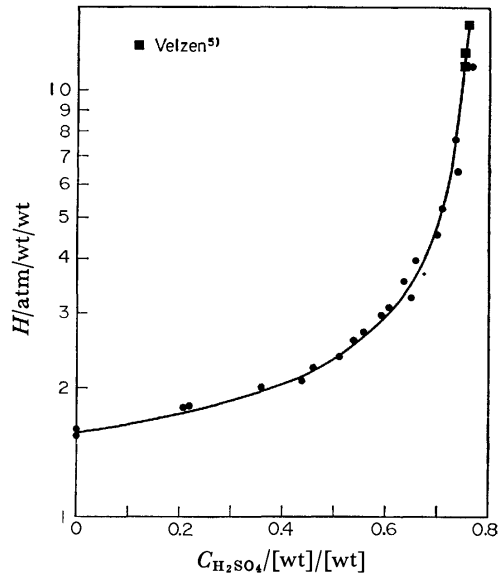

Fig. 4. Relation between Henry's law constant for HBr and concentration of H_2SO_4 in solution at 25 °C.

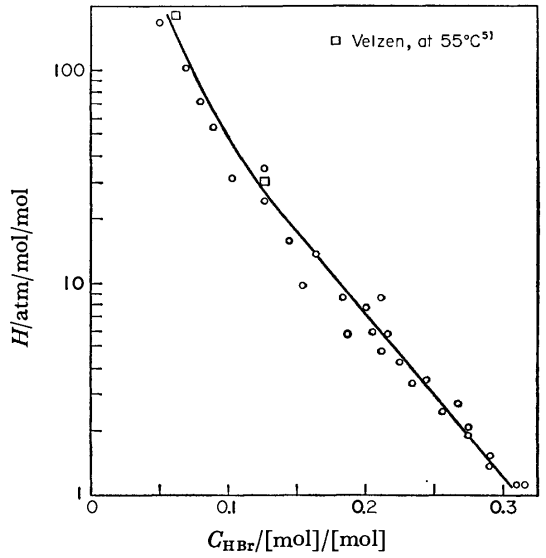

Fig. 5. Relation between Henry's law constant for Br_2 and concentration of HBr in solution at 25 °C.
$C_{H_2SO_4}$: 0.40→0.0 [mol]/[mol].

of H given by Velzen[5] in the high-H_2SO_4-concentration region were in fair agreement with our data. The presence of Br_2 up to a concentration of 10 wt% had little effect on the solubility of HBr.

Solubility of Br_2. The solubility of Br_2 in the liquid phase of the reaction mixture depends strongly on the HBr concentration. Figure 5 shows Henry's law constant for Br_2 as a function of the relative HBr concentrations, ranging from 0.05 to 0.31 [mol]/[mol]. The corresponding H_2SO_4 concentrations in the solution can be seen in Fig. 3 to range from 0.40 to 0.0 [mol]/[mol]. It has already been shown by Velzen[5] that the values of H at 23 °C and 55 °C are nearly identical; their values are also in good agreement with our data at 25 °C. It thus appears that the effect of the temperature was negligibly small.

Figure 6 gives the content of Br_2 saturated in the solution of the reaction mixture at a low HBr concentration, *i.e.*, at a high H_2SO_4 concentration. In this case, liquid Br_2 insoluble in the solution was also present, and the partial pressure of Br_2 in the gas phase was equal to that of liquid Br_2, *i.e.*, 0.28 atm at 25 °C, as shown by Run No. 10 in Table 1.

Partial Pressure of SO_2 in the Gas Phase. Since only the equilibrium partial pressure of SO_2 in the gas phase was required for the reaction kinetic measurements and the succeeding design of a reactor unit, the concentration of SO_2 in the solution of the reaction mixture was not determined. The partial pressure of SO_2 evolved in the gas phase in equilibrium with the liquid phase was strongly influenced by both the H_2SO_4 and Br_2 concentrations. It was found that the relation between the partial pressure of SO_2 in the gas phase and the composition of the liquid phase could be expressed by the following empirical formula:

$$P_{SO_2} = K \cdot \frac{C_{HBr} \cdot C_{H_2SO_4}}{C_{Br_2}} \qquad (6)$$

where the value of K was *ca.* 7×10^{-4} when C was expressed as a weight fraction or a relative weight concentration for each species in the liquid phase. The validity of this formula (6) is shown in Fig. 7. When C was defined by a mole fraction or a relative molar concentration for each species, the value of K was *ca.* 8×10^{-4}. Figure 8 shows the calculated

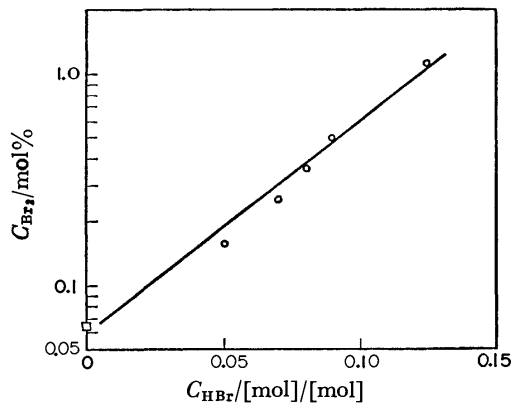

Fig. 6. Solubility of Br_2 in HBr saturated H_2SO_4-H_2O mixtures at 25 °C.
$C_{H_2SO_4}$: 0.43→0.34 [mol]/[mol].

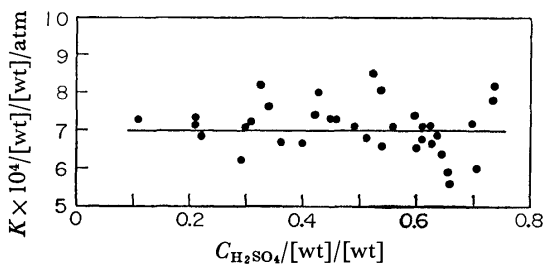

Fig. 7. Validity of empirical formula (6).

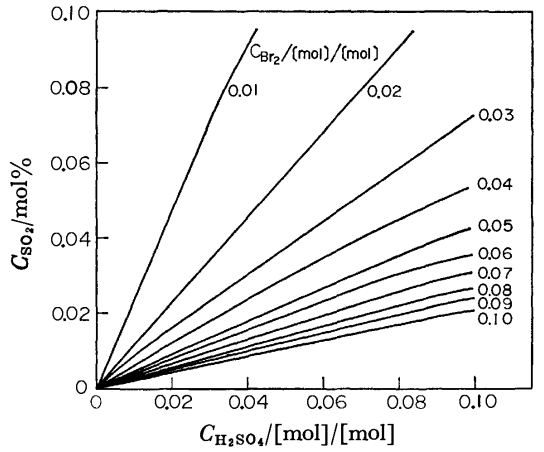

Fig. 8. Calculated equilibrium SO_2 concentration in gas phase as a function of H_2SO_4 and Br_2 concentrations in solution.

equilibrium SO_2 concentration in the gas phase as a function of the relative H_2SO_4 and Br_2 concentrations in the liquid phase.

It can be seen from Fig. 8 that, when HBr contaminated by SO_2 is placed in contact with a HBr saturated aqueous solution of H_2SO_4 and Br_2 at relative concentrations of, for example, 0.03 and 0.07 [mol]/[mol] respectively, the SO_2 content of the gas mixture in equilibrium is reduced to 0.01 mol%. The corresponding relative HBr concentration in the solution obtainable from Fig. 3 was 0.30 [mol]/[mol]; the value of H for Br_2 also obtainable from Fig. 5, was 1.2 atm/mol/mol. Therefore, the Br_2 concentration in the gas phase is expected to amount to 5.9 mol%, since the Br_2 concentration in the solution is calculated to be 4.9 mol%.

Conclusion

As a part of research and development of the thermochemical hydrogen production from water by the iron-bromine family cycle, the vapor-liquid equilibrium for the reaction of SO_2 with Br_2 and H_2O has been investigated. It could be concluded that the development of a continuously HBr-producing process was feasible by combining a packed column reactor with an absorber of unconverted SO_2. The absorbent liquid can be fed into the reactor as a reaction agent when it was condensed into concentrated H_2SO_4. Studies of the reaction kinetics are under way in order to design a practical unit.

Studies on the Preparation of Cuprous Oxide. VIII. A Spectrophotometric Study of Halogenocopper(I) Complexes in Aqueous 5 M $Na(ClO_4)$ Solutions

Kazuhiko SUGASAKA* and Ayako FUJII

Government Industrial Research Institute, Shikoku, Hananomiya-cho 2-3-3, Takamatsu 761

(Received November 12, 1979)

The complex formation of copper(I) with bromide and iodide ions in aqueous 5 M (1 M = 1 mol dm^{-3}) $Na(ClO_4)$ solutions was studied spectrophotometrically over a pH range from acidic to alkaline. Over the concentration range of 0.05—5 M bromide ions in acidic solutions, the $CuBr_2^-$ and $CuBr_3^{2-}$ complexes were found. On the other hand, in the iodide system the CuI_2^-, CuI_3^{2-} complexes and a higher complex were found under the same experimental conditions, although the composition and the formation constant of the last complex could not be determined in this study. The equilibrium constants for the reactions, $CuX_2^- + X^- = CuX_3^{2-}$, were 13 and 1.6 for the bromide and iodide complexes respectively. A hydrolyzed species of copper(I), $Cu(OH)_2^-$, was found in an alkaline solution of the two systems. The formation constants, $\beta_{-22} = [Cu(OH)_2^-][X^-]^2/[CuX_2^-][OH^-]^2$, were evaluated as follows: $\beta_{-22} = (10.0 \pm 0.7) \times 10^7$ ($[Br^-] < 2$ M), $(2.6 \pm 0.7) \times 10^7$ ($[Br^-] = 3$ M), $(1.7 \pm 0.7) \times 10^7$ ($[Br^-] = 4$ M) in the bromide solutions, $(4.0 \pm 0.4) \times 10^3$ ($[I^-] < 2$ M), $(2.5 \pm 0.4) \times 10^3$ ($[I^-] = 3$ M), $(2.2 \pm 0.4) \times 10^3$ ($[I^-] = 4$ M) in the iodide solutions.

During the course of an investigation of copper(I) oxide by the hydrolysis of copper(I) halides, it was shown that the color of copper(I) oxide changed from yellow to red depending upon the concentration of halide ions in solutions.[1,2] For the precipitation of copper(I) oxide by the hydrolysis of copper(I) iodide crystals, the dissolution of the crystals is the rate-determining step in water, whereas the crystal growth of copper(I) oxide is the rate-determining step in a concentrated sodium iodide solution.[3] Based on these observations, we aimed at studying the equilibria of the formation of copper(I) halide complexes in aqueous solutions in order to obtain information on reactions between copper(I) and halide ions.

Bodländer and Storbeck[4,5] suggested the formation of the CuX_2^- and CuX_3^{2-} complexes (X denotes halide ions) on the basis of solubility measurements of copper(I) halides in sodium halide solutions. Fromherz and Menschick[6] and Doehlemann and Fromherz[7] found that a concentrated lithium bromide solution containing both copper(I) and copper(II) showed absorption maxima at 272, 338, and 512 nm. Sukhova *et al.*[8] reported that a copper(I) chloride solution has λ_{max} at 200, 235, and 273 nm and broad bands at 300—400 and 1200—2000 nm, analogous to the absorption maxima of copper(I) bromide and iodide solutions. The formation constants of copper(I) bromo-[9] and iodo-complexes[10] have been reported in the basis of solubility measurements.

In spite of the existence of many results in the literature, investigations of the complex formation of copper(I) ions with halide ions have been restricted to acidic media.

In a previous paper[11] we dealt with the complex formation of copper(I) in an aqueous 5 M Na(Cl, ClO_4) solution and found that $CuCl_2^-$ and $CuCl_3^{2-}$ complexes were formed in acidic media, together with these mixed halogeno–hydroxo complexes, $CuClOH^-$, $CuCl_2OH^{2-}$, and $CuCl(OH)_2^{2-}$, in alkaline media. In this paper we wish to describe the complex formation of copper(I) ions with bromide and iodide ions in 5 M $Na(ClO_4)$ aqueous solutions over a wide pH range, the total anionic concentration being kept constant.

Experimental

Reagents. Copper(I) bromide was recrystallized according to a procedure described ealier.[11] Copper(I) iodide was purified in the following way: reagent-grade crystals were dissolved into a saturated sodium iodide solution, and then after filtration, the solution was diluted with water. The precipitates thus formed by dilution were washed with water and then with acetic acid before being dried at 130 °C under a nitrogen atmosphere.[12] The stock solutions of copper(I) bromide and iodide were prepared by dissolving copper(I) bromide and iodide crystals into 0.5 M sodium bromide and sodium iodide solutions respectively, both types of solutions containing sufficient amounts of sodium perchlorate and perchloric acid to maintain the total anionic concentration and pH at 5 M and 1 respectively. Since the stock solutions contained pieces of pure copper wire (99.99% purity) for reducing the trace amount of copper(II) ions, the concentrations of copper(II) ions in the bromide and iodide solutions were estimated to be less than 8×10^{-8} M and 3.6×10^{-11} M respectively; these values were calculated on the basis of the equilibrium constants of copper(I) and (II) bromo- and iodo-complexes reported in the literature.[13] Sample solutions were prepared from the stock solutions; sodium bromide, sodium iodide, and sodium hydroxide solutions. The sodium bromide, sodium iodide, sodium perchlorate, and sodium hydroxide were of a reagent grade. The preparation of sample solutions and measurements were carried out under an atmosphere of nitrogen.

Spectrophotometric Measurements. These were run with a Hitachi EPS-3T spectrophotometer. The absorption spectra of the sample solutions were obtained using 1-, 2-, 10-, and 20-mm cells at 25 °C by referring to blank solutions which were the same in composition with the samples except for the copper(I) ions. Since the amount of copper(II) ions in the sample solutions prepared by the dilution of the stock solutions was estimated to be less than 2×10^{-9} M, and since the molar extinction coefficients of the copper (II) bromide complexes were estimated to be about 10^2—10^3 mol^{-1} dm^3 cm^{-1} over the wavelength region of 260—300 nm,[14–16] the influence of copper(II) ions on the measurements in the bromide solutions was neglected. Although no spectrophotometric data for copper(II) iodide complexes have been given in the literature, the absorption due to copper(II)–iodide complexes was also neglected because of the much lower concentration of copper(II) ions in the iodide

solutions than in the bromide solutions. When the sample solution came in contact with air, the solution turned yellow within 20 min. Therefore, an effort was made to avoid the contact of the sample with air by the introduction of nitrogen gas into the cells and to finish the measurements within a few minutes.

Determination of Concentrations of Ions in the Solutions. The copper(I) ions in the stock solutions were determined by atomic-absorption spectrometry. The concentration of halide ions was determined by means of argentometric titration. Since the concentration of the halide ions in the samples was in a large excess compared with that of the copper(I) ions, the concentration of the free halide ions [X^-] was assumed to be equal to the total concentration of the sodium halide in the solutions.

Results and Discussion

Spectra of Copper(I) Halide Solutions. Absorption spectra of copper(I) halide solutions containing various amounts of sodium halide and sodium hydroxide are shown in Figs. 1 and 2. In the absorption spectra of copper(I) bromide in acidic solutions, a maximum absorbance appeared at 278 nm (Fig. 1). The absorbance at 278 nm increased as the concentration of bromide ions increased. When the concentration of hydroxide ions increased, the absorbance at 278 nm decreased, while the absorbance at 240 nm increased.

The absorption maximum appeared at 274—285 nm in the copper(I) iodide solutions in acidic media, depending upon the concentration of iodide ions, as is shown in Fig. 2. The absorption at a wavelength shorter than 270 nm was not measured because the intense absorption due to the iodide ions overlapped with that of the complexes at that wavelength. The absorbance at these wavelengths decreased with the concentration of hydroxide ions.

Complex Formation in Acidic Media. The apparent molar extinction coefficient, $\bar{\varepsilon}=E/[\mathrm{Cu(I)}]_{\mathrm{TOT}}$, at 278 nm is shown in Fig. 3, where E denotes the absorbance

$-\log[OH^-]=8$—12, $[Cu(I)]_{TOT}/10^{-4}$ M=0.2 : ○, 0.7 : □, 2.0 : △, 6.6 : ▽.

of a solution for a unit of the optical pathlength. The plot was dependent upon the concentration of bromide ions, but independent of the total copper(I) ions. These results show that no polynuclear complex of copper(I) ions was formed in the solutions. The absorbance at 235 nm remained practically unchanged when the concentrations of both the copper(I) and bromide ions were varied. Therefore, the data were not used for analysis.

Since copper(I) halides hardly dissolve in water, but dissolve only in solutions containing an excess amount of the halide ions, the species in the solution may have the composition of $CuX_m^{(m-1)-}$ (the possibility of the formation of a polynuclear complex is excluded). Therefore, the CuX_2^- complex may be formed in the first stage of complex formation in a halide solution and then higher complexes may be formed by the further addition of halide ions to the CuX_2^- ion:

$$CuX(s) + X^- = CuX_2^- \quad (1)$$

$$CuX_2^- + nX^- = CuX_{2+n}^{(n+1)-}. \quad (2)$$

Since we used solutions without solid CuX, the equilibrium constant of the first reaction could not be determined though the constants of Reaction 2 were determined.

From the material balance of copper(I) and the absorbance, E, per unit of the path, the following equation is derived:

$$\bar{\varepsilon} = \frac{E}{[Cu(I)_{TOT}]} = \frac{\varepsilon_0 + \sum_n \varepsilon_n \beta_n [X^-]^n}{1 + \sum_n \beta_n [X^-]^n}, \quad (3)$$

as long as the ligand shows no absorbance over the entire wavelength range studied or as long as the absorbance due to the ligand has been subtracted as a blank in the measurement of ε. β_n is defined as $\beta_n = [CuX_{2+n}^{(n+1)-}]/[CuX_2^-][X^-]^n$. The molar extinction coefficient of the $CuX_{2+n}^{(n+1)-}$ complex is denoted as ε_n. The values of ε_0, ε_n, β_n, and n may be determined by comparing the plots of log ε *vs.* log $[X^-]$ with a family of the normalized curves, $y = \log\{x^n/(1+x^n)\} = f(\log x)$, because Eq. 3 may be rearranged as:

$$\log(\bar{\varepsilon} - \varepsilon_0) = \log(\varepsilon_n - \varepsilon_0) + \log \frac{\beta_n [X^-]^n}{1 + \beta_n [X^-]^n}, \quad (4)$$

by assuming that only one complex, $CuX_{2+n}^{(n+1)-}$, besides the CuX_2^- complex, is present in the solution. The plots of log $\bar{\varepsilon}$ at 278 nm against log $[Br^-]$ (Fig. 2) fit a normalized curve, $y = \log\{x/(1+x)\}$; thus, $n=1$, the molar extinction coefficient of the $CuBr_2^-$ complex, $\varepsilon_0 = 0$, $\varepsilon_1 = 8.5 \times 10^3$, and $\beta_1 = 13$ were obtained. The values were refined by means of a least-squares calculation with an electronic computer; the values are summarized in Table 1.

For the iodide system, on the other hand, the apparent molar extinction coefficient, $\bar{\varepsilon}$, at 274 nm first increased and then sharply decreased with an increase in the concentration of iodide ions (Fig. 4). This fact obviously showed that at least two complexes, one with a larger value and the other with a much smaller value of ε than ε_0, must exist in the solution. Since the ε's at both 274 and 285 nm were independent of the concentration of the copper(I) ions, the formation of any polynuclear complex of copper(I) ions was ruled out.

At first, the formation of two complexes, $CuI_{2+l}^{(l+1)-}$ and $CuI_{2+l+m}^{(l+m-1)-}$, besides the CuI_2^- complex, was assumed. The apparent molar extinction coefficient, $\bar{\varepsilon}$, of the solution may thus be given by Eq. 5:

$$\bar{\varepsilon} = \frac{\varepsilon_0 + \varepsilon_l \beta_l [I^-]^l + \varepsilon_{l+m} \beta_{l+m} [I^-]^{l+m}}{1 + \beta_l [I^-]^l + \beta_{l+m} [I^-]^{l+m}}. \quad (5)$$

Since the $\bar{\varepsilon}$ values at 274 nm steeply decreased at about $[I^-] \simeq 3$ M, we assume that the second species may be formed in a solution of $[I^-] \gtrsim 3$ M, and that, in the concentration region of $[I^-]$ lower than 3 M, the equilibrium between CuI_2^- and the first complex, $CuI_{2+l}^{(l+1)-}$ may be established, where the molar extinction coefficient of the solution may approximately be given as follows:

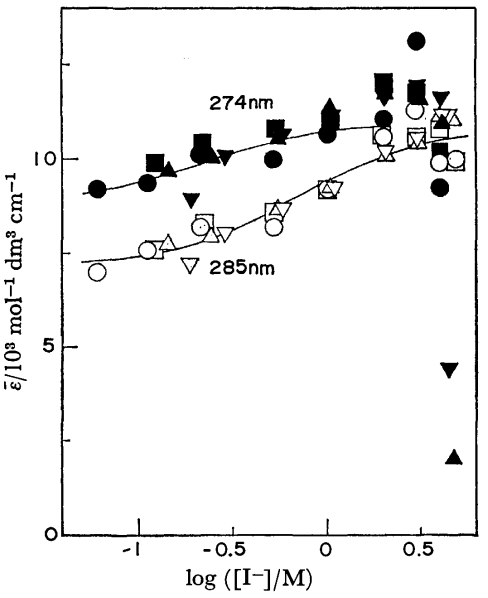

Fig. 4. The plots of $\bar{\varepsilon}$ at 274 and 285 nm *vs.* log $[I^-]$. $-\log[OH^-] = 8$—12, $[Cu(I)]_{TOT}/10^{-4}$ M = 0.6 : ○, 1.3 : □, 2.4 : △, 4.8 : ▽.

$$\bar{\varepsilon} = \frac{\varepsilon_0 + \varepsilon_l \beta_l [I^-]^l}{1 + \beta_1 [I^-]^l}. \quad (6)$$

A curve-fitting method may be applied to the plot of log $\bar{\varepsilon}$ *vs.* log $[I^-]$ in order to determine ε_0, ε_l, and β_l, as well as l, by comparing the plots with the normalized curve, $y = \log\{x^n/(1+x^n)\}$, at various n's, or by comparing $\bar{\varepsilon}$ *vs.* log $[I^-]$ with a family of normalized curves, $u = \log\{a/(1+v^n)\}$, with various sets of a and n. In both the curve-fitting procedures, the data fit the curve of $n=1$; thus, the value of l was determined to be unity. The values estimated by the curve-fitting method were as follows: at 274 nm, $\varepsilon_0 = 9.4 \times 10^3$, $\varepsilon_1 = 1.3 \times 10^4$, and log $\beta_1 = 0.22$ ($\beta_1 = 1.7$); at 285 nm, $\varepsilon_0 = 7.0 \times 10^3$, $\varepsilon_1 = 1.1 \times 10^4$, and log $\beta_1 = 0.18$ ($\beta_1 = 1.5$).

The variation in $\bar{\varepsilon}$ at 274 nm in the $[I^-] > 3$ M region was so steep that no reasonable assumption to explain the data was given; the $l+m$ value must, though, be very large ($l+m \gg 2$). However, since the data at 285 nm showed no clear indication for the formation of such a high complex, we concluded that the $l+m$ value was not so large, but that the ionic-medium principle to keep constant the activity coefficients of all reacting species did not hold in the region of $[I^-] >$ 3—5 M. Therefore, we did not use these data for the determination of the formation constant of the second complex, $CuI_{2+l+m}^{(l+m-1)-}$. The $l+m$ value was also not determined for this complex.

The formation constant, β_1, and the molar extinction coefficients, ε_0 and ε_1, at 274 and 285 nm were refined by means of a least-squares calculation with the aid of an electronic computer. The final results are summarized in Table 1 together with the results for the copper(I) chloro complexes.[11]

Halogenocopper(I) Complexes in Alkaline Solutions. The absorbance of a copper(I) bromide solution at 278 nm decreased when sodium hydroxide was added

to the solution (see Fig. 1). Typical examples of the change in $\bar{\varepsilon}$ at 278 nm of copper(I) bromide solutions with the concentration of the hydroxide ions are shown in Fig. 5. Patterns similar to those of bromide system were obtained for the iodide system at 285 nm; they are shown in Fig. 6. It is obvious from the plots that no polynuclear complex was formed,

Table 1. The molar extinction coefficients and the formation constants of the copper(I) halide complexes

Species	λ_{max} (nm)	ε (mol^{-1} dm^3 cm^{-1})	β
$CuBr_2^-$	278	0.0	—
$CuBr_3^{2-}$	278	$(8.3\pm0.1)\times10^3$	13.0 ± 0.4
CnI_2^-	274	$(9.0\pm0.4)\times10^3$	—
	285	$(7.0\pm0.1)\times10^3$	
CuI_3^{2-}	274	$(1.2\pm0.1)\times10^4$	1.6 ± 0.1
	285	$(10.0\pm0.2)\times10^3$	
$CuCl_2^-$	233	$(1.45\pm0.1)\times10^3$	—[11]
$CuCl_3^{2-}$	273	$(3.33\pm0.1)\times10^3$	1.95[11]

because $\bar{\varepsilon}$ was independent of the concentration of the copper(I) ions in both the bromide and iodide solutions. Since the curves depend on the concentration of the halide ions, we assumed the formation of complexes with the general formula of $CuX_{2+p}(OH)_q^{(p+q-1)-}$ in the alkaline solutions. The formation constant, β_{pq}, of the complex is defined as follows:

$$CuX_2^- + pX^- + qOH^- = CuX_{2+p}(OH)_q^{(p+q-1)-} \quad (7)$$

$$\beta_{pq} = [CuX_{2+p}(OH)_q^{(p+q-1)-}]/[CuX_2^-][X^-]^p[OH^-]^q. \quad (8)$$

The material balance for copper(I) ions may be represented by the following equation:

$$[Cu(I)]_{TOT} = [CuX_2^-] + \sum_n \beta_n[CuX_2^-][X^-]^n + \sum_p \sum_q \beta_{pq}[CuX_2^-][X^-]^p[OH^-]^q, \quad (9)$$

where p is either positive, zero, or negative, and where q is zero or a positive integer. The apparent molar extinction coefficient, $\bar{\varepsilon}$, is given as follows:

$$\bar{\varepsilon} = \frac{\varepsilon_0 + \sum_n \varepsilon_n\beta_n[X^-]^n + \sum_p \sum_q \varepsilon_{pq}\beta_{pq}[X^-]^p[OH^-]^q}{1 + \sum_n \beta_n[X^-]^n + \sum_p \sum_q \beta_{pq}[X^-]^p[OH^-]^q}. \quad (10)$$

$^*\beta_{pq}$ symbolizes a conditional constant, $\beta_{pq}[X^-]^p$, at a constant $[X^-]$; here $[X^-]$ is approximated to $[X^-]_{TOT}$. By inserting $^*\beta_{pq}$ into Eq. 10 and rearranging it, we obtain:

$$\frac{\bar{\varepsilon}(1 + \sum_n {}^*\beta_n) - (\varepsilon_0 + \sum_n \varepsilon_n {}^*\beta_n)}{\varepsilon_{pq} - \bar{\varepsilon}} = {}^*\beta_{pq}[OH^-]^q. \quad (11)$$

Since $\bar{\varepsilon}$ decreased with the increase in the concentration of hydroxide ions and approached zero, ε_{pq} may be assumed to be zero as a first approximation.

One function, F_1 is defined as follows:

$$F_1 = \log\left\{\frac{(\varepsilon_0 - \sum_n \varepsilon_n {}^*\beta_n) - \bar{\varepsilon}(1 + \sum_n {}^*\beta_n)}{\bar{\varepsilon}}\right\} = \log {}^*\beta_{pq} + q \log [OH^-]. \quad (12)$$

The plots of F_1 *vs.* log $[OH^-]$ are shown in Figs. 7 and 8 for the bromide and iodide systems respectively. Both plots gave straight lines with a slope of 2: thus, q=2 was estimated for both the bromide and iodide solutions. Therefore, Eq. 10 is rewritten as follows:

$$\bar{\varepsilon} = \frac{\varepsilon_0 + \sum_n \varepsilon_n {}^*\beta_n + \sum_p \varepsilon_{p2} {}^*\beta_{p2}[OH^-]^2}{1 + \sum_n {}^*\beta_n + \sum_p {}^*\beta_{p2}[OH^-]^2}. \quad (13)$$

Another function, F_2 is defined, after the rearrangement of Eq. 13, as follows:

$$F_2 = \{\bar{\varepsilon}(1 + \sum_n {}^*\beta_n) - (\varepsilon_0 + \sum_n \varepsilon_n {}^*\beta_n)\}[OH^-]^2 = \sum_p \varepsilon_{p2} {}^*\beta_{p2} - \bar{\varepsilon}_p {}^*\beta_{p2}. \quad (14)$$

Since F_2 is experimentally determinable at a given $[X^-]$, F_2 can be plotted against $\bar{\varepsilon}$. The plots are shown in Figs. 9 and 10 for the bromide and iodide systems respectively. Although the data are scattered to some extent, straight lines may be drawn through the points, as may be seen in the figures. In both plots, the lines pass a point near the original point of the coordinate: therefore, ε_{p2} may be zero or small compared with ε_0 and ε_n. The slopes of the lines,

$\sum_p {}^*\beta_{p2}$, thus obtained are plotted against log [X⁻] in Fig. 11. For both the bromide and iodide systems, $p=-2$ was found. Therefore, we concluded that, in the bromide and iodide solutions, $Cu(OH)_2^-$ was produced in alkaline solutions.

The formation constant of the complex proposed here was refined by means of a least-squares calculation: the final results are tabulated in Table 2, as are the values for the copper(I) chloro–hydroxo mixed complexes.[11] The solid lines in Figs. 5 and 6 show the curves calculated by using the constants finally obtained. In the solutions containing halide ions larger than 3 M, the formation constants obtained were slightly different from those found in the solutions with concentrations of the halide ions lower than 3 M;

TABLE 2. THE FORMATION CONSTANTS OF THE DIHYROXOCOPPER(I) COMPLEX, $Cu(OH)_2^-$

Solution	$[X^-]_{TOT}$ (M)	β_{pq}
Bromide	4	$(1.7\pm0.1)\times10^7$
	3	$(2.6\pm0.1)\times10^7$
	2–1	$(10.0\pm0.1)\times10^7$
Iodide	4	$(2.2\pm0.2)\times10^3$
	3	$(2.5\pm0.2)\times10^3$
	2–0.5	$(4.0\pm0.1)\times10^3$
Chloride[11]	$CuClOH^-$	$(1.1\pm0.1)\times10^4$
	$CuCl_2OH^{2-}$	$(4.1\pm0.3)\times10^3$
	$CuCl(OH)_2^{2-}$	$(3.8\pm0.1)\times10^6$

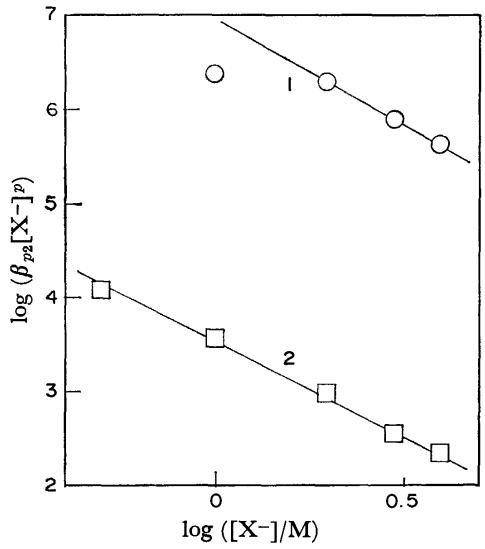

Fig. 11. Relationship between log (β_{p2}[X⁻]ᵖ) and log [X⁻].
1 : Bromide solutions, 2: iodide solutions.

this was due to the change in the property of the ionic media by the introduction of a large amount of the halide ions to the sodium perchlorate medium.

We have already reported in a previous paper[11] that the mixed halogeno–hydroxo complexes of copper(I) were found in alkaline solutions of the chloride system, whereas the dihydroxocopper(I) complex was not so found. In the bromide and iodide systems, the mixed halogeno–hydroxo complexes were not found, only the dihydroxocopper(I) complex was found in alkaline media.

The following formation constants of the $CuX_n^{(n-1)-}$ complexes have been reported in the literatures: for the chloride system, $CuCl_2^- + Cl^- = CuCl_3^{2-}$: log K_3= 0.29±0.04 by spectrophotometry;[17] for the bromide system, $CuBr_2^- + Br^- = CuBr_3^{2-}$: $K_3 = 10.2 \times 0.9\ M^{-1}$,[9] and for the iodide system, $[CuI_2^-]/[I^-] = (0.91—1.13) \times 10^{-3}$, $[CuI_3^{2-}]/[I^-]^2 = (4.32—5.9) \times 10^{-3}$. The results obtained in our experiments for the chloride and bromide systems are the same or nearly the same as the values in literature, but for the iodide system ones is smaller than the value in the literature.

The formation constant of the CuX_3^{2-} complex is smaller in the iodide system than in the bromide system. At a glance, this trend seems to be in the direction opposite to that expected from the hard-and-soft acid-and-bases concept. However, these results may be well explained on the HSAB basis as follows: a very soft acid the Cu^+ ion, may combine with a very soft base, I^-, to form the fairly stable CuI_2^- complex, which may have a linear structure; hence, the CuI_2^- complex may not be deformed by the insertion of the next iodide ion into the complex. On the other hand, the $CuBr_2^-$ complex may be less than the CuI_2^- complex, thus allowing for the addition of the third bromide ion to the complex to form the $CuBr_3^{2-}$ complex.

The much smaller formation constant of the $Cu(OH)_2^-$ complex in the iodide system than in the bromide system may be interpreted much like the fact that the stable CuI_3^{2-} complex (the overall formation constant of the CuI_3^{2-} may be large than that of the $CuBr_3^{2-}$, according to the HSAB concept) is not easily decomposed to form the $Cu(OH)_2^-$ complex with hydroxide ions by releasing the iodide ions within the complex.

It is thought that the difference in the behavior of the complex formation of copper(I) among the three halides may be related to the precipitation process of copper(I) oxide by the hydrolysis of copper(I) halide. In the precipitation of the less-soluble salt, the size of the nucleus depends on the ratio of the concentration of the supersaturation to the saturation of the solute.[18] As the halogeno complexes of copper(I) are stable in a concentrated solution of sodium halide and are much more stable in an iodide solution than in other halide solutions, the ratio of the concentration of the supersaturation to the saturation of copper(I) oxide is kept low: that is, large crystals of copper(I) oxide are easily precipitated in a concentrated solution of sodium halide, especially in an iodide solution.

The authors wish to express their gratitude to Professor Hitoshi Ohtaki of the Tokyo Institute of Technology at Nagatsuda for his guidance and helpful discussions.

The Raman Spectra of Cobalt(III) Complexes. I. Differentiation between *cis* and *trans* Isomers of Bis(ethylenediamine)cobalt(III) Complexes

Kan KANAMORI* and Kiyoyasu KAWAI

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received November 15, 1979)

The Raman spectra of bis(ethylenediamine)cobalt(III) complexes have been studied with a view toward differentiating between the *cis* and *trans* configurations. It is shown that a correlation can be made between the configurations of the complexes and the intensity of the band due to the chelate-ring-deformation vibration, δ(cycle). Thus, *trans* isomers exhibit a strong and sharp band near 270 cm^{-1} due to this mode, while *cis* isomers exhibit no intense band at this frequency.

Several attempts have been made, with varying degrees of success, to correlate the configurations of bis(ethylenediamine)cobalt(III) complexes with the infrared spectra. Merritt and Wiberley[1] have suggested that a differentiation between *cis* and *trans* isomers of bis(ethylenediamine)cobalt(III) complexes may be made on the basis of the shift of the band in the 1500—1600 cm^{-1} region to lower frequencies from a *cis* to a *trans* configuration. Chamberlain and Bailar[2] have proposed a means for differentiating the *cis* and *trans* isomers by the number of bands in the 1120—1150 cm^{-1} region. Morris and Busch[3] and Baldwin[4] have attempted to correlate the splitting of the 1600 cm^{-1} and the 870—900 cm^{-1} bands respectively with the *cis* configuration. Hughes and McWhinnie[5] have suggested that a differentiation between the *cis* and *trans* isomers may be made on the basis of the complexity of the spectra in the 500—600 cm^{-1} region.

The present study was undertaken to correlate the configuration of the bis(ethylenediamine)cobalt(III) complex with the Raman spectrum. All the previous infrared studies, with the exception of the one by Hughes and McWhinnie,[5] have been concerned with the intra-ligand vibrations. The difference between the symmetries of the *cis* and *trans* isomers of bis(ethylenediamine)cobalt(III) complexes should, however, be reflected more sensitively in the skeletal vibrations than in the intra-ligand vibrations. It was thought worthwhile to study the metal-ligand vibrations of the *cis* and *trans* isomers, and Raman spectroscopy is suitable for this purpose. The Raman spectra were measured for the complexes whose geometrical configurations has already been determined, and on the basis of the observed Raman spectral difference between the *cis* and *trans* isomers, the Raman spectral criterion for differentiating the isomers was established. This criterion was then applied to the $[CoX(SO_3)(en)_2]$-type complexes ($X=N_3^-$, NCS^-, NH_3) obtained in the present work.

Experimental

Preparation. cis-$[Co(NCS)(SO_3)(en)_2]\cdot 0.5H_2O$: *trans*-$[CoCl(SO_3)(en)_2]$ (6 g) and NaSCN (1.7 g) were dissolved in 50 cm^3 of water, and the mixture was heated on a water bath for 3 h. The resulting mixture was cooled to room temperature. Then pale brown needles (*trans*-$[Co(NCS)(SO_3)(en)_2]$) were filtered off, and the filtrate was left standing overnight at room temperature. Orange-yellow leaflet crystals were deposited; they were then filtered off and recrystallized from hot water. Absorp. max. $10^{-3}\sigma$/cm^{-1} (log ε): 21.5 (2.44), *ca.* 29 sh (2.9), 35.0 (4.12). Found: C, 18.22; H, 5.29; N, 21.44%. Calcd for $[Co(NCS)(SO_3)(C_2H_8N_2)_2]\cdot 0.5H_2O$: C, 18.41; H, 5.25; N, 21.46%.

trans-$[Co(N_3)(SO_3)(en)_2]\cdot 0.5H_2O$: *trans*-$[Co(SO_3)(en)_2(H_2O)]ClO_4$ (6 g) was dissolved in 100 cm^3 of water, and then NaN_3 (5 g) was added. On occasional heating at 40 °C, the mixture was stirred for 1 h. On cooling and the addition of ethanol, a reddish-brown powder appeared; this was filtered off and dried. Absorp. max. $10^{-3}\sigma/cm^{-1}$ (log ε): 21.2 (2.55), *ca.* 30 sh (3.5), 36.5 (4.68). Found: C, 15.40; H, 5.54; N, 31.04%. Calcd for $[Co(N_3)(SO_3)(C_2H_8N_2)_2]\cdot 0.5H_2O$: C, 15.49; H, 5.52; N, 31.61%.

trans-$[Co(SO_3)(NH_3)(en)_2]Cl\cdot H_2O$: *trans*-$[CoCl(SO_3)(en)_2]$ (6 g) was dissolved in 50 cm^3 of liquid ammonia. The ammonia was then allowed to evaporate spontaneously, leaving behind a brown solid, which was recrystallized from hot water. Absorp. max. $10^{-3}\sigma/cm^{-1}$ (log ε): 21.6 (2.22), *ca.* 28 sh (2.3), 36.4 (4.15). Found: C, 14.58; H, 6.40; N, 21.18%. Calcd for $[Co(SO_3)(NH_3)(C_2H_8N_2)_2]\cdot H_2O$: C, 14.57; H, 6.42; N, 21.24%.

Other Complexes: *cis*-$[Co(CN)(SO_3)(en)_2]$ and *cis*-$[CoBr(CN)(en)_2]Br$ were prepared according to the method of Ohkawa, Hidaka, and Shimura.[6] *trans*-$[Co(CN)(SO_3)(en)_2]$ was prepared according to the method of Chan and Tobe.[7] *trans*-$[CoBr(CN)(en)_2]Br$ was prepared by the method of Chan.[8] *cis*-$[Co(CN)(NO_2)(en)_2]Br$ and *trans*-$[Co(CN)(NO_2)(en)_2]ClO_4$ were prepared by the method of Ohkawa, Hidaka, and Shimura.[9] *trans*-$[Co(NCS)(SO_3)(en)_2]$ and *cis*-$[Co(SO_3)(NH_3)(en)_2]Cl$ were prepared by the method of Baldwin.[10] *cis*-$[Co(N_3)(SO_3)(en)_2]$ was prepared by the method of Hughes and McWhinnie.[5] *cis*-$Li[Co(S_2O_3)_2(en)_2]$ was prepared by the method of Akamatsu, Hidaka, and Shimura.[11] All the other complexes are well known and were prepared by standard means. All the complexes were identified by means of the visible and ultra-violet spectra.

Measurements. The Raman spectra were recorded on a JASCO Laser Raman spectrometer (model R-800), using a He–Ne laser (632.8 nm) or an Ar^+ ion laser (514.5 or 457.9 nm) as the excitation source. Generally, the spectra were measured in aqueous solutions in order to avoid the appearance of lattice modes and the band splitting due to a crystal field.

Results and Discussion

The Raman spectra in the skeletal vibration region of *trans*- and *cis*-bis(ethylenediamine)cobalt(III) complexes whose geometrical configurations have previously been determined are shown in Fig. 1 and 2. The isomeric pair of complexes reveals a quite different Raman spectrum in this region. In general, the spectra of the *cis* isomers reveal more complicated

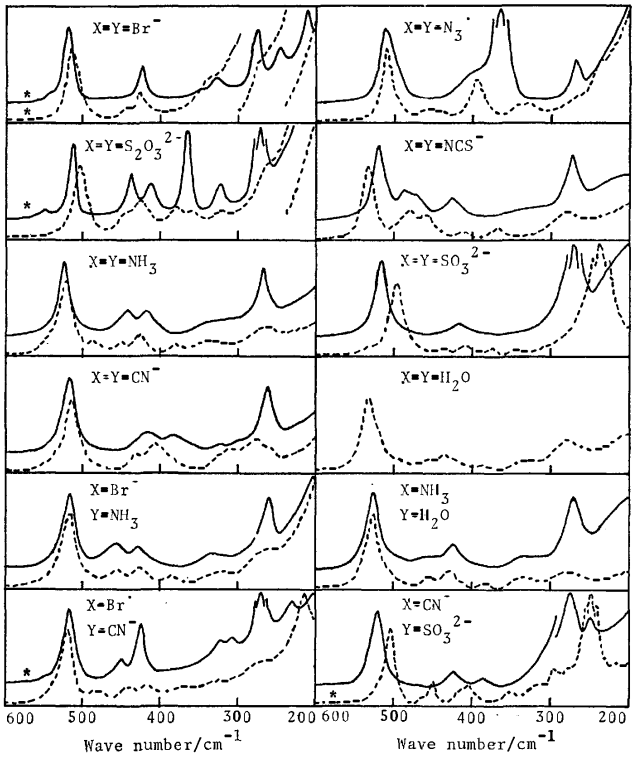

Fig. 1. Raman spectra of $[CoXY(en)_2]$-type complexes. *trans* isomer (——) and *cis* isomer (----). (* Denotes a solid-state spectrum.)

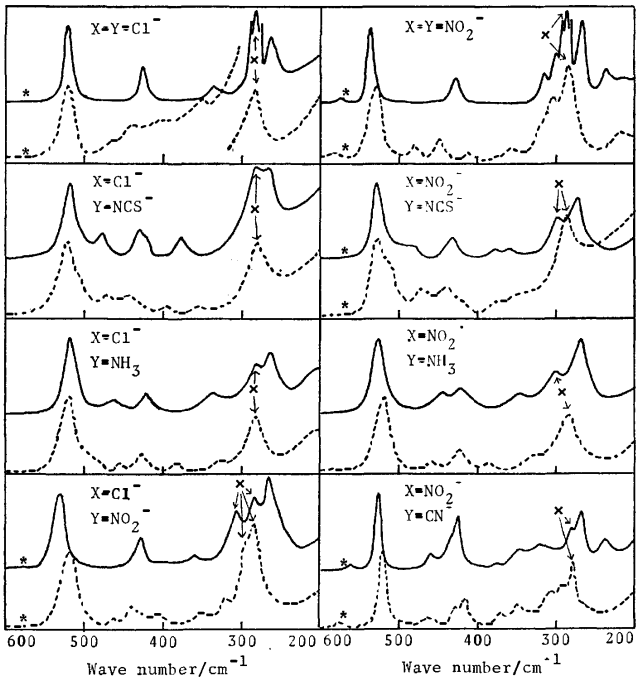

Fig. 2. Raman spectra of $[CoXY(en)_2]$-type complexes, where X or Y is a chloro or nitro group. *trans* isomer (——) and *cis* isomer (----). (* Denotes a solid-state spectrum; × denotes ν(Co–Cl) or ν(Co–NO_2).)

features than those of the *trans* isomers. The most striking difference is found near 270 cm^{-1}. That is, the Raman spectra of the *trans* isomers have a strong and sharp band near 270 cm^{-1}, while those of the *cis* isomers have no intense band at that frequency.

Two different assignments for the *ca.* 270 cm^{-1} band have been proposed. Gouteron-Vaissermann[12] has assigned the *ca.* 270 cm^{-1} band of $[Co(en)_3]^{3+}$ to the bending vibration of the N–Co–N angle, which does not include the chelate ring. On the other hand, Krishnan and Plane[13] have assigned the corresponding band to the chelate-ring-deformation vibration, δ(cycle), in their Raman study of complexes of ethylenediamine with zinc(II), cadmium(II), and mercury(II). The latter assignment is regarded as reasonable because the band at *ca.* 270 cm^{-1} in the Raman spectrum of *trans*-$[CoX_2(en)_2]$-type complexes is polarized and only the symmetric chelate-ring deformation of the nine skeletal deformation modes belongs to a totally symmetric species. Therefore, the strong band obserbed near 270 cm^{-1} in the Raman spectrum of *trans*-bis(ethylenediamine)cobalt(III) complexes may confidently be assigned to δ(cycle).

In the case of complexes containing a nitro or chloro group (see Fig. 2), careful measurements are required in estimating the intensity of δ(cycle) because ν(Co–NO_2) or ν(Co–Cl) appears as a intense band in the vicinity of δ(cycle). For example, the low-resolution Raman spectra of *cis*- and *trans*-$[Co(NO_2)_2(en)_2]^+$ are similar to each other in the *ca.* 270 cm^{-1} region; *i.e.*, the aqueous Raman spectrum of each isomer apparently shows a strong band in the region because of the band overlapping of δ(cycle) with ν(Co–NO_2). The differentiation between δ(cycle) and ν(Co–NO_2) or ν(Co–Cl) is performed by means of the Raman measurement of *N*-deuterated complexes. The band due to δ(cycle) shows a shift to a lower frequency (about 5 cm^{-1}) following a deuteration of the amino protons of the ethylenediamine group, while the band due to ν(Co–NO_2) or ν(Co–Cl) is not affected.

In conclusion, *cis-trans* isomeric pairs of $[CoX_2(en)_2]$-type and $[CoXY(en)_2]$-type complexes were successfully differentiated on the basis of the examination of the Raman intensity of the band due to δ(cycle) near 270 cm^{-1}.

It is obviously of interest to apply the present results to complexes of unknown or doubtful geometrical configurations. For the geometrical configuration of $[Co(NO_3)_2(en)_2]NO_3$, two different assignments have been proposed. Shimura and Tsuchida[14] have proposed that the complex has a *trans* configuration because the electronic absorption spectrum in the visible region shows the splitting of the first d-d absorption band. On the other hand, Krebs and Diewald[15] have regarded the complex as a *cis* isomer on the basis of the optical resolution by starch chromatography. Figure 3 shows the Raman spectrum of solid $[Co(NO_3)_2(en)_2]NO_3$. This complex is very unstable in water, and the Raman spectrum in an aqueous solution could not be obtained. The presence of the strong band at 276 cm^{-1} due to the δ(cycle) and the simple features of the spectrum reveal that the complex has a *trans* configuration. It can, therefore, be presumed that the complex which was optically resolved by Krebs and Diewald[15] might be an aquation-and-

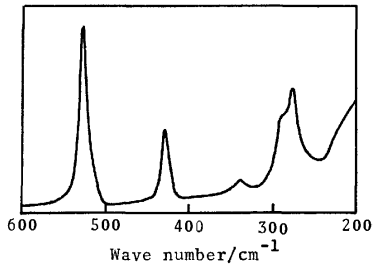

Fig. 3. Raman spectrum of solid $[Co(NO_3)_2(en)_2]NO_3$.

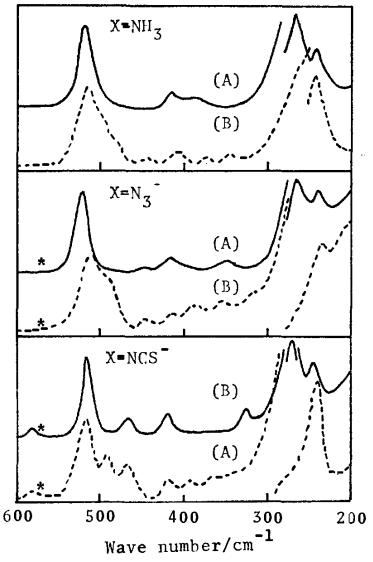

Fig. 4. Raman spectra of $[CoX(SO_3)(en)_2]$-type complexes.
trans isomer (——) and *cis* isomer (----). (* Denotes a solid-state spectrum; (A) refers to the spectra of the complexes which were prepared in the present work, and (B), to those of the complexes which were prepared by the methods in the Refs. 5 and 10.)

isomerisation product of the complex. The Raman spectrum of the aquation product of the complex does not show an intense band near 270 cm^{-1}.

Baldwin[10] has obtained a geometrical isomer of $[CoX(SO_3)(en)_2]$-type complexes ($X=H_2O$, NCS^-, NH_3) by means of substitution reactions of $[CoCl(SO_3)(en)_2]$. Hughes and McWhinnie[5] have also obtained a geometrical isomer of $[Co(N_3)(SO_3)(en)_2]$ by a similar method. These complexes have been assumed to have a *cis* configuration on the basis of the infrared spectra. However, the X-ray studies of $[Co(SO_3)(en_2)(H_2O)]ClO_4 \cdot H_2O$[16] and $[Co(NCS)(SO_3)(en)_2] \cdot 2H_2O$[17] show that these complexes have a *trans* configuration.

We have applied the Raman intensity criterion for δ(cycle) to the ammine and the azido complexes and have also prepared another isomer of the $[CoX(SO_3)(en)_2]$-type complexes ($X=NH_3$, N_3^-, NCS^-). The Raman spectra of the isomeric pairs of the complexes are shown in Fig. 4, where the (A) spectra refer to the isomers which have been prepared in the present work, and the (B) spectra, to the isomers which have been obtained by the methods in the literature. The Raman criterion indicates that the ammine and the azido complexes prepared by the present method have a *trans* configuration, while the complexes prepared by the methods in Refs. 5 and 10 have a *cis* configuration, consistent with the prediction made on the basis of the infrared spectra. It is also confirmed that the isothiocyanato complex obtained in the present work has a *cis* configuration.

The authors are indebted to Professor Yoichi Shimura of Osaka University and Dr. Isao Kanesaka of our university for their valuable discussions.

Synthesis and Circular Dichroism Spectra of [Co(a)(gly)(1,4,7-triazacyclononane)]-type Complexes

Satoru SHIMBA, Shuhei FUJINAMI, and Muraji SHIBATA*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received November 21, 1979)

Complexes of the [Co(a)(gly)(tacn)]-type, where tacn represents 1,4,7-triazacyclononane and a is CN^-, NO_2^-, NH_3, NCS^-, H_2O, OH^-, N_3^-, or Cl^-, have been prepared and resolved. The CD spectra of these complexes have been measured. On the basis of the X-ray analysis of $(-)_{589}$[Co(gly)(NH_3)(tacn)]$I_2\cdot H_2O$, the absolute configurations of the other complexes have been assigned by referring to the CD spectra. These complexes have exhibited a common CD pattern in the T_{1g}-band region, and from this fact a criterion for the assignments of the absolute configurations for the complexes of the *fac*(D)-[Co(a)(BC)(DDD)]-type has been established.

Most circular dichroism (CD) spectral studies of cobalt(III) complexes have been undertaken to investigate various sources of optical activity, such as the distribution of chelate rings, the conformation of chelate rings, the vicinal effect due to asymmetric carbon in an optically active ligand, and the vicinal effect due to an asymmetric donor atom.[1] In contrast to those investigations, little work has been reported on complexes whose optical activity arises from the arrangement of unidentate ligands. The paucity of research on such complexes seems mainly a result of the lack of preparative methods. In our laboratory some complexes of *cis-cis*-[Co(a)$_2$(b)$_2$(CC)]- and *all-cis*-[Co(a)$_2$(b)$_2$(c)$_2$]-types have been prepared through a few steps of ligand substitution, and then resolved into enantiomeric isomers.[2] Shimura *et al.*[3,4] prepared and resolved complexes of the *fac*(D)-[Co(a)(BC)(DDD)]-type, using 2-aminomethyl-2-methyl-1,3-propanediamine (1,1,1-tris(aminomethyl)ethane, TAME) or $Nb_6O_{19}^{8-}$ as the DDD ligand and glycinate as the BC ligand. However, the absolute configurations of these complexes have not been established. Very recently, we reported a complex of the *fac*(D)-[Co(a)(b)(c)(DDD)]-type, where DDD was 1,4,7-triazacyclononane (=TACN) and where a, b, and c were CN^-, Br^-, and NH_3 respectively.[5]

This paper will deal with the syntheses and optical resolution of a series of $[Co(a)(gly)(tacn)]^{n+}$ complexes (a=CN^-, NO_2^-, NH_3, NCS^-, H_2O, OH^-, N_3^-, Cl^-, or I^-). Since TACN coordinates facially in an octahedral complex, the chirality of these complexes is derived from the arrangement of the complexed gly and unidentate ligands, as is shown in Fig. 1. The absolute configurations of these complexes are assigned by referring to the CD spectra, on the basis of the results of the X-ray analysis of $(-)_{589}$[Co(gly)(NH_3)(tacn)]$I_2\cdot H_2O$.[6]

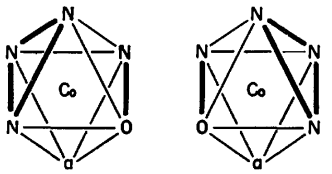

Fig. 1. Enantiomers of [Co(a)(gly)(tacn)]-type complex.

Experimental

Ligand. 1,4,7-Triazacyclononane trihydrochloride (TACN·3HCl) was prepared by the literature method.[7]

Preparation of Complexes. *1) Aquaglycinato-1,4,7-triazacyclononanecobalt(III) Perchlorate Dihydrate, [Co(gly)(tacn)$(H_2O)](ClO_4)_2\cdot 2H_2O$:* The *mer*(N)-*trans*$(NH_3)$-[Co$(CO_3)(gly)(NH_3)_2$] complex (5.0 g, 0.022 mol)[8] was dissolved in water (20 cm^3), and then the ligand, TACN·3HCl (5.0 g, 0.022 mol), was added to this solution in portions, with care taken to the evolution of carbon dioxide. After the compounds had been dissolved, the solution was adjusted to pH 2 with $HClO_4$ (60%), whereupon the diaqua complex, $[Co(gly)(NH_3)_2(H_2O)_2]^{2+}$, was formed. The solution was alkalized with 5 M (1 M=1 mol dm^{-3}) KOH until pH 9, stirred for 15 min, and then acidified with $HClO_4$ until pH 6. The resulting solution was filtered once and diluted to 2 dm^3 with water. This solution was poured into a column containing SP-Sephadex C-25 (4.5×25.0 cm, Na^+ form). The adsorbed band was eluted with 0.1 M $HClO_4$, and a red band corresponding to the bivalent cation of the desired complex was collected. The eluate was concentrated to a small volume by means of a rotary evaporator, after which a small amount of ethanol and a large amount of ether were added to the concentrate successively. This solution was kept in a refrigerator until the red material of the desired complex was deposited. The crude product was recrystallized from warm water (*ca.* 60 °C). The yield was about 2.0 g. Found: C, 18.55; H, 4.95; N, 10.62%. Calcd for $[Co(gly)(tacn)(H_2O)](ClO_4)_2\cdot 2H_2O = C_8H_{25}O_{13}N_4Cl_2Co$: C, 18.65; H, 4.90; N, 10.88%. This aqua complex was used as the starting material for the following syntheses (*2)—7)*).

2) Glycinatonitro-1,4,7-triazacyclononanecobalt(III) Chloride Monohydrate, $[Co(NO_2)(gly)(tacn)]Cl\cdot H_2O$: To a solution of the aqua complex (1.5 g in 20 cm^3 H_2O) we added $NaNO_2$ (1 g, 0.014 mol), and then the solution was adjusted to pH 4 with $HClO_4$. The solution was stirred at 50—60 °C until its color changed from red to yellow. The resulting solution was subjected to Sephadex column chromatography in a way similar to that in *1)*. The eluate obtained by elution with 0.05 M NaCl was concentrated to a small volume by means of a rotary evaporator, with the simultaneous removal of the NaCl deposited; a large amount of ethanol was then added to the concentrate. The ethanolic solution was kept in a refrigerator to obtain yellow crystals. The crystals were recrystallized from warm water (*ca.* 50 °C). The yield was *ca.* 0.8 g. Found: C, 26.25; H, 5.69; N, 19.47%. Calcd for $[Co(NO_2)(gly)(tacn)]Cl\cdot H_2O = C_8H_{21}O_5N_5ClCo$: C, 26.56; H, 5.89; N, 19.37%.

3) Ammineglycinato-1,4,7-triazacyclononanecobalt(III) Iodide Monohydrate, $[Co(gly)(NH_3)(tacn)]I_2\cdot H_2O$: The aqua complex (1.5 g) was dissolved in aqueous ammonia (28%,

100 cm³), after which the solution was allowed to stand in a flask with a stopcock at 60 °C until it turned orange (several hours). The resulting solution was poured into a column of Dowex 50W-X8 (4.5×10.0 cm, Na^+ form). The eluate obtained by subsequent elution with 0.3 M NaI was treated in a way similar to that in *2)*. When the concentrated solution was kept in a refrigerator, orange crystals were deposited; they were recrystallized from warm water (60 °C). The yield was *ca.* 1.0 g. Found: C, 17.37; H, 4.26; N, 12.52%. Calcd for $[Co(gly)(NH_3)(tacn)]I_2 \cdot H_2O = C_8H_{24}O_3N_5I_2Co$: C, 17.31; H, 4.37; N, 12.62%.

4) Glycinatoisothiocyanato-1,4,7-triazacyclononanecobalt(III) Bromide, [Co(NCS)(gly)(tacn)]Br: An aqueous solution (20 cm³) containing starting aqua complex (1.5 g) and KSCN (1.5 g, 0.015 mol) was adjusted to pH 4 with $HClO_4$ and then stirred at 50—60 °C for 2—3 h. The resulting red solution was chromatographed in the same manner as *3)*. The elution was carried out with 0.1 M NaBr. The yield of the desired complex was *ca.* 0.8 g. Found: C, 26.91; H, 4.81; N, 17.31%. Calcd for $[Co(NCS)(gly)(tacn)]Br = C_9H_{19}O_2N_5SBrCo$: C, 27.01; H, 4.79; N, 17.50%.

5) Azidoglycinato-1,4,7-triazacyclononanecobalt(III) Iodide Monohydrate, [Co(N₃)(gly)(tacn)]I·H₂O: This complex was prepared in the same manner as the isothiocyanato complex, except for the use of NaN_3 (1.0 g, 0.015 mol) in place of KSCN. The elution was carried out with 0.1 M NaI. Red-violet crystals were obtained in a yield of *ca.* 0.8 g. Found: C, 21.23; H, 4.33; N, 21.42%. Calcd for $[Co(N_3)(gly)(tacn)]I \cdot H_2O = C_8H_{21}O_3N_7ICo$: C, 21.29; H, 4.70; N, 21.73%.

6) Chloroglycinato-1,4,7-triazacyclononanecobalt(III) Chloride 1.5-hydrate, [Co(Cl)(gly)(tacn)]Cl·1.5H₂O: Starting aqua complex (1.5 g) was dissolved in 6 M HCl (20 cm³), after which the solution was stirred at 60 °C for 2—3 h. The resulting solution was poured into a column of Dowex 50W-X8 (5.5×10.0 cm, H^+ form). The eluate obtained by elution with 0.1 M NaCl was treated by the same way as *3)*. The yield of violet crystals was *ca.* 0.5 g. Found: C, 26.66; H, 5.77; N, 15.31%. Calcd for $[Co(Cl)(gly)(tacn)]Cl \cdot 1.5H_2O = C_8H_{22}O_{3.5}N_4Cl_2Co$: C, 26.68; H, 6.17; N, 15.56%.

7) Glycinatoiodo-1,4,7-triazacyclononanecobalt(III) Iodide, [Co(I)(gly)(tacn)]I: When, in the preparation of the aqua complex, elution was carried out with 0.1 M NaI and the eluate was concentrated to a small volume, the solution turned green. From the solution, powdery green crystals of the iodo complex separated out. The yield was *ca.* 1.0 g. Found: C, 18.53; H, 3.54; N, 10.92%. Calcd for $[Co(I)(gly)(tacn)]I = C_8H_{19}O_2N_4I_2Co$: C, 18.48; H, 3.69; N, 10.78%.

8) Cyanoglycinato-1,4,7-triazacyclononanecobalt(III) Chloride Dihydrate, [Co(CN)(gly)(tacn)]Cl·2H₂O: So far as this cyano complex was concerned, attempts at derivation from the aqua complex in an aqueous medium were unsuccessful. Instead, the desired complex was obtained by means of a reaction in dimethyl sulfoxide (DMSO); the chloro complex, $[Co(Cl)(gly)(tacn)]Cl \cdot 1.5H_2O$ (2.0 g, 0.0056 mol), was carefully dissolved in a minimum amount of conc. HNO_3; after the evolution of Cl_2 and NO_2 gases had ceased, ethanol (15 cm³) was added to the solution to precipitate the nitrate of the complex, $[Co(Cl)(gly)(tacn)]NO_3$. The nitrate was dissolved in DMSO (300 cm³) containing KCN (1.0 g, 0.015 mol), after which the solution was heated at 85—90 °C for 2—3 h. The resulting yellow solution was poured into a column of SP-Sephadex C-25 (4.5×25.0 cm, Na^+ form). Elution was carried out with 0.05 M NaCl to collect a portion of the desired species. When the concentrate of the fraction was kept in a refrigerator, yellow crystals separated out; yield, *ca.* 0.6 g. Found: C, 29.92; H, 6.05; N, 19.45%. Calcd for $[Co(CN)(gly)(tacn)]Cl \cdot 2H_2O = C_9H_{23}O_4N_5ClCo$: C, 30.05; H, 6.46; N, 19.47%.

Optical Resolution. Each of the cyano, nitro, and ammine complexes was resolved into two optically active forms by the column chromatography of SP-Sephadex C-25 (2.5×110.0 cm, Na^+ form), using 0.05 M $K_2[Sb_2(d\text{-tart})_2]$ as the eluent. The remaining isothiocyanato, aqua, azido, and chloro complexes were all resolved into two forms each using columns of Dowex 50W-X8 (200—400 mesh, 2.5×34.5 cm, Na^+ form) and a 0.3 M $Na_2[Sb_2(d\text{-tart})_2]$ solution as the eluent. When the adsorbed band had descended to four-fifths of the column height, the band was washed with water and eluted with 0.1 M NaCl or 0.3 M $NaClO_4$. The eluate thus concentrated was submitted to the measurement of the CD spectra, while the concentration of the complex species was evaluated from the absorption spectral data.

Derivations from Optically Active Complexes. Several optically active complexes, $(-)_{589}[Co(NO_2)(gly)(tacn)]^+$, $(-)_{589}[Co(NCS)(gly)(tacn)]^+$, $(+)_{589}[Co(N_3)(gly)(tacn)]^+$, and $(-)_{589}[Co(Cl)(gly)(tacn)]^+$, could be directly derived from the optically active aqua complex, $(-)_{589}[Co(gly)(tacn)(H_2O)](ClO_4)_2 \cdot 2H_2O$, according to the methods described in *2)*, *4)*, *5)*, and *6)* respectively. The reaction of aqueous ammonia of the $(-)_{589}[Co(gly)(tacn)(H_2O)]^{2+}$ complex resulted in the formation of the racemic $[Co(gly)(NH_3)(tacn)]^{2+}$ complex. On the other hand, the oxidation of the $(-)_{589}[Co(NCS)(gly)(tacn)]^+$ complex by aqueous H_2O_2 at *ca.* pH 3 produced the $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$, $(-)_{589}[Co(CN)(gly)(tacn)]^+$ and $(-)_{589}[Co(gly)(tacn)(H_2O)]^{2+}$ complexes, which were separated chromatographically.

Measurements. The absorption spectra in aqueous solutions were recorded with a Hitachi 323 recording spectrophotometer. The CD spectra were measured with a JASCO J-40C automatic recording spectropolarimeter equipped with a JASCO Model J-DPZ data processor for CD. For the measurement of the optical rotation, a JASCO Model DIP-SL automatic polarimeter was used. The absorption and CD spectra of hydroxo complex species were measured with an alkalized solution (pH 9) of the aqua complex with 5 M NaOH. The hydroxo complex species was chromatographically pure, and its absorption and CD spectra were changed into the original spectra of the parent aqua complex when the solution was again acidified with $HClO_4$. This fact suggests that the base-hydrolysis proceeds with retention of the configuration.

The CD measurement was carried out for an aqueous solution of bis(1,4,7-triazacyclononane)cobalt(III), $[Co(tacn)_2]^{3+}$,[9] in the presence of $[Sb_2(d\text{-tart})_2]^{2-}$ ($[Co(tacn)_2]Cl_3$ 4.0×10^{-3} M; $K_2[Sb_2(d\text{-tart})_2] \cdot H_2O$ 8.0×10^{-2} M).

Results and Discussion

Preparation and Resolution. A feature of the present method of preparation is that a series of complexes with various unidentates, a, $[Co(a)(gly)(tacn)]^{n+}$, could be derived from one complex, $[Co(gly)(tacn)(H_2O)]^{2+}$. An exception was the case of the cyano complex; the reaction of potassium cyanide on an aqueous solution of the aqua complex resulted in the formation of a hydroxo complex, $[Co(OH)(gly)(tacn)]^+$, which was not isolated because of its great solubility. Instead, the reaction of the chloro complex, $[Co(Cl)(gly)(tacn)]^+$, with potassium cyanide in DMSO yield-

ed the desired complex.

For the optical resolution of the complexes, column chromatography using an ion-exchanger and *d*-tartratoantimonate(III) was useful. It is worth noting that a complete resolution was attained by using a Dowex cation exchanger for the complexes containing unidentates whose ligand-field-strengths are weaker than that of ammonia. On the other hand, the chromatographic resolutions of the same complexes on Sephadex columns were partial. The attempted resolution of the iodo complex was unsuccessful becasue of the great lability of the complexed iodide ion.

Absorption and CD Spectra. The absorption spectrum of the racemic $[Co(gly)(NH_3)(tacn)]^{2+}$ complex and the CD spectra of the two resolved isomers are illustrated in Fig. 2, the CD curves being mirror images of each other. Since the same situation was encountered in the resolved pairs of the other complexes, the CD spectra for only the isomers obtained from the earlier eluates are illustrated, together with the absorption spectra, in Figs. 3—5. The numerical data are summarized in Table 1. Every complex has a rhombic ligand field in which there are three electronic transition components for each of the first absorption (T_{1g}) and second absorption (T_{2g}) bands. However, no appreciable splittings are observed even in the T_{1g} bands of the cyano and chloro complexes. The maximum positions of the first absorption bands ($\tilde{\nu}_{Imax}$) shift to a higher-frequency side in accord with the spectrochemical series[10], $I^- < Cl^- < N_3^- < OH^- < H_2O < NCS^- < NH_3 < NO_2^- < CN^-$, with respect to the unidentates used.

The observed CD spectra are classified into three groups on the basis of the patterns in the T_{1g} band region: 1) one negative broad peak, 2) a positive and a negative peak from a lower frequency, and 3) a negative, a positive, and a negative peak from a lower frequency. The $(-)_{589}[Co(CN)(gly)(tacn)]^+$ complex belongs to Group 1. The extremum is located at a lower frequency compared with the corresponding absorption maximum ($\tilde{\nu}_{Imax}$), and a shoulder is observed at a higher frequency. The

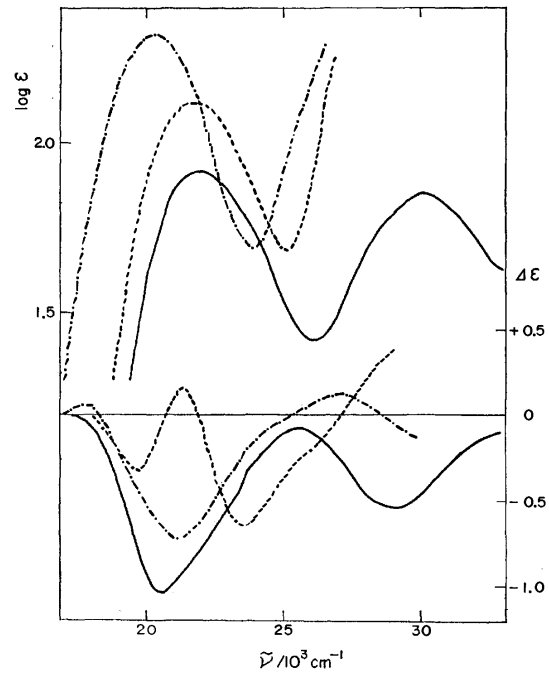

Fig. 3. Absorption and CD spectra of $(-)_{589}[Co(CN)(gly)(tacn)]^+$ (——), $(-)_{589}[Co(NO_2)(gly)(tacn)]^+$ (----), $(-)_{589}[Co(NCS)(gly)(tacn)]^+$ (—·—·—).

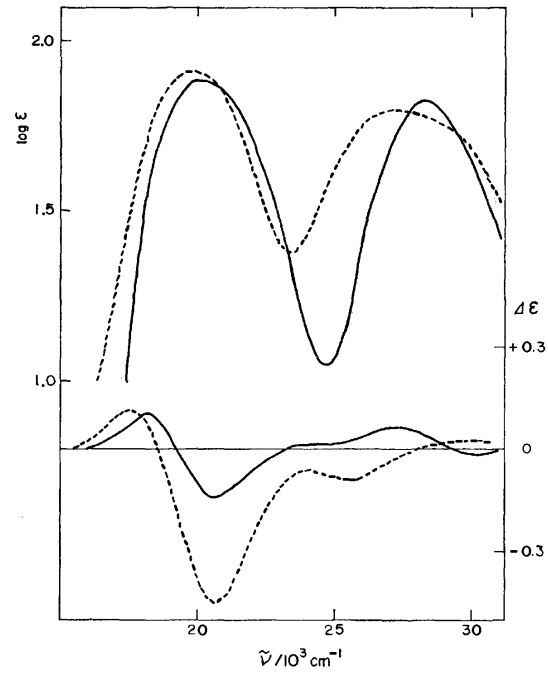

Fig. 4. Absorption and CD spectra of $(-)_{589}[Co(gly)(tacn)(H_2O)]^{2+}$ (——), $(-)_{589}[Co(OH)(gly)(tacn)]^+$ (----).

$(-)_{589}$[Co(NCS)(gly)(tacn)]$^+$, $(-)_{589}$[Co(gly)(tacn)-(H_2O)]$^{2+}$, $(-)_{589}$[Co(OH)(gly)(tacn)]$^+$, $(+)_{589}$[Co-(N_3)(gly)(tacn)]$^+$, and $(-)_{589}$[CoCl(gly)(tacn)]$^+$ complexes exhibit the pattern of Group 2. Two complexes, $(-)_{589}$[Co(NO_2)(gly)(tacn)]$^+$ and $(-)_{589}$[Co-(gly)(NH_3)(tacn)]$^{2+}$, show the pattern of Group 3. However, the negative extremum observed at the lowest frequency in the spectrum of the $(-)_{589}$[Co-(gly)(NH_3)(tacn)]$^{2+}$ complex is extremely weak. A striking characteristic in the CD spectra for the earlier-eluted enantiomers is that a major CD peak of a negative sign is observed at a higher frequency in the T_{1g}-band region, except for the case of the cyano complex, where a negative shoulder appears at a higher frequency. Another characteristic is that the intensity is very weak in comparison with that of bis- or tris-diamine complexes.

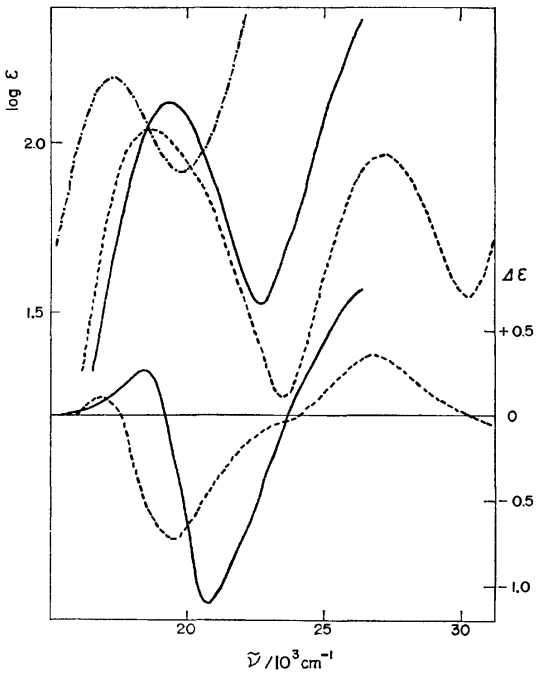

Fig. 5. Absorption and CD spectra of $(+)_{589}$[Co(N_3)-(gly)(tacn)]$^+$ (——), $(-)_{589}$[Co(Cl)(gly)(tacn)]$^+$ (----), [Co(I)(gly)(tacn)]$^+$ (—·—·—).

For the present chiral complexes, three sources of d-electron optical activity can be considered; the helical distribution of a H_2N–CH_2–COO^- chelate and the –NH–CH_2–CH_2–NH– moiety of tacn, the conformations of the three chelate rings of the tacn or glycinate ring, and the arrangement of the three donors of the glycinate and unidentate ligands. Recently, the absolute configuration of the $(-)_{589}$[Co(gly)(NH_3)-(tacn)]$I_2 \cdot H_2O$ was determined by X-ray analysis.[6] It was thereby found that the glycinate chelate ring was nearly planar (that is, it was achiral), and the five-membered chelate rings of the tacn ligand had all a δ-conformation. However, it is thought that the conformations of the tacn chelate rings are not fixed in a solution, judging from the following fact. When a solution CD spectrum of the $[Co(tacn)_2]^{3+}$ complex was measured in the presence of $[Sb_2(d\text{-tart})_2]^{2-}$, a negative peak ($\Delta\varepsilon = -0.40$) was observed

at 21200 cm^{-1} in the T_{1g}-band region, indicating the preferential formation of a fixed conformation (probably δ) of the chelate rings. A similar CD spectrum was observed for $[Co\{(2R\text{-Me})\text{-tacn}\}_2]^{3+}$;[11-13] it shows a very strong positive peak in the T_{1g}-band region, probably as a result of the chiral puckering of the chelate rings with the λ-conformation.[14] This experimental result indicates a small contribution from a fixed conformation to the solution CD spectrum of the present $[Co(a)(gly)(tacn)]^{n+}$ complex. There are two kinds of helical distributions in the $[Co(a)(gly)(tacn)]^{n+}$ complex, however, one is designated Δ, and the other, Λ. Therefore, the optical activity due to the helical distribution is probably very small in the complex.

On the other hand, the CD spectra of $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$ and $(-)_{589}[Co(gly)(NH_3)(tame)]^{2+}$, where tame is a tripod ligand, resemble each other well in both shape and peak intensity; *i.e.*, the $\Delta\varepsilon$ value for the dominant peak of $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$, $\Delta\varepsilon=-0.42$, corresponds well with that of $(-)_{589}[Co(gly)(NH_3)(tame)]^{2+}$, $\Delta\varepsilon=-0.44$. These facts also support the idea that the first and second sources make little contribution to optical activity. Therefore, it may be concluded that the optical activity of $[Co(a)(gly)(tacn)]^{n+}$ is due to the arrangement of the three donors of the glycinate and unidentate ligands.

Absolute Configuration. In order to investigate the relation between the Cotton signs and the absolute configuration on the $[Co(a)(gly)(tacn)]^{n+}$ complexes, we tried to obtain optically active complexes directly from the $(-)_{589}[Co(gly)(tacn)(H_2O)]^{2+}$ complex. The conversions were successful in giving the corresponding $(-)_{589}[Co(NO_2)(gly)(tacn)]^{+}$, $(-)_{589}[Co(NCS)(gly)(tacn)]^{+}$, $(+)_{589}[Co(N_3)(gly)(tacn)]^{+}$, and $(-)_{589}[Co(Cl)(gly)(tacn)]^{+}$ complexes. This fact indicates that the configurations of the gly and tacn ligands are retained in the course of the reaction. The oxidation of the $(-)_{589}[Co(NCS)(gly)(tacn)]^{+}$ complex with aqueous H_2O_2 at *ca.* pH 3 produced $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$, $(-)_{589}[Co(CN)(gly)(tacn)]^{+}$ and $(-)_{589}[Co(gly)(tacn)(H_2O)]^{2+}$ complexes. Similar oxidative degradation reactions have been reported by Gillard and Maskill[15]; $(-)_{589}[Co(NCS)_2(en)_2]^{+}$ was converted into $(-)_{589}[Co(NH_3)_2(en)_2]^{3+}$ and $(-)_{589}[Co(CN)_2(en)_2]^{+}$, and these three complexes have the same absolute configuration. Therefore, the four tacn complexes also have the same absolute configuration.

On the basis of the above results, it is concluded that the earlier-eluted enantiomers, whose major CD peaks have a negative sign, have the same arrangement with respect to the donors of gly and the unidentates (CN^-, NO_2^-, NH_3, NCS^-, H_2O, OH^-, N_3^-, and Cl^-), as is shown in Fig. 6. We can now assign the absolute configurations of $(-)_{589}[Co(gly)(NH_3)(tame)]^{2+}$, $(-)^{CD}_{546}[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$, and $(-)^{CD}_{546}[Co(Nb_6O_{19})(gly)(H_2O)]^{6-}$ complexes,[3,4] which belong to the *fac*(D)-[Co(a)(BC)(DDD)]-type, by comparing the sign of the CD peak in the T_{1g}-band region with that of the $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$ or $(-)_{589}[Co(gly)(tacn)(H_2O)]^{2+}$ complex. Thus, the three complexes, $(-)_{589}[Co(gly)(NH_3)(tame)]^{2+}$, $(-)^{CD}_{546}[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ and $(-)^{CD}_{546}[Co(Nb_6O_{19})(gly)(H_2O)]^{6-}$, have the same arrangement with respect to the donors of the glycinate and unidentate ligands, as is shown in Fig. 6.

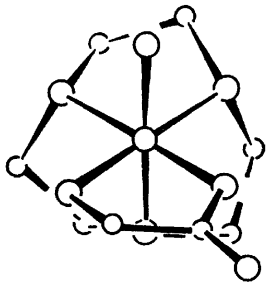

Fig. 6. Absolute configuration of the earlier eluted enantiomer of $[Co(a)(gly)(tacn)]^{n+}$ Complex.

The authors wish to express thanks to Dr. Nonoyama, Nagoya University, for his aid in the preparation of the ligand.

Voltammetric Studies of Tris(1-pyrrolidinecarbodithioato)manganese(III) and -iron(III) and Bis(1-pyrrolidinecarbodithioato)copper(II) in Nonaqueous Solvents

Akio Ichimura and Toyokichi Kitagawa*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received December 24, 1979)

The voltammetric behavior of the title complexes has been studied. These complexes give a one-electron oxidation wave and a one-electron reduction wave in most solvents. A linear correlation between the ($E_{1/2}^{ox}$—$E_{1/2}^{red}$) values and the solubility parameters of the solvents was obtained. The ($E_{1/2}^{ox}$—$E_{1/2}^{red}$) values were interpreted in terms of the solvation energy of the complexes.

A number of electrochemical studies of transition metal complexes with *N,N*-disubstituted dithiocarbamates have been reported. Considerable work has been carried out at the platinum electrode in acetone or acetonitlile as the solvent, where the electrode reactions have been shown to be relatively simple; *e.g.*, the dithiocarbamato complexes of the first-row transition metals from chromium to copper give a one-electron oxidation wave as well as a one-electron reduction wave.[1-7] Solvent effects on the redox potential of complexes have been widely studied. Golding *et al.*[8] investigated the redox behavior of iron(III) dithiocarbamates and interpreted the variation in the redox potentials of the complexes in acetone–water solutions by considering the effect of the solvent as a perturbation of the energy-level scheme. Recently Austrian workers have described the solvent effects on the half-wave potentials of tetraethylammonium hexacyanoferate(III)[9] and hexacyanomanganate(III),[10] tris(ethylenediamine)cobalt(III) perchlorate,[11] and tris(acetylacetonato)manganese(III)[12] by means of the donor-acceptor approach. In the present paper the voltammetric behavior of manganese(III), iron(III), and copper(II) complexes with 1-pyrrolidinecarbodithioate [$Mn(pcd)_3$, $Fe(pcd)_3$, and $Cu(pcd)_2$] is examined in eleven nonaqueous solvents, and the solvent effects are discussed.

Experimental

$Mn(pcd)_3$, $Fe(pcd)_3$, and $Cu(pcd)_2$ were prepared according to previously described methods.[3,13,6] All the solvents used were purified in a conventional manner.[14,15] Tetrabutylammonium perchlorate (TBAP) was prepared by metathesis from an aqueous solution of sodium perchlorate and tetrabutylammonium bromide, which has been synthesized with tributylamine and butyl bromide, thoroughly washed with water, and recrystallized twice from ethanol. The voltammetric studies were carried out at the platinum disk electrode by the rotating electrode method, cyclic voltammetry, pulse voltammetry, and differential pulse voltammetry with a Yanagimoto P-1000-type polarograph. An aqueous SCE and a platinum wire were used as the reference electrode and the counter electrode respectively. All the sample solutions containing 0.1 M TBAP as supporting electrolyte were deoxygenated with pre-dried nitrogen and kept in the dark throughout the experiment because the complexes were relatively unstable to light.

Results and Discussion

Studies of the diffusion current are described for only $Fe(pcd)_3$ in this paper because $Cu(pcd)_2$ is slightly soluble in most solvents used and $Mn(pcd)_3$ decomposes slowly in solution except in the cases of *N,N*-dimethylformamide and dimethyl sulfoxide, in which $Mn(pcd)_3$ decomposes immediately. $Fe(pcd)_3$ underwent both a one-electron oxidation to $Fe(pcd)_3^+$ and a one-electron reduction to $Fe(pcd)_3^-$ in all the solvents studied. The limiting current at the rotating electrode was proportional to the square root of the rotation speed, and the peak current in cyclic voltammetry was proportional to the square root of the scan rate, indicating that both the electrode reactions in the respective solvents are controlled by diffusion. The differential pulse and the cyclyc voltammetric behavior shows that the electrode reaction of the oxi-

dation and the reduction are reversible or nearly reversible, and that the oxidation process is more reversible than the reduction process in the respective solvents. Table 1 shows that there is a marked dependence of the normalized pulse voltammetric diffusion current (I_d/C^*) and the normalized convective diffussion current ($I_l/\omega^{1/2}C^*$) of the oxidation wave for $Fe(pcd)_3$ on the viscosity of the solvents (η). $Fe(pcd)_3$ is too insoluble in the alcohols for us to obtain reliable data on the normalized diffusion currents. According to the Cottrell equation, the pulse voltammetric diffusion current is proportional to the square root of the diffusion coefficient (D). Using the Stokes-Einstein relation, $I_d\eta^{1/2}/C^*$ can be expected to be constant, provided the diffusion coefficient is due solely to a change in the viscosity. The value of $I_d\eta^{1/2}/C^*$ in Table 1 are almost constant, indicating that there is no specific interaction between $Fe(pcd)_3$ and the molecule of each solvent. As is shown in Table 1, this is also confirmed by the rotating disk electrode method with the aid of the Levich equation and the Stokes-Einstein relation.

The half-wave potential of the oxidation ($E^{ox}_{1/2}$) and the reduction ($E^{red}_{1/2}$) of the pcd complexes were found to vary appreciably with different solvents. To aviod the difficulty in evaluating the liquid-junction potential between the reference electrode used (SCE) and the solvent studied, the difference between $E^{ox}_{1/2}$ and $E^{red}_{1/2}$ was used to discuss the solvent effect. The ($E^{ox}_{1/2}-E^{red}_{1/2}$) values for $Fe(pcd)_3$, $Mn(pcd)_3$, and $Cu(pcd)_2$ are listed in Table 2, together with the solubility parameter (δ),[16,17] the relative dielectric constant (ε), the donor number (DN),[18] and the acceptor number (AN),[19] of the solvents. As may be seen from Table 2, there is a correlation only between the ($E^{ox}_{1/2}-E^{red}_{1/2}$) values and the solubility parameters. When the oxidation and the reduction processes at the rotating electrode are reversible, $E^{ox}_{1/2}$ and $E^{red}_{1/2}$ can be written as follows:

$$E^{ox}_{1/2} = E^{\circ}_{ox} + (RT/F)\ln(f_{M^+}D_M^{2/3}/f_M D_{M^+}^{2/3}) \quad (1)$$

and:

$$E^{red}_{1/2} = E^{\circ}_{red} + (RT/F)\ln(f_M D_{M^-}^{2/3}/f_{M^-}D_M^{2/3}) \quad (2)$$

where E°_{ox} and E°_{red} are the standard potentials of the M/M^+ and M^-/M couples respectively, and where f is the activity coefficient, the subscripts M, M^+, and M^- representing the neutral complex, the cation formed by oxidation, and the anion formed by reduction respectively. By applying the Born-Haber cycle, the ($E^{\circ}_{ox}-E^{\circ}_{red}$) can be written as follows:

$$F(E^{\circ}_{ox}-E^{\circ}_{red}) = I_p - E_A + \Delta G^s_{M^+} + \Delta G^s_{M^-} - 2\Delta G^s_M, \quad (3)$$

where I_P and E_A are the ionization potential and the electron affinity of the neutral complex respectively, and where ΔG^s is the solvation energy. From Eqs. 1—3, the ($E^{ox}_{1/2}-E^{red}_{1/2}$) can be expressed by:

$$F(E^{ox}_{1/2}-E^{red}_{1/2}) = I_p - E_A + \Delta G^s_{M^+} + \Delta G^s_{M^-} - 2\Delta G^s_M + 2RT\ln(f_{M^\pm}/f_M) + (2/3)RT\ln(D_M^2/D_{M^+}D_{M^-}). \quad (4)$$

Among the values of the last five terms on the right-hand side of Eq. 4, which may vary with different solvents, those of the last two terms are considered to be almost constant. The solvation energy of the ion is predominantly electrostatic in nature and is, then, expressed by the modified Born equation.[20] The variation in the ΔG_{M^+} and ΔG_{M^-} with different solvents, evaluated from the modified Born equation with the crystallographic radius of 6.42 Å for $Fe(pcd)_3$,[21] is too little to explain the difference in ($E^{ox}_{1/2}-E^{red}_{1/2}$). Consequently, the remaining term, that is, the solvation energy of the neutral complex, must be largely responsible for the difference in ($E^{ox}_{1/2}-E^{red}_{1/2}$) values. When the complex with a solubility parameter, δ_M, is transferred from the gas phase to the polar solvent of the molar volume, V_S, and solubility parameter, δ_S, ΔG_M is approximately expressed by:[22]

$$\Delta G_M = V_S\delta_S(\delta_S-\delta_M). \quad (5)$$

Since the first and second terms on the right-hand side of Eq. 4 are inherent in the complexes, and since the remaining terms except ΔG_M are considered to be almost constant in all the solvents studied, Eq. 4 can be written as:

$$F(E^{ox}_{1/2}-E^{red}_{1/2}) = -2V_S\delta_S(\delta_S-\delta_M) + k \quad (6)$$

or:

$$F(E^{ox}_{1/2}-E^{red}_{1/2}) + 2V_S\delta_S^2 = 2V_S\delta_S\delta_M + k. \quad (7)$$

Figure 1 shows the plot of the value of the left-hand side of Eq. 7 for $Fe(pcd)_3$ *vs.* $2V_S\delta_S$. It gives a straight line with a slope of 11.44 (cal $cm^{-3})^{1/2}$, corresponding to the δ_M of $Fe(pcd)_3$. The δ_M values of $Mn(pcd)_3$

δ_M: 11.44 (cal cm^{-3})$^{1/2}$. Numbers correspond to those in Table 2.

and $Cu(pcd)_2$, as obtained from a similar plot, are 11.40 and 11.32 (cal cm^{-3})$^{1/2}$ respectively. These δ_M values are considered reasonable compared with the value of other complexes.[23] Using the δ_M value thus evaluated, the $(E^{ox}_{1/2}-E^{red}_{1/2})$ value was plotted against $V_S\delta_S(\delta_S-\delta_M)$. The plot for $Fe(pcd)_3$ is shown in Fig. 2, which gives two straight lines, one for the aprotic solvents, and the other, for the alcohols. These linear relationship indicates that Eq. 6 is a valid expression of the solvent effect. The difference between the alcohols and the other solvents may be due to the difference in the entropy change of the solvation being neglected in Eq. 5. Similar relations were obtained for $Mn(pcd)_3$ and $Cu(pcd)_2$. It may be concluded from these results that the variation in the half-wave potential of these pcd complexes with different solvents is not dependent on the solvation energy of the ions formed by oxidation and reduction, but is dependent on the solvation energy of the neutral complexes.

The authors wish to thank Professor Sachio Murakami for his many helpful discussions.

Mixed-ligand Complexes of Cobalt(III) with 1-(2-Pyridylazo)-2-naphthol (PAN) and Diethylenetriamine (dien) or Triethylenetetramine (trien)†

Katsura Mochizuki and Masatoshi Fujimoto*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 14, 1980)

New mixed-ligand complexes $[Co^{III}(pan)(dien)](ClO_4)_2 \cdot EtOH$ and $[Co^{III}(pan)(trien)](ClO_4) \cdot NaClO_4$ were synthesized. The ^1H NMR and the visible absorption spectra of these complexes were compared with those of the free ligand PAN and $[Co^{III}(pan)_2]Cl$. A remarkable down-field shift observed in the ^1H NMR signal for the proton H_{10} of the cobalt(III) complexes reflects the structural changes in the PAN molecule upon chelate-ring formation. The reaction between $[Co^{III}Cl_2(trien)]Cl$ and PAN gave two kinds of products, which confirmed a strong tendency for the ligand PAN to behave as a planar terdentate ligand.

In previous papers on the reaction mechanisms of the complex formation of cobalt(II) ion with PAN or its analogs, it was reported that the reaction proceeds in two steps to form a cobalt(III) complex, *i.e.*, the fast formation of a 1:2 cobalt(II) complex followed by the slower oxidation of the central cobalt(II) ion.[1] However, for the elucidation of detailed mechanisms involved in each step further information concerning the coordination fashion of the multidentate ligands like PAN in solution is required.

The complex formation of a terdentate ligand PAN with a metal ion has been assumed to involve predominantly an N,N,O-coordination by the heterocyclic nitrogen, the azo nitrogen, and the phenolic oxygen as revealed by X-ray analysis of $[Cu(pan)(OH_2)](ClO_4)$[2] supporting a terdentate structure (Fig. 1). On the other hand, another possibility remains for the terdentate ligand PAN to behave in the metal complex only as a bidentate ligand; two types of N,N-coordination and one N,O-coordination are possible.

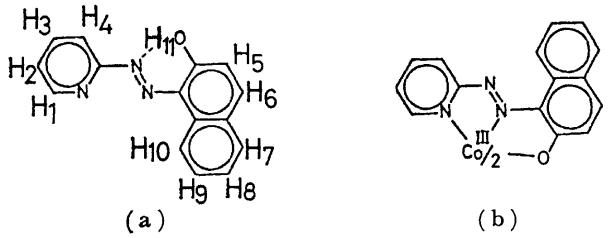

Fig. 1. Structural formulae of (a) PAN with numbering of the protons and (b) its cobalt(III) complex.

In the present study we have synthesized mixed-ligand complexes of cobalt(III) with PAN and a terdentate ligand dien or a qudridentate ligand trien and suggested the possibility for the coordination fashions of PAN as a bidentate or a terdentate ligand in these complexes based on the ^1H NMR and the spectral data.

Experimental

Materials. Reagent grade materials were used unless otherwise specified. A commercial specimen of PAN (Dojindo) was used without further purification, the purity being confirmed by elemental analysis. $[Co^{III}(pan)_2]Cl$ was prepared as reported in a previous paper.[3]

$[Co^{III}(pan)(dien)](ClO_4)_2 \cdot EtOH$ was prepared from $[Co^{III}Cl_3(dien)]$ in the same manner as in the preparation of $[Co^{III}(par)(dien)]Cl \cdot NaCl$.[4] Two grams of PAN dissolved in 200 cm^3 of ethanol was added with stirring at 50 °C to 100 cm^3 of an ethanolic suspension, containing 2.1 g of $[Co^{III}Cl_3(dien)]$ and 0.6 g of charcoal. Addition of 2.1 cm^3 of a 20% aqueous solution of $AgNO_3$ to the reaction mixture gave a deep green solution. The solution was filtered. The filtrate was evaporated to dryness. The residue was dissolved in a minimum amount of water. After the addition of 0.3 g of NaCl, the solution was filtered. Thirty cm^3 of a saturated solution of $NaClO_4$ was added to the filtrate. The precipitates were recrystallized several times from ethanol to yield crystals with green luster. Found: C, 38.38; H, 4.40; N, 13.00%. Calcd for $C_{19}H_{23}N_6O_9Cl_2Co \cdot C_2H_5OH$: C, 38.49; H, 4.46; N, 12.82%. The elemental analysis shows that the isolated mixed-ligand complex contains one mol of ethanol. The complex is soluble in water.

$[Co^{III}(pan)(trien)](ClO_4)_2 \cdot NaClO_4$ was prepared from *cis*-α-$[Co^{III}Cl_2(trien)]Cl$ as follows. The reaction mixture obtained by the same treatment as in the synthesis of $[Co^{III}(pan)(dien)](ClO_4)_2 \cdot EtOH$ was passed through a column of a cation-exchange resin SP-Sephadex C-25 in the Na-form (400×30 mm i.d.) and eluted with a 0.2 mol dm^{-3} aqueous solution of NaCl. The chromatogram consisted of two main bands, a red and a green band **A**, which were eluted in this order. The green eluate from the green **A** band evaporated to a small volume at 40—50 °C. Sodium chloride precipitated was filtered off and the filtrate was evaporated to dryness. The residue was extracted with a small amount of ethanol. The extract was filtered in order to remove residual sodium chloride. After the procedure, filtration, evaporation, and extraction, had been repeated, the final extract was dissolved in a small amount of water. To the solution was added 30 cm^3 of a saturated solution of $NaClO_4$ in order to deposit the perchlorate. The crystals were recrystallized several times from ethanol–ether (1:1 v/v). Found: C, 32.74; H, 3.98; N, 12.26%. Calcd for $C_{21}H_{28}N_7O_9Cl_2Co \cdot NaClO_4$: C, 32.56; H, 3.64; N, 12.66%.

Larger slender plates with green luster were also obtained by slow evaporation of the aqueous solution of the products containing a large amount of $NaClO_4$. Found: C, 30.05; H, 4.02; N, 11.87%. Calcd for $C_{21}H_{28}N_7O_9Cl_2Co \cdot NaClO_4 \cdot 3H_2O$: C, 30.43; H, 4.14; N, 11.83%. Elemental analysis shows that this complex contains 1 mol of $NaClO_4$ and 3 mol of water.

The red eluate from the red band was treated rapidly in the same manner as mentioned above to remove sodium chloride. The precipitate obtained was immediately subjected to measurements without further recrystallization.

The isolated perchlorates of the mixed-ligand complexes

† Presented at the 29th Annual Meeting on Coordination Chemistry, Hamamatsu, October 2, 1979, Abstract, p. 310.

with PAN and trien are soluble in water.

Measurements. 100 MHz ^{1}H NMR spectra were measured with a JEOL spectrometer model PS-100 or FX-100. Tetramethylsilane (TMS) for measurements in $CDCl_3$ or CD_3OD and sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) for those in D_2O solutions were used as internal standards. The perchlorates of cobalt(III) complexes were converted to the more water-soluble chlorides by passing through a column of an anion-exchange resin in the chloride-form, in order to facilitate measurements. The values of the chemical shifts hardly changed with the concentration of the complexes under the experimental conditions. Absorption spectra were measured at 25 °C with a Hitachi recording spectrophotometer Model EPS-3T.

Results and Discussion

The ^{1}H NMR spectrum of the free ligand PAN in $CDCl_3$ is shown in Fig. 2(a). First-order analysis of the spin-spin coupling constants, values of the chemical shifts, and application of a method of double irradiation allowed the assignment of signals to the protons H_1, H_5, H_6, H_{10}, and H_{11} (*cf.* Fig. 1 as regards the numbering of the protons). The spectra of the free ligand PAN and the PAN coordinated in the complexes were too complicated to attain complete assigments for the other protons of PAN. The assignment of the signals to H_1 and H_{10} was further confirmed by a comparison of the spectrum of the free PAN with that of the coordinated PAN in the cobalt(III) complexes. The values of the chemical shifts for the signals of H_1, H_5, H_6, H_{10}, and H_{11} are summarized in Table 1.

The ^{1}H NMR spectrum of $[Co^{III}(pan)(dien)]^{2+}$ in D_2O at pH *ca.* 5 is shown in Fig. 2(b). The integrated intensities of the signals show the presence of ten aromatic protons and six methylene protons (complex multiplet centered at *ca.* 3.3 ppm) corresponding to the coordinated ligands, PAN and dien, respectively.

The ^{1}H NMR spectrum of $[Co^{III}(pan)_2]^+$ in CD_3OD (Fig. 2(c)) indicates that two ligand molecules in $[Co^{III}(pan)_2]^+$ are both magnetically and chemically equivalent.

A remarkable feature found in the ^{1}H NMR spectra of the cobalt(III)–PAN complexes in comparison with those of the free PAN is a large difference in the chemical shift of the proton H_{10}. The H_{10} signal for the free ligand appeared at 8.19 ppm, while the corresponding signals for the coordinated PAN appeared at 9.37 ppm in $[Co^{III}(pan)(dien)]^{2+}$ and 9.64 ppm in $[Co^{III}(pan)_2]^+$. As shown in Fig. 1, the terdentate planar N,N,O-coordination of PAN molecule is necessarily accompanied by a rupture of the intramolecular hydrogen-bond and an internal rotation of the naphthol ring moiety around the C–N axis by 180 °. The molecular model (Fig. 3) suggests that a fairly close contact takes place between the proton H_{10} and the azo group. The proton H_{10} in such a chemical environment would be susceptible to the effect of the magnetic anisotropy due to the π-electron system of the azo group in addition to the effect of the ring current of the naphthol ring. The location of the

proton H_{10} in such an environment causes a down-field shift when the complexes are in the magnetic field. A similar phenomenon was observed in the case of the cobalt(III) complexes with 4-(2-pyridylazo)-resorcinol (PAR) which has a structure similar to that of PAN.[4]

The resonance signal of the H_1 in $[Co^{III}(pan)_2]^+$ shows a definite up-field shift as compared with that in the free PAN hidden among the complex multiplet appearing at the upper field. On the other hand, no such up-field shift was observed for the H_1 signal for $[Co^{III}(pan)(dien)]^{2+}$ (Fig. 1 and Table 1). We see by inspection of molecular models that the difference in the chemical shift observed for the H_1 is caused by the number of PAN molecule involved. The proton H_1 of one of the PAN molecules in $[Co^{III}(pan)_2]^+$ is disposed close to and above the azo group of the other PAN molecule, only when these two PAN molecules coordinate to the cobalt(III) ion in a planar fashion as terdentate ligands (Fig. 3). Consequently, the observed up-field shift can be explained as being caused by the magnetic anisotropy due to the π-electron system of the azo group in the neighboring ligand PAN. Similar up-field shifts have been observed for the protons in the ortho position to the pyridyl nitrogen in $[Co^{III}(par)_2]$[4] and other complexes.[5]

The observed down-field shift of H_{10} signal and the up-field shift of the H_1 signal should give a useful support for the mer configuration also in the similar complex containing ligands with a structure as in Fig. 3 (*e.g.*, the complexes of TAR, TAN, *etc.*).

The data of visible spectra for the cobalt(III) complexes are summarized in Table 2. The positions of absorption bands and the spectral features are essentially the same for these complexes. The values of absorption coefficients for the complexes containing one molecule of PAN, $[Co^{III}(pan)(dien)]^{2+}$ and $[Co^{III}(pan)(trien)]^{2+}$, were about a half of the corresponding absorption coefficients for $[Co^{III}(pan)_2]^+$. The characteristic spectra with three absorption bands at *ca.* 450, 580, and 620 nm were always obtained; in contrast with the case of $[Co^{III}(pan)_2]^+$, for the complexes containing one molecule of PAN the value of absorption coefficient of the absorption band around 580 nm was smaller than that of the absorption around 620 nm. The results indicate that the absorption for these PAN complexes is primarily due to the coordinated PAN molecule and that the PAN molecules in the complexes are in the same electronic state irrespective of the numbers of the ligand.

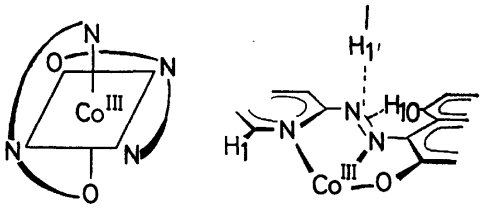

Fig. 3. The mer configuration and the disposition of two PAN molecules in $[Co^{III}(pan)_2]^+$ suggested from a molecular model.

Absence of the pH-dependence in the absorption spectra of these complexes supports the terdentate coordination of the ligand PAN to the central cobalt(III) ion.

Mixed-ligand complexes of cobalt(III) with PAN and trien were synthesized by the reaction of *cis*-α-$[Co^{III}Cl_2(trien)]Cl$ with PAN. Since the coordination sites in the cobalt(III) ion were occupied with a quadridentate triethylenetetramine, only two coordination sites are available for the coordination of the terdentate ligand PAN. If the ligand PAN coordinates to the central cobalt(III) ion as a terdentate ligand, one of the coordination sites in the trien molecule should be dissociated from the cobalt(III) ion.

The data of the ^1H NMR spectra for the red and the green **A** cobalt(III) complex are given in Table 1 (see Experimental for the red and the green **A** complex). The spectral feature and the chemical shifts of the protons H_5, H_6, H_1, and H_{10} in the green **A** complex are very similar to those of $[Co^{III}(pan)(dien)]^{2+}$, which show down-field shift of the resonance for the proton H_{10} and no up-field shift of the resonance for the proton H_1. This suggests that in the green **A** complex the ligand PAN coordinates to the cobalt(III) ion in a planar terdentate fashion and one of the sites of coordination in the ligand trien should be dissociated from the cobalt(III) ion. On the other hand, the spectral feature and the chemical shifts for H_1 and H_{10} of the red cobalt(III) complex differ from those of the green **A** complex, the free PAN, $[Co^{III}(pan)_2]^+$, and $[Co^{III}(pan)(dien)]^{2+}$; in the ^1H NMR spectrum of the red complex no corresponding down-field shift of the resonance for H_{10} was observed, suggesting the possibility of the contribution of some other coordination structure in the ligand PAN.

The visible spectrum of the green **A** complex is essentially the same as that of $[Co^{III}(pan)(dien)]^{2+}$. On the other hand, the spectrum of the red complex differs from that of (1) PAN, $[Co^{III}Cl_2(trien)]^+$, and $[Co^{III}(OH_2)_2(trien)]^{3+}$, (2) the cobalt(III) complex with nitrosonaphthol[6] which is assumed to be a decomposition product of PAN, and (3) a bivalent cobalt

Table 2. Data of absorption spectra

$[Co^{III}(pan)_2]^+$ in DMSO		$[Co^{III}(pan)(dien)]^{2+}$ in H_2O (DMSO)		$[Co^{III}(pan)(trien)]^{2+}$ in H_2O[a]	
λ_{max}/nm	$\varepsilon/10^4$ mol^{-1} dm^3 cm^{-1}	λ_{max}/nm	$\varepsilon/10^4$ mol^{-1} dm^3 cm^{-1}	λ_{max}/nm	$\varepsilon/10^4$ mol^{-1} dm^3 cm^{-1}
453	2.38	444 (448)	1.32 (1.41)	452	1.11
582	2.23	570 (574)	1.08 (1.11)	577	0.90

a) Green **A** complex (see text).

complex, $[Co^{II}(pan)_2]$.[1] The observations suggest the possibility that the ligand PAN in the red complex coordinates to the cobalt(III) ion not in a planar terdentate fashion but in some other way.

Upon standing for a long time or heating with a small amount of 0.1 mol dm^{-3} solution of NaOH, the color of the solution of the red complex turned green, showing the formation of a green complex **B**. The color of the solution of this green **B** complex was not changed reversibly to red under the experimental conditions. The visible spectrum of the solution of the green **B** complex was essentially the same as that of the green **A** complex in the eluate from the ion-exchange column. The ^1H NMR spectra of the green **B** product also showed down-field shift of the H_{10} signal, though the spectra corresponding to the trien in the green **B** complex differ a little from those in the green **A** complex in the eluate.

The results suggest that the multidentate ligand PAN in these two green complexes **A** and **B** coordinates to the cobalt(III) ion in a planar terdentate fashion and the green cobalt(III) complex is more stable than the red cobalt(III) complex. When the synthesis of the mixed-ligand PAN-trien complex of cobalt(III) was carried out in a slightly basic media containing a small amount of NaOH, only the green complexes were obtained, the formation of the red complex was no longer observed.

On the basis of these results, we conclude that the multidentate lignad PAN has a very strong tendency to function as a planar terdentate lignad in the cobalt(III) complexes.

Spin-state Equilibria of the Nickel(II) Complexes of 2,12-Dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),2,11,13,15-pentaene Analogs in Water

(Received February 21, 1980)

Spin-state equilibria between a singlet low-spin and a triplet high-spin species of the title complexes in water were investigated by means of electronic spectra. The equilibrium constants and the thermodynamic parameters, ΔH and ΔS, were evaluated from detailed analysis of the temperature-dependence of the electronic spectra. The electronic spectra of the singlet and the triplet species involved were also derived, from the same analysis. The formation of the triplet species was found to be exothermic, which reflects the predominant contribution of the exothermic change to the formation of nickel(II)–water bond over the contribution of the endothermic change in the bond length caused by the change in spin state. The absolute values of ΔS almost correspond to those expected for the effective liberation of two molecules of water in aqueous solution.

Nickel(II) complexes with the title macrocyclic quadridentate ligands, $[Ni(L+nH)]^{2+}$ (n=−2 (**1**), 0 (**2**), 2 (**3**), and 4 (**4**): Fig. 1), have been reported to be often in an equilibrium between a singlet low-spin (diamagnetic square planar) and a triplet high-spin (paramagnetic pseudo octahedral) species in coordinating solvents,[1-3] as described by

$$[Ni(L+nH)]^{2+} + 2S \rightleftharpoons [Ni(L+nH)S_2]^{2+}, \quad (1)$$

where S denotes a coordinating solvent such as water, methanol, dimethyl sulfoxide, *N*,*N*-dimethylformamide, or acetonitrile.

Fig. 1. Structural formulae of the complexes, $[Ni(L-2H)](ClO_4)_2$ (**1**), $[Ni(L)](ClO_4)_2$ (**2**), $[Ni(L+2H)](ClO_4)_2$ (**3**), and $[Ni(L+4H)](ClO_4)_2$ (**4**).

Though the exact electronic spectra of the component species are required for the spectrophotometric evaluation of the equilibrium constant and the thermodynamic parameters for Equilibrium 1, evaluation of such component spectra was difficult because of the equilibrium immediately attained in a coordinating solvent.

In the present study we applied detailed analysis of the temperature-dependence of the electronic spectra to the spin-state equilibria of $[Ni(L+nH)]^{2+}$ in water for the evaluation of electronic spectra of the components, which allow the evaluation of equilibrium constants and thermodynamic parameters.

Experimental

Materials. Deionized water was distilled. Sodium perchlorate for the adjustment of ionic strength was recrystallized three times after traces of heavy metal ions had been removed. The nickel(II) complexes, $[Ni(L+nH)](ClO_4)_2$ (**1**—**4**), were synthesized according to the literature.[1,2,4,5] The purity was confirmed by elemental analysis.

Measurements. The absorption spectra were measured with a Hitachi recording spectrophotometer model 340 equipped with a data printer, the absorbance being recorded within ±0.001. The temperature was measured with a copper-constantan thermocouple and a digital thermometer TAKEDA TR-2121, and maintained within ±0.1 °C. All measurements were carried out at a constant ionic strength, I=0.1 ($NaClO_4$) (see below).

Analyses of the Data

Derivation of the electronic spectra of the component species and calculations of the equilibrium constants and the thermodynamic parameters were carried out as follows, an appropriate computer program being designed for the present purpose.[6]

The equilibrium constant for Eq. 1 is defined as

$$K = [\text{triplet}]/[\text{singlet}]. \quad (2)$$

This equation is transformed into Eq. 3 by introducing the molar absorption coefficients at an arbitrary wavelength λ_n, ε_{sn} and ε_{tn}, for the singlet and the triplet species, respectively, and the apparent molar absorption coefficient, ε_{obsn}, for the solution in equilibrium,

$$K = (\varepsilon_{sn}-\varepsilon_{obsn})/(\varepsilon_{obsn}-\varepsilon_{tn}). \quad (3)$$

At the wavelength λ_0 where ε_{s0} equals 0, Eq. 3 becomes

$$K = \frac{\varepsilon_{obs0}}{\varepsilon_{t0}-\varepsilon_{obs0}}. \quad (4)$$

The temperature-dependence of the equilibrium constant, K, is given by Eq. 5, provided that the molar absorption coefficients for the singlet and the triplet species do not depend on the temperature

$$\ln K = \ln\left(\frac{\varepsilon_{obs0}}{\varepsilon_{t0}-\varepsilon_{obs0}}\right) = \frac{\Delta S_0}{R} - \frac{\Delta H_0}{RT}. \quad (5)$$

Since Eq. 3 also holds at an arbitrary wavelengh λ_n, the following relationship is immediately derived:

$$\varepsilon_{obsn} = \varepsilon_{sn} - \frac{(\varepsilon_{sn}-\varepsilon_{tn})}{\varepsilon_{t0}}\cdot\varepsilon_{obs0}, \quad (6)$$

where ε_{obsn} and ε_{obs0} denote the apparent molar absorption coefficients at T K observed at λ_n and λ_0, respectively. This equation enables the calculation of the absorption coefficients, ε_{sn} and ε_{tn}, at any arbi-

trary wavelength λ_n from the plot of ε_{obsn} against ε_{obs0} at various temperatures. The absorption spectra for the singlet and the triplet form are constructed by plotting the values of ε_{sn} and ε_{tn} against the wavelengths λ_n, respectively.

The Arrhenius equation holds also in terms of ε_{sn} and ε_{obsn}:

$$\ln K = \ln\left(\frac{\varepsilon_{sn}-\varepsilon_{obsn}}{\varepsilon_{obsn}-\varepsilon_{tn}}\right) = \frac{\Delta S_n}{R} - \frac{\Delta H_n}{RT}. \quad (7)$$

The thermodynamic parameters, ΔS_n and ΔH_n, are evaluated from Eq. 7. The values of molar absorption coefficient at λ_n could be calculated by Eq. 8 with respect to K,

$$\varepsilon_{calcn} = \varepsilon_{sn} + \frac{\varepsilon_{sn}-\varepsilon_{tn}}{1+K}. \quad (8)$$

Actual calculations were carried out according to the following directions by means of an appropriate computer program which includes the least-square fits for Eqs. 5 and 7.[6]

(1) Choose the wavelength λ_0 where $\varepsilon_{s0}=0$ (In some cases λ_0 where $\varepsilon_{t0}=0$ should be chosen).

(2) Calculate the value of K at T K by means of Eq. 4 for an appropriate value of ε_{t0} and plot the value of log K against T^{-1} by means of Eq. 5.

(3) Repeat the calculations in (2) by changing the values of ε_{t0} until a linear plot is obtained. Determine the optimum value for ε_{t0}.

(4) For the optimum value of ε_{t0} evaluated in (3), plot the values of ε_{obsn} against those of ε_{obs0} at various temperatures by means of Eq. 6. Evaluate the values of ε_{sn} and ε_{tn} at λ_n from the slope $(\varepsilon_{sn}-\varepsilon_{tn})/\varepsilon_{t0}$ and the intercept ε_{sn}.

(5) Calculate the value of K_n at T K with the values of ε_{sn} and ε_{tn} by means of Eq. 7 and plot the Arrhenius relationship. Evaluate the values of ΔH_n and ΔS_n at λ_n from the slope and the intercept. Confirm the coincidence of all values with each other for ΔH_n and ΔS_n obtained at λ_n.

(6) Calculate the values of ε_{calcn} at various λ_n with the values of K, ΔH and ΔS, and ε_{sn} and ε_{tn}. Confirm the coincidence of the calculated values of ε_{calcn} with those of ε_{obsn} measured at λ_n.

Results and Discussion

Figure 2 shows the electronic spectra of $[Ni(L)]^{2+}$ in water at various temperatures. The spectrum changes reversibly with an isosbestic point at 590 nm. With rise in temperature the absorption at 395 nm remarkably increases and the absorption at 720 nm decreases. Based on the assignment of the absorption maxima at 450 and 720 nm to the singlet and the triplet species, respectively, we deduced that the given spectral change corresponds to the temperature-dependence of the spin-state equilibrium of the given complex between the singlet square planar and the triplet pseudo octahedral species. Similar temperature-dependence in the electronic spectra was observed also for the other analogous $[Ni(L+nH)]^{2+}$–H_2O systems, indicating the temperature-dependent equilibrium between the triplet and the singlet species.

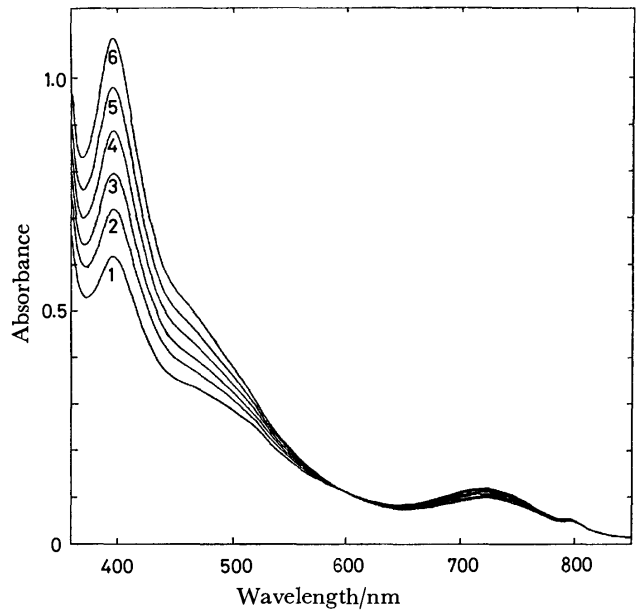

Fig. 2. Absorption spectra of $[Ni(L)](ClO_4)_2$ in H_2O (4.98×10^{-3} mol dm^{-3}) at various temperatures. At I=0.1 ($NaClO_4$). Measured at 279.2 (1), 285.6 (2), 290.0 (3), 294.8 (4), 299.3 (5), and 303.8 K (6).

The detailed analyses of the temperature-dependence of the spectra as described in the foregoing section allowed us to calculate the equilibrium constant, K, and the thermodynamic parameters, ΔH and ΔS, of Equilibrium 1 and also to derive the individual spectrum of the singlet and the triplet species. Since in the $[Ni(L)]^{2+}$–H_2O system an absorption peak at 720 nm assigned to a triplet species is well separated from the absorption peaks of the singlet species appearing at shorter wavelengths, 720 nm was adopted as an appropriate wavelength λ_0 for the $[Ni(L)]^{2+}$–H_2O system, where $\varepsilon_{s0}=0$.

Figure 3 shows a set of plots of log K for the $[Ni(L)]^{2+}$–H_2O system against T^{-1} as derived from Eq. 5 for various values of ε_{t0}. We see that only the plot for $\varepsilon_{t0}=27.6$ mol^{-1} dm^3 cm^{-1} gives a straight line; for any values of ε_{t0} larger than 27.6 mol^{-1} dm^3 cm^{-1} the plot always gives a curve with positive curvature, and for any values of ε_{t0} smaller than 27.6 mol^{-1} dm^3 cm^{-1} a curve with negative curvature. The values of ε_{sn} and ε_{tn} at an arbitrary wavelength λ_n are evaluated using this value of ε_{t0} and the values of ε_{obsn} by means of Eq. 6. The validity of the value 27.6 mol^{-1} dm^3 cm^{-1} as ε_{t0} was again confirmed for the linear dependence on T^{-1} of the values of K derived from the values of ε_{sn} and ε_{tn} using Eq. 7. The values of ΔH and ΔS were calculated as slopes and intercepts by means of Eqs. 5 and 7. The adopted wavelength λ_0 and the evaluated ε_{t0} for the series of $[Ni(L+nH)]^{2+}$–H_2O systems are summarized in Table 1.

Figure 4(a) shows the electronic spectra of the singlet and the triplet species, $[Ni(L)]^{2+}$ and $[Ni(L)(OH_2)_2]^{2+}$, reproduced by plotting against λ_n the values of ε_{sn} and ε_{tn} calculated by means of Eq. 6, respectively. The absorption maximum at 395 nm (ε=1011 mol^{-1}

$dm^3\ cm^{-1}$) and the d-d absorption band around 450 nm are clearly shown in the spectrum of the singlet species. A remarkable feature in the electronic spectrum of the triplet species is the clear discrimination of a weak absorption band around 520 nm by the analysis of electronic spectra. The band is almost included in the envelope of a very strong singlet band and is observed only as an indiscernibly weak shoulder in Fig. 2. Figure 4(b) shows the electronic spectra of the singlet and the triplet species in the *meso*-[Ni-(L+4H)]$^{2+}$-H_2O system. The weak absorption band around 500 nm of the triplet species, not recognized in the spectrum of the equilibrium mixture of the triplet and the singlet species, is also clearly discriminated by the same analysis. The results indicate that the proposed analysis is useful also for the de-

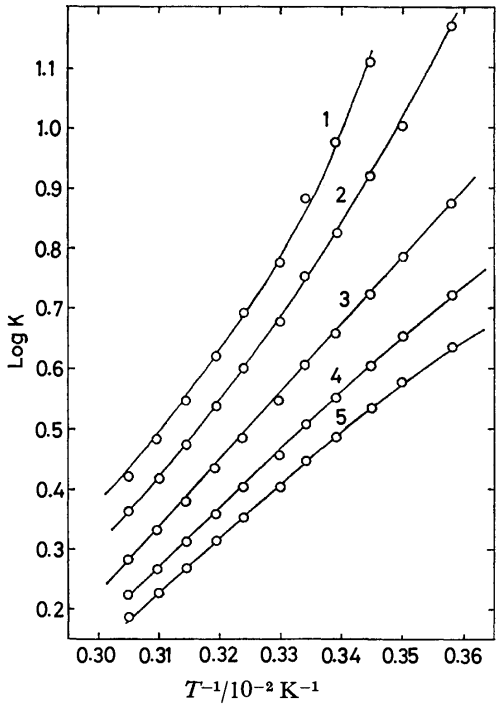

Fig. 3. Plots of $\log K$ *vs.* T^{-1} for $[Ni(L)](ClO_4)_2$ (4.98×10^{-3} mol dm^{-3}) for various values of ε_{t0} at 720 nm. The values of ε_{t0} at 720 nm: 25.0 (1), 26.0 (2), 27.6 (3), 29.0 (4), and 30.0 $mol^{-1}\ dm^3\ cm^{-1}$ (5).

tection of unknown weak absorption bands of the components hidden in the spectrum of an equilibrium mixture.

The values of equilibrium constants, K, at 299.3± 0.1 and 303.4±0.4 K are given in Table 2. The value of K at 299.3 K is larger than that at 303.4 K, indicating a decrease in the triplet form with rise in temperature. The degree of formation of the triplet species for $[Ni(L)](ClO_4)_2$ is the largest among the given $[Ni(L+nH)](ClO_4)_2$–H_2O systems. This can be interpreted as follows. The in-plane ligand-field strength is assumed to be in the order, $[Ni(L+4H)]^{2+}<[Ni(L+2H)]^{2+}<[Ni(L)]^{2+}<[Ni(L-2H)]^{2+}$.[7] On the other hand, the steric hindrance at an axial coordination site caused by the proton of secondary amine and/or methyl moiety in the ligand molecule is assumed to be in the reversed order. The ease with which an axial ligand coordinates to the central atom is expected to be the largest at $[Ni(L)]^{2+}$ having moderate effects both in the in-plane ligand-field strength and in the steric hindrance at an axial coordination site.

The thermodynamic parameters for Equilibrium 1 are given in Table 3 (see Experimental). The negative values of ΔH indicate that formation of the triplet species is exothermic for all $[Ni(L+nH)]^{2+}$–H_2O systems. For the complexes of similar quadridentate ligands the Ni–N bond length has been reported to be $(2.07—2.10)\times10^{-8}$ cm in the high-spin complexes and $(1.88—1.91)\times10^{-8}$ cm in the singlet low-spin complexes.[7,8] For the formation of a triplet species the Ni–N bonds in a complex should be elongated; this change in the bond length in the in-plane ligand should cause the endothermic effects. The negative values of ΔH obtained reflect the exothermic contribution of the formation of Ni–water bond exceeding the endothermic contribution of change in the spin-state.

a) Under the same conditions as in Table 1. b) α-*C-meso* isomer (see Ref. 5). c) *C-rac* isomer.

The absolute values of ΔS nearly correspond to those expected for the effective liberation of two water molecules from the title complexes in aqueous solution, *viz.*, $(30\sim40)\times2$ J K^{-1} mol^{-1}.[9]

Table 4 shows the effects of the addition of $NaClO_4$ on the spin-state equilibria in the $[Ni(L)]^{2+}$– and the *rac*-$[Ni(L+4H)]^{2+}$–H_2O system. In both cases addition of $NaClO_4$ enhanced the intensity of the singlet bands, which shows the increase in the singlet species in equilibrium. In a solution containing high concentrations of $NaClO_4$, *e.g.*, 6 mol dm^{-3}, no temperature-dependence of the spectrum was observed, showing the predominance of the singlet species in the equilibrium. The value of molar absorption coefficient ($\varepsilon=1167$ mol^{-1} dm^3 cm^{-1}) measured in 6 mol dm^{-3} $NaClO_4$ at 395 nm, absorption maximum for the singlet species, agreed with that evaluated from the above calculation. The decrease in K with increasing concentrations of $NaClO_4$ was almost the same in the case of the $[Ni(L)]^{2+}$– and the *rac*-$[Ni(L+4H)]^{2+}$–H_2O system. A similar effect has been reported in other spin-state equilibria such as $[Ni(trien)]^{2+}$–H_2O,[10] $[Ni(cyclam)]^{2+}$–H_2O,[11] and $[Ni(isocyclam)]^{2+}$–H_2O systems,[12] where trien, cyclam, and isocyclam denote quadridentate ligands, triethylenetetramine, 1,4,8,11-tetraazacyclotetradecane, and 1,4,7,11-tetraazacyclotetradecane, respectively. On the basis of these observations, all measurements in the preceding paragraphs were carried out at a constant ionic strength, $I=0.1$ ($NaClO_4$).

(Received January 31, 1980)

trans-Chloro(3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II) (**1**) reacted with 1,2-bis(diphenylphosphino)ethane (dppe), 1,10-phenanthroline (phen), sodium diethyldithiocarbamate–water (1/3), and sodium tetra(1-pyrazolyl)borate {Na[BPz_4]} (Pz=1-pyrazolyl) to give the corresponding new (3-oxo-1-cyclohexenyl)-palladium(II) complexes, [Pd(oxch)Cl(dppe)] (oxch=3-oxo-1-cyclohexenyl) (**2**), [Pd(oxch)Cl(phen)], [Pd(oxch)(S_2CNEt_2)(PPh_3)], and [Pd(oxch)(BPz_4)(PPh_3)], respectively. Complex **2** was treated with carbanions derived from methyl and ethyl cyanoacetates and malononitrile, and new diorganopalladium(II) complexes were obtained. These complexes were characterized by means of elemental analyses and IR and ^{1}H-NMR spectroscopy. The stereochemical nonrigidity of the BPz_4 complex was discussed.

In our previous study,[1] linear and cyclic (β-carbonylvinyl)chlorobis(triphenylphosphine)palladium(II) complexes were prepared by oxidative addition reactions of [$Pd(PPh_3)_4$] towards the corresponding linear and cyclic chlorovinyl ketones. Little has been known about the reactivity of the (β-carbonylvinyl)-palladium(II) complexes.

This paper deals with some new (3-oxo-1-cyclohexenyl)palladium(II) complexes, derived from the reactions of the cyclic β-carbonylvinyl palladium(II) complex, *trans*-chloro(3-oxo-1-cyclohexenyl)bis(triphenylphosphine)palladium(II) [Pd(oxch)Cl(PPh_3)$_2$] (oxch=3-oxo-1-cyclohexenyl) (**1**) towards bidentate ligands. In addition, one of the new complexes, {1,2-bis(diphenylphosphino)ethane}chloro(3-oxo-1-cyclohexenyl)palladium(II) (**2**) was treated with carbanions formed from active methylene compounds, and new stable diorganopalladium(II) complexes were obtained. Organopalladium(II) complexes have already been prepared from reactions of chloropalladium(II) complexes with the carbanions.[2-4]

Experimental

General Procedure. Melting points and IR and ^{1}H-NMR spectra were measured according to the previous paper.[1] Complex **1**, 1,2-bis(diphenylphosphino)ethane (dppe),[5] and sodium tetra(1-pyrazolyl)borate{Na[BPz_4]} (Pz=1-pyrazolyl)[6] were synthesized in the described methods. 1,10-Phenanthroline (phen), sodium diethyldithiocarbamate–water(1/3) {Na[dedc]·$3H_2O$}, and the other reagents were commercial samples, and were used without further purification.

*Reaction of **1** with dppe or phen.* A benzene solution (110 ml) containing **1** (1.68 mmol) and dppe (1.85 mmol) was stirred at room temperature for 48 h. The resulting greyish white solids were collected and washed with benzene and diethyl ether to give [Pd(oxch)Cl(dppe)] (**2**). Complex **1** reacted similarly with phen to afford [Pd(oxch)Cl(phen)] (**3**).

*Halogen Metathesis of **3**.* An acetone suspension (20 ml) involving **3** (0.08 mmol) and lithium bromide (0.80 mmol) was refluxed for 40 h. The resulting solids were separated and added to 20 ml of ethanol, followed by stirring for 20 h at room temperature. Off-white powders were collected and washed with ethanol and diethyl ether to yield [PdBr(oxch)(phen)] (**4**).

*Reaction of **1** with Na[dedc]·$3H_2O$.* A benzene suspension (35 ml) containing **1** (0.25 mmol) and Na[dedc]·$3H_2O$ (0.28 mmol) was heated at 55 °C for 8 h. After the resulting solid was filtered off, the solvent was removed under reduced pressure. The residue was recrystallized from benzene–hexane to give [Pd(oxch)(dedc)(PPh_3)] (**5**).

*Reaction of **1** with Na[BPz_4].* A benzene suspension (30 ml) involving **1** (0.23 mmol) and Na[BPz_4] (0.24 mmol) was refluxed for 3 h. After the resulting precipitate was filtered off, the solvent was evaporated to dryness. The residue was recrystallized from benzene–diethyl ether to afford [Pd(oxch)(BPz_4)(PPh_3)] (**6**).

*Reactions of **2** with Carbanions Formed from Alkyl Cyanoacetates or Malononitrile.* A methanol solution (30 ml) of sodium methoxide (0.19 mmol) was added dropwise to a THF suspension (30 ml) containing **2** (0.19 mmol) and methyl cyanoacetate (0.37 mmol). The mixture was stirred at room temperature for 20 h. After filtration, the filtrate was evaporated to dryness. The residue was extracted with dichloromethane, and the solvent was removed under reduced pressure. The resulting solids were recrystallized from THF–hexane to give [Pd{CH(CN)CO_2Me}(oxch)(dppe)] (**7**).

Complex **2** reacted similarly with ethyl cyanoacetate and malononitrile in the presence of sodium ethoxide in an equimolar amount of **2**, followed by the analogous treatments to the case of **7**, to afford [Pd{CH(CN)CO_2Et}(oxch)(dppe)] (**8**) and [Pd{$CH(CN)_2$}(oxch)(dppe)] (**9**), respectively.

Results and Discussion

General Properties. The *trans*-bis(triphenylphosphine) type complex **1** underwent substitution by the bidentate ligands, dppe, phen, [dedc]$^-$, and [BPz_4]$^-$, affording new neutral complexes **2**, **3**, **5**, and **6**, respectively. Furthermore, the dppe type complex **2** reacted with carbanions formed from methyl and ethyl cyanoacetates and malononitrile, to give novel diorganopalladium(II) complexes, **7**—**9**, respectively. The phen-type complex **3** underwent halogen metathesis to afford the bromo complex **4**. The yields, analytical data, and some properties of these new complexes are summarized in Table 1. Complexes **2** and **5**—**9** are soluble in usual organic solvents except saturated hydrocarbons, whereas **3** and **4** are highly insoluble in the solvents.

All the new complexes showed two strong IR bands near 1630 and 1540 cm^{-1}, ascribable to ν(C=O) and ν(C=C) frequencies, respectively (Table 2). In addi-

a) Measured in nitrogen atmosphere. All complexes except **8** decomposed without melting.

tion, each of **2** and **5**—**9** exhibited a strong band and a medium one near 1425 and 1475 cm^{-1}, respectively, characteristic of ν(P–C) frequencies.

Complexes **2**—**5**. Complexes **2**—**5** are stable in a solid state in air. However, **2** begins to decompose in deoxygenated dichloromethane at ambient temperature after 1 h, in contrast to **1** and its 5,5-dimethyl homologue. The relatively low stability of **2** is probably due to the lowering of the bond order of the palladium-carbon bond, owing to a considerably strong *trans* influence of the phosphino group located at the *trans* position to the palladium-carbon bond.

In the ^{1}H-NMR spectrum of **2** in CD_2Cl_2, the olefinic proton (2-H) of the oxch moiety resonated as a multiplet at δ 5.95{$^4J(HP_{trans})$=12.0 Hz, $^4J(HP_{cis})$=4.5 Hz, and ^4J(H-6-H)=1.3 Hz}, indicating unambiguously that two phosphino groups were coordinated at *trans* and *cis* positions to the oxch moiety. The IR spectrum of **2** exhibited a ν(Pd–Cl) band at 300 cm^{-1}, which was higher by 20 cm^{-1} than that for **1** (Table 2). This shift to the higher wave number is associated with the difference between the *trans* influence of the phosphino group in **2** and that of the oxch moiety in **1**. The ν(Pd–Cl) frequency of **3** appeared at higher wave number, corresponding to the nitrogen donor site located at a *trans* position to the palladium-chlorine bond.

The anionic bidentate ligand $[dedc]^-$ substituted both the chloro ligand and one of the two triphenylphosphine ligands in **1**, giving the neutral complex **5**, in contrast with the neutral bidentate ligand, such as dppe or phen. It is the case with the $[BPz_4]^-$ ligand, affording the neutral complex **6**, too. The ^{1}H-NMR spectrum of **5** exhibited two ethyl resonances, besides proton signals attributable to the oxch moiety (Table 3) and to the phenyl groups. This proves a double bond character of the carbon-nitrogen bond in the dedc ligand.[7]

a) In cm^{-1}, in KBr disk.

The [BPz_4] *Complex* **6**. Complex **6** shows a considerably high stability not only in the solid state in the air, but also in the solution of benzene, chloroform, or dichloromethane. It is worthy to note that the [BPz_4] ligand serves as a stabilizing ligand for the palladium-carbon bond, presumably owing to the electronic and steric effects of the ligand. The [BPz_4] ligand in **6** was believed to act as a bidentate chelate, since a relatively electron-rich palladium atom in **6** prevents coordination to the third pyrazolyl group in similar fassion to its related BPz_4–palladium(II) complexes.[8-10]

The ^{1}H-NMR spectra of **6** in $CDCl_3$ showed a temperature dependency in the region 50——31 °C, implying a stereochemically nonrigid motion of the BPz_4 ligand (Fig. 1). The pyrazolyl proton resonances

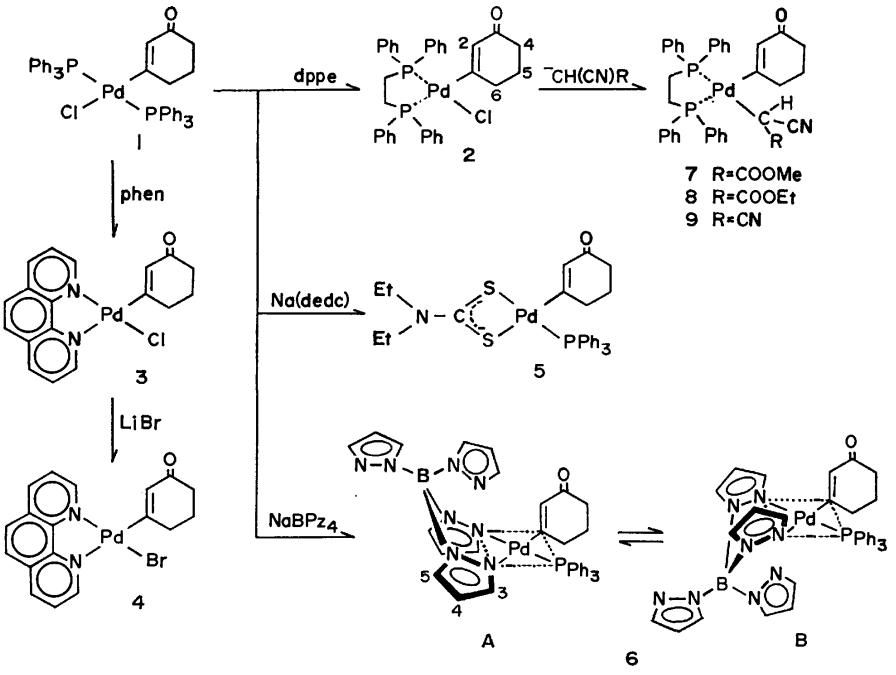

Scheme 1.

at 50 °C indicate that the four pyrazolyl groups are spectroscopically equivalent and move in a tumbling process[8] at a fairly fast rate on the NMR time scale, while the fast-exchange limiting spectrum was not obtained.

At −2 °C, the 4-H signal of the BPz_4 ligand separated into a slightly broad triplet at δ 5.76 (1H, $^3J_{HH}$=2 Hz) and two broad signals at δ 6.3 (2H, overlapping with 2-H of the oxch moiety) and 6.43 (1H). The larger broad signal at δ 6.3 was ascribed to two uncoordinated pyrazolyl groups, which exchanged rapidly with each other, accompanied both by the inversion of the Pd-(N-N)$_2$-B boat-type six-membered ring and by the fluttering of two coordinated pyrazolyl groups (**6A** and **6B** in Scheme 1). The third pyrazolyl group, corresponding to the smaller broad signal at δ 6.43, was one of the two coordinated pyrazolyl groups and exchanged slowly with the former two uncoordinated pyrazolyl ones. The fourth pyrazolyl group, associated with the triplet at δ 5.76, was virtually fixed at this temperature. Similar type of motion of the BPz_4 ligand has been reported concerning [Pd(cdamb)(BPz_4)] (cdamb=2-chloro-3-dimethylamino-3-methyl-1-butenyl-1-*C*,*N*)[10] and its related complexes.[10]

At −31 °C, the larger broad signal separated into two broad signals at δ 6.28 (1H) and 6.50 (1H), indicating that the motion of the BPz_4 ligand turned considerably sluggish. However, **6** gave no slow-exchange limit spectrum even at this temperature.[11]

The Diorganopalladium(II) Complexes 7—9. The IR and ^{1}H-NMR data of **7**—**9** indicate undoubtedly that each of **7**—**9** retains the oxch moiety unchanged and the dppe chelate, while the ^{1}H-NMR spectra of **7** and **8** exhibit complicated signals near δ 1.5—2.5 for 4-, 5-, and 6-H's of the oxch moiety. The nonionic character of these complexes was confirmed by their low molar conductivities (Λ=2.5—5.0 Ω^{-1} cm^2 mol^{-1} in 1.0 mmol/dm^3 acetone solution). The IR spectrum of **7** showed a moderate band at 2180 cm^{-1}, which was assigned to a ν(C≡N) frequency but not to a ν(C=C=N) one in a keteniminato type [Pd-N=C=CH(CO_2Me)].[2,12] In addition, the methine proton of the cyano(methoxycarbonyl)methyl moiety in **7** resonated as a doublet at δ 3.43 ($^3J_{HP}$=9.8 Hz). The chemical shift is considerably similar to those of the methine protons in [Pd{CH(CN)CO_2Me}(pip)] {pip=2-(2-picolylimino)-4-pentanonato-*N,N,O*} and its related complexes.[4] The value of the coupling constant $^3J_{HP}$ is consistent with the protons adjacent to the carbon atom located at a *trans* position to a tertiary phosphine.[13,14] This evidence comfirms unambiguously that the cyano(methoxycarbonyl)methyl moiety in **7** is bonded to the palladium atom with the methine-carbon-palladium σ-bond but not with a nitrogen-palladium bond in the keteniminato type. It is the case with **8**, the ethyl ester homologue of **7**, or with **9**, which has a dicyanomethyl moiety in place of the cyano(methoxycarbonyl)methyl one in **7**.

Complexes **7**—**9** are considerably stable both in the solid state and in the deoxygenated solution of dichloromethane. Moreover, **7**—**9** are inactive to alcohol in THF, as expected from the preparative methods, and are in contrast to [$PdMe_2(PEt_3)_2$].[15] It seems likely that the thermal stability of **7**—**9** is actually comparable with that of [$PdMe_2$(dppe)] and related dimethylpalladium complexes.[14,15] However, **7**—**9** are more sluggish to aerial oxidation than the dimethylpalladium complexes.[14] These stabilities of **7**—**9** and their insensitivity to air are possibly due to the electron-delocalization effect of the electron-withdrawing substituents in the organic moieties attached to the palladium atom.

Complex **2** reacted with the carbanion derived from dimethyl malonate in a procedure similar to the preparation of **7**, giving no isolated pure product. However, **2** did not react with the carbanion formed from methyl acetoacetate, remaining the starting complex **2** recovered. The inertness of the latter carbanion was due to its lower nucleophilicity in comparison with the former carbanion or with the carbanion conducted from methyl cyanoacetate.[16] Complex **3** did not react with the carbanion from methyl cyanoacetate, probably owing to the high insolubility.

We wish to express our gratitude to Mrs. Hisako Mazume and Miss Yumi Kojima, Nagasaki University, for their technical assistance.

Deuteration Reaction of Malonate Hydrogens in Some Monomalonatocobalt(III) Compounds[1]

Ushio SAKAGUCHI, Michie NAKANO, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received February 25, 1980)

The rate of deuteration at malonate hydrogens has been measured for $[Co(mal)(N)_4]^+$ and $[Co(malH)(NH_3)_5]^{2+}$ ions in aqueous solution over the pD range of 2 to 8, where mal=malonate dianion, malH=malonate monoanion, and $(N)_4=(NH_3)_4$, (ethylenediamine)$_2$, (1,3-propanediamine)$_2$, (1,10-phenanthroline)$_2$, or (2,2′-bipyridine)$_2$. For the tetraamine type complexes with a chelated malonate ligand, the deuteration process is acid-catalysed up to pD=about 4 and base-catalysed at higher pD values. This contrasts with the behavior of the unidentate malonate ligand, for which the deuteration is base-catalysed up to pD=3.5, whereupon the deprotonation of the carboxylate group takes place and the deuteration rate steps down to a constant, pH-independent value. The deuteration mechanisms are discussed.

In 1967, Yoneda and Morimoto[2] found that the methylene hydrogens of malonate chelated to a cobalt (III) ion exchange with deuterium in deuterium oxide. Since the exchange was observed simply by dissolving the cobalt(III) compounds in deuterium oxide, this facile exchange was ascribed to the electron-withdrawing power of the central metal ion. Subsequently, a similar facile deuteration was confirmed to take place for several malonatocobalt(III) complexes.[3-7] Buckingham *et al.* noted that the malonate hydrogens in $[Co(mal)_2(en)]^-$ and $[Co(mal)(en)_2]^+$ ions[4] appear to undergo acid-catalysed and probably base-catalysed exchange. Farago and coworkers[5-7] recently measured the deuteration rates for $[Co(mal)(bpy)_2]^+$, $[Co(mal)_2(en)]^-$, and $[Co(mal)(en)_2]^+$ in the pD range of about 2 to 3 at several temperatures. They confirmed that the exchange reaction is in fact acid-catalysed. We have measured the exchange rates at 36.4 °C over a wide pH region for $[Co(mal)(N)_4]^+$ type of complexes, as well as $[Co(malH)(NH_3)_5]^{2+}$, where $(N)_4$ represents $(NH_3)_4$, $(en)_2$, $(tn)_2$, $(phen)_2$, or $(bpy)_2$.

Experimental

Materials. Deuterium oxide (99.8 atom% D minimum) was obtained from E. Merck (Darmstadt). Malonic acid and other chemicals were purchased from Katayama Chemical Industries Co., Ltd. (Osaka).

Pentaamminemalonatocobalt(III) perchlorate,[8] tetraamminemalonatocobalt(III) perchlorate,[9] and bis(ethylenediamine)malonatocobalt(III) iodide hemihydrate,[10] were prepared by the literature methods and the identity was confirmed by visible absorption and NMR spectra. The en compound was optically resolved by (−)-$[Co(edta)]^-$ after Jordan *et al.*[10] The tn compound was prepared from $[Co(CO_3)(tn)_2]ClO_4$ and malonic acid. Found: N, 13.46; C, 26.46; H, 5.42%. Calcd for $[Co(mal)(tn)_2]ClO_4$: N, 13.71; C, 26.45; H, 5.43%. The bis(phen) compound was synthesized from $[CoCl_2(phen)_2]Cl\cdot 3H_2O$[11] and sodium malonate in aqueous solution. The solution was heated on a water bath until the color of the solution changed to red and then filtered while hot. Cooling the filtrate to room temperature yielded needle-like crystals. These were recrystallized from warm water and suction filtered. Found: N, 8.37; C, 48.41; H, 3.67%. Calcd for $[Co(mal)(phen)_2]Cl\cdot NaCl\cdot 3H_2O$: N, 8.37; C, 48.45; H, 3.61%. The absorption maximum in water was at 510 nm (ε=94). The bipyridine compound, $[Co(mal)(bpy)_2]Br\cdot H_2O$,[5] was prepared by a method similar to that for the phen compound. Since the chloride salt was too soluble to obtain good crystals and the iodide and perchlorate were too insoluble to allow NMR measurements, the complex was obtained in the bromide by adding excess potassium bromide to the hot, filtered reaction mixture and cooling in ice. This procedure gave the crystals of the composition consistent with $[Co(mal)(bpy)_2]Br\cdot 0.5KBr\cdot H_2O$. Recrystallization from warm water gave an analytically pure compound, for which the identity was confirmed by the visible absorption and NMR spectra, and by chemical analysis.[5]

Measurements. The solubilities of the $(N)_4$ compounds were rather small; they are about 0.10, 0.22, 0.084, 0.16, and 0.05 mol dm^{-3} for the en, tn, phen, bpy, and tetraammine complexes, respectively. Therefore these complexes were dissolved in deuterium oxide to near saturation.

Nuclear magnetic resonance spectra were taken at 36.4 °C on a Varian T-60 spectrometer operating at 60 MHz. Owing to the low solubilities of the $(N)_4$ compounds, we measured the peak height (rather than integrated intensity) of the malonate singlet at suitable time intervals after dissolution. The exchange rates were obtained from the slope of the plots of ln(intensity) *vs.* time. Chemical shifts were referred to internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS). The stability of these complexes against acid- and base-hydrolysis could be checked easily by NMR spectra thanks to the fact that the chemical shifts of coordinated malonates and the uncoordinated malonic acid or malonate anion are different.

The solution pD was adjusted by appropriate amount of HCl or Na_2CO_3 and measured by a Hitachi-Horiba Model F-7 pH meter with a microelectrode accessory, immediately after kinetic measurements. The pH meter readings were converted to the pD values by the empirical formula developed by Fife and Bruice,[12] pD=pH(meter readings)+0.35(at 36.4 °C).

Absorption spectra were run on a Shimadzu UV-200 double beam spectrophotometer and circular dichroism spectra on a JASCO J-40CS spectropolarimeter.

Results and Discussion

The NMR spectrum of the pentaammine compound was reported previously for dimethyl-d_6 sulfoxide solution.[8c] In D_2O the compound gave a sharp peak at δ 3.41 due to coordinated malonate and two broad absorptions at δ 3.79 and 2.84 with an intensity ratio of 4:1. The latter two absorptions are due to coordinated *cis* and *trans* (to coordinated oxygen) ammine groups and their chemical shift differences are explained

by the magnetic anisotropy of the central cobalt(III) ion.[13] Figure 1 shows the NMR spectra of the $(N)_4$ complexes used in this work, taken in pure deuterium oxide and the chemical shift values are summarized in Table 1. The malonate hydrogens of the $(N)_4$ compounds appear as a singlet between $\delta=3.19$ and 3.33. The tetraammine compound exhibits two broad absorptions at $\delta=4.23$ and 3.29 with equal intensities and they are due to coordinated ammine groups. The high field signal at $\delta=3.29$ can be assigned to ammine groups *trans* to the oxygen atoms of coordinated malonate ion on the basis of the magnetic anisotropy effect of the cobalt(III) ion.[13] The spectrum of the en compound has been reported[2,3,7] and consists of four peaks at $\delta=5.25$ (*cis* NH_2), 4.49 (*trans* NH_2), 3.32 (malonate CH_2), and 2.62 (CH_2CH_2 of en). The tn compound showed, in addition to malonate resonance, two broad peaks at $\delta=4.70$ (*cis* NH_2) and 4.07 (*trans* NH_2) and two complex multiplets at about $\delta=2.57$ (C_1 and C_3 methylenes) and 1.87 (C_2 methylene). The latter two methylene peaks sharpen as the deuteration at NH_2 groups proceeds, as shown in the inset of Fig. 1. The assignment of the NH_2 resonances of the en and tn compounds has been made previously[13] and the high-field signals are due to *trans* NH_2 groups. In the pentaammine, tetraammine, bis(en), and bis(tn) compounds, all the ammine and amine groups undergo hydrogen-deuterium exchange in basic deuterium oxide.[14] The resonances due to phen and bpy ligands appear in fine structures between $\delta=9.15$ and 7.12, and $\delta=8.96$ and 7.32, respectively.

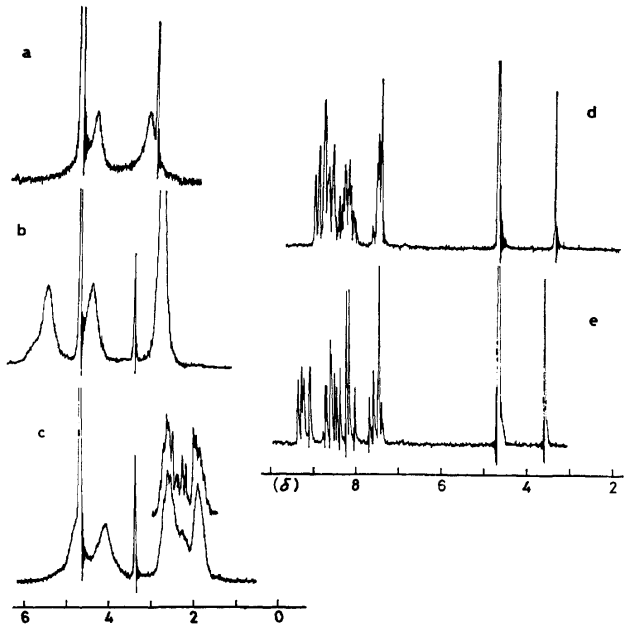

Fig. 1. The 60 MHz NMR spectra of $[Co(mal)(N)_4]^+$ complexes in deuterium oxide, where $(N)_4$ is (a) $(NH_3)_4$, (b) $(en)_2$, (c) $(tn)_2$, (d) $(bpy)_2$, and (e) $(phen)_2$. Inset of (c) illustrates the spectrum after complete deuteration of all NH_2 groups of tn. The strong peak at δ 4.62 is due to solvent HDO.

Exchange Reaction of the $(N)_4$ Compounds. The malonate singlet of all the compounds examined here decreased in intensity with time. The ln(intensity) *vs.* time plots gave a straight line, indicating that the deuteration process follows the kinetic equation

$$\frac{d}{dt}[Co\ mal_H] = -k[Co\ mal_H],$$

where $[Co\ mal_H]$ is the concentration of an undeuterated malonatocobalt(III) complex and k is the pseudo-first-order rate constant for the deuteration of malonate ligand. In Fig. 2, the $\log(k)$ values are plotted against the solution pD. The solid lines in Fig. 2 have slopes of $+1$ and -1. Though the low solubilities of the $(N)_4$ compounds made the quality of the pD-rate

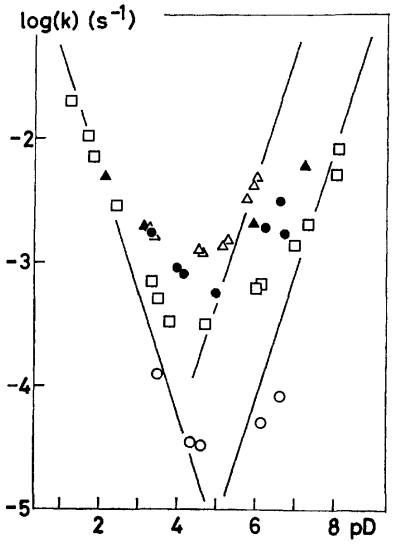

Fig. 2. The $\log(k)$ *vs.* pD plots for the deuteration of malonate hydrogens of $[Co(mal)(N)_4]^+$ complexes, where $(N)_4$ is $(NH_3)_4$ (○), $(tn)_2$ (□), $(en)_2$ (●), $(phen)_2$ (△), and $(bpy)_2$ (▲). Solid lines are with slopes of $+1$ or -1.

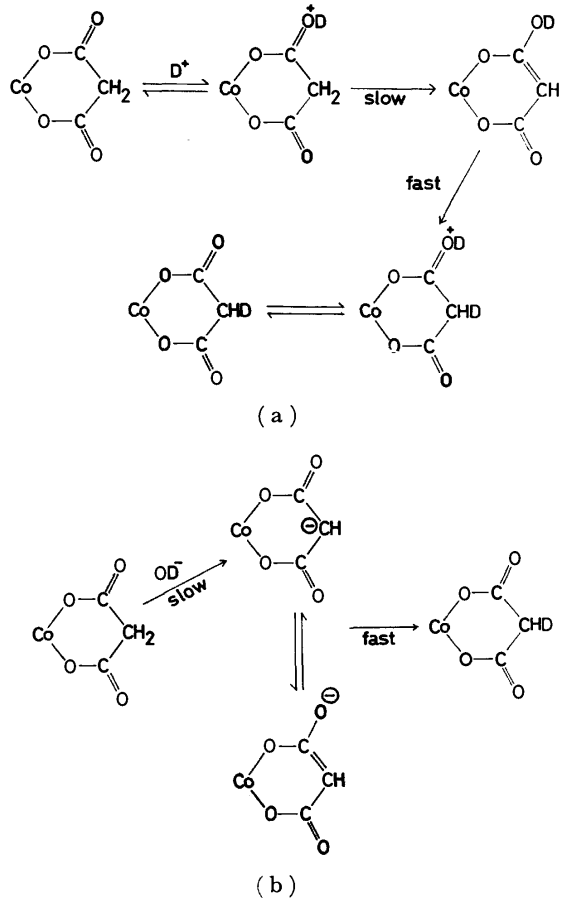

Fig. 3. A probable mechanism of hydrogen-deuetrium exchange catalysed by (a) D_3O^+ and (b) OD^- ions.

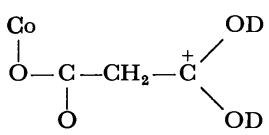
profile rather poor, Fig. 2 indicates that $\log(k)$ is proportional to $-$pD at lower pD while at higher pD it is proportional to pD. From this pD dependence it follows that k is proportional to $[D_3O^+]$ at lower pD and to $[OD^-]$ at higher pD. Therefore, the exchange reaction is acid-catalysed at pD values less than about 4 and base-catalysed at higher pD.

The mechanism of acid-catalysed deuteration will be considered in an analogous way to that proposed for the deuteration of glycine residues in $[Co(edta)]^-$ ion.[15,16] Farago and Smith[5] proposed such a mechanism as illustrated in Fig. 3(a). In this mechanism, the initial step is the rapid protonation of carbonyl oxygen, which is followed by the rate-determining step of a hydrogen abstraction to give an enol. This enol will tautomerize, upon deuteration, to regenerate the carboxyl group. The deuteration is thus effected by D_2O molecule donating D^+ to the enol intermediate.

The second mechanism proposed originally by Terrill and Reilley[15] also for $[Co(edta)]^-$ involves the carbonyl protonation and the subsequent rupture of carboxylate-cobalt bond. This mechanism seems at first sight to be adapted to the present case. Since this mechanism assumes the monodentate carbonium ligand of the form,



we may reasonably expect concomitant racemization at the metal center. For $[Co(edta)]^-$ ion, Terrill and Reilley in fact confirmed that deuteration is accompanied by racemization. For the optically active en compound, however, we did not observe any measurable change in the circular dichroism spectrum over the whole pD region examined here and over several half-lives of deuteration. In highly basic solution, this ion undergoes base-hydrolysis and decreases its optical activity as reproted by Farago and Keefe.[17] Though both mechanisms are consistent with the $[D_3O^+]$ dependence of the rate constant, the second mechanism does not seem to play the dominant role in our systems.

The mechanism of base-catalysed reaction will involve the carbanion intermediate, see Fig. 3(b). The first step may be a hydrogen abstraction by OD^- to give the carbanion. This carbanion can be resonance stabilized with the enol form, which favors the planar structure of the malonate moiety of this intermediate. The rate-determining step in base-catalysed reaction will be the C-H bond rupture. As for the acid-catalysed reaction, the deuteration is effected by D_2O donating D^+ to the carbanion intermediate. For the en and bpy compounds, Farago and Smith[5] made temperature dependence studies between 20 and 37 °C at around pD=2 to 3. Their results at 37 °C are in good agreement with our data shown in Fig. 2. Figure 2 indicates also that in acid-catalysed reaction the rates for all the compounds are not so different but in base-catalysed reaction the rates vary from compound to compound and the rate is in the order $(phen)_2$—$(bpy)_2$>$(en)_2$>$(tn)_2$>$(NH_3)_4$.

Deuteration Reaction of The Pentaammine Compound. Figure 4 shows the $\log(k)$ *vs.* pD plots for $[Co(malH)(NH_3)_5]^{2+}$ ion. This plots contrast with Fig. 2 in the following points; (i) the deuteration is base-catalysed even at lower pD values, (ii) at about pD=3.95, the rate constant steps down to a value of 5×10^{-5} s^{-1}, and (iii) at higher pD region the rate constant does not depend on acid or base concentration. Clearly the sudden decrease at pD=3.95 corresponds to the deprotonation of the unidentate malonate ligand, for which the pK_a value was estimated by Svatos and Taube[8a] at 3.41(μ=0.1). By applying the deuterium

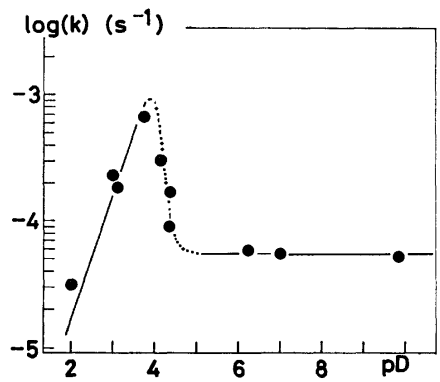


Fig. 4. The $\log(k)$ *vs.* pD plots for the deuteration of malonate in $[Co(OOCCH_2COOH)(NH_3)_5]^{2+}$. Solid lines are with slopes of +1 or zero.

isotope effect of 0.35 pH meter unit[12] to 3.41, we obtain the value 3.76. This value compares well with the pD value that corresponds to the kink in the pD-rate profile of Fig. 4. At low pD, the reaction should involve the coordinated carbanion intermediate produced by hydrogen abstraction by OD^- catalyst. The pD-independent rate at high pD region suggests that the methylene group in the $[Co(OOCCH_2COO)(NH_3)_5]^+$ ion undergoes either "water-catalysed" exchange or mixed D^+–OD^- (zwitterionic) catalysed exchange. The deuteration of methylene group of free ethyl malonate anion has been studied by Kirby and Lloyd[18] and the observed pH-independent exchange rate is reported at $3.33\times10^{-4}\ s^{-1}$ at 39.6 °C. This value is approximately an order of magnitude larger than our corresponding value for the Co(III)-$OOCCH_2COO^-$ group. In this context, the effect of the electron-withdrawing power of the cobalt(III) ion upon the exchange rate does not appear significant.

Use of the Copper(II) Ion-selective Electrode for the Determination of the Stability Constant of Binuclear Copper(II) Complex with 3,6-Dioxaoctane-1,8-diamine-*N,N,N',N'*-tetraacetric Acid

Kunio Ohzeki, Masakuni Saruhashi, and Tomihito Kambara*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 18, 1980)

The stability constant of binuclear copper(II) complex with 3,6-dioxaoctane-1,8-diamine-*N,N,N',N'*-tetraacetic acid (ethylene glycol bis[2-[bis(carboxymethyl)amino] ethyl] ether, customarily abbreviated to EGTA of Y) was determined on the basis of potentiometric titration by means of a copper(II) ion-selective electrode. In acetate buffer solution of pH 5.8 titration curves of copper(II) with EGTA show two distinct end points corresponding to Cu_2Y and CuY complexes. The formation constant of the binuclear copper(II) complex was determined from the potential response in the titration fraction between first and second end points. The logarithmic value was found to be log $K_{Cu_2Y}=6.40$ at ionic strength of 0.2 M (KNO_3–acetate buffer solution) at 25± 0.5 °C.

The response of copper(II) ion-selective electrode in the aqueous solution of complexing agent has been studied. Nakagawa *et al.*[1] found that the stability constants of copper(II) complexes with several ligands such as acetate, ammonia, ethylenediamine, *etc.* agreed very well with those given in the literature, except EDTA and NTA complexes. Similar behavior has recently been observed by Heijine and Linden.[2]

In the present paper a successful application of copper(II) ion-selective electrode to the determination of binuclear copper(II)–EGTA complex is described.

Theoretical

When copper(II) is titrated with EGTA forming only two complexes CuY and Cu_2Y, the total concentration of copper(II) and EGTA in the titration vessel can be written as:

$$C_{Cu} = [CuY] + 2[Cu_2Y] + [Cu]\alpha_{Cu} \quad (1)$$

and

$$C_Y = [CuY] + [Cu_2Y] + [Y]\alpha_Y, \quad (2)$$

where α_{Cu} denotes the side reaction coefficient of copper(II) with component of buffer system, and α_Y indicates that of titrant with hydrogen ion. The stability constants of CuY and Cu_2Y are given

$$K_{CuY} = \frac{[CuY]}{[Cu][Y]} \quad (3)$$

and

$$K_{Cu_2Y} = \frac{[Cu_2Y]}{[Cu][CuY]}. \quad (4)$$

Introducing Eqs. 3 and 4 into Eqs. 1 and 2 and eliminating [Y], one obtains

$$\frac{C_Y}{C_{Cu}} = \frac{K_{CuY}[Cu]+K_{CuY}K_{Cu_2Y}[Cu]^2+\alpha_Y}{K_{CuY}[Cu]+2K_{CuY}K_{Cu_2Y}[Cu]^2}\left(1-\frac{[Cu]\alpha_{Cu}}{C_{Cu}}\right). \quad (5)$$

Between the first and second end points, Eq. 5 can be simply written as:

$$\frac{C_Y}{C_{Cu}} = \frac{1+K_{Cu_2Y}[Cu]}{1+2K_{Cu_2Y}[Cu]}. \quad (6)$$

When a ml of copper(II) solution in the initial concentration of C_{Cu}° is diluted in the titration vessel to V ml, and then titrated with ΔV ml of titrant of the concentration of C_Y°, the titration fraction is given by

$$\frac{C_Y}{C_{Cu}} = \frac{\Delta VC_Y^\circ}{aC_{Cu}^\circ}. \quad (7)$$

Combination of Eqs. 6 and 7 yields

$$K_{Cu_2Y}[Cu] = \frac{aC_{Cu}^\circ-\Delta VC_Y^\circ}{2\Delta VC_Y^\circ-aC_{Cu}^\circ}. \quad (8)$$

When the titration is carried out in acetate or ammonia buffer solution, the formation of the mixed ligand complex such as $Cu_2Y(NH_3)$ should be considered. In this case, K_{Cu_2Y} in Eq. 8 is replaced by

$$K'_{Cu_2Y} = K_{Cu_2Y}(1+K_{Cu_2YL}[L]+K_{Cu_2YL}K_{Cu_2YL_2}[L]^2), \quad (9)$$

where K'_{Cu_2Y} is the apparent formation constant, K_{Cu_2YL} and $K_{Cu_2YL_2}$ are the formation constants of the mixed ligand complexes, and L denotes the acetate or ammonia. In the logarithmic expression of the resulting equation, one derives

$$pCu = \log K'_{Cu_2Y} - \log\frac{aC_{Cu}^\circ-\Delta VC_Y^\circ}{2\Delta VC_Y^\circ-aC_{Cu}^\circ}. \quad (10)$$

A plot of pCu against the logarithmic term in the right-hand side will show a straight line with a negative slope of unity and K'_{Cu_2Y} value is estimated from the intercept of the line.

Experimental

Reagents. A Dotite reagent EGTA (Dojindo Lab.) was used as received. Other chemicals used were all of analytical reagent grade. A 10^{-2} M (1 M=1 mol dm^{-3}) copper(II) stock solution was prepared from copper(II) sulfate pentahydrate. A 10^{-2} M EGTA solution (pH=4.8) was prepared by dissolving the acid with appropriate amount of potassium hydroxide, the ionic strength being adjusted to 0.2 M with potassium nitrate. The EGTA solution was standardized against the copper(II) solution. A solution containing 0.1 M acetate buffer solution (pH=6.0) and 0.1 M potassium nitrate was used for conditioning the copper(II) ion-selective electrode.

Apparatus. The copper(II) ion activities were measured with an Orion copper(II) ion-selective electrode, Model 94-29. A Horiba double junction SCE with the outer compartment filled with 0.2 M potassium nitrate was used as the reference electrode. The potential measurements were made by the aid of a Hiranuma recording auto titrator, Type RAT-11. A Hitachi-Horiba pH meter, F-5, was used

for pH measurements.

Procedure. All experiments were carried out in a thermostat kept at 25±0.5 °C. The electrode potential was recorded while the solution was gently stirred.

Conditioning: The surface of copper(II) ion-selective electrode was polished gently with a tooth paste and then soaked in the conditioning solution until a constant potential value was attained.

Calibration: A series of standard copper(II) solution from 10^{-3} to 10^{-7} M was prepared by diluting the stock solution immediately before the measurements, the ionic strength being adjusted to 0.2 M with potassium nitrate. The pH of final solution was in the range of 5.0—5.4. The potenital was recorded for 30 s with a Hiranuma recording auto titrator without titrant supply.

Titration: Titrations of copper(II) with EGTA were performed in acetate or ammonia buffer solution. The ionic strength of test solutions was adjusted to 0.2 M with potassium nitrate. The EGTA solution was automatically supplied to a 50-ml portion of the test solution containing copper(II) in the analytical concentration range from 2×10^{-4} to 10^{-3} M. A 30-μl portion of the titrant was delivered to a titration vessel within 0.5 s and the electrode potential was measured after 9.5 s, and the procedure was repeated. Titration curves with stepwise potential decreases were recorded automatically.

Results and Discussion

Calibration Curve. The electrode potential drifted slightly in the 10^{-7} M copper(II) solution, while above 10^{-6} M a stable potential was observed during 30 s. The Nernstian response was found to hold from 10^{-3} to 10^{-6} M of copper(II), obeying the equation:

$$E = E' + S\log a_{Cu^{2+}}$$
$$= E'' + S\log[Cu]$$
$$= 260 + 29.9\log[Cu].$$

In the equations, E' and E'' are constants, S the Nernstian coefficient, and the figures in the last equation are expressed in mV.

Titration in Acetate Buffer Solution. Titrations were made with varying acetate buffer concentrations, namely, 0.06, 0.10, 0.14, and 0.20 M. The pH values of test solutions were in the range 5.76—5.80. These values decreased slightly as titration proceeded. A typical titration curve was shown in Fig. 1. Two distinct end points were found. The ratio of amount of titrant at the second end point to that at the first end point was found to be 2.00 (number of determinations $n=6$). The first end point is due to the formation of binuclear copper(II) complex Cu_2Y. The results of log-log plot according to Eq. 10 were shown in Fig. 2. Each plot gave a straight line with a negative slope of unity as expected theoretically. The apparent formation constant is evaluated from the intercept of each line at the abscissa zero line, where the titration fraction is two-thirds. A constant K'_{Cu_2Y} value was obtained irrespective of the initial copper(II) concentration ranging from 2×10^{-4} to 10^{-3} M. However, the value increased with increasing concentration of buffer solution as shown in Fig. 2, which suggests the formation of mixed ligand binuclear copper(II) complex such as $Cu_2Y(CH_3COO)$. When the forma-

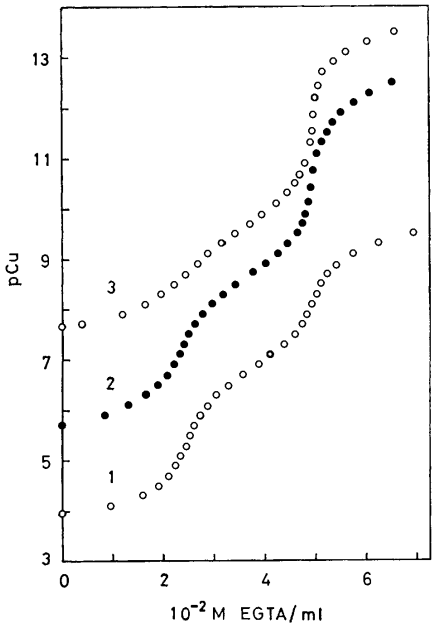

Fig. 1. Titration of a 50-ml portion of 10^{-3} M (f= 0.995) copper(II) with 10^{-2} M (f=1.000) EGTA performed in: 1; 0.10 M (CH_3COOH–CH_3COONa), pH 5.8, 2; 0.06 M (NH_3–NH_4Cl), pH 8.0, 3; 0.20 M (NH_3–NH_4Cl), pH 8.4.

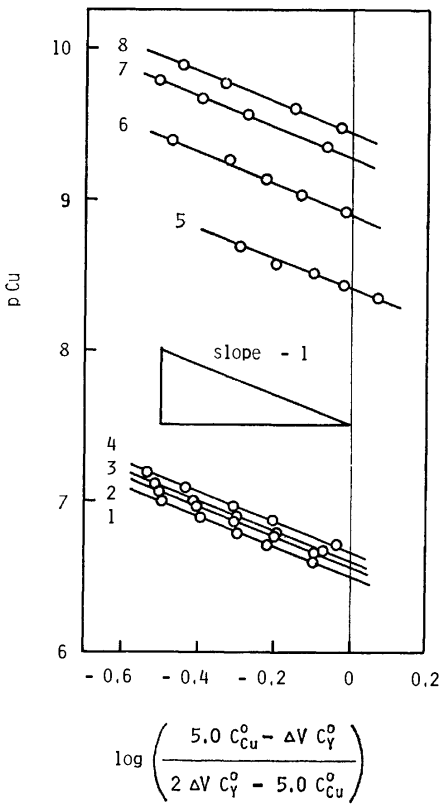

Fig. 2. Plots according to Eq. 10. Titrations were made in: 1; 0.06, 2; 0.10, 3; 0.14, 4; 0.20 M acetate buffer solution (nominal pH=5.8) and 5; 0.06, 6; 0.10, 7; 0.16, 8; 0.20 M ammonia buffer solution (nominal pH=8.5).

tion of $Cu_2Y(CH_3COO)_2$ is negligible, Eq. 9 is expressed as:

$$K'_{Cu_2Y} = K_{Cu_2Y} + K_{Cu_2Y}K_{Cu_2Y(CH_3COO)}[CH_3COO^-] \quad (12)$$

and a plot of the apparent formation constant K'_{Cu_2Y} against the concentration of acetate ion at the titration fraction of two-thirds will show a straight line. The result given in Fig. 3 supports the above assumption. The values of intercept and slope of the regression equation of Eq. 12 were determined with 95% confidence limits as $(2.50\pm0.19)\times10^6$ and $(1.29\pm0.16)\times10^7$, respectively. The logarithms of the constants were 6.40 for K_{Cu_2Y} and 0.71 for $K_{Cu_2Y(CH_3COO)}$. The value of log K_{Cu_2Y} is much greater than the value 4.31 determined by a pH-potentiometric method.[3]

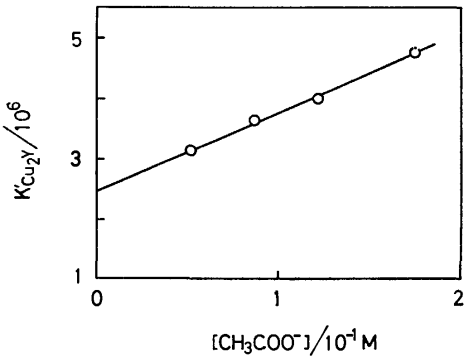

Fig. 3. Determination of K_{Cu_2Y} and $K_{Cu_2Y(CH_3COO)}$ according to Eq. 12.

Titration in Ammonia Buffer Solution. Titrations were performed with varying ammonia buffer concentrations, namely, 0.06, 0.10, 0.16, and 0.20 M. The pH values of test solutions were in the range 8.04—8.35. The values increased slightly as titration proceeded. Typical titration curves were shown in Fig. 1. Two end points were found while the potential change at the first end point decreased with increasing amount of ammonia. On the whole, the titration curves were shifted to lower potential values than those in acetate buffer solution. The formation of fairly stable mixed ligand complexes such as $Cu_2Y(NH_3)$ and $Cu_2Y(NH_3)_2$ are postulated. Equation 9 is transformed into:

$$\left(\frac{K'_{Cu_2Y}}{K_{Cu_2Y}}-1\right)[NH_3]^{-1} = K_{Cu_2Y(NH_3)}(1+K_{Cu_2Y(NH_3)_2}[NH_3]) . \quad (13)$$

From the plot of left-hand side of Eq. 13 against the concentration of ammonia, the formation constants were evaluated. The values for K'_{Cu_2Y} were obtained from the plots shown in Fig. 2. The concentration of ammonia was calculated from the solution pH and the total concentration of ammonia at the titration fraction of 2/3, where average mole ratio of copper(II) to ammonia was assumed to be unity. The result was shown in Fig. 4. The values of intercept and slope of the regression equation were determined with 95% confidence limits as $(2.99\pm0.40)\times10^4$ and $(2.55\pm0.36)\times10^6$, respectively. The logarithms of the constants were 4.48 for $K_{Cu_2Y(NH_3)}$ and 1.88 for $K_{Cu_2Y(NH_3)_2}$.

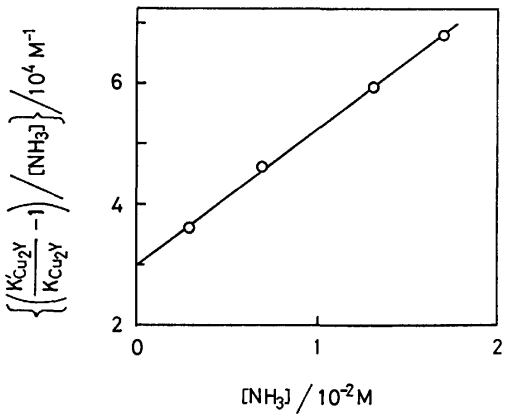

Fig. 4. Determination of $K_{Cu_2Y(NH_3)}$ and $K_{Cu_2Y(NH_3)_2}$ according to Eq. 13.

Theoretical Titration Curves. When 10^{-3} M (f= 0.995) copper(II) in a 50-ml portion of acetate or ammonia buffer solution is titrated with ΔV ml of 10^{-2} M (f=1.000) EGTA, the following equation holds:

$$\Delta V = \frac{0.995\times10^{-3}-\alpha_{Cu}[Cu]}{\frac{10^{-2}}{50}\left(\frac{K_{CuY}[Cu]+2K_{CuY}K'_{Cu_2Y}[Cu]^2}{K_{CuY}[Cu]+K_{CuY}K'_{Cu_2Y}[Cu]^2+\alpha_Y}\right)+\frac{\alpha_{Cu}[Cu]}{50}} \quad (14)$$

The values of K'_{Cu_2Y}, α_{Cu}, and α_Y were calculated from the concentration of ammonia or acetate ion and pH at the titration fraction of 2/3; namely, $K'_{Cu_2Y(CH_2COO)}=3.61\times10^6$, $\alpha_{Cu(CH_3COO)}=6.23$, and $\alpha_{Y(H)}=1.17\times10^7$ for titration in acetate buffer solution and $K'_{Cu_2Y(NH_3)}=2.64\times10^6$, $\alpha_{Cu(NH_3)}=9.23\times10^2$, and $\alpha_{Y(H)}=1.81\times10^2$ for titration in ammonia buffer solution, respectively. These values were assumed to be con-

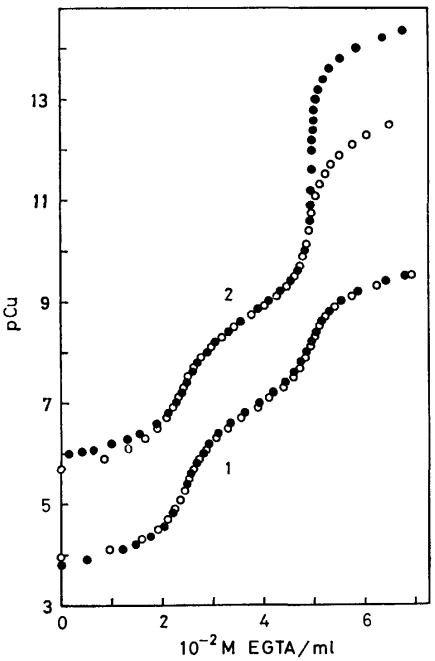

Fig. 5. Comparison of the experimental titration curves (○) with the theoretically obtained curves (●). Curves 1 (○) and 2 (○) are the same as curves 1 and 2 in Fig. 1, respectively.

stant during titration. The formation constant[4] K_{CuY} is reported to be 10^{17}. Introducing these values and copper(II) concentration into Eq. 14, one can illustrate theoretical titration curves as shown in Fig. 4. In the case of acetate buffer solution, a fairly good agreement was observed between the theoretically obtained titration curve and the experimental one. On the other hand, in ammonia buffer solution, the potential change at the second end point is much less than the theoretically expected value. Since the membrane of the Orion copper(II) electrode is made up of mixed sulfides of copper(II) and silver, the formation of silver–EGTA complex at the electrode surface may be responsible for the depression of response for copper (II).[1]

It should be noted from Eq. 14 that when titration is carried out in the acetate buffer solution of pH lower than 5, where the value of $\alpha_{Y(H)}$ is approximately equal to 10^{10}, the second end point disappears, only the first end point corresponding to the formation of Cu_2Y being obtained. On the contrary, in concentrated ammonia buffer solution where $\alpha_{Cu(NH_3)}$ is around 10^6, the first end point disappears and only the second end point is observed.

A New Synthesis of 1-Amino-4-butylaminoanthraquinone from 1-Aminoanthraquinone Promoted by Metal Ions

Katsuhira YOSHIDA,* Masaru MATSUOKA,*,† Yoshio YAMASHITA, and Teijiro KITAO†

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

†*Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591*

(Received November 14, 1979)

In the presence of some metal ions and atmospheric oxygen, 1-aminoanthraquinone(**1**) reacts readily with butylamine to give 1-amino-4-butylaminoanthraquinone(**2a**), along with a small amount of 1,4-diaminoanthraquinone, which is produced by the dealkylation of **2a**. The activity of the metal ions decreased in the following order: Co(II)≫Ni(II)>Cu(II)>Al(III). The reaction is remarkably affected by the substitution of an alkyl group into the amino group of **1**, the addition of a chelating agent, the counter anion of metal ions, and the reaction temperature. By the use of cobalt(II) chloride, the reaction proceeds most smoothly at about 30 °C. Both anthraquinone and 2-aminoanthraquinone show no sign of the reaction under the same conditions. A possible mechanism involving the formation of a metal complex, followed by the nucleophilic attack of amine at the 4-position and the oxidative abstraction of the hydride anion by atmospheric oxygen is proposed.

Aminoanthraquinone derivatives are very important compounds as dyes or dye intermediates. A large number of papers and patents have been reported on reactions introducing amino groups into the anthraquinone nucleus. The displacement of sulfonyl, halogeno,[1] nitro, and hydroxy groups by amino groups is widely adopted.

The direct amination of anthraquinone or aminoanthraquinones with hydroxylamine in concentrated sulfuric acid catalyzed by iron(II) sulfate or vanadium pentaoxide has also been described, but it produces random substitution products.[2] Russkikh *et al.*[3] reported that the reaction of the boric esters of quinizarin with aromatic amines gave 2-arylaminoquinizarins in the presence of atmospheric oxygen. Recently, we ourselves reported a metal-promoted alkylamination of α-substituted anthraquinones, in which the amination products were obtained in good yields under mild conditions.[4] This is a useful method for preparing some 1-amino-4-alkylaminoanthraquinones from 1-aminoanthraquinone.

In this paper, we wish to report on the reaction of 1-aminoanthraquinone with butylamine in detail and to propose the possible mechanism of this direct amination.

Results and Discussion

The reaction of 1-aminoanthraquinone(**1**) with butylamine in the presence of metal salts gave 1-amino-4-butylaminoanthraquinone(**2a**), along with a small amount of 1,4-diaminoanthraquinone(**2b**) produced by the dealkylation of **2a**.[5] A partial dealkylation of alkylaminoanthraquinones has already been noted in previous papers.[6] The activities of metal salts in this direct amination are shown in Table 1.

Table 1. Effect of metal chlorides on the butylamination of **1**[a]

Run	Metal chloride	Recovered(%)[b] **1**	Yield(%)[b] **2a**	Yield(%)[b] **2b**
1	None	99.0	0	0
2	$CuCl_2$	70.9	5.4	3.2
3	$NiCl_2$	57.2	11.1	trace
4	$CoCl_2$	0	58.7	4.7
5	$AlCl_3$	65.9	3.1	trace
6	$FeCl_3 \cdot 6H_2O$	99.1	0	0
7	$MgCl_2 \cdot 6H_2O$	90.1	0	0
8	$ZnCl_2$	93.8	0	0

a) The reactant, **1** (9 mmol), was stirred in 1-butanol (15 ml) with butylamine (15 ml) and metal salt (9 mmol) at 80—82 °C for 24 h. b) Determined by means of a TLC-scanner.

No reaction occurred in the absence of metal salts, but in the presence of metal salts two direct amination products (**2a** and **2b**) were obtained. Metal chlorides were arranged in the order of the activity as follows: Co(II)≫Ni(II)>Cu(II)>Al(III). The activity of the cobalt(II) ion was particularly superior to those of other metal ions, while the Fe(III), Mg(II), and Zn(II) ions did not promote the reaction. As is shown in Table 2, the activity of the cobalt ion is affected by its counter anion. Cobalt(II) chloride and cobalt(II) bromide have good activity, but cobalt(II) fluoride has poor activity.

The 1-amino group plays a great role on this reaction, since both anthraquinone and 2-aminoanthraquinone show no sign of the reaction.[4a] Furthermore, the butylamination of 1-alkylaminoanthraquinones, such as 1-methylamino- or 1-butylaminoanthraquinones, gave the corresponding 1,4-bis(alkylamino)anthraquinones, though in only low yields, in the presence of copper(II) acetate, but none of them in the presence of cobalt(II) chloride. These results suggest that the formation of a metal complex in which the amino and carbonyl groups of **1** coordinate to the metal ion may play an important role during the course of this direct amination. Neither anthraquinone nor 2-aminoanthraquinone can form such a chelate complex

Table 2. Effect of the counter anion of the cobalt ion on the butylamination of **1**[a]

Run	Cobalt salt	Time (h)	Recovered(%)[b] **1**	Yield(%)[b] **2a**	Yield(%)[b] **2b**

a) The reactant, **1** (4.5 mmol), was stirred in 1-butanol (5 ml) with butylamine (15 ml) and metal salt (4.5 mmol) at 30 °C. b) Determined by means of a TLC-scanner. c) Isolated yield.

with the metal ion. The substitution of an alkyl group into the amino group of **1** may prevent the formation of a chelate complex by its steric hindrance.

The addition of a small amount of ethylenediamine completely inhibited the reaction. This suggests that the metal ion is preferentially combined with ethylenediamine rather than with **1** and that, consequently, the reaction was prohibited.[4a]

The effect of the molar ratio of cobalt(II) chloride to **1** on the yield of **2a** is shown in Table 3. The yield of **2a** increases with the increase in the molar ratio of cobalt(II) chloride up to 1.0. The addition of another mole of $CoCl_2$ depresses the yield to 54% because of such undesirable side reactions as dealkylation (Run 20). The yields of **2a**, based on $CoCl_2$, are approximately kept constant at about 64% up to the molar ratio of 1.0 (Runs 15, 17, and 18). In the presence of a 0.1 molar equivalent of $CoCl_2$, a prolonged reaction time results in an increase of the yield of **2a** (Run 16) but the yield based on $CoCl_2$ does not exceed 100%. From these results, the cobalt complex (**1**: Co(II)=1:1) was proposed as an activated intermediate for this direct amination. Also, it was found that atmospheric oxygen is also necessary for this amination because, under a nitrogen atmosphere, the yield of **2a** is depressed drastically to 2.9% and 92% of **1** is recovered, even in the presence of an equimolar amount of cobalt(II) chloride (Run 19).

The reaction was also considerably affected by the reaction temperature. Figure 1 shows the effect of the reaction temperature on the butylamination of **1** in the presence of $CoCl_2$. The yield of **2a** increased up to 30 °C and then decreased gradually with the increase in the temperature. The optimum temperature for this reaction was 30 °C. The decrease in the yield of **2a** at higher temperatures seems to be caused by the fact that the chelate complex may be unstable at higher temperature.

On the basis of the experimental results described above, the following possible mechanism for this amination may be proposed (Scheme 1). The formation of the chelate complex (**3**) probably increases the electrophilicity of the substituted anthraquinone nucleus and, consequently, facilitates the nucleophilic attack of butylamine on the nucleus. Russkikh *et al.*[3,7] reported that the formation of boron-chelate rings of 1,4-dihydroxy-, 1-amino-4-hydroxy-, and 1,4-diaminoanthraquinones increases the electrophilicity of the

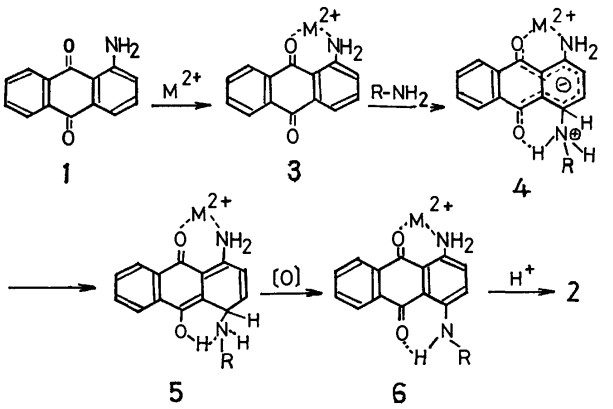
substituted anthraquinone nucleus and facilitates the direct amination at the 2-position of these compounds.

The preferential substitution of the amino group at the 4-position, but not at the 2-position, seems to be caused by the fact that the formation of hydrogen-bonding between the *N*-hydrogen atom and the oxygen

atom of the carbonyl group stabilizes the adduct (**4**). A similar role of hydrogen-bonding has also been inferred in previous reports.[8] The oxidative abstraction of the hydride anion from the adduct (**5**) by atmospheric oxygen is proposed from the experimental results. The final step of acid hydrolysis of **6** gives rise to **2**. The details of the reaction mechanism for each step are still not clear, however, and are under investigation.



Scheme 1.

Experimental

All the melting points are uncorrected. The visible spectra were measured using a Hitachi EPS-3T spectrometer. The ^{1}H NMR spectra were taken on a JEOL Model MH-100 spectrometer, with TMS as the internal standard. The elemental analyses were recorded on a Yanaco CHN recorder MT-2. Column chromatography was carried out on activated alumina (Sumitomo KCG-30), using xylene as the eluent. Thin-layer chromatography was performed on silica gel (Merck Kieselgel 60) using the following solvent system (volume ratio); System A (benzene), and System B (cyclohexane: acetone: ethyl acetate=13:1:1). The resulting thin-layer chromatograms were measured on a chromatoscanner(Shimadzu CS-900). The yields were determined on the basis of measurements made using calibrations with standard solutions of the pure compounds.

Materials. The 1-aminoanthraquinone was supplied by the Mitsubishi Chemical Industry, Inc., and was purified by column chromatography, followed by recrystallization from xylene. 1,4-Diaminoanthraquinone (Mitsui Toatsu Chemicals), used as an authentic sample, was purified by column chromatography and subsequent recrystallization from ethanol. All the metal salts were reagent-grade and were used without further purification. The amines and solvents were purified by the ordinary methods.

Reaction of 1 with Butylamine. The general procedure was as follows. A mixture of **1**, metal salt, butylamine, and 1-butanol was stirred in a open flask (see Tables 1, 2, and 3, and Fig. 1). The mixture was then poured into a cold 3.0% hydrochloric acid solution, and the separated products were filtered, washed with water, and dried. The R_f values of the components were as follows:

1: R_f 0.43 (System A), R_f 0.26 (System B)
2a: R_f 0.26 (System A), R_f 0.20 (System B)
2b: R_f 0.10 (System A), R_f 0.05 (System B).

The yields were determined by means of a TLC-scanner or after isolation by column chromatography.

2a: λ max (Methanol) 617 (ε 17300), 573 (ε 15200); mp 140—141 °C (lit,[9] 142.6—143.1 °C(cor)); Found: C, 73.06; H, 6.14; N, 9.51%. Calcd for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 9.52%. PMR ($CDCl_3$): δ=0.98 (3H, t, $-CH_3$), 1.2—2.0 (4H, m, $-(CH_2)_2-$), 3.36 (2H, q, NH–CH_2-), 6.9—7.3 (4H, m, $H^{2,3}$, and NH_2), 7.72 (2H, m, $H^{6,7}$), 8.36 (2H, m, $H^{5,8}$), 10.68 (1H, broad, NH–Bu).

Compound (**2b**) was identified with the authentic sample.

Reaction of Anthraquinone (7) with Butylamine. A mixture of **7** (4.5 mmol), $CoCl_2$ (4.5 mmol), butylamine (15 ml), and 1-butanol (5 ml) was stirred under reflux for 8 h. The subsequent procedures were the same as those in the case of **1**. Reactant **7** was recovered in a 99% yield.

Reaction of 2-Aminoanthraquinone (8) with Butylamine. A mixture of **8** (4.5 mmol), $CoCl_2$ (4.5 mmol), butylamine (15 ml), and 1-butanol (5 ml) was stirred under reflux for 8 h. The reactant, **8**, was recovered quantitatively.

Reaction of 1-Methylamino-(9) or 1-Butylamino-anthraquinone (10) with Butylamine. A mixture of the reactant (4.5 mmol), metal salt (4.5 mmol), butylamine (15 ml), and 1-butanol (5 ml) was stirred under reflux for 8 h. After the solvent and the excess amine had been distilled off under reduced pressure, the mixture was poured into a cold 3.0% hydrochloric acid solution. The separated precipitate was filtered, washed with water, and dried. The crude product was extracted with xylene and separated by column chromatography. The results are shown in Table 4.

Table 4.

Studies of Unusual Amino Acids and Their Peptides. XII. The Chemistry of *N*-(Carboxymethyl)amino Acids. I. The Preparation, Properties, and Characterization of *N*-(Carboxymethyl)amino Acids and Their Esters

Toshifumi Miyazawa

Department of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada-ku, Kobe 658

(Received November 16, 1979)

N-Carboxymethyl(Cm-)amino acids and their mono- and diesters were prepared by several routes, and their physical and chiroptical properties were compared with those of the parent amino acids and their esters. The isolation procedure was improved for the preparation of the free Cm-amino acids obtained from the corresponding amino acids and bromoacetic acid; the aimed-at compounds were also obtained by the catalytic hydrogenolysis of the dibenzyl esters. The isomeric pairs of monoalkyl esters of Cm-amino acids were similarly accessible via the benzyl alkyl esters. The diesters proved to be suitable for the GLC and MS analyses of Cm-amino acids. All the free Cm-L-amino acids and the dicyclohexylammonium salts of their *N*-ethylthiocarbonothioyl derivatives show positive Cotton effects at 200—225 nm and at 335—350 nm respectively in CD measurements; therefore, these correlations can be used for the configurational assignments of Cm-amino acids.

Up to the present, various kinds of unusual amino acids have been found in nature. Among them there is a group which can be represented by the general formula **1**. Some typical examples of such amino

acids are octopine ($R=CH_3$, $R'=(CH_2)_3NHC(=NH)NH_2$),[1] lysopine ($R=CH_3$, $R'=(CH_2)_4NH_2$),[2] and nopaline ($R=(CH_2)_2CO_2H$, $R'=(CH_2)_3NHC(=NH)NH_2$).[3] The importance of this group seems to have been becoming increasingly great, for the occurrence of *N*-carboxymethyl(Cm-)amino acids (**2**), simple-structured members of this group, has recently been reported.

Cm-*t*-leucine[4] has been found in a peptide antibiotic, bottromycin A_2, and Cm-alanine has been isolated from an extract of *Strombus gigas* as a fish attractant and designated as strombine.[5]

Unfortunately, though synthetic Cm-amino acids have been referred to in the literature, with regard to their physical properties and chemical behavior little has yet been investigated systematically, except for their coordination chemistry.[6] For some of the synthetic Cm-amino acids even their melting points and/or optical rotations remain undetermined. In particular, nothing is known about the chemistry of peptides containing Cm-amino acids. In connection with the synthetic work of bottromycin[7] the present author felt an interest in this kind of unusual amino acids and started a systematic investigation of them.

Preparation of Cm-amino Acids and Their Esters. The Cm-amino acids[8] listed in Table 1 were prepared by condensing the corresponding amino acids with bromoacetic acid according to the method of Snyder and Angelici.[6a] Even after 4 h, the consumption of the starting amino acid was always incomplete, as determined by following its ninhydrin reaction;[14] nevertheless, an appreciable amount of the *N,N*-biscarboxymethylated derivative was produced in some cases. For the isolation of the Cm-amino acid from the reaction mixture, ion-exchange chromatography, recommended by the above authors, was useful, but elution with aq ammonia did not always give a satisfactory separation. In general, water proved to be a better eluent; through a short column of cation-exchange resin the *N,N*-biscarboxymethylated amino acid was eluted first, and the Cm-amino acid next, while the unchanged amino acid was usually immobile. The rate of elution was quite fast for such Cm-amino acids as Cm-alanine, Cm-aspartic acid, Cm-proline, and Cm-serine. On the other hand, such Cm-amino acids with a low solubility as Cm-phenylalanine and Cm-*t*-leucine could be purified merely by recrystallizing the crude products from water.

As alternative routes[15] to the aimed-at compounds the following reactions were also attempted: the condensations of (i) an amino acid with a haloacetic ester, (ii) an amino ester with a haloacetic acid, and (iii) an amino ester with a haloacetic ester. Though the resulting esters must be hydrolyzed (or hydrogenolyzed) to obtain free Cm-amino acids, they can be used as intermediates for peptide synthesis. Especially by Method (iii) it is possible to prepare derivatives of a Cm-amino acid carrying selectively removable *C*-protecting groups.

However, Methods (i) and (ii) were of no practical use, because of the low rates of conversion, probably because of the heterogeneity of the reaction (Method (i)), or because of the difficulty in the isolation of the desired products (Methods (i) and (ii)). On the other hand, Method (iii) always gave a satisfactory result. In this method, the formation of the *N,N*-biscarboxymethylated derivative was not observed. After the crude mixture had been washed with aq citric acid to remove the unchanged amino ester, it was further purified by extracting in acid. If the product obtained here was not pure enough, it was necessary to resort to column or thin-layer chromatography. The dimethyl or diethyl esters were also accessible from the free Cm-amino acids by the usual method. The diesters (**3**) of Cm-amino acids thus obtained are listed in Table 2.

To obtain a free Cm-amino acid, the diester was heated in 6 M HCl (1 M=1 mol dm^{-3}) at 110 °C for *ca.* 15 h. Even on heating with a more dilute acid or with 6 M HCl for a few hours, the diester disappeared completely, but there remained an appreciable amount of the monoester(s). Under these conditions, the formation of neither glycine nor the other amino acid was observed.[16] The rate of the acidic hydrolysis of a benzyl ester, especially of a dibenzyl ester, was quite slow compared with that of a dimethyl (or diethyl) ester.

On the other hand, its debenzylation by catalytic hydrogenolysis proceeded quite smoothly; thus, the Cm-amino acid was obtained from the corresponding dibenzyl ester in a good yield. Similarly, the monoalkyl esters (**4** and **5**) of Cm-amino acids were obtained from the corresponding benzyl alkyl esters, which are listed in Table 3. In the preparation of **5b**, the crude benzyl ethyl ester (**3f**), contaminated by benzyl valinate, was also used, because the desired compound could easily be separated from the reduction mixture. This is not the case with its isomer (**4b**).

Properties of Cm-amino Acids and Their Esters. As can be seen from Table 1, the melting (or decomposition) point of a Cm-amino acid is much lower than that of the parent amino acid. The optical rotation of a sample of Cm-phenylalanine prepared by the condensation of phenylalanine with bromoacetic acid was in good agreement with that of a different sample prepared by the hydrogenolysis of the dibenzyl ester (**3o**) or by the acidic hydrolysis of the dimethyl ester (**3l**), obtained by the condensation of a phenylalanine ester with a bromoacetic ester (see Experimental). The coincidence of the optical rotations of the Cm-amino acid prepared in these different ways apparently means that little or no racemization occurred during

The signal attributable to -NHC$\underline{H_2}$CO- is underlined.

the preparation by the former method.

The diesters of Cm-amino acids were oily substances with a low viscosity. They were far more stable than the free esters of the parent amino acids; they could be kept at room temperature for a week without any detectable change, though in a few months they had gradually changed into a solid mass.[17] The diesters formed crystalline substances with *p*-toluenesulfonic or picrolonic acid (Table 2). In general, the picrolonate crystallized more easily than the *p*-toluenesulfonate. These crystals were practically non-hygroscopic, and they could be stored for a long time.

Though the monoesters of Cm-amino acids have zwitter-ionic structures, they have low and sharp melting points and are highly soluble in hot ethanol.

Characterization of Cm-amino Acids and Their Esters. The detection of Cm-amino acids with ninhydrin was unsuccessful in most cases, while ninhydrin–formic acid[18] could generally be used for this purpose. The diesters of Cm-amino acids gave a distinct blue spot on a pink background when sprayed with cobalt(II) thiocyanate.[19] Such coloration was specific for the diesters, for neither the monoesters nor the Cm-amino acids themselves gave this coloration. In contrast to the free Cm-amino acids and the diesters, the monoesters gave a distinct coloration with ninhydrin. The initial color (on TLC) was purple for the monoesters (**4**), while it was yellow for the monoesters (**5**).

In general, a Cm-amino acid and the parent amino acid could not be satisfactorily separated by thin-layer or paper chromatography, while paper electrophoresis was useful for this purpose. The Cm-amino acid migrated a fairly long distance toward the anode in an acidic medium.

The ^{1}H-NMR spectrum of a Cm-amino acid showed a signal attributable to the methylene protons in the carboxymethyl group near δ 4.4 in trifluoroacetic acid (TFA) and near δ 3.2 in D_2O–NaOD. For Cm-proline, Cm-*t*-leucine, and Cm-valine, it appeared as an AB quartet with J=15—16 Hz in the latter solvent (Table 1).

The R_f value on TLC of the diester of a Cm-amino acid was much larger than that of the corresponding parent amino ester, so their separation was extremely easy.

It is worth noting that GLC (or even TLC) could be used to distinguish among various kinds of Cm-amino acid diesters, including the isomeric pairs (Table 4). Consequently, the diesters of Cm-amino acids seem to be an excellent derivative for the analysis of these amino acids by GLC; they were volatile and stable enough for the purpose.

The diesters of Cm-amino acids could also be well analyzed by mass spectrometry. For example, in the mass spectra of the isomeric benzyl ethyl esters (**3e** and **3f**) of Cm-valine, the benzyl fragment and the fragment resulting from the removal of the alkoxycarbonyl group of the valine moiety appeared strongly, as expected. The discrimination of the isomers was quite easy.

In the ^{1}H-NMR spectra of the isomeric pair of diesters (*e.g.*, **3e** and **3f**), there was a tendency for a signal attributable to the methylene protons in the benzyloxycarbonylmethyl group of one isomer (*e.g.*, **3e**) to appear in a slightly lower field than that in the methoxy- or ethoxycarbonylmethyl group of the other (*e.g.*, **3f**) (Table 2). On the other hand, the ^{13}C-NMR method proved to be ineffective for their discrimination.

TABLE 4. R_f AND t_R VALUES ON TLC AND GLC FOR THE DIESTERS OF Cm-L-VALINE

Compound	TLC, R_f[a]		GLC, t_R (min)[b]
	A	B	
3a	0.18	0.35	0.5
3b	0.26	0.46	0.8
3c	0.36	0.60	4.4
3d	0.34	0.61	4.2
3e	0.38	0.63	5.3
3f	0.33	0.56	4.9
3g	0.44	0.69	34.9

a) Solvent systems: A, benzene : AcOEt=9 : 1; B, $CHCl_3$: AcOEt=9 : 1. b) Column temp, 180 °C; injector temp, 250 °C; carrier gas, N_2 60 ml/min.

For the monoesters, though it was difficult to differentiate between a pair of isomers (*e.g.*, **4a** and **5a**) by TLC, they could clearly be distinguished by the difference in the chemical shifts in the ^{1}H-NMR of the methylene protons in the two types of carboxymethyl groups; a signal attributable to the methylene protons in the alkoxycarbonylmethyl group of one isomer (*e.g.*, **5a**) appeared in a lower field than that in the free carboxymethyl group of the other (*e.g.*, **4a**) (Table 3).

Configurational Assignments of Cm-amino Acids. The chiroptical behavior of α-amino acids has been widely used for their configurational assignments. Concerning the Cm-amino acids, however, no useful data are available for this purpose, except for a few reports on their metal complexes.[6c]

As can be seen from Table 1, the Clough-Lutz-Jirgensons rule[20] for α-amino acids could not be applied to the Cm-amino acids. This is also the case with the monoesters of Cm-amino acids listed in Table 3, though the absolute values of their optical rotations are generally small.

The ORD and CD techniques have been employed for the correlations of the configurations of α-amino acids,[21] and recently such methods have also been applied to *N*-methyl-[22] and *N*,*N*-dimethylamino acids.[23] Table 5 shows the ORD and CD data for Cm-L-amino acids and their monoesters, recorded in water and in a hydrochloric acid solution. Every aliphatic Cm-L-amino acid thus far examined shows one positive CD Cotton effect both in water (at 200—206 nm) and in an acidic solution (at 206—210 nm). The CD maxima appear at wavelengths approximately identical with those of the parent α-amino acids, but the intensities are somewhat enhanced. This is also the case with the wavelengths of the first extremum and the molecular rotations in ORD measurements. The relatively small changes on the carboxymethyla-

tion of the amino group suggest the same transition, *i.e.*, the n→π^* transition of the carbonyl group, and a similar predominant conformation[24] may be responsible for the observed Cotton effect.

Similarly, the aromatic Cm-L-amino acids exhibit a positive CD band at 216 nm (Cm-phenylalanine and Cm-phenylglycine) or at 226 nm (Cm-tyrosine) in an acidic solution, the intensity being somewhat enhanced.[25]

Thus, the dominant positive Cotton effect generally observed between 200 and 225 nm can be utilized for the configurational assignments of Cm-amino acids.

Even when the carboxymethyl group is replaced by the methoxycarbonylmethyl or ethoxycarbonylmethyl group, the wavelength where the Cotton effect appears and its intensity are little affected either in water or in an acidic solution (*e.g.*, Cm-valine, **5a**, and **5b**) (Table 5). This result suggests that neither the electronic state nor the bulkiness of the carboxymethyl group has a profound influence on the predominant conformation of a Cm-amino acid.

In addition to the strong positive maximum at 210—218 nm, the CD spectra of the diesters of Cm-L-amino acids show a very weak negative band at 236—246 nm in 95% ethanol (Table 6); the occurrence of such a band has previously been reported on the free esters of some amino acids and interpreted in terms of the existence of an alternative conformation.[26] This band could not be observed in an aqueous solution of such Cm-amino acid esters as **4a** listed in Table 5.

For a preferable approach to the configurational assignments of amino acids, a number of their derivatives have been recommended which exhibit the Cotton effects at longer wavelengths. The *N*-ethylthiocarbonothioyl (ETCT) derivative of an α-amino acid has been used as one of the most suitable compounds for this purpose,[27] and this approach has recently been applied to β-amino acids also.[28] In the ETCT derivatives of these amino acids, the solvents influence the Cotton effects in a striking manner. Thus, in certain cases, the sign of the Cotton effect is inverted by changing the solvent.

The Cm-amino acids (except Cm-proline) listed in Table 1 were converted into the ETCT derivatives, and their Cotton effects examined in four different solvents (methanol, dioxane, chloroform, and benzene).

Table 6. CD data for the diesters of Cm-L-amino acids in 95% EtOH[a]

a) c 0.25, l=5 mm.

The results obtained by measurement in methanol are summarized in Table 7. All the ETCT derivatives of Cm-L-amino acids show a CD maximum at 345—370 nm and the ORD first extremum at 360—380 nm in the above solvents, similarly to those of the parent α-amino acids. In contrast to the latter, however, the sign of the Cotton effect is independent of the solvents, though the intensity fluctuated somewhat depending on the solvents used. This is also the case with many more solvents of widely differing polarities, as is illustrated with ETCT-Cm-L-valine (Table 8). The Cotton effects of the ETCT derivatives of prolines, pipecolic acid, and *N*-methylalanine have been reported to be little influenced by solvents.[27] Consequently, the insusceptibility to solvent effects may be regarded as a feature common to the ETCT derivatives of imino acids. As can be seen from Table 8, there is a tendency for the CD maximum to be bathochromically shifted upon a decrease in the solvent polarity.

TABLE 9. EFFECTS OF ADDED AMINES ON THE CD COTTON EFFECT OF ETCT-Cm-L-VALINE IN $CHCl_3$[a]

Amine[b]		λ(nm)	Δε
N-Ethyldiisopropylamine	(10.4)	349	+1.68

CmVal	363	+71	340	+1.24

a) c 0.2—0.4, l=5 mm. b) 1st extremum. c) Shoulder.

This is also suggestive of the same transition as in the case of the ETCT derivative of the parent α-amino acid, *i.e.*, the $n \rightarrow \pi^*$ transition of the NCS_2 chromophore.[27]

Most of the ETCT derivatives of Cm-L-amino acids show a positive Cotton effect, while those of Cm-L-valine, Cm-L-isoleucine, and Cm-L-*t*-leucine show a negative one; there could be recognized no simple correlation between the sign of the Cotton effect and the configuration of the parent amino acid. In the case of the ETCT derivatives of α-amino acids[27] or β-amino acids,[28] an empirical rule correlating the sign of the Cotton effect with the configuration has been achieved through the salt formation with such a base as cyclohexylamine or dicyclohexylamine (DCHA). Table 9 shows the effects of added amines

on the Cotton effect of ETCT-Cm-L-valine. The effects are surprisingly great,[29] and some kinds of amines such as DCHA invert the sign of the Cotton effect. Therefore, the Cotton effect of all the ETCT derivatives were reexamined in the presence of three molar amounts of DCHA in the same four solvents as above. The results obtained by measurement in methanol are summarized in Table 10.

All the DCHA salts of ETCT-Cm-L-amino acids show a positive Cotton effect (with a CD maximum at 335—350 nm and the ORD first extremum at 360—370 nm) in all the solvents used, except in some cases where the insolubility of the salts made the measurements impossible. Therefore, the correlation observed here can also be used for the configurational assignments of Cm-amino acids.

Experimental

All the melting points are uncorrected. The optical rotations were measured with a JASCO DIP-4 polarimeter. The ^{1}H- and ^{13}C-NMR spectra were recorded on a Hitachi R-24B spectrometer and a JEOL JNM-PS-100 spectrometer respectively. The chemical shifts are given in δ values with respect to TMS or DSS as an internal standard. The IR spectra were recorded on a Hitachi EPI-S2 spectrophotometer, and the mass spectra (MS) on a JEOL-OIS instrument at an ionization energy of 75 eV. The ORD and CD measurements were carried out with a JASCO ORD/UV-5 spectropolarimeter with its CD attachment. The TLC and preparative TLC were performed on Merck Kieselgel 60 F_{254} and Kieselgel GF_{254} (Type 60) respectively. Merck Kieselgel 60 was used for column chromatography, and Amberlite CG-120 (Type I) in the H^+ form for ion-exchange chromatography. The GLC analyses were performed on a Hitachi 063 Gas Chromatograph equipped with a flame-ionization detector using a ϕ3 mm×1 m 10% SE-30 column. Paper electrophoresis was carried out on a Yanagimoto EC-10 instrument, using a buffer with this composition: pyridine:AcOH:H_2O=25:1:225 (pH 6.4).

Benzyl bromoacetate (bp 112.5—113 °C/3 mmHg)[30] and *t*-butyl bromoacetate (bp 73—75 °C/25—25.5 mmHg)[31] were prepared according to the literature. The optical rotations of the less common amino acids used here as starting materials are as follows: L-Abu,[32] $[\alpha]_D^{16}$ +20.8° (*c* 4.8, 6 M HCl); D-Phg,[33] $[\alpha]_D^{20}$ −111.1° (*c* 1.0, 1 M NaOH); L-Tle,[34] $[\alpha]_D^{26}$ +30.0° (*c* 1.0, AcOH).

General Procedure for the Preparation of N-*(Carboxymethyl)-amino Acids (2).* N-*Carboxymethyl-L-2-aminobutyric Acid (L-CmAbu)*: H-L-Abu-OH (2.23 g) was allowed to react with bromoacetic acid (3.01 g) at pH 11 and at *ca.* 50 °C according to the method of Snyder and Angelici.[6a] After 4 h the reaction mixture was neutralized with 6 M HCl to pH 7. Then the solution was concentrated to some extent, loaded onto a column of cation-exchange resin (ϕ 3 cm×13 cm), and eluted with water. The front of the zone containing the desired product had clearly been observed throughout the elution. The pH of the eluate first went steeply down to 1, then rose gradually near 7, became acidic again, and finally reached *ca.* 7. The second acidic eluate with pH 2—4 (1.8 l), which showed only one spot in the paper electrophoresis, was evaporated to dryness under reduced pressure; yield, 2.28 g (65%). Recrystallization from water afforded large plates; mp 205.5—207 °C, $[\alpha]_D^{25}$ +9.8° (*c* 1.0, 1 M HCl).

N-*Carboxymethyl-L-t-leucine (L-CmTle)*: H-L-Tle-OH (786 mg) was allowed to react with bromoacetic acid (840 mg) for 4 h in a manner similar to that described above. Then the reaction mixture was acidified with concd HCl to pH 2. The deposited crystals were collected, and the concentration of the filtrate afforded a second crop. They were combined and recrystallized from water to afford prisms; yield, 850 mg (75%); mp 247—250 °C (dec), $[\alpha]_D^{25}$ −23.3° (*c* 1.0, 1 M HCl). Paper-electrophoresis showed only one spot.

Cm-DL-*t*-leucine and Cm-L-phenylalanine were likewise prepared in this way.

Preparation of the Diesters (3) of N-*(Carboxymethyl)amino Acids.* To a stirred mixture of an amino ester *p*-toluenesulfonate (or hydrochloride) (10 mmol), and TEA (20 mmol) in dry THF (30 ml), we added, drop by drop, a solution of a bromoacetic ester (12 mmol) in dry THF (10 ml). Then the mixture was stirred for 4—7 d at room temperature, with an occasional filtration of the precipitates (TEA salts). After the solvent had been removed under reduced pressure, the residual syrup was distributed between AcOEt and water, and the organic layer was washed successively with water, 10% citric acid, and water. After the solvent had been removed under reduced pressure again, 4—6 M HCl was added to the residue and the resulting solution was washed with AcOEt.[35] The aqueous layer was basified with solid K_2CO_3, and the liberated oil was extracted into AcOEt. The extracts were combined, washed with water, and dried over Na_2SO_4. The subsequent removal of the solvent yielded a syrup, the purity of which was checked by TLC, GLC, or ^{1}H-NMR. If the product thus obtained was not pure enough, it was further purified by column chromatography or preparative TLC, as will be described in the examples below.

For characterization, the diester was converted into the crystalline derivatives, the *p*-toluenesulfonate and/or the picrolonate. Even when the *p*-toluenesulfonate was difficult to crystallize, the corresponding picrolonate easily became crystalline.

Some typical examples of the procedures for the isolation of the diesters will be given below.

Ethyl N-*Benzyloxycarbonylmethyl-L-valinate (3e)*: H-L-Val-OEt·TosOH (3.17 g) was allowed to react with benzyl bromoacetate for 7 d. After the work-up described above, a colorless liquid was obtained in a pure state; yield, 2.24 g (76%); n_D^{32} 1.4825, $[\alpha]_D^{25}$ −18.5° (*c* 1.0, MeOH). Found: C, 65.56; H, 7.71; N, 4.52%. Calcd for $C_{16}H_{23}NO_4$: C, 65.51; H, 7.90; N, 4.78%. *p*-Toluenesulfonate, mp 87.5—89 °C; picrolonate, mp 120—122 °C (from EtOH).

When the reaction mixture was heated under reflux for 40 h, a similar work-up yielded the diester (**3e**) in a little poorer yield (71%).

The free diester was recovered from the *p*-toluenesulfonate as follows. The salt was distributed between Et_2O (or AcOEt) and 10% K_2CO_3, and the organic layer was further washed with the alkali and water, and then dried over Na_2SO_4. The subsequent removal of the solvent, followed by the addition of $CHCl_3$ to the residue and its successive evaporation, gave the diester (**3e**); n_D^{25} 1.4849.

Methyl N-*Benzyloxycarbonylmethyl-L-phenylalaninate (3m)*: H-L-Phe-OMe·HCl (2.16 g) was allowed to react with benzyl bromoacetate for 4 d. After the work-up described above, the residual syrup (3.25 g) was chromatographed on a silica-gel column, using $CHCl_3$–AcOEt (9:1) as the eluent. The fractions which indicated coloration (on TLC) with $Co(SCN)_2$ and not with ninhydrin were collected and then evaporated under reduced pressure; yield, 1.86 g (57%). *p*-Toluenesulfonate, mp 147.5—149 °C; picrolonate, 168—169 °C (from EtOH).

Benzyl N-*Benzyloxycarbonylmethyl-*L*-phenylalaninate (**3o**)*: H–L-Phe–OBzl·TosOH (915 mg) was allowed to react with benzyl bromoacetate for 7 d. The syrup (752 mg) obtained by the work-up described above was chromatographed on preparative TLC, using benzene–AcOEt (9:1) as the developing solvent; yield, 563 mg (65%). *p*-Toluenesulfonate, mp 123.5—124.5 °C; picrolonate, mp 153—153.5 °C (from EtOH).

General Procedure for the Direct Esterification of N-*(Carboxymethyl)amino Acids. Methyl* N-*Methoxycarbonylmethyl-*L*-alaninate (**3i**)*: To a chilled solution of $SOCl_2$ (0.6 ml) in dry MeOH (5 ml), Cm-L-alanine (500 mg) was added, after which the mixture was stirred at room temperature for 2 d. After it had then been refluxed for 4 h, it was evaporated to dryness under reduced pressure. The residue was dissolved in water and basified with solid K_2CO_3 to pH 9; the mixture was extracted with AcOEt. The organic extracts were combined, washed with water, and dried over Na_2SO_4. The subsequent removal of the solvent afforded **3i** as a liquid in a pure state; yield, 397 mg (67%); $[\alpha]_D^{25}$ −24.4° (*c* 1.0, MeOH). Picrolonate, mp 134.5—135.5 °C.

Preparation of N-*(Carboxymethyl)amino Acids (**2**) via Their Diesters (**3**). N-Carboxymethyl-*L*-phenylalanine (L-CmPhe), a) by the Hydrogenolysis of the Dibenzyl Ester (**3o**)*: The dibenzyl ester (**3o**) (270 mg) was hydrogenolyzed in AcOH–H_2O (2:1) (30 ml) in the presence of 5% Pd–C (60 mg). After the absorption of hydrogen had ceased (*ca.* 2 h), the catalyst was filtered off and the filtrate was evaporated under reduced pressure, affording a white crystalline mass in a quantitative yield. It was then recrystallized from water; $[\alpha]_D^{25}$ +15.8° (*c* 1.0, 1 M HCl).

*b) By the Acidic Hydrolysis of the Dimethyl Ester (**3l**)*: The dimethyl ester (**3l**) (710 mg) was heated in 20% HCl (7 ml) at 100—110 °C. The progress of the hydrolysis was followed by TLC on cellulose or by circular paper chromatography. Within 2 h the spot due to the starting material disappeared, while those spots corresponding to the monoester(s) (**4d** and/or **5d**) and the desired compound appeared on the chromatograms. After *ca.* 10 h, the color of the former faded considerably, but it did not completely vanish even after a further 7 h. Even at this time, though, the formation of neither glycine nor phenylalanine could be detected. The reaction mixture was evaporated under reduced pressure. After the addition of water to the residue and its successive evaporation has been repeated, the residual solid mass was recrystallized from water; yield, 565 mg (90%); $[\alpha]_D^{25}$ +15.9° (*c* 1.0, 1 M HCl).

*General Procedure for the Preparation of the Monoesters (**4** and **5**) of* N-*(Carboxymethyl)amino Acids. Methyl* N-*Carboxymethyl-*L*-phenylalaninate (**4d**)*: The benzyl methyl ester (**3m**) (290 mg) was hydrogenolyzed in AcOH–H_2O (2:1) (10 ml) in the presence of 5% Pd–C (90 mg). After the absorption of hydrogen had ceased (*ca.* 3.5 h), the catalyst was filtered off and the filtrate was evaporated under reduced pressure, affording a crystalline mass (210 mg); mp 145—153 °C. It was recrystallized from EtOH; yield 139 mg (66%); mp 157.5—159 °C, $[\alpha]_D^{25}$ +17.2° (*c* 1.0, 1 M HCl).

N-*Ethoxycarbonylmethyl-*L*-valine (**5b**)*: The crude benzyl ethyl ester (**3f**) (3.96 g), obtained from 5.36 g of H–L-Val–OBzl·TosOH and contaminated by the unchanged starting ester, was hydrogenolyzed in a manner similar to that described above. The catalyst was filtered off, and the filtrate evaporated under reduced pressure. After it had been dried sufficiently, the residue was treated with hot EtOH and the insoluble materials (valine) were filtered off. From the filtrate, the desired product (**5b**) was obtained; yield, 1.94 g (68%, based on H–L-Val–OBzl·TosOH); mp 167—168 °C, $[\alpha]_D^{25}$ +0.6° (*c* 1.0, 1 M HCl).

^{13}C-NMR and MS Spectra of the Isomeric Diesters of N-*Carboxymethyl-*L*-valine, **3e** and **3f**. **3e***: ^{13}C-NMR ($CDCl_3$): δ 14.33 (q, $-OCH_2\underline{C}H_3$), 18.40 and 19.17 (each q, $-CH(\underline{C}H_3)_2$), 31.56 (d, $-\underline{C}H(CH_3)_2$), 49.80 (t, $-NH\underline{C}H_2CO-$), 60.49 (t, $-O\underline{C}H_2CH_3$), 66.45 (t, $-O\underline{C}H_2C_6H_5$), 66.70 (d, $-NH\underline{C}HCO-$), 128.30 (d, C2,6* and C4 of C_6H_5), 128.53 (d, C3,5* of C_6H_5), 135.69 (s, C1 of C_6H_5), 171.60 (s, $-\underline{C}H_2CO-$), 174.03 (s, $=CH\underline{C}O-$). An alternative assignment is probable for the peak marked with an asterisk.

MS *m/e* (rel intensity): 293 (M^+, 0.5), 250 ($M^+-(CH_3)_2CH$, 5.2), 221 ($250^+-C_2H_5$, 9.2), 220 ($M^+-COOC_2H_5$, 63.2), 202 ($M^+-C_6H_5CH_2$, 1.6), 158 (202^+-CO_2, 7.6), 130 ($221^+-C_6H_5CH_2$, 4.6), and 91 ($C_6H_5CH_2^+$, base peak).

3f: ^{13}C-NMR ($CDCl_3$): δ 14.18 (q, $-OCH_2\underline{C}H_3$), 18.36 and 19.19 (each q, $-CH(\underline{C}H_3)_2$), 31.60 (d, $-\underline{C}H(CH_3)_2$), 49.83 (t, $-NH\underline{C}H_2CO-$), 60.77 (t, $-O\underline{C}H_2CH_3$), 66.45 (t, $-O\underline{C}H_2C_6H_5$), 66.77 (d, $-NH\underline{C}HCO-$), 128.31 (d, C2, 6* of $\underline{C}_6H_5$), 128.56 (d, C3,5* and C4 of C_6H_5), 135.74 (s, C1 of C_6H_5), 171.74 (s, $-CH_2\underline{C}O-$), 174.10 (s, $=CH\underline{C}O-$).

MS *m/e* (rel intensity): 293 (M^+, 0.4), 278 (M^+-CH_3, 0.2), 250 ($M^+-(CH_3)_2CH$, 5.4), 221 ($250^+-C_2H_5$, 0.8), 220 ($M^+-COOC_2H_5$, 5.4), 202 ($M^+-C_6H_5CH_2$, 0.9), 158 (202^+-CO_2, base peak), 130 ($221^+-C_6H_5CH_2$, 2.6), and 91 ($C_6H_5CH_2^+$, 58.3).

Measurements of the ORD and CD Spectra. All the measurements were carried out at room temperature. The sample solution concentration and the length of the cell, l, are given in the footnotes of each table.

The Cm-amino acids (**2**) listed in Table 1 were converted into the corresponding ethyl dithiocarbamates according to the methods in the literature.[27] Their ORD and CD spectra were measured in several solvents, with or without the addition of three molar amounts of DCHA.

The author is grateful to Profs. (the late) Hiroshi Watanabe and Shigeru Kuwata of Kōnan University, and to Prof. Kazuhiro Maruyama of Kyoto University, for their helpful suggestions and encouragement.

Reactions of Substituted Epoxides with Alkyl Chloroacetate

Tokuji TAKEDA,* Satoshi YASUHARA, and Shoji WATANABE
Osaka Municipal Technical Research Institute, Ogimachi, Kita-ku, Osaka 530

(Received December 14, 1979)

The reactions of substituted epoxides with alkyl chloroacetate in the presence of lithium salts, quarternary salts and zinc chloride were studied. The reaction of 1-chloro-2,3-epoxypropane (**1a**) with butyl chloroacetate (BCA) in the presence of any of these catalysts yielded exclusively butyl [2-chloro-1-(chloromethyl)ethoxy]acetate (**2a**) via the normal cleavage of **1a** followed by the reaction with the chloroacetate. On the other hand, the reaction of 1,2-epoxypropane(**1b**) with BCA yielded a mixture of isomeric products resulting from the normal and abnormal cleavages of **1b**, and the ratio of the normal and abnormal products is dependent on the type of the catalyst. Moreover, it was found that lithium salt alone catalyzed the insertion reaction in a polar aprotic solvent, whereas the reaction in aromatic solvent needed a suitable co-catalyst such as hexamethylphosphoric triamide and triphenylphosphine oxide.

Insertion of an epoxide into the carbon-halogen bond of an alkyl halide had not been investigated to any noticeable extent. In our previous papers, we reported the insertion of ethylene oxide into the carbon-halogen bond of benzyl chlorides[1] and halooctanes[2,3] using zinc halide as a catalyst. The reaction of ethylene oxide with benzyl chlorides and halooctanes in *N,N*-dimethylacetamide(DMA) gave 2-chloroethyl benzyl ethers and 1-(2-haloethoxy)octanes, respectively, while the reaction of ethylene oxide with secondary halooctanes in the absence of any solvent gave the mixture of 2-(2-haloethoxy)octane, 3-(2-haloethoxy)octane and 4-(2-haloethoxy)octane.

In this study, we obtained the novel insertion compounds from the reaction of substituted epoxides with butyl chloroacetate(BCA) and investigated the distribution of isomers of the insertion products. Moreover, we searched for more effective catalysts and reaction systems from the limitation of zinc halide hitherto used as a catalyst. It was found that the isomer distribution of the insertion product caused by the direction of ring opening was dependent on the substituent of the epoxide ring and the type of the catalyst and that lithium salt complexed with suitable co-catalyst was effective for the present insertion reaction.

Results and Discussion

*Reaction of 1-Chloro-2,3-epoxypropane(**1a**) with BCA.* The reaction of the epoxide **1a** with BCA in DMA in the presence of lithium chloride gave only product, butyl [2-chloro-1-(chloromethyl)ethoxy]acetate(**2a**), in the yield of 35.6%.

$$\underset{\textbf{1a}}{ClCH_2CHCH_2O} + ClCH_2COOC_4H_9 \xrightarrow[\text{in DMA}]{LiCl} \underset{\textbf{2a}}{(ClCH_2)_2CHOCH_2COOC_4H_9}$$

The structure of this novel compound **2a** could not be determined clearly by ^{1}H-NMR spectrum because the signals of methylene and methine proton between the chlorine and the ether oxygen of the normal and abnormal products, $(ClCH_2)_2CHO-$ and $ClCH_2CH(Cl)CH_2O-$, would appear at similar chemical shifts. However, the presence of seven signals above 80.00 in ^{13}C-NMR unambiguously supported the structure of **2a**. Chemical shifts were assigned on the basis of Lindeman-Adams' equation,[4] the substituent effect and off-resonance spectrum. The effect of catalyst on the yield of the product **2a** is shown in Table 1. Zinc chloride and triethylamine gave a small amount of **2a**. Lithium salts and tetraethylammonium bromide gave considerable amounts of **2a**. In the reaction of **1a** with BCA in DMA, a very small amount of dibutyl oxydiacetate(**3**) was detected by GLC analysis. This could be due to a trace amount of water in DMA. Thus, the reaction of **1a** with BCA was tried in benzene and toluene to avoid the formation of **3**. Lithium salt alone is insoluble in benzene and toluene, and refluxing a benzene or toluene solution of **1a** and BCA in the presence of lithium salt gave no reaction. However, by the addition of an equimolar amount of hexamethylphosphoric triamide(HMPA) to lithium salt the insertion reaction took place smoothly. These results suggest that DMA, added as a solvent in the former reaction, and HMPA, added as a co-catalyst in the latter reaction, may play the same role for the insertion reaction. DMA and HMPA act not only simply as solvents, but also specifically solvate the lithium ion to enhance the nucleophilicity of the resulting "naked" halide ion. It was reported by Rickborn[5] that a 1:1 complex of LiBr–HMPA was an efficient catalyst for the rearrangement of epoxides, but the catalytic activity of the complex was quenched by the addition of a second

Table 1. Effect of catalysts on the yield of **2a**[a]

Catalyst	Recovery of BCA (%)	Yield of **2a** (%)[b]
LiCl	43.3	33.0
LiBr	60.0	35.8
TEAB	61.0	28.6
TEA[c]	79.5	4.9
$ZnCl_2$[d]	73.3	8.2

a) Reaction temperature is 80 °C and other conditions are the same as those in the case of LiCl, described in Experimental Section. The reactions were carried out in homogeneous system. b) Based on BCA. c) Triethylamine. d) Reaction temperature is 100 °C.

Table 2. Catalysis by lithium salt-cocatalyst for the reaction of the epoxide **1a** with BCA in benzene[a)]

Catalyst	Recovery of BCA (%)	Yield of **2a** (%)[b)]
LiCl–HMPA	59.2	27.2
LiBr–HMPA	33.5	46.3
LiBr–4HMPA[c)]	16.9	48.1
LiI–HMPA	38.3	33.9
LiCl–DMF[d)]	87.8	9.9
LiCl–DMA	83.2	10.3
LiCl–NMP[e)]	87.0	10.7
LiCl–DMSO[f)]	92.4	1.7
LiBr–TMU[g)]	95.0	3.3
LiCl–TPPO	66.6	15.9
LiBr–TPPO	31.4	51.0
LiBr–TBPO[h)]	63.7	19.9

LiCl–$(PhO)_3PO$[j)]	93.5	2.8
LiBr–12-Crown-4	95.6	4.3
LiBr–15-Crown-5	57.4	16.2
LiBr–18-Crown-6	95.0	0.4
LiBr–Dibenzo-18-crown-6	83.2	5.4

a) Reaction temperature is 90 °C and other conditions are described in Experimental section. The reaction mixtures were not clear solution because of the inadequate solubility of catalysts. b) Based on BCA. c) A mixture of 6 mmol of LiBr and 24 mmol of HMPA was used. d) *N*,*N*-Dimethylformamide. e) *N*-Methyl-2-pyrrolidone. f) Dimethyl sulfoxide. g) Tetramethylurea. h) Tributylphosphine oxide. i) Triethyl phosphate. j) Triphenyl phosphate.

equivalent of HMPA. Although such quenching was not observed in the present reaction, it was found that an equimolar amount of HMPA to lithium salt was sufficient to promote the insertion (Table 2). In DMA the yield of **2a** is not different regardless of the kind of lithium salts, as shown in Table 1, while in benzene the yield of **2a** by LiBr catalyst is higher than by LiCl catalyst. The difference in the catalysis may be ascribed to the difference in the solubility of these catalysts in DMA and benzene; both LiCl and LiBr are soluble in DMA, but LiBr is more soluble in benzene than LiCl.

The effectiveness of other polar aprotic additives, phosphates, phosphine oxides and crown ethers as promoting agents is shown in Table 2. Triphenylphosphine oxide (TPPO) was the best promoting agent except for HMPA. The best yield of **2a** was 57.6% in the reaction using LiBr–TPPO catalyst at 90 °C for 24 h. 15-Crown-5 was the most effective among the crown ethers inspected when used with lithium bromide. The effect of solvents on the yield of the insertion product **2a** is shown in Table 3. The yield of **2a** was lower in toluene at a higher temperature than in benzene at a lower temperature. This may be due to inadequate solubility of lithium bromide–HMPA in toluene. Tetrahydrofuran was effective at a lower temperature.

Quarternary salts were also effective for the insertion

Table 3. Effect of solvents on the yield of **2a**[a)]

Solvent	Recovery of BCA (%)	Yield of **2a** (%)[b)]
Toluene[c)]	41.6	29.2
Dioxane[d)]	57.8	20.5
THF[e)]	54.2	28.2

a) Lithium bromide and HMPA were used as a catalyst and a co-catalyst, respectively. The reaction mixture were not clear solutions because of the inadequte solubility of catalysts. b) Based on BCA. c) Reaction temperature is 110 °C. d) Reaction temperature is 90 °C. e) Reaction temperature is 70 °C.

Table 4. The reaction of **1a** with BCA in the presence oe quarternary salts[a)]

Catalyst	Recovery of BCA (%)	Yield of **2a** (%)[b)]
TEAB–HMPA	90.8	6.0
TBAB–HMPA	42.8	30.1
TBAB	51.6	20.7
MTPPI–HMPA	63.1	23.3

a) A mixture of 6 mmol each of quarternary salt and HMPA, 60 mmol each of BCA and **1a** in 20 ml of benzene was stirred at 90 °C for 5 h. The reaction mixtures were clear solutions, except for TEAB–HMPA and MTPPI–HMPA. b) Based on BCA.

reaction in benzene (Table 4). Tetraethylammonium bromide (TEAB) and methyltriphenylphosphonium iodide (MTPPI) are not sufficiently soluble in benzene to cause reaction, unlike tetrabutylammonium bromide (TBAB). Thus, the former two quarternary salts were not effective in benzene in the absence of HMPA, whereas TBAB alone promoted the insertion in this nonpolar solvent. However, with TBAB the yield of **2a** increased upon addition of HMPA. This result suggests that the nucleophilicity of the halide ion of TBAB was enhanced by the addition of HMPA.

*Reaction of 1,2-Epoxypropane (**1b**) with BCA.* The reaction of the epoxide **1b** with BCA in DMA in the presence of lithium chloride gave a mixture of butyl [1-(chloromethyl)ethoxy]acetate (the normal isomer, **4a**) and butyl (2-chloropropoxy)acetate (the abnormal isomer, **4b**).

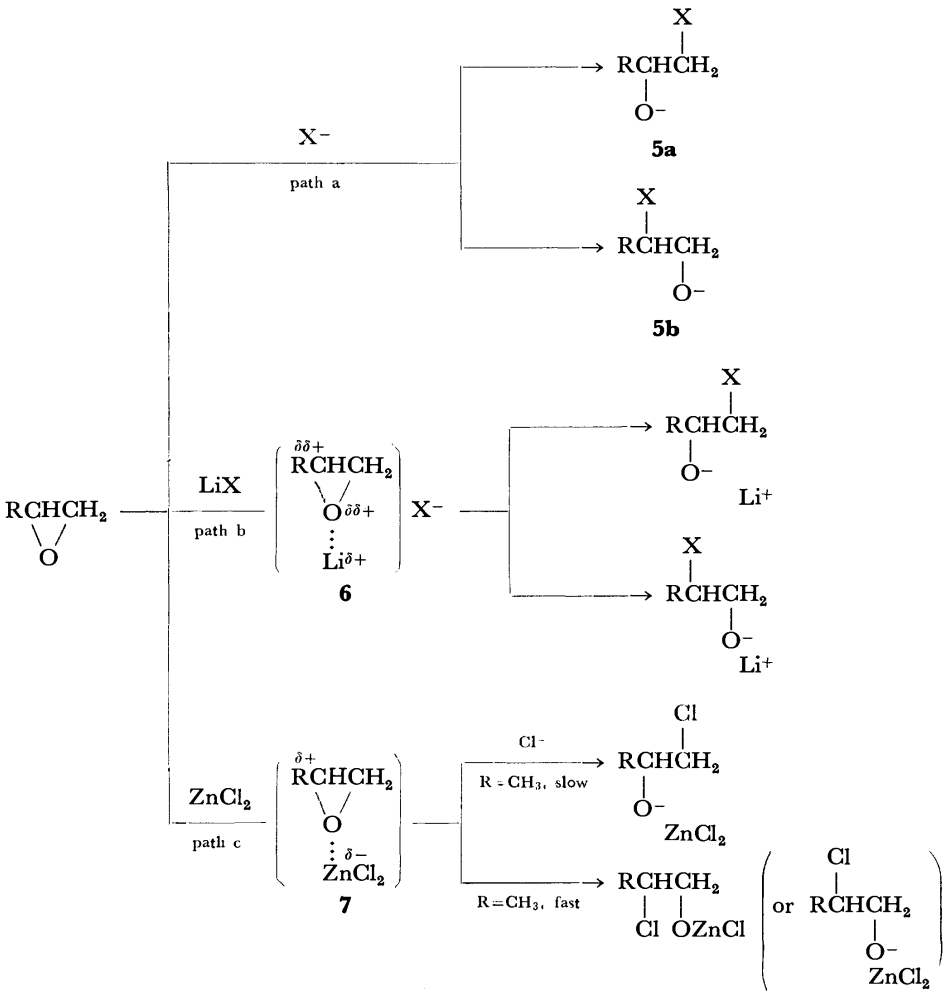
These novel compounds, the normal and abnormal isomers, were separated and isolated by GLC using DEGS liquid phase. ^{1}H-NMR spectrum of the isolated **4a** showed a characteristic doublet peak at δ 1.30 due to the methyl proton adjacent to the methine carbon.

$$CH_3CH\underset{\backslash\,/}{CH_2}O + ClCH_2COOC_4H_9 \xrightarrow[\text{in DMA}]{\text{LiCl}}$$

1b

$$CH_3\underset{\displaystyle CH_2Cl}{\underset{|}{C}}HOCH_2COOC_4H_9 + CH_3\underset{\displaystyle Cl}{\underset{|}{C}}HCH_2\underset{\displaystyle COOC_4H_9}{\underset{|}{O}}CH_2$$

4a 41.2% **4b** 58.8%



Scheme 1.

^{1}H-NMR spectrum of the isolated **4b** showed a characteristic doublet peak at 1.56 ppm due to the methyl proton adjacent to the methine carbon attached to the chlorine atom. In mass spectra, the normal isomer **4a** gave characteristic fragment peaks at *m/e* 159 and 103 based on the elimination of chloromethyl group and the abnormal isomer **4b** gave characteristic fragment peaks at *m/e* 172 and 71 based on dehydrochlorination. From these results the structures of the normal and abnormal isomers were confirmed.

Isomer Distribution and Probable Mechanism. The reaction of the epoxide **1a** with BCA exclusively gave the normal insertion product **2a**, regardless of the type of catalyst. However, the reaction of the epoxide **1b** with BCA gave the mixture of the isomeric products, **4a** and **4b**. The present reaction may proceed by the following mechanism, as shown in Scheme 1.

The exclusive formation of the normal isomer in the reaction of the epoxide **1a** may be explained by the inductive (electron-withdrawing) and large steric effects of chloromethyl group. The stability of a transition state such as **6** or **7** is disturbed by the electron-withdrawing power of chloromethyl group.

On the other hand, the formation of the normal and abnormal isomers in the reaction of the epoxide **1b** can be attributable to the inductive (electron-donating) and steric effects of methyl group. The isomer distribution of the products from the reaction of the epoxide **1b** with BCA was dependent on the type of the catalyst. The results are summarized in Table 5. Use of tetraethylammonium salts resulted in a little preferential formation of the normal isomer. In this case, the nucleophilic attack by halide ion may an important role in the ring opening of epoxide. The isomer distribution may be ascribed to the steric

Table 5. Isomer distribution of the reaction product of BCA with the epoxide **1b**[a]

Catalyst	Isomer distribution		Yield of **4a**+**4b**(%)[b]
	4a(%)	**4b**(%)	
$ZnCl_2$	20.0	80.0	34.5
LiCl	41.2	58.8	31.5
LiCl+TEAB[c]	44.8	55.2	44.2
TEAC[d]	58.5	41.5	—
TEAB	60.0	40.0	21.0

a) A mixture of 0.5 mmol of catalyst, 5 mmol each of BCA and DMA, and 20 mmol of **1b** was stirred at 100 °C for 5 h. The reactions were carried out in homogeneous system. b) Based on BCA. c) A mixture of 0.5 mmol each of lithium chloride and tetraethylammonium bromide was used. d) Tetraethylammonium chloride.

effect of methyl group which is smaller than that of chloromethyl group (path a). Use of lithium halide led to a little preferential formation of the abnormal isomer. Lithium ion, solvated by (or complexed with) DMA, HMPA, or TPPO, would coordinate to the oxygen of the epoxide ring and polarize the C–O bond of the epoxide, thus facilitating the ring opening by nucleophilic attack by halide ion. The isomer distribution may be attributable to the inductive and steric effects of methyl group of the epoxide **1b** (path b). Zinc chloride highly preferentially gave the abnormal isomer. In this case, the chloride ion seems to be less nucleophilic, which is in accord with the fact that the reaction of **1a** is very slow as shown in Table 1. Zinc chloride would coordinate stronger to the oxygen of the epoxide ring. Predominant formation of **4b** can be explained by the attack (intramolecular or not) of the chloride ion on the highly polarized transition state like **7** or the secondary carbonium ion which is preferentially formed by the inductive effect of the methyl group (path c).

Experimental

^{1}H-NMR and ^{13}C-NMR spectra were recorded with JEOL JNM-MH-100 and JNM-FT-100 Spectrometers in carbon tetrachloride and deuterochloroform solution, respectively. Mass spectra were determined with a JEOL JMS-07 Spectrometer at an ionizing voltage of 30 eV.

*Reaction of 1-Chloro-2,3-epoxypropane (**1a**) with Butyl Chloroacetate (BCA) in N,N-Dimethylacetamide (DMA).* LiCl 0.13 g (3 mmol) was dried under vacuum prior to use and was dissolved in 5.2 g (60 mmol) of DMA. Then, 9.0 g (60 mmol) of BCA and 5.5 g (60 mmol) of **1a** were added to the solution and the mixture was stirred at 100 °C for 5 h. The resulting reaction mixture was extracted (Et_2O–H_2O), and the ethereal extract was washed with H_2O and dried with $MgSO_4$. 2.5 g of BCA was recovered by distillation and 5.5 g (37.5% based on BCA) of crude butyl 2-chloro-1-(chloromethyl)ethoxy acetate (**2a**, 95% purity by GLC) was obtaned. The product purified further by distillation had the following properties: Bp 108—109 °C/2 mmHg (1 mmHg=133.322 Pa). ^{13}C-NMR (excluding COO) δ 13.68 (Off-resonance decoupling; q, CH_3), 19.14 (t, $\underline{C}H_2CH_3$), 30.65 (t, $\underline{C}H_2C_2H_5$), 43.37 (t, $ClCH_2$), 65.00 (t, $COO\underline{C}H_2$), 68.02 (t, $O\underline{C}H_2COO$), 79.58 (d, $\underline{C}HO$). ^{1}H-NMR δ 0.98 (3H, t, J=7.5 Hz, CH_3), 1.30—1.70 (4H, m, CH_2), 3.70—3.72 (5H, m, $ClCH_2CHCH_2Cl$), 4.16 (2H, t, J=7.5 Hz, $COOCH_2$), 4.26 (2H, s, OCH_2COO). Found: C, 44.26; H, 6.37; Cl, 29.1%.[6] Calcd for $C_9H_{16}O_3Cl_2$: C, 44.46; H, 6.64; Cl, 29.16%.

*Reaction of **1a** with BCA in Benzene and Other Nonpolar Solvents.* A mixture of 6 mmol of lithium salt, dried prior to use, and co-catalyst (1.0 g in the case of crown ethers), and 60 mmol of BCA and **1a** in 20 ml of a solvent was stirred at 70—110 °C for 5 h. The yield of **2a** and the recovery of BCA, as shown in Tables 2 and 3, were determined by GLC.[7]

*Reaction of 1,2-Epoxypropane (**1b**) with BCA.* A mixture of 3.15 g (15 mmol) of tetraethylammonium bromide (TEAB), 13.1 g (150 mmol) of DMA, 22.6 g (150 mmol) of BCA and 17.4 g (300 mmol) of **1b** was heated in a glass autoclave at 100 °C for 5 h. The reaction product was isolated by the same procedure as in the case of **2a** and 4.5 g (14.4%) of the pure product was obtaned. Bp 65—66 °C/20 mmHg. Found: C, 51.53; H, 8.39; Cl, 17.1%; Mol. weight, 213.3.[8] Calcd for $C_9H_{17}O_3Cl$: C, 51.80; H, 8.21; Cl, 16.99%; Mol. weight, 208.5. This product contained the normal cleavage product **4a** and the abnormal cleavage product **4b**. Each isomer was isolated by GLC using DEGS 20%, 3 m column. **4a**: ^{1}H-NMR δ 0.93 (3H, t, J=6.5 Hz, terminal CH_3), 1.30 (3H, d, J=6.0 Hz, CH_3C–O–), 1.43—1.47 (4H, m, CH_2), 3.35—3.84 (3H, m, $ClCH_2$–CHO), 4.07—4.20 (4H, m, CH_2OCOCH_2O). **4b**: 0.98 (3H, t, J=6.5 Hz, terminal CH_3), 1.56 (2H, d, J=6.0 Hz, CH_3CCl), 3.57—3.77 (3H, m, OCH_2CHCl), 4.06—4.21 (4H, m, CH_2OCOCH_2O). The reactions using various catalysts were carried out in a 20 ml sealed tube. Product distribution was determined by GLC[9] using standard mixtures, and the overall yield of the insertion products was determined by GLC.[10]

The authors would like to thank Professor Mitsuo Okahara and Assistant Professor Isao Ikeda of Osaka University for helpful discussion and to Dr. Mitsuo Komatsu of Osaka University for obtaining the C-13 NMR spectra.

(Received December 19, 1979)

N-Acetylmuramyl-L-alanyl-D-isoglutamine (MDP) and thirteen new analogs were synthesized by the conventional organic chemical procedure using dicyclohexylcarbodiimide-*N*-hydroxy-5-norbornene-2,3-dicarboximide as a coupling agent. Their ability to induce delayed-type hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine in guinea pigs was assayed. The results indicate that the presence of an α-amino acid adjacent to the lactic acid moiety in MDP is important for the high biological activity, the valine analog having the most favorable effect. The structure-activity relationship is discussed.

Freund's complete adjuvant (FCA) is a most widely used adjuvant consisting of heat-killed mycobacterial cells in mineral oil.[2)] Ellouz *et al.*[3)] and Kotani *et al.*[4)] independently elucidated that *N*-acetylmuramyl-L-alanyl-D-isoglutamine (MDP) (**9a**) is the minimal structure responsible for the activity elicited by peptidoglycan of the bacterial cell walls. MDP can be substituted for mycobacterial cells in FCA to potentiate both B cell- and T cell-mediated immune responses.[5)] Recently, MDP has been found to have biological activities such as enhancement of the nonspecific resistance in mice infected by *Klebsiella pneumoniae*,[6)] stimulation of the thymidine uptake in mouse spleen cell cultures,[7)] and the activation of reticuloendothelial system[8)] and macrophages *in vitro*.[9)]

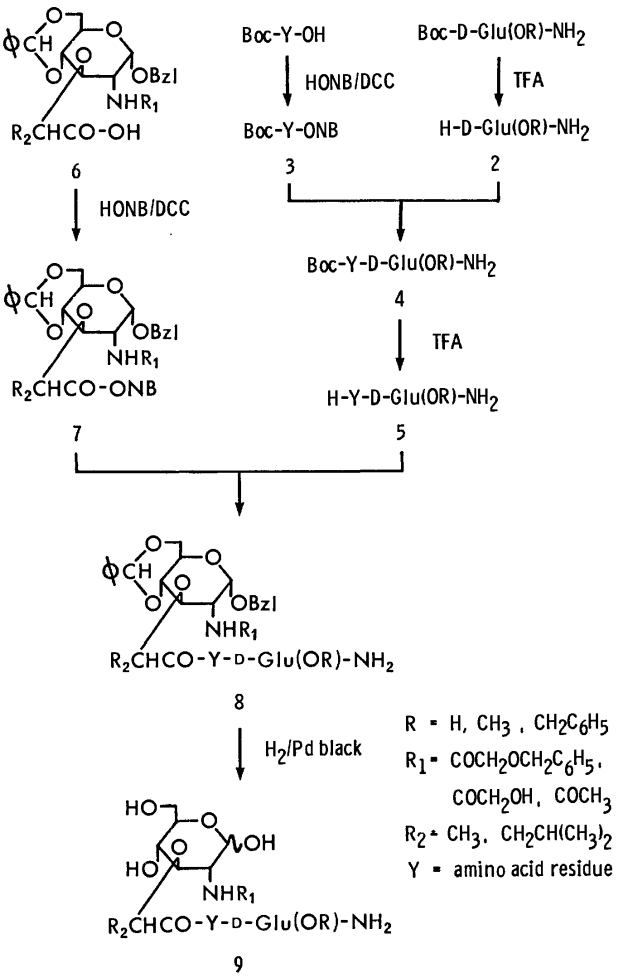
In view of possible clinical applications of immunomodulators, it is important to prepare MDP analogs with enhanced activities. In this report, we describe the synthesis and immunological activities of 13 new MDP analogs (Table 3). MDP has also been synthesized for the sake of comparison in our biological system.

Chemistry

MDP and its analogs were synthesized by the conventional organic chemical procedure using dicyclohexylcarbodiimide (DCC)-*N*-hydroxy-5-norbornene-2,3-dicarboximide (HONB)[10)] as a coupling agent at each step. The *t*-butoxycarbonyl (Boc) group was used for α-amino protection and the benzyl group for side chain hydroxyl and carboxyl protection. The Boc group was removed with trifluoroacetic acid prior to each coupling. The final deprotection of all the protecting groups was effected by catalytic hydrogenation.[11)] Details of the synthesis are summarized in Scheme 1.

The protected dipeptides (**4**) were synthesized by coupling D-isoglutamine benzyl (**2a**) or methyl (**2b**) ester with Boc-amino acid HONB ester (**3**). The dipeptides (**4**) thus obtained are given together with their physicochemical properties in Table 1.

The protected glycopeptides (**8**) were prepared by coupling suitably protected dipeptides (**5**) with protected muramic acid derivatives, such as benzyl 2-acetamido-4,6-*O*-benzylidene-3-*O*-[1-(*R*)-carboxyethyl]-2-deoxy-α-D-glucopyranoside (**6a**), the (*S*)-isomer (**6b**), benzyl 2-acetamido-4,6-*O*-benzylidene-3-*O*-[1-(*R*)-carboxyisopentyl]-2-deoxy-α-D-glucopyranoside (**6c**), or benzyl 4,6-*O*-benzylidene-2-benzyloxyacetamido-3-*O*-[1-(*R*)-carboxyethyl]-2-deoxy-α-D-glucopyranoside (**6d**). These protected muramic acids (**6**) were converted into the HONB active esters (**7**) for coupling.



Scheme 1.

Protected *N*-acetylmuramic acid (**6a**) was prepared by the method of Flowers and Jeanloz[12)] and protected

a) Lit,[11b] mp 137.5—138.5 °C. b) Aib: α-aminoisobutyric acid. c) Lit,[11c] mp 65—66 °C; $[\alpha]_D^{25}$ +5.8°(MeOH).

N-acetylisomuramic acid (**6b**) by that of Petit and Sinäy.[13] Compound **6c** was obtained by treating benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside[12] with sodium hydride, followed by condensation with (*S*)-2-chloro-4-methylpentanoic acid.[14] (The compound obtained after hydrogenolytic deprotection of **6c** is referred to as *N*-acetyl *C*-isobutylnormuramic acid in this text). Acylation of benzyl 2-amino-4,6-*O*-benzylidene-α-D-glucopyranoside[15] with benzyloxyacetic anhydride gave benzyl 4,6-*O*-benzylidene-2-benzyloxyacetamido-α-D-glucopyranoside (**10**), which was then treated with sodium hydride and condensed with (*S*)-2-chloropropionic acid[16] as in the synthesis of **6a** to give protected *N*-glycolylmuramic acid (**6d**). The protected glycodipeptides (**8**) obtained are given in Table 2 together with their physicochemical properties.

The *N*-acetylmuramyl dipeptides (**9a**—**9h**), *N*-acetylisomuramyl dipeptide (**9i**), *N*-glycolylmuramyl dipeptides (**9j**—**9m**) and *N*-acetyl *C*-isobutylnormuramyl dipeptide (**9n**) were obtained after elimination of all the protecting groups by catalytic hydrogenation in acetic acid. The final products (**9**) were purified by column chromatography on Sephadex LH-20 with ethanol–0.1 M acetic acid as a solvent. The physicochemical properties of the desired MDP analogs are given in Table 3.

During the hydrogenolytic deprotection of the isomuramyl derivative (**8i**) in acetic acid, TLC showed the generation of L-alanyl-D-isoglutamine (**13**), an unknown by-product (**11**) and a small amount of isomuramic acid (**12**) as well as the desired *N*-acetylisomuramyl-L-alanyl-D-isoglutamine (**9i**). Attempts to isolate the unknown by-product were unsuccessful, the only compound obtained being isomuramic acid.

Treatment of **9i** in acetic acid at 80 °C for 1 h gave nearly the same result on TLC as that obtained by the hydrogenolytic deprotection of **8i**. Quantitative analysis of the liberated L-alanyl-D-isoglutamine by means of an amino acid analyzer showed that the conversion of **9i** into **11** and **12** reaches up to 49.9%. However, hydrogenolysis of **8i** under aprotic conditions (in DMF) gave **9i** with no side reaction.

The results can be explained by assuming that the deprotected *N*-acetylisomuramyl dipeptide (**9i**) is gradually decomposed to give the intramolecular ester (**11**) and the dipeptide through *N* to *O* migration of the amide bond under acidic conditions. The resulting intramolecular ester can readily be hydrolyzed to isomuramic acid (**12**) (Scheme 2). MDP treated in a similar way gave the dipeptide in only 5% yield, suggesting that the *S*-isomer (**9i**) more easily undergoes migration than its *R*-isomer (**9a**).

Biological Results

The adjuvant activity of the synthetic MDP analogs (**9**) was assayed for the induction of delayed-type hypersensitivity to *N*-acetyl-3-(4-arsonophenylazo)-L-tyrosine (ABA–Tyr) in guinea pigs[17] (Table 4).

We see that the *N*-acetylisomuramyl derivative (**9i**) greatly reduces the adjuvant activity (compare **9a** and **9i**), indicating that the configuration of the lactic acid moiety of MDP has to be the *R*-form to elicit the activity.

Replacement of alanine by β-alanine (**9b**) led to complete loss of activity. This indicates that lengthening of the peptide chain by one methylene group (as in **9b**) is unfavorable, since glycine analog of MDP has a distinct although weak as compared with MDP,

adjuvant activity.[18] No activity of the sarcosine analog (**9c**) and reduced activity of the proline analog (**9e**) show the necessity of the NH group adjacent to the lactic acid moiety.

The results indicate that alanine or some other α-amino acid adjacent to the lactic acid moiety is important for high biological activity. Replacement of alanine by α-aminoisobutyric acid (**9e**), threonine (**9f**) and valine (**9g**) gave rise to an increase in activity, the valine analog showing the most favorable effect on biological potency. The *N*-glycolyl leucine analog (**9m**), however, has moderate but slightly weak activity as compared with other *N*-glycolyl analogs (**9j**—**9l**), indicating that the size or lipophilicity of the amino acid adjacent to the lactic acid moiety has an effect on the activity. An increase in the size or lipophilicity of the lactic acid residue in muramic acid (**9n**) also caused a decrease in the activity.

The *N*-glycolylmuramyl analogs have activities equipotent to those of the corresponding *N*-acetylmuramyl analogs (compare **9a** with **9j**, and **9g** with **9l**), indicating that *N*-glycolyl and *N*-acetyl groups caused no marked difference in activity.[19] The methyl ester (**9h**) of the valine analog in which a carboxyl group of the D-isoglutamine residue is esterified also possesses activity equipotent to that of the carboxyl-free analog (**9g**).

Experimental

Melting points were taken in open capillaries and are uncorrected. Optical rotations were determined with a Perkin-Elmer Model 141 polarimeter. Amino acid analyses were performed on a Hitachi KLA-3B amino acid analyzer. All chemicals and solvents were of reagent grade and used without further purification with the exception of dioxane which was dried by refluxing in the presence of CaH_2. The reactions were monitored on TLC with Merck F_{254} silica gel plates, which were developed with $CHCl_3$–MeOH (19:1, v/v) for compounds **4**, $CHCl_3$–acetone–MeOH (10:3:2, v/v) for **8**, and *n*-BuOH–EtOAc–AcOH–H_2O (1:1:1:1, v/v) for **9**. Evaporation was carried out in a rotary vacuum evaporator under reduced pressure at temperatures below 45 °C.

D-*Glutamic Acid γ-Benzyl Ester.* This was synthesized according to the method of Guttman and Boissonnas:[20] mp 176—178 °C (lit for L-form 189 °C,[20] 174 °C[21]); $[\alpha]_D^{25}$ −18.6° (*c* 6.0, AcOH) [lit for L-form[20] $[\alpha]_D^{23}$ +19.6°±0.2° (*c* 6.0, AcOH)].

t-*Butoxycarbonyl*-D-*glutamic Acid γ-Benzyl Ester DCHA Salt.* A suspension of D-glutamic acid γ-benzyl ester (5.93 g, 25

mmol) in water (14 ml) was combined with a DMF solution (14 ml) of *O*-*t*-butyl *S*-(4,6-dimethyl-2-pyrimidinyl)thiocarbonate[22] (7.21 g, 30 mmol), Et_3N (3.5 ml, 25 mmol) being then added. The mixture was stirred overnight, becoming a clear solution, to which was added water (40 ml). After extraction with EtOAc (50 ml), the pH of the aqueous layer was adjusted to 2 by addition of 5 M HCl under cooling and the mixture was extracted with EtOAc (40 ml×3). The EtOAc layer was washed with 1 M HCl (25 ml×3) and satd. aq NaCl (25 ml×2), and dried over Na_2SO_4. Evaporation of the solvent gave an oil (7.00 g) of *t*-butoxycarbonyl-D-glutamic acid γ-benzyl ester, which was converted into its DCHA salt in a mixture of EtOAc (50 ml) and Et_2O (50 ml) by addition of a petroleum ether solution (10 ml) of DCHA (3.63 g, 20 mmol) under cooling. The precipitate was filtered to give crystalline *t*-butoxycarbonyl-D-glutamic acid γ-benzyl ester DCHA salt: 10.15 g (78.3%). Mp 141—143 °C (lit for L-form[23] 138—139 °C). $[\alpha]_D^{19}$ −12.5° (*c* 1.0, MeOH) [lit for L-form[23] $[\alpha]_D^{25}$ +11.9° (MeOH)]. Found: C, 67.01; H, 9.16; N, 5.56%. Calcd for $C_{29}H_{46}O_6N_2$: C, 67.15; H, 8.94; N, 5.56%.

t-*Butoxycarbonyl*-D-*glutamic Acid* α-p-*Nitrophenyl* γ-*Benzyl Diester.* A suspension of *t*-butoxycarbonyl-D-glutamic acid γ-benzyl ester DCHA salt (9.86 g, 19 mmol) in EtOAc (100 ml) was shaken with 0.2 M H_2SO_4 (100 ml). The EtOAc layer was washed with satd. aq NaCl (25 ml×2) and dried over Na_2SO_4. After filtration, *p*-nitrophenol (2.69 g, 19 mmol) and DCC (3.92 g, 19 mmol) were added under cooling, and the mixture was stirred at 0 °C for 2 h and kept in a refrigerator overnight. The resulting *N,N'*-dicyclohexylurea was filtered and the filter cake was washed with EtOAc. The combined EtOAc layer was then concentrated to 50 ml and the resulting precipitate was filtered: 7.55 g (86.8%). Mp 121—122 °C (lit for L-form[24] 120—121 °C). $[\alpha]_D^{23}$ +25.0° (*c* 0.5, EtOAc) [lit for L-form[24] $[\alpha]_D^{25}$ −32.7° (MeOH)]. Found: C, 60.19; H, 5.76; N, 6.07%. Calcd for $C_{23}H_{26}O_8N_2$: C, 60.25; H, 5.72; N, 6.11%.

t-*Butoxycarbonyl*-D-*isoglutamine Benzyl Ester.* *t*-Butoxycarbonyl-D-glutamic acid α-*p*-nitrophenyl γ-benzyl diester (4.58 g, 10 mmol) was dissolved in tetrahydrofuran (40 ml), ammonia water (25%, 6.8 ml) being added to the solution. After being stirred for 2 h at room temperature, the solution was concentrated and the residue was dissolved in EtOAc (150 ml). After the usual work-up, the residue was recrystallized from EtOAc–petroleum ether: 2.38 g (70.8%). mp 123—124 °C. $[\alpha]_D^{20}$ −28.0° (*c* 0.5, MeOH). Found: C, 60.63; H. 7.15; N, 8.07%. Calcd for $C_{17}H_{24}O_5N_2$: C, 60.70; H, 7.19; N, 8.23%.

t-*Butoxycarbonyl*-L-*valine HONB Ester.* *t*-Butoxycarbonyl-L-valine (15.2 g, 70 mmol), HONB (13.8 g, 77 mmol) and DCC (15.9 g, 77 mmol) were combined in a mixture of acetonitrile (300 ml) and DMF under cooling. The mixture was stirred at 0 °C for 1 h and at room temperature for 4 h and filtered. After evaporation of the solvent, the residue was dissolved in EtOAc. The EtOAc layer was washed with 5% $NaHCO_3$ and water, then dried over Na_2SO_4. The solvent was removed and the residue was triturated with petroleum ether giving crystalline *t*-butoxycarbonyl-L-valine HONB ester: 26.5 g (quantitative). mp 120—122 °C. $[\alpha]_D^{27}$ −33.6° (*c* 0.5, DMF). Found: C, 60.14; H, 7.21; N, 7.11%. Calcd for $C_{19}H_{26}O_2N_6$: C, 60.30; H, 6.93; N, 7.40%.

t-*Butoxycarbonyl*-D-*glutamic Acid* γ-*Methyl Ester.* This was synthesized from D-glutamic acid γ-methyl ester[25] (19.7 g, 0.1 mol) in a similar way to that described for *t*-butoxycarbonyl-D-glutamic acid γ-benzyl ester: 23.5 g (89.9%). An analytical sample was converted into its DCHA salt as described for the preparation of *t*-butoxycarbonyl-D-glutamic acid γ-benzyl ester DCHA salt: mp 155 °C (lit for L-form[26] 155—157 °C). $[\alpha]_D^{23}$ −10.2° (*c* 0.5, MeOH) [lit for L-form[26] $[\alpha]_D$ +10.5° (MeOH)]. Found: C, 62.45; H, 9.61; N, 6.17%. Calcd for $C_{23}H_{42}O_6N_2$: C, 62.47; H, 9.57; N, 6.33%.

t-*Butoxycarbonyl*-D-*glutamic Acid* α-N-*Succinimidyl* γ-*Methyl Diester.* To a solution of *t*-butoxycarbonyl-D-glutamic acid γ-methyl ester (23.0 g, 88 mmol) and *N*-hydroxysuccinimide (11.2 g, 97 mmol) in acetonitrile (200 ml) was added DCC (20.0 g, 97 mmol) under cooling, and the mixture was stirred at 0 °C for 3 h and at room temperature for 12 h. After filtration and evaporation of the solvent, the residue was dissolved in EtOAc (175 ml). The EtOAc layer was washed with 5% $NaHCO_3$ (70 ml×3), water (70 ml×3) and 10% citric acid (70 ml×3) successively, and dried over Na_2SO_4. After evaporation, the residue was triturated with petroleum ether giving the desired compound: 22.9 g (72.7%). Mp 96 °C. $[\alpha]_D^{23}$ +33.8° (*c* 0.5, DMF).

t-*Butoxycarbonyl*-D-*isoglutamine Methyl Ester.* *t*-Butoxycarbonyl-D-glutamic acid α-*N*-succinimidyl γ-methyl diester (17.9 g, 50 mmol) was dissolved in tetrahydrofuran (50 ml), ammonia water (25%, 18 ml) being added to the resulting solution. After being stirred at 0 °C for 30 min and at room temperature for 30 min, the solution was concentrated and the residue was dissolved in EtOAc (250 ml). After the usual work-up, the residue was recrystallized from EtOAc–petroleum ether: 6.4 g (49.2%). Mp 129—130 °C. $[\alpha]_D^{23}$ −4.2° (*c* 0.5, DMF). Found: C, 51.08; H, 6.25; N, 7.74%. Calcd for $C_{11}H_{20}O_2N_5$: C, 50.75; H, 6.19; N, 7.82%.

t-*Butoxycarbonyl*-L-*valyl*-D-*isoglutamine Methyl Ester (**4h**).* *t*-Butoxycarbonyl-D-isoglutamine methyl ester (5.0 g, 19.1 mmol) was dissolved in cold trifluoroacetic acid (20 ml) and the resulting solution was stirred at room temperature for 15 min. Trifluoroacetic acid was then removed and the residue was triturated with Et_2O. Oily D-isoglutamine methyl ester trifluoroacetate was dried over NaOH pellets, dissolved in acetonitrile (40 ml), and neutralized with Et_3N (2.8 ml, 20 mmol). *t*-Butoxycarbonyl-L-valine HONB ester (7.22 g, 19.1 mmol) was added to this solution and the mixture was stirred at room temperature for 15 h. The solution was then concentrated and the residue extracted with EtOAc (500 ml). The EtOAc layer was washed successively with 5% $NaHCO_3$, 10% citric acid, and water (100 ml×3), then dried over Na_2SO_4 and evaporated. The residue was triturated with petroleum ether giving crystals which were recrystallized from EtOAc–petroleum ether: 5.8 g (84.3%).

*Other protected dipeptides (**4**)* were similarly prepared from appropriate *t*-butoxycarbonylamino acid HONB esters and *t*-butoxycarbonyl-D-isoglutamine benzyl ester.

*Benzyl 4,6-O-Benzylidene-2-benzyloxyacetamido-2-deoxy-α-D-glucopyranoside (**10**).* DCC (7.48 g, 36.3 mmol) was added at 0 °C to a solution of benzyloxyacetic acid[27] (11.0 g, 66 mmol) in dichloromethane (100 ml). The mixture was stirred at 0 °C for 2 h and at room temperature for 15 h. After filtration, the solvent was removed to give oily bis(benzyloxyacetic) anhydride which was dissolved in tetrahydrofuran (300 ml) without further purification together with benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside[15] (10.7 g, 30 mmol). The mixture was heated under reflux for 1 h and the solvent was evaporated. The resulting crystalline residue was collected by filtration and washed with Et_2O to give **10** in a quantitative yield: 15.2 g. Mp 161—162 °C. $[\alpha]_D^{27}$ +48.6° (*c* 0.5, $CHCl_3$). Found: C, 68.70; H, 6.31; N, 2.40%. Calcd for $C_{29}H_{31}ON_7$: C, 68.89; H, 6.18; N, 2.77%.

*Benzyl 2-Acetamido-4,6-O-benzylidene-3-O-[1-(R)-carboxyisopentyl)-2-deoxy-α-D-glucopyranoside (**6c**).* Benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (3.2 g, 8 mmol) was dissolved in dioxane (300 ml) at 90 °C. Sodium hydride (1.80 g, 60% in oil) was then added to the solution at 70 °C and the mixture was kept at 90 °C for 1 h. A solution of (*S*)-2-chloro-4-methylpentanoic acid[14] (6.3 g, 42 mmol) in dioxane (10 ml) was added when the temperature had cooled to 65 °C. After 1 h, additional sodium hydride (7.48 g) was added and the mixture was stirred at 65 °C for 15 h. Water was then added carefully to the reaction mixture under cooling, and the dioxane of the upper phase separated by decantation was evaporated. The residue was dissolved in water (100 ml) and the solution extracted with $CHCl_3$ (50 ml). The aqueous phase was adjusted to pH 3 with 2 M HCl under cooling, the precipitate being extracted with $CHCl_3$ (100 ml×3). The combined organic layer was washed with water and dried (Na_2SO_4). After filtration and evaporation, the residue was purified by silica-gel column (4×12 cm) chromatography using $CHCl_3$–MeOH (95:5, v/v) as solvent: 1.2 g (29.9%). Mp 156—157 °C. $[\alpha]_D^{23}$ +118.4° (*c* 0.5, DMF). Found: C, 65.56; H, 6.88; N, 2.74%. Calcd for $C_{27}H_{36}ON_8$: C, 65.48; H, 6.87; N, 2.73%.

*Benzyl 4,6-O-Benzylidene-2-benzyloxyacetamido-3-O-[1-(R)-carboxyethyl]2-deoxy-α-D-glucopyranoside (**6d**).* Sodium hydride (2.0 g, 50 mmol, *ca.* 60% in oil) was added to a dioxane (300 ml) solution of **10** (10.1 g, 20 mmol) and the mixture was stirred at 90 °C for 1 h. (*S*)-2-Chloropropionic acid (7.54 g, 70 mmol) was added when the temperature had cooled to 65 °C. After 1 h, additional sodium hydride (3.2 g, 80 mmol, 60% in oil) was added and the mixture was stirred at 65 °C for 15 h. Water (40 ml) was then added carefully under cooling, the pH of mixture being adjusted to 7 with 10% citric acid. After evaporation of dioxane, 10% citric acid (250 ml) was added. The resulting precipitate was filtered and washed with water, then with $CHCl_3$–petroleum ether. Recrystallization from MeOH gave **6d**: 6.70 g (58.1%). Mp 230 °C (dec.). $[\alpha]_D^{27}$ +67.5° (*c* 0.3, DMF). Found: C, 65.59; H, 5.89; N, 2.50%. Calcd for $C_{32}H_{35}ON_9 \cdot {}^1/_2H_2O$: C, 65.51; H, 6.19; N, 2.38%.

*Benzyl 2-Acetamido-4,6-O-benzylidene-3-O-[1-(R)-carboxyethyl]-2-deoxy-α-D-glucopyranoside HONB Ester (**7a**).* DCC (3.71 g, 18 mmol) was added to a solution of benzyl 2-acetamido-4,6-*O*-benzylidene-3-*O*-[1-(*R*)-carboxyethyl]-2-deoxy-α-D-glucopyranoside[12] (7.07 g, 15 mmol) and HONB (3.22 g, 18 mmol) in tetrahydrofuran (110 ml) under cooling, and the mixture was stirred at 4 °C for 3 h and at room temperature for 16 h. After filtration, the solvent was removed and the resulting crystalline residue was recrystallized from EtOAc–Et_2O: 7.42 g (78.4%). Mp 122—124 °C. $[\alpha]_D^{27}$ +86.0° (*c* 0.5, DMF). Found: C, 64.52; H, 5.67; N, 4.25%. Calcd for $C_{34}H_{36}O_{10}N_2$: C, 64.55; H, 5.74; N, 4.43%.

*Benzyl 4,6-O-Benzylidene-2-benzyloxyacetamido-3-O-[1-(R)-carboxyethyl)-2-deoxy-α-D-glucopyranoside HONB Ester (**7d**)* was synthesized in a similar way to that described for **7a**: 99.6%. Mp 98—99 °C. $[\alpha]_D^{27}$ +69.0° (*c* 0.5, DMF). Found: C, 66.64; H, 5.99; N, 3.77%. Calcd for $C_{41}H_{42}O_{11}N_2$: C, 66.65; H, 5.73; N, 3.79%.

*N-Acetyl-1-O-Benzyl-4,6-O-benzylidene-α-muramyl-L-valyl-D-isoglutamine Methyl Ester (**8h**).* *t*-Butoxycarbonyl-L-valyl-D-isoglutamine methyl ester (**4h**) (359 mg, 1 mmol) was treated with trifluoroacetic acid (5 ml) at room temperature for 20 min. After evaporation, the residue was triturated with Et_2O and collected. L-Valyl-D-isoglutamine methyl ester trifluoroacetate thus obtained was dissolved in acetonitrile (10 ml) and the solution was neutralized with Et_3N (0.17 ml) under cooling. A solution of **7a** (633 mg, 1 mmol) in acetonitrile (10 ml) was added and the the mixture was stirred at room temperature for 15 h. The resulting precipitate was collected and washed with hot acetonitrile to give **8h**: 656 mg (92.0%).

*Other protected muramyl dipeptides (**8**)* were similarly prepared from appropriate protected muramic acid HONB esters and protected dipeptides.

*N-Acetylmuramyl-L-valyl-D-isoglutamine Methyl Ester (**9h**).* Compound **8h** (31.2 mg, 0.05 mmol) was hydrogenolyzed in a mixture of MeOH (5 ml) and AcOH (0.5 ml) with palladium black as a catalyst at room temperature for 3 h. After filtration and evaporation, the residue was kept in a refrigerator to allow crystallization. Et_2O was then added and the crystals were filtered to give **9h**: 23 mg (86.1%).

*Other muramyl dipeptides (**9**)* were similarly prepared from appropriate protected muramyl dipeptides (**8**).

*Isolation of N-Acetylisomuramic Acid (**12**) and L-Alanyl-D-isoglutamine (**13**) from a Side Reaction.* *N*-Acetyl-1-*O*-benzyl-4,6-*O*-benzylidene-α-isomuramyl-L-alanyl-D-isoglutamine benzyl ester (**8i** 857 mg) was subjected to hydrogenolysis in AcOH (50 ml) in the presence of palladium black at room temperature for 5 d. After filtration and evaporation, the residue was applied to a column of Sephadex LH-20 (3×90 cm) and eluted with 0.1 M AcOH. The fractions from 155 to 175 ml containing the probable internal ester (**11**) and *N*-acetylisomuramic acid (**12**), identical on TLC with an authentic sample,[13] were collected and lyophilized. The residual syrup was solidified with Et_2O and filtered. The powder obtained was highly hygroscopic, showing a single spot corresponding to *N*-acetylisomuramic acid on TLC: 60 mg. Found: C, 42.25; H, 6.50; N, 4.43%. Calcd for $C_{11}H_{19}ON_8$: C, 42.44; H, 6.78; N, 4.50%.

Other 125—140 ml fractions were also collected and lyophilized. The resulting powder was applied to a column (2×40 cm) of CM-cellulose and eluted with dilute AcOH (pH 4.5). The fraction 63—98 ml was collected and lyophilized to give L-alanyl-D-isoglutamine (**13**, 95 mg), which had an R_f value on TLC identical to that of the authentic dipeptide. Amino acid analysis (hydrolysis with 6 M HCl at 110 °C for 24 h): Ala, 1.00; Glu, 1.01.

*Comparison of Degradation (Side Reaction) Rate of **9a** and **9i**.* Solutions of AcOH (0.5 ml each) containing *N*-acetylmuramyl-L-alanyl-D-isoglutamine (**9a**, 10.34 μmol) or *N*-acetylisomuramyl-L-alanyl-D-isoglutamine (**9i**, 10.10 μmol) were heated at 80 °C for 1 h. After evaporation, the residue was subjected to amino acid analysis (column length: 20 cm, buffer: pH 5.28, flow rate: 60 ml/h). The quantity of liberated dipeptide was calculated on the basis of the standard experiment using L-alanyl-D-isoglutamine[11b] (retention time: 25 min), and was 0.52 μmol (5.0%) from **9a** and 5.04 μmol (49.9%) from **9i**.

Biological Assay. Determination of the adjuvant activity on the induction of delayed-type hypersensitivity was carried out according to the method reported.[17]

We wish to thank Prof. T. Shiba, Drs. E. Ohmura, and M. Nishikawa for valuable discussions.

The Kinetics of the β-Cyclodextrin-catalyzed Decarboxylation of Trichloroacetic Acid in an Alkaline Solution

Yoshiaki MOTOZATO, Yoshiaki FURUYA,* Toshikazu MATSUMOTO, and Tsukasa NISHIHARA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received December 20, 1979)

The rate of the decarboxylation of trichloroacetic acid (abbreviated as TCAH) in the presence of β-cyclodextrin(βCD) in an aqueous solution of sodium hydroxide has been followed by the determination of the remaining TCAH. The rate equation was given by

$$\text{Rate} = (k_{1T}+k_{1TC}C_{\beta CD})C_{TCAH}^{1/2} + (k_{2T}-k_{2TC}C_{\beta CD})C_{TCAH}.$$

A probable bimolecular decarboxylation mechanism which involves the unionized molecule of TCAH rather than the anion was proposed and discussed.

Since it was pointed out that TCAH was split quantitatively into chloroform and carbon dioxide when heated in organic bases,[1] the decarboxylation mechanism has been studied by many chemists. Verhoek and his co-workers have suggested that the reaction is a unimolecular reaction of the anion.[2] In opposition to this, Clark has assumed that the reaction is a bimolecular decomposition of the anion.[3]

Some facts of interest were found when we were dealing with the decarboxylation of TCAH as a part of the studies of βCD-catalyzed reactions. We should like to note that the title reaction involves a bimolecular reaction of the unionized TCAH with the solvent water molecule. We will also discuss the catalysis of βCD.

Experimental

Materials. Guaranteed reagents of TCAH (Wako Pure Chemical Industries), βCD (Tokyo Kasei Kogyo Co.), and the sodium hydroxide were used without further purification. The molarities (denoted by M, 1 M=1 mol dm^{-3}) of an aqueous solution of TCAH and of sodium hydroxide were determined by titration with aqueous solutions of sodium hydroxide or hydrochloric acid of known concentrations. The molecular weight of βCD was measured vapor pressure-osmometrically. M_n 1078; calcd 1135.

Typical Rum for the Rate Measurements. Aqueous solutions of TCAH (0.4961 M, 59.97 ml) and sodium hydroxide (0.2957 M, 100.46 ml) were kept separately in a thermostatted water bath of a specified temperature. After appropriate temperature equilibration, the two solutions were mixed together. Aliquots (9.99 ml each) were taken out at appropriate intervals of time, and to each one was added a 9.94 ml portion of a 0.4833 M aqueous solution of hydrochloric acid. Then, they were titrated by 0.4912 M aqueous sodium hydroxide, with Methyl Orange as an indicator. The initial concentration and concentration at time t are given by the following equations:

$$C^0_{TCAH} = ad_1/(d_1+d_2+w)$$

$$C^t_{TCAH} = \{bV+9.99bd_2/(d_1+d_2+w)-9.94c\}/9.99.$$

Here, C^0_{TCAH} and C^t_{TCAH} denote the concentrations of TCAH at time 0 and t, and a and b are the molarities of, and d_1 and d_2 are the quantities (in ml) of aqueous solutions of TCAH and sodium hydroxide respectively. The character, w, is the volume of water added, and c and V are the molarity of an aqueous solution of hydrochloric acid and a titer (at time t) of an aqueous solution of sodium hydroxide respectively.

Measurement of Dissociation State for TCAH in an Aqueous Solution. The degree of dissociation for TCAH in an aqueous solution containing about an equimolar amount of sodium hydroxide was measured by means of a Yanagimoto Conductivity Outfit, model MY-7, in pH 9.0 at 60 °C. The molar conductivities are plotted against the square root of the TCAH concentrations in Fig. 1. From Fig. 1, the degrees of dissociation may be found to be 0.7038—0.8694 in the range of 0.25—0.06 M TCAH at 60 °C. Therefore, it was concluded that the trichloroacetate anion may coexist with the unionized TCAH molecule.

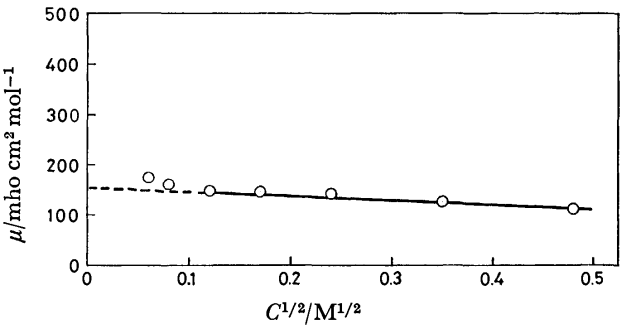

Fig. 1. The Kohlrausch plot of TCAH in aqueous solution of equimolar sodium hydroxide at 60 °C.

Results and Discussion

The pseudo first-order rate plot fit closely to a straight line, as is shown in Fig. 2. The rate data are tabulated in Table 1. The pseudo first-order rate constant, k_{1obs}, increases linearly in proportion to the reciprocal of the square root of the initial concentration of TCAH, as is shown in Fig. 3. Thus, the following equation can be derived:

$$k_{1obs} = k_1 C_{TCAH}^{-1/2} + k_2. \quad (1)$$

The values of k_{1obs} in the decarboxylation of 0.05 M TCAH (6.21×10^{-5} s^{-1} and 1.33×10^{-4} s^{-1}) at 80 °C in the absence or the presence of 0.02 M βCD agreed well with those (7.00×10^{-5} s^{-1} and 1.36×10^{-4} s^{-1}) calculated from the half-life periods given by Cramer and Kampe.[4]

The rate constant k_1 increases, while k_2 decreases, with an increase in the βCD concentration, as is shown in Figs. 4 and 5. Therefore, each constant can be divided into two terms:

Table 1. Rate data and activation parameters for the decarboxylation of trichloroacetic acid

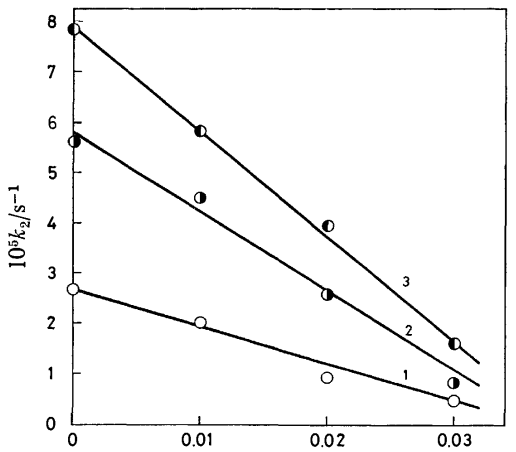

Fig. 5. The plot of k_2 *vs.* βCD concentration for the decarboxylation of TCAH in aqueous solution of sodium hydroxide.
Reaction temp: 1, 75 °C: 2, 80 °C; 3, 83 °C.

$$k_1 = k_{1T} + k_{1TC}C_{\beta CD} \quad (2)$$

$$k_2 = k_{2T} - k_{2TC}C_{\beta CD}. \quad (3)$$

From these relationships, the overall kinetics of this reaction is given by the following equation:

$$\text{Rate} = (k_{1T}+k_{1TC}C_{\beta CD})C_{TCAH}{}^{1/2}+(k_{2T}-k_{2TC}C_{\beta CD})C_{TCAH}. \quad (4)$$

The first and second terms represent the decarboxylation of the anion, for $C_{TCAH}^{1/2}$ is expressed by $K^{-1/2}C_{TCA^-}$ under our reaction conditions (Equivalent of TCAH≃ Equivalent of NaOH).[2] Here, K and C_{TCA^-} are the dissociation constant of TCAH and the anion concentration respectively. The third and fourth terms express the decomposition of the unionized molecule and concecutive reactions. In spite of its strong acidity, a measurable amount of TCAH still remains un-

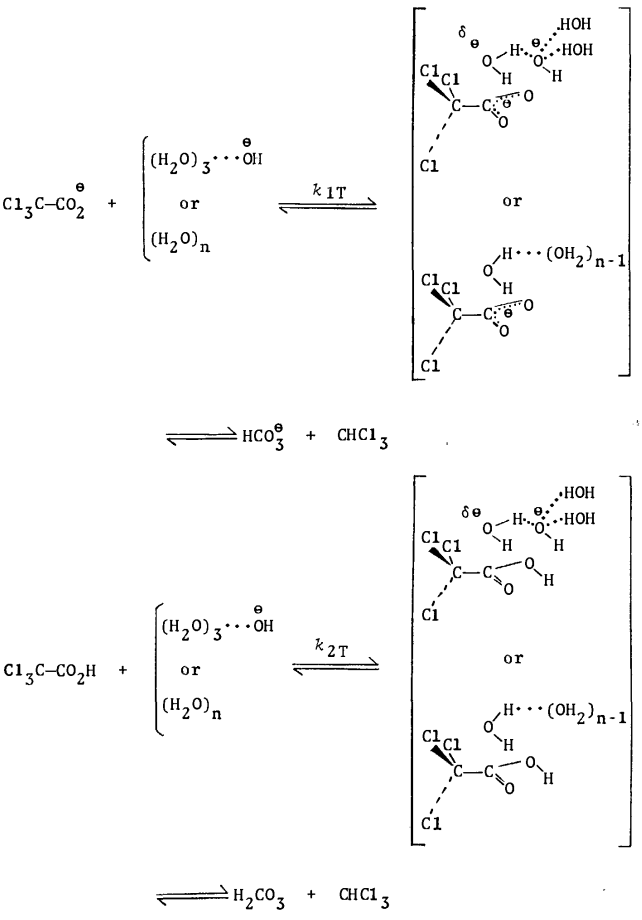
ionized, as has been mentioned above. Accordingly, it seems reasonable to assume that the chemical species which takes part in the decarboxylation is not only the anion, but also the unionized molecule.

The loss of a proton to form the anion increases the electron density on the oxygen of the carboxylate residue, thus decreasing the effective positive charge on the polarized carboxyl carbon atom. This leads to a weakening of the attraction between the nucleophile and the carboxylate carbon; this may account for the observed increase in the enthalpy of activation[5] of the first term as compared with that of the third term. On the other hand, a comparison of the kinetic data for the decarboxylation of malonic and trichloroacetic acids in various amines[6] showed that the steric effect hinders the approach of the nitrogen of amine to the carboxyl carbon, thus decreasing the probability of the formation of the activated complex. This leads to the decrease in the entropy of activation in the formation of the activated complex, as is shown in Table 2. Analogously to this, the smaller entropy of the activation of the third term than that of the first term, as is found in Table 1, may be ascribed to the hindrance of the approach of the oxygen of water to the carboxylic carbon of TCAH caused by the free-rotating carboxylic hydroxyl group. As a result of these findings, the pathways of the decarboxylation of TCA^- and of TCAH will be expressed by the first and the third terms respectively.

Furthermore, the kinetic behavior of TCAH bears some resemblance to that of malonic acid, as is shown in Table 2. Malonic acid apparently does not ionize not only in water and/or alcohol and dioxane containing water,[7] but also in aromatic amines and in acid solvents.[6] Therefore, an un-ionized TCAH molecule will probably take part in a decarboxylation reaction. This pathway, to be expressed as the first-order kinetics, seems to correspond to the third term, which constitutes the main part of the decarboxylation reaction (70—90%).

The values of the overlap population between two carbons in both TCAH and TCA^- were calculated by means of the CNDO/2 method in a closed system.[8] The geometries of the chemical species are cited from Sutton's Tables[9] and are fixed. When the oxygen of water, which is parallel to the Cl–C–C(=O)–O plane, approaches the carboxylic carbon of TCAH or TCA^- up to 0.2 nm on its p_z-axis, the diminution degree of the value of Mulliken's population between C–C in the free acid (0.0052) is larger than that in its anion (0.0008). Thus, the anion seems to be less liable to decarboxylate than the free acid.

The value of $\log k_{1T}$ decreases slightly and linearly with an increase in the pH, whereas $\log k_{2T}$ increases slightly and linearly with an increase in the pH value. It seems reasonable to assume that there are two kinds of water as the attacking species in a basic aqueous solution; one is the water affected by the hydroxide anion, and the other is the one unaffected by the anion. The hydroxide anion is hydrated by three molecules of water.[10] The oxygen of such water may have a larger negativity. As the ratio of the participation of such water increases with an increase in the pH,



the rate constants, k_{1T} and k_{2T}, will decrease and increase respectively with an increase of the pH value.

The value of k_{1T} decreases, and that of k_{2T} increases, with a decrease in the pH value in this acidic range. The former still has some value (0.173×10^{-5} $M^{1/2}$ s^{-1}) even at pH 1.30, however, the concentration of the anion will decrease remarkably, but not to zero. The latter phenomenon is considered to be due to the formation of the protonated TCAH, which is liable to be attacked by the oxygen of water.

The second and fourth terms constitute a βCD-catalyzed mechanism. The value of log k_{1TC} is affected to a small extent by the pH. On the other hand, log k_{2TC} is independent of the basicity of the reaction medium. In the reaction catalyzed by βCD, the activated complex formed by the attack of the water molecule on the TCA^- anion included in βCD will be more stable than that in the case of free TCA^-, but the approach of the water molecule will be controlled by the severe steric factor. Therefore, both the enthalpy and the entropy of activation of the second term will have smaller values than those of the first term, as may be found in Table 1.

The fourth term of Eq. 4 may be a βCD-catalyzed hydrolysis of the trichloromethyl anion formed:[11]

$$TCAH + \beta CD \rightleftharpoons \underset{[I]}{\beta CD\cdots TCAH} \quad (5)$$

$$I + H_2O \rightleftharpoons \underset{[II]}{\beta CD\cdots Cl_3C^-} + H^+ + H_2CO_3 \quad (6)$$

$$II + H^+ \xrightarrow{\text{slow}} \beta CD + HCl + CCl_2 \quad (7)$$

$$CCl_2 + 2H_2O \longrightarrow 2HCl + HCO_2H. \quad (8)$$

In a reaction mixture, both the chloride and formate anions are detected. As the concentrations of formic and hydrochroric acids are added to the remaining TCAH concentration, the fourth term should have a minus sign.

Thione *S*-Imide. Reaction with Heterocumulenes

Takao Saito, Isao Oikawa, and Shinichi Motoki*

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 28, 1979)

9-Fluorenethione *S*-*p*-toluenesulfonimide reacted with diphenylketene to give two regioisomeric 1,3-dipolar cycloadducts. The thione *S*-imide and symmetrical dialkylcarbodiimides produced 3-tosylimino-1,2,4-thiadiazolidines. In the reaction with ketenimines, there occurred siteselective cycloaddition reactions on C=N *vs.* C=C bonds in the imines and further rearrangement of the 1,2,4-thiadiazolidine adducts.

In the preceding papers, we reported that 9-fluorenethione *S*-*p*-toluenesulfonimides (**1**)[1] prepared by a Wittig-type reaction of phosphonium fluorenylides with *N*-sulfinyl-*p*-toluenesulfonamide underwent 1,3-dipolar and Diels-Alder type cycloaddition and ene reactions as a 4π or 2π component with the compounds containing C=C[2] or C=X[3] (X=NR, S, O) double bonds. The present report involves cycloaddition reactions of **1** with some heterocumulenes, *i.e.* diphenylketene, ketenimines, and carbodiimides.

When **1** was allowed to react with diphenylketene (**2**) in 1,2-dichloroethane at room temperature for a week, two regioisomeric (3+2)cycloadducts (**3**, **4**) were obtained. Their IR spectra showed νC=O absorptions at 1715 and 1718 cm^{-1} respectively, so four-membered structures such as **5** were excluded by a comparison with the νC=O values of the related compounds (**6**, **7**).[4] However, it was difficult to distinguish these adducts from each other strictly for the following reasons. (1) Assignment of the νC=O absorptions to Ph_2C–CO–N or Ph_2C–CO–Fl group was difficult. (2) Both adducts showed similar mass-spectral fragmentation patterns. (3) Both adducts were inert to hydrolysis and to 2,4-dinitrophenylhydrazine.

The reaction of **1** with symmetrical dialkylcarbodiimides (**8**) in 1,2-dichloroethane at room temperature afforded 1:1 cycloadducts (**9**). The IR spectra showed strong and broad absorptions at 1530—1560 cm^{-1} assigned to the νC=N–Ts but not to the νC=N–R (alkyl).[5] The mass-spectral fragmentation patterns which exhibited Fl=S$^{\cdot+}$, Ts–NCN–R$^{\cdot+}$, and Fl=NR$^{\cdot+}$ ion peaks also supported the 1,2,4-thiadiazolidine structure. Furthermore, in the NMR spectra of **9a**, the resonance for one CH_3CH_2N group appeared at a rather high field, probably due to the shielding effect exerted by the diamagnetic anisotropy of the adjacent fluorenylidene group (δ 0.56 (CH_3), δ 2.79 (CH_2)). The NMR signal of the other CH_3CH_2N group shifted to lower field (δ 1.42 (CH_3), δ 4.13 (CH_2)) than is found in the usual case. This may be attributed to the deshielding effect of the fluorenylidene ring because this ethyl group would be located near the plane of the fluorenylidene ring. The adduct **9** is considered to be the rearranged product of the hypothetical initial adduct **10**, but we cannot elucidate this at present.[6]

Reactions with diarylcarbodiimides did not proceed under the same reaction conditions, while **1** and unsymmetrical carbodiimides (**11**) afforded guanidines (**12**) and fluorenone (**13**) as unexpected products.

In the reaction of **1** with ketenimines (**14**), 1,3-thiazolidine (**15**) and 1,2,4-thiadiazolidine (**16**) deriv-

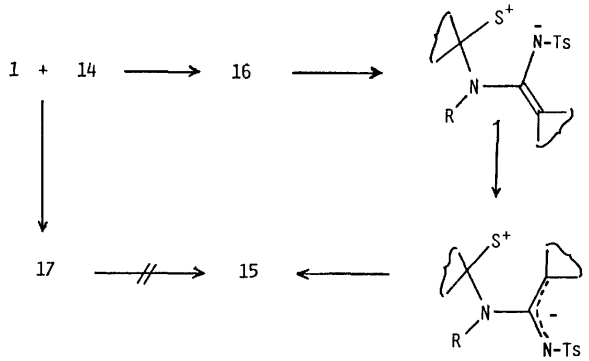
s: Singlet, q: quartet in SFORD measurement.

atives were obtained (Table 1). The IR spectra of **15** and **16** displayed strong νC=N–Ts absorption at 1560—1565 cm^{-1} and νC=C at 1670—1685 cm^{-1}, respectively. The ^{13}C NMR spectra of **15a, b, f** (indicating the presence of two quarternary carbon atoms and one ring-carbon atom attached to the tosylimino group) and **16a,b** (indicating the presence of one quarternary carbon atom and one olefinic ring-carbon atom bonded with nitrogens) also supported the proposed structures (Table 2). In the reaction of **1** and **14b**, a third adduct (**17b**) which exhibits νC=N–Tol-*p* absorption at 1595 cm^{-1} was obtained. This is the 1,3-cycloadduct of **1** onto the C=C bond in **14**. The adducts **16a,b** were found to rearrange gradually into **15a,b** on standing in dichloromethane or deuteriochloroform; this conversion was confirmed by monitoring the NMR spectra and by isolating **15a,b**. The reaction is rationally explained by assuming the sulfur-nitrogen bond cleavage in **16** and a subsequent recombination of sulfur-carbon bond, as considered in the formation of **9**.[7] On the other hand, **17b**, a direct 1,3-cycloadduct, did not rearrange into **15b** (and *vice versa*) at room temperature. The sum of the yields of **15** and **16** which result from the cycloaddition of **1** onto the C=N bond in **14** is much larger than that of **17**, as shown in Table 1. Therefore the



Scheme 5.

cycloaddition of **1** onto the C=N bond predominates with kinetic preference over that onto the C=C bond.

Experimental

All the melting points are uncorrected. The IR spectra were determined on a Hitachi Model 260-10 spectrometer. The ^1H NMR and ^{13}C NMR spectra were measured on JEOL JNM-PMX 60 and/or JNM-FX 100 spectrometers in δ values from Me_4Si as an internal standard in deuteriochloroform. The mass spectra were recorded on a Hitachi double-focusing mass spectrometer RMU-7M operating at an ionizing potential of 70 eV. The elemental analyses were performed using a Shimadzu universal organic micro analyzer UM-3B and a rapid-nitrogen analyzer NA-1.

Starting Materials. Diphenylketene (**2**)[8] and carbodiimides (**8, 11**)[9] were prepared by the methods in the literature. New ketenimines (**14**) were synthesized from the corresponding isocyanates and triphenylphosphonium fluorenylides by the modified method reported by Frøyen.[10]

A mixture of phenyl isocyanate (1.19 g, 0.01 mol) and triphenylphosphonium fluorenylide (4.26 g, 0.01 mol) was refluxed in 50 ml of dry benzene for 2 h until the IR absorption of νN=C=O at 2200 cm^{-1} disappeared; the ketenimine formation was recognized from the strong maximum νC=C=N absorption at 2025 cm^{-1}. After the evaporation of the benzene solvent, the residue was extracted with 60 m of hot ligroine and the yellow-orange extract was passed through a short Florisil column. From the colored fraction, the ketenimine **14a** was obtained quantitatively as yellow plates (recrystallized from hexane); mp 85.0—85.5 °C; MS (70 eV) *m/e* 267 (100, M^+), 190 (58), 164 (66). Found: C, 89.94; H, 4.73%. Calcd for $C_{20}H_{13}N$: C, 89.86; H, 4.90%. The other ketenimines **14b—f** were similarly prepared, as is shown in Table 3.

Reaction of Thione S*-Imide (1) with Diphenylketene (2).* A mixture of **1** (2.46 g, 6.7 mmol) and **2** (1.30 g, 6.7 mmol)

Table 3. Ketenimines (**14**)

Compound	Reaction time	Yield %	Mp (°C) [Bp(°C/mm)]	IR νC=C=N	Appearance
